Given the good yields and simplicity of the process, this procedure has been used to prepare intermediates for oligonucleotide synthesis, e.g. in the synthesis of 5´-*O*-monomethoxytritylthymidine 3´-phenylphosphate (**7**) (eq 3). Phosphorylation of 5´-*O*-monomethoxytritylthymidine (**5**) gave the protected nucleoside phosphate (**6**) in 98% yield which, after removal of the aniline protecting group and workup, gave the pyridinium salt in 85% yield.

This chemistry has additionally been utilized in the preparation of nucleoside phosphorothioates.[4] Reaction of (**6**) with NaH to remove the *P*-anilido group followed by CS_2 gave the corresponding 5´-monomethoxytritylthymidine 3´-*O*-phenylphosphorothioate (as a mixture of diastereomers, **8**) which was converted to the *S*-methyl ester (**9**) (eq 4). Owing to the chiral nature of pentavalent phosphorus, the compound (**9**) could exist as a mixture of diastereomers; however, the above reaction was the first example of an asymmetric synthesis of a phosphorothioate. There are now more examples of stereospecific synthesis of nucleoside derivatives utilizing this type of chemistry.[5]

There are numerous reviews on phosphorylation methods in biological molecules, some of which include aryl phosphoramidochloridates.[6]

Activation of Carboxylic Acids.

Formation of Symmetrical Anhydrides.

Symmetrical carboxylic anhydrides are useful reagents for peptide or amide synthesis.[7,8] Unfortunately, most methods require transformation of the acid first into the acid chloride or the use of condensation agents, e.g. ***1,3-Dicyclohexylcarbodiimide*** (DCC), which can lead to separation problems of the product anhydride from the hydrated derivatives of the condensation reagents. The use of ***Thionyl Chloride***/***Pyridine*** to form the acid chloride is often complicated by racemization with amino acid derivatives.

However, carboxylic acids are converted almost quantitatively to their corresponding symmetrical anhydride by treatment with 1 equiv of ***Triethylamine*** or ***1-Ethylpiperidine*** and 0.5 equiv of phenyl *N*-phenylphosphoramidochloridate (or ***Diphenyl Phosphorochloridate***) in acetone or dichloromethane, with the product anhydride (**10**) being obtained by filtration or from evaporation of the solvent after washing with water.[9] The resulting crude products are very nearly pure and the phenyl *N*-phenylphosphoramidochloridate can be regenerated as the aqueous solutions yield the phosphoramidic acid on acidification, which can be converted to (**1**) by reaction with ***Phosphorus(V) Chloride***. The proposed pathway for this is through the mixed anhydride (**11**), which then reacts with a second molecule of acid. The only limitation of this method is the reaction of some of the anhydrides with water, e.g. as observed with trichloroacetic acid.

The Synthesis of Polyanhydrides by Dehydrative Coupling.

The synthesis of polyanhydrides was first reported in 1909[10] and led on to a series of aliphatic polyanhydrides being prepared in the 1930s, as potential materials for the textile industry. One method for the formation of such polyanhydrides, particularly where sensitive monomers are involved, is to find suitably powerful dehydrating agents that function in mild reaction conditions. Organophosphorus compounds appear to be one such group of compounds. Phenyl *N*-phenylphosphoramidochloridate was found to be one of the most successful dehydrating agents.[11] The

proposed mechanism of polyanhydride formation is shown in eq 6.

Formation of Carboxamides.

There are many reagents for the conversion of carboxylic acids to carboxamides.[8,12-14] Activating agents such as DCC[15] can lead to purification problems, whilst involvement of the acid chloride can lead to racemization; there are also examples using phosphorus containing reagents, e.g. ***Diethyl Phosphorocyanidate***,[13,16] but again these reagents only react well in certain systems. Other methods involve long reaction times, high temperatures, or low yields.

However, the use of phenyl *N*-phenylphosphoramidochloridate as a condensing agent for carboxylic acids and amines yields carboxamides in a one-step method (eq 7).[17] The amide (**12**) is prepared from the carboxylic acid, 2 equiv of triethylamine, 1 equiv of amine, and 1 equiv of reagent (**1**) and isolated by filtration or evaporation of solvent and washing with water. Once again, a mixed anhydride intermediate (**13**) is presumed, which results from nucleophilic attack by the carboxylate anion on the phosphorus atom with elimination of a chloride ion; a further nucleophilic attack by the amine on the carbonyl group of (**13**) and breakdown of the complex yields the amide (**12**) and phenyl *N*-phenylphosphoramidate (**14**) which can be recycled to (**1**) by reaction with phosphorus pentachloride.

A distinct order of reactivity is observed in these reactions with (**1**): carboxylate anion &egt; aliphatic amines >> aromatic amines. This has led to slight variations in the practical procedures for preparing the amides but these are well documented in the literature.[17] The first route involves a one-step procedure; the second involves reaction of (**1**) with the carboxylate anion and subsequent treatment with the amine and is the preferred method for converting alkanamines to the amides since the first one-step method produces large amounts of phenyl phosphorodiamidates as well as the amide, by nucleophilic attack of (**1**) by the amine. The final method prevents the formation of phenyl phosphorodiamidates as the carboxylic acid first reacts with 0.5 equiv of (**1**) to form its anhydride, which is then converted to the amide in almost quantitative yield (this is largely utilizing the anhydride-formation chemistry described above) (eq 8).

Generally, phenyl *N*-phenylphosphoramidochloridate and other very similar related organophosphorus reagents e.g. phosphorus oxychloride, phenyl dichlorophosphate, diphenylchlorophosphate and *N,N´*-bis(2-oxo-3-oxazolinyl)phosphorodiamidic chloride have been utilised in recent years not only to form symmetrical carboxylic acid

anhydrides but also in esterification and thiol esterification reactions; although phenyl *N*-phenylphosphoramidochloridate is not so efficient for the latter two reactions compared to its analogs but is probably the best choice for forming the anhydride.[18]

Two Important Derivatives of Phenyl *N*-Phenylphosphoramidochloridate.

Phenyl *N*-Phenylphosphoramidoazidate.

This compound (**15**) is a white solid, which is easily prepared from (**1**) (eq 9).[19] It is obtained in excellent yields and is unusual for an organophosphorus compound in that it shows little sensitivity to moisture at room temperature for several months.

(9)

It is an excellent reagent for the preparation of *N*,*N*′-diarylureas. Reaction of a carboxylic acid, primary amine, and (**15**) in acetonitrile leads to the disubstituted urea (**16**) (eq 10). There is an additional competing reaction to the formation of the diarylurea: formation of phenyl *N*-phenylphosphorodiamidates, involving nucleophilic attack of the carboxylate ion and the alkylamine on the phosphorus atom of phenyl *N*-phenylphosphoramidoazidate. This work has been fully reviewed.[20]

(10)

Phenyl *N*-Methyl-*N*-phenylphosphoramidochloridate.

Like (**1**), phenyl *N*-methyl-*N*-phenylphosphoramidochloridate (**17**) reacts under analogous conditions to give anhydrides and carboxamides (see above). However, phenyl *N*-methyl-*N*-phenylphosphoramidochloridate undergoes one additional reaction which is not observed to any significant degree in (**1**). It is used for the conversion of imines to α-substituted β-lactams (eq 11).[21] The reaction is believed not to work for (**1**) as it requires an excess of triethylamine in the presence of a less nucleophilic imine, which is unfavorable to a mixed anhydride intermediate. The proposed pathway for this reaction is shown in eq 11, and has been performed on a wide variety of imines, proceeding in good

yields (44-78%).

Phenyl Phosphorodi(1-imidazolate)

[15706-68-0] · $C_{12}H_{11}N_4O_2P$ · Phenyl Phosphorodi(1-imidazolate) · (MW 274.24)

(used in phosphorylation,[1] as a peptide coupling reagent,[1] and in the dehydration of aldoximes to nitriles[2])

Alternate Name: phenyl diimidazol-1-ylphosphinate.

Physical Data: an exceedingly hygroscopic white solid, mp 96-97 °C[2] (mp 90-92 °C also reported[1]).

Solubility: sol acetonitrile, dioxane, THF; relatively insol benzene, ether.

Form Supplied in: not commercially available.

Preparative Methods: this reagent was first prepared in 81% yield by reaction of 4 equiv of imidazole with 1 equiv of phenyl phosphorodichloridate in benzene at 60 °C.[4] The use of 2 equiv of imidazole and 2 equiv of triethylamine as base has been reported to give a yield of 98% of (**1**) (eq 1).[2]

Purification: recrystallization from benzene, filtration under a water-free atmosphere, and drying under vacuum.

Handling, Storage, and Precautions: owing to its hygroscopic nature, exclusion of moisture in handling and use is essential; should be stored in a sealed tube at -20 °C.[3]

Phosphorylation.

The title reagent (**1**) reacts with amines, alcohols, and water to give amides and esters of phenyl phosphate (eqs 2-4).[1] The monoimidazole derivatives are formed rapidly with a much slower reaction to give the disubstitution products.[1]

This behavior can be used to synthesize mixed diphosphates by treatment with a small excess of alcohol followed by hydrolysis of the monoimidazole derivative. In this manner the monophenyl ester of 2´,3´-isopropylideneadenosine 5´-phosphate (**2**) has been synthesized in 53.5% yield (eq 5).[1]

B = adenine

(**2**)

Peptide Synthesis.

Reagent (**1**) has been used as a coupling reagent in the synthesis of benzyloxycarbonylalanylalanine (**3**).[1] Initial treatment of benzyloxycarbonylalanine with (**1**) in acetonitrile at 45 °C for 12 h followed by reaction with an excess of an aqueous solution (pH 8-9) of alanine gave the protected dipeptide in 85% yield (eq 6). No reference to the stereochemistry of the starting materials or product was made.

Acylimidazolides have been isolated from the reaction of (**1**) with carboxylic acids[1] and may be involved in the above reaction.

Dehydration of Aldoximes to Nitriles.

Reagent (**1**) has been shown to be excellent for the dehydration of aldoximes of both aromatic and aliphatic aldehydes.[2] This is accomplished by reacting the aldoxime with (**1**) in dioxane at 20 °C for 20 h (eq 7).[2]

Reagent (**1**) is superior in terms of yield to a variety of phosphorochloridates, including ***Phosphorus Oxychloride***. For example, in the case of 2-pyridyl aldoxime, with (**1**) a yield of 52% was obtained, whereas with phosphorus oxychloride the yield was 33% and with phenyl phosphorodichloridate the yield was 47%.[2] The reaction is thought to proceed via an intermediate formed by *O*-phosphorylation of the aldoxime.[2] The use of spin-labeled versions of (**1**) has been explored, in which the phenyl is replaced with the 2,2,6,6-tetramethylpiperidyl *N*-oxide group.[3,5]

(*S*)-(+)-1-Phenyl-2-propylamine[1,2]

[51-64-9] · $C_9H_{13}N$ · (*S*)-(+)-1-Phenyl-2-propylamine · (MW 135.23)

(chiral reagent for the resolution of racemic acids and aldehydes; chiral directing group for the enantioselective conjugate addition of ketones)

Alternate Names: (+)-amphetamine; *d*-amphetamine; dexamphetamine; dextroamphetamine.

Physical Data: bp 200-203 °C; *d* 0.913 g cm^{-3}; [α]19D +38° (benzene); mp (HCl salt) 154-155 °C.[3]

Solubility: readily sol all common organic solvents and acids; slightly sol water.

Form Supplied in: the free base (**1**) is a colorless liquid. A number of salts of (**1**) and its enantiomer (including the hydrochloride and sulfate) are commercially available.

Preparative Methods: enantiomerically pure (**1**) can be obtained by resolution of racemic (**1**) with (+)-tartaric acid.[4] Several highly stereospecific syntheses have been described.[5]

Analysis of Reagent Purity: enantiomeric and chemical purity of the reagent can be assayed by GC or HPLC analysis of its ***(S)-(-)-α-Methoxy-α-(trifluoromethyl)phenylacetic Acid*** amide.[3,6]

Handling, Storage, and Precautions: the reagent is a central stimulant and should be handled with gloves in a well-ventilated hood. Both the free base and its salts are stable at room temperature for extended periods of time.

Reagent for the Resolution of Carboxylic Acids.

Reagent (**1**) and its enantiomer have been used, although not as extensively as the more common ***(S)-α-Methylbenzylamine***, as resolving agents for carboxylic acids via fractional crystallization of the corresponding diastereomeric salts.[7] Examples of acids resolved this way include (**2**)-(**6**).[8-10] Additional examples, such as mandelic, hydratopic, and α-aryloxypropionic acids, can be found in the literature.[11,12]

Phenylselenium Trichloride

$PhSeCl_3$

[42572-42-9] · $C_6H_5Cl_3Se$ · Phenylselenium Trichloride · (MW 261.43)

(for introduction of unsaturation into organic molecules by hydrolytic selenoxide elimination; chlorinating agent)

Alternate Name: benzeneselenenyl trichloride.

Physical Data: mp 133-134 °C (dec).

Solubility: insol ether, hexanes, carbon disulfide; sol DMSO, acetonitrile; slightly sol chloroform, methylene chloride.

Form Supplied in: pale yellow solid; not widely available.

Preparative Methods: conveniently prepared on a large scale by chlorination of ***Diphenyl Diselenide*** with ***Sulfuryl Chloride*** (eq 1).[1]

Handling, Storage, and Precautions: unstable under normal laboratory conditions. However, if the freshly prepared material is rapidly dried and kept in a freezer (-20 °C), it can be stored and used for several months without any visible decomposition. Organoselenium compounds are reputed to be toxic. Use in a fume hood.

Hydrolytic Selenoxide Elimination.

Phenylselenium trichloride readily introduces a $PhSeCl_2$ group into the α-position of ketonic substrates with loss of HCl (eq 2).[1,2] The resulting selenium(IV) dichlorides are crystalline and easy to purify. Upon mild hydrolysis (aq $NaHCO_3$), the $SeCl_2$ group is hydrolyzed to the corresponding selenoxide, which undergoes the usual thermal elimination reaction to give an enone (eq 2). Thus, phenylselenium trichloride is complementary to ***Benzeneseleninic Acid*** and ***Benzeneseleninyl Chloride*** for the introduction of unsaturation into organic molecules via direct selenation

with selenium(IV) compounds.

For the preparation of certain enones, the hydrolytic selenoxide elimination reaction has definite advantages (easier operation and purification, higher overall yields) compared to methodology relying on introduction of divalent selenium[3] (see ***Benzeneselenenyl Bromide***, ***Benzeneselenenyl Chloride***, and ***2-Pyridineselenenyl Bromide***) followed by oxidation-elimination. To some extent, depending on the substrate, phenylselenium trichloride acts as a chlorinating agent towards ketones.[1] The benzeneselenenyl chloride formed in this process reacts readily with ketones to give an α-phenylselenenyl ketone (eq 3). For efficient utilization of the selenium reagent it is therefore desirable to use an excess (50-100%) of the ketone and to treat the reaction mixture with sulfuryl chloride to convert the α-phenylselenenyl ketone formed to the desired selenium(IV) dichloride (eq 3).

Unfortunately, the reaction of phenylselenium trichloride with unsymmetrical ketones usually shows a poor regioselectivity.[1] Thus ethyl methyl ketone afforded a 57:43 mixture of methyl- and methylene-substituted products (**1**) and (**2**). For this reason, the hydrolytic variation of the selenoxide elimination reaction is best suited for the conversion of symmetrical ketones or aryl alkyl ketones to their corresponding enones (eq 4).

(1)

(2)

(4)

The chlorination of divalent organoselenium compounds, followed by hydrolysis to effect selenoxide elimination, has been used as an alternative to other methods of oxidation-elimination. In this way, 2-chloro-1-alkenes[4] and allylic and vinylic acetates[5] were successfully prepared.

Phenylselenium trichloride undergoes a stereospecific *anti* addition to alkenic compounds to give (β-chloroalkyl)phenylselenium dichlorides.[6] The regiochemistry of addition is highly substrate dependent. Whereas styrene affords only the Markovnikov addition product, 1-butene produces an 81:19 mixture of anti-Markovnikov and Markovnikov products. The presence of an oxygen substituent (acyloxy or aryloxy group) in the allylic position of the alkene causes addition of $PhSeCl_3$ to occur anti-Markovnikov (eq 5). When the addition products are submitted to the usual conditions for hydrolytic selenoxide elimination, allylic and/or vinylic chlorides are formed. Chloroselenation products derived from alkenes containing a directing allylic substituent show a high preference for elimination away from the oxygen substituent to afford an (*E*/*Z*) mixture of vinylic chlorides (eq 5). Other alkenes, including cyclic ones, afford mixtures of allylic and vinylic chlorides in varying proportions. Symmetrical alkenes without allylic hydrogens are converted to vinylic chlorides with retention of the alkene geometry.

Chlorinating Agent.

Selenium(IV) dichlorides (**3**), prepared from $PhSeCl_3$ and methyl ketones, undergo a Pummerer-like reaction[7] when treated with ***Pyridine*** in methylene chloride (eq 6).[8] The resulting α-chloro-α-phenylselenenyl ketones (**4**) can be chlorinated on selenium and the Pummerer reaction repeated to afford α,α-dichloro-α-phenylselenenyl ketones. The chlorinating properties of phenylselenium trichloride have also been used in the preparation of mono-, di-, tri-, and tetrachlorinated porphyrins.[9]

(Phenylseleno)acetaldehyde

$PhSeCH_2CHO$

[71338-48-2] · C_8H_8OSe · (Phenylseleno)acetaldehyde · (MW 199.12)

(vinyl cation equivalent[1-6] and reagent for two-carbon homologation[7])

Physical Data: bp 110 °C/0.5 mmHg;[1] 57 °C/0.01 mmHg.[7]

Solubility: sol common organic solvents; insol water.[7]

Preparative Methods: reaction of ***Ethyl Vinyl Ether*** with ***Benzeneselenenyl Bromide***, followed by hydrolysis;[1,7] phenylselenenylation of ***Acetaldehyde***;[8] reaction of ***Vinyl Acetate*** with ***Benzeneselenenyl Chloride***.[9]

Handling, Storage, and Precautions: best kept in refrigerator and protected from light. Old material should be redistilled before use.[10]

Vinyl Cation Equivalent.

(Phenylseleno)acetaldehyde serves as a vinyl cation equivalent.[1-6] Aldol condensation with ketones gives keto hydroxy selenides that are convertible, by treatment with ***Methanesulfonyl Chloride*** and ***Triethylamine***, into α-vinyl ketones (eq 1).[2]

The aliphatic reagent (methylseleno)acetaldehyde appears to be less efficient as a vinyl cation equivalent.[2] The latent vinyl group can also be released by successive action of ***Trifluoroacetic Anhydride***/triethylamine and ***Trimethyl Phosphite*** (eq 2).[1] Similar transformations to that shown in eq 1 can be effected with dicarbonyl(cyclopentadienyl)(ethyl vinyl ether)iron tetrafluoroborate[11] or (*t*-butyldimethylsilyl)acetaldehyde.[12]

Two-Carbon Homologation.

Grignard reagents can be converted into (phenylseleno) ketones by reaction with (phenylseleno)acetaldehyde, followed by oxidation of the resulting alcohol (eq 3).[7,13] It should be noted, however, that oxidation of hydroxy selenides can be problematic.[14]

Use in Radical Chemistry.[15,16]

Hydroxy selenides, made using (phenylseleno)acetaldehyde, have been used in radical cyclizations (eqs 4 and 5). The example of eq 4 involves initial use of the reagent in an aldol condensation; in eq 5 the aldehyde is first used to form an iminium species which, on reduction with ***Sodium Cyanoborohydride***, affords the substrate for radical cyclization.

Formation of Allylic Selenides.

Wittig[17] and related[8a,18] alkenations give allylic selenides when applied to (phenylseleno)acetaldehyde (eqs 6 and 7).

Related Reagents.

Phenylsulfinylethylene.

(Phenylseleno)acetic Acid

$PhSeCH_2CO_2H$

[17893-46-8] · $C_8H_8O_2Se$ · (Phenylseleno)acetic Acid · (MW 215.12)

(dianion reacts with electrophiles, such as aldehydes[1] and epoxides;[2,3] especially useful for the preparation of 2(5*H*)-furanones)

Physical Data: white prisms, mp 35.5-36.5 °C (from 5% ether/hexane).[1] IR,[1,4] ^{1}H NMR,[1,4] and ^{13}C NMR[5] spectra have been reported. The pK_a (25 °C) has been calculated to be 3.75.[6]

Solubility: sol THF, ether, and alcohol; crystallizes from hexane.

Preparative Methods: the best methods involve the displacement of a halogen atom from an α-haloacetic acid molecule by a phenylselenide moiety. The selenide anion can be obtained by reduction of ***Diphenyl Diselenide*** (eqs 1 and 2)[1,4] or from ***Benzeneselenol*** in basic medium (eq 3).[4]

$$Ph_2Se_2 \xrightarrow[\text{2. } ClCH_2CO_2H]{\text{1. } NaBH_4,\ EtOH} PhSeCH_2CO_2H \qquad (1)$$

$$Ph_2Se_2 \xrightarrow[\text{2. } ICH_2CO_2^-\ \text{3. } HCl]{\text{1. } NaBH_4} PhSeCH_2CO_2H \qquad (2)$$

$$PhSeH + ClCH_2CO_2Na \xrightarrow{NaOH} PhSeCH_2CO_2H \qquad (3)$$

The best yield is described from benzeneselenol through a thallium(I) benzeneselenolate intermediate (eq 4).[4] This method has also been applied to the preparation of 2-phenylselenopropanoic acid.

$$PhSeH \xrightarrow{PhOTl} PhSeTl \xrightarrow{BrCH_2CO_2H} PhSeCH_2CO_2H \qquad (4)$$

Handling, Storage, and Precautions: may be kept in crystalline form in the refrigerator for several months.

Use in a fume hood.

Synthesis of Alkenes.

The dianion of α-phenylselenoacetic acid, usually prepared by deprotonation with ***Lithium Diisopropylamide***, may be employed as a Wittig reagent equivalent for the synthesis of alkenes from aldehydes (eq 5).[1] The reductive elimination of PhSeOH proceeds with high *anti* stereospecificity under very mild conditions compatible with virtually all functionalities.

Synthesis of α,β-Unsaturated Esters and Lactones.

The reaction of the dianion of α-phenylselenoacetic acid with epoxides leads to γ-hydroxy acids, which can be dehydrated either with ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride***[2] or under acidic conditions;[3] the oxidation of the α-phenylselenolactone and subsequent pyrolysis of the selenoxide yields 2(5*H*)-furanones, i.e. α,β-butenolides (eq 6).

Although a similar route has been described using ***(Phenylthio)acetic Acid***,[7] the selenium pathway allows the pyrolysis step to take place in milder conditions. An additional advantage is the possibility of carrying out the oxidation in the presence of other oxidizable heteroatoms such as nitrogen or sulfur (eq 7).[3]

(7)

When optically pure epoxides are used as the starting electrophiles, no loss of the sense of chirality has been observed.[2] Therefore the method has been successfully applied to the synthesis of various natural products, including mevinic acids,[8] ionomycin,[9,10] and cladospolide A.[11] In this last case an α,β-unsaturated ester was prepared instead of a lactone (eq 8).

(8)

Related Reagents.

2-Phenylselenopropanoic acid[4,12] has been used as a masked acrylate unit in a crucial step of the synthesis of frullanolide (eq 9).[13] In that example an allylic halide acted as the electrophile and the elimination of the selenoxide resulted in the formation of the exocyclic double bond. Interestingly, in an analogous situation, sulfoxides led exclusively to the formation of an endocyclic double bond (eq 10).[7] See also ***(Phenylthio)acetic Acid***.

9-Phenylseleno-9-borabicyclo[3.3.1]nonane[1]

[94348-51-3] · $C_{14}H_{19}BSe$ · 9-Phenylseleno-9-borabicyclo[3.3.1]nonane · (MW 277.10)

(reagent for nucleophilic phenylselenylation of enones)

Preparative Methods: stock solutions of this reagent can be prepared by heating equimolar amounts of ***Benzeneselenol*** and ***9-Borabicyclo[3.3.1]nonane*** in toluene at 60 °C for 5 h. Stock solutions are stable indefinitely when stored at -20 °C in the dark.[1]

Handling, Storage, and Precautions: use in a fume hood.

Crossed Aldol Condensations.

This reagent has been found to add to a variety of cyclic and acyclic α,β-unsaturated ketones to give the corresponding β-phenylselenoboron enolates. These species condense in situ with aldehydes to provide the corresponding unsaturated aldol adducts and aldol acetates after oxidative workup and acetylation (eq 1).[1] It was subsequently found that dimethyl(phenylseleno)aluminum[2] was, in general, a superior reagent for effecting this[3] and related[2] transformations. In this connection, the latter reagent would appear more effective than dimethyl(phenylthio)aluminum.[4]

Related Reagents.

Diisobutylaluminum Phenyl Selenide; ***Dimethylaluminum Methylselenolate***; ***Phenyl Trimethylsilyl Selenide***; ***Tris(phenylseleno)borane***.

Phenylselenocopper(I)

PhSeCu

[41962-55-4] · C_6H_5CuSe · Phenylselenocopper(I) · (MW 219.62)

(source of nucleophilic phenylselenide for preparation of lithium alkylphenylselenocuprates and organophosphinecopper(I) phenylselenolate complexes)

Physical Data: mp 150 °C (dec).

Solubility: partially sol cold THF.

Preparative Methods: phenylselenocopper can be prepared by two different procedures (eq 1). In the more straightforward procedure, ***Benzeneselenol*** is reacted with copper(I) oxide in ethanol at reflux to yield PhSeCu as a yellow or brown precipitate in 94% yield.[1] Similarly, uncharacterized $(PhSeCu)_n$ has been prepared from benzeneselenol and ***Copper(II) Acetate*** (2:1) in methanol.[2] A second type of preparation involves reaction of $Bu_2Sn(SePh)_2$ with copper(II) nitrate in methanol;[3] an observed byproduct in this reaction is PhSeSePh. The tin reagent is obtained from PhSeH by reaction with Bu_2SnCl_2. PhSeCu has also been prepared by direct electrochemical oxidation of ***Diphenyl Diselenide***.[6]

Handling, Storage, and Precautions: selenium reagents should always be used in a fume hood.

Cuprate Reagents.

Lithium alkyl(phenylseleno)cuprates, which are reacted with alkylseleno-substituted vinyl sulfones to effect stereoselective alkylation at the selenium-bearing carbon (eq 2), are prepared by the reaction of PhSeCu with the requisite alkyllithium in THF at 0 °C.[1b] The cuprates are generated in situ and then treated with the sulfone and warmed to rt.[1b,4] Interestingly, these cuprates have afforded superior yields to the traditional cyano and thiophenyl mixed cuprates; the latter reagents also added in a conjugate fashion to give saturated products. Alkyl groups which have been coupled in good yield are Me, *i*-Pr, *n*-Bu, *s*-Bu, *t*-Bu, and 3-pentyl (67-97%).

(2)

Organophosphine Complexes.

A cyclohexylphosphinecopper(I) phenylselenolate complex has been synthesized from $(PhSeCu)_n$ to study its 1:1 adduct formation and subsequent stability with SO_2 (eq 3).[5] Addition of solid tricyclohexylphosphine to an acetonitrile suspension of $(PhSeCu)_n$ followed by stirring for 30 min yields the precipitated complex.

(3)

Related Reagents.

Phenylthiocopper(I).

Phenyl Selenocyanate[1]

PhSeCN

[2179-79-5] · C_7H_5NSe · Phenyl Selenocyanate · (MW 182.09)

(a specific source of nucleophilic[2-5] and electrophilic selenium species[6-8])

Physical Data: light yellow oil; bp 125 °C/16 mmHg, 118 °C/11 mmHg,[9] 104 °C/4 mmHg.[10]

Solubility: sol organic solvents such as THF, dichloromethane, and acetonitrile.

Analysis of Reagent Purity: spectral data (IR, NMR)[10] and physical constants (bp, TLC).

Preparative Methods: diazotization of aniline followed by treatment with ***Potassium Selenocyanate*** in buffer solution containing sodium acetate;[9,11] condensation reaction of ***Benzeneselenenyl Chloride*** with ***Cyanotrimethylsilane*** in dry THF or in dry dichloromethane, giving phenyl selenocyanate in almost quantitative yield.[10]

Purification: the product obtained by above methods contains a slight amount of ***Diphenyl Diselenide*** as impurity, which is usually not troublesome in its application to organic reactions. Pure phenyl selenocyanate can be obtained by fractional distillation or silica gel column chromatography.

Handling, Storage, and Precautions: highly toxic and unpleasant smell. Use in a fume hood.

Nucleophilic Reactions.

Phenyl selenocyanate quantitatively generates a nucleophilic selenium species ($PhSe^-$ equivalent) upon treatment with ***Sodium Borohydride***,[11] which reacts with primary alkyl bromides[11] and mesylates[12] to form alkyl phenyl selenides (see also ***Diphenyl Diselenide*** and ***o-Nitrophenyl Selenocyanate***). A more useful aspect of phenyl selenocyanate is its reactions with electrophilic substrates in the presence of ***Tri-n-butylphosphine***. For example, primary[2] and secondary[2,3] alcohols can be directly converted into the corresponding alkyl phenyl selenides by the reaction with phenyl selenocyanate (eq 1). Yields are somewhat lower for secondary alcohols. Aldehydes react with phenyl selenocyanate to produce cyanoselenenylation adducts in good yields (eq 2), while ketones give rearranged products in only modest yields.[4] Carboxylic acids react with phenyl selenocyanate to form selenol esters in high yields (eq 3).[5]

Electrophilic Reactions.

Highly reactive alkenes, such as ketene acetals[13] and enamines,[14] react with phenyl selenocyanate in ethanol to form cyanoselenenylation products regioselectively, which can be converted into β,γ-unsaturated nitriles and α,β-unsaturated aminonitriles,[1] respectively (eqs 4 and 5). Simple alkenes react with phenyl selenocyanate in the presence of Lewis acids. For example, in the presence of ***Copper(II) Chloride*** or ***Copper(II) Bromide*** or in the presence of ***Nickel(II) Chloride*** or ***Nickel(II) Bromide***, phenyl selenocyanate reacts with alkenes in methanol or phenol to produce electrophilic selenium adducts in high yields (eq 6).[6] With dienes in acetonitrile, 1:2 adducts having a cyclic ether skeleton are produced (eq 7).[7] In the presence of ***Tin(IV) Chloride***, phenyl selenocyanate reacts with simple alkenes to form cyanoselenenylation products (eq 8).[8]

Phenyl Selenocyanate-Copper(II) Chloride

PhSeCN-$CuCl_2$

(PhSeCN)

[2179-79-5] · C_7H_5NSe · Phenyl Selenocyanate-Copper(II) Chloride · (MW 182.09) ($CuCl_2$)

[7447-39-4] · Cl_2Cu · Phenyl Selenocyanate-Copper(II) Chloride · (MW 134.45)

(oxyselenates alkenes, dienes, and α,β-unsaturated aldehydes with regio- and stereoselectivity; forms cyclic ethers)

Physical Data: see ***Phenyl Selenocyanate*** and ***Copper(II) Chloride***.

Form Supplied in: both components are commercially available.

Preparative Methods: the reagent is prepared as needed. PhSeCN can be made[5] from phenyldiazonium salts and commercially available KSeCN or, particularly for small-scale experiments, from the available reagents PhSeCl and Me_3SiCN.[6,7]

Handling, Storage, and Precautions: selenium reagents are highly toxic and corrosive. All reactions should be conducted in a well-ventilated fume hood.

General Discussion.

Phenyl selenocyanate in alcohols, wet THF, or acetic acid/chloroform reacts, in the presence of copper(II) or -(I) chloride, on the C=C double bond of alkenes[1] and dienes[2,3] and produces β-alkoxy-, β-hydroxy-, and β-acetoxyalkyl phenyl selenides and cyclic ethers in good yields. The reaction is best achieved (1-10 h) at 65 °C with stoichiometric amounts of the copper salts. Although it still proceeds at lower temperature (25 °C) and with smaller amounts of catalyst (down to 0.025 mol equiv), it becomes particularly slow. It does not occur in the absence of copper salts or when a pyridine-$CuCl_2$ complex is used.[1] It has nevertheless been reported[4] that this reaction can be catalyzed by copper-loaded polymers, but the yields are lower.

This reaction has been successfully carried out on terminal, alicyclic, and cyclic α,β-disubstituted alkenes as well as on vinyl acetate, α,β-unsaturated aldehydes (eq 1), and their dimethyl acetals.[1] The two latter compounds provide, on reaction in methanol, the same β-methoxy-β´-dimethoxyalkyl phenyl selenide. Oxyselenation does not occur with compounds possessing electron-withdrawing groups attached to the C=C double bonds, such as methyl vinyl ketone, methyl acrylate, and acrylonitrile.[1] Successful reaction of α,β-unsaturated aldehydes is probably due to the

intermediate formation of the corresponding α,β-unsaturated acetal.[1]

The oxyselenation is regioselective, the phenylseleno group being introduced at the least substituted carbon of styrene, vinyl acetate, and 1-hexene (eq 2).[1] In the last case the highest ratio of primary alkyl selenide is achieved, presumably under thermodynamic control, when the reaction is performed at higher temperature and for a longer time. The selectivity is reversed with acrolein, allowing the synthesis of α-phenylseleno-β-methoxy aldehydes (eq 1).[1]

R	Conditions	Yield (ratio)
Hexyl	$CuCl_2$, 25 °C, 15 h	88% (83:13)
Ph	$CuCl_2$, 25 °C, 7 h	87% (100:0)
AcO	CuCl, 25 °C, 12 h	74% (100:0)

The reaction is stereoselective and occurs via *anti* addition (eq 3) except with crotonaldehyde. The intermediate formation of a seleniiranium ion might account for the reported regio- and stereoselectivity. The lower reactivity of the unsaturated aldehydes and the possible (*Z*/*E*) isomerization prior to oxyselenation might be responsible for the lower stereocontrol.

(3)

$n = 0\text{-}2$	MeOH, 3-5 h	66-100%	R = Me
$n = 1$	*i*-PrOH, 0.5 h	88%	R = *i*-Pr
$n = 1$	AcOH-$CHCl_3$, 5 h	80%	R = Ac
$n = 1$	H_2O-THF (5:2), 19 h	45%	R = H

Reaction of *cis,cis*-1,5-cyclooctadiene with phenyl selenocyanate-copper(II) chloride in alcohols, aq THF, or acetonitrile produces[2,3] a mixture of [3.3.1] and [4.2.1] bicyclic ethers in good yields (eq 4).

(4)

Solvent	Ratio [3.3.1]:[4.2.1]
MeOH	95:5
i-PrOH	82:18
t-BuOH	38:62
THF-H_2O	0:100

The isomer ratio depends upon the solvent used; a suitable choice of solvent results in a more selective formation of each isomer (eq 4). Synthesis of the [3.3.1] ethers is best achieved in methanol; aq THF provides the other isomer. The

intermediate formation of a β-hydroxyalkyl selenide, rather than the corresponding ether, proved to be responsible for the result observed in aq THF. The PhSeCN-$CuCl_2$ monitored oxyselenation reaction has been successfully applied to other dienes such as 1,5-hexadiene, diallyl ether, and diallyl sulfide (eq 5).

Related Reagents.

Copper(II) Chloride; ***o-Nitrophenyl Selenocyanate***; ***Phenyl Selenocyanate***.

Phenylselenomethyllithium[1a-i]

$PhSeCH_2Li$

[22859-62-7] · C_7H_7LiSe · Phenylselenomethyllithium · (MW 177.04)

(nucleophilic introduction of phenylselenomethyl group; used for one-carbon homologation of alkyl halides, conversion of aldehydes to terminal epoxides, oxetanes, and tetrahydrofurans; synthesis of terminal alkenes from alkyl halides or carbonyl compounds)

Solubility: sol THF-pentane or ether-pentane.

Preparative Methods: [1a,1d-1f,5] has been prepared by (i) metalation of methyl phenyl selenide with lithium amides or butyllithium-TMEDA,[3,6] (ii) halogen-metal exchange from bromomethyl phenyl selenide and butyllithium,[7] or (iii) Se-Li exchange from bis(phenylseleno)methane and ***n-Butyllithium*** (THF, -78 °C, method of choice).[1b,2,3] The same reaction can be achieved in ether but requires the use of the more reactive ***s-Butyllithium***.[8]

Handling, Storage, and Precautions: stable at 0 °C in THF for more than 10 h,[2,3] but products resulting from its decomposition have been trapped in some cases at lower temperature even after a few minutes. Phenylselenomethyllithium seems to be in equilibrium with lithium benzeneselenolate and methylene.[4] Use in a fume hood.

General Discussion.

Phenylselenomethyllithium reacts with alkyl halides to produce alkyl phenyl selenides,[2,3] epoxides and oxetanes[4] to produce 3-hydroxy- and 4-hydroxyalkyl phenyl selenides, respectively, and aldehydes and ketones to produce 2-hydroxyalkyl phenyl selenides.[2,3,6-13]

Alkylation has been successfully achieved with ***Iodomethane***, primary alkyl halides, and terminal epoxides. In the latter two cases the presence of HMPA minimizes the products resulting from substitution of the electrophiles by lithium phenylselenolate (5% instead of 40%).[4]

Phenylselenomethyllithium adds to hindered or enolizable carbonyl compounds such as 2,2,6,6-tetramethylcyclohexanone or deoxybenzoin.[13] Phenylselenomethyllithium mainly produces the alcohol resulting from equatorial attack on reaction with 4-*t*-butylcyclohexanone (THF, -78 °C, axial:equatorial alcohol = 85:15).[11] It adds on the carbonyl group of enones if the reaction is carried out in THF and 1,4 in THF/HMPA.[1,14-17] The latter conditions have been successfully used to produce a valuable intermediate in the synthesis of (+)-pederin from an α,β-unsaturated

lactone.[15,16]

Phenylselenomethyllithium is a valuable reagent for homologation.[1b] Phenylselenoalkanes, prepared by alkylation of phenylselenomethyllithium, can be transformed to alkanes by reduction with ***Raney Nickel***,[18] ***Lithium-Ethylamine***[18] or, more conveniently, by ***Tri-n-butylstannane*** or ***Triphenylstannane*** (eq 1).[19]

(1)

The phenylseleno group can be replaced by iodide.[20] The reaction proceeds through a selenonium salt, works with functionalized alkyl phenyl selenides such as 3-(hydroxy)nonyl phenyl selenide (eq 2),[4] and allows the one-carbon homologation of primary alkyl halides.[20] A wider range of nucleophiles (I^-, Br^-, Cl^-, OH^-, N_3^-, MeOH,[21,22] PhS^-, CN^-) can be used[23] if the selenide is oxidized to a selenone (eq 3).[24] In the transformations reported (eqs 2 and 3), phenylselenomethyllithium has played alternatively the role of $LiCH_2X$ (X = halogen), $LiCH_2N_3$, $LiCH_2OH$, $LiCH_2OMe$, $LiCH_2SPh$, and $LiCH_2CN$, respectively.

(2)

(3)

X = I (2 equiv NaI, 20 °C, 1 h, 97%)
X = Br (1.5 equiv $MgBr_2$ or EtMgBr, 20 °C, 1 h, 77%)
X = Cl (1.5 equiv BuMgCl, 20 °C, 1 h, 51%)
X = N_3 (5 equiv NaN_3, 20 °C, 0.7 h, 93%)
X = OH (H_2O, 80 °C, 1.25 h, 95% or KOH, 80 °C, 22 h, 76%)
X = OMe (1.1 equiv MeONa, 20 °C, 3 h, 73%)
X = SPh (1.1 equiv PhSNa, 20 °C, 3 h, 94%)
X = CN (2 equiv KCN, 75 °C, 2 h, 66%)

Primary alkyl selenides are converted to 1-alkenes on oxidation to the selenoxide with ***Hydrogen Peroxide***,[25] ***Sodium Periodate***,[25] or ***t-Butyl Hydroperoxide***,[26] or by treatment with methyl fluorosulfonate and base-catalyzed elimination of the selenonium intermediate (eq 4).[27]

(4)

2-Hydroxyalkyl phenyl selenides, easily prepared from phenylselenomethyllithium and carbonyl compounds, are valuable precursors for the following.

Terminal Epoxides.[10,13,28,29]

Activation of the selenium moiety can be achieved by formation of selenonium salts (eq 5), oxidation to selenone (***m-Chloroperbenzoic Acid***, CH_2Cl_2, 20 °C)[10] or treatment with thallium(I) ethoxide in chloroform, which produces a dichlorocarbene intermediate (eq 6)[30]

(5)

(6)

1. *m*-CPBA, CH_2Cl_2, 20 °C, 4 h; 2. aq K_2CO_3, 20 °C, 0.5 h 44%
5.5 equiv TlOEt, $CHCl_3$, 20 °C, 24 h 80%

Terminal Alkenes.[12]

This reaction, which probably involves the intermediate formation of a seleniranium ion, is best achieved with ***Methanesulfonyl Chloride*** in the presence of ***Triethylamine***[6,12] or with ***p-Toluenesulfonic Acid*** (eq 7).[31]

(7)

Ketones.

Ketones, resulting from the rearrangement of the intermediate 2-hydroxyalkyl selenones, are obtained on reaction of 2-hydroxyalkyl selenides derived from aromatic ketones with *m*-CPBA (eq 8).[10,28] Extension of this reaction to 1-phenyl-2-(phenylseleno)ethanol affords methyl phenylacetate in very good yield (86%) resulting from oxidation of the phenylacetaldehyde intermediate by the excess of *m*-CPBA used (3-5 equiv, MeOH, reflux, 3 h, eq 9).[32]

The processes reported above allow the synthesis of terminal epoxides and alkenes from a carbonyl compound in a way similar to that involving methylenesulfuranes and methylenetriphenylphosphorane. Phenylselenomethyllithium has the advantage that terminal epoxides and alkenes derived from hindered or enolizable carbonyl compounds, which are unavailable from ylides, can be prepared.[1g]

3-Hydroxyalkyl and 4-hydroxyalkyl phenyl selenides are available from phenylselenomethyllithium and terminal epoxides or oxetanes. They have been transformed to oxetanes (eq 2) and to tetrahydrofurans.[4] The whole process allows the stepwise homologation of carbonyl compounds to epoxides, oxetanes, and tetrahydrofurans.[4]

Phenylselenomethyllithium is the first member of the series of α-selenoalkyllithiums. These can be prepared on reaction of butyllithiums with selenoacetals, which are readily available from carbonyl compounds and phenyl- or methylselenols. The reactions reported above can be advantageously extended to the higher homologs of selenides, but some further examples must be given (eqs 10-12).[1a,1c,1e-i,33] The synthesis of the most strained or hindered alkenes is best achieved from methylseleno derivatives using ***Phosphorus(III) Iodide*** as reagent.[1g,34] Methylseleno derivatives are also more appropriate for the synthesis of epoxides.[1g,29,34] In such cases best results are obtained by using the two-step sequence involving the intermediate formation of β-hydroxyalkylselenonium salts. This allows the synthesis of the whole range of epoxides including those derived from α,β-unsaturated or hindered carbonyl compounds as well as those derived from selenoalkyllithiums bearing two alkyl groups on their carbanionic center. The latter compounds cannot be

produced using the dichlorocarbene method since pinacol-type rearrangement leads instead to a ketone.[35-38]

Phenyl(seleno)phosphonic Dichloride[1]

[39078-30-3] · $C_6H_5Cl_2PSe$ · Phenyl(seleno)phosphonic Dichloride · (MW 257.94)

(reagent for effecting oxygen-selenium exchange reactions of polarized carbonyl groups;[1] exchanges O for Se in some O-heterocycles[1])

Physical Data: bp 60 °C/0.01 mmHg; suffers progressive decomposition into $PhPCl_2$ and Se on being heated.

Solubility: sol most inert solvents; most useful are xylene, toluene, benzene, dichloromethane.

Preparative Methods: $PhPCl_2$ is treated at ambient temperature with ca. 6 mol % ***Aluminum Chloride*** under dry N_2 followed by ***Selenium*** powder. The resulting $PhP(Se)Cl_2$ is distilled in a good vacuum.[2] More convenient is to heat $PhPCl_2$ with a 20 mol % excess of powdered black Se at 170-175 °C under dry N_2 for 40 min.[1] The $PhP(Se)Cl_2$, which is formed quantitatively, is cooled and dissolved in dry xylene. The mixture is filtered through a glass frit to remove the excess Se and sufficient additional xylene is added to give a 2 M solution. Other inert solvents may be used in place of xylene.

Handling, Storage, and Precautions: $PhP(Se)Cl_2$, alone or in solution, is sensitive to moisture. Solutions of $PhP(Se)Cl_2$ should be stored in dark bottles which are tightly closed by crown or screw caps fitted with a septum. Required volumes are transferred by means of graduated syringes. For best results, $PhP(Se)Cl_2$ and solutions thereof should be used within 2-3 days after preparation. Reactions involving prolonged times should be carried out in a dry inert atmosphere.

Oxygen-Selenium Exchange Reactions.

Various types of carbonyl compounds in which the carbonyl group is highly polarized undergo O-Se exchange reactions with $PhP(Se)Cl_2$. The carbonyl substrate is allowed to react with an aliquot of a 2 M solution of $PhP(Se)Cl_2$ in xylene, either with or without addition of more xylene or a different inert solvent. Tertiary amides of aliphatic[1], aromatic[1], and electron-rich heterocyclic carboxylic acids[3] are converted into the corresponding selenocarboxamides (eqs 1-4), and *N*-substituted lactams yield the corresponding *N*-substituted selenolactams (eq 5).[1]

(1)

(2)

(3)

(4)

(5)

A recommended workup procedure for small-scale (<25 mmol) reactions is to add chromatographic alumina (activity I-II) to the reaction solution, transfer the resulting slurry to a column of alumina (activity II-III), and elute. Unreacted $PhP(Se)Cl_2$ and its reaction product $PhP(O)Cl_2$ are retained on the basic column.

Indolizine-1- and 3-carbaldehydes are converted into the corresponding indolizineselenocarbaldehydes at room temperature (eq 6).[1] In one case a 1,2-dithiol-3-one was converted into the corresponding 1,2-dithiol-3-selone (eq 7).[1]

(6)

(7)

Conversion of Oxygen Heterocycles into Selenium Heterocycles.

1-Oxa-6,6aλ^4-dithiapentalenes and 6-oxa-6aλ^4-thia-1,2-diazapentalenes, which are masked carbonyl compounds, react at room temperature with $PhP(Se)Cl_2$ in the presence of ***Triethylamine*** to give the corresponding Se-containing heterocycles (eqs 8 and 9).[1] The Et_3N suppresses acid-catalyzed side-reactions

of the substrates.

N-Phenylselenophthalimide[1]

[71098-88-9] · $C_{14}H_9NO_2Se$ · *N*-Phenylselenophthalimide · (MW 302.20)

(reagent for electrophilic phenylselenenylation of alkenes, dienes, enols, and other nucleophiles)

Alternate Name: NPSP.

Physical Data: mp 171-175 °C (dec).

Form Supplied in: colorless solid.

Preparative Methods: prepared in 87% yield by the reaction of ***Benzeneselenenyl Chloride*** with potassium ***Phthalimide*** in hexane.[1]

Handling, Storage, and Precautions: indefinitely stable when stored at -20 °C in the dark. Use in a fume hood.

Selenenylation.

N-Phenylselenophthalimide is a very mild reagent for electrophilic selenenylation and reacts with a wide variety of organic substrates to provide products bearing the PhSe group. The generalized stepwise conversion of an alkene to a functionalized selenide with this reagent is shown in eq 1.

Various alkenes have been found to react in the intermolecular sense with nucleophiles in condensation reactions mediated by NPSP. Representative examples are given in eqs 2 and 3.[1-3]

(2)

(3)

Nu = HO; X = OH	90%
Nu = OMe; X = OMe	97%
Nu = F; X = F	80%

Dialkenes react with NPSP in the presence of water in a closely related manner to provide cyclic ethers with the net incorporation of two PhSe moieties (eq 4).[3]

(4)

NPSP is a very efficient reagent for effecting the cyclization of unsaturated substrates containing internal nucleophiles and has been used for macrocyclizations (eqs 5-10)[3] as well as cyclizations of homogeranic acid derivatives.[4] In addition, NPSP has been used to effect annulations leading to carbohydrates.[5]

(8)

(9)

(10)

In several instances the use of NPSP has been found advantageous when compared to the more classical reagents ***Benzeneselenenyl Bromide*** or ***Benzeneselenenyl Chloride***. In this connection the latter reagents have been reported to be useful for the selenenylative cyclization of unsaturated alcohols,[6] carboxylic acids,[7] thio compounds,[8] and urethanes.[9]

Selenolactonization of alkynoic acids also proceeds efficiently in the presence of NPSP (eq 11).[10]

(11)

In addition, suitably disposed β-keto ester moieties can be induced to stereoselectively cyclize onto alkenes in the presence of NPSP (eq 12).[11]

(12)

Heterocyclizations leading to oxazolidine derivatives have been reported to proceed efficiently via the selenenylation of alkenyl amides by NPSP (eq 13).[12] Danishefsky and collaborators have reported an interesting phenylselenenylation-radical functionalization sequence using NPSP[13] and have also used this reagent in the synthesis of mitomycin congeners.[14]

(13)

Ley and co-workers have published extensively on the use of NPSP in the presence of Lewis acids to effect carbocyclizations (e.g. eq 14).[15] In addition, these authors have utilized NPSP for the synthesis of spiroacetals.[16] For the majority of the preceding transformations, NPSP has been found the superior reagent both in terms of chemical efficiency as well as the mild nature of the reaction conditions that are typically employed.[17]

(14)

Alcohols and carboxylic acids have been found to condense with NPSP in the presence of ***Tri-n-butylphosphine*** to provide the corresponding selenoethers (eq 15) and acyl phenyl selenides (eq 16), respectively.[18-20]

(15)

(16)

Sequential hydrozirconation-phenylselenenylation of conjugated enynes has provided a convenient route to stereodefined dienyl selenides (eq 17).[21]

Phenylsilane-Cesium Fluoride

$PhSiH_3$-CsF

($PhSiH_3$)

[694-53-1] · C_6H_8Si · Phenylsilane-Cesium Fluoride · (MW 108.23) (CsF)

[13400-13-0] · CsF · Phenylsilane-Cesium Fluoride · (MW 151.91)

(mild nucleophilic non-Lewis acidic hydride donor[1] used under aprotic conditions)

Physical Data: phenylsilane: bp 120 °C; *d* 0.877 g cm^{-3}. Cesium fluoride: mp 683 °C.

Solubility: phenylsilane: sol THF, MeCN. Cesium fluoride: sol H_2O; slightly sol THF, MeCN.

Form Supplied in: phenylsilane is a clear liquid; cesium fluoride is a white solid; both widely available.
Drying: anhydrous cesium fluoride is prepared by flame drying under vacuum, taking care not to fuse the salt.

Handling, Storage, and Precautions: no particular requirements.

4-Oxazoline Formation.

The $PhSiH_3$-***Cesium Fluoride*** reagent[1,2] is a nonnucleophilic hydride donor without Lewis acid character with characteristics similar to the ***Diphenylsilane-Cesium Fluoride***,[2] α-$NaphSiH_3$-CsF,[2] and $(RO)_3SiH$-CsF[2] reagents on which it is based. In aprotic solvents, it has been used to reduce 4-oxazolium salts to 4-oxazolines.[1] The 4-oxazolines open at -40 °C to azomethine ylides, which are trapped with dipolarophiles to give 3-pyrrolines (**2**) (eq 1). For isolation purposes the 3-pyrrolines are oxidized to pyrroles (**3**). The mildness of the reagent allows for the selective reduction of the oxazolium salt without further reduction of the 4-oxazoline, azomethine ylide, or dipolarophile which are present at different stages of the reaction. Of the reducing agents tried for (**1**), $PhSiH_3$ gave the highest yield (95%), although Ph_2SiH_2 (93%) worked nearly as well.[1b] Other reducing agents gave much poorer yields. Propiolates, acrylates, ***N-Phenylmaleimide***, and vinyl sulfone dipolarophiles have been used in this [3 + 2] cycloaddition without dipolarophile reduction.

Dipolarophiles such as ***Ethyl Acrylate*** exhibit regiochemical preference for *meta* acyl or carboxyl groups (eq 2).[1] With one exception (entry 6), all cases are consistent with FMO approximation in which the largest dipole HOMO coefficient is at the acceptor-substituted carbon (Table 1).[1b]

Table 1 Regiochemistry of Acrylate Trapping (eq 2)

Entry	Group		Isolated yield (%)	
	R^1	R^2	(**4**)	(**5**)
1	Ph	Ph	55	9
2	Ph	OEt	63	10
3	Ph	Me	87	0
4	Me	Ph	40	20
5	Me	OEt	61	0
6	H	Ph	0	67
7	H	OEt	47	0
8	Ph	H	57	0

A comparison of methods to generate azomethine ylides via 4-oxazoline ring opening vs. aziridine thermolysis has shown that the oxazoline method can produce the same azomethine dipole under kinetic control as the aziridine method under thermodynamic control.[3] Since the 4-oxazoline method allows improved regiochemical selectivity in many cases, the synthesis of 4-oxazolines from $PhSiH_3$-CsF-induced reduction of oxazolium salts possesses greater potential for azomethine ylide applications in stereocontrolled synthesis.

Intramolecular trapping of an azomethine ylide generated from an oxazolium salt has been accomplished (eq 3).[4] This approach allows a new entry into the mitosene skeleton.

Related Reagents.

Diphenylsilane-Cesium Fluoride.

Phenylsodium[1]

PhNa

[1623-99-0] · C_6H_5Na · Phenylsodium · (MW 100.10)

(reagent for metalation;[1a,b] nucleophilic addition and substitution;[1b,c] initiator of anionic polymerization[2])

Physical Data: amorphous, infusible solid.

Solubility: insol hydrocarbons and reacts with ethers; can be solubilized as complexes, e.g. with ***N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine***.[3] Also forms more soluble complexes, but with modified reactivity, with phenyllithium, diphenylmagnesium, and magnesium 2-ethoxyethoxide.[4]

Preparative Methods: usually by reaction of chlorobenzene with ***Sodium*** dispersion; also by metalation of benzene with alkylsodium compounds (e.g. as a one-pot process by reaction of 1-chloropentane with sodium dispersion in benzene); by reaction of ***Phenyllithium*** with sodium *t*-butoxide;[3] and by transmetalation of ***Diphenylmercury***, e.g. with sodium.[5]

Purification: the reagent is normally prepared and used in situ. Its composition, and therefore its properties, may depend on the method of preparation.

Handling, Storage, and Precautions: reacts explosively with air and violently with water; hydrolysis gives benzene (carcinogen) and sodium hydroxide (corrosive). It must be handled in an inert atmosphere under strictly anhydrous conditions.

Metalation.

Despite a considerable amount of early work,[1a] phenylsodium has been underutilized as a reagent for metalation. While it is probably less superbasic than, for example, butylpotassium, it is certainly more basic than most organolithium compounds. For example, reaction of phenylsodium with acetophenone results in enolate formation and nucleophilic addition in a ratio of 2:1, whereas with ***Phenyllithium*** the ratio is 1:23.[6] Some examples of its use, chosen with the emphasis on reactions where it differs from organolithium compounds, are shown in the following equations.

Eq 1 represents a convenient synthesis of benzylsodium, via the preparation of phenylsodium in situ in toluene.[7] Toluene is metalated by ***n-Butyllithium*** only in the presence of e.g. ***N,N,N´,N´-Tetramethylethylenediamine***.

$$PhCl \xrightarrow[\text{toluene}]{Na} PhCH_2Na \qquad (1)$$

In contrast to eq 2,[8] reaction of benzyldimethylamine with butyllithium leads mainly to *ortho* metalation.

$$PhCH_2NMe_2 \xrightarrow{PhNa} PhCH(Na)NMe_2 \qquad (2)$$

Both 2- and 4-alkylpyridines may be metalated with phenylsodium as an alternative to ***Sodium Amide*** or organolithium compounds (eq 3).[9]

(3)

Nucleophilic Addition and Substitution.

Phenylsodium resembles phenyllithium in its reactions with carbonyl compounds (including α,β-unsaturated carbonyl compounds, where 1,2-addition predominates), ***Carbon Dioxide***, ***Iodomethane***, oxirane (***Ethylene Oxide***), etc.,[1b,c] but generally offers no significant advantage (except possibly cost). Indeed, its higher basicity may be a disadvantage when the substrate contains α-hydrogens, as in its reaction with acetophenone noted above.

A less routine example involves both nucleophilic ring-opening and addition to a carbon-nitrogen double bond (eq 4).[10] In this case also, phenyllithium gave a similar yield of phenol, though a lower yield of the sulfonamide.

Initiation of Polymerization.

Early studies on the polymerization of dienes and styrene initiated by phenylsodium[2] have not been extensively followed up or exploited, although various patents listed in *Chem. Abstr.* include the use of phenylsodium.

Phenylsulfinylethylene[1]

[20451-53-0] · C_8H_8OS · Phenylsulfinylethylene · (MW 152.23) (±)

[88180-53-4] (*S*)

[89299-86-4] (*R*)

[89299-86-5]

(acetylene equivalent in Diels-Alder, dipolar cycloaddition, and Michael reactions; can be deprotonated to the unsaturated α-sulfinyl carbanion; undergoes additive Pummerer reactions)

Physical Data: bp 93-95 °C/0.2 mmHg; *n*20D 1.5865; *d* 1.139 g cm^{-3}; (*S*)-(-): [α]20D -376° (*c* 1.0, MeOH).

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid; commercially available.

Preparative Methods: racemic reagent can be prepared from dibromoethane in one pot by substitution with thiophenolate and elimination of HBr (50-65%), followed by oxidation (68-70%).[2] The preparation of optically active phenylsulfinylethylene has been reported in a few instances only. It is noted, however, that optically active sulfoxides can be prepared by reaction of a carbanion with chiral arylsulfinates derived from menthol[3a] or glucose,[3b] or *N*-sulfinyloxazolidinones of norephedrine or phenylalanine,[3c,d] or by sequential arylation-vinylation of sulfites derived from lactic acid[3e] or aminosulfites derived from ephedrine (99+% ee).[3f] Alternatively, they can be prepared by enantioselective oxidation of sulfides with Sharpless-type reagents,[3g,h] oxaziridines,[3i] and by microbial oxidation.[3j] Finally, resolution is possible via cocrystallization with 1,1´-binaphthol[3k,1] or by chiral HPLC.[3m]

Purification: enantiomeric purity can be determined by ^{1}H NMR using chiral solvating agents.[3n]

Handling, Storage, and Precautions: as with most optically active sulfoxides, optically active phenylsulfinylethylene racemizes in the presence of acids. Use in a fume hood.

Diels-Alder Reactions.

One use of phenylsulfinylethylene is as an acetylene equivalent in Diels-Alder reactions.[4] Indeed, it is the only reagent of this type able to lose the activating functionality (phenylsulfenic acid) spontaneously after the cycloaddition.[5] The examples in eqs 1 and 2 are representative.[5,6]

(1)

(2)

In most cases the reaction conditions needed for cycloaddition also cause desulfinylation of the adducts, but sometimes the primary cycloadduct can be isolated and subjected to different transformations. For example, adducts can be alkylated[7a] or transformed into a ketone (eq 3).[7b] In such cases, phenylsulfinylethylene can be considered an equivalent of allene or ketene in [4 + 2] cycloadditions. It is notable that phenylsulfinylethylene will react with deactivated dienes as cyclopentadienones,[8a] pyrones (eq 4),[8b] and thiophene dioxides (eq 5).[9]

(4)

(5)

A close relative of the title reagent, optically active tolylsulfinylethylene (*[36832-47-0]*; (±) *[110455-66-8]*; (*R*) *[54828-68-1]*; (*S*) *[27328-17-2]*), adds to cyclopentadiene with modest *endo-exo* and face selectivity.[10] The stereochemistry of addition favors the *endo-syn* adduct (eq 6).[7] The selectivity is improved if the sulfoxide is transformed into the oxysulfonium salt by alkylation with Meerwein reagent. In this case the product is the *endo-anti* adduct, but treatment with sodium hydroxide regenerates the sulfoxide with inversion of configuration, so that products identical to the cycloaddition of tolylsulfinylethylene itself are obtained.[11a] The method has been used to prepare the Corey prostaglandin intermediate (eq 7).[11b]

(6)

Dipolar Cycloadditions.

In view of the mild conditions of elimination, phenylsulfinylethylene can be used in the synthesis of heterocycles. For example, α- and β-nicotyrines[12a] and indolizines[12b] have been prepared using phenylsulfinylethylene as a dipolarophile. In asymmetric synthesis, the adducts formed between enantiomerically pure tolylsulfinylethylene and nitrones have been converted to optically active amino alcohols (eq 8),[13a] and with 1-methyl-3-oxidopyridinium to enantiomerically pure 2α-tropanol (eq 9).[13b]

(8)

(9)

Michael Additions.

Phenylsulfinylethylene can react as a Michael acceptor, as illustrated in eqs 10 and 11.[14a,b] In these instances the adducts have been subjected to the Pummerer reaction,[15] but adducts can be simply heated to obtain the alkene. In the latter case, phenylsulfinylethylene functions as a vinyl cation equivalent.[14c] In one case the vinyl sulfoxide has been shown to cyclize to a cyclobutane (eq 12).[16]

(10)

(11)

(12)

Pummerer Reactions.[15]

Phenylsulfinylethylene reacts with ***Isopropenyl Acetate*** and catalytic ***p-Toluenesulfonic Acid*** to give phenylthioacetaldehyde via a presumed 3,3-sigmatropic shift (eq 13).[17a] ***Thionyl Chloride***,[17b] ***Trifluoroacetic Anhydride***,[17c] and ***Dichloroketene***[17d] also react with the title reagent in additive-type Pummerer reactions. Pummerer-ene reactions occur in the presence of alkenes with formation of the products shown in eq 14.[18]

(13)

(14)

Reactions as Acids.

Strong bases such as ***Lithium Diisopropylamide*** deprotonate phenylsulfinylethylene to give the vinylic α-sulfinyl carbanion;[19] the latter adds to aldehydes and ketones, e.g. with *o*-acetylphenols it affords 4-substituted chromans (eq 15).[20]

Phenylsulfonylacetylene[1]

[32501-94-3] · $C_8H_6O_2S$ · Phenylsulfonylacetylene · (MW 166.21)

(acetylene equivalent in cycloaddition reactions;[2] powerful Michael acceptor;[1b] precursor to substituted alkynes[3])

Alternate Name: ethynyl phenyl sulfone.

Physical Data: oil; bp 103-105 °C/0.01 mmHg. The 4-methyl derivative, *p*-TolSO_2C&tbond;CH *[13894-21-8]*, is a solid; mp 75 °C (from 95:5 hexane/ethyl acetate).

Solubility: sol common organic solvents.

Preparative Methods: a convenient preparation of the title reagent and *p*-TolSO_2C&tbond;CH involves $AlCl_3$-mediated substitution of one trimethylsilyl group from ***Bis(trimethylsilyl)acetylene*** by an arylsulfonyl chloride followed by hydrolysis.[4] Older procedures involve oxidation of the corresponding ethynyl thioethers,[5a,b] diazotization of 4-arylsulfonyl-5-aminoisoxazoles,[5c] dehydrobromination of (*Z*)- and (*E*)-bromovinyl phenyl sulfone with fluoride ion,[5d] and oxidative elimination of β-(phenylseleno) vinyl sulfones.[5e]

Handling, Storage, and Precautions: store tightly closed and refrigerated, possibly under an inert gas. Use in a fume hood.

Cycloaddition Reactions.

Phenylsulfonylacetylene undergoes Diels-Alder addition to a number of dienes including 2,3-dimethylbutadiene, cyclopentadiene, and anthracene (eq 1).[2a] The resulting adducts can be reductively desulfonylated to the corresponding 1,4-dienes using ***Sodium Amalgam*** in buffered (NaH_2PO_4) methanol, ***Samarium(II) Iodide*** in HMPA (eq 2),[2b] or tin reagents.[2c] This reaction sequence makes arylsulfonylacetylenes equivalent to acetylene in cycloaddition reactions.[6] The same sequence carried out on the adducts of tolyl trimethylsilylethynyl sulfone (TolSO_2-C&tbond;C-TMS) leads to the formal adducts of trimethylsilylacetylene,[7a] itself a poor dienophile.[7b] The mildness of the reaction conditions allows the synthesis of otherwise inaccessible molecules. 7-Azanorbornadiene (eq 3)[8] and [4]-peristylane (eq 4)[9] are

examples.

(1)

(2)

(3)

(4)

Tolylsulfonylacetylene gives ene reactions with appropriate alkenes under ***Ethylaluminum Dichloride*** catalysis (eq 5).[10] In dipolar cycloadditions, arylsulfonylalkynes react with nitrile oxides and nitrile imines to give 4-arylsulfonyl-substituted isoxazoles[11a] and diazoalkanes (eq 6).[11b] They also react with sydnones[11a] to give 4-arylsulfonyl-substituted pyrazoles. In general, the regiochemistry of addition is opposite to that observed with ***Phenylsulfonylethylene***. 4-Chloro-substituted pyridine *N*-oxides and pyridinium-*N*-dicyanomethylides give furopyridines[11c] and indolizines.[11d] Cycloaddition reactions have also been reported with ynamines. With these reagents the products are substituted furans (eq 7).[12]

(5)

(6)

(7)

Nucleophilic Additions.

Arylsulfonylalkynes display powerful Michael acceptor properties. Examples of addition include heteroatomic nucleophiles such as amines,[13] hydroxylamines,[14] alkoxides,[15] thiols,[16,17] and boranes.[18] The stereochemistry of addition depends on the nucleophile and on the solvent and can be controlled to some extent to obtain the (*Z*) or (*E*) adduct. For example, 10-mercaptoisoborneol adds to phenylsulfonylacetylene in acetonitrile in a *trans* fashion (eq 8), affording the corresponding (*Z*) adduct in high yield.[17] The latter was oxidized by ***m-Chloroperbenzoic Acid*** to one diastereomerically pure sulfoxide that proved to be an efficient chiral dienophile.[17] Strong carbon nucleophiles such as malonate anions[19] and cuprates (eq 9)[20] also add to phenylsulfonylacetylene in a Michael fashion with good *syn* stereoselectivity depending upon the reaction conditions. Poorer nucleophiles such as organolithium and Grignard reagents can give the substitution of the phenylsulfonyl group via an electron transfer process (eq 10).[3] A similar substitution occurs with the tin amide of pyrrole that permits direct stannylation of tolylsulfonylacetylene to $TolSO_2$-C&tbond;C-$SnEt_3$ in quantitative yield.[21]

(8)

(9)

R = Me, Ph, Bu

(10)

Radical Additions.

The ***Hexabutyldistannane***-promoted radical addition of alkyl iodides to phenylsulfonylacetylene (tertiary > secondary > primary) is a method to prepare (*Z*) adducts of α-iodo-β-alkyl-vinyl sulfones (eq 11).[22a] ***Triethylborane*** can replace hexabutyldistannane in such reactions.[22b] Functionalized vinylcyclopentenes, as mixture of

stereoisomers, can be obtained from vinylcyclopropanes and the title reagent by a radical reaction initiated by phenylthio radicals (eq 12).[23]

Phenylsulfonylallene[1]

[2525-42-0] · $C_9H_8O_2S$ · Phenylsulfonylallene · (MW 180.24)

(Michael acceptor;[2] dienophile;[3] dipolarophile;[4] [2 + 2] cycloadditions[5])

Alternate Name: 1-phenylsulfonyl-1,2-propadiene.

Physical Data: mp 44-45 °C (isopropyl ether-light petroleum).[6]

Analysis of Reagent Purity: can be distinguished from the isomeric alkynes by NMR: allene resonances, 5.46 (d, 2H) and 6.30 (t, 1H) in $CDCl_3$.

Preparative Methods: prepared via oxidation of the corresponding thioether[2] or by reaction of ***Propargyl Alcohol*** with phenylsulfinyl chloride in high yield.[6] In the latter case the product arises from a 2,3-sigmatropic shift of the intermediate sulfinate ester. It can be also obtained from the reaction of the isomeric alkynes, 1- and 3-phenylsulfonylpropyne, with bases.[7a]

General Discussion.

The title reagent (or the compound tolylsulfonylallene *[17534-15-5]*) is thermodynamically more stable than either of the two related isomeric alkynes (**1**) or (**2**) and thus can be obtained from these under a variety of reaction conditions, among which the most practical appears to be elution over basic alumina.[2] When exposed to a basic reagent, (**1**) or (**2**) first isomerize to the corresponding allene.

(1)

(2)

Sulfur, oxygen, and nitrogen nucleophiles react at the central carbon atom of the allene to produce an alkene that is normally the kinetic product, which isomerizes to the thermodynamically more stable alkene, the *trans*-2-substituted 1-phenylsulfonylpropene (eq 1).[2]

(-)-Ephedrine reacts with the allene to give the enamine that cyclizes stereospecifically to the 1,3-oxazolidine (eq 2).[7] Allyl oxides[8a] and the conjugated bases of hydroxylamines[8b] give adducts that undergo carbanionic Claisen rearrangement. In the example shown in eq 3, this sequence has been used for the synthesis of 2-substituted indoles. Carbon nucleophiles also give addition products at the central carbon atom that eventually isomerize to the more stable isomer. A case in point is the addition of dimethyl malonate (eq 4).[9] The reaction with bis(phenylsulfonyl)methane in the presence of traces of base affords the expected Michael-type adduct in only 6%. The major product in this case was the isomeric adduct shown (eq 4). It was demonstrated that the latter product forms via an initial addition of the phenylsulfonyl anion present in traces in the reaction mixture.[9]

(4)

The intermediate α-sulfonyl carbanion generated in the Michael addition can be trapped with electrophilic alkenes, eventually leading to functionalized five-membered rings (eq 5).[9] The reaction with enamines of cyclic ketones (acyclic enamines give [2 + 2] cycloadducts)[5] produces adducts that can be transformed in a simple way into dienes (eq 6).[10]

The title reagent, because of its markedly lowered LUMO energy level compared with allene, displays rich cycloaddition chemistry and can be used as the synthetic equivalent of the parent allene after reductive desulfonylation of the adducts.

Diels-Alder reactivity occurs with reactive cyclic dienes such as cyclopentadienes or activated electron-rich acyclic 1,3-

dienes.[3] With cyclic dienes it furnishes mixtures of *endo* and *exo* adducts of which the *endo* form usually predominates. The adducts can be subjected to desulfonylation to mimic the addition of allene[3b] or transformed with bases into α-sulfonyl anions that can be reacted with electrophiles to give a variety of products that can eventually lead to trienes (eq 7).[3b] The adduct with furan, upon hydrogenation, provides a simple entry into substituted cyclohexenols (eq 8).[3c] Higher order cycloadditions occur with tropone and derivatives (eq 9).[3b]

(7)

(8)

[2 + 2] Cycloadditions with enamines of acyclic ketones and some alkenes give cyclobutanes.[5] In the latter case, the cycloaddition was proved to be catalyzed by ***Ethylaluminum Dichloride*** (eq 10).[5b] This is one of the rare cases in which a sulfonyl-substituted alkene has been shown to be activated by a Lewis acid.

The large field of dipolar cycloadditions include reaction with diazoalkanes,[11] nitrones,[12] and nitrile oxides[13] among others.[14] The reactive site is always the double bond α to the phenylsulfonyl group,[4] at variance with the lower oxidized molecules (i.e. phenylthio- and phenylsulfinylallene). Among the several examples of dipolar cycloadditions of the title reagent, those worth mentioning are the preparation of benzazepines with *N*-phenyl-substituted nitrones (eq 11)[12b,c] and of α,β-unsaturated carbonyl compounds with alkyl-substituted ones (eq 11).[12d]

Electrophilic addition of bromine or iodine to phenylsulfonylallene gives 2,3-dihalo-1-phenylsulfonyl-1-propenes, which display a rich chemistry.[15a,b] An example is reported (eq 12).[15a] Similarly useful are the adducts of thiophenol, $PhSO_2CH_2C(SPh)=CH_2$,[15c] and phenylsulfinic acid, $PhSO_2CH_2C(SO_2Ph)=CH_2$.[15d]

4-Phenylsulfonyl-2-butanone Ethylene Acetal

[56161-54-7] · $C_{12}H_{16}O_4S$ · 4-Phenylsulfonyl-2-butanone Ethylene Acetal · (MW 256.35)

(a reagent for synthesizing various derivatives of 2-alkanones)

Alternate Name: PSB-EA.

Physical Data: colorless crystals; mp 33-34 °C or 41-42 °C.[1,2]

Preparative Method: by the Michael addition of benzenesulfinic acid (see ***Sodium Azide***) to 3-buten-2-one followed by acetalization with ethylene glycol.[1,2]

Synthesis of 2-Alkanones and 3-Alken-2-one.

Monoalkylation of 4-phenylsulfonyl-2-butanone ethylene acetal (**1**) takes place at the position α to the phenylsulfonyl group on successive treatment with ***n-Butyllithium*** and then with an alkyl halide (or tosylate). Deprotection of the acetal group and subsequent elimination of the benzenesulfinic acid moiety with a base transforms the monoalkylation product to the corresponding 3-alken-2-one (eq 1).[1,3] A 2-alkanone is obtainable from the monoalkylation product by reductive desulfurization and subsequent acidic deprotection (eq 2).[2-5]

Alkane-2,5-dione Synthesis.

On treatment with *n*-BuLi and an acyl chloride, (**1**) affords an α-acylated product, which easily undergoes reductive desulfurization with ***Aluminum Amalgam*** or ***Sodium Amalgam***. Deprotection forms an alkane-2,5-dione (eq 3).[6,7]

Synthesis of 6-Hydroxy-2-alkanones.

The lithio derivative of (**1**) reacts with a terminal epoxide to give a ring-opened product. Acidic deprotection of the product forms 6-hydroxy-2-alkanone which cyclizes to give a δ-lactol (eq 4).[8]

Related Reagents.

3-(Phenylsulfonyl)propanal Ethylene Acetal.

4-Phenylsulfonyl-3-buten-2-one[1]

[21860-46-8] · $C_{10}H_{10}O_3S$ · 4-Phenylsulfonyl-3-buten-2-one · (MW 210.27)

(methyl vinyl ketone equivalent which does not undergo polymerization; dienophile)

Physical Data: needles, mp 61-62 °C.

Solubility: insol water; sparingly sol pentane, hexane; sol most other organic solvents.

Preparative Methods: from ***Methyl Vinyl Ketone*** and ***Thiophenol*** in chloroform followed by treatment with ***N-Chlorosuccinimide*** and base-catalyzed dehydrochlorination to give the 4-phenylthiobut-3-en-2-one,[2] oxidation of which with ***m-Chloroperbenzoic Acid*** in ether gives a mixture of geometric isomers of the sulfone.[3] ***Sodium Benzenesulfinate*** and ***(E)-4-Chloro-3-buten-2-one*** in methanol give the (*E*) isomer only.[4] Other preparations are from acetylaldehyde dimethyl acetal[5] and phenylsulfonylmethyl *p*-tolyl sulfoxide and propionaldehyde.[6]

Purification: recrystallization from ether/pentane.[3,4]

Handling, Storage, and Precautions: no special precautions are required although storage at 4 °C or lower will prolong its shelf-life. It is also recommended to protect from light as isomerization to the (*Z*) isomer takes place.

Reactions with Nucleophiles.

Like 4-chlorobut-3-en-2-one, the sulfone serves as an effective methyl vinyl ketone equivalent in the conjugate addition of lithiated carbanions under aprotic conditions.[4,7] In an addition-elimination sequence the sulfonyl group is less reactive than the chlorine and sometimes leads to addition only to give sulfone products.[8] When elimination is desired under very mild conditions, then the related 4-sulfinylbut-3-en-2-one is a preferred reagent.[8] For example, the latter reagent undergoes conjugate addition with heteronucleophiles such as ***Furan*** and pyrroles in the presence of ***p-Toluenesulfonic Acid*** to form ketovinyl derivatives[8] and a double conjugate addition with diimines under neutral conditions to afford 2-acetonyl-1,2-dihydropyrimidines (eq 1).[5]

4-Phenylsulfonylbut-3-en-2-one as a Dienophile.

With two electron-withdrawing substituents the sulfone has an electron-deficient double bond and as such is a good dienophile. Under solvent-free conditions it reacts rapidly and cleanly with relatively inactive dienes. For example, when 4-phenylsulfonylbutenone and cyclohexadiene are adsorbed on silica, adduct formation proceeds in nearly quantitative yield after 35 h at room temperature.[9] However, stereoselectivity is poor, giving an *endo*:*exo* ratio of 5:6. When more reactive dienes are employed such as furan and 1-methoxycyclohexa-1,3-diene, selectivity for the *endo* adduct increases to 8:1 and 12:1, respectively. Elimination of the sulfonyl group by the use of ***Sodium Ethoxide*** is facile, affording the corresponding alkenes in very high yields. Thus the sulfone functions as an α,β-alkynic ketone equivalent (eq 2).

N-(Phenylsulfonyl)(3,3-dichlorocamphoryl)oxaziridine[1]

(-)

[22270-28-4] · $C_{16}H_{19}Cl_2NO_3S$ · *N*-(Phenylsulfonyl)(3,3-dichlorocamphoryl)oxaziridine · (MW 376.33) (+)

[138874-52-9]

(asymmetric oxidizing reagent for the enantioselective oxidation of sulfides to sulfoxides,[1] selenides to selenoxides,[2] and sulfenimines to sulfinimines[3])

Physical Data: mp 121-122 °C; (3´*S*,2*R*)-(-) [α]20D -159° (*c* 4.2, $CHCl_3$); (3´*R*,2*S*)-(+) [α]20D +157° (*c* 4.1, $CHCl_3$).

Solubility: insol H_2O; sol CH_2Cl_2, $CHCl_3$, THF, alcohols; sparingly sol CCl_4.

Form Supplied in: white solid.

Analysis of Reagent Purity: by mp and specific rotation determination.

Preparative Methods: the (-)-oxaziridine (**1**) is prepared from (1*R*)-(+)-camphor by condensation with benzenesulfonamide/$TiCl_4$ (eq 1). The chlorine atoms are introduced via the sulfonimine azaenolate by treatment with ***Sodium Hexamethyldisilazide*** and ***N-Chlorosuccinimide*** or preferably with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** and 1,3-dichloro-5,5-dimethylhydantoin.[4,5] Although oxidation of the dichlorosulfonimine (**2**) requires >95% ***m-Chloroperbenzoic Acid*** and 4-5 days for completion, the oxidation can be carried out on a multigram scale (>60 g). Higher yields of (**1**) are obtained when (**2**) is dissolved in a minimum of the CH_2Cl_2 solvent. The antipode, (+)-(**1**), is similarly available from (1*S*)-(-)-camphor.

In contrast to 2-(phenylsulfonyl)-3-phenyloxaziridine, this less reactive reagent does not epoxidize alkenes or oxidize amines to amine oxides.

Purification: flash chromatography.

Handling, Storage, and Precautions: store at room temperature.

Asymmetric Oxidation of Sulfides to Sulfoxides.

Enantiopure sulfoxides are important as auxiliaries in the asymmetric construction of C-C bonds.[6] The reaction of an organometallic reagent with a diastereomerically pure ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***, the Andersen synthesis, is the method most often employed for the preparation of nonracemic sulfoxides.[7,8] However, this methodology is limited in the synthesis of highly functionalized sulfoxides as well as certain dialkyl sulfoxides. Alternatively, enantiomerically enriched sulfoxides are available via the asymmetric oxidation of prochiral sulfides to sulfoxides using Kagan's modification of the Sharpless reagent, synthetically useful (>90% ee) only for aryl methyl sulfides (Ar-S-Me)[9] or the more general *N*-sulfonyloxaziridines (**1**).[1]

The asymmetric oxidation of sulfides to the sulfoxides by (-)-(**1**) is carried out at rt in nonpolar solvents (eq 2). Oxidations are generally complete within 1-6 h, although sulfides having electron-withdrawing or sterically demanding groups may require up to 48 h for completion. In these examples, heating to ca. 65 °C increases the rate of oxidation without significantly lowering the ee value. The sulfoxides and the sulfonimines (**2**) are isolated by TLC in >90% yield, with the latter being recycled. The highest enantioselectivities are observed for oxidations in low dielectric solvents such as CCl_4 and for those sulfides (R_L-S-R_S) where the difference in size of the R_L and R_S groups is large, e.g. R_L = aryl or *t*-butyl and R_S = CH_2R. Both enantiomeric sulfoxides are available by choice of the appropriate reagent because the configuration of the oxaziridine three-membered ring controls the absolute stereochemistry of the product, e.g. (-)-(**1**) gives (*S*)-sulfoxides while (+)-(**1**) gives

(*R*)-sulfoxides (eq 2). The molecular recognition is predictable in terms of minimization of nonbonded steric interactions in the transition state. Examples are given in Table 1.[1,8c,10]

Table 1 Asymmetric Oxidation of Sulfides to Sulfoxides[a] using (+)- and (-)- **(1)**[1]

Sulfide	Oxaziridine	% ee (config.)	Yield (%)	Time (h)
p-Tol-S-Me	(-)- **(1)**	>95 (*S*)	95	1
p-Tol-S-Bu	(-)- **(1)**	91 (*S*)	90	3
	(+)-**(1)**	91 (*R*)	90	3
p-Tol-S-- *i*-Pr	(-)- **(1)**	66 (*S*)	95	6

	(-)-(**1**)	86 (*S*)	84	96[8c]
	(-)-(**1**)	42 (*S*)	87	18[10]
	(-)-(**1**)	64 (*S*)	87	6[10]

[a] At rt in CCl_4.

Asymmetric oxidation of 2,3-epoxy sulfides with (-)-(**1**), double stereodifferentiation, gives 2,3-epoxy sulfoxide diastereoisomers (eq 3).[11] Lower de values were observed for the other epoxy sulfide enantiomer. The modified Sharpless reagent gave better de values (5.1:1) with the methyl sulfides.

R = Ph	13:1	65%
R = Me	1.5:1	85%

Asymmetric Oxidation of Selenides to Selenoxides.

The difficulty in preparing optically active selenoxides is that they are configurationally unstable, forming achiral hydrates, $ArSe(OH)_2R$, with trace amounts of water.[12] Enantioselective oxidation of alkyl aryl selenides by (-)-(**1**), because of its aprotic nature, gives the selenoxides in 91% to >95% ee (eq 4). Oxidations are carried out as before (eq 2) except that moisture and trace amounts of acids in the solvents need to be rigorously excluded. The optically active selenoxides (Ar = 2,4,6-triisopropylphenyl) can be isolated by chromatography on basic alumina, but with some racemization (85-87% ee).[12]

(4)

Ar = Ph, 2,4,6-*i*-$Pr_3C_6H_2$; R = Me, Et, $CH_2C_6H_4OMe$-*p*

Asymmetric oxidation of allylic selenides gives allylic alcohols via a [2,3]-sigmatropic selenoxide-selenate rearrangement (eq 5).[2] In both oxidations, eqs 4 and 5, the configuration at the selenoxide is that predicted based on the sulfoxide model.

(5)

Ar = 2,4,6-*i*-$Pr_3C_6H_2$

Aryl vinyl selenides (**3**) are oxidized by (-)-(**1**) to selenoxide intermediates which undergo elimination to chiral allenic sulfones (eq 6).[12] Somewhat better ee values were observed using the modified Sharpless reagent (up to 38% ee). Asymmetric oxidation of cyclohexyl selenides by oxaziridine (-)-(**1**) give axially chiral cyclohexylidene derivatives in up to 83% ee (eq 7).[13]

R = Pr, Ar = *o*-$O_2NC_6H_4$

(6)

(*R*) 28% ee

(7)

83% ee

Asymmetric Oxidation of Sulfenimines to Sulfinimines.

Enantiopure sulfinimines are ammonia imine synthons useful in the asymmetric synthesis of amines and β-amino acid derivatives.[3,14,15] Sulfinimines unavailable via the Andersen synthesis (R = H)[14,15] are prepared by asymmetric oxidation of the sulfenimines, ArS-N=C(R)PhX, with (+)-(**1**) or (-)-(**1**) at -20 to 20 °C in CCl_4 (eq 8).[3] Crystallization improves the ee to >95%. The sulfoxide chiral recognition model correctly predicts the configuration of the product.

(8)

Ar = Ph, R = X = H	(-)-(**1**) 88% ee (*R*)
Ar = Ph, R = X = H	(+)-(**1**) 88% ee (*S*)
Ar = *p*-Tolyl, R = Me, X = H	(-)-(**1**) 87% ee (*R*)

Phenylsulfonylethylene[1]

[5535-48-8] · $C_8H_8O_2S$ · Phenylsulfonylethylene · (MW 168.23)

(Michael acceptor;[2] equivalent to ethylene,[3] terminal alkenes,[3] and ketene[4] in cycloaddition reactions; adds radicals;[5] precursor to α-substituted vinyl sulfones[6])

Alternate Name: phenyl vinyl sulfone.

Physical Data: mp 67-69 °C.

Solubility: sol common organic solvents.

Form Supplied in: colorless solid; commercially available.

Preparative Methods: usually prepared by ***Hydrogen Peroxide*** oxidation of ***Phenyl Vinyl Sulfide***. The latter can be prepared by nucleophilic substitution of one mole of phenylthiolate with one mole of dibromoethylene and elimination,[7] or by other methods.[8]

Handling, Storage, and Precautions: good alkylating agent; should be handled with care. Use in a fume hood.

Nucleophilic Additions.

Phenylsulfonylethylene is a powerful Michael acceptor. It readily adds heteroatomic nucleophiles such as amines,[9] alkoxides,[10] and thiolates.[11] Amines and especially thiolates can be reverted back to the sulfonylethylene and nucleophile under mildly basic conditions, thus providing a method for protection of these functional groups.[11,12] The reaction with hydroperoxides and hydrogen peroxide in basic media may be controlled to give either the epoxide or the Michael addition product.[13]

Stabilized carbon nucleophiles add readily to phenyl vinyl sulfone and examples abound. As one example, a step in the synthesis of the biologically active natural product (+)-brefeldin A can be cited (eq 1).[14] The base is usually a nonnucleophilic amine but the reaction can also be carried out under solid-liquid phase-transfer catalysis.[15] In general, the Michael addition of phenylsulfonylethylene provides a method for two-carbon chain elongation.

Nucleophilic nonstabilized carbanions, as Grignard or lithium reagents, can add to vinyl sulfones.[16] The direct addition can be complicated by polymerization arising from deprotonation of the α-vinyl proton and self-condensation.[6] Addition of the more nucleophilic organocuprates is more efficient (eq 2),[17a] but is not always devoid of problems.[17b]

The enolate of cyclohexenone reacts with phenylsulfonylethylene in the presence of HMPA to give tricyclic derivatives in a single synthetic step (eq 3).[18] A method for α-alkylation of α,β-enones involves the addition of α,β-enones to phenylsulfonylethylene under ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** catalysis at high temperature (eq 4).[19] In this case, phenylsulfonylethylene functions as the electrophile in a Baylis-Hillman-type reaction.[20]

(3)

(4)

Neutral carbon nucleophiles such as enamines give [2 + 2] cycloadducts that can be isolated[21] or hydrolyzed to the keto sulfones.[22] Chiral imines react with phenylsulfonylethylene to lead, after hydrolysis, to substituted ketones in high yield with high regio- and enantioselectivity (eq 5).[23a] Enamino esters are far less reactive than imines and activation by high pressure is necessary.[23b]

(5)

The Stetter reaction is an unusual type of Michael addition. It involves a mechanism that resembles the benzoin condensation where the aldehydic carbon functions as the nucleophile. It makes available γ-keto sulfones, and hence 1,4-diketones, by a thiazolium salt-catalyzed addition (eq 6).[24]

Diels-Alder Cycloadditions.[1c]

Phenylsulfonylethylene enters into [4 + 2] π cycloadditions as a relatively reactive dienophile, usually with modest to high regioselectivity. The reactivity is such to allow addition to most dienes,[3,25] either symmetrical as cyclopentadiene, 1,3-cyclohexadiene, 2,3-dimethylbutadiene, and anthracene, or nonsymmetrical as isoprene, myrcene, 1-methoxy-3-trimethylsilyloxy-1,3-butadiene (Danishefsky's diene), 1,5,5´-trimethylcyclopentadiene,[25b] 1-methoxy-1,3-cyclohexadiene, steroids,[25e] and many others.[25] Studies on the stereoselectivity of addition to norbornyl- and norbornenyl-fused cyclopentadienes (eq 7)[26a] as well as *anti,anti*-2,3-diethylenenorbornane and -norbornene,[27a] or other similar systems,[27b] in comparison with those observed using other dienophiles have been reported.

(7)

The sulfonyl group can be replaced with hydrogen by reductive desulfonylation with ***Sodium Amalgam*** or ***Samarium(II) Iodide*** in HMPA.[28] In these cases the cycloaddition-reduction sequence equals the cycloaddition of ethylene, as in the example of eq 7. Since the adducts can be alkylated prior to desulfonylation, phenylsulfonylethylene can be viewed also as an equivalent of terminal alkenes in cycloaddition reactions[3] (eq 8).[29] Thermal or base-induced elimination of benzenesulfinic acid from the adducts makes phenylsulfonylethylene equivalent to acetylene in cycloaddition reactions. This thermal reaction, however, seldom occurs in acceptable yields[30] and the base-induced β-elimination occurs only when a relatively acidic proton at the β-carbon is available.

(8)

(8)

Cycloaddition to 1-methoxy-3-trimethylsilyloxy-1,3-butadiene followed by direct acetalization provides an adduct that undergoes regiospecific γ-alkylation. This process has been applied in a synthesis of zingiberenol as described in eq 9.[31] Phenylsulfonylethylene efficiently traps 1,3-diradicals generated by extrusion of nitrogen (eq 10). During this research an efficient oxidative desulfonylation of the resulting adducts with the molybdenum complex ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** (MoOPH) was developed so that phenylsulfonylethylene can be also used as a ketene equivalent in cycloadditions (eq 10).[4]

(9)

(10)

Dipolar Cycloadditions.

Pyrazoles are synthesized in excellent yield by reaction of diazomethanes with phenylsulfonylethylene or other α,β-unsaturated sulfones.[32] Nitrile oxides react with phenyl vinyl sulfone with high selectivity to give the 5-phenylsulfonylisoxazoline as the sole or predominant product (eq 11).[32] 1-Methyl-3-oxidopyridinium affords regio- and stereoselectively an adduct that can be transformed into 2α- and 2β-tropanols (eq 12).[33]

(11)

(12)

Oximes undergo tandem Michael addition dipolar cycloaddition to give isoxazolidine derivatives. In this reaction the nitrones generated by the Michael addition are trapped by an external dipolarophile such as *N*-methylmaleimide (eq 13),[34a] or intramolecularly if an alkene is available (eq 14).[34b] A somewhat similar reactivity is displayed by pyridinium or isoquinolinium methylides.[34c]

(13)

(14)

Radical Additions.[5]

Alkyl radicals derived from decarboxylation of carboxylic acids by the Barton method add to phenylsulfonylethylene.[35] The adducts undergo a wide variety of transformations including conversion to a two-carbon homologous carboxylic

acid or to substituted vinyl sulfones. The conversion of the adducts into hydrocarbons, ketones, and other functional groups is also possible. An example of an application to the synthesis of substituted 2-azetidinones from tartaric acid is shown in eq 15.[36] Multiple radical additions occur when the carboxylic acid possesses accessible double bonds, as in eq 16.[37] The adduct incorporates stereoselectively (three out of four stereogenic centers) two molecules of phenylsulfonylethylene.

(15)

Radicals generated by other means also add to phenylsulfonylethylene.[38]

α-Substituted Vinyl Sulfones via Direct Lithiation or Baylis-Hillman and Related Reactions.

The direct alkylation of the vinyl anion of phenylsulfonylethylene is made difficult by a rapid polymerization due to self-condensation of the vinyl anion with the reagent itself.[6] Indirect methods to overcome this problem are available. These engage in protection of the double bond by means of secondary amines (eq 17)[6b] or trimethylsilyl compounds.[39] With aldehydes as electrophiles, the Baylis-Hillman reaction[20] is possible (eq 18).[40] The allylic alcohols produced can be subjected to numerous transformations; for example, (*E*)-selective dehydration to give 1,3-alkadienes (eq 18)[41a] or modified Jones oxidation to α-methylene-β-keto sulfones.[41b]

(18)

(19)

Other Reactions.

Phenylsulfonylethylenes are dimerized by low cathodic currents to give *trans*-1,2-substituted cyclobutanes.[42] Carbonyl-stabilized sulfur ylides give cyclopropanes (eq 19).[43] Finally, the hydroformylation catalyzed by a rhodium complex gives mostly the branched-chain aldehyde $PhSO_2CH(CHO)Me$.[44]

α-Phenylsulfonylethyllithium

(R = H)

[69291-71-0] · $C_8H_9LiO_2S$ · α-Phenylsulfonylethyllithium · (MW 176.18)

(versatile stabilized carbon nucleophile for forming C-C, C=C, and C&tbond;C bonds with a wide range of carbon and heteroatom electrophiles[1-3])

Physical Data: pK_a in DMSO 31.0.

Solubility: sol THF, Et_2O.

Preparative Methods: prepared in situ as needed by metalation of ethyl phenyl sulfone with ***n-Butyllithium*** or ***Lithium Diisopropylamide***.

Handling, Storage, and Precautions: moisture sensitive; handle under nitrogen or argon.

General Considerations.

The sulfone group is perhaps second only to the carbonyl group in its versatility and utility. It serves the dual role of C-H activator and leaving group under a wide range of conditions,[1] thereby enabling creation of up to three C-C bonds from a single functional group. Alkyl aryl sulfones have a pK_a of ca. 31 and are therefore quantitatively deprotonated by strong bases such as ***n-Butyllithium***, ***Lithium Diisopropylamide***, or Grignard reagents. The resultant colored carbanions (yellow or red-orange)[4] are usually stable at rt. It is also possible to form an α,α-dianion which reacts with even relatively poor electrophiles.[5] In the following discussion, α-phenylsulfonylethyllithium serves as a paradigm for the class of a^1d^1 reagents represented by $ArSO_2$-CH(M)R.

α-Phenylsulfonylethyllithiums as Donors.

α-Arylsulfonylalkyllithiums react with all the typical carbon electrophiles to form a C-C bond in generally good yield; some indication of the scope of the procedure can be gleaned from eqs 1-9. For example, alkylation with primary alkyl bromides (or iodides; eq 1),[6] tosylates (eq 2),[7] or triflates[8] occurs even when there is an α-branch in the chain. In the case of sluggish reactions, additives such as ***Hexamethylphosphoric Triamide*** or ***N,N,N´,N´-***

Tetramethylethylenediamine can be added to accelerate alkylation.

(1)

(2)

The reaction of sulfonyl carbanions with halocarbenoids (see ***Tribromomethyllithium***) gives a 1,1-dibromoalkene or a 1-bromoalkene (eq 3).[9] The reaction probably does not involve a carbene intermediate.

(3)

Terminal epoxides react slowly with sulfonyl carbanions such as the homoenolate equivalent (**1**) (eq 4).[10] With disubstituted epoxides and cyclic epoxides the reactions are slower still. For example, reaction of the lithio derivative of ethyl phenyl sulfone with cyclopentene oxide occurs in excellent yield (98%) after 10 h reflux in toluene.[11] It has been reported that, in some cases, the addition of a Lewis acid (***Magnesium Bromide***,[12] ***Boron Trifluoride Etherate***,[13,14] ***Titanium Tetraisopropoxide***,[15] MeOAl(i-Bu)$_2$[16]) or HMPA[17] improves the yield dramatically.

(4)

In the presence of HMPA, the homoenolate equivalent (**1**) underwent conjugate addition to cyclohexenone. In the absence of HMPA, a mixture of 1,2- and 1,4-adducts was obtained (eq 5).[18,19]

(5)

The addition of metalated sulfones to aldehydes is reversible and in simple cases the reaction displays modest selectivity for the *erythro* isomer (eq 6).[20] The reverse reaction is favored when the adducts are sterically compressed (e.g. ketone adducts) or when the sulfone anion is stabilized by conjugation (i.e. allylic or benzylic sulfones) or proximate heteroatoms. However, in unfavorable cases the position of the equilibrium can be tuned by varying the metal. For example, the lithio sulfone (**2**) did not give a stable adduct with aldehyde (**4**) but the ate complex derived from the lithio derivative and BF_3 gave the desired adduct (**5**) (eq 7).[21]

(6)

(5)

(7)

α-Phenylsulfonylethyllithium adds to acylsilanes to give an adduct which undergoes a Brook rearrangement with subsequent loss of benzenesulfinate anion. The product of the reaction is an enol silane (eq 8).[22]

(8)

Reaction of the metalated sulfones with esters,[23,24] lactones,[25,26] amides and carbonates[27] leads to the corresponding β-keto sulfone (eq 9).[23] The β-keto sulfones thus formed display chemistry reminiscent of β-keto esters in their enhanced acidity and tendency to undergo *C*- and *O*-alkylation and acylation.

(9)

Aryl Sulfones as Acceptors: Desulfonylation Reactions.

The sulfone group is a powerful electron acceptor which can be cleaved under a wide range of conditions. We have already seen that mild base will cause elimination of benzenesulfinate from β-arylsulfonyl-substituted carbonyl derivatives (eq 5). α-Arylsulfonyl-substituted carbonyl derivatives undergo reductive desulfonylation[28] under very mild conditions using ***Aluminum Amalgam*** (eq 10),[29] but in the absence of carbonyl activation, reductive cleavage of the sulfone group requires much stronger reducing agents such as ***Sodium Amalgam*** in MeOH buffered with Na_2HPO_4,[30] ***Sodium-Ammonia***,[31] ***Magnesium*** in refluxing MeOH,[32] or ***Samarium(II) Iodide*** in THF-HMPA.[33]

(10)

The Julia Alkenation and Related Reactions.

In 1973, Julia and Paris[34] reported a new connective and regioselective alkene synthesis (eq 10) based on the reductive elimination of β-acyloxy sulfones. The Julia alkenation is now one of the principal methods for fragment linkage in complex natural product synthesis.[35,36] Mono-, di-, tri-, and tetrasubstituted alkenes can be prepared in moderate to good yield, depending on the substrate. The three-step sequence, illustrated in eq 11, entails (a) condensation of a metalated sulfone with an aldehyde or ketone, (b) *O*-functionalization of the adduct as the acetate, benzoate, or mesylate (to prevent retroaldolization), and (c) reductive elimination using 6% Na(Hg) in THF-MeOH (3:1) at -20 °C.[37] In favorable cases, step (b) can be omitted and the reductive elimination performed on a β-hydroxy sulfone intermediate. Potential problems attending each step have been summarized.[35]

(11)

A detailed investigation of the scope and stereochemistry of the reductive elimination leading to 1,2-disubstituted alkenes revealed high *trans* stereoselectivity which is *independent* of the stereochemistry of the β-acyloxy sulfone adducts.[37,38] Furthermore, the stereoselectivity increases with increasing steric congestion about the nascent alkene and maximum yields and rate are observed for the formation of conjugated dienes and trienes. The Julia procedure has also been adapted to the synthesis of alkynes (eq 12).[39,40]

There are two further variants of the Julia alkenation which deserve wider recognition. Both methods surmount the inherent limitation in scale of the reductive elimination step imposed by the use of Na(Hg). The first method involves a radical-induced elimination of thiocarbonyl derivatives of β-hydroxy sulfones,[41] as illustrated in eq 13.[42]

(13)

The second recent variant, developed by Julia and co-workers, avoids reductive elimination altogether and provides a remarkable one-pot connective synthesis of alkenes.[43] The procedure, illustrated in eq 14, involves condensation of an aldehyde or ketone with a lithiated benzothiazolyl alkyl sulfone to give an adduct which first cyclizes and then fragments with extrusion of sulfur dioxide, benzothiazolone (which then tautomerizes to 2-hydroxybenzothiazole), and the alkene. Generally a mixture of (*E*)- and (*Z*)-alkenes is obtained, but in sterically hindered substrates the (*E*) isomer can be obtained selectively. The same reaction has been observed with the pyridinyl sulfone analogs, in which case the separable β-hydroxy sulfone intermediates undergo stereospecific *anti* elimination to the corresponding alkene.

54%, (*E*):(*Z*) = 98:2 (14)

Alternative Desulfonylation/C-C Bond-Forming Procedures.

The foregoing discussion has focussed on reductive methods for removing sulfones and, in the case of the Julia alkenation, desulfonylation is accompanied by the formation of a new C-C bond. Another method which accomplishes desulfonylation with the concomitant construction of a C=C bond entails fluoride-induced elimination of β-silyl sulfones (see ***(2-Phenylsulfonylethyl)trimethylsilane***).

Allylic sulfones undergo S_N2' displacement by cyanocuprates with high *syn* stereoselectivity (eq 15).[44] Stabilized enolates also displace allylic arylsulfonyl groups in the presence of Pd^0 or Ni^0 catalysts.[45]

(15)

Allylic and tertiary alkyl sulfones can also participate in electrophilic cyclizations in the presence of ***Aluminum Chloride*** (Friedel-Crafts reaction; eq 16).[46]

(16)

Base-catalyzed elimination of β-acetoxy sulfones is highly stereoselective, leading to (*E*)-alkenyl sulfones which undergo transition metal-catalyzed coupling with Grignard reagents with retention of configuration to provide a stereoselective synthesis of trisubstituted alkenes.[47] Either ***Nickel(II) Acetylacetonate***, ***Tris(acetylacetonato)iron(III)***, or ***Iron(III) Chloride*** can be used as the catalyst (eq 17).[48]

Oxidative Desulfonylation of Arylsulfonylalkyllithiums.

Aryloxysulfonylalkyllithiums can be converted to ketones in one pot by reaction with ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)***,[49] ***Bis(trimethylsilyl) Peroxide***,[50] or ***Chlorodimethoxyborane/m-Chloroperbenzoic Acid***.[51]

Related Reagents.

(2-Phenylsulfonylethyl)trimethylsilane

[73476-18-3] · $C_{11}H_{18}O_2SSi$ · (2-Phenylsulfonylethyl)trimethylsilane · (MW 242.45)

(reagent for the synthesis of mono- and 1,1-disubstituted alkenes via sulfone metalation, alkylation, and fluoride-induced elimination[1])

Physical Data: mp 52 °C.

Solubility: sol all common ethereal, halocarbon, and hydrocarbon solvents.

Form Supplied in: solid; commercially available.

Preparative Methods: (2-phenylsulfonylethyl)trimethylsilane (**2**) is prepared by radical addition of ***Thiophenol*** to ***Vinyltrimethylsilane*** to give (2-phenylthioethyl)trimethylsilane (**1**), which is then oxidized with ***Hydrogen Peroxide*** (eq 1).[2,3]

General Considerations.

A sequence involving metalation, alkylation, and fluoride-induced elimination of benzenesulfinate allows the conversion of (**2**) to a terminal alkene. An analogous sequence involving a double alkylation of (**2**) provides a 1,1-disubstituted alkene (eq 2).[4,5] The lithio derivative of (**2**) has also been used to prepare cyclopropylidene derivatives,[6] homoallylic alcohols,[7] and allyl silanes via the Julia alkenation.[3]

Alternative Routes to Substituted (2-Phenylsulfonylethyl)trimethylsilanes.

Although the fluoride-induced elimination is a reliable and efficient method for synthesizing alkenes, the requisite silyl sulfone precursors are often better prepared by methods which avoid the use of (**2**). For example, eq 3 illustrates an alternative synthesis of 2,2-dialkyl-2-(phenylsulfonylethyl)trimethylsilanes involving alkylation of a lithio sulfone with ***(Iodomethyl)trimethylsilane***.[8,9]

(2-Phenylsulfonylethyl)trimethylsilane

(3)

2-(Phenylsulfonylvinyl)trimethylsilane (**3**) is a useful acetylene equivalent for use in Diels-Alder reactions (eq 4).[10,11]

(4)

(2-Phenylsulfonylethyl)trimethylsilane

Phenylsulfonylethylene derivatives undergo conjugate addition reactions. Thus (**3**) reacts with unsaturated Grignard reagents and organocuprates,[12] while the substituted sulfone (**5**) undergoes conjugate addition by the enolate derivative (**4**) to give a bicyclomycin intermediate (eq 5).[13]

Related Reagents.

1,1-Bis(phenylsulfonyl)ethylene; ***Phenylsulfonylethylene***; ***α-Phenylsulfonylethyllithium***; ***1-Phenylsulfonyl-2-(trimethylsilyl)acetylene***; ***(E)-1-Phenylsulfonyl-2-trimethylsilylethylene***; ***Phenylsulfonyl(trimethylsilyl)methane***.

Phenylsulfonylnitromethane

[21272-85-5] · $C_7H_7NO_4S$ · Phenylsulfonylnitromethane · (MW 201.22)

(precursor for α-nitro sulfones;[1] precursor for phenylsulfonylnitrile oxide for 1,3-dipolar cycloadditions[2])

Physical Data: mp 78-79 °C; pK_a 5.69 (MeOH-H_2O, 50:50).[3]

Solubility: insol water; sol CH_2Cl_2, hot alcohol. Sodium salt (**1**) sparingly sol DMSO but not THF; lithium salt (**2**) sol THF.

Form Supplied in: white crystalline solid.

Analysis of Reagent Purity: analytical TLC (CH_2Cl_2 elution) should give one spot, R_f 0.35; a possible impurity is 1,3-bis(phenylsulfonyl)-1,3-dinitropropane, R_f 0.1, which can be removed by sublimation.

Preparative Methods: ***Nitromethane***, ***Sodium Benzenesulfinate***, and ***Iodine*** are added sequentially to a cold (0-5 °C) DMF solution of ***Sodium Methoxide***. The reagent can be converted to $NaO_2N{=}CHSO_2Ph$ (**1**) and $LiO_2N{=}CHSO_2Ph$ (**2**) using NaOMe and LiOMe, respectively.[1]

Handling, Storage, and Precautions: indefinitely stable; the nitronate salts (**1**) and (**2**) can be stored dry without decomposition for several weeks but, *like all nitronate salts, they are explosive*: (2) *vigorously decomposes above 150 °C*.

Alkylation Reactions.

The reagent can be *C*-monoalkylated via its nitronate salts (**1**) and (**2**). α-Nitro sulfones were obtained by reaction of (**1**) with a variety of benzyl halides and primary alkyl iodides (eq 1).[1,4] α-Nitro sulfones were similarly obtained by reaction of (**2**) with allylic acetates in the presence of Pd^0 catalysts (eqs 2 and 3).[1,5] High regioselectivity for the less hindered carbon of the π-allylpalladium intermediate was typically observed. Displacement of the acetate usually occurs with net retention.[6]

(1)

(2)

(3)

C,*C*-Dialkylates were not formed in the alkylation reactions owing to congestion at the monoalkylated α-nitro sulfone center. However, internal *O*-alkylation can occur,[1,7] subsequent to *C*-alkylation, affording cyclic nitronic esters (eq 4) which can be deoxygenated to provide 3-phenylsulfonyl-4,5-dihydroisoxazoles. The reagent has also been used to prepare α-nitro sulfones by Michael addition to 3-buten-2-one.[4a] α-Nitro sulfones can be converted to carboxylic acids,[1,5] desulfonated nitro compounds,[1,4a,8] and nitriles.[1]

(4)

Cycloaddition Reactions.

The reagent is used to make three precursors for generation of the 1,3-dipole benzenesulfonyl cyanide *N*-oxide ($PhSO_2C$&tbond;+N-O^-). The first precursor, *N*-hydroxy-1-phenylsulfonylmethanimidoyl bromide (**3**), is obtained from the reagent by sequential bromination, methylation, and mild thermolysis (eq 5).[2a] Bromooxime (**3**) is preferred because it gives the nitrile oxide most cleanly.

(5)

However, nitronic ester (**4**), *which has been known to explode*, is a more easily obtained precursor: the reagent is simply methylated using diazomethane.[2b,10] The reagent also reacts with nitric acid to provide bis(phenylsulfonyl)furazan 2-oxide (**5**), which is a third nitrile oxide precursor.[9,2c]

(4) (5)

Any of these precursors, for example (**3**), can be used to generate the nitrile oxide which then reacts in situ with a wide variety of alkenes to give 3-phenylsulfonyl-4,5-dihydroisoxazoles (eq 6).[2,10,11]

(6)

The alkene configuration is retained in the dihydroisoxazole and regioselectivity is high for monosubstituted, *gem*-disubstituted, and trisubstituted alkenes. Conditions for generation of the nitrile oxide vary: (**3**) requires mild base[2a] or ***Silver(I) Nitrate***,[2b] while nitronic ester (**4**) requires strong base[2b] or strong acid,[12] and (**5**) requires heating (140 °C).[2c] The phenylsulfonyl group of the dihydroisoxazoles can be replaced using a variety of nucleophiles including organolithium reagents and sodium methoxide.[13,7] Reductive cleavage using 2% ***Sodium Amalgam***[14] or

Hexacarbonylmolybdenum[7] affords *cis*-β-hydroxynitriles, and this is the most general route to these compounds (eq 7).

(7)

Related Reagents.

(Phenylthio)nitromethane.

(*E,E*)-*N*-Phenylsulfonyl-4-phenyl-1-aza-1,3-butadiene[1]

[118922-13-7] · $C_{15}H_{13}NO_2S$ · (*E,E*)-*N*-Phenylsulfonyl-4-phenyl-1-aza-1,3-butadiene · (MW 271.36)

(electron-deficient acyclic 1-azadiene capable of participation in inverse electron demand Diels-Alder reactions with electron-rich dienophiles[2a])

Alternate Name: (*E,E*)-*N*-(3-phenyl-2-propenylidene)benzenesulfonamide.

Physical Data: mp 107-109 °C.

Solubility: sol CH_2Cl_2, C_6H_6.

Form Supplied in: pale yellow solid.

Preparative Methods: a solution of cinnamaldehyde in toluene (0.10 M) is treated with benzenesulfonamide (1.1 equiv) and $MgSO_4$ (2 g $mmol^{-1}$) and the reaction mixture is stirred at reflux for 120 h. The reaction mixture is cooled to 25 °C, the $MgSO_4$ is removed by filtration, and the filtrate is concentrated in vacuo. Flash chromatography (SiO_2, 15% EtOAc/hexane eluent) gives the title reagent (typical yield 50%).[2]

Additional general methods for the synthesis of *N*-sulfonylimines based on the in situ generation of *O*-sulfinate derivatives of oximes employing sulfinyl chlorides (phenyl- and methylsulfinyl chloride)[2a,3-8] or sulfonyl cyanides (*p*-toluenesulfonyl cyanide)[2b] and their subsequent rt rearrangement have been detailed.

Handling, Storage, and Precautions: stable at room temperature but susceptible to hydrolysis and must be stored free of moisture.

Cycloaddition Reactions.

Stable, electron-deficient *N*-(phenylsulfonyl)-1-aza-1,3-butadiene is one of a series of α,β-unsaturated *N*-benzenesulfonyl imines capable of participation in regio- and *endo*-selective inverse electron demand Diels-Alder reactions with a range of electron-rich dienophiles employed in the diastereoselective preparation of substituted *N*-benzenesulfonyl-1,2,3,4-tetrahydropyridines (eq 1).[2a,3]

(1)

N-Benzenesulfonyl aldimines have been shown to be more reactive than *N*-benzenesulfonyl ketimines (eq 2),[1,2a,3] and the complementary addition of a C-3 or the noncomplementary addition of C-2 and C-4 electron-withdrawing substituents substantially accelerate the Diels-Alder reaction and maintain the expected cycloaddition regioselectivity and exceptionally high *endo* diastereoselectivity (eqs 3-5).[2a,3-5]

(±)-*trans*-2-(Phenylsulfonyl)-3-phenyloxaziridine[1]

[63160-13-4] · $C_{13}H_{11}NO_3S$ · (±)-*trans*-2-(Phenylsulfonyl)-3-phenyloxaziridine · (MW 261.32)

(neutral, aprotic, electrophilic oxidizing agent for the chemoselective oxidation of many nucleophilic substrates[1])

Physical Data: mp 95-95.5 °C.

Solubility: sol CH_2Cl_2, $CHCl_3$, THF; insol hexane, pentane, water.

Form Supplied in: white solid.

Analysis of Reagent Purity: ^{1}H NMR analysis and mp determination.

Preparative Methods: the title reagent (**1**) can be readily prepared on a 100 g scale in 88% yield via oxidation of *N*-benzylidenebenzenesulfonamide with buffered ***m-Chloroperbenzoic Acid***[2] or more conveniently with ***Potassium Monoperoxysulfate*** (Oxone).[3] This Baeyer-Villiger type of oxidation of sulfonimine affords only the *trans*-oxaziridine. A number of other (±)-*trans*-2-(arylsulfonyl)-3-aryloxaziridines (**2**) can also be prepared by these methods.[2,3]

(2a) Ar = Ph, Ar' = $C_6H_4NO_2$-*p*
(2b) Ar = C_6H_4Me-*p*, Ar' = $C_6H_4NO_2$-*p*
(2c) Ar = C_6H_4Cl-*p*, Ar' = C_6H_4Cl-*p*

Purification: recrystallization from ethyl acetate-pentane.[2]

Handling, Storage, and Precautions: can be stored in a brown bottle in the refrigerator for years without noticeable decomposition. Storage at rt for long periods of time, however, is potentially hazardous.[2] The

nitro-substituted oxaziridines (**2**) are more thermally stable and are recommended for reactions at elevated temperatures.

Oxidation of Organosulfur Compounds.

(±)-*trans*-2-(Arylsulfonyl)-3-aryloxaziridines oxidize a variety of sulfides to sulfoxides without over-oxidation to sulfones, even in the presence of excess oxidant.[1a,4] However, longer reaction times (>20 h) can produce sulfones.[4] An example is the oxidation of mustard to the sulfoxide in less than 2 min by *trans*-2-(phenylsulfonyl)-3-(*p*-nitrophenyl)oxaziridine (**2a**) (eq 1).[5] In contrast to *m*-CPBA or Oxone, oxaziridine-mediated oxidation of alkynyl phenyl sulfides at 60 °C gives none of the corresponding sulfone (eq 2).[6] The oxidation of sulfides has been developed in a catalytic manner.[7] Disulfides are usually oxidized to thiosulfinates which are difficult to obtain using acidic oxidants such as *m*-CPBA (eq 3).[8] Enantiopure *N*-sulfonyloxaziridines afford enantiomerically enriched sulfoxides and thiosulfinates.[9]

$$(ClCH_2CH_2)_2S + \textbf{(2a)} \xrightarrow{CHCl_3} (ClCH_2CH_2)_2SO + (ClCH_2CH_2)_2SO_2 \quad (1)$$

100:0

(2)

(3)

Thiols are oxidized to sulfenic acids (**3**) which can then be trapped by alkynes to give vinyl sulfoxides (**4**). In the

absence of the trapping agent, the initial sulfenic acid (**3**) is usually further oxidized to a sulfinic acid (**5**) due to the α-effect (eq 4).[10] 2-Mercaptopyridine, however, gives rise to the disulfide (eq 5).[11] Silyl sulfides (silyl ether of thiols), afford silyl sulfinates regardless of the stoichiometry of the reaction (eq 6).[12] Oxidation of thiones gives thione *S*-oxides which may undergo desulfurization to ketones (eq 7).[13] By the oxidation of the corresponding thiones with oxaziridine (**2b**), thiocamphor *S*-oxide (**6**) and thiofenchone *S*-oxide (**7**) are prepared in 91% and 76% yield, respectively.[13] Reaction of phosphorothionate with (**2a**) yields the phosphate (eq 8).[14]

(4)

(5)

(6)

(7)

(6)

(7)

(8)

Oxidation of Organoselenium Compounds.

Selenides, like sulfides, are quantitatively oxidized to selenoxides without overoxidation.[1a,15] The resulting selenoxides may undergo [2,3]-sigmatropic rearrangement to allylic alcohols or β-elimination to alkenes (eq 9).[1a,16] The reaction can be run in the presence of a number of other functional groups such as aldehyde,[17] alkene,[18] and sulfide.[16] Compared to ***Hydrogen Peroxide*** or *m*-CPBA, improved yields are reported using oxaziridine (**2a**).[19] Oxaziridine-mediated selenide oxidations in the presence of pyridine have been used to suppress side products of the selenoxide elimination.[15] Diphenyl diselenide gives benzeneseleninic anhydride (eq 10).[17]

(9)

(10)

Oxidation of Organonitrogen and Organophosphorus Compounds.

Tertiary amines react with (**1**) to yield amine oxides (eq 11).[1a,20] Oxidation of secondary amines with one equiv of (**1**) affords the hydroxylamine (eq 12),[21] while excess oxaziridine gives rise to nitrones.[20] Aliphatic primary amines give,

(+/-)-trans-2-(Phenylsulfonyl)-3-phenyloxaziridine

on oxidation, nitroso compounds (eq 13).[20] Although pyridine is not reactive towards oxaziridines,[20] imines are oxidized to nitrones (eq 14).[22] With (**2b**), 1,3,2-λ^3-oxazaphospholanes gave 1,3,2-λ^5-oxazaphospholanes (eq 15).[23]

(11)

(12)

$$RNH_2 + \textbf{(1)} \longrightarrow RN{=}O \qquad (13)$$

(14)

(+/-)-trans-2-(Phenylsulfonyl)-3-phenyloxaziridine

Oxidation of Carbon-Carbon Double Bonds and Aromatic Hydrocarbons.

Like peroxy acids, *N*-sulfonyloxaziridines epoxidize alkenes in a *syn* stereospecific manner, but the epoxidation is slower requiring higher temperature (e.g. 60 °C) for satisfactory yields.[1a,24] For this reason, the more thermally stable *p*-nitrophenyl oxaziridine (**2a**) is recommended. The neutral and aprotic *N*-sulfonyloxaziridine oxidizing reagents can be used to prepare acid-sensitive epoxides. For example, epoxidation of indene with (**2a**) gave the acid-sensitive indene oxide in 63% yield (eq 16).[24] Usually, electron-deficient alkenes are not epoxidized by *N*-sulfonyloxaziridines; however, isoxazoline (**8**) gave epoxides (**9**) and (**10**) in 36% yield on heating with (**2a**) (eq 17).[25] In general, more nucleophilic substrates such as sulfides, amines, selenides, etc., can be oxidized in the presence of C=C double bonds (e.g. eq 2). Alkynes, on the other hand, are not oxidized by *N*-sulfonyloxaziridines such as (**2**).

(16)

(17)

Oxidation of silyl enol ethers followed by acid hydrolysis gives α-hydroxy carbonyl compounds.[1a,26] The aprotic nature of *N*-sulfonyloxaziridines makes possible the isolation of the α-siloxy epoxide intermediate in high yield (eq 18).[26] α-Hydroxy ketones of high enantiomeric purity (&egt;98% ee) can be prepared via the oxidation of chiral silyl enol ethers (eq 19).[27]

(18)

(19)

Disubstituted enamines are rapidly oxidized to α-amino ketones, while tertiary enamines give, after hydrolysis, α-hydroxy ketones (eq 20).[1a,28] Oxidation of bicyclic enamines with (**1**) followed by reduction of the iminium ion with ***Sodium Borohydride*** affords the β-amino alcohol (eq 21).[29] Reaction of diene carboxylic acid with oxaziridine (**1**) is reported to give a diastereomeric mixture of hydroxy lactones (eq 22).[30] Heating anisole with *N*-sulfonyloxaziridine (**2a**) gives a mixture of 2- and 4-methoxyphenols.[31]

(20)

(21)

Oxidation of Carbanions and Organometallic Compounds.

Lithium and Grignard (RM) reagents react instantaneously with *N*-sulfonyloxaziridines to give alcohols and phenols (eq 23).[1a,32] Yields are comparable to those obtained using alternative oxidants such as O_2, *t*-BuOOLi, ***Bis(trimethylsilyl) Peroxide***, and ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** (MoOPH). The oxaziridine reagent is particularly recommended for substrates having certain sensitive functionality. Bishydroxylation is also possible with (**1**) (eq 24).[33] Oxidation of phosphorus ylides (Wittig reagents) with (**1**) gives *trans*-alkenes or ketones depending on the structure of the phosphoranes (eq 25).[34] Bis-ylides dimerize to cycloalkadienes.[34] Reaction of dimethyloxosulfoniummethylide with (**1**) results in the formation of azetidines (eq 26).[35] Unsymmetrical α-diketones are prepared in good yield by oxidation of the carbanions derived from α-sulfonyl ketones with oxaziridine (**2c**) (eq 27).[36]

(25)

(26)

(27)

2-(Arylsulfonyl)-3-aryloxaziridines oxidize a variety of metal enolates to the corresponding α-hydroxy carbonyl compounds (eq 28).[1,37,38] Unlike MoOPH and molecular oxygen, over-oxidation is not a problem with these reagents.[1,39] With chiral enolates, the oxidation takes place from the least hindered face of the enolate.[1,40] α-Hydroxy ketones, aldehydes, and carboxylic acid derivatives of high enantiomeric purity are available using chiral auxiliaries (eqs 29 and 30).[1,41,42]

3-(Phenylsulfonyl)propanal Ethylene Acetal

[56161-51-4] · $C_{11}H_{14}O_4S$ · 3-(Phenylsulfonyl)propanal Ethylene Acetal · (MW 242.32)

(synthetic reagent for 2-alkenals, 4-oxoalkanals, and 5-hydroxyalkanals)

Physical Data: mp 62-63 °C or 67-68 °C.[1,2]

Form Supplied in: colorless crystals.

Preparative Methods: by oxidation of 3-(phenylthio)propanal ethylene glycol[1] or by reaction of ***Sodium Benzenesulfinate*** with 3-bromopropanal ethylene acetal.[2]

Synthesis of Alkanals.

Monoalkylation of 3-(phenylsulfonyl)propanal ethylene acetal (**1**) takes place at the position α to the phenylsulfonyl group on successive treatment with ***n-Butyllithium*** and then with an alkyl halide. Deprotection of the acetal group and subsequent elimination of benzenesulfinic acid with a base produces the corresponding 2-alkenal (eq 1).[1]

A second alkylation is also possible by treatment with alkyl iodide and *n*-BuLi. Acidic deprotection of the dialkylated product gives the corresponding 2-alkenal (eq 2).[1]

4-Oxoalkanal Synthesis.

The lithio derivative of (**1**) can be acylated with a methyl ester to afford an acylated product which easily undergoes reductive desulfurization with ***Aluminum Amalgam*** or ***Sodium Amalgam*** to produce a 4-oxoalkanal ethylene acetal, an important synthetic precursor (eq 3).[3,4]

(3)

Synthesis of 5-Hydroxyalkanals.

The lithio derivative of (**1**) reacts with terminal epoxides to give ring-opened products. Reductive desulfurization followed by acidic deprotection forms 5-hydroxyalkanal, which cyclizes to give a δ-lactol (eq 4).[5]

(4)

Multiple Bond Formation.

Lithiated (**1**) adds to aldehydes. After acetylation, treatment of the adduct with ***Potassium t-Butoxide*** causes elimination of benzenesulfinic acid and acetic acid to form an acetal having a triple bond or a conjugated double bond, depending on circumstances (eqs 5 and 6).[6,7]

(5)

(6)

Related Reagents.

