
(3)

Fluorodeamination.

Substitution of F for NH_2 is achieved by an in situ diazotization-fluorinative dediazotization sequence. For example, α-fluorocarboxylic acids are obtained from α-amino acids, as shown for 2-aminobutanoic acid (eq 4).[4] Retention of configuration is usually observed.

(4)

Addition Reactions.

Hydrofluorination of Alkenes and Alkynes.

Addition of HF takes place in Markovnikov fashion. Among alkenes, branched derivatives and cycloalkenes give higher yields (eq 5).[1d,e] As expected, *gem*-difluoro derivatives are obtained from alkynes (eq 6).[1d] THF is often used as a cosolvent since the starting materials are generally insoluble in py.$(HF)_x$. The related melamine.$(HF)_x$ reagent is especially effective for hydrofluorination of unsaturated substrates and can be used repeatedly in pentane or CCl_4 two-phase systems.[1c]

(5)

(6)

Halofluorination of Alkenes and Alkynes.

When these unsaturated compounds are combined with py.$(HF)_x$ and a source of halonium ion (e.g. *N*-halosuccinimides, *N*-haloacetamides, or ***1,3-Dibromo-5,5-dimethylhydantoin*** (DBH)), addition of XF (X = Cl, Br, I) to the multiple bond is the result. Alkenes provide several potentially useful extensions from the initial 1,2-halofluoroalkane products.[1a] For example, addition of ***Silver(I) Fluoride*** to the initial product results in halogen exchange yielding vicinal difluorides without isolation of the intermediates. Similarly, reduction of the intermediates with a tin hydride reagent gives products corresponding to Markovnikov addition of HF to the starting alkene. Elimination reactions of the intermediates with base lead to vinyl fluorides. Alkene halofluorination was found to exhibit Markovnikov and anti-Markovnikov orientation in the case of 1-phenyl-4-*t*-butylcyclohexene.[13]

Bromofluorination of phenylacetylene using py.$(HF)_x$ and DBH in sulfolane (eq 7)[5] gave a mixture of (*Z*) and (*E*) isomers but with good regio- and stereoselectivity.

(7)

Ring-Opening Fluorination.

The fluoride ion donor ability of py.$(HF)_x$ is shown by the cleavage of cyclopropane (eq 8),[14] in which fluoride traps the primary cation before it can rearrange. Regioselective conversion of oxiranes to fluorohydrins has become an important process in the steroid field (eq 9).[15] An iterative cyclization/ring opening approach has served in the conversion of a tetrachlorocyclohexanol to its tetrafluoro analog with complete regio- and stereoselectivity.[16] In the case of aziridines the ring opening is regioselective in that fluoride becomes bound to the carbon best able to stabilize a positive charge, but the stereochemistry depends strongly on the starting material and the fluorinating agent.[1c,e] Substituted 1-azirines give difluorinated amines or α-fluoro ketones, depending on the substituents.[1c,e]

(8)

Oxidative Fluorination.

With py.$(HF)_x$ and stoichiometric amounts of Pb^{IV}, phenols are converted to difluorodienones (eq 10). Benzene reacts very slowly to give the same product.[1b,c] Similar reactions can be conducted using anodic oxidation in place of the lead compounds. In both situations, cations or radical cations are proposed as the initially generated species, which then react with fluoride. For these reactions, ***Triethylamine***.3HF is used most often.

Related Reagents.

Several applications of Et_3N.3HF and melamine.$(HF)_x$ have been mentioned above. In addition, 2,4,6-trimethylpyridine.$(HF)_x$ [*45725-47-1*] is useful since it is a commercially available solid melting at 90 °C. A polymer-supported agent containing about 35-40% HF, poly[4-vinylpyridinium poly(hydrogen fluoride)], is also available.[17]

Pyridinium *p*-Toluenesulfonate

[24057-28-1] · $C_{12}H_{13}NO_3S$ · Pyridinium *p*-Toluenesulfonate · (MW 251.33)

(used as an acid catalyst for the protection and deprotection of alcohols and acetals)

Alternate Name: PPTS.

Physical Data: mp 120-121 °C.[1,2]

Solubility: sol benzene, toluene, dichloromethane, chloroform, ethanol, and acetone.

Form Supplied in: white, moisture-sensitive crystalline solid.

Preparative Method: prepared in a 95% yield by the addition of ***p-Toluenesulfonic Acid*** to ***Pyridine*** at 22-24 °C.[1,2]

Purification: recrystallized from acetone.[1,2]

Handling, Storage, and Precautions: the title reagent is moisture sensitive, requiring storage under nitrogen in a desiccator over a suitable drying agent. Stored in this manner, the reagent has an excellent shelf life. Irritant; handle with gloves.

Properties and General Considerations.

PPTS (**1**) is a weakly acidic salt frequently used in catalytic quantity for the protection of alcohols as tetrahydropyranyl (eq 1)[1] and trimethylsilyl ethers (eq 2).[3]

(1)

(2)

PPTS is particularly favored for use with acid-sensitive functionalities such as allylic alcohols, epoxides, and acetals. *N*-Tosyl-L-norephedrine has been converted to its oxazolidine using a catalytic amount of (**1**) (25 mol%) and ***Triethyl Orthoformate*** (eq 3).[3]

(3)

p-Methoxyphenol has been protected as its THP ether (80% yield) using 4 equiv of (**1**).[4] All these reactions are run in dry aprotic solvent (benzene, toluene, or dichloromethane) and water formed during the course of the reaction is removed by azeotropic distillation or by 4 Å molecular sieves. Yields are good to excellent.

Cleavage of *t*-Butyldimethylsilyl Ethers.

A catalytic quantity of (**1**) (30 mol %) in ethanol selectively cleaves *t*-butyldimethylsilyl ethers in the presence of *t*-butyldiphenylsilyl ethers (eq 4).[5]

(4)

Acetalization.

PPTS is an excellent catalyst for the preparation of 1,3-dioxolane acetals from ketones and ethanediol (90-95% yield).[6] The weak acidic nature of (**1**) makes it ideal for acid-sensitive compounds.

(5)

The reaction is carried out using 10-30 mol % of (**1**) in refluxing benzene, accompanied by the azeotropic removal of water (Dean-Stark apparatus). Similar conditions have been used for the preparation of acetals using (*R*,*R*)-hydrobenzoin and a tricyclic benzaldehyde derivative.[7]

Deprotection of Acid-Sensitive Protecting Groups via Transacetalization.

PPTS is a versatile catalyst for the deprotection of acid-sensitive acetal protecting groups. For example, 10-30 mol % of (**1**) efficiently cleaves tetrahydropyran ethers (THP) (eq 6),[1] 1,3-dioxolanes (eq 7),[6] methoxymethyl ethers (MOM), and methoxyethoxymethyl ethers (MEM) (eq 8).[8]

(6)

(7)

(8)

R = CH_2OMe (MOM), 94%
R = $CH_2OCH_2CH_2OMe$ (MEM), 93%

2-Methoxybutadienes.

PPTS catalyzes the isomerization of allenyl ethers to 1-alkyl-2-methoxybutadienes. Freshly prepared crude allenyl ethers are treated with (**1**) (1 mol %) in dichloromethane at room temperature (eq 9).[9]

(9)

2-Alkyl-3-acylfurans.

PPTS converts 5-acetoxy-4,5-dihydrofurans to the corresponding furans (eq 10).[10] The reaction is carried out in refluxing toluene for 3-6 h. Yields are poor to modest.

(10)

α-Alkoxyhydrazines.

Reaction of α-sulfinylhydrazones with alcohols in the presence of (**1**) (10-30 mol %) results in α-oxy substituted hydrazines (eq 11).[11]

2-Pyridone[1]

[142-08-5] · C_5H_5NO · 2-Pyridone · (MW 95.11) (iminol tautomer)

[72762-00-6]

(ambident nucleophile,[2] diene for [4 + 2] cycloaddition;[3] used to form active esters in peptide synthesis[4])

Alternate Name: α-pyridone.

Physical Data: mp 105-107 °C; bp 280-218 °C; λ_{max} 293 nm (ε 5900, H_2O).

Solubility: sol H_2O, EtOH, $CHCl_3$; moderately sol Et_2O, C_6H_6; sparingly sol ligroin, hexane.

Form Supplied in: crystalline; widely available.

Purification: commercial material is distilled under vacuum (181-185 °C/24 mmHg) to remove colored impurities. The distillate is recrystallized from EtOH, $CHCl_3$/ether, C_6H_6, C_6H_6/hexane, or CCl_4.[5] Alternatively, high purity material can be prepared by sequential recrystallization,[2] sublimation,[6] or a combination of both techniques.[7]

Handling, Storage, and Precautions: store refrigerated, preferably under an inert atmosphere. Uses of the iminol tautomer of this reagent as a coupling agent are considered under ***2-Hydroxypyridine***.

General Considerations.

2-Pyridone (**1**) is a classical substrate for the study of iminol-amide tautomerism (eq 1). In polar media the pyridone form is favored;[6] the tautomeric equilibrium shifts to the hydroxypyridine form as solvent polarity decreases. In the vapor phase the hydroxypyridine form predominates.[8] Consequently, nucleophilic substitution reactions using various electrophilic reagents can and sometimes do provide mixtures of isomeric products. In the case of simple alkylation, *N*-alkylation is most commonly observed when the conjugate base of (**1**) is used as nucleophile,[2,9,10] as illustrated by the conjugate addition-elimination product (**2**) (eq 2) formed by addition of (**1**) to 3-chloro-5,5-dimethyl-2-cyclohexenone in the presence of ***Potassium Carbonate***.[11]

(1)

Regiospecific *N*-alkylation also is observed with Pt- and Pd-catalyzed allylations[12] and with sulfenium ions generated from a Pummerer reaction of tetramethylene sulfoxide.[13] Solvent and counterion effects are substantial: polar solvents favor *N*-alkylation, while the Ag salt of (**1**) is highly biased towards *O*-alkylation.[2] Silyl ethers form when ***Trimethylsilyl Trifluoromethanesulfonate*** is used as electrophile with ***Triethylamine*** present;[13] similarly, the dimethylphosphinite is the sole product when (**1**) is reacted with chlorodimethylphosphine.[7a] Kinetically controlled methylation of (**1**) with ***Diazomethane*** provides ~60:40 ratio of *N*-methyl and *O*-methyl products,[7b] while hard electrophiles such as 2-methoxybiphenyl-2´-yldiazonium fluoroborate provide exclusive *O*-methylation.[14] Other things being equal, substrate identity can influence the regiospecificity of alkylation (eq 3).[15]

(3)

n		
1	19%	38%
2	-	76%

Acylations of (**1**) are less well known: acetylation at cold temperatures results in a mixture of products; the *N*-acetyl derivative rearranges to the thermodynamically preferred *O*-acetyl isomer upon warming to room temperature (eq 4).[16] Benzoylation[17] and triflation[18] provide only ester products from attack at the oxygen of (**1**).

(4)

[4 + 2] Cycloaddition reactions of (**1**) usually are difficult to achieve.[3] 2-Pyridone itself is prone to undergo conjugate addition reactions with dienophiles,[19] but *N*-alkyl derivatives, especially *N*-methyl and *N*-alkenyl derivatives, are found to form *N*-alkylated isoquinuclidine adducts with highly reactive dienophiles such as ***Dimethyl Acetylenedicarboxylate*** (eq 5),[19,20] ***Maleic Anhydride***, and benzyne[21] under thermal or high pressure conditions. When heated, the adducts can aromatize via alkyl isocyanate extrusion. Related *N*-arylsulfonyl-3-(*p*-toluenesulfonyl)-2-pyridones are relatively good dienes in inverse electron demand Diels-Alder reactions with vinyl ether dienophiles;[3] these cycloadditions are facilitated by high pressure.

+ MeNCO (5)

Although intramolecular [4 + 2] cycloadditions of *N*-(o-alkenyl)-2-pyridones have been unsuccessful,[21a] photosensitized intramolecular [2 + 2] cycloadditions of these substrates provide a simple route to stereochemically defined tricyclic lactams.[10] A unique intramolecular 1,3-dipolar cycloaddition between DMAD and an azomethine ylide generated from *N*-(3´-diazoacetonyl)-2-pyridone provides indolizinone products.[9]

2-Pyridone is useful in the preparation of active esters for solid-phase peptide synthesis;[4] these esters are considerably more reactive than the corresponding *p*-nitrophenyl esters when peptide coupling is performed in CH_2Cl_2. In one application to peptide synthesis, 2-pyridyl esters serve as intermediates in the preparation of 2,2,2-trichloroethyl esters of amino acids (eq 6).[22]

Other uses of 2-pyridone include that as a ligand in transition metal complexes, such as the preparation of complexes derived from chloro-bridged Ru^{IV} bis(allyl) dimers[23] and triruthenium carbonyl complexes from $Ru_3(CO)_{12}$.[24] *N*-Hydroxy-2-pyridone can be used to effect radical decarboxylation: *N*-dihydrocinnamyloxy-2-pyridone is reduced by ***Tri-n-butylstannane*** with ***Azobisisobutyronitrile*** initiation to provide ethylbenzene in 73% yield.[25] Finally, 2-hydroxypyridinium tosylate acts as an acid catalyst in the dimerization of α-aminoacrylonitrile.[26]

Related Reagents.

Methanesulfonic Anhydride.

Creighton University, Omaha, NE, USA

2-Pyrone[1]

[504-31-4] · $C_4H_4O_2$ · 2-Pyrone · (MW 96.08)

(diene for cycloadditions[2] and inverse electron demand cycloadditions;[3] used in the synthesis of cyclobutadiene[4])

Physical Data: mp 8-9 °C; bp 206-209 °C (slight dec), 102-103 °C/20 mmHg; *d*204 1.200 g cm^{-3}; *n*20D 1.530.

Solubility: miscible with H_2O.

Form Supplied in: liquid; available in 95-98% purity commercially.

Preparative Methods: can be prepared in 66-70% chemical yield by pyrolytic decarboxylation of coumalic acid on copper turnings at 650 °C.[5] Alternatively, the dihydro analog, 5,6-dihydro-2*H*-pyran-2-one, can be prepared by acid-catalyzed condensation of vinylacetic acid and ***Formaldehyde***.[6] Allylic bromination followed by dehydrobromination provides 2-pyrone in overall chemical yields of ca. 18%.

Handling, Storage, and Precautions: decomposes upon heating.

General Considerations.

2-Pyrone and its analogs (see ***3-Hydroxy-2-pyrone***, ***2-Pyridone***) find use in cycloaddition reactions, providing bicyclolactone adducts which can be elucidated into a variety of highly functionalized cyclohexadienes and benzenes. This pyranone reacts with a wide variety of standard dienophiles, including ***Maleic Anhydride***,[7] ***Dimethyl Acetylenedicarboxylate***,[8] fumarates,[9] ***Methyl Vinyl Ketone***,[10] and acrylates.[9,10] Under typical thermal conditions the bicyclolactone intermediate is not isolated; in situ decarboxylation leads to cyclohexadiene or benzene products. In the former case, a second equivalent of dienophile may undergo cycloaddition with the initial product, leading to 2:1 adducts from tandem cycloaddition.[11] High pressure cycloaddition conditions may alter this outcome (eq 1).[7,9]

(1)

This approach has been used to prepare barrelene[10] and other molecules of interesting topologies.[12] A two-step, intramolecular version of this tandem cycloaddition using an unactivated double dienophile (eq 2)[13a] represents a convergent approach to polycyclic compounds of interest in natural products synthesis.[13,14]

(2)

When itaconic anhydride is used as dienophile and the resultant adduct decarboxylated, the interesting toluene tautomer 5-methylene-1,3-cyclohexadiene is produced;[15] similarly, use of benzocyclobutene as the dienophile, followed by in situ decarboxylation, provides a route to chemically and theoretically interesting benzocyclooctatriene.[16] With benzoquinones as dienophiles, substituted 2-pyrones provide strategic diene subunit synthons in anthraquinone synthesis.[17] Alkyne dienophiles always result in *o*-disubstituted benzene products,[8,18] with rare exception.[19] [4 + 2] Cycloaddition reactions using cyclopropanes[20] and nitrosobenzene[21] have been reported, as have [4 + 2], [3 + 4], and [3 + 2] cycloadditions using a 1,1-/1,3-dipole cyclopropenone acetal.[22]

Thermal or high pressure dimerizations for the most part lead to polymerization.[23] At very high (625 °C) temperatures, rearrangement by reversible electrocyclic ring opening to provide intermediate ketene aldehydes can be observed.[24] On the other hand, photosensitized dimerization of 2-pyrone yields a mixture of the expected *exo* dimers (**1**) and (**2**).[25] Direct irradiation of 2-pyrone in ether leads to bicyclo[2.2.0]pyran-2-one (**3**),[26] the direct precursor to cyclobutadiene via photodecarboxylation (eq 3).[27]

(1)

(2)

(3)

(3)

Nucleophilic addition reactions of 2-pyrone can be complex; benzylthiolate, cysteine, cysteine methyl ester, and *N*-acetylcysteine all give complex mixtures of products when reacted with 2-pyrone.[28] Grignard reagents undergo 1,2-additions to the carbonyl moiety,[29] as do alkoxides.[30] Metal hydrides can provide either 1,2-addition or 1,6-addition.[31] Reaction with ammonia affords 2-pyridone; ***Diazomethane***[32] and cyanide attack at C-6 (eq 4).[33]

(4)

Electrophilic substitutions of 2-pyrones are possible.[1] In the case of bromination or chlorination, 3-halo-2-pyrones form by means of sequential halogenation-dehydrohalogenation, rather than by direct electrophilic substitution.[34] 3-Bromo-2-pyrone itself undergoes metal-halogen exchange with ***Lithium Dimethylcuprate***, resulting in 3-cuprio-2-pyrone.[35] This organocopper reagent, which is the least nucleophilic of those reported in the literature, has properties reminiscent of organocopper reagents derived from α-bromoacrolein and α-bromoacrylates (see ***Lithium (3,3-Diethoxy-1-propen-2-yl)(phenylthio)cuprate***).

Pyrophosphoryl Chloride

[13498-14-1] · $Cl_4O_3P_2$ · Pyrophosphoryl Chloride · (MW 251.74)

(phosphorylating agent used in nucleoside synthesis;[5,7] used in Vilsmeier formylation and glyoxylation reactions[4,8])

Alternate Names: diphosphoryl chloride; pyrophosphoryl tetrachloride.

Physical Data: bp 60-65 °C/0.1 mmHg, 90 °C/12 mmHg.

Solubility: sol most organic solvents but reacts with alcohols.

Form Supplied in: liquid; available commercially.

Purification: redistil under reduced pressure.

Preparative Methods: prepared in 30% yield by heating ***Phosphorus(V) Oxide*** and ***Phosphorus Oxychloride*** in a sealed tube and separating the resulting mixture by fractional distillation.[1] Alternatively, can be prepared by reaction of phosphoryl chloride with a controlled amount of water.[2] Until recently, the most convenient method involved the reaction of phosphoric anhydride with ***Phosphorus(III) Chloride*** and ***Chlorine***.[3] A recent procedure involves the reaction at reflux of phosphoryl chloride with 0.2 equiv of methanol for 21 days followed by removal of the excess phosphoryl chloride and distillation of the residue to give the reagent (**1**) in 49% yield (eq 1).[4]

Handling, Storage, and Precautions: corrosive; reacts violently with water; irritating to eyes, respiratory system, and skin. Use in a fume hood.

Phosphorylation.

Pyrophosphoryl chloride (**1**) has been used in the phosphorylation of a variety of primary alcohols. It reacts with primary alcohols according to the scheme in eq 2. Thus reaction at low temperature between (**1**) and a primary alcohol in the absence of solvent gives a dichlorophosphoric acid derivative (**2**), which on treatment with water gives a monophosphate (**3**).

This is a particularly effective sequence for the synthesis of nucleoside monophosphates. For example, treatment of 2´,3´-isopropylideneadenosine (**4**) with (**1**) below rt followed by treatment with water and subsequent removal of the isopropylidene group gave adenosine 5´-phosphate in 65-85% yield (eq 3).[5] 2´,3´-Isopropylideneguanosine reacted similarly. This method avoids the need for base catalysis and removal of organic residues.

This has been applied to systems other than nucleotides. For example, a range of C-21-hydroxylated steroids have been phosphorylated in high yield by reaction with (**1**) at 0 °C followed by quenching in ice water.[6] The reaction fails with cortisone and produces considerable quantities of dehydration product with C-11-hydroxy steroids. These authors also report that little or no phosphorylation was observed when (**1**) was used in organic solvents.

Pyrophosphate Esters.

In addition to the synthesis of monophosphates, pyrophosphoryl chloride has also been used to prepare pyrophosphate esters. Reaction of (**1**) with 2´,3´-isopropylideneadenosine (**4**) in the presence of ***Triethylamine*** gave the pyrophosphate ester (**5**), which on hydrolysis with aqueous ***Formic Acid*** gave a 22% yield of adenosine diphosphate (ADP) (**6**) (eq 4).[7]

This approach to pyrophosphate esters has been extended to mixed esters such as coenzyme A, although the yield was very low (<1%).[7]

Formylation.

In the classical Vilsmeier reaction, ***N,N-Dimethylformamide*** and phosphoryl chloride are used and the reaction is usually assumed to involve the

N,*N*-dimethylchloromethyleneiminium ion as the electrophile (see also ***Dimethylchloromethyleneammonium Chloride***). Recently, pyrophosphoryl chloride (**1**) has been investigated as the activating agent.[4] Reaction of (**1**) with an excess of DMF or *N*-methylformanilide at 0 °C in the presence of an electron-rich aromatic compound followed by heating (for unreactive aromatics) or simply standing (for reactive substrates) followed by treatment with ***Sodium Hydroxide*** gave aromatic aldehydes in good yields (eq 5). The reaction gave 4-methoxybenzaldehyde from the usually unreactive anisole in 72% yield.

This reaction has been extended to a greater range of heterocycles, including furan and thiophene derivatives, and it has been shown that the bulky nature of the electrophilic species biases the reaction to give attack at the least hindered position.[8] In addition, glyoxylation of dioxygenated benzenes, *N*-alkylpyrroles, and *N*-alkylindoles has been achieved in good yield using (**1**) and methyl oxamates derived from methyl oxalyl chloride and either pyrrolidine or morpholine (eq 6).[8]

Pyrrolidine

[123-75-1] · C_4H_9N · Pyrrolidine · (MW 71.14)

(secondary amine used for the formation and utilization of enamines;[2] catalyst for aldol cyclization[17] and Mannich condensation;[23] formation of secondary amides[28])

Physical Data: bp 88.5-89 °C; *d* 0.8618 g cm^{-3}; pK_a 11.1.

Solubility: miscible with water; sol alcohol, chloroform, and ether.

Form Supplied in: liquid, 99%; widely available.

Purification: distilled under nitrogen after drying with sodium or BaO.[1]

Handling, Storage, and Precautions: flammable; fumes in air; strong base; irritant. Use in a fume hood.

Enamine Preparation and Utilization.[2]

The principal use of pyrrolidine in synthesis is in the formation and utilization of ketone and aldehyde enamines. For preparation of the enamine a benzene or toluene solution of the carbonyl compound and pyrrolidine is heated at reflux with azeotropic removal of water. Acid catalysts or molecular sieves as water trapping agents are frequently employed. Cyclopentanone[3-5] and cyclohexanone,[3-6] for example, react in benzene to form enamines without added acid catalyst (eqs 1 and 2), as does β-tetralone (eq 3).[7]

(1)

(2)

(3)

In toluene solution, cyclododecanone is converted to the pyrrolidine enamine in the presence of ***Boron Trifluoride Etherate*** (eq 4).[8]

(4)

Acyclic ketones form pyrrolidine enamines sluggishly or with significant self-condensation. The enamine of diethyl ketone may be prepared in modest yield in the presence of 4 Å molecular sieves (eq 5).[5]

(5)

The pyrrolidine enamine of a relatively low-boiling aldehyde, isobutyraldehyde,[9] may be prepared by heating the base and the carbonyl component without additional solvent (eq 6).

(6)

The reaction of ketones with pyrrolidine, ***Dimethyl Diazomethylphosphonate***, and base yields the pyrrolidine enamine of the homologous aldehyde (eq 7).[10]

(7)

Enamino ketones have been prepared from β-chlorovinyl ketones (eq 8)[11] or directly from the corresponding β-dicarbonyl compound (eq 9).[12]

(8)

(9)

The reaction of pyrrolidine with monoalkylated cyclohexanones results in the formation of the less substituted enamine as the major product (eq 10).[5]

(10)

Regioselectivity is also observed in the formation of an enamine from 3-tri-*n*-butylstannylcyclohexanone and pyrrolidine (eq 11).[13]

(11)

Pyrrolidine enamines react with both alkyl halides and electrophilic alkenes[2-5,7,14] to provide α-alkylated ketones and aldehydes (eqs 12 and 13). The great advantage of enamines over simple enolates in these reactions is that they do not overalkylate. Monosubstitution products are generally obtained. Acylation at carbon to afford β-dicarbonyl compounds occurs upon exposure of pyrrolidine enamines to acyl halides, but less effectively than with the corresponding morpholine enamine.[5]

(12)

(13)

Pyrrolidine enamines also undergo [2 + 4] cycloaddition reactions with ***1,2,4-Triazine*** to provide, following loss of dinitrogen and aromatization, substituted pyridines (eq 14) and isoquinolines.[15,16]

(14)

Condensation Reactions.

Pyrrolidine is a common catalyst for the aldol cyclization phase of the Robinson annulation process for both diketones[14,17-20] and keto aldehydes (eqs 15 and 16).[21]

(15)

(16)

Spirocyclization has been shown to be favored over hydronaphthalenone closure in the reactions of substituted formylcyclohexanedione ethers (eq 17).[22]

(17)

In similar fashion to aldol cyclizations, Mannich-type condensations are frequently carried out with pyrrolidine as the secondary amine component. The enamine of cyclohexanone reacts with an *o*-hydroxyacetophenone to afford a spirochromanone product (eq 18).[23]

(18)

Phenols acting as the enol component of the Mannich process react with aldehydes in the presence of pyrrolidine (eq 19).[24]

(19)

Pyrrolidine is also the most effective catalyst for the condensation of both aldehydes and ketones with cyclopentadiene to provide fulvenes (eqs 20 and 21).[25-27] In these cases the pyrrolidine has been shown to play the roles of both base catalyst and enamine-forming amine. The rates of such condensations are greater with pyrrolidine than with other secondary amine catalysts, a result attributable to the minimum steric hindrance exhibited by the cyclic amine.

(20)

(21)

Amide Formation.

Pyrrolidine is an effective reagent for the formation of secondary amides from esters (eq 22) and urethanes from thiocarbonates (eq 23).[28,29]

[13815-46-8] · $C_8H_{15}N$ · Dimethylamino-1-cyclohexene · (MW 125.24)

(both the enamine nitrogen and its β-carbon atom are nucleophilic, undergoing substitution or conjugate addition;[1] can take part in 1,2- or 1,4-cycloadditions;[1] iminium salts act as electrophiles[1,2])

Physical Data: (**1**) bp 114-115 °C/15 mmHg; *n*20D 1.5217; IR (C=C) 1638 cm^{-1}. (**2**) bp 118-120 °C/10 mmHg; *n*20D 1.5146; IR (C=C) 1641 cm^{-1}. (**3**) bp 108-109 °C/12 mmHg; *n*20D 1.5144; IR (C=C) 1637 cm^{-1}. (**4**) bp 122-126 °C/8 mmHg; *n*20D 1.5251; IR (C=C) 1632 cm^{-1}. (**5**) bp 171-172 °C; *n*20D 1.4747.

Preparative Methods: the most commonly used method of preparation for these enamines is the acid-catalyzed condensation of a secondary amine with cyclohexanone.[3] An example is the reaction of ***Pyrrolidine*** with cyclohexanone (eq 1).[3a] The use of a preformed ***Titanium(IV) Chloride***-amine complex with cyclohexanone greatly decreases the reaction time while maintaining high yields.[4]

This technique is also is effective with functionalized cyclohexanones.[5] When unsymmetrical tin(II) amides are allowed to react with cyclohexanone, good yields of enamines result.[6,7]

Handling, Storage, and Precautions: readily reacts with water or atmospheric oxygen; should be stored under dry nitrogen.

Alkylation.

Alkylation at the carbon α to a carbonyl group can be accomplished by use of metal alkoxides to form an enolate anion. However, this may lead to poor results with ketones because of rapid proton exchange and incomplete conversion to the enolate. Although the introduction of lithium dialkylamide bases has solved this long-standing problem, enamine alkylation has certain other advantages. These advantages are the following: (1) strongly basic (or acidic) conditions are not required; (2) the major product is the monoalkylated derivative; (3) when dialkylation is observed (using excess of alkyl halide), it occurs at the least substituted carbon, in contrast to alkylation with base, where the α-disubstituted product is formed; hence 1-pyrrolidino-1-cyclohexene on treatment with 2 equiv of ***Allyl Bromide*** followed by hydrolysis gives 2,6-diallylcyclohexanone (eq 2);[8] (4) the byproduct formed by alkylation at nitrogen is easily removed from the desired *C*-alkylation product.

The size of the heterocyclic amine rings is an important factor in determining the ratios of *C*-alkylation to *N*-alkylation. The pyrrolidine enamine gives some of the best yields whereas morpholine enamines give poorer yields. Since enamines are generally weaker nucleophiles than enolate anions, the list of generally useful alkylation agents is restricted to methyl-, allyl-, or benzyl-type halides (eq 3).[9]

Electrophilic radicals have been used to alkylate cyclic enamines (eq 4),[10] and reductive alkylation of enamines via a radical pathway has been shown to be stereoselective (eq 5).[11,12]

A photoinduced electron transfer reaction with difluorodiiodomethane gives 2-(trifluoromethyl)cyclohexanone (eq 6).[13] This reaction apparently involves elimination of iodide and addition of fluoride, either before or after the α-alkylation reaction.

(6)

The series of electrophilic alkenes that typically undergo Michael addition to cyclic enamines are α,β-unsaturated ketones (eq 7),[14] α,β-unsaturated nitriles (eq 8),[1a] α,β-unsaturated esters,[1a] α,β-unsaturated sulfones,[15] and nitroalkenes (eq 9).[16] Electrophilic alkenes generally attack enamines of cycloalkanones in a stereospecific antiparallel manner.[1,17,18]

(7)

(8)

(9)

Acylation.

