A chiral reagent within the family of Horner-Emmons phosphonates has been used with MVK, but the results were disappointing in that the major product was the dialkylated adduct (eq 14). In addition, preparations of these reagents are often multistep and tedious.[41]

(14)

In a recent synthesis of (+)-*O*-methyljoubertiamine, Taber utilized very mild conditions for the addition of a chiral enolate to MVK in which the chiral auxiliary is the effective naphthyl camphor system (eq 15).[42]

(15)

There are several polymer-based methods which induce some asymmetry to certain substrates. The degree of asymmetric induction is not particularly high (66% ee) and as yet does not appear to be very general. One such example is the cobalt-based diamine polymer which provides modest yields of the Michael adduct (eq 16).[43]

(16)

In terms of high yields and efficiency of asymmetric induction, the Evans procedure using chiral acyl oxazolidones stands apart as a method of choice. In the MVK example the chiral reagent adds, with the assistance of titanium tetrachloride activation at 0 °C, with an impressive 88% chemical yield and 99% ee (eq 17). The oxazolidone can be recycled and the method is general for a variety of α,β-unsaturated systems.[44]

(17)

Alkylation/Cyclization Tandems: The Robinson Annulation.

The most prevalent use of MVK in modern synthesis is the annulation of a six-membered ring onto a pre-existing ketone: the Robinson annulation (see above). In its original format,[45] the sequence involves the generation of an enolate under basic conditions followed by Michael addition to MVK, thus affording a 1,5-dione. The dione can be subjected to basic conditions which induce aldol cyclization-dehydration, resulting in a newly formed cyclohexenone appended to the starting ketone (eq 2). Since its inception, the sequence has been handicapped by a variety of problems: (1) proton transfer; (2) regiochemistry of Michael addition to MVK; (3) *O*- vs. *C*-alkylation; (4) polyalkylation; (5) poor yields in the conjugate addition step; and (6) base-promoted polymerization of MVK itself. In spite of these drawbacks, the procedure is so synthetically important that development and refinement of Robinson's protocol continues to this very day. Most of the problems which are unique to MVK are often overcome by the use of a synthetic equivalent (see above). This section will deal with the annulation procedures which involve MVK itself and can be grouped into linear vs. spiroannulation sequences. In addition, some of these methods involve asymmetric induction, resulting in chiral cyclohexenones. When chirality is involved, it is usually induced in the alkylation (Michael addition) step, but there are a few examples in which the aldol cyclization of the dione or keto aldehyde features the chiral auxiliary.

The Linear Robinson Annulation.

This was the earliest class of Robinson annulation procedure and represents the majority of examples. When simple ketones are used in this sequence with MVK, the results are often unsatisfactory. However, when acidic dicarbonyl compounds are employed, the results are quite viable and practical. For example, 1,3-diones may be treated with a catalytic amount of base to generate a stable enolate which is subsequently trapped with MVK. The alkylated adduct is then cyclized-dehydrated under standard Knoevenagel conditions (eq 18). The acidic conditions of the cyclization help retard reversible β-elimination of MVK.[46]

(18)

In a classic case of stereochemical control, chiral auxiliaries were not involved, but rather a simple reversal of order in alkylations of enolates resulting in the preparation of isomeric decalenones (eq 19).[47] Although this is a dialkylation procedure leading to a specific product, the overall strategy of stereochemical control in the Robinson annulation has been extensively studied and discussed.[48]

(19)

With the advent of kinetic, sterically hindered bases (such as LDA), which could be used under aprotic conditions, the regiochemistry of enolates could be controlled. In the following sequence, a slight excess of the ketone allows the Michael addition to occur at the most hindered site via the thermodynamic enolate, thus resulting in a quaternary carbon center with stereochemical control. Aldol cyclization-dehydration then affords the cyclohexenone in 60% yield (eq 20).[49]

(20)

A highly successful approach to Robinson annulation involves the use of trimethylsilyl enol ethers with MVK under Lewis acid conditions, which thwarts MVK polymerization. The yields of the Michael addition itself are greatly improved (see above), and the resulting diones can be cyclized-dehydrated under standard aldol (basic) conditions. This particular example affords the decalenones in 89% overall yield from MVK (eq 21).[27]

(21)

The Chiral Robinson Annulation.

Perhaps the most important extensions involving the Robinson annulation protocol have concerned the production of chiral cyclohexenones. In general, the asymmetric induction takes place at the Michael addition step with a chiral reactive intermediate and MVK, although there are a few examples in which the aldol cyclization-dehydration step affords the stereochemical control. However, great care must be exercised in the cyclization step in order to avoid epimerization at the newly created chiral center. One of the earliest methods for chiral Robinson annulation is a general procedure in which a chiral ***Pyrrolidine*** enamine is condensed with MVK; the resulting keto imines are then hydrolyzed to give the chiral δ-keto aldehydes, which in turn are cyclized under (acidic) Knoevenagel conditions, finally affording chiral 4,4-disubstituted cyclohexenones (eq 22).

(22)

This methodology was highlighted in the chiral total synthesis of the *Sceletium* alkaloid (+)-mesembrine.[50] More recently, an even milder, shorter sequence was used in the key step for the synthesis of the *Sceletium* alkaloid (+)-*O*-methyljoubertiamine. In this case, the chiral auxiliary was the naphthylcamphor system (see above), which governed the condensation of the enolate with MVK using mild ***Potassium Carbonate*** as the base (eq 23).[42]

The use of chiral imines has recently received attention as reactive intermediates for Michael additions to MVK. Their advantage is that they are derived from α-methylbenzylamine, which is affordable and can be recycled. The Michael addition itself is activated with titanium tetrachloride and gives good yields (61%) of the Michael adduct with high ee (91%). Hydrolysis concomitant with cyclization provides the decalenone (eq 24).[51]

A very useful procedure for inducing chirality in the cyclization step was reported some years ago but has recently been optimized for scale-up. ***2-Methyl-1,3-cyclopentanedione*** serves as the reactive enolate system for the Michael addition with MVK, providing the trione in quantitative yield. The chiral cyclization is a modified Knoevenagel reaction using ***(S)-Proline*** as the asymmetric catalyst. This sequence provides the enedione in 93% optical purity (eq 25).[52]

The Spirocyclic Robinson Annulation.

Procedures which attach two carbocyclic rings to one another by a single carbon atom (spiroannulation)[53] are not commonplace. The major synthetic problem to overcome in such an operation is the construction of the common, quaternary carbon center. Although there are a number of ingenious ways to construct quaternary carbon centers,[54] those involving spiroannulations with MVK are generally limited to the reactions of trisubstituted enamines with MVK as the conjugate addition step of the sequence (eq 26).[55] The starting carbonyl compounds are usually aldehydes, but there is also a highly efficient homologation procedure which commences from ketones.[56] In either case, the intermediate at the alkylation stage is a δ-keto imine which is subjected to mild acid hydrolysis, thus generating a δ-keto aldehyde, which is then cyclized-dehydrated with base. Enamines from ***Piperidine*** and ***Morpholine*** have been used successfully in this procedure. There is flexibility in the carbonyl starting materials as well: five-, six-, seven-, and eight-membered carbonyl systems have all been satisfactory substrates in this methodology. The spiroannulation procedure of MVK with enamines is summarized below (Table 2).

(26)

Table 2 Spiroannulation Procedures Involving Enamines and Methyl Vinyl Ketone

Ketone	Enamine	Yield of spirocycle (%)	Ref.
Cyclopentane-carbaldehyde	Piperidino	59	55c
Isopropylidene-cyclopentane-carbaldehyde	Piperidino	45 65	55a
Cyclohexane-carbaldehyde	Piperidino	45 65	55b,c
Cyclohexanone	Morpholino	41	56
2-Methylcyclo-hexanone	Morpholino	36	56
4-*t*-Butylcyclo-hexanone	Morpholino	41	56
Isophorone	Morpholino	30	56
2-Norbornanone	Morpholino	41	56
Cycloheptane-carbaldehyde	Piperidino	45 65	55b,c
Cyclooctane-carbaldehyde	Piperidino	45 65	55b,c

2-Methyl-6-vinylpyridine[1]

[1122-70-9] · C_8H_9N · 2-Methyl-6-vinylpyridine · (MW 119.18)

(stable, masked methyl vinyl ketone equivalent; bis-annulation reagent useful for the synthesis of fused ring systems;[2,3] 1,5-diketone precursor[4])

Physical Data: clear liquid, bp 65-70 °C/12 mmHg.

Solubility: sol all common organic solvents.

Preparative Method: prepared in a two-step procedure from ***2,6-Lutidine*** in an overall 30% yield.[5]

Handling, Storage, and Precautions: store under nitrogen at rt; unpleasant odor; use in a fume hood.

Annulations.

2-Methyl-6-vinylpyridine is a stable, masked equivalent of two moles of ***Methyl Vinyl Ketone*** that has been utilized in the synthesis of steroid ring systems.[2,3] In addition, 2-methyl-6-vinylpyridine derivatives have found use as a convenient synthon of 1,5-diketones.[4] Alkylation of the vinylpyridine[2,3,6] followed by Birch reduction of the appropriately protected substrate generates a cyclohexenone (eq 1).

The mode of cyclization of the intermediate 1,5-diketone is predictable and dependent on the substitution pattern (eq 2). Thus Birch reduction of 2-cyclohexylethyl-6-methylpyridine (**1**) (R = cyclohexyl) produces 100% of 3-cyclohexylethylcyclohex-2-enone (**2**) (R = cyclohexyl), while reduction of the corresponding 2-ethyl-6-methylpyridine (**1**) (R = H) affords >90% 2,3-dimethylcyclohex-2-enone (**3**) (R = H).[4c]

Other examples of heterocyclic bis-annulation reagents include 3-chloromethyl-2,4-dimethylisoxazole,[7] *N*-benzyl-2,6-dicyanopiperidine,[8] and 2,6-dimethyl-4*H*-pyran-4-one.[9]

Related Reagents.

Methylzirconium Tributoxide

$MeZr(OBu)_3$

[79950-18-8] · $C_{13}H_{30}O_3Zr$ · Methylzirconium Tributoxide · (MW 325.65)

(nucleophile, methylating agent)

Solubility: sol diethyl ether, tetrahydrofuran, CH_2Cl_2.

Form Supplied in: not commercially available.

Preparative Methods: synthesized from $Zr(OBu)_4$ and ***Zirconium(IV) Chloride*** via $ClZr(OBu)_3$.[1] The reaction of ***Methyllithium*** with a solution of tributoxyzirconium chloride in diethyl ether at -10 °C yields the reagent (eq 1). For subsequent reactions the etheral solution of the reagent is used. Both ether and ether solutions in dichloromethane have been used as solvents in the subsequent reactions.[1]

$$ClZr(OBu)_3 \xrightarrow[\text{-10 to 0 °C, 2 h, Ar}]{MeLi,\ Et_2O} MeZr(OBu)_3 \qquad (1)$$

Purification: used as generated in solution.

Handling, Storage, and Precautions: extremely hygroscopic, decomposed by moist air; must be handled under N_2 or Ar; reagent causes burns, and is harmful if inhaled or swallowed. Use in a fume hood.

Nucleophilic Addition to Carbonyls.

Methylzirconium tributoxide, like its higher alkyl, aryl, and vinyl homologs, is a selective nucleophile of low basicity. The selectivity is less, however, than in the titanium analogs, as seen in the preference for aldehydes in the presence of ketones (eq 2).[1]

(2)

Several functional groups are compatible (eq 3).

(3)

Basic nitrogen atoms in the substrate molecules do not influence the apparent basicity of the zirconium reagents as much as they do the lithium, Grignard, or titanium derivatives (eq 4).[1]

(4)

The alkylzirconium tributoxides are less basic than the titanium analogs, and considerably less basic than the lithium and Grignard reagents and are therefore the reagents of choice in reactions with easily enolizable ketones. In the sugar example given, the reaction is chemo- and stereospecific; only the β-methyl isomer was formed (eq 5).[2] Tetramethylzirconium affords a mixture of the α- and β-stereoisomers, and other organometallic reagents failed because of enolization reactions.

Molecular Sieves[1]

(electrocyclic reaction cocatalyst; mild acid catalyst; desiccant)

Form Supplied in: the most common forms are bead, pellet, and powdered solids with cavity sizes of 3, 4, 5 and 10 Å. The bead and pellet forms are adequate for drying solvents, while the powdered form is preferred for use in most reactions.

Preparative Methods: sieves are most effective if activated prior to use by drying under vacuum (<1 mmHg) at 300 °C for at least 15 h.

Handling, Storage, and Precautions: all forms of sieves readily absorb water upon exposure to air and are therefore best stored in a desiccator. Sieves can be recycled by (a) washing well with an organic solvent, (b) drying at 100 °C for several hours, and (c) reactivation at &egt;200 °C. Skin contact should be avoided as the desiccant properties of the sieves cause irritation.

General Information.

Molecular sieves are metal aluminosilicates of the general formula $M_{2/n}O.Al_2O_3.xSiO_2.yH_2O$ (where *n* is the valence of the metal, M) characterized by a regular (zeolite) structure and cavity size which is retained even with loss of hydration.[2,3] Although they occur in Nature, most sieves are manufactured commercially as they can be designed with properties specific to their application. Many variations have been synthesized and the field of zeolite design is one of intense investigation.[4] The Linde Division of the Union Carbide Corporation is a major supplier of molecular sieves for synthetic organic applications. Of their products, the 3, 4, and 5 Å as well as 13X sieves are the most commonly employed; these differ both in pore size (3, 4, 5, and 10 Å, respectively) and cation constitution (K, Na, Ca, and Na, respectively).[5] Thus a sieve appropriate to a specific application can be selected.

Diels-Alder Catalysis.

Whether combined with a Lewis acid or used alone, molecular sieves are powerful accelerators of this concerted process. In the former case, great progress has been made toward combining this reagent with a chiral Lewis acid to induce asymmetry during reaction between two achiral molecules.[6-12] This has been achieved through the use of the chiral titanate (**1**) and achiral auxiliary (**2**) which aids in coordination of the dienophile (eqs 1 and 2). Not only is this a highly successful method for the enantioselective generation of the stereocenters, but it is also catalytic. The power of this methodology is elegantly demonstrated in eq 2, taken from Narasaka's synthesis of the hydronaphthalene portions of mevinic acids, where this catalyst system is employed to introduce four contiguous chiral centers with complete diastereoselectivity and very high enantioselectivity from an achiral precursor. Although a less dramatic example, eq 3 displays the ability of sieves to function independently as cycloaddition catalysts,[13] as attested to by the mild temperature and short reaction time.

Ene Reactions.

Utilization of the reagent in ene reactions parallels its use in Diels-Alder cycloadditions, although the choice of the Lewis acid cocatalyst is substrate dependent. The three most effective chiral metal complexes employed to date are either the tartrate-based titanate (**1**), titanium-complexed commercially available 1,1´-binaphthol (see ***(R)-1,1´-Bi-2,2´-naphthotitanium Dichloride***), or the more bulky binaphthol-derived system (**3**) (eqs 4-6).[14-16] Performance of these catalytic systems is comparable to those employed in the Diels-Alder reaction in both enantioselectivity and mildness of reaction conditions.

(3)

(4)

(5)

(6)

Other Electrocyclic Reactions.

Finally, molecular sieves have been successful in facilitating asymmetric [2 + 2] cycloadditions when (**1**) is present, and in promoting [3 + 2] dipolar cycloadditions. Again, in the former case, the optical yields are extremely good as can be seen from eqs 7-9.[17-20] In the latter case, the sieves generate the nitrile oxide in situ and this species then reacts with the acrylate acceptor to yield the isoxazole (eq 10). Although this method requires a relatively long reaction time, the mild conditions have the advantage of suppressing side reactions, including dimerization of the nitrile oxide, resulting in high yields of very pure material.[21]

(9)

(10)

Acid Scavenging.

In addition to their use as cocatalysts, molecular sieves also function as acid scavengers, making them especially suited to the suppression of acid-catalyzed side reactions such as polymerization. For example, they are employed in the preparation of high-purity methacrylic acid esters from methacryloyl chloride and various alcohols (primary, secondary, tertiary, and benzylic).[22] This acid-scavenging ability has also proven useful in the direct acylation of acid-sensitive, unreactive tertiary hydroxyl groups and of acid- and base-sensitive amides with acyl chlorides.[23,24]

Sorbtion.

The reagent's sorbtion ability has been exploited in a wide range of carbonyl and carboxylate transformations. Key to their utility is the inclusion of molecules such as water and small alcohols into the sieve cavities while excluding the larger compounds, thus allowing greater control of equilibria. By this method, ketimines and enamines derived from sterically encumbered precursors are more accessible.[25,26] Likewise, triphenylphosphazenes can be obtained by reaction of *N*-aminotriphenylphosphinime with various aldehydes and ketones.[27] Reductive amination of carbonyls proceeds in better yield with molecular sieves present to absorb water.[28] When coupled with tertiary amines such as ***1,5-Diazabicyclo[4.3.0]non-5-ene*** or ***1,8-Diazabicyclo[5.4.0]undec-7-ene***, 3 or 4 Å sieves can effect the alkenation of δ-alkoxy-α,β-unsaturated aldehydes efficiently.[29,30] Amide synthesis with molecular sieves provides a general, high yielding, and chemoselective route to secondary amides free of byproducts and impurities.[31] Transesterification of

methyl esters with branched primary, secondary, and tertiary alcohols has been reported with the 5 Å sieve.[3] Zeolites have been utilized in the preparation of an asymmetric hydrocyanating agent by reaction with titanate (**1**) followed by treatment with 2 equiv of ***Cyanotrimethylsilane*** at ambient temperature.[32,33] Addition of this reagent to aldehydes at -78 °C in toluene provides the corresponding cyanohydrins in yields of 67-92% and optical purities ranging from 61% to 93%.

Acid Catalysis.

The Lewis acid reactivity of this reagent can be applied to Michael-type reactions as shown in eqs 11 and 12.[34,35] The resulting ring systems can be further transformed into a variety of useful synthetic building blocks. Molecular sieves can also be coupled with Lewis acids to promote acetal formation and exchange. When used with ***p-Toluenesulfonic Acid*** as a cocatalyst, sieves provide a facile synthesis of acetals from carbonyls, not only when primary but also when secondary alcohols are involved.[36,37] Employment with ***Boron Trifluoride Etherate*** catalyzes exchange between (tributylstannyl)methanol and ***Dimethoxymethane*** to produce the useful hydroxymethyl anion equivalent ***Tri-n-butyl[(methoxymethoxy)methyl]stannane*** in high yield.[38,39]

Oxidations.

Titanium silicate molecular sieves have served as catalysts in the selective oxidation of thioethers to sulfoxides.[40] They effect this transformation under mild conditions (1 equiv of H_2O_2 in refluxing acetone) with little over-oxidation to the sulfone. When used as a promoter in ***Pyridinium Chlorochromate*** and ***Pyridinium Dichromate*** oxidations of nucleoside derivatives, sieves work remarkably well, in contrast to other additives such as ***Alumina***, Celite, or silica gel which fail to accelerate these reactions.[41] As drying agents, sieves are a crucial component of the Sharpless catalytic asymmetric epoxidation.[42]

Miscellaneous Reactions.

The shape selectivity of zeolites has been exploited to selectively brominate either a hindered double bond in the presence of an unhindered double bond or vice versa, depending on the reaction conditions.[43] If the hindered and unhindered alkene mixture is allowed to equilibrate prior to bromine addition, bromination of the hindered alkene is greatly favored (up to a 95:5 preference). Conversely, inclusion of the bromine in the sieves followed by addition of the alkene mixture shows opposite selectivity.

Molecular sieves have been employed as acid scavengers in the transition metal-catalyzed synthesis of carboxylic acids and esters from iodides under base-free conditions, as represented in eq 13.[44] Another transition metal-catalyzed reaction (eq 14) applies sieves as a cocatalyst with ***Iron(III) Chloride*** to form a nonreducing disaccharide in an alternative to the conventional Koenigs-Knorr method.[45] In concert with ***Tin(II) Trifluoromethanesulfonate*** and ***2,4,6-Collidine***, molecular sieves promote the coupling of acetobromoglucose with various protected sugar derivatives to form exclusively *trans*-β-D-glucosides with glucose as the reducing unit.[46] Finally, the use of zeolites as cocatalysts in palladium-catalyzed oxidative cyclizations has led to substantial improvements in the diastereoselectivity of these reactions.[47,48] This is exemplified in eq 15, which shows only a 17% de in the absence of molecular sieves.

Molybdenum(V) Chloride

$MoCl_5$

[10241-05-1] · Cl_5Mo · Molybdenum(V) Chloride · (MW 273.19)

(chlorinating agent for alkyl halides,[5] alkenes,[7] and alkynes;[8] used as a Lewis acid and as a catalyst for CO_2 insertion to oxiranes,[9] for C-C coupling of alkenyllithium reagents,[10] and for condensation of nitrobenzene with alcohols;[11] easily reduced to Mo^{III} species, useful as a reagent of deoxygenation;[12,13] methylenemolybdenum reagents for chemoselective carbonyl alkenation are prepared from $MoCl_5$[17,18])

Alternate Name: molybdenum pentachloride.

Physical Data: mp 204 ± 1 °C; bp 276.5 °C; *d* 2.936 g cm^{-3}.

Solubility: sol H_2O, where it undergoes hydrolysis; slightly sol $TiCl_4$, diethyl ether.

Analysis of Reagent Purity: pure reagent (99.9%) is commercially available, packaged in ampules.

Preparative Methods: by the reaction of molybdenum(VI) oxide and carbon tetrachloride or $CCl_2{=}CClCCl_3$ as very dark-colored crystals.[1-3] The industrial method is the direct chlorination of molybdenum metal. A convenient laboratory technique is the liquid-phase reaction system that uses refluxing thionyl chloride and MoO_3.[4]

Handling, Storage, and Precautions: moisture sensitive; store under nitrogen. Use in a fume hood.

Chlorination of Alkyl Halides.[5]

Alkyl iodides, bromides, and fluorides are converted to alkyl chlorides in fair to good yields by reaction with $MoCl_5$ in CH_2Cl_2 at room temperature (eq 1). The reaction sequence is applicable to the conversion of secondary and tertiary halides (I, Br, or F). $MoCl_5$ does not effect halogen interchange with primary alkyl bromides. The conversion of 1-fluorooctane to 1-chlorooctane is accompanied by rearrangement producing 2-chlorooctane (eq 2). A Lewis acid-assisted ionization of the carbon-halogen bond followed by conversion of the carbonium ion to chlorocarbon by the reaction with halometallo-ate complex is a likely mechanism for this transformation.

Vicinal Chlorination.[6]

The reaction of alkyl chlorides with an excess of $MoCl_5$ leads to vicinal chlorides in fair to excellent yields. For example, 2-chlorobutane is converted (eq 3) to (±)-2,3-dichlorobutane (58%) and *meso*-2,3-dichlorobutane (38%). The reaction sequence has been applied to the chlorination of alkyl halides containing either a secondary or tertiary vicinal carbon (eq 4).

Chlorination of Alkenes and Alkynes.[7,8]

Chlorination of alkenes with $MoCl_5$ was first observed in the preparation of molybdenum(IV) chloride under irradiation, where upon hexachloroethane was produced from tetrachloroethylene (eq 5). Molybdenum(V) chloride

reacts with vicinal disubstituted alkenes and internal alkynes to produce dichloroalkanes and -alkenes, respectively, in fair to good yields. In this case, irradiation is not necessary. Typically (eq 6), cyclohexene in CH_2Cl_2 was treated with $MoCl_5$ to give *cis*-1,2-dichlorocyclohexane (68%), *trans*-1,2-dichlorocyclohexane (2%), cyclohexylcyclohexane (2%), and chlorocyclohexane (2%). Vicinal dichlorination may not proceed via the ionic or radical pathway characteristically observed in the reaction of alkenes with molecular chlorine. Chlorination of alkynes gives *cis*-addition (eq 7).

$$Cl_2C{=}CCl_2 \xrightarrow[\substack{CH_2Cl_2 \\ -2\ MoCl_4}]{2\ \text{equiv}\ MoCl_5} Cl_3C\text{-}CCl_3 \qquad (5)$$

Catalyst for Insertion and Coupling Reactions.

The reagent ***Molybdenum(V) Chloride-Triphenylphosphine*** (1:6) promotes the insertion of CO_2 into methyloxirane at 20 °C under 1 atm (eq 8). This catalyst system gave best conversions and yields when using a 100- to 200-fold excess of oxirane relative to $MoCl_5$.[9]

(8)

The conversion of *trans*-propenyllithium to 2,4-hexadiene is catalyzed by $MoCl_5$ (eq 9). Comparable yields were obtained with $MoCl_5$ and Ni^{II} reagents.[10]

(9)

Nitrobenzene reacts with ethanol and higher alcohols in the presence of this reagent to form 2-methyl- or 2,3-dialkylquinolines (eq 10). The best yields and conversions are obtained in the presence of about equimolar or 0.5:1.0 mixtures of ***Tetracarbonyl(di-μ-chloro)dirhodium*** and $MoCl_5$ at 180 °C. Molybdenum species, due to their Lewis acidity, catalyze mainly the condensation reaction.[11]

(10)

Deoxygenation with $MoCl_5$/Zn.[12,13]

An Mo^{III} species obtained by reaction of $MoCl_5$ with ***Zinc*** in aqueous THF reduces sulfoxides to sulfides in 78-91% yields (eq 11) and aromatic *N*-oxides in 45-65% yield (eq 12). The reagent also reduces aromatic and heteroaromatic nitro compounds to amines in 30-70% yields (eq 13). See also ***Molybdenum(V) Chloride-Zinc***.

(11)

(12)

(13)

Lewis Acid-Catalyzed Reactions.[14,15]

Molybdenum(V) chloride is used as a Lewis acid for selective cleavage of carbon-oxygen bond of *O,S*-acetals and acetals in the reaction of trimethylstyrylsilanes, leading to the corresponding styryl adducts (eqs 14 and 15).

(14)

(15)

Chemoselective Carbonyl Methylenating Reagents.

$MoCl_5$ and substitution products of $MoCl_5$, such as $MoOCl_3(THF)_2$ or $(MeO)_2MoCl_3$ (= $MoCl_5$ + addition of THF or MeOH), are educts for a series of carbonyl methylenating reagents which are generated by reaction with ***Methyllithium***[16-18] or ***Trimethylaluminum***.[19] The reaction with MeLi is believed to occur according to eq 16 and yields carbonyl methylenating μ-methylene complexes which are in contrast to the carbonyl alkenating reagents of Wittig, Horner-Emmons, Peterson, Schrock, and Tebbe Lewis-acids and are highly chemoselective.

(16)

A limiting factor is the high thermolability of the reagents. The most closely investigated reagents are the following.

Reagent $MoCl_5$ + 2 MeLi.[17]

This reagent is inert towards the groups -COCl, $-CO_2R$, and $-CONR_2$, but methylenates aldehydes and ketones in good yields and discriminates well between aldehyde and keto groups in favor of the aldehyde group (e.g. eq 17). A corresponding reaction occurs with azomethines. The reaction with aromatic epoxides yields the corresponding alkenes, whereas in the case of aliphatic epoxides, chlorohydrins are produced.

(17)

$X = O, Y = CH_2$; 80%
$X = CH_2, Y = O$; 0%
$X = Y = CH_2$; 1%

Reagent $MoOCl_3(THF)_2$ + 2 MeLi.[18]

This reagent allows regioselective carbonyl methylenation due to high aldehyde vs. ketone selectivity and cheleselectivity (preference of a keto group in the α- or β-position to a hydroxy group before an isolated keto group, e.g. eq 18), and tolerates the groups -COCl, $-CO_2R$, and $-CONR_2$ as well as water or alcohols in the solvent. It allows highly selective monomethylenation of dialdehydes, diketones, and triketones (e.g. eq 19).[16]

Molybdenocenes.

Stirring NaCp with $MoCl_5$ in THF at rt produces $Mo^{IV}Cp_2Cl_2$; CpMgCl reacts with $MoCl_5$ to give $[Cp_2Mo^{IV}Cl]^+$ ions, which can be precipitated by Reinecke acid.[20]

Molybdenum(V) Chloride-Triphenylphosphine

$MoCl_5$-PPh_3

($MoCl_5$)

[10241-05-1] · Cl_5Mo · Molybdenum(V) Chloride-Triphenylphosphine · (MW 273.19)
(PPh_3)

[603-35-0] · $C_{18}H_{15}P$ · Molybdenum(V) Chloride-Triphenylphosphine · (MW 262.30)

(carbon dioxide insertion;[2] cyclic carbonate preparation; Lewis acid catalysis)

Physical Data: see ***Molybdenum(V) Chloride*** and ***Triphenylphosphine***.

Solubility: $MoCl_5$: sol most organic solvents. PPh_3: sol Et_2O, $CHCl_3$, and most common organic solvents; slightly sol EtOH; insol H_2O.

Form Supplied in: $MoCl_5$: green-black solid; widely available. PPh_3: white crystalline solid; widely available.

Handling, Storage, and Precautions: $MoCl_5$ is air- and moisture-sensitive and somewhat corrosive. Ph_3P is fairly air-stable, but is slowly converted to its oxide, Ph_3PO, upon prolonged exposure. Ph_3P can be recrystallized from Et_2O. Use in a fume hood.

Cyclic Carbonates.

Molybdenum(V) chloride-triphenylphosphine (1:5) catalyzes the insertion of CO_2 into methyloxirane to afford the cyclic carbonate of propane-1,2-diol in 78% yield (eq 1). The reaction proceeds at room temperature and 1 atm CO_2 pressure. Other Lewis acids can be used in place of $MoCl_5$, although the molybdenum reagent is the most efficient.[1] Previously reported catalytic processes required elevated CO_2

pressure (5-200 atm) and temperature (100-200 °C).[2,3]

Molybdenum(V) Chloride-Zinc

$MoCl_5$-Zn

($MoCl_5$)

[10241-05-1] · Cl_5Mo · Molybdenum(V) Chloride-Zinc · (MW 273.19) (Zn)

[7440-66-6] · Zn · Molybdenum(V) Chloride-Zinc · (MW 65.39)

(nitro group, *N*-oxide reduction;[5] amine preparation[4])

Physical Data: see ***Molybdenum(V) Chloride*** and ***Zinc***.

Solubility: $MoCl_5$: sol organic solvents. Zn: insol.

Form Supplied in: $MoCl_5$: green-black solid; widely available. Zn: metallic solid; widely available as powder, wire, or granular solid.

Handling, Storage, and Precautions: $MoCl_5$ is air- and moisture-sensitive and somewhat corrosive. Use in a fume hood.

Sulfoxide Reduction by Low-Valent Molybdenum Species.

Olah reported that treatment of a THF solution of $MoCl_5$ with H_2O followed by Zn metal produces a low-valent molybdenum species which effectively converts organic sulfoxides to sulfides at room temperature in high yields (78-91%). The active deoxygenating species in solution is believed to be some form of Mo^{III}. ***Vanadium(II) Chloride*** was found to mediate the same deoxygenation, although somewhat less efficiently.[1] Sulfoxide reduction has also been reported for low-valent molybdenum and tungsten species obtained by other means.[2,3]

Deoxygenation of *N*-Oxides and Reduction of Nitro Groups.[4]

Molybdenum(V) Chloride-Zinc is a mild, selective reagent for the deoxygenation of pyridine and pyridazine *N*-oxides and for the reduction of aromatic and heteroaromatic nitro groups to amines. Reported yields are moderate (29-71%); however, potentially sensitive functionality is tolerated (eqs 1-3).

Molybdenum(VI) Fluoride[1]

MoF_6

[7783-77-9] · F_6Mo · Molybdenum(VI) Fluoride · (MW 209.94)

(metathetic fluorination of carbonyl groups;[2] oxidation[3] or oxidative fluorination[4] of selected organic compounds)

Alternate Name: molybdenum hexafluoride.

Physical Data: mp 17.5 °C; bp 35 °C; *d* 2.543 g cm^{-3} (l, 19 °C).

Solubility: sol saturated hydrocarbons, chlorinated and fluorinated hydrocarbons. The rate of decomposition of the solution of MoF_6 in *n*-hexane is 1% h^{-1}. The reaction of MoF_6 with CCl_4 takes place at ca. 150 °C. MoF_6 reacts violently with H_2O and protic solvents.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: the purity of a MoF_6 solution can be checked by ^{19}F NMR: $\delta^{19}F$ (MoF_6) +290 ($MeCN/CFCl_3$, δ +ve for downfield shifts); $\delta^{19}F$ ($MoOF_4$) +148.

Handling, Storage, and Precautions: can be handled in normal glassware at or below room temperature. It attacks silica at 120-150 °C to give $MoOF_4$[5] and must be handled in stainless steel autoclaves for reactions at high temperature. Any leak can be detected by the deep blue color which results from the reaction of MoF_6 with moisture. Normal precautions when working with MoF_6 include gloves, glasses, and a good fume hood. Contact of a CH_2Cl_2 solution with the skin leads to superficial burnings, readily detected by their blue color. Molybdenum is reputed to be of low toxicity.

Oxygen to Fluorine Exchange Reactions.

The difference between the formation enthalpies of MoF_6(g) and $MoOF_4$(g) is ca. 55 kcal mol^{-1},[6] which may be compared with ca. 2 × 50 kcal mol^{-1} for the SF_4/SO_2 system. Hence, MoF_6 is expected to reproduce the oxygen to fluorine exchange reactions performed by ***Sulfur Tetrafluoride***. Indeed, in methylene chloride at room temperature with ***Boron Trifluoride*** as a catalyst, MoF_6 readily reacts with ketones and aldehydes to give the corresponding *gem*-difluoro compounds (eq 1).[2,7]

The transformation is compatible with organic functionalities such as Cl, Br, CO_2R, $C(O)NR_2$, CN, NO_2, and $P(O)R_2$. Alcohols, amines, ethers, and double bonds are attacked. MoF_6 is significantly stronger than SF_4 as a Lewis acid. This technique has been used inter alia for the preparation of *gem*-difluoro-substituted fatty acids.[8]

At high temperature and without a catalyst, MoF_6 is also able to convert aliphatic[9] and aromatic[10] carboxylic acids into *gem*-trifluoro derivatives (eqs 2 and 3).

Aryl trifluoromethyl derivatives can also be obtained under less drastic conditions by fluorination of aromatic acid chlorides (eq 4).[11]

Ortho substitution of the arene ring blocks the reaction. In a related transformation, aryl chlorothioformates can be converted into aryl trifluoromethyl ethers (eq 5).[12]

Owing to the presence of the oxygen spacer, the interconversion is no longer sensitive to *ortho* substitution and the yields are consistently high. Finally, two results worthy of note: MoF_6 converts ***Ethylene Oxide*** and trifluoroethanol,

respectively, into 1,1-difluoroethane (42%) and 1,1,1,2-tetrafluoroethane (85%).[9]

Oxidizing Agent.

Electrochemical studies in acetonitrile have shown that MoF_6 is a rather powerful oxidizing agent. The order $UF_6 > MoF_6 > NO^+ > Cu^{2+}$ &egt; WF_6 has been proposed.[13]

This property of MoF_6 can be used in organic synthesis. For example, Olah et al. have described the oxidative cleavage of hydrazones (eq 6).[3]

(6)

MoF_6 has also been used for the oxidative fluorination of phosphines into fluorophosphoranes (eqs 7 and 8).[4]

Monochloroalane[1]

AlH_2Cl

[14644-71-4] · $AlClH_2$ · Monochloroalane · (MW 64.45)

(reducing agent for a variety of functional groups[1])

Alternate Name: aluminum chloride hydride.

Physical Data: the reagent is generated and used in situ. See ***Aluminum Chloride*** and ***Lithium Aluminum Hydride***.

Solubility: sol ether.

Preparative Methods: (a) A solution of 0.57 g (15 mmol) of $LiAlH_4$ in 15 mL of dry ether is mixed with a solution of 1.99 g (15 mmol) of $AlCl_3$ in 15 mL of dry ether at -5 °C. The resulting mixed hydride solution is stirred at room temperature for 15 min.[2] (b) To a precooled (0-5 °C) 20 mL of ether are added ground $AlCl_3$ (400 mg, 3.00 mmol) and $LiAlH_4$ (114 mg, 3.00 mmol), and the suspension is heated under reflux for 30 min.[3] This procedure provides AlH_2Cl as a suspension in ether.

Analysis of Reagent Purity: Metal Hydrides Technical Bulletin No. 401 describes an apparatus and methodology for assay by means of hydrogen evolution. See also Rickborn and Quartucci.[4] The IR spectrum of AlH_2Cl shows a strong Al-H stretching absorption band at 1852 cm^{-1}.[5]

Handling, Storage, and Precautions: solutions or suspensions of AlH_2Cl in ether are highly flammable and must be stored in the absence of moisture. Tetrahydrofuran is cleaved by AlH_2Cl to yield the corresponding aluminum alkoxide and is thus not a suitable solvent.

General Discussion.

This reagent readily reacts with aldehydes, ketones, esters, and epoxides to give alcohols, and also with amides, nitriles, and azides to give amines. Unlike ***Lithium Aluminum Hydride***, this reagent does not reduce nitro groups (eq 1).[6] Simple alkyl halides and tosylates are not readily reduced (eq 2).[7] Optically active azetidin-2-ones are reduced to the corresponding azetidines without cleavage of the β-lactam ring or loss of enantiomeric purity (eqs 3 and 4).[3]

(1)

(2)

(3)

(4)

Aluminum chloride hydride is a milder reducing agent than $LiAlH_4$, which acts as a Lewis acid as well as a hydride donor. For example, epoxides are reduced to the corresponding alcohols, where the ring cleavage takes place at the more substituted carbon (eqs 5 and 6).[8] These results clearly show the strong Lewis acidity of this reagent.

(5)

(6)

Reduction of cyclopropene esters proceeds with carbon-carbon bond migration, giving cyclobutenes in good yield (eq 7).[9] Reaction of 6β-methoxy-3α,5-cyclocholestane with AlH_2Cl gives 3α,5-cyclo-5α-cholestane as the major product (eq 8).[10]

(7)

(8)

This reagent has a greater tendency to bring about hydrogenolysis than $LiAlH_4$. Conjugated ketones and esters are frequently reduced to hydrocarbons (eqs 9-11).[11]

(9)

(10)

Aluminum chloride hydride is a convenient reagent for reductive cleavage of acetals to the corresponding ethers (eq 12),[1] and hemithioacetals to thioethers (eq 13).[12] Cyclic acetals are converted into hydroxy ethers (eqs 14 and 15).[13,14] The regioselectivity of the reaction is governed by the electronic and steric effects of the substituents of the acetals (eq 16).[15]

(14)

(15)

$\xrightarrow[\text{ether}]{AlH_2Cl}$ 80-86%

(1) **(2)** (16)

$R^1 = H$;	$R^2 =$ Me, Et, *i*-Pr, *t*-Bu	0:100
$R^1 = H$;	$R^2 =$ Ph	100:0
$R^1 =$ *t*-Bu;	$R^2 =$ Me	100:0
$R^1 =$ *i*-Pr;	$R^2 =$ Me	86:14
$R^1 =$ Ph	$R^2 =$ Me	15:85

Enamines are reduced to alkenes and amines in ether at reflux for 5-24 h, as exemplified in eq 17.[16]

Monochloroborane Diethyl Etherate[1]

$BH_2Cl.OEt_2$

[36594-41-9] · $C_4H_{12}BClO$ · Monochloroborane Diethyl Etherate · (MW 122.42)

(hydroborating agent providing access to dialkylchloroboranes,[2] dialkenylchloroboranes,[2] and *B*-chloro bora heterocycles,[3] all useful intermediates for the synthesis of alkenes, dienes, ketones, esters, secondary amines, hydroperoxides, and aminoboranes)

Physical Data: mp -105 to -85 °C.[4]

Solubility: sol diethyl ether.

Preparative Methods: conveniently prepared by the reaction of ***Lithium Borohydride*** with ***Boron Trichloride*** in diethyl ether.[2] The reaction can be monitored by ^{11}B NMR analysis. A 1.0-1.5 M solution of monochloroborane is obtained, existing in an equilibrium with a small amount of dichloroborane and borane (eq 1).[1a] The solution cannot be concentrated to obtain a neat product, since it loses diborane when excess ether is removed.[5]

$$\underset{\sim 90\%}{2\,BH_2Cl \cdot OEt_2} \rightleftharpoons \underset{\sim 5\%}{BHCl_2 \cdot OEt_2} + \underset{\sim 5\%}{BH_3 \cdot OEt_2} \quad (1)$$

Analysis of Reagent Purity: concentration of the reagent is determined by the analysis for hydride, chloride, and boron.[2,6] If the hydride and chloride are not in the proper ratio of 2:1, a calculated quantity of the solution in deficiency is added. In the ^{11}B NMR spectrum, the resonances for dichloroborane and borane should be of equal intensity; δ (ppm) 5.0 (t, $J_{B\text{-}H}$ = 131 Hz).[2a]

Handling, Storage, and Precautions: corrosive, flammable liquid; reacts violently with water. Monochloroborane solutions in diethyl ether are stable for several weeks when kept at 0 °C, protected from moisture and air. Handle and store under nitrogen or argon. Use in a fume hood.

Hydroboration of Alkenes.

Monochloroborane diethyl etherate reacts readily at 0 °C with alkenes to give dialkylchloroboranes in quantitative

yields (eq 2).[2] Regioselectivity of the hydroborations is greater than with ***Borane-Tetrahydrofuran*** (Figure 1).

The hydroboration of alkenes with monochloroborane diethyl etherate can be controlled to stop at the monoalkylchloroborane stage by the addition of 1-2 equiv. of THF. Monoalkylchloroboranes can be isolated and characterized as complexes with ***Trimethylamine***. However, in diethyl ether solution, monoalkylchloroboranes readily disproportionate.[7] The stepwise hydroboration of two different alkenes with monochloroborane diethyl etherate in the presence of THF or ***Dimethyl Sulfide*** does not provide the mixed dialkylchloroboranes cleanly.[1a] Other procedures leading to these products and totally mixed trialkylboranes have been developed.[7-11]

Dialkylchloroboranes are useful synthetic intermediates. Since they are formed in excellent purity, they can often be used without isolation. Thus dialkylchloroboranes undergo facile reaction with ***Ethyl Diazoacetate*** at -78 °C to give the corresponding ethyl alkylacetates in nearly quantitative yield (eq 3).[12] Bulky alkyl groups are readily accommodated. Consequently, the reaction provides a general two-carbon homologation under remarkably mild conditions.

Treatment of dialkylchloroboranes with alcohols provides esters of dialkylborinic acids. These compounds react with ***Dichloromethyl Methyl Ether*** in the presence of lithium triethylcarboxide (DCME reaction) to give α-chloroborinic esters (eq 4). The esters are converted into alkenes by mild thermal treatment,[13,14] while oxidation provides ketones (eq 5).[14]

(5)

Unsymmetrical ketones can be synthesized by the reaction of dialkylchloroboranes with lithium aldimines (eq 6).[15]

(6)

Dialkylchloroboranes react with organic azides to give secondary amines in 50-60% yields (eq 7).[16]

(7)

All reactions described above proceed with retention of configuration of the alkyl group.

B-Chlorodiisopinocampheylborane (Dip-chloride), an asymmetric dialkylchloroborane, can be prepared by hydroboration of α-pinene with $BH_2Cl.OEt_2$[17] (see also ***Monochloroborane-Dimethyl Sulfide***). It is a highly enantioselective reducing agent for ketones,[18] and is also used as a chiral catalyst in the asymmetric Diels-Alder reaction (see ***(+)-B-Chlorodiisopinocampheylborane***).[19] Other chiral dialkylboranes have been used in the asymmetric aldol reaction.[20] Alkyl hydroperoxides can be prepared by oxidation of dialkylchloroboranes with molecular oxygen under controlled conditions.[21] The reaction of $BH_2Cl.OEt_2$ with silazenes has been used for the synthesis of silylated aminoboranes.[22]

Hydroboration of Dienes.

α,o-Dienes react with monochloroborane to give a mixture of monomeric and polymeric products. Heating the mixture under vacuum provides *B*-chloroboracycloalkanes in good yields (eq 8).[3]

Pure *B*-chloroborinane, *B*-chloro-3,5-dimethylborinane, and *B*-chloroborepane are readily isolated. They find application in the synthesis of pheromones.[23-26] *B*-Chloroborocane, an eight-membered ring bora heterocycle, can also be prepared. However, higher medium-ring bora heterocycles are not available by this method. They can be prepared by a stepwise ring enlargement.[27]

Limonene is transformed into *B*-chlorolimonylborane which, upon reduction, gives limonylborane, an asymmetric hydroborating agent.[28] The monohydroboration of limonene and other cycloalkadienes gives unsaturated alcohols in 30-80% yields.[29]

Hydroboration of Alkynes.

The monohydroboration of alkynes with monochloroborane diethyl etherate proceeds cleanly at 0 °C to give dialkenylchloroboranes (eq 9).[2]

(9)

Internal alkynes react in a stoichiometric ratio, whereas 30-40% excess of a terminal alkyne must be used to avoid undesired dihydroboration. Dialkenylchloroboranes undergo the usual reactions of vinylboranes, e.g. protonolysis with ***Acetic Acid*** to alkenes and oxidation with alkaline ***Hydrogen Peroxide*** to carbonyl compounds. The most useful reactions of dialkenylchloroboranes is their conversion to stereochemically pure (*E*,*Z*)-1,3-dienes by the Zweifel reaction,[2] and to symmetrical (*E*,*E*)-1,3-dienes,[30] 1,4-dienes, and alkenes via vinylcopper intermediates[31] (eq 10).[2,30]

(10)

Dialkenylchloroboranes have been used for the preparation of dialkenylaminoboranes.[32]

Monochloroborane-Dimethyl Sulfide[1]

$BH_2Cl.SMe_2$

[63348-81-2] · C_2H_8BClS · Monochloroborane-Dimethyl Sulfide · (MW 110.43)

(hydroborating agent providing access to thexylmonochloroborane,[2] dialkylchloroboranes,[3a] *B*-chloro bora heterocycles[4]; reagent for the cleavage of acetals[5] and epoxides[6])

Alternate Name: MCBS.

*Physical Data: d*204 1.059 g cm^{-3}.

Solubility: sol dichloromethane, pentane, diethyl ether.

Form Supplied in: colorless liquid.

Preparative Methods: by redistribution of ***Borane-Dimethyl Sulfide*** (BMS) and ***Boron Trichloride***.SMe_2[7] and by the reaction of BMS with CCl_4.[8] The reagent is in an equilibrium with approximately 15% each of $BHCl_2.SMe_2$ and BMS.[2,8-10]

Analysis of Reagent Purity: active hydride is determined by hydrolysis of an aliquot and measuring the hydrogen evolved according to the standard procedure.[11] ^{11}B NMR (CCl_4; δ, ppm) -7.2 (t),[9] -6.7 (t, J_{B-H} = 131 Hz).[7]

Handling, Storage, and Precautions: corrosive liquid; flammable; stench; reacts violently with water. Handle and store under nitrogen or argon. Stable indefinitely when stored under nitrogen at 25 °C. Use in a fume hood.

Hydroboration of Alkenes.

Monochloroborane dimethyl disulfide is a more convenient reagent than ***Monochloroborane Diethyl Etherate***. It is stable at room temperature, has higher concentration (9.5 M in BH_2Cl), and is soluble in various solvents. MCBS hydroborates both terminal and internal alkenes in less than 2 h at 25 °C in dichloromethane, pentane, or diethyl ether.[3a] The regioselectivity of addition to alkenes is similar to monochloroborane diethyl etherate. Even relatively hindered alkenes produce dialkylchloroboranes, e.g. α-pinene and 2-ethylapopinene are transformed into *B*-chlorodiisopinocampheylborane (Dip-chloride)[12a] and *B*-chlorobis(2-ethylapoisopinocampheyl)borane (Eap_2BCl),

respectively. Both are highly enantioselective reducing agents for ketones (see ***(+)-B-Chlorodiisopinocampheylborane***).[12]

With very hindered alkenes, the hydroboration stops at the monoalkylborane stage. Thus 2,3-dimethyl-2-butene gives cleanly ***Chloro(thexyl)borane-Dimethyl Sulfide*** (eq 1),[2] a useful hydroborating and reducing agent;[2,13-17] for example, it reduces carboxylic acids to aldehydes.[17]

(1)

Nopol methyl ether also reacts with MCBS in 1:1 molar ratio, the intramolecular complexation halting further reaction (eq 2).[9]

(2)

Synthesis of (*E*)- and (*Z*)-Alkenes and Ketones.

Dialkylchloroboranes are useful synthetic intermediates. They are readily methanolyzed, affording methyl dialkylborinates, which can be further transformed into ketones by the ***Dichloromethyl Methyl Ether*** (DCME) reaction (eq 3).[3]

(3)

The hydride reduction (hydridation) of dialkylchloroboranes provides access to a variety of dialkylboranes not available by direct hydroboration with borane itself.[18] These dialkylboranes are convenient intermediates for the Zweifel synthesis of (*E*)-[19] (eq 4) and (*Z*)-disubstituted[20] alkenes and trisubstituted alkenes.[21]

(4)

Only one R group of R_2BCl is utilized in these reactions and an excess of a terminal alkyne has to be used to minimize dihydroboration. These inconveniences can be circumvented by using alkenylborinate intermediates[22] or alkyldibromoboranes (see ***Dibromoborane-Dimethyl Sulfide***).

Cyclic Hydroboration of Dienes.

Hydroboration of 1,5-cyclooctadiene[4] and 1,3,5,7-cyclooctatetraene[23] with MCBS gives *B*-chloro-9-BBN and the 2,6-diboraadamantane skeleton, respectively. *B*-Chloro-9-BBN is useful for the preparation of ***9-Borabicyclo[3.3.1]nonane*** derivatives not directly available by hydroboration with 9-BBN, e.g. allenyl-9-BBN, a reagent for the synthesis of homopropargylic alcohols.[24]

Cyclic hydroboration with MCBS has been used in the synthesis of a hydrozaulene skeleton with three contiguous chiral centers (eq 5).[25] MCBS is more reactive than ***Thexylborane*** in this transformation.

(5)

Synthesis of Aldehydes, Ketones, and Acids.

Oxidation of dialkylchloroboranes derived from terminal alkenes with ***Pyridinium Chlorochromate*** and ***Chromium(VI) Oxide*** in acetic acid produces aldehydes and acids, respectively[26,27] (eq 6).[27] Similarly, ketones can be obtained from internal alkenes.[26]

(6)

Reagents for Enolboration.

Aldol reactions of boron enolates are remarkably stereoselective.[28] Consequently, generation of stereodefined boron enolates is of primary synthetic importance. Dialkylchloroboranes obtained by hydroboration of alkenes with MCBS and also by other methods are convenient reagents for enolboration of ketones and other carbonyl derivatives;[29] for example, dicyclohexylchloroborane gives the (*E*)-enolate predominantly for diethyl ketone and exclusively for propiophenone (eq 7).[30]

(7)

Computer modeling applied to design boron enolates effective for asymmetric *anti*-aldol reactions has led to the preparation of $[(Menth)CH_2]_2BCl$ (eq 8).[31]

(8)

(1)

Highly selective formation of (*E*)-enolates is achieved by treating ketones with (**1**). Addition to aldehydes gives *anti*-aldols with diastereoselectivity of 86:14 to 100:0 (*anti*:*syn*) in 56-88% ee.[31]

Cleavage of Acetals, Ketals, and Epoxides.

MCBS chemoselectively cleaves acetals of cyclic ketones, even in the presence of double bonds. Unsaturated aliphatic acetals undergo preferential hydroboration of the double bond[5] (for opposite chemoselectivity, see ***Monochloroborane Diethyl Etherate***). Epoxides are stereoselectively cleaved to *anti*-chlorohydrins[6,32] (eq 9).[6]

(9)

Certain dialkylhaloboranes are also effective reagents for the epoxide cleavage, e.g. Dip-chloride cleaves *meso*-epoxides with high enantioselectivity[33] (see also ***Chlorodiethylborane***).

Other Applications.

MCBS has been used for the synthesis of metallacarboranes,[34] boron-metal cluster compounds[35] and boron-containing polymers.[36]

Monoisopinocampheylborane[1]

[64234-27-1] · $C_{10}H_{19}B$ · Monoisopinocampheylborane · (MW 150.10)

(asymmetric hydroboration of *trans* and trisubstituted alkenes;[2] asymmetric reduction of ketones[3])

Physical Data: a crystalline adduct with ***N,N,N´,N´-Tetramethylethylenediamine*** ($2IpcBH_2$.TMEDA) has mp 140.5-141.5 °C; [α]23D +69.03° (*c* 9.33, THF).

Solubility: sol THF, Et_2O.

Analysis of Reagent Purity: the optical purity of the reagent is assayed by oxidation (NaOH, H_2O_2) to give isopinocampheol, [α]27D -35.8° (*c* 0.9, benzene).

Handling, Storage, and Precautions: best used as prepared. Guidelines for the handling of air- and moisture-sensitive materials should be followed.[1c]

Preparation.

Hydroboration of alkenes with ***Borane-Tetrahydrofuran*** or ***Borane-Dimethyl Sulfide*** proceeds rapidly past the monoalkylborane stage with all but the most sterically demanding alkenes. Thus, attempts to prepare a solution of monoisopinocampheylborane ($IpcBH_2$) by simple admixture of 1:1 (+)-α-pinene:borane result in an equilibrium mixture of $IpcBH_2$, diisopinocampheylborane (Ipc_2BH), and borane.[4] Although several indirect methods for the preparation of $IpcBH_2$ have been devised,[5a-f] the preparation of $IpcBH_2$ by displacement of α-pinene from Ipc_2BH with TMEDA is recommended (eq 1).[5e,6] It is unique to this procedure that the crystalline adduct[7] incorporates two $IpcBH_2$ units which are of higher optical purity than the starting (+)-α-pinene used. Analysis of the mother liquor reveals that the minor enantiomer accumulates in the more soluble diastereomeric adduct.

$IpcBH_2$ of essentially 100% ee is liberated from the TMEDA adduct by addition of ***Boron Trifluoride Etherate*** in THF. Filtration of the TMEDA.$2BF_3$ adduct provides a solution of $IpcBH_2$ in THF ready for subsequent hydroboration reactions (eq 2).

Asymmetric Hydroboration.

The steric requirements of $IpcBH_2$ are such that hydroboration of *trans* and trisubstituted alkenes proceeds with little or no displacement of α-pinene from the reagent, a phenomenon which is observed with the more hindered

Diisopinocampheylborane (Ipc_2BH). Ipc_2BH is most effective for the hydroboration of relatively unhindered *cis* alkenes, which are hydroborated with low asymmetric induction by $IpcBH_2$ (eq 3). The two reagents are therefore complementary in this respect. (For a reagent which hydroborates *cis*, *trans*, and trisubstituted alkenes with excellent asymmetric induction, see also ***(R,R)-2,5-Dimethylborolane***)

(3)

Representative *trans* alkenes are asymmetrically hydroborated by $IpcBH_2$ derived from (+)-α-pinene to give (*S*)-alcohols in the range of 65-76% ee. With highly hindered *trans* alkenes, the enantioselectivity can be somewhat higher (eq 4).[2]

(4)

Aliphatic trisubstituted alkenes are likewise hydroborated to give (*S*)-alcohols in the range of 53-72% ee. When the trisubstituted alkene bears a phenyl substituent, a significant increase in enantioselectivity is observed (eq 5).[2,8]

(5)

In the asymmetric hydroboration of 1-heteroarylcycloalkenes,[9] $IpcBH_2$ exhibits enantioselectivities of 83-90% ee, comparable to the phenyl-substituted alkenes examined (eq 6).

(6)

Many intermediate dialkylboranes derived from hydroboration with $IpcBH_2$ can be recrystallized to enantiomeric purities approaching 100%, thus giving alcohols of 98-99% ee upon oxidation.[10] If, instead of being oxidized in situ, the dialkylborane intermediate is treated with ***Acetaldehyde***,[11] α-pinene is displaced for recovery and a chiral boronate bearing the R group of the alkene is obtained (eq 7).

(7)

This reaction is general, and these boronic esters are versatile synthetic intermediates in their own right.[12]

Asymmetric Reduction of Ketones.

The reduction of prochiral ketones with $IpcBH_2$ is mechanistically complex. Although the secondary alcohols obtained are consistantly enriched in the (*S*) enantiomer when the reagent is prepared from (+)-α-pinene, the degree of asymmetric induction observed, 11-46% ee, varies with the reaction stoichiometry.[3] This has been attributed to the ability of the 1:1 $IpcBH_2$:ketone addition product to serve as a reducing agent for an additional equivalent of ketone (eq 8).

Monoperoxyphosphoric Acid[1]

[13598-52-2] · H_3O_5P · Monoperoxyphosphoric Acid · (MW 114.00)

(electrophilic reagent capable of reacting with many functional groups; delivers oxygen to alkenes,[2] alkynes,[3] arenes,[4] and amines[5])

Alternate Names: peroxymonophosphoric acid; PMPA.

Solubility: sol acetonitrile, dioxane.

Form Supplied in: not available commercially.

Analysis of Reagent Purity: assay using iodometry.[6]

Preparative Methods: (a) to a stirred suspension of 14.2 g of ***Phosphorus(V) Oxide*** in 60 mL of acetonitrile at 0 °C, 10 g of 70% ***Hydrogen Peroxide*** (**caution**!) in 20 mL of acetonitrile was added over a period of 45 min. The mixture was stirred at rt for 16 h.[6] (b) 87% H_2O_2 is used;[7] the latter is the more common procedure.

Handling, Storage, and Precautions: should be used immediately after preparation; reagent stored at 5 °C for 26 days lost 30% of active oxygen. Since H_3PO_5 is a peroxy acid, care should be exercised while carrying out the reactions; during workup, check for peroxides before solvent removal. This reagent should be handled in a fume hood.

Oxidations of Alkenes, Arynes, and Arenes.

Epoxides which are not readily opened by acids can be prepared by reacting alkenes with H_3PO_5. *trans*-Stilbene oxide (**1**) has been prepared in 74% yield through epoxidation of *trans*-stilbene with H_3PO_5 in dioxane.[2] Oxidation of diphenylacetylene with H_3PO_5 at rt in acetonitrile furnishes the diketone (**2**) in 48% yield;[3] this reaction can be carried out with ***Trifluoroperacetic Acid*** (TFPAA) but not with the normal peroxycarboxylic acids.

(1)

(2)

H_3PO_5 is an effective reagent for aromatic hydroxylation, the reactivity being comparable to that of TFPAA; oxidation of mesitylene in acetonitrile (25 °C, 4 h) furnishes mesitol in 77% yield.[4]

Baeyer-Villiger Reaction.

Reaction of acetophenone (**3**) with H_3PO_5 in acetonitrile at 30 °C furnished the aryl acetate (**6**) in 91% yield. The ketones (**4**) and (**5**) were also oxidized to (**7**) and (**8**) in yields of 95% and 98%, respectively; the corresponding methyl benzoates were not obtained. Baeyer-Villiger reaction of acetophenones with H_3PO_5 has nearly 100-fold higher rate than that with peroxycarboxylic acids such as ***Perbenzoic Acid***.[8]

(3) R = H
(4) R = Cl
(5) R = Me

(6) R = H
(7) R = Cl
(8) R = Me

Baeyer-Villiger reaction of (**9**) with H_3PO_5 furnished the phenol (**10**) (eq 1).[6] However, the reagents ***Peracetic Acid*** or TFPAA furnished the carboxylic acid (**11**).

(1)

Other Applications.

Oxidation of *N*,*N*-dimethylaniline in aqueous acetonitrile at 30 °C afforded the *N*-oxide in 82% yield.[5] Oxidation of THF with H_3PO_5 in acetonitrile or without solvent at 25 °C furnishes γ-butyrolactone in 40-45% yield.[9] This oxidation cannot be performed with percarboxylic acids such as $MeCO_3H$.

Related Reagents.

Peroxymaleic Acid; ***Trifluoroperacetic Acid***.

Monoperoxyphthalic Acid[1]

[2311-91-3] · $C_8H_6O_5$ · Monoperoxyphthalic Acid · (MW 182.14) (Mg salt.$6H_2O$)

[84665-66-7] · $C_{16}H_{22}MgO_{16}$ · Magnesium Monoperoxyphthalate Hexahydrate · (MW 494.69)

(mild peroxycarboxylic acids for effecting epoxidation of π-bonds, Baeyer-Villiger reactions, and the oxidation of diverse heteroatoms including nitrogen, sulfur, and selenium)

Alternate Name: MPP.

Physical Data: monoperoxyphthalic acid: mp 110-112 °C (dec).[2]

Solubility: monoperoxyphthalic acid: sol ether; magnesium monoperoxyphthalate: sol water, low molecular weight alcohols; very low sol organic solvents such as dichloromethane.

Form Supplied in: magnesium monoperoxyphthalate: white crystalline powder; commercially available as the hexahydrate.

Preparative Methods: monoperoxyphthalic acid is prepared as required by the addition of phthalic anhydride to 30% aqueous ***Hydrogen Peroxide***,[3a] in the presence of ***Sodium Hydroxide***[3b] or ***Sodium Carbonate***.[3c] Magnesium monoperoxyphthalate is prepared by the addition of phthalic anhydride and ***Magnesium Oxide*** to aqueous hydrogen peroxide.[3d] *Drying:* magnesium monoperoxyphthalate should be dried over calcium chloride in a desiccator.

Handling, Storage, and Precautions: magnesium monoperoxyphthalate may be stored at room temperature. *All work should be carried in an efficient fume hood behind a polycarbonate safety screen.*

Monoperoxyphthalic Acid.

Before the introduction of ***m-Chloroperbenzoic Acid*** (*m*-CPBA), one of the most frequently used peroxy acids was monoperoxyphthalic acid (MPP). Although MPP is a weaker acid than *m*-CPBA, the fact that phthalic acid is essentially insoluble in ether is an advantage with MPP. A disadvantage of the reagent is that MPP has to be made each time that it is used, whereas *m*-CPBA (60%) is commercially available admixed with *m*-chlorobenzoic acid and water. The epoxidation of a number of alkenes can be achieved in reasonable yields using MPP. Cyclohexene, limonene, and α-pinene were converted into the respective epoxides in 64, 71, and 48% yields, respectively.[3a] The oxidation of bicyclo[2.2.1]heptadiene gave, in addition to a low yield of the expected epoxide, bicyclo[2.2.1]hex-2-ene-5-carbaldehyde.[4] The epoxidation of a number of acid-sensitive alkenes, such as α-keto enol ethers, has been achieved in good yields in the presence of disodium phthalate as a buffer and is exemplified in eq 1.[5] It is of interest to note that the yields in these reactions were halved in the absence of the buffer.

The oxidation of indole derivatives gives rise to a number of products, including those where ring fragmentation has occurred. Thus 2-*t*-butylindole affords *N*-pivaloylanthranilic acid.[6] Monoperoxyphthalic acid has also been used to prepare *N*-oxides; for example, quinoline derivatives have been converted into their *N*-oxides.[7] Although MPP is now not used as frequently as formerly, some useful examples have been published recently. The epoxidation reactions shown in eqs 2 and 3 and the Baeyer-Villiger type rearrangement (eq 4) are illustrative.[8-10]

(4)

Magnesium Monoperoxyphthalate.

The production of magnesium monoperoxyphthalate (MMPP) in commercial quantities has led to its use in a number of different types of oxidation reactions since its introduction.[11] The use of MMPP has been reviewed in detail to early 1993.[1c] The different reaction types are outlined and exemplified in the following sections.

Epoxidation Reactions.

The majority of the successful examples of epoxidation reactions using MMPP have been carried out using water or a low molecular weight alcohol as a solvent. Where the substrate to be epoxidized is insoluble in such a solvent, water has been used together with a phase-transfer agent to take the monoperoxyphthalate ion into an organic phase, for example chloroform or dichloromethane. The formation of the monoepoxide from [$^2H_6$]buta-1,3-diene has been reported in a reaction where one atmosphere of the gas was kept over an aqueous solution of MMPP.[12] There have also been cases reported where attempted epoxidation reactions have failed in the presence of MMPP.[13] Typically these involve terminal alkenes where electron density in the double bond is relatively low. Epoxidation may then be successful using Kishi's high-temperature method in which the radical inhibitor 4,4´-thiobis(6-*t*-butyl-3-methylphenol) is employed together with *m*-CPBA.[14] An efficient alternative method for the epoxidation of terminal alkenes involves the use of ***Trifluoroperacetic Acid*** (TFPAA) generated by the interaction of urea-hydrogen peroxide (UHP) with trifluoroacetic anhydride (see ***Hydrogen Peroxide-Urea***).[15] It is of interest to note that the epoxidation of cholesterol proceeds efficiently in dichloromethane in the absence of a phase-transfer catalyst. Presumably in this case the hydroxyl group that is present in cholesterol acts as a crystal disrupting agent. This explanation may also apply to the observation that the MMPP epoxidation of *cis*-but-2-ene-1,4-diol proceeds efficiently, whereas a reaction of the diacetate does not.[16] As with all peroxycarboxylic acid epoxidations of cholesterol, a reaction using MMPP results in the formation of a mixture of products in which the α:β ratio is about 4:1. It appears that the larger the peroxycarboxylic acid, the larger the amount of the α-epoxide formed. A direct comparison with *m*-CPBA can be made in the case of the epoxidation of 1,2-dimethylcyclohexa-1,4-diene,[17,18] and also in the reactions with ***Ethyl Vinyl Ether***.[19] The oxidation shown in eq 5 gave about a 4:1 mixture of diastereomers in very good yield when carried out in a water-isopropanol mixture.[20] Hydrogen bonding between the peroxy acid and the hydroxyl group is presumed to be responsible for the preferred formation of the α-epoxide. The failure of *m*-CPBA to effect epoxidation of the diene ester shown in eq 6 is surprising. However, MMPP and TFPAA both gave the α-epoxide exclusively. On the other hand, a reaction using 3,5-dinitroperbenzoic acid gave a 3:1 mixture of the α- and β-epoxides.[21] As with epoxidation reactions carried out using *m*-CPBA, the reactions of MMPP with dienes (for example limonene) involve initial reaction at the more electron-rich double bond.

(5)

(6)

High diastereofacial selectivity can be anticipated where a neighboring functional group can be involved to control the stereochemical course of the reaction. Both of the diastereomers of the phosphine oxides shown in eq 7 are epoxidized with de values in excess of 95%.[22] Very low selectivities were observed where the chirality only involved the phosphorus center. Evidently the stereoselectivity is dominated by the effect of the chiral carbon center. Control may be less satisfactory when two functional groups have opposite influences. The epoxidation reaction shown in eq 8 was used in a study involving an enantiospecific synthesis of the nonproteinogenic α-amino acid anticapsin.[23] The desired product (**1**) was formed along with (**2**) in the ratio 5:2 using MMPP, whereas a 1:1 mixture was obtained using *m*-CPBA. Hydrogen bonding of the peroxy acid to the amide group evidently competes with the sterically demanding *t*-butyldiphenylsilyl residue in this reaction.

(7)

The synthesis of a number of naturally occurring fused 3-methylfuran derivatives was achieved using, as a key step, the epoxidation-aromatization shown in eq 9.[24] The oxidation of a number of heteroaromatic compounds has also been studied using MMPP and some of the products clearly result from initial epoxidation. A number of furan derivatives that carry electron-releasing substituents in the 2- and 5-positions are oxidized to give acyclic dienones in reactions with either *m*-CPBA or MMPP.[25] The oxidation shown in eq 10 was used in a synthesis of bromobeckerelide,[26] and the oxidation of 1-benzenesulfonylindole using MMPP gives the indoxyl derivative shown in eq 11.[27]

(11)

Baeyer-Villiger and Related Reactions.

The ease with which Baeyer-Villiger oxidation reactions of ketones occur is related to the strength of the conjugate acid of the leaving group. Since phthalic acid is not a particularly strong acid, it is not surprising that monoperoxyphthalic acid and MMPP are not used as frequently as trifluoroperacetic acid in Baeyer-Villiger reactions. Cyclohexanone and 3,3-dimethylbutanone are converted into ε-caprolactone and *t*-butyl acetate, respectively, in good yields.[11] The oxidative rearrangement reactions of the β-lactams shown in eq 12 have been reported to give higher yields when using MMPP than using *m*-CPBA.[28] The conversion of an aromatic aldehyde into a phenol via the formate ester (the Dakin reaction) is evidently related to the Baeyer-Villiger reaction. These reactions proceed well when the aromatic aldehyde has an electron releasing substituent *ortho* or *para* to the formyl residue. A number of peroxy acids have been used, for example *m*-CPBA and ***Peracetic Acid***, including cases where the peroxy acid was generated using UHP and ***Acetic Anhydride***. A limited number of examples have been reported using MMPP; the example shown in eq 13 is illustrative.[29]

(12)

(13)

Oxidation of Sulfur and Selenium.

The oxidation of sulfides to sulfoxides and sulfones can be achieved with a wide range of oxidizing agents, including various peroxycarboxylic acids. The second oxidation step is normally slower than the first and so using a controlled amount of peroxy acid normally allows the formation and isolation of either product. Thus tetrahydrothiophene can be

oxidized either to the sulfoxide or to the sulfone using MMPP.[11] A number of cases have been reported where good yields of sulfoxides have been obtained,[30-32] including the example shown in eq 14 which was used in a synthesis of artemisinin.[32] The oxidation of the selenide that is involved in the sequence shown in eq 15 also proceeds in high yield.[33]

(14)

(15)

The use of an excess of MMPP has allowed a number of research groups to obtain sulfones from sulfides in good yields.[34 -37] The oxidation of phosphothionate to phosphate has been studied using a wide variety of oxidants. It was shown that MMPP was better than *m*-CPBA in the oxidation of malathion to malaoxon.[38] The example shown in eq 16 exemplifies the successful use of a phase-transfer catalyst.[34]

(16)

Oxidation of Nitrogen Functional Groups.

The oxidations of a number of pyridine derivatives,[11] pyrimidines,[39] and pyridothiophenes[40] to the related *N*-oxides have been reported. The oxidation of quinoxaline (eq 17) to the di-*N*-oxide also proceeds efficiently.[29] The oxidative cleavage of suitable bicyclic isoxazolidines has been studied in connection with the synthesis of indolizidine alkaloids.[41] In the example shown in eq 18 the use of *m*-CPBA afforded a mixture of the products (**3**) and (**4**) in which (**3**) predominated. Regiochemical control was better when using MMPP and in that case the nitrone (**4**) was the only

product.

(17)

(18)

A number of methods are available for the oxidative regeneration of ketones from hydrazones. Very good yields have been reported for the conversion of *N*,*N*-dimethyl- and SAMP-hydrazones into their precursor ketones using MMPP. In the latter case (eq 19), the stereochemical integrity of the chiral center α to the carbonyl group was maintained.[42] The oxidation of *N*,*N*-dimethylhydrazones derived from aldehydes has also been studied using MMPP. Nitriles are obtained in high yields in these reactions and once again (eq 20) there is no racemization of a chiral center α to the original formyl group.[43]

Monoperoxysulfuric Acid[1]

H_2SO_5

[7722-86-3] · H_2O_5S · Monoperoxysulfuric Acid · (MW 114.07)

(strong oxidizing agent for many functional groups;[1] can selectively oxidize amines;[2] in alcohol solvent can directly convert conjugated aldehydes to esters;[3] can effect regioselective Baeyer-Villiger oxidations;[4] can promote regioselective oxidative rearrangement of tertiary alcohols to o-hydroxy ketones[5])

Alternate Name: Caro's acid.

Physical Data: mp 45 °C.

Solubility: sol water (see also ***Potassium Monoperoxysulfate*** (Oxone)).[1c,d]

Analysis of Reagent Purity: a spectrophotometric method is available for analysis of the components of an $H_2SO_5/H_2S_2O_8/H_2O_2$ mixture.[6]

Preparative Methods: prepared as needed from $K_2S_2O_8$ (see ***Ammonium Peroxydisulfate***), concentrated ***Sulfuric Acid***, and water;[1b,e,f] or ***Hydrogen Peroxide*** (60-90%) and concentrated H_2SO_4.[3]

Handling, Storage, and Precautions: may react explosively with acetone, and primary or secondary alcohols.

Selective Oxidations.

Neutralized Caro's acid can chemoselectively oxidize arylamines to nitroso compounds (eq 1);[1b,2a,7] a simpler procedure for this transformation uses ***Acetic Acid/Hydrogen Peroxide*** 30%.[2b] An alternative pathway leading to the formation of azoxybenzenes (eq 1);[7] or nitro compounds (eq 2)[8] is also possible and depends upon substrate, solvent, pH, and reaction conditions. Caro's acid oxidation of polyhalodiazines is unfruitful, except for pyrazines. While chloropyrazines and chloroquinoxalines react with 30% H_2O_2 in glacial acetic acid to give mono-*N*-oxides with selective *N*-4 oxidation,[9] Caro's acid affords mono-*N*-oxides with regioselective oxidation at *N*-1 (eq 3).

(1)

(2)

(3)

Conjugated aldehydes can be oxidized directly to α,β-unsaturated esters by Caro's acid in alcoholic media (eq 4).[3] The reaction probably proceeds through a hemiacetal and not the carboxylic acid.

(4)

Baeyer-Villiger Oxidation.

Caro's acid has proven useful in the Baeyer-Villiger oxidation of cyclic ketones and steroids.[4] The regioselective Baeyer-Villiger oxidation of isatins to 2,3-dioxo-1,4-benzoxazines observed with Caro's acid contrasts sharply with formation of isatoic anhydrides using ***Peracetic Acid*** (eq 5).[4a] The related buffered reagent ***Bis(trimethylsilyl) Monoperoxysulfate*** is a strong Baeyer-Villiger oxidant. This aprotic reagent is soluble in methylene chloride and generally gives higher yields and purer product than Caro's acid.[10]

(5)

Alkyl Hydroperoxide Synthesis and Rearrangement.

Caro's acid oxidizes tertiary alcohols to hydroperoxides, which rearrange in the acid medium. The procedure is useful for the conversion of cycloalkanols to o-hydroxy ketones (eq 6).[5] Cyclic o-hydroxy ketones exist as oxonium ions in sulfuric acid and thus are resistant to further Baeyer-Villiger oxidation.

Montmorillonite K10

[1318-93-0]

(catalyzes protection reactions of carbonyl and hydroxy groups; promotes ene,[22] condensation,[25] and alkene addition[27] reactions)

Physical Data: the surface acidity of dry K10 corresponds to a Hammett acidity function H_0 = -6 to -8.[13]

Form Supplied in: yellowish-grey dusty powder. Forms with water a mud that is difficult to filter, more easily separated by centrifugation; with most organic solvents, forms a well-settling, easy-to-filter suspension.[6]

Handling, Storage, and Precautions: avoid breathing dust; keep in closed containers sheltered from exposure to volatile compounds and moisture.

General.

Montmorillonite clays are layered silicates and are among the numerous inorganic supports for reagents used in organic synthesis.[1,2] The interlayer cations are exchangeable, thus allowing alteration of the acidic nature of the material by simple ion-exchange procedures.[3,4] Presently, in fine organic synthesis, the most frequently used montmorillonite is K10, an acidic catalyst, manufactured by alteration of montmorillonite (by calcination and washing with mineral acid; this is probably a proprietary process).

The first part of this article specifically deals with representative laboratory applications to fine chemistry of clearly identified, unaltered K10, excluding its modified forms (cation-exchanged, doped by salt deposition, pillared, etc.) and industrial uses in bulk. This illustrative medley shows the prowess of K10 as a strong Brønsted acidic catalyst. The second part deals with cation-exchanged (mainly Fe^{III}) montmorillonite. Clayfen and claycop, versatile stoichiometric reagents obtained by metal nitrate deposition on K10,[5] are used in oxidation and nitration reactions. They are treated under ***Iron(III) Nitrate-K10 Montmorillonite Clay*** and ***Copper(II) Nitrate-K10 Bentonite Clay***.

K10 is often confused, both in name and in use, with other clay-based acidic catalysts (KSF, K10F, Girdler catalyst, acid treated or H^+-exchanged montmorillonite or clay, etc.) that can be effectively interchanged for K10 in some applications. Between the 1930s and the 1960s, such acid-treated montmorillonites were common industrial catalysts, especially in petroleum processing, but have now been superseded by zeolites.

Activation.[6]

K10 clay may be used crude, or after simple thermal activation. Its acidic properties are boosted by cation exchange

(i.e. by iron(III)[7] or zinc(II)[8]) or by deposition of Lewis acids, such as zinc(II)[9,10] or iron(III)[11] chloride (i.e. clayzic and clayfec). In addition, K10 is a support of choice for reacting salts, for example nitrates of thallium(III),[12] iron(III) (clayfen),[5] or copper(II) (claycop).[5] Multifarious modifications (with a commensurate number of brand names) result in a surprisingly wide range of applications; coupled with the frequent imprecise identification of the clay (K10 or one of its possible substitutes mentioned above), they turn K10 into a Proteus impossible to grab and to trace exhaustively in the literature.

Preparation of Acetals.

Trimethyl orthoformate (see ***Triethyl Orthoformate***) impregnated on K10 affords easy preparation of dimethyl acetals,[14] complete within a few minutes at room temperature in inert solvents such as carbon tetrachloride or hexane (eq 1). The recovered clay can be reused.

(1)

Cyclic diacetals of glutaraldehyde are prepared in fair yields by K10-promoted reaction of 2-ethoxy-2,3-dihydro-4*H*-pyran with diols, under benzene azeotropic dehydration (eq 2).[15]

(2)

Diastereoisomeric acetal formation catalyzed by K10 has been applied to the resolution of racemic ketones, with diethyl (+)-(*R*,*R*)-tartrate as an optically active vicinal diol.[16]

1,3-Dioxolanes are also prepared by K10-catalyzed reaction of 1-chloro-2,3-epoxypropane (***Epichlorohydrin***) with aldehydes or ketones, in carbon tetrachloride at reflux (eq 3).[17] In the reaction of acetone with the epichlorohydrin, the efficiency of catalysts varies in the order: K10 (70%) > ***Tin(IV) Chloride*** (65%) > ***Boron Trifluoride*** (60%) = ***Hydrochloric Acid*** (60%) > ***Phosphorus(V) Oxide*** (57%).

(3)

Preparation of Enamines.

Ketones and amines form enamines in the presence of K10 at reflux in benzene or toluene, with azeotropic elimination of water (eq 4). Typical reactions are over within 3-4 h. With cyclohexanone, the efficiency depends on the nature of the secondary amine: ***Pyrrolidine*** (75%) > ***Morpholine*** (71%) > ***Piperidine*** (55%) > ***Dibutylamine*** (34%).[18] Acetophenone requires longer heating.[19]

(4)

The K10-catalyzed reaction of aniline with β-keto esters gives enamines chemoselectively, avoiding the competing formation of anilide observed with other acidic catalysts.[20,21]

Synthesis of γ-Lactones via the Ene Reaction.

K10 catalyzes the ene reaction of diethyl oxomalonate and methyl-substituted alkenes at a rather low temperature for this reaction (80 °C), followed by lactonization (eq 5).[22] When alkene isomerization precedes the ene step, it results in a mixture of lactones. Using kaolinite instead of K10 stops the reaction at the ene intermediate, before lactonization.

(5)

Synthesis of Enol Thioethers.

Using a Dean-Stark water separator, K10 catalyzes formation of alkyl- and arylthioalkenes from cyclic ketones and thiols or thiophenols, in refluxing toluene (eq 6). A similar catalysis is effected by KSF (in a faster reaction) and K10F.[23] The isomer distribution is under thermodynamic control.

(6)

Preparation of Monoethers of 3-Chloro-1,2-propanediol.

Alcohols react regioselectively with 1-chloro-2,3-epoxypropane to form 1-alkoxy-2-hydroxy-3-chloropropanes. The K10-catalyzed process is carried out in refluxing carbon tetrachloride for 2.5 h (eq 7).[24] Yields are similar to those obtained by ***Sulfuric Acid*** catalysis.

α,β-Unsaturated Aldehydes via Condensation of Acetals with Vinyl Ethers.

K10-catalyzed reaction of diethyl acetals with ***Ethyl Vinyl Ether*** leads to 1,1,3-trialkoxyalkanes. Hydrolysis turns these into *trans*-α,β-unsaturated aldehydes.[25] The reaction is performed close to ambient temperatures (eq 8). K10 is superior to previously reported catalysts, such as ***Boron Trifluoride*** or ***Iron(III) Chloride***. The addition is almost instantaneous and needs no solvent. Cyclohexanone diethyl acetal gives an analogous reaction.

Protective Tetrahydropyranylation of Alcohols and Phenols.

With an excess of ***3,4-Dihydro-2H-pyran***, in the presence of K10 at room temperature, alcohols are transformed quantitatively into their tetrahydropyranyl derivatives. Run in dichloromethane at room temperature, the reaction is complete within 5-30 min (eq 9). The procedure is applicable to primary, secondary, tertiary, and polyfunctional alcohols as well as to phenols.[26]

Markovnikov Addition of Hydrochloric Acid to Alkenes.

1-Chloro-1-methylcyclohexane, the formal Markovnikov adduct of hydrochloric acid and 1-methylcyclohexene, becomes largely predominant when ***Sulfuryl Chloride*** is the chlorine source and K10 the solid acid.[27] The reaction at 0 °C, in dry methylene chloride, is complete within 2 h (eq 10).

(10)

Porphyrin Synthesis.

Meso-tetraalkylporphyrins are formed in good yields from condensation of aliphatic aldehydes with pyrrole; thermally activated K10 catalyzes the polymerization-cyclization to porphyrinogen, followed by ***p-Chloranil*** oxidation (eq 11).[28]

(11)

Meso-tetraarylporphyrins, with four identical or with tuneable ratios of different aryl substituents, are made by taking

advantage of modified K10 (clayfen or Fe^{III}-exchanged) properties.[29,30]

Iron(III)-Doped Montmorillonite.

General Considerations.

The acid strength of some cation-exchanged montmorillonites is between ***Methanesulfonic Acid*** (a strong acid) and ***Trifluoromethanesulfonic Acid*** (a superacid) and, in some instances, their catalytic activity is greater than that of a superacid.[31] Iron montmorillonite is prepared by mixing the clay with various Fe^{III} compounds in water.[8,32] The resulting material is filtered and dehydrated to afford the active solid-acid catalyst. These solid-acid catalysts are relatively inexpensive and are generally used in very small quantities to catalyze a wide variety of reactions, including Friedel-Crafts alkylation and acylation, Diels-Alder reactions, and aldol condensations.[1,5]

Diels-Alder Reactions.[33]

Stereoselective Diels-Alder reactions involving an oxygen-containing dienophile are accelerated in the presence of Fe^{III}-doped montmorillonite in organic solvents (eq 12).[34] Furans also undergo Diels-Alder reactions with ***Acrolein*** and ***Methyl Vinyl Ketone*** in CH_2Cl_2 to give the corresponding cycloadducts in moderate yield (eq 13).[35] The iron-doped clay also catalyzes the radical ion-initiated self-Diels-Alder cycloaddition of unactivated dienophiles such as 1,3-cyclohexadiene and 2,4-dimethyl-1,3-pentadiene (eq 14).[36]

(12)

(13)

(14)

The role of Fe^{III}-impregnated montmorillonite, and other cation-exchanged montmorillonites, in asymmetric Diels-Alder reactions was found to be limited to the use of small chiral auxiliaries; the results obtained from these reactions are similar to those of homogeneous aluminum catalysts (eq 15).[33]

(15)

Friedel-Crafts Acylation and Alkylation.[37,38]

The Friedel-Crafts acylation of aromatic substrates with various acyclic carboxylic acids in the presence of cation-exchanged (H^+, Al^{3+}, Ni^{2+}, Zr^{2+}, Ce^{3+}, Cu^{2+}, La^{3+}) montmorillonites has been reported.[39] Curiously, the use of iron-doped montmorillonite was not included in the report; however, some catalysis is expected. Under these conditions, the yield of the desired ketones was found to be dependent on acid chain length and the nature of the interlayer cation.

The direct arylation of a saturated hydrocarbon, namely adamantane, in benzene using $FeCl_3$-impregnated K10 was recently reported.[11] Additionally, Friedel-Crafts chlorination of adamantane in CCl_4 using the same catalyst was also reported. The alkylation of aromatic substrates with halides under clay catalysis gave much higher yields than conventional Friedel-Crafts reactions employing ***Titanium(IV) Chloride*** or ***Aluminum Chloride*** as catalyst.[8] Higher levels of dialkylation were observed in some cases. The alkylation of aromatic compounds with alcohols and alkenes was also found to be catalyzed with very low levels of cation-exchanged montmorillonites, as compared to standard Lewis acid catalysis; however, iron-doped clays performed poorly compared to other metal-doped clays.

Aldol Condensations.

Cation-exchanged montmorillonites accelerate the aldol condensation of silyl enol ethers with acetals and aldehydes.[40] Similarly, the aldol reaction of silyl ketene acetals with electrophiles is catalyzed by solid-acid catalysts. Neither report discussed the use of iron montmorillonite for these reactions; however, some reactivity is anticipated.

Miscellaneous Reactions.

The coupling of silyl ketene acetals (enolsilanes) with pyridine derivatives bearing an electron-withdrawing substituent, namely cyano, in the *meta* position is catalyzed by iron montmorillonite and other similar solid-acid catalysts (eq 16).[41]

The resulting *N*-silyldihydropyridines easily undergo desilylation by treatment with ***Cerium(IV) Ammonium Nitrate*** to afford the desired dihydropyridine derivative. The reactivity was found to be dependent on the montmorillonite counterion and to follow the order: Fe^{3+} > Co^{2+} > Cu^{2+} &AApprox; Zn^{2+} > Al^{3+} &AApprox; Ni^{2+} &AApprox; Sn^{4+}.

Morpholine

[110-91-8] · C_4H_9NO · Morpholine · (MW 87.14)

(secondary amine base; reagent for enamine formation and utilization; condensation catalyst for Mannich condensations)

Physical Data: bp 128.9 °C; *d* 1.007 g cm^{-3}; pK_a 8.8.

Solubility: miscible with water, acetone, diethyl ether.

Form Supplied in: liquid, >99%.

Purification: dried with KOH, fractionally distilled, dried for a second time over sodium metal, then redistilled.[1]

Handling, Storage, and Precautions: eye and skin irritant; flammable liquid; use in a fume hood.

Willgerodt Reaction.[2]

Morpholine is employed as the amine component of the Kindler modification of the Willgerodt reaction. The process effects the rearrangement of aryl alkyl ketones to carboxylic acid derivatives (eqs 1 and 2).[3,4] Morpholine is particularly useful in the reaction as its high boiling point makes the use of sealed tubes unnecessary.

(1)

Willgerodt-like processes are effected by treatment of benzylphosphonates[5] and chlorides[6] with morpholine and ***Sulfur*** (eqs 3 and 4).

Enamine Formation and Utilization.

Morpholine is one of the three principal secondary amines used in the formation of enamines.[7-10] A weaker base than either ***Piperidine*** or ***Pyrrolidine***, it forms enamines more slowly than the other two bases. The regioselectivity of morpholine enamine formation is significantly less than with pyrrolidine.[11]

The lower reactivity of morpholine has been used as a method for the separation of monoalkylated cyclohexanones from unalkylated material (eq 5).[12]

(5)

Morpholine enamines of saturated ketones and aldehydes are prepared by heating the base and the carbonyl compound alone in benzene solution (eq 6),[10] by catalysis with ***p-Toluenesulfonic Acid*** in toluene (eq 7),[13] and by catalysis with ***Titanium(IV) Chloride*** (eq 8).[14] Aldehyde enamines may also be prepared by decarboxylation of the morpholine enamines of substituted pyruvic acids (eq 9).[15]

(6)

(7)

(8)

(9)

Enaminones may be prepared by conjugate addition of morpholine to an alkynic ketone (eq 10),[16] and the morpholine enamine of pyruvaldehyde has been prepared by conjugate addition and rearrangement of 2-chloroacrolein (eq 11).[17]

(10)

(11)

Utilization of Morpholine Enamines.

The less reactive morpholine enamines have been shown to acylate in better yield than the corresponding pyrrolidine derivatives.[10] A typical example is the acylation of the morpholine enamine of cyclopentanone (eq 12).[18]

Miscellaneous Reactions.

Morpholine is used as a base for dehydrobromination (eq 13)[19] and in conjunction with molecular ***Iodine*** for the iodination of alkynic alcohols (eq 14).[20]

Treatment of benzyl phenyl ketone with ***Thionyl Chloride*** and morpholine results in the formation of benzil, a reaction which presumably occurs through the intermediacy of the ketone enamine (eq 15).[21]

Under high pressure, *p*-nitrophenyl triflate undergoes addition-elimination with morpholine (eq 16).[22]

(16)

Morpholine, like other secondary amines, may be used for Mannich-type condensations (eq 17).[23]

(17)

Related Reagents.

N-Chloromorpholine; ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide***; ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide Metho-p-toluenesulfonate***; ***N,N´-Dicyclohexyl-4-morpholinecarboximidamide***; ***Diethyl Morpholinomethylphosphonate***; ***Lithium Morpholide***; ***N-Methylmorpholine N-Oxide***; ***2-Morpholinoethyl Isocyanide***; ***N-Morpholinomethyldiphenylphosphine Oxide***; ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***.

2-Morpholinoethyl Isocyanide

[78375-48-1] · $C_7H_{12}N_2O$ · 2-Morpholinoethyl Isocyanide · (MW 140.21)

(coupling reagent for amino acids; amide synthesis)

Physical Data: bp 72-73 °C/0.7 mmHg; *d* 1.017 g cm^{-3}; n_D 1.469.

Solubility: usually used in CH_2Cl_2.

Form Supplied in: liquid, >98% pure.

Analysis of Reagent Purity: comparison with literature boiling point; also ν_{max} (liquid film) at 2150 cm^{-1} is indicative of isocyanide functionality.

Preparative Methods: by the reaction of 2-morpholinoethylamine with ***Formic Acid*** in boiling toluene with a water separator, to yield the formamide which is treated either with ***Phosgene*** and ***Triethylamine*** in CH_2Cl_2 or with ***Phosphorus Oxychloride*** and ***Diisopropylamine***.[1,2] The use of diisopropylamine as base is favored as yields are improved, typically to 68%. ***Trichloroacetic Anhydride*** has also been used as an alternative for $COCl_2$, giving a yield of 74%.[3]

Purification: when phosphorus oxychloride and diisopropylamine are employed, purification is not required.[2]

Introduction.

The principal synthetic application of 2-morpholinoethyl isocyanide is as a coupling reagent of amino acids to yield peptides.[2] It also reacts with aldehydes or ketones to yield amides,[4] with acids to yield imidazolinium salts,[5] and has been used as a ligand in spectroscopic studies to examine shielding effects.[6]

Coupling of Amino Acids.[2]

The coupling reaction is performed in CH_2Cl_2 with ***N-Hydroxysuccinimide*** or ***1-Hydroxybenzotriazole*** and 2-

morpholinoethyl isocyanide (**1**) to yield products in 61-95% yield (eq 1).

No racemization is observed, as determined by the coupling reaction of CF_3CO-Phe-OH with H-Phe-O-*t*-Bu in the presence of HOSu.

Formation of Amides.[4]

The isocyanide moiety of 2-morpholinoethyl isocyanide reacts with aldehydes and ketones to form amides in good yields (eq 2).

Formation of Imidazolinium Salts by Cyclization.[5]

Treatment of the isocyanide with HZ (Z = Cl, TsO) gives 40-60% of the spiroimidazolium salt which on addition of excess HZ provides the imidazolinium salt in 70-95% yield (eq 3).

Use in Spectroscopic Studies.[6]

2-Morpholinoethyl isocyanide has been used to study the NMR ^{14}N NMR signals of molybdenum (^{95}Mo) and tungsten (^{183}W) carbonyl isocyanide complexes $M(CO)_{6-n}(CNR)_n$ (n = 0-6). When isocyanide is coordinated to the metal center, the ^{14}N signal is deshielded but, with further substitution, the N becomes more shielded again. With UV and IR studies, substitution of CO by isocyanide shifts the absorption toward longer wavelength so that the color of the complexes changes from white to orange-red.

N-Morpholinomethyldiphenylphosphine Oxide[1]

[20684-76-8] · $C_{17}H_{20}NO_2P$ · *N*-Morpholinomethyldiphenylphosphine Oxide · (MW 301.35)

(Horner-Wittig reagent useful for the preparation of homologous aldehydes,[2] their morpholino enamines,[2a,b,3] and α-morpholinomethyl ketones[4])

Physical Data: mp 159 °C.

Solubility: insol H_2O; sol THF, $CHCl_3$.

Form Supplied in: white crystalline solid, not commercially available.

Preparative Methods: has been prepared in several ways, most efficiently by two related sequences involving an Arbuzov reaction (eqs 1 and 2).[3,5] In both approaches the crude product is sufficiently pure for use in subsequent synthesis applications.

Purification: most easily purified by recrystallization from benzene or from CH_2Cl_2/hexane. It can also be purified by column chromatography on silica gel.

Handling, Storage, and Precautions: stable for extended periods of storage under nitrogen; its toxicity is unknown.

Horner-Wittig Formation of Enamines.

The utility of the title reagent lies in its application as an α-amino-substituted Horner-Wittig reagent. Deprotonation with ***n-Butyllithium*** in THF at 0 °C gives a reasonably stable, orange-colored anion (**1**). This anion adds to aliphatic, aromatic, and α,β-unsaturated aldehydes to give good yields of the addition adducts as lithium alkoxides, which are sufficiently stable that they do not undergo direct elimination of lithium diphenylphosphinate.[2a] Rather, protonation yields the alcohols as diastereomeric mixtures of products (eq 3). Treatment with ***Potassium t-Butoxide***, ***Potassium Hydride***, or ***Sodium Hydride*** forms the corresponding potassium or sodium alkoxide which eliminates potassium or sodium diphenylphosphinate to give mixtures of (*E*)- and (*Z*)-enamines; these isomerize to the more stable (*E*)-enamines upon purification (eq 4).

This reagent has certain advantages over related phosphonates[6] and phosphonium salts,[7] both of which have shown only limited success for the synthesis of homologous enamines of aldehydes. However, the utility of this reagent is limited by

the basicity of the anion (**1**) in that its reaction with ketones results in partial to complete enolization.[2b] The related reagent [(*N*-methylanilino)methyl]diphenylphosphine oxide has been used successfully with ketones, due to the lower basicity of its derived anion relative to (**1**).[8]

Formation of Homologous Aldehydes.

The enamines prepared with the title reagent can be readily hydrolyzed to the corresponding aldehydes (eq 5).[2a] Thus, the overall transformation exemplified by eqs 3-5 represents a method for the one-carbon homologation of aldehydes. Related reagents having an additional α-substituent, which can be prepared by Mannich-type condensation of ***Diphenylphosphine Oxide*** with aldehydes and morpholine,[5b] show promise as acyl anion equivalents.[9]

(5)

Formation of α-Morpholinomethyl Ketones.

The initial addition adduct of (**1**) with aldehydes can also be elaborated to α-morpholinomethyl ketones by heating in a protic solvent (e.g. ethylene glycol) or by heating in an aprotic solvent in the presence of a catalytic amount of ***p-Toluenesulfonic Acid*** (eq 6).[4] This reaction is consistent with following an E1-type mechanism in which the β-hydroxyl group is not directly involved in the elimination step.

Nafion-H

$$(\sim CF_2CF_2)_n\text{-}CF_2\text{-}(CF\sim)\text{-}O\text{-}(CF_2CF(CF_3)O)_m\text{-}CF_2CF_2\text{-}SO_3H$$

[63937-00-8] · - · Nafion-H · (MW ~1250 maximum)

(highly acidic solid; used as an acid catalyst for alkylation, aroylation, and nitration reactions; also used for ether, ester, and acetal synthesis[1])

Alternate Name: Nafion ND50

Solubility: insol polymer; will swell with solvent, but will not dissolve.

Form Supplied in: available commercially (Nafion ND50 in 10-35 mesh beads) as a white powder.

Handling, Storage, and Precautions: irritant; hygroscopic.

Introduction.

Nafion-H is a perfluorinated resinsulfonic acid, and its primary use in organic synthesis is as a superacid catalyst. The acidity of the surface acid groups on Nafion-H is comparable to that of 96-100% ***Sulfuric Acid***,[1] and as such will promote a wide variety of acid-catalyzed reactions.

Alkylation Reactions.

Gas-phase alkylations of aromatic hydrocarbons over Nafion-H catalyst give superior yields and cleaner products than the usual Friedel-Crafts alkylations in solution.[2] Several methods of alkylation are available.

Alkylation with Alkenes.

It should be noted that alkylation with alkenes (eq 1) results in a slow reduction in the catalytic activity of Nafion-H due to surface polymerization, which deactivates the catalytic sites.[1]

(1)

Alkylation with Alcohols.

The life of the catalyst is improved with this method.[3] The best example of this case is the methylation of phenol with methyl alcohol (eq 2).[4]

(2)

Alkylation with Alkyl Halides.

Unlike Friedel-Crafts alkylation in which polyalkylation is a problem, the gas-phase alkylation reaction over the Nafion-H catalyst shows a high selectivity for monoalkylation (eq 3).[5]

(3)

Alkylation with Alkyl Esters.

This may be performed in either the gas or liquid phase over Nafion-H.[6] Unlike the Friedel-Crafts method which may produce both alkylated and acylated products, the Nafion-H catalyst shows high selectivity for alkylation (eq 4).[7]

$$\mathrm{ArH} + \mathrm{R^1CO_2R^2} \xrightarrow{\text{Nafion-H}} \mathrm{ArR^2} + \mathrm{R^1CO_2H} \qquad (4)$$

Acylation.

Nafion-H may be used to catalyze the acylation of benzene with aroyl chlorides and anhydrides (eq 5).[8] A great advantage of the Nafion-H catalyst over the typical Friedel-Crafts catalyst is that only 10-30% of the Nafion-H catalyst is needed, unlike acylations typically performed in solution where more than a molar equivalent of the catalyst is required.[8]

Nitration.

Nitration of substituted benzenes and other aromatic hydrocarbons may be performed with *n*-butyl nitrate,[9] acetone cyanohydrin nitrate,[10] or ***Nitrogen Dioxide***.[10] The advantage of nitration with Nafion-H catalyst over electrophilic aromatic substitution of nitrate using ***Nitric Acid*** in solution is that no aqueous workup is required. Also, the nitro compounds produced may be easily isolated by filtration of the catalyst.[10]

Ether Synthesis.

Ethers are commonly synthesized by an acid-catalyzed mechanism, but require basic workup procedures in typical methods. Nafion-H, however, provides a method for ether synthesis that does not require basic workup, but only filtration of the solid catalyst and evaporation of the solvent.[11] ***Dimethoxymethane*** may be reacted with primary and secondary alcohols over the Nafion-H catalyst to produce good yields of methoxymethyl ethers,[11] which are commonly used as a means for protecting hydroxyl groups (eq 6).[12] Tertiary alcohols give only the dehydration products.[11]

Cyclization of 1,4-butanediols to the corresponding tetrahydrofurans may also be accomplished by simply heating the 1,4-butanediol over the Nafion-H catalyst (eq 7). No workup is required, high yields are obtained (~90%),[13] and product isolation is very easy. This method is far superior to the aqueous mineral-acid version of the same reaction, which does require elevated reaction temperatures and aqueous basic workup.[13]

Acetal Synthesis.

Acid-catalyzed acetal synthesis is possible with Nafion-H, particularly in the reaction of trimethyl orthoformate with ketones or aldehydes (eq 8).[14]

Other Reactions.

Synthesis of 1,3 Dioxanes.

Nafion-H is capable of catalyzing the reaction of ketones with ***Paraformaldehyde*** to form 1,3-dioxanes in high yield (eq 9).[15]

Diels-Alder Reaction Catalyst.

Nafion-H has a particular advantage as a catalyst for the Diels-Alder reaction. Nafion-H may be used in catalytic amounts and provides high yields of product with no diene polymerization in many cases.[16] Also, product isolation is

easy as it involves only filtration of the catalyst.[16] Lewis acid catalysts may be used, but these cause polymerization of the diene. Two molar equivalents of the Lewis acid are usually necessary, and Lewis acid complexes with reactants and products may form. All of this causes difficulties in the workup.[17,18] As an example of the effectiveness of Nafion-H catalysis, the uncatalyzed reaction of 1,3-cyclohexadiene with ***Acrolein*** gives only 25% of the Diels-Alder product when heated to 100 °C for 3.5 h. However, Nafion-H catalysis gives 88% yield after stirring for 40 h at 25 °C (eq 10).[16]

(10)

Condensation of Acetone to Mesitylene.

Nafion-H catalyzes the condensation of ***Acetone*** to mesitylene with a selectivity of greater than 99%.[19] Unlike other acid-catalyzed condensations which may produce other condensation products such as propene,[19] isobutene,[19] and pentenes,[19] the Nafion-H-catalyzed mechanism is superior in its selectivity for mesitylene (eq 11). It should be noted, however, that overall percentage yields are lower for the Nafion-H-catalyzed mechanism than for other acid-catalyzed mechanisms.[19]

(11)

Azidobromination of Alkenes.

Nafion-H catalyzes the azidobromination of alkenes to form β-bromoalkyl azides.[20] ***N-Bromosuccinimide*** and ***Azidotrimethylsilane*** are reacted over the Nafion-H surface in a solvent that is 3:1 in methylene chloride-nitromethane. One postulated mechanism is outlined by eqs 12 and 13.[20]

Nafion-H and Pd/C.

The combination of the acid catalyst Nafion-H with the ***Palladium on Carbon*** hydrogenation catalyst in the presence of hydrogen is useful for performing an aldol condensation followed by hydrogenation of the condensation product.[21] Pittman and Liang have effected one-step conversions of acetone to methyl isobutyl ketone,[21] benzaldehyde and acetone to 4-phenyl-2-butanone,[21] and 2,5-hexanedione to 2,5-dimethyltetrahydrofuran.[21] The reaction is simply carried out by reacting the anhydrous starting materials over a mixture of 30-60 mesh Nafion-H into which dry Pd/C catalyst has been mixed. The reacting system is pressurized with H_2 gas, and is heated to promote the reaction (eq 14). In the example of the condensation of acetone to methyl isobutyl ketone, Nafion-H acts as a simple acid catalyst to cause condensation to mesityl oxide.

Overall production of mesityl oxide is limited by the equilibrium between it and the original starting materials. If mesityl oxide were isolated and then hydrogenated, yields of methyl isobutyl ketone would be only about 20%. However, the sequential condensation/hydrogenation that may be performed by the Nafion-H and Pd/C catalyst combination results in a yield of methyl isobutyl ketone that is about twice as high. This is because mesityl oxide is continuously removed from the equilibrium by hydrogenation, which pulls the equilibrium to the right.[21]

1,4-Naphthoquinone[1]

[130-15-4] · $C_{10}H_6O_2$ · 1,4-Naphthoquinone · (MW 158.16)

(dienophile used to synthesize various aromatic rings via Diels-Alder or cycloaddition-type reactions;[1] undergoes amination,[2] allylation,[3] cyclooligomerization,[4] and Thiele-Winter acetoxylation to give the 1,2,4-triacetoxynaphthalene[5])

Physical Data: mp 126 °C, begins to sublime below 100 °C; *d* 1.422 g cm^{-3}.

Solubility: sparingly sol cold water; slightly sol pet ether; freely sol hot alcohol, ether, benzene, chloroform, carbon disulfide, acetic acid; sol alkali hydroxide solutions, giving a reddish brown solution.

Form Supplied in: yellow triclinic needles from alcohol or pet ether.

Handling, Storage, and Precautions: toxic and irritant.

Synthesis of Aromatic Systems.

1,4-Naphthoquinone is used to synthesize various products that contain an aromatic ring. These syntheses are most commonly executed via Diels-Alder and cycloaddition-type reactions.

Diels-Alder Reactions.

A method for preparing naphthacenequinones employs a very convenient, three-step, one-pot sequence consisting of an initial Diels-Alder cycloaddition of an isobenzofuran with an appropriate dienophile such as 1,4-naphthoquinone (eq 1).[6]

The Diels-Alder reactivity of in situ-generated *N*-benzoylindole-2,3-quinodimethane has been expanded considerably to include reactions with carbon dienophiles (e.g. 1,4-naphthoquinone) which furnish a variety of [*b*] annulated indoles as well as functionalized and annulated carbazoles.[7] In another variation of this reaction, 2- and 3-vinylindoles react with 1,4-naphthoquinone to afford new six-ring annulated carbazoles (eqs 2 and 3).[8]

1,4-Naphthoquinone is the reagent of choice in a new approach to the synthesis of 2*H*-isoindole-4,7-diones (eq 4).[9]

A simple synthesis of spirodiones via $_{\pi}6_{s}$ + $_{\pi}2_{s}$ photocyclization of the Diels-Alder adducts obtained by reaction of spiro[4.2]heptadiene and spiro[4.4]nonadiene with 1,4-naphthoquinone in homogeneous and miscellar media is illustrated in eq 5.[10]

Stereoselective syntheses of quinone-annulated 2,3-bis(methylene)-7-oxabicyclo[2.2.1]heptanes involves 1,4-naphthoquinone as a dienophile. The products are promising building blocks for the synthesis of antineoplastic antibiotics.[11] Treatment of furan-annulated 3-sulfones with 1,4-naphthoquinone at 150 °C for 4 h gave 1,4-epoxy-2,3-bis(methylene)-1,4,4a,9a-tetrahydroanthraquinone in 58% yield (eq 6).[11]

Biologically Significant Products.

Several Diels-Alder reactions involving 1,4-naphthoquinone have importance for the preparation of biologically active compounds. For example, the trifluoromethyl group is an increasingly popular aromatic substituent in compounds synthesized for biological applications. However, only a handful of methods are available for its introduction into aromatic compounds. Its use was consequently limited, but a new method using 1,4-naphthoquinone was found to be effective for this purpose. Triethyl(trifluoromethyl)silane and tri-*n*-butyl(trifluoromethyl)silane were found to react with the quinone by addition to one of the carbonyl atoms, giving dienones containing geminal trifluoromethyl substituents.[12]

Another application involves the reaction of 1,4-naphthoquinone and pyrroline, giving one major new product (eq 7) which was isolated in moderate yield (25%).[13] This new product has significance in the synthesis of ansamyocin and mitomycin

antibiotics.

(7)

Aromatic polyketide antibiotics generally fall into two structural classes, linear and nonlinear polyketides. Although enormous effort has been devoted to the synthesis of the linear polyketides, the nonlinear aromatic polyketides have received relatively little attention.[14] With a vinylquinone acetal as the diene and 1,4-naphthoquinone as the dienophile, the nonlinear benzathracenedione can be synthesized in 24% yield (eq 8).[14]

(8)

Additional Cycloadditions.

Allylic cyanides cycloadd to 1,4-naphthoquinone at room temperature. Treatment of the crude mixture with ***Potassium Fluoride*** in refluxing methanol gives compound (**1**) in 61% yield (eq 9).[15]

(9)

(1)

A general and simple route to the synthesis of triptycene derivatives involves cycloaddition of 1,4-naphthoquinone with anthracene and subsequent treatment of the resulting adduct with ***Lithium Aluminum Hydride*** followed by ***p-Toluenesulfonyl Chloride*** in pyridine (eq 10).[16]

A reaction of 1,4-naphthoquinone with the diene 3-vinylpyrrole gives an indole in 21% yield (eq 11).[17]

(11)

Amination of Naphthoquinones.

A new method for the synthesis of aminonaphthoquinones uses 1,4-naphthoquinone and ***Azidotrimethylsilane*** (eq 12).[2]

(12)

Allylation of Substituted *p*-Quinones.

1,4-Naphthoquinone reacts with allylindium sesquiiodide to give allylquinols in excellent yield.[3] This reaction has been extended to prenylation and nerylation of napthoquinone as well (Table 1; Scheme 1).

Table 1 Prenylation and Nerylation of 2,3-Disubstituted Quinones

Quinone	Allyl-indium	Molar ratio of quinone: allylindium	Product ratio monoallyl:diallyl	Total Yield %
1,4-Naphtho-quinone	Prenyl	1:1	61:39	86
		2:1	22:78	100
		4:1	77:23	79
		6:1	97:3	100

		6:1	100:0	84

Allylquinone

Prenyl

Neryl

Scheme 1

Cyclooligomerization of Quinones.

When treated with acid, 1,4-naphthoquinone gives a dimer, 5,8-dihydroxydinaphtho[1,2-*b*:2´,1´-*d*]furan (**2**), 15,18-dihydroxydinaphtho[2,1-*d*:2´,1´-*d*]naphtho[1,2-*b*:4,3-*b*´] difuran (**3**) and a tetramer, tetranaphthyleno[5,6-*bcd*:11,12-*b*´*c*´*d*´:17,18-*b*´´*c*´´*d*´´]tetrafuran (**4**).[4]

(2)

(3)

(4)

Thiele-Winter Acetoxylation.

1,4-Naphthoquinone can undergo the Thiele-Winter reaction.[19] From a synthetic point of view the most important feature is the introduction of an oxygen onto an aromatic nucleus. Burton and Praill showed that perchloric acid is probably the most effective catalyst for effecting the transformation (eq 13).[19]

Related Reagents.

1,4-Benzoquinone; ***1,3-Diphenylisobenzofuran***.

1-(1-Naphthyl)ethylamine

(±)

[42882-31-5] · $C_{12}H_{13}N$ · 1-(1-Naphthyl)ethylamine · (MW 171.26) (+)

[3886-70-2] (-)

[10420-89-0]

(chiral reagent used for resolution of carboxylic acids,[1] alcohols,[2] and lactones;[3] a chiral derivatization agent used for chromatographic resolution of carboxylic acids[4] and alcohols;[5] can serve as a chiral solvating agent[6])

Alternate Name: NEA.

Physical Data: (±) form: bp 156 °C/15 mmHg; *d* 1.063 g cm^{-3}. Oxalate: mp 221 °C (dec). (*S*)-(-) isomer: bp 153 °C/11 mmHg; *d* 1.060 g cm^{-3}; $[\alpha]^{25}$ -80.8° (neat); $[\alpha]^{20}$ -59° (*c* = 5, MeOH). Oxalate: mp 232 °C (dec). (*R*)-(+) isomer: bp 153 °C/11 mmHg; *d* 1.060 g cm^{-3}; $[\alpha]^{25}$ +82.8° (neat); $[\alpha]^{20}$ +60° (*c* = 5, MeOH). Oxalate: mp 240 °C.

Solubility: sol alcohol, ether; insol H_2O.

Form Supplied in: clear liquid; both enantiomers and the racemate are all widely available.

Analysis of Reagent Purity: the enantiomeric purity of the reagent can be determined by either NMR or HPLC analysis of derivatives produced from α-methoxy-α-(trifluoromethyl)benzyl isocyanate,[7] α-methoxy-α-(trifluoromethyl)benzyl acid chloride,[8] or 2´-methoxy-1,1´-binaphthyl-2-carboxylic acid chloride.[9]

Preparative Methods: racemic 1-(1-naphthyl)ethylamine can be resolved with camphoric acid,[10] tartaric acid,[11] L-menthyl hydrogen phthalate,[11] di-*O*-isopropylidene-2-ketogulonic acid,[11,12] and (*S*)-(-)-(2-

phenylcarbamoyloxy)propionic acid.[13] These procedures can also be used to enhance the enantiomeric purity of the reagent.

Handling, Storage, and Precautions: use in a well-ventilated fume hood.

Resolution of Carboxylic Acids.

The enantiomers of 1-(1-naphthyl)ethylamine are used to resolve racemic carboxylic acids by selective crystallization of diastereomeric salts. For example, crystallization of racemic 3-bromobutyric acid with (*R*)-(+)-NEA followed by acidification of the diastereomeric salt afforded (*S*)-(+)-3-bromobutyric acid (eq 1).[1] In the same manner, resolution with (*S*)-(-)-NEA yielded (*R*)-(-)-3-bromobutyric acid after liberation of the amine (eq 1).[1]

(1)

Resolution of alcohols can be achieved following derivatization with phthalic anhydride.[2] Racemic 1-undecyn-3-ol was converted into a phthalic monoester derivative and resolved with (*R*)-(+)-NEA (eq 2). Liberation of the resolved phthalic ester and saponification yielded (*R*)-(+)-alcohol in 92% optical purity (eq 2). Similarly, the (*S*)-(-) alcohol is obtained upon resolution with (*S*)-(-)-NEA (eq 2).

Optically active lactones are also readily available through this classical resolution technique. The racemic lactone is hydrolyzed to the hydroxy acid and resolved with (*S*)-(-)-NEA (eq 3).[3] After crystallization, the *dextro* (+)-lactone is regenerated upon acidification of the chiral salt. Resolution of the lactone with (R)-(+)-NEA leads to the *levo* (-)-lactone (eq 3).[3]

Chromatographic Resolutions.

1-(1-Naphthyl)ethylamine serves as a chiral derivatization agent useful in preparing diastereomeric amides from racemic acids for chromatographic resolution.[4] For example, various terpenoid acids, after conversion to the diastereomeric amides using (*R*)-(+)-NEA, were analyzed by HPLC to define the enantiomeric composition (eq 4).[4]

Application of the procedure has been used to analyze the enantiomeric purity of several carboxylic acid derivatives.[14]

(4)

In some cases the resolution of the diastereomeric amides on silica gel is sufficiently large to achieve preparative separation. The preparative separation of diastereomeric hydroxy amides has proved useful in supplying quantities of enantiomerically pure lactones (eq 5).[15]

Nonracemic NEA is equally useful in preparing diastereomeric carbamates. Typically, the carbamates are derived from alcohols and (*R*)-(+)-naphthylethyl isocyanate,[16] which is conveniently prepared from (*R*)-(+)-NEA (see ***(R)-1-(1-Naphthyl)ethyl Isocyanate***). However, the diastereomeric carbamates may also be produced by treating the chloroformate derivative of a racemic alcohol with (*R*)-(+)-NEA.[5] Preparative separation of racemic 1-heptyn-3-ol was achieved through chromatographic separation of the diastereomeric carbamates prepared via the chloroformate derivative (eq 6).[17] The carbamates are conveniently cleaved by the action of trichlorosilane (see ***Trichlorosilane***).[18]

Chiral Solvating Agent.

NEA is an effective chiral solvating agent for NMR determination of enantiomeric purity.[6,19] The combination of enantiomerically pure NEA (3-5 mol excess) and racemic solute causes the NMR spectra of the diastereomerically solvated enantiomers to differ. Since NEA is an efficient hydrogen-bond acceptor, it solvates better if the solute is a hydrogen-bond donor. (*R*)-(+)-NEA has been used to determine the enantiomeric purity of a variety of substrates.[20]

Chiral Stationary Phases for GC and HPLC.

Enantiomerically pure NEA has been used to prepare a variety of chiral stationary phases for liquid,[21] gas,[22] and supercritical fluid[23] chromatography. These stationary phases are used to separate enantiomers without derivatization of the substrate with a chiral agent.

Related Reagents.

(R)-1-(1-Naphthyl)ethyl Isocyanate.

(*R*)-1-(1-Naphthyl)ethyl Isocyanate

(*R*)-(-)

[42340-98-7] · $C_{13}H_{11}NO$ · (*R*)-1-(1-Naphthyl)ethyl Isocyanate · (MW 197.25) (*S*)-(+)

[73671-79-1]

(enantiomeric resolving agent for alcohols,[1,2] thiols,[1,3] sulfonamides,[4] and amines[5] (forms diastereomers separable by chromatography or crystallization); used in creating enantiomeric stationary phases for liquid chromatography;[6,7] reagent in the synthesis of chiral nonracemic allenes[8])

Alternate Names: NEI; (*R*)-1-isocyano-1-naphthylethane.

Physical Data: bp 106-108 °C; fp 93 °C; *d* 1.13 g cm^{-3}; optical rotation [α]20D = -47° (*c* 3.5, toluene), [α]24.1D = -50.5° (*c* 27.9, benzene).

Solubility: freely sol benzene, toluene, and a variety of dry organic solvents; reacts with water.

Form Supplied in: colorless liquid; available commercially >99% pure.

Preparative Methods: from (*R*)-(+)-***1-(1-Naphthyl)ethylamine*** by reaction with ***Phosgene*** or by a method using ***Trichlorosilane***.[1]

Handling, Storage, and Precautions: stable when stored between 0 and 4 °C; reacts with water; highly toxic; should be handled with proper skin and eye protection in a well-ventilated fume hood.

Resolution of Alcohols.

The reagent (*R*)-(-)-1-(1-naphthyl)ethyl isocyanate, (*R*)-NEI, as well as its enantiomer, (*S*)-NEI, forms diastereomeric carbamates with racemic secondary alcohols (eq 1);[1,2] the reaction may be facilitated by base or Lewis acid

catalysts.[4] The diastereomers can usually be separated by liquid chromatography on silica or alumina, providing a convenient means for analysis or preparative purification of the enantiomers: the resolved alcohols are recovered in high yield under mild, or nonracemizing, conditions by treatment with trichlorosilane/triethanolamine (TEA) (eq 1).[9]

(1)

This general strategy has found wide application in synthesis. Enantiomerically pure cyano alcohols obtained in this way are starting materials in the synthesis of uni- and multicyclic lactones.[10-13] High purity enantiomeric epoxides can be prepared by resolution of the appropriate alcohol precursor followed by ring closure.[14] Propargylic alcohol enantiomers resolved by this technique are intermediates in the synthesis of the four stereoisomers of 1,2,3-decanetriol,[15] and of the sesquiterpene fungal metabolite (+)-sterpurene.[16,17] The purification of stereoisomers of secondary alkan- and alkenols by this method is an essential step in the synthesis of biologically active enantiomers of 8-methyl-2-decanol propanoate,[18] and of the germination inhibitor (-)-gloeosporone.[19] The general method given in eq 1 is used to isolate enantiomerically pure intermediates in the synthesis of the fungal metabolites ascofuranone and ascofuranol,[20] of the fungitoxic hydroquinone zonarol,[21] and of naturally occurring *C*-nucleosides and their analogs.[22] A hindered *endo* alcohol is also resolved after derivatization with (*R*)-NEI.[23] In the synthesis of vitamin D_3 metabolites, an enynyl alcohol intermediate is resolved with the help of both (*R*)- and (*S*)-NEI using crystallization rather than chromatography to separate the diastereomers.[24]

Indirect analysis of the enantiomeric ratio of an alcohol can be accomplished via separation and quantitation of the diastereomers of eq 1 by high-performance liquid chromatography (HPLC), gas-liquid chromatography (GLC), or

supercritical fluid chromatography (SFC). For example, diastereomeric diacylglycerol 1-(1-naphthyl)ethyl carbamates are separated by HPLC on a silica gel column,[25] as are the diastereomeric derivatives of the tertiary monoterpene alcohol linalool,[26] diastereomers of (unsymmetrically substituted) 1,3-dialkylglycerol ethers are separable by GLC,[27] and secondary alcohol enantiomers are derivatized with (*R*)-NEI and separated by SFC using several different stationary phases.[28] The use of a bonded amine HPLC column is reported for the analysis of enantiomers of several 2,3-epoxy-1-propanols following derivatization with (*R*)- and (*S*)-NEI.[29] Enantiomeric purity of a thiol, a derivative of the enkephalinase inhibitor thiorphan, is also determined after derivatization with (*R*)-NEI.[3]

Resolution of Amines.

Amines react with (*R*)- or (*S*)-NEI to form the corresponding urea diastereomers which can be separated in a manner analogous to the alcohols in eq 1. Secondary amines thus resolved can be recovered from the diastereomers by hydrolysis, as in the synthesis of chiral nonracemic lactams,[5] or by decomposition in refluxing alcohols, as demonstrated by the resolution of several amine drugs.[30]

Analysis of the enantiomeric ratios of several β-blocking drugs (1-aryloxy-3-isopropylamino-2-propanol derivatives) is carried out by HPLC with UV or fluorescence detection after derivatization with (*R*)-NEI or (*R*)-(+)-1-(1-phenyl)ethyl isocyanate (in a reversed-phase system),[31,32] or (*S*)-NEI (on silica gel);[33] only the amine function of the drugs reacts with the NEI; the hydroxy group does not.[31] Similar schemes for HPLC determination of enantiomeric purity of tetrahydrofolate derivatives[34] and of fluoxetine[35] are also reported.

In analysis, the original compound need not be recovered after separation, and therefore primary amines such as amino acids can be derivatized and analyzed in the same manner.[36] (*S*)-NEI is employed as a derivatizing reagent in an Edman-like sequencing scheme to assess the extent of racemization of amino acid residues in synthetic peptides.[37]

Enantiomeric Stationary Phases.

Chiral nonracemic chromatographic stationary phases prepared from β-cyclodextrin, derivatized with (*R*)- and (*S*)-NEI, and covalently bonded to a silica support are useful for the direct separation of enantiomers of a wide variety of compounds in both normal-phase and reversed-phase HPLC.[6,7,38]

Determination of Absolute Configuration of Enantiomeric Compounds.

Empirical rules for the elution order in normal-phase chromatography of diastereomeric carbamates are used to assign absolute configurations of chiral nonracemic compounds resolved by the general method of eq 1.[2] Owing to the inflexibility of the carbamate linkage, the relative positions of the most hydrophobic (or repulsive) group on the original compound and the naphthyl group of NEI are fixed in either a *syn* or an *anti* configuration in the two diastereomers. The *syn* conformer is likely to elute last, as its less repulsive moieties are more directly available for interaction with the silica surface.[2] The rules fail occasionally.[39] ^{1}H NMR[39,40] and single crystal X-ray diffraction[41,42] of purified diastereomers are also used in determining absolute conformation.

Synthesis of Chiral Nonracemic Allenes.

Enantiomerically enriched chiral allenes can be prepared by derivatization of a racemic propargyl alcohol with (*R*)-NEI, followed by chromatographic separation of the resulting diastereomers and reaction of the purified diastereomers with lithium dialkylcuprates at -78 °C, as shown in eq 2.[8,43]

(2)

Alternative Reagents.

1-(1-Phenyl)ethyl isocyanate (PEI) is a cheaper alternative to NEI; however, diastereomers formed from NEI are usually easier to separate by liquid chromatography.[2,5,9] Other alternatives are also used, e.g. in determining the enantiomeric purity of 3-aminoquinuclidine, PEI, NEI, 2,3,4,6-tetraacetyl-β-D-glucopyranosyl isothiocyanate, and (*R,R*)- and (*S,S*)-*O,O*-dibenzoyltartaric acid anhydride are all employed successfully.[44] ***Mandelic Acid*** and Mosher's reagent, α-methoxytrifluoromethylphenylacetyl chloride, may not be quite as effective as NEI when resolutions are carried out by liquid chromatography.[2]

Nickel

Ni^0

[7440-02-0] · Ni · Nickel · (MW 58.71)

(homocoupling of halobenzenes;[1,2] benzyl halide coupling;[3,4] synthesis of β-hydroxynitriles;[5] xylylene cycloadditions;[6] synthesis of 3-arylpropanenitriles[7])

Form Supplied in: black powder; activated nickel is not commercially available and must be prepared prior to use.

Preparative Methods: activated nickel is prepared by the reduction of nickel iodide with ***Lithium*** metal under argon with a catalytic amount of naphthalene in glyme.[6]

Handling, Storage, and Precautions: all reactions should be carried out in an inert atmosphere. Appropriate precautions are necessary since the reagent is a cancer suspect agent. Use in a fume hood.

Homocoupling Reactions of Halobenzenes.

Activated metallic nickel powder is a simple and convenient reagent for coupling iodobenzenes and bromobenzenes (eqs 1 and 2).[1] Best results are obtained with unsubstituted or 4-substituted iodobenzenes. *Ortho* substitutents, particularly nitro groups, seem to inhibit coupling. Electron-donating substitutents seem to lower the reactivity. Carbonyl groups and nitriles are compatible and afford good yields of the corresponding biphenyls. Glyme, DMSO, and DMF have all been used as solvents with very little difference in yields.

(1)

(2)

The use of activated nickel powder is superior to the Ullmann synthesis in that reaction temperatures are much milder (80 °C compared to 150-280 °C) and yields are generally better.

Unsubstituted and monosubstituted benzylic halides react with metallic nickel at room temperature to afford the corresponding 1,2-diarylethanes in good yield (eq 3).[2] Substituents such as methoxy, chloro, bromo, nitro, cyano, and alkoxycarbonyl groups are well tolerated. Reactions of benzylic di- and trihalides gives mixtures of *cis*- and *trans*-ethylenes (eq 4).[2]

(3)

74% *cis* 26% *trans*

(4)

Coupling of Benzyl Halides.

Metallic nickel is a convenient reagent for the reductive coupling of benzyl halides with acyl halides to afford benzyl ketones (eq 5).[4] Best results are obtained in refluxing glyme, although some reactions proceed even at room temperature.

Synthesis of β-Hydroxynitriles.

Metallic nickel can effect Reformatsky-type addition of haloacetonitriles to aldehydes at 85 °C in glyme to give β-hydroxynitriles (eq 6).[5] Bromoacetonitriles give the best results, but chloro- and iodoacetonitriles also react.

Cycloadditions of *o*-Xylylenes with Dienophiles.

Activated nickel reacts with α,α´-dihalo-*o*-xylene in the presence of electron-deficient alkenes to yield 1,2,3,4-tetrahydronaphthalene derivatives in moderate yield (eq 7).[6] This reaction proceeds, presumably, via an *o*-xylylene intermediate. A variety of alkenes give the expected cycloaddition products. In general, *cis*-alkenes yield a mixture of *cis* and *trans* products (eq 8), while *trans*-alkenes only give *trans* products (eq 9).[6] Although the cycloaddition has not been proven to be either concerted or stepwise, the mixtures of *cis* and *trans* products can be explained by isomerization of the alkenes prior to the cycloaddition.

(7)

(8)

cis:*trans* = 1:1

(9)

Preparation of 3-Arylpropanenitriles.

Benzylic halides react with haloacetonitriles in the presence of nickel to form 3-arylpropanenitriles (eq 10).[7] The reaction conditions are compatible with a variety of substituents including halogens, nitriles, and alkoxycarbonyl groups (eqs 11 and 12).