4-Phenylsulfonyl-2-butanone Ethylene Acetal.

1-Phenylsulfonyl-1*H*-tetrazole

[59128-90-4] · $C_7H_6N_4O_2S$ · 1-Phenylsulfonyl-1*H*-tetrazole · (MW 210.24)

(coupling reagent for oligonucleotide solution synthesis using the phosphotriester method[1-4])

Physical Data: mp 86-92 °C.

Solubility: insol H_2O; sol pyridine, CH_2Cl_2; reacts slowly with H_2O and protic solvents.

Form Supplied in: white crystals; not available from commercial sources.

Analysis of Reagent Purity: prior to use, the purity should be determined by mp.

Preparative Method: by reaction of ***Benzenesulfonyl Chloride*** (1 equiv) and tetrazole (1 equiv) in the presence of ***Triethylamine*** (1 equiv) in dioxane at 5 °C for 2 h. A crystalline product was obtained after dissolving the crude material in benzene, shaking with silica gel, filtering, and evaporating in vacuo to dryness.

Handling, Storage, and Precautions: the dry solid should be stored in a desiccator with drierite at 4 °C. The material decomposes completely after 20 days at 25 °C, and it should be used immediately following preparation. **Cation**: Avoid contact with metals and metal salts, since tetrazole may form explosive metal salts. Contact with strong oxidizers or strong heat may cause fire or explosion.

1-Phenylsulfonyl-1*H*-tetrazole (**1**) has been used as a condensing reagent in deoxyoligonucleotide solution synthesis by the phosphotriester method.[1-3] It activates 5´-dimethoxytrityl (DMT) deoxynucleoside 3´-(*p*-chorophenyl) phosphates in anhydrous pyridine, allowing the coupling reaction with 5´-hydroxy nucleoside in 30 min at 25 °C, yielding the corresponding *p*-chlorophenyl phosphate dimer in 74% yield. This reaction has been extended for the preparation of oligodeoxynucleotides containing up to 12 bases with coupling times in the range of 30-120 min at 25 °C (eq 1). Couplings mediated by (**1**) occur more rapidly than with the corresponding 2,4,6-trimethyl and 2,4,6-triisopropyl analogs and no sulfonation at the 5´-hydroxy group has been observed.[1,3]

Furthermore, (**1**) has been used in anhydrous pyridine for 24 h at 25 °C for the preparation of a ribonucleotide dimer in 60% yield (eq 2).

Although (**1**) has not been used in solid-phase oligonucleotide synthesis, another more stable arylsulfonyl derivative, 1-(mesitylsulfonyl)-3-nitro-1,2,4-triazole (MSNT),[5,6] is commonly used in that strategy by the phosphotriester approach.[7]

1-Phenylsulfonyl-2-(trimethylsilyl)acetylene[1]

[32501-93-2] · $C_{11}H_{14}O_2SSi$ · 1-Phenylsulfonyl-2-(trimethylsilyl)acetylene · (MW 238.41)

(reagent for preparation of α-vinyl carbonyls, and for use in cycloadditions and preparation of *cis*- and *trans*-vinyl sulfones)

Physical Data: mp 68-70 °C.

Solubility: sol most organic solvents.

Form Supplied in: colorless hygroscopic crystals.

Handling, Storage, and Precautions: very sensitive to alkaline or acidic conditions.

Addition Reactions.

Enolates of 1,3-dicarbonyl compounds add smoothly to the title reagent (**1**) to provide mainly the *cis*-vinyl sulfones (**2**). These are reduced by treatment with ***Aluminum Amalgam*** to give vinyl ketones (**3**) (eq 1).[2] Similarly, addition of organocuprates leads to the *cis*-vinyl sulfones (**4**) (eq 2).[1]

Reduction of (**1**) with hydrogen and palladium in pyridine gives the *cis*-vinyl sulfone, while in the absence of pyridine the *trans* isomer is obtained.[3] These products may also be obtained by reduction with ***Diisobutylaluminum Hydride***, giving the *trans* isomer, or treatment with ***Bis(1,5-cyclooctadiene)nickel(0)*** to produce the *cis* isomer.[1] These vinyl sulfones have been used as acetylene equivalents in a variety of organometallic addition reactions, as well as in cycloaddition reactions.[1,3,4]

Cycloaddition Reactions.

Cycloaddition of (**1**) with ***1-Methoxy-3-trimethylsilyloxy-1,3-butadiene*** (Danishefsky's diene) (**5**) has been reported to yield the phenol (**6**) (eq 3), which may be further elaborated to a variety of products.[5] (**1**) has also been used in reactions with azide (**7**) to produce the triazole (**8**) (eq 4).[6]

Related Reagents.

(*E*)-1-Phenylsulfonyl-2-trimethylsilylethylene[1]

[64489-06-1] · $C_{11}H_{16}O_2SSi$ · (*E*)-1-Phenylsulfonyl-2-trimethylsilylethylene · (MW 240.43)

(dienophile equivalent to a variety of alkynes in Diels-Alder cycloadditions;[2] used to prepare α-substituted allylsilanes[3])

Physical Data: mp 59-60 °C (petroleum ether).[4]

Solubility: sol common organic solvents.

Form Supplied in: colorless solid; not commercially available.

Preparative Methods: prepared by hydrogenation of the corresponding readily available acetylene in 48% yield (this method is also amenable to the synthesis of the deutero derivative)[2] or by phenylsulfonyl chloride addition to trimethylsilylethylene (78%) followed by ***Triethylamine***-mediated dehydrochlorination (97%);[2] selenosulfonation, followed by ***Hydrogen Peroxide*** oxidation, can also be used (84%);[5] an alternative method of preparation involves dehydrochlorination of 1-phenylsulfonyl-1-chloro-2-trimethylsilylethane ($PhSO_2CHClCH_2SiMe_3$) with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (quantitative);[4] can also be prepared by treating the lithium salt of the anion of methylthiomethyl phenyl sulfone ($PhSO_2CH_2SMe$) with ***(Iodomethyl)trimethylsilane*** to give $PhSO_2CH(SMe)CH_2SiMe_3$, followed by oxidation to the sulfoxide and elimination of methanesulfenic acid (60%).[3b]

Handling, Storage, and Precautions: potential alkylating agent; use in a fume hood.

Cycloadditions.

The dienophilic properties of (*E*)-phenylsulfonyl-2-trimethylsilylethylene allow the preparation of adducts with reactive dienes such as ***Cyclopentadiene*** and anthracene.[2] The adducts are smoothly converted to alkenes upon treatment with fluoride ion, establishing the equivalence of the title reagent to ***Acetylene***. Alkylation of the α-sulfonyl carbanion can precede the elimination such that synthetic equivalents to HC&tbond;CH, HC&tbond;CD, and RC&tbond;CH are available. The use of this reagent is highlighted by the synthesis of several functionalized dibenzobarrelenes (eq 1).[2] The

equivalency to DC&tbond;CD and RC&tbond;CD is illustrated by the preparation of deuterated derivatives.

(1)

The somewhat low reactivity of (*E*)-phenylsulfonyl-2-trimethylsilylethylene in Diels-Alder reactions is probably due to steric hindrance exerted by both substituents and by the poor activation imparted by the silyl group. This drawback is partially offset by the effective elimination to the alkene performed under very mild conditions with fluoride ion. The low dienophilic reactivity of the title reagent is evident in the reaction with isodicyclopentadiene, for which it was demonstrated that only the isomer arising from the [1,5]-hydrogen sigmatropic shift was captured by dienophiles of low reactivity. Highly reactive dienophiles react with the symmetric structure, which is obviously a less reactive diene (eq 2).[6]

(2)

Addition Reactions.

The utility of (*E*)-phenylsulfonyl-2-trimethylsilylethylene in the synthesis of α-substituted allylsilanes[3] is exemplified in eq 3 for γ-hydroxyvinylsilanes,[3a] and in eq 4 in the preparation of isoprenoid structures.[3b] In these reactions the reagent functions as a Michael acceptor, but α-lithiation may compete with less nucleophilic bases such as butyllithium.[3b]

(3)

The availability of analogous reagents bearing different atoms in the place of silicon, such as tin,[3] boron,[7a] and chlorine[7b] as well as the alkynic homologs, is notable.[8] Finally, the sulfide related to the title reagent merits mention.[9]

Phenylsulfonyl(trimethylsilyl)methane[1]

[17872-92-3] · $C_{10}H_{16}O_2SSi$ · Phenylsulfonyl(trimethylsilyl)methane · (MW 228.42)

(the lithio anion reacts with carbonyl compounds to afford vinyl sulfones[2] via a modified Peterson alkenation procedure;[3] double alkylation, reduction, and sila-Pummerer rearrangement provides ketones[4])

Alternate Name: phenyl trimethylsilylmethyl sulfone.

Physical Data: mp 28-30 °C; bp 121 °C/0.01 mmHg.

Solubility: readily sol THF, DME, ether.

Form Supplied in: white solid; widely available.

Preparative Method: can be readily prepared via several routes,[5] of which the most suitable for large-scale preparation involves the reaction of sodium thiophenolate with ***(Chloromethyl)trimethylsilane***, the sulfide obtained then being oxidized to the sulfone with buffered ***Peracetic Acid***.[6]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: store under an inert atmosphere at 0-4 °C.

Preparation of Vinyl Sulfones from Carbonyl Compounds.

The Peterson alkenation reaction provides a useful method for the preparation of alkenes.[3] The scope of the reaction can be expanded to give α-heterosubstituted alkenes by the use of α-heteroatom-substituted carbanions. The lithio anion generated from the title reagent (**1**) reacts with carbonyl compounds to give the corresponding vinyl sulfones via a modified Peterson alkenation procedure (eq 1).[2,5,7,8] Both aldehydes and ketones are suitable substrates, although complications can arise when enolizable ketones are employed.[5] The solvent has a marked effect on the reaction, with the highest yields being obtained with DME.[5]

(1)

(*E*):(*Z*) = 1:1

The reaction can tolerate a wide range of functionality, including ethers, esters, and epoxides. The vinyl sulfones are generally obtained as mixtures of (*E*) and (*Z*) isomers, although the degree of selectivity is highly substrate dependent.[5,9] The aldehyde (**2**) was converted to the corresponding vinyl sulfone as a single (*E*) isomer in 96% yield. The vinyl sulfone obtained is an intermediate in the total synthesis of the antifeedant ajugarin I (eq 2).[10]

(2)

(2)

The use of ether as solvent allows the trapping of the intermediate alkoxide by acetylation.[5] The β-acetoxy-α-silyl sulfone (**3**), isolated from the reaction of benzaldehyde and the lithium anion of (**1**) followed by trapping with ***Acetic Anhydride*** (eq 3), was shown by NMR to be a single diastereoisomer. However, attempted stereospecific elimination was found to give mixtures of (*E*)- and (*Z*)-sulfones.[5]

(3)

(3)

Greater (*E*) stereoselectivity can be achieved in the preparation of vinyl sulfones from carbonyl compounds by the use of the related α-sulfonylphosphonates.[11]

Preparation of Ketones via Dialkylation, Reduction, and Sila-Pummerer Rearrangement.

α-Silyl sulfides undergo sila-Pummerer rearrangement to provide aldehydes and ketones.[12] Access to the ketones is inhibited by the difficulty in deprotonating and hence alkylating the α-silyl sulfides. The α-silyl sulfone (**1**) is readily deprotonated with ***n-Butyllithium*** and subsequent alkylation with an alkyl halide proceeds smoothly.[13] The process can be repeated a second time to provide dialkylated α-silyl sulfones (eq 4).[4]

(4)

The lithio anion is formed in THF at 0 °C and can be alkylated with a range of simple alkyl and alkenyl halides. The α-silyl sulfones thus obtained are then reduced with either ***Diisobutylaluminum Hydride*** or ***Lithium Aluminum Hydride*** to give α-silyl sulfides capable of undergoing the sila-Pummerer rearrangement.[4]

Other Applications.

α-Silyl sulfone (**1**) can be doubly deprotonated by the use of a second equivalent of *n*-BuLi.[14] Reaction of the dianion (**4**) with ***Dichlorotitanium Diisopropoxide*** prior to reaction with benzaldehyde provides the α-silylvinyl sulfone (eq 5). The α-silylvinyl sulfone is obtained in good yield as a 2:1 mixture of (*E*) and (*Z*) isomers.[14a]

The lithio anion of (**1**) also reacts with simple amides to provide 2-aminovinyl sulfones.[15] Deprotonation is performed with ***Lithium Diisopropylamide*** at -70 °C in THF, and the resultant 2-aminovinyl sulfones are obtained in moderate to good yields with excellent (*E*) selectivity.

1-Phenyl-2-tetrazoline-5-thione

[86-93-1] · $C_7H_6N_4S$ · 1-Phenyl-2-tetrazoline-5-thione · (MW 178.24) (Na salt)

[15052-19-4]

(in combination with isocyanides, activates carboxylate for lactonization,[1] peptide formation;[2] source of nucleophilic sulfur[3])

Physical Data: mp 150 °C (dec).

Solubility: sol organic solvents.

Form Supplied in: red solid; widely available.

Handling, Storage, and Precautions: store in dark.

Introduction.

While this reagent has a wide variety of applications of great value to the photographic industry, it is also a synthetic reagent of some utility. These applications relate to activation of the carboxylate group, introduction of nucleophilic sulfur, and as a heterocyclic building block.

Reaction with Isocyanides.

Treatment of the reagent with ***t-Butyl Isocyanide*** affords an intermediate of the nature indicated (eq 1). Subsequent reaction with a carboxylic acid at -40 °C gives an equilibrium mixture of compounds (eq 2) in which the carbonyl group is activated toward nucleophilic substitution. This intermediate can be effectively utilized in two ways.

Lactone Formation.

Long-chain hydroxy acids can, by this method, be converted into lactones (eq 3).[1] Of note is the observation that even macrocyclic lactones can be formed in high yields without high dilution or other catalysts.

Peptide Formation.

Amino acids can be coupled to form amides using this technology.[2] A nitrogen-protected amino acid is activated and allowed to react with a carboxylate-protected amino acid, thus forming the peptide linkage. The reagent can be recovered unchanged at the end of either of these sequences.

Sulfur Nucleophile.

The nucleophilic nature of the sulfur in 1-phenyl-2-tetrazoline-5-thione can be utilized for the introduction of sulfur into organic compounds. Thus Mitsunobu reaction of a protected sugar with the reagent affords the substituted sugar (eq 4).[3]

(4)

In a similar fashion, substitution of a cephalosporin could be achieved (eq 5).[4]

(5)

Alkylation at nitrogen (or redirected to nitrogen) affords the substituted tetrazolinethione. Under photolysis conditions, such compounds undergo loss of sulfur and nitrogen to afford the carbodiimide (eq 6),[5] subsequent hydrolysis providing the urea.

Phenylthallium Bis(trifluoroacetate)[1]

$PhTl(OCOCF_3)_2$

[23586-54-1] · $C_{10}H_5F_6O_4Tl$ · Phenylthallium Bis(trifluoroacetate) · (MW 507.53)

(reagent for preparation of substituted benzenes)

Physical Data: mp 184-189 °C

Solubility: sol MeOH, EtOH, MeCN, THF, DMSO.

Form Supplied in: colorless crystalline solid. *Drying:* in vacuo over sodium hydroxide.

Preparative Method: readily prepared from benzene.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic (cumulative toxicity) to inhalation, skin contact, and ingestion; extreme caution should be used when handling these materials; use in a fume hood.

General Discussion.

Phenylthallium bis(trifluoroacetate) is a readily accessed and versatile reagent for conversion into a wide variety of other aromatic compounds. Uses for this reagent flourished once the straightforward route to aryl bistrifluoroacetates (treatment of the aromatic compound with a solution of ***Thallium(III) Trifluoroacetate*** (TTFA) in TFA) was published in 1969.[2] The preparation of phenylthallium bis(trichloroacetate) has also been described. This reagent undergoes iodination, chlorination, nitrile formation, selenation, nitration, coupling, and palladium-catalyzed alkenation in good yield.[3] A more recent modification[4] allows the replacement of a trimethylsilyl group with thallium bis(trifluoroacetate) (eq 1).

(1)

Phenylthallium bis(trifluoroacetate) can be subsequently converted into numerous aromatic compounds, often without isolation of the bis(trifluoroacetate) salt. Transformation into aryl iodides is readily accomplished (eq 2)[5] with rapid replacement of the thallium by iodine in high yield.

(2)

A method for the preparation of *m*-iodonitrobenzene from phenylthallium bis(trifluoroacetate) has been developed (eq 3).[6] This simple method, noteworthy for its regiospecificity, avoids the often circuitous route of dinitration, mono-reduction to the amine, diazotization, and iodination.

(3)

Preparation of aryl nitroso and nitrile compounds from arylthallium salts has also been reported. In the case of nitrosation, a one-pot reaction of the arylthallium bis(trifluoroacetate) with *n*-propyl nitrite and HCl at rt in chloroform leads directly to the *para*-substituted nitroso compound.[7] For the preparation of aryl nitriles, a variety of nitrile-delivery reagents have been examined (***Potassium Cyanide***,[8] $Cu(CN)_2$,[9a] ***Copper(I) Cyanide***[9]) under varying conditions (photolysis in aqueous solution,[8] pyridine,[9a] or acetonitrile[9] reflux). The reaction of the aryl bis(trifluoroacetate) with copper(I) cyanide in acetonitrile gives the most reliable results in moderate to good yields, and is quite general (eq 4).[9b]

(4)

Phenols are also readily accessed by this methodology. In an interesting illustration of both boron and thallium chemistry, it was found that treatment of phenylthallium bis(trifluoroacetate) with ***Diborane*** yields ***Dihydroxy(phenyl)borane***, which can be oxidized under standard conditions to give phenol (eq 5).[10]

(5)

Conversions of phenylthallium bis(trifluoroacetate) into thiocyanates, selenium compounds, and unsymmetric sulfones have also been described.[11] All these transformations are carried out by heating the arylthallium salt with the appropriate reagent in dioxane. Copper(II) is critical to the success of these transformations, which proceed in moderate yield.

Carbonylation of phenylthallium bis(trifluoroacetate) has also been successfully demonstrated, providing methyl benzoate.[12]

In yet another demonstration of the synthetic utility of arylthallium bis(trifluoroacetates), the preparation of unsymmetrical biphenyl compounds has been developed (eq 6).[13] Capture of the aryl radical by the solvent (benzene) leads to the product. Attempts to extend this methodology by the use of pyridine as solvent were unsuccessful. Use has been made of arylthallium reagents in a ***Palladium(II) Chloride***-catalyzed preparation of symmetrical biaryls in yields ranging from 12 to 75% (eq 7).[14]

(6)

(7)

Related Reagents.

(Phenylthio)acetic Acid

[103-04-8] · $C_8H_8O_2S$ · (Phenylthio)acetic Acid · (MW 168.23)

(preparation of various PhS-containing compounds, such as 3- or 4-hydroxy-2-(phenylthio)alkanoic acids, 4-oxo-2-(phenylthio)alkanoic acids, and α-phenylthio-β-lactams)

Alternate Name: PTAA.

Physical Data: mp 61-62 °C,[1] 62-63 °C;[2] pK_a 3.02 × 10^{-4} (0 °C), 2.76 × 10^{-4} (25 °C).

Form Supplied in: colorless crystals; commercially available.

Preparative Methods: by the substitution reaction of sodium chloroacetate with sodium benzenethiolate, or by the treatment of bromoacetic acid with thallium(I) benzenethiolate.[2]

Derivation of Various PhS Compounds.

(Phenylthio)acetic acid is a synthetic precursor for a variety of PhS-containing compounds such as $PhSCH_2N{=}C{=}O$,[3] $PhSCH_2CON{=}C{=}S$,[3] $PhSCH_2CO_2Me$,[4] $PhSCH_2NO_2$,[5,6] $MeCH{=}C(NO_2)SPh$,[5,6] $PhSCHClCO_2H$,[7] $PhSCH_2Cl$,[7] and 2-(phenylthio)methyl-1-oxazolidine derivatives.[8]

PTAA generates a dianion by the action of 2 equiv of ***n-Butyllithium*** or ***Lithium Diisopropylamide***. The C-anion site of the PTAA dianion is more reactive than the C-anion of methyl (phenylthio)acetate. Treatment of the dianion with alkyl halide gives a monoalkylated product (eq 1).[9-11] Reaction of the dianion with a carboxylic ester accompanied by decarboxylation provides a useful method for introduction of the $PhSCH_2$ moiety (eq 2).[12] Introduction of PTAA into a furan ring has also been achieved by means of [3,3]-sigmatropic rearrangement (eq 3).[13]

(3)

Synthesis of 4-Hydroxy-2-(phenylthio)alkanoic Acids.

The dianion of PTAA reacts with a terminal epoxide to give a ring-opened product, 4-hydroxy-2-(phenylthio)alkanoic acid, which can be transformed into the corresponding γ-lactone (eq 4),[14] α,β-unsaturated γ-lactones (eq 5),[15] or 4-hydroxy-2-alkanoic ester.[16]

(5)

Synthesis of 3-Hydroxy-2-(phenylthio)alkanoic Acids.

The dianion of PTAA adds to aldehydes and ketones, leading to 3-hydroxy-2-(phenylthio)alkanoic acids.[17,18] These can be converted to the corresponding β-lactones which, on treatment with ***Magnesium Bromide***, give the β-phenylthio-γ-lactone (eq 6) or α-phenylthio β,γ-unsaturated carboxylic acid (eq 7).[18]

4-Oxo-2-(phenylthio)alkanoic Acid Synthesis.

The dianion of PTAA adds to nitroalkenes, and subsequent acid hydrolysis yields 4-oxo-2-(phenylthio)alkanoic acids, synthetic intermediates of the corresponding 4-hydroxy-2-(phenylthio)alkanoic acids (eq 8).[19]

(8)

Synthesis of Cyclic Compounds.

PTAA has two reactive sites, the carboxy group and the active methylene group, providing a useful method for constructing various cyclic compounds (eqs 9 and 10).[20-22] Activation of the carboxy group of PTAA and subsequent treatment with a base in the presence of an imine gives an α-phenylthio-β-lactam (eq 11).[23]

Phenylthioacetylene

[6228-98-4] · C_8H_6S · Phenylthioacetylene · (MW 134.21)

(synthesis of phenylthioalkynes;[1] synthesis of phenyl thiolesters;[1a] synthesis of vinyl sulfides;[1b,1d,2] synthesis of carbonyl compounds[3])

Physical Data: bp 48-50 °C/1.5 mmHg, 86-88 °C/14 mmHg; *d* 1.084 g cm^{-3}.

Solubility: sol organic solvents.

Form Supplied in: pale yellow to dark brown-green liquid.

Analysis of Reagent Purity: gas chromatography; ^1H NMR.

Preparative Methods: stepwise elimination of HBr from the dibromide obtained by bromination of ***Phenyl Vinyl Sulfide*** (eqs 1 and 2).[4]

This procedure is recommended due to problems encountered with the reproducibility of the one-pot dehydrobromination of phenylthio-1,2-dibromoethane.[5] Phenylthioacetylene has also been prepared by elimination of thiophenol from *cis*-1,2-bis(phenylthio)ethylene,[6] dehydrobromination of the *cis* isomer of ***(E)-1-Bromo-2-phenylthioethylene***,[7] LDA-induced double elimination of ethanol from bromoacetaldehyde diethyl acetal,[8] and reaction of ***Lithium (Trimethylsilyl)acetylide*** with either

phenylsulfinyl chloride[9] or the relatively expensive ***Phenyl Benzenethiosulfonate***[1b,1d,10] and subsequent desilylation.

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: use in a fume hood; use immediately after distillation for best results (pale yellow); turns dark brown-green upon storage at -10 °C (freezer) and is stable for a few months under these conditions; methyl phenyl sulfide can act as a stabilizer, and the reagent shows no tendency to darken in its presence.[6b]

Phenylthioalkynes.

A large variety of phenylthio-substituted alkynes can be conveniently prepared via the reactions of phenylthioacetylene metalated derivatives (eqs 3-5);[1] this strategy is more flexible than the one based on nucleophilic substitution of a terminal alkali-metal acetylide with ***Phenyl Benzenethiosulfonate***,[1b,1d,10] ***Benzenesulfinyl Chloride***,[9] or ***Diphenyl Disulfide***.[11]

(3)

R = CH_2OH, $CH_2OTBDMS$, Me, Bu, TMS, $CH(OH)CH_2OTBDMS$, CO_2Me, $C(O)CH_2OTBDMS$, $CH_2OCH_2C(O)N(OMe)Me$

(4)

(5)

In addition to serving as precursors to vinyl sulfides, phenylthioalkynes can be hydrolyzed to phenyl thiolesters (eq 6).

(6)

Vinyl Sulfides.

Regio- and stereoselective syntheses of functionalized vinyl sulfides[2] from phenylthioalkynes are accomplished by palladium(0)-catalyzed hydrostannation (eq 7),[1b] hydroboration,[12] treatment with low-valent tantalum,[13] stannylcupration,[5] or carbocupration.[14]

(7)

R = CH_2OH, $CH_2OTBDMS$, Me, Bu, TMS, $CH(OH)CH_2OTBDMS$, CO_2Me, $C(O)CH_2OTBDMS$, $CH_2OCH_2C(O)N(OMe)Me$, Ph

Vinyl sulfides have been shown to be very useful intermediates in organic synthesis, not only as carbonyl-masking moieties[3] but also in a variety of other transformations[15] including the nickel(0)-catalyzed cross-coupling reactions with alkyl, aryl, and alkenyl Grignard reagents.[16] The important role of the phenylthio group (and its higher oxidation states) in activating and directing alkenes in cycloaddition reactions has been reviewed.[17] The synthesis of the hexacarbonyldicobalt complex[18] and the polymerization of phenylthioacetylene[19] have also been described.

Phenylthiobis(trimethylsilyl)methane[1]

[62761-90-4] · $C_{13}H_{24}SSi_2$ · Phenylthiobis(trimethylsilyl)methane · (MW 268.62)

(formation of vinylsilanes and as a methoxycarbonyl anion equivalent)

Physical Data: bp 88 °C/0.16 mmHg.

Solubility: sol most common organic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Method: synthesized from phenylthiotrimethylsilylmethane.[2]

Handling, Storage, and Precautions: use in a fume hood.

Vinylsilane Preparation.

The most general utility of the title reagent (**1**) involves Peterson alkenation reactions. Deprotonation of this reagent, followed by addition to carbonyl-containing substrates, affords phenylthiovinylsilanes (eq 1).[3]

(1)

The reduction of the carbon-sulfur bond in (**1**) with ***Lithium Naphthalenide*** also produces an alkenation reagent (eq 2).[4] This protocol is limited, however, to use with nonenolizable ketones and aldehydes.

Lithiobis(trimethylsilyl)methane, the active intermediate in this reaction, can also be produced through the deprotonation of ***Bis(trimethylsilyl)methane***.

When (**1**) is treated with a fluoride source, a mild alkenation reagent is produced (eq 3).[5] The efficient transformation of enolizable ketones and aldehydes under these conditions, as opposed to the lithium naphthalenide reduction process, aptly demonstrates this fact.

Conjugate Addition.

The lithium anion of (**1**) adds exclusively in Michael fashion to cyclohexenone (eq 4).[6] In comparison, lithiobis(phenylthio)methane predominantly adds to the carbonyl, providing a 2:1 mixture of the possible regioisomers. As with many other 1,4-conjugate additions, substitution at the alkene terminus alters the reaction regioselectivity (eq 5).[6]

(5)

Homo-Peterson Alkenation.

Styrene oxide reacts with lithiophenylthiobis(trimethylsilyl)methane to afford cyclopropane-containing products (eq 6).[7] This reaction is limited, due to the complexity of its mechanism: the alkenation reagent must serve to generate both alkenic and carbenic species. For this reason, only styrene oxide and trimethylsilyloxirane undergo this transformation.

(6)

Methoxycarbonyl Anion Equivalent.

The alkylation of lithiophenylthiobis(trimethylsilyl)methane with an alkyl halide, followed by electrochemical oxidation of the resulting thiobis(silane), provides a homologated methyl ester (eq 7).[8] The electrochemical oxidation, due to its mild nature, can be tolerated by a wide variety of functional groups.

PhSCu

[1192-40-1] · C_6H_5CuS · Phenylthiocopper(I) · (MW 172.71)

(source of nucleophilic phenyl sulfide for preparation of lithium alkyl(phenylthio)cuprates and organophosphinecopper(I) phenylthiolate complexes)

Physical Data: mp 280 °C (dec).

Solubility: sol cold THF.

Form Supplied in: yellow solid; widely available.

Preparative Methods: one method is to treat ***Thiophenol*** with ***Copper(I) Oxide*** in ethanol at reflux to give phenylthiocopper as a yellow suspension (eq 1).[1-3]

Alternatively, lithiation of thiophenol and quenching with ***Copper(I) Iodide*** affords a yellow solution, which is typically reacted in situ with organometallic reagents.[4]

Handling, Storage, and Precautions: use in a fume hood (stench).

Cuprate Reagents.

Lithium alkyl(phenylthio)cuprates, prepared by the addition of alkyllithiums to phenylthiocopper, are highly reactive reagents which effect selective alkyl group transfers (eq 2).[5] These cuprates have been employed in a singular approach to various cyclohexenone annulation products via α-acetone Gilman reagent addition to

cyclohexenecarboxylate (eq 3).[6] Michael additions of these copper reagents have also provided the regioselective alkylation of octahydroisoquinolines utilizing Grignard precursors (eq 4),[7] and 3-spiroannulation of cyclohexenones via an organobis(cuprate) (eq 5).[8] An example of a vinylcuprate addition to an alkyl iodide in the synthesis of graveolide has been reported (eq 6).[9]

(2)

(3)

(4)

(5)

(6)

Miscellaneous.

Phenylthiocopper has been employed in displacement reactions of activated aryl bromides to give aryl phenyl sulfides (eq 7).[10] Reports of similar reactions of vinyl bromide derivatives have been published.[11] Organophosphinecopper(I) thiophenoxide complexes have been isolated by reaction of trialkylphosphines with PhSCu (eq 8).[12] When treated with liquid ***Sulfur Dioxide***, these complexes have formed sulfur dioxide adducts. Other applications of phenylthiocopper include thiophenolatocopper coating of Pt, Mo, and CdS,[13] and formation of thiol esters upon reaction with acid chlorides.[14]

(7)

(8)

Related Reagents.

Lithium Cyclopropyl(phenylthio)cuprate; ***Lithium Methyl(phenylthio)cuprate***; ***Lithium Phenylthio(trimethylstannyl)cuprate***; ***Phenylselenocopper(I)***.

Phenylthiocyclopropane[1a,1c]

[14633-54-6] · $C_9H_{10}S$ · Phenylthiocyclopropane · (MW 150.26)

(a particularly valuable building block able to transfer a three-carbon unit to various organic molecules, allowing the synthesis of cyclobutanones from aldehydes or ketones)

Alternate Name: cyclopropyl phenyl sulfide.

Physical Data: bp 51-52 °C/0.1 mmHg or 62-63 °C/1 mmHg.[2]

Preparative Methods: easily prepared from 1-phenylthio-3-chloropropane (itself obtained on reaction of 1-bromo-3-chloropropane and phenylthiolates) and ***Potassium Amide*** in liquid ammonia (eq 1).[3]

1,3-Bis(phenylthio)propane reacts with ***n-Butyllithium*** in THF to produce the title reagent (**1**) on reaction with only 1 equiv *n*-Buli, or 1-lithio-1-phenylthiocyclopropane (**2**) if 2 equiv are used (eq 2).[4,5]

(2)

(**1**) has also been synthesized from 3-tributylstannylpropanal (available from tributylstannyllithium and ***Acrolein***) and trimethylsilyl phenyl sulfide in the presence of ***Titanium(IV) Chloride*** as acid catalyst (eq 3),[6] and on

substitution of (i) ***Cyclopropyllithium*** with ***Diphenyl Disulfide*** (eq 4), (ii) cyclopropyl bromide with potassium benzenethiolate (eq 5)[7] or (iii) 1,1-dibromocyclopropane,[8] also with benzenethiolates, and by reduction of α-bromocyclopropyl phenyl sulfide with sodium methanethiolate (eq 6).[9] In addition, cyclopropyl phenyl sulfoxide can be reduced to (**1**) in more than 70% yield with ***Chlorotrimethylstannane***-benzenethiol (eq 7).[10]

Handling, Storage, and Precautions: use in a fume hood.

Reactions of Phenylthiocyclopropane.

The reactions of (**1**) are those typical of sulfides. Oxidation or alkylation can occur at the sulfur, whereas halogenation or

metalation can occur on the cyclopropane ring at the carbon bearing the phenylthio group. The latter reaction, which produces phenylthiocyclopropyllithium, is the one most frequently used in organic synthesis. (**1**) also reacts with ***Hydrogen Chloride*** and ***Hydrogen Bromide*** to produce thiophenol,[11] and higher homologs provide ethyl ketones in reasonably good yields (eq 8).[12]

(8)

Oxidation and Alkylation of Phenylthiocyclopropane.

Oxidation of (**1**) to the corresponding sulfoxide, sulfone, and sulfoximine is easily achieved. However, the best synthetic route to the sulfone involves the cyclization of 3-halopropyl phenyl sulfone on reaction with bases.[3] Oxidation to the sulfoxide has been typically carried out with peroxy acids or ***Sodium Periodate*** (eq 9, route a).[13-15] Asymmetric oxidation of (**1**) has been efficiently carried out by Holland[14] using the fungus *Mortierella isabellina* ((*R*)-cyclopropyl phenyl sulfoxide, 58% yield, ee 66%) or better by Kagan[16] using the modified Sharpless method (***Titanium Tetraisopropoxide*** (+)-diethyl tartrate, H_2O, ***t-Butyl Hydroperoxide***, CH_2Cl_2, -20 °C, 24 h, (*R*)-cyclopropyl phenyl sulfoxide, 73% yield, ee 95%) or by Davis[17,18] using (-)-α,α-dichlorocamphorsulfonyloxaziridine (CCl_4, 20 °C, 18 h, (*S*)-cyclopropyl phenyl sulfoxide, 90% yield, ee 92%).

Acid-catalyzed addition of (**1**) to ***1,4-Benzoquinone***, followed by methylation of the resulting dihydroxysulfonium salt with ***Diazomethane*** affords the corresponding diarylcyclopropylsulfonium salt in reasonably good yield (eq 10).[19] Otherwise the synthesis of ***Cyclopropyldiphenylsulfonium Tetrafluoroborate***, a valuable precursor of the corresponding cyclopropylide, is best achieved by cyclization in basic media of 3-chloro-1-propyldiphenylsulfonium tetrafluoroborate.[20] The synthesis of the related (dimethylamino)cyclopropylsulfonium tetrafluoroborate has been carried out from cyclopropyl phenyl sulfoxide by a sequence which involves reaction with ***Hydrazoic Acid*** (eq 11).[13]

(11)

(**1**) reacts with ***N-Chlorosuccinimide*** (1.2 equiv NCS, pyridine, benzene, 20 °C, 12 h) to produce 1-chloro(phenylthio)cyclopropane in quantitative yield (eq 9, route b).[15,21] Similar results are obtained from cyclopropyl phenyl sulfoxide and ***Thionyl Chloride*** (1.2 equiv $SOCl_2$, CH_2Cl_2, 20 °C, 2 h) or ***Sulfuryl Chloride*** in the presence of pyridine (eq 9, route a).[15,21] It is remarkable that ring-opened products are not found in these reactions, since solvolysis of 1-chloro(phenylthio)cyclopropane affords some allylic derivatives. These chlorinations may proceed via the initial formation of chlorosulfonium salts, which then decompose affording the α-chloro sulfides through an ylide-ylidene ion-pair intermediate as in the Pummerer reaction, rather than involving a free carbonium ion.[15,21]

The synthesis of 1-iodo(phenylthio)cyclopropane has been achieved by metalation of (**1**) with ***n-Butyllithium*** and subsequent reaction with iodine (eq 12).[22] This compound is a valuable precursor of 1-methoxy(phenylthio)cyclopropane and of 1-lithio-1-methoxycyclopropane.[22,23] 1-Methoxy(phenylthio)cyclopropane has also been synthesized from cyclopropyl phenyl sulfoxide via a sequence of reactions which involve the intermediate formation of the corresponding methoxysulfonium salt and its rearrangement (of Pummerer type) on reaction with sodium methoxide in methanol (eq 13).[24]

(12)

(13)

Reactions involving 1-Lithio-1-phenylthiocyclopropane (2).

This compound is easily synthesized according to the Trost procedure by metalation of (**1**) with *n*-butyllithium (1 equiv, THF, 0 °C, 2 h, 20 °C, 2 h, >90% yield) (eq 12).[1a,25-28] (**2**) is the only α-thio carbanion bearing two alkyl substituents to be generated by hydrogen-metal exchange.[29] It has been alternatively generated[4,5] from 1,3-bis(phenylthio)propane and 2 equiv *n*-butyllithium in THF (-78 to 0 °C, >85% yield, eq 2), or by reductive lithiation of 1,1,3-tris(phenylthio)propane[30] and of 1,1-bis(phenylthio)cyclopropane[31] using ***Methyllithium-N,N,N´,N´-Tetramethylethylenediamine*** or 1-(dimethylamino)naphthalenide, respectively.

(**2**) is a useful reagent in the preparation of:

- 1)cyclobutanones,[1a,26-28,32-35] including cyclobutanone itself (eq 14),[26] the α-vinyl[1a,27,28,32,35-39] and α-aryl[40] analogs, α-(1-phenylthiocyclopropyl)cyclobutanones,[41] γ-ketocyclobutanones,[42] 2-alkyl(or aryl)-1,1-bis(phenylthio)cyclobutanes (eq 15),[43] 1-phenylthiocyclobutenes (eq 15),[28,32,44] 3-alkyl(or aryl)-2-(phenylthio)-1,3-butadienes (eq 15),[43] cyclobutanes,[32,44] annulated cyclopentanones[45] cyclohexen-3-ols,[38] γ,δ-cyclooctenones,[36]
- 2)alkylidenecyclopropanes (eq 16),[46] allylidenecyclopropanes (eq 17),[47] γ-keto sulfides (eq 8),[12] ethyl ketones (eq 8),[12] γ-methoxycarbonyl-1,1-bis(phenylthio)acetals,[35] vinyl sulfides (eq 18),[48] 1-methoxy-1-(phenylthio)cyclopropane (eq 13),[22] and 1-trimethylsilyl-1-(phenylthio)cyclopropane,[31,49] as well as 1-lithio-1-methoxycyclopropane (eq 12) and 1-lithio-1-trimethylsilylcyclopropane.[49]

(18)

1-Lithio-1-phenylthiocyclopropane reacts with many electrophiles. In reactions where lithium phenylthiolate is formed (from cyclopropanone thioacetal or from 1,3-bis(phenylthio)propane), ***Copper(I) Iodide*** is used to scavenge the thiolate to improve yields of alkylated or hydroxyalkylated derivatives.[5,31]

Very high yields of β-hydroxyalkyl sulfides are obtained from saturated aldehydes and ketones,[1a,4,5,25-28,32,34,40,43,44,50] including ***Formaldehyde*** (80% yield)[26] and hindered or quite enolizable ketones such as tetramethylcyclohexanone (92% yield)[25,27] or trispiro[3.1.3.1.3.1]pentadecane-1,5,10-trione (54% yield) (eq 19).[44] The reaction occurs regioselectively on the carbonyl group of α,β-unsaturated aldehydes and ketones,[1a,25,27,32,37-39,45,51] including 2-hydroxymethylene ketones,[42] and proceeds stereoselectively with 4-*t*-butylcyclohexanone to produce almost exclusively the alcohol resulting from an equatorial attack (THF, 0 °C, 98% yield, 99:1 ratio of stereoisomers, eq 14).[28] With α-selenoaldehydes, (**2**) leads predominantly to the stereoisomer of β-hydoxyalkyl selenide predicted on the basis of Cram's rules.[41,52]

(19)

$R^1, R^2 = CH_2$ 60%
$R^1 = Me, R^2 = Et$ 40%

Alkylation of 1-phenylthiocyclopropyllithium takes place in good yield with primary alkyl bromides and iodides but not with secondary alkyl halides (eq 8).[12,31,46] With ***Benzyl Bromide***, however, halogen-metal exchange occurs, leading to bibenzyl and 1-bromocyclopropyl phenyl sulfide.[12] Allylation works successfully if copper(I) iodide (0.5 equiv) is present and the reaction is carried out at low temperature (eq 15).[47,53] (**2**) adds to epoxides to form 1-(β-hydroxy)cyclopropyl phenyl sulfides (eq 8).[12] Excellent regioselectivity of attack occurs at the less hindered primary carbon of 1,2-epoxybutane, and even with cyclohexene oxide a high yield of adduct is obtained.[12] Reaction with ***Chlorotrimethylsilane***, ***Iodine***, esters, or DMF and carbonic anhydride leads to 1-trimethylsilyl(phenylthio)cyclopropane (Me_3SiCl, 88% yield),[31,49] 1-iodo(phenylthio)cyclopropane (eq 12),[22] 1-alkoyl-1-(phenylthio)cyclopropanes (80% yield),[38,41] and 1-(phenylthio)cyclopropanecarboxylic acid (55% yield),[41] respectively.

Thus 1-phenylthiocyclopropylcarbinols are valuable precursors of cyclobutanones.[1a,26-28,32-40,42] The rearrangement takes place in the presence of an acid catalyst. The more general and vigorous conditions involve the use of ***Tin(IV) Chloride*** in methylene chloride (eq 14).[32] Protic acids with a nonnucleophilic anion, such as 48% aqueous ***Tetrafluoroboric Acid***, work nicely with β-hydroxy sulfides derived from sterically unhindered ketones, but increasing steric hindrance led to no reaction.[32] The reaction has also been performed with ***p-Toluenesulfonic Acid*** in wet benzene[32] or tetralin.[26] These conditions require heating and are particularly useful for the adducts derived from saturated aldehydes.[32] They have been used for the synthesis of the parent cyclobutanone[26] (70-120 °C in the presence of ***Mercury(II) Chloride*** as a thiol trap). The rearrangement is stereoselective.[28,32,33] For example, the β-hydroxyalkyl sulfide derived from 4-*t*-butylcyclohexanone shown in eq 14 leads selectively to the cyclobutanone arising from axial migration[1a,28,32] and allows the introduction of the substituted carbon-carbonyl bond on the sterically less crowded face. The stereochemical outcome of this process is complementary to the one which involves cyclopropylidenediphenylsulfurane[20] and introduces instead the carbon-carbonyl bond on the more sterically hindered face.[32]

1-Phenylthiocyclopropylcarbinols produce cyclobutanone enol thioethers on reaction with anhydrous *p*-toluenesulfonic acid

in refluxing benzene (eq 19) or more efficiently with the Burgess reagent ((carboxysulfamoyl)triethylammonium hydroxide inner salt methyl ester).[32] Alternatively, reaction of 1-phenylthiocyclopropylcarbinols derived from aldehydes with excess of thiophenol (5 equiv) in the presence of 48% hydrobromic acid-zinc bromide affords cyclobutanone phenylthio acetals (eq 15).[43] Their further reaction with copper triflate and Hünig's base produces very good yields of cyclobutanone enol thioethers[43] precursors of 2-(phenylthio)-1,3-butadienes (eq 15).[32,43]

1-Alkyl- and 1-allylcyclopropyl phenyl sulfides are efficiently converted to alkylidenecyclopropanes[46] and allylidenecyclopropanes (eqs 16 and 17),[47] respectively on methylation to the corresponding sulfonium salt followed by reaction with a base. The reaction is expected to occur via the intermediate formation of a sulfur ylide of the type described in eq 12.[46] Otherwise 1-alkylcyclopropyl phenyl sulfides afford[12] ethyl ketones on reaction with hydrobromic acid-acetic acid, and β-keto sulfides on reaction with mercury(II) chloride (see eq 8).

Related Reagents.

Cyclopropyldiphenylsulfonium Tetrafluoroborate; ***Cyclopropyllithium***; ***1-Lithio-1-methoxycyclopropane***.

Phenylthiomethyllithium

[13307-75-0] · C_7H_7LiS · Phenylthiomethyllithium · (MW 130.15)

(nucleophilic organolithium reagent useful for addition to ketones, aldehydes, esters; synthesis of alkenes, epoxides, cyclopentenones, allylic sulfides, γ-phenylthioenones, α-phenylthiofurans and butenolides, and (phenylthiomethyl)trimethylsilane)

Preparative Methods: by the treatment of methyl phenyl sulfide with ***n-Butyllithium*** in ether (reflux, 15 h),[1] or in THF containing 1 equiv of DABCO (eq 1, 0 °C, 45 min).[2]

Handling, Storage, and Precautions: is generated in situ, under anhydrous conditions, in an inert atmosphere, and used shortly after preparation; as *n*-BuLi is employed, the precautions for preparation and use would mirror those of *n*-BuLi and related reactive organometallic reagents.

Alkene Synthesis.

Phenylthiomethyllithium (**1**) is a versatile reagent for the preparation of alkenes from ketones, and is particularly useful when the carbonyl compound is susceptible to base-catalyzed epimerization.[3-5] Addition of (**1**) to ketones followed by aqueous quench gives rise to β-hydroxy sulfides (which are not generally isolated).[2] Conversion to a β-thioester is accomplished by successive treatment with butyllithium and an acylating agent (typically ***Benzoyl Chloride*** or ***Acetic Anhydride***).[6,7] Alternatively, the lithium alkoxide produced by the addition of (**1**) to the ketone can be trapped in situ with ***Benzoic Anhydride*** to afford the β-benzoyloxy sulfide.[6] ***Lithium Amide*** or ***Sodium Naphthalenide*** reduction affords exocyclic methylene compounds in good to high yields,[6,7] even in the case of hindered ketones (eq 2).[8]

(2)

Alternatively, in the case of β-benzoyloxy sulfides derived from ketones, the reduction to methylene compounds may be accomplished by the use of low-valent titanium compounds (prepared by treating pyridine solutions of ***Titanium(IV) Chloride*** with ***Zinc*** metal)[9] or with ***Titanium*** metal.[10] In a further extension, the reduction of the intermediate β-hydroxy sulfides formed from both ketones and aldehydes may be reduced with titanium tetrachloride-***Lithium Aluminum Hydride*** to provide the methylene compounds in high yields.[11]

Epoxide Synthesis.

Epoxides are produced when the intermediate β-hydroxy sulfides, from the addition reaction of (**1**), are alkylated (for example, with ***Triethyloxonium Tetrafluoroborate*** or its trimethyl analog) and treated with aqueous base (eq 3).[12a] The overall yields for the three-step process are high and compare favorably to the one-step methylene transfer accomplished by sulfur ylides, a reaction that is sometimes hindered by steric interference and proton abstraction. Vinyl epoxides can be prepared by the addition of (**1**) to an α,β-unsaturated aldehyde to give a vinylphenylthiomethylcarbinol, which is alkylated with triethyloxonium tetrafluoroborate, followed by base-catalyzed (***Sodium Hydride***) epoxide closure (eq 4).[12b]

(3)

Cyclopentenone Synthesis.

The reagent (**1**) has also found use in the synthesis of cyclopentenones. The addition of (**1**) to α-chloro-β,γ-unsaturated esters has been demonstrated to lead directly to 5-phenylthio-2-cyclopentenones (eq 5).[13]

Allylic Sulfides, γ-Phenylthio-α,β-unsaturated Ketones.

The reagent (**1**) adds smoothly to cyclic ketones (ring sizes 5-10, 12, 15) and the resultant tertiary alcohols can be readily dehydrated to furnish allylic sulfides (eq 6).[14] The addition of (**1**) to an α,β-unsaturated ketone affords the related tertiary allylic alcohol, which gives a γ-phenylthio-α,β-unsaturated ketone on treatment with ***Pyridinium Chlorochromate*** on silica gel and ultrasound (eq 7).[15]

Phenylthiofuran and Butenolide Synthesis.

The reagent (**1**) has been utilized for phenylthiofuran and butenolide formation in the synthesis of the sesquiterpene (±)-colorata-4(13),8-dienolide (**2**).[16] (**1**) was added to an α-butylthiomethylene ketone, to afford an α,β-unsaturated aldehyde after hydrolysis (eq 8). The hydrolysis reaction to provide the conjugated aldehyde required 4 weeks at 20 °C, in order to prevent double bond isomerization. Oxidation (***Sodium Periodate***) and treatment with acetic anhydride and heat led to the desired α-phenylthiofuran in 70% yield.

(8)

The conversion of the phenylthiofuran to the target butenolide was again complicated by long exposure times to acid and ***Mercury(II) Chloride*** (1 week) to avoid double bond isomerization and give the butenolide (**2**) in 60% yield (eq 9).

(9)

(**2**)

Phenylthiomethyltrimethylsilane.

(**1**), produced by the Gilman method,[1] readily reacts with ***Chlorotrimethylsilane*** to give ***(Phenylthiomethyl)trimethylsilane*** (eq 10).[17]

(10)

Related Reactions.

Nucleophilic phenylthiomethyl equivalents have been prepared from phenylthiomethyltrimethylsilane[18] and ***Chloromethyl Phenyl Sulfide***.[19] Phenylthiomethyltrimethylsilane can be treated with ***Tetra-n-butylammonium Fluoride*** (eq 11, path 1)[18a] or ***Potassium t-Butoxide*** (eq 11, path 2)[18b] to furnish species which will add to ketones. Phenylthiomethyltrimethylsilane has also seen use in the synthesis of aldehydes,[17] alcohols,[17] ketones,[20] and alkenes,[21] in conjugate additions to cycloalkenones,[21] and in the preparation of chloro(phenylthio)methyltrimethylsilane.[22] Phenylthiochloromethane produces a reactive organometallic species when treated with ***Samarium(II) Iodide*** and a ketone (eq 12).[19] These mild conditions permit the use of readily enolized ketones as substrates for phenylthiomethyl addition.

(11)

(12)

Methyl phenyl sulfide can be treated with 2.2 equiv of *n*-butyllithium-TMEDA to generate a dianion which can be efficiently reacted with a range of electrophiles (eq 13).[23] Attempts to alkylate the dianion sequentially with two different electrophiles have not been very successful.

1-Phenylthio-1-lithioethane is prepared from 1,1-bisphenylthioethane by reductive cleavage with lithium naphthalenide (eq 14).[17] The 1-phenylthio-1-lithioethane thus produced is then captured with chlorotrimethylsilane in 90% yield (eq 14).

Related Reagents.

Bis(phenylthio)methane; ***Dibromomethane-Zinc-Titanium(IV) Chloride***; ***S,S-Dimethyl-N-(p-toluenesulfonyl)sulfoximine***; ***2-Lithio-1,3-dithiane***; ***Methylenetriphenylphosphorane***; ***Phenylselenomethyllithium***.

(Phenylthiomethyl)trimethylsilane

[17873-08-4] · $C_{10}H_{16}SSi$ · (Phenylthiomethyl)trimethylsilane · (MW 196.42)

(lithio derivative is a one-carbon homologating agent leading to aldehydes via sila-Pummerer rearrangement,[1] vinyl sulfides via Peterson alkenation,[2] and vinylsilanes from silyl epoxides[3])

Physical Data: bp 158-159 °C/52 mmHg; d^{20} 0.967 g cm^{-3}; *n*20D 1.5390.

Solubility: sol most common organic solvents.

Form Supplied in: oil; commercially available.

Analysis of Reagent Purity: by GC or ^{1}H NMR analysis.

Preparative Methods: by reaction of ***Phenylthiomethyllithium*** with ***Chlorotrimethylsilane***.[4]

Purification: by distillation under reduced pressure.

Handling, Storage, and Precautions: irritant; foul smelling; use in a fume hood.

Formylation Reactions.

Metalation of the title reagent (**1**) with ***n-Butyllithium*** gives the fairly stable anion phenylthio(trimethylsilyl)methyllithium (**2**), which is a formyl anion equivalent as illustrated by the sequence in eq 1.[1] Anion (**2**) reacts with primary alkyl bromides and iodides to yield 1-phenylthio-1-trimethylsilylalkanes (**3**) in high yields. These intermediates are easily oxidized by ***m-Chloroperbenzoic Acid*** to the corresponding sulfoxides. Subsequent heating promotes a sila-Pummerer rearrangement[5] to produce aldehydes after hydrolysis.[1] Reagent (**1**) is superior to ***1,3-Dithiane*** for the synthesis of aldehydes from alkyl halides, in view of the greater ease of hydrolysis of (**3**). Application of this procedure to the synthesis of unsymmetrical ketones has also been reported.[6]

The ***Zinc Bromide*** catalyzed alkylation of enol silanes by α-halo-α-(phenylthio)methyltrimethylsilanes (eq 2) provides an efficient method for electrophilic formylation (i.e. an umpolung of the transformation in eq 1) which is useful for the synthesis of β-ketoaldehydes.[7] The sequence can also be diverted for the synthesis of β-trimethylsilylenones (eq 2).[8]

Phenylthiobis(trimethylsilyl)methane (**4**), prepared by the reaction of (**2**) with Me_3SiCl, serves as a synthetic equivalent of $LiCO_2Me$.[9] Metalation of (**4**) with BuLi in the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** gives phenylthiobis(trimethylsilyl)methyllithium (**5**); subsequent alkylation and electrochemical oxidation achieves chain homologation to form an ester (eq 3). Alternatively, alkylation of (**5**) with a terminal oxirane followed by

cycloelimination in situ generates 1-phenylthio-1-trimethylsilylcyclopropanes.[10] Anion (**2**) itself reacts with oxiranes to give adducts which can also be converted to 1-phenylthio-1-trimethylsilylcyclopropanes, but two intermediary steps are required to accomplish cycloelimination (eq 4).[11]

Synthesis of Vinyl Sulfides.[2]

Anion (**2**) adds to aldehydes, ketones, and enones, in the last-named case in either 1,2- or 1,4-manner depending on the reaction conditions.[12] In the case of 1,2-addition the β-hydroxysilane adduct usually cannot be isolated owing to rapid elimination (Peterson alkenation) to vinyl sulfides (eq 5), which can be hydrolyzed to the corresponding aldehydes.[2] The vinyl sulfides are not formed stereoselectively unless there are proximate bulky substituents.[13] Peterson alkenation products have also been observed in the reaction of (**2**) with amides, ureas, and carbonates.[14]

(Phenylthiomethyl)trimethylsilane

The reaction of (**2**) with esters provides α-phenylthio-α-trimethylsilyl ketones, which can be easily converted to α-phenylthio ketones (eq 6).[15] β-Hydroxy sulfides are obtained from the reaction of (**1**) with carbonyl compounds in the presence of a catalytic amount of fluoride ion (eq 7).[16]

(6)

(7)

Synthesis of Vinylsilanes.[3]

Lithiated reagent (**2**) reacts with α-trimethylsilyloxiranes to yield vinylsilanes (eq 8). The reaction involves nucleophilic opening of the oxirane ring by (**2**), followed by 1,2-elimination of a silyl and a phenylthio group.[3]

(8)

Vinylsilanes are also prepared from (**2**) as illustrated in eq 9.[17] Treatment of (**2**) with ***Bis(trimethylsilyl) Peroxide*** provides (**6**) which reacts with phosphonium ylides in the presence of ***Tetra-n-butylammonium Fluoride*** to give mixtures of vinylsilanes favoring the (*Z*)-isomer.

(9)

Other Reactions.

In addition to haloalkanes, carbonyl derivatives, and oxiranes, anion (**2**) reacts with a wide range of other electrophiles including ***N-Chlorosuccinimide***,[18] ***Chlorotrimethylsilane***,[8] Bu_3SnCl,[15] ***Diphenyl Disulfide***, and ***Benzenesulfenyl Chloride***,[15] and trialkylboranes.[19]

Related Reagents.

Methoxy(phenylthio)(trimethylsilyl)methane (**7**) is prepared by metalation-silylation of phenylthiomethyl methyl ether.[20] [Methoxy(phenylthio)(trimethylsilyl)methyl]lithium (**8**), prepared from (**7**) by metalation with ***s-Butyllithium*** in the presence of TMEDA, undergoes clean and efficient Peterson alkenation with aldehydes to give (*E*)-ketene-*O*,*S*-acetals stereoselectively, which can then be hydrolyzed to thioesters (eq 10).[21]

The selenium analog of (**2**) is prepared by deprotonation of (phenylselenomethyl)trimethylsilane with ***Lithium Diisopropylamide*** or ***Lithium 2,2,6,6-Tetramethylpiperidide*** (eq 11). The anion (**9**) thus formed can be alkylated in good yields, and the alkylated product can be oxidized to the corresponding selenoxide at low temperature, but selenoxide elimination leading to a vinylsilane competes with the sila-Pummerer rearrangement.[22,23]

See also ***2-Lithio-1,3-dithiane***, ***Phenylthiomethyllithium***, and ***Bis(phenylthio)methane***.

(Phenylthio)nitromethane[1]

[60595-16-6] · $C_7H_7NO_2S$ · (Phenylthio)nitromethane · (MW 169.22)

(precursor for 1-nitro-1-phenylthioalkenes,[2] furans,[3] bicyclic β-lactams,[4] and amino acids[5])

Alternate Name: nitro(phenylthio)methane

Physical Data: bp 85-95 °C/0.05 mmHg;[6] *n*23D 1.5785;[7] pK_a (DMSO) 11.9.[7]

Solubility: insol cold H_2O; sol CH_2Cl_2, benzene, THF.

Analysis of Reagent Purity: ^{1}H NMR: 5.45 (s, 2H) and 7.25-7.5 ppm (m, 5H).[6]

Preparative Method: most conveniently prepared by reaction of the sodium salt of ***Nitromethane*** with ***Benzenesulfenyl Chloride***.[6,8]

Handling, Storage, and Precautions: may be stored essentially unchanged in a freezer at -25 °C; unpleasant odor; best handled in a well-ventilated hood; any spillage may be cleaned up with commercial bleach.

Nitroalkene Synthesis.

Henry reaction of (phenylthio)nitromethane with aldehydes followed by dehydration has been used to prepare (*Z*)-1-nitro-1-phenylthioalkenes.[2-5] ***Potassium t-Butoxide***-catalyzed addition and dehydration via mesylation (eq 1), or direct condensation catalyzed by piperidinium acetate (eq 2),[9] are the methods of choice. Henry reaction can be also carried out by reaction of the nitroalkene dianion with aldehydes.[8,10,11] The adducts of cyclic ketones and (phenylthio)nitromethane undergo ring expansion to provide 2-(phenylthio)cycloalkanones on ***Aluminum Chloride***-mediated denitration.[11]

(2)

1-Nitro-1-phenylthioalkenes (**1**), on reaction with ***t-Butyl Hydroperoxide***, are converted into epoxides and these species react with nucleophiles (halide salts, ***Boron Trifluoride Etherate***, ***Trifluoroacetic Acid***, MsOH) to provide α-substituted phenylthio esters (eq 3).[9] Alternatively, Michael addition of nucleophiles (alkoxides, $Phth^-$, Ts^-, malonate) to 1-nitro-1-phenylthioalkenes and ozonolysis of the intermediate nitronate gave similar adducts (eq 4), including α-amino and α-hydroxy acid derivatives.[2]

(3)

(4)

(Phenylthio)nitromethane is useful in polyoxin synthesis.[5,12] A ribose nitroalkene (**2**), derived from (phenylthio)nitromethane and the corresponding aldehyde (93%), was found to react with opposite stereochemical biases with potassium trimethylsilanoate (eq 5) and ***Phthalimide*** (eq 6) followed by ozonolysis. The hydroxy acid (eq 5) was further transformed into polyoxin C.

(5)

(6)

Synthesis of Heterocycles.

1-Nitro-1-phenylthiopropene is an excellent reagent for the synthesis of furanoterpenoids.[3,13] Condensation with β-diketones and sulfoxide elimination gave ligularone and isoligularone, respectively (eq 7). The methods were also used to prepare curzerenone, epicurzerenone, and pyrocurzerenone.

(7)

Nitroalkenes derived from β-lactam aldehydes may be converted into diverse bicyclic β-lactams via intramolecular Michael addition and ozonolysis (eq 8). The method is appropriate for penam, carbapenam, carbacephem, and oxapenam arrays.[4] In some cases, (benzyloxy)nitromethane is a superior reagent.[14] This Michael addition-oxidation strategy is also useful for the synthesis of tetrahydrofuran (eq 9) and -pyran systems.[15]

(8)

(9)

(Phenylthio)nitromethane has been dehydrated and the resultant phenylthionitrile oxide trapped with alkenes to provide isoxazolines (eq 10).[16] These compounds are convenient precursors for 3-(phenylsulfonyl)isoxazolines (see ***Phenylsulfonylnitromethane***) and β-hydroxy ketones. The cycloaddition-ring contraction of ynamines with 1-nitro-1-phenylthioalkenes has been used to prepare cyclic nitrones (eq 11).[17]

(10)

(11)

The Michael addition of (phenylthio)nitromethane to a steroidal enone and nitro displacement (eq 12) has been employed in the stereoselective 16-methylation of corticosteroids.[18]

N-Phenylthiophthalimide[1]

[14204-27-4] · $C_{14}H_9NO_2S$ · *N*-Phenylthiophthalimide · (MW 255.31)

(mild sulfenylating reagent)

Physical Data: mp 160-161 °C; colorless solid.

Preparative Method: by reaction of ***Benzenesulfenyl Chloride*** with ***Phthalimide*** in the presence of ***Triethylamine***.[1]

General Discussion.

N-Phenylthiophthalimide has been shown to be a mild sulfenylating reagent that is useful for a range of synthetic applications. This reagent reacts with amines[2] and thiols[3] to give the corresponding sulfenyl amines and disulfides respectively (eq 1).

Upon reaction with Grignard reagents or organolithium compounds, mixed sulfides are formed (eq 2).[4]

(2)

M = MgBr, Li

Activated carbonyl compounds can be cleanly bis-sulfenylated by this reagent in the presence of Et_3N (eq 3).[5]

(3)

R = CO_2Et, 94%; MeCO, 93%

Bis-sulfenylation of γ-butyrolactone, as well as of cyclic ketones, has been achieved with this reagent via the corresponding lithium enolates.[6] This reaction has been utilized in an efficient synthesis of 3-substituted 2-buten-4-olides (eq 4).

(Phenylthio)trimethylsilane

$PhSSiMe_3$

[4551-15-9] · $C_9H_{14}SSi$ · (Phenylthio)trimethylsilane · (MW 182.39)

(selective carbonyl protection;[1,2] preparation of thioesters;[3] cleavage of ethers[4])

Physical Data: bp 93-99 °C/12 mmHg; *d* 0.967 g cm^{-3}.

Solubility: sol organic solvents; incompatible with strong acids and strong oxidizing agents.

Preparative Method: commercially available, but can be prepared.[5]

Handling, Storage, and Precautions: moisture sensitive; use in a fume hood.

Thioacetalization.

In the presence of an acid catalyst (***Zinc Iodide***, ***Aluminum Chloride***, anhyd ***Hydrogen Chloride***, ***Titanium(IV) Chloride***), (phenylthio)trimethylsilane reacts with aldehydes and ketones at rt or below to form the corresponding thioacetals (eqs 1 and 2).[1,2,6] With α,β-unsaturated aldehydes and ketones, initiation of the reaction with ***Potassium Cyanide-18-Crown-6*** leads to exclusive formation of the 1,4-addition product (eq 3).[1]

(1)

(2)

(3)

Cleavage of Ethers.

Methyl and benzyl ethers can be readily cleaved under mild conditions (eq 4).[4] The reagent also effects the stepwise and selective dealkylation of phosphotriesters.[7]

(4)

Miscellaneous Transformations.

(Phenylthio)trimethylsilane effects the direct conversion of glycosides into 1-thioglycosides,[8,9] esters into thioesters,[3] epoxides into β-(trimethylsilyloxy) thioethers and β-hydroxy ethers (eq 5),[10] sulfoxides into sulfides,[11] chalcone-derived acetals into α-alkoxy-α,β-unsaturated nitriles,[12] and silyl enol ethers into vinyl sulfides (eq 6).[13] The $AlCl_3$-catalyzed reaction of (phenylthio)trimethylsilane with electrophilic cyclopropanes leads to the formation of ring-opened products (eq 7).[14]

1-(Phenylthio)-1-(trimethylsilyl)cyclopropane[1]

[74379-74-1] · $C_{12}H_{18}SSi$ · 1-(Phenylthio)-1-(trimethylsilyl)cyclopropane · (MW 222.46)

(Peterson alkenation;[1] cyclobutane synthesis[2] and cyclopentane[3] annulation via 1-lithio-1-(trimethylsilyl)cyclopropane)

Physical Data: bp 64 °C/0.1 mmHg; *d* 0.991 g cm^{-3}.

Form Supplied in: liquid; commercially available.

Analysis of Reagent Purity: FT-IR;[1c] also by NMR, IR, and mass spectrometry.[1b]

Preparative Methods: by reductive lithiation of 1,1-bis(phenylthio)cyclopropane followed by trimethylsilylation with ***Chlorotrimethylsilane***.[4,5]

Purification: by distillation.[1b]

Handling, Storage, and Precautions: use in a fume hood.

Peterson Alkenation.

1-Lithio-1-(trimethylsilyl)cyclopropane, derived from 1-phenylthio-1-(trimethylsilyl)cyclopropane by reductive lithiation with ***Lithium 1-(Dimethylamino)naphthalenide*** (LDMAN), condenses with aldehydes to give carbinols which are converted to alkylidenecyclopropanes under Peterson alkenation conditions (eq 1).[1]

Synthesis of Cyclobutanes.

m-Chloroperbenzoic Acid oxidation of 1-phenylthio-1-(trimethylsilyl)cyclopropane furnishes a sulfoxide which could undergo thermal sila-Pummerer rearrangement to give the masked cyclopropanone 1-(phenylthio)-1-trimethylsiloxy)cyclopropane (eq 2).[2a]

Alternative treatment of the sulfoxide with aldehydes in the presence of ***Tetra-n-butylammonium Fluoride*** gives the phenylsulfinylcarbinol and thence the phenylthiocarbinol following reduction. The two last-named compounds are intermediates in the synthesis of cyclobutanones and cyclobutenes, respectively (eqs 3 and 4).[2b,2c,2e]

(4)

Cyclopentane Annulation.

Condensation of 1-lithio-1-(trimethylsilyl)cyclopropane with ketones gives vinylcyclopropane intermediates, which upon pyrolysis undergo vinylcyclopropane rearrangement to give annulated cyclopentene derivatives (eq 5).[3]

1-Phenylthio-1-trimethylsilylethylene

[62762-20-3] · $C_{11}H_{16}SSi$ · 1-Phenylthio-1-trimethylsilylethylene · (MW 208.43)

(a reagent for C_2 homologation and a Michael acceptor)

Physical Data: colorless liquid; bp 130-134 °C/15 mmHg;[1] IR,[1,2] ^{1}H NMR,[1] and MS data[1] are available.

Solubility: very sol most organic solvents.

Preparative Methods: by lithiation of ***Phenyl Vinyl Sulfide*** with ***Lithium Diisopropylamide***, followed by silylation,[1,2] or the base-induced elimination of 2-chloro-1-trimethylsilyl-1-phenylthioethane,[2] or the lithiation of ethyl phenyl sulfoxide with LDA followed by silylation,[3] or the Pd-catalyzed coupling reactions of trimethylstannyl phenyl sulfide with 1-bromo-1-trimethylsilylethylene.[4]

Handling, Storage, and Precautions: use in a fume hood.

Addition of Organolithiums.

Organolithiums undergo smooth additions to 1-phenylthio-1-trimethylsilylethylene at low temperature. The resulting adduct anions are stabilized by two anion-stabilizing substituents, phenylthio and trimethylsilyl. They can be quenched with a variety of electrophiles. Sulfines are formed by treatment with ***Sulfur Dioxide*** (eq 1),[5] phenyl 1-silylalkyl sulfides by hydrolytic quenching with NH_4Cl,[1] alkanals by oxidation with ***m-Chloroperbenzoic Acid*** and subsequent rearrangement reaction (eq 2),[6,7] phenyl silylalkyl sulfides by alkylation with a variety of alkylating agents,[8] and vinyl sulfides by condensation with aldehydes.[8]

(1)

Cyclopentenone Synthesis.

When activated with Lewis acid catalysts or silver ion, 1-phenylthio-1-trimethylsilylethylene reacts with α,β-unsaturated acid chlorides at a low temperature in CH_2Cl_2.[2,9] The cation intermediates undergo a silicon-directed Nazarov cyclization to give 3-phenylthio-substituted cyclopentenone derivatives (eq 3). The phenylthio moiety at the β-position of cyclopentenones can be effectively utilized for the introduction of an alkyl substituent by addition/elimination.

Cyclopropanation.

Although the adduct anions formed by addition of organolithiums to 1-phenylthio-1-trimethylsilylethylene have high stability at low temperature, at higher temperatures (0 °C) in THF the anions may react with another molecule of 1-phenylthio-1-trimethylsilylethylene. The final anions undergo intramolecular alkylation under the reaction conditions to give cyclopropane derivatives in high yields (eq 4).[10] Employment of sulfur-stabilized anions as donor molecules is even more effective (eq 5).[11]

Cyclohexanone Annulation.

The benzyllithium intermediates formed by metalation of *o*-toluamide derivatives with LDA at -78 °C react with 1-trimethylsilyl-1-phenylthioethylene. The resulting adduct anions undergo intramolecular cyclization on to the adjacent amide moiety to provide a convenient route for cyclohexanone annulation (eq 6).[12]

Analogous Reagents.

1-Phenylsulfinyl-1-trimethylsilylethylene (**1**)[2] and 1-phenylsulfonyl-1-trimethylsilylethylene (**2**) are used as synthetic analogs of 1-phenylthio-1-trimethylsilylethylene. The sulfoxide (**1**) is an electron-deficient alkene so it is a highly reactive dienophile in Diels-Alder reactions. The cycloadduct with ***Cyclopentadiene*** undergoes the sila-Pummerer rearrangement to a thioacetal, which is then hydrolyzed to the ketone (eq 7).[6] By this sequence, (**1**) becomes a useful

synthetic equivalent of ketene. The sulfone (**2**) works as an excellent acceptor molecule for the Michael addition reactions using the aryllithium donors generated by the directed lithiation of *o*-chloroarenes. The adducts then undergo intramolecular cyclizations by the aid of metal amides to offer an excellent entry to benzocyclobutene derivatives.[13]

2-(Phenylthio)-2-(trimethylsilyl)propane[1]

[89656-96-2] · $C_{12}H_{20}SSi$ · 2-(Phenylthio)-2-(trimethylsilyl)propane · (MW 224.48)

(Peterson alkenation[1] and preparation of ketones via 2-lithio-2-(trimethylsilyl)propane[2,3])

Physical Data: bp 70-80 °C/0.6 mmHg.

Preparative Method: by reductive lithiation of 2,2-bis(phenylthio)propane followed by trimethylsilylation with ***Chlorotrimethylsilane***.[2,3]

Purification: by flash chromatography and by Kugelrohr distillation.[3]

Handling, Storage, and Precautions: use in a fume hood.

Synthesis of Dienes via Peterson Alkenation.

Reductive lithiation of 2-(phenylthio)-2-(trimethylsilyl)propane with ***Lithium 1-(Dimethylamino)naphthalenide*** (LDMAN) furnishes 2-lithio-2-(trimethylsilyl)propane, which is an intermediate for Peterson alkenation. The specific example in eq 1 features silicon-directed diene synthesis.[1]

Synthesis of Ketones.

m-Chloroperbenzoic Acid oxidizes 2-(phenylthio)-2-(trimethylsilyl)propane to the sulfone, which is then converted to the ketone via sila-Pummerer rearrangement (eq 2).[3]

Se-Phenyl *p*-Tolueneselenosulfonate[1]

[68819-94-3] · $C_{13}H_{12}O_2SSe$ · *Se*-Phenyl *p*-Tolueneselenosulfonate · (MW 311.28)

(undergoes 1,2-additions to alkenes, allenes, dienes, and alkynes, affording various unsaturated sulfones after selenoxide elimination or sigmatropic rearrangement[1])

Physical Data: mp 79.5-80 °C.

Solubility: sol chloroform, dichloromethane, THF, benzene.

Form Supplied in: yellow, crystalline, odorless solid.

Preparative Methods: add ***p-Toluenesulfonylhydrazide*** in methanol dropwise to an equimolar amount of ***Benzeneseleninic Acid*** in methanol at 0 °C; cool at -5 °C overnight, filter the highly pure crystalline selenosulfonate (96% yield);[2] alternatively, use 2 equiv ***p-Toluenesulfinic Acid*** instead of *p*-toluenesulfonylhydrazide;[3] *Se*-phenyl benzeneselenosulfonate is prepared in the same way and can be employed similarly for most purposes.

Purification: recrystallization from methanol.

Handling, Storage, and Precautions: routine handling is possible; for prolonged storage, keep in the dark at 0 °C; probably toxic. Use in a fume hood.

Selenosulfonation of Alkenes, Allenes, and Dienes.

The selenosulfonate adds stereospecifically (*anti*) and regioselectively (Markovnikov) to alkenes in the presence of ***Boron Trifluoride Etherate*** to afford 1,2-adducts (eq 1).[4] The addition can also be effected by a nonstereospecific radical process, initiated thermally in the presence of ***Azobisisobutyronitrile*** (AIBN), or photochemically, to give anti-Markovnikov products (eq 2).[3,4] These processes are known as selenosulfonations.[4] Selenoxide *syn* elimination of the adducts can be effected with ***m-Chloroperbenzoic Acid*** (*m*-CPBA) or ***Hydrogen Peroxide***, and affords high yields of the corresponding vinyl sulfones.

Allenes undergo radical selenosulfonation with regioselective incorporation of the sulfonyl moiety at the central carbon atom, producing 2-sulfonyl allylic alcohols after oxidation and [2,3]-sigmatropic rearrangement (eq 3).[5] Conjugated dienes react with the selenosulfonate in the presence of Lewis acids to afford chiefly the corresponding 1,2-adducts, in turn producing 2-sulfonyl-1,3-dienes after selenoxide elimination (eq 4),[4,6] while 1,6-dienes are converted into cyclopentanes by radical cyclization.[7]

Selenosulfonation of Alkynes.

The radical selenosulfonations of alkynes proceed in a stereo- and regioselective manner to give the products of *anti* addition and anti-Markovnikov orientation in generally high yield.[8] Subsequent selenoxide eliminations produce alkynic sulfones from terminal alkynes (eq 5) and allenic sulfones from internal ones (eq 6). Moreover, the initial adducts can be alkylated in the α-position and isomerized to the corresponding allylic sulfones under base-catalyzed conditions, thereby also providing access to allenic sulfones from terminal alkynes (eq 7).[9] The adducts or their selenoxides also react with various nucleophiles by addition-elimination or elimination-addition processes to give the products of overall substitution of the selenium residue (eq 8). Possible nucleophiles include organocuprates, alcohols, amines, cyanide, active methylene compounds, dithianes, and propargylic anions.[8a,10] When such reactions are employed in conjunction with reductive desulfonylation, the overall transformation renders alkynes the synthetic equivalents of vinyl cations.

Enynes with terminal alkyne moieties cleanly afford the products of 1,2-addition to the triple bond (eq 9), but more highly substituted derivatives and those containing terminal alkene groups give more complex mixtures containing the products of addition to the double bond, as well as 1,4-adducts.[11] Products such as the example in eq 9 smoothly generate allenic alcohols after oxidation and [2,3]-sigmatropic rearrangement. ***1,4-Dichloro-2-butyne*** can be employed as an enyne equivalent, since reductive dehalogenation generates an additional unit of unsaturation. The resulting 2,3-adduct can be used to prepare 3-substituted 2-sulfonyl-1,3-dienes,[11] as shown in eq 10.

(9)

(10)

Selenosulfonation of Unsaturated Cyclopropanes.

The radical selenosulfonation of vinylcyclopropanes is accompanied by ring-opening to give 1,5-addition products that afford 1-sulfonyl-2,4-dienes by selenoxide elimination (eq 11).[12] Similar ring-opening is observed in cyclopropylidenes, whereas cyclopropylacetylene undergoes mainly 1,2-addition and provides the corresponding alkynic sulfone after selenoxide elimination (eq 12).[12]

Related Reagents.

Benzeneselenenyl Bromide; ***Benzeneselenenyl Chloride***; ***Benzeneselenenyl Trifluoromethanesulfonate***; ***Diphenyl Diselenide***; ***N-Phenylselenophthalimide***.

4-Phenyl-1,2,4-triazoline-3,5-dione[1]

[4233-33-4] · $C_8H_5N_3O_2$ · 4-Phenyl-1,2,4-triazoline-3,5-dione · (MW 175.16)

(highly reactive dienophile and enophile)

Alternate Names: PTAD; *N*-phenyl-1,2,4-triazoline-3,5-dione.

Physical Data: mp 179 °C (dec).[2]

Form Supplied in: PTAD and 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) *[13274-43-6]*) are widely available commercially.

Preparative Methods: there are several reported preparations,[2-9] particularly for the in situ preparation.

Handling, Storage, and Precautions: normal precautions against exposure to moisture and air; reacts with alcohols and water.

Diels-Alder Cycloaddition Reactions.

4-Substituted 1,2,4-triazoline-3,5-diones (e.g. PTAD and MTAD) are exceptionally reactive dienophiles and are more reactive than good dienophiles such as ***Maleic Anhydride***, ***N-Phenylmaleimide***, ***Diethyl Azodicarboxylate***, and ***Dimethyl Acetylenedicarboxylate***. For example (eq 1), PTAD reacts rapidly with ***Cyclopentadiene*** without a catalyst at -78 °C and with ***1,3-Butadiene*** at -50 °C.[10-12]

(1)

Given the facility with which PTAD undergoes [4 + 2] cycloaddition, mechanistic aspects of its reaction have been extensively studied,[13,14] and PTAD has become the classic reagent for probing the reactivity of weak Diels-Alder dienes. For example (eq 2), ***1,3,5-Cycloheptatriene*** reacts via its norcaradiene isomer to afford the PTAD [4 + 2] cycloadduct.[15-17] Cyclooctatetraene,[18] styrenes,[19] and 2-vinylindoles[20] also undergo [4 + 2] cycloaddition with PTAD.

(2)

The synthetic utility of PTAD [4 + 2] cycloadducts has been relatively modest. The cycloadducts have been used in the synthesis of certain piperazic acids.[21] The PTAD group can be removed from the cycloadduct by treatment with ***Lithium Aluminum Hydride***,[22] ***Potassium Carbonate*** in DMSO,[23] refluxing ***1,1,3,3-Tetramethylguanidine***,[24] and ***Potassium Hydroxide*** in 95% ethanol.[9] Thus PTAD can be considered as a protecting group for 1,3-dienes. For example (eq 3), Barton and co-workers[9] reported that ergosterol reacts with PTAD in near-quantitative yield and the diene can be regenerated from the cycloadduct by treatment with 2.1 N KOH in 95% ethanol (1.5 h, 65 °C, 98%).

(3)

PTAD cycloadducts can be converted to the corresponding azoalkanes via hydrolysis and subsequent oxidation, and in

some cases this offers advantages over the use of diethyl azodicarboxylate. For example, Adam and co-workers[25] reported the preparation of the bicyclic azoalkane shown in eq 4 in good yield from the PTAD cycloadduct. More commonly PTAD [4 + 2] cycloadducts have found use as a tool for structure elucidation via classical chemical reactivity,[26,27] crystallographic,[19,28-30] or mass spectral analysis.[31,32]

(4)

Ene Reactions.

PTAD and other 4-substituted 1,2,4-triazoline-3,5-diones are exceptionally reactive enophiles, PTAD reportedly being some 10^4 times more reactive than diethyl azodicarboxylate in the reaction with cyclohexene (eq 5).[33,34] The ene reactions of PTAD with alkenes[35-39] and enones[40,41] have been the subject of several mechanistic investigations.

(5)

PTAD reacts with β-diketones and β-keto esters to afford novel 1:1 and 2:1 adducts, perhaps via an ene pathway involving the enol form of the β-dicarbonyl compound. For example (eq 6), PTAD reacts with ***2,4-Pentanedione*** to give the 2:1 adduct in 95% yield.[42]

(6)

The reactions of allylsilanes,[43-45] -germanes,[45] and -stannanes[46] with PTAD partition between ene and metallo-ene pathways. For example, the allylsilane[43] in eq 7 undergoes ene reaction with PTAD to afford the adduct in 95% yield, while the allylstannane[46] in eq 8 undergoes predominantly metallo-ene reaction with PTAD. Silyl enol ethers and PTAD condense with *O*- to *N*-silyl transfer to afford α-amino ketone derivatives.[47] PTAD can participate in the relatively rare acyl-ene reaction.[48]

(7)

(8)

Miscellaneous Reactions.

PTAD has been used as an efficient trap for certain reactive intermediates, including radical species[49] and disilirane.[50] PTAD can effect the oxidation of certain alcohols[51] and sulfides[52] and MTAD has been employed for the mild oxidation of a hydrazine to the corresponding diazene.[52b] PTAD reacts with electron-rich alkenes or aromatic rings to give dipolar intermediates,[53-55] and with ***Ethyl Diazoacetate*** to afford the unusual cycloadduct shown in eq 9.[56,57]

(9)

PTAD undergoes [2 + 2] cycloaddition with ***Diphenylketene***[58] and certain alkenes.[59,60] Strained ring systems often undergo unusual cycloaddition modes with PTAD. For example, the strained bicycloalkene in eq 10 affords the rearranged urazole in 95% yield,[61,62] and the alkenylidenecyclopropane shown in eq 11 affords the bicyclic structure.[63,64]

Phenyl(tribromomethyl)mercury[1]

$PhHgCBr_3$

[3294-60-8] · $C_7H_5Br_3Hg$ · Phenyl(tribromomethyl)mercury · (MW 529.41)

(precursor for the generation of dibromocarbene under neutral conditions)

Physical Data: mp 119-120 °C (dec).

Form Supplied in: commercially available.

Preparative Method: readily prepared from ***Phenylmercury(II) Chloride*** and ***Bromoform*** using ***Potassium t-Butoxide*** in THF.[2]

Handling, Storage, and Precautions: highly toxic; should be handled in an efficient fume cupboard with caution. Best stored as a solid below 5 °C.

General Discussion.

Phenyl(tribromomethyl)mercury is a source of dibromocarbene and as such has been employed in cyclopropanation and insertion reactions.[1] The carbene is generated by gently heating phenyl(tribromomethyl)mercury in a hydrocarbon solvent (often benzene).[3] The mild reaction conditions make this a good method for the generation of dibromocarbene under neutral conditions.

The most widespread application of phenyl(tribromomethyl)mercury has been in the dibromocyclopropanation of alkenes. The mechanism of this and related reactions has been studied in some detail and it has been proposed that they proceed via a free carbene intermediate.[4] The reagent has proven particularly useful for the dibromocyclopropanation of base-sensitive systems and of relatively unreactive alkenes.[1] For example, vinyl chlorides[5] and monosubstituted alkenes[6] can be successfully transformed to the corresponding cyclopropanes using this methodology (eqs 1 and 2). Cyclopropane (**1**) was produced in only 7% yield using a more conventional method ($HCBr_3$/*t*-BuOK) to generate the dibromocarbene.

(1)

(2)

This method for preparing cyclopropanes is highly chemoselective and tolerates a wide range of functional groups. Notable exceptions are alcohols, amines, and carboxylic acids, which undergo competitive insertion reactions.[1] The mildness of this reagent is well illustrated by the conversion of tricyclic ketone (**2**) into (**3**) in near quantitative yield (eq 3).[7,8] This reaction is also stereospecific, with attack of the carbene occurring on the least hindered side of the double bond.

(2) (3)

Systems containing several double bonds can be regioselectively cyclopropanated at the most nucleophilic position. For example, treatment of costunolide (**4**) with phenyl(tribromomethyl)mercury in refluxing benzene produces (**5**) as the sole carbene addition product (eq 4).[9] It has been speculated that the Lewis acidity of the organomercury reagent is responsible for the competitive formation of the undesired cyclocostunolide (**6**).

(4)

(5) 34% (6) 57% (4)

Phenyl(bromodichloromethyl)mercury has been prepared in a fashion similar to phenyl(tribromomethyl)mercury.[2] Thermal decomposition of this reagent occurs via loss of phenylmercury(II) bromide, producing dichlorocarbene as the only carbene intermediate.[10] Phenyl(bromodichloromethyl)mercury has been utilized in the dichlorocyclopropanation of unreactive[11] and base-sensitive alkenes (eqs 5 and 6).[12] Dichloromethyl esters can readily be prepared from the corresponding carboxylic acids using this reagent by insertion of the carbene into the OH bond.[13]

Phenyl(trichloromethyl)mercury[1]

$PhHgCCl_3$

[3294-57-3] · $C_7H_5Cl_3Hg$ · Phenyl(trichloromethyl)mercury · (MW 396.06)

(transfers **:**CCl_2 to many unsaturated systems, to heteroatoms, and to several σ-bonds)

Physical Data: mp 117-118 °C.

Solubility: sol ether, benzene, chloroform.

Form Supplied in: colorless solid; commercially available.

Preparative Methods: prepared from PhHgBr either by reaction with ***Potassium t-Butoxide-Chloroform*** in benzene at 10 °C in 66% yield,[2] or by treatment with ***Sodium Methoxide-Ethyl Trichloroacetate*** in 62% yield.[3] ***Phenylmercury(II) Chloride*** furnishes $PhHgCCl_3$ by reaction with ***Sodium Trichloroacetate*** in refluxing DME (65%).[4] A two-phase approach from PhHgCl and $CHCl_3$ using aqueous ***Sodium Hydroxide-Potassium Fluoride*** and small amounts of ***Benzyltriethylammonium Chloride*** furnishes $PhHgCCl_3$ in 72% yield.[5]

Purification: recrystallization from chloroform.

Handling, Storage, and Precautions: flame-dried glassware and an atmosphere of dry nitrogen are used for the reactions. Organomercury(II) compounds should be carefully handled and skin contact and inhalation should be particularly avoided. All reactions must be conducted in a well-ventilated fume hood. The reagent is light sensitive and should be stored under nitrogen at 4 °C.

Cyclopropanation of Alkenes.

A wide and representative set of alkenes react with $PhHgCCl_3$ to afford *gem*-dihalocyclopropanes in good yield (eq 1).[6] Reactions are carried out under nitrogen, using dry benzene as solvent, and can be easily monitored by TLC analysis. When all the starting mercurial has been consumed, PhHgCl is filtered off, the solvent and the excess alkene are removed in vacuo, and the resulting cyclopropanes are generally purified by distillation. The simplicity of product isolation represents an important synthetic advantage of this procedure.

A distinctive feature of $PhHgCCl_3$ as a cyclopropanating reagent is that it reacts with alkenes that are electron-poor (eq 2).[6] In contrast, attempts to cyclopropanate tetrachloroethylene using *t*-BuOK-$CHCl_3$ or thermal decomposition of Cl_3CCO_2Na give only modest (less than 10%) yields of hexachlorocyclopropane.[7]

$PhHgCCl_3$ competes well in several aspects with $PhHgCCl_2Br$ as a **:**CCl_2 transfer reagent for *gem*-dichlorocyclopropanation of alkenes; in particular, the former is a cheaper reagent and is more easily prepared. Conversely, the latter behaves as a milder source of **:**CCl_2, requiring shorter reaction times that enhance its synthetic potential.[6]

A simple modification of the experimental protocol, involving addition of ***Sodium Iodide***, has been developed. It decreases either the reaction time or the reaction temperature of the cyclopropanation with respect to that required when using α-haloorganomercurials.[8] Following this procedure, *trans*-stilbene smoothly undergoes cyclopropanation in high yield (eq 3).[9]

Using the above-mentioned conditions, cyclohexene is cyclopropanated (3 h, 85 °C) in 91% yield, while the cyclopropane derivative is formed in only 15% yield in the absence of NaI. Interestingly, the NaI method allows cyclopropanation by $PhHgCCl_3$ to take place at rt (eq 4).[9]

The activating effect of added NaI has been interpreted in terms of iodide attack at mercury and concomitant displacement of $^{-}CCl_3$, which generates in turn the dihalocarbene species ($^{-}CX_3$ -> **:**CX_2 + X^{-}). Consistent with that assumption, the reaction of NaI with equimolecular amounts of $PhHgCCl_3$ in dry acetone at 25 °C yields products that arise from ketone trapping by CCl_3^{-}.[9] The NaI-based procedure has some limitations. It reacts sluggishly with alkenes like tetrachloroethylene, reputed to be quite unreactive towards **:**CCl_2. Also, in good agreement with the electrophilic nature of the intermediate, the observed trend of alkene reactivity in this process ($R_2C{=}CR_2$ > $R_2C{=}CHR$ > $R_2C{=}CH_2$ > $RCH{=}CHR$ > $RCH{=}CH_2$)[9] matches well with that observed for the reactivity of carbenes generated by thermal treatment of Cl_3CCO_2Na in DME.

A major advantage of $PhHgCCl_3$ in *gem*-dichlorocyclopropanation reactions is realized when dealing with base-sensitive alkenes. In these cases, conventional carbene generation by treatment of chloroform with strong bases does not afford significant cyclopropane formation.[6] Many examples are known, and several synthetic applications have been reported. For example, 2-vinyl-4,4,6,6-tetramethyl-1,3,2-dioxaborinane is cleanly cyclopropanated with $PhHgCCl_3$ (eq 5);[10] cyclopropanation of this compound through thermal decomposition of Cl_3CCO_2Na as a source of **:**CCl_2 gives the desired cyclopropane in only 4% yield.[10]

Diketene is also smoothly *gem*-dichlorocyclopropanated by $PhHgCCl_3$ (eq 6).[11] Interestingly, further reactions on the resulting dichlorocyclopropanespirolactone do not induce opening of the three-membered ring, in contrast with the behavior of the cyclopropanation product obtained by reaction of diketene with α-diazo ketones.[11]

Vinyl Acetate, a base-sensitive compound that cannot be cyclopropanated by traditional methods, reacts readily with trihalomercurial reagents,[6] forming *gem*-dichlorocyclopropanes which are useful synthons leading to pyrazole rings (eq 7).[12]

(7)

In this respect, if the size of the cycloalkenyl acetate is reduced then the yield of metacyclophane goes down, and the 1,2-function becomes significant. Treatment of cyclohexenyl acetate with $PhHgCCl_3$ and further reaction of the resulting *gem*-dichlorocyclopropane with ***Hydrazine*** yields exclusively 4,5,6,7-tetrahydroindazole (1,2-ring fusion) in 40% yield.[13] 2-Aminopyrimidines are also accessible by treating the α,α-dichlorocyclopropyl acetates with ***Guanidine*** (eq 8).[14]

(8)

Similarly, the enol acetate function of steroids reacts with $PhHgCCl_3$ to give the corresponding cyclopropane derivatives; these are useful compounds for furnishing new skeletal rearrangements through ring-expansion reactions in basic media (eq 9).[15]

(9)

Depending on the strain of the system, ring-opening processes take place spontaneously under the reaction conditions,

as illustrated in eq 10.[16]

(10)

Carbene transfer from $PhHgCCl_3$ to 5-enyl acetate steroids occurs from the less-hindered side, the so-called α-face.[17] Thus the stereochemical outcome is generally opposite to that observed when using the Simmons-Smith procedure, suggesting that precoordination of the reagent does not occur.[17]

The cyclopropane derived from norbornene and $PhHgCCl_3$ also undergoes spontaneous ring expansion under the reaction conditions, affording 3,4-dichlorobicyclo[3.2.1]oct-2-ene.[18] This sequence, cyclopropanation/thermal ring expansion, has been successfully applied to cyclophane synthesis by starting from substituted indenes[19] and indoles.[20] Recently, cyclopropanation of alkenes has been used for the preparation of 1*H*-cyclopropa[*a*]naphthalene in a multistep sequence (eq 11).[21]

(11)

In short, the merit of $PhHgCCl_3$ as a **:**CCl_2 transfer reagent to cyclopropanate alkenes is derived from experimental facts; namely, the carbene is generated under neutral conditions at moderate reaction temperatures. The absence of side reactions clearly underlines the aforementioned comments. The accepted mechanism for the thermally induced cyclopropanation of alkenes with $PhHgCCl_3$ involves carbene generation from the α-halo organomercurial in the rate limiting step, followed by fast trapping of **:**CCl_2 by the alkene. The body of knowledge derived from the above

described reactions supports this assumption. Of special relevance in this context is the easy cyclopropanation of vinyl acetates that clearly rules out participation of the trichloromethyl anion; in fact, all attempts to cyclopropanate this base-sensitive alkene using *t*-BuOK-$CHCl_3$ as carbene source were unsuccessful. Indirect evidence is provided by kinetic studies of related processes using $PhHgCCl_2Br$ as the carbene precursor.[22] Further support for the proposed mechanism is obtained from gas-phase pyrolysis studies on $PhHgCCl_3$,[23] and subsequent characterization of the thermally generated carbene by matrix isolation techniques.[24]

Reaction with Methoxynaphthalene.

$PhHgCCl_3$ adds to the C-3-C-4 double bond of 1-methoxynaphthalene to give, after ring expansion under the reaction conditions, 5-chloro-2,3-benzotropone (eq 12),[25] a structure which was initially misassigned.[25a]

(12)

Reaction with Diiodoacetylene.

The addition of *gem*-dichlorocarbene (generated from $PhHgCCl_2Br$) to different alkynes has been described.[26] On this ground, some of the products of the reaction mixture obtained from $PhHgCCl_3$ and IC&tbond;CI were mechanistically interpreted to arise from initial addition of dichlorocarbene to the diiodoacetylene. Using a 2:1 ratio of $PhHgCCl_3$/IC&tbond;CI, 1-iodo-3,3,3-trichloropropyne and tetrachlorocyclopropene were formed as the major components of the reaction mixture (eq 13).[27]

(13)

Reaction with 1,3-Dienes.

1,1,2,2,3,3-Hexamethyl-4,5-bis(methylene)cyclopentane is an interesting 1,3-diene to check whether 1,4-addition is a feasible reaction path for a given transformation. Its reaction with $PhHgCCl_3$ shows clearly that this possibility is a true alternative for a singlet carbene (eq 14).[28]

Reaction with Nitrogen- and Other Heteroatom-Substituted Compounds.

Tertiary amines react with $PhHgCCl_3$ in boiling benzene; for instance, Et_3N gives EtCl, PhHgCl, and *N*,*N*-diethyltrichlorovinylamine ($Et_2NCCl{=}CCl_2$) in low yield.[29] Short reaction times have been noticed, suggesting an initial nucleophilic substitution reaction on mercury by the amine and $^{-}CCl_3$ displacement. Subsequent decomposition reactions would eventually lead to the nitrogen ylide (Et_3N^{+}-CCl_2-$^{-}CCl_2$) from which reaction products will be formed.[29] These findings are consistent with the interesting behavior shown by several allylamines towards $PhHgCCl_3$ (eq 15).[30] The yield of cyclopropane increases as the nucleophilic character of the nitrogen decreases. For more nucleophilic nitrogen atoms, competitive enamine formation could be the major pathway.

The reaction of *N*,*N*-dimethylaniline with $PhHgCCl_3$ has also been described.[31] In this case, a novel class of compound is formed via electrophilic substitution on the starting amine, along with the expected products arising from an attack on nitrogen. Thermal reaction of $PhHgCCl_3$ with the C=N double bond should offer a simple entry to aziridines. However, its synthetic utility is severely limited due to the presence of PhHgCl, formed in the reaction.[32] To overcome this, cyclopropanation was attempted in the presence of NaI.[9] Although remarkable examples have been recorded (eq 16), the procedure lacks generality since the PhHgI formed catalyzes aziridine ring opening at rt.[32]

(16)

The C=N function of azirines reacts with $PhHgCCl_3$, giving ring-opened products (eq 17).[33] A minor byproduct, identified as the corresponding *N*-vinylaziridine, results from further attack of **:**CCl_2 on the C=N rather than the C=C bond of the azadiene.[33]

(17)

The reaction of oxygen-containing compounds with **:**CCl_2 generated from α-halo organomercurials ($PhHgXCCl_2$) is known, but most of the work deals with $PhHgCCl_2Br$ (reactions with ROH,[34] RCO_2H,[35] RCHO,[36] and RCOR[37] have been studied). $PhHgCCl_3$ attack at oxygen of the carbonyl group of several unsaturated steroidal ketones triggers skeletal rearrangements, and subsequent aromatization of the A ring.[38] $PhHgCCl_3$ is reported to deoxygenate pyridine *N*-oxides by carbene attack onto the oxygen atom to afford deoxygenated products.[39]

With respect to sulfur-containing substrates, sulfoximines react with $PhHgCCl_3$ to furnish sulfur ylides in modest yields via nitrogen displacement.[40] Of synthetic interest is the reaction of penams with $PhHgCCl_3$, offering a nonbasic approach to the corresponding azetidinones via thiazolidine ring opening (eq 18).[41] For these substrates, addition of NaI not only permits the use of milder reaction conditions, but results in a different type of product formation,[41b] probably due to $^-CCl_3$ acting as a base.

(18)

Insertion Reactions.

$PhHgCCl_3$ easily inserts **:**CCl_2 into the Si-H bond.[42] In this respect, good yields of insertion product are obtained with silanes having bulky groups (eq 19).[42a] In contrast, carbenes generated following the *t*-BuOK-$CHCl_3$ protocol fail to react with these silicon compounds. Optically active silanes have been used to study the mechanism.[43] Since retention of configuration is mainly observed,[43a] the insertion process is seen to take place through a three-centered transition state.[43b]

$$t\text{-}Bu_3SiH \xrightarrow[120\ ^\circ C]{PhHgCCl_3} \underset{55\%}{t\text{-}Bu_3SiCHCl_2} + PhHgCl \qquad (19)$$

Insertion of **:**CCl_2, generated by thermal treatment of $PhHgCCl_3$, into C-H bonds usually does not compete with the addition to C=C bonds in typical alkenes, although some examples have been described in steroidal systems.[17] Several examples of insertion into Si-Br and Ge-Cl bonds are also known for $PhHgCCl_3$.[44]

Phenyltrichlorotungsten[1]

$PhWCl_3$

[54161-21-6] · $C_6H_5Cl_3W$ · Phenyltrichlorotungsten · (MW 367.31)

(transition metal catalyst for the alkene metathesis reaction)

Physical Data: brown crystalline solid; diamagnetic; mp >108 °C (dec).

Solubility: slightly sol toluene, diethyl ether.

Preparative Method: from the reaction of ***Tungsten(VI) Chloride*** with 2 equiv of Ph_4Sn in refluxing pentane.

Handling, Storage, and Precautions: highly air sensitive; reacts vigorously with water or alcohols to liberate benzene.

Alkene Metathesis.[2]

Phenyltrichlorotungsten in combination with ***Aluminum Chloride*** is one of a large number of transition metal catalysts[3] for the alkene metathesis reaction (eq 1). The mechanism has been extensively studied.[4]

The phenyltrichlorotungsten-aluminum chloride catalyst is extremely air sensitive and must be prepared in oxygen-free conditions. Typically, phenyltrichlorotungsten (1 mmol) is added to a centrifuge tube fitted with a rubber septum containing aluminum chloride (1 mmol) in an inert atmosphere of nitrogen. Oxygen-free chlorobenzene (25 mL) is then added and the mixture is shaken for 0.5 h and centrifuged. The supernatant liquid contains the active catalyst. Reaction of 1,7-octadiene with the above catalyst for ca. 21 h gives cyclohexene and ethylene (eq 2).[5]

(2)

In general, although cyclobutanes are not products from the alkene metathesis reaction, Gassman and Johnson[6] have found that treatment of a strained diene, 11,12-bis(trifluoromethyl)-(*i*,*o*)-bicyclo[8.2.2]tetradeca-11,13-diene, with the above catalyst for 5 min results in equilibration with the corresponding, less strained, cyclobutane derivative (eq 3). Both 2,3-bis(trifluoromethyl)bicyclo[2.2.1]hepta-2,5-diene and 2,3-bis(trifluoromethyl)bicyclo[2.2.2]octa-2,5-diene, are unreactive under these conditions; however, the reverse reactions are readily achieved (eqs 4 and 5).

(3)

(4)

(5)

Retro-Carbene Additions.

Treatment of 1-alkylcyclopropanes with a catalytic quantity of phenyltrichlorotungsten-aluminum chloride in a

sealed Carius tube at rt in dimethyl ether-chlorobenzene (5:1) results principally in the formation of the corresponding 1-alkene through loss of a methylene fragment (eq 6). Similar treatment of bicyclo[2.1.0]pentane with $PhWCl_3/EtAlCl_2$ gives cyclobutene (eq 7).[7]

(6)

R = Et	83%	11%
R = Bu	80%	9%
R = *i*-Pr	72%	10%

(7)

Cyclopropane-Alkene Cross Metathesis.

Treatment of a mixture of ethylcyclopropane and ethyl acrylate with catalytic phenyltrichlorotungsten-aluminum trichloride results in the formation of ethyl cyclopropanecarboxylate in low yield (eq 8). By using ***Ethylaluminum Dichloride*** rather than aluminum trichloride, the yield is slightly improved.[8]

N-Phenyltrifluoromethanesulfonimide[1]

$(CF_3SO_2)_2NPh$

[37595-74-7] · $C_8H_5F_6NO_4S_2$ · *N*-Phenyltrifluoromethanesulfonimide · (MW 357.28)

(mild triflating agent[2] for amine protection;[3,4] vinyl triflate formation from thermodynamic[2] and kinetic enolates[5] generated by deprotonation, conjugate reduction,[6,7] or conjugate addition;[7] formation of aryl triflates[2])

Alternate Names: N-phenyltriflimide; Hendrickson-McMurray reagent.[6]

Physical Data: mp 101-103 °C (Aldrich), 93-94 °C.[2]

Form Supplied in: white solid; widely available.

Preparative Methods: prepared in 92% yield from the reaction of aniline with 2 equiv each of ***Trifluoromethanesulfonic Anhydride*** and ***Triethylamine*** in CH_2Cl_2 at -78 °C.[2]

Handling, Storage, and Precautions: nonhygroscopic and extremely stable.

Utility and Selectivity with Amines and Alcohols.

The trifluoromethanesulfonyl group provides for effective protection of primary and secondary amines[4] and the monoalkylation of secondary trifluoromethanesulfonamides.[3] These substrates are typically formed by the reaction of the amine with ***Trifluoromethanesulfonic Anhydride*** (triflic anhydride, Tf_2O). As a less reactive triflating reagent, *N*-phenyltrifluoromethanesulfonimide[2] (Tf_2NPh) is more convenient to use and provides higher selectivity than that encountered with triflic anydride. Triflates of secondary aliphatic amines are easily isolated from the byproduct phenyltriflamide by carbonate extraction[3] and Tf_2NPh does not react with aromatic secondary amines under similar or more vigorous conditions.[3] This selectivity is also observed in selective triflation of primary over secondary alcohols, allowing selective dehydration in a series of dipeptides (eq 1).[9]

Formation of Enol Trifluoromethanesulfonates (Enol Triflates).

Kinetic or thermodynamic enolate formation, through reaction of unsymmetrical ketones with properly selected strong bases, followed by treatment with Tf_2NPh provides regioselective formation of vinyl triflates[7,8,10,11] in good to excellent yields (eq 2). Minor discrepancies to these generalities have been documented, but appear to be substrate (eq 3)[12,13] or base dependent (eq 4).[13] This sequence surpasses the triflic anhydride/base protocol (which provides predominantly thermodynamic products) both in regiocontrol and material yield and has led to preparation of enol triflates where triflic anhydride fails (eq 5).[7,14-16] Enol triflates of symmetrical and unidirectionally enolizable ketones[13,14,17-20] are produced in typically higher yield by trapping with Tf_2NPh compared with Tf_2O[7,16] or (trifluoromethylsulfonyl)imidazole[14,17] and enolates of five- to seven-membered lactones have been isolated as their trifluoromethanesulfonyl ketene acetals (eq 6).[21]

(3)

9:1

(4)

1. LDA; 2. Tf_2NPh — No reaction

1. $KN(TMS)_2$; 2. Tf_2NPh — >74%

(5)

(6)

$n = 1$ — 75%

$n = 2$ — 89%

Regiospecific Generation of Enol Triflates.

A variety of enolate generation methods followed by exposure to Tf_2NPh provides regiospecific vinyl triflates. Regiospecific enolates generated from conjugate reduction of enones with ***Lithium***[7,22] in liquid ***Ammonia***, from pure silyl enol ethers with ***Methyllithium***,[6] and by conjugate addition of dialkylcuprate reagents to enones[6,23] are all successfully trapped by Tf_2NPh. *N*-Phenyltriflimide efficiently captures regiospecific enolates generated from conjugate reduction of cyclopentenones[6] and cyclohexenones[6,24] with ***Lithium Tri-s-butylborohydride*** (eqs 7 and 8), with the exception of sterically encumbered substrates.[6] *N*-Phenyltriflimide has become a widely utilized reagent for the conversion of phenols to aryl triflates. Optimal yields[2] and chemoselectivity[2,25] allow aryl triflate formation in the presence of amines, alcohols, or carboxylates[2] and on relatively sensitive substrates.[25]

(7)

(8)

Utility of Enol and Aryl Triflates.

Enol triflates have been utilized for the generation of vinyl cations and carbenes,[26] and the transient 1,2,3-cyclohexatriene.[27] Enol triflates and trifluoromethanesulfonyl ketene acetals[21] undergo coupling with diorganocuprate reagents to give alkenes and substituted enol ethers, respectively. Palladium-catalyzed coupling and carbonylation reactions of enol and aryl triflates with organostannanes, alkenes, and alkynes abound in the literature.[14]

Other Applications.

A selected number of primary and secondary saturated triflones are available from the reaction of the respective alkyllithium or dialkylcuprate reagent with *N*-phenyltriflimide.[28]

N-Phenyltrimethylacetimidoyl Chloride[1]

[50993-08-3] · $C_{11}H_{14}ClN$ · *N*-Phenyltrimethylacetimidoyl Chloride · (MW 195.71)

(strong iminating agent, used in forming imines[2] and amidines,[3] and in peptide synthesis[1,4])

Physical Data: bp 112 °C/13 mmHg.

Solubility: sol most organic solvents.

Form Supplied in: liquid; must be synthesized.

Preparative Method: the amide precursor (**1**) is treated with a chlorinating agent such as ***Phosphorus(V) Chloride***[1] or ***Thionyl Chloride***[3] (eq 1).

Purification: redistill under reduced pressure.[5]

Handling, Storage, and Precautions: irritant and moisture sensitive. Incompatible with strong bases (see Aldrich safety index for trimethylacetyl chloride).[6]

Addition-Elimination Reactions.

Most reactions of *N*-phenyltrimethylacetimidoyl chloride involve an addition-elimination reaction (similar to the reactions of the oxa analogs, the acid chlorides) with a C-,[7] O-,[1] N-,[8] P-,[9] or As-centered[10] nucleophile. However, the imine products (**2**) can isomerize, the double bond shifting to give enamine derivatives (**3**) (eq 2).

Cyclizations.

Several N-, P-, and As-containing heterocyclic compounds have been synthesized using *N*-phenyltrimethylacetimidoyl chloride (eq 3).[11,12]

Peptide Synthesis.

N-Phenyltrimethylacetimidoyl chloride was initially used to activate the carboxylic acid group on *N*-tosylalanine (**4**) to form peptide links with amines (eq 4).[1]

Phenyltrimethylammonium Perbromide

$Ph^{+}NMe_3\ Br_3^{-}$

[4207-56-1] · $C_9H_{14}Br_3N$ · Phenyltrimethylammonium Perbromide · (MW 375.94)

(α-bromination of acetals;[1-5] selective bromination of ketones;[1,6] oxidation of tosylhydrazones to tosylazoalkenes[7])

Alternate Names: phenyltrimethylammonium tribromide; PTAB; PTT.

Physical Data: mp 115.5-116.5 °C.

Solubility: very sol THF, CH_2Cl_2; sol acetic acid.

Form Supplied in: orange crystals; widely available.

Preparative Methods: prepared in situ by reaction of equimolar amounts of phenyltrimethylammonium bromide and ***Bromine*** in THF (eq 1).[5,6,8] The stable reagent, suitable for storage, is prepared by quaternization of *N*,*N*-dimethylphenylamine with ***Dimethyl Sulfate*** in toluene, followed by bromination with bromine in aqueous hydrogen bromide (eq 2).[6]

Handling, Storage, and Precautions: the reagent is highly stable but should be protected from moisture as it is slightly hygroscopic. For some applications, phenyltrimethylammonium perbromide must be strictly anhydrous in order to achieve maximum selectivity.

Introduction.

Phenyltrimethylammonium perbromide has the same properties as ***Pyridinium Hydrobromide Perbromide*** without the disadvantages.[1]

α-Bromination of Acetals.

This reagent is widely used for the α-bromination of ethylene acetal derivatives of ketones. Phenyltrimethylammonium perbromide in THF converts 3β-acetoxy-20-ethylenedioxypregna-5,16-diene into 3β-acetoxy-20-oxo-21-bromopregna-5,16-diene;[1] various other ethylene acetals have been transformed into the corresponding brominated acetals, which are readily hydrolyzed to α-bromo ketones (eqs 3 and 4).[1-3,5]

This conversion has also been performed as a one-pot procedure starting with a ketone, ethylene glycol, and PTAB in THF (eq 5).[4] Anhydrous THF is important to the selectivity of this process because of the stability of Br_3^- in this solvent. Moreover, THF acts as a buffer by reacting with liberated HBr, and is therefore very useful for reactions of substrates

bearing acid-sensitive functions.

(5)

R = H, 90%; Me, 89%; R,R = $(CH_2)_2$, 68%; $(CH_2)_3$, 89%

Selective Bromination of Ketones.

Ketones are selectively monobrominated at the α-position with PTAB in anhydrous THF. Small amounts of water can greatly retard the rate of bromination and can result in decreased selectivity. α-Monobromination of methyl aryl ketones with PTAB occurs smoothly, and α,α-dibromination is also possible (eq 6).[6]

(6)

α-Bromo ketones have been selectively obtained in substrates containing carbon-carbon double bonds[3] and cyclopropane rings.[9-11] Thus *trans*-dihydroaristolone can be α-brominated and dehydrobrominated to (±)-aristolone (eq 7), a sesquiterpene from *Aristolochia debilis*,[9] while methyl *cis*-2-oxo-7,7-dimethylnorcarane-4-carboxylate has been α-brominated and further converted into methyl *cis*-chamic ester (eq 8).[10] α-Bromination of cyclic ketones with PTAB has been used for the construction of *anti*-bishomoquinone[12] and triasteranedione[13] from cyclooctane-1,5-dione and bicyclo[3.3.1]nonane-3,7-dione, respectively (eqs 9 and 10).

trans-Dihydroaristolone

(7)

(±)-Aristolone

(8)

Methyl *cis*-chamic ester

(9)

(10)

Oxidation of Tosylhydrazones into Tosylazoalkenes.

Tosylazoalkenes are obtained from the reaction of tosylhydrazones and PTAB, followed by treatment with base (eq 11).[7,14] The reaction fails with bromine and *N*-bromosuccinimide.[14]

Phenyl Trimethylsilyl Selenide

$PhSeSiMe_3$

[33861-17-5] · $C_9H_{14}SeSi$ · Phenyl Trimethylsilyl Selenide · (MW 229.28)

(synthesis of benzeneselenol;[1a] introduction of the phenylseleno function into a variety of oxygen-containing compounds[2-4,6])

Physical Data: bp 92-93 °C/5 mmHg. ^1H NMR ($CDCl_3$) δ 0.35 (Me_3Si); ^{13}C NMR ($CDCl_3$) δ 1.49 (Me_3Si).

Solubility: sol benzene, Et_2O, THF, MeCN.

Preparative Methods: conveniently prepared by the reduction of ***Diphenyl Diselenide*** with ***Sodium*** in THF, followed by silylation of thus formed PhSeNa with ***Chlorotrimethylsilane***.[1a,b] In a small scale reaction, silylation of PhSeLi, which can be prepared in situ from metallic ***Selenium*** and ***Phenyllithium*** in THF, is alternatively utilized.[1c]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: although phenyl trimethylsilyl selenide isolated as a colorless liquid is somewhat sensitive to atmospheric moisture, it can be handled conveniently using syringe techniques and can be stored indefinitely under dry nitrogen (or argon). Use in a fume hood.

Reaction with Aldehydes and Ketones.

Phenyl trimethylsilyl selenide does not react with carbonyl compounds at 25 °C or on heating. However, use of ***Aluminum Chloride*** as catalyst results in selective formation of selenoacetals, whereas the copresence of zinc halide in place of $AlCl_3$ leads to *O*-(trimethylsilyl) monoselenoacetals,[2a-d] which can be utilized as α-siloxy radical precursors (eq 1).[2e]

Reaction with Acetates and Lactones.

In the presence of a catalytic amount of ***Zinc Iodide***, alkyl acetates and lactones react with phenyl trimethylsilyl selenide to afford alkyl phenyl selenides and o-(phenylseleno)carboxylic acids, respectively (eq 2).[3]

Reaction with α,β-Unsaturated Carbonyl Compounds.

Conjugate addition of phenyl trimethylsilyl selenide to α,β-unsaturated aldehydes and ketones has been attained by using ***Triphenylphosphine***,[2c] ***Zinc Chloride***,[2c] or ***Trimethylsilyl Trifluoromethanesulfonate***[4] as the catalyst. Combination of this reaction with selenoxide elimination[5] provides a one-pot procedure for α-alkoxyalkylation of α,β-unsaturated ketones (eq 3).

Reaction with Cyclic Ethers.

Ring opening of epoxides, oxetanes, and tetrahydrofurans with phenyl trimethylsilyl selenide takes place in the presence of ZnI_2 to provide β-, γ-, and δ-siloxyalkyl phenyl selenides, respectively, in good yields (eq 4).[6]

Miscellaneous.

Introduction of a phenylseleno function into organic molecules has also been attained by the reaction of phenyl trimethylsilyl selenide with organic halides.[7] Palladium-catalyzed addition of $PhSeSiMe_3$ to arylacetylenes takes place regio- and stereoselectively to give β-silyl substituted vinylic selenides (eq 5).[8] $PhSeSiMe_3$ serves as a mild reducing agent for deoxygenation of sulfoxides, selenoxides, and telluroxides.[9]

Phenyl Trimethylsilyl Telluride.

$PhTeSiMe_3$ is synthesized by the reaction of Me_3SiCl with PhTeLi,[10a] PhTeNa,[10b] or PhTeMgBr,[10c] and is purified by distillation (bp 77-79 °C/2 mmHg). It can be stored as a 2.5 M hexane solution in a Schlenk flask. Like

$PhSeSiMe_3$, $PhTeSiMe_3$ reacts with cyclic ethers and lactones to give ring-opened products.[10b] Upon treatment with MeOH, benzenetellurol is formed in situ.[10d]

Related Reagents.

Benzeneselenol; ***Bis(trimethylsilyl) Selenide***.

Phenyl Trimethylsilyl Sulfide

$PhSSiMe_3$

[4551-15-9] · $C_9H_{14}SSi$ · Phenyl Trimethylsilyl Sulfide · (MW 182.39)

(hemithioacetal formation;[1] ether deprotection[9])

Physical Data: bp 72 °C/8 mmHg; *d* 0.963 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: liquid; commercially available.

Analysis of Reagent Purity: GC.

Handling, Storage, and Precautions: flammable liquid; moisture sensitive; avoid inhalation and body contact; use in a fume hood.

Hemithioacetal Formation.

The reaction of phenyl trimethylsilyl sulfide with aldehydes or acetals under base or acid catalysis affords the corresponding hemithioacetals in moderate to high yields (eq 1). Omission of the catalyst results in longer reaction times, harsher reaction conditions, and substantially reduced yields (eq 2).[1,2] This method has been used extensively to convert carbohydrates into versatile coupling reagents (eq 3).[3-5]

(1)

(2)

(3)

Conjugate Additions.

Under nucleophilic catalysis, phenyl trimethylsilyl sulfide adds to α,β-unsaturated aldehydes, ketones, and esters exclusively in 1,4-fashion (eq 4).[1,6,7] As with the addition to saturated carbonyl systems, reactions carried out in the absence of cyanide, thiolate, or fluoride require elevated reaction temperatures and extended reaction times. This process allows the mild protection of enones and enals as well as the production of highly functionalized, silicon-containing synthetic building blocks (eq 5).[8]

(4)

(5)

Nucleophilic Displacements.

Phenyl trimethylsilyl sulfide reacts with a large variety of ethers to afford the corresponding alcohols or silylated alcohols. Methyl and benzyl ethers are mildly and efficiently deprotected upon treatment with the reagent and a Lewis acid (eq 6).[9] When exposed to the same reaction conditions, epoxides are opened to afford vicinal hydroxy thiophenolates (eq 7).[10] Dioxaphospholanes also react in this fashion, providing functionalized silyl ethers upon expulsion of triphenylphosphine oxide (eq 8).[11]

(6)

(7)

(8)

Preparation of Thiohydroxamate Esters.

Thiohydroxamate esters result when primary nitro compounds are sequentially treated with ***n-Butyllithium*** and phenyl trimethylsilyl sulfide (eq 9).[12] This method is milder and involves fewer transformations than more traditional methods (i.e. reaction of hydroximic acid chlorides with thiols).

Phenyl Vinyl Sulfide

$PhSCH{=}CH_2$

[1822-73-7] · C_8H_8S · Phenyl Vinyl Sulfide · (MW 136.23)

(deprotonation gives 1-phenylthiovinyllithium,[1] an acyl anion equivalent which reacts with electrophiles; utilized as a probe in [4 + 2],[2,3] [3 + 2],[4] and [2 + 5][5] cycloaddition reactions; serves as a Diels-Alder dienophile synthetic equivalent of ethylene, acetylene, and ketene)

Physical Data: bp 94-95 °C/25 mmHg; *d* 1.042 g cm^{-3}.

Form Supplied in: liquid; widely available.

Preparative Methods: recent preparative methods include: the reaction of ***Ethylene*** with ***Thiophenol*** and ***N-Chlorosuccinimide*** to give the β-chloroethyl sulfide followed by dehydrohalogenation with ***1,8-Diazabicyclo[5.4.0]undec-7-ene***;[6] reaction of acetaldehyde diphenyl dithioacetal with ***Copper(I) Trifluoromethanesulfonate***;[7] reaction of ***Phenylmagnesium Bromide*** with 2-chloroethyl thiocyanate followed by dehydrohalogenation with ***Potassium t-Butoxide***;[8] phenylthiolate addition to ***1,2-Dibromoethane*** followed by dehydrohalogenation with ***Potassium Hydroxide*** under phase transfer catalysis;[9] reaction of acetaldehyde diphenyl dithioacetal with ***Benzenesulfenyl Chloride*** followed by dehydrohalogenation with ***Diisopropylethylamine***;[10] and as a recoverable byproduct of the reaction of 1,3-oxathiolanes with benzyne.[11]

Handling, Storage, and Precautions: stench; it is imperative that phenyl vinyl sulfide be used in a well-ventilated fume hood.

1-Phenylthiovinyllithium.[1]

This reagent has been prepared by metalation of phenyl vinyl sulfide with ***Lithium Diisopropylamide*** in THF/HMPA[12] or as a slurry in hexanes[13] or with ***n-Butyllithium/N,N,N´,N´-Tetramethylethylenediamine***[14] or ***Lithium 2,2,6,6-Tetramethylpiperidide***/TMEDA,[15] providing specific lithiation in the α-position (eq 1).[1] Under these conditions, alkyllithium addition[16] is suppressed. 1-Phenylthiovinyllithium reacts with a variety of electrophiles (eq 2)[13,16,17] to give substituted phenyl vinyl sulfides, useful compounds in their own right. This vinyllithium species undergoes addition reactions with alkyl halides[15,18] to give substituted phenyl vinyl sulfides, which under hydrolytic conditions with aqueous Brønsted[12,14] or Lewis[12,14] acids provide the corresponding ketones. Hence, 1-phenylthiovinyllithium belongs to the acyl anion equivalent class of umpolung reagents.

RX = Bu_3SnCl	R = $SnBu_3$	87%

Aldehydes react with 1-phenylthiovinyllithium to give 2-phenylthioallylic alcohols (eq 3),[12,14] which have been converted to vinyl ketones[14] and 1,4-diketones.[12] Addition of 1-phenylthiovinyllithium to ketones has provided valuable substrates for the study of [3,3]-sigmatropic rearrangements of divinylcyclobutanols[19] and tandem cationic aza-Cope rearrangement-Mannich cyclization reactions.[20]

(3)

R = C_5H_{11}	76%
R = C_6H_{13}	81%

Utility in [4 + 2], [3 + 2], and [2 + 2] Cycloadditions.

The electron richness and half-wave potential of the double bond in phenyl vinyl sulfide have been used to advantage in reverse-electron demand and cationic radical[2] Diels-Alder reactions. Phenyl vinyl sulfide reacts with tropone regiospecifically to provide bicyclo[3.2.2]nonadienone systems (eq 4),[21] reacts with pyrone sulfoxide[22] with high

diastereoselectivity under high pressure (eq 5), has trapped the transient [1,5]-sigmatropic shift isomer of isodicyclopentanediene,[3] and undergoes photosensitized electron transfer (PET) initiated cycloaddition[23] with dienes to give Diels-Alder products (eq 6). The resulting sulfides of these adducts have been cleaved to the corresponding alkanes,[3] oxidized to the sulfoxides followed by thermolysis to give the corresponding alkenes,[22] and oxidized to the sulfones followed by α-hydroxylation to give the corresponding ketones.[23] Thus phenyl vinyl sulfide can represent Diels-Alder dienophile equivalents of ethylene, acetylene, and ketene.

(4)

1.5:1 epimeric ratio

(5)

(6)

1,4-DCB = 1,4-dicyanobenzene

Phenyl vinyl sulfide participates in 1,3-dipolar cycloadditions with 2-azaallyl anions, generated from *N*-(tributylstannyl)methanimines and *n*-BuLi, to provide substituted pyrrolidines (eq 7)[4] and highly stabilized isoquinolium methylides,[24] and also undergoes thiyl-radical catalyzed chain cyclizations to give methylenecyclopentanes.[25] ***Tetracyanoethylene*** undergoes spontaneous [2 + 2] cycloaddition with phenyl vinyl sulfide[5,26] and oxetanes are derived from ***Boron Trifluoride Etherate*** catalyzed reaction of sugar-derived aldehydes with electron-rich alkenes (eq 8).[27]

(7)

(8)

Other Applications.

Phenyl vinyl sulfides exhibit higher selectivity and better yields than enol acetates and enol ethers in palladium catalyzed Heck-like reactions with aryl halides.[28] Phenyl vinyl sulfide has been transformed into ***Phenylthioacetylene*** via a bromination-bis(dehydrobromination) sequence,[29] converted to the *S*-vinyl sulfilimine, and utilized as an acetaldehyde enolonium ion equivalent ($^{+}CH_2CHO$),[30] and utilized as a sensitive substrate for examination of novel hydrosilylation,[31] diimide reduction,[32] and asymmetric oxidation to the corresponding sulfoxide.[33,34]

S-Phenyl-*S*-vinyl-*N*-(*p*-toluenesulfonyl)sulfilimine[1]

[56692-06-9] · $C_{15}H_{15}NO_2S_2$ · *S*-Phenyl-*S*-vinyl-*N*-(*p*-toluenesulfonyl)sulfilimine · (MW 305.45)

(vinylation;[1,2] cyclopropanation;[3] hetero-ring construction[4])

Physical Data: mp 111-113 °C.