Acylation of cyclohexanone enamines using acyl halides takes place readily.[19] The morpholine enamine gives the best yields (eq 10).[1a] An extra mole of enamine must be present to remove the liberated HCl. Alternatively, an organic base such as ***Triethylamine*** can be used for this purpose. Acylation using acid chlorides having a β-hydrogen in the presence of triethylamine usually proceeds via the ketene and subsequent cycloaddition. The intermediate cyclobutanone is then opened to give the enamino ketone, which is hydrolyzed to the 2-acylcyclohexanone.[20]

(10)

Arylation.

Aryl halides with a halogen activated by electron-withdrawing groups react with enamines (eq 11).[21]

(11)

Cycloaddition.

Cycloadditions and annulation reactions take place when cyclohexanone enamines are allowed to react with 1-buten-3-one,[1a] 1,3-butadienephosphonate,[22] acrolein,[23-25] 1,4-diacetoxy-2-butene with ***Palladium(II) Acetate***,[26] or 5-nitropyrimidine (Scheme 1).[27]

Scheme 1

Further 2,3-(ethylenedisulfonyl)-1,3-butadiene acts as a diene in Diels-Alder reactions with enamines (eq 12).[28]

(12)

[2 + 2] Cycloaddition takes place with benzyne[21] and ***Dimethyl Acetylenedicarboxylate*** (Scheme 2).[29]

Scheme 2

Oxidation and Reduction.

Photooxygenation using singlet oxygen leads to α-diketones.[30] Use of *N*-sulfonyloxaziridines gives α-amino ketones (Scheme 3).[31]

Scheme 3

Use of trimethylene dithiotosylate produces the dithiane of cyclohexanone (eq 13).[3a]

(13)

The enamine is readily converted to cyclohexene via hydroboration (Scheme 3).[32]

Related Reagents.

Acrolein; ***Dimethyl Acetylenedicarboxylate***; ***1-(N,N-Dimethylamino)-2-methyl-1-propene***; ***Morpholine***; ***Pivalaldehyde***; ***Pyrrolidine***; ***1-Pyrrolidino-1-cyclopentene***; ***Bis[N,N-bis(trimethylsilyl)amino]tin(II)***.

1-Pyrrolidino-1-cyclopentene

(**1**; R = 1-pyrrolidino)

[7148-07-4] · $C_9H_{15}N$ · 1-Pyrrolidino-1-cyclopentene · (MW 137.25) (**2**; R = 4-morpholino)

[936-52-7] · $C_9H_{15}NO$ · 4-Morpholino-1-cyclopentene · (MW 153.25) (**3**; R = 1-piperidino)

[1614-92-2] · $C_{10}H_{17}N$ · 1-Piperidino-1-cyclopentene · (MW 151.28) (**4**; R = 1-perhydroazepino)

[7374-91-6] · $C_{11}H_{19}N$ · 1-Perhydroazepino-1-cyclopentene · (MW 165.31) (**5**; R = Me_2N)

[4840-12-4] · $C_7H_{13}N$ · Dimethylamino-1-cyclopentene · (MW 111.21)

(either the enamine nitrogen or its β-carbon atom is nucleophilic, undergoing substitution or conjugate addition;[1] can take part in 1,2- or 1,4-cycloadditions[1])

Physical Data: (**1**) bp 88-92 °C/15 mmHg; *n*20D 1.5155; IR (C=C) 1630 cm^{-1}. (**2**) bp 105-106 °C/12 mmHg; *n*20D 1.5118; IR (C=C) 1630 cm^{-1}. (**3**) bp 90-91 °C/12 mmHg; *n*20D 1.5042; IR (C=C) 1634 cm^{-1}. (**4**) bp 83-85 °C/1 mmHg; *n*20D 1.517; IR (C=C) 1630 cm^{-1}. (**5**) bp 68 °C/45 mmHg; IR (C=C) 1648 cm^{-1}.

Preparative Methods: the most commonly used method of preparation for these enamines is the acid-catalyzed condensation of a secondary amine with cyclopentanone (eq 1).[1a]

The use of a stoichiometric amount of ***Titanium(IV) Chloride*** makes it possible to produce highly hindered as well as ordinary enamines.[2,3] More highly hindered ketones react more rapidly with dimethylamine than with heterocyclic secondary amines such as ***Pyrrolidine*** (eq 2).[2]

Handling, Storage, and Precautions: readily reacts with water or atmospheric oxygen; should be stored under dry nitrogen.

Alkylation.[4]

Alkylation of these enamines can take place with activated alkyl halides or electrophilic alkenes. A biphilic combination of these two alkylating agents has been used in an annulation sequence (eq 3).[5]

(3)

Acylation.[6]

Acylation of morpholine enamines with acyl halides can take place in a normal manner (eq 4).[7]

(4)

Cycloadditions.

Diethyl maleate and ***Methyl Propiolate*** rapidly add to the enamines to form [2 + 2] adducts.[8,9] The propiolate adduct upon heating rearranges to a cycloheptadiene derivative (Scheme 1).[9]

Scheme 1

A similar cycloaddition takes place with ***Dimethyl Acetylenedicarboxylate*** in nonpolar solvents, but a pyrrolizine is formed in the polar solvent methanol.[10]

Reduction.

Hydroboration of 1-morpholino-1-cyclopentene with ***9-Borabicyclo[3.3.1]nonane*** followed by mild heating in methanol produces cyclopentene (eq 5).[11]

(5)

Related Reagents.

Dimethyl Acetylenedicarboxylate; ***(Dimethylamino)methyl Methyl Ether***; ***Methyl Propiolate***; ***Morpholine***; ***Pivalaldehyde***; ***Pyrrolidine***; ***1-Pyrrolidino-1-cyclohexene***.

2-Pyrrolidone Hydrotribromide

[52215-12-0] · $C_{12}H_{22}Br_3N_3O_3$ · 2-Pyrrolidone Hydrotribromide · (MW 496.07)

(selective brominating reagent for ketones;[1] used in bromination/dehydrobromination and bromination/oxidation sequences when high selectivity is required)

Alternate Name: PHT.

Physical Data: mp 88-90 °C.

Solubility: sol THF, dioxane, DMSO.

Form Supplied in: commercially available as red crystalline solid.

Analysis of Reagent Purity: active bromine content by $KI/Na_2S_2O_3$ titration.

Handling, Storage, and Precautions: irritant, hygroscopic solid; complex is stable.

Selective Brominations.

The reaction of molecular ***Bromine*** with 2-pyrrolidone in $CHCl_3$ yields the crystalline 2-pyrrolidone hydrotribromide. PHT contains 31.6% available bromine and has been found to be a remarkably selective brominating agent.[2] The relative reactivities towards bromination are: ketones >> alkenes >> enol acetates.[1] Reactions are generally run in THF. As the reaction proceeds, the solution loses the red color of the PHT and $(pyrrolidone)_2.HBr$ is precipitated from solution as colorless needles. This not only facilitates the recovery of the pyrrolidone, but offers a convenient method of monitoring the reaction.

Acid sensitive molecules can be protected by adding excess pyrrolidone to the reaction to trap liberated HBr. The mild conditions have allowed many functional groups to survive. These include enones (eq 1),[1] nitroxyl radicals (eq 2),[3] ergot alkaloids (eq 3),[4] benzothiophenes,[5] and numerous polyfunctional intermediates in natural products synthesis (eqs 4 and 5).[6,7]

(1)

(2)

(3)

(4)

(5)

The solvent used can also play an important role in PHT brominations. Since the bromination is a radical reaction, trace hydroperoxides present in solvents such as THF and dioxane facilitate the bromination. If hydroperoxide-poor solvents are used, radical initiators may be used.[4] When DMSO is used, either dehydrobromination[8] or oxidation[9] can occur, depending on the molecule (eqs 6 and 7).

(6)

(7)

The use of PHT selectivity followed by subsequent dehydrobromination[10-12] or oxidation[13] has contributed to the value of this reagent. The selectivity of PHT is considered superior to that of ***Phenyltrimethylammonium Perbromide*** (PHAT).[1]

1-Pyrroline 1-Oxide[1]

[24423-88-9] · C_4H_7NO · 1-Pyrroline 1-Oxide · (MW 85.12)

(prototypical cyclic nitrone for intermolecular 1,3-dipolar cycloadditions[1,2])

Physical Data: bp 74-76 °C/0.1 mmHg.

Solubility: sol dichloromethane, chloroform, ether, aromatic hydrocarbons, water.

Form Supplied in: not commercially available.

Preparative Methods: usually prepared by oxidation of 1-hydroxypyrrolidine with two equivalents of yellow ***Mercury(II) Oxide*** (HgO) in dichloromethane or chloroform at 0-10 °C.[3] After 4 h, the mixture is filtered to remove mercury salts and the nitrone is most often used without further purification, with or without solvent exchange. An alternative procedure is the direct oxidation of pyrrolidine with 30% aqueous ***Hydrogen Peroxide*** catalyzed by $Na_2WO_4.H_2O$ in water, followed by extraction with dichloromethane and chromatographic purification.[4] Although the yield is lower, this method has the advantages of pyrrolidine as the starting material and of avoiding the use and disposal of large quantities of mercury(II) salts.

A regiospecific oxidative decarboxylation of *N*-alkyl-α-amino acids under phase transfer conditions using H_2O_2 and Na_2WO_4 catalyst has been used successfully with proline to afford 1-pyrroline 1-oxide in 55% yield.[10] The method appears to be efficient and convenient for other cyclic as well as acyclic nitrones.

1,3-Dipolar Cycloadditions.

One of the more recent reviews cites 20 examples of cycloaddition between 1-pyrroline 1-oxide and acyclic and cyclic alkenes to give bicyclic (or tricyclic) isoxazolidines.[1a] These reactions are carried out in toluene at reflux or neat at 100 °C; however, α,β-unsaturated esters often react smoothly at room temperature. Numerous substituted 1-pyrroline 1-oxides have been studied, and intramolecular examples are known. The six-membered ring analog, 2,3,4,5-tetrahydropyridine 1-oxide, is also useful.[1a,4] The cycloadditions are both stereoselective and regioselective. Terminal alkenes give exclusively 5-substituted isoxazolidines with the substituent *cis* to the hydrogen at the ring fusion (*exo* transition state) (eq 1).[5] This is the expected regiochemistry for a nitrone LU-controlled process. When methyl crotonate was the educt alkene, the methoxycarbonyl group showed a preference for an *endo* transition state, as well as being positioned at C-4 in the isoxazolidine under conditions of kinetic control (eq 2).[6]

(1)

Ar = *p*-$MeOC_6H_4$

(2)

Electron-rich alkenes, i.e. vinyl ethers and enamines, undergo cycloaddition at slow rates and often give poor yields because of decomposition of the nitrone. High pressure conditions can obviate the problem (eq 3).[7]

(3)

One of the two syntheses of (±)-cocaine by Tufariello and co-workers[3] involved both an intermolecular and an intramolecular cycloaddition, and it utilized some of the numerous further transformations of the isoxazolidine ring that enhance the versatility of 1,3-dipolar cycloadditions of nitrones in synthesis (eq 4). A similar approach was taken to synthesize anatoxin-a.[8] The oxidative ring opening with ***m-Chloroperbenzoic Acid*** to generate an intermediate nitrone, the key to the success of this strategy, has recently been carried out on other polycyclic isoxazolidines with magnesium monoperoxyphthalate hexahydrate (MMPP).[9]

(4)

Other Reactions.

Like other nitrones, 1-pyrroline 1-oxide undergoes reactions with nucleophiles, electrophiles, and radicals, addition of organometallic reagents,[4] reduction, oxidation, etc.[2a] However, these reactions have their greatest utility with substituted analogs such as 5,5-dimethyl-1-pyrroline 1-oxide (DMPO), a useful spin trapping reagent for biologically generated radicals.

Pyruvaldehyde Diethyl Acetal

(R = Et)

[16330-13-5] · $C_7H_{14}O_3$ · Pyruvaldehyde Diethyl Acetal · (MW 146.21) (R = Me)

[18218-94-5] · $C_5H_{10}O_3$ · Pyruvaldehyde Dimethyl Acetal · (MW 118.15) (R,R = $-CH_2CH_2-$)

[39050-39-0] · $C_5H_8O_3$ · Pyruvaldehyde Ethylene Acetal · (MW 116.12)

(reagents for preparation of α-ethylenic[1] and α-allenic[2] carbonyl compounds)

Alternate Names: 2,2-diethoxypropanal; methylglyoxal diethyl acetal.

Physical Data: R = Et: bp 27-29 °C/3 mmHg. R = Me: bp 27.5-28 °C/6 mmHg. R,R = $-CH_2CH_2-$: bp 32-35 °C/5 mmHg.

Preparative Methods: preparations involve either reductive ozonolysis of methyl vinyl ketone dioxolane[3] or reduction of ***Ethyl Pyruvate Diethyl Acetal*** followed by oxidation of the resulting alcohol.[2,4] 2,2-Dialkoxypropionaldehydes can also be obtained by alcohol addition to α-alkoxyacroleins.[5]

Handling, Storage, and Precautions: these liquid compounds should be stored under inert gas and at low temperature.

Wittig Reactions.

Reaction with ***Cyclopropylidenetriphenylphosphorane*** gives the expected α,β-ethylenic acetal, which leads to the corresponding α,β-ethylenic carbonyl compound by deacetalization with moist silica gel (eq 1).[1]

(1)

Reactions with Organometallic Compounds.

Reaction between methylglyoxal ethylene acetal and ***Ethynylmagnesium Bromide*** followed by oxidation of the intermediate alcohol leads to 1-pentyne-3,4-dione 4-ethylene acetal (eq 2).[3] Other propargylic alcohols can also be prepared by reaction with organomagnesium compounds. Their corresponding mesylates react with organocopper species prepared from a Grignard reagent and ***Copper(I) Bromide*** to give α,β-allenic acetals. These acetals are hydrolyzed to α,β-allenic ketones by column chromatography on silica gel. Overall yields are fair to moderate (eq 3).[2] The same reactions may be carried out with phenylglyoxal diethyl acetal.[2]

Related Reagents.

(2-Dimethylaminoethyl)triphenylphosphonium Bromide; ***Ethyl 3,3-Diethoxypropanoate***; ***Pyruvaldehyde 2-Phenylhydrazone***.

Pyruvaldehyde 2-Phenylhydrazone

[7013-79-8] · $C_9H_{10}N_2O$ · Pyruvaldehyde 2-Phenylhydrazone · (MW 162.21)

(synthesis of α,β-unsaturated γ-diketones,[1] γ-halo-α,β-unsaturated esters,[4] pyrroles,[1] 1,4-diones,[1] pyridazin-3-ones;[5] aldol-type condensation with a pyruvaldehyde unit[1])

Alternate Name: 2-(phenylhydrazono)propanal.

Physical Data: mp 125 °C,[1] 125.5-126 °C.[2]

Solubility: weakly sol benzene, ethanol, dioxane; can be used in suspension.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: condensation of 1,1-dimethoxy-2-propanone with ***Phenylhydrazine*** in aqueous medium, followed by acidic hydrolysis (eq 1).[1]

Alternative methods, giving lower yields, involve condensation of 1-(*N*-piperidino)-1-propene with phenyldiazonium salts (eq 2),[2,3] or oxidation of acetone phenylhydrazone with ***Selenium(IV) Oxide*** (eq 3).[4]

Handling, Storage, and Precautions: fairly stable pyruvaldehyde derivative; store in the refrigerator, well-protected from moisture; in acidic medium, isomerization takes place to the more stable 1-phenylhydrazone. Use in a fume hood.

Synthesis of Enediones.[1]

Condensation of equimolar amounts of pyruvaldehyde 2-phenylhydrazone with acetophenones, 2-acetylfuran, or 2-acetylpyridine, in the presence of potassium ethoxide in ethanol at rt gives aldol-type condensation products, i.e. γ-(phenylhydrazono)-α,β-unsaturated ketones, which are converted into α,β-unsaturated γ-diketones upon treatment with aqueous ***Hydrogen Chloride*** in the presence of ***Formaldehyde*** (eq 4).[1] This aldol-type reaction with acetone gives various side products.[1] However, the use of pyruvaldehyde 2-(4-nitrophenyl)hydrazone in condensations with aliphatic methyl ketones, e.g. ***Acetone*** and 3-methyl-2-butanone, does not show this disadvantage.[1] The aldol reaction is not limited to methyl ketones as the title reagent condensed smoothly with indanone to afford the corresponding enedione monohydrazone and 1,4-dione (eq 5).[1]

(4)

(5)

As shown by the condensation reactions above, pyruvaldehyde 2-phenylhydrazone is a suitable building block in aldol-type reactions. This behavior contrasts with the reactivity of pyruvaldehyde, which is known to undergo predominantly self condensation under aldol-type reaction conditions.

Synthesis of γ-Keto-α,β-unsaturated Esters.[4]

Pyruvaldehyde 2-phenylhydrazone condensed with ***(Ethoxycarbonylmethylene)triphenylphosphorane*** to yield the corresponding γ-hydrazono-α,β-unsaturated ester, which is hydrolyzed to ethyl 4-oxo-2-pentenoate (eq 6).[4]

Synthesis of Pyridazin-3-ones.[5]

Active methylene compounds such as ***2,2-Dimethyl-1,3-dioxane-4,6-dione*** (Meldrum's acid) condensed with pyruvaldehyde 2-phenylhydrazone under the catalytic influence of piperidine acetate at room temperature to afford the expected Knoevenagel condensation product (eq 7).[5] However, if the reaction is performed at reflux, cyclization to 2,3-dihydro-6-methyl-2-phenyl-3-oxopyridazine-4-carboxylic acid takes place (eq 8).[5]

At 0 °C or below, pyruvaldehyde combines with phenylhydrazine to give the 2-phenylhydrazone in a kinetically controlled reaction.[6] In acidic solution, isomerization to the more stable 1-phenylhydrazone occurs at room temperature, the latter compounds being suitable building blocks for the synthesis of 4-hydroxypyrazoles (eq 9).[5]

Synthesis of 1,4-Diones and Pyrroles.

Reduction of γ-(phenylhydrazono)-α,β-unsaturated ketones with ***Tin(II) Chloride*** and concentrated aqueous hydrogen chloride in dioxane provides good yields of 1,4-diones (eq 10),[1] while direct access to pyrroles is obtained via reaction of the same starting materials with ***Sodium***

Dithionite (eq 11).[1]

Related Reagents.

Acetone Cyclohexylimine; ***Acetone Hydrazone***; ***1-(N,N-Dimethylamino)-2-methyl-1-propene***; ***Ethyl Pyruvate Diethyl Acetal***; ***Propionaldehyde t-Butylimine***; ***Pyruvaldehyde Diethyl Acetal***.

Pyruvoyl Chloride[1]

[5704-66-5] · $C_3H_3ClO_2$ · Pyruvoyl Chloride · (MW 106.51)

(α-ketoacylating agent; selective oxidation of alcohols)

Physical Data: light yellow liquid; bp 53 °C/126 mmHg.

Solubility: sol CCl_4, Et_2O, THF, etc.

Preparative Methods: most of the conventional reagents for the synthesis of acid chlorides from carboxylic acids are unsatisfactory for the preparation of pyruvoyl chloride. For example, treatment of pyruvic acid with ***Phosgene*** or ***Oxalyl Chloride***[11] affords the acid chloride in low yield. The method of choice for the preparation of the title compound[1] is the reaction of pyruvic acid with ***Dichloromethyl Methyl Ether***[12,13] to yield chloromethoxymethyl pyruvate, which readily decomposes into pyruvoyl chloride and methyl formate at 50 °C (eq 1).[13] This simple and economical procedure has also been used for the preparation of other α-keto acid chlorides.[1]

Another facile, but less often used, method for the preparation of pyruvoyl chloride involves the treatment of trimethylsilyl pyruvate, derived from pyruvic acid and ***Chlorotrimethylsilane***, with oxalyl chloride in DMF solution (eq 2).[2]

Handling, Storage, and Precautions: pyruvoyl chloride reacts vigorously with moisture, giving off fumes of HCl. It should be stored at -20 °C as the pure liquid in a sealed tube or in CCl_4 solution. The compound may be characterized as the *p*-nitroanilide derivative.[1a] Use in a fume hood.

Reaction of the Acyl Chloride Function.

Of the two functional groups present in pyruvoyl chloride, the acyl chloride function is more reactive than the keto group. The title compound seems to be the reagent of choice for the formation of esters of pyruvic acid.[3,4] This method offers the advantage of mild reaction conditions and broad applicability compared to the older procedure starting from pyruvic acid.[14] Irradiation of the resulting pyruvate esters furnishes aldehydes, ketones, lactones, enones,[3,4] etc., depending on the starting materials employed. Primary alcohols are oxidized to aldehydes without further reaction (eq 3). This procedure is more versatile than ***Dipyridine Chromium(VI) Oxide*** or

Ruthenium(VIII) Oxide oxidation and it seems to be more consistent than the DMSO-based reactions.

(3)

In the presence of the proper base, pyruvoyl chloride reacts with amines,[5] phenol,[6] and anilines[7-9] to furnish the corresponding α-keto-amides, phenyl α-keto acetates, and α-keto anilides. Other nucleophiles employed are hydroxylamine, oxime amine, and amides.[10,15] In general, amines are more reactive than alcohols or amides, and anilines react faster than phenols.

Palladium and platinum complexes of pyruvoyl chloride have been prepared by the oxidative addition of the acid chloride to both $Pt(PPh_3)_4$ and ***Tetrakis(triphenylphosphine)palladium(0)*** in benzene.[16] Both classes of compounds are stable as solids and in benzene solution at 25 °C, but slowly decompose to acyl complexes when heated at 65 °C. They can serve as synthetic equivalents of the acetyl moiety, e.g. reaction with Et_2NH affords Et_2NAc as the major product.[16]

At rt, pyruvoyl chloride adds to C=N double bonds[10] to form chloroacetoamides (Leuch's reaction).[17] In an analogous manner, condensation of the acyl chloride with nitriles gives the chloroformamidines.[18] Pyruvoyl chloride also adds to C=C double bonds,[19] provided an electron-withdrawing group is attached to the alkene.

Reaction of the Keto Function.

Once the acyl chloride function of the title compound has reacted with nucleophiles the α-keto function can manifest its reactivity. With phosphorus ylides it undergoes a Wittig reaction to form the corresponding alkenes.[19,20] Asymmetric reduction with ***B-3-Pinanyl-9-borabicyclo[3.3.1]nonane***[21] or catalytic hydrogenation[22] using chiral rhodium(I) complexes and subsequent hydrolysis furnishes optically active α-hydroxypropanoic acid. Diastereoselective reduction of the keto group in a chiral ester[23] or amide[24] has also been reported.

The dual reactivity of pyruvoyl chloride has been used to construct both five-membered[7] and six-membered[8,10,15,25] rings. An example of the latter synthesis is given in eq 4.[15b]

Quinine

[130-95-0] · $C_{20}H_{23}N_2O_2$ · Quinine · (MW 324.45)

(chiral catalyst[1-14])

Physical Data: mp 173-175 °C.

Solubility: sol hot water, methanol, benzene, chloroform, ether, glycerol; insol pet ether.

Form Supplied in: crystalline solid; 90% purity.

Analysis of Reagent Purity: NMR, mp.

Preparative Methods: commercially available from several sources.

Purification: recrystallize from absolute ethanol.

Handling, Storage, and Precautions: toxic; irritant.

Asymmetric Diels-Alder Reactions.

Chiral bases, including quinine, have been used as catalysts in Diels-Alder reactions (eq 1).[1] The reactions take place at room temperature or below and require 1-10% equiv of the alkaloid. The asymmetric induction that is observed can be attributed to complex formation between the achiral dienolate and the chiral amine.[1]

(1)

Preparation of Chiral Sulfinates.

Optically active sulfinates can be prepared by reaction of a symmetrical sulfite with ***t-Butylmagnesium Chloride*** in the presence of an optically active amino alcohol. The best enantioselectivity has been observed using quinine as the optically active amine (eq 2).[2] An alternative approach to this new enantioselective asymmetric synthesis of alkyl *t*-butylsulfinates would be reaction of a racemic sulfinate with *t*-butylmagnesium chloride complexed by optically active alkaloids (eq 3).[2] In this case, kinetic resolution of the racemic sulfinate leads to an optically active sulfinate and an optically active sulfoxide.

(2)

(3)

Stereoselective Addition of Diethylzinc to Aldehydes.

Wynberg has found that the cinchona alkaloids catalyze the reaction of ***Diethylzinc*** and aldehydes to form optically active alcohols (eq 4).[3] The highest enantiomeric excess obtained was from reactions which used quinine as the catalyst. Results show that the hydroxyl group of the catalyst hydrogen bonds with the aldehyde and that the diethylzinc interacts with the vinyl group of the catalyst as well, but it has not been determined if one or two catalyst molecules are involved in the transition state. Similar results have been obtained using a furan aldehyde.[4]

(4)

Synthesis of Optically Active Epoxides.

Alkaloids and alkaloid salts have been successfully used as catalysts for the asymmetric synthesis of epoxides. The use of chiral catalysts such as quinine or quinium benzylchloride (QUIBEC) have allowed access to optically active epoxides through a variety of reaction conditions, including oxidation using ***Hydrogen Peroxide*** (eq 5),[5] Darzens condensations (eq 6),[6] epoxidation of ketones by ***Sodium Hypochlorite*** (eq 7),[6] halohydrin ring closure (eq 8),[6] and cyanide addition to α-halo ketones (eq 9).[6] Although the relative stereochemistry of most of the products has not been determined, enantiomerically enriched materials have been isolated. A more recent example has been published in which optically active 2,3-epoxycyclohexanone has been synthesized by oxidation with ***t-Butyl Hydroperoxide*** in the presence of QUIBEC and the absolute stereochemistry of the product established (eq 10).[7]

(5)

(optical purity not determined)

(6)

8% ee

(7)

25-30% ee

(8)

6% ee

(9)

(optical purity not determined)

(10)

20-23% ee

Asymmetric Michael Reactions.

Asymmetric induction has been observed in Michael-type addition reactions that are catalyzed by chiral amines.[8] The *N*-benzyl fluoride salt of quinine has been particularly successful since the fluoride ion serves as a base and the aminium ion as a source of chirality.[9] Drastic improvements in optical purity (1-23%) have resulted by changing from quinine to the *N*-benzyl fluoride salt (eq 11).[9]

(11)

23% ee

Asymmetric Synthesis of β-Keto Sulfides.

Quinine can be used to catalyze asymmetrically the addition of thiols to cyclohexenone, thus forming β-keto sulfides (eq 12).[10] The absolute stereochemistry of the products has not been determined.

(12)

46% ee

Asymmetric Reduction of Ketones.

Alkyl phenyl ketones can be asymmetrically reduced to the corresponding alcohol using ***Sodium Borohydride*** under phase-transfer conditions in the presence of a catalytic amount of QUIBEC (eq 13).[11] The results indicate that the asymmetric reduction is due to the rigidity of the catalyst as well as the β-position of the hydroxyl group on the quinine molecule. The asymmetric induction is much lower with a γ-hydroxyl group.[11]

(13)

Synthesis of Optically Active β-Hydroxy Esters.

Chiral amino alcohols such as quinine have been used in the enantioselective synthesis of β-hydroxy esters via an indium-induced Reformatsky reaction (eq 14).[12] Although the enantioselectivities are not particularly high, aromatic aldehydes have produced the best results to date. The absolute stereochemistry of the products has not yet been assigned.

(14)

Preparation of Polymeric Catalyst.

A quinine/***Acrylonitrile*** copolymer has been successfully synthesized via radical polymerization using ***Azobisisobutyronitrile*** (AIBN) as initiator (eq 15).[13] The polymer can be prepared such that the vinyl group is the connecting site and the amino alcohol portion can either be free or protected. These copolymers are thermally stable and are soluble in polar aprotic solvents such as DMF and DMSO, but insoluble in common organic solvents. Preliminary experiments have shown that these copolymers can be used as asymmetric catalysts.[13]

Asymmetric Addition of Thioglycolic Acid to Nitro Alkenes.

Quinine has been used to catalyze the addition of thioglycolic acid to nitro alkenes (eq 16).[14] Enantiomerically enriched materials have been isolated, although the absolute stereochemistry of the products has not been assigned. The direction and extent of asymmetric induction seems to be dependent on the catalyst/acid ratio, thereby pointing to interaction between the carbonyl of the acid and the alkaloid nitrogen as being responsible for the asymmetric induction.[14]

Quinoline

[91-22-5] · C_8H_7N · Quinoline · (MW 129.16)

(useful as a base, solvent and/or catalyst, especially for decarboxylation reactions[1] and the Rosenmund reaction[2,3])

Physical Data: mp -15 °C; bp 237.6 °C;[4] steam volatile; *d* 1.0858 g cm^{-3} at 30 °C; pK_a 9.5.[5]

Solubility: sol ethanol, ethyl ether, acetone, carbon disulfide; more readily sol hot water than cold water; quinoline dissolves sulfur, phosphorus, and arsenic trioxide.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: GLC.

Purification: distillation.

Handling, Storage, and Precautions: very hygroscopic; darkens on storage in light; package with protection from light and moisture; LD_{50} rat (oral) 460 mg kg^{-1}; incompatible with strong oxidizing agents and strong acids.[5,6]

Dehydrohalogenation Reactions.

Quinoline is sometimes used as a base or solvent for dehydrohalogenation reactions because of its basic properties. A wide variety of substrates, ranging from very simple to quite complex compounds, have been effectively dehydrohalogenated with quinoline. For example, 3-bromo-3-methyl-2-butanone (**1**) underwent reaction with quinoline to give a mixture of products, 3-methyl-2-butanone (**2**) and 2-methyl-1-buten-3-one (**3**) (eq 1).[7]

(1)

Trans-3-penten-2-one (**5**) has been prepared from 4-chloropentan-2-one (**4**) using quinoline as the acid scavenger (eq 2).[8]

(2)

(4)

(5) 25-37% overall from propylene and acetyl chloride

Dehydrochlorination of 2-oxa-7,7-dichloronorcarane (**6**) in quinoline gives an 83% yield of 2,3-dihydro-6-chlorooxepine (**7**) (eq 3).[9]

(3)

Similarly, when 7,7-dibromonorcarane (**8**) is treated with quinoline, by manipulation of reaction conditions the bromocyclohepta-1,3-diene derivatives can be isolated or total dehydrobromination to ***1,3,5-Cycloheptatriene*** (**9**) can be effected (eq 4).[10]

(4)

Selective dehydrobromination of (α-bromovinyl)chlorosilanes can be carried out in quinoline, affording fair to good yields of the corresponding ethynylchlorosilanes (eq 5).[11]

(5)

Decarboxylation Reactions.