Nickel(II) Acetate

$(AcO)_2Ni.4H_2O$

[6018-89-9] · $C_4H_{14}NiO_8$ · Nickel(II) Acetate · (MW 248.87)

(autoxidation catalyst;[1] hydrogenation catalyst;[2] catalyst for isomerization of aldoximine[4] to amides;[3] template for Schiff base condensations[4])

Physical Data: decomposition above 250 °C; d = 1.798 g cm^{-3}.

Solubility: sol H_2O and MeOH; insol most organic solvents.

Form Supplied in: widely available as tetrahydrate in high purity as a green powder or small crystals.

Purification: anhydrous nickel acetate can be obtained by heating the tetrahydrate to 100 °C under vacuum over P_2O_5 or other desiccants.

Handling, Storage, and Precautions: excellent shelf life, carcinogen, toxic.

Autoxidation of Benzoin.

Anhydrous nickel acetate in methanol can be used to catalyze the autoxidation of benzoin to benzil.[1] The reaction is first order in nickel acetate and in benzoin, and extensive mechanistic studies suggest that a complex is formed between nickel acetate and benzoin that subsequently reacts rapidly with dioxygen. Both formaldehyde and H_2O_2 were identified as byproducts. No other α-hydroxy ketones have been studied.

Hydrogenation.

A heterogeneous catalyst for hydrogenation can be prepared from ***Sodium Hydride***, RONa, and $Ni(OAc)_2$ and used for hydrogenation of alkynes, alkenes, and carbonyl compounds at room temperature and atmospheric pressure.[2] The catalyst is prepared by adding a stirred suspension of 1 equiv anhydrous $Ni(OAc)_2$ in THF to 6 equiv NaH. After heating to 45 °C, 2 equiv of the desired alcohol, for example *t*-pentyl alcohol, is added and heating is continued for 3 h. The resulting solution is used directly for reduction of 1 equiv of substrate at room

temperature for reaction times of 5-60 min. This catalyst selectively reduces alkynes to *cis*-alkenes in reaction times of 10-20 min. Conjugated dienes react more slowly, so that a mixture of dienes may be selectively reduced as well. Ketones are reduced to alcohols more slowly, requiring 2-9 h for completion of the reaction. See ***Sodium Hydride-Nickel(II) Acetate-Sodium t-Pentoxide***.

Isomerization of Aldoximes to Amides.

Aldoximes are isomerized to amides by heating in xylenes in the presence of 0.2-5.6 mol % $Ni(OAc)_2$ as catalyst.[3] For example, benzaldoxime is converted to benzamide in 91% purified yield by heating to reflux in xylenes for 5 h with 2 mol % catalyst (eq 1). Aliphatic oximes, including acid-sensitive ones, and aromatic oximes with either electron-donating or -withdrawing substituents are all good substrates for this reaction.

(1)

Schiff Base Condensations.

Simple nickel(II) salts such as $Ni(OAc)_2$ are used as templates for Schiff base condensation of amines with carbonyl compounds to form polydentate nickel chelates.[4] In particular, acetylacetone and its analogs will condense with ***1,2-Diaminoethane*** to form a macrocyclic complex. The reaction is exemplified with phenyldiazomalondialdehyde (eq 2).

Nickel(II) Acetylacetonate[1]

[3264-82-2] · $C_{10}H_{14}NiO_4$ · Nickel(II) Acetylacetonate · (MW 256.93)

(catalyst for oligomerization, telomerization, hydrosilylation, hydrogenation, reduction, cross-coupling, oxidation, conjugate addition, addition to multiple bonds, and rearrangements[1])

Alternate Name: bis(acetylacetonato)nickel(II).

Physical Data: pale green solid, mp 240 °C (dec); see also ***2,4-Pentanedione***.

Solubility: sol ethers and aromatic and halogenated hydrocarbons.

Analysis of Reagent Purity: atomic absorption is the method most commonly used.

Preparative Methods: commercially available; can be prepared from ***Nickel(II) Chloride***.[1d]

Purification: recrystallize from benzene and sublime under vacuum (10^{-3} mmHg).[1c]

Handling, Storage, and Precautions: nickel is now recognized as a cancer suspect agent as well as a possible teratogen and due precautions should be taken when handling the reagent. The anhydrous solid is stable, but is an irritant and hygroscopic and should preferably be stored in a sealed container to preclude contact with air and moisture. Solutions are more susceptible to atmospheric oxidation.

Catalysts for Oligomerization, Cooligomerization, and Telomerization.

Active catalytic systems used for these reactions have been prepared from many Ni^{II} salts and Ni^0 complexes. The most common are $Ni(acac)_2$, nickel halides, and nickel-alkene complexes. The reactive species are formed from the

combination of Ni^0, a Lewis acid usually based on aluminum, and a suitable ligand. They are referred to as Ziegler catalysts. When Ni^{II} salts are used, a reducing agent is required to produce the active Ni^0. The Lewis acid present, commonly a trialkylaluminum, is generally sufficiently reactive to reduce the nickel salt. Other reducing agents such as ***n-Butyllithium***,[2] ***Sodium Borohydride***,[3] or an electric current[4] have also been used. The oligomerization reactions are usually done in hydrocarbon or halogenated solvents. The mechanism is believed to involve nickel hydride, formed in situ via β-hydride elimination. First, an alkene inserts into the Ni-H bond. Further insertion of a second alkene into the C-Ni bond and reductive elimination regenerates nickel hydride and produces the oligomer. While some very interesting carbocyclic systems can be accessed via these catalysts, the product distribution can vary depending on the nickel precatalyst/Lewis acid/ligand combination chosen. The better activity resulting from using one precatalyst over another for a specific transformation is not always well understood, and often results from careful tuning of the catalytic system. Below are those in which $Ni(acac)_2$ has been successful. Other articles and monographs on ***Nickel*** should also be consulted.[1a,1b]

Oligomerization and Cooligomerization of Alkenes.

Cooligomerization of monoalkenes is generally of limited synthetic interest due to the formation of many isomers and oligomers and the difficulty in establishing conditions displaying suitable selectivity. It is, however, very important in the industrial production of lower alkenes. This topic is certainly well beyond the scope of this article. Some cyclic and bicyclic alkenes have proven more suitable (eq 1), the rigidity of which provides lesser oportunities for isomerizations by ways of insertion/migration.[5,6]

(1)

Cooligomerization of 1,3-Dienes.

The cyclotrimerization of butadiene is performed in the presence of a ligand-free nickel catalyst, giving cyclododecatrienes (eq 2),[7] with the all-*trans*-1,5,9-isomer as the major product. Lesser amounts of the other double-bond isomers are also found, the quantity of which are temperature and concentration dependent.[8] Substituted 1,3-dienes have not received as much attention due to the large number of isomers formed during the reaction, as well as the much lower reaction rates. The cyclooligomerization can be stopped at the stage of the dimer by introducing a phosphite or phosphine ligand.[9] In the reaction of butadiene the major product is 1,5-cyclooctadiene (eq 3),[9] which is accompanied by small amounts of divinylcyclopropane and 4-vinylcyclohexene. The three products are believed to originate from the same di-π-allylnickel intermediate (eq 4).[10] The proportion of these intermediates and consequently the product distribution is affected by the presence of a ligand, effects of which have been related to their electronic and steric nature. The less basic and more bulky ligands favor a di-π-allyl intermediate which eventually closes by reductive elimination to the 1,5-cod via a terminal, rather than internal, di-σ-allyl complex.[10]

(2)

(3)

(4)

Codimerizations of a variety of 1,3-dienes provide a convenient access to substituted 1,5-cyclooctadienes (eq 5)[11] and cyclohexenes (eq 6).[12] The presence of an activating group such as an ester can provide further stabilization of the σ-allyl/π-allyl complex, increasing the selectivity of the reaction (eq 7).[13]

(5)

(6)

(7)

The cooligomerization of 1,3-dienes and alkenes involves two molecules of the diene and one of the alkene to form substituted cyclodecadienes (eq 8)[14] and variable amounts of the linear cotrimers. In the case of symmetrical alkenes it is possible to obtain a single product, in contrast to unsymmetrical alkenes in which mixtures of isomers result, in addition to those resulting from the other modes of oligomerization (i.e. linear vs. cyclic). These reactions work best in the presence of the catalytic system $Ni(acac)_2$/ligand/diethylethoxyaluminum. This is among the few methods giving direct access to 10-membered rings.

(8)

Disubstituted alkynes as well as allenes have also served as substrates in cooligomerizations with butadienes. With the former, *cis*-4,5-divinylcyclohexenes and mixtures of cyclodecadienes result. Other nickel precatalysts, such as ***Bis(1,5-cyclooctadiene)nickel(0)***, have, however, proved to be more specific with regard to the type and number of products formed.[15]

Alkynes.

The oligomerization of unsubstituted (eq 9)[16] and monosubstituted alkynes, also known as the Reppe reaction, produces variable mixtures of linear dimers, 1,2,4- and 1,3,5-trisubstituted benzenes, and cyclooctatetraene[17] isomers. Disubstituted alkynes are known not to undergo such a process although they can be used in cooligomerizations with mono- and unsubstituted alkynes. The product distribution depends on the nature of the ligands.[18] Weak ligands such as acac[19] or cod favor cyclotetramerization while stronger ones such as PPh_3 induce cyclotrimerization.[20] When coordinating solvents such as pyridine or DMF are used, only the linear dimer is formed.[21]

(9)

Strained systems are also reactive and their synthetic utility has been elegantly demonstrated.[22] In the synthesis of 12-

nor-13-acetoxymodhephene, advantage was taken of the facile Ni^0-induced transannulation that can take place in eight-membered rings, made possible by coordination of Ni^0 to the two double bonds (eq 10).[23]

Telomerization is also an important reaction catalyzed by $Ni(acac)_2$ and other nickel species in the presence of ligands and reducing agents.[24] In this process, a diene is inserted in a 1,2- or 1,4-fashion into an activated C-H bond (eq 11)[25] or into the X-H bond of an alcohol (eq 12),[26] phenol, amine, or silane.[27]

1,7-Diynes also undergo cyclization with 1,8-insertion into a Si-H bond.[28] Finally, dimethylsilane adds efficiently and with excellent regioselectivity to functionalized electron-rich or -poor alkenes in a 1,2-fashion, providing access to a wide variety of silane-containing substrates.[29]

A catalytic asymmetric version of the codimerization of alkenes has also appeared.[30] Homochiral phosphine ligands are used to induce chirality and, in selected examples, have resulted in appreciable levels of asymmetric induction (eq 13).[31,32]

(13)

Nickel hydride generated in situ has been postulated as the active catalyst in the transformations described above and, not surprisingly, a large number of precatalysts have been reported. Only those dealing specifically with $Ni(acac)_2$ have been described here. A more comprehensive account is provided in the excellent reviews by Jolly and Wilke.[1a,1b]

Catalyst for Oxidations.

A very efficient protocol for the air oxidation of ketones, alkenes, and aldehydes, catalyzed by nickel (1,3-diketonates) has been developed by Mukaiyama and co-workers. Baeyer-Villiger oxidation of ketones to esters and lactones (eq 14)[33] is achieved in moderate to high yields with 1% $Ni(acac)_2$ or $Ni(dpm)_2$ (dpm = dipivaloylmethanato) and 2-3 molar equivalents of isovaleraldehyde or benzaldehyde under one atmosphere of air or oxygen, in 1,2-dichloroethane at ambient temperature. High regioselectivities were observed for unsymmetrical ketones (eq 15).[33] The aldehyde, which functions as a reducing agent, is converted to the acid in high yield.[34] This represents a mild, convenient, and ecologically sound oxidation protocol.

1	84
2	91
3	33

(14)

(15)

The epoxidation of alkenes[35] can also be realized in moderate to high yields under the same conditions using an aldehyde, or under more forcing conditions using an alcohol,[36] as the coreducing agent. Very low stereospecificity is obtained for disubstituted alkenes, which provide nearly equal mixtures of *cis*- and *trans*-epoxides, irrespective of the initial alkene geometry. This is, however, a good protocol for some 1,1-symmetrical trisubstituted alkenes.[37] Little information is available on the chemoselectivity and compatibility of other functional groups under the reaction conditions.

Catalyst for Conjugate Additions.

The conjugate addition of organozinc reagents in a 1,4-fashion to α,β-unsaturated ketones in the presence of 1-10 mol% of $Ni(acac)_2$ in ethereal or aromatic solvents proceeds in good to excellent yields (eq 16).[38] The reaction is fast and the conditions are very mild. This represents a nice alternative to organocopper reagents since diorganozinc reagents are much more stable than their organocopper analogs and can be used at ambient temperatures without decomposition. Addition occurs even with the most sterically demanding substrates, as demonstrated by the synthesis of (±)-β-cuparenone by Greene and co-workers (eq 17).[39] Aryl-, *t*-butyl-, cyclohexyl-, and alkenylzinc reagents have also been used. It should be noted that only one of the two alkyl groups is transferred and monoalkylzinc halides do not add, which results in the loss of one equivalent of the nucleophile. Articles on copper reagents should be consulted for related transformations.

(16)

(17)

In the presence of $Ni(acac)_2$ and a coreducing agent such as ***Diisobutylaluminum Hydride*** (DIBAL), alkenylzirconium reagents[40] (but not alkylzirconium[41] undergo 1,4-additions to α,β-enones in 60-95% yield, which decrease with substitution at C-1 of the organometallic. Similarly, the complex formed by addition of $Ni(acac)_2$ and DIBAL (1:1) catalyzes the 1,4-addition of dialkylaluminum acetylides to α,β-enones (eq 18).[42] Again, the reaction works well even with highly hindered substrates. Trimethylsilylalkynes add efficiently but the yields are considerably lower with acetylene itself. Trialkylaluminums have been used directly on enones with in situ generation of the active nickel species.[43] Other nucleophiles such as lithium thiophenoxide[43] and 1,3-dicarbonyls (eq 19)[44,45] can be used but generally require more forcing conditions. Although the mechanism of these nickel-catalyzed additions has not been clearly established, it is believed to involve ketyl radicals resulting from single-electron transfer (SET) from a nickel(I) species.[46]

(18)

(19)

Catalytic Enantioselective Conjugate Additions.

In recent years, much work has been done to achieve enantioselective addition of organozinc reagents to various enones using homochiral ligands.[47,46b] Respectable levels of induction have been achieved with selected aromatic substrates, but attempts with simpler enones such as cyclohexenone have been unsuccessful. The accepted model to test the activity of a particular catalytic system is the addition of ***Diethylzinc*** to chalcone. Yields are generally good and enantiomeric excesses (ee) range from 25 to 95%. A variety of bi- and tetradentate ligands have been designed and the most successful are shown in eq 20. Nonlinear relationships between the ee of the ligand and the ee of the final product have been frequently observed.[48,46b]

Catalyst for Cross-Coupling Reactions.

While not as popular as other Ni^{II} precatalysts, Ni^0 complexes, or other metals such as Pd^0 complexes, $Ni(acac)_2$ has found many applications as a catalyst for cross-coupling reactions. It is fairly stable and sufficiently soluble to be used in a large variety of solvents. Aryl halides,[49] silyl enol ethers,[50] enol phosphates[51] and, more recently, aryl-*O*-carbamates and triflates[52] have been successfully coupled with alkyl, aryl, and alkenyl organometallics (eq 21).[53] The yields are generally good and chemoselectivity can be achieved in some cases (eq 22).[54,52]

(21)

(22)

The addition of mono- and bidentate phosphine ligands in ethers or aromatic solvents often has a beneficial effect on the yield and speed of the reaction. The mechanism has been well documented and involves an oxidative addition of the aryl halide to Ni^0 followed by addition of the organometallic species to the Ni^{II} complex. Reductive elimination of the cross-coupling product and regeneration of Ni^0 completes the catalytic cycle. The coupling of stereodefined 1-alkenylalanes and zirconium with a variety of aryl halides proceeds in good yield and stereospecifically (eq 23).[55] Vinylic sulfones can serve as the electrophilic partner, coupling efficiently with phenyl- or methylmagnesium bromide (eq 24).[56] An interesting example was reported in which both electrophilic and nucleophilic components are borne by the same carbon. In this example, an α-(bromomagnesium)sulfone dimerizes head-to-head to produce a mixture of *cis*- and *trans*-alkenes (eq 25).[57]

(23)

(24)

(25)

Again, $Ni(acac)_2$ is only one of the many precatalysts which have been used (often interchangeably) for these transformations. The choice of proper precatalyst has, in many instances, been the result of a more or less exhaustive screening of the five or six most common ligands. Other metal ions such as palladium, copper, or chromium are often similarly effective in promoting the transformation.

Other Additions.

Grignard reagents add regioselectivity and stereoselectively to substituted trimethysilylalkynes, in presence of $Ni(acac)_2$ and ***Trimethylaluminum***, to give a *syn* addition product (9:1). These additions occur exclusively at the carbon-substituted end of the alkyne.[58] If a heteroatom, such as an ether or an amine, is present on the carbon chain, isomerization to the *trans* product occurs (eq 26). The intermediate organometallic species can be subsequently trapped with a variety of electrophiles.

(26)

Functionalization of an unactivated terminal alkene is possible via remote chelation of a halomagnesium alkoxide (eq 27).[59] Addition of Grignard reagents to propargyl chlorides proceeds in a S_N2' fashion to provide good yields of the corresponding allenes. Methyl ketones can be prepared by $Ni(acac)_2$-catalyzed addition of trimethylaluminum to a nitrile followed by hydrolysis.[60a]

(27)

$Ni(acac)_2$ has been shown to promote the intramolecular coupling of a vinyl iodide with an aldehyde in the presence of ***Chromium(II) Chloride***, to form a 13-membered ring lactone. However, only a moderate stereoselectivity was observed, as both diastereomeric alcohols were produced (60% yield).[60b]

In the presence of a catalytic amount of $Ni(acac)_2$ (in addition to other metals), ***Cyanotrimethylsilane*** reacts smoothly with acetals or orthoesters derived from α,β-unsaturated carbonyls to give the corresponding *O*-methylcyanohydrins under neutral conditions (eq 28).[61]

(28)

β-Diketonates add to ***Malononitrile*** in moderate yield to give β-amino cyanides (eq 29).[62] In contrast, β-keto esters, 1,3-diesters, and β-keto amides are all poor substrates. Other electrophiles have been used such as cyanogen, benzoyl cyanide,[63] and ***Trichloroacetonitrile***.[64] Reaction of acetylacetonate with cyanogen has been reported to produce highly substituted pyrimidines in moderate yields.[65]

(29)

Optically active trialkylsilanes react with ***Vinylmagnesium Bromide*** via a pentacoordinate intermediate to produce, after loss of a hydride, tetrasubstituted silanes with almost complete retention of configuration.[66]

Reductions.

$Ni(acac)_2$ has seldom been used as a reduction catalyst. Hydrogenation of alkenes has been realized under photochemical conditions in the presence of a ketone as a sensitizer.[67] Monohydrogenation of 1,4-cyclohexadiene was effected using a homogeneous nickel catalyst generated from $Ni(acac)_2$, $Et_3Al_2Cl_3$, and PPh_3. Substituted cyclohexadienes produce mixtures of cyclohexene isomers, isomerization of which was shown to be promoted by the catalyst itself. A zeolite-supported complex formed between $Ni(acac)_2$ and an optically active 2-(aminocarbonyl)pyrrolidine ligand catalyzes the asymmetric hydrogenation of ethyl (*Z*)-α-benzoylaminocinnamate with ee values up to 85%. Other metals that have been studied have resulted in even higher enantioselectivities.[68]

Vinylic sulfones are reduced in fair to good yield to the corresponding alkenes with retention of configuration upon treatment with *n*-butylmagnesium bromide and a catalytic amount of $Ni(acac)_2$.[69] 2-Arenesulfonyl-1,3-dienes are also reduced stereospecifically to conjugated (*Z*,*E*)-dienes under the same conditions (eq 30).[70]

(30)

Miscellaneous Uses of Ni(acac)$_2$.

The isomerization of aldoximes to amides catalyzed by Ni(acac)$_2$ and ***Palladium(II) Acetylacetonate*** has been described.[71] The determination of the absolute configuration of vicinal glycols and amino alcohols complexed with Ni(acac) in protic or aprotic organic solvents has been claimed to be feasible by examination of the induced CD.[72] However, this method is not very general.

Nickel Boride[1]

Ni_2B

(Ni_2B)[2]

[12007-01-1] · BNi_2 · Nickel Boride · (MW 128.19)

(selective hydrogenation catalyst,[1a,c,3] desulfurization catalyst;[4] reduces nitro[5] and other functional groups;[1a] dehalogenation catalyst;[1b,6] hydrogenolysis[7] catalyst)

Physical Data: mp 1230 °C.[8]

Solubility: insol aqueous base and most organic solvents; reacts with concentrated aqueous acids.

Form Supplied in: black granules, stoichiometry varies with supplier.

Preparative Methods: to a stirred suspension of 1.24 g (5 mmol) of powdered ***Nickel(II) Acetate*** in 50 mL of 95% ethanol is added 5 mL of a 1 M solution of ***Sodium Borohydride*** in 95% ethanol at room temperature (control frothing). Stirring is continued until the gas evolution ceases (usually 30 min). The flask is used directly in the hydrogenation.[1c,9a] This catalyst is nonpyrophoric.

Handling, Storage, and Precautions: caution must be taken in handling nickel salts. Ingestion of soluble nickel salts causes nausea, vomiting, and diarrhea. Nickel chloride has an LD_{50} (iv) = 40-80 mg kg^{-1} in dogs. Many nickel salts will sublime in vacuo. Nickel metal is carcinogenic and certain nickel compounds may reasonably be expected to be carcinogenic.

Catalyst Composition and Structure.

The composition of the catalyst produced by the reaction of Ni^{II} salts and ***Sodium Borohydride*** is dependent on reaction conditions (solvent, stoichiometry, temperature, etc.).[9] X-ray photoelectron spectroscopy[10] showed that the main difference between the P1 form of nickel boride (P1 Ni) and the P2 form of nickel boride (P2 Ni) is the amount of $NaBO_2$ adsorbed on to the surface of the catalyst. P1 Ni (which is prepared in water) has an oxide:boride ratio of 1:4, while P2 Ni (which is prepared in ethanol) has a ratio of 10:1. Early studies of the reaction of borohydrides with transition metal salts[11] (Fe^{II}, Cu^{II}, Pd^{II}, Ni^{II}, Co^{II}, etc.) showed that the reaction product is either the metal (as in the case of Pd^{II}) or a black granular solid (as in the case of Ni^{II}); in both cases, H_2 is evolved.[11c,12] Analysis of the black solid formed from the Ni^{II} suggested the catalyst to be a boride.[11c,13] Paul et al.[11b] examined several Ni^{II} salts and found nickel acetate to be most acceptable.

Hydrogenation of Alkenes and Alkynes.

Brown has described two forms of nickel boride (P1 Ni and P2 Ni)[9] which are hydrogenation catalysts. In a comparison of P1 Ni to W2 ***Raney Nickel*** (Ra Ni) as a hydrogenation catalyst, P1 Ni was found to be somewhat more active (as measured by the $t_{1/2}$ for hydrogenation of several alkenes).[9a] What is more important in the comparison of Ra Ni and P1 Ni is the lower incidence of double-bond isomerization observed with P1 Ni vs. Ra Ni (3% vs. 20%). P1 Ni reduces mono-, di-, tri-, and tetrasubstituted alkenes under mild conditions (1 atm H_2, rt) while leaving many groups unaffected (e.g. a phenyl ring). There is a significant difference in the rate of reduction among the various substituted alkenes allowing for selectivity. However, P2 Ni is very sensitive to steric hindrance and to the alkene substitution pattern. Little or no hydrogenolysis of allylic, benzylic, or propargylic substituents is observed with this catalyst; partial reduction of alkynes and dienes are also possible. Some examples of the use of P2 Ni as a hydrogenation catalyst are shown in Table 1.

Table 1 Reduction of Alkenes, Dienes, and Alkynes with P2 Ni

Substrate	Product	Yield (%)	Ref.
1-Hexyne	Hexane	16	9a

		70	17
		50	18

Under more forcing conditions (30 psi in a Parr apparatus), Russell[19] was able to reduce unsaturated ethers, alcohols, aldehydes, esters, amines, and amides to their saturated counterparts without hydrogenolysis. Unsaturated nitriles[19b] were reduced to primary amines while epoxides were unaffected by the reagent. Both dimethoxyborane (eq 1)[20] and ***Lithium Aluminum Hydride*** (eq 2)[21] can replace $NaBH_4$ in these reactions.

(1)

(2)

Heteroarenes.

Nose and Kudo[22] examined the reduction of quinaldine (**1**) with a variety of transition metal salts ($CoCl_2$, $NiCl_2$, $CuCl_2$, $CrCl_3$) in the presence of $NaBH_4$; only ***Nickel(II) Chloride*** was effective (eq 3).

(1) (3)

Partial reduction of a series of heteroaromatics was examined using $NiCl_2/NaBH_4$ in methanol at room temperature (Table 2). The authors suggest that the reduction proceeds through a $NiCl_2$ complex of the arene; however, other workers[1a] dispute this mechanism.

Table 2 Reduction of Heteroaromatics with $NiCl_2/NaBH_4$

	52

Desulfurization.

While Raney nickel[23] is the traditional reagent for desulfurization reactions, it has several drawbacks (i.e. strongly basic, pyrophoric, sensitivity to air and moisture). In 1963, Truce and Roberts[24] reported the use of $NiCl_2/NaBH_4$ in the partial cleavage of a dithioacetal (eq 4).

(4)

Since then, there have been numerous examples of the use of Ni^{II} salt/$NaBH_4$ in desulfurization reactions;[4] in many cases the yields are greater than those seen with Raney nickel[25] (eq 5) *(note: caution must be exercised when using $NaBH_4$ in DMF)*.

(5)

Boar et al.[26] used nickel boride in a protection-deprotection scheme for triterpenoid ketones (eq 6).

(6)

$Ni^{II}/NaBH_4$ is an effective reagent for desulfurization of thioamides,[27] thioethers,[28] and sulfides.[4,29] Back and co-

workers[4,30] has reported extensive studies of the scope, stereochemistry, and mechanism of nickel (and cobalt) boride desulfurizations. In general, nickel boride is a more effective desulfurization catalyst than ***Cobalt Boride*** (other metals such as Mo, Ti, Cu, and Fe were completely ineffective). ***Lithium Borohydride*** can be used in place of $NaBH_4$ while ***Sodium Cyanoborohydride*** cannot. Sulfides, thioesters, thiols, disulfides, and sulfoxides are reduced to hydrocarbons by Ni_2B, while sulfoxides are stable. Esters, chloro groups, and phenyl groups are stable to Ni_2B. Iodides, nitro groups, nitriles, and alkenes are reduced completely by Ni_2B, while bromides, aldehydes, ketones, and cyclopropanes show variable reactivity (eqs 7-10).

Using deuterium labelling, Back showed that desulfurization occurs with retention of configuration, unlike Raney nickel, which involved a radical mechanism. The suggested mechanism of desulfurization involves an oxidative addition-reductive elimination sequence via a nickel hydride intermediate.

Reduction of Other Nitrogenous Functional Groups.

Primary, secondary, and tertiary aliphatic nitro groups are reduced to amines with $NiCl_2/NaBH_4$.[5c] ***Hydrazine*** hydrate has also been used with Ni_2B to reduce both aryl and aliphatic nitro groups in a synthesis of tryptamine (eqs 11 and 12).[31]

(11)

(12)

Reductive cleavage of thioethers and reduction of nitro groups has been combined in a synthesis of pyrrolidones (eq 13).[32]

(13)

Like Co_2B, Ni_2B[5b] reduces nitroarenes to anilines and azoxybenzenes to azobenzenes (Table 3); unlike Co_2B, Ni_2B reduces oximes[33] to amines (Table 4).

Table 3 Reduction of Nitroarenes with Ni^{II}/Borohydride Reagents

Substrate	Reagent	Product	Yield (%)
$PhNO_2$	2 equiv Ni_2B, MeOH	$PhNH_2$	3[5a]

Reduction of Other Nitrogenous Functional Groups.

Borane-Tetrahydrofuran/$NiCl_2$ has been used to reduce chiral cyanohydrins to ethanol amines in high yield.[35] Azides are cleanly reduced to amines in good yield with nickel boride.[36] Azides are reduced in preference to hindered aliphatic nitro groups (eq 14).[37]

(14)

Isoxazoles are reduced to β-amino enones in high yield using the $NiCl_2/NaBH_4$ system.[38] Dihydroisoxazolones are reduced with a high degree of diastereoselectivity with the $NiCl_2/NaBH_4$ system.[39]

Dehalogenation.

Many α-bromo ketones[6a] are cleanly reduced to the parent ketone with nickel boride in DMF (caution). Vicinal dibromides are reduced to alkenes (eq 15).

(15)

Aryl and certain alkyl chlorides can be dehalogenated[1a,1b,6b] with a variety of Ni^{II}/hydride agents (e.g. $NaBH_2(OCH_2CH_2OMe)_2$, ***Triethylsilane***, $NaBH_4$). Lin and Roth have effected the clean debromination of aryl bromides[40] using ***Dichlorobis(triphenylphosphine)nickel(II)***/$NaBH_4$ in DMF (**caution**); ***Tris(triphenylphosphine)nickel(0)*** is assumed to be the active catalyst. Russel and Liu[41] demonstrated that reductive cleavage of an iodide goes with retention when $NiCl_2/NaBH_4$ is used (cf. inversion seen with $LiAlH_4$; eq 16).

(16)

Hydrogenolysis.

Ni_2B has been used to hydrogenolyze benzylic (eqs 17-19),[7a] allylic (eqs 20-22),[7b,42] and propargylic (eq 23)[7b] esters in good yields.

(17)

(18)

(19)

(20)

(21)

1:1

(22)

(23)

Enol tosylates and aryl tosylates are deoxygenated in good to excellent yields[43] (eqs 24 and 25)

(24)

(25)

A variety of allylic functional groups[44] (alcohols, esters, silyl ethers, ketones, and hydroperoxides) have been reduced with Ni_2B. The combination of ***Chlorotrimethylsilane***/Ni_2B will selectively reduce an aldehyde in the presence of a ketone.[45]

Selenides[46] and tellurides[47] are reductively cleaved by Ni_2B with retention of stereochemistry. The phenyl selenyl group is

cleaved in preference to the thio phenyl group.

Physical Data: mp 963 °C; *d* 5.098 g cm^{-3}.

Solubility: sol water, alcohol, ether.

Form Supplied in: yellowish green for hydrate; golden yellow when anhydrous; widely available.
Drying: anhydrous nickel bromide can be obtained by heating at 300 °C and storing in a desiccator.

Handling, Storage, and Precautions: nickel(II) is reputed to be toxic and a cancer suspect agent. Use in a fume hood.

General Considerations.

Most reactions promoted by ***Nickel(II) Chloride*** can also be mediated by nickel(II) bromide. This section covers certain specific applications using nickel bromide as a reagent.

Displacement Reactions.

Li_2NiBr_4 prepared from anhydrous ***Lithium Bromide*** and $NiBr_2$ in THF serves as a source of soft nucleophilic bromide and reacts regioselectively with epoxides to give bromohydrins in high yield (eq 1).[1]

(1)

Like $NiCl_2$, reduction of $NiBr_2$ with a number of reducing agents generates useful catalytic species. To illustrate this, $NiBr_2$-***Zinc*** can catalyze the halogen exchange reaction of aryl bromides with ***Potassium Iodide*** under mild conditions.[2] At elevated temperature, $NiBr_2$-***Tri-n-butylphosphine*** is also an effective catalyst for this transformation. With a catalytic amount of a Ni^0 complex generated in situ from $NiBr_2$, ***1,1´-Bis(diphenylphosphino)ferrocene***, and zinc powder, aryl thiols react with an equimolar amount of aryl iodide at 25 °C or bromide at 60 °C to afford symmetric aryl sulfides in excellent yields (eq 2).[3]

(2)

The conversion of aryl and vinyl bromides into the corresponding iodides is also achieved using a low-valent nickel catalyst generated in situ.[4] This reaction turns out to be useful to activate the carbon-chlorine bond in aryl chlorides in the Heck reaction (eq 3).[4e]

(3)

$NiBr_2$-BuLi.

The addition of ***n-Butyllithium*** to a suspension of $NiBr_2$ in THF at -78 °C forms material which catalyzes an efficient substitution reaction of lithium ester enolates with aryl or vinyl bromides or iodides (eqs 4 and 5).[5] The reaction occurs with clean retention of stereochemistry at the halogen-bearing carbon. Addition of phosphine ligands gives

totally inactive material.

Cross-Coupling Reactions.

Most nickel-promoted cross-coupling reactions use nickel halide phosphine complexes as the catalyst and are discussed under ***Nickel(II) Chloride***. The addition of the phosphine ligand to a solution of nickel bromide also serves as a useful catalytic system for this purpose. For example, enol phosphates are converted into the corresponding allylsilanes when trimethylsilylalkyl Grignard reagents are employed (eq 6).[6]

Nickel bromide has been shown to convert aryl bromides into the corresponding aryl phosphine derivatives (eqs 7-9).[7]

(7)

(8)

(9)

$NiBr_2$ catalyzes the reaction of aryl iodides with red phosphorus to give triphenylphosphine oxide in excellent yield after hydrolysis (eq 10). Under modified conditions, triphenylphosphine is obtained (eq 11).[8]

(10)

(11)

Five- and six-membered cyclic 3-iodo enones undergo spiroannulation with symmetric internal alkynes in the presence of $NiBr_2$ and zinc powder to afford spiro[4.4]nonadienones and spiro[4.5]decadienones in good to excellent yields at temperatures of 60-100 °C (eq 12).[9]

(12)

Miscellaneous.

Primary and secondary alcohols are oxidized to their respective carbonyl compounds in high yield by ***Dibenzoyl Peroxide*** through the action of $NiBr_2$, which serves as an effective mediative catalyst and as an alcohol template in these transformations.[10]

The Ni^0 species generated by electrochemical reduction of the $NiBr_2$(bipy) complex exhibits catalytic activity for the dimerization of aryl, benzyl, alkyl, or vinyl halides in good yields.[11] Zinc plays a similar role as reducing agent in the homocoupling reactions.[12] Like the nickel chloride-mediated reactions, the presence of iodide ion and thiourea accelerates the reaction (eq 13).[13] Aryl bromides can also be efficiently reduced with ***Sodium Hydride*** in the presence of $NiBr_2$.[14] In a manner similar to that observed with the $NiCl_2$ catalyst, the reduction of $NiBr_2$ by magnesium in a boiling THF solution of symmetrical alkynes quantitatively leads to cyclotrimerization products.[15]

(13)

The reaction of divinylphenylphosphine with 1-phenyl-3,4-dimethylphosphole in the presence of anhydrous $NiBr_2$ leads to the formation of a single diastereomer of the product as the result of two sequential stereoselective intermolecular [4 + 2] Diels-Alder cycloadditions. This reaction provides a facile route to a new type of conformationally rigid tridentate phosphine (eq 14).[16]

Nickel Catalysts (Heterogeneous)

Ni^0

[7440-02-0] · Ni · Nickel Catalysts (Heterogeneous) · (MW 58.71)

(hydrogenolyses and hydrogenations[1])

Physical Data: mp 1453 °C; bp 2730 °C; *d* 8.908 g cm^{-3}.

Form Supplied in: powder, rod, wire, foil, or pellet; 75% nickel on graphite is available.

Preparative Methods: nickel on alumina can be prepared from $Ni(NO_3)_2.6H_2O$ slurried with ***Alumina*** and then dried at 120 °C. The catalyst is activated before use by heating at 400 °C for 30 min.[2]

Handling, Storage, and Precautions: nickel is stable to air, yet care should be taken to avoid moisture when using finely divided nickel catalysts. Nickel is a possible carcinogen. Use in a fume hood.

Heterogeneous Nickel Catalysts.

This class of compounds covers Ni^0 on a variety of supporting media. Raney nickel and Urushibara nickel are discussed under separate headings (see ***Raney Nickel*** and ***Urushibara Nickel***). There have been many significant contributions to this field, yet a comprehensive study of reactions involving these heterogeneous processes has not been produced. Therefore, many of the catalysts described have been applied to only a limited subset of substrates.

Hydrogenolyses.

Hydrogenolysis reactions have been the subject of many studies involving heterogeneous nickel catalysts.[3-6] Most of these reactions have involved the use of substituted adamantanes in the gas phase over supported nickel catalysts (i.e. 30% nickel on alumina). These gas phase hydrogenolyses have been performed upon a variety of functional groups such as halides, amines, alcohols, carboxylic acids, esters, nitriles, ethers, hydroxymethylenes, and halomethylenes.[3] The removal of alkyl groups from substituted adamantanes at elevated temperatures is even possible.[4] Eq 1 demonstrates the temperature dependence of hydrogenolyses utilizing nickel on alumina.[5]

(1)

At lower temperatures the nitrile is hydrogenolyzed to a methyl group, yet at higher temperatures the resulting methyl group can be removed. Similar hydrogenolysis reactions have been performed using platinum and palladium catalysts; however, these reactions tend to be low yielding (<10%) due to random cracking of the parent hydrocarbon.[6]

Hydrogenations.

Supported nickel catalysts have been used to hydrogenate both alkynes and alkenes in high yield. Nickel on graphite has been used extensively to semihydrogenate alkynes to (*Z*)-alkenes using notably mild conditions (eq 2).[7]

(2)

Similar hydrogenations have been performed using supported palladium with similar stereoselectivity. However, nickel on graphite offers a reasonably priced alternative that can produce results comparable with, and in some cases better than, those with palladium catalysts. Further, nickel catalysts are nonpyrophoric, making filtration during workup safer than with other catalysts. A disadvantage of nickel on graphite is that the catalyst should be prepared fresh prior to each hydrogenation.

Caubere[8] has described a heterogeneous catalyst (Nic), which is a complex reducing agent of the type NaH-RONa-NiX_2 (see ***Nickel Complex Reducing Agents***). Nic is highly reactive, capable of rapidly reducing alkenes, alkynes, and

carbonyls. Reduction of alkynes occurs with high stereoselectivity to the corresponding (*Z*)-alkene. Nic offers several advantages over Raney nickel in that it is nonpyrophoric, stable to long-term storage, and provides higher stereoselectivity.

There have also been reports of aromatic saturation in excellent yields by passing hydrogen and gaseous substrate over nickel on alumina.[9] Hydrogenation of nitriles to the corresponding amines are known. For example, hydrogenating propionitrile with nickel on silica in methanolic ammonia at 125 °C for 45 min resulted in a 97% yield of *n*-butylamine.[10]

Nickel(II) Chloride[1]

$NiCl_2$

($NiCl_2$)

[7718-54-9] · Cl_2Ni · Nickel(II) Chloride · (MW 129.59) ($NiCl_2.6H_2O$)

[7791-20-0] · $Cl_2H_{12}NiO_6$ · Nickel(II) Chloride · (MW 237.71)

(mild Lewis acid;[2-5] catalyst for coupling reactions,[1a,7-12] and in combination with complex hydrides as a selective reducing agent[16,33,36-38])

Physical Data: mp 1001 °C; *d* 3.550 g cm^{-3}.

Solubility: sol H_2O, alcohol; insol most organic solvents.

Form Supplied in: yellow solid when anhydrous, green solid for the hydrate; widely available. *Drying:* for anhydrous nickel chloride, standard procedure for drying metal chlorides can be used by refluxing with ***Thionyl Chloride*** followed by removal of excess $SOCl_2$.[45]

Handling, Storage, and Precautions: nickel(II) is reputed to be toxic and a cancer suspect agent. Use in a fume hood.

Mild Lewis Acid.

Nickel chloride serves as a mild Lewis acid which promotes the regioselective rearrangement of dienols in aqueous *t*-BuOH at 60 °C in satisfactory yield (eq 1).[2] Brønsted acids give dehydration products, whereas other Lewis acids such as ***Nickel(II) Acetate***, ***Palladium(II) Chloride***, and ***Copper(II) Chloride*** proved less effective than nickel chloride and yield a mixture of rearranged and dehydration products. When anhydrous alcohol solvent is used, rearranged products bearing terminal alkoxy groups are obtained.

(1)

In the presence of a catalytic amount of $NiCl_2$, ***Cyanotrimethylsilane*** smoothly reacts with acetals or orthoesters derived from aromatic and α,β-unsaturated carbonyl compounds to give the corresponding α-cyano derivatives under neutral conditions (eq 2).[3] $NiCl_2$ can also accelerate the conversion of acrylamide to ethyl acrylate[4a] and catalyze the amination of 5,8-quinolinediones.[4b] The ring-opening reaction of epoxides with $LiAlR_4$ is catalyzed by $NiCl_2$ or ***Nickel(II) Bromide*** (eq 3).[5]

(2)

(3)

Nickel(II) Chloride-Chromium(II) Chloride.

Although the ***Chromium(II) Chloride***-mediated reaction of an aldehyde with a vinylic iodide provides a useful entry for the preparation of allylic alcohol,[1a,6] the presence of a catalytic amount of $NiCl_2$ is essential to ensure the completion of the reaction.[7-12] Vinyl iodides (eq 4)[7] or triflates[8a] are commonly used. Alkynyl iodides behave similarly (eq 5).[9] Silyl enol ethers or enol phosphates are unreactive. The stereochemistry of iodoalkenes is retained in the majority of cases with the exceptions of trisubstituted *cis*-iodoalkenes and *cis*-iodoenones, which afford exclusively the *trans*-alkenes instead of the expected *cis*-alkenes.[7a]

(4)

(5)

Functional groups such as esters, amides, nitriles, ketones, acetals, ethers, silyl ethers (TBDMS or TBDPS), alcohols, alkenes, and triple bonds are stable under the reaction conditions. Substrates containing structural complexity can be

employed in this transformation. Thus, the reaction served as the key step for the formation of C(7)-C(8) and C(84)-C(85) bonds in the total synthesis of palytoxin,[10] as well as for the synthesis of other natural products and C-saccharides. The reagent has also been proved to be useful in the intramolecular cyclization of the aldehyde (eqs 6 and 7).[11,12]

(6)

(7)

A simple and selective method for the conversion of an aldehyde to vinyl iodides, (*E*)-RCH=CHX, by means of a $CHX_3/CrCl_2$ system has been developed (eq 8).[13]

(8)

DMF happens to be the most effective solvent for this coupling reaction. The reaction goes slowly but cleanly in the DMSO solvent.[8a] The presence of a phosphine ligand in the nickel catalyst gives a diene sideproduct.[4a] Nevertheless, this later system has been used in the intramolecular cyclization of enynes (eq 9).[14]

(9)

Monosubstituted α,β-unsaturated aldehydes are converted to cyclopropanols in the presence of $NiCl_2/CrCl_2$ in moderate yields (eq 10).[15]

(10)

Selective Reductions.

Low-valent transition metal complexes generated in situ from metal halides and reducing agents are particularly useful for the selective reduction of various functionalities.[16] Nickel chloride and nickel bromide have demonstrated a unique role in these reduction reactions. To illustrate this, in the presence of an equimolar quantity $NiCl_2$, ***Lithium Aluminum Hydride*** can reduce alkenes to alkanes in excellent yields.[17] Under similar conditions at -40 °C, alkynes are reduced to *cis*-alkenes in good yield.[17] Haloalkanes are also smoothly converted into the corresponding hydrocarbons under these conditions.[18a,b] Even chlorobenzene and 1-bromoadamantane can be reduced efficiently by this reagent. ***Sodium Hydride*** in the presence of $NiCl_2$ or $NiBr_2$ and a sodium alkoxide can also serve a similar purpose.[16c,18c]

The N-O bond in isoxazolidines is cleaved efficiently by $LiAlH_4/NiCl_2$ at -40 °C (eq 11).[19] Styrene oxide yields β-phenylethanol in 95% yield by this complex reagent, whereas $LiAlH_4$ alone gives α-phenylethanol.[19]

(11)

Nickel Boride, prepared in situ from the reaction of nickel chloride and ***Sodium Borohydride***, behaves like ***Raney Nickel***.[1b] In DMF, the dark brown/black solution comprises an efficient system for alkene hydrogenation. The carbon-carbon double bonds of the α,β-unsaturated carbonyl compounds are reduced selectively (eq 12).[20] It is noted that carbon-sulfur bonds are selectively reduced under similar conditions (eq 13).[16b,21] Thiols, sulfides, disulfides, dithioacetals, as well as sulfoxides can all be hydrodesulfurized smoothly. Sulfones, on the other hand, remain intact under the reaction conditions.[21d,e]

(12)

(13)

Reduction of α-halo ketones with nickel boride produces the corresponding ketones.[22] The carbon-oxygen bonds in allylic ethers,[23a] benzylic esters,[23b] as well as aryl tosylates[23c] are reduced to the corresponding C-H bonds (eq 14).

(14)

Upon treatment with $NiCl_2/NaBH_4$, nitro,[24a-c] azide,[24d,e] and oxime[24f] groups are smoothly transformed into amino groups in good yields. Carbon-carbon double bonds are occasionally reduced under these conditions.[24a,f] Nitro and cyano groups are also reduced to amines by the reagent mixture $NiCl_2/B_2H_6$.[25] Ketones, aldehyde, carboxylic acid, alkene, ester, and amide moieties are unaffected under these conditions.

Addition of TMSCN to an allene is catalyzed by nickel boride generated in situ, although the reaction is nonstereoselective (eq 15).[26]

(15)

Treatment of ***Diphenylacetylene*** with excess TMSCN in the presence of the $NiCl_2$/***Diisobutylaluminum Hydride*** or $NiCl_2$/***Triethylaluminum*** catalyst affords a substituted pyrrole in high yield (eq 16).[27]

(16)

Hydrosilylation of conjugated dienes with $HSiR_3$ is catalyzed by $NiCl_2/Et_3Al$ in excellent yield; 1,4-addition is observed exclusively (eq 17).[28]

(17)

A combination of ***Aluminum*** and $NiCl_2$ promotes the selective reduction of α,β-enones to the corresponding saturated carbonyl compounds (eq 18).[29] Both nitro groups[30] and aryl ketones[29] are reduced to amines and benzylic alcohols, respectively.

(18)

Nickel(II) Chloride-Zinc.

Finely divided nickel with high catalytic activity is readily obtained by the treatment of $NiCl_2$ with ***Zinc*** dust.[31] This reagent reduces aldehydes, alkenes, and aromatic nitro compounds in good yields.[32a] Nitriles as well as aryl ketones give a mixture of reduced products under these conditions. Zn/$NiCl_2$ in the presence ***Ammonia***/NH_4^+ buffer (pH 6-10)[3] has been shown to effect the selective reduction of α,β-enones to the corresponding saturated carbonyl compounds.[32b] Aryl, allyl, and alkyl halides are reduced by water, zinc, and a catalytic amount of $NiCl_2$, ***Triphenylphosphine***, and iodide ion.[32c]

Reductive Heck-Like Reactions.

Reductive Heck-like reactions (eq 19) can be achieved when alkyl, aryl, and vinyl bromides are treated with

zinc/$NiCl_2.6H_2O$ in the presence of an excess quantity of α,β-unsaturated esters.[33] A trace amount of water is essential for this conversion. Similar reactions are observed when alkenes are treated with iodofluoroacetate or iododifluoroacetate under the same conditions (eq 20).[34] Tandem reaction can also occur to give cyclic products (eq 21).[35]

(19)

(20)

(21)

Homocoupling Reactions.

In the absence of a Michael acceptor, aryl and vinyl halides undergo dimerization reaction upon treatment with the $NiCl_2$/Zn reagent.[36-38] Under sonication conditions and in the presence of excess Ph_3P and ***Sodium Iodide*** in DMF, the $NiCl_2$/Zn reagent promotes homocoupling of aryl triflates in good yields.[36] Bipyridyls having electron-donating groups, such as methoxy groups, are obtained in satisfactory yields under these conditions (eq 22).[37] Thiophene derivatives behave similarly.[38] Vinyl bromides dimerize to yield the corresponding butadienes.[39] It is interesting that the presence of iodide ion or thiourea can accelerate the reaction.

(22)

Cross-Coupling Reactions.

Most cross-coupling reactions using nickel catalysts require phosphine ligands and are therefore discussed in detail under ***Dichlorobis(triphenylphosphine)nickel(II)***. The reaction of aryl iodides or bromides with trialkyl phosphites in the presence of $NiCl_2$ is the premier method for preparing dialkyl arylphosphonates (eq 23).[40a,b] Thermolysis of allyl phosphite in the presence of $NiCl_2$ yields the corresponding allyl phosphonates (eq 24).[40c]

(23)

(24)

Miscellaneous Reactions.

Symmetrical alkynes in the presence of $NiCl_2$ or $NiBr_2$ and ***Magnesium*** undergo trimerization to give the corresponding hexasubstituted aromatic compounds (eq 25). Terminal alkynes yield a mixture of regioisomers.[41]

(25)

Grignard reagents activated by a catalytic quantity of $NiCl_2$ can substitute the germanium-hydrogen bond with a germanium-carbon bond (eq 26).[42] It is noted that the stereochemistry of the original organogermane is retained.

(26)

Hydromagnesiation of a styrene with ***Ethylmagnesium Bromide*** followed by treatment with ***Carbon Dioxide*** gives the 2-arylpropionic acid in good yield (eq 27).[43]

(27)

Thermolysis of 1-phenyl-3,4-dimethylphosphole in the presence of $NiCl_2$ yields the corresponding nickel complex of the dimeric product. The ligand can be liberated upon treatment with ***Sodium Cyanide*** (eq 28).[44]

Related Reagents.

Chromium(II) Chloride-Nickel(II) Chloride; ***Lithium Aluminum Hydride-Nickel(II) Chloride***.

Nickel Complex Reducing Agents[1]

NaH-*t*-$C_5H_{11}ONa$-$Ni(OAc)_2$

(NaH)

[7646-69-7] · HNa · Nickel Complex Reducing Agents · (MW 24.00) (*t*-$C_5H_{11}ONa$)

[14593-46-5] · $C_5H_{11}NaO$ · Nickel Complex Reducing Agents · (MW 110.15) ($Ni(OAc)_2.4H_2O$)

[6018-89-9] · $C_4H_{14}NiO_8$ · Nickel Complex Reducing Agents · (MW 248.87)

(reduces many functional groups; couples organic halides; desulfurizes organic substrates; source of hydrogenation catalyst[1])

Alternate Name: nickel-containing complex reducing agents (NiCRAs).

Physical Data: black solid of uncertain structure containing Ni^0 species.[2]

Solubility: insol organic solvents.

Preparative Methods: *t*-$C_5H_{11}ONa$-NiCRA (*x.y.z*) is conveniently prepared by the reaction of *t*-$C_5H_{11}OH$ (*y* equiv) with a mixture of ***Sodium Hydride*** (*x* + *y* equiv) and ***Nickel(II) Acetate*** (*z* equiv) in THF or DME. Commercial NaH (55-60% in oil) is used after three washings with anhydrous THF or DME under N_2. *t*-$C_5H_{11}OH$ is distilled from sodium. $Ni(OAc)_2$ is dried in vacuo (15 mmHg) for 16 h at 120-130 °C. Note: *t*-$C_5H_{11}ONa$-NiCRA (*x.y.z*) means a reagent obtained from *x*,*y*, and *z* equivalents of NaH, *t*-$C_5H_{11}ONa$, and $Ni(OAc)_2$, respectively.

Handling, Storage, and Precautions: NiCRAs are nonpyrophoric but are handled and stored under inert atmosphere (N_2 or, better, Ar). Hydrolysis must be performed by slow addition of cold water or EtOH to destroy the hydride.

Reductions.

t-$C_5H_{11}ONa$-NiCRAs are significantly less basic than NaH and *t*-$C_5H_{11}ONa$. *t*-$C_5H_{11}ONa$-NiCRA (4.2.1) reduces under mild conditions and in good yields aryl halides, including aryl fluorides,[3] vinyl, allyl, benzyl, and alkyl halides (I > Br > Cl; primary &egt; secondary &egt; tertiary)[4] and monoreduces *gem*-dihalocyclopropanes.[5] It thus allows the removal of a tertiary hydroxy group (eq 1) while all other classical methods were unsuccessful.[6]

NiCRAs are sensitive to the nature and structure of the halides and allow selective reductions of polyhalogenated substrates, as exemplified in eq 2.[5]

Except with substrates very sensitive to bases, chemoselective reduction of halides may be easily performed in the presence of alkoxy, acetal, hydroxy, OTHP, carboxy, alkoxycarbonyl, keto, and cyano groups.[5] No elimination takes place with 1,2-alkoxy halides (eqs 3 and 4).

NiCRAs are much more powerful than ZnCRAs (see ***Zinc Complex Reducing Agents***) in the reduction of halides. *t*-C_5H_{11}ONa-NiCRA (4.1.1) reduces all classes of ketones or aldehydes and is not very sensitive to steric hindrance.[7,8] The efficiency of the reduction may be increased by the addition of electrophilic salts such as ***Magnesium Bromide*** or ***Lithium Chloride*** (eqs 5 and 6).

(5)

(6)

Under appropriate conditions, t-$C_5H_{11}ONa$-NiCRAs easily epimerize alcohols.[9] This property may be used to reduce ketones with a very high selectivity for the most stable alcohol. In such reactions t-$C_5H_{11}ONa$ may be advantageously replaced by the sodium salt of 2,5-dimethyl-2,5-hexanediol.[8b]

In the presence of ***Chlorotrimethylsilane*** (1 equiv), t-$C_5H_{11}ONa$-NiCRA (5.2.1) (or 5.1.1) (t-$C_5H_{11}ONa$-NiCRASi) very efficiently reduces carbon-carbon double bonds. The reagent is sensitive to steric hindrance as well as to electronic effects and allows the selective reduction of dienes, unsaturated ketones, esters, and acids.[10] The high selectivity is illustrated in eqs 7-9.

(7)

(8)

(9)

t-$C_5H_{11}ONa$-NiCRA (4.1.1) also selectively reduces a number of α,β-unsaturated ketones, although sometimes less efficiently than t-$C_5H_{11}ONa$-NiCRASi.[11] In the reduction of unsaturated carbonyl substrates, NiCRAs are complementary to ZnCRAs, which only reduce the carbonyl groups.

t-C_5H_{11}ONa-NiCRA (4.2.1) regioselectively reduces epoxides,[12] with the major or only product formed coming from the regioselective attack on the most hindered carbon. This regioselectivity is opposite to that observed with ZnCRAs.

Finally, anilines are easily prepared from the corresponding nitro derivatives using *t*-C_5H_{11}ONa-NiCRA (7.1.1) as the reducing agent.[13]

Reductive Desulfurization.

t-C_5H_{11}ONa-NiCRAs as such or in the presence of a ligand (*t*-C_5H_{11}ONa-NiCRALs) very efficiently and chemoselectively desulfurize thiols, thioethers, dithioacetals, sulfoxides, and sulfones.[14] Ketones, esters, and carbon-carbon double bonds are tolerated (eqs 10-12). Under appropriate conditions, monodesulfurization of dithioacetals may be easily performed (eq 13).

(10)

(11)

(12)

(13)

Coupling Reactions.

t-C_5H_{11}ONa-NiCRALs very efficiently couple aryl as well as heteroaryl halides (eqs 14 and 15).[15]

Unsymmetrical cross-couplings may be performed in fair to good yields simply by addition of two aryl halides to the reagent (eq 16).

Hydrogenation Catalyst.

A nonpyrophoric hydrogenation catalyst, referred to as Nic, may be easily obtained from *t*-$C_5H_{11}ONa$-NiCRA by simple addition of a catalytic amount of the reagent to the reaction medium when the solvent is protic. In aprotic solvent, NaH is neutralized with *t*-$C_5H_{11}OH$ before use. If necessary, soluble alkoxide is removed by washing with EtOH (Nic_w). Nic is very efficient in atmospheric hydrogenation of carbon-carbon double bonds, ketones, and aldehydes and in the selective partial hydrogenation of carbon-carbon triple bonds.[16]

Related Reagents.

Sodium Hydride-Nickel(II) Acetate-Sodium t-Pentoxide.

Nickel(II) 2-Ethylhexanoate

[4454-16-4] · $C_{16}H_{30}NiO_4$ · Nickel(II) 2-Ethylhexanoate · (MW 345.15)

(catalyst in conjunction with bromine for regioselective oxidation of diols and conversion of diols to lactones[1,2])

Solubility: sol toluene, xylenes; slightly sol hexane.

Form Supplied in: available as a viscous solution in mineral spirits containing 10-15 wt % Ni. Contains excess 2-ethylhexanoic acid.

Analysis of Reagent Purity: elemental analysis of Ni (weight percent).

Handling, Storage, and Precautions: not hygroscopic; nickel compounds are cancer suspect agents.

Oxidation of Alcohols.

Nickel(II) 2-ethylhexanoate is used in conjunction with anhydrous ***Bromine*** in acetonitrile for the selective oxidation of 1,4-diols in which one alcohol moiety is primary and one is secondary.[1] The reaction leads to selective oxidation of the primary alcohol and concomitant cyclization to a lactone. In the case of 1,4-butanediols with substituents in the 2 position, the less sterically hindered of the two primary alcohol groups is preferentially oxidized (eq 1).[2] The steric bulk of 2-ethylhexanoate is also an important factor in comparison to other nickel carboxylates such as ***Nickel(II) Acetate***, nickel(II) benzoate, and nickel(II) pivalate. Use of chlorine or NaOCl in place of bromine gives inferior results.

Reactions are carried out in acetonitrile at room temperature for 1 h using 8 mol Br_2 and 5 mol nickel compound per mol of diol. Some adjustment of the molar ratio of bromine may be necessary to give optimal regioselectivity.

Nickel-Graphite

Ni-Gr

[134067-47-3] · Ni · Nickel-Graphite

(Ni-Gr1 is a hydrogenation catalyst for alkynes;[1] Ni-Gr2 reduces carbon-carbon, carbon-oxygen, and carbon-nitrogen multiple bonds and is selective for unsaturated carbonyl compounds and β-diketones[2])

Form Supplied in: not commercially available.

Preparative Methods: Ni-Gr1 catalyst is prepared in situ by reduction of bis(dimethoxyethane)dibromonickel ($NiBr_2$.2DME) by ***Potassium-Graphite*** in THF/HMPA at room temperature under argon.[1] Exposure of Ni-Gr1 to air produces Ni-Gr2, a less active catalyst.[2]

Handling, Storage, and Precautions: due to the air sensitivity of Ni-Gr1, it is advisable to prepare and use it in situ for each application. Exposure of Ni-Gr1 to air produces a less active catalyst, Ni-Gr2, which can be stored in polyethylene bottles for at least four months before catalytic activity is decreased. Neither form of the catalyst is pyrophoric.

Hydrogenation Catalyst.

Catalytic hydrogenation of terminal alkynes with Ni-Gr1 affords the alkene as the major product (eq 1).[1] Prolonged exposure to hydrogen will result in complete conversion to the alkane regardless of the presence of ethylenediamine. Disubstituted unconjugated alkynes are stereospecifically converted to the corresponding (*Z*)-alkenes (eq 2). The specificity is comparable to that obtainable with other catalysts such as Lindlar's catalyst and P2 nickel. Ni-Gr2 also reduces disubstituted alkynes, but with slightly lower stereoselectivity than Ni-Gr1.[2] Attempts to improve the selectivity by addition of amines such as ethylenediamine, quinoline, or piperidine failed, due to complete loss of activity.

(1)

(2)

The reactivity of Ni-Gr2 is in agreement with most common catalysts. Reactivity towards catalytic hydrogenation decreases in the following order: alkyne > alkene &AApprox; nitro > carbonyl > nitrile. Stereoselective reduction of disubstituted alkynes affords (*Z*)-alkenes, although further reduction to the alkane also takes place (eqs 3 and 4).[2] Alkenes are quantitatively reduced to alkanes (eq 5).[2] Conjugation of the double bond with an aromatic ring increases reactivity toward alkenes and ketones.

(3)

(4)

(5)

Ni-Gr2 is a poor catalyst for reduction of nitro groups,[2] presumably due to poisoning of the catalyst. In order to achieve some reaction, a large excess of catalyst relative to substrate is needed.[2] Additionally, nitriles can be reduced to amines even in the presence of ketones.[2]

Selective Hydrogenation of Unsaturated Carbonyls

and β-Diketones.

As a consequence of its reduced activity, Ni-Gr2 selectively reduces the double bond of an α,β-unsaturated ketone in the presence of other alkenes (eq 6),[2] although the reactivity appears to be temperature dependent. In all cases, no reaction takes place at room temperature and elevated temperatures are needed to reduce carbonyl groups as well as hindered double bonds. Similarly, in unsymmetrical β-diketones the less hindered carbonyl group is reduced most easily (eq 7).[2]

Nickel(II) Peroxide[1]

NiO_2

[12035-36-8] · NiO_2 · Nickel(II) Peroxide · (MW 90.69)

(reagent for oxidation of alcohols,[2] phenols,[3] and amines,[4] and for dehydrogenation of heterocycles[5])

Physical Data: black hydrous powder, reportedly a mixture of higher nickel oxides.

Form Supplied in: supplied as nickel peroxide hydrate, $NiO_2.xH_2O$, with Ni content >25%, active oxygen content >30%.

Preparative Methods: by treatment of alkaline nickel sulfate with sodium hypochlorite.[2]

Handling, Storage, and Precautions: as with most nickel compounds, a presumed carcinogen which should be handled with extreme care. Irritating to mucous membranes and upper respiratory tract. Causes dermatitis and may cause allergic respiratory reactions. Use in a fume hood.

Alcohol Oxidations.

Nickel peroxide has been used as a mild, selective reagent for the oxidation of a variety of primary alcohols to the corresponding carboxylic acids in alkaline medium. Saturated primary aliphatic alcohols oxidize cleanly, but some unsaturated alcohols, such as allyl alcohol, give mostly cleavage products. The scope of the reaction is illustrated by the oxidation of 1-butanol and cinnamyl alcohol to the corresponding acids (eqs 1 and 2).[6] Oxidation of 6-hydroxymethyl-1-methyl-2-thiouracil to 1-methylorotic acid also involves replacement of sulfur by oxygen in the thiocarbonyl group (eq 3).[7]

When organic solvents such as petroleum ether or benzene are used in place of water, conversion of alcohols to the corresponding carbonyl compounds is observed. Although the reaction is poor with simple aliphatic alcohols, good to excellent yields of allylic or benzylic aldehydes and ketones are obtained using 1.0-1.2 equiv NiO_2. Allyl alcohol, furfuryl alcohol, benzyl alcohol, and diphenylmethanol in benzene are all smoothly converted to the corresponding aldehyde or ketone in 78-98% yield.[6] Oxidation of 3-phenylpropargyl alcohol under these conditions reportedly gives the aldehyde in 70% yield.[8] The conversion of geraniol to citral (eq 4) is illustrative of the selectivity of this process.[6] Oxidation of vitamin A_1 to retinene[6] and monooxidiation of the terpenoid diol lutein to 3-hydroxy-3´-α-carotene[9] are similarly achieved. Related alcohol oxidations were recently reported using NiO_2 deposited on alumina.[10] Oxidation of polyhydroxy compounds with NiO_2 gives rise to various cleavage products similar to periodate oxidations, depending on the solvent and reaction conditions.[11]

(4)

Oxidation of Phenols.

Treatment of most simple phenols with NiO_2 leads to polymerization, although oxidation of sterically cluttered phenols may lead to dimers, oligomers, or quinonoid structures, depending on the substitution pattern of the phenol.[12] Thus oxidation of 2,6-di-*t*-butyl phenol gives rise to the dimeric 4,4´-diphenoquinone (eq 5),[12] while oxidation of more hindered phenols affords 3,5-disubstituted fuchsones (eq 6).[3] NiO_2 also oxidizes 4-cyanocatechol to the corresponding *ortho*-quinone, whereas Ag_2O oxidation fails.[13]

(5)

(6)

Amides from Alcohols or Aldehydes.

Primary allenic alcohols are cleanly oxidized to the corresponding aldehydes with NiO_2 in benzene (eq 7), but are converted to amides when the oxidation is carried out in the presence of ammonia (eq 8).[14] Secondary allenic alcohols give the corresponding ketones when oxidized.

(7)

(8)

Oxidation of allylic and benzylic aldehydes with NiO_2 in ether at -20 °C in the presence of ammonia also gives the corresponding amides in good yield, as illustrated by the conversion of piperonal to piperonamide (eq 9).[15] At higher temperatures, an intermediate imine forms which is oxidized to the corresponding nitrile.[15] In the absence of ammonia, oxidation of aldehydes leads to the corresponding acid,[16] while oxidation of ketones in some cases affords 1,4-diketones via a dehydrodimerization process.[17]

(9)

Amine Oxidations.

NiO_2 oxidation of primary aliphatic and benzylic amines affords the corresponding nitriles, while primary aromatic amines afford the symmetrical azo compounds. Thus oxidation of *n*-heptylamine gives *n*-hexyl cyanide (eq 10), while *p*-nitroaniline gives 4,4´-azonitrobenzene (eq 11).[4]

(10)

(11)

Secondary aromatic amines undergo oxidative dimerization, affording the symmetrical hydrazines (eq 12).[18]

(12)

Oxidation of 1,2-diaminoaromatics leads to ring-opened dinitriles, although the yields are uniformly poor.[19] Thus oxidation of *o*-phenylenediamine with NiO_2 gives *cis,cis*-1,4-dicyano-1,3-butadiene (eq 13), whereas oxidation with ***Manganese Dioxide*** gives only 2,2´-diaminoazobenzene.[20]

(13)

Heterocycle Synthesis.

Early work indicated that pyrazolines[21] or indolines[22] could be dehydrogenated to pyrazoles or indoles using NiO_2 in refluxing benzene. Subsequent efforts showed that a variety of partially reduced oxygen-, sulfur-, and nitrogen-containing heterocycles could be cleanly dehydrogenated in hydrocarbon or halogenated solvents using NiO_2.[5] These findings included the previously unreported conversion of oxazolines to oxazoles. More recently, it has been found that dihydrotriazoles[23] and flavanones[24] are converted to triazoles and flavones, respectively, by oxidation with NiO_2. Table 1 shows some representative examples of these transformations.[5]

Table 1 NiO_2-Induced Dehydrogenation of Selected Heterocycles

Heterocycle	Equiv of NiO_2	Solvent	Conditions	Product	Yield (%)
	1.5	C_6H_{12}	6 h, reflux		69
	2.0	$CHCl_3$	3 d, 25 °C		81
	2.2	C_6H_6	11 h, reflux		52
	1.6	C_6H_6	4 h, reflux		71
	4.4	C_6H_6	24 h, reflux		54
	1.7	C_6H_6	4 h, reflux		92

Treatment of Schiff bases derived from *o*-aminophenols and benzaldehyde with NiO_2 in benzene leads to benzoxazoles via an intramolecular oxidative cyclization (eq 14).[25] The monoimines derived from *o*-phenylendiamine and substituted benzaldehydes are similarly cyclized to benzimidazoles.[26] Hydrazones of pyridine-2-carbaldehyde and 2-acetylpyridine are also oxidatively cyclized to ring-fused triazoles by NiO_2 in benzene (eq 15).[27]

R = OMe, 72%; H, 73%; NO_2, 73%

R = H, 97%; Me, 94%

Miscellaneous Reactions.

NiO_2 oxidizes benzophenone hydrazone to diphenyldiazomethane in quantitative yield[28] and, in the absence of solvent, converts diphenylmethane and fluorene to benzophenone and fluorenone in 79% and 66% yields, respectively.[21] Thiols and sulfides give disulfides in high yield when treated with the reagent.[29,30]

Nickel(II) Tetraphenylporphyrinate

[14172-92-0] · $C_{44}H_{28}N_4Ni$ · Nickel(II) Tetraphenylporphyrinate · (MW 671.45)

(electron transfer agent and catalyst for aryl halogen exchange reactions;[1] used in cyclizations of saturated o-iodo ketones[2] and hydrogenation of alkenes[3])

Alternate Name: NiTPP.

Physical Data: sublimes with decomp at 400-450 °C.

Solubility: insol H_2O; sol $CHCl_3$; slightly sol ether, benzene, hexane, methanol.

Form Supplied in: purple powder, widely available.

Handling, Storage, and Precautions: stable in air and water. Some nickel compounds are known carcinogens so standard safety precautions apply.

Aryl Halogen Exchange.

Simple aryl bromides have been converted to aryl chlorides using aqueous ***Sodium Hypochlorite*** under phase-transfer conditions and NiTPP as a catalyst (eq 1).[1] Yields were quantitative when aryl bromides were used. Chlorination of aryl iodides led to competitive I-chlorination, and substrates with alkyl substituents gave poorer yields because of benzylic chlorination.

(1)

Cyclization of Iodo Ketones.

The dianion of NiTPP has been prepared by reaction with ***Lithium Naphthalenide*** in THF at 0 °C.[2] It has proved to be effective in converting o-iodo ketones to cyclic alcohols (eq 2). Other reagents (Li/NH_3, Na/naphthalene, or Na/phenanthrene) gave lower yields.[2] $NiTPP^{2-}$ failed to convert vinylic iodo ketones to cyclic alcohols.

(2)

$n = 1$, 61%; $n = 2$, 88%

Hydrogenation of Alkenes.

$NiTPP^{2-}$ has been deposited on silica wool by reaction of a 1:3 mixture of NiTPP with Na or Na benzophenone ketyl in THF. In the presence of H_2 at 90 °C, this catalyst has been used to hydrogenate alkenes and alkynes. For example, butadiene gave 1-butene, and hydrogenation of propyne to propene was fast compared to subsequent reduction to propane.[3]

Niobium(IV) Chloride

$NbCl_4$

($NbCl_4$)

[13569-70-5] · Cl_4Nb · Niobium(IV) Chloride · (MW 234.71) ($NbCl_4(THF)_2$)

[61247-55-2] · $C_8H_{16}Cl_4NbO_2$ · Niobium(IV) Chloride · (MW 378.95)

(reductively couples imines and nitriles[1])

Physical Data: $NbCl_4$: subl. 200 °C/10^{-4} mmHg. $NbCl_4(THF)_2$: mp 110 °C (dec), yellow crystals.

Solubility: sol ethereal and thioether solvents.

Form Supplied in: not commercially available.

Preparative Method: tetrachlorobis(tetrahydrofuran)niobium is prepared from commercially available niobium(V) chloride in two steps.[2]

Purification: filter and wash with THF and dry under vacuum.

Handling, Storage, and Precautions: corrosive; moisture sensitive. Use in a fume hood.

Reductive Coupling of *N*-Silylimines and Nitriles.

Treatment of *N*-silylimines with niobium(IV) chloride leads to 1,2-diamines (eq 1). The reaction is the nitrogen analog of the pinacol coupling reaction. The reaction produces initially the bis(metal imido) complex, which is hydrolyzed to the corresponding diamine by reaction with aqueous ***Potassium Hydroxide***. Alternatively, reaction of nitriles, ***Tri-n-butylchlorostannane***, and niobium(IV) chloride produces a similar coupling product (eq 2). Both aryl- and alkyl-substituted imines are suitable substrates for the reaction. Predominantly the (±)-isomer is produced in the coupling reaction; however, the selectivity is considerably greater when imines derived from aryl aldehydes are employed in the reaction.

Related Reagents.

Niobium(V) Chloride-Zinc; ***Samarium(II) Iodide***; ***Titanium(III) Chloride***.

Niobium(V) Chloride-Zinc

$NbCl_5$-Zn

($NbCl_5$)

[10026-12-7] · Cl_5Nb · Niobium(V) Chloride-Zinc · (MW 270.15) (Zn)

[7440-66-6] · Zn · Niobium(V) Chloride-Zinc · (MW 65.37)

(synthesis of allylic alcohols, dienes, and naphthols; selective reduction of alkynes to (*Z*)-alkenes)

Solubility: sol THF-PhH, DME-PhH, HMPA.

Preparative Method: generated in situ from pentachloroniobium and ***Zinc***.

Handling, Storage, and Precautions: should be prepared and used under an inert atmosphere of nitrogen or argon.

A combination of $NbCl_5$ with Zn in either THF or DME presumably generates a $NbCl_3(L)_2$ species, which reacts with alkynes to give intermediate metallacyclopropenes.[1] These metallacyclopropenes can then be quenched with $NaOD/D_2O$ to give *cis*-dideuterated alkenes (eq 1). In addition, reaction of the metallacyclopropenes with aldehydes or ketones gives either allylic alcohols or dienes, and reaction with phthalic dicarbaldehyde yields naphthols. The latter two transformations can be effected in higher yield using $TaCl_5$-Zn and $NbCl_3$(DME), respectively.

Nitric Acid

HNO_3

[7697-37-2] · HNO_3 · Nitric Acid · (MW 63.02) (fuming)

[52583-42-3]

(nitration and oxidation of organic molecules)

Physical Data: mp -41.6 °C; bp 83 °C; *d* 1.50 g cm^{-3}.[1]

Solubility: sol H_2O.

Form Supplied in: clear colorless liquid (69-71% in H_2O); fuming nitric acid is a colorless to pale yellow liquid, HNO_3 content >90% widely available.

Preparative Methods: anhydrous nitric acid can be prepared by distilling fuming nitric acid from an equal volume of concentrated sulfuric acid.

Handling, Storage, and Precautions: strong acid; oxidizing agent. Colorless acid may discolor on exposure to light. Anhydrous nitric acid decomposes above the freezing point to give NO_2, H_2O, and O_2. Emits toxic fumes of nitrogen oxides. Hygroscopic. Contact with other material may cause fire. Poison. Corrosive. Avoid contact and inhalation. May be fatal if inhaled, swallowed, or absorbed through skin. Material is extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin.[2] Many of the reactions mentioned in this article require special care in order to avoid uncontrollable reactions and the possibility of explosions. Many nitrated compounds are unstable. The reader is therefore strongly urged to refer to original literature procedures.

Nitric acid holds an important place in the history of organic synthesis. It is used primarily for the nitration of organic molecules and to effect a wide variety of oxidative transformations. The advantage of nitric acid as a reagent is that it allows simple and straightforward isolation of products. However, it is not a very selective oxidant.

Nitration of Simple Aromatic Systems.[3]

Nitration of aromatics has been studied extensively. The mechanism by which nitration occurs is believed to involve electrophilic attack by NO_2^+. The concentration of the active species increases in the presence of the more acidic ***Sulfuric Acid***. With this mixed reagent, the nitration of simple benzene derivatives[4] and polyaromatic ring systems[5]

has been accomplished. For example, treatment of methyl benzoate with concentrated nitric acid gives methyl 3-nitrobenzoate in 81-85% yield.[4a] In polyaromatic ring systems, nitration usually occurs selectively on the more electron rich aromatic ring (eq 1).[6] Under the reaction conditions, anilines are protonated and the aniline ring is relatively unreactive (eq 2).[5e]

(1)

(2)

Nitration of Aromatic Heterocycles.

Several types of aromatic heterocycles have been nitrated with nitric acid.[7] For example, when thiophene is treated with nitric acid in acetic anhydride, 2-nitrothiophene is formed in 70-85% yield. In order to prepare 3-nitrothiophene, a deactivating strategy is required (eq 3). 2,4-Dinitrothiophene can be obtained by nitration of either 2-nitro- or 3-nitrothiophene.[7a] Nitration of the *N*-oxide of 2-methylpyridine allows the introduction of a nitro group at the 4 position in good yield (eq 4).[7b]

(3)

(4)

Nitration of Alkenes.[8]

Alkenes may also be nitrated by nitric acid. This reaction has been exploited in the synthesis of a number of steroid derivatives.[9] Fuming nitric acid converts cholesteryl acetate to 6-nitrocholesteryl acetate in good yield (eq 5). The nitration of the more highly functionalized dienyl acetate (eq 6) provides the corresponding nitro steroid. Treatment of 1,1-dichloro-2-fluoroethylene with nitric acid in concentrated sulfuric acid provides fluoronitroacetyl chloride in 16% yield.[10] 2-Sulfolenes have also been nitrated.[11]

(5)

(6)

Nitration of Active Methylene Carbons.[8,12]

Active methylene carbons are nitrated by a number of reagents.[12,13] With nitric acid the nitration of β-diketones can be achieved (eq 7). Nitration of diethyl malonate provides diethyl nitromalonate in 92% yield. α-Nitro ketones are obtained by nitration of ketones or enol acetates with the reagent derived from nitric acid and ***Acetic Anhydride*** in moderate to good yields (eq 8).[14]

(7)

(8)

Nitration of Heteroatoms.

Secondary amines and primary and secondary amides can be converted to *N*-nitro compounds by direct nitration with nitric acid.[15,16] Although most primary amines cannot be nitrated directly, it is possible to obtain primary nitramines by nitration of the corresponding dichloroamines (eq 9).[17] Treatment of pyrrolidone with nitric acid and acetic acid in the presence of copper provides *N*-nitroso-2-pyrrolidone in 70% yield;[18] note that this transformation represents *N*-nitrosation.

(9)

Nitrolysis of dialkyl *t*-butylamines with nitric acid and sulfuric acid or acetic anhydride provides secondary nitramines (eq 10).[19] More recently, Suri has shown that the reagent derived from ammonium nitrate and trifluoroacetic acid is effective for *N*-nitration.[20]

(10)

Acyl nitrates can be prepared conveniently on a laboratory scale by treatment of 90% nitric acid with a tenfold excess of the corresponding acid anhydrides.[21]

Oxidation of Alcohols, Aldehydes, and Esters.

Nitric acid oxidizes alcohols and aldehydes to the corresponding carboxylic acids. For example, 1-chloro-3-propanol is oxidized to 3-chloropropanoic acid in 78-79% yield.[22] 3-Chloropropionaldehyde affords the same product.[23] Primary alcohols protected as esters are oxidized to the carboxylic acids (eq 11).[24] In a two-phase solvent system (for example dimethyl ether and water), the oxidation of benzyl alcohols can be controlled so that aldehydes are obtained.[25]

(11)

Oxidative Cleavage.

Treatment of cyclohexanone with 33% nitric acid gives adipic acid in quantitative yield;[26] oxidation of cyclohexanol affords the same product (eq 12).[27] Glutaric acid is obtained in 70-75% yield by oxidative cleavage of 3,4-dihydro-2*H*-pyran.[27]

(12)

Oxidation at Benzylic Position.

Nitric acid oxidizes many aromatic alkyl substituents to the carboxylic acid group. Thus toluene is oxidized to

benzoic acid in 85-90% yield.[28] Oxidation of ethylbenzene with 15% nitric acid also gives benzoic acid in 80% yield. The reaction is general and has also been applied to the oxidation of pyridine derivatives. When 4-methylpyridine is treated with 10% nitric acid in phosphoric acid at elevated temperature and pressure, 4-pyridinecarboxylic acid is obtained in 93% yield.[29] The reaction of *p*-isopropyltoluene can be controlled to give the partially oxidized product, *p*-methylbenzoic acid, in 56-59% yield.[27] Additional examples of selective benzylic oxidations are shown in eqs 13 and 14.[30,31]

(13)

(14)

Oxidation to Quinones.

Nitric acid oxidizes a wide variety of hydroquinone derivatives to quinones (eq 15).[32] Aminonaphthols can be converted to naphthoquinones by treatment with nitric acid (eq 16).[27] Perhalogenated aromatic systems have also been oxidized to quinones (eq 17).[33]

(15)

(16)

(17)

Dehydrogenation and Aromatization.

Dihydropyridines can be aromatized by dilute nitric and sulfuric acid (eq 18).[34] Diethyl hydrazodicarboxylate is dehydrogenated by fuming nitric acid to diethyl azodicarboxylate in 70-80% yield.[35]

(18)

Oxidation of Heteroatoms.

The nitroso group is oxidized efficiently to the nitro group by nitric acid.[36] For example, 2,4-dinitrosoresorcinol is converted efficiently to 2,4,6-trinitroresorcinol with concentrated nitric acid (eq 19).[37]

(19)

Azoxycyclohexane can be obtained by oxidation of azocyclohexane.[38] Dialkyl sulfides have been oxidized to the corresponding sulfones[39] and sulfoxides;[40] thiols provide sulfonic acids (eq 20).[41] Iodoso compounds have been obtained from oxidation of aryl iodides (eq 21).[42] Nitric acid converts 2-amino-6-nitrobenzonitriles to substituted 1,2,3-benzotriazin-4(3*H*)-one N^2-oxides (eq 22).[43]

(20)

(21)

(22)

Other Uses.

Dichloromaleic anhydride has been obtained in 81% yield by treatment of hexachlorobutadiene with fuming nitric acid followed by concentrated sulfuric acid.[25] Pyrroles react rapidly with nitric acid to give pyrrolinones (eq 23).[44] Desulfurization of 1,2,4-triazole-3-thiol with nitric acid presumably involves the formation of the sulfonic acid, which is then hydrolyzed to triazole in 52-58% yield.[27,45]

(23)

Primary alkyl halides have also been oxidized to provide the corresponding carboxylic acids. On treatment with concentrated nitric acid, *trans*-2,3-bis(iodomethyl)-*p*-dioxane provides *trans*-*p*-dioxane-2,3-dicarboxylic acid in 73% yield.[46]

o-Nitrobenzeneseleninic Acid

[56790-59-1] · $C_6H_5NO_4Se$ · *o*-Nitrobenzeneseleninic Acid · (MW 234.08)

(catalyst with hydrogen peroxide for the epoxidation of alkenes,[1,2] the oxidation of sulfides,[2] the Baeyer-Villiger oxidation of aromatic aldehydes and ketones,[3] and the conversion of aldehydes to esters[4] and nitriles[5])

Physical Data: mp 184-186 °C (dec).

Solubility: slightly sol water; sol DMF.

Preparative Methods: obtained from the oxidation of bis(2-nitrophenyl) diselenide with 30% ***Hydrogen Peroxide***[6] or concd ***Nitric Acid***.[7] Bis(2-nitrophenyl) diselenide is prepared by reaction of ***Lithium Diselenide*** with 2-nitrochlorobenzene[8] or from the base hydrolysis of 2-nitrophenyl selenocyanate.[1]

Handling, Storage, and Precautions: both 2-nitrobenzeneseleninic acid and bis(2-nitrophenyl) diselenide are stable indefinitely at room temperature. Selenium compounds are potentially toxic and should be handled in a fume hood.

2-Nitrobenzeneseleninic acid catalyzes the epoxidation of alkenes in CH_2Cl_2 under two-phase reaction conditions with 30% ***Hydrogen Peroxide*** (eq 1).[1,2,9,10] Bis(2-nitrophenyl) diselenide is typically used as an in situ source for 2-nitrobenzeneseleninic acid, and anhydrous $MgSO_4$ is added to facilitate epoxidation by scavenging excess water (see also ***2,4-Dinitrobenzeneseleninic Acid***).[1]

(1)

As a safe, convenient, and inexpensive alternative to peroxycarboxylic acids, 2-nitroperoxybenzeneseleninic acid (eq

2),[11] catalytically generated, converts sulfides either to sulfoxides (>95%) or cleanly to sulfones depending on the amount of H_2O_2 used.[2] The low solubility of catalyst in both CH_2Cl_2 and H_2O allows acid-sensitive substituents to remain intact during the Baeyer-Villiger oxidation of aromatic aldehydes (eq 3).[3] α,β-Unsaturated aldehydes give vinyl formates as the major products, but the oxidation of ketones is limited to polymethoxyacetophenones, with 90% H_2O_2 being recommended to obtain reasonable reaction rates.[12]

(2)

(3)

Aromatic and aliphatic aldehydes are converted into esters via their aldoximes or aldoxime *O*-methyl ethers by treatment with alcohol solutions of 30% H_2O_2 in the presence of a catalytic amount of 2-nitrobenzeneseleninic acid (eq 4).[4] These oxidation conditions are also effective for converting aldehyde dimethylhydrazones to nitriles (eq 5).[5] ***Selenium(IV) Oxide*** catalyzes both transformations, but the yields are generally lower.

(4)

(5)

Related Reagents.

Benzeneseleninic Acid.

o-Nitrobenzenesulfenyl Chloride[1]

[7669-54-7] · $C_6H_4ClNO_2S$ · *o*-Nitrobenzenesulfenyl Chloride · (MW 189.63)

(protection of amino groups[1d,2] and thiols;[3] sulfenylation of alkenes;[4] preparation of sulfoxides from alcohols[5])

Alternate Name: NPS-Cl.

Physical Data: mp 74-76 °C.

Preparative Methods: by addition of ***Chlorine*** to (*o*-$O_2NC_6H_4S)_2$.[6]

Form Supplied in: yellow solid; widely available.

Handling, Storage, and Precautions: corrosive and moisture sensitive; decomposes within a few days when exposed to moist air, with liberation of HCl.

Protection of Amines.

Reaction of amines with *o*-$O_2NC_6H_4SCl$ in the presence of a base produces the corresponding sulfenamide (eq 1). Such 2-nitrophenylsulfenyl (NPS)-protected amines have been used primarily in peptide chemistry.[2] They have also seen service in the synthesis of cephalosporins,[7] nucleosides,[8] and *N*-acyl β-lactones.[9] The NPS group is cleaved by acid hydrolysis (e.g. HOAc or HCl),[2] by nucleophiles (e.g. $HSCH_2CH_2OH$, $HSCH_2COOH$, 2-mercaptopyridine,[10] NaI,[7] thioacetamide,[11] Bu_3P[8,12]), or with Raney nickel.[13] Other arylsulfenyl chlorides have been used for amine protection, but those with *ortho*-nitro groups provide the most stable derivatives.[1d] *N*-NPS-saccharin has been proposed as a more stable substitute for NPS-Cl.[14]

(1)

Protection of Thiols.

Mercapto groups (e.g. on cysteine) may be protected as mixed disulfides using NPS-Cl (eq 2).[3] The free thiol may be regenerated by reduction ($NaBH_4$) or by treatment with other thiols (e.g. $HSCH_2CO_2H$, $HSCH_2CH_2OH$). Treatment of *t*-butyl thiols with NPS-Cl followed by reduction constitutes a useful method for the removal of the *t*-butyl group.[3c,3d] Sulfenates of sugar derivatives have been prepared but sulfenates have not been widely used as hydroxyl protecting groups in synthesis.[15]

(2)

Sulfenylation of Alkenes.

Treatment of alkenes bearing suitably disposed nucleophilic functionalities with sulfenyl chlorides gives rise to cyclic products (eq 3). ***Benzenesulfenyl Chloride*** has been used most commonly in this capacity,[1a-c] but NPS-Cl has also been employed.[4]

(3)

Preparation of Sulfoxides from Alcohols.

Allylic and propargylic alcohols react with sulfenyl chlorides to produce intermediate sulfenates which undergo a [2,3]-sigmatropic rearrangement to allylic and allenic sulfoxides, respectively (eq 4).[5] There has been considerable interest in the mechanism, stereochemistry, and synthetic applications of this

reaction.[5,16] Many sulfenyl chlorides have been used, including NPS-Cl.[17]

p-Nitrobenzenesulfonyloxyurethane[1]

[2955-74-0] · $C_9H_{10}N_2O_7S$ · *p*-Nitrobenzenesulfonyloxyurethane · (MW 290.28)

(generation of ethoxycarbonylnitrene by α-elimination[2,3] under mild conditions, including phase-transfer conditions[4])

Physical Data: mp 116.4-116.8 °C.

Solubility: sol ether, acetone, $CHCl_3$, CH_2Cl_2, DMSO, DMF, ethyl acetate, alcohols; moderately sol benzene; insol hydrocarbon solvents, CCl_4, H_2O.

Preparative Method: by the reaction of *N*-hydroxyurethane with *p*-nitrobenzenesulfonyl chloride.[2]

Treatment of the title compound with a base such as ***Triethylamine*** leads to deprotonation followed by α-elimination to generate singlet ethoxycarbonylnitrene.[2,3] The mild conditions required offer an advantage over ***Ethyl Azidoformate*** as a source of the ethoxycarbonylnitrene. The synthetic utility of this nitrene is limited to two types of reactions: (1) aziridination of alkenes and (2) addition to heteroatoms, which is often followed by rearrangement. A common side-reaction is the insertion of the nitrene into C-H bonds. The synthetic utility of the insertion reaction itself is severely limited since ethoxycarbonylnitrene shows poor selectivity toward different types of C-H bonds. The development of procedures to generate this nitrene under phase-transfer conditions has enhanced its utility.[4,5]

Ethoxycarbonylnitrene generated by α-elimination adds to alkenes to give the corresponding aziridines in moderate yields. Thus reaction of ethoxycarbonylnitrene with the strained alkene 2-azabicyclo[2.2.0]hex-5-ene under phase-transfer conditions produces the aziridine in 42% yield (eq 1).[6] Thermolysis of the adduct gives rise to a 1,4-diazepine. This method has been used to access a variety of substituted 1,4-diazepines, 1*H*-1,4-diazepines,[7] and other heterocyclic ring systems.[8]

Addition of ethoxycarbonylnitrene across the double bond of a symmetric propelladiene has been reported to give a mixture of stereoisomeric aziridines in 46% yield.[9] Additions to vinylsilanes under phase-transfer conditions[10] and to vinyl chlorides[11] produce the corresponding aziridines in moderate yields. Addition to azo compounds yields azimines which, on subsequent photolysis, give the triaziridines.[12] Aziridination of isolated double bonds occurs preferentially over the double bond of allylic ethers.[13] Attempted addition to enamines[14] and allenes[15] gives very low yields of the desired products. Addition to a chiral, optically active enol ether has been reported to proceed in low yield, but with high diastereoselectivity.[16] Additions to allylic and homoallylic acetals have also been reported.[17]

There are few examples of synthetically useful reactions involving addition of ethoxycarbonylnitrene to heteroatoms. Addition to phospholes gives the corresponding iminophospholes in good yield.[18] Addition of ethoxycarbonylnitrene to trialkylboranes gives the corresponding *N*-alkyl carbamates after rearrangement and hydrolysis (eq 2).[19] This procedure allows access to a variety of ethyl *N*-alkylcarbamates in high yields.

Related Reagents.

t-Butyl Azidoformate; ***Ethyl Azidoformate***.

o-Nitrobenzenesulfonyl Azide

[6655-31-8] · $C_6H_4N_4O_4S$ · *o*-Nitrobenzenesulfonyl Azide · (MW 228.21)

(1,3-dipolar reagent that undergoes cycloaddition to alkenes, enamines, enol ethers, and enynes[1])

Physical Data: mp 71-73 °C.

Solubility: sol most organic solvents.

Preparative Method: by the reaction of *o*-nitrobenzenesulfonyl chloride with an aqueous acetone solution of ***Sodium Azide***, first at 0 °C and then at 25 °C.[2]

Purification: crystallization from ethanol.[2]

Handling, Storage, and Precautions: azides should be expected to be sensitive to electrical, thermal, and/or mechanical shock. The parent sulfonyl azide, benzenesulfonyl azide, in the crude state, detonates violently when heated.

Dipolar Cycloaddition.

o-Nitrobenzenesulfonyl azide has been used for the ring enlargement-conversion of methylenecycloalkanes into the homologous *o*-nitrobenzenesulfonimidocycloalkanes. For example, methylenecycloheptane affords the imido product in quantitative yield. Hydrolysis of the imide with acid then affords the corresponding ketone (eq 1).[3]

The reagent has also been employed for the cycloaddition-rearrangement of both methyl and trimethylsilyl enol ethers (eqs 2 and 3).[4,5]

Decomposition of the reagent in boiling benzene-cyclohexene affords a quantitative yield of a 3:1 mixture of imide and enesulfonamide (eq 4).[6]

(4)

With a cyclic enamine, *o*-nitrobenzenesulfonyl azide affords an *N*-sulfonyl amidine following decomposition of an unstable intermediate triazoline (eq 5).[7]

(5)

The reaction of *o*-nitrobenzenesulfonyl azide with an ynamine leads to a 2-diazoalkanamidine as the only isolable product. An equilibrium between the amidine and the ring-closed triazole exists, however, in solution (eq 6).[8]

p-Nitrobenzenesulfonyl-4-nitroimidazole

[81006-79-3] · $C_9H_6N_4O_6S$ · *p*-Nitrobenzenesulfonyl-4-nitroimidazole · (MW 298.26)

(condensing agent for the triester coupling of nucleotide fragments[1])

Alternate Name: p-NBSNI.

Physical Data: mp (sealed tube) 179-185 °C (dec); UV (dioxane) 253 nm.

Solubility: sol pyridine, DMSO; slightly sol dioxane, ethyl acetate.

Form Supplied in: white needles; not available commercially; may be contaminated with *p*-nitrobenzenesulfonic acid.

Analysis of Reagent Purity: ^{1}H NMR (60 MHz, DMSO-d_6) δ 8.45 (s, 4H); 8.55 (d, J = 2 Hz, 1H); 9.10 (d, J = 2 Hz, 1H); sulfonic acid impurities are easily detected as higher field signals.

Preparative Method: by treatment of 4-nitroimidazole (1.025 equiv) and *p*-nitrobenzenesulfonyl chloride (1.0 equiv) with ***Triethylamine*** (1.1 equiv) in dry dioxane at 0 °C.[1]

Purification: recrystallization from ethyl acetate.

Handling, Storage, and Precautions: stable to air and moisture in screw cap bottles at rt for over six months.

Condensing Agent.

p-Nitrobenzenesulfonyl-4-nitroimidazole has been used as a condensing agent in the triester synthesis of oligonucleotides. The reagent activates the phosphodiester towards attack by the incoming 5´-hydroxyl through formation of a mixed phosphoric-sulfonic anhydride. Typically, the suitably protected nucleotide fragments, in pyridine solution, are treated with *p*-NBSNI (2.5 equiv) and stirred at rt for approximately 15 h. After workup,

purification is achieved through two chromatographic separations over silica gel, affording the desired polynucleotide in 60-83% yield (eq 1).[1]

DMTr = 5'-*O*-dimethoxytrityl; P^1 = *p*-ClC_6H_4; P^2 = cyanoethyl

p-Nitrobenzenesulfonyl-4-nitroimidazole holds the advantage over older reagents, such as triisopropylbenzenesulfonyl chloride, of giving fewer side products resulting from sulfonation of the free 5´-hydroxyl. The long reaction times necessary are a disadvantage and the condensing agents 2,4,6-triisopropylbenzenesulfonyl-1,2,3,4-tetrazole (TPSTe) and 1-(mesitylenesulfonyl)-3-nitro-1,2,4-triazole (MSNT) are preferable.[2]

m-Nitrobenzenesulfonyl Peroxide[1]

[6209-71-8] · $C_{12}H_8N_2O_{10}S_2$ · *m*-Nitrobenzenesulfonyl Peroxide · (MW 404.36)

(oxidation of heteroatoms including selenium,[4] tellurium,[5] sulfur,[5] and nitrogen;[6] electrophilic aromatic substitution[7])

Alternate Name: m-NBSP.

Physical Data: mp 107 °C (dec); decomposition at the melting point is exothermic.

Solubility: (>1 g 100 mL^{-1}) ethyl acetate, acetone, acetonitrile; slightly sol dichloromethane, diethyl ether, chloroform; insol pentane, water.

Form Supplied in: off-white or pale yellow powder.

Analysis of Reagent Purity: purity is determined by iodometric titration. A weighed quantity (70 mg) of the peroxide is dissolved in ethyl acetate (20 mL) and treated with glacial acetic acid (10 mL) and 10% potassium iodide (10 mL). The solution is titrated to a starch endpoint with standardized thiosulfate (~0.01 N).

Preparative Method: m-nitrobenzenesulfonyl chloride (11.1 g, 0.05 mol) is dissolved in chloroform (15 mL) and added with stirring to a cold (-20 °C) solution of ***Potassium Carbonate*** (8.5 g) in water (140 mL), ethanol (70 mL), and 30% ***Hydrogen Peroxide*** (20 g) in a Waring blender cup. Agitation is slowly increased to full power and held there for 1 min. Ethanol (100 mL), is then added and the mixture is agitated slowly for a few minutes. The resulting precipitate is collected by filtration, washed thoroughly with water, and dried under vacuum.

Purification: the crude product is dissolved in acetone at room temperature, the solution is filtered, and the filtrate is concentrated under reduced pressure to yield 97% pure peroxide (5.0 g, 49%) which decomposes at 107 °C.[2,3]

Handling, Storage, and Precautions: can be stored at -20 °C for a considerable time without loss of purity. Plastic spatulas are recommended for transfer. It can decompose vigorously in the presence of electron donors,[3] and should only be handled with suitable protection. Use in a fume hood.

Being a strong electrophile, *m*-nitrobenzenesulfonyl peroxide reacts readily with good electron donors. This reactivity has been exploited in several useful synthetic processes. Heteroatom oxidations, aromatic substitutions, and additions to unactivated alkenes have been reported. In addition *m*-nitrobenzenesulfonyloxy radicals can be produced homolytically.

Electrophilic Additions to Alkenes and Arenes.

m-NBSP reacts with diselenides,[4] ditellurides,[5] and disulfides[5] to generate electrophilic intermediates (**1**) (eq 1), which react with alkenes in the presence of various nucleophiles to give addition products (**2**) (eq 2).

(1)

(2)

(1) (2)

The intermediate (**1**) initiates the electrophilic cyclization of unsaturated alcohols to form cyclic ethers and can be used for phenylsulfolactonization or phenylselenolactonization of unsaturated carboxylic acids to lactones (eq 3).[4,5] Selenium works particularly well in these reactions. Furthermore, intermediate (**1**) (X = Se) is sufficiently electrophilic to react with aromatic compounds such as anisole, phenol, acetanilide, and toluene to produce benzeneselenated aromatic products in variable yields (12-94%).[4b]

(3)

The reaction of *m*-NBSP with the nitrogen atom of substituted benzylamines has been used to produce *N*-[(*m*-nitrobenzenesulfonyl)oxy]benzylamines, which undergo base induced elimination to imines.[6] It has also been reported that *O*-(*m*-nitrobenzenesulfonyl) hypochlorites and *O*-(*m*-nitrobenzenesulfonyl) hypobromites formed by the reaction of *m*-NBSP with chloride and bromide ions, respectively, are effective reagents for the electrophilic halogenation of aromatic rings (50-93%).[7]

Aromatic Substitution.

m-NBSP reacts with methyl benzoate, anisole, nitrobenzene, halobenzenes, and alkylbenzenes (as well as many other aromatic compounds) to give aryl *m*-nitrobenzenesulfonates (**3**) (eq 4).[1] Hydrolysis or reductive cleavage of these products gives phenols.[8] Attempted oxygenation of toluene failed in the presence of salts known to catalyze radical reactions.[9]

(4)

(3)

Radical Reactions.

Decomposition of *m*-NBSP in chloroform solution gives *m*-nitrobenzenesulfonic acid (eq 5), in addition to hexachloroethane and phosgene.[10] The same process is also found for other arylsulfonyl peroxides and constitutes an excellent method for the preparation of arylsulfonic acids.[11] Activation parameters and the

reaction products indicate that the decomposition in chloroform proceeds by homolytic cleavage of the O-O bond.[10]

Additions to Alkenes.

m-NBSP undergoes electrophilic addition to alkenes such as norbornene and gives *syn*-7-(arylsulfonyloxy)norbornene and 2,7-bis(arylsulfonyloxy)norbornane. Norbornadiene reacts with *m*-NBSP to give arylsulfonyloxytricycloheptane products.[12]

Related Reagents.

p-Nitrobenzenesulfonyl Peroxide[1]

[6209-72-9] · $C_{12}H_8N_2O_{10}S_2$ · *p*-Nitrobenzenesulfonyl Peroxide · (MW 404.36)

(oxygen electrophile for addition to unsaturated compounds;[1] preparation of α-nosyloxy ketones and esters;[3] addition to 1-alkoxy-1-silyloxy-1,3-dienes;[6] addition to enols[3] to give tricarbonyl esters and amides;[3] addition to amines to give *N*-nosyloxyamines[1])

Alternate Name: *p*-NBSP.

Physical Data: mp 128 °C (dec); decomposition at the melting point is exothermic; typical preparations with mp >124 °C are generally satisfactory.

Solubility: sol (>1 g 100 mL^{-1}) ethyl acetate, acetone, acetonitrile; slightly sol dichloromethane, ether, chloroform; insol pentane, water.

Form Supplied in: off-white or pale yellow powder; typical impurities are *p*-nitrobenzenesulfonic acid and water.

Analysis of Reagent Purity: purity is determined by iodometric titration. A weighed quantity (~70 mg) of the peroxide is dissolved in ethyl acetate (20 mL) and treated with glacial acetic acid (10 mL) and 10% potassium iodide (10 mL). The solution is titrated to a starch endpoint with standardized thiosulfate (~0.01 N).

Preparative Method: prepared by the addition of *p*-nitrobenzenesulfonyl chloride (20 g) in chloroform (40 mL) to a -20 °C solution of ***Potassium Carbonate*** (15.6 g) and 30% ***Hydrogen Peroxide*** in 2:1 water-ethanol (360 mL).[2] The mixture is agitated in a chilled Waring Blender cup at full power for 1.5 min. The mixture is filtered on a large Buchner funnel and the oily

solid is washed copiously several times with water. A good washing protocol is to suspend the solid in water and stir in the Waring Blender at medium power for 1 min and refilter. The faintly yellow solid is dried by passing air through the solid on the filter, and then in vacuo at room temperature. It is prudent to use plastic implements when manipulating the peroxide.

Purification: the crude peroxide is dissolved in reagent grade acetone (360 mL), the solution is cooled to -78 °C, and a vigorous stream of air is directed onto the surface of the stirred solution. When the volume has been reduced to 180 mL, the mixture is filtered and air is passed through the solid until it is completely dry. Purities of >97% normally result if care is taken to completely dry the peroxide when it is first isolated. Yields of 40-50% of purified product are normal. An alternate method of purification which delivers material suitable for most purposes (>95% purity) is to suspend the peroxide in acetone (150 mL) and stir at -78 °C for 1.5-2 h. Filtration and air drying give acceptable product. It is even more crucial that the crude product be quite dry before using this procedure as the major impurity seems to be water that is not easily removed by this method of purification.

Handling, Storage, and Precautions: can be stored for long periods of time at -20 °C without loss of purity and can be handled in the laboratory using normal laboratory procedures and precautions. Plastic spatulas are recommended for transfer. Vigorous reaction occurs with neat or concentrated solutions of good electron donors such as amines, alkenes, or alkoxides, but *p*-NBSP is relatively stable towards oxygen, water, acids, and a variety of common solvents such as acetone, ethyl acetate, dichloromethane, and acetonitrile. Because *p*-NBSP can decompose exothermically (but not explosively), personal protection in the form of eye protection, gloves, etc. is necessary when handling the peroxide.

Electrophilic Addition.

p-Nitrobenzenesulfonyl peroxide is a pseudohalogen reagent whose reactivity is comparable to that of chlorine. It provides a source of electrophilic oxygen for attachment of the *p*-nitrobenzenesulfonyloxy (nosyloxy) group to electron donors. Subsequent chemistry depends on the donor function and the reactions that the *p*-nitrobenzenesulfonate adduct undergoes.[3]

Enol Derivatives.

Electrophilic addition of *p*-NBSP to compounds with electron-rich double bonds provides a smooth method for the electrophilic attachment of the nosylate group. Reaction with enol derivatives of ketones (R^1,R^2 = alkyl, aryl) gives 2-nosyloxy ketones in generally high yields (60-90%) (eq 1).[4] These are excellent precursors for α-amino ketones, α-hydroxy acetals, and α-hydroxy ketones.[3] Reaction with ketene silyl acetals (X = Me_3SiO, R^1 = alkoxy, R^2 = alkyl, aryl) gives 2-nosyloxy esters, also in excellent

yields (65-90%);[5] these are easily converted in high yields to amino acids and their *N*-substituted derivatives.[3] Reactions with other nucleophiles give other 2-substituted esters.[3]

(1)

Silyloxy dienes.

Silyl enol ether derivatives of unsaturated esters (1-alkoxy-1-trimethylsilyloxy-1,3-dienes) react with *p*-NBSP to give both 2-nosyloxy and 4-nosyloxy unsaturated esters.[6] Replacement of the nosyloxy group by nucleophiles yields 4-substituted 2,3-unsaturated esters.[3]

Enols.

Compounds with naturally high enol contents react directly with *p*-NBSP to give α-nosyloxy carbonyl compounds. β-Keto esters[7] and β-keto amides[8] react readily to give the corresponding 2-nosyloxy β-keto esters and amides (eq 2). These derivatives undergo reductive elimination to give tricarbonyl esters and tricarbonyl amides in high yields. They can also be reduced to 3-hydroxy-2-nosyloxy esters, which are convertible to many densely functionalized products.[3]

(2)

Amines.

Amines react with *p*-NBSP at -78 °C to give *N*-[(*p*-nitrobenzene)sulfonyl]oxy amines (eq 3).[1] These adducts undergo facile base-promoted eliminations to imines.[9] In the absence of base, they undergo

ionization-rearrangement reactions which yield skeletally rearranged iminium ions. These adducts are also effective reagents for the preparation of *N*-substituted lactams from cyclic ketones and acetals.[3]

5-Nitro-3*H*-1,2-benzoxathiole *S,S*-Dioxide

[14618-10-1] · $C_7H_5NO_5S$ · 5-Nitro-3*H*-1,2-benzoxathiole *S,S*-Dioxide · (MW 215.20)

(peptide coupling reagent)

Physical Data: very pale yellow crystals; mp 148.5-149.5 °C.

Analysis of Reagent Purity: satisfactory microanalytical data have been reported.[1]

Preparative Method: by nitration of the corresponding sultone.[1]

5-Nitro-3*H*-1,2-benzoxathiole *S,S*-dioxide is a peptide coupling reagent.[2,3] Its reactivity derives from the inherent strain present in cyclic five-membered sulfonate esters. These species react with nucleophiles such as carboxylates to form mixed carboxylic sulfonic anhydrides (**1**) (eq 1), which rearrange via an intramolecular acyl transfer to phenyl esters (**2**) (eq 2). When the carboxylate nucleophile in eq 1 is that of an *N*-protected α-amino acid, (**2**) reacts with α-amino esters to give peptides (eq 3 and Table 1). The process offers the advantage that the byproduct of the coupling reaction (sulfonate (**3**)) is water-soluble and, therefore, easily removed from the reaction mixture.

o-Nitrobenzoyl Chloride

[610-14-0] · $C_7H_4ClNO_3$ · *o*-Nitrobenzoyl Chloride · (MW 185.57)

(acylating agent in reaction with amines and alcohols; produces crystalline esters from alcohols; building block for the synthesis of several classes of heterocycles)

Physical Data: mp 17-20 °C; bp 148-149 °C/9 mmHg; *d* 1.404 g cm^{-3}.

Solubility: sol THF, CH_2Cl_2, $CHCl_3$; reacts with water and alcohols.

Form Supplied in: commercially available; low melting solid.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: extremely irritating to skin and eyes. Can cause burns. Use in a fume hood. Reacts with water, liberating HCl. Explosion of distillation residue has been reported.[1]

Ester Formation.

o-Nitrobenzoyl chloride forms crystalline esters with alcohols (see ***p-Nitrobenzoyl Chloride***) and these esters are readily hydrolyzed under standard conditions for benzoyl removal (eqs 1 and 2). The crystalline nitrobenzoyl esters enable enhancement of enantiomeric excess by recrystallization.[2]

Synthesis of Heterocycles.

o-Nitrobenzoyl chloride has been used in the synthesis of various heterocycles, particularly quinazolinones (eq 3),[3] benzodiazepines (eq 4),[4] and xanthones.[5] In the quinazolinone synthesis (eq 3), and in many other cases, the nitro group acts as a masked amine. Initial condensation of the acetyl chloride is followed by nitro reduction to the free amine which then participates in further condensation and cyclization. In other cases, *o*-nitrobenzoyl chloride undergoes initial Friedel-Crafts acylation before cyclization of the amine.[5]

p-Nitrobenzoyl Chloride

[122-04-3] · $C_7H_4ClNO_3$ · *p*-Nitrobenzoyl Chloride · (MW 185.57)

(characterization of amines and alcohols by formation of crystalline amide and ester derivatives; forms suitable directing group for glycosidation reactions)

Physical Data: mp 72-74 °C; bp 202-205 °C/105 mmHg.

Solubility: sol THF, CH_2Cl_2, $CHCl_3$, pyridine; reacts with water and alcohols.

Form Supplied in: commercially available; yellow crystalline solid.

Purification: recrystallization from CCl_4 or C_6H_6.

Handling, Storage, and Precautions: extremely irritating to skin and eyes. Can cause burns. Use in a fume hood. Reacts with water, liberating HCl.

Amide Formation.

p-Nitrobenzoyl chloride forms *p*-nitrobenzamides by reaction with amines and these have been used in the characterization of amphetamines.[1] These derivatives are chemically stable, easily prepared (eq 1), and have enhanced UV detectability.

Ester Formation.

The crystalline *p*-nitrobenzoate (PNB) esters formed by reaction of alcohols and *p*-nitrobenzoyl chloride are widely used in simplifying the characterization,[2] purification, and isolation[3,4] of alcohols. In certain cases, they allow ready enhancement of enantiomeric excess by recrystallization.[3] They can be prepared from the alkoxide (eq 2)[5] (useful for acid sensitive alcohols) or, more commonly, from the free alcohol, *p*-nitrobenzoyl chloride, and amine base such as pyridine[4] (often as solvent), lutidine,[2] or triethylamine.[3]

p-Nitrobenzoyl chloride has been used for the in situ derivatization of low molecular weight, water-soluble epoxy alcohols (eq 3).[3]

Glycosidations.

p-Nitrobenzoyl chloride forms *O*-*p*-nitrobenzoyl esters which are used in carbohydrate chemistry as protecting groups that can also direct the steric course of glycosidation reactions. The 4-*O*-*p*-nitrobenzoyl group gives steric control (by anchimeric assistance) in the coupling reactions of certain sugars to give *trans*-C-1,C-4 products.[6,7] The *O*-PNB esters can also act as precursors to the glycosyl halides required for the Koenigs-Knorr coupling reaction. The example in eq 4 illustrates both these features.[7] The 4-*O*-PNB group gives somewhat better selectivities than the 4-*O*-trifluoroacetyl or the 4-*O*-acetyl group.[8] *p*-Nitrobenzoyl chloride is also used in the synthesis of highly crystalline *p*-nitrobenzoylaminobenzoyl esters of sugars.[9]

o-Nitrobenzyl Alcohol

[612-25-9] · $C_7H_7NO_3$ · *o*-Nitrobenzyl Alcohol · (MW 153.15)

(photoremovable protective group for ketones and aldehydes,[1] carboxylic acids,[2] anhydrides,[3] acid chlorides,[4] and amines;[5a] reaction with isocyanates to generate protected amines;[5b,c,d] protection of amino acids;[2b,6] protection of the hydroxyl groups of ribonucleotides,[7a,b,c] dinucleotides,[7d] and furanoses;[7e] synthesis of a novel catalyst in the polymerization of epoxides;[8] formation of leaving groups of enhanced ability;[9] reaction with formyl Meldrum's acid to afford the formylacetate;[10] oxidation to the corresponding aldehyde[11] or carboxylic acid[12])

Alternate Name: *o*-NBA.

Physical Data: mp 70-72 °C; bp 270 °C. The thermal stability of nitrobenzyl alcohols has been examined.[17] Its conformation in solution has been studied using ^{17}O NMR[18a] and ^{13}C NMR[18b] analysis.

Form Supplied in: light tan powder.

Handling, Storage, and Precautions: light-sensitive. Harmful if swallowed or inhaled.

Mechanism of Action.

Under photolysis,[19] acidic,[20] and electron bombardment[21] conditions, the transformation of *o*-nitrobenzyl alcohol or its derivatives involves an internal redox reaction sequence followed by liberation of the deprotected alcohol or amine (eq 1). Analogously, the photorearrangement of esters of *o*-NBA, obtained through its reaction with acid chlorides[2a,4] or anhydrides,[3] also induces an internal redox reaction (eq 2).

R = H or protected functionality, X = O or N

Protection of Ketones and Aldehydes.

o-NBA serves as a photoremovable protective group for aldehydes and ketones. Bis-acetals are prepared in a high-yield exchange reaction, except with hindered ketones for which it is necessary to employ the diol *o*-$O_2NC_6H_4CH(OH)CH_2OH$. The acetals are removed in excellent yield by irradiation at 350 nm in benzene (eq 3).[1]

Generation of Carboxylic Acids.

Photolabile phosphatidylcholine (PLPC) has been synthesized by reaction of *o*-NBA with dodecanedioyl dichloride followed by ***1,3-Dicyclohexylcarbodiimide*** coupling. Subsequent photolysis of the resulting 2-nitrobenzyl esters results in the instantaneous disintegration of the PLPC liposomes, thus opening up the possibility of their use as drug carriers in vivo.[4] Irradiation of copolymers with *o*-nitrobenzyl ester side groups, synthesized from methacrylyl chloride, generates free carboxylic acids, as illustrated in eq 4.[2a] The positive photosensitive polyiimide biphenyl precursor pictured in eq 5 has been made by treatment of biphenyltetracarboxylic acid dianhydride (BPDA) with *o*-NBA.[3]

Protection of Amines.

Reaction of *o*-NBA with ***Phosgene*** yields the stable compound *o*-nitrobenzyloxycarbonyl chloride (eq 6).[5a] Subsequent reaction with 2-amino-2-deoxy-D-glucose cleanly affords the protected amine. The yields of the free amines obtained upon irradiation (eq 7) are lowered by side reactions with the *o*-nitrobenzaldehyde generated under the reaction conditions.[2a,5a,b] Yields are increased by the addition of polymeric aldehydes or sulfuric acid to the reaction mixture during irradiation,[5a] or by utilizing the related 2,6-dinitrobenzyl alcohol in the first step.[5b] Functional group tolerance

for this entire reaction sequence is impressively high.

(6)

(7)

Reaction with isocyanates also provides a route to carbamates, which serve as masked amines[5b,c] (eq 8) or as diamines[5d] for epoxy resin curing. Carbamates of *o*-NBA possess moderate antitumor activity.[22]

Protection of Amino Acids.

Photolabile *N*-protected amino acids and peptides have also been synthesized via their chloroformates.[2b,6] Quantitative deprotection proceeds without racemization[23,24] when an excess of ***Sulfuric Acid*** or ***Semicarbazide*** hydrochloride is added to the reaction mixture (eq 9). Conversely, treatment of serine with *o*-NBA in the presence of catalytic ***p-Toluenesulfonic Acid*** provides the *o*-nitrobenzyl ester of serine (eq 10).[2b]

(10)

Protection of Hydroxyl Groups.

Photolabile 2´-*O*-(*o*-nitrobenzyl) derivatives of various ribonucleotides[7a-c] as well as dinucleotides[7d] have been synthesized, and their subsequent photodeprotections, which yield the corresponding alcohols, examined (eq 11). Protection of the anomeric hydroxyl functionality of 2-deoxy-D-ribofuranose has been accomplished using *o*-NBA (eq 12).[7e] This protective group is quite stable to acidic conditions, and has proven invaluable in the synthesis of abasic oligonucleotides. Similar conditions are employed in the synthesis of bis(*o*-nitrobenzyl) ethers.[25]

(11)

B = purine or pyrimidine

(12)

Miscellaneous Reactions.

o-Nitrobenzyl triphenylsilyl ether, a latent photogenerated source of triphenylsilanol, has been synthesized from *o*-NBA (eq 13). This new catalyst, upon irradiation at 365 nm, serves as a coinitiator in the polymerization of epoxides.[8]

(13)

Greatly enhanced leaving group ability has been realized by use of *o*-NBA. Steroidal sulfonates synthesized from the sulfonylating agent formed in eq 14 undergo bimolecular azide displacements more efficiently than traditional sulfonates.[9]

(14)

o-Nitrobenzyl formylacetate has been made by the reaction of formyl Meldrum's acid with *o*-NBA in dry toluene (eq 15).[10] α-Hydroxyimino phosphonates can serve as precursors to alkyl metaphosphates when photolabile ester groups are incorporated (eq 16).[26]

(15)

(16)

Oxidations and Reductions.

Oxidation of *o*-nitrobenzyl alcohol to its aldehyde has been accomplished using bis(dihydrogentellurato)M^{III} where M = Cu^{III} and Ag^{III},[11a] chromium trioxide and alumina,[11b] biphasic nitric acid,[11c] bromamine-B,[11d] ethyl chlorocarbamate,[11e] potassium bromate in aqueous HCl,[11f] pyridinium fluorochromate,[11g] *N*-bromoacetamide,[11h] thallium(III),[11i] ammonium molybdate tetrahydrate in 6 M HCl,[11j] 1-chlorobenzotriazole,[11k] pyridine oxodiperoxychromium(VI),[11l] cobalt(III) hydroxide,[11m] cerium(IV) perchlorate,[11n] or silver(II) oxide in acidic media.[11o] Oxidation to *o*-nitrobenzoic acid is possible using methyltrioctylammonium tetrakis(oxodiperoxotungsto)phosphate,[12a] electrogenerated superoxide,[12b] $(NH_4)VO_3$ and dilute $HClO_4$,[12c] or benzyltrimethylammonium tribromide.[12d] Biological oxidation of *o*-nitrotoluene to *o*-NBA by *Pseudomonas* sp. strain JS150 and *Pseudomonas putida* F1 has also been reported.[13]

Reduction of esters of *o*-nitrobenzyl alcohol to yield *o*-NBA can be accomplished using sodium borohydride in aqueous media.[14] Reductions of *o*-nitrobenzaldehyde to *o*-NBA using sodium borohydride under phase transfer conditions,[15a] dimethoxyborane-$CoCl_2$,[15b] and trimethoxysilane-lithium methoxide[15c] have been reported. Reduction of the nitro group of *o*-NBA to the amine using catalytic hydrogenation with Pd^0 and polybenzimidazole resin in DMF is likewise known.[16]

Related Reagents.

o-Nitrobenzyl Bromide

(R = Br)

[3958-60-9] · $C_7H_6BrNO_2$ · *o*-Nitrobenzyl Bromide · (MW 216.04) (R = Cl)

[612-23-7] · $C_7H_6ClNO_2$ · *o*-Nitrobenzyl Chloride · (MW 171.58)

(introduction of the 2-nitrobenzyl protecting group which can be cleaved selectively by photolysis[1-4])

Alternate Name: 2-nitrobenzyl bromide.

Physical Data: (X = Br) mp 45-48 °C. (X = Cl) mp 46-48 °C, bp 127-133 °C/10 mmHg.

Solubility: sol most solvents; alkylations are frequently carried out in polar solvents such as DMF.

Form Supplied in: commercially available from many sources.

Handling, Storage, and Precautions: 2-nitrobenzyl halides are lachrymators and should be used in a well-ventilated fume hood.

The 2-Nitrobenzyl Group as a Protecting Group.

The 2-nitrobenzyl group is one of an increasing number of functions that have been employed as photolabile protecting groups in organic synthesis,[1-4] and photolytic cleavage usefully adds to the range of deprotecting strategies in the armory of the organic chemist. One of the first examples of such a protecting group was in the use of 2-nitrobenzyl esters as protected carboxylic acids.[5] UV irradiation of the esters yields the free acid and initially 2-nitrosobenzaldehyde (the mechanism of the rearrangement has been studied extensively[1-4]). The benzaldehyde is further converted to azobenzene-2,2´-dicarboxylic acid which then acts as an internal light filter and so severely hampers the reaction. Benzylic substituents remove this problem and derivatives such as the α-phenyl-2-nitrobenzyl esters give much better yields (eq 1). The 2-nitrobenzyl unit has also been incorporated into a wide variety of photolabile polymer supports for solid phase peptide synthesis.[6] Polystyrene supported 2-nitrobenzyl bromide has been used as a resin for anchoring the *C*-terminus amino acid residue to the solid phase as its 2-nitrobenzyl ester.[7]

Phosphate esters incorporating the photolabile 2-nitrobenzyl group have also been synthesized.[8]

2-Nitrobenzyl halides have been used extensively in the field of oligonucleotide synthesis[9-15] as a protecting group (eqs 2 and 3) for the 2´-OH of uridine,[9] adenosine,[10] cytidine,[10] and guanosine.[11] Treatment of the nucleoside with a strong base such as ***Bis(tri-n-butyltin) Oxide***[9] or ***Sodium Hydride***[10,11] followed by 2-nitrobenzyl bromide gives the expected ethers, though in very poor yields (ca. 25-30%). The benzylic protons of nitrobenzyl halides are quite acidic and so decomposition of the halides is significant under the strongly basic conditions. To bypass this problem some workers have used 2-nitrophenyldiazomethane instead of the substituted benzyl halide,[16] but the increased yields are accompanied by poorer selectivity for the 2´-OH over the 3´-OH and introduce the problem of product separation. Another method, which has been used for making 4-nitrobenzyl ethers of simple alcohols, is to use *p*-nitrobenzyl trifluoromethanesulfonate derived from the corresponding alcohol.[17]

(3)

In the etherification of an alcohol using 2-nitrobenzyl bromide, Ireland[18] used BaO/***Barium Hydroxide*** instead of the stronger bases mentioned above (eq 4). The reaction is still capricious, and investigation of silver-assisted alkylations resulted in failure. Deprotection near the end of the synthesis though is effected smoothly and cleanly with UV irradiation (eq 5). For the protection of phenolic hydroxyl groups both ***Silver(II) Oxide*** in benzene[19] and a ***Potassium Carbonate***/***Cesium Carbonate*** mixture[20] (eq 6) have been used successfully.

(4)

(5)

R = complex spiroacetal

(6)

The photolabile 2-nitrobenzyl group has been employed in carbohydrate chemistry[21] for the protection of anomeric hydroxyl groups, and has also been used for other acetals.[22] These derivatives, synthesized from 2-nitrobenzyl alcohol, are particularly useful as they impart greater crystallinity to the compounds and aid in purification.

The 2-nitrobenzyl group has been used to protect heteroatoms other than oxygen. The sulfur atom in the phosphorothioate group of some nucleotides has been protected as the *S*-(2-nitrobenzyl)phosphorothioate (eq 7), and with this protection the nucleotides can be successfully coupled and deprotected to give di- and trinucleotides.[23]

The N-1 atom in pyrazolidin-3-ones has been protected using 2-nitrobenzyl bromide in DMF (eq 8),[24] as has the N^{im}-3 atom in histidine (eqs 9 and 10).[25]

(10)

In Williams' synthesis of (±)-aplysiatoxin, he used a *N*-(2-nitrobenzyl) protected glycine unit.[26] The 2-nitrobenzyl group has been used to *N*-protect other biologically important compounds such as 5-fluorouracil, 2´-deoxy-5-fluorouridine (eq 11),[27] and purine bases.[28] Glycine, an important inhibitory neurotransmitter, has been *N*-derivatized with the 2-nitrobenzyl group so that the biologically active compound can be released with UV photolysis as desired.[29] This use of photolabile protecting groups for biologically active molecules has been reviewed recently.[30]

(11)

The 2-nitrobenzyl substituent has also found a use in the protection of amino groups (eq 12) as urethanes using 2-nitrobenzyloxycarbonyl chloride, giving a photolabile equivalent to the benzyloxycarbonyl (Z) group.[31]

p-Nitrobenzyl 2-Diazo-3-trimethylsilyloxy-3-butenoate

[93788-47-7] · $C_{14}H_{17}N_3O_5Si$ · *p*-Nitrobenzyl 2-Diazo-3-trimethylsilyloxy-3-butenoate · (MW 335.43)

(annulation of β-lactams[1] and aromatic aldehydes and ketones[13])

Physical Data: mp 75 °C (dec).[4] The corresponding TBDMS ether has mp 133 °C (dec).

Solubility: sol acetonitrile, ethyl acetate, ether, methylene chloride, toluene; poorly sol hexane.[4] The reagent hydrolyzes in water and protic solvents, whereas the TBDMS enol ether is stable to neutral aqueous workup.[2]

Form Supplied in: stored and used in methylene chloride or toluene solution. *p*-Nitrobenzyl 2-diazoacetoacetate, the hydrolysis product, is the expected impurity.

Analysis of Reagent Purity: ^{1}H NMR.[1,2]

Preparative Methods: by silylation of the corresponding diazoacetoacetate[2] with a silyl triflate (***Trimethylsilyl Trifluoromethanesulfonate*** or ***t-Butyldimethylsilyl Trifluoromethanesulfonate***) and ***Triethylamine*** in CH_2Cl_2.[2] For large scale preparations the use of ***Chlorotrimethylsilane***, ***Potassium Iodide*** (one equivalent), and Et_3N in acetonitrile is more advantageous.[6]

Handling, Storage, and Precautions: should be stored in solution in a dry, dark, cold place. The solid form is stable for several months in the refrigerator. The solid reagent is not shock sensitive but exothermic decomposition takes place on melting, generating 200 cal g^{-1} (138 cal g^{-1} for the TBDMS ether).[5] Decomposition can also be initiated by metallic impurities (Cu, Rh, etc.).

Annulation of β-Lactams.

This bifunctional reagent was developed for the stereospecific construction of the carbapenem skeleton in the conversion of penicillin to thienamycin.[1a] The annulation scheme is based on condensation of the enol silane with the iminium ion intermediate followed by ring closure via rhodium-catalyzed carbenoid insertion into the NH bond (eq 1).

(1)

Subsequently, it was shown that the condensation is more facile when the nitrogen is not silylated[1b,7] and that acetoxy[1b] or benzoyloxy[8] groups may serve as the leaving group for generation of the iminium ion. Lewis acids such as $ZnCl_2$, $ZnBr_2$, ZnI_2, and TMSOTf in CH_2Cl_2 initiate the reaction (eq 2). This mode of annulation has formed the basis of the syntheses of thienamycin [R = MeCH(OH)-],[1,2,7-9] asparenomycin [R = $HOCH_2C(Me)$=],[10] PS-5 (R = Et),[3,11,12] and PS-6 (R = *i*-Pr).[3] The [3*R*(1´*R*),4*R*]-4-acetoxy-3-(1-hydroxyethyl)-2-azetidinone is commercially available. The patent literature contains numerous examples of this type of annulation. Variations of this annulation scheme, such as condensation of the β-lactam with bis-silylated acetoacetate (unstable reagent), followed by diazo transfer[1a] and nucleophilic displacement with the lithium enolate of diazoacetoacetate (3.2-14.1% yield),[12] are clearly inferior alternatives.

(2)

Annulation of Aldehydes and Ketones.[13]

Titanium(IV) Chloride-catalyzed condensation of the reagent and aldehydes or ketones followed by rhodium-catalyzed carbene insertion into the OH bond affords furanone derivatives (eq 3).