Solubility: insol H_2O; sol EtOH, MeOH, acetone, chloroform, other common polar organic solvents.

Preparative Method: the title reagent (**1**) is prepared via sulfimination of 2-chloroethyl phenyl sulfide[5] followed by dehydrochlorination.[6] The sulfimination is carried out as follows. A solution of the sulfide (10 mmol) in CH_2Cl_2 (70 mL) and a solution of ***Chloramine-T*** trihydrate (11 mmol) and tetrabutylammonium chloride (0.2 mmol) in water (70 mL) are vigorously stirred at 40 °C for 4 h. The resulting *S*-(2-chloroethyl)-*S*-phenyl-*N*-tosylsulfilimine (**2**) is recrystallized from CH_2Cl_2-Et_2O. The yield is almost quantitative (mp 101-103 °C).[5] The dehydrochlorination is carried out as follows. A solution of (**2**) (10 mmol) in benzene (100 mL) and a solution of NaOH (10.5 mmol) and tetrabutylammonium bromide (0.05 mmol) in water (50 mL) are vigorously stirred at rt overnight. The crude product is recrystallized from CH_2Cl_2-Et_2O. The yield of (**1**) is almost quantitative (mp 111-113 °C).[6]

Handling, Storage, and Precautions: stable and storable at rt in a sealed bottle. Use in a fume hood.

Vinylation.[1,2]

Sulfilimine (**1**) undergoes Michael-type addition with various protic nucleophiles (RZH) such as alcohols, thiols, amines, and amides. The reactions of (**1**) with an excess of RZH in the presence of ***Sodium Hydride*** in THF are carried out at rt for several hours to 1 day to give the corresponding adducts in high yields. The amount of NaH used depends on the basicity of attacking nucleophile. The basicity of the intermediate carbanion formed is estimated to be between those of alcohols and amines. When alcohols and thiols are used as RZH, the addition reactions proceed in the presence of catalytic amounts of NaH (eqs 1-3), while the reactions of (**1**) with amines require equimolar amounts of NaH. The

adducts obtained decompose at higher temperature (ca. 20-30 °C) than their melting points to give vinyl compounds in almost pure form (eq 4).[1]

Similarly, allyl vinyl ethers[2a] and alkynyl vinyl ethers[2b] can be obtained from the addition reactions between (**1**) and allyl or alkynyl alcohols followed by the thermal decomposition of the adducts (eqs 5 and 6). The times required for completion of the addition reaction are about 24 h for primary alcohols in THF and for secondary and tertiary ones used as cosolvents. Under these conditions the corresponding vinyl ethers can be obtained from allyl, methallyl, crotyl, and 1-methylallyl alcohols in high overall yields (>80%). Alkynyl vinyl ethers are also formed efficiently.

Cyclopropanation.[3]

When the sulfilimine (**1**) is allowed to react with diprotic nucleophiles (RZH_2) in the presence of equimolar amounts of NaH, cyclic compounds incorporating the vinyl carbons are produced. When the compounds RZH_2 are active methylene compounds, cyclopropane derivatives are obtained (eq 7). The addition is carried out at rt for 24 h and then the cyclization at 35-40 °C for 4 h. In this way, the corresponding cyclopropanes are formed from dibenzoylmethane, anthrone, and fluorene in 60-77% yields.

Hetero-ring Construction.[4]

Amides, as diprotic nucleophiles RZH_2, react with (**1**) in THF to give 2-substituted oxazolines (eq 8). The addition is carried out at rt for 24 h and then the cyclization at 40 °C for 5 h. The yields of 2-aryloxazolines (ca. 70%) are superior to those of the alkyl analogs.

Miscellaneous.

The reaction of (**1**) with ***Methyllithium*** in THF gives mainly a polymer,[7] whereas the reactions with Grignard reagents (R = Ph, *p*-Tol, Et, *i*-Pr) give 2-substituted phenyl vinyl sulfides in 45-76% yields via addition and elimination of the tosylamino group (eq 9).[7]

Related Reagents.

S,S-Dimethyl-N-(p-toluenesulfonyl)sulfilimine; ***S,S-Diphenylsulfilimine***; ***Ethyl Vinyl Ether***; ***Phenyl Vinyl Sulfide***; ***p-Tolyl Vinyl Sulfoxide***; ***Vinyl Acetate***.

Phenylzinc Chloride

PhZnCl

[28557-00-8] · C_6H_5ClZn · Phenylzinc Chloride · (MW 177.95)

(phenyl coupling reagent in the presence of palladium(0) or copper(I) complexes)

Solubility: sol ether, THF; reacts rapidly with H_2O and protic solvents.

Preparative Methods: usually prepared by transmetalation of ***Phenylmagnesium Bromide*** with ***Zinc Chloride***.[1] Related arylzinc halides can either be prepared by the direct insertion of zinc,[2] by a transmetalation from the corresponding aryllithium,[3] or electrochemically.[4] Diarylzincs have been generated under Barbier conditions.[5]

Handling, Storage, and Precautions: reacts with oxygen; should be handled and stored under an inert atmosphere in the absence of moisture.

Palladium- and Nickel-Catalyzed Reactions.

Although arylzinc halides display a low reactivity toward many organic electrophiles, the use of late transition metal (Ni, Pd) complexes allows cross-coupling reactions to be performed with a variety of electrophiles. In pioneering work by Negishi,[1,6] the coupling of phenylzinc chloride with various aromatic, allenic, and alkenyl[7] iodides or bromides in the presence of 1-5 mol % of a Pd^0 catalyst provides a unique preparation of polyfunctionalized unsaturated molecules (eqs 1 and 2).[8,9] Cross coupling with alkenyl triflates is also possible (eq 3).[10]

(1)

(2)

(3)

The Pd-catalyzed reaction of phenylzinc chloride with acid chlorides gives an efficient preparation of various types of ketones (eq 4).[11] The Ni-catalyzed coupling of α-bromo nitriles and esters furnishes the arylated carbonyl derivatives in satisfactory yields.[12] The Pd-catalyzed substitution with allylic acetates proceeds at the more hindered position of the allylic system, whereas the substitution reaction with stabilized nucleophiles occurs at the less hindered position (eq 5).[13] Also, contrary to the reaction with stabilized nucleophiles, the substitution with phenylzinc chloride always proceeds with formal inversion (eq 6).[14] 1-Vinylcyclopropyl tosylate reacts with high regioselectivity with phenylzinc chloride.[15] An intramolecular carbopalladation of alkynes triggered by an oxidative addition of a phenylpalladium complex to aromatic iodides provides an interesting synthesis of various cyclic systems (eq 7).[16] Finally, diphenylzinc undergoes a 1,4-addition to unsaturated aldehydes and ketones in the presence of a nickel catalyst.[5]

(4)

(5)

(6)

(7)

Copper-Mediated Reactions.

Transmetalation of phenylzinc halides to the corresponding copper reagents allows the reaction with allylic halides, enones, and acid chlorides in satisfactory yields (eq 8).[2]

Phosgene[1]

$COCl_2$

[75-44-5] · CCl_2O · Phosgene · (MW 98.91)

(chlorinating agent;[2] carbonylating agent; dehydrating agent;[1] with DMF forms a chloromethyleniminium salt, used in formylation reactions[3])

Alternate Name: carbonyl chloride.

Physical Data: mp -118 °C; bp 8.3 °C; *d* 1.381 g cm^{-3}.

Solubility: slightly sol H_2O (dec); sol toluene, chloroform.

Form Supplied in: liquefied gas in cylinders; solution in toluene.

Purification: chlorine is an impurity which can be detected by bubbling through mercury (gives discoloration) and removed by bubbling through two wash bottles containing cottonseed oil.

Handling, Storage, and Precautions: highly toxic gas; avoid contact or inhalation; there may be a delay of several hours before symptoms of exposure develop (pulmonary edema); keep container tightly closed and well-ventilated; excess phosgene should be vented into a water-fed scrubbing tower. Use in a fume hood.

Reactions with Carboxylic Acids, Alcohols, and Amines.

Phosgene reacts with carboxylic acids to give anhydrides, with liberation of carbon dioxide.[4] This has been used to activate acids to attack from nucleophiles, e.g. in esterification,[5] lactonization,[6] and thiolation.[7] For example, acids can be protected as 3-butenyl esters using phosgene and ***Pyridine***,[5] followed by addition of 3-buten-1-ol (eq 1).

(1)

The ester is removed under mild conditions by ozonolysis and β-elimination of the resulting aldehyde. In contrast, reaction with acids in the presence of a variety of catalysts (including ***Imidazole***, ***1,8-Diazabicyclo[5.4.0]undec-7-ene***,

and ***1,3-Dicyclohexylcarbodiimide***) cleanly affords the corresponding acid chloride.[2] ***N,N-Dimethylformamide*** has also been used as a catalyst (eq 2).[8]

(2)

Phosgene reacts with alcohols to give chloroformates,[9,1b] and with secondary amines to give chloroformamides[10] (it reacts preferentially with the latter).[11] The formation of a chloroformate is the first step in the Barton oxidation of primary alcohols to aldehydes,[12] which is followed by complex formation with ***Dimethyl Sulfoxide*** and elimination by base (eq 3),[12b] a mechanism closely related to that of the Swern and Moffatt oxidations.[13]

(3)

There are many examples of further displacement of the chloroformate in an intramolecular or intermolecular sense by suitably disposed second nucleophiles (e.g. hydroxy, amino, thio, or acid groups), resulting in carbonates (eq 4),[14] ureas (eq 5),[15] carbamates,[11,16] dithiocarbonates (eq 6),[17] etc.

(4)

(5)

(6)

The reaction of phosgene with primary amines initially forms chloroformamides which on heating above 50 °C eliminate HCl to give isocyanates. This useful reaction constitutes a general method for isocyanate synthesis (eq 7).[18]

$$RNH_2 + COCl_2 \longrightarrow RNHCOCl \xrightarrow{-HCl} RN{=}C{=}O \qquad (7)$$

With tertiary amines, phosgene-amine complexes can be formed.[1a] Warming results in decomposition to an *N*,*N*-dialkylchloroformamide by elimination of alkyl chloride.[19] This has been utilized for the mild and high yielding deprotection of *N*-methyl amines (eq 8).[20] α-Chloroethyl chloroformate, prepared from phosgene and ***Acetaldehyde***, has also been used for this purpose.[21]

(8)

Reactions with Amides and Thioamides.

The action of phosgene on amides (and thioamides) initially gives dehydration to a chloromethyleneiminium chloride (eq 9). Primary amides react further, losing HCl to form nitriles in the presence of a base such as pyridine[22] (this can also be accomplished by the Vilsmeier-Haack reagent generated using phosgene - see below). Secondary formamides are converted to isocyanides in the presence of ***Triethylamine*** or pyridine (eq 10).[23] *N*-Formyl enamines also form isocyanides (eq 11);[24] ***1,4-Diazabicyclo[2.2.2]octane*** is claimed to be a more efficient base due to the avoidance of azeotrope formation with the low boiling vinyl isocyanide products. Other secondary amides lose HCl to give imidoyl chlorides, which can undergo further reaction, e.g. to form pyrroles (eq 12)[25] and oxazolones (eq 13).[26]

(13)

Secondary thioureas can be dehydrated to carbodiimides (eq 14).[27]

(14)

Tertiary amides give stable chloromethyleneiminium chlorides. A particularly important example is the complex formed between phosgene and DMF (known as the Vilsmeier-Haack reagent), which is a versatile formylating agent.[3] An identical or equivalent species can be generated with ***Oxalyl Chloride***, ***Thionyl Chloride***, or ***Phosphorus Oxychloride***, and these are perhaps preferred in view of phosgene's toxicity. However, the Vilsmeier reagent generated from phosgene is claimed to be a more efficient reagent for the dehydration of primary amides to nitriles.[28]

Tertiary amides (and thioamides)[29] with an α-proton react instead to give chloro enamines.[30] These can undergo nucleophilic substitution (eq 15).[30,31] Chloro enamines are also intermediates in synthetically useful dehydrogenation reactions, using ***Pyridine N-Oxide*** or DMSO as oxidant (eq 16).[32] Tertiary ureas and thioureas form related adducts which have been utilized in the synthesis of hindered guanidine bases by further reaction with amines (eq 17).[33]

(15)

(16)

(17)

Phosgene Equivalents.

In recent years, ***Bis(trichloromethyl) Carbonate*** (triphosgene) has been introduced as a crystalline phosgene source;[34] similarly, ***Trichloromethyl Chloroformate*** (diphosgene) has been used as a liquid equivalent[35] (bp 128 °C, d_{15} 1.65 g mL^{-1}). They have the advantages of much easier manipulation (particularly for small-scale work), safer transport and

storage, and they are less susceptible to hydrolysis. Triphosgene has so far been shown to perform several reactions undergone by phosgene itself, e.g. carbonylation[36] and Barton oxidation.[37] Diphosgene generates phosgene slowly at elevated temperatures, or rapidly in the presence of a charcoal catalyst;[38] it is also effective in several of the reactions of phosgene, including *N*-carboxyanhydride formation[38] and the conversion of amino alcohols to oxazolidinones,[39] where it has been recommended for large-scale use.

Related Reagents.

Dimethyl Sulfoxide-Phosgene.

Phosphazene Base P_4-*t*-Bu

[111324-04-0] · $C_{22}H_{63}N_{13}P_4$ · Phosphazene Base P_4-*t*-Bu · (MW 633.86)

(extremely strong, highly hindered, kinetically highly active base;[1] generates exceptionally nucleophilic naked carbanions from a wide range of carbon acids;[2] the very low Lewis acidity of the cation suppresses side reactions commonly observed with metal organyls, e.g. aldol and ester condensations[3] and β-eliminations[4])

Alternate Name: 3-*t*-butylimino-1,1,1,5,5,5-hexakis(dimethylamino)-3-{[tris(dimethylamino)phosphoranylidene]amino}-1λ^5,3λ^5,5λ^5-1,4-triphosphazadiene.

Physical Data: mp ca. 207 °C (dec); pK_{BH^+} 30.1.[5]

Solubility: very sol THF, ether, hexane, benzene, toluene; sol with protonation in protic solvents, MeCN; reacts rapidly with all types of haloalkanes except fluoroalkanes.

Form Supplied in: 1 M solution in hexane; commercially available.

Analysis of Reagent Purity: NMR in benzene-d_6. ^{1}H NMR: δ 1.83 (s, 9 H), 2.73 (d, *J* = 10 Hz, 54 H); ^{13}C NMR: δ 35.6 (br d, *J* &AApprox; 13 Hz), 38.08 (d, *J* = 4 Hz), 51.31 (d, *J* = 5.5 Hz); ^{31}P NMR: δ -24.44 (q, *J* = 20 Hz), 5.74 (br m).

Purification: all water-soluble salts of P_4-*t*-Bu can be converted to the HBF_4 salt by precipitation from aqueous solution with $NaBF_4$. Water-insoluble salts are first converted to the chloride by means of a column charged with strongly basic anion exchange resin (Cl^- form, MeOH). P_4-*t*-Bu.HBF_4 is recrystallized from aqueous ethylamine and dried in vacuo at 60 °C. 2.35 g (60 mmol) of potassium metal and 5 mg of $Fe(NO_3)_3.9H_2O$ are added to 50 mL of anhydrous NH_3(l) with stirring (glass-covered stirring bar) under N_2 and the solution kept at ca. -40 °C until the color turns to gray and evolution of H_2 ceases. A

solution of 21.6 g (30.0 mmol) of P_4-*t*-Bu.HBF_4 in 50 mL of THF is added and the mixture stirred at -40 °C for another 15 min. After evaporation of solvents in vacuo, the residue is extracted with 60 mL of hexane (caution! KNH_2 is pyrophoric), rigorously protecting from moisture. The solvent is removed at reduced pressure, affording up to 18.3 g (96%) of the crystalline base. P_4-*t*-Bu can be sublimed at 160 °C/10^{-3} mmHg, but protic impurities are not removed thereby.

For most applications, P_4-*t*-Bu must be strictly anhydrous, but water content is not readily detected by NMR. The following procedure has proven to be effective in the elimination of small amounts of protic impurities: to a 0.5 M solution of the base in hexane or heptane, ethyl bromide (at least 3 mol per mol of H_2O) is added. After 0.5 h at rt, diethyl ether and excess ethyl bromide (bp 31 °C) are removed by evaporating part of the solvent in vacuo, the precipitated hydrobromide salt of the base is filtered off, the solvent is removed completely in vacuo, and the residue is dried in a high vacuum.

Handling, Storage, and Precautions: P_4-*t*-Bu is extremely hygroscopic and must be stored and handled so as to rigorously exclude moisture. It is thermally stable up to ca. 120 °C, extremely resistant towards (basic) hydrolysis, and likewise insensitive to dry oxygen.

Alkylations of Carbanions.

P_4-*t*-Bu is a member of a novel class of kinetically highly active uncharged bases,[1,2,6-8] with pK_{BH^+} values ranging from 13[5,6] to ca. 34;[1,2,5,7,8] among the strongest of these phosphazene bases, it is the most readily available.[1] In the presence of alkylating agents, in situ alkylation of low acidic substrates in concentrated (ca. 0.5 M) THF solution is generally extremely rapid on (gradual) addition of P_4-*t*-Bu at -100 °C to -78 °C. Due to the high solubilizing power of phosphazene bases, solubility problems are scarce. Separation of products from salts of the base is easily achieved, e.g. by direct precipitation of its halide salts with diethyl ether or benzene, by extraction (CH_2Cl_2) or precipitation ($NaBF_4$) of salts from aqueous solution, or by filtration over silica gel. The very low Lewis acidity of the huge cation contrasts sharply with the characteristics of lithium amide bases. Thus Lewis acid-catalyzed side reactions, e.g. aldol or ester condensations in alkylations of enolates, are effectively suppressed; even β-lactones are easily mono-[2] or peralkylated (eq 1).[8] In cases where the corresponding lithium organyls decompose entirely via β-alkoxide elimination,[4,9] naked enolates of β-alkoxy esters undergo clean alkylation.

(1)

Using more hindered bases like P_4-*t*-Oct[2,7,10] (*t*-Oct = 1,1,3,3-tetramethylbutyl) enhances the selectivity for monoalkylation considerably (eq 2).[2] This tendency also holds for selective monoalkylation of secondary carbon centers.[8] Even sterically congested quaternary centers are formed with great ease (eq 3).[4]

(2)

	starting material		
P_4-*t*-Bu	28%	41%, 97% de	14%
P_4-*t*-Oct	9%	71%, 98% de	8%
LDA, HMPA		no alkylation product	
K[N(TMS)$_2$]		no alkylation product	

(3)

Alkylation of nitriles is not complicated by Thorpe condensation, as observed with ***Lithium Diisopropylamide*** as base. Alkylation of 1,2-dinitriles with no elimination of hydrocyanic acid (eq 4)[8] is achieved in high yield.

(4)

P_4-*t*-Bu	98%
LDA	0.5%
LDA, HMPA	15%
$KN(TMS)_2$	2%

Alkylation of Nitrogen Acids.

N-Perbenzylation of rather insoluble *N*-Boc-protected or cyclic peptides leads to easily soluble, fully protected derivatives.[11] Occasionally, regioselective *C*-alkylation of glycine or sarcosine subunits is also observed (eq 5).

(5)

Anionic Polymerization.

Polymerization of methyl methacrylate occurs in the presence of P_4-*t*-Bu. Using ethyl acetate as initiator in THF at

elevated temperatures, high molecular weights and narrow molecular weight distributions are achieved,[3] back-biting by ester condensation[12] being effectively suppressed. Presumably due to lack of chelate control by the cation, the stereochemistry differs from that of polymerizations with metal organyls, syndiotactic diads being favored (eq 6).

Other Applications.

The high steric hindrance of P_4-*t*-Bu enables the formation of isomerically pure 1-alkenes from primary halides at rt in almost quantitative yield.[1] The simplicity of the NMR spectra, the UV transparency (end absorption below 230 nm), and the simplicity of handling recommends P_4-*t*-Bu and other phosphazene bases for obtaining spectroscopic data of highly basic or unstable naked anions.[13]

Related Commercially Available Bases.

A number of other phosphazene bases are commercially available. P_1-*t*-Oct (**1**), P_1-*t*-Bu (**2**), BEMP (**3**), BEMP bound to a Merrifield polymer, and BTPP (**4**)[10] are hindered bases, suitable for *O*-alkylation of carbohydrates[6,14] and cyanohydrins,[6] *N*-alkylation of nucleosides[6] and carbamates,[15] *C*-alkylation of alkyl malonic esters,[6] *O*-tosylation of amino alcohols,[16] and aldol condensations;[17] reactions with these bases are often considerably more selective than with metal bases.

(1)
P_1-*t*-Oct
$pK_{BH}^{+} = 14.0$

(2)
P_1-*t*-Bu
$pK_{BH}^{+} = 14.4$

(3)
R = Me: BEMP
$pK_{BH}^{+} = 15.1$

R = H_2C-(P)

(4)
BTPP
$pK_{BH}^{+} = 15.8$

N-Alkylation of phthalimide (Gabriel synthesis) occurs in homogeneous acetonitrile solution at rt.[18] In contrast to DBU or guanidines, all phosphazene bases are highly resistant towards basic hydrolysis, thus representing easy-to-recover catalysts for the basic hydrolysis of sensitive esters in a relatively apolar medium (eq 7).[19]

(7)

P_2-Et (**5**)[10,20] is only a moderately hindered base (pK_{BH^+} = 20.2),[5] suitable for E2 elimination reactions of secondary halides, which is ca. 4 orders of magnitude more reactive and less easily alkylated than DBU (pK_{BH^+} = 11.8).[5]

Phosphoric Acid

H_3PO_4

[7664-38-2] · H_3O_4P · Phosphoric Acid · (MW 98.00)

(acid catalyst; dehydrating agent; phosphorylating agent[1])

Physical Data: mp 41 °C; bp 158 °C.

Solubility: sol water, formic acid, acetic acid.

Form Supplied in: commercially available; low melting white solid or colorless liquid.

Analysis of Reagent Purity: titration.

Preparative Method: anhydrous H_3PO_4 can be prepared by dissolving P_2O_5 in 85% H_3PO_4.

Purification: dry at 150 °C. At temperatures above 200 °C, monomeric H_3PO_4 changes to oligomeric metaphosphoric acid.

Handling, Storage, and Precautions: corrosive.

Introduction.

Phosphoric acid is a strong, nonoxidizing acid that is available in a number of different forms. Anhydrous, monomeric H_3PO_4 (orthophosphoric acid) is a low melting solid that can be purchased commercially or prepared by adding P_2O_5 to commercial 85% aqueous H_3PO_4. This combination has been used to iodinate alcohols, cleave ethers, and hydroiodinate alkenes, in addition to a variety of uses listed below.[2] Metaphosphoric acid [*37267-86-0*] is an oligomeric form, also commercially available.[3]

Hydrolysis of Imines, Amides, and Nitriles.

The hydrolysis of imines,[4] amides, and nitriles to carboxylic acids (eq 1) using H_3PO_4 is a time-honored technique.[5] There are numerous methods for accomplishing this transformation.[6]

(1)

Preparation of Phosphates.[1]

Phosphate mono- and dialkyl esters have been prepared from phosphoric acid (see also ***Phosphorus Oxychloride***). Treatment of (**1**) with H_3PO_4 at rt provides the corresponding phosphate in good yield (eq 2).[7] At high temperatures, diesterification can occur (eq 3).[8]

(1) (2)

(3)

An effective, large-scale synthesis of diammonium acetylphosphate has been developed, and involves direct acylation of H_3PO_4. Either ketene[9] or acetic anhydride[10] (eq 4) can be used in this process.

(4)

Acid Cyclization Catalyst.

A common use for H_3PO_4, as a solution in water, a liquid acid, or in anhydrous form, is as an acid cyclization catalyst. Cyclization of cross-conjugated ketones in H_3PO_4/formic acid leads to 2,3-dialkylcyclopentenones (eq 5)

rather than the 3,4-dialkyl products expected of the Nazarov cyclization.[11] This result is obtained when either the ketone or the corresponding ethylene acetal is used as starting material. Similar results are obtained using HBr/HOAc, although, in these examples, some of the 3,4-dialkyl products are obtained as well.

(5)

An intermolecular example of an alkene-cation addition reaction provides access to chromenes through isoprenylation of a phenol (eq 6).[12]

(6)

Cyclization of (**2**) in phosphoric acid results in an azabicyclononane (eq 7).[13]

(7)

(2)

Phosphoric acid-mediated condensation of indole derivatives with ketones provides access to 3-substituted indoles (eq 8).[14]

(8)

Cyclization of enol acetates (eq 9), δ,ε-unsaturated aldehydes,[15] and ketene dithioacetals (eq 10) can also be accomplished by heating in H_3PO_4. The cyclization of (**3**) results in dithiopyridines by way of an intramolecular Ritter reaction followed by a 1,3-methylthio shift. Lewis acids, ***Boron Trifluoride Etherate*** in particular, lead to simple dehydration.[16]

(9)

(10)

(3)

Debenzylation.

Treatment of (**4**), an *N*-benzyl derivative of biotin, with anhydrous H_3PO_4 and phenol at elevated temperature leads to debenzylation (eq 11).[17] This reaction provides a nonreductive route to deprotection of the urea while not attacking the unsaturated ester.

Phosphorus(III) Bromide

[7789-60-8] · Br_3P · Phosphorus(III) Bromide · (MW 270.67)

(brominating agent for conversion of alcohols to bromides)

Alternate Name: phosphorus tribromide.

Physical Data: mp 41.5 °C; bp 168-170 °C/725 mmHg; *d* 2.85 g cm^{-3}.

Solubility: sol acetone, CH_2Cl_2, CS_2.

Form Supplied in: widely available as liquid and 1.0 M solution in CH_2Cl_2.

Preparative Method: from ***Bromine*** and red phosphorus.[1]

Purification: generally used without purification; can be distilled under N_2 at atmospheric pressure.

Handling, Storage, and Precautions: corrosive. The colorless, fuming liquid has a very penetrating odor. It has a vapor pressure of 10 mmHg at 48 °C. The reagent is stable if kept dry, but reacts violently with water. It is extremely destructive to tissue of mucous membranes, upper respiratory tract, eyes, and skin. This reagent should only be used in a fume hood.

Conversion of Alcohols to Bromides.

The conversion of alcohols (ROH) into bromides (RBr) using PBr_3 is very general. Reaction conditions for this transformation are quite varied. Each of the bromine atoms in the reagent is available for reaction with an alcohol. The reagent can be used to prepare chiral bromides from chiral alcohols (eq 1).[2] It is generally important to carry out the conversion under relatively mild conditions (between 4 °C and rt). Addition of HBr at the end of workup increases both the optical purity and the isolated yield. An example is provided by eq 2. A polyhydroxylic compound has been converted to a polybrominated product (eq 3).[3]

(1)

(2)

(3)

Bromination of Allylic Alcohols.

The reaction of an allylic alcohol with PBr_3 in ether at 0 °C leads to both stereoselective and regioselective replacement of the hydroxy group by bromine.[4] Examples of this transformation are given in eqs 4 and 5.[5,6] The latter example shows that the reaction can be run in the presence of significant unsaturation. There are many examples of similar reactions.[7]

(4)

Silverstein[8] followed an older procedure[9] that results in rearrangement of a secondary allylic alcohol to a terminal bromide (eq 6). In a similar fashion, the conversion of propargylic alcohols to allenyl bromides has been noted (eq 7).[10]

Remote π-bond participation provides important stereochemical control in the reaction. Heathcock (eq 8)[11] has reported retention of stereochemistry due to π-bond participation, in contrast to a similar system without the π-system (eq 9).[12]

(8)

(9)

The reagent will convert an alcohol to a bromide in the presence of an ether (eq 10).[13] Acetals are also stable to the bromination procedure,[14] although an interesting reaction of a cyclopropanone acetal has been reported (eq 11).[15]

(10)

(11)

Use for Alkene Preparation.

Replacement of two alcohol groups by bromine, followed by zinc dehalogenation, provides an interesting alkene synthesis methodology (eq 12).[16] The preparation of 1,3,5-hexatriene is readily accomplished via a PBr_3 step (eq 13).[17] In the presence of DMF, PBr_3 has been used to eliminate a hindered diallylic tertiary alcohol (eq 14).[18] See also ***Phosphorus(III) Bromide-Copper(I) Bromide-Zinc***.

(12)

(13)

(14)

Other Reactions.

A simple one-step preparation of 2-bromo-2,3-dihydro-1,3,4,2-oxadiazaphospholes has been reported (eq 15).[19] An interesting preparation of 1,5-dibromopentane from piperidine is available (eq 16).[20]

(15)

(16)

Related Reagents.

A number of related reagents have been used for the conversion of alcohols to bromides. Other reagents for this purpose covered in this encyclopedia include ***Hydrogen Bromide***, ***Triphenylphosphine Dibromide***, ***Triphenylphosphine-Carbon Tetrabromide***, ***Bromine-Triphenyl Phosphite***, and ***1,2-Bis(diphenylphosphino)ethane Tetrabromide***.

Phosphorus(V) Bromide

PBr_5

[7789-69-7] · Br_5P · Phosphorus(V) Bromide · (MW 430.47)

(bromination agent for conversion of alcohols to bromides)

Alternate Name: phosphorus pentabromide.

Physical Data: mp 179-181 °C; *The Merck Index* (11th ed.) reports dec above 100 °C.

Solubility: sol CS_2, CCl_4.

Form Supplied in: yellow solid; commercially available.

Preparative Method: from ***Bromine*** and ***Phosphorus(III) Bromide***,[1] with which it is in equilibrium.

Handling, Storage, and Precautions: corrosive and highly toxic; stable if kept dry, but reacts violently with water; store under N_2 at rt; use in a fume hood.

Conversion of Alcohols to Bromides.

The conversion of alcohols (ROH) into bromides (RBr) using PBr_5 would appear to be quite general for alcohols; however, the literature does not report many examples of this reaction. Eliel[2] reported that PBr_5 is better able to convert 4-*t*-butylcyclohexanol to 4-*t*-butylbromocyclohexane than ***Phosphorus(III) Bromide*** (eq 1).

(1)

In the steroid series, D-ring enlargement accompanies reaction of a secondary alcohol with PBr_5 (eq 2).[3] It should be noted that reaction of ***Phosphorus(V) Chloride*** with this same substrate gave direct replacement of the OH with Cl with inversion of configuration.[4] Rearrangement and addition of bromine across a double bond has been noted in the reaction with a propargyl alcohol derivative (eq 3).[5]

Cleavage of Ethers.

PBr_5 has been used to cleave diisopropyl ether to isopropyl bromide.[5]

Reaction with Ketones.

A regioselective dibromination of a diketone has been reported (eq 4).[6]

(4)

Related Reagents.

Many related reagents are available for the conversion of alcohols to bromides (see ***Phosphorus(III) Bromide*** and related reagents cited therein).

Phosphorus(III) Bromide-Copper(I) Bromide-Zinc

PBr_3-Cu_2Br_2-Zn

(PBr_3)

[7789-60-8] · Br_3P · Phosphorus(III) Bromide-Copper(I) Bromide-Zinc · (MW 270.67) (Cu_2Br_2)

[7787-70-4] · Br_2Cu_2 · Phosphorus(III) Bromide-Copper(I) Bromide-Zinc · (MW 286.90) (Zn)

[7440-66-6] · Zn · Phosphorus(III) Bromide-Copper(I) Bromide-Zinc · (MW 65.39)

(conversion of enediols into 1,3-dienes)

Physical Data: see entries for ***Phosphorus(III) Bromide***, ***Copper(I) Bromide***, and ***Zinc***.

General Discussion.

Transformation of 3-ene-1,2-diols into 1,3-dienes can be accomplished in the presence of PBr_3 and Cu_2Br_2, followed by addition of excess Zn powder.[1,2] Excess Cu_2Br_2 (2.5 equiv) is utilized for the best results. It is thought that the Cu_2Br_2 facilitates both bromination and debromination to afford the conjugated dienes. Treatment of the reaction with zinc should be monitored carefully, since longer reaction times can cause cyclization induced by the ***Zinc Bromide*** and reduce yields of the desired alkenes. A variety of dienes can be produced by this method. Overall, allylic alcohols can be transformed into 1,3-dienes (eq 1). First, the allylic alcohol is epoxidized using the Sharpless epoxidation procedure, followed by protection of the alcohol as the silyl ether. Conversion of the epoxy silyl ether into the 3-ene-1,2-diol can be accomplished by treatment with ***Diethylaluminum 2,2,6,6-Tetramethylpiperidide*** (DATMP). Deoxygenation using PBr_3-Cu_2Br_2-Zn gives moderate yields of the diene. Deoxygenation using other standard methods gives low yields of alkene products. Geraniol can likewise be converted to the corresponding 1,3-diene (eq 2), and cyclic enediols can also be deoxygenated to afford cyclic dienes (eq 3).

Related Reagents.

Chlorodiphenylphosphine; ***Potassium Hexachlorotungstate(IV)***.

Phosphorus(III) Chloride[1]

PCl_3

[7719-12-2] · Cl_3P · Phosphorus(III) Chloride · (MW 137.32)

(reactive chlorinating agent;[1,2] strong oxo, aza, thio, and dienophilicity; reactive with organometallics and metal salts; phosphorus source for metal ion ligand synthesis[28])

Alternate Name: phosphorus trichloride.

Physical Data: mp -112 °C; bp 76 °C; *d* 1.586 g cm^{-3}.

Solubility: sol benzene, $CHCl_3$, CH_2Cl_2 ether, CS_2; dec in water or alcohols.

Form Supplied in: water-white liquid; widely available.

Purification: generally used as received without further purification. To purify, heat under reflux to expel dissolved hydrogen chloride, then distill at atmospheric pressure under N_2. Further purification is possible by vacuum fractionation several times through a -45 °C trap into a -78 °C receiver.

Handling, Storage, and Precautions: the liquid is highly toxic by ingestion and slightly toxic by single dermal applications. Inhalation can cause delayed, massive, acute pulmonary edema and death. Contact with water will be violent and result in sufficient gas evolution to rupture closed or inadequately vented containers. Acids produced by contact with water can evolve hydrogen on contact with metals. This reagent must be used in a fume hood.

Chlorinations.

Alcohols, aldehydes, ketones, and carboxylic acids have been chlorinated with PCl_3. The alternative phosphorochloridites, $SOCl_2$, HCl, PCl_5, Ph_3PCl_2, Ph_3P-hexachloroacetone, Ph_3P-CCl_4, and NCS-SEt_2,[1,2] have been used to convert alcohols to chlorides. Aldehydes and ketones are converted to phosphites by PCl_3. Conversion of a carboxylic acid to the acid chloride has been accomplished using PCl_3, PCl_5, $POCl_3$, and $SOCl_2$. In some cases, these reactions tend to be sluggish and substrate, solvent, and temperature dependent. Modified phosphorus halides, i.e. 2,2,2-trichloro-1,3,2-benzodioxaphospholes or Ph_3PCl_2, are superior phosphorus reagents for acid chloride formation.[1] Carboxylic acids are α-brominated with a combination of PCl_3 and Br_2.[3] Imidoyl halides, generated from amides, thioamides, or hydroxamic acid derivatives with PCl_3, are valuable synthetic intermediates and provide

access to a wide range of heterocycles, e.g. quinazolinones and oxadiazoles.[4]

Preparation of Phosphites.

Alcohols, diols, and phenols are readily converted to phosphites. Analogous reactions are seen with thiols[1] and amines.[5] Diaryl phenols react to form medium-sized heterocyclic ring systems (eq 1).[6]

(1)

Dihydroxyarenes yield dioxaphospholes with PCl_3.[7] A special subclass of phosphite reactions are phosphitylations. Dichlorophosphite derived from PCl_3 and an alcohol, epoxide, or $P(OMe)_3$ are common phosphitylation reagents. Replacement of the alcohol by an amine leads to dialkylaminodichlorophosphites and subsequent phosphoramidation of the substrate.[8] Direct phosphitylation with PCl_3 is useful with sterically hindered axial hydroxy functions which fail to phosphorylate with other reagents (eq 2).[9]

(2)

$R^1 = 4\text{-}MeOC_6H_4CO$, $R^2 = 1\text{-menthol}$

Oxidations.

Oxidation of PCl_3 with ozone,[10] diazomethane/chlorine,[11] or oxygen/ethylene,[12] produces $POCl_3$ or, in the latter two cases, phosphate esters.

Deoxygenations.

Sulfoxides,[13] amine *N*-oxides,[14] and hydroxy amides[15] are readily reduced with PCl_3 to the corresponding sulfides, amines, and amides. Alternative sulfoxide reducing agents include AcCl, RCOCl, I^-, Sn^{2+}, Fe^{2+}, $SiHCl_3$, $Si_2H_2Cl_2$, $LiAlH_4$, $NaBH_4/CoCl_2$, $BHCl_2$ (aliphatic >> aryl), Rh/H_2, $Pd/C/H_2$, $Fe(CO)_5$, $TiCl_3$, TMSI, TMSBr, I_2, and $PhSiMe_3$. The presence of active hydrogens will complicate attempts to reduce amine *N*-oxides. Amine *N*-oxides can also be reduced using H_2SO_3, Raney Ni, $Pd/C/H_2$, and R_3P (R = alkyl or aryl).

Amines.

Reaction of PCl_3 with quaternary ammonium salts yields phosphaindolizines and thiazolodiazaphospholes.[16] Imines produce phosphonates[17] whereas hydrazones are converted to pyrazoles, indoles, and nitriles.[18] Nitrones undergo rearrangement to secondary or tertiary amides[19] and primary alkylnitro compounds are reduced to nitriles (eq 3).[20] Diazonium salts are transformed to phosphonic acids.[21]

(3)

Reaction with Organometallic Compounds.

Organomagnesium (eq 4),[22,23] lithium,[24] and other main group metals[25] readily undergo ligand transfer with PCl_3 to form mono-, di-, or trialkyl(aryl) phosphines. A subclass of reactions include ***Aluminum Chloride***-assisted transformations to form phosphetanes (eq 5).[26]

(4)

Enols and Ketene Silyl Acetals.

Reaction of a silyl enol ether with PCl_3/***Zinc Chloride*** leads to the formation of dichlorophosphine addition products (see also ***Phosphorus(III) Chloride-Zinc(II) Chloride***). Ketene silyl acetals react directly with PCl_3 under very mild conditions to form similar addition products (eq 6).[27]

Ligands.

Synthesis of some phosphorus-containing ligand molecules have utilized PCl_3 as a key reagent for introduction of the phosphorus atom.[28]

Related Reagents.

Acetyl Chloride; ***Bromotrimethylsilane***; ***N-Chlorosuccinimide-Dimethyl Sulfide***; ***Dichloroborane Diethyl Etherate***; ***Hydrogen Chloride***; ***Iodine***; ***Iodotrimethylsilane***; ***Lithium Aluminum Hydride***; ***Pentacarbonyliron***; ***Phosphorus(V) Chloride***; ***Phosphorus Oxychloride***; ***Sodium Borohydride***; ***Thionyl Chloride***; ***Titanium(III) Chloride***; ***Trichlorosilane***; ***Triphenylphosphine Dichloride***; ***Triphenylphosphine-Hexachloroacetone***.

Phosphorus(V) Chloride[1]

PCl_5

[10026-13-8] · Cl_5P · Phosphorus(V) Chloride · (MW 208.22)

(chlorination of alcohols,[2] carboxylic acids,[3] amides,[4] aldehydes, ketones, and enols; Bischler-Napieralski synthesis of 3,4-dihydroisoquinolines;[5] Beckmann rearrangement of oximes[6])

Alternate Name: phosphorus pentachloride.

Physical Data: mp 179-181 °C (sublimes); *d* 1.6 g cm^{-3}.

Solubility: sol CS_2, CCl_4. Typical solvents for reactions which use PCl_5 are CCl_4, $CHCl_3$, CH_2Cl_2, hexane, decane, benzene, toluene, and diethyl ether.

Form Supplied in: white to pale yellow solid; widely available. In the solid state, PCl_5 exists in the ionic form, $[PCl_4]^+$ $[PCl_6]^-$.

Purification: by vacuum sublimation.[7]

Handling, Storage, and Precautions: reacts with moisture to liberate hydrochloric acid and phosphoric acids. It is extremely corrosive to the skin, eyes, and mucous membranes. It should be stored in a dry area in containers impervious to moisture and resistant to corrosion. Laboratory quantities may be stored in polyethylene bags placed within glass containers. This reagent should be used in a fume hood.

Chlorides from Alcohols and Phenols.

Alcohols are converted to alkyl chlorides with the formation of 1 equiv of HCl and $POCl_3$ by the action of PCl_5.[2] The stability of the substrate and product to acidic reaction conditions and the ease by which the product can be separated from the reaction byproducts greatly influences the suitability of PCl_5 for this functional group transformation. Depending upon the structure of the alcohol, dehydration to form an alkene[8] or rearrangement[9] may be significant competing processes. The conversion of the 3-hydroxymethyl cephalosporin to the 3-chloromethyl derivative[10] shown in eq 1 illustrates the use of PCl_5 for the chlorination of a primary alcohol with a substrate of considerable functional complexity and lability.

In select cases, secondary alcohols undergo chlorination with inversion of configuration upon reaction with PCl_5 (eq 2).[11]

Tertiary alcohols are converted to tertiary chlorides under mild conditions with retention of configuration, presumably through an S_N1, tight ion-pair mechanism (eq 3).[12] The reactions are complete within minutes of mixing the tertiary alcohol with PCl_5 in $CHCl_3$ or ether at 0 °C in the presence of calcium carbonate. Chlorination of 1,1,1-trifluoro-2-(trifluoromethyl)-3-butyn-2-ol with PCl_5 leads to 1-chloro-3,3-bis(trifluoromethyl)allene (eq 4).[13] This tertiary alcohol is unreactive towards $SOCl_2$, $POCl_3$, PCl_3, concd. HCl, and $POCl_3$/pyridine. Phenols substituted with strong electron-withdrawing groups can be converted to aryl chlorides with PCl_5.[14]

A polymer-supported form of PCl_5 has been developed by slurrying PCl_5 with Amberlite IRA 93 resin in CCl_4.[15] The resulting resin is effective for the chlorination of primary and secondary alcohols in yields of 70-98%. Some elimination products are observed with secondary alcohols. The reaction may be conducted in hydrocarbon, ether, or halogenated hydrocarbon solvents. The phosphorus byproducts are retained on the resin and separated from the product by filtration. Regeneration of the resin is possible by washing with aqueous acid and base. Acid-sensitive substrates are susceptible to degradation.

Carboxylic Acid Chlorides from Acids.

PCl_5 may be employed for the conversion of carboxylic acids to their acid chlorides.[16] Typically, the acid is combined with PCl_5 either neat[17] or in solvents such as ether[18] or benzene.[19] The use of PCl_5 is most convenient when the product can be isolated by direct crystallization[20] or distillation[21] from the crude reaction mixture. In some cases, aqueous workups may be employed to remove acidic byproducts without significant hydrolysis.[22] Because of the difficulties associated with separating the acid chloride from the byproduct $POCl_3$, the use of PCl_5 for this functional group transformation has largely been supplanted by $SOCl_2$, $COCl_2$, or $(COCl)_2$,[23] particularly in conjunction with catalytic amounts of DMF.[24] The polymer-supported form of PCl_5,[15] described above for the chlorination of alcohols, also converts carboxylic acids to the corresponding acid chlorides in 48-91% yields.

Nitriles from Amides.

Primary amides are dehydrated to afford nitriles upon heating with PCl_5.[4a-e] Due to the severity of the reaction conditions, substrates of limited functional complexity are tolerated. The reactions are generally conducted either neat[25] or with $POCl_3$[26] as a solvent. This method is useful for products which can be isolated by distillation from the crude reaction mixture. Secondary amides, most notably *N*-alkylbenzamides, when subjected to PCl_5 may undergo the von Braun degradation to produce a benzonitrile and an alkyl chloride.[27]

Chloromethyleneiminium Chlorides and Imidoyl Chlorides from Amides, Oximes, Hydroxamic Acids, and Ureas.

Tertiary amides react with PCl_5 to afford chloromethyleneiminium chlorides,[4d,g-i] whereas secondary amides afford imidoyl chlorides.[4d-f,j] In each case, $POCl_3$ and HCl are generated as reaction byproducts. The amide chlorides and imidoyl chlorides are frequently used as intermediates for subsequent chemical transformation and are not isolated. When desired, isolation has been accomplished by either distillation or crystallization. In choosing PCl_5 as a reagent for this transformation, consideration must be given to the acid lability and reactivity of the substrate. Depending upon the substrate and reaction conditions, the formation of imidoyl chlorides by the action of PCl_5 may be accompanied by further reaction to produce a nitrile and alkyl chloride via the von Braun degradation.[27] α-Chlorination can be a problem if excess PCl_5 is used, and self-condensation can occur at elevated temperatures if an α-CH is present in the imidoyl chloride.[4g] The presence of a strong electron-withdrawing group α to the amide carbonyl can influence the course of the chlorination of an amide with PCl_5, as seen by the formation of the diazadiphosphetidine (eq 5) when *N*-methyltrifluoroacetamide is reacted with PCl_5.[28]

(5)

A highly practical example of the reaction of PCl_5 with a tertiary amide is the synthesis of ***Dimethylchloromethyleneammonium Chloride***, the Vilsmeier reagent. This salt is obtained in 88% yield by the careful addition of PCl_5 to ***N,N-Dimethylformamide*** while allowing the reaction to exotherm to 100 °C followed by cooling to 0 °C, filtration, and washing.[29] The Vilsmeier reagent is useful for the chlorination of alcohols and acids.

PCl_5 has found considerable application for the removal of amide side chains[30] in the industrial scale manufacture of semisynthetic cephalosporins[31] and penicillins.[32] The intermediate imidoyl chlorides, produced by the action of PCl_5 on a secondary amide, are converted to imino ethers upon the introduction of an alcohol to the reaction mixture. The imino ethers undergo further reaction to afford the deprotected C(7)-amino cephalosporin or C(6)-amino penicillin.[33]

Iminium and imidoyl chlorides have a prominent position as intermediates for the synthesis of heterocyclic compounds. In this regard, PCl_5 has found extensive application. Imidoyl chlorides derived from the treatment of *N*-(2-phenylethyl)carboxamides with PCl_5 can undergo Bischler-Napieralski cyclization[5] to form 3,4-dihydroisoquinolines (eq 6).[34] In addition to PCl_5, this cyclization has been effected with P_2O_5, $POCl_3$, $POCl_3$ in refluxing xylene or decalin, P_2O_5 in pyridine, and polyphosphoric acid. *N,N´*-Disubstituted oxamides (eq 7)[35] and the imines or hydrazones of α-acylamino ketones (eq 8)[36] react with PCl_5 to form imidoyl chlorides which undergo subsequent intramolecular cyclization to produce imidazoles.

(6)

(7)

(8)

The reaction of oximes with PCl_5 can lead to imidoyl chlorides via Beckmann rearrangement.[6] The reaction is frequently conducted in ether at or below ambient temperature. Aromatic, hydrocarbon, and halogenated hydrocarbon solvents are also used. The oxime of 4-phenyl-3-methyl-3-buten-2-one undergoes Beckmann rearrangement within 5 to 15 min upon treatment with PCl_5 in decalin at 0 °C to give an imidoyl chloride.[37] Subsequent treatment with P_2O_5 at reflux affords 1,3-dimethylisoquinoline (eq 9). 2-(Oximino)indan-1-ones afford 1,3-dichloroisoquinolines when subjected to 1 equiv of PCl_5 in $POCl_3$ followed by treatment with anhydrous HCl and then a second equiv of PCl_5 (eq 10).[38] Treatment of an oxime which contains an α-alkoxy, α-alkylthio, or α-alkylamino group with PCl_5 can lead to second-order Beckmann rearrangement,[39] as exemplified in eq 11.[40]

(9)

(10)

The reaction of alkylbenzohydroxamates with PCl_5 in ether offers a general preparative method for the synthesis of *O*-alkylbenzohydroximoyl chlorides.[41] Ketenimines[42] can be derived by the treatment of secondary amides bearing a single α-CH with PCl_5 followed by dehydrohalogenation with triethylamine.[43] Alkoxycarbonylimidoyl chlorides are obtained by the reaction of the esters of *N*-acylcarbamic acids with PCl_5.[44] *N,N´*-Dialkylureas in which the alkyl groups are primary react with PCl_5 to form 1,3-diaza-2-P^V-phosphetidinones, whereas chloroformamidinium chlorides are produced when the alkyl groups are secondary.[45] *N*-Alkyl-*N*-nitrosamides undergo rearrangement to the corresponding *N*-alkyloxamides via an intermediate *N*-nitrosochloroiminium chloride upon reaction with PCl_5.[46]

gem-Dichlorides from Ketones, Aldehydes, and Esters.

Ketones and aldehydes may be converted into *gem*-dichlorides by the action of PCl_5.[47] Formate esters[48] and esters with strong electron-withdrawing groups α to the carbonyl[47] react with PCl_5 to give the corresponding *gem*-dichlorides. Conversions have been effected either neat,[49] or with PCl_3,[50] $POCl_3$,[51] or halogenated hydrocarbons[52] as solvents. The reaction rate and product distribution are influenced by the solvent employed.[52a,b] Polar solvents, such as nitromethane and acetonitrile, greatly retard the reaction. The presence of an α-CH group can lead to the formation of vinyl chlorides as frequent byproducts.[52a,53] Perhaloacetones are resistant to chlorination with PCl_5 under the typical conditions employed for this conversion; however, the *gem*-dichlorides can be obtained in modest yields upon heating at 275-300 °C in an autoclave.[54]

Vinyl Chlorides from Enols.

PCl_5 reacts with the enolic form of enolizable cyclic[55] and acyclic[56] carbonyls to form vinyl chlorides. A side-reaction encountered with esters has been formation of the acid chloride, in which case reesterification during the reaction workup affords improved yields (eq 12).[55] Hydroxypyridines,[57] hydroxyquinolines,[58] and hydroxyisoquinolines[38] are converted to chloropyridines, chloroquinolines, and chloroisoquinolines by the action of PCl_5.

Other Applications.

Alkanes,[59] arylalkanes,[59a] heteroaromatics,[60] and alkenes[59,61] have been chlorinated with PCl_5 to afford chloro alkanes, chloro aromatics and *vic*-dichlorides. The use of PCl_5 as a catalyst for the chlorination of alkanes, cycloalkanes, and arylalkanes has been reported.[62] Secondary nitriles are α-chlorinated when subjected to PCl_5 either neat[63] or in an inert solvent such as CCl_4 or $CHCl_3$.[64] Anhydrides are converted to diacid chlorides by the action of PCl_5.[65] Sulfonyl and sulfamoyl chlorides may be prepared by heating the corresponding acid[66] or acid salt[67] either neat or in an inert solvent with PCl_5. PCl_5 has been used to deoxygenate *N*-oxides,[68] hydroxylamines,[69] and sulfoxides.[70] Hydroxylamines in which the α-carbon is tertiary can undergo the Stieglitz rearrangement to afford imines when treated with PCl_5.[71] Highly fluorinated carbinols bearing an α-CH, which prove resistant to the action of $SOCl_2$, SO_2Cl_2, HCl, and $ZnCl_2$, are converted to alkenes by the action of PCl_5.[72] Cyclic acetals of α-keto acids, when reacted with PCl_5 in CH_2Cl_2, afford esters of halohydrins.[73] Glyoxal bis-acetals are converted to 1,2-dichloro-1,2-dialkoxyethanes by the action of PCl_5.[74] This has been developed into a procedure for the synthesis of alkynic diethers.[75] Imines have been converted into amides upon heating with PCl_5, either neat or in a solvent such as xylene, followed by treatment with water.[76] A method has been developed for the synthesis of alkyl chlorides by the reaction of PCl_5 with the alkyl salicylates.[77] The yields are higher in several cases for this procedure when compared to other methods for the chlorination of alcohols; however, synthesis of the alkyl salicylate is required.

Phosphorus(III) Chloride-Zinc(II) Chloride

PCl_3-$ZnCl_2$

(PCl_3)

[7719-12-2] · Cl_3P · Phosphorus(III) Chloride-Zinc(II) Chloride · (MW 137.32) ($ZnCl_2$)

[7646-85-7] · Cl_2Zn · Phosphorus(III) Chloride-Zinc(II) Chloride · (MW 136.29)

(preparation of aminodiphosphonic acids,[1] trialkylphosphines,[2] and arylphosphonic acids;[3] conversion of alcohols to alkyl chlorides[4])

Physical Data: see entries for ***Phosphorus(III) Chloride*** and ***Zinc Chloride***.

Handling, Storage, and Precautions: freshly fused $ZnCl_2$ is used in most cases.

Phosphorylation.

PCl_3 and $ZnCl_2$ can be used to prepare phosphonic acids and trisubstituted phosphines. Aminodiphosphonic acids can be formed by the reaction of nitriles and PCl_3 in the presence of a Lewis acid. In particular, HCN can be converted to (aminomethylene)diphosphonic acid by reaction of PCl_3 and $ZnCl_2$ (eq 1).[1] A proton source such as HCl is required.

(1)

Arylphosphonic acids and diarylphosphonic acids can also be obtained by reacting diazonium salts with PCl_3.[5] Although diazonium tetrafluoroborates are most often used, because of their stability and ease of isolation, diazonium chlorozincates (zinc chloride double salts of diazonium chlorides) can be used to prepare the arylphosphonic acids. Thus diazonium chlorozincate is reacted with PCl_3 in the presence of Cu^I to afford the arylphosphonium salt. Arylphosphonic acids are formed after aqueous workup (eq 2).[3] Use of diazonium chlorozincates does not offer any advantages over use of the tetrafluoroborate salts.

(2)

Tertiary phosphines can be prepared by the Friedel-Crafts reaction of aromatic compounds with PCl_3 in the presence of $ZnCl_2$. When 3 equiv of aromatic compound are utilized, triarylphosphines are produced.[6] However, if 1 equiv of aromatic compound is used, the aryldichlorophosphine is formed. These aryldichlorophosphines can be hydrolyzed to give arylphosphonous acids, or reacted with 2 equiv of Grignard reagent to give unsymmetrical trisubstituted phosphines (eq 3).[2]

(3)

Chlorination.

Conversion of an alcohol to an alkyl chloride can also be accomplished with PCl_3 and $ZnCl_2$. Although this transformation is usually attained from simple alcohols with a number of reagents including $POCl_3$, conversion of *O*,*O*-diethyl *S*-(hydroxymethyl) phosphorodithioate to the chloromethyl phosphorodithioate is not successful when $POCl_3$ is used, and only dehydration occurs. Conversion of the hydroxymethyl to the chloromethyl phosphorodithioate can be accomplished in good yield (eq 4) by reaction of the alcohol with PCl_3 followed by addition of a catalytic amount of anhydrous $ZnCl_2$.[4] Other Lewis acid catalysts such as $SnCl_4$ are not as effective. Use of PCl_5 in inert solvents also gives chlorinated products.

(4)

Related Reagents.

Phosphorus(V) Chloride; ***Phosphorus Oxychloride***.

Phosphorus(III) Iodide

[13455-01-1] · I_3P · Phosphorus(III) Iodide · (MW 411.67)

(conversion of alcohols to iodides; deoxygenation of epoxides to alkenes; reduction of sulfoxides, selenoxides, selenones, ozonides, and α-halo ketones; elimination of β-hydroxy sulfides, dithioacetals, and orthothioesters or their selenium counterparts to form alkenes; conversion of aldoximes and nitro compounds to nitriles; cleavage of dimethyl acetals; water-soluble phosphorus byproducts are usually formed)

Alternate Name: phosphorus triiodide.

Physical Data: mp 61 °C.

Solubility: very sol CS_2; reacts with protic solvents.

Form Supplied in: red solid; widely available commercially.

Handling, Storage, and Precautions: commercial samples are generally suitable for use without purification; store under an inert atmosphere.

Conversion of Alcohols to Iodides.

PI_3 is a classic reagent for the conversion of iodides to alcohols. For example, cetyl alcohol is converted to 1-iodohexadecane in 85% yield by treatment with PI_3 (neat).[1] More recently, Krief and co-workers[2] found that a cyclopropyl carbinol (eq 1) is cleanly converted to the iodide with ring opening upon treatment with PI_3 (Et_3N, CH_2Cl_2, 0 °C, 0.5 h, 73%). ***Diphosphorus Tetraiodide***, a commercially available phosphorus halide which is in equilibrium with PI_3 in solution, is a more commonly employed reagent for the conversion of alcohols to iodides and effects many of the same transformations as PI_3.[3] See also ***Triphenylphosphine-Iodine*** for the conversion of alcohols to iodides.

(1)

Deoxygenations and Reductions.

PI_3 has found use as a deoxygenating and reducing agent. Epoxides are stereospecifically deoxygenated to the corresponding alkenes in good yield and with retention of configuration. For example, the *cis*- and *trans*-epoxides shown in eq 2 are converted (CS_2, 20 °C, 6-8 h) to *cis*- and *trans*-9-octadecene in 83 and 90% yields, respectively.[4] Diphosphorus tetraiodide (P_2I_4) and ***Iodotrimethylsilane*** (TMSI) give similar results. A number of other methods for epoxide deoxygenation have been developed.[5]

(2)

(a) $R^1, R^3 = (CH_2)_7Me$; $R^2 = H$; 83%
(b) $R^1 = H$; $R^2, R^3 = (CH_2)_7Me$; 90%

A variety of methods for the reduction of sulfoxides to sulfides are available.[6] PI_3 rapidly reduces aryl alkyl and dialkyl sulfoxides and selenoxides, usually at -78 °C (eq 3).[7] For example, treatment of ethyl phenyl sulfoxide with 1 equiv of PI_3 (CH_2Cl_2, -78 °C, 15 min) affords ethyl phenyl sulfide in 91% yield. Others have successfully employed this procedure.[8,9] Dialkyl sulfoxides generally react in somewhat lower yield. A phenyl vinyl sulfoxide (eq 3, entry c) requires ambient temperatures to react. Selenoxides behave similarly, and P_2I_4 can usually be used in place of PI_3.[10] Treatment of decyl phenyl selenone with PI_3 (CH_2Cl_2, 0 °C, 30 min) affords a mixture of the reduced product, decyl phenyl selenide (69%), and the substitution product, *n*-decyl iodide.[11]

(3)

(a) X = S; R^1 = Ph; R^2 = Et; 91%
(b) X = S; R^1, R^2 = Pr; 71%
(c) X = S; R^1 = Ph; R^2 = CH=CHC_5H_{11}; 75%
(d) X = Se; R^1 = Ph; R^2 = $C_{10}H_{21}$; 93%
(e) X = Se; R^1 = Me; R^2 = CH(Me)C_6H_{13}; 87%

PI_3 can be used for the efficient reduction of an ozonide, as illustrated by the formation of the cyclopropanecarbaldehyde in eq 4.[12,13] An advantage over the traditional ***Triphenylphosphine*** reduction is the formation of water-soluble phosphorus byproducts from PI_3. It should be noted, however, that PI_3 is reported to react with certain aldehydes.[14]

(4)

PI_3 is reported to dehalogenate α-bromo and α-iodo ketones.[15] For example, as shown in eq 5, 1-iodo-2-dodecanone is reduced to 2-dodecanone by PI_3 in CH_2Cl_2 (25 °C, 1 h, 89%). 1-Bromo-2-octanone affords 2-octanone in 75% yield (25 °C, 4.5 h). This PI_3 reduction can be coupled with the regioselective opening of terminal epoxides by TMSI and alcohol oxidation for a three-step transformation of a terminal epoxide to a methyl ketone.[15,16] P_2I_4,[15] triphenylphosphine,[17] ***1,3-Dimethyl-2-phenylbenzimidazoline***,[18] $PhSiH_3/Mo^0$,[19] ***Samarium(II) Iodide***,[20] ***Zinc-Acetic Acid***,[21] ***Iron-Graphite***,[22] ***Tri-n-butylstannane***,[23] ***Sodium O,O-Diethyl Phosphorotelluroate***,[24] lithium 2-thiophenetellurolates,[25] and a wide variety of other reagents[26,27] can also be used for the reduction of α-halo carbonyl compounds.

(5)

$R^1 = C_{10}H_{21}$, $R^2 = H$, $X = I$; 89%
$R^1 = C_6H_{13}$, $R^2 = H$, $X = Br$; 75%
$R^1, R^2 = C_8H_{17}$, $X = I$; 97%

Elimination Reactions.

PI_3 or P_2I_4 effects the stereospecific *anti*-elimination of β-hydroxy sulfides to alkenes.[28] For example (eq 6), treatment of the *anti*-β-hydroxy sulfide with PI_3 (CH_2Cl_2-Et_3N, 50 °C, 1.5 h) affords (*E*)-9-octadecene (93% yield). Treatment of the *syn*-isomer affords (*Z*)-9-octadecene (93% yield, *Z*:*E* = 94:6). Trisubstituted, but apparently not tetrasubstituted, alkenes can also be formed from the appropriately substituted β-hydroxy sulfides using these reagents. Similarly, β-hydroxy selenides undergo elimination to the corresponding alkenes. With these latter substrates, certain tetrasubstituted alkenes are accessible.[29] ***Methanesulfonyl Chloride***/Et_3N[30] and *N*-ethyl-2-fluoropyridinium tetrafluoroborate/lithium iodide[31] are alternative reagents.

(6)

anti; $R^1 = C_8H_{17}$, $R^2 = H$ (*E*) isomer, 93%
syn; $R^1 = H$, $R^2 = C_8H_{17}$ (*Z*) isomer, 90%

Vinyl sulfides and ketene dithioacetals[32] are available via treatment of β-hydroxy thioacetals and β-hydroxy orthothioesters with PI_3 or P_2I_4.[33] For example (eq 7), treatment of the β-hydroxy orthothioester (entry a) with PI_3 (CH_2Cl_2-Et_3N, 0 °C, 0.5 h) affords the thioketene acetal (**1**) in 69% yield. With certain substitution patterns the rearranged product (**2**) competes (e.g. entry b) or is the predominant product (e.g. entry c). The rearrangement is less of a problem with the corresponding β-hydroxy orthoselenoester (i.e. entry c vs. entry d). ***Thionyl Chloride*** is also a useful reagent in some cases.

(a) $R^1 = c\text{-}C_3H_5$, $R^2 = Me$, X = S (1):(2) = 69: 0
(b) $R^1 = C_5H_{11}$, $R^2 = H$, X = S (1):(2) = 63:13
(c) $R^1 = Ph$, $R^2 = H$, X = S (1):(2) = 7:68
(d) $R^1 = Ph$, $R^2 = H$, X = Se (1):(2) = 86: 0

Vinyl sulfides and ketene thioacetals[32] are also available via treatment of thioacetals and orthothioesters with PI_3 or P_2I_4 (eqs 8 and 9).[34] The corresponding seleno analogs are similarly available. For example (eq 8), treatment of the trimethyl orthoselenoester with PI_3 (CH_2Cl_2-Et_3N, 20 °C, 1 h) affords the ketene selenoacetal in 90% yield. ***Tin(IV) Chloride*** or ***Titanium(IV) Chloride*** in combination with ***Diisopropylamine*** is also effective for the transformation of orthothioesters and orthoselenoesters to ketene acetal derivatives.[35] ***Copper(I) Trifluoromethanesulfonate***,[36] ***Mercury(II) Trifluoroacetate***/***Lithium Carbonate***,[37] and ***Benzenesulfenyl Chloride***[38] are useful reagents for the conversion of dithioacetals to vinyl sulfides.

In the presence of ***Triethylamine***, PI_3[7] or P_2I_4[10] effects the conversion of aldehyde oximes or primary nitro compounds to nitriles. For example, treatment of the aldoxime derived from phenylacetaldehyde with 1 equiv of PI_3 (CH_2Cl_2-Et_3N, 25 °C, 15 min) affords benzyl cyanide in 83% yield (eq 10). Similarly, treatment of 1-nitrodecane with 2 equiv of PI_3 (CH_2Cl_2-Et_3N, 25 °C, 15 min) affords 1-cyanononane (82%) (eq 11). Other reagents for the direct conversion of primary nitro compounds to nitriles include $Sn(SPh)_4$/Ph_3P/DEAD,[39] TMSI,[40] ***Sulfur Dioxide***/Et_3N,[41] and ***Phosphorus(III) Chloride***.[42]

(10)

$R = PhCH_2$, 83%
$R = C_{10}H_{21}$, 85%

(11)

$R = C_9H_{19}$, 82%

Miscellaneous Transformations.

PI_3 has been used for the cleavage of dimethyl acetals under nonaqueous conditions.[43] For example (eq 12), treatment of the dimethyl acetal derived from 2-decanone with PI_3 (CH_2Cl_2, 20 °C, 15 min; aq workup) affords the ketone in 85% yield. Alternative nonaqueous acetal cleavage reagents include P_2I_4,[43] TMSI,[44,45] ***Diiodosilane***,[46] $TiCl_4$/***Lithium Iodide***,[47] ***Bromodimethylborane*** or bromodiphenylborane,[48] and ***Samarium(III) Chloride***/***Chlorotrimethylsilane***.[49]

(12)

(a) $R^1 = C_9H_{19}$, $R^2 = Me$, 85%
(b) $R^1 = C_8H_{17}$, $R^2 = H$, 57%

PI_3 is a useful ***Hydrogen Iodide*** precursor in the silica- and alumina-mediated additions of HI to alkenes.[50,51] PI_3 has also found use as a source of electrophilic phosphorus in the synthesis of novel organophosphorus compounds (e.g. $(CF_3)_3P$[52]) and novel phosphorus-containing organometallic compounds.[53]

Phosphorus(V) Oxide

(P_2O_5)

[1314-56-3] · O_5P_2 · Phosphorus(V) Oxide · (MW 141.94) (P_4O_{10})

[16752-60-6] · $O_{10}P_4$ · Phosphorus(V) Oxide · (MW 283.88)

(dehydrating agent for acids and amides;[1] cyclization catalyst)

Alternate Names: phosphorus pentoxide; phosphoric anhydride.

Physical Data: mp 569 °C; sublimes at 250 °C under vacuum.

Solubility: sol H_2SO_4, $MeSO_3H$.

Form Supplied in: white powder; commercially available from many sources.

Preparative Method: prepared by combustion of phosphorus in dry air.

Purification: generally used without further purification; can be sublimed under vacuum.

Handling, Storage, and Precautions: corrosive! Reacts violently with water, releasing H_3PO_4 and heat.

Dehydration of Amides to Nitriles.

Dehydration of amides with P_2O_5 is one of many methods for the synthesis of nitriles.[2] Distillation of an unsubstituted amide from an excess of P_2O_5 leads to good yields of the nitrile (eq 1).[3,4] In many cases the reaction is carried out in the absence of solvents, although suitably high-boiling solvents can be used. These conditions are not compatible with many common functional groups, and this transformation can be achieved by other reagents,[5] including ***Thionyl Chloride*** and ***Phosphorus Oxychloride***.

(1)

Amides can be made by treatment of silyl esters with P_2O_5, followed by treatment with ***Hexamethyldisilazane***.[6] Some *N*-substituted amides convert to ketene imines upon treatment with P_2O_5 (eq 2).[7]

(2)

Formation of Anhydrides.

Dehydration of carboxylic acids with P_2O_5 is an effective method for the preparation of carboxylic anhydrides (eq 3). Acids have been converted to anhydrides with silica gel-supported P_2O_5, marketed as Sicapent by Merck.[8] Similar results are obtained by heating a suspension of a carboxylic acid with a powdered mixture of P_2O_5, $CuSO_4$, and Na_2SO_4 in a primary alcohol. This gives the ester in 60-80% yields.[9]

(3)

Cyclization Catalyst.

A 10% by weight (approximately saturated) solution of P_2O_5 in ***Methanesulfonic Acid*** (Eaton's reagent) has been used as an effective replacement for ***Polyphosphoric Acid*** (PPA) as an acid cyclization catalyst. Advantages to this reagent include the ease of stirring $MeSO_3H$ solutions relative to PPA and the greater solubility of many organic compounds in $MeSO_3H$ relative to PPA. Yields are comparable to or better than those obtained with PPA in Beckmann rearrangements (eq 4).[10] The combination of P_2O_5 and methanesulfonic acid is an efficient catalyst for

acid/alkene cycloadditions (eq 5).[11] See also ***Phosphorus(V) Oxide-Methanesulfonic Acid***.

(4)

(5)

This mixture is a particularly useful catalyst in the synthesis of 2-substituted indole derivatives via the Fischer indole reaction of asymmetrical ketones (eq 6).[12] Other catalysts (PPA, H_2SO_4/MeOH, PPSE, Amberlyst 15) give lower regioselectivity. Decomposition of the starting material can be minimized by dilution of the P_2O_5/$MeSO_3H$ mixture with CH_2Cl_2. Treatment of (**1**) with P_2O_5 at high temperature results in cyclization to produce 7-deazahypoxanthines (eq 7).[13]

(6)

(7)

(1)

Condensing Agent.

Heating a mixture of P_2O_5, a primary or secondary amine (often using the amine as solvent), and a heterocyclic ketone or alcohol is a general route to substituted adenines (eq 8),[14,15] purines,[16,17] and pyrimidines.[18] Cyclization and ketone/amine condensations can often be combined in the one-pot transformations of 4,5-disubstituted imidazoles to substituted adenines (eqs 9 and 10).[19]

(8)

(9)

(10)

Cyclodehydrations.

The Pictet-Gams modification of the Bischler-Napieralski reaction is an important method for the preparation of isoquinolines.[19] This reaction relies on the dehydration of molecules such as (**2**) with P_2O_5 at high temperature (eq 11).[20] Lower temperatures lead to oxazoles, which can be converted to the isoquinolines by heating to 196 °C.

(2)

(11)

Trimethylsilyl Polyphosphate.

Heating a mixture of P_2O_5 with ***Hexamethyldisiloxane*** results in the formation of ***Trimethylsilyl Polyphosphate*** (PPSE), an organic soluble, aprotic alternative to PPE or PPA.[21] This reagent has proven useful for Beckmann rearrangements (eq 12),[21-23] and for generation and cyclization of nitrilium ions.[24]

(12)

Formamidines.

Condensation of formanilides with secondary amines in the presence of P_2O_5 produces formamidines in good yield (eq 13).[25] The reaction is compatible with electron-rich and electron-deficient arenes, but is limited to secondary amines.

(13)

Related Reagents.

Dimethyl Sulfoxide-Phosphorus Pentoxide; ***Phosphorus(V) Oxide-Methanesulfonic Acid***; ***Phosphorus(V) Oxide-Phosphoric Acid***.

Phosphorus(V) Oxide-Methanesulfonic Acid[1]

P_2O_5-$MeSO_3H$

[39394-84-8] · $CH_4O_8P_2S$ · Phosphorus(V) Oxide-Methanesulfonic Acid · (MW 238.06) (P_2O_5)

[1314-56-3] · O_5P_2 · Phosphorus(V) Oxide-Methanesulfonic Acid · (MW 141.94) ($MeSO_3H$)

[75-75-2] · CH_4O_3S · Phosphorus(V) Oxide-Methanesulfonic Acid · (MW 96.12)

(acidic dehydrating agent used in cycloalkenone synthesis,[1] Friedel-Crafts reactions,[1] the Fischer indole synthesis,[2] the Beckmann rearrangement,[1] and other dehydrations; an alternative to polyphosphoric acid[1])

Alternate Name: Eaton's reagent.

Physical Data: 7.5 wt% solution: bp 122 °C/1 mmHg; *d* 1.500 g cm^{-3}.

Solubility: sol ether, alcohol, MeCN, CH_2Cl_2; insol toluene, hexane.[2,3]

Form Supplied in: 7.5 wt% solution is commercially available.

Preparative Method: prepared[1] by adding ***Phosphorus(V) Oxide*** (P_2O_5, 36 g) in one portion to ***Methanesulfonic Acid*** (360 g) and stirring at rt[3] until the P_2O_5 dissolves.[4] Although Eaton recommends the use of freshly distilled methanesulfonic acid to allow for a clean workup and good yields,[1] others report using the acid as purchased.[5,6]

Handling, Storage, and Precautions: Eaton's reagent is toxic and corrosive. Direct contact with this reagent should be avoided. The solution begins to yellow upon standing for long periods of time; however, this does not appear to affect the viability of the reagent.[1] Use in a fume hood.

Reagent Description.

The reagent was conceived as an alternative to the widely used, but often inconvenient, ***Polyphosphoric Acid*** (PPA) (see also ***Polyphosphate Ester***, PPE).[1] Eaton's reagent successfully addresses the drawbacks of PPA's physical properties. It is much less viscous, and is, therefore, easier to stir. Organic compounds are generally soluble in Eaton's

reagent, and the hydrolytic workup is less tedious.[1] Reactions are run at ambient or slightly elevated temperatures. Standard aqueous workup is easy and clean. Eaton recommends quenching the reaction with water; quenching in ice may cause methanesulfonic anhydride to precipitate and be extracted into the organic layer; quenching in aqueous base may cause extensive foaming.[1] In addition to its ease of handling, yields obtained with Eaton's reagent compare favorably with those obtained with PPA.[7] Few modifications of Eaton's original procedure have appeared. A 1:5 by weight ratio has been reported to be as effective as a 1:10 ratio.[8] It has been noted that, to avoid polymer formation, only the minimum amount of reagent needed to effect condensation should be used.[9] The nature of the reagent has not been rigorously determined. It appears that the reactive or catalytic species may vary by reaction. In certain acid-catalyzed reactions, P_2O_5 has been found to be superfluous.[10]

Cycloalkenones.

$P_2O_5/MeSO_3H$ is used as a reagent in several reactions leading to cycloalkenones. First described in Eaton's original paper, the lactone-to-cyclopentenone rearrangement (eq 1)[1] has since found wide use.[11]

(1)

In a related reaction, readily available nitroalkanoic acids cyclize to form cyclopentenones (eq 2).[12] As illustrated in eq 3,[13a] vinylcyclobutanones undergo acyl migration to produce either cyclopentenones or cyclohexenones.[13]

(2)

(3)

R = H	65%	0%
R = Me	13%	51%

Vinylcyclopentenones have undergone the Nazarov cyclization in good yield in the presence of Eaton's reagent (eq 4).[14] However, other reagents may be more generally useful, since there are reports of Eaton's reagent not providing optimal results in this reaction.[15]

(4)

Friedel-Crafts Acylations of Aromatic Rings.

Eaton's reagent has been used widely and very effectively[16a] to catalyze Friedel-Crafts acylations.[16] One of the few potential drawbacks is the deprotection of an aryl ether. The examples shown below compare the utility of Eaton's reagent vs. PPA with regard to this deprotection problem. In eq 5, although the cyclization proceeds with an undesired protecting group exchange, the cyclization fails in PPA.[17] Deprotection of an aryl methyl ether is avoided by using Eaton's reagent in place of PPA in one case (eq 6),[18] but not in another.[19] Intramolecular Friedel-Crafts acylations have been observed to occur without the addition of P_2O_5.[10] A comparative study found this observation to be generally applicable to intramolecular acylations, but not intermolecular acylations.[10b,20]

(5)

(6)

Eaton's reagent R = Me, 70%
PPA R = H, 28%

Friedel-Crafts Alkylations.

$P_2O_5/MeSO_3H$ compares favorably with other reagents in the Friedel-Crafts alkylation reaction.[21] Mechanistic aspects of this reaction have been discussed.[21b] Eq 7 shows an alkene-initiated alkylation that provides (+)-*O*-methylpodocarpate selectively.[22]

Dehydration.

Alcohols have been dehydrated to alkenes with Eaton's reagent (eq 8).[23] In a formal dehydration, a cyclopentenone has been transformed into a diene (eq 9).[24]

Fischer Indole Synthesis.

The use of Eaton's reagent as the acid catalyst in the Fischer indole reaction results in unprecedented regiocontrol

favoring 2-substituted indoles (eq 10).[2] In cases where the harshness of the reagent results in low yields of indoles, dilution of the reaction mixture in sulfolane or CH_2Cl_2 attenuates the problem. Mechanistic studies indicate that the catalytic species, in this reaction, is $MeSO_3H$. The role of P_2O_5 is to act as a drying agent. Further experiments indicate that for the Friedel-Crafts acylation this is not the case; a mixed anhydride is the catalytic species.[2]

Heterocycle Preparation.

Various heterocycles have been prepared through $P_2O_5/MeSO_3H$-mediated cyclizations. Condensation, and subsequent dehydration, of aminothiophenol and the appropriate acid provides benzothiazoles (eq 11).[25]

Oxadiazoles can be prepared from diacylhydrazines (eq 12).[26] Furans are formed from the cyclodehydration of a phenolic ketone (eq 13).[27]

(12)

(13)

Butenolides have been prepared by cyclization of keto esters (eq 14)[28] or by elimination of H_2O from a preformed hydroxy butenolide (eq 15).[29]

(14)

(15)

Yields in the synthesis of thiadiazolo[3,2-*a*]pyrimidin-5-ones have been greatly improved by using Eaton's reagent in the place of PPA (eq 16).[8b]

(16)

P_2O_5, $MeSO_3H$; 1:5	87%
PPA	18%

Eaton's reagent is superior to PPA in the addition of an amide across a double bond (eq 17).[30] In another synthesis of lactams, 3-alkenamides reacted stereoselectively with benzaldehyde to provide lactams containing three contiguous stereogenic centers (eq 18).[31]

(17)

(18)

Beckmann Rearrangement.

Eaton's disclosure of $P_2O_5/MeSO_3H$ as an alternative to PPA compared the two reagents' ability to effect the

Beckmann rearrangement.[1] Eaton's reagent has been reported to be superior to other reagents at inducing stereospecific rearrangement of the (*E*)- and (*Z*)-oximes of phenylacetone.[4] However, this is not a general finding. Rearrangement of the oxime in eq 19 does not provide the product expected from an *anti*-migration process.[32]

Phosphorus(V) Oxide-Phosphoric Acid

P_2O_5-H_3PO_4

(P_2O_5)

[1314-56-3] · O_5P_2 · Phosphorus(V) Oxide-Phosphoric Acid · (MW 141.94) (H_3PO_4)

[7664-38-2] · H_3O_4P · Phosphorus(V) Oxide-Phosphoric Acid · (MW 98.00)

(moderately strong mineral acid with a range of dehydrating properties; used for cyclizations and phosphorylations)

Physical Data: hygroscopic; viscous to highly viscous; colorless or light amber; specific gravity is dependent upon the concentration of the reagent, 2.060 at 83% phosphorus pentoxide content (see below).

Solubility: dissolution in any protic solvent will result in *violent* solvolysis of the reagent; dissolution in polar aprotic solvents can result in dehydration or destruction of the solvent; these reagents are not soluble in and do not react with nonpolar organics such as toluene or hexane.

Preparative Methods: best carried out by heating P_2O_5 with 85% H_3PO_4. A solution which is theoretically 76% P_2O_5 (see below) is obtained when 3*x* g of ***Phosphorus(V) Oxide*** is mixed with 4*x* g of 85% orthophosphoric acid. This mixture is heated and stirred until complete dissolution occurs.[1] When concentrations over 83% are desired, polyphosphoric acid (PPA) is used to dissolve the P_2O_5. A concentration of 86% P_2O_5 (super polyphosphoric acid) is reported to be useful in reactions which fail when PPA is used.[2] Preparation of super polyphosphoric acid is accomplished by mechanically stirring *x* g of P_2O_5 and 5*x* g of PPA while heating to 170-180 °C for 1 h. The reagent is kept warm while the substrate is added to avoid the extremely viscous mixture which results upon cooling to rt. Workup is accomplished by pouring the hot mixture onto ice.

Handling, Storage, and Precautions: when diluting P_2O_5 or any partially hydrolyzed derivative, care must be taken to avoid spattering caused by the exothermic hydrolysis. PPA has the ability to burn mucous membranes immediately and unprotected skin with time. Other than its corrosive nature, it has low inherent toxicity. Use in a fume hood.

Description of the Reagent.

P_2O_5/H_3PO_4 is not a discrete molecular entity, but can be considered to be any mixture which results from partial hydration of P_2O_5. The resulting solution is a complex mixture of phosphoric acids, which consists of

orthophosphoric acid and linear phosphoric acid chains. In order to avoid discussion of this complicated equilibrium, these mixtures are described empirically by stating the weight percent of the solution as if it were simply a solution of P_2O_5 in water. When the theoretical weight percent of P_2O_5 reaches 83%, the resulting mixture is commonly known as ***Polyphosphoric Acid*** (PPA). As the weight percent of P_2O_5 goes above 83%, longer chain phosphoric acids begin to predominate until at 89% P_2O_5 the mixture is 87% hypolyphosphoric acid (greater than 14 phosphoric acid units).

Cyclizations.

In work directed toward the synthesis of jasmone, the utility of a PPA/P_2O_5 (86% P_2O_5) mixture was first evidenced when a lactone was converted into a cyclic ketone (eq 1).[3]

(1)

The term super polyphosphoric acid was first coined when 86% P_2O_5 successfully effected the Pomeranz-Fritsch cyclization even though the resulting isoquinoline is sterically congested (eq 2).[2] Super PPA was also used to effect a Bischler-Napieralski cyclization to obtain isoquinolines in higher than normal yields (eq 3).[2] Some confusion exists about this report since *N*-formylphenethylamines should yield dihydroisoquinolines and not the tetrahydroisoquinolines reported.[4] It would appear that reduction of the intermediate dihydroisoquinoline was inadvertently omitted. In an efficient synthesis of a benzindolone (6-methoxy-Uhle's ketone), use of super PPA improved the low yield route which utilized normal PPA (eq 4).[5] In an attempt to develop methodology to convert methylcyclohexenones into indolones and pyrroloazepinediones, cyclization of a pyrrolo acid was found to proceed in 85% yield using super PPA while normal PPA gave poor yields (eq 5).[6]

(2)

(3)

(4)

(5)

Phosphorylations.

A mixture of P_2O_5 and H_3PO_4 (78% P_2O_5) was used to phosphorylate proteins in the first reported use of this reagent.[1] This methodology was applied to small molecules in the synthesis of pyridoxal phosphate (eq 6).[7]

Phosphorus Oxychloride

$POCl_3$

[10025-87-3] · Cl_3OP · Phosphorus Oxychloride · (MW 153.32)

(formylation of aromatic rings[1,2] (Vilsmeier-Haack reaction); phosphorylating agent;[3] dehydrating agent for amides; halogenation of alcohols, phenols, and heterocycles)

Alternate Name: phosphoryl chloride.

Physical Data: mp 1 °C; bp 106 °C; *d* 1.675 g cm^{-3}; *n* 1.461.

Solubility: sol THF, MeCN, CH_2Cl_2, many other solvents.

Form Supplied in: colorless, fuming liquid; commercially available.

Purification: by distillation in vacuo.[4]

Handling, Storage, and Precautions: toxic and corrosive; reacts vigorously with alcohols and water, liberating HCl, phosphoric acid, and heat. Protect from water. Use in a fume hood.

Chloromethyleneiminium Ions.[5-8]

Phosphorus oxychloride (**1**) is a strong Lewis acid that is widely used in synthesis. Of particular importance are reactions of (**1**) with substituted amides, most often ***N,N-Dimethylformamide*** or dimethylacetamide (DMA). These reactions lead to the formation of chloromethyleneiminium salts (**2**) (eq 1). These salts (Vilsmeier reagents, see ***Dimethylchloromethyleneammonium Chloride***) are highly versatile intermediates[6] and are involved in numerous important reactions, including the Vilsmeier-Haack[2,6] and Bischler-Napieralski[9] reactions. Formation of (**2**) can be achieved using ***Thionyl Chloride*** or ***Phosgene***, although there have been reports of differences in reactivity between $POCl_3$/DMF, $SOCl_2$/DMF, and $COCl_2$/DMF systems.[7,10,11]

(1)

(2)

Formylation of Aromatic Rings.[2,5,6,8,11]

The Vilsmeier reagent attacks electron-rich aromatic systems to form arylmethyleneiminium ions which liberate a formylated aromatic compound upon hydrolysis (eq 2). Thio- and selenoaldehydes can be prepared by hydrolysis in the presence of ***Sodium Hydrogen Sulfide***[6,12] or ***Sodium Hydrogen Selenide***.[13] A wide range of aromatic systems[6,11] can be formylated in this fashion, including benzene derivatives, polyaromatic hydrocarbons (eq 3), and azulene.[11] Substitution occurs at relatively electron-rich positions.

(2)

(3)

Formylation of Heterocycles.[6,11,14]

Many heterocycles are readily formylated by $POCl_3$/DMF, including pyrroles, thiophenes, furans, indoles, quinolines, pteridines, and purines.[6] Reaction at the 2- and 5-positions of pyrroles, furans, and thiophenes is preferred, and indoles undergo attack at the 3-position (eq 4).[6]

(4)

Formylation of Alkenes.[10,11]

Both activated and unactivated alkenes undergo electrophilic attack by (**2**).[5] Reaction at terminal positions is preferred.[6] Styrene derivatives give cinnamaldehydes; enamines[6] and aryl polyenes[15,16] react at terminal positions (eq 5).

(5)

Bischler-Napieralski Reaction.

A widely used method for cyclization of *N*-β-phenylethyl amides to form dihydroisoquinolines and isoquinolines (eq 6)[17-19] is the Bischler-Napieralski reaction.[9] A nitrilium ion intermediate has been implicated in this reaction.[20,21]

(6)

Fragmentation of the nitrilium ion interferes with the cyclization[20,21] of 1,2-diphenylethane derivatives, leading to formation of stilbenes rather than cyclization products. This problem has been overcome by using ***Oxalyl Chloride*** instead of (**1**).[22] Fragmentation (von Braun reaction or retro-Ritter reaction) occurs whenever a highly stable cation can be formed, such as benzyl[20] or *t*-butyl (eq 7).[21,23,24]

(7)

Treatment of tertiary amides with $POCl_3$/DMF (**2**) results in formation of β-dimethylamino α,β-unsaturated amides. The highly electrophilic iminium ion (**3**) is formed in this reaction, and in the presence of an alkene this undergoes cyclization (eq 8).[14,25]

(3)

(8)

Excess $POCl_3$ and DMF can lead to formylation of the initial heterocycle (eq 9). A series of α-substituted acrylonitriles has been prepared by dehydration of α,β-unsaturated amides (eq 10). $POCl_3$/DMF and $SOCl_2$/DMF give comparable results.[26]

Chloroaldehydes from Carbonyl Compounds.[7]

The enol tautomers of ketones react with $POCl_3$/DMF to form β-chloroacrolein derivatives (eq 11). The regiochemistry is determined both by the stability of the enol as well as by steric factors. Nonsymmetrical ketones often give a mixture of regioisomers, and most ketones produce a mixture of (*E*) and (*Z*) isomers of the product.[27] Aldehydes will undergo this type of reaction, although there are relatively few reports.

Reaction of $POCl_3$/DMF with carboxylic acids results in vinamidinium ions (eq 12).[28,29] These ions react with a variety of nucleophiles to produce pyrazoles, oxazoles, pyrimidines, diazepines, quinolines, quinolizines, and vinylogous sulfonamides.[30]

(12)

The Vilsmeier reagent (**2**) reacts with Grignard reagents as well as with alkylzinc and alkylaluminum reagents to form tertiary amines.[31] It also reacts with heteroatom nucleophiles, including thiols,[32] alcohols, and amines,[8] as well as with nucleophilic amines containing other functional groups.[5,33,34] Aromatic alcohols react with $POCl_3$/DMF to form aryl formates in 50-80% yield,[35] but aliphatic alcohols are more efficiently formylated with ***Benzoyl Chloride***/DMF.[36] Homoallylic alcohols such as (**4**) produce biphenyls in 30-98% yield[16] through initial dehydration[6] (eq 13) followed by electrophilic attack on the resulting aryl diene.

(13)

(**4**)

Halogenation of Alcohols.

The combination of $POCl_3$ and DMF can be used to halogenate primary, secondary, and tertiary aliphatic alcohols (eq 14),[37] whereas the reaction of primary alcohols and $POCl_3$ without DMF or DMA will generally lead to the formation of trialkyl phosphates.

(14)

A comparison of $POCl_3$ with SO_2Cl_2, PCl_3, MsCl, and $SOCl_2$ indicated that optimum conditions for the conversion of (**5**) to (**6**) (eq 15) are 1.1 equiv $POCl_3$ in DMF at 0 °C.[38]

(15)

Halogenation of Heterocycles.

Phosphorus oxychloride is widely used in the chlorination of heterocycles. In general, heterocyclic ketones (eq 16) or alcohols (eq 17) react readily with (**1**), including pteridines,[39] purines,[40,41] and others.

(16)

(17)

In the chlorination of the isoxazole (**7**), it was noted that freshly distilled $POCl_3$ is ineffective but that an older sample leads to the formation of the chloride (**8**). Further investigation showed that a mixture of $POCl_3$, acid (H_3PO_4), and an additional chloride source (pyridinium chloride) leads to reliable conversion of (**7**) to (**8**) (eq 18).[42]

(18)

Phosphorylation.[3,43]

Phosphorus oxychloride reacts with alcohols, amines, and thiols, resulting in phosphorylation of these functional groups. Trimethyl phosphate is a particularly effective solvent,[44] and tertiary amine bases are generally used as well. Treatment of primary alcohols with $POCl_3$ results in the formation of phosphonyl dichloride intermediates which, in the presence of excess alcohol, convert to symmetrical trialkyl phosphates.[10] It is generally possible to isolate aryl phosphorodichloridates when a two-fold excess of (**1**) is used and $AlCl_3$, KCl, or pyridine is used as a catalyst.[45,46] Secondary and tertiary alcohols tend to form alkyl chlorides and phosphoric acid.

Phosphorus oxychloride is very useful in the preparation of nucleoside 5´-phosphates (eq 19) given appropriate mixtures of $POCl_3$, pyridine, and water.[44,47] The primary hydroxy (5´) is sufficiently reactive for there to be minimal formation of cyclic phosphates at the 2,3-positions of nucleosides. The intermediate phosphorodichloridate can be converted to the corresponding triphosphate by treatment with inorganic phosphate in a convenient one-pot fashion.

(19)

Under anhydrous conditions, $POCl_3$ can be used to produce cyclic dialkyl phosphonyl chlorides from diols, and these can be hydrolyzed with water to the cyclic phosphates or with an alcohol to trialkyl phosphates. Treatment of forskolin (**9**) with $POCl_3$ leads to the formation of the cyclic phosphoryl chloride (**10**) in 55% yield as a mixture of two stereoisomers at phosphorus (eq 20).[48] A comparison of several phosphorylating agents showed that $POCl_3$, $(MeOC_6H_4)_2POCl$, and 2-chloro-2-oxo-1,3,2-dioxaphospholane all give the analogous products in virtually identical yield.[48]

Similar results can be obtained with primary amines,[49] although it is possible to obtain diamidophosphorochloridates by reaction of $POCl_3$ with substoichiometric amounts of amine.[50] Phosphorus oxychloride reacts more readily with primary amines than with primary alcohols, so that it is possible to prepare phosphoramides.[51] Alkoxides, however, react more rapidly than amines so it is possible to phosphorylate hydroxyls in the presence of amines. Again, like the reaction of $POCl_3$ with diols, diamines react with $POCl_3$ to form diazaphospholidines (eq 21).[52]

Carboxylic anhydrides can be prepared by treatment of carboxylic acids with $POCl_3$,[32] allowing the formation of both esters[32] and amides, although other methods are more common.[53] Dichloroacetyl chloride produces dichloroketene when treated with $POCl_3$ and ***Zinc/Copper Couple***.[54]

Dehydration of Amides.

Unsubstituted amides undergo dehydration upon treatment with $POCl_3$. This reaction can also be performed with P_2O_5, $SOCl_2$, or other reagents, and in a study of racemization at the α-position it was determined that dehydration with $POCl_3$ leads to more (albeit little) epimerization than dehydration with P_2O_5 or $SOCl_2$ (eq 22).[55]

Dehydration of alkyl and aryl *N*-formyl compounds with $POCl_3$ is one of the more general routes to alkyl and aryl isocyanides (eq 23).[56-59] A base, typically an amine base or ***Potassium t-Butoxide***, is also required. The method is simple and effective, although less useful for small, volatile isocyanides than other techniques.[60] The Bischler-Napieralski reaction can occur preferentially to isocyanide formation.[17]

Dehydration of Alcohols.

The combination of $POCl_3$ and ***Pyridine*** is an effective dehydrating agent for alcohols (eq 24)[61] and cyanohydrins.[62] The stereochemistry of elimination is *anti*, although the regioselectivity is often not high, particularly for tertiary alcohols.[63]

The combination of phosphorus oxychloride and ***Tin(II) Chloride*** reduces halohydrins to alkenes (eq 25). The elimination proceeds in an *anti* fashion.[64]

Beckmann Rearrangement.

Treatment of ketoximes with $POCl_3$ induces Beckmann rearrangement to form amides (eq 26).[65] Numerous other Lewis acids can be used for this transformation.[66,67]

Related Reagents.

Bis(trichloromethyl) Carbonate; ***Phosphorus(V) Oxide***; ***Phosphorus Oxychloride-Zinc(II) Chloride***; ***Thionyl Chloride***; ***p-Tolyl Vinyl Sulfoxide***; ***Trichloromethyl Chloroformate***.

Phosphorus Oxychloride-Zinc(II) Chloride

$POCl_3$-$ZnCl_2$

($POCl_3$)

[10025-87-3] · Cl_3OP · Phosphorus Oxychloride-Zinc(II) Chloride · (MW 153.32) ($ZnCl_2$)

[7646-85-7] · Cl_2Zn · Phosphorus Oxychloride-Zinc(II) Chloride · (MW 136.29)

(powerful Lewis Acid used in Friedel-Crafts reactions to prepare xanthones,[1] benzophenones,[2] coumarins,[3] and chromanones;[4] phosphorylation of alcohols[5])

Physical Data: see entries for ***Phosphorus Oxychloride*** and ***Zinc Chloride***.

Handling, Storage, and Precautions: in most cases, freshly fused $ZnCl_2$ must be used for the best results. See ***Phosphorus Oxychloride*** for potential hazards.

Friedel-Crafts Reactions.

Phosphorus oxychloride and zinc(II) chloride combined are used as a catalyst[6] in Friedel-Crafts reactions. Hydroxyxanthones can be prepared by reaction of *o*-hydroxybenzoic acid and hydroxybenzenes in the presence of $POCl_3$ and $ZnCl_2$ (eq 1).[1] Although hydroxybenzophenones are also isolated by this method, they can be converted to xanthones by heating to 200 °C. A variety of hydroxyxanthones[7,8] and methoxyxanthones,[9] as well as benzophenones,[2] can be prepared in this manner.

In a similar fashion, the Friedel-Crafts reaction of phenol and malonic acid in the presence of $POCl_3$ and $ZnCl_2$ gives 4-hydroxycoumarin (eq 2).[3] Neither $POCl_3$ nor $ZnCl_2$ are effective alone. Additionally, the use of $AlCl_3$ instead of $ZnCl_2$ is not effective. Other coumarins can also be prepared in a similar manner.[10,11]

Phosphorus oxychloride and $ZnCl_2$ can also be employed to prepare chromanones from hydroxybenzenes and 3,3-dimethylacrylic acid in one step (eq 3).[4]

Phosphorylation of Alcohols.

The phosphorylation of alcohols with $POCl_3$ and $ZnCl_2$ can also be accomplished. Simple alcohols,[12] as well as fluorinated alcohols (eq 4),[5] when added in excess to $POCl_3$ and $ZnCl_2$, form phosphates readily.

$$\underset{(3.4\text{-}6\ \text{equiv})}{CF_3CO_2H} \xrightarrow{POCl_3,\ ZnCl_2} (CF_3CH_2O)_3PO \qquad (4)$$

Phosphorus(V) Sulfide[1]

[1314-80-3] · P_2S_5 · Phosphorus(V) Sulfide · (MW 222.29) (P_4S_{10})

[15857-57-5] · P_4S_{10} · Phosphorus(V) Sulfide · (MW 444.58)

(thiating agent for many different types of compounds;[1,2] can activate carboxylic acids and alcohols;[3] deoxygenating agent;[4] dehydrating agent;[5] can undergo electrophilic aromatic substitution at phosphorus[6])

Alternate Name: phosphorus pentasulfide.

Physical Data: mp 286-290 °C; bp 514 °C; *d* 2.09 g cm^{-3}.

Solubility: sol CS_2 (0.2 g/100 g) and aq soln of alkali hydroxides; modestly sol ethers, aromatics, tertiary amines, chlorinated solvents, MeCN; reacts with DMSO, primary and secondary amines, alcohols, and neutral or acidic H_2O.

Form Supplied in: exists as P_4S_{10}; light yellow crystalline solid; widely available.

Analysis of Reagent Purity: melting point, IR.[7]

Handling, Storage, and Precautions: a highly flammable solid which decomposes in the presence of moisture (including moist air) to form the toxic gas H_2S and H_3PO_4. It is harmful if inhaled or absorbed through the skin. This reagent should be handled with care in a fume hood in the absence of moisture and oxygen.

Use as a Thiating Agent.

Phosphorus pentasulfide accompanied by a base such as pyridine[8] or $NaHCO_3$ (Scheeren's reagent)[9] has been extensively used as a thiating agent for the conversion of amides,[2,10] ketones,[11] aldehydes,[12] esters,[13] *S*-substituted thioesters,[14] phosphinates,[15] and acid chlorides[16] to thioamides, thiones, thioaldehydes, thioesters, dithioesters, phosphothionates, and thioketenes, respectively. Due to milder reaction conditions, higher yields, and ease of handling, Lawesson's reagent (***2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide***) is usually the preferred reagent for these conversions.[13,17] Nevertheless, P_2S_5 accompanied by other agents such as Na_2CO_3/CF_3SO_3Me,[10] ultrasound,[18] alkyllithiums,[19] or Et_3N[20] have been reported to be just as effective and in some

cases more cost efficient than Lawesson's reagent. When used in excess, P_2S_5 has also been shown to convert esters to dithioesters in high yield (eq 1).[20b] Since the substitution of oxygen by sulfur has been reported to be sensitive to steric effects, the least hindered carbonyl compound will react first when given a choice (eq 2).[21]

(1)

(2)

The presence of other functional groups during these conversions can lead to tandem reactions. The reaction of this reagent with 1,4-dicarbonyl compounds results in the formation of thiophenes (eq 3)[22] or mesoionic thieno[3,4-*f*]benzo[*c*]thiophenes (eq 4).[23] On the other hand, 1,3-dicarbonyl compounds give way to different sets of heterocycles depending on the solvent and temperature (eqs 5, 6).[24,25] The presence of a nucleophilic amine elsewhere in the molecule can lead to further reactions as well (eqs 7, 8).[26,27]

(6)

(7)

(8)

Some advantage has also been taken of the enhanced nucleophilic character of thiocarbonyl compounds. Strategically placed leaving groups can thus lead to sulfur-containing heterocycles from thioaldehydes (eq 9),[12] thioamides (eqs 10, 11),[28,29] and vinylogous thiocarboxylic acids (eq 12).[30]

(9)

(10)

(11)

(12)

In some cases, the conversion of a carbonyl to a thiocarbonyl promotes other reactions as well. When acyclic enones are converted to α,β-unsaturated thiones, for example, a [4 + 2] cycloaddition has been observed (eq 13).[31]

(13)

The conversion of a furan to a thiophene under the aegis of P_2S_5 has also been reported.[5]

Activation of Acids and Alcohols.

Similar to other pentavalent phosphorus compounds, P_2S_5 activates the free hydroxyls of carboxylic acids or alcohols to become good leaving groups. When this activation is done in the presence of another nucleophile, substitution reactions can occur (eq 14).[31] Although P_2S_5/Cl_2 has been used to substitute primary alcohols with chlorides,[3] other reagents appear to be superior for such transformations.

(14)

Use as a Deoxygenating Agent.

P_2S_5 is one of the most mild and selective reagents for the conversion of sulfoxides to sulfides.[4] This reduction will take place selectively without affecting functional groups such as esters, amides (eq 15),[32] or ketones.[33] Interestingly, sulfones are also unreactive under these conditions.[34] Moreover, this reagent can be used for the reduction of sulfilimines to sulfides (eq 16),[35] sulfonic acids to polysulfides,[36] and sulfines to thiones.[37]

(15)

(16)

Use as a Dehydrating Agent.

Surprisingly little use of P_2S_5 as a dehydrating agent has been reported. The aromatization of furan Diels-Alder adducts (eq 17)[5] using P_2S_5 in CS_2 has been reported to be far superior than either HCl/HOAc[38] or polyphosphoric acid.[5]

(17)

Use in Electrophilic Aromatic Substitution Reactions.

The formation of Lawesson's reagent from P_2S_5 and anisole (eq 18)[39] is an example of an electrophilic aromatic substitution reaction with this reagent. The addition of ***Aluminum Chloride*** facilitates the ability of P_2S_5 to undergo electrophilic aromatic substitution reactions (eq 19).[6]

Phthalimide[1]

(**1**; R = H)

[85-41-6] · $C_8H_5NO_2$ · Phthalimide · (MW 147.14) (**2**; R = K)

[1074-82-4] · $C_8H_4KNO_2$ · Potassium Phthalimide · (MW 185.23)

(reagent for preparation of primary amines and amino compounds via Gabriel synthesis;[2] building block for synthesis of heterocyclic compounds)

Physical Data: (**1**) mp 238 °C; bp 366 °C; *d* 1.47 g cm^{-3}; dipole moment 2.91 D (dioxane; 30 °C); pK_a 9.90 (H_2O; 25 °C). (**2**) mp >300 °C.

Solubility: (**1**) sol boiling AcOH, H_2O (0.036 g/100 mL at 25 °C; 0.4 g/100 mL at bp), ethanol (5 g/100 mL at bp); insol benzene, ligroin. (**2**) sol H_2O, DMF; insol ethanol, ether.

Form Supplied in: both are white solids.

Handling, Storage, and Precautions: (**2**) may be harmful by inhalation, ingestion, or skin absorption. May cause irritation. Moisture sensitive. Use in a fume hood.

Reactions at the Nitrogen Atom.

A widely used method for the preparation of primary amines comprises reaction of a halo compound with potassium phthalimide and subsequent hydrolysis of the *N*-substituted phthalimide; this method is commonly referred to as the Gabriel synthesis (eq 1).[2]

Gabriel Synthesis. First Step: Formation of *N*-Alkylphthalimide.

In the original method of conducting the reaction, potassium phthalimide and the alkyl halide are heated without solvent, or in the presence of a high-boiling, nonpolar solvent (e.g. xylene). Because potassium phthalimide is insoluble under these conditions, the long periods of heating required at relatively high temperatures (150-240 °C) result in lowered yields and impure products (eq 2).[3] Alkyl sulfonates have been used as an alternative for organic halides.[4] Later it was found that DMF, in which potassium phthalimide is appreciably soluble, is an excellent solvent for the alkylation, which often starts at rt and is completed within minutes for the more reactive halides (eq 3).[5]

Another convenient procedure for alkylation of the potassium salt with alkyl halides or methanesulfonates, in solvents like benzene or toluene, makes use of solid-liquid phase-transfer catalysis by quaternary phosphonium[6] or ammonium[7] salts or ***18-Crown-6***[8] (eqs 4 and 5).[6,7b] In the case of the phosphonium salt, even 2-octyl derivatives have been obtained in high yield.

(4)

X = Cl, Br, I, Ms
R = primary alkyl, 2-octyl

(5)

The Gabriel synthesis can be extended to include aromatic and vinylic halides. Under appropriate conditions, the copper-catalyzed nucleophilic substitution with the potassium salt is effective with a wide range of aryl bromides or iodides, which may contain either electron-withdrawing or electron-donating substituents. The polar effect of the substituents is small, and the reaction is strongly subject to steric inhibition (eq 6).[9] Similar reaction conditions have been used for vinylic bromides RCH=CHBr (R = H, alkyl, aryl).[10] Copper(II) oxide has been used for condensing phthalimide with aryl or ferrocenyl halides.[11]

Gabriel Synthesis. Second Step: Formation of the Primary Amine.

Hydrolysis of the *N*-substituted phthalimides is usually carried out by refluxing in 20% hydrochloric acid[2] (eq 7).[2b] In certain cases, concentrated hydrochloric acid at temperatures up to 200 °C (sealed tube) may be necessary. Other acids, such as HBr, HI, and H_2SO_4, have also been used. Alkaline hydrolysis of the *N*-substituted phthalimides (e.g. 10% KOH or NaOH) is not commonly used.

Mild cleavage with ***Hydrazine***[12] is the method of choice for *N*-substituted phthalimides not containing functional groups like halogen, aldehyde, or ketone that react with hydrazine. Usually the phthalimide compound is refluxed in ethanol with an equivalent amount of hydrazine hydrate. Upon removal of the ethanol, the residue is heated with hydrochloric acid. The phthalyl hydrazide is filtered off, leaving a solution of the amine hydrochloride (eq 8).

The primary amines may also be liberated by reactions with 40% aqueous methylamine,[13a] *n*-pentylamine,[13b] ***Sodium Borohydride***-2-propanol followed by acetic acid,[13c] and ***Sodium Sulfide*** in aqueous THF or acetone.[13d]

Miscellaneous Alkylations.

A mild alternative for the above-described reaction of potassium phthalimide and alkyl halides is the direct coupling of phthalimide with alcohols under Mitsunobu's conditions.[14a] The advantage of this method is that a primary or secondary alcohol is activated in situ by using ***Triphenylphosphine*** and $RO_2CN{=}NCO_2R$, and then reacts (with inversion of configuration) with phthalimide under aprotic conditions at rt or below (eq 9).[14b]

N-Alkylations through base-catalyzed conjugate additions to acrylonitrile[15] and acrolein or its methyl congeners[16] are

known. The smooth reaction of phthalimide and aqueous ***Formaldehyde*** leads to the *N*-hydroxymethylimide (eq 10),[17] which can be used in the acid-catalyzed amidomethylation[17] of aromatic compounds (Tscherniac-Einhorn reaction) or, upon conversion into the *N*-halomethyl derivative, in the amidomethylation of aliphatic nucleophiles. Unfortunately, higher aldehydes do not undergo this reaction with phthalimide. The α-haloalkyl derivatives can be prepared, however, via the α-chloroalkyl phenyl sulfide as an aldehyde equivalent (eq 11).[18]

(10)

R = H, Me, Ph

(11)

Epoxides can be used to alkylate phthalimide. Ethyl glycidate, for instance, reacts with phthalimide in the presence of a catalytic amount of base to give exclusively the β-substitution product (eq 12).[19]

A highly stereoselective route to (*E*)-allylamines has been developed via *N*-alkylation of sodium phthalimide with vinyltri-*n*-butylphosphonium bromide in the presence of an aldehyde, leading to the allylic phthalimide with high (*E*) stereoselectivity (71-100%), which upon subsequent hydrazinolysis gives the desired amine (eq 13).[20] Use of the vinyltriphenylphosphonium salt (Schweizer reaction) gives predominantly the (*Z*)-isomer.

Reactions at the Carbonyl Group.

Though intermolecular Wittig reactions of phthalimide are known, yields are usually poor and rather severe conditions (refluxing xylene for 20 h) are required.[21] Certain tandem reactions, consisting of an *N*-alkylation followed by an intramolecular Wittig-type condensation, lead to fused heterocyclic compounds in high yield. Ring opening of an activated cyclopropane derivative with potassium phthalimide, and Wittig reaction of the intermediary stabilized ylide at the imide carbonyl function, affords the pyrrolo[2,1-*a*]isoindole derivative (eq 14).[22]

Reaction of sodium phthalimide with 2 equiv of triethyl 2-phosphonoacrylate provides the pyrido[2,1-*a*]isoindole derivative (eq 15).[23] Apparently the carbanion formed upon addition of the first equivalent of the vinylphosphonate

does not undergo the intramolecular Wittig-Horner type reaction to the strained four-membered ring. Upon addition of the intermediary carbanion to a second molecule of the vinylphosphonate, formation of the six-membered ring readily occurs.

Related Reagents.

Benzophenone Imine; ***Isocyanic Acid***; ***Glutarimide***; ***Hexamethylenetetramine***; ***Sodium Azide***; ***Succinimide***.

Phthalimidosulfenyl Chloride[1]

[54974-07-1] · $C_8H_4ClNO_2S$ · Phthalimidosulfenyl Chloride · (MW 213.65)

(reacts as a pseudohalogen;[1] synthetic equivalent of inaccessible sulfenyl chlorides;[2-4] adds across double and triple bonds;[2,3,5] reagent for the formation of episulfides;[6] reacts with ketones to give β-keto sulfides[7])

Alternate Names: phthalimide-*N*-sulfenyl chloride; 1,3-dihydro-1,3-dioxo-2*H*-isoindole-2-sulfenyl chloride; *N*-(chlorothio)phthalimide.

Physical Data: mp 115-117 °C.

Solubility: sol chlorobenzene, benzene, CH_2Cl_2, MeOH; insol pentane.

Form Supplied in: yellow crystals; not commercially available.

Preparative Method: prepared by treatment of potassium phthalimide with S_2Cl_2 to form the disulfide which is then cleaved with chlorine in warm chloroform.[1]

Purification: recrystallization from methanol.

Handling, Storage, and Precautions: can be stored at 0 °C for several months.

Addition to Alkynes.

Phthalimidosulfenyl chloride adds to unsymmetrically substituted alkynes, via a thiirenium ion, to give regioisomeric mixtures of (*E*)-β-chlorovinyl sulfenamides arising predominantly from anti-Markovnikov addition (eq 1).[2,3]

(1)

Alkynes	Adducts anti-M:M
$R^1 = Bu$, $R^2 = H$	89:11
$R^1 = t\text{-}Bu$, $R^2 = H$	100:0
$R^1 = Ph$, $R^2 = H$	85:15
$R^1 = Me$, $R^2 = Ph$	100:0

The sulfur-nitrogen bond of the alkyne adduct enhances this reagent's usefulness since the sulfenamide products are mild sulfur electrophiles, useful for the introduction of sulfur-substituted residues into organic molecules. The phthalimido group has been displaced with various nucleophiles such as carbanions,[2-4,8,9] amines,[2-4,10] thiols,[11] and alcohols;[12] the regio- and stereochemical integrity of the double bond is maintained during such displacements. This suggests that phthalimidosulfenyl chloride may be considered a synthetic equivalent of synthetically inaccessible sulfenyl chlorides such as *t*-butylsulfenyl chloride and *N*,*N*-bis(trimethylsilyl)aminosulfenyl chloride (eq 2).[2-4]

(2)

Reaction of the alkyne adducts with aluminum and boron hydride reagents such as ***Lithium Aluminum Hydride***, ***Sodium Borohydride***, or ***Lithium Triethylborohydride***, however, leads to the formation of unexpected thiirane derivatives (eq 3).[13] These can be desulfurized to give divinyl sulfides.

Addition to Alkenes.

Phthalimidosulfenyl chloride can be added to alkenes to yield α-chloro thioethers[5] which, after treatment with lithium aluminum hydride, produce episulfides (eq 4).[6] Sodium borohydride is unsuccessful in transforming the alkene adduct to the episulfide. The alkene addition is stereospecifically *trans* and proceeds through a thiiranium ion intermediate, the opening of which is governed predominantly by steric factors and usually gives a predominance of the anti-Markovnikov addition product.[14] As in the addition of phthalimidosulfenyl chloride to alkynes, the phthalimido group can also be displaced with nucleophiles.[4]

Reaction with Enolizable Carbonyl Compounds.

Good yields of β-keto thioadducts can be obtained from the reaction of phthalimidosulfenyl chloride with ketones at

0 °C using the required carbonyl compound as solvent (eq 5).[5,7] β-Diketones and β-keto esters also react in this manner.[7]

(5)

R^1	R^2	% yield
H	Me	85
H	Ph	71
Me	Ph	87

In contrast, cyclohexanone does not react under the above conditions. The corresponding adduct can be formed by reaction of the trimethylsilyl enol ether with phthalimidosulfenyl chloride (eq 6).[7]

Phthaloylbis(triphenylphosphine)cobalt Chloride[1]

[75895-97-5] · $C_{44}H_{34}ClCoO_2P_2$ · Phthaloylbis(triphenylphosphine)cobalt Chloride · (MW 751.10)

(complex which reacts with alkynes to give naphthoquinones;[1-3] precursor to other phthaloyl complexes which react with alkynes more readily to give naphthoquinones[4,5])

Physical Data: mp 245-246 °C.

Solubility: sol CH_2Cl_2; slightly sol MeCN.

Form Supplied in: brick red solid; not commercially available.

Analysis of Reagent Purity: ^{1}H NMR, IR, microanalysis.

Preparative Method: reaction of benzocyclobutenedione with ***Chlorotris(triphenylphosphine)cobalt*** in chlorobenzene for 24 h at 40 °C.[3,6]

Purification: crystallization from dichloroethane-hexane.

Handling, Storage, and Precautions: the pure complex should be stored in solid form in a sealed container at reasonable ambient temperatures. Quality may deteriorate over time when exposed to air.

Direct Synthesis of Naphthoquinones.

Phthaloyl transition metal complexes can be used in the synthesis of naphthoquinones according to the following scheme: first, an alkyne must coordinate to a free site on a coordinatively unsaturated metal center; secondly, the alkyne must insert into the metal-carbonyl bond; and thirdly, the metal must reductively eliminate to give the naphthoquinone (eq 1).

This particular complex will not react with alkynes unless activated by &egt;2 equiv of ***Silver(I) Tetrafluoroborate***; then it will react with a wide variety of alkynes to give naphthoquinones (eq 2).

(2)

R^1	R^2	Yield (%)
Me	Me	73
Et	Et	90
Ph	Ph	68
Ph	Me	78
Bu	H	65
Ph	H	57

Et	allyl	80
EtO	Et	89
Bu	TMS	68
Ph	$(CH_2)_2OH$	27
Me	CO_2Et	0
Et	COMe	0

Complexes of this type are prepared by the insertion of $CoCl(PPh_3)_3$ into cyclobutenediones,[1,3,6] a preparation which is found to occur quite generally (eq 3).

(3)

The overall potential of this synthetic strategy was demonstrated in the synthesis of the natural product (±)-nanaomycin A (eq 4).[7] In this scheme, the alkyne was linked via a tether to control the regiochemistry of the alkyne addition.

(4)

Precursor to More Reactive Phthaloyl Complexes.

With the method described above, terminal alkynes generally show reduced yields, silyl alkynes are sensitive to desilylation, some alkynes containing heteroatoms require more than 2 equiv of $AgBF_4$, and alkynes containing propargyl ethers or acetals give no naphthoquinone product.[2,3] $AgBF_4$ aids in the ionization of the Co-Cl bond and it complexes with free phosphine ligands to keep an open axial coordination site on cobalt, which seems to be necessary for the quinone-forming reaction (see eq 1).[4,5] By reacting this complex with only one equiv of $AgBF_4$, in the mildly coordinating solvent ***Acetonitrile*** (AN), a somewhat stable cationic cobalt complex is obtained.[4] Although this species cannot be crystallized, it reacts with alkynes to give naphthoquinones. Reaction of this cation with ***1,2-Bis(diphenylphosphino)ethane*** (diphos) affords a very stable diphos cation complex (eq 5).[4] This diphos cation (BF_4^- salt) is crystalline and can be stored in a closed container indefinitely.

(5)

The diphos cation complex is quite reactive with alkynes, giving naphthoquinones (eq 6). This method is simpler than the $AgBF_4$-mediated reaction of phthaloylbis(triphenylphosphine)cobalt chloride with alkynes because it does not have the complications associated with the use of $AgBF_4$ (use of a hygroscopic reagent and sensitivity of alkynes to Ag^+).

(6)

diphos cation

R^1	R^2	Time (h)	Yield (%)
H	Bu	2	90
Et	Et	2	85
TMS	Bu	4	86
Me	CH_2OEt	2	63
Me	$CH(OEt)_2$	2	51
Et	$(CH_2)_2OTHP$	2	73

The fact that the diphos ligand cannot occupy both axial sites on cobalt allows the labile MeCN ligand to occupy an axial site, which is necessary for coordination of the incoming alkyne.[3-5] In further studies it was found that phthaloylbis(triphenylphosphine)cobalt chloride reacts with 1.1 equiv of dimethylglyoxime (dmg) in pyridine to give phthaloyl(dmg)(pyridine)cobalt chloride. The dmg ligand in cobalt complexes is known to prefer chelating in an equatorial sense; this allows both axial sites to be occupied by more labile ligands (pyridine and chloride) (eq 7).[3-5]

(7)

This dmg complex is the most useful of the cobalt complexes derived from phthaloylbis(triphenylphosphine)cobalt chloride since it reacts with the widest variety of alkynes, both electron rich and electron deficient. In contrast to phthaloylbis(triphenylphosphine)cobalt chloride, phthaloyl(dmg)(pyridine)cobalt chloride reacts with alkynes under relatively mild thermal conditions with no need for $AgBF_4$. For example, 1.5 equiv of 3-hexyne in 1,2-dichloroethane

heated at 80 °C for 18 h gives a 77% yield of 2,3-diethyl-1,4-naphthoquinone. Lewis acidic additives enhance the rate of the reaction of the dmg complex. $AgBF_4$ works well, but the most generally useful Lewis acid catalysts are ***Cobalt(II) Chloride***, which significantly enhances the rate of quinone formation at 80 °C, and ***Tin(IV) Chloride***, which actually gives good quinone yields from many alkynes at rt (eq 8).

(8)

General Considerations.

Naphthoquinones can be prepared from a wide variety of alkynes with the methods outlined above. This approach also works for a variety of cyclobutenediones, giving rise to many substituted benzoquinones[1,3,8-10] as well as substituted naphthoquinones.[3,5,7] Much work has been done investigating the regioselectivity of the alkyne additions in cases where the phthaloyl and maleoyl ligands are unsymmetrical.[3,7-9] In particular, the dmg -cobalt complexes show good regioselectivity in the alkyne additions.[8,9] In using this approach to prepare quinone-containing molecules, the key considerations are: (1) is the necessary cyclobutenedione available? and (2) can the regiospecificity of the alkyne addition be controlled sufficiently? Recent advances in the preparation of cyclobutenediones,[11-18] coupled with the information from reported regiochemical studies, will provide strong guidance in the preparation of some complicated structures containing a quinone nucleus.

Related Reagents.

Carbonyl(cyclopentadienyl)(phthaloyl)cobalt.

Phthaloyl Dichloride[1]

[88-95-9] · $C_8H_4Cl_2O_2$ · Phthaloyl Dichloride · (MW 203.02)

(converts carboxylic acids to acid chlorides;[2] phthaloyl protecting group for amines;[3] useful Friedel-Crafts synthon[4])

Physical Data: mp 15-16 °C; bp 281 °C, 131-133 °C/9-10 mmHg; *d* 1.409 g cm^{-3}.

Solubility: sol CH_2Cl_2, THF, sulfolane, nitrobenzene.

Form Supplied in: liquid; commercially available; phthalic anhydride is an impurity.

Handling, Storage, and Precautions: store in the absence of moisture; corrosive, handle with gloves in a fume hood.

Conversion of Acids and Esters to Acid Chlorides.

Phthaloyl dichloride has been used for the conversion of acids into acid chlorides,[2] and anhydrides into bis-acid chlorides (eq 1).[5]

(1)

It is particularly suited to the preparation of fairly volatile acid chlorides which can be simply distilled out of the reaction mixture, though a greater range of chlorides can be prepared than with lower boiling ***Benzoyl Chloride***. ***Zinc Chloride*** has been used as a catalyst. Phthaloyl dichloride has been used in a two-pot sequence for the in situ generation

of acetyl chloride from ***Carbon Dioxide***, using catalytic ***N,N-Dimethylformamide***.[6] In the presence of ***Chlorosulfonic Acid***, it performs the useful conversion of ethyl esters into acid chlorides (eq 2).[7]

(2)

Protection of Amines.

Amines can be protected with the phthaloyl group using phthaloyl dichloride and ***4-Dimethylaminopyridine*** or ***Pyridine***.[3] This method may offer an advantage over more usual procedures, e.g. phthalic anhydride, in hindered cases.

Friedel-Crafts Reactions.

Though not strictly acting as a reagent, phthaloyl dichloride undergoes Friedel-Crafts acylation of hydroquinones to give 1,4-dihydroxyanthraquinones, the ring system of the daunomycin antitumour family (eq 3).[4]

(3)

Miscellaneous.

Aromatic nitro groups have been reported to undergo displacement with fluorine using ***Potassium Fluoride*** as the fluoride source (eq 4). Phthaloyl dichloride was found to be an effective trapping agent for K_2O, formed by the decomposition of KNO_2, by conversion to phthalic anhydride.[8]

4-Picolyl Chloride Hydrochloride

[1822-51-1] · $C_6H_7Cl_2N$ · 4-Picolyl Chloride Hydrochloride · (MW 164.04)

(protection of alcohols,[1,2] phenols,[3] thiols,[3,4] and carboxylic acids[5])

Alternate Name: 4-(chloromethyl)pyridine hydrochloride.

Physical Data: mp 160-163 °C.

Solubility: sol H_2O, EtOH; insol CH_2Cl_2, acetone.

Form Supplied in: white or off-white crystalline solid; available from several commercial sources.

Handling, Storage, and Precautions: the free base is reported to be unstable,[1] and should be generated shortly before use.

Protection Reagent.

Alcohols (eq 1)[1,2] (including hydroxy-containing amino acid derivatives),[2] phenols,[3] carboxylic acids (eq 2),[5] and thiols (eq 3)[3,4] have all been alkylated by this reagent (**1**). Esters (**2**) are also available from the respective acids by ***1,3-Dicyclohexylcarbodiimide*** coupling with 4-pyridylmethanol in CH_2Cl_2[5] in comparable yield.

Dihydric alcohols such as (**3**) are preferentially alkylated on the primary OH, but (**4**) yields a mixture of dialkylated and both monoalkylated products.[1]

(3)

(4)

The protected materials have been of particular value in peptide chemistry. Cleavage[5] of esters (**2**) takes place not only under the more obvious aqueous alkali or catalytic hydrogenation conditions, but also with ***Sodium-Ammonia*** or by electrolytic reduction at a mercury cathode. The protected alcohols,[1,2] phenols,[3] and thiols[3,4] are similarly deprotectable by electrolysis.

The use of 2-[1] and 3-picolyl[2] ethers in such cases has also been investigated, and an *N*-protecting group, (4-picolyloxy)carbonyl,[6] has also been described. The increased polarity of these picolyl-containing materials, relative to the more typical benzylic protecting groups, can appreciably assist in their purification.[2] Nevertheless, these protecting groups remain outside the mainstream of peptide chemistry, probably due to the greater familiarity and availability of, for example, the benzyl- or *t*-butyl-based groups, and the fact that the Na/NH_3 or electrolytic deprotection of the 4-picolyl group is likely to be incompatible with these. In this regard, the use of 2-(2´- or 4´-pyridyl)ethyl protecting groups[7] (Pyoc carbamates,[7a] Pet esters,[7b,7c]), likely to impart similar polarity, but deprotectable cleanly in the presence of these other common functionalities, appears distinctly advantageous.