Taking advantage of its basic properties, quinoline is generally useful as a solvent for decarboxylation reactions. It is especially suitable because its relatively high boiling point facilitates the decarboxylation. Examples include the decarboxylation of 3-methyl-2-furoic acid (**10**) to 3-methylfuran (**11**) (eq 6),[12] *m*-nitrocinnamic acid (**12**) to *m*-nitrostyrene (**13**) (eq 7),[1] and α-phenylcinnamic acid (**14**) to *cis*-stilbene (**15**) (eq 8).[13] Copper catalysts such as ***Copper*** or ***Copper Chromite*** are used to effect the decarboxylations.

(6)

(7)

(8)

Preparation of Isothiocyanates.

Ethoxycarbonyl Isothiocyanate (**18**), useful as a synthetic reagent for heterocyclic syntheses,[14] can be prepared in excellent yield from the reaction of ***Ethyl Chloroformate*** (**16**) with ***Sodium Thiocyanate*** (**17**) using quinoline as a base catalyst (eq 9).[15] Only trace amounts of the isomeric thiocyanates are formed in the reaction. In the absence of the base catalyst, only a moderate (65%) yield of the desired product is obtained, along with significant (10%) contamination by the isomeric ethoxycarbonyl thiocyanate. ***Pyridine*** can also be used as the catalyst here; however, it reacts faster, which sometimes leads to undesired byproduct formation.

(9)

Quinoline as a Solvent.

When quinoline is used as a solvent for the reaction of ***Phenylcopper*** with iodoarenes, metal-halogen exchange and unsymmetrical coupling reactions occur as shown in eq 10.[16] The products suggest that basic solvents such as quinoline solvate the phenylcopper, leading to a complex mixture of products. Similar activity is observed in pyridine solvent.

(10)

4:3:1

Acylation Reactions.

Many basic catalysts have been used to carry out acylation reactions. The stereoselectivity of the reaction of diacetoxy or dibenzoyloxysuccinic anhydrides with racemic alcohols is affected by the choice of base catalyst. Quinoline is one of the most effective base catalysts for enhancing the stereoselectivity of the reaction of (2*R*,3*R*)-2,3-diacetoxysuccinic anhydride with 1-phenylethanol in comparison with catalysts such as pyridine, 3- and 4-methylpyridines, and isoquinoline. Other effective basic catalysts are pyridine derivatives substituted in the 2-position of the ring such as 2-methylpyridine and 2,6-dimethylpyridine.[17]

Formation of Allenes.

Quinoline can be used as an acid scrubber in the preparation of allenes via vinyl triflate intermediates. The elimination of ***Trifluoromethanesulfonic Acid*** in quinoline proceeds in good yield (eqs 11 and 12).[18]

(11)

(12)

Rosenmund Reaction.

A catalyst poison prepared from quinoline and ***Sulfur*** is useful for controlling the reaction of β-naphthoyl chloride (**19**) with hydrogen gas and ***Palladium on Barium Sulfate*** catalyst.[2] If control of the reaction is not maintained by catalyst poisoning to reduce activity, further reduction beyond the desired β-naphthaldehyde product (**20**) is often observed (eq 13).[3]

(13)

(19) **(20)**

Elimination Reactions.

Quinoline in DMSO facilitates the elimination of dimethyl sulfide from sulfonium salt (**21**), affording the very reactive cyclobutenone derivative (**22**) (eq 14).[19]

(14)

(21) **(22)**

Related Reagents.

Chromium(VI) Oxide-Quinoline; ***Copper Chromite-Quinoline***.

3-Quinuclidinol

[1619-34-7] · $C_7H_{13}NO$ · 3-Quinuclidinol · (MW 127.21)

(cleavage of β-keto esters;[1] catalyst for Baylis-Hillman reaction;[2-6] synthesis of monoesters;[7] oxygenation of branched aldehydes[8])

Physical Data: mp 223-224 °C.

Solubility: sol water, ethanol, methanol.

Form Supplied in: crystalline solid; >98% purity.

Analysis of Reagent Purity: NMR, mp.

Preparative Methods: commercially available from several sources.

Purification: recrystallize from benzene or acetone.

Handling, Storage, and Precautions: corrosive.

Cleavage of β-Keto Esters.

3-Quinuclidinol selectively cleaves β-keto esters to ketones (eq 1).[1] Typical reaction conditions involve heating the ester with a fivefold excess of quinuclidinol in *o*-xylene. The reaction is also successful for cleavage of vinylogous β-keto esters (eq 2).[1]

(1)

(2)

Baylis-Hillman Reaction.

3-Quinuclidinol is a much more efficient catalyst than ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO) for the Baylis-Hillman reaction, yielding 2-hydroxyalkenoate esters (eqs 3 and 4).[2] Reaction times are much shorter, typically less than 24 h as compared to 4-7 days.[3] The same results have been observed for the synthesis of hydroxy enones (eq 5).[4] It has been speculated that the rate enhancement can be due to hydrogen-bonding stabilization of the catalyst-acrylate adduct[5] by the hydroxyl group of quinuclidinol, which does not occur with DABCO. This methodology has also been extended to include the use of aromatic aldehydes (eq 6).[6]

(3)

(4)

(5)

(6)

Synthesis of Monoesters.

Geminal diesters are converted to the corresponding monoester with quinuclidinol (eq 7).[7] Other bicyclic amines such as DABCO and ***1,5-Diazabicyclo[4.3.0]non-5-ene*** (DBN) can also be used.[7] These cleavage conditions are advantageous in that they involve a one-step process compared with two steps involving formation of the monoacid followed by esterification. More importantly, these reaction conditions are perfectly suited to cases where acid or base labile groups are present or where the compounds are not soluble in aqueous solutions.

(7)

Oxygenation of Branched Aldehydes to Ketones.

Copper-catalyzed oxygenation of α-branched aldehydes in weakly basic media yields ketones having one less carbon (eq 8).[8] Van Rheenen found that the optimum reaction conditions use ***Copper(II) Acetate*** complexed with 2,2´-bipyridyl or 1,10-phenanthroline as catalyst and bicyclic amines such as DABCO or 3-quinuclidinol in polar aprotic solvents rather than in alcohols.[8]

Raney Nickel[1]

Ni

[106-51-4] · Ni · Raney Nickel · (MW 58.69)

(useful as a reducing agent for hydrogenation of organic compounds[1])

Solubility: insol all organic solvents and water.

Form Supplied in: black solid.

Preparative Methods: there are many types of Raney nickel; they differ based on their methods of preparation. These methods essentially determine the hydrogen content as well as the reactivities of various types of Raney nickel. The most popular W-type Raney nickels can be prepared as the seven different types listed in Table 1.

Table 1 Types of Raney Nickel

Type	NaOH/Al (molar)	NaOH soln. conc. (wt%)	Temp. (°C) (time, h)	Water wash method
W-1	1.35	17	115 120 (4)	Decant to neutral
W-2	1.71	20	75 80 (8 12)	Decant to neutral
W-3	1.73	20	50 (0.83)	Continuous to neutral
W-4	1.73	20	50 (0.83)	Continuous to neutral
W-5	1.80	21	50 (0.83)	Continuous to neutral
W-6	1.80	21	50 (0.83)	Cont. to neut. under H_2
W-7	1.80	21	50 (0.83)	Directly washed with EtOH[1c]

Handling, Storage, and Precautions: Raney nickel is generally stored in an alcoholic solvent, or occasionally in water, ether, methylcyclohexane, or dioxane. The activity of Raney nickel decreases due to loss of hydrogen over a period of about 6 months. Raney nickel ignites on contact with air and should never be allowed to dry.

Desulfurization.

The most widespread application of Raney nickel is the desulfurization of a wide range of compounds including thioacetals, thiols, sulfides, disulfides, sulfoxides, sulfones, thiones, thiol esters, and sulfur-containing heterocycles.

The well-known desulfurization of dithianes remains one of the most efficient methods for reductive deoxygenation of ketones. Recently, Rubiralta demonstrated an example in his synthesis of the aspidosperma alkaloid framework. Dithiane (**1**) was reduced to indole derivative (**2**) in 85% yield without reduction of the alkene (eq 1).[2]

(1)

Raney nickel is frequently used to remove the sulfur atom of thiols,[3] sulfides, and disulfides from a carbon skeleton, regardless of whether the sulfur is attached to an alkyl carbon,[4] an aryl carbon,[5] or a carbon atom in a heterocycle.[6] Several examples are shown in eqs 2-5. A solvent effect was observed in the Raney nickel reduction of vinyl sulfide (**11**), which gave glycoside (**12**) in methanol, whereas the double bond remained intact to produce alkene (**13**) in THF (eq 6).[7]

(2)

(3)

(4)

(9) (10) (5)

(11) Pht = phthaloyl (13)

(6)

(12)

The sulfur atom can be part of a heterocycle. Högberg[8] and Tashiro[9] used Raney nickel to remove sulfur from thiophene derivatives (**14**) and (**16**) to give compounds (**15**) and (**17**), respectively (eqs 7 and 8).

(14) (15) (7)

(16) (17) (8)

Raney nickel can remove the sulfinyl and sulfonyl groups from sulfoxides and sulfones under neutral conditions (eqs 9 and 10).[10,11] Cox demonstrated the cleavage of both sulfur-carbon bonds in sulfoxide (**22**) and noted that the stereogenic center remained untouched (eq 11).[12]

(9)

(18) **(19)**

(10)

(20) R = alkyl, aryl **(21)** 3 examples

(11)

(22) **(23)**

Some thioamides are reduced by Raney nickel to the corresponding imines. Two typical examples are shown in eqs 12 and 13.[13,14] Thiones have been reported to give alkanes, but only low or unstated yields are reported (eqs 14 and 15).[15,16]

(12)

(24) **(25)**

(13)

(26) **(27)**

(28) (29) (14)

(30) (31) (15)

Liu and Luo[17] used Raney nickel to reduce glycidic thioester (**32**) to the corresponding 1,3-diol (**33**) in good yield (eq 16). With ***Sodium Borohydride*** at ambient temperature or ***Lithium Aluminum Hydride*** at -78 °C, glycidic thioester (**32**) was reduced chemoselectively to furnish 2,3-epoxy alcohol (**34**) in 82% yield (eq 16).[17]

(32) (33) (34) (16)

Deoxygenation and Deamination.

Besides the widely used desulfurization process, Raney nickel can be used to reduce benzylic nitrogen and oxygen atoms. Behren's report shows the partial deoxygenation of diol (**35**) to mono alcohol (**36**) in 75-96% yields (eq 17).[18] Ikeda used W-2 Raney nickel to remove the benzyl protecting group from compound (**37**). However, partial epimerization occurred in this reaction to produce a 3.7:1 mixture of the 6α- and 6β-alcohols (**38**) (eq 18).[19] Azetidine (**39**) was opened by Raney nickel in refluxing ethanol, to give acyclic amine (**40**) in 88% yield (eq 19).[20]

(17)

(35) **(36)**

R = H, CN, NH_2, CH_2NH_2

(18)

(37) **(38)**

α:β = 3.7:1

(19)

(39) **(40)**

Krafft reported that tertiary alcohols were also deoxygenated to alkanes by Raney nickel (eq 20). On the other hand, primary alcohols were oxidized to aldehydes and then subsequently decarbonylated (eq 21), and secondary alcohols were oxidized to the corresponding ketones (eq 22).[21]

(20)

(41) **(42)**

(21)

(43) **(44)**

(22)

Recently, Ohta reported Raney nickel would deoxygenate *N*-oxide (**47**) to pyrazine (**48**), while ***Phosphorus(III) Bromide*** gave many side products (eq 23).[22]

(23)

Cleavage of Heteroatom-Heteroatom Bonds.

Both N-N and N-O bonds can be cleaved by Raney nickel in the presence of hydrogen. Alexakis reported that hydrazine (**49**) was easily cleaved to the free amine by Raney nickel under hydrogen atmosphere, then protected to give carbamate (**52**) (eq 24).[23] In addition, he found even hindered hydrazines (**50**) and (**51**) were successfully deaminated to free amines (**56**) and (**57**), respectively, without racemization if the reactions were assisted by ultrasound.[24]

(24)

The N-O bonds in 1,2-oxazine (**58**) and isooxazolidine (**60**) were cleaved by Raney nickel via a radical mechanism to produce 1,4-diketone (**59**) and β-lactam (**61**), respectively (eqs 25 and 26).[25,26]

(58)

(59) (25)

(60) (61) (26)

Hydrogenation of Multiple Bonds.

Applications in this area are not very popular for Raney nickel. Raney nickel in dilute base is, however, an effective reagent for reduction of pyridines to the corresponding piperidines. The reaction is accelerated by substituents in the 2-position and by electron-withdrawing groups in the 3- and 4-positions, while electron-donating groups in the 3- and 4-positions retard the reaction (eq 27).[27] Occasionally, Raney nickel is used to reduce acyclic multiple bonds. An example for selective reduction of triple bonds to *cis* double bonds is shown in eq 28.[28]

(62) (63) (27)

18 other examples

(28)

Deselenation.

Similar to the desulfurization process, Raney nickel can be used to remove selenium from selenoketones, diselenides, selenides, and selenooxides. Typical examples are shown in eqs 29-33.[29-31] Moreover, Raney nickel has been used for a hydrodetelluration of chiral compound (**76**) without any racemization (eq 34).[32]

(29)

(30)

(31)

(72) (73) (32)

(74) (75) (33)

(76) (77) (34)

Reductive Amination of Carbonyl Groups.

Reactions of this type can be accomplished by reduction of intermediate imines or oximes.[33-35] Recently, Chan and co-workers found that Raney nickel can be an efficient catalyst in the preparation of phenylalanine. Treatment of sodium phenylpyruvate with either ***Ammonia*** gas or aqueous ammonia solution in the presence of Raney nickel under 200 psi pressure gave >98% of phenylalanine (eq 36). Other α-keto esters such as 4-hydroxyphenylpyruvic acid, pyruvic acid, and benzoyl acid also gave the corresponding amino acids in excellent yield.[36]

(78) (79) (35)

(80) (81) (36)

Asymmetric Reduction.

Recently, asymmetric synthesis has become a center of attention for synthetic chemists. The use of Raney nickel and tartaric acid was recently reported by Bartok. Reduction of ketone (**82**) gave alcohols (**83**) and (**84**) as a 92:8 mixture in 70% chemical yield.[37] Takeshita et al.[9] also reported an asymmetric reduction of β-keto ester (**85**) to give the corresponding β-hydroxy ester (**86**) in 80% ee (eq 38). In addition, it was found that enantioselectivities were improved by treatment of the Raney nickel with ultrasound prior to use.[38] Blacklock et al. reported an asymmetric reductive amination of α-keto ester (**88**) in which they used the chiral amine (**87**) instead of a chiral catalyst. The result, shown in eq 39, indicates that the amino ester (**89**) was produced in 80% yield with 74% de.[39]

Rhodium on Alumina[1]

Rh/Al_2O_3

[7440-16-6] · Rh · Rhodium on Alumina · (MW 102.91)

(active catalyst under mild conditions for hydrogenation of unsaturated compounds including aldehydes, ketones,[1h,7] and aromatic carbocyclic[1] and heterocyclic structures;[1a,g,k] high stereospecificity and low hydrogenolytic activity)

Form Supplied in: rhodium supported on alumina, carbon, or silica containing 0.5-5.0% of the metal are available commercially.

Handling, Storage, and Precautions: the unused supported catalysts are not pyrophoric but rhodium supported on a finely divided carbon, like carbon itself, can undergo a dust explosion. After use, the catalysts are likely to contain adsorbed hydrogen which may ignite when the catalyst dries.[1f,h] Use in a fume hood.

Introduction.

The catalytic properties of rhodium, like the other platinum metals, depend secondarily on the support. ***Alumina*** is commonly used but other supports may furnish advantages in particular circumstances. Rhodium black avoids possible influences of the support.[2] The high activity of rhodium often permits its use at room temperature and atmospheric pressure but higher temperatures and pressures may be used to advantage.

Alkenes and Alkynes.

Although rhodium catalyzes the hydrogenation of alkenes, dienes, and alkynes under mild conditions, it is not the most selective platinum catalyst if double bond migration or isomerization can adversely affect the desired stereochemistry or if a selective hydrogenation of a diene or alkyne is sought.[1h] The tendency of rhodium for alkene isomerization relative to hydrogenation is only a little greater than that of ruthenium (see ***Ruthenium Catalysts***), which results in the formation of a greater fraction of *cis*-1,2-dimethylcyclohexane using Ru (93.5%) than using Rh (87.6%) in hydrogenating 1,2-dimethylcyclohexene at 25 °C/1 atm H_2.[3]

The hydrogenation of the double bond in vinyl or allylic compounds is achieved with some success with Rh but generally Pd or Ru is more effective, particularly with vinyl ethers.[1h] However, the high activity of Rh allows the reaction to be conducted at lower temperatures than with other metals. For example, the asperuloside tetraacetate, which contains both a vinyl and an allyl ether structural unit, was hydrogenated over Rh/C starting at -30 °C and raising the temperature slowly during 3 h to 0 °C to give a virtually quantitative yield of the tetrahydro product (eq 1).[4]

The activity of Rh/C also is shown by the hydrogenation of the double bond in the β-acyloxy-α,β-unsaturated esters and ketones without causing hydrogenolysis as given by ***Platinum(IV) Oxide*** (eq 2).[5]

(2)

Rh/Al_2O_3 in combination with ***Palladium on Carbon*** effected the saturation of an isomer of dodecamethyl[6]radialene (**1**) to all-*trans*-hexaisopropylcyclohexane (**2**) when separately the same catalysts failed (eq 3).[6] Apparently the reduction required high reactivity for both hydrogenation (Rh) and alkene isomerization (Pd).

(3)

(1) (2)

Aldehydes and Ketones.

Rhodium is an excellent catalyst for the hydrogenation of aldehydes and ketones under mild conditions.[1a,e,h,7] The reduction of aliphatic carbonyl compounds can be accomplished without the hydrogenolysis of susceptible groups attached elsewhere in the molecule.

In the hydrogenation of cyclohexanones, rhodium excels in the formation of the axial hydroxyl group from monosubstituted compounds; the effect is especially notable for alkyl substituents.[1d,8] With methoxy groups in place of alkyl groups at the 2- and 4-positions the fraction of axial isomer increases markedly for Pd, Ir (see ***Iridium***), and Pt but not Rh.[9a] Hydrogenation of unhindered cyclohexanones in isopropyl alcohol or THF in the presence of small amounts of ***Hydrogen Chloride*** gives excellent yields of axial alcohols (eq 4).[9b] Steroidal 3,17- and 3,20-diones are selectively hydrogenated at C-3 to yield the corresponding 3-axial-hydroxy ketones.

(4)

Imines.

Imines are thought to be important intermediates in the hydrogenation of nitriles, anilines, and oximes.[1] ***Ammonia*** and primary amines condense with aldehydes to give imines which may be hydrogenated. Freifelder describes the conversion of 3,4-dimethoxybenzaldehyde to the benzylamine over Rh/C in 95% ethanol containing ammonia (aq) and NH_4OAc, (rt, 3 atm, 64% yield).[1k]

Nitriles.

The products of hydrogenating a nitrile depend on the catalyst and whether the nitrile is aliphatic or aromatic.[1a,h] The reaction conditions including the solvent, the temperature, and the H_2 pressure, are important variables. Rhodium catalysts are most useful in the preparation of either primary or secondary amines.

The hydrogenation of an aliphatic nitrile leads to the formation of an imine which in turn may be hydrogenated to a primary amine.[1a,g,h] However, secondary amines are often the principal product, which apparently follows the condensation of the imine and the primary amine.[1g] Whether the condensations occur in the homogeneous medium, as first proposed by von Braun et al.,[10] or on the surface of the catalyst, is unsettled.[11] Recently, the analysis of a kinetic study of the hydrogenation of propionitrile on Rh/C and Rh/Al_2O_3, to form propylamine and dipropylamine, led to the claim that the results do not support the proposal that the condensations occur in the liquid phase.[11] A mechanism involving only surface reactions is proposed to explain the authors' results as well as the literature record.

The catalyst's support influences the effect of increasing pressure on the distribution of the products of hydrogenating pentanenitrile in methanol at rt.[12] At 4 atm, Rh/C, Rh/Al_2O_3, and Rh_2O_3 mainly yield dipentylamine (93%, 87%, and 77% respectively). Raising the pressure increases the yield of the primary amine. At 90 atm it is the sole product from unsupported Rh (Rh_2O_3), 54% yield is obtained from Rh/Al_2O_3, and 29% yield from Rh/C, the remainder being the secondary amine. At an intermediate pressure (50 atm), Rh/C yields only the secondary amine.[1g] Using Rh/C in the presence of a large excess of butylamine (mole ratio 1.7-6.6) the yield of butylpentylamine is 95-100%.[1g]

Aromatic nitriles are hydrogenated over Rh/C under mild conditions to dibenzylamines in excellent yields (25 °C, 4 atm).[1g]

Most recently, acetic acid was shown to be an excellent solvent for the Rh/Al_2O_3 or Rh/C catalyzed hydrogenation of aliphatic, aromatic carbocyclic, and aromatic heterocyclic nitriles to secondary amines (eq 5).[13] 3-Hydroxypropanenitrile formed a tertiary amine as a single isomer (eq 6) and the reduction of the tosylate of β-cyanoalanine formed a lactam (eq 7).

(5)

(6)

(7)

Oximes.

Although few examples of its use for the reduction of oximes have been recorded, rhodium has given excellent results, being especially useful in place of catalysts which yield excessive amounts of secondary amines.[1h] Freifelder et al. found the 5% Rh/Al_2O_3-catalyzed hydrogenation of cycloheptanone oxime in methanol (60 °C, 0.75-1.0 atm) gave an 80% yield of cycloheptylamine.[1a,14] 3-Amino-2-methyl-2-butanone and 1-(1-aminoethyl)cyclohexanol were prepared by the 5% Rh/Al_2O_3-catalyzed hydrogenation of the oximes of 3-hydroxy-3-methyl-2-butanone and 1-acetylcyclohexanol (eq 8) in 90-92% yields.[15]

(8)

Carbocyclic Aromatic Compounds.

Rhodium provides highly active catalysts for the hydrogenation of the aromatic carbocycle under mild conditions (25-80 °C and 1-3 atm).[1] It is particularly useful when hydrogenolysis of attached hydroxy or alkoxy groups or benzylic alcohols or ethers is to be avoided.[16] The selectivity of rhodium under mild conditions is shown by the Rh/Al_2O_3-catalyzed hydrogenation in acetic acid at room temperature of (2-methoxyphenyl)propan-2-one to *cis*-1-(2-methoxycyclohexyl)propan-2-one (eq 9).[17]

(9)

The consecutive addition of hydrogen atoms to the adsorbed cycle presumably proceeds through adsorbed cyclohexadienes and cyclohexenes, but only the desorption of the latter has been observed.[18] Of the platinum metals, ruthenium yields the largest amount of cyclohexenic intermediates when hydrogenated in the presence of water, which is also an unusual promoter of ruthenium's catalytic activity (see ***Ruthenium Catalysts***). In nonaqueous media, Rh yields the largest concentrations of cyclohexenic intermediates, as in the hydrogenation of *t*-butylbenzenes and *t*-butylbenzoic acids or esters in EtOH, HOAc, or saturated hydrocarbon solvents.[1f,19]

The Rh/C-catalyzed hydrogenation of 2-*t*-butylbenzoic acid initially yields *cis*-2-*t*-butylcyclohexanecarboxylic acid (75%), 6-*t*-butyl-1-cyclohexenecarboxylic acid (22%), and 2-*t*-butyl-1-cyclohexenecarboxylic acid (2%); *trans*-2-*t*-butylcyclohexanecarboxylic acid is formed only after the unsaturated intermediates begin to be reduced, which occurs when about 80% of the benzoic acid has been converted.[19] The result supports the earlier proposal that the formation of *trans* isomers in the hydrogenation of the xylenes arises from the saturation of desorbed cyclohexenes, even though the latter are undetected.[18]

The rate of the rhodium-catalyzed hydrogenation of the aromatic ring diminishes with alkyl substitution but with multiple substituents the arrangement of the groups affect the reactivity. The selective hydrogenation of the unsubstituted ring in *o*-anisylmethylphenylphosphine oxide illustrates that alkoxy groups also lower the reactivity of the benzene ring (eq 10).[20]

(10)

Although rhodium is generally effective in saturating polycarbocyclic aromatic compounds, it is not useful if the selective reduction of a particular cycle is sought.[1g-i]

Phenols and Phenyl Ethers.

A useful application of rhodium catalysts is the hydrogenation of phenols and phenyl ethers which are sensitive to hydrogenolysis, a particular problem in hydrogenating di- and polyhydroxybenzenes.[1a-c,21] Smith and Stump furnish an informative study, both kinetic and preparative, of the hydrogenation of hydroxybenzenes catalyzed by Pt and Rh/Al_2O_3.[22] The kinetic evidence indicates that the mechanism of formation of the cyclohexanols from the phenols does not require ketone intermediates, although some are formed. The authors propose that cyclohexenols are intermediates which may be reduced to cyclohexanols, hydrogenolyzed to cyclohexanes, or isomerized to cyclohexanones. The conversion of resorcinol to dihydroresorcinol (1,3-cyclohexandione) in high yield is described (eq 11).

(11)

The hydrogenation of the cresols at 80 °C and 80-100 atm forms intermediate ketones in amounts which permit a quantitative analysis of the kinetics of the process to give a good estimate of the fraction of the cresol which is converted via the ketone to the cyclohexanol.[23] The stereochemistry of the final product is determined by the fraction formed via the cyclohexanone (knowing the fraction of *cis* and *trans* isomers it forms upon reduction), with the remainder of the product alcohol being the *cis* isomer. In principle, if cyclohexenol intermediates desorb from the catalyst, readsorption followed by the suprafacial addition of hydrogen could yield some *trans* isomers.[18]

The hydrogenation of 1-naphthol over Rh/Al_2O_3 in ethanol or methanol (25 °C, 4 atm) gave good yields of the isomeric decalols in the ratio of 13.3:3.2:1, the largest component being the *cis,cis* isomer; the configurations of the others were not specified; hydrogenolysis to decalin was low (3%).[24] Of the unsupported platinum metals used to catalyze the hydrogenation of 2-naphthol and the intermediate tetrahydro-2-naphthol (*t*-BuOH, 80 °C, 50 atm), Rh and Ru are highly stereospecific in forming the *cis,cis*-2-decalols and afford only small amounts of hydrogenolysis products.[25]

Anilines.

Ruthenium is generally the preferred catalyst for the hydrogenation of anilines to cyclohexyl amines (see ***Ruthenium Catalysts***), but rhodium catalysts have been used successfully.[1g,h] To diminish the formation of dicyclohexylamine, the best solvents were found to be *t*-butyl or isopropyl alcohol; the addition of a small amount of a strong base, preferably ***Lithium Hydroxide***, to Rh hydroxide furnished a catalyst that almost eliminated the diamine's formation.[26] Rhodium oxide prepared by $LiNO_3$ fusion with ***Rhodium(III) Chloride***, and used in isopropyl or *t*-butyl alcohol, leads to excellent yields of the isomeric methoxy- or ethoxycyclohexylamines from the corresponding anilines (eq 12).[27] Aniline has been converted to cyclohexylamine (96%, dicyclohexylamine 4%) catalyzed by Rh/Al_2O_3 in *i*-PrOH (23-26 °C, 55-70 atm).[28]

(12)

Heterocyclic Aromatic Compounds.

Rhodium has been used effectively to catalyze the hydrogenation of furans, pyrroles, pyridines, and other structures containing aromatic heterocycles.[1a,h]

Furans.

Furans are saturated under mild conditions with Rh/C. 2,5-Diferrocenylfuran is hydrogenated quantitatively to *cis*-2,5-diferrocenyltetrahydrofuran (5% Rh/C, rt, 1 atm, 2 h) (eq 13); after a time (6 h) at higher pressures (60 atm) the ether linkages are hydrogenolized to form 1,4-diferrocenylbutane.[29]

(13)

Pyrrole.

Rhodium is the preferred catalyst for the hydrogenation of pyrroles.[30] Pyrrole and 1-methylpyrrole, without solvent, are reduced to the pyrrolidines in high yield over Rh/Al_2O_3 (rt, 2-3 atm).[1g] In compounds containing an aromatic carbocycle which is not fused to the pyrrole, the carbocycle tends to be reduced preferentially,[1g] but the reverse selectivity has also been observed (eq 14)[31] and attributed to the trisubstitution in the carbocyclic ring.[1g]

(14)

The high *cis* selectivity in the Rh/Al_2O_3-catalyzed hydrogenation of a 2,5-disubstituted pyrrole is illustrated in (eq 15).[32]

(15)

Pyridine.

For the hydrogenation of pyridines, rhodium is the most effective catalyst under mild conditions and maintains its advantage at higher pressures.[1h] 2,6-Dimethylpyridine in glacial AcOH is hydrogenated to *cis*-2,6-dimethylpiperidine over 5% Rh/Al_2O_3 (eq 16).[33]

(16)

Although a variety of catalysts can affect satisfactorily the reduction of the 2- and 4-pyridinecarboxylic acids, the decarboxylation observed with the other catalysts in the hydrogenation of nicotinic acid (pyridine-3-carboxylic acid) is avoided by 5% Rh/Al_2O_3 in aqueous ammonia (eq 17).[34]

(17)

Generally, catalytic hydrogenation of pyridines with attached or fused aromatic carbocycles occurs preferentially in the pyridyl ring.[1h] 4-Benzylpyridine is converted quantitatively to 4-benzylpiperidine (5% Rh/C, EtOH, 60 °C, 4 atm).[35] The pyridine ring in (3-methoxy-2-pyridyl)-2-propanone is reduced selectively with Rh/Al_2O_3 in water containing one equiv of ***Hydrogen Bromide***, the selectivity is achieved only when the pyridylpropanone has been carefully purified by distillation (eq 18).[36]

(18)

A variety of other nitrogen heterocycles have been hydrogenated successfully over rhodium catalysts.[1g,1k]

Rhodium(III) Chloride

$RhCl_3$

[10049-07-7] · Cl_3Rh · Rhodium(III) Chloride · (MW 209.26) (hydrate)

[20765-98-4]

(isomerizes alkenes and strained carbocycles;[1] reduction precatalyst;[5] oxidation catalyst[7])

Physical Data: mp 450 °C.

Solubility: insol water; sol aq sodium hydroxide, aq potassium cyanide.

Form Supplied in: available as anhydrous solid and hydrated solid.