$R^1 = Ph; R^2 = H, Me$

(3)

Analogous condensation with benzophenone using 2 equiv of $TiCl_4$ yields the unsaturated diazo ketone in 80% yield. ***Boron Trifluoride***-initiated ring closure produces the β-naphthol analog, while rhodium-promoted reaction generates the isomeric α-naphthol via Wolff rearrangement, followed by ketene cyclization, in quantitative yield (eq 4).

(4)

It is expected that this versatile bifunctional reagent will find application in other areas of synthetic chemistry. The *t*-butyldimethylsilyl ether analog is frequently used. The benzyl,[1] *p*-methoxybenzyl,[2] diphenylmethyl,[3] allyl,[2] and trimethylsilyl esters[2] have also been used.

p-Nitrobenzyl *p*-Toluenesulfonate[1]

[4450-68-4] · $C_{14}H_{13}NO_5S$ · *p*-Nitrobenzyl *p*-Toluenesulfonate · (MW 307.35)

(conversion of a carboxylate anion into the *p*-nitrobenzyl ester, principally for use as a protecting group[1,2])

Physical Data: mp 103-104 °C.

Solubility: sol most organic solvents.

Form Supplied in: not commercially available.

Preparative Methods: by reaction of (a) ***p-Toluenesulfonyl Chloride*** with *p*-nitrobenzyl alcohol[3] for 30 min in dry pyridine at -10 °C; or (b) dry ***Silver(I) p-Toluenesulfonate*** with *p*-nitrobenzyl bromide in refluxing dry $CHCl_3$ for 24 h in the dark.[2]

Purification: recrystallize from 2-propanol-petroleum ether,[2] ligroin,[3] or anhydrous ethyl ether.[4]

Handling, Storage, and Precautions: mutagenic in the Ames *Salmonella* plate incorporation assay (using strain TA100);[5] should be treated as a potential carcinogen; can induce skin sensitization in guinea pigs.[6] Can be kept for long periods without apparent decomposition.[3]

p-Nitrobenzyl *p*-toluenesulfonate (PNB-OTs) is used as a reagent for protecting carboxylic acids. Formation of the ester involves conversion of the acid to a carboxylate salt (e.g. to the sodium salt using NaOMe in methanol,[2] or to the Et_3NH^+ salt using Et_3N[7]), followed by reaction with PNB-OTs in Me_2CO[2,7] or Me_2CO-DMF (2:1).[2,8] The PNB esters are stable to HBr/HOAc at room temperature (permitting cleavage of *N*-Cbz groups) and are readily cleaved by catalytic hydrogenation[2] (or NaOH/aq acetone[8]); the conditions of protection and deprotection minimize racemization of amino acids and peptides. In the example in eq 1, the protection-deprotection sequence was used[9] to avoid formation of a lactone along with the diacetate.

PNB-OTs has also been used as a UV labeling agent for detecting monocarboxylic acids in HPLC analyses.[10]

Nitroethane

$EtNO_2$

[79-24-3] · $C_2H_5NO_2$ · Nitroethane · (MW 75.08)

(building block in synthesis; polar solvent)

Physical Data: mp -90 °C; bp 115 °C; *d* 1.04 g cm^{-3}; pK_a 8.5.

Solubility: completely misc most organic solvents; slightly sol water; sol alkaline solution.

Form Supplied in: colorless liquid, widely available; contains 2-nitropropane as the chief contaminant.

Purification: by drying over $MgSO_4$ and distillation at reduced pressure; a small acidic forerun is discarded.

Handling, Storage, and Precautions: stable compound. Flammable; toxic.

Introduction.

The reactions of nitroethane discussed here can, in principle, be applied to most primary nitroalkanes. Nitroethane reacts with metal alkoxides and hydroxides to form metal nitronates which are often applied as in situ generated reagents. They are unstable and it is advisable not to isolate them.

The Nitroaldol Reaction (Henry Reaction).[1,2]

Reactions with Aldehydes.

In the presence of base, nitroethane reacts with aliphatic aldehydes in an aldol-type reaction with formation of 2-nitro alcohols (nitroaldols). Due to its reversibility, the reaction is normally carried out in the presence of only catalytic quantities of base. The reaction of nitroethane with an aldehyde in the presence of one equivalent of base gives the salt of the *aci*-nitro tautomer of the product, which must be carefully acidified to avoid the Nef reaction. Alkali metal hydroxides, alkoxides, or carbonates and tertiary amines have been applied as catalysts.[2a] Elimination of water, the aldol reaction, and the Cannizzaro reaction are competing side reactions.[2a,b] 2-Nitro alcohols are unstable compounds and care has to be exercised during workup (decomposition during distillation). Higher yields are often obtained when

the reaction is catalyzed in heterogeneous systems with catalysts such as powdered NaOH,[3] Al_2O_3,[4] and Al_2O_3-supported KF.[5] The 2-nitro alcohols are readily converted into a variety of functionalities (eq 1).[1b,4-10,13-17]

(1)

Aromatic aldehydes react with nitroethane under the same conditions.[11] Elimination of water to give β-nitrostyrenes takes place on acidification.[2a] Synthesis of β-nitrostyrenes can be accomplished in one step by heating aromatic aldehydes in acetic acid with NH_4OAc as catalyst.[12] In the presence of NaOAc in refluxing acetic acid, aldehydes are converted into nitriles (eq 2).[12b]

(2)

Dehydration of 2-nitro alcohols to nitroalkenes has been accomplished with ***Methanesulfonyl Chloride***,[13], phthalic anhydride,[14] ***1,3-Dicyclohexylcarbodiimide***,[15] pivaloyl chloride,[16] ***Trifluoroacetic Anhydride***,[17] and ***Acetic Anhydride***.[17] Heating 2-nitro alcohols in dichloromethane in the presence of basic aluminium oxide is another mild method for the synthesis of nitroalkenes.[18] Nitroalkenes can be converted into a variety of functionalities (eq

3),[2,19a,21-26] and have found utility as heterodienes in hetero Diels-Alder reactions and as reactants in Lewis acid promoted tandem [4 + 2]/[3 + 2] cycloadditions (eq 4).[20]

(3)

Nitroethane can be silylated to form stable trimethylsilyl or *t*-butyldimethylsilyl nitronates.[27] In the presence of a catalytic amount of ***Tetra-n-butylammonium Fluoride*** at -78 °C in THF, the silyl nitronates react with aldehydes to give 2-nitro alcohol *O*-silyl ethers in high yields.[6b,28] The TBDMS nitronate reacts in the presence of freshly dried Bu_4NF to give the *erythro*-isomer of the product in >95% de (eq 5).

The dilithium salt of nitroethane is formed by treatment of nitroethane with 2 mol equiv of ***n-Butyllithium*** in THF/HMPA at -90 °C.[28,29] It reacts with aldehydes at -70 to -60 °C to form the doubly deprotonated nitro alcohols which must be carefully acidified at -90 °C with acetic acid. The dilithium salt is a much harder carbon nucleophile than the sodium nitronate and the reaction with carbonyl compounds is irreversible; this often leads to higher yields of 2-nitro alcohols than the conventional Henry reaction. The reaction proceeds diastereoselectively to give the *threo* and *erythro* isomers in a ratio of characteristically 3-5:1 (eq 6).[28]

Diastereomeric mixtures of nitro alcohols derived from nitroethane can be transformed to the *threo*-isomer, predominantly, by double deprotonation and protonation or to the *erythro*-isomer by double deprotonation, silylation with ***t-Butyldimethylchlorosilane***, protonation, and desilylation (eq 7).[28]

Nitroethane can react with two mol equiv of formaldehyde.[2a] With acetaldehyde and higher analogs, the reaction with a second molecule is difficult.[2b,d]

Dialdehydes derived from periodate cleavage of a sugar react with nitroethane in an one-pot cyclization reaction to give predominantly one stereoisomer (eq 8).[30]

meso-1,5-Dialdehydes react with nitroethane in methanol in the presence of a catalytic amount of NaOH to give a crude mixture of 2,6-dihydroxynitrocyclohexanes from which the major *trans,trans*-isomer precipitates (eq 9).[31] The diacetate of 2,6-dihydroxy-1-methyl-1-nitrocyclohexane formed by this reaction can be saponified enantioselectively with pig liver esterase (PLE) to give the monoacetate of >95% ee (eq 9).[31]

In the presence of primary or secondary amines, aldehydes react with nitroethane in a Mannich-type reaction.[2d]

Reactions with Ketones.

The reaction is complex and depends on the ratio of reactants, base, temperature, and time (eq 10).[2a]

(10)

With alkali metal hydroxides or alkoxides, quaternary ammonium hydroxides, or primary or tertiary amines, low yields (10-30%) of nitro alcohols are normally obtained.[2a,b] Nitroethane reacts with methylcyclohexanones under pressure with TBAF as catalyst to give nitro alcohols in 41-87% yields.[32] With *N*,*N*-dimethylethylenediamine as base, it is possible to selectively synthesize allylic nitro compounds in moderate to high yields from both acyclic and alicyclic ketones (eq 11).[33] The doubly deprotonated forms of primary nitroalkanes give (with nitromethane as an exception) higher yields of 2-nitro alcohols in the reaction with ketones.[34]

(11)

Michael Reactions.

Conjugate addition of nitroethane to activated double bonds is an important C-C bond forming reaction (eq 12).

(12)

EWG = CHO, COR, CO_2R, CN, SOR, SO_2R, NO_2

Michael additions with nitroethane are catalyzed in homogeneous solution with catalysts such as alkali metal hydroxides in alcohol,[35] organic nitrogen bases,[36] fluoride ion,[37] and sodium hydride.[8] The reaction is also catalyzed in heterogeneous systems with alumina[38] and Al_2O_3-supported KF or CsF.[39] When combined with the Nef reaction,[1a,9] synthetically useful 1,4-dicarbonyl compounds can be synthesized. Nitroethane reacts with 2 mol equiv of Michael acceptors to give a variety of coupling products (eq 13).[37]

(13)

Acylation of Nitroethane.

With few exceptions, acylation of sodium ethanenitronate with acyl halides or anhydrides occurs on oxygen. The

unstable products rearrange into hydroxamic acid derivatives.[40] *C*-Acylation can be accomplished with acylimidazoles[41] and acyl cyanide (eq 14).[42] Carboxylation can be accomplished by reaction with methoxymagnesium methyl carbonate (Stiles reagent).[43]

(14)

The dilithium salts of nitroethane and higher primary nitroalkanes react with carboxylic esters, anhydrides, and dialkyl carbonates to form β-oxo nitronates or β-carboxy nitronates, which must be carefully acidified at -90 °C to avoid Nef reaction with acetic acid.[34]

Alkylation of Nitroethane.

The ambident ethanenitronate ion reacts with alkyl iodides to give a mixture of *C*-alkylated and, primarily, *O*-alkylated compounds. The alkyl nitronates of nitroethane are unstable and decompose to carbonyl compounds and acetaldoxime.[44] The reaction has found some utility in the oxidation of primary alkyl iodides to aldehydes.[45] The methyl and ethyl nitronate of nitroethane are stable below -78 °C and can be synthesized from the sodium nitronate and ***Trimethyloxonium Tetrafluoroborate*** and ***Triethyloxonium Tetrafluoroborate***, respectively, at -60 °C in excellent yields.[44] The sodium salt of nitroethane can selectively be *C*-benzylated with 1-benzyl-2,4,6-triphenylpyridinium tetrafluoroborate in moderate yields.[46] The pyridinium cations are readily available from ***2,4,6-Triphenylpyrylium Tetrafluoroborate*** and the corresponding benzylamines. The dilithium salts of primary nitroalkanes are *C*-alkylated with primary iodo- and bromoalkanes.[47] A homoallylic nitro compound is formed when nitroethane, after treatment with lithium methoxide in methanol, reacts with cinnamyl acetate in the presence of 10 mol % ***Tetrakis(triphenylphosphine)palladium(0)*** as catalyst (eq 15).[48]

1,3-Dipolar Cycloadditions of Nitroethane.[49]

The in situ generated trimethylsilyl ethanenitronate reacts with activated terminal alkenes in a 1,3-dipolar cycloaddition to form 5-substituted 3-methyl-*N*-trimethylsilyloxyisoxazolidines which, upon acid treatment or heating, give isoxazolines.[27a,50] Asymmetric isoxazolines have been synthesized in this manner. The cycloaddition of *N*-acryloyl-(2*R*)-bornane-10,2-sultam (acrylate of ***10,2-Camphorsultam***) with the silyl nitronate, followed by acid-catalyzed elimination of trimethylsilyl alcohol, gives the corresponding isoxazoline in high yields and 78% ee of the C-5 (*R*)-isomer (eq 16).[51]

Acetonitrile N-Oxide is formed when nitroethane is treated with ***Phenyl Isocyanate*** in the presence of ***Triethylamine*** in the Mukayiama reaction.[52] The nitrile oxide is a potent dipole and reacts with alkenes and alkynes to give isoxazolines and isoxazoles, respectively. With terminal alkenes or alkynes, the reaction is regioselective, giving 5-substituted 3-methylisoxazolines or -isoxazoles. 1,2-Disubstituted *cis*- and *trans*-alkenes react in a stereospecific manner giving *cis*- and *trans*-4,5-substituted isoxazolines, respectively.[49] Acetonitrile oxide reacts stereoselectively with optically active acrylic esters and amides to give the isoxazolines illustrated in eq 17.[53-56] With Curran's bis-lactam chiral auxiliaries, products with about 98% ee are obtained (eq 17).[53]

(17)

75% ee 82% ee >80% ee

>90% ee 98% ee

3-Methylisoxazolines can easily be reduced to β-hydroxy ketones (an alternative route to the products from aldol reactions with acetone)[57] and 3-amino alcohols (eq 18).[58]

(18)

Related Reagents.

t-Butyldimethylsilyl Ethylnitronate; ***Lithium α-Lithiomethanenitronate***; ***O,O-Dilithio-1-nitropropene***; ***Nitromethane***; ***1-Nitropropane***; ***1-Nitro-1-propene***.

(Diels-Alder dienophile;[3] Michael acceptor[3])

Physical Data: bp 38-39 °C/80 mmHg.[2]

Analysis of Reagent Purity: titration against tetraphenylcyclopentadienone.[3]

Preparative Methods: best prepared by dehydration of 2-nitroethanol using phthalic anhydride (eq 1).[2,3] It can also be generated for reactions in situ from several precursors, especially 2-nitroethyl phenyl sulfoxide.[4]

Handling, Storage, and Precautions: lachrymatory oil. Polymerizes readily in the presence of water and violently with base. Purified compound darkens quickly, but 10% solutions in dry benzene can be kept for 6 months or longer when refrigerated.[3]

Cycloadditions.

Nitroethylene is a very electron-deficient and highly reactive dienophile in Diels-Alder reactions with electron-rich or unactivated dienes. Its reactions with cyclopentadiene derivatives exhibit particularly high reactivity and selectivity, proceeding at temperatures as low as -100 °C to form only the *endo* product (eq 2).[3,5] Many other cyclic dienes show

similar selectivity.[6] The adducts are readily converted to ketones, making nitroethylene a useful ketene equivalent.[5]

(2)

Reactions with acyclic dienes proceed much more slowly, and are often carried out at 80-120 °C.[7] These reactions exhibit high regioselectivity with simple dienes.[8] Subsequent alkylation and denitration (***Tri-n-butylstannane***) of the adducts (eq 3) effects the overall synthetic equivalent of a regiocontrolled Diels-Alder reaction with 1-alkenes.[8]

(3)

Nitroethylene is also a reactive dipolarophile in 1,3-dipolar cycloadditions.[3,9] An interesting observation, rationalizable from FMO considerations, is that the regiochemistry of nitroethylene reactions with nitrones is often reversed from that observed with less electron-deficient alkenes (eq 4).[9a,c]

(4)

Radical Additions.

Nitroethylene is a reactive and useful acceptor for nucleophilic radicals (eq 5).[10]

(5)

Nucleophilic Additions.

A wide variety of nucleophiles have been used in conjugate additions to nitroethylene.[3,11] Avoiding the facile base-mediated polymerization of nitroethylene is crucial to the success of these additions. A broad study found that additions of amines with pK_a values between 2 and 8 are highly successful, while more basic amines lead to polymerization.[12] An exception is the pyrrolidine synthesis in eq 6, in which a second Michael addition traps the intermediate nitronate anion.[13]

(6)

Traditional Michael additions of β-dicarbonyl compounds to nitroethylene in protic solvents are best carried out under the most mildly basic conditions possible (KF catalyzed,[14] for example). Kinetic Michael additions of preformed

enolates at low temperatures have also been reasonably successful.[15]

Related Reagents.

2-Acetoxyacrylonitrile; ***2-Chloroacrylonitrile***.

Nitrogen Dioxide

NO_2

(NO_2)

[10102-44-0] · NO_2 · Nitrogen Dioxide · (MW 46.01) (N_2O_4)

[10544-72-6] · N_2O_4 · Nitrogen Dioxide · (MW 92.02)

(nitration of aromatic[1,2] and unsaturated[3,4] compounds; conversion of oximes into dinitromethanes;[3,5,6] halogenation of arenes;[7,8] oxidation of many functional groups.[9-11])

Alternate Names: nitrogen tetroxide; dinitrogen tetroxide.

Physical Data: a reddish-brown gas above 21.15 °C and a brown or yellow-brown liquid below 21.15 °C; mp 11.2 °C; bp 21.15 °C; *d*204 1.448 g cm^{-3}, *d*21.3(gas) 3.3 g L^{-1}; exists as N_2O_4 in liquid and solid state; as a mixture of NO_2 and N_2O_4 in the gas phase; and as NO_2 above 135 °C.

Solubility: sol CCl_4, CH_2Cl_2, DMF, ether, concd sulfuric and nitric acids.

Form Supplied in: brown liquid under pressure.

Preparative Methods: prepared by thermal decomposition of lead nitrate or from N_2O_5.[12]

Handling, Storage, and Precautions: deadly poison! One of the most insidious gases. 100 ppm is dangerous and 200 ppm may be fatal. Decomposes in water or alkaline solutions. Use in a fume hood.

Nitration of Aromatic Compounds.

Examples of arene nitration with nitrogen dioxide at high temperature or in the presence of concentrated acids are numerous, but they are often messy.[1] In the best cases, mixtures of *o*- and *p*-nitro compounds are formed with predomination of the former (eq 1).[13]

(1)

Activated arenes and even porphyrins can be nitrated directly by nitrogen dioxide in benzene or dichloromethane solution.[14,15] Phenols usually give di-*o*-nitro substituted compounds as well as 4-nitrocyclohexadienones (eq 2).

(2)

o-Nitrophenols have been obtained in high yield using pyridinium salts as NO_2 transfer agents.[16] Anthracene reacts with nitrogen dioxide to give *cis*- and *trans*-9,10-dinitro-9,10-dihydroanthracene.[17] Compounds of lower reactivity than benzene can be nitrated by nitrogen dioxide in the presence of ***Ozone*** even at low temperatures.[18,19] Thus, treatment of acetanilides with nitrogen dioxide and ozonized air gives a high proportion of *o*-nitro derivatives in good yields (eq 3).[19] Polynitration of arenes or nitration of strongly deactivated compounds requires the use of catalysts such as ***Boron Trifluoride Etherate*** or ***Methanesulfonic Acid***.[18]

Nitration of Unsaturated Compounds.

Alkenes react with liquid nitrogen dioxide to give a complex mixture of compounds that include mainly 1,2-dinitroalkanes and 1-nitro-2-nitrosooxyalkanes.[3,5,9] However, tetrasubstituted or halogenated alkenes usually give good yields of dinitro compounds (eq 4).

Addition of nitrogen dioxide to 1,1-dialkyl substituted alkenes affords good yields of nitroso nitrates.[3,9] The same reaction in the presence of halogens leads to 1-nitro-2-haloalkanes which may undergo dehydrohalogenation to nitroalkenes.[3,20] Alkynes react with nitrogen dioxide to give moderate yields of 1,2-dinitroalkenes.[3,10]

Oxidation.

Oxidation of alcohols and ethers with nitrogen dioxide gives aldehydes or ketones (eq 5).[9,10,21] Nitrogen dioxide oxidizes primary amines to nitroalkanes, trialkylphosphines to phosphine oxides, and dialkyl sulfides to sulfoxides (without further oxidation to sulfones).[9-11,22] Sulfides react with nitrogen dioxide to afford good yields of sulfonic acid anhydrides.[9]

(5)

Ponzio Reaction.

A general method for direct preparation of dinitromethylarenes is the oxidation of oximes with nitrogen dioxide (eq 6).[3,5,6,10,11]

(6)

Halogenation.

Nitrogen dioxide has been used in combination with halogens and metal halogenides for the halogenation of unreactive aromatic compounds and adamantane (eq 7).[7,8,23]

(7)

Related Reagents.

Iodine-Nitrogen Tetroxide.

Nitromethane

$MeNO_2$

[75-52-5] · CH_3NO_2 · Nitromethane · (MW 61.05)

(building block in synthesis; polar solvent)

Physical Data: mp -28.5 °C; bp 101 °C; *d* 1.13 g cm^{-3}; dipole moment 3.5 D.

Solubility: completely misc most organic solvents; slightly sol petroleum ether, water; sol alkaline solution.

Form Supplied in: colorless liquid, widely available.

Purification: purified by drying over $MgSO_4$ and distilling; a small acidic forerun is discarded.

Handling, Storage, and Precautions: stable compound. It is advised not to distill large quantities at reduced pressure. Flammable; toxic. Gives shock- and heat-sensitive alkali and heavy metal salts. Do not dry the sodium salt.

Introduction.

Nitromethane is a common starting material for the synthesis of aliphatic nitro compounds, which serve as valuable building blocks, providing access to a variety of other functionalized products such as 2-nitro alcohols, nitroalkanes, nitroalkenes, hydrocarbons, amines, oximes, carbonyl compounds, and heterocycles.[1] Nitromethane reacts with alkali metal hydroxides and alkoxides to form the metal nitronates which are used as in situ generated reagents. The alkali metal nitronates are unstable and it is advisable not to isolate them. The sodium salt of nitromethane undergoes violent decomposition or detonation on heating and drying.

The Nitroaldol Reaction (Henry Reaction).[2]

Reactions with Aldehydes.

In the presence of base, nitromethane reacts with aliphatic aldehydes in an aldol-type reaction with formation of 2-nitro alcohols (nitroaldols). Due to its reversibility, the reaction is normally carried out in the presence of only catalytic quantities of base, although in certain cases stoichiometric amounts are used to precipitate the product.[3] The reaction of nitromethane with aldehydes in the presence of one equivalent of base gives the salt of the *aci*-nitro tautomer of the

product, which must be carefully acidified to avoid the Nef reaction. Alkali metal hydroxides, alkoxides or carbonates, and tertiary amines are effective catalysts.[2a] Elimination of water, the aldol reaction, and the Cannizzaro reaction are competing side reactions.[2a,b] 2-Nitro alcohols are unstable compounds and care has to be exercised during workup (decomposition during distillation). Fluoride ion catalysts often give higher yields.[4] The reaction has been carried out in the absence of solvent using powdered NaOH,[5] Al_2O_3,[6] and Al_2O_3-supported KF[7] as catalysts. The 2-nitro alcohols are readily converted into a variety of functionalities (eq 1).[1b,4,5,7-13,16-21]

Aromatic aldehydes react smoothly with nitromethane under the same conditions.[14] Elimination of water to give β-nitrostyrenes takes place on acidification.[2a] Synthesis of β-nitrostyrenes can be accomplished in one step by heating aromatic aldehydes in acetic acid and with NH_4OAc as catalyst.[15] Dehydration of 2-nitro alcohols to nitroalkenes has been accomplished with ***Methanesulfonyl Chloride***,[16] phthalic anhydride,[17] ***1,3-Dicyclohexylcarbodiimide***,[18] pivaloyl chloride,[19] ***Trifluoroacetic Anhydride***,[20] and ***Acetic Anhydride***.[20] Heating 2-nitro alcohols in dichloromethane in the presence of basic aluminium oxide is another mild method for the synthesis of nitro alkenes.[21] Nitroalkenes can be converted into a variety of functionalities (eq 2)[2,5,22,24-30] and have found utility as heterodienes in hetero Diels-Alder reactions and as reactants in Lewis acid promoted tandem [4 + 2]/[3 + 2] cycloadditions.[23]

(2)

A catalytic asymmetric nitroaldol reaction has been developed.[31] The catalyst is formed from ***Lanthanum(III) Chloride***, the dilithium salt of ***(R)-1,1´-Bi-2,2´-naphthol***, NaOH, and H_2O in a 1:1:1:10 molar ratio in THF. Nitromethane reacts with various aldehydes in the presence of 10% of the catalyst to give 2-nitro alcohols in high yields and with an ee as high as 93% (eq 3). Chiral binaphthol complexes of other rare earth metal trichlorides show similar catalytic effects. The optical purities of nitroaldols obtained using these rare earth metal complexes as asymmetric catalysts are highly dependent on the amount of water present and on the relation between substrate and radius of the rare earth metals.

(3)

Nitromethane can react with two mol equiv of an aldehyde.[2a] The reaction with the second aldehyde molecule proceeds slower than that with the first due to the lower acidity of the α-proton in 2-nitro alcohols and enhanced steric

hindrance. With sterically hindered aldehydes, the reaction with the second aldehyde is difficult.[2b,d] Seebach et al.[32] synthesized the multiple coupling reagent 2-nitro-2-propenyl 2,2-dimethylpropanoate (NNP) from nitromethane. In the initial step, nitromethane reacts with two moles of formaldehyde to give 1,3-dihydroxy-2-nitropropane in 95% yield. Subsequent acylation with two mol equiv of pivaloyl chloride and elimination of pivalic acid gives NNP. The reaction may be run on a 40 to 200 g scale without problems (eq 4). NNP allows succesive introduction of two different nucleophiles Nu^1 and Nu^2 (eq 5).

(4)

(5)

With dialdehydes, nitromethane forms cyclic nitro compounds.[33] Nitromethane reacts with glyoxal at pH 10 to give a mixture of isomeric inositol derivatives from which *neo*-inositol, one of 14 possible diastereomers, precipitates (72% yield) (eq 6).

(6)

Tartaraldehyde gives a mixture of stereomeric nitro-2,3,4,5-cyclopentanetetraols.[33] With *o*-phthalaldehydes, nitromethane reacts in alcoholic alkali to give, after acidification, 2-nitro-3-hydroxyindenes.[33] Dialdehydes derived from periodate cleavage of sugars react with nitromethane in a one-pot cyclization reaction to give, frequently, one predominant stereoisomer (eq 7).[33,34]

(7)

meso-1,5-Dialdehydes react with nitromethane in methanol and a catalytic amount of NaOH to give a crude mixture of 2,6-dihydroxynitrocyclohexanes from with the major *trans*,*trans*-isomer precipitates (eq 8).[35] The diacetates of carbocyclic and heterocyclic six-membered compounds formed by this reaction can be saponified enantioselectively with pig liver esterase (PLE) to give monoacetates of >95% ee.[35]

In the presence of primary or secondary amines, aldehydes react with nitromethane in a Mannich-type reaction.[2d]

Reactions with Ketones.

Unlike other nitroalkanes, nitromethane often gives satisfactory yields in the reaction with ketones.[2b] The reaction is complex and depends on the ratio of reactants, base, temperature, and time (eq 9).[2a]

With alkali metal hydroxides or alkoxides, quaternary ammonium hydroxides, primary or tertiary amines, or ***Tetra-n-butylammonium Fluoride*** under pressure[36] it is usually possible to stop the reaction at the nitro alcohol stage.[2d] When the reaction is catalyzed by secondary amines, nitroalkenes are isolated.[37] From 3β-hydroxyandrost-5-en-17-one, nitromethane, and 1% ***1,2-Diaminoethane*** as catalyst, an exocyclic nitroalkene is obtained (eq 10),[38] although

exocyclic nitroalkenes often rearrange to the endocyclic β,γ-nitroalkenes. With *N*,*N*-dimethylethylenediamine as base, it is possible to selectively synthesize allylic nitro compounds from both acyclic and alicyclic ketones (eq 11).[39]

(10)

(11)

Nitromethane has been used in the Tiffeneau-Demjanov ring expansion of cyclic ketones by reduction of the nitro alcohol to the β-hydroxy amine and diazotization (eq 12).[40]

(12)

Michael Reactions.

Conjugate addition of nitromethane to activated double bonds is another important C-C bond forming reaction (eq 13). Unsaturated aldehydes give rise to competing 1,2-addition (Henry reaction), which can be controlled to some extent by the choice of catalyst.[2a] Michael additions with nitromethane are catalyzed in homogeneous solution with catalysts such as alkali metal hydroxides in alcohol,[41] organic nitrogen bases,[42] and fluoride ions.[43] The reaction is also catalyzed in heterogeneous systems with alumina[44] or Al_2O_3-supported KF or CsF.[45] Nitromethane reacts smoothly with two moles of Michael acceptors to give a variety of coupling products (eq 13).[43,44]

(13)

EWG = CHO, COR, CO_2R, CN, SOR, SO_2R, NO_2

Nitromethane has been employed in cyclopropanation.[46] The product is formed by Michael addition of nitromethane to a double bond with two geminal electron withdrawing groups followed by elimination of the nitro group (eq 14).

(14)

Acylation of Nitromethane.

With few exceptions, acylation of sodium methanenitronate with acyl halides or anhydrides occurs on oxygen. The unstable products rearrange into hydroxamic acid derivatives. *C*-Acylation can be accomplished with acylimidazoles,[47] acyl cyanide,[48] and phenyl benzoates[49] and from benzoic acids by the action of ***Diethyl Phosphorocyanidate*** (eq 15).[50]

(15)

Carboxylation can be accomplished by reaction with methoxymagnesium methyl carbonate (Stiles reagent).[51] Another method for the preparation of methyl 2-nitroacetate is by heating nitromethane at 160 °C in the presence of KOH, followed by acidification of the nitronate salt at -15 °C in the methanolic solution (eq 16).[52]

(16)

The dilithium salt of nitromethane reacts with carboxylic esters at -30 °C to form the β-oxo nitronate, which must be carefully acidified at -90 °C with acetic acid (eq 17).[53] The dilithium salt of nitromethane is formed by treatment of nitromethane with ***n-Butyllithium*** in THF/HMPA at -65 °C.[53] The dilithium salt is a much harder carbon nucleophile than the sodium nitronate.

Alkylation of Nitromethane.

The ambident methanenitronate ion reacts with alkyl iodides to give a mixture of *C*-alkylated and primarily *O*-alkylated compounds. The alkyl nitronates of nitromethane are very unstable and decompose to carbonyl compounds and formaldoxime.[54] The sodium salt of nitromethane can be selectively *C*-benzylated with 1-benzyl-2,4,6-triphenylpyridinium tetrafluoroborate in good to moderate yields.[55] The pyridinium cations are readily available from ***2,4,6-Triphenylpyrylium Tetrafluoroborate*** and the corresponding benzylamines.[55]

The dilithium salt of nitromethane is *C*-alkylated with 1-iodohexane in moderate yield.[56] Kornblum et al. has reported on a general high yielding method for the *C*-alkylation of nitromethane with tertiary nitro compounds (eq 18).[57] The tertiary nitro group is substituted with nitromethane in a radical chain process. The reaction is carried out at 25 °C in DMSO with exposure to fluorescent light and the molar ratio of tertiary nitro compound, nitromethane, and NaH is 1:4:8.

1,3-Dipolar Cycloadditions of Nitromethane.

Nitromethane can be *O*-silylated with ***Chlorotrimethylsilane*** in the presence of ***Triethylamine***.[58a] The trimethylsilyl methanenitronate is unstable and dimerizes, but it can be trapped with an activated alkene in a 1,3-dipolar cycloaddition to give isoxazolidines which, upon acid treatment, give isoxazolines (eq 19).[58]

(19)

In contrast to other primary nitro compounds, the corresponding nitrile oxide (fulminic acid) of nitromethane is not formed in the Mukaiyama reaction.[59] When nitromethane is treated with ***Phenyl Isocyanate***, α-nitroacetanilide is formed first and is subsequently transformed to the nitrile oxide with a second mol equiv of phenyl isocyanate (eq 20). The nitrile oxide reacts with terminal double bonds in a regioselective manner to give 3,5-substituted isoxazolines.[59]

(20)

Related Reagents.

t-Butyldimethylsilyl Ethylnitronate; ***Lithium α-Lithiomethanenitronate***; ***O,O-Dilithio-1-nitropropene***; ***Nitroethane***; ***1-Nitropropane***; ***1-Nitro-1-propene***.

3-Nitro-9-nitrosocarbazole

[5393-41-9] · $C_{12}H_7N_3O_3$ · 3-Nitro-9-nitrosocarbazole · (MW 241.22)

(mild nitrosating reagent[1])

Physical Data: mp 166-168 °C.

Solubility: sol benzene; insol methanol.

Form Supplied in: brown-yellow needles.

Analysis of Reagent Purity: IR (KBr, cm^{-1}) 3050, 1530, 1440, 1310, 840, 780, 760, 725; MS (m/e (intensity)) 242 (3.8), 241 (M^+, 13.5), 222 (11.5), 211 (90.4), 210 (86.5), 204 (9.6), 181 (32.7), 167 (13.5), 166 (52.9), 165 (28.8), 153 (46.1), 150 (13.5), 149 (100.0).

Preparative Methods: an aqueous solution of ***Sodium Nitrite*** (1.5 g, 22 mmol) is added to a suspension of carbazole (3.0 g, 18 mmol) in nitrobenzene (30 mL), and HCl (2 mL) is then introduced dropwise for 1 h. The reaction mixture is kept at 15 °C for 1 h. To the resulting solution of 9-nitrosocarbazole is added HNO_3 (1 mL) slowly for 30 min, and the solution is kept for 1.5 h. Crystalline 3-nitro-9-nitrosocarbazole (3.5 g, 14 mmol) is obtained when the solvent is evaporated.[2] 3-Nitro-9-nitrosocarbazole (6.65 g, 28 mmol) is also prepared by the reaction of 3-nitrocarbazole (6.39 g, 30 mmol) and sodium nitrite (2.76 g, 40 mmol) in acetic acid (120 mL) at 70 °C.[3]

Purification: recrystallization from acetone or 2-butanone.

Nitrosation.[1]

3-Nitro-9-nitrosocarbazole is a mild nitrosating reagent, which is suitable for nitrosating secondary amines. *N*-Methylaniline (**1**) reacts with 3-nitro-9-nitrosocarbazole (**2**) in refluxing benzene to afford *N*-nitrosomethylaniline (**3**) in 55% yield (eq 1). 3-Nitrocarbazole (**4**) is obtained as a byproduct. However, attempted nitrosation of aziridine (**5**) by

(**2**) does not produce *N*-nitrosoaziridine. Instead, ethylene (42%) and nitrous oxide (50%) are isolated; these might arise from decomposition of *N*-nitrosoazirine (eq 2).

Nitronium Tetrafluoroborate[1]

$NO_2^+BF_4^-$

[13826-86-3] · BF_4NO_2 · Nitronium Tetrafluoroborate · (MW 132.82)

(electrophilic nitrating agent;[1] mild oxidant;[2] hydride and halide abstracting agent[2])

Physical Data: decomposes to NO_2F and BF_3 at temperatures >180 °C.

Solubility: sol sulfolane, acetonitrile; slightly sol nitromethane. Compared with $NO_2^+BF_4^-$, $NO_2^+PF_6^-$ has much higher solubility in organic solvents.

Form Supplied in: colorless crystalline compound; commercially available.

Handling, Storage, and Precautions: due to its hygroscopic nature, $NO_2^+BF_4^-$ should be stored and used under anhydrous conditions. Commercial $NO_2^+BF_4^-$ often contains varying amounts of $NO^+BF_4^-$. Removal of the NO^+ from $NO_2^+BF_4^-$ is difficult. Therefore, pure nitronium tetrafluoroborate should be prepared directly from urea-treated purified HNO_3.[3]

Nitration.

$NO_2^+BF_4^-$ is a highly efficient electrophilic nitrating agent for organic compounds.[1] A variety of arenes have been nitrated by this reagent (eq 1). The ability of $NO_2^+BF_4^-$ to nitrate under anhydrous conditions makes it a reagent of choice for the nitration of aromatics with acid sensitive functional groups, such as nitriles, acid halides, and esters. The nitrations are conveniently carried out in sulfolane solution, although methylene chloride and nitromethane are also used. With severely deactivated arenes such as polyhaloarenes and 1,3-dinitrobenzene, superacids such as ***Fluorosulfuric Acid*** and ***Trifluoromethanesulfonic Acid*** are used as solvents to achieve satisfactory results.[4] The increased reactivity of the nitronium ion in strongly acidic solution results from protosolvation (protonation) of the lone pair electron of NO_2^+ to form the protonitronium dication.[5] Nitration of hexamethylbenzene, nitropentamethylbenzene, bromopentamethylbenzene, and pentamethylbenzoic acid with excess $NO_2^+BF_4^-$

leads to formation of 1,2-dinitro-3,4,5,6-tetramethylbenzene.[6] $NO_2^+BF_4^-$ reacts with methylheptafluoronaphthalene to form addition products.[7]

(1)

Due to its less oxidative nature compared with conventional mixed acids (HNO_3/H_2SO_4), $NO_2^+BF_4^-$ is widely applied in the nitration of heterocyclic compounds. Alkylpyridines,[8] thiophene,[9] and furan,[9] as well as polyheteroatom cyclic compounds[10-12] such as uracils and pentaazaphenalenes, are nitrated under mild conditions. Even macroheterocyclic compounds like porphyrins and metal phthalocyanines (metal = iron, cobalt, nickel) are nitrated with $NO_2^+BF_4^-$.[13]

Electrophilic nitration of alkanes is still of little preparative value in organic synthesis. However, in special cases such as adamantane, nitration with $NO_2^+BF_4^-$ occurs readily to give 1-nitroadamantane in 66% yield (eq 2).[14]

(2)

The reaction of $NO_2^+BF_4^-$ with alkenes generally gives a mixture of addition, addition-elimination, and oligomerization products, with the ratio depending on the nature of the substrates and the reaction conditions.[1c] However, with alkenes such as allyl esters[15] and vinyl halides[16] which contain functional groups capable of stabilizing the reaction intermediates, the addition (nitrofluorination) products can be obtained preferentially. When ***Pyridinium Poly(hydrogen fluoride)*** is used as additional fluoride source, alkenes react with $NO_2^+BF_4^-$ to give β-nitroalkyl fluorides in good yields.[17] With acetonitrile[18] and acetic anhydride,[19] solvoaddition products are also obtained (eq 3).

(3)

Nitration of alkenyloxysilanes and enol acetates with $NO_2^+BF_4^-$ leads to formation of α-nitro ketones.[20] Allylsilanes react with the salt readily to yield nitroalkenes.[21] Nitration of trimethylsilylacetylene or alkynylstannanes with $NO_2^+BF_4^-$ leads to formation of nitroalkynes.[22]

Both primary and secondary amines react with $NO_2^+BF_4^-$ to form nitro amines (eq 4).[1,23] Pyridines are *N*-nitrated to form *N*-nitropyridinium tetrafluoroborates, which have been widely used as transfer nitrating agents.[24] The advantage of using *N*-nitropyridinium salts as nitrating agents is that they react under acid-free conditions. Unsubstituted sulfodiimides or their *N*,*N*-bis(trimethylsilyl) derivatives react with $NO_2^+BF_4^-$ to afford interesting *N*,*N*-dinitrosulfodiimides.[25]

(4)

Nitration of amides with $NO_2^+BF_4^-$ yields *N*-nitroamides.[26] The nitroamides of benzoic and chloroacetic acid are obtained in satisfactory yields but the yield of nitroacetamide is only 12%. *N*-alkyl- and *N*,*N*-dialkylamides are nitrolyzed to form corresponding nitroamines and *N*,*N*-dinitroamines in satisfactory yields.[27] *N*-Alkyl-*N*-nitroamides react similarly with $NO_2^+BF_4^-$ to form dinitroamines in good yields.[28]

Aliphatic isocyanates react with $NO_2^+BF_4^-$ in ethyl acetate or acetonitrile to form nitroamines (after hydrolysis).[29] On the other hand, in conjunction with HNO_3, $NO_2^+BF_4^-$ reacts with isocyanates to yield *N*,*N*-dinitroamines.[30] Alcohols are nitrated with $NO_2^+BF_4^-$ to alkyl nitrates (eq 5).[31] In the presence of other nucleophiles, epoxides are ring-opened by $NO_2^+BF_4^-$.[32]

(5)

Oxidation.

$NO_2^+BF_4^-$ is a mild oxidant. The oxidative ability of the salt is manifested by the formation of products resulting either from coupling or from oxidation in its reaction with electron rich aromatics.[33] The oxidative property of $NO_2^+BF_4^-$ has been utilized to regenerate the masked carbonyls from 1,3-dithioacetals, oximes, and dimethylhydrazones.[34] $NO_2^+BF_4^-$ is also capable of oxidizing ethers to carbonyls,[35a] or converting them into *N*-alkylacetamides by trapping the intermediates with acetonitrile.[35b]

Organic sulfides are oxidized with $NO_2^+BF_4^-$ to form sulfoxides (eq 6).[36] With additional added $NO_2^+BF_4^-$, the sulfoxides can be further converted to sulfones.[36] Phosphines are similarly oxidized to phosphine oxides in quantitative yield.[36] More recently, fullerene (C_{60}) has been oxidized to fullerols by $NO_2^+BF_4^-$ in the presence of carboxylic acids.[37]

(6)

Hydride and Halide Abstraction.

Like ***Nitrosonium Tetrafluoroborate***, $NO_2^+BF_4^-$ is a hydride and halide abstracting agent.[38-41] However, it is less efficient in this aspect compared to $NO^+BF_4^-$.

Related Reagents.

Nitric Acid.

p-Nitroperbenzoic acid[1]

[943-39-5] · $C_7H_5NO_5$ · *p*-Nitroperbenzoic acid · (MW 183.13)

(electrophilic reagent which delivers oxygen to alkenes[2])

Alternate Names: *p*-nitroperoxybenzoic acid; PNPBA.

Physical Data: white crystalline solid; mp 136-137 °C.

Solubility: sol THF, ether, $CHCl_3$, benzene.

Form Supplied in: white powder, 80% purity.

Analysis of Reagent Purity: iodometric titration.

Preparative Method: the reaction between Na_2O_2 and ***p-Nitrobenzoyl Chloride*** in THF in the presence of small quantities of water below -5 °C furnishes the sodium salt of PNPBA. *p,p´*-Dinitrobenzoyl peroxide and *p*-nitrobenzoic acid are removed from the reaction mixture during workup. PNPBA (purity 94-96%) is obtained in 85% yield (0.1 mol scale).[2]

Purification: recrystallization from ether-petroleum ether.

Handling, Storage, and Precautions: at room temperature, PNPBA is stable for long periods.

It should be stored in polyethylene containers in a refrigerator. Since PNPBA is a peroxide and potentially explosive, care should be exercised when carrying out reactions with it; during workup, check for the presence of peroxide before evaporating solvent.

Epoxidation of Alkenes.

Due to the presence of the electron withdrawing NO_2 group, PNPBA epoxidizes alkenes about ten times more rapidly than ***Perbenzoic Acid*** (PBA); ***m-Chloroperbenzoic Acid*** is only slightly more reactive than PBA. *trans*-Stilbene is thus oxidized to *trans*-stilbene oxide (eq 1).[3] A solution of 5.4 g of stilbene (30 mmol) in 60 mL of $CHCl_3$ is added dropwise with stirring to a suspension of 7.5 g (33 mmol) of 80% PNPBA in 100 mL of $CHCl_3$; the reaction mixture is kept at rt for 24 h with occasional shaking, and filtered. The filtrate is washed with 10% aq Na_2CO_3, dried, and the solvent is evaporated. The residue is recrystallized from petroleum ether to give 5.5 g (93%) of the epoxide.

(1)

The monosubstituted alkene (**1**) reacts with PNPBA (22 h, rt) to furnish the epoxidation product in 75% yield.[4] The epoxide (**2**), an intermediate for the synthesis of cyclobutanone, has been prepared in 90% yield by treating methylenecyclopropane with PNPBA in CH_2Cl_2 at -10 °C.[5]

(1)

(2)

Reaction of the α,β-unsaturated ketone (**3**) with PNPBA in benzene (24 h, rt) furnishes the 5β,10β-epoxide in 91% yield.[6] This epoxide cannot be prepared from (**3**) using *m*-CPBA or H_2O_2/MeOH/NaOH. Reaction of the alkene (**4**) with PNPBA in $CHCl_3$ (reflux, 3 days) in the presence of the radical inhibitor 4,4´-thiobis(6-*t*-butyl-3-methylphenol) furnishes the 4α,5α-epoxide in 30% yield.[7] *m*-CPBA and benzonitrile/H_2O_2 are not useful reagents for the epoxidation of (**4**); TBHP/$Mo(CO)_6$ furnishes the epoxide in low yields.

(3)

(4)

Oxidation of Unactivated Hydrocarbons.

Reaction of alicyclic hydrocarbons with PNPBA results in regio- and stereoselective hydroxylation (eq 2).[8] Tertiary alcohols are obtained with high selectivity (>97%); hydroxylation takes place with retention

(>98%) of configuration. Dioxiranes are excellent reagents for the hydroxylation of alicyclic hydrocarbons under mild conditions (see ***Dimethyldioxirane***).[9]

(2)

Baeyer-Villiger reaction.

For an example, see eq 3.[10]

o-Nitrophenol

[88-75-5] · $C_6H_5NO_3$ · *o*-Nitrophenol · (MW 139.12)

(preparation of active esters for peptide synthesis[1])

Physical Data: mp 45 °C; bp 216 °C; pK_a 7.23 (at 25 °C).

Solubility: sol ether, benzene; sparingly sol H_2O.

Form Supplied in: yellow solid, commercially available.

Purification: crystallizes as yellow needles or prisms from ethanol or ether.

Handling, Storage, and Precautions: moderately toxic by inhalation and skin absorption.

Preparation of Active Esters for Peptide Synthesis.

Esters of *o*-nitrophenol, prepared by the ***1,3-Dicyclohexylcarbodiimide*** coupling method, can be used in peptide synthesis (eq 1)[1] in the same way as are the corresponding *p*-nitrophenyl esters (see ***p-Nitrophenol***). *o*-Nitrophenol is less reactive than *p*-nitrophenol in the DCC coupling step; use of pyridine as solvent instead of ethyl acetate increases the nucleophilicity of the hydroxyl group and minimizes side reactions. In the aminolysis step, the *o*-nitrophenyl esters are more reactive than the *p*-isomers, and the reaction rates are less sensitive to changes in solvent or to steric hindrance. *o*-Nitrophenyl esters have been used in a stepwise synthesis of a nonapeptide in which all synthetic operations are performed in the same reaction vessel, without isolation of intermediates (in situ peptide synthesis).[1]

p-Nitrophenol

[100-02-7] · $C_6H_5NO_3$ · *p*-Nitrophenol · (MW 139.12)

(preparation of active esters for peptide synthesis[1])

Physical Data: mp 114 °C; pK_a 7.15 (at 25 °C); dimorphous.

Solubility: moderately sol cold water; sol alcohol, chloroform, ether.

Form Supplied in: generally obtained as a mixture of the two crystalline forms.

Purification: recystallization from toluene gives the metastable α-form if performed at >63 °C; the β-form is obtained as yellow prisms at <63 °C.

Handling, Storage, and Precautions: the α-form is light stable, whereas the yellow β-form gradually turns red in light. Moderately toxic by inhalation and skin absorption.

Preparation of Active Esters for Peptide Synthesis.

p-Nitrophenyl esters, prepared by ***1,3-Dicyclohexylcarbodiimide***-mediated coupling between *N*-protected amino acids and *p*-nitrophenol, are among the most useful activated esters for peptide synthesis (eq 1).[1] They are readily purified by recrystallization, often from alcoholic solvents with which they do not react. Aminolysis occurs at a reasonable rate, generally at room temperature without a catalyst. The *p*-nitrophenol generated as a byproduct in this step is easily removed. *o*-Nitrophenyl esters can be used similarly (see ***o-Nitrophenol***); a study of the rates of aminolysis of Boc-L-leucine nitrophenyl esters showed the *o*-isomer to react 4-9 times faster than the *p*-isomer.[2]

p-Nitrophenol

o-Nitrophenyl Selenocyanate[1]

[51694-22-5] · $C_7H_4N_2O_2Se$ · *o*-Nitrophenyl Selenocyanate · (MW 227.09)

(reagent for alkene synthesis[2-4])

Physical Data: light brown crystals; mp 139-141 °C.

Solubility: sol common organic solvents such as dichloromethane, THF, DMF, and ethanol.

Form Supplied in: commercially available in 98% purity.

Preparative Method: obtained in 66% yield from *o*-nitroaniline by diazotization followed by treatment with ***Potassium Selenocyanate*** in buffer solution containing sodium acetate.[2,5]

Purification: recrystallization from ethanol.

Handling, Storage, and Precautions: highly toxic and irritant agent. Use in a fume hood.

Specific Features of the Reagent.

o-Nitrophenyl selenocyanate is used as an analog of ***Phenyl Selenocyanate*** and is a useful reagent for introducing an *o*-nitrophenylselenenyl group into organic molecules. Advantages of the reagent are: (1) the more facile oxidative elimination ability of the *o*-nitrophenylselenenyl group than that of a simple phenylselenenyl group (~24 times as fast) (eq 1);[2] and (2) the large steric effect of the nitro group at the *ortho* position which allows enantioselective oxidation of prochiral selenides (eq 2).[6] 4,4´-Dichlorodiphenyl diselenide is also a useful reagent for alkene synthesis because of its easy access and facile oxidative elimination.[2a] The yields in elimination reactions of phenyl selenoxides can be improved by a proper choice of reaction conditions.[2b]

(1)

(2)

Alkene Synthesis.

Because of its excellent functional group selectivity and facile elimination ability, the reagent has been widely used for the conversion of primary alcohols into terminal alkenes in the synthesis of numerous natural products. In early applications by Grieco et al., primary alcohols were first transformed to the corresponding bromides or mesylates and then substituted with the *o*-nitrophenylselenolate anion, which was quantitatively generated by treatment of *o*-nitrophenyl selenocyanate or di-*o*-nitrophenyl diselenide with ***Sodium Borohydride***. The substitution products were finally subjected to oxidative rearrangement to afford terminal alkenes (eqs 3 and 4).[7,8]

(4)

More useful methodology for the transformation of primary alcohols to terminal alkenes is the direct reaction with *o*-nitrophenyl selenocyanate in the presence of ***Tri-n-butylphosphine*** to produce the corresponding *o*-nitrophenyl selenides (eq 5),[3] followed by oxidative elimination. This methodology has been extensively employed in the stereoselective synthesis of (±)-antirhine (eq 6),[9] in the total synthesis of erythromycin (eq 7),[10] and in other syntheses.[11]

(5)

(6)

In the presence of tri-*n*-butylphosphine, *o*-nitrophenyl selenocyanate reacts with aldehydes to produce cyanoselenenylation adducts. Oxidation of the adducts with ***Hydrogen Peroxide*** gives α,β-unsaturated nitriles in high yields (eq 8).[4]

Rearrangement of Allylic Alcohols.

Oxidation of allylic selenides provides allylic alcohols via 2,3-sigmatropic rearrangement of the allylic selenoxides.[12] This rearrangement is useful for the conversion of primary allylic alcohols into the rearranged compounds (eq 9).[13]

Ketone Synthesis.

o-Nitrophenylselenolate anions react with epoxides to form ring-opened adducts. These adducts can be easily transformed to ketones by oxidation with hydrogen peroxide (eq 10).[14] This methodology is useful for the one-step synthesis of deoxy-keto sugars.[14]

Synthesis of Selenol Esters.

Like phenyl selenocyanate, *o*-nitrophenyl selenocyanate reacts with carboxylic acids to give selenol esters in the presence of tri-*n*-butylphosphine (eq 11),[15] but the yield is normally modest.

Related Reagents.

Diphenyl Diselenide; ***Phenyl Selenocyanate***.

1-Nitro-2-phenylsulfonylethylene[1]

[101933-29-3] · $C_8H_7NO_4S$ · 1-Nitro-2-phenylsulfonylethylene · (MW 213.23)

(Michael acceptor;[3-5] acetylene equivalent in the Diels-Alder reaction[8,9])

Alternate Name: 1-phenylsulfonyl-2-nitroethylene.

Physical Data: mp 148-150 °C.

Solubility: sol THF, Et_2O, $CHCl_3$, CH_2Cl_2.

Analysis of Reagent Purity: IR 1160, 1350, 1550 cm^{-1}; NMR δ 7.50-7.96.

Preparative Method: by oxidation of ***1-Nitro-2-phenylthioethylene*** with ***m-Chloroperbenzoic Acid*** (2 equiv).[2]

Michael Acceptor.

Addition-elimination reactions of various nucleophiles to this reagent provide a useful method for the preparation of various 1-nitroalkenes. Polyfunctional organozinc and copper reagents react with this reagent to give polyfunctional 1-nitroalkenes. Organometallics bearing an ester (eq 1),[3] diene (eq 2),[4] or oxygen function (eq 3)[5] give terminal nitroalkenes substituted with these functional groups. Thus a precursor for an intramolecular Diels-Alder reaction and new allylic acetates bearing terminal nitroalkenes are readily prepared by this procedure.

Acetylene Equivalent.

This reagent is an excellent dienophile in the Diels-Alder reaction and reacts with various dienes to give the adducts under mild conditions. Subsequent treatment of the resulting β-nitro sulfones with ***Tri-n-butylstannane*** results in the reductive elimination of the nitro and sulfonyl groups[6] to give 1,4-cyclohexadienes. Thus this reagent serves as a very reactive ***Acetylene*** equivalent,[7] and various dienes have been converted into 1,4-cyclohexadienes by this procedure (eqs 4 and 5).[8,9]

1-Nitro-2-phenylthioethylene[1]

[101933-27-1] · $C_8H_7NO_2S$ · 1-Nitro-2-phenylthioethylene · (MW 181.23)

(Michael acceptor for the preparation of nitro enamines,[3,4] α-nitro aldehyde acetals,[5] and indolizines;[6] dienophile in the Diels-Alder reaction[3,7])

Alternate Name: 1-phenylthio-2-nitroethylene.

Solubility: sol EtOH, acetone, THF, Et_2O, $CHCl_3$, CH_2Cl_2.

Analysis of Reagent Purity: NMR δ 6.66 (d, *J* = 12 Hz, 1H), 7.24-7.56 (m, 5H), 8.18 (d, *J* = 12 Hz, 1H).

Preparative Method: from 2-nitroethanol[2] by the sequence shown in eq 1,[3] which can be extended into a general synthesis of β-phenylthio nitroalkenes.[3]

Michael Acceptor.

Electron-deficient alkenes substituted with nitro and phenylthio groups are useful reagents for the preparation of 1-nitroalkenes via the addition-elimination sequence. The reaction with various amines affords a general method for the synthesis of nitro enamines (eq 2).[3,4] However, the reaction with alkoxides does not give 1-alkoxynitroethylenes, but gives 2,2-dialkoxynitroethanes; this affords a useful method for the synthesis of α-nitro aldehyde acetals (eq 3).[5]

(2)

(3)

This reagent reacts with the pyridinium salts in the presence of ***Triethylamine*** to give the indolizine (eq 4)[6] via the azomethine ylide.

(4)

Dienophile.

Although this reagent undergoes the Diels-Alder reaction with reactive dienes (eq 5),[3] its reactivity is low compared to that of the corresponding sulfoxide and sulfone.

(5)

Oxidation of this reagent with ***m-Chloroperbenzoic Acid*** gives 1-phenylsulfinyl-2-nitroethylene, which is an excellent dienophile and acts as a nitroacetylene equivalent in the Diels-Alder reaction (eq 6).[7]

(6)

Related Reagents.

p-Nitrophenyl Trifluoroacetate

[658-78-6] · $C_8H_4F_3NO_4$ · *p*-Nitrophenyl Trifluoroacetate · (MW 235.13)

(preparation of active esters for peptide synthesis[1,2])

Physical Data: mp 36-38 °C (sublimed material).

Form Supplied in: commercially available solid.

Preparative Method: prepared in quantitative yield by heating at reflux a mixture of ***p-Nitrophenol*** and ***Trifluoroacetic Anhydride*** in benzene. Evaporation gives crude, crystalline material (mp 37-39 °C) of sufficient purity for use in peptide synthesis.[1]

Purification: by vacuum sublimation.

Handling, Storage, and Precautions: water sensitive; should be stored in a tightly closed bottle.

Preparation of Active Esters for Peptide Synthesis.

p-Nitrophenyl trifluoroacetate reacts readily with *N*-Cbz protected amino acids in pyridine to give the corresponding *p*-nitrophenyl esters (eq 1),[1,2] without racemization; these activated esters can be employed in peptide synthesis (see also ***p-Nitrophenol***). Protection of side-chain functionality such as hydroxyl or amino groups is necessary in order to avoid side reactions. The only coproduct, trifluoroacetic acid, is water soluble. Isolation of the active ester is not necessary; direct addition of an amino component and 2 equiv of ***Triethylamine*** allows amide formation in the same reaction vessel as active ester formation.[2] This procedure is particularly useful when the activated ester will not crystallize. Formation of the active esters of *N*-Cbz protected peptides by this method is slower and requires heating or longer reaction times. Presumably for this reason, complete racemization is observed in the Anderson test (coupling of CbzGly-L-Phe to Gly-OEt).[3]

2-Nitro-3-pivaloyloxypropene[1]

[78551-14-1] · $C_8H_{13}NO_4$ · 2-Nitro-3-pivaloyloxypropene · (MW 187.22)

(multicoupling reagent; reacts stepwise with two different nucleophiles[1])

Alternate Name: NPP.

Physical Data: mp 18 °C; bp 40-45 °C/0.01 mmHg.

Solubility: sol all organic solvents; decomposes in pyridine and slowly in protic solvents.

Preparative Method: prepared in four steps from ***Formaldehyde***, ***Nitromethane***, and pivaloyl chloride (ca. 25% overall yield at a 0.7 mol scale).[1]

Handling, Storage, and Precautions: can be stored six months at -10 °C without decomposition. Use in a fume hood.

Selective Multicoupling Reagent.

2-Nitro-3-pivaloyloxypropene (NPP) is an exceptionally reactive nitroalkene, since both the nitro group and the allylic pivaloyloxy group contribute to enhance the acceptor properties of the double bond. It reacts under very mild conditions with a broad range of nucleophiles producing polyfunctional nitroalkenes which under the reaction conditions do not react further with the nucleophile added (eq 1).[1-3] The resulting nitroalkenes can react with a different second nucleophile, providing highly functionalized nitroalkanes (eq 2).[3] They also can be converted into ketones by a Nef reaction (eq 3)[3] or reduced to amines.[3] NPP readily undergoes Diels-Alder reactions with various dienes; after an elimination reaction, cyclic enol pivalates are obtained (eqs 4 and 5).[4] The related reagent 2-nitro-3-acetoxypropene can also be prepared. It reacts selectively with the functionalized zinc-copper reagents RCu(CN)ZnI (eq 6).[5]

Substituted NPP Reagents.

A wide range of substituted NPP reagents can be prepared regio- and enantioselectively.[6,7] They display the same reactivity pattern (eqs 7 and 8)[7] and can be used for performing highly diastereoselective cyclizations with chiral enamines (eq 9)[8,9] or β-enamino esters (eq 10).[10]

(8)

(9)

(10)

Interestingly, using enzymatic methods, the preparation of enantiomerically pure NPP derivatives becomes

possible.[11,12] These chiral reagents have been used successfully for performing the above-mentioned [3 + 3] carbocyclization.[9] The NPP reagents demonstrate well the synthetic utility of multicoupling building blocks in organic synthesis.[13,14]

2-Nitropropane[1]

[79-46-9] · $C_3H_7NO_2$ · 2-Nitropropane · (MW 89.11)

(as nitronate, oxidant for allyl and benzyl halides;[2] acyl anion equivalent of acetone, reacts with electrophiles;[3] reactant in electron-transfer reactions;[4] isopropylidene equivalent in cyclopropanations[5])

Physical Data: mp -91 °C; bp 120 °C; *d* 0.988 g cm^{-3}.

Solubility: 1.7 g wt % in H_2O at 25 °C; sol ethanol and ether at 20 °C.

Form Supplied in: liquid; widely available. *Drying:* use calcium chloride, calcium sulfate, or magnesium sulfate.

Handling, Storage, and Precautions: flammable; avoid contact with base; cancer suspect agent; dry nitronate salts can be explosive; bases such as NaOH, TEA, DBU, TMG, NaH, or LDA can be used to deprotonate 2-nitropropane (pK_a = 7.67) to give the ambident nucleophile 2-nitropropane nitronate, which is the reactive form of the reagent. Use in a fume hood.

Oxidizing Agent.

Primary benzylic halides,[2] including heterocyclic halides,[6] are converted to aldehydes by means of 2-nitropropane-***Sodium Ethoxide*** (eq 1).

(1)

Secondary benzylic halides are not oxidized, but secondary allyl halides are oxidized regioselectively and

stereoselectively to α,β-unsaturated aldehydes with sodium 2-nitropropane nitronate in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** (eq 2).[7]

C-Allylation.

Unlike secondary allyl halides, which alkylate the oxygen atoms of the nitronate of 2-nitropropane, primary allyl alcohols, acetates, and phenyl ethers alkylate the carbon atom, leading to *C*-allylated 2-nitropropanes (eq 3).[8] Dichlorobis(triphenylphosphine)palladium(II) with 2 additional equiv of ***Triphenylphosphine*** is used as catalyst.

C-Alkylation.

A variety of alkylating reagents, including *o*- and *p*-nitrobenzyl chlorides,[3] *N*-substituted pyridinium salts,[9] hypervalent iodofluoroalkanes,[10] and organomercury compounds,[11] can be used to alkylate the potassium salt of 2-nitropropane (eq 4).

(4)

Conjugate Addition.

The nitronate salt of 2-nitropropane adds to electron-deficient alkenes (Michael reaction) and with subsequent radical denitration serves as an isopropyl anion equivalent (eq 5).[12]

(5)

Synthesis of 1,1-Dimethylethylenes.

The nitronate salt of 2-nitropropane reacts with geminal dinitroalkanes, resulting in vicinal dinitroalkanes[13a] which can be converted to tetrasubstituted alkenes by reduction (eq 6).[13b]

(6)

Synthesis of Substituted *gem*-Dimethylcyclopropanes.

The sodium or potassium salts of 2-nitropropane can be used as isopropylidene-transfer reagents. In a one-pot, tandem Michael addition-nitrite displacement sequence of reactions, electron-deficient alkenes react with the nitronate salt of 2-nitropropane to give *gem*-dimethylcyclopropanes in good yields (eq 7).[5] The reaction appears to be stereoselective with the various substrates that have been used.[5]

C-C Coupling at β-Carbon.

The α,β-doubly deprotonated 2-nitropropane can be benzylated, benzoylated, and hydroxybenzylated at the β-carbon in modest yields (eq 8).[14]

Related Reagents.

O,O-Dilithio-1-nitropropene; ***1-Nitropropane***.

1-Nitropropane[1]

[108-03-2] · $C_3H_7NO_2$ · 1-Nitropropane · (MW 89.11)

(for aromatic aldehyde to nitrile conversion;[2] nitronate, as acyl anion equivalent of *n*-propanal, as a *n*-propyl anion equivalent, reaction with electrophiles[3])

Physical Data: mp -104 °C; bp 131 °C; *d* 1.001 g cm^{-3}.

Solubility: 1.5 g wt % in H_2O at 25 °C; sol ethanol, ether.

Form Supplied in: liquid, widely available. *Drying:* use calcium chloride, calcium sulfate, magnesium sulfate.

Handling, Storage, and Precautions: flammable; avoid contact with bases; toxic; dry nitronate salts can be explosive; 1-nitropropane (pK_a = 8.98) can be deprotonated by bases such as NaOH, TEA, DBU, TMG, NaH, or LDA. The resulting 1-nitropropane nitronate is the usual reactive form of the reagent.

Conversion of Aromatic Aldehydes to Nitriles.

A one-step method for the conversion of aromatic and heterocyclic aldehydes to nitriles utilizes 1-nitropropane (as the source of hydroxylamine) and $(NH_3)_2HPO_4$ as the reagents (eq 1).[4]

(1)

1,2-Addition to Carbonyl Compounds.

As a nucleophile, 1-nitropropane nitronate reacts with the carbonyl group of aldehydes and ketones (Henry reaction[5]); this is a method of chain extension by three carbon atoms (eq 2).[6]

(2)

The diastereoselectivity of the products obtained from the reaction with aldehydes is dependent upon the reaction conditions employed. The nitro aldol products have been used extensively in synthesis.

1,4-Addition to Carbonyl Compounds.

In the Michael reaction,[7] 1-nitropropane can serve as an *n*-propanoyl equivalent by a subsequent Nef reaction of the conjugate addition product (eq 3).[8]

(3)

Alternatively, 1-nitropropane can serve as an *n*-propyl anion equivalent in the Michael reaction by subsequent radical denitration of the conjugate addition product (eq 4).[9]

(4)

α,α-Doubly Deprotonated 1-Nitropropane.

C-Alkylation, *C*-acylation, and *C*-hydroxyalkylation products are obtained in good yields by the reaction of α,α-doubly deprotonated 1-nitropropane with alkyl halides, carboxylic acid derivatives, and aldehydes and ketones (Henry reaction). In the Henry reaction of the dianion with aldehydes, *threo*-enriched products are obtained. With ketones, better yields of the nitro aldol products are realized than under classical conditions (eq 5).[10]

Silyl Esters of *aci*-1-Nitropropane.

Nitropropane is converted to its *O*-*t*-butyldimethylsilyl ester, which is used as a reagent in the fluoride ion-catalyzed Henry reaction with aldehydes. The reaction gives good yields of products with a >95% *erythro* stereoselectivity (eq 6).[11]

1,3-Dipolar cycloaddition reactions of the silyl nitronates of 1-nitropropane with alkenes have been used to prepare 2-oxazolines, which can be transformed into a variety of nonheterocyclic compounds (eq 7).[12]

Propanenitrile Oxide Precursor.

The 1,3-dipolarophile propanenitrile oxide is prepared from 1-nitropropane for use in situ[13] and can be used to synthesize heterocycles (eq 8).[14]

Related Reagents.

t-Butyldimethylsilyl Ethylnitronate; ***O,O-Dilithio-1-nitropropene***; ***Nitroethane***; ***Nitromethane***.

1-Nitro-1-propene[1]

[3156-70-5] · $C_3H_5NO_2$ · 1-Nitro-1-propene · (MW 87.09)

(Michael addition of various nucleophiles such as organolithium reagents,[5,6] enamines,[13,15,19] allylstannane,[9] and alkyl radicals[22])

Physical Data: bp 58 °C/35 mmHg, 54 °C/28mmHg.

Solubility: sol THF, Et_2O, acetone, CH_2Cl_2, toluene.

Analysis of Reagent Purity: IR: 1655, 1520 cm^{-1}; NMR: δ 1.95 (d, 3H, *J* = 6Hz), 6.83-7.55 (m, 2H).

Preparative Methods: dehydration of 1-nitro-2-propanol with ***Methanesulfonyl Chloride*** and ***Triethylamine*** (30% yield),[2] ***Acetic Anhydride***-AcONa (85% yield),[3] or phthalic anhydride (55% yield).[4]

Handling, Storage, and Precautions: see ***2-Nitro-1-propene***.

Michael Acceptor.

1-Nitropropene is a useful reagent as a Michael acceptor for the addition of various nucleophiles (eq 1) including amines,[1] alcohols,[1] thiols,[1] organolithium reagents (eqs 2 and 3[5,6]), Grignard reagents,[7] enamines,[8] allylstannanes (eq 4),[9] and lithium trialkylalkynylborates.[10] Other organometallic reagents such as organoaluminum compounds[11] and zinc-copper reagents RCu(CN)ZnI[12] are also good candidates as nucleophiles.

(1)

(2)

(3)

syn:*anti* = 84:16

(4)

Formaldehyde dimethylhydrazone readily adds to 1-nitropropene in the absence of base, giving the β-nitrodimethylhydrazone, which is converted into the β-nitroaldehyde by ozonolysis (eq 5).[13]

The Michael addition of 1,3-diketone dianions or 2-aminoenones to 1-nitropropene and subsequent aldol reaction (eqs 6, 7 and 8[14,15,16]) provides a useful strategy for organic synthesis. In addition 1-nitropropene is an efficient reagent for bicycloannulation, as illustrated in eq 7.[17]

Allyl alcohols are prepared by the reaction of 1-nitropropene with thiols and aldehydes followed by reductive elimination of β-nitro sulfides with ***Tri-n-butylstannane*** (eq 9).[16]

As the addition of enolates[18] or enamines[19] to 1-nitropropene proceeds in a stereoselective way, asymmetric Michael addition is possible using chiral enolates (eq 10)[20] or the titanated bislactim ether of cyclo(L-Val-Gly) (eq 11).[21]

1-Nitropropene reacts with alkyl radicals derived from *O*-acyl 2-thiopyridylhydroxamate to from new carbon-carbon bonds (eq 12).[22]

(12)

Diels-Alder Reaction.

1-Nitropropene is a very reactive dienophile in the Diels-Alder reaction, and the regiochemistry is controlled by the nitro group (eq 13).[23]

(13)

Related Reagents.

Nitroethylene; ***2-Nitro-1-propene***.

2-Nitro-1-propene[1]

[4749-28-4] · $C_3H_5NO_2$ · 2-Nitro-1-propene · (MW 87.09)

(Michael addition to afford 1,4-diketones,[4] furans,[7] and pyrroles,[11] and an electrophilic reagent for α-keto cation in the Friedel-Crafts reaction[12])

Physical Data: bp 56-57 °C/86 mmHg, 50 °C/60 mmHg; *n*20D 1.4348, d^{20} 1.0492 g cm^{-3}.

Solubility: sol Et_2O, THF, acetone, CH_2Cl_2.

Preparative Methods: by dehydration of 2-nitro-1-propanol (ca. 98% purity commercially or prepared from ***Nitroethane*** and formalin, yield 70%[2]) with phthalic anhydride (73%)[3] or ***Acetic Anhydride***-AcONa (85%).[4]

Handling, Storage, and Precautions: pure 2-nitro-1-propene may be stored in a freezer for several weeks; best prepared immediately before use since it tends to polymerize; this reagent is a powerful lachrymator. Use in a fume hood.

Michael Acceptor.

This reagent readily undergoes addition reactions with many different nucleophiles to give saturated nitro compounds,[5] which are readily converted into a variety of compounds such as amines or ketones via reduction or the Nef reaction, respectively (eq 1).[1]

Lewis acid-promoted addition of silyl enol ethers to this reagent provides a very useful method for the preparation of 1,4-diketones (eq 2).[4] The 1,4-diketones thus obtained are converted into cyclopentenones in high yields.[5]

Carboxylic acid dianions or ester enolates react with this reagent to give γ-keto acids after hydrolysis (eq 3). However, a low temperature is required to suppress the polymerization of the nitroalkene.[6]

The base-catalyzed addition of 1,3-diketones to 2-nitropropene followed by heating the initial Michael adducts results in the formation of furans. Thus dimedone and acetylacetone react with 2-nitropropene to give the furans shown in eqs 4 and 5.[7]

(4)

(5)

The reaction of this reagent with ketone enolates followed by treatment with ***Acetic Anhydride*** gives acetic nitronic anhydrides, which are converted into 1,4-diketones or pyrroles (eq 6).[8]

(6)

The conjugate addition of sulfonyl carbanions to 2-nitropropene, followed by ozonolysis or acid treatment of the

resulting nitronates (Nef reaction[9]) and subsequent elimination of sulfinic acid from β-ketosulfones with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU), gives α,β-unsaturated ketones (eq 7).[10]

(7)

A unique pyrrole synthesis is realized by the reaction of nitroalkenes with isocyanoacetates. For example, 2-nitropropene condenses with methyl isocyanoacetate in the presence of DBU to produce the pyrrole which is a trail marker pheromone (eq 8).[11]

(8)

Friedel-Crafts-Type Reactions.

A novel electrophilic reagent is formed by diprotonation of nitroalkenes in ***Trifluoromethanesulfonic Acid***. *O,O*-Diprotonated 2-nitropropene undergoes two alternative electrophilic reactions with benzene which yields α-phenylacetone[12] or 4*H*-1,2-benzoxazine,[13] depending on the reaction conditions. These products are not readily synthesized by the conventional Friedel-Crafts reaction. Benzoxazine acts as a precursor of *o*-benzoquinone methide (eq 9).[14]

Diels-Alder Reaction.

This reagent is an excellent dienophile in the Diels-Alder reaction and it reacts with various dienes.[15] The regiochemistry of the Diels-Alder reaction is effectively controlled by the nitro group.[16]

Related Reagents.

Nitroethylene; ***1-Nitro-1-propene***.

3-Nitro-2-pyridinesulfenyl Chloride

[68206-45-1] · $C_5H_3ClN_2O_2S$ · 3-Nitro-2-pyridinesulfenyl Chloride · (MW 190.60)

(for transfer of the 3-nitro-2-pyridinesulfenyl (Npys) group, used as a protecting group both for terminal NH_2 groups and also side-chain NH_2, OH, and SH groups in amino acid chemistry, and for activation of RS groups)

Alternate Name: NpysCl.

Physical Data: mp 217-222 °C (dec).

Solubility: sol CH_2Cl_2.

Analysis of Reagent Purity: may be determined by standard analytical techniques, although one group[1] reports that it observed a melting point different from that previously published.[2]

Preparative Method: may be prepared by chlorination of bis(3-nitro-2-pyridyl) disulfide with gaseous chlorine.[2]

Handling, Storage, and Precautions: moisture sensitive, but stable for several weeks at rt under dry conditions; no decomposition is seen after 6 months in a refrigerator.

Synthesis of N$^{\alpha}$Npys Amino Acids and Peptides.[3,4]

The amino acid or peptide is reacted with the title reagent (**1**) (1.3 equiv) in the presence of ***Triethylamine*** (1.2 equiv) (eq 1). If the amino acid used is in its zwitterionic form, it may be reacted under aqueous conditions, using aqueous ***Sodium Hydroxide*** as the base.

(1)

Protection of Side-Chain Functionalities of Boc-N Amino Acids.[5,6]

The *N*-protected amino acid is reacted with NpysCl (1.3 equiv) in the presence of a base (1.2 equiv), which can be either triethylamine or ***4-Dimethylaminopyridine*** (eq 2). Yields are moderate to good.

(2)

Activation of RS groups.[1,6]

Npys-protected thiols are activated towards attack by free thiols (eq 3). This leads to the formation of disulfides, and is particularly useful in the formation of disulfide bridges in peptide chemistry.

5-Nitro-2-pyridyl Diphenylphosphinate

[80944-63-4] · $C_{17}H_{13}N_2O_4P$ · 5-Nitro-2-pyridyl Diphenylphosphinate · (MW 340.29)

(reagent for peptide synthesis[1])

Physical Data: mp 125-127 °C.

Preparative Method: from diphenylphosphinyl chloride and 2-hydroxy-5-nitropyridine in the presence of ***Triethylamine***.[1]

Peptide Synthesis.

Tetrabutylammonium salts of *N*-protected amino acids can be coupled with amino acid methyl or ethyl esters in the presence of 5-nitropyridyl diphenylphosphinate (**1**).[1] Reaction between tetrabutylammonium *N*-benzoyl-L-leucinate and glycine ethyl ester hydrochloride (Young test) proceeded with little racemization (98% L-isomer) (eq 1). The 2-hydroxy-5-nitropyridine byproduct is water soluble and so is easily separated from the dipeptide. Protection of side-chain functionality such as aliphatic or phenolic hydroxyl groups or imidazole or indole rings is unnecessary.

Using pyridine as solvent, the method was applied to the one-pot cyclization of linear peptides, including the synthesis of gramicidin S (eq 2).[1]

Nitrosocarbonylmethane

[63115-45-7] · $C_2H_3NO_2$ · Nitrosocarbonylmethane · (MW 73.06)

(ene reactions and [4 + 2]cycloadditions)

Solubility: sol commonly used organic solvents.

Preparative Method: prepared in situ by oxidation of acetohydroxamic acid with tetrapropylammonium periodate.

General Discussion.

Nitrosocarbonylmethane, like other acylnitroso compounds, is an exceptionally reactive substance which must be generated in situ. It participates in a variety of reactions, most notably [4 + 2] cycloadditions and ene reactions. A review by Kirby summarizes much of the early work on this class of compounds.[1]

Two methods for generation of nitrosocarbonylmethane have been most commonly employed. The first is via oxidation of acetohydroxamic acid. Tetraalkylammonium periodates such as ***Tetra-n-butylammonium Periodate*** or tetrapropylammonium periodate have been widely used for this process. Keck examined tetraethyl-, tetrapropyl-, and tetra-n-butylammonium periodates and found the tetrapropylammonium periodate to provide the best balance between ease of preparation and solubility properties. Commonly used solvents include DMF, $CHCl_3$, and CH_2Cl_2.

Nitrosocarbonylmethane generated in this way undergoes [4 + 2] cycloaddition with simple dienes in which the nitroso moiety functions as the dienophile (eq 1).

(1)

Oxidation of acetohydroxamic acid in the presence of 9,10-dimethylanthracene leads to the Diels-Alder adduct in good yield. As originally demonstrated by Kirby, this [4 + 2] adduct serves as a very convenient source of nitrosocarbonylmethane under strictly neutral nonoxidizing conditions. Thus (**1**) is a crystalline solid which is easily purified and stable upon storage as the solid; however, heating to 80-110 °C in solution results in release of nitrosocarbonylmethane (and 9,10-dimethylanthracene) (eq 2).[1] The nitrosocarbonylmethane can be employed as a dienophile with other dienes present.

(1)

+ 9,10-DMA (2)

Diels-Alder adducts of other simple nitrosocarbonyl compounds with 9,10-dimethylanthracene can be utilized in similar fashion.

Nitrosocarbonylmethane also participates in ene reactions with appropriate alkenes, and here generation of nitrosocarbonylmethane from (**1**) is preferred. Keck and Yates have provided several examples of ene reactions of simple alkenes using this method (eqs 3 and 4).[2]

Diels-Alder adduct (**1**) is very useful in the preparation of other more complex nitrosocarbonyl compounds. Keck has demonstrated that the lithium enolate of (**1**) can be generated uneventfully with ***Lithium Diisopropylamide*** and used in a variety of alkylation and condensation reactions (eq 5). This methodology thus provides a surrogate for the enolate of nitrosocarbonylmethane, which is, of course, inaccessible by direct means.

Keck and co-workers have utilized this methodology to effect intramolecular [4 + 2] cycloadditions and intramolecular ene reactions of such substituted derivatives of nitrosocarbonylmethane.[3] For example, condensation of (**2**) with sorbaldehyde affords (**3**); subsequent heating of (**3**) in refluxing benzene then affords (**4**) in very high yield (eq 6).

In a synthesis of (+)-perhydrohistrionicotoxin, Keck and Yates used this approach to effect an intramolecular type ene reaction (eq 7).[4]

≡

(7)

quantitative

Additional selected examples of this methodology, i.e. utilization of enolate (**2**) to construct substrates for intramolecular Diels-Alder reactions or ene reactions of substituted derivatives of nitrosocarbonylmethane, are shown (eqs 8 and 9).[5]

≡

(8)

The N-O bond in such Diels-Alder or ene products is easily cleaved reductively. Reagents commonly employed include ***Zinc-Acetic Acid***, ***Aluminum Amalgam***, ***Sodium Amalgam***, ***Titanium(III) Chloride***, and various catalytic hydrogenation protocols. The ease of this reduction, and the possibility for hydroxylation of the C=C double bond produced in the [4 + 2] cycloaddition, has made this a popular strategy for the synthesis of numerous polyhydroxylated nitrogen containing compounds.

For nitrosocarbonylmethane itself, the regioselectivity of bimolecular Diels-Alder reactions is often low. For example, reaction with 1-*t*-butyldimethylsilyloxybutadiene leads to a 1:1 mixture of regioisomeric Diels-Alder adducts (eq 10).[6]

Kirby has also noted the formation of a very unusual product upon reaction of nitrosocarbonylmethane with dienamine (**5**) (eq 11).[7]

Related Reagents.

Benzyloxyhydroxamic Acid.

N-Nitrosodimethylamine[1]

(R = Me)

[62-75-9] · $C_2H_6N_2O$ · *N*-Nitrosodimethylamine · (MW 74.10) (R = Et)

[55-18-5] · $C_4H_{10}N_2O$ · *N*-Nitrosodiethylamine · (MW 102.16) (R = $-(CH_2)_4-$)

[130-55-2] · $C_4H_8N_2O$ · *N*-Nitrosopyrrolidine · (MW 100.14)

(lithiation of the title reagent and its analogs generates α-amino carbanion equivalents which can be alkylated and denitrosated to form secondary amines, 1,2-amino alcohols, α-amino acids, and related compounds[1])

Physical Data: R = Me: bp 154 °C/760 mmHg; *d* 1.006 g cm^{-3}. R = Et: bp 177 °C/760 mmHg; *d* 0.943 g cm^{-3}. R = $(CH_2)_4$: bp 104-106 °C/20 mmHg; *d* 1.085 g cm^{-3}.

Form Supplied in: the three nitrosamines shown are commercially available; others may be prepared from secondary amines and ethyl nitrite by transfer of the nitroso group.

Handling, Storage, and Precautions: nitrosodialkylamines are carcinogenic;[2] use a fume hood; handling and precautions are described by Seebach and Enders.[1]

Introduction.

Nitrosodimethylamine and analogous compounds are important for synthesis of 1.1-dialkylhydrazines (being substrates, not reagents for this purpose). Nitrosodimethylamine (**1**) can be a source of either the dimethylamino group or the nitroso group,[3] but due to its carcinogenicity it is no longer a competitor to other sources of these groups. It is, however, very useful for C-C bond formation with carbon electrophiles. By the reaction sequence lithiation (in this case a typical umpolung), action of an electrophile El-X, and denitrosation, the starting amine is converted to another secondary amine with formal substitution of an α-H by the electrophile (eq 1).

Lithiation.

Solutions of the nitrosamine can be used after removal of the ethanol without isolation or purification. Lithiation is carried out with ***Lithium Diisopropylamide***; 5 min at -80 °C is sufficient time for metalation of a methyl group, 1 h at rt is necessary for a methylene group. Kinetically controlled regiospecific lithiation at the methyl group of an unsymmetrical *N*-nitrosamine can be effected. ***Hexamethylphosphoric Triamide*** increases the metallation rate and stabilizes the solutions of the reagents. Metalation yields of simple aliphatic *N*-nitrosamines often exceed 90%, whereas those of cyclic aliphatic *N*-nitrosamines with four- to seven-membered rings are in the 50-70% range.

C-Alkylation.

C-Alkylation proceeded smoothly in all investigated cases. Alkylation yields for lithiated *N*-nitrosodimethylamine with ***Iodomethane***, *n*-butyl iodide, ***Allyl Bromide***, and ***Benzyl Bromide*** were 75, 75, 90, and 95%, respectively. Alkylation of alkyl lithiomethylnitrosamines with the same alkyl halides gave the corresponding products in ca. 90% yields, whereas alkylation of the cyclic *N*-nitrosamines occurred in ca. 60% yield. Aldehydes and ketones undergo addition to give 1,2-amino alcohols. Thus the pharmaceutically important arylamino alcohols are easily accessible (eq 2). Carboxylations proceed smoothly (eq 3); reaction with acid halides leads to derivatives of α-amino ketones (eq 4). Michael additions to α,β-unsaturated ketones (eq 5) lead to nitrosamines of γ-amino ketones. Additions to nitroalkenes are also possible (eq 6).

(1)

(2)

(1) (3)

(1) (4)

(1) (5)

(1) (6)

Nitriles react with subsequent formation of triazoles (eq 7). The following hetero electrophiles also afforded the expected substitution products: ***Chlorotrimethylsilane***, ***Chlorotrimethylstannane***, disulfides, and diselenides.[4]

(7)

Denitrosation.

Denitrosation by acid alone is a very slow reaction,[5] and a reducing species must be present. Preference is given to either ***Hydrogen Bromide/Acetic Acid*** or ***Raney Nickel***. Catalysis by a copper salt is also reported. The review of the inventors of the method recommends a one-pot procedure combining nitrosation, metalation, alkylation, and denitrosation without isolation of any intermediates.

When the lithiation-alkylation sequence is to be carried out twice, the conformation of the nitrosamino group controls the kinetic position of lithiation.[6] The position of entry of the second alkyl group also depends on temperature.

When two alkylations are carried out at the two α-positions of e.g. nitrosopyrrolidine, the steric result depends on the final protonation step,[7] and may be controlled by the conditions of protonation.

Related Reagents.

N-t-Butoxycarbonyl-N-methylaminomethyllithium; ***N´-t-Butyl-N,N-dimethylformamidine***; ***Dimethylaminomethyllithium***; ***N-(Diphenylmethylene)methanamine***.

Nitrosonium Tetrafluoroborate[1]

$NO^+BF_4^-$

[14635-75-7] · BF_4NO · Nitrosonium Tetrafluoroborate · (MW 116.82)

(efficient nitrosating and diazotizing agent;[1] mild oxidant;[2] hydride- and halide-abstracting agent[2])

Physical Data: d 2.185 g cm^{-3}.[3]

Solubility: sol acetonitrile.

Form Supplied in: colorless crystalline compound; commercially available.

Purification: commercial $NO^+BF_4^-$ frequently contains some $NO_2^+BF_4^-$; NO_2^+ can be removed from $NO^+BF_4^-$ by washing with dry benzene; sublimation (200-250 °C/0.01 mmHg) can be used if highly pure $NO^+BF_4^-$ is needed.[3]

Handling, Storage, and Precautions: due to its hygroscopic nature, $NO^+BF_4^-$ should be stored and used under anhyd conditions; use in a fume hood.

Nitrosation.

$NO^+BF_4^-$ is a highly efficient nitrosating agent, and has been used widely for synthetic purposes. Alcohols and secondary amines react readily with $NO^+BF_4^-$ to form alkyl nitrites and nitrosamines, respectively, in high yields (eqs 1 and 2).[4] Nitrosation of less reactive *N*-alkylamides and sulfonamides can also be achieved without difficulty, where other nitrosating agents are not effective.[5,6] Reaction of $NO^+BF_4^-$ with pyridine yields *N*-nitrosopyridinium tetrafluoroborate.[7] Aziridines react with $NO^+BF_4^-$ to yield nitrosoaziridines. Extrusion of N_2O from the products under thermal decomposition conditions led to formation of carbon-carbon double bonds.[8] This reaction has been employed for the synthesis of *cis*-diazabis-σ-homobenzene.[8a]

$$ROH + NO^+BF_4^- \longrightarrow RONO \qquad (1)$$

$$R^1R^2NH + NO^+BF_4^- \longrightarrow R^1R^2NNO \qquad (2)$$

$$R^1 = \text{alkyl};\ R^2 = \text{alkyl, acyl}$$

Diazotization and Related Reactions.

When primary amines react with $NO^+BF_4^-$, diazonium tetrafluoroborates are generated.[1] This reaction has been extensively studied with arylamines, since it is particularly useful for the isolation of the corresponding diazonium tetrafluoroborates (eq 3).[9] Decomposition of these salts produces fluoroarenes.[10] Isocyanates also react with $NO^+BF_4^-$ to yield diazonium salts.[2a,11] Primary amides can be converted to acids by $NO^+BF_4^-$ via diazotization and subsequent hydrolysis.[12]

$$ArNH_2 \xrightarrow{NO^+BF_4^-} ArN_2^+BF_4^- \longrightarrow ArF \qquad (3)$$

Treatment of alkyl azides with $NO^+BF_4^-$ led to the formation of carbenium ions, which can be intercepted with various nucleophiles such as fluoride, hydroxide, carboxides, and nitriles.[13] The reaction using nitriles has been utilized to prepare dihydroisoquinolines and oxazoles. Vinyl azides react with $NO^+BF_4^-$ to form 1,2,5-oxadiazoles and/or 1,2,4-oxadiazoles, depending on the structures of the substrates.[14] When 1,2-dialkylvinyl azides are used, 1,2,5-oxadiazoles were obtained as the only heterocyclic compounds in 75-80% yields.

Various substituted hydrazines react with $NO^+BF_4^-$ to form azides.[15]

Oxidation.

$NO^+BF_4^-$ is a mild oxidant, with NO/NO^+ having 1.5 V standard oxidation-reduction potential in acetonitrile.[16] It has been widely used as a single electron transfer oxidant. Many arene- and sulfur-containing radical cations have been prepared by treatment of corresponding precursors with $NO^+BF_4^-$ (eq 4).[17,18] The easy removal of the side-product NO makes the procedure especially convenient. These radical cations have played a significant role in the development of organic ferromagnets and conductors.

The oxidative property of $NO^+BF_4^-$ has also been synthetically utilized to regenerate carbonyl groups from masked derivatives such as 1,3-dithioacetals, oximes, and dimethylhydrazones.[19]

The same principle was applied to stereospecific construction of *O*-glycosidic linkages.[20] Treatment of readily available methyl *S*-glycosides with an equimolar amount of $NO^+BF_4^-$ in dry methylene chloride at temperatures between 0 and 25 °C gives high yields of *O*-glycosides in the presence of a hydroxylic component (eq 5). The stereospecificity and lack of complications compared with earlier methods make this procedure very attractive.

(5)

Noteworthy is the oxidative iodination of aromatic compounds with $NO^+BF_4^-$ as catalyst.[21] A wide range of arenes were iodinated with the system $I^-/O_2/NO^+BF_4^-$.[21b] This method is not as effective as I_2/Ag^+, but much more efficient than the use of other oxidative iodination systems such as I_2/Ce^{IV} salts and $I_2/(NH_4)_2S_2O_8$. The more important feature of this transformation is the suppression of side-chain oxidation of alkylarenes.[21c]

Electrophilic Addition to Unsaturated Carbon-Carbon Bonds.

As an electrophilic agent, $NO^+BF_4^-$ is able to initiate electrophilic addition to unsaturated carbon-carbon bonds. Reaction of alkenes with $NO^+BF_4^-$ in the presence of acetonitrile yields imidazoles after reduction (eq 6).[22a] Changing acetonitrile to dimethyl sulfide led to formation of nitrososulfonium tetrafluoroborate (in dimer form).[22b] The dimer can be depolymerized, tautomerized, and hydrolyzed to give oxosulfonium salt, which can be utilized synthetically. $NO^+BF_4^-$ was reported to dimerize certain alkenes and alkynes.[22c,d] In the latter case, the true identity of the reagent that initiates the reaction (whether it is NO^+ or NO_2^+) is unclear. $NO_2^+BF_4^-$ is known to induce the same reaction.[22d]

NO^+ can also insert into the cyclopropane ring, offering a new route to 2-isoxazolines.[23]

Hydride and Halide Abstraction.

$NO^+BF_4^-$ is able to abstract a hydride from a tertiary C-H bond, generating a carbocation. The carbocationic intermediate can be trapped by a fluoride or alkyl nitriles, forming alkyl fluorides or *N*-alkylamides respectively.[24] Silanes also react with $NO^+BF_4^-$ to form fluorosilanes.[25]

In a similar fashion, NO^+ can also abstract a halogen atom from alkyl halides. In the presence of alkyl nitriles, *N*-alkylamides were obtained as a consequence of the Ritter reaction.[26]

Addition to Allenylsilanes.

Allenylsilanes react with nitrosonium tetrafluoroborate in acetonitrile at -30 °C to form 4-trialkylsilylisoxazole derivatives in good yield.[27] This method provides a regiospecific [3 + 2] annulation route to unsymmetrically substituted isoxazoles. The silylisoxazole products can be further elaborated by electrophilic substitution in the same operation (eqs 7 and 8). In these [3 + 2] annulations, $NOBF_4$ is distinctly superior to other nitrosating agents such as ***Nitrosyl Chloride*** and ***Nitrosylsulfuric Acid***.

Nitrosyl Chloride[1]

ClNO

[2696-92-6] · ClNO · Nitrosyl Chloride · (MW 65.46)

(electrophilic and radical nitrosating agent for synthesis of a wide range of nitroso compounds, diazotization, and deamination; addition to alkenes yields chloronitroso derivatives; at high temperatures will chlorinate alkanes)

Physical Data: mp -61.5 °C; bp -6.4 °C; *d* (-12 °C) 1.417 g cm^{-3}; *d* (gas) 2.99 g L^{-1}.

Solubility: sol alcohols, ethers, $CHCl_3$; hydrolyzed in water to give HNO_2, HNO_3, NO, and HCl.

Form Supplied in: readily available as an orange-yellow gas in cylinders, easily condensed to a deep red liquid; often more convenient to generate ClNO in situ from alkyl nitrites and HCl in ether, ethanol, or other organic solvents, or in water from HNO_2 and HCl (or H^+ and Cl^-).

Handling, Storage, and Precautions: ClNO gas is highly irritating to the skin, eyes, and mucous membranes; very irritating odor; can cause fatal pulmonary edema; use in a fume hood; can react violently with acetone.

Nitrosation.

ClNO acts as a powerful electrophilic nitrosating agent,[2] reacting with primary amines to give diazonium ions, secondary amines to give nitrosamines (eq 1), alcohols to give alkyl nitrites, thiols to give thionitrites, and carbonyl compounds to give (usually) keto oximes.[3] The product of *C*-nitrosation can be the monomeric nitroso compound (blue), dimeric nitroso compound (white), or the tautomeric oxime, depending on substrate structure. Cyclic ketones often yield dioximes. ClNO is the effective reagent when diazotization, etc., is carried out in hydrochloric acid[4] (using ***Sodium Nitrite***) due to the equilibrium given in eq 2, for which the equilibrium constant at 25 °C is 1.1×10^{-3} L^2 mol^{-2}.[5]

$$R_2NH + ClNO \longrightarrow R_2NNO + H^+ + Cl^- \quad (1)$$

$$HNO_2 + H^+ + Cl^- \rightleftharpoons ClNO + H_2O \quad (2)$$

The use of ClNO dissolved in organic solvents (or generated in situ from alkyl nitrites and HCl) has some advantage synthetically over acidic aqueous solutions of HNO_2, for reactions of compounds (for example, amines or amides) which only have a limited solubility in water.

ClNO is a very reactive species and reacts with aromatic amines of pK_a >~4 at the encounter limit.[6] BrNO is, as expected, less reactive but bromide ion (and thiocyanate ion) catalysis of nitrosation in water is more pronounced because of the much larger equilibrium constant for BrNO formation.

Ring opening of cyclic ketones can occur by reaction with ClNO and EtOH in liquid SO_2 (eq 3).[7]

(3)

With alkenes, addition occurs to give chloronitroso products (eq 4),[8] a reaction which has some synthetic utility, for example in aziridine synthesis[9] (after reduction of the NO group to NH_2 and ring closure). Generally, ClNO addition follows the Markovnikov rule for unsymmetrical alkenes (and is interpreted as proceeding via a nitroso carbocation intermediate). This reaction was much used in the past to characterize terpenes.[10] With some bicyclic systems (including norbornene and norbornadiene), there is evidence of *syn* addition via a four-center transition state.[11] Generally good yields for this reaction can be obtained by using $NaNO_2$ and HCl.

(4)

Nitroso products can also be obtained photochemically via a radical pathway.[12] An example is shown in eq 5. Under some conditions, *gem*-chloronitroso products are formed (eq 6). The former reaction is used industrially with cyclohexanecarboxylic acid in the manufacture of ε-caprolactam.

(5)

(6)

Peroxycarboxylic acids react with ClNO to give *C*-nitroso compounds.[13] Organometallic compounds such as alkyl (and aryl) Grignard reagents[14] also give nitroso compounds with ClNO.

Chlorination.

At higher temperatures than those used for nitrosation, ClNO will act as a chlorinating agent, particularly for alkanes, again probably by a radical pathway. Chlorinations have also been achieved in other solvents; for example, that of sulfoxides in $CHCl_3$-pyridine (eq 7)[15] and the conversion of thioamides to imidoyl chlorides (eq 8).[16]

Nitrosylsulfuric Acid

$NOHSO_4$

[7782-78-7] · HNO_5S · Nitrosylsulfuric Acid · (MW 127.09)

(nitrosating and diazotizing agent; moderate oxidizing agent)

Physical Data: mp 70 °C.

Solubility: sol sulfuric acid; slightly sol acetic acid, acetonitrile, nitromethane, DMF insol most other organic solvents.

Form Supplied in: pale yellow crystals; commercially available.

Preparative Method: dry SO_2 is allowed to pass into a mixture of 98% nitric acid and acetic acid (3:1) at 0 °C; the precipitated $NOHSO_4$ is washed with acetic acid and carbon tetrachloride and dried under vacuum to give the analytically pure reagent.[1]

Handling, Storage, and Precautions: stable at rt; protect from moisture; use in a fume hood.

Nitrosation.

Like other nitrosonium salts, namely ***Nitrosonium Tetrafluoroborate*** and $NOPF_6$, nitrosylsulfuric acid is an efficient nitrosating agent. It has been reported that $NOHSO_4$ is superior to ***Nitrosyl Chloride*** for the nitrosation of *N*-acylarylamines such as 4-methoxy-3-nitroacetoanilide and 5-acetamido-6-methoxyquinoline (eq 1).[2] $NOHSO_4$ has also been shown to be more efficient than other classical nitrosating agents such as ***Isopentyl Nitrite***, phenyl nitrite, and ***Sodium Nitrite***. For example, successful nitrosation of 3-methyl-5-acetamidoisothiazole was achieved by utilizing nitrosylsulfuric acid in DMF, whereas previous attempts using isopentyl nitrite or sodium nitrite in acetic acid had failed (eq 2).[3] Nitrosation of thebaine in methanol under different conditions using nitrosyl chloride, phenyl nitrite, and $NOHSO_4$ all gave the oxime together with varying amounts of other bimolecular products.[4]

(1)

(2)

The conversion of cyclohexanecarboxylic acid or cyclohexyl aryl ketone to ε-caprolactam by treatment with $NOHSO_4$ in the presence of SO_3 (eq 3) may involve the nitrosation of an enol and Beckmann rearrangement.[5] Nitrosation of pentamethyleneketene under similar conditions also gives ε-caprolactam.[6] Lactams with 11 and 12 carbon atoms in their rings were obtained in good yields by treating cycloundecanoic acid and cyclododecanoic acid with $NOHSO_4$ in chloroform.[7]

(3)

Diazotization and Related Reactions.

Ar-NH_2 to Ar-N_2^+.

Aromatic amines are readily diazotized by $NOHSO_4$ to give the corresponding diazonium hydrogen sulfates. Although solutions of sodium nitrite in concentrated H_2SO_4, instead of pure $NOHSO_4$, have been used for diazotization, the yields of solid diazonium salts were in some cases relatively poor. For the purpose of preparation of pure diazonium hydrogen sulfates free from other mineral acids and salts, solutions or suspensions of the amines in acetic acid were added to a solution of solid $NOHSO_4$ in acetic acid, then ether was added to precipitate the diazonium salts.[8] Nitrosylsulfuric acid is also suitable for the diazotization of weakly basic amines such as nitroanilines (eq 4) and polynitroanilines,[8,9] tetrafluoroanthranilic acid,[10] aminonaphthoquinones,[11] 1,4-diaminoanthraquinones (eq 5)[12] and 2-cyano-4-nitroaniline.[13] In some cases the diazonium salts formed undergo

intramolecular coupling with aryl rings to give azo compounds (eq 6).[14,15]

(4)

(5)

(6)

Ar-NHNH$_2$ to Ar-N$_3$.

Aryl and acyl hydrazines are converted to azides in good yields on treatment with an equimolar amount of $NOHSO_4$ or $NOBF_4$ (eq 7).[16]

(7)

Addition to Alkenes and Dienes.

$NOHSO_4$ adds to trisubstituted alkenes to give β-sulfatooximes (eq 8), which are relatively unstable and react readily with nucleophiles such as ***Piperidine***, MeOH, or AcOK to give the corresponding α-substituted oximes.[17] Conjugated dienes react with $NOHSO_4$ at low temperature in liquid SO_2, giving 1,4-addition products which spontaneously cyclize to 6*H*-1,2-oxazine hydrogen sulfates (eq 9).[18]

(8)

(9)

Other Applications.

Amides and sulfonamides are converted to the corresponding acids by $NOHSO_4$ and other nitrosonium salts at low temperature in acetonitrile or nitromethane (eq 10).[19] Sterically hindered amides also react with ease and good yields, although higher reaction temperatures are needed. A mild cleavage of ethylene dithioacetals to ketones has been achieved with $NOHSO_4$ in methylene chloride or $NaNO_2$ in aq CF_3CO_2H (eq 11).[20]

(10)

(11)

The treatment of 2-amino-4*H*-pyrans with nitrosylsulfuric acid brings about their transformation into 2-pyridones (eq 12).[21]

(12)

All nitrosonium ions are in principle hydride-abstracting agents, and nitrosylsulfuric acid has occasionally been used as a dehydrogenating agent (eq 13).[22]

Nonacarbonyldiiron[1]

$Fe_2(CO)_9$

[15321-51-4] · $C_9Fe_2O_9$ · Nonacarbonyldiiron · (MW 363.79)

(precursor for iron carbonyl complexes, carbonylation, dehalogenation, deoxygenation, and reduction reactions)

Alternate Names: diiron enneacarbonyl; diiron nonacarbonyl; tri-μ-carbonylhexacarbonyldiiron.

Physical Data: mp 100-120 °C (dec); *d* 2.08 g cm^{-3}; X-ray diffraction study.[3]

Solubility: insol organic solvents.

Form Supplied in: orange flaky solid.

Preparative Method: formed by exposing ***Pentacarbonyliron*** to light (eq 1).[1] The complex contains six terminal carbonyl groups and three bridging carbonyl groups.[2]

$$2\ Fe(CO)_5 \xrightarrow[74\%]{h\nu} Fe_2(CO)_9 + CO \qquad (1)$$

Handling, Storage, and Precautions: because of its much lower solubility and volatility, $Fe_2(CO)_9$ is less dangerous to handle than $Fe(CO)_5$, though it should be remembered that $Fe(CO)_5$ is often formed in reactions using $Fe_2(CO)_9$; when handling $Fe_2(CO)_9$, avoid dust formed by this light flaky substance; use in a fume hood; store in a freezer; when fully dried, commercial samples can be pyrophoric.[4]

Diene Complexation.

Cyclohexadiene Series.

Tricarbonyliron complexes are formed by reaction of $Fe(CO)_4$ with dienes. $Fe_2(CO)_9$ is an important starting material for this reaction because it offers a convenient source of $Fe(CO)_4$ generated under much milder conditions than from pentacarbonyliron (eq 2).

$$Fe_2(CO)_9 \longrightarrow Fe(CO)_4 + Fe(CO)_5 \qquad (2)$$

Starting from a cisoid 1,3-diene, $Fe_2(CO)_9$ can yield, under mild thermal conditions, tricarbonyl(η^4-1,3-diene)iron complexes. Cyclohexa-1,4-dienes (readily available from the Birch reduction of substituted benzenes) often require prior conjugation, but conjugated 1,3-dienes (both cyclic and acylic) can be converted into tricarbonyliron complexes directly. Some of the earliest examples[5-9] of complexation of 1,3-dienes employed $Fe_2(CO)_9$ (eq 3, dates shown in parentheses). (Alternative reagents in the early days were ***Pentacarbonyliron*** or ***Dodecacarbonyltriiron***.)

More recently, the use of $Fe_2(CO)_9$ has been increasingly valued because, under mild conditions, improved regio- and stereocontrol are possible, and sensitive functionality is less severely affected by the complexation conditions. Regiocontrol is often a problem in the complexation of 1,4-dienes by high-temperature direct reaction with $Fe(CO)_5$. Preparation of the diene complex (**1**), for example, can be improved by preconjugation of the 1,4-diene with ***p-Toluenesulfonic Acid***[10] and by complexation of the resulting equilibrium concentration of the 1,3-diene with $Fe_2(CO)_9$ under conditions in which the 1,4-isomer does not react (eq 4). Bis-alkene complexes are formed when rearrangement to bring the double bonds into conjugation is not possible.[11]

(4)

(1)

Good diastereoselectivity can also be a significant advantage. The dioxygenation of arenes by *Pseudomonas putida* provides optically active *cis*-diol products.[12] In the mild complexation conditions using $Fe_2(CO)_9$, the chirality of the diol is relayed to tricarbonyliron complexes, providing enantiopure intermediates for use in asymmetric synthesis.[13]

Cycloheptadiene Series.

The treatment of (**2**) with $Fe_2(CO)_9$ in acetone at 35 °C gives a 1:4 mixture in favor of (**4**). Enriched samples of (**3**) or (**4**) are accessible directly (eq 5), according to the reaction conditions.[14]

(5)

(2)

(3) **(4)**

Cycloheptatrienone (tropone) reacts efficiently in 60% yield with $Fe_2(CO)_9$ to give a complex (**5**) in which one double bond remains uncomplexed (eq 6).[15] This double bond displays normal reactivity, while the remaining unsaturation is effectively protected. Dinuclear bis-η^3-tricarbonyliron complexes can also be formed.[16]

(6)

(5)

Complexation of Natural Products.

The $Fe(CO)_3$ moiety can provide a method for diene protection. Steroid interconversions employed tricarbonyl(ergosteryl acetate)iron(0)[17] and tricarbonyl(ergosteryl benzoate)iron(0).[18] Thus treatment of ergosteryl acetate or benzoate with tricarbonyl(4-methoxybenzylideneacetone)iron(0) (preformed by complexation using $Fe_2(CO)_9$, or with $Fe_2(CO)_9$ in the presence of 4-methoxybenzylideneacetone[19]), gives the pure desired steroid complex in good yield (60% and 80%, respectively). Nopadiene has been complexed by reaction with $Fe_2(CO)_9$ to form an optically active metal complex.[20]

Exocyclic Diene Complexation.

Formation of iron carbonyl complexes of (**6**) illustrates the mild nature of the complexation conditions (eq 7).[21]

(6)

(7)

(7) **(8)**

Reaction with $Fe_2(CO)_9$ is *exo* face selective, giving a mixture of the corresponding mono complexes (**7**) (*anti-exo*) and (**8**) (*syn-exo*). Further complexation of (**8**) with $Fe_2(CO)_9$ occurs in a nonstereoselective fashion to give mixtures of the diiron complexes (*anti-exo, syn-endo*), (*anti-exo, syn-exo*), and (*anti-endo, syn-exo*).

On treatment of (**9**) with $Fe_2(CO)_9$, the endocyclic double bond is first coordinated to yield the *exo*-$Fe(CO)_4$ complex (**10**), which then further reacts with $Fe_2(CO)_9$ to afford the diiron complex as a major product (eq 8).

(8)

(9) **(10)**

Heating promotes deoxygenation to form the substituted tricarbonyl(*o*-quinodimethide)iron complex (**11**). Oxidative removal of the $Fe(CO)_3$ moiety in (**11**) affords the indanone derivative (**12**) by CO insertion (eq 9).[22]

(9)

(11) **(12)**

Complexes of 7-azanorbornadienes have been examined as sources of nitrenes.[23]

Complexation of Acyclic Dienes.

Complexation of *trans*-4-methyl-2,4-pentadienol (**13**) with $Fe_2(CO)_9$ gives the dienol complex (**14**) as a yellow oil. The product is valuable as a precursor for the cation (**15**) by reaction with $HPF_6/Ac_2O/Et_2O$ (eq 10).[24] Substituted dienes with the (*Z*) configuration at a methyl-bearing terminus complex less efficiently.[25]

(10)

(13) **(14)** **(15)**

$Fe(CO)_3$-diene aldehydes have been formed using $Fe_2(CO)_9$ in work that culminated in an efficient asymmetric induction using chiral allylborane reagents to give access to metal complexes in high optical purity.[26]

1-Methoxybutadiene has been complexed photochemically using $Fe_2(CO)_9$, instead of the more conventional thermal conditions.[27] Complexation of acyclic dienes with $Fe_2(CO)_9$ constituted the first step toward trimethylenemethane complexes.[28] All details concerning the preparation and spectral properties of tricarbonyl(butadiene)iron complexes are gathered in recent reviews.[29]

$Fe_2(CO)_9$/Ultrasound Method of Complexation.

The reaction of $Fe_2(CO)_9$ with sensitive dienes can be promoted by ultrasound (eq 11). Syntheses of a variety of tricarbonyl(η^4-diene)iron(0) complexes (**16**) use the convenient high-yielding sonication method.[30]

(11)

(16)

$R^1 = OAc$; R^2, R^3, $R^4 = H$; 100%

$Fe_2(CO)_9$ Used with a Tertiary Amine.

Aliphatic trialkylaminotetracarbonyliron(0) complexes result from direct reaction between R_3N and $Fe_2(CO)_9$.[31] Fair to good yields of (**17**) can be obtained (eq 12).

$$R_3N + Fe_2(CO)_9 \xrightarrow[\text{rt, } N_2]{\text{hexane or THF}} R_3N \cdot Fe(CO)_4 + Fe(CO)_5 \quad (12)$$

(17)

The complex (**17**) transfers $Fe(CO)_4$ to dienes, monoenes (resulting in isomerization), and $Fe(CO)_5$ (to form $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$). The R_3N unit can also be replaced by other amines and by phosphines. The amine/phosphine exchange was performed with $Me_3N.Fe(CO)_4$ at 60 °C in quantitative yield after 0.5 h. The amine/diene exchange reaction has been studied with 1,3-cyclohexadiene in hydrocarbon solution at 52 °C (eq 13).

(13)

Other Routes to η^4 Complexes.

Alternative access to $Fe(CO)_3$ complexes are afforded by a variety of more unusual starting materials: cyclopropenes, dibromides, dihydrothiophene dioxides, alkynes/CO, allenes, and cyclohexadienones are all discussed below.

Enone Complexation.

Various α,β-unsaturated ketones form moderately stable tricarbonyliron complexes (**18**),[32,37] and offer access to 1,4-diketones (**19**) by reaction with Grignard reagents, organolithium reagents (eq 14), or organocuprates.[33] Trimethylsilyloxybutadienes require phenyl substituents to form stable complexes by reaction with $Fe_2(CO)_9$.[34] Enone complexes are also useful as transfer reagents to place $Fe(CO)_3$ on diene ligands.[32,35] A related procedure employs complexes of α,β-unsaturated imines in the same way.[36]

(14)

Reagents for asymmetric transfer of $Fe(CO)_3$ to dienes have been obtained thermally from (+)-pulegone[37,38] and (-)-3β-acetyloxypregna-5,16-dien-20-one[38] by reaction with $Fe_2(CO)_9$. The chiral enone complexes are used without isolation to provide a direct synthesis of optically active (diene)$Fe(CO)_3$ complexes in up to 40% ee.[38,39]

Complexes from Alkenediols.

2-Butene-1,4-diols react with $Fe_2(CO)_9$ in the presence of Lewis acids under ultrasound conditions to form η^3-allyliron complexes.[40]

Ferralactone Complexes.

From Oxazines.

The first ferralactone complex (**21**) was obtained during studies on π-allyliron complexes by Heck. The same compounds are also obtained by treatment of oxazines (**20**) with $Fe_2(CO)_9$ (eq 15).[41]

Formation of β- and α-Lactones from Vinyloxiranes.

An oxidative addition of vinyloxiranes (**22**) to iron(0) complexes provides the most usual synthesis of ferralactone complexes (**21**) (eq 16).[42,43]

Efficient preparations are possible using $Fe_2(CO)_9$ according to two different methods (in THF, or in lower polarity solvents with ultrasound) to produce the ferralactone complexes in moderate to excellent yields.[44] Removal of the metal to form δ-lactones has been successfully applied to total syntheses of parasorbic acid (**23**), the carpenter bee pheromone (**24**), and malyngolide (**25**).[45] Epoxide-derived ferralactone complexes have provided key intermediates in syntheses of routiennocin,[46] avermectin B1a,[47] and (-)-valilactone.[48]

Demetalation of ferralactone complexes with ***Cerium(IV) Ammonium Nitrate*** produces β-lactones (at low temperature) and/or δ-lactones (at high temperature, under a high pressure of carbon monoxide).

Formation of β-Lactams.

The synthesis and oxidative demetallation of ferralactam complexes affords a route to β-lactams.[42] The difficulty of preparation of the monoaziridines limits the scope of direct ring opening, but ferralactam complexes are more readily obtained from ferralactones by reaction with an amine and a mild Lewis acid catalyst.[49] This methodology has been successfully applied to the synthesis of (+)-thienamycin (**28**),[50] via the key intermediates (**26**) and (**27**).

(26)

(27)

(28)

Complexes from Electrophilic Cyclopropenes.

Methyl- and phenyl-substituted cyclopropenes have been shown to react with iron carbonyls by ring opening and carbonylation to yield tricarbonyl(η^3,η^1-allylcarbonyl)iron complexes (eq 17).[51]

Franck-Neumann, starting from the easily accessible electrophilic *gem*-dimethylcyclopropenes (**29**), could obtain the carbonyliron adducts (**30**) and (**31**) in excellent yields.[52,53] The reaction of $Fe_2(CO)_9$ with the isomers of Feist's ester (**32**) leads first to the formation of the corresponding tetracarbonyliron alkene complexes (**33**) (eq 18).[54] Reaction of naphthalenocyclopropene with $Fe_2(CO)_9$ has also been studied.[55]

The products from cyclopropene ring opening have the advantage of easy conversion into tricarbonyl(η^4-diene)iron complexes (**34**), its regioisomer and (**35**), by thermal loss of carbon monoxide, or photochemically without CO evolution (eqs 19 and 20).[52,56]

Opening of Cyclopropane Rings.

Ring enlargement of compounds such as bicyclo[4.1.0]hept-2-ene (**36**) or its derivatives (+)-2-carene (**37**) or (+)-3-carene (**38**) by carbonylation results in the formation of bicycloheptenones or cycloheptadiene complexes, depending on the reaction conditions.[57]

Under mild reaction conditions, (+)-2-carene affords the optically active (η^1,η^3) complex (**39**) (eq 21).

Metal and Lewis acid induced carbonylative ring enlargement of chiral and prochiral cyclohexadienes can give access to bicyclo[3.2.1]octanes.[58]

Dehalogenation Reactions.

Formation of Quinonedimethide Complexes.

Formation of a stable quinonedimethide complex (**40**) can be achieved by dehalogenation.[59] The product (**40**) decomposes to benzocyclobutene at 500 °C (eq 22).

(40) (22)

In the bis(bromomethyl)naphthalene series, a σ-bonded $Fe(CO)_4$ product has been reported.[60]

Formation of Cyclobutadiene Complexes.

Cyclobutadiene can be prepared as the stable complex tricarbonyl(cyclobutadiene)iron(0) (**41**), by reaction of 3,4-dichlorocyclobutene with $Fe_2(CO)_9$ (eq 23).[61]

(23)

(41)

Dehalogenation of α,α´-dihaloalkenes and Ketones.

The preparation (eq 24) of the iron carbonyl complex of trimethylenemethane (**42**)[62] and some $Fe_2(CO)_9$-mediated rearrangements of dibromo ketones[63] constitute the pioneering work in this area. Noyori has extended the dehalogenation reaction of α-halo ketones to α,α´-dibromo ketones and α,α,α´,α´-tetrabromo ketones which can be dehalogenated with $Fe(CO)_5$ or $Fe_2(CO)_9$.[64]

(24)

(42)

Iron-stabilized oxallyl cations (generated in situ (eq 25) from α,α´-dibromo ketones and $Fe_2(CO)_9$) react with alkenes. Noyori used this [3 + 2] cycloaddition reaction to produce cyclopentanone or cyclopentanone derivatives, as illustrated by a single-step synthesis of (±)-α-cuparenone (**43**) (eq 26).[65] The reaction of α,α´-dibromo ketones with enamines and $Fe_2(CO)_9$ yields substituted cyclopentenones in 50-100% yield (eq 27), as illustrated by the reaction with the α-morpholinostyrene (**44**).[66]

(25)

(26)

(43)

(27)

(44)

The reaction with dienes can be carried out either in benzene at 60-80 °C using α,α´-dibromo ketone, diene, and $Fe_2(CO)_9$ (1:large excess:1.2), in benzene at room temperature with irradiation (same ratio of reagents), or in benzene at 80-120 °C using the dibromide and tricarbonyl(η^4-diene)iron(0) complex (1:1.3). Formation of (**45**) (eq 28) provides a typical example.[67]

(28)

(45) 44%

Noyori et al. have reported a general synthesis of tropane alkaloids from α,α´-dibromo ketones.[68] Reaction of tetrabromoacetone, *N*-methoxycarbonylpyrrole, and $Fe_2(CO)_9$ (3:1:1.5 mol ratio) in benzene (50 °C, N_2) produces two isomeric cycloadducts in a 2:1 mixture, which can be used in the preparation of the alcohol (**46**), a key intermediate in the synthesis of scopine and other tropane alkaloids.[69] A more recent example gives access to the

bicyclo[5.2.0]nonene skeleton.[70]

(46)

Reactions with Sulfur Compounds.

Desulfurization of Episulfides.

The reaction of cyclohexene episulfide with $Fe_3(CO)_{12}$, reported by King[71] to produce cyclohexene, has been improved:[72] 2-butene episulfides, e.g. (**47**) ($R^1 = R^2 = Me$, $R^3 = R^4 = H$), yield alkenes by treatment with $Fe_2(CO)_9$ in refluxing benzene (eq 29). The reaction occurs with retention of the stereochemistry in yields superior to 80%.

(47)

(29)

Tetramethylallene episulfide, on the other hand, affords a thioallyl $Fe(CO)_3$ complex.[73]

Reaction with Thioketones.

The reaction of thiobenzophenone derivatives (**48**) and similar compounds with $Fe_2(CO)_9$ has been studied by Alper.[74] It has been shown to result in the formation of *ortho*-metalated complexes (**49**) in reasonable to high yields (eq 30). Treatment of the complexes (**49**) with ***Mercury(II) Acetate*** effects *ortho*-mercuration.[75] Thioketene complexes have also been examined.[76] Complexes of type (**49**) offer a new route to lactones.[74]

(48) **(49)**

(30)

R = H, Me, OMe, NMe_2

Reaction with 2,5-Dihydrothiophene 1,1-Dioxide.

2,5-Dihydrothiophene 1,1-dioxides are known to be converted into 1,3-dienes after thermal displacement of sulfur dioxide.[77] Reaction in situ with $Fe_2(CO)_9$ offers a general preparation of highly functionalized tricarbonyl(η^4-buta-1,3-diene)iron(0) complexes (**50**) (eq 31).[78]

(31)

(50)

Reactions with Alkynes.

$Fe_2(CO)_9$ reacts with acetylene by carbonylation/cyclotrimerization leading to the formation of tricarbonyl(tropone)iron(0) (**51**) (eq 32). (For comparison with direct complexation of tropone, see eq 6.) This complex is obtained in low yield (28%) with $Fe_2(CO)_9$, but this represents a significant improvement on results obtained with $Fe(CO)_5$.[79]

(32)

(51)

Hexyne is carbonylated by $Fe_2(CO)_9$. An intermediate can be isolated.[80] Alkylthioalkynes are not desulfurized but form iron complexes.[81]

Reaction with Acid Chlorides.

The reaction of an acid chloride with one equivalent of $Fe_2(CO)_9$ affords symmetrical ketones.[82]

Formation of 1,2,4-Triazines.

1,2,4-Triazines, e.g. (**54**), are formed regioselectively (eq 33) by cocyclization of adiponitrile (**52**) and a nitrile (**53**) in the presence of $Fe_2(CO)_9$.[83]

(33)

Deprotection and Deoxygenation Reactions of Oximes and Isobenzofurans.

Oximes, oximic ethers, or oxime *O*-acetates can be converted into the corresponding ketones by reaction with $Fe_2(CO)_9$ in methanol at 60 °C.[84] Deoxygenation of 7-oxabicyclo[2.2.1]dienes with $Fe_2(CO)_9$ affords aromatic products.[85] This method is particularly recommended for deoxygenation of (**55**) in the formation of (**56**) (eq 34).[86]

(34)

Reaction with Electrophilic Allenes.

Formation of tricarbonyl(1,3-butadiene)iron(0) complexes from allenes (e.g. **57**) is possible via tricarbonyl(trimethylenemethane)iron(0) intermediates (eq 35).[87]

Cyclohexadienone Reductions with $Fe_2(CO)_9$ and Water.

Tricarbonyl(cyclohexadienol)iron(0) complexes are formed by selective monohydrogenation of cyclohexadienones (**58**) by reaction with $Fe_2(CO)_9$ and water, under unusually mild conditions (eq 36).[88]

These reactions have been examined with a variety of substrates.[88,89] Regio- and stereoselectivity depends on the pH of the reaction mixture.

Nonafluorobutanesulfonyl Fluoride[1]

[375-72-4] · $C_4F_{10}O_2S$ · Nonafluorobutanesulfonyl Fluoride · (MW 302.11)

(mild alkylating reagent for amines and alkoxysilanes; precursor for nonafluorobutanesulfinic and -sulfonic acids and various nonafluorobutyl sulfones)

Alternate Name: NfF.

Physical Data: bp 65-66 °C/760 mmHg; *d* 1.682 g cm^{-3}.

Solubility: sol ether, THF; insol CH_2Cl_2.

Form Supplied in: colorless to pale yellow liquid of 90% purity; impurities are branched nonafluorobutanesulfonyl fluorides.

Analysis of Reagent Purity: ^{19}F NMR;[1] MS.[2]

Preparative Methods: by electrochemical fluorination of alkanesulfonyl halides in anhyd HF at 4-6 V,[3] or, better, by electrochemical fluorination of sulfolene.[1]

Purification: dried over $CaCl_2$ and distilled.

Handling, Storage, and Precautions: store in amber colored bottles protected from light; for prolonged storage, PVC bottles are recommended.

Reactions with Alcohols and Phenols.

The title reagent reacts with alcohols containing electronegative groups in the presence of ***Triethylamine*** to afford the nonafluorobutanesulfonate esters (nonaflates) (eqs 1 and 2).[4,5] Under these conditions ethanol, for example, affords diethyl ether by alkylation of the ethanolate anion (from EtOH and Et_3N) with the formed ethyl nonaflate (eq 3).

$$Cl_3CCH_2OH + C_4F_9SO_2F \xrightarrow[\text{40\%}]{Et_3N,\ CH_2Cl_2,\ -HF} Cl_3CCH_2ONf \quad (1)$$

$$EtOH + C_4F_9SO_2F \xrightarrow{Et_3N,\ CH_2Cl_2} EtONf \xrightarrow{EtO^-} EtOEt \quad (3)$$

Phenols react with NfF in the presence of Et_3N to form aryl nonaflates in good yields, and these were hydrogenated using Pd/C (10%) as catalyst to give arenes (eq 4).[6] This has found application in the steroid field.[7]

$$ArOH + C_4F_9SO_2F \xrightarrow[\text{80-93\%}]{Et_3N,\ Et_2O} ArONf \xrightarrow[\text{81-100\%}]{\text{10\% Pd/C, MeOH}} ArH \quad (4)$$

Sodium phenolates also react with NfF in ether to afford aryl nonaflates (eq 5).[8a] For ether insoluble systems, especially heterocyclic hydroxy compounds, dimethoxyethane can be substituted as a more suitable solvent.[6]

$$ArOH \xrightarrow[\text{ether or DME}]{NaH} ArONa \xrightarrow[\text{81-98\%}]{C_4F_9SO_2F} ArONf \quad (5)$$

A milder method of preparation of aryl nonaflates is the reaction of aryloxysilanes with NfF in the presence of fluoride ion (eq 6).[9] This reaction has been extended to prepare vinyl nonaflates from the corresponding silyl ethers (eq 7).[8b,c]

$$ArOTMS + C_4F_9SO_2F \xrightarrow[\text{80-93\%}]{Et_3NF,\ -TMSF} ArONf \quad (6)$$

(7)

X = Na, TMS
n = 3-6

Reaction with Amines.

Nonafluorobutanesulfonamides have been prepared by the reaction of NfF with an excess of NH_3 (eq 8).[10] The corresponding ammonium salt formed during this reaction has been isolated,[11] and on acidification with HCl liberates the weakly acidic sulfonamide (eq 9). The sulfonamides have been used in preparing imides and their chemistry studied.[12]

$$C_4F_9SO_2F + 2\ NH_3 \longrightarrow C_4F_9SO_2NH_2 + NH_4F \qquad (8)$$

$$C_4F_9SO_2F + 3\ NH_3 \xrightarrow[-\ NH_4F]{} C_4F_9SO_2NHNH_4 \xrightarrow[-\ NH_4Cl]{HCl} C_4F_9SO_2NH_2 \qquad (9)$$

Other Applications.

NfF was hydrolyzed with aqueous ***Barium Hydroxide***, and the barium salt formed was acidified to give nonafluorobutanesulfonic acid. This acid was converted to the nonafluorobutanesulfonic anhydride (Nf_2O) by treatment with ***Phosphorus(V) Oxide*** (eq 10).[13] Nf_2O can be used instead of ***Trifluoromethanesulfonic Anhydride*** to prepare the homologous nonaflates, which solvolyze about twice as fast as do the triflates.[13]

$$C_4F_9SO_2F + Ba(OH)_2 \xrightarrow{Ba(OH)_2} (C_4F_9SO_3)_2Ba \xrightarrow{H_2SO_4} C_4F_9SO_3H \xrightarrow{P_2O_5} (C_4F_9SO_2)_2O \qquad (10)$$

Hydrazine is found to reduce NfF in ether to give hydrazinium nonaflinate (eq 11), which is hydrolyzed by passing gaseous HCl into the mixture (eq 12).[14] The nonafluorobutanesulfinic acid obtained is useful in preparing nonafluorobutane sulfones (nonaflones) (eq 13).[14]

$$C_4F_9SO_2F + 2\,N_2H_4 \longrightarrow C_4F_9SO_2H \cdot N_2H_4 + 1/2\,[N_2H_4 \cdot 2HF] + 1/2\,N_2 \quad (11)$$

$$C_4F_9SO_2H \cdot N_2H_4 \xrightarrow[-\,N_2H_4 \cdot HCl]{HCl} C_4F_9SO_2H \quad (12)$$

$$C_4F_9SO_2H \xrightarrow{MeI,\ Et_3N,\ HMPA} C_4F_9SO_2Me \quad (13)$$

Nonaflones are also obtained by the reaction of NfF with Grignard reagents (eq 14)[15] and with organolithium reagents (eq 15).[16]

$$C_4F_9SO_2F + RMgBr \xrightarrow{THF} C_4F_9SO_2R \quad (14)$$

$$C_4F_9SO_2F + LiCH_2CN \xrightarrow{THF} C_4F_9SO_2CH_2CN \quad (15)$$

NfF reacts with the sodium salt of ***Diethyl Malonate*** at 20 °C to afford the corresponding nonaflone, which can be hydrolyzed with 40% H_2SO_4 (eq 16).[17]

$$C_4F_9SO_2F + NaCH(CO_2Et)_2 \longrightarrow C_4F_9SO_2CH(CO_2Et)_2 \xrightarrow{40\%\ H_2SO_4} C_4F_9SO_2CHCO_2Et \quad (16)$$

The nonaflones are useful synthetic intermediates in preparing vinyl nonaflones.[16]

Norephedrine-Borane[1]

(+)

[154145-14-9] · $C_9H_{15}B_2NO$ · Norephedrine-Borane · (MW 174.87) (-)

[161512-50-1]

(chirally modified hydride reagent[1])

Alternate Name: (4*S*,5*R*)-(4-methyl-5-phenyl-1,3,2-oxazaborolidine).borane

Physical Data: the title reagent has never been isolated; the structure shown above has been assigned on the basis of related studies[2] and by analogy to other well-characterized 1,3,2-oxazaborolidines.[3]

Solubility: THF.