Pinacol (Chloromethyl)boronate[1]

[83622-42-8] · $C_7H_{14}BClO_2$ · Pinacol (Chloromethyl)boronate · (MW 176.45)

(precursor to allylic boronic esters for stereoselective reactions with aldehydes to form homoallylic alcohols;[2] precursor to heterosubstituted methylboronates[1])

Alternate Name: 2-(chloromethyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane.

Physical Data: bp 81 °C/14 mmHg; ^{1}H NMR δ 1.22 (s, C*H*$_3$), 2.77 (s, C*H*$_2$Cl).[3]

Preparative Method: addition of BuLi to stirred $ClCH_2Br$ and $B(OMe)_3$ in THF at -78 °C followed by Me_3SiCl yields $ClCH_2B(OMe)_2$, which is transesterified with pinacol.[4]

Handling, Storage, and Precautions: (halomethyl)boronic esters are lachrymators and must be handled in a fume hood. As usual with reactive alkyl halides, skin contact should be avoided.

Reagent Preparation.

The first efficient preparation of (chloromethyl)boronic esters was via reduction of (dichloromethyl)boronic esters with ***Tri-n-butylstannane***.[3]

The most economical route to pinacol (chloromethyl)boronate (**1**) is the addition of ***n-Butyllithium*** to a vigorously stirred solution of bromochloromethane and ***Trimethyl Borate*** in THF cooled with a dry ice-acetone bath. After quenching with ***Chlorotrimethylsilane***, the product is treated with pinacol and distilled (73-85%) (eq 1).[4]

Diisopropyl (chloromethyl)boronate has been made via a similar route from ***Chloroiodomethane***, ***Triisopropyl Borate***, and butyllithium, followed by quenching with ethereal HCl and distillation (84%).[5] Yields have been higher with ICH_2Cl than with $BrCH_2Cl$ in our laboratory. The diisopropyl ester is easily transesterified with a variety of diols.[1,6]

An especially convenient preparation of diisopropyl (bromomethyl)boronate has been reported recently.[7] ***Dibromomethane*** is used in place of chloroiodomethane in the foregoing procedure, there is no halide exchange during workup, and 85% yields are routinely obtained on a 2-mol scale.

For some purposes, especially reactions with enolates, pinacol (chloromethyl)boronate (**1**) is not reactive enough in S_N2 displacements.[5,8] The chloride is easily displaced by ***Sodium Iodide*** in acetone to produce pinacol (iodomethyl)boronate.[3] It remains to be investigated how the bromo analog will compare in reactivity with the chloro and iodo compounds.

Allylic Boronic Esters.

A major use of pinacol (chloromethyl)boronate (**1**) and related compounds has been for the synthesis of allylic boronic esters (**2**),[2] which react diastereoselectively with aldehydes to form homoallylic alcohols. The configuration of the double bond is retained in the synthesis (eq 2),[2] and the required alkenylmetallic reagents are often easily prepared in high isomeric purity, for example, via organocopper chemistry.[9]

$R^1, R^3 = H, R^2 = Me$ or $THPOCH_2$; $R^1, R^2 = H, R^3 = Me$ or $C(OEt)_3$;
$R^1 = H$ or $Me, R^2 = H, R^3 = Me$; alkene = 1-cyclohexenyl;
$R^3 = H, R^1 = Me$ or $Bu, R^2 = Bu$ or Me

Major byproducts limiting yields in the synthesis of (*Z*)-allylic boronic esters (**3**) were found to include alkenylboronic ester (**4**) and alkene (**5**) (eq 3).[10,11] When (*Z*)-1-propenylmagnesium bromide was used in place of the lithium reagent, formation of alkenylboronic ester (**4**) was reduced below 1%.[11] When (*E*)-1-lithiopropene was used, the (*E*) analog of (**4**) was not a problem. However, either of the simple crotylboronates was more efficiently prepared via reaction of lithiated (*Z*)- or (*E*)-2-butene with $FB(OMe)_2$.[11]

Reaction With Enolates.

Pinacol (iodomethyl)boronate (**6**) reacts with ester, ketone, or amide enolates to form γ-boryl carbonyl compounds (eqs 4 and 5).[4,8] The iodo boronic ester (**6**) has been found superior to the less reactive chloro compound (**1**) for this purpose. Intramolecular interaction of the boron atom with the carbonyl oxygen provides stereocontrol in subsequent reactions of the products.[4]

Dibutyl (iodomethyl)boronate and pinacol (chloromethyl)boronate (**1**) alkylate malonic ester anions.[12] Pinacol (iodomethyl)boronate (**6**) also alkylates secondary and tertiary amines.[13]

Zinc Derivative.

Pinacol (iodomethyl)boronate (**6**) reacts with activated zinc to form the zinc reagent (**7**).[14] The zinc reagent is in turn converted to a cuprate, which reacts with electrophiles, for example as illustrated in eq 6.[14]

Homologs and Related Reagents.

α-Haloalkylboronic esters constitute a broadly useful class of reagents for making C-C bond connections with organometallics, especially for asymmetric synthesis[1] (see also ***Diisopropyl (Dichloromethyl)boronate***).

α,α-Disubstituted allylic boronic esters are readily prepared from pinacol (1-bromo-1-methylethyl)boronate (**8**) and alkenyllithiums (eq 7).[11]

α-Bromoalkyl boronic esters react diastereoselectively with *t*-butyl lithiopropionate (eq 8).[15] Diastereomeric excesses were 88-96%, enantiomeric excesses >98% (R = *i*-Pr, Bu).

B-3-Pinanyl-9-borabicyclo[3.3.1]nonane

(*R*)

[173624-47-2] · $C_{18}H_{31}B$ · *B*-3-Pinanyl-9-borabicyclo[3.3.1]nonane · (MW 258.30) (*S*)

[42371-63-1]

(asymmetric reducing agent which is particularly effective for aldehydes[1] and alkynic ketones[2])

Alternate Name: Alpine-Borane®.

Solubility: sol most organic solvents.

Form Supplied in: 0.5 M solution in THF. (*R*)-Alpine-Borane is prepared from (+)-α-pinene, and (*S*)-Alpine-Borane from (-)-α-pinene. High purity α-pinene is available commercially.

Preparative Methods: readily prepared by hydroboration of either (+)- or (-)-α-pinene[4] with ***9-Borabicyclo[3.3.1]nonane*** (9-BBN) (eq 1).

Since the neat reagent is most effective, the solvent is usually removed before reduction of the ketone. Brown has reported a synthesis using neat α-pinene and solid 9-BBN.[5] The deuterium- or tritium-labeled compound may be prepared by hydroboration with labeled 9-BBN.[6] Alternatively *B*-methoxy-9-BBN may

be reduced with $LiAlD_4$ (see ***Lithium Aluminum Hydride***) in the presence of α-pinene.[7,8]

Handling, Storage, and Precautions: organoboranes are spontaneously flammable in air and must be handled under an inert atmosphere. They are generally stable to moisture. Alpine-Borane can slowly undergo dehydroboration.[3] Use in a fume hood.

Reduction of Aldehydes.

Stereospecificially labeled primary alcohols are useful in biochemical and physical organic studies. Such compounds may be prepared by enzymatic reduction of a labeled aldehyde using yeast.[9] However, isolation of the product is often tedious. Alpine-Borane greatly simplifies the process and provides compounds of high enantiomeric purity. It is the most efficient reagent available for reduction of aldehydes. The limiting factor is often the enantiomeric purity of the starting α-pinene. Either enantiomer of the labeled primary alcohol may be obtained by using either (+)- or (-)-α-pinene or by placing the label either on the aldehyde or on the reducing agent (eq 2).

The reduction is bimolecular and thus the rate is dependent on concentration. Running the reaction neat provides the fastest rates. Usually an excess of Alpine-Borane is used to insure that the reaction does not become excessively slow at the end of the reduction. The excess organoborane may be destroyed by addition of an aldehyde such as ***Acetaldehyde***. The resulting alkoxy-9-BBN may be treated with ***Ethanolamine*** to liberate the alcohol and precipitate the majority of the 9-BBN. Any remaining borane impurities may be removed by oxidation with basic ***Hydrogen Peroxide***.

The absolute configuration of the product may be predicted by using a simple six-membered ring transition state model (structures **1** and **2**). In this model the predicted transition state resembles a boat cyclohexane with the small group occupying an axial-like position.

(1) favored

(2) disfavored

Alkynic Ketones.

The reagent is very sensitive to the steric requirements of the carbonyl group. Ketones are reduced at considerably slower rates than aldehydes.[10] Alkynic ketones are reduced at somewhat slower rates than aldehydes, but generally proceed at 25 °C. An alkynic ketone may be reduced in the presence of a methyl ketone (eq 3).

(3)

Aromatic, *n*-alkyl, and branched alkyl alkynic ketones are effectively reduced (eq 4).

(4)

90-100% ee

Methyl alkynic ketones are reduced with slightly lower efficiency and *t*-butyl alkynic ketones are reduced very slowly. In the latter case, dehydroboration of Alpine-Borane to give 9-BBN competes with the rate of reduction and the liberated 9-BBN reduces the ketone to give products of lower enantiomeric purity. This problem may be overcome by using high pressure[11] or by using *B*-10-*cis*-myrtanyl-9-BBN (eqs 5 and 6).[12]

α-Keto Esters.

In general, electron-withdrawing groups enhance the rate of reduction of ketones with Alpine-Borane. Thus α-keto esters are generally good substrates for reduction. Methyl pyruvate is reduced within 4 h at rt with neat Alpine-Borane.[13] The use of *t*-butyl pyruvate increases the efficiency (eq 7).

Methyl, *n*-alkyl, and isobutyl behave as small groups in the transition state model for reduction, while isopropyl or aromatic groups behave as large groups (eq 8).

Other Ketones.

Ketones such as acetophenone are reduced rather slowly by THF solutions of Alpine-Borane (eq 9). A competing dehydroboration process leads to reduction via 9-BBN (eq 10).

At 65 °C, Alpine-Borane undergoes 50% dehydroboration in 500 min.[3] At rt there is approximately 1-2% dehydroboration per day. Running the reaction neat increases the rate of the favorable bimolecular reduction.[5] Alternatively, high pressure may be used to increase the rate of the bimolecular process and retard the rate of the dehydroboration reaction (eq 11).[11]

The simple steric model for the transition state may be used to predict the absolute configuration of the product. The

related reagent ***(+)-B-Chlorodiisopinocampheylborane*** reduces ketones with greater ease and efficiency (eq 12).[14]

Piperidine[1]

[110-89-4] · $C_5H_{11}N$ · Piperidine · (MW 85.17)

(secondary amine base;[1] condensation catalyst for aldol,[4] Knoevenagel,[3] and Michael condensations;[20] thiophile for mediation of sulfoxide-sulfenate rearrangement;[13] reagent for enamine formation and utilization[22])

Physical Data: mp -9 °C; bp 106 °C; *d* 0.862 g cm^{-3}; secondary amine base of pK_a 11.12.

Solubility: miscible with water; sol common organic solvents (alcohol, benzene, chloroform).

Form Supplied in: liquid (99%). *Drying:* by treatment with standard drying agents, e.g. CaH_2, BaO, sodium metal, P_2O_5, or KOH.

Purification: distillation may be carried out directly from CaH_2, P_2O_5, or sodium.[2]

Handling, Storage, and Precautions: toxic either by absorption through the skin or by breathing. It is highly flammable, with a flash point of 16 °C. Use in a fume hood.

Condensation Catalyst.

Piperidine has had wide usage as a catalyst for aldol condensations, particularly cyclization processes. It is typically also the catalyst of choice, usually in combination with a carboxylic acid, for condensations of relatively acidic carbonyl compounds with aldehydes and ketones: the Knoevenagel condensation.[3] Michael addition of 2-methylcyclohexane-1,3-dione to methyl vinyl ketone in the presence of potassium hydroxide affords a triketone which upon treatment with piperidine[4] (or ***Pyrrolidine***) cyclizes to produce the Wieland-Miescher ketone (eq 1).[5]

(1)

The particular choice of secondary amine catalyst and acid copartner has been noted to affect the chemoselectivity, and by extension the regioselectivity, of dialdehyde cyclization. Thus piperidine-***Acetic Acid*** mediates the closure of dialdehyde (**1**) to enals (**2**) and (**3**) in a ratio of 19:1 (eq 2).[6] The combination of ***Morpholine*** and camphoric acid affords a 1:25 ratio of the two cyclization products. Similar ratios were observed with related dialdehyde substrates.

(1)

(2)

(2) **(3)**

Piperidine in protonated form and accompanied by a carboxylate counterion is, as noted, the reagent of choice for classical Knoevenagel condensation.[3] Typical among these are condensations of malonic esters and acetoacetic esters

with aromatic aldehydes (eq 3),[7] aliphatic aldehydes (eq 4),[8] and ketones (eq 5).[9]

(3)

(4)

(5)

The entire Robinson annulation sequence for preparing substituted cyclohexenones has also been carried out with piperidine itself as the catalyst for both the Michael and the aldol steps (eq 6).[10-12] In these cases, only a catalytic quantity of piperidine is employed and deethoxycarbonylation of an intermediate β-hydroxycyclohexanone is achieved by heating of the initial reaction products to 100 °C.

(6)

R = Me, Et, Pr, Bu, C_5H_{11}, C_6H_{13}

Piperidine also serves as an effective thiophile and has been used as both the condensation catalyst and the oxygen-sulfur bond cleavage reagent in Knoevenagel/sulfoxide-sulfenate rearrangement sequences,[13-17] leading to γ-hydroxy-α,β-unsaturated nitriles (eq 7), esters, and sulfones.

(7)

In many of these cases of piperidine catalysis, the amine presumably acts not only as a simple base for deprotonating relatively acidic β-dicarbonyl compounds but in two other critical and important ways.[18] First, piperidine, particularly when used in conjunction with a carboxylic acid, serves to convert aldehydes and ketones to their electrophilically more reactive iminium derivatives, and second, through the formation of enamines from the donor components of condensation reactions, it effects the conversion of the initial carbonyl compound into a reactive nucleophilic center. Illustrative of the role of piperidine as an imine/enamine-forming agent rather than as a simple base is the selective cleavage of a bis-β-alkoxycarbonyl system (eq 8).[19] Only the less-hindered carbonyl suffers β-elimination, indicating that the cleavage is initiated by enamine formation rather than by simple proton removal. The product is stable to the reaction conditions.

(8)

Piperidine catalyzes Michael addition reactions by both carbon[20] and heteroatom[21] nucleophiles (eqs 9 and 10).

(9)

(10)

Enamine Formation.

Piperidine forms enamines more slowly than does pyrrolidine. The enamines have no particular synthetic advantages over the corresponding pyrrolidine or morpholine derivatives and have seen limited utilization. The piperidine enamines of cycloalkyl carbaldehydes are useful for the preparation of spiro bicyclic unsaturated ketones (eq 11).[22]

Pivalaldehyde

[630-19-3] · $C_5H_{10}O$ · Pivalaldehyde · (MW 86.15)

(sterically demanding electrophile;[1] coreagent in molecular oxygen oxidations; production of reagents for enantioselective synthesis[2])

Alternate Names: 2,2-dimethylpropanal; trimethylacetaldehyde.

Physical Data: mp 6 °C; bp 77-78 °C; *d* 0.793 g cm^{-3}.

Solubility: sol alcohol, ether.

Form Supplied in: colorless liquid.

Preparative Methods: the most accepted preparative method is the reaction of ***t-Butylmagnesium Chloride*** with ***Methyl Formate***.[3] Recently, the use of ***N,N-Dimethylformamide*** as the formylating reagent has been studied,[4] as well as the direct reaction of ***t-Butyllithium*** with ***Carbon Dioxide*** and metal hydrides.[5]

Sterically Demanding Electrophile.

The unique structural characteristics of this reagent include the most sterically demanding, and highly symmetric, simple alkyl group[1] adjacent to a reactive electrophilic center, and the absence of acidic protons on the carbon atom adjacent to the carbonyl functionality. These attributes have made pivalaldehyde a standard reagent in the study of carbanion reactivity, with intensified use in the more recent era of stereoselective synthesis. Thus the oxonium ion generated from pivalaldehyde reacts with the expected high degree of stereoselectivity (eq 1).[6] Likewise, in the reaction of boron enolates derived from α-carbonyl radicals (eq 2),[7] pivalaldehyde consistently affords the highest *erythro*:*threo* selectivity (0:100) with no loss of chemical yield compared to other aldehydes.

However, there are numerous examples in the literature to indicate that the steric bulk of the *t*-butyl group can severely deactivate the electrophilicity of the aldehyde functionality, resulting in drastically reduced yields. The suggestion that pivalaldehyde is a nonchelating aldehyde, and therefore a poor participant in reactions which progress through chelation of the electrophile prior to C-C bond formation, seems to be reasonable given the experimental results. The reactions of this aldehyde with the lithium anions of amides (eq 3)[8] and esters,[9] the intermolecular pinacol cross-coupling reaction using vanadium(II) reagents (eq 4),[10] and the addition of vinylzinc reagents (eq 5)[11] all suffer severely reduced yields and, in the latter case, significantly reduced stereoselectivity in the C-C bond forming event.

Coreagent in Molecular Oxygen Oxidations.

Pivalaldehyde has been shown to be one of several aldehydes that function as effective reductants in the oxidation of alkenes to epoxides by molecular oxygen. In the process, which is most often metal catalyzed, the aldehyde is oxidized to the corresponding carboxylic acid. At least two different mechanisms appear to be operating. In the nickel(II)-catalyzed case,[12,13] the oxidation occurs through a singlet oxygen-type species.[14] The reaction is characterized by the loss of stereochemistry in the oxidation of both *cis*- and *trans*-2-butene.[13] In addition, the epoxidation of cholesteryl benzoate affords a 31:69 mixture of stereoisomers, with the β-isomer as the major component. This result is opposite to those from more traditional expoxidation reagents (***m-Chloroperbenzoic Acid***, MMPP), which afford the α-epoxide as the major product. Pivalaldehyde is not an effective reductant in the nickel(II)-catalyzed Baeyer-Villiger oxidation of ketones,[15] but is the most effective aldehyde in the manganese(III)-catalyzed enantioselective epoxidation of 1,2-dihydronaphthalene by oxygen in the presence of various enantiomerically pure salen ligands (eq 6).[16] Similar results have been obtained by Jacobsen[17,18] and Katsuki[19] using ***Iodosylbenzene*** or ***Sodium Hypochlorite*** as oxidant.

(6)

Epoxidations can also be effected without the use of metal catalysts.[20] In this case it appears as if peroxy acids (formed by oxygen interacting with pivalaldehyde) are the ultimate oxidizing agent. Pivalaldehyde is the most effective aldehyde of those studied in this reaction, which show the usual profile of reactivity and selectivity expected for a peroxy acid oxidation (eq 7).

(7)

Reagents for Enantioselective Synthesis.

A large body of work has been accumulated since the mid-1980s which employs the *t*-butyl group of pivalaldehyde as a sterically demanding presence for enantioselective synthesis. The transformation of 4-hydroxyproline to α-methyl-4-hydroxyproline (eq 8)[21,22] in enantiomerically pure form presents both the concept and practice of the self-reproduction of chirality[23] technique, in which substituted α-amino acids are obtained without the use of external chiral auxiliaries. Pivalaldehyde has been employed almost exclusively in the cyclization event, with a small amount of work having been done with benzaldehyde.

(8)

Analogous transformations have been performed on heterocycles prepared from alanine,[24-26] valine,[24,25] methionine,[24,25] cysteine,[27] phenylglycine,[24] phenylalanine,[24,25] aspartic acid,[28] glutamic acid,[28] serine,[29-31] and 2-azetidinecarboxylic acid.[32] The list is not exhaustive. All have involved the formation of five-membered *N*,*O*-(oxazolidinone) or *N*,*N*-acetals (imidazolidinone), or both, from cyclization with pivalaldehyde. The *N*,*N*-acetals arise from cyclization of the corresponding amino acid *N*-methylamide. Diastereoselection in the cyclization event varies from 0 to 100%. Reactions of the heterocyclic anions with other alkylating reagents (beyond methyl iodide), aldehydes, ketones, heteroelectrophiles, and Michael acceptors are described. Dipeptide derivatives have also been synthesized.[33] A complete discussion of the structures of the heterocycles and the factors controlling the

diastereoselectivity of the anion reactions has been published.[34] It is argued that in certain cases the high diastereoselectivity is not a direct result of steric effects dictated by the *t*-butyl substituent. Rather, it arises from torsional effects exemplified by significant pyramidalization at the trigonal centers in the molecules.[35]

A more general approach to amino acids begins from the corresponding cyclized glycine heterocycle. The enantiomers of the imidazolidinone have been prepared from the degradation of other amino acids,[36] resolution of the racemic mixture with mandelic acids,[37] and by asymmetric synthesis employing α-methylbenzylamine.[38] The corresponding oxazolidinone can be chromatographically resolved.[39] The imidazolidinone can function as both a nucleophilic (eq 9) and electrophilic glycine equivalent (eq 10),[40] similar to molecules developed by other researchers,[41] while the products from oxazolidinone nucleophile reactions are claimed to be more easily isolated.[42]

(9)

(10)

The utility of these chiral building blocks is extended by the formation of unsaturated derivatives. Cyclic dehydroalanine molecules[43] function as radical[44] and nucleophile[45] acceptors (eq 11). Internal alkenes are prepared[46,47] and reacted[48-50] with a wide variety of reagents, offering additional entries into enantiomerically pure compounds with chirality centers bearing oxygen, nitrogen, and/or sulfur.

(11)

More recent work has focused on β-amino acid synthesis through pyrimidinone structures, again prepared by this reagent in a cyclization reaction. Enantiomerically pure dihydro- and perhydropyrimidinones can be obtained directly from asparagine[51,52] or 3-aminobutanoic acid.[53] Alternatively, racemic perhydropyrimidinones arise from β-alanine,[54] and the enantiomers have been separated by chromatographic resolution.[39] These compounds all exhibit axial *t*-butyl groups,[34,55] and selectivity is dictated by steric effects. An unusual palladium-catalyzed arylation reaction leads to β-aryl-β-amino acids in enantiomerically pure form (eq 12). A mechanism has been presented.[55]

Parallel strategies have been developed with dioxolanones,[56] dioxoanones, and dioxinones[57,58] (*O*,*O*-acetals), leading to a variety of enantiomerically pure oxygen-containing products via the pivalaldehyde-derived stereogenic center. While a wide variety of β-hydroxy carboxylic acids have been employed as starting materials,[59,60] the bulk of the work has been performed on dioxanones and derivatives originating from (*R*)- or (*S*)-β-hydroxybutyric acid. As in the case of the *N*,*O*-acetals, diastereoselectivity in the cyclization event is quite variable, with best success in the formation of bicyclic structures.[60] Transacetalization with mild acid appears promising.[61] Although the *t*-butyl substituent on the six-membered ring heterocycles is in an equatorial environment, these systems nonetheless exhibit high stereocontrol in many different reactions. It has been suggested that torsional effects are responsible.[62] Other explanations have been made.[63] Both nucleophilic (enolates and dienolates[64]) and electrophilic (bromides[65] and both endo-[66] and exocyclic[67] enoates) six-membered ring heterocycles have been prepared and reacted to afford a wide range of products. An interesting example is the production of chiral tris(hydroxymethyl)methane derivatives (eq 13).[68]

Dioxolanones derived from pivalaldehyde cyclization have been employed in Diels-Alder reactions as captodative dienophiles.[69-71] The corresponding heterocycle with a cyclohexanecarbaldehyde-generated stereogenic center gives somewhat inferior diastereoselectivity in the formation of *exo* cycloaddition products.[72]

Pivalic Acid

[75-98-9] · $C_5H_{10}O_2$ · Pivalic Acid · (MW 102.15)

(hindered Brønsted acid)

Alternate Names: 2,2-dimethylpropanoic acid; trimethylacetic acid.

Physical Data: mp 35.5 °C; bp 163.8 °C, 78 °C/20 mmHg, 72 °C/0.1 mmHg; pK_a 5.04 (25 °C).[1]

Solubility: sol EtOH, ether, H_2O (2.5 g 100 mL^{-1} at 25 °C).[1]

Form Supplied in: crystalline solid (needles). The sodium salt hydrate is also available.

Preparative Methods: from the bromoform reaction on pinacolone or from *t*-butyl chloride, ***Magnesium***, and ***Carbon Dioxide***; recent improvements involve the reaction of *t*-BuCl, ***Lithium***, and magnesium 2-ethoxyethoxide.[14]

Purification: fractionally distilled in vacuo; recrystallized from benzene.[15]

Handling, Storage, and Precautions: corrosive and can cause burns; it should be treated with the same precautions as ***Acetic Acid***.

Acid Catalyst for Asymmetric Reductions.

Investigations into the use of asymmetrically modified ***Raney Nickel*** for asymmetric hydrogenations have revealed that the use of pivalic acid as catalyst often provides superior optical yields. In a study of the reduction of 2-octanone to 2-octanol over tartaric acid-***Sodium Bromide***-modified Raney nickel, use of a THF/carboxylic acid mixture as the reaction medium resulted in a substantial increase in the optical yield; pivalic acid gave the highest optical yield.[2] In subsequent studies,[3,4] the reduction of a variety of methyl ketones via catalytic hydrogenation over modified Raney nickel in the presence of pivalic acid provided the corresponding (*S*)-RCH(OH)Me compounds in optical yields of 63-80%.

Acid Catalyst for Rearrangements.

When guaiacol and triethyl orthoacrylate were reacted in refluxing benzene using ***Propionic Acid*** as a catalyst, only 50% of the desired Claisen rearrangement/ring closure product was obtained, due to esterification of the catalyst. Use of the more hindered pivalic acid furnished the desired product in quantitative yield (eq 1);[5] see also Sato et al.[6] and Dorsey et al.[7]

(1)

Regioselective Protonation of Enolates.

In a study of the regioselectivity of protonation of allenyl enolates, pivalic acid demonstrated superior selectivity; in the example shown (eq 2),[8] allene (**1**), resulting from protonation at C-2, was formed exclusively when the intermediate enolate was quenched with pivalic acid at -80 °C.[8,9]

(2)

Generation of *t*-Butyl Radicals via Oxidative Decarboxylation.

Silver-catalyzed decarboxylation of carboxylic acids by persulfate generates alkyl radicals, which have been used for homolytic alkylation of aromatic bases. Pivalic acid is a source of *t*-butyl radicals in this process. 2-*t*-Butylquinoline is formed regioselectively by this method (eq 3);[10] 6-*t*-butylnicotine has been prepared in a similar way.[11]

(3)

Preparation of 2-*t*-Butylpyrimidines.

2-*t*-Butylpyrimidines are precursors for 2-*t*-butylpyrimidinyl thiophosphates, which are active insecticides. Syntheses of these compounds from butyldiamines and pivalic acid have recently been described.[12,13]

Related Reagents.

Acetic Acid; ***Hydrochloric Acid***; ***Propionic Acid***; ***p-Toluenesulfonic Acid***; ***Trifluoroacetic Acid***; ***2,4,6-Trimethylbenzoic Acid***.

Platinum on Alumina

Pt/Al_2O_3

[7440-06-4] · Pt · Platinum on Alumina · (MW 195.08)

(catalyst for the hydrogenation of many functional groups;[1-8] used to prepare aromatic compounds by dehydrogenation[9,10])

Solubility: insol all organic solvents.

Form Supplied in: typically supplied as 0.5-5 wt % of Pt on alumina, but higher metal content may be custom made; dark brown to black powder or pellets.

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: can be stored safely in a closed container under air, but away from solvents and potential poisons such as sulfur- and phosphorus-containing compounds; Pyrophoric in the presence of solvents; general precautions for handling hydrogenation catalysts should be followed; the catalyst must be suspended in the organic solvent under an atmosphere of N_2; during filtration the filter cake must not be allowed to go dry.

Hydrogenation.

The use of Pt/Al_2O_3 is not as widespread as ***Platinum on Carbon*** or ***Platinum(IV) Oxide***, but like the latter two reagents, Pt/Al_2O_3 has been used for certain selective reactions, including hydrogenation and dehydrogenation reactions. The use of Pt/Al_2O_3 for the reduction of a diene to a *trans*-decalin was shown to give the highest selectivity (eq 1).[1]

The formation of residual monoenes and the *cis* product was minimized with this catalyst. Pt/Al_2O_3 was also used in the reduction of an α,β-unsaturated enone to an alcohol (eq 2).[2] The stereochemical course of this reduction was attributed to an alumina-alcohol interaction.

A tetrasubstituted enamine has been hydrogenated to the amine in good yield with no hydrogenolysis of the *N*-benzyl group using Pt/Al_2O_3 (eq 3).[3] Similar to other Pt catalysts, hydrogenolysis is not common with this catalyst.

A *cis*-1,2-diamine has been obtained using Pt/Al_2O_3 as the hydrogenation catalyst (eq 4).[4] The allylic pyrrolidine directed the hydrogenation to give the *cis* product.

Heterocyclic ring reductions have been reported and quinoline is reduced selectively at the pyridine ring.[5] Even with a 2,4-disubstituted quinoline, only reduction of the substituted pyridine ring in the quinoline system occurred when ***Carbon Disulfide*** was used as a poison. Without the poison the selectivity was only 88% (eq 5). Acridine and indole can also be hydrogenated exclusively in the heterocyclic ring.

Halogenation.

Pt/Al_2O_3 has been used to catalyze the formation of halogenated compounds. Chlorination of methane with chlorine has been catalyzed by Pt/Al_2O_3 to give ***Chloromethane*** with 99% selectivity. The minor product (1%) was dichloromethane.[6] Another halogenation reaction involving Pt/Al_2O_3 is the decarboxylation of aryl fluoroformates at high catalyst loading and temperature to give acyl fluorides (eq 6).[7]

(6)

Dehydrogenation.

Dehydrogenation in the presence of Pt/Al_2O_3 has given various heterocyclic aromatics and hydrocarbon derivatives. Cyclohexane, cyclohexene, cyclohexylamine, and cyclohexanol have been aromatized to give benzene in 100% yield. Toluene has been obtained from methylcyclohexane, 1-methylcyclohexene, 2-methylcyclohexanone, and 3-methylcyclohexanone. Decalin and tetralin produced naphthalene in quantitative yield. *N*-Methylpyrrolidine gave *N*-methylpyrrole in 81% yield.[8] Pyridine derivatives have been obtained from dihydropyrans with NH_3 in the presence of Pt/Al_2O_3 (eq 7).[9]

(7)

The last C-C bond coupling in the preparation of dodecahedrane was effected with Pt/Al_2O_3 mixed with a reactive Ti^0 metal.[10] Other substituted dodecahedranes were also prepared via this method.

Platinum on Carbon

Pt/C

[7440-06-4] · Pt · Platinum on Carbon · (MW 195.08)

(catalyst used for the hydrogenation of alkenes,[1,2] alkynes,[1] nitro groups,[4,5] ketones,[13,14] aromatics;[17] used for hydrogenolysis of cyclopropanes;[3] catalyzes oxidation of alcohols[19])

Solubility: insol all organic solvents and aqueous acidic and basic media.

Form Supplied in: black powder and pellets containing 0.5-10 wt % of Pt (typically 5 wt %); can be either dry or moist (50 wt % of H_2O).

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: can be stored safely in a closed container under air but away from solvents and potential poisons such as sulfur- and phosphorus-containing compounds; pyrophoric in the presence of solvents; general precautions for handling hydrogenation catalysts should be followed; the catalyst must be suspended in the organic solvent under an atmosphere of N_2; during filtration the filter cake must not be allowed to go dry; if a filter aid is necessary, a cellulose-based material should be used if catalyst recovery is desired.

Hydrogenations.

In many instances where ***Platinum(IV) Oxide*** is used, Pt/C can be a less expensive substitute. Pt/C is a widely used catalyst for many applications. The reduction of alkenes and alkynes can be carried out under mild conditions. Alkenes can be hydrogenated in the presence of terminal alkynes if the latter are protected with a trialkylsilyl group. Without protection the selectivity is not satisfactory (eq 1).[1]

(1)

The diastereoselective reduction of an enamino ketone with Pt/C under acidic conditions is shown in eq 2. This reaction provided the (*SSR-R*) diastereomer in 63% yield plus 15-18% of the (*RRS-R*) diastereomer and other byproducts. After acid-catalyzed lactonization, the desired lactone was conveniently isolated in 57% yield. This intermediate was used in a total synthesis of (+)-thienamycin (eq 2).[2]

(2)

Hydrogenolysis of cyclopropanes has been accomplished with this catalyst at high temperatures. The example in eq 3 shows the resilience of a cyclobutane to these reaction conditions.[3]

(3)

The reduction of a nitro group in the presence of an aryl bromide (or chloride) can be accomplished using this catalyst. Aryl fluorides are generally stable to all catalysts. In many instances the amine products undergo further cyclization reactions to form a variety of heterocyclic compounds. The bromide was hydrogenolyzed when Pd/C was used under similar conditions (eq 4).[4]

(4)

Varying the pH of the media has been shown to affect the product outcome in a reduction of a nitro amino acid. A 1-hydroxycarbostyril derivative was obtained under acidic conditions, whereas a lactam was produced under basic conditions (eq 5).[5]

(5)

Reduction of aliphatic nitriles under neutral conditions in the presence of Pt/C gave trialkylamines with high

selectivity.[6] With aromatic nitriles, dibenzylamines were obtained.[7] This can be used to advantage in the preparation of unsymmetrical amines. Thus the reduction of a nitrile, in the presence of a different amine provided the unsymmetrical dialkylamine with greater than 95% selectivity.[8] If the desired product is the primary amine, acidic conditions should be used.

Imines can be reduced selectively in the presence of aryl bromide and chloride and hydrazine functions using Pt/C.[9] Reductive amination between a ketone and an amine or amine precursor proceeds to give a good yield of dialkylamine.[10] Amines can also be formed from the reduction of azides and hydrazines.[9b,11] Hydrogenolysis of C-N σ-bonds with Pt/C is uncommon, but not unknown. For example, hydrogenolysis of decahydro-1,8-naphthyridines in the presence of this catalyst gave 3-(γ-aminopropyl)piperidines (eq 6).[12]

(6)

Pt catalysts are used for the reduction of ketones to minimize hydrogenolysis, especially in the case of aromatic ketones. The solvents used for ketone reduction are important. In the case of ***Ethyl Acetoacetate***, the Pt/C-catalyzed hydrogenation in water gave 12% hydrogenolyzed product, but no hydrogenolysis was observed in THF. The hydrogenolysis side reaction in water can be completely suppressed by the addition of a small amount of zinc acetate.[13] Under acidic conditions, dialkyl ketones have been hydrogenolyzed to the hydrocarbon products, but these conditions are impractical for acid-sensitive substrates. The conversion of ketones to the corresponding enol phosphates followed by hydrogenolysis over Pt/C is a mild and efficient route for the overall removal of an oxygen (eq 7).[14]

(7)

O-Acetyl sugar lactones have been cleanly converted to the corresponding 2,3-dideoxy sugar derivatives under mild conditions with Pt/C. A trialkylamine base was necessary for the hydrogenolysis to proceed. The mechanism may involve the alkenic intermediates (**1**) and (**2**) (eq 8). This procedure is only applicable to lactones since no deacetylated product was observed with aliphatic and cyclohexyl enol acetates (**3**) and (**4**).[15]

$R = \begin{cases} OAc \\ OAc \end{cases}$ 99%

The Pt/C-catalyzed hydrogenation of 4,4-difluorocyclohexadienone provided β-fluorophenol in 90% yield. The dienone had been prepared from phenol via an oxidative fluorination method.[16]

Although Pt/C has been used for the hydrogenation of aromatic rings, PtO_2 is usually the catalyst of choice. High selectivity (>95% *cis*) was observed in the hydrogenation of pyrroles at atmospheric pressure and rt. Under these conditions, both the phenyl ring and the benzyl ether remained intact (eq 9).[17]

Pt/C is an effective catalyst for dehydrogenation of reducing sugars under basic conditions. For example, glucose was oxidized to the carboxylic acid in excellent yield (eq 10).[18]

The mild reaction conditions under which reducing sugars are dehydrogenated with Pt/C also makes them good transfer hydrogenation agents. For example, fructose has been reduced to a mixture of glucitol and mannitol (0.77:1) in the presence of glucose and Pt/C.

The selective oxidation of benzylic alcohols to aldehydes by oxygen and Pt/C in the presence of ***Cerium(III) Chloride*** and $Bi_2(SO_4)_3$ cocatalysts has been reported. The selectivity to the aldehyde was excellent. Without the cocatalysts, carboxylic acids were obtained (eq 11).[19]

Platinum(IV) Oxide

PtO_2

[1314-15-4] · O_2Pt · Platinum(IV) Oxide · (MW 227.08)

(catalyst for hydrogenation of various functional groups with minimal hydrogenolysis problems; used as dehydrogenation catalyst; used for selective oxidation of primary alcohols)

Alternate Name: Adams' catalyst.

Solubility: insol most organic solvents.

Form Supplied in: dark brown solid, usually hydrated with 2 or more mol of H_2O.

Analysis of Reagent Purity: elemental analysis.

Handling, Storage, and Precautions: no precaution is necessary with the oxide, but after exposure to H_2 the Pt black must be handled as a pyrophoric reagent; the general precautions for handling hydrogenation catalysts should be followed; during filtration the filter cake must not be allowed to go dry; if a filter aid is necessary, a cellulose-based material should be used if catalyst recovery is desired.

Hydrogenations and Hydrogenolysis.

Platinum oxide has been used to catalyze the hydrogenation and hydrogenolysis of many functional groups. It has also found use in dehydrogenation and oxidation reactions. PtO_2 is not an active catalyst, but in the presence of H_2 the oxide is reduced to Pt black which is the active form. Pt black can also be made via other procedures.[1] A more recent method for the preparation of Pt black via the reduction of chloroplatinic acid or PtO_2 with ***Sodium Borohydride*** gives a catalyst with slightly increased activity.[2] Unlike the reaction between $NaBH_4$ and ***Nickel(II) Acetate***, which generates ***Nickel Boride*** (Ni_2B),[3] the reaction with Pt gives only pure Pt black. This catalyst, which is generally prepared in situ and used without isolation, was shown to be slightly more active than the Pt black generated from PtO_2 and H_2 in the reduction of 1-octene.

The reduction of alkenes, catalyzed by PtO_2, has been carried out in acidic, neutral, and basic conditions and, in some cases, different results are observed. In the example shown in eqs 1 and 2, stereoselective hydrogenation of a double bond to give the *cis*- or the *trans*-fused product was effected with PtO_2 in either acidic or neutral media.[4] With certain alkenic compounds, PtO_2 acted as an isomerization catalyst and no reduction occurred (eq 3).[5] Isomerization followed

by hydrogenation to give a *cis-trans* mixture of dimethylcyclopentanes has also been observed (eq 4).[6] The normally expected product is the *cis* isomer.

(1)

(2)

(3)

(4)

PtO_2 is generally not a satisfactory catalyst for the reduction of alkynes to alkenes. Even when the reaction is stopped after 1 equiv of H_2 is absorbed, a substantial amount of alkane has already been formed,[7] but a number of exceptions have been reported.[8] Lindlar catalyst (***Palladium on Calcium Carbonate (Lead Poisoned)***), ***Palladium on Barium Sulfate***, nickel boride (P-2Ni), and ***Palladium on Poly(ethylenimine)*** are better catalysts for this task.

Amines can be obtained by reduction of several functional groups. Nitro compounds are readily hydrogenated to amines under PtO_2 catalysis. The reduction of a benzylated nitro compound gave the aniline without loss of the benzyl ether functions (eq 5). Use of Pd/C gave the hydrogenolyzed product (eq 6).[9] In general, Pt catalysts are used in place of Pd catalysts when hydrogenolysis is to be minimized.

(5)

(6)

Hydrogenation of nitrobenzene in the presence of ***Hydrogen Fluoride*** gave *p*-fluoroaniline.[10] Hydrogenation of oximes is best carried out in acidic media to minimize secondary amine formation.[11] A quantitative yield of the amine was obtained when 3-hydroxy-5-hydroxymethyl-2-methylpyridine-4-carbaldoxime was reduced in alcoholic ***Hydrogen Chloride*** with this catalyst.[12] Amines can also be generated easily from azides,[13] imines,[14] and nitriles.[15] Similar to oximes, hydrogenation of nitriles should be conducted in acidic solvents to minimize di- or trialkylamine formation.

Hydrogenation of ketones in the presence of this catalyst can be carried out in acidic, neutral, or basic media. In general, with cyclic ketones axial alcohols predominate in acidic media while equatorial alcohols are favored in neutral or basic media. Thus the stereochemical outcome of ketone reduction may be controlled by varying the pH of the solvent.[16] In strong acids the reduction of dialkyl ketones in the presence of alcoholic solvents at rt with PtO_2 leads to the formation of ethers instead of alcohols.[17] It was suggested that acetals and enol ethers are generated under the reaction conditions before hydrogenation or hydrogenolysis. Although PtO_2 is often used to minimize hydrogenolysis of functional groups such as alcohols and halides, the hydrogenolysis of ketones under acidic conditions can give methylenic products (eq 7).[18]

(7)

By converting enolizable ketones to the enol triflates, neutral conditions can be used to effect the overall hydrogenolysis of ketones (eq 8).[19]

Certain α-diketones can be selectively hydrogenolyzed to monoketones by conversion to cyclic unsaturated oxyphosphoranes followed by treatment with hydrogen in the presence of the catalyst (eq 9).[20] The benzylic position, which is the more reactive site, was hydrogenolyzed selectively. Amide carbonyls are very difficult to reduce in general, but reduction has been observed in special cases (eq 10).[21] In one report, an anhydride was reduced to an ether at 5000 psi H_2 in HF.[22]

Benzyl groups attached to a heteroatom, such as oxygen and nitrogen, are removed using Pd catalysts, but the removal of phenyl groups of diphenyl phosphonates with these catalysts is ineffective. These phenyl groups can be hydrogenolyzed using PtO_2, but high catalyst loading is necessary.[23] *p,p´*-Dinitrobenzhydryl has been used for the protection of alcohols. This protecting group can be selectively removed in the presence of other hydrogenolyzable protecting groups, such as benzyl and trityl, by the use of platinum oxide followed by mild acid hydrolysis (eq 11).[24]

Hydrogenolysis of the N-N bond of hydrazines,[25] the N-O bond of nitrones,[26] and the C-C bond in cyclopropanes[27] are readily accomplished using this catalyst.

Aromatic ring reduction can be carried out with PtO_2 in acidic solvents such as acetic acid and alcoholic or aqueous HCl.[28] Complete ring reduction without the concomitant hydrogenolysis of benzylic alcohols has been accomplished.[29] Reduction of phenols provides cyclohexanols[30] and pyridines are reduced to piperidines.[31] ***Imidazole*** is difficult to reduce, but this has been accomplished in the presence of ***Acetic Anhydride*** to give the diamide.[32] Oxazoles are cleaved to amides (eq 12),[33] and isoxazoles give enamino ketones (eq 13).[34]

(13)

Dehydrogenation.

PtO_2 has also been used as a dehydrogenation catalyst. An example to obtain a pyridazine from a 1,4-diketone and hydrazine is shown below (eq 14).[35]

(14)

Oxidation.

The Pt black generated from prereduction of PtO_2 with hydrogen, also catalyzes the oxidation of alcohols to carbonyl compounds with oxygen. Primary alcohols are preferentially oxidized to carboxylic acids in the presence of secondary alcohols. Amides, sulfonamides, and azides are stable under the oxidizing reaction conditions.[36] Benzyldimethylamine can be oxidized to *N*-benzyl-*N*-methylformamide in 85% yield using benzene as the solvent.[37] When water was used as the solvent, *N*-demethylation was observed instead.[38]

Pt black was also used in the electrolytic *N*-ethylation of benzylamine in ethanol to give *N*-ethylbenzylamine in 96% yield. The Pt black anode first oxidized the ethanol to acetaldehyde which in turn formed a Schiff base with the amine. H_2 was generated at the Pt coil cathode and was picked up by the suspended Pt black for the hydrogenation of the imine.[39]

Irradiation of primary amines in the presence of a mixture of Pt black and TiO_2 gave low yields of secondary amines (8-67%). For example, diethylamine was formed in 33% yield from ethylamine and 1,4-diaminobutane gave pyrrole in 67% yield.[40]

Platinum (Sulfided) on Carbon

Pt(S)/C

[7440-06-4] · Pt · Platinum (Sulfided) on Carbon · (MW 195.08)

(catalyst for the hydrogenation of nitro compounds;[1-4] hydrogenolysis of disulfides;[5] reductive alkylation of amines with ketones[5])

Solubility: insol all organic solvents.

Form Supplied in: typically 5 wt % of Pt on black powder or granules poisoned with S; in dry or 50 wt % water wet form; commercially available.

Analysis of Reagent Purity: atomic absorption.

Handling, Storage, and Precautions: can be stored safely in a closed container under air but away from solvents and potential poisons such as sulfur- and phosphorus-containing compounds; pyrophoric in the presence of solvents; general precautions for handling hydrogenation catalysts should be followed; the catalyst must be suspended in the organic solvent under an atmosphere of N_2; during filtration the filter cake must not be allowed to go dry; if a filter aid is necessary, cellulose-based materials should be used if catalyst recovery is desired. Use in a fume hood.

Hydrogenations.

Sulfided platinum on carbon is a deactivated catalyst which gives useful selectivity in hydrogenation of polyfunctionalized compounds. Because of the deactivation, hydrogenation reaction conditions needed with this catalyst can be quite vigorous sometimes. Even so, many functional groups, including aromatic rings, ketones, aryl halides, sulfides, nitriles, amides, and esters, are stable under these conditions.

The reduction of halogenated nitrobenzenes to amines was effected without dehalogenation. Both chlorine (eq 1)[1] and bromine (eq 2)[2] survived the reduction conditions.

(1)

(2)

Appropriately substituted nitro compounds may lead to cyclized products after amine formation (eq 3).[3]

(3)

The catalyst is also insensitive to poisons. Even in the presence of a sulfide, a nitro group was reduced readily to the amine (eq 4). The benzhydryl (diphenylmethyl) protecting group was stable to the reaction conditions and was not hydrogenolyzed.[4] The diamine was reacted directly with alloxan monohydrate to give 10-[2-(diphenylmethylthio)ethyl]isoalloxazine in 51% yield.

(4)

Aryl disulfides are hydrogenolyzed to thiophenols and no further reduction to the hydrocarbons and hydrogen sulfide was observed.[2]

The low reactivity of this catalyst towards ketone hydrogenation and hydrogenolysis allows the reductive alkylation of amines or amine precursors and ketones in excellent yields with no competitive reduction of the ketone to an alcohol.[5] The absence of ketone reduction is further illustrated in eq 5. When compared with ***Palladium on Carbon*** and ***Platinum on Carbon*** catalysts, which gave the nitro alcohol and the amino alcohol, respectively, Pt(S)/C is by far the most selective catalyst.

Polyhexamethylenecarbodiimide[1]

$$-[(CH_2)_6N{=}C{=}N]_n-$$

[31667-72-8] · $(C_7H_{12}N_2)_n$ · Polyhexamethylenecarbodiimide · (MW)*n*(124.21)

(insoluble carbodiimide condensation reagent)

Solubility: insol CH_2Cl_2.

Preparative Method: by catalytic decarboxylation of 1,6-diisocyanatohexane, followed by several purification steps.[1]

Peptide Bond Formation.[1]

In what may be termed a reverse Merrifield approach, an *N*-protected amino acid is reacted with a sizable molar excess of the polymeric carbodiimide, suspended in CH_2Cl_2, and an equimolar amount of a *C*-protected amino acid (side chain reactive groups of the amino acid derivatives also appropriately protected). After removal of the catalyst by filtration, and washing with aqueous acid and base, evaporation of solvent leaves the substantially pure coupled material in good yields (82-93%).

The coupling and workup procedures are similar to those used in the classical ***1,3-Dicyclohexylcarbodiimide*** coupling. Both this and the water-soluble carbodiimide ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride***, which requires no filtration step, are commercially available, and perform these same reactions with equal facility. They are, moreover, required in only stoichiometric proportions, and are accordingly very widely used, in distinct contrast to this polymeric reagent.

Other insoluble polymeric carbodiimides[2] have also been reported. Another,[3] which is soluble in typical reaction solvents (CH_2Cl_2, DMF, DMSO), but subsequently precipitated by addition of ether, is also known. None of these appear to have found any great popularity either.

Polyphosphate Ester

[-] · $C_8H_{20}O_{12}P_4$ · Polyphosphate Ester · (MW 432.14)

(dehydrating agent; used in the Bischler-Napieralski reaction;[1] Friedel-Crafts acylation;[2] conversion of carboxylic acids to esters,[3] thiol esters,[4] amides,[5,6] and nitriles;[6,7] Beckmann rearrangement;[7] and heterocycle preparation; an alternative to PPA in dehydration reactions)

Alternate Name: PPE.

Physical Data: d 1.463 g cm^{-3}; *n* 1.440.[8]

Solubility: sol $CHCl_3$; reacts vigorously with H_2O.

Form Supplied in: not commercially available. May be prepared as described below. It is a colorless to yellowish substance which forms a stiff gel below 0 °C.

Analysis of Reagent Purity: PPE (3% solution in $CHCl_3$) shows a characteristic band in its IR spectrum at 1330 cm^{-1}. This band disappears and a new, broad band appears at 1200-1260 cm^{-1} when PPE is treated with a trace amount of H_2O.[5] ^1H and ^{31}P NMR techniques may be employed to determine composition of the mixture and structural features of each component.[9] Elemental analysis is not reliable.[9]

Preparative Methods: was originally prepared by Langheld,[12] and has been referred to as Langheld esters.[9,10] The preparation reported by Cava et al.[13] is a compilation of three previous procedures.[8,14,15] ***Phosphorus(V) Oxide*** (150 g) is added to a solution of anhydrous ether (300 mL) and alcohol-free ***Chloroform*** (150 mL). The reaction mixture is refluxed under dry nitrogen for 4 d and the resulting clear solution decanted from a small amount of residue. The solution is concentrated to a colorless syrup in a rotary evaporator; residual traces of solvent are removed by heating the syrup for 36 h at 40 °C in vacuo.[13] More harsh conditions result in unusable material.[11] While this preparation is sufficient for most synthetic applications, Van Wazer et al. reported that PPE prepared from triethyl orthophosphate and phosphorus pentoxide was superior for biochemical studies.[9]

Handling, Storage, and Precautions: Usually prepared fresh, but may be stored for at least 1 month.[4] PPE is unstable above 110-120 °C. A gradual decomposition occurs which becomes vigorous with evolution of gas at 150-160 °C.[11] Direct contact with PPE should be avoided. Use in a fume hood.

Reagent Description.

PPE is another of the phosphate-based reagents that are related to ***Polyphosphoric Acid*** (PPA) (see also

Phosphorus(V) Oxide-Methanesulfonic Acid). It differs from PPA in that it is aprotic and soluble in organic media. It is often compared to the related polyphosphoric acid trimethylsilyl ester (PPSE). In general, the advantages of PPE include its solubility in organic solvents, the mild conditions under which it is used, and its relatively nonhazardous, nonnoxious nature. A disadvantage is its time-consuming preparation.[16] The reagent is composed of a mixture of polymeric phosphoric acid esters.[8-10] Variations in the reactants and the reaction conditions may result in differences in the reagent's composition.[5,9,10] It is presumed to activate carboxylic acids through formation of mixed anhydrides.[17]

Bischler-Napieralski Reaction.[1,18]

One of the most cited uses of PPE is as a reagent in the Bischler-Napieralski reaction (eq 1).[18a] The utility of PPE compares favorably to other reagents, such as ***Phosphorus Oxychloride***, ***Phosphorus(V) Oxide***, and PPA.[18a,b,h,i]

(1)

Friedel-Crafts Acylation.[2,19]

Intramolecular Friedel-Crafts acylations have been carried out by treatment of aromatic acids with PPE (eq 2).[19a] Depending on the substrate, PPE may be as effective[20] or more effective[21] than other reagents.

(2)

Carboxylic Acid Derivatives.

Esters,[3] lactones,[22] thiol esters,[4] thiolactones,[23] amides,[5] and acylureas[24] have all been prepared from a PPE-mediated reaction of a carboxylic acid and the appropriate coupling partner. There are many excellent methods for effecting the above transformations;[25] PPE is distinguished from these mainly by its low cost. Eq 3 describes the synthesis of phenyl esters,[3a] which were shown to be stable in PPE. This is in contrast to PPA, which can effect the Fries rearrangement of phenyl esters.[3a] Aryl and alkyl thiols have been condensed with alkyl, alkenyl, and aryl carboxylic acids,[4] and malonic acid.[26] Hindered thiol esters can be prepared by this method (eq 4).[4] Sensitive

substrates such as penicillin G could be reacted at low temperature with the addition of pyridine.[4]

(3)

(4)

Conversion of Carboxylic Acids and Amides to Nitriles.

PPE has been used to dehydrate amides to nitriles.[27] More recently, a one-pot conversion of carboxylic acids to nitriles has been reported.[6] Treatment of an acid with PPE under an atmosphere of ammonia results in the formation of an intermediate amide, which upon further treatment with PPE undergoes dehydration to provide the nitrile (eq 5).[6] The amide may be obtained upon quenching the reaction after the initial condensation. Advantages of this method include use of a nonnoxious reagent, and reaction conditions that are relatively mild.[5,6,16] In an example of this reaction in a more complex substrate, this methodology has been applied to a synthesis of the canthine alkaloid skeleton.[28]

(5)

Beckmann Rearrangement.

Upon treatment with PPA, ketoximes have undergone the Beckmann rearrangement (eq 6).[7] Under more forcing

conditions, ketoximes provide amidines (eq 6). Submission of the oxime of benzaldehyde to similar conditions failed to produce benzamide; the only product obtained was benzonitrile. Treatment of benzamide under the same conditions did not lead to the nitrile. This suggests that dehydration of the aldoxime did not proceed through the intermediacy of the amide.[7] PPE was found to be equivalent to PPSE in terms of yields obtained in the Beckmann rearrangement of oximes.[29]

(6)

Fischer Indole Synthesis.

PPE has been utilized in the Fischer indole synthesis. Yields obtained ranged from 21 to 86% (eq 7).[30] A side product was the C-3 alkylated indole (see the section on ethylation).[30]

(7)

Heterocycle Preparation.

Various heterocycles have been produced through PPE-mediated cyclization reactions. Benzimidazoles (eq 8),[14] benzoxazoles,[31] and benzothiazoles[31] have been prepared through condensation of an *ortho*-substituted aniline and an acid (eq 8).[14]

In related work, it was reported that PPE was utilized in the synthesis of benzothiazoles.[32] However, in the preparation of benzimidazoles, 6 N HCl was reported to be the preferred reagent; in the preparation of benzoxazoles, PPA was a better reagent.[32a] Other heterocycles prepared using PPE as a reagent include pyrrolo[2,3-*b*]pyridines,[33] pyrrolo[3,4-*b*]pyridines,[34] pyrrolo[3,2-*b*]pyridines,[35] benzimidazo[1,2-*c*]indazolo[2,3-*a*]quinazolines,[36] 1,3-diazepines,[37] 1,3-diazocines,[37] 1,4-dihydro-4-oxoquinolines,[38] and 1,3-thiazin-4-ones.[39]

Miscellaneous Transformations.

5,6-Dihydro-2(1*H*)-pyridinones have been prepared stereoselectively by condensing 3-alkenamides with aryl aldehydes (eq 9).[40] PPA is also effective in this reaction; however, the yields are lower.

A one-carbon homologation of benzyl alcohols to amides or esters is shown in eq 10. Alkyl (and aryl) alcohols and secondary amines react with a cobalt intermediate to provide products with yields ranging from 20-82%.[41]

Ethylation.

During a Fischer indole synthesis, PPE was observed to alkylate indoles.[30] Further studies revealed that at 160 °C the ethyl indolenine was obtained in moderate yield. The diethyl and *N*-ethyl compounds were obtained in minor amounts

(eq 11).[11]

N-Alkylation of various amines has been reported. A tautomeric imidazole was alkylated in 74% yield (eq 12).[42] Yields for other methylation (polyphosphate methyl ester) or ethylation (polyphosphate ethyl ester) reactions varied from 44-74%.[42]

Polyphosphoric Acid[1]

[8017-16-1]

(moderately strong mineral acid with powerful dehydrating properties; used for intramolecular and intermolecular acylations, heterocyclic synthesis, and acid-catalyzed rearrangements)

Alternate Name: PPA.

Physical Data: hygroscopic, highly viscous, clear, colorless, or light amber; specific gravity 2.060 at 83% phosphorus pentoxide content.

Solubility: dissolution in any protic solvent will result in solvolysis of the reagent; dissolution in polar aprotic solvents could result in dehydration or destruction of the solvent; polyphosphoric acid is neither soluble in nor reacts with nonpolar organics such as toluene or hexane.

Form Supplied in: inexpensive and commercially available from most major suppliers.

Preparative Methods: by mixing *x* mL of ***Phosphoric Acid*** (85%, *d* 1.7 g mL^{-1}) with 2.2 *x* g of ***Phosphorus(V) Oxide*** (P_2O_5) followed by heating to 200 °C for 30 min.

Handling, Storage, and Precautions: normally used as the solvent so that a 10-50 fold excess is routinely employed. Due to high viscosity, PPA is difficult to pour and stir at rt, but is much easier to work with at temperatures above 60 °C. Addition of cosolvents, such as xylene, has facilitated the difficult workup usually associated with PPA.[2] Eaton's reagent (see ***Phosphorus(V) Oxide-Methanesulfonic Acid***) has been found to perform similar chemistry at lower temperatures without the viscosity problems. When diluting PPA or working up a reaction, ice is normally used to moderate the exothermic reaction that occurs with water. PPA has the ability to burn mucous membranes immediately and unprotected skin with time. Other than the corrosive nature of this reagent it has low inherent toxicity. Use in a fume hood.

Description.

Polyphosphoric acid is a mixture of orthophosphoric acid and linear phosphoric acids. In order to simplify discussion of this reagent, the complex mixture is described empirically as a wt % of P_2O_5 in water. The distribution of phosphoric acids that are found in PPA is dependent upon the wt % of P_2O_5. Commercially available PPA contains 82-85% P_2O_5, with 83% P_2O_5 considered to be the standard. At this concentration there is no free water and the distribution of phosphoric acids is approximately 6% orthophosphoric acid, 19% pyrophosphoric acid, and 11% triphosphoric acid, while the remaining material is linear phosphoric acids up to a chain length of approximately 14 phosphoric acid units.[3] Only at wt % of P_2O_5 over 84% do appreciable high weight polymeric species occur.

Neutralization of the most acidic protons in PPA is accomplished at pH 3.8-4.2 and corresponds to one strongly acidic proton for each phosphorus atom.

The powerful dehydrating properties of PPA, low nucleophilicity of the phosphoric acid media, and moderate acidity explain why this reagent is so widely used. Unlike ***Sulfuric Acid***, PPA has a low propensity to cause oxidation of the substrate and is also able to dissolve organic compounds. PPA has demonstrated rates of dehydration equal to that of 100% sulfuric acid even though it is a much weaker acid.

Cyclization of Acids, Esters, Ketones, Aldehydes, Acetals, Alcohols, and Alkenes onto Aromatic Rings.

Polyphosphoric acid is the reagent of choice to cyclize aromatic carboxylic acids to indanones (eq 1),[4] tetralones (eq 2),[5] and benzosuberones (eq 3).[6] Anomalous results for the cyclization of 3-(2-methoxyphenyl)propionic acid led researchers to discover a method for synthesis of metacyclophanes (eq 4).[7] Another interesting reaction that demonstrates the utility of PPA in forming cyclic aromatic ketones is the double cyclization of biscarboxylic acids (eq 5).[8] Carboxylic esters often demonstrate the ability to be cyclized as readily as the acids (eq 6).[9]

(1)

(2)

(3)

(4)

(5)

(6)

R = H, 74%
R = Et, 72%

Methoxy or alkyl substitution of the aromatic ring has also been found to allow shorter reaction times and lower reaction temperatures.[10] Cyclization of ketones (eq 7),[11] aldehydes (eq 8),[12] and acetals (eq 9)[13] occurs with dehydration to give cyclic alkenes. Tertiary or benzylic alcohols are usually the only alcohols which give straightforward cyclization products (eq 10).[14] Secondary and primary alcohols usually rearrange (Wagner-Meerwein rearrangements) before cyclization can occur. Just as in alcohols, alkenes are also prone to rearrangement unless the carbonium ion formed upon protonation is tertiary or benzylic. Low to moderate yields have been reported for cyclization of alkenes onto aromatic rings (eq 11).[15]

Cyclization onto Nonaromatic Moieties.

Cyclopentenones have been synthesized from carboxylic acids in good yield (eqs 12-14).[16] Compared with other protic acids, PPA has demonstrated the ability to favor carbon-carbon bond formation over lactone formation.[17]

(12)

(13)

(14)

Synthesis of cyclohexenones from alkenyl acids has been demonstrated (eq 15);[18] however, formation of methylcyclopentenones and lactones may occur when possible (eq 16).[19]

Cyclization Reactions which Form Heterocycles.

Use of PPA as an acid catalyst to form heterocyclic compounds has been exhaustively reviewed in the literature.[1] The ability of PPA to be used in place of more acidic or more nucleophilic reagents has led to applications in a variety of heterocyclic systems.

Nitrogen Heterocycles.

Although ***Zinc Chloride*** is normally used as catalyst, indoles substituted in the 2-position can be obtained from hydrazones by ring closure with PPA (Fisher indole synthesis) (eq 17).[20]

(17)

Use of PPA in the Bischler-Napieralski reaction has shown superior results to other reagents for construction of the isoquinoline ring system.[21] For example, dihydroisoquinolines are obtained from phenethylformamides in yields superior to phosphorus pentoxide (eq 18).[22] In the first report which popularized the use of PPA in organic synthesis, treatment of *N*-acetyl-β-phenethylamine with PPA gave the 1-methyl-3,4-dihydroisoquinoline in 23% yield (eq 19).[23] Synthesis of isoquinolines using a PPA-catalyzed Pomeranz-Fritsch reaction has been reported (eq 20),[24] but the low yields and poor reproducibility of this reaction have been overcome by the use of ***Hydrogen Chloride***/dioxane to

cyclize the *N*-tosyl derivative.[25]

(18)

(19)

(20)

The quinoline carbon framework can be assembled by ring closure of an aromatic acid to give a keto quinoline (eq 21).[26] Using PPA as catalyst, phenylquinolinones can be prepared from 3-aryl-3-hydroxypropionanilides (eq 22),[27] or from amido ketones (eq 23).[28]

(21)

(22)

(23)

When attempting to effect a Beckmann rearrangement it was found that the oxime of a hexahydrobenzindolizine did not give the expected amide but instead dehydrated. This was followed by ring opening then ring closure to give a dihydrobenzonaphthyridinone (eq 24). When the hexahydrobenzindolizine itself was treated with PPA the compound simply dehydrated without rearrangement to give the dihydrobenzindolizone (eq 25). Sulfuric acid completely failed to effect this dehydration and Eaton's reagent was reported to give lower yields of product.[29]

(24)

(25)

Alkyl- or chloro-substituted isatins were obtained more conveniently with PPA than with sulfuric acid (eq 26).[30] Synthesis of the bacterial coenzyme methoxatin was facilitated by use of PPA to synthesize the pivotal isatin intermediate (eq 27).[31]

26% 43%

(26)

(27)

Complex lactams were stereoselectively assembled in a beautifully simple reaction between 3-alkenamides and benzaldehyde (eq 28).[32] Oxazolinones can be made utilizing the Erlenmeyer azlactone synthesis. Use of PPA cleanly affords the (*E*) isomer whereas other methods provide only the (*Z*) isomers or mixtures of (*E*) and (*Z*) isomers (eq 29).[33] Other nitrogen-containing heterocyclic systems which can be obtained using PPA include benzimidazoles (eq 30)[34] and triazoles (eq 31).[35]

Oxygen and Sulfur Heterocycles.

Diphenylfurans are formed in higher yields with PPA than with sulfuric acid, ***Acetic Anhydride***, or phosphorus pentoxide as the dehydrating/cyclization agent (eq 32).[36] Similar to cyclization of aromatic acids to form aromatic cyclic ketones, the replacement of the benzylic methylene group with an oxygen affords chromanones in good yield (eq 33).[37] The structurally related flavones can be prepared by an intramolecular 1,4-addition catalyzed by PPA (eq

34).[38] Seven-membered rings which contain oxygen, such as benzoxepinones, can be made in good yield from 4-phenoxybutyric acids (eq 35).[39] Benzofurans are formed in good yield by cyclization of α-phenoxy ketones (eq 36).[40] Thienopyrroles are obtained by ring closure of a pyrrolecarboxylic acid (eq 37).[41]

(32)

(33)

(34)

(35)

(36)

(37)

Rearrangements and Isomerizations.

The same characteristics which facilitate cyclizations, such as media with low nucleophilicity, good solvation power, relatively mild acidity, and low oxidation potential, are also conducive to clean, high-yielding acid-catalyzed rearrangements. PPA has been considered to be an effective reagent to carry out conversion of oximes into amides (Beckmann rearrangement) (eq 38).[42] Rearrangement of a decalin oxime could be carried out with ***p-Toluenesulfonyl Chloride*/*Pyridine*** to maintain the original *cis*-decalin stereochemistry or PPA could be used to allow formation of the *trans*-decalin system through an alternative mechanism (eq 39).[43]

(38)

(39)

yield not specified

Treatment of aromatic carboxylic acids with ***Nitromethane*** and PPA (Lossen rearrangement) gives high yields of anilines (eq 40).[44] Although PPA can be used to catalyze the reaction of ***Hydrazoic Acid*** with carboxylic acids, ketones, and aldehydes (Schmidt rearrangement), sulfuric acid is usually the reagent of choice. One example of PPA being equivalent to sulfuric acid in the Schmidt rearrangement is when it is applied to acetophenone (eq 41).[45]

(40)

(41)

Wagner-Meerwein rearrangements and, more generally, carbonium ion-mediated carbon skeleton rearrangements can be effected with PPA. Lewis acids are generally preferred due to the ease of use and workup. An example of a high yield PPA induced Wagner-Meerwein rearrangement is formation of the phenanthrene skeleton from substituted fluorenes (eq 42).[46] Ring contraction was found to occur when a thiochromene was treated with PPA (eq 43).[47]

(42)

(43)

Acid-catalyzed isomerizations which can be affected with PPA include conversion of *trans*-cinnamic acid to *cis*-cinnamic acid (eq 44), *trans,trans*-diene conversion to *trans,cis*-dienes (eq 45),[48] and azlactone isomerizations (eq 46).[33]

(44)

(45)

(46)

Intermolecular Reactions.

PPA is generally used as an intramolecular catalyst but has demonstrated limited utility for intermolecular alkylations.

Due to the elevated temperatures necessary to achieve catalysis (and reduce PPA viscosity), most reactions give mixtures of products favoring multiple substitution. Consequently, most Friedel-Crafts alkylations are carried out with ***Aluminum Chloride*** or another Lewis acid which can be more readily controlled. In the case of activated aromatics, such as phenol, alkylation can proceed under moderate conditions (eq 47).[49]

Acylations with PPA are much more prevalent. In the seven years between the first popularized use of PPA in 1950[23] and the Popp and McEwen review,[1b] over 200 intermolecular acylations were reported. One of the first acylations was the reaction between cyclohexene and ***Acetic Acid*** (eq 48).[50] Acylation of activated aromatics proceeds in high yield (eq 49).[51] Acylation of phenols is problematic due to competing ester formation (eq 50).[52]

Miscellaneous Uses of Polyphosphoric Acid.

Nitrile hydrolysis to amides is commonly carried out using PPA. At 100-110 °C, nitriles are routinely converted to amides (eq 51).[53]

When the temperature is raised to 200 °C, decyanation of aromatic nitriles often results.[54] Reagents with unique abilities have been developed by mixing PPA with other agents. The reduced acidity of PPA compared to other mineral acids proved beneficial when a PPA/***Ethanethiol*** mixture was used to open one epoxide selectively in a bis-epoxy steroid (eq 52).[55] PPA/$POCl_3$ affords a medium which is used to convert tertiary alcohols into chlorides (eq 53).[56]

(53)

In an attempt to generate HCl in situ during cyclization of a tetraamine, a PPA/NaCl mixture was superior to PPA alone (eq 54).[57] PPA/***Acetic Acid*** was used to synthesize nonenolizable β-diketones (eq 55).[58] Although Wagner-Meerwein rearrangements predominate when primary carbonium ions are formed with PPA, a mixture of PPA/***Potassium Iodide*** allowed conversion of a primary methyl ether to a primary alkyl iodide in high yield (eq 56).[59] It has been reported that nitrations carried out using PPA/***Nitric Acid*** are less hazardous than Ac_2O/HNO_3 mixtures (eq 57).[60]

Poly(4-vinylpyridine)[1]

[9017-40-7] · $(C_7H_7N)_n$ · Poly(4-vinylpyridine) · (MW)*n*(105.15) (.HCl)

[29323-87-3] · $(C_7H_8ClN)_n$ · Poly(4-vinylpyridine hydrochloride) · (MW)*n*(141.60)

(pyridine functional group in easily regeneratable solid form;[1] acid scavenger;[2] basic catalyst for Knoevenagel reactions;[2] acid salts are mild acid catalysts[3])

Alternate Names: P(4-VP); Reillex™.

Physical Data: Reillex 402: *d* 0.45 g cm^{-3}. Reillex 425: *d* 0.29 g cm^{-3}.

Solubility: insol all solvents; polymer swells when added to aqueous and nonaqueous solvents.

Form Supplied in: Reillex 402: 60 mesh, off-white granular powder. Reillex 425: 18-50 mesh, off-white beads. *Drying:* water may be removed from the polymer with toluene or other solvents that form water azeotropes.

Analysis of Reagent Purity: aqueous titration with acid; Reillex 402 has 8.8 mequiv/g H^+ capacity and Reillex 425 has 5.5 mequiv/g H^+ capacity.

Handling, Storage, and Precautions: extremely stable polymer best stored in tightly closed containers; after use the free base form of the polymer can be regenerated for further use by treatment with aqueous NaOH.

Acid Scavenger and Basic Catalyst.

Poly(4-vinylpyridine) is a polymeric reagent that replaces liquid ***Pyridine*** as acid acceptor in aqueous and nonaqueous media for reactions that produce acids as a byproduct.[2] ***Hydrogen Chloride*** generated during esterification using acyl

halides (eq 1),[4] from silylation of a primary alcohol with diphenyl-*t*-butylchlorosilane (DPBSiCl) (eq 2),[5] and mixed acid anhydride preparation from acyl halides and acids were trapped on the polymer (eq 3).[6] Since the polymer is a solid, filtering it from the reaction mixture simplifies workup. After recovery, the polymer can be regenerated and used in further reactions.

(1)

(2)

(3)

In a recent method for the synthesis of azulenes, P(4-VP) was uniquely effective as an ***Tetrafluoroboric Acid*** scavenger that does not react with the tropylium tetrafluoroborate reagent or the carbocationic intermediates involved in the [3 + 2] annulation (eq 4).[7] In the absence of this scavenger, protodesilylation of the allenylsilane starting material is observed.

(4)

In the synthesis of hydroxylamines, the polymer has also been used to trap benzoic acid in the oxidation of secondary amines with ***Dibenzoyl Peroxide*** (eq 5).[8]

(5)

Poly(4-vinylpyridine) also functions as a basic catalyst in Knoevenagel reactions (eq 6).[2]

(6)

Mild Acid Catalyst.

The hydrochloride salt of poly(4-vinylpyridine) is a polymeric reagent that acts as a mild acid catalyst in the preparation of acetals and carboxylic acid esters (eq 7)[3] and in the preparation of tetrahydropyranyl derivatives of alcohols and phenols (eq 8).[9]

Poly(4-vinylpyridinium bromide perbromide)[1]

[91650-35-0] · $(C_7H_8Br_3N)_n$ · Poly(4-vinylpyridinium bromide perbromide) · (MW)*n*(345.86)

(polymeric reagent used in the bromination of alkenes and ketones[2])

Alternate Name: P(4-VPBPB).

Solubility: insol all solvents; polymer swells when added to aqueous and nonaqueous solvents.

Form Supplied in: orange solid granules with ~4 mequiv Br_3^-/g resin.

Handling, Storage, and Precautions: store in a tightly closed container in a cool dry place; handle in a fume hood.

Bromination of Alkenes and Ketones.

Poly(4-vinylpyridinium bromide perbromide) can replace free ***Bromine*** in bromination of alkenes (eq 1) and ketones (eq 2).[2] This reagent is stable in storage and is safer to use than liquid bromine. Product isolation is simplified since the polymer can be removed from the reaction mixture by filtration. After

use, the reagent may be regenerated by addition of bromine or it can be converted to ***Poly(4-vinylpyridine)*** by treatment with aqueous ***Sodium Hydroxide***.[2] A variation of this reagent is the poly(4-vinylpyridine bromine complex) which brominates alkenes and alkynes[3] and effects side chain allylic bromination of alkyl-substituted aromatic molecules.[4]

Poly(4-vinylpyridinium dichromate)[1]

[82246-45-5] · $(C_{14}H_{16}Cr_2N_2O_7)_n$ · Poly(4-vinylpyridinium dichromate) · (MW)*n*(428.32)

(polymeric oxidizing agent used to convert alcohols to aldehydes and ketones[2])

Alternate Name: P(4-VPDC).

Physical Data: mp >300 °C.

Solubility: insol all solvents; polymer swells when added to aqueous and nonaqueous solvents.

Form Supplied in: brown powder.

Handling, Storage, and Precautions: store in a tightly closed container in a cool dry place.

Oxidation of Alcohols to Aldehydes and Ketones.

Poly(4-vinylpyridinium dichromate) is a solid polymeric reagent that readily oxidizes primary and secondary alcohols to aldehydes and ketones (eq 1).[2,3] The reagent works best when it is soaked in water, filtered, and used in a nonpolar solvent such as cyclohexane. All chromium ions in oxidized or reduced form are retained on the polymer. Product isolation is simplified since the polymer is removed from the reaction mixture by filtration. This reagent may be regenerated.[2,3] A variation of this polymeric reagent

is a silver dichromate-poly(4-vinylpyridine) complex that rapidly converts alcohols to the corresponding aldehyde or ketone.[4]

Potassium

[7440-09-7] · K · Potassium · (MW 39.10)

(reducing agent for aromatic rings,[1] carbonyl compounds,[2] and various functional groups,[3] including alcohols[4] in the presence of crown ethers; reagent for the preparation of Rieke's metals;[5] reacts with proton donors;[6] promotes $S_{RN}1$ arylation reactions;[7] modified reactivity occurs with deposition on alumina,[8] insertion in graphite,[9] or dispersion by ultrasound[10])

Physical Data: mp 64 °C; bp 760 °C; *d* 0.86 g cm^{-3}; soft silvery (fresh cut) metal.

Solubility: sol liquid ammonia, 1,2-ethylenediamine, aniline; slightly sol ethers.

Form Supplied in: widely available as ingots, sticks, under mineral oil, or in ampules; common impurities are other alkali metals, aluminum, calcium, boron, silicon.

Handling, Storage, and Precautions: reacts violently with water, oxygen, halogens. In air, potassium forms the yellow peroxide KO_2, which is dangerous in contact with organic compounds. Reacts with many solvents; inert in saturated and some aromatic hydrocarbons. For safe handling, see Fieser and Fieser.[6] Potassium fires should be treated with inert powders or sand.

Reduction of Aromatic Compounds.

[1] Birch- and Benkeser-type reductions of aromatic rings are achieved by potassium dissolved in liquid ***Ammonia*** or amines. However, potassium is used less often than ***Lithium*** or ***Sodium***. The reducing ability of potassium is illustrated by the total reduction of the B-ring of equilenin to estrone, which cannot be achieved with sodium (eq 1).[11]

(1)

Proton donors are frequently used in potassium reductions. The accepted mechanism consists of a sequence of single-electron transfer (SET), a protonation, and a second SET. The anion thus formed can be trapped by an electrophile to give the reduction-alkylation product (eq 2).[12]

(2)

Reduction of Saturated and Unsaturated Carbonyl Groups.

Alkali metal reduction of ketones to alcohols in the presence or absence of proton donors has been studied in detail.[2] The use of potassium decreases the amount of pinacol coupling products,[13] and increases the reaction rate and yields of desired product.[14] The stereoselectivity, which depends on the structure of the intermediate ketyl radical anion, is frequently lower with K in comparison to lighter alkali metals. Recently, reductions with K have been conducted in THF under sonication with stereoselectivity similar to that of the usual method (eq 3).[15]

(3)

When an unsaturated functional group is closely positioned with respect to the carbonyl group, the ketyl radical anion adds to the multiple bond producing products of reductive cyclization (eq 4).[16]

(4)

In the case of α,β-unsaturated carbonyl groups,[2a,17] the radical anion is readily transformed to the dianion, especially with K. When protonation occurs, an enolate results which can be trapped with an electrophile, giving rise to alkylation on the α-carbon. The stereoselectivity at the β-position does not seem to be strongly dependent on the nature of the metal, although exceptions are known (eq 5).[18]

(5)

In the absence of a proton source, the dianion can be alkylated on the β-carbon. The increased yields obtained in some cases with potassium result from the higher reactivity of the potassium dianion, as compared with reactions with lithium or sodium (eq 6).[17,19]

(6)

Reduction of Functional Groups.

Various functional groups are reduced by potassium in liquid ammonia (eqs 7-9).[3,20,21] In many cases the reaction is accomplished in the presence of crown ethers, which generate K^+K^- ion pairs.

(7)

(8)

(9)

Alcohol deoxygenation occurs[4] via carboxylic, thiocarbamic (eq 10),[22] and phosphoric esters (eq 11).[23] Free benzylic alcohols can be reduced with potassium in the presence of 4,4´-di-*t*-butylbiphenyl in THF under sonication.[24]

(10)

(11)

Reduction of Metal Salts (Rieke's Metals).

Potassium reduces metal salts to finely dispersed metals in refluxing THF or DME (eq 12). Activated metal slurries can be prepared, which exhibit a high reactivity with organic compounds.[5] The method was improved by replacing potassium with lithium in the presence of an electron transport agent.[25]

Reaction with Proton Donors.

Potassium reacts with acidic hydrogen compounds such as alcohols. This reaction is used to prepare the useful potassium alkoxides (e.g. ***Potassium t-Butoxide***).[6] Some potassium amides, such as 3-aminopropanamide, are readily prepared in quantities up to 25 mmol from the metal and 1,3-propanediamine in the presence of a trace of iron(III) nitrate under sonication (eq 13).[26]

Alkylation and $S_{RN}1$ Reactions.

Deprotonation-alkylation of γ-lactones has been reported. In the case of acylation, it occurs only on the carbon atom (eq 14).[27]

Substitution of aromatic halides, phosphate esters, trialkylammonium groups, and sulfides by an anionic nucleophile occurs with complete regioselectivity in the presence of potassium in liquid ammonia or DMSO (eq 15).[7] These reactions are now more generally effected with a potassium alkoxide under photochemical activation.[28]

(15)

Supported Potassium on Alumina (K/Al_2O_3) or Graphite (C_8K).

Potassium on Alumina is prepared by melting the metal in the presence of Al_2O_3. ***Potassium-Graphite*** is obtained by vaporizing the metal on graphite. Both reagents are sensitive to oxygen and moisture. Various reductive processes take place with alkenes, nitriles, or halides (eqs 16 and 17).[8,29]

(16)

(17)

Ultrasonically Dispersed Potassium (UDP).

Sonication of potassium metal in aromatic solvents (toluene, xylene) produces a silvery blue suspension. The reaction of this reagent with water is much milder than that of potassium metal. This suspension can behave as a base or as a single-electron transfer agent. The Dieckman cyclization of diethyl adipate (eq 18)[10] and the dimerization of succinates (eq 19)[30] occur readily at rt in excellent yield.

(18)

(19)

The carbon-sulfur bond in sulfolene is cleaved to a radical anion, which can be alkylated to provide open chain sulfones. The inconvenience of long irradiation times was solved by running the reaction in the presence of proton sources, water, or phenol (eq 20).[31]

Potassium on Alumina

K/Al_2O_3

[7440-09-7] · K · Potassium on Alumina · (MW 39.10)

(catalyst for hydrogenations,[1,7] double bond isomerizations,[1-4] dehydrations, and skeletal rearrangements;[2-4] metalating agent;[5] effects reductive decyanation[6])

Physical Data: blue powder if the metal content is in the range of 2-15%; at higher loading the reagent has a gray to black appearance. The X-ray spectrum of a 14% K on Al_2O_3 reagent shows no observable reflections due to potassium.[6] A metal content in the range of 2-15% usually leads to the highest catalytic activity.[1]

Preparative Method: by adding potassium to thoroughly dried basic or neutral alumina under argon with vigorous stirring at temperatures >100 °C until a homogeneous appearance is reached.

Handling, Storage, and Precautions: nonpyrophoric solid which can be stored under argon for extended periods of time; must be handled under inert atmosphere; catalytic activity may decrease if impure or moist solvents are used; can be safely destroyed by slowly adding isopropanol to a suspension of the reagent in hexane with good stirring.

Catalytic Activity.

K/Al_2O_3 is the most efficient among the series of alkali metals finely dispersed on alumina, although ***Sodium-Alumina*** (sometimes termed high surface sodium) essentially effects the same types of transformations. In a model system, the following order of activity for the different alkali metals supported on alumina has been established: K &egt; Rb >> Cs &AApprox; Na.[1a]

K/Al_2O_3 readily effects both configurational as well as positional alkene isomerizations with the following three trends being observed. Firstly, alkene groups are usually shifted (with few exceptions) towards higher degrees of substitution (eq 1).[2] Secondly, an alkene of accentuated conformational preference will accumulate; this is evidenced, for example, by the formation of the thermodynamically more stable (*Z*,*Z*)-cyclodeca-1,6-diene from (*E*,*Z*)-cyclodeca-1,5-diene (eq 2),[1] as well as by the preponderance of (-)-aristolene in the equilibrium mixture obtained upon treatment of (+)-calaren with K/Al_2O_3 (eq 3).[2] Thirdly, the double bonds in 1,*n*-(cyclo)alkadienes are shifted towards conjugation independent of their initial position in the starting material (eqs 4 and 5).[1,2] Similarly, 1,2,4-trivinylcyclohexane quantitatively affords 1,2,4-triethylbenzene in a highly exothermic process.[3] Although the mechanism responsible for such positional changes is not yet elucidated, allyl anion intermediates are likely.[1] This

picture is supported by the observation that successive treatment of γ-***Alumina*** with ***Sodium Hydroxide*** and Na leads to a solid superbase (pK_b &egt; 37), which effects the same types of alkene isomerizations via allyl anion species.[8]

(1)

(2)

(3)

(4)

(5)

Macrocyclic 1,3-cycloalkadienes produced by isomerization of 1,*n*-cycloalkadienes are slowly reduced to cycloalkenes even in the absence of external hydrogen.[1] Residual water or -OH groups on the alumina in combination

with the adsorbed potassium may serve as the hydrogen source in this process. Under a hydrogen atmosphere (1 atm), however, this selective hydrogenation of conjugated dienes by M/Al_2O_3 (M = Na, K) is considerably accelerated, with no overreduction to the respective cycloalkane being observed.[1]

K/Al_2O_3 exhibits a distinct propensity to catalyze transannular reactions of unsaturated macrocyclic systems as well as skeletal rearrangements leading to ring contraction, as shown with (+)-longifolene as substrate.[2]

Catalytic Cascades.

Six-membered rings bearing two alkene and/or cyclopropyl groups in the vicinity are smoothly aromatized when exposed to M/Al_2O_3 (M = Na, K) as catalyst by a sequence of double-bond isomerizations followed by dehydrogenation (eq 6).[2,3]

In a one-pot procedure (*Z*,*E*,*E*)-cyclododeca-1,5,9-triene as substrate runs through a cascade of catalytic processes induced by Na/Al_2O_3. This sequence comprises a transannular reaction, double bond isomerizations, and selective hydrogenation of the conjugated diene produced in the presence of hydrogen. Final ozonolysis of the crude reaction mixture afforded cyclododeca-1,7-dione in good yield (eq 7).[4]

Organometallic Synthesis.

K/Al_2O_3 has been used as base to metalate ketones, ethyl phenylacetate, alkyl nitriles, aldehyde-*N*,*N*-dimethylhydrazones, or *N*-cyclohexylketimines.[5] However, an excess of the reagent was necessary and the yields reported for alkylation of the intermediate potassium carbanions were moderate. In the case of alkyl nitriles as starting materials, the choice of solvent turned out to be decisive for the reaction path: while deprotonation of these substrates predominates in THF, they are readily decyanated when treated with K/Al_2O_3 in hexane as the reaction medium.[6] Residual -OH groups on the alumina may be the proton sources in this reductive C-C bond cleavage. While the reaction leaves acetal groups and disubstituted alkene moieties in the substrates unaffected (eq 8), terminal double bonds are rearranged to internal ones during the decyanation process (eq 9).[6] Recently, Na/Al_2O_3 has been used as reducing agent for ketones, esters, and oximes.[9] It also serves as a catalyst for the Tischenko coupling of benzaldehyde to benzyl benzoate,[10] and may be employed for preparing activated zinc and titanium samples.[11]

Potassium Amide

KNH_2

[17242-52-3] · H_2KN · Potassium Amide · (MW 55.13)

(strong base and nucleophile; used for the generation and trapping of arynes; has been used extensively to study the reactivity of heterocyclic systems)

Solubility: 1.7 M in liquid ammonia;[1] 1.3×10^{-4} M in THF.[2]

Preparative Methods: a solution of potassium amide in liquid ammonia is prepared by adding pieces of ***Potassium*** to liquid ***Ammonia*** in an ordinary three-necked flask equipped with a mechanical stirrer.[3] A piece of potassium is added to liquid ammonia and after the appearance of a blue color, a few crystals of iron(III) nitrate hydrate are added as catalyst. The remaining pieces of potassium are added at a rate which maintains active hydrogen evolution. Discharge of the deep blue color indicates complete conversion to potassium amide. External cooling is not required since the evaporation of ammonia will provide ample cooling.[4] If the reaction must be maintained at -78 °C then a dry ice-acetone condenser is necessary, otherwise an air condenser is sufficient. The resulting opaque mixture contains potassium amide which is mostly in solution. A more elaborate two-flask assembly for the generation and transfer of a potassium amide solution has also been described.[5]

Handling, Storage, and Precautions: potassium amide is flammable and ignites on contact with moisture. Excess material is destroyed by careful treatment with ethanol or isopropanol. In the preparation of potassium amide the following precautions should be noted. Potassium is a silvery gray metal but it can form an explosive peroxide coating. If it acquires an orange or red color or an appreciable oxide coating it should be considered extremely hazardous. Extreme caution should be exercised in any attempt to isolate potassium amide as it is suspected to be shock sensitive following partial oxidation. An explosion has been reported during the isolation of dry potassium amide.[6] Reactions should be performed in a fume hood to prevent exposure to ammonia. Hydrogen is evolved during the generation of potassium amide. No ignition source should be present.

Introduction.

Potassium amide is both a strong base and a strong nucleophile and thus it has been used most effectively in reactions which exploit both of these properties, such as the generation and trapping of arynes, the amination of aromatic systems, and the rearrangement of various heterocyclic systems. Examples of these types of transformations are described below. The reagent has also been used simply as a strong base to induce deprotonation or elimination reactions, provided there are no competing nucleophilic reaction pathways available. This is currently a less important

feature of the reagent given the ready availability of strong, nonnucleophilic bases, but a few examples are described at the end of this section.

Aryne Formation.

Potassium amide in liquid ammonia has been used extensively in the generation and trapping of benzynes via dehydrohalogenation of phenyl halides.[7] One of the definitive experiments providing evidence for the existence of benzyne involved the treatment of [1-^{14}C]chlorobenzene with potassium amide in liquid ammonia to provide equal amounts of [1-^{14}C]aniline and [2-^{14}C]aniline (eq 1).[8] The potassium amide-ammonia system has since been used for the preparation of various substituted anilines.[9]

Potassium amide has also been utilized extensively for the generation and trapping of various six-membered hetarynes including those generated from halogenated pyridines, diazines, isoquinolines, naphthyridines, and certain multicyclic systems.[10] Of the various hetarynes, the evidence supporting the existence of 3,4-pyridyne is recognized as the most convincing. Treatment of either 3- or 4-chloropyridine with potassium amide in liquid ammonia provides a constant ratio of the isomeric amine products (eq 2).[11]

Although mixtures of amines are usually formed in potassium amide-induced aryne formations, in some cases selectivity for one isomer can be achieved. For example, it was found that treatment of a tricyclic

bromobenzo[*f*]quinoline with potassium amide in liquid ammonia provided only one product via its postulated hetaryne intermediate (eq 3).[12] Steric interference by the angular ring is presumed to block formation of the other isomer.

(3)

Even in the presence of potassium amide, an intramolecular nucleophile can often compete effectively with amide ion to trap an aryne intermediate, resulting in ring closure. For example, 2-phenylbenzothiazole has been prepared in 90% yield utilizing this strategy (eq 4).[13] Intramolecular cyclization onto potassium amide-generated benzyne derivatives has been achieved with carbon, nitrogen, oxygen, and sulfur nucleophiles.[14] The strategy has also been successfully used with certain hetarynes, particularly 5-substituted 3,4-pyridynes (eq 5).[15] In some cases, however, when potassium amide is used as the aryne-generating base, competitive amination can occur to a significant extent (eq 6).

(4)

Potassium amide-generated arynes can also be trapped intramolecularly by a sufficiently nucleophilic phenyl ring. For example, appendage of a negatively charged atom to an aromatic ring can confer sufficient nucleophilicity to the *ortho* and *para* positions for this type of reaction.[16] An example of this strategy is shown in the synthesis of phenanthridines from haloanils (eq 7).[17] In this case, potassium amide is used not only to generate the requisite benzyne but also to activate the system to ring closure via addition of amide ion to the azomethine linkage. For the reaction to succeed, the nucleophilic addition of the amide ion must be very fast relative to the formation of the benzyne. This phenanthridine synthesis tolerates a variety of substituents in the aniline ring, with the exception of hydroxy and nitro groups which are thought to slow the amide addition to the azomethine group significantly.[18]

Rearrangement of Heterocyclic Systems.

The generation of pyridyne utilizing potassium amide prompted the investigation of the reaction of potassium amide with other heterocyclic azine systems in a search for other hetarynes. However, the halogenated precursors to hetarynes are often more reactive toward nonaryne reactions and in some cases alternative mechanisms for amination are involved. Although it was initially believed that 4-bromo-6-phenylpyrimidine reacted with potassium amide via a 6-substituted 4,5-didehydro intermediate, extensive examinations of the reaction of potassium amide with halopyrimidines led to the elucidation of another mechanism for nucleophilic substitution which proceeds through a ring opened intermediate (eq 8).[19] This mechanism is referred to as S_N(ANRORC) for addition of the nucleophile, ring opening, and ring closure. The evidence accumulated to support its existence has been reviewed.[20] In particular, labeling studies have been used to demonstrate that the amide anion nitrogen becomes incorporated into the ring system (eq 9). This mechanism has been shown to be operative (to a greater or lesser extent) in the reaction of potassium amide with a variety of halogen-substituted heterocyclic systems in addition to pyrimidines, including quinazolines, triazines, and purines. A review of the extensive literature in the area, categorized by ring type, is available.[21]

Under the conditions of potassium amide in liquid ammonia, many other examples of skeletal rearrangements of heterocyclic systems are known.[22] For example, ring contractions have been documented, such as that of 2-chloropyrazine to 2-cyanoimidazole (eq 10).[23] In this system, as in many cases, multiple rearrangement pathways lead to multiple products. The details of these potassium amide-induced heterocyclic ring transformation studies are available in a monograph.[22a]

A particularly useful transformation is the rearrangement of 2-substituted 4-halopyrimidines into *s*-triazines via a ring-opened intermediate (eq 11).[24] This reaction allows for the preparation of unsymmetrically substituted *s*-triazines which are difficult to obtain by other methods. Competing formation of the 4-aminopyrimidine is minimized by utilizing the chloro derivatives (X = Cl).

Direct Amination of Aromatic Rings.

Potassium amide can be used to induce a direct nucleophilic substitution of amide anion for hydrogen in certain azines.[25] Potassium amide in liquid ammonia adds readily to pyrazine, pyrimidine, and pyridazine to give anionic σ-

adducts which can be oxidized by ***Potassium Permanganate*** to give the corresponding aminoaza heterocycle in good yield (eq 12).[26] More highly electron deficient systems, like pteridines and nitroaza aromatics, are able to add ammonia itself to give neutral σ-adducts which are also oxidized by $KMnO_4$ to heteroarylamines.[27] This modified Chichibabin reaction has been reviewed elsewhere.[28]

(12)

Potassium amide can also displace a suitably situated halide on a heteroaromatic ring to provide the aromatic amine, but this reaction is often accompanied by other products from competing rearrangement pathways (eq 10). Simple phenols can be converted to the corresponding aniline in a two-step process involving treatment of the aryl diethyl phosphate ester with potassium amide and potassium metal in liquid ammonia (eq 13).[29]

(13)

Anion Generation.

Potassium amide is a strong base which can be used in simple deprotonation reactions for the generation of various anions. In enolate chemistry, potassium amide in liquid ammonia has been used to generate the dianions of β-diketones and β-ketoaldehydes.[30] These species can then be regioselectively alkylated at the γ-position. In unsymmetrical β-diketones the second deprotonation occurs at the less substituted γ-position (eq 14). The scope of this reaction, including a tabular survey of known examples, has been carefully reviewed.[30] Potassium amide in liquid ammonia has also been used for the preparation of 1,3-dinitro-2-keto derivatives from the reaction of cycloalkanones with alkyl nitrates.[31]

(14)

Deprotonation of benzyl ethers by potassium amide in liquid ammonia has been used to effect the Wittig rearrangement.[32] In a preparation of phenanthrene, use of potassium amide accomplished the rearrangement to the carbinol in 90% yield after 1 h, whereas ***Phenyllithium*** required 1 week (eq 15).[33]

(15)

Examples of large-scale preparations utilizing potassium amide in liquid ammonia for the benzylic deprotonation of lutidine and diphenylacetonitrile have been published.[3,34] Allylic deprotonation of 2-chloromethyl-1-butene with potassium amide in THF at 65 °C has been used in an effective preparation of vinylcyclopropane (eq 16).[35]

(16)

Elimination Reactions.

Potassium amide in liquid ammonia can be used as a base to induce elimination reactions.[36] For example, this reagent has been used in a preparation of dimethoxycyclopropene via an intramolecular alkylation followed by elimination (eq 17).[37] Potassium amide-induced elimination followed by an additional deprotonation has also been used to generate 8,8-dimethylcyclooctatrienyl anion (eq 18).[38]

(17)

Potassium 3-Aminopropylamide

$KNH(CH_2)_3NH_2$

[56038-00-7] · $C_3H_9KN_2$ · Potassium 3-Aminopropylamide · (MW 112.24)

(strong base[1] used primarily for the isomerization of internal alkynes to terminal alkynes;[2] can also be used to isomerize alkenes;[3] also used to promote intramolecular transamidation reactions[4])

Alternate Name: KAPA.

Solubility: highly sol (&egt;1.5 M) in excess 1,3-diaminopropane

Preparative Methods: usually prepared as a solution in excess, dry 1,3-diaminopropane.[5] The most common preparation involves the direct, quantitative reaction of ***Potassium Hydride*** with excess amine at 20-25 °C.[6] Alternative preparations have been developed to avoid the handling and purification of KH. The reagent has been prepared by the reaction of ***Potassium Amide*** and 1,3-diaminopropane followed by evaporation of excess ***Ammonia*** in vacuo.[7] The reagent has also been prepared by heating ***Potassium*** and 1,3-diaminopropane under sonication.[8] A trace of iron(III) nitrate increases the rate of reagent formation, although it is not essential. Addition of ***Potassium t-Butoxide*** to lithium 3-aminopropylamide (from ***Lithium*** and 1,3-diaminopropane) probably generates KAPA in situ via cation exchange.[9]

Handling, Storage, and Precautions: moisture sensitive. A solution of KAPA in 1,3-diaminopropane appears stable for at least 8 h at rt and possibly even for 2-3 days.[2,10] Use in a fume hood.

Isomerization of Alkynes.

Potassium 3-aminopropylamide is best known for its use in the acetylene zipper reaction.[2] This reagent induces a rapid migration of triple bonds from the interior of a carbon chain to the terminus. Previously reported isomerizations of alkynes required very strong bases (e.g. ***Sodium***, ***Sodium Amide***) and elevated temperatures to effect a one-position isomerization of a 2-alkyne to a 1-alkyne. Migrations over more than one position were reported to be generally unsatisfactory or very slow. By contrast, KAPA produces rapid, multiposition alkyne migrations to provide the terminal alkyne within seconds at 0 °C (eq 1). Although internal alkynes are favored thermodynamically, this isomerization is driven forward by the formation (possibly aided by precipitation) of the stable metal acetylide. Quenching of the acetylide with water provides the terminal alkyne in excellent yield. In nonlinear systems, migration is blocked by branching in the chain.

The reaction has also been studied in functionalized systems. In alkynic alcohols, KAPA-induced migration of the triple bond proceeds to the chain terminus which is remote from the OH function (eq 2).[11] It is believed that the anionic intermediate in the migration of the triple bond is inhibited from migrating toward the similarly charged alkoxide.[11a] If the hydroxy group is attached to a chiral carbon, this phenomenon protects the configuration of that carbon during the migration process. Isomerization of chiral propargylic alcohols proceeds to give the terminal alkynic alcohols with no significant loss of enantiomeric purity (eq 3).[12]

Successful isomerizations have also been carried out with o-alkynylorganoboranes and propynyl ethers.[13] Isomerizations of alkynic carboxylic acids generally lead to a mixture of products and poor yields of the terminal alkyne.[14] However, if the carboxylic acid group is separated from the alkyne by an intervening carbinol, the carboxylate can be carried through the migration reaction without difficulty.[15]

KAPA can also be used for the in situ generation of an internal alkyne which then rapidly isomerizes to the terminal position. Allenes, vinyl sulfides, and cyclic ethers have been used as alkyne equivalents to provide terminal alkynes (eq 4).[16]

Isomerization of Exocyclic Alkenes.

Trace quantities of KAPA can be used in a two-phase reaction to effect the rapid, low-temperature isomerization of neat, exocyclic alkenes on a large scale.[3] In particular, KAPA has been used for the isomerization of (-)-β-pinene to the less accessible (-)-α-pinene in high yield and without racemization (eq 5).[17]

Intramolecular Transamidation Reactions.

KAPA is recommended for use in the zip reaction for the ring enlargement of aminolactams (eq 6).[4,18] It is believed that the reaction is driven in part by formation of the resonance-stabilized amide anion.

Related Reagents.

Lithium Amide; ***Lithium Diisopropylamide***; ***Potassium Hexamethyldisilazide***; ***Potassium Diisopropylamide***.

Potassium Azodicarboxylate

[4910-62-7] · $C_2K_2N_2O_4$ · Potassium Azodicarboxylate · (MW 194.24)

(used for the generation of diimide[1])

Alternate Name: azodicarboxylic acid, potassium salt.

Physical Data: crystalline yellow solid; properties do not appear to be recorded.

Solubility: insol aprotic organic solvents; partially sol protic organic and aqueous organic solvents.

Form Supplied in: not currently commercially available.

Preparative Method: by the reaction of potassium hydroxide with $H_2NCON{=}NCONH_2$[2] (which is commercially available).

Handling, Storage, and Precautions: there has been one report that potassium azodicarboxylate exploded violently when left exposed to bright sunlight for about 30 min;[3] there have been other reports of suspected nonviolent decomposition of the compound on storage;[4] it is advisable to dry the compound in vacuo and not store in a sealed container. Extreme care must be exercised in the preparation, isolation, storage, and use of potassium azodicarboxylate.

The treatment of potassium azodicarboxylate with a carboxylic acid in protic or aprotic organic solvents results in the ultimate formation of ***Diimide***, which is a very useful reagent for the mild, noncatalytic reduction of C-C π-systems. Potassium azodicarboxylate is prepared by the reaction of ***Potassium Hydroxide*** with azodicarboxamide (eq 1).[2]

HN=NH (1)

The use of potassium azodicarboxylate as a source of diimide is particularly useful for the generation of deuterium- and tritium-labeled diimide in aprotic organic solvents for the position-, facial- and stereoselective reduction of C-C π-systems, as illustrated in eq 2.[5] In these reduction reactions the substrate and an excess of the potassium azodicarboxylate are placed in an appropriate solvent and a slight excess of the carboxylic acid is slowly added to the mixture. The yields of product are generally very high.

(2)

This procedure is also very useful for the *syn* reduction of alkynyl halides, as illustrated in eq 3.[6]

Daniel J. Pasto

Potassium Bromate

$KBrO_3$

[7758-01-2] · $BrKO_3$ · Potassium Bromate · (MW 167.00)

(convenient source of molecular bromine;[1a] used for bromination of deactivated aromatics;[2] used in chemical oscillating reactions[3])

Physical Data: mp ~350 °C, dec ~370 °C with evolution of oxygen; *d* 3.27 g cm^{-3}.

Solubility: sol 12.5 parts water, 2 parts boiling water; almost insol alcohol.

Form Supplied in: white crystals or granules; widely available. *Drying:* for analytical work dry at 100-110 °C for 1 h.

Handling, Storage, and Precautions: potassium bromate is a strong oxidizing agent (standard potential 1.44 V). Toxicity is low. Keep from contact with mineral acids and organic compounds during storage. Potassium bromate is an analytical standard for iodometry. Standard solutions are stable indefinitely.

Generation of Bromine and Bromination Reactions.

Potassium bromate and ***Sodium Bromate*** react with bromide ion in dilute acid solution[1] to produce bromine according to eq 1.

$$BrO_3^- + 5\,Br^- + 6\,H^+ \longrightarrow 3\,Br_2 + 3\,H_2O \qquad (1)$$

As such, it is a convenient reagent for the bromination of alkenes, phenols, salicylic acid, aniline, and other activated compounds.[4] Synthetically useful brominations of methyl ketones,[5,6] 3-substituted cyclohexenones,[7] thiophene (in a two-phase system),[8] organoboranes (to produce an α-bromoorganoborane which rearranges to the alcohol),[9] cyclopentamethylenediphenylstannane (to form cyclopentamethylenedibromostannane),[10] and sulfonylhydrazides (to form sulfonyl bromides)[11] have been reported.

Bromination of Deactivated Aromatics.

Potassium bromate in the absence of added bromide is an effective brominating agent. An early report[12] that

potassium bromate in ***Sulfuric Acid***, in the absence of added bromide, brominated benzene went unnoticed for over 100 years. An efficient procedure for the bromination of deactivated aromatic compounds has appeared.[2] For example, nitrobenzene[2] has been brominated in 88% yield in this fashion (eq 2). The reaction is dependent on the concentration of the sulfuric acid. This method is arguably superior to other methods for nitrobenzene bromination.[13] (Warning! potassium bromate decomposes rapidly in 70% sulfuric acid solution with the evolution of heat.[2])

(2)

Other deactivated aromatics that can be brominated by this method include benzoic acid,[2,14] halobenzoic acids,[15] phthalic acid,[2] hydroxybenzoic acid,[16] halobenzenes,[15,17] benzonitrile,[16] benzanilide,[16] cinnamic and hydrocinnamic acids,[16] phenylacetic acid,[16] benzophenone,[16] acetophenone,[2] and 2,5-dimethyl-1,3,4-oxadiazoles.[18] In the case of acetophenone, the bromination occured at the aromatic ring and not on the methyl group,[19] which is the normal position for attack using molecular bromine (eq 3).

(3)

One report in which sodium bromate is used in combination with ***Bromotrimethylsilane*** for the bromination of aromatic rings has appeared.[20] While activated rings such as anisole and phenol react satisfactorily, deactivated rings do not. Toluene gave the benzyl bromide product instead of the ring brominated product.[20]

Chemical Oscillators.

Chemical oscillating reactions such as the Belousov-Zhabotinski reaction[3] and a clock reaction[21] have been reported using potassium bromate/sodium bromate. Chemical oscillations such as these are driven by a combination of bromination and oxidation reactions. A generalized mechanism for bromate-driven oscillators controlled by bromide has appeared.[22] This is still an active area for investigation.[23]

Potassium *t*-Butoxide

***t*-BuOK**

[865-47-4] · C_4H_9KO · Potassium *t*-Butoxide · (MW 112.23)

(strong alkoxide base capable of deprotonating many carbon and other Brφnsted acids; relatively poor nucleophile[1])

Physical Data: mp 256-258 °C (dec).

Solubility: sol/100g solvent at 25-26 °C: hexane 0.27 g, toluene 2.27 g, ether 4.34 g, *t*-BuOH 17.80 g, THF 25.00 g.

Form Supplied in: white, hygroscopic powder; widely available commercially; also available as a 1.0 M solution in THF.

Preparative Methods: sublimation (220 °C/1 mmHg; 180 °C/0.05 mmHg) of the commercial material prior to use is recommended. For critical experiments, the reagent should be freshly prepared prior to use. Solutions of the reagent in *t*-BuOH may be prepared by reaction of the anhydrous alcohol with ***Potassium*** under nitrogen,[2] or the solvent may be removed (finally at 150 °C/0.1-1.0 mmHg for 2 h) and solutions prepared using other solvents.[3]

Handling, Storage, and Precautions: do not breathe dust; avoid contact with eyes, skin, and clothing. Reacts with water, oxygen, and carbon dioxide, and may ignite on exposure to air at elevated temperatures. Handle in an inert atmosphere box or bag and conduct reactions under an inert atmosphere in a fume hood. Store in small lots in sealed containers under nitrogen.

Introduction.

Potassium *t*-butoxide is intermediate in power among the bases which are commonly employed in modern organic synthesis. It is a stronger base than the alkali metal hydroxides and primary and secondary alkali metal alkoxides,[1] but it is a weaker base than the alkali metal amides and their alkyl derivatives, e.g. the versatile strong base ***Lithium Diisopropylamide***.[4] The continued popularity of *t*-BuOK results from its commercial availability and the fact that its base strength is highly dependent on the choice of reaction solvent. It is strongly basic in DMSO, where it exists primarily as ligand-separated ion pairs and dissociated ions, but its strength is significantly decreased in solvents such as benzene, THF, and DME, where its state of aggregation is largely tetrameric. DMSO is able to enhance the basicity of the *t*-butoxide anion by selectively complexing with the potassium cation. Other additives, such as the dipolar

aprotic solvent ***Hexamethylphosphoric Triamide*** (HMPA) and ***18-Crown-6***, have a similar effect. This section will provide cursory coverage of the reactions of *t*-BuOK in *t*-BuOH and in relatively nonpolar aprotic solvents. The unique features of ***Potassium t-Butoxide-Dimethyl Sulfoxide***, ***Potassium t-Butoxide-Hexamethylphosphoric Triamide***, and ***Potassium t-Butoxide-18-Crown-6***, as well as those of the ***Potassium t-Butoxide-t-Butyl Alcohol Complex*** (1:1), are described elsewhere in this encyclopedia.

Alkylations.

Many bases which are weaker than *t*-BuOK are capable of essentially quantitative conversion of active methylene compounds into the corresponding enolates or other anions.[5] However, the alkylation of diethyl malonate with a bicyclic secondary tosylate (eq 1)[6] and the alkylation of ethyl *n*-butylacetoacetate with *n*-BuI (eq 2)[7] provide examples of cases where the use of *t*-BuOK in *t*-BuOH is very effective. In the latter reaction, cleavage of the product via a retro-Claisen reaction is minimized with the sterically hindered base and yields obtained are higher than when ***Sodium Ethoxide*** or EtOK in EtOH, ***Sodium*** in dioxane or toluene, or ***Sodium Hydride*** in toluene are used for the enolate formation.

Potassium *t*-butoxide in *t*-BuOH or ethereal solvents is not capable of effecting quantitative formation of enolates of unactivated saturated ketones;[8] also, because potassium enolates are subject to rapid proton transfer reactions, their intermolecular alkylations are complicated by equilibration of structurally isomeric enolates, polyalkylation, and aldol condensation reactions.[9] Thus reactions of preformed lithium enolates (generated by deprotonation of ketones with LDA or by indirect procedures) with alkylating agents provide the method of choice for regioselective alkylation of

unsymmetrical ketones.[9,10] However, as illustrated in eqs 3 and 4,[11,12] ketones capable of forming only a single enolate, such as symmetrical cyclic ketones and those containing α-methylene blocking groups, are readily alkylated via *t*-BuOK-promoted reactions. Also, *t*-BuOK in *t*-BuOH or benzene frequently has been employed for the alkylation of α,α-disubstituted aldehydes.[9]

(3)

(4)

As illustrated in eq 5, α,β-unsaturated ketones undergo α,α-dialkylation when treated with excess *t*-BuOK/*t*-BuOH and an alkylating agent.[13] The α,α-dimethylated β,γ-unsaturated ketone is formed by conversion of the initially produced α-methylated β,γ-unsaturated ketone to its dienolate, which undergoes a second methylation faster than the β,γ-double bond is isomerized to the α,β-position.[14]

(5)

In contrast to intermolecular processes, intramolecular alkylations are frequently performed with *t*-BuOK in various solvents.[19] In eqs 6 and 7 are shown examples of *endo*- and *exo*-cycloalkylations of cyclic saturated ketones which lead to new five-membered rings.[15,16]

(6)

(7)

An interesting example of how a change in the base can influence the course of a cycloalkylation reaction is shown in eq 8.[17] Since the reaction with *t*-BuOK involves equilibrating conditions, *exo*-cycloalkylation occurs via the more-substituted enolate, which is more thermodynamically stable. On the other hand, when LDA is used as the base, *endo*-cycloalkylation occurs via the kinetically formed terminal enolate.

(8)

Intramolecular alkylations of α,β-unsaturated ketones may occur at the α-, α´-, or γ-positions depending upon the nature of the base, the leaving group, and other structural features. A recent example involving α-cycloalkylation using *t*-BuOK is shown in eq 9.[18]

(9)

The reaction of α-halo esters, ketones, nitriles, and related compounds with appropriate organoboranes in the presence of *t*-BuOK can lead to replacement of the halogen with an alkyl or an aryl group.[19] An example of this reaction using an α-bromo ester is shown in eq 10.[20] THF is a more effective solvent than *t*-BuOH for alkylations of α-bromo ketones using this methodology.[21] Potassium 2,6-di-*t*-butylphenoxide, a mild, sterically hindered base, is much more effective than *t*-BuOK for the alkylation of highly reactive α-halo ketones, e.g. bromoacetone, and α-halo nitriles.[22]

(10)

Condensation Reactions.

Traditionally, intermolecular aldol condensation reactions have been performed under equilibrating conditions using weaker bases than *t*-BuOK in protic solvents.[23] Since the mid-1970s, new methodology has focused on directed aldol condensations which involve the use of preformed ***Lithium*** and Group 2 enolates,[24] Group 13 enolates,[25] and transition metal enolates.[26] Although examples of the use of *t*-BuOK in intramolecular aldol condensations are limited, complex diketones (eq 11)[27] and keto aldehydes (eq 12)[28] have been cyclized with this base.

(11)

(12)

t-BuOK is the most commonly used base for the Darzens condensation of an α-halo ester with a ketone or an aromatic aldehyde to yield an α,β-epoxy or glycidic ester.[29] In the example shown in eq 13,[30] the aldol step is reversible and the epoxide ring closure step is rate limiting. This leads to the product with the ester group and the bulky β-substituent *trans*. However, in other systems the opposite stereochemical result often occurs because the aldol condensation step is rate limiting. In addition to esters, a wide variety of α-halo compounds that contain electron-

withdrawing groups may participate in these types of reaction.[29c]

(13)

The Dieckmann cyclization of diesters and related reactions has found an enormous amount of use in the synthesis of five-, six-, seven-, and even larger-membered rings.[31] In unsymmetrical systems, steric effects and the stability of the product enolates determine the regiochemistry of the reaction. As shown in eqs 14 and 15,[32,33] *t*-BuOK is an effective base for these reactions when used in *t*-BuOH or other solvents such as benzene. In the former example, 40% of unchanged starting material is recovered when MeONa/PhH is used to effect the cyclization.

(14)

(15)

The nature of the base can profoundly influence the regiochemistry of the reaction. *t*-BuOK favors kinetic control in the reaction shown in eq 16 and the product derived from cyclization of the enolate having a β-amino group is obtained. However, when EtONa/EtOH is employed, the more stable β-keto ester enolate resulting from thermodynamic control is obtained.[34] In addition to diesters, dinitriles, ε-keto esters, ε-cyano esters, ε-sulfinyl esters, and ε-phosphonium esters may participate in these reactions.[31]

(16)

t-BuOK is a better base than EtONa for the Stobbe condensation (eq 17) because yields are higher, reaction times are shorter, and frequent side reactions of ketone or aldehyde reduction are avoided.[35]

Base, solvent	Yield (%)
EtONa (2 equiv), EtOH, reflux, 6 h	79
t-BuOK (1.1 equiv), *t*-BuOH, reflux, 40 min	89-94

Although the use of *t*-BuOK for the generation of unstabilized ylides from phosphonium salts has been rare, it is the base of choice for the generation of ***Methylenetriphenylphosphorane*** for the Wittig reaction of hindered ketones (eq 18).[36] No 1,1-di-*t*-butylethylene is obtained from di-*t*-butyl ketone when NaH/DMSO is used to generate the ylide.[37]

Elimination Reactions.

t-BuOK is a widely used base for both α- and β-elimination reactions. It is the most effective base in the conventional alkoxide-haloform reaction for the generation of dihalocarbenes.[38] This procedure still finds general use (eq 19),[39] but since it requires anhydrous conditions, it has been replaced to a degree by use of phase-transfer catalysts.[40] Vinylidene carbenes have also been produced from the reaction of α-halo allenes with *t*-BuOK.[41]

Substrates containing a host of leaving groups, such as alkyl chlorides (eqs 20 and 21),[42,43] bromides (eqs 22-24),[44-46] tosylates, mesylates (eq 25),[47] and even sulfenates and sulfinates (eq 26),[48] undergo β-eliminations with *t*-BuOK in the solid phase or in *t*-BuOH or various nonpolar solvents.

(20)

(21)

(22)

(23)

anti-elimination

(24)

(25)

(26)

The regiochemical and stereochemical results of β-eliminations of 2-substituted acyclic alkanes with *t*-BuOK in various solvents have been extensively investigated.[49] Space does not permit the details of these investigations to be presented, but a few brief generalizations may be noted. (1) *t*-BuOK normally gives more of the terminal alkene than primary alkoxide bases but less than extremely bulky bases such as potassium tricyclohexylmethoxide. (2) A greater proportion of the terminal alkene is produced in solvents such as *t*-BuOH, where the base is highly aggregated, than in DMSO where it is substantially monomeric and partially dissociated. (3) The lower the state of aggregation of the base, the higher the *trans*:*cis* ratio of the disubstituted 2-alkene. (4) As base aggregation increases, the *syn*:*anti* elimination ratio increases. As far as the *trans*:*cis* ratio is concerned, cyclic halides give the opposite results from open-chain systems, i.e. this ratio is higher when base aggregation is greater (eq 27).[50]

(27)

Solvent	*trans* (%)	*cis* (%)
PhH	83	1.5
PhH, dicyclo-hexyl-18-crown-6	9	76
DMF	7	72

Fragmentation Reactions.

Because it is a relatively strong base and a relatively weak nucleophile, *t*-BuOK has been the most popular base for effecting Grob-type fragmentations of cyclic 1,3-diol derivatives.[51] In *t*-BuOH or nonpolar solvents, sufficiently high concentrations of alkoxide ions of 1,3-diol derivatives are produced for fragmentations to proceed smoothly if relatively good leaving groups are present (eq 28).[52] When relatively poor leaving groups, e.g. sulfinates, are involved, it is necessary to increase the strength of *t*-BuOK by the addition of a dipolar aprotic solvent (eq 29).[53] Other base-solvent combinations which may offer advantages over *t*-BuOK/*t*-BuOH for certain fragmentation substrates include NaH/THF, $DMSO^-$ Na^+/DMSO, and LAH/ether.[51]

(28)

(29)

Isomerizations of Unsaturated Compounds.

t-BuOK is an effective base for bringing about migrations of double bonds in alkenes and alkynes via carbanion intermediates,[1] but since the base promotes these reactions most effectively in DMSO, they will be described in more detail under ***Potassium t-Butoxide-Dimethyl Sulfoxide***. Important examples of enone deconjugations with *t*-BuOK/*t*-BuOH which proceed via di- and trienolate intermediates are shown in eqs 30 and 31.[54,55] Potassium *t*-pentoxide is effective in promoting the latter reaction, but various lithium amide bases are not, apparently because they deprotonate the enone at the α´-position regioselectively. The isomerization of α,β-unsaturated imines to alkenyl imines (eq 32) is an important step in an alternative method for reduction-alkylation of α,β-unsaturated ketones.[56]

(30)

(31)

(32)

Ketone Cleavage Reactions.

t-BuOK in ether containing water is the medium of choice for the cleavage of nonenolizable ketones such as nortricyclanone (eq 33).[57] Optically active tertiary α-phenyl phenyl ketones are cleaved in fair yields with high retention of configuration with the base in *t*-BuOH or PhH (eq 34).[58] *t*-BuOK is more effective than *t*-BuONa or ***Lithium t-Butoxide*** in these reactions.

(33)

(34)

Michael Additions.

t-BuOK is one of an arsenal of bases that can be used in Michael addition reactions.[59] A catalyst prepared by impregnation of xonotlite with the base promotes the Michael addition of the β-diketone dimedone to 2 mol of MVK (eq 35).[60] Unsymmetrical ketones like 2-methylcyclohexanone yield Michael adducts primarily at the more substituted α-carbon atom (eq 36).[8a] Active methylene compounds undergo double Michael additions to enynes in the presence of *t*-BuOK (eq 37).[61] This type of reaction has been used in the total synthesis of griseofulvin. A tricyclo[5.3.1.0^{1,5}]undecanedione, a precursor of (±)-cedrene, is available by a highly regioselective intramolecular Michael addition using *t*-BuOK (eq 38).[62]

Oxidation Reactions.

The use of *t*-BuOK to convert organic substrates to carbanionic species which react with molecular oxygen via a radical process has been reviewed.[1] Ketones and esters are the most common substrates for these reactions. Oxidations of unsymmetrical ketones occur via the more thermodynamically stable potassium enolates; tetrasubstituted enolates yield stable hydroperoxides, while hydroperoxides derived from trisubstituted enolates are further oxidized to α-diketones or their enol forms.[9a]

Rearrangement Reactions.

Benzil is converted into the ester of benzylic acid in high yield upon treatment with *t*-BuOK in *t*-BuOH/PhH (eq 39).[63] Lower yields are obtained if the individual solvents alone are used or if the base is replaced by MeONa or EtONa.

Monotosylates of *cis*-1,2-diols, such as that derived from α-pinene, undergo pinacol-type rearrangements upon treatment with *t*-BuOK (eq 40).[64] The *trans* isomer is converted to the epoxide under the same conditions (eq 41).[64] 4-Benzoyloxycyclohexanone undergoes a mechanistically interesting rearrangement to benzoylcyclopropanepropionic acid when treated with *t*-BuOK/*t*-BuOH (eq 42).[65]

(40)

(41)

(42)

The Ramberg-Bäcklund rearrangement of α-halo sulfones is frequently carried out with *t*-BuOK.[66] This reaction provides a useful route to deuterium-labeled alkenes (eq 43).[67] *t*-BuOK is presumably the active base in a modification which involves the direct conversion of a sulfone into an alkene with KOH and a mixture of *t*-BuOH/CCl_4.[68] The base converts the sulfone to the α-sulfonyl carbanion, which undergoes chlorination with CCl_4 by a single-electron transfer process. Proton abstraction from the α´-position of the α-chloro ketone by the base yields a thiirane 1,1-dioxide which loses SO_2 to yield the alkene. *t*-BuOK is frequently used directly in this modified procedure (eq 44).[69] Cyclic enediynes are available from the corresponding α-chloro sulfones using *t*-BuOK to effect the Ramberg-Bäcklund rearrangement.[70]

(43)

(44)

Bromomethylenecyclobutanes undergo ring enlargement reactions to 1-bromocyclopentenes when heated in the presence of solid *t*-BuOK (eq 45).[71]

(45)

Reduction Reactions.

A modification of the Wolff-Kishner reduction, which is particularly useful for the reduction of α,β-unsaturated ketones, involves the reaction of carbonyl hydrazones and semicarbazones with *t*-BuOK in PhMe at reflux.[72] The reduction of (±)-3-oxo-α-cadinol to (±)-α-cadinol and its isomer (eq 46) provides an example of this method.[73]

Related Reagents.

Potassium *t*-Butoxide-Benzophenone

***t*-BuOK-Ph_2CO**

(*t*-BuOK)

[865-47-4] · C_4H_9KO · Potassium *t*-Butoxide-Benzophenone · (MW 112.23) (Ph_2CO)

[119-61-9] · $C_{13}H_{10}O$ · Potassium *t*-Butoxide-Benzophenone · (MW 182.23)

(Oppenauer-type oxidations of amino alcohols[1])

Physical Data: Ph_2CO: mp 49-51 °C; bp 158 °C/10 mmHg. For *t*-BuOK, see ***Potassium t-Butoxide***.

Solubility: Ph_2CO: nonpolar organic solvents; insol H_2O.

Form Supplied in: Ph_2CO: white crystalline solid; widely available commercially.

Preparative Methods: in situ, usually in a ca. 1:3 molar ratio of the base to the ketone.

Purification: commercially available benzophenone is normally of sufficient purity to be used directly; if further purification is needed, it should be recrystallized from a nonpolar solvent such as cyclohexane and sublimed.[2]

Handling, Storage, and Precautions: Ph_2CO: irritant; avoid contact with the eyes, skin, and clothing; use in a fume hood.

Oppenauer-Woodward Oxidation.

The Oppenauer oxidation of alcohols is usually carried out with ***Aluminum Isopropoxide*** and a ketone.[3] However, since the aluminum alkoxide complexes with amino groups, this procedure is not useful for oxidizing amino alcohols to amino aldehydes or ketones. This difficulty has been overcome by the use of a procedure often called the Oppenauer-Woodward oxidation, which employs *t*-BuOK as the base to generate the alkoxide anion of the alcohol and Ph_2CO as the hydride acceptor.[1] The hydroxy groups of alkaloids are oxidized by the reagent; for example, quinine is oxidized to quininone (eq 1)[1a] and various morphine derivatives are oxidized to the corresponding ketones in good to excellent yields.[1b,c]

(1)

Oppenauer-Woodward oxidations are normally conducted in refluxing benzene. If the more reactive hydride acceptor fluorenone is substituted for Ph_2CO, oxidations can be accomplished at rt,[4] although extended reaction times may be required.[4b] The oxidation of a 4-hydroxypiperidine derivative to the corresponding 4-ketopiperidine, as shown in eq 2, provides an example of this modification.[4c] *t*-BuOK/fluorenone is also useful for the oxidation of nonnitrogenous alcohols.[4a,5] For example, the less-hindered hydroxy group of a proanthocyanidine derivative is preferentially oxidized by the reagent (eq 3).[5]

(2)

(3)

The allylic anion produced upon reaction of the $Cr(CO)_3$ complex of *p*-allylanisole with *t*-BuOK in THF undergoes addition followed by in situ oxidation when treated with excess PhCHO (eq 4).[6] Benzaldehyde and other aldehydes have been used as hydride acceptors in a modification of the Oppenauer oxidation which utilizes magnesium alkoxides as hydride donors.[7]

(4)

Tandem Oppenauer-Woodward oxidations-aldol condensations can be performed with appropriate substrates. Eqs 5 and 6 provide examples of the use of these reactions in connection with the total synthesis of lycopodine[8] and elaeocarpine[9] alkaloids, respectively.