Analysis of Reagent Purity: elemental analysis.

Isomerizations.

Rhodium trichloride catalyzes the isomerization of alkenes, typically generating the thermodynamically more stable isomer. The exposure of an arylmethylenechroman-4-one to this reagent results in the efficient migration of the exocyclic alkene (eq 1).[1a] This example nicely illustrates the mild nature of the isomerization method as basic media induce degradation of the chroman-4-one, acidic media do not produce a reaction, and ***Raney Nickel*** affords a mixture of the desired alkene isomer and a reduced compound. Enones to which alkenes are attached are transformed into phenols upon reaction with rhodium trichloride (eq 2).[2] Unsaturated imines are converted to anilines via an analogous process (eq 3).[2] This reagent also allows the removal of an allyl protecting group from a wide variety of heteroatoms through an isomerization-hydrolysis pathway (eq 4).[3]

(1)

(2)

(3)

(4)

Furthermore, rhodium trichloride can isomerize strained carbocycles (eq 5).[4] In comparison, Ir^{III}, Ru^{III}, and Pt^{IV} are effective in bringing about similar rearrangements; Fe^{III}, Ni^{II}, and Hg^{II} are not active in the same fashion. Deuterium exchange studies indicate that this process most likely involves a metal hydride.

(5)

Reductions.

A mixture of ***Sodium Borohydride*** and rhodium trichloride forms a selective reagent for the reduction of aromatic systems (eq 6).[5] This method does not affect carboxylic acids, esters, or amides; ketones are partially reduced; alkenes are competitively reduced. The fact that aromatic nuclei typically require severe conditions for reduction underscores the usefulness of this mild process.

(6)

Rhodium trichloride, in the presence of the phase transfer catalyst Aliquat 336, serves as a hydrogenation catalyst that preferentially reduces alkenes in the presence of aromatic nitro groups (eq 7).[6] In general, the reduction of the nitro functionality is the most facile hydrogenation process.

(7)

Oxidation.

Phase transfer catalysis allows the oxidation of alkenes to proceed in the presence of rhodium trichloride (eq 8).[7] Tetrabutylammonium hydrogen sulfate (THS) is of general use as a catalyst. Other quaternary ammonium salts will also serve this role. Mechanistically, it is thought that this reaction is analogous to the Wacker oxidation. This is in contrast to another report describing the use of rhodium trichloride as a homogeneous oxidation catalyst.[8]

(8)

Acetylene Hydration.

Rhodium trichloride in acidic media catalyzes the hydration of ***Acetylene*** (eq 9).[9] The rate of this reaction is accelerated by the introduction of ligating additives such as ***Lithium Chloride***. In comparison, ***Ruthenium(III) Chloride*** also catalyzes alkyne hydration but at one-third the rate of rhodium trichloride.

(9)

Hydrosilylation Catalyst.

The hydrosilylation of α,β-unsaturated esters to form dimethylketene trimethylsilyl acetals is catalyzed by rhodium trichloride (eq 10).[10] The use of rhodium trichloride rather than ***Chlorotris(triphenylphosphine)rhodium(I)***, the typical rhodium catalyst employed, results in a faster reaction with improved yields and product purities.

Ruthenium Catalysts[1]

Ru

[7440-18-8] · Ru · Ruthenium Catalysts · (MW 101.07)

(selective hydrogenation catalysts,[1] high regio- and stereoselective addition to alkenes,[2] low activity for alkene isomerization,[3] actively hydrogenates carbonyls,[4] low hydrogenolytic activity,[5] high stereoselective perhydrogenation of aromatic carbocyclic and many aromatic heterocyclic compounds[6,7])

Form Supplied in: ruthenium supported on alumina or carbon and RuO_2 are available commercially.

Preparative Methods: ***Ruthenium(III) Chloride*** is converted by aq. ***Sodium Hydroxide*** or ***Lithium Hydroxide*** to $Ru(OH)_3$, which may be dried in a vacuum at room temperature for later use.[6] Ruthenium black can be prepared by the reduction of $RuCl_3.3H_2O$ with ***Formaldehyde***, washed repeatedly with distilled water, and stored in ethanol.[8]

Handling, Storage, and Precautions: the unused supported catalysts are not pyrophoric but ruthenium on finely divided carbon, like carbon itself, can undergo a dust explosion.[1d] After use, the catalysts are likely to contain adsorbed hydrogen which may ignite when dried.[1c,1d] Use in a fume hood.

Introduction.

The catalytic characteristics of ruthenium, like other platinum metals, depend secondarily on the support.[1c,d] The discovery of RuO_2 as a selective hydrogenation catalyst encouraged its use.[5,7,9] Later the supported catalysts Ru/C and Ru/Al_2O_3 became readily available. Supported catalysts are the more efficient users of the metal but may not furnish the maximum yield of a desired product if, for example, intraparticle mass transport affects the product distribution.[1d]

Ruthenium-catalyzed hydrogenations often show a variable and sometimes lengthy induction period which can be avoided by agitating the catalyst and solvent mixture in hydrogen (1 atm) for 1-2 h before introducing the substrate.[2,10] The common solvents are water, water-acetic acid, alcohols, and dioxane. Water is a powerful promoter of the activity of ruthenium hydrogenation catalysts.[1d,2,6]

Alkenes and Alkynes.

Ruthenium exhibits a lower tendency than rhodium (see ***Rhodium on Alumina***) to isomerize alkenes (relative to hydrogenation), particularly at high pressures which are often used with ruthenium catalysts.[1c,1d] Under mild conditions, a monoalkyl substituted ethylene is hydrogenated selectively in the presence of di- and trisubstituted ethylenes; hydrogenation of alkynes gives the corresponding alkane.[2] Ruthenium catalysts add hydrogen suprafacially (*cis*) to a carbon-carbon double bond, as in the hydrogenation of alkyl substituted cyclohexenes (eq 1),[3,11] bicyclo[2.2.0]hexenes or bicyclo[2.2.0]hexadienes (eq 2),[12] and bicyclo[4.4.0]decene.[13]

(1)

(2)

Carbonyl Compounds.

Ruthenium is an excellent catalyst for the hydrogenation under mild conditions of aliphatic carbonyl compounds and aldehydes such as furfural (eq 3).[4] Industrially, it is used for the conversion of glucose to sorbitol.[1d]

(3)

Elevated temperatures and pressures have been used successfully, as in the 5% Ru/C catalyzed hydrogenation of tetramethyl-1,3-cyclobutanedione which gave a mixture of stereoisomers (98%), a far better result than that given by Pd, Pt, or Rh (eq 4).[14]

(4)

Felföldi has given a broad review of the stereochemistry of the hydrogenation of substituted cyclic ketones which includes comparisons of ruthenium with other metals as catalysts.[15]

Carboxylic Acids to Alcohols.

Either RuO_2 or Ru/C catalyzes the hydrogenation of carboxylic acids, both mono- and dicarboxylic, in water to the corresponding alcohols at around 150 °C and 500-700 atm (eq 5).[16] Rhenium oxides, particularly ReO, effect this reduction under less vigorous conditions.[17]

(5)

Hydrogenation of Nitro Alkynes.

Ru/C or Ru/Al_2O_3 favor the reduction of the aromatic nitro group in (3-nitrophenyl)acetylene.[18] To avoid the observed deactivation of the catalyst, the alkyne was converted to the acetone adduct, 2-methyl-4-(3-nitrophenyl)-3-butyn-2-ol, which was hydrogenated to 2-methyl-4-(3-aminophenyl)-3-butyn-2-ol (eq 6). The base-catalyzed removal of acetone released the amino alkyne quantitatively.

Carbocyclic Aromatic Compounds.

Ruthenium, as well as rhodium, is noted for its effective catalysis of the hydrogenation of aromatic carbocycles.[1e,6] Other reducible functional groups usually remain intact. With more than one substituent attached, the configuration of the saturated product corresponds mainly to addition of hydrogen to one face of the aromatic cycle. As with other platinum metals, the selectivity is affected by the extent to which unsaturated intermediates desorb from the catalytic sites and whether the intermediates are readsorbed and reduced with selectivities differing from that of their precursor, or transformed to products other than those of simple hydrogen addition.

Aromatic Hydrocarbons.

Of all the platinum metals studied, ruthenium forms the largest amount of an observable cyclohexene in the hydrogenation of benzene or the xylenes at near atmospheric pressures.[19] Don and Scholten showed the importance of water in maximizing the yield of cyclohexene when ruthenium is the catalyst.[20] The formation of *trans* saturated isomers from substituted benzenes has been attributed to the hydrogenation of the desorbed intermediates.[21]

The $Ru(OH)_3$-catalyzed hydrogenation of *o*-xylene at 85 °C and 80-100 atm yields a *cis*/*trans* ratio of 1,2-dimethylcyclohexanes of 12.3 compared to 9.5 for Rh (eq 7).[6] Only Os and Ir (see ***Iridium***) yield larger fractions of the *cis* isomer.

Ruthenium is the most stereoselective catalyst for the perhydrogenation of naphthalene or methylnaphthalenes (95% *cis*).[13] High stereoselectivity is shown in the hydrogenation of triptycene to the *cis*-*anti*-perhydrotriptycene (eq 8).[22]

Fullerenes C_{60} and C_{70} in a ca. 85:15 ratio, dissolved in toluene and with an equal volume of water added, were hydrogenated over 5% Ru/C to yield a mixture of hydrogenated fullerenes from $C_{60}H_2$ to $C_{60}H_{40}$.[23] The hydrides retain the fullerene carbon skeleton.

Phenols and Phenyl Ethers.

Among the first reported uses of Ru was the hydrogenation of a phenolic ring contained in a polycyclic compound.[9] The reductions were performed with RuO_2 at 50 °C and 100 atm H_2, which avoided hydrogenolysis of the hydroxyl group and was stereoselective.

The hydrogenation of phenols produces cyclohexanone intermediates which probably arise from the isomerization of a cyclohexenic intermediate, a vinyl alcohol. Palladium gives the highest yields of cyclohexanone, approaching 100%; ruthenium yields are smaller but more than is obtained with other platinum metals.[24] The maximum diminishes with an increase of pressure while the fraction of the *cis* saturated product increases. This result indicates that the hydrogenation of the ketone is not as *cis* stereoselective as is the direct hydrogenation of the phenol.

That enols are among the initial desorbed intermediates in the hydrogenation of phenols is supported by the study of the hydrogenation of ethyl *p*-tolyl ether in ethanol over unsupported platinum metals (25 °C, 1 atm).[25] Ruthenium affords the simplest result in that the enol ether is the principal intermediate; ethyl 4-methyl-3-cyclohexenyl ether is formed in smaller amounts (eq 9). With platinum metals other than Ru, the hydrogenation is accompanied by the formation of 4-methyl-1,1-diethoxycyclohexane and loss of the ethoxy group, leading to 4-methylcyclohexanone and 4-methylcyclohexanol. For Ru, the *cis*/*trans* ratio diminishes with conversion as the fraction of the saturated ether formed via the direct path diminishes.

(9)

To avoid the hydrogenolysis of the ether linkages, 5% Ru/Al_2O_3 was used to hydrogenate ***Dibenzo-18-crown-6*** in 1-butanol to ***Dicyclohexano-18-crown-6*** (eq 10).[26] Other crown ethers were treated similarly using RuO_2 or the supported catalyst and the conversions were thought to be nearly quantitative.

(10)

Using Ru/Al_2O_3 (110-126 °C, 70 atm) the cresols are converted to the methylcyclohexanols with high selectivities (94-98%) but with moderate *cis* stereoselectivities, which are larger in ethanol than in water.[27]

The selectivities of the platinum metals in the hydrogenation of 2-naphthol are comparable in the formation of the two tetrahydro derivatives, 1,2,3,4- and 5,6,7,8-tetrahydronaphthols, for their tendency towards hydrogenolysis, and for their stereochemistry in the formation of the saturated products (eq 11).[28]

Anilines.

A large number of substituted anilines have been hydrogenated successfully to the cyclohexyl amines over ruthenium catalysts.[1c-f] Normally, varying amounts of dicyclohexylamines are formed which arise from the reaction of the unsaturated intermediates. At elevated pressures, ruthenium catalysts usually give the least amount of such coupled products.[29]

The formation of the dicyclohexylamine from aniline as a function of the alcohol used as solvent decreases in the order methyl > ethyl >> isopropyl &AApprox; *t*-butyl; the addition of a small amount of either NaOH or LiOH further inhibits the formation of the dialkylamine.[30]

Ru/Al_2O_3 catalyzes the hydrogenation of alkyl-substituted anilines with high chemoselectivities to the substituted cyclohexylamine (>90% except for *o*- and *m*-*t*-butylaniline) and stereoselectivities, mainly *cis*, in ethanol on Ru/Al_2O_3 (110 °C, 70 atm).[1e,27] On the same catalyst the hydrogenation of the isomeric toluidines, aminophenols, and alkoxyanilines gives similar results. Although the rate of hydrogenation diminishes by substituting acetyl or alkyl for H in the amino group, the yields and stereoselectivities remain equally good (eq 12).

Substituted Benzoic Acids.

Ruthenium has been used to hydrogenate benzoic acids, or their esters, which are substituted with alkyl, hydroxyl, amino, or additional carboxyl groups.[1e,31] Generally, the stereoselectivities are greater than those observed with other metals except possibly Rh, which may be used at lower temperatures.

Ru/C is included amongst the catalysts used in the study of the hydrogenation of *o*-, *m*-, and *p*-*t*-butylbenzoic acids (20 °C, 1 atm).[32] Rh/C gave the largest amount of the unsaturated intermediate while Ru/C resulted in the higher stereoselectivity (*cis*). The Ru/C-catalyzed hydrogenation of terephthalic acid qualifies as a preparative procedure for *cis*-cyclohexene-3,6-dicarboxylic acid (70%) (eq 13).[33]

(13)

Heterocyclic Compounds.

Ruthenium is most effective for the perhydrogenation of aromatic heterocycles such as pyrroles, pyridines, and furans. Hydrogenolysis of the cycle or that of attached negative groups is generally small.[1d] ***Pyridine*** is converted quantitatively to ***Piperidine*** using RuO_2 at 95 °C and 70-100 atm of H_2, in less than 0.5 h.[7] A large variety of substituted pyridines also were hydrogenated in water, methanol, or ethanol under comparable conditions, with 80-94% yields.

Reaction conditions can affect the chemoselectivity. The RuO_2-catalyzed hydrogenation of 3-cyanopyridine to 3-aminomethylpyridine was done in a mixed solvent, methanol and ***Ammonia***, at 95 °C and 120 atm H_2 (68%); 3-aminomethylpiperidine was obtained in comparable yield from the cyanopyridine in ammonia at 100-125 °C and 150 atm (eq 14).

(14)

A kinetic study of the Ru/C-catalyzed hydrogenation of ***Quinoline***, 2- and 8-methylquinoline, and isoquinoline shows the high selectivity towards 1,2,3,4-tetrahydroquinolines.[34] The latter as well as the 5,6,7,8-tetrahydro derivatives are converted more slowly to the decahydroquinolines (eq 15).

(15)

Five-membered heterocyclic aromatic compounds which contain nitrogen or oxygen also have been hydrogenated over ruthenium catalysts. 2,5-Bis-(3-oxobutyl)furan in dioxane is converted to 2,5-bis(3-hydroxybutyl)tetrahydrofuran over Ru/C (eq 16).[35] RuO_2 or Ru/C (70-100 °C, 100 atm) catalyze the perhydrogenation of pyrrole, 2-methylpyrrole, and carbazole.[1b]

(16)

Aromatic heterocyclic diazines such as 2-methylpyrazine and cinnoline (5,6-benzopyridazine) also are hydrogenated on RuO_2 or Ru/C.[1b]

Ruthenium(III) Chloride

$RuCl_3$

[10049-08-8] · Cl_3Ru · Ruthenium(III) Chloride · (MW 207.42) (hydrate)

[14898-67-0]

(Lewis acid;[1] catalyst for alkyne functionalization[4] and oxidation[6a])

Physical Data: mp >500 °C for anhydrous material.

Solubility: α-$RuCl_3$ (black lustrous crystals) insol alcohol, water; β-$RuCl_3$ (dark-brown, fluffy crystals) sol alcohol.

Form Supplied in: available as anhydrous solid and hydrated solid.

Analysis of Reagent Purity: elemental analysis.

Lewis Acid.

Ruthenium trichloride can serve as a mild Lewis acid. Treatment of norbornene oxide with this reagent results in a hydrocarbon skeletal rearrangement (eq 1).[1] Other ruthenium reagents such as ***Ruthenium(VIII) Oxide*** are ineffective at bringing about the desired transformation. Ruthenium trichloride, in the presence of alcohols, also catalyzes the formation of allylic ethers from allylic alcohols (eq 2).[2] It is likely that this process occurs via an allylic carbonium ion since racemization ensues when enantiomerically pure allylic alcohols are employed. The Prins reaction is catalyzed by ruthenium trichloride (eq 3).[3] While it is possible that this reaction is proceeding in a fashion analogous to the Wacker oxidation, simple Lewis acid activity can explain the observed products.

(1)

(2)

(3)

Alkyne Functionalization.

Ruthenium trichloride catalyzes the reaction of ***Acetylene*** with ***Carbon Dioxide*** and secondary amines, providing vinyl carbamates in low to moderate yields (eq 4).[4] Primary amines do not participate in this reaction and ruthenium dodecacarbonyl fails to catalyze this process. In an analogous transformation, ruthenium trichloride catalyzes the addition of carboxylic acids to terminal alkynes (eq 5).[5] Higher selectivities and increased yields are obtained when ***Tri-n-butylphosphine*** is added to the reaction mixture.

(4)

(5)

Oxidations.

Ruthenium trichloride catalyzes the oxidation of alcohols in the presence of stoichiometric ***N-Methylmorpholine N-Oxide*** (eq 6).[6a] A slight preference is noted for primary over secondary alcohols. Also, tertiary amines are oxidized to amine oxides in the presence of ruthenium trichloride and molecular ***Oxygen***.[7a]

(6)

C-H Activation.

Furan and thiophene undergo an alkylation-coupling process when exposed to ruthenium trichloride, an alcoholic solvent, and elevated temperatures (eq 7).[8]

Ruthenium(VIII) Oxide[1]

RuO_4

[20427-56-9] · O_4Ru · Ruthenium(VIII) Oxide · (MW 165.07)

(strong oxidant for many functional groups; can cleave double bonds, aromatic rings, and diols[1])

Alternate Name: ruthenium tetroxide.

Physical Data: yellow form: mp 25.5 °C; bp 40 °C; *d* 3.29 g cm^{-3}. Brownish orange form: mp 27 °C; bp 108 °C (dec).

Solubility: slightly sol water; highly sol $CHCl_3$, CCl_4.

Form Supplied in: although the reagent is commercially available either in solid form or stabilized aqueous solution, it is usually prepared in situ from black solid RuO_2 (mw 133.07) *[120236-10-1;.x*H_2O*, 32740-79-7]* or dark brown (or black) $RuCl_3$ (mw 207.42) *[10049-08-8;.x*H_2O*, 14898-67-0]*, in stoichiometric or catalytic amounts, and an oxidation agent; both of the above Ru salts are widely available.

Handling, Storage, and Precautions: handle in a fume hood only. Inhalation should be avoided; vapors irritating to eyes and respiratory tracts, since it readily oxidizes tissue, leaving a deposit of ruthenium dioxide.[2] It attacks rubber and reacts explosively with paper filter and alcohol, and violently with ether, benzene, and pyridine.[3] However, *the use of the catalytic system greatly minimizes the risk in its manipulation*, and its usage is strongly recommended.

Introduction.

When RuO_4 was introduced into organic synthesis it was generally used in stoichiometric amounts, usually prepared by oxidation of ***Ruthenium(III) Chloride*** or RuO_2 with aqueous periodate or hypochlorite and then extracted into carbon tetrachloride. This yellow solution could be roughly analyzed by treating an aliquot with ethanol to reduce the tetroxide to the black dioxide, which was collected and weighed.[4]

However, since ruthenium compounds are expensive and occasionally it is difficult to separate the products from precipitated ruthenium dioxide, it is more convenient to use a system formed by a catalytic amount of the ruthenium compound (RuO_2 or $RuCl_3$) along with an appropriate co-oxidant, usually in a biphasic solvent system. These reagents actually act as catalysts, because they are reoxidized after the reaction with organic compounds by one of the oxidants previously mentioned. Ruthenium tetroxide is usually prepared in situ from ruthenium dioxide or ruthenium trichloride by oxidation with ***Sodium Hypochlorite***,[5] ***Sodium Bromate***,[6] ***Peracetic Acid***,[6] periodic acid,[7] ***Sodium Periodate***,[8] ***Oxygen***,[9] cerium sulfate,[10] ***Potassium Permanganate***,[10] electrochemically generated ***Chlorine***,[11] or ***Potassium Monoperoxysulfate*** (Oxone®).[12]

It appears that contact between RuO_4 and the material to be oxidized takes place in the organic phase, where they are both most soluble. The ruthenium dioxide produced when oxidation occurs is insoluble in all solvents and migrates to the interface where it contacts the co-oxidant (in the aqueous layer) and is reoxidized. Thus best results are obtained when the mixture is shaken or stirred vigorously throughout the course of the reaction to achieve good contact between all components.

It has been pointed out that $RuCl_3.H_2O$ is not a good Ru source under acidic conditions (pH < 5), because it initially gives an orange Ru^{IV} chloro aquo complex, which is slowly oxidized to RuO_4. In such cases, RuO_2 is the alternative recommended.[10] In the reactions carried out at pH > 9, any RuO_4 produced in the aqueous phase is unstable, being reduced to green perruthenate (RuO_4^-), and subsequently to orange ruthenate (RuO_4^{2-}). Both species are insoluble in CCl_4. Although in most of the cited mixtures RuO_4 is considered the oxidant, it cannot be ruled out that the real oxidant is another lower valent ruthenium species. The only way to ensure that RuO_4 is really the oxidizing agent is if it is isolated after its preparation, as cited in the early literature.[2,4] UV analysis of the RuO_4 solutions can provide some information about this, because RuO_4 gives absorption bands at λ_{max} 310 nm (strong) and 380 nm. These bands are replaced by others at λ_{max} 310 nm (strong), 385 nm (strong), and 460 nm when base is added to the solution, corresponding to the formation of the perruthenate ion (RuO_4^-) and subsequently to absorption bands at λ_{max} 385 nm and 460 nm (strong), produced by RuO_4^{2-}.[1,13]

RuO_4 is a strong oxidant. However, conditions for ruthenium-catalyzed reactions are very mild; usually a few hours (or less) at room temperature (or below) is sufficient. A thorough study of oxidations with RuO_4 generated in situ from $RuO_2.xH_2O$ and $RuCl_3.xH_2O$ shows the importance of the presence of water in the reaction.[10,14] Thus many ruthenium-catalyzed reactions have been performed in the CCl_4-H_2O solvent system. The addition of ***Acetonitrile*** to the system greatly improves yields and reaction times,[8] especially when carboxylic groups are present or generated in the reaction. MeCN probably disrupts the insoluble carboxylate complexes and returns the ruthenium to the catalytic cycle, acting as a good ligand for the lower valent (III/II) ruthenium present.[15]

An important feature of RuO_4-catalyzed oxidations is that the stereochemistry of the stereocenters close to the reaction site (eqs 1 and 2)[16,17] remains unaffected.

In a typical procedure,[8] to a stirred mixture of 2 mL of CCl_4-2 mL of MeCN-3 mL of H_2O/mmol of organic compound are added 4.1 mmol of ***Sodium Periodate***/mmol of organic compound and 2.2 mmol% of $RuCl_3.xH_2O$ ($RuO_2.xH_2O$ is equally effective) sequentially. The mixture is stirred vigorously at 0-25 °C until the end of the reaction (TLC or GC monitoring). Then 20 mL of diethyl ether are added and the vigorous stirring is continued for 10 min to precipitate black RuO_2. The reaction mixture is then dried ($MgSO_4$) and filtered through qualitative Whatman filter paper 2. The solid residue is then washed with diethyl ether (3 × 5 mL). The combined organic phases are concentrated to yield the crude oxidation product.

Functional Group Oxidations without Bond Cleavage.

One of the most common synthetic uses of ruthenium-catalyzed oxidations is the reaction with alcohols. A mixture of RuO_2 or $RuCl_3$ with strong co-oxidants converts primary alcohols to carboxylic acids[18] (eq 3),[19] including epoxy alcohols (eq 4),[8] but under milder (***Iodosylbenzene***,[20] molecular oxygen,[21] ***Calcium Hypochlorite*** (eq 5),[22] or amine *N*-oxides[23]) or controlled conditions,[19] aldehydes are obtained (eq 6).[24]

(3)

(4)

(5)

(6)

Secondary alcohols are transformed into ketones.[1,3,25] The yields obtained from the oxidation of secondary alcohols are usually excellent. Since the reactions are carried out under very mild conditions, there is little danger of the product undergoing secondary reactions. Ketones can also be prepared using a great variety of other oxidants[26] (see, for example ***Chromium(VI) Oxide*** and ***Dimethyl Sulfoxide*** based oxidant reagents), which in some cases are more readily available and less expensive. However, RuO_4 is recommended for reactions which require a vigorous oxidant under mild conditions. Thus it can be used to oxidize alcohols which are resistant to other oxidants: (**1**) is successfully oxidized with RuO_4, while attempts made with 15 other standard oxidizing procedures failed (eq 7);[27] oxidation of (**2**) is successful in good yield using RuO_4 (eq 8), being fruitless with CrO_3 in either ***Pyridine***, ***Acetone***, ***Acetic Acid***, or Al(O-*i*-Pr)$_3$, $KMnO_4$, ***Lead(IV) Acetate*** in acetone, with CrO_3 in *i*-BuOH giving the ketone in very low yield.[28] Numerous examples of the advantages of RuO_4 over ***Dipyridine Chromium(VI) Oxide*** for the oxidation of carbohydrates have been cited.[29]

(1) (7)

(2) (8)

RuO_4 is also reported to provide higher yields when other oxidizing procedures give poor yields. As examples can be cited the conversions of cyclobutanols to cyclobutanones (eq 9)[30] and the transformation of lactones into the corresponding ketocarboxylates under basic conditions (60-97%) (eq 10). Significantly higher yields are obtained compared with $KMnO_4$ under alkaline conditions.[31]

(9)

(10)

Vicinal diols can be oxidized to diketones but only in low yields, the principal reaction being the oxidative cleavage of the C-C bond.[1] If the hydroxyl groups are not adjacent, then diketones can be prepared (eq 11).[32]

(11)

The catalytic procedure is also applicable to the oxidation of aldehydes to carboxylic acids,[1,2,23,33] primary alkyl iodides to carboxylic acids (eq 12),[34] aromatic hydrocarbons to quinones,[25] and sulfides to sulfones,[25] including an improved and simple method to obtain water-soluble sulfones using periodic acid as the co-oxidant in high concentration conditions (eq 13).[35]

(12)

(13)

Oxidation of 1,2-cyclic sulfites to 1,2-cyclic sulfates with RuO_4 has been reported as a part of a method to activate diols for further nucleophilic attack (eq 14).[36]

(14)

Along with these types of oxidations, RuO_4 is used to carry out transformations that involve oxidation of methylene groups α to heteroatoms such as oxygen and nitrogen. Thus it is possible to convert acyclic ethers into esters, such as methyl ethers into methyl esters (eq 15),[8] ethyl ethers into acetates,[37] and benzyl ethers into benzoates (eq 16).[38] It is possible to avoid the benzyl-benzoyl group transformation by carrying out the reaction at 0 °C and/or in the presence of base (eq 17).[39]

(15)

(16)

(17)

Cyclic ethers are also oxidized, yielding lactones (eq 18).[40] Although secondary positions are usually more reactive towards oxidation than tertiary positions, the regioselectivity of RuO_4 can be strongly dependent on steric factors (eq 19).[41] In those cases in which lactones are unstable under aqueous conditions (notably δ- and ε-lactones), the corresponding diacids are the final products, presumably via the intermediacy of lactols (eq 20).[42]

(18)

(19)

(20)

RuO_4 also oxidizes alkyl amines to mixtures of nitriles and amides,[43] cyclic amines to lactams,[44] and amides (cyclic or acyclic) to imides (eq 21),[45] including an improved procedure that uses ethyl acetate as the organic solvent in the biphasic solvent system, enhancing both the solubility of the substrates and the rate of reaction.[46]

(21)

RuO_4 usually reacts with unsaturated systems, giving cleavage of the C-C bonds. Although epoxide formation has been detected in small amounts (ca. 1%),[47] it can be the principal reaction when the double bond is located in a very hindered position (eq 22).[48] With 1,5-dienes, unexpected oxidation results are obtained. Thus oxidation of geranyl acetate leads to a tetrahydrofuran mixture, instead of the cleavage products (eq 23).[8] Nonterminal alkynes are also oxidized without cleavage, yielding vicinal diketones (eq 24).[49]

(22)

(23)

(24)

RuO_4 is also capable of oxidizing C-H bonds in bridged bicyclic and tricyclic alkanes to alcohols by insertion of oxygen (eq 25).[50] Although epoxides survive RuO_4 oxidations, when such functionality is located in this kind of bridged system a tandem ruthenium-catalyzed rearrangement/oxidation occurs (eq 26).[51]

(25)

(26)

Most of the common protecting groups used in organic synthesis are stable under RuO_4 oxidation conditions (eq 27).[52] Generally it is only necessary to carry out the reaction at 0 °C or perform it under buffered conditions when acid-sensitive groups are present, such as tetrahydropyranyl (eq 28)[33] or silyl ethers (eq 29).[53]

(27)

(28)

(29)

Functional Group Oxidations with Bond Cleavage.