Preparative Method: a 1M THF solution of BH_3 (3.0 mmol) was added to a THF solution of (-)-norephedrine (1.5 mmol) at -30 °C and the resulting mixture was warmed to 20 °C; the thus-formed chiral hydride reagent was used in situ for enantioselective reductions.

Handling, Storage, and Precautions: moisture sensitive; handle under a dry, inert atmosphere.

Enantioselective Reductions.

This chiral hydride reagent reduces aromatic ketones to the corresponding alcohols with high enantioselectivity (eq 1).[4]

(1)

Anti and *syn* ketoxime ethers are also reduced by this reagent to the corresponding amines in up to 92% ee. The absolute configuration of the resulting amine is dependent on the geometry of the starting oxime ethers: *anti* oximes give (*S*) configurated amines whereas *syn* oximes afford the (*R*) antipodes (eqs 2 and 3); see Table 1.[4,5]

(2)

(3)

Table 1 Enantioselective Oxime Reductions[2,3]

Oxime	R_L	R_S	Config	ee (%)	Yield (%)
anti	Ph	*p*-TolCH_2	*S*	92	64
syn	*p*-TolCH_2	Ph	*R*	92	58
anti	2-Naphthyl	Me	*S*	92	73
syn	Me	2-Naphthyl	*R*	92	
anti	Ph$(CH_2)_2$	Me	*S*	86	40
syn	Me	Ph$(CH_2)_2$	*R*	81	46
anti	Ph	Me	*S*	93	99

Similar results can be obtained if the borane is substituted for the system ***Sodium Borohydride*/*Aluminum Chloride***.[6]

On the basis of experimental[3b] as well as theoretical[7] studies on similar systems, the mechanism of carbonyl reduction is expected to involve:

- 1)In situ formation of the 1,3,2-oxazaborolidine from borane and the 1,2-amino alcohol with 2 equiv of H_2 uptake;
- 2)coordination between the N atom of the oxazaborolidine and a second equivalent of borane;
- 3)coordination at the heterocyclic B atom by the oxygen of the solvent and then by that of the carbonyl compound;
- 4)hydride transfer from the NBH_3^- unit to the substrate via a six-membered transition state.

Although these reactions are expected to be catalytic in oxazaborolidine, the reported examples use the chiral ligand in stoichiometric amounts.

Related Reagents.

Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole.

Octacarbonyldicobalt

$Co_2(CO)_8$

[10210-68-1] · $C_8Co_2O_8$ · Octacarbonyldicobalt · (MW 341.94)

(catalyst for carbonylation and related reactions; major source of other synthetically useful organocobalt compounds)

Alternate Names: di-μ-carbonylhexacarbonyldicobalt; cobalt carbonyl.

Physical Data: mp 51-52 °C (dec); subl 40 °C/vac.

Solubility: insol H_2O; sol common org solvents.

Form Supplied in: dark orange crystals (commonly stabilized with 5-10% hexane).

Handling, Storage, and Precautions: toxic, moderately air sensitive, and unstable at ambient temperature, slowly releasing carbon monoxide (residual finely divided metal may become pyrophoric); may be stored for long periods at or below 0 °C in tightly closed vessels under inert gas (N_2, Ar) or (best) CO; brief handling (including weighing) in air causes no problems; heating in inert solvents yields the less reactive $Co_4(CO)_{12}$; use in a fume hood.

Introduction.

In the crystal, the molecule of this reagent consists of two cobalt atoms linked both directly and by two bridging carbonyls and each carrying three terminal carbonyls (cf. eq 33).[1] In solution this form is in equilibrium with unbridged $(OC)_4Co\text{-}Co(CO)_4$.

Halogen oxidation only leads to a halocarbonyl species in the case of iodine; the unstable and incompletely characterized product, probably $ICo(CO)_4$, has found little use. The anion $Co(CO)_4^-$, readily formed by reduction (***Sodium Amalgam***) or by disproportionation on reaction with bases, including not only pyridine and other nitrogen bases but also such donor solvents as methanol and acetonitrile, is treated separately. (See ***Sodium Tetracarbonylcobaltate***.) However, reactions which utilize $Co_2(CO)_8$ as starting material are included here even if the reaction conditions imply that this anion or its conjugate acid, $HCo(CO)_4$ (also formed from $Co_2(CO)_8 + H_2$), may be the active intermediate. The chemistry of the reagent has been reviewed.[2,3]

Catalytic Uses.

Hydroformylation and Hydrogenation.

Octacarbonyldicobalt catalyzes a wide range of reactions of carbon monoxide (alone or with hydrogen),[2,4-8] of which the best known is probably the hydroformylation (oxo reaction) of alkenes. Depending on reaction conditions, notably $CO:H_2$ ratio and temperature, the products are aldehydes (eq 1) or alcohols (hydroalkylation) (eq 2).

$$RCH{=}CH_2 + CO + H_2 \xrightarrow{130\text{-}180\ ^\circ C} RCH_2CH_2CHO + RCH(Me)CHO \quad (1)$$

$$RCH{=}CH_2 + CO + 2\,H_2 \xrightarrow{160\text{-}200\ ^\circ C} RCH_2CH_2CH_2OH + RCH(Me)CH_2OH \quad (2)$$

A valuable feature is the preference for straight chain over branched chain products; since $HCo(CO)_4$ is an efficient alkene isomerization catalyst, this is true even for internal alkenes. Much research has been devoted to optimizing the product ratio for specific uses, e.g. by adding phosphines or other catalyst modifiers. While cobalt carbonyl (probably as $HCo(CO)_4$) is an effective catalyst for these and many related reactions and has found extensive industrial use (albeit commonly generated in situ rather than introduced as such), it has largely been superseded by related rhodium catalysts; the greater cost of the latter is offset by much higher activity and hence efficient conversions using small catalyst concentrations under much milder reaction conditions. Alkyl halides and alcohols can replace alkenes in many such reaction.

Whereas, in general, reduction of the formyl group (cf. eqs 1 and 2) requires a higher temperature than hydroformylation, reduction of the C=C double bond can be a major side-reaction of cobalt-catalyzed hydroformylation. Thus, in the reaction of eugenol, which is accompanied by cyclization (eq 3), 40% of the starting material is reduced to dihydroeugenol.[9]

(3)

The $Co_2(CO)_8$-catalyzed alkene hydrogenation can be useful, as in the smooth reduction of alkylcinnamaldehydes (eq 4),[10] the highly selective hydrogenation of methyl (*E*,*E*)-octadeca-9,11-dienoate to methyl elaidate (eq 5),[11] and of a range of polycyclic aromatics,[12] e.g. naphthacene (eq 6).

Dehydration or loss of alcohol accompanies hydroalkylation (eq 2) when applied to allylic alcohols (giving tetrahydrofurans rather than 1,4-diols) or to acrylic acids or esters, which give butyrolactones (eq 7) in moderate to excellent yields.[13]

In more or less related reactions, $Co_2(CO)_8$ is a useful catalyst in carboxylation (viz. alkoxycarbonylation) and a wide range of carbonylation reactions. Both catalysis of the water-gas shift reaction[14] and of Fischer-Tropsch processes[15] have been demonstrated on solid supports and probably involve $Co_2(CO)_8$-derived polynuclear carbonyls.[16]

Carboxylation and Related Reactions.

Although nickel, palladium, and other catalysts have been widely studied for carboxylation reactions and are clearly preferable in the case of alkynes, octacarbonyldicobalt (especially in combination with ***Pyridine***) is an effective catalyst for the conversion of alkenes into acids and esters (eq 8) and differs significantly in selectivity from the nickel-based systems. Thus, whereas styrene gives predominantly the branched esters with both types of catalyst, terminal *n*-alkenes give predominantly branched esters with nickel catalysts, but straight-chain esters with $Co_2(CO)_8$, as in eq 9.[4] The related hydrocyanation reaction, on the other hand, gives branched-chain products and, except with the most reactive alkenes, poor yields[17] when using $Co_2(CO)_8$ and better nickel-based catalysts are available.

$$\mathrm{RCH{=}CH_2} + \mathrm{CO} + \mathrm{R'OH} \xrightarrow{\mathrm{Co_2(CO)_8,\ py}} \mathrm{RCH_2CH_2CO_2R'} + \mathrm{RCH(Me)CO_2R'} \quad (8)$$

$\mathrm{R' = H, Me, etc}$

$$+ \mathrm{CO} + \mathrm{H_2} + \mathrm{MeOH} \xrightarrow[\text{(1:12), 175 °C; 95\% conversion}]{\mathrm{Co_2(CO)_8,\ py}}$$

190 bar 10 bar

$$\underset{79\%}{\mathrm{C_8H_{17}CO_2Me}} + \underset{14\%}{\mathrm{Me(CH_2)_5CHMeCO_2Me}} + \underset{4\%}{\mathrm{Me(CH_2)_4CHEtCO_2Me}} + \underset{3\%}{\mathrm{Me(CH_2)_3CHPrCO_2Me}} \quad (9)$$

The condensation of two alkene molecules with ***Carbon Monoxide*** to yield ketones [e.g. ethylene -> 3-pentanone (95%)][4] succeeds well only in special cases, e.g. with methyl acrylate (eq 10).[18]

(10)

Octacarbonyldicobalt-catalyzed homologation of alcohols (eq 11) is difficult to control and of little practical value, while the related carboxylation of methanol to acetic acid requires such extreme conditions that it cannot compete with the technically important rhodium-catalyzed process.

$$ROH + CO + 2\,H_2 \xrightarrow[135\ ^\circ C]{Co_2(CO)_8,\ I_2} RCH_2OH \qquad (11)$$

Relatively mild conditions suffice for the regioselective carbonylation (eq 12)[19] and carboxylation of epoxides (eq 13).[20] The rather poor yields quoted in these examples have been attributed to extensive side-reactions, but specific cases giving excellent results are also known, e.g. with a carbohydrate epoxide (eq 14).[21]

(12)

(13)

(14)

Carboxylations of halogen compounds include the technically useful conversion of chloroacetate to malonate (eq 15),[22] and several patent reports of quantitative conversion of ***Benzyl Chloride*** to phenylacetic acid.[23] The incorporation of two molecules of carbon monoxide to give α-keto-acids, as exemplified by the reaction of benzyl chloride (eq 16), is remarkably solvent-dependent[24] and almost certainly involves reaction of the halide with $Co(CO)_4^-$.

$$ClCH_2CO_2Et + CO + NaOEt \xrightarrow[\substack{7\ bar \\ 55\ ^\circ C \\ 85\%}]{Co_2(CO)_8} CH_2(CO_2Et)_2 \qquad (15)$$

A carboxylation which is followed by a Michael addition occurs with high overall efficiency when ***Acrylonitrile*** reacts in the presence of an alcohol and pyridine (eq 17).[25]

Carbonylation.

This term is used here to denote carbon monoxide insertions (with or without cyclization) which do not involve H_2 or ROH.

Unlike epoxides, oxetanes react with carbon monoxide in the presence of $Co_2(CO)_8$ by ring expansion to γ-butyrolactones, rather than ring opening; thietanes (eq 18) as well as azetidines (eqs 19 and 20) behave similarly. Mixtures of cobalt and ruthenium carbonyls (1:1) are reported to give better yields than either catalyst separately.[26] The examples shown illustrate the strong dependence of regioselectivity on substitution pattern in the azetidine case.[27]

(19)

(20)

$Co_2(CO)_8$-catalyzed reactions of a variety of other nitrogen compounds, e.g. azo compounds (eq 21),[28] imines (eq 22),[29] and amides (eq 23),[30] involve CO insertion into N-N and N-H bonds and cyclizations which probably proceed via cyclometalation.

(21)

(22)

(23)

The mechanism of the remarkable formation of furans[31] from 3-diethylamino-1-propyne (or -butyne) (eq 24) (R = H or Me) is unknown, but it must involve CO insertion into a C-N bond.

(24)

The carbonylation of ***Diphenyl Diselenide*** (eq 25) illustrates the general behavior of diaryl diselenides and ditellurides,[32] but proceeds more smoothly than most other examples studied.

(25)

Reversibility of carbonylation processes is illustrated by decarbonylation of phthalic anhydride by $Co_2(CO)_8$ under H_2 to benzoic acid,[33] and of ***Diphenylketene*** to tetraphenylethylene.[34]

Carbonylation of alkynes is discussed below in connection with the stoichiometric reactions of alkyne-cobalt compounds.

Amidocarbonylation.

The reaction of aldehydes with primary amides and carbon monoxide in the presence of cobalt carbonyl (eq 26) provides a valuable alternative to the Strecker reaction as a route to *N*-acyl-α-amino acids.[8,34-36] Its convenience is enhanced by the possibility of generating the aldehyde in situ by isomerization of an allylic alcohol for which a cocatalyst [$PdCl_2(PPh_3)_2$, ***Carbonylhydridotris(triphenylphosphine)rhodium(I)***, or ***Nonacarbonyldiiron***] is advantageous,[37] (e.g. eq 27), or by hydroformylation of an alkene (e.g. by the reactions of eq 28 which can be combined

to give the *N*-acetylamino acid in 83% yield[8,38]), or of an alcohol (e.g. eq 29). In the last example[39] the product is isolated (as the methyl ester after ***Diazomethane*** treatment) in 73% total yield as a mixture of *threo* and *erythro* isomers.

(26)

(27)

(28)

(29)

Other Octacarbonyldicobalt-Catalyzed Reactions.

A retro-Diels-Alder reaction catalyzed by $Co_2(CO)_8$ was observed in which a barrelene derivative loses a C_2H_2 fragment (eq 30).[40] An analogous cleavage accompanies the cyclopentenone synthesis (see below) when norbornadiene reacts in certain solvents with alkynehexacarbonyldicobalts, as shown by the formation of dicarbonylcyclopentadienylcobalt,[41] whereas a Diels-Alder addition catalyzed by a cobalt carbonyl species is involved when the same reaction is applied to cyclohexadiene.[42]

(30)

Efficient and appreciably regioselective ring-opening addition of ***Cyanotrimethylsilane*** to tetrahydrofurans is illustrated by the example shown (eq 31).[43] The same reagent undergoes $Co_2(CO)_8$ (or ***Dicarbonyl(cyclopentadienyl)cobalt(I)***) catalyzed addition to alkynes to give pyrrole derivatives (eq 32).[44]

(31)

(32)

Octacarbonyldicobalt shares with many other metal carbonyls and other organometallics the ability to catalyze the cyclotrimerization of alkynes[45] and related condensations, e.g. of two alkyne and one nitrile molecule to give pyridines. Derived compounds including $Hg[Co(CO)_4]_2$, $Co(CO)_3NO$ (obtained from $Co_2(CO)_8$ with NO or other nitrosating agents) and the alkyne complexes $(RC_2R')Co_2(CO)_6$ (see below) all share this activity, but none of these compare in

efficiency with the preferred $CpCoL_2$ catalysts.

The few examples of catalytic cyclopentenone formation from alkyne, alkene, and CO are discussed below, as is the bifurylidenedione synthesis from alkyne and CO. It should also be noted that $Co_4(CO)_{12}$, obtained by heating the dinuclear carbonyl, can probably replace the latter in most of the above catalytic reactions, but without obvious advantage.

Stoichiometric Reactions.

Reactions with Dienes.

Conjugated dienes and norbornadiene displace two terminal carbonyl groups from first one and then both metal atoms of the octacarbonyl (eq 33).[46]

(33)

Either of these products can be oxidized to $[(diene)Co(CO)_3]^+$ salts,[47] whose synthetic potential arises from their reactivity towards nucleophiles.[47b,48] Whether 1- or 2-substituted butadiene ligands react highly regioselectively at the 4-position (e.g. eq 34),[47b] or at both C-1 and C-4, depends both on the substituent and on the nucleophile, but attack at C-2 has only been found in the reaction of the butadiene complex with ***Lithium Diisopropylamide***.[48b]

Greater synthetic interest attaches to the cycloaddition of dienolates of β-diketones or β-keto esters, illustrated for the cyclohexadiene complex (eq 35), which leads, after ***Tetra-n-butylammonium Fluoride*** treatment of an intermediate (not isolated), to dihydrofuran derivatives.

Cyclopentadiene does not yield an isolable diene complex when reacting with $Co_2(CO)_8$, yielding instead ***Dicarbonyl(cyclopentadienyl)cobalt(I)***.

Reactions with Alkynes.

In contrast to dienes (see above), alkynes replace the two bridging carbonyls of $Co_2(CO)_8$ producing stable, readily isolated complexes in reactions which are normally rapid at room temperature (eq 36).[49] The alkyne moiety lies at right angles to the Co-Co bond, so that the alkyne carbons form a tetrahedron with the two cobalt atoms. If the alkyne is terminal (R^2 = H), these products (hereafter drawn in the simplified form of eq 37) react with acids (e.g. ***Sulfuric Acid*** in MeOH) to give the trinuclear compounds $RCH_2C[Co_3(CO)_9]$,[50] which also form directly from the alkyne with $Co_2(CO)_8$ at 85 °C.[49b] (For further elaboration of such trinuclear complexes see ***Sodium Tetracarbonylcobaltate***, from which a wider range of such compounds is most conveniently prepared.)

(36)

Reactions of the $(RC_2H)Co_2(CO)_6$ complexes with carbon monoxide under pressure give lactone complexes[51a,b] (reducible to γ-butyrolactones[51c]) by insertion of two CO groups into the Co-C bonds (eq 37); the further stepwise insertion of CO and alkyne provides the mechanism for the efficient $Co_2(CO)_8$-catalyzed synthesis of 2,2´-bifurylidene-5,5´-diones (eq 38).[52] Under relatively mild conditions and with a 1:1 ratio of C_2H_2:CO, the extended bifurandiones of eq 39 also become significant products.[53]

(37)

(38)

(39)

The lactone complexes react with tertiary propynylamines at room temperature in moderate to good yield to give unsaturated aminolactones (eq 40),[54] while bifurandiones incorporating the propynyl group and a solvent-derived hydrogen atom result when quaternary propynylammonium salts are employed under similar conditions (eq 41).[54]

(40)

(41)

Without CO pressure, the monoalkyne complexes react on warming with an excess of alkyne to incorporate two more molecules of the latter, giving flyover complexes (eq 42).[55] These cyclize on oxidation (by Br_2) or on heating (typically to 150-170 °C, but in refluxing toluene in the case of the flyover complex from 3 moles of PhC_2COMe[55b]), yielding benzene derivatives. This reaction sequence represents a significantly different mechanism for alkyne cyclotrimerization under $Co_2(CO)_8$ catalysis compared, for example, to the dicarbonylcyclopentadienylcobalt-catalyzed process. The possibility of employing two different alkynes (eq 42) should permit synthesis of a wider range of benzene derivatives and, indeed, the use of alkynes with bulky R^2 groups (e.g. R^2 = *t*-Bu) provides a route to benzene derivatives with two

such groups in adjacent positions (e.g. 1,2-di-*t*-butyl- and 1,2,4,5-tetra-*t*-butylbenzenes from the flyovers with R^1 = H or *t*-Bu and R^2 = *t*-Bu).[56] However, since the initial complex, $(R^1C_2H)Co_2(CO)_6$, also undergoes alkyne exchange with the added alkyne, yields are severely limited and product mixtures are inevitably formed.[56]

(42)

Intermediates of the reaction of eq 42 are not normally observed, but some examples of complexes formed from octacarbonyldicobalt and two alkyne moieties are known, e.g. from cyclooctyne, giving a product which promotes the cyclotrimerization of cyclooctyne (eq 43),[57] and also from $MeN(CMe_2C_2H)_2$.[58] The product of the latter reaction has been treated with phenylacetylene,[58] forming an arene system (eq 44). Thus, both of these examples show that this type of bis(alkyne)cobalt complex can also be on the cyclotrimerization pathway.

(43)

Alkyne Protection, Distortion, and Altered Substituent Reactivity.

The hexacarbonyldicobalt moiety of the bridged alkyne complexes $(R^1C_2R^2)Co_2(CO)_6$ can serve as a valuable protecting group which allows one to perform on other parts of the organic ligand reactions which would not be possible with the free alkyne. At the same time, complexation reduces the bond order from triple to approximately that of a double bond, with corresponding change in bond angles. Hence substituents are in much more favorable locations for many cyclization reactions. Some of the most elegant synthetic applications use both of these features in combination with the α-cation stabilization discussed in the next subsection.

The first demonstration of the stabilizing effect[59] involved Friedel-Crafts acetylation of the tolane complex to give regioselectively the 4-acetyl and 4,4´-diacetyl derivatives and the smooth liberation of the free alkynes by cerium(IV) oxidation. Open-chain enyne complexes (even with the double and triple bonds conjugated) were shown[60] to undergo smooth acid-catalyzed hydration and hydroboration/***Hydrogen Peroxide*** oxidation (e.g. eq 45), as well as reduction of the double bond (by N_2H_2) and again oxidative decomplexation, while the 5,6-double bond of complexed Δ^5-17-ethynylandrostene-3,17-diol was reduced by hydroboration followed by acetic acid treatment.[60] The protective effect has also been utilized to prevent alkyne-to-allene isomerization during oxidation of an allylic alcohol function.[61]

The effect of distortion is clearly revealed in the macrocyclization of the but-2-yne-1,5-diol complex with diphenyldichlorosilane (eq 46),[62] by elegant syntheses of cycloene-diynes related to calicheamicin (e.g. eq 47),[63] 10- and 11-membered ring lactones (e.g. eq 48),[64] but most strikingly in the construction of the cyclooctadecanonayne system by oxidative coupling of 1,3,5-hexatriyne, complexed to phosphine-substituted cobalt carbonyl (eq 49).[65]

(46)

(47)

(48)

(49)

Steric effects of the hexacarbonyldicobalt moiety may be responsible for altered reactivity, notably enhanced stereoselectivity in reactions of adjacent substituents, e.g. formyl groups in aldol condensations.[66] Thus, condensation of trimethylsilylpropynal with the silyl enol ether of cyclopentanone gives a 90% yield of the aldol product (eq 50) as a 40:60 *erythro:threo* mixture, whereas reaction of the $Co_2(CO)_6$-complexed aldehyde followed by cerium(IV) oxidation gives the same total yield, but in an 87:13 diastereomeric ratio.[66a]

(50)

Cobalt-Complexed Propargyl Cations and Their Reactions.

The stability and synthetic utility of hexacarbonyldicobalt complexed cations was first reported in 1971.[60,67] They are readily formed by protonation of propargyl alcohol complexes or addition of electrophiles (protons, or alkyl or acyl cations) to vinylacetylene complexes. They can be isolated in pure form, usually by precipitation as hexafluorophosphates or tetrafluoroborates, but are more commonly generated in situ and used directly. Most of the early work is due to Nicholas, who has comprehensively reviewed the work up to 1986.[68] A detailed description of the procedure for generating the 1-methyl-2-propynyl complex and for its reaction with trimethylsilyloxycyclohexene (eq

51) has been given.[69]

(51)

More recent studies of the utility of the complexed cations in synthesis have paid particular attention to stereoselectivity in their reaction with silyl enolates[70] and enol borates,[71] e.g. eq 52; in this case the same products result, but with only 2.5:1 stereoselection when using the triethylsilyl enol ether and ***Boron Trifluoride Etherate*** catalysis.

(52)

Replacement of one carbonyl group by phosphine (thus creating chirality at cobalt) has been shown to permit enantioselective addition of nucleophiles to the cations.[72] Regioselectivity of aromatic substitution by the cations has been studied in resorcinol derivatives[73] and examples of aromatic substitution extended to include indoles.[74]

An alternative approach to the antitumor active enediyne systems (cf. eq 47) using Nicholas cations has been

extensively studied[75] and applied to the dynemycin core structure (eq 53).[75c] Another example of the use of such cations in forming strained rings is the preparation of a cobalt complex of a trithia-crown ether (eq 54), which has been shown to complex Cu^I and Ag^I.[76]

(53)

(54)

Cyclopentenone Synthesis.

Synthesis of cyclopentenones from alkynes + alkenes + CO has become a widely used process and is variously known as the Khand reaction or the Pauson-Khand reaction. Although inter alia examples promoted by ***Pentacarbonyliron***, ***Hexacarbonylmolybdenum***, tetracarbonylbis(cyclopentadienyl)ditungsten or -molybdenum, and carbene(pentacarbonyl)chromium have been described, octacarbonyldicobalt is the generally used reactant. The method has been extensively reviewed.[52a,77]

The general reaction (eq 55) is most commonly conducted by preparing the intermediate alkyne complex $(R^1C_2R^2)Co_2(CO)_6$, with or without isolation, before adding the alkene component, but this is not necessary. Under a

CO atmosphere, regeneration of this complex from added free alkyne occurs and in at least one case[78] efficient catalytic synthesis has been achieved (eq 56). Under conditions of complete conversion of 1-heptyne, the product was obtained in 47-49% yield and contained only 1-2% of the regioisomer, 3-pentylcyclopent-2-en-1-one.

(55)

(56)

Such high regioselectivity is typical of terminal alkynes, and the less reactive internal alkynes show only slightly lower selectivity in forming the products with the bulkier group (R^1) in the 2-position. Only strong electronic effects may override this sterically determined preference (e.g. see eq 63 below). Regioselectivity with respect to the alkene is much more variable. Simple terminal alkenes show little or no selectivity when the alkyne is also terminal, but significant preference for 5-substitution (R^3 in eq 55) when the alkyne is internal. More efficient regioselection may be achieved with functional substituents, notably electron-donor groups in the homoallylic position, which favor formation of the 5-substituted product.[79] Thus, the example shown in eq 57 is the key step in a formal synthesis of PGA_2;[80] it also illustrates the good yields obtainable by the simple thermal reaction in the case of alkenes with donor substituents.

(57)

Three more general techniques have greatly improved the earlier yields. Discussion of the solid-phase adsorption method is included in more recent reviews.[77a-d] It probably remains the method of choice in selected cases and sometimes has results different from those of other methods. For example, the predominant reduction to cyclopentanone in the intramolecular reaction of *N*-acetyl-*N*-allylpropargylamine (eq 58)[81] and the reductive ether cleavage when related ethers react on alumina (eq 59),[82] is avoided on silica, in the presence of oxygen, with formation of the expected bicyclic products.

(58)

(59)

This solid-phase technique has made possible efficient syntheses of bi- and polycyclic systems from precursors frequently generated via Nicholas cations, (e.g. eq 60)[83] and has been used for intermolecular reactions with methylenecyclopropane (eq 61) and methylenecyclobutane to give spirocyclic cyclopentenone derivatives. (**1**) is the major product when the alkyne is terminal (R^2 = H), but only (**2**) was isolated when EtC_2Et or Me_3SiC_2Me were used.[84]

The more recent and now widely used improvement involves the use of amine oxides, usually ***Trimethylamine N-Oxide***[85a] or ***N-Methylmorpholine N-Oxide***.[86] Alternatively, while requiring slightly higher temperature and longer reaction time, DMSO (or other sulfoxides) can give equally good yields. A range of other polar solvents (e.g. MeOH, MeCN, HCO_2Et) also exert a distinct, but smaller, promoting effect.[87]

N-Methylmorpholine *N*-oxide, preferably as monohydrate,[79b] as well as Me_3NO not only induces cyclopentenone formation under very mild conditions (0-20 °C) and in frequently excellent yields, but also removes some earlier limitations. The reductive processes (eqs 58 and 59) do not occur when these promoters or DMSO are used under oxygen.[85,87] Hence two efficient syntheses of (-)-kainic acid[88] have employed cyclizations of allylpropargylamine derivatives as the key step; in one of these (eq 62), as well as in a synthesis of the dendrobine skeleton,[89] use of a chiral precursor was shown to result in enantiospecific bicyclization.[88a]

Intramolecular cyclizations of enynes using catalytic amounts of octacarbonyldicobalt (3 mol %) succeed in the presence of biphenyl phosphite (10 mol %) undr 3 atm of CO, typically in DMF at 120 °C.[85b]

Whereas in earlier work the (uncatalyzed) reaction of alkenes bearing electron-withdrawing groups with the alkynecobalt complexes gave conjugated dienes as the only or major products,[77] intramolecular cyclizations involving such groups have now been accomplished by both the solid-state method[90] and using *N*-oxide promotion.[91] Moreover, electron-deficient alkynes have been successfully employed in both inter- and intramolecular cases. The use of ethyl 2-butynoate (eq 63) illustrates the preferred orientation in this case.[92]

Further examples of the efficiency of the *N*-oxide method are the formation of bicyclic lactols (e.g. eq 64), utilized in a synthesis of (±)-loganin,[93] and the quantitative cyclization (eq 65) which is the key step in a synthesis of decarboxydemethylquadrone.[94]

(64)

(65)

Finally, reference is made to the remarkably facile cyclization which alkynyl Fischer carbene complexes can undergo[95] under conditions normally leading only to alkyne-cobalt complex formation (eq 66) (M = Cr or W; R = Ph or Et).

(66)

Related Reagents.

Dicarbonyl(cyclopentadienyl)cobalt(I); ***Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide***; ***Sodium Tetracarbonylcobaltate***.

Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide[1]

$Co_2(CO)_8$-$HSiEt_2Me$-CO

($Co_2(CO)_8$)

[10210-68-1] · $C_8Co_2O_8$ · Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide · (MW 341.94)
($HSiEt_2Me$)

[760-32-7] · $C_5H_{14}Si$ · Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide · (MW 102.28)
(CO)

[630-08-0] · CO · Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide · (MW 28.01)

(silyloxymethylenation of alkenes,[2] esters,[3] and aldehydes;[4] silyloxymethylation of epoxides,[8] glycosyl acetates,[11] benzylic esters,[12] and orthoesters;[13] carbonylative ring expansion[5])

Physical Data: $HSiEt_2Me$: bp 77.4 °C; *d*204 0.705 g cm^{-3}; *n*20D 1.3984.

Form Supplied in: $HSiEt_2Me$: colorless oil.

Handling, Storage, and Precautions: see ***Octacarbonyldicobalt*** and ***Carbon Monoxide***.

Silyloxymethylenation.

The $Co_2(CO)_8$/$HSiEt_2Me$/CO reaction of alkenes results in incorporation of CO to give enol silyl ethers (eq 1).[2] The reaction of terminal alkenes such as 1-hexene gives four possible regio- and stereoisomers.[2b]

(1)

The reaction of oxygen-containing compounds with the catalytic system at higher reaction temperatures (140-200 °C) under higher CO pressure (50-80 atm) results in silyloxymethylenation with concomitant cleavage of a carbon-oxygen bond. Esters derived from secondary alcohols are converted to (silyloxymethylene)alkanes (enol silyl ethers), which are useful synthetic intermediates (eq 2).[3] The reaction of lactones can proceed at 120-140 °C when pyridine is used as an additive. $HSiMe_3$, ***Triethylsilane***, and ***Dimethyl(phenyl)silane*** are also effective for the synthesis of enol silyl ethers. For handling of $HSiMe_3$ (bp 6.7 °C) a special syringe has been devised,[4] which should be also useful for storing and handling other low-boiling materials. The reaction of aldehydes affords 1,2-bis(siloxy)alkenes (enediol disilyl ethers) (eq 3).[5] Carbonylative ring-expansion of cyclobutanones to 1,2-bis(siloxy)cyclopentenes can also be achieved (eq 4).[6]

(2)

(3)

(4)

Silylformylation.

Aldehydes are catalytically converted into homologated α-silyloxyaldehydes (eq 5).[7] Ring-opening silylformylation of cyclic ethers, including oxiranes, oxetane, and THF, are also effective (eq 6).[8]

(5)

(6)

Silyloxymethylation.

The catalytic silyloxymethylation has been revealed to have wide applicability to various oxygen-containing compounds such as oxiranes, oxetanes, tetrahydrofurans, glycosyl acetates, benzylic esters, and orthoesters. The reactions are carried out at near-ambient temperatures (0-40 °C) under 1 atm of CO. Generally, the reaction is faster in the order of $HSiMe_3$ > $HSiEtMe_2$ > $HSiEt_2Me$ > $HSiEt_3$. The use of $HSiMe_3$ sometimes causes reduction of substrates, depending on the substrates and solvent used.

Various oxiranes react with $HSiEt_2Me$ and CO in the presence of $Co_2(CO)_8$ to afford 1,3-diol disilyl ethers with *trans* ring opening (eq 7).[4,9] Stereospecific silyloxymethylation is demonstrated in the reaction of *cis*- and *trans*-2-butene oxide. The reactions of oxetanes[10] and tetrahydrofurans[11] also involve ring-opening silyloxymethylation.

(7)

Highly stereoselective silyloxymethylation at the anomeric center of glycosyl acetates can be attained with the $Co_2(CO)_8$/$HSiMe_3$/CO catalytic system under mild reaction conditions (eq 8).[12] The reaction of benzyl acetates gives β-phenethyl alcohol derivatives (eq 9).[13] The reaction is applicable to furanyl-, thienyl-, and ferrocenylmethyl acetates. The reaction of cyclic orthoesters results in CO incorporation to give diols having one additional carbon atom (eq 10).[14]

Octacarbonyl(zinc)dicobalt

$Zn[Co(CO)_4]_2$

(*2Co-Zn*)

[16985-99-2] · $C_8Co_2O_8Zn$ · Octacarbonyl(zinc)dicobalt · (MW 407.33) ($Cd[Co(CO)_4]_2$(*2Co-Cd*))

[16986-00-8] · $C_8CdCo_2O_8$ · Octacarbonyl(cadmium)dicobalt · (MW 454.35) ($Hg[Co(CO)_4]_2$(*2Co-Hg*))

[13964-88-0] · $C_8Co_2HgO_8$ · Octacarbonyl(mercury)dicobalt · (MW 542.54)

(air-sensitive yet readily available organometallic species capable of catalyzing the selective dimerization of norbornadiene;[1] in an isolated example catalyzes the linear dimerization of a propargyl amine[2])

Alternate Names: bis(tetracarbonylcobalt)zinc; di(cobalttetracarbonyl)zinc.

Physical Data: mp 71-72.5 °C; subl 60 °C/0.005 mmHg. X-ray crystal structure shows each Co to be trigonal bipyramidal (with CO and Zn occupying axial positions) and unbridged Co-Zn-Co.[3]

Solubility: sol heptane, hexane, benzene, toluene, THF, and in acetone to provide enhanced stability; forms complexes with THF from which solvent is difficult to remove.

Form Supplied in: commercially not readily available.

Purification: IR,[4] ^{59}Co NQR,[5] MS,[4a] and Raman.[4b,c]

Preparative Methods: most conveniently prepared from the analogous mercury compound, $Hg[Co(CO)_4]_2$, by reaction with Zn (granular or powder) at 25 °C under argon at atmospheric pressure (93% yield).[4a,b] A variety of procedures which utilize high pressures of CO with ***Octacarbonyldicobalt*** (or various Co salts) and ***Zinc*** are also known.[1a,6] Preparation from ***Sodium Tetracarbonylcobaltate*** and ***Zinc Chloride*** at atmospheric pressure is disfavored due to the numerous manipulations of air-sensitive materials required.[7] A less widely used method from $Co_2(CO)_8$ and powdered Zn in hexanes at atmospheric pressure has been reported[8] as has a simple, yet lower yielding, electrochemical synthesis.[9] The cadmium analog, $Cd[Co(CO)_4]_2$ (recrystallized from hexane at -60 °C;[4a] yellow/orange plate-like crystals mp 79-81 °C;[4b] IR,[4a,c,9,10] ^{59}Co NQR,[5] MS,[4a,11] and Raman[4c,12]), is also available by the techniques described above,[1a,4a,b,6,9] as well by an alternative route from $Hg[Co(CO)_4]_2$.[13]

Octacarbonyl(mercury)dicobalt ($Hg[Co(CO)_4]_2$, recrystallized from acetone/H_2O[13,14] or MeOH;[4a] orange air-stable crystals mp 81-82 °C,[14] partially sublimed at 50 °C/0.1 mmHg;[14] sol heptane, hexane, benzene,

Et_2O, acetone, insol H_2O; IR,[4a,c,10,15] ^{59}Co NQR,[16] MS,[4a,17] Raman,[4c,12,18] and X-ray[19]) is a useful intermediate in the preparation of other cobalt carbonyl derivatives which, unlike $Zn[Co(CO)_4]_2$, $Cd[Co(CO)_4]_2$, and $Co_2(CO)_8$, is stable in air for prolonged periods (in excess of one year). This mercury derivative is conveniently and commonly prepared without the requirement for high-pressure equipment by two general routes. In the first technique, readily available cobalt(II) nitrate hexahydrate is used in a room temperature reaction with CO and mercury(II) cyanide (90% yield).[13,14] Alternatively, $Co_2(CO)_8$ can be treated with either Hg (quantitative yield)[20a] or 1% ***Sodium Amalgam*** (62% yield),[20] again at room temperature and atmospheric pressure. Procedures which utilize higher pressures of CO have also been reported.[6]

Purification: can be recrystallized from toluene at -80 °C,[4a] sublimed at 60 °C/0.005 mmHg;[4b] yellow prismatic crystals.[4b]

Handling, Storage, and Precautions: decomposes readily in air and has been reported as being pyrophoric.[6] Can be handled and stored as a solid or solution in the organic solvents quoted above under inert gas (argon or nitrogen).

Dimerization of Norbornadiene.

The dinuclear catalyst $Zn[Co(CO)_4]_2$ has two cobalt centers connected by zinc and is capable of catalyzing the dimerization of norbornadiene (eq 1).[1] The product of this dimerization has been shown unequivocally to be Binor-S (**1**) and is obtained exclusively and quantitatively when a high catalyst to monomer ratio (1:28) is used in nonpolar solvents (e.g. heptane or toluene) under an inert atmosphere (N_2 or Ar). At lower catalyst to monomer ratios (e.g. 1:238) a mixture of isomeric dimers of norbornadiene results. Furthermore, it was found that Lewis acids (as co-catalysts) activate the dimerization and enhance the formation of Binor-S (**1**). In particular, ***Boron Trifluoride Etherate*** and ***Aluminum Bromide*** were the most effective co-catalysts for the specific dimerization reaction. In the presence of Lewis acids, $Cd[Co(CO)_4]_2$, $In[Co(CO)_4]_3$, and $Co_2(CO)_8$ (all with $BF_3.OEt_2$) also gave quantitative yields of (**1**).

(1)

The use of $Zn[Co(CO)_4]_2$ has significant advantages over other metal-catalyzed dimerizations of norbornadiene (e.g. with $Fe(CO)_5$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$ or, when used in isolation, $Co_2(CO)_8$), where an array of dienes, ketones, and saturated hydrocarbons result in relatively low yields under similar conditions.[21] Additionally, in the reaction with acetylene, octacarbonyl(zinc)dicobalt produces benzene as the main volatile product and approximately 3% of cyclooctatetraene.[1]

By way of a comparison to the use of the title compound as a catalyst for the dimerization shown in eq 1, a range of alternative catalysts which are nearly as effective but which are more readily accessible have been reported.[22] These include $CoBr_2.2PPh_3$, $CoI_2.2PPh_3$, and $RhCl(PPh_3)_3$, all being used with $BF_3.OEt_2$ as the co-catalyst. The complexes are air-stable and are readily obtained from the corresponding anhydrous halides and ***Triphenylphosphine***. When compared to the original $Zn[Co(CO)_4]_2$, these mononuclear catalysts have an induction period prior to reaction. Following initial gentle heating, caution must be observed since the dimerization is exothermic and occasional cooling is required. As with the Zn system, metal-metal bonded intermediates are proposed as the catalytically active species. As part of independent studies, the $CoBr_2.2PPh_3$ catalyst has been utilized to prepare Binor-S (**1**) in 85% yield as part of an efficient synthetic route towards diamantane.[23]

The intermolecular condensation product of $Zn[Co(CO)_4]_2$, the mixed-metal cluster (**2**), can be prepared by heating the title compound in *n*-octane at 70 °C in the dark under a partial vacuum (eq 2).[24] The orange needle-like crystals of bis[μ-(tetracarbonylcobalt)zincio](μ-carbonyl)hexacarbonyldicobalt(*Co-Co*) (**2**) when dissolved in toluene and heated with norbornadiene catalyze the dimerization to Binor-S (**1**) in 70% yield.[24a] This reaction proceeds without the induction periods observed for the previously discussed catalysts.

(2)

(2)

Propargyl Amine Linear Dimerization.

During a study, which generally shows the title compound to be a less efficient catalyst for the isomerization of allyl ethers and the cyclotrimerization of propargyl ethers and amines than alternative cobalt complexes, one unusual reaction is observed. In this isolated example, when 3-diethylaminopropyne is treated with $Zn[Co(CO)_4]_2$ a linear dimer is formed from reaction of the methylene carbon of an amino ethyl group (eq 3).[2]

(3)

Reactions of the Analogous Mercury Compound, $Hg[Co(CO)_4]_2$.

Cyclotrimerization reactions of alkynes in the presence of metal carbonyls is a well-known phenomenon in organometallic chemistry.[25] In particular, octacarbonyl(mercury)dicobalt is an efficient catalyst for this process and, furthermore, when unsymmetrical alkynes are used, good selectivities for the 1,2,4-trisubstituted products are observed (eq 4).[26] In addition, partial intramolecular cyclization resulted when terminal 1,7- or 1,8-diynes were used.[27] The zinc species has not been shown to be an efficient catalyst for the alkyne cyclotrimerization process.

(4)

Two further $Hg[Co(CO)_4]_2$ catalyzed reactions which have not been reported as being mediated by the analogous zinc species are illustrated in eqs 5 and 6. In the former case, symmetrical diaryl ketones can be formed from the corresponding diarylmercury compound under photolysis conditions.[28] Despite good to high yields being observed for diaryl ketones, this process is not applicable to the synthesis of dialkyl ketones. In the latter procedure, *gem*-dihalides can be coupled to give tetrasubstituted alkenes (eq 6).[29] When $Hg[Co(CO)_4]_2$ is employed as the catalyst, higher yields are observed when the reaction is carried out photolytically. A number of alternative metal-cobalt carbonyl species also mediate this transformation.

1,7-Octadien-3-one

[70855-06-0] · $C_8H_{12}O$ · 1,7-Octadien-3-one · (MW 124.20)

(used mainly as a bisannulation reagent to prepare two annulated six-membered rings)

Physical Data: colorless liquid, bp 38-42 °C/3 mmHg, 65 °C/20 mmHg; semicarbazone: mp 180-182 °C.

Solubility: sol most organic solvents.

Preparative Methods: prepared most conveniently by the palladium-catalyzed reaction of ***1,3-Butadiene*** with ***Acetic Acid*** affording an equilibrium mixture (1:3) of 1-acetoxy-2,7-octadiene (**2**) and 3-acetoxy-1,7-octadiene (**1**) (eq 1);[1,2] the lower-boiling (**1**) (90-95 °C/25 mmHg) can be separated from the higher-boiling (**2**) (103-108 °C/25 mmHg) by distillation. The desired allylic acetate (**1**) can also obtained by the palladium-catalyzed allylic rearrangement of the isomeric allylic acetate (**2**); hydrolysis of (**1**) affords 1,7-octadien-3-ol; this allylic alcohol is oxidized with ***Manganese Dioxide*** in CCl_4, or with CrO_3-pyridine in CH_2Cl_2, to afford the title reagent.

In another method, 1,7-octadien-3-ol is prepared in 80% yield by the reaction of ***Acrolein*** with the Grignard reagent prepared from 4-pentenyl bromide (eq 2); Jones oxidation of the alcohol affords 1,7-octadien-3-one in 89% yield.[3]

(2)

Handling, Storage, and Precautions: use in a fume hood.

Bisannulation.

1,7-Octadien-3-one can be regarded as a masked equivalent for 1-octene-3,7-dione, and can be used as a bisannulation reagent for the preparation of two annulated cyclohexene rings. The enone portion of the reagent is used for Michael and aldol reactions, while the terminal double bond serves as a masked methyl ketone which can be unmasked by Wacker-type oxidation with ***Palladium(II) Chloride-Copper(I) Chloride*** in aq DMF.[4] A typical application is shown by the annulation of 2-methylcyclopentane-1,3-dione (eq 3).[1] The first step involves Michael addition to the diketone, which is followed by aldol condensation to give the annulated cyclohexenone. The terminal double bond is then oxidized with catalytic $PdCl_2$/CuCl, yielding the trione. The last step is aldol condensation to generate a new cyclohexenone ring.

(3)

1,7-Octadien-3-one

(+)-19-Nortestosterone has been prepared from a CD ring intermediate by the bisannulation method using 1,7-octadien-3-one according to the sequence of reactions summarized in eq 4.[1,5]

Synthesis of a Trisannulation Reagent.

1,7-Octadien-3-one is converted to 7-acetoxydodeca-1,11-dien-3-one, used as a trisannulation reagent, by the sequence of reactions shown in eq 5.[6] This compound is a masked equivalent for 1-dodecene-3,7,11-trione, with the C-7 and C-11 ketones masked as an acetoxy group and terminal double bond, which can be unmasked in a stepwise manner to generate the ketones.

A steroid synthesis based on the trisannulation is also carried out using the trisannulation reagent described above (eq 6).[6]

[87248-50-8] · $C_{24}H_{38}O_3$ · [(2*S*)-(2α,3aα,4α,7α,7aα)]-2,3,3a,4,5,6,7,7a-Octahydro-7,8,8-trimethyl-4,7-methanobenzofuran-2-ol Acetal Dimer · (MW 374.62) (enantiomeric acetal dimer)

[108031-79-4]

(useful for resolving racemic alcohols via formation of diastereomeric acetals,[1] and also for determining the absolute configuration of certain types of chiral alcohols[2])

Alternate Name: MBF-OH.

Physical Data: monomeric lactol: bp 120 °C/0.005 mmHg, [α]20D + 100° (*c*, 11.24, THF); acetal dimer: mp 150-151 °C, $[\alpha]^{21}$ + 199.1° (*c*, 2.25, THF).

Solubility: monomeric lactol: sol ether, $CHCl_3$, THF; acetal dimer: sol $CHCl_3$, THF, hot petroleum ether.

Form Supplied in: the acetal dimer, and its enantiomer, are available as the neat solids.

Analysis of Reagent Purity: NMR,[3] mp.

Preparative Methods: the [(2*S*)-(2α,3aα,4α,7α,7aα)]-isomer is prepared from (+)-camphor,[3a] and the (2*R*)-enantiomer from (-)-borneol via oxidation to (-)-camphor.[3b]

Purification: the monomeric lactols can be purified by distillation, and the acetal dimers by recrystallization from petroleum ether.

Handling, Storage, and Precautions: no reported instability or toxicity.

Resolving Agent for Chiral Alcohols.

The title lactol reagent (known as the Noe reagent) has been used mainly for resolving racemic alcohols through formation of diastereomeric, separable acetals.[1] From each alcohol enantiomer, a single diastereomer of the product acetal is formed with high selectivity. Separation of the diastereomeric derivatives by chromatography or crystallization, followed by mild methanolysis, gives the resolved alcohol in good yield and high enantiomeric purity. If an excess of the racemic alcohol is employed, enantiomer-selective acetal formation results in one of the product diastereomers being produced in excess, which increases the yield of pure diastereomer obtained (eq 1).[4]

(1)

$R^1 = H$ or MBF

major diastereomer

$R^2 = Me$, 49%; $R^2 = t\text{-Bu}$, 64%

The commercially available acetal dimer (**1**), and the enantiomeric dimer, can also be used as reagents instead of the lactols.[1] As an alternative to the (2*R*)-enantiomer of the *endo*-lactol, one can use the *exo*-lactol (**2**), or the corresponding acetal dimer.[5] Compound (**2**) is prepared from (+)-camphor, as is the (2*S*)-enantiomer of the *endo*-lactol, but the two reagents show opposite sense of enantiomer selectivity in acetal formation.

(1)

(2)

Using these reagents, resolutions of various types of racemic alcohols, including alkylarylcarbinols,[1] alkylthienylcarbinols,[6] cyanohydrins,[1,7] α-hydroxyalkynes,[2b] and α-hydroxyphosphonates,[8] and also of a thiol[1] and an amine,[1] have been performed.

An alternative procedure has been reported for the resolution of alcohols through separation of diastereomeric *O*-methylmandelates;[9] a drawback of this approach is that partial racemization of the mandelic acid derivative sometimes occurs during the esterification. In contrast, the Noe reagents are configurationally stable; also, complete separation of the derived diastereomeric acetals can usually be achieved, which gives access to enantiomerically pure alcohols when the selectivity of the acetal formation is low. An additional advantage of the title reagents is that the derived acetal can be used as an ordinary hydroxyl-protecting group in subsequent synthetic operations, with a reactivity similar to a THP group.[7,10] Of other alternative methods for resolution of racemic alcohols, kinetic resolutions by enzyme-catalyzed transformations often give very high selectivities.[11]

Determination of Absolute Configuration for Chiral Alcohols.

Using NMR data for the derived acetals, in combination with the known sense of enantiomer selectivity for the Noe reagent used, one can also determine the absolute configuration of the starting alcohol.[2] Gas chromatography data can be used as well.[2c] This method for determining absolute configuration should be a useful complement to the more commonly used methods based on NMR analysis of Mosher esters[12] or *O*-

methylmandelates.[9]

Osmium Tetroxide[1]

O_4sO

[20816-12-0] · O_4Os · Osmium Tetroxide · (MW 254.20)

(*cis* dihydroxylation of alkenes; osmylation; asymmetric and diastereoselective dihydroxylation; oxyamination of alkenes)

Physical Data: mp 39.5-41 °C; bp 130 °C; *d* 4.906 g cm^{-3}; chlorine- or ozone-like odor.

Solubility: sol water (5.3% at 0 °C, 7.24% at 25 °C); sol many organic solvents (toluene, *t*-BuOH, CCl_4, acetone, methyl *t*-butyl ether).

Form Supplied in: pale yellow solid in glass ampule, as 4 wt % solution in water, and as 2.5 wt % in *t*-BuOH.

Handling, Storage, and Precautions: vapor is toxic, causing damage to the eyes, respiratory tract, and skin; may cause temporary blindness; LD_{50} 14 mg/kg for the rat, 162 mg/kg for the mouse. Because of its high toxicity and high vapor pressure, it should be handled with extreme care in a chemical fume hood; chemical-resistant gloves, safety goggles, and other protective clothing should be worn; the solid reagent and its solutions should be stored in a refrigerator.

Dihydroxylation of Alkenes.

The *cis* dihydroxylation (osmylation) of alkenes by osmium tetroxide to form *cis*-1,2-diols (*vic*-glycols) is one of the most reliable synthetic transformations (eq 1).[1]

The reaction has been proposed to proceed through a [3 + 2] or [2 + 2] pathway to give the common intermediate osmium(VI) monoglycolate ester (osmate ester), which is then hydrolyzed reductively or oxidatively to give the *cis*-1,2-

diol (eq 2). The *cis* dihydroxylation of alkenes is accelerated by tertiary amines such as ***Pyridine***, quinuclidine, and derivatives of dihydroquinidine (DHQD) or dihydroquinine (DHQ) (eq 3).

Due to the electrophilic nature of osmium tetroxide, electron-withdrawing groups connected to the alkene double bond retard the dihydroxylation.[2] This is in contrast to the oxidation of alkenes by ***Potassium Permanganate***, which preferentially attacks electron-deficient double bonds. However, in the presence of a tertiary amine such as pyridine, even the most electron-deficient alkenes can be osmylated by osmium tetroxide (eq 4).[3] The more highly substituted double bonds are preferentially oxidized (eq 5).

Under stoichiometric and common catalytic osmylation conditions, alkene double bonds are hydroxylated by osmium tetroxide without affecting other functional groups such as hydroxyl groups, aldehyde and ketone carbonyl groups, acetals, triple bonds, and sulfides (see also ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***).

The *cis* dihydroxylation can be performed either stoichiometrically, if the alkene is precious, or more economically and conveniently with a catalytic amount of osmium tetroxide (or its precursors such as osmium chloride or potassium osmate) in conjunction with a cooxidant. In the stoichiometric dihydroxylation, the diol product is usually obtained by the reductive hydrolysis of the osmate ester with a reducing agent such as ***Lithium Aluminum Hydride***, ***Hydrogen Sulfide***, K_2SO_3 or Na_2SO_3, and $KHSO_3$ or $NaHSO_3$. The reduced osmium species is normally removed by filtration. Osmium can be recovered as osmium tetroxide by oxidation of low-valent osmium compounds with hydrogen peroxide.[4] In the catalytic dihydroxylation, the osmate ester is usually hydrolyzed under basic aqueous conditions to produce the diol and osmium(VI) compounds, which are then reoxidized by the cooxidant to osmium tetroxide to continue the catalytic cycle. Normally 0.01% to 2% equiv of osmium tetroxide or precursors are used in the catalytic dihydroxylation. Common cooxidants are metal chlorates, ***N-Methylmorpholine N-Oxide*** (NMO), ***Trimethylamine N-Oxide***, ***Hydrogen Peroxide***, ***t-Butyl Hydroperoxide***, and ***Potassium Ferricyanide***. ***Oxygen*** has also been used as cooxidant in dihydroxylation of certain alkenes.[5] Excess cooxidant and osmium tetroxide are reduced with a reducing agent such as those mentioned above during the workup. The stoichiometric dihydroxylation can be carried out in almost any inert organic solvent, including most commonly MTBE, toluene, and *t*-BuOH. In the catalytic dihydroxylation, in order to dissolve the inorganic cooxidant and other additives, a mixture of water and an organic solvent are often used. The most common solvent combinations in this case are acetone-water and *t*-BuOH-water. Because of the high cost and toxicity of osmium tetroxide, the stoichiometric dihydroxylation has been mostly replaced by the catalytic version in preparative organic chemistry (see also ***Osmium Tetroxide-t-Butyl Hydroperoxide***, ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***, and ***Osmium Tetroxide-Potassium Ferricyanide***).

Diastereoselective Dihydroxylation.

Dihydroxylation of acyclic alkenes containing an allylic, oxygen-bearing stereocenter proceeds with predictable stereochemistry. In general, regardless of the double-bond substitution pattern and geometry, the relative stereochemistry between the pre-existing hydroxyl or alkoxyl group and the adjacent newly formed hydroxyl group of the major diastereomer will be *erythro* (i.e. *anti* if the carbon chain is drawn in the zig-zag convention) (eq 6).[6,7]

(6)

In the osmylation of 1,2-disubstituted allylic alcohols and derivatives, *cis*-alkenes provide higher diastereoselectivity than the corresponding *trans*-alkenes (eqs 7 and 8).[6] Opposite selectivities have been observed in the osmylation of (*Z*)-enoate and (*E*)-enoate esters (eqs 9 and 10).[8] High selectivity has also been observed in the osmylation of 1,1-disubstituted[9] and (*E*)-trisubstituted allylic alcohols and derivatives[10] and bis-allylic compounds[11] (eqs 11-13).

The diastereoselective osmylation has been extended to oxygen-substituted allylic silane systems, and the general rule observed for the allylic alcohol system also applies (eq 14).[12] High selectivity is also observed in the osmylation of allylsilanes where the substituent on the chiral center bearing the silyl group is larger than a methyl group (eq 15).[13] These diastereoselectivities have been achieved in both stoichiometric and catalytic dihydroxylations. Slightly higher selectivity has been observed in the stoichiometric reaction than in the catalytic reaction; this may be due to less selective bis-osmate ester formation in the catalytic reaction using NMO as the cooxidant. Use of $K_3Fe(CN)_6$ may solve this discrepancy. Several rationales have been proposed for the observed selectivity.[14] The conclusion appears to be that the osmylation of these systems is controlled by steric bias, rather than by the electronic nature of the allylic system, and osmylation will occur from the sterically more accessible face. The high diastereoselectivity of osmium tetroxide in the dihydroxylation of chiral unsaturated compounds has been applied widely in organic synthesis.[8,15]

(14)

(15)

Sulfoxide groups direct the dihydroxylation of a remote double bond in an acyclic system perhaps by prior complexation of the sulfoxide oxygen with osmium tetroxide (eqs 16 and 17).[16] Chiral sulfoximine-directed diastereoselective osmylation of cycloalkenes has been used for the synthesis of optically pure dihydroxycycloalkanones (eq 18).[17] Nitro groups also direct the osmylation of certain cycloalkenes, resulting in dihydroxylation from the more hindered side of the ring. In contrast, without the nitro group the dihydroxylation proceeds from the less hindered side (eq 19).[18]

Enantioselective Dihydroxylation.

The acceleration of osmylation by tertiary amines brought about the use of chiral amines as chiral ligands for the asymmetric dihydroxylation (AD).[1] The AD can be classified into two types: (a) noncatalytic reaction, where stoichiometric amounts of ligand and osmium tetroxide are used, and (b) catalytic reaction, where catalytic amounts of ligand and osmium tetroxide are employed in conjunction with stoichiometric amounts of cooxidant. Generally, in the stoichiometric AD systems, chiral chelating diamines are used as chiral auxiliaries with osmium tetroxide for the introduction of asymmetry to the diol products.[1,19] Although high asymmetric inductions have been achieved in these systems, the stoichiometric ADs have limited use in practical organic synthesis because of the cost of both ligand and osmium tetroxide. The discovery of the ligand-accelerated catalysis in AD made the transition from stoichiometric to

catalytic AD possible.[1c,1d,20] In the most effective catalytic system, osmium tetroxide or its precursors and chiral ligands derived from cinchona alkaloids, dihydroquinidine (DHQD), or dihydroquinine (DHQ), are used catalytically in the presence of a stoichiometric amount of cooxidant such as NMO or $K_3Fe(CN)_6$. Besides alkaloid-derived ligands, other types of ligand have been designed and used in the catalytic AD with moderate success.[21] (see also ***Osmium Tetroxide-N-Methylmorpholine N-Oxide*** and ***Osmium Tetroxide-Potassium Ferricyanide***).

Double Diastereoselective Dihydroxylation.

AD of homochiral alkenes gives matched and mismatched diastereoselectivities due to the steric interaction of the chiral osmium tetroxide-ligand complex with the chiral center in the vicinity of the alkene double bond. For example, in the noncatalytic osmylation of the monothioacetal (eq 20),[22] the ratio of (2*S*,3*R*) to (2*R*,3*S*) diastereomers is 2.5:1 with the achiral quinuclidine as ligand, 40:1 with ***Dihydroquinidine Acetate*** (DHQD-OAc) as ligand in the matched case, and 1:16 with ***Dihydroquinine Acetate*** (DHQ-OAc) as ligand in the mismatched case.

Diastereoselectivities in the catalytic AD with OsO_4-NMO of several α,β-unsaturated uronic acid derivatives are significantly enhanced when the alkenes are matched with the chiral ligands DHQ-CLB (dihydroquinine *p*-chlorobenzoate) and DHQD-CLB (dihydroquinidine *p*-chlorobenzoate) (eq 21).[23] Using the chiral ligands $(DHQD)_2$-PHAL and $(DHQ)_2$-PHAL, the double diastereoselective dihydroxylation of a chiral unsaturated ester has been tested using ***Osmium Tetroxide-Potassium Ferricyanide*** (eq 22).[1c] These results show that enhanced diastereoselectivity in the dihydroxylation can be achieved by matching of alkene diastereoselectivity with catalyst enantioselectivity. Double diastereoselective dihydroxylation with a bidentate ligand has also been reported.[24] Kinetic resolutions of racemic alkenes with OsO_4 in the presence of a chiral ligand have been demonstrated.[25] An elegant example is the kinetic resolution of the enantiomers of C_{76}, the smallest chiral fullerene, by asymmetric osmylation in the presence of DHQD-

and DHQ-derived ligands.[26]

R	Reagent	Ratio

Oxyamination of Alkenes and Oxidation of Other

Functional Groups.

Osmium tetroxide catalyzes the vicinal oxyamination of alkenes to give *cis*-vicinal hydroxyamides with ***Chloramine-T*** (eq 23)[27] and alkyl *N*-chloro-*N*-argentocarbamate, generated in situ by the reaction of alkyl *N*-chlorosodiocarbamate (such as ethyl or *t*-butyl *N*-chlorosodiocarbamate) with ***Silver(I) Nitrate*** (eq 24).[28]

(23)

(24)

Since chloramine-T is readily available, the former method offers a practical and direct method for introducing a vicinal hydroxyl group and a tolylsulfonamide to a double bond. While the sulfonamide protecting group is difficult to remove (and undesirable in some cases), the *N*-chloro-*N*-argentocarbamate system provides an alternative method, since the carbamate group can be easily removed to give free amine. This latter system is also more regioselective and reactive towards electron-deficient alkenes such as ***Dimethyl Fumarate*** and (*E*)-stilbene than the procedures based on chloramine-T. In all of these oxyamination reactions, monosubstituted alkenes react more rapidly than di- or trisubstituted alkenes. In the presence of tetraethylammonium acetate, trisubstituted alkenes can be oxyaminated with catalytic OsO_4 and *N*-chloro-*N*-metallocarbamates. So far, attempts to effect catalytic asymmetric oxyamination have not been successful.

Osmium tetroxide also catalyzes the oxidation of organic sulfides to sulfones with NMO or trimethylamine *N*-oxide (see ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***). In contrast, most sulfides are not oxidized with stoichiometric amounts of OsO_4. Oxidations of alkynes and alcohols with OsO_4 without and in the presence of cooxidants have also been reported.[1a,1b] However, these reactions have not found wide synthetic applications because of the availability of other methods.

Osmium Tetroxide-*t*-Butyl Hydroperoxide[1]

OsO_4-*t*-BuOOH

(OsO_4)

[20816-12-0] · O_4Os · Osmium Tetroxide-*t*-Butyl Hydroperoxide · (MW 254.20) (TBHP)

[75-91-2] · $C_4H_{10}O_2$ · Osmium Tetroxide-*t*-Butyl Hydroperoxide · (MW 90.14)

(*cis* dihydroxylation of alkenes; osmylation)

Physical Data: for 70% aq TBHP: bp 96 °C; mp -2.8 °C; *d* 0.935 g cm^{-3}. See also ***Osmium Tetroxide***.

Solubility: TBHP: sol acetone, *t*-butyl alcohol.

Form Supplied in: 70% aq TBHP (remaining water) in plastic bottle.

Handling, Storage, and Precautions: TBHP is an eye and skin irritant. Safety goggles and gloves should be worn when handling TBHP solution. Avoid contamination of high-strength TBHP solution with strong acids and transition metal salts known to be good autooxidation catalysts (e.g. Mn, Fe, and Co). Never work with pure TBHP. Do not distill reaction mixtures containing TBHP without prior reduction with reducing agents such as Na_2SO_3. Store 70% aq TBHP in plastic containers below 38 °C but not much below 25 °C. Keep away from bright light and heat sources. See also ***Osmium Tetroxide***.

Dihydroxylation of Alkenes.

Although, in some cases, catalytic *cis* dihydroxylation with OsO_4 using ***Hydrogen Peroxide*** or metal chlorates as cooxidant gives good yields of diols, over-oxidation leading to high yields of ketols or aldehyde products becomes a problem.[1] Thus alkaline ***t-Butyl Hydroperoxide*** was introduced as a superior cooxidant in the catalytic *cis* dihydroxylation. In the OsO_4-TBHP system, 70% aq TBHP is normally used and the reaction is usually performed in *t*-BuOH or acetone when tetraethylammonium acetate (Et_4NOAc) is used as the base (see below). In most cases, only 0.2 mol % OsO_4 is sufficient for completion of the oxidation.[2]

The key to the success of the OsO_4-TBHP system is the presence of a nucleophile in the form of tetraethylammonium hydroxide (Et_4NOH) or Et_4NOAc. The role of the nucleophile is to increase the turnover rate of the catalytic cycle by facilitating the hydrolysis of the osmate ester intermediate. For example, it is possible to dihydroxylate even some tetrasubstituted alkenes using the OsO_4-TBHP-Et_4NOH combination (eq 1).[2a]

(1)

Tetraethylammonium acetate gives higher yields of diol than Et_4NOH in the *cis* dihydroxylation of base-sensitive alkenes even though, as a weaker base, it fails with tetrasubstituted alkenes (eq 2).[2b] In another example, alkenylphosphonates are dihydroxylated with OsO_4-TBHP in acetone in the presence of Et_4NOAc to give *threo*-dihydroxyalkylphosphonates in >80% yields. In contrast, using OsO_4-H_2O_2, a mixture of diol and ketol is obtained.[3] The OsO_4-TBHP system does not work well in the dihydroxylation of sterically hindered tri- and tetrasubstituted alkenes such as cholesterol (for oxidation of these alkenes, see ***Osmium Tetroxide-Potassium Ferricyanide***).

(2)

The OsO_4-TBHP system and OsO_4-NMO system (see ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***) are quite comparable for the dihydroxylation of simple alkenes. The ability to use less OsO_4 and the lower expense of TBHP are the main advantages with the OsO_4-TBHP system. However, no asymmetric catalytic dihydroxylation using the OsO_4-TBHP system has been developed, and probably due to safety concerns there have been few synthetic applications of the OsO_4-TBHP system.[3,4]

Osmium tetroxide-TBHP is also used for the oxidation of 1-trimethylsilylalkynes to produce α-keto esters in about 60% yield (eq 3). It is most likely that the oxidation involves an α-keto acylsilane which then undergoes a Brook-type rearrangement to the final product.[5]

(OsO_4)

[20816-12-0] · O_4Os · Osmium Tetroxide-*N*-Methylmorpholine *N*-Oxide · (MW 254.20) (NMO)

[7529-22-8] · $C_5H_{11}NO_2$ · Osmium Tetroxide-*N*-Methylmorpholine *N*-Oxide · (MW 117.17)

(*cis* dihydroxylation of alkenes; osmylation; asymmetric dihydroxylation of alkenes; oxidations of enol ethers, sulfides)

Physical Data: NMO monohydrate: mp 75-76 °C; 60 wt % aqueous solution: bp 118.5 °C, mp -20 °C, *d* 1.13 g cm^{-3}. See also ***Osmium Tetroxide***.

Solubility: NMO: sol water, acetone, *t*-butyl alcohol, THF.

Form Supplied in: NMO: as monohydrate or 60 wt % aqueous solution.

Handling, Storage, and Precautions: NMO is irritating to eyes, respiratory system, and skin. Store refrigerated. Use in a fume hood. See also ***Osmium Tetroxide***.

Dihydroxylation of Alkenes.

The use of an amine *N*-oxide such as ***N-Methylmorpholine N-Oxide*** as cooxidant for osmium tetroxide-catalyzed *cis* dihydroxylation has become the standard method for the preparation of *cis*-1,2-diols because of the higher yield of diol product and less byproduct formation compared with oxidations carried out with ***Hydrogen Peroxide***, metal chlorates, and ***t-Butyl Hydroperoxide***.[1] Other alkylamine *N*-oxides such as ***Trimethylamine N-Oxide*** have also been used in the catalytic *cis* dihydroxylation. NMO (as monohydrate and 60 wt % aq solution) is commercially available and readily prepared or regenerated by treatment of *N*-methylmorpholine (NMM) with H_2O_2. Normally, aqueous acetone or aqueous *t*-BuOH is used in the catalytic *cis* dihydroxylation with OsO_4-NMO. Workup involves reduction by sodium sulfite or

sodium bisulfite and extraction with ethyl acetate. A detailed procedure for the preparation of NMO (eq 1) and dihydroxylation of cyclohexene with OsO_4-NMO (eq 2) has been published.[2] Functional groups such as alcohols, esters, lactones, carboxylic acids, ketones, and electron-poor alkenes such as α,β-unsaturated ketones are not affected. For unstable or water-soluble diols, the osmylation can be performed in the presence of ***Dihydroxy(phenyl)borane*** and the product is isolated as the borate ester (eq 3).[3]

(1)

(2)

(3)

The OsO_4-NMO system works well with mono- and disubstituted alkenes. Bases such as ***Pyridine*** accelerate the *cis* dihydroxylation in the OsO_4-amine *N*-oxide system, especially for hindered alkenes.[4,5] For example, the α-pinene derivative nopol is hydroxylated in low yield by the ***Osmium Tetroxide-t-Butyl Hydroperoxide*** system; however, it is hydroxylated in 62% yield with OsO_4-Me_3NO in the presence of pyridine in aqueous *t*-BuOH. Other hindered alkenes are also oxidized by this system in 78-93% yield. By switching the solvent to aqueous acetone, the OsO_4-Me_3NO-pyridine system has been used for the *cis* dihydroxylation of an intermediate for the preparation of an HMG-CoA reductase inhibitor on a 20-kg scale with 95% diastereoselectivity in 78% yield (eq 4).[6]

(4)

Diastereoselective Osmylation.

Diastereoselective dihydroxylations with OsO_4-NMO have been extensively studied (see also ***Osmium Tetroxide***). In general, in the osmylation of acyclic alkenes containing an allylic, oxygen-bearing stereocenter, the relative configuration between the pre-existing hydroxyl or alkoxyl group and the adjacent newly formed hydroxyl group in the major diastereomer is *erythro* (*anti*).[7] Taking advantage of the high diastereoselectivity in the osmylation reaction, the OsO_4-NMO or OsO_4-Me_3NO system has been used in many stereoselective organic syntheses. One example is the synthesis of octoses based on the catalytic osmylation of allylic alcohols with OsO_4-NMO (eq 5).[8]

(5)

Opposite selectivity has been observed in the dihydroxylation of a cyclopentene derivative for the synthesis of

carbonucleoside aristeromycin (eq 6).[9] Dihydroxylation of (**1**) with alkaline permanganate proceeds from the less hindered side to give the desired diol, which is then converted to aristeromycin (**2**). However, dihydroxylation of (**1**) with OsO_4-NMO proceeds from the more hindered side to give the *cis*-diol, which is subsequently transformed to *lyxo*-aristeromycin (**3**). This surprising stereoselectivity is attributed to the complexation of osmium tetroxide with the nitro group, resulting in a nitro-directed osmylation from the more hindered side.

(6)

Asymmetric Dihydroxylation (AD).

AD of alkenes with OsO_4-NMO is usually performed in aqueous acetone in the presence of dihydroquinidine (DHQD) or dihydroquinine (DHQ) derived chiral ligands such as dihydroquinidine *p*-chlorobenzoate (DHQD-CLB) or dihydroquinine *p*-chlorobenzoate (DHQ-CLB) (eq 7) (see also ***Osmium Tetroxide-Potassium Ferricyanide***).[10]

(7)

For example, using OsO_4-NMO in the presence of the DHQD-CLB ligand, *trans*-stilbene is converted to (*R*,*R*)-

stilbenediol in 88% ee, which is further enriched by recrystallization to >99% ee.[11] This method has also been used for the preparation of optically pure (2*S*,3*R*)-methyl 2,3-dihydroxyphenylpropionate, useful for the synthesis of the taxol sidechain.[12] A catalytic cycle of AD with OsO_4-NMO has been proposed.[13] The presence of a second catalytic cycle results in a reduced ee for some alkenes in comparison with the ee obtained under stoichiometric conditions, due to the slow hydrolysis of the intermediate osmate ester. Although addition of base such as tetraethylammonium acetate accelerates the hydrolysis of the osmate ester, thereby diminishing the second cycle, the best solution is to add the alkene slowly to prevent the build-up of the osmate ester. In this manner, many alkenes have been dihydroxylated to the corresponding diols in ee close to those obtained under stoichiometric conditions.[14]

Since the AD with OsO_4-$K_3Fe(CN)_6$ suppresses the second cycle in the aqueous *t*-BuOH solvent system, the OsO_4-NMO system has been largely superseded by the OsO_4-$K_3Fe(CN)_6$ system in catalytic AD. However, by employing the most effective ligands such as $(DHQD)_2$-PHAL or $(DHQ)_2$-PHAL and using the slow-addition technique, higher enantioselectivity in the AD with OsO_4-NMO can be expected.

Other Oxidations.

Vinylsilanes are converted to silyl enol ethers with retention of the double bond configuration by dihydroxylation with OsO_4-Me_3NO followed by an anti β-elimination with ***Sodium Hydride*** (eqs 8 and 9).[15] α-Keto acylsilanes are prepared in over 40% overall yields from (*Z*)-vinylsilanes by dihydroxylation with OsO_4-NMO followed by oxidation with ***Dimethyl Sulfoxide-Oxalyl Chloride*** (eq 10).[16]

(8)

(9)

(10)

Enol ethers are transformed to α-hydroxy ketones with OsO_4-NMO (eq 11).[17] In the presence of a chiral ligand, optically active α-hydroxy ketones are obtained (also see ***Osmium Tetroxide-Potassium Ferricyanide***).[14] Although OsO_4 does not normally oxidize organic sulfides, the OsO_4-NMO system can oxidize sulfides to sulfones in good yields (eq 12).[18]

Osmium Tetroxide-Potassium Ferricyanide[1]

OsO_4-$K_3Fe(CN)_6$

(OsO_4)

[20816-12-0] · O_4Os · Osmium Tetroxide-Potassium Ferricyanide · (MW 254.20) ($K_3Fe(CN)_6$)

[13746-66-2] · $C_6FeK_3N_6$ · Osmium Tetroxide-Potassium Ferricyanide · (MW 329.27)

(*cis* dihydroxylation of alkenes; asymmetric dihydroxylation of alkenes, enynes, polyenes, and enol ethers)

Physical Data: $K_3Fe(CN)_6$: orange crystals, *d* 1.89 g cm^{-3}. See also ***Osmium Tetroxide***.

Solubility: $K_3Fe(CN)_6$: sol water (0.33 g mL^{-1} at 4 °C, 0.78 g mL^{-1} at 100 °C); slightly sol alcohol; decomposed by acids.

Handling, Storage, and Precautions: $K_3Fe(CN)_6$: wear gloves and goggles. The aqueous solution decomposes slowly on standing. Store away from light. This reagent system should be used in a fume hood. See also ***Osmium Tetroxide***.

Dihydroxylation of Alkenes.

Alkali metal ferricyanides, notably ***Potassium Ferricyanide***, have been used as cooxidants in the studies of OsO_4-catalyzed oxidations of lower molecular weight organic compounds.[1a] For example, propene is dihydroxylated with OsO_4-$K_3Fe(CN)_6$ in aqueous alkaline solutions to propylene glycol in almost quantitative yield. Potassium ferricyanide and alkali consumed in the reaction have been regenerated electrochemically, resulting in an overall reaction with consumption of alkene, water, and electricity to produce the glycol (eq 1).[2]

(1)

Recently, it has been found that water-insoluble alkenes can be dihydroxylated with the OsO_4-$K_3Fe(CN)_6$ system in an alkaline aqueous *t*-BuOH solution to give 1,2-diols in good yields.[3] Addition of tertiary amines such as quinuclidine or ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO) accelerates the dihydroxylation with OsO_4-$K_3Fe(CN)_6$, resulting in an increased yield of diol product. For example, in the presence of DABCO the yield of dihydroxylation of cholesterol increases from 19% to 74%. In this case it appears that DABCO or quinuclidine promotes the hydrolysis of the stable osmate ester intermediate.

The use of $K_3Fe(CN)_6$ as a cooxidant for the osmium-catalyzed asymmetric dihydroxylation (AD) in place of ***N-Methylmorpholine N-Oxide*** results in across-the-board increases in the level of asymmetric induction for all classes of alkenes.[1b,1c] The enhanced enantioselectivity is due to the complete suppression of the second cycle observed in the OsO_4-NMO system (see ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***) and the use of the *t*-BuOH-water solvent system, which under the reaction conditions forms a biphasic mixture.[4] Both osmium(III) chloride hydrate and potassium osmate(VI) dihydrate [$K_2OsO_4.2H_2O$] have been used in place of osmium tetroxide. For safety and convenience in handling reasons, potassium osmate is used in the standard set of conditions for the catalytic AD with OsO_4-$K_3Fe(CN)_6$ and in the commercially available AD mixes.[5] Many ligands derived from dihydroquinidine (DHQD) and dihydroquinine (DHQ) have been developed for catalytic AD.[1b,6] 1,4-Bis(dihydroquinidine) phthalazine ether [$(DHQD)_2$-PHAL] and its diastereomer 1,4-bis(dihydroquinine) phthalazine ether [$(DHQ)_2$-PHAL] have shown significant improvements in enantioselectivity over other ligands for the AD of most alkenes. Polymer-supported DHQD and DHQ derived ligands have been examined for the purpose of recycling of the catalyst.[7]

For most alkenes, 0.2 mol % of osmium and 1.0 mol % of ligand are sufficient to provide a satisfactory rate of reaction even at 0 °C using 3.0 equiv each of $K_3Fe(CN)_6$ and K_2CO_3. Ready-made mixture containing the four solid components named AD-mix-β (containing $(DHQD)_2$-PHAL) and AD-mix-α (containing $(DHQ)_2$-PHAL) are currently commercially available. Increasing the amount of osmium and ligand and the reaction temperature up to 25 °C can accelerate the AD of more substituted and sterically hindered alkenes.[8] In addition, for 1,2-disubstituted, tri- and tetrasubstituted alkenes, addition of up to 3 equiv of sulfonamide (usually methanesulfonamide) enhances the overall rate of the AD by accelerating the hydrolysis of the osmate ester intermediate.[5] A mnemonic scheme showing alkene orientation and face selectivity is illustrated in eq 2. However, this mnemonic should be considered as only suggestive of new diol configurations due to the large structural diversity of alkenes.

(2)

Table 1 summarizes results of the AD of six types of alkenes using the OsO_4-$K_3Fe(CN)_6$ system with the preferred DHQD- or DHQ-derived ligands. In general, slightly lower ees are observed in the AD with DHQ-derived ligands than with DHQD-derived ligands.

Table 1 Results of AD of Six Types of Alkenes with Preferred Ligands

PHAL class	PYR class	IND class		
Alkene type	Alkene example	Preferred ligand	ee range (%)	Ref.

	 	PHAL, PYR	80-97	5, 8
		PHAL	70-97	5
		PHAL	90-99.5	5
		IND	20-80	5
		PHAL	90-99	5
		PYR, PHAL	20-97	5, 8

Besides simple alkenes, enol ethers can be oxidized enantioselectively to give optically active α-hydroxy ketones (eq 3).[10]

(3)

Enynes are dihydroxylated selectively at only the double bond[11] and dienes at the more substituted and/or more electron-rich double bond.[12] Polyenes such as squalene have been enantioselectively perhydroxylated with OsO_4-$K_3Fe(CN)_6$ in the presence of $(DHQD)_2$-PHAL or $(DHQ)_2$-PHAL.[13] Under buffered condition (in the presence of $NaHCO_3$), even α,β-unsaturated ketones can be dihydroxylated to the corresponding optically active α,β-dihydroxy ketones.[14] Kinetic resolution of racemic alkenes have also been reported.[15] Diastereoselective dihydroxylation of optically pure alkenes with OsO_4-$K_3Fe(CN)_6$ in the presence of DHQD- or DHQ-derived ligand results in matched and mis-matched selectivities (also see ***Osmium Tetroxide***). Synthetic transformations of optically pure 1,2-diols to other useful intermediates such as chiral cyclic sulfites, cyclic sulfates,[16] and epoxides[17] have been developed (eq 4). These new synthetic transformations and the catalytic AD are being increasingly used in the synthesis of optically pure natural products, pharmaceuticals, and other interesting compounds.[1,18]

1-Oxa-2-azaspiro[2.5]octane[1]

[185-80-8] · $C_6H_{11}NO$ · 1-Oxa-2-azaspiro[2.5]octane · (MW 113.18)

(selective electrophilic aminating agent for N-, S-, C-, and O-nucleophiles;[1] transfers either the NH function or the entire cyclohexylideneamino unit)

Alternate Name: 3,3-pentamethyleneoxaziridine.

Solubility: sol toluene, ether, chloroform, and other organic solvents; insol H_2O.

Form Supplied in: freshly prepared solutions in organic solvents, preferably toluene, 0.2-0.5 M; main impurities are excess cyclohexanone from the preparation and *N*-chlorocyclohexylimine (5-10%), both in most applications without influence.

Preparative Methods: a mixture containing 125 mL of toluene, 25 mL of cyclohexanone, 25 mL of 2 N NH_3 soln, and 100 g of finely crushed ice is shaken in a separatory funnel with 50 mmol NaOCl soln. (e.g. 31 mL of a 1.6 M soln.) for 30 s. The upper layer is washed with 0.1 N HCl and can be used directly for amination reactions or it can be dried with Na_2SO_4 or by removing of some solvent in vacuo.[2] Solutions having less remaining cyclohexanone can be obtained from the reaction of hydroxylamine-*O*-sulfonic acid with cyclohexanone and NaOH.[3]

Analysis of Reagent Purity: redox titration:[2] a 2 mL aliquot of the reagent soln. is added to 12 mL of acetic acid and 3 drops of a concentrated solution of KI in H_2O; titration of the liberated iodine by 0.2 N thiosulfate soln. until decolorization (concn. in mol L^{-1} = 0.05 mL of $S_2O_3^{2-}$ soln.).

Handling, Storage, and Precautions: solutions of the reagent are stable at 0-20 °C for 1-6 weeks without loss of more than 15% of the initial activity. Appropriate precautions should be taken for some evolution of gases during storage. With 0.2-0.4 M solutions, no problems have been encountered on a 0.1-2000 L scale. Use in a fume hood. *Caution*: no experience with solutions having reagent concentration of more than 0.5 mol L^{-1} has been acquired in the authors' laboratory or is reported in the literature.

N-Amination.

Secondary amines are aminated by oxaziridine (**1**) at 20-30 °C within a few minutes, yielding cyclohexanone hydrazones which can be hydrolyzed to the free hydrazines or used for further transformations (eq 1),[1] e.g. morpholine,[2] tetrahydroisoquinolines.[4] With 2,4-dibromo-6-(*trans*-4-hydroxycyclohexylaminomethyl)aniline, the amination takes place at the aliphatic amino group exclusively.[1]

(1)

Primary aliphatic amines are not aminated selectively or, if deactivated, they need higher temperatures (80-100 °C), e.g. amino acids,[1] peptides,[5] and 2-aminophosphonates.[6] Aromatic and heteroaromatic amines can be aminated after acetylation and (partial) deprotonation (***1,4-Diazabicyclo[2.2.2]octane***). Thus even 3-hydrazinopyridines can be obtained, whereas other amination reagents exclusively attack the ring nitrogen.[7]

S-Amination.

All (potential) thiols react exothermically with the reagent. Hydrolysis of the primary intermediate yields cyclohexanone and sulfenamides (eq 2). Elimination of water yields cyclohexanone thioximes (eq 3). Depending on the nature of the other functional groups in the starting material, the sulfenamides or thioximes can be stable or undergo further reactions to give a variety of heterocyclic products. A third possibility to be considered is the formation of sulfur-free final products.[1]

(2)

(3)

For example, the following heterocyclic compounds can be prepared using oxaziridine (**1**):

- 1)via cyclohexanone thioximes: 1,2,4-thiadiazolidines,[9] 5a-amino-5a,6,7,8,9,9a-hexahydro-4*H*-pyrimido[2,1-*b*]benzothiazoles,[10] 2-(2-hydroxycyclohexenethio)benzothiazoles and -benzoxazoles;[10]
- 2)via sulfenamides: 1,2-thiazoles,[1] 1,2-thiazolones,[1] 1,2,4-thiadiazoles,[8] and benzothiazoles;[1]
- 3)via desulfurization reactions: 2-amino-5-substituted 1,2,4-oxadiazoles,[1] triazino[3,4-*a*]azepines,[1] and nitriles (from thioamides).[1]

C-Amination.

Hydrophilic cyanoacetic amides are converted into α-amino malondiamides by (**1**) in toluene/2 N NaOH (eq 4). Less hydrophilic cyanoacetic amides yield cyclic spirocyclohexane glycine amides with DABCO as base. Cyanoacetic amides, monosubstituted at the N-function, can give ring transformed amination products. Double amination often predominates, giving stable α,α-diamino acid derivatives (eq 5).[11] All reactions are finished after few minutes at 0-20 °C, with complete hydration of the nitrile group. In some cases only 5 mol % of the base DABCO is necessary.[11]

(4)

(5)

Many other CH acidic compounds can be aminated by oxaziridine (**1**) if the generation of the carbanion can be realized under mild conditions.[11] However, nitrobenzyl aryl sulfones are converted into aryl aldehydes or ketones.[12] In contrast to other oxaziridines no direct hydroxylation reactions have been observed with (**1**).

Aziridination of Alkenes.

Aziridines are obtained in 20-68% yield from substituted styrenes, acrylonitrile (41% 2-cyanoaziridine), and norbornene (20% *exo*-product). Cyclohexene gives the corresponding *N*-aminoaziridine by successive *C*- and *N*-amination.[13]

O-Amination.

Possible conversions, e.g. water to hydroxylamine, methanol to cyclohexanone oxime *O*-methyl ether (40%),[14] are not of preparative value.

Related Reagents.

(Camphorylsulfonyl)oxaziridine; ***Chloramine***; ***Hydroxylamine-O-sulfonic Acid***; ***O-Methylhydroxylamine***; ***(±)-trans-2-(Phenylsulfonyl)-3-phenyloxaziridine***.

Oxalic Acid

(free acid)

[144-62-7] · $C_2H_2O_4$ · Oxalic Acid · (MW 90.04) (dihydrate)

[6153-56-6] · $C_2H_6O_6$ · Oxalic Acid · (MW 126.08)

(mild Brønsted acid; chelating[5] and quenching[23-25] agent; catalyst for hydrolysis,[6-9] protection-deprotection,[10-21] dehydration-elimination,[28-33] decarboxylation,[34] and condensation[35-40] reactions)

Alternate Name: ethanedioic acid.

Physical Data: anhydrous acid: hygroscopic, exists in rhombic and monoclinic forms; mp (rhombic) 189.5 °C; pK_{a1}, 1.46; pK_{a2}, 4.40. Anhydrous acid has substantial vapor pressure; begins to sublime at slightly below 100 °C; sublimes rapidly at 125 °C. Dihydrate: monoclinic crystals, mp 101 °C.[1]

Solubility: anhydrous acid: v sol H_2O, alcohol; sl sol ether; insol benzene.

Purification: crystallized from distilled water;[43] see below for drying.

Form Supplied in: readily available as the dihydrate; anhydrous form also available.

Analysis of Reagent Purity: by titration of reductive capacity; impurity tests known.[42]

Preparative Methods: preparation of the anhydrous acid may be accomplished by refluxing the dihydrate in carbon tetrachloride with removal of water;[2] alternatively, the hydrate may be heated in an oven at 98 °C for several hours.[3] The latter process may be harmful to the oven.

Handling, Storage, and Precautions: the dihydrate should be stored in a cool area at 50-70% relative humidity to prevent caking. Oxalic acid and its solutions are corrosive and highly toxic; ingestion of oxalic acid and its salts can cause death. Use of gloves, aprons, and goggles when handling the material is strongly recommended. A review of oxalic acid as a hazardous material, with extensive references, is available.[4] Use in a fume hood.

Introduction.

Oxalic acid is the simplest of the dicarboxylic acids and is typical of its class with respect to the preparation of its simple salts and esters. Several of its simple derivatives are important reagents in organic chemistry (see ***Diethyl Oxalate***, ***Oxalyl Chloride***); these will not be discussed here. Oxalic acid has been widely used in inorganic chemistry as a precipitant and chelating agent; a review of metal oxalato complexes may be consulted for these uses.[5] Oxalic acid is utilized extensively in synthetic organic chemistry as a mild Brønsted acid for various acid-catalyzed processes. It is particularly useful in cases where the reactants or products contain potentially acid-labile functionality. In many cases it furnishes a degree of selectivity which would otherwise be difficult to attain.

Protections/Deprotection and Hydrolyses.

Aqueous oxalic acid is an excellent reagent for the hydrolysis of enol ethers to ketones.[6] Hydrolysis of the enol ethers obtained by Birch reduction of aromatic ethers, by mineral acid, typically gives the conjugated ketone. In contrast, use of oxalic acid provides the ketone without concomitant migration of the double bond.[7-9] In the example shown (eq 1),[9] hydrolysis and closure of the hydroxy acid to the lactone occurred simultaneously.

Oxalic acid may be used for both incorporation and removal of acetal and ketal functionalities. Ketones and aldehydes may be reacted with ethylene glycol or methanol in the presence of oxalic acid (anhyd) to effect conversion to the ketals and acetals, respectively.[10,11] Dimethylmethoxymethyl ethers have been prepared by stirring alcohols with 2-methoxypropene in the presence of oxalic acid.[12] Ketalization of progesterone with oxalic acid proceeds without isomerization of the double bond, whereas use of ***p-Toluenesulfonic Acid*** results in migration to the 5,6-position.[13] Cleavage of acetals to regenerate the carbonyl group may be accomplished in aqueous solution.[14-17] Acid-sensitive functionality is well tolerated by this method (eq 2).[16] A two-phase system of methylene chloride and water has also been used.[18]

(2)

A particularly mild method for deacetalization is the use of oxalic acid and moist silica gel.[19] Cleavage of β-hydroxy ketals to the corresponding hydroxy ketones may be effected without accompanying dehydration (eq 3),[20] and vinylsilanes have not undergone protodesilylation under these conditions.[21] Vinylogous phosphoramides have been hydrolyzed to ketophosphonates using this method.[22]

(3)

Oxalic acid is a frequently used mild acid quench for a variety of reaction types, including oxidations with ***Dimethyl Sulfoxide*** activated with ***1,3-Dicyclohexylcarbodiimide***[23,24] and ***Phenyl Dichlorophosphate*** (Pfitzner-Moffatt oxidation),[25] as well as organometallic reactions and anion additions. Oxalic acid in methanol has been used to effect protodesilylation[26] and protodestannylation[27] of dihydropyridine compounds.

Heating alcohols with anhydrous oxalic acid[28] or refluxing in aqueous oxalic acid[29] effects dehydration to alkenes, often with results superior to other methods. Appropriately disposed hydroxy ketones have been cyclodehydrated to cyclic ethers (eq 4).[30-32] Elimination of amines from Mannich adducts with oxalic acid in ethanol, to yield unsaturated ketones, has also been reported.[33]

(4)

β-Ketoesters may be decarboxylated by aqueous oxalic acid in dioxane (eq 5).[34]

(5)

Oxalic acid has been used as an acidic agent in a number of condensation processes, including condensation of allylic alcohols with aromatic rings[35] and condensations with carbonyl groups.[36] Oxalic acid can itself serve as a reaction partner in such processes, for example in condensations between aromatic amines and aldehydes,[37] and between phenols.[38] Oxalic acid has been utilized as a bifunctional condensation partner in the synthesis of heterocyclic systems.[39] Palladium-catalyzed hydroxycarboxylation of alkenes and alkynes by oxalic acid provides alkanoic and alkenoic carboxylic acids, respectively.[40]

Oxalic acid is frequently used for the characterization of amines as their oxalate salts.[41]

Related Reagents.

Oxalyl Bromide

[15219-34-8] · $C_2Br_2O_2$ · Oxalyl Bromide · (MW 215.82)

(reactive acid halide;[1] heterocycle synthesis[2])

Physical Data: bp 16-17 °C/10 mmHg; *d* 2.30 g cm^{-3}.

Form Supplied in: liquid or solution in CH_2Cl_2; commercially available

Preparative Methods: originally prepared by Staudinger in 1913 by treating ***Oxalyl Chloride*** with HBr;[3] a more recent report describes a convenient alternative using ***Bromotrimethylsilane*** which provides the reagent in 85% yield.[4]

Handling, Storage, and Precautions: corrosive; lachrymator. Use in a fume hood.

Brominations.

Oxalyl bromide is useful for the preparation of acid bromides from carboxylic acids or salts.[5] These acid bromides are quite reactive and will often acylate nucleophiles under milder conditions than those required for the corresponding acid chlorides.[1]

Oxalyl bromide has found use for the preparation of a number of brominated heterocycles. Reaction of oxalyl bromide with α-amino- or α-hydroxynitriles yields substituted 2(1*H*)-pyrazinones (eq 1)[2a] and 2*H*-1,4-oxazin-2-ones (eq 2),[2b] respectively.

(1)

(2)

Reaction of cyanogen with oxalyl bromide affords the tetrabromopyrazine (**1**) in greater than 70% yield (eq 3).[6] A completely different product is obtained in this reaction when ***Oxalyl Chloride*** is used.

(3)

Oxalyl Chloride

[79-37-8] · $C_2Cl_2O_2$ · Oxalyl Chloride · (MW 126.92)

(versatile agent for preparation of carboxylic acid chlorides;[1] phosphonic acid dichlorides;[2] alkyl chlorides;[3] β-chloro enones;[4] acyl isocyanates[5])

Physical Data: mp -12 °C; bp 63-64 °C/763 mmHg; *d* 1.48 g cm^{-3}; *n*20D 1.4305.

Solubility: sol hexane, benzene, diethyl ether, halogenated solvents, e.g. dichloromethane and chloroform, acetonitrile.

Form Supplied in: colorless, fuming liquid; widely available; 2M soln in dichloromethane.

Handling, Storage, and Precautions: liquid and solution are toxic, corrosive, and severely irritating to the eyes, skin, and respiratory tract. Use in a fume hood and wear protective gloves, goggles, and clothing. Bottles should be stored in a cool, dry place and kept tightly sealed to preclude contact with moisture. Decomposes violently with water, giving toxic fumes of CO, CO_2, HCl.

Preparation of Carboxylic Acid Chlorides (and Anhydrides).

Oxalyl chloride has found general application for the preparation of carboxylic acid chlorides since the reagent was introduced by Adams and Ulich.[1] Acid chlorides produced by this means have subsequently featured in the synthesis of acyl azides,[6] bromoalkenes,[7] carboxamides,[8] cinnolines,[9] diazo ketones,[10] (thio)esters,[11] lactones,[12] ketenes for cycloaddition reactions,[13] intramolecular Friedel-Crafts acylation reactions,[14] and the synthesis of pyridyl thioethers.[11]

Like ***Thionyl Chloride***, oxalyl chloride gives gaseous byproducts with acids and the chlorides can be readily isolated in a pure form by evaporation of the solvent and any excess reagent, or used in situ for further elaboration (eq 1).

Prior formation of an amine or alkali metal salt, with or without pyridine,[1] has been used to advantage with substrates that are sensitive to strong acids or are bases (see also ***Oxalyl Chloride-Dimethylformamide*** for a procedure conducted under neutral conditions using silyl esters). By adjusting the molar proportions of oxalyl chloride to substrate, anhydrides can also be prepared using these methods (eq 2).[15] *N*-Carboxy-α-amino acid anhydrides can also be made this way.[16]

The use of nonpolar solvents such as hexane or toluene allows for the removal of inorganic or amine salts which may otherwise interfere with subsequent reactions.

Under the mild conditions employed (eqs 3 and 4),[17] racemization of stereogenic centers, skeletal rearrangement, or byproduct formation, seen with other reagents such as thionyl chloride/pyridine,[18] are seldom observed.

(4)

Conversion of β-bromoacrylic acid to the acid chloride using thionyl chloride/DMF, ***Phosphorus(III) Chloride***, or benzotrichloride/zinc chloride also resulted in bromine for chlorine exchange. Use of oxalyl chloride with the preformed ammonium salt provided a mild, general method to β-bromoacryloyl chlorides (eq 5)[19] without halogen exchange or (*E*/*Z*) equilibration. β-Fluoro- and iodoacrylic acids have been cleanly converted to the acid chlorides without prior salt formation.

(5)

As well as forming acid chlorides, α-tertiary amino acids can react with oxalyl chloride and undergo an oxidative decarboxylation to give iminium salts, or ring expansion, depending on the substituents and their stereochemistry (eq 6).[20]

(6)

			% Yield	
R^1	R^2	R^3	(A)	(B)
Me	H	*t*-Bu	0	69
H	CO_2Me	*c*-Hex	0	59
H	Me	Me	30	0

Preparation of Phosphonic Acid Chlorides.

Phosphonic acid dichlorides have been obtained in high yield (determined by ^{31}P NMR) at low temperature from the corresponding acids using oxalyl chloride and ***Pyridine*** (eq 7).[2]

(7)

R = Et, $PhCH_2$, CF_2H, arabinomethyl, phthalidyl

Similarly, monoalkyl methylphosphonochloridates (eq 8)[21] can be made from dialkyl esters; thionate acid chlorides could not be made by this method. Thionyl chloride and PCl_5 were also used to make this type of compound (see also ***Oxalyl Chloride-Dimethylformamide***).

(8)

R = Me, Et, Pr, *i*-Pr, Bu

Numerous other reagents such as PCl_3, PCl_5, $POCl_3$, and Ph_3P/CCl_4 are available for the preparation of acid chlorides and anhydrides but may not be as convenient as the byproducts are not so easily removed, or the reactions require more vigorous conditions.

Direct Introduction of the Chlorocarbonyl Group (Halocarbonylation).

Alkanes or cycloalkanes react with oxalyl chloride under radical conditions; typically, mixtures are produced.[22] However, bicyclo[2.2.1]heptane undergoes regio- and stereospecific chlorocarbonylation, giving the ester on subsequent methanolysis (eq 9).[23]

(9)

Certain alkenes such as 1-methylcyclohexene and styrene react with oxalyl chloride, under ionic conditions without added catalyst, to give alkenoic acid chlorides in variable yields. Alkenes such as octene and stilbene did not react under these conditions.[24]

Reactions of aromatic compounds with oxalyl chloride/Lewis acid catalysts have been reviewed.[25] Anthracene is unusual as it undergoes substitution without added catalyst (eq 10).[26]

(10)

Preparation of Chloroalkanes.

Alcohols react with oxalyl chloride to give oxalyl monoalkyl esters, which if heated in the presence of pyridine give the alkyl chloride (eq 11).[3]

(11)

Tertiary alcohols have been converted to tertiary chlorides in a Barton-Hunsdiecker type radical process using hydroxamate esters (eq 12).[27]

(12)

e.g. R = $Me(CH_2)_{16}CMe_2$-

Chlorination of Alkenes.

A novel stereospecific dichlorination of electron rich alkenes has been reported using a manganese reagent generated

from ***Benzyltriethylammonium Chloride*** and oxalyl chloride (eqs 13-17).[28] No oxygenation byproducts are observed.

Reactions with Carbonyl Groups.

Unsaturated 3-keto steroids give the corresponding 3-chloro derivatives with oxalyl chloride (eq 18).[4] Prolonged heating can give rise to aromatization.[4] Tropone gives the chlorotropylium chloride in high yield.[4] In a related reaction, 1,2-dithiol-3-ones and -3-thiones give dithiolium salts when heated in toluene or chloroform with the reagent.[4] A range of β-chloro enones has been prepared from diketones. Dimedone gives the β-chloro enone in high yield (eq 19).[29] Keto esters did not react to give β-chloro esters.

(18)

(19)

β-Keto aldehydes give a single regio- and stereospecific isomer, the chlorine being *cis* to the carbonyl group (eq 20).

(20)

Certain triketones give 3-chlorides with excess oxalyl chloride, in good yield (eq 21).[30]

(21)

Preparation of Acyl Isocyanates and Aryl Isocyanates.

Certain primary carboxamides can be converted to acyl isocyanates in yields from 36-97% with the reagent (eq 22);[5] ***Phosgene*** gives nitriles under similar conditions. Oxalyl chloride has found limited application for the preparation of triazine and quinone isocyanates.[5]

Miscellaneous Applications.

Oxalyl chloride has been used in the preparation of 2,3-furandiones from alkenyloxysilanes,[31] *o*-aminophenols from *N*-aryl nitrones,[32] dihydroquinolines via a modified Bischler-Napieralski ring closure,[33] 2,3-β-furoquinoxalines from quinoxazolones,[34] sterically hindered salicylaldehydes from phenoxyoxalyl chlorides,[35] and in mild cleavage of 7-carboxamido groups in cephalosporin natural products, without cleavage of the lactam ring or disruption of optical centers.[36]

Related Reagents.

Dimethyl Sulfoxide-Oxalyl Chloride; ***Oxalyl Chloride-Aluminum Chloride***.

Oxalyl Chloride-Aluminum Chloride

$(COCl)_2$

[79-37-8] · $C_2Cl_2O_2$ · Oxalyl Chloride-Aluminum Chloride · (MW 126.92) ($AlCl_3$)

[7446-70-0] · $AlCl_3$ · Oxalyl Chloride-Aluminum Chloride · (MW 133.33)

(useful for the preparation of benzoyl chlorides and derivatives;[1] 2-acylpyrrole synthesis[2])

Physical Data: see entries for ***Oxalyl Chloride*** and ***Aluminum Chloride***.

Handling, Storage, and Precautions: Caution! Both phosgene and carbon monoxide are formed upon mixing equimolar amounts of oxalyl chloride and aluminum chloride at room temperature. Use this reagent only in an efficient fume hood.

General Discussion.

The combination of oxalyl chloride and aluminum chloride is a reagent system which has proven generally useful for the preparation of substituted benzoic acid derivatives. For example, 4-alkyl- or 4-halobenzoyl chlorides can be prepared in good yield and free of any positional isomers using this reagent combination.[1] The reaction is equivalent to a Friedel-Crafts acylation using ***Phosgene***, and in fact the presence of both carbon monoxide and phosgene has been detected by IR spectroscopy in the gases formed upon mixture of these reagents. The reaction works best for alkylated aromatic substrates and fails when attempted on those bearing either activating (such as alkoxy) or deactivating substituents. Carbon disulfide appears to be the solvent of choice for these reactions. The acid chloride products obtained by this method can also be directly subjected to either hydrolysis[3] or alcoholysis[4] to provide the corresponding carboxylic acids or esters (eqs 1 and 2).

(1)

(2)

Similarly, the combination of oxalyl chloride/aluminum chloride will introduce an acyl group at the 2-position of 1-(phenylsulfonyl)pyrrole (**1**) to give the corresponding acid chloride (**2**) (eq 3).[2]

(3)

(1) **(2)**

There is a report describing the reaction of paracyclophane (**3**) with oxalyl chloride/aluminum chloride under mild conditions (-10 °C) to produce the glyoxyl chloride derivative (**4**) in quantitative yield.[5] Refluxing (**4**) for 3 h in chlorobenzene effects complete decarbonylation to the acid chloride (**5**).

(4)

An interesting ring closure of the tricarbonylmyrceneiron complex (**6**) has been reported.[6] Treatment of (**6**) with oxalyl chloride/aluminum chloride (1:2) in dichloromethane at -78 °C led to the immediate formation of two diastereomeric keto chlorides (**7**). Dehydrohalogenation of one of the stereoisomers using ***Silver(I) Nitrate*** afforded the enone (**8**) (eq 5).

Oxalyl Chloride-Dimethylformamide

$(COCl)_2$

[79-37-8] · $C_2Cl_2O_2$ · Oxalyl Chloride-Dimethylformamide · (MW 126.92) (DMF)

[68-12-2] · C_3H_7NO · Oxalyl Chloride-Dimethylformamide · (MW 73.11)

(versatile agent combination for in situ generation of Vilsmeier reagent used in preparation of carboxylic acid chlorides and other acid derived products,[1] phosphonic acid chlorides,[2] β-chloro enones,[3] ketoximes[4] and formyl derivatives[5])

Physical Data: see entries for ***Oxalyl Chloride*** and ***N,N-Dimethylformamide***.

Form Supplied in: generated in situ under anhydrous conditions from oxalyl chloride and either catalytic or stoichiometric dimethylformamide, typically in halogenated solvents such as dichloromethane; acetonitrile, or hexane. The intermediate dimethylforminium chloride (DMFCl) can be isolated as a hygroscopic solid, mp 140 °C (see also ***Thionyl Chloride***, ***Phosphorus Oxychloride***).

Handling, Storage, and Precautions: (see also ***Oxalyl Chloride***); reagent generated in situ under anhydrous conditions; corrosive, toxic. Oxalyl chloride should be used in the fume hood.

Synthesis of Carboxylic Acid Chlorides and Anhydrides.

Carboxylic acids, including amino acids,[6] readily react with DMFCl generated in situ to produce acid chlorides on heating (eq 1).[1] The procedure has been shown to be general, and may provide acid chlorides not available with oxalyl chloride alone.[7,8]

The mild reaction conditions employed enables the preparation of chlorides without disrupting chiral or other sensitive functionality. The use of hexane has been found particularly suitable for microscale preparation of high purity Mosher's acid chloride as it enables residual DMFCl to be filtered from solution (eq 2).[9]

DMFCl has been used to prepare carboxylic esters (eq 3),[10] *N*-hydroxycarboxamides and *O*,*N*-dimethylcarboxamides,[11] and α-hydroxycarboxamides (eq 4),[12] via a one pot process.

A procedure using silyl esters, developed to allow synthesis of acid chlorides under neutral conditions, has been applied to a range of substrates (eq 5),[13] including amino acid anhydrides.[1]

Reduction of the intermediate generated from a carboxylic acid and DMFCl provides aldehydes with ***Lithium Tri-t-butoxyaluminum Hydride***,[14] and alcohols with ***Sodium Borohydride***,[15] both in high yield and chemoselectivity.

Preparation of Phosphonic Acid Chlorides.

Disilyl esters of phosphonic acids react with oxalyl chloride-DMF to give the phosphonyl chlorides and silyl chlorides under mild conditions (eq 6).[2] Prior treatment of an acid-sensitive phosphonate monoester with ***Trimethylsilyldiethylamine*** was used to minimize exposure to HCl (eq 7).[16]

A general process suitable for large scale synthesis of phosphonic acid dichlorides, which avoids the need for preforming silyl esters, has been reported (eq 8).[17]

(8)

β-Chloro (or Bromo) Enones.

Cyclic diketones in solution with DMF and dichloromethane react with oxalyl chloride (or bromide) to give β-halo enones in high yield (eq 9).[3] The reported procedure reduces overall reaction time and avoids solubility problems.

(9)

Formylation.

Vilsmeier formylation reactions have been reviewed.[1] Oxalyl chloride-dimethylformamide has found occasional use; one application has been preparation of a piperidine substituted dialdehyde (eq 10).[5]

(10)

Alkyl Chlorides.

N,*N*-Diphenylformamide is reported to be an improvement on DMF when used with oxalyl chloride to prepare primary and secondary alkyl chlorides from alcohols.[18]

Ketoximes.

Lithium salts of nitroalkanes react with DMFCl, preformed from oxalyl chloride and DMF, to give intermediates which

on reaction with Grignard reagents give ketoximes on workup (eq 11).[4]

Oxazole[1,2]

[288-42-6] · C_3H_3NO · Oxazole · (MW 69.07)

(2-aza Diels-Alder diene,[2] precursor to *N*-formylformamide[3])

Physical Data: mp -87 to -84 °C; bp 69-70 °C; *d* 1.050 g cm^{-3}; λ_{max} 205 nm (ε 3900).

Form Supplied in: colorless oil.

Preparative Methods: two methods have been reported for the preparation of oxazole.[4,5] The more recent approach entails three steps (eqs 1 and 2) and an overall yield of 39%.

General Discussion.

Oxazole functions as an azadiene in the Diels-Alder reaction.[2] The resulting [4 + 2] product is normally not isolated, instead rearranging to pyridines (eq 3). High regioselectivity has been reported[6] for this reaction (see also ***4-Phenyloxazole***). Oxazole can also perform as a dienophile, as in the reaction with tetrazines (eq 4).[7]

(3)

(4)

Treatment of oxazole with one equivalent of ***Ozone*** cleaves the C-C bond and yields *N*-formylformamide (**4**) (eq 5).[3] Subsequent addition of primary or secondary amines gives high yields of formamides (eq 6). Formylation of alcohols is substantially slower.

(3) (4) (5)

(6)

Metalation at C-2 of oxazole is rapid with ***n-Butyllithium***, and the metalated product is in equilibrium with the ring-opened isocyanide (eq 7). Highly reactive electrophiles yield products from the enolate form of (**5**) (eqs 8 and 9), while less reactive electrophiles react with the carbanion form (eqs 10 and 11).[8]

(7)

(8)

(9)

(10)

(11)

Palladium-catalyzed coupling of chloropyrazines with oxazole occurs at C-2, yielding the diaryl in good yield (eq 12).[9]

(2-Oxoisopentyl)triphenylarsonium Bromide

[-] · $C_{23}H_{24}AsBrO$ · (2-Oxoisopentyl)triphenylarsonium Bromide · (MW 471.29)

(highly stereoselective alkenation reagents for the synthesis of (*E*)-β-enones; especially suitable for unstable aldehyde substrates in natural products synthesis)

Physical Data: mp 181-182 °C.

Solubility: insol ether; sol THF, MeCN, etc.

Preparative Methods: from ***Triphenylarsine*** and 1-bromo-3-methyl-2-butanone, which is obtained from 3-methyl-2-butanone and bromine in methanol.[1]

Handling, Storage, and Precautions: the toxicity of this reagent is unknown at present; use in a fume hood.

General Discussion.

The synthesis of (*E*)-β-enones is usually accomplished by the Wittig or Horner-Emmons reaction. It has been shown that arsonium ylides with electron-withdrawing substituents in the alkylidene moiety are more reactive than the corresponding phosphorane[2,3] and a facile approach to achieve the alkenation using arsonium salts has been disclosed.[4,5]

β-(*E*)-Enones are prepared in high yields with high stereoselectivity by reaction of (**1**) with aldehydes under PTC conditions (eq 1).[6]

(1)

Similarly, 2-(oxoheptyl)triphenylarsonium bromide ($C_{25}H_{28}OAsBr$, mp 156-159 °C) (**4**) reacts with aldehydes to give (**5**) (eq 2).[6]

(2)

The aldehyde (**6**) reacts with the arsonium salt (**1**) in acetonitrile to give the key intermediate (**7**) for the synthesis of brassinosteroid in 78% yield (eq 3).

(6)

(3)

(7)

The construction of the alkenyl side chain of $PGF_{2\alpha}$ and its analogs has frequently been accomplished by alkenation of the Corey aldehyde (**8**) with phosphonic esters or phosphoranes.[7] However, the reactions must be strictly controlled and elimination of the acetoxy group often occurs in large scale reactions. When the reaction of (**9**) and (**4**) is carried out in acetonitrile, the elimination product is formed predominantly. However, with the CH_2Cl_2/THF solvent system in which the salt (**4**) is more soluble, the elimination is completely prevented. Thus the unstable aldehyde (**9**) reacts smoothly with (**4**) to give $PGF_{2\alpha}$ intermediate (**10**) in 63% overall yield from (**8**) (eq 4).[6]

The related arsonium salt (4-oxopent-2(*E*)-enyl)triphenylarsonium bromide (**11**) (mp 127-128 °C) is prepared from triphenylarsine and (*E*)-5-bromo-3-penten-2-one without solvent at 50 °C for 4 h in 43% yield (eq 5).

Aldehydes react with (**11**) in ether (trace H_2O) and K_2CO_3 at 0-3 °C to give a mixture of (*E*,*E*) and (*E*,*Z*) isomers in 81% yield, with the former predominating. The latter can be easily isomerized to the (*E*,*E*) isomer when treated with catalytic amount of I_2 under daylight.

A naturally occurring trail-breaking alarm pheromone of sea slug, navenone A, has been synthesized in 46% yield by a two-step alkenation sequence (eq 6).[8] In contrast, an alternative seven-step sequence provided navenone A in 1.1% overall yield.[9]

μ-Oxobis(chlorotriphenylbismuth)[1]

[35952-85-3] · $C_{36}H_{30}Bi_2Cl_2O$ · μ-Oxobis(chlorotriphenylbismuth) · (MW 967.52)

(mild oxidant for alcohols and α-glycol cleavage[4])

Physical Data: mp 148-154 °C.[2]

Solubility: sol CH_2Cl_2, $CHCl_3$, THF, hot benzene.

Preparative Methods: by treatment of ***Triphenylbismuth Dichloride*** with NaOH in MeOH-acetone.[3]

Handling, Storage, and Precautions: stable white solid. Can be stored in the refrigerator under inert gas (N_2 or Ar) for some weeks. This reagent should be handled in a fume hood.

Oxidation of Alcohols.[3,4]

Oxobis(chlorotriphenylbismuth) is a mild oxidant for primary, secondary, allylic, and benzylic alcohols, which are converted smoothly and in high yields to the corresponding carbonyl derivatives under mild conditions of pH and temperature. The oxidation is generally performed by addition of the alcoholic substrate to a solution of the reagent in CH_2Cl_2 in the presence of K_2CO_3 or $KHCO_3$ at rt or under reflux. The carbonyl products are easily separated from the triphenylbismuth byproduct, either by chromatography on silica gel, or by heating the reaction mixture with acetic acid followed by aqueous workup and ether extraction. Unfortunately this latter procedure curtails the advantage of the near neutral reaction conditions. The reagent is especially effective for the oxidation of allylic alcohols. Examples of the efficiency of the reagent are found in the oxidation of natural products. The oxidation of methyl hederagenin to methyl hederagonate was performed in 24 h with a 36% yield (eq 1), significantly better than the previously reported oxidation.[5] In the synthesis of digitoxin derivatives, the oxidation of a furyl alcohol to the 15-keto derivative was achieved in 94% yield (eq 2).[6] In the oxidation of cembranolide diterpenes,[7] the reaction was accomplished without disturbing the oxirane ring (eq 3).

μ-Oxobis[tris(dimethylamino)phosphonium] Bis(tetrafluoroborate)[1]

[55881-03-3] · $C_{12}H_{36}B_2F_8N_6OP_2$ · μ-Oxobis[tris(dimethylamino)phosphonium] Bis(tetrafluoroborate) · (MW 516.10)

(a mild dehydrating agent, useful in peptide synthesis,[2] dehydration of aldoximes to nitriles[3] and Beckmann or Lossen-type rearangements[3])

Alternate Name: Bates' reagent.

Physical Data: mp 194-204 °C.

Solubility: insol ether, EtOAc, THF, CH_2Cl_2, $CHCl_3$; sol MeCN, DMF, HMPA.

Form Supplied in: white crystalline solid; limited commercial availability.

Preparative Methods: by treatment of ***Hexamethylphosphoric Triamide*** with *p*-toluenesulfonic anhydride at 55 °C for 3 h, isolation of the bis(*p*-toluenesulfonate), then treatment with $NaBF_4$ in MeCN.[2]

Handling, Storage, and Precautions: can be used with care without special precautions; however, it reacts with water to produce HMPA (carcinogenic) and HBF_4 (corrosive).

Peptide Synthesis.

Bates' reagent is a dehydrating agent used in the synthesis of peptides (eq 1).[1] It has the advantage over ***1,3-Dicyclohexylcarbodiimide*** (DCC) that the byproducts of the reaction (HMPA, etc.) are water-soluble and easily removed. A disadvantage is that it results in extensive racemization. This can be overcome, however, by the addition of ***1-Hydroxybenzotriazole*** (HOBT).[1] Bates' reagent, even in conjunction with HOBT, is not as popular as the closely related reagent ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate*** (BOP).[4] The latter

reagent is more readily available, considerably cheaper, has a lower molecular weight (less reagent is required), produces less acid (less base is required), and is more efficient for solid-phase peptide synthesis.[5]

Activation of *N*-Hydroxy Compounds.

Bates' reagent is a useful reagent for the Beckmann rearrangement of ketoximes (eq 2), dehydration of aldoximes to nitriles (eq 3), and Lossen-type rearrangement of hydroxamic acids (eq 4).[3]

It is much less reactive as an activating/dehydrating agent than is the analogous Ph_3+P-O-+PPh_3 2OTf$^-$,[6] where reactions are often complete in a few minutes at rt. However, a disadvantage of the latter reagent is the difficulty of separating the product from Ph_3PO.

Oxodimethoxyphosphoranesulfenyl Chloride[1]

(**1**; $R^1 = R^2 = OMe$)

[13894-35-4] · $C_2H_6ClO_3PS$ · Oxodimethoxyphosphoranesulfenyl Chloride · (MW 176.57) (**2**; $R^1 = R^2 = OEt$)

[1186-08-9] · $C_4H_{10}ClO_3PS$ · Oxodimethoxyphosphoranesulfenyl Chloride · (MW 204.63) (**3**; $R^1 = R^2 =$ O-*i*-Pr)

[55655-36-2] · $C_6H_{14}ClO_3PS$ · Oxodimethoxyphosphoranesulfenyl Chloride · (MW 232.69)

(reacts as a pseudohalogen;[1] adds across alkenes and alkynes with little regioselectivity;[2-5] can thiophosphorylate aldehydes and ketones α to the carbonyl[6])

Physical Data: (**1**) bp 50 °C/0.06 mmHg. (**2**) bp 50 °C/0.2 mmHg. (**3**) bp 86 °C/2 mmHg.

Solubility: sol CH_2Cl_2, CCl_4, benzene, diethyl ether, THF.

Form Supplied in: yellow liquids; not commercially available.

Preparative Methods: prepared from a variety of different precursors using the procedures shown in eq 1.[1]

Handling, Storage, and Precautions: stability is in the order: phosphoro, $(R^1O)_2P$- > phosphono, $(R^1O)R^2P$- > phosphino, R^1R^2P-. Phosphoryl derivatives are quite stable and may be distilled under vacuum. They decompose upon storage, even at low temperatures, and are often prepared and used in situ. Phosphono derivatives lose sulfur on heating and phosphino derivatives lose sulfur at 20 °C and are only moderately stable at 0 °C.

Additions to Alkenes.

The addition of phosphoranesulfenyl chlorides to alkenes is not as regioselective as similar additions of methanesulfenyl chloride or other alkyl- and arylsulfenyl chlorides where anti-Markovnikov products tend to predominate.[2] This is due to the fact that additions of phosphoranesulfenyl chlorides proceed by an Ad_E2 mechanism which does not necessarily involve a thiiranium ion intermediate, in contrast to those of *C*-sulfenyl chlorides.[3,7] The electron-withdrawing property of the phosphorus impairs the bridging ability of the sulfur atom sufficiently to make

the intermediate possess more carbonium ion character, with the chloride counterion more closely associated with the sulfur atom.[2,8] Also, the oxygen atom attached to phosphorus may contribute to stabilization of cationic intermediates (eq 2).[3]

(2)

The additional regiochemical dependence of these additions on the steric and electronic effects of the alkene and phosphorus substituents can contribute to the low regioselectivity of these reactions (eqs 3 and 4).[3,4]

(3)

R = Me	X = Cl, Br, CH_2Cl, NO_2	100:0
R = *i*-Pr	X = Cl, Br, CH_2Cl, NO_2	50:50

X = CN, SO_2Me, $SiEt_2Me$	0:100
X = Ph	100:0
X = CO_2Me	66:34
X = P(O)(OEt)$_2$	50:50

Addition to Alkynes.

The substantial amount of *cis* product produced in the addition of phosphoranesulfenyl chlorides to alkynyl compounds is evidence for an unsymmetrical reaction intermediate in which an appreciable amount of positive charge is localized on one carbon atom (eq 5).[5]

Addition to Allylsilanes and Allylstannanes.

Reaction of phosphoranesulfenyl chlorides with allylsilanes and allylstannanes is similar, with both giving the products of an S_E2' mechanism (although this mechanistic pathway has not been proven).[5] In the case of allylsilanes, however, other products are also formed (eq 6).

Reaction with Aldehydes and Ketones.

Aldehydes and ketones may be thiophosphorylated α to the carbonyl by reaction of silyl enol ethers with phosphoranesulfenyl chlorides (eq 7).[6]

Reaction with Acetylide Anions.

The preparation of *S*-ethynyl esters of thiophosphoric acids occurs in moderate yield by the reaction of phosphoranesulfenyl chlorides with ***Ethynylmagnesium Bromide*** (eq 8).[9]

R = Et, Pr, Bu
X = H, Bu, CH_2SEt, CH_2Bu, $S(O)P(OEt)_2$

Reaction with α-Diazo Ketones.

Reaction of phosphoranesulfenyl chlorides with α-diazo ketones may be performed in CH_2Cl_2 or ether at -15 °C, or in benzene at 6 °C. Since these reaction conditions preclude the formation of a carbene intermediate, the reaction is thought to proceed via a diazonium cation to give α-chloro-substituted esters of thiophosphoric acid (eq 9).[10]

Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)

[23319-63-3] · $C_{11}H_{23}MoN_4O_6P$ · Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide) · (MW 434.29)

(hydroxylation of enolates[1] and nitrile anions;[2] preparation of carbonyl compounds by oxidative degradation of anions of sulfones;[3] nitroalkanes;[4] phosphonates;[5] for *N*-hydroxylation of amides;[6] for oxidative cleavage of C-B bonds[7])

Alternate Name: MoOPH.

Physical Data: mp 103-105 °C (dec).

Solubility: insol ether; sparingly sol THF; sol dichloromethane.

Form Supplied in: finely divided yellow crystals; not available commercially.

Analysis of Reagent Purity: no convenient assay has been reported. Decomposition is indicated if the reagent smells of pyridine or becomes sticky.[1b]

Preparative Methods: a detailed procedure is available:[1b] (1) MoO_3 + 30% H_2O_2 (<40 °C); (2) add HMPA; vacuum dry MoO_5.HMPA.H_2O to MoO_5.HMPA; (3) pyridine in THF gives MoOPH.

Purification: attempted recrystallization causes decomposition of MoOPH. Purity depends on the quality of MoO_5.HMPA.H_2O, which can be recrystallized from methanol.

Handling, Storage, and Precautions: MoOPH should be stored in the freezer and protected from light.[1b] The reagent should be treated as an

explosion hazard due to its peroxidic nature.[1b,8] Properly stored MoOPH is a freely flowing, yellow crystalline powder, and can be handled in the air at room temperature using a safety shield and protective gloves.

Enolate Hydroxylation.

MoOPH[1,9] is a useful reagent for the hydroxylation of lithium, sodium, and potassium enolates of ketones,[1,10] aldehydes,[11] esters,[1,12] and lactones,[1,13,14] and related anions.[15] Similar hydroxylations can be performed with 1-*p*-toluenesulfonyl-2-phenyloxaziridine (Davis' reagent; see ***(±)-trans-2-(Phenylsulfonyl)-3-phenyloxaziridine***), but the latter reagent works best with Na or K enolates that are sensitive to equilibration.[16] MoOPH oxidation of the lithium enolate in THF is the method of choice when regiospecific hydroxylation is desired [examples (**1**)-(**6**)].

(6) 62%

Byproducts may include α-diketones (with aryl *n*-alkyl ketone enolates) or aldol adducts (methyl ketone or enone enolates), and recovery of 5-20% unreacted ketone is common. Inverse addition techniques and temperature optimization (usually -78 to -20 °C) may prevent side reactions with difficult substrates.[1a] Cyclohexanone enolates prefer axial hydroxylation [(**1**) 7:1 α:β;[1a] (**3**) only isomer reported;[10a] (**6**) 2:1 β:α[10d]]. Several stereoselective ester[12] and lactone[13,14] hydroxylations have also been reported [(**8**) 7:1 α:β;[13a] (**9**) 8.5:1 α:β[14a]]. The MoOPH hydroxylation of the Evans imide enolates has a small selectivity advantage compared to the Davis oxaziridine, but yields are lower.[15a] MoOPH is relatively bulky, and prefers bonding to the less hindered enolate face in the absence of stereoelectronic factors. These oxidations involve enolate attack at the O-O bond (eq 1).

(7) 85%

(8) 80%

(9) 58%

Hydroxylation of Other Stabilized Anions.

Nitrile anions are hydroxylated by MoOPH to afford cyanohydrins.[2,17] The cyanohydrins can be isolated starting from unbranched nitriles[2,17c] or strained cyclic nitriles (eq 2).[17a] More typical α-branched nitrile anions afford the ketones directly,[2,17b] and condensation of this ketone with the starting nitrile anion may complicate these reactions.[2]

(2)

Sulfone anions can also be hydroxylated.[3] The resulting α-hydroxy sulfones fragment spontaneously to the corresponding ketone[3,18] or aldehyde.[19] Condensation between the carbonyl product and the sulfone anion can be a major reaction pathway.[19b] Similar oxidative degradation occurs with nitroalkane and phosphonate anions.[4,5]

Miscellaneous Hydroxylations with MoOPH.

Other strongly basic carbanions have been hydroxylated with MoOPH, including an aryllithium derivative,[20] a dipole-stabilized benzyllithium PhC(O)N(Me)CH(Li)Ph,[21] and a lithiated vinylogous amide.[22] Certain relatively nonbasic substrates can also react with MoOPH, resulting in net hydroxylation. The reagent cleaves C-B bonds with retention,[7] and is useful for the oxidative workup of boron enolate aldol reactions.[23] In the presence of ***t-Butyl Hydroperoxide***, MoOPH converts α- or β-naphthols into ketols derived from *ortho* hydroxylation of the naphthalene ring.[24] Finally, MoOPH reacts with *N*-trimethylsilylamides to afford the *N*-hydroxy amides (eq 3).[6,25]

μ_3-Oxohexakis(μ-trimethylacetato)tris(methanol)triiron(III) Chloride

$[Fe_3O(OCOCMe_3)_6(MeOH)_3]Cl$

[55216-31-4] · $C_{33}H_{66}ClFe_3O_{16}$ · μ_3-Oxohexakis(μ-trimethylacetato)tris(methanol)triiron(III) Chloride · (MW 921.99)

(one of several (μ_3-oxo)triiron cluster complexes used to catalyze the epoxidation of alkenes with molecular oxygen[1])

Physical Data: orange-yellow crystalline solid.