Potassium *t*-Butoxide-*t*-Butyl Alcohol Complex

***t*-BuOK/*t*-BuOH**

[135329-82-7] · $C_8H_{19}KO_2$ · Potassium *t*-Butoxide-*t*-Butyl Alcohol Complex · (MW 186.37)

(see ***Potassium t-Butoxide***)

Physical Data: white, hygroscopic powder.

Preparative Methods: by removal of the solvent from a solution of *t*-BuOK in *t*-BuOH at 50 °C/1 mmHg.[1]

Wittig Reactions.

When ***Methylenetriphenylphosphorane*** is prepared by treating the corresponding phosphonium salt with an organolithium compound in an aprotic solvent, the betaine-lithium ion pairs produced upon reaction with aldehydes and ketones undergo decomposition to alkenes extremely slowly.[2] The addition of at least 1.1 equiv of the *t*-BuOK/*t*-BuOH complex markedly accelerates the betaine decomposition rate and improves the yields of the products. The solvent-free base is less effective than the complex in these reactions.[2] The role of the additive is probably to exchange the lithium cation for the potassium cation, which allows more of the free betaine to be present in equilibrium with the ion pair.[2] The *t*-BuOH proton donor may play an important role as well. Wittig reactions involving methylenetriphenylphosphorane can be run more efficiently by treating the phosphonium salt directly with *t*-BuOK in *t*-BuOH or aprotic solvents, e.g. ether, prior to addition of the carbonyl component.[3] The proton donor solvent is particularly effective.

Alkene Isomerization Reactions.

Dialkyl 2-propynylamines are efficiently isomerized into the corresponding dialkylamino allenes using the *t*-BuOK/*t*-BuOH complex in HMPA (eq 1).[4] The use of *t*-BuOK/DMSO as the base-solvent combination leads to the formation of substantially more of the isomeric 1-dialkylamino alkyne. Nitrogen-substituted allenes are also available from the corresponding 2-propynes by reaction with *t*-BuOK in THF followed by addition of an equivalent amount of *t*-BuOH.[5]

t-BuOK/*t*-BuOH, HMPA, >85%	96:4
t-BuOK, DMSO	80:20

Intramolecular Acyl Transfer Reactions.

The *t*-BuOK/*t*-BuOH complex is a useful base for the intramolecular transfer of aliphatic acyl groups in the Baker-Venkataraman reaction for the synthesis of β-diketones (eq 2).[6] Variable yields of the β-diketone are obtained when 5-(allyloxy)-2-hydroxyacetophenone is converted to its dianion with ***Lithium Diisopropylamide*** (2 equiv) at 0 °C or -78 °C and reacted with crotonoyl chloride.[6] The X-ray crystal structure of the *t*-BuOK/*t*-BuOH complex has recently been determined.[7]

Related Reagents.

Potassium *t*-Butoxide-18-Crown-6

(*t*-BuOK)

[865-47-4] · C_4H_9KO · Potassium *t*-Butoxide-18-Crown-6 · (MW 112.23) (18-crown-6)

[17455-13-9] · $C_{12}H_{24}O_6$ · Potassium *t*-Butoxide-18-Crown-6 · (MW 264.36)

(basic and especially nucleophilic crown ether complex of *t*-BuOK)

Preparative Method: prepared in situ by mixing the base and the crown ether in an appropriate solvent.

Handling, Storage, and Precautions: see ***18-Crown-6*** and ***Potassium t-Butoxide***.

General Discussion.

The ability of 18-crown-6 to complex potassium cations is well known.[1] When the crown ether is added to solutions of *t*-BuOK in nonpolar, aprotic solvents, where it exists primarily in the form of aggregated ion pairs,[2] the equilibrium is shifted in the direction of ligand-separated ion pairs and dissociated *t*-butoxide anions.[3] Thus in the presence of the crown ether, the basicity and especially the nucleophilicity of the *t*-butoxide anion are enhanced. Dipolar aprotic solvents such as DMSO, which strongly solvate potassium cations, also produce relatively high concentrations of *t*-butoxide anions.[2] However, in such media these anions exhibit high basicity vis-à-vis nucleophilicity because solvent-assisted deprotonation reactions are favorable.[4] 18-Crown-6 is an expensive reagent, but it is useful in catalytic as well as stoichiometric amounts to activate *t*-BuOK. As already noted, the combination of this additive and a nonpolar solvent provides a relatively favorable medium for the *t*-butoxide ion to behave as a nucleophile.[2] If an increase in the basicity of *t*-BuOK is all that is required, there still may be an advantage in using 18-crown-6 instead of DMSO, the most popular activator of the base (see ***Potassium t-Butoxide-Dimethyl Sulfoxide***), for certain substrates. The recovery of relatively water-soluble reaction products from DMSO solutions is

difficult, while the crown ether can usually be removed easily with silica gel. Also, DMSO solutions contain significant concentrations of $DMSO^{-}K^{+}$ which may cause unwanted side reactions.[2]

18-Crown-6 catalyzes the conversion of phosphonium salts to unstabilized phosphoranes with potassium *t*-butoxide in nonpolar solvents.[5] The nature of the solvent has a remarkable effect on the stereochemistry of the subsequent Wittig reactions with aldehydes. The use of THF favors the production of *cis*-alkenes, while CH_2Cl_2 favors the formation of *trans*-isomers. When stabilized ylides are employed, *trans*-alkenes are favored in both solvents. Methylenations of 2-(dimethylaminomethyl)cycloalkanones occur in high yield using this procedure (eq 1).[5c]

(1)

Dihalotoluenes yield free halophenyl carbenes when treated with *t*-BuOK in benzene in the presence of 18-crown-6, but halophenyl carbenoids are produced in the absence of the crown ether.[6] Primary and other alkyl halides are readily converted into alkenes with *t*-BuOK in petroleum ether solvents with a catalytic amount of 18-crown-6.[7] This procedure is particularly useful for primary halides (eq 2), which yield alkyl *t*-butyl ethers under the usual conditions.[7] Alkynes are produced in excellent yields from 1,1- and 1,2-dihalides (eq 3) under similar conditions.[8]

(2)

(3)

Benzyl *t*-butyl ether is obtained in good yield upon treatment of ***Benzyl Chloride*** with *t*-BuOK in the presence of 5-10 mol % 18-crown-6 (eq 4).[3] The enhanced nucleophilicity of the *t*-butoxide ion in the presence of 18-crown-6 is evident, because in its absence the reaction is extremely slow. If *t*-BuOK is used in dipolar aprotic solvents (e.g. DMSO), stilbene, which is derived from initial deprotonation of benzyl chloride, is the major reaction product.

18-Crown-6 improves yields in the *t*-BuOK-catalyzed oxidations of nitriles to carboxylic acids with loss of the cyano group (eq 5).[9] *N*-Alkylations of aromatic nitrogen heterocycles are accomplished in high yields using crown ether-activated *t*-BuOK in ether or benzene (eq 6).[10]

Alkynyloxiranes undergo isomerization to furan derivatives when treated with *t*-BuOK in the presence of 18-crown-6 (eq 7).[11] *t*-BuOK complexes of C_2-symmetric chiral derivatives of 18-crown-6 are efficient catalysts for the asymmetric Michael addition of phenylacetic acid esters to ***Methyl Acrylate***.[12]

Potassium *t*-Butoxide-Dimethyl Sulfoxide[1]

***t*-BuOK/Me_2SO**

(*t*-BuOK)

[865-47-4] · C_4H_9KO · Potassium *t*-Butoxide-Dimethyl Sulfoxide · (MW 112.23) (DMSO)

[67-68-5] · C_2H_6OS · Potassium *t*-Butoxide-Dimethyl Sulfoxide · (MW 78.15)

(highly basic reagent; useful for β-elimination and alkene isomerization reactions[1])

Preparative Methods: prepared in situ from anhydrous *t*-BuOK and anhydrous DMSO.[2a] Anhydrous DMSO is prepared by distillation from ***Calcium Hydride*** or ***Sodium Hydride*** under reduced pressure at 60 °C.

Handling, Storage, and Precautions: see ***Potassium t-Butoxide*** and ***Dimethyl Sulfoxide***. Store over 4 Å molecular sieves.[2b] Use in a fume hood.

Introduction.

Solutions of *t*-BuOK in DMSO are highly basic because the solvent strongly complexes with potassium cations, producing activated ligand-separated and dissociated *t*-butoxide anions in a medium of high dielectric constant.[1,2a,3] This base/solvent system is capable of deprotonating weakly acidic carbon and other acids.[2a,3] It is widely used to effect β-elimination reactions and isomerizations of unsaturated systems.[1,2a,3] $DMSO^-K^+$ is present in low concentrations in *t*-BuOK/DMSO solutions.[4]

β-Elimination Reactions.

A change in solvent from *t*-BuOH to DMSO affects the regiochemistry and stereochemistry of β-eliminations of alkyl halides with *t*-BuOK. For example, for 2-iodobutane both the 2-butene:1-butene and the *trans*:*cis*-2-butene ratios are increased (eq 1).[6] This is because the base is much more hindered in *t*-BuOH, where it is highly aggregated, than in DMSO, where the equilibrium is shifted toward less bulky free *t*-butoxide anions.[1,5,6] Chlorocyclodecane is dehydrochlorinated to *cis*-cyclodecene in good yield with *t*-BuOK/DMSO.[7a] Interestingly, if the elimination is effected with lithium dicyclohexylamide in Et_2O-hexane, the *trans*-isomer is produced. It was suggested that the dissociated *t*-butoxide anion should favor *anti* elimination, while the associated amide base should favor *syn* elimination.[1] However, it was later shown that isomerization of the thermodynamically less stable *trans*-isomer to the more stable *cis*-isomer accounts for the formation of the latter with *t*-BuOK/DMSO.[7b] For hindered acyclic substrates the reagent favors the usual *anti*-coplanar β-elimination mechanism, whereas *syn* elimination is the major pathway

when solutions of the base in THF or *t*-BuOH are employed (eq 2).[3] Presumably, the aggregated ion pairs of the base in the latter solvents assist in the removal of the leaving group and the β-proton in a *syn* alignment.[5,8] *Anti* elimination also results when ***18-Crown-6*** is added to THF solutions of *t*-BuOK because dissociated *t*-butoxide anions are produced. The strained alkene 3,3-dimethylcyclopropene is obtained in good yield from 1-halo-2,2-dimethylcyclopropanes with the reagent;[9] the presence of *t*-BuOH reduces the yield considerably.

(1)

Base/solvent			*trans*/*cis* 2-butene ratio
t-BuOK/DMSO	~21%	~79%	2.99
t-BuOK/*t*-BuOH	34%	66%	2.17

(2)

Solvent/temp		
DMSO, 20 °C	93	7
THF, 60 °C	8	92
THF + 18-crown-6, 60 °C	87	13

β-Phenylthio chlorides, tosylates, and mesylates undergo β-elimination to vinyl sulfides in high yield upon treatment with *t*-BuOK/DMSO (eq 3).[10] This type of reaction is an important step in a synthetically useful 1,2-carbonyl transposition sequence.[10]

(3)

Primary tosylates are more prone than bromides to form *t*-butyl ethers by S_N2 displacement by the *t*-butoxide anion in DMSO.[11] Sulfonate esters of flexible cyclic and secondary acyclic alcohols give predominately alkenes in the presence of *t*-BuOK/DMSO.[12] With sulfonate esters of 3-hydroxy steroids, there is competition between β-elimination and attack of the *t*-butoxide ion on sulfur to form alcohols;[13] mesylates are more prone to this reaction than tosylates. Sulfonate esters of 3α-acetoxy-12α-hydroxycholanate undergo mainly β-elimination with *t*-BuOK/DMSO (eq 4).[14] In this case, substitution of various other aprotic solvents for DMSO and $DMSO^-Na^+$ for *t*-BuOK was not as effective. Treatment of both the mesylate and the tosylate of cholesterol with *t*-BuOK/DMSO gives the conjugated diene, 3,5-cholestadiene, in high yield.[15]

(4)

R = Ts, ~74%; Ms, ~55%

1,2-Dibromo-[16a] and 2,2-dichloro-3,3-dimethylbutane derivatives[16b] undergo double dehydrohalogenation with *t*-BuOK/DMSO to yield *t*-butylacetylene (eq 5). The reagent converts eight- and nine-membered ring 2-bromo-3-methoxy *trans*-cycloalkenes into the corresponding methoxy cycloalkynes via *anti* elimination in reasonably good yields (eq 6).[17] 1-Chloro-4-methylcyclohexene is converted largely into the corresponding 1-*t*-butyl ether derivative in the presence of the base (eq 7).[18] An allene, 5-methyl-1,2-cyclohexadiene, is probably an intermediate in the reaction.

The related allene derived from 1-bromocyclohexene has been trapped with 1,3-diphenylbenzo[*c*]furan under similar conditions.[19] *t*-BuOK/DMSO reacts with bromobenzene to give *t*-butyl phenyl ether in low yield, presumably via the intermediacy of benzyne.[20]

(5)

(6)

(7)

β-Elimination with Double Bond Isomerization.

t-BuOK in DMSO is sufficiently basic to isomerize less thermodynamically stable multiple bond systems to more

stable isomeric compounds (see below). Therefore, it is not surprising that β-eliminations with this reagent are frequently accompanied by isomerizations of initially formed products. *gem*-Dihalocyclopropane derivatives are particularly prone to these reactions (eqs 8 and 9);[21] such reactions may also occur with *t*-BuOK in other solvents.[21c] Certain *gem*-dichlorocyclopropanes yield enynes by processes involving cleavage of the three-membered ring upon reaction with *t*-BuOK/DMSO.[21d,e] The base converts 7,7-dichlorobicyclo[4.1.0]heptane to a complex mixture of products containing mainly ethylbenzene.[22] The extra carbon atom apparently comes from the solvent, DMSO. An example of an isomerization of an initially formed diene to a more stable isomer is found in the reaction of the tosylate of the terpene alcohol nopol with excess *t*-BuOK/DMSO (eq 10).[23]

(8)

(9)

(10)

Isomerizations of Unsaturated Systems.

t-BuOK/DMSO is a sufficiently powerful base to produce carbanions in a low equilibrium concentration by the deprotonation of sp^3-hybridized carbon atoms adjacent to multiple C-C bonds.[1] Thus the base can effect isomerizations of less thermodynamically stable unsaturated systems to more stable isomers. The rearrangement of terminal alkenes into internal isomers,[2a,3] alkylcyclopropenes into alkylidenecyclopropanes (eq 11),[24] and a variety of allylic compounds into the corresponding vinylic compounds are representative examples of these reactions. It is interesting that this base converts allyl ethers to *cis*-enol ethers stereospecifically and in high yields (eq 12).[25]

(11)

R = H, 100%
R = Me, 85%

(12)

R = Ph, 99%
R = , 85-90%

The base converts steroidal 1,4-dien-3-ones into 1,3,5-trienolates which yield 1,5-dien-3-ones upon addition of water (eq 13).[26] This reaction does not occur with *t*-BuOK/*t*-BuOH. The *t*-BuOK/DMSO reagent isomerizes cyclic 1,4- (eq 14)[27] and 1,5-dienes (eq 15)[28] into the corresponding conjugated dienes.

(13)

(14)

(15)

Acyclic enynes and cumulenes are converted into conjugated trienes with a catalytic amount of *t*-BuOK in DMSO.[29] The conversion of a cyclic allene into a cyclic alkyne (eq 16) occurs with this base, while ***Potassium t-Butoxide-t-Butyl Alcohol Complex*** and other bases are ineffective.[30]

(16)

Other Reactions.

In the reaction shown in eq 17, *t*-BuOK/DMSO effects the conversion of a γ-bromophosphonium salt into a cyclopropylidenephosphorane which reacts with cyclopropanecarbaldehyde to form cyclopropylmethylenecyclopropane.[31] This product is converted into dicyclopropylidenemethane in two steps.

(17)

Oxiranes are obtained by treating β-hydroxy alkylselenonium or β-hydroxy alkylsulfonium salts with *t*-BuOK/DMSO.[32] Although the stereochemistry of the reactant is uncertain, only the *cis*-oxirane is obtained in the reaction shown in eq 18.[32b] An interesting example of oxirane formation involving a fragmentation of a β,δ´-dihalo ether is shown in eq 19.[33]

(18)

(19)

Upon reaction with *t*-BuOK/DMSO, medium-ring β-keto esters containing 4-oxopentyl side chains undergo three-carbon ring expansion reactions via an aldol-retroaldol process (eq 20).[34] Similar reactions of related cyclic ketones containing electron-withdrawing α-substituents occur in *t*-BuOK/THF.[35]

(20)

An interesting modification of the Wolff-Kishner reduction involves the slow addition of a preformed hydrazone to *t*-BuOK/DMSO at rt.[36] However, other modifications of this reduction reaction are more widely used in organic synthesis.[37] *t*-BuOK/DMSO effects O-alkyl cleavage of sterically hindered methyl esters in high yields (eq 21).[38]

(21)

Protiodesilylations of α- (eq 22) and certain β-hydroxysilanes with *t*-BuOK in wet DMSO occur with retention of configuration.[39] Similar conditions allow protiodesilylations of cyclic saturated (eq 23)[40] and unsaturated siloxanes.[41]

Potassium *t*-Butoxide-Hexamethylphosphoric Triamide

t-BuOK/$(Me_2N)_3PO$

(*t*-BuOK)

[865-47-4] · C_4H_9KO · Potassium *t*-Butoxide-Hexamethylphosphoric Triamide · (MW 112.23) (HMPA)

[680-31-9] · $C_6H_{18}N_3OP$ · Potassium *t*-Butoxide-Hexamethylphosphoric Triamide · (MW 179.24)

(useful base for deprotonating weakly acidic substrates[2])

Preparative Method: prepared in situ from anhydrous *t*-BuOK and anhydrous HMPA. Anhydrous HMPA is obtained by distillation from ***Sodium*** metal or ***Calcium Hydride*** under reduced pressure at 60 °C.[1]

Handling, Storage, and Precautions: see ***Potassium t-Butoxide*** and ***Hexamethylphosphoric Triamide***. HMPA is a cancer-suspect agent which should be handled with extreme care; do not breathe the vapor and avoid contact of the solid or liquid with eyes, skin, or clothing. Store over 4 Å molecular sieves. Use in a fume hood.

Introduction.

HMPA is capable of strongly solvating potassium cations and producing solutions of *t*-BuOK which contain substantial amounts of highly basic ligand-separated ion pairs and dissociated *t*-butoxide anions.[2] Deprotonation reactions are favored by the highly polar medium. Unlike ***Dimethyl Sulfoxide***, HMPA is not deprotonated by the *t*-butoxide anion.

Michael Addition-Intramolecular Alkylation Reactions.

t-BuOK is an effective additive for accelerating the rates of cycloalkylation of lithium enolates produced in the Michael addition of lithium enolates of esters to ε-iodo-α,β-unsaturated esters.[3] Three-, five-, six-, and seven-membered ring carbocyclic diesters are available by these reactions. When a six-membered ring is produced in the cycloalkylation reaction (eq 1), the stereochemistry of the cyclic diester products is strongly dependent upon the nature of the solvent. If THF alone is employed, the *syn*-diester is the major product, but if a 4:1 mixture of THF-HMPA is used, the *anti*-diester is highly favored.[3] The observation of such a high degree of stereochemical control in the production of extracyclic stereocenters is remarkable.

Autooxidation Reactions.

HMPA is more effective than sulfolane, ***Dimethyl Sulfone***, or DMSO as an activator for *t*-BuOK in the base-promoted autooxidation of alkylbenzene derivatives to aromatic acids.[4] The medium is also useful for the autooxidation of acetophenone to benzoic acid,[5] and for oxidation of a variety of other benzene derivatives.[6]

Other Reactions.

The expansion of the 12-membered ring of the epoxy sulfone shown in eq 2 to a 15-membered ring enone occurs in a reasonable yield with *t*-BuOK in *t*-BuOH-HMPA.[7] This reaction involves formation of an α-sulfonyl carbanion, intramolecular nucleophilic opening of the epoxide ring by this species, and Grob fragmentation of the γ-sulfonyl alkoxide intermediate. *t*-BuOK/HMPA efficiently isomerizes 2-alkynyl dialkylamines to dialkylamino allenes and 2-alkynyl ethers to allenic ethers.[8] A catalytic amount of *t*-BuOK in HMPA has been used to generate 1,1-difluoroallyl anions from difluoroallyl(dimethylphenyl)silanes by attack of the *t*-butoxide anion on silicon.[9] These anions undergo addition to carbonyl compounds (eq 3).[9]

Potassium Carbonate[1]

K_2CO_3

[584-08-7] · CK_2O_3 · Potassium Carbonate · (MW 138.21)

(inorganic base used in the alkylation of phenols[2] and 1,3-dicarbonyl compounds;[7] generation of sulfur[12] and phosphorus ylides;[13] also used to dry organic solvents[16])

Physical Data: mp 891 °C; *d* 2.43 g cm^{-3}; hygroscopic until 16.4% water is absorbed; pH of saturated aqueous solution is 11.6.

Solubility: 1.12 g mL^{-1} in water at 20 °C; practically insol alcohol.

Form Supplied in: white solid; widely available. Use in form supplied for best results.

Purification: crystallize from water 70 °C; dry over H_2SO_4.

Handling, Storage, and Precautions: keep in a tightly sealed container; avoid inhalation.

Alkylation of Phenols.

The mildly basic nature of this reagent makes it ideal for the selective deprotonation of organic acids. This property makes K_2CO_3 a useful reagent for the alkylation of phenols. The procedure[2] for phenol alkylation involves dissolving the phenol and alkylating agent in acetone with excess K_2CO_3 added as an insoluble component (eq 1). The reaction is run at reflux. Workup consists of removal of solvent and addition of water. The product is isolated by either extraction or filtration. Popular alternative solvents are DMF[3] and MeCN.[4] If the aqueous solution needs to be neutralized, it is convenient to remove excess K_2CO_3 via filtration before solvent removal and subsequent water addition.

Sulfides can also be alkylated using K_2CO_3 in DMF, as demonstrated in the shell closure reaction used to capture guests within linked anisyl moieties.[5]

Hydrolysis Reactions.

Ester hydrolysis using K_2CO_3 in MeOH was found to give clean conversion to the allylic alcohol (eq 2).[6]

When amides that contain α,β-amino alcohols undergo diazotization followed by treatment with aqueous K_2CO_3,[7] they are cleanly converted to the epoxide (eq 3), while the β-amino ester gives the corresponding alcohol (eq 4).

Reactions of 1,3-Dicarbonyl Compounds.

The enolate of β-keto esters can be alkylated in a procedure developed by Claisen[8] that is analogous to the alkylation of phenols. The β-keto ester and alkylating agent are combined with K_2CO_3 in acetone and the reaction heated to reflux. The reaction is useful for the *C*-alkylation of substrates. In the case of ethyl 2-oxocyclopentanecarboxylate[9] the reaction gave good yields and high selectivity for *C*-alkylation with unobstructed alkylating agents (eq 5).

RX	*C*-alkylation (%)	*O*-alkylation (%)
MeI	100	<1
$(MeO)_2SO_2$	100	<1
$H_2C{=}CHCH_2Br$	91	<1
$BrCH_2CO_2Et$	92	<1
i-PrI	78	18
$PhCH_2OCH_2Cl$	49	21

The reagent also shows good selectivity in the monoalkylation of β-dicarbonyl compounds. The reaction of 2-chloro-2-methylproponal with malonic esters in THF or ether gives good yield of the monoalkylated malonic ester (eq 6).[10]

Aldehydes can be reacted with 1,3-dicarbonyl compounds in THF to give α,β-unsaturated carbonyl compounds with good (*Z*/*E*) selectivity (eq 7).[11]

The reagent is also useful for the generation of intramolecular Michael addition products with excellent stereoselectivity (eq 8).[12]

(8)

Generation of Phosphorus Ylides.

Wittig reactions can be done either under heterogeneous (water-1,4-dioxane) conditions[13] or more conveniently using 18-crown-6 as a phase-transfer catalyst (see ***Potassium Carbonate-18-Crown-6***).[14] The phase-transfer conditions give alkenes in good yields with a preference for the (*E*)-isomer (eq 9). The procedure involves the combination of alkylphosphonium salt, K_2CO_3, aldehyde, and ***18-Crown-6*** in either CH_2Cl_2 or THF. The solvent is removed, product extracted with petroleum ether, and filtered through silica gel.

$$R^1CHO + Ph_3\overset{+}{P}CH_2R^2\ X^- \xrightarrow[CH_2Cl_2 \text{ or THF}]{K_2CO_3,\ 18\text{-crown-}6} R^1CH{=}CHR^2 \quad (9)$$

Ph	Ph	70
Ph	Me	78
Et	Ph	75

Generation of Sulfur Ylides.

β-Ketosulfonium salts react with K_2CO_3 to generate the corresponding ylide. α-Methylthio ketones are reacted with allylic halides to afford sulfonium salts that are reacted with aqueous K_2CO_3 to generate a sulfur ylide[15] that can undergo [2,3]-sigmatropic rearrangement (eq 10).

Potassium Carbonate-18-Crown-6

(K_2CO_3)

[584-08-7] · CK_2O_3 · Potassium Carbonate-18-Crown-6 · (MW 138.21) (18-crown-6)

[17455-13-9] · $C_{12}H_{24}O_6$ · Potassium Carbonate-18-Crown-6 · (MW 264.36)

(basic reagent combination that operates efficiently under catalytic two-phase conditions, yet is sufficiently gentle not to hydrolyze or otherwise destroy sensitive products;[1,2] capable of promoting *trans*-alkene formation during Wittig condensations;[3] heightens selectivity and reactivity of carbanions in nonpolar solvents[4])

Physical Data: prepared in situ.

Solubility: while 18-crown-6 is soluble in aprotic solvents, potassium carbonate exhibits very limited solubility. As a consequence, it is believed that proton abstraction occurs on the surface of the solid carbonate.[1] For this reason, it is particularly important to recognize that K_2CO_3 is a finely powdered material that exhibits no tendency to aggregate and form lumps.

Handling, Storage, and Precautions: this reagent combination eliminates the need to prepare anhydrous solvents and is convenient because the prior preparation of carbanions is unnecessary. Furthermore, hazardous and expensive ingredients are not involved.

Efficiency as a Base.

Phase-transfer catalysis of reactions by aqueous hydroxide in an inert organic medium is often disadvantaged by competing saponification if the starting materials are prone to hydrolysis. To regain efficiency, it is advantageous to turn instead to a liquid-solid two-phase system constituted of ***Potassium Carbonate*** and an aprotic solvent, such as

CH_2Cl_2 or benzene, to which ***18-Crown-6*** is added to facilitate transport of the conjugate base into the organic phase. Under these conditions, ***Diethyl Malonate*** readily undergoes highly selective monoalkylation (eq 1).[1] Other notably sensitive esters respond well to this rather mild base (eqs 2 and 3),[1] despite the fact that somewhat higher temperatures are sometimes required.

(1)

(2)

(3)

In addition to the Darzens reaction, it is also possible to prepare dibromocarbene, ethers by the Williamson synthesis, phosphonates by Michaelis-Becker alkylation, and alkenes by the Wittig reaction. In this last process, the conditions are sufficiently mild that solvent effects can be utilized to control product stereochemistry.[3] When nonstabilized ylides are involved, the use of THF leads predominantly to the *cis*-alkenic isomer in a manner akin to salt-free conditions (eq 4). In CH_2Cl_2 solution the product distribution is reversed. If the ylide is stabilized, either solvent leads to the *trans*-alkene.

K_2CO_3, 18-crown-6, THF, Δ, 96%	85:15
K_2CO_3, 18-crown-6, CH_2Cl_2, Δ, 93%	22:78

Dendritic polymers having an average molecular weight in excess of 100 000 have been produced by initiating polycondensation with the title reagent system.[5]

Methylation and Silylation Reactions.

Neat dimethyl carbonate can supplant ***Dimethyl Sulfate*** as methylating agent when reaction is promoted by potassium carbonate and 18-crown-6 (eq 5).[6] The same catalyst system appears ideally suited to the methylation of carboxylic acids and phenols with methyl trichloroacetate (eqs 6 and 7).[7,8] Since the byproducts are $CHCl_3$ and CO_2, product isolation is conveniently realized. Primary and allylic trichloroacetates can be substituted with equal success. An added major advantage of this technology is its lack of dependence on stoichiometric base.

The companion reagent trimethylsilyl trichloroacetate has been developed into a convenient tool for the salt-free silylation of compounds carrying an acidic hydrogen (carboxylic acids, phenols, amides, thiols, terminal alkynes, etc). As before, a catalytic amount of potassium carbonate/18-crown-6 gives rise to CO_2 and $CHCl_3$ in addition to product (eq 8).[9] When aldehydes or ketones are involved, trimethylsilyl trichloromethyl carbinols are formed efficiently (eq 9).

Intramolecular Wadsworth-Emmons Cyclizations.

Attempts to prepare bicyclo[3.3.0]oct-1-en-3-one and derivatives thereof by intramolecular cyclization have been

fraught with complications because of the sensitivity of both the starting material and product to basic conditions. This problem has been resolved by making recourse to potassium carbonate and 18-crown-6 in benzene or toluene at 60 °C (eq 10).[2] The gentle nature of this reagent has proven highly serviceable in a number of related ring closures (eqs 11 and 12),[10,11] including macrocyclizations (eq 13).[12]

(10)

(11)

(12)

(13)

Formation of Carbonate Esters.

Historically, it has not been practical to prepare organic carbonates from inorganic carbonate. However, the advent of solid-liquid phase techniques has opened the door to striking developments in this area. A catalyst other than potassium carbonate is necessary for acceleration and the realization of high-yield conversions. Suitable candidates are ***Tri-n-butylchlorostannane***,[13] hexabutyldistannoxane,[13] hexabutyldistannathiane (eq 14),[13] potassium hydrogen carbonate,[14] and quaternary ammonium salts.[15] Polycarbonates have similarly been produced from α,α´-dibromo-*p*-xylene.[13]

(14)

Cyclic carbonates are likewise readily available via the reaction of oxiranes with ***Carbon Dioxide*** under phase-transfer catalysis of potassium carbonate/18-crown-6 (eq 15).[16] Homopolymerization is not a serious complication as long as

the crown ether is present.

Potassium Chromate

[7789-00-6] · CrK_2O_4 · Potassium Chromate · (MW 194.20)

(reagent for converting primary allylic and benzylic halides to aldehydes)

Physical Data: mp 968.3 °C; *d* 2.732 g cm^{-3}.

Solubility: H_2O (62.9 g/100 mL at 20 °C).

Form Supplied in: yellow crystals.

Preparative Methods: the reagent is prepared in ***Hexamethylphosphoric Triamide*** (HMPA) in the presence of ***Dibenzo-18-crown-6*** or ***Dicyclohexano-18-crown-6***.[1]

Handling, Storage, and Precautions: potassium chromate is a highly toxic cancer suspect agent. All chromium(VI) reagents must be handled with care. The mutagenicity of Cr^{VI} compounds is well documented.[2] HMPA is also a highly toxic cancer suspect agent. This reagent should be handled in a fume hood.

Oxidation of Primary Allylic and Benzylic Halides to Aldehydes.

Potassium chromate in HMPA in the presence of dibenzo-18-crown-6 or dicyclohexano-18-crown-6 at 100 °C converts primary allylic (eq 1) and benzylic (eq 2) halides to aldehydes.[1] The yields are lower with alkyl halides. The yields of all primary halides are improved by use of polymer-supported chromic acid in benzene[3] or ***Bis(tetrabutylammonium) Dichromate*** in $CHCl_3$.[4]

(1)

(2)

Other Applications.

Primary and secondary alcohols are oxidized to aldehydes and ketones, respectively, by potassium chromate and sulfuric acid in a two-phase system (water-$CHCl_3$) in the presence of tetrabutylammonium hydrogen sulfate catalyst.[5] Allylic alcohols and acid-sensitive alcohols are oxidized to carbonyl compounds in good yields.

Related Reagents.

In addition to polymer supported ***Chromic Acid*** in benzene[3,6] and ***Bis(tetrabutylammonium) Dichromate*** in $CHCl_3$,[4] other reagents oxidizing halides to carbonyl compounds include ***Chromium(VI) Oxide*** in aqueous acetic acid, which oxidizes α-chlorohydrindene to α-hydrindanone,[7] and chromic acid in aqueous acetone in the presence of silver chromate, which oxidizes a steroidal vicinal dibromide to an α-bromo ketone in the synthesis of corticoids.[8] In aqueous systems it is possible that the halide is hydrolyzed to an alcohol which is oxidized to the carbonyl compound.

Potassium Cyanide[1]

KCN

[151-50-8] · CKN · Potassium Cyanide · (MW 65.12)

(reagent for the synthesis of nitriles,[2] cyanohydrins,[3] and α-amino nitriles;[4] catalyst for benzoin condensation[5] and transesterification[6])

Physical Data: mp 634 °C; *d* 1.520 g cm^{-3}.

Solubility: sol 2 parts cold water, 1 part boiling water, 2 parts glycerol, 100 parts ethanol, 25 parts methanol. The aq soln is strongly alkaline (pH = 11.0) and rapidly dec.

Form Supplied in: white granular powder or fused pieces; widely available.

Purification: see Perrin[7] for purification and recrystallization procedures.

Handling, Storage, and Precautions: highly toxic; may be fatal if inhaled, swallowed, or absorbed through the skin. Exposure may cause nausea, dizziness, headache, lung irritation, and cyanosis (toxicity data: orl-hmn LDLo 2857 μg kg^{-1}, orl-rat LD_{50} 5 mg kg^{-1}). Air and moisture sensitive; keep in a tightly closed container and store in dry area. Use only in a chemical fume hood. Do not breath the dust or allow it to get in eyes, on skin, or on clothing. In case of fire, water spray must be used with caution since direct contact of KCN with water or steam will cause decomposition, liberating highly toxic HCN gas as well as generating a highly hazardous solution of dissolved cyanide which must be kept out of sewers and watercourses. KCN also forms explosive mixtures, sometimes spontaneously, with chlorates, nitrates, and nitrogen trichloride plus ammonia. Incompatible with acids, strong oxidizing agents, alkaloids, chloral hydrate, iodine, and metallic salts. Thermal decomposition produces toxic fumes of hydrogen cyanide, carbon monoxide, carbon dioxide, and nitrogen oxides.

Nitrile Synthesis.

The transformation of alcohols to nitriles is an important method for the elongation of carbon chains or the synthesis of useful intermediates in organic synthesis.[8] The usual procedure involves activation of alcohols by conversion into halides or sulfonates, followed by displacement with a cyano group. Among the methods for direct one-pot conversion of alcohols to nitriles,[9,10] the most general and convenient is treatment with KCN in the presence of ***Tri-n-butylphosphine***, CCl_4, and ***18-Crown-6*** (eq 1).[10] Displacement of primary, benzylic, or allylic halides with KCN produces nitriles in very good yields; the same reaction proceeds in moderate yield with secondary halides,[8,11] while

it fails completely for tertiary halides, giving elimination under these conditions. The use of KCN in MeCN containing 18-crown-6 produces cyanide anions (naked anions)[12] which are strong nucleophiles and displace halides smoothly and quantitatively (eq 2).[13] Mesylates are converted into nitriles in about 70% yield by reaction with KCN in H_2O/C_6H_6 at 5-6 h reflux with phase-transfer catalysis.[14] 2,3´-*O*-Isopropylidene-5´-*O*-tosylates of nucleosides react with KCN only when the reagent has been complexed with 18-crown-6 (eq 3),[15] while reaction of substituted benzylamines with cyanide ions furnish the corresponding benzonitriles.[16] Ketones are converted into nitriles by way of tosylhydrazones[17a,b] or methoxycarbonyl hydrazones.[17c] Thus the tosylhydrazone derivative of a ketone upon treatment with KCN in MeOH/AcOH is converted into a cyano hydrazide, which is heated at 180 °C for 2 h to give the nitrile (eq 4).[18] Hydrocyanation of conjugated double[19] or isolated double[20] and triple[21] bonds proceed smoothly with KCN. Similarly, KCN in combination with NH_4Cl results in 1,4-addition of HCN to cholestanone derivatives, affording the 5α- and 5β-cyano ketones in 1:1 ratio.[22] The use of organoaluminum cyanides increases the selectivity of the reaction.[19]

(1)

(2)

(3)

(4)

Vinyl bromides are converted into α,β-unsaturated nitriles by reaction with KCN in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** and 18-crown-6. The reaction is highly stereospecific and proceeds in almost quantitative yield (eq 5).[23] Vinyl sulfones on exposure to KCN and ***Dicyclohexano-18-crown-6*** in refluxing *t*-butyl alcohol are smoothly converted to α,β-unsaturated nitriles, providing a particularly useful route for the construction of trisubstituted alkenes.[24]

(5)

Treatment of benzaldoximes with KCN in the presence of a phase-transfer catalyst (18-crown-6 or quaternary ammonium salt) produces a 3:1 mixture of a benzonitrile and benzamide (eq 6),[25] thus providing a general, one-pot conversion of aromatic aldehydes to aryl nitriles. Photochemically induced cyanation of arenes[26] furnishes only moderate to low yields of aryl nitriles, but the use of KCN in conjunction with 18-crown-6 (naked cyanide ion) doubles the yield.[27] Photolysis of arylthallium ditrifluoroacetates in the presence of excess KCN proceeds via in situ formation of the complex ions $[ArTl(CN)_3]^-K^+$ and produces aryl nitriles in good yields.[28] Cyanation of aromatic heterocycles by means of KCN and ***Benzyltriethylammonium Chloride*** followed by reaction with an acyl chloride furnishes the corresponding Reissert products (eq 7)[29] in better yields than the conventional conditions.[30]

(6)

(7)

The classical method for the synthesis of acyl cyanides is the reaction of an acyl halide with heavy metal cyanides at high temperatures.[31] Recent modifications using aryl iodide[32] or a phase-transfer catalyst[33] have led to some improvements. On the contrary, aroyl cyanides are prepared by reaction of aroyl chlorides with KCN in MeCN. The presence of trace amounts of water markedly accelerates the rate and improves the yield (eq 8).[34] However, the use of too much water lowers the yield of the product due to hydrolysis and dimer formation.[34] Aromatic or heteroaromatic acyl cyanides may be prepared at lower reaction temperatures by ultrasonic treatment of the heterogeneous mixture of an aroyl chloride and KCN in MeCN (eq 9).[35] Several phenylacetonitriles are obtained in good yield by reaction of the appropriate benzyl halide with the cyanide form of an anion exchange resin.[36] The direct conversion of aromatic iodides into aroyl nitriles in good yields is accomplished by their carbonylation catalyzed with ***Iodo(phenyl)bis(triphenylphosphine)palladium(II)***[37] and in situ reaction with KCN (eq 10).[38] Cyanoformates are obtained from the corresponding chloroformates by reaction with KCN in the presence of 18-crown-6 as catalyst (eq 11).[39]

(8)

(9)

(10)

(11)

α-Cyanoenamines are obtained either by conversion of amides to α-chloroenamines and subsequent treatment with KCN in MeCN (eq 12),[40] or starting with aldehydes and proceeding via α-chloroaldimines and reaction with KCN in MeOH (eq 13).[41] These compounds are recognized as reactive intermediates since they can easily be converted to the corresponding α-diketones or dihydropyrazine derivatives.[40]

(12)

(13)

Cyanotributylstannane, which is an efficient cyanation agent for acyl chlorides, is obtained in very good yield by treatment of ***Tri-n-butylchlorostannane*** with KCN in MeCN (eq 14).[42] Similarly, ***Cyanotrimethylsilane*** is prepared by treatment of ***Chlorotrimethylsilane*** with H_2SO_4 and KCN (eq 15).[43]

(14)

$$2\ TMSCl + H_2SO_4 \xrightarrow[-2HCl]{} [TMSO]_2SO_2 \xrightarrow[-K_2SO_4,\ 65\text{-}83\%]{2\ KCN} 2\ TMSCN \quad (15)$$

Cyanohydrin Synthesis.

Cyanohydrins are versatile starting materials for the synthesis of several classes of compounds.[44] They are prepared by treatment of aldehydes or ketones with KCN and AcOH in various organic solvents.[45] This is an equilibrium reaction which proceeds smoothly except with sterically hindered ketones or aromatic aldehydes, in which case the benzoin condensation competes. Cyanohydrin synthesis was first applied to carbohydrates by Kiliani[46] in 1885 as the key step of a route (modified later by Fischer[47]) which allows the construction of two epimeric aldoses having one carbon atom more than the parent aldose. More recent studies have confirmed that the ratio of epimers (eq 16) is pH dependent.[48] Thus reaction of D-arabinose with KCN at acidic pH furnishes D-glucononitrile as the predominant epimer, while under alkaline conditions D-mannonitrile is the predominant epimer. Similarly treatment of formaldehyde with KCN gave glyconitrile (eq 17).[49] Cyanohydrin synthesis is important in the construction of steroid sidechains.[50] Thus 17-keto steroids are transformed to corticoids via their 17β-cyanohydrins (eq 18).[51] Treatment of β-hydroxy ketones with KCN/TMSCN in the presence of ***Zinc Iodide*** produces *syn*-β-hydroxy cyanohydrins in high distereomeric excess (eq 19).[52]

(16)

$$CH_2O + KCN + H_2O \xrightarrow[80\%]{} HOCH_2CN + KOH \quad (17)$$

(18)

(19)

Optically active cyanohydrins are obtained using KCN and enzymatic catalysis.[53] Thus treatment of benzaldehyde with oxynitrilase (extracts of ground defatted almonds) in 1N KCN/AcOH buffer (pH 5.4) furnishes exclusively (*R*)-(+)-α-hydroxyphenylacetonitrile (eq 20).[54] The other enantiomer is obtained by kinetic resolution of racemic cyanohydrins either by using a lipoprotein lipase from *Pseudomonas* species[55] or by incubation with *Pichia miso* (IAM 4682), which hydrolyzes selectively the acetate of the (*R*)-enantiomer, leaving the (*S*)-enantiomer intact.[56] Silylated cyanohydrins are obtained in high yields by a one-pot reaction using KCN in combination with TMSCl (eq 21).[57,58] The presence of ZnI_2 enhances the rate of cyanosilylation, while the presence of 18-crown-6 has very little effect on the yield or the rate.[57]

(20)

(21)

α-Amino Nitriles.

The preparation of α-amino nitriles is the key reaction of the Strecker synthesis,[59] which is considered to be the most

convenient experimental protocol for the preparation of α-amino acids[4] and 1,2-diamines[60] on the preparative scale. The classical procedure in which an aldehyde or ketone is treated with KCN, NH_4Cl,[59] is sensitive to the nature of the ketone substitution, involves lengthy reaction times and tedious work-up procedures, and leads to considerable amounts of cyanohydrin byproduct.[61] Modifications using Al_2O_3 and ultrasound in MeCN have improved the yield slightly.[62] On the contrary, stepwise synthesis either by displacement of the hydroxy group of α-amino alcohols with cyanide[63] using KCN, AcOH, or via cyanohydrins[64] by treatment with ammonia or NaN_3 have greatly improved the yields. Recently, however, two simple one-pot procedures have been reported. These produce α-amino nitriles efficiently, in almost quantitative yields, by treatment of carbonyl compounds with KCN and either alkyl- or benzylamines in an aqueous solution of $NaHSO_3$ (eq 22)[65] or benzylamine in methanolic AcOH (eq 23).[66] It is noteworthy that the α-amino nitrile synthesis (Strecker method) with substituted cyclic ketones furnishes preferentially α-amino acids of one geometrical isomer (eq 24),[67] while the opposite isomer is obtained via the spirohydantoin synthesis (Bucherer method) (eq 25).[67] Optically active α-amino nitriles are obtained when a chiral auxiliary is used. Thus reaction of *R*-(-)-2-phenylglycinol with isobutylaldehyde furnishes the two diastereomers in an 84:16 ratio (eq 26).[68]

Benzoin Condensation.

Aromatic[69] or heteroaromatic aldehydes[70] are condensed in a KCN-catalyzed process to form benzoins (α-hydroxy ketones) (eq 27). The reaction mechanism involves the formation of a cyano-stabilized carbanion,[71] facilitated by the use of an aprotic solvent. KCN is a highly specific catalyst, since it performs three functions:[72] (i) acts as a nucleophile, (ii) permits loss of the aldehyde proton with its electron-withdrawing ability, and (iii) at the end, acts as a leaving group. The benzoin-type reaction has been extended to include a catalyzed addition of aldehydes to α,β-unsaturated nitriles.[73] Thus 4-keto nitriles are obtained by addition of aromatic aldehydes to α,β-unsaturated nitriles under KCN catalysis (eq 28). Similarly, benzoin-type condensation of tetraphthalaldehyde bisbisulfite with benzaldehyde under KCN catalysis furnishes the bisbenzoin product (eq 29).[74]

(27)

(28)

(29)

Transesterification.

KCN is a mild and effective catalyst for the transesterification of α,β-unsaturated esters without isomerization of the conjugated double bond. Thus methyl *trans,trans*-farnesoate is readily converted into the ethyl ester with very slight *cis*/*trans* isomerization (eq 30).[75] Similarly, KCN in combination with 18-crown-6 is an effective catalyst for cyanoesterification.[76] On the other hand, treatment of δ-lactones with methanol in the presence of KCN results in lactone ring opening and methyl ester formation (eq 31).[77]

(30)

2-trans:*2-cis* = 94:3

(31)

Ring Formation and Ring Opening.

Reaction of α-chloro ketimines with KCN in MeOH results in nucleophilic addition and subsequent intramolecular nucleophilic substitution, yielding the corresponding α-cyano aziridines (eq 32).[78] Treatment of 2-bromodeoxybenzoin with KCN in the presence of solid adsorbent (silica gel or alumina) gives stereoselectively *cis*-2,3-diphenyl-2-cyanooxirane in good yield (eq 33).[79] Cold aqueous ethanolic KCN converts *N*-methyl-*C*-phenyl nitrone into 1-methyl-4,5-diphenylimidazole via the intermediate cyanoimine (eq 34).[80] *N*-Allyl-*N*-3-butenyl-*N*-Cbz-amine on treatment with thexylborane, followed by cyanidation, affords an azacyclone, which can be transformed into δ-coniceine by catalytic reduction (eq 35).[81] On the other hand, alkaline solutions of KCN in the presence of ***Tetra-n-butylammonium Bromide*** open 1,2-epoxides, yielding β-hydroxy nitriles (eq 36).[82] Similarly activated cyclopropane rings are cleaved by reaction with KCN.[83]

(32)

(33)

(34)

(35)

(36)

Aromatization.

KCN in DMF is an effective reagent for the conversion of 2,4-cyclohexadien-1-ols to benzene derivatives.[84] The same conditions were applied for the aromatization of 2,4-cyclohexadiene-6-imine derivatives (eq 37).[85]

(37)

Reduction.

0.1 N aqueous KCN solutions of aromatic nitro compounds upon UV irradiation undergo deoxygenation to the corresponding nitroso compounds (eq 38).[86]

Potassium Decacarbonylhydridochromate

(M = K)

[61453-56-3] · $C_{10}HCr_2KO_{10}$ · Potassium Decacarbonylhydridochromate · (MW 424.21)
(M = Na)

[12082-96-1] · $C_{10}HCr_2NaO_{10}$ · Sodium Decacarbonylhydridochromate · (MW 408.10)

(selectively hydrogenates α,β-unsaturated carbonyl compounds[1])

Physical Data: red crystals.

Solubility: sol THF.

Form Supplied in: not commercially available.

Preparative Methods: prepared by treating ***Hexacarbonylchromium*** with ***Potassium-Graphite*** or ***Sodium Amalgam***.[1]

Purification: used in situ following the above preparation.

Handling, Storage, and Precautions: air and moisture sensitive.

Hydrogenation of α,β-Unsaturated Carbonyl Compounds.

Hydrogenation of α,β-unsaturated carbonyl compounds is readily effected by treatment with either potassium or sodium decarbonylhydridochromate. Unsaturated ketones, aldehydes, esters, and nitriles are all reduced by this reagent, with no problems arising from reduction of the carbonyl or nitrile functionalities. The reagent is totally specific for reduction of the α,β-unsaturated site. Neither isolated double bonds, nor the γ,δ-unsaturated site in α,β,γ,δ-unsaturated carbonyl compounds are reduced by these reagents. Although these reagents exhibit excellent selectivity, the procedures are operationally more difficult than other reducing agents (eq 1).[2]

Potassium Dichromate

[7778-50-9] · $Cr_2K_2O_7$ · Potassium Dichromate · (MW 294.20)

(reagent for converting alcohols to aldehydes, carboxylic acids, and ketones)

Physical Data: mp 398 °C; *d* 2.676 g cm^{-3}.

Solubility: H_2O (4.9 g/100 mL at 0 °C), DMSO, polyethylene glycol (PEG).

Form Supplied in: red crystals.

Handling, Storage, and Precautions: highly toxic cancer suspect agent. All chromium(VI) reagents must be handled with care. The mutagenicity of Cr^{VI} compounds is well documented.[1] This reagent should be handled in a fume hood.

Oxidation of Alcohols to Carbonyl Compounds.

Primary alcohols in CH_2Cl_2 are oxidized to aldehydes and secondary alcohols are oxidized to ketones in high yields by potassium dichromate in 9 M sulfuric acid in the presence of tetrabutylammonium hydrogen sulfate as a phase-transfer catalyst. The reaction is complete in a few seconds at rt, the yields are lower with water-soluble alcohols, and double bonds may be cleaved.[2] Adogen 464, a mixture of methyltrialkylammonium chlorides, facilitates the solubilization of potassium dichromate in several apolar organic solvents including benzene, CH_2Cl_2, $CHCl_3$, and CCl_4.[3] The solution in benzene is a mild oxiding agent which converts alcohols to carbonyl compounds with some selectivity.

Allylic and benzylic alcohols are oxidized to carbonyl compounds (70-80%) by potassium dichromate in either ***Dimethyl Sulfoxide*** (DMSO) or polyethylene glycol (PEG).[4] Oxidations with potassium dichromate in PEG are comparable to those in crown ethers or ***Hexamethylphosphoric Triamide***.[5] A novel one-pot procedure for the selective oxidation of 5-substituted 2-hydroxy-3-hydroxymethylbenzaldehydes (**1**), via the *N,N´*-ethylene bis(5-substituted 3-hydroxymethylsalicylaldimino)copper complexes (**2**), to 5-substituted 2-hydroxy-1,3-benzenedicarbaldehydes (**3**) by potassium dichromate in DMSO at 100 °C is shown in eq 1.[6] The complexes (**2**), which were prepared (90-95%) from (**1**), ***1,2-Diaminoethane***, and ***Copper(II) Acetate***, are oxidized by ***Potassium***

Permanganate in aqueous ***Pyridine*** to 5-substituted 3-formyl-2-hydroxybenzoic acids (25-40%).[6]

Oxidation of Cyclobutanols and Cyclobutanones to γ-Butyrolactones.

Cyclobutanols and cyclobutanones are oxidized by potassium dichromate in aqueous sulfuric acid to γ-butyrolactones.[7] Cyclobutanones tetrasubstituted at C-2, C-3, or at C-2, C-4 are oxidized to γ-butyrolactones in good yields (eqs 2 and 3).[8] The oxidation is not applicable to larger cyclic ketones.

(3)

Oxidation of α-Nitro Alcohols to α-Nitro Ketones.

α-Nitro alcohols are oxidized to α-nitro ketones by potassium dichromate under phase-transfer conditions (CH_2Cl_2, tetrabutylammonium sulfate, 30% sulfuric acid).[9] Reaction of an aldehyde and a nitroalkane on alumina followed by in situ oxidation allows for a one-pot synthesis (eq 4).

(4)

Oxidation of Primary Alcohols to Acids.

Adding primary alcohols to an excess of potassium dichromate in sulfuric acid affords the corresponding carboxylic acids in good to excellent yields.[10,11]

Other Applications.

Potassium dichromate in benzene in the presence of Adogen 464[3] oxidizes *o*-allylphenols to 3-chromenes (eq 5).[12] *o*-Quinone methides are postulated intermediates. Although *o*-quinones are generally prepared from the corresponding catechol, potassium dichromate in sulfuric acid oxidizes 2-amino-4,5-dimethylphenol to 4,5-dimethyl-*o*-quinone (45%).[13] 4-Aminonaphthol is oxidized to 1,4-naphthoquinone (78-81%) by potassium dichromate in sulfuric acid.[14] Furfural is oxidized to furoic acid (75%) by potassium dichromate in aqueous sulfuric acid.[15] Potassium dichromate in aqueous acetic acid oxidizes *N*,*N*-bis-4-nitrobenzylhydroxylamine to the 4-nitrophenyl nitrone of 4-

nitrobenzaldehyde (98%).[16] Aqueous potassium dichromate selectively oxidizes 2-methylnaphthalene to 2-naphthoic acid without ring degradation or formation of a considerable amount of 2-methylnaphthoquinone.[17,18]

Potassium Diisopropylamide

KN(*i*-Pr)$_2$

[67459-71-6] · $C_6H_{14}KN$ · Potassium Diisopropylamide · (MW 139.31)

(non-nucleophilic strong base)

Alternate Name: KDA.

Solubility: sol THF; insol benzene.

Analysis of Reagent Purity: amide bases can be titrated utilizing 1,6-dihydro-6-butyl-2,2´-bipyridine.[1] This indicator is able to determine the concentration of amide base solutions even in the presence of alkoxide.

Preparative Methods: KDA is prepared in situ immediately prior to use. In the original paper, the reagent was prepared either by the addition of diisopropylamine to a mixture of *n*-butylpotassium-lithium *t*-butoxide in hexane at 0 °C, or by the addition of ***n-Butyllithium*** to a solution of ***Potassium t-Butoxide*** and ***Diisopropylamine*** in THF at -78 °C.[2] It is also common to treat a solution of ***Lithium Diisopropylamide*** with potassium *t*-butoxide.[3] This reagent has been referred to in the literature as KDA, KDA-lithium *t*-butoxide, and LIDAKOR (lithium diorganylamide potassium alcoholate), but an examination of the experimental procedures indicates that all of the authors are, for practical purposes, referring to the same reagent. The exchange of lithium for potassium between organolithium compounds and potassium alkoxides is well established and has been reviewed.[4]

Handling, Storage, and Precautions: moisture sensitive. Use in a fume hood.

Deprotonation Reactions.

KDA is used to effect deprotonations when a strong, non-nucleophilic base is required. It is considerably more reactive than its lithium counterpart and thus it is often used in situations where ***Lithium Diisopropylamide*** (LDA) has been tried and shown to be ineffective. Even in cases where LDA is effective for deprotonation, KDA can be used advantageously to promote anion generation more rapidly and at lower temperatures and to provide a more reactive derivative. KDA is also used when the potassium counterion is important for the outcome of a reaction. For example, it is well recognized that, in contrast to lithium enolates, when potassium enolates are employed, enolate equilibration is normally faster than alkylation, resulting in predominant alkylation of the thermodynamically more stable enolate.[5] The examples outlined below have been selected to illustrate these types of situations in which the unique properties of KDA are exploited.

KDA is used periodically for the generation of enolates. In a recent example, an oxindole system was successfully alkylated with an aziridine via the dianion formed by treatment with 2 equiv of KDA in THF at -78 °C (eq 1).[6] KDA can also be used to generate the dianions of carboxylic acids which then add predominantly 1,2 to α,β-unsaturated carbonyl compounds.[7] The counterion in this reaction has a pronounced effect on the ratio of 1,2- to 1,4-addition. The heightened reactivity of KDA has proved useful when enolate stability is a concern. In one example it was determined that the enolate of a particular pyrrolidinone was unstable above -70 °C, but the compound was successfully deprotonated at -90 °C within 20 min using KDA.[8] KDA has also been used when greater reactivity is required in the generated enolate. Potassium enolates have been shown to undergo a conjugate addition to a vinyl sulfone in cases where the lithium enolate was completely unreactive.[9]

(1)

In one of the first reports of this reagent, it was shown that KDA can be used for the metalation of nitrosamines (eq 2).[10] The reaction takes place more rapidly than with LDA and gives a more reactive intermediate toward alkylation. KDA is also preferred over LDA for the generation of alkyl phosphonate anions prior to mono- or difluorination using *N*-fluorobenzenesulfonimide.[11] In the deprotonation of alkoxyalkyl phenyl sulfones (acyl anion equivalents), KDA must be used if the anion is to be added to a ketone rather than simply alkylated.[12]

(2)

Base	Time (min)	Yield
LDA	210	37%
KDA	30	41%
LDA, HMPA	90	49%
KDA, HMPA	30	60%

KDA has been used for the deprotonation of dimethylhydrazones and oxime ethers.[13] In most cases, deprotonation is complete in THF at -78 °C within 15 min. By contrast, the conditions for successful deprotonations using *n*-butyllithium or LDA are substrate dependent, requiring more time for optimization on a case by case basis. The anion of acetone dimethylhydrazone, generated by treatment with KDA, has been added to a vinyl sulfone and the resulting α-sulfonyl anion further alkylated (eq 3).[14]

(3)

KDA appears to be the base of choice for the generation of selenium-stabilized carbanions. It has been used to effect the deprotonation of 1-(phenylseleno)alkenes and bis(phenylseleno)acetals to give carbanions which react rapidly with a variety of electrophiles (eq 4).[15] Carbonyl compounds which contain an α-hydrogen undergo carbonyl addition rather than enolate formation. By comparison, LDA does not deprotonate these systems at an appreciable rate. In the case of α-aryl bis(phenylseleno)-acetals, the use of LDA results in the recovery of a significant amount of starting material while the use of KDA produces only the desired product (eq 4).[16] KDA will also successfully deprotonate simple benzyl selenides and 1,1,1-tris(trifluoromethylseleno)methane.[16,17] However, when dibenzyl diselenide is treated with KDA, cleavage of the Se-Se bond is the predominant reaction in a rare example of KDA acting as a nucleophile.[18]

(4)

R^1	Base	E	R^2	Yield
Me	LDA	$PhCH_2Br$	H	0%
Me	KDA	$PhCH_2Br$	H	88%
Ph	LDA	PhCHO	OH	26%
Ph	KDA	PhCHO	OH	79%

KDA has been used for the deprotonation of phenylthiotributylstannyltrimethylsilylmethane (eq 5).[19] The potassium anion is formed in 15 min and readily alkylated, whereas the analogous lithium anion is formed in only 80% after 1 h and requires a complexing agent like TMEDA to achieve good yields of alkylated product. Transmetalation of the tributylstannyl group with *n*-butyllithium followed by alkylation provides α-silyl sulfides which can be subsequently converted to ketones. If, instead of an alkyl halide, the potassium anion is reacted with a nonenolizable carbonyl compound, a vinylstannane is obtained via a Peterson reaction (eq 5).[20] No control over alkene geometry was observed in this case. However, cation dependent geometric control has been shown to occur in the Peterson reaction between bistrimethylsilyl acetate enolates and aldehydes (eq 6).[21] Employing the potassium enolate generated with KDA gives significant selectivity for the (*E*)-isomer, suggesting that elimination occurs largely from a nonchelated intermediate.

(5)

(6)

M	R	(*E*):(*Z*)
K	*i*-Pr	>100:1
Li	*i*-Pr	6.5:1
K	Ph	17:1
Li	Ph	9.4:1

KDA has been used for the metalation of imidazoles in cases where *n*-butyllithium and LDA were ineffective.[22] In a synthesis of a dinucleating hexaimidazole ligand, both rings of a bis-imidazole system were metalated and derivatized using KDA.[23]

The high reactivity and kinetic basicity of KDA allow it to deprotonate even simple aromatic methyl groups. For this reason, toluene is not recommended as a solvent for KDA reactions. The deprotonation of dimethylnaphthalene, dimethylanthracene, and dimethyltriptycene systems have been studied using KDA.[24] KDA has also been used for the direct metalation of isoprene.[25]

Elimination Reactions.

KDA has been used for the generation of dienols from homoallylic cyclic ethers (eq 7).[26] KDA promotes the ring-opening elimination without reacting with the resulting diene. By contrast, the use of LDA decreases yields dramatically. In this system, KDA is generated from LDA in the presence of a catalytic amount (10 mol %) of potassium *t*-butoxide. Presumably the product potassium alkoxide that is formed reacts with remaining LDA to generate a constant, low level of KDA which helps to minimize undesirable side reactions.

(7)

KDA has also been used to promote the smooth ring opening of epoxides to generate allylic alcohols in good yields.[27] It is felt that the combination of lithium and potassium bases used in the generation of KDA both play important roles in facilitating this reaction: the electrophilic lithium may help to open the epoxide while the heavier alkali metal potassium confers maximum basicity to its anion to facilitate deprotonation. Where possible, *trans*-alkenols are the preferred or exclusive product, probably arising via a *syn*-periplanar elimination route.

KDA has been cited in an improved procedure for the Wharton transposition.[28] This multistep 1,3-transposition of oxygen proceeds through a base-induced rearrangement of an α,β-epoxyhydrazone. For stable epoxyhydrazones, yields are improved considerably by the use of KDA or potassium *t*-butoxide (eq 8).

Potassium Ferrate

K_2FeO_4

[13718-66-6] · FeK_2O_4 · Potassium Ferrate · (MW 198.05)

(selective oxidant for alcohols and amines[1])

Solubility: sol water; insol typical organic solvents.

Form Supplied in: violet solid; typical impurities present include potassium chloride and iron(III) oxide.

Analysis of Reagent Purity: analysis of K_2FeO_4 by chromite ion has been reported.[2] The ferrate concentration may be determined by measurement of the absorption band at 510 nm.[3]

Preparative Methods: NaOCl (20 g) is added to a solution of NaOH (30 g in 75 mL H_2O) while keeping the solution temperature under 20 °C. Solid NaOH (70 g) is added with stirring, while maintaining the solution temperature at 25-30 °C, the solution cooled to 20 °C and filtered. $Fe(NO_3)_3.9H_2O$ (25 g) is added slowly, and the solution saturated with NaOH while being kept at 30 °C. After filtration, the filtrate of sodium ferrate is placed in a 20 °C bath and treated with saturated aqueous KOH (100 mL), stirred for 5 min, and filtered. The precipitate is washed several times with 10 mL portions of 3 M KOH into 50 mL of chilled saturated KOH solution, and a further 50 mL of chilled saturated KOH solution added to the washings. After stirring for 5 min, the solution is filtered, and the precipitate washed with benzene (10 mL) and several times with ethanol (20 mL). The precipitate is stirred with ethanol (1 L) for 20 min and the ethanol removed by filtration; this process is repeated three times. The precipitate is finally washed with Et_2O under a drying tube, and drying continued in a vacuum desiccator.[4]

Handling, Storage, and Precautions: dry K_2FeO_4 is stable and should be stored in a desiccator. K_2FeO_4 is very unstable in acidic solutions, but decomposes only slowly in basic solutions.

Oxidations.

Potassium ferrate has been reported to be a mild reagent for the oxidation of primary and secondary alcohols to aldehydes and ketones, respectively (eq 1).[1,5,6] In addition, primary and secondary amines are also oxidized to aldehydes and ketones (eq 2). Allylic and benzylic alcohols react much more readily than saturated ones, and

primary alcohols react more readily than secondary ones. Reactions are normally carried out in basic aqueous (or water/*t*-butanol) solution. Yields are normally high with allylic and benzylic alcohols and amines, but much more variable for saturated alcohols. Several functional groups are stable to this reagent, including carbon-carbon double bonds, nitro groups, tertiary alcohols and amines, aldehydes, and ketones. Sulfur compounds (sulfides, sulfoxides) do not tolerate this reagent.

(1)

(2)

A modification employing a two-phase system (benzene/10% aqueous NaOH) and ***Benzyltriethylammonium Chloride*** as a phase-transfer catalyst has been reported to be highly successful for allylic and benzylic substrates (eq 3).[7] A second modification using a mixture of K_2FeO_4 (8 mmol), aluminum oxide (0.8 g), and $CuSO_4.5H_2O$ (0.8 g) for 2 mmol of substrate affords a simple workup and highly selective oxidations (eq 4).[6]

Potassium Ferricyanide[1]

$K_3Fe(CN)_6$

[13746-66-2] · $C_6FeK_3N_6$ · Potassium Ferricyanide · (MW 329.27)

(mild oxidizing agent for functional groups;[1] capable of oxidative coupling of phenols;[2] can function as reoxidant in osmium-catalyzed asymmetric dihydroxylation of alkenes[3])

Alternate Name: potassium hexacyanoferrate(III).

Physical Data: d 1.890 g cm^{-3}.

Solubility: sol 33 g/100 ml in cold water, 77.5 g/100 ml in hot water; insol alcohol.

Form Supplied in: orange crystalline solid; widely available.

Handling, Storage, and Precautions: stable in air; light sensitive. Aqueous solutions decompose slowly on standing. Contact with strong acid liberates highly toxic gas. Avoid contact with skin and eyes. Avoid breathing dust. Use in a fume hood.

Functional Group Oxidations.

$K_3Fe(CN)_6$, a one-electron oxidant, is often used in an alkaline solution with an organic solvent. Since it is soluble in the aqueous phase but insoluble in most organic solvents, the reaction can be easily worked up by simple aqueous extraction. $K_3Fe(CN)_6$ has been reported to oxidize quaternary ammonium salts to pyridones,[4] acyloins to diketones,[5] and 3,4-disubstituted 4-halo-2-pyrazolin-5-ones to disubstituted alkynes (eq 1).[6] Demethylation has been reported for certain tertiary amines,[7] while diacids have been shown to undergo decarboxylation.[8]

(1)

Oxidative Coupling of Phenols.

One of the most important uses of $K_3Fe(CN)_6$ is the oxidation of phenols. Stable aroxyl radicals can be prepared by reacting 2,4,6-trisubstituted phenols with alkaline $K_3Fe(CN)_6$ (eq 2).[9] With appropriate substituents, the dimer product from intermolecular oxidative coupling can be obtained in good yield (eqs 3 and 4).[10,11]

(2)

(3)

(4)

A stereospecific and stereoselective oxidative coupling of a chiral tetrahydronaphthol using $K_3Fe(CN)_6$ has also been demonstrated (eq 5).[12]

(5)

$K_3Fe(CN)_6$ has been used extensively for intramolecular oxidative coupling of phenolic substrates,[2] often with remarkably high yields (eqs 6 and 7).[13,14]

(6)

Other oxidants that have been commonly used for oxidative phenolic coupling are ***Iron(III) Chloride***, ***Iron(III) Chloride-Silica Gel***, ***Manganese Dioxide***, ***Lead(IV) Oxide***, ***Mercury(II) Oxide***, ***Silver(II) Oxide***, ***Phenyliodine(III) Bis(trifluoroacetate)***, ***Thallium(III) Trifluoroacetate***, ruthenium trifluoroacetate, ***Vanadyl Trichloride***, and ***Vanadyl Trifluoride***.[2] For the oxidation of a phenolic β-diketone, $K_3Fe(CN)_6$ gives the coupling product in very good yield (eq 8),[15] while several other oxidants (e.g. $FeCl_3$, VOF_3, $VOCl_3$, ***Copper(II) Chloride***) were unsuccessful. However, $VOCl_3$ has been shown to be superior to $K_3Fe(CN)_6$ in the oxidation of a diphenolic substrate (eq 9).[16]

$K_3Fe(CN)_6$ has also been used in the synthesis of hydroxyindoles by the oxidation of suitably substituted hydroquinones.[17]

As Reoxidant in Osmium-Catalyzed Dihydroxylation.

Another very important use of alkaline potassium ferricyanide is as a stoichiometric reoxidant in the osmium-catalyzed dihydroxylation of alkenes to give diols (eq 10).[18] Sodium sulfite is usually added to the reaction mixture to quench the excess ferricyanide before work-up.

(10)

Other co-oxidants, such as sodium or potassium chlorate,[19] ***Hydrogen Peroxide*** in *t*-butyl alcohol,[20] ***t-Butyl Hydroperoxide*** under alkaline conditions,[21] and amine *N*-oxides,[22] have also been used for this purpose. Although catalytic *cis*-dihydroxylation using perchlorates or hydrogen peroxide usually gives good yield of diol, over-oxidation is difficult to avoid. Both $K_3Fe(CN)_6$ and ***N-Methylmorpholine N-Oxide*** (NMO) have proven to be very mild and effective co-oxidants. However, $K_3Fe(CN)_6$ has been shown to be the most efficient oxidant in the osmium-catalyzed asymmetric dihydroxylation of prochiral alkenes with derivatives of dihydroquinidine (DHQD) and dihydroquinine (DHQ) as chiral ligands to give chiral diols. The use of this oxidant precludes the second cycle which gives very low enantioselectivity and leads to enantioselectivities not obtainable with the use of other oxidants (eqs 11 and 12).[23]

Potassium Fluoride[1]

KF

[7789-23-3] · FK · Potassium Fluoride · (MW 58.10)

(fluorinating reagent;[1] desilylating reagent;[11] base[29])

Physical Data: mp 846 °C; bp 1505 °C; *d* 2.48 g cm^{-3}; vapor pressure 1 mmHg at 885 °C.

Solubility: sol water, HF, NH_3; slightly sol alcohol; insol most organic solvents.

Form Supplied in: white to colorless crystals and powder.

Handling, Storage, and Precautions: anhydrous KF should be handled and used under dry N_2 for best results. KF reacts with acid to form the toxic gas hydrogen fluoride.

Fluorination Reagent.

Potassium fluoride is widely used as a fluorinating reagent to prepare various organic fluorides. Aromatic[1] or vinyl fluorides[2] activated by electron-withdrawing groups are readily prepared from an exchange reaction of KF with aromatic or vinyl chlorides in polar aprotic solvents such as DMF, DMSO, or tetramethylene sulfone. In the presence of Ph_4PBr[3] or phthaloyl difluoride,[4] the fluoride ion replaces not only chlorine but also the nitro group in activated nitrobenzenes in DMSO. Reaction of polychlorobenzenes with KF gives mono-, di-, and trifluorobenzenes, depending on the reaction conditions.[1f,5] Perfluorobenzene and perfluoropyridine have been available from chlorine-fluorine exchange reactions.[6] The best results are obtained from heating a mixture of perchloroaromatic substrates and KF in the absence of solvent at an elevated temperature. Displacement of halide by fluoride ion also occurs with alkyl halides,[7] particularly in the presence of CaF_2,[8] but it becomes more difficult with polychloroalkanes.

The chlorine-fluorine exchange reaction has been applied to prepare acyl or sulfonyl fluorides.[9] Aryl acyl fluorides, alkyl acyl fluorides and sulfonyl fluorides are readily obtained from the reaction of acyl or sulfonyl chlorides with KF in the presence of CaF_2 in MeCN at rt, although the reaction is slow with KF alone.[8] Perfluorinated analogs are more active and the exchange reaction with KF is completed within a few hours in MeCN at rt.[10]

Desilylating Reagent.

Due to formation of a strong silicon-fluorine bond, KF readily reacts with trialkylsilyl ethers[11] or acyl,[12] alkyl,[13] vinyl,[14] and alkynyl[15] silanes to remove the trialkylsilyl group. In the presence of a leaving group in the β-position, the silanes undergo smooth β-elimination reactions with KF in DMSO. Alkenes are obtained from saturated silanes (eq 1),[16] and alkynes[17] and allenes (eq 2)[18] are produced from vinyl silanes. Silylvinyl triflates are decomposed with KF and a crown ether at -20 °C to give vinylidene carbenes in essentially quantitative yield and which can be trapped by alkenes to give cyclopropanes (eq 3).[19]

(1)

(2)

(3)

Vinyl trialkylsilyl ethers liberate ketones or aldehydes with KF and a proton source.[20] In the presence of a carbonyl group, aldol condensation occurs to give β-hydroxy ketones (eq 4).[21] The intramolecular aldol reaction also goes smoothly to produce a cyclic product (eq 5).[22]

(4)

(5)

In the presence of KF, perfluoroalkyl-[23] or perfluorophenyltrimethylsilanes[24] react with aldehydes, ketones, and acyl fluorides to give fluoro alcohols (eq 6). Sulfones were obtained in good yields when sulfonyl fluorides were used as substrates. These reactions usually proceed in aprotic solvents, such as MeCN and PhCN, at or near rt.

(6)

Certain carbon-silicon bonds can be oxidized with 30% ***Hydrogen Peroxide*** and KF to give the corresponding alcohols in good yields.[25] This method is applicable to one-pot synthesis of anti-Markovnikov alcohols from terminal alkenes by hydrosilylation and oxidation (eq 7).[26] The oxidizing ability of 90% H_2O_2 is only slightly greater than that of 30% H_2O_2; 70% ***t-Butyl Hydroperoxide*** is less active. Although ***m-Chloroperbenzoic Acid*** also works well, 30% H_2O_2 is more economical and the reaction is cleaner. The stereochemistry of the reaction center is retained under these conditions (eq 8).[27] Various chiral diols are available by asymmetric catalytic intramolecular hydrosilylation of internally substituted alkenes using Rh complexes as catalysts, followed by oxidation with H_2O_2 and KF (eq 9).[28] Vinylsilanes are also oxidized with H_2O_2 and KF to give ketones.[26]

(7)

(8)

(9)

KF promotes carbonylative coupling reactions of organofluorosilanes with aryl iodides in the presence of a palladium catalyst (eq 10).[52]

(10)

Use as a Base.[29]

KF in DMSO is a good dehydrohalogenation reagent for vinyl and alkyl halides to form alkynes,[30] allenes,[30] alkenes,[31] and dienes.[32] The presence of crown ethers facilitates the elimination reaction, particularly when MeCN is

used as a solvent.[30]

Alkylation of alcohols,[33] phenols,[34] thiols,[35] and amines[36] with alkyl halides is promoted by KF. This method has been applied to synthesis of crown ethers.[37] Heterocycles are also readily alkylated with allyl halides (eq 11).[38] Arylation of phenols with activated aryl fluorides has been accomplished by using KF as a catalyst.[39]

The conversion of carboxylic acids and alkyl halides to esters (eq 12) has proven especially useful since employment of KF gives high yields of products.[39] This reaction may be conducted by using the reactant acid as the bulk solvent; DMF can be used as a solvent when starting acids are solids.[40] The alkyl iodides are the most reactive substrates.[35]

KF is widely used as a catalyst in Michael additions and aldol and Knoevenagel condensations. The use of KF has several advantages: a strong base is not required; catalytic amounts of KF are sufficient; separation of the catalyst is easy; yields are high with high selectivity; and the reactions are often successful when other strong bases are ineffective. Nitro compounds,[41] nitriles,[42] esters,[43] 1,3-diketones,[44] and heterocycles such as imidazoles (eq 13)[45] are usually used as Michael addition donors, and α,β-unsaturated aliphatic ketones, esters, nitro compounds, and nitriles are employed as the acceptors. Protic solvents such as ethanol are the most common, presumably due to the good solubility of KF in these solvents.[46] MeCN and benzene are also employed, but the presence of a crown ether such as ***18-Crown-6*** is necessary for this reaction.[47]

(13)

Various nitro alcohols are obtained by aldol condensation of nitroalkanes with aldehydes.[48] At elevated temperatures, the Knoevenagel reaction occurs to give unsaturated products (eq 14).[49] The cyclization of 1,4-diketones to cyclopentenones is also achieved with KF and a crown ether in refluxing xylene (eq 15).[50] Aromatic compounds are, however, usually obtained upon treatment of 1,3-diketones with KF in DMF (eq 16).[51] Reaction of 1,2-diketones with KF/DMF gives 1,4-benzoquinone derivatives (eq 17).[51]

[1344-28-1] · Al_2O_3 · Potassium Fluoride-Alumina · (MW 101.96)

(demethylation and desilylation of phenol ethers;[1,2] a solid base catalyst for elimination,[3] addition,[17] and condensation reactions[3])

Form Supplied in: white powder.

Preparative Method: to a stirred solution of ***Potassium Fluoride*** (20 g) in water (150 mL) is added neutral ***Alumina*** (60-80 mesh, 30 g) in water (150 mL); after 30 min the water is then evaporated in a rotary evaporator at ~60 °C. When most of the water has been removed, the remaining mixture is heated to 140-150 °C and maintained at that temperature under vacuum (5 mmHg) for 6 h to give 50 g of KF-alumina reagent.

Handling, Storage, and Precautions: anhydrous KF-alumina is usually handled and used in dry N_2 for best results, but in some cases a trace amount of water facilitates reactions. KF reacts with acid to form the toxic gas hydrogen fluoride. Use in a fume hood.

Deprotecting Reagent.

KF-alumina is an effective reagent for demethylation of methyl phenyl ethers. Heating various methyl phenyl ethers with KF-alumina at 210-215 °C gives phenols. Ethyl phenyl ethers, alkyl methyl ethers, and methylamines do not react with KF-alumina (eq 1).[1] It is also used to remove *t*-butyldimethylsilyl groups from aryl ethers at rt, whereas benzyl *t*-butyldimethyl ethers and 2-(trimethylsilyl)ethoxymethyl ethers of phenols are stable to the reagent (eq 2).[2]

(1)

(2)

Use as a Base.

KF-alumina reagent is a stronger base than KF alone, and it is used as a solid base for eliminations,[3] alkylations, additions, isomerizations,[4,5] and condensations.[3] These reactions can be carried out without any solvent, but addition of a trace amount of water facilitates some reactions, such as Wittig and Wittig-Horner reactions.[6]

Phenethyl bromides react with KF-alumina to give the corresponding alkenes in good yield. Vinyl bromides or dibromides afford alkynes. However, when simple alkyl halides are used as substrates, hydrolysis becomes the main reaction and alcohols are obtained along with the desired alkenes.[3]

KF-alumina promotes alkylations of amides, lactams, and N-heterocycles in MeCN or DME at rt.[7] The alkylations occur exclusively at nitrogen atoms. In addition to simple acyclic amides, cyclic amides of various ring sizes are readily alkylated in excellent yields (eq 3). Methylation of uracil and xanthine derivatives is very effective (eq 4).[7] Arylation of phenols, thiophenols, and anilines with fluorobenzonitriles is also achieved by using KF-alumina as a catalyst.[8]

(3)

1-Hydroxyalkane phosphonic esters are readily available from KF on alumina catalyzed addition of dialkyl phosphites to aldehydes or activated ketones.[9] By using KF-γ-alumina, the addition proceeds smoothly with nonactivated ketones such as dialkyl, diaryl, and aryl alkyl ketones at rt (eq 5).[10] Reactions of nitroalkanes with aldehydes also occur to give 2-nitroalkanols.[11] The reaction times are shorter than with alumina alone so that aromatic nitroalcohols are readily obtained without dehydration to nitroalkenes.

Michael addition proceeds readily at rt or below in the presence of catalytic amounts of KF-alumina.[3,12] Aprotic solvents, such as THF and MeCN, are mostly used, in contrast to employment of KF alone as a catalyst in protic solvents.[13] Secondary nitroalkanes readily add to α,β-unsaturated esters with KF on neutral alumina while primary nitroalkanes give byproducts resulting from multiple Michael additions.[14] When basic alumina is used as the support, the side reaction can be avoided and the reaction proceeds well with α,β-unsaturated ketones and acrylate esters.[14] With α,β-unsaturated α-cyano esters and α,β-unsaturated α-cyano nitriles, cyclopropane derivatives are formed (eq 6).[15] On the other hand, reactions of secondary nitroalkanes with α,β-unsaturated keto esters and sulfones give dihydrofurans instead of cyclopropanes (eq 7).[16] When primary nitroalkanes are used as Michael addition donors, the major products are furans along with dihydrofurans as byproducts (eq 8).[16] The isoxazoline *N*-oxides are available from nitroalkenes (eq 9).[16]

KF-alumina is an efficient base for condensation of active methylene groups with carbonyl compounds. Reaction of various sulfones[17] and phosphonates[6] containing active methylene groups with aldehydes in the absence of solvent under microwave irradiation gave α,β-unsaturated sulfones and phosphonates, respectively (eqs 10 and 11). However, condensation of malononitrile and acetone gives a 2-azabicyclo[2.2.2]octane derivative in 92% yield; presumably the initial product is isopropylidenemalononitrile, which undergoes KF-alumina-catalyzed Michael addition and cyclization reactions to give the final cyclic product (eq 12).[18] Even less acidic methylene compounds condense with aldehydes to afford alkenes (eq 13).[19] Under similar conditions, trimethylsulfonium iodide[6] or arsonium salts[20] react with aldehydes to give epoxides (eq 14).

(12)

(13)

(14)

α-Diazo ketones and esters can be prepared by KF-alumina-catalyzed diazo transfer reactions of tosyl azide with the ketones or esters (eq 15).[21]

(15)

Condensations of active methylene compounds with carbon disulfide lead to ketene thioacetals under KF-alumina catalysis. Various α-keto, α-cyano, and α-carboxyl ketene thioacetals,[22] as well as α-phosphonic ketene dithioacetals (eq 16),[23] are available from the reaction of active methylene compounds with ***Carbon Disulfide***, followed by methylation with ***Iodomethane***. The dithioacetals are also directly obtained by reaction of the methylene compounds with 2 equiv of *S*-methyl methanesulfonothioate under microwave irradiation.[24] α-Alkynic alcohols react with carbon disulfide to give 4-alkylidene-2-thione-1,3-oxathiolanes without solvent at rt (eq 17).[25] The presence of solvent in the previous reaction causes side reactions.[25] Aldehydes can be directly converted into the corresponding nitriles by treatment with carbon disulfide, KF-alumina, hydroxylamine, and HCl in one pot (eq 18).[26] KF-alumina also promotes hydrolysis of nitriles into amides in refluxing butanol.[27]

Potassium Fluoride-Celite[1]

KF/Celite

(KF)

[7789-23-3] · FK · Potassium Fluoride-Celite · (MW 58.10) (Celite)

[61790-53-2]

(mild heterogeneous basic catalyst for alkylation[1] and Michael addition[5])

Form Supplied in: white solid.

Preparative Method: ***Celite*** 545 (20.0 g) is mixed with ***Potassium Fluoride*** (20.0 g) in water (500 mL), and the water removed at 50-60 °C in a rotary evaporator. The solid obtained is then shaken in MeCN (100 mL), filtered, washed with two portions (50 mL) of MeCN and dried in a desiccator at rt.

General Discussion.

The main use of KF/Celite is as a catalyst for alkylation with alkyl halides. The alkylation proceeds smoothly with aniline, amines, and thiophenol in MeCN between rt and 70 °C, dependent on reactivity of the alkyl halides.[1] Workup can be carried out under nonaqueous conditions: addition of ether, filtration, washing with ether, evaporation of the solvents, and distillation or recrystallization.[1] Alkylation of 1,3-diketones gives monoalkylated products.[1] 1,3-Indanedione gives rise to dialkylated 1,3-indanedione exclusively, even if less than 2 equiv of alkylating reagent are used (eq 1).[2]

(1)

A nucleophilic aromatic substitution on activated nitro- or chlorobenzenes is effected by KF/Celite. Reaction of various 1,3-diketones with cyclopentadienyliron-complexed nitro- or chlorobenzenes gives the corresponding 1,3-diketone substituted products without deacetylated byproducts (eq 2).[3] In contrast, deacetylated byproducts are often observed using alternative methods unless precautions are taken during workup.[4]

(2)

KF/Celite-catalyzed intramolecular Michael addition provides a new approach to flavanones. One example is the synthesis of bavachinin by intramolecular addition of a phenol group to an α,β-unsaturated ketone in methanol (eq 3).[5] Use of free KF, KF/alumina, and ***Tetra-n-butylammonium Fluoride*** in this reaction is less successful.[5]

Potassium-Graphite Laminate

[12081-88-8] · C_8K · Potassium-Graphite · (MW 135.18)

(powerful reducing agent for many functional groups;[1] metalating agent;[1] Lewis base;[1] hydrogenation catalyst;[1,2] catalyst for double bond isomerization and for anionic polymerization;[2] tool for preparing activated metals[1])

Physical Data: paramagnetic bronze-colored powder; *d* ~0.73 g cm^{-3}; interlayer distance 5.34 Å; all carbon layers are separated by one layer of potassium; space group D^6_2 *C*222.

Solubility: may be suspended in hydrocarbon and ethereal solvents; reacts violently with water, alcohols, and ammonia; THF, DME, 1,4-dioxane, and many arenes (e.g. benzene, toluene, pyridine, furan) are able to penetrate into the interlayer space, causing considerable swelling.

Preparative Methods: by stirring potassium and graphite powder at &egt;150 °C under argon without any solvent for 5-10 min. Natural as well as synthetic graphite are suited for its preparation.

Handling, Storage, and Precautions: pyrophoric and must be handled under argon in thoroughly dried solvents. Small quantities should be weighed in a glove box; it can be stored under argon without any significant loss in activity for extended periods of time.

Introduction.

Potassium-graphite laminate may be regarded as a polymeric array of naphthalenide anions and effects almost any reaction that the latter would promote. A major advantage in using C_8K as a substitute for ***Lithium Naphthalenide***, for example, lies in its increased reactivity and the easy work-up, consisting of filtration of the graphite only instead of the sometimes tedious removal of naphthalene.[1] Moreover, C_8K-promoted reactions can be readily monitored by the characteristic color change from bronze of the reagent to black of the graphite host.[1]

Functional Group Reductions.

Alkyl chlorides and aryl halides are generally reduced to the corresponding hydrocarbons, whereas alkyl iodides afford Wurtz-type coupled products. Alkyl bromides show a reactivity pattern between alkyl chlorides and alkyl iodides. Single-electron transfer is an important pathway in these reductions, since characteristic radical

rearrangements are observed with hex-5-enyl halides as mechanistic probes (eq 1).[3] *vic*-Dihalides form alkenes in high yield (eq 2).[3,4] C_8K leads to reductive cleavage of the C-O bond of aryl ethers, whereas in sulfonate esters the S-O rather than the C-O bond is broken selectively, with formation of the parent alcohols (eq 3).[3] Aryl ether and C-Cl cleavage can be done simultaneously, thus allowing the ready destruction of toxic polyhalodibenzodioxines or -dibenzofurans at rt.[5] Vinyl sulfones and allyl sulfones afford the corresponding alkenes (the latter after initial isomerization of their double bond) (eq 4).[6] The (*E*):(*Z*) ratio in these desulfuration reactions is low, with the (*E*)-isomer being slightly favored.

(1)

(2)

(3)

(4)

With ***Hexamethyldisilazane*** as cosolvent, C_8K in THF selectively reduces the double bond of enones at rt without affecting nonconjugated alkenes (eq 5).[7] α,β-Unsaturated acids are similarly reduced at 55 °C, while enoates give dimerization products. Imines afford amines in high yields with this reagent (eq 6),[7] whereas ketones may afford mixtures of alcohols and pinacols.[8] A large excess of the reagent is required to effect Birch-type reductions of arenes, as exemplified by a series of substituted naphthalene derivatives.[9] On treatment with C_8K in THF, benzil undergoes a unique coupling of the phenyl rings with formation of 9,10-phenanthrenequinone (eq 7).[10] This arene coupling can be extended to 2,3-diphenylquinoxaline and related heterocycles, which afford dibenzo[*a*,*c*]phenazine derivatives.[11]

(5)

(6)

(7)

Although C_8K was considered for a long time to be of limited value in organic synthesis due to its high reactivity,[3] it turned out to be the reagent of choice for the synthesis of furanoid glycals in terms of yield, reaction rate, and flexibility. The intermediate potassium alcoholates, formed upon treatment of 2,3-*O*-alkylidene glycosyl halides with C_8K in THF at low temperature, can be protected in situ with a wide variety of electrophiles (eq 8).[12] Aryl thioglycosides can also be reduced to the corresponding glycals by means of C_8K.[12b] Comparable reaction sequences consisting of C_8K-induced fragmentations followed by trapping of the intermediate alcoholates have also been carried out successfully with a series of carbohydrate-derived primary halides (eq 9).[13]

Chlorosilanes are rapidly converted by C_8K to disilanes in high to quantitative yields in THF at ambient temperature.[14] Phenyl-substituted disilanes may be further reduced to the corresponding silyl potassium reagents, which can be transmetalated with various transition metal halides (***Copper(I) Iodide***, ***Copper(I) Cyanide***, MnI_2, VCl_3) to highly selective nucleophilic silylating agents. They react cleanly with enoates, enones, and acid chlorides, the last affording acyl silanes in a one-pot procedure (eq 10).[14a]

C_8K as Polymeric Lewis Base.

The reactivity of C_8K towards Brønsted acids is substrate size dependent.[3] C_8K has been used to achieve selective monoalkylation of alkyl nitriles and phenylacetic acid esters (substrate:C_8K:alkyl halide = 1:2:2) at -60 °C in 40-70% yield, with only small amounts of dialkylated products (0-7%) interfering.[15] Imines and dihydro-1,3-oxazine derivatives can likewise be deprotonated by this reagent at rt, followed by exclusive *C*-alkylation of the azaallyl anion (eq 11).[16] Some examples of selective dehydrohalogenations in the carbohydrate series due to the basisity of C_8K have also been reported (eq 12).[17]

Organometallic Chemistry.

C_8K is an effective reducing agent for transition metal compounds.[1] Particularly relevant to organic synthesis is the ready reduction of ***Hexacarbonylchromium*** to $K_2Cr(CO)_5$, which forms chromium carbenes upon reaction with amides or esters in presence of ***Chlorotrimethylsilane*** (eq 13). This procedure allows an improved entry into the rich chemistry of chromium carbenes, with a comparative study clearly pointing out the superiority of C_8K as reducing agent over naphthalenide anions.[18] Moreover, C_8K is the only reagent that cleanly reduces $[CpNi_2(CO)]_2$ to the highly nucleophilic nickelate $[Cp(CO)Ni]^- K^+$, which affords allylnickel complexes on reaction with ***Allyl Bromide***.[19]

(13)

Metal-Graphite Reagents.[1]

C_8K may be used to reduce metal salts in ethereal solvents to metal-graphite reagents (eq 14). Due to the even distribution and small size (usually in the range of 2-10 nm in diameter) of the metal particles adsorped on the surface of the graphite support, these reagents exhibit very high and sometimes unprecedented degrees of reactivity and are easily removed by simple filtration after use.[1] Almost any metal may be activated by this technique.

$$MX_n + n\,C_8K \longrightarrow M^* \text{ on graphite} + n\,KX \qquad (14)$$

$$MX_n = ZnCl_2\ (AgOAc),\ TiCl_3,\ TiCl_4,\ SnCl_2,\ PdCl_2,\ PtCl_2,\ NiBr_2,\ MgCl_2,\ FeCl_3$$

Zinc-Graphite doped with 10 mol % ***Silver*** exhibits an exceptionally high reactivity and wide scope. This reagent promotes Reformatsky reactions at temperatures well below 0 °C with different kinds of halo esters, including the

rather unreactive chloroalkanoates (see also ***Ethyl Bromozincacetate***).[20] Tandem reactions comprising a Reformatsky step followed by glycidate formation or a Peterson elimination, respectively, have been carried out.[21] Zn/Ag-graphite transforms glycosyl halides to the corresponding glycals under aprotic conditions, independent of the ring size and the protecting groups employed (eq 15).[22] Deoxyhalosugar derivatives are reductively ring opened by Zn/Ag-graphite with formation of enantiomerically pure enal building blocks of wide applicability to natural product synthesis (eq 16).[13,17,23] It is the only reagent that affords such fragmentations under essentially neutral conditions in anhydrous ethereal solvents, exhibits excellent tolerance towards a wide range of functional groups in the substrates, and is therefore well suited for selective transformations of polysubstituted molecules.[24] This was shown in a total synthesis of 9-dihydro-FK-506 (eq 17).[25] Zn/Ag-graphite is also suitable for metalating functionalized aryl halides at rt.[31]

(17)

Titanium on graphite deserves special emphasis as one of the most efficient reagents for all kinds of carbonyl coupling reactions. It promotes both inter- as well as intramolecular McMurry reactions of (di)ketones and (di)aldehydes (eq 18),[26-28] cyclizes oxo esters to cyclanones,[26] and was successfully applied to polyoxygenated substrates in cases when other titanium reagents failed to effect any conversion (eq 19).[28] Recently, it was used to cyclize acyloxycarbonyl and acylamidocarbonyl compounds to furans, benzo[*b*]furans, and indoles (eq 20), respectively.[29] This new entry to aromatic heterocycles by reductive C-C bond formation of easily accessible precursors is compatible with a variety of other reducible sites in the substrates.[29]

(18)

The performance of magnesium-graphite in reductive carbonyl coupling processes compares favorably to all other kinds of pinacol-forming agents described so far (eq 21).[26b] Metal-graphite combinations of platinum, palladium, and nickel have been used as highly efficient and selective catalysts for hydrogenation reactions as well as for catalytic C-C bond formations.[30] Preparative advantages have also been drawn from the use of other graphite reagents in organic and organometallic synthesis.[1,27a]

Potassium *t*-Heptoxide

Et_3COK

[20484-37-1] · $C_7H_{15}KO$ · Potassium *t*-Heptoxide · (MW 154.32)

(strong, sterically hindered alkoxide base; particularly capable of effecting Hofmann elimination of alkyl halides[1])

Alternate Name: potassium triethylmethoxide.

Solubility: sol THF, DME, aromatic hydrocarbons.

Preparative Methods: 3.0 M solution of the red reagent in Et_3COH is prepared by reacting potassium metal with an excess of the anhydrous alcohol at 140 °C for 2.5 h.[1] Solutions of the base of approximately 2.0 M concentration in xylene or undecane are obtained by heating potassium metal with 1.2 equiv of the alcohol at 160 °C for 6.0 h.[1] The reaction of the anhydrous alcohol with a slight excess of oil-free ***Potassium Hydride*** in THF or other solvents produces the reagent in 3-15 min.[2] After the excess insoluble KH settles, the solution of the base is removed via a cannula or a syringe.

Handling, Storage, and Precautions: Et_3COK solutions should be handled with the same precautions that are employed for ***Potassium t-Butoxide*** solutions, i.e. avoid contact with the eyes, skin, and clothing. Conduct reactions under a dry nitrogen or argon atmosphere. For critical experiments, it is recommended that the reagent be freshly prepared. Use in a fume hood.

Formation of Potassium Enolates.

The basicity of tertiary potassium alkoxide bases increases as the bulk of the alkyl substituents increases. Therefore Et_3COK is a stronger base than *t*-BuOK or ***Potassium 2-Methyl-2-butoxide***.[3] For example, the value of the equilibrium constant for the reaction of pinacolone with Et_3COK in THF to form its potassium enolate and the alcohol is 57 (eq 1), while it is only 6.7 and 10.0 for *t*-BuOK and $EtCMe_2OK$, respectively.[3]

(1)

β-Elimination Reactions.

Et_3COK is a poor nucleophile, and its steric bulk and high basicity make it an excellent reagent for effecting Hofmann-type eliminations of alkyl halides.[1] As indicated in eq 2, the reaction of 2-bromo-2-methylbutane with Et_3COK gives a higher 1-alkene/2-alkene ratio than when either *t*-BuOK or $EtCMe_2OK$ are employed under the same conditions.[1a] Also, other tertiary halides such as 1-chloro-1-methylcyclohexane (eq 3), the hydrochloride of α-cedrene, and 2-chloro-2,3-dimethylbutane give the less-substituted alkenes in good yields when treated with an excess of the base in xylene solution at 60 °C.[1b] Because the three fluorine atoms enhance the acidity of the protons at C-3, dehydrohalogenation of 2-chloro-4,4,4-trifluoro-2-methylbutane with Et_3COK in Et_3COH at 40 °C gives largely 4,4,4-trifluoro-2-methyl-2-butene.[4] However, the corresponding 1-butene derivative is obtained if a highly hindered pyridine derivative or a metal oxide is employed as the base.[4] The reaction of 2-bromobutane with Et_3COK/Et_3COH also gives a higher 1-butene/2-butene ratio than does *t*-BuOK/*t*-BuOH (eq 4).[5]

(2)

Base/solvent		
Et_3COK/Et_3COH	89%	11%
t-BuOK/*t*-BuOH	73%	27%
$EtCMe_2OK/EtCMe_2OH$	78%	22%

(3)

Ramberg-Bäcklund Rearrangement.

Et_3COK in DME/HMPA at 70 °C is effective for promoting the Ramberg-Bäcklund reaction of the complex α-chloro sulfone shown in eq 5.[6] The use of less-hindered bases causes dechlorination of the reactant or partial decomposition of the product. This reaction is a key step in the recent total synthesis of the natural product (+)-eremantholide.[6]

Metalation Reactions.

Mixtures of alkyllithium reagents and potassium tertiary alkoxides are powerful metallating agents for weakly acidic compounds.[7] Because of higher solubilities of Et_3COK and $EtCMe_2OK$ in hydrocarbons, mixtures of these bases and ***n-Butyllithium*** are more effective than *n*-BuLi/*t*-BuOK in promoting dimetalation of benzene.[8]

Potassium Hexachloroosmate(IV)-Zinc

K_2OsCl_6-Zn

(K_2OsCl_6)

[16871-60-6] · Cl_6K_2Os · Potassium Hexachloroosmate(IV)-Zinc · (MW 481.10) (Zn)

[7440-66-6] · Zn · Potassium Hexachloroosmate(IV)-Zinc · (MW 65.39)

(catalyst for the cycloadditive dimerization of α,β-unsaturated ketones[1])

Physical Data: K_2OsCl_6: mp dec.

Solubility: K_2OsCl_6: sol EtOH, MeOH.

Form Supplied in: K_2OsCl_6: hydrated crystals. Zn: powder. Both are commercially available.

Purification: K_2OsCl_6: recrystallized from hot dilute aqueous HCl. Zn: stirred with 2% aqueous HCl (3 L kg^{-1} Zn dust) for 1 min, filtered, washed with 2% HCl (3 L), three times with distilled water (1 L each), twice with 95% ethanol (1 L each), and once with diethyl ether (2 L), and then dried under vacuum. The reagents, along with the substrate, are mixed prior to reflux.

Handling, Storage, and Precautions: zinc dust is flammable.

Dimerization-Cyclopentannulation of Enones.

Treatment of α,β-unsaturated ketones with potassium hexachloroosmate(IV) and ***Zinc*** leads to the reductive dimerization-cyclization product, the cyclopentanol derivative, in nearly quantitative yield (eq 1).[1] This unique transformation has unfortunately only been examined for two substrates, dibenzylideneacetone and 1,3-diphenyl-2-propenone.

Potassium Hexachlorotungstate(IV)

K_2WCl_6

[16923-43-6] · Cl_6K_2W · Potassium Hexachlorotungstate(IV) · (MW 474.75)

(reduces 1,2-diols to alkenes[1])

Physical Data: red crystals.

Solubility: sol liquid ammonia.

Form Supplied in: not commercially available.

Preparative Method: prepared by heating a mixture of ***Tungsten(VI) Chloride*** and ***Potassium Iodide*** at 130 °C in the absence of air.[2]

Purification: the compound from the above procedure is used without further purification.

Handling, Storage, and Precautions: air and moisture sensitive.

Conversion of 1,2-Diols to Alkenes.

Treatment of potassium hexachlorotungstate(IV) with the dialkoxides derived from deprotonation of 1,2-diols leads to alkenes.[1] The procedure represents a one-pot method to effect this transformation; sequential treatment of 1,2-diols with ***n-Butyllithium***, followed by potassium hexachlorotungstate(IV), leads to the desired alkene in high yield. The reaction is fastest for tetrasubstituted diols and slows with decreasing substitution (eq 1). Predominant but not exclusive retention of stereochemistry is observed in the reaction, due to partial isomerization of the dialkoxides under the conditions of the reaction; the isomerization is thought to proceed via a reversible pinacol coupling. The advantages of this method are that it is a one-pot procedure, and that it is efficient for hindered substrates.[3]

Potassium Hexacyanodinickelate

$K_4Ni_2(CN)_6$

[52186-89-7] · $C_6K_4N_6Ni_2$ · Potassium Hexacyanodinickelate · (MW 429.90)

(hydrocyanation-reduction of alkynes;[2] dimerization of benzylic, allylic, and vinylic halides;[3] carbonylation of halides to afford ketones and esters;[3] conversion of vinylic halides to nitriles[3])

Physical Data: diamagnetic red solid.

Solubility: sol water; insol ethanol, liquid ammonia.

Form Supplied in: deep red solid.

Preparative Method: prepared from the reduction of potassium tetracyanonickelate with ***Potassium*** in ammonia. The product precipitates from solution as a deep red solid.[1]

Handling, Storage, and Precautions: blood red aqueous solutions of the reagent are decolorized by oxygen. The reagent must be handled under an inert atmosphere.

Preparation of Nitriles.

The title reagent has been little used in organic synthesis, but several reports indicated that it has some potential. For example, potassium hexacyanodinickelate reacts with alkynes in the presence of ***Sodium Borohydride*** to afford nitriles (eq 1).[2] Conversion of cinnamyl bromide to the corresponding nitrile can be accomplished in aqueous acetone at rt in 83% yield.[3]

(1)

Halide Coupling.

Treatment of benzylic halides with potassium hexacyanodinickelate in water affords bibenzyls in good yields (eq 2).[4]

The coupling of α-bromo ketones to 1,4-dicarbonyl compounds has also been reported although the yields are modest.[3] When the reactions are performed in the presence of ***Carbon Monoxide***, ketones are obtained (eq 2).[3] Similar reactions have been reported with vinylic and allylic halides with varying results.[3]

Potassium Hexafluorophosphate

KPF_6

[17084-13-8] · F_6KP · Potassium Hexafluorophosphate · (MW 184.07)

(production of diaryliodonium and alkylaryliodonium hexafluorophosphates and triarylsulfonium hexafluorophosphates used as photoinitiators for cationic polymerization; used for the preparation of organic hexafluorophosphates; used to produce catalysts for peptide coupling reactions)

Physical Data: mp 575 °C; *d* 2.55 g cm^{-3}.

Solubility: sol water (9.3 g/100 ml at 25 °C and 20.6 at 50 °C), sol diglyme (40 g/100 ml at 25 °C).

Form Supplied in: white powder; commercially available.

Analysis of Reagent Purity: volumetric method for determination of total fluoride;[1,2] ion selective electrode for determination of soluble fluoride (KF) impurity;[3] gravimetric method of analysis for determination of PF_6 by using tetraphenylarsonium chloride.[4]

Handling, Storage, and Precautions: stable at ambient temperature. This material can be stored in polyethylene, Teflon® or metal containers. The OSHA permissible exposure limit[5] and American Conference of Governmental Industrial Hygienists (ACGIH) established Threshold Limit Value[6] (TLV) as a time-weighted average for fluorides is 2.5 mg (as fluoride) per cubic meter of air.

Diaryliodonium Hexafluorophosphates.

Diaryliodonium hexafluorophosphates are prepared by the metathesis reaction of diaryliodonium bisulfates and potassium hexafluorophosphate. There are many methods reported in the literature for the synthesis of diaryliodonium bisulfates.[7-10] Aromatic substrates bearing electron-withdrawing groups such as NO_2, halogens, CO_2H, or $MeSO_2$ are best coupled by the method used by Masson and co-workers[7] employing iodyl sulfate to produce symmetrical diaryliodonium bisulfate (eq 1).

Diaryliodonium bisulfates having electron-donating groups on the aromatic ring are readily prepared by the direct coupling of their aromatic precursor compounds using an alkali iodate in a mixture of acetic acid, acetic anhydride, and sulfuric acid (eq 2).[8,9]

Unsymmetrical iodonium bisulfates can be prepared by the direct coupling of an aromatic compound with an iodoso compound in the presence of a strong protonic acid (eq 3).[10]

Diaryliodonium hexafluorophosphates are efficient photoinitiators for the cationic polymerization of a variety of monomers (eqs 4-6). The 4,4´-dimethyldiphenyliodonium hexafluorophosphate, bis(4-*t*-butylphenyliodonium) hexafluorophosphate, and diphenyliodonium hexafluorophosphate can be prepared by using Crivello and Lam's method.[11-13]

(6)

Diphenyliodium hexafluorophosphate is used in copper(I or II) catalyzed polymerization (eq 7).[14]

(7)

Diaryliodium hexafluorophosphates are used to prepare trialkylsulfonium hexafluorophosphate (eqs 8 and 9).[15,16]

(8)

(9)

Diaryliodium hexafluorophosphates are also used in polymerization, where ring opening of the monomer takes place (eq 10).[17]

Ar2I+ MXn-
hν
(10)

Triarylsulfonium Hexafluorophosphates.

To a solution of 21.5 g (0.05 mol) of tris(3,5-dimethyl-4-hydroxyphenyl)sulfonium chloride in hot ethanol was added 9.2 g (0.05 mol) of potassium hexafluorophosphate. About 100 mL of water was added and crystallization of the sulfonium hexafluorophosphate took place. The salt was filtered, washed thoroughly with water, then with ether, and dried (eqs 11 and 12).

Triarylsulfonium hexafluorophosphates are used in photoinitiated cationic polymerization (eqs 13-15).[18]

Potassium Hexamethyldisilazide

$KN(SiMe_3)_2$

[40949-94-8] · $C_6H_{18}KNSi_2$ · Potassium Hexamethyldisilazide · (MW 199.53)

(sterically hindered base)

Alternate Names: KHMDS; potassium bis(trimethylsilyl)amide.

Solubility: sol THF, ether, benzene, toluene.[1]

Form Supplied in: commercially available as moisture-sensitive, tan powder, 95% pure, and 0.5 M solution in toluene.

Analysis of Reagent Purity: solid state structures of $[KN(SiMe_3)_2]_2$[3] and $[KN(SiMe_3)_2.2\ toluene]_2$[4] have been determined by X-ray diffraction; solutions may be titrated using fluorene,[2] 2,2´-bipyridine,[5] and 4-phenylbenzylidene benzylamine[6] as indicators.

Preparative Methods: prepared and isolated by the procedure of Wannagat and Niederpruem.[1] A more convenient in situ generation from ***Potassium Hydride*** and ***Hexamethyldisilane*** is described by Brown.[2]

Handling, Storage, and Precautions: the dry solid and solutions are inflammable and must be stored in the absence of moisture. These should be handled and stored under a nitrogen atmosphere. Use in a fume hood.

Use as a Sterically Hindered Base for Enolate Generation.

Potassium bis(trimethysilyl)amide, $KN(TMS)_2$, has been shown to be a good base for the formation of kinetic enolates from carbonyl groups bearing α-hydrogens.[7] For example, treatment of 2-methylcyclohexanone with $KN(TMS)_2$ at low temperature followed by trapping with ***Triethylborane*** and ***Iodomethane*** gave good selectivity for 2,6-dimethylcyclohexanone (eq 1). In comparison, the use of ***Potassium Hydride*** for this transformation gave good selectivity for 2,2-dimethylcyclohexanone, which is the product derived from the thermodynamic enolate (eq 2).[8]

(1)

(2)

This reagent has been shown to be a good base for the generation of highly reactive potassium enolates;[9] for example, treatment of various ketones and esters bearing α-hydrogens with $KN(TMS)_2$ followed by 2 equiv of N-F-saccharinsultam allowed isolation of the difluorinated product (eq 3).

(3)

In a study on the electrophilic azide transfer to chiral enolates, Evans[10] found that the use of potassium bis(trimethylsilyl)amide was crucial for this process. The $KN(TMS)_2$ played a dual role in the reaction; as a base, it was used for the stereoselective generation of the (*Z*)-enolate (**1**). Reaction of this enolate with trisyl azide gave an intermediate triazene species (**2**) (eq 4). The potassium counterion from the $KN(TMS)_2$ used for enolate formation was important for the decomposition of the triazene to the desired azide. Use of other hindered bases such as ***Lithium Hexamethyldisilazide*** allowed preparation of the intermediate triazene; however, the lithium ion did not catalyze the decomposition of the triazene to the azide.[10a] This methodology has been utilized in the synthesis of cyclic tripeptides.[10b]

(4)

(2)

Treatment of carbonyl species bearing acidic α-hydrogens with potassium bis(trimethylsilyl)amide has also been shown to generate anions which, due to the larger, less coordinating potassium cation, allow the negative charge to be stabilized by other features in the molecule rather than as the potassium enolate. Treatment of 9-acetyl-*cis,cis,cis,cis*-cyclonona-1,3,5,7-tetraene with this reagent gave an anionic species which was characterized by spectroscopic methods to be more like the [9]annulene anion than the nonafulvene enolate. In this case the negative charge is more fully stabilized by delocalization into the ring to form the aromatic species rather than as the potassium enolate. Use of the bis(trimethylsilyl)amide bearing the more strongly coordinating lithium cation led to an intermediate which appeared to be lithium nonafulvene enolate. Addition of ***Chlorotrimethylsilane*** to each of these intermediates gave the same nonafulvenesilyl enol ether (eq 5).[11]

(5)

Selective Formation of Linear Conjugated Dienolates.

Potassium bis(trimethylsilyl)amide has been shown to be an efficient base for the selective generation of linear-conjugated dienolates from α,β-unsaturated ketones.[12] As shown in eqs 6 and 7, treatment of both cyclic and acyclic α,β-unsaturated enones with $KN(TMS)_2$ in a solvent mixture of DMF/THF (2:1) followed by quenching with ***Methyl Chloroformate*** gave excellent selectivities for the products derived from the linear dienolate anion. In comparison, the use of lithium bases for this reaction gave products derived from the cross-conjugated dienolate anions. This methodology, however, did not work for 1-cyclohexenyl methyl ketone, in which case the product from the cross-conjugated dienolate anion was isolated exclusively (eq 8).

(6)

Base	Linear	Cross	Yield (%)
$KN(TMS)_2$	>99	-	34

Stereoselective Generation of Alkyl (*Z*)-3-Alkenoates.

Deconjugative isomerization of 2-alkenoates to 3-alkenoates occurs via γ-deprotonation of the α,β-unsaturated ester to form an intermediate dienolate anion. In most cases, the α-carbon is more reactive to protonation[13] and allows for the isolation of the 3-alkenoate. If the C-4 position bears a methyl group, this transformation is usually stereospecific, leading to the (*Z*)-3-alkenoate; however, when groups larger than a methyl occupy the C-4 position, the reaction becomes increasingly stereorandom.[13d] Potassium bis(trimethylsilyl)amide, however, was shown to be a good base for the stereoselective isomerization of 2,4-dimethyl-3-pentyl (*E*)-2-dodecenoate, which bears a long C-4 substituent, to the corresponding (*Z*)-3-dodecenoate (eq 9).[14a]

(9)

Base	(*Z*):(*E*)	Yield (%)
LDA/HMPA	84:16	85
$KN(TMS)_2$	97:3	64

This reagent has been used to stereoselectively prepare (*Z*)-3-alkenoate moieties for use in the syntheses of insect pheromones.[14]

Generation of α-Keto Acid Equivalents (Dianions of Glycolic Acid Thioacetals).

Potassium bis(trimethylsilyl)amide was found to be the optimal reagent for the generation of the dianion of glycolic acid thioacetals. This reagent may be used to effect a nucleophilic α-keto acid homologation. Treatment of the starting bis(ethylthio)acetic acid with $KN(TMS)_2$ proceeded to give the corresponding soluble dianionic species. This underwent alkylation with a variety of halides and tosylates (eq 10) and subsequent hydrolysis allowed isolation of the desired α-keto acids.[15]

(10)

RX	Yield (%)
MeI	100
EtOTs	100
i-PrOTs	72
CyOTs	64
$PhCH_2Cl$	100

The dianion was also shown to undergo ring-opening reactions with epoxides and aziridines (eq 11).

(11)

Generation of Ylides and Phosphonate Anions.

Ylides.

In the Wittig reaction, lithium salt-free conditions have been shown to improve (*Z*/*E*) ratios of the alkenes which are prepared;[16] ***Sodium Hexamethyldisilazide*** has been shown to be a good base for generating these conditions. In a Wittig-based synthesis of (*Z*)-trisubstituted allylic alcohols, potassium bis(trimethylsilyl)amide was shown to be the reagent of choice for preparing the starting ylides.[17] These were allowed to react with protected α-hydroxy ketones and depending upon the substitution pattern of the ylide and/or the ketone, stereoselectivities ranging from good to excellent were achieved (eqs 12-14).

(12)

Phosphonates.

In a Horner-Emmons-based synthesis of di- and trisubstituted (*Z*)-α,β-unsaturated esters, the strongly dissociated base system of potassium bis(trimethylsilyl)amide/***18-Crown-6*** was used to prepare the desired phosphonate anions. This base system, coupled with highly electrophilic bis(trifluoroethyl)phosphono esters, gave phosphonate anions which, when allowed to react with aldehydes, gave excellent selectivity for the (*Z*)-α,β-unsaturated esters (eq 15).[18]

(15)

Intramolecular Cyclizations.

Haloacetal Cyclizations.

Intramolecular closure of a carbanion onto an α-haloacetal has been shown to be a valuable method for the formation of carbocycles.[19a] Potassium bis(trimethylsilyl)amide was found to be the most useful base for the formation of the necessary carbanions. This methodology may be used for the formation of single carbocycles (eq 16), for annulation onto existing ring systems (eq 17), and for the formation of multiple ring systems in a single step (eq 18). In the case of annulations forming decalin or hydrindan systems, this ring closure proceeded to give largely the *cis*-fused bicycles (eq 17). For the reaction shown in eq 18, in which two rings are being formed, the stereochemistry of the ring closure was found to be dependent upon the counter ion of the bis(trimethylsilyl)amide; use of the potassium base allowed isolation of the *cis*-decalin system as the major product (95%), whereas use of lithium bis(trimethylsilyl)amide led to the isolation of the *trans*-decalin (95%).[19]

(16)

(17)

95% *cis* + 5% *trans* (18)

Intramolecular Lactonization.

In a general method for the formation of 14- and 16-membered lactones via intramolecular alkylation,[20] potassium bis(trimethylsilyl) amide was shown to be a useful base for this transformation (eq 19).

$n = 5$, 0%; 7, 75%; 8, 71% (19)

Intramolecular Rearrangement.

Potassium bis(trimethylsilyl)amide was shown to be a good base for the generation of a diallylic anion which underwent a biogenetically inspired intramolecular cyclization, forming (±)-dicytopterene B (eq 20).[21]

(20)

Synthesis of Vinyl Fluorides.

Addition of potassium bis(trimethylsilyl)amide to β-fluoro-β-silyl alcohols was shown to selectively effect a Peterson-type alkenation reaction to form vinyl fluorides (eq 21).[22] Treatment of a primary β-fluoro-β-silyl alcohol with $KN(TMS)_2$ led cleanly to the terminal alkene. Use of a *syn*-substituted secondary alcohol led to the stereoselective formation of the (*Z*)-substituted alkene (eq 22); reaction of the *anti*-isomer, however, demonstrated no (*Z*:*E*) selectivity.

(21)

(22)

Oxyanionic Cope Rearrangement.

Potassium bis(trimethylsilyl)amide/18-crown-6 was shown to be a convenient alternative to potassium hydride for the generation of anions for oxyanionic Cope rearrangements (eq 23).[23]

(23)

Stereoselective Synthesis of Functionalized Cyclopentenes.

Potassium bis(trimethylsilyl)amide was shown to be an effective base for the base-induced ring contraction of thiocarbonyl Diels-Alder adducts (eq 24).[24] ***Lithium Diisopropylamide*** has also been shown to be equally effective for this transformation.

Potassium Hydride[1]

KH

[7693-26-7] · HK · Potassium Hydride · (MW 40.11)

(base and hydride donor to Lewis acids such as boranes and borates; used for deprotonation, cyclization-condensation, elimination, rearrangement reactions, and as a reducing agent).

Physical Data: solid; dec on heating; *d* 1.47 g cm^{-3}; n_D 1.453.

Solubility: dec in cold and hot water; insol CS_2, ether, benzene.

Form Supplied in: as a dispersion in mineral oil, 20-35% by weight. A standardization procedure has been published.[1]

Purification: commercial KH dispersion is made by reduction of metallic potassium,[2] and so KH is often contaminated with traces of potassium or potassium superoxide. These can be removed by pretreatment with iodine to produce a reagent with superior consistency in several reactions that are sensitive to such impurities.[3]

Handling, Storage, and Precautions: dispersion is a liquid, and tends to settle upon standing. Prolonged storage produces a compacted solid that must be broken up to achieve a homogeneous dispersion. Brown suggests[1] using a long-handled screwdriver to break up the compacted material and leaving a Teflon-covered stir bar in the container to aid dispersion. Clamping the sealed polyethylene bottle containing the dispersion to a Parr shaker for 15 min also works well.

The mineral oil may be removed by adding pentane to small quantities of the dispersion, stirring the slurry, then allowing the hydride to settle. The pentane/mineral oil supernatant may be pipetted off, but care should be exercised to quench carefully any hydride present in the supernatant with a small amount of methanol or ethanol before disposal. Two or three such rinses are sufficient to remove all traces of mineral oil.

Irritant. Great care must be taken in handling, and all operations involving the manipulation of the dry solid material should be conducted under an inert atmosphere in a fume hood.

Introduction.

The following is divided into two major classes of reactions: KH as a base, and KH as a reducing agent. The acid-base reactions are further divided into the type of acid (OH, NH, CH, or Sn/GeH). Secondary effects, such as rate acceleration in oxy-Cope reactions, are listed under the appropriate acid-base reaction.

The reactions of saline hydrides occur at the crystal surface. The crystal lattice energies decrease from LiH to CsH; KH appears to have the optimum lattice energy and hydride radius for surface reactions. It is thus usually superior to LiH or NaH in the reactions discussed below.

Acid-Base Reactions.

Oxygen Acids.

Potassium hydride reacts rapidly and quantitatively with acids such as carboxylic acids, phenols, and alcohols.[1] Of particular note is its ability to rapidly deprotonate tertiary alcohols and hindered phenols, instances where ***Sodium Hydride*** or elemental ***Potassium*** react sluggishly or not at all. For example, triethylcarbinol and 2,6-di-*t*-butylphenol are quantitatively deprotonated in less than 5 min by KH in either ether or diglyme at 20 °C (eqs 1 and 2). For triethylcarbinol, NaH is ineffective, and K is sluggish in comparison.[4]

(1)

(2)

An interesting conformational effect is seen when *p-t*-butylcalix[4]arene is tetraethylated. When KH is used as the base, the partial cone conformation predominates, whereas with NaH, the cone is produced exclusively (eq 3).[5]

(3)

An unusual cyclization of hydroxyallenes to dihydrofurans is mediated by KH (eq 4).[6] The reaction only proceeds when the K is complexed to ***18-Crown-6***, or when the base is ***Potassium t-Butoxide*** in refluxing *t*-butanol. Interestingly, no products of [1,3]- or [3,3]-rearrangement were detected.

(4)

Cyclization of a KH-generated alkoxide is a method for the 100% stereoselective formation of spiroacetals by an intramolecular 1,4-addition to sulfoxides (eqs 5 and 6).[7] Lower selectivity resulted when either NaH or ***n-Butyllithium*** was used in the first step.

The elimination of trimethylsilanol from β-hydroxysilanes is a highly selective *syn* elimination when mediated by KH (eq 7).[8] In contrast, acid-catalyzed elimination is *anti* selective. The KH reaction is complete in 1 h at rt, whereas NaH requires 20 h in HMPA and results in a lower yield of product.

The *syn* elimination (eq 7) can be coupled with an intramolecular epoxide ring-opening to effect a stereoselective synthesis of α-alkylidenetetrahydrofurans (eq 8).[9]

Rate enhancements on the order of 10^{10} to 10^{17} are observed for a [3,3]-sigmatropic rearrangement (oxy-Cope) of an *endo*-vinylbicyclo[2.2.2]octene alkoxide (generated with KH in the presence of HMPA or crown ether) vs. the alcohol (eq 9).[10] Certain substrates for this reaction are quite sensitive to impurities in the KH, but pretreatment with ***Iodine*** eliminates the problem.[3]

Rate accelerations of &egt;10^6 by alkoxides have been observed for a [4 + 2] cycloreversion (Alder-Rickert reaction).[11] Eq 10 illustrates an example; replacement of the methyls with either BOM or acetonide protecting groups is also possible.[12]

Nitrogen Acids.

Amines such as ***Diisopropylamine*** are not deprotonated by KH, although ***1,2-Diaminoethane***, diisobutylamine, and ***Pyrrolidine*** may be kaliated in excess amine solvent.[4a] *N*-Isopropylaniline and ***Hexamethyldisilazane*** are kaliated effectively and quantitatively in THF (eqs 11 and 12).[1,4b]

(12)

Deprotonation of indoles is also effective, and has been used to protect the N-H bond prior to a lithium-halogen exchange.[13] Subsequent reaction with an electrophile occurs selectively at the lithiated position (eq 13).

(13)

E = CHO, MeCO, $CONH_2$, TMS, $SnMe_3$

Carbon Acids.

Dimethyl Sulfoxide is deprotonated in <=10 min with KH in THF at rt (eq 14).[1] Under similar conditions, NaH is essentially unreactive. Cyclopentadiene (eq 15) and fluorene are deprotonated quantitatively as well.[1]

(14)

(15)

Triphenylmethane is not deprotonated directly by KH, unless a catalytic amount of DMSO[1] (via in situ formation of dimsylpotassium, which in turn deprotonates triphenylmethane) or a crown ether is present (eq 16).[14]

(16)

Potassium hydride deprotonates ketones such as acetone, cyclohexanone, and isobutyrophenone with little or no self-condensation or reduction.[1] For unsymmetrical ketones such as 2-methylcyclohexanone, a mixture of regioisomers is produced. *O*-Acylation[15] and silylation[16] are thus facilitated. Permethylation of cyclopentanone can be achieved by addition of the ketone to a THF suspension of KH, followed by ***Iodomethane*** (eq 17).[17]

(17)

Monoalkylation can be achieved by treating the potassium enolate with ***Triethylborane*** prior to alkylation (eq 18).[18]

(18)

α,β-Unsaturated ketones give γ-alkylation, although polymerization can be a problem.[1] The enamines of β-diketones, however, can be alkylated in good yield (eq 19).[19] KH also mediates the Claisen condensation of esters (eq 20).[20]

(19)

(20)

Potassium hydride facilitated a tandem intramolecular Michael reaction-Claisen condensation in the synthesis of aklavinones.[21] In the absence of any additive, the unnatural *C*-10 isomer was the only product observed in the NMR, but in the presence of 2.2.2-cryptand, the desired isomer was produced in 53% isolated yield (eq 21).

(21)

Ester enolate formation has been used to eliminate an acylamino group in a synthesis of condensed heterocycles, such as the indanone shown in eq 22.[22] The azabicycloheptene starting material is available by a Diels-Alder reaction, and the *N*-acyl group is removed in situ.

(22)

Silicon, Tin, and Germanium Acids.