Carbon-carbon double bonds are readily cleaved by RuO_4 to give ketones and aldehydes or carboxylic acids. In this respect the greater vigor of RuO_4 as an oxidant stands in marked contrast to that of ***Osmium Tetroxide*** (eq 30),[54] which also reacts with C-C double bonds but does not cleave them. While carboxylic acids are usually the final products, sometimes under neutral conditions aldehydes can be obtained from double bonds that are not fully substituted.[55] The cleavage of such double bonds proceeds by the route: alkene -> dialdehyde -> diacid.[5a] RuO_4 is also indicated to carry out oxidations of substrates with double bonds resistant to other oxidizing agents, such as OsO_4, ***Potassium Permanganate***, and ***Ozone*** (eq 31).[56] Degradative oxidations of unsaturated C-C bonds with loss of carbon atoms occur with terminal alkynes (eq 32),[5b] cyclic allylic alcohols (eq 33),[57] and α,β-unsaturated ketones.[57]

(30)

(31)

(32)

(33)

RuO_4 also cleaves α-chloroenol derivatives obtained from α,α´-dichlorocyclobutanones to give dicarboxylic acids through successive treatment with ***n-Butyllithium***, ***Acetic Anhydride***, and ***Sodium Periodate***-RuO_2 (eq 34).[58,59]

(34)

RuO_4-catalyzed oxidation of arenes can proceed in two ways: (a) the phenyl ring can be cleaved from R-Ph to R-CO_2H (eq 35);[8] (b) the phenyl ring can be degraded to form a dicarboxylic acid in polycyclic aromatic hydrocarbons (eq 36).[60] An electron-donating substituent favors cleavage of the substituted ring, while an electron-withdrawing substituent favors cleavage of the unsubstituted ring. Thus selective oxidation of the more activated ring can be performed with high selectivity. When acid-sensitive groups are not present, an improved procedure that utilizes periodic acid instead of sodium periodate can be used, preventing the problems associated with the precipitated sodium iodate, allowing the reaction to go to completion, and permitting oxidation reactions to be run on larger scales (eq 37).[61]

(35)

(36)

Furan[62] (eq 38),[63] thiophene (eq 39),[64] and benzopyridine rings (eq 40)[65] are also cleaved by catalytic RuO_4 to carboxylic acids. When pyridine derivatives are not oxidized, they can be transformed into their *N*-oxides prior to the oxidation to decrease the ability of the nitrogen to complex with ruthenium, albeit with low yields (eq 41).[64]

Vicinal diols are cleaved to give carboxylic acids (eq 42) following the route: glycol -> α-ketol -> diacid. A diketone is apparently not an intermediate in this oxidation.[5a] The mildness of the reaction conditions is underscored by the lack of epimerization shown in eq 43.[8] This feature has been proved to be general when RuO_2-$NaIO_4$ is used to oxidize chiral diol benzoates, this being a useful method to synthesize chiral α-benzoylcarboxylic acids (eq 44).[66]

(42)

(43)

(44)

Other vicinal dioxygenated functionalities present (eq 45)[5a] or generated in situ undergo oxidation with C-C bond cleavage by RuO_4 to give carboxylic acids, with (eq 46)[67] or without (eq 47)[68] loss of carbon atoms.

(45)

(46)

(47)

RuO_4 is also used to cleave oxidatively carbon-boron bonds in cyclic alkylboranes, presenting advantages over the usage of Cr^{VI} for the same purpose or even the oxidation of the corresponding alcohols (eq 48).[69]

(48)

Another formal carbon-heteroatom bond cleavage occurs in the oxidation of cyclic ethers that give cyclic products unstable to the oxidation conditions (eq 49).[42]

(49)

As pointed out, ketones are stable under RuO_4 oxidation conditions, although cyclic ketones can undergo Baeyer-Villiger reaction when ***Sodium Hypochlorite*** is used as co-oxidant (eq 50).[70]

(50)

Other Ruthenium-Based Oxidation Reagents.

Less reactive oxidants are obtained by lowering the oxidation state of ruthenium. One example is the ruthenate ion (RuO_4^{2-}) which, as mentioned above, is formed when RuO_4 is treated with alkaline solutions. The most important synthetic applications of such ions is in the oxidation of alcohols in basic media to give carboxylic acids or ketones.[71] In general, RuO_4^{2-} does not appear to oxidize isolated C-C double bonds at room temperature (eq 51).[72]

(51)

When there is no reductive pathway for the elimination of ruthenate esters, RuO_4^{2-} has been used as an alternative to RuO_4 (eq 52).[40]

(52)

The perruthenate ion RuO_4^- is also useful for the oxidation of primary alcohols, nitroalkanes, primary halides, and aldehydes to acids.[73] When tetraalkylammonium salts are added to the RuO_4^- solutions, stable tetraalkylammonium perruthenates are obtained. Tetra-*n*-butylammonium perruthenate (TBAP) and tetra-*n*-propylammonium perruthenate (TPAP) are used to oxidize successfully alcohols to carbonyl compounds (eq 53),[23] and sulfides to sulfones[74] under very mild conditions, employing as co-oxidant ***N-Methylmorpholine N-Oxide*** (NMO) (see ***Tetra-n-propylammonium Perruthenate***).

(53)

The behavior of inorganic transition metal oxidizing agents can be modified by the introduction of ligands. Electron-rich ligands, which increase the basicity of the metal and moderate its oxidizing power, have been used to improve the selectivity of these oxidation reactions.

Thus porphyryl-[75] and bipyridyl-Ru complexes epoxidize alkenes, instead of cleaving the double bond (eq 54).[47]

(54)

Several other Ru complexes, along with co-oxidants or hydrogen acceptors, are used as catalysts in oxidation reactions, $RuCl_2(PPh_3)_3$ and $RuH_2(PPh_3)_4$ being the most commonly utilized. The conversion of alkanes and alcohols to aldehydes or ketones is achieved with $RuCl_2(PPh_3)_3$[76] and molecular oxygen,[77] ***Bis(trimethylsilyl) Peroxide***,[78] ***Iodosylbenzene***,[20] ***N-Methylmorpholine N-Oxide*** (eq 55),[79] ***t-Butyl Hydroperoxide***,[80] and hydrogen acceptors.[81] Selective oxidations of primary vs. secondary alcohols are possible (eq 56),[78] and it is also possible to stop the oxidation of primary alcohols at the aldehyde stage by simply controlling the co-oxidant equivalents and reaction times.[20] α-Diketones can be obtained from vicinal diols (eq 57)[82] and nonterminal alkynes (eq 58).[83]

(55)

(56)

(57)

(58)

The combination of $RuH_2(PPh_3)_4$ plus a hydrogen acceptor, like benzalacetone or ***Acetone***, converts unsymmetrically substituted 1,4- and 1,5-diols into β-substituted γ-lactones and γ-substituted δ-lactones, respectively (eqs 59 and 60),[84] also allowing the oxidative condensation of alcohols, or aldehydes and alcohols, to give esters (eq 61).[85]

(59)

(60)

(61)

Oxoruthenium species are also useful in organic oxidations. Thus oxoruthenium(V) complexes obtained from lower valent ruthenium species effect α-oxygenation of tertiary amines[86] and β-lactams (eq 62).[87] $[PPh_4][RuO_2(OAc)Cl_2].2AcOH$ generated from RuO_4 is used to oxidize alcohols and benzyl halides to carbonyl compounds.[88]

Salcomine[1]

[14167-18-1] · $C_{16}H_{14}CoN_2O_2$ · Salcomine · (MW 325.25)

(oxidizing agent for conversion of phenols to quinones;[3-8] *N*-dealkylation of anilines;[10] 1,4-acetoxylation of dienes;[14] nonoxidative hydration of alkenes and alkynes;[16-18] oxidative carbonylation of amines;[19,20] oxidative cleavage of fused heterocycles;[21,22] oxidation of hydrazones to diazo compounds;[23] catalyst for rearrangements[25,26])

Alternate Names: bis(salicylidene)ethylenediiminocobalt(II); Co^{II}(salen); Co(salen).

Solubility: sol nonpolar solvents including DMF, methanol, chloroform.

Form Supplied in: brown or black-grey powder.

Preparative Method: see Diehl and Hack.[1]

Handling, Storage, and Precautions: may be stored at room temperature in air for long periods of time.

Phenol and Aniline Oxidations.

Salcomine is usually the reagent of choice for the oxidation of *para*-unsubstituted phenols to 1,4-quinones. It serves as a catalyst in this transformation in which molecular ***Oxygen*** is the stoichiometric oxidant. Salcomine compares favorably in ease of preparation, handling, and convenience of workup with the well-known Fremy's salt, previously the standard reagent for this conversion. Reactions take place at room temperature and are generally conducted in DMF.

Originally studied as a synthetic oxygen carrier,[2] salcomine attracted attention in the 1980s when its catalysis of the phenol-to-quinone oxidation[3] was discovered and exploited by synthetic chemists.[4] Its use appears to be restricted to the oxidation of phenols which do not bear electron-withdrawing groups. For example, Parker and Petraitis were unable to oxidize 2-hydroxy-3-methoxypropiophenone to the corresponding *p*-quinone,[5] but found that the acetalized substrate gave a good yield of the acetal quinone (eq 1).[6]

A particularly useful example of the phenol-to-quinone conversion is the oxidation of inexpensive 1,5-naphthalenediol to a 5:1 mixture of juglone and its *o*-quinone regioisomer (eq 2). The salcomine oxidation of 5-methoxy-1-naphthol produces juglone methyl ether and its regioisomer as a 4:1 mixture.[7]

Thymoquinone, viewed as a convenient starting material for the synthesis of sesquiterpenes, was conveniently obtained from thymol in 71-84% yield and from carvacrol in 79-93% yield (eq 3).[8]

The oxidation of estrone to the corresponding quinol and an interesting, highly oxygenated steroid was effected by salcomine catalysis (eq 4).[9]

Salcomine-catalyzed O_2 oxidation of *N*-alkyl aromatic amines (substituted at the *meta* or *para* position) has been examined. Optimized conditions convert *N*-*n*-butyl-4-phenylaniline to 4-phenylaniline in 69% yield.[10] For some examples the imine intermediate has been isolated.[11,12] A 4-methoxy-2,6-disubstituted aniline was converted to the corresponding quinone imine. However, 2,4,6-trisubstituted anilines (where the substituents are *t*-butyl and aryl) are converted to 4-peroxy-2,5-cyclohexadien-1-imines and nitrobenzenes.[13]

Other Oxidations.

A triple catalytic system involving Pd^{II}, ***1,4-Benzoquinone***, salcomine, and air was used to effect the 1,4-acetoxylation of conjugated dienes (eq 5).[14] Co(salophen) (**1**) and Co(TPP) (TPP = tetraphenylporphyrin) were more efficient reagents for this transformation, however. Co(salophen) and Co(TPP) also served to reoxidize hydroquinone to quinone in an allylic oxidation system (eq 6). ***Iron(II) Phthalocyanine*** (Fe(Pc)) was more effective in this system and Co(salen) was not active.

(1)

An oxidation-reduction mechanism is postulated for the salcomine-catalyzed hydration of styrenes. Further oxidation of the product affords aryl ketones.[15] The Co(TPP) oxidation can be carried out in the presence of borohydride, and under these conditions only the benzylic alcohol product is obtained.[16] When chiral Co(salen) derivatives were used in the styrene hydration, modest yields (18-31%) of 1-phenylethanol with modest enantiomeric excesses (0-38%) were reported.[17]

The analogous hydration of terminal alkynes is also proposed to proceed through an oxidation-reduction mechanism.[18] Mandelic and glyoxylic ester byproducts are also produced.

Salcomine catalyzes the oxidative carbonylation of primary aromatic amines in methanol. The primary products in most cases are the symmetrical urea and the methyl carbamate. Under optimized conditions, *o*-aminobenzamide affords the quinazolinedione in 64% yield (eq 7).[19] Iodide was found to promote the oxidative carbonylation in some systems.[20]

Several other oxidations have been the subject of limited studies. Salcomine and its derivatives catalyze the oxidative cleavage of fused heterocycles, including the conversion of 3-hydroxyflavones to *o*-aryloxybenzoates[21] and 3-substituted indoles to *o*-formylaminoacetophenone derivatives.[22] Hydrazones are oxidized to diazo compounds.[23] The reduction of NO to N_2 is effected by ***Sodium Borohydride*** in the presence of Co^{II}(salen).[24]

Nonoxidative Conversions.

Co(TPP) and Co^{II}(salen) catalyze the rearrangement of monocyclic endoperoxides to furans.[25] Salcomine and several analogs are reported to catalyze the cycloreversion of TMDC-Q to TMDC-NBD (eq 8). Carboxy-*N*,*N*-disalicylidenephenylenediiminatocobalt was immobilized on alumina to afford a packing material for a fixed bed reactor which was effective in catalyzing this reaction.[26]

Samarium(0)[1]

Sm

[7440-19-9] · Sm · Samarium(0) · (MW 150.36)

(used with diiodomethane to iodomethylate ketone and aldehyde substrates;[2] cyclopropanates esters and α-halo ketones in the presence of diiodomethane to generate the one-carbon homologated product;[2a,b,3] promotes the selective and directed cyclopropanation of allylic alcohols[4-6])

Physical Data: mp 1072 °C; bp 1900 °C; *d* 7.470 g cm^{-3}.

Form Supplied in: silvery metal; tarnishes on exposure to air; 40 mesh solid, ingot, chip, and foil (all commercially available).

Handling, Storage, and Precautions: moderately air- and moisture-sensitive. Should be handled accordingly under an inert atmosphere.

Iodomethylation of Ketones and Aldehydes.

Samarium metal may be utilized in conjunction with ***Diiodomethane*** to accomplish iodomethylation reactions.[2] A wide variety of ketone and aldehyde substrates may be converted to the corresponding iodohydrins in good to high yields, providing an efficient means for one-carbon homologation (eq 1).

(1)

Even readily enolizable substrates such as cyclopentanone are converted to the corresponding iodohydrin in high yield upon treatment with samarium and diiodomethane (eq 2). Highly hindered ketones do not undergo iodomethylation; α,β-unsaturated carbonyl compounds subjected to these reaction conditions provide only moderate yields of the desired products.

(2)

Cyclopropanation of Esters and α-Halo Ketones.

Esters react with diiodomethane in the presence of samarium to afford the 1-substituted cyclopropanols, thereby providing a one-carbon homologation route to these molecules (eq 3).[3] Likewise, α-halo substituted ketones react in a similar manner to provide cyclopropanols (eqs 4 and 5) via a Simmons-Smith-type cyclopropanation of the samarium enolate.[2a,b]

(3)

(4)

R, R', X=Ph, H, Br	81%
Ph, H, I	88%
$-(CH_2-)_4$, Br	81%

(5)

Directed Cyclopropanation of Allylic Alcohols.

A more efficient method of achieving cyclopropanation involves the use of Sm(Hg) in the presence of ***Chloroiodomethane*** (eq 6).[4] The resulting samarium carbenoid generated under these reaction conditions reacts exclusively with allylic alcohols. Many other functionalities such as isolated alkenes, homoallylic alcohols, and other functionalized alkene substrates are inert under these reaction conditions.

(6)

Thus geraniol and nerol, when subjected to these reaction conditions, undergo cyclopropanation at only the allylic alkene, each producing a single diastereomeric product in excellent yield (eqs 7 and 8).[4a,b] Consequently, the Sm(Hg) protocol is preferential to the Simmons-Smith and related reagents which typically provide approximately 5% of byproducts resulting from cyclopropanation at the isolated alkene in geraniol. In addition to the exceptional chemoselectivity that this reagent possesses, the Sm(Hg) reagent displays excellent stereospecificity with respect to alkene geometry. Cyclopropanation of geraniol and nerol demonstrates that complete stereospecificity is obtained when subjected to the Sm(Hg) reagent.

(7)

Use of metalated alkenes containing tin or silicon substituents also react with excellent diastereoselectivity under similar reaction conditions, providing highly functionalized cyclopropanes (eq 9).[4d] The stannylated product may be transmetalated and the resulting lithium anion may be reacted with various electrophiles, thereby providing a route to diastereomers inaccessible by direct cyclopropanation (eq 10).

The samarium amalgam-mediated cyclopropanation has been used in the synthesis of 1,25-dihydroxycholecalciferol to generate the cyclopropyl alcohol stereospecifically and in high yield (eq 11).[5] Likewise, the desired stereochemistry was generated under the influence of the two stereogenic centers on the (*R*,*R*)-2,3-butanediol acetal (eq 12).[5]

The Sm(Hg) method may also be utilized to perform ethylidenation reactions (eq 13).[4a,b,6] This protocol is preferential since use of pyrophoric ***Diethylzinc*** may be avoided; additionally, the samarium-promoted reaction permits higher diastereoselectivities to be realized in this transformation.

Samarium(III) Chloride

[10361-82-7] · Cl_3Sm · Samarium(III) Chloride · (MW 256.71)

(promotes electrochemical coupling reactions of aromatic diketones and aromatic esters to yield the 1,2-diol or 1,2-diketone, respectively;[1,2] catalyzes aldol condensations and facilitates cyanohydrin formation;[3] forms an organosamarium species with stannanes that adds 1,2 to conjugated ketones;[5] catalyzes the ring opening of epoxides and chemoselective removal of acetal protecting groups;[6,7] promotes acetylation of aldehydes[8])

Physical Data: mp 678 °C; *d* 4.46 g cm^{-3}.

Solubility: sol 6.4 g/100mL pyridine; 99.9 g/100 mL hot water; 92.4 g/100 mL cold water.

Form Supplied in: white-yellowish powder, ampouled under argon.

Handling, Storage, and Precautions: somewhat air and water sensitive. Reactions are typically performed under an inert atmosphere of argon or nitrogen.

Formation of Cyclopropane Diols and 1,2-Diketones.

Samarium(III) chloride can be utilized in the formation of cyclopropane diols via the coupling of carbonyl compounds (eq 1). In this process an active Sm^{II} species is generated by the electrochemical reduction of a catalytic amount of Sm^{III}.[1] The use of this method, however, is restricted to carbonyls containing aromatic functionality.

(1)

Diaryl 1,2-diketones are obtained in moderate to good yields in a similar method by electrochemical coupling of aromatic esters (eq 2).[2] This transformation utilizes the in situ preparation and regeneration of the Sm^{II} species but is limited to substrates with aromatic functionality on the ester. Halides on the aromatic moiety undergo reduction under these conditions.

(2)

Aldol Reactions and Cyanohydrin Formation.

$SmCl_3$ catalyzes the aldol addition of silyl enol ethers to aldehydes wherein the product is isolated as a mixture of the alcohol and TMS

ether (eq 3).[3]

(3)

Additionally, samarium(III) chloride facilitates the formation of cyanohydrins from aryl or alkyl aldehydes and ***Cyanotrimethylsilane*** (eq 4).[3] Epoxides undergo regioselective ring opening when treated with $SmCl_3$ and Me_3SiCN to afford the corresponding cyanohydrin (eq 5).[3]

(4)

(5)

Ether Formation.

Ethers and thioethers are formed in good yield upon treatment of allylic alcohols with catalytic $SmCl_3$ (eqs 6 and 7).[4]

(6)

(7)

1,2-Addition to Conjugated Ketones.

Treatment of α,β-unsaturated ketones with samarium(III) chloride, ***n-Butyllithium***, and ***Tetraallylstannane*** results in excellent yields of product resulting from 1,2-addition of the organosamarium reagent generated under the reaction conditions (eq 8).[5]

(8)

Epoxide Ring Opening and Protecting Group Removal.

$SmCl_3$ catalyzes the stereoselective and regioselective ring opening of epoxides (eqs 9 and 10) by thiol nucleophiles to generate the resulting thioalcohol in high yield.[6] The samarium(III) chloride protocol has advantages over other Lewis acid catalysts in that shorter reaction times are required.

(9)

R	R'	% Yield
Me	*p*-anisyl	84
Et	CH_2Ph	77

(10)

R = Ph, 48 h, 84%
R = Bn, 120 h, 78%

Samarium(III) chloride is also effective in the removal of protecting groups. Cyclic acetals undergo cleavage faster than acyclic acetals, providing an efficient means for selective removal of protecting group functionality (eqs 11 and 12).[7] Additionally, transformation of acetals to aldehydes is slower than that to ketones, providing excellent chemoselectivity in protecting group removal. Acid-sensitive functionalities such as *t*-butyldimethylsilyl ethers and methoxymethyl ethers are inert to these reaction conditions, as are methyl and benzyl ethers.

(11)

(12)

Chemoselective Acetalization of Aldehydes.

Samarium(III) chloride possesses the ability to chemoselectively acetalize aldehydes in the presence of the carboxylic acid functionality, i.e. no esterification occurs under these reaction conditions (eq 13).[8]

Samarium(II) Iodide[1]

SmI_2

[32248-43-4] · I_2Sm · Samarium(II) Iodide · (MW 404.16)

(one-electron reducing agent possessing excellent chemoselectivity in reduction of carbonyl, alkyl halide, and α-heterosubstituted carbonyl substrates;[1] promotes Barbier-type coupling reactions, ketyl-alkene coupling reactions, and radical cyclizations[1])

Physical Data: mp 527 °C; bp 1580 °C; *d* 0.922 g cm^{-3}.

Solubility: soluble 0.1M in THF.

Form Supplied in: commercially available as a 0.10 M solution in THF.

Preparative Methods: typically prepared in situ for synthetic purposes. SmI_2 is conveniently prepared by oxidation of ***Samarium(0)*** metal with organic dihalides.[2]

Handling, Storage, and Precautions: is air sensitive and should be handled under an inert atmosphere. SmI_2 may be stored over THF for long periods when it is kept over a small amount of samarium metal.

Reduction of Organic Halides and Related Substrates.

Alkyl halides are readily reduced to the corresponding hydrocarbon by SmI_2 in the presence of a proton source. The ease with which halides are reduced by SmI_2 follows the order I > Br > Cl. The reduction is highly solvent dependent. In THF solvent, only primary alkyl iodides and bromides are effectively reduced;[2] however, addition of HMPA effects the reduction of aryl, alkenyl, primary, secondary, and tertiary halides (eq 1).[3,4] Tosylates are also reduced to hydrocarbons by SmI_2. Presumably, under these reaction conditions the tosylate is converted to the corresponding iodide which is subsequently reduced.[4,5]

(1)

Samarium(II) iodide provides a means to reduce substrates in which the halide is resistant to reduction by hydride reducing agents (eq 2).

(2)

Samarium(II) iodide has been utilized as the reductant in the Boord alkene-type synthesis involving ring scission of 3-halotetrahydrofurans (eq 3).[6] SmI_2 provides an alternative to the sodium-induced reduction which typically affords mixtures of

stereoisomeric alkenes and overreduction in these transformations. When SmI_2 is employed as the reductant, isomeric purities are generally >97% and overreduction products comprise <3% of the reaction mixture.

(3)

Reduction of α-Heterosubstituted Carbonyl Compounds.

Samarium(II) iodide provides a route for the reduction of α-heterosubstituted carbonyl substrates. A wide range of α-heterosubstituted ketones is rapidly reduced to the corresponding unsubstituted ketone under mild conditions (eq 4).[7] The reaction is highly selective and may be performed in the presence of isolated iodides as well as isolated ketones.[7]

(4)

Y	Isolated yield (%)
Cl	100
SPh	76
S(O)Ph	64
SO_2Ph	88

Samarium(II) iodide-induced reductive cleavage of α-hydroxy ketones provides a useful entry to unsubstituted ketones (eq 5).[8]

(5)

Samarium(II) iodide promotes the reductive cleavage of α-alkoxy ketones. Pratt and Hopkins have utilized this protocol in synthetic studies en route to betaenone B (eq 6).[9]

(6)

Likewise, this procedure provides a route for the reduction of α,β-epoxy ketones and α,β-epoxy esters to generate the corresponding β-hydroxy carbonyl compounds (eqs 7 and 8).[3,10] The epoxy ketone substrates may be derived from Sharpless asymmetric epoxidation. Consequently, this procedure provides a means to prepare a variety of chiral, nonracemic β-hydroxy carbonyl compounds that are difficult to acquire by more traditional procedures.

(7)

(8)

Vinyloxiranes undergo reductive epoxide ring opening with samarium(II) iodide to provide (*E*)-allylic alcohols (eq 9).[3,10b,11] These reaction conditions are tolerant of ketone, ester, and nitrile functional groups. Again, Sharpless asymmetric epoxidation chemistry may be utilized to gain entry to the desired nonracemic substrates, thereby providing a useful entry to highly functionalized, enantiomerically enriched allylic alcohols.

Y	Isolated yield (%)
COSEt	80
SO_2Ph	82
$P(O)(OEt)_2$	84
H	69
Me	42
SPh	54

A useful method for preparation of β-hydroxy esters is accomplished by SmI_2-promoted deoxygenation of an α-hydroxy ester followed by condensation with a ketone (eq 10).[12] In some instances, excellent diastereoselectivities are achieved, although this appears to be somewhat substrate dependent.

A useful reaction sequence for transforming carbonyl compounds to one-carbon homologated nitriles has evolved from the ability of SmI_2 to deoxygenate cyanohydrin *O,O′*-diethyl phosphates (eq 11).[13] The procedure is tolerant of a number of functional groups including alcohols, esters, amides, sulfonamides, acetals, alkenes, alkynes, and amines. Furthermore, it provides a distinct advantage over other previously developed procedures for similar one-carbon homologations.

Deoxygenation Reactions.

Sulfoxides are reduced to sulfides by SmI_2 (eq 12).[2,3,14] This process is rapid enough that reduction of isolated ketones is not a competitive process. Likewise, aryl sulfones are reduced to the corresponding sulfides by SmI_2 (eq 13).[3,12]

(12)

(13)

Barbier-Type Reactions.

Samarium(II) iodide is quite useful in promoting Barbier-type reactions between aldehydes or ketones and a variety of organic halides. The efficiency of SmI_2 promoted Barbier-type coupling processes is governed by the substrate under consideration in addition to the reaction conditions employed. In general, alkyl iodides are most reactive while alkyl chlorides are virtually inert. Typically, catalytic ***Iron(III) Chloride*** or ***Hexamethylphosphoric Triamide*** can be added to SmI_2 to reduce reaction times or temperatures and enhance yields. Kagan and co-workers have recently applied an intermolecular SmI_2-promoted Barbier reaction towards the synthesis of hindered steroidal alcohols. An intermolecular Barbier-type reaction between the hindered ketone and ***Iodomethane*** produced a 97:3 mixture of diastereomers in excellent yield (eq 14).[15]

(14)

R = TBDMS

97:3

Samarium(II) iodide-promoted intramolecular Barbier-type reactions have also been employed to produce a multitude of cyclic and bicyclic systems.[1] Molander and McKie have employed an intramolecular Barbier-type reductive coupling reaction to promote the formation of bicyclo[*m.n.*1]alkan-1-ols from the corresponding iodo ketone substrates in good yield (eq 15).[16]

(15)

Annulation of five- and six-membered rings proceeds with excellent diastereoselectivity via an intramolecular Barbier-type process (eq 16).[17] The Barbier-type coupling scheme provides a reliable and convenient alternative to other such methods for preparing fused bicyclic systems.

(16)

The SmI_2-promoted Barbier-type reaction has also been utilized in the synthesis of polyquinanes. Cook and Lannoye have employed this method to effect a bis-annulation of an appropriately substituted diketone (eq 17).[18]

(17)

Substituted β-keto esters also provide excellent substrates for the intramolecular Barbier cyclization (eq 18).[19] Diastereoselectivities are typically quite good but are highly dependent on substituent and solvent effects.

(18)

Nucleophilic Acyl Substitutions.

Samarium(II) iodide facilitates the highly selective intramolecular nucleophilic acyl substitution of halo esters (eqs 19 and 20).[20]

(19)

(20)

Unlike organolithium or organomagnesium reagents, SmI_2-promoted nucleophilic substitution does not proceed with double addition to

the carbonyl, nor are any products resulting from reduction of the final product observed. With suitably functionalized substrates, this procedure provides a strategy for the formation of eight-membered rings (eq 21).

Ketone-Alkene Coupling Reactions.

Ketyl radicals derived from reduction of ketones or aldehydes with SmI_2 may be coupled both inter- and intramolecularly to a variety of alkenic species. Excellent diastereoselectivities are achieved with intramolecular coupling of the ketyl radical with α,β-unsaturated esters.[21] In the following example, ketone-alkene cyclization took place in a stereocontrolled manner established by chelation of the resulting Sm(III) species with the hydroxyl group incorporated in the substrate (eq 22).[21b]

A similar strategy utilizing β-keto esters provided very high diastereoselectivities in the ketyl-alkene coupling process. In these examples, chelation control about the developing hydroxyl and carboxylate stereocenters was the source of the high diastereoselectivity achieved (eq 23).[22]

Alkynic aldehydes likewise undergo intramolecular coupling to generate five- and six-membered ring carbocycles. This protocol has been utilized as a key step in the synthesis of isocarbacyclin (eq 24).[23] SmI_2 was found to be superior to several other reagents in this conversion.

Samarium(II) iodide in the presence of HMPA effectively promotes the intramolecular coupling of unactivated alkenic ketones by a reductive ketyl-alkene radical cyclization process (eq 25). This protocol provides a means to generate rather elaborate carbocycles through a sequencing process in which the resulting organosamarium species is trapped with various electrophiles to afford the cyclized product in high yield.[24]

Pinacolic Coupling Reactions.

In the absence of a proton source, both aldehydes and ketones are cleanly coupled in the presence of SmI_2 to the corresponding pinacol.[25] Considerable diastereoselectivity has been achieved in the coupling of aliphatic 1,5- and 1,6-dialdehydes, providing near exclusive formation of the *cis*-diols (eq 26).[26]

Intramolecular cross coupling of aldehydes and ketones proceeds with excellent diastereoselectivity and high yield in suitably functionalized systems wherein chelation control by the resulting Sm^{III} species directs formation of the newly formed stereocenters (eq 27).[22a,27] A similar strategy has been utilized with a β-keto amide substrate to provide a chiral, nonracemic oxazolidinone species. This strategy permits entry to highly functionalized, enantiomerically pure dihydroxycyclopentanecarboxylate derivatives (eq 28).

Radical Addition to Alkenes and Alkynes.

Samarium(II) iodide has proven effective for initiation of various radical addition reactions to alkenes and alkynes. Typically, tin reagents are used in the initiation of these radical cyclization reactions; however, the SmI_2 protocol often provides significant advantages over these more traditional routes.

Samarium(II) iodide-mediated cyclization of aryl radicals onto alkene and alkyne acceptors provides an excellent route to nitrogen- and oxygen-based heterocycles (eq 29).[28]

The SmI_2 reagent is unique in that it provides the ability to construct more highly functionalized frameworks through a sequential radical cyclization/intermolecular carbonyl addition reaction.[29] Thus the intermediate radical formed after initial cyclization may be further reduced by SmI_2, forming an organosamarium intermediate which may be trapped by various electrophiles, affording highly functionalized products (eq 30).

Samarium(II) iodide further mediates the cyclization reactions of alkynyl halides (eq 31).[30] When treated with SmI_2, the alkynyl halides are converted to the cyclized product in good yield. Addition of DMPU as cosolvent provides slightly higher yields in some instances.