Preparative Methods: equimolar aqueous solutions of $Fe^{III}Cl_3$ and sodium pivalate are mixed and the resulting precipitate is filtered and dried in vacuo.[2]

Purification: recrystallization from chloroform-methanol.

Epoxidation of Alkenes.[3]

$[Fe_3O(OPiv)_6(MeOH)_3]^+Cl^-$ (Piv = $OCCMe_3$) is a useful catalyst for the epoxidation of alkenic alcohol acetates with molecular oxygen. The reaction requires one equivalent of oxygen to effect the peroxidation, half of which is apparently consumed in undesirable side reactions. The regiospecificity of the oxidation is similar to that observed when conventional peroxy acid epoxidation reagents are used,[4] but is opposite to that observed under Sharpless epoxidation conditions.[5] This polynuclear transition metal catalyst affords higher yields and better selectivity than alternative transition metal catalysts known to effect alkene epoxidation with oxygen. However, two particularly good alternatives are $[Fe_3O(OAc)_6(H_2O)_3](OAc)$ *[60797-92-4]* and $[Fe_3O(OAc)_6(py)_3]Cl$ *[69554-73-0]*.[6] Mononuclear iron catalysts, such as $FeCl_3$, failed under the prescribed conditions. Depending on the substrate, the reaction may be performed in the absence of a solvent. For instance, 6,7-epoxygeranyl acetate was produced from geranyl acetate in the absence of a solvent (60 °C, 20 h) and without formation of the 2,3-epoxide isomer (eq 1).

Oxo(methoxy)molybdenum(V) 5,10,15,20-Tetraphenylporphyrin

[74751-79-4] · $C_{45}H_{31}MoN_4O_2$ · Oxo(methoxy)molybdenum(V) 5,10,15,20-Tetraphenylporphyrin · (MW 755.74)

(able to catalyze selective and specific oxidation of alkenes by peroxy-bond heterolysis[1,2])

Solubility: sol methylene chloride, benzene.

Preparative Methods: the alkoxo complex is obtained[1,2] by chromatography of O=Mo(TPP)Cl[1] over alumina using 20% MeOH in methylene chloride as eluant, followed by crystallization from MeOH-CH_2Cl_2.

Stereoselective Epoxidation.[2]

The reagent has been used as a catalyst in the selective epoxidation of alkenes with ***t-Butyl Hydroperoxide***. In a typical experiment, OMo(TPP)OMe (5×10^{-6} mol) was dissolved in dry oxygen-free benzene. Cyclohexene (24.6 mmol) was added. The accurate catalyst concentration was measured by

UV-Vis spectrometry, and the mixture was heated to 80 °C under argon. After equilibration, *t*-BuOOH (5 mmol) was added and aliquots were periodically monitored.

O=Mo(TPP)OMe, O=Mo(TPP)Cl, and *cis*-O_2Mo(TPP) catalyze the epoxidation of cyclohexene with *t*-butyl hydroperoxide with formation of the insoluble $[OMo(TPP)]_2O$. These Mo complexes are comparable to ***Hexacarbonylmolybdenum***, but exhibit a longer induction period. A high selectivity to cyclohexene oxide was obtained at total conversion of the hydroperoxide. The rates of epoxide formation, expressed as the turnover number of the catalyst, are, respectively, $Mo(CO)_6$ 283 and OMo-(TPP)OMe 51 h^{-1}. Monitoring the reaction by UV-Vis spectrometry revealed a complicated spectrum evolution during the induction period. However, after a time of reaction corresponding to three times the duration of the induction period, i.e. when the reaction had reached its stage of full catalytic activity, the concentration of Mo^V porphyrin complexes in solution was still 98-100% of that measured before addition of *t*-BuOOH.

OMo(TPP)Cl-catalyzed epoxidation of *cis*- and *trans*-2-hexene was found to be highly stereoselective, affording, respectively, 97% and 99% of the corresponding *cis*- and *trans*-2-epoxides. Relative rates of formation of *cis*- and *trans*-2-hexene oxides are significantly different. The *cis*-2-hexene oxide is formed 3.5 times faster than the *trans* isomer, showing a specific behavior of the porphyrin complex. The higher rate of formation observed for *cis*-2-hexene oxide indicates a more efficient steric control, as expected if the bulky rigid porphyrin ligand is present in the activated complex.

This effect is clearly evidenced in the case of 2-methylbutadiene (isoprene) where 3-methyl-3,4-epoxy-1-butene and 2-methyl-3,4-epoxy-1-butene, corresponding respectively to the epoxidation of the di- and monosubstituted double bond, are obtained in a 4:1 ratio by using $Mo(CO)_6$[3] compared to 0.7:1 with OMo(TPP)OMe (eq 1).

(1)

$Mo(CO)_5$	1:4
O=Mo(TPP)OMe	1:0.7

OMo(TPP)X complexes represent the first example of metalloporphyrins able to catalyze selective and specific oxidation of alkenes by peroxy-bond heterolysis.[2] With other transition metals like iron or cobalt, radical chain processes are observed for the oxidation of alkenes, giving only extremely low selectivity to epoxide[4] or the hydroxylation of saturated hydrocarbons.[5] This oxomolybdenum porphyrin-*t*-butyl hydroperoxide system may be considered as a simple chemical model for activation of hydroperoxides by cytochrome P-450 dependent monooxygenases.

Oxoperoxobis(*N*-phenylbenzohydroxamato)molybdenum(VI)

[77402-46-1] · $C_{26}H_{20}MoN_2O_7$ · Oxoperoxobis(*N*-phenylbenzohydroxamato)molybdenum(VI) · (MW 568.42)

(oxidizes primary and secondary alcohols to the corresponding carbonyl compounds;[1] can epoxidize allylic alcohols stereoselectively[1])

Physical Data: mp 150 °C (dec).

Solubility: sol dichloromethane, 1,2-dichloroethane; insol water, hexane.

Form Supplied in: orange-yellow crystals.

Preparative Methods: by stirring a mixture of $MoO_2(acac)_2$ (1 mmol) and hydroxamic acid (PhCON(Ph)OH) (2 mmol) at 25 °C for 3 h, followed by treating the white solid of $MoO_2(PhCON(Ph)O)_2$, so formed, with excess of 30% H_2O_2 at 25 °C.

Oxidation of Primary and Secondary Alcohols.[1]

Primary alcohols are oxidized to aldehydes and secondary alcohols to ketones. Yields are fair to good. The mixture of the Mo complex and the alcohol in 1,2-dichloroethane is refluxed for 4 h. The product is isolated after the usual workup. Cyclododecanol and 2-octanol have been oxidized in >95% yield to their corresponding ketones, whereas aldehydes are obtained from benzyl alcohol and dodecanol in 80 and 63% yield, respectively.

Epoxidation of Alkenic Alcohols.

The reagent is quite reluctant to react with simple alkenes, although molybdenum diperoxo compounds such as Mimoun's reagent are known to epoxidize alkenes.[2] However, allylic alcohols were converted easily to α,β-epoxy alcohols in fair yields (60-70% isolated). It is worth noting that more stereoselectivity is obtained in this reaction using a stoichiometric

amount of the monoperoxo complex than that observed with ***t-Butyl Hydroperoxide*** in combination with ***Hexacarbonylmolybdenum***.[3] This is illustrated in Table 1.

Table 1 Epoxidation of Alkenic Alcohols

Alternate Name: manganese triacetate.

Solubility: insol most organic solvents; sol hot acetic acid; hydrolyzed by water.

Form Supplied in: brown or gray powder and chunks; widely available.

Preparative Methods: often referred to as anhydrous $Mn(OAc)_3$, which does not exist.[2] Can be prepared from $Mn(OAc)_2$ and $KMnO_4$ in $AcOH/Ac_2O$, or prepared in situ from $Mn(OAc)_2$ and $KMnO_4$ in AcOH.[3,4]

Purification: not usually necessary.

Handling, Storage, and Precautions: hygroscopic; avoid heat, sparks, and open flames.

Preparation of Lactones from Alkenes.

In the presence of manganese triacetate, simple alkenes react with carboxylic acids (often solvent ***Acetic Acid***) to give γ-lactones (eqs 1 and 2)[3,4] in a reaction which is thought to involve radical intermediates. This reaction can be performed on dienes[5] and on alkenes which possess other potentially reactive groups such as alkynes[6] (eq 3).[7] A range of other carboxylic acids has been used in place of acetic acid.[8,9]

(1)

(2)

(3)

In addition to simple carboxylic acids, a variety of β-keto acids also undergo reaction with alkenes to give lactones (eq 4),[9] and the intramolecular version of this reaction can be used effectively to produce polycyclic lactones (eq 5).[10] This latter reaction has been adapted to the total synthesis of polycyclic natural products.

(4)

(5)

The formation of C-C bonds using Mn^{III} salts is not restricted to the reaction of alkenes and carboxylic acids. A range of β-dicarbonyl compounds will also undergo additions to give dihydrofurans (eq 6)[11] and other types of products. In particular, the intramolecular cyclization can be used to construct a variety of cyclic systems, using both monocyclizations (eq 7)[12] and tandem cyclizations (eq 8).[13] A sulfoxide group can take the place of one of the carbonyl groups, and in this case the chirality of the sulfoxide controls the absolute configuration of the product. In effect, the sulfoxide group has been used as a chiral auxiliary in this cyclization (eq 9).[14]

(6)

(7)

(8)

(9)

Enol ethers and enol esters can also serve as the alkene component of this type of reaction, the products being useful as precursors for furans and 1,4-dicarbonyl compounds (eqs 10 and 11).[15,16] It is also possible to use simple ketones as the carbonyl component, although the yields are relatively low, and if the ketone is unsymmetrical, mixtures of products are obtained.[17]

Allylic Oxidation and Oxidation α to Carbonyl Groups.

Acetoxylation adjacent to both C=C and C=O double bonds is possible using manganese triacetate.[18,19] Although the reaction tends to be substrate dependent and the yields variable (eq 12),[19] it has been used to good effect in the synthesis of relatively complex polyfunctional systems that contain groups which might interfere (eqs 13 and 14).[20,21]

(14)

Other Applications.

Manganese triacetate is reported to be superior to ***Ruthenium(VIII) Oxide*** and ***Cerium(IV) Ammonium Nitrate*** for the oxidation of *N*-protected indolines to indoles (eq 15).[22] On treatment with manganese triacetate, aryldialkylamines undergo dealkylation, in which one alkyl group is replaced by an acetyl group,[23] and in combination with ***Diphenyl Disulfide*** alkenes undergo regioselective addition of PhS and OH.[24] Manganese triacetate was found to be the reagent of choice for the final step in a total synthesis of cyanocycline, which required the oxidation of the *p*-methoxyphenol to the corresponding quinone (eq 16).[25]

Oxygen

[7782-44-7] · O_2 · Oxygen · (MW 32.00)

(oxidizing agent for many organic systems, including, most commonly, organometallic compounds, carbon radicals, and heteroatoms such as sulfur)

Physical Data: mp -218 °C; bp -183 °C; *d* 1.429 g L^{-1} (0 °C), 1.149 g L^{-1} (-183 °C).

Solubility: sol to some extent in most solvents. Selected data, expressed as mL of O_2 (at 0 °C/760 mmHg) dissolved in 1 mL of solvent when the partial pressure of the gas is 760 mmHg, are as follows: Me_2CO (0.207/18 °C), $CHCl_3$ (0.205/16 °C), Et_2O (0.415/20 °C), EtOAc (0.163/20 °C), MeOH (0.175/19 °C), petroleum ether (0.409/19 °C), PhMe (0.168/18 °C), H_2O (0.023/20 °C).

Form Supplied in: dry gas; dilutions in Ar, He, or N_2; $^{18}O_2$; $^{17}O_2$.

Handling, Storage, and Precautions: of itself, oxygen gas is essentially nontoxic. However, it will support and vigorously increase the rate of combustion of most materials. It may ignite combustibles and can cause an explosion on contact with oil and grease. The potential for autoxidative formation of explosive peroxides (e.g. with Et_2O) should always be borne in mind.

Oxygenation of Carbanions and Organometallic Compounds.

Many organometallic species react with triplet oxygen to form the corresponding hydroperoxides,[1,2] although the products are more usually reduced in situ or during workup to afford alcohols as the isolated products. A number of other sources of electrophilic oxygen have been developed (e.g. ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** (MoOPH), sulfonyloxaziridines) and compete for this niche, but no single reagent is universally preferable. As carbon anion equivalents, Grignard reagents are optimal for simple hydrocarbons,[2] but organolithiums are more frequently employed. The potential for radical-mediated oxidative dimerization can constrain utility (particularly for aryl organometallics). Useful oxygenations of alkyl,[3] vinylic,[4] allylic,[5] benzylic,[6] and aryl (eq 1)[6] organolithium compounds have been reported. 1,1-Diorganometallics give the corresponding carbonyl derivatives (eq 2).[7]

(1)

(2)

Effective oxygenation of enolate anions is generally restricted to tertiary centers where over-oxidation is not possible.[8] Nonetheless, ketones (eq 3),[9] esters/lactones,[8] amides/lactams (eq 4),[10] and carboxylic acids[8] can all be usefully α-hydroxylated. In most cases the intermediate α-hydroperoxides are reduced in situ (usually with ***Triethyl Phosphite***),[11] although they can be isolated if desired.[12] The small size of the electrophile and the potential for radical involvement[8] do not encourage stereochemical chastity in these processes, but where sufficient bias exists, good discrimination can be observed (see eqs 3 and 4). A slightly different approach uses enolates derived from aqueous base treatment. These species have been usefully hydroxylated where there was little or no ambiguity in the direction of enolization[8] and this process forms the basis for a surprisingly effective catalytic, enantioselective oxygenation (eq 5).[13]

(3)

from anionic oxy-Cope

(4)

(5)

In cases where the activating group is also a leaving group, oxygenation can provide the corresponding carbonyl compound. Thus oxidative decyanation can be effected under either phase transfer[14] or anhydrous conditions (eq 6).[15] The latter procedure is more general, although it does require treatment with ***Tin(II) Chloride*** and base to reduce and fragment the α-hydroperoxide, and this method is not effective for the primary nitrile to aldehyde conversion. α,β-Unsaturated nitriles generally react at the α-position to give α,β-unsaturated ketones.[15]

(6)

Oxygenation of sulfone anions and the consequent desulfonylation is frequently effected with the MoOPH reagent. In

some cases, however, molecular oxygen has proved effective where MoOPH failed.[16] This perhaps illustrates a functional advantage over more bulky reagents and a counterpoint to the stereochemical disadvantages (see above). It should be noted that one such attempt resulted in a minor explosion[17] although, of course, any reaction involving peroxides bears this possibility. A similar process, preceded by nickel transmetalation, demonstrated the oxidation of the C-Ni bond, but the synthetic advantage is not clear.[18] However, this report did demonstrate the conjugative oxygenation of an allylic sulfone anion to give a γ-hydroxy sulfone.

Oxygenation of phosphorus-stabilized anions also produces the corresponding carbonyl compounds. The anions derived from phosphonates[19] (eq 7)[20] (including α-heteroatom substituted phosphonates)[19] and phosphine oxides[21] react smoothly with oxygen. Similarly, phosphorane ylides are readily oxidized.[22] In all these cases, however, the reaction of primary substrates suffers from competing self-condensation, giving alkenes.[22] It should be noted that a two-stage procedure involving the reaction of phosphonate anion with chlorodimethyl borate followed by oxidation with ***m-Chloroperbenzoic Acid*** has been advocated as a more efficient method[23] (and, interestingly, allows isolation of the intermediate hydroxy phosphonate).

(7)

Oxygenation of Carbon Radicals.

Not surprisingly, triplet oxygen reacts rapidly with carbon centered radicals.[24] Classical autoxidation is the most obvious example of this behavior. Traditionally, autoxidation refers to hydroperoxide formation from alkanes, aralkanes, alkenes, ethers, alcohols, and carbonyl compounds, where the initiating homolysis is induced thermally or photochemically.[25,26] There is an extensive literature concerning these processes dating back many years. While very important commercially, they are generally too promiscuous to be of wide synthetic value, particularly when dealing with complex molecules. Interestingly, however, a deformylative hydroxylation of an allylic neopentyl aldehyde has been observed that bypasses the classical autoxidative fate of aldehydes (eq 8).[27]

(8)

Radical oxygenation is most valuable where there is more strict control over the site of radical formation and subsequent oxygenation. Good stereochemical control is, of course, not usually achieved, although exceptions can be found in most cases. The mild and controlled methods of radical generation that have seen much use in synthesis are readily applicable to oxygenation. The thermal or photochemical decarboxylation of the esters of thiohydroxamic acids,[28] or their room temperature decomposition in the presence of tris(phenylthio)antimony[29] (i.e. Barton's methodology), can be intercepted

by triplet oxygen to generate the nor-alcohols. The addition of heteroatom radicals to alkenes can provide the source of carbon centered radicals for trapping. An interesting example of oxygenation initiated by phenylthio or phenylseleno radical addition to vinylcyclopropanes showcases the use of this methodology (eq 9).[30] Here, instances of moderately successful stereocontrol in the C-O bond forming step were noted. This transformation also demonstrates the potential of the initially formed hydroperoxy radical to participate in further steps (where higher levels of stereochemical discrimination are observed as a consequence of the intramolecular nature of the radical trapping). ***Samarium(II) Iodide*** induced radical processes have been quenched with oxygen to provide hydroxyl functionalized products.[31]

(9)

One of the most prevalent uses of molecular oxygen in modern synthesis is for oxidative demercuration.[32] Carbon radicals generated by the reduction of organomercurials with borohydride are efficiently trapped by oxygen, most frequently in DMF solution, to give hydroperoxides which are reduced under the reaction conditions to generate the corresponding alcohols directly.[33] The alkene oxymercuration-oxidative demercuration sequence is commonly practised (usually through a β-alkoxymercury species, since β-hydroxy fails[33]), particularly where the oxymercuration is an intramolecular cyclization (eq 10).[34] Typically, any stereocontrol observed in the oxymercuration (or other C-Hg bond forming step) is effaced in the oxygenation (as in eq 10).

Oxidation of Organoboranes.

Boranes, most frequently accessed by hydroboration of alkenes, can be oxidized by triplet oxygen.[35,36] If the oxidation is carried out in fairly concentrated solution (~0.5 N) at 0 °C, intermolecular redox reaction of the intermediate diperoxyborane is facilitated and workup provides the corresponding alcohol.[36] While this is quite efficient, ***Hydrogen Peroxide*** is more commonly used in synthetic applications. This is partly for convenience, but also a consequence of stereochemical issues. The oxidation with H_2O_2 occurs with retention of configuration at the carbon center. The radical characteristics of the dioxygen reaction generally lead to at least partial racemization. That this stereochemical corruption is not always complete is an indication of the uncertainty about the mechanism.[35] Interestingly, rhodium(III) porphyrin has been shown to promote stereoselective oxidation in the dioxygen procedure (eq 11).[37] In dilute solution (0.01-0.05 N) the intermolecular redox process is suppressed and diperoxyboranes are produced. Oxidation of the third B-C bond with H_2O_2 or peroxy acid and workup allows isolation of the corresponding alkyl hydroperoxides.[36] Alternatively alkyl hydroperoxide formation is facilitated by the use of alkyldichloroboranes.[36] This is one of the most convenient approaches to this functionality. The oxygen mediated approach to alcohols may be more convenient than H_2O_2 for radiolabeling; ^{17}O (eq 12) and ^{15}O alcohols have been prepared in this way.[38,39]

(11)

(12)

Heteroatom Oxidation.

Oxidation of nitrogen functionality with oxygen, while well precedented[40] and of continuing interest,[41,42] does not generally represent the method of choice for those processes of synthetic significance. However, a report of a mild procedure for the oxidation of silylamines to carbonyl compounds bears some synthetic potential (eq 13).[43] Oxidation of phosphorus functionality by oxygen can be quite facile.[44] For example, tertiary phosphines are very readily oxidized to their phosphine oxides, and secondary chlorophosphines can give the phosphinic acids.[44] Perhaps the most common heteroatom air oxidations are those of Group 16 RX-H bonds to their corresponding dimers ($(RX)_2$) and particularly the thiol to disulfide oxidation.[45] This, of course, is related to the importance of the disulfide bond to peptide and protein secondary structure. One example that reflects current interest in the control of multiple disulfide bond formation in synthetic peptides is given in eq 14.[46] Oxidation may be promoted by heavy metal ions.[45] Higher oxidations (for example sulfide to sulfoxide) are best performed with other reagents (oxone, peroxy acid, etc.).

(13)

Other Uses.

The oxidative dimerization of organometallics, alluded to above, is particularly prevalent for organocuprates,[47] although not totally unavoidable.[48] In fact it is efficient enough to be regarded as a synthetic strategy and has been used as such (eq 15).[49] Baeyer-Villiger oxidations generally employ peroxy acids, but a recent report indicates that 1 atm of oxygen can effect the rearrangement even in the absence of either metal catalysts or light.[50] Epoxidation by oxygen is possible[51] but, of course, is not usually the method of choice for laboratory synthesis.

(15)

There is a vast literature concerning metal-catalyzed oxidative processes involving molecular oxygen,[52] of which only a fraction have seen synthetic use. Many metal catalysts behave as oxygen fixing species, that deliver oxygen to the substrate through a peroxo complex. Reports frequently concern experimental systems, probing substrate reactivity and/or asymmetric induction. The function of oxygen in metal-catalyzed oxidations is not necessarily that of a reagent. Thus, for example, in the Wacker oxidation of terminal alkenes it operates as a re-oxidant for copper(II) chloride which in turn is a re-oxidant for the Pd^{II} species. All of these applications are best regarded as functions of the metal component and, for this reason, are not discussed here.

Related Reagents.

Copper(I) Chloride-Oxygen; ***Diethylzinc-Bromoform-Oxygen***; ***Iron(II) Sulfate-Oxygen***; ***Oxygen-Platinum Catalyst***; ***Singlet Oxygen***.

Oxygen-Platinum Catalyst[1]

O_2-Pt

[7740-06-4] · Pt · Oxygen-Platinum Catalyst · (MW 195.08)

(selective oxidant; highly regioselective oxidant for cyclic polyols; lactones obtained from diols; primary alcohols oxidized to carboxylic acids)

Solubility: reaction usually heterogeneous.

Form Supplied in: fine powder; widely available.

Preparative Methods: various methods[1] are employed, depending on the catalyst: for Pt/C, charcoal, concentrated HCl, and aqueous chloroplatinic acid are reduced with hydrogen or formaldehyde; Adams catalyst (PtO_2) is hydrogenated in the solvent to be used for the oxidation; after purging hydrogen, store under chosen solvent.

Purification: dry at 50 °C under reduced pressure.

Handling, Storage, and Precautions: avoid sources of ignition; take precautions against static discharge.

Introduction.

Oxygen (often as air) and a platinum catalyst are used in the oxidation of primary alcohols to yield usually carboxylic acids (eq 1)[2] and for oxidation of secondary alcohols. It has been widely used in the selective oxidation of carbohydrates and related systems, and some general guidelines have been developed. Primary alcohols are oxidized more rapidly than secondary alcohols; for secondary cyclic alcohols, axial hydroxyl groups are oxidized more rapidly than equatorial hydroxyl groups.

(1)

Oxidation of Aldoses and Ketoses.

Aldonic acids are produced by oxidation of aldoses (eq 2)[3] and ketoses undergo reaction at the primary position (eq 3).[4] Oxidation of reducing sugars at positions other than the aldehyde position is simply achieved by protection of this position as the corresponding acetal or acetonide, and, as expected, oxidation of the next most reactive position takes place (eq 4).[5] For deoxyamino sugars, the amino function is usually protected as a suitable acyl derivative (eq 5).[6]

(2)

(3)

(4)

(5)

Oxidation of Cyclitols.

A considerable amount of work has been carried out on the oxidation of cyclitols with oxygen-platinum catalysts[1] and a set of general rules has been developed: (a) only axial hydroxyl groups are oxidized; (b) oxidation stops at the monoketone even when more than one axial hydroxyl is present; (c) if several nonequivalent axial hydroxyl groups are present, then usually oxidation of only one of these will take place. These general rules are exemplified by eqs 6 and 7.[7]

(6)

(7)

Oxidation of Diols to Lactones.

The oxidation of 1,4-diols in which one of the hydroxyls is primary gives the corresponding lactones, a reaction which has found use in natural product synthesis,[8] including hydroazulenes (eq 8)[9] and prostaglandins (eq 9).[10]

(8)

Other Applications.

It has been shown that visible light and a catalyst of H_2PtCl_6-$CuCl_2$ (1:2) can be used to oxidize a series of alcohols,[1c] and that the oxidation of reducing sugars does not need oxygen if platinum catalysts are used under basic conditions.[11] 12a-Hydroxylation of a deoxytetracycline has been carried out using oxygen and a platinum catalyst,[12] although the usefulness this reaction appears to depend strongly on the structure of the substrate.[13]

University of Salford, UK

Ozone[1]

[10028-15-6] · O_3 · Ozone · (MW 48.00)

(powerful oxidant; capable of oxidizing many electron rich functional groups;[1c,d] most widely used to cleave alkenes, affording a variety of derivatives depending on workup conditions[1b,2])

Physical Data: mp -193 °C; bp -111.9 °C; *d* (0 °C, gas) 2.14 g L^{-1}.

Solubility: 0.1-0.3% by weight in hydrocarbon solvents at -80 to -100 °C.[3]

Preparative Methods: ozone is a colorless to faint blue gas which is usually generated in the laboratory by passing dry air or oxygen through two electrodes connected to an alternating current source of several thousand volts. From air, ozone is typically generated at concentrations of 1-2%; from oxygen, concentrations are typically 3-4%. Several laboratory scale generators are commercially available.

Analysis of Reagent Purity: the amount of ozone generated can be determined based on the liberation of iodine from potassium iodide solution followed by thiosulfate titration to determine the amount of iodine produced.[4] Photometric detectors are available which can determine the concentration of ozone in a metered gas stream. In this manner, exact amounts of ozone introduced into a reaction can be determined.

Handling, Storage, and Precautions: ozone is irritating to all mucous membranes and is highly toxic in concentrations greater than 0.1 ppm by volume. It has a characteristic odor which can be detected at levels as low as 0.01 ppm. All operations with ozone should be carried out in an efficient fume hood and scrubbing systems employing thiosulfate solutions can be used to destroy excess ozone. Liquefied ozone poses a severe explosion hazard.

Ozonolysis of Alkenes.

Ozone has been most widely used for cleavage of carbon-carbon double bonds to produce carbonyl compounds or alcohols, depending on workup conditions. These reactions usually are performed by passing a stream of ozone in air or oxygen through a solution of the substrate in an inert solvent at low temperature (-25 to -78 °C). Useful solvents include pentane, hexane, ethyl ether, CCl_4, $CHCl_3$, CH_2Cl_2, EtOAc, DMF, MeOH, EtOH, H_2O, or HOAc. The solvents most commonly used are CH_2Cl_2 and MeOH or a combination of the two. Reaction endpoint can be determined using photometric monitors to detect ozone in the exit gas stream, or by the appearance of a blue color in the reaction medium, which indicates excess ozone in solution. A wide variety of alkenes undergo ozonolysis, and those in which

the double bond is connected to electron-donating groups react substantially faster than alkenes substituted with electron-withdrawing groups.[1b,5] With haloalkenes, the rate of ozone attack is decelerated and a greater variety of products are obtained, although double bond cleavage is still prevalent.[6]

The reaction mechanism for ozonolysis has been studied extensively and is thought to involve a 1,3-dipolar cycloaddition to afford an initial 1,2,3-trioxolane or primary ozonide, which cleaves to a carbonyl compound and a carbonyl oxide (eq 1).[7] The carbonyl oxide generally forms at the fragment containing the more electron donating group. Recombination of the fragments affords a 1,2,4-trioxolane or ozonide which is sometimes isolated, but due to the danger of explosion is usually directly converted to carbonyl compounds via either a reductive or oxidative procedure. If alcoholic solvents are used, trapping of the carbonyl oxide can occur to afford an α-alkoxy hydroperoxide.

(1)

Reductive workup procedures afford aldehydes, ketones, or alcohols. An extensive number of reducing agents have been used including catalytic hydrogenation, sulfite ion, bisulfite ion, iodide, phosphine, phosphite, tetracyanoethylene (TCNE), Zn-HOAc, BH_3, $SnCl_2$, Me_2S, thiourea, or, to obtain alcohols, $LiAlH_4$ or $NaBH_4$.[1a,b,8] ***Dimethyl Sulfide*** offers several advantages. It rapidly reduces peroxidic ozonolysis products to carbonyl compounds, it operates under neutral conditions, excess sulfide is easily removed by evaporation, and the oxidation product is DMSO.[9] In cases where the odor of Me_2S is a problem, ***Thiourea*** is a convenient substitute: results are comparable to those obtained with Me_2S, and thiourea *S*,*S*-dioxide separates out from the reaction mixture.[10] A polymer-based diphenylphosphine system also has been developed which offers the advantage of a simple filtration and evaporative workup and eliminates potential product contamination by PPh_3 or its oxide.[11] A comparison of these workup options is shown in eq 2.

(2)

Oxidative workup procedures convert peroxidic ozonolysis products to ketones or carboxylic acids. Typical oxidative

reagents include peroxy acids, silver oxide, chromic acid, permanganate, molecular oxygen, and the most widely used reagent, ***Hydrogen Peroxide***.[1a,b,8]

Additional terminal functionalization can be accomplished by several methods. Schreiber has developed general ozonolysis and workup procedures which enable a variety of products to be prepared from cycloalkenes (eq 3).[12] Also, iron or copper salts can be used to convert ozonides or α-alkoxy hydroperoxides to chlorides or alkenes with one less carbon atom than in the original alkene (eqs 4 and 5),[13] and treatment of ozonides with hydrogen and an amine in the presence of a catalyst provides a direct route for the production of amines from alkenes (eq 6).[14] In a more specific case, stilbenes can be converted to alkyl benzoates by treatment of the intermediate α-alkoxybenzyl hydroperoxides with amines or DMSO.[15]

(3)

(4)

(5)

(6)

Vinyl ethers are more reactive toward ozone than alkenes due to the electron-donating oxygen substituent and double bond cleavage products are often obtained.[16] Notably, the ozonolysis of cyclic vinyl ethers provides a path to aldol and homoaldol type products.[17] In addition, silyloxyalkenes undergo clean oxidative cleavage with ozone to afford diacids by using oxidative workups (eq 7),[18] or hydroxyl or oxo derivatives by using reductive workups (eqs 8-10).[19] Overall, the two-step process of forming and cleaving a silyloxyalkene provides a method for regiospecific cleavage of an unsymmetrical ketone. Eq 10 shows that the silyloxyalkene double bond is sufficiently nucleophilic to allow for selective oxidative cleavage of this bond in the presence of less activated double bonds; with appropriate workup conditions, the method can thus complement Baeyer-Villiger oxidation.

(7)

(8)

(9)

(10)

While ozone generally reacts with vinyl sulfides and enamines to provide both the expected products of double bond cleavage and anomalous products,[20,21] ketene dithioacetals have been efficiently cleaved to ketones using ozone (eq 11).[22]

(11)

The reaction of α,β-unsaturated ketones with ozone usually affords keto acids containing one less carbon than in the original molecule (eq 12).[23]

(12)

In the ozonolysis of 1,3-dienes, one double bond often can be cleaved selectively, and in 1,3-cyclodienes, the regioselectivity in fragmentation of the primary ozonide depends upon the size of the rings (eq 13).[24] Eq 13 shows that as the ring size contracts from cyclooctadiene to cyclohexadiene, the α,β-unsaturated ester becomes favored over the enal.

(13)

$n = 4$, 71% 15:1
$n = 2$, 50% 1:8

Hindered alkenes often afford epoxides upon ozonation due to difficulty in forming the primary ozonide by a cycloaddition process.[25] Examples are displayed in eqs 14 and 15.[26,27]

(14)

(15)

Overall, ozone compares favorably with other approaches for oxidative alkene cleavage involving ***Osmium Tetroxide***, ***Potassium Permanganate***, ***Ruthenium(VIII) Oxide***, ***Sodium Periodate***, or chromyl carboxylates which are costly, toxic, involve metal wastes, and may require detailed workup procedures.

Ozonation of Alkynes.

Reactions of alkynes with ozone afford either carboxylic acids or, if reductive procedures are used, α-dicarbonyl compounds.[1c] For the production of carboxylic acids, MeOH has been shown to be superior to CH_2Cl_2 as reaction solvent.[28] As with alkenes, a number of reducing agents can be used to produce α-dicarbonyl compounds. An easy option which results in high yields of α-dicarbonyl compounds involves the addition of ***Tetracyanoethylene*** directly to an ozonation reaction mixture as an in situ reducing agent (eq 16).[29]

(16)

R = Ph, 92%; H, 60%; Pr, 71%

Alkynes react slower with ozone than do alkenes and selective reaction of alkenes can be achieved in the presence of alkynes (eq 17).[30] Conversely, the example of eq 18 shows that alkynes are more reactive toward ozone than aromatic rings.[31]

(17)

(18)

The ozonation of terminal alkynes to afford α-oxoaldehydes is significant (see eq 16). While reagents such as $KMnO_4$, RuO_4, OsO_4, and ***Thallium(III) Nitrate*** can be used to convert internal alkynes to α-dicarbonyl compounds, terminal alkynes are generally cleaved to carboxylic acids. Only ***Mercury(II) Acetate***-catalyzed oxidations using a molybdenum peroxide complex afford α-oxoaldehydes.[32] However, high catalyst loads are required, the oxidant is not commercially available, and metal wastes are generated.

Oxygenated alkynes also can be ozonated. The reaction of ozone with alkynyl ethers followed by reductive workup provides a convenient method for the production of α-keto esters in moderate yields (eq 19).[33]

(19)

Ozonation of Aromatic Systems.

Aromatic compounds are less reactive toward ozone than either alkenes or alkynes. As a consequence, more forcing conditions are required to ozonize aromatic systems. These conditions typically involve the use of acetic acid as solvent, excess ozone, and oxidative decomposition often using H_2O_2. Electron-withdrawing groups deactivate aromatic systems toward electrophilic ozone attack, while electron-donating groups activate aromatic systems toward ozone attack. An example of this is provided in Woodward's strychnine synthesis where methoxy substitution allows for selective oxidation of one aromatic ring over two others to afford an often difficult to prepare, terminally functionalized, conjugated (*Z*,*Z*)-diene (eq 20).[34]

(20)

With polycyclic aromatic hydrocarbons, the site of ozone attack may be dependent upon substrate structure and reaction solvent (eq 21).[35]

(21)

Synthetically useful ozonolyses of heteroaromatic systems include the preparation of pyridine derivatives from quinolines (eq 22),[36] the preparation of versatile *N*-acyl amides by the ozonolysis of imidazoles (eq 23),[37] and the unmasking of a latent carboxylic acid function by the ozonolysis of a furan system (eq 24).[38]

(22)

(23)

(24)

Ozonation of Heteroatoms.

Phosphines are converted to phosphine oxides and phosphites to phosphates by ozone.[39,40] These reactions are quite general and a wide range of substitutents can be tolerated. Phosphine oxides also can be produced by the ozonation of alkylidenetriphenylphosphoranes or of thio- or selenophosphoranes.[41,42] Organic sulfides are converted to sulfoxides and sulfones by ozonation.[40,43] Tertiary amines are converted to amine oxides, while nitro compounds can be produced in modest yields by ozonation of primary amines.[43,44] This preparation of nitroalkanes compares well with alternate approaches using peroxides, peroxy acids, permanganate, or ***Monoperoxysulfuric Acid***, but ozonation on silica gel has proven to be superior (see ***Ozone-Silica Gel***). Selenides are converted to selenoxides by ozone and this reaction is often used to achieve overall production of unsaturated carbonyl compounds. An example is shown in eq 25.[45]

(25)

Modification of Ozone Reactivity.

The reactivity of ozone toward various unsaturated moieties can be moderated by the addition of either Lewis acids or pyridine to the ozonations. Enhanced electrophilic ozone reactivity toward aromatic substrates is observed when the Lewis acids ***Aluminum Chloride*** or ***Boron Trifluoride*** are added to reaction mixtures.[46] Conversely, an apparent decrease in ozone reactivity and a concurrent increase in the regioselectivity of ozone attack can be achieved by adding small amounts of pyridine to ozonolyses (eq 26).[47] It is thought that coordination of either the Lewis acid or basic pyridine to ozone results in the modified reactivity.

(26)

In a related procedure, ozonizable dyes have been used as endpoint indicators for selective ozonation of substrates containing multiple unsaturated linkages.[48] The dye affords colored solutions and the ozonation is carried out just until the color is discharged. If the dye is of suitable reactivity such that the most reactive substrate unsaturated linkage reacts first, and the dye second, the reaction can be stopped before further oxidation of the substrate occurs.

Interestingly, addition of BF_3 etherate to the ozonolysis of *o*-dimethoxybenzene derivatives results in increased yields of (*Z*,*Z*)-dienes (eq 27, compare to eq 20).[49] In this case, it is thought that coordination of the Lewis acid to the diene reduces its electron density and suppresses further attack by ozone. Also, the fact that the BF_3 is already coordinated to ether may limit its ability to coordinate to ozone and increase its electrophilic reactivity.

Ozonation of Acetals.

Ozone reacts very efficiently with acetals to afford the corresponding esters (eqs 28 and 29).[50] The aldehyde and alcohol components of the acetal function can be varied and yields are excellent. Cyclic acetals react much faster than acyclic acetals as a result of conformational effects.

Miscellaneous Ozonations.

Ozonation offers a simple neutral alternative for oxidation of secondary alcohols to ketones (eq 30).[51]

(30)

R^1	R^2	%
Me	Me	83
Me	Me	72
$-(CH_2)_4-$		53
$-(CH_2)_5-$		65

Upon reaction of allene with one equivalent of ozone, trisection occurs to provide carbon monoxide derived from the central carbon atom and carbonyl compounds from the remaining carbon atoms.[52] In the example of eq 31, allene ozonolysis is used to prepare a versatile protected α-hydroxyaldehyde.[53]

(31)

$R = C_5H_{11}$, Ph, *t*-Bu, 89-99%

Ozonation of benzyl ethers affords high yields of benzoate esters (eq 32).[54] Coupled with deacylation by NaOMe, this reaction offers a mild alternative for removal of benzyl ether protecting groups (eq 33).[55] However, due to the higher reactivity of alkenes, selective oxidative cleavage of carbon-carbon double bonds can be accomplished in the presence of benzyl ethers (eq 34).[56]

(32)

(33)

(34)

Ozone has been used to cleave nitronate anions, resulting in the high yield production of either aldehydes or ketones.[57] An example of this reaction is shown in eq 35.[57a] This is a very general method and has advantages over the Nef reaction which requires strong acid conditions, and other procedures utilizing permanganate or ***Titanium(III) Chloride***.

(35)

Aldehydes can be converted to peroxy acids via ozonation in methyl or ethyl acetate,[58] or to methyl esters via ozonation in 10% methanolic KOH (eq 36).[59] Ethyl esters can be produced analogously, but the use of higher alcohols results in low KOH solubility and poor conversion. This problem can be overcome by adding the aldehyde to a solution of lithium alkoxide in THF at -78 °C and treating this mixture with ozone (eq 37). Additionally, the direct preparation of methyl esters can be accomplished via alkene ozonolysis in methanolic NaOH or by addition of NaOMe to a MeOH-CH_2Cl_2 ozonolysis solvent system.[60]

Ozone-Silica Gel[1]

[10028-15-6] · O_3 · Ozone-Silica Gel · (MW 48.00)

(powerful oxidizing agent; capable of oxidizing carbon-hydrogen bonds[2] and a variety of electron-rich functional groups; provides a high effective concentration of ozone[2a])

Physical Data: ozone, mp -193 °C; bp -111.9 °C; *d* (0 °C, gas) 2.14 g L^{-1}.

Solubility: 4.5% ozone by weight is adsorbed on silica gel at -78 °C.[2]

Preparative Methods: ozone is generated in the laboratory by passing dry air or oxygen through two electrodes connected to an alternating current source of several thousand volts. Silica gel 60 (70-230 mesh, available from several suppliers) usually is dried prior to use and is saturated with ozone at low temperature.

Handling, Storage, and Precautions: ozone is irritating to all mucous membranes and is highly toxic in concentrations greater than 0.1 ppm by volume. It has a characteristic odor which can be detected at levels as low as 0.01 ppm. All operations with ozone should be carried out in an efficient fume hood and scrubbing systems employing thiosulfate solutions can be used to destroy excess ozone. Liquified ozone poses a severe explosion hazard.

General Procedure.

The organic substrate is preadsorbed on silica gel either by direct mixing or by slurrying in an appropriate solvent followed by removal of the solvent under vacuum. A stream of ozone then is passed through the silica gel at low temperature (usually -78 °C) until it is saturated and a deep blue color. The mixture is then warmed slowly to rt and organic material is isolated by elution. Multiple saturation and warming cycles may be necessary to achieve complete consumption of substrate. This dry ozonation procedure complements ozonation carried out in organic solvents. The high ozone concentration which can be achieved on silica gel allows for a more facile oxidation of substrates normally difficult to ozonize, and problems associated with solvent interference are eliminated.

Oxidation of Carbon-Hydrogen Bonds.

Dry ozonation most often has been used for hydroxylation of tertiary centers in saturated cyclic hydrocarbons with stereoselective retention of configuration. Hydrotrioxides have been detected as intermediates in these reactions.[3] The yields of tertiary alcohols from dry ozonation typically are higher than those obtained using either ***Chromic Acid*** or

solution ozonolysis (eq 1).[2,4,5]

(1)

While the method is generally applicable to cyclic hydrocarbons, the use of acyclic substrates often results in the production of significant amounts of ketones due to carbon-carbon bond cleavage (eq 2).[6] Eq 2 shows that in dry ozonation, ozone attack is directed at exposed positions remote to the silica gel binding site. This results from molecules being ordered in a close packed array on the solid support with steric effects hindering reactivity at the proximal positions. Bridgehead hydroxylation of polycyclic hydrocarbons,[2,7] and derivatization of terpenoids[8] and steroidal systems,[9] have been accomplished using dry ozonation. Additionally, remote methylene units have been transformed to ketones in cyclic acetates.[10]

(2)

Dry ozonation also can be used to functionalize cyclopropyl hydrocarbons at the α-position, affording cyclopropyl alkyl ketones.[11] The method is quite general and reaction α to the cyclopropyl group is preferred over hydroxylation at tertiary positions (eqs 3 and 4).[12]

(3)

(4)

Ozonolysis of Alkenes and Alkynes.

Alkene ozonolysis on dry silica gel results in the efficient formation of ozonides, while reaction on nontreated or hydrated silica gel affords mixtures of aldehydes, ketones, or carboxylic acids (eq 5).[13-15] Products from these reactions usually are obtained directly upon elution from the silica gel without the need for either a reductive or oxidative workup.

(5)

Notably, ozonides of tetrasubstituted alkenes,[16] vinyl ethers,[17] vinylic esters,[18] and α,β-unsaturated ketones[19] (which are normally not observed in solution reactions) can be obtained using ozonation on polyethylene as the solid support. It is believed that solid-supported ozonolysis favors ozonide formation due to the proximity of initial cleavage products and the resulting ease of recombination. Also, since cleavage fragments are fixed on the support, combination to form cross ozonides is reduced dramatically.

In addition to providing a route to otherwise inaccessible ozonides, dry ozonation has been used to cleave normally unreactive alkenes directly to carbonyl compounds (eq 6).[20] In another example, bulky tetramethylethylene affords acetone in 95% yield upon dry ozonation using untreated or hydrated silica gel.[14]

(6)

An overall hydroxylation of alkenes using the dry ozonation procedure can be accomplished if the more reactive alkene functionality is first converted to a dibromide. After hydroxylation, deblocking liberates the alkene (eq 7).[21]

(7)

Dry ozonation of alkynes generally results in cleavage to carboxylic acids and carbonyl compounds. Only in the case of diphenylacetylene has a diketone been observed.[14,15]

Oxidation of Primary Amines.

Aliphatic primary amines are efficiently oxidized by ozone on silica gel to the corresponding nitro compounds (eq 8).[22] This procedure is an improvement over solution ozonations in which yields are lower due to solvent interaction with partial oxidation products and competing oxidation of the α-carbon atom (see ***Ozone***).

R	%
t-Bu	70
Bu	65
Bn	66

(8)

Ozonation of Aromatic Systems.

Phenyl rings are cleaved to carboxylic acids using dry ozonation, although multiple ozone saturation and warming cycles may be required for high conversions (eq 9).[23] Compared to oxidations utilizing ***Ruthenium(VIII) Oxide***, yields are significantly higher.[24]

(9)

Alternate Procedure.

A modification of the dry ozonation procedure employs a microwave discharge of a He-O_2 or a He-CO_2 gas stream to produce ground-state oxygen atoms [O(^{3}p) atoms] which, when passed over silica gel or Florisil preadsorbed with substrate at low temperature, combine with oxygen on the adsorbent to slowly form ozone in low concentration in situ. The ozone then can react with the absorbed organic substrate.[25] This is a milder method than conventional dry ozonation, and this procedure can afford regiospecific ozonation of polyunsaturated compounds or partial oxidative cleavage of polycyclic aromatics (eq 10).[26] Conventional solvent ozonolyses or standard dry ozonations often result in cleavage of several bonds.

Palladium(II) Acetate[1]

$Pd(OAc)_2$

[3375-31-3] · $C_4H_6O_4Pd$ · Palladium(II) Acetate · (MW 224.52) (trimer)

[53189-26-7]

(homogenous oxidation catalyst[3] that, in the presence of suitable co-reagents, will effect the activation of alkenic and aromatic compounds towards oxidative inter- and intramolecular nucleophilic attack by carbon, heteroatom, and hydride nucleophiles[1,3,4,5])

Alternate Name: bis(acetato)palladium; diacetatopalladium(II); palladium diacetate.

Physical Data: mp 205 °C (dec).

Solubility: sol organic solvents such as chloroform, methylene chloride, acetone, acetonitrile, diethyl ether. Dissolves with decomposition in aq HCl and aq KI solutions. Insol water and aqueous solutions of NaCl, NaOAc, $NaNO_3$ as well as in alcohols and petroleum ether. Decomposes when heated with alcohols.

Form Supplied in: orange-brown crystals; generally available.

Preparative Methods: preparation of palladium diacetate from palladium sponge was developed by Wilkinson et al.[2]

Purification: palladium nitrate impurities can be removed by recrystallization from glacial acetic acid in the presence of palladium sponge.

Handling, Storage, and Precautions: can be stored in air. Low toxicity.

General Considerations.

Salts of palladium that are soluble in organic media, for example $Pd(OAc)_2$, ***Dilithium Tetrachloropalladate(II)***, and $PdCl_2(RCN)_2$, are among the most extensively used transition metal complexes in metal-mediated organic synthesis. Palladium acetate participates in several reaction types, the most important being: (i) Pd^{II}-mediated activation of alkenes towards nucleophilic attack by (reversible) formation of Pd^{II}-alkene complexes, (ii) activation of aromatic, benzylic, and allylic C-H bonds, and (iii) as a precursor for Pd^0 in Pd^0-mediated activation of aryl, vinyl, or allyl halides or acetates by oxidative addition to form palladium(II)-aryl, -vinyl and -(π)-allyl species, respectively.[1b] All reactions proceed via organopalladium(II) species which can undergo a number of synthetically useful transformations.

Alkenes complexed to Pd^{II} are readily attacked by nucleophiles such as water, alcohols, carboxylates, amines, and stabilized carbon nucleophiles (eq 1). Attack occurs predominantly from the face opposite to that of the metal (*trans* attack), thus forming a new carbon-nucleophile bond and a carbon-metal σ-bond.

The σ-complex obtained is usually quite reactive and unstable, and can undergo a number of synthetically useful transformations such as β-hydrogen elimination (eq 1) to give a vinyl substituted alkene and insertion of CO (eq 1) or alkenes (eq 1) into the carbon-palladium bond, which permit further functionalization of the original alkene. The same general chemistry is observed for complexes generated from Pd^0 (eq 2). Heck vinyl couplings and carbonylations together with allylic nucleophilic substitution reactions are among the synthetically most interesting reactions employing palladium acetate.[5]

The transformations in eqs 1 and 2 ultimately produce palladium(0), while palladium(II) is required to activate alkenes (eq 1). Thus, if such a process is to be run using catalytic amounts of the noble metal, a way to rapidly regenerate palladium(II) in the presence of both substrate and product is required. Often this reoxidation step is problematic in palladium(II)-catalyzed nucleophilic addition processes, and reaction conditions have to be tailored to fit a particular type of transformation. A number of very useful catalytic processes, supplementing the processes that employ stoichiometric amounts of the metal, have been developed.[1,3-5]

Oxidative Functionalization of Alkenes with Heteroatom Nucleophiles.

Oxidation of Terminal Alkenes to Methyl Ketones.

The oxidation of ethylene to acetaldehyde with water acting as the nucleophile using a $Pd^{II}Cl_2$-$Cu^{II}Cl_2$ catalyst (see ***Palladium(II) Chloride*** and ***Palladium(II) Chloride-Copper(II) Chloride***) under an oxygen atmosphere is known as the Wacker process. On a laboratory scale the reaction conveniently allows the transformation of a wide variety of terminal alkenes to methyl ketones.[6] Some synthetic procedures that employ $Pd(OAc)_2$ in chloride-free media have been developed (eq 3).

(3)

By this, both the use of the highly corrosive reagent combination $PdCl_2$-$CuCl_2$ and the occurrence of chlorinated byproducts are avoided. The stoichiometric oxidant used in these reactions can be a peroxide,[7] ***1,4-Benzoquinone***,[8] or molecular ***Oxygen***.[8a,9] An electrode-mediated process has also been described.[10]

Other Heteroatom Nucleophiles.

Alcohols and carboxylic acids also add to metal-activated alkenes,[1a] and processes for the industrial conversion of ethylene to vinyl acetate and acetals are well established.[1c] However, these processes have not been extensively used with more complex alkenes. In contrast, a number of intramolecular versions of the processes have been developed, a few examples of which are given here. Allylphenols cyclize readily in the presence of palladium(II) to form benzofurans (eq 4). Catalytic amounts of palladium acetate can be used if the reaction is carried out under 1 atm of molecular oxygen with copper diacetate as cooxidant, or in the presence of ***t-Butyl Hydroperoxide***. If instead of palladium acetate a chiral π-allylpalladium acetate complex is used, the cyclization proceeds to yield 2-vinyl-2,3-dihydrobenzofuran with up to 26% ee.[11]

(4)

Methyl glyoxylate adducts of *N*-Boc-protected allylic amines cyclize in the presence of a catalytic amount of palladium acetate and excess ***Copper(II) Acetate*** to 5-(1-alkenyl)-2-(methoxycarbonyl)oxazolidines (eq 5).[12] These heterocycles are easily converted to unsaturated *N*-Boc protected β-amino alcohols through anodic oxidation and mild hydrolysis.

(5)

Nitrogen nucleophiles such as amines, and in intramolecular reactions amides and tosylamides, readily add to alkenes complexed to Pd^{II} derived from $PdCl_2(RCN)_2$ (see ***Palladium(II) Chloride***) with reactivity and regiochemical features paralleling those observed for oxygen nucleophiles.[3,4] Intramolecular nucleophilic attack by heteroatom nucleophiles also occurs in conjunction with other palladium-catalyzed processes presented in the following sections.

Allylic C-H Bond Activation.

Internal alkenes, in particular cyclic ones, can be transformed into allylic acetates in a palladium-catalyzed oxidation (eq 6).[13] With benzoquinone as stoichiometric oxidant or electron transfer mediator,[9a] the allylic acetoxylation proceeds with high selectivity for the allylic product and usually in excellent yield.

(6)

This one-step transformation of an alkene to an allylic acetate compares well with other methods of preparation such as hydride reduction of α,β-unsaturated carbonyl compounds followed by esterification. The scope and limitations of the reaction have been investigated.[14] The allylic acetoxylation proceeds via a π-allylpalladium intermediate,[15] and as a result, substituted and linear alkenes generally give several isomeric allylic acetates. With oxygen nucleophiles the reaction is quite general, and reactants and products are stable towards the reaction conditions. This is normally not yet the case with nitrogen nucleophiles, although one intramolecular palladium-catalyzed allylic amination mechanistically related to allylic acetoxylation has been reported.[16]

Functionalization of Conjugated Dienes.

Electrophilic transition metals, particularly palladium(II) salts which do not form stable complexes with 1,3-dienes, do activate these substrates to undergo a variety of synthetically useful reactions with heteroatom nucleophiles.[17] Some examples are presented below.

Telomerization.

Conjugated dienes combine with nucleophiles such as water, amines, alcohols, enamines and stabilized carbanions in the presence of palladium acetate and ***Triphenylphosphine*** to produce dimers with incorporation of one equivalent of the nucleophile.[1,18] Telomerization of butadiene (eq 7) yields linear 1,6- and 1,7-dienes and has been used for the synthesis of a variety of naturally occurring materials.[19]

(7)

Oxidative 1,4-Functionalization.

The regio- and stereoselective palladium-catalyzed oxidative 1,4-functionalization of 1,3-dienes (eq 8) constitutes a synthetically useful process.[20-23]

A selective catalytic reaction that gives high yields of 1,4-diacetoxy-2-alkenes occurs in acetic acid in the presence of a lithium carboxylate and benzoquinone. The latter reagents act as the activating ligand and reoxidant for palladium(0).[24] The reaction can be made catalytic also in benzoquinone by the use of ***Manganese Dioxide***,[20] electrochemistry,[25] or metal-activated molecular oxygen[9a] as stoichiometric oxidant. If the reaction is carried out in alcoholic solvent in the presence of a catalytic amount of a nonnucleophilic acid, *cis*-1,4-dialkoxides can be obtained.[23] An important feature of the 1,4-diacetoxylation reaction is the ease by which the relative sterochemistry of the two acetoxy substituents can be controlled (eq 9).

The first step in the reaction sequence is a regioselective and stereoselective *trans*-acetoxypalladation of one of the double bonds, thus forming a π-allylpalladium(II) intermediate, which is then attacked by a second nucleophile. By variation of the concentration of chloride ions, reactions selective for either the *trans*-diacetate or the *cis*-diacetate (eq 9) can be accomplished. The use of other chloride salts resulted in poor selectivity. The selectivity for the *trans* product at chloride-free conditions is further enhanced if the reaction is carried out in the presence of a sulfoxide co-catalyst.[26] Enzymatic hydrolysis of the *cis-meso*-diacetate yields *cis*-1-acetoxy-4-hydroxy-2-cyclohexene in more than 98% ee,[27] thus giving access to a useful starting material for enantioselective synthesis.[28]

In a related catalytic procedure, run in the presence of a stoichiometric amount of ***Lithium Chloride*** (eq 10), it is possible to obtain *cis*-1-acetoxy-4-chloro-2-alkenes with high 1,4-selectivity and in high chemical yield.[21] A selective nucleophilic substitution of the chloro group in the chloroacetate, either by palladium catalysis or by classical methods (eq 10), and subsequent elaboration of the acetoxy group, offer a number of useful transformations.[22] The methodology has been applied to, for example, a synthesis of a naturally occurring 2,5-disubstituted pyrrolidine, some tropane alkaloids, and perhydrohistrionicotoxin.[29]

(10)

The use of two different nucleophiles can lead to unsymmetrical dicarboxylates.[30] Palladium-catalyzed oxidation of 1,3-cyclohexadiene in acetic acid in the presence of CF_3CO_2H/LiO_2CCF_3, with MnO_2 and catalytic benzoquinone, yielded 70% of *trans*-1-acetoxy-4-trifluoroacetoxy-2-cyclohexene (more than 92% *trans*), with a selectivity for the unsymmetrical product of more than 92%. 1,3-Cycloheptadiene afforded the *cis* addition product in 58% yield with a selectivity for the unsymmetrical product of more than 95%. Since the two carboxylato groups have different reactivity, for example toward hydrolysis, further transformations can be carried out at one allylic position without affecting the other.

Intramolecular versions of the 1,4-oxidations have been developed.[31] In these reactions the internal nucleophile can be a carboxylate, an alkoxide, or nitrogen functionality, and the result of the first nucleophilic attack is the regioselective and stereoselective formation of a *cis*-fused heterocycle (eq 11).

(11)

The second attack can be directed as described above to yield either an overall *trans* or *cis* product in >70% yield. With internal nucleophiles linked to the 1-position of the 1,3-diene, spirocyclization occurs. The synthetic power of the method has been demonstrated in the total syntheses of heterocyclic natural products,[32] and further developed into a tandem cyclization of linear diene amides (eq 12) to yield bicyclic compounds with trisubstituted nitrogen centers.[33]

(12)

Functionalization of Alkenes with Palladium-Activated Carbon Nucleophiles.

Heck Coupling.[5]

The Heck reaction is the common name for the coupling of an organopalladium species with an alkene and includes both inter- and intramolecular reaction types. However, no general reaction conditions exist and the multitude of variations can sometimes seem confusing.

The original version of the Heck reaction involved the coupling of an alkene with an organomercury(II) salt in the presence of stoichiometric amounts of palladium(II),[34] a method still used in nucleoside chemistry.[35] The finding that the organomercury reagent can be replaced by an organic halide, however, greatly increased the versatility of the process.[36] The modified process is catalyzed by zerovalent palladium, either in the form of preformed tertiary phosphine complexes or, preferentially, formed in situ from palladium acetate (eq 13).

To keep the active catalyst in solution, reactions are often carried out in the presence of tertiary phosphines such as ***Triphenylphosphine***,[37] or rather tri(*o*-tolyl)phosphine,[38] which is now the phosphine most widely employed in Heck coupling reactions.[5] Other ligands successfully employed include tris(2,6-dimethoxyphenyl)phosphine and the bidentate ligands ***1,2-Bis(diphenylphosphino)ethane*** (dppe), ***1,3-Bis(diphenylphosphino)propane*** (dppp), ***1,4-Bis(diphenylphosphino)butane*** (dppb), and ***1,1´-Bis(diphenylphosphino)ferrocene*** (dppf). Coupling reactions can occur in homogenous aqueous media if a water-soluble palladium ligand, trisodium 3,3´,3´-(phosphinetriyl)tribenzenesulfonate, is employed. This greatly facilitates workup procedures, and good yields of coupled products were obtained from reacting aryl and alkyl iodides with alkenes, alkynes, and allylic acetates.[39] In all cases, an inert atmosphere and the presence of a base, normally ***Triethylamine***, is required.

Phase-Transfer Conditions.

The Heck conditions described above are not useful, however, for a large number of alkenic substrates.[40] A sometimes serious drawback is the high temperature (ca. 100 °C) often required. Upon addition of tetrabutylammonium chloride (phase-transfer conditions or Jeffery conditions), aromatic halides or enol triflates react under mild conditions with vinylic substrates or allylic alcohols.[5,41] Variations of these conditions include the optional or additional presence of silver or thallium salts. The effect of using different salts, bases, catalysts, solvents, and protecting groups in the coupling of aminoacrylates with iodobenzene has been studied.[42]

Cross Coupling.

In cross-coupling reactions, an aryl, vinyl, or acyl halide or triflate undergoes a palladium-catalyzed Heck-type coupling to an aryl-, vinyl-, or alkyl-metal reagent (eq 14) to give a new carbon-carbon bond.[5]

Mg, Zn, and Zr are examples of metals used in cross-coupling reactions,[43] but, in particular, organostannanes have been employed in mild and selective palladium acetate-catalyzed couplings with organic halides and triflates.[44] Aryl arenesulfonates undergo a cross-coupling reaction with various organostannanes in the presence of palladium diacetate, dppp, and LiCl in DMF.[45] An advantage of the arylsulfonates over triflates is that the former are solids whereas the latter are liquids. Also, arylboranes and boronic acids also undergo a palladium-catalyzed cross-coupling with alkyl halides, although the catalysts of choice are ***Tetrakis(triphenylphosphine)palladium(0)***, ***Dichloro[1,4-bis(diphenylphosphino)butane]palladium(II)***, or ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)***.[46]

Arylation of Alkenes by Coupling and Cross Coupling.

Alkenes can be functionalized with palladium-activated arenes, yielding styrene derivatives in a process applicable to a wide range of substrate combinations. An early demonstration of the possibilities of the Heck arylation was the coupling of 3-bromopyridine with *N*-3-butenylphthalimide (eq 15), the first step of four in a total synthesis of nornicotine.[47]

N-Vinylimides readily undergo palladium-catalyzed vinylic substitution with aryl bromides to yield 2-styryl- and 2-phenylethylimines. With aryl iodides (eq 16), the reaction proceeds even in the absence of added phosphine,[48] which opens the possibility of a sequential disubstitution of bromoiodoarenes.

Vicinal dibromides undergo a twofold coupling reaction with monosubstituted alkenes to yield 1,3,5-trienes (eq 17). The reaction, catalyzed by palladium acetate in the presence of triphenylphosphine and triethylamine, can also be applied to aromatic tri-and tetrabromides.[49]

(17)

A double coupling of 2-amidoacrylates with 3,3´-diiodobiphenyl constitutes a key step in a short preparation of a biphenomycin B analog.[50] Palladium acetate-catalyzed double coupling reactions of 1,8-diiodonaphthalene with substituted alkenes and alkynes under phase-transfer conditions are useful also for the synthesis of various acenaphthene and acenaphthylene derivatives.[51]

1,2-Disubstituted alkenes are generally less reactive towards coupling than are monosubstituted alkenes. However, the use of the more reactive aryl iodides can result in reasonable yields of the coupled product, usually as a mixture of (*E*) and (*Z*) isomers.[52] The reaction has been applied to a coupling of 2-iodoaniline derivatives with ***Dimethyl Maleate*** (eq 18), the product of which spontaneously cyclizes to form quinolone derivatives in 30-70% yield. If, instead, the 2-iodoaniline is coupled with ***Isoprene*** or cyclohexadiene in the presence of palladium acetate, triphenylphosphine, and triethylamine, indole and carbazole derivatives are obtained by a coupling followed by intramolecular nucleophilic attack by the heteroatom.[53]

(18)

X = H (71%), OH (55%), Br (30%)

2-Alkylidenetetrahydrofurans can be prepared via intramolecular oxypalladation and subsequent coupling by treatment of aryl or alkyl alkynic alcohols with ***n-Butyllithium*** followed by palladium acetate and triphenylphosphine. The reaction proceeds to yield furans in moderate yields.[54]

Formation of Dienes and Enynes by Coupling and Cross Coupling.

The vinylation of methyl acrylate, methyl vinyl ketone, or acrolein with (*E*) or (*Z*) vinylic halides under phase-transfer conditions gives high yields of (*E*,*E*) (eq 19) or (*E*,*Z*) (eq 20) conjugated dienoates, dienones, and dienals, respectively.[55] Coupling of vinyl halides or triflates with α,β- or β,γ-unsaturated acids under phase-transfer conditions yields vinyl lactones.[56]

(19)

(20)

Commercially available trimethylvinylsilanes can be vinylated using either vinyl triflates or vinyl iodides in the presence of silver salts, in a reaction catalyzed by palladium acetate in the presence of triethylamine. The resulting 3-substituted 1-trimethylsilyl-1,3-dienes are obtained in reasonable to good yields.[57]

Alkenylpentafluorosilicates derived from terminal alkynes react readily with allylic substrates in a palladium-catalyzed cross-coupling reaction to yield (*E*)-1,4-dienes (eq 21).[58] Treatment of 1-alkenylstannanes with t-BuOOH in the presence of 10% of palladium acetate gives 1,3-dienes (eq 22), whereas coupling between 1- and 2-alkenylstannanes provides 1,4-dienes in good yields (eq 23).[59]

(21)

(22)

R = Ph, 80%, (*E*):(*Z*) = 4:1
R = C_6H_{13}, 76%, only (*E*)

(23)

Cross coupling of enol triflates under neutral conditions with allyl-, vinyl-, or alkynylstannanes in the presence of palladium diacetate and triphenylphosphine proceeds to give high yields of 1,4- and 1,3-dienes and 1,3-enynes, respectively (eq 24).[60]

(24)

Terminal alkynes react to form 1-en-3-ynes in a process catalyzed by palladium acetate and tris(2,6-dimethoxyphenyl)phosphine. A number of functional groups such as internal alkenes, esters, and alcohols are tolerated, and good yields of homo- (eq 25) as well as hetero-coupled enynes (eq 26) are obtained.[61]

(25)

An interesting approach to 1-en-5-ynes is the palladium-catalyzed tandem coupling of a *cis*-alkenyl iodide, a cyclic alkene, and a terminal alkyne (eq 27). With norbornene as the alkene, the coupling occurs in a stereodefined manner, and the enyne products are obtained in good yields.[62] ***Potassium Cyanide*** can be used instead of an alkyne to yield the corresponding cyanoalkene.[63]

Formation of Aldehydes, Ketones, and Allylic Dienols by Coupling to Allylic Alcohols.

Allylic alcohols can be coupled with aryl or vinyl halides or triflates. The outcome of the reaction depends on the coupling agent and the reaction conditions. Thus arylation of allylic alcohols under Heck conditions constitutes a convenient route to 3-aryl aldehydes and 3-aryl ketones (eq 28).[64]

Coupling of primary allylic alcohols with vinyl halides carried out under phase-transfer conditions (cat $Pd(OAc)_2$ in the presence of Ag_2CO_3 and *n*-Bu_4NHSO_4 in acetonitrile) gave 4-enals,[65] whereas secondary allylic alcohols, when treated

with a vinyl halide or enol triflate, afforded conjugated dienols with good chemoselectivity, regiochemistry, and stereoselectivity.[66] Since the coupling reaction under these conditions proceeds without touching the carbon bearing the alcohol functional group, it was possible to prepare optically active dienols from vinyl iodides and optically active allylic alcohols (eq 29).[67]

Formation of Allyl and Aryl Primary Allylic and Homoallylic Alcohols from Vinyl Epoxides and Oxetanes.

Vinylic epoxides can be coupled with aryl (eq 30) or vinyl (eq 31) iodides or triflates to form allylic alcohols in 40-90% yield.[68] When employing palladium acetate as the catalyst, a reducing agent such as sodium formate is required in addition to the salts normally present under phase transfer conditions.

Vinyloxetane couples with aryl or vinyl iodides or triflates to form homoallylic alcohols under essentially the same reaction conditions (eq 32).[69] The process has also been applied to the preparation of aryl-substituted 3-alkenamides from 4-alkenyl-2-azetidinones (eq 33).[70]

(32)

(33)

Homoallylic alcohols can also be prepared using a one-pot transformation of homopropargyl alcohols. Intramolecular hydrosilylation followed by a palladium-catalyzed coupling of the in situ generated alkenoxysilane with an aryl or alkenyl halide, in the presence of fluoride ions, affords the alcohol product.[71] This process has also been applied to the preparation of 1,3-dienes.

Carbonylation.

Carbon monoxide readily inserts into Pd-C σ-bonds. The resulting acylpalladium intermediate can react intermolecularly or intramolecularly with amines or alcohols to form ketones, amides, or esters, respectively, or with alkenes to yield unsaturated ketones.[1a,5] Thus treatment of vinyl triflates with $Pd(OAc)_2$, PPh_3, and MeOH in DMF results in one-carbon homologation of the original ketone to α,β-unsaturated esters.[72] Benzopyrans with a *cis*-fused γ-lactone can be prepared in high yield from *o*-disubstituted arenes by carbonylation of the intermediate formed upon intramolecular attack of the phenol on the terminal alkene (eq 34). The sequence affords the *cis*-fused lactone, regardless of the relative stereochemistry of the hydroxide and the methylenepalladium in the intermediate.[73]

Vinyl triflates undergo carbonylative coupling with terminal alkynes to yield alkenyl alkynyl ketones in a reaction catalyzed by palladium acetate and dppp in the presence of triethylamine.[74] When applied to 2-hydroxyaryl iodides (eq 35), subsequent attack by the hydroxyl group on the alkyne yielded flavones and aurones. The cyclization result depends on the reaction conditions. ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** as base in DMF yields mainly the six-membered ring flavone, whereas the only product observed when employing potassium acetate in anisole was the five-membered ring aurone.[75]

base	sol	
AcOK	anisole	0:100
DBU	DMF	92:8

Chiral α,β-unsaturated oxazolines can be obtained by a carbonylation-amidation of enol triflates or aryl halides with chiral amino alcohols (eq 36).[76] The palladium catalyst can be either $Pd(PPh_3)_4$, ***Bis(dibenzylideneacetone)palladium(0)*** and PPh_3, or $Pd(OAc)_2$ and dppp in the presence of triethylamine.

N-Substituted phthalimides are obtained from coupling *o*-dihalo aromatics with carbon monoxide and primary amines. The best catalysts for this reaction, however, were $PdCl_2L_2$ species.[77]

Formation of Heterocyclic Compounds.

Coupling reactions of 2-halophenols or anilines with molecules containing functionalities that allow the heteroatom nucleophile to form a heterocycle either by intramolecular oxy- or amino-palladation of an alkene, or by lactone or lactam formation, has already been mentioned in the preceding sections.[78] In addition to these powerful techniques, carbon-heteroatom bonds can be constructed in steps prior to the cyclization. For example, the enamine 3-((2-bromoaryl)amino)cyclohex-2-en-1-one undergoes a palladium-catalyzed intramolecular coupling to yield 1,2-dihydrocarbazoles in moderate yields.[79] Intramolecular coupling of 2-iodoaryl allyl amines gave high yields of indoles under phase-transfer conditions (eq 37).[80] The corresponding aryl allyl ethers require the additional presence of sodium formate in order to give benzofurans in good yields (eq 38).

R	Base	Time	Temp.	Yield
H	Na_2CO_3	24 h	25 °C	97%
Me	Et_3N	48 h	25 °C	81%
MeCO	NaOAc	24 h	80 °C	90%

(38)

R = H (47%), Me (83%), C_5H_{11} (83%), Ph (81%)

The principle has been applied to the preparation of pharmaceutically interesting heterocyclic compounds,[81] and to the assembly of fused or bridged polycyclic systems containing quaternary centers.[82]

Formation of Carbocycles.

By Intramolecular Heck Coupling.

1-Bromo-1,5-dienes and 2-bromo-1,6-dienes cyclize in the presence of ***Piperidine*** and a palladium acetate-tri-*o*-tolylphosphine catalyst to produce cyclopentene derivatives (eq 39).[83] 2-Bromo-1,7-octadiene, when subjected to the same reaction conditions, cyclized to yield a mixture of six and five-membered ring products, whereas competing dimerization and polymerization was observed for the more reactive 2-bromo-1,5 dienes.

(39)

The influence of phosphine ligands, added salts, and the type of metal catalyst on the selectivity of the cyclization have been studied.[84] With K_2CO_3 as base, Wilkinson's catalyst (***Chlorotris(triphenylphosphine)rhodium(I)***) showed higher selectivity for the formation of 1,2-dimethylenecyclopentanes over 1-methylene-2-cyclohexenes than the palladium acetate-triphenylphosphine catalyst.

The palladium-catalyzed cyclization of acyclic polyenes to form polycyclic systems (eq 40) constitutes a very powerful further development of the above method. σ-Alkylpalladium intermediates, produced in an intramolecular Heck reaction, can be efficiently trapped by neighboring alkenes to give bis-cyclization products of either spiro or fused geometry. The second cyclization also produces a σ-alkylpalladium intermediate which can also be trapped.

(40)

R	*n*	Ratio	
Me	1	1:1.5	
Me	2	100:0	(1:1 H_α:H_β)
H	1	0:100	

1-Iodo-1,4- and -1,5-dienes can be transformed into α-methylenecyclopentenones and -hexenones, respectively, by palladium-catalyzed carbonylation and subsequent intramolecular coupling.[85] Better results, however, were obtained using ***Tetrakis(triphenylphosphine)palladium(0)***.

Via (π-Allyl)palladium Intermediates.

Allylic substitution, by nucleophilic attack on (π-allyl)palladium complexes generated from allylic substrates, are most often catalyzed by Pd^0-phosphine complexes.[86,87] There are, however, a few examples of intramolecular reactions where the active catalyst is generated in situ from palladium acetate. For example, ethyl 3-oxo-8-phenoxy-6-octenoate reacts to yield cyclic ketones in the presence of catalytic amounts of palladium diacetate and a phosphine or phosphite ligand (eq 41).[88] The product distribution between five- or seven-membered rings depends on the ligand employed and the solvent used. With a chiral phosphine, (*E*)-methyl 3-oxo-9-methoxycarbonyloxy-7-nonenoate was cyclized to give (*R*)-3-vinylcyclohexane with 41-48% ee.[89]

Another example is based on the palladium-catalyzed 1,4-chloroacetoxylation methodology,[21,22,29] where a common intermediate, by proper choice of reaction conditions, can be transformed into *cis*- or *trans*-annulated products.[89]

By Cyclization of Alkenyl Silyl Enol Ethers.

Treatment of alkenyl silyl enol ethers with stoichiometric amounts of palladium acetate induces an intramolecular attack to form carbacycles (eqs 42 and 43). Good to high yields of α,β-unsaturated ketones were obtained.[90]

With slightly different substrates, the observed products were not α,β-unsaturated ketones but nonconjugated bicycloalkenones.[91] The method, which affords bridged (eq 44) as well as spirocyclic (eq 45) bicycloalkenones in acceptable to good yields, has been applied to the preparation of bicyclo[3.3.1]nonadienones[92] and to a total synthesis of quadrone.[93]

By Cyclization of Simple Dienes.

Treatment of 1,5-dienes with catalytic amounts of $Pd(OAc)_2$ and benzoquinone with MnO_2 as stoichiometric oxidant in acetic acid leads to an oxidative cyclization reaction (eqs 46, 47).[94] The reaction normally yield cyclopentanes with acetate and exomethylene groups in a 1,3-configurational relationship.[95]

The selectivity of the reaction depends strongly upon the structure of the starting alkene. Substituents in the 1,3- and/or 4-positions of the diene are tolerated, but not in the 2- and 5-positions; thus the reaction most likely proceeds via an

acetoxypalladation of the 1,2-double bond followed by insertion of the 5,6-alkene into the palladium-carbon σ-bond and subsequent reductive elimination.[96] The cyclization is compatible with the presence of several types of functional groups such as alcohols, acetate (even in the allylic position), ethers, nitriles, and carboxylic acids. An improved diastereoselectivity was observed in reactions carried out with chiral nucleophiles in the presence of water-containing molecular sieves.[97] The synthetic utility of the reaction was demonstrated by a synthesis of diquinanes.[98]

By Cycloisomerization of Enynes.

When 1,6-enynes, prepared by a $Pd(PPh_3)_4$-catalyzed coupling of an allylic carboxylate with dimethyl propargylmalonate anion, is treated with a catalytic amount of a palladium(II) species, a carbocyclization leading to cyclopentanes carrying an exocyclic double bond occurs (eq 48).[99] Yields of 1,4-dienes ranging from 50% to 85% are observed. If the enyne has oxygen substituents in the allylic positions, the reaction instead yields a 1,3-diene (eq 49).[100] Cycloisomerization could also be induced for internal enynes carrying alkynic electron-withdrawing substituents.[101]

(48)

(49)

By Cycloaddition.

Palladium acetate, combined with $(i\text{-PrO})_3P$, catalyzes the [2 + 3] cycloaddition of trimethylenemethane to alkenes carrying electron-withdrawing substituents (eq 50). The yields of five-membered carbocycle varied from 35-89%.[102] With 1,3-dienes, a [4 + 3] cycloaddition gave seven-membered ring products in good yield (eq 51), and in some cases excellent diastereomeric ratios were observed.[102]

(50)

(51)

By Cyclopropanation.

Alkenes undergo a cyclopropanation reaction with diazo compounds (caution)[103] such as ***Diazomethane*** or ***Ethyl Diazoacetate*** in the presence of a catalytic amount of palladium acetate.[104] With diazomethane, a selective cyclopropanation of terminal double bonds can be obtained (eq 52).[105]

(52)

With diazo esters, the regioselectivity in transition metal-catalyzed cyclopropanation of dienes and trienes was generally not as good with palladium acetate as with a rhodium carboxylate catalyst,[106] although both palladium and rhodium carboxylates were better catalysts for the reaction than ***Copper(II) Trifluoromethanesulfonate***. α,β-Unsaturated carbonyl compounds also undergo palladium-catalyzed cyclopropanation, yielding the corresponding cyclopropyl ketones (eq 53) and esters (eq 54).[107]

(53)

(54)

Asymmetric cyclopropanations of α,β-unsaturated carboxylic acid derivatives with CH_2N_2 proceeds in greater than 97.6% diastereomeric excess when Oppolzer's sultam is used as a chiral handle.[108] The stereoselectivity of the reaction was found to be temperature dependent, with the best results obtained at higher temperatures. A coupling of norbornene and a *cis*-alkenyl iodide in the presence of a hydride donor resulted in a cyclopropanation of the norbornene (eq 55).[65]

Other examples of palladium-catalyzed cyclopropanation are intramolecular processes catalyzed by, for example, ***Dichloro[1,2-bis(diphenylphosphino)ethane]palladium(II)***,[109] ***Tetrakis(triphenylphosphine)palladium(0)***,[110] or ***Bis(allyl)di-μ-chlorodipalladium***.[111]

Oxidations.

Carbonyl Compounds by Oxidation of Alcohols and Aldehydes.

Salts of palladium, in particular $PdCl_2$ in the presence of a base, catalyze the CCl_4 oxidation of alcohols to aldehydes and ketones. Allylic alcohols carrying a terminal double bond are transformed to 4,4,4-trichloro ketones at 110 °C, but yield halohydrins at 40 °C. These can be transformed to the corresponding trichloro ketones under catalysis of palladium acetate (eq 56).[112] The latter transformation could be useful for the formation of ketones from internal alkenes provided the halohydrin formation is regioselective.

Secondary alcohols can be oxidized in high yield to the corresponding ketones by bromobenzene in a reaction catalyzed by palladium acetate in the presence of a base and a phosphine ligand. These reaction conditions, when applied to Δ^2-, Δ^3-, and Δ^4-unsaturated secondary alcohols, yielded product mixtures. When the stoichiometric oxidant was bromomesitylene and a $Pd(OAc)_2$:PPh_3 ratio of 1:2 was used, the oxidation proceeded smoothly for a wide variety of alcohols (eqs 57 and 58).[113]

(57)

Ox = PhBr, 48%, MesBr, 77%

(58)

Ox = PhBr, 100%

Oxidation of aldehydes in the presence of ***Morpholine*** proceeded effectively to yield 50-100% of the corresponding morpholine amides.[114]

α,β-Unsaturated Ketones and Aldehydes by Oxidation of Enolates.

Palladium diacetate-mediated dehydrosilylation of silyl enol ethers proceeds to yield unsaturated ketones in high chemical yield and with good selectivity for the formation of (*E*)-alkenes (eqs 59 and 60).[115] Although stoichiometric amounts of $Pd(OAc)_2$ are employed, this method for dehydrogenation has been employed in key steps in the total synthesis of some polycyclic natural products.[116]

(59)

94% 5%

(60)

Oxidation of primary vinyl methyl ethers yields α,β-unsaturated aldehydes. The method has been applied to a transformation of saturated aldehydes to one-carbon homologated unsaturated aldehydes (eq 61) by a Wittig reaction and subsequent palladium acetate-mediated oxidation.[117] The oxidations, which were carried out in $NaHCO_3$-containing aqueous acetonitrile, yielded 50-96% of the unsaturated aldehydes.

(61)

Allyl β-keto carboxylates and allyl enol carbonates undergo a palladium-catalyzed decarboxylation-dehydrogenation to yield α,β-unsaturated ketones in usually high chemical yield and with good selectivity.[118] Following this approach, it was possible to obtain 2-methyl-2-cyclopentenone in two steps from diallyl adipate in a procedure that could be convenient for large-scale preparations (eq 62).[119]

(62)

Activation of Phenyl and Benzyl C-H bonds: Oxidation of Aromatics.

If palladium diacetate is heated in an aromatic solvent, oxidation of the solvent by cleavage-substitution of a C-H bond occurs, resulting in a mixture of products.[120] Depending on the reaction conditions, biaryls and phenyl or benzyl acetates are isolated. Seemingly small changes can result in large changes in product distribution (eq 63). For example, the oxidation of toluene by a palladium(II) salt yields benzyl acetate in reactions mediated by palladium acetate, whereas bitolyls are the major products in reactions carried out in the presence of chloride ions (eq 63).[121]

(63)

Oxygen Nucleophiles.

A reagent such as permanganate oxidizes toluene to benzoic acid,[122] whereas benzylic oxidation by palladium acetate results in benzyl alcohol derivatives. The oxidation is favored by electron-releasing substituents in the phenyl ring.[123] Catalytic amounts of palladium acetate and tin diacetate, in combination with air, effects an efficient palladium-catalyzed benzylic oxidation of toluene and xylenes. For the latter substrates, the α,α´-diacetate is the main product.[124] A mixed palladium diacetate-copper diacetate catalyst has also been found to selectively catalyze the benzylic acyloxylation of toluene (eq 64).[125]

(64)

Benzene can be oxidized to phenol by molecular oxygen in the presence of catalytic amounts of palladium diacetate and 1,10-phenanthroline (eq 65).[126] If potassium peroxydisulfate is used as a stoichiometric oxidant with 2,2´-bipyridyl as a

ligand, a process yielding mainly *m*-acetoxylated aromatics results (eq 66).[127]

(65)

(66)

Palladium diacetate in ***Trifluoroacetic Acid*** ($Pd(O_2CCF_3)_2$) gives a mixture of *o*- and *p*-trifluoroacetoxylated products.[128] The reagent is also capable of oxidizing saturated hydrocarbons such as adamantane and methane. In the presence of carbon monoxide and with sodium acetate as co-catalyst, carbonylation of aromatic C-H bonds occurs, eventually yielding acid anhydrides.[129]

Naphthalenes and methylbenzenes can be oxidized to *p*-quinones by aqueous H_2O_2 in acetic acid catalyzed by a Pd^{II}-DOWEX polystyrene resin. Yields and selectivities are generally higher for the methylnaphthalenes (50-65% *p*-quinone) than for methylbenzenes (3-8%).[130]

Carbon Nucleophiles.

Palladium-mediated homocoupling of substituted arenes generally yields mixtures of all possible coupling products. If the reaction is carried out with a catalytic amount of palladium diacetate and with ***Thallium(III) Trifluoroacetate*** as stoichiometric oxidant (eq 67), aryls carrying substituents such as alkyl or halide afford mainly the 4,4´-biaryls in yields ranging from 60% (R = ethyl) to 98% (R = H).[131] Biaryls can also be formed without the palladium catalyst.[132]

(67)

R = Me, 40 h, 95% (74% 4,4')

Oxidative substitution of aromatics with a heteroatom substituent in a benzylic position generally yields *o*-substituted products.[1b,5] The reaction probably proceeds via a cyclopalladated phenylpalladium species (eq 68), which decomposes to form substituted products. For example, the alkylation of a number of acetanilides proceeds with high selectivity for the *o*-alkylated product.[133]

(68)

81%

With *t*-butyl perbenzoate as hydrogen acceptor, it is possible to couple benzene or furans with alkenes. In the absence of alkene, benzoxylation of the aromatic compound is observed.[134]

When heated in palladium acetate-containing acetic acid, diphenyl ether, diphenylamine, benzophenone, and benzanilide gave high yields of cyclized products (eq 69). A large number of ring substituents were tolerated in the cyclization.[135]

(69)

X = O, NH, CO

Oxidation of benzoquinones and naphthoquinones by palladium diacetate in arene-containing acetic acid gave the corresponding aryl-substituted quinones (eq 70).[136] Treatment of 1,4-naphthoquinone with aromatic heterocycles, for example furfural, 2-acetylfuran, 2-acetylthiophene, and 4-pyrone, yielded the corresponding 2-heteroaryl-substituted 1,4-naphthoquinones.

(70)

arene = C_6H_6 (85%), 2,5-$Me_2C_6H_4$ (78%), 2,5-$Cl_2C_6H_4$ (70%)

Palladium-Catalyzed Reductions.

Reduction of Alkynes.

Alkynes are selectively reduced to (*Z*)-alkenes by a reduction catalyst prepared from NaH, *t*-$C_5H_{11}OH$, and $Pd(OAc)_2$ (6:2:1) in THF. The reactions, carried out in the presence of quinoline under near atmospheric pressure of H_2, are self-terminating at the semihydrogenated stage, and are more selective than the corresponding reductions catalyzed by Lindlar's catalyst. Omitting the *t*-$C_5H_{11}OH$ gave a catalyst that effected complete reduction.[137]

Alkenyldialkylboranes from internal alkynes undergo palladium acetate-catalyzed protonolysis to yield (*Z*)-alkenes under neutral conditions and (*E*)-alkenes in the presence of Et_3N.[138]

Hydrogenolysis of Allylic Heterosubstituents.

Chemoselective removal of an allylic heterosubstituent in the presence of sensitive functional groups is a sometimes difficult transformation since nucleophilic displacement with hydride donors is efficient only if the heterosubstituent is a good leaving group or the hydride donor is powerful. However, removal of an allylic heterosubstituent is a reaction readily performed by Pd^0.[87] The resulting (π-allyl)palladium complexes are readily attacked by hydride nucleophiles (eq 71). Thus, mild hydride donors such as ***Sodium Borohydride*** or ***Sodium Cyanoborohydride*** can be employed.[139] Treatment of allylic oxygen, sulfur, and selenium functional groups with a combination of $Pd(PPh_3)_4$ and ***Lithium Triethylborohydride*** yielded the corresponding hydride-substituted compounds with good regio- and stereoselectivity, with the more highly substituted (*E*)-alkene as the predominant product (eq 71).[140] Similar results are observed for all hydride donor systems but one: that derived from formic acid yields predominantly or exclusively the less substituted alkene (eq 71).[142]

The regio- and stereoselective hydride attack on the more substituted terminus of (π-allyl)palladium complexes derived from allylic formates has been applied to the palladium acetate-*n*-Bu_3P-catalyzed formation of ring junctions in hydrindane, decalin, and steroid systems, and to stereospecific generation of steroidal side-chain epimers.[141]

Deoxygenation of Carbonyls.

Carbonyl compounds can be deoxygenated to form alkenes in a palladium-catalyzed reduction of enol triflates (eq 72). The reaction is quite general, and has been applied to aryl as well as alkyl enol triflates.[142]

Related Reagents.

Palladium(II) Acetylacetonate

[14024-61-4] · $C_{10}H_{14}O_4Pd$ · Palladium(II) Acetylacetonate · (MW 304.66)

(occasionally used as a homogeneous Pd^{II} catalyst; used mainly as source of Pd^0 catalysts after reduction in the presence or absence of ligands)

Physical Data: mp 205 °C (dec).

Solubility: insol H_2O; slightly sol benzene, ether, ethanol; sol chloroform.

Form Supplied in: orange needle-like crystals; widely available.

Purification: recrystallization from benzene.

Generation of Carbenes from Diazo Compounds.

$Pd(acac)_2$ is used as a catalyst for carbene generation from diazo compounds. For example, treatment of the α-diazo-β-keto ester shown in eq 1 with $Pd(acac)_2$ (9 mol %) at 80 °C in benzene gave the cyclopropane derivative in 78% yield as the only isolated product.[1] This product is different from the furan derivative obtained by the catalysis of $Rh_2(OAc)_4$.

(1)

Generation of Pd^0 Species.

Many reactions are catalyzed by Pd^0 catalysts.[2] The Pd^0 complexes ***Tetrakis(triphenylphosphine)palladium(0)*** and ***Bis(dibenzylideneacetone)palladium(0)*** are commercially available. More conveniently, Pd^{II} salts are reduced in situ to Pd^0. For this purpose, ***Palladium(II) Acetate*** is most widely used, but $Pd(acac)_2$ is sometimes preferable because it can be easily obtained in better quality by recrystallization. $Pd(acac)_2$ is reduced in situ in the presence or absence of a ligand (L) to form Pd^0L_n complexes, which can be used as catalysts. Various reducing agents such as metal hydrides ($NaBH_4$, $LiAlH_4$, *i*-Bu_2AlH), RLi, RMgX, CO, alkenes, and phosphines are used. In the most convenient method of reduction, $Pd(acac)_2$ is treated with ***Tri-n-butylphosphine*** in THF (eq 2). The solution turns quickly to pale yellow, and a very active Pd^0 catalyst is generated.[3] Reactions catalyzed by Pd^0 in the presence, or absence, of a phosphine ligand are shown below.

(2)

Hydrogenolysis of Allylic Formates and Carbonates.

The catalyst shown in eq 2 has been used for the regioselective and stereoselective generation of either C-20 epimer in steroid side chains by the Pd^0-catalyzed hydrogenolysis of C-20 allylic carbonates.[4] The unnatural stereochemistry at C-20 was generated from the *trans*-allylic carbonate (eq 3), and the natural stereochemistry was generated by the hydrogenolysis of the *cis*-allylic carbonate (eq 4). Commonly used $Pd(Ph_3P)_4$ or $Pd_2(dba)_3$ were inactive. This method

of the palladium-catalyzed hydrogenolysis has been applied to the regioselective and stereoselective generation of *cis*- and *trans*-fused decalins and hydrindanes.[5]

(3)

Displacement Reactions of Vinyl Sulfones.

Pd^0 species generated from $Pd(acac)_2$ and a Grignard reagent catalyze the reaction of vinyl sulfones with Grignard reagents. Displacement takes place with ***Methylmagnesium Bromide*** and hydrogenolysis takes place with ***Ethylmagnesium Bromide*** (eq 5).[6,7]

Palladium on Barium Sulfate[1]

$Pd/BaSO_4$

[7440-05-3] · Pd · Palladium on Barium Sulfate · (MW 106.42)

(usually supported on $BaSO_4$, or an appropriate form of carbon, when used to catalyze the hydrogenation of acyl chlorides to aldehydes, the Rosenmund reduction;[2] useful catalyst for many other hydrogenations[1b-e])

Alternate Name: Rosenmund catalyst.

Form Supplied in: Pd-on-$BaSO_4$ and Pd-on-C are available commercially or may be prepared.[3]

Handling, Storage, and Precautions: the catalysts may be stored indefinitely in well-sealed containers.[1e] Although the unused catalysts can be exposed to a clean atmosphere, they may ignite organic solvent vapors; heating a Pd-on-C catalyst in a vacuum drying oven at 115 °C for more than 48 h causes it to become extremely pyrophoric.[4] After use, all catalysts are liable to contain adsorbed hydrogen and may ignite when dried. The filtered catalyst should be kept wet and away from combustible vapors or solvents.

Traditional Rosenmund Procedures.

The palladium-catalyzed hydrogenation of an acid chloride to an aldehyde is known as the Rosenmund reduction (eq 1). In the original procedure, hydrogen is bubbled through a heated suspension of the catalyst, $Pd/BaSO_4$, in a xylene or toluene solution of the acyl chloride.[2] The HCl formed is absorbed in water and titrated to monitor the reaction's progress. Although the procedure works well for many acyl chlorides, for others the further reduction of the aldehyde to the alcohol, and the consequential formation of esters, ethers, and hydrocarbons, seriously lowers the yield of the aldehyde.[1] In initial experiments, it was reported that benzoyl chloride was converted almost completely to benzaldehyde; however, repetition of the same experiment, but with all reactants carefully purified, gave none.[5] Seeking possible catalyst modifiers or regulators, it was found that quinoline-sulfur, a crude preparation of thioquinanthrene, was most suitable.[5,6] Other regulators which have been recommended are pure thioquinanthrene, thiourea, and tetramethylthiourea.[5,7] The purity of the solvent, which is used in much larger amounts than any of the reactants or the catalyst, is a key to reproducible reductions.[8,9] Attaining the lowest temperature at which HCl is evolved was reported to optimize the yield of aldehyde.[1a]

(1)

In a 1948 review, it is claimed that For accomplishing this transformation, RCO_2H -> RCHO, the Rosenmund reduction is probably the most useful method for application to a large number of aldehydes of varied types.[1a] This critical review describes the scope and limitations of the reaction, the experimental conditions, reagents, and procedures and includes tables recording the acid chlorides whose reduction by the Rosenmund method had been reported to November 1947.

Rosenmund described a simple apparatus for performing the reduction.[5] A detailed description of a more elaborate apparatus and procedure used for the hydrogenolysis of β-naphthoyl chloride (0.30 mol) in xylene catalyzed by 5% $Pd/BaSO_4$ and regulated by quinoline-sulfur was given by Hershberg and Cason (eq 2).[10] They recommended that a poison always be added to ensure controlled conditions. The hydrogenolysis of mesitoyl chloride in xylene over unpoisoned $Pd/BaSO_4$ is described in the same volume; vigorous stirring shortens the reaction time by about one third.[11]

(2)

The omission of catalyst poisons is common and the original Rosenmund procedure[2] has been successful with acid halides containing other functional groups, or condensed benzenoid or heterocyclic systems.[1a] For example, discouraged by attempts to obtain high yields with a variety of metal hydride reducing reagents, Danishefsky et al. found that the original Rosenmund procedure converts the acid chloride (eq 3) in an essentially quantitative yield.[12] The reduction of the related compound with a methyl group proximate to the C(O)Cl group gave only a 49% yield of the aldehyde (eq 4) (however, see below).

(3)

(4)

A procedure for the unpoisoned 10% ***Palladium on Carbon*** catalyzed hydrogenation of α-phthalimido acid chlorides to the aldehydes in benzene at 40 °C has been described.[13] To cause the benzene to reflux at 40 °C, the pressure is lowered with a vacuum pump which is attached to the outlet in a manner which allows the collection and titration of the evolved HCl. This procedure was suited particularly for the preparation of the phthaloyl methionine aldehyde (eq 5) but the (±)-phenylalanine and (±)-alanine derivatives gave yields of 93% and 94% respectively with benzene refluxing at 1 atm. An almost identical low temperature (reduced pressure) procedure was used to hydrogenate a diacid chloride to the dialdehyde in 92-94% yield (eq 6).[14]

(5)

(6)

Rosenmund Reductions within Closed Systems.

To avoid the higher temperature and the hazard of free flowing hydrogen of the classical Rosenmund procedure, particularly for large scale preparations, an autoclave can be used for the Pd/C catalyzed hydrogenolysis of 3,4,5-trimethoxybenzoyl chloride to the aldehyde (yield, 64-83%); the reduction was done at 35-40 °C and H_2 (4 atm) in

toluene containing quinoline-S with anhydrous sodium acetate as HCl adsorber (eq 7).[4,15] The same reaction has been achieved repeatedly in 80-90% yields by the Rosenmund procedure without added regulators and either Pd/$BaSO_4$ or Pd/C catalysts and either xylene or PhOMe as solvent.[1a]

Sakurai and Tanabe were the first to report the use of a closed system for the Pd/$BaSO_4$ catalyzed hydrogenolysis of an acyl halide.[16] The reduction (H_2, 1 atm) was conducted at rt in the presence of a hydrogen chloride acceptor, *N*,*N*-dimethylaniline, and acetone as solvent. *N*-Phthaloyl derivatives of (±)-α-amino acid chlorides have been hydrogenated to the aldehydes using 10% Pd/C in the solvent ethyl acetate (H_2, 3 atm) in the presence of dimethylaniline, with yields of over 90%.[13]

The Sakurai and Tanabe procedure (5% Pd/$BaSO_4$) gave high yields of arachidaldehyde (72%) and stearaldehyde (96%); for convenience, *N*,*N*-dimethylacetamide was used as the acid acceptor to obtain excellent yields of palmitaldehyde (96%) and decanaldehyde (96%).[17] Peters and van Bekkum chose ethyldiisopropylamine as HCl acceptor due to the competitive reduction of *N*,*N*-dimethylaniline, which obscured the end-point (vol H_2) of the hydrogenolysis of the acid chloride.[18] The mild conditions converted the sterically hindered carbonyl chloride function in 1-*t*-butylcyclohexanecarbonyl chloride to the aldehyde (78%), although *t*-butylcyclohexane was the sole product of the original Rosenmund procedure (eq 8). Burgstahler and Weigel also modified the Sakurai and Tanabe procedure by using 2,6-dimethylpyridine in place of *N*,*N*-dimethylaniline and THF as solvent with either Pd/$BaSO_4$ or Pd/C as catalyst to obtain excellent yields of 15 sensitive aliphatic and alicyclic aldehydes such as hexanedial (74%) and (*Z*)-9-octadecenal (96%) (eq 9).[19] The reaction temperature was lowered to 0 °C to convert dehydroabietic acid chloride to the aldehyde (92%) (eq 10).[19]

Both aliphatic and aromatic acid chlorides are reduced smoothly at room temperature and atmospheric pressure to aldehydes with 10% Pd/C as catalyst, acetone or ethyl acetate as solvent, and ethyldiisopropylamine as HCl acceptor.[20] The reaction proceeds with high selectivity; over reduction is less than 1%, and nitro and chloro substituents in benzoyl chlorides are unaffected, as is the double bond in cinnamoyl chloride.

Recent Practice.

Some more recent examples show that both the older and the newer procedures are used successfully. As an important step in the preparation of 10-nor-*cis*-α-irone, the classical Rosenmund reduction (H_2, 5% Pd/$BaSO_4$, toluene/reflux) converted the acid chloride (**1**) to the product aldehyde in 93% yield (eq 11).[21]

The semialdehyde derivatives of aspartic and glutamic acids have been obtained in good yields and in higher purity than by hydride reductions; acid-sensitive protecting groups are unaffected.[22] The acid chlorides (**2**) and (**3**) (benzyloxycarbonyl (*Z*) derivatives) were converted to the aldehydes using an unpoisoned catalyst (5% Pd/$BaSO_4$, boiling toluene, H_2) (eq 12). The same procedure was used to reduce the acid chloride (**4**), derived from L-alanine, to the aldehyde in 93% yield (eq 13).[23]

(12)

(2) $n = 1$
(3) $n = 2$

$n = 1$, 87%
$n = 2$, 82%

(13)

(4)

To protect the acid labile *t*-butoxycarbonyl protecting group in acid chloride (**5**), the Burgstahler procedure (H_2, 5% Pd/C, 2,6-lutidine, THF, 10-15 °C) converted (**5**) to the aldehyde (eq 14).[19,22]

(5)

(14)

The quinoline-sulfur system was used to prepare methyl 4-oxobutanoate from 3-methoxycarbonyl chloride as the first of a three-step synthesis of a series of 5-vinyl γ-lactones.[10,24]

Kinetics and Mechanism of the Rosenmund Reaction.

The kinetics of the amine-modified Rosenmund reduction has been examined in detail.[20] In the absence of the tertiary amine, the hydrogenolysis of 4-*t*-butylbenzoyl chloride proceeds beyond the aldehyde stage to a complex mixture with bis(4-*t*-butylbenzyl) ether as the main product. In the presence of the efficient HCl acceptor zeolite NaA, most of the side reactions (acid catalyzed) are suppressed, but reduction proceeds to 4-*t*-butylbenzyl alcohol. In the presence of the

tertiary amine, the aldehyde is the sole product. However, benzaldehydes subjected to the conditions of the amine-modified reduction are hydrogenated to the alcohols, but more slowly than in the absence of the amine and substantially slower on a catalyst which has been used previously in a hydrogenation of an acid chloride. The nature of the deactivation is a subject of speculation.[20,25]

The tertiary amine not only neutralizes HCl, but also acts as a nucleophile which serves to moderate the reaction and enhance the selectivity by competing with both the acid chloride and the product aldehyde for active sites on the catalyst. A useful analogy is the effect of tertiary amines upon increasing the selectivity of the hydrogenation of alkynes to alkenes on palladium catalysts.[1b,26,27] The solvent also may compete for active sites; for example, the rate constants for the Pd-catalyzed hydrogenation of cyclohexene, corrected for the difference in the solubility of H_2 in the solvents, are smaller in benzene and smaller still in xylene, both commonly used in the Rosenmund reduction, than in saturated hydrocarbons.[28] The presence of nucleophilic groups elsewhere in the acid chloride may also act to moderate the reduction and affect selectivity in the absence of an added catalyst poison.

Aliphatic acid chlorides generally are more easily hydrogenolyzed than are aromatic ones; however, the Peters and van Bekkum paper contains the most direct comparison of relative reactivities for some representative carbonyl chlorides (15 compounds including 10 aromatic).[20] For benzoyl chlorides, electron-donating substituents increase the reaction rate while electron-withdrawing substituents have a retarding effect. The rates of hydrogenation of aroyl chlorides generally are faster in the solvents ethyl acetate or THF than in acetone.

The mechanism of the Rosenmund reduction has been discussed in relation to the characteristic reactions of transition metal complexes.[29] It has been proposed that the acid chloride adds oxidatively to the palladium metal, forming a complex which gives rise to the observed products which depend upon the reaction conditions, e.g. temperature, H_2 pressure, and solvent. Some dissolution of the palladium when heated with an acid chloride at about 100 °C was observed. However, exposing single crystals of palladium to heptanoyl chloride in pentane and H_2 at room temperature for 52 h did not change the (755) crystal surface which had catalyzed the formation of the aldehyde.[25] A means of representing catalytic processes on such crystal surfaces by analogy with the reactions of transition metal complexes has been given for catalytic hydrogenation.[26]

Other Hydrogenations.[1b-e]

$Pd/BaSO_4$ has also been used in the conversion of alkynes to *cis*-alkenes.[30] In some cases, where results of the reduction of alkynes to *cis*-alkenes with Lindlar catalysts (see ***Palladium on Calcium Carbonate (Lead Poisoned)***) are unsatisfactory, the use of $Pd/BaSO_4$ as the catalyst has been effective (eqs 15 and 16).[31]

(15)

(16)

The reverse has also been observed.[32] Interestingly, the saturation of the trisubstituted alkene in humulinic acid B has also been reported with this catalyst.[33]

Hydrogenolysis of various functional groups has also been reported with Pd/$BaSO_4$. For example, the conversion of vinyl epoxides to homoallylic alcohols,[34] α-bromo-β-mesyluridines to hydrocarbons (eq 17),[35] *N*,*N*-dibenzylamino acids to *N*-benzylamino acids,[36] and the enantioselective mono-dehydrohalogenation of α,α-dichlorobenzazepin-2-one[37] have all been reported.

(17)

The maximum % ee observed for α-chlorobenzazepin-2-one was 50%, but surprisingly the method was not effective for other substrates, including α,α-dibromobenzazepin-2-one. Eq 17 also shows the C-O bond of a benzyl ether was not cleaved while the C-O bond of a mesylate and a C-Br bond were both hydrogenolyzed.

Regioselective opening of a 1,2-disubstituted epoxide was observed with this catalyst (eq 18).[38] The benzylic ketone was not reduced or hydrogenolyzed under the reaction conditions.

Palladium *t*-Butyl Peroxide Trifluoroacetate

[75123-99-8] · $C_6H_9F_3O_4Pd$ · Palladium *t*-Butyl Peroxide Trifluoroacetate · (MW 308.57)

(oxidizing agent for the selective transformation of terminal alkenes to methyl ketones;[1,2] oxidative ring cleavage of cyclic acetals[5])

Alternate Name: PPT.

Physical Data: yellow crystals, mp 130-150 °C (dec).

Solubility: sol most common organic solvents, e.g. CH_2Cl_2, toluene, THF; destroyed by alcohols through anion exchange.

Analysis of Reagent Purity: IR: ν(O-O) = 855-860 cm^{-1}; $\nu(C{=}O)_{asym}$ = 1615-1630 cm^{-1}; ^1H NMR: δ 1.36-1.41 (*t*-Bu).

Preparative Methods: 1 g ***Palladium(II) Acetate*** is dissolved in 2 mL of ***Trifluoroacetic Acid***, and 10 mL of anhydrous 80% ***t-Butyl Hydroperoxide*** is added to the brown slurry at room temperature. After stirring for ca. 6 h, fine yellow crystals precipitate from the reaction mixture. The solid is filtered, washed repeatedly with pentane, and dried in vacuo; yield 85%.

Handling, Storage, and Precautions: not explosive or shock sensitive, but must be stored in a refrigerator.

Oxidation of Terminal Alkenes to Methyl Ketones.

PPT is a powerful and selective reagent for the oxidation of terminal alkenes to methyl ketones according to eq 1. The reaction is carried out at rt in solvents such as benzene, toluene, or dichloromethane, using a large excess of alkene (alkene/Pd > 5). Alkenes such as 1-hexene, 1-octene, or styrene are selectively converted to 2-hexanone, 2-octanone, and acetophenone, respectively.

Internal alkenes are not oxidized, but form stable η^3-allyl Pd complexes (eq 2).

The mechanism of the ketonization of terminal alkenes (eq 3) has been shown to proceed via coordination of the alkene to palladium followed by intramolecular Markovnikov nucleophilic attack of the *t*-BuOO moiety on the coordinated alkene, forming the five-membered peroxometallocycle (pseudocyclic peroxymetalation); this decomposes with a β-hydride migration to form the methyl ketone and the palladium *t*-butoxy complex. The latter can react with excess alkene to give the η^3-allyl complex, or with excess *t*-BuOOH in a catalytic ketonization of terminal alkenes which is less effective than the oxidation by ***Hydrogen Peroxide*** (see below).

Palladium complexes are powerful catalysts for the selective oxidation of terminal alkenes to methyl ketones. In contrast to the Wacker ***Palladium(II) Chloride-Copper(II) Chloride***-H_2O-O_2 system, this reagent system (eq 4) can be successfully applied to most terminal higher alkenes, does not give chlorinated byproducts, and is not corrosive.

This reaction can be carried out at room to moderate (70 °C) temperature in a two-phase (benzene, toluene, AcOEt, MTBE) or single-phase (*t*-BuOH, AcOH) mixture. Several palladium complexes (particularly $Pd(OAc)_2$) can be used as catalysts for this transformation in concentrations as low as 10^{-4} molar in solution, with turnover numbers higher than 400 mol ketone produced per mol Pd and per hour. The reaction can be applied to most terminal alkenes, e.g. 1-hexene, 1-octene, 1-dodecene, or allyl acetate, and gives the corresponding methyl ketones with conversions and selectivities higher than 80%. Byproducts include mainly the internal isomers of the starting alkenes, and some internal ketones. During the reaction, a Pd-catalyzed parallel decomposition of H_2O_2 occurs, and two equiv or more are often necessary to reach a complete conversion of the substrate.

The mechanism of this reaction (eq 5) has been shown to proceed through a hydroperoxypalladation of the coordinated alkene, similar to that described in eq 3. Labeling studies have shown that the oxygen atom incorporated into the methyl ketone exclusively derives from H_2O_2, not H_2O.[2]

Almost quantitative yields of methyl ketones were obtained in biphasic conditions by adding a terminal alkene (from 1-hexene to 1-octadecene) to a suspension of ***Tetrakis(triphenylphosphine)palladium(0)*** in a 3.2 M aqueous solution of H_2O_2 at 40-80 °C (alkene:Pd = 2000; H_2O_2:alkene = 10). The ketonization is thought to proceed via the formation of an active anionic intermediate $[(Ph_3P)_3Pd(OOH]^-H^+$ which transfers oxygen to the alkene as in eq 5.[3]

A heterogenized reusable Pd complex on layered montmorillonite silylpropylethylenediamine (Figure 1) was shown to exhibit a much higher activity for the selective ketonization of terminal alkene by H_2O_2 (substrate:Pd = 4500; AcOH, 80 °C, with alkenes ranging from 1-hexene to 1-dodecene, styrene, allyl alcohol, and allyl acetate; yields higher than 90%). Consistent activity was found for 4 catalyst recycles.[4]

Oxidative Cleavage of Cyclic Acetals.

The trifluoroacetate catalyzes the oxidative cleavage of cyclic acetals by *t*-butyl hydroperoxide to give diol monoesters. In a typical reaction, the cyclic acetal and two equivalents of *t*-butyl hydroperoxide were mixed with 5 mol % of the catalyst in dry benzene at 50 °C (eqs 6, 7).[5]

Palladium on Calcium Carbonate (Lead Poisoned)

$Pd/CaCO_3/Pb$

[7440-05-3] · Pd · Palladium on Calcium Carbonate (Lead Poisoned) · (MW 106.42)

(catalyst used for selective hydrogenation of alkynes to *cis*-alkenes;[1-7] used to reduce azides and nitro compounds to amines;[8] used infrequently for oxidation of aldehydes to acids[10])

Alternate Name: Lindlar catalyst.

Solubility: insol most organic solvents; incompatible with water or acids.

Form Supplied in: dark gray to black powder, typically 5 wt% of palladium.

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: can be stored safely in a closed container under air but away from solvents and potential poisons such as sulfur- and phosphorus-containing compounds. The reagent is pyrophoric in the presence of solvents. General precautions for handling hydrogenation catalysts should be followed. The catalyst must be suspended in the organic solvent under an atmosphere of N_2. During filtration the filter cake must not be allowed to go dry.

Hydrogenations.

Lead-poisoned palladium on calcium carbonate, also known as Lindlar catalyst, is mainly used for the selective conversion of alkynes to *cis*-alkenes.[1] The catalyst has been used frequently in the presence of an amine. The hydrogenation in most cases stops sharply after one equiv of hydrogen uptake. For example, the reduction of 1,2-epoxydec-4-yne over Lindlar catalyst and quinoline gave (*Z*)-1,2-epoxydec-4-ene in 95% yield. The epoxide was stable under the reaction conditions.[2] Terminal alkynes can be reduced selectively to 1-alkenes. The ease of reduction was established to be 1-alkyne > internal alkyne > 1-alkene.[3] Conjugated enynes can be reduced smoothly to the corresponding dienes with excellent selectivity (eq 1).[4]

Alkynes in conjugation with one or two carbonyl functions are also reduced smoothly to the alkene. Lactone formation was observed when the hydroxyalkynoic acid shown in eq 2 was hydrogenated.[5]

The reduction of 1-octynyldiisopropoxyborane with Lindlar catalyst in 1,4-dioxane with a small amount of pyridine gave a 95:5 (*cis*:*trans*) ratio of vinyl boronates. High selectivity was also observed with a variety of 1-alkynyl-1,3,2-dioxaborinanes under the above optimized reaction conditions.[6] It is important to note that other catalysts, such as ***Palladium on Barium Sulfate***, ***Nickel Boride***, and, more recently, ***Palladium on Poly(ethylenimine)***, have also been used to effect the reduction of alkynes to *cis*-alkenes with excellent results and are sometimes superior to Lindlar catalyst.[7]

Azides are readily hydrogenated to amines with this catalyst. As expected, alkenic groups are stable under the reaction conditions.[8]

Under catalytic transfer hydrogenation conditions, nitrobenzenes and azoxybenzenes are converted to hydrazobenzenes (eq 3).[9]

Oxidation.

The catalyst has also been used in oxidation reactions. Methacrolein in MeOH was oxidized to give 93% yield of methyl methacrylate with a selectivity of 95% at 98% conversion.[10]

Palladium on Carbon

Pd/C

[7440-05-3] · Pd · Palladium on Carbon · (MW 106.42)

(catalyst for hydrogenation of alkenes, alkynes, ketones, nitriles, imines, azides, nitro groups, benzenoid and heterocyclic aromatics; used for hydrogenolysis of cyclopropanes, benzyl derivatives, epoxides, hydrazines, and halides; used to dehydrogenate aromatics and deformylate aldehydes)

Solubility: insol all organic solvents and aqueous acidic media.

Form Supplied in: black powder or pellets containing 0.5-30 wt % of Pd (typically 5 wt %); can be either dry or moist (50 wt % of H_2O).

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: can be stored safely in a closed container under air but away from solvents and potential poisons such as sulfur- and phosphorus-containing compounds. Pyrophoric in the presence of solvents. General precautions for handling hydrogenation catalysts should be followed. The catalyst must be suspended in the organic solvent under an atmosphere of N_2. During filtration the filter cake must not be allowed to go dry. If a filter aid is necessary, a cellulose-based material should be used if catalyst recovery is desired.

Hydrogenation and Hydrogenolysis: Carbon-Carbon Bonds.

The use of Pd/C for the selective reduction of alkynes to alkenes is generally not satisfactory, but a few examples have been reported. For example, the Pd/C-catalyzed reduction of 3,6-dimethyl-4-octyne-3,6-diol gave the enediol in 98% yield after absorption of 1 mol of H_2.[1] Further reduction gave the diol in 99% yield. Pd on other supports, such as $Pd/CaCO_3$ and $Pd/BaCO_3$, are much more effective for this conversion. Pd/C is usually used for the complete saturation of alkynes and alkenes to their corresponding hydrocarbons.[2] In some instances, isomerization of the double bond during hydrogenation occurs before reduction, which leads to unexpected results. For example, reduction of car-3-ene gave the cycloheptane with Pd/C instead of the expected cyclohexane derivative (eq 1).[3]

(1)

Isomerization of a double bond from one position to a hydrogenation inaccessible location has also been observed (eq 2).[4]

(2)

Next to the reduction of nitro groups, double and triple bonds are generally the next easiest functional groups to undergo hydrogenation. Some less reactive functional groups include ketones,[5] esters,[6] benzyl ethers,[7] epoxides,[8] and N-O bonds.[9] These remain intact under conditions needed to reduce alkenes and alkynes. Under longer reaction times and/or more forcing conditions, some of these functional groups will also be affected. Allylboron compounds can be hydrogenated to the propylboron derivatives, the C-B bond remaining intact (eq 3).[10]

(3)

Treatment of acylated aldonolactones with hydrogen in the presence of Pd/C and triethylamine provided 3-deoxyaldonolactones in excellent yields (eq 4).[11] The α,β-unsaturated intermediate was hydrogenated stereospecifically to give the product. Substituting Pd with Pt catalysts gave the 2-acetoxy hydrogenolyzed product (**1**) instead. Hydrogenolysis of the acetate preceded the double bond hydrogenation.

(1)

Hydrogenolysis of C-C bonds using Pd/C is mainly limited to cyclopropane opening. The less substituted and electronically activated bond cleavage is preferred. An example is shown in (eq 5).[12]

Carbon-Nitrogen Bonds.

The hydrogenation of nitriles to primary amines is best accomplished with Pd/C in acidic media or in the presence of ammonia. In the absence of acid or ammonia, a mixture of primary and secondary amines is observed. This effect was taken advantage of and mixed secondary amines were obtained selectively by the reduction of a nitrile in the presence of a different amine (eq 6).[13] Hydrogenation in aqueous acidic conditions can lead to aldehydes and/or alcohols.[14]

Reductive alkylation is a convenient and efficient way of obtaining secondary and tertiary amines.[15] *N*,*N*-Dimethyl tertiary amines can be obtained from both aromatic and aliphatic primary amines or their precursors. Using α-methylbenzylamine as the chiral auxiliary, highly diastereoselective reduction of the intermediate imine has been observed (eq 7).[16]

This method also provides a convenient route to nitrogen containing heterocycles. Hydrogenolysis of the Cbz group followed by an in situ reductive alkylation process gave a bicyclic heterocycle (eq 8).[17] The alkene was also reduced.

(8)

Other amine precursors, such as azides, can be utilized in the reductive alkylation reaction. For example, a furanose ring was opened and reclosed to form a piperidine ring system (eq 9).[18] A pyranyl azide similarly provided the seven-membered nitrogen heterocycle.

(9)

Similar to nitriles, hydrogenation of oximes is best carried out under acidic conditions to minimize secondary amine formation.[19]

Benzylic amines can be readily hydrogenolyzed to give less alkylated amines.[20] The C-N bond can be cleaved under both transfer hydrogenation[21] and regular hydrogenation conditions.[22] In many cases the newly debenzylated amines can further react, resulting in more structurally complex products (eq 10).[23]

(10)

The heterogeneous catalytic debenzylation of *N*-benzylated amides with Pd/C is generally a difficult process and should not be considered in a synthetic scheme.

Allylamines have also been deallylated using Pd/C catalysis (eq 11).[24]

(11)

Aziridines are hydrogenolyzed to give ring-opened amines. In eq 12, the more reactive benzylic C-N bond was cleaved selectively.[25]

(12)

Carbon-Oxygen Bonds.

Pd/C is best suited for the hydrogenation and hydrogenolysis of benzylic ketones and aldehydes. The reduction of dialkyl ketones to the alcohols is more sluggish and further hydrogenolysis to the alkane is even slower.[26] The hydrogenation of benzylic ketones (aryl alkyl and diaryl ketones) to alcohols is a very facile process with Pd/C.[27] Further hydrogenolysis of the benzylic alcohols to the alkane products can be a major problem with Pd/C catalysts, but can be controlled.[28] In general, aryl ketones and aldehydes can be reduced to alcohols under neutral conditions or in the presence of an amino functional group or an added amine base.[29] In the presence of acids, hydrogenolysis is more prone to occur. Using other catalysts such as ***Platinum on Carbon*** Ru/C, Rh/C and ***Raney Nickel***, is an alternative.

Trifluoromethyl ketones are reduced to alcohols without dehalogenation or further hydrogenolysis.[30] The hydrogenation of a chiral proline derivative provided the α-hydroxyamide product in 77% de and 100% yield (eq

13).[31]

Hydrogenolysis of a benzyl group attached to an oxygen atom is a common step in complex synthetic schemes. Benzyl esters,[32] benzyl carbamates,[33] and benzyl ethers[34] are readily hydrogenolyzed to acids, amines, and alcohols, respectively. *N*-Oxides protected as the benzyl ethers can be deprotected without hydrogenolysis of the N-O bond.[35] Hydrazines protected with benzyloxycarbonyl (Cbz) groups have been deprotected without N-N bond cleavage or the hydrogenolysis of benzylic C-O bonds (eq 14).[36]

Benzyl carbamates have been transformed into *t*-butyl carbamates under transfer-hydrogenolysis conditions, but high catalyst loading was needed (eq 15).[37] A benzyl ether function survived these reaction conditions but a 1-alkene was saturated.

1,2-Diols protected as the acetal of benzaldehyde were deprotected under hydrogenolysis conditions (eq 16).[38]

(16)

3-Acyltetronic acids were easily hydrogenolyzed to 3-alkyltetronic acids. Further reduction of the enol was not observed under the reaction conditions (eq 17).[39]

(17)

R = Me 96%
R = CH_2Ph 93%

The C-O bond of epoxides can be hydrogenolyzed to give alcohols. Regioselective epoxide ring opening has been observed in some cases (eq 18).[40]

(18)

Nitrogen-Oxygen Bonds.

Both aliphatic and aromatic nitro groups are reduced to the corresponding amines (eq 19).[41] N-O bonds are also readily hydrogenolyzed using Pd/C (eq 20).[42a]

(19)

(20)

Carbon-Halogen Bonds.

Aromatic halides (Cl, Br, I) are readily hydrogenolyzed with Pd/C.[43] The reaction generally requires the presence of a base to neutralize the acid formed. In the absence of an acid neutralizer, dehalogenation is slower and may stop short of completion. Vinyl halides are also dehalogenated but concomitant saturation of the alkene can also occur (eq 21).[44a] Defluorination is a very slow process but one case has been reported (eq 22).[45]

(21)

(22)

Selective dehalogenation of acyl halides can also be carried out with Pd/C and H_2 in the presence of an amine base to give aldehydes. This type of dehalogenation is commonly known as Rosenmund reduction (see ***Palladium on Barium Sulfate***).[46]

Nitrogen-Nitrogen Bonds.

Azides[47] and diazo[48] compounds can be reduced over Pd/C to give amines. These groups have also been used as latent amines which, when hydrogenolyzed, can react with amine-sensitive functional groups in the molecule to give other amine products (eq 23).[47c]

(23)

Carbocyclic and Heterocyclic Aromatics.

Hydrogenation of carbocyclic aromatic compounds can be accomplished with Pd/C under a variety of reaction conditions.[49] The conditions are generally more vigorous than those used with Pt or Rh catalysts.

Pyridine and pyridinium derivatives are hydrogenated readily to give piperidines.[50] Other heterocyclic aromatic ring systems such as furan,[51] benzofuran,[52] thiophene,[53] pyrrole,[54] indole,[55] quinoline,[56] pyrazine,[57] and pyrimidine[58] have also been hydrogenated over Pd/C.

Dehydrogenation.

At high temperatures, Pd/C is an effective dehydrogenation catalyst to provide carbocyclic and heterocyclic aromatic compounds.[59] An enone has been converted to a phenol (eq 24)[59f] and a methoxycyclohexene derivative has provided an anisyl product (eq 25).[59g]

(24)

(25)

Miscellaneous Reactions.

Decarbonylations can be carried out under the same conditions used for dehydrogenation (eq 26).[60] In this case, a trisubstituted alkene remained intact.

(26)

Reduction of an acylsilane gave an aldehyde without further hydrogenation to the alcohol or the hydrogenolysis of the benzyl ether (eq 27).[61]

(27)

Pd/C also catalyzed the cycloaddition reaction of an alkyne with a heterocycle to give a tricyclic heteroaromatic compound (eq 28).[62]

(28)

In conjunction with ***Copper(II) Chloride***, Pd/C catalyzed the biscarbonylation of norbornene derivatives (eq 29).[63] Norbornadiene itself was tetracarbonylated but in only 30% yield.

(29)

Related Reagents.

Palladium on Barium Sulfate; ***Palladium(II) Chloride***; ***Palladium(II) Chloride-Copper(II) Chloride***; ***Palladium-Graphite***.

Palladium(II) Chloride[1]

$PdCl_2$

[7647-10-1] · Cl_2Pd · Palladium(II) Chloride · (MW 177.32)

(used as an oxidizing agent and to a lesser extent as a source of Pd^0 complexes)

Physical Data: mp 678 °C (dec).

Solubility: slightly sol H_2O; sol H_2O in the presence of chloride ion; sol aqueous HCl; sol PhCN, forming $Pd(PhCN)_2Cl_2$; insol organic solvents.

Form Supplied in: commercially available as a rust-colored stable powder or crystalline solid.

Handling, Storage, and Precautions: air stable; not hygroscopic.

General Considerations.

Many of the reactions described below can be accomplished using derivatives of palladium chloride such as ***Potassium Tetrachloropalladate(II)***, ***Disodium Tetrachloropalladate(II)***, ***Bis(benzonitrile)dichloropalladium(II)***, dichlorobis(acetonitrile)palladium, and dichlorobis(triphenylphosphine)palladium. The physical properties of these alternative reagents are described under their separate entries, but their chemistry is included in this article.

Synthetic applications of $PdCl_2$ and its derivatives can be classified into three types: use as oxidizing agents, use as Pd^{II} catalysts, and use as a source of Pd^0 catalysts. Characteristic features of these applications are briefly summarized below.

Use as Oxidizing Agents.

$PdCl_2$ and ***Palladium(II) Acetate*** are representative Pd^{II} salts used for various oxidation reactions, but their uses are different. For example, oxidative reactions of aromatic compounds are possible only with $Pd(OAc)_2$; $PdCl_2$ and its derivatives cannot be used. Oxidation reactions of various substrates with $PdCl_2$ are stoichiometric and Pd^0 is formed after the oxidation. Sometimes, but not always, Pd^0 can be reoxidized in situ to Pd^{II} with proper reoxidizing agents. In such a case, the oxidation reaction can be carried out with a catalytic amount of $PdCl_2$. Examples of reoxidants include $CuCl_2$, CuCl, $Cu(OAc)_2$, MnO_2, HNO_3, benzoquinone, alkyl nitrites, H_2O_2, and organic peroxides. Since solubility of $PdCl_2$ in water and organic solvents is small, the more soluble ***Dilithium Tetrachloropalladate(II)***, Na_2PdCl_4, K_2PdCl_4, and $Pd(PhCN)_2Cl_2$ are sometimes used for similar purposes.

Use as Pd^{II} Catalyst.

$Pd(PhCN)_2Cl_2$ is used as a homogeneous Pd^{II} catalyst for some non-oxidative reactions such as rearrangement reactions.

Use as Source of Pd^0 Catalyst.

Pd^{II} salts are reduced to Pd^0 catalysts with various reducing agents. Although $Pd(OAc)_2$ is more convenient for this purpose than $PdCl_2$ and its derivatives, $PdCl_2$ derivatives are used in many cases. Typically, $Pd(Ph_3P)_2Cl_2$ is reduced to form a Pd^0 phosphine complex.

Oxidations.

Oxidative Reactions of Alkenes.[2]

Oxidative reactions of alkenes can be classified into two types: oxidative substitution and oxidative addition, as shown in eq 1. Here X^- and Y^- represent nucleophiles such as HO^-, RO^-, RCO_2^-, R_2N^- and CO, as well as soft carbon nucleophiles such as active methylene compounds.

Reaction with Water.[2a,b]

Oxidation of ethylene to acetaldehyde under oxygen atmosphere is an industrial process called the Wacker process. $PdCl_2$ and ***Copper(II) Chloride*** in aqueous HCl are used as the catalysts. As shown by eq 2, the Wacker process comprises three unit reactions; $CuCl_2$ is a unique reoxidant of Pd^0.

$$CH_2{=}CH_2 + H_2O + PdCl_2 \longrightarrow MeCHO + 2\,HCl + Pd^0$$

$$Pd^0 + 2\,CuCl_2 \longrightarrow PdCl_2 + 2\,CuCl$$

$$2\,CuCl + 2\,HCl + 0.5\,O_2 \longrightarrow 2\,CuCl_2 + 2\,H_2O \qquad (2)$$

$$CH_2{=}CH_2 + 0.5\,O_2 \longrightarrow MeCHO$$

Higher terminal alkenes are also oxidized in organic solvents containing water; DMF is most widely used as the solvent.[3] On a laboratory scale the oxidation can be carried out easily in a way similar to the hydrogenation of alkenes under atmospheric pressure. Instead of Pd black and hydrogen, the oxidation is carried out with $PdCl_2$ and the copper salt under an oxygen atmosphere at room temperature using a similar apparatus. Since the reaction proceeds under mild neutral conditions, many functional groups such as esters, acetals, THP ethers, alcohols, halogens, and amines are tolerated. The ketones obtained by the oxidation are sometimes chlorinated with $CuCl_2$ to give chloro ketones as byproducts. For this reason, nonchlorinating ***Copper(I) Chloride*** is recommended as the reoxidizing agent. This is easily preoxidized to the Cu^{II} state with oxygen.[4] In a laboratory synthesis, a stoichiometric amount of ***1,4-Benzoquinone*** is conveniently used as the reoxidant.