Trimethylsilane, tributylstannane, and tributylgermane are efficiently metalated by KH (eq 23).[23] These reactions are sensitive to impurities in the KH,[24] but pretreatment of the KH with iodine alleviates the difficulties.[3]

$$R_3XH \xrightarrow[60\text{-}80\%]{KH,\ THF} R_3X^-\ K^+ \qquad (23)$$

X = Si, Sn, Ge
R = Me, Bu, Ph

Reductions.

Potassium salts of selenanes,[25] silanes, and stannanes are also produced by reduction of Se-Se, Si-Si, and Sn-Sn bonds by KH (eq 24).[23]

$$R_nXXR_n \xrightarrow{KH,\ THF} R_nX^-\ K^+ \qquad (24)$$

X = Se ($n = 1$), Si, Sn ($n = 3$)
R = Me, Ph

Potassium hydride reduces hindered boranes and borates to trialkyl (or trialkoxy) borohydrides.[1,26] For example, tri-*s*-butylborane is reduced in 93% yield (eq 25).

(25)

Reduction of butylpotassium with hydrogen produces a superactive form of KH that reduces ketones and alkyl halides in high yields (eq 26).[27] This active hydride also deprotonates aldehydes and ketones at low temperature, but reduction is often a side reaction.

$$C_9H_{19}CH_2Br \xrightarrow[95\%]{KH^*,\ THF} C_9H_{19}Me \qquad (26)$$

Related Reagents.

(α,β-dideprotonation of γ,δ-unsaturated ketones[1,2] and their analogs,[1,3,4] producing dianions, d^5-synthons,[5] which react with electrophiles exclusively at the δ-position[2,3])

Physical Data: see entries for ***Potassium Hydride***, ***s-Butyllithium***, and ***N,N,N´,N´-Tetramethylethylenediamine***.

α,β-Dideprotonation of Unsaturated Ketones.

This combination of reagents is used to dideprotonate γ,δ-enones in two steps. The relatively acidic α-proton is abstracted with 1 equiv of KH in THF (eq 1) and the less acidic β-proton is removed with 1 equiv of *s*-BuLi and 1 equiv of TMEDA (eq 2).[1,3] These last two reagents are simply added to the solution of the enolate. The resulting dianions, (**1**) (eq 3) and (**2**) (eq 4), react with suitable electrophiles exclusively at the δ-position[2,3] and are thus d^5-synthons.[5]

Analogous α,β-dideprotonation of γ,δ;ε,ζ-dienones yields dianions which also react with electrophiles exclusively at the terminal position. Higher yields are generally obtained when the nucleophile lacks any readily enolizable α´-protons.[1] Aldehydes, ketones (eq 4), and alkyl halides (eq 5) are all suitable electrophiles.[1,2]

Acylation of dianions (**1**) and (**2**) does not give good yields.[1] Isolated double bonds in the electrophile (eq 6) are usually not affected, and conjugated double bonds (eq 7) give Michael adducts.[1]

Alkylations and carbonyl condensations using dianions (**1**) and (**2**) are not very diastereoselective.[1] Excellent stereoselectivity can, however, be obtained with the use of epoxides as the electrophiles (eq 8).[1]

Enols such as the products of eq 4 and eq 8 cyclize, when treated with ***Sodium Methoxide*** in methanol, into THF (eq 9) and THP (eq 10) derivatives, respectively.[1,2]

α,β-Dideprotonation of Ketone Analogs.

While carboxylic acids, esters, and amides do not undergo this reaction,[3] other ketone analogs do.[1,3,4] α´-Hydroxy ketones work well (eq 11),[1] but the trianion, instead of the dianion, derivative must first be made. This is accomplished by using an extra equivalent of KH in the first step. The resulting ketones are very useful products, since they may be reacted with glycol cleaving agents to yield carboxylic acids which are then amenable to many useful transformations.[1]

(11)

Dideprotonation of dithioesters yields dianions of type (**3**) that react with electrophiles in the same fashion (eq 12).[1,4] Alternatively, the adduct (**4**) can be quenched with methyl iodide to give ketene thioacetals (eq 13).[1,4]

(3) (4)

(12)

(13)

These ketene thioacetals can be deprotonated using excess ***Lithium Diisopropylamide*** and protonated with acid or alkylated with an alkyl halide at the acetal carbon to give products of type (**5**) which can then be hydrolyzed to the ketone (eq 14).[1]

(5)

(14)

Most of the reaction products illustrated here can undergo further functional group transformations, furnishing a variety of useful synthetic intermediates.[1] There are a variety of other d^5-synthons[5] reported in the literature, some similar to those presented here. They range from Wittig reagents derived from carboxylic acid salts[6] or protected ketones,[7] to nitro compounds,[8] alkynes,[9] Grignard reagents,[10] thio-Claisen substrates,[11] and others.[12] A similar combination of reagents has also been used to dideprotonate β-carboline formamidine to produce a dianion that alkylates at C-1 (eq 15).[13]

R = Me, Bu or *t*-Bu

Potassium Hydride-Hexamethylphosphoric Triamide[1]

$KH/(Me_2N)_3PO$

(KH)

[7693-26-7] · HK · Potassium Hydride-Hexamethylphosphoric Triamide · (MW 40.11) (HMPA)

[680-31-9] · $C_6H_{18}N_3OP$ · Potassium Hydride-Hexamethylphosphoric Triamide · (MW 179.24)

(strong base used for the deprotonation of alcohols, ketones, and silanes; HMPA appears to facilitate subsequent transformations such as fragmentations and sigmatropic rearrangements)

Physical Data: see entries for ***Potassium Hydride*** and ***Hexamethylphosphoric Triamide***.

Oxygen Acids.

Potassium hydride is superior to both ***Sodium Hydride*** and lithium hydride in the deprotonation of a number of weak acids (see ***Potassium Hydride***). In the presence of HMPA, alkoxides of several allylic alcohols may be induced to fragment to allyl anions and ketones. Subsequent deprotonation of the ketone by the allylpotassium liberates propene, and workup affords a mixture of unsaturated ketones (eqs 1 and 2).[2]

In the total synthesis of the antibiotic ionomycin, Evans used the asymmetric alkylation of a prolinol amide (eq 3). Deprotonation of the

hydroxy group with KH, then deprotonation of the amide with ***Lithium Diisopropylamide***, produced the dianion. Addition of HMPA and a primary alkyl iodide afforded the alkylation product in good yield and excellent stereoselectivity.[3] Note that there are relatively few methods for the highly selective alkylation of enolates, since most enolates tend to be unreactive toward unactivated (nonallylic) alkyl halides at the low temperatures required for high selectivity.

(3)

When α-hydroxysilanes are treated with KH in HMPA, the alkoxide undergoes a stereospecific Brook rearrangement[4] producing a silyl ether which, upon hydrolysis, affords the desilylated alcohol. This rearrangement has been observed for aryl-, alkyl-, and vinyl-substituted α-hydroxysilanes (eq 4).[5]

(4)

Potassium salts of 1-vinylcyclobutanols rearrange readily to form cyclohexanones when a sulfur substituent is present at the 2-position. This reaction proceeds by a fragmentation/Michael addition mechanism (eqs 5 and 6) and provides a synthetically useful route to cyclohexanones functionalized with a 4-phenylthio group.[6]

(5)

(6)

The KH/HMPA combination reagent also accelerates [1,3]- and [3,3]-sigmatropic rearrangements. For medium-sized ring 1-vinyl alcohols, [1,3]-sigmatropic shifts predominate at rt under the influence of KH and HMPA (eq 7).[7] In contrast, thermal rearrangements of the corresponding trimethylsilyl ethers require temperatures of approximately 300 °C.

Evans found rate enhancements on the order of 10^{10} to 10^{17} for a [3,3]-sigmatropic rearrangement of an *endo*-vinyl-bicyclo[2.2.2]octene alkoxide (in the presence of HMPA or crown ether) vs. the alcohol (eq 8).[8]

Carbon Acids.

Potassium hydride may be used for the deprotonation of ketones, as illustrated by eq 9. In this example, attempts to alkylate the lithium enolate were unsuccessful.[9]

Deprotonation and alkylation of β-keto esters using KH/HMPA constitutes a key step in a cyclopentenone annulation strategy (eq 10).[10] In the absence of HMPA, the yield of this one-pot annulation drops to 27%.

In an enantiodivergent synthesis of (+)- and (-)-nonactic acid, Bartlett employed a deprotonation and intramolecular *O*-alkylation of a carbonate to obtain a tetrahydrofuran in 90% yield (eq 11).[11] It was noted that this intramolecular reaction was surprisingly facile due to the stereoelectronic effect of the *syn-syn* geometry of the carbonate. A diastereomeric furan was obtained by acid-catalyzed cyclization of the corresponding diol.

Deprotonation of a ketone with KH/HMPA may also be used in an enolate acylation process (eq 12).[12]

Rate accelerations of Claisen rearrangements were observed when aryl sulfones were deprotonated with KH/HMPA (eq 13);[13] thus significant improvements in yield (from 40 to 78%) resulted. Note that the regiochemistry of the rearrangement is thermodynamically controlled, as the more stable anion is formed even though rearrangement takes place at the more hindered site.

Silicon Acids.

Finally, when triphenylsilane is treated with KH in 1:1 HMPA/DME, triphenylsilylpotassium is produced in high yield (eq 14).[14]

Potassium Hydrogen Sulfate

$KHSO_4$

[7646-93-7] · HKO_4S · Potassium Hydrogen Sulfate · (MW 136.18)

(used in the preparation of acetals;[1] dehydrating agent[2])

Alternate Name: potassium bisulfate.

Physical Data: mp 214 °C; *d* 2.322 g cm^{-3}.

Solubility: sol water, isopropyl alcohol, acetone.

Form Supplied in: white powder or granules; fused solid.

Purification: crystallized from ethanol.

Handling, Storage, and Precautions: store in a cool dry place; hygroscopic, corrosive; wash thoroughly after repeated handling; causes burns.

Acetalization Reagent.

Isobutyraldehyde is efficiently protected as its acetal with 2-ethylhexanol in the presence of $KHSO_4$ in 93% yield (eq 1).[1] $KHSO_4$ is comparable as a catalyst to benzenesulfonic acid in yield and crude product purity and gives a better colored product as compared to the same reaction catalyzed by ***Sulfuric Acid*** (see also ***p-Toluenesulfonic Acid***).

(1)

Dehydrating Agent.

Dienones can be generated using $KHSO_4$ under acidic conditions. For example, a steroidal tosylate was refluxed for 45 min with $KHSO_4$ in acetic acid to produce the dienone as the major product (eq 2).[3] A carotenoid aldehyde has been prepared by dehydrating a monoprotected triol with $KHSO_4$ at 150 °C (eq 3).[4] The unsaturated aldehyde was produced in quantitative yield.

(2)

(3)

Treating aryl alcohols with fused $KHSO_4$ affords the corresponding alkene. For example, *m*-chlorophenylmethylcarbinol, $KHSO_4$, and a catalytic amount of *p*-*t*-butylcatechol under partial vacuum for 6 h gave *m*-chlorostyrene in 80-83% yield (eq 4).[2] Aryl alcohols are also dehydrated when treated with $KHSO_4$ in the presence of ***Copper*** powder. For example, treatment of 1-(2-fluorenyl)ethanol with a mixture of $KHSO_4$/Cu followed by sublimation at 180-200 °C for 30 min afforded the corresponding terminal aryl alkene in 31% yield and a coupled product in 17% yield.[5] $KHSO_4$ has also been used to prepare butadienes. Dehydration of 4-phenylbut-3-en-2-ol with $KHSO_4$ gave *trans*-1-phenylbuta-1,3-diene (see also ***Alumina***).[6]

(4)

Pyruvic acid has been prepared by dehydrating tartaric acid with $KHSO_4$ at 210-220 °C (eq 5).[7] Key intermediates in the synthesis of branched long chain fatty acids involve the use of $KHSO_4$. For example, treatment of the diol produced from the reaction of methyl *n*-pentyl ketone with the Grignard complex of but-4-yn-1-ol with $KHSO_4$ followed by catalytic hydrogenation and oxidation afforded 4-methylnonane-1-carboxylic acid (eq 6).[8]

(5)

(6)

Dehydrative coupling using $KHSO_4$ has been used in the synthesis of vitamin K_1. Thus treatment of 2-methyl-1,4-naphthohydroquinone-1-acetate and phytol with $KHSO_4$ in dioxane for 90 min at 76 °C gave the corresponding allene (eq 7).[9] Hydrolysis of this product gave vitamin K_1 in 50% overall yield.

(7)

$KHSO_4$ can be used to generate ethers. For example, naphthalan has been prepared in 81% yield by heating fused $KHSO_4$ and 1,8-naphthalyl alcohol for 10 min at 120 °C (eq 8).[10] Highly selective monoetherification of symmetrical diols has been accomplished by using $KHSO_4$ supported on silica gel. Treating 1,4-butanediol and dihydropyran with a catalytic amount of $KHSO_4$-SiO_2 in hexane afforded, after 50 min, 91% yield of monoether and 6% diether.[11] This catalyst system also efficiently dehydrates alcohols.[12]

Potassium Hydrogen Sulfide

KSH

[1310-61-8] · HKS · Potassium Hydrogen Sulfide · (MW 72.18)

(a nucleophile and reducing agent similar to NaSH; useful in the synthesis of thiols,[1] thioethers,[2] and thiocarbonyl compounds[3])

Physical Data: mp 455 °C; *d* 1.68-1.70 g cm^{-3}.

Solubility: very sol H_2O; sol EtOH.

Form Supplied in: commercially available as a crystalline solid; colorless when pure. May be contaminated with $K_2S_2O_3$ and K_2CO_3.

Preparative Methods: saturation of ethanolic KOH by H_2S.[4]

Handling, Storage, and Precautions: extremely hygroscopic. Darkens on heating to yellow, then deep red at mp. Aqueous solutions evolve H_2S on heating (KSH + H_2O &ibond; KOH + H_2S), and decompose in air to polysulfides and H_2S. Oxygen also yields $K_2S_2O_3$ and traces of K_2SO_3. Carbon dioxide yields H_2S and K_2CO_3. For other precautions and toxicity see ***Sodium Hydrogen Sulfide***.

Thiols.[1]

Yields from organic halides may be less satisfactory than with NaSH because of formation of greater amounts of thioether with KSH.[5] The amount of thiol may be increased at the expense of the thioether by addition of ***Hydrogen Sulfide*** or ***Sulfuric Acid***. Phase transfer catalysis is useful (eq 1).[6]

Thiocarboxylic Acids.[7]

Thiobenzoic acid (PhCOSH) is obtained in 61-76% yield by addition of ***Benzoyl Chloride*** to ethanolic KSH;[4b] it is an intermediate in the preparation of benzoyl disulfide.[4c] Anhydrides (eq 2)[8] and esters also are suitable.

Thioethers (Sulfides).[2]

As noted above, thioether formation from organic halides occurs to a greater extent with KSH than with NaSH. Modest yields (15-50%) of sulfides are obtained, along with polymers, by Michael addition of KSH to α,β-unsaturated ketones or sulfones generated in situ from ketone or sulfone and formaldehyde (eq 3).[9]

(3)

Thiocarbonyl Compounds.[3]

In general, KSH and NaSH are interchangeable with respect to their use in the generation of the thiocarbonyl functional group. The thiolysis of benzotrichloride yields the potassium salt of dithiobenzoic acid, an intermediate in the preparation of thiobenzoylthioglycolic acid, a useful thiobenzoylating agent (eq 4).[4a] Other trichlorides behave similarly.

(4)

Miscellaneous.

Treatment of 2-alkoxy-2-oxo-1,3,2-dioxaphospholanes with KSH gives a phosphodiester with a β-mercaptoethyl group that functions as a protective group easily removed by treatment with base (eq 5).[10] The *S*-substituted derivatives are more useful as protective groups since they are stable to bases as well as acids.

(5)

Related Reagents.

Bis(trimethylsilyl) Sulfide; ***Hydrogen Sulfide***; ***Sodium Hydrogen Sulfide***; ***Sodium Sulfide***.

Potassium Hydroxide

KOH

[1310-58-3] · HKO · Potassium Hydroxide · (MW 56.11)

(very strong alkali; reacts readily with acids; used in nucleophilic substitution reactions, addition reactions, and basic hydrolysis reactions; occasionally employed as a catalyst for aldol-type reactions; ethanolic solution (alcoholic KOH) is traditionally used in dehydrohalogenation of halides)

Physical Data: mp 361 °C; *d* 2.044 g cm^{-3}.

Solubility: sol 0.9 part water, 0.6 part boiling water, or 3 parts ethanol; its dissolution in water is exothermic.

Form Supplied in: white lumps, rods, or pellets; commercially available pellets contain 85-88% KOH and 10-15% water.

Handling, Storage, and Precautions: toxic (oral-rat: LD_{50}: 365 mg kg^{-1}). Corrosive. Harmful if swallowed, inhaled, or absorbed through skin. Material is extremely destructive to tissue of the mucous membranes and upper respiratory tract. Inhalation may be fatal. Do not breathe dust. Avoid contact with eyes, skin, and clothing. Store in a cool dry place. Extremely hygroscopic. Wash thoroughly after handling.[1]

Incompatible with acids, acid chlorides, acid anhydrides, and aluminum metal. Absorbs moisture and CO_2 from air.

Elimination Reactions.

Alcoholic KOH is the most frequently used base for dehydrohalogenation of alkyl halides in the synthesis of alkenes.[2] Some representative examples showing the use of KOH in elimination reactions are listed here.

Preparation of Diphenylacetylene.

Diphenylacetylene was prepared via the dehydrohalogenation of stilbene dibromide. The dibromide was heated at reflux temperature with KOH in absolute ethanol for 24 h. After workup and recrystallization, a 66-69% yield of pure diphenylacetylene was obtained (eq 1).[3]

(1)

An alternative procedure for the synthesis of diphenylacetylene used the quaternary enammonium salt of deoxybenzoin via a Hofmann elimination reaction. Thus treatment of the methylated pyrrolidine enamine of deoxybenzoin (**1**) with 40% aq KOH at reflux afforded an 86% yield of diphenylacetylene (eq 2). The reaction was not as successful with other enamines.[4]

Preparation of Muconic Acid.

Muconic acid (1,3-butadiene-1,4-dicarboxylic acid) (**3**) was prepared by dehydrohalogenation and hydrolysis of diethyl α,δ-dibromoadipate (**2**) upon heating with KOH in MeOH at reflux (eq 3). The acid was obtained in 37-43% yield.[5]

Synthesis of Coumarilic Acid.

2-Benzofurancarboxylic acid (coumarilic acid) (**5**) was prepared from coumarin dibromide (**4**) by the action of alcoholic KOH (eq 4). The product was isolated, after acidification, in 82-88% yield.[6]

Hydrolysis of Hindered Esters.

A solid-liquid phase-transfer catalysis system without organic solvents was developed for the hydrolysis of hindered esters such as mesitoic esters. The system consists of powdered KOH and 2% Aliquat 336 (methyltrioctylammonium chloride). The best results were obtained with 5 mol equiv of powdered KOH + 2% Aliquat 336 at 85 °C for 5 h (eq 5).[7]

Hydrolysis of Nitriles to Amides.

Several nitriles were chemoselectively hydrolyzed to the corresponding amides when heated at reflux in *t*-butyl alcohol containing powdered solid KOH. Thus benzonitrile was converted to benzamide in 94% yield when refluxed in *t*-BuOH containing powdered KOH for 20 min (eq 6). The amides were not further hydrolyzed to the carboxylic acids under these conditions; this was explained by the formation of an insoluble K salt which thus precluded further nucleophilic attack. The use of MeOH as a solvent resulted in a lower yield and more hydrolysis to the carboxylic acid.[8]

$$\mathrm{PhCN} \xrightarrow[\text{reflux, 20 min, 94\%}]{\text{solid KOH, } t\text{-BuOH}} \mathrm{PhCONH_2} \qquad (6)$$

Formation of Hydroxamic Acids from Ethyl Benzoate.

Potassium benzohydroxamate was prepared in 60% yield by treatment of ethyl benzoate with hydroxylamine in the presence of KOH in MeOH. The K salt was converted to benzohydroxamic acid with dil AcOH (eq 7).[9]

$$\mathrm{PhCO_2Et} + \mathrm{H_2NOH} \xrightarrow[\text{2. AcOH, 60\%}]{\text{1. KOH, MeOH}} \mathrm{PhCONHOH} \qquad (7)$$

Reduction of Aromatic Aldehydes via Crossed Cannizzaro Reaction.

Certain benzyl alcohols were prepared from the corresponding aromatic aldehydes via the crossed Cannizzaro reaction with formaldehyde and KOH in 80-90% yield.[10] Thus the reaction of *p*-tolualdehyde with formalin and KOH in methanol at 60-70 °C gave about 80% yield of *p*-methylbenzyl alcohol (eq 8).[11]

$$p\text{-}\mathrm{MeC_6H_4CHO} \xrightarrow[\text{MeOH, 60-70 °C}]{\text{HCHO, KOH}} p\text{-}\mathrm{MeC_6H_4CH_2OH} + \mathrm{HCO_2K} \qquad (8)$$

Intramolecular Aldol Reactions.

Treatment of several substituted 5-keto-2-hexenals (**6**) with KOH (2-3 equiv) in anhyd MeOH at rt for 2-3 h resulted in intramolecular aldol condensation reactions which led to the formation of the substituted phenols (**7**) in 74-100% yields (eq 9). Other catalysts including pyrrolidinium acetate, pyridinium tosylate, and $BF_3.Et_2O$ were ineffective.[12]

(9)

R^1	$R^2 + R^3$	Yield
H	$-CH_2CH_2CH(t\text{-Bu})CH_2-$	92%
Me	$-CH_2CH_2CH(t\text{-Bu})CH_2-$	96%
Me	$-CH_2CH_2CH_2-$	80%
Me	$-CH_2CH_2CH_2CH_2CH_2-$	74%

Hydroxydeamination of Primary Amines.

Treatment of 1-substituted 1-tosylhydrazines (**8**) with KOH in refluxing ethanol in the presence of atmospheric oxygen afforded the corresponding alcohols (**9**) in high yields (eq 10). The reaction is believed to proceed via the hydroperoxide (**10**), since it was the major isolated product at rt. When the hydroperoxide was subjected to the typical reaction conditions, the corresponding alcohol (**9**) was obtained in excellent yield, with ethanol presumably acting as the reductant. The procedure provides a convenient route for replacement of the nitrogen of a primary amine by a hydroxy group. The sequence includes the conversion of the primary amine into the corresponding *p*-toluenesulfonamide followed by *N*-amination using ***Chloramine*** or ***O-(Mesitylsulfonyl)hydroxylamine*** to form the tosylhydrazine.[13]

(10)

yields from tosylhydrazine:	$R = p\text{-}MeOC_6H_4$	98%
	$R = p\text{-}ClC_6H_4$	95%
	$R = C_{14}H_{29}$	91%

Reactions with Alkyl Halides.

The alkali hydroxides including KOH are very effective in nucleophilic substitution reactions of alkyl halides. Aq KOH is traditionally used to convert alkyl halides to alcohols.[14] Occasionally, it is used to convert *gem*-dihalides to ketones and trihalomethyl compounds to carboxylic acids.[15]

Reactions with Trichloromethyl Derivatives.

Treatment of a trichloromethyl derivative with KOH usually gives the corresponding carboxylic acid, e.g. 1,1-bis(*p*-chlorophenyl)-2,2,2-trichloroethane (**11**) was converted to bis(*p*-chlorophenyl)acetic acid (**12**) in 69-73% yield when reacted with KOH in aq diethylene glycol at 134-137 °C (eq 11).[15]

Substituted 1,1,1-trichloromethyl-2-ols [(trichloromethyl)carbinols] react with methanolic KOH to form substituted α-methoxyacetic acids (**15b**) in excellent yields if the substituent group is aryl, alkyl or dialkyl, or vinyl. The reaction fails with ethynylcarbinols. The reaction works equally well if methanol is replaced by ethanol or other alcohols. In a proposed mechanism, the (trichloromethyl)carbinol (**13**) is converted in situ to the dichloro epoxide (**14**). The epoxide is opened by methanol to give (**15a**) which is converted to the acid (**15b**) under the reaction conditions and workup (eq 12).[16]

Preparation of (Trichloromethyl)carbinols.

Several (trichloromethyl)carbinols were synthesized in very good yields from aldehydes or ketones upon treatment with $CHCl_3$ in DMF in the presence of methanolic KOH (eq 13). The MeOH/DMF mixture provided a homogeneous reaction that permitted facile product formation at low temperature and was superior to using either solvent alone.[17]

Oxidation of Aromatic Compounds.

2,3-Dimethyltetrahydroanthraquinone (**16**) was dehydrogenated to 2,3-dimethylanthraquinone (**17**) upon treatment with ethanolic KOH and air for 24 h (eq 14). The product was isolated in 94-96%.[18]

(14)

(16) **(17)**

Benzylation of Aromatic Primary Amines.

Heating a mixture of a primary aromatic amine and benzyl alcohol in the presence of KOH at a temperature between 250-280 °C (eq 15) gave the corresponding *N*-benzyl aromatic amine in high yield.[19] For example, heating a mixture of 2-aminopyridine (1 equiv) and benzyl alcohol (1.4 equiv) to 250 °C in the presence of a catalytic amount of KOH (0.14 equiv) afforded 2-(benzylamino)pyridine in 98-99% yield.[20]

$$ArNH_2 + PhCH_2OH \xrightarrow[250\text{-}280\ ^\circ C]{KOH} ArNHCH_2Ph \qquad (15)$$

Ar = 2-pyridyl, 98-99%

Reductive Benzylation of Aromatic Nitro Compounds.

Treatment of various aromatic nitro compounds with excess benzylamine and KOH at 225-260 °C, while removing the water generated, resulted in the formation of *N*-benzyl aromatic amines in low yields (11-51%). Under these conditions the nitro compound was first reduced to the aniline, which was benzylated according to the previous reference (eq 16).[21]

$$ArNO_2 \xrightarrow[KOH]{PhCH_2OH} [ArNH_2] \xrightarrow[KOH]{PhCH_2OH} ArNHCH_2Ph \qquad (16)$$

Conversion of Lactones into Benzyloxy Carboxylic Acids.

Treatment of lactones with benzyl chlorides and powdered KOH in dry toluene at reflux temperature resulted in their conversion to the corresponding benzyloxy carboxylic acids.[22] The reaction was used to prepare γ-, δ-, and ε-benzyloxy or *p*-methoxybenzyloxy carboxylic acids from the appropriate lactones (eq 17).[23]

(17)

$n = 1$, 2, or 3 Ar = Ph, p-$MeOC_6H_4$

Rearrangement.

The substituted 4-hydroxycyclohexanone (**18**) rearranged partially to the isomeric compound (**19**) when heated with KOH in 35:1 *t*-BuOH-H_2O at reflux (eq 18). The reaction was reversible and the ratio of (**18**):(**19**) at equilibrium was 65:35. The rearrangement was explained by

a base-induced transannular 1,4-hydride shift.[24]

(18)

Epimerization of *meso*-Hydrobenzoins.

(±)-Hydrobenzoin (**21**) was obtained in 64% yield by heating either *erythro*- or *threo*-3-phenylglyceric acid (**20a**) with KOH to 160 °C under reduced pressure. Under these conditions the (±)-diastereomer of hydrobenzoin is the thermodynamically more stable isomer. Thus applying the reaction to *meso*-hydrobenzoin (**20b**) gave the pure (±)-isomer in 90% yield in a few minutes (eq 19). Lower conversion (70%) was obtained with ***Potassium*** metal in refluxing toluene, and an attempt to use NaOH was unsuccessful. The KOH epimerization was applied successfully to certain other substituted *meso*- and *erythro*-hydrobenzoins.[25]

(19)

Huang-Minlon Modification of the Wolff-Kishner Reduction.

The use of KOH was introduced as a substitute for metallic ***Sodium*** or ***Sodium Methoxide*** in Wolff-Kishner reductions of ketones. This modification allowed the use of ***Hydrazine*** hydrate and made the procedure simpler and economical.[26]

Removal of 2-Hydroxypropyl Group in *p*-Ethynylbenzoic Acid Synthesis.

Potassium *p*-ethynylbenzoate (**23**) was obtained from 4-[4-(methoxycarbonyl)phenyl]-2-methyl-3-butyn-2-ol (**22**) in 98.5% yield and 99% purity upon heating at reflux in BuOH and 4 equiv of KOH (or NaOH) for 10 min (eq 20). The salt was precipitated from solution as it was formed.[27]

Potassium Hydroxide-Alumina

KOH/Al_2O_3

(KOH)

[1310-58-3] · HKO · Potassium Hydroxide-Alumina · (MW 56.11) (Al_2O_3)

[1344-28-1] · Al_2O_3 · Potassium Hydroxide-Alumina · (MW 101.96)

(hydrolysis of esters; alkylation of alcohols, amides, and phenylacetonitrile)

Physical Data: see entries for ***Potassium Hydroxide*** and ***Alumina***.

Preparative Methods: mixing neutral alumina and a KOH solution produces a nearly homogeneous adsorbate (reagent **1**), referred to as basic alumina.[1] Another form of basic alumina (reagent **2**) is prepared by mixing dried neutral alumina (100 °C for 24 h) with solid KOH.[2]

Hydrolysis of Esters.

Cholestan-3β-yl 3,5-dinitrobenzoate and other steroidal and triterpenoid 3,5-dinitrobenzoate esters were readily hydrolyzed by adsorbing a benzene solution of the ester on a column of reagent (**1**) and eluting it with a 3:1 benzene-ether mixture to give the alcohol in good yield (eq 1).[3]

Reagent (**1**) gave slower reaction rates with less reactive esters[3] and better results were obtained from reagent (**2**). Stirring a solution of *n*-decyl benzoate in ether with reagent (**2**) at rt for 48 h gave *n*-decyl alcohol and benzoic acid in 91% and 89% isolated yields, respectively (eq 2).[2] Other esters were hydrolyzed in isolated yields between 80-100% for either the alcohol or acid product. Control experiments showed that a dried KOH/alumina reagent at 110 °C gave no reaction and a small amount of water was required for the hydrolytic activity.[2]

Various reactions of basic alumina (reagent **1**) with several classes of organic compounds were reported in an early short review.[4] Some of these reactions are presented in eqs 3-5. Treatment of allyl bromide or propargyl bromide with basic alumina in ether for 4 days gave diallyl ether and dipropargyl ether, respectively, in low yields (eq 3).[4]

Either 1-chloro- or 1-bromocyclohexanone was converted to 2-hydroxycyclohexanone in 64% yield after a few minutes upon treatment with basic alumina.[4] The product dimerized slowly upon standing at rt (eq 4).

Preparation of β-ethoxycinnamaldehyde by the hydrolysis of the corresponding dimethyliminium perchlorate salt was achieved with basic alumina in nearly quantitative yield (eq 5).[4]

Selective α-Monoalkylation of Phenylacetonitrile.

Alumina impregnated with KOH acted as an efficient base for the selective α-monoalkylation of phenylacetonitrile with alkyl halides in benzene (eq 6). It was suggested that the reaction occurs predominantly in the pores of the KOH/Al_2O_3 solid base. The high selectivity towards monoalkylation in nonpolar solvents was explained by the tight adsorption of the anion of the initial monoalkyl product onto the wall of the pore, thus rendering it strongly sterically hindered for a second alkylation.[5]

Selective *N*-Monoalkylation of Amides with Alkyl Halides.

Selective *N*-monoalkylation of amides was carried out successfully using KOH-alumina (eq 7). The best solvent for this reaction was dioxane which gave consistently the highest mono:dialkyl ratio. Unlike the previous reaction, the use of a mixture of powdered KOH and alumina was superior to the use of the KOH-impregnated alumina in both yield and selectivity. Also, alkyl bromides were better than the iodides. Reported yields ranged from 56% to 80% with selectivity towards *N*-monoalkylation ranging between 82-99%.[6]

$$R^1CONH_2 + R^2X \xrightarrow[\text{dioxane}]{KOH/Al_2O_3} R^1CONHR^2 \qquad (7)$$

Potassium Hydroxide-Carbon Tetrachloride

KOH-CCl_4

(KOH)

[1310-58-3] · HKO · Potassium Hydroxide-Carbon Tetrachloride · (MW 56.11) (CCl_4)

[56-23-5] · CCl_4 · Potassium Hydroxide-Carbon Tetrachloride · (MW 153.81)

(ketones, alcohols, and sulfones react with CCl_4/KOH, usually in *t*-BuOH, to give a variety of products[1])

Physical Data: see entry for ***Potassium Hydroxide***.

Reactions with Ketones.

Reactions of ketones with CCl_4-KOH in *t*-BuOH generally fall into four categories.[1,2]

- 1)Ketones with α- and α´-hydrogens were transformed into carboxylic acids, resulting from Favorskii rearrangement of an intermediate α-chloro ketone (eq 1).[1,2]

- 2)Hindered ketones with α- but no α´-hydrogens were α-chlorinated but do not undergo any further reaction, e.g. the reaction with ketone (**1**) to give the α-chloro ketone (**2**) (eq 2).[2]

- 3)Some ketones with α- but no α´-hydrogens were α-chlorinated and then converted to the α-hydroxy derivative (eq 3).[2]

- 4)Some ketones with α- but no α´-hydrogens were α-chlorinated and subsequently cleaved into carboxylic acids,[1,2] e.g. pinacolone gave ***Pivalic Acid*** in 80% yield (eq 4).

Another example was the reaction with estrone and estrone 3-methyl ether (**3a,b**) which gave the α,α-dichloro derivatives (**4**) that were rapidly cleaved to the 16,16-dichlorodoisynolic acids (**5**) (eq 5).[2]

Reactions with Alcohols.

Primary and secondary alcohols were oxidized to aldehydes and ketones respectively upon reaction with CCl_4-KOH in *t*-BuOH. Both initial products further react to form other products. Stable aldehydes (e.g. pivalaldehyde) and stable ketones (e.g. benzophenone) could be isolated. Tertiary alcohols were unreactive.[1]

Reactions with Sulfones.

Based on their structure and the outcome of the reaction, sulfone reactions can be classified into three categories.[1]

- 1)Aryl alkyl sulfones were mono-, di-, and trichlorinated (eq 6). Intermediate trichloromethyl sulfones may be cleaved to aryl sulfonic acids under the reaction conditions (eq 7).[1]

$$PhSO_2CH_2Ph \xrightarrow[100\%]{KOH,\ CCl_4} PhSO_2CCl_2Ph \qquad (6)$$

$$ArSO_2Me \xrightarrow[CCl_4]{KOH} ArSO_2CH_2Cl \rightleftharpoons ArSO_2CCl_3 \longrightarrow ArSO_3H \qquad (7)$$

- 2)Dibenzyl sulfones were converted to stilbenes. This was explained by the initial formation of α-chloro sulfones, then a 1,3-elimination of HCl, followed by extrusion of SO_2 to form the alkene; a sequence known as the Ramberg-Bäcklund reaction (eq 8).[1]

Treatment of the cyclic sulfone (**6**) with KOH-CCl_4 and *t*-BuOH at 50 °C overnight resulted in a similar Ramberg-Bäcklund reaction to give a mixture of the hydroindenones (**7**) and (**8**) (eq 9).[3]

The conjugated triene (**10**) was similarly obtained from the diallyl sulfone (**9**) by KOH-CCl_4 at rt (eq 10).[4]

(10)

(9) **(10)**

Di-primary alkyl sulfones (**11**) gave, unexpectedly, the *cis*-dialkylethylenesulfonic acid K salts (**12**) (eq 11). Symmetrical sulfones gave single isomeric *cis* products while unsymmetrical sulfones gave two isomeric *cis* products.[5,6]

(11)

(11) **(12a)** **(12b)**

- 3)Di-*s*-alkyl sulfones were converted into alkenes and alkene-dichlorocarbene adducts (1,1-dichlorocyclopropanes).[1]

Dichlorocyclopropanation of Alkenes.

The generation of dichlorocarbene in the reaction of KOH-CCl_4 with sulfones in *t*-BuOH was used as a tool for dichlorocyclopropanation of alkenes in yields ranging from 45-93%, e.g. the reaction of 1,1-diphenylethylene with KOH, CCl_4, *t*-BuOH, and Me_2SO_2 to give 1,1-dichloro-2,2-diphenylcyclopropane in 93% yield (eq 12).[7]

Potassium Hydroxide-18-Crown-6

(KOH)

[1310-58-3] · HKO · Potassium Hydroxide-18-Crown-6 · (MW 56.11) (18-crown-6)

[17455-13-9] · $C_{12}H_{24}O_6$ · Potassium Hydroxide-18-Crown-6 · (MW 264.36) (dicyclohexano-18-crown-6)

[16069-36-6] · $C_{20}H_{36}O_6$ · Potassium Hydroxide-Dicyclohexano-18-crown-6 · (MW 372.56) (dibenzo-18-crown-6)

[14187-32-7] · $C_{20}H_{24}O_6$ · Potassium Hydroxide-Dibenzo-18-crown-6 · (MW 360.44)

(ester hydrolysis; nucleophilic substitutions; ketone alkylation)

Physical Data: see entries for ***Potassium Hydroxide***, ***18-Crown-6***, ***Dicyclohexano-18-crown-6***, and ***Dibenzo-18-crown-6***.

Hydrolysis of Sterically Hindered Esters.

Methyl and *t*-butyl esters of mesitoic acid were saponified by the KOH complex of dicyclohexano-18-crown-6 in aromatic hydrocarbons such as toluene at reflux temperature (104-111 °C) for 5 h to give mesitoic acid in high yields (eq 1).[1]

(1)

R = Me, 93%; *t*-Bu, 94%

Aromatic Nucleophilic Substitutions.

The KOH/dicyclohexano-18-crown-6 complex in toluene was prepared by solvent exchange from MeOH.[1] It contained 11% hydroxide ion and 89% methoxide ion.[2] Reaction of *o*-dichlorobenzene with this complex at 90 °C for 1 h gave *o*-chloroanisole in 40-50% yield. No phenol or other products from hydroxide ion were obtained. *m*-Chloroanisole was obtained from *m*-dichlorobenzene in a low yield.[2]

2-Alkoxy-3-cyanopyridines were prepared by the nucleophilic displacement of 2-chloro-3-cyanopyridine with alcohols in toluene and KOH/18-crown-6. Primary alcohols reacted within 3 h at 25 °C and gave the 2-alkoxy-3-cyanopyridines in about 85% yields (eq 2).

Secondary alcohols reacted slower and gave lower yields, while *t*-BuOH did not react. The less reactive 2-chloropyridine required heating.[3] Similar results were obtained from ***Sodium Hydroxide***-Aliquat 336 in toluene (see ***Methyltrioctylammonium Chloride***).

(2)

R	time	yield (%)
Bn	3 h	85
C_8H_{17}	3 h	85
i-Pr	18 h	67

Removal of Benzylidene Blocking Groups.

Benzylidene groups blocking the α-methylene positions of several ketones were removed under relatively mild conditions when treated with 4-aminobutyric acid and KOH in DMSO or HMPA in the presence of dibenzo-18-crown-6 as a catalyst. The reaction temperature varied from 85 to 115 °C and the isolated yields were 41-56%. The yields were lower in the absence of the amine and the reaction was slower in the absence of the crown ether. The retroaldol cleavage of the intermediate β-hydroxy ketone is facilitated by the imine formation (eq 3).[4]

(3)

Alkylation of Arylalkynes.

Terminal arylalkynes were alkylated efficiently with alkyl iodides in benzene at 80 °C in the presence of powdered KOH and a catalytic amount of 18-crown-6 (eq 4).[5]

Permethylation of Ketones.

Several ketones were completely methylated at their α-position(s) when treated with ***Iodomethane***, powdered KOH, and a catalytic amount of 18-crown-6 in toluene at 70 °C,[6] e.g. 2,2,6,6-tetramethylcyclohexanone was prepared from cyclohexanone and pivalophenone from acetophenone (eq 5) in 93% and 89%, respectively, via this procedure.

Reduction of Aromatic Nitro Compounds.

Aromatic amines were prepared by reduction of the corresponding nitroarenes with ***Dodecacarbonyltriiron*** in benzene and the catalytic effect of KOH/18-crown-6 at rt under N_2 in 60-84% yield. Twice the amount of $Fe_3(CO)_{12}$ at reflux temperature was needed in the absence of the KOH/18-crown-6 system.[7]

Decarboxylation of Activated Esters.

Malonic esters, β-keto esters, and α-cyano esters were decarboxylated via a one-pot procedure upon treatment with KOH and equimolar amounts of 18-crown-6 in benzene-ethanol or dioxane-ethanol (eq 6).[8]

Synthesis of α,β-Unsaturated Nitriles.

MeCN was condensed smoothly with a variety of aldehydes and ketones when treated with KOH in the presence or absence of 18-crown-6 to give α,β-unsaturated nitriles in isolated yields ranging from 50 to 86% (eq 7).[9]

Potassium Hydroxide-Dimethyl Sulfoxide

KOH-Me_2SO

(KOH)

[1310-58-3] · HKO · Potassium Hydroxide-Dimethyl Sulfoxide · (MW 56.11) (DMSO)

[67-68-5] · C_2H_6OS · Potassium Hydroxide-Dimethyl Sulfoxide · (MW 78.15)

(very strong base; low nucleophilicity due to low solubility which allows only surface reactivity[2])

Physical Data: see entries for ***Potassium Hydroxide*** and ***Dimethyl Sulfoxide***; KOH/DMSO has pK_a of 27 or higher.[1]

Alkylation of Amides, Phenols, Alcohols, and Acids.

A variety of carboxamides were alkylated with primary alkyl halides using KOH in DMSO to give the *N*-alkyl amides (eq 1) in 54-90% yield. Most reactions were carried out at rt, but in some cases heating to 90 °C was required.[3] Similar conditions were applied to alcohols, phenols, and acids to form ethers and esters.[4] The procedure applies to MeI and all primary halides. Secondary alkyl halides show evidence of competitive dehydrohalogenation, while tertiary halides do not give any alkylation products. The procedure was applied to the *N*- and *O*-permethylation of peptides.[4] It was also applied to the methylation of hydroxypyridines in 39-78% yield.[5] In all the above cases, the substrate and alkyl halide were added to powdered KOH in DMSO and stirred at rt. It was unnecessary to use especially dry DMSO or to protect the reaction mixture from atmospheric moisture.

(1)

N-Alkylation of Indoles and Pyrroles.

N-Alkyl indoles and pyrroles were prepared in high yields (85-95%) by reaction of indoles and pyrroles with primary alkyl halides in DMSO and powdered KOH at rt (eq 2). The yields were lower with secondary halides (60% for *N*-isopropylindole), while tertiary halides gave no alkylation products.[6]

(2)

Alkylation of Ketones.

Ketones can be permethylated with ***Iodomethane*** in DMSO containing solid KOH. Cyclobutanone, cyclopentanone, and indanone gave the corresponding tetramethyl ketones in 49, 90, and 75% yields, respectively. All reagents can be used without drying and KOH can be used as pellets or as a powder.[2]

Synthesis of *O*-Arylhydroxylamines.

Reaction of tricarbonylchromium complexes of aryl halides (**1**) with *N*-*t*-butoxycarbonylhydroxylamine (**2**) in DMSO and powdered KOH under N_2 at rt resulted in the nucleophilic substitution of the Cl to give the corresponding tricarbonyl[(*t*-butoxycarbonylaminoxy)arene]chromium complexes (**3**) (eq 3). Consecutive I_2 treatment and acid hydrolysis gave the *O*-arylhydroxylamines in high overall yields.[7]

Hydroxylation of Ketones.

Treatment of the ketone (**4**) with KOH in warm DMSO in the presence of O_2 followed by the in situ reduction of the intermediate hydroperoxide with dithionite gave (**5**) as a 1:1 mixture of diastereomers (eq 4).[8]

Synthesis of (*E*)-β-(Benzyloxy)styrenes from Benzyl Alcohols.

(*E*)-β-(Benzyloxy)styrenes (**7**) were obtained from the reaction of benzyl alcohols (**6**) with KOH/DMSO (eq 5) in 56-92% yields. This result was explained by an initial oxidation to the benzaldehyde followed by a condensation with DMSO anion to form intermediate (**8**). Subsequent addition of benzyloxide anion to (**8**) and elimination of $MeSO^-$ gives the product (**7**). The incorporation of the DMSO carbon was confirmed by ^2H and ^{13}C labelling. The methyl styryl sulfoxide intermediate (**8**) was independently synthesized and converted into (**7**) under identical reaction conditions.[9]

(5)

Preparation of *N*-Vinylpyrroles.

The reaction of ketoximes having at least one α-CH_2 group with acetylene in DMSO/KOH at 80-120 °C under atmospheric pressure gave *N*-vinylpyrroles in average yields of 70-80% via an intermediate pyrrole (eq 6). The conditions are also suitable for *N*-vinylation of pyrroles and other NH heterocycles in good yields.[1b]

Potassium Hydroxide-Hexamethylphosphoric Triamide

$KOH\text{-}(Me_2N)_3PO$

(KOH)

[1310-58-3] · HKO · Potassium Hydroxide-Hexamethylphosphoric Triamide · (MW 56.11) (HMPA)

[680-31-9] · $C_6H_{18}N_3OP$ · Potassium Hydroxide-Hexamethylphosphoric Triamide · (MW 179.24)

(strongly basic; esterification of hindered acids; additions to alkynes; ketone oxidations)

Physical Data: see entries for ***Potassium Hydroxide*** and ***Hexamethylphosphoric Triamide***.

Esterification of Hindered Carboxylic Acids.

Esters of hindered carboxylic acids, such as dialkyl and trialkyl acetic acids and mesitoic acid, were synthesized in high yields using alkyl halides, HMPA and EtOH as cosolvents, and KOH at 50 °C (eq 1). Esterifications were very rapid, near quantitative, and allowed the preparation of methyl and other alkyl esters.

$$RCO_2H + R'X \xrightarrow[\text{EtOH, 50 °C}]{\text{KOH/HMPA}} RCO_2R' \qquad (1)$$

Under these conditions, some dialkyl acetic acids were esterified to the methyl esters in 5 min with 98% conversion. The trialkyl acetic acid 2-methyl-2-propylpentanoic acid (**1a**) was quantitatively converted to the methyl ester (**1b**) in 30 min. Interestingly, the rate of reaction for the branched acid (**1a**) was about 5 times that of its straight chain analog, nonanoic acid. Mesitoic acid (**2a**) was esterified with ***Iodomethane*** in 20 min to give the methyl ester (**2b**) in 96% yield and with 2-iodooctane to give the 2-octyl ester (**2c**) in 80% yield in 2 h. The reaction was slower in the absence of HMPA as a cosolvent and gave significantly lower conversions.[1]

(1a) R = H
(1b) R = Me

(2a) R = H
(2b) R = Me
(2c) R = 2-octyl

Additions to Acetylene.

Addition of H_2S to acetylene in the superbasic medium of KOH/HMPA gave ethanethiol as the only product. Under these conditions, the initial addition product, the vinylthiol anion, was reduced to give the product (eq 2).[2] The reaction in DMSO gave, among other products, divinyl sulfide.[2]

The reaction of elemental tellurium with acetylene in HMPA and KOH gave divinyl telluride in >50% yield (eq 3).[2]

Preparation of Divinyloxypropenes.

Divinyloxypropenes (**3**) and (**4**) were obtained from the reaction of glycerol with acetylene in HMPA in the presence of KOH under a pressure of 10 atm at 150-160 °C for 2 h (eq 4). The product mixture (~25% overall yield) contained *cis*- and *trans*-1,2-divinyloxypropenes (**3**) (11%) and 2,3-divinyloxypropene (**4**) (1%) in addition to 2-methyl-4-vinyloxymethyl-1,3-dioxolane (**5**) (~7%) and 2-vinyloxy-1,3-butadiene (**6**) (~5%).[3] In the absence of HMPA the major reaction product was the 1,3-dioxolane (**5**) (33-66%), depending on the reaction conditions.[4]

(3) **(4)** **(5)** **(6)**

Oxidation of Ketones.

Oxidations of acetophenone to benzoic acid (eq 5) and cyclic ketones to dicarboxylic acids (eq 6) were carried out with O_2 in the presence of KOH (or NaOH) in HMPA. The use of HMPA was superior to hydroxylic solvents, water, DMF, or DMSO. Either KOH or NaOH was an equally effective base catalyst, but LiOH was extremely poor. In the oxidation of acetophenone, addition of water slowed down the rate of oxidation but minimized the side reactions arising from the ketone enolate, thus increasing the selectivity to acidic products. Yields were moderate to excellent.[5]

Potassium Iodide[1]

KI

[7681-11-0] · IK · Potassium Iodide · (MW 166.00)

(source of iodide ion for nucleophilic displacement reactions;[4-9] cleaves some ethers in the presence of acid;[10-12] acts as a mediator in electrochemical oxidations of aldehydes;[13] reacts with sulfonyl chlorides to give symmetrical thiosulfonic *S*-esters;[14] with oxidizing agents, iodinates aromatic compounds;[15] iodinates organothallium compounds[16])

Physical Data: mp 681 °C; bp 1330 °C; *d* 3.130 g cm^{-3}.

Solubility: very sol cold H_2O (127.5 g/100 mL, 6 °C), hot H_2O (208.0 g/100 mL, 100 °C); sol alcohol (1.88 g/100 mL, 25 °C), acetone (1.31 g/100 mL, 25 °C); slightly sol ether, ammonia.[2]

Form Supplied in: white solid (crystalline, granular, or powder); widely available. *Drying:* can be dried under vacuum over P_2O_5 at 70-100 °C.[3]

Handling, Storage, and Precautions: slightly deliquescent in moist air, and upon long exposure to air will turn yellow due to liberation of iodine; storage in a dry or inert atmosphere recommended.

Introduction.

KI is used primarily as a source of iodide in organic synthesis. KI can often be used interchangeably with NaI (see ***Sodium Iodide*** and ***Tetra-n-butylammonium Iodide***).

Displacement Reactions.

KI will react with alkyl halides to give alkyl iodides. Alkyl iodides have been prepared from alkyl chlorides and bromides using KI supported on alumina.[4] The product iodide may be isolated or may react with a second nucleophile (e.g. ***Dimethyl Sulfoxide***).[5] KI/***Phosphoric Acid*** has been used to convert 1,6-hexanediol to 1,6-diiodohexane[6] and cyclohexene to cyclohexyl iodide.[7] KI reacts with aryl diazonium compounds to give aryl iodides.[8] This reaction has been shown to involve radicals, and proceeds faster and in higher yield in the absence of oxygen.[9]

Ether Cleavage Reactions.

KI in acetic acid or formic acid has been used to cleave aryl methyl ethers in high yield (yields were somewhat higher with KI than with NaI).[10] KI/H_3PO_4 has been used to convert THF to 1,4-diiodobutane.[11] KI/***Boron Trifluoride Etherate*** cleaves methyl, allyl, and benzyl ethers and opens cyclic alkyl ethers (including THF and epoxides) to give iodo alcohols.[12] Aryl methyl ethers are cleaved slowly by this reagent, allowing for some selectivity.

Electrochemical Oxidations.

KI has been used as a catalytic mediator in the electrochemical oxidation of aldehydes to esters[13] and nitriles.[13c] (NaI and Et_4NI may be used in place of KI in these electrochemical oxidations.)

Preparation of Symmetrical Thiosulfonic *S*-Esters.

KI reacts with sulfonyl chlorides (RSO_2Cl) to give thiosulfonic *S*-esters (RSO_2SR).[14]

Iodination of Aromatic Hydrocarbons.

$KI/O_2/NO^+BF_4^-$ in TFA/CH_2Cl_2 or TFA iodinates aromatic hydrocarbons; however, the reaction fails with electron-deficient aromatics.[15] (NaI, *n*-Bu_4NI, and ***Iodine*** may be substituted for KI.) KI reacts with arylthallium bis(trifluoroacetate) compounds to give aryl iodides (and thallium triiodide) (eq 1).[16] Vinyl iodides have been prepared similarly from vinylthallium bis(trifluoroacetates).[16f]

Potassium Iodide-Zinc/Copper Couple

KI-Zn/Cu

(KI)

[7681-11-0] · IK · Potassium Iodide-Zinc/Copper Couple · (MW 166.00) (Zn/Cu)

[53801-63-1]

(agent for elimination of vicinal oxygen functionality[1])

Physical Data: see entries for ***Potassium Iodide*** and ***Zinc/Copper Couple***.

Vicinal Oxygen Elimination.[1]

Vicinal sulfonyloxy groups are eliminated by this reagent (eq 1). Although the reported yield from (**1**) is low, this procedure represented an improvement in both yield and reproducibility over previous methodology (zinc dust-sodium iodide).[2] With different *O*-protection, however, the fairly vigorous conditions caused loss of the 4-benzoyl group of (**2**) (eq 2), although it is still noteworthy that, in both cases, epimerization was not observed. The reaction is reported[1] to be slightly slower if ***Sodium Iodide*** is used in place of the potassium salt, although such a modification has been reported elsewhere[3] as quite adequate to eliminate the diol monosulfonate (**3**) (eq 3).

This reductive elimination of vicinal disulfonates has also been reported with NaI alone[4] in ketonic solvent, and with ***Sodium Anthracenide***[5] (for mesylates but not tosylates). With the exception, perhaps, of the latter, all of these comparable methods seem to be sufficiently mild to work effectively in the area of stereochemically sensitive molecules, the carbohydrates.

Related Reagents.

Sodium Iodide; ***Sodium Iodide-Copper***; ***Zinc***; ***Zinc-Acetic Acid***; ***Zinc Iodide***.

Potassium Methoxide-Dicyclohexano-18-crown-6

[52374-55-7] · $C_{21}H_{39}KO_7$ · Potassium Methoxide-Dicyclohexano-18-crown-6 · (MW 442.70)

(complex provides a strongly basic and nucleophilic methoxide ion[2])

Physical Data: reagent is prepared in situ.

Form Supplied in: MeOK is commercially available as a white powder in 95% purity; a mixture of the *syn-cis* and *anti-cis* crown ethers is commercially available.[1]

Preparative Methods: a toluene solution referred to as containing ***Potassium Hydroxide*** and ***Dicyclohexano-18-crown-6*** is obtained by mixing the crown ether and 85% KOH in MeOH, adding toluene, removing the MeOH at 100 °C under vacuum, and filtering the mixture.[3] However, the solubility of the KOH-crown ether complex is apparently much less than the MeOK complex.[2] Thus the toluene solution contains ca. 89% of the methoxide ion and only 11% of the hydroxide ion.[2] The direct preparation of the hydroxide complex was unsuccessful.[4]

Experimentally, complexes are most often generated in situ by adding 1.0 equiv or more of the crown ether to a solution of the base in MeOH or another solvent.

Handling, Storage, and Precautions: do not breathe dust from the base or vapor from the crown ether; avoid contact of both substances and the complex with the eyes, skin, or clothing. Handle reagents and conduct reactions under an inert nitrogen or argon atmosphere.[1] Use in a fume hood.

Nucleophilic Substitution Reactions.

The ability of dicyclohexano-18-crown-6 to dissociate MeOK by complexation with the potassium cation clearly manifests itself in various nucleophilic aromatic substitution reactions. The complex prepared by the solvent exchange reaction described above reacts with *o*-dichlorobenzene at 90 °C over 16 h to give *o*-chloroanisole in 40-50% yield (eq 1).[2] *m*-Dichlorobenzene is converted into *m*-chloroanisole under the same conditions, but the yield is much lower. Isomeric products which may arise from a benzyne intermediate are not produced in either case. Thus the nucleophilic aromatic substitution must proceed by an addition-elimination mechanism.[2]

(1)

The rates of nucleophilic aromatic substitution of *o*- and *p*-fluoronitrobenzene by MeOK/MeOH are approximately the same; also, the addition of dicyclohexano-18-crown-6 has a negligible effect on the *ortho*:*para* rate ratio.[5] On the other hand, if ***Potassium t-Butoxide-t-Butyl Alcohol Complex*** is employed for the reaction, the *ortho*:*para* reactivity ratio is 3.6×10^2. The higher reactivity of the *ortho* isomer in the solvent of lower polarity, i.e. *t*-BuOH, is attributable to bridging between the oxygen atoms of the nitro group and the potassium cation. When 1.0 equiv of dicyclohexano-18-crown-6 is added to the *t*-BuOK/*t*-BuOH, the *ortho*:*para* reactivity ratio approaches unity because the potassium ion is strongly complexed to the crown ether and is unable to assist in the substitution reaction of the *o*-fluoronitrobenzene.[5]

When 1.0 equiv of dicyclohexano-18-crown-6 is added to a solution of MeOK in 99% PhH-MeOH, there is a 300-fold increase in the rate of nucleophilic aromatic substitution of 1-chloro-2,4-dinitrobenzene.[6] However, in MeOH containing less than 50% by weight of benzene, the addition of the crown ether has a negligible effect on the rate.[4] Because of the relatively high polarity of MeOH, the reactivity of the methoxide ion is not influenced significantly by the presence of the crown ether.

Dehydrohalogenation Reactions.

In the dehydrohalogenation of 2-bromobutane, the use of MeOK in MeOH, or other primary alkoxides in the corresponding alcohols, greatly favors Saytzeff elimination and gives a relatively large *trans*:*cis*-2-butene ratio, i.e. 3.34:1 (eq 2).[7] However, with tertiary alkoxides, e.g. *t*-BuOK, in the corresponding alcohols Hofmann elimination becomes much more important and the *trans*:*cis*-2-butene ratio approaches unity.[7] This trend is explained by the postulate that in the solvent of lower polarity, the elimination is promoted by the associated metal alkoxide. As expected, the addition of 1.0 equiv of dicyclohexano-18-crown-6 to the MeOK/MeOH has little effect on the 1-butene:2-butene ratio or the *trans*:*cis*-2-butene ratio.[7] However, when the crown ether is added to the *t*-BuOK/*t*-BuOH, the 1-butene:2-butene ratio decreases and the *trans*:*cis*-2-butene ratio increases.

(2)

			trans:*cis*-2-butene
MeOK/MeOH	15.4%	84.6%	3.34:1
MeOK/dicyclohexano-18-crown-6/MeOH	16.3%	83.7%	3.43:1
t-BuOK/*t*-BuOH	41.6%	58.4%	1.78:1
t-BuOK/dicyclohexano-18-crown-6	31.2%	68.8%	3.20:1

Experiments in which metal alkoxides are used to effect β-elimination of methoxide ion from 1-methoxy-2-deuterioacenaphthenes show that an ElcB mechanism is involved (eq 3).[8] The more associated bases, e.g. *t*-BuOLi/*t*-BuOH, strongly favor exchange and elimination of the hydrogen *syn* to the methoxy group. This is attributable to strong coordination between the metal cation of the ion pair and the ether oxygen of the substrate. With a relatively dissociated base such as MeOK/MeOH, the *syn* and *anti* protons undergo exchange at comparable rates and *anti* elimination of the methoxide ion is slightly favored over *syn* elimination. The addition of dicyclohexano-18-crown-6 does not alter the stereochemistry of the exchange with MeOK. The use of *t*-BuOK/*t*-BuOH favors *syn* elimination and exchange somewhat, but in the presence of 1.0 equiv of the crown ether *anti* exchange and elimination

are both favored.[8] Apparently, when the potassium cation is no longer able to complex with the oxygen of the substrate, the *t*-butoxide ion abstracts the *anti* proton preferentially for steric reasons.

Other Reactions.

MeOK/dicyclohexano-18-crown-6 has been used rather infrequently for transformations other than nucleophilic aromatic substitutions and β-eliminations. However, it is a useful base for the deprotonation of a ketone in the formation of the TMS enol ether of acetophenone using ethyl trimethylsilylacetate (eq 4).[9]

Potassium Methoxide-Dimethyl Sulfoxide

MeOK/Me_2SO

(MeOK)

[865-33-8] · CH_3KO · Potassium Methoxide-Dimethyl Sulfoxide · (MW 70.14) (DMSO)

[67-68-5] · C_2H_6OS · Potassium Methoxide-Dimethyl Sulfoxide · (MW 78.15)

(highly basic reagent; used occasionally for deprotonation of weakly acidic carbon acids, β-elimination, and alkene isomerization reactions[2])

Physical Data: prepared in situ.

Form Supplied in: MeOK: commercially available in 95% purity; white powder. DMSO: commercially available (see ***Dimethyl Sulfoxide***).

Preparative Methods: prepared from anhydrous MeOK and anhydrous DMSO,[2b] in much the same manner as ***Potassium t-Butoxide-Dimethyl Sulfoxide***.[5]

Handling, Storage, and Precautions: MeOK: solid is flammable, corrosive, and hygroscopic.[1] Use the same precautions as for *t*-BuOK/DMSO. Use in a fume hood.

Deprotonation Reactions.

MeOK in DMSO solution forms a highly basic and nucleophilic medium, since the dipolar aprotic solvent strongly coordinates with potassium cations producing activated, solvent-separated, and dissociated methoxide anions in a medium of high dielectric constant.[2] Rate constants of base-catalyzed racemization and hydrogen isotope exchange reactions, as well as dehydrohalogenation and alkene isomerization reactions, indicate that MeOK/DMSO is a less basic medium than *t*-BuOK/DMSO. Apparently, the *t*-butoxide anion is not solvated as well as the methoxide ion in DMSO.[2b] In this dipolar, aprotic solvent it might have been expected that the order of basicity of the anions would be the same as in the gas phase, i.e. MeO^- > *t*-BuO^-.[3] Solutions of *t*-BuOK in DMSO are known to contain dimsyl anions;[4] this may have an influence on the basicity of the medium.[2b]

The rate of the MeOK-catalyzed racemization of (+)-2-methyl-3-phenylpropionitrile increases by 10^9 when the solvent is changed from MeOH to DMSO.[5] In MeOH the methoxide ion has relatively lower activity because it is strongly hydrogen bonded by the solvent molecules. MeOK catalyzes the hydrogen-tritium exchange reaction between tritiated toluene and DMSO, but the reaction rate is ca. 250 times faster when *t*-BuOK is employed as the base.[2b]

Substitution and Elimination Reactions.

Upon treatment with alkoxide bases in 83.7 mol % DMSO/alcohol mixtures, 1-bromodecane gives mixtures of alkyl decyl ethers via substitution (S_N2) reactions and 1-decene via an elimination (E2) reaction (eq 1).[6] The E2/S_N2 ratio is 0.14 for MeOK, but it is ca. 1.8 for *t*-BuOK; thus under these conditions the methoxide ion is a much better nucleophile than the *t*-butoxide ion. The addition of ***18-Crown-6*** to the above solution has very little effect on the overall reaction rate or the E2/S_N2 ratio when MeOK is employed as the base. The same is true for KOH and EtOK. However, in the presence of the crown ether the reaction is ca. 3.6 times faster, and the E2/S_N2 ratio increases slightly when *t*-BuOK is used as the base. From linear extrapolation of the Brønsted relation (ln *k* vs. H_-), it has been suggested that at very high values of the acidity function (H_-), where the anions would be largely desolvated, the order of basicity of alkoxide ions should be MeO^- > EtO^- > *t*-BuO^-, i.e. the same as in the gas phase.[6]

R = Me	88%	12%
R = *t*-Bu	35.6%	64.4%

Alkene Isomerization Reactions.

Both MeOK and *t*-BuOK effect the isomerization of 1-butene to *cis*-2-butene primarily in DMSO (eq 2).[7,2b] However, the rates are markedly dependent upon the anion; the reaction is ca. 125 times faster with *t*-BuOK than with MeOK. The stereoselectivity of the reaction is presumably controlled by the fact that the *cis*-allylic anion produced upon deprotonation of the alkene is more thermodynamically stable than its *trans* isomer.[7]

R = Me	14:1
R = *t*-Bu	13:1

Potassium 2-Methyl-2-butoxide

[41233-93-6] · $C_5H_{11}KO$ · Potassium 2-Methyl-2-butoxide · (MW 126.26)

(strong, sterically hindered alkoxide base)

Alternate Name: potassium *t*-pentoxide.

Form Supplied in: 1.5-2.0 M solution in benzene.

Solubility: sol THF, DME, aromatic hydrocarbons.

Preparative Methods: amber-colored 0.15-0.20 M $EtCMe_2OH$ solutions of the reagent are prepared in situ by refluxing oxide-free potassium metal in the anhydrous alcohol for 3-4 h.[1] Solutions of the base which are 1.0-2.0 M in THF, benzene, or toluene are prepared by treating oil-free ***Potassium Hydride*** with an equivalent amount of anhydrous *t*-pentyl alcohol in the anhydrous solvent under an inert atmosphere.[2]

Handling, Storage, and Precautions: solutions should be handled with the same precautions that are used for solutions of *t*-BuOK (see ***Potassium t-Butoxide***). Avoid contact with the eyes, skin, and clothing. Conduct all reactions under a dry nitrogen or argon atmosphere. In the absence of air and moisture, solutions of the base in benzene or toluene may be stored in a refrigerator for up to 1 year without significant deterioration.[2b] However, for critical experiments it is recommended that the reagent be freshly prepared. Use in a fume hood.

Enolate Formation and Alkylation.

The basicity of tertiary potassium alkoxides increases as the bulk of the alkyl substituents increases.[2a] For example, the equilibrium constant for the conversion of pinacolone into its enolate anion by $EtCMe_2OK$ in THF (eq 1) is 10, while it is 6.7 for the less bulky base *t*-BuOK, and 57 and 710, respectively, for the more bulky bases Et_3COK and Cy_3COK.[2a] Increased steric hindrance, which interferes with aggregation and solvation of the ion pair, presumably accounts for this.

Although potassium alkoxides can produce potassium enolates of most ketones in high concentrations, alkylation of these species is frequently a problem because of their tendency to undergo rapid proton transfer reactions which lead to polyalkylation, aldol condensation, and equilibration of structural isomers in unsymmetrical systems.[3] However, monoalkylation products are obtained in satisfactory yields even with cyclopentanone, which is highly prone to side reactions, using $EtCMe_2OK$ in DME as the base and a large excess of a reactive alkylating agent such as ***Iodomethane*** or ***Benzyl Bromide*** with a very short reaction time (eq 2).[4] The α-alkylation of α,β-unsaturated ketones such as 1-carvone is also accomplished in good yield using this base/solvent system and a reactive alkylating agent (eq 3).[4] The weakly acidic enone 1,10-dimethyl-$\Delta^{1,9}$-2-octalone is converted into its linearly conjugated dienolate with $EtCMe_2OK$ in benzene. This species can be α-methylated with MeI in 93% yield;[5] the yield is only 24% if *t*-BuOK is employed as the base.[6]

(2)

RX = MeI, 75%; BnBr, 77%

(3)

80%

Wittig Reactions.

Potassium alkoxides are frequently used as bases in Wittig reactions because the potassium cation does not strongly associate with the oxyanion of the betaine intermediate, and thus decomposition of this species to the alkene is relatively rapid.[7] The Wittig alkenation of sterically hindered 20-keto steroids such as pregnenolone with various triphenylalkylphosphoranes occurs in good yields using $EtCMe_2OK$ in benzene as the base/solvent system (eq 4).[2b] (*E*)-20(22)-Dehydro steroid derivatives are the exclusive products. These products are isolated in poor yields when $EtCMe_2ONa$ in benzene is used to generate the phosphorane from the phosphonium salt.[8]

(4)

Dehydrohalogenation Reactions.

As illustrated for the dehydrobromination of 2-bromo-2-methylbutane in eq (5), an increase in the steric hindrance of the potassium alkoxide base increases the 1-alkene/2-alkene ratio of the β-elimination products.[9] $EtCMe_2OK$ gives a 1-alkene/2-alkene ratio which is

intermediate between that of the less bulky *t*-BuOK and the more bulky Et_3COK.[9]

(5)

base		
t-BuOK, *t*-BuOH	73%	27%
$EtCMe_2OK$, $EtCMe_2OH$	78%	22%
Et_3COK, Et_3COH	89%	11%

Lethargic Reactions.

Highly hindered acetophenone derivatives are converted to their oximes by treatment with ***Hydroxylamine*** hydrochloride in the presence of 2.0 equiv of $EtCMe_2OK$ in $EtCMe_2OH$ at rt for 1 month or longer (eq 6).[1b] Efforts to force the reaction by using higher temperatures result in lower yields. The $NHOH^-$ anion is presumed to be the reactive species.[1b]

(6)

Rearrangement Reactions.

The reagent is used to extrude selenium from Se-acylmethyl selenocarboxylates to produce β-diketones (eq 7),[10] and for rearranging nitronates into hydroxamates (eq 8).[11]

(7)

(8)

Metalation Reactions.

Mixtures of alkyllithium reagents and tertiary potassium alkoxides are powerful metalating agents for weakly acidic compounds.[12] For example, phenylpotassium is produced from the combination of ***n-Butyllithium*** and $EtCMe_2OK$ in benzene.[13]

Related Reagents.

Potassium t-Butoxide; ***Potassium t-Heptoxide***.

Potassium Methylsulfinylmethylide[1]

[15590-26-8] · C_2H_5KOS · Potassium Methylsulfinylmethylide · (MW 116.24)

(a strong base and nucleophile, very useful for the introduction of the methylsulfinylmethyl group[1])

Alternate Name: potassium dimsylate; dimsylpotassium; KDMSO.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: titration with formanilide or 2,6-di-*t*-butylphenol using triphenylmethane as indicator.[2,3]

Preparative Methods: prepared by the reaction of ***Potassium Amide*** or ***Potassium Hydride*** with ***Dimethyl Sulfoxide*** (DMSO).[3,4] Equilibrium quantities of KDMSO may be prepared using ***Potassium t-Butoxide*** in DMSO.[5]

Handling, Storage, and Precautions: best prepared as needed although synthesis and storage procedures similar to those used in some preparations of ***Sodium Methylsulfinylmethylide*** (NaDMSO) would probably result in long shelf life.[6] Hydrogen gas may be emitted during the preparation of this reagent and due caution should be exercised in its preparation, particularly on a large scale. Problems encountered in the preparation of NaDMSO may be relevant to KDMSO.[7]

Introduction.

The conjugate base of dimethyl sulfoxide (pK_a = 35) represents a powerful base and nucleophile. It is expected that much of the chemistry of KDMSO will be the same as that of related metal salts and this is indeed the case (see ***Lithium Methylsulfinylmethylide*** and ***Sodium Methylsulfinylmethylide***).

It should be noted that the generation of KDMSO with *t*-BuOK in DMSO results in the formation of only equilibrium amounts of carbanion. While this is sufficient to make products derived from KDMSO attack preponderant in many instances (e.g. nucleophilic addition), when this combination is used for its basic properties it is likely that the active agent is *t*-BuOK and not KDMSO.[8]

Potassium Methylsulfinylmethylide as Base.

Alkene Isomerization.

KDMSO has been used to conjugate dienes in natural oils such as linseed oils.[9] KDMSO works much better than NaDMSO in facilitating this reaction. This isomerization procedure has also been used with synthetic compounds (eq 1).[10]

In work involving the nature of stabilizing effects in dianions it has been demonstrated that in the presence of excess KDMSO, 2-(diphenylmethyl)-1,1,3,3-tetraphenylpropene can be deprotonated to a dianion which is y-aromatic (eq 2).[11]

(2)

Elimination Reactions.

Elimination reactions allegedly using KDMSO probably involve *t*-BuOK when the latter is used to generate KDMSO in DMSO.[8] Such eliminations are not covered here. There are bona fide examples of eliminations using KDMSO produced stoichiometrically.

For example, as part of a total synthesis of elfamycin, treatment of bis-epoxide (**1**) gave the tetrahydrofuran (**2**) in a tandem elimination-ring closure sequence (eq 3).[12]

(3)

A new, general synthesis of *ortho*-alkenyl anilines is based on an elimination reaction of benzothiazines to give sulfinanilides in high yield (eq 4).[13] The latter are easily hydrolyzed to free anilines.

(4)

Ether Synthesis.

The exhaustive *O*-alkylation of oligo- and polysaccharides (Hokomori reaction) greatly facilitates the handling and analysis of such compounds. The use of KDMSO as a base in this application of the Williamson ether synthesis and its superiority over NaDMSO have been documented.[14]

Potassium Methylsulfinylmethylide as Nucleophile.

Reactions with Esters.

The reaction of dimsyl anions with esters leads generally to β-keto sulfoxides. KDMSO generated from *t*-BuOK in DMSO has been used for this purpose (eq 5).[15] The importance of this reaction lies in the synthetic utility of β-keto sulfoxides.[16] For example, they are readily and regioselectively alkylated and desulfurized to give ketones (eq 6) and, inter alia, can be converted to α-keto aldehydes (eq 7).[15]

(5)

(6)

(7)

Reactions with Aldehydes and Ketones.

KDMSO derived from *t*-BuOK in DMSO reacts with aromatic aldehydes to give the expected products.[5] Interestingly, at higher temperatures and in the presence of diphenylmethane, a series of transformations takes place which result in the formation of an alkene containing no sulfur, but including a molecule of diphenylmethane (eq 8).[17]

(8)

Even more interesting is the report of diene diol formation from an epoxy ketone (eq 9).[18] A related reaction may be taking place in the conversion of cyclohexanone to 2-methylenecyclohexanol (eq 10).[19]

(9)

(10)

Reactions with Alkenes.

Dimsyl anions do undergo additions to Michael acceptors, even those which are not very activated. Two examples using KDMSO are illustrative of the diverse types of alkenes which can be expected to be subject to nucleophilic attack using KDMSO (eqs 11 and 12).[10,20] Cyclopropane formation, though potentially useful, is probably better accomplished using sulfur ylides or related compounds.

Potassium Naphthalenide

[4216-48-2] · $C_{10}H_8K$ · Potassium Naphthalenide · (MW 167.28)

(functions as a base in the α-alkylation of γ- and δ-lactones;[1] deprotonates β-lactones to provide α,β-unsaturated carboxylic acids and esters;[1] reductively cleaves *O,S*-acetals[2] and alkyl halides[3,4])

Solubility: sol THF, DME.

Analysis of Reagent Purity: ^{39}K NMR (0.2 M THF, 20 °C) 20 ppm.

Preparative Methods: a 1.0 M solution of the reagent is prepared by adding ***Potassium*** metal (1.0 equiv) to a solution of naphthalene (1.0 equiv) in THF (or DME) under an argon atmosphere. The mixture is stirred until all of the potassium metal has dissolved (ca. 2 h). The resulting solution exhibits the characteristic dark green color of the radical anion.[5] Potassium is an extremely flammable solid and should always be handled with care under an argon atmosphere.

Handling, Storage, and Precautions: both air and moisture sensitive. Stock solutions of the reagent are flammable and should be handled under an inert atmosphere.

Use as a Base.

Potassium naphthalenide acts as an efficient base in the α-alkylation of γ- and δ-lactones (eqs 1 and 2).[1] Lactone enolates prepared from alternate bases (e.g. ***Sodium Methoxide***, ***Lithium Diisopropylamide***) undergo competitive self-condensation and dialkylation reactions.[6]

(1)

(2)

β-Lactones fragment to α,β-unsaturated carboxylate anions when reacted with potassium naphthalenide/***18-Crown-6***. α,β-Unsaturated carboxylic acids or esters are readily prepared by subsequent protonation or alkylation of the carboxylate anions (eq 3). Products of (*E*)-alkene configuration are formed exclusively.

(3)

Use as a Reducing Agent.

α-Alkoxy potassium compounds are generated by the reductive cleavage of *O*,*S*-acetals with potassium naphthalenide. The *O*,*S*-acetals derived from allylic alcohols undergo reduction followed by [2,3]-Wittig rearrangement.[2] Homoallylic alcohols of preferential (*Z*)-alkene configuration are prepared in this manner (eq 4). K-, Li-, Cs-, and Rb-naphthalenides are equally effective at initiating the [2,3]-Wittig rearrangement. Reduced yields occur with ***Sodium Naphthalenide***.

(4)

Cyclopropyl halides react with potassium naphthalenide to form dehalogenated products (eq 5).[3] The *gem*-dihalocyclopropane in eq 6 undergoes skeletal rearrangement with potassium naphthalenide, while the parent hydrocarbon is formed upon treatment with ***Sodium-Ammonia***.[4]

(5)

(6)

Related Reagents.

Copper(I) Iodide-Potassium Naphthalenide.

Potassium *o*-Nitrobenzeneperoxysulfonate

[-] · $C_6H_4KNO_6S$ · Potassium *o*-Nitrobenzeneperoxysulfonate · (MW 257.28)

(epoxidizes alkenes[1] and arenes;[2] oxidizes aryl methylenes,[3] thiocarbonyl compounds,[4] and sulfoxides[5])

Solubility: sol MeCN, DMF.

Form Supplied in: not commercially available.

Preparative Methods: reactive intermediate (**1**) is generated in situ according to eq 1. Many experiments suggest that the reactive intermediate formed by mixing (**3**) and (**4**) is a radical;[6] however, the existence of the anion (**2**) cannot be ruled out.

Handling, Storage, and Precautions: intermediate (**1**) cannot be stored, but is generated and reacted in situ. Reactions are carried out under dry argon atmosphere.

Epoxidation of Alkenes.

Alkenes are epoxidized under mild conditions in high yields by the peroxy intermediate (**1**); for example, see the preparation of epoxide (**6**) from (-)-carvone (**5**) (eq 2).

(2)

(5) (6)

A solution of sulfonyl chloride (**3**) (0.22 g, 1.0 mmol) and (-)-carvone (**5**) (0.09 g, 0.6 mmol; MeCN, 2.0 mL) is added to a heterogeneous solution of KO_2 (0.222 g; 3.0 mmol, MeCN, 1.0 mL) at -35 °C under dry argon atmosphere. After stirring at -35 °C for 4 h, the reaction mixture is concentrated and then extracted with $CHCl_3$. The residue obtained after removal of solvent is purified by preparative TLC to furnish (**6**) in 83% yield.[1]

Epoxidation of *cis*-stilbene (**7**) by reaction with the intermediate (**1**) furnishes a 70:30 mixture of oxides (**8**) and (**9**); this reaction suggests that the reactive intermediate is a radical.[2]

(7) (8) (9)

Metal peroxides have low solubility in organic solvents and are usually used in the presence of crown ethers. KO_2 is soluble enough in aprotic solvents such as MeCN and DMF; hence there is no need to use crown ether for preparing the intermediate according to eq 1.[2]

Epoxidation of Arenes.

Certain arenes (acenaphthylene, phenanthrene, and pyrene) are readily oxidized to the corresponding arene oxides by the peroxy intermediate (**1**) generated from sulfonyl chloride (**3**) in polar aprotic solvents such as MeCN and DMF. Superoxide (**4**) is a strong base and reactions with (**1**) take place under mild and basic conditions. Acenaphthylene oxide (**10**) is unstable under acidic conditions but is more stable under basic conditions. Oxide (**10**) was obtained in 95% yield.[2]

(10)

Oxidation of Benzylic Methylene Compounds.

The peroxy intermediate (**1**) generated from sulfonyl chloride (**3**) oxidized compounds containing benzylic methylene groups to

ketones under mild conditions (-35 °C) (eq 3).[3]

(3)

Oxidative Desulfurization of Thiocarbonyl Compounds.

Thiocarbonyl compounds such as substituted thioureas, thioamides, and thiocarbamates undergo oxidative desulfurization in high yields when reacted with the peroxy intermediate (**1**) under mild conditions (eq 4).[4]

(4)

Oxidation of Sulfoxides.

Dialkyl, alkyl aryl, and diaryl sulfoxides are readily oxidized to sulfones in excellent yields under mild conditions (-30 °C) in MeCN by the peroxy intermediate (**1**). Oxidation of the unsaturated sulfoxide (**11**) was chemoselective; it furnished the sulfone (**12**) in 70% yield when reacted with (**1**) for 5 h. The double bond was not epoxidized.[5] Similar chemoselective epoxidation has been carried out with only one other reagent (potassium hydrogen persulfate).[7]

(11)

(12)

The peroxy intermediate (**1**) is an excellent reagent for the synthesis of acid-sensitive benzylic epoxides from alkenes, the oxidation of benzylic CH_2 to C=O, and the chemoselective oxidation of alkene sulfoxides to alkene sulfones. It is noteworthy that the reactions are carried out under mild conditions (-35 °C).

Potassium Nitrosodisulfonate[1]

$(KSO_3)_2NO$

[14293-70-0] · $K_2NO_7S_2$ · Potassium Nitrosodisulfonate · (MW 268.35)

(oxidizing reagent for synthesis of quinones from phenols,[2] naphthols,[9] and anilines;[18] oxidant for conversion of benzylic alcohols to aldehydes or ketones[30] and amino acids to α-keto acids;[31] preparation of heterocyclic quinones;[20-22] oxidative aromatization[29])

Alternate Name: Fremy's salt.

Solubility: sol H_2O.

Form Supplied in: orange powder; widely available.

Preparative Methods: see Zimmer et al.[1]

Handling, Storage, and Precautions: in solid form, this reagent is rather unstable. It sometimes undergoes spontaneous decomposition which occasionally results in a violent explosion attributed to impurities such as chloride ion, manganese dioxide, or nitrite ion. Stored in a desiccator over calcium oxide in the presence of ammonium carbonate to provide an ammoniacal atmosphere, it is stable for several months.

Phenol Oxidations.

This reagent oxidizes phenols to the corresponding 1,2- or 1,4-quinones under mild conditions and usually in good yield. The substituents on the aromatic ring control the ratio of *ortho*- and *para*-quinones.[2] *para*-Unsubstituted phenols bearing a variety of substituents in the *ortho* and *meta* positions (e.g. alkyl,[3,4] alkyloxy and/or bromine,[5] crown ether substituents,[6] and *p*-hydroxybenzylamines and primary *p*-hydroxybenzamides[7]) are generally converted to 1,4-quinones. Phenols with easy-to-displace *para* substituents, such as CH_2OH, Br, Cl, CO_2H, $CONH_2$, and CH(OH)CN, undergo oxidation to form 1,4-quinones. 1,2-Quinones are formed if the *para* substituents are alkoxy, alkyl, or aryl.[8] See also ***Lead(IV) Oxide*** and ***Salcomine***.

Naphthol Oxidations.

α-Naphthols can be oxidized to 1,2- or 1,4-naphthoquinones by Fremy's salt.[9] Again, the nature of the *para* substituent is critical. 1,4-Naphthoquinones predominate if the *para* position is unsubstituted.[10] 1,2-Naphthoquinones are formed if an alkyl or aryl group occupies the *para* position,[9] if there is a hydroxy group in the 2-position,[9] or if the *para* position is hindered.[11] Approximately equal amounts of 1,2- and 1,4-naphthoquinones are obtained if a hydroxy group occupies the 5-position.[9] It has been reported that 1,4-naphthoquinones are produced from oxidation of 2- or 9-SMe substituted phenols.[12] β-Naphthols are generally oxidized to 1,2-naphthoquinones (eq 1).[13]

(1)

The methyl ether of a β-naphthol has been reported to afford a 1,2-quinone (eq 2).[14]

(2)

X = F, Cl, Br

Aniline Oxidations.

1,4-Quinones are formed by the reaction of 2,6-disubstituted and 2,3,6-trisubstituted anilines and Fremy's salt.[15] Other *ortho* or *meta* methoxy-substituted aromatic amines were converted to the corresponding 1,4-quinones[16] and 1,2-quinones.[17] In one case the oxidation intermediate, a quinone imine which subsequently undergoes hydrolysis to the quinone, has been isolated (eq 3).[18]

(3)

Hypoxanthine analogs were formed by Fremy's salt oxidation (eq 4).[19]

(4)

R = H, OMe

Oxidations to Quinoline Quinones.

Quinolinols are converted to quinoline quinones (eq 5).[20]

(5)

In an approach to streptonigrin, Fremy's salt was utilized to oxidize a methoxy aniline by a phase-transfer procedure (eq 6).[21]

Oxidations to Indole Derivatives.

The derivatives of *ortho*-hydroxy phenethylamine were converted into indoles (eq 7).[22] Presumably the primary oxidation product is protected from secondary oxidation by protonation at lower pH. Likewise, in solution at different pH, 2-methylindole dimerizes to different products (eq 8).[23]

(8)

The derivatives of *ortho*-aminophenethylamine were converted to indoline 1,4-quinone imides (eq 9).[24] No oxidation at the 3-position or 4-position was observed if the α-position was occupied by two alkyl groups.

(9)

A novel route to heterocyclic quinones, based on Fremy's salt promoted oxidation, has been developed recently (eq 10).[25]

(10)

With this methodology, isoquinoline derivatives were converted with ring contraction to the 1,2-quinone indoles in a buffered (pH 6.1) two-phase (CH_2Cl_2-H_2O) system (eq 11).

(11)

R = H or OMe

5-Hydroxybenzofuran is oxidized to the 4,5-*ortho*-quinone.[26] Bisquinones[27] and other heterocyclic quinones[28] were prepared by Fremy's salt oxidation.

Tetrahydroisoquinoline Oxidation.

Papaveraldine could be produced by Fremy's salt oxidation over 7 days in 30% yield (eq 12). The corresponding *N*-alkyl tetrahydroisoquinolines give cleavage products (eq 13).[29]

(12)

(13)

(a) $R^1 = R^2 = Me$; (b) $R^1 + R^2 = CH_2$

Other Reactions.

Benzylic alcohols could be selectively oxidized to aldehydes or ketones in the presence of allylic alcohols and saturated alcohols by Fremy's salt in a phase-transfer system.[30]

Some α-amino and α-hydroxy acids were oxidized to the corresponding α-keto acids (dehydrogenation) and/or to the acids or amides (with decarboxylation) (eq 14).[31]

Potassium Permanganate[1-4]

$KMnO_4$

[7722-64-7] · $KMnO_4$ · Potassium Permanganate · (MW 158.04)

(oxidant; conversion of arenes into carboxylic acids,[10,11] α-ketones,[12-15] or α-alcohols;[14] degradation of aromatic rings;[3] preparation of diols,[17,18] ketols,[5,19,20,22] and α-diketones[22-24] from nonterminal alkenes; preparation of carboxylic acids,[27] aldehydes[26] and 1,2-diols[28] from terminal alkenes; oxidation of alkynes to α-diones;[29,30] oxidation of enones to 1,4-diones;[31] conversion of 1,5-dienes into substituted tetrahydrofurans[32,33] or lactones;[34] conversion of primary and secondary alcohols into carboxylic acids[1,2,37] and ketones,[1-4,9,35] respectively; oxidation of allylic alcohols to α,β-unsaturated ketones[35] and other unsaturated alcohols and α,o-diols to lactones;[36,37] oxidation of aliphatic thiols to disulfides and aromatic thiols to sulfonic acids;[4] oxidation of sulfides and sulfoxides to sulfones,[4,38-40] sulfinic acids to sulfonic acids,[43] sulfites to sulfates,[44] and thiones to ketones;[45] preparation of tertiary nitroalkanes from the corresponding amines;[47] oxidation of tertiary amines to amides or lactams;[48-50] allylic oxidations when used in conjunction with *t*-butyl hydroperoxide;[51] preparation of iodoaromatic compounds when used with I_2 and sulfuric acid;[52] oxidation of nucleic acids to the corresponding diols and ketols;[53] oxidation of guaiol and related compounds to rearranged ketols;[54] oxidation of poly(vinyl alcohol) to poly(vinyl ketone);[56] oxidation of nitroalkanes to aldehydes or ketones; oxidation of imines to nitrones)

Alternate Name: potassium manganate(VII).

Physical Data: d 2.70 g cm^{-3}; decomposition 237 °C.

Solubility: water (at 20 °C) 63.8 g L^{-1}; sol acetone, methanol.

Form Supplied in: purple solid; commercially available.

Handling, Storage, and Precautions: stable at or below rt. Because it is a strong oxidant it should be stored in glass, steel, or polyethylene vessels. Sulfuric acid should never be added to permanganate or vice versa. Permanganate acid, an explosive compound, is formed under highly acidic conditions.

Introduction.

Permanganate is an inexpensive oxidant that has been widely used in organic syntheses. Its most common salt, $KMnO_4$, is soluble in water and as a consequence oxidations have traditionally been carried out in aqueous solutions or in mixtures of water and miscible organic solvents such as acetone, acetic acid, acetonitrile, benzonitrile, tributyl phosphate, or pyridine. The discovery that $KMnO_4$ can, with the aid of phase-transfer agents, be readily dissolved in nonpolar solvents such as CH_2Cl_2, and the recent observation that is adsorption onto a solid support produces an effective heterogeneous oxidant, has further expanded its usefulness.

The general features of the reactions of permanganate dissolved in aqueous solutions, or in organic solvents with the aid of a phase-transfer agent, and as a heterogeneous oxidant will be briefly described, followed by specific examples.

Aqueous Permanganate Oxidations.

Potassium permanganate is a general, but relatively nonselective, oxidant when used in aqueous solutions. When an organic compound contains only one site at which oxidation can readily occur, this reagent is a highly efficient and effective oxidant. For example, oleic acid is converted into dihydroxystearic acid in quantitative yield when oxidized in a dilute aqueous solution of $KMnO_4$ at 0-10 °C.[5]

If the aqueous solution is made acidic by addition of mineral acid, the rate of reaction increases, most probably because of formation of permanganic acid[1] which is known to be a very strong oxidant.[6] The rate of the reaction is also accelerated by addition of sodium or potassium hydroxide. It has been proposed that this acceleration may be due to ionization of the organic reductant; for example, conversion of an alcohol into an alkoxide ion.[1] However, similar observations for the oxidation of compounds such as sulfides, which lack acidic hydrogens, suggests that other factors may be involved.[7]

Under acidic conditions, permanganate is reduced to soluble manganese(II) or -(III) salts, thus allowing for a relatively easy workup. However, under basic conditions the reduction product is a gelatinous solid, consisting primarily of manganese dioxide, that is difficult to separate from the product. As a consequence, for laboratory scale preparations the reaction product is not isolated until after the MnO_2 has been reduced by addition of HCl and sodium bisulfite. For large scale (industrial) processes, MnO_2 is removed either by filtration or by centrifugation.

Phase-Transfer Assisted Permanganate Oxidations.[2]

$KMnO_4$ may be dissolved in nonpolar solvents such as benzene or CH_2Cl_2 by complexing the potassium ion with a crown ether or by replacing it with a quaternary ammonium or phosphonium ion. Although most reactions observed are similar to those found in aqueous solutions, the ability to dissolve permanganate in nonpolar solvents has greatly increased the range of compounds that can be oxidized.

The first example of a phase-transfer assisted permanganate oxidation involved the complexing of the potassium ion by a crown ether in benzene;[8] however, it was later found that the use of quaternary ammonium or phosphonium salts was less expensive and just as efficient.[2]

Phase transfer into a nonpolar solvent can occur either from an aqueous solution or from solid $KMnO_4$. Evaluation of various phase-transfer agents for these purposes has indicated that benzyltributylammonium chloride is highly efficient for transfer from aqueous solutions while alkyltriphenylphosphonium halides, tetrabutylammonium halides, and benzyltriethylammonium halides are all effective for the transfer from solid $KMnO_4$.[2] Adogen 464, an inexpensive quaternary ammonium chloride commercially available, is usually satisfactory for both purposes.

Quaternary ammonium and phosphonium permanganates can also be used as stoichiometric oxidants. For descriptions of their properties, refer to the separate articles on ***Methyltriphenylphosphonium Permanganate*** and ***Benzyltriethylammonium Permanganate***.

Heterogeneous Permanganate Oxidations.

The use of permanganate, activated by adsorption on a solid support, as a heterogenous oxidant has further increased the scope of these reactions. CH_2Cl_2 or 1,2-dichloroethane (if a high reflux temperature is required) are the preferred solvents and ***Alumina***, silica, or hydrated ***Copper(II) Sulfate*** are the most commonly used solid supports. The selectivity of the oxidant is dramatically altered by use of a solid support. For example, although carbon-carbon double bonds are very easily cleaved in homogeneous permanganate solutions, secondary allylic alcohols can be cleanly oxidized to the corresponding α,β-unsaturated ketones without disruption of the double bond under heterogeneous conditions.[9]

In addition to increased selectivity, the use of permanganate under heterogeneous conditions allows for easy product isolation. It is necessary only to remove spent oxidant by filtration followed by flash evaporation or distillation of the solvent. Products isolated in this way are often sufficiently pure to permit direct use in subsequent synthetic procedures.

Benzylic Oxidations.

Permanganate oxidizes side chains of aromatic compounds at the benzylic position.[3] In aqueous solution, carboxylic acids are usually obtained (eqs 1 and 2).[10,11]

(1)

(2)

The oxidation of alkylbenzenes proceeds through the corresponding α-ketones, which can occasionally be isolated (eqs 3 and 4).[12,13]

(3)

(4)

Under heterogeneous conditions where alumina (acid, Brockman, activity 1)[14] or copper sulfate pentahydrate[15] is used as the solid support, α-ketones and alcohols are obtained with little or no carbon-carbon cleavage (eqs 5-8).

(5)

(6)

(7)

(8)

Oxidation of Aromatic Rings.

Permanganate will oxidatively degrade aromatic rings under both acidic and basic conditions.[3] The effect of acid and base on the reaction has been demonstrated by the oxidation of 2-phenylpyridine; under basic conditions the product is benzoic acid (presumably because the oxidant attacks the site of greatest electron density) (eq 9), while under acidic conditions (where the nitrogen would be protonated) the product is picolinic acid (eq 10).[3]

(9)

(10)

Polycyclic aromatic compounds are also oxidatively degraded to a single-ring polycarboxylic acid (eq 11).[16]

(11)

Oxidation of Nonterminal Alkenes.

Nonterminal alkenes can be converted into 1,2-diols, ketols, or diketones by choice of appropriate conditions. The reaction, which proceeds by *syn* addition of permanganate to the double bond as indicated, gives the corresponding *cis*-diol under aqueous alkaline conditions (eq 12).[17]

(12)

Syn addition can also be achieved in nonaqueous solvents with the aid of a phase-transfer agent (PTA). Subsequent treatment with aqueous base gives 1,2-diols in good yields[2] (eq 13).[18] Equally good results were reported when the reaction was carried out in aqueous *t*-butyl alcohol.[18]

(13)

Under neutral conditions the product obtained from the oxidation of alkenes is the corresponding ketol.[5] Good yields are obtained when aqueous acetone containing a small amount of acetic acid (2-5%) is used as the solvent. The function of acetic acid is to neutralize hydroxide ions produced during the reduction of permanganate. The oxidations of 5-decene and methyl 2-methylcrotonate provide typical examples (eqs 14 and 15).[19,20]

(14)

(15)

Heterogeneous oxidations of alkenes with a small amount of *t*-butyl alcohol and water present to provide an omega phase[21] results in the formation of α-ketols in modest to good yields (eqs 16 and 17).[22]

(16)

(17)

Under anhydrous conditions, 1,2-diones are formed in good yields when alkenes are oxidized by permanganate. Appropriate conditions can

be achieved by using acetic anhydride solutions (eq 18)[23] or by dissolving permanganate in CH_2Cl_2 with the aid of a phase-transfer agent (eq 19).[24]

(18)

(19)

Similar yields are obtained under heterogeneous conditions, where workup procedures are much easier.[22]

The carbon-carbon double bonds of alkenes can also be oxidatively cleaved to give carboxylic acids in good yield by use of the Lemieux-von Rudloff reagent (aqueous potassium periodate containing catalytic amounts of permanganate).[3,25] Under heterogeneous conditions, either aldehydes or carboxylic acids are obtained, depending on the conditions used (eqs 20 and 21).[26]

(20)

(21)

Oxidation of Terminal Alkenes.

Although oxidation of terminal alkenes by permanganate usually results in cleavage of the carbon-carbon double bond to give either a carboxylic acid[27] or an aldehyde,[26] 1,2-diols can be obtained through use of a phase-transfer assisted reaction (eqs 22-24).[2,28]

(22)

(23)

(24)

Oxidation of Alkynes.

Oxidation of nonterminal alkynes results in the formation of α-diones. Good yields are obtained when aqueous acetone containing $NaHCO_3$ and $MgSO_4$,[29] or CH_2Cl_2 containing about 5% acetic acid,[30] is used as the solvent (eqs 25-27). A phase-transfer agent to assist in dissolving $KMnO_4$ must be used when CH_2Cl_2 is the solvent. Terminal alkynes are oxidatively cleaved, yielding carboxylic acids containing one carbon less than the parent alkyne.

(25)

(26)

(27)

Oxidation of Enones to 1,4-Diones.

Enones react with nitroalkanes (Michael addition) to form γ-nitro ketones that can be oxidized in good yield to 1,4-diones under heterogeneous conditions (eq 28).[31]

(28)

Oxidation of 1,5-Dienes.

The oxidation of 1,5-dienes results in the formation of 2,5-bis(hydroxymethyl)tetrahydrofurans with the indicated stereochemistry (eq 29).[32] When R^6 in (eq 29) is chiral, a nonracemic product is obtained.[33] Use of heterogeneous conditions results in the formation of lactones (eq 30).[34]

Oxidation of Alcohols and Diols.

Primary and secondary alcohols are converted to carboxylic acids and ketones, respectively, when oxidized by aqueous permanganate under either acidic or basic conditions (eq 31).[1] Similar results are obtained with phase-transfer assisted oxidations in organic solvents such as CH_2Cl_2 (eq 32).[2]

Heterogeneous oxidations are very effective with secondary alcohols (eq 33)[35] and provide the added advantage that allylic secondary alcohols can be converted to the corresponding α,β-unsaturated ketones without disruption of the double bond (eq 34).[9] Unsaturated secondary alcohols in which the double bond is not adjacent to the carbon bearing the hydroxy group are resistant to oxidation (eq 35) unless an omega phase[21] is created by adding a small amount of water (50 µL per g $KMnO_4$). The products are lactones under these conditions (eq 36).[36]

(33)

(34)

no product (35)

(36)

Good yields of carboxylic acids are obtained from primary alcohols under heterogeneous conditions ($KMnO_4/CuSO_4.5H_2O$) only when a base such as KOH or $Cu(OH)_2.CuCO_3$ is intermixed with the solid support.[37] Under these conditions the reagent has also been reported to be selective for primary alcohols.[37]

The oxidation of α,o-diols under heterogenous conditions results in the formation of lactones. A good example is found in the preparation of 3-hydroxy-*p*-menthan-10-oic acid lactone (eq 37).[37]

(37)

Oxidation of Organic Sulfur Compounds.

Aromatic thiols are oxidized by permanganate to the corresponding sulfonic acids while aliphatic thiols usually give disulfides, which are resistant to further oxidation.[4] Sulfides and sulfoxides are easily oxidized in CH_2Cl_2 to the corresponding sulfones under both homogeneous[38,39] and heterogeneous conditions (eqs 38-42).[40]

(38)

(39)

(40)

(41)

(42)

Permanganate oxidizes sulfoxides more readily than sulfides, as indicated by the products obtained from the oxidation of compounds containing both sulfide and sulfoxide functional groups (eqs 43 and 44).[41,42]

(43)

(44)

Q = benzyltriethylammonium ion

The greater ease of oxidation of sulfoxides is also responsible for the observation that *gem*-disulfides are oxidized to monosulfones.[42] Monosulfoxides, although not isolated, are likely to be intermediates in these reactions (eq 45).

(45)

Oxidation of sulfinic acids results in the formation of sulfonic acids,[43] while sulfites give sulfates (eqs 46 and 47).[44]

(46)

(47)

Cyclic thiones are readily oxidized to the corresponding ketones by permanganate (eq 48).[45]

(48)

Oxidation of Amines.

The synthetic usefulness of permanganate as an oxidant for aliphatic amines is decreased by the fact that a complex mixture of products is often obtained.[4,46] Good yields of tertiary nitroalkanes can, however, be obtained from the oxidation of the corresponding amines (eq 49).[47]

(49)

Primary and secondary amines react with permanganate in buffered, aqueous *t*-butyl alcohol to give aldehydes and ketones (eq 50).[46]

(50)

Amides (or lactams, if the amine is cyclic) are obtained from the oxidation of tertiary amines (eqs 51 and 52).[48-50]

(51)

(52)

Miscellaneous Oxidations.

Use of permanganate in conjunction with ***t-Butyl Hydroperoxide*** results in allylic oxidation (eq 53).[51]

(53)

Aromatic compounds are oxidized to aryl iodides when treated with permanganate, ***Iodine***, and ***Sulfuric Acid*** (eq 54).[52]

(54)

Chemical modification of nucleic acids by treatment with permanganate results in oxidation of the Δ^5 double bond to give either diols or ketols (eq 55).[53]

(55)

Guaiol and related compounds can be oxidized to rearranged ketols using aqueous glyme as the solvent (eq 56).[54]

(56)

cis-2,5-Dihydro-2,5-dimethoxyfuran is oxidized to the corresponding α-diol in preference to the *trans* compound (eqs 57 and 58).[55]

(57)

(58)

Oxidation of poly(vinyl alcohol) by permanganate results in the formation of poly(vinyl ketone) (eq 59).[56]

(59)

Treatment of Δ^5-unsaturated steroids with $KMnO_4/CuSO_4.5H_2O$ in CH_2Cl_2 containing catalytic amounts of *t*-butyl alcohol and water results in formation of the corresponding 5β,6β-epoxide (eq 60).[22,57]

(60)

The oxidation of Δ^7-cholesterol acetate by $KMnO_4$ under neutral or slightly basic conditions results in formation of all-*cis*-epoxydiol (eq 61).[58]

(61)

Aliphatic nitro compounds are converted into the corresponding oxo compounds on treatment with basic permanganate.[59,60] Because these reactions are carried out under basic conditions, it is likely that anions are intermediates, as suggested in eqs 62-64.

(62)

(63)

(64)

Nitrones can be obtained from the oxidation of imines by $KMnO_4$ in a two-phase CH_2Cl_2/H_2O solution containing a phase-transfer agent (PTA) such as tetrabutylammonium chloride (eq 65).[61]

Potassium Permanganate-Copper(II) Sulfate

$KMnO_4$-$CuSO_4.5H_2O$

($KMnO_4$)

[7722-64-7] · $KMnO_4$ · Potassium Permanganate-Copper(II) Sulfate · (MW 158.04) ($CuSO_4.5H_2O$)

[7758-99-8] · CuO_4S · Potassium Permanganate-Copper(II) Sulfate · (MW 249.72)

(oxidant; capable of converting saturated primary alcohols into carboxylic acids,[1] saturated secondary alcohols into ketones,[2] α,β-unsaturated alcohols into α,β-unsaturated ketones,[3] dialkyl and diaryl sulfides into sulfones,[4] diphenyl selenide into diphenyl selenone,[4] α,o-diols into lactones,[1] alkenes into diketones and α-hydroxy ketones,[5] o-hydroxy alkenes into o-lactones,[6] 1,5-dienes into 5-substituted butanolides,[7] and Δ^5-unsaturated steroids into the corresponding 5β,6β-epoxy steroids)

Physical Data: mixture of high melting solids; see entries for ***Potassium Permanganate*** and ***Copper(II) Sulfate***.

Solubility: sol cold H_2O; insol CH_2Cl_2.

Form Supplied in: $KMnO_4$: purple solid. $CuSO_4.5H_2O$: blue solid.

Handling, Storage, and Precautions: oxidant; store in glass containers at rt.

Introduction.

The use of $KMnO_4$ adsorbed on a solid support as a heterogeneous oxidant in nonaqueous solvents such as CH_2Cl_2 has two very practical advantages. First, in common with most heterogeneous reactions, the product can be isolated simply by filtering to remove the spent oxidant, followed by flash evaporation of the solvent. Second, adsorption of potassium permanganate onto a solid support remarkably improves its selectivity. Various supports have been used (e.g. molecular sieves,[9] ***Alumina***,[10,11] and silica[10,12,13]) with ***Copper(II) Sulfate*** being the most convenient and versatile.

The water of hydration is important; without it very little or no product is obtained.[2] While the role of water in controlling the nature of the products is empirically well documented, a theoretical understanding of its function has been the subject of only preliminary discussions.[11,14]

Oxidation of Secondary Alcohols to Ketones.

When potassium permanganate (3 g) and copper(II) sulfate pentahydrate (2 g) are ground together, a reagent capable of oxidizing both saturated and α,β-unsaturated secondary alcohols into the corresponding ketones is produced. When the alcohols (3 mmol) dissolved in 20 mL of CH_2Cl_2 are added and the heterogeneous mixture refluxed for several hours, ketones are formed in excellent yields;[3] however, primary alcohols, alkenes, and alcohols unsaturated at a more remote position are not oxidized unless water or a base are added.

Oxidation of Sulfides and Selenides.

Under similar conditions, sulfides and selenides are converted to sulfones and selenones.[4]

Oxidation of Primary Alcohols and α,o-Diols.

If a base ($Cu(OH)_2.CuCO_3$ or KOH) is added, primary alcohols are oxidized to the corresponding carboxylic acids in yields of 80-96% and in a competition experiment it was found that primary alcohols are oxidized in preference to secondary alcohols.[1] Under similar

conditions, α,o-diols are converted to lactones in good yields (eq 1).

(1)

Oxidation of Alkenes.

The presence of a small additional amount of moisture along with some *t*-butyl alcohol introduces a modification to the reactivity of the reagent by formation of an omega phase[15] surrounding the solid support. Under such conditions alkenes are oxidized to α-diketones and/or α-hydroxy ketones. For example, when 200 µL of water was added to a finely ground mixture of potassium permanganate (4.0 g) and copper(II) sulfate pentahydrate (2.0 g) followed by cyclooctene (4 mmol) in CH_2Cl_2 (15 mL) and *t*-butyl alcohol (1.0 mL), α-hydroxycyclooctanone was obtained in 50% yield after refluxing for 30 min. Under similar conditions, but with the addition of $Cu(OAc)_2.H_2O$ (1.0 g), 1,2-cyclooctadione was obtained in 48% yield (eq 2).

(2)

With some alkenes, epoxides are obtained instead of ketones. For example, Δ^5-unsaturated steroids are readily converted into the corresponding 5β,6β-epoxides in 90-95% yield (eq 3).[5,8]

(3)

Oxidation of o-Hydroxy Alkenes and 1,5-Dienes.

When the omega phase is produced by adding 400 µL of water to powdered $KMnO_4$ (8 g) and $CuSO_4.5H_2O$ (4 g), o-hydroxy alkenes are oxidized with the loss of one or more carbons (eq 4).[6]

(4)

Under similar conditions, 1,5-dienes are converted to 5-substituted butanolides,[7] as opposed to 2,5-bis(hydroxymethyl)tetrahydrofurans

which are formed in the corresponding aqueous reactions (eq 5).[16]

Potassium Monoperoxysulfate

$2KHSO_5.KHSO_4.K_2SO_4$

[37222-66-5] · $H_3K_5O_{18}S_4$ · Potassium Monoperoxysulfate · (MW 614.81)

(oxidizing agent for a number of functional groups, including alkenes,[16] arenes,[17] amines,[26] imines,[30] sulfides;[37] used for the preparation of dioxiranes[5])

Alternate Names: potassium caroate, potassium hydrogen persulfate, Oxone®.

Physical Data: mp dec; *d* 1.12-1.20 g cm^{-3}.

Solubility: sol water (25.6 g 100 g, 20 °C), aqueous methanol, ethanol, acetic acid; insol common organic solvents.

Form Supplied in: white, granular, free flowing solid. Available as Oxone® and as Curox® and Caroat®.

Analysis of Reagent Purity: iodometric titration, as described in the Du Pont data sheet for Oxone®.

Handling, Storage, and Precautions: the Oxone triple salt $2KHSO_5.KHSO_4.K_2SO_4$ is a relatively stable, water-soluble form of potassium monopersulfate that is convenient to handle and store. Oxone has a low order of toxicity, but is irritating to the eyes, skin, nose, and throat. It should be used with adequate ventilation and exposure to its dust should be minimized. Traces of heavy metal salts catalyze the decomposition of Oxone. For additional handling instructions, see the Du Pont data sheet.

Oxidation Methodology.

Oxone ($2KHSO_5.KHSO_4.K_2SO_4$) is a convenient, stable source of potassium monopersulfate (caroate), which serves as a stoichiometric oxidizing agent under a variety of conditions. Thus aqueous solutions of Oxone can be used to perform oxidations in homogeneous solution and in biphasic systems using an immiscible cosolvent and a phase-transfer catalyst. Recently, solid-liquid processes using supported Oxone reagents have been developed. Other oxidation methods involve the generation and reaction of a secondary reagent under the reaction conditions, as with the widely employed aqueous Oxone-ketone procedures, which undoubtedly involve dioxirane intermediates.[1-4] In other instances, oxaziridine derivatives and metal oxo complexes appear to be the functional oxidants formed in situ from Oxone. Synthetically useful examples of these oxidations are grouped below according to the functional groups being oxidized.

Ketones and Other Oxygen Functions.

Various ketones can be converted to the corresponding dioxiranes by treatment with buffered aqueous solutions of Oxone (eq 1). Of particular interest are dimethyldioxirane[5] ($R^1 = R^2 = Me$) and methyl(trifluoromethyl)dioxirane[6] ($R^1 = Me$, $R^2 = CF_3$) derived from acetone and 1,1,1-trifluoro-2-propanone, respectively. The discovery of a method for the isolation of dilute solutions of these volatile dioxiranes in the parent ketone by codistillation from the reaction mixture has opened an exciting new area of oxidation chemistry (see ***Dimethyldioxirane*** and ***Methyl(trifluoromethyl)dioxirane***). Solutions of dioxiranes derived from higher molecular weight ketones have also been prepared.[5,7]

(1)

Interestingly, the reaction of a solid slurry of Oxone and wet ***Alumina*** with solutions of cyclic ketones in CH_2Cl_2 provokes Baeyer-Villiger oxidation to give the corresponding lactones (eq 2).[8] The same wet alumina-Oxone reagent can be used to oxidize secondary alcohols to ketones (eq 3).[9] Aldehydes are oxidized to acids by aqueous Oxone.[5,10]

(2)

(3)

Alkenes, Arenes, and Alkanes.

Aqueous solutions of Oxone can epoxidize alkenes which are soluble under the reaction conditions; for example, sorbic acid (eq 4)[11] (the high selectivity for epoxidation of the 4,5-double bond here is noteworthy). Alternatively, the use of a cosolvent to provide homogeneous solutions promotes epoxidation (eq 5).[11] Control of the pH to near neutrality is usually necessary to prevent hydrolysis of the epoxide. Rapidly stirred heterogeneous mixtures of liquid alkenes and aqueous Oxone solutions buffered with $NaHCO_3$ also produce epoxides, as shown in eq 6.[12]

(4)

(5)

(6)

An in situ method for epoxidations with dimethyldioxirane using buffered aqueous acetone solutions of Oxone has been widely applied.[1-4] The epoxidation of 1-dodecene is particularly impressive in view of the difficulty generally encountered in the epoxidation of relatively unreactive terminal alkenes (eq 7).[13] A biphasic procedure using benzene as a cosolvent and a phase-transfer agent was utilized in this case. Equally remarkable is the epoxidation of the methylenecyclopropane derivatives indicated in eq 8, given the propensity of the products to rearrange to the isomeric cyclobutanones.[14]

(7)

(8)

The epoxidation of conjugated double bonds also proceeds smoothly with the Oxone-acetone system, as illustrated by eq 9.[15] The conversion of water-insoluble enones can be accomplished with this method using CH_2Cl_2 as a cosolvent and a quaternary ammonium salt as a phase-transfer catalyst. However, a more convenient procedure utilizes 2-butanone both as a dioxirane precursor and as an immiscible cosolvent (eq 10).[16] No phase-transfer agent is required in this case.

(9)

(10)

The epoxides of several polycyclic aromatic hydrocarbons have been prepared by the use of a large excess of oxidant in a biphasic Oxone-ketone system under neutral conditions, as shown for the oxidation of phenanthrene (eq 11).[17] However, the use of isolated dioxirane solutions is more efficient for the synthesis of reactive epoxides, since hydrolysis of the product is avoided.[5,18] A number of unstable epoxides of various types have been produced in a similar manner, as discussed for ***Dimethyldioxirane*** and ***Methyl(trifluoromethyl)dioxirane***.

(11)

Epoxidations have also been performed with other oxidizing agents generated in situ from Oxone. An intriguing method uses a catalytic amount of an immonium salt to facilitate alkene epoxidation in a process which apparently involves an intermediate oxaziridium species as the active oxidant.[19] This procedure is carried out by adding solid Oxone and $NaHCO_3$ to a solution of the alkene and catalyst in MeCN containing a very limited quantity of water (eq 12). Finally, Oxone is the stoichiometric oxidant in interesting modifications of the widely

studied metal porphyrin oxidations, where it has obvious advantages over some of the other oxidants commonly used.[20] The potential of this method is illustrated by the epoxidation reaction in eq 13.[21] In this conversion, only 1.4 mol % of the robust catalyst tetrakis(pentafluorophenyl)porphyrinatomanganese chloride (TFPPMnCl) is required. The catalytic hydroxylation of unactivated hydrocarbons is also possible (eq 14).[22] Other metal complexes promote similar oxidations.[23-25]

(12)

(13)

(14)

Nitrogen Compounds.

The aqueous Oxone-acetone combination has been developed for the transformation of certain anilines to the corresponding nitrobenzene derivatives, as exemplified in eq 15.[26] This process involves sequential oxidation steps proceeding by way of an intermediate nitroso compound. In the case of primary aliphatic amines, other reactions of the nitrosoalkane species compete with the second oxidation step (for example, dimerization and tautomerization to the isomeric oxime), thereby limiting the synthetic generality of these oxidations.[27] An overwhelming excess of aqueous Oxone has been used to convert cyclohexylamine to nitrocyclohexane (eq 16).[27]

(15)

(16)

Pyridine is efficiently converted to its *N*-oxide by the Oxone-acetone oxidant.[5] Cytosine and several of its derivatives give the N^3-oxides selectively upon reaction with buffered Oxone (eq 17).[28] A similar transformation of adenosine 5´-monophosphate yields the N^1-oxide.[29]

(17)

The very useful *N*-sulfonyloxaziridines are conveniently prepared by treating *N*-sulfonylimines with Oxone in a biphasic solvent system (eq 18).[30,31] Either bicarbonate or carbonate can be used to buffer this reaction, but reaction is much faster with carbonate, suggesting that the monopersulfate dianion is the oxidizing species (for illustrations of the remarkable chemistry of these oxaziridines, see ***N-(Phenylsulfonyl)(3,3-dichlorocamphoryl)oxaziridine***).

(18)

The Oxone-acetone system has also been employed for the synthesis of simple oxaziridines from *N*-alkylaldimines (eq 19).[32] Interestingly, the *N*-phenyl analogs produce the isomeric nitrones rather than the oxaziridines (eq 20). It is noteworthy that MeCN can replace acetone as the solvent in this procedure.

(19)

(20)

Finally, the chlorination of aldoximines gives the corresponding hydroximoyl chlorides, as shown in eq 21.[33] The combination of Oxone and anhydrous HCl in DMF serves as a convenient source of hypochlorous acid, the active halogenating agent.

(21)

Sulfur Compounds.

Some of the earliest applications of Oxone in organic synthesis involved the facile oxidation of sulfur functions. For example, aqueous Oxone selectively oxidizes sulfides to sulfones even in highly functionalized molecules, as illustrated in eq 22.[34] Sulfones can also be prepared by a convenient two-phase system consisting of a mixture of solid Oxone, wet ***Montmorillonite K10*** clay, and a solution of the sulfide in an inert solvent.[35]

(22)

The partial oxidation of sulfides to sulfoxides has been accomplished in a few cases by careful control of the reaction stoichiometry and conditions.[34] A biphasic procedure for sulfoxide formation from diaryl sulfides is shown in eq 23.[36] However, a more attractive and versatile procedure uses a solid Oxone-wet alumina reagent with a solution of the sulfide.[37] This method permits control of the reaction to form either the sulfoxide or the sulfone simply by adjusting the amount of oxidant and the reaction temperature, as illustrated in eq 24. These oxidations are compatible with other functionality.

(23)

(24)

Another intriguing method for the selective oxidation of sulfides to sulfoxides (eq 25) uses buffered Oxone in a biphasic solvent mixture containing a catalytic amount of an *N*-phenylsulfonylimine as the precursor of the actual oxidizing agent, the corresponding *N*-sulfonyloxaziridine.[38] The oxaziridine is smoothly and rapidly formed by reaction of the imine with buffered Oxone and regenerates the imine upon oxygen transfer to the sulfide. The greater reactivity of the sulfide relative to the sulfoxide accounts for the preference for monooxidation in this procedure. The biphasic nature of this reaction prevents direct oxidation by Oxone, which would be less selective.

(25)

Oxone sulfoxidations can show appreciable diastereoselectivity in appropriate cases, as demonstrated in eq 26.[39] Enantioselective oxidations of sulfides to sulfoxides have been achieved by buffered aqueous Oxone solutions containing bovine serum albumin (BSA) as a chiral mediator (eq 27).[40] As little as 0.05 equiv of BSA is required and its presence discourages further oxidation of the sulfoxide to the sulfone. Oxone can be the active oxidant or reaction can be performed in the presence of acetone, trifluoroacetone, or other ketones, in which case an intermediate dioxirane is probably the actual oxidizing agent. The level of optical induction depends on structure of the sulfide and that of any added ketone. Sulfoxide products show ee values ranging from 1% to 89%, but in most examples the ee is greater than 50%.

(26)

(27)

1-Decanethiol is efficiently oxidized to decanesulfonic acid (97% yield) by aqueous Oxone.[10] In a similar manner an acylthio function was converted into the potassium sulfonate salt, as shown in eq 28.[41]

(28)

Finally, certain relatively stable thioketones can be transformed into the corresponding thione *S*-oxides by the aqueous Oxone-acetone reagent (eq 29).[42]

(29)

Related Reagents.

Dimethyldioxirane; ***Methyl(trifluoromethyl)dioxirane***.

Potassium Ruthenate

K_2RuO_4

[14931-42-1] · K_2O_4Ru · Potassium Ruthenate · (MW 243.27)

(powerful oxidant capable of oxidizing primary alcohols to carboxylic acids and secondary alcohols to ketones;[1] in combination with persulfate can oxidize nitro compounds[2] and activated halides[3] and will selectively oxidize allylic alcohols under phase-transfer conditions[4])

Alternate Name: potassium tetraoxoruthenate(VI).

Physical Data: d 3.07 g cm^{-3}.

Solubility: sol H_2O; insol organic solvents.

Form Supplied in: green-black crystals (anhyd), deep red crystals (hyd); not commercially available.

Preparative Method: K_2RuO_4 has been prepared according to the method of Krauss.[5] To molten KOH in a nickel crucible is added equimolar amounts of Ru and KNO_3. The mixture is cooled, dissolved in H_2O, and K_2RuO_4 crystallized by slow evaporation over P_2O_5.

Handling, Storage, and Precautions: unstable in all but basic media and should be prepared and used as such. The toxicological properties of Ru have not been thoroughly investigated.

Functional Group Oxidations.

K_2RuO_4 functions as a two-electron oxidant in the oxidation of aliphatic alcohols, allylic alcohols, diols, aldehydes, halides, and nitro compounds. The reactions are generally performed in aqueous base using catalytic $[RuO_4]^{2-}$ with persulfate ($S_2O_8^{2-}$) as the secondary oxidant. A typical workup procedure involves either extraction of the solution with ether if the product is a ketone, or acidification of the solution to pH 2 with H_2SO_4, followed by ether extraction if carboxylic acids are produced. The organic extracts are combined and concentrated before passage through a Celite pad to remove any residual Ru. The solvent is then removed under reduced pressure to give the pure ketone or carboxylic acid. Alternatively, phase-transfer conditions[1,4] may be used to effect the oxidation of alkyl halides and alcohols.

Oxidation of Primary Alcohols.

Primary alcohols are oxidized to carboxylic acids by the $[RuO_4]^{2-}/S_2O_8^{2-}$ system (eq 1).[1,3] Under phase-transfer conditions[3] this reagent gives aldehydes in good yields (eq 2).

(1)

(2)

The rate of oxidation of a series of substituted benzyl alcohols varies according to the electron-withdrawing or -donating capacity of the substituent; the oxidation rate decreases in the order 4-NO_2 > 4-H > 4-OMe.[1] Similar rate effects have been noted for oxidations with CrO_3[6] and $[FeO_4]^{2-}$.[7]

Oxidation of Secondary Alcohols.

Secondary alcohols are oxidized to ketones by catalytic ruthenate in a similar manner (eq 3).[1,3] However, oxidation of secondary alcohols under phase-transfer conditions results in poor yields of the desired ketone.[3]

(3)

Oxidation of mandelic acid and hydrobenzoin gives benzoic acid arising from additional carbon-carbon bond cleavage.[1] However, this only occurs with oxidatively sensitive substrates, as oxidation of methyl mandelate proceeds to give the corresponding glyoxylate with no such cleavage.[1]

Allylic Alcohols.

Unlike other two-electron oxidants such as ***Chromium(VI) Oxide***, ***Ruthenium(VIII) Oxide*** and ***Osmium Tetroxide***,[8] catalytic ruthenate exhibits low reactivity towards double bonds and as such is particularly useful for the oxidation of allylic and homoallylic alcohols.[1,9] Thus allyl alcohol[1] and *trans*-cinnamyl alcohol (eq 4)[1,9] are cleanly oxidized to the corresponding unsaturated acids.

(4)

Diols.

These are oxidized to their corresponding dicarboxylic acids under similar conditions (eq 5).[1,10]

(5)

Aldehydes.

As expected, aldehydes are oxidized to carboxylic acids under both aqueous[1,3,9] and phase-transfer[3] conditions.

Activated Halides.

The best known methods for the oxidation of alkyl halides are the noncatalytic Sommelet or Kornblum reactions.[11] Ruthenate may be used catalytically to effect the (large scale) oxidation of allylic and benzylic primary alkyl halides to acids and secondary halides to ketones.[3]

Nitro Compounds.

Catalytic ruthenate oxidizes primary nitroalkanes to carboxylic acids[3] and on one occasion has been used for the production of a ketone from a secondary nitro compound (eq 6).[2]

(6)

Selective Oxidations.

Although several reagents for the selective oxidation of allylic and benzylic alcohols have been reported,[12] these oxidants suffer from variable selectivity and lack of general applicability. For example, the widely used reagent ***Manganese Dioxide*** oxidizes aliphatic alcohols in certain cases[13] and even Cr^{VI} reagents such as ***Bis(tetrabutylammonium) Dichromate*** and ***4-(Dimethylamino)pyridinium Chlorochromate*** oxidize primary and secondary alcohols to a significant extent.[12b,c] However, catalytic ruthenate under phase-transfer conditions is a selective oxidant for allylic and benzylic alcohols in the presence of aliphatic alcohols (eq 7).[4]

Potassium Selenocyanate[1]

KSeCN

[3425-46-5] · CKNSe · Potassium Selenocyanate · (MW 144.08)

(synthesis of organoselenocyanates;[1] deoxygenation of epoxides;[2,3] isomerization of disubstituted alkenes;[4] synthesis of selenoaldehydes and selenoketones;[5,6] in combination with Me_3SiCl, selective cyanosilylation of aldehydes[7])

Physical Data: mp 100 °C; *d* 2.347 g cm^{-3}.

Solubility: sol H_2O, DMF, DME, HMPA, MeCN, MeOH; slightly sol THF.

Form Supplied in: colorless crystalline solid; widely available.

Handling, Storage, and Precautions: crystalline KSeCN is hygroscopic and decomposes with elimination of selenium upon prolonged exposure to air. It should be stored in sealed containers. KSeCN is highly toxic and foul smelling. Use in a fume hood.