(31)

Highly functionalized bicyclic and spirocyclic products are obtained in good yield and high diastereoselectivity by a tandem reductive cleavage-cyclization strategy (eq 32).[31] Radical ring opening of cyclopropyl ketones mediated by samarium(II) iodide-induced electron transfer permits the elaboration of a tandem ring opening-cyclization strategy wherein the resultant samarium enolate may be trapped by either oxygen or carbon electrophiles.

(32)

Related Reagents.

Samarium(II) Iodide-1,3-Dioxolane.

Samarium(II) Iodide-1,3-Dioxolane

(SmI_2)

[32248-43-4] · I_2Sm · Samarium(II) Iodide-1,3-Dioxolane · (MW 404.16) (1,3-dioxolane)

[646-06-0] · $C_3H_6O_2$ · Samarium(II) Iodide-1,3-Dioxolane · (MW 74.09)

(used as a formyl anion equivalent in carbonyl addition reactions of aldehyde and ketone substrates)

Solubility: sol 0.1 M in dioxolane.

Preparative Methods: SmI_2 prepared in dioxolane with addition of ***Acetonitrile*** to aid in dissolving SmI_2.

Handling, Storage, and Precautions: SmI_2 is air sensitive and should be handled accordingly.

General Discussion.

Samarium(II) Iodide in conjunction with 1,3-dioxolane and an aryl halide has been utilized in the masked formylation of aldehydes and ketones (eqs 1 and 2).[1] Aryl halides do not undergo Barbier-type coupling reactions with ketones in the presence of samarium diiodide; instead, the generated aryl radical abstracts a hydrogen atom from 1,3-dioxolane, which is used as the solvent in these types of reactions. The resulting dioxolanyl radical may then couple with the aldehyde or ketone substrate, yielding the carbonyl addition product.

(1)

(2)

Little selectivity is achieved with chiral substrates as the reaction of 4-*t*-butylcyclohexanone yielded a 1:1 mixture of diastereomers (eq 3).

(3)

Typical yields for the reaction are in the range of 73-77%. This reagent provides a useful method for introduction of a one-carbon unit in the aldehyde oxidation state and is in general quite mild. The reaction is limited, however, in that 1,3-dioxolane must be utilized as solvent. Consequently, more highly functionalized dioxolane substrates which are less readily available may not be suitable partners in similar reactions.

Selenium[1-4]

Se

[7782-49-2] · Se · Selenium · (MW 78.96)

(source of selenium compounds,[5,6] catalyst of alkene isomerization,[43-46] dehydrogenation reagent of cyclic hydrocarbons,[48-54] carbonylation catalyst of amines, alcohols, thiols, and related compounds with carbon monoxide[60])

Physical Data: mp 220.5 °C; bp 685 °C; *d* 4.82 g cm^{-3}.

Solubility: insol H_2O and organic solvents.

Form Supplied in: powder, pieces, or ingot.

Preparative Methods: red amorphous selenium is prepared by reduction of selenious acid in cold water with reducing reagents such as sulfur dioxide and hydrazine or by oxidation of its reduced form (hydrogen selenide or its salts) with air.

Handling, Storage, and Precautions: storage under inert atmosphere is recommended since it is oxidized gradually in air at room temperature. Elemental selenium is harmless upon ingestion. Use in a fume hood.

Formation of Organoselenium Compounds.[5-42]

Selenium reacts with organolithium, -sodium, and -magnesium compounds at room temperature or below to form metal selenolates (RSeM, M = Li,[7-10] Na,[11] MgX[12,13]) which afford selenides by the reaction with electrophiles (eqs 1 and 2),[7-11] diselenides by oxidation,[12] and selenols by acidification.[13]

Selenium is reduced in several ways[14-31] to ammonium or metal salts of hydrogen selenide or diselenide (H_2Se, H_2Se_2) which are also useful precursors of selenides and diselenides, respectively, as well as selenoamides.[28,29] Commonly used reducing reagents are rongalite (***Sodium Hydroxymethanesulfinate***, $NaSO_2CH_2OH$) in aq NaOH,[14] ***Hydrazine***,[15,16] Li or Na in liq. NH_3[17-20] or THF (eq 3),[21] Mg in MeOH,[22] ***Samarium(II) Iodide*** in THF,[23] ***Sodium Borohydride*** in EtOH or H_2O (eq 4),[24] ***Lithium Triethylborohydride*** in THF,[25] and ***Carbon Monoxide*** in H_2O.[26-30] Reduction with tetraalkylammonium borohydride in toluene directly affords dialkyl selenides.[31]

Elemental selenium reacts with hydrazones,[32-34] sulfonium[35] or phosphonium[36,37] ylides, and α-halo carbanions[38] to give selones. Sterically hindered selones can be isolated (eq 5).[32-34] Less hindered selones generated in situ readily react with ylides or dienes to afford alkenes (see below) or selenium-containing heterocycles (eqs 6 and 7).[35-38]

Selenium adds to a diaminoalkyne[39] and isocyanides[40-42] to yield a diselenoamide and isoselenocyanates, respectively (eqs 8 and 9). Selenium catalyzes the formation of isothiocyanates from isocyanides and ***Sulfur*** less efficiently than ***Tellurium***.[40] Reactions of selenium with ***Potassium Cyanide***, phosphines, or dichloromethane afford KSeCN, $R_3P{=}Se$, or CSe_2, respectively.[5,6]

Synthesis and Isomerization of Alkenes.

Selones prepared from selenium and hydrazones are useful precursors of hindered alkenes (eq 10).[32-34] Wittig reagents afford alkenes with the aid of selenium (eq 11).[36,37]

(*E*):(*Z*) = 84:16

Selenium catalyzes isomerization of alkenes at high temperatures (ca. 200 °C) to give an equilibrium mixture of *cis* and *trans* isomers when complete (eq 12).[43-46] Kinetic studies suggest the intermediacy of π-complexes of alkenes with selenium. For the isomerization of *cis*-stilbene, the activation energy of the selenium-catalyzed reaction is about 63 kJ mol^{-1} (15 kcal mol^{-1}) lower than that of thermal isomerization[44] and the relative rates using selenium, ***Methanesulfonic Acid***, and ***Potassium t-Butoxide*** are 734:20.6:1, respectively, at 190 °C.[43] In the isomerization of alkenes having an allylic hydrogen, some regioisomers are formed concomitantly, especially at high temperatures, and selenium gradually loses its catalytic activity by the formation of selenium-containing byproducts.[45]

Reduction by the Use of Se.

Selenols, hydrogen selenide, and their salts are very useful reagents not only for introduction of selenium moieties into organic molecules but also for reduction of a variety of functional groups (for details, see ***Benzeneselenol***, ***Methaneselenol***, ***Diphenyl Diselenide***, ***Hydrogen Selenide***, ***Sodium Hydrogen Selenide***, ***Lithium Selenide*** or ***Sodium Selenide***, etc). What should be emphasized here is that reduction can be performed by the use of a catalytic amount of selenium or diselenides in the presence of an appropriate reducing reagent, as shown generally by eq 13.[5,47]

Oxidation with Selenium.

Six-membered cyclic and polycyclic hydrocarbons undergo dehydrogenation at ca. 300 °C to give aromatic compounds in moderate yields by reaction with an excess amount of metallic or amorphous selenium, where selenium is reduced to hydrogen selenide (eq 14).[48,49] The selenium-promoted aromatization may be accompanied by elimination of alkyl or heteroatom groups. Ethyl groups are cleaved in preference to hydrogen with the formation of ethaneselenol (eq 15).[49] Hydroxyl groups are also prone to removal (eq 16).[50] Methyl groups can be lost when attached to a quaternary carbon.[51] At higher temperatures, hydrogenation of double bonds, rearrangement of carbon skeletons, and cyclization of side chains may take place during aromatization (eq 17).[52] This reaction is applicable to dehydrogenation of heterocyclic compounds (eq 18).[53] Similar dehydrogenation with sulfur is known, but the reaction hardly proceeds with tellurium.[54]

(18)

Formates are oxidized to carbonates with selenium in the presence of a sodium alkoxide (eq 19). Since NaSeH formed in this process regenerates selenium upon oxidation, the reaction can be carried out by the use of a catalytic amount of selenium in the presence of oxygen.[55] Formamides can be oxidized to carbamates similarly, but less efficiently.[56]

(19)

Selenium-Catalyzed Carbonylation and Related Reactions.

A variety of primary amines are carbonylated with carbon monoxide to give urea derivatives by the use of a catalytic amount of selenium under mild conditions in the presence of oxygen (eq 20).[57-59] The turnover number of selenium reaches up to 10^4 at 120 °C under 30 atm of carbon monoxide.[60]

(20)

In these reactions, ureas are probably formed by the aminolysis of isocyanates generated by the elimination of hydrogen selenide from ammonium carbamoselenoates (**3**), which are formed in situ by the reaction of selenium, an amine, and carbon monoxide. Oxidation of the hydrogen selenide formed with air regenerates selenium. Some secondary amines such as ***Pyrrolidine***, ***Piperidine***, and dimethylamine afford corresponding ureas in excellent yields under similar conditions.[60] Several control experiments suggest that carbonylation of secondary amines proceeds via aminolysis of biscarbamoyl diselenides formed by the oxidation of ammonium carbamoselenoate intermediates (**3**) (eq 21).[61]

Unsymmetrical ureas can be obtained by the addition of a different amine to the ammonium salts (eqs 22 and 23).[57,62] Under mild conditions, acyclic dialkylamines other than dimethylamine do not afford corresponding ureas due to the steric hindrance. In this case, biscarbamoyl diselenides (**4**) are formed, which eliminate selenium to yield ureas upon pyrolysis via biscarbamoyl selenide (**5**) (eq 24).[63] Biscarbamoyl diselenides are good carbamoylation reagents of arenes[64] and cyclic ethers[65] (eqs 25 and 26). Carbamoselenoates (**3**) quantitatively afford carbonyl selenide by acidification[66] and *Se*-alkyl carbamoselenoates by trapping with alkyl halides (eq 24).[67]

This selenium-mediated carbonylation with CO was discovered and expanded by Sonoda to include synthesis of a variety of cyclic and acyclic ureas (eq 27),[68-70] carbamates (eqs 28 and 29),[69-73] thiocarbamates (eqs 30 and 31),[70,72-75] carbonates (eq 32),[76,77] thiocarbonates (eq 33),[78] and heterocyclic compounds (eqs 34-37).[69,70,79-81]

Selenium(IV) Oxide

SeO_2

[7446-08-4] · O_2Se · Selenium(IV) Oxide · (MW 110.96)

(oxidant of activated, saturated positions)

Alternate Name: selenium dioxide.

Physical Data: mp 315 °C (subl); *d* 3.95 g cm^{-3}.

Solubility: sol water, methanol, ethanol, acetone, acetic acid.

Form Supplied in: off-white powder;[1] widely available.

Purification: by sublimation, or by treatment with HNO_3.[28]

Handling, Storage, and Precautions: toxic; corrosive; causes intense local irritation of skin and eyes; use in a fume hood.

Allylic Hydroxylation.

Selenium(IV) oxide is known primarily for hydroxylation of activated carbon-bearing positions, particularly at allylic (or propargylic) sites. Studies by Guillemonat and others have led to the following hydroxylation selectivity rules:[2,3]

- 1)Hydroxylation occurs α to the more substituted end of the double bond.
- 2)The order of facility of oxidation is $CH_2 > CH_3 > CH$.
- 3)When the double bond is in a ring, oxidation occurs within the ring when possible, and α to the more substituted end of the double bond.
- 4)Oxidation of a terminal double bond affords a primary alcohol with allylic migration of the double bond.

An example of rules (1) and (2) is shown in the oxidation of 3-methyl-3-butene, where the allylic methylene position is oxidized in preference to the methyl or methine positions (eq 1).[2] Alkene-selective oxidation of 5,6-dihydroergosterol in ethanol, an example of rule (3), occurs at C-14 and is followed by allylic rearrangement to give a 7α-ethoxy product (eq 2).[4] The mechanism of the allylic oxidation reaction is proposed to be initiated by ene addition, followed by dehydration and [2,3]-sigmatropic rearrangement of the resultant allylseleninic acid.[5,6] In a key step of the synthesis of α-onocerin, α-oxidation in acetic acid leads to an unsaturated γ-lactone product in good yield (eq 3).[7] The milbemycins have been hydroxylated in the 13β-position by selenium dioxide.[8] Because selenium dioxide forms selenious acid (H_2SeO_3) in the presence of water, hydroxylations of alkenes containing acid-labile groups (e.g. acetals) have been run in pyridine.[9]

(2)

(3)

Higher-Order Oxidations.

Selenium dioxide can introduce carbonyl functionality at activated positions, and can also effect dehydrogenation[10-13] at highly activated saturated sites. For instance, phenylglyoxal is isolated in high yield from α-oxidation of acetophenone (eq 4).[14] On a large scale, dissolution of the selenium dioxide in aqueous dioxane at 55 °C is required prior to acetophenone addition. Similarly, 6-methyluracil is readily converted to orotaldehyde in acetic acid (eq 5).[15] Oxidation of aryl-substituted succinic acids to maleic anhydride analogs occurs readily in acetic anhydride (eq 6).[16] This is a preferred method, since oxidations of this type with ***N-Bromosuccinimide*** give bromoarene byproducts. Additionally, selenium dioxide in the presence of ***Trimethylsilyl Polyphosphate*** has been used to aromatize cyclohexenes and cyclohexadienes.[17] Using only a slight excess (1.2 molar equiv) of selenium dioxide in pyridine, methyl 2-methyl-4-pyrimidinecarboxylate has been prepared regioselectively from 2,4-dimethylpyrimidine after methanolysis of the carboxylic acid product (eq 7).[18] Interestingly, ***Sulfuric Acid***-catalyzed oxidation of 1-octene in acetic acid affords a 1,2-diacetate product (eq 8).[19] Only a trace amount of 1-acetoxy-3-octene is observed.

(4)

(5)

(6)

(7)

(8)

Oxidative Cleavage.

Attack of selenium dioxide at activated positions can lead to oxidative bond cleavage when appropriate leaving groups are present. Aryl propargyl ethers undergo oxidation at the α-alkynyl position to afford a phenolic species and propargyl aldehyde (eq 9).[20] The analogous aryl allyl ether fragmentations occur in somewhat lower yields. (Hydroxyaryl)pyrazolines have been oxidized, with nitrogen extrusion, to afford 2´-hydroxychalcone products (eq 10).[21] Oxidations of pyrazolines with ***Bromine***, ***Potassium Permanganate***, ***Chromium(VI) Oxide***, and other reagents result in pyrazole formation.

(9)

(10)

Miscellaneous Transformations.

Alkyl and aryl nitriles can be prepared from the corresponding aldehydes via conversion to the aldoxime, followed by catalytic selenium dioxide-mediated elimination (eq 11).[22,23] Aliphatic nitriles are formed at rt, while aryl nitrile formation requires heating. 1,2,3-Selenadiazoles have been synthesized by treatment of an *N*-benzylazepine 4-semicarbazone with selenium dioxide (or selenoyl dichloride) (eq 12).[24,25] The *N*-benzyl proximal product is formed with high regioselectivity vis-à-vis the distal product in polar solvents. Nonpolar solvents give ca. 3:1 mixtures (proximal/distal). The oxygen-catalyzed reaction of trialkylboranes with 1 equiv of selenium dioxide affords a dialkyl selenide as the major product.[26] Similarly, dialkyl selenides have been prepared by reaction of alkyllithiums or Grignard reagents with selenium dioxide.[27]

Selenium(IV) Oxide-*t*-Butyl Hydroperoxide[1]

SeO_2-*t*-BuOOH

(SeO_2)

[7446-08-4] · O_2Se · Selenium(IV) Oxide-*t*-Butyl Hydroperoxide · (MW 110.96) (*t*-BuOOH)

[75-91-2] · $C_4H_{10}O_2$ · Selenium(IV) Oxide-*t*-Butyl Hydroperoxide · (MW 90.14)

(oxidizes alkenes to allylic alcohols or to α,β-unsaturated aldehydes or ketones)

Physical Data: SeO_2:[2] mp 340 °C. 90% *t*-BuOOH:[3] fp 35 °C; *d* 0.901 g cm^{-3}. See ***Selenium(IV) Oxide*** and ***t-Butyl Hydroperoxide***.

Form Supplied in: SeO_2: solid. *t*-BuOOH: liquid. Commercially available.

Handling, Storage, and Precautions: SeO_2[2] is irritating to the eyes and skin and is highly toxic and corrosive. *t*-BuOOH[1,3] is a flammable liquid and, as with all peroxides, should be handled with care. Use in a fume hood.

Allylic Oxidations.

Selenium(IV) oxide in combination with *t*-butyl hydroperoxide (TBHP) is an effective system for insertion of oxygen into an allylic carbon-hydrogen bond (eq 1).[4] Reaction conditions (CH_2Cl_2, 0 °C) are much milder than those required for oxidation with selenium(IV) oxide alone and, as a result, yields are higher with fewer oxidation, dehydration, and rearrangement byproducts. Furthermore, the problem of the removal of colloidal selenium is circumvented, and in many cases only catalytic amounts of selenium(IV) oxide are required to effect oxidations in high yields. Over-oxidations to the corresponding aldehyde or ketone products are observed. The rules regarding allylic oxidations by selenium(IV) oxide, proposed by Guillemonat[5] and Rapoport,[6] apply to these reaction conditions: (1) oxidation occurs at the more highly substituted end of the alkene; (2) the order of reactivity of C-H bonds is $CH_2 > CH_3 > CH$ (rule 1 takes precedence over rule 2); (3) when the double bond is within a ring, oxidation occurs within the ring; (4) *gem*-dimethyl trisubstituted alkenes oxidize stereospecifically to give (*E*)-α-hydroxy alkenes.

Studies of the reaction intermediates suggest that the reaction proceeds via a combination-dissociation-recombination pathway,[7] which may explain the double bond migration seen in some selenium(IV) oxide oxidations (eq 2).[8]

(2)

Selenium(IV) oxide supported on silica gel in the presence of TBHP oxidizes methyl allylic sites with no evidence of competing oxidation at methylene allylic positions (eq 3).[9]

(3)

The selenium(IV) oxide-TBHP combination has also been used to oxidize alkenes to their corresponding α,β-unsaturated ketones (eq 4)[10] or aldehydes[11] using either the standard conditions over extended reaction periods or silica gel-supported selenium(IV) oxide.[11a]

(4)

Oxidation of Alkynes.

Alkynes are similarly oxidized to give α-hydroxy alkynes in good to moderate yields.[1] Methine and methylene C-H bonds are more reactive than methyl C-H bonds. Internal alkynes can be oxidized to give alkynediols in good yields with little or no oxidation of the alcohols to ketone products (eq 5).[12]

Oxidation of Allylic Alcohols.

Selenium(IV) oxide supported on silica gel with TBHP has been used to selectively oxidize primary allylic alcohols to α,β-unsaturated aldehydes in high yields.[13] Secondary allylic, benzylic, and saturated alcohols are unaffected by these reaction conditions.

Semicarbazide[1]

[57-56-7] · CH_5N_3O · Semicarbazide · (MW 75.09) (HCl salt)

[563-41-7] · CH_6ClN_3O · Semicarbazide Hydrochloride · (MW 111.55)

(potent nucleophile; forms many crystalline carbonyl derivatives[1])

Physical Data: HCl salt: mp 175-177 °C (dec).

Solubility: HCl salt: relatively sol water.

Form Supplied in: the HCl salt is widely available from commercial suppliers as a crystalline material; it can be further purified by recrystallization from 75% aq. ethanol and dried under vacuum over calcium sulfate.[2]

Handling, Storage, and Precautions: reactive nucleophile with significant ability to bind to various enzymes; exercise reasonable caution.

Derivatization.

The most straightforward use of semicarbazide is in its reaction with the carbonyl group of aldehydes and ketones (eq 1) to afford derivatives known as semicarbazones.[3] These semicarbazones are commonly crystalline with characteristic melting points. An excellent procedure for isolation of aldehydes and/or ketones from other functionalized materials in a mixture is to heat that mixture with semicarbazide on a silica gel support, filter off the solid, and regenerate the carbonyl compound by heating the support with oxalic acid in a two-phase aqueous/organic system.[4]

Role as a Nucleophile.

Semicarbazide often serves as a typical nucleophilic reagent in studies involving carbonyl chemistry. The mechanism of semicarbazone formation has been repeatedly studied.[5] Many fundamental physical organic studies have been published on the interconversion of a trigonal carbonyl carbon into a tetrahedral carbon intermediate. Investigations focusing on generation of these tetrahedral intermediates, especially the formation of carbinolamines via addition of nitrogen-containing nucleophiles (eq 2), have often employed semicarbazide as a reactant.[6] These include specialized experimental studies such as examination of secondary isotope effects[7] and proton NMR.[8] Because of the presence of the two adjacent nitrogen atoms in semicarbazide, this molecule has figured prominently in several studies of the so-called α effect.[9] Semicarbazide has often been employed in comparisons of relative nucleophilicity.[10] Especially significant are the many investigations of aminolysis.[11] Application of this research to enzymes has been extensive, as is illustrated by work on arylamine *N*-acetyltransferase,[12] monoamine oxidase,[13] urease,[14] chymotrypsin,[15] *N*-methylglutamate synthetase,[16] and pyruvamide-dependent histidine decarboxylase.[17] A comparison of semicarbazide with other nucleophiles in nucleophilic aromatic substitution (eq 3) has been

published.[18] Diaryl and heteroaryl disulfides are cleaved to the corresponding thiols by semicarbazide.[19]

(2)

Z = R, R', H, OR", etc.

(3)

Generation of Heterocycles.

Conversion of cyclic ketones to semicarbazones followed by ***Selenium(IV) Oxide*** oxidation produces 1,2,3-selenadiazoles. Pyrolysis of the selenadiazole affords the corresponding cycloalkyne (eq 4).[20] Conversion of a pyranulose glycoside to the semicarbazone, reaction with HCl/dioxane, and heating in acetic acid leads to the novel triazine (**1**) (eq 5).[21] The antimicrobial activity of the nitrofurans has inspired a tremendous effort directed at the preparation of analogs. Many of these have involved elaboration of various appended side chains by reaction of the carbonyl functionality with semicarbazide.[22] Reaction of semicarbazide with enones[23] (eq 6) and ynones[24] with subsequent dehydration provides an efficient route to pyrazole derivatives. Certain pyrimidines can be made to undergo ring-contraction to pyrazoles by heating with semicarbazide in an acidic medium (eq 7).[25] Reaction of α-hydroxymethylene ketones with semicarbazide has been shown[26] to generate pyrazoline derivatives (eq 8). α-Diketones afford *as*-triazines upon reaction with semicarbazide followed by dehydration and hydrogenolysis (eq 9).[27] Heating of an acylanthranilic acid in the presence of semicarbazide provides the corresponding 2,3-disubstituted 4-oxo-3,4-dihydroquinazoline.[28] Reaction of dithioesters with semicarbazide with subsequent dehydration and aromatization has been employed for the preparation of thiadiazoles.[29] In an investigation of heterocyclic quinones, combination of semicarbazide with 6-chloroquinoline-5,8-dione hydrochloride provided a reasonable yield of oxadiazino[6,5-*g*]quinoline-5,10-dione (eq 10).[30]

Applications to Biological Chemistry.

In studies concerned with the effects of atmospheric pollutants on erythrocyte membranes, semicarbazide has been utilized as an ozone scavenger.[31] The effect of semicarbazide on the course of various photochemical processes that occur in chloroplasts has been investigated.[32] In reconstitution experiments, semicarbazide has a significant effect on collagen fiber formation and properties.[33]

Silicon(IV) Fluoride[1]

[7783-61-1] · F_4Si · Silicon(IV) Fluoride · (MW 104.08)

(efficient Lewis acid and fluorination reagent)

Physical Data: mp -90.2 °C; bp -86.0 °C; *d* (-95 °C) 1.66 g cm^{-3}.

Solubility: sol ether, chloroform, dichloromethane, acetonitrile.

Form Supplied in: colorless gas, commercially supplied in cylinders.

Handling, Storage, and Precautions: very pungent odor similar to that of hydrogen chloride; highly irritating; corrosive to skins and eyes. See also ***Hydrogen Fluoride***.

General Discussion.

Silicon tetrafluoride is an abundant byproduct of fertilizer manufacture. Several attempts have been made to use SiF_4 as a fluorinating agent.[2] However, tedious experimental procedures and the low nucleophilicity of the fluorine attached to silicon have restricted application of SiF_4 as a fluorinating agent. In the presence of ***Aluminum Chloride***, ethyl orthoformate is fluorinated with silicon tetrafluoride (eq 1). Besides ethyl fluoride, the reaction products are ethyl formate and ether.[3]

$$HC(OEt)_3 + SiF_4 \xrightarrow[88\%]{AlCl_3} EtF + HCO_2Et + EtOEt \qquad (1)$$

The reactions of silicon tetrafluoride with carbon tetrachloride (eq 2) and ***Phosgene*** (eq 3) in the vapor phase at elevated temperature give chlorofluorocarbons and carbonyl fluorochloride, respectively.[4] The reactions are carried out by passing a mixture of the substrate and silicon tetrafluoride through an electrically heated quartz tube, which is filled with Henger quartz granules.

$$CCl_4 + SiF_4 \longrightarrow CF_3Cl + CF_2Cl_2 + CFCl_3 \qquad (2)$$

	conv.			
600 °C	57.8%	0%	18.9%	81.1%
800 °C	77.1%	17.2%	51.3%	31.5%

$$ClCOCl + SiF_4 \xrightarrow[42\%]{420\ °C} ClCOF \qquad (3)$$

The ability of silicon tetrafluoride to function as a mild fluorination reagent is demonstrated in the ring-opening fluorination of epoxides (**1**) and (**3**) (eqs 4 and 5).[5] Aromatic epoxides undergo ring-opening fluorination with silicon tetrafluoride in the presence of ***Diisopropylethylamine***, whereas aliphatic epoxides give fluorohydrins with silicon tetrafluoride only in the presence of ***Tetra-n-butylammonium Fluoride*** or water; the involvement of hypervalent fluorosilanes (SiF_5^- or SiF_6^{2-}) is postulated.[6] Application of this methodology to epoxysilanes affords, after Peterson-type alkenation, fluoroalkenes (**5**).[7] Desilylation of the initially formed fluorohydrin (**4**) is effected by a catalytic use of ***Sodium Hydride*** in the presence of ***18-Crown-6***, giving the desilylated compound (**6**) with retention of

the configuration at the carbon bearing fluorine.

(4)

(5)

Alkenes are converted into the corresponding bromofluorides with silicon tetrafluoride-***1,3-Dibromo-5,5-dimethylhydantoin*** (DBH) and water in 1,4-dioxane.[8] Stereoselectivity in the bromofluorination of (*E*)- and (*Z*)-1-phenylpropenes (**7**) is noteworthy (eq 6). Both give the *anti*-bromofluoride (**8**) selectively, making a contrast to the reagents previously reported for the halofluorination of alkenes.

(6)

Silicon tetrafluoride is a useful catalyst for glycosylation.[9] The condensation of appropriately protected glycopyranosyl fluorides (**9**) and trimethylsilyl ethers is conducted under the action of silicon tetrafluoride (eq 7). The pronounced solvent effect is noteworthy: the glycosylation in acetonitrile gives the β-glycosides (**11**) with moderate to high selectivity, whereas the reaction in ether affords the α-anomers (**10**) predominantly.

2-Oxazolines (**13**) are formed from the reaction of epoxides (**12**) with nitriles promoted by silicon tetrafluoride (eq 8).[10] Control experiments show that the ability of silicon tetrafluoride to promote this type of reaction is similar to that of aluminum chloride.

Silicon tetrafluoride is a mild and selective reagent for the cleavage of silyl-protected alcohols.[11] The cleavage of various *t*-butyldimethylsilyl groups by silicon tetrafluoride takes place at ambient temperature in methylene chloride or acetonitrile (eq 9).

Silicon(IV) Methoxide[1]

$Si(OMe)_4$

[681-84-5] · $C_4H_{12}O_4Si$ · Silicon(IV) Methoxide · (MW 152.25)

(methanol synthon in aprotic media[2])

Alternate Names: tetramethyl orthosilicate; tetramethoxysilane.

Physical Data: bp 121-122 °C; mp 4-5 °C; *d* 1.032 g cm^{-3}; *n*20D 1.3688.

Solubility: sol common organic solvents.

Form Supplied in: commercially available as a colorless liquid.

Analysis of Reagent Purity: ^1H NMR.

Purification: by distillation.

Handling, Storage, and Precautions: can be stored in a glass bottle but must be protected from moisture. Can cause blindness; special eye protection is required.

Acetal Synthesis.[2]

Acetalization of carbonyl compounds can be achieved by using an alkoxysilane and a catalytic amount (10 mol %) of ***Iodotrimethylsilane*** (eqs 1 and 2). Silicon(IV) methoxide is convenient for use in these reactions because silicon(IV) can be readily removed from the reaction mixture as a siloxane polymer after hydrolysis.

$$PhCHO + (MeO)_4Si \xrightarrow[87\%]{\text{TMSI, -78 °C to rt}} PhCH(OMe)_2 \qquad (1)$$

$$Me(CH_2)_2CHO + (MeO)_4Si \xrightarrow[91\%]{\text{TMSI, -40 to 0 °C}} Me(CH_2)_2CH(OMe)_2 \qquad (2)$$

In a related reaction, 1,2-bis(trimethylsiloxy)ethane can be used for the formation of cyclic acetals (eq 3). Ketones react with alkyl silyl ethers in the presence of a catalytic amount of ***Trimethylsilyl Trifluoromethanesulfonate*** to give the corresponding acetals; cyclohex-2-enone forms the acetal without double bond migration.[3]

(3)

Synthesis of Homoallyl Ethers.

Treatment of a mixture of an aldehyde, silicon(IV) methoxide, and ***Allyltrimethylsilane*** gives homoallyl ethers exclusively (eqs 4 and 5).[4]

Silver

Ag

[7440-22-4] · Ag · Silver · (MW 107.87)

(catalyst for valence isomerizations[1] and for coupling reactions involving Grignard reagents,[2] alkenes,[3] and carbenoid species[4])

Physical Data: white, lustrous, malleable metal; mp 960.5 °C.

Solubility: insol most solvents, but see preparation of soluble silver below.

Form Supplied in: widely available as rods, wire, foil, powder, etc.

Preparative Method: soluble silver is prepared as follows: ***Silver(I) Nitrate*** (5 mmol) is treated in ether with a 1.0 M solution of ***Ethylmagnesium Bromide*** (30 mL) at 0 °C for 3 h; the supernatant is 7.5 M in soluble silver and stable at refrigerator temperatures.[2]

Handling, Storage, and Precautions: the powder is flammable, and may cause skin and/or eye irritation.