The reaction is a unique method for the one-step synthesis of ketones from alkenes, and allows alkenes to be regarded as masked ketones which are stable to acids, bases, and nucleophiles. Particularly useful is the oxidation of terminal alkenes, which provides methyl ketones (eq 3).[5] As a typical application, the allylation of a ketone, followed by the oxidation, affords a 1,4-diketone. A cyclopentenone can then be prepared by an aldol condensation (eq 4).[5] The annulation method has widespread uses in the synthesis of natural products such as pentalenene,[6] muscone,[7] and coriolin.[8] 1,5-Diketones are prepared by 3-butenylation of a ketone followed by the oxidation. This process has been used to prepare cyclohexenones (eq 5).[5]

(3)

(4)

(5)

Simple internal alkenes are difficult to oxidize. However, the regioselective oxidation of internal alkenes takes place in the presence of suitably disposed oxygen functional groups by neighboring group participation. For example, α,β-unsaturated esters are oxidized to β-keto esters using Na_2PdCl_4 as catalyst and ***t-Butyl Hydroperoxide*** as the reoxidant (eq 6).[9] Allylic ethers are oxidized to β-alkoxy ketones which can be converted to α,β-unsaturated ketones for use in annulation reactions (eq 7).[10] Cyclohexene and cyclopentene can not be oxidized under the usual conditions, but are oxidized to cyclohexanone and cyclopentanone under different conditions. For example, chloride-free Pd^{II} salts, prepared from $Pd(OAc)_2$ and $HClO_4$, H_2SO_4, or HBF_4, are active catalysts (eq 8).[11] For additional examples of the Wacker process, see ***Palladium(II) Chloride-Copper(I) Chloride*** and ***Palladium(II) Chloride-Copper(II) Chloride***.

(6)

Reaction with Alcohols and Phenols.[2c]

The reaction of alcohols with terminal alkenes affords acetals of ketones (eq 9).[12] An elegant application of the reaction was a brevicomin synthesis (eq 10).[13]

Alkenes with an electron-withdrawing group such as styrene, ***Acrylonitrile***, and acrylate are converted to acetals of the aldehydes rather than the ketones. The reaction of styrene with ethylene glycol affords the cyclic acetal (eq 11).[12a] 3,3-Dimethoxypropionitrile is produced commercially using methyl nitrite as the reoxidant. The nitrite can be regenerated easily by the oxidation of NO with oxygen (eq 12).[14]

(11)

(12)

The intramolecular reaction of phenols or enols affords furans and pyrans (eq 13).[15]

(13)

Reaction with Carboxylic Acids.[2c]

The intramolecular reaction of carboxylic acids with alkenes affords unsaturated lactones (eq 14).[16]

(14)

Reaction with Amines and Amides.[2c]

Reaction of amines with alkenes proceeds most smoothly as an intramolecular version. Amides can be used in the intramolecular reaction to afford various heterocyclic compounds. In the example shown in eq 15, it should be noticed that the Pd^{II} species is regenerated by the β-elimination of OH, rather than the β-hydrogen. For this reason the reaction proceeds catalytically without a Pd^{0} reoxidant.[17]

Reaction with Carbon Nucleophiles.

The cyclooctadiene (cod) complex of $PdCl_2$, which is insoluble in organic solvents, reacts in ether with malonate or acetoacetate under mild heterogeneous conditions; facile carbon-carbon bond formation takes place to give a new complex in a quantitative yield. Further intramolecular reaction of the complex with a base affords the cyclopropane derivative. Attack of a second malonate on the complex yields the [3.3.0] system (eq 16).[18] Carbopalladation of the double bond of *N*-vinylcarbamate with acetoacetate at -78 °C, and subsequent carbonylation of the Pd-carbon bond, proceeds smoothly to yield the carbocarbonylation product in 92% yield (eq 17).[19]

π-Allypalladium Complex Formation.[20]

π-Allylpalladium complexes are prepared by the reaction of alkenes with $PdCl_2$ or its soluble forms under various conditions (eq 18).[21] These π-allylpalladium chloride complexes react with carbon nucleophiles in DMSO as a coordinating solvent to form carbon-carbon bonds.[22] Thus π-allylpalladium complexes are clearly different in chemical reactivity from other organometallic reagents, which normally react with electrophiles (eq 19).

Based on this reaction, allylic alkylation of alkenes is possible. Active methylene compounds, such as malonates and β-keto esters, can be introduced to a steroid skeleton by the reaction of the steroidal π-allylpalladium complex in DMSO (eq 20).[23] The reaction of carbon nucleophiles also proceeds in the presence of an excess of ***Triphenylphosphine*** (eq 21).[24]

(21)

ortho-Palladation of Aromatic Compounds and Cyclopalladation of Allyl and Homoallyl Compounds.[25]

Azobenzene,[26] *N*,*N*-dimethylbenzylamine,[27] and related aromatic compounds react with Na_2PdCl_4 in ethanol to form stable *ortho*-palladation complexes. These carbon-palladium σ-bonded complexes are useful for the preparation of *ortho*-substituted aromatic compounds by the facile insertion of alkenes, alkynes, and CO. For example, insertion of CO to the azobenzene complex affords 2-aryl-3-indazolone (eq 22),[28] and facile insertion of styrene to the benzylamine complex yields a stilbene derivative (eq 23).[1a,29]

(22)

The cyclopalladation of allylic or homoallylic amines and sulfides proceeds due to the chelating effect of N and S atoms, and has been used for functionalization of alkenes. For example, *i*-propyl 3-butenyl sulfide is carbopalladated with methyl cyclopentanecarboxylate and Li_2PdCl_4. Reduction of the chelated complex with ***Sodium Cyanoborohydride*** affords the alkylated keto ester in 96% yield (eq 24).[30] Functionalization of 3-*N*,*N*-dimethylaminocyclopentene for the synthesis of a prostaglandin skeleton has been carried out via a *N*-chelated palladium complex as an intermediate. In the first step, malonate was introduced regio- and stereoselectively by carbopalladation (eq 25).[31] Elimination of a β-hydrogen generated a new cyclopentene, and its oxypalladation with 2-chloroethanol, followed by insertion of 1-octen-3-one and β-elimination, afforded the final product.

(25)

Oxidative Carbonylation.[32]

Oxidative Carbonylation of Alkenes.

Oxidative carbonylation of alkenes with $PdCl_2$ in benzene affords β-chloroacyl chlorides (eq 26).[33] Oxidative carbonylation of alkenes in alcohol affords α,β-unsaturated esters and β-alkoxy esters by monocarbonylation and succinate derivatives by dicarbonylation (eq 27).[34]

(26)

Intramolecular oxycarbonylation and aminocarbonylation are also known. As an example, frenolicin has been synthesized using oxycarbonylation at 1.1 atm of CO as a key step (eq 28).[35] The intramolecular aminopalladation of a carbamate group and subsequent carbonylation of the substituted 3-hydroxy-4-pentenylamine proceeds smoothly in AcOH (eq 29).[36]

Oxidative Carbonylation of Alkynes.

Terminal alkynes are carbonylated to give acetylenecarboxylates using $PdCl_2$ and $CuCl_2$ as catalysts (eq 30).[37] The

acetylenecarboxylate in a β-lactam has been prepared by this procedure and then converted to a β-keto ester (eq 31).[38]

Oxidative dicarbonylation of acetylene with $Pd(PhCN)_2Cl_2$ in benzene affords the chlorides of maleic, fumaric, and muconic acids (eq 32).[39] Methyl muconate is obtained by passing acetylene and oxygen through MeOH containing thiourea and a catalytic amount of $PdCl_2$.[40] The oxidative dicarbonylation of alkynes produces maleate derivatives as a main product using $PdCl_2$ and $CuCl_2$ as catalysts under oxygen in alcohol.[41]

Oxidative Carbonylation of Alcohols.

Oxalates and carbonates are formed by the oxidative carbonylation of alcohols. The reaction can be made catalytic by using $PdCl_2$ and $CuCl_2$ under oxygen in the alcohol.[42] Either oxalate or carbonate is obtained chemoselectively under different conditions (eq 33). Alkyl oxalates are produced commercially using alkyl nitrites as reoxidants (eq 34).[43]

(33)

(34)

Reactions via Transmetallation of Organometallic Reagents.

Transmetalation of organometallic compounds of Hg, B, Sn, Si, Tl, etc., with $PdCl_2$ produces the reactive organopalladium species, which undergoes insertion and coupling reactions. Aryl- or alkenylpalladium complexes, generated in situ from aryl- or alkenylmercury compounds, undergo insertion reactions with alkenes;[44,45] an example is shown in eq 35.[46] The arylmercury compound with 1,3-cyclohexadiene and Li_2PdCl_4 generates a π-allylpalladium intermediate, which then attacks the amide group intramolecularly to yield the cyclized product (eq 35).[46] CO insertion produces ketones and esters.[47] The *ortho*-thallation of benzoic acid and subsequent transmetalation with Pd^{II} generates a reactive arylpalladium complex, which reacts with butadiene to give an isocoumarin (eq 36).[48]

(35)

α,β-Unsaturated esters are obtained by the carbonylation of alkenylboranes[49] and alkenyl- or arylpentafluorosilicates (eq 37).[50] Conjugated dienes and diaryls are formed by the coupling of alkenyl- and arylstannanes. The homocoupling of the vinylstannane of benzoquinone is catalyzed by $PdCl_2(PhCN)_2$ with benzoquinone as the reoxidant (eq 38).[51]

Miscellaneous Oxidation Reactions.

Some oxidative reactions can be carried out only with $Pd(OAc)_2$, but not with $PdCl_2$. However, $Pd(OAc)_2$ can be generated in situ by the reaction of $PdCl_2$ with AcOK or AcONa. The oxidative coupling of aromatic rings is a typical example of a $Pd(OAc)_2$-promoted reaction. The following coupling reaction proceeds by $Pd(OAc)_2$ generated in situ from $PdCl_2$ (eq 39).[52]

(39)

The following oxidative rearrangement of a propargylic ester proceeds with a catalytic amount of $PdBr_2$ under oxygen. Interestingly, the reoxidation of Pd^0 takes place with oxygen without addition of other reoxidants (eq 40).[53]

Catalytic Reactions with Pd^{II}.

Exchange Reactions of Vinyl Ethers and Esters.[54]

Vinyl ethers are activated by Pd^{II}. Exchange with other alcohols to give mixtures of acetals and vinyl ethers is catalyzed by $PdCl_2$ (eq 41).[55] This reaction was used as the key step in the total synthesis of rhizobitoxine (eq 42).[56]

(42)

The exchange reaction of the acid component of vinyl esters with other acids is catalyzed by $PdCl_2$ (eq 43).[54] Thus various vinyl esters are prepared from easily available ***Vinyl Acetate***. As an example, vinyl itaconate is prepared by the reaction of vinyl acetate with itaconic monomethyl ester (eq 44).[57] *N*-Vinyllactams and cyclic imides are prepared by the exchange reaction of lactams and imides with vinyl acetate (eq 45).[58]

(43)

(44)

(45)

Pd^{II}-Catalyzed Rearrangement Reactions.

Cope rearrangements are accelerated by catalytic amounts of $Pd(PhCN)_2Cl_2$, such that they proceed at room temperature in benzene or CH_2Cl_2 (eq 46).[59] Successful Pd^{II} catalysis appears to require that atoms 2 and 5 of the substituted 1,5-hexadienes have one H and one nonhydrogen substituent.[60] Oxy-Cope rearrangements proceed at room temperature

using $Pd(PhCN)_2Cl_2$ catalysis (eq 47).[61]

(46)

(47)

The $Pd(PhCN)_2Cl_2$ catalyzed Claisen rearrangement of allyl vinyl ethers has been studied to a lesser extent. The Claisen rearrangement shown in eq 48 proceeds smoothly even at room temperature to give the *syn* product with high diastereoselectivity.[62] The Claisen rearrangement of 2-(allylthio)pyrimidin-4-(3*H*)-one affords the *N*-1 allylation product as a main product rather than the *N*-3 allylation product (eq 49).[63]

(48)

(49)

The rearrangement of allylic esters, a useful reaction, is catalyzed efficiently by Pd^{II}.[64] The allylic rearrangement shown

in eq 50, used in a prostaglandin synthesis, proceeds in one direction irreversibly, yielding the thermodynamically more stable product possibly due to steric reasons.[65] The diacetate of a 1,5-diene-3,4-diol is isomerized to the more stable conjugated diene with complete transfer of chirality (eq 51).[66] The Pd^{II}-catalyzed allylic rearrangement has been explained by an oxypalladation or cyclization-induced rearrangement. It is mechanistically different from rearrangements catalyzed by Pd^0 complexes, which proceed by formation of π-allylpalladium intermediates.

Skeletal rearrangements of some strained compounds, such as bulvalene to bicyclo[4.2.2]deca-2,4,7,9-tetraene,[67] cubane to cuneane,[68] hexamethyl Dewar benzene to hexamethylbenzene (eq 52),[69] and quadricyclane to norbornadiene (eq 53),[70] are catalyzed by derivatives of $PdCl_2$.

(53)

Intramolecular Reactions of Alkynes with Carboxylic Acids, Alcohols, and Amines.

Addition of carboxylic acids, alcohols, and amines to alkynes via oxypalladation and aminopalladation proceeds with catalysis by Pd^{II} salts. Intramolecular additions are particularly facile.[71] Unsaturated γ-lactones are obtained by the treatment of 3-alkynoic acid and 4-alkynoic acid with $Pd(PhCN)_2Cl_2$ in THF in the presence of Et_3N (eq 54), and δ-lactones are obtained from 5-alkynoic acids.[72] 5-Hydroxyalkynes are converted to the cyclic enol ethers (eq 55).[71] The oxypalladation is a *trans* addition. Thus stereoselective enol ether formation by reaction of the alkynoic alcohol with $Pd(PhCN)_2Cl_2$, followed by reduction with ***Ammonium Formate***, has been applied to the synthesis of prostacyclin (eq 56).[73] Intramolecular addition of amines affords cyclic imines. 3-Alkynylamines are cyclized to 1-pyrrolines while 5-alkynylamines are converted to 2,3,4,5-tetrahydropyridines (eq 57).[74]

(54)

(55)

(56)

(57)

Simple alkynes cannot be hydrated with a palladium catalyst, but triple bonds are hydrated regioselectively to yield ketones with participation of suitably located carbonyl or hydroxy groups. 1,5-Diketones are prepared by the participation of a 5-keto group (eq 58).[75] 4-Hydroxyalkynes are converted to 4-hydroxy ketones and then oxidized to 1,4-diketones (eq 59).[71]

(58)

(59)

Cyclopentenone formation by the isomerization of 3-acetoxy-1,4-enynes is catalyzed by $Pd(PhCN)_2Cl_2$ (eq 60).[76]

(60)

Generation of Carbenes from Diazo Compounds.

Both $PdCl_2$ and $Pd(OAc)_2$ are used for carbene generation from azo compounds.[77] The cyclopentenone carboxylates have been prepared by intramolecular insertions of the carbenes generated from α-diazo-β-keto esters (eq 61).[78]

(61)

Generation of Pd^0 catalysts.

Pd^0 catalysts can be generated in situ from Pd^{II} in the presence or absence of phosphine ligands. ***Tetrakis(triphenylphosphine)palladium(0)*** is a commercially available Pd^0 complex used frequently as a catalyst, but it is air unstable. Therefore in situ generation of $Pd^0(Ph_3P)_n$ catalysts by the reduction of Pd^{II} in the presence of Ph_3P is convenient to use. In many cases the in situ reduction to Pd^0 takes place without addition of reducing agents. Alkenes, alcohols, CO, and phosphines, present in the reaction medium, behave as the reducing agent and react with Pd^{II} to give Pd^0. Generation of Pd^0 by reduction of $Pd(OAc)_2$ with phosphines has been reported.[79] Similarly, $PdCl_2$ and its derivatives have been converted to Pd^0 species with phosphines and bases.

$PdCl_2$ itself is used for the carbonylation of an aryl iodide in the presence of a base (eq 62).[80] More frequently, ***Bis(benzonitrile)dichloropalladium(II)*** is used for various Pd^0-catalyzed reactions. The coupling reaction of an acyl chloride with a disilane is catalyzed by Pd^0, generated from $Pd(PhCN)_2Cl_2$ and Ph_3P (eq 63).[81] The intermolecular coupling of a vinylenedistannane with two alkenyl iodides has been carried out using $Pd(PhCN)_2Cl_2$ without addition of Ph_3P in a total synthesis of rapamycin (eq 64).[82]

(63)

83%

Dichlorobis(triphenylphosphine)palladium is used for Pd^0-catalyzed reactions without adding a reducing agent. For example, the coupling of terminal alkynes with halides is carried out with $Pd(Ph_3P)_2Cl_2$ and ***Copper(I) Iodide*** in the presence of ***Triethylamine*** without addition of a reducing agent. Hexaethynylbenzene is prepared by the coupling of hexabromobenzene with trimethylsilylacetylene (eq 65).[83] Similarly, the carbonylation of cinnamyl acetate, to give

naphthyl acetate, is carried out in the presence of Et_3N (eq 66).[84]

(65)

(66)

In some cases, $Pd(Ph_3P)_2Cl_2$ is reduced to Pd^0 in situ with reducing agents such as metal hydrides, and used for Pd^0 catalyzed reactions. For example, $Pd(Ph_3P)_2Cl_2$ is reduced with ***Diisobutylaluminum Hydride*** and used for coupling reactions (eq 67).[85]

(67)

The carbonylation of alkenes in alcohols to give saturated esters proceeds smoothly with $PdCl_2$ or $Pd(Ph_3P)_2Cl_2$ as a catalyst (eq 68).[86] Alkynes are carbonylated efficiently to give α,β-unsaturated esters with the same catalyst in the

presence of ***Iodomethane*** (eq 69).[87] In some reactions the Pd^0 species generated from $PdCl_2$-Ph_3P and $Pd(OAc)_2$-Ph_3P show different reactivities. For example, in the carbonylation of ***1,3-Butadiene***, 3-pentenoate is obtained with $PdCl_2$-Ph_3P, while 3,8-nonadienoate is obtained with $Pd(OAc)_2$-Ph_3P. The presence of chloride anion in the coordination sphere of palladium gives different catalytic activity (eq 70).[88]

Palladium(II) Chloride-Copper(I) Chloride[1]

$PdCl_2$-CuCl

($PdCl_2$)

[7647-10-1] · Cl_2Pd · Palladium(II) Chloride-Copper(I) Chloride · (MW 177.31) (CuCl)

[7758-89-6] · ClCu · Palladium(II) Chloride-Copper(I) Chloride · (MW 99.00)

(oxidation of alkenes[2])

Physical Data: $PdCl_2$, mp 680 °C; CuCl, mp 430 °C.

Solubility: $PdCl_2$ sol water, acetone, alcohol; CuCl insol most solvents.

Form Supplied in: $PdCl_2$, red-brown crystals; CuCl white/pale green powder; both widely available.

Handling, Storage, and Precautions: CuCl is oxygen, moisture, and light sensitive and should be stored in the dark under an inert atmosphere.

Oxidation of Alkenes to Ketones and Aldehydes.

The combination of ***Palladium(II) Chloride*** and ***Copper(I) Chloride*** to oxidize alkenes to ketones and aldehydes is a variant of the well-known Wacker reaction, first used to make acetaldehyde from ethylene.[3] The catalytic reaction comprises three individual steps (eq 1).

$$\begin{array}{l} PdCl_2 + H_2O + CH_2{=}CH_2 \longrightarrow Pd^0 + 2\,HCl + MeCHO \\ Pd^0 + 2\,CuCl_2 \longrightarrow PdCl_2 + 2\,CuCl \\ 2\,CuCl + 0.5\,O_2 + 2\,HCl \longrightarrow 2\,CuCl_2 + H_2O \\ \hline 0.5\,O_2 + CH_2{=}CH_2 \longrightarrow MeCHO \end{array} \qquad (1)$$

The first step is the Pd^{II}-induced oxidation of the alkene to give aldehyde/ketone and Pd^0. The reduced palladium is reoxidized by ***Copper(II) Chloride*** which in turn is reduced to CuCl. Finally, CuCl is oxidized by O_2 in the presence of HCl to regenerate $CuCl_2$. A variety of other oxidants have been used to reoxidize the palladium, including $CuCl/O_2$ (discussed herein), benzoquinone, $FeCl_3$, H_2O_2, *t*-BuOOH, and heteropoly acids (reactions using $CuCl_2$ or other Pd salts will be referenced occasionally in this article, given the similarity of various systems). $CuCl_2$ is problematic because it produces chlorinated byproducts or otherwise lowers the yields. For this reason, CuCl in combination with O_2 is favored.[4]

The solvent of the original Wacker reaction is water, which causes solubility problems and correspondingly lower rates with higher alkenes. This has been partially resolved by adding surfactants, both ionic and non-ionic,[5] or by using solvents that dissolve both water and the organic substrate to a certain extent such as DMF.[6] Alcohols, however, give acetals. Another problem is double bond isomerization, which is particularly severe in alcohols or acetic acid, but minor in DMF. For these reasons, DMF has become the solvent of choice for the oxidation of alkenes with $PdCl_2/CuCl$.

Terminal alkenes are more reactive than disubstituted alkenes (eq 2),[7] and are generally oxidized with good selectivity to methyl ketones. Aldehydes can also be formed in certain cases as discussed below. Indeed, terminal alkenes, which are easy to synthesize and relatively inert under a variety of conditions, may be considered masked methyl ketones because they are readily oxidized by the existing procedures.[8] They can generally be oxidized selectively in the presence of various functional groups such as internal alkenes, alcohols, ketones, aldehydes, carboxylic acids and esters, ethers, acetals, chlorides, bromides, and sulfones among others, although cyclization reactions can sometimes occur. Alcohols can be oxidized if the reaction conditions become severe, and acetals are somewhat prone to hydrolysis due to the acidic nature of the reaction. Amine-containing substrates can be oxidized provided that the amine is protonated by acid.[9]

(2)

The reagents can distinguish among several terminal alkenes, with the least sterically hindered being more readily oxidized. For instance, in eq 3 the least hindered double bond required 3 h whereas the more hindered double bond required 36 h (71% overall yield).[2] There are numerous applications of this procedure in natural product synthesis,[10] with some of the more important being the preparation of 1,4-dicarbonyl compounds, cyclopentenones (eq 4), 1,5-dicarbonyl compounds, cyclohexenones (eq 5),[11] and steroids.

(3)

(4)

(5)

Aldehydes can sometimes be obtained instead of methyl ketones, if the alkene is conjugated with an electron withdrawing group or if certain remote functionalities are present.[12] The reaction conditions can also influence the ketone/aldehyde selectivity. For instance, the use of *t*-BuOH as solvent,[13] or anhydrous 1,2-dichloroethane and HMPA,[14] can significantly enhance the selectivity toward aldehyde formation.

Alkenes conjugated to carbonyl groups are poorly oxidized by $PdCl_2$/CuCl and better results are obtained with peroxide reoxidants.[15] Benzofurans can be hydrolytically and oxidatively cleaved.[16] Internal alkenes are oxidized much more slowly than terminal alkenes,[17] and are only poorly oxidized with the $PdCl_2$ system unless certain functionality is present. For instance β,γ-unsaturated esters or ketones can be oxidized to the respective ketones in 45-61% yield provided that the reaction is done in aqueous dioxane or THF (π-allyl Pd compounds are formed in DMF).[18] In all cases, only the 1,4-dicarbonyl products were obtained (eq 6).

(6)

Similarly, allylic and homoallylic ethers and esters are regioselectively oxidized at the carbon more remote from the functional group (eq 7).[19]

(7)

Oxidation of Alkenes to Acetals.[20]

In alcohol solvents, acetals can be obtained from alkenes, but since an equivalent amount of water is generated under catalytic conditions, often the ketone is ultimately obtained.[21] The yield of acetal is increased by using diol solvents. Electron withdrawing groups conjugated to a terminal double bond[22] or the presence of certain remote functionalities[23] favor oxidation at the terminal carbon. α,β-Unsaturated ketones require the use of Na_2HPO_4 to prevent simple Michael addition of the diol.[22b] The presence of a chiral auxiliary can lead to diastereomeric excesses as high as 95% (eq 8).[24]

(8)

Cyclization.

Intramolecular oxidative addition of an O-H or N-H bond to an alkene is a useful way to make heterocycles and can be accomplished with a number of Pd catalysts.[20a,25] Specific examples with $PdCl_2$/CuCl (or $CuCl_2$) are given here. Diol alkenes can be cyclized to bicyclic acetals such as brevicomin;[26] intramolecular optical induction can be observed, as in a similar synthesis of frontalin (eq 9).[27]

(9)

Aromatic heterocycles such as indoles can be synthesized by cyclizing β-amino alkenes and their toluenesulfonamide derivatives using Pd^{II} catalysts.[28] Acetanilide derivatives, which cyclize poorly with other Pd catalysts,[29] cyclize especially well with $PdCl_2/CuCl/O_2$ in 1,3-propanediol (eq 10).[30] Styryl amides cyclize well under similar conditions (eq 11).[31] Aliphatic amino alkenes, whose basicity interferes with catalytic cyclization, can be cyclized well in the presence of acid.[32]

(10)

Palladium(II) Chloride-Copper(II) Chloride[1]

$PdCl_2$-$CuCl_2$

($PdCl_2$)

[7647-10-1] · Cl_2Pd · Palladium(II) Chloride-Copper(II) Chloride · (MW 177.32) ($CuCl_2$)

[7447-39-4] · Cl_2Cu · Palladium(II) Chloride-Copper(II) Chloride · (MW 134.45)

(oxidation and carbonylation of alkenes; carbonylation of amines, alcohols)

Physical Data: $PdCl_2$, mp 680 °C; $CuCl_2$, mp 630 °C (dec).

Solubility: $PdCl_2$ sol water, acetone, alcohol; $CuCl_2$ sol water, acetone, alcohol.

Form Supplied in: $PdCl_2$, red-brown crystals; $CuCl_2$, yellow/brown powder; both widely available.

Handling, Storage, and Precautions: $CuCl_2$ is deliquescent and forms the green-blue dihydrate on exposure to moist air.

Oxidation of Alkenes to Ketones, Aldehydes, and Acetals.[2]

Palladium(II) Chloride combined with ***Copper(II) Chloride*** is the catalyst for the Wacker reaction, which was originally used to oxidize ethylene to acetaldehyde.[3] Subsequent work broadened the application to a variety of alkenes. Typically, terminal alkenes yield only methyl ketones.[4] In the presence of alcohols, acetals are obtained.[5] Cyclization reactions can occur with hydroxyalkenes.[6] In general, these reactions can be accomplished more selectively with ***Palladium(II) Chloride-Copper(I) Chloride***.

Hydrocarboxylation/Hydroesterification of Alkenes.

$PdCl_2$/$CuCl_2$ is a useful reagent for hydrocarboxylating alkenes to carboxylic acids (eq 1).[7] The reaction proceeds in good yield and is highly regioselective, favoring the branched carboxylic acid over the linear isomer. Hydroesterification to give the analogous ester occurs equally well, again with the branched isomer predominating (eq 2).[8] With a diol as the alcohol, only the monoester is obtained.[9]

(1)

(2)

Internal alkynes are hydroesterified to (*E*)-unsaturated monoesters resulting from *cis* addition (eq 3).[10] However, terminal alkynes are oxidatively carbonylated to give predominantly the (*Z*)-unsaturated diesters (eq 4). Under similar conditions in the presence of base, terminal alkynes can also be non-oxidatively carbonylated to the acetylenecarboxylate ester.[11]

(3)

(4)

Hydroxyalkenes will cyclize under similar conditions to give the five- or six-membered ring saturated lactone (eq 5).[12] Chiral additives, especially poly-L-leucine, afford the cyclized lactone with as high as 61% ee.[13]

(5)

Oxidative Carbonylation of Alkenes.

In contrast to hydroesterification, oxidative carbonylation (or alkoxycarbonylation) is an oxidation that converts alkenes to vinyl esters, α-alkoxy esters, or diesters depending on the reaction conditions.[14] Typically, $CuCl_2$ is used as a stoichiometric oxidant, because in the presence of oxygen and water (which would be coproduced in the presence of oxygen) the CO can be oxidized to CO_2 and the alkene can be oxidized to the ketone or aldehyde. Linear, terminal alkenes are oxidized to either the alkoxy ester or to the diester, depending on whether base (NaOAc) is present or not (eq 6).[15] The alkoxyester arises from *trans* addition whereas the diester arises from a *cis* addition. The choice of re-oxidant can also control the reaction pathway: $CuCl_2/O_2$ favors the branched alkoxy monoester, whereas $CuCl/O_2$ favors the diester.[16] Oxidative carbonylation can also occur using acetic anhydride solvent with NaCl.[17] Cyclic alkenes give both the *cis*-1,2- and *cis*-1,3-diesters along with a variable amount of *trans*-2-methoxy ester.[15] Allenes are oxidatively carbonylated to the α-alkoxy ester.[18] Butadiene can be dicarbonylated to linear hexenedioate diesters in high yields.[15e] Terminal alkynes are dicarbonylated to maleic anhydride derivatives.[19]

(6)

Cyclization can occur with hydroxyalkenes to give pyran or furan carboxylates;[20] allenes are similarly cyclized.[21] The carbon-oxygen bond tends to form at the more substituted end of the double bond; the geometry of the alkene can also determine the ring size (eq 7).[20] Aminoalkenes cyclize similarly, especially if protected as the carbamates, tosylamides, or ureas.[22] The latter can use both nitrogen atoms to form bicyclic molecules (eq 8).

(7)

(8)

Bis-carbonylation occurs with homoallylic alcohols (eq 9).[23] The use of CuCl appears to mitigate the need for additives such as epoxides or orthoesters in these reactions.[18] Dihydroxy alkenes can form bicyclic ether-lactones (eq 10).[24] A similar reaction occurs with a carboxylic acid group at the terminus.[25]

(9)

(10)

Oxidative Carbonylation of Heteroatoms.

Amines and alcohols can be oxidatively carbonylated to the carbamate and carbonate esters in alcohol solvents.[26]

Palladium(II) Chloride-Silver(I) Acetate

$PdCl_2$-AgOAc

($PdCl_2$)

[7647-10-1] · Cl_2Pd · Palladium(II) Chloride-Silver(I) Acetate · (MW 177.32) (AgOAc)

[563-63-3] · $C_2H_3AgO_2$ · Palladium(II) Chloride-Silver(I) Acetate · (MW 166.92)

(catalyst system used for the allylic oxidation of alkenes and for altering the regioselectivity of intermolecular Heck reactions of allylic alcohols)

Physical Data: see ***Palladium(II) Chloride*** and ***Silver(I) Acetate***.

Allylic Oxidation.

Treatment of alkenes with palladium chloride (5 mol %), silver acetate (10 mol %), tellurium oxide (5 mol %), and ***t-Butyl Hydroperoxide*** (50 mol %) in acetic acid affords allylic oxidation products.[1] This procedure is especially useful for cyclic alkenes which fail to react with the ***Selenium(IV) Oxide-t-Butyl Hydroperoxide*** system for allylic oxidations (eq 1).

(1)

Two mechanisms appear to be operative depending on substrate structure. The reaction may proceed via either π-allyl palladium complexes[2,3] (best explains compound (**1**), eq 2) or via acetoxypalladation followed by dehydropalladation[4] (best explains compound (**2**), eq 3). The extent of regiocontrol is highly substrate dependent (eqs 2 and 3).

(2)

(3)

Intermolecular Heck Reactions.

Closely related to the palladium chloride/silver acetate catalyst system is the use of ***Palladium(II) Acetate***/silver acetate in Heck reactions of aryl and vinyl halides. Silver carbonate is usually equally effective in this process (eqs 4 and 5). The use of silver acetate completely reverses the regioselectivity of β-hydride elimination in Heck reactions of allyl alcohols (eq 4).[5,6]

(4)

The stereochemistry of chiral allylic alcohols is maintained in the silver acetate promoted process (eq 5), indicating that reversible β-hydride elimination to the enol does not occur.[7]

Related Reagents.

Palladium(II) Acetate; ***Silver(I) Carbonate***; ***Silver(I) Phosphate***.

Palladium-Graphite

Pd-Gr

[59873-73-3] · Pd · Palladium-Graphite · (MW 106.42)

(hydrogenation catalyst for aromatic nitro compounds, alkenes, and alkynes;[1] catalyzes arylation and vinylation of activated double bonds[2,3])

Physical Data: 31-33% Pd by weight.

Form Supplied in: not commercially available.

Preparative Method: by reduction of ***Palladium(II) Chloride*** by ***Potassium-Graphite*** in 1,2-dimethoxyethane at 100 °C.[1]

Handling, Storage, and Precautions: no special handling or storage necessary; the catalyst is stable in air and can be stored for a long time without loss of activity.

Hydrogenation Catalyst.

Palladium-graphite is an effective catalyst for hydrogenation of aromatic nitro compounds to anilines (eq 1) and alkenes to alkanes (eq 2).[1] The results of these investigations indicated that palladium-graphite is an alternative to the more commonly used ***Palladium on Carbon*** catalyst.

(1)

(2)

The catalyst has also been found to be effective in the stereospecific semihydrogenation of mono- and disubstituted alkynes to (*Z*)-alkenes (eqs 3 and 4).[1] Addition of ***1,2-Diaminoethane*** (EDA) is required for this stereospecificity to be achieved. Full hydrogenation is almost completely suppressed and results are comparable to those obtained by Lindlar or P-2 nickel catalysts. In fact, higher specificity is achieved with palladium-graphite compared to palladium on carbon in the presence of ethylenediamine although the rate of hydrogenation is slower.

(3)

(4)

Arylation and Vinylation of Activated Double Bonds.

Palladium-graphite undergoes oxidative addition into the carbon-halogen bond of aryl and vinyl iodides, which, after reductive elimination, yield the corresponding arylated or allylated compounds.[2] Aryl bromides should not be used as they are not as reactive under these reaction conditions. By using a stoichiometric amount of a tertiary amine to trap the HI, the reaction can be carried out with a catalytic amount of palladium. When monosubstituted alkenes are used, high stereospecificity is achieved, thereby affording substituted (*E*)-alkenes (eqs 5 and 6). The yields are comparable with those reported using other palladium catalysts such as ***Palladium(II) Acetate***.

(5)

(6)

Substitution reactions of allylic esters are also catalyzed by palladium-graphite.[3] The reaction between allyl acetate and ***Sodium Benzenesulfinate*** in the presence of catalytic amounts of Pd-Gr and ***Triphenylphosphine*** afforded the allyl phenyl sulfone in quantitative yield (eq 7). In fact, the catalyst can be recovered and after ten runs the yield was 93%, showing that the catalyst retains its activity.

Palladium(II) Hydroxide on Carbon

$Pd(OH)_2$

[7440-05-3] · H_2O_2Pd · Palladium(II) Hydroxide · (MW 140.44)

(catalyst for hydrogenolysis of benzyl groups and epoxides; used to reduce nitro compounds to amines and as dehydrogenation reagent)

Alternate Name: Pearlman catalyst.

Solubility: insol all organic solvents.

Form Supplied in: black powder, typically containing 20 wt % of Pd and 10-15 wt % of H_2O.

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: can be stored safely in a closed container under air but away from solvents and potential poisons such as sulfur- and phosphorus-containing compounds. The reagent is pyrophoric in the presence of solvents. General precautions for handling hydrogenation catalysts should be followed. The catalyst must be suspended in the organic solvent under an atmosphere of N_2. During filtration the filter cake must not be allowed to go dry. If a filter aid is necessary, a cellulose-based material should be used if catalyst recovery is desired.

Hydrogenolysis and Hydrogenation.

Palladium hydroxide on carbon has been used for difficult debenzylations when other supported palladium catalysts were not effective or satisfactory.[1] For example, although *para*- and *meta*-substituted benzyl alcohols were easily hydrogenolyzed with 10% ***Palladium on Carbon***, hydrogenolysis of the *ortho*-substituted substrate was only effective with 20% $Pd(OH)_2/C$ (eq 1).[2] This catalyst also catalyzes hydrogenation and hydrogenolysis of other functional groups.

(1)

The transfer hydrogenolysis of a benzyl ether proceeded in high yield without the hydrogenolysis of the chlorine or the hydrogenation of the alkene (eq 2).[3] Evidence showed that an oxidative mechanism, rather than the usual reductive mechanism, might be involved in this case.

(2)

Deprotection of a benzyl carbamate and concomitant reduction of a double bond with the Pearlman catalyst has provided an amino acid in 82% yield (eq 3).[4]

Debenzylations of *N*-benzylated imidazole derivatives are very difficult, but in the case of the imidazole derivative in eq 4, hydrogenolysis proceeded to give 84% yield of the desired product. The N-N bond was not cleaved under the reaction conditions, but the formyl group was hydrogenolyzed (eq 4).[5]

An *N*-protected azete hydrochloride was deprotected in EtOH to provide the azete hydrochloride in 86% yield. The azete ring was stable under the reaction conditions. This intermediate was converted to δ-coniceine in four steps (eq 5).[6]

Excellent regioselective opening of an epoxide has been accomplished with the Pearlman catalyst. The epoxide opening with ***Lithium Aluminum Hydride*** (LAH) gave no selectivity and a 50/50 mixture of the triol isomers was obtained. Hydrogenolysis with the Pearlman catalyst gave 99% selectivity. An equivalent weight of catalyst vs. substrate must be used to obtain the excellent 92% yield (eq 6).[7]

Deuterium studies showed that the ring opening proceeded with inversion of configuration at C-3 to give the deuterated product (**1**). This is a common observation with Pd catalysts.

(1)

The reduction of a variety of azides to amines was carried out under transfer hydrogenation conditions with hydrazine and Pearlman catalyst in refluxing MeOH. The yields ranged from 71 to 90%.[8]

An *o*-substituted dinitrostyrene has been reduced in THF/HOAc at 150 psi H_2 and 50 °C to provide an indole in 75% yield. Interestingly, when the H_2 pressure was lowered to atmospheric pressure, the reaction proceeded only to 30% conversion to give an unidentified intermediate (eq 7).[9]

(7)

Dehydrogenation.

The reagent has also been used as a dehydrogenation catalyst. The ketone shown in eq 8 was converted to the enone in 79% yield. *trans*-4-Phenyl-3-buten-2-one was obtained in 50% conversion in toluene from 4-phenylbutan-2-one, but no dehydrogenation was observed with propiophenone, indanone, α-tetralone, or cyclohexanone.[10]

Palladium(II) Nitrate

$Pd(NO_3)_2$

[10102-05-3] · N_2O_6Pd · Palladium(II) Nitrate · (MW 230.44)

(catalyst for alkene nitration to glycol dinitrates[1])

Physical Data: no mp (dec).

Solubility: sol nitric acid; sol w/dec. water.

Form Supplied in: brown, deliquescent crystals; probably exists as the dihydrate;[2] commercially available.

Handling, Storage, and Precautions: store under anhydrous conditions, protected from light.

Palladium(II) nitrate is a useful stoichiometric reagent for the nitration of alkenes to glycol dinitrates.[3] The reaction can be made catalytic in the presence of nitric acid and nitrite ion, the latter being necessary to reoxidize the metallic Pd that is formed (eq 1).[1] Alternatively, oxygen can be used to reoxidize the NO_2 coproduct back to nitric acid and water (eq 2). This reaction is most useful for the production of ethylene glycol dinitrate, which is formed in up to 88% selectivity in a 1:1 mixture of dioxane and ***Nitric Acid***. With higher α-alkenes the NO_2 coproduct adds to the alkene at rates that are competitive with oxidation, even in the presence of oxygen, so that the selectivity for dinitrate is reduced to the 40-60% range.

Palladium nitrate can often be substituted for other palladium salts in catalyst mixtures, but the catalyst performance varies with the particular salt chosen. For instance, although $Pd(NO_3)_2$ can be used in Wacker-like oxidation reactions,[4] ***Palladium(II) Chloride*** or related salts often give better results.[5] However, $Pd(NO_3)_2$ is often preferred in

industrial oxidation processes, such as the oxidative coupling of ***Carbon Monoxide*** to give oxalic acid esters (eq 3).[6]

Another example where $Pd(NO_3)_2$ appears to work better than other Pd salts is in the stoichiometric carboxylation of aromatic compounds to give aryl carboxylic acids (eq 4).[7]

Palladium(II) nitrate can also be used in place of other palladium salts as a precursor to palladium catalysts formed in situ, such as Pd^{II} or Pd^{0} phosphine complexes. One example where only $Pd(NO_3)_2$ works well is in the ***Triphenylphosphine***-promoted dimerization of ***1,3-Butadiene*** with Schiff bases to give divinylpiperidines (eq 5).[8]

Palladium(II) nitrate is also commonly used as a precursor to supported Pd catalysts.[9]

Palladium on Poly(ethylenimine)

Pd/PEI

[7440-05-3] · Pd · Palladium on Poly(ethylenimine) · (MW 106.42)

(catalyst used for the reduction of alkynes to *cis*- or *trans*-alkenes;[1] hydrogenolysis of benzyloxycarbonyl protecting groups on peptides[2])

Solubility: sol many organic solvents except when deposited on a support such as silica gel; insol water and alcohols.

Form Supplied in: commercially available as deposit on a porous silica support.

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: nonpyrophoric and air stable.

Preparation and Properties.

The deposition of Pd on a minimally cross-linked poly(ethyleneimine) polymer has produced a new type of catalyst that features interesting characteristics.[1] The catalyst is very active and also readily recyclable without loss of activity. Unlike Pd on other solid supports, this polymer is soluble in different solvent media and necessitates membrane separation technology for its removal after the desired synthetic conversion is completed. The catalyst is not soluble in water and alcoholic solvents and can be removed by filtration at the end of the reaction.

Hydrogenations.

The catalyst mediates the reduction of 2-pentyne at 20 °C and 0.1 mPa H_2 pressure in 40 min to give *cis*-2-pentene with 98% stereoselectivity. The stereoselectivity and catalyst turnover were cited to be superior to the Lindlar catalyst (***Palladium on Calcium Carbonate (Lead Poisoned)***). By binding benzonitrile to the Pd on the support, a dramatic change in the reduction of 2-pentyne occurred. The

result was the formation of *trans*-2-pentene selectively.[2] The versatility of this catalyst in providing either *cis*- or *trans*-alkenes selectively from alkynes has never been demonstrated by any other heterogeneous catalyst. With formic acid as the hydrogen source, transfer hydrogenolysis of the benzyloxycarbonyl (Cbz) protecting group on polypeptides was readily carried out in a mixture of MeOH and H_2O at rt.[1a] The catalyst used in this case was highly cross linked and was insoluble in the MeOH/H_2O solvent mixture, and removal of the catalyst by a simple filtration was possible.

(transfer hydrogenation system used with a variety of palladium catalysts for hydrogenation and hydrogenolysis reactions; hydrogenation of alkynes, alkenes, nitro compounds; hydrogenolysis of *N*-benzyl and *O*-benzyl groups; hydrogenolysis of allyic esters and allylic carbonates)

Alternate Name: triethylammonium formate (TEAF).

Physical Data: see ***Palladium on Carbon***, ***Triethylamine***, and ***Formic Acid***.

Solubility: heterogeneous catalyst system.

Hydrogenation and Hydrogenolysis.

Triethylammonium formate, prepared most frequently in situ from triethylamine and formic acid, has been used in conjunction with both heterogeneous and homogeneous palladium catalysts for a variety of chemical transformations. With heterogeneous palladium catalysts, such as palladium on charcoal, both hydrogenation and hydrogenolysis are observed. When used in combination with homogeneous catalysts, hydrogenolysis is mainly observed. Many of these reactions can also be carried out by replacing triethylammonium formate with ***Ammonium Formate*** or hydrogen. The use of a hydrogen transfer agent, such as triethylammonium formate, enables the use of ordinary laboratory glassware and no special hydrogenation equipment is required.

The following reactions have been carried out with heterogeneous palladium catalysts. The reduction of alkynes and conjugated enynes with Pd/C or Pd/$CaCO_3$ catalyst was not stereoselective and gave mixtures of (*E*)- and (*Z*)-dienyl esters along with substantial amounts of over-reduced byproducts. The yields of the dienyl esters ranged from 59 to 84%.[1] A combination of triethylammonium formate and Pd/C was used to reduce alkynes to alkenes or alkanes. Reduction of 3-hexyne was not selective, giving a mixture of 3-hexenes (70%) and hexanes (18%). Diphenylacetylene, on the other hand, gave *cis*-stilbene (93%) with only 2% of bibenzyl. Selective reduction of the double bond in α,β-unsaturated carbonyl compounds, such as citral (91%), crotonaldehyde (81%), 2-cyclopentenone

(83%), methyl crotonate (83%), and methyl cinnamate (86%), provided good yields of the carbonyl compounds.[2]

The facile reduction of aromatic nitro compounds to anilines has been reported and oxindole and benzolactam can be formed directly from *o*-nitrophenylacetic acid and *o*-nitrocinnamic acid, respectively, in 72-75% yields.[3] Some selectivity was observed in the reduction of one nitro group in dinitro aromatic compounds. The best results were observed with 2,4-dinitrotoluene, in which 2-nitro-4-aminotoluene was obtained in 92% yield. The yields of other dinitro compounds ranged from 24 to 77%.[4]

Hydrogenolyses of aryl benzyl ethers and allylic acetates or amines have been reported to give phenols and alkenes, respectively.[5] Hydrogenolysis of aryl halides with triethylammonium formate in the presence of heterogeneous catalysts is another useful synthetic method. Some interesting selectivity was observed when the heterogeneous catalysts were replaced with homogeneous catalysts. For example, reduction of 1-nitro-3-bromobenzene in the presence of 5% Pd/C gave a mixture of nitrobenzene (46%) and aniline (15%). Replacement of the 5% Pd/C with ***Palladium(II) Acetate*** and 2 equiv of tri-*o*-tolylphosphine gave nitrobenzene (81%) and only 2% of aniline. Similarly, the yield of benzonitrile from 4-bromobenzonitrile was improved from 53 to 83% with the homogeneous catalyst.[3]

The homogeneous catalytic system, on the other hand, is also able to deoxygenate phenols via their aryl sulfonates (eq 1).[6] By varying the phosphine ligands, the phenol starting materials could be regenerated and thus the sulfonyl group only acts as a protecting group (eq 2). Similarly, aryl triflates are also hydrogenolyzed in excellent yields (eq 3).[7] Selective hydrogenolysis of the triflates was realized in the presence of alkenes.

(1)

(2)

(3)

Allyl esters (eq 4) and carbonates (eq 5) are converted to alkenes under the homogeneous catalysis reaction conditions.[8] The least substituted alkene is formed preferentially.

(4)

(5)

The Pd-catalyzed Carroll rearrangement of allyl β-ketocarboxylates to give α-allyl ketones was realized in THF (eq 6).[9]

(6)

Switching the solvent to MeCN provided α,β-unsaturated ketones instead (eq 7).[10]

(7)

Allyl β-keto esters can also be hydrogenolyzed to form ketones without allylation (eq 8).[11]

Palladium(II) Trifluoroacetate

$(CF_3CO_2)_2Pd$

[42196-31-6] · $C_4F_6O_4Pd$ · Palladium(II) Trifluoroacetate · (MW 332.46)

(palladium catalyst used in the oxidation of alkenes[3-5] and C-C bond formation[6-8])

Physical Data: mp 210 °C (dec).

Solubility: sol diethyl ether, acetone; insol benzene, chloroform, trifluoroacetic acid.

Form Supplied in: brown powder; commercially available.

Analysis of Reagent Purity: IR: ν 1690, 1435 cm^{-1}.

Preparative Methods: by reaction of ***Palladium(II) Acetate*** with excess ***Trifluoroacetic Acid*** on a steam bath, to yield a brown powder after drying in vacuo.[1] The reagent is also prepared in 89% yield by reaction of ***Palladium(II) Chloride*** with aqueous hydrochloric acid, then 15% sodium hydroxide solution at 85 °C, followed by excess trifluoroacetic acid at 80 °C.[2]

Handling, Storage, and Precautions: stable solid; irritant and hygroscopic.

Oxidation of Alkenes.

Photolysis of oxygenated acetone solutions of allylsilanes with an arylsulfonyl group at the allylic position in the presence of the title reagent (**1**) affords α,β-enals and α,β-enones (eq 1).[3] Palladium(II) trifluoroacetate also catalyzes the oxidation of styrene to acetophenone in the presence of an oxygen atom donor such as a molozonide (**2**) (eq 2).[4]

(1)

(2)

(2)

Allylic Acetoxylations.

The terminal allylic methyl group of geranylacetone is selectively oxidized with a catalytic amount of (**1**), ***1,4-Benzoquinone*** as oxidant, *o*-methoxyacetophenone as added ligand, and acetic acid as solvent (eq 3).[5]

(3)

1.94:1.0

Alkylidenecyclopentenedione Synthesis.

The 4-alkynyl-4-hydroxycyclobutenone ring system rearranges with ring expansion to alkylidenecyclopentenediones in the presence of (**1**) (eq 4).[6] A similar selective ring expansion has provided 2-alkylideneindene-1,3-dione monoacetals (eq 5).[6] In both cases the nonvinylic C-C bond migrates more rapidly.

(4)

(5)

$(Z):(E) = 36:1$

Tetraene Carbocyclizations.

Cyclization of a tetraene employing a catalytic amount of (**1**) with ***Triphenylphosphine*** as an additive in THF afforded a 73% yield of the cyclized and intramolecularly trapped diene (eq 6).[7]

(6)

π-Allyl Palladium Complex.

The dimethyl ester of *N*-(ethoxycarbonyl)kainic acid forms a π-allyl palladium complex upon treatment with (**1**)

followed by conversion to the more stable chloride complex.[2] This π-allyl complex reacts with the anion of *t*-butyl acetoacetate to afford the alkylated product (eq 7).[8]

Related Reagents.

Palladium(II) Acetate is similar to palladium(II) trifluoroacetate. Comparable results are obtained in most of the reactions, except acetate is a better nucleophile than trifluoroacetate.

(*R*)-Pantolactone[1]

[599-04-2] · $C_6H_{10}O$ · (*R*)-Pantolactone · (MW 130.16)

(effective chiral auxiliary in diastereoselective Diels-Alder reactions,[1] and for diastereoselective addition to ketenes;[2] used as a chiral pool reagent; also used as a covalently bound resolving agent[3])

Alternate Name: (*R*)-dihydro-3-hydroxy-4,4-dimethyl-2(3*H*)-furanone.

Physical Data: mp 92 °C; bp 120-122 °C/15 mmHg; [α]25D -50.7° (*c* 2.05, H_2O).

Solubility: sol water, alcohols, benzene, ether, chlorocarbons, THF.

Form Supplied in: crystalline white solid; commercially available.

Handling, Storage, and Precautions: hygroscopic.

Availability.

Although commercially available via the degradation of pantothenic acid, (*R*)-pantolactone is also conveniently prepared by enantioselective reduction of its corresponding keto lactone employing homogeneous catalysis,[4a-g] or by microbial methods.[5] The (*S*)-enantiomer has been prepared by inversion of the natural product in 90% yield and 97% ee via triflate activation, acetate displacement, and ***Lithium Hydroxide*** hydrolysis.[6] The enantiomers were also prepared by resolution of the racemate with (*R*)- and (*S*)-phenethylamine.[7] A gas chromatographic method exists for ee determination.[8]

Diels-Alder Reactions.

(*R*)-Pantolactone is one of the most effective chiral auxiliaries for preparative scale Diels-Alder additions of simple enoate esters in the presence of Lewis acids (eq 1).[9]

Endo-exo selectivity typically ranges from 20:1 to 45:1 with a maximum of 97.5:2.5 diastereoselection. Preparatively convenient reaction conditions are employed (CH_2Cl_2, CH_2Cl_2/cyclohexane; temp. approx. 0 °C; ca. 0.3 M concentration; and 0.1-1.0 molar equiv of Lewis acid). Products are typically crystalline and brought to high optical purity by recrystallization. Epimerization-free hydrolysis is effected with LiOH in THF/water. This procedure has been successfully applied in a nine-step synthesis of cyclosarkomycin in 17% overall yield (eq 2),[10] and to syntheses of the sandalwood fragrances.[11]

(R)-Pantolactone

+ *exo* isomers (2)

98:2

78%, >99% ee

Cyclosarkomycin
17% overall yield

The cyclohexane unit of the C(30) stereocenter of the C(18)-C(35) segment of FK-506 was established in excellent yield and de employing the same concept (eq 3).[6]

(R)-Pantolactone

(3)

(*E*)-2-Cyanocinnamates have been similarly used as dienophiles. An *endo-exo* selectivity of 85:15 at a diastereoselectivity of 99:1 was obtained (eqs 4 and 5).[12,13]

(4)

(5)

Further variations in dienophile have been equally successful (eqs 6 and 7),[14] including applications to the Michael

reaction (eq 7)[15] and in the synthesis of a prostaglandin intermediate (eq 8).[16]

(6)

(7)

98:2 de

Corey lactone (8)

Ketene Additions.

Reaction of the ketene derived from ibuprofen (Ar = *p*-isobutylphenyl) with (*R*)-pantolactone in the presence of simple tertiary amine bases in apolar solvents yielded a >99% de favoring the (*R*,*R*)-ester (eq 9).[3] The reaction is first order in each component and possesses a pronounced deuterium isotope effect (k_H/k_D &AApprox; 4). The ketene from naproxen (Ar = 2-(6-methoxynaphthyl)) affords a de of 80% under similar conditions.

(9)

Extension of this work to a series of bromo- and iodoketenes proceeds with good to excellent de (eq 10).[17] Reaction of the products with azide ion affords a ready entry into amino acid synthesis (eq 11). However, with R = aryl, no selectivity was noted, possibly due to base-mediated epimerization under the reaction conditions.

(10)

(11)

Chiral Pool Reagent.

(*R*)-Pantolactone has been used as a source of chiral fragments for synthesis. Applications include use in the syntheses of the elfamycins (eq 12)[18] and the bryostatins (eq 13).[19a,b] It has also been used to prepare potentially useful chiral epoxide synthons possessing a quaternary *gem*-dimethyl carbon.[20]

Elfamycins (12)

Bryostatins (13)

Miscellaneous Applications.

Only one attempt to use (*R*)-pantolactone as an enantioselective protonating agent for enolates has been reported.[21] A series of structurally diverse chiral alcohols afforded modest ee's with (*R*)-pantolactone affording the largest ee noted for the series. The complexities of attempting a protonation of this sort in the presence of base and under exchanging conditions are discussed. Finally, the lactone has been used to resolve chiral acids by crystallization and chromatographic techniques applied to the (*R*)-pantolactone-derived esters.[3,22,23]

Related Reagents.

(S)-Ethyl Lactate; ***Ethyl Mandelate***; ***3-Hydroxyisoborneol***.

Paraformaldehyde

$(CH_2O)_n$

[30525-89-4] · CH_2O · Paraformaldehyde · (MW 30.03)

(convenient source of anhydrous monomeric formaldehyde for aldol condensation;[1] electrophilic source of halomethyl[2] and hydroxymethyl groups;[3] convenient source of Mannich reaction intermediates;[4] homologation of alkynes;[5] synthesis of macrocyclic ligands[6])

Physical Data: mp 160-165 °C.

Solubility: sol organic solvents.

Form Supplied in: solid; widely available.

Handling, Storage, and Precautions: generally stable; irritant.

Introduction.

The need to carry out one-carbon homologations during the course of organic syntheses is widespread. Since ***Formaldehyde*** itself is a hygroscopic gas which forms the hydrate easily, the ability to utilize functional equivalents of formaldehyde is quite useful. The proper choice for the synthetic equivalent of a tenuous species like formaldehyde is dictated by the context. Unlike the two other most common precursors, formalin and trioxane, paraformaldehyde is rather easy to handle. It is compatible with most organic systems and displays useful reaction patterns. The polymeric acetal system cleaves easily under acidic conditions and, to a lesser extent, under basic and neutral conditions, to afford one-carbon homologs. On those occasions when a solution of the monomeric formaldehyde is needed, the best approach is the thermal cracking of paraformaldehyde, with the evolved gaseous monomer bubbled into a solution and used immediately.

Reactions with Enolates and Enols.

As the functional equivalent of formaldehyde, paraformaldehyde can afford aldol products, especially under acidic conditions wherein the enol intermediate is generated and conditions lead to unsaturated carbonyl compounds. Methyl ketones undergo reaction (eq 1) with paraformaldehyde to afford the vinyl ketones under acidic conditions.[7] Similar results are obtained with other active hydrogen reactants such as the treatment of methyloxazolines with paraformaldehyde and acid.[8] Under neutral aqueous conditions, multiple aldol reactions with cyclohexanone have been reported (eq 2).[9]

(1)

(2)

Noteworthy observations in this particular reaction are the ultimate reduction of the ketone, presumably via a crossed Cannizzaro reaction, and the ability to utilize large excesses of paraformaldehyde without major difficulties. Of course, both phenomena are related to the absence of α-hydrogens and resultant inability of formaldehyde to enolize.

While paraformaldehyde can be effective in enolate chemistry,[10] the more common practice, when condensation onto a preformed enolate is required, is to generate a solution of monomeric formaldehyde through pyrolysis.[1,11] One can isolate the resultant hydroxy ketone (eq 3),[12] or force dehydration through the use of ***Methanesulfonyl Chloride***,[12] or a variety of organometallic agents.[13] The monomer generated in this way also reacts readily with the dianions of carboxylic acids.[14]

(3)

Halomethyl and Hydroxymethyl Electrophiles.

The chloromethylation of aromatic systems[2] and heteroaromatic compounds[15] can be accomplished using paraformaldehyde, ***Zinc Chloride***, and ***Aluminum Chloride***. Similar chemistry allows bromomethylation of aromatic systems.[16] Halomethyl esters can be obtained from carboxylic acids as well.[17] The hydroxymethylation of anthraquinones has been reviewed[3] and paraformaldehyde can be used for the protection of alcohols as the methoxymethyl group.[18-20]

The Mannich Reaction and other Iminium Ion Reactions.

While the trapping of an iminium ion (generated by the acid-catalyzed reaction of an amine and paraformaldehyde) by enols[4] has been well investigated (eq 4),[21,22] a variety of other nucleophiles are available, such as allylstannanes.[23] Of particular note are those reactions which bring about cyclization. In this context a vinylsilane (eq 5)[24] is effective, as is an alkene (eq 6).[25]

(4)

(5)

(6)

Homologation of Alkynes.[5]

While the terminal alkyne group is a relatively weak nucleophile, strong Lewis acids can bring about homologation, albeit with some isomerization (eq 7).

Macrocyclic Ligands.[6]

By making use of template control, aza macrocycles can be formed which act as organometallic ligands and sequestering agents (eq 8).

Pentacarbonyliron[1]

$Fe(CO)_5$

[13463-40-6] · C_5FeO_5 · Pentacarbonyliron · (MW 195.90)

(diene complexation;[4] carbonyl insertion;[62-64] cycloaddition; reduction[96] and deoxygenation)

Physical Data: mp -20 °C; bp 103 °C; fp -15 °C; *d* 1.490 g cm^{-3}; *n* 1.5196; X-ray diffraction studies at -100 °C confirm the trigonal bipyramidal structure of $Fe(CO)_5$.[2]

Solubility: miscible with organic solvents.

Form Supplied in: straw-yellow liquid.

Handling, Storage, and Precautions: $Fe(CO)_5$ is a volatile, flammable, and highly toxic liquid,[3] which does not react with air at room temperature. It has a relatively high vapor pressure (21 mmHg at 20 °C). When $Fe(CO)_5$ is exposed to light, $Fe_2(CO)_9$ impurity slowly accumulates. The monomeric pentacarbonyl complex can be purified by trap-to-trap distillation in a vacuum system, but for routine use this purification step is usually omitted. Use in a fume hood.

Diene Complexation.

Tricarbonyl(η^4-butadiene)iron(0), the first iron-diene complex, was prepared as long ago as 1930 by Reihlen and co-workers, by heating butadiene with $Fe(CO)_5$.[4] Subsequently, substituted derivatives were studied by Pettit's group and by others.[5] The first complex of a cyclic diene, tricarbonyl(η^4-cyclohexadiene)iron(0), became available in 1958.[6] The real breakthrough for the development of synthetic methods sprang from pioneering work with substituted complexes in the cyclic (particularly cyclohexadiene) series in the 1960s and 1970s, by Birch,[7-10] Lewis,[11,12] and co-workers, then of the group of Pearson,[13] work which was initiated by the discovery by Fischer and Fischer in 1960[14] of hydride abstraction from tricarbonyl(η^4-cyclohexadiene)iron(0) to yield an η^5 iron-complexed cyclohexadienyl cation.

A wide range of methods are now available for the preparation of η^4-diene tricarbonyliron complexes, but by far the most common technique remains the direct complexation of free dienes. $Fe(CO)_5$ is less reactive than $Fe_2(CO)_9$ or $Fe_3(CO)_{12}$, but under the right conditions it provides an inexpensive and efficient route to iron-alkene complexes, particularly from the 1,4-cyclohexadienes.

1,4-Diene Complexation.

Thermal Complexation.

Because 1,4-cyclohexadienes are readily available from the metal-ammonia reduction (Birch reduction) of the corresponding aromatic compounds,[15] they have been extensively studied as substrates for direct 1,4-diene complexation, leading to isomerized 1,3-diene complexes. This methodology suffers, however, from the disadvantage that products are often obtained as mixtures of regioisomers. $Fe(CO)_5$ provides a simple, low-cost source of $Fe(CO)_4$ for initial addition to the π-system of a double bond. By recycling the reagents and the uncomplexed ligand, preparations on a 50-60 g scale can be achieved from a series of overnight thermal reactions. The procedure most frequently used, that of Cais and Maoz,[16] modified by Birch,[8] involves heating a cyclohexadiene with pentacarbonyliron in boiling di-*n*-butyl ether. In the extensive literature on the formation of differently functionalized tricarbonyl(1,3-cyclohexadiene)iron complexes from substituted 1,4-cyclohexadienes[8,9,11,12,17,20] (including the tricarbonyliron complexes of a number of dihydroanisic esters,[18] various cyclohexadiene esters,[9,19] and 1-methoxy-2,4-dimethyl-1,4-cyclohexadiene[21]), at present the most useful and representative intermediates for synthetic applications carry methoxy substituents on the diene ligand. For example, 2,5-dihydroanisole (**1**) or 4-methyl-2,5-dihydroanisole (**2**) upon treatment with pentacarbonyliron at elevated temperature afford a mixture of the 1- and 2-OMe substituted complexes (**3**) and (**5**) or (**4**) and (**6**) (eq 1).[7-9,11,12,22]

(1) R = H
(2) R = Me

(3) R = H
(4) R = Me

(5) R = H
(6) R = Me

Although 1-methoxy-1,4-cyclohexadiene itself leads to a mixture of the 1- and 2-OMe complexes, bicyclic compounds of substitution type (**7**) do not give the 2-OMe regioisomer, affording instead a mixture of complexes (**8**) and (**9**) in a 1:1 ratio (eq 2).[22,23] In a more unusual case, an amide substituent was present on the 1,4-diene.[24]

(7) **(8)** 1:1 **(9)**

More extensive rearrangement of the position of unsaturation in α,o-dienes also leads to η^4-diene complexes.[25] In other cases where rearrangement is blocked, homoconjugated dienes can form stable bis(alkene) complexes by thermal

reaction with $Fe(CO)_5$.[26] Isotetralene offers an unusual case where rearrangement to the 1,3-diene is possible, but a 1,4-diene complex is reported.[27]

Photolysis.

Photolysis offers an alternative for the direct conversion of 1,4-dienes into 1,3-diene complexes. In eq 3 the deuterium labeling reveals that isomerization during complexation of the 1,4-diene precursor proceeds by a 1,3-hydrogen transfer.[28]

(3)

The direct complexation of 1,4-dienes can form specific stereoisomers. Initial π-complexation occurs before the conjugation step, and the hydrogen atom moves only on the face of the ligand carrying the metal.[29] Unfortunately, a mixture of regioisomers usually results, which may present separation problems. Loss of OMe can also sometimes occur, particularly from some 1,3-dimethoxy-1,4-cyclohexadienes. In these cases, preconjugation of the diene is essential[30] if a dimethoxydiene complex is required. Mixtures of complexes obtained from 1,4-dienes may also be equilibrated[31] to thermodynamic ratios of isomeric complexes, which do not correspond to the equilibrium ratios of the free dienes.[32,33]

1,3-Diene Complexation.

Thermal Complexation.

Low yields and mixed products render some nonconjugated dienes unattractive as precursors for η^4-complexes. For many synthetic applications, cleaner routes are required to form a single defined compound in good yield. A good approach employs a conjugation step prior to complexation.[30] The 1-NR_2 series can usually be conjugated thermally.[33] Equilibration of 1-methoxy-1,4-cyclohexadiene with the 1,3-diene (ca. 75%) using potassium in liquid ammonia as catalyst yields only the 1-OMe substitution pattern on the conjugated isomer.[34] Other conjugation catalysts include bases,[35] Wilkinson's catalyst,[36] Cr derivatives,[29] and charge-transfer complexation reagents such as dichloromaleic anhydride.[37] Frequently, only about 70-80% of the conjugated isomer is present at equilibrium,[38] but the complexation product, if formed under mild conditions, corresponds to the conjugated isomer present. This process of preconjugation followed by complexation, using the usual $Fe(CO)_5$ thermal methodology, has led, for example, to an important key intermediate in the synthesis[39] of limaspermine. The use of azadiene catalysts improves the thermal complexation reaction.[40]

Complexation of dienes with several methyl,[41] alkyl,[42] or methoxy[43] groups is straightforward, but with bulky substituents, rearrangements can lead to the formation of mixtures of products,[44] and care is also needed in the presence

of side-chain leaving groups.[45] Trialkylsilyl-substituted dienes complex well. In the reactions of 2-(trimethylsilyl)-1,3-cyclohexadiene derivatives with excess pentacarbonyliron in refluxing di-*n*-butyl ether,[46] (**10**) gave rise to an 8:2 mixture of (**11**) and its epimer (**12**), with coordination to $Fe(CO)_3$ occurring preferentially on the less hindered face of the 1,3-cyclohexadienyl ring (eq 4).

(4)

Photochemical Complexation.

The studies of Birch et al. on the thebaine modification using tricarbonyliron complexes[47,48] exemplify the possibility of complexation of 1,3-dienes by photolysis, and illustrate the potential for iron complexes to ensure control of skeletal rearrangement. Thus, via the initial step of complexation of the methoxycyclohexadiene ring of thebaine (**13**), practically quantitative access to northebaine (**14**) and 14α-substituted thebainone derivatives could be easily obtained with $Fe(CO)_5$ under UV irradiation (eq 5).[47]

(5)

(13) R = Me
(14) R = H

Thermal and Photochemical Reactions in Other Ring Sizes.

Similar complexation reactions can be performed in seven- and eight-membered rings,[49] but with cyclopentadiene the reaction takes a different course, producing a dimeric cyclopentadienyl complex.[50] Complexation of silyl-substituted cyclopentadienes afforded dinuclear products.[51] In more unsaturated systems, competing reduction processes are possible. Cycloheptatriene reacts with pentacarbonyliron to give a mixture of tricarbonyliron complexes of cycloheptatriene and 1,3-cycloheptadiene.[52] Substituted cycloheptatrienes[53] and cycloheptadienes[54] can also be

complexed. Thermal complexation of divinylpyrrolidines forms exocyclic diene complexes by rearrangement of the location of unsaturation.[55]

Complexation Using $Fe(CO)_5$ and Me_3NO.

Reaction of a conjugated diene with $Fe(CO)_5$ in the presence of ***Trimethylamine N-Oxide*** resulted in the formation of tricarbonyl(1,3-diene)iron complexes. The use of amine oxides, preferably Me_3NO, permits fast reactions even at low temperatures. Reduction of amine oxides by $Fe(CO)_5$ has been described by Alper et al.[56] and, in the case of trimethylamine *N*-oxide, the intermediate compound trimethylaminotetracarbonyliron was isolated (eq 6).[57,58]

$$Fe(CO)_5 + Me_3NO \longrightarrow Me_3N \cdot Fe(CO)_4 + CO_2 \qquad (6)$$

The reverse reaction, namely the known disengagement of the ligand from the (diene)$Fe(CO)_3$ complex, presents no problem because of the lower reaction temperature and the smaller molar ratio of Me_3NO:$Fe(CO)_5$ employed in the complexation procedure.[57] Trimethylaminotetracarbonyliron is attractive as a mild reagent but further generalization is needed.

Acyclic Series.

The first complex in the acyclic series was prepared from butadiene by the thermal method.[4] Heating isoprene and pentacarbonyliron at high temperature, however, is inefficient due to competitive Diels-Alder dimerization. Despite the formation of some bis(diene) iron carbonyl complexes on prolonged irradiation, the photochemical method is superior in this case. Complexation of acyclic dienes by $Fe(CO)_3$ is limited to those that can adopt a cisoid conformation, with the *syn* substitution pattern normally preferred. 2,4-Hexadienoic acid, for example, can be conveniently complexed by a photolytic procedure.[59] Trialkylsilyl-substituted dienes have also been complexed.[60]

Isomerization of Alkenes.

In some cases the positional rearrangement of alkenes affords useful products which are not 1,3-diene complexes. The isomerization of allyl ethers in the presence of $Fe(CO)_5$ under UV irradiation has also been reported.[61]

Ring-Opening Reactions with Carbonyl Insertion.

Cyclopropane rings.

Synthesis of (diene)$Fe(CO)_3$ complexes, and of cyclohexenones, lactones, ketones, or sulfones, can follow from the opening of vinylcyclopropanes with $Fe(CO)_5$ under either thermal or photochemical conditions. Reactions of the vinylcyclopropane (**15**) with $Fe(CO)_5$ under thermal conditions resulted in ring opening with concomitant hydrogen shift to form the diene complex (**16**) (eq 7).[62,63,64]

The reaction of (**16**) under photochemical conditions led to (**17**) by ring opening and carbonyl insertion. Conjugation may occur, forming the cyclohexenone (**18**) (eq 7).[65] The expansion of the carbon skeleton of terpene hydrocarbons via carbonylation offers an interesting means to prepare optically active strained ketones (eq 8).[66]

Regiocontrol, however, is a limitation. In the reaction between (+)-2-carene (**19**) and $Fe(CO)_5$, five compounds are

isolated. A recent study[67] improved the reaction with (+)-2-carene and extended the method to (+)-3-carene.

Epoxide Rings.

The synthesis of alcohols, β-lactones, and bicyclic derivatives occurs via a ferralactone complex. Irradiation of α,β-unsaturated epoxides in the presence of $Fe(CO)_5$ yields ferralactone complexes by ring opening and CO insertion (eq 9). For example, the vinyloxirane (**20**) gives the lactone (**21**).[68]

(9)

While the photochemical reaction[69] proceeds stereospecifically, the thermal process between $Fe(CO)_5$ and vinyl epoxides gives mixtures of diastereoisomers. Subsequent treatment of ferralactones with ***Cerium(IV) Ammonium Nitrate*** results predominantly in the formation of β-lactones, with a few exceptions where δ-lactones are obtained.[70]

A thermal treatment of the ferralactone displaces one molecule of CO. The α,β-unsaturated epoxide (**22**) forms the lactone (**23**) after irradiation in the presence of $Fe(CO)_5$, but subsequent heating leads to the formation of the (hydroxycyclohexadiene)$Fe(CO)_3$ complex (**24**) (eq 10).[67]

(10)

UV irradiation of 9-oxabicyclo[6.1.0]nona-2,4,6-triene (**25**) (the monoepoxide of cyclooctatetraene) in the presence of $Fe(CO)_5$ promotes an overall 1,2 to 1,4 skeletal rearrangement via the lactone (**26**) and the $Fe(CO)_3$ complex (**27**) to form the $Fe(CO)_3$-$Fe(CO)_4$ complex (**28**). Subsequent decomposition of the bis(iron) complex (**28**) gave the previously unknown 9-oxabicyclo[4.2.1]nona-2,4,7-triene (**29**) (eq 11).[71]

(11)

Carbonylative Ring Expansion.

When either α- or β-pinene (**30**) or (**31**) is heated neat with an equimolar amount of $Fe(CO)_5$ under an initial pressure of 30 psi CO at 160 °C, two ketones (**32**) and (**33**) are obtained, formed by insertion of CO into the cyclobutane ring (eq 12).[72] Both ketones are optically active.

Dehalogenation Reactions.

Coupling of *gem*-Dihalides.

Pentacarbonyliron effects dehalogenative coupling of dichloro- or dibromodiphenylmethane and benzylic *gem*-dihalides to form alkenic compounds in good yields (eq 13).[73]

α-Halo Ketones.

Treatment of α-halo ketones (**34**) with $Fe(CO)_5$ was found by Alper to result in formation of coupled 1,4-diketones (**35**) and reduced monoketones (**36**) (eq 14).[74]

α,α´-Dibromo Ketones and α,α,α´,α´-Tetrabromo Ketones.

Although dehalogenation combined with carbon-carbon bond formation is more commonly performed with ***Nonacarbonyldiiron***, $Fe(CO)_5$ may also be used. The use of a tribromo ketone, followed by a separate reductive dehalogenation step, is illustrated for the synthesis of carbocamphenilone (eq 15), a compound of interest as a skewed glyoxal model.[75]

The reaction between the allylic bromide (**37**) and $Fe(CO)_5$ constitutes an alternative method of preparation of tricarbonyl(1,3-cyclohexadiene)iron (**38**) (eq 16).[76] Allylic alcohols react in a similar way (eq 17) under neutral conditions,[77] but in the presence of acid (HBF_4), cationic η^3 iron carbonyl complexes are produced.[78]

(17)

Benzohydroxamoyl Chlorides.

Benzohydroxamoyl chlorides (**39**) are converted into nitriles (**40**) when refluxed with $Fe(CO)_5$ in THF (eq 18).[79]

(18)

Dehydration and Dehydrosulfuration Reactions.

Certain amides and thioamides, on treatment with $Fe(CO)_5$, yield nitriles or imines depending on the degree of substitution present (eq 19).[80] Dithioesters, on the other hand, form trinuclear iron carbonyl complexes.[81]

(19)

Reaction with Oximes; Deprotection of Ketones.

Regeneration of protected ketones from their oximes can be achieved by refluxing the oxime in di-*n*-butyl ether with one equiv of $Fe(CO)_5$ and a catalytic amount of a Lewis acid (eq 20).[82]

(20)

Other Reactions Occurring with Carbonyl Insertion.

Carbonylation of Benzyl Halides.

Benzyl halides can be converted into phenylacetic acids by reaction with $Fe(CO)_5$.[83] Phase-transfer catalysis is useful in this reaction.[84]

Diazonium Salts.

Carboxylic acids or ketones are obtained from the reaction of diazonium salts with $Fe(CO)_5$, depending on the reaction conditions.[85]

Nucleophiles.

Nucleophiles such as amines (eq 21)[86] and organolithium reagents (eq 22)[87] are also found to react with $Fe(CO)_5$ to give products of CO insertion. Cyclopentadienide, on the other hand, undergoes an unusual tricarbonylation reaction to form a cyclopentadienyl complex with an iron-acyl bridge connecting the metal and the cyclopentadienyl ring (eq 23).[88] The product was isolated by protecting the two OH groups. An aryllithium reagent, in which the aromatic ring is bound to a tricarbonylchromium group, also follows a different reaction path, and bimetallic tetracarbonyliron ferrate derivatives are isolated.[89]

$$RNH_2 + Fe(CO)_5 \longrightarrow RNHCHO$$
$$R_2NH + Fe(CO)_5 \longrightarrow R_2NCHO \qquad (21)$$

(22)

(23)

An arylmethylmalonate derivative, with an *ortho* iodine substituent on the aromatic ring, undergoes a carbonylative cyclization by oxidative addition to the aryl iodide and reaction at the nucleophilic center of the malonate group.[90]

Formylation and Acylation of Pyridine.

Direct formylation and acylation at the β-position of pyridine is possible by reaction with phenyllithium and then with $Fe(CO)_5$. 2-Phenylpyridine is also formed in these reactions.[91]

Formation of *N,N´*-Disubstituted Ureas.

The substituted ureas are prepared in about 50-95% yield by reaction of aryl or alkyl nitro compounds with the MgBr derivative of an amine in the presence of $Fe(CO)_5$ (eq 24).[92]

$$R^1NHMgBr + R^2NO_2 \xrightarrow[2.\ H_2SO_4]{1.\ Fe(CO)_5} R^1NHCONHR^2 \qquad (24)$$

Formation of Carboxylic Esters[93,95] and Ketones.[94]

Grignard reagents can also be converted into esters and ketones by $Fe(CO)_5$ (to supply CO). A cathodic ester synthesis from alcohols and alkyl halides uses carbon monoxide (at 1 atm) and $Fe(CO)_5$ as a catalyst.[95]

Deoxygenation Reactions and Reductions.

Deoxygenation of N-O Bonds.

Deoxygenation of amine oxides has been discussed above (see eq 6); pyridine *N*-oxides provide a further illustration (eq 25).[96]

(25)

Nitroso Compounds.

Similar treatment of nitrosobenzene resulted in a 75% yield of azobenzene. Aromatic *N*-nitroso amines have been converted into the secondary amines in 85-92% yields.[97] Under photolytic conditions, azoxyarenes are produced.[98] The choice of solvent is important. Dialkylnitrosoamines afford ureas (eq 26).[97]

(26)

Aromatic Nitro Compounds.

Indoles are formed[99] by $Fe(CO)_5$ catalyzed deoxygenation of *o*-nitrostyrenes with CO (eq 27).

Deoxygenation of Epoxides.

$Fe(CO)_5$ in *N*,*N*-dimethylacetamide or tetramethylurea deoxygenates epoxides (2 h, 145 °C). The reaction is not stereospecific: *trans*-stilbene oxide is converted into both *trans*- (56%) and *cis*-stilbene (22%).[100] Epoxides of 1-alkenes are converted mainly into mixtures of internal alkenes.

Stabilization of Reactive or Unstable Species.

The complex (**42**), formed from the reaction between the dibromoxylene (**41**) and $Fe_2(CO)_9$ or $Na_2Fe(CO)_4$, reacts with $Fe(CO)_5$ to yield the mixture of stereoisomers (**43**) and the complex (**44**) (eq 28).[101] With pentacarbonyliron, however, (**41**) is taken directly on to an indanone by carbonylative cyclization (see above).[102]

A pentafulvalene has been trapped as a diiron complex using $Fe(CO)_5$.[103] Thiophene dioxide has also been stabilized as its tricarbonyliron complex.[104] The irradiation of α-pyrone (**45**) in the presence of $Fe(CO)_5$ gives cyclobutadiene stabilized by complexation with the $Fe(CO)_3$ moiety (**46**), together with the (α-pyrone)$Fe(CO)_3$ complex (**47**) (eq 29).[105]

Reactions with Alkynes.

Dimerization.

Two alkynes can be combined to form a cyclobutadiene ligand. The reaction has been reported for a dialkylamino trimethylsilyl-substituted alkyne, and forms a diaminocyclobutadiene complex.[106]

Dimerization with Insertion of One Molecule of CO.

A number of tricarbonyliron complexes of substituted cyclopentadienones have been prepared from alkynes. The

reaction was first described by Jones et al.[107] for $Fe(CO)_5$ and Ph-C&tbond;CH in the presence of $Ni(CO)_4$. A number of other alkynes (PhC_2Me, PhC_2SiMe_3, Me_3SiC_2R, $BrC_6H_4C_2H$, $CF_3C_2CF_3$, PhC_2Ph and α,o-diynes) give cyclopentadienone complexes (eq 30).[108]

Cyclization of an alkyne to an alkene with carbonyl insertion (analogous to the Pauson-Khand reaction) has also been achieved using pentacarbonyliron.[109]

Dimerization with Insertion of Two Molecules of CO.

By manipulating reaction conditions, formation of benzoquinones can be achieved (eq 31).[110]

Reaction with Allenes.

A diallene, hexatetraene (eq 32), reacts with $Fe(CO)_5$ with insertion of carbon monoxide to form 2,5-dimethylenecyclopent-3-enone.[111] Allenyl ketones, on the other hand, form dinuclear complexes.[112]

Formation of Naphthoquinones via Iron Metallocycles.

Benzocyclobutenedione (**48**) forms the iron complex (**49**) by irradiation with $Fe(CO)_5$.[113] Complex (**49**) reacts with a

wide variety of alkynes to give naphthoquinones, in yields usually >70% (eq 33).

(33)

Trimerization of Benzonitriles.

Benzonitrile is trimerized in good yield by heating with $Fe(CO)_5$ for several hours (eq 34).[114]

(34)

Formation of Carbodiimides.

Carbodiimides are obtained in ca. 50% yield from the reaction of azides with isocyanides catalyzed by $Fe(CO)_5$.[115]

Anionic Iron Carbonyl Reagents.

The reagent $[HFe(CO)_4]^-$ can be generated in situ from pentacarbonyliron, allowing straightforward, regiocontrolled, hydroxycarboxylation of acrylic acid by $Fe(CO)_5$, $Ca(OH)_2$, and H_2O/*i*-PrOH under 1 atm of CO.[116]

Formation of Iron Carbene Complexes.

$Fe(CO)_5$ is the starting material for the preparation of the tetracarbonyl(ethoxyphenylmethylidene)iron(0) (**50**) (eq 35).[117]

(35)

Iron carbene complexes react with alkynes under CO atmosphere to form (α-pyrone)$Fe(CO)_3$ complexes.[118]

Modified Corey-Winter Alkene Synthesis.

Daub et al.[119] have obtained satisfactory yields by using $Fe(CO)_5$ in an iron-mediated version (eq 36) of the reaction of thionocarbonates with ***Trimethyl Phosphite***, which gives poor yields in the case of thermally labile alkenes.

Pentacarbonylchloromanganese[1]

$(CO)_5MnCl$

[14100-30-2] · C_5ClMnO_5 · Pentacarbonylchloromanganese · (MW 230.44)

(precursor to reactive carbonyl halide complexes;[2] precatalyst for the oligomerization of benzyl chloride[3])

Physical Data: pale yellow crystals; sublimes at 40 °C/0.1 mmHg.

Solubility: sol CH_2Cl_2; moderately sol benzene, toluene; v sl sol hexane.

Form Supplied in: not commercially available. $(CO)_5MnBr$ is available from commercial sources as orange-yellow crystals.

Analysis of Reagent Purity: IR (CCl_4, cm^{-1}) 2140 (w), 2054 (s), 2021 (vw), 1998 (m).[4] Related compounds: $(CO)_5MnBr$ 2134 (w), 2051 (s), 2020 (vw), 2000 (m); $(CO)_5MnI$ 2127 (w), 2045 (s), 2016 (vw, sh), 2005 (m)

Preparative Methods: (a) treatment of a CH_2Cl_2 solution of ***Decacarbonyldimanganese*** with 30 equiv ***Sulfuryl Chloride*** at rt, followed by evaporation, washing with ethanol, and drying in vacuo, affords pure $(CO)_5MnCl$ in 91% yield (eq 1).[5] (b) a solution of ***Chlorine*** in CCl_4 is added slowly to $Mn_2(CO)_{10}$ in CCl_4 at 0 °C under a dry nitrogen atmosphere. After stirring at room temperature for 4 h, the precipitate is filtered in air, washed with CCl_4, and dried in vacuo. The product is approximately 90% pure, the remainder being $[MnCl(CO)_4]_2$.[1,6,7] (c) A solution of $Mn_2(CO)_{10}$ in CCl_4 irradiated with UV-visible light gives $(CO)_5MnCl$ with high quantum yield; $(CO)_5MnI$ is also available by photolysis in the presence of I_2.[8]

The related compounds $(CO)_5MnBr$ and $(CO)_5MnI$ may be prepared by methods similar to (b).[1] In addition, the iodide may be obtained from $Na[Mn(CO)_5]$ and I_2.[1]

Purification: $(CO)_5MnCl$ (40 °C/0.1 mmHg), $(CO)_5MnBr$ (50 °C/0.05 mmHg), and $(CO)_5MnI$ (50 °C/0.05 mmHg) are purified by sublimation and/or recrystallization from hydrocarbon solvents such as pentane or hexane.

Handling, Storage, and Precautions: light sensitive; dimerizes slowly in solution with loss of CO. The product, $[MnCl(CO)_4]_2$, is readily detected by IR (2104 (m), 2045 (vs), 2012 (s), 1975 (vs)).[9] Pentacarbonylmanganese halides are indefinitely stable when stored as solids in the absence of air at -20 °C. While no information concerning the toxicity of these compounds is available, one should assume that metal carbonyls are highly toxic; since they are volatile solids, extra care should be taken to avoid exposure. Use in a fume hood.

Carbonyl Substitution.

Substitution of a CO ligand with a two-electron donor usually occurs *cis* to the halide (eq 2). The products are configurationally stable. Attacking ligands include monodentate or chelating phosphines and arsines,[2] and silylphosphines, with subsequent hydrolysis of the P-Si bond to afford parent phosphine (P-H) complexes and dinuclear compounds under some conditions.[10]

(2)

Halide Substitution.[11]

Treatment with ***Silver(I) Trifluoromethanesulfonate*** affords the labile $Mn(CO)_5(OTf)$ complex, which may be treated by a variety of neutral two-electron donors to give cationic complexes $[(CO)_5Mn\text{-}L](OTf)$ (L = THF, MeCN, PBu_3).[11] The following compounds are available by displacement of both halide and CO ligands: $(\eta^3\text{-allyl})Mn(CO)_4$, from attack of hydroxide ion on coordinated CO followed by loss of CO_2 and alkylation with allyl bromide;[12] $(\eta^5\text{-}C_5Z_4X)Mn(CO)_3$ (Z = H or Cl), from reaction with diazocyclopentadienides with transfer of the halide of the Cp fragment;[7,13] and aminooxy- or dioxycarbene compounds from reaction with oxirane or aziridine and catalytic bromide ion.[14]

Oligomerization of Benzyl Chloride.

When heated at 100 °C with catalytic quantities of $(CO)_5MnCl$ or $(CO)_5MnBr$, benzyl chloride is converted to highly branched oligomers linked at benzylic and aromatic ring sites.[3] An average of 30-50 monomer units are incorporated per oligomer. The analogous rhenium complexes are also active, as are Group 6 carbonyl halides.

Pentacarbonyl(methoxyphenylcarbene)chromium(0)

[27436-93-7] · $C_{13}H_8CrO_6$ · Pentacarbonyl(methoxyphenylcarbene)chromium(0) · (MW 312.21)

(metal-carbene complex[1])

Alternate Name: pentacarbonyl[methoxy(phenyl)methylene]chromium.

Physical Data: mp 46 °C.

Solubility: sol THF, ether, benzene, hexane.

Form Supplied in: orange-red crystals; not commercially available.

Preparative Method: prepared from ***Phenyllithium***, ***Hexacarbonylchromium***, and ***Trimethyloxonium Tetrafluoroborate*** according to the procedure of Fischer.[2]

Purification: recrystallized from petroleum ether at -78 °C. Can also be purified by column chromatography on silica gel using pure hexane as the eluent.

Handling, Storage, and Precautions: slightly air sensitive; should be stored in a refrigerator. Chromium compounds display variable toxicity. Care is recommended. Use in a fume hood.

Benzannulation.

Reaction of pentacarbonyl(phenylmethoxycarbene)chromium (**1**) with alkynes leads to *p*-methoxynaphthol derivatives (eq 1).[1] The reaction is tolerant of a variety of substitution patterns on the alkyne. The regiochemistry is such that the larger alkyne substituent preferentially ends up *ortho* to the hydroxy group, and the smaller substituent ends up *ortho* to the methoxy group. The observed regioselectivity is proportional to the size difference of the alkyne substituents. Terminal alkynes react with complete control of regiochemistry (eq 2), but unsymmetrical internal alkynes provide mixtures of products (eq 3).[3] The initially obtained arene complexes (**2**) are not very stable, and are converted to the free arene (**3**) upon exposure to air and light. Treatment of the arene complex with oxidants leads to naphthoquinone (**4**) or naphthoquinone monoacetal derivatives (**5**). In most cases, naphthalene derivatives are the major products from reaction of complex (**1**) and alkynes; however, in some cases other products such as cyclobutenones[4] or furans[5] are significant products in the reaction.

Photochemical Conversion to the Ketene and Subsequent Trapping.

Upon irradiation by UV light, complex (**1**) undergoes conversion to a ketene-metal complex (**7**), which can subsequently be intercepted (eq 4) if the irradiation is performed in the presence of suitable traps. Irradiation of complex (**1**) in the presence of imines leads to β-lactam derivatives (**8**),[6] while treatment with alkenes leads to cyclobutenones (**9**).[7] Compounds (**8**) and (**9**) are produced with excellent control of relative stereochemistry.[8] Irradiation in the presence of alcohols leads to α-hydroxy esters (**10**).[9]

(4)

Cyclopropanation.

Complex (**1**) effects cyclopropanation of selected alkenes (eqs 5-7). The reaction is restricted to highly polarized alkenes such as α,β-unsaturated esters (eqs 5 and 6)[10,11] and enol ethers (eq 7).[12] The cyclopropanation of electron-rich alkenes must be conducted under ***Carbon Monoxide*** pressure; in the absence of CO, alkene metathesis is the major reaction pathway. In the case of dienoic acid esters, cyclopropanation occurs primarily at the 4,5-double bond (eq 6).

(5)

Alkenation.

Treatment of complex (**1**) with sulfur ylides leads to vinylogous carbonate derivatives (eq 8).[13] Similar ylide-type alkenation reactions have been reported for the tungsten analog of complex (**1**),[14] and although not reported, should proceed similarly for the molybdenum complex. Similar transformations using the electronically similar compound methyl benzoate are considerably more difficult.[15]

Reaction with Isocyanides.

Treatment of complex (**1**) with isocyanides leads to the ketimine complex (**11**), whose reactivity is best characterized by the zwitterionic structure (**12**) (eq 9).[16] The reactivity of the ketimine complex is very different from that of free ketimines, which are nucleophilic at the α-carbon. This reactivity profile is demonstrated by the addition of methanol (eq 10), which leads to carbene complex (**13**) (this result was obtained using the *ethoxy* analog of complex **1**).[17]

(10)

(1)-Et **(13)**

Insertion into σ-Bonds.

Certain compounds undergo net bond insertion reactions upon treatment with carbene complexes (e.g. complex **1**). Notable classes of compounds undergoing this transformation with complex (**1**) include Group 14 metal hydrides (eq 11)[18] and 1,2-cyclobutenediones.[19] In the latter case, the initial insertion product (**15**) might undergo isomerization to the observed product, alkylidenefuranone (**16**) (eq 12).

Pentacarbonyl(methoxyphenylcarbene)tungsten(0)

[37823-96-4] · $C_{13}H_8O_6W$ · Pentacarbonyl(methoxyphenylcarbene)tungsten(0) · (MW 444.06)

(metal-carbene complex[1])

Alternate Name: pentacarbonyl[methoxy(phenyl)methylene]tungsten.

Physical Data: mp 59 °C.

Solubility: sol THF, ether, benzene, hexane.

Form Supplied in: orange-red crystals; not commercially available.

Preparative Method: prepared from ***Phenyllithium***, ***Hexacarbonyltungsten***, and ***Trimethyloxonium Tetrafluoroborate*** according to the procedure of Fischer.[2]

Purification: recrystallized from petroleum ether at -78 °C. Can also be purified by column chromatography on silica gel using pure hexane as the eluent.

Handling, Storage, and Precautions: slightly air sensitive; should be stored in a refrigerator.

Alkenation.

Treatment of pentacarbonyl(methoxyphenylcarbene)tungsten (**1**) with Wittig reagents leads to the corresponding enol ether (eq 1),[3a] and pentacarbonyl(triphenylphosphine)tungsten. Alternatively, the same transformation can be effected using diazo compounds (eq 2).[3b] In each case the reaction occurs via nucleophilic attack at the carbene carbon followed by an elimination reaction. Similar transformations using the electronically similar compound methyl benzoate are considerably more difficult.[4]

(2)

Reaction with Alkynes.

Treatment of alkynes with (**1**) leads to intermediate vinylcarbene complexes (e.g. **2**),[5] which undergo subsequent transformations (eq 3).[1] The reaction of ***Diphenylacetylene*** with complex (**1**) produces the indene in high yield (eq 4).[6] Treatment of enyne (**3**) with complex (**1**) leads to vinylphenanthrene derivative (**4**) (eq 5).[7] Formation of (**4**) involves alkyne insertion, followed by alkene insertion and alkene metathesis. The chromium analog of complex (**1**) (***Pentacarbonyl(methoxyphenylcarbene)chromium(0)***) has been better studied in its reaction with alkynes.[1]

(3)

(4)

(5)

Reaction with Alkenes.

Pentacarbonyl(methoxyphenylcarbene)tungsten effects cyclopropanation of some alkenes (eqs 6 and 7).[8] The reaction is restricted to highly polarized alkenes such as α,β-unsaturated esters and enol ethers. Cyclopropanation of electron-rich alkenes proceeds through zwitterionic intermediates.[9] Although stereoselectivity is poor, the method does generate highly functionalized cyclopropanes which

Pentacarbonyl(methoxyphenylcarbene)tungsten(0)

would be difficult to prepare by other methods.

Reaction with Isocyanides.

Treatment of complex (**1**) with isocyanides leads to the ketimine complex (**5**), whose reactivity is best characterized by the zwitterionic structure (**6**) (eq 8).[10] The reactivity of the ketimine complex is very different from that of free ketimines, which are nucleophilic at the α-carbon. This reactivity profile is demonstrated by the cycloaddition reaction in eq 9, which leads to hydantoin (**7**) after oxidative removal of the metal (this result was obtained using the *ethoxy* analog of complex **1**).[11]

Synthesis of Diaziridines.

Treatment of complex (**1**) with some azo compounds leads to the corresponding diaziridine derivatives (eq 10).[12] The reaction is restricted to electron-deficient azo compounds since electron-rich azo compounds undergo metathesis reactions when treated with complex (**1**).

Pentacarbonylmethylmanganese[1,2]

$(CO)_5MnMe$

[13601-24-6] · $C_6H_3MnO_5$ · Pentacarbonylmethylmanganese · (MW 210.03)

(prototypical reagent for migratory insertion of CO into metal-alkyl bonds;[3,4] can acylate alkenes and alkynes;[2] can cyclometalate keto- and iminoarenes[1,5])

Physical Data: colorless crystals; mp 95 °C; sublimes at 25-40 °C/0.1 mmHg.

Solubility: sol organic solvents.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: IR.

Preparative Methods: (a) alkylation of ***Sodium Pentacarbonylmanganate*** under N_2 atmosphere (eq 1).[1,6,7] (b) decarbonylation of pentacarbonylacetylmanganese; not used on a preparative scale, but often the method of choice for synthesis of analogous alkyl- and arylmanganese complexes.

Purification: sublimation (25-40 °C/0.1 mmHg).

Handling, Storage, and Precautions: slightly light sensitive; may be handled in air, but decomposes upon prolonged exposure to oxygen. Indefinitely stable when stored as a solid in the absence of air at -20 °C. While no information concerning this compound is available, one should assume that metal carbonyls are

highly toxic; since this is a volatile solid (vapor pressure ~2 mmHg at 20 °C),[6] extra care should be taken to avoid exposure. Use in a fume hood.

Migratory Insertion Reactions: Alkyl Carbonylation.

$(CO)_5MnMe$ was employed in seminal studies elucidating the mechanism of migratory insertion reactions of alkyl ligands to coordinated CO.[3,4,8-12] Stereochemical and labeling experiments demonstrated (a) that the methyl group migrates to an adjacent CO, opening a *cis* coordination site, and (b) that the coordinatively unsaturated intermediate is a configurationally stable square pyramid in the absence of a coordinating solvent.[4,13] The process is faster in polar solvents than nonpolar ones, consistent with the formation of solvent-bound species,[14,15] although recent flash photolysis experiments suggest the intermediacy of an η^2-coordinated acyl moiety.[16] The migratory insertion step is accelerated by Lewis[17-20] or Brønsted[21] acids. Thermochemical measurements have been reported,[20] and the reaction has been subjected to theoretical analysis.[19,22-26] The Mn-Me bond dissociation energy is 44.7 ± 1 kcal mol^{-1}.[27]

Much of the synthetic chemistry of pentacarbonylmanganese alkyl compounds derives from the trapping of the coordinatively unsaturated acyl intermediate $(CO)_4Mn(COR)$ produced from migratory insertion. Addition of simple donor ligands such as phosphine or CO provide good yields of acyl complexes (eq 2). In addition to the processes outlined below, the following miscellaneous trapping agents have been reported (product type in parentheses): a W&tbond;C triple bond (bridging dinuclear acyl-carbyne complex),[28] various metal hydrides (metal-metal bound dinuclear complexes,[29] including those bearing an η^1-coordinated aldehyde resulting from formylation of the starting alkyl);[30] Ph_2PSiMe_3 (metallacyclic α-silyloxymanganese phosphide complex);[31,32] and chiral and achiral germyl anions, R_3GeLi, or $Mn(CO)_5^-$ (*cis*-tetracarbonylacyl complexes bearing Mn-Ge or Mn-Mn bonds, leading to Fischer carbene compounds).[33-35]

(2)

Hydroacylation of Alkenes and Alkynes: Sequential CO/Alkene or CO/Alkyne Insertion.

Electron-deficient or strained alkenes are metalloacylated by exposure to $(CO)_5Mn$-alkyl complexes under high pressure (2-10 kbar; eq 3).[2,36-40] Alkynes undergo a similar reaction, sometimes at ambient pressure (eq 4).[39,41,42] Advantages include: (1) no β-elimination is observed; (2) multiple insertion of alkenes and alkynes does not occur; (3) addition is regiospecific for terminal (R^2 = H) or trimethylsilyl-substituted ($R^2 = SiMe_3$) alkynes;[41] and (4) demetalation is accomplished under mild oxidative (replacing Mn with H), acidic (Mn -> H), or reductive

conditions.[42,43] Yields are low for sterically hindered alkenes. ^{55}Mn NMR chemical shifts have been used to characterize the products and predict reactivity.[40,42-44] The alkene insertion methodology has been used in the synthesis of spiroacetal systems present in natural products[39,40] and in the elaboration of glycosyl halides.[45]

(3)

(4)

Cyclometalation.

Aromatic imines and ketones, when treated with $(CO)_5$MnMe, are metalated *ortho* to the directing group with loss of methane and carbon monoxide (eq 5).[5,41,46-48] The same types of cyclometalated ketone are available from $(CO)_5$MnR and ***Diphenylmercury*** (R = alkyl).[48] The products are stable in air and may be purified by column chromatography.

Methyl Transfer.

Reaction with the highly nucleophilic $Fe(CO)_4^{2-}$ dianion results in clean transfer of Me^+ from manganese to iron, giving $MeFe(CO)_4^-$ and $Mn(CO)_5^-$.[49]

Protonolysis.

Alkanes may be liberated from pentacarbonylmanganese alkyls by protonation with strong acids.[50]

Pentacarbonylphenylmanganese

$(CO)_5MnPh$

[13985-77-8] · $C_{11}H_5MnO_5$ · Pentacarbonylphenylmanganese · (MW 272.10)

(undergoes migratory insertion of CO into metal-aryl bonds;[1] can acylate alkynes and alkenes[2])

Physical Data: white crystals; mp 51-52 °C.

Solubility: sol organic solvents.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: IR (CCl_4, cm^{-1}) 2115 (m), 2019 (vs), 1997 (s);[2] (KBr, cm^{-1}) 2126 (w), 2058 (m), 2015 (vs).[3]

Preparative Methods: decarbonylation of $(CO)_5MnCOPh$ by heating under N_2 atmosphere (eq 1), either in situ or after isolation of the acyl complex.[2-5] The complex is also available in 93% yield from irradiation (254 nm) of ***Decacarbonyldimanganese*** and ***Diphenylmercury*** in cyclohexane/THF solvent.[6]

Purification: sublimation (25-40 °C/0.1 mmHg); recrystallization from pentane, hexane, or light petroleum ether; column chromatography on silica gel with hexane. Complexes bearing electron-donating substituents on the aromatic ring (*p*-Me, *p*-OMe) are apparently less stable to chromatography than the parent or electron-deficient (*p*-Cl) compounds.[6]

Handling, Storage, and Precautions: may be handled in air, but decomposes upon prolonged exposure to oxygen. Indefinitely stable when stored as a solid in the absence of air at -20 °C. While no information concerning the toxicity of this compound is available, one should assume that metal carbonyls are highly toxic; since this is a volatile solid (vapor pressure ~2 mmHg at 20 °C), extra care should be taken to avoid exposure. Use in a fume hood.

Migratory Insertion Reactions: Aryl Carbonylation.

Much of the synthetic chemistry of pentacarbonylmanganese aryl compounds derives from the trapping of the coordinatively unsaturated acyl intermediate $(CO)_4Mn(COR)$ produced from migratory insertion. In the absence of added ligand the pentacarbonyl aryl complex is favored, but the addition of simple donor ligands such as phosphine or phosphite provides good yields of *cis*-substituted acyl complexes (eq 2).[1,4,7] The migratory insertion step is assisted by polar solvents.[8] In addition to the processes outlined below, the following miscellaneous trapping agents have been reported (product type in parentheses): Ph_2PSiMe_3 (metallacyclic α-silyloxymanganese phosphide complex);[9,10] chiral and achiral germyl anions, R_3GeLi, or $Mn(CO)_5^-$ (*cis*-tetracarbonylacyl complexes bearing Mn-Ge or Mn-Mn bonds, leading to Fischer carbene compounds).[11-13] Substitution of a *cis*-CO ligand without aryl migratory insertion may be achieved by the addition of *N*-oxides.[7]

Acylation of Alkenes and Alkynes: Sequential CO/Alkene or CO/Alkyne Insertion.

The interception of coordinatively unsaturated aromatic acyl intermediates with alkenes has been reported for a few cases. Dicyclopentadiene affords β-benzoyl alkyl complexes stabilized by intramolecular coordination of the ketone oxygen.[14] The use of dienes gives rise to η^3-ketoallyl products (eq 3).[15] Under photolytic conditions, CO is ejected and alkene insertion directly into the Mn-Ph bond is observed (eq 4).[16] Interestingly, cycloheptatrienes afford noncarbonylated η^5-pentadienyl products from a similar alkene insertion process upon heating.[17]

Alkynes are also acylated by $(CO)_5$Mn-aryl complexes, although this reaction has not been used as frequently as the analogous reactions of $(CO)_5$Mn-alkyls (eq 5).[2,18,19] Demetalation is accomplished under mild acidic (replacing Mn with H) or reductive conditions.[2,19,20]

Cyclometalation.

Aromatic imines and ketones, when treated with $(CO)_5$MnPh, are metalated *ortho* to the directing group (see ***Pentacarbonylmethylmanganese***).[21,22] The same type of cyclometalated ketones are available from $(CO)_5$Mn-R and Ph_2Hg (R = alkyl).[6] The products are stable in air and may be purified by column chromatography.

Protonolysis.

Arenes may be liberated from pentacarbonylmanganese alkyls by protonation with strong acids.[23]

Pentacarbonyl(trimethylsilyl)manganese[1,2]

$(CO)_5MnSiMe_3$

[26500-16-3] · $C_8H_9MnO_5Si$ · Pentacarbonyl(trimethylsilyl)manganese · (MW 268.20)

(carbon-carbon bond formation with strained cyclic ethers by ring opening followed by CO insertion;[1,3] synthesis of enol ethers from acetals;[2] can add to aldehydes and ketones[2]).

Physical Data: white crystals; mp 26.5 °C;[3] 25.6-26.2 °C.[4]

Solubility: sol most organic solvents.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: IR (cyclohexane, cm^{-1}) 2094 (w), 2000 (s), 1993 (vs); NMR (cyclohexane, δ) 0.49 ppm.[4]

Preparative Methods: [3-5] (a) a suspension of $KMn(CO)_5$ in pentane is stirred with ***Bromotrimethylsilane*** for two days at rt to afford $(CO)_5MnSiMe_3$ in 60-80% yield after purification (eq 1);[3] a similar reaction with ***Chlorotrimethylsilane*** gives a lower yield.[4] (b) The desired product is obtained in 70% yield by heating Me_3SiH and ***Decacarbonyldimanganese*** without solvent for 48 h at 132 °C.[4] (c) Heating Me_3SiH and $HMn(CO)_5$ in similar fashion to method (b) provides $(CO)_5MnSiMe_3$ in 23% yield.[4]

The related compound $(CO)_5MnSi(t\text{-}Bu)Me_2$ is obtained by treating ethereal solutions of $NaMn(CO)_5$ with ***t-Butyldimethylsilyl Trifluoromethanesulfonate*** and is used in situ.[6]

Purification: by sublimation or vacuum line transfer at ambient temperature.

Handling, Storage, and Precautions: the solid may be handled in air; upon prolonged exposure, it oxidizes to a brown material and should therefore be stored under inert atmosphere. Solutions of $(CO)_5MnSiMe_3$ react readily with water, giving $HMn(CO)_5$ and $Me_3SiOSiMe_3$. While no information concerning the toxicity of this compound is available, one should assume that metal carbonyls are highly toxic; since this is a volatile solid, extra care should be taken to avoid exposure. Use in a fume hood.

Ring Opening of Cyclic Ethers.

Much of the chemistry of $(CO)_5$Mn-silyl compounds derives from the apparent heterolysis of the Mn-Si bond, making available a combination of Lewis acidic (SiR_3^+) and nucleophilic ($Mn(CO)_5^-$) moieties. Thus exposure to ***Trimethylamine*** immediately gives the salt $[Me_3N\text{-}SiMe_3]^+[Mn(CO)_5]^-$.[4] More useful examples are provided by the ring opening of strained cyclic ethers to give manganese alkyls in good to excellent yields by treatment with $(CO)_5$Mn-silyl complexes under moderate pressures of CO (eq 2).[1,3,4,7] The insertion is regioselective, with the manganese fragment ending up on the less-hindered carbon (one isomer for epoxides; 10:1 ratio for 2-methyltetrahydrofuran).[6] The reaction mechanism is thought to involve interaction of the ether oxygen with Me_3Si^+, followed by attack of $Mn(CO)_5^-$ on a C-O bond.[4]

(2)

When performed in the presence of alkynes or activated alkenes, products derived from the sequential insertion of CO and the unsaturated substrate into the Mn-C single bond are obtained in good to excellent yields (eq 2; see ***Pentacarbonylmethylmanganese***).[8] This methodology has been employed in the efficient synthesis of spiroacetal systems.[6,8] Alternatively, carbonylation may be followed by desilylation to produce lactones.[2]

Conversion of Acetals to Vinyl Ethers.

Treatment of acetals with $(CO)_5MnSiMe_3$ under mild conditions affords vinyl ethers (eq 3).[2,9,10] Mixtures of (*E*)- and (*Z*)-isomers are produced under thermodynamic control, consistent with the mechanism shown in eq 3. Related reagents are *cis*-$(CO)_4Fe(SiMe_3)_2$ and $(CO)_4CoSiMe_3$.[2]

(3)

Reductive Silylation of α-Halocarbonyl Compounds.

Silyl enol ethers and silyl ketene acetals are available from $(CO)_5MnSiMe_3$ and aromatic α-halo ketones or α-halo esters bearing simple aromatic and aliphatic substituents (eqs 4 and 5).[2,11] The tolerance of the reaction to more sensitive functionality has not been explored.

(4)

Addition to Aldehydes and Ketones.

The facile addition of $(CO)_5Mn\text{-}SiMe_3$ across the carbonyl of aldehydes and ketones has been observed. The α-siloxymanganese alkyl intermediates may undergo CO insertion under CO pressure to give α-silyloxyacyl complexes, reductive coupling upon heating to give 1,2-diol TMS ethers, or β-hydride elimination to give silyl enol ethers (eq 6).[1,2,7,12] Yields for the first pathway range from 26-72% for a selection of alkyl, aryl, and vinyl aldehydes,[12] and are improved if the reaction is performed in the presence of $(CO)_5MnH$.[1] β-Hydride elimination is rapid for ketones.

Pentachlorophenol

[87-86-5] · C_6HCl_5O · Pentachlorophenol · (MW 266.32)

(coupling reagent in peptide synthesis, to form active esters; a probe in various NQR studies on pentachlorophenol-amine hydrogen bonded complexes;[1] a standard in GC analysis[2]

Physical Data: mp 188-191 °C (anhyd); bp 310 °C; *d* 1.978 g cm^{-3}.

Solubility: sol ether, alcohol, hot benzene, ligroin; insol H_2O.

Form Supplied in: widely commercially available.

Purification: recrystallize from alcohol (monoclinic prisms) or benzene (needles) and vacuum dry.

Handling, Storage, and Precautions: highly toxic and possible teratogen. May be fatal if inhaled, swallowed, or absorbed through the skin. Causes skin and eye irritation and irritation to the mucous lining of respiratory tract. Do not breathe dust; avoid prolonged exposure. Readily absorbed through the skin. Incompatible with strong oxidizing agents, strong bases, acid chlorides, and anhydrides. More basic in organic solvents. Store in a cool dry place. There are concerns as to its environmental chemical effects.[2,3]

Polypeptide Synthesis.

The most important stage in peptide synthesis is the coupling step of one amino acid or peptide to another. Coupling reagents have been proposed following early attempts at coupling because of their inherent convenience. These generally work by peptide bond formation between a carboxyl and an amine component in the presence of a specific condensing or coupling agent. In the late 1950s and early 1960s, considerable effort was made to synthesize polypeptides with a known repeating sequence of amino acids. The problem until then with the more traditional methods[4a,b] (e.g. mixed anhydrides and the ***1,3-Dicyclohexylcarbodiimide*** method) was undesirable side reactions[4] which could lead to early termination of polymerization; in addition, various other methods which avoid this, e.g. thiophenyl and *p*-nitrophenyl esters, may not be used when *N*-protecting groups are removed by catalytic

hydrogenation.[4,5] The use of pentachlorophenyl esters was first fully reported in 1965[6] although there had been brief references to their use before then.[7a,b]

The use of pentachlorophenyl active esters in the synthesis of polypeptides of known repeating amino acid sequence has several advantages:

- 1)Pentachlorophenyl esters work particularly efficiently when coupled with benzyloxycarbonyl and *t*-butyl protecting groups in trifunctional amino acids for polymerization, e.g. a protecting *N*-Cbz group is selectively cleaved by catalytic hydrogenation,[6] leaving pentachlorophenyl and *t*-butyl groups intact. Compare HBr cleavage of the Cbz group which would prevent the use of *t*-butyl groups (*t*-butyl groups are essential when utilizing aspartic or glutamic acids to prevent *trans*-peptidation reactions).
- 2)Pentachlorophenyl esters of both amino acids and peptides tend to be easier to purify since they generally have higher melting points compared to other active esters. This assists in the purification of *C*- or *N*-activated peptide intermediates which must be very pure in polymerization to avoid early termination reactions. Table 1[8] gives some illustrative examples of this, along with melting point values of other active esters for comparison.

Table 1 Peptide Active Esters

Active ester derivative	OC_6Cl_5 mp (°C)	$OC_6H_2Cl_3$ mp (°C)	$OC_6H_4NO_2$ mp (°C)
Cbz-Ala	172-173	104	78
Cbz-Val	144	94	66
Cbz-Gly	185	107-108	128
Cbz-Phe	158	142	126
Cbz-Glu-O-*t*-Bu $NH(CH_2)_2CO_2H$	151	96	56-57

Given these requirements, pentachlorophenyl esters give polypeptides of higher molecular weights than those obtained by other methods, as determined by end-group analysis and viscometry.

Pentachlorophenyl active esters are amongst the most reactive esters, e.g. aminolysis of Cbz-L-phenylalanine pentachlorophenyl ester has a half life of 1.34 min on treatment with benzylamine in dioxane; cf. the half life of the 2,4,5-trichlorophenyl ester which is 4.9 min and the *p*-nitrophenyl ester which is 23.2 min.[8] This short reaction time limits the time available for side reactions to occur during coupling reactions.

The first cited example of pentachlorophenyl esters being utilized was in the synthesis of poly-β-L-aspartic acid.[9] This polymer was required in optically pure form for various chemical, biological, and immunochemical investigations.[10] In summary, the coupling of the amino acid with pentachlorophenol using the DCC method (see below) gives an active ester which polymerizes rapidly in the presence of a tertiary amine to give a poly(amino acid) of higher molecular weight than is obtained using other methods, notably the *p*-nitrophenyl ester.

Another example is the synthesis of poly-β-L- (or -D-) glutamyl-β-alanine[11] (**3**) from the precursor α-*t*-butylglutamyl-β-alanine pentachlorophenyl ester hydrochloride (**2**).

(2)

(3) R = *t*-Bu or H

The precursor (**2**) was prepared according to eq 1. *N*-Benzyloxycarbonyl-α-*t*-butylglutamic acid pentachlorophenyl ester was coupled to the methyl ester of β-alanine to give (**4a**). This was hydrolyzed using NaOH to give the free acid (**4b**) which was subsequently coupled to pentachlorophenol with DCC to give *N*-benzyloxycarbonyl-α-*t*-butylglutamyl-β-alanine pentachlorophenyl ester (**4c**; 60% yield, >97% optically pure). The same method was used to prepare the 2,4,5-trichloro- (**4d**) and *p*-nitrophenyl (**4e**) esters for comparison, but the pentachlorophenyl esters immediately proved easier to purify, for the reasons already described.

Hydrogenation of (**4c**) using 10% ***Palladium on Carbon*** catalyst in the presence of HCl in methanol gave (**2**) in good yield (59%). Polymerization in DMF with an excess of ***Triethylamine*** at the highest possible concentrations gave (**3**) with *t*-Bu protecting groups which were readily removed with 90% ***Trifluoroacetic Acid*** to give the free polypeptide.

There are many other examples of pentachlorophenyl active esters being used in peptide syntheses similar to those described above, but these will not be described in detail here.[8,12a-f]

Very little by way of modification or variation in pentachlorophenyl active ester coupling procedures has occurred; they have mostly found new applications. There is, however, one exception where a different procedure has been used to prepare pentachlorophenyl esters of *N*-protected amino acids.[13] The pentachlorophenyl di- (**5**) or tri- (**6**) chloroacetates (known plant growth regulators) were prepared and subjected to ester exchange reactions with trialkylammonium salts of acylamino acids (**7**) in DMF, rapidly giving good yields of the desired esters (eq 2).

One last novel reaction which may involve pentachlorophenyl esters is the formation of polypeptides and Leuchs' anhydrides from carbamic acid derivatives of *C*-activated amino acids.[14] *C*-Activated *N*-Cbz amino acids (**8**) on catalytic hydrogenation give the carbamic acid derivative (**9**), which cyclizes to the corresponding Leuchs' anhydride (**10**) (eq 3); in some cases this immediately polymerizes to the polypeptide, e.g. the mixed anhydride *N*-Cbz-DL-phenylalanine polymerized to poly-L-phenylalanine via the Leuchs' anhydride.

1,3-Pentadiene

[504-60-9] · C_5H_8 · 1,3-Pentadiene · (MW 68.13) (*cis*)

[1574-41-0] (*trans*)

[2004-70-8]

(widely used diene for Diels-Alder cycloaddition reactions;[1] common ligand in transition metal-pentadienyl complexes[2])

Alternate Name: piperylene.

Physical Data: cis: mp -141 °C; bp 44 °C; *d* 0.691 g cm^{-3}. *trans*: mp -87.5 °C; bp 42 °C; *d* 0.683 g cm^{-3}. Mixture of isomers: bp 42 °C; *d* 0.683 g cm^{-3}.

Solubility: sol alcohol, acetone, ether, benzene, heptane; insol H_2O.

Form Supplied in: widely available as *cis* isomer, *trans* isomer, and as a mixture of isomers.

Purification: colorless liquid distilled from $NaBH_4$; purified by preparative gas chromatography.

Handling, Storage, and Precautions: flammable liquid, irritant.

Diels-Alder Reactions.[1]

The *trans* isomer of piperylene has been widely used in cycloaddition reactions to construct six-membered carbocyclic[3-10] and heterocyclic rings.[11-15] The electron-donating ability of the methyl group causes *trans*-piperylene to be 3-5 times more reactive than ***1,3-Butadiene*** in Diels-Alder reactions with ***Maleic Anhydride*** or ***Tetracyanoethylene*** (TCNE).[3c,4] Unlike *trans*-piperylene, the *cis* isomer is known to be very unreactive except with highly activated dienophiles, and generally undergoes polymerization reactions (eq 1).[3] In reaction with TCNE, *cis*-piperylene has been estimated to be over 10^5 less reactive than the *trans* isomer.[3c] The unfavorable steric interactions between the methyl group and the vinyl hydrogens in the *s-cis* conformation of *cis*-piperylene, required in the transition state for the Diels-Alder, are thought to be responsible for the lower reactivity.[1] Both piperylenes give predominently the *endo* Diels-Alder products.

(1)

X = O	PhH, reflux 30 min	100%	-
X = NPh	PhH, reflux 1 h	100%	-
X = NMe	PhMe, reflux 18 h	87%	-

X = O	Ac_2O, 94-100 °C 8 h	-	4%
X = O	CuCl, NH_4Cl 130 °C, 2 h	9%	49%
X = NPh	CuCl, NH_4Cl 130 °C, 13 h	-	35%

As with other unsymmetrical dienes, the Diels-Alder reactions of piperylene obey the *ortho* rule,[1] which predicts that the electron-donating group will be adjacent (*ortho*) to the electron-withdrawing substituent on the dienophile (eq 2).[5] Similar selectivities are observed for ***Acrylonitrile*** and ***Acrolein***.[1,3] In general, the regio- and endoselectivities are higher at lower reaction temperatures and, especially, in the presence of Lewis acids such as ***Aluminum Chloride***.[6]

(2)

(1) **(2)**

		(1) (*cis*/*trans*):**(2)** (*cis*/*trans*)
R = H	120 °C, 7 h, 52%	89 (64/36):11 (62/38)
R = Me	120 °C, 6 h, 53%	84 (54/46):16 (66/34)
R = Me	25 °C, 70 d, 39%	90 (57/43):10 (73/27)
R = Me	10-20 °C, $AlCl_3$ (cat), 3 h, 50%	98 (95/5) :2 (mostly *cis*)

The reactions with more complex dienophiles have shown similar regio- and endoselectivities.[6] The cycloadditions between *trans*-1,3-pentadiene and substituted quinones give products with high endoselectivity and with expected regiochemistry based on electronic considerations (eqs 3 and 4).[7,8] A remarkable reversal in regioselectivity was achieved for 2,6-dimethylbenzoquinone by using a Lewis acid for the reaction (eq 4).[8] In the cycloadditions with a substituted 2,5-cyclohexadienone, exclusive addition from the ester face was observed (eq 5).[9] Other examples showing endo-, regio-, and facial selectivity are known (eq 6).[10,6]

(3)

(4)

(5)

(6)

The use of 1,3-pentadiene in hetero-Diels-Alder reactions is well precedented.[11] It reacts with carbonyls,[12] imines,[13] nitroso groups,[14] and other heterodienophiles[15] to yield the corresponding heterocycles. For example, the in situ generated sulfonyl imine from propanal can be effectively trapped by 1,3-pentadiene in a [4 + 2] cycloaddition reaction (eq 7).[13a]

More recently, 1,3-pentadiene has been used in asymmetric Diels-Alder reactions, yielding carbocycloadditions[16] and heterocycloadditions.[13] The asymmetry can be induced by a chiral auxiliary on the dienophile (eq 8)[16a] or by a chiral Lewis acid (eq 9).[17]

>100:1 diastereoselection

The rhodium(II)-catalyzed decomposition of vinyldiazomethanes in the presence of *cis*- and *trans*-1,3-pentadienes generates cycloheptadienes with complete stereocontrol (eq 10).[18]

Complexes with Transition Metals.

Many transition metal complexes of 1,3-pentadiene, which coordinates as the pentadienyl ligand, are known. The complexes are generally η^5 (e.g. **3, 4**) or η^3 (e.g. **5-8**).[2] Both modes of coordination are found in compound (**9**).[19]

(3) **(4)** **(5)** **(6)**

(7)

(8)

(9)

While the first complex of a pentadienyl ligand, $Fe(C_5H_7)(CO)_3$, was prepared in 1962 by protonation of the neutral Fe(η^4-pentadienyl)$(CO)_3$,[20] until recently there was little indication that pentadienyl complexes might lead to potentially useful carbon-carbon bond-forming reactions. Recent reports have described the addition of nucleophiles to neutral (η^5-pentadienyl)maganese,[21] -iron, or -ruthenium[19] complexes to generate novel (σ,η^3-pentadienyl) complexes (eq 11).[21] Under photochemical conditions, the tricarbonyl(η^5-pentadienyl)manganese complex reacts with conjugated dienes, such as *trans*- or *cis*-piperylenes, in a formal [4 + 5] cycloaddition to give macrocyclic complexes (eq 12).[22]

Pentadienyllithium[1]

[54962-98-0] · C_5H_7Li · Pentadienyllithium · (MW 74.06)

(pentadienylating agent in substitutions and additions; used to attach pentadienyl groups to other metals and nonmetals)

Physical Data: orange crystals. Solution NMR studies and trapping experiments indicate a predominant planar W shape; pentadienylpotassium prefers a U shape under most conditions and is used when a U shape is desired.[2]

Solubility: usually prepared and used without isolation, in hydrocarbon/ether mixtures.

Preparative Methods: by metalating 1,4-pentadiene with BuLi/THF[3] or Li/amines,[4] or the more readily available ***1,3-Pentadiene*** with Li/amines (best for large scale),[4] or by cleaving alkyl 2,4-pentadienyl ethers with alkyllithiums.[5]

Form Supplied in: prepared in situ and used directly.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas to exclude oxygen and moisture.

Reactions.

Alkylations give mixtures of products from reaction at the central and end carbons.[1] Borylation,[2a,b] silylation,[2c -e,6] and related reactions[6] occur almost exclusively at an end carbon to provide (*E*) derivatives (eq 1; cf. eq 2[2c]). The TMS derivatives thus produced are more selective in their additions to aldehydes and ketones than are the pentadienylmetals.[7] Additions of pentadienyllithium to aldehydes[5] and ketones[8] were found to be reversible, with the product on the left (eq 3) reverting to the thermodynamic product on the right under more vigorous conditions. Pentadienyllithium has been used to make open versions of the well-known cyclopentadienyl transition metal complexes.[1,9]

Related Reagents.

Table 1 lists some useful pentadienyllithium derivatives.[1,10-14] See also ***Allyllithium***, ***Allylmagnesium Bromide***, and ***Crotyllithium***.

Pentafluorophenol

[771-61-9] · C_6HF_5O · Pentafluorophenol · (MW 184.07)

(preparation of pentafluorophenyl active esters for peptide synthesis;[1] formylating agent; preparation of aromatic fluoro derivatives)

Physical Data: white solid, mp 34-36 °C; bp 143 °C; fp >72 °C; n_D 1.4263.

Solubility: sol most organic solvents, particularly aprotic ones.

Form Supplied in: available commercially.

Handling, Storage, and Precautions: toxic and irritant. Harmful if swallowed, inhaled, or absorbed through the skin. Incompatible with strong oxidizing agents, bases, acid chlorides, and anhydrides. Keep away from heat and naked flames: combustible solid/liquid. Store in a cool, dry place.

Use in Peptide Synthesis.

Solution Techniques.

Simple alkyl esters of amino acids (which may be protected) undergo aminolysis at a rate too slow for peptide bond synthesis. Phenyl esters are more reactive and, if electronegative substituents are present on the ring, may undergo aminolysis at rates similar to those of anhydrides. The overriding requirements in peptide bond formation are efficiency and freedom from side reactions. Esters of pentafluorophenol have found wide application in the synthesis of peptides (cf. ***Pentachlorophenol***).[1a-c] Pentafluorophenol (**1**) serves as a coupling reagent, i.e. a compound added to a mixture of carboxyl and amino components to promote condensation. However it is very difficult to find efficient coupling reagents which do not give undesirable side reactions. Kinetic studies have shown the superiority of pentafluorophenyl esters compared to other coupling reagents with respect to speed of coupling (and thus lowering or eliminating undesirable reactions, e.g. α-hydrogen abstraction leading to racemization).[2a,b] Relative rates are OPFP >> OPCP > ONp, corresponding to 111:3.4:1, where PFP = pentafluorophenyl; PCP = pentachlorophenyl; Np = nitrophenyl.

Pentafluorophenyl esters have been used in both solution and solid phase peptide syntheses, the difference being that solid phase synthesis involves linking the peptide to a solid support (see below), whilst solution techniques involve just one phase. There are many examples of pentafluorophenyl esters being used in peptide synthesis,[1a,3a-e] e.g. the peptide sequence *t*-Boc-Phe-Pro-Pro-Phe-Phe-Val-Pro-Pro-Ala-Phe-OMe[3a] and the alkaloid peptide (**2**)[3b] have been synthesized by these methods.

(2)

More recently, the base labile 9-fluorenylmethoxycarbonyl (Fmoc) group has become well established in peptide synthesis for the protection of amino functionalities.[4,5] The problem associated with this group is cleavage of the Fmoc group by the free amino component to be acylated, which results in double acylations. The principal method of avoiding this now is to use the Fmoc group in association with highly reactive pentafluorophenyl esters to greatly increase the rate of coupling compared with the undesirable reactions. Formation of these esters is shown in eq 1.[4]

(1)

For example, this methodology was first used in the synthesis of Fmoc-glycyl-L-tryptophyl-L-leucyl-L-aspartyl-L-phenylalaninamide (Fmoc-Gly-Trp-Leu-Asp-Phe-NH_2) with the isolation of all pentafluorophenyl ester intermediates in excellent yields (75-99%); the coupled amino acids were subsequently prepared stepwise, again in very good yields, with the minimum of undesirable side reactions.[4]

This method has since been modified and improved further by utilizing 9-fluorenylmethyl pentafluorophenyl carbonate (eq 2).[5a]

There is a newer alternative method of synthesizing Fmoc-protected pentafluorophenyl ester amino acids employing pentafluorophenyl trifluoroacetate (**3**).[5b]

(3)

Table 1 gives some typical examples of the *N*-9-Fluorenylmethoxycarbonyl (Fmoc) amino acids and their pentafluorophenyl (PFP) esters which have been prepared by these methods.[4,6,7] The physical data are in agreement with either preparative method, and with early preparations of these compounds.[4,5a,b]

Table 1 Examples of Fmoc-Protected Amino Acids and their Pentafluorophenyl (PFP) Esters

Amino acid	Fmoc derivative mp (°C)	Fmoc derivative yield (%)	Fmoc amino acid PFP ester mp (°C)	Fmoc amino acid PFP ester yield (%)	Ref.