Organic Selenocyanates.

Organoselenocyanates are useful synthetic intermediates that participate in a variety of reactions.[1] KSeCN is a versatile reagent for the preparation of organoselenocyanates. Nucleophilic displacement of halides and tosylates with KSeCN is the most convenient route to aliphatic selenocyanates, whereas nucleophilic displacement of diazo group is preferred in aromatic compounds.[1] Owing to the high nucleophilicity of selenium,[8] the selenocyanate ion reacts predominantly at selenium in reactions at electrophilic carbon centers. This reactivity contrasts that of their sulfur analog, the thiocyanate ion, which reacts at both sulfur and nitrogen.[9] Electrophilic substitution reactions involving dicyanodiselenide, $(SeCN)_2$, obtained by oxidation of KSeCN, also have been used for the preparation of organoselenocyanates.[1,10,11] Other known selenocyanate salts include AgSeCN, CsSeCN, $(Me_4N)SeCN$, and $LiSeCN.Et_2O$.[12,13] The latter offers greater solubility compared to KSeCN and could represent a useful alternative source of selenocyanate ion in less polar solvents.[12] Synthetic organic application of KSeCN originate mainly from the synthesis and reactivity of organoselenocyanates. Some potentially promising synthetic organic transformations based on the chemistry of organoselenocyanates derived from KSeCN are summarized below.

Deoxygenation of Epoxides.

Epoxides can be deoxygenated upon treatment with KSeCN in polar protic solvents at 23-65 °C to afford alkenes with retention of configuration (eq 1).[2,3] The reaction depends on the solvent; best results are obtained in polar protic solvents such as H_2O/MeOH, while the reaction fails in aprotic solvents such as DMF and DMSO.[3] The reaction proceeds in high yields for straight chain terminal epoxides, but for cyclic epoxides the reactivity is varied.[3] For instance, reaction of cyclohexene oxide affords cyclohexene in a quantitative yield at 23 °C; however, epoxides of cyclopentene and cyclooctene remain unreacted even after prologed heating at 65 °C.[3] KSeCN-mediated deoxygenation of epoxides has been utilized in the synthesis of (+)-aucantene and other selectively functionalized cyclohexenes.[14]

(1)

Isomerization of Disubstituted Alkenes.

Conversion of disubstituted alkenes to bromohydrins followed by sequential treatment with KSeCN in DMF and a base results in overall isomerization of the starting alkenes (eq 2).[4] The reaction of bromohydrin with KSeCN results in nucleophilic displacement of bromide with inversion of configuration to stereospecifically afford the α-hydroxy selenocyanate intermediate, treatment of which with a base

affords the isomerized alkenes.

Synthesis of Selenoaldehydes and Selenoketones.

Certain organoselenocyanates derived from KSeCN undergo fluoride-[5] and base-induced[5,6] elimination of cyanide to afford highly reactive selenocarbonyl intermediates (eqs 3 and 4). These selenocarbonyl intermediates exhibit rich cycloaddition chemistry (Diels-Alder and 1,3-cycloadditions) to afford selenium-containing heterocycles.[5,6]

Selective Cyanosilylation of Aldehydes.

Trimethylsilylisoselenocyanate ($Me_3SiNCSe$), generated in situ from the reaction of KSeCN with ***Chlorotrimethylsilane***, can be used for the chemoselective cyanosilylation of aldehydes in presence of a catalyst (eq 5).[7] Higher reactivity and yields are obtained in hexane with ***Zinc Chloride*** catalysis. Ketones do not undergo this reaction.

Related Reagents.

Potassium Thiocyanate; ***Sodium Thiocyanate***; ***Isoselenocyanatotrimethylsilane***.

Potassium 9-Siamyl-9-boratabicyclo[3.3.1]nonane[1]

(R = siamyl, 3-methyl-2-butyl)

[125392-39-4] · $C_{13}H_{26}BK$ · Potassium 9-Siamyl-9-boratabicyclo[3.3.1]nonane · (MW 232.30) (R = *n*-Bu)

[119875-90-0] · $C_{12}H_{24}BK$ · Potassium 9-Butyl-9-boratabicyclo[3.3.1]nonane · (MW 218.27) (R = *t*-Bu)

[119875-89-7] · $C_{12}H_{24}BK$ · Potassium 9-*t*-Butyl-9-boratabicyclo[3.3.1]nonane · (MW 218.27)

(selective reducing agent for ketones[2] and aromatic nitriles to aldehydes[3])

Physical Data: colorless in THF solution.

Solubility: sol THF; evolves hydrogen in protic solvents.[1]

Analysis of Reagent Purity: the reagents exhibit typical upfield ^{11}B NMR resonances in THF (e.g. KHR-9-BBN: R = *n*-Hx, δ -13.2 (d, J_{B-H} = 70 Hz); R = Ipc, -6.1 (d, J_{B-H} = 73 Hz); R = *t*-Bu, -10.4 (t, J_{B-H} = 75 Hz) ppm).[2,4]

Preparative Methods: prepared as stable THF solutions from the reaction of a purified suspension of ***Potassium Hydride*** in THF with the appropriate *B*-alkyl-9-BBN.[4] KH is purified by removal of the mineral oil by successive pentane washing and decantation of the supernatant under an inert atmosphere, treatment with a solution of ***Lithium Aluminum Hydride*** in THF followed by additional washings with fresh dry THF. This provides KH which reacts with *B*-alkyl-9-BBN in THF to form the borohydrides in <30 min at 25 °C. It is recommended that the initial addition be carried out at 0 °C to prevent an exothermic reaction with unhindered derivatives. Stable solutions of $KHB(O\text{-}i\text{-}Pr)_3$ can be used stoichiometrically to prepare KHR-9-BBN from *B*-R-9-BBN or, alternatively, as a catalyst for the KH method.[5]

Handling, Storage, and Precautions: THF solutions of the reagent are indefinitely stable at 25 °C when stored under a nitrogen atmosphere. Exposure to atmospheric oxygen, moisture, or protic solvents results in its potentially dangerous rapid oxidation and/or the exothermic generation of hydrogen gas. The generation and use of KHR-9-BBN involves the handling of dangerously pyrophoric or flammable reagents (i.e. KH, $LiAlH_4$, or *B*-R-9-BBN). Individuals should thoroughly familiarize themselves with the special handling techniques required for such reagents prior to their

use.[1] The reagent should be used in a well ventilated hood.

Selective Reduction of Ketones.

Cyclic and bicyclic ketones are quantitatively reduced to the corresponding alcohols with KHR-9-BBN reagents, the diastereofacial selectivities being determined both by steric and conformational effects in the substrate and the steric bulk of the *B*-R substituent in the reagent (eq 1).[2] Thus KH(*t*-Bu)-9-BBN exhibits selectivities which are comparable to the high selectivity ***Lithium Trisiamylborohydride*** reagent, exceeding those of less hindered borohydrides such as ***Lithium Tri-s-butylborohydride*** or KH(OR)-9-BBN.

(1)

R		
Bu	61	39
Sia	90	10
t-Bu	94	6

Aldehydes from Nitriles.

Aromatic nitriles are efficiently reduced to aldehydes (60-98%) with 1 equiv of KH(Sia)-9-BBN (24 h, 25 °C; eq 2).[3] In competitive experiments, the selective reduction of aromatic nitriles can be accomplished in the presence of their aliphatic counterparts which are recovered intact. The reagent also readily reduces acid chlorides, esters, lactones, aldehydes, ketones, and epoxides to the corresponding alcohols. Amines, carboxylic acids, oximes, and aliphatic nitro compounds are not reduced.[2b]

(2)

Related Reagents.

Potassium Sodium Tartrate[1]

[304-59-6] · $C_4H_4KNaO_6$ · Potassium Sodium Tartrate · (MW 210.17) (.4H_2O)

[6381-59-5] · $C_4H_{12}KNaO_{10}$ · Potassium Sodium Tartrate · (MW 282.25)

(chelating agent for metal ions)

Alternate Names: Rochelle salt; Seignette salt.

Physical Data: tetrahydrate:[1c] mp 70-80 °C; loses 3H_2O at 100 °C; becomes anhydrous at 130-140 °C; dec 220 °C; *d* 1.79 g cm^{-3}. The physicochemical properties of this tartrate salt are well documented.[1b]

Solubility: (g 100 mL^{-1} H_2O) 42 at 0 °C, 82 at 16 °C, 140 at 29 °C, 225 at 40 °C;[11] insol alcohol.

Form Supplied in: the tetrahydrate is widely available as translucent crystals or as a white crystalline solid.

Analysis of Reagent Purity: by nonaqueous titration.[2]

Purification: can be recrystallized from a chilled solution of distilled H_2O.[3]

Handling, Storage, and Precautions: purgative; reactions should be performed in a well-ventilated fume hood.

Introduction.

Tartrate esters and metal salts of tartaric acid have found increasing synthetic use as metal chelating agents. Although Rochelle salt has been extensively studied with regard to its electrical, magnetic, and optical properties, and has found industrial utility, e.g. in photography, ceramics, electrodeposition, and analytical spectrophotometry, its use in organic synthesis has been limited. It is perhaps best known as a constituent of Fehling's solution (alkaline copper(II) tartrate), the classic reagent for the characterization of aldehydes.[1a,4]

Chelating Agent.

The complexing ability of the tartrate ion has been utilized in the workup of reactions involving metal alkoxides. For example, in the Oppenauer oxidation of cholesterol,[5] a saturated aqueous solution of Rochelle salt was used to keep the resulting aluminum byproduct in the aqueous layer during the workup (eq 1). The Δ^4-cholesten-3-one was thus readily isolated by extraction and subsequent crystallization in ca. 80% yield.

In a later study,[6] after reduction of the cholesten-3-one was accomplished with ***Lithium Tri-t-butoxyaluminum Hydride***, the resulting mixture was hydrolyzed with ice-cold alkaline Rochelle salt (eq 2). The resulting Δ^4-cholesten-3β-ol was easily extracted with ether in 87% yield.

With Rochelle salt workup, 6α-methylandrost-4-ene-3,17-dione has been prepared from the corresponding 5α-hydroxy-6β-methylandrostane derivative in the presence of ***Aluminum t-Butoxide*** (eq 3).[7] Isolation of the ***Lithium Aluminum Hydride*** reduction products of α-silyl esters (eq 4) is also facilitated by ice-cold aqueous Rochelle salt.[8]

In a synthesis of a leukotriene antagonist, introduction of the required asymmetric center was achieved by chiral reduction of the ketone precursor with (-)-*B*-chlorodiisopinocampheylborane eq 5).[9] Acetone quenching and addition of 20% aqueous Rochelle salt solution allowed isolation of the product alcohol in 87% yield.

(5)

Chiral Metal(II) (+)-Tartrate Lewis Acids.

A number of metal(II) tartrates synthesized from Rochelle salt have found recent use as heterogeneous chiral Lewis acid catalysts in the asymmetric ring-opening reactions of *meso*-epoxides (eqs 6 and 7).[10] Thiols, aniline, and trialkylsilyl azides give the corresponding adducts in varying chemical yields and enantiomeric excess using 10 mol % concentrations of metal (+)-tartrate catalyst.

Potassium Superoxide[1]

KO_2

[12030-88-5] · KO_2 · Potassium Superoxide · (MW 71.10)

(reactive species is the superoxide anion, O_2^-; solubility of KO_2 in aprotic organic solvents is facilitated by crown ethers[2,3] or other phase-transfer catalysts;[4] O_2^- reacts with most organic substrates either as an anion or as an electron-transfer (reducing) agent; reacts as a nucleophilic anion toward alkyl halides, sulfonates, and carbonyl groups; other net displacement reactions such as with halocarbons may be initiated by electron transfer; reacts as a basic anion toward substrates bearing acidic protons; used in situ with a variety of activated halogens to form peroxy anions useful for further oxygen transfer, e.g. epoxidations[1])

Physical Data: mp 500 °C.[5]

Solubility: slightly sol DMSO; crown ethers are useful for bringing KO_2 into organic solvents such as DMSO,[2] DMF, MeCN, THF, benzene;[3] reacts rapidly with H_2O and protic solvents.

Form Supplied in: small chunks of light yellow powdery solid.

Handling, Storage, and Precautions: chunks of solid may be handled briefly in the atmosphere; prolonged exposure to the atmosphere results in reaction with H_2O; storage should be under dry conditions such as a desiccator; reaction with H_2O produces O_2, H_2O_2, and OH^-.

Dialkyl Peroxide Synthesis.

Primary and secondary alkyl bromides[9] and alkyl sulfonates react with KO_2 in aprotic organic solvents (except DMSO, see below), giving acyclic (eq 1)[3,10] and cyclic (eq 2)[11] dialkyl peroxides. The reactions are greatly facilitated by the addition of crown ethers or other phase-transfer catalysts to the reaction medium. The reaction at secondary carbon atoms proceeds with >95% inversion of configuration[3,12] and is accompanied by formation of significant amounts of alkene due to elimination reactions. Because of the mechanism by which the dialkyl peroxides are generated, this method is best suited for synthesis of symmetrical dialkyl peroxides.

(1)

(2)

Alcohol Inversion.

When the reaction between alkyl bromides or alkyl sulfonates and KO_2 is performed in DMSO, the major product is an alcohol[12] as a consequence of oxygen transfer from the intermediate peroxy anion to the DMSO (eq 1).[13] Such displacements of tosylate (eq 3)[14] or mesylate (eqs 4 and 5)[15,16] by KO_2 in DMSO have been used for inversion of the configuration of secondary alcohols and this method is of comparable efficiency to the modified[18] Mitsunobu sequence[17] used for the same purpose.

(3)

(4)

(5)

Ester Cleavage.

Carboxylic acid esters are cleaved by O_2^-, giving the corresponding carboxylic acid and alcohol.[19] Several studies of the mechanism of this process have been reported.[20] Qualitatively, displacement of halide or sulfonate ester occurs in preference to ester hydrolysis (see eq 2). The use of KO_2 for ester cleavage generally offers no advantage over conventional ester saponification methods.

Diacyl Peroxide Synthesis.

Acid chlorides react with O_2^- to give diacyl peroxides,[21] which in turn are susceptible to further reaction with O_2^-.[22] Acyl peroxy anions are formed as intermediates in the reactions with acid chlorides and diacyl peroxides as well as in the reaction of O_2^- with anhydrides as detected by epoxidation of alkenes.[22] Applications of this approach to oxygen-transfer chemistry is discussed further below. Eq 6 summarizes the primary events but is an incomplete account of all the reactions occurring between O_2^- and these substrates. Amides, aldehydes, and nitriles are unreactive with KO_2 under most conditions.

(6)

Oxygen Transfer via Peroxy Anions.

A number of reagents react with superoxide to form transient peroxy anions which oxidize electrophilic functional groups such as alkenes, sulfides, sulfoxides, etc. Among the reagents forming peroxy anions useful in such oxidations are aryl sulfonyl halides[23] (especially 2-nitrobenzenesulfonyl chloride[24]), acid chlorides,[22,25] halocarbons such as carbon tetrachloride,[26] dialkyl chlorophosphates[27] and alkyl dichlorophosphates,[28] carbon dioxide,[29] *N*-(-)-menthoxycarbonyl-4-tolylsulfonimidoyl chloride,[30] and phosgene.[31] Representative examples of oxidations by these systems include the epoxidation of limonene (eq 7),[24] the oxidation of sulfides to sulfoxides (eq 8),[32] selective oxidation of sulfoxides to sulfones in the presence of alkenes (eq 9),[33] oxidation of benzylic methylenes to ketones (eq 10),[34] and

cleavage of tosylhydrazones to ketones or aldehydes (eq 11).[35]

(7)

(8)

(9)

(10)

(11)

These approaches to oxygen transfer have not been tested beyond the original reports. Comparisons with other established oxygen-transfer reagents such as the peracids (e.g. ***m-Chloroperbenzoic Acid***) and the dioxiranes (e.g. ***Dimethyldioxirane***) still must be explored.

Electron-Transfer Chemistry.

Certain reactions of O_2^- whose net result appears to be that of either a nucleophilic addition or displacement reaction, instead may be the result of an electron transfer followed by capture of oxygen, giving the peroxy radical. Oxygen labeling experiments are necessary to distinguish between the two mechanisms.

Nucleophilic Displacement of Aromatic Halides.

Aromatic halides substituted with electron-withdrawing groups undergo nucleophilic displacement by KO_2[36] (eq 12)[37] as well as by electrochemically generated O_2^-.[38] Yields of phenols are generally good to excellent in these reactions.

(12)

Reactions with Electron-Deficient Alkenes.

cis-2,2,6,6-Tetramethylhept-4-en-3-one, a molecule designed as a probe for electron transfer, is isomerized to the *trans*-enone by KO_2, consistent with electron transfer from reagent to the enone.[39] Cyclohexenone is epoxidized (30% yield) by electrochemically generated superoxide anion,[10] but is converted to a trimeric ketone structure with KO_2.[40] Other cyclohexenones react with KO_2 only when acidic protons are present in the molecule, and then are transformed into mixtures of oxidized products.[40] The cyclohexenone system of cholest-4-en-3-one reacts with KO_2 to give a mixture of at least five oxidation products.[41] Chalcones react with KO_2 in a series of steps initiated by electron transfer to yield aryl carboxylic acids (52-72%) (eq 13).[42] A series of alkenes highly substituted with electron-withdrawing groups (e.g. 1,2-diphenyl-1-nitroethylene) react with KO_2 yielding products of oxidation, e.g. benzoic acid (85%) (eq 14).[43] The conversions by KO_2 of tetraarylcyclopentadienones to 2-hydroxy-2,4,5-triarylfuran-3-ones[44] or to furan-3-ones, 3,4,5,6-triarylpyran-2-ones, and carboxylic acids[45] are initiated by electron transfer.

(13)

(14)

Reactions with Anilines.

Aniline, various substituted anilines, and α-naphthylamine do not react with KO_2 suspended in THF at 80 °C,[46] but several anilines are converted into azobenzenes by KO_2 in benzene containing a crown ether[47,48] or in DMSO.[49] Both *o*- and *p*- but not *m*-phenylenediamines are converted into azobenzenes by KO_2 suspended in THF or pyridine as shown in eq 15. Both *o*- and *p*-aminophenol likewise are transformed into azobenzenes[46] (**Caution**: two laboratories have reported violent explosions of mixtures containing *o*-aminophenol and KO_2 in either THF or toluene[50]). 2-Mercaptoaniline with KO_2 gives 2,2´-dithiobisaniline in 85% yield,[46] the result of coupling of the thiol rather than of the amine substituent.

(15)

Reaction with Thiols.

Under mild conditions (suspension of KO_2 in toluene), thiophenols and aliphatic thiols are converted into disulfides by KO_2 (eq 16).[51] Under more vigorous reaction conditions (elevated temperature[51] or KO_2/crown ether in pyridine[52]) these thiols are converted into sulfonic acids. Certain thiols (e.g. 2-mercaptophenol) are transformed into sulfonic acids even under the mild reaction conditions. Ethane-1,2-dithiol and propane-1,3-dithiol are converted under mild conditions into the cyclic disulfides 1,2,5,6-tetrathiocan and 1,2,6,7-tetrathiothiecan (eq 17), respectively, while butane-1,4-dithiol forms 1,2-dithian by reaction with KO_2.[51]

(16)

(17)

Reactions with Phenols, including Catechols and Tocopherols.

Monophenolic compounds do not generally undergo any net change with KO_2. Naphthalene diols react with KO_2 suspended in a toluene-pyridine mixture under an inert atmosphere to form mono- or dihydroxynaphthoquinones in good yields (eq 18).[53]

(18)

Catechols are first oxidized to *o*-quinones upon treatment with KO_2 followed by further oxidation to a variety of products.[54,55] Catechol itself is converted to *cis,cis*-muconic acid in very low yields accompanied by much polymeric byproduct. 9,10-Dihydroxyphenanthrene is converted to diphenic acid in good yield (90%). 3,5-Di-*t*-butylcatechol is converted to a mixture of oxidized products. The tocopherol model compound 2,2,5,7,8-pentamethylchroman-6-ol is converted by KO_2 suspended in THF into 6-hydroxy-2,2,6,7,8-pentamethylchroman-5(6*H*)-one (20%)[56] but, with a solution of KO_2 in AcCN, a low yield (12%) of a diepoxide together with as many as six other compounds are isolated.[57] The analogous diepoxide together with a complex mixture was isolated from the reaction of tocopherol with KO_2.[57]

Miscellaneous Transformations.

Practical syntheses of ethyl glyoxylate (72%) and diethyl oxomalonate (83%, via diethyl cyanomalonate) from ethyl cyanoacetate with electrochemically generated superoxide have been reported, as shown in eq 19.[58]

(19)

Aromatic nuclei to which quinones, cyclic alcohols, or cyclic ketones are fused are converted (52-88%) into the aromatic dicarboxylic acids upon reaction with a large excess of KO_2/crown ether in DMF (eq 20).[59]

(20)

Tetramethyl- and tetraethylammonium ozonide, whose uses as reagents in organic chemistry are unexplored, have been prepared from the reaction of tetraalkylammonium superoxide and an alkali metal ozonide in liquid ammonia.[60] The question of whether the oxygen released following transfer of an electron from superoxide to a substrate is singlet oxygen is discussed in Frimer's excellent review.[1a] Potassium superoxide was considered to have the molecular formula K_2O_4 until quantum mechanics predicted the structure of O_2^- and experimental

confirmation of the radical anion nature of the molecule was performed.[61]

Related Reagents.

Electrochemically generated O_2^- (for which a tetraalkylammonium cation usually serves as the counter ion);[6] tetramethylammonium superoxide (Me_4NO_2);[7] NaO_2; radiolysis of O_2 in water is used to generate transient O_2^- in aqueous media.[8]

Potassium Tetrachloropalladate(II)

K_2PdCl_4

[10025-98-6] · Cl_4K_2Pd · Potassium Tetrachloropalladate(II) · (MW 326.42)

(used as a soluble form of $PdCl_2$)

Physical Data: mp 534 °C (dec).

Solubility: sol water, MeOH, EtOH.

Form Supplied in: brown powder; commercially available.

Preparative Method: easily prepared by the reaction of $PdCl_2$ with 2 equiv of KCl in methanol and used without isolation.

Handling, Storage, and Precautions: air stable; not hygroscopic.

General Considerations.

The title reagent is most often used as a soluble source of palladium chloride (see ***Palladium(II) Chloride***). For a related reagent see ***Disodium Tetrachloropalladate(II)***.

Potassium Tetrafluorocobaltate(III)[1]

$KCoF_4$

[22391-97-5] · CoF_4K · Potassium Tetrafluorocobaltate(III) · (MW 174.03)

(moderately strong reagent used for the fluorination of a wide range of organic substrates in the solid/vapor phase)

Physical Data: mp unknown; *d* ca 3.9 g cm^{-3}.

Solubility: reacts violently with water and hydroxylic solvents. Will fluorinate most organic compounds at relatively low temperatures.

Form Supplied in: pink-purple solid when pure, darkens on exposure to moisture; not commercially available.

Preparative Methods: usually prepared by the reaction of potassium cobaltate(II) with elemental fluorine at temperatures in the range 250-350 °C, usually in a stirred bed or static bed reactor preferably constructed of nickel or less satisfactorily of copper. The reagent is reacted with organic substrates in the same reactor in the manner described for reactions of ***Cobalt(III) Fluoride***.[2] Its crystal structure has been reported by Hoppe.[3]

Handling, Storage, and Precautions: normally prepared and used in situ. Can be stored under dry conditions under nitrogen for a considerable period. Releases HF on contact with moist air and must be handled with suitable protection. This reagent should be handled in a fume hood.

General Considerations.

Until recently, the whole of the published work on the reactions of this reagent have been by the Birmingham group over the period 1962-1993.

Whereas cobalt(III) fluoride is a very indiscriminate fluorinating agent which generally produces saturated fluorocarbons and fluorohydrocarbons with the loss of functional groups, $KCoF_4$ is a much milder reagent and affords more lightly fluorinated materials, often without affecting functionality and unsaturation present in the substrate. This makes it especially useful for the fluorination of heterocyclic materials.

Fluorination of Alkanes.

The fluorination of hydrocarbons to give perfluorocarbons by CoF_3 has been described,[2] but there is relatively little known concerning the preparation of the potentially useful fluorohydrocarbons (HFCs) with this reagent. With its milder reactivity, probably due to its lower oxidation potential relative to CoF_3,[4] $KCoF_4$ was an obvious reagent to use for this kind of fluorination. The fluorination of ethane (the only full study so far reported[5]) was shown to yield a mixture of fluorinated ethanes (eq 1). It is notable that even at 420 °C there is still only a low degree of fluorination; for comparison, CoF_3 at 165 °C affords almost exclusively penta- and hexafluoroethane in equal proportions. This work has recently been repeated with essentially the same results in a Japanese patent.[6]

$$C_2H_6 \xrightarrow{420\ ^\circ C} \underset{25.4\%}{CH_2FCH_2F} + \underset{10.9\%}{MeCHF_2} + \underset{29.1\%}{CH_2FCHF_2} + \underset{3.3\%}{MeCF_3} + \underset{9.8\%}{CHF_2CHF_2} + \underset{6.2\%}{CH_2FCF_3} + \underset{1.6\%}{C_2F_5H} + \underset{2.1\%}{C_2F_6} + \underset{2.1\%}{CF_4} \quad (1)$$

Fluorination of Alkenes.

The fluorination of alkenes with $KCoF_4$ has again only been sparsely studied. The original work (reported only in the patent literature) describes the fluorination of vinyl halides (eqs 2-4). These fluorinations provide a very simple one-step route to a number of halofluorocarbons which are quite difficult to prepare by conventional fluorine technology. The fluorination of ethylene has been described and yields essentially the same products as found for the fluorination of ethane.[5,6]

$$C_2H_4 \xrightarrow{300\ ^\circ C} \underset{45.7\%}{CH_2FCH_2F} + \underset{5.1\%}{MeCHF_2} + \underset{37.2\%}{CH_2FCHF_2} + \underset{5.8\%}{CHF_2CHF_2} \qquad (2)$$

$$CHBr{=}CBr_2 \longrightarrow \underset{25\%}{CHF_2CBr_2F} + \underset{75\%}{CHBrFCBr_2F} \qquad (3)$$

$$CCl_2{=}CCl_2 \longrightarrow \underset{88\%}{CCl_2FCCl_2F} + \underset{12\%}{CClF_2CCl_2F} \qquad (4)$$

Fluorination of Arenes.

The fluorination of arenes by $KCoF_4$ might be expected, if the proposed mechanism for high valency metal fluoride fluorinations is tenable, to be significantly different from that of CoF_3.[7] This proved to be so, as shown for the case of benzene (eq 5). Fluorobenzene and *p*-difluorobenzene gave essentially the same products in the same proportions, suggesting that they are intermediates in the fluorination. The fluorination of polycyclic arenes has been investigated for naphthalene (eq 6)[8] and tetralin,[9] anthracene (eq 7), phenanthrene (eq 8), and pyrene (eq 9).[10] The compounds from these reactions have been used as sources of the corresponding perfluoroarenes.[10,11]

Fluorination of Heterocycles.

A wide range of heterocycles have been fluorinated, ranging from THF to 4-methylpyridine and some polyfluoropyridines. At temperatures between 200 and 400 °C, fluorination of THF yields a mixture of six products (eq 10). In this reaction there are two major products, again illustrating the relative mildness of the reagent.[12] This is further illustrated by the fluorination of 2-methyltetrahydrofuran,[13] where essentially only one product is isolated (eq 11).

(10)

(11)

The fluorination of thiophene (eq 12), tetrachlorothiophene (eq 13),[14] and 2-methylthiophene (eq 14)[15] have also been carried out, with results essentially similar to those obtained for THF.

(4)

(12)

Fluorination of 1-methylpyrrole at 200-240 °C gave a mixture of products slightly different from the pattern of the other heterocycles in that they are all saturated (eq 15).[16]

Fluorination of pyridine (eq 16) is a notable exception in the fluorination of heterocycles in that the major products are all ring-opened, although small amounts of fluoropyridines are detected.[17] Fluorination of polyfluoropyridines (eqs 17 and 18), however, lead to ring-retained compounds.[18]

(16)

(17)

(18)

Miscellaneous Fluorinations.

Limited studies of the fluorination of functional group-containing compounds have been made. In strong contrast to CoF_3 fluorinations, the functional group is largely retained. Thus, fluorination of diethyl ketone (eq 19) yields a mixture of fluorinated ethanes and a nonvolatile fraction of acyl fluorides which was isolated by reaction withe ethanol to give a mixture of the ethyl esters of 2-fluoro- and 2,2-difluoropropionic acids.[19] This clearly comes from some kind of Lewis acid-induced cleavage of the ketone followed by fluorination, since at low temperatures the unfluorinated acyl fluoride is the sole product. The fluorination of halo ketones leads mostly to cleavage products (e.g. fluorotrichloromethane from hexachloroacetone) but some fluorodichloro esters (ca. 25%) are isolated. The fluorination of esters (eqs 20 and 21) and acyl halides yields mixtures of fluorinated esters.[20]

Clearly there is scope for optimization of these fluorinations since the compounds formed are extremely difficult to prepare by other routes; even though the yields here are relatively modest, they nonetheless do yield working quantities of the desired products in a simple single-step reaction. There is but one example of the fluorination of nitriles and the main result of value which comes from the work is that MeCN is a good solvent for fluorinations at or below its boiling point.[21] The fluorination of ethers has also been reported without significant differences from the results obtained from cobalt trifluoride fluorination.[22]

It is clear that potassium tetrafluorocobaltate is a useful fluorinating agent but has the constraints of needing special apparatus and a good reliable source of elemental fluorine.

Potassium Thiocyanate[1]

KSCN

[333-20-0] · CKNS · Potassium Thiocyanate · (MW 97.19)

(reagent for the thiocyanation and isothiocyanation of many compounds;[1] converts oxiranes to thiiranes stereospecifically[11])

Physical Data: mp 173 °C; *d* 1.886 g cm^{-3}.

Solubility: very sol H_2O (217 g/100 mL at 20 °C); sol acetone (21 g/100 mL at 22 °C); sol EtOH.

Form Supplied in: colorless or white crystals; also available as volumetric standard in water (0.1 N). *Drying:* by heating to 165 °C under vacuum.

Purification: recrystallized from water or alcohol.

Handling, Storage, and Precautions: should be stored in a dark bottle.

Substitution Reactions.

Many early substitution reactions of metal thiocyanate salts were plagued by the ambident character of thiocyanate. Substitution via S affords a thiocyanate while attack via N yields an isothiocyanate. Often both products were formed and the efficiency of a synthesis of one product was measured by the rate ratio for the formation of both possible products, k_S/k_N. Reactions of KSCN with primary and secondary halides and sulfonates usually afforded products with a high k_S/k_N ratio, while the reaction of tertiary halides gave a ratio close to 1.[2] The use of other metal thiocyanates (Ba or $Ca(SCN)_2$) on an inorganic solid support provides a method for switching the S or N nucleophilicity for reactions with tertiary bromides (eq 1).[3] Solid-supported KSCN gives exclusive S attack of primary and simple benzylic halides but the k_S/k_N ratio remains moderate for tertiary systems.[4] Phase transfer catalysts enhance the smooth transformation of halides to thiocyanates with KSCN.[1,5] Alkyl isothiocyanates can be prepared in good yield by preparing the analogous thiocyanate and heating, preferably in the presence of metal salts, acids, or excess thiocyanate.[6] The isothiocyanate is usually the thermodynamically preferred product.[1] Various metal thiocyanates have been used to prepare acyl, phosphoryl, and sulfonyl isothiocyanates, probably by S attack of thiocyanate on a reactive acid derivative and then isomerization.[1]

$$t\text{-BuBr} \xrightarrow[\text{cyclohexane}]{\text{MSCN}} t\text{-BuSCN} + t\text{-BuNCS} \qquad (1)$$

KSCN on Al_2O_3	72%	8%
$Ba(SCN)_2$ on $CaCO_3$	54%	3%
$Ba(SCN)_2$ on CaF_2	0.8%	78%

Potassium thiocyanate is an effective reagent for the substitution on unsaturated systems to form thiocyanates. Nitrogen of diazonium salts is replaced by thiocyanate, but use of a cocatalyst is recommended to improve the yield and the k_S/k_N ratio. Thiocyanates have also been formed from the substitution reaction of KSCN with imidoyl chlorides,[1] allenyl chlorides,[7] some

chloroalkenes,[1] and nitrophenyl halides.[1] Thiocyanate supplants the halide of some phenyl iodides and bromides when these are treated with charcoal-supported CuSCN, a reagent which was prepared with the aid of KSCN (eq 2).[8] KSCN performs a selective alkyne substitution on alkynyl(*p*-phenylene)bisiodonium ditriflates (eq 3).[9] KSCN is the preferred reagent for the thiocyanation of saccharides.[10]

(2)

(3)

Sulfur Heterocycles.

Potassium thiocyanate is one of several reagents that converts oxiranes to thiiranes. KSCN seems to be the reagent of choice for a broad range of substituted oxiranes,[11] but reagents such as ***Thiourea***,[11] ***N,N-Dimethylthioformamide***,[12] or 3-methylbenzothiazole-2-thione[13] may have advantages in specific cases. With KSCN, various ring fused thiiranes can be formed (eq 4). In its reaction with substituted oxiranes, KSCN reacts by a stereospecific mechanism in that the substituent geometry of the oxirane is preserved in the thiirane. However, the reaction of KSCN with bromohydrins derived from *trans*-alkenes affords *cis*-thiiranes.[14] Hence, starting with a single 1,2-disubstituted alkene, a thiirane of either substituent geometry can be obtained. KSCN supported on silica is also effective for thiirane synthesis (eq 4).[15]

(4)

The reaction of cyclic carbonates with KSCN has been shown to be a method for the synthesis of some thiiranes[16] and thietanes,[17] depending on the number of carbons and nature of substituents in the starting material (eq 5).[7]

Potassium Tri-*s*-butylborohydride[1]

K(*s*-Bu)$_3$BH

[54575-49-4] · $C_{12}H_{28}BK$ · Potassium Tri-*s*-butylborohydride · (MW 222.31)

(reducing agent for various functional groups;[2] selective reducing agent;[3-7] stereoselective reducing agent for ketones;[8-10] used for reduction of conjugated enones;[11] regioselective reducing agent for cyclic anhydrides;[12] reacts with carbon monoxide in the presence of free trialkylborane;[13] used for stereoselective synthesis of *cis*-alkenylboranes[14])

Alternate Names: K-Selectride®; potassium hydrotris(1-methylpropyl)borate.

Physical Data: not isolated; prepared and used in solution.

Solubility: solubility limits have not been established. The reagent is normally used as a 1.0 M solution in THF or Et_2O, but use of toluene as solvent is also reported.

Form Supplied in: 1.0 M solutions in THF or Et_2O.

Analysis of Reagent Purity: solutions of pure reagent exhibit doublets (J = 68-71 Hz) centered in the range δ -7.1 to δ -7.5 in the ^{11}B NMR spectrum.[15,16a,17] Concentration of hydride is determined by hydrolysis of aliquots and measurement of the hydrogen evolved or by quenching aliquots in excess 1-iodooctane and analysis of the octane formed by GLC.[18] Concentration of boron is verified by oxidizing aliquots using alkaline hydrogen peroxide and analyzing the 2-butanol formed by GLC.[19]

Preparative Methods: direct reaction of tris(1-methylpropyl)borane with ***Potassium Hydride*** is satisfactory,[15] especially with activated KH.[16] The reagent is also formed by reaction of the trialkylborane with ***Potassium Triisopropoxyborohydride***.[17]

Handling, Storage, and Precautions: solutions are air- and water-sensitive and should be handled in a well ventilated hood under an inert atmosphere using appropriate techniques.[20] Potentially pyrophoric tris(1-methylpropyl)borane is a byproduct of reductions; thus standard organoborane oxidation[19] is recommended as part of the workup.

Functional Group Reductions.

The reducing characteristics of the reagent have been studied systematically.[2a] At 0 °C it liberates H_2 quantitatively with various active hydrogen compounds, including primary alcohols, phenols, thiols, carboxylic acids, primary amides, aliphatic nitro compounds, and oximes. Secondary and tertiary alcohols and primary amines are inert. Carboxylic acids, amides, nitro compounds, and oximes are not reduced further. Aldehydes, ketones, and acyl chlorides are reduced rapidly to the alcohol stage. Acyclic esters are reduced more slowly, but lactones are rapidly reduced to diols. Cyclic anhydrides are reduced to lactones if steps are taken to avoid further reduction of the latter. Terminal epoxides are reduced rapidly and cleanly to the Markovnikov alcohols. Internal epoxides are reduced slowly. Nitriles are reduced sluggishly. Pyridine and quinoline consume hydride, but the products have not been characterized. Disulfides are reduced to thiols. Primary iodides and bromides are reduced rapidly, chlorides more slowly. Cyclohexyl bromide and tosylate react sluggishly.

A reagent derived by adding 2 equiv of K-Selectride to 1 equiv of CuI effectively displaces halide from various aryl halides, and in one example an internal alkyne, dec-5-yne, is converted predominantly to the (*Z*)-alkene (*Z*:*E* = 88:12).[2b]

Selective Reductions.

Ketones are reduced selectively in the presence of other functional groups: esters,[3] including methyl esters[3a,d] and γ-lactones;[3b] a cyclic carbamate;[4] amides[5] including 2-acetyl β-lactams[5a-c] and benzenesulfonamides;[5f] azides;[6] and internal epoxides.[3d] Steroid 3,17- or 3,20-dione systems undergo selective reduction at the 3-position,[7] as does a 5-ene-3,17-dione system.[11c] Conjugated enones are reduced selectively in the presence of esters.[11e-g]

Stereoselective Reductions.

Like L-Selectride (***Lithium Tri-s-butylborohydride***), K-Selectride is useful for diastereoselective reduction of alkyl-substituted cyclic ketones to alcohols.[15a] Other applications to various types of cyclic ketones have been reported.[3d,4,7,8] Diastereoselective reduction is also observed for acyclic ketones,[9] including keto esters,[3a-c] keto amides,[5] and a keto azide.[6] A chiral dione is diastereoselectively reduced to a diol.[10]

Various theoretical models are used to rationalize observed diastereoselectivity.[21] In simple cases, the bulk of the reagent appears to dictate that hydride approach from the less sterically hindered face of the carbonyl.[15a] However, complexation effects of heteroatoms,[8a] crown ethers,[3c,9i] and cryptands[9i] may reverse the direction of approach. Also, the coordinating ability of the solvent influences the ratio of diastereomers.[3b]

Reduction of Conjugated Enones.

A reasonably systematic study of conjugated enone reductions has been conducted.[11a] Acyclic enones undergo 1,2-addition with stereoselective formation of allylic alcohols upon protonation. Cyclohexenones with no β-substitution yield saturated ketones as a consequence of 1,4-addition with 1 equiv of hydride, while a β-methyl results in exclusive 1,2-addition; 3 equiv of hydride results in stereoselective formation of saturated alcohols. Both cyclopentenones and cycloheptenones give mixtures of products. The enolate resulting from 1,4-addition may be alkylated instead of protonated, but this α-alkylation appears to work better with L-Selectride. Attempted reduction of α,β-unsaturated esters leads to Claisen condensation products.

Further examples of 1,2-addition to cyclohexenones involve the 5-en-3-one function of steroids[11b,c] or analogous systems.[11b] This is reduced selectively in 2α-fluoro-4-androstene-3,17-dione.[11c] Stereoselectivity in reduction of testosterone, which yields predominantly the 3β,17β-diol (3β:3α = 88:12), is reversed for 2α-fluorotestosterone, which yields exclusively the 3α,17β-diol.[11c]

A conjugated cyclohexadienone undergoes 1,4-addition so that only the α,β-double bond is reduced.[11d] Stereoselectivity results on 1,4-addition to (*S*)-(+)-carvone (eq 1).[11e]

(1)

X = Me; Y = H (79%)
X = H; Y = Me (17%)

An enone incorporated into a 14-membered macrolide undergoes stereoselective 1,2-addition while the lactone is not affected.[11f] With 3 equiv of K-Selectride, the cyclopentenone in the prostanoid 15(*S*)-PGA_2 is reduced stereoselectively to the corresponding cyclopentanol while a methyl ester remains untouched.[11g] A procedure utilizing 2 equiv of K-Selectride in the presence of 2 equiv of ethanol reduces a cyclohexenone stereoselectively to the cyclohexanol in the presence of methyl ester, acetate, and γ-lactone functions (eq 2).[11h] An α,β-alkynic ketone undergoes exclusive 1,2-addition with stereoselective formation of the propargylic alcohol.[9b]

(2)

Regioselective Reduction of Cyclic Anhydrides.

Various succinic and phthalic anhydrides are reduced by the reagent to lactones.[12] With certain exceptions (eq 3),[12b] reduction occurs preferentially at the less hindered carbonyl function. A mechanistic interpretation of the results has been proposed.[12b,e]

(3)

Reaction with Carbon Monoxide.

Carbonylation of KBH-(*s*-Bu)$_3$ followed by treatment with refluxing aqueous ***Sodium Hydroxide*** yields 2-methyl-1-butanol.[13a] It is now evident that KBH(*s*-Bu)$_3$ is an intermediate in the hydride-induced carbonylation of *s*-Bu$_3$B using ***Potassium Triisopropoxyborohydride***,[13b,17] so that different workup procedures may produce 2-methylbutanal[13c] or 3,5-dimethyl-4-heptanol.[13d]

Stereoselective Synthesis of *cis*-Alkenylboranes.

Reaction of 1-halo-1-alkenylboranes with KBH(*s*-Bu)$_3$ produces *cis*-alkenylboranes, but the ease of removing triethylborane makes ***Lithium Triethylborohydride*** the reagent of choice.[14]

Potassium Triethylborohydride

$KBEt_3H$

[22560-21-0] · $C_6H_{16}BK$ · Potassium Triethylborohydride · (MW 138.13)

(reducing agent in organic and organometallic synthesis)

Physical Data: mp 95 °C,[1] *d*204 0.902 g cm^{-3} for 1 M solution in THF.

Solubility: sol THF, diethyl ether, benzene, toluene.

Form Supplied in: 1 M solution in THF.

Analysis of Reagent Purity: ^{11}B NMR (THF, standard $BF_3.Et_2O$), δ -12.83 ppm (d, J_{B-H} 70 Hz).[2] Active hydride is determined by hydrolysis and measuring the hydrogen evolved according to the standard procedure;[4] potassium, by hydrolysis and titration against standard acid;[2] boron, by oxidation and GC analysis of alcohol produced after oxidation.[2]

Preparative Methods: by the reaction of ***Potassium Hydride*** with ***Triethylborane*** in THF,[2] or benzene.[1] From ***Potassium Triisopropoxyborohydride*** and triethylborane in THF[3] and from sodium triethylborohydride and potassium amalgam in benzene.[1]

Handling, Storage, and Precautions: the solution in THF is moisture- and air-sensitive, corrosive, and flammable. Reacts violently with water. Handle and store under nitrogen or argon in a cool place. Stable over prolonged periods of time. Use in a fume hood. Avoid contact with eyes, skin, and clothing.

Selective Reductions.

Potassium triethylborohydride belongs to the family of trialkylborohydrides. It is a powerful reducing agent, reacting with many functional groups. Lower *O*-chelating ability of potassium as compared to lithium and sodium cations, bulkiness, and stability to disproportionation of the anion are its features. The reducing characteristics of potassium triethylborohydride are shown in Table 1.[5]

Table 1 Reactivity of Various Functional Groups Toward Potassium Triethylborohydride in THF at 0 °C

Functionality or compound	Reactivity[a]	Products (remarks)
Aldehydes, ketones	f	Alcohol
Carboxylic acids		(Hydrogen evolution, no further reaction)
Esters	f	Alcohol
Acid chlorides	f	Alcohol
Acid anhydrides	f	Alcohol and acid
Lactones	f	Alcohol
Epoxides	m	Alcohol (Markovnikov opening)
Amides, primary	s or nr	(Benzamide not reduced, capramide slow rate)
Amides, tertiary	s	
Nitriles	s or nr	Amine (benzonitrile 2 hydrides used, capronitrile 1 hydride used)
Nitro compounds	f	(2 Hydrides used)
Azo, azoxy compounds	s	
Oximes		(Hydrogen evolution, no further reaction)
Phenyl isocyanate	f	Formanilide (1 hydride used)
Pyridine	f	(2 Hydrides used)
Sulfoxides, sulfonic acids	nr	
Disulfides	f	Thiol
Sulfones, cyclohexyl tosylate	s	(Diphenyl sulfone reduced to eth ylbenzene at reflux)
n-Octyl bromide	f	Octane
n-Octyl chloride	m	Octane
Cyclohexyl bromide	s	Cyclohexane

[a] f, fast; m, moderate; s, slow; nr, no reaction.

2-Methylcyclohexanone is reduced to 2-methylcyclohexanol (*cis*:*trans* = 79:21), 4-*t*-butylcyclohexanone to 4-*t*-butylcyclohexanol (*cis*:*trans* = 20:80), norcamphor to norborneol (*endo*:*exo* = 97:3), and anthraquinone to 9,10-dihydro-9,10-dihydroxyanthracene.[5] Ethyl caproate, ethyl cyclohexylcarboxylate, and ethyl and isopropyl benzoate are reduced in the presence of cyclohexanone oxime, *N*,*N*-dimethylcaproamide, and capronitrile. Ethyl esters are reduced preferentially to *t*-butyl esters.[6]

2´-Alkyl-3´-oxo amides are reduced to the corresponding 3-hydroxy amides with high *anti* diastereoselectivity (20:1 to 80:1). Optically active 2´-alkyl-3´-oxo amides give even higher stereoselectivity (>99:1). The reaction provides an alternative to asymmetric aldol condensation (eq 1).[7] ***Zinc Borohydride***, having a cation of higher chelating ability than potassium, reacts with *syn* diastereoselectivity, presumably via an intermediate six-membered chelate. 2-Aryl-2-methyl-1-indanones are stereoselectively reduced to 2-aryl-2-methyl-1-indanols.[8]

Carbonylation of Organoboranes.

In the presence of triethylborane, potassium triethylborohydride reacts with carbon monoxide. The organoborane intermediate produced yields 1-propanol upon oxidation (eq 2).[9] The reaction is an example of a hydride-induced carbonylation of organoboranes leading to alcohols and aldehydes.[10] Lithium trimethoxyaluminum hydride (LTMA)[11] and ***Potassium Triisopropoxyborohydride*** (KIPBH)[12] are the hydrides most often used in these reactions.

Organometallic Synthesis.

Potassium triethylborohydride finds application in the reduction of metal-metal bonds in transition metal dinuclear carbonyl complexes, e.g. Bi-Mo,[13] and Fe-Fe.[14,15] Metal carbonyl monoanions and dianions are generated and can be used for further transformations (eq 3).

Mononuclear anionic transition metal formyl complexes are prepared by the reduction of neutral carbonyl complexes with potassium triethylborohydride and other dialkylborohydrides (eq 4).[16] The method is of considerable generality. Formyl-transition metal complexes appear to be the intermediates in the Fischer-Tropsch industrial process. The reagent is also used in other organometallic syntheses.[17]

Related Reagents.

Diisobutylaluminum Hydride; ***Lithium Aluminum Hydride***; ***Lithium Tri-s-butylborohydride***; ***Lithium Trisiamylborohydride***; ***Potassium Tri-s-butylborohydride***; ***Sodium Borohydride***.

Potassium Triisopropoxyborohydride[1]

$KBH(O\text{-}i\text{-}Pr)_3$

[42278-67-1] · $C_9H_{22}BKO_3$ · Potassium Triisopropoxyborohydride · (MW 228.22)

(mild reducing agent for carbonyl compounds,[1] disulfides,[2c,3] and haloboranes[2a-c])

Alternate Name: KIPBH.

Physical Data: d (1.0 M THF solution) 0.912 g cm^{-3}.

Solubility: sol THF, Et_2O, monoglyme.[2]

Form Supplied in: no longer commercially available (formerly available as 1.0 M THF soln).

Analysis of Reagent Purity: IR (THF): 2210 cm^{-1} ($\nu_{B\text{-}H}$), 1375 cm^{-1} ($\nu_{B\text{-}O}$). ^{11}B NMR (THF; $BF_3.Et_2O$ as ref, with δ downfield from $BF_3.Et_2O$ assigned as positive): 6.1 δ (d, $J_{B\text{-}H}$ 118 Hz).[2] Samples can be hydrolyzed with H_2O and K and B contents measured as KOH and H_3BO_3, while hydride concentration can be estimated by measuring the H_2 evolved from acidic hydrolysis,[2] and isopropoxide can be evaluated by GLC analysis as *i*-PrOH.[2a]

Preparative Methods: THF solutions can be obtained by adding 1.0 mol of freshly distilled ***Triisopropyl Borate*** to 1.5 mol of ***Potassium Hydride*** suspended in 400 ml of solvent.[2c] Solutions in Et_2O or monoglyme were prepared in a similar way.[2a]

Purification: if THF solutions are contaminated by $K(i\text{-}PrO)_4B$, they can be purified by gentle reflux over an excess of KH for about 24 h.[2]

Handling, Storage, and Precautions: the solution must be stored under N_2 in the absence of moisture, but it is quite stable to disproportionation (over 6 months, when stored in the presence of a slight excess of KH at ambient temperature[2a]). It is incompatible with strong oxidizing agents, water, and acids (H_2 is evolved).

General Considerations.

Potassium triisopropoxyborohydride, in contrast to the less hindered trialkoxyborohydrides, is stable in THF solution toward disproportionation. It is a mild reducing agent, similar to ***Sodium Borohydride*** in that it reduces only aldehydes and ketones while almost all other functional groups are unaffected. KIPBH offers some advantages over simple borohydrides: it is soluble in nonhydroxylic solvents, it is more chemo- and stereoselective, and its kinetics are easier to study since it carries only 1 equiv of hydride per molecule.[1,2b]

Active hydrogen compounds (alcohols, phenols, thiols, amines, carboxylic acids) evolved H_2 sluggishly when treated with KIPBH in THF at 0 °C.[2c] Anhydrides, acyl chlorides, esters, lactones, epoxides, amides, nitriles, nitro compounds, oximes, isocyanates, quinones are not cleanly reduced by KIPBH. With few exceptions, most of these functional groups are completely unaffected by KIPBH.[2c]

Reduction of Carbonyl Compounds.

Both aldehydes and ketones are rapidly reduced to the corresponding alcohols by KIPBH, even at temperatures below 0 °C.[2b-c,4] Unsaturated carbonyl compounds are usually reduced to allylic alcohols (1,2-attack).[2c] KIPBH is particularly efficient for the diastereoselective reduction of cyclic ketones. The less stable *cis* epimer (from axial attack) is usually obtained in high diastereomeric excess (up to 96% de),[2c,4] but even better results can be obtained using other complex boro- or aluminium hydrides.[2b,d,4,5]

Chiral 2-oxo esters (from (-)-8-phenylmenthol[6a] or (-)-menthol[6b,c]) have been reduced to the corresponding 2-hydroxy esters (up to 90% de) by using KIPBH in THF. The new chiral center has the (*R*) configuration (eq 1). It is worth noting that, by using the same chiral auxiliary, addition of the Grignard reagent to the aldehyde or reduction of the ketone affords products with opposite configuration.[6a] In

some examples, better diastereoselectivity can be obtained using other complex boro- or aluminum hydrides.[6b,c] Similarly, the *anti* diastereoselective reduction of chiral 2-alkyl-3-oxoamides[6d] (from *trans*-2,5-bis(methoxymethoxymethyl)pyrrolidine) can be performed in high de by using KIPBH, but ***Potassium Triethylborohydride*** gives the best results.

Reduction of Disulfides.

Both aryl and alkyl disulfides are reduced to the corresponding thiols by KIPBH in THF at 0 °C.[2c,3] Aromatic disulfides can be selectively reduced in the presence of aliphatic ones.[3] Other reducing reagents ($LiAlH_4$, $NaBH_4/AlCl_3$, $NaBH_4$, Zn/AcOH) suffer serious disadvantages, since they are either less chemoselective or give rise to heterogeneous systems.

Reduction of Heterocycles.

KIPBH has been tested (along with other boro- and aluminum hydrides) in the Fowler synthesis of dihydropyridines (eq 2), i.e. the reduction of the *N*-alkoxycarbonylpyridinium ions (**1**) formed in situ from a pyridine and a chloroformate ester.[7] The regiochemistry of the reduction depends mainly on the ring substituents. Sterically undemanding donor substituents favor reduction at C-2, despite the bulkiness of the reductant. However, branched substituents are more sensitive to steric factors in the hydride and acceptor substituents are poorly regiodirective.

Applications to Boron Chemistry.

Although KIPBH is a very mild reducing agent, it is very effective in reducing haloboranes. This reaction has been used to synthesize unsymmetrically substituted trialkylboranes, from which unsymmetrical ketones can be obtained via carbonylation or cyanidation (eq 3).[2c,8] In contrast to the method using ***Thexylborane***, terminal alkenes can be employed in the reaction with thexylchloroborane and many different functional groups may be present in the alkenes introduced in the third step. The overall process is best carried out if the reduction of the thexylalkylborane (**2**) is performed in the presence of the second alkene. Use of a diene allows the synthesis of cyclic ketones.[8]

Reaction of KIPBH with (*Z*)-(1-bromo-1-alkenyl)boronic esters (obtained from reaction of 1-bromoalkynes with dibromoborane, followed by treatment of the resulting alkenyldibromoboranes with an alcohol) in Et_2O at ambient temperature provides a rapid access to stereochemically pure (*Z*)-1-alkenylboronic esters (**3**) (eq 4).[2b-c,9] These intermediates have found broad application in the stereoselective synthesis of arylated alkenes, conjugated alkadienes,[9b] conjugated dienones,[9c] and conjugated alkanedienoates[9d] via palladium-catalyzed cross-coupling reactions with aryl iodides, 1-bromoalkenes, 3-halo-2-alken-1-ones, and 3-bromo-2-alkenoates, respectively. Moreover, (*Z*)-1-alkenylboronic esters (**3**) can be employed in the synthesis of stereochemically defined (*E*)-1-bromo-1-alkenes (via reaction with Br_2, followed by treatment with MeONa) and (*Z*)-1-iodo-1-alkenes (via reaction with $NaOH/I_2$).[9e]

(4)

One-carbon homologation of boronic esters can be realized through reaction with ***Dichloromethyllithium***, followed by in situ reduction with KIPBH.[10] This procedure is of value in permitting the synthesis of boron derivatives not directly available through hydroboration and can be applied also to α-chiral boronic esters in order to obtain β-chiral boronic esters in an enantiospecific manner.[10b,c] The KIPBH reduction of α-chloro boronic esters is thought to proceed through the intermediate formation of the corresponding borohydride.[10b]

KIPBH is also effective in the carbonylation of organoboranes at 0 °C to obtain aldehydes or primary alcohols.[11] This reagent is superior to complex aluminum hydrides (lithium trimethoxyaluminum hydride and ***Lithium Tri-t-butoxyaluminum Hydride***, for example) because of its greater stability, chemoselectivity, and its simpler workup (no gelatinous precipitates). $LiBH_4$ undergoes the same reaction at ambient temperature.

KIPBH rapidly transfers hydride even to severely hindered trialkylboranes, which fail to react with KH, providing a convenient route to highly hindered potassium trialkylborohydrides.[2c,12]

Miscellaneous.

Transition metal formyl complexes can be prepared by reaction of transition metal carbonyl compounds with KIPBH.[12,13a-c]

Other uses of KIPBH in organometallic chemistry have been reported.[13d,e]

(*S*)-Proline[1]

[147-85-3] · $C_5H_9NO_2$ · (*S*)-Proline · (MW 115.15)

(chiral auxiliary[1] in asymmetric synthesis)

Physical Data: mp 228-233 °C (dec.); [α]20D = -84° (*c* = 4, H_2O); ninhydrin yellow in color.

Solubility: sol H_2O, alcohol; insol ether.

Form Supplied in: white solid; widely available; inexpensive.

Analysis of Reagent Purity: measurement of optical rotation; mp.

Handling, Storage, and Precautions: cold and dry storage.

General Considerations.

In addition to its use in peptide chemistry, (*S*)-proline is often applied as a chiral precursor in the total syntheses of natural products, e.g. odorin,[2] pumiliotoxin,[3] petasinecine,[4] or threonine.[5] Some highly effective pharmaceuticals, such as optically pure ACE inhibitors, are prepared from L-proline.[6] In the last two decades, (*S*)-proline has attracted much attention as an optically active auxiliary in asymmetric synthesis.

Asymmetric Aldolization.

Proline mediates the asymmetric aldol cyclization of the prochiral triketone (**1a**) to the optically active bicyclic enedione (*S*)-(**3a**) (eq 1).[7,8] Optical yields up to 94% are realized, depending on the solvent used. The enedione (**3**) is prepared directly in the presence of an acid such as $HClO_4$. In the absence of acid, the aldol (**2**) is frequently isolated. Among the amino acids tested, (*S*)-proline gives the best results in almost every case. With (*S*)-proline the (*S*) configured products (**3**) are usually obtained. Enediones such as (**3**) are important building blocks for the synthesis of steroids or alkaloids[9] because natural steroids have the same configuration at C-13. Analogously, the Wieland-Miescher ketone (*S*)-(**3e**) is prepared with 70% ee from the cyclic prochiral triketone (**1e**) in the presence of (*S*)-proline.[10] Optically pure enedione (*S*)-(**3e**) is obtained by a single crystallization of the product mixture having an enantiomeric excess over 50%.

(1a) R = H, R^2 = Me, $n = 1$ **(2)** **(3)**
(1b) R = H, R^2 = Et, $n = 1$
(1c) R = $(CH_2)_2CH{=}CH_2$, R^2 = Me, $n = 1$
(1d) R = $(CH_2)_2$-2-(6-Me-pyridyl), R^2 = Me, $n = 1$
(1e) R = H, R^2 = Me, $n = 2$
(1f) R = Me, R^2 = Me, $n = 2$

An asymmetric aldolization was successfully applied to the preparation of gibbane.[11] The total synthesis of the macrolide antibiotic erythromycin was developed involving an asymmetric aldolization step catalyzed by proline.[12] Since the mid-1970s, a flood of papers has appeared dealing with the asymmetric aldolization of various triketones. Some results are listed for comparison in Table 1.

Table 1 Asymmetric Aldolization of Prochiral Triketones (**1**)

Educt	(*S*)-Proline (mol %)	Solvent	Product	Chemical yield (%)	Optical yield (%)
(1a)	4	DMF	**(2a)**[13]	97	94
(1a)	47/$HClO_4$	MeCN	**(3a)**[13]	90	82
(1a)	100	MeCN	**(2a)**[8]	97	97
(1a)	50/$HClO_4$	MeCN	**(3a)**[7]	87	84
(1a)	3	DMF	**(2a)**[8]	100	93
(1b)	30	DMF	**(2b)**[8]	71	100
(1b)	50/HCl	DMF	**(3b)**[7]	76	80
(1c)	100/$HClO_4$	MeCN	**(3c)**[14]	22	20
(1d)	120/$HClO_4$	MeCN	**(3d)**[15]	67	26
(1e)	5	DMSO	**(3e)**[10]	71	70
(1e)	50/$HClO_4$	MeCN	**(3e)**[7]	83	71
(1f)	13.7	DMSO	**(3f)**[16]	43	38
(1f)	50/$HClO_4$	MeCN	**(3f)**[17]	74	15

The intramolecular asymmetric cyclization of open chain symmetrical triketone (**4**) leading to (*R*)-(**5**) proceeds with 16% ee (eq 2).[18]

(2)

Even acyclic 1,5-diketones (**6**) are cyclized enantioselectivitely in the presence of (*S*)-proline.[19] Depending on the structure of the cyclic α,β-unsaturated ketone, (R)-(**7**) is obtained in up to 43% (R = Me) optical yield (eq 3).

(3)

The mechanism of the proline-catalyzed enantioselective aldol reaction has been studied.[20] An extension of the asymmetric aldolization deals with the cyclization of diketones.[21] Also investigated was the dehydration of racemic β-ketols in the presence of (*S*)-proline and a kinetic resolution was observed.[22]

Asymmetric Michael Addition.

An intramolecular Michael reaction catalyzed by (*S*)-proline leads to the chiral thiadecalin (**9**) and thiahydrindan (**11**) and (**12**).[23] Enone (**8**) undergoes cyclization in the presence of (*S*)-proline to give exclusively the *trans* isomer (**9**) (eq 4). The thiahydrindandions (**11**) and (**12**) are obtained from (**10**) as a 1:1 mixture of the *cis* and *trans* isomers (eq 5).

(4)

(5)

The intramolecular asymmetric Michael reaction of acyclic compounds obtained from chiral alkaloid building blocks using amines and (*S*)-proline has been investigated.[24] The Michael addition of dimethyl malonate to α,β-unsaturated aldehydes proceeds smoothly with a catalytic amount of (*S*)-proline lithium salt.[25] However, no asymmetric induction was observed.

Asymmetric Halolactonization.

An asymmetric halolactonization reaction using proline as a chiral auxiliary has been reported.[26] Optically active α-hydroxy acids (**16**) are prepared from α,β-unsaturated acids via the corresponding (*S*)-proline amide (**13**) involving an asymmetric bromolactonization step (eq 6).[26a]

The unsaturated carboxylic acid (**13**) undergoes an asymmetric bromolactonization when treated with ***N-Bromosuccinimide*** in DMF. The bromolactone (**14**) and its diastereomer are obtained in a 94.5:5.5 ratio. Reduction and hydrolysis yields the α-hydroxy acid (**16**) in an overall optical yield of 90%. The same procedure gives chiral α-hydroxy ketones.[26c]

A modification of the asymmetric bromolactonization leads to optically active α,β-epoxy aldehydes (**18**).[26d,e] Treatment of the bromolactone (**14**) with ***Sodium Methoxide*** results in the formation of the epimeric epoxy ester (**17**) in a ratio of 2:1 (eq 7).

(14)

(7)

(17a) 2:1 (17b) (2*R*,3*S*)-(**18**)

The reductive cleavage of the proline derivative yields the chiral α,β-epoxy aldehyde (2*R*,3*S*)-(**18**) in 98% ee. Even natural product syntheses can be realized utilizing the bromolactonization procedure.[26h,i]

Reduction of C=O and C=N Bonds.

Asymmetric reductions of prochiral ketones (**19**) to the corresponding chiral alcohols (**20**) using (*S*)-proline-modified borohydride reagents as the reductant have been published. The borane reductions of ketones (**19**) employing (*S*)-proline as chiral mediator proceeds with enantiomeric excesses up to >95%. It is proposed that the in situ produced (*S*)-prolinol reacts with borane to form the oxazaborolidine (*S*)-(**21**) as the reducing catalyst (eq 8).[27]

(8)

(**19**) (*R*)-(**20**) (*S*)-(**21**)

The (*S*)-prolinate-borane complex (*S*)-(**22**) reduces ketones to the corresponding alcohols with optical yields up to 50%.[28] The asymmetric reduction of cyclic imines (**24**) with chiral sodium triacyloxyborohydride (*S*)-(**23**) was utilized to prepare optically active alkaloids (**25**) with optical yields up to 86% (eq 9).[29]

(*S*)-(**22**)

(*S*)-(**23**)

(9)

The hydrogenation of various ketones with heterogeneous ***Palladium on Carbon*** or ***Raney Nickel*** catalysts in the presence of (*S*)-proline proceeds to produce the corresponding optically active alcohols with low optical yields (up to 23%).[30]

Reduction of C=C Bonds.

The reduction of the C=C double bond of isophorone (**26**) with Pd/C in the presence of (*S*)-proline yields the saturated ketone (**27**) with 60% optical purity (eq 10).[30a,31] With (*S*)-proline ester/Pd (or Pt) systems the hydrogenation of ethyl pyruvate, an α-keto ester, was investigated, but only insignificant enantioselectivities were reached.[32]

(10)

An efficient synthesis of (*S*)-amino acids from α-keto acids via a diastereoselective hydrogenation step with (*S*)-proline as the chiral inducer was reported (eq 11).[33] Optical yields up to 90% were reached.

(11)

Racemization of Amino Acids.

The synthesis of (*R*)-alanine was achieved starting from (*S*)-alanine via formation of the imidazoline with (*S*)-proline.[34] This result can be explained in terms of epimerization and stereoselective protonation with asymmetric induction by the chiral center originating from (*S*)-proline.

Resolution of Amino Acids.

For the optical resolution of racemic threonine via replacing resolution, (*S*)-proline was utilized as an optically active cosolute although the structure of the imino acid is different from that of threonine.[35] The same procedure was applied less sucessfully to the resolution of (*R*,*S*)-thiazolidine carboxylic acid.[36]

Synthesis of Unnatural (*S*)-Proline Derivatives.

The condensation of pivaladehyde with (*S*)-proline yields stereoselectively, after lithiation and reaction with an electrophile, the bicyclic compound (**28**), which is a versatile educt for the synthesis of many α-substituted proline analogs (**29**) (eq 12).[37] The reactions proceed via the formation of a chiral lithium enolate without the use of a chiral auxiliary (self-reproduction of chirality). The reaction with a variety of electrophiles *cis* to the *t*-Bu group yields a plethora of α-substituted (*S*)-proline derivatives (**29**). A limitation of this strategy is the acetal cleavage of some substituted products (**28**).[38]

The β-amino acid homoproline can be synthesized via an Arndt-Eistert reaction from (*S*)-proline.[39]

Synthesis of Optically Active Phophorus Compounds.

A series of chiral organophosphorus compounds (**33**) have been prepared in which the phophorus atom is the stereogenic center (eq 13).[40] The best stereoselectivity is reached with (*S*)-proline esters (**30**) as the chiral auxiliary. The reaction of phosphonic acid chloride (**31**) with (*S*)-proline ethyl ester affords a mixture of diastereomeric amides (**32**) in high stereoselectivity. The diastereomers can easily be purified by chromatography. The chiral organophosphorus compounds (**33**) are obtained from hydrolysis of (**32**).

Alkylations and Allylations.

The asymmetric alkylation of chiral enamines derived from (*S*)-proline esters has been disclosed.[41] The α-alkylation of cyclohexanone proceeds with an optical purity of 59%. (*S*)-Proline catalyzes the alkylation of xanthopurpurin (**34**) by 2-hydroxytetrahydropyran[42] yielding (**35**), which was later used in the synthesis of the racemate of the pigment averufanin (eq 14).[43] With phenylacetaldehyde, two molecules react to build up an anomeric mixture of lactols with a new pyran ring.[44] In each case, no enantioselectivity is detected.

The stereoselective allylation of aldehydes was reported to proceed with allyltrifluorosilanes in the presence of (*S*)-proline.[45] The reaction involves pentacoordinate silicate intermediates. Optical yields up to 30% are achieved in the copper-catalyzed allylic acetoxylation of cyclohexene with (*S*)-proline as a chiral ligand.[46]

The intramolecular asymmetric palladium-catalyzed allylation of aldehydes, including allylating functionality in the molecules, via chiral enamines prepared from (*S*)-proline esters has been reported (eq 15).[47] The most promising result was reached with the (*S*)-proline allyl ester derivative (**36**). Upon treatment with ***Tetrakis(triphenylphosphine)palladium(0)*** and PPh_3 in THF, the chiral enamine (**36**) undergoes an intramolecular allylation to afford an α-allyl hemiacetal (**37**). After an oxidation step the optically active lactones (**38**) with up to 84% ee were isolated in high chemical yields. The same authors have also reported sucessful palladium-catalyzed asymmetric allylations of chiral allylic (*S*)-proline ester enamines[48] and amides[49] with enantiomeric excesses up to 100%.

Universität Oldenburg, Germany

1,3-Propanediol[1]

[504-63-2] · $C_3H_8O_2$ · 1,3-Propanediol · (MW 76.10)

(preparation of acetals,[2,3] quinolines,[4] indoles,[5] boron esters;[6] traps Wacker aldehyde intermediates;[7] reaction solvent for Wolff-Kishner reduction[8])

Alternate Name: trimethylene glycol.

Physical Data: liquid, bp 214 °C; mp -27 °C; *d* 1.053 g cm^{-3}.

Solubility: sol H_2O, alcohol; ν sol ether; sol (hot) benzene.

Form Supplied in: >97% purity, depending on supplier.

Purification: dried with K_2CO_3 and distilled under reduced pressure.

Reactions with Carbonyls.

The chemistry of 1,3-propanediol (**1**) is dominated by acetal[2,3,9,10] formation.[11] Its ketone acetals show differential hydrolytic stability: cyclopentanone acetals hydrolyze faster than cyclohexanone acetals, and both hydrolyze faster than ethylene glycol-derived acetals (Table 1).[3a] The ketone-acetal equilibrium lies far to the left.[3] Its aldehyde acetals, however, show the opposite behavior and are hydrolytically more stable than ethylene glycol acetals.[3b,12] Polyketones[3] and 1,4-diones[13] may be selectively protected by judicious choice of substituted 1,3-propanediols. For protection of steroidal ketones, (**1**) is preferred over ethylene glycol, which is susceptible to attack by alkyllithium reagents.[10]

Table 1 Relative Hydrolysis Rates of 5α-Androstane Acetals

Glycol	3-Acetal	17-Acetal
Ethylene glycol	1.0	1.64
1,3-Propanediol	14.5	40.5

Conversion to Reactive Intermediates.

Acrolein condenses with (**1**) to give 2-(2-bromoethyl)-1,3-dioxane,[2] which finds use as a three-carbon homologating agent (eq 1)[14] and in the preparation of γ-keto aldehydes.[15] Use of (**1**) is essential as the corresponding ethylene glycol dioxolane is thermally unstable[2] and gives Grignard reagents that tend to autodestruct.[15,16] Hydrolysis of the product acetals requires special conditions.[14,15]

(1)

Diol (**1**) is used to prepare cyclopropenone acetal (**2**).[17,18] Its highly nucleophilic double bond forms addition products with alcohols and amines[17] and cycloaddition products with dienes to give norcarenes,[17] ketones to give furanones and oxetanes,[17] aldehydes to give butenolide, furan, and γ-keto ester derivatives (eq 2),[18] electrophilic alkenes to give cyclopropanes[19] and functionalized cyclopentenones,[20] and an α-pyrone to give a cycloheptatrienone.[21]

(2)

Formation of Boron Esters.

Esterification of boronic acid derivatives occurs readily with (**1**), and has been used in many hydroboration reaction sequences.[6,22] The six-membered ring boronates are more stable than the corresponding five-membered ring or acyclic products made from 1,2-diols or alcohols. The title reagent has been used to regenerate carbohydrates from boronate derivatives.[23]

Heterocycle Synthesis.

Alkyl (**3**)[24] and alkoxy (**4**)[25] 1,3,2-dioxophosphorinane 2-oxides are prepared in good yields by base-catalyzed condensation of (**1**) with the appropriate phosphonous dichloride. Iminosulfinyl dichlorides react similarly.[26] With DCC, (**1**) gives 2-imino-1,3-oxazine (**5**) (CuCl, 95%) which is converted into urea derivatives in high yields.[27]

(3) (4) (5)

In an alternative route to the Skraup synthesis, quinolines are prepared from (**1**) and primary anilines (eq 3). Choice of stoichiometry, solvent, and ligand greatly affect yield.[4]

(3)

Regioselective synthesis of indoles is accomplished by in situ trapping of Wacker aldehydes with (**1**) (eq 4). *o*-Vinylacetanilides give indoles directly under similar reaction conditions.[5] Isocoumarins and 1-isoquinolinones are also prepared by this chemistry.[28] Electron-deficient alkenes give acetals with (**1**) under Wacker conditions (see ***Palladium(II) Chloride-Copper(I) Chloride***).[7]

(4)

Miscellaneous Transformations.

1,3-Propanediol can be converted to 3-chloro-1- (60%),[29] 3-iodo-1- (68%),[30] and 3-bromo-1-propanol (90%)[31] or to 1,3-dibromopropane (85-95%).[32] With imidoyl chlorides, 3-chloropropyl benzoates are produced.[33] The title reagent has good solvent properties and finds use in the Wolff-Kishner reduction.[8] Cyclohexenones and (**1**) give hydroxypropyl phenols under oxidative conditions (eq 5).[34]

1,3-Propanedithiol[1]

[109-80-8] · $C_3H_8S_2$ · 1,3-Propanedithiol · (MW 108.25)

(1,3-dithiane formation; reduction (carbonyl to methylene, azide to primary amine, peptidic disulfide to dithiol, demercuration); ketene dithioacetal formation)

Physical Data: d^{20} 1.077 g cm^{-3}; bp 170 °C/760 mmHg, 92-98 °C/56 mmHg.

Solubility: slightly sol water; miscible with many organic solvents.

Form Supplied in: liquid; widely available.

Handling, Storage, and Precautions: stench! Use in a fume hood. Can undergo air oxidation to form disulfides. The cyclic disulfide forms a polymeric precipitate in methanol.[17a] Extraction into aqueous NaOH serves to separate thiols from nonacidic impurities.[1f] For toxicity data, see ***1,2-Ethanedithiol***.

1,3-Dithiane Formation.

1,3-Propanedithiol (**1**) condenses under protic or Lewis acid catalysis with aldehydes and ketones to afford 1,3-dithianes (eqs 1-4).[2-5] Useful for carbonyl protection, the 1,3-dithianyl group is compatible with aqueous acid, strong bases, anionic (eq 3)[4] and Pd-catalyzed (eq 5)[6a] C-C bond-forming reactions, catalytic hydrogenation in the presence of the Crabtree catalyst,[6b] and many other synthetic processes.[7] Often, (**1**) shows useful selectivity in reactions with dicarbonyl compounds (eq 3; structures **2-5**).[4,8] In contrast to acetalization with diols,[9a] (**1**) reacts selectively with α,β-alkenyl ketones in the presence of moderately hindered saturated ketones;[1c] double bond migration is not observed;[1a] conjugate addition can compete if sterically favored.[9b] In α,β-alkynyl ketones (not aldehydes),[10a] conjugate addition prevails (eq 6).[10b]

(1)

(2)

(2) [**(1)**, $BF_3 \cdot OEt_2$, 55-65%]

(3) [**(1)**, $TeCl_4$, 68%]

(4) [(**1**), $BF_3 \cdot OEt_2$, >98%]

(5) [bis-TMS-(**1**), ZnI_2, 88%]

(6)

Acetals, enol ethers, and oxazolidines also give dithianes with (**1**) (eqs 7-12).[11a-f,12] This reaction can be useful for opening resistant cyclic structures;[13a,c] ***Titanium(IV) Chloride*** is an especially effective catalyst in such cases.[13b] Reaction of (**1**) with dihalomethanes,[14a,b] or with carboxylic acids in the presence of ***Tin(II) Chloride***,[14c] also yields 1,3-dithianes.

(7)

(8)

(9)

R = $SiPh_2$-*t*-Bu

(10)

(11)

(12)

1,3-Dithianes derived from aldehydes are important synthetic intermediates because they undergo deprotonation to 2-lithio-1,3-dithianes which function as carbonyl anion equivalents (umpolung reagents).[1b-e] The vinylogous process (eq 4)[5] is a subject of current study.[15]

Regeneration of the carbonyl group can entail a trial-and-error process with the many procedures available.[1a-e] Hg^{II} salts and *N*-halo amides remain the most frequently employed reagents. Aqueous ***Iodomethane*** is a mild alternative.[8c] Epimerization at an α stereocenter does not normally attend the formation or removal of the dithianyl group (eqs 8, 9, 12, 13).

(13)

Reduction.

Raney Nickel treatment of thioacetals is a standard method for carbonyl-to-methylene reduction.[1b] In the presence of ***Triethylamine***, (**1**) reduces azides to primary amines (eq 14).[16a,b] Under the acidic conditions employed for thioacetal formation, this reduction does not occur (eq 8).[11b,16c] Reduction of peptidic disulfides to dithiols can be conveniently accomplished with (**1**).[17] Treatment with (**1**) effected demercuration α to an ester diastereoselectively (eq 15).[18]

Ketene Dithioacetal Formation.

These versatile intermediates[1c] arise from 1,3-dithiane anions by elimination (eq 8)[11b,19] or vinylogous alkylation (eq 4),[5] and by condensation of carboxylic acid derivatives with (**1**) (eq 13).[20a] Ketene dithioacetals derived from lactones can cyclize to give dithio orthoesters, which can be selectively deprotected (eq 16).[20b]

Related Reagents.

1,2-Ethanedithiol.

1,3-Propanedithiol Bis(*p*-toluenesulfonate)[1]

(*n* = 3)

[3866-79-3] · $C_{17}H_{20}O_4S_4$ · 1,3-Propanedithiol Bis(*p*-toluenesulfonate) · (MW 416.65) (*n* = 2)

[2225-23-2] · $C_{16}H_{18}O_4S_4$ · 1,2-Ethanedithiol Bis(*p*-toluenesulfonate) · (MW 402.62)

(dithianylation and dithiolanylation of methylene groups adjacent to carbonyl;[2] α,α-dithianyl cycloalkanones undergo oxidative ring scission;[3] oxidation of ketones to 1,2-diketones can be achieved by α,α-dithianylation or dithiolanation of ketones followed by hydrolysis[4])

Physical Data: 1,3-propanedithiol bis(*p*-toluenesulfonate): mp 67 °C; 1,2-ethanedithiol bis(*p*-toluenesulfonate): mp 76 °C.

Preparative Methods: treatment of potassium thiotosylate, itself made by the reaction of ***p-Toluenesulfonyl Chloride*** with ***Potassium Hydrogen Sulfide***, with 1,3-dibromopropane or 1,2-dibromoethane in the presence of ***Potassium Iodide*** affords 1,3-propanedithiol bis(*p*-toluenesulfonate) and 1,2-ethanedithiol bis(*p*-toluenesulfonate), respectively.[5]

Oxidative Ring Cleavage of Cycloalkanones.

Ketones can be α,α-dithianylated or α,α-dithiolanylated by treatment of their enamines or α-formyl derivatives with 1,3-propanedithiol or 1,2-ethanedithiol bis(*p*-toluenesulfonate), respectively.[1,2] Subjection of α,α-dithianyl ketones to ***Potassium Hydroxide*** in *t*-BuOH results in carbonyl carbon-dithiane carbon bond cleavage, affording o-dithianyl acids (eq 1).[3] Presumably, a mechanism similar to the benzilic acid rearrangement is operative. Consistent with this assumption is the observation that easily enolizable and sterically hindered dithianyl ketones are inert to these conditions. The lack of examples of similar cleavage of α,α-dithiolanyl ketones may be related to the inability of dithiolanes to support anion formation.[6] Alternative methods for effecting this type of cleavage, such as ozonolysis of an enol derivative, frequently are poorly reproducible.

(1)

The exquisite regioselectivity possible in enamine formation or α-formylation of cycloalkanones, followed by α,α-dithianation and ring cleavage, has been exploited in several natural product syntheses (eqs 2-4).[7-10]

(2)

(3)

(4)

Addition of organometallics to the carbonyl carbon, followed by base cleavage of the resulting α,α-dithianyl carbinols, generates o-dithianyl ketones (eq 5).[11]

(5)

1,2-Carbonyl Transposition and Methylene Protection.

Dithianes and dithiolanes can be removed under hydrolytic or reductive conditions (see ***1,3-Propanedithiol*** and ***1,2-Ethanedithiol***). As α,α-dithianyl- and dithiolanylation of ketones effects oxidation of the α-carbon, hydrolytic removal of the protecting group affords 1,2-diketones (eq 6).[4,12] Chemical modification of the carbonyl carbon before hydrolytic removal of the dithiane or dithiolane effects 1,2-carbonyl transposition (eq 7).[13]

(6)

The ability to convert a dithianyl or dithiolanyl carbon to methylene by treatment with ***Raney Nickel*** enables methylene protection α to a carbonyl. For example, the less enolizable α-methylene of a cycloalkanone can be alkylated by the sequence: (a) dithiolanylation of the more enolizable methylene; (b) enolization and alkylation at the remaining methylene; (c) reductive removal of the dithiolane group (eq 8).[14]

Propargyl Alcohol

[107-19-7] · C_3H_4O · Propargyl Alcohol · (MW 56.07)

(cyclopentenone annulation;[1] three-carbon building block for organic synthesis[2,3])

Alternate Name: 2-propyn-1-ol.

Physical Data: mp -53 °C; bp 114-115 °C; *d* 0.963 g cm^{-3}. Monohydrate: fp -20 to -60 °C; *d* 0.968 g cm^{-3}.

Solubility: insol aliphatic hydrocarbons; sol H_2O, benzene, chloroform, 1,2-dichloroethane, ethanol, ether, acetone, dioxane, tetrahydrofuran, pyridine; mod sol carbon tetrachloride.

Form Supplied in: colorless liquid; commercially available.

Purification: commercial material contains a stabilizer. An aq solution of propargyl alcohol can be concentrated by azeotropic distillation with butanol or butyl acetate. Dry over K_2CO_3 and distil under reduced pressure in the presence of about 1% succinic acid through a column packed with glass helices.

Handling, Storage, and Precautions: this highly toxic reagent causes severe irritation and is readily absorbed through the skin. Flammable liquid. Forms explosive mixtures in air. Use only in a chemical fume hood. Polymerized by heat or base. Distillation just prior to use is recommended.

Preparation of the Dilithium Derivative.

A hexane solution of ***n-Butyllithium*** (2 equiv) is added to a THF solution of propargyl alcohol.[4] When 1 equiv of *n*-BuLi is added, the viscosity of the reaction mixture increases. Therefore, more than 3 mL of THF per 1 mmol of propargyl alcohol should be used.

Cyclopentenone Annulation.

The adducts of propargyl alcohol and ketones have been employed as divinyl ketone equivalents for the Nazarov cyclization.[1] The particular significance of this reaction is the regio- and stereochemical outcome in cyclopentenone annulation.[4] The more substituted α-carbon of 2-methylcyclohexanone is selectively incorporated into a five-membered ring (eq 1). This transformation exhibits stereoselectivity as summarized in eq 2 when applied to alkyl-substituted derivatives of the adduct. These results are explained in terms of the conrotatory ring closure of the thermodynamically most favorable pentadienyl cation intermediates. Analogous reactions have been applied to the total synthesis of (±)-nootkatone (eq 3)[5] and (±)-muscopyridine (eq 4).[6]

(1)

(2)

(3)

Nootkatone

(4)

Three-Carbon Building Block for Organic Synthesis.

Propargyl alcohol has been widely employed as a C_3 building block for homologation (eqs 5-7).[7-9] Dihydrofurans are obtained from the adducts of propargyl alcohol and ketones or aldehydes (eq 8).[10] Propargyl alcohol has been used for alkylation under acidic conditions (eq 9).[11]

Propargyl Aldehyde

[624-67-9] · C_3H_2O · Propargyl Aldehyde · (MW 54.05)

(conjugate acceptor; dienophile)

Alternate Names: 2-propynal; propiolaldehyde.

Physical Data: bp 59-61 °C.

Solubility: sol H_2O, alcohol, ether, benzene, toluene, acetone.

Form Supplied in: not commercially available.

Preparative Method: most simply prepared by oxidation of ***Propargyl Alcohol***.[1,2]

Handling, Storage, and Precautions: great care should be taken in handling the neat liquid as an explosion has been reported.[3] The explosion was attributed to rapid polymerization, probably catalyzed by base or a radical initiator. It is recommended that handling of 2-propynal should include the use of a nonglass container and dilution with a sufficient volume of an inert solvent to absorb the heat of polymerization without boiling, e.g. <=10% in toluene. Use in a fume hood.

Addition to the Carbonyl Group.

Grignard reagents add well to 2-propynal, as in the preparation of 1-hexyn-5-en-3-ol (eq 1).[4] Aryl Grignard reagents also add successfully.[5] Although most heteronucleophiles add in a conjugate fashion (see next section), aniline has been reported to form the corresponding imine.[6] A pyrrole synthesis has been developed which relies on an aldol reaction of 2-propynal with a 3-silyl-2-azetidinone (eq 2).[7]

Addition to the Triple Bond.

Conjugate additions of nucleophiles based on oxygen (eq 3),[8,9] nitrogen (eq 4),[10] and sulfur (eq 5)[11] leading to 3-substituted acroleins have been reported.

Cycloadditions.

2-Propynal reacts as a typical dienophile in Diels-Alder reactions with a variety of dienes. Nucleophilic dienes add without catalysis (eqs 6 and 7).[12,13] Some dienes require Lewis-acid catalysis to react, as in the preparation of *ansa*-secosteroids (eq 8).[14]

(6)

(7)

(8)

Lanthanide salts catalyze the 1,2-cycloaddition of 2-propynal to ketene imines (eq 9).[15] ***Sodium Azide*** cycloadds to 2-propynal across the triple bond, yielding a 1,2,3-triazole.[16]

(9)

Cyclocondensations.

Heating 2-propynal with 3-amino-2-cyclohexenones provides a simple route to tetrahydroquinoline derivatives as in eq 10.[17,18] Tetraazaannulenes may be prepared simply by heating *o*-phenylenediamines with 2-propynal (eq 11).[19]

(10)

(11)

Related Reagents.

3-Butyn-2-one; ***3,3-Diethoxy-1-propyne***; ***Ethyl Lithiopropiolate***; ***Methyl Propiolate***; ***Propargyl Alcohol***.

Propargyl Chloride

(X = Cl)

[624-65-7] · C_3H_3Cl · Propargyl Chloride · (MW 74.51) (X = Br)

[106-96-7] · C_3H_3Br · Propargyl Bromide · (MW 118.96) (X = OTf)

[41029-46-3] · $C_4H_3F_3O_3S$ · Propargyl Triflate · (MW 188.14)

(three-carbon alkylating agent;[1] acetone carbenium ion equivalent and annulating agent;[2] propargylic or allenic nucleophile after conversion to an organometallic[3])

Alternate Name: 3-chloro-1-propyne.

Physical Data: X = Cl: bp 58 °C; *d* 1.030 g cm^{-3}. X = Br: bp 88-90 °C; *d* 1.579 g cm^{-3}; *d* (80% toluene solution) 1.335 g cm^{-3}.

Form Supplied in: propargyl chloride is supplied as a liquid in 98% purity. Because of a reported shock-sensitivity of the neat material, propargyl bromide is supplied as an 80% (by weight) solution in toluene.

Preparative Method: propargyl triflate is not commercially available but is prepared by treating ***Propargyl Alcohol*** with ***Pyridine/Trifluoromethanesulfonic Anhydride***.[4]

Handling, Storage, and Precautions: in the presence of copper(I) halides, propargyl halides can isomerize to a mixture of the parent compound and a halopropadiene.[5] Because of an instability at ambient temperature, the triflate is typically prepared in solution and used directly. Purification of the triflate by distillation is possible, albeit in low yield.[6]

Electrophilic Alkylation.

As an electrophile, propargyl chloride has been employed in the propynylation of a variety of substrates, including Grignard reagents,[1,7] carbanions,[8] enolates,[9] carbonyl compounds,[10] alcohols,[4,11] phenols,[12] carboxylates,[13] amines,[14] amides,[15] sulfonamides,[16] sulfones,[17] thiols,[18] thioamides,[19] and alkyl phosphonates.[20] An unusual *N*-alkylation of a phenothiazine has been reported whereby the 1-propynyl derivative is isolated.[21] Because of the basic nature of the above alkylation reactions, isomerization to the allene can take place.[22] The extent to which isomerization occurs is dependent upon the reaction time, temperature, and the specific base employed.[15a,23] Trialkyl borates[24] and alkylaluminum species,[25] in the presence of a copper(I) halide, couple with propargyl bromide (preferred over the chloride) to give exclusively the terminal allene. By contrast, the reaction of bromopropadiene (derived from propargyl bromide) with an alkylaluminum affords solely the terminal alkyne.[26] Alkylation of a trithiocarbonate, followed by intramolecular cyclization, leads to the formation of a thione.[27] In a similar manner, thioamides can be alkylated and further elaborated to thiazoles[28] or thiophenes.[29]

Annulation Reactions.

When the alkylation with propargyl bromide is followed by hydration with ***Mercury(II) Oxide*** the net result is equivalent to an alkylation with ***Acetone***. More often, when alkylation occurs α to a carbonyl, the product is further treated with base to give a fused cyclopentenone (eq 1) (see also ***Isopropenyl Acetate***, ***Methallyl Chloride***, ***2-Methoxyallyl Bromide***).[2,30] A radical-based annulation is also possible. By generating a radical center δ to the triple bond, cyclization to a five-membered ring system with an exocyclic methylene occurs.[16,31]

(1)

Sigmatropic Rearrangements.

Because of the triple bond, alkylation with propargyl chloride can provide intermediates further capable of intramolecular rearrangement. Crotyl propargyl ethers undergo [2,3]-Wittig rearrangement with high *erythro* or *threo* selectivity, dependent upon the starting alkene geometry.[32] The corresponding chiral analog allows for an asymmetric [2,3]-Wittig rearrangement with a high degree of enantioselectivity.[33] Under thermal conditions, propargylated phenols undergo a [3,3]-sigmatropic rearrangement to give an allenyl enol. A [1,5]-hydrogen shift, followed by electrocyclic ring closure results in the formation of a benzopyran (eq 2).[34,35]

(2)

Cycloadditions.

When appropriately appended, the propargyl group can serve as a dienophile for the intramolecular Diels-Alder reaction with ***Furan***,[36] styrene,[37] and triazine[38] derivatives. Under the typically basic reaction conditions, cycloaddition is believed to proceed via the allenyl ether intermediates. Propargyl bromide can also function as a 1,3-dipolarophile in the [3 + 2] cycloaddition reaction with nitrile oxides to form isoxazoles.[39]

Nucleophilic Additions.

As a halide, propargyl bromide can be converted to a variety of organometallic species, which then add to aldehydes and ketones. The Grignard reagent[40] is proposed to exist in the allenic form,[41] and reacts to form predominantly homopropargylic alcohols. Whereas the organozinc reagent reacts to give both α-allenic and β-alkynic alcohols,[42] the organoaluminum reagent can be used to generate products which are free of allenic isomers.[43] The reaction between carbonyl compounds and the tin reagent favors α-allenic alcohol formation.[44] However, the mixed metal system of tin and aluminum allows for selective formation of the homopropargylic alcohol.[45] A chiral tin complex can be formed with propargyl bromide and (+)-diethyl tartrate and made to react with aldehydes to give enantiomerically enriched α-allenic alcohols.[46] Other organometallic species prepared from propargyl halides include those of chromium,[3] lead,[47] and mercury.[48]

The Grignard reagent reacts with ***Trimethyl Borate*** to give, after hydrolysis, allenylboronic acid (eq 3). Further reaction with diethyl tartrate (DET) generates a chiral allenylboronic ester which enantioselectively adds to aldehydes to give chiral homopropargylic alcohols.[49]

Because of the acidic C-H bond, deprotonation generates the propargylic anion which may also serve as a nucleophile. In addition to simple acylation,[50] lithium chloropropargylide adds to trialkylboranes to give a lithium trialkylalkynylborate. Dependent upon the subsequent reaction conditions, substituted allenes,[51] alkynes,[52] or homopropargylic and α-allenic alcohols[53] may be formed.

Propargylmagnesium Bromide

[13254-27-8] · C_3H_3BrMg · Propargylmagnesium Bromide · (MW 143.27)

(propargylation and propadienylation of electrophilic centers)

Physical Data: prepared and used in situ.

Solubility: sol ether, THF.

Preparative Methods: prepared from propargyl bromide (see ***Propargyl Chloride***) and amalgamated magnesium, generated in situ from ***Magnesium*** and ***Mercury(II) Chloride***. Without $HgCl_2$, only a mixture of acetylenic and allenic hydrocarbons is obtained. Reaction at reflux temperature in ether using a recycling reactor[1] results in a greater than 90% yield of Grignard reagent consisting of a 4:1 ratio of allenic and acetylenic forms.[2] Low temperature and slow addition of a dilute solution of a mixture of propargylic bromide and substrate to a reacting mixture, initiated with a small amount of the bromide, is a technique that reduces equilibration of the Grignard reagent before its reaction with the substrate.[3,4] The same slow addition of a dilute ether solution of propargyl bromide to an initiated reaction is said to lead to the pure allenic Grignard reagent.[5] The Grignard reagent prepared from propargyl bromide has been converted into a solid powder by complexation with tris(3,6-dioxaheptyl)amine.[6]

Handling, Storage, and Precautions: the reagent should be prepared and used when needed. Solutions undergo disproportionation to propyne, allene, the acetylenic Grignard reagent, and di-Grignard reagent over days. The reagent is easily hydrolyzed to gaseous hydrocarbons and must be handled and used in a dry and inert atmosphere. Pure propargyl bromide, the compound required for preparing the Grignard reagent, is shock sensitive.[7] Propargyl bromide is also supplied as an 80% by wt solution in toluene, which does not show this hazardous property.[8]

Propargylation by Addition to Carbonyl Compounds.

Propargylmagnesium bromide adds to ketones,[9] aldehydes,[10] esters,[11] and ***Carbon Dioxide***[12] to give a mixture of propargylic and allenic adducts. Additions to ketones and aldehydes (which can be present in the reaction mixture as the Grignard reagent is produced)[3,4] lead to mixtures of homopropargylic and allenic alcohols. Low reaction temperatures, ranging from 25 to -100 °C have been employed to favor formation of the acetylenic alcohol. Addition of propargylmagnesium bromide to benzaldehyde at 0 °C is highly regioselective for the acetylenic isomer (eq 1).[10c] The selectivity of this reaction is better than the 93:7 obtained by the addition of propargylzinc bromide to phenacyltrimethylsilane. The propargylzinc halide/acyltrimethylsilane route gives consistently higher selectivity for the acetylenic alcohol than the aldehyde/Grignard route with higher propargyl homologs (eq 2).[10c]

(1)

(2)

The 1,2-addition to α,β-unsaturated ketones gives consistently high yields and is a highly regioselective process that does not show competition from conjugate additions (eq 3).[9] A protocol is available, however, for conjugate propargylation of α,β-unsaturated ketones using stannylallenes generated from propargylmagnesium bromide.[13] The addition of propargyl Grignard reagents to esters is usually a low yield reaction.[11] Low temperature and reverse addition techniques ensure that the reaction gives the ketone as the product. Predominance of the acetylenic or allenic ketone depends on the ester. For example, ethyl acetate is converted in 18% yield to a mixture of ketones consisting of 70% of 1,2-pentadien-4-one and 30% of 1-pentyn-4-one. Ethyl propionate gives a 30% yield of a 63:37 mixture of 1-hexyn-4-one and 1,2-hexadien-4-one, respectively.[11b,c] Carboxylation of propargylmagnesium bromide with CO_2 is also a low yield reaction that gives a mixture of acetylenic and allenic carboxylic acids.[12] The yield of carboxylic acids is better with the higher homologs of the propargyl Grignard reagent.

(3)

Propargylation by Addition to C=N Bonds.

A Grignard reagent prepared from propargyl bromide, described as allenylmagnesium bromide, adds efficiently to the C=N bonds of benzoxazoles, benzothiazoles,[14] quinoxalines,[15] and pyrimidines.[16] Benzoxazoles and unsubstituted benzothiazole add two propargyl groups at the 2-position to give ring-opened compounds (eqs 4 and 5). 2-Substituted benzothiazoles, on the other hand, add only one propargyl group, no matter how much Grignard reagent is present (eq 6). Quinoxaline adds a propargyl group to each of the C=N bonds (eq

7), whereas 2,3-dimethylquinoxaline affords a monoadduct regardless of how much excess Grignard reagent is present. 2-Chloro-3-methylquinoxaline gives 2-propargyl-3-methylquinoxaline, the product of nucleophilic aromatic substitution, when treated with a 50% excess of allenylmagnesium bromide (eq 8). Chloropyrimidines, however, only undergo addition to the C=N bond with allenylmagnesium bromide, uncomplicated by nucleophilic aromatic substitution (eq 9).

(4)

(5)

(6)

(7)

(8)

(9)

Propargylation by Substitution.

The Grignard reagent from propargyl bromide reacts poorly with saturated alkyl halides, but very well with allylic,[17] benzylic,[17] and some propargylic[18] halides. For example, *trans*-1,4-dibromo-2,3-dimethyl-2-butene is converted to an enediyne in 51% yield using allenylmagnesium bromide (eq 10), whereas use of 3-lithio-1-trimethylsilylpropyne gives less than a 5% yield. ***Allyl Bromide***, however, gives a mixture in which the allenic product predominates (eq 11).[19] With benzylic halides, bromides react better than chlorides. The palladium(0)-catalyzed cross coupling with benzyl halides is more efficient (eq 12).[20] The reaction of propargylmagnesium bromide with

trimethylsilylpropargyl bromide is reported to be a high yield route to the 1,5-diyne (eq 13).[18] Propargylmagnesium bromide can open epoxides with regioselectivity that depends on the steric effect of substituents on the epoxide (eq 14).[21] Alkoxymethyldialkylamines are converted in high yields to β-acetylenic tertiary amines.[22] Regioselectivity is usually high and is also affected by steric factors at the carbon bearing the alkoxy leaving group (eq 15). β-Acetylenic amines are accessible from the addition of propargylmagnesium bromide to *N*-trimethylsilyl imines followed by hydrolysis.[23] Propargyl Grignard reagents also displace the acetoxy group from dialkoxymethyl acetates to give homopropargylic acetals.[24]

Propargyltriphenylphosphonium Bromide

[2091-46-5] · $C_{21}H_{18}BrP$ · Propargyltriphenylphosphonium Bromide · (MW 381.26)

(Wittig reagent; synthon for β-amino- and β-iminopropenyltriphenylphosphonium bromides, precursors of heterocyclic systems)

Physical Data: mp 156-158 °C,[1] 179 °C;[2] IR;[3] ^{1}H NMR;[2] ^{13}C NMR;[4] pK_a.[5]

Preparative Method: readily available from ***Triphenylphosphine*** and propargyl bromide (see ***Propargyl Chloride***) (eq 1).[1,2] The presence of hydrogen bromide is absolutely necessary, otherwise the base Ph_3P causes the formation of tarry products.[1]

Wittig Reactions.

Deprotonation of propargyltriphenylphosphonium bromide with liquid ***Ammonia*** affords the corresponding phosphonium ylide which, in the presence of aldehydes, undergoes Wittig reaction to give enynes (eq 2).[1] Other bases which are usually used for the generation of phosphonium ylides from their salts give rise to the formation of dark, resinous products. Furthermore, only conjugated aldehydes are suitable substrates for the Wittig reactions under these conditions, leading to stereoisomeric mixtures.[1,6] Formation of an isomeric cumulene instead of the expected enyne, presumably as a consequence of an isomerization of the propargylidenephosphorane to the corresponding allylidene species, has been observed when ***n-Butyllithium*** is used as base.[7]

Isomerization.

Isomerization of propargyltriphenylphosphonium bromide to give the corresponding propadienyl and prop-1-ynyl salts can be accomplished by treatment with a catalytic amount of ***Potassium t-Butoxide*** or by heating with phenol, respectively (eq 3).[2]

(3)

Addition of Nucleophiles.

Propargyltriphenylphosphonium bromide adds oxygen, sulfur, and nitrogen nucleophiles, yielding β-substituted propenyltriphenylphosphonium bromides (eq 4),[2,8-18] obviously via intermediate formation of propadienyltriphenylphosphonium bromide.[2]

(4)

Y = OR, SR, NR^1R^2

The addition of various amino compounds has been investigated in most detail (eq 5).[2,8-15,18]

(5)

The resulting β-aminovinylphosphonium salts, which can be in equilibrium with the isomeric β-iminopropyl compounds,[2] are very useful reagents for Wittig reactions. Deprotonation affords the corresponding phosphoranes, which can be used in typical ylide reactions. Ylide generation followed by a Wittig reaction represents an efficient synthesis of 2-amino-1,3-butadienes (eq 6).[18]

A variety of heterocycles has been synthesized starting from propargyltriphenylphosphonium bromide and amino compounds (eq 7). This can be realized if the intermediate phosphonium salt is substituted in such a manner to allow intramolecular Wittig reaction[2,8] or intramolecular attack at the β-C-atom of the vinyl group followed by extrusion of methylenetriphenylphosphorane.[2,9,12]

Heterocycles may also result from thermal rearrangement of primarily formed open-chain Wittig products which are available from β-hydrazonopropylphosphonium bromides.[11,14,15] The phosphonium salts resulting from azirines and propargyltriphenylphosphonium bromide also undergo rearrangements affording phosphorus-substituted heterocycles.[13]

Reaction with Iminophosphoranes.

Reactions of propargyltriphenylphosphonium bromide with iminophosphoranes or phosphazines give 2-imino-3-phosphoranylidene phosphonium salts (eq 8), which can formally be rationalized as the result of a [2 + 2] cycloaddition followed by an electrocyclic ring opening.[8,11,19,20]

The resulting ylide salts are versatile precursors for the synthesis of β-enamino phosphonium salts, divinylic ketimines, and the corresponding ketones.[19,20] In some cases the resulting Wittig products undergo cyclization, affording heterocyclic compounds.[11]

1-Propenyl Bromide[1]

(*Z*)

[590-13-6] · C_3H_5Br · 1-Propenyl Bromide · (MW 120.98) (*E*)

[590-15-8]

(precursor for (*E*)- or (*Z*)-1-propenyllithium and 1-propenylmagnesium bromide; reagent for electrophilic propenylation)

Alternate Name: 1-bromo-1-propene.

Physical Data: bp 58.5 °C (*Z*), 64.5 °C (*E*); *d* 1.420 g cm^{-3} (*Z*), 1.428 g cm^{-3} (*E*); *n*25D 1.4508 (*Z*), 1.4534 (*E*).

Solubility: insol water; sol alcohol, ether, most other organic solvents.

Form Supplied in: colorless liquid; commercially available (*Z*-isomer of 97% purity or a 70:30 *Z*/*E* mixture).

Preparative Methods: (*Z*)- and (*E*)-1-propenyl bromides can be obtained through spinning band distillation of the commercially available mixture of isomers (*Z*/*E* = 70/30). However, the (*E*)-isomer can only be obtained with difficulty due to thermal isomerization to the (Z)-isomer. Pure (*Z*)-1-propenyl bromide can be prepared by bromination of (*E*)-crotonic acid followed by bromodecarboxylation of the resulting *erythro*-2,3-dibromobutanoic acid in the presence of ***Triethylamine*** or ***Diisopropylethylamine*** at 40 °C (eq 1).[2] (*E*)-1-Propenyl bromide can be obtained[3] in 98% purity by treatment of the commercially available mixture of isomers (*Z*/*E* = 70/30) with ***Sodium Hydroxide*** in *n*-BuOH at reflux until no (*Z*)-1-propenyl bromide is detected by GLC.

Handling, Storage, and Precautions: stored in a refrigerator to inhibit thermal and acid-catalyzed isomerization. Avoid breathing vapor and contact with skin and eyes. Use in a fume hood.

General Discussion.

Both (*E*)- and (*Z*)-1-propenylmagnesium bromides are prepared in THF[4] from the corresponding bromides with 80% and 90% retention of the configuration,[5] respectively. They react with various electrophiles[1,6] (eqs 2 and 3)[7] (see also ***Isopropenylmagnesium Bromide*** and ***Vinylmagnesium Bromide***). Pure (*E*)-1-propenylmagnesium bromide can also be prepared from ***1-Propenyllithium*** and anhydrous ***Magnesium Bromide*** in diethyl ether.[8]

(*Z*)- or (*E*)-1-propenyl bromide gives (*Z*)- or (*E*)-***1-Propenyllithium*** by reaction with ***Lithium*** powder (eq 4)[9] or by metal-halogen exchange reaction with ***t-Butyllithium*** (eq 5).[10]

Vinylation of Grignard reagents can be achieved easily with (*Z*)- or (*E*)-propenyl bromide in the presence of an iron or palladium complex catalyst[11] (eqs 6 and 7).[3,11a]

Under the influence of ***Nickel(II) Chloride*** hydrate, in the presence of ***Zinc*** and ***Pyridine***, (*Z*)-1-propenyl bromide reacts with ***Ethyl Acrylate***, ***Acrylonitrile***, and ***Methyl Vinyl Ketone*** (eq 8).[12]

In the presence of a palladium(0) complex and ***Copper(I) Iodide***, (*Z*)-1-propenyl bromide reacts stereospecifically with terminal alkynes to give (*Z*)-enynes (eq 9).[13]

(9)

Under palladium catalysis, reaction of (*E*)-1-propenyl bromide with an allene hydrocarbon generates a transient π-allyl palladium complex which is trapped by sodium ***Diethyl Malonate*** to give a conjugated diene in high yield (eq 10).[14]

(10)

Magnesio Derivatives.

In the presence of ***Silver(I) Nitrate*** and palladium or nickel complexes, (*Z*)- or (*E*)-1-propenyl magnesium bromide couples with alkyl (eq 11),[15] vinyl (eq 12),[16,17] and aryl halides (eq 13).[17]

(11)

(12)

(13)

(*E*)-1-Propenylmagnesium bromide stereospecifically dimerizes on treatment with ***Copper(I) Chloride***.[18] However, the propenyl unit can be transferred by standard cuprate reactions[19] (eq 14)[20] (see also ***2-Propenylmagnesium Bromide-Copper(I) Iodide***).

(14)

The transmetalation of 1-propenylmagnesium bromide with ***Tri-n-butylchlorostannane***[6e,21] or ***Manganese(II) Chloride***[22] forms 1-propenyl tin and manganese compounds. The latter react with α,β-unsaturated aldehydes in 1,4-fashion (eq 15).[23]

1-Propenyllithium[1]

(*E*)

[6386-72-7] · C_3H_5Li · 1-Propenyllithium · (MW 48.02) (*Z*)

[6524-17-0]

(precursor of propenyl metals[2])

Physical Data: ^1H and ^{13}C NMR spectra have been reported.[2g]

Preparative Methods: prepared by reaction of 1-chloro- or 1-bromopropene with ***Lithium*** powder (containing 2% of sodium in the case of the chloride) in diethyl ether (eqs 1 and 2).[4] This reaction occurs with a slight loss of stereochemistry.[4d] The reagent can also be prepared by metal-halogen exchange reaction between 1-bromopropene and ***t-Butyllithium*** (eq 3),[5] and by transmetalation of tin derivatives by an organolithium compound (eq 4).[2g,6] In the two latter cases, the reactions are stereospecific.

Handling, Storage, and Precautions: the solution of propenyllithium in diethyl ether must be handled with care since it is flammable and may ignite on contact with moisture and air. It should be stored and handled in an inert atmosphere (argon) and measured or transferred by means of a hypodermic syringe or cannula. The solution may deteriorate with time and the concentration of the reagent should be titrated before use.[3]

General Discussion.

Both (*Z*)- and (*E*)-1-propenyllithium reagents react with various electrophiles[2g,4-6] with retention of configuration (eqs 5 and 6).[7,8]

(5)

(6)

When treated with 2-halogenoalkyl boronates in diethyl ether, (*Z*)- or (*E*)-1-propenyllithium leads to allyl boronates (eqs 7 and 8).[9]

(7)

(8)

The reaction of (*Z*)- or (*E*)-1-propenyllithium with ***Copper(I) Iodide*** or silver iodide leads to the corresponding organometallic compound which undergoes thermal decomposition to give 2,4-hexadiene with retention of configuration at the double bonds (eq 9).[4d,f]

(9)

Pure (*Z*)- and (*E*)-1-propenylcuprates, prepared according to standard cuprate procedures,[2] undergo conjugate addition to α,β-unsaturated carbonyl compounds[10] (eqs 10 and 11)[10a] and react readily with alkyl halides (eq 12)[11] and epoxides (eq 13).[12]

(10)

(11)

(12)

(13)

When treated with allylic chlorides (e.g. (*E*)-1-chloro-2-octene), they lead to skipped dienes without isomerization or rearrangement (eq 14).[13]

(14)

Addition of (*E*)-1-propenylcuprate to α-hydroxy aldehydes in the presence of ***Magnesium Bromide*** etherate proceeds stereoselectively to give allylic alcohols (eq 15).[14]

(15)

The transmetalation of 1-propenyllithium with tributyltin bromide allows the preparation of 1-propenyltributyltin with retention of configuration (eq 16).[15]

(16)

In the presence of lithiated (+)-*N*-methylephedrine or (+)-2-(dimethylamino)-1,2-diphenylethanol, (*Z*)-1-propenylzinc bromide (prepared by transmetalation of (*Z*)-1-propenyllithium) adds enantioselectively to a variety of aldehydes (eq 17).[16]

(17)

Related Reagents.

(*E*)- and (*Z*)-alkenyllithium derivatives, prepared in the same way as (*E*)- and (*Z*)-propenyllithium reagents, are useful precursors of alkenyl organometallic compounds, particularly alkenyl cuprates.

Alkenylmanganese compounds, obtained by transmetalation of organolithium derivatives with manganese halides, are chemoselective reagents and react with acid chlorides to give α,β-unsaturated ketones (eq 18).[17] Under copper catalysis, they add to α,β-unsaturated ketones in 1,4-fashion (eq 19).[18]

(18)

(19)

Alkenyllithium reagents bearing an alcohol function in the allylic position[6a] are useful intermediates in synthesis[2f] (eq 20).[19] The corresponding cuprates react regioselectively with epoxides (eq 21).[20]

(20)

(21)

(*E*)-3-Hydroxy-1-octenyllithium is a key intermediate in prostaglandin synthesis.[21] Several convenient approaches to prostaglandins commence with a preformed cyclopentane nucleus bearing suitable functionality for elaboration of at least one of the side chains. The second chain may be attached by a variety of methods. However, by far the most successful approach involves the conjugate addition of a vinyl copper to a cyclopentenone precursor (eq 22).[22]

Related Reagents.

Isopropenyllithium; ***Vinyllithium***.

2-Propenylmagnesium Bromide-Copper(I) Iodide[1]

(2-propenylmagnesium bromide)

[13291-18-4] · C_3H_5BrMg · 2-Propenylmagnesium Bromide-Copper(I) Iodide · (MW 145.29) (CuI)

[7681-65-4] · CuI · 2-Propenylmagnesium Bromide-Copper(I) Iodide · (MW 190.45)

(undergoes conjugate addition to cyclohexenone;[2] adds regioselectively to β,γ-epoxides[3])

Preparative Method: prepared in situ under anhydrous conditions by reacting 2-propenylmagnesium bromide (**1**) with ***Copper(I) Iodide*** (**2**) in varying molar ratios.

Handling, Storage, and Precautions: use in a fume hood.

Conjugate Addition.

Cyclohexenone reacts with (**1**) in the presence of catalytic (**2**) to give 3-isopropenylcyclohexanone (**3**) (eq 1).[2] Attempts to access (**3**) via dehydration of (**4**) result in mixtures of (**3**) and the cyclohexenone (**5**) (eq 2).

(1)

Regioselective Opening of β,γ-Epoxy Alcohols.

Epoxy alcohol (**6**) reacts with (**1**) and catalytic (**2**) to give 1,3 diol (**7**) with high regioselectivity for addition at C-2; none of the 1,2-diol resulting from addition to C-3 is observed (eq 3).[3] The reaction is dependent upon temperature and solvent. Reactions involving vinylic Grignard reagents give best results when carried out at -20 to -25 °C; THF is an essential cosolvent. Regioselectivity in related epoxy alcohols ranges from 4:1 to 7:1.

β-Propiolactone[1]

[57-57-8] · $C_3H_4O_2$ · β-Propiolactone · (MW 72.07)

(three-carbon homologating electrophile for synthesis of carboxylic acids and β-hetero propionates; β-hydroxypropionylating reagent)

Physical Data: mp -33.4 °C; bp 162 °C; *d* 1.146 g cm^{-3}.

Solubility: miscible with alcohol, acetone, ether, chloroform.

Form Supplied in: colorless oil: widely available.

Preparative Methods: prepared by reaction of ***Ketene*** and ***Formaldehyde*** under the influence of a Friedel-Crafts catalyst,[1,3] by ring-closure of β-halo propionic acids with base,[4] or by dehydration of 3-hydroxypropionic acid with various condensation reagents.[5]

Handling, Storage, and Precautions: can be stored in the refrigerator for several months without noticeable changes; reacts with bacteriophage DNA causing inactivation, repair, and recombination.[2] Owing to its carcinogenic property, β-propiolactone should be handled with due care.

General Discussion.

Although β-propiolactone (**1**) is prone to polymerization,[6] it also readily undergoes ring opening with a variety of nucleophiles to give selectively alkylated products, in which two reaction pathways are involved (eq 1).[1a]

The addition to carbonyl carbon predominates to give α,β-unsaturated ketones or 1,4-diols (path A), when organolithium reagents,[7] Grignard reagents,[8] and (trifluoromethyl)trimethylsilane-fluoride anion[9] are used as nucleophiles, while organocadmium reagents,[7] enamines,[10] thiols,[11] and aminosilanes[12] effect C-O bond fission to give propionic acid derivatives (path B). Studies using Group 14 organometallics such as Me_3MNEt_2 (M = Sn, Ge, Si) indicate that the regiochemistry of the ring opening is also dependent on the metal used.[13] For example, the acyl-oxygen bond is cleaved by the tin reagent (path A), whereas the alkyl-oxygen bond is cleaved by the silicon and germanium reagents.

Organocopper reagents exhibit interesting regiochemistry in the ring opening of β-propiolactone. Selective β-attack is accomplished by the use of organocopper reagents.[14] As shown in eq 2 and Table 1, organocuprate prepared from 2 equiv of Grignard reagent and 1 equiv of ***Copper(I) Iodide*** gives β-alkylated propionic acids in better yields than those prepared from the corresponding organolithium reagents. In the presence of a catalytic amount of a copper(I) salt, Grignard reagents open up the lactone ring at the β-carbon to the carbonyl in good yields.[15] However, organolithium reagents, in the presence of catalytic amounts of copper(I) salts effect ring opening at the carbonyl carbon to give acylated products.[7] The organocopper-phosphine complexes,[16] prepared from organolithium reagents with ***Tri-n-butylphosphine*** and copper(I) iodide, attack selectively at the β-carbon.

Table 1 Ring Opening of b-Propiolactone with Organocopper Reagents (eq 2)

R	Yield of (2) (%)		
	R_2CuMgX	$RCu{\cdot}PBu_3$	RMgX + cat CuCl
Me	86	80	87
Bu	92	92	90
t-Bu	88	76	85
Ph	80	69	77
Vinyl	87	37	59
Allyl	65	8	trace

The application of this three-carbon elongation reaction to the construction of naturally occurring products has been demonstrated in several examples. Dialkylcopper reagents prepared from Grignard reagents and copper(I) iodide react with acetylene to give the corresponding di-(*Z*)-1-alkenylcuprates (**3**), which in turn react with β-propiolactone to afford (*Z*)-4-alkenoic acids (**4**), in good yields with excellent (*Z*) selectivity (eq 3).[17] (*Z*)-4-Heptenoic acid (**4**) (R = Et) serves as a useful starting material for syntheses of perfume and flavor components such as *cis*-jasmone (**5**), methyl jasmonate (**6**), and jasmolone (**7**) (eqs 4-6).[18]

(4)

(5)

(6)

Lactones possessing large-membered rings are prepared by ring opening of β-propiolactone. In the presence of a catalytic amount of a copper salt, o-alkoxy or metalloxy Grignard reagents react with β-propiolactone to give the corresponding homologated carboxylic acids, which can cyclize to form macrocyclic lactones (**8**) (eq 7)[19] α,o-Di-Grignard reagents also serve as good chain elongation reagents for the synthesis of macrolides (**9**) (eq 8).[20] β-Propiolactone is converted into the β-lactam (**10**) (eq 9) by ring opening with a nitrogen nucleophile and the products are used for the synthesis of β-lactam antibiotics.[21]

The ring opening of β-lactams with nitrogen nucleophiles is used for the synthesis of macrocyclic polyamine derivatives (**11**) (eq 10).[22] The regiochemistry of the ring opening is dependent on the solvent; acetonitrile is the solvent of choice for *N*-alkylation.

An intriguing C-C bond fission occurs upon reaction of β-propiolactone with ***Potassium-18-Crown-6*** or ***Potassium Naphthalenide*** to give acetates or their alkylated derivatives in good yield (eq 11). The potassium solution generated by contact of a potassium mirror with a solution of 18-crown-6 in THF at -20 °C effects the formation of enolate anion (**12**) derived from C-C bond cleavage. Upon treatment with ***Hydrochloric Acid*** or alkyl halides, the acetate (**13**) or its alkylated derivatives (**14**) are obtained, respectively.[23] On the other hand, acrylic acid (**15**) is formed by the action of the potassium naphthalenide-18-crown-6 complex.[24] Subsequent alkylation with alkyl halides gives the α,β-unsaturated esters (**16**).

β-Propiolactone readily interacts with transition metals such as platinum,[25] cobalt, and rhodium to give ring-opened products, (eq 12) and, under an atmosphere of carbon monoxide, γ-butyrolactone (**17**) is formed (eq 13).[26]

Propionaldehyde *t*-Butylimine[1]

(R = *t*-Bu)

[7020-81-7] · $C_7H_{15}N$ · Propionaldehyde *t*-Butylimine · (MW 113.23) (R = *t*-Bu, Li salt)

[75261-61-9] · $C_7H_{14}LiN$ · 2-Lithiopropionaldehyde *t*-Butylimine · (MW 119.16) (R = Cy)

[6898-80-2] · $C_9H_{17}N$ · Propionaldehyde Cyclohexylimine · (MW 139.27)

(two-carbon nucleophile in enolate alkylations, conjugate addition reactions, and directed aldol condensations; especially useful for α-monoalkylations and three-carbon homologations[1])

Physical Data: R = *t*-Bu: bp 103 °C,[2] 48-50 °C/115 mmHg,[3] 47-49 °C/95 mmHg.[4] R = Cy: bp 63-64 °C/15 mmHg,[4] 62-63 °C/12 mmHg;[5] *n*16D 1.4450.

Solubility: sol THF, ether, CCl_4, pentane, benzene, toluene.

Form Supplied in: colorless liquid when freshly distilled; darkens on prolonged standing

Analysis of Reagent Purity: NMR or IR.

Preparative Methods: the general method adapted by Stork and Dowd from the procedure developed earlier by Tiollais is said to be highly efficient for the synthesis of aldimines from low-boiling aldehydes.[2] Quantitative yields have also been reported when propanal is added to a preformed amine-***Titanium(IV) Chloride*** complex.[6] Lithiopropionaldehyde *t*-butylimine is usually prepared by reaction with a slight excess of a hindered nonnucleophilic base like ***Lithium Diethylamide*** in THF or ether at -78 °C under N_2 or argon.[7,8] A variation of this method calls for addition of ***Hexamethylphosphoric Triamide*** to the reaction mixture.[8b]

Handling, Storage, and Precautions: best used when freshly prepared. Imines can be distilled, but they tend to polymerize upon long standing. Stored samples are distilled over KOH to remove high-boiling condensation products prior to use. Storage as neat liquids is not recommended for long periods, but solutions in dry THF (0.4 M) can be stored at -20 to -30 °C with minimal deterioration.[9] In acidic solutions, the imine reverts to propanal and the amine. The lithiated imine is generally prepared in situ under N_2 or argon. Use in a fume hood.

Condensation Reactions.

The synthetic value of these reagents lies in their facile conversion to imine anions and their low propensity for self-aldol condensation. These characteristics favor their use over propionaldehyde in directed crossed-aldol condensation reactions. (*E*)-α,β-Unsaturated aldehydes are stereoselectively formed upon hydrolysis and dehydration of the α-methyl-β-hydroxy aldehyde adducts. This strategy is illustrated in the synthesis of nuciferal (eq 1) and sinensal,[7] and in a variety of intermediates for the synthesis of natural products,[1,10]

These reagents can tolerate the presence of other functional groups in the electrophile (eq 2).[10] Phosphonates[11] and trialkylsilyl groups[3,8,12] have been used to stabilize the lithio imine anions in these reactions.

γ-Diketones have been prepared by Michael-type additions of the *t*-Bu imine anion and by alkylation with allylic halides followed by ozonolysis.[13]

Heterocycles.

The ease with which metalloenamines undergo α-monoalkylation in the presence of alkyl halides extends the usefulness of these reagents. Yields are usually high and no rearrangement is observed even with allyl halides. In contrast, propionaldehyde tends to undergo self-aldol condensation in the presence of base and is not alkylated by primary and secondary alkyl halides. Enamines, on the other hand, tend to undergo *N*-alkylation.[14] With dihalides as alkylating agents, subsequent intramolecular reactions can be utilized to effect ring closure. Nitrogen heterocycles like tetrahydropyridines (eq 3)[15] and substituted azetidines (eq 4)[16] have been synthesized in this manner. Other ring closure reactions using these imines have afforded 2-amino-5-cyanopyrroles,[17] azaphosphorines,[18] azaphospholenes,[18] substituted 4-methylpyrrolidines,[19] and substituted 3-pyridinecarboxylic acids and their derivatives.[20]

Other Reactions.

Functionalization at the α-position can be achieved using a variety of reagents. ***N-Chlorosuccinimide*** can be used for α-chlorination. A stereoselective reaction with a chiral sulfinate ester affords (*Z*)-β-enamino sulfoxides,[4] while nitration with an alkyl nitrate yields 1-alkylamino-2-nitro-1-alkenes (eq 5).[21] The (*Z*) stereochemistry is preferred due to stabilization by intramolecular H-bonding. These reagents also provide a useful route for the synthesis of vinyl isocyanates by reaction with ***Phosgene***[22] and secondary propanamines by chemical reduction using ***Sodium Cyanoborohydride***[23] or catalytic hydrogenation with ***Raney Nickel***.[24] Hydrolysis of the elaborated imines is often a final step in a reaction sequence involving these reagents. Such hydrolyses are facile and are often carried out using cold,

aqueous acid, e.g. NaOAc-HOAc-H_2O (1:2:2),[25] ***Oxalic Acid***,[7] NH_4Cl,[16] and ***Zinc Chloride***.[3] Cold 10% oxalic acid is most commonly used.

Propionic Acid

[79-09-4] · $C_3H_6O_2$ · Propionic Acid · (MW 74.09)

(catalyst for orthoester Claisen rearrangement;[1] solvent for malonate diester decarboxylation[13] and porphyrin synthesis[14])

Alternate Name: propanoic acid.

Physical Data: clear liquid, bp 141 °C, 40 °C/10 mmHg; mp -23 °C; *d* 0.993 g cm^{-3}.[1]

Solubility: miscible with water, ethanol, ether, chloroform.

Form Supplied in: neat liquid; commercially available.

Analysis of Reagent Purity: by titrimetric assay; carbonyl compound impurity tests are known.[15]

Purification: usually by repeated fractional distillation.[16]

Handling, Storage, and Precautions: corrosive organic acid with an acrid odor. It is especially destructive to tissue of mucous membranes and upper respiratory tract, eyes, and skin. Inhalation is a major hazard and may be fatal. Use of a NIOSH/MSHA approved respirator is recommended. Use gloves, eye protection, and protective clothing to avoid contact. The acid should never be mixed with basic solvents, oxidizers, and reducing agents. Use in a fume hood.

Orthoester Claisen Rearrangement.