Although the predominant use of silver as a catalyst is in industrial oxidation processes,[5] it has found use in laboratory applications, as in the valence isomerization of benzvalene to benzene (eq 1).[1] It also enables the smooth coupling of Grignard reagents with bromides, although both alkyl groups must be the same to ensure acceptable yields (eq 2).[2]

(1)

$$BuBr + BuMgBr \xrightarrow[\text{25 °C, 5 h; 79\%}]{\text{Ag, THF}} C_8H_{18} \qquad (2)$$

When supported on ***Alumina*** silver effects the coupling of perfluoroalkyl iodides with alkenes at high temperatures (eq 3),[3] and, in combination with ***Zinc***, it enables the preparation of highly strained alkenes from halogen-bearing precursors (eq 4).[4]

$$C_8H_{17}I + H_2C{=}CH_2 \xrightarrow[\text{125 °C, 11 h; 94.5\%}]{\text{Ag/Al}_2\text{O}_3} C_8H_{17}CH_2CH_2I \qquad (3)$$

Silver(I) Acetate

$MeCO_2Ag$

[563-63-3] · $C_2H_3AgO_2$ · Silver(I) Acetate · (MW 166.92)

(nucleophilic substitutions;[5] cyclizations;[1] couplings;[14] disulfide cleavage[13])

Alternate Names: silver acetate; silver monoacetate.

Physical Data: d 3.26 g cm^{-3}.

Solubility: sol in 100 parts of cold water, 35 parts of boiling water; freely sol dil nitric acid.

Form Supplied in: white to slightly grayish lustrous needles or crystal powder.

Handling, Storage, and Precautions: causes irritation to skin, eyes, mucous membranes, and upper respiratory tract. May cause discoloration of skin and deep tissues. In case of contact with skin or eyes, immediately rinse with copious amounts of water. Light sensitive. Store in cool dry place. Incompatible with strong oxidizing agents and strong acids. May discolor on exposure to light.

Formation of Cyclic Ethers.

Alcohols that have a hydrogen in the δ-position can be cyclized with silver acetate and ***Bromine*** (eq 1). The ring closure occurs via an intermediate hypobromite. The reaction can be run under a variety of conditions (presence/absence of light, acidity, solvent, temperature). Because of this variety and the products formed, there has been some disagreement about the role silver plays in the hypobromite decomposition.[1]

Rearrangements.

Regioselective ring contractions are possible via bromination of cyclobutyl ketones. The intermediate bromo ketone, when treated with silver acetate in acetic acid (120 °C, 6 h), affords a mixture of the cyclopropyl ketone and the acetoxy ketone (57% and 28% isolated yield, respectively, eq 2).[2]

Ring expansions and chain extensions are observed when *gem*-dihalocyclopropanes, derived from alkenes, are treated with silver acetate and acetic acid (eqs 3 and 4).[3]

Displacement.

When *meso*-stilbene dibromide is heated with silver acetate under anhydrous conditions, the product is the *meso*-diol diacetate (eq 5). However, when the starting material is heated for 10 min on a steam bath with silver acetate, acetic acid, and water, a significant amount of (±)-diol monoacetate is formed.[4]

(5)

There has been extensive reporting of the use of silver acetate for direct nucleophilic substitution.[5] 3-Chloroindolenines react with silver acetate to give the product of direct displacement (eq 6). This is in contrast to reactions with softer nucleophiles (I^-, PhS^-, PO_3) which give the parent indole.[6]

(6)

Reacting π-cyclohexenylpalladium complexes with stoichiometric amounts of silver acetate, and then with carbon monoxide and benzene, produces the diastereoisomerically pure (>95%) allylic acetate (yield 70%) (eq 7).[7]

(7)

Other Reactions.

Halofluorocyclopropanes are opened with silver acetate in acetic acid (eq 8).[8] Arenes can be oxidized with silver acetate in the presence of 2,2´-bipyridine and potassium peroxydisulfate in high yields (eq 9).[9]

(8)

(9)

Acetyl hypobromite is generated when a bromine/carbon tetrachloride solution is added to a stirred suspension of silver acetate in carbon tetrachloride. This solution can then be used in the conversion of alkenes to bromohydrin acetates (eq 10).[10]

(10)

The Simmons-Smith reagent is generated by adding granular ***Zinc*** to a hot solution of silver acetate in acetic acid (eq 11). The ***Zinc/Silver Couple*** is decanted and washed with acetic acid and ether. The addition of a small amount of silver wool assures stabilization. Silyl enol ethers can be cyclopropanated using this reagent in good to moderate yields (ca. 75%). Acid hydrolysis can be avoided by the addition of an amine to the mixture.[11] An example of the use of this reagent is in the conversion of 2,3-bis(trimethylsiloxy)-1,3-butadiene to the bicyclopropyl derivative (eq 12).[12]

$$AgOAc + AcOH + Zn^0 \longrightarrow Zn(Ag) \qquad (11)$$

(12)

Sulfenamides can be synthesized by a metal-assisted reaction with disulfides and amines (eq 13).[13] Conjugated dienols can be synthesized in a highly chemo-, regio-, and stereoselective manner from vinylic halides and allylic alcohols (eq 14). Silver acetate (or silver carbonate) and a catalytic amount of ***Palladium(II) Acetate*** in DMF are the preferred conditions. The reaction is very attractive because it requires only one functionalized alkene reactant and the addition of the vinylic group only occurs at the terminal carbon of the allylic alcohol.[14]

$Ag(SCH_2Ph) + PhCH_2SN(i\text{-}Pr)_2$ (13)

(14)

Related Reagents.

N-Bromoacetamide-Silver Acetate-Acetic Acid; ***Iodine-Silver Acetate***; ***Palladium(II) Chloride-Silver(I) Acetate***.

Silver(I) Benzoate

$PhCO_2Ag$

[532-31-0] · $C_7H_5AgO_2$ · Silver(I) Benzoate · (MW 228.99)

(nucleophile;[2-4] Wolff rearrangement promoter[1])

Solubility: sol water (0.262 g/100 mL); alkali (0.017 g/100 mL).

Form Supplied in: white powder and chunks.

Preparative Methods: prepared by equimolar reaction of solutions of ***Silver(I) Nitrate*** and sodium benzoate. The solid is collected and dried in vacuo.[1]

Handling, Storage, and Precautions: may be harmful by inhalation, ingestion, or skin absorption and may cause argyria. Store in a tightly closed container away from light in a cool, dry place. Incompatible with strong oxidizing agents. May discolor on exposure to light. Hazardous products from decomposition are carbon monoxide and carbon dioxide.

Introduction.

For additional information on silver benzoate and its reaction with iodine, see ***Iodine-Silver Benzoate***.

Silver Benzoate as a Nucleophile.

The first use of silver benzoate was reported by Larock in which *n*-butyl iodide was reacted with silver benzoate in the presence of $B(O_2CPh)_3$ to give *n*-butyl benzoate in low yield (20%) (eq 1).[2]

(1)

It has been used in a reaction with 4,7-dichloro-3,8-diphenyl-1,2-diazocine to prepare 4-benzoyloxy-7-chloro-3,8-diphenyl- and 4,7-bis(benzoyloxy)-3,8-diphenyl-1,2-diazocine (eq 2).[3]

Isomides (Ar^1 = *p*-$MeOC_6H_4$, Ph, *p*-BrC_6H_4, *p*-$NO_2C_6H_4$; Ar^2 = 2,4-$(NO_2)_2C_6H_3$) have been prepared by the reaction of the appropriately substituted silver benzoate with *N*-(2,4-dinitrophenyl)benzimidoyl chloride (eq 3).[4]

Wolff Rearrangement.

Newman and Bead developed a procedure for a Wolff rearrangement under mild, homogeneous reaction conditions. In an example of this protocol, diazoacetophenone is treated with a few drops of filtered silver benzoate in triethylamine (eq 4). Nitrogen evolution commences immediately. Silver benzoate is added in portions until gas evolution ceases. The product is obtained in 92% yield.[1]

Related Reagents.

Iodine-Silver Benzoate.

Silver(I) Carbonate on Celite

Ag_2CO_3/Celite

(Ag_2CO_3)

[534-16-7] · CAg_2O_3 · Silver(I) Carbonate · (MW 275.75)

(mild oxidizing agent, which operates under neutral and heterogeneous conditions[1-3])

Physical Data: Ag_2CO_3: mp 210 °C (dec); *d* 6.077 g cm^{-3}.

Solubility: insol water, organic solvents; destroyed by acids.

Form Supplied in: green-yellow powder. Commercially available reagent contains ca. 50 wt% Ag_2CO_3.

Preparative Method: ***Silver(I) Nitrate*** (30 g) is dissolved in 200 mL of distilled water, and ***Celite*** (30 g) is added. To the stirred mixture, a solution of ***Sodium Carbonate*** ($Na_2CO_3.10H_2O$) (30 g) in distilled water (300 mL) is slowly added. The yellow-green precipitate is filtered and washed to neutrality with distilled water. It is then dried (4 h) by rotatory evaporation on a steam bath, preferably in the dark. The reagent can be stored in the dark at room temperature for several years without significant loss of activity. When prepared according to this procedure, 0.6 g of this reagent contains approximately 1 mmol of Ag_2CO_3. Since an excess of silver carbonate on Celite is necessary for the reaction to proceed at a reasonable rate, recovery of silver is often required. This can be easily achieved by dissolving the used reagent in nitric acid. The filtered solution after concentration gives back silver nitrate (poorly soluble in nitric acid).

Handling, Storage, and Precautions: can be safely handled in the dry state. Moisture or exposure to light are not critical; can be stored for years in the dark. Silver salts are toxic.

Introduction.

Silver carbonate on Celite oxidizes primary alcohols to aldehydes, and secondary alcohols to ketones. 1,2-Diols are either cleaved or oxidized to α-hydroxy ketones or sometimes to α-diketones; 1,4-, 1,5-, and 1,6-diols with one primary hydroxyl group may give lactones. Lactols are converted to lactones. Hydroquinones and catechols afford quinones. Steric factors play an important role in determining the outcome of these reactions, including the generally high regioselectivity in polyol oxidations.

Oxidation, rearrangement, or glycosylation with the help of silver carbonate on Celite are usually carried out in aromatic solvents, sometimes in chloroform or methylene chloride, and, in the case of carbohydrates, in methanol. Reactions are easily monitored by TLC. As soon as the reaction is over, the solid is filtered off, and the solution evaporated. The price of the reagent makes it difficult to use on a large scale, unless the recovery of silver is contemplated. The mildness and the simplicity of the workup may, in some cases, overcome this drawback. Many protective groups (acetals, formate, acetate, tetrahydropyranyl, silyl derivatives), as well as sensitive functionality such as furan, indole, and *N*-substituted pyrrole ring systems, are not affected by the reagent. A critical evaluation of several solid supported reagents has been published.[52]

Oxidation of primary alcohols.

Primary alcohols (saturated, allylic, polyunsaturated, benzylic) are normally converted into aldehydes in good to excellent yield. A few examples out of many reported are listed in Table 1.[4-6]

Table 1 Oxidation of Primary Alcohols to Aldehydes

Alcohol	Solvent	Yield (%)
	Benzene	80
	Benzene	100
	Benzene	~30

In contrast to the oxidation of other primary alcohols, α-hydroxymethyl cyclic ethers give lactones instead of the expected aldehydes (Table 2).[7,8]

Table 2 Oxidation of α-Hydroxymethyl Cyclic Ethers

Alcohol	Product	Solvent	Yield (%)
		Benzene	70
		Benzene	80
		Benzene Toluene	31 37

Due to a strong isotope effect, tritiated primary alcohols are oxidized to aldehydes, with virtually no loss of tritium (eq 1).[9]

(1)

Ketones from Secondary Alcohols.

A large number of secondary alcohols, usually bearing other functional groups sensitive to acids and oxidizing agents, has been transformed into ketones.[3] A few typical examples are recorded in Table 3.[10-13]

Table 3 Oxidation of Secondary Alcohols to Ketones

Alcohol	Solvent	Yield (%)
	Toluene	70
	Benzene	86
	Benzene	84
	Benzene	75

Allylic alcohols are rapidly oxidized. In sharp contrast, oxidation of a homoallylic alcohol such as cholesterol (in carefully deoxygenated benzene, under argon) leads to an intractable mixture of unidentified products. Celite (the best inert support tested so far) is essential. Thus codeine has been oxidized either by standard silver carbonate, or by silver carbonate on Celite, but only the latter reagent could oxidize dihydrocodeine. Some strained cyclobutanols afford γ-lactones in addition to the expected ketone (eq 2).[14] A case of molecular rearrangement has been mentioned (eq 3).[15]

Oxidation of Tertiary Alcohols.

Tertiary alcohols are generally quite stable towards the reagent, with the exception of ethynyl carbinols which are cleaved in quantitative yield (Table 4)[16] at a rate comparable to that of allylic alcohol oxidation. Cyanohydrins behave similarly. The use of the ethynyl group as a ketone protective group has been suggested.

Table 4 Oxidation of Tertiary Alcohols

Alcohol	Product	Yield (%)
		100
		100

Oxidation of Diols.

Depending upon their structure and stereochemistry, and the experimental conditions (reaction time) chosen, 1,2-diols are either cleaved (to dialdehydes or keto aldehydes) or oxidized to α-hydroxy ketones. In some cases, α-diketones have been obtained in reasonable yield (Table 5).[17-23]

Oxidation of 1,3-diols with silver carbonate on Celite leads to β-hydroxy ketones. Retroaldolization has occasionally been observed.[29] In benzene as solvent, a secondary hydroxyl group seems to be oxidized somewhat faster than a primary one. Aliphatic 1,4-, 1,5-, and 1,6-diols behave in the same manner, unless one of the hydroxyl groups is primary. Many diols of this type, in which one of the functions is primary, have been oxidized to lactones, generally in good yield (Table 6).[24-28]

[a] In benzene.

Quite often, oxidations of polycyclic polyols with silver carbonate on Celite are highly regioselective. A tentative mechanism has been proposed which explains most of the results obtained so far[3,30] and has therefore reasonable predictive power for the synthetic organic chemist. A few examples are listed in Table 7.[1,31-34]

Oxidation of Lactols to Lactones.

Silver carbonate oxidation of lactols is faster than the oxidation of any other type of hydroxyl derivative, and can therefore be achieved without protection of alcohols in the same molecule. Some representative examples are shown in Table 8.[35-37]

Table 8 Selective Oxidation of Lactols[a]

[a] In benzene.

Oxidation and Degradation of Carbohydrates.

A considerable amount of work has been devoted to the oxidation and degradation of carbohydrates using silver carbonate on Celite. If the hydroxyl at C-1 is free, and the reaction is carried out in benzene, toluene, or a mixture of benzene and DMF, then the corresponding lactone is obtained. However, if there is an unprotected OH group at C-2, and especially in methanol, a cleavage between C-1 and C-2 takes place as illustrated in eq 4.[38] Hydrolysis of the intermediate formate leads to D-threose.

(4)

Methyl Esters from Aldehydes.

With the exception of α-substituted aldehydes of the type reported in Table 2, the oxidation of aldehydes in benzene does not lead to carboxylic acid derivatives. Those which can spontaneously give hemiacetals with another hydroxyl group of the molecule are not an exception, since lactols are very rapidly oxidized to lactones. It is therefore noteworthy that, in methanol, some aldehydes can be converted to methyl esters in modest yield (Table 9).[39,40]

Table 9 Oxidation of Aldehydes to Esters

Starting material	Product	Solvent	Yield (%)
		MeOH	55
		MeOH	56
		MeOH	68

Oxidation of Phenols.

Hydroquinones and catechols are oxidized to *p*-quinones and *o*-quinones, respectively, with this reagent.[41,42] 4,4´-Dihydroxybiphenyls and 4,4´-dihydroxystilbenes lead to diphenoquinones and stilbenequinones. Hindered phenols (e.g. 2,6-dimethylphenol, 2,4,6-trimethylphenol) are dimerized, and give diphenoquinones or stilbenequinones in high yield, as illustrated in eq 5. Unhindered phenols give complex mixtures. For instance, *p*-cresol affords a 65% yield of Pummerer's ketone (eq 6).[43] A systematic survey of silver carbonate on Celite oxidation of phenols has been published.[44]

(5)

(6)

acetonitrile, 65%

Oxidation of Amines.

Very little is known so far on the oxidation of aliphatic amines. Anilines give azobenzenes in modest yield (Table 10).[3,45]

Oxidation of Hydrazines and Hydrazones.

Symmetrically disubstituted hydrazines and hydrazides are rapidly oxidized to the corresponding azo compounds (Table 10). Hydrazones are converted in a few minutes into diazoalkanes, generally in high yield (Table 10).[45,46]

[a] In benzene.

Nitroso Compounds from Hydroxylamines.

N-Monosubstituted hydroxylamines lead to nitroso compounds, or their dimers, in good yield upon treatment with silver carbonate on Celite.[47] If a double bond is suitably placed, a cyclization of the nitroso intermediate gives a nitroxide free radical (Table 11).[48]

Nitrile Oxides from Oximes.

Benzaldoximes react with silver carbonate on Celite to give nitrile oxides, which undergo 1,3-dipolar cycloaddition with the original oxime. The nitrile oxides can also be trapped by other dipolarophiles such as nitriles and ethylenic compounds (Table 11).[46-48]

		CH_2Cl_2	90
		CH_2Cl_2	95
		$CFCl_3$	57

Miscellaneous Reactions.

Halohydrins are smoothly converted by this reagent into epoxides or rearranged into aldehydes or ketones.[49,50] Silver carbonate on Celite has also been proposed to improve *O*-glycosylation[51] (Koenigs-Knorr reaction).

Silver(I) Cyanide

AgCN

[506-64-9] · CAgN · Silver(I) Cyanide · (MW 133.89)

(preparation of isocyanides,[1] preparation of hindered esters[5])

Physical Data: mp >300 °C; dec 320 °C; *d* 3.95 g cm^{-3}.

Solubility: sol nitric acid, ammonium hydroxide; slightly sol cold water; sparingly sol methylene chloride.

Form Supplied in: white to off-white powder.

Handling, Storage, and Precautions: may be fatal if inhaled, swallowed, or absorbed through the skin. It causes eye and skin irritation and may cause argyria (blackening of the skin). It is highly toxic and light sensitive; contact with acids should be avoided (releases HCN gas). The solid should be stored in a cool dry place under an inert atmosphere. Use in a fume hood.

Preparation of Isocyanides.

Silver cyanide can be used to prepare a number of isocyanides. Ethyl isocyanide,[1] for example, can be prepared by heating ***Ethyl Iodide*** with silver cyanide (eq 1). This reaction should be carried out in a well ventilated area because of its vile odor. Ethyl isocyanide has also been known to explode, so all heated operations should be done behind a safety shield. *N*-Acyl isocyanides[2] are highly unstable compounds which can be readily prepared by the reaction of acyl iodides with AgCN (eq 2). These compounds are capable of reacting as electrophilic carbenes, unlike alkyl and aryl isocyanides, which makes them attractive for cycloadditions (eq 3).[2] Silver cyanide also reacts with 4-ethoxybromobutane to give the corresponding isocyanide.[3]

(2)

(3)

1-Isocyano sugars can be prepared in good yields by the reaction of AgCN with benzyl-protected halogenated glycosides at room temperature (eq 4).[4]

(4)

Preparation of Highly Hindered Esters.

The conventional method for preparing esters by the reaction of an acyl chloride with an alcohol in the presence of pyridine is not useful in certain hindered ester cases, where this method is too slow and incomplete. Hindered esters can generally be synthesized rapidly and in higher yields by reacting an acyl chloride with an alcohol in the presence of AgCN.[5] Highly hindered steroidal esters,[6] for example, have been prepared from the appropriate steroidal alcohol and a hindered acid chloride, such as pivaloyl chloride, using AgCN (eq 5).

(5)

Treatment of o-hydroxyamines with ***t-Butyl Isocyanide*** in the presence of AgCN yields cyclized products in high yields. By varying the structure of the starting material, a wide variety of heterocycles are available including 2-oxazolines, 2-imidazolines, tetrahydro-2-pyrimidines, thiazolines, and dihydro-1,3-oxazines (eq 6).[7]

(6)

Silver cyanide can also be used as a catalyst in the reactions of organomagnesium reagents with chlorosilanes, which afford tetraorganosilanes[8] in higher yields than in the uncatalyzed reactions. When dioctylmagnesium reacts with ***Methyltrichlorosilane*** in the presence of AgCN (eq 7) an 80% yield is achieved while in the uncatalyzed reaction the product yield is only 16%.

(7)

Other Applications.

Although phosphoroisothiocyanatidates (**1**) are readily accessible compounds, an isomer[9] (eq 8) was first prepared in 1972 by the reaction of AgCN and bis(neopentyloxy)phosphorosulfenyl chloride which yielded dineopentyl phosphorothiocyanatidate.

(1)

The first trifluoromethyl-iodine compound with more than one iodine-carbon bond was obtained by the reaction of AgCN with trifluoromethyliodine dichloride in methylene chloride (eq 9).[10] Silver cyanide reacts with difluoroaminocarbonyl chloride (eq 10) to give *N*,*N*-difluoroaminocarbonyl cyanide.[11]

$$CF_3ICl_2 + 2\ AgCN \longrightarrow CF_3I(CN)_2 + 2\ AgCl \qquad (9)$$

$$NF_2C(O)Cl + AgCN \longrightarrow NF_2COCN + AgCl \qquad (10)$$

Silver(I) Fluoride

AgF

[7775-41-9] · AgF · Silver(I) Fluoride · (MW 126.87)

(fluorinating agent[1])

Physical Data: mp 435 °C; bp 1150 °C; *d* 5.852 g cm^{-3}.

Solubility: highly sol water (182 g/100 g H_2O), anhydrous hydrogen fluoride (83.2 g/100 g at 11.9 °C); slightly sol methanol (1.5 g/100 mL).

Form Supplied in: golden-yellow powder; commercially available, but very expensive.

Preparative Methods: by the reaction of Ag_2CO_3 or ***Silver(I) Oxide*** in anhydrous ***Hydrogen Fluoride*** or aqueous ***Hydrofluoric Acid***

Handling, Storage, and Precautions: a light sensitive, hygroscopic solid. It should be stored in a dark container under an inert atmosphere. It is extremely destructive to tissues of the mucous membranes and upper respiratory tract, eyes, and skin. It emits toxic fumes under fire conditions. It also forms explosive adducts with ammonia; reactions involving liquid or gaseous ammonia should be carried out with extreme caution. Use in a fume hood.

Fluorinations with Silver Fluoride.

Reaction of AgF with alkyl and aryl halides often results in the formation of the corresponding fluorides usually under mild conditions. With geminal dihalides, this conversion has been shown to involve a carbonium ion intermediate (eq 1).[2] Chloro quinones react with AgF under high pressure and temperature conditions to give partial conversion to the fluoro quinone (eq 2).[3] *Cis*- and *trans*-2,3-difluoro-2,3-dihydrobenzofuran can be similarly obtained by the reaction of AgF with *trans*-2,3-dibromo-2,3-dihydrobenzofuran (eq 3).[4] Bromoadamantanes[5] and 1-bromobicyclo[3.3.1]nonan-3-one[6] undergo fluorination with AgF to yield bridgehead fluorine derivatives (eq 4).

(1)

(2)

(3)

(4)

Fluorination of Alkenes by Addition Reactions.

β-Fluoro thioethers can be prepared by the addition of sulfenyl chlorides to alkenes in the presence of AgF. The addition to alkyl-substituted terminal alkenes usually produces anti-Markovnikov adducts with a primary fluorine. Unlike the corresponding chlorides, these materials do not undergo rearrangement to the thermodynamically more stable Markovnikov products (eq 5).[7]

(5)

Silver fluoride adds to electron deficient alkenes. The reaction of 1,1-dichloro-2,2-dicyanoethylene with AgF, for example, does not produce the expected 1,1-difluoro derivative. Instead, this reaction yields the silver salt of trifluoromethylmalononitrile, presumably through the 1,1-difluoro derivative by subsequent addition of AgF to the strongly electrophilic double bond.[8] Perfluoroalkylsilver compounds can be prepared by the addition of AgF to perfluoroalkenes.[9] The fluorination of tetrabromo-2,3-diaza-1,3-butadiene affords the tetrafluoro derivative.[10]

Other Fluorinations using AgF.

α-Fluoro-α,β-unsaturated ketones and esters can be formed by the reaction of α-diazo esters with benzeneselenenyl fluoride (prepared by the reaction of ***Benzeneselenenyl Bromide*** with AgF).[11] ***Trifluoromethylthiocopper(I)*** can be readily prepared by the reaction of AgF, carbon disulfide, and copper(I) bromide in acetonitrile. This reagent reacts with iodoaromatics to yield the corresponding trifluoromethylthio derivatives.[12] Certain geminal dibromocyclopropanes undergo solvolysis with subsequent fluorination and ring expansion by treatment with AgF in acetonitrile (eq 6).[13] Silver fluoride mediates the opening of perfluoro sultones which, in the presence of an appropriate trapping agent, lead to the formation of fluoroalkoxysulfinyl fluorides (eq 7).[14]

Silver Fluoride as a Desilylating Agent.

A number of unrelated synthetic methods take advantage of AgF as a strong fluoride source. In these methods, fluoride unmasks a reactive intermediate by desilylation, allowing for the desired reaction, in most examples a cyclization or cycloaddition, to take place. For example, *t*-butyldimethylsilyl carbamates can be treated with AgF, resulting in formation of cyclic carbamates by an intramolecular reaction (eq 8). Only (*E*)-allyl chlorides provide the cyclic carbamate, since the proposed cyclic transition state is not possible with the corresponding (*Z*)-allyl chlorides.[15] *Threo* selectivities for the cyclization are poor (3-5:1), but can be dramatically improved by using catalytic allylpalladium(II) chloride. In the absence of a suitable intramolecular trap, decarboxylation takes place. The reaction of AgF with a silyloxycyclopropane, followed by treatment with an allylic chloride, results in the formation of an δ,ε-unsaturated ketone (eq 9).[16]

Treatment of a silylmethylindole with AgF, followed by exposure to an appropriate dipolarophile, results in the formation of a 2,3-dihydro-1*H*-pyrrolo[1,2-*a*]indole (eq 10). This cycloaddition works well with a number of related *N*-[(trimethylsilyl)methyl]-substituted indoles, providing cycloadducts with yields in the range 53-83%. The formation of the azomethine ylide assumes that silver is acting as a very specific Lewis acid, attacking the indole ring to give a silver-bonded carbonium ion.[17] α-Cyanoaminosilanes have also been used to generate azomethine ylides for the preparation of pyrrolidines in high yields.[18] Reaction of these azomethine ylides with ethyl propiolate yields the fully aromatized pyrroles (eq 11).[19]

(10)

(11)

In work by Evans and co-workers, deprotection of a silyl ether with AgF leads to the formation of an intermediate positioned to undergo a rapid Cope rearrangement. Subsequent loss of methanol results in the formation of the deoxylapachol product in 95% yield (eq 12).[20] Additionally, certain nitrosoalkenes, which can be active dienes in [4 + 2] cycloadditions, can be prepared from α-chlorosilyloximes by 1,4-elimination in the presence of an appropriate fluoride source, such as AgF.[21] Successful cycloadditions are also observed with ***Cesium Fluoride*** and ***Potassium Fluoride*** (eq 13).

(12)

(13)

Other Reactions with AgF.

Treatment of vicinal dibromo steroids with aqueous AgF results in the formation of epoxides.[22,23] The AgF-initiated methanolysis of 2,2-dibromo-1,3-dimethylcyclopropanecarboxylic acid has also been studied in detail.[24] Thiophilic heavy metal salts such as AgF have been used for ring opening of penicillin derivatives (eq 14),[25] although other catalysts such as ***Silver(I) Oxide*** are better. Treatment of (*E*)-aryl- and -alkenylpentafluorosilicates with silver fluoride affords symmetrical (*E*,*E*)-1,3-dienes in high yields (eq 15).[26]

(14)

(15)

Related Reagents.

Iodine-Silver(I) Fluoride; ***Silver(I) Fluoride-Calcium Fluoride***.

Silver(I) Fluoride-Calcium Fluoride[1]

AgF/CaF_2

(AgF)

[7775-41-9] · AgF · Silver(I) Fluoride-Calcium Fluoride · (MW 126.87) (CaF_2)

[7789-75-5] · CaF_2 · Silver(I) Fluoride-Calcium Fluoride · (MW 78.08)

(fluorination reagent,[2] useful for conversion of alkyl halides to alkyl fluorides and for halofluorination of alkenes)

Form Supplied in: white free-flowing granular powder.

Preparative Method: ***Silver(I) Fluoride*** is supported on calcium fluoride by slowly evaporating a mixture of silver carbonate, 50% aqueous ***Hydrofluoric Acid***, and CaF_2 in water to a dry granular powder.[2]

Handling, Storage, and Precautions: highly hydroscopic and light sensitive.

Halogen Exchange.

Silver fluoride dispersed on the surface of calcium fluoride shows improved fluoride nucleophilicity for halogen exchange with alkyl and benzyl halides. Thus treatment of 1-bromooctane with AgF/CaF_2 in acetonitrile for 30 min at 75 °C affords 1-fluorooctane in 41% yield (eq 1).

(1)

This reagent also proves superior to KF/CaF_2 and CsF/CaF_2, although the presumably high cost of the reagent could outweigh the increase in yield when used on a large scale. A comparative example is shown in eq 2. In general, alkyl iodides give better yields than bromides, which in turn give better yields than chlorides.

(2)

Alkene Additions.

Silver fluoride has been used in the presence of a halogen or a suitable *N*-haloamide for the in situ generation of halogen fluorides XF (X = I, Br, Cl) which add to alkenes.[3] Halofluorination of alkenes using the AgF/CaF_2 reagent has also been reported.[2] Bromofluorination is most effective with ***1,3-Dibromo-5,5-dimethylhydantoin*** (DBH) (eq 3). ***N-Bromosuccinimide*** gives poor results, as dibromide byproducts are formed. Iodofluorination is equally effective using either ***Iodine*** or ***N-Iodosuccinimide*** with AgF/CaF_2; the yield of ca. 50% is similar to the literature values (eq 4).[3]

(3)

(4)

Related Reagents.

Bromine Monofluoride; ***Cesium Fluoride***; ***Iodine Monofluoride***; ***Potassium Fluoride***.