Ser (*t*-Bu)			67 71	67	4, 7

Solid Phase Peptide Synthesis (SPPS).

Pentafluorophenyl esters have been used in both solution and solid phase peptide synthesis. So far, only solution methods have been considered. The principal of SPPS is incorporation of single amino acid residues into peptide chains built on insoluble polymeric supports. The famous Merrifield paper[8] started the tradition of SPPS using *t*-butoxycarbonyl (Boc) amino acids activated with ***1,3-Dicyclohexylcarbodiimide***, although this has now been superseded with the introduction of the Fmoc group in polystyrene- and polyamide-based SPPS. The theory of SPPS will not be discussed here. Needless to say, the use of pentafluorophenyl esters in SPPS was inevitable and was first reported by Atherton in 1985.[9] Fmoc-amino acid pentafluorophenyl active esters were used in the polyamide solid phase series in polar DMF solutions in the presence of ***1-Hydroxybenzotriazole*** as a catalyst.

The preparation of the decapeptide H-Val-Gln-Ala-Ile-Asp-Tyr-Ile-Asn-Gly-OH (**4**) will be used as an example of pentafluorophenyl esters in SPPS.[9,10] This is a good example to use since it contains normal, sterically hindered, and functionalized amino acids. All Fmoc-pentafluorophenyl esters were prepared by the method of Kisfaludy and Schön already described.[4,5] Beaded polymethylacrylamide gel resin was used as the solid phase with fivefold excesses of the pentafluorophenyl esters dissolved in a minimum of DMF. The resin was first functionalized with a reference norleucine residue and then with an acid-labile linkage agent (**5**).

(5) R = 2,4,5-$Cl_3C_6H_2O$

Esterification of the first residue, glycine, to the free OH used the symmetrical anhydride/***4-Dimethylaminopyridine*** procedure.[11] The subsequent peptides were all coupled using standard techniques like those already described above and are fully documented. Slightly varying conditions and catalysts were required for some of the amino acids.[10] After addition of the last amino acid, the final Fmoc group was cleaved and the complete decapeptide detached from the support resin using 95% aqueous ***Trifluoroacetic Acid***. Side chain protecting groups were also cleaved simultaneously. Crude peptide analysis was achieved by HPLC and showed the samples obtained by this method to be extremely pure.

More recently, SPPS has also been employed in glycopeptide synthesis.[12] There is an excellent review of active esters in SPPS, including pentafluorophenyl esters.[13]

A New and Efficient Derivative of Pentafluorophenol.[14]

Pentafluorophenol has found many applications in both solution and solid phase peptide syntheses. Diphenylphosphinic mixed anhydrides are also well known in peptide chemistry. A new and efficient reagent has been prepared from these precursors: pentafluorophenyl diphenylphosphinate (FDPP; **6**) which can be used directly as a coupling reagent without side reactions. FDPP is prepared from mixing equimolar amounts of ***Diphenylphosphinic Chloride***, pentafluorophenol (**1**), and ***Imidazole*** in CH_2Cl_2 at room temperature (eq 3).[14]

FDPP may be kept refrigerated for several months and is used as an efficient coupling reagent, by simply mixing the carbonyl and amine components with a tertiary amine and FDPP in an organic solvent, of which DMF was found to be the most efficient (eq 4).

FDPP has been used in both solid and solution peptide syntheses and analysis has shown it to have the lowest rate of racemization of any of the common coupling reagents.[14]

Comparison of Pentafluorophenyl Active Esters with Pentachlorophenyl Esters.[15]

It is interesting to compare these two compounds with respect to active ester formation since they are very closely related and both have been employed in both liquid and solid phase peptide syntheses (see ***Pentachlorophenol***). Pentachlorophenyl esters generally have higher melting points, which can be of advantage if crystallization is difficult or a compound is of low melting point, e.g. for serine and threonine the oily pentafluorophenyl esters are usually replaced by the pentachlorophenyl esters.

As already mentioned, pentafluorophenyl derivatives are much more reactive than pentachlorophenyl ones. The reason for this is still not clear. Many calculations have been performed on the net atomic energies of these esters and show that there is no significant difference between the environment of the electrophilic center in OPFP esters compared to OPCP ones. Analysis of the carbonyl stretching frequencies of these compounds is quite revealing (Table 2), i.e. there is no significant difference in the carbonyl stretching frequencies of these functionalized esters. This, plus additional evidence from MM

calculations and NMR studies, suggests that electronic factors do not play a significant role in determining the reactivity of these esters.

Table 2 IR Stretching Frequencies of Carbonyl Groups in Pentachlorophenyl (OPCP) and Pentafluorophenyl (OPFP) Active Esters[a]

Amino acid	OPCP	OPFP	Δn
Z Gly	1794	1800	6
Boc Val	1782	1788	6
Boc Phe	1784	1790	6
Boc Tyr(*t*-Bu)	1786	1794	8
Z Cys(Bn)	1784	1794	10

[a] In $CHCl_3$; in cm^{-1}.

There is however, an important steric effect, as would be expected given the differing sizes of the halogens involved (van der Waals atomic radii = 1.75 Å for Cl and 1.47 Å for F). X-ray crystal analysis is interesting in that it shows there is no intramolecular interaction in OPFP esters and the structure is an extended conformation. The main interaction is the strong dipole-dipole of a negative fluorine to a positive carbon of another PFP ring in a neighboring molecule. CO...NH interactions appear to be only minor in comparison and the carbonyl group and PFP ring are almost perpendicular. Studies have shown that the same conformation applies whether in solid or solution.

One of the explanations offered for the high reactivity of the OPFP ester is neighboring group participation of an *ortho* fluorine atom in accelerating the collapse of a tetrahedral intermediate transition state, i.e. anchimeric acceleration. This would explain the low solvent effect on aminolysis rates, the high second-order rate constant, and unaffected third-order rate constant. Pentahalogen esters fall midway between quinol-8-yl esters, where there is definite participation, and nitrophenol esters where there is none (from studies on the model system of phenyl acetates and piperidine).[15] The PFP ester shows greater interaction than the PCP ester. There are other possible explanations: this could still be explained in steric terms, or by the high solvation of the leaving group (pentafluorophenol is much more soluble and reactive in aprotic solvents than pentachlorophenol).

Formylation Reactions.[16]

The problem with ***Acetic Formic Anhydride***, the most commonly used formylating agent, is undesirable side reactions, particularly if there are acid sensitive functionalities in the compound. One of the best alternatives is to use pentafluorophenyl formate (**7**), an easily prepared and stable compound which reacts with N-nucleophiles in minutes at

room temperature to yield the *N*-formyl derivative (eq 5) (Table 3). Significantly, no reaction occurs with alcohols, thiols, or sterically hindered amines.

Table 3 Examples of *N*-Formylamines Prepared from Primary Amines and Pentafluorophenyl Esters

Amine	Solvent	Yield (%)	mp (°C)	R_f
Aniline	$CHCl_3$	90	48	0.6[a]
2-Aminobiphenyl	$CHCl_3$	99	67 70	0.6[a]
Benzylamine	$CHCl_3$	90	62 63	0.35[a]
H Met Leu Phe OMe	$CHCl_3$	93	135 136	0.4[b]

[a] Chloroform methanol (9:1). [b] Ethyl acetate.

Preparation of Aromatic Fluoro Derivatives.

Reaction of (**1**) with VF_2, VF_4, ***Vanadyl Trifluoride***, or ***Xenon(II) Fluoride*** in HF, $CFCl_3$, or MeCN at -30 to 20 °C yields mixtures of perfluoro-2,5-cyclohexadien-1-one together with its 2- and 4-pentafluorophenoxy derivatives and/or perfluoro-6-phenoxy-2,4-cyclohexadien-1-one, along with traces of perfluoro-2-cyclohexen-1-one or perfluoro-*p*-benzoquinone. Using ***Antimony(V) Fluoride*** or NbF_4, however, only gives stable complexes or pentafluorophenolates.[17]

Pentafluorophenol (**1**) reacts with ***Phosphorus(V) Chloride*** in the presence of a base, triethylamine or γ-collidine, to yield perfluoropentaphenoxyphosphorane (**8**) plus perfluorotriphenyl phosphate (**9**) and perfluorodiphenyl ether (**10**) (eq 6).[18]

This reaction has also been used to prepare pentafluorothiophenol phosphorus derivatives. These compounds have been utilized in ^{31}P, ^{19}F, and ^{1}H variable temperature NMR studies on intramolecular ligand rearrangement processes in phosphorus compounds.[18]

The preparation and reactions of Polyfluoroaromatics, including pentafluorophenol derivatives, have been studied by various Russian workers, who have also evaluated the pentafluorophenoxy group as a leaving group (eq 7).[19a]

The main product of the reaction was the 4-substituted tetrafluoropyridine, although varying yields of the 2-, 2,6- and 2,4,6-pentafluorophenoxypyridines were obtained depending on the ratios of (**11**):(**1**) and also on the levels of ***Potassium Fluoride***, ***18-Crown-6***, the reaction temperature, and solvent. This reaction has been studied in comparison with 4-$NO_2C_6H_4$ (which is of similar basicity) and in competition with F^- anions.

More recently it has been shown that the substitution reaction of pentafluoropyridine with (**1**) in the presence of ***Cesium Fluoride***/graphite gave much better yields of (**12**), but still with traces of the other products. The catalyst activity was found to increase in the order: NaF < KF < RbF < CsF and was similar for the free fluorides and their graphite-supported analogs.[19b]

1,1,2,3,3-Pentaisopropylguanidine

[81236-11-5] · $C_{16}H_{35}N_3$ · 1,1,2,3,3-Pentaisopropylguanidine · (MW 269.54)

(hindered amine base; used in oxidations of ketone hydrazones, and in eliminations of hydrogen iodide and *p*-toluenesulfonic acid)

Preparative Method: the reagent is not commercially available, but is easily prepared in two steps. First, ***Thiophosgene*** is slowly added to ***Diisopropylamine*** to give *N,N,N´,N´*-tetraisopropylthiourea, as a pale yellow liquid, in 44% yield. A Vilsmeier salt is then formed from the reaction of tetraisopropylthiourea with ***Phosgene***, and subsequently treated with isopropylamine to give 1,1,2,3,3-pentaisopropylguanidine (69% yield) as a liquid, bp 60 °C/0.01 mmHg (eq 1).[1] The compound solidifies on storing at -20 °C under argon.

Handling, Storage, and Precautions: Use in a fume hood.

Oxidation of Ketone Hydrazones.

Ketone hydrazones are oxidized to vinyl iodides when treated with ***Iodine*** in the presence of a base. Yields of vinyl iodides improve significantly with the use of strong guanidine bases under anhydrous conditions (eq 2).[2]

(2)

Conditions	base	Yield (%) vinyl iodide
A	Et_3N	38
A		78
B		87
B		89
A		78

A. Normal addition: iodine solution was added to a solution of base and hydrazone at room temperature.
B. Inverse addition: hydrazone solution was added to a mixture of base and iodine.

Eliminations.

The base-induced elimination of hydrogen iodide from β-iodo-α,β-unsaturated ester (**1**) is effected by reaction with

pentaisopropylguanidine in methylene chloride at -35 °C to give alkynic ester (**2**) in 70% yield (eq 3).[3] Likewise, reaction of β-iodo-α,β-unsaturated ester (**3**) with pentaisopropylguanidine in chloroform at -30 °C affords alkynic ester (**4**) in 69% yield (eq 4).[4]

(3)

(1) (2)

(4)

(3) (4)

Pentaisopropylguanidine is also used in the elimination of sulfonic acids from the corresponding esters to afford alkenes. For example, heating cholestan-3β-yl *p*-toluenesulfonate (**5**) with pentaisopropylguanidine at 120 °C for 26 h gives a mixture of cholest-2-ene (**6**) and cholest-3-ene (**7**) in 85% yield (eq 5).[1] This compares favorably with the literature method involving ***2,4,6-Collidine*** (170 °C, 6 h, 63% yield).[5] The same reaction performed using ***1,5-Diazabicyclo[4.3.0]non-5-ene*** (DBN) only gives 31% of the mixed alkenes but at a lower temperature (80-90 °C).

Related Reagents.

1,1,3,3-Tetramethylguanidine.

N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine

[3030-47-5] · $C_9H_{23}N_3$ · *N,N,N´,N´´,N´´*-Pentamethyldiethylenetriamine · (MW 173.35)

(ligand for lithium which enhances the reactivity of organolithium compounds)

Alternate Names: PMDTA; PMDETA.

Physical Data: mp -20 °C; bp 198 °C; *d* 0.830 g cm^{-3}; n_D 1.4420.

Solubility: sl sol H_2O; sol ethanol, acetone, ethers, alkanes.

Form Supplied in: liquid; widely available. *Drying:* distilled from CaH_2 at 10 mmHg, then stored under N_2 or argon in the absence of moisture and oxygen.

Handling, Storage, and Precautions: use in a fume hood.

N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine forms monomeric complexes with several organolithium compounds[1a-e] in which lithium is tridentately coordinated to PMDTA as determined by ^{13}C NMR (**1a**[1] and **1b**[2]) and X-ray crystallography (**1c**,[3] **1d**,[4] and **1e**[5]) and the interesting chloride-bridged monocation in salt (**2**).[6]

(1)

(PMDTA)Li--Cl--Li(PMDTA)$^+$ LiC(TMS)$_2$

(2)

(1a) R = neopentyl
(1b) R = 2,4,6-tri-*t*-butylphenyl
(1c) R = TMSCH
(1d) R = η^3-allyl
(1e) R = phenyl

Allylamine (**3**) undergoes, in diethyl ether, metalation at the vinyl carbon (to form **4**), whereas in the presence of PMDTA, metalation takes place at the allylic carbon (to form **5**). The dilithium species react with electrophiles (eq 1) in the expected fashion.[7]

Reagent	E	Et_2O (6c)	PMDTA + Et_2O (7a)	(7b)	(7c)
D_2O	D	92	94	80	65
Bu_3SnCl	Bu_3Sn	90	72	70	63
PhCHO	PhCHOH	78	-	-	57

The metalation of *o*- and *p*-fluoroanisole also shows dramatic changes in regiochemistry (eqs 2 and 3). With PMDTA, complete metalation *ortho* to fluoro was observed; in its absence, metalation occurred *ortho* to the methoxy group.[7]

Cosolvent		
none	100:0	50%
PMDTA	0:100	85%

Cosolvent		
none	100:0	50%
PMDTA	0:100	77%

Metalation of PMDTA by *s*-BuLi in cyclohexane at 25 °C yields a mixture of the two lithiomethyl compounds (**8**) and (**9**) in ratio of 98:2, as indicated by NMR and the products of reactions (**10** and **11**) with electrophiles (eq 4).[8] Products (**10**) and (**11**) were not separated.

(4)

Electrophile	E
Me_3SnCl	Me_3Sn
PhCHO	PhCHOH

In hydrocarbon and benzene solution, the 1-lithiomethyl derivative of PMDTA, (**8**) has been shown, from NMR studies, to form two monomeric species in which lithium is tridentately coordinated.[9] NMR lineshape analysis reveals Δ*H*&DDagger; for interconversion of the two monomers (A &ibond; B) to be 10.3 ± 1 kcal mol^{-1} with Δ*S*&DDagger; = -27 ± 1 cal K^{-1} mol^{-1}.[9]

A variety of substituted 5-hexen-yllithiums (e.g. **12**) are formed from the corresponding iodides (**13**) by halogen lithium exchange using ***t-Butyllithium***.[10] These compounds cyclize to the cyclopentylmethyllithiums (**14**) on warming to 20 °C in the presence of different lithium ligands such as THF, ***N,N,N´,N´-Tetramethylethylenediamine***, and PMDTA (eq 5).[10] The reaction is totally regiospecific and more stereospecific than the analogous radical-mediated cyclization which forms the same products.

Product distribution from electrogenerated (magnesium anode) nickel(0)-catalyzed ***Carbon Dioxide*** incorporation into α,o-diynes (**16**) is influenced by the nature of the ligands L used (eq 6).[11] With L = PMDTA at 65 °C the ratio of (**17**):(**18**) is 80:20, whereas using TMEDA the ratio is 50:15; with bipy a 5:95 (**17**):(**18**) ratio was obtained.

Related Reagents.

N,N´-Dimethylpropyleneurea; ***Hexamethylphosphoric Triamide***; ***N,N,N´,N´-Tetramethylethylenediamine***.

(2*R*,4*R*)-2,4-Pentanediol[1]

[42075-32-1] · $C_5H_{12}O_2$ · (2*R*,4*R*)-2,4-Pentanediol · (MW 104.17)

(diol used for the preparation of chiral acetals[1])

Physical Data: mp 48-50 °C; bp 111-113 °C/19 mmHg.

Form Supplied in: white solid; widely available.

Preparative Methods: via asymmetric hydrogenation of ***2,4-Pentanedione***.[2] Its enantiomer *[72345-23-4]* is also available by the same method.

Purification: recrystallization from ether.

Handling, Storage, and Precautions: should be stored in a tightly closed container since it is hygroscopic.

Cleavage of Acetals.

Acetals of 2,4-pentanediol are easily prepared from aldehydes via standard procedures (e.g. cat. PPTS, PhH, Dean-Stark removal of H_2O). These acetals have been cleaved with a variety of nucleophiles in the presence of Lewis acids to yield hydroxy ethers with high (typically 90-95% de) diastereoselectivities. Oxidation and β-elimination then provides enantiomerically enriched alcohols (eq 1). Nucleophiles have included allylsilanes to produce homoallylic alcohols,[3] alkynylsilanes to give propargylic alcohols,[4] Me_3SiCN to provide (after hydrolysis) α-hydroxy acids,[5] and enol silyl ethers, α-silyl ketones, or silyl ketene acetals to yield aldol-type products.[6] The same strategy using organometallic reagents/Lewis acid combinations (e.g. $RCu/BF_3.OEt_2$,[7] $RMgX/TiCl_4$,[8] $RLi/TiCl_4$,[8,9] $R_2Zn/TiCl_4$[9]) is a general route to secondary alcohols. Other nucleophile/Lewis acid combinations that have been used include alkynylstannanes/$TiCl_4$[10] and zinc enolates/$TiCl_4$.[11] These acetals have also been used in polyene cyclizations.[3a,12]

(2R,4R)-2,4-Pentanediol

2,4-Pentanediol is often superior to other diols such as 2,3-butanediol for these reactions because of higher distereoselectivities in reactions with nucleophiles and the more facile cleavage of the resulting hydroxy ether by oxidation-β-elimination.[3] Removal of the chiral auxiliary is usually carried out with ***Pyridinium Chlorochromate*** oxidation followed by β-elimination using KOH,[3] K_2CO_3,[13] piperidinium acetate,[6] dibenzylammonium trifluoroacetate,[14] or DBU.[4c] In some cases, 1,3-butanediol is preferred because the final β-elimination may be effected under milder conditions.[14]

A detailed study of the mechanism and origin of stereoselectivity in reactions of allyltrimethylsilane with dioxane acetals has been published.[15]

Reduction of Acetals.

Reductions of acetals of 2,4-pentanediol can provide (after removal of the chiral auxiliary by oxidation and β elimination) secondary alcohols with good enantioselectivity. The choice of reagents dictates the configuration of the final product. Use of ***Dibromoalane*** gives products from selective *syn* cleavage of the acetal while ***Triethylsilane/Titanium(IV) Chloride*** gives the more usual *anti* cleavage products (eq 2).[13]

Elimination of Acetals.

Treatment of 2,4-pentanediol acetals of *meso* ketones with ***Triisobutylaluminum*** gives enol ethers with high diastereoselectivities (eq 3).[16]

(3)

Acetals as Chiral Auxiliaries.

There have been many applications of acetals of 2,4-pentanediol as chiral auxiliaries to control the diastereoselectivity of reactions on another functional group.[1] Examples include cyclopropanation of alkenyl dioxanes,[17] lithium amide-mediated isomerization of epoxides to allylic alcohols,[18] and addition of dioxane-substituted Grignard reagents[19] or organolithiums[20] to aldehydes.

Other Uses.

Acetals of 2,4-pentanediol have also been prepared in order to determine the enantiomeric purity of aldehydes and ketones by analysis of diastereomers by GC or NMR.[21] ***2,3-Butanediol***[22] is more commonly used for this purpose but has been shown to be less effective in some cases.

2,4-Pentanedione

(keto)

[123-54-6] · $C_5H_8O_2$ · 2,4-Pentanedione · (MW 100.13) (enol)

[1522-20-9]

(carbon-carbon condensations involving mono-, di-, and trianions; formation of pyrazoles, isoxazoles, pyrroles, and pyridines; catalysis by metal chelates)

Alternate Names: acetylacetone; acac.

Physical Data: liquid, bp 45 °C/30 mmHg;[26] *d* 0.975 g cm^{-3}. Keto form: mp -23 °C; bp 134-136 °C.[24] Enol form: mp -9 °C.[24]

Solubility: misc organic solvents; sol dil HCl; slightly sol hot H_2O.[24]

Form Supplied in: commercially available liquid, in which the enol form predominates; the keto form predominates in aq soln.

Preparative Methods: conveniently prepared by BF_3-catalyzed reaction of acetone and acetic anhydride, or by reaction of ethyl acetate, acetone, and NaOEt.[25]

Purification: distillation after drying over anhyd K_2CO_3; several other methods are available.[26]

Handling, Storage, and Precautions: moderately toxic; reactions should be conducted in a well-ventilated fume hood.

General Considerations.

2,4-Pentanedione (**1**) is weakly acidic (pK_a &AApprox; 9) and exists as a solvent-dependent tautomeric mixture. The enol form is favored by aprotic organic solvents, being stabilized by internal hydrogen bonding. Reactions of (**1**) involve (i) reactions of electrophiles at the 3-position via the enolate anion (eq 1), (ii) reactions at the terminal methyl

position via the 1,3-dianion (eq 1), (iii) reactions at the terminal position via the 1,3,5-trianion, and (iv) nucleophilic attack on the carbonyl groups, often to form heterocyclic compounds.

Alkylations of monoanions of (**1**) and homologs can occur on either carbon or oxygen, the site of reaction depending on alkylating agent, counterion, and solvent.[1] Dialkylation can be a serious complication. The highly toxic Tl^{I} chelates were reported to be effective for alkylation,[2] but claims for carbon specificity with alkyl halides other than MeI have been disputed.[3] Preferable counterions for *C*-alkylation include Ni^{II} [4] and R_4N^+.[5] Alkylations carried out with K_2CO_3 in EtOH lead to the corresponding alkylated ketones via retro-Claisen reactions of the alkylated diketone.[6] For arylations, $S_{RN}1$ processes have been observed in a few cases, but the processes are by no means general.[7]

Other widely used reactions[1] involving the monoanions of (**1**) and homologs include conjugate additions (Michael reactions) to α,β-unsaturated compounds,[8] and aldol[9] and Knoevenagel[10] reactions with carbonyl compounds. The Knoevenagel reactions employ secondary amine catalysts and are likely to involve iminium ion and/or enamine intermediates. Enol esters of (**1**) are produced by treatment with acid chlorides in pyridine.[11]

The reagent can be converted to the 1,3-dianion by treatment with alkali amides in liquid ammonia or ***Lithium Diisopropylamide*** in THF.[12] The dianion undergoes reaction exclusively at the 1-position and is markedly more reactive than the monoanion. Reactions of the dianion include alkylation, arylation by benzyne and radical pathways, aldol condensations, conjugate additions, acylations, and carboxylation.[12] Condensations with aliphatic carbonyl compounds subject to ionization are best carried out with dilithio-(**1**). Dianions of higher aliphatic homologs of (**1**) form preferentially at the less-branched sites. Acylations of (**1**) and benzoylacetone by aromatic esters to give 1,3,5-triketones can also be achieved using ***Sodium Hydride*** as the ionizing base; the reactions may not involve dianions.[13] Other types of electrophiles have given fair to poor results in the NaH system. The strongly basic 1,3,5-trianion has been prepared; only limited studies of its reactivity have been made.[14]

Heterocycles.

The difunctionality of 2,4-pentanedione has frequently been used in the synthesis of heterocyclic compounds. Examples include reactions to form pyrazoles, isoxazoles, pyrroles, and pyridines.[15]

Transition Metal Chelates.

Metals form highly crystalline chelated complexes with (**1**), some of which have useful applications as synthetic reagents. ***Copper(II) Acetylacetonate*** modifies the reactivity of carbenes generated from diazo compounds.[16] Reactions appear to involve copper-carbene complexes. For example, it stabilizes benzoylcarbene sufficiently to permit 1,3-dipolar additions and catalyzes intramolecular dimerization of 1,7-bis(diazo)-1,6-heptanediones to cyclohept-2-ene-1,4-diones. ***Tris(acetylacetonato)iron(III)*** catalyzes reductive decyanation of alkyl nitriles by sodium and epoxidations of alkenes by H_2O_2 in MeCN.[17] ***Manganese(III) Acetylacetonate*** oxidizes phenols to dimers without formation of quinones.[18] ***Nickel(II) Acetylacetonate***, a cancer suspect agent, is a highly effective catalyst for addition of β-diketones to Michael acceptors; it catalyzes coupling of aryl Grignard reagents with aryl iodides, and in the Wilke catalytic system ($Ni(acac)_2$-PPh_3-$AlEt_3$) it alters the regiochemistry of some Diels-Alder reactions between dienes.[19,20] The pyridine complex of ***Palladium(II) Acetylacetonate*** is a homogeneous catalyst for reduction of nitrobenzene.[20,21] ***Vanadyl Bis(acetylacetonate)*** catalyzes oxidation by ***t-Butyl Hydroperoxide*** of tertiary amines to *N*-oxides, alkenes to epoxides, and aniline to nitrobenzene.[22] Organoboranes require addition of ***Bis(acetylacetonato)zinc(II)*** to achieve Pd-catalyzed cross-coupling with aryl and benzyl halides.[23] $Zr(acac)_4$ *[17501-44-9]* catalyzes acylation of amines, thiols, and alcohols (primary > phenol > secondary) by 3-acyl-2-oxazolones.[24]

trans-3-Penten-2-one

[3102-33-8] · C_5H_8O · *trans*-3-Penten-2-one · (MW 84.13)

(undergoes conjugate addition as in Michael[1-3] and cuprate[4] reactions; reagent for Robinson annulation[5-11] and Diels-Alder[12] reaction)

Physical Data: bp 121.5-124 °C; *d*204 0.8624 g cm^{-3}; *n*25D 1.4329.

Solubility: sol water and all organic solvents.

Form Supplied in: liquid; commercial material is often contaminated with 3-penten-2-ol which is difficult to remove by distillation.

Analysis of Reagent Purity: IR, NMR, and GC.[13]

Preparative Methods: an excellent method[14] involves the Wittig reaction of ***Acetylmethylenetriphenylphosphorane*** and ***Acetaldehyde*** (2.5 mol equiv) in methylene chloride (reflux, 6 h, 76% yield). Another good method[13] proceeds via the ***Aluminum Chloride*** catalyzed addition of ***Acetyl Chloride*** to propene followed by dehydrochlorination.

Purification: fractional distillation.[13,14]

Handling, Storage, and Precautions: best stored in refrigerator; moderately toxic;[15] lachrymator. This reagent should only be handled in a fume hood.

Conjugate Addition Reactions.

Enolates of esters,[1] amides,[2] ketones (eq 1),[1] and organocuprates[4] participate in conjugate addition reactions with *trans*-3-penten-2-one.

(1)

Basic conditions can be avoided by using the Lewis acid-catalyzed Michael reaction of enol silyl ethers with the reagent (eq 2).[3]

(2)

Robinson Annulation.

An important application of *trans*-3-penten-2-one is in the Robinson annulation reaction,[5-11] which has been widely used for the synthesis of natural products such as eremophilane sesquiterpenes.[5-7] Annulations involving this enone have been involved as key steps (eqs 3 and 4) in the total synthesis of isonootkatone[5] and calarene.[6]

(3)

trans-3-Penten-2-one

(4)

The steric outcome of these reactions is very dependent on the reaction conditions.[5-9] In eq 4 the use of benzene as solvent gave a 10:1 ratio of the *trans*- and *cis*-dimethyl products while formamide gave a 1:1 ratio. Likewise, reaction of 2-methylcyclohexanone and *trans*-3-penten-2-one using ***Sodium Hydride*** in dioxane gave the *cis*-dimethyl product (eq 5), but DMSO gave the *trans* product.[8] However, other workers reexamined this work and observed somewhat different yields and stereoselectivities.[9]

(5)

A variation of the Robinson annulation involves the Lewis acid-catalyzed reaction of a silyl enol ether with the enone (eq 6).[11]

1-Pentynylcopper(I)[1]

[19093-51-7] · C_5H_7Cu · 1-Pentynylcopper(I) · (MW 130.67)

(coupling agent for delivery of PrC&tbond;C group;[2] formation of mixed lithium cuprates[3])

Physical Data: canary yellow polymeric solid.[4,5]

Solubility: sol pyridine (10^{-5} M, 25 °C); slightly sol ether, THF; insol DMF, water.

Preparative Methods: an aqueous ammoniacal solution of ***Copper(I) Iodide*** is added to 1-pentyne in ethanol, and the resulting precipitate is filtered and washed.[5,6]

Purification: can be dried under vacuum (20 mmHg) at 50 °C; traces of unremoved ammonia impart a greenish-yellow color.[5]

Handling, Storage, and Precautions: all copper(I) acetylides are potentially explosive when dry and should be treated with due caution. Use in a fume hood.

Copper(I) Substitutions.

Mild substitutions of acyl and sulfenyl halides can be accomplished with high efficiency (eqs 1 and 2).[7] Thermolysis is either carried out neat or in acetonitrile solution.

(1)

(2)

R = Me 75%
R = $PhCH_2CH_2$ 81%

Halides that are prone to homolytic scission, however, instead of yielding substitution products give rise to acetylenic oxidative coupling products.[7] Addition of pentynylcopper to aryl iodides results in formation of coupled tolanes; *ortho*-amino substituted tolanes can be thermolyzed to give a range of 2-propyl indoles in good yield (eq 3).[2,5,7] The cyclizations, which can be carried out either neat or in refluxing pyridine, cyclohexane or DMF, can be catalyzed by copper(I) iodide or a range of salts including HgI_2, $AgNO_3$, Hg_2Cl_2, $PdCl_2$, and $PtCl_2$.[7]

(3)

55-100%

A similar protocol has been used to convert substituted *o*-bromophenols into the corresponding 2-propylbenzofurans (eq 4).[2] In this series it is not possible to isolate the intermediate tolanes.

(4)

Intramolecular additions to tolanes can be effected by other groups, including carboxylic acids, yielding isocoumarins and benzylidenephthalides (eq 5). The yields of such bicyclic adducts are very dependent on both the conditions used and ring size. Intramolecular cyclization of the tolane derived from addition to *o*-iodobenzyl alcohol gives a 50% yield of the corresponding dihydrobenzopyran bearing an *n*-propyl substituent. However, reaction of pentynylcopper with *o*-iodophenethyl alcohol results in formation of dihydrobenzofuran and 1-pentyne in 79% yield.[7]

(5)

Pentynylcopper has been employed to effect coupling to acetylenic halides. Treatment with bromoethynyltrimethylsilane in pyridine at room temperature results in a near-quantitative yield of 1-trimethylsilyl-1,3-heptadiyne (eq 6).[8]

(6)

Mixed Organocuprates.

Mixed organocuprates derived from addition of the copper acetylide to vinyllithium reagents can be used to selectively transfer the vinylic group to a suitable electrophile (eq 7).[9] In this manner the pentynyl group behaves as a nontransferable dummy ligand.[3] The solubility of pentynylcopper in ether and THF is increased on addition of HMPA; thus the complex is more versatile for use in the preparation of mixed lithioorganocuprates for selective ligand transfer (see ***1-Pentynylcopper(I)-Hexamethylphosphorous Triamide***).[3]

(7)

Dilithium Trialkynylcuprates.

Dilithium tris(1-pentynyl)cuprate, prepared by addition of pentynyllithium to copper iodide, adds to α,β-unsaturated systems with 1,2-chemoselectivity (eq 8).[10] The additions, which are best effected in the presence of HMPA, are effective in cyclohexenone and cyclopentenone systems, and tolerate β-substitution on the enone.[10] As an example of its utility, oxidative rearrangement of the product of addition to 2-allylcyclopent-2-enone gives access to a possible prostaglandin precursor (eq 8).

Related Reagents.

Dilithium Tris(1-pentynyl)cuprate; ***1-Hexynylcopper(I)***; ***Lithium (1-Hexynyl)(2-tri-n-butylstannylvinyl)cuprate***; ***Lithium (1-Pentynyl)(2-tri-n-butylstannylvinyl)cuprate***.

1-Pentynylcopper(I)-Hexamethylphosphorous Triamide[1]

[67840-54-4] · $C_{17}H_{43}CuN_6P_2$ · 1-Pentynylcopper(I)-Hexamethylphosphorous Triamide · (MW 457.15)

(freely soluble, nontransferable dummy ligand employed in mixed lithioorganocuprates[2])

Physical Data: clear solution in ether (also see entries for ***1-Pentynylcopper(I)*** and ***Hexamethylphosphorous Triamide***).

Solubility: sol ether, THF at -78 °C.

Preparative Methods: addition of $P(NMe_2)_3$ (HMPT) to pentynylcopper in ether or THF at 25 °C.[2]

Handling, Storage, and Precautions: all copper(I) acetylides are potentially explosive when dry. Use in a fume hood.

Mixed Organocuprates.

Since initial disclosures by Corey,[2] copper(I) acetylides have found widespread use for the preparation of mixed lithiocuprates R_rR_tCuLi where R_t is a transferable group and R_r is a residual dummy group.[2-13] Copper(I) acetylides can be prepared in pure form and, due to the stabilizing d-π backbonding that exists between copper and alkynes connected by a σ-bond, alkynes represent ideal nontransferable ligands. For preparation of mixed cuprates (R_rR_tCuLi), alkynylcopper species (R_rCu) are combined with appropriate alkyllithium reagents (R_tLi). The relative insolubility of pentynylcopper in ether or THF at low temperature precluded its use for this purpose; however, the bis(HMPT) complex is soluble and reactive to alkyllithium reagents at -80 °C. The HMPT residues are water-soluble, allowing uncomplicated workup after delivery of R_t to the desired electrophile.[2]

Alkyl-Transferable Groups.

The first reported applications of the HMPT complex involved addition of alkyllithiums to the complex, forming in situ mixed lithioorganocuprates which alkylated cyclohexenone in excellent yield and chemoselectivity (eq 1).[2]

Since this initial report, general application in synthesis has been widespread, reflecting the importance of such transformations[3-5] (see also ***3,3-Dimethyl-1-butynylcopper(I)***, ***1-Hexynylcopper(I)***, and ***(3-Methoxy-3-methyl-1-butynyl)copper(I)***). It has been shown that in situ generation of the R_t group, by way of its lithio derivative using sonication methods, can result in superior yields of 1,4-addition products.[4] A representative example of a complex alkyl R_t is displayed in a synthesis of ceroplastol I (eq 2).[5]

Alkenyl-Transferable Groups.

The numerous applications of this transformation underline its strategic importance in the synthesis of many natural product systems.[6-13] Perhaps the most widely celebrated uses of lithiovinyl-pentynylcuprates have been in the synthesis of prostaglandins and their derivatives.[9-12] Vinylogous organocuprates have also been used to construct the framework of prostaglandin endoperoxides (eq 3),[6] again highlighting chemoselectivity and efficiency. Chemoselectivity has also been observed in the vinylation of alkyl iodides.[7] One-pot conjugate addition-enolate alkylation procedures have been reported, giving moderate yields of the functionalized products (eq 4).[8]

Peracetic Acid[1]

[79-21-0] · $C_2H_4O_3$ · Peracetic Acid · (MW 76.06)

(electrophilic reagent capable of reacting with many functional groups; delivers oxygen to alkenes, sulfides, selenides, and amines)

Alternate Name: peroxyacetic acid.

Physical Data: mp 0 °C; bp 25 °C/12 mmHg; *d* 1.038 g cm^{-3} at 20 °C.

Solubility: sol acetic acid, ethyl acetate, $CHCl_3$, acetone, benzene, CH_2Cl_2, ethylene dichloride, water.

Form Supplied in: 40% solution in acetic acid (*d* 1.15 g cm^{-3}) having approximately the following composition by weight: peracetic acid, 40-42%; H_2O_2, 5%; acetic acid, 40%; H_2SO_4, 1%; water, 13%; diacetyl peroxide, nil; other organic compounds, nil; stabilizer, 0.05%. A solution of the peracid in ethyl acetate is also available commercially.

Analysis of Reagent Purity: assay using iodometry;[2] estimation of diacetyl peroxide.[3]

Preparative Methods: prepared in the laboratory by reacting ***Acetic Acid*** with hydrogen peroxide in the presence of catalytic quantities (1% by weight) of ***Sulfuric Acid***; when 30% H_2O_2 is used the concentration of the peracid reagent obtained is less than 10%.[1a] If a stronger solution of the reagent is required, 70-90% H_2O_2 must be used. Caution: for hazards see ***Hydrogen Peroxide***. ***Hydrogen Peroxide-Urea*** (which is commercially available and is safe to handle) has been used as a substitute for anhydrous hydrogen peroxide.[3] In the preparation of peracetic acid from acetic anhydride and H_2O_2, the dangerously explosive diacetyl peroxide may become the major product if the reaction is not carried out properly.[1a]

Purification: peracetic acid is rarely prepared in pure undiluted form for safety reasons. The commercially available material contains acetic acid, water, H_2O_2, and H_2SO_4. After neutralization of the sulfuric acid, this reagent is satisfactory for most reactions. If water is undesirable, an ethyl acetate solution of the reagent may be used. Details for the preparation of the H_2O_2-free reagent are available.[4]

Handling, Storage, and Precautions: peracetic acid is an explosive compound but is safe to handle at room temperature in organic solutions containing less than 55%. Use in a fume hood. Since peroxides are potentially explosive, a safety shield should generally be used.[5] Peracetic acid can be stored at 0 °C with

essentially no loss of active oxygen and at rt with only negligible losses over several weeks.

General Considerations.

Peracetic acid oxidizes simple alkenes, alkenes carrying a variety of functional groups (such as ethers, alcohols, esters, ketones, and amides), some aromatic compounds, furans, sulfides, and amines. It oxidizes β-lactams in the presence of catalysts. Ketones and aldehydes undergo oxygen insertion reaction (Baeyer-Villiger oxidation).

Epoxidation of Alkenes.

Peracetic acid is a comparatively safe reagent for small-scale reactions. In industry, to avoid the hazards involved in handling large quantities of the reagent, it is prepared in situ. Peracetic acid prepared in this fashion is widely used for epoxidation of vegetable oils and fatty acid esters. To the substrate in acetic acid containing catalytic (1% by weight) quantities of H_2SO_4 maintained around 50 °C is added gradually, with stirring, 50% H_2O_2 at such a rate that there is no buildup in the concentration of H_2O_2. The peracid is consumed as it is formed (eq 1). The addition of H_2O_2 is usually completed in 2 h and then the temperature is raised to and maintained at 60 °C until all the H_2O_2 is consumed (about 3 h). The reaction mixture is diluted with water, at which point the epoxides (being water-insoluble) separate out. The use of hexane during the reaction minimizes epoxide ring opening. Since the catalyst (H_2SO_4) is essential for the speedy formation of peracetic acid, in situ methods can be used for preparing only those epoxides which can tolerate the presence of the acid catalyst. Epoxides of fatty acid esters are obtained in good yields if the reaction temperature and time taken for completion of the reaction are properly controlled.

$$MeCO_2H + H_2O_2 \overset{H^+}{\rightleftharpoons} MeCO_3H + H_2O \qquad (1)$$

Peracetic acid in ethyl acetate is a better reagent for preparing epoxides from alkenes than the reagent in acetic acid since the large quantities of acetic acid in the latter reagent facilitate epoxide ring opening. However, since the reagent in acetic acid is more readily available, it is normally used for epoxidation; the sulfuric acid present in the commercial sample has to be neutralized by adding sodium acetate before the epoxidation. After epoxidizing the alkene with peracetic acid, the reaction mixture is diluted with water. The unreacted peracid, acetic acid, and traces of hydrogen peroxide are removed in the aqueous layer. The separated epoxide is filtered if it is a solid; when the epoxide is a liquid, the organic layer is separated using a small quantity of solvent, if needed. Another method of workup is to remove unreacted peracid and acetic acid through evaporation under reduced pressure.

Epoxidation of terminal alkenes with organic peracids is sluggish since the double bond is not electron rich (eq 2).[6]

(2)

Adequately substituted acrylic esters furnish epoxides in good yields. Ethyl crotonate has been epoxidized in kg quantities according to eq 3;[7] the workup is simple, involving direct fractionation of the reaction mixture. For the preparation of epoxide (**1**) from ethyl crotonate using ***Trifluoroperacetic Acid***, the yield is 73%.[8] The sensitive allylic epoxide (**2**) has been prepared according to eq 4.[9] This procedure has been applied successfully for the preparation of allylic epoxides from 1,3-cyclopentadiene, 1,3-cycloheptadiene, and 1,3-cyclooctadiene.

(3)

(4)

Epoxidation of the triene (**3**)[2] is regioselective, involving reaction at the tetrasubstituted double bond (eq 5). Epoxidation of (**3**) using ***m-Chloroperbenzoic Acid*** furnishes the monoepoxide in 76% yield.[10] Epoxidation of the diene (**4**) was regio- and stereoselective (eq 6);[11] the more substituted double bond was epoxidized from the less hindered side.

(5)

Epoxidation of the unsaturated γ-lactone (**5**) furnished stereoselectively the epoxide (**6**), involving approach of the reagent from the more hindered side of the double bond (eq 7).[12] This selectivity is observed only when acetic acid is the solvent. The selectivity was much less when *m*-CPBA was used.

Moderate stereoselectivity is observed during the epoxidation of sterically unbiased 3,3-diarylcyclopentenes; the major product is formed through approach of the electrophile from the side *trans* to the better electron donor (eq 8).[13]

A systematic study of the epoxidation of the acyclic allyl alcohol (**7**) has been carried out, employing several reagents.[14] Epoxidation with peracetic acid generated from urea/H_2O_2 showed small *syn* selectivity (eq 9). *m*-CPBA epoxidation of (**7**) furnished in 87% yield a 40:60 mixture of the epoxy alcohols (**8**) and (**9**).

Epoxidation of Alkenes via Peracids Generated In Situ.

Alkenes have been epoxidized by reacting them with peracids generated in situ. The system consisting of molecular oxygen and aldehydes, particularly isobutyraldehyde and ***Pivalaldehyde***, converts various alkenes to epoxides in high yields when they are reacted at 40 °C for 3-6 h (eq 10).[15]

Oxidation of Furans.

2,5-Disubstituted furans are oxidatively cleaved by peracids; for example, see eq 11.[16] *m*-CPBA can also be used for this reaction. Δ^3-Butenolides have been synthesized by oxidizing 2-trimethylsilyl furans with peracetic acid; as in eq 12.[17]

(11)

(12)

This reaction does not proceed smoothly when there is a hydroxyl group in the furfuryl position; however, the reaction is facile if the furfuryl OH is blocked. The reaction does not take place if electron-withdrawing groups are present on the furan ring. *m*-CPBA is not a good reagent for this oxidation. An interesting application of this reaction has been published.[18]

Oxidation of Aromatic Compounds.

Suitably substituted aromatic compounds are oxidized efficiently to the quinones by peracetic acid. The quinone (**10**) is obtained in 22% yield by oxidizing naphtho[*b*]cyclobutene.[19] Slow addition of 1,5-dihydroxynaphthalene to excess peracetic acid furnished juglone (**11**) in 46-50% yield.[20]

(10)

(11)

Baeyer-Villiger Oxidation.

A systematic study of the Baeyer-Villiger reaction of the bicyclic ketone (**12**) has been carried out employing different organic peracids.[21] Selective formation of lactone (**13**) was highest when peracetic acid was used (eq 13). Reaction of (**12**) with *m*-CPBA furnishes a 55:45 mixture of (**13**) and (**14**) in 81% yield.

Position-specific Baeyer-Villiger rearrangement has been observed in the reaction of peracetic acid with some polycyclic ketones.[22,23] An ε-lactone, required for the synthesis of erythronolide B, was synthesized in 70% yield through position-specific Baeyer-Villiger rearrangement of a cyclohexanone having substituents on all the ring carbons;[24] the ketone was treated with excess 25% peracetic acid in ethyl acetate for 6 days at 55-58 °C. Peracetic acid oxidation of the keto β-lactam (**15**) furnishes stereoselectively the interesting β-lactam (**16**) (eq 14);[25] the initially formed Baeyer-Villiger reaction product undergoes further reaction. Ketone (**15**) has also been reacted with *m*-CPBA in acetic acid but the selectivity is slightly less, forming (**16**):(**17**) in 10:1 ratio.

Ruthenium- and Osmium-Catalyzed Oxidations.

α-Ketols have been synthesized by reacting alkenes with peracetic acid in the presence of a ***Ruthenium(III) Chloride*** catalyst.[26] α-Ketol (**19**) was synthesized from the alkene (**18**) chemo- and stereoselectively (eq 15). The two-phase aqueous system is essential for this reaction. Conjugated dienes, allylic azides, and α,β-unsaturated esters have been oxidized with this reagent.

(15)

The methylene group adjacent to the nitrogen of β-lactams has been oxidized with peracetic acid in the presence of a ruthenium catalyst (eq 16).[27] Peracetic acid is the best oxidant for this reaction. Instead of ruthenium, $OsCl_3$ can be used to catalyze the oxidation.[28] The peracetic acid required for the reaction can be generated in situ from acetaldehyde and molecular oxygen (eq 17).[29]

(16)

(17)

Other Applications.

Peracetic acid has been used to (a) oxidize primary amines to nitroso compounds,[30] (b) oxidize secondary alcohols to ketones in the presence of a Cr^{VI} ester catalyst (eq 18)[31] or sodium bromide,[32] (c) oxidize sulfenamides to sulfonamides (eq 19),[33] (d) oxidize iodobenzene to iodosobenzene diacetate[34] and iodoxybenzene,[35] and (e) oxidize N-heterocycles such as pyridine to *N*-oxides.[36] α,β-Unsaturated aldehydes (and α,β-unsaturated ketones) do not undergo facile epoxidation with peracetic acid since the double bond is not electron rich. However, the acetals of α,β-unsaturated aldehydes can be oxidized readily (eq 20).[37] For the epoxidation of α,β-unsaturated aldehydes with H_2O_2/base see ***Hydrogen Peroxide***.

(18)

(19)

(20)

For industrial applications, peracetic acid is the most widely used organic peracid since it is inexpensive. It is the only commonly used peracid which can be prepared in situ for epoxidation reactions, since the acid catalyst (1% H_2SO_4; eq 1), which can facilitate epoxide ring opening, is used in low concentrations; the accompanying acetic acid, being a weak acid, is not very efficient in epoxide opening. The in situ method is not hazardous. Although the reagent is available commercially, it is also prepared in the laboratory since its preparation is easy, fairly fast, and no solvent is required for isolation. Epoxidation reactions and subsequent workup can be performed with no solvent, or only small quantities of solvent since the peracid and accompanying acetic acid are both water soluble and volatile. It is not essential that the substrate should dissolve in the reagent (peracetic acid-acetic acid).

Related Reagents.

Indian Institute of Chemical Technology, Hyderabad, India

Perbenzoic Acid[1]

[93-59-4] · $C_7H_6O_3$ · Perbenzoic Acid · (MW 138.13)

(electrophilic reagent capable of delivering oxygen to alkenes,[1] amines,[2] and sulfides[3])

Alternate Name: peroxybenzoic acid; PBA.

Physical Data: mp 41-42 °C.

Solubility: sol $CHCl_3$, CH_2Cl_2, benzene, ethyl acetate, ether; slightly sol water.

Form Supplied in: long white needles, but usually handled in solution; not available commercially.

Analysis of Reagent Purity: iodometric assay.[4,6]

Preparative Methods: ***Sodium Methoxide*** reacts readily with ***Dibenzoyl Peroxide*** (**1**) (eq 1); complete experimental details are available for preparing perbenzoic acid based on this reaction.[4] Alkaline perhydrolysis (HOO^-) of (**1**) in aqueous organic solvents has been employed for preparing PBA in 90% yields.[5] PBA has been prepared in 85-90% yield by adding 70% ***Hydrogen Peroxide*** (**Caution**!) to a suspension of benzoic acid (**2**) in methanesulfonic acid (eq 2).[6] PBA has been prepared in 90% yield by passing oxygen containing catalytic quantities of ozone through a solution of benzaldehyde in ethyl acetate.[7]

$$\underset{\textbf{(1)}}{(PhCO)_2O_2} + MeONa \longrightarrow PhCO_3Na + PhCO_2Me \qquad (1)$$

$$\underset{\textbf{(2)}}{PhCO_2H} + H_2O_2 \overset{H^+}{\rightleftharpoons} PhCO_3H + H_2O \qquad (2)$$

Purification: PBA can be purified by recrystallization at -20 °C from a 3:1 mixture of petroleum ether-diethyl ether.

Handling, Storage, and Precautions: analytically pure PBA can be stored for long periods in a refrigerator without significant loss of active oxygen. Since PBA is a peroxide and potentially explosive, care must be exercised in carrying out the reactions with it; during workup, check for peroxides before evaporating the solvent. This reagent should be handled in a fume hood.

Functional Group Oxidations.

This reagent oxidizes simple alkenes, including alkene substrates incorporating a variety of functional groups (ethers, alcohols, esters, etc.), amines, and sulfides. Ketones undergo oxygen insertion reactions (Baeyer-Villiger oxidation).

Epoxidation of Alkenes.

PBA, like other organic peracids, reacts with alkenes readily under mild conditions to furnish epoxides in good yields (see, for example ***m-Chloroperbenzoic Acid***).[8] Styrene is thus oxidized to styrene oxide (**3**) (eq 3).[9] To PBA (0.33 mol) in 500 mL of $CHCl_3$ is added at 0 °C, with stirring, 0.3 mol of styrene. The reaction mixture is kept at 0 °C for 24 h. Assay of PBA at this stage will show that one equivalent of PBA has been consumed. The reaction mixture is shaken with aq 10% NaOH solution, water, and then dried (Na_2SO_4). The solvent is evaporated and the residue is fractionated using a Vigreux column to furnish the epoxide (**3**) in 70-75% yield.

(3)

(3)

Oxidation of the alkene (**4**) furnishes the epoxide (**5**) (eq 4).[10] The disubstituted *cis*-alkene (**6**) gave in quantitative yield the corresponding *cis*-epoxide (**7**).[11] Epoxidation of cycloheptene in $CHCl_3$ (3.2% solution, 48 h, 0 °C) furnished cycloheptene oxide in 78% yield.[12]

(4)

(4)

(5)

(6)

(7)

Reaction of the diene (**8**), having two trisubstituted double bonds, with 1 equiv of PBA proceeded regio- and stereoselectively to give monoepoxide (**9**) (eq 5).[13]

(8) (9)

The benzylic epoxide (**10**) has been obtained in 77% yield by epoxidizing 1-phenylcyclohexene with a $CHCl_3$ solution of PBA at 0 °C.[14] A pure sample of (**10**) was obtained by distilling the crude reaction product over powdered KOH; this epoxide is very sensitive to acids but is stable in basic medium. It has been observed that 7α,8α-epoxides of steroids and triterpenes are stable in basic media but these epoxides are readily cleaved even with traces of acids.[15]

(10)

Epoxidation of the diene (**11**) takes place regioselectively at the tetrasubstituted double bond to furnish the monoepoxide (**12**) in 61% yield.[16] 3β-Acetoxy-8α,9α-epoxyergostane was prepared in 85% yield by epoxidizing the alkene (**13**) using benzene as solvent.[17]

(11)

(12)

(13)

Epoxidation of 3-acetoxycholest-2-ene (**14**) in $CHCl_3$ solution (-12 °C, 42 h) is stereoselective; the 2α,3α-epoxide is isolated in 80% yield.[18] Epoxidation of the vinyl chloride (**15**) ($CHCl_3$ solution, 12 h, rt) furnished the corresponding chloro epoxide in 68% yield.[19]

(14)

(15)

The sensitive epoxide (**17**) has been prepared from the enol ether (**16**) in 90% yield (eq 6).[20] An ether solution of (**16**) and PBA is allowed to react for 30 s; benzoic acid is removed by passing the reaction mixture rapidly (30 s) through an alumina column.

(6)

(16) (17)

Epoxidation of the α,β-unsaturated ketone pulegone (**18**) (5-10 °C, 24 h) is not stereoselective; a 2:1 mixture of α,β-epoxy ketones (**19**) and (**20**) is obtained in 86% yield.[21]

(18) (19) (20)

Hydroxy-directed stereoselective epoxidation has been observed with allylic cyclohexenols (eq 7).[22]

(7)

Baeyer-Villiger Reaction.

Fe_2O_3-catalyzed oxidation of ketones with molecular oxygen in the presence of benzaldehyde at rt gives the lactones efficiently (eq 8).[23] The reacting species may be PBA or the radical $PhCO_3$&bdot;. Baeyer-Villiger reaction of (-)-(**21**) furnishes the ester (-)-(**22**) in 85% yield with retention of configuration.[24]

(8)

(21) R = COMe
(22) R = OCOMe

Reaction with Compounds Containing Nitrogen and Sulfur.

Aromatic primary amines containing electron-withdrawing groups are oxidized to nitroso compounds.[2] Oxidation of (**23**) thus furnishes the nitroso compound (**24**) in 85% yield. This reaction cannot be carried out with peracetic acid. The oxaziridine (**25**) has been prepared in 56-74% yield by reacting the corresponding aldimine with PBA.[25] Episulfides are oxidized to episulfoxides.[3] The episulfoxide (**26**) has been obtained in 77% yield by oxidizing the episulfide in CH_2Cl_2 at -20 °C.

(23) R = NH_2
(24) R = NO

(25)

(26)

In the epoxidation of alkenes which are moderately or highly reactive, the yields obtained with PBA are comparable to the yields obtained using ***m-Chloroperbenzoic Acid*** or ***Peracetic Acid***. However, *m*-CPBA and $MeCO_3H$ are available commercially; PBA is not available commercially, but can be prepared conveniently in a short time. For the epoxidation of alkenes which react sluggishly (e.g. α,β-unsaturated esters) *m*-CPBA and ***Trifluoroperacetic Acid*** are preferred.

Related Reagents.

Monoperoxyphthalic Acid.

Perchloryl Fluoride[1]

$FClO_3$

[7616-94-6] · $ClFO_3$ · Perchloryl Fluoride · (MW 102.45)

(electrophilic reagent capable of fluorinating a variety of activated methylene compounds,[1-3] steroids,[1,4-13] and organometallics;[1,14] useful for the formation of covalent aromatic perchlorates[1,15])

Alternate Names: chlorine fluoride oxide; chlorine oxyfluoride.

Physical Data: mp -147.7 °C; bp -46.7 °C; d^{25} 1.412 g cm^{-3} (liq), 0.065 g cm^{-3} (g).[1b,16]

Solubility: sol THF, Me_2O, MeOH, DMF, MeCN, H_2O. Specific solubilities have been measured.[17,18]

Form Supplied in: colorless gas shipped in cylinders under its own vapor pressure[1b] (12 atm at 25 °C).

Analysis of Reagent Purity: assessed in the condensed phase using ^{19}F NMR spectroscopy and in the gas phase using vibrational spectroscopy.[1f]

Preparative Methods: the synthesis of $FClO_3$ involves extremely hazardous materials[1f] and should not be attempted by inexperienced or untrained personnel.

Handling, Storage, and Precautions: mixtures of $FClO_3$ and organic compounds are potentially hazardous because explosions are always possible. Numerous serious accidents involving $FClO_3$, including those resulting in fatalities, have been documented.[1,19] These incidents are normally violent and destructive and occur unexpectedly, e.g. *a mixture of $FClO_3$ and THF exploded violently and without warning at room temperature*.[20] Toxicity, health, and safety information as well as recommendations for selection and use of personal protective equipment can be found in numerous publications.[21] Perchloryl fluoride should only be handled by experienced and thoroughly trained personnel and should only be used in a fume hood.

General Considerations.

Safer alternative reagents are commercially available which perform as well and in many cases better than $FClO_3$ in all of its chemistry, e.g. XeF_2, $(CF_3SO_2)_2NF$, *N*-fluoropyridinium triflate, *N*-fluoropyridinium pyridine heptafluorodiborate, *N*-alkyl-*N*-fluorotoluenesulfonamides, *N*-fluoroquinuclidinium triflate, and *N*-fluorodibenzenesulfonamide. A safer, cost-effective, and easily handled reagent, ***1-(Chloromethyl)-4-fluoro-1,4-***

diazoniabicyclo[2.2.2]octane Bis(tetrafluoroborate) (F-TEDA-BF_4), particularly useful for selective fluorination of steroids as well as a wide range of other activated substrates, including methylene and methine carbons,[22,23] has recently become available in commercial quantities.

Perchloryl fluoride was one of the first readily available sources of electrophilic fluorine and, as such, gained immense popularity for selective fluorinations of a wide variety of substrates. However, numerous accidents involving $FClO_3$ and the advent in subsequent years of cleaner and safer-to-use electrophilic fluorination reagents have all but abolished perchloryl fluoride from the synthetic chemist's repertoire. Nevertheless, a short summary of the major synthetic transformations which are possible with $FClO_3$ is given below.

Fluorination of Activated Methylenes.

The acidic hydrogen(s) of a methylene group can be substituted by fluorine with $FClO_3$ providing an equimolar amount of a sufficiently strong base is also used. Selectivity in these reactions does vary, depending on the choice of base and solvent. Thus, the fluorination of diethyl malonate in ethanol (eq 1)[3] yields four different products, whereas in toluene (eq 2),[3] only two products are obtained.

$$H_2C(CO_2Et)_2 \xrightarrow[\text{2. } FClO_3\text{, 10-15 °C}]{\text{1. Na, EtOH}}$$

$$\underset{26.2\%}{F_2C(CO_2Et)_2} + \underset{28.2\%}{HCF(CO_2Et)_2} + \underset{5.2\%}{EtCH(CO_2Et)_2} + \underset{0.5\%}{EtCF(CO_2Et)_2} \quad (1)$$

$$H_2C(CO_2Et)_2 \xrightarrow[\text{2. } FClO_3\text{, 10-15 °C}]{\text{1. Na, toluene}} \underset{29.2\%}{F_2C(CO_2Et)_2} + \underset{41.6\%}{HCF(CO_2Et)_2} \quad (2)$$

Fluorination of Activated Methines.

Perchloryl fluoride can be used in many cases to substitute the proton of an activated methine carbon with fluorine. While the majority of examples come from the steroid literature, some nonsteroidal examples have also been reported, e.g. the fluorination of cyclohexene enol ether (eq 3)[8].

(3)

Fluorination of Activated Steroid Enol Ethers and Esters, Enamines, and Enamides.

Perchloryl fluoride can be used for regioselective incorporation of fluorine at a number of positions on activated steroidal substrates. Thus 2-fluoro steroids can be prepared from their corresponding enol ethers, e.g. 3-ethoxy-5α-cholest-2-ene (eq 4),[8] enamines, e.g. cholest-2-en-3-one pyrrolidylenamine (eq 5),[4] α-hydroxymethylene ketones, e.g. 2,17β-dihydroxyandrostan-3-one (eq 6),[6] and from alkoxalyl enolates,[24-26] e.g. 2-methoxalylhydrocortisone 20-ethylene acetal (eq 7).[25]

(6)

(7)

Perchloryl fluoride and 3-keto steroids conjugated via 3,5-dienes yield different products depending on the functional group at position 3. Thus 21-acetoxy-3-ethoxy-11β-hydroxy-3,5,17(20)-*cis*-pregnatriene, an enol ether, and the analogous enol acetate of progesterone yield 6-fluoro products (eqs 8 and 9),[27,28] respectively, while methyl 11-oxo-3-pyrrolidyl-3,5,17(20)-*cis*-pregnatrien-21-oate, a dienamine, gives the 4,4-difluoro product (eq 10).[27]

(8)

(9)

Incorporation of fluorine at the 16-position of steroids using $FClO_3$ requires highly activated substrates such as 16-formylandrost-5-en-17-one[29] and 16-ethoxalylandrost-5-en-17-one.[30] In addition, a noteworthy activating group is found in the 17-amino-Δ^{16}-steroid (enamide) prepared by Beckmann rearrangement of the corresponding 20-keto-Δ^{16}-steroid.[31] Thus treatment of the androstane derivative 3β-acetoxy-17-acetaminoandrosta-5,16-diene, in pyridine, with $FClO_3$ leads to the 16α-fluoro product, 16α-fluoro-3β-acetoxyandrost-5-en-17-one, in 70% yield (eq 11).[31] The same transformation can be accomplished in higher yield using either ***Xenon(II) Fluoride*** (95% yield) or *N*-fluoroquinuclidinium triflate (85% yield).

Fluorination of Organometallic Compounds.

Perchloryl fluoride can be used for the fluorination of carbon-metal bonds in ether or THF at low temperature, yielding the monofluoro and, in most cases, protonated derivatives (eqs 12 and 13).[14] This type of reaction has also been applied to the fluorination of organolithium heterocycles.[32]

(13)

The fluorinated products in eqs 12 and 13 can be prepared in higher yields under milder conditions using F-TEDA-BF_4.[23]

Perchlorylation of Aromatic Compounds.

A capability unique to perchloryl fluoride is its use for the Friedel-Crafts perchlorylation of activated aromatics (eq 14).[15] This type of electrophilic aromatic substitution can be applied to substituted benzene compounds such as toluene, fluorobenzene, and *p*-xylene, but does not work for deactivated systems such as nitrobenzene. While perchloryl aromatics are resistant to reduction, oxidation, and hydrolysis, they are easily detonated with either heat or shock.[15]

(14)

Other Applications.

Perchloryl fluoride can be used for a number of other applications, including the fluorination of nitro and polynitro hydrocarbons,[20,33-36] the fluorination of steroidal-ring phenols,[37] the *N*-fluorination and *N*-perchlorylation of certain amines,[38] and the oxofluorination of certain alkenes.[39]

Related Reagents.

1-(Chloromethyl)-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane Bis(tetrafluoroborate); ***N-Fluoro-N-t-butyl-p-toluenesulfonamide***; ***N-Fluoro-N-(phenylsulfonyl)benzenesulfonamide***; ***N-Fluoropyridinium Triflate***; ***Xenon(II) Fluoride***.

Perfluoro-*N*-fluoropiperidine[1]

[836-77-1] · $C_5F_{11}N$ · Perfluoro-*N*-fluoropiperidine · (MW 283.06)

(liquid, site-selective, mild electrophilic fluorinating agent for stabilized carbanions[2])

Physical Data: bp 49.5 °C; d^{25} 1.7043 g cm^{-3}; *n*20D 1.2752.

Solubility: sol MeOH, EtOH, Me_2CO, Et_2O, THF, toluene, perfluorocarbons (PFCs); slightly sol $CHCl_3$; insol H_2O; unaffected and insol hot (70 °C) 18% aq HCl or 8% aq NaOH; oxidizes ethanol slowly at 100 °C (EtOH -> acetaldehyde, diethyl ether, diethyl hexafluoroglutarate).[3]

Form Supplied in: colorless liquid (bp 48-50 °C) of ca. 97% purity; inert PFC impurities are *n*- and *i*-C_5F_{12}, perfluoro(*N*-methylpyrrolidine).

Analysis of Reagent Purity: ^{19}F NMR, GC, iodimetric titration (treat with KI in warm Me_2CO/H_2O (9:1 v/v); estimate I_2 with thiosulfate, 1 NF &tbond; 1 I_2).

Preparative Methods: electrochemical fluorination in anhydrous HF (Simons process) of pyridine (8% yield) or 2-fluoropyridine (13%) in specialized metal equipment.[3]

Handling, Storage, and Precautions: this toxic, highly volatile, nonflammable liquid should be stored (preferably at 0-5 °C) in tightly stoppered glass vessels (hydrocarbon or silicone greases are not affected) or in sealed ampoules (PTFE/glass stopcocks). Always cool the reagent before transferring it to reaction vessels to avoid losses by evaporation and toxicity hazards. Transfer, in vacuo, from a storage ampule is desirable. Use in a fume-hood. Take standard precautions to avoid breathing vapor, contact of vapor or liquid with eyes, and liquid or its solution with the skin: avoid contamination of clothing. Beware the high toxicity of perfluoro-1-azacyclohexene,

produced initially (see below) when using the reagent to effect electrophilic fluorinations. Treatment of mixtures of the reagent and its defluorination product with alkaline aq KI converts them to alkali metal salts of hexafluoroglutaric acid.

Undergoes defluorination to perfluoro-1-azacyclohexene ($CF_2(CF_2)_3CF{=}N$) and thence pentafluoropyridine with mild steel at temperatures above 200 °C.[3] (Perfluoro-1-azacyclohexene is best prepared by defluorination of the reagent with triphenylphosphine (-> Ph_3PF_2)).[2,4] The N-F bond is broken homolytically by UV light[5] or pyrolysis in platinum.[3] Stable in Pyrex at rt in Manchester daylight.

Fluorination of Carbanions.

The reagent delivers F^+ to carbon centers in highly stabilized carbanions, e.g. sodium salts of nitroalkanes (eq 1),[2] substituted malonates (eq 2),[2] β-keto esters (eq 3),[2] and tris(alkanesulfonyl)methanes (eq 4).[6] Yields can be increased by adding an alkali metal fluoride or chloride to reaction mixtures to scavenge perfluoro-1-azacyclohexene produced through fluorine transfer from nitrogen to carbon (eq 5).[2] This highly electrophilic imidoyl fluoride competes with the NF reagent for carbanionic species (eq 6),[2] a situation which detracts from the use of perfluoro-*N*-fluoropiperidine with expensive or hard-won substrates; the same situation applies for the analogous NF reagent perfluoro-*N*-fluoromorpholine[7] (noncommercial at present).

(1)

(2)

(3)

(4)

(5)

(6)

Perfluoro-*N*-fluoropiperidine (and its 2,6-bis(trifluoromethyl) analog) proved unsatisfactory compared with the hazardous gaseous reagent ***Perchloryl Fluoride*** as a means for effecting site-selective fluorination of tetraethyl methylenebisphosphonate.[8]

Fluorination at Nucleophilic Heteroatom Sites.

The reagent has been used to convert piperidine to *N*-fluoropiperidine (eq 7; exothermic: care!) and triphenylphosphine, -arsine, and -stibine to the corresponding pentavalent difluorides (eq 8).[9] The formation of perfluoro-1-azacyclohexene leads to serious consumption of substrates only in the case of piperidine.

(7)

(8)

M = P, 84%; As, 81%; Sb, 69%

Sodium sulfinates smoothly yield sulfonyl fluorides (eqs 9 and 10),[6] although restricted choice of solvent can cause loss of product (eq 10).

(9)

(10)

Fluorination of Electron-Rich Aromatics.

This application has received relatively scant attention (eqs 11 and 12),[10,11] the main objective being to probe the mechanism of F^+ transfer (see a recent discussion of $S_N2(F)$ vs. SET mechanisms for NF and $^+$NF reagents[2,12]). As with carbanions, the formation of the imidoyl fluoride perfluoro-1-azacyclohexene leads to loss of substrate material.

(11)

R = Me, 18% (conv. 88%)
R = Et, 48% (conv. 59%)

(12)

Utilization.

Although its fluorinating ability was discovered in the early 1960s,[13] perfluoro-*N*-fluoropiperidine has received little attention owing to its low-yield specialized synthesis. The commercial availability of the reagent, coupled with its ease of use and recovery, should lead to far more interest in its applications.

Peroxyacetimidic Acid

(R = Me)

[64415-45-8] · $C_2H_5NO_2$ · Peroxyacetimidic Acid · (MW 75.08) (R = Ph)

[20996-66-1] · $C_7H_7NO_2$ · Peroxybenzimidic Acid · (MW 137.15)

(oxygen atom transfer that is useful for the epoxidation of alkenes)

Preparative Methods: these reagents are generated in situ by the reaction of 30% aqueous H_2O_2 with either ***Acetonitrile*** or benzonitrile at room temperature.

Alkene Epoxidation.

Although ***Hydrogen Peroxide*** is readily available and relatively inexpensive, it is not a very reactive oxidant. For example, H_2O_2 will not effect the epoxidation of a nonconjugated carbon-carbon double bond. Heterolytic cleavage of the O-O bond in H_2O_2 has a relatively high activation barrier since the hydroxy anion is a poor leaving group. Alkene epoxidation[1] is typically achieved by its reaction with a peroxy acid (**1**) such as ***Peracetic Acid*** or ***m-Chloroperbenzoic Acid*** (*m*-CPBA).[2]

(1)

When the -OOH functional group is placed in conjugation with a carbonyl group, a carboxylate anion is the leaving group upon heterolylic cleavage of the O-O bond. ***Trifluoroperacetic Acid*** (CF_3CO_3H) is a highly reactive epoxidizing reagent since electron-withdrawing groups stabilize the departing carboxylate anion.

The O-O bond in H_2O_2 can also be activated by its conjugative interaction with an imine functionality. One of the

earliest and most useful adaptations of this type of O-O bond activation was accomplished by Payne.[3] The peroxyimidic acid derived from the alkaline hydrogen peroxide/benzonitrile system has been used with steroids[4a] and in the total synthesis of prostaglandin $F_{2\alpha}$.[4b] Hydrogen peroxide reacts with nitriles under controlled pH conditions (~pH 8) to generate a peroxyimidic acid (eq 1). Although peroxyimidic acids (**2**) have not been isolated, they react rapidly with a variety of reducing agents.

(1)

Acetonitrile, benzonitrile, and ***Trichloroacetonitrile***[3,5a] have been used as coreactants to produce peroxyimidic acids that are highly effective oxidants for the epoxidation of alkenes. This oxidation reaction has the advantage of being useful for both large- and small-scale reactions. For example, the epoxidation of (*Z*)-cyclooctene has been carried out with acetonitrile and H_2O_2 (eq 2) on a 4.4 mol scale to afford (*Z*)-cyclooctene oxide in 60-61% isolated yield.[5b]

(2)

The epoxidation procedure is usually carried out in methanol solvent using $KHCO_3$ as a buffer. The reaction does not proceed well when sodium bicarbonate is employed and omission of a protic solvent such as methanol results in substantially reduced yields. The rate limiting step appears to be the nucleophilic attack of the alkene on the O-O bond.[6] Formation of the epoxide is an exothermic reaction and caution should be exercised to keep the temperature of the reaction mixture from rising.

Wiberg[7] has investigated the mechanism of the addition of H_2O_2 to a nitrile in the pH range 7-8. At higher pH values the mechanism can change and nucleophilic attack by the anion of (**2**) on H_2O_2 can result in the formation of dioxygen and the corresponding amide.[8] Radical pathways for the decomposition of (**2**) have also been proposed.[9] The epoxidation of aliphatic alkenes with peroxybenzimidic acid (**2**; R = Ph) has been shown to be less selective and have greater steric requirements than a peroxy acid.[10] Differences in the stereoselectivity of diepoxide formation between peroxy acids and peroxyimidic acids have also been noted.[11]

Peroxyacetyl Nitrate

[2278-22-0] · $C_2H_3NO_5$ · Peroxyacetyl Nitrate · (MW 121.06)

(convenient source of acetylperoxy radicals;[1] epoxidizes alkenes;[2] oxidizes aldehydes,[3] thiols and sulfides;[4] acetylates primary amines[5])

Alternate Name: acetyl nitro peroxide; PAN.

Physical Data: mp -48.5 °C; bp 104 °C (extrapolated).

Solubility: sol pentane, benzene, CCl_4, $CHCl_3$, acetone.

Form Supplied in: not available commercially.

Analysis of Reagent Purity: GLC.[6]

Preparative Methods: to a stirred mixture of ***Peracetic Acid*** (5 mmol) and 10-15 mL of dry pentane maintained at -5 to 0 °C is added 90% ***Nitric Acid*** (1 equiv) and ***Sulfur Trioxide*** (30% SO_3 in H_2SO_4, 1 equiv). The reaction mixture is stirred at -5 °C for 3 h and then treated with ice water. The organic layer is dried over $MgSO_4$ at -20 °C. The yield of unpurified PAN in pentane solution is 39%.[1]

Purification: by GLC.[1,6]

Handling, Storage, and Precautions: explosions occur when pure PAN is condensed as a liquid.[7] PAN is thermally unstable above 0 °C.[8] Purified PAN is stored as an N_2-diluted gas at 1000 ppm, 100 psi in gas cylinders at 0 °C.[4,9] Use in a well ventilated fume hood.[10]

General Considerations.

PAN is formed in polluted air by the photochemical action of sunlight on hydrocarbons and nitrogen oxides. It is an eye irritant and it also damages plants. It reacts with biologically important materials such as enzymes. Hence, there is considerable interest in studying its reactions.[7]

PAN is a convenient source of radicals; it decomposes rapidly (t_{12} for decomposition at 25 °C = 30 min) to yield acetylperoxy radicals (**1**) and NO_2 (eq 1).[1]

Epoxidation of Alkenes.

Reaction of PAN with alkenes yields epoxides (eq 2).[2] PAN reacts with either *cis*- or *trans*-stilbene to give only (>95%) *trans*-stilbene oxide (eq 3).

The acid-sensitive acenaphthylene oxide (**2**) has been prepared in 50% yield by epoxidizing acenaphthylene. PAN may find applications in the synthesis of acid sensitive oxides.

(2)

Oxidation of Aldehydes.

Aldehydes are oxidized by PAN in $CDCl_3$, CCl_4, benzene, or acetone to the corresponding acids in good yield.[3] The reaction proceeds by a radical mechanism. Ketones are not oxidized by PAN.

Acetylation of Primary Amines.

When liquid *n*-propylamine is injected into a solution of PAN (0.5 M in $CDCl_3$), vigorous evolution of oxygen is observed.[5] The reaction is complete in less than 1 min after mixing the reactants; the amide (**3**) is formed (yield >90%).

(3)

Action of KOH on PAN.

When 0.4 M KOH in benzene-methanol (9:1) is added to dilute solutions of PAN (0.2-0.3 M in benzene), there is vigorous evolution of oxygen (eq 4).[11] Singlet oxygen, which may be important in oxidations involving PAN, has been shown to be a product of this reaction.

Oxidations at Sulfur Atoms.

Thiols are oxidized by PAN to disulfides; cysteine (**4**) is oxidized to cystine.[4] Sulfides are oxidized to sulfoxides (e.g. methionine (**5**) to methionine sulfoxide). PAN rapidly oxidizes dimethyl sulfide to DMSO (t_{12} <1 min).[2]

(4)

(5)

Considering the hazards involved in handling large quantities of PAN, it is not yet particularly useful in synthetic

organic chemistry. Oxidation reactions presented above can be carried out conveniently and in good yields using ***m-Chloroperbenzoic Acid*** or ***Hydrogen Peroxide***.

Peroxybis(triphenylphosphine)palladium

[29933-60-6; 15614-66-1] · $C_{36}H_{30}O_2P_2Pd$ · Peroxybis(triphenylphosphine)palladium · (MW 663.02)

(an oxygen carrier for mild oxidation of alkenes,[1] sulfur compounds,[2] and oximes[3])

Alternate Name: dioxygenbis(triphenylphosphine)palladium.

Physical Data: described as green crystalline solid; mp 105 °C (darkens); 140-143 °C (melts);[4] also described as pale blue powder; mp 100 °C (dec).[5]

Solubility: sol CH_2Cl_2.

Preparative Methods: prepared by bubbling oxygen through a solution of ***Tetrakis(triphenylphosphine)palladium(0)*** in a carbon dioxide-free mixture of CH_2Cl_2 and diethyl ether[4] or benzene,[6] or by bubbling oxygen through a carbon dioxide-free solution of bis(triphenylphosphine)palladium in benzene.[5]

Purification: recrystallization from a 1:1 mixture of CH_2Cl_2 and ether with oxygen bubbling through continuously.[4]

Handling, Storage, and Precautions: the solid and its solutions decompose in a few days to metallic palladium and oxygen or phosphine oxide.

Oxygenation of Alkenes.

Electron-deficient alkenes and α,β-unsaturated carbonyl compounds react with $(PPh_3)_2PdO_2$ to form five-membered ring dioxapalladacycles in high yields below room temperature (eq 1).[1] At temperatures above 25 °C these dioxapalladacycles break down to a ketone and an oxapalladacyclopropane, where the lone carbon in the heterocyclopropane is the carbon of the alkene bearing the electron-withdrawing groups (eq 2).[1] If the dioxapalladacycle is treated with ***Trifluoroacetic Acid***, an epoxide is obtained in high yield and with high stereoselectivity where applicable (eq 2).[1]

(1)

(2)

Electron-rich alkenes are epoxidized by $(PPh_3)_2PdO_2$ only in the presence of acid derivatives (eq 3).[2] The need for the acid derivative has been suggested to imply that a peroxy acid-palladium complex is the active oxidizing agent. The O_2 of $(PPh_3)_2PdO_2$ adds to reactive dienes under thermal or photochemical conditions to give endoperoxides which can break down to diketones.[7] For example, 1,3-diphenylisobenzofuran reacts with $(PPh_3)_2PdO_2$ to give a mixture of endoperoxide and *o*-dibenzoylbenzene (eq 4). 9,10-Diphenylanthracene, however, is unreactive under thermal conditions, but on irradiation gives an endoperoxide which breaks down to *o*-dibenzoylbenzene (eq 5). Photochemical reactions involving $(PPh_3)_2PdO_2$ must avoid the presence of alkyl halides and the use of alkyl halogenated solvents, because zerovalent palladium species that may be present react with aliphatic halides to give $(PPh_3)_2PdX_2$ and the oxygen atoms of the peroxy complex are diverted to the formation of phosphine oxide under these conditions.[8]

(3)

(4)

(5)

Other Oxygenation Reactions.

$(PPh_3)_2PdO_2$ effectively converts base- and acid-sensitive ketoximes to ketones (eq 6).[3] In the presence of acid derivatives, sulfides are oxidized to sulfoxides and sulfoxides are oxidized to sulfones in good yield (eq 7).[2]

Peroxymaleic Acid[1]

[3851-95-4] · $C_4H_4O_5$ · Peroxymaleic Acid · (MW 132.08)

(electrophilic reagent capable of reacting with many functional groups; delivers oxygen to alkenes and amines[2])

Alternate Names: permaleic acid; PMA.

Solubility: sol CH_2Cl_2, $CHCl_3$ and water.

Form Supplied in: not available commercially.

Analysis of Reagent Purity: assay using iodometry.[3]

Preparative Methods: (a) to a cooled (0 °C) and stirred mixture of 90% ***Hydrogen Peroxide*** (**caution**!) (11.6 g, 0.34 mol) and CH_2Cl_2 (150 mL) is added in one batch 39.2 g (0.4 mol) of freshly crushed ***Maleic Anhydride***. When the major portion of the anhydride has reacted, the reaction mixture is heated to reflux.[2] (b) 0.1 mol of 88% H_2O_2, 0.13 mol of maleic anhydride, $CHCl_3$ (19.5 mL), and DMF (0.5 mL) are stirred at 20 °C for 1.5 h to give the reagent, essentially free from H_2O_2.[4]

Handling, Storage, and Precautions: reasonably stable in CH_2Cl_2 solution, decomposing to the extent of 5% in 6 h at rt. Since peroxy acids are potentially explosive, care is required while carrying out the reactions; during workup, test for peroxides before solvent removal. This reagent should be handled in a fume hood.

Baeyer-Villiger Reaction.

Simple acyclic ketones and cyclic ketones having seven or more carbon atoms in the ring do not undergo facile Baeyer-Villiger reaction with normal peroxy acids like ***m-Chloroperbenzoic Acid***; only PMA and ***Trifluoroperacetic Acid*** (TFPAA) are useful for this reaction. Although PMA is not as powerful an oxidizing agent as TFPAA, its reactivity is adequate. When TFPAA is used, an inorganic buffer reagent has to be added; when PMA is used there is no need for such a buffer reagent.[2]

Baeyer-Villiger reaction of the ketone (**1**) furnishes the ester (**2**) (eq 1).[2] Oxidation of the diketone (**3**) furnishes the lactone (**4**) in 77% yield; the reaction was performed on a 1.0 mol scale.[5] Baeyer-Villiger reaction of the ketone (**5**) furnished in 93% yield the acetate (**6**).[6] Ketone (**7**) gave the acetate (**8**) in 90% yield;[7] this oxidation cannot be carried out with *m*-CPBA.

(1)

(3)

(4)

(5) R = COMe

(6) R = OCOMe

(7) R = COMe

(8) R = OCOMe

Cyclododecanone has been oxidized to the lactone (**9**) (eq 2).[8] The reaction has been carried out on the 250 g scale. In this case, PMA satisfactory for the Baeyer-Villiger reaction was prepared with 30% H_2O_2 by using enough ***Acetic Anhydride*** to react with the water present.

(2)

(9)

It has been observed that reaction of maleic anhydride with 86% H_2O_2 in CH_2Cl_2 is incomplete even at reflux temperature. PMA prepared by method (b) above reacted rapidly (15-30 min) with a slight excess of cyclohexanone at 35-40 °C to provide hexanolide in 90-100% yield.[4]

Oxidation of Nitrogen-Containing Compounds.

Aromatic primary amines (**10**) and (**12**) have been oxidized by PMA to the nitro compounds (**11**)[2] and (**13**)[9] in yields of 40% and 61%, respectively. The nitro compound (**11**) cannot be prepared from (**10**) using TFPAA.[2]

(10) R = NH_2
(11) R = NO_2

(12) R = NH_2
(13) R = NO_2

Other Applications.

Alkenes which are not electron rich can be epoxidized by PMA; 1-octene and methyl methacrylate have been epoxidized in 80% and 74% yields.[2] Adenine 1-oxide nucleotides have been prepared by oxidation of natural compounds in 75-80% yields with PMA in aqueous solution at neutral pH.[10]

Peroxydisulfuryl Difluoride[1]

[13709-32-5] · $F_2O_6S_2$ · Peroxydisulfuryl Difluoride · (MW 198.14)

(fluorosulfating agent, capable of halogen[2-7] and hydrogen abstraction[2,8,9] reactions to give esters of fluorosulfuric acid; powerful oxidant[10,11])

Physical Data: bp 67.1 °C; mp -55.4 °C.[1,11,12]

Form Supplied in: colorless liquid with unpleasant odor.

Preparative Methods: can be obtained by the reaction of SO_3 with F_2 in the presence of AgF_2[11] or by electrolysis of fluorosulfuric acid.[12]

Handling, Storage, and Precautions: although the reagent appears to be stable and there are no reports of explosive properties, it should be handled with care. It can ignite organic materials upon contact. It is hydrolyzed by water to give oxygen and fluorosulfuric acid.[12] Use in a fume hood.

Synthesis of Fluorosulfates.

The chemical behavior of $F_2S_2O_6$ is determined by two features of its reactivity: (a) the ability to generate the radical species &bdot;OSO_2F in the reversible dissociation reaction,[2,13] and (b) the high oxidation ability[10,11] and, in particular, the generation of high-valent species containing two fluorosulfate groups.[1] The reagent (**1**) smoothly substitutes halogen atoms (Cl, Br, I) for fluorosulfate groups, probably via transient formation of hypervalent species of type (**2**) (eq 1).[3]

$$\underset{(1)}{RX + FSO_2OOSO_2F} \longrightarrow \underset{(2)}{\left[RX(OSO_2F)_2\right]} \longrightarrow ROSO_2F \quad (1)$$

For example, methyl chloride or bromide reacts with $F_2S_2O_6$ at -25 °C to give methyl fluorosulfate.[2] The reaction is applicable to fluorochlorocarbons (eq 2).[4]

$$CF_2ClCFCl_2 \xrightarrow{F_2S_2O_6} CF_2ClCFClOSO_2F \qquad (2)$$

In the case of perfluoroalkyl iodides the relatively stable hypervalent iodine derivatives of type $R_fI(OSO_2F)_2$ can be isolated; they are also readily transformed into the corresponding fluorosulfates R_fOSO_2F.[5-7]

Perfluoroalkenes react with (**1**) to give *vic*-difluorosulfates,[14 -17] e.g. eq 3.[15]

(3)

C_6F_6 also gives a 1,4-addition product and then 1,2,3,4- and 1,2,3,4,5,6-addition products.[18]

Hydrogen Abstraction.

Reactions of (**1**) with a variety of organic compounds such as amines, alcohols, thiols, aromatics, and even saturated hydrocarbons, proceed by hydrogen abstraction and addition of an OSO_2F moiety (R-H -> $ROSO_2F$).[1,2,8,9,19,20] For example, methane gives a mixture of methyl fluorosulfate and methylene difluorosulfate.[20] Methyl fluorosulfate also gives methylene difluorosulfate in reaction with (**1**).[2] Hexafluoropropane[8] and propionic acid[20] react in accordance with eqs 4 and 5.

$$(CF_3)_2CH_2 \xrightarrow{F_2S_2O_6} (CF_3)_2CHOSO_2F \qquad (4)$$

(5)

Hexafluoroacetone imine also reacts with substitution of the imine hydrogen atom (eq 6).[19]

$$(CF_3)_2C{=}NH \xrightarrow{F_2S_2O_6} (CF_3)_2C{=}NOSO_2F + (CF_3)_2C(FO_2SO)-N{=}N-C(OSO_2F)(CF_3)_2 \quad (6)$$

Benzene gives phenyl fluorosulfate[1] and nitrobenzene gives *m*-nitrophenyl fluorosulfate[21], respectively, in reaction with (**1**).

Oxidation.

Peroxide (**1**) is a powerful oxidant and can be used for the oxidation of noble metals (Ag, Au, Re, Pt, Os, Rh) to the salts of fluorosulfuric acid.[10,22] For example, the oxidation of metallic silver by $F_2S_2O_6$ in the presence of $HOSO_2F$ gives $Ag(SO_3F)_2$.[22] Oxidation of organic compounds can produce radicals. For example, the trimer (**3**) of perfluoropropylene reacts with (**1**) to give stable radical (**4**), isolated in analytically pure form (eq 7).[23]

$$\underset{\textbf{(3)}}{[(CF_3)_2CF]_2C{=}CFCF_3} \xrightarrow{F_2S_2O_6} \underset{\textbf{(4)}}{[(CF_3)_2CF]_2C^{\cdot}-CF(OSO_2F)CF_3} \quad (7)$$

Dimethyl ether reacts with (**1**) to give dimethoxyethane as the sole product, presumably via selective dimerization of transient methoxymethyl radicals (eq 8).[24]

$$2\,Me_2O + \underset{\textbf{(1)}}{FSO_2OOSO_2F} \xrightarrow{FSO_3H} MeOCH_2CH_2OMe + 2\,FSO_3H \quad (8)$$

Carbon monooxide is oxidized by (**1**) to CO_2.[3] Nitroso groups in perfluoronitrosoalkanes are either oxidized to nitro groups or undergo substitution by an OSO_2F group.[25]

Phenacyl Bromide

[70-11-1] · C_8H_7BrO · Phenacyl Bromide · (MW 199.05)

(protecting group for acids and phenols;[1] removable by zinc reduction)

Alternate Name: 2-bromoacetophenone.

Physical Data: mp 48-51 °C; bp 135°/18 mmHg.

Solubility: insol H_2O; sol common organic solvents.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: corrosive lachrymator; use in a fume hood.

Carboxylic Acids.

The phenacyl group was introduced[1] as a useful protecting group for carboxylic acids since it is easily attached, stable to a range of conditions, and removable again under conditions which do not affect most other functional groups. The ester is made by S_N2 displacement of phenacyl bromide by the salt of the acid, in water or other solvents, rapidly and in good yields.[2] It has also been made using crown ethers,[3] phase transfer,[4,5] KF catalysis,[6] and with ion-exchange resins loaded with the carboxylate salt.[7] It may be removed again by zinc reduction in glacial or aqueous acetic acid in about an hour at room temperature, affording the acid and acetophenone.[1] The ***Zinc-Acetic Acid*** reduction has been improved by using chelating agents to sequester the formed zinc salts.[8] It has also been expeditiously removed by displacement with thiophenoxide[9] and telluride[5] ions, which do not affect carbonyls. As a variation, the *p*-bromophenacyl esters have been used in the same way and have the advantage of higher melting points and of clear AB patterns in the NMR.

Because of its ease of introduction, high yields, and selectivity, the phenacyl protecting group has found extensive use in peptide synthesis[10] as it is stable to the hydrogenation conditions used to remove benzyl protecting groups and to the acid conditions removing Boc. In general, the phenacyl esters have not caused racemization during amino acid coupling, except for a report of racemization of proline.[11] Phenacyl esters have also been employed to derivatize fatty acid mixtures for chromatographic analysis.[12]

A special feature of the method lies in the opening of lactones that spontaneously reclose. Since esterification of 4-bromophenacyl bromide occurs via S_N2 displacement with the carboxylate anion, from the base-opened lactone, the hydroxy ester can often be isolated, for further reactions on the hydroxyl group. This is illustrated in the conversion of the *trans*-lactone of santonin to its *cis*-lactone diastereomer[13] in eq 1. Conversion in the reverse direction in this case was not effective, however, since alkali on the *cis*-lactone only caused elimination.

Phenols.

While much used for acids, the phenacyl group has seen less use for phenol protection.[14,15] Commonly made by alkylation of the phenols with K_2CO_3 in refluxing acetone for 1-2 hours, the phenacyl ethers are as easily removed with

zinc.[1] As in peptide synthesis the group is valued for its selectivity, being stable to hydrogenation and the acid conditions used to remove MEM ethers.[15] Under stronger acid conditions, however, the phenacyl ethers are apt to cyclize to benzofurans, as in eq 2.

(2)

Amines.

In a variant on the Gabriel synthesis, phenacylsulfonyl amines were made (from phenacylsulfonyl chloride and primary amines) and could be efficiently monoalkylated on nitrogen, then the phenacylsulfonyl group removed as above with zinc and acid, releasing the secondary amine product with SO_2 and acetophenone (eq 3).[16] As protecting groups, these were found to be sensitive to alkali (cleavage to benzoic acid), and in the monoalkylation of the nitrogen, the methylene of phenacylsulfonyl was also alkylated.

Phenoxyacetic Acid

[122-59-8] · $C_8H_8O_3$ · Phenoxyacetic Acid · (MW 152.16) (dilithio dianion)

[67774-23-6] · $C_8H_6Li_2O_3$ · Dilithiophenoxyacetate · (MW 164.02)

(dianion used for α-alkylation,[1] carboxymethylation of organoboranes,[2,3] aldol addition reactions to give α-phenoxy-β-hydroxy acids,[2-5] and phenyl enol ether synthesis;[2,3] phenoxymethylation of quinones;[6] OH and NH protection of nucleosides[7,8])

Physical Data: mp 98-99 °C; pK_a 5.12.

Form Supplied in: commercially available.

Preparative Methods: the title reagent and other substituted aryloxyacetic acids are easily synthesized by a Williamson ether synthesis using a phenol, base, and an α-haloacetic acid derivative.[9]

Purification: recrystallization from H_2O.

General Discussion.

Deprotonation of phenoxyacetic acid by ***Lithium Diisopropylamide*** (LDA) generates dilithiophenoxyacetate that can be alkylated by alkyl halides and carbonyl compounds (eq 1).[1,4]

(1)

The dilithio anion formed in the above chemistry is useful as a reagent to carboxymethylate organoboranes (eq 2).[2,3] The yields are poor with very hindered alkyl groups; only a single alkyl group is transferred. ***9-Borabicyclo[3.3.1]nonane*** can be used to maximize the efficiency and yield in terms of transfer of the alkyl group.

(2)

Reaction of the dianion with carbonyl compounds gives the expected α-phenoxy-β-hydroxy acids.[4,10] The reaction with aldehydes can be stereoselective for the *threo* isomer.[4,5] Subsequent cyclization of the intermediate β-hydroxy acid to the β-lactone then allows for a thermal decarboxylation to provide phenyl enol ethers (eq 3).[10] ***Magnesium Bromide***-catalyzed rearrangement of the β-lactone derived from the dianion and cyclopentanecarbaldehyde provides an entry to *trans*-fused cyclohexane butyrolactones.[4]

(3)

1,2-Addition occurs in reaction of the dianion with α,β-unsaturated aldehydes and again high stereoselection can be observed.[5]

Decarboxylation of phenoxyacetic acid with ***Ammonium Peroxydisulfate-Silver(I) Nitrate*** in the presence of ***1,4-Benzoquinone*** gives 2-phenoxymethyl-1,4-benzoquinone by a radical alkylation (eq 4).[6]

(4)

Phenoxyacetyl derivatives are useful for the protection of hydroxy and amino groups. Phenoxyacetate esters can be

selectively cleaved by aqueous or methanolic ammonia in the presence of simple acetate or benzoate esters.[7] Similarly, phenoxyacetamide derivatives are reportedly useful in nucleotide synthesis.[8] Specifically, the acid chloride of phenoxy acetic acid has been used to protect the exocyclic amino group of purine or pyrimidine nucleic acid bases. The phenoxyacetamide group increases the lipophilicity of the intermediate nucleic acid bases and improves their stability to acid treatment in oligodeoxyribonucleotide synthesis.

Related Reagents.

Dilithioacetate; ***Ethyl Lithioacetate***; ***Ethyl Mandelate***; ***Ethyl Trimethylsilylacetate***; ***Methyl O-Methyllactate***; β-***Propiolactone***; ***Trimethylsilylacetic Acid***.

(2*R*,3*R*)-(*Z*)-*cyclo*-Phenylalanine

(.HCl)

[110716-95-5] · $C_{10}H_{12}ClNO_2$ · (2*R*,3*R*)-(*Z*)-*cyclo*-Phenylalanine · (MW 213.68)

(reagent for syntheses of conformationally constrained peptidomimetics)

Physical Data: (HCl salt) mp 201 °C (dec); [α]25D +105° (*c* 0.69, H_2O).

Solubility: the compounds of this series closely resemble the parent amino acids; they are sol water, moderately sol lower alcohols, and insol apolar solvents.

Form Supplied in: colorless solid; not currently commercially available on a routine basis.

Analysis of Reagent Purity: chemical purities are accessed by mp and NMR; optical purities are deduced by forming diastereomeric derivatives, or by derivatization and analysis in the presence of chiral NMR shift reagents.

Preparative Methods: substituted 2,3-methanoamino acids are difficult to prepare. Unfortunately, most of the reported syntheses give racemic materials whereas stereochemically pure compounds are required for studies of cyclopropane-based peptidomimetics. The only 2,3-methanologs of protein amino acids prepared in optically active form are (*E*)- and (*Z*)-*cyclo*-Phe[1-4] and -Tyr,[5] all four stereoisomers of *cyclo*-Met,[6] (*Z*)-*cyclo*-Arg[7] and (2*S*,3*S*)-(*Z*)-*cyclo*-Trp,[8] although several routes to enantio-enriched 2,3-methanologs of simple nonproteogenic amino acids have been reported.[9-12] The most practical synthesis of the title compound is that based on a diastereoselective, rhodium-catalyzed cyclopropanation reaction.[3]

Handling, Storage, and Precautions: some compounds in this series are slightly hygroscopic,

but they are otherwise quite stable, and indefinitely so under an inert atmosphere in a freezer. For good results in peptide syntheses these compounds must be used with the same precautions taken for any common amino acid derivative.

Background.[13]

One of the least drastic perturbations of amino acid structure is to link the α- and β-carbons of the side chain with a methylene group, giving 2,3-methanoamino acid analogs (or methanologs, e.g. the cyclopropyl analogs of phenylalanine, *cyclo*-Phe, and of methionine, *cyclo*-Met). Incorporation of a cyclopropane ring locks the side chain substituent *cis* or *trans* to the amino functionality. Designation of the absolute configurations of the two chiral centers completely defines the stereochemistry, whereas (*Z*) and (*E*) nomenclature specifies the diastereomeric, but not the enantiomeric, form. Both systems are shown on the examples in Figure 1, even though it is redundant to specify (*Z*) or (*E*) stereochemistry if the absolute configuration is marked.

These amino acid surrogates have side chains locked *cis* or *trans* to the amino functionality and the cyclopropane ring also restricts rotations about the N-C_α and C_α-CO bonds (i.e. φ and ψ, respectively).[14 -16] A Ramachandran plot[17] for a related compound indicates these conformational restrictions are severe.[14 -16,18,19] Consequently, systematic variations of stereoisomeric 2,3-methanolog substitutions facilitate controlled restrictions on the conformational freedom of peptidomimetics,[20,21] and it is possible to constrain them into molecular orientations that resemble bioactive conformations of the parent peptide. Substitution of a protein amino acid with its 2,3-methanolog therefore can enforce or preclude structural shapes required for various bioactivities. They can also impart considerably enhanced resistance to proteolytic degradation.[22-27] These are the main applications of this class of compounds.

At the present time, 2,3-methanoamino acid analogs can only be viewed as *reagents* in the context of syntheses of peptidomimetics. Consequently, this entry describes only that chemistry related to incorporation of protein amino acid methanologs into peptide sequences.

Incorporation into Peptidomimetics.

Solution phase methods have been used to incorporate *cyclo*-Phe stereoisomers into enkephalin analogs. The mixed anhydride method (*i*-BuOCOCl, ***Isobutyl Chloroformate***) was used as illustrated in Figure 2, which depicts the deprotection/coupling sequence used in the preparation of Tyr-D-Ala-Gly-(*cyclo*-Phe)-Leu-OH. Thus the first step was *N*-Cbz protected *cyclo*-Phe being coupled with Leu-OMe via the mixed anhydride method; the dipeptide so formed was coupled with Cbz-Tyr-D-Ala-Gly-OH after ***Trifluoroacetic Acid*** deprotection.[22] Methyl ester protecting groups were used at the *C*-terminus, and benzyloxycarbonyl (Cbz) protection was employed at the *N*-termini. The Cbz groups were removed by acid deprotection and not hydrogenolysis, since the latter conditions cause extremely facile ring-opening

of methanologs with aromatic substituents connected to the strained ring.[2]

Peptide syntheses have undergone extensive improvements in the decade since the preparations described above were performed.[28,29] A more contemporary approach to syntheses of peptidomimetics using the solid phase Fmoc (9-fluorenylmethoxycarbonyl) approach is illustrated in Figure 3.[23,30] The couplings were performed using Castro's reagent (BOP, ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate***) in the presence of ***1-Hydroxybenzotriazole*** (HOBt).[31]

Other peptides in the F{*cyclo*-M}RF-NH_2 series have been prepared using a more acid stable resin (MBHA, methoxybenzhydrylamine) and Boc (*t*-butoxycarbonyl) protecting groups, but the Fmoc approach above gives superior yields.[23,30]

Phenyl Azide[1]

PhN_3

[622-37-7] · $C_6H_5N_3$ · Phenyl Azide · (MW 119.14)

(reagent for the synthesis of 4,5-dihydro-1,2,3-triazolines, 1,2,3-triazoles, aziridines, and other heterocycles via 1,3-dipolar cycloaddition with alkenes, alkynes, and other unsaturated functional groups;[2] allows measurement of the degree of strain present in alkenes and alkynes by their relative rates of dipolar cycloaddition;[2a,3,4] converts organoboranes into *N*-alkylanilines;[5] in combination with Lewis or protic acids, produces nitrenium ions or their equivalent, which react as electrophiles at nitrogen or aromatic carbon to produce substituted anilines;[6,7] reagent for the synthesis of 2-hetero-3*H*-azepines by ring expansion;[7,8] related aryl azides undergo the above reactions as well as thermally or photochemically induced intramolecular C-H insertions to produce a variety of nitrogen heterocycles;[7-10] substituted aryl azides are commonly used in photoaffinity labeling;[11] aryl azides act as electrophiles toward carbon, nitrogen, and phosphorus nucleophiles, leading to new N-C, N-N, and N-P bonds.[1,8a,b,9])

Alternate Name: azidobenzene.

Physical Data: bp 49-50 °C/5 mmHg, 66-68 °C/21 mmHg.[12]

Solubility: freely sol common organic solvents; insol water, aqueous acids, and aqueous alkalis.

Form Supplied in: colorless to pale yellow oil; odor resembling benzaldehyde, benzonitrile, or nitrobenzene; not available commercially.

Analysis of Reagent Purity: the concentration of toluene solutions can be determined by an iodometric titration.[13]

Preparative Methods: diazotization of phenylhydrazine.[12,14]

Handling, Storage, and Precautions: phenyl azide is explosive. A blast shield should be used during its purification by distillation, and the temperature should be controlled as recommended.[12,14] The pure substance may be stored in a brown glass bottle in a cool, dark place for up to a month. It is slowly discolored by light. It is often stored and used as a solution in ether or toluene. Doering's procedure results in material that has a longer shelf-life, due to the absence of traces of phenol.[14] This reagent should only be handled in a fume hood.

Cycloaddition Reactions: Formation of Triazolines, Triazoles, Imines, and Aziridines.

The 1,3-dipolar cycloaddition of phenyl azide and other aryl azides with various π-systems is well known.[2] Cycloaddition with alkenes initially produces triazolines, which may be isolated in many cases. However, triazolines are thermally sensitive and are often converted to other products (e.g. triazoles, aziridines, imines, and diazo compounds) under the conditions required for cycloaddition. While simple alkenes undergo sluggish cycloadditions with phenyl azide,[2] strained alkenes can be quite reactive.[2a,3,4] Since the original observations by Alder and Stein,[3] phenyl azide has been used frequently to trap strained and reactive alkenes and alkynes. The relative rate of reaction of aryl azides with alkenes has been used to measure their relative strain energies.[2,4] The reaction of *trans*-cyclooctene with trinitrophenyl azide serves to illustrate the types of products observed in such cycloadditions (eq 1).[4] The initially formed triazoline fragments easily to a zwiterionic intermediate, which undergoes 1,2-shifts to give imines or direct closure to produce aziridines.

(1)

Conjugated dienes are sufficiently reactive to allow useful cycloadditions.[2a] Simple, unstrained alkenes can be used in intramolecular 1,3-dipolar cycloadditions with aryl azides (eq 2).[2,15]

(2)

Electron-poor alkenes and alkynes are excellent dipolarophiles.[2a] Aziridines or diazo compounds may be produced from electron-poor alkenes by fragmentation of the initially formed triazoline intermediate, depending on the exact nature of the electron-withdrawing group and the presence or absence of an adjacent hydrogen on the alkene. Eq 3

illustrates the efficient formation of an aziridine.[16] The triazoline was observed by NMR when the cycloaddition was run at 40 °C. In contrast, the triazoline derived from the cycloaddition of phenyl azide with ***Methyl Acrylate*** was easily transformed to the α-diazoester with base (eq 4).[17] Alternatively, the triazoline could be oxidized to a triazole. Cycloadditions with electron-poor alkynes are also facile, producing triazoles directly. For example, phenyl azide reacts with ***Dimethyl Acetylenedicarboxylate*** to produce a triazole,[18] which was transformed into a bis(hydroxymethyl)triazole derivative for evaluati on as an antineoplastic agent (eq 5).[19]

(3)

(4)

Electron-rich alkenes and alkynes are also reactive dipolarophiles toward aryl azides.[2a] Enol ethers and enamines are particularly useful,[20a] providing an excellent route to 1,2,3-triazoles after loss of the alcohol or amine from the intermediate triazoline (eq 6).[20]

Generation of Nitrenes: C-H Insertion and Aziridination.

The thermal or photochemical decomposition of aryl azides to nitrenes has been an active area of research.[7-10] Singlet nitrenes are produced initially, which may undergo insertion reactions. Triplet nitrenes may be produced by sensitized photolysis of aryl azides or by thermolysis in the presence of certain external agents. Triplet nitrenes often participate in hydrogen atom abstraction reactions. While the thermal and photochemical decomposition of phenyl azide has been well studied, intramolecular reactions of substituted aryl azides are the most synthetically useful. For example, the thermolysis of *o*-azidobiphenyl is an excellent method for the formation of carbazoles (eq 7).[8c,d,21] This reaction is not a direct C-H insertion, since evidence for an intermediate other than the nitrene has been obtained. A likely mechanism is an intramolecular aziridination followed by rearrangement to the carbazole.

A recent application of aryl azides to natural product synthesis illustrates the complementary chemistry of singlet and triplet nitrenes (eq 8).[22] Thermolysis led to pyridocarbazole formation via a singlet nitrene. Sensitized photolysis led to benzylic C-H insertion, presumably by hydrogen atom abstraction by a triplet nitrene followed by diradical combination. This route was used to make the natural product cystodytin A.

Indoles may be produced by formal C-H insertion of *o*-azidostyrenes (eq 9).[23] If a heteroatom is suitably tethered, reaction with a nitrene may be observed, producing a variety of heterocycles (e.g. eq 10).[24] A wide variety of unsaturated groups in the *ortho* position lead to heterocycle formation, including imines, azo groups, azides, carbonyl groups, amides, imides, and nitro groups.[8a] The photolysis and thermolysis of phenyl azide itself (or of aryl azides with no *ortho* substituents) is complex.[7-10]

(9)

(10)

One useful insertion reaction is the formation of 2-hetero-3*H*-azepines by photolysis of aryl azides in the presence of nucleophiles such as amines and alcohols (eq 11).[25] A proposed mechanism for this reaction is ring expansion of the nitrene to a dehydroazepine followed by nucleophilic addition and tautomerization. Azides are commonly used to generate nitrenes for photoaffinity labeling investigations in biological experiments.[11]

(11)

Reaction with Electrophiles: Nitrenium Ions and Their Equivalents.

Although azides are weak Lewis bases, they may form complexes reversibly with protic acids or Lewis acids. Complexation at the most substituted nitrogen atom is preferred, which generates an electron-deficient nitrogen species which may undergo substitution or deazoniation.[6,7,8a,b,9]

Complexation of trialkylboranes, dialkylchloroboranes, or alkyldichloroboranes with phenyl azide (and other azides) leads to a 1,2-shift of an alkyl group to the electron-deficient nitrogen, producing anilines after hydrolysis (eq 12).[5] Complexation of phenyl azide with ***Aluminum Chloride*** generates an electrophilic reagent which may react with

alkenes to produce aziridines or addition products (eq 13).[26]

(12)

(13)

Protonation of aryl azides with strong acids followed by loss of nitrogen produces nitrenium ions, which are potent electrophiles at both the nitrogen atom and the *ortho* and *para* positions on the arene.[6] Intermolecular reactions with arenes commonly produce diarylamines (eq 14),[27] but *C*-arylation is a competing process.[6] Other nucleophiles, such as sulfides, can be used in intermolecular reactions with nitrenium ions, producing *o*- and *p*-thioanilines.[28] Intramolecular reactions of nitrenium ions with arenes (eq 15)[29] or other nucleophiles (eq 16)[29] are more chemoselective.[6]

(14)

(15)

(16)

Reactions with Nucleophiles.

The terminal nitrogen of aryl azides is moderately electrophilic.[1,8a,b,9] Reactions with phosphines (the Staudinger reaction, eq 17),[30,31] cyanide ion (eq 18),[32] organometallic reagents (eq 19),[8a,b,33] and amide anions (eq 20)[34] produce a variety of adducts. The phosphazenes decompose rapidly to iminophosphoranes (eq 17), which are useful for the conversion of carbonyl compounds to imines (the aza-Wittig reaction).[30] The cyanotriazenes (eq 18) are easily decomposed to anilines by alkali.[32] The triazenes derived from organometallic compounds (eq 19) may be converted to anilines by reduction,[33] although there are other azides which better fit this purpose.[8a,b] Dilithiotetrazenes (eq 20) have found use as ligands for transition metals, producing metallacyclotetraazapentadienes.[34] Not shown is the use of metal hydrides to reduce aryl azides.[8a,b]

(17)

(18)

(19)

A particularly useful type of nucleophilic addition to azides is their reaction with the anions of active methylene compounds and related nucleophilic carbon species (the Dimroth reaction), leading to 1,2,3-triazoles.[8a,35] An example with phenylacetonitrile is shown in eq 21.[36] Intramolecular reactions of enolates and amide anions (e.g. eq 22) have also been reported, leading to cyclization with nitrogen loss.[37]

Phenyl Benzenethiosulfonate[1]

[1212-08-4] · $C_{12}H_{10}O_2S_2$ · Phenyl Benzenethiosulfonate · (MW 250.36)

(sulfenylating agent)

Physical Data: mp 38-42 °C; bp 125 °C/0.01 mmHg.

Form Supplied in: white solid.

Preparative Method: prepared by oxidation of ***Diphenyl Disulfide*** with 30% ***Hydrogen Peroxide*** (72%).[2]

Purification: crystallization from methanol (mp 36-37 °C).[2]

Introduction.

Phenyl benzenethiosulfonate ($PhSSO_2Ph$) is a preferred sulfenylating reagent to ***Methyl Methanethiosulfonate*** and ***Methyl p-Toluenethiosulfonate*** because it possesses higher intrinsic reactivity and because, at times, the latter reagents are not particularly effective, possibly due to the acidity of their methyl and *p*-methyl groups which are activated by the thiosulfonate group.[2] $PhSSO_2Ph$ is also a more reactive sulfenylating agent than the widely used ***Diphenyl Disulfide***, and the reactions are somewhat cleaner and less odoriferous than with PhSSPh. This reactivity difference gives $PhSSO_2Ph$ certain advantages over PhSSPh. For example, it increases the regioselectivity of sulfenylation of 2-methylcyclohexanone (eq 1).[3] This regioselectivity corresponds to the kinetic selectivity in enolate generation.

Preparation of 1,2-Diketones via β-Keto Sulfides.[2]

Direct sulfenylation of cyclic ketone enolates with $PhSSO_2Ph$ yields β-keto sulfides which are acetoxylated by ***Lead(IV) Acetate*** in warm benzene. The β-keto acetoxy sulfide represents a monoprotected form of a 1,2-dicarbonyl compound. Oxidation and sulfoxide elimination produce, regiospecifically, the monoenol acetate of the diketone. Treatment with I_2 in MeOH gives the monoacetal. Exposure to basic H_2O_2 leads to the ring-cleaved diacids which can also be obtained directly from the β-keto sulfides upon treatment with basic H_2O_2 (eq 2). Application of this methodology is exemplified by eqs 3 and 4, which show stereo- and regiospecific sulfenylation, respectively.

(2)

(3)

(4)

1,2-Carbonyl Transposition via Bissulfenylation.

Yee and Schultz have modified the above method of Trost to achieve 1,2-carbonyl transposition via bissulfenylation of the lithium enolate generated with ***Lithium 2,2,6,6-Tetramethylpiperidide*** (eq 5).[4] The method has been employed successfully in a total synthesis of a more complex molecule, (±)-lycoramine, in which the carbonyl transposition was accomplished in 64% overall yield.[5]

Preparation of 2-(Phenylthio)alkanoic Acids and Esters.

2-(Phenylthio)alkanoic acids and esters are synthesized by successive treatment of substituted malonic esters with ***Sodium Ethoxide*** and $PhSSO_2Ph$, followed by alkaline hydrolysis which causes concurrent decarboxylation (eq 6).[6] Ogura et al. have reported[7] a more convenient method for preparation of 2-(phenylthio)alkanoic esters from the 2-acetylalkanoate (eq 7).

(7)

$PhSSO_2Ph$ can be replaced with PhSSPh as the sulfenylating agent in this transformation, but the reaction with PhSSPh takes much longer. Advantages of the methods described in eqs 6 and 7 over others such as the sulfenylation of alkanoic acids and esters and the alkylation of (phenylthio)acetic acid are: (1) simplicity of the procedure; (2) efficiency and convenience of using an inexpensive base (EtONa) and EtOH as solvent with high product yields; and (3) no bissulfenylation. Moreover, the method described in eq 7 allows direct α-sulfenylation of 2-acetylalkanoates which also contain an additional unprotected keto group (see ***Methyl Methanethiosulfonate***).

Sulfenylated Enolates for Aldol Condensation.

Bissulfenylation followed by monodesulfenylation with a Grignard reagent cleanly provides magnesium enolates of α-phenylthiocarbonyl compounds for aldol condensation (eq 8).[8] The Grignard reagent serves as a nucleophile towards sulfur, not the carbonyl group, to give a clean mixture of the magnesium enolate contaminated only by the byproduct, alkyl phenyl sulfide. In cases where the competitive attack at the carbonyl may become severe, addition of 5 mol % of $CuBr.SMe_2$ (see ***Copper(I) Bromide***) facilitates the chemoselectivity toward sulfur. A related desulfenylation reaction induced by ***Lithium Diisopropylamide*** from a bissulfenylated cyclic imide has also been reported.[9]

(8)

Dimethyl [(Phenylthio)methyl]phosphonate.

Sulfenylation of dimethyl α-lithiomethylphosphonate with $PhSSO_2Ph$ is a convenient method for synthesis of the title compound. Diethyl ether is a superior solvent to THF in this sulfenylation reaction (eq 9).[10] The method is applicable for the preparation of alkyl- and allylthiomethylphosphonates.

(9)

Formation of Symmetrical or Unsymmetrical Sulfides.

The nucleophilic attack of alkyl- and aryllithiums at the sulfenyl S atom in phenyl benzenethiosulfonate provides a convenient method for the synthesis of both symmetrical and unsymmetrical aromatic sulfides in excellent yields (>90%).[11] The example in eq 10 shows that the reaction is not affected by the steric bulk of the lithiated species.

Stereoselective Synthesis of Ethyl (2*E*,4*E*)-Alkadienoates from Ethyl Sulfolane-2-Carboxylate.

α,β;γ,δ-Unsaturated esters are conveniently synthesized with high (*E*,*E*) selectivity from ethyl sulfolane-2-carboxylate through alkylation and oxidation followed by SO_2 extrusion from the 3-sulfolene derivatives resulting from base-induced isomerization.[12] This efficient method has been applied to the synthesis of an insecticidal compound, pellitorine, by simple operations (eq 11).

The optimal conditions for general application of this procedure are: (1) RI/$PhSSO_2Ph$ or RBr/PhSCl combination for the alkylation/sulfenylation step and THF as solvent; and (2) ***m-Chloroperbenzoic Acid*** as oxidant of the sulfide formed (critical). Alkyl bromides and alkyl tosylates can also be used in combination with $PhSSO_2Ph$. Secondary alkyl halides, which generally do not react with the α-anion of 3-sulfolene, can also be used with this method.

Regioselective Vinylcarbene Formation and [3 + 2] Cycloaddition under Mild Conditions.

Phenylthio-substituted cyclopropenone acetals undergo highly regioselective vinylcarbene formation below room temperature to permit the thermal [3 + 2] cycloaddition to take place under extremely mild conditions (eq 12).[13] The method is useful for the synthesis of substituted cyclopentenone derivatives.

N-Sulfinyloxazolidinones, a New Class of Chiral Sulfinyl Transfer Reagents.[14]

N-Sulfinyloxazolidinone reagents are synthesized either by sulfinylation of the metalated oxazolidinones or by oxidation of the derived *N*-sulfenimides, to afford the diastereomeric *N*-sulfinyloxazolidinones which are readily purified by chromatography (eq 13).

These sulfinylating agents react with a wide range of nucleophiles such as Grignard reagents, enolates, lithium alkoxides, or metalated amides, with inversion of configuration at the sulfur center, to afford chiral sulfoxides, sulfinate esters, and sulfinamides in high yields and enantioselectivities (eq 14). This family of chiral sulfinylating agents is at least 100 times more reactive than the corresponding menthyl sulfinate esters toward Grignard reagents.

(14)

Related Reagents.

Benzenesulfenyl Chloride; ***Diphenyl Disulfide***.

N-Phenylbenzylimine

[538-51-2] · $C_{13}H_{11}N$ · *N*-Phenylbenzylimine · (MW 181.25)

(hetero Diels-Alder and cycloaddition reactions; stereospecific β-lactam synthesis; secondary amine and quinoline syntheses)

Alternate Name: N-benzylideneaniline.

Physical Data: mp 52-54 °C; bp 310 °C; fp >110 °C; *d* 1.038 g cm^{-3}. Generally exists in the *trans* form; theoretical studies have shown that the *cis-trans* interconversion occurs by inversion rather than rotation.[1]

Solubility: sol ether, alcohol, chloroform, acetic anhydride, liquid SO_2, NH_3; insol H_2O.

Form Supplied in: commercially available.

Analysis of Reagent Purity: IR.[18]

Purification: recrystallize from CS_2 (pale yellow needles) or dilute alcohol (plates) and vacuum dry.

Handling, Storage, and Precautions: harmful and irritant. Use in a fume hood.

Cycloaddition Reactions.

The initial example of an imino compound participating as a dienophile was reported by Alder in 1943.[2] Whilst full mechanistic details are not known, these [4 + 2] cycloadditions of C=N dienophiles (and also of N=N, N=O and C=O dienophiles) are believed to be $HOMO_{diene}$-$LUMO_{dienophile}$ controlled and concerted pericyclic processes. However, a dipolar mechanistic model is normally sufficient for quantitative predictions as to the regiochemical outcome of these reactions and may even be indicative of dipolar character in a concerted pericyclic transition state. Unless X and Y are very good at stabilizing carbanions, only intermediates (i) and (iii) need to be considered (eq 1). Imino Diels-Alder reactions show excellent *syn* stereoselectivity with respect to the diene component. Krow, however,[3] states that lone pair inversion on the nitrogen in both the imine and product tetrahydropyridine leads to stereochemical ambiguities that are missing in all carbon Diels-Alder reactions. Using a cyclic imine tends to remove this problem.

Imine cycloaddition reactions have become generally well known,[4] and there are also examples of iminium salts participating in these reactions.[5] Electron-rich dienes (**3**), in considerable excess, react with imines under the influence of Lewis acids (eq 2).[6,7] Only the one regioisomer (**2**) is detected in the product mixture and this is in keeping with the postulated mechanism in eq 1. The Danishefsky group has done considerable work in this field,[6] with both catalyzed and uncatalyzed reactions and with differing imines and dienes. There are also examples of ***Aluminum Chloride***, dialkylaluminium halides,[8a] ***Boron Trifluoride Etherate***, and ***Zirconium(IV) Chloride*** catalyzing these cycloadditions.[8b] Finally, various studies have been performed on the effects of the nitrogen substituent on the reaction course and heterocycle conformation in these imino Diels-Alder reactions.[8b]

(3) 4.3 equiv **(1)** **(2)**

β-Lactam Synthesis.

Condensation Reactions.

Imines and silyl ketene acetals condense in the presence of a ***Trimethylsilyl Trifluoromethanesulfonate*** (TMSOTf) catalyst to give mainly *anti*-β-amino esters, which can be cyclized to give *trans*-β-lactams (eq 3).[9] Table 1 shows some typical results obtained, mainly using *N*-phenylbenzylimine as the imine (**5**), but another imine is given for comparison.

Table 1 Typical Results from Silyl Ketene Acetal Condensation with Imines in the Presence of TMSOTf.[9]

R	(*E*):(*Z*) in (**4**)	R^1	R^2	Solvent	*T* (°C)	(**4**):(**5**)	Yield (%)	*syn*:*anti*
Ph	36:64	Ph	Ph	CH_2Cl_2	- 65	1:1	85	14:86
Me	75:25	Ph	Ph	CH_2Cl_2	- 65	1:1	85	0:100
Ph	36:64	PhCH=CH	*p*-$MeOC_6H_4$	THF	- 65	2:1	78	15:85

All these examples involve an acid-catalyzed condensation between an isomeric mix of silyl ketene acetal and nonenolizable imines. The yields obtained are normally good, with a preference for the *anti*-isomer, irrespective of the starting geometry of the silyl ketene acetal. The isomeric products can be separated by silica gel chromatography. The utility of this reaction is that the *anti*-β-amino esters can be cyclized to the *trans*-β-lactam in excellent yields (eq 4).[9]

The one well known exception to this is the silyl ketene acetal (**8**) derived from ethyl 3-hydroxybutanoate, which reacts with *N*-phenylbenzylimine with *syn* selectivity and cyclizes to give the *cis*-β-lactam (**9**) (eq 5).[10]

Another group has performed similar reactions to form chiral *trans*-β-lactams with high stereoselectivity using ***Titanium(IV) Chloride*** (eq 6).[11] The silyl ketene acetal (**10**) is derived from (1*S*,2*R*)-*N*-methylephedrine and in the presence of $TiCl_4$ gives the *trans*-β-lactam (**11**) in 79% yield and 95% ee. There are also reports of ***Zinc Iodide*** being used to promote these reactions, with some degree of stereoselectivity.[12]

Transition Metal-Mediated.

Simultaneous studies between groups in America and Britain have shown that the condensation of certain transition metal complexes with imines can give unprecedented asymmetric induction (eq 7).[13,14] Previous studies had shown that the enolate (**13**) derived from (**12**) is sufficiently nucleophilic to react with electrophiles, of which readily available imines (from amines and aldehydes/ketones) are a good example, and that the resulting β-aminoacyl complexes are formed stereoselectively. The American group have also shown that the diethylaluminum enolate is also as effective as the lithium enolate, and in some cases leads to greater stereoselectivity, although the yields drop.[14]

Preparation of Secondary Amines.

The addition of a carbon nucleophile to imines is a useful preparative method for secondary amines.[15] Alkyl organolithiums and Grignard reagents have been used to form secondary amines and considerable attention has been paid to forming allylated derivatives. The general reaction is shown in eq 8 and is an example of an indium-mediated Barbier-type allylation.

Quinoline Synthesis.

Treatment of *N*-phenylbenzylimine with diisopropyl peroxydicarbonate generates the arylimidoyl radical (**18**) which reacts with 1-alkynes to form 4-alkylquinolines (**19**) (eq 9). This is a useful route to substituted quinolines in high yields.[16] There are other examples of imines being used in annulation reactions with a variety of promoting reagents.[17]

Phenylboron Dichloride[1]

$PhBCl_2$

[873-51-8] · $C_6H_5BCl_2$ · Phenylboron Dichloride · (MW 158.82)

(Lewis acidic reagent for ether cleavage and selective condensations; phenylating agent)

Physical Data: mp 7 °C; bp 175 °C; *d* 1.194 g cm^{-3}.

Solubility: dec by water, alcohols, or ethers; sol saturated and halogenated hydrocarbons, aromatic solvents.

Form Supplied in: fuming liquid; widely available.

Preparative Methods: by transmetalation between ***Boron Trichloride*** and Ph_4Sn[2] or ***Phenylmercury(II) Chloride***.[3] Treatment of phenylboronates with boron trichloride in the presence of catalytic ***Iron(III) Chloride*** provides an alternative and efficient process.[4] For large scale preparation, a direct boronation of benzene with boron trichloride and ***Aluminum Chloride*** has been reported.[5]

Handling, Storage, and Precautions: stable under N_2; should be stored in a sealed ampule since it is highly susceptible to air and moisture.

General Discussion.

Phenylboron dichloride has been used in a manner similar to boron trichloride for the cleavage of ethers, but there are no data on their comparative merits.[6] Boron enolates, available by treating ketones with $PhBCl_2$ and ***Diisopropylethylamine*** at -78 °C, undergo highly *syn* selective crossed aldol reaction with aldehydes (eq 1).[7] The formation of the boron enolates is kinetically controlled and produces (*Z*)-enolates stereoselectively. Ketones condense with excess ketene in the presence of 2 equiv of $PhBCl_2$ to give stable cyclic boroles and α,β-unsaturated acid chlorides (eq 2).[8]

The *ortho*-hydroxyalkylation of anilines is achieved by in situ formation of anilinoboranes which condense with aromatic aldehydes at room temperature (eq 3).[9] The boron atom acts as an efficient template to achieve selective *ortho* substitution via the intermediate (**1**) through a cyclic transition state. The *ortho*-hydroxyalkylation of *N*-alkylanilines and aldehydes may also be performed with BCl_3, but the reaction fails with primary anilines because of competing Schiff base formation.[10]

(1)

The reagent is useful for phenylation of azides,[11] e.g. in the stereoselective synthesis of *N*-phenylaziridine (eq 4).[12] Similar reactions of phenylboron dichloride and several other arylboron dichlorides with ***Ethyl Diazoacetate*** at -25 °C provide quantitative yields of ethyl arylacetates (eq 5).[13] The reactions proceed through initial coordination of the azide or diazo group to the boron atom, followed by transfer of the phenyl group from boron to carbon or nitrogen.

(4)

(5)

A variety of phenylboron derivatives have been synthesized via transmetalation with other organometallic compounds, e.g. the transmetalation with Sn provides borepin derivatives (eq 6).[14]

N-Phenylcampholylhydroxamic Acid

[62668-00-2] · $C_{16}H_{23}NO_2$ · *N*-Phenylcampholylhydroxamic Acid · (MW 261.40)

(chiral ligand in asymmetric epoxidation of allylic alcohols[1])

Solubility: sol toluene, acetonitrile.

Preparative Method: phenylhydroxylamine (2 equiv) is added to a solution of campholyl chloride (1 equiv) in acetonitrile.[1]

Asymmetric Epoxidation.

N-Phenylcampholylhydroxamic acid has been used as a chiral ligand in the transition metal-catalyzed asymmetric epoxidation of allylic alcohols.[1] Three allylic alcohols [geraniol (**1**), (*E*)-α-phenylcinnamyl alcohol (**2**), and 1-hydroxymethyl-2-methylcyclohexene (**3**)] have been oxidized to the corresponding epoxides in the presence of the chiral hydroxamate complex of vanadium. The best asymmetric induction (50% ee) is observed for alcohol (**2**) at -78 °C. Generally, low temperature reactions give higher asymmetric inductions but lower yields. The optimum inductions are attained when a 5:1 ratio of hydroxamic acid and ***Vanadyl Bis(acetylacetonate)*** is used. ***t-Butyl Hydroperoxide*** gives substantially better inductions than ***Cumyl Hydroperoxide***. The asymmetric oxidation is proposed to go through the intermediate (**4**),[1,2] in which the alcohol is coordinated to the metal during the oxygen atom transfer step.