Propionic acid is the classic acid catalyst for the Johnson orthoester Claisen rearrangement of an allylic alcohol and trialkyl orthoester (see ***Triethyl Orthoacetate***). Examples have been reported for all allylic bond substitutions, including 1,1-disubstituted (eq 1),[2] (*E*),[3] (*Z*),[4] trisubstituted,[5] and tetrasubstituted.[6]

(1)

The reaction of a propargyl alcohol and triethyl orthoacetate produces an allene ester (eq 2).[7] Allenic alcohols react in a similar manner to give diene esters in moderate yield (eq 3).[8]

(2)

The reaction of 2-butynediol with excess trimethyl orthopropionate and catalytic propionic acid yields a symmetrical diene diester through the novel double Claisen orthoester rearrangement (eq 4).[9]

Other Variations on the Orthoester Claisen Rearrangement.

The condensation of a dialkyl acetal and a primary allylic alcohol to form an unsaturated ketone has been catalyzed with propionic acid (eq 5).[10] The condensation of an allylic alcohol with ***Triethyl Methanetricarboxylate*** yields, after decarboxylation, an unsaturated ester (eq 6).[11]

Decarboxylation of Malonic Esters.

The decarboxylation of malonic ester derivatives to esters is general in propionic acid (eq 7).[12] This reaction is complementary to the basic hydrolysis of malonate esters to carboxylic acids.

(7)

Synthesis of Porphyrins.

The condensation of an aldehyde and pyrrole in propionic acid leads to the formation of a tetrasubstituted porphyrin.[13] In an improved porphyrin synthesis, 2-acylpyrroles are reduced to the corresponding alcohols and converted to porphyrins by condensation and oxidation in refluxing propionic acid (eq 8).[14]

(8)

Related Reagents.

Acetic Acid; ***Pivalic Acid***; ***p-Toluenesulfonic Acid***; ***Trifluoroacetic Acid***; ***2,4,6-Trimethylbenzoic Acid***.

3-Propionylthiazolidine-2-thione[1]

[85260-51-1] · $C_6H_9NOS_2$ · 3-Propionylthiazolidine-2-thione · (MW 175.30)

(synthesis of β-hydroxy-α-methyl carboxylic esters, amides, and aldehydes,[2] propionate equivalent for the diastereo- and enantioselective aldol reactions[2,3])

Physical Data: bp 151 °C/4 mmHg.

Form Supplied in: sticky, slightly yellow oil.

Preparative Methods: from propionyl chloride and ***1,3-Thiazolidine-2-thione*** in the presence of ***Triethylamine***, or from ***Propionic Acid*** and thiazolidine-2-thione in the presence of triethylamine and ***2-Chloro-1-methylpyridinium Iodide***.[4]

Handling, Storage, and Precautions: use in a fume hood.

Diastereoselective Aldol Reactions.

The tin(II) enolate generated from 3-propionylthiazolidine-2-thione (**1**), ***Tin(II) Trifluoromethanesulfonate***, and ***1-Ethylpiperidine*** reacts with aldehydes at -78 °C to afford the aldol adducts in high yields with high *syn* selectivities (eq 1).[2,3] 3-Acetylthiazolidine-2-thione (**2**) (bp 125-128 °C/2 mmHg)[2,3,5,8] and 3-(3-phenylpropanoyl)thiazolidine-2-thione (**3**) (mp 66.0-67.5 °C)[2-4] also work well under the same reaction conditions.[2,3]

(1)

(4) *syn*:*anti* = >97:3

(2)

(3)

The aldol adducts (**4**) are easily converted to the corresponding β-hydroxy-α-methyl esters, amides, and aldehydes. Treatment of (**4**) (R = Ph) with methanol or ethanol in the presence of ***Potassium Carbonate*** at room temperature gives the methyl or ethyl ester in high yield (eq 2).[2] Similarly, the amide is spontaneously formed by mixing (**4**) with the amine in dichloromethane (eq 3).[2] The preparation of the aldehyde is carried out by using ***Diisobutylaluminum Hydride*** as a reductant after protection of the hydroxy function of (**4**) with the dimethylisopropylsilyl group (eq 4).[2,4] No isomerization occurs during these conversions.

(4a) (4; R = Ph) (2)

(3)

(4)

Enantioselective Aldol Reactions.

A highly enantioselective aldol reaction of the tin(II) enolate derived from (**2**) with aldehydes is carried out in the presence of the chiral diamine (**5**) as a ligand (eq 5).[3,5,6] Aromatic and aliphatic ketones instead of (**2**) are good substrates in the present asymmetric aldol reaction,[3,7] and enantioselectivities are influenced strongly by the structure of the chiral diamines.

The tin(II) enolate of (**2**) reacts with α-keto esters in the presence of the chiral diamine (**6**) to give optically active 2-substituted malic acid ester derivatives in high yields with high ee (eq 6).[8]

The tin(II) enolate of (**2**) also reacts with chiral aldehydes in the presence of (**5**). Diastereoselectivities can be controlled by the absolute configuration of the chiral diamines (eqs 7 and 8).[1f]

(7)

syn:*anti* = 7:93

(8)

syn:*anti* = 83:17

In the reaction of the tin(II) enolate derived from (**1**) with aldehydes, enantioselectivities are disappointingly low, while good diastereoselectivities are observed. Highly diastereo- and enantioselective aldol reactions of propionate derivatives with aldehydes have been achieved by using the ketene silyl thioacetal (**7**) instead of the tin(II) enolate. The complex (**8**) produced by mixing tin(II) triflate and the chiral diamine (**6**) works as an efficient chiral Lewis acid. The reaction of (**7**) with various aldehydes proceeds smoothly in the presence of (**8**) and dibutyltin diacetate in dichloromethane to afford the *syn* aldol adducts in high yields with almost perfect stereochemical control (eq 9).[9]

(7)

(8)

(9)

While stoichiometric amounts of tin(II) triflate, (**6**), and the tin(IV) compound are necessary in the reaction shown in eq 9, the truly catalytic asymmetric aldol reaction of (**7**) with aldehydes is realized by using (**8**) as a Lewis acid catalyst (eq 10).[10] The reaction is carried out in propionitrile by slow addition of the substrates to the catalyst.

(10)

Related Reagents.

3-(2-Benzyloxyacetyl)thiazolidine-2-thione; ***2,6-Dimethylphenyl Propionate***; ***2-Methyl-2-(trimethylsilyloxy)-3-pentanone***; ***1,3-Thiazolidine-2-thione***; ***Tin(II) Trifluoromethanesulfonate***.

Propylene Oxide[1]

[75-56-9] · C_3H_6O · Propylene Oxide · (MW 58.09)

(monomer for polymerization; electrophile; chiral building block)

Alternate Names: 1,2-epoxypropane; methyloxirane.

Physical Data: mp -112 °C; bp 34 °C; *d* 0.859 g cm^{-3}; [α]20D +14.6° for the (*R*)-enantiomer, corrected to 100% ee.

Solubility: sol H_2O (405 g L^{-1}); miscible with organic solvents.

Form Supplied in: colorless liquid; commercially available as a racemic mixture and as the enantiomers. *Drying:* distillation from calcium hydride or calcium. Upon cooling, a hydrate $C_3H_6O.(H_2O)_{16}$ of mp -3 °C is precipitated from the moist oxirane as white crystals.[2]

Analysis of Reagent Purity: ^{13}C NMR ($CDCl_3$): δ 47.1, 46.8 (C-1, C-2), 17.2 (C-3) ppm; determination of ee by complexation gas chromatography on nickel(II) bis[3-heptafluorobutanoyl-(1*R*)-camphorate] in squalane, separation factor α 1.24 at 50 °C;[3] other suitable chiral stationary phases are nickel(II) bis[2-heptafluorobutanoyl-(*S*)-4-methylthujan-3-onate] and manganese(II) bis[3-heptafluorobutanoyl-(1*R*)-camphorate].[4]

Preparative Methods: (*R*)-propylene oxide is prepared (eq 1) in three steps: diazotization of (*S*)-alanine with ***Sodium Nitrite*** in hydrochloric acid; to give (*S*)-2-chloropropanoic acid; reduction to 2-chloropropan-1-ol with ***Lithium Aluminum Hydride***; and cyclization by distillation from ***Potassium Hydroxide*** pellets.[4,5]

The (*S*)-enantiomer is prepared from ***(S)-Ethyl Lactate*** via (*S*)-propane-1,2-diol, and cyclization of a mixture of (*S*)-2-acetoxy-1-bromopropane and (*R*)-2-bromo-1-acetoxypropane (eq 2).[6,7]

Alternatively, conversion of (*S*)-ethyl lactate into the mesylate is followed by reduction of the ester group with ***Aluminum Hydride***/THF and ring closure with aqueous KOH.[8] Another route to (*S*)-propylene oxide involves protection of the (secondary) hydroxyl group of (*S*)-ethyl lactate with ***Ethyl Vinyl Ether***, followed by reduction of the ester group with $LiAlH_4$, conversion of the primary hydroxyl group into the tosylate, acidic deprotection of the secondary hydroxyl group, and cyclization with aqueous KOH.[9] By means of a combined microbial/chemical synthesis, (*R*)-propylene oxide is obtained from glucose with ee >99%.[10] Metal-mediated access to both enantiomers is provided by either chromatographic or kinetic resolution of racemic propylene oxide, and also by asymmetric epoxidation of propylene.[11]

Handling, Storage, and Precautions: a suspected carcinogen for humans; it is inflammable and explosive; because of its high volatility, cooling to 0 °C before use is recommended. Use in a fume hood.

Polymerization of Propylene Oxide.

Monoalkyl-substituted oxiranes are polymerized by a great variety of initiators (cationic, anionic, or ionic-coordinated). Cationic initiators tend to give irregular enchainments, as ring opening occurs in both the α- and β-positions. With anionic initiators, such as ***Potassium t-Butoxide*** and KOH, the stereoselective formation of head-to-tail polymers is straightforward; in the case of propylene oxide, the chain ends are left unsaturated, giving rise to secondary reactions.[12] Enantioselective polymerization of racemic propylene oxide is mediated by initiators formed from ***Diethylzinc*** and various chiral auxiliaries;[13] the reaction proceeds with complete inversion at the stereogenic center and, with achiral initiators, an equimolar mixture of homochiral polymers (*R*)-(*R*)-(*R*)... and (*S*)-(*S*)-(*S*)... is formed.[14] Oligoethers are formed with tetraphenylporphinatoaluminium chloride as initiator species (eq 3); ring opening in the β-position is followed by insertion of the monomer unit into the Al-Cl bond. In subsequent steps, the monomer is inserted into the Al-O bond, leading to a polymer that bears a secondary hydroxyl group at one chain end and a chloromethyl group at the other.[15]

Reaction with Carbon Dioxide.

The stereoselective reaction of propylene oxide with ***Carbon Dioxide*** to give 4-methyl-1,3-dioxolan-2-one (eq 4) is catalyzed by metal salts and also by transition metal complexes; high pressures and high temperatures are necessary.[16]

Reaction with Heteronucleophiles.

Nucleophiles preferentially attack the unsubstituted carbon atom; since secondary amines are more basic than primary amines, the reaction of (*S*)-propylene oxide with the latter leads to polyfunctional amino diols (eq 5).[17]

As shown in eq 6, a primary amino group is introduced into an alkyloxirane by ring opening with lithium dibenzylamide, followed by hydrogenolytic deprotection of the amine.[18]

(*S*)-Propylene oxide reacts with ***Hydrogen Chloride/Lithium Chloride*** to give (*S*)-1-chloro-2-propanol (eq 7). This can be converted to 1-benzylthio-2-propanol by lithiation with ***n-Butyllithium*** followed by reaction with ***Lithium Naphthalenide*** to give highly reactive C-metalated alkoxides.[19]

Reaction with Grignard Reagents.

The C-C-coupling reaction between oxiranes and Grignard reagents is catalyzed by copper(I) compounds. As depicted in eq 8, (*R*)- and (*S*)-sulcatol are prepared in a straightforward manner from (*R*)- and (*S*)-propylene oxide, respectively, and an allylic Grignard reagent, using ***Copper(I) Iodide*** as catalyst.[20]

(8)

A convenient route to (*R*)-α-methylene-γ-lactones (eq 9) comprises reaction of a vinylic Grignard reagent with propylene oxide, electrophilic replacement of the trimethylsilyl group, and ring closure with ***Tetrakis(triphenylphosphine)palladium(0)*** and ***Carbon Monoxide*** in acetonitrile.[21]

(9)

In eq 10, the total synthesis of (*R*)-mellein is depicted via the *O*-methoxymethylene-protected aryl Grignard compound derived from 3-bromophenol, which is added to (*R*)-propylene oxide using $CuBr.SMe_2$ (see ***Copper(I) Bromide***) as the catalyst. After ring lithiation with ***n-Butyllithium*** and carboxylation with ***Carbon Dioxide***, treatment with methanolic hydrochloric acid leads to the final product.[22]

An illustration of protection and deprotection of two hydroxy groups is displayed in eq 11. Reaction of an aliphatic bromomagnesium compound with propylene oxide in the presence of 1,4-cyclooctadiene-***Copper(I) Chloride***, followed by protection with ***3,4-Dihydro-2H-pyran***, hydrogenolytic debenzylation of the primary hydroxy group, and oxidation with ***Pyridinium Chlorochromate*** yields an aldehyde that is transformed into melochinine by a multistep procedure.[23]

This scheme is paralleled by eq 12, where an aliphatic chloromagnesium compound reacts with propylene oxide. In a multistep procedure, the secondary hydroxy group is protected, and the primary hydroxy group is deprotected and eventually oxidized to a carboxylic function. The final product, (*S*)-13-methyl-(*Z*)-5-tridecenolide, is a macrolide aggregation pheromone of the flat grain beetle.[24]

Reaction with Organoaluminum Compounds.

The macrocyclic lactone (*R*)-recifeiolide is prepared via ring opening of (*R*)-propylene oxide with a lithium vinylaluminate, and conversion of another vinyl group into a carboxymethylene function via the sequence shown in eq 13.[25]

Reaction with Organolithium Compounds.

(*R*)-2-Hydroxypropylfuran is available by lithiation of furan with *n*-BuLi and alkylation with (*R*)-propylene oxide (eq 14).[26]

(14)

The total synthesis of grahamimycin A_1, a macrolide antibiotic, starts with ring opening of propylene oxide by means of a lithium acetylide (eq 15). Initially, (*S*)-propylene oxide was used to prepare the unnatural (*S*,*S*)-(+)-enantiomer;[27] the use of the (*R*)-enantiomer to produce the natural (*R*,*R*)-(-)-grahamimycin has also been described.[28]

(15)

As outlined in eq 16, ring opening of (*S*)-propylene oxide with a lithiated sulfone serves as a key step in the synthesis of (2*R*,5*S*)-*cis*-2-methyl-5-hexanolide, a sex pheromone of the carpenter bee. In the same way, the (*R*)-enantiomer is used to prepare (2*S*,5*R*)-*cis*-2-methyl-5-hexanolide in high enantiomeric purity.[29]

(16)

Reaction with Enolates.

The pheromone components of *Paravespula vulgaris*, the (*E*)- and (*Z*)-isomers of 2-methyl-1,6-dioxaspiro[4.5]decane with the (*S*)-configuration at C-2, are obtained by alkylation of the α-acetyl-δ-valerolactone dianion with (*S*)-propylene oxide (eq 17).[30]

Alkylation of methyl acetoacetate with (*R*)-propylene oxide yields (*R*)-2-acetyl-4-pentanolide. This is converted into a mixture of (*E*,*E*)- and (*Z*,*E*)-exogonic acid (eq 18).[31]

Related Reagents.

Ethylene Oxide; ***Glycidol***; ***Isoprene Epoxide***.

n-Propylphosphonic Anhydride

[68957-94-8] · $C_9H_{21}O_6P_3$ · *n*-Propylphosphonic Anhydride · (MW 318.21)

(peptide coupling reagent[1])

Alternate Name: 2,4,6-tripropyl-1,3,5,2,4,6-trioxatriphosphorinane 2,4,6-trioxide.

Physical Data: colorless, water-clear syrup, bp 200 °C/0.3 mmHg. The structure is considered to be a trimer.

Solubility: sol dichloromethane, dioxane, THF, DMF, *N*-methyl-2-pyrrolidinone.

Form Supplied in: not commercially available.

Preparative Method: prepared in high yield by hydrolysis of propylphosphonic dichloride to propylphosphonic acid, followed by heating and distillation under reduced pressure (eq 1).[2]

Purification: can be purified by vacuum distillation.

Handling, Storage, and Precautions: as a 50% w/v solution in dichloromethane, the anhydride can be stored in a brown bottle for several months.[1] It is reported to be relatively nontoxic.[1]

Peptide Synthesis.

Alkylphosphonic anhydrides have been explored as condensing agents for the synthesis of peptides and this reagent (**1**) was identified as the most useful of this class.[1,2] It shows good shelf stability and good solubility and leads to little racemization of the protected amino acid substrates. In addition, unlike reagents such as the carbodiimides, the byproduct formed from the condensing agent (an alkylphosphonic acid derivative) is soluble in water and easily removed from the peptide product by extraction with aqueous alkaline buffers (eq 2).

The use of (**1**) on a technical scale has been explored and its toxicity has been investigated.[1] It appears to be relatively nontoxic (no intoxication at 2000 mg kg^{-1} in mice, orally administered). In addition to the synthesis of dipeptides, (**1**) has been used for the synthesis of larger peptides such as a dodecapeptide from the *C*-terminal region of adenovirus 82 K-protein, a dodecapeptide related to ACTH, and other ACTH and LHRH derivatives.[1,3,4] The level of racemization observed using (**1**) has been shown to be as low as with the best other peptide condensing agents and it has been shown to couple sterically hindered peptides with little problem.[1,3] A recent patent has appeared covering the use of (**1**) in a quick and technically simple synthesis of tripeptides.[5] A brief reference has been made to the use of (**1**) in the esterification of *N*-protected amino acids with alcohols.[3]

Cyclic Peptides.

(**1**) has also been used in the synthesis of the linear undecapeptide precursor of the cyclic undecapeptide cyclosporin.[6] In addition, the use of (**1**) in excess along with ***4-Dimethylaminopyridine*** at 10^{-3} M leads to cyclization of the unprotected linear undecapeptide to give cyclosporin in 65% yield (eq 3).[6]

Polyamides.

Propylphosphonic anhydride (**1**) in ***1-Methyl-2-pyrrolidinone*** (NMP) has been used for the direct synthesis of polyamides from dicarboxylic acids and diamines.[7] Thus reaction of isophthalic acid and 4,4´-oxydianiline with an excess of (**1**) in NMP at 100 °C for 2 h gives a virtually quantitative yield of the polyamide (eq 4).[7] The same authors also describe the use of (**1**) in the synthesis of a number of simple amides from carboxylic acids and amines.[7]

Propynenitrile

[1070-71-9] · C_3HN · Propynenitrile · (MW 51.05)

(nucleophilic conjugate addition to give (*Z*)-alkenes;[1,2] Diels-Alder reactions,[3] dipolar cycloadditions with nitrones[4] and diazo compounds[5])

Alternate Names: cyanoacetylene; propiolonitrile.

Physical Data: mp 5 °C; bp 41 °C.

Solubility: sol benzene, EtOH, acetonitrile, cyclohexane, toluene, ether.

Analysis of Reagent Purity: IR (gas) 863, 2077, 2272, 3327 cm^{-1}.

Preparative Method: not commercially available, but can be prepared[6,7] on a several gram scale by the dehydration of propynamide (propiolamide) with ***Phosphorus(V) Oxide*** (eq 1). The reactants are well ground together under nitrogen, and upon subjection of the resulting solid mixture to high temperature treatment, propynenitrile is collected as a distillate in a receiver held at 5 °C.

Purification: distillation.

Handling, Storage, and Precautions: decomposes in solution; sensitive to air and light.

Procedures Involving Nucleophilic Conjugate Addition.

Propynenitrile is an excellent conjugate addition electrophile. Simple transformations of this sort are given in eqs 2 and 3,[1,7] which show the (*Z*) stereoselectivity that is expected.

(3)

An interesting heterocycle-forming process that depends on nucleophilic conjugate addition to propynenitrile as well as to the reagent's nitrile group is illustrated in eq 4.[8] This transformation evidently proceeds through the indicated tricyclic intermediate, which is further transformed hydrolytically in situ.

(4)

Propynenitrile affords (*Z*)-enynes that arise formally from the conjugate addition of an acetylide nucleophile. This clever transformation is brought about by the in situ conjugate addition of bromide to give (*Z*)-3-bromopropenenitrile and its subsequent palladium-induced coupling with an alkyne (eq 5).[2]

(5)

Ritter Reactions.

This reagent can be involved in the Ritter reaction, but with only modest success (eq 6); other examples proceed even less efficiently.[9] A more successful transformation that operates on the nitrile group is shown in eq 7.[9]

(6)

(7)

Diels-Alder Cycloadditions.

Propynenitrile engages suitable dienes in Diels-Alder cycloadditions. For example, a neat mixture of propynenitrile and ***Cyclopentadiene*** held at rt affords the expected bicyclo[2.2.1]heptadiene product in good yield (eq 8).[10] A more elaborate example is shown in eq 9,[3] in which the regiochemical directive effects of the substituents converge to give the cyclohexadiene product shown.

(8)

(9)

Dipolar Cycloadditions.

Reactions of this type include examples involving nitrones (eq 10)[4] and diazo compounds (eq 11).[5]

(10)

R = H, 79%; Me, 93%

(11)

Miscellaneous Ring-Forming Processes.

Two ring-forming transformations brought about with this reagent that are not mechanistically straightforward are illustrated in eqs 12 and 13. In eq 12, two molecules of propynenitrile are incorporated in the product, whose structure was determined by X-ray crystallography.[6] Eq 13 depicts an unusual cyclooctatetraene synthesis.[11]

(12)

(13)

Related Reagents.

Dimethyl Acetylenedicarboxylate; ***Methyl Propiolate***.

Propynyllithium[1]

[4529-04-8] · C_3H_3Li · Propynyllithium · (MW 46.00)

(powerful nucleophilic source of the propynyl unit for many electrophiles)

Solubility: sol liquid ammonia; partially sol THF, ether.

Form Supplied in: white suspension in THF; prepared in situ and used directly.

Preparative Methods: prepared in situ under nitrogen by reaction of propyne (condensed into cold THF) with ***n-Butyllithium*** in THF at -78 °C[2] or ***Lithium Amide*** in ether/liquid ammonia below -50 °C,[3] or by reaction of 1,2-dibromopropane with 3 equiv of ***Lithium Diisopropylamide*** (double elimination of hydrogen bromide and deprotonation) at -60 °C to 0 °C in THF.[4]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture.

Additions to Carbonyl Compounds.

Propynyllithium adds readily to aldehydes and ketones to give the corresponding secondary and tertiary alcohols. The reaction with isobutyraldehyde at -78 °C gives a precursor to the (+)-Prelog-Djerassi lactone after oxidation and enantioselective ketone reduction (eq 1).[2] Additions proceed under nonchelation-controlled conditions and are less stereoselective than the corresponding additions of ***Propynylmagnesium Bromide***.[5] The linear nature of the reagent allows addition to hindered ketones to give the propargylic alcohols which can be transformed into allenyl sulfoxides with ***Benzenesulfenyl Chloride*** (eq 2).[6] Propynyllithium prepared from 1,2-dibromopropane also reacts smoothly with aldehydes and ketones in high yield (eq 3).[4]

(1)

(2)

(3)

Direct methylation of the lithium alkoxide, formed from addition of propynyllithium to easily enolizable ketones such as cyclopentanone and cyclohexanone, with ***Iodomethane*** is achieved by addition of a polar cosolvent such as ***Dimethyl Sulfoxide*** (eq 4).[7] Optimum results are observed with 50 mol % of anhydrous ***Lithium Bromide*** as an additive and a ratio of hexane/THF/DMSO of 2:2:3. Alkylation of the adduct formed from propynyllithium and dimethyl squarate with a propargyl iodide gives the cyclobutenone (**1**), which undergoes thermolysis in refluxing xylene to give the methylenebenzofuran (**2**) (eq 5).[8]

(4)

(2) (5)

Additions to Carboxylic Acid Derivatives.

Propynyllithium adds to valerolactone[9] at low temperature and to *N*,*N*-dialkyl carboxamides[10] to give the corresponding acetylenic ketones after acidic workup. ***Boron Trifluoride Etherate*** has been used to promote the coupling to elaborate the side chain of pseudomonic acid C (eq 6).[11] Alternatively, reaction with anhydrous ***Zinc Chloride*** in THF produces propynylzinc chloride, which couples smoothly with acid chlorides.[10]

(6)

Additions to Epoxides.

Propynyllithium, generated in ether/liquid ammonia by the addition of propyne and ether to a suspension of lithium amide at -50 °C, reacts with ***Ethylene Oxide*** to give the β-hydroxyalkylated product (eq 7). The reaction is sluggish in THF or ether and fails with the sodio derivative.[3] Boron trifluoride has been used to promote epoxide opening in an approach to rifamycin (eq 8).[12]

Reactions with Other Electrophiles.

Lithium 1-propynyltrialkylborates, formed by addition of propynyllithium to trialkylboranes, react with ***Trimethylsilylmethyl Trifluoromethanesulfonate*** followed by protonolysis to give allylsilanes (eq 9).[13] Propynyllithium displaces the nitro group of 3-nitro-4,5-dihydroisoxazole to give a precursor for deoxy-3-aminohexoses,[14] and reacts with the hindered aromatic chlorophosphine to give the 3*H*-phosphaallene after rearrangement (eq 10), while the less basic propynylmagnesium bromide gives the tautomeric alkynyl-1*H*-phosphine.[15] *N*,*N*-Bis(trimethylsilyl) ynamines, synthetic equivalents for primary ynamines, have been prepared by addition of propynyllithium to the crystalline hindered hydroxylamine mesitylenesulfonate (eq 11).[16]

Related Reagents.

The lithium derivatives of various protected forms of propargyl alcohol display very similar reactivity. ***3-Tetrahydropyranyloxy-1-propyne***, after lithiation in THF with *n*-BuLi, selectively displaces the bromide of 1-chloro-3-bromopropane after 20 h at 70 °C[17] or couples with one end of 1,3-dibromopropane in the presence of ***Hexamethylphosphoric Triamide***.[18] The sluggishness of these alkylations has been overcome by the use of triflate as the leaving group and a mixed solvent system of THF-***N,N´-Dimethylpropyleneurea*** (6:1). Under these conditions, the TBS ether of propargyl alcohol, after lithiation, displaces the primary triflate, which is a particularly difficult substrate due to the β-oxygen functionality, in 10 min at -20 °C (eq 12).[19] The α-ethoxyethyl ether of propargyl alcohol, after lithiation in THF with *n*-BuLi, has been used in a double addition to a dione in an approach to [5]peristylane (eq 13).[20]

Related Reagents.

3-Chloro-1-propynyllithium; ***1-Lithio-3-trimethylsilyl-1-propyne***; ***Lithium Acetylide***; ***Lithium (Trimethylsilyl)acetylide***; ***Propynylmagnesium Bromide***.

Propynylmagnesium Bromide[1]

[32423-84-0] · C_3H_3BrMg · Propynylmagnesium Bromide · (MW 143.27)

(powerful nucleophilic source of the propynyl unit for many electrophiles)

Solubility: sol THF, ether.

Form Supplied in: green viscous oil in ethereal solution; prepared in situ and used directly.

Preparative Method: prepared in situ by bubbling dried propyne through a solution of ***Ethylmagnesium Bromide*** in refluxing ether[2] or THF[3] at room temperature.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture.

Additions to Carbonyl Compounds.

Propynylmagnesium bromide adds readily to aldehydes[2] and ketones to give the corresponding secondary and tertiary alcohols. Addition of the optically active 2-chromanylacetaldehyde to propynylmagnesium bromide in ether gives a 2:1 mixture of the corresponding alcohols (eq 1).[4] Intramolecular Diels-Alder/retro-Diels-Alder reactions of alkynones, prepared by propynylmagnesium bromide addition to aldehydes and Swern oxidation (see ***Dimethyl Sulfoxide-Oxalyl Chloride***) of the resulting alcohols, give ring-fused thiophene derivatives (eq 2).[5] Stereoselective addition to the *exo* face of a norbornenone is observed with only 4% of the minor isomer being formed (eq 3).[6] Chelation-controlled addition to the β-alkoxy enone gives the (*R*) enantiomers of both geometric isomers with only traces of the diastereoisomers (eq 4), whereas addition of ***Propynyllithium*** to the corresponding aldehyde is less selective.[3] ***Lithium Aluminum Hydride*** reduction of the propargylic alcohol, generated by addition of propynylmagnesium bromide to α-chlorocyclohexanone, is accompanied by migration to give the homoallylic alcohol (eq 5).[7]

(1)

Alkylations of Alkyl Halides.

α-Chlorination of cyclic sulfides with ***N-Chlorosuccinimide*** gives the corresponding chlorides, which react with propynylmagnesium bromide to give the propargylic sulfides. Sulfonium salt formation followed by treatment with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) causes a ring expansion via [2,3]-sigmatropic rearrangement to the diene (eq 6).[8] In a related transformation, propynylmagnesium bromide couples with a cationic glycine equivalent to give the α-alkynic amido ester free from allenic products (eq 7).[9]

(6)

(7)

Reactions with Other Electrophiles.

Enynes can be prepared by a double ring contraction sequence which involves reaction of propynylmagnesium bromide with cyclooctatetraene oxide to give the cycloheptatrienyl alcohol and subsequent dehydration with ***Thionyl Chloride*** (eq 8).[10] Activation of ***Pyridine*** by reaction with ***Methyl Chloroformate*** facilitates addition of propynylmagnesium bromide to the resulting iminium salt (eq 9).[11] Propynylmagnesium bromide reacts with the hindered aromatic chlorophosphine to give the alkynyl-1*H*-phosphine by direct substitution (eq 10), while the more basic propynyllithium gives the tautomeric 3*H*-phosphaallene.[12]

(8)

(9)

(10)

Related Reagents.

Ethynylmagnesium Bromide; ***Propynyllithium***.

1*H*-Pyrazole-1-carboxamidine Hydrochloride

[4023-02-3] · $C_4H_7ClN_4$ · 1*H*-Pyrazole-1-carboxamidine Hydrochloride · (MW 146.60)

(electrophilic agent capable of specific reaction with nitrogen nucleophiles such as amines and hydrazines, yielding substituted guanidines and aminoguanidines by displacement of pyrazole;[1,2] synthesis of substituted *s*-triazines[1,3])

Alternate Name: 1-guanylpyrazole hydrochloride.

Physical Data: mp 167-168 °C.

Solubility: insol ether, hexane; very sol H_2O, DMF, alcohol; in the presence of 1 equiv ***Diisopropylethylamine*** (free base), very sol (>1.5 M) DMF, H_2O, and alcohol, and sol CH_2Cl_2, $CHCl_3$, THF, acetone, and acetonitrile; the free base is slightly sol EtOAc, ether.

Form Supplied in: nonhygroscopic, white crystalline solid.

Preparative Method: to a mixture of pyrazole (0.36 mol) ***Cyanamide*** (0.36 mol), and 320 mL of *p*-dioxane is added 95 mL of 4 N HCl in *p*-dioxane. The mixture is gradually warmed to 55-60 °C with mechanical stirring under N_2. After about 1 h the product crystallizes and the mixture is cooled to rt. Ether (100 mL) is added with stirring and the product is collected by filtration, washed with ether, and dried in vacuo, yielding 51.2 g (97%).

Handling, Storage, and Precautions: indefinitely stable (at least two years) at rt in a tightly sealed bottle. Cool, dry, and dark conditions are recommended for long term storage. The toxicological properties are not known, but pyrazole is considered a possible teratogen. Use in a fume hood.

Synthesis of Substituted Guanidines.

1*H*-Pyrazole-1-carboxamidine (**1**) reacts with many amines and hydrazines at room temperature under a variety of conditions to give substituted guanidines in good yields (eq 1).[1,2] In this context, the carboxamidine (**1**) is significantly more reactive than 3,5-dimethylpyrazole-1-carboxamidine nitrate[4] and other commercially available guanylating agents (see also ***Cyanamide***, ***O-Methylisourea***, and ***S-Methylisothiourea***).[2] Because of its superior reactivity, good solubility properties, stability, and ease of preparation, the carboxamidine (**1**) is the guanylating agent of choice for many applications, including solid-phase peptide synthesis of arginine-containing peptides by quantitative guanylation of the δ-amino group(s) of ornithine-containing precursor sequences.[2] The general use of the guanylating agent (**1**) for the preparation of various arginine peptides by such a strategy (eq 2) in this author's laboratory has not yet necessitated the evaluation of commercially unavailable ***Aminoiminomethanesulfonic Acid***,[5,6] with questionable stability[7] and solubility properties, as an alternative guanylating agent for this purpose.

X = CH_2, CH, C, NH
R = aryl, alkyl, H
R' = aryl, alkyl, H

$AA_1....AA_n$ = arbitrary amino acids
P = α-amino protecting group
P^{ω} = ω-side chain protecting group
P^{δ} = δ-amino protecting group
PS = polystyrene solid support

For amine guanylation, the reactivity of the carboxamidine (**1**) appears to be limited to primary, secondary, and aryl amines that are not deactivated by steric, electronic, or resonance effects. For example, guanidine products cannot be obtained from diisopropylamine, dicyclohexylamine, 2,2,2-trifluoroethylamine, *p*-nitroaniline, and α- or β-naphthylamine. In these cases only the diguanidine (**2**), formed by slow self condensation of (**1**), can be isolated (eq 3).[2] The diguanidine (**2**) also slowly forms at room temperature in the presence of tertiary amines and is unreactive with cyclohexylamine at room temperature.[2]

Modification of Proteins.

Like 3,5-dimethylpyrazole-1-carboxamidine nitrate, the carboxamidine (**1**) in aqueous buffer can guanylate the ε-amino groups of lysine residues (and to a lesser extent the *N*-terminal α-amino group) in proteins to produce homoarginine residues.[8] The extent of guanylation by these reagents depends on molar ratio, concentrations, pH, temperature, and time.[8] These reagents are particularly suitable

when extensively modified proteins are desired. For more specific, less extensive lysine modification, the use of other less reactive, water soluble reagents may be advantageous.

Synthesis of *N,N´*-Disubstituted and Diprotected Guanidines.

The *N*-allyl derivative (**3**) of the reagent (**1**) has been prepared (eq 4)[9] and, although less reactive, has been found to react slowly, specifically and essentially completely at room temperature with the δ-amino group of L-ornithine (eq 5) to allow facile isolation of N^G-allyl-L-arginine (**4**) in 70% yield.[9] This result suggests that other *N,N´*-dialkylguanidines may be obtainable via the appropriate *N*-alkyl derivatives of the reagent (**1**).

The *N,N´*-bis-Cbz and bis-Boc derivatives (**5a,b**) of the carboxamidine (**1**) have been recently prepared in good yields by two sequential acylations (eq 6).[10,11] These derivatives are substantially more reactive than the parent carboxamidine (**1**) and react readily with aniline and 2,2,2-trifluoroethylamine at room temperature to give *N,N´*-bis-protected guanidines that can be smoothly deprotected under typical conditions to provide otherwise inaccessible monosubstituted guanidines in good yields (eq 7).[10] Although the *N,N´*-bis-urethane-protected carboxamidines (**5a,b**) fail to guanylate diisopropylamine and dicyclohexylamine,[10] they nonetheless represent a valuable and complementary alternative to the use of the reagent (**1**) when the guanylation of relatively nonnucleophilic amines under mild conditions is required, they also provide more flexibility in the formulation of synthesis schemes targeting complex guanidine-containing molecules. Alternative reagents reported for the preparation of *N,N´*-bis-Boc-guanidines from amines are *N,N´*-bis-Boc-thiourea[12] and *N,N´*-bis-Boc-*S*-methylisothiourea.[13]

Synthesis of 2-Amino-Substituted *s*-Triazines.

The carboxamidine (**1**) reacts readily with ***1,3,5-Triazine*** yielding 2-(pyrazol-1-yl)-*s*-triazine (**6**) which reacts with ***Ammonia***, many amines, and ***Hydrazine*** to produce 2-monosubstituted *s*-triazines (**7**) in good yields (eq 8).[1,3]

Related Reagents.

Aminoiminomethanesulfonic Acid; ***Diphenyl Cyanocarbonimidate***; ***S-Methylisothiourea***; ***O-Methylisourea***.

Pyridine

[110-86-1] · C_5H_5N · Pyridine · (MW 79.11)

(weak base useful as acid scavenging solvent or catalyst, especially for condensation,[1] dehalogenation,[2] halogenation,[3] and acylation[4] reactions)

Physical Data: [5] bp 115.3 °C; mp -41.6 °C; forms azeotropic mixture with water, bp 93.6 °C (41.3 wt % H_2O); steam volatile; *d* 0.9830 g cm^{-3} at 20 °C; pK_a 5.22 (in H_2O at 20 °C).

Solubility: miscible water, alcohol, ether, petroleum ether, and numerous other organic solvents.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: titration, GLC.

Purification: distillation.

Handling, Storage, and Precautions: flammable solvent with flash point 20 °C; hygroscopic; LD_{50} rat (oral) 891 mg kg^{-1};[5] minimum detectable odor 0.012 ppm;[5] incompatible with acids, acid chlorides, oxidizing agents, and chloroformates.[6]

Use as a Base in Condensation Reactions.

Pyridine can be used as a base in cyclocondensation reactions. When the reaction of 2-acylphenoxyacetic acids in acetic anhydride is carried out in the presence of pyridine, formation of benzofuran-2-carboxylic acids is preferred. When weaker bases such as sodium acetate or sodium formate are used for the reaction, mixtures of benzofurans and benzofuran-2-carboxylic acids are produced, with the benzofuran derivatives as the major products.[7] For example, 2-acetyl-4-nitrophenoxyacetic acid (**1**) gives 65% 3-methyl-5-nitrobenzofuran-2-carboxylic acid (**2**) and 25% 3-methyl-5-nitrobenzofuran (**3**) when treated with ***Acetic Anhydride*** in pyridine. The same reaction in the presence of sodium acetate instead of pyridine gives a reversal of products with (**2**) as the minor product (33%) and (**3**) as the major product (60%) (eq 1).

Pyridine has been used effectively as a catalyst in the Knoevenagel condensation reaction.[8] Depending upon the nature of the base employed, the product selectivity can be altered. Different stereochemistry has been observed for aromatic heterocyclic bases such as pyridine and aliphatic tertiary amines such as ***Triethylamine***. Reaction of hexanal (**4**) with ***Malonic Acid*** (**5**) in the presence of pyridine as the base gives the α,β-unsaturated acid (**6**) as the major product (91:9 α,β:β,γ). When bases such as triethylamine are used in the reaction, a higher overall yield is obtained (76%); however, the corresponding β,γ-unsaturated acid (**7**) is the predominant product[1] (2:98 α,β:β,γ) (eq 2). One factor that appears important in determining the product ratio is the steric hindrance of the base. Pyridine, without the steric hindrance, shows a definite preference for the α,β-unsaturated carboxylic acid.

Condensation of furfural (**8**) with malonic acid (**5**) in the presence of pyridine affords an excellent yield of furylacrylic acid (**9**) (eq 3).[9] Similarly, condensation of *m*-nitrobenzaldehyde with malonic acid proceeds in the presence of pyridine as catalyst.[10]

Yield improvements in the Knoevenagel condensation reaction have been obtained when the reaction is carried out in the presence of ***Titanium(IV) Chloride*** and pyridine in either tetrahydrofuran or dioxane solvent.[11] For example, the condensation of ***Acetaldehyde*** (**10**) with ***Diethyl Malonate***, (**11**) affords an 86% yield of product (**12**), as compared to a 25% yield without the promoter (eq 4).[8,12]

Condensation of carboxylic acids with amines in pyridine in the presence of a phosphorous(III) acid/iodine complex is an effective method for the synthesis of amides (eq 5).[13] Pyridine acts as a base and a solvent in this reaction.

Organoaluminum compounds such as ***Diisobutylaluminum Phenoxide*** with pyridine are good reagents for the regioselective aldol condensation of methyl ketones.[14] This system works effectively with pyridine acting as a base to inhibit undesirable proton transfer reactions (eq 6). Commonly used methods such as formation of the silyl enolate are not practicable here since they do not undergo regioselective attack on the methyl side of the ketone. Cross-aldol condensation reactions can also be carried out regiospecifically in the presence of a tertiary amine such as pyridine or ***2,6-Lutidine***.[15]

Oxidation Reactions.

An extensive amount of research has been carried out on the Gif system, and related systems, for the selective oxidation of saturated hydrocarbons. Pyridine is commonly used as a solvent in these reactions which involve a metal-catalyzed oxidation using ***Hydrogen Peroxide*** in a pyridine-acetic acid solvent system (eq 7). Copper, zinc, and iron are commonly used in the reactions.[16-19] Conversions are typically in the range of 10-25%; however, the selectivities are nearly quantitative.

Oxidation reactions of alcohols by ***Lead(IV) Acetate*** can be accelerated in the presence of pyridine. A kinetic study of this reaction has been carried out by Banerji using benzyl alcohol (**13**) as substrate (eq 8).[20]

(8)

(13)

Oxidation of alcohols can also be effectively carried out using ***Chlorine*** in pyridine to give aldehydes and ketones. Secondary alcohols can be selectively oxidized in the presence of primary alcohols.[21] For example, treatment of 5β-cholestane-3β,19-diol (**14**) with chlorine and pyridine affords selective oxidation to 19-hydroxy-: 5β-cholestan-3-one (**15**) in almost quantitative yield (eq 9).

(14)

(9)

(15)

Aqueous pyridine is a very effective solvent for the oxidation of sulfides to sulfoxides with ***Phenyliodine(III) Dichloride***. High yields of the sulfoxides are typically obtained without contamination by sulfones (eq 10).[22]

(10)

Halogenation Reactions.

Treatment of enones with ***Iodine*** and pyridine in carbon tetrachloride results in direct iodination. Good yields of 2-iodo enones are obtained when a solution of iodine (1.2-1.4 equiv) dissolved in a 1:1 (v/v) mixture of pyridine/carbon tetrachloride is added to cycloalkenones (eq 11).[23]

(11)

Pyridine is employed as a base in the conversion of tetrahydrofurfuryl alcohol (**16**) to the corresponding bromide (**17**). A fair yield of the bromide is obtained (eq 12).[24] Addition of pyridine greatly increases the yield of product.[3]

(12)

In the bromination of 1-methylaminoanthraquinone (**18**), a good yield of 1-methylamino-4-bromoanthraquinone (**19**) is obtained using pyridine as acid scavenger and solvent (eq 13).[25]

(13)

Pyridine and 2,6-lutidine are useful as acid scavengers in the chlorination of α,β-unsaturated ketones and esters. For the ketones, the pyridine bases typically favor the Markovnikov isomer; however, for esters, pyridine shows little effect on the Markovnikov (alkoxy adjacent to carbonyl)/anti-Markovnikov isomer ratios (eq 14).[26]

(14)

Dehalogenation Reactions.

Dehalogenation of α-halo ketones can be effected by a number of reagents including pyridine and ***Tin(II) Chloride*** (eqs 15 and 16).[2] In the absence of the pyridine, the yield of acetophenone (**20**) drops to 75% and the yield of cyclohexanone (**21**) to 10%. Sulfur compounds such as sodium sulfite and ***Sodium Sulfide***, as well as benzene and aniline, are capable of dehalogenation in the presence of a promoter such as tin(II) chloride. An advantage of this reaction is that both aliphatic and aromatic α-halo ketones can be dehalogenated in good to excellent yields.

(15)

(16)

Dehydrochlorination of 2-(1-chloroethyl)thiophene (**22**) in the presence of pyridine gives 2-vinylthiophene (**23**) in 50-55% overall yield starting from thiophene (eq 17).[27] Didehydrochlorination of 2,2-dichloro-4-alkylbutanolides affords 4-alkylidene-2-butenolides upon reflux in pyridine (eq 18).[28]

(17)

(18)

Epoxidations.

Taking advantage of its utility as a base, pyridine has been used for epoxidations in anhydrous organic systems with α-azo hydroperoxides as the epoxidizing reagents (eq 19).[29] ***Sodium Hydroxide*** works equally well or better with some of the epoxidizing agents; however, with the hydroperoxide (**24**), sodium hydroxide is a poor catalyst. Sodium hydroxide-catalyzed dehydration of the azo hydroperoxide, which affords *N*-(4-bromophenyl)-*N*´-benzyldiazene, is a competing side reaction.[30]

(24)

Coupling Reactions.

Dimerization of aromatic nitrile oxides can be catalyzed by pyridine, affording 3,6-diaryl-1,4,2,5-dioxadiazines in good yields (eq 20).[31] Other nucleophiles such as 4-phenylpyridine, 4-methylpyridine, ***4-Dimethylaminopyridine***, and ***N-Methylimidazole*** are also suitable catalysts for the reaction.

Esterifications.

Pyridine is a widely used catalyst for acylation reactions. Acetylation reactions are effectively carried out in the presence of hexachlorocyclophosphazatriene and pyridine.[32] Acetylation of phenols by ***Acetic Anhydride*** in carbon tetrachloride is also catalyzed by pyridine. In the absence of the pyridine catalyst, at 0 °C and 25 °C, no acylation of the phenols is observed (eq 21).[4]

Acylation of 6,7-dimethoxy-1-methyl-3,4-dihydroisoquinoline (**25**) with acetic anhydride in pyridine affords 2-acetyl-6,7-dimethoxy-1-methylene-1,2,3,4-tetrahydroisoquinoline (**26**) in 72-77% yield (eq 22).[33]

(25) (26)

Treatment of *o*-hydroxyacetophenone (**27**) with ***Benzoyl Chloride*** in pyridine affords *o*-benzoyloxyacetophenone (**28**) in excellent yield (eq 23).[34]

(23)

Synthesis of Benzonitriles.

Arylthallium(III) salts with ***Copper(I) Cyanide*** or copper(II) cyanide afford fair to excellent yields of benzonitriles when heated at reflux in pyridine solvent (eq 24).[35] The use of acetonitrile as solvent gives lower product yields.

(24)

Catalyst Poison.

Pyridine and ***Quinoline*** have been used in conjunction with ***Palladium on Barium Sulfate*** as a catalyst system for the reduction of alkynes to *cis*-alkenes.[36]

Related Reagents.

Borane-Pyridine; ***Chlorine-Pyridine***; ***Copper(II) Sulfate-Pyridine***; ***Di-t-butyl Chromate-Pyridine***; ***Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine***; ***Sulfur Trioxide-Pyridine***.

Pyridine *N*-Oxide

[694-59-7] · C_5H_5NO · Pyridine *N*-Oxide · (MW 95.11)

(oxidation of alkyl halides to aldehydes; oxidative decarboxylation of certain carboxylic acids, anhydrides, and α-halo acids; dehydrogenation of carboxamides)

Physical Data: mp 66 °C; bp 270 °C.

Solubility: sol water, most polar solvents.

Form Supplied in: deliquescent colorless solid.

Analysis of Reagent Purity: ^{1}H NMR δ 7.35 (3H, m), 8.35 (3H, m).

Purification: distillation at aspirator pressure.

Handling, Storage, and Precautions: very hygroscopic; irritant; use in a fume hood.

Oxidative Decarboxylation.

Certain substituted acetic acids and their anhydrides undergo oxidative decarboxylation to aldehydes and ketones on treatment with pyridine *N*-oxide in toluene or xylene at reflux (eqs 1-3). Acids require an equivalent of ***Acetic Anhydride*** to dehydrate them to the anhydride.[1,2]

(3)

In a reaction of perhaps greater synthetic interest, α-halo acids are converted with 4 equiv of pyridine *N*-oxide to aldehydes and ketones, losing a carbon atom in the process (eqs 4-6).[3,4]

(4)

(5)

(6)

Oxidation of Alkyl Halides.

Pyridine *N*-oxide oxidizes even unactivated alkyl halides to carbonyl compounds (eqs 7-9). This is of some importance as most related methods[9] (e.g. Kröhnke and Kornblum oxidations) are limited to activated halides. The reaction can be performed in two ways. In the first, the halide is treated with the *N*-oxide in the presence of a base such as $NaHCO_3$. In the second, the intermediate *N*-alkoxypyridinium salt is isolated before base treatment.[5-7] 2-Picoline *N*-oxide may be used in a similar oxidation reaction.[8]

(7)

(8)

(9)

The method is excellent for the synthesis of α-keto esters.[9] In the examples in eqs 10 and 11, the α-bromo ester or acid is treated with pyridine *N*-oxide and ***Silver(I) Nitrate*** at 0 °C. Decomposition of the isolated salt with mild base gives the dicarbonyl compound in high yield.

(10)

In some cases (e.g. eq 11), it is unnecessary to add silver nitrate, and the bromide salt may be used. For some substrates (e.g. secondary halides), the more powerful nucleophile DMAP 1-oxide may offer some advantages (eq 12).[10] However, oxidation of cyclohexyl bromide still fails, due to elimination.

Dehydrogenation of Carboxamides.

Treatment of the imidoyl chlorides of tertiary amides with pyridine *N*-oxide and ***Triethylamine*** in $CHCl_3$ results in dehydrogenation, giving the α,β-unsaturated amides (eqs 13-15).[11]

(14)

(15)

Diphenyl sulfoxide may be used as the oxidant, but purification is more difficult. The synthesis of dehydroamino acids derivatives by this reaction is noteworthy (e.g. eq 15).[12] The amide must be branched in the α-position, otherwise the sole product formed is the α-chloro amide (eq 16).

2-Pyridineselenenyl Bromide

[91491-61-1] · C_5H_4BrNSe · 2-Pyridineselenenyl Bromide · (MW 236.96)

(selenoxide elimination to afford alkenes;[1-4] episelenonium ions[3,4])

Physical Data: mp 115-116 °C (dec).

Solubility: sparingly sol THF, dichloromethane, methanol.

Preparative Method: by reaction of ***2,2´-Dipyridyl Diselenide*** with ***Bromine*** in an appropriate solvent. An analytically pure sample is obtained by the filtration of the precipitate thus formed and washing. This preparation should not be carried out in ***Acetonitrile*** since 2-pyridineselenenyl bromide adds to acetonitrile.

Handling, Storage, and Precautions: use in a fume hood.

Selenoxide Elimination.[1-4]

For the dehydrogenation of ketones to enones, the introduction of a 2-pyridineselenenyl group on the α-carbon of the ketone and subsequent oxidation of the selenide to induce the selenoxide elimination is one of the most convenient procedures.[1,2] 2-Pyridineselenenyl bromide (or chloride) is a useful reagent for this sequence and three kinds of reaction have been reported for the introduction of a 2-pyridineselenenyl group onto the α-carbon of the ketones. They are: (1) the reaction of ketones with 2-pyridineselenenyl bromide (PySeBr) in the presence of ***Hydrochloric Acid*** (eq 1); (2) the reaction of the lithium enolate of the ketones with PySeBr (eq 2); and (3) the reaction of the enol silyl ether of the ketones (or aldehydes) with PySeBr (eq 3). The 2-pyridineselenenyl group has been reported to be a better leaving group than the benzeneselenenyl group. The 2-pyridineselenenyl group has also been used in selenoxide eliminations to afford vinylic amides[4] and vinylic ethers.[3]

(1)

(2)

Vinylic Selenides.

2-Pyridineselenenyl bromide is an important starting material for the preparation of 2-pyridyl vinylic selenides from alkenes via β-methoxyalkyl 2-pyridyl selenides (eq 4).[3] Deprotonation and subsequent alkylation of 2-pyridyl vinylic selenides proceed with retention of the stereochemistry, which has not yet been realized by the use of other vinylic selenides.[3] It should also be noted that the reaction conditions for the deprotonation of 2-pyridyl vinylic selenides are much milder than those required for the corresponding phenyl vinylic selenides. This may be due to the chelation of the nitrogen atom of the pyridine with a lithium atom, as depicted in eq 5.

Episelenonium Ions.

β-Methoxyalkyl 2-pyridyl selenides have also been used as intermediates for the introduction of 2-pyridineselenenyl and acylamino groups into trisubstituted alkenes (eq 6).[4] This reaction represents the preparation of tertiary amine derivatives. The use of the 2-pyridineselenenyl group is essential as phenyseleno-substituted tertiary carbocations are too stable and do not react with nitriles.

Related Reagents.

Benzeneselenenyl Bromide; ***Benzeneselenenyl Chloride***; ***2,2´-Dipyridyl Diselenide***; ***2,2´-Dipyridyl Disulfide***.

2-Pyridinesulfenyl Bromide

(X = Br)

[66715-65-9] · C_5H_4BrNS · 2-Pyridinesulfenyl Bromide · (MW 190.07) (X = Cl)

[59089-57-5] · C_5H_4ClNS · 2-Pyridinesulfenyl Chloride · (MW 145.62)

(electrophilic sulfenylation agents used for unsymmetrical disulfide synthesis,[1] deprotection of specific thiol protecting groups,[2] enolate sulfenylation,[3] and *N*-sulfenylation of amides[4])

Physical Data: yellow powder.

Solubility: normally used in anhydrous HOAc; may also be used in dry DMF; rapidly decomposes in the presence of moisture.

Preparative Method: the 2-pyridinesulfenyl halides are generated as needed from ***2,2´-Dipyridyl Disulfide***. Treatment of 2,2´-dipyridyl disulfide in petroleum ether or dichloromethane with either ***Chlorine*** or ***Bromine*** at 20 °C results in 2-pyridinesulfenyl halide generation after 1-2 h. Isolation through evaporation of solvent provides a yellow powder with a pungent odor.[1,2,5]

Handling, Storage, and Precautions: the 2-pyridinesulfenyl halides demonstrate instability, especially in the presence of moisture. Although the isolated powder may tolerate short-term storage in a well sealed vial or ampule, most work involving these reagents has utilized freshly prepared material. Solutions in anhydrous HOAc are reported to be stable for several hours.[2] The reagent is corrosive and must be handled accordingly. The reaction with moisture generates HCl and 2-pyridylsulfenic acid (stench, toxic). Handling of these reagents should be confined to a fume hood.

Deprotection of the Thiol Group.

The initial application of 2-pyridinesulfenyl chloride as a deprotection reagent focused on a synthesis program based on cysteine.[2] Specifically, cysteine residues protected as the trityl, diphenylmethyl, or acetamidomethyl derivatives, or as the *t*-butyl sulfide or the *t*-butyl disulfide, react with 2-pyridinesulfenyl chloride to generate a mixed disulfide (eq 1).

(1)

This reaction occurs rapidly at room temperature and can be conducted to utilize the endpoint provided by the bright yellow 2-pyridinesulfenyl chloride solution. Deprotection under these conditions tolerates 10-20 mol % of ***Triethylamine*** for the protection of the Boc group from any HCl generated from residual moisture. 2-Pyridinesulfenyl chloride avoids the use of strong acid (TFA, HBr)

conditions that are associated with the removal of the listed protecting groups. The resulting mixed disulfide is stable to acids, but is unstable to alkali. Several equivalents of ***2-Mercaptoethanol*** generates a cysteine thiol group from the mixed disulfide.

Unsymmetrical Disulfides.

The mixed disulfide indicated in eq 1 provides a route to other mixed disulfides through the reaction of a thiol with the intermediate disulfide in HOAc. Unsymmetrical 2-pyridyl disulfides result from the reaction of 2-pyridinesulfenyl chloride and a thiol (eq 2).[1,5]

Enolate Sulfenylation.

2-Pyridinesulfenyl bromide provides an opportunity for regiocontrol in the synthesis of methyl dehydrojasmonate.[3] A 2,3-disubstituted cyclopentenone is regiochemically activated through formylation, resulting in a β-diketo enolate. 2-Pyridinesulfenyl bromide reacts with the enolate and promotes a deformylation (eq 3). 2,2´-Dipyridyl disulfide also provides the desired product, but in a lower yield. Attempts to trap the enolate with dimethyl disulfide or diphenyl disulfide are not successful. Subsequent oxidation and sulfoxide thermolysis provides the desired cyclopentenone product.

N-Sulfenylation of Amides.

A solution of 2-pyridinesulfenyl bromide in DMF has been used to sulfenylate a deprotonated amide (eq 4).[4]

2-Pyridinesulfonyl Chloride

[66715-65-9] · $C_5H_4ClNO_2S$ · 2-Pyridinesulfonyl Chloride · (MW 177.62)

(heteroarylsulfonyl chloride for the formation of 2-pyridinesulfonate esters which are excellent metal-assisted leaving groups in S_N2 displacement reactions with magnesium halides,[2] as well as in elimination reactions;[2] alkyl 2-pyridinesulfonate esters are transformed into 2-alkylpyridines upon treatment with organometallic reagents[3])

Physical Data: colorless crystalline solid.

Solubility: sol chlorinated hydrocarbons and in dipolar aprotic solvents; insol cold water (gradual hydrolysis).

Preparative Method: prepared essentially according to the published procedure.[1] ***Chlorine*** gas is bubbled into a solution of ***2-Pyridinethiol*** (4 g, 36 mmol) in concd. ***Hydrochloric Acid*** (32 mL) at 0 °C for 90 min. The solution is poured into ice-water (100 mL), and the precipitate is rapidly filtered and washed with ice-cold water (50 mL). The colorless crystalline product is dried at 0 °C (pump), then stored at 0 °C for use; yield 3.6 g (55%).

Handling, Storage, and Precautions: the crystalline reagent is stable when stored at 0 °C under argon for several months. Use in a fume hood.

Preparation of 2-Pyridinesulfonates.[2]

The reagent (3.0 g, 3.5 mmol) is added in portions to a solution of the alcohol (3.00 mmol) in dry pyridine (5 mL) at 0 °C. After stirring for a few hours (cholestanol, 3 h; *t*-butylmethyl alcohol, 18 h), the solution is poured into ice-water and the 2-pyridinesulfonate is isolated by filtration in some cases. Otherwise, the aqueous solution is extracted with dichloromethane, which is then washed with dil. HCl and water and processed in the usual way. The 2-pyridinesulfonate is isolated by crystallization or by flash chromatography. For example, 2-pyridinesulfonates are prepared from cholestanol (quant.), mp 127-128 °C; 1,2:3,4-di-*O*-isopropylidene-D-galactose (97%), mp 89-90 °C; L-borneol (93%), mp 99-100 °C; *t*-butylmethanol (90%), mp 47 °C; 1-octanol (94%), 2-octanol (85%), and ethyl lactate (93%), isolated as oils.

Preparation of Alkyl Halides from 2-Pyridinesulfonates.

The conceptual basis in designing novel nucleofugal esters such as 2-pyridinesulfonates was predicated upon the anticipation of an accelerated, metal-assisted S_N2 displacement reaction especially with divalent ions. Indeed, upon treatment of primary and secondary 2-pyridinesulfonates with ***Magnesium Bromide*** etherate (1.3 equiv) in dichloromethane at 0 °C, the corresponding bromides are obtained within seconds or minutes (eq 1).[2] With carbohydrate derivatives, the displacements are slower (several hours) presumably because of the presence of ether-type oxygen atoms which can also coordinate with the reagent. Comparisons of the reaction of various norbornyl sulfonates demonstrates the extremely efficient transformations using 2-pyridinesulfonates (1.3 equiv $MgBr_2.Et_2O$, 5 mL CH_2Cl_2): 8-quinolinesulfonate (120 min); tosylate (70 min); *p*-nitrobenzenesulfonate (40 min); 2-pyridinesulfonate (30 s, 70% of isolated bromide). Replacement of $MgBr_2.Et_2O$ with other sources of bromide ion (***Lithium Bromide***, ***Tetra-n-butylammonium Bromide*** in DMF or CH_2Cl_2), requires heating and longer reaction times, while the addition of an external source of bromide does not accelerate the reaction.

(1)

Typical products are 1-octyl bromide (0 °C, 5 min; 88%); 2-octyl bromide, $[\alpha]_D^{25}$ +33.4° (*c*, 4.23), (0 °C, 30 s, 74%); 2-benzyloxy-1-bromoethane (0 °C, 30 min, 94%); (*R*)-ethyl 2-bromopropionate, $[\alpha]_D^{25}$ +32.4° (*c*, 3.93), (0 °C, 10 min, 81%); *exo*-2-bromobicyclo[2,2,1] heptane, (0 °C, 30 s, 70%); and 3α-cholestanyl bromide, mp 102 °C, $[\alpha]_D^{25}$ +30° (*c*, 1.0), (0 °C, 5 min, 82%). Nucleophilic displacement reactions based on the remote activation of the nucleofugal component have also been demonstrated with alkyl imidazolylsulfonates,[4] and in the synthesis of *O*-, *C*-, and related glycosides.[5,6] Related heteroatom and metal-assisted S_N2 displacement reactions of tosylates have been recently reported.[7]

Miscellaneous Reactions of 2-Pyridinesulfonates.

Other reactions well known for arenesulfonates are also possible with 2-pyridinesulfonates. For example, treatment of 3β-cholestanyl 2-pyridinesulfonate with ***Sodium Borohydride*** (DMF, 80 °C), ***Lithium Iodide*** (1,2-dichloroethane, 25 °C, 3 h), and LiN_3 (DMF, 80 °C, 4 h), gives cholestane (78%), 3α-iodocholestane (76%), and 3α-azidocholestane (63%), respectively.[8] Treatment of 3β-cholestanyl 2-pyridinesulfonate with ***Palladium(II) Chloride*** (2 equiv) in DMF (80 °C, 30 min), gives 2-cholestene (80%).[9]

2-Substituted Pyridines.

Although there are examples of the synthesis of 2-alkylpyridines[10] by direct and indirect methods, the yields in some cases are low and the conditions harsh. Treatment of alkyl 2-pyridinesulfonates (methyl, propyl, *t*-butylmethyl) with ***n-Butyllithium***, *n*-butylmagnesium bromide, ***Allylmagnesium Bromide***, and ***Phenyllithium*** at -78 °C (lithium reagents) or at 0 °C (Grignard reagents), gives the corresponding 2-substituted pyridines in 68-80% yields (eq 2). In principle, any alkyl 2-pyridinesulfonate can be used. However, for convenience of handling, the crystalline *t*-butylmethyl 2-pyridinesulfonate can be used.

2-Pyridinethiol

[2637-34-5] · C_5H_5NS · 2-Pyridinethiol · (MW 111.18)

(reagent for the synthesis of thiolesters which acylate nucleophiles[1] or yield ketones with organometallic reagents;[2] utilized in protection and deprotection chemistry;[3,4] glycoside coupling agent;[5,6] component of a selective reducing agent;[7] precursor of electrophilic sulfur reagents;[8,9] applied to dienophile synthesis[10])

Physical Data: mp 128-130 °C.

Solubility: sol most organic solvents; sol aqueous base.

Form Supplied in: crystalline solid, available from various suppliers.

Analysis of Reagent Purity: mp measurement is indicative of purity; values below 120 °C suggest an impure sample.

Purification: recrystallization from benzene.

Handling, Storage, and Precautions: demonstrates good stability if stored in a well sealed vial under an inert atmosphere at room temperature. On continued exposure to air the reagent becomes contaminated with moisture and disulfide. 2-Pyridinethiol is irritating to eyes and skin and imparts a stench.

Thiolester Synthesis and Utility.

Thiolesters represent a class of acylating agents.

Synthesis.

Pyridine-based thiolester generation utilizes carboxylic acids and 2-pyridinethiol under ***1,3-Dicyclohexylcarbodiimide*** coupling conditions (EtOAc, 0 °C).[11] Quantitative conversions of the carboxylic acid to the 2-pyridyl thiolester involve premixing 2-pyridinethiol and ***Phosgene*** before introduction of the acid.[12] A mixed anhydride method (***Trichloroacetyl Chloride***, ***Triethylamine***) of acid

activation successfully generates the thiolester[13] as does use of an acyl chloride.[14] Other methods of acid activation provide routes to the 2-pyridyl thiolesters.[15] Alternate methods are available from ***2,2´-Dipyridyl Disulfide***.[16] 2-Pyridyl thiolesters may also be generated from ketenes[17] using the tin(II) sulfides obtained from 2-pyridinethiol.[18] This technique provides a tin(II) enolate which reacts with aldehydes with *syn* selectivity and provides a 3-hydroxy thiolester.

Acylation of Nucleophiles.

2-Pyridyl thiolesters and 2-pyridyl esters provide a coupling technique in peptide synthesis.[11a] Macrolactonization with a thiolester has been demonstrated.[16] Alkylation of the 2-pyridylthiolester with nonthiophilic agents such as ***Triethyloxonium Tetrafluoroborate*** provides successful acylation of phenols, amines, and carboxylic acids.[1] Using 2 equiv of ***Methylenetriphenylphosphorane***, 2-pyridyl thiolesters provide a route to stabilized ylides.[11d]

Ketone Generation from a Carboxylic Acid Derivative.

An historical quest for organic chemists has been the generation of ketones from carboxylic acid derivatives. Carbon nucleophiles select the intermediate ketone in preference to the acid derivative, resulting in alcohol products. The stabilized intermediate provided by Grignard addition to a 2-pyridyl thiolester provides isolation of ketones from a carboxylic acid derivative.[2] Successful application of this technique to complex molecules requires a tolerance for other functional groups. Ketone formation has been accomplished in the presence of imide,[19] *t*-butoxycarbonyl, and ester[11b,13] moieties. A comparison of acid activation agents used for ketone formation from Grignard reagents examined 2-pyridyl thiolesters.[20] Investigations of ketone formation using alkynylmetals suggest that *N*-alkoxyamides may be better substrates for these organometallic reagents[21] (see ***N,O-Dimethylhydroxylamine***).

Protecting Group Chemistry.

2-Pyridinethiol provides reagents for facile protection of amines as the benzyloxycarbonyl or *t*-butoxycarbonyl protected species.[3,22] 2-Pyridinethiol protects the imide function of uridine and guanosine units in nucleotide synthesis and is displaced by nucleophiles such as amines.[23] Deprotection of thiols[24] and the azetidinone nitrogen[4] is accomplished with 2-pyridinethiol as the reagent of choice.

Glycoside Synthesis.

Thioglycosides generated from 2-pyridinethiol provide important synthetic intermediates in glycoside chemistry. The synthesis of the thioglycosides utilizes an acid[5,6,25] or Lewis acid catalyst.[26] Silyl enol ethers react with the 2-pyridylthioglycosides generating *C*-glycosides. Using ***Silver(I) Trifluoromethanesulfonate*** (silver triflate) activation, the electrophilic glycoside center accomplishes electrophilic aromatic substitution of electron-rich aromatic rings.[5] *N*-Alkylation of the 2-pyridyl thioglycoside provides the activation for facile glycosidic linkage formation.[6]

Selective Reducing Agent.

2-Pyridinethiol, ***Tin(II) Chloride***, and Et_3N produce a complex that provides selective reduction of azides to primary amines, primary and secondary nitro alkanes to oximes, and tertiary nitro alkanes and nitro aromatics to hydroxylamines.[7] This complex tolerates ketone, sulfoxide, sulfone, nitrile, and ester functional groups. Applications to macrolactamization have been demonstrated.[27]

Synthesis of Electrophilic Agents.

The chloramine generated from ***Morpholine*** reacts with 2-pyridinethiol to generate an electrophilic sulfenylation agent.[8] This reagent provides a mixed disulfide containing a 2-pyridyl unit (see also ***2-Pyridinesulfonyl Chloride*** and ***2-Pyridinesulfenyl Bromide***) which is *N*-alkylated by nonthiophilic agents such as ***Triethyloxonium Tetrafluoroborate***. The resulting salt is readily displaced to generate mixed disulfides (from thiols, thioamides, dithiocarbamates, thiocyanate), sulfenamides (from amines), or sulfides (from β-dicarbonyl nucleophiles).

2-Pyridinethiol is transformed into methyl 2-pyridinesulfinate using MeOH and ***N-Bromosuccinimide***. Enolate sulfinylation with this reagent, followed by thermal elimination, provides a formal dehydrogenation to an enone with (*E*) selectivity. Generating this reagent from 2-pyridinethiol provides an internal buffering during the elimination step.[9]

Application to Diels-Alder Chemistry.

Conjugate addition of 2-pyridinethiol to menthol propiolate results in a *cis*-alkene which undergoes a diastereoselective oxidation of sulfur using ***m-Chloroperbenzoic Acid*** to yield a highly reactive dienophile. Subsequent application to cycloaddition chemistry has been demonstrated.[10,28]

Other Applications.

2-Pyridinethiol photochemically adds to alkenes to yield a bis(2-pyridylethyl) disulfide.[29] 2-Pyridinesulfenylation of 2,5-piperazinediones provides an opportunity for carbon-carbon bond formation using silver triflate activation in the presence of a silyl enol ether.[30] Under nickel catalysis, 2-pyridinethiol provided a 2-pyridyl unit in an aryl-aryl coupling with subsequent loss of sulfur.[31]

Pyridinium Chloride

[628-13-7] · C_5H_6ClN · Pyridinium Chloride · (MW 115.57)

(cleavage of oxiranes to chlorohydrins;[3] cleavage of phenol methyl ethers;[1,5] removal of *N*-trityl protecting groups;[6] catalyst for Fischer indole synthesis[7])

Alternate Name: pyridine hydrochloride.

Physical Data: mp 144 °C (dec).

Solubility: sol water, chloroform, ethanol; insol ethyl ether.

Form Supplied in: white hygroscopic crystalline solid.

Preparative Method: precipitates as a 98% yield of 99.8% pure white crystals when ***Hydrogen Chloride*** gas is passed through a solution of ***Pyridine*** in ether.[1,2]

Purification: recrystallize from chloroform/ethyl acetate and wash with ethyl ether. Can be dried by refluxing in benzene with azeotropic removal of water.

Handling, Storage, and Precautions: stable solid, with no apparent decomposition after several years of storage at room temperature. The salt is very hygroscopic and must be protected from moist air.

Cleavage of Oxiranes.

The title reagent (**1**) reacts with a variety of cyclic and acyclic oxiranes to give chlorohydrins. Typically, a 2:1 ratio of (**1**) to oxirane is employed and the reactions are carried out at ambient temperature in chloroform or pyridine (eqs 1 and 2).[3]

(1)

(2)

Cleavage of Phenol Methyl Ethers.

Treatment of anisole with 3 equiv of (**1**) at 200-220 °C provides phenol (eq 3).[4] A modification of the procedure is reported which allows

for a more convenient in situ preparation of (**1**).[5] The use of the title reagent to cleave phenol methyl ethers avoids the strong acidic or basic conditions of alternative methods. This has found utility in the cleavage of substrates with acid- or base-sensitive moieties (eq 4).[5]

(3)

(4)

Cleavage of *N*-α- and *N*-τ-Trityl Groups from Histidine.

The title reagent (**1**) catalyzes cleavage of trityl protecting groups from the *N*-α position of histidine, as well as the *N*-τ position on the imidazole moiety of histidine.[6] In a typical reaction, the trityl group is cleaved with 5% of (**1**) in MeOH at 60 °C. It appears to have application in orthogonal peptide protection schemes. Boc and Fmoc protecting groups are unaffected under these conditions (eq 5).

(5)

Catalysis of the Fischer Indole Synthesis.

Reagent (**1**) displays utility as a mild catalyst for the Fischer indole synthesis of substrates with strong acid sensitivity (eq 6).[7]

Pyridinium Chlorochromate[1]

[26299-14-9] · $C_5H_6ClCrNO_3$ · Pyridinium Chlorochromate · (MW 215.57)

(stable versatile oxidizing agent for many functional groups;[1a] can oxidize activated C-H bonds,[2b] C-C bonds,[2b] and C-B bonds;[2b] can halogenate enol silyl ethers[2b])

Alternate Name: PCC.

Physical Data: mp 205 °C (dec).

Solubility: insol dichloromethane, benzene, diethyl ether; sol acetone, acetonitrile, THF.

Form Supplied in: yellow-orange solid; widely available.

Handling, Storage, and Precautions: the dry solid may be stored in contact with air, but in the absence of moisture. Reaction solvents should generally be purified and anhydrous. Reported to be a cancer suspect agent. Should be used in a fume hood.

Oxidation of Primary and Secondary Alcohols.

PCC has the capability to convert primary and secondary alcohols to aldehydes and ketones with great efficiency. The yields are typically equal to or greater than those obtained by the Collins method (see ***Dipyridine Chromium(VI) Oxide***), which customarily requires a fivefold excess of reagent. PCC oxidations are normally carried out in dichloromethane with 1.5 equiv of reagent suspended in the organic solvent at room temperature and are usually complete within 1-2 h (eqs 1-4).[2a]

(1)

(2)

(3)

(4)

More polar solvents, such as acetonitrile or acetone, in which PCC has higher solubility, lead to longer reaction times. Overoxidations are rare, but acids can be directly prepared from aldehydes with stoichiometric ***Sodium Cyanide*** and PCC in THF.[3] The reagent shows a slightly acidic character. With compounds bearing acid-sensitive groups, the reaction can be buffered with powdered sodium acetate. However, *cis-trans* isomerization of some allylic alcohols can occur under these conditions (eq 5).[2a]

(5)

PCC appears to be particularly suitable for moderate to large scale preparations, and it has proven to be the reagent of choice for the oxidation of primary alcohols to aldehydes and of secondary alcohols to ketones.[2a,b] Good yields of ketones and aldehydes are regularly obtained.[2a,b] Advantages of PCC include the fact that it does not possess the hygroscopic nature of the chromium trioxide-pyridine complex, and it is prepared via a much less hazardous procedure. However, workup and removal of chromium-containing byproducts is often tedious and difficult with the oxidant.[2a] Several modifications of PCC have been developed to increase both the efficiency and the selectivity of the reagent, and to reduce side reactions.[4] The chlorochromate anion has been supported on a polymeric matrix. Poly(vinylpyridinium chlorochromate), easily prepared, is a recyclable and useful reagent in the oxidation of alcohols to carbonyl compounds in 60-100% yield. This reagent has advantages with regard to product isolation, although its use is limited by the scale of the reaction that can be performed conveniently.[5] Furthermore, the reactivity of PCC in the oxidation of alcohols can be increased by adding anhydrous ***Acetic Acid*** as catalyst to the reaction mixture[6] or by using sonochemical conditions.[7] The addition of ***Molecular Sieves*** in the oxidation of various alcohols results in a dramatic rate enhancement.[8a] Comparative studies indicate that 3 Å sieves give the best results (3 Å > 4 Å > 10 Å > 5 Å).[8b] PCC can perform oxidations of slow-reacting alcohols, such as the secondary hydroxyl groups in carbohydrates and nucleosides. These reactions proceed readily in refluxing benzene, but they are very slow in dichloromethane.[9] The oxidations are conveniently carried out by adding 3 Å molecular sieves to a suspension of PCC in dichloromethane, providing an efficient synthesis of keto sugars and keto nucleosides (eq 6).[8a]

(6)

The use of molecular sieves in many types of oxidations is now commonplace. 2-Nitro alkanols, available by a nitro-aldol reaction, can be oxidized by PCC and molecular sieves to α-nitro ketones in 60-85% yield. Usually the starting compounds undergo a retro-aldol reaction under acidic conditions (eq 7).[8c] On the other hand, (*Z*)-2-butene-1,4-diols are converted by reaction with PCC and molecular sieves into substituted furans in 35-90% yields (eq 8).[10]

(7)

(8)

Synthetically useful changes in the properties of pyridinium chlorochromate have been introduced in the oxidation of hydroxy steroids. PCC, in refluxing benzene, is a convenient reagent for the oxidation and concomitant isomerization of steroidal Δ^5-3β-alcohols to the corresponding Δ^4-3-ketones in high yield.[11] However, in the presence of anhydrous calcium carbonate, PCC can effect the high yield, selective oxidation of steroidal homoallylic alcohols to the corresponding β,δ-unsaturated ketones.[12] Remarkable selectivity is obtained in the oxidation of steroid allylic alcohols by adding 2% of ***Pyridine*** to the reagent in dichloromethane at 2-3 °C. Quasiequatorial allylic alcohols are oxidized faster than nonallylic axial ones (eq 9).[13] Similar properties are found for the combination of PCC and pyrazole (2%),[14] PCC and 2,3-dimethylpyrazole (2%),[15] and PCC and benzotriazole (2%).[16]

(9)

Oxidation of Unsaturated and Cyclopropyl Tertiary Alcohols.

Tertiary allylic alcohols, obtained by the addition of ***Vinyllithium*** or vinylmagnesium chloride to a ketone, undergo oxidative rearrangements to α,β-unsaturated aldehydes in good yields in the presence of PCC. The absence of diene products is remarkable in view of the sensitivity of the starting compounds towards dehydration. The process involves a two-carbon chain-lengthening of the starting ketones, and is synthetically equivalent to a direct crossed-aldol condensation between a ketone and acetaldehyde (eq 10).[17]

(10)

The oxidation of tertiary cyclopropyl alcohols leads to the formation of the corresponding β,γ-unsaturated ketones (eq 11). The reaction represents an excellent method for converting ketones to chain-extended β,γ-enones, since the starting compounds can be prepared by addition of cyclopropyl organometallic reagents to ketones.[18]

(11)

Cyclic tertiary allylic alcohols, prepared by 1,2-addition of alkyllithium reagents to α,β-enones, are oxidized by PCC to transposed γ-alkyl-α,β-unsaturated ketones. Yields are excellent in the case of cyclic alcohols, but only moderate with acyclic alcohols. The overall result of this reaction sequence is an efficient method for alkylative 1,3-carbonyl transposition (eq 12).[19a-d]

(12)

When the tertiary allylic alcohol is suitably disposed near an alkene double bond, PCC is able to perform synthetically useful substituent-directed oxidations, the result of which depends on the relative position of the two groups. Cyclic tertiary γ-hydroxy alkenes can undergo a regio- and stereoselective cyclization, giving a single β-hydroxy cyclic ether through an intramolecular C=C oxidation initiated by PCC (eq 13),[20a] while linear γ,δ-dihydroxy alkenes are cyclized to *cis*-2,5-disubstituted tetrahydrofurans (eq 14).[20b]

(13)

(14)

On the other hand, the oxidation of tertiary γ-hydroxy terminal alkenes brings about both oxidative cyclization and fragmentation of the double bond with loss of one carbon atom, and thus provides an efficient route to γ-lactones (eq 15).[21]

(15)

When a tertiary alcohol is homoallylic, reaction with PCC can yield a ketone resulting from oxidative fragmentation. The cyclic tertiary homoallylic alcohol shown in eq 16 furnishes a mixture of two isomeric cyclopentenones in a 1:1.7 ratio in 62% yield.[22] Another interesting example of PCC reactivity is the conversion of the acyclic tertiary homoallylic alcohol in eq 17 to a keto lactone, albeit in moderate yield. A large excess of oxidant is necessary.[21d]

(16)

(17)

If a homoallylic alcohol is secondary, reaction with PCC leads to the formation of a mixture of γ-hydroxy-α,β-unsaturated enones, through a γ-oxy functionalization (eq 18).[23]

(18)

Oxidative Cationic Cyclization.

The mild acidic character of PCC has been used to advantage in an essential one step conversion of (-)-citronellol to (-)-pulegone (eq 19).[24]

(19)

The oxidative cationic cyclization is useful for the annulation of linear and cyclic unsaturated alcohols or aldehydes to form cyclohexenones (eqs 20 and 21).[25]

(20)

(21)

A limitation is that this reaction cannot be used for formation of cyclopentenones. The reaction is also limited to preparation of β,β-disubstituted α,β-unsaturated cyclohexenones: in fact, cyclization is only observed with substrates capable of affording a tertiary cation as the initial cyclic intermediate. Other substrates (e.g. **1**) do not undergo cyclization, even under more forcing conditions. However, the process represents a milder and more efficient alternative to the two-step cationic cyclization for preparing α,β-unsaturated enones.[26]

(1)

Oxidation of Activated C-H Bonds.

PCC is of value in the allylic oxidation of compounds containing activated methylenes. 5,6-Dihydropyrans (eq 22)[27] and 2,5-dihydrofurans (eqs 23 and 24) are oxidized to the corresponding lactones.[28] The reaction is limited to cyclic benzylic and allylic ethers.

(22)

(23)

(24)

PCC is the reagent of choice in the allylic oxidation of Δ^5-steroids to 7-keto derivatives. The reaction can be carried out using PCC in refluxing benzene or PCC in DMSO solution at 100 °C (eq 25).[29] These solvents are claimed to be superior to dichloromethane, which must be used in large excess in this reaction.[30]

(25)

The capability of PCC to selectively perform allylic oxidation of methylene groups has frequently been utilized,[31] as in the synthesis of a key intermediate related to the taxol ring A (eq 26).[31b]

(26)

In a similar fashion, the smooth oxidation of benzylic hydrocarbons to aryl ketones can be achieved by adding a powdered and homogenized mixture of PCC and ***Celite*** to a benzene solution of the substrates (eqs 27 and 28).[32] The reaction has been successfully applied to a variety of compounds, such as 1,2,3,4-tetrahydrophenanthrene,[33] 12-methoxypodocarpa-8,11,13-triene,[34] and biscyclophanes.[35]

(27)

(28)

The transformation of activated methylene groups to ketones shows particular applicability to the conversion of benzyl alkyl ketones to the corresponding 1,2-diketones in high yields (eq 29).[28] Since the starting materials appear to be sensitive to the acidic PCC, anhydrous pyridine must be added to the reaction. This oxidation fails with dialkyl ketones.[28]

(29)

PCC is able to oxidize cyclic 1,4-dienes to dienones (eq 30).[36] PCC does not effect oxidation of isolated double bonds, or of more reactive systems such as diphenylmethane or allylbenzene. Complementary selectivity (1:3) is achieved with the Collins reagent.

(30)

Phenyloxiranes can undergo a one step C-C bond cleavage to carbonyl compounds by reaction with PCC and molecular sieves (52-75%) (eq 31).[37] The presence of a phenyl group seems to be essential for efficient C-C cleavage. Under similar conditions, alkyl-substituted oxiranes are prevalently converted into α-hydroxy ketones (eq 32).

(31)

(32)

PCC is reported to perform oxidative fragmentation of carbon-carbon bonds of 1,2-diols to give carbonyl compounds in excellent yields (eq 33).[38] Hydroxymethyl cyclic ethers also undergo fragmentation; tetrahydrofuranmethanol derivatives lead to γ-lactones in 52-95% yield (eqs 34 and 35),[39] while 5-hydroxymethyl groups of 1-methoxy-2,3-*O*-isopropylidene-D-ribose are cleaved to γ-lactone derivatives in 50-60% yield (eq 36).[40] These transformations usually require more vigorous conditions than those needed for alcohol oxidation.

(33)

(34)

(35)

(36)

Oxidation of C=C Activated Double Bonds.

PCC can behave as an oxidizing, weakly electrophilic species, capable of attacking particularly nucleophilic alkenes and of bringing about interesting reactions. PCC oxidizes linear and cyclic enol ethers to esters and lactones in 75-95% yield (eqs 37 and 38).[41]

(37)

(38)

According to the reported mechanism, the key step involves a 1,2-hydride shift from the α- to the β-carbon of the ether. When the enol ethers are α,α´-disubstituted, there is no possibility for such a hydride shift; reaction with PCC then yields a smooth oxidative cleavage of the nucleophilic alkene to esters or keto lactones in 45-90% yield (eqs 39 and 40).[42]

(39)

(40)

The reaction can be applied only to cyclic enol ethers. However, the simplicity of the procedure and the high yields obtained make the methodology synthetically useful for preparative purposes. In fact, the reaction has been extensively applied as a general approach to γ-lactones from the corresponding α-alkylidene five-membered enol ethers using as conditions treatment with 4 equiv of PCC and celite at room temperature in dichloromethane (eqs 41 and 42).[43] An important feature of this procedure is that, under the reaction conditions, other isolated carbon-carbon double bonds and benzylic groups present in the molecule are not affected.

(41)

(42)

PCC has proven to be the reagent of choice for the selective oxidation of a specific class of cyclic enol ethers: 1,4-dioxenyl alcohols. The allylic alcohols can be easily obtained by addition of 2-lithio-5,6-dihydro-1,4-dioxin to ketones and aldehydes. Reaction with PCC thus provides a method for one-carbon homologation of ketones and aldehydes to α-hydroxy acids (39-61%) (eq 43) and α-keto acids (54%) (eq 44), respectively.[44] The oxidation occurs regiospecifically at the dioxene site. While the oxidation of the allylic alcohols occurs in a few minutes, the α,β-unsaturated ketones require a longer reaction time, owing to the deactivation of the carbon-carbon double bond.

(43)

(44)

Aryl-substituted alkenes can be selectively cleaved in the presence of alkyl-substituted alkenes. Treatment of acyclic aryl alkenes with PCC and celite in dichloromethane under reflux results in oxidative opening of the carbon-carbon double bond to the corresponding carbonyl compounds in 72-90% yield (eq 45).[45] Alkyl-substituted acyclic alkenes are in general unreactive towards PCC, while cyclic alkenes undergo allylic oxidation, albeit in low yield (eq 46).[45]

(45)

(46)

PCC has demonstrated its particular reactivity towards furan derivatives, which are well known for their sensitivity to oxidizing and electrophilic reagents.[46] Thus 5-methyl-2-furylcarbinols undergo oxidative ring enlargement to hexenuloses in very high yields (90-94%) (eq 47).[47]

(47)

Another application involves 5-bromo-2-furylcarbinols, which are converted by PCC into γ-hydroxybutenolides in 60-75% yield (eq 48).[48] Both conversions point out an unusual regiospecific reactivity of pyridinium chlorochromate, since only the oxidation of the furan ring occurs, in spite of the presence of a secondary alcoholic function, which remains untouched. Different behavior is observed when the heteroaromatic nucleus is deactivated by the presence of a nitro group; in this case, PCC oxidizes the alcohol function, leading to alkyl 5-nitro-2-furyl ketones (eq 49).[49]

(48)

(49)

A further and important application of PCC involves the conversion of 2,5-dialkylfurans, via oxidative ring fission, to *trans*-α,β-unsaturated 1,4-dicarbonyl compounds in a very simple manner. The reagent must be utilized in a large excess in dichloromethane at reflux for 24 h. Invariably, the products are obtained with *trans* configuration. The *cis*-isomers are formed first and are then isomerized by the acidic reagent (eq 50).[50] Lower yields of enedicarbonyl compounds are obtained from 2-alkylfurans (eq 51).[50]

(50)

(51)

PCC shows a remarkable reactivity towards more nucleophilic furans, such as 2-alkylthiofurans, which are rapidly converted by action of the reagent in dichloromethane at room temperature for 2 h into *S*-alkyl 4-oxo-2-alkenethioates in high yields (eq 52).[51] (*Z*)-(*E*) Isomerization can be observed with longer reaction times, due to the acidic character of PCC. 2-Methoxy-5-methylfuran, which requires only 10 min of reaction, affords methyl (*Z*)-4-oxo-2-pentenoate, without the (*E*)-isomer being detectable (eq 53).[51]

(52)

(53)

Oxidation of Carbon-Boron Bonds.

PCC is a superior reagent for the oxidation of organoboranes to carbonyl derivatives by a convenient and mild procedure. Trialkylboranes, obtained by treatment of linear and cyclic di- and trisubstituted alkenes with ***Boron Trifluoride-Lithium Borohydride*** or ***Borane-Tetrahydrofuran***, afford the corresponding ketones by reaction with PCC in high yields (eqs 54 and 55).[52,53] Similar oxidation of dialkylchloroboranes, derived from cyclic alkenes by reaction with ***Monochloroborane-Dimethyl Sulfide***, gives ketones in 70-85% yield (eq 56).[54]

(54)

(55)

(56)

The success of this method for the conversion of terminal alkenes into aldehydes often depends on the nature of the hydroborating agent. In view of the poor regioselectivity (only 94% primary alkyl groups) and functional group tolerance of borane-THF and borane-dimethyl sulfide,[54] ***Disiamylborane*** is frequently utilized as a more selective hydroborating agent. Alkyldisiamylboranes are oxidized by PCC to aldehydes in 55-72% yield. The ester groups are compatible with the reaction (eq 57).[54,55b] The need for a large excess of PCC (6 equiv) for the oxidation of alkyldisiamylboranes can be avoided by using dialkylhaloboranes, which can be prepared with excellent regioselectivity (>99% primary alkyl groups) by hydroboration of terminal alkenes with monochloroborane-dimethyl sulfide complex. Dialkylchloroboranes are hydrolized in the presence of pyridine, and the resulting boronic anhydride is oxidized with PCC (3 equiv) to aldehydes in satisfactory yields (eq 58).[54]

(57)

(58)

The selective formation of aldehydes from various types of double bonds in dienes can be conveniently carried out via PCC oxidation of the resulting organoboranes, prepared by utilizing either disiamylborane (eq 59) or ***Chloro(thexyl)borane*** (eq 60) for the regioselective monohydroboration of the diene.[54]

(59)

(60)

Other organoboranes, such as trialkyl borates and trialkyl boroxins, can also be oxidized with PCC. Trialkyl borates are rapidly prepared either by esterification of boric acids or by reaction of alcohols with ***Borane-Dimethyl Sulfide***. These intermediates, on reaction with PCC in boiling dichloromethane, are oxidized to give good yields of aldehydes and ketones (eq 61).[56] The method does not seem to have significant advantages over the direct oxidation of the alcohols, but it may prove useful for the one-pot conversion of carboxylic acids into the corresponding aldehydes. Both aliphatic and aromatic carboxylic acids are easily reduced by borane-dimethyl sulfide to trialkoxyboroxins, which are smoothly oxidized to aldehydes with PCC (eq 62).[57]

(61)

(62)

Oxidation of Silicon-Containing Molecules.

PCC is able to effect the deprotection-oxidation of *p*-hydroquinone silyl ethers to *p*-quinones, except where there are electron-withdrawing substituents on the aromatic ring. The reaction proceeds both with bis(trimethylsilyl) and bis(*t*-butyldimethylsilyl) ethers of *p*-hydroquinones in 60-99% yield. The bis(trimethylsilyl) ethers are slightly more reactive than the bis(*t*-butyldimethylsilyl) ethers (eq 63).[58]

(63)

The deprotection-oxidation method can be applied to the preparation of ketones from trimethylsilyl-protected secondary alcohols.[59] However, the ***Pyridinium Dichromate-Chlorotrimethylsilane*** combination seems to be more efficient for the transformation. A related application of PCC involves its capability to selectively convert 1-trialkylsilyl-1,2-diols into aldehydes, presumably by electrofugal loss of the silicon moiety (eq 64).[60]

(64)

Both cyclic and linear enol silyl ethers can be converted to α-iodocarbonyl compounds by treatment with the pyridinium chlorochromate-***Iodine*** system in dichloromethane in 76-100% yield (eq 65). The yields of α-iodocarbonyl compounds from enol methyl ethers and dihydropyran are lower (19-53%) (eq 66). The method fails with enamines.[61]

(65)

(66)

Oxidation of Oximes.

PCC can be conveniently employed for oxidative cleavage of oximes to carbonyl compounds. Aldehydes and ketones can be recovered from the oxime derivatives by treatment with PCC in dichloromethane at room temperature for 12-24 h in 30-85% yield.[62] PCC-***Hydrogen Peroxide*** is more effective as a deblocking agent: cleavage of oximes occurs within 10 min at 0-10 °C when 30% hydrogen peroxide is added to an acetone solution of PCC. Ketoximes are converted to ketones in 55-88% yield. For aldoximes, over-oxidation to acids has been observed.[63] On the other hand, aryl hydroxylamines can be oxidized to aryl *C*-nitroso compounds by treatment with PCC in tetrahydrofuran in 50-90% yield.[64]

Oxidation of Sulfur-Containing Molecules.

PCC dimerizes aromatic, but not aliphatic, thiols to their corresponding disulfides in good yields.[65] Sulfides may undergo oxidation to give sulfones.[4]

Changes in the properties and reactivity of pyridinium chlorochromate have been brought about by altering the amine ligand associated with the chlorochromate anion. It has been found that heterocyclic chlorochromates show a trend where their strength as oxidant is inversely proportional to the donor strength of the heterocyclic ligand. Several aromatic amines have been examined, which give rise to the related chlorochromate-derived reagents. Enhanced reactivity is found for complexes containing a bidentate ligand.[4]

Related Reagents.

Pyridinium Chlorochromate-Alumina[1]

(PCC)

[26299-14-9] · $C_5H_6ClCrNO_3$ · Pyridinium Chlorochromate-Alumina · (MW 215.57) (Al_2O_3)

[1344-28-1] · Al_2O_3 · Pyridinium Chlorochromate-Alumina · (MW 101.96) (SiO_2)

[7631-86-9] · O_2Si · Pyridinium Chlorochromate-Silica Gel · (MW 60.09)

(mild and selective oxidizing agent for primary and secondary alcohols;[2] can aromatize 1,4-dihydropyridines[5])

Solubility: insol *n*-hexane, benzene, dichloromethane.

Form Supplied in: PCC-alumina: yellow orange solid; not commercially available. PCC-silica: light orange solid; not commercially available.

Preparative Methods: PCC-alumina:[2a] ***Pyridine*** (60 mmol) is added to a solution of ***Chromium(VI) Oxide*** (60 mmol) in 11 mL of 6 N ***Hydrochloric Acid*** over 10 min at 40 °C. The mixture is then kept at 10 °C until a yellow-orange solid forms. Reheating to 40 °C gives a solution. Neutral ***Alumina*** (50 g) is then added to the solution with stirring at 40 °C. After concentration (rotary evaporator), the resulting orange solid is dried in vacuum for 2 h at rt. Care must be taken not to evaporate pyridine during this process; some workers recommend that additional pyridine should be added to ensure that the reagent is not acidic. The average capacity of the dried reagent is 1 mmol g^{-1} of alumina. PCC-silica:[2c] commercial grade PCC (12 mmol) is ground with 70-240 mesh silica gel (1 wt equiv) in a mortar; the resultant free-flowing light orange solid is ready for use in oxidations.

Handling, Storage, and Precautions: PCC-alumina: the reagent can be stored for several weeks under vacuum in the absence of light without losing its activity. PCC-silica: no data are available. Pyridinium chlorochromate is reputed to be a cancer suspect agent. The reagent should be used in a fume hood.

Oxidation of Primary and Secondary Alcohols.

Pyridinium Chlorochromate oxidizes a wide variety of alcohols to carbonyl compounds with high efficiency. However, workup and removal of the chromium-containing byproducts are often tedious and difficult. In addition, PCC shows acidic character which can give rise to complications and side reactions. PCC adsorbed on alumina has been demonstrated to be a mild and selective reagent for the oxidation of primary and secondary alcohols to the corresponding aldehydes and ketones (eqs 1 and 2).[2]

(1)

(2)

The acidic nature of PCC is diminished by alumina, which presumably acts as a buffer and enhances the reactivity of PCC as well, often resulting in cleaner oxidations. These reactions are performed by stirring excess oxidant with alcohols in solvents such as *n*-hexane, benzene, and dichloromethane at rt for 2-3 h. An additional advantage of using a solid support is that it acts as an in situ adsorbent of the reduced byproduct chromium tars,[2] and workup then requires only filtration and then concentration. The oxidation seems compatible with many acid-sensitive groups (eq 3).[3]

(3)

Citronellol is directly oxidized to citronellal in 82% yield without any cationic cyclization.[2] The oxidation of cholesterol to 5-cholesten-3-one is performed in 80% yield.[2] No formation of 4-cholesten-3-one is observed. γ,δ-Unsaturated alcohols can be smoothly oxidized in good yield to the corresponding γ,δ-unsaturated aldehydes by using PCC in the presence of alumina (eq 4).[4]

(4)

Oxidative Aromatization.

Interestingly, PCC-alumina is efficient for the oxidative aromatization of 1,4-dihydropyridines into pyridines in yields exceeding 90% (eq 5).[5] It is noteworthy that dealkylation (in addition to aromatization) occurs when the starting dihydropyridines bear a secondary alkyl group or a benzyl group at the 4-position.

Oxidations using PCC-Silica.

The oxidation of primary and secondary alcohols with PCC-silica employs dichloromethane as solvent and requires no added buffers, even for compounds bearing acid-sensitive groups. As with PCC-alumina, this reagent offers superior results in terms of simplicity of workup, since silica gel absorbs the byproduct chromium tars and is easily filterable. However, oxidations with this reagent require longer reaction times than the usual PCC procedure. The use of ultrasound in PCC-silica oxidations of alcohols gives rise to a great reaction rate enhancement, reducing the oxidation times generally from hours to minutes and improving the yields of the corresponding carbonyl compounds (60-94%). Acid-labile groups resist the experimental conditions. Neither (*E*)-(*Z*) isomerization nor overoxidation are observed (eq 6).[6]

PCC-silica was found to be the most efficient reagent system for the 1,3-oxidative rearrangement of an unsaturated secondary alcohol to the corresponding α,β-unsaturated aldehyde (eq 7).[7]

Pyridinium Dichromate[1]

[20039-37-6] · $C_{10}H_{12}Cr_2N_2O_7$ · Pyridinium Dichromate · (MW 376.24)

(mild and selective oxidizing agent for primary and secondary alcohols;[2a] can oxidize unsaturated tertiary alcohols,[2b] silyl ethers,[11] the carbon-boron bond,[20] and oximes[23])

Alternate Name: PDC.

Physical Data: mp 152-153 °C

Solubility: sol DMF, DMSO, acetonitrile; sparingly sol dichloromethane, chloroform, acetone; insol hexane, ether, ethyl acetate.

Form Supplied in: bright orange solid; widely available.

Handling, Storage, and Precautions: the dry solid can be stored in contact with air. Reaction solvents must be anhydrous and free of reducing impurities. Pyridinium dichromate is reported to be a cancer suspect agent. The reagent should be used in a fume hood.

Oxidation of Primary and Secondary Alcohols.

PDC is an oxidizing agent complementary to ***Pyridinium Chlorochromate*** (PCC) for alcohols containing acid-sensitive groups. PDC is less acidic than pyridinium chlorochromate, and has more neutral character than the Collins reagent (***Dipyridine Chromium(VI) Oxide***). PDC is reported to exhibit greater oxidation efficiency than the Collins reagent, especially for large scale preparations. Initially, PDC was used either as a solution in DMF or as a suspension in dichloromethane. In solution in DMF, PDC oxidizes primary and secondary allylic alcohols to the corresponding α,β-unsaturated carbonyl compounds (eqs 1 and 2). Overoxidation of primary allylic alcohols is not observed, and (*E*)-(*Z*) isomerization does not take place.[2a]

(1)

(2)

Under similar conditions, saturated primary alcohols and aldehydes yield carboxylic acids. The preparation of carboxylic acids from primary alcohols (via the aldehyde intermediate) is usually achieved using 3.5 equiv of PDC at rt for 7-9 h (eqs 3 and 4).[2a]

(3)

(4)

An interesting example of the mildness of PDC is the oxidation of citronellol to the corresponding acid in 83% yield. The same oxidation with acidic PCC is complicated by cationic cyclization of the aldehyde intermediate. Aliphatic methyl esters can be directly prepared from aldehydes by oxidation with PDC (6 equiv) in the presence of methanol in yields of 60-80%. This method is not useful for aromatic aldehydes or higher esters.[3] Saturated secondary alcohols are rapidly and conveniently converted into ketones, even in the presence of very sensitive groups, such as a thioacetals.

In suspension in dichloromethane, PDC shows considerably different behavior, becoming a milder and selective reagent for the preparation of both saturated and unsaturated aldehydes and ketones (eqs 5-7). Allylic alcohols are oxidized faster than saturated ones, but some (*E*)-(*Z*) isomerization is observed.[2a]

(5)

(6)

(7)

PDC does not attack isolated alkenic and alkynic bonds; in fact, o-alkynyl alcohols are oxidized by PDC in dichloromethane to the corresponding o-alkynyl carbonyl compounds in good yield (eq 8).[4]

PDC and PCC may show a different chemoselectivity. Thus PDC oxidizes the secondary hydroxyl groups of 5-bromo-2-furylcarbinols to the corresponding ketones in 80% yield, while PCC attacks the furan ring giving γ-hydroxy Δ^2-butenolides (eq 9).[5]

Several modified procedures have been employed to enhance the rate and the efficacy of PDC. Addition of pyridinium trifluoroacetate (0.4 equiv) causes an increase in the reaction rate, and less oxidant is necessary for oxidation (eq 7). ***Molecular Sieves*** enhance the oxidation rate with a wide variety of substrates.[6] A combination of PDC, molecular sieves, and ***Acetic Acid*** has a dramatic effect on the oxidation of carbohydrate alcohols, reducing oxidation time from days to minutes (eq 10).[7] Furthermore, the addition of acetic acid has been utilized for the selective oxidation of secondary allylic alcohols in carbohydrates (eq 11).[8]

The PDC-***Acetic Anhydride*** combination gives rise to a strong and neutral oxidant. This system (0.6-0.7 equiv of PDC and 3 equiv of Ac_2O) can be used for the selective oxidation of primary and secondary alcohols of carbohydrates to the corresponding carbonyl

compounds in high yields. The addition of DMF as cosolvent to the reaction mixture prevents overoxidation (eq 12).[9] Interestingly, the PDC-Ac_2O combination is able to perform an oxidative fragmentation of 5´-hydroxymethyl groups in 2´,3´-*O*-isopropylidene nucleosides to form the corresponding γ-lactone nucleosides, albeit in moderate yield (eq 13).[10]

Oxidation of primary and secondary alcohols to carbonyl compounds can be carried out with PDC-***Chlorotrimethylsilane***, which is a rapid and selective oxidant.[11] This combined reagent system can effect the deprotection-oxidation of silyl ethers and enol silyl ethers. Primary and secondary trimethylsilyl and *t*-butyldimethylsilyl ethers, usually stable to PDC, may be converted by the above combination directly into the corresponding carbonyl groups in high yields (eq 14). The method can be applied to the preparation of quinones from hydroquinone silyl ethers (eq 15) with higher efficiency than that using PCC and this reagent is applicable to substrates both with electron-donating and electron-withdrawing groups.[11]

Catalytic PDC Oxidation of Alcohols.

PDC can be utilized as a catalytic oxidant when coupled with ***Bis(trimethylsilyl) Peroxide*** as cooxidant. The method has proven to be mild and useful not only for the oxidation of a wide range of primary and secondary alcohols, saturated and unsaturated, but also for the conversion of homoallylic alcohols to the corresponding β,γ-enones (eq 16).[12]

(16)

Oxidation of Cyanohydrins.

Cyanohydrins of nonconjugated aldehydes are oxidized to carboxylic acids by PDC-***N,N-Dimethylformamide*** in excellent yields. Cyanohydrins from α,β-enals (as the *O*-trimethylsilyl derivatives) behave differently, being converted by PDC-DMF into α,β-unsaturated γ-lactones (Δ^2-butenolides), in cases in which the β-carbon is disubstituted and the γ-carbon possesses at least one hydrogen. This reaction is performed with PDC (3 equiv) in DMF at rt for 12 h, and provides a mixture of two isomeric Δ^2-butenolides, whose ratio (4:1) indicates that oxidative attack at the γ-methyl is favored over the γ-methylene (eq 17).[13]

(17)

Oxidation of Activated Methylene Groups.

PDC can perform allylic oxidation of methylene groups, but a large excess of oxidant is required. Δ^5-Steroids are selectively transformed into Δ^5-7-keto steroids by treatment with PDC (25 equiv) and molecular sieves in pyridine at 100 °C for 24 h; yields range from 63-86% (eq 18).[14]

(18)

R = Bz	PDC, py, 100 °C, MS	64%
R = Ac	PDC, *t*-BuOOH, Celite, rt	81%

A PDC-***t-Butyl Hydroperoxide*** mixture (1:1) has proven to be useful for the mild oxidation of cyclic 1,4-dienes to the corresponding cyclic 2,5-dienones (eq 19).[15] The use of the combination of PDC, *t*-butyl hydroperoxide, and ***Celite*** is particularly suitable for the oxidation of benzylic methylenes into aryl ketones (eq 20)[16] and for the highly regioselective conversion of Δ^5-steroids into the corresponding Δ^5-7-keto steroids (eq 18).[16] The method is rather poor for allylic oxidation of linear and cyclic alkenes, furnishing α,β-enones in 23-44% yield (eq 21).[16]

(19)

(20)

(21)

Oxidative Rearrangement of Unsaturated Alcohols.

Linear and cyclic secondary homoallylic alcohols are oxidized by PDC-DMF to *trans*-enediones in 53-75% yield. The one-pot procedure seems to be particularly convenient for the oxidation of steroidal substrates, which contain a rigid and sterically congested structure. Thus 3β-hydroxy Δ^5-steroids afford the corresponding 3,6-diketo-Δ^4-steroids (eq 22).[17] The method is rather unsatisfactory for linear homoallylic alcohols and fails with alcohols possessing a terminal allylic group.

(22)

PDC is the oxidant of choice for the oxidation of tertiary allylic dienols. These alcohols, easily prepared by addition of ***Vinyllithium*** to conjugated cyclohexenones or cyclopentenones, undergo a 1,3-oxidative rearrangement to afford the corresponding conjugated dienones in moderate to good yield (eq 23). The rearrangement is completely regiospecific, leading to the formation of the more stable isomers. The reaction does not suffer from the presence of withdrawing substituents on the alkene system, but linear α-dienols give lower yields of rearranged isomeric products (eq 24).[18]

(23)

(24)

In a similar fashion, tertiary α-enynols are converted by reaction with PDC in dichloromethane to the corresponding conjugated enynones; yields are good to excellent. These rearrangements are completely regioselective, involving only the alkene. The procedure is limited to cyclic allylic alcohols and shows wide applicability only with enynols containing (*Z*) double bonds (eq 25).[19]

(25)

Oxidation of Carbon-Boron Bonds.

A synthetically useful procedure has been developed for the conversion of terminal alkenes into carboxylic acids via oxidation of organoboranes obtained by hydroboration of terminal alkenes. The oxidation works well with organoboranes derived from ***Dibromoborane-Dimethyl Sulfide***, but other reagents may be utilized such as monobromoborane-dimethyl sulfide, ***Monochloroborane-Dimethyl Sulfide***, ***Thexylborane***, and ***Dicyclohexylborane***. Alkyldibromoboranes are hydrolyzed to alkylboronic acids, which undergo a facile oxidation with PDC-DMF (5 equiv) at rt for 24 h to provide carboxylic acids in 62-78% yield (eq 26).[20] In some cases PCC may effect the same reaction in higher yields; however, carboxylic acids are often best obtained with ***Chromium(VI) Oxide*** as oxidant in 90% aqueous acetic acid.[20]

Hexanoic acid (26)
75%

Oxidation of Enol Ethers.

PCC is a selective reagent for the oxidative cleavage of enol ethers and PDC shows a similar but modest reactivity. PDC can effect oxidative double bond fragmentation of cyclic enol ethers to esters and keto lactones (eq 27).[21]

(27)

Interestingly, the PDC-*t*-BuOOH combination can achieve the one-step conversion of 3,4-dihydro-2*H*-pyrans into 5,6-dihydro-2*H*-pyran-2-ones under very mild conditions; yields are moderate. The reaction is performed at 0 °C in dichloromethane with PDC-*t*-BuOOH for 2-4 h. *t*-Butylperoxy derivatives are obtained as byproducts (eq 28).[22] This reagent system can chemoselectively oxidize 3,4-dihydro-2*H*-pyrans to the corresponding α,β-unsaturated lactones without affecting pendant hydroxyl groups (eq 29).

50% 6% (28)

30% 14% (29)

Oxidative Cleavage of Oximes.

PDC can perform oxidative cleavage of oximes to ketones and aldehydes in excellent yield (eq 30). The reagent seems to be superior to PCC for this transformation. The rate of deoximation is increased by adding 3 Å molecular sieves, but the yields of carbonyl compounds are lowered.[23]

(30)

Oxidation with Iodine and PDC.

PDC has been utilized for oxidation of cyclic alkene-iodine complexes to α-iodo ketones (eq 31). The yields range from 50 to 70%.[24] The reaction shows a wide applicability; Δ^2-cholestene is selectively converted, by the same procedure, into 3α-iodocholestan-2-one in 70% yield (eq 32). The reaction fails with linear alkenes; however, it seems to be characteristic of PDC. In contrast, PCC converts the cyclohexene-iodine complex into *trans*-1-chloro-2-iodocyclohexane (66%), while the α-iodo ketone is a byproduct (8%).[24]

(31)

(32)

Cyclic trisubstituted alkenes, activated with ***Iodine***, are easily converted into iodohydrins and epoxides by PDC, which acts as nucleophilic and iodide removing agent. Iodohydrins can be isolated in 48-65% yield when the starting alkenes have a mobile conformation. The reaction is performed in dichloromethane with PDC (2.5 equiv) and 4 Å molecular sieves at rt for 3 h. More prolonged reaction times (16 h) lead to epoxides in 50% yield (eq 33).[25] Conformationally rigid alkenes are directly converted into epoxides in 51-86% yield, since the iodohydrin intermediates undergo a fast elimination of iodide by the oxidant (eq 34).

(33)

(34)

Some naturally-occurring polyenes such as (*E*,*Z*)-geranyl acetate undergo a regioselective conversion to terminal epoxides by a two-step sequence, which includes the formation of the corresponding terminal iodohydrins by reaction with PDC-iodine and subsequent conversion to the epoxides by adsorption on neutral alumina (30-65% yield) (eq 35).[25]

(35)

The nucleophilic and oxidizing properties of PDC can be utilized for a one-pot conversion of α-ynol-iodine complexes to α,β-unsaturated α-iodo aldehydes in 30-66% yield. This reaction is performed by adding PDC (2.2 equiv) to a solution of α-ynol and iodine (1:1), in the presence of 4 Å molecular sieves at rt for 24 h (eq 36). The conversion is regio- and stereospecific, yielding only one of two possible geometrical isomers and shows wide applicability.[26]

Pyridinium Fluorochromate[1]

[83042-08-4] · $C_5H_6CrFNO_3$ · Pyridinium Fluorochromate · (MW 199.12)

(mild oxidizing agent for primary and secondary alcohols;[2] can oxidize activated C-H bonds[2b])

Alternate Name: PFC.

Physical Data: mp 106-108 °C.

Solubility: sol DMF, acetonitrile, acetone; less sol dichloromethane; sparingly sol benzene, carbon tetrachloride, chloroform, hexane.

Form Supplied in: not commercially available.

Preparative Method: prepared from ***Pyridine***, aqueous 40% ***Hydrofluoric Acid***, and ***Chromium(VI) Oxide*** in a molar ratio 1:1.5:1. The bright orange, crystalline reagent is isolated by filtration and dried in vacuo; yield 93-94%. The procedure can be performed on a 200 g scale.[2]

Handling, Storage, and Precautions: the dry orange crystalline reagent can be stored in sealed polythene bags for long periods without decomposition. Reaction solvents must be anhydrous and free of reducing impurities. Chromium(VI) derivatives are reputed to be toxic agents. The reagent should be used in a fume hood.

Oxidation of Primary and Secondary Alcohols.

PFC is an effective reagent for the oxidation of a wide range of alcohols. With 1.5 equiv of reagent in dichloromethane at rt for 1-3 h, primary and secondary alcohols are converted to aldehydes and ketones in yields ranging from 77 to 98% (eqs 1-3).[2,3] (*E*)-(*Z*) isomerization has been observed during the oxidation of some allylic alcohols.[3]

(1)

(2)

PFC seems to have certain advantages over similar oxidizing agents in terms of the amount of oxidant and solvent required, shorter reaction times, and improved yields of products. Since its acidity is less pronounced than that of ***Pyridinium Chlorochromate***, compounds with acid-sensitive groups can be oxidized without buffering the reaction mixture. PFC can be used in the oxidation of a secondary alcohol in the presence of a primary alcohol protected as a silyl ether (eq 4).[3] The more acidic PCC does attack silyl ether groups.

The fluorochromate anion has been supported on a polymeric matrix, the cross-linked ***Poly(4-vinylpyridine)***. Poly(4-vinylpyridinium fluorochromate) oxidizes primary and secondary alcohols to aldehydes and ketones in very good yield in both hexane or benzene. It is essential that the reagent be wet; use of dry reagent does not afford the desired product.[4] No products of overoxidation are found in the reaction mixture. In addition, the wet supported oxidant can be employed as an efficient reagent for the cleavage of aldoximes and ketoximes to the corresponding parent carbonyl compounds in excellent yield.[4]

Oxidation of Activated C-H Bonds.

PFC can be utilized for selective oxidation of certain aromatic hydrocarbons. Anthracene and phenanthrene are converted by the oxidant (2.5 equiv) at rt into the corresponding anthraquinone (eq 5) and phenanthrene-9, 10-quinone in 68% and 52% yield. The yields may be raised to 98% and 72% by using ***Acetic Acid*** as the reaction medium.[2]

Several reports have suggested that PFC is a suitable oxidant for both allylic[5] and benzylic C-H bonds,[6] although no yields have been reported. Oxidation of Δ^3-carene in aqueous acetic acid containing perchloric acid gives rise to a variety of ketonic products.[5] By the same procedure, oxidation of substituted toluenes afford the corresponding aldehydes as the main products.[6c] Diphenylmethane and fluorene are converted mainly into benzophenone and fluorenone.[6b] PFC can oxidize a tertiary benzylic C-H bond: triphenylmethanol is obtained in 90% yield from triphenylmethane by reaction with the oxidant in acetic acid containing perchloric acid (eq 6).[7]

(6)

PFC in DMF has the capability to oxidize selectively organic sulfides into sulfoxides. No yields are reported.[8]

Pyridinium Hydrobromide Perbromide[1]

[39416-48-3] · $C_5H_6Br_3N$ · Pyridinium Hydrobromide Perbromide · (MW 319.86)

(selective brominating reagent for ketones,[2] acetals,[3] alkenes,[4] activated phenols,[5] anilines,[6] and nitrogen heterocycles;[7] mild oxidation/dehydrogenation reagent[8])

Alternate Names: PHBP; pyridinium bromide perbromide; pyridinium perbromide; pyridinium tribromide.

Physical Data: mp 101-103 °C (39.7% Br), mp 132-134 °C (47% Br),[7] 135 °C (50% Br).[9]

Solubility: sol acetic acid, methanol, ethanol, *n*-butanol, THF, ether (wet); insol water, carbon tetrachloride, ethyl bromide, ether (anhydrous), benzene, toluene, ligroin, petroleum ether.[9]

Form Supplied in: red-orange solid, generally 90-97% pure; commercially available.

Analysis of Reagent Purity: iodometric titration.[10]

Preparative Method: from pyridine, 48% hydrobromic acid, and bromine.[1,7] The bromine content varies depending on the method of preparation.[7,11]

Purification: recrystallization from ethanol.[12] Recrystallization from acetic acid reduces the bromine content. Pure material can be obtained by adding bromine to impure material until a paste is produced. Excess bromine is allowed to evaporate, giving pure material, mp 135 °C (50% Br).[9]

Handling, Storage, and Precautions: protect from moisture, strong acids, and bases. This toxic reagent must be used in a fume hood.

Introduction.

Pyridinium hydrobromide perbromide is a solid complex of ***Pyridine*** with bromine that is used as a source of ***Bromine***. It is more convenient to measure small amounts of active bromine with this stable reagent than with bromine itself. Its mild reactivity makes it ideal for selective brominations and dehydrogenations of sensitive molecules.[1]

α-Bromination of Ketones.

PHBP has been used to α-brominate steroid keto groups in good yields with high stereoselectivity.[2,13] Flavinones react with PHBP giving α-brominated products.[14] Tetrahydroindoles also react with PHBP (eq 1); however, better yields were obtained for this transformation with ***Copper(II) Bromide***.[15] PHBP reacts with cyclohexanones in ***Acetic Acid*** to give equatorially substituted α-bromocyclohexanones. In contrast, bromine in carbon tetrachloride gives mostly axial products.[16] The cyclopentenone shown in eq 2 was successfully brominated with PHBP when an equivalent of pyridine was present.[17] ***Phenyltrimethylammonium Perbromide*** is reported to give better yields of monobrominated ketones.[18]

(1)

(2)

α-Bromination of Acetals.

PHBP reacts with acetals to give good yields of their α-brominated derivatives.[3] With chiral acetals, different ratios of stereoisomers can result when the solvent or the brominating agent are changed (eq 3).[19]

(3)

PHBP:	THF	(R):(S) = 95:5
	CH_2Cl_2	(R):(S) = 58:42
Br_2:	THF	(R):(S) = 1:99
	CH_2Cl_2	(R):(S) = 25:75

Phenyltrimethylammonium perbromide is a comparable acetal bromination reagent which has better solubility in THF at low temperatures.[20] Acetals of benzophenone derivatives are more effectively brominated with ***Bromine-1,4-Dioxane*** rather than PHBP.[21]

Bromination of Alkenes.

PHBP readily adds in an *anti* fashion to carbon-carbon double bonds to give predominantly one stereoisomer.[4] Studies of PHBP addition to cyclohexenes show that diaxial products are favored over diequatorial ones.[22] There is a preference for 1,2- rather than 1,4-addition with conjugated dienes.[23] Enones react with PHBP in methanol to give anti-Markovnikov addition products.[24] Unlike bromine, this reagent adds to the double bond of unsaturated alcohols without brominating the alcohol.[25] Alkenes can be protected by generating their dibromides with PHBP. Deprotection using controlled-potential electrolysis or cathodic debromination regenerates the alkenes.[26]

Bromination of Aromatic Compounds.

The reduced reactivity of PHBP is ideal for monobrominating activated aromatic ethers and phenols such as pyrogallol.[5,27] A kinetic study of the reaction of phenols with PHBP has been reported.[28] Anilines are selectively monobrominated with mostly *para* substitution in 75-95% yield.[6] PHBP has been used for the analytical detection of phenols[30] and anilines.[31] Bromine-dioxane is a comparable reagent for brominating phenols. [18]Annulene has been monobrominated with PHBP in 44% yield.[29]

Heating PHBP to 230 °C affords 3-bromopyridine (37%) and 3,5-dibromopyridine (33%).[7] In contrast, indoles,[32] imidazoles,[33] phenothiazines,[34] and azathiabenzenes[35] are readily monobrominated with PHBP at rt or at lower temperatures.

Dehydrogenations/Oxidations.

PHBP is a convenient reagent for conversion of cyclohexenones to phenols in steroids,[8] tricyclic diterpenoids (eq 4),[36] and other polycyclic compounds.[37]

(4)

Combination oxidation-brominations have been reported to occur using PHBP in conjunction with *t*-butyl alcohol (eq 5).[38] Enediol silyl ethers are converted to 1,2-diones with PHBP (eq 6).[39] Oxidations of phosphinic and phosphonic acids are reported to be first order in both the oxyacid and PHBP.[40] Phosphites are oxidized to phosphates in the presence of alcohols and PHBP.[41]

(5)

(6)

Kinetic and mechanistic studies on the oxidation of primary alcohols by PHBP have been reported;[10] however, many other more selective reagents are commonly used to oxidize alcohols (e.g. see Jones reagent (see ***Chromic Acid***), ***Manganese Dioxide***, ***Pyridinium Dichromate***, etc.).

Bromination of Organometallic Compounds.

PHBP is an effective bromination reagent for compounds that are highly sensitive or prone to decomposition. If bromine is substituted for PHBP in eq 7, the nickel-cyclobutadiene complex decomposes.[42] Good yields are obtained when bromine from PHBP displaces an aryl group from the bismuth compound of eq 8.[43] Studies of brominations of metal chelates of β-diketones and β-keto esters have been described.[44]

(7)

(8)

R = $C_6H_4CF_3$, 88%; C_6H_4Me, 82%; Me, 70%

Other Applications.

PHBP has been used to prepare alkyl bromides from alcohols.[45] It is also effective in phase transfer nitrosation of amines.[46] Thioacetals are oxidized in 78-91% yield to ketones and aldehydes with PHBP under phase transfer conditions.[47] Dihydropyridines have been heated with PHBP to afford lactones via the postulated bromomethyl intermediate shown in eq 9.[48] This intermediate is stable at low temperatures and can be reacted with nucleophiles to give varying yields of substituted dihydropyridines.[49] PHBP has also been used to monobrominate active methylene groups.[50]

Pyridinium Poly(hydrogen fluoride)[1]

($C_5H_5N.9HF$; 30% pyridine, 70% HF by wt)

[32001-55-1] · $C_5H_{14}F_9N$ · Pyridinium Poly(hydrogen fluoride) · (MW 259.20)

(convenient, less volatile form of anhydrous HF with enhanced nucleophilicity; substitutes F for secondary or tertiary hydroxy groups,[2] other halides,[3] or primary amine[4] groups; adds HF to alkenes and alkynes;[1d] with halonium ion sources, halofluorinates alkenes and alkynes;[1a,5] opens and adds HF to oxiranes (epoxides), aziridines, azirines, and cyclopropanes;[1] oxidatively fluorinates when combined with electrolytic processes or Pb^{IV} compounds[1c,e])

Alternate Names: Olah's reagent; hydrogen fluoride-pyridine

Physical Data: dissoc 55 °C; at 80-110 °C, liq phase is primarily py.5HF; at reflux (160-170 °C) the stoichiometry is py.3HF; low-temperature phase behavior and X-ray crystal structures for some phases are known.[6]

Solubility: sol CH_2Cl_2, MeCN, Et_2O, THF, toluene, sulfolane.

Form Supplied in: light brown liquid in plastic bottles; H_2O most likely impurity (from HF used); commercially available.

Preparative Method: condensation of anhydrous ***Hydrogen Fluoride*** into ***Pyridine*** at -78 °C, followed by gradual warming to rt; *caution*: highly exothermic.[1d,e]

Purification: best approach is to purify components (pyridine, HF) before mixing.[7] HF can also be dried using ***Antimony(V) Fluoride***,[8] BiF_5,[8,9] high-pressure ***Fluorine***,[10] or electrolysis.

Handling, Storage, and Precautions: toxic, hygroscopic, corrosive. Moisture drastically inhibits fluorination activity. Compatible materials: polyethylene, fluoro polymers (FEP, PFA, PTFE). Hydrogen pressure may accumulate in metal HF storage containers. Avoid contact with glass. ***Sodium Fluoride***, aq base, and $CaCl_2$ are useful for neutralization and workup. Reagent contains a small equilibrium concentration of HF. Although the reduced HF vapor pressure in py.$(HF)_x$ reduces the potential for exposure, extreme care should be used in handling this material; handle only in a fume hood, wear safety goggles or a face shield, and wear appropriate impermeable clothing. Effects of exposure to HF are often delayed for several hours, but the burns are extremely painful and can be slow to heal. Exposure to py.$(HF)_x$ should be treated in the same way as for HF. Thus users and coworkers should be familiar with and be prepared to administer the proper first aid treatment.[11]

Substitution Reactions.

Fluorodehydroxylation.

Secondary and tertiary alcohols react with py.$(HF)_x$ to give alkyl fluorides. The tertiary compounds react quickly at temperatures as low as -70 °C, while rt is usually sufficient for secondary alcohols. This can provide significant regioselectivity as shown for reactions at the competitive sites in a steroid (eq 1).[12] Primary alcohols require the addition of NaF for the substitution to occur. The probable S_N2 mechanism of the reaction is illustrated by the lack of rearrangement upon fluorination of neopentyl alcohol (eq 2)[2] (for alternative reagents, see fluoroalkylamine reagents (FAR), ***N,N-Diethylaminosulfur Trifluoride*** (DAST)).

(1)

(2)

Halogen Exchange.

No fluorination of tertiary alkyl halides occurs unless the halide is abstracted by an agent such as a nitronium salt (eq 3).[3] Related $R_3N.3HF$ complexes are more effective for nucleophilic halide replacement.[1c]