Phenyl Chlorothionocarbonate

[1005-56-7] · C_7H_5ClOS · Phenyl Chlorothionocarbonate · (MW 172.64)

(forms thionocarbonate ester derivatives of alcohols which can be deoxygenated with tin hydride reagents;[1-5] converts ribonucleosides to 2´-deoxynucleosides;[2] provides allylic thionocarbonates which undergo [3,3]-sigmatropic shifts;[6-9] provides precursors for radical bond-forming reactions;[10,11] reagent for thioacylation[12-16])

Physical Data: bp 81-83 °C/6 mmHg; fp 81 °C; *d* 1.248 g cm^{-3}.

Solubility: sol chloroform, THF.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: corrosive; moisture sensitive; should be stored in airtight containers which exclude moisture; incompatible with alcohol solvents.

Deoxygenation of Secondary Alcohols.

Reaction of secondary alcohols with the reagent in the presence of ***Pyridine*** or ***4-Dimethylaminopyridine*** (DMAP) provides thiocarbonate ester derivatives which can be reduced to alkanes using ***Tri-n-butylstannane*** (eq 1).[1] The advantage of this method is the ability to deoxygenate alcohols via radical intermediates and thereby avoid problems associated with ionic reaction conditions (i.e. carbonium ion rearrangements, reduction of other functional groups). This method is particularly useful for the conversion of ribonucleosides to 2´-deoxynucleosides. For example, adenosine can be converted to 2´-deoxyadenosine in 78% overall yield by initial protection of the 3´- and 5´-hydroxyl groups as a cyclic disiloxane, thiocarbonylation, reductive cleavage, and then final deprotection using a fluoride source (eq 2).[2] Treatment of 2´-bromo-3´-phenoxythiocarbonyl nucleosides with tributyltin hydride affords 2´,3´-didehydro-2´,3´-dideoxy nucleosides via radical β-elimination.[3]

Synthetic intermediates can be selectively deoxygenated without reduction of other functional groups such as esters, ketones, and oxime ethers (eq 3),[4] as well as epoxides, acetate esters, and alkenes.[5]

Sigmatropic Rearrangements of Allylic Thionocarbonates.

The reaction of allyl alcohols with aryl chlorothionocarbonates affords *S*-allyl aryl thiocarbonates by [3,3]-sigmatropic rearrangement via the intermediate thionocarbonate esters.[6-9] For example, treatment of 2-methyl-1-penten-3-ol with the reagent in pyridine at -20 °C affords phenyl 2-methyl-2-pentenyl thionocarbonate in 67% yield (*E*:*Z* = 96.5:3.5).[7] This type of rearrangement, coupled with tin hydride mediated reduction of the phenyl thiocarbonate ester product, was used as a key step in the synthesis of isocarbacyclin (eq 4).[8] Rearrangement of cyclic thionocarbonates contained in eight-membered rings or smaller provides two-atom ring enlarged thiocarbonates having (*Z*) double bond geometry (eq 5).[9] Depending on the system, the cyclic thiocarbonates are obtained by either treatment of the diol

monothionocarbonate with base or by reaction of the diol with 1,1´-thiocarbonyldi-2,2´-pyridone. Cyclic thionocarbonates of ring size nine or larger afford ring expanded products with exclusive (*E*) double bond geometry in modest yields.

(5)

Radical Coupling and Cyclization Reactions.

Phenyl thionocarbonate esters derived from alcohols serve as efficient precursors for the generation of radical intermediates which can be used for the formation of new carbon-carbon bonds. For example, a 4-thionocarbonate ester derived from L-lyxose undergoes a stereoselective allylation upon photolysis in toluene in the presence of 2.0 equiv of ***Allyltributylstannane*** (eq 6).[10] Photochemical initiation is preferable to chemical initiation using ***Azobisisobutyronitrile*** which results in the formation of side products at the expense of the desired product. The allylation product was used further in a total synthesis of pseudomic acid C.

Oxime ethers derived from hydroxy aldehydes, upon conversion to their phenyl thionocarbonate esters, undergo radical cyclizations resulting in the formation of carbocycles.[11] For example, an oxime ether obtained from D-glucose is converted into its phenyl thionocarbonate ester at C-5 and, upon heating in benzene in the presence of tributyltin hydride, affords cyclopentanes in 93% yield as a 62:38 mixture of two diastereomers (eq 7). In general, only low to modest stereoselectivity between the newly formed stereocenters is observed in a number of substrates examined.

Thioacylation Reagent.

The regioselective thioacylation of unprotected carbohydrates via the agency of ***Di-n-butyltin Oxide*** and the reagent has been investigated.[12] Glycopyranosides having a *cis*-diol arrangement, e.g. galactose, form cyclic thiocarbonates which can be either converted into dihydropyranosides using the Corey elimination procedure or deoxygenated to a mixture of 3- and 4-deoxyglycopyranosides (eq 8). Methyl D-glucopyranoside is monothioacylated with the regioselectivity dependent upon the configuration at the anomeric carbon; the α-epimer gives 83% of 2-thionocarbonate and the β-epimer gives 85% of 6-thionocarbonate. Further treatment with tributyltin hydride affords the corresponding deoxyglucose derivatives in high yield.

(8)

In a key step leading to a synthesis of saxitoxin, radical fragmentation of a pyrazolidine ring followed by intramolecular thioacylation afforded the ring expanded tetrahydropyrimidine intermediate (eq 9).[13] The thionocarbamate activation of the pyrazolidine *N*-H was found to be necessary to effect the desired transformation.

The intramolecular thioacylation of an ester enolate was used for the synthesis of 2-alkylthiopenem carboxylic acid derivatives.[14] Sequential acylations have led to the synthesis of zwitterionic pyrazole-5-thiones from acyclic precursors,[15] whereas 2-ethoxyoxazolidines react with the reagent to afford the products of *N*-acylation.[16]

(9)

Heating of *O*-phenyl thionocarbonates of pyrrolidine and piperidine-2-ethanols in acetonitrile gives a ring expanded

azepine or an octahydroazocine accompanied by the pyrrolidine and piperidine *O*-phenyl ethers (eq 10).[17] These products arise via the internal expulsion of carbonyl sulfide, leading to formation of an azetidinium intermediate followed by nucleophilic ring opening with phenoxide ion.

Related Reagents.

Carbon Disulfide; ***RT143-***.

Phenylcopper[1]

PhCu

[3220-49-3] · C_6H_5Cu · Phenylcopper · (MW 140.66)

(nucleophilic reagent for substitution reactions;[1a,b] selective reagent for conjugate additions;[1a,c,d,2] couples with aryl halides to form biaryls[3])

Alternate Name: copper phenyl.

Physical Data: slightly yellow solid; mp 100 °C (dec).[13]

Solubility: insol ether, tetrahydrofuran.

Preparative Methods: phenylcopper and other arylcopper species are most commonly prepared from equimolar amounts of alkyllithium or Grignard reagent and purified copper(I) halide in ether or THF.[4] Arylcoppers can be prepared from the corresponding aryl halides and highly active zerovalent ***Copper***.[5]

Handling, Storage, and Precautions: decomposes on heating in solution. Hydrolyzed by H_2O.[13] Use in a fume hood.

Nucleophilic Substitutions.

Arylcoppers are suitable nucleophiles for reaction with acid chlorides (to prepare aryl ketones),[5,6] primary alkyl halides,[5a,b] epoxides,[5c] β-lactones (to prepare β-aryl carboxylic acids),[7] and 1,3-dioxolan-4-ones (to prepare protected secondary alcohols).[8] Arylcopper species favor S_N2' substitutions of allylic bromides[9] and propargyl sulfonates.[4d] See also ***Methylcopper***.

Conjugate Additions.

Phenylcopper will add in Michael fashion to conjugated enones,[6] cyanoalkynes,[10] alkynyl sulfoxides,[4c] and alkenyl sulfones.[11] When performed in the presence of ***Chlorotrimethylsilane***[12a,b] or ***Iodotrimethylsilane***,[12b,c] Michael addition of arylcoppers to enones, enals, and enoates is accelerated and 1,4-selectivity (vs. 1,2) is enhanced. Rate and selectivity can also be improved by the presence of ***Dimethyl Sulfide***.[6] See also ***Phenylcopper-Boron Trifluoride Etherate***.

Biaryl Synthesis.

Although arylcoppers are not typically used for the synthesis of unsymmetrical biaryls, a combination of phenylcopper and 2-iodopyridine, or 2-pyridylcopper and an iodoarene, provides 2-arylpyridines in good yield.[4b]

Phenylcopper-Boron Trifluoride Etherate[1]

PhCu + BF_3.OEt_2

(PhCu)

[3220-49-3] · C_6H_5Cu · Phenylcopper-Boron Trifluoride Etherate · (MW 140.66) (BF_3.OEt_2)

[109-63-7] · $C_4H_{10}BF_3O$ · Phenylcopper-Boron Trifluoride Etherate · (MW 141.95)

(selective nucleophilic reagent for substitution reactions[2,3] and conjugate additions[1])

Physical Data: see entries for individual components.

Preparative Method: prepared by the addition of ***Boron Trifluoride Etherate*** to a suspension of ***Phenylcopper*** in diethyl ether or tetrahydrofuran at -70 °C.[2]

Handling, Storage, and Precautions: see entries for individual components. Use in a fume hood.

Nucleophilic Substitutions.

Substitution reactions involving phenylcopper/BF_3 exhibit chemoselectivities, rates, and regioselectivities which are similar to those observed with alkylcopper/BF_3 (see ***Methylcopper-Boron Trifluoride Etherate***). In the presence of ***Tri-n-butylphosphine***, phenylcopper/BF_3 adds to chiral enal acetals in an S_N2' substitution (eq 1). The result, on hydrolysis of the enol ether, is an effective asymmetric conjugate addition to the enal.[4]

(1)

Conjugate Additions.

Again, the observed chemistry is similar to that observed with alkylcopper/BF_3.

Phenyldiazomethane[1]

[334-88-3] · $C_7H_6N_2$ · Phenyldiazomethane · (MW 118.15)

(alkylating agent for carboxylic acids and alcohols; synthesis of phenylaziridines and phenylcyclopropanes from imines and alkenes[1])

Physical Data: liquid at room temperature, bp 37-41 °C/1.5 mmHg.

Solubility: sol most organic solvents, including ether, dichloromethane, methanol, acetonitrile.

Preparative Methods: prepared by several methods.[2] The highest yielding and most commonly used method is vacuum pyrolysis of the sodium salt of the tosylhydrazone derived from benzaldehyde.[3] In this preparation, the solid sodium salt is heated in the absence of solvent to a temperature of 220 °C at 0.1 mmHg. The red phenyldiazomethane that is produced is collected in a receiving flask cooled to -50 °C. It is then distilled at reduced pressure below room temperature and is typically used immediately.

Handling, Storage, and Precautions: can be stored at -80 °C for several months; however, storage at -20 °C leads to substantial decomposition after a few weeks. This material is also potentially explosive. For example, a solution which had been allowed to stand at room temperature for an hour underwent violent decomposition a few minutes after exposure to air. Explosions have also been reported when the distillation is carried out at temperatures higher than 30 °C. For these reasons, extreme care must be observed in the synthesis and use of this compound, with all operations being conducted behind a blast shield in a hood. Diazo compounds, as a class, are toxic and irritating and can be sensitizers. They must be used in a well ventilated fume hood and not come in contact with skin. For a description of the hazards associated with this class of compounds, see the handling and storage precautions listed for ***Diazomethane***

Alkylation of Heteroatoms.

As with diazomethane, the most widely used feature of the chemistry of phenyldiazomethane is the alkylation of carboxylic acids. The reaction occurs upon addition of the diazoalkane to the carboxylic acid. The only byproduct is N_2, thus reducing the workup to simple solvent removal. The reaction requires the protonation of the diazoalkane on carbon by the carboxylic acid to give the corresponding benzyl diazonium salt. This then undergoes nucleophilic attack by the carboxylate to give the benzyl ester and N_2. This method has been used to protect carboxylic acids as their benzyl esters. Liberation of the acid can be accomplished by hydrogenolysis, making this a useful reagent for the

protection of carboxylic acids which are base sensitive and cannot tolerate saponification to liberate the acid. This method is compatible with a variety of functional groups such as ketones, amides, alcohols (eq 1),[4] imines, sulfides (eq 2),[5] nitro groups (eq 3),[6] and other nonacidic functional groups.

(1)

(2)

(3)

Other acidic functional groups are also alkylated with phenyldiazomethane. Thus, phosphoric acid esters (eq 4)[7] and isoxazoles (eq 5)[8] readily undergo esterification with phenyldiazomethane. In the case of the isoxazole, a mixture of *N*-alkylated and *O*-alkylated products is observed. As with diazomethane, less acidic functional groups require the addition of a catalyst to promote the reaction. ***Tetrafluoroboric Acid*** is an effective catalyst for the alkylation of alcohols and amines (eqs 6 and 7).[9] Amines react more slowly under these conditions, thus enabling preferential reaction at the hydroxyl group of molecules containing both functional groups. Another catalyst which has been used to benzylate alcohols is ***Tin(II) Chloride***.[10] This reagent is only effective for the monoalkylation of 1,2-diols (the reaction can even be carried out in methanol as a cosolvent) and proceeds in moderate to low yield.

(4)

2:1

(5)

(6)

(7)

Cycloadditions.

As with other diazoalkanes, phenyldiazomethane undergoes cycloadditions with alkenes to provide pyrazolines.[11] Upon heating, pyrazolines extrude N_2 and provide the corresponding cyclopropane. In cases where the alkene is substituted with a TMS group, the product pyrazoline can undergo loss of TMS with concomitant extrusion of N_2 to provide the corresponding phenyl substituted β,γ-unsaturated ester (eq 8).[12] This is not a general reaction of diazoalkanes but one which works well only with certain reagents, such as phenyldiazomethane. Phenyldiazomethane has also been used to synthesize cyclopropanes from alkenes. The reaction can be performed photochemically[13] or by using metal complexes such as Rh^{II} or ***Zinc Bromide*** as catalysts.[14] Interestingly, both reactions provide the *cis*-substituted cyclopropanes as the major product (eqs 9 and 10) in varying ratios. The metal-catalyzed reaction using Rh^{II} complexes works well only for very electron rich alkenes such as vinyl ethers, while the method using zinc halides

typically utilizes an excess of the alkene. Finally, aziridines have been synthesized by the addition of phenyldiazomethane to imines in the presence of ***Zinc Iodide***.[15] The yields depend on the structure of the imine and range from poor (9%) to good (74%) with typical values being in the 50% range. This is not a general reaction of diazoalkanes and is not successful with diazomethane, ethyl diazoacetate, diazoacetonitrile, or dimethyl diazomalonate.

(8)

(9)

(10)

Homologation.

Phenyldiazomethane has been used in the homologation of aldehydes (eq 11). The reaction requires the addition of ***Lithium Bromide*** and gives good yields with a variety of aldehydes, with the exception of α,β-unsaturated aldehydes. Other lithium halides are not as effective as lithium bromide, and other alkali metals are ineffective.[16]

5-Phenyl-5*H*-benzophosphindole

[1088-00-2] · $C_{18}H_{13}P$ · 5-Phenyl-5*H*-benzophosphindole · (MW 260.28)

(synthesis of phosphorus compounds required for Wittig reactions;[1] ring expansion to the dibenzophosphorin system;[2] synthesis of ligands used in asymmetric hydroformylation,[3a-c] hydrosilylation,[4] and hydrogenation[3a,5])

Alternate Name: 5-phenyldibenzophosphole.

Physical Data: mp 95-97 °C.[6]

Solubility: sol THF, benzene.

Form Supplied in: not commercially available.

Preparative Methods: prepared in one step from commercially available tetraphenylphosphonium bromide which has been vacuum dried at 100 °C prior to use.[6] *Drying:* no particular requirements.

Handling, Storage, and Precautions: best kept in an O_2-free container. Slow phosphine oxide formation will occur upon exposure to O_2.

Wittig and Wittig-like Reactions.

Heterolytic C-P bond cleavage of 5-phenyldibenzophosphole (DBP-Ph) with lithium gives lithium dibenzophosphole (DBP-Li). Alkylation of lithium dibenzophosphole with alkyl halides generates the corresponding phosphonium salts. Deprotonation of these phosphonium salts under salt-free conditions (i.e. Na^+ or K^+ derived base) and treatment of the resulting phosphorus ylide with an aldehyde provides *trans*-alkenes predominantly (eq 1).[1] A 5-phenyldibenzophosphole-derived ylide has been used in the synthesis of (+)-dictyopterene C´ for the generation of an intermediate alkene with >99:1 *trans* selectivity.[7]

The stability of the intermediate 5-phenyldibenzophosphole-derived oxaphosphetanes has been exploited to show that the only observable intermediates in Wittig reactions are oxaphosphetanes[1] and to demonstrate that betaines are unlikely intermediates in the Wittig reaction.[1c] The reaction of *trans*-stilbene epoxide with DBP-Li (as in eq 1) generates a phosphine oxide.[8] After base treatment of the phosphine oxide, *cis*-stilbene is obtained.

Ring Expansion to Dibenzophosphorin Oxides.

Dibenzophosphorins are obtained after treatment of 5-dibenzophosphole with ***Benzoyl Chloride*** in the presence of ***Triethylamine*** and subsequent hydrolysis (eq 2).[2a,b] A similar reaction occurs with ***Methyl Propiolate***.[2c]

Preparation of Catalysts for Asymmetric Reactions.

5-Phenyldibenzophosphole has been used to prepare bidentate ligands for rhodium[3a] and platinum complexes.[3b-c] Platinum complexes with dibenzophosphole-derived ligands are readily obtained (eq 3), and they can be used as catalysts for the hydroformylation of styrene with high ee's (>95%).[3b] These complexes give the highest ratio of branched to nonbranched aldehydes; however, the conversion is low (eq 4). For rhodium complexes, the 5-phenyldibenzophosphole-based catalysts give the best ee's (40%) in the hydroformylation reaction.[3a]

Other alkenes have been hydroformylated with poor to average ee's with similar 5-phenyldibenzophosphole-derived platinum complexes.[3c] A rhodium catalyst with 5-phenyldibenzophosphole ligands does not increase the diastereoselectivity during hydrosilylation of 4-*t*-butylcyclohexanone (eq 5).[4] Hydrogenation of α-acetamidocinnamic acid[3a,5] and 2-phenyl-1-butene[3a] with 5-phenyldibenzophosphole-derived rhodium complexes gives poor ee's (eq 6).

Related Reagents.

Triphenylphosphine.

Phenyl Dichlorophosphate

[770-12-7] · $C_6H_5Cl_2O_2P$ · Phenyl Dichlorophosphate · (MW 210.98)

(DMSO activation for Pfitzner-Moffatt oxidation;[1] activation of carboxylic acids for acylation of amine, alcohol, and azide nucleophiles;[4-7] acetal and thioacetal cleavage;[8] phosphorylating agent[10])

Alternate Names: PDCP; phenyl phosphorochloridate.

Physical Data: bp 241-243 °C; *d* 1.412 g cm^{-3}.

Solubility: sol ethyl acetate (50 mg mL^{-1}), most organic solvents.

Form Supplied in: colorless liquid; commercially available.

Purification: redistil under reduced pressure.

Handling, Storage, and Precautions: corrosive; irritant; moisture sensitive; incompatible with strong bases.

Moffatt Oxidation of Alcohols.

The high reactivity of phosphorus-containing compounds towards oxygen functionalities makes them attractive candidates for ***Dimethyl Sulfoxide*** (DMSO) activation in the Pfitzner-Moffatt oxidation of alcohols.[1] Phenyl dichlorophosphate has given better results than other phosphorus-containing compounds such as ***Diphenyl Phosphorochloridate***, ***Diethyl Phosphorochloridate***, ***Phosphorus Oxychloride***, and ***Phosphorus(III) Chloride***.[2] Comparison studies with ***Oxalyl Chloride*** show that the latter is more prone to give chlorine-containing byproducts. The complex (**1**) produced from PDCP and DMSO is believed to be involved as the oxidant for the efficient conversion of primary and secondary alcohols to the corresponding aldehydes and ketones, respectively. A salient feature of the procedure (eq 1) lies in its operational simplicity, low temperatures (20 °C or below), and generally high yields (75-95%).

(1)

(1)

In the oxidation of 1-octadecanol using Swern conditions, the starting alcohol is recovered intact, whereas octadecanal is formed in 77% yield after 45 min using PDCP. Complex (**1**) has also been used as an oxidant for the conversion of primary and secondary benzylic amines to the corresponding carbonyl compounds (eq 2) in a process that involves formation and subsequent hydrolysis of intermediate imines.[3] The oxidative deamination process is apparently general for benzylic amines and yields are good (57-80%) with one exception, 1-indanone (28%). Nonbenzylic amines failed to give the corresponding carbonyl derivatives under the prescribed conditions.

(2)

β-Lactam Formation.

When β-amino acids are treated with equimolar amounts of PDCP in acetonitrile at room temperature for 30-40 h, cyclization proceeds smoothly to give high yields (78-95%) of β-lactams (eq 3).[4]

(3)

The reaction works well with both *erythro*- and *threo*-β-amino acids to give the corresponding *cis*- and *trans*-β-

lactams, respectively. Colvin[5] reported an efficient method for the preparation of chiral *cis*-3,4-disubstituted β-lactams (eq 4), based on reaction between imines from homochiral protected lactaldehydes and furfurylamine and PDCP activated carboxylic acid derivatives.

(4)

Esterification.

Activation of carboxylic acids via use of the PDCP/DMF complex is particularly useful for the esterification of substituted malonic acids which easily undergo decarboxylation. For example, the resolution of racemic cyanophthalimido acetic acid (**2**) by reaction with a chiral amine leads to partial or total decarboxylation in basic medium (eq 5). On the other hand, when PDCP and a chiral alcohol such as ***(S)-Ethyl Lactate*** are used, the desired diastereomers are obtained in high yields (90%).[6]

(5)

X = H, Me, OMe
Phth = Phthalimido

Acyl azides have also been prepared by reaction of a carboxylic acid or the potassium salt with PDCP, ***Pyridine***, ***Sodium Azide***, and ***Tetra-n-butylammonium Bromide*** in CH_2Cl_2 at room temperature.[7]

Dethioacetalization.[8]

The combination of PDCP and ***Sodium Iodide*** converts acetals to the corresponding aldehydes or ketones but has little, if any, effect on thioacetals. However, the reagent obtained by addition of DMF converts thioacetals into the corresponding carbonyl compounds at room temperature in 1-17 h in 70-95% yield.

Other Applications.

Primary alcohols are converted to alkyl chlorides by reaction with PDCP at 80 °C. Tertiary alcohols are dehydrated by PDCP to alkenes.[9] PDCP serves as an effective phosphorylating agent in the synthesis of L-glycerylphosphorylethanolamine (**3**),[10] an intermediate in the preparation of α-lecithins and α-cephalins. Cyclic β-diketones have been converted to β-chloro-α,β-enones by reactions with PDCP and LiH in the presence of LiCl (eq 6).[11]

Phenyl Dichlorophosphite[1]

[3426-89-9] · $C_6H_5Cl_2OP$ · Phenyl Dichlorophosphite · (MW 194.98)

(strong phosphorylating agent, used in forming phosphite and phosphate triesters[2] and phospholes;[3] reagent in forming polymers;[4] dehydration of amides[5])

Physical Data: bp 90 °C/11 mmHg.

Solubility: sol most organic solvents.

Form Supplied in: liquid; not commercially available.

Preparative Methods: phenyl dichlorophosphite was first identified in the reaction between ***Phosphorus(III) Chloride*** and phenol (eq 1).[1] However, the yield is low due to formation of side-products, bis- and tris-phosphite esters. Later, phenyl dichlorophosphite was formed in the reaction of phosphorus trichloride and triphenyl phosphite (eq 2), but, again, yields were not particularly high,[8] even when the reaction was later optimized.[9] By introducing $MgCl_2$ into the former reaction and carefully monitoring the reaction by IR spectroscopy, phenyl dichlorophosphite is formed in high yield (eq 3).[10]

$$PCl_3 + PhOH \longrightarrow \underset{25\text{-}50\%}{PhOPCl_2} + (PhO)_2PCl + (PhO)_3P \qquad (1)$$

$$PCl_3 + (PhO)_3P \underset{47\%}{\overset{150\ ^\circ C}{\rightleftharpoons}} PhOPCl_2 \qquad (2)$$

$$PCl_3 + PhOH \xrightarrow[84\%]{MgCl_2} PhOPCl_2 \qquad (3)$$

Purification: redistil under reduced pressure.[6]

Handling, Storage, and Precautions: irritant and moisture sensitive; incompatible with strong oxidizing agents and bases.[7]

Synthesis of Organophosphorus Compounds.

The main use of phenyl dichlorophosphite is in the formation of phosphorus-containing compounds, particularly phosphite triesters (eq 4). These compounds are synthesized by adding alcohols to phenyl dichlorophosphite in the presence of a tertiary amine.[11] However, use of one equivalent of each reagent produces phosphate esters instead (eq 5).[11] Two equivalents of alcohol and base are needed to produce phosphite triesters (eq 4).

$$PhOPCl_2 + 2\,ROH + 2\,Et_3N \xrightarrow[33\%]{} PhOP(OR)_2 \qquad (4)$$

$$PhOPCl_2 + 1\,ROH + 1\,Et_3N \xrightarrow[47\%]{} \text{PhO}\!-\!\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle OR}{|}}{P}}\!-\!OR \qquad (5)$$

Phosphite triesters carrying three different alkoxy groups are chiral and can be synthesized from phenyl dichlorophosphite under carefully controlled conditions involving the use of a $PtCl_2$ complex (eq 6).[12] The racemic triesters have been resolved via a platinum complex carrying a chiral scalemic ligand.[12]

$$PhOPCl_2 \xrightarrow[\substack{4\text{-}ClC_6H_4OH \\ 51\%}]{\substack{(Z)\text{-}Cl_2Pt(NCPh)_2 \\ 4\text{-}MeC_6H_4OH}} (Z)\text{-}Cl_2Pt[(\pm)\text{-}(4\text{-}MeC_6H_4O)(4\text{-}ClC_6H_4O)POPh \qquad (6)$$

Cyclic phosphorus compounds (phospholes) can be synthesized from phenyl dichlorophosphite with α-hydroxy acids (eq 7),[13] α-amino acids (eq 7),[13] and dilithiated benzyl alcohol (eq 8).[3]

(7)

(8)

Phenyl dichlorophosphite can also be used to synthesize organophosphates by preparing the phosphite triester derivative and either oxidizing it to the phosphate triester[14] (when ozone is used, the isolable intermediate, a trioxaphosphetane, decomposes to give singlet oxygen and the phosphate triester[11a]) or alkylating it with an alkyl halide (eq 9).[15]

(9)

Phenyl Dichlorophosphite as an Activating Agent.

Phenyl dichlorophosphite has been used in several reactions as an activating agent. Carboxylic acids form symmetrical anhydrides on reaction with phenyl dichlorophosphite;[16] with amines or β-diamines; these form amides[17] or imidazoles,[18] respectively (eq 10). This methodology has been extended to the formation of polyamides/hydrazides from the reaction of diacids with diamines or hydrazines in the presence of phenyl dichlorophosphite.[4]

Phenyl Dichlorophosphite as a Dehydrating Agent.

Phenyl dichlorophosphite has also been used with DMF to dehydrate amides to nitriles in high yields (eq 11).[5]

(Phenyldimethylsilyl)methoxymethyl Chloride

[128784-94-1] · $C_{10}H_{15}ClOSi$ · (Phenyldimethylsilyl)methoxymethyl Chloride · (MW 214.79)

(reagent for the protection of hydroxyl groups[1])

Alternate Name: SMOM-Cl.

Solubility: sol most organic solvents.

Preparative Method: prepared by a three-step sequence starting from (chloromethyl)dimethylphenylsilane. Displacement with NaOAc followed by reduction with ***Lithium Aluminum Hydride*** furnishes $PhMe_2SiCH_2OH$. Subsequent reaction with ***Formaldehyde-Hydrogen Chloride*** provides the crude chloride (>90% pure) which can be used without further purification.

Handling, Storage, and Precautions: although stability and toxicological data for this compound are not available, it is expected to be readily hydrolyzed, toxic, and carcinogenic.

Protection of Hydroxyl Groups.

Hydroxyl groups on sugars may be protected as (phenyldimethylsilyl)methoxymethyl (SMOM) ethers using $PhMe_2SiCH_2OCH_2Cl$ and ***Diisopropylethylamine*** in MeCN (76-91%). Removal of the SMOM group is effected by treatment with ***Peracetic Acid***/KBr in AcOH/NaOAc (82-92%) (eq 1); this presumably proceeds through a Si -> OH conversion[2] and decomposition of the resultant hemiacetal. The SMOM group is stable to hydrogenolysis conditions (H_2, Pd/C), benzylation conditions (NaH, BnBr), fluoride (excess *n*-Bu_4NF in dioxane, 20 °C, 15 h), and base (4 N NaOH, dioxane, MeOH, 20 °C, 8 h). It also survives conditions required to remove an isopropylidene or a trityl group (HOAc, H_2O) (eq 2).

The SMOM group was developed for use in sugar chemistry. It has the advantage of being stable under many reaction conditions including halophilic promoter mediated glycosidation conditions [e.g. $Hg(CN)_2$, $HgBr_2$, MeCN] and being readily removed under mild conditions. It differs from the trimethylsilylethoxymethoxy (SEM) group[3] in its resistance to fluoride cleavage. A closely related function is the phenyldimethylsilyl unit which may be used to protect anomeric hydroxyl groups.[1] It is attached by treatment of a glycosyl halide with phenyldimethylsilylmethanol under glycosidation conditions. It has comparable stability to the SMOM group and is also removed by oxidative cleavage (AcOOH, KBr). ***2-(Trimethylsilyl)ethanol*** has been used in a similar capacity.[4]

Related Reagents.

2-Methoxyethoxymethyl Chloride; ***2-(Trimethylsilyl)ethanol***; ***2-(Trimethylsilyl)ethoxymethyl Chloride***.

1,2-Phenylene Phosphorochloridate

[1449-17-8] · $C_6H_4ClO_3P$ · 1,2-Phenylene Phosphorochloridate · (MW 190.52)

(phosphorylating agent for primary alcohols,[1,2] particularly in nucleoside chemistry[3])

Physical Data: bp 120 °C/9 mmHg; 91 °C/0.9 mmHg.

Solubility: sol most organic solvents; react with alcohols.

Form Supplied in: liquid; commercially available.

Analysis of Reagent Purity: FT-IR.[11]

Preparative Methods: reaction of ***Catechol*** with ***Phosphorus(V) Chloride*** gives the intermediate (**2**) which on warming with ***Acetic Anhydride*** decomposes giving acetyl chloride and 1,2-phenylene phosphorochloridate (**1**) in 88% yield (eq 1).[1]

Purification: redistil under reduced pressure.

Handling, Storage, and Precautions: will keep indefinitely in a sealed tube. Harmful and irritant; moisture sensitive. Incompatible with alcohols and water.[4] Use in a fume hood.

Phosphorylation.

1,2-Phenylene phosphorochloridate is a convenient and efficient phosphorylating agent. Reaction with primary alcohols in the presence of base (***Pyridine***) gives the phosphate ester (**3**). This is readily hydrolysed to the *o*-hydroxyphenyl ester

(**4**), which on treatment with ***Bromine*** in neutral aqueous buffer gives the monophosphate ester (**5**) in good yield (eq 2).[2,5]

Adams' catalyst[6] has been used as an alternative to bromine in the last step and the use of other oxidative conditions involving periodic acid and ***Lead(IV) Acetate*** has also been reported.[3] Unsaturated alcohols are not compatible with some of the reaction conditions used to cleave (**4**).

The reagent is particularly useful for the phosphorylation of nucleotides (eq 3).[3] Reaction of (**1**) with 2´,3´-*O*-isopropylidene ribonucleosides (**6**) is carried out at room temperature in the presence of ***2,6-Lutidine*** for 3 hours. Addition of water hydrolyses the intermediate phosphotriesters and gives the 5´-*o*-hydroxyphenyl phosphates (**7**) in good yields. This functionality is stable to the acidic conditions required for removal of the isopropylidene group and subsequent treatment with an excess of bromine water gives the 5´-phosphates (**8**) as the sole nucleotide products. For example, with B = adenine, the overall yield for the sequence was 78%.[3] Phosphorylation of a 2´-deoxyribonucleotide using this procedure was successful.[3]

Phosphorylation of Hydrazines.

The reaction of 3-trifluoromethylphenylhydrazine with (**1**) gives the ring-opened monohydrazide (**9**) in 66% yield (eq 4).[7]

Spirophosphoranes.

Reaction of (**1**) with 1,2-diols, 2-hydroxy acids, or 2-keto acids leads to the formation of spirophosphoranes (**10**) which are in equilibrium with the phosphotriesters (**11**) (eq 5).[8] The use of (**1**) in the synthesis of a hexacovalent phosphate ester has also been reported.[9]

Reaction with Grignard Reagents.

Reaction of (**1**) with a range of aryl Grignard reagents leads to the formation of *o*-hydroxyphenyl phosphinates (**12**) (eq 6).[10]

(*S*)-(-)-5-(α-Phenylethyl)semioxamazide

[6152-25-6] · $C_{10}H_{13}N_3O_2$ · (*S*)-(-)-5-(α-Phenylethyl)semioxamazide · (MW 207.26)

(optical resolution of carbonyl compounds[2,3])

Physical Data: $[\alpha]_D$ -103° (*c* 1.0, $CHCl_3$).

Solubility: sol polar aprotic solvents; limited sol hexane, toluene, etc.

Preparative Method: conveniently prepared by sequential addition of (*S*)-(-)-α-phenylethylamine and ***Hydrazine*** to ***Diethyl Oxalate*** (eq 1).[1]

Optical Resolution.

This reagent is commonly used for the optical resolution of various compounds. Racemic spiro[4.4]nonane-1,6-dione was the first compound to be resolved (55% overall yield).[2] The corresponding semioxamazone was obtained in optically active pure form in two or three recrystallizations and hydrolyzed to (-)-(*S*)-spiro[4.4]nonane-1,6-dione in a refluxing methanol-water mixture in the presence of ***Iodine*** (eq 2).

In the field of arene tricarbonyl chromium complexes, racemic aldehydes can be resolved quantitatively by chromatographic separation of the corresponding semioxamazones. The first optical resolution was carried out on the semioxamazone made from the chromium tricarbonyl complex of *o*-anisaldehyde.[3,4] The separation of the diastereomers was done by silica gel chromatography (eq 3). Chromium tricarbonyl complexes of *m*-anisaldehyde,[4] of the trifluoromethyl analog of *o*-anisaldehyde,[5] and of *o*-trimethylsilylbenzaldehyde[6] have also been resolved by the same procedure.

R^1	R^2	R^3
OMe	H	H
H	OMe	H
CF_3	H	H
TMS	H	H
OMe	OMe	H
H	OMe	OMe

The iron tricarbonyl complex of 2-formylbutadiene has been resolved by chromatographic separation of its chiral semioxamazones (eq 4).[7]

(S)-(-)-5-(alpha-Phenylethyl)semioxamazide

2,3-Dihydro-2-phenyl-4(1*H*)-quinolone has also been resolved by fractional crystallization of the corresponding chiral semioxamazones (eq 5).[8]

Phenylethynylcopper(I)[1]

[13146-23-1] · C_8H_5Cu · Phenylethynylcopper(I) · (MW 164.68)

(mild nucleophilic agent for the introduction of the phenylethynyl group,[2] formation of phenylallenes,[3] and Glazer cross-coupling products[4])

Alternate Name: copper(I) phenylacetylide.

Physical Data: bright yellow solid, mp 229 °C;[5a] IR ν(C&tbond;C) 1933 cm^{-1}.[5a] Vibrational spectra have been reported.[5b]

Solubility: sol pyridine, THF, ether, acetonitrile, hot cyclohexane, dioxane; insol water.

Analysis of Reagent Purity: gravimetric analysis of derived salts.[9] Traces of ammonia are reported to impart a green tinge to the solid.

Preparative Methods: (i) phenylacetylene is treated with either ammoniacal ***Copper(II) Sulfate*** and ***Hydroxylamine*** hydrochloride (reductant)[6] or ***Copper(I) Iodide*** in ethanol;[7] (ii) phenylacetylene is lithiated, then treated with copper(I) iodide; (iii) phenylacetylene is treated with ***Copper(I) t-Butoxide***.[8] *Drying:* heat (65 °C) under vacuum.

Handling, Storage, and Precautions: all copper(I) acetylides are potentially explosive in the solid state. Use in a fume hood.

Alkynic Couplings.

Copper(I) phenylacetylide participates in efficient coupling with a range of aryl iodides and bromides to give substituted tolanes[2,6,7,10,11] which, if possessing an *ortho* amino or hydroxy group, can be thermolyzed to yield 2-phenylbenzofurans, -indoles, and -furo[3,2-*b*]pyridines (eq 1).[12] The reactions are usually conducted in refluxing DMF or pyridine (see also ***3-Methyl-3-buten-1-ynylcopper(I)***, ***1-Hexynylcopper(I)***, ***1-Pentynylcopper(I)***).

(1)

X = NH_2, Y = CH, 89% X = OH (O), Y = N, 82%
X = NHEt, Y = CH, 50% X = OH (O), Y = CH, 88%

Application of the cross-coupling sequence has been extended to bromo quinones, where milder conditions ensuing from use of a palladium catalyst (eq 2) allow this transformation to proceed with ease and high efficiency (77% yield).[13]

(2)

Coupling to acyl chlorides is reported to be facile (eq 3),[14] allowing direct access to α-alkynones. The couplings are promoted by ***Lithium Iodide***, as lithium chloride was found to be inferior;[14] in some cases addition of ***Hexamethylphosphorous Triamide*** is necessary.[15] This protocol has been applied in the synthesis of natural products.[16] By forming copper(I) phenylacetylide in situ using phenylacetylene and ***Copper(I) Bromide*** in the presence of ***Diisopropylamine***, intermolecular addition to formaldehyde has been demonstrated, giving a potentially versatile route to other substituted allenes (eq 4).[3] Under oxidative conditions, it is possible to couple copper(I) acetylides to form (in this instance) diphenylbutadiyne. The procedure, known as the Glaser coupling, has been reported to proceed either in solution or in the solid state.[4] It is also possible to couple copper(I) phenylacetylide with cyanogen bromide to form phenylpropynenitrile,[17] and with alkylcopper reagents to form disubstituted alkynes.[18] Nucleophilic addition of copper phenylacetylide to organotungsten complexes proceeds with regiocontrol (eq 5), giving ultimate access to enynes.[19]

(3)

R = Me, 82%; Ph, 90%

(4)

(5)

Other applications of copper(I) phenylacetylide include 2-phenylethynylation of *N*-benzyloxypyridinium salts,[20] [3 + 2] cycloaddition to nitrones (which gives mixtures of azetidin-2-ones: see ***1-Hexynylcopper(I)***),[21] nucleophilic addition to the tetrathiatriazepinium cation,[22] and coupling to activated amines to yield terminal *N*,*N*-dialkylalkynic amines.[23]

Related Reagents.

3,3-Dimethyl-1-butynylcopper(I); ***Phenylethynylcopper(I)-Tris(tributylphosphine)***.

Phenylethynylcopper(I)-Tris(tributylphosphine)[1]

[58659-24-8] · $C_{44}H_{86}CuP_3$ · Phenylethynylcopper(I)-Tris(tributylphosphine) · (MW 771.76)

(carbionic agent for formation of phenylpropiolates;[2] reversible CO_2 uptake carrier[3])

Alternate Name: copper(I) phenylacetylide-tributylphosphine.

Physical Data: prepared in situ.

Solubility: sol THF, pyridine, DMF.

Preparative Method: metalation of phenylacetylene with ***Copper(I) t-Butoxide*** followed by addition of ***Tri-n-butylphosphine*** in THF.[2]

Handling, Storage, and Precautions: all copper(I) acetylides are potentially explosive when dry. Use in a fume hood.

Coupling Agent.

When ***Phenylethynylcopper(I)*** is treated with tributylphosphine in THF and heated to 80 °C, addition to CO_2 can be effected giving, on esterification, methyl phenylpropiolate in moderate yield (eq 1).[2] In the absence of tributylphosphine, the addition does not take place, suggesting that the tributylphosphine may help solubilize and increase the effective nucleophilicity of the copper salt, presumably by dissociating its polymeric form.[4,5] A similar effect is observed with the corresponding ***t-Butyl Isocyanide*** complex, where the yield of carboxylated product increases to 71%.[2]

Reversible CO_2 Carrier.

When copper phenylpropiolate is heated to 35 °C in DMF, irreversible decarboxylation ensues, giving copper phenylacetylide. However, when tributylphosphine is added, the decarboxylation is not quantitative, and instead becomes reversible (eq 2).[3] The equilibrium that exists at room temperature can be demonstrated by addition of ***Iodomethane*** as both methyl phenylpropiolate and methylphenylacetylene are isolated. The rate of carboxylation of copper phenylacetylide can be increased by elevating the number of equivalents of tributylphosphine from 1 to 3, but not beyond this, suggesting the species to be coordinatively saturated with three phosphine ligands attached.

Phenylhydrazine[1]

$PhNHNH_2$

[100-63-0] · $C_6H_8N_2$ · Phenylhydrazine · (MW 108.16)

(forms hydrazones with carbonyl compounds;[1,3] useful reagent for the formation of indoles[4-19] and other heterocyclic ring systems[20-27,31])

Physical Data: mp 18-20 °C; bp 238-241 °C, 52-53 °C/0.06 mmHg; *d* 1.098 g cm^{-3}.

Solubility: misc EtOH, Et_2O, $CHCl_3$, benzene; sol dil acids; slightly sol H_2O, petroleum ether.

Form Supplied in: yellow solid or yellow oil.

Preparative Method: from aniline via diazotization, followed by reduction of the resultant benzenediazonium chloride with Na_2SO_3.[2]

Handling, Storage, and Precautions: keep in tightly closed container; protect from light; toxic, possible carcinogen, irritant.

Introduction.

Although $PhNHNH_2$ readily forms hydrazones with ketones and aldehydes, too many of the products thus formed tend to be oils and are difficult to detect visually.[3] For this reason, ***2,4-Dinitrophenylhydrazine*** is, instead, the preferred reagent of choice for making carbonyl derivatives. Phenylhydrazine, however, is very useful in the synthesis of various heterocyclic compounds.

Fischer Indole Synthesis.

Indolization of a phenylhydrazone, in the presence of a catalyst, was first observed by Fischer.[4] Although ***Zinc Chloride*** is the classical reagent of choice for catalyzing these transformations, several other catalysts have since been successfully used.[1b] This method has emerged as a general and powerful method for making indoles (eq 1).[5]

(1)

The generally accepted mechanism for this reaction was originally proposed by Robinson and Robinson.[6] There exists substantial evidence for this mechanism which involves a [3,3] sigmatropic rearrangement as a key step (eq 2).[7-10] The phenylhydrazones are generally not isolated since many of these intermediates either cyclize under mild conditions or decompose upon attempted purification. The phenylhydrazone of cyclohexanone, for instance, is generated and converted into tetrahydrocarbazole in one step by adding phenylhydrazine to a refluxing mixture of the ketone and AcOH (eq 3).[11] A mild, one-step protocol for preparing 2,3-disubstituted indoles in good yields (70-90%) involves treating a solution of a ketone and phenylhydrazine in benzene with ***Phosphorus(III) Chloride*** at room temperature for a few minutes.[12-14] Elaborate polycyclic structures can be rapidly assembled by using this methodology. Indeed, when 4-oxo-1,2,3,4-tetrahydro-β-carboline (**1**) is heated with an excess of phenylhydrazine, the pyridinodiindole (**2**) is readily obtained (eq 4).[15]

(2)

(3)

(4)

Use of the bis-Fischer indole synthesis has culminated in the total synthesis of indolo[2,3-*a*]carbazole alkaloids.[16,17] In a variation of the Rubottom oxidation of silyl enol ethers,[18] the Diels-Alder adduct (**3**) is treated with ***m*-Chloroperbenzoic Acid** to presumably provide the dione (**4**), which is then exposed to 2 equiv of phenylhydrazine. Treatment of the osazone (**5**), thus obtained, with ***Trimethylsilyl Polyphosphate*** (PPSE), a mild catalyst, followed by aromatization of the central ring provides *N*-methylarcyriaflavin A (**6**) (eq 5).[16]

(5)

A variation of the Fischer protocol has been used for the preparation of the dihydropyrrole ring system. Reaction of phenylhydrazine with propionic anhydride (**7**) provides β-propionylphenylhydrazine (**8**) which, upon treatment with ***Calcium Hydride***, loses NH_3 and leads to the formation of 3-methyloxindole (**9**) (eq 6).[19]

Pyrazoles and Pyrazolines.

Phenylhydrazine has also been used in the synthesis of various five-membered heterocycles.[20] Thermal treatment of 3-acetyl-1,4,5,6-tetrahydropyridine (**10**) with $PhNHNH_2$, under acidic conditions, leads to a 1:1 mixture of isomeric pyrazoles (**11**) and (**12**) (eq 7).[21] The oxidative cyclization of stannylhydrazones (**13**) provides the azocyclopropanes (**14**) in good yields. Whereas the formation of pyrazolines (**15**) is not observed via the direct ring-closure of (**13**), treatment of (**14**) with catalytic amounts of ***Tin(II) Chloride*** in benzene, at refluxing temperature, furnishes the five-membered heterocycles (**15**) in high yields (eq 8).[22]

(8)

Synthesis of β-Lactams.

Phenylhydrazones (**16**), when treated with phenoxyketene, give *N*-acylated products (**17**), which do not cycloadd to the ketene. However, *N*-alkylated phenylhydrazones (**18**)[23] undergo [2 + 2] cycloaddition reactions with in situ generated phenoxyketene to provide β-lactams (**19**) (eq 9).[24]

(9)

Synthesis of Piperidines.

Reactions of ***Glutaraldehyde*** and hydrazines, in the presence of benzotriazole, lead to the formation of piperidines (eq 10).[25]

(10)

Reactivity with Heterocumulenes.

Reactions of phenylhydrazones with ***Phenyl Isocyanate***, under thermal conditions, provide triazolidines (eq 11).[26] A 1,3-dipolar reaction between ketone phenylhydrazones and ***Phenyl Isothiocyanate***, in the presence of ***Sodium Hydride*** in DMF, leads to the formation of 4-phenyl-5-phenylimino-1,3,4-thiadiazolidines (eq 12).[27] Reactions using ***Carbon Disulfide***, instead of isothiocyanate, under similar conditions provide 4-phenyl-1,3,4-thiadiazolidine-5-thiones.[27]

(11)

(12)

Generation of Amines.

Phenylhydrazine has been used for the generation and regeneration of different kinds of amines. Reduction of phenylhydrazones has been utilized, for example, in the synthesis of aminophosphonates. The reaction of $PhNHNH_2$ with oxophosphonates (**20**) provides hydrazones (**21**) in almost quantitative yields. Catalytic hydrogenation yields amines (**22**), and the diethylphosphonate moiety in (**22**) can be hydrolyzed to provide 1-aminoalkanephosphonic acids (**24a**) (eq 13).[28] In a variation of the Ing-Manske procedure,[29] where a phthalimide is heated with hydrazine to liberate a primary amine in an exchange reaction, the *N*-protective phthaloyl group of an amino acid or a peptide can be cleaved. Thus refluxing phthaloyl-L-leucine, in the presence of a tertiary amine in EtOH, can be used to access crystalline L-leucine (eq 14).[30]

(20) **(21)** **(22)**

R = alkyl, aryl

(13)

(23)

(14)

Synthesis of Quinazolines.

Further utility of phenylhydrazine is apparent in the synthesis of quinazolines. Treatment of methyl anthranilate esters (**24a**) with orthoesters provides *N*-(2-methoxycarbonylphenyl) imidate esters (**24b**). The reaction of these imidate esters with $PhNHNH_2$ leads to the formation of 3-amino-4(3*H*)-quinazolinones (**26**) in a stepwise mechanism, presumably via the intermediate amidrazones (**25**) (eq 15).[31]

(24a) **(24b)**

(15)

(25) **(26)**

X = H, Cl, Br; R = Me, Et

Osazones.

Treatment of α-dicarbonyl compounds, α-hydroxy aldehydes and ketones,[32,33] and α-halo ketones[34-36] with $PhNHNH_2$ leads to the formation of osazones (eq 16). Osazones are particularly important in carbohydrate chemistry and have been used in alkaloid synthesis (eq 5). In a reaction of phenacyl chloride (**27**) with $PhNHNH_2$, the yellow crystalline pyridazine derivative (**28**) is rapidly formed and the gradual formation of the osazone (**29**) is also observed. Also produced from this reaction is another compound, a tetrahydropyridazine (**30**). It has been rationalized that the pathway to (**28**) involves the formation of the hydrazone followed by 1,4-elimination of HCl and a subsequent dimerization of the resultant ene-azo intermediate (**31**).[37] It has also been proposed that a retro-Diels-Alder type reaction of (**28**) furnishes the intermediate (**31**), which then participates as the diene in a 1,4-cycloaddition reaction with the osazone (**29**) to provide cyclic (**30**) (eq 17).[38]

(16)

(17)

(31)

Triazolo Compounds.

Hydrazones of acylated heterocycles are widely used as precursors for the preparation of 1,2,4-triazolo compounds.[39,40] Indeed, oxidative cyclizations of arylhydrazones of 2-acylpyridines, in the presence of ***Mercury(II) Acetate*** or ***Lead(IV) Acetate*** (LTA), are efficient means of accessing fused 1,2,4-triazoles and 1,2,3-triazolium systems. A coupling reaction of 2-benzoylpyridine (**32**) with $PhNHNH_2$ provides the (*E*)-isomer of hydrazone (**33**), as established by X-ray structure analysis. An oxidative ring-closure of (**33**) with LTA leads to the formation of the corresponding 1,2,3-triazolium salt (**34**) in high yield (eq 18).[41]

Related Reagents.

N,N-Dimethylhydrazine; ***2,4-Dinitrophenylhydrazine***.

Phenyliodine(III) Bis(trifluoroacetate)[1]

$(CF_3CO_2)_2IPh$

[2712-78-9] · $C_{10}H_5F_6IO_4$ · Phenyliodine(III) Bis(trifluoroacetate) · (MW 430.05)

(cyclopropyl groups undergo ring opening,[2] alkynes are cleaved,[3] phenols are oxidized to quinones[4-8] and in some cases oxidative intramolecular coupling occurs,[9-13] ketones yield α-hydroxy ketones,[14] certain β-diketones undergo cyclization,[15] Pummerer-type reaction occurs,[16] and deprotective dethioacetalization is an important use[17])

Alternate Names: bis(trifluoroacetoxyiodo)benzene; iodobenzene bis(trifluoroacetate); PIFA; BTI.

Physical Data: mp 121-125 °C.

Solubility: sol CH_2Cl_2, CCl_4, CF_3CH_2OH, $(CF_3)_2CHOH$.

Form Supplied in: white solid; commercially available.

Preparative Method: can be synthesized by reaction of ***(Diacetoxyiodo)benzene*** with ***Trifluoroacetic Acid***.[18]

Handling, Storage, and Precautions: moisture sensitive; irritant.

Bond Cleavage.

1,3-Dehydroadamantane underwent ring-opening with 1,3-addition of $CF_3CO_2^-$ upon reaction with $PhI(OCOCF_3)_2$ (BTI) (eq 1).[2] Alkynes are cleaved upon treatment with three equivalents of BTI.[3] Dibenzyl ether is cleaved to benzaldehyde and benzyl trifluoroacetate (eq 2). Benzylalkyl (or trityl and benzhydryl) ethers react analogously.[19]

(1)

(2)

Oxidation of Phenolic Compounds.

Hydroquinones and catechol derivatives are oxidized to *o*- or *p*-benzoquinones (eq 3).[4-7] In the presence of water, a quinone is formed, while in the presence of methanol the quinone monoacetal is formed (eq 4).[8]

(3)

(4)

Intramolecular oxidative cyclization is also an important reaction pathway, as in the case of *N*-acetyltyramines (eq 5),[9] and it has been applied in the syntheses of several natural products. For example, phenolic oxidative coupling with BTI was a key step in the synthesis of 6a-epipretazettine (eq 6).[10]

(5)

(6)

A similar intramolecular spirodienone formation was observed in a naphthoquinone system (eq 7).[11] An extension of this type of oxidative coupling formed the key step in the synthesis of the marine alkaloid discorhabdin C (eq 8).[12] Intramolecular cyclization has also been used as a key step in a synthetic approach to the natural product aranorosin (eq 9).[13]

(7)

(8)

Discorhabdin C

Table 1 illustrates the oxidative cyclization and gives a useful comparison of yields as a function of reagent, solvent, and temperature. All hypervalent iodine oxidations were carried out in acetonitrile or acetonitrile-pyridine (yields in parentheses) at 0 °C.[13]

Table 1 Oxidative Cyclization of 3-(4-Hydroxyphenol)propanoic Acid

Starting material	Reagent	Product	Yield (%)
			
	$PhI(OCOCF_3)_2$		83 (45-65)
	$PhI(OCOMe)_2$		27 (27)
	$4\text{-}MeC_6H_4I(OCOCF_3)_2$		69 (35)
	$4\text{-}MeC_6H_4I(OCOCF_3)_2$		52 (17)
	$4\text{-}NO_2C_6H_4I(OCOCF_3)_2$		65 (56)
	$1,4\text{-}[I(OCOCF_3)_2]_2C_6H_4$		67 (-)
	$PhI(OH)OTs$		53 (-)

Oxidation of Carbonyl Compounds.

BTI and trifluoroacetic acid in $MeCN/H_2O$ react with aromatic, heteroaromatic, and aliphatic ketones to afford α-hydroxy ketones in moderate to good yields (eq 10).[14] β-Dicarbonyl compounds with α-aralkyl systems can undergo cyclization (eq 11).[15]

$R^2 = Me$; $R^1 = Ph$, 36%; *p*-BuC_6H_4, 21%

(11)

R = OMe, OTBDMS; R^1 = Me, Et; R^2 = Me, Et, OH, OAc; n = 1, 2

N-[(2-Methylthio)acetyl]-*N*-phenylaniline upon reaction with BTI undergoes Pummerer-type cyclization to yield 3-methylthio-*N*-phenylindol-2(3*H*)-one. This process appears to be a general method of cyclization for appropriate methylthio derivatives (eqs 12-15).[16]

(12)

(13)

(14)

(15)

Dethioacetalization.

BTI is the reagent of choice for dethioacetalization (eq 16).[17] Functional groups, R, such as esters, nitriles, secondary amides, alcohols, halides, alkenes and alkynes, thioesters, and amines are unaffected in this process.

University of Illinois at Chicago, IL, USA

Phenyliodine(III) Dichloride

$PhICl_2$

[932-72-9] · $C_6H_5Cl_2I$ · Phenyliodine(III) Dichloride · (MW 274.91)

(selective chlorinating reagent by either radical or ionic mechanisms; reagent for electrophilic chlorination; oxidizing agent)

Alternate Names: phenyliodo dichloride; phenyliodoso chloride; phenylchloroiodonium chloride; dichloroiodobenzene; iododichlorobenzene; iodobenzene dichloride; iodosobenzene dichloride; IBD.

Physical Data: yellow solid; mp 115-120 °C (dec.) from $CHCl_3$; *d* 2.2 g cm^{-3}.

Solubility: sol CCl_4, $CHCl_3$, CH_2Cl_2, $POCl_3$, pyridine; sl sol. Et_2O, pet. ether, CS_2.

Form Supplied in: not commercially available due to lack of stability.

Preparative Methods: by passage of chlorine gas into a solution of iodobenzene in $CHCl_3$ followed by cooling in ice and filtration (87-94%).[1] These recipes specify the use of dry $CHCl_3$ although a later report suggests that ethanol-free solvent is suitable.[2] An alternative preparation is by oxidation of iodobenzene using 5 equiv. of $NaBO_3.4H_2O$ and HCl in MeCN (82%).[3] Some substituted homologs may be obtained by these protocols. Other methods include treatment of iodosylbenzene (PhIO) with Me_3SiCl in CH_2Cl_2[4] and generation in situ by adding sulfuryl chloride to a catalytic amount of PhI.[5,6a] $PhICl_2$ belongs to a useful class of polyvalent iodine reagents, the utility of which in organic synthesis has been reviewed.[6] $PhICl_2$ is a precursor to iodosobenzene, PhIO.[7]

Purification: purity levels can be determined by iodometric titration (typical values: 98-100%).

Handling, Storage, and Precautions: decomposes slowly on standing; corrosive; sensitive to moisture and light; refrigerate and store under nitrogen.

Chlorination of Alkanes.

$PhICl_2$ is widely used as a selective agent for homolytic chlorination of alkanes, alkenes, and alkynes. Radical chain reactions involving PhICl&bdot; as a hydrogen abstracting species or as a chlorine atom donor to multiple bonds were first recognized by Bloomfield in the chlorination of natural rubber.[8] A high selectivity in photochemical chlorination

of branched chain alkanes in iodobenzene solution was subsequently ascribed to the intermediacy of PhICl&bdot;.[9] Using $PhICl_2$ as the chlorinating agent in a photochemically stimulated chlorination of 2,3-dimethylbutane produced the tertiary chloride with <1% of the primary alkyl chloride.[10] High yields of tertiary alkyl chlorides are produced in reactions initiated by traces of $B(C_6H_{13})_3$, possibly in the presence of traces of O_2.[11] Relative reactivities of primary:secondary:tertiary hydrogen atoms in butane and 2,3-dimethylbutane towards PhICl&bdot; are 1:21:368 at 40 °C in CCl_4[12] (vs. 1:3.9:5.1 for Cl&bdot;), although with 1,4-dimethylcyclohexane a tertiary:secondary reactivity of ~10:1 is reported.[13] Towards alkanes substituted with electronegative groups where reactivities are determined by polar effects (e.g. BuCl or PrCN), the isomer distribution of monochlorides is very similar upon photochlorination with Cl_2 or $PhICl_2$. For example, with PrCl at 40 °C in CCl_4 the ratio of 1,1-, 1,2-, and 1,3-dichlorides is 12:58:31 with Cl_2 and 18:48:35 with $PhICl_2$.[12] However, competitive reactions of substituted alkanes indicate a slight difference in overall reactivity using Cl_2 and $PhICl_2$ as the chlorinating agents.[12]

The possibility exists that mixed chains occur for substrates with a low homolytic reactivity, involving both PhICl&bdot; and Cl&bdot; as hydrogen abstracting species. The selectivity of PhICl&bdot; for tertiary attack has been applied in the chlorination of various cholestanyl derivatives, when the major products are derived from attack at the axial hydrogen atoms at the 5α-, 9α-, 14α-, or 17α-positions.[14] In 3α-(trifluoroacetoxy)androsterone the electronegative substituents cause attack to occur nearly exclusively at the 9-position.[15] The remote functionalization of steroids at the 9α-, 14α-, or 17α-positions has been achieved by use of templates which direct the attack of a tethered ArICl&bdot; to the appropriate tertiary position. Thus steroid derivatives with a 3α-substituent (**1a**) yield nearly exclusively chlorine substitutions at C-9 (eq 1), while with (**2**) attack is directed to C-14.[16] The chlorinations are conveniently performed in a relay method by use of a tethered ArI (**1b, 2b, 4**) with $PhICl_2$ or ***Sulfuryl Chloride*** as the source of chlorine.[17] Using this technique with substituent (**1b**) at the 17α-position of 17α-hydroxyprogesterone, a quantitative yield of the 9α-chloride is observed.[18] Template (**3**) at the 3α-position of cholestanol also directs hydrogen abstraction to the C-9 position upon photolysis with $PhICl_2$.[19] With the 3α-substituent (**1b**), tandem radical reactions have also been observed by use of Cl_2 in CBr_4 (to form 9-bromo-3-cholestanol) or in the presence of thiocyanogen (to form the 9-thiocyanate).[20] With the 3α-substituent (**4**), attack of the tethered ArICl&bdot; is directed (>54%) to the axial hydrogen at C-17.[21]

(3)

(4)

(1)

Chlorination of Alkenes.

In general, chlorinations of alkenes using $PhICl_2$ follow a radical pathway when the reaction is initiated by heat or light; in such cases the stereochemical outcome is much influenced by steric factors.[22] By contrast, ionic mechanisms predominate when no initiation is used or when ***Trifluoroacetic Acid*** is added; Wagner-Meerwein shifts can become important in such cases but are not observed in thermal- or light-induced reactions.[22] $PhICl_2$ has been found to be the most selective of a number of chlorinating reagents in the selective formation of *trans*-1,2-dichlorocyclohexane from cyclohexene (eq 2).[23]

(2)

Similarly, both *p*-dioxene and 1,4-dihydronaphthalene are converted selectively into the corresponding *trans*-1,2-dichloro derivatives.[24] Under radical conditions (i.e. thermally (40-80 °C) or light-induced) norbornene is converted into mixtures of the *exo*-*cis*- and *trans*-dichloro derivatives (eq 3).[25] However, ionic mechanisms appear to operate when the same substrate is treated with $PhICl_2$ in the presence of molecular oxygen, leading to the nortricyclyl chloride (**5**) together with the 2,7-dichloride (**6**).[25] In general, such reactions are much cleaner using $PhICl_2$ than is the case when using other chlorination reagents. The *exo*-*cis*-dichloro acid (**7**) is the major product when the corresponding *endo*-norbornenyl acid is treated with $PhICl_2$.[26]

(5)

(6)

(7)

(3)

The selectivity of $PhICl_2$ is further emphasized by its ability to chlorinate a variety of terpenoid alkenes efficiently and without rearrangement.[27] Under strictly anhydrous conditions, $PhICl_2$ in dry $CHCl_3$ converts cholesterol into the 5α,6α-dichloro derivative (eq 4), probably via a cyclic transition state, whereas molecular chlorine gives the 5α,6β-epimer via an ionic mechanism.[28] Under radical conditions, $PhICl_2$ converts acenaphthylene into the *trans*-dichloride whereas molecular chlorine leads to the corresponding *cis*-isomer; both transformations are not especially efficient however.[29] Chlorinations of 1,3-dienes are, in general, not especially useful except in special cases[30] and rearrangements can occur in chlorinations of alkenyl cyclopropanes by $PhICl_2$ (eq 5).[31]

(4)

(5)

Chlorinations of Alkynes.

Disubstituted alkynes are chlorinated by $PhICl_2$ under radical conditions ($CHCl_3$, AIBN, reflux) to give mainly (*E*)-dichloroalkenes (eq 6).[32] Depending upon the conditions used, molecular chlorine gives either predominantly the corresponding (*Z*)-isomers or complex mixtures.

(6)

Electrophilic Substitution.

The chlorination of aromatic systems by $PhICl_2$ is often very efficient. For example, salicylic acid is converted into the 5-chloro derivative in 89% yield (eq 7)[33] and high yields of chlorinated pyrroles[34] and 5-chlorouracils[35] can be similarly obtained.

(7)

Other Chlorinations.

α-Chloro ketones can be prepared from the parent ketones or 1,3-diones using $PhICl_2$ under either ionic or radical conditions, although the latter photo-induced method is often more selective.[5] The reagent when prepared in situ from iodobenzene (cat.) and sulfuryl chloride is suitable for these conversions, for which a full recipe is given in a review.[6a] Perchloro-α,α-dichloro ketones have been prepared by treatment of the corresponding perchloro-α-diazo ketones with $PhICl_2$.[36] Similarly, α-chloro ethers can be obtained from the parent compounds using $PhICl_2$; when chlorine is used, α,α-dichloro ethers are generally obtained.[37] Stabilized phosphorylides such as Ph_3PCHCO_2Me are converted into the corresponding α-chloro derivatives upon exposure to $PhICl_2$.[38] In the case of an acylphosphorane, the intermediate α-chlorophosphonium salt can be hydrolyzed by base to give the corresponding α-chloro ketone. Perhaps surprisingly, α-alkoxyphosphoranes from the SCOOPY reaction sequence react with $PhICl_2$ to provide reasonable yields of (*Z*)-vinyl

chlorides (eq 8), whereas reaction with ***N-Chlorosuccinimide*** gives the corresponding (*E*)-isomers.[39]

(8)

In similar fashion to the foregoing, aryl aldoximes also undergo α-chlorination by $PhICl_2$; these intermediates are deprotonated in situ to give the corresponding nitrile oxides which are also trapped in situ, leading finally to 60-75% yields of the [1,3]-dipolar adducts (eq 9).[40] By contrast, similar treatment of aryl ketoximes simply results in hydrolysis back to the parent alkaryl ketone.[41] The reaction fails with oximes derived from dialkyl ketones.

(9)

Remote Functionalization of Steroids.

$PhICl_2$ is a key reagent in a method for the remote functionalization of steroids developed by Breslow and his colleagues. The reaction is a radical relay mechanism in which an aryliodine dichloride is generated in situ from a suitable iodobenzene derivative (e.g. eq 10).[42] A chlorine atom is then transferred to an adjacent tertiary position (the 14-position in the example shown); subsequent elimination of HCl and esterification completes the sequence leading to a Δ^{14}-unsaturated derivative. By varying the length and position of the side chain carrying the iodoaryl function, selective chlorination at both C-9 and C-17 positions can be achieved.[42,43] More recent developments feature a somewhat different mechanism wherein an *S*-chloro species, derived from a similarly tethered heteroaromatic ligand and $PhICl_2$, is a key chain component.[44] Prior to these developments, $PhICl_2$ alone, under photolytic conditions,[45-47] was found to show considerable selectivity for C-9 in suitably designed steroids.[48]

Oxidations of Sulfides and Selenides.

Sulfides[49] and diaryl selenides[6a,50] are rapidly oxidized to the corresponding sulfoxides and selenoxides by $PhICl_2$, which is a more powerful oxidant than metaperiodate in such reactions. Despite this, the reactions can be controlled such that sulfones are not formed. Sulfoxides can also be converted into α-chloro derivatives using $PhICl_2$;[51] it is therefore not surprising that sulfides can be directly transformed into α-chloro sulfoxides (sulfone formation may compete) by lengthier exposure to excess reagent (eq 11),[52] which can also be used to obtain perfluorosulfuryl chlorides from the corresponding sulfinic acids.[53]

Oxidation of Alcohols.

$PhICl_2$ in the presence of a weak base such as pyridine can be used to oxidize secondary alcohols to ketones (eq 12).[54] The method is not suitable for primary alcohols or diols or to unsaturated substrates due to competing chlorination.[22-32]

Phenyl Isocyanate[1]

PhNCO

[103-71-9] · C_7H_5NO · Phenyl Isocyanate · (MW 119.13)

(organic heterocumulene capable of forming heterocycles via cycloaddition to dipolarophiles;[1a-e] adds nucleophiles producing polyfunctional compounds;[1a,b,f,g] readily inserts into metal-element bonds providing metal-mediated construction of new C-C bond;[1g,h] used as dehydrating agent)

Physical Data: mp -30 °C; bp 55 °C/13 mmHg; *d*19.64 1.10 g cm^{-3}; *n*20D 1.5350.

Solubility: sol ether, alcohol, benzene, toluene, xylene, DMF, MeCN.

Form Supplied in: liquid with acrid odor; purity about 98%.

Analysis of Reagent Purity: GLC.

Purification: addition of Grignard reagent solution and rapid distillation.

Handling, Storage, and Precautions: moisture sensitive; corrosive; highly toxic; irritating to eyes; lachrymator. Use in a fume hood.

Nucleophilic Addition.

Oxygen, nitrogen, sulfur, phosphorus, and carbon nucleophiles add across the C=N bond of phenyl isocyanate (**1**). Due to a high affinity to water, (**1**) is used in ***Triethylamine***-promoted dehydration of primary nitroalkanes to nitrile oxides (Mukaiyama reaction) (eq 1),[2] and of aldoximes[3] and α-hydroximino acids[4] to nitriles. The phenylcarbamic acid formed from (**1**) immediately decomposes with CO_2 evolution. In a similar way, (**1**) reacts with alcohols to produce *N*-phenylurethanes.[1a,b,5] *N*-Phenyl-*O*-arylurethanes can be hydrogenolyzed to give arenes.[5b] Hydroxamic acid azides behave as oxygen nucleophiles toward (**1**) and give 5-phenyloxadiazoles.[6]

Nitrogen nucleophiles of high basicity (*N*,*N*-acetals, hexahydro-*s*-triazine, iminophosphoranes) are especially active in additions to (**1**),[1a,f,7] while aminoalkylphosphoramidates react regioselectively at the nitrogen of the P-N bond giving carbodiimides (eq 2).[8] Even carboxamides readily react with (**1**) to form uracils after cyclization.[9a] To compensate for the low basicity of tosylamides, their reactions with (**1**), yielding *N*-tosylureas, are carried out in the presence of ***Copper(I) Chloride***.[9b]

(2)

α,ο-Alkanedithiols react with (**1**) to give biscarbamothioates in good yields.[10] Comparatively weak P-nucleophiles are not very active in additions to (**1**). However, trialkylphosphine-induced dimerization and trimerization of (**1**) does involve intermediate betaine formation due to addition of the phosphorus nucleophile to the isocyano group.[11] Hydride-ion or enolate addition to the isocyanate carbon provides *N*-functionalized *N*-phenylformamido compounds[12] and highly substituted β-keto amides (eq 3),[13] respectively.

(3)

Aziridines react with (**1**) with ring expansion (eq 4).[14,1f,1g] This is formally a 1,3-dipolar cycloaddition reaction (see below). With more complex bifunctional nucleophiles (silylamines,[15] aminoboranes, and organoboranes[16]) the reactions of (**1**) provide a facile route to polyfunctional organosilicon and organoboron compounds.

(4)

Cycloaddition.

Phenyl isocyanate undergoes polar cycloaddition reactions with unsaturated substrates to give both heterocycles and

functionalized open-chain compounds. Although both the C=N and C=O double bonds can participate in cycloadditions, usually the process takes place with high regioselectivity across the C=N bond. The structure of cycloadducts and the cycloaddition mode are defined by the nature of the unsaturated substrate and also by the substrate:phenyl isocyanate ratio. Nucleophilic alkenes react with (**1**) to afford unstable [2 + 2] cycloadducts (2-azetidinones), which are readily cleaved to give polyfunctional aliphatic compounds (eq 5).[17]

(5)

Reactions of (**1**) with C=N-containing substrates[1d] are sensitive to the nucleophilicity of the C=N double bond. *N*-Alkyl-*N*′-arylcarbodiimides add to (**1**) exclusively at the *N*-alkyl-substituted C=N bond to give 4-arylimino-1,3-diazetidin-2-ones.[18] Six-membered heterocycles can be synthesized from unsaturated substrates and phenyl isocyanate via [2 + 2 + 2′], [2 + 2′ + 2′], or [4 + 2] dipolar cycloaddition reactions. The first two modes are realized due to low stability [2 + 2] adducts which react further (especially at elevated temperature) with an excess of phenyl isocyanate. In a [2 + 2′ + 2′] reaction, ketene *S*,*N*-acetals react with (**1**) (2 equiv reflux in toluene) to afford 1,3-diphenyl-2-pyrimidinones,[19] whereas the [2 + 2 + 2′] route occurs in the reaction with 3*H*-indole (eq 6).[20]

(6)

[4 + 2] Cycloaddition reactions are based on a condensation of (**1**) with a suitable 1,4-dipolar synthon (4-amino-1-

azabutadienes,[21] 1,3-diazabutadienes,[22] 2-aza-1,3-dienes,[23] 1-(triphenylphosphinimido)dienes[24]) and give the corresponding heterocycles (2-imino-1,2-dihydropyrimidines,[21] 5,6-dihydro-1,3,5-triazine-2,4(1*H*,3*H*)-diones,[22] 1,2-dihydropyrimidin-4(3*H*)-ones (eq 7),[23] 2-phenylaminopyridines,[24a] or condensed quinazolines.[24b,c]). Phenyl isocyanate also enters 1,3-dipolar [3 + 2] cycloaddition reactions (with *N*-oxides, 1,2-diimines, 2-imino ketones, azides) to produce five-membered ring heterocycles.[1a,c,e,25]

Metal-Promoted C-C Bond Forming Reactions.

The most widely exploited route to new C-C bond formation at the isocyanate carbon is based on insertion of (**1**) into main-group metal-carbon bonds[26] or transition metal-carbon bonds.[27] ***Samarium(II) Iodide***-promoted self-coupling of (**1**) affords *N*,*N*´-diphenyloxamide.[28]

Regiospecific *C*-(*N*-phenylcarbamoylation) reactions of copper and nickel β-keto imine complexes,[29a] phenols (in the *ortho*-position in the presence of ***Boron Trichloride***),[29b] and 5*H*-azepino[1,2-*a*]benzimidazol-7(8*H*)-one at C-6[29c] are examples of electrophilic substitution reactions in which the acidic proton of the substrate or ligand is transferred to the nitrogen atom of phenyl isocyanate.

Numerous coupling reactions of (**1**) with unsaturated substrates are catalyzed by nickel(0) complexes.[1h] These serve as templates providing intermediate formation of nickel azaheterocycles stabilized by strong Ni-N coordination. These heterocycles decompose with formation of unsaturated amides and liberation of coordinated Ni^0 that enables one to employ only a catalytic amount of the Ni^0 source.[1h]

In contrast to 1,1-difluoroalkenes, which produce saturated β,β-difluorocarboxamides with (**1**),[30] alkenes and arylalkenes undergo substitutive *N*-phenylcarbamoylation at the terminal or allylic carbon, yielding the corresponding alkenic carboxamides.[1h,31] 1,3-Pentadiene reacts analogously to form sorbanilide in 250% yield (based on Ni^0) (eq 8).[32] Both acyclic and five-membered carbocyclic amides are formed from 1,5-hexadiene and 1,6-heptadiene (eq 9).[33]

(8)

(9)

Nickel(0) complexes[1h] as well as low-valent tantalum complexes[34] promote reductive carbamoylation of alkynes with (**1**) to produce 2-alkenyl- and 2,4-alkadienylcarboxamides (eq 10).[34] [2 + 2 + 2´] Cycloaddition occurs in the presence of basic phosphine ligands under very mild conditions to give 2-pyridones.[1h,35] On the contrary, in ***Pentacarbonyliron***-mediated reactions, [2 + 2´ + 2´] cycloaddition occurs to afford hydantoins (eq 11).[36]

(10)

(11)

Strained rings readily undergo ring expansion upon metal-mediated reactions with (**1**). For example, Pd^0 complexes catalyze condensation of (**1**) with vinylcyclopropanes to give 5-vinyl-4-phenylpyrrolidin-2-ones.[37] The direction of ring cleavage of oxiranes with (**1**) depends on the catalyst employed. For example, Sb^V and Pd^0 compounds,[38,39] as well as trialkyltin reagents coordinated by HMPA,[40] affect α-cleavage yielding 4-substituted 3-phenyloxazolidin-2-ones (eq 12), while other organotin reagents afford also the 5-substituted isomers.[41] These heterocycles are masked β-amino alcohols, which are readily liberated on hydrolysis.

(2)

(12)

Related tin-mediated cleavage of four-membered oxetanes, γ-bromo-β-lactones, or β-lactams has been used in facile one-pot syntheses of tetrahydro-1,3-oxazin-2-ones,[42a] 5-(methoxycarbonyl)methyl-3-phenyloxazolidin-2-ones, and 1,3-imidazolidin-2-ones.[42b] ***Tetrakis(triphenylphosphine)palladium(0)***-promoted reaction of propylene carbonates with (**1**)[43] also effectively leads to tetrahydro-1,3-oxazin-2-ones which hydrolyze to the corresponding γ-amino alcohols.

[931-54-4] · C_7H_5N · Phenyl Isocyanide · (MW 103.13)

(synthesis of heterocycles)

Physical Data: bp 54 °C/13 mmHg; *d* 0.98 g cm^{-3}.

Solubility: sol most organic solvents, e.g. methanol, ethanol, ether, toluene, dichloromethane.

Form Supplied in: pure liquid; not commercially available.

Analysis of Reagent Purity: gas chromatography.

Preparative Methods: see Grundmann,[3a] Ugi and Meyr,[3b] and Obrecht et al.[3c]

Handling, Storage, and Precautions: should be used freshly distilled. Foul smelling liquid; should be stored and used in a fume hood. Contaminated equipment should be washed with 5% methanolic sulfuric acid.

Synthesis of Heterocycles.[1,2]

The pharmacologically interesting barbituric acid derivative 6-phenylaminofuro[2,3-*d*]pyrimidine-2,4(1*H*,3*H*)-dione can be synthesized from readily available benzylidene-*N*,*N*´-dimethylbarbituric acid with phenyl isocyanide by Michael-type addition and cyclization with tautomerization (eq 1).[4]

Benzofuran derivatives can be prepared in a general procedure by an Ugi-type reaction from substituted *o*-hydroxybenzaldehydes and isocyanides (eq 2).[5] The reaction of the intermediate iminium compound, from the aldehyde and the ammonium salt, with the isocyanide stops at the addition step of the Ugi reaction. The resulting amino group reacts with another equivalent of the aldehyde, because the phenoxy function, which behaves as an acid equivalent, cannot be cleaved as is usual in the Ugi reaction.

(2)

[4 + 1] Cycloaddition of dimethyl tetrathiooxalate with phenyl isocyanide leads to 2-imino-1,3-dithioles under simple reaction conditions in remarkably high yield (eq 3).[6]

(3)

Another [4 + 1] cycloaddition of kinetically stabilized azetes with phenyl isocyanide affords sterically hindered pyrrole derivatives (eq 4).[7] A simple route to cyclopentane-fused quinolines involves [4 + 1] radical annulation of γ-iodoalkynes with phenyl isocyanide.[8]

(4)

(5)

1,2-Benzo-4-boraimidazolines are available by [4 + 1] cycloaddition of dialkylboryl derivatives with 2-aminopyridine in high yields (eq 6).[9] Another structurally interesting boron heterocycle, namely a borapyrrole derivative, can also be obtained by [4 + 1] cycloaddition and alkyl tautomerization (eq 7).[10]

(6)

(7)

Phenyl isocyanide is also an effective reagent to form α-(methoxycarbonylamino) amides from α-methoxy urethanes in reasonable yields. As shown in eq 8, a Lewis acid catalyzes formation of the α-methoxycarbonylvalinamide.[11] The insertion of phenyl isocyanide into the C-O bond of *N*-(ethoxymethyl)piperidine gives the α-piperidino acetimidate shown in eq 9.[12]

(8)

(9)

Syntheses Based on the Passerini Reaction.

Cyclization of levulinic acid[13a] and *o*-formylbenzoic acids[13b] with phenyl isocyanide produces γ-carbamoyl γ-lactones (eqs 10 and 11). The Ugi four-component reaction between cycloalkanones, phenyl isocyanide, and ammonium formate affords α-formylamino *N*-phenylcarboxamides (eq 12).[14]

(10)

(11)

(12)

Other Applications.

Polymerization of isocyanides under the action of Ni^{II} catalysts leads to helical polymethyleneimines (eq 13).[15] Oxidation of phenyl isocyanide by Tl^{I}-catalyzed reaction with dibenzoyl disulfide gives the isothiocyanate in excellent yield (eq 14).[16] Also, the direct oxidation of phenyl isocyanide with elemental selenium gives phenyl isoselenocyanate in high yield (eq 15).[17]

Phenyl Isothiocyanate

Ph-N=C=S

[103-72-0] · C_7H_5NS · Phenyl Isothiocyanate · (MW 135.20)

(Edman degradation of peptides; synthesis of heterocyclic systems)

Physical Data: bp 221 °C; mp -21 °C; *d* 1.1288 g cm^{-3}.

Solubility: insol H_2O; sol alcohol, ether.

Form Supplied in: liquid; widely available.

Handling, Storage, and Precautions: use in a fume hood.

Edman Degradation.

Identification of terminal amino acid residues of peptides can readily be accomplished by an Edman degradation.[1] Treatment of the peptide with phenyl isothiocyanate in pyridine-water (1:1) produces a phenylthiocarbamoyl derivative which, upon exposure to anhydrous ***Hydrogen Chloride*** in nitromethane, rapidly cleaves to form a 3-phenyl-2-thiohydantoin and a peptide with one less amino acid residue. If needed, the free amino acid can be isolated by hydrolysis of the thiohydantoin with ***Barium Hydroxide*** (eq 1).

The procedure, which is amenable to complex peptides containing a variety of sensitive functionalities, has been applied to the vancomycin group of antibiotics,[2-4] and was instrumental in the structure elucidation of avoparcin (**1**).[5,6] In this case, the thiohydantoin of the deoxysugar amino acid fragment forms in the first step without a need for acid-catalyzed cyclization.

(1)

An interesting method for the resolution of amines involves preparing its amide with L-phenylalanine. Chromatographic separation of the corresponding diastereomers followed by an Edman degradation furnishes either pure enantiomer (eq 2).[7] In this manner, dibenzo[*a*,*d*]cycloalkenimines (**2**)[8] and 3-amino-1-hydroxypyrrolidin-2-one (**3**)[9] have been resolved and evaluated for their *N*-methyl-D-aspartate and glycine antagonist activities, respectively.

(2)

(3)

Cyclization Reactions.

The elements of phenyl isothiocyanate can be incorporated into cyclization motifs to form a variety of heterocyclic systems. For example, treatment of 2-amino-5-chlorobenzhydrol with phenyl isothiocyanate, followed by cyclization of the intermediate thiourea with dilute HCl, produces 6-chloro-3,4-diphenyl-2-thioxo-1,2,3,4-tetrahydroquinazoline in 60% yield (eq 3).[10]

(3)

The core of the penem heterocyclic system can readily be assembled using phenyl isothiocyanate to supply the sulfur and one carbon atom for its five-membered ring. Treatment of a suitable azetidinone with ***Lithium Hexamethyldisilazide*** at -40 °C, followed by phenyl isothiocyanate and acetic anhydride, affords a ketene derivative. Deprotection, chlorinolysis, and hydrolysis produce the 2-phenylaminopenem (eq 4).[11]

(4)

Dehydration Reactions.

N-Benzoylanthranilic acid, when heated with phenyl isothiocyanate at 160-170 °C in the presence of ***Pyridine*** as a catalyst, gives 2-phenyl-3,1-benzoxazin-4-one in 30% yield (eq 5).[12] Analogously, oxazolones are produced by a phenyl isothiocyanate-mediated cyclodehydration of *N*-acylglycines at 160-170 °C.[13,14] When the reaction is performed in the presence of a salicylaldehyde, 3-*N*-acylaminocoumarins are isolated in yields of 20-68% (eq 6).[15]

Phenyllithium[1]

PhLi

[591-51-5] · C_6H_5Li · Phenyllithium · (MW 84.05)

(organometallic agent useful as nucleophile for addition and substitution reactions,[1,3-20] and in the preparation of organolithium building blocks via metalation[32] and lithium-metalloid exchange reaction[1])

Physical Data: X-ray structures of the PMDTA-complexed monomer,[2i] the TMEDA-complexed dimer,[2a] the diethyl ether-complexed tetramer,[2b] and the PhLi:LiBr (3:1) mixed tetramer[2b] have been reported. Cryoscopic[2h] and NMR[2c-e] studies have shown that a monomer-dimer equilibrium exists in THF solution and that monomers exist in THF/HMPA[2f] and THF/PMDTA.[2c] PhLi is tetrameric in ether.

Solubility: sol ether solvents; sol hydrocarbon solvents only by the addition of donor solvents/additives such as ether or TMEDA.[2a]

Form Supplied in: commercially available in cyclohexane/ether solution.

Analysis of Reagent Purity: standard titration methods should be used.

Preparative Methods: prepared from phenyl halide (PhCl,[2j] PhBr,[2k,l] PhI[2m]) and lithium metal in ether. Several procedures have been used to prepare solid, salt-free PhLi.[2n-r] The synthesis of ^{13}C-labeled PhLi (*ipso* carbon only) has been described.[2h]

Handling, Storage, and Precautions: moisture and oxygen sensitive. Concentrated solutions are pyrophoric. Ether solutions slowly undergo proton abstraction to generate benzene and should be stored in the freezer.

Addition and Substitution Reactions.

The greatest number of synthetic methodologies using PhLi involve carbon-carbon single bond formation through nucleophilic addition and substitution reactions. PhLi undergoes nucleophilic addition in a 1,2-fashion to a variety of carbonyl containing compounds including ***1,4-Benzoquinone***,[3a,b] cyclobutenediones,[3c] γ-amino enals,[3d] *N*-(alkyl)phthalimides,[3e] optically-active dienone-iron tricarbonyl complexes,[3f] α-silyl ketones[4] (eq 1),[4a] and β-lactams (eq 2).[5] PhLi adds similarly to cumulated carbonyl groups: isocyanates afford amides,[1] ketenes[6] yield enolates (eq 3),[6b] and ***Carbon Dioxide***[7] produces phenyl ketones (eq 4).[7b]

(1)

(2)

(3)

(4)

In general, organolithium compounds preferentially undergo addition to the carbonyl of α,β-unsaturated carbonyl compounds rather than Michael addition. However, conjugate addition is promoted by increased solvent polarity, delocalized organolithium compounds, and lower temperatures which allow for thermodynamic control.[1,9] Conjugate addition of PhLi to vinyl sulfones[8] and α,β-unsaturated esters,[10a] ketones,[10b] and imines[11] has been reported. Thiophilic attack of thiocarbonyl compounds by PhLi has been observed for thioketones,[12] thioketenes (eq 5),[13] and thiocarbonates.[14] Addition of PhLi to carbon-nitrogen double and triple bonds, including the formal carbon-nitrogen double bond of azaaromatic heterocycles such as pyridine[15a] and quinoline,[15b] is general.[15] Arylation of 3,4-dihydro-β-carboline was accomplished by activation with ***Boron Trifluoride Etherate*** (eq 6).[15c] Similarily, the addition of PhLi to 2-isoxazolines[15d] and oxime ethers[15e] in the presence of boron trifluoride has been demonstrated. Addition reactions to nitriles containing no α-hydrogens have been reported to effectively afford ketimines and ketones.[16] Lithium aldimines

have been prepared through the addition of PhLi to isocyanides.[17]

(5)

(6)

PhLi undergoes alkylation with primary halides, allylic halides (eq 7),[18a] and benzyl halides.[1a-c,18] Although not nearly as prevalent, displacement of sulfonate has also been reported.[1,19] Nucleophilic ring opening of epoxides with PhLi is general.[20] The reaction of PhLi with α,β-epoxy silanes yields β-hydroxy silanes which subsequently undergo Peterson reaction to afford alkenes (eq 8).[20d] Addition reactions to oxetanes[21a] and substituted aziridines[21b] are known, but have comparatively little utility.

(7)

Nucleophilic addition and substitution reactions with PhLi often may be accompanied or followed by other reactions such as lithium-metalloid exchange, enolization, metalation, or carbanionic rearrangements.

Lithium-Metalloid Exchange Reaction.

Phenyllithium undergoes lithium metalloid exchange[1] which is a reversible process with an equilibrium constant that reflects the difference in stability of PhLi and the new organolithium species generated. Mechanistic studies of this reaction abound.[1d,e] Lithium-halogen exchange is most prevalent, although related transmetalations involving selenium,[22] tellurium,[23] tin,[24] and mercury[25] are also common. In general, PhLi/M exchange is characteristically fast (I > Te, Sn > Br > Se > Cl)[1d] even at low temperatures. Exchange rates increase with increased solvent polarity, but are slowed by the presence of lithium salts.[2f,26] PhLi/M exchange reactions have been utilized for the preparation of functionalized aryllithiums (e.g. 4-methoxyphenyllithium,[27a] lithio-nitrobenzenes),[27b,c] substituted benzyllithiums (eq 9),[28] 3-thienyllithium derivatives (eq 10),[29] ***Vinyllithium***,[24c] 2-lithiophosphinines,[30] and other stabilized organolithium reagents which are not readily available by metalation or the reduction of halides. ***Allyllithium*** generated through reaction of PhLi and ***Tetraallylstannane***,[24d,e] can be converted with ***Potassium t-Butoxide*** to the more reactive allylpotassium which subsequently undergoes conjugate addition to vinyl sulfones (eq 11).[31]

(10)

(11)

Lithiation Reactions.[32-36]

Replacement of hydrogen by lithium in an organic compound is perhaps the most versatile method for preparing organolithium compounds. Although not nearly as prevalent as ***n-Butyllithium***, PhLi has been used as a base in heteroatom-facilitated lithiations, lithiations of relatively strong hydrocarbon acids (pK_a of benzene = 43),[37] and in the formation of stabilized anions where a milder reagent is warranted. Thiophenes,[32] sulfones,[8] nitriles,[33] 1,3-dimethoxybenzenes,[34] and α-methylpyridines[35] (eq 12)[35a] have been metalated with PhLi. Reaction of 2 equiv of PhLi

with a β-epoxy sulfone resulted in base-catalyzed β-elimination and subsequent conjugate addition to produce a dianion which was alkylated with ***Iodomethane*** (eq 13).[8] PhLi has been used to deprotonate secondary amines to form lithium amides.[36]

(12)

(13)

Related Reagents.

Lithium Diphenylcuprate; ***Lithium Di-p-tolylcuprate***; ***Phenylmagnesium Bromide***.

Phenylmagnesium Bromide[1]

PhMgX

(X = Br)

[100-58-3] · C_6H_5BrMg · Phenylmagnesium Bromide · (MW 181.32) (X = Cl)

[100-59-4] · C_6H_5ClMg · Phenylmagnesium Chloride · (MW 136.87)

(adds to many unsaturated functional groups; phenyl can displace halide and like groups; functions as a strong base and a Lewis acid[1b-f])

Physical Data: NMR and calorimetric observations indicate that PhMgBr in Et_2O and THF and PhMgCl in THF are actually mixtures of PhMgX, Ph_2Mg, and MgX_2.[2,3] Although PhMgBr and PhMgCl are essentially monomeric in THF, PhMgBr is associated significantly in Et_2O except at low concentrations.[3,4] Solids isolated include $PhMgBr(Et_2O)_2$[5] and $PhMgBr(THF)_2$,[6] both shown by X-ray diffraction studies to have four-coordinate Mg.

Solubility: both sol Et_2O, THF; insol hydrocarbons.

Form Supplied in: solutions of PhMgBr in Et_2O and THF and of PhMgCl in THF and THF/toluene are commercially available.

Analysis of Reagent Purity: see ***Methylmagnesium Bromide***.

Preparative Methods: in spite of their commercial availability, solutions of PhMgBr[8] and PhMgCl[9] are frequently prepared from reaction of a phenyl halide and Mg, usually in Et_2O or THF.[1c,e,7] Preparation of PhMgBr in Et_2O is routine, but the formation of PhMgCl from PhCl and magnesium is difficult to initiate and sustain. By contrast, preparation is generally successful in THF.[9] Use of activated[10] ***Magnesium*** makes possible otherwise difficult preparations, allows the use of lower temperatures which may minimize undesired reactions with other functional groups in the reagent, and allows the use of Et_2O, other less favorable ethers, and hydrocarbons. Stirring Mg under nitrogen is one activation procedure;[11] other effective procedures (chemical treatment of the Mg,[12] preparation of Mg by reduction of salts,[13] use of ethylene bromide as a coreagent during the preparation[14]) can introduce other species.

Handling, Storage, and Precautions: see ***Methylmagnesium Bromide***. Phenyl Grignard reagents do not significantly attack Et_2O or THF at normal reaction temperatures.

Representative Applications.[1b-f]

See also ***Methylmagnesium Bromide***. Phenyl Grignard reagents are used most frequently in reactions that result in attachment of the organic group to an electrophilic carbon atom of the substrate, most often of a carbonyl group, nitrile, or other unsaturated function. The oxazoline function, easily transformed into other functions, facilitates displacement of a methoxyl group (eq 1), probably both by its electronic effects and by coordinating with the Grignard reagent.[15]

N-Phenylmaleimide

[941-69-5] · $C_{10}H_7NO_2$ · *N*-Phenylmaleimide · (MW 173.18)

(dienophile[2,3] and dipolarophile; Michael acceptor; radical acceptor)

Alternate Name: NPM.

Physical Data: mp 89-90 °C; bp 162-163 °C/12 mmHg.

Solubility: insol H_2O; sol alcohol, ether, benzene.

Form Supplied in: yellow solid; widely available.

Purification: recrystallizaton from benzene/ligroin or from cyclohexane.

Handling, Storage, and Precautions: irritant.

Cycloadditions.

N-Phenylmaleimide is a common dienophile which reacts with a wide variety of dienes. Its advantages relative to other dienophiles are that it gives products in high yield and the Diels-Alder adducts are not susceptible to hydrolysis or retro-Diels-Alder reactions. High *endo* selectivity is usually observed in Diels-Alder reactions with NPM. Exceptionally high *endo* selectivity has been reported with the related *N*-methylmaleimide (NMM) relative to *N*-phenylmaleimide in [4 + 2] reactions with isobenzofuran.[1] Studies which have examined the effect of a stereogenic center adjacent to the diene on the facial selectivity of a Diels-Alder reaction have frequently employed *N*-phenylmaleimide as a representative dienophile.[2,3] Acyclic and cyclic 1,3-dienes containing an allylic stereogenic center have been examined (eqs 1-3). The bromo derivative of NPM, N-*p*-bromophenylmaleimide, has been used to obtain crystalline adducts suitable for single crystal X-ray analysis and unambiguous assignment of stereochemistry.[2c]

(3)

N-Phenylmaleimide readily reacts with a variety of 1,3-dipoles including azomethine ylides (eqs 4 and 5),[4] carbonyl ylides (eq 6),[5] and nitrones (eq 7).[6] The carbene generated by the photolysis of the sodium salt of a glyconolactone tosylhydrazone has been trapped by NPM to provide a 9:1 mixture of isomeric cyclopropanes (eq 8).[7]

(4)

(5)

(6)

(7)

(8)

Miscellaneous.

Substituted amines add in a Michael fashion to *N*-phenyl- and *N*-alkylmaleimides. In this manner, *N*-alkyldaunorubicin derivatives have been prepared in good yield (eq 9).[8] Similarly, ***Tri-n-butylstannane-Azobisisobutyronitrile*** radical additions of glycosyl halides and selenides with *N*-alkylmaleimides provide *C*-glycosyl compounds (eq 10).[9]

(-)-8-Phenylmenthol

(1*R*,2*S*,5*R*)

[65253-04-5] · $C_{16}H_{24}O$ · (-)-8-Phenylmenthol · (MW 232.37) (1*S*,2*R*,5*R*)

[100101-42-6] (1*S*,2*R*,5*S*)

[57707-91-2]

(chiral auxiliary for asymmetric induction)

Alternate Name: (1*R*,2*S*,5*R*)-5-methyl-2-(1-methyl-1-phenylethyl)cyclohexanol.

Physical Data: $[\alpha]_D$ -26° (*c* 2, EtOH); *d* 0.999 g cm^{-3}.

Solubility: sol organic solvents.

Form Supplied in: commercially available as a colorless oil (98%) and as the chloroacetate ester.

Analysis of Reagent Purity: NMR and $[\alpha]_D$.

Preparative Methods: (1*R*,2*S*,5*R*)-(-)-8-phenylmenthol is prepared by the reaction of ***Phenylmagnesium Bromide*** (cat. ***Copper(I) Iodide***) with (+)-pulegone, equilibration of the resulting conjugate addition product, and reduction of the ketone (***Sodium***, isopropanol).[1] The (1*R*,2*S*,5*R*)-isomer is accompanied by the (1*S*,2*R*,5*R*)-isomer and is conveniently separated by recrystallization of the chloroacetate ester.[2] This separation is essential to obtaining high optical yields since it has been shown that the two diastereomers have opposite chiral directing

ability.[3] The preparation of the enantiomeric (1*S*,2*R*,5*S*)-(+)-8-phenylmenthol from (+)-pulegone has been reported.[4]

Handling, Storage, and Precautions: no special precautions are necessary other than those used for combustible organic compounds.

Chiral Auxiliary for Asymmetric Induction.

Numerous derivatives of (-)-8-phenylmenthol have been utilized for asymmetric induction studies. These include inter-[5] and intramolecular[6] Diels-Alder reactions, dihydroxylations,[7] and intramolecular ene reactions[8] of α,β-unsaturated 8-phenylmenthol esters. These reactions usually proceed in moderate to good yield with high diastereofacial selectivity. α-Keto esters of 8-phenylmenthol (see ***8-Phenylmenthyl Pyruvate***) have been used for asymmetric addition to the keto group,[9] as well as for asymmetric [2 + 2] photoadditions[10] and nucleophilic alkylation.[11] Ene reactions of α-imino esters of 8-phenylmenthol with alkenes provide a direct route to α-amino acids of high optical purity.[12]

Vinyl and butadienyl ethers of 8-phenylmenthol have been prepared and the diastereofacial selectivity of nitrone[13] and Diels-Alder[14] cycloadditions, respectively, have been evaluated. α-Anions of 8-phenylmenthol esters also show significant diastereofacial selectivity in aldol condensations[15] and enantioselective alkene formation by reaction of achiral ketones with 8-phenylmenthyl phosphonoacetate gives de up to 90%.[16]

Related Reagents.

8-Phenylmenthyl Crotonate; ***8-Phenylmenthyl Pyruvate***.

8-Phenylmenthyl Acrylate

[72526-00-2] · $C_{19}H_{26}O_2$ · 8-Phenylmenthyl Acrylate · (MW 286.45)

(reagent used in asymmetric synthesis for cycloadditions and conjugate additions)

Alternate Name: (1*R*,2*S*,5*R*)-2-(1-methyl-1-phenylethyl)-5-methylcyclohexyl acrylate.

Solubility: sol CH_2Cl_2, toluene, most organic solvents.

Analysis of Reagent Purity: ^{1}H and ^{13}C NMR.[1] $[\alpha]_D$ +16.21° (*c* 1.68, CH_2Cl_2).[2]

Preparative Method: prepared by the reaction of ***(-)-8-Phenylmenthol***, acryloyl chloride, ***Triethylamine***, and ***4-Dimethylaminopyridine*** in CH_2Cl_2 at 0 °C. Following an aqueous workup, the compound is purified by chromatography on silica gel.[1]

Handling, Storage, and Precautions: acrylates are prone to polymerization and are best stored below room temperature under N_2.

[4 + 2] Cycloadditions.

The asymmetric Diels-Alder reaction[3] of phenylmenthyl acrylate with 5-benzyloxymethylcyclopentadiene in the presence of ***Aluminum Chloride*** produces an 89% yield of the *endo* cycloadduct (eq 1), accompanied by 7% of the *exo* adduct. This provides a useful intermediate for the preparation of various prostaglandins.[2] The ***Tin(IV) Chloride*** and ***Titanium(IV) Chloride*** catalyzed reactions with ***Cyclopentadiene*** deliver a mixture of *endo* and *exo* adducts in 89% de, and 90% de, respectively (eq 2). The $TiCl_4$ reaction gives an 89:11 *endo*:*exo* ratio, while the $SnCl_4$ reaction gives an 84:16 *endo*:*exo* ratio. From a practical point of view, the titanium and tin catalysts are the best of the various Lewis acids surveyed.[4] The use of $TiCl_4$ is also the most effective for the reaction of the acrylate with ***1,3-Butadiene*** (eq 3).[5] The increased asymmetric induction over the simpler menthyl acrylate is attributed to the shielding of the C(α)-*re* face of the dienophile by the phenyl ring.[6]

1,3-Dipolar Cycloadditions.

The asymmetric induction for a 1,3-dipolar cycloaddition of phenylmenthyl acrylate is not as good as in the [4 + 2] cycloadditions. The thermal decomposition of diazofluorene in the presence of the acrylate produces the spirocyclopropane in 96% yield, but with only a 20% de (eq 4).[7]

(4)

Conjugate Additions.

The reaction of this acrylate derivative with lithium *t*-butyl hydroperoxide (generated from anhydrous ***t-Butyl Hydroperoxide*** and ***n-Butyllithium***) in THF leads to the corresponding epoxide (eq 5) in 95% yield with a de of 40%.[8]

(5)

In an asymmetric approach to the bicyclo[2.2.2]octane ring system, a double Michael addition has been employed using phenylmenthyl acrylate as the initial Michael acceptor. The condensation of the dienolate, generated with ***Lithium Diisopropylamide***, reacts with the acrylate to afford the bicyclo[2.2.2]octane derivative (eq 6). The de for the reaction is only 50%; however, it is highly *endo* selective (>95%).[9]

(6)

A Lewis acid-mediated two-fold asymmetric Michael addition allows access to *cis*-decalin derivatives. The reaction of the trimethylsilylenol ether of acetylcyclohexene with phenylmenthyl acrylate in the presence of ***Diethylaluminum Chloride*** (eq 7) yields the decalone in 64% yield (70% de). This has been shown not to be a Diels-Alder reaction. If the reaction is worked-up early, the initial Michael adduct can be isolated.[10]

(7)

Phenylmenthyl acrylate has been used as a component in an asymmetric Baylis-Hillman reaction. Treatment of the acrylate with ***1,4-Diazabicyclo[2.2.2]octane*** and benzaldehyde at 8 kbar of pressure delivers the α-(hydroxyalkyl)acrylate (eq 8). The product obtained has an 86% de. Menthyl acrylate is superior to the phenylmenthyl acrylate in this particular application.[11] In a radical-mediated addition, phenylmenthyl acrylate gives rise to the α-pyridyl sulfide in 68% yield (eq 9).[12] The final product is isolated with a 56% de.

(8)

(9)

56% de

Miscellaneous.

The acrylate provides a synthon for the preparation of ***8-Phenylmenthyl Glyoxylate***, which is useful for asymmetric ene reactions.[1] Thus ozonolysis and removal of the water of hydration produces the glyoxylate in 89% yield (eq 10).

8-Phenylmenthyl Crotonate

[81002-19-9] · $C_{20}H_{26}O_2$ · 8-Phenylmenthyl Crotonate · (MW 300.46)

(chiral ester for asymmetric induction)

Alternate Name: (1*R*,2*S*,5*R*)-5-methyl-2-(1-methyl-1-phenylethyl)cyclohexyl crotonate.

Solubility: sol organic solvents.

Form Supplied in: not commercially available.

Preparative Methods: isolated as an oil from the esterification of ***(-)-8-Phenylmenthol*** with 2-butenoic acid (DCC, DMAP, CH_2Cl_2).[1]

Analysis of Reagent Purity: NMR[2] and $[\alpha]_D$.

Handling, Storage, and Precautions: no special precautions are necessary other than those used for combustible organic compounds.

General Discussion.

Reaction of the crotyl ester of (-)-8-phenylmenthol with organocopper reagents in the presence of ***Boron Trifluoride*** gives good chemical yields and >99% de of the 1,4-addition product where addition has taken place from the *re* face (eq 1).[1] Extension of this methodology to the 8-phenylmenthyl *cis*-butenoate gives significantly lower de.[1] Epoxidation of 8-phenylmenthyl crotonate with ***t-Butyl Hydroperoxide-n-Butyllithium*** gives 50% de.[2] Chiral β-amino esters of 8-phenylmenthol have been prepared in 50-60% de by the addition of amines to the *re* face of 8-phenylmenthyl crotonate under 14-15 kbar pressures (eq 2). Much higher (75 to >99%) de is obtained using 8-(β-naphthyl)menthol crotonate. The β-amino esters obtained are of the proper configuration for conversion to biologically active β-lactams.[3]

8-Phenylmenthyl Glyoxylate[1]

[129444-92-4] · $C_{18}H_{24}O_3$ · 8-Phenylmenthyl Glyoxylate · (MW 288.42)

(two-carbon unit utilized as a versatile chiral reagent in ene reactions,[2] Diels-Alder reactions,[3] various nucleophilic additions,[4] and aromatic substitutions.[5])

Physical Data: bp 135-140 °C/0.3 mmHg; [α]20589 -169° (*c* 0.51, benzene).[6]

Solubility: sol most common organic solvents.

Preparative Methods: ozonolysis of ***8-Phenylmenthyl Acrylate***, NaOAc-catalyzed elimination of nitrite ion from nitrate esters, and direct esterification with glyoxylic acid.[7]

Handling, Storage, and Precautions: heating the glyoxylate monohydrate to 90 °C/0.1 mmHg for 4.5 h or distillation provides material which is sufficiently anhydrous for most practical applications. Due to its tendency to form a monohydrate and/or polymerize, 8-phenylmenthyl glyoxylate should be stored under nitrogen in the refrigerator.

Ene Reactions.

Lewis acid (***Tin(IV) Chloride*** or ***Titanium(IV) Chloride***) catalyzed ene reactions of the glyoxylate esters of 8-phenylmenthol and 2-*epi*,*ent*-8-phenylmenthol, as well as *trans*-2-phenylcyclohexanol, with terminal, monosubstituted alkenes proceed with excellent levels of stereocontrol (eq 1).[8] The phenyl group presumably forms a π-complex with the aldehyde-Lewis acid complex thereby blocking one face of the dicarbonyl, rendering the opposite face accessible to incoming reagents. This has been demonstrated through the systematic study of the effect of auxiliary structure on asymmetric induction in the glyoxylate-ene reaction, as well as by photophysical studies involving a family of α-carbonyl esters of 8-phenylmenthol.[7,9] The ene reactions of glyoxylates with nonterminal alkenes proceed with a high level of relative asymmetric induction to give the (*S*)-configuration at the newly created stereocenter with 8-phenylmenthol and the (*R*)-configuration with *trans*-2-phenylcyclohexanol. The reaction of 8-phenylmenthyl glyoxylate with *trans*-2-butene produces a 93:7 mixture of diastereomers at C-3 in 85% yield; introduction of a TMS group into *trans*-2-butene increases the *anti*-selectivity up to ~100% (eq 2).[8f,g] Double bond isomerization in the

substrate under the reaction conditions, as well as contamination of halogen adducts in the products, point to a cationic mechanism for these ene reactions.[8e]

The asymmetric glyoxylate-ene reactions have been exploited in the total synthesis of (-)-specionin, which involves

asymmetric desymmetrization of a prochiral diene (eq 3), and (-)-xylomollin, which involves an efficient kinetic resolution of a racemic diene (eq 4).[10a-c]

Nucleophilic Additions.

A variety of nucleophiles have been added to 8-phenylmenthyl (and *trans*-2-phenylcyclohexyl) glyoxylates with high levels of asymmetric induction. These include organomagnesium[4] and organotin reagents,[11] as well as nitroalkane anions (eq 5).[12] Other applications of 8-phenylmenthyl glyoxylate include asymmetric hetero-Diels-Alder reactions to produce chiral dihydropyran derivatives[3] and *o*-hydroxylation of phenols producing the corresponding chiral 2-hydroxymandelic acid derivatives.[5] α-Imino esters derived from 8-phenylmenthyl glyoxylate undergo nucleophilic additions[13] as well as ene reactions[14] to produce nonproteinogenic α-amino acid derivatives.

8-Phenylmenthyl Pyruvate

(1*R*,2*S*,5*R*)

[88292-41-5] · $C_{19}H_{26}O_3$ · 8-Phenylmenthyl Pyruvate · (MW 302.45) (1*S*,2*R*,5*R*)

[100101-44-8]

(chiral ester for asymmetric induction)

Alternate Name: (1*R*,2*S*,5*R*)-5-methyl-2-(1-methyl-1-phenylethyl)cyclohexyl pyruvate.

Solubility: sol organic solvents.

Form Supplied in: not commercially available.

Preparative Method: isolated as an oil from the acid-catalyzed esterification of ***(-)-8-Phenylmenthol*** with pyruvic acid.[1]

Handling, Storage, and Precautions: susceptible to hydrate formation on exposure to moisture. No other special precautions other than those for combustible organic compounds are necessary.

Chiral α-Hydroxy Acids.

Grignard reagents add to the pyruvate ester of (-)-8-phenylmenthol from the *si*-face to afford the *S*-α-hydroxy esters (eq 1).[2] Chelation of the pyruvate with magnesium ensures the *s-cis* conformation and is required for high diastereoselectivity.[1] The high degree of diastereoselectivity is attributed to a favorable FMO interaction of the pyruvate with the phenyl moiety.[3] The corresponding *R*-α-hydroxy ester is available by reversing the order of bond formation starting with 8-phenylmenthyl glyoxylate.[4]

Reduction of 8-phenylmenthyl pyruvate with ***Potassium Triisopropoxyborohydride*** in THF gives 90% de of the (*R*)-lactate ester (eq 2), but other reducing reagents show little selectivity.[2] The stereochemical outcome of this reduction is explained as occurring in the *s-trans* conformation of the pyruvate.

Tin(IV) Chloride-catalyzed ene reaction of the pyruvate ester of (-)-8-phenylmenthol with 1-hexene gives a single diastereomer of the unsaturated (*S*)-α-hydroxy ester (de > 90%) (eq 3).[2] Similarly, tin(IV) chloride-catalyzed ene reactions of 8-phenylmenthyl glyoxylates afford unsaturated secondary alcohols with 93-98% de of the (*S*) configuration.[5]

Phenylmercury(II) Chloride[1]

PhHgCl

[100-56-1] · C_6H_5ClHg · Phenylmercury(II) Chloride · (MW 313.15)

(phenylating agent for allylic halides[3] and alkenes;[4-8] converts primary and secondary allylic alcohols into 3-phenyl alcohols and 3-phenyl aldehydes;[9] reacts with carbon monoxide to give ketone[10-13])

Physical Data: mp 250-252 °C. ^{1}H NMR:[16,17] δ (DMSO, ppm) H_o 7.46 ($^3J_{H_o\text{-}Hg}$ = +203 Hz); H_m 7.37 ($^4J_{H_m\text{-}Hg}$ = +49 Hz); H_p 7.46. ^{13}C NMR:[18,19] δ (DMF + $(CD_3)_2CO$ (20%) at 340 K (ppm)) C_α 150.5, ($^1J_{Hg\text{-}C}$ = 2530 Hz), C_β 136.4 ($^2J_{Hg\text{-}C}$ = 117 Hz); C_γ 128.0 ($^3J_{Hg\text{-}C}$ = 205 Hz); C_δ 127.9 ($^4J_{Hg\text{-}C}$ = 35 Hz). ^{199}Hg NMR:[18] (CH_2Cl_2) -1192, ($(CD_3)_2SO$) -1182 ppm. MS:[20] mass of ions observed: $C_6H_5HgCl^+$&bdot;, $C_6H_5Hg^+$, $HgCl^+$. IR: ν(Hg-Cl) 331-332 cm^{-1}.[15]

Solubility: sparingly sol H_2O; sol C_6H_6, ether, pyridine; slightly sol hot ethanol.[2]

Form Supplied in: white satiny leaflets; stable in air; widely available.

Preparative Methods: by mercuration of benzene[21] with ***Mercury(II) Chloride*** (eq 1) or red ***Mercury(II) Oxide***.

$$\mathrm{PhH} + \mathrm{HgCl_2} \rightleftharpoons [\mathrm{PhH}\quad \mathrm{HgCl_2} \rightleftharpoons \mathrm{H\overset{+}{P}hHgCl} + \mathrm{Cl^-}] \rightleftharpoons \mathrm{PhHgCl} + \mathrm{HCl} \qquad (1)$$

Copper or ***Copper(I) Chloride***[22] promotes facile displacement of nitrogen from double salts of ***Benzenediazonium Chloride*** and mercury(II) chloride in good yield (eq 2).

$$\mathrm{PhN_2Cl} + \mathrm{HgCl_2} \xrightarrow{\mathrm{HCl}} [\mathrm{PhN_2ClHgCl_2}] \xrightarrow{2\ \mathrm{Cu}} \mathrm{PhHgCl} + 2\ \mathrm{CuCl} + \mathrm{N_2} \qquad (2)$$

Phenylmercury(II) chloride can also be prepared by the Peters reaction[23] involving mercury(II) chloride and sulfinic acid (eq 3), by the decomposition of the phenyl-tin bond in $PhSn(alkyl)_3$ with mercury(II) chloride (eq 4),[24] by mixing equimolar mercury(II) chloride and ***Diphenylmercury*** (eq 5),[25] or by photolysis of diphenylmercury in CCl_4 (eq 6).[26]

$$PhSO_2H + HgCl_2 \longrightarrow PhHgCl + SO_2 + HCl \quad (3)$$

$$PhSnR_3 + HgCl_2 \longrightarrow PhHgCl + ClSnR_3 \quad (4)$$

$$Ph_2Hg + HgCl_2 \longrightarrow 2\ PhHgCl \quad (5)$$

$$Ph_2Hg + CCl_4 \xrightarrow{h\nu,\ 100\ °C} PhHgCl + PhCl + C_2Cl_6 \quad (6)$$

In PhHgCl the Ph-Hg bond is less polar than the Hg-Cl bond. The Ph-Hg bond is weak and undergoes homolytic cleavage.

Handling, Storage, and Precautions: highly toxic irritant; LD_{50} orally in rats 60 mg kg^{-1}. Use in a fume hood.

Coupling Reactions.

PhHgCl undergoes dimerization[27] to biphenyl in the presence of 10% ***Palladium(II) Chloride*** and an excess of copper in pyridine solution at 115 °C. The disadvantage of using copper, pyridine, and a high temperature is overcome by replacing the catalyst by 0.5% $[ClRh(CO_2)_2]_2$ (eq 7).[28]

$$2\ PhHgCl \xrightarrow[4\ LiCl,\ HMPA,\ 24\ h,\ 80\ °C]{0.5\%\ [ClRh(CO_2)_2]_2} PhPh + HgCl_2 + Hg^0 \quad (7)$$

PhHgCl undergoes disproportionation on halogenation[29] (eq 8) and when heated in sulfolane with sulfur gives diphenyl sulfide (eq 9).[30]

$$PhHgCl + Cl_2 \longrightarrow PhCl + HgCl_2 \quad (8)$$

$$2\ PhHgCl \xrightarrow[140\text{-}180\ °C]{S_8} PhSSPh \quad (9)$$

PhHgCl undergoes oxidation to phenol[31] by first treating it with ***Borane-Tetrahydrofuran*** and then oxidizing the resulting phenylborane with alkaline ***Hydrogen Peroxide*** (eq 10). It also undergoes transmetalation with borane halide to give aryl borates (eq 11).[32]

$$\mathrm{PhHgCl} \xrightarrow{\mathrm{BH_3}} \mathrm{PhBH_2} \xrightarrow[\mathrm{NaOH}]{\mathrm{H_2O_2}} \mathrm{PhOH} \qquad (10)$$

$$\mathrm{PhHgCl} + \mathrm{BCl_3} \longrightarrow \mathrm{PhBCl_2} + \mathrm{HgCl_2} \qquad (11)$$

Replacement of Counterion.

The chloro group is replaced easily on treatment with $LiCCl_2CH_3$ in THF or with acidic hydrocarbon under basic conditions (eqs 12-14).[33] Replacement of the chloro group by acetate, nitrate, sulfate or perchlorate may be effected using silver salts[34] or Group 14 metals[35] (e.g. Ge or Sn) (eqs 15 and 16).

$$\mathrm{PhHgCl} + \mathrm{LiCCl_2Me} \xrightarrow[\mathrm{THF}]{-100\ ^\circ\mathrm{C}} \mathrm{PhHgCCl_2Me} \qquad (12)$$

$$\mathrm{PhHgCl} + \mathrm{PhF} \xrightarrow{^-\mathrm{OH}} \mathrm{Ph_2Hg} + \mathrm{HCl} \qquad (13)$$

$$\mathrm{PhHgCl} + \mathrm{CHCl_3} \xrightarrow{t\text{-BuOK}} \mathrm{PhHgCCl_3} + \mathrm{HCl} \qquad (14)$$

$$\mathrm{PhHgCl} + \mathrm{AgOAc} \longrightarrow \mathrm{PhHgOAc} + \mathrm{AgCl} \qquad (15)$$

$$\mathrm{PhHgCl} + \mathrm{Bu_3MSPh} \longrightarrow \mathrm{PhHgSPh} + \mathrm{Bu_3MCl} \qquad (16)$$

$$\mathrm{M = Ge\ or\ Sn}$$

Nucleophilic Phenylation.

PhHgCl couples with allylic halides in the presence of a catalytic amount of $PdCl_2$/***Lithium Chloride*** to give allylbenzene (eq 17). The yields are better when the catalyst used is a mixture of 10-30% ($PdCl_2$/LiCl) and 10-30% ***Copper(II) Chloride*** (yield 31-87%).[3] The reaction proceeds at below rt with the transposition of the double bond of the allylic chloride.

$$\mathrm{PhHgCl} + \mathrm{CH_2{=}CHCHClMe} \xrightarrow[\mathrm{CuCl_2}]{\mathrm{LiCl} + \mathrm{PdCl_2}} \mathrm{PhCH_2CH{=}CHMe} \qquad (17)$$

Alkenes undergo a $PdCl_2$-catalyzed addition-elimination reaction with PhHgCl in a wide variety of polar organic solvents and in the presence of O_2 and H_2O to give vinylic hydrogen-substituted products (eqs 18 and 19).[4,5]

$$\mathrm{PhHgCl} \xrightarrow{\mathrm{PdCl_2}} \mathrm{PhPdCl} \xrightarrow{\mathrm{CH_2{=}CHY}} [\mathrm{PhCH_2CH(PdCl)Y}] \longrightarrow \mathrm{PhCH{=}CHY} + \mathrm{HPdCl} \quad (18)$$

$$\mathrm{HPdCl} \longrightarrow \mathrm{HCl} + \mathrm{Pd^0} \quad (19)$$

The direction of addition of PhPdCl is determined more by steric effects than electronic effects, the PdCl adding to the carbon with least hydrogens.[6,7] HPdCl elimination can occur in more than one direction, leading to mixtures of regioisomers as well as stereoisomers. The reaction can be catalytic in palladium if a reoxidant such as $CuCl_2$ is added. When the catalyst $PdCl_2$ is used along with 2M $CuCl_2$, 2-phenylalkyl chlorides are produced instead.[8] The reaction is valuable for the synthesis of 1-halocarbonyl compounds (eqs 20 and 21).

$$\mathrm{PhHgCl} + \mathrm{CH_2{=}CHR} \xrightarrow{\mathrm{CuCl_2,\ PdCl_2}} \mathrm{PhCH_2CHClR} \quad (20)$$

$$\mathrm{PhHgCl} + \mathrm{CH_2{=}CHCHO} \xrightarrow{\mathrm{CuCl_2,\ PdCl_2}} \mathrm{PhCH_2CHClCHO} \quad (21)$$

The reaction of primary and secondary allylic alcohols takes an entirely different course and produces 3-phenyl aldehydes and ketones, respectively (eq 22).[9] The reaction of enol esters provides 2-phenyl aldehydes and ketones.[36]

$$\mathrm{PhHgCl} + \mathrm{CH_2{=}CHCH_2OH} \xrightarrow[\mathrm{MeCN}]{\mathrm{LiCl,\ PdCl_2}} \mathrm{PhCH_2CH_2CHO} \quad (22)$$

PhHgCl with conjugated dienes in the presence of $LiCl/PdCl_2$ gives a π-allyl palladium compound (**1**)[37] by palladium hydride rearrangement. The π-allyl palladium compound on decomposition with a tertiary or secondary amine gives a phenylated diene or phenylated secondary amine,[38] respectively.

(1)

Direct carbonylation of PhHgCl by CO requires high temperature and pressure.[10-13] $PdCl_2$ promotes carbonylation to give PhCOCl in MeCN (eq 23), esters in alcohol, and anhydride in the presence of PdOAc.

$$\mathrm{PhHgCl} + \mathrm{CO} \xrightarrow[\mathrm{MeCN}]{\mathrm{PdCl_2}} \mathrm{PhCOCl} \qquad (23)$$

PhHgCl reacts with CO under pressure (50 psi) in the presence of $PdCl_2$ to give Ph_2CO.[39] Rhodium(I) and rhodium(III) complexes give better yields at atmospheric pressure. Reaction with ***Tetracarbonylnickel***[40] gives considerably higher yields of Ph_2CO.

PhHgCl undergoes acylation to give the corresponding ketones (eq 24).[41] Ketenes also react with PhHgCl to give ketones (eq 25).[42,43]

$$\mathrm{PhHgCl} + \mathrm{ClCOR} \longrightarrow \mathrm{PhCOR} + \mathrm{HgCl_2} \qquad (24)$$

$$\mathrm{PhHgCl} + \mathrm{CH_2{=}C{=}O} \longrightarrow \mathrm{CH_2{=}C(Ph)OHgCl} \xrightarrow{\mathrm{H^+}} \mathrm{MeCOPh} \qquad (25)$$

PhHgCl forms weak complexes with bidentate ligands. The latter undergo complete or partial disproportionation in boiling benzene solution (eq 26).[44,45]

$$\mathrm{PhHgCl} + 2\,\mathrm{L} \longrightarrow \mathrm{PhHgClL_2} \xrightarrow[\Delta]{\mathrm{C_6H_6}} \mathrm{Ph_2HgL} + \mathrm{LHgCl_2} \qquad (26)$$

$$\mathrm{PhHgClL_2} \longrightarrow \mathrm{PhHgCl} + \mathrm{L_2}$$

L_2 = phen, bipy

Related Reagents.

4-Phenyloxazole[1,2]

[20662-89-9] · C_9H_7NO · 4-Phenyloxazole · (MW 145.17)

(Diels-Alder reaction with alkynes leads to 3,4-disubstituted furans[3] and with alkenes leads to 2-phenylpyridines;[4] the *N*-methylide derivative leads to 3-pyrrole esters[5])

Physical Data: mp 6 °C; bp 220-222 °C, 60-61 °C/0.1 mmHg; λ_{max} 243 nm (ε 17 420).[6]

Preparative Methods: two different approaches have been described (eqs 1 and 2).[7,8] Four detailed experimentals have been published for the phenacyl bromide route, including a multikilo preparation.[7c]

General Discussion.

4-Phenyloxazole (**1**) undergoes Diels-Alder reactions with activated[3a,b] and unactivated[3c-e] alkynes. The

cycloadduct (eq 3) is unstable to the reaction temperatures and undergoes a retro-Diels-Alder reaction with expulsion of benzonitrile, forming a 3-mono- or 3,4-disubstituted furan in good to excellent yield (eqs 4 and 5).

Alkenes also undergo a Diels-Alder reaction with (**1**), and with reactive dienophiles the initial adduct (e.g. (**2**), largely *endo*) can be isolated (eq 6).[4] Adduct (**2**) dehydrates with traces of acid to yield pyridines (eq 7).

(**2**)

(7)

Trimethylsilylmethyl Trifluoromethanesulfonate readily *N*-alkylates (**1**) (eq 8) and the resulting salt, on treatment with fluoride, generates ylide (**4**). When (**4**) is generated in the presence of an alkynic ester, an unstable cycloadduct is formed that fragments to give pyrroles such as (**5**) (eq 9).[5]

Phenylpalladium Acetate[1]

[35742-60-0] · $C_8H_8O_2Pd$ · Phenylpalladium Acetate · (MW 228.58)

(used for the phenylation of alkenes)

Solubility: sol acetonitrile, methanol, acetic acid, THF, benzene, chloroform, monoglyme, and diglyme.

Preparative Methods: (1) from PhN(NO)COMe (1 mmol) and ***Bis(dibenzylideneacetone)palladium(0)*** (0.2 mmol) in acetonitrile at 40 °C for 2 h;[2] (2) from $SbPh_3$ or ***Triphenylphosphine*** (0.5 mmol) and ***Palladium(II) Acetate*** (0.5 mmol) under the same conditions;[2] (3) from PhHg(OAc) (10 mmol) and $Pd(OAc)_2$ (10 mmol) in 1:1 acetone-water (200 mL) at 30 °C for 2 h.[3]

Handling, Storage, and Precautions: very reactive and unstable, and is therefore formed in situ. Decomposition gives palladium metal which should be retained for recycling.

Phenylation of Alkenes.

The reagent is used for the stereospecific phenylation of alkenes. Only the *trans* product is formed. In contrast to traditional methods, the solvent exhibits only a small terminal vs. internal directing effect. The tendency of electron-withdrawing groups on the double bond to favor terminal substitution is reduced. In reaction with methylstyrene, PhPdCl and PhPdBr give some hydroxyphenylated products, whereas PhPd(OAc) gives only phenylated products.[3] The stereo- and regiochemistry have also been studied with propene and other alkenes.[4]

Recently, the reaction of alkenylsilanes has been studied (eqs 1 and 2).[2] The reaction was stereospecific with inversion of the relative disposition of alkene substituents. In contrast, $[PhPd]BF_4$ gave nonspecific aryldesilylation products.

Phenyl *N*-Phenylphosphoramidochloridate

[51766-21-3] · $C_{12}H_{11}ClNO_2P$ · Phenyl *N*-Phenylphosphoramidochloridate · (MW 267.66)

(phosphorylating agent in oligonucleotide synthesis via the phosphotriester approach; for the conversion of acids to their symmetrical anhydrides and for the coupling of acids and amines to give amides; two important derivatives are also considered)

Physical Data: mp 132-134 °C.

Solubility: sol org solvents, e.g. acetone, dichloromethane.

Form Supplied in: white solid; widely available commercially.

Analysis of Reagent Purity: FT-IR;[22] R_f (pure) = 0.63 (chloroform-acetone (5:1) on silica). *Drying:* is moisture sensitive; dry in vacuo (<=10^{-2} mmHg) over P_2O_5 at rt.

Preparative Methods: obtainable from phenyl phosphorodichloridate (**2**) and aniline (eq 1).[1]

Handling, Storage, and Precautions: irritant and moisture sensitive. May be harmful by inhalation (irritating to mucous membranes and upper respiratory tract), ingestion, or skin absorption. Incompatible with strong oxidizing agents and strong bases.

Phosphorylating Agent.

Phenyl *N*-phenylphosphoramidochloridate (**1**) reacts readily at 0 °C in dry pyridine with equimolar amounts of a

corresponding alcohol or phenol to give the *O*-alkyl-*O*-phenyl-*N*-phenylphosphoramides (eq 2).[2]

The compound (**3**) is a useful intermediate for the synthesis of mixed diesters of phosphoric acid (**4**). There are several methods of cleaving the N-P bond, of which the method of Ikehara is the most convenient.[3] Reaction of (**3**) with a 40 molar excess of 3-methylbutyl nitrite in acetic acid-pyridine (1:1 v/v) is successful in removing the aniline protecting group from the phosphoryl moiety in almost quantitative yields, giving the *O*-alkyl/aryl-*O*-phenyl hydrogen phosphate.