Silver(I) Heptafluorobutanoate

[3794-64-7] · $C_4AgF_7O_2$ · Silver(I) Heptafluorobutanoate · (MW 320.91)

(decomposition of 3-diazocamphor;[2] NMR shift reagent)

Physical Data: mp 292-294 °C.

Solubility: no readily available data, but probably soluble in a range of solvents, e.g. $CHCl_3$, CH_2Cl_2, MeCN, alcohol, THF.

Form Supplied in: white powder; widely available.

Handling, Storage, and Precautions: handle in a fume hood with rubber gloves and safety glasses; avoid skin contact and inhalation. Store in a tight container in a cool place. Light sensitive. Severe eye irritant with an obnoxious smell. The toxicology of this compound has not been fully evaluated.

Little published work has appeared describing the use of this compound as a reagent since the work reviewed in Fieser and Fieser[1] on the $AgOCOC_3F_7$-assisted decomposition of 3-diazocamphor and its 4-methyl analog, via a carbene intermediate, to the corresponding tricyclanone (eq 1).[2] The reaction also occurs with ***Silver(I) Tetrafluoroborate*** at 0 °C but no other silver salts have been evaluated.

Shift Reagent.

The reagent has also been used in combination with the lanthanide agent $Ln([^2H_9]fod)_3$ as an NMR shift reagent for alkenes.[3]

Silver(I) Hexafluoroantimonate

$AgSbF_6$

[26042-64-8] · AgF_6Sb · Silver(I) Hexafluoroantimonate · (MW 343.62)

(metathetical reagent with organic[1] and organometallic halides; mild Lewis acid catalyst for rearrangement of α-halo ketones,[3] pinacols,[4] epoxides,[5] and propargyl esters[6])

Physical Data: white crystalline powder; *d* 4.75 g cm^{-3}.[23]

Solubility: sol (and forms 1:2 complexes with) benzene, toluene, xylene;[24] sol nitromethane, liq SO_2;[7] insol HF, petroleum ether.[7,25]

Form Supplied in: anhydrous white powder; commercially available.

Analysis of Reagent Purity: the SbF_6^- ion can be determined as the nitron salt.[26]

Preparative Methods: has been made from SbF_3 (or Sb_2O_3), AgCl, and ***Bromine Trifluoride***,[27] but is more readily prepared by reacting ***Antimony(V) Fluoride*** and ***Silver(I) Fluoride*** in anhydrous HF at -78 to 0 °C, washing with pet ether, and drying in vacuo.[7]

Handling, Storage, and Precautions: this heavy metal salt is hygroscopic, light sensitive, and very corrosive. Storage in tightly sealed, opaque bottles in a moisture-free atmosphere is recommended. Incompatible with strong oxidizing agents; decomposition products include HF.[28] Reactions should be performed in a well-ventilated fume hood.

Metathesis.

Silver hexafluoroantimonate provides a useful alternative, as a metathetical reagent, to ***Silver(I) Perchlorate*** and ***Silver(I) Tetrafluoroborate***.[2] Thus in a similar fashion to the $AgBF_4$ reagent, silver hexafluoroantimonate has been utilized in the generation of stable carbocation salts for solution NMR or crystal structure analysis. Examples include the 4-chloro-1,2,3,4-tetramethylcyclobutenium cation,[1] the parent benzenonium cation,[8] and the red crystalline salt derived from phenyl(2-chlorophenyl)dichloromethane (eq 1).[9] Acylium salts, $RCO^+SbF_6^-$, are available from treatment of acid halides with $AgSbF_6$ in liq SO_2.[7] Stable thiobenzoyl hexafluoroantimonate salts are generated in a like manner.[10] Application of this silver-assisted ionization method to chloroformates provides an interesting route to highly reactive carbocation species (eq 2).[11]

(1)

(2)

Rearrangements.

Silver(I) salts are noted for dehalogenative rearrangements of a variety of halide substrates, and $AgSbF_6$ is no exception. Dehalogenative rearrangement of α-bromo ketones appears to be a particularly effective niche for this salt of a super acid. Select examples include cases of multiple hydride shifts to functionalize remote carbons (eq 3)[3] and 1,2-aryl (and vinyl) shifts (eq 4).[12] A recent X-ray study of stable crystalline complexes of α-bromo ketones with $AgSbF_6$ and $SbCl_5$ has established an interesting difference in the coordination of the soft Lewis acid (Ag^+) with that of $SbCl_5$ which accounts for the preferential activation of the C-Br bond by silver(I).[13]

(3)

(4)

In a 1:1 combination, ***Antimony(V) Chloride*** and $AgSbF_6$ form a potent Lewis acid catalyst which is superior to either reagent alone in Friedel-Crafts acylations,[14] in Beckmann[14] and pinacol[4] rearrangements, and in the formation of ethers directly from epoxides via a tandem rearrangement-reductive condensation process (eq 5).[5] Trityl hexafluoroantimonate is an effective and superior catalyst in the latter case. Thiophenylation of aromatics is also promoted by the mixed catalyst system (eq 6).[15]

(5)

The silver(I) salt-catalyzed allylic rearrangement of propargyl esters to their allenyl counterparts[16] has found increasing synthetic development with the discovery[17] that extended exposure to Ag^+, with heating, promotes further isomerization to the 1,3-dienylic esters. ***Silver(I) Trifluoroacetate***[17] and ***Silver(I) Acetate***[18] have been employed in this respect, but the hexafluoroantimonate salt appears to be equally effective (eq 7).[6] Silver perchlorate is also reported to effect the similar isomerization and subsequent cyclization of butyne-1,4-diol monoacetates (eq 8).[19]

Although the use of $AgClO_4$ as a weak Lewis acid catalyst is frequently cited, as in the facile rearrangement of substituted cyclopropenes (eq 9),[20] it is not to be recommended, especially in stoichiometric quantities (e.g. eq 10)[21] in view of the well-known explosive hazard of perchlorate salts in organic solvents. Occasionally, however, there are reports of this salt being the reagent of choice, an example being the macrolactonization of o-hydroxy thiol esters of 2-amino-4-mercapto-6-methylpyrimidine (eq 11).[22] Otherwise, the hexafluoroantimonate or tetrafluoroborate salts of silver(I) should constitute acceptable substitutes.

Silver(I) Imidazolate

[42879-93-6] · $C_3H_3AgN_2$ · Silver(I) Imidazolate · (MW 174.95)

(preparation of glycosides)

Preparative Method: prepared by precipitation from an alkaline solution of ***Silver(I) Nitrate*** and ***Imidazole***.[1,2]

Glycosidation.

2,3,4,6-Tetra-*O*-benzyl-D-glucopyranosyl chloride reacts with aglycones such as 1,2:3,4-di-*O*-isopropylidene-D-α-galactopyranose, in the presence of silver imidazolate and ***Mercury(II) Chloride***, to give predominantly the 1,2-*cis*-glycoside with lesser amounts of the 1,2-*trans*-glycoside (eq 1).[2] Without either reagent, only degradation of the starting materials occurs. With the more hindered glycone 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, only the 1,2-*cis*-glycoside is formed (eq 2).

(2)

Tetrabutylammonium chloride greatly enhances glucosidation rates without affecting product ratios. Better yields of the 1,2-*trans*-glycosides are obtained when the pyranosyl bromide, glycone, silver imidazolate, and ***Zinc Chloride*** are reacted in a ratio of 1.5:1:0.75:~6, respectively.[3] In this way the unhindered alcohol 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose gives the 1,2-*trans*-glycoside in 90% yield (eq 3), and the hindered alcohol 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose gives the corresponding 1,2-*trans*-glycoside in 30% yield (eq 4).

(3)

2-Iodo-α-pyranosyl Chlorides.

Treatment of 3,4,6-tri-*O*-acetyl-D-glucal with silver imidazolate and ***Iodine*** in the presence of $HgCl_2$ gives an almost quantitative yield of a mixture of 2-iodo-α-D-glucopyranosyl chloride and 2-iodo-β-D-mannopyranosyl chloride in a ratio of 5:1 (eq 5), which is an improvement over the existing method using ***Iodine Monochloride***.[4]

Silver(I) Nitrate

$AgNO_3$

[7761-88-8] · $AgNO_3$ · Silver(I) Nitrate · (MW 169.88)

(mild oxidizing agent and Lewis acid used in a wide variety of chemical reactions)

Physical Data: mp 212 °C; *d* 4.352 g cm^{-3}.

Solubility: sol H_2O, MeCN, alcohol, acetonitrile, DMF.

Form Supplied in: white crystalline solid; widely available.

Handling, Storage, and Precautions: mild oxidizing agent; may be fatal if inhaled or swallowed.

Deprotection.

Silver nitrate is used as a deprotecting agent for a number of functional groups. Thus *S*-trityl ethers are readily cleaved ($AgNO_3$/***Pyridine***, 5 min, rt)[1a] to the thiol silver salts which are converted to the thiols on treatment with ***Hydrogen Sulfide***. The method has been applied to *S*-trityl ethers in nucleoside,[1a] peptide,[1b] and β-lactam[1c] chemistry, although it is not always successful.[2] Selective cleavage of an *S*,*S*-diaryl phosphorodithioate in the presence of an *O*-dimethoxytrityl group occurs using a large excess of $AgNO_3$ (eq 1).[3] Other deprotecting agents such as $NaIO_4$, H_2O_2, and NCS are unsuccessful in this process.[3]

Thioacetals,[4] 1,3-dithianes,[5] and 1,3-oxathianes[6] are converted, on treatment with $AgNO_3$/***N-Chlorosuccinimide*** (or ***N-Bromosuccinimide***), to the corresponding ketones. The method is specially useful when sensitive 1,4-unsaturated diones are being liberated.[5b] Cyanuric acid can be used in place of NCS for the particularly difficult task of converting a diphenyl thioacetal to its ketone derivative.[7] Benzothiazoles are readily converted, via their 2-lithio derivatives, to a variety of intermediates.[8] Treatment of these derivatized benzothiazoles with ***Iodomethane*** followed by ***Sodium Borohydride*** gives the corresponding *N*-methylbenzothiazolines, which are readily cleaved with $AgNO_3$ in methanol to the corresponding aldehydes in high yields. This is a useful high yielding procedure for the preparation of α,β-unsaturated aldehydes.[8] Cleavage of *O*-methylethoxymethoxy ethers (OMEM ethers) in the presence of a dithiane is accomplished by converting the OMEM ether to the *O*-isopropylthiomethyl ether, which is then cleaved to the desired alcohol with $AgNO_3$ in the presence of ***2,6-Lutidine***.[9] $AgNO_3$ has also been used for the hydrolysis of enol thioethers,[10] tetrahydropyranylthio ethers,[11] *S*-*t*-butyl esters,[12] and thiobenzoates,[12] to the respective alcohols, for the conversion of dithiobenzoates to *S*-benzoates,[13] thioamides to amides,[14] thioureas to ureas,[15] and for the conversion of orthothioesters to orthoesters.[16]

Protection.

Reaction rates for the conversion of the primary OH groups of nucleosides to the protected *O*-trityl ethers with 4,4´,4´´-tris(4,5-dichlorophthalimido)trityl bromide are considerably enhanced by the addition of $AgNO_3$.[17] $AgNO_3$ is also used for the selective

preparation of primary *t*-butyldimethylsilyl ethers by the reaction of nucleosides with ***t-Butyldimethylchlorosilane*** in MeCN.[18] Yields in both reactions are high. $AgNO_3$ is an effective agent for the conversion of several glucopyranoses to their 1,2-orthoacetates[19] and as an agent for the formation of glycosides[20] (see also ***Silver(I) Nitrite***).

Ring Expansions, Contractions, and Rearrangements.

$AgNO_3$-promoted rearrangements occur in numerous instances; a few examples are given. Thus the 4-cyano-4,5-dihydroazepine in eq 2 gives the furo[2,3-*b*]pyridine on heating with an aqueous solution of $AgNO_3$.[21] Treatment of the *N*-chloroenolamine in eq 3 with a threefold excess of $AgNO_3$ gives the β-lactam; yields are about 50%, depending on the substituent used.[22] The 1,1´-bishomocubane in eq 4, on treatment with $AgNO_3$ in aqueous methanol, rearranges to the pentacycle in quantitative yield.[23]

Dehalogenations.

$AgNO_3$ has been widely used for solvolysis with concomitant rearrangement of dihalocyclopropanes. Thus the trichlorocyclopropa[*c*]chromene in eq 5 gives the (dichloromethylene)chroman-4-one in 93% yield.[24] Many other examples are known. Dehydrobromination of the bromotetralone in eq 6 with $AgNO_3$ gives exclusively the endocyclic unsaturated ketone in 90% yield; other reagents for this reaction give mixtures of the exo- and endocyclic alkenes.[25]

(6)

Solvolysis of arylmethyl halides with $AgNO_3$ in hot aqueous ethanol gives the corresponding alcohols,[26] whereas a similar reaction on alkyl bromides in MeCN is reported to be an excellent procedure for the preparation of pure nitrate esters.[27] Benzyl dibromides are converted to the corresponding aldehydes in high yields,[28] and α-bromo ketones give high yields (>80%) of the corresponding α-diketones on treatment with $AgNO_3$ in MeCN.[29]

Cycloadditions.

The electrophilic nature of $AgNO_3$ enables it to complex with alkynes and allenes, thus enabling intramolecular cycloadditions to proceed. For example, treatment of a series of phenolic keto-ynes (eq 7) with a catalytic amount of $AgNO_3$ in methanol promotes cycloaddition to the triple bond in high yield.[30] Similarly, α-hydroxyallenes are rapidly converted to 2,5-dihydropyrans on treatment with $AgNO_3/CaCO_3$ in aq acetone (eq 8).[31]

(7)

(8)

On extending the hydroxy alkyl chain from the allenic group by two or three carbon atoms, cyclization results in the formation of the corresponding α-vinyltetrahydrofuran[32] or α-vinyltetrahydropyran,[33] respectively, both in high yields. In a similar manner, treatment of α-, γ- and δ-aminoallenes with $AgNO_3$ in aqueous acetone gives the corresponding 2,3-dihydropyrroles,[34] α-vinylpyrrolidines,[35] and α-vinylpiperidines,[35] respectively, in good yields.

Oxidative Couplings.

Alkylboranes, formed on reaction of terminal alkenes with diborane, dimerize on treatment with an aqueous solution of $AgNO_3$/NaOH. Thus hexene gives a 66% yield of dodecane,[36] and the dienes 1,5-hexadiene and geranyl acetate are converted to cyclohexane (66%) and *trans-p*-menthane (85%).[37] Although the use of $AgNO_3$/NaOH for these coupling reactions is, to all accounts, equivalent to the use of ***Silver(I) Oxide***, oxidative cyclization is reported to be less successful when this latter reagent is used. Oxidative dimerization of the dianions of α,β-unsaturated carboxylic acids with $AgNO_3$/THF gives moderate yields of the dienedioic acids, but the use of ***Iodine*** for this coupling gives higher yields (40-80%).[38]

Coverage of the use of $AgNO_3$/NaOH for oxidation of alcohols, aldehydes, etc., has not been included in this section as this ostensively amounts to the use of ***Silver(I) Oxide***.

Silver(I) Nitrite

$AgNO_2$

[7783-99-5] · $AgNO_2$ · Silver(I) Nitrite · (MW 153.88)

(preparation of aliphatic nitro compounds[2] and *N*-nitroso compounds;[8,9] aromatic nitration;[6,7] preparation of other reagents such as nitryl iodide,[10] phenylselenium nitrite,[14,15] thionyl chloride nitrite,[16] and palladium complexes[17,18])

Physical Data: mp 140 °C (dec); *d* 4.453 g cm^{-3}.

Solubility: sol water, acetonitrile, acetic acid, NH_4OH; insol alcohol.

Form Supplied in: pale yellow solid; widely available.

Introduction.

The main use of $AgNO_2$, particularly in the older literature, is in the Victor Meyer[1] reaction for the preparation of primary nitroalkanes from the corresponding primary bromo- or iodoalkanes (eq 1). Good conditions for this reaction have been established[2] and, provided the reaction temperatures are kept low, the amount of the nitrite ester can be kept to a minimum. Higher temperatures[3] shorten the reaction time, but lower yields are obtained. The reaction is best suited for alkyl halides with >3 carbon atoms, although, exceptionally, in a series of o-ethoxyalkyl bromides, the reaction was successful only for a four-carbon chain.[4] Branching on the bromoalkyl halide at the γ-carbon does not seriously affect the yield of nitro product, but branching on the β-carbon atom lowers the yield considerably.[2a] The reaction is generally unsuccessful for secondary and tertiary halides although, in an analogous reaction,[5] adamantyl hexafluoroantimonate gives 1-nitroadamantane (eq 2) on treatment with $AgNO_2$ using ***Arsenic(III) Fluoride*** as a suitable (sic) solvent. The corresponding reactions with trityl and *t*-butyl hexafluoroantimonates are unsuccessful.

$$RCH_2X \xrightarrow[\text{0-25 °C, 48 h}]{AgNO_2\text{, ether}} \underset{80\%}{RCH_2NO_2} + \underset{11\text{-}13\%}{RCH_2ONO} \qquad (1)$$

(2)

Aromatic Nitration.

Nitration of azupyrene with $AgNO_2$ gives 4-nitroazupyrene (eq 3).[6] In a similar reaction, azulene is converted to 1-nitroazulene (77%).[6] Direct substitution of 1,3-dibromoazulene results in the displacement of only one bromine atom to give 1-nitro-3-bromoazulene (eq 4).[7]

(3)

(4)

N-Nitrosation.

$AgNO_2$ is a mild reagent for *N*-demethylation of *N*,*N*-dimethyl amines, resulting in *N*-nitroso-*N*-methyl amines in moderate yields.[8] The reagent is also used for the conversion of imidoyl or sulfonimidoyl chlorides to *N*-nitroso amides (eq 5).[9]

(5)

$AgNO_2$ as an Adjunct for the Preparation of Other Reagents.

Nitryl Iodide.

This pseudohalogen, prepared by the reaction of $AgNO_2$ with ***Iodine***, adds stereo- and regiospecifically to alkenes to give 1-nitro-2-iodo compounds which, on loss of HI, afford nitroalkenes (eq 6).[10]

In a similar manner, β-substituted styrenes give *trans*-β-nitrostyrenes (eq 7).[11] Since ring nitration does not occur with this reagent, it offers an advantage over the use of ***Mercury(II) Chloride***/***Sodium Nitrite***. A reverse addition to alkenes has also been reported.[12]

The ambident nature of nitryl iodide is also demonstrated in its use as a mild agent for the iodination of alkylbenzenes (eq 8).[13]

Phenylselenium Nitrite.

This reagent, prepared by the reaction of ***Benzeneselenenyl Chloride*** and $AgNO_2$, is useful for the nitroselenation of alkenes[14] (eq 9) or conjugated dienes (eq 10).[15] Both reactions are catalyzed by $HgCl_2$ which also inhibits nitrite formation. Oxidative deselenation with ***Hydrogen Peroxide*** gives nitroalkenes in high yields.

This process has the advantage over nitromercuration in that reactions can be carried out in nonaqueous solvents, thus opening up the procedure to a wider range of alkenes. The reaction with dienes is particularly useful since the reactive 2-nitro-1,3-dienes, formed by

oxidative deselenation or by treatment of the nitro selenide with ***4-Dimethylaminopyridine***,[15b] can be trapped as the epoxides or reacted in situ with, for example, ***Ethyl Vinyl Ether*** to give, after acidification of the intermediate nitronate, unsaturated 1,4-diketones (eq 10).

Thionyl Chloride Nitrite.

This compound, prepared by the reaction of $AgNO_2$ with ***Thionyl Chloride*** (1:1), is a mild and selective agent for the preparation of nitrite esters (eq 11).[16]

Palladium complexes.

$AgNO_2$ has been used in the preparation of Pd complexes for the conversion of terminal alkenes to nitroalkenes[17] or as a catalyst[18] for the oxidation of terminal alkenes to methyl ketones.

Silver(I) Oxide

Ag_2O

[20667-12-3] · Ag_2O · Silver(I) Oxide · (MW 231.74)

(oxidizing reagent for conversion of hydroquinones to quinones,[1] alkylphenols to quinone methides,[5] and aldehydes to acids;[7] oxidative coupling reactions;[12,13] a Lewis acid with halides[18,20] and thioethers;[24] Wolff rearrangement[26])

Physical Data: dec at about 200 °C; *d* 7.22 g cm^{-3}.

Solubility: practically insol alcohol; sol in 40 000 parts H_2O; sol dilute nitric acid, ammonia; moderately sol NaOH.

Form Supplied in: brownish-black, heavy, odorless powder; widely available.

Handling, Storage, and Precautions: protect from light. Reduced by hydrogen, carbon monoxide, and most metals. Skin contact with this toxic reagent should be carefully avoided.

Hydroquinone Oxidation.

This reagent is a powerful oxidizing reagent for the conversion of hydroquinones to the corresponding quinones. 1,4-Hydroquinones are generally converted to quinones by treatment with Ag_2O (eq 1).[1] Other reagents (e.g. ***Cerium(IV) Ammonium Nitrate***) are less expensive and easier to handle. However, Ag_2O in nonhydroxylic solvents can be used to produce electron-deficient quinones which are unstable to nucleophiles. For example, Ag_2O oxidation of nitro hydroquinones affords nitro quinones (eq 2).[2]

(1)

(2)

A one-pot technique has been developed to oxidize 1,4-hydroquinones and utilize the quinone products as dienophiles in Diels-Alder reactions (eq 3).[3] Tetrahydrophenanthrene-9,10-quinones have also been prepared by a one-pot double Diels-Alder reaction (eq 4).[4]

A = CO_2Me or CHO
R^1 = OTMS, CH_2CO_2Et

R = CHO, COMe, CO_2Me, CN

Alkylphenol Oxidation.

1,4-Quinone methides can be obtained by the reaction of *p*-alkylphenols with Ag_2O. These reactive compounds may undergo subsequent transformations, for example, a Lewis acid promoted cyclization (eq 5).[5] 1,2-Quinone methides can also be formed by Ag_2O oxidation of appropriately substituted phenols (eqs 6 and 7).[6]

(6)

(7)

Other Oxidation Reactions.

Ag_2O oxidizes aldehydes to acids,[7] and conjugated keto aldehydes to conjugated keto acids.[8] For example, Ag_2O was used to selectively oxidize one of two formyl substituents of an intermediate in the total synthesis of inhibitor K-76 (eq 8).[9] The unreactive formyl substituent is conjugated with the hydroxyl and alkoxy substituents.

(8)

Oxidative Coupling Reactions.

Radicals produced by Ag_2O oxidation can undergo coupling reactions. For example, 2-(vinyloxy)phenols undergo Ag_2O oxidation-induced coupling.[10] Acylacetates and monosubstituted malonates are oxidatively dimerized in the presence of Ag_2O and DMSO (eq 9).[11]

(9)

Radical coupling followed by nucleophilic attack of hydroxyl on a quinone methide intermediate is postulated as the mechanism of the

key step in the syntheses of silybin and eusiderin (eq 10).[12] 1,4-Diketones are produced in the reaction of silyl enol ethers with Ag_2O in DMSO (eq 11).[13]

(10)

(11)

Lewis acid with Halides.

Ag_2O can activate halide as a leaving group by coordination. Methylation of carbohydrates[14] and 5-benzylidenebarbituric acid[15] have been carried out with Ag_2O and ***Iodomethane*** in DMF. Triphenyltin trifluoroacetate was obtained from the reaction of triphenyltin iodide and trifluoroacetic acid in the presence of silver oxide.[16] Ag_2O converts *trans*-halohydrins to epoxides (eq 12)[17] or rearranged products (eq 13)[18]. It is reported that the reaction is nonstereoselective, and that *trans*-epoxides are the major products when *cis*-alkenes are the reactants.[19]

(12)

(13)

2-Arylpropionaldehydes are produced from 1-aryl-1-propene by oxidative rearrangement with ***Iodine*** and Ag_2O in dioxane-H_2O (eq 14).[20] The mechanism may involve the 1,2-shift of the aryl group through a bridged phenonium ion in the iodohydrin intermediate.

(14)

In the total synthesis of mycophenolic acid, electrophilic substitution was promoted by Ag_2O (eq 15).[21] α,β-Unsaturated nitriles are formed from the corresponding γ-bromo-β-oxo nitriles with Ag_2O (eq 16).[22] Arylsulfenylation and arylselenenylation at the 5-position of uracils are promoted by Ag_2O (eq 17).[23]

(15)

(16)

(17)

$R^1 = H, Me; R^2 = Me$, acyclic chain, ribose; $R^3 = H, Me, N{=}PPh_3$
$X = S, Se$

Lewis Acid with Thioethers.

Ag_2O has been applied to the 1,2-cleavage of penicillins in a strong nonnucleophilic base, such as ***1,5-Diazabicyclo[4.3.0]non-5-ene***,[24] and to the hydrolysis of thioacetals.[25]

Wolff Rearrangement.

The Wolff rearrangement of diazo ketones is promoted by Ag_2O (eq 18).[26]

(18)

Silver(II) Oxide

AgO

[1301-96-8] · AgO · Silver(II) Oxide · (MW 123.87)

(oxidizing reagent for conversion of hydroquinone ethers[1] and alkoxy anilines[5] to quinones, of alcohols to aldehydes or ketones,[11] of allylic alcohols to conjugated acids,[12] of aldehydes to acids, of amines to azo compounds, and of amino acids to aldehydes;[13] radical coupling reactions;[8,9] utilized in oxidative decarboxylation of carboxylic acids[10])

Physical Data: dec above 100 °C; *d* 7.483 g cm^{-3}.

Solubility: insol H_2O; sol alkali; sol NH_4OH (with decomposition and evolution of N_2).

Form Supplied in: charcoal-gray powder; widely available.

Handling, Storage, and Precautions: protect from light. Highly irritating to skin, eyes, mucous membranes, and respiratory tract. Avoid contact with skin, organic matter, strong ammonia, and alkali.

Oxidation of Hydroquinone Ethers and Alkoxy Anilines.

This reagent effects the oxidative demethylation of hydroquinone ethers to afford *para*-quinones in acidic media (eq 1).[1] A mechanism has been proposed in which oxidative hydration takes place at the aromatic carbon.

(1)

AgO in dioxane-nitric acid solution also oxidizes hydroquinone mono- and diesters to the corresponding quinones (eq 2).[2] The order of reaction is 4-acetoxyphenols > hydroquinone dimethyl ethers > hydroquinone diacetates.[2]

(2)

AgO is effective in oxidizing electron-deficient 1,4,5-trimethoxy-9,10-anthraquinone to the corresponding diquinone, an intermediate in anthracyclinone synthesis (eq 3).[3] This bifunctional dienophile undergoes the Diels-Alder reaction at the internal double bond with

electron-rich dienes (e.g. 2-ethoxybutadiene), and at the external double bond with slightly electron-poor or unsubstituted dienes (e.g. 1,3-butadiene and 2-acetoxybutadiene).[4]

(3)

In the presence of AgO in aqueous nitric acid, *p*-methoxyanilines are oxidized with hydrolysis to quinones (eq 4).[5]

(4)

Tautomerization of a tetracyclic keto quinone obtained from AgO oxidation affords an aromatized anthracycline intermediate (eq 5).[6] The crude product subsequently undergoes tautomerization at rt in acetone with a few drops of concd. HCl.

(5)

The trimethoxyphenyl lactam derivatives of hydroquinone methyl ethers are oxidized by AgO in an acidic milieu to give the lactam-substituted quinones (eq 6).[7]

(6)

Radical Coupling Reactions.

The addition of acetone to terminal alkenes is accomplished by the action of AgO (eq 7).[8] 2-Alkanones are formed in 73-83% yield. Internal alkenes are less reactive. A radical mechanism is proposed for this transformation in which AgO acts as a heterogeneous initiator for the hydrogen atom abstraction from acetone to generate an acetonyl radical; this is followed by the addition of this radical to the alkene.

(7)

R = H, alkyl

The oxidative dimerization of 2-(vinyloxy) phenols by AgO under anhydrous conditions proceeds with rearrangement. A [3,3]-sigmatropic process involving an intermediate cyclohexadienol radical has been proposed (eq 8).[9]

(8)

R = OMe or 
Other Oxidation Reactions.

AgO has been utilized in the oxidative decarboxylation of carboxylic acids such as pivalic acid, isobutyric acid, and *n*-butyric acid.[10] The reaction proceeds significantly faster when acetonitrile is utilized as a cosolvent. AgO oxidizes primary alcohols to aldehydes, secondary alcohols to ketones,[11] allylic alcohols to conjugated acids,[12] aromatic hydrocarbons to aromatic aldehydes and ketones, α-amino acids and α-amino esters to aldehydes (with decarboxylation), aldehydes to acids,[13] and amines, aniline, *p*-toluidine, and *N*,*N*-dimethyl-*p*-phenylenediamine to the corresponding azo derivatives.[14]

Silver(I) Perchlorate[1]

$AgClO_4$

[7783-93-9] · $AgClO_4$ · Silver(I) Perchlorate · (MW 207.32)

(cyclization, dehydration, glycosylation, rearrangement of strained systems, solvolysis of halides)

Physical Data: mp 486 °C (dec); *d* 2.806 g cm^{-3}.[2]

Solubility: sol aniline, benzene, chlorobenzene, ethanol, glycerol, nitrobenzene, nitromethane, pyridine, toluene, water.[2,3]

Form Supplied in: white crystalline anhydride; white crystalline monohydrate *[14242-05-8]*.

Purification: dissolve 1g of the monohydrate per 6mL of benzene and heat at reflux under Dean-Stark conditions until the water is removed. Allow to cool and dilute with 4 mL of pentane per gram of the perchlorate. Filter the precipitate and place it in a desiccator containing P_2O_5 under high vacuum (1 mmHg) for 24 h.[4]

Handling, Storage, and Precautions: the anhydrous crystal readily forms the monohydrate, which is stable up to 43 °C and therefore should be stored in a desiccator. The salt is irritating to the skin and mucous membranes, corrosive, shock sensitive, and can be explosive in the presence of organic compounds.[3,4]

Cyclization Reactions.

The thiophilicity of silver perchlorate has been exploited in two types of cyclization processes. Nicolaou and co-workers[5] have developed a thioacetal cyclization strategy for oxocene synthesis that employs a silver perchlorate-sodium bicarbonate system to effect the transformation (eq 1). This protocol shows a marked increase in efficiency over other methods of oxocene construction. Similar tactics have been applied to the macrolide ring closure in eq 2 by Nimitz and Wollenberg,[6] and to the synthesis of the BCD ring framework of brevetoxin A developed by Nicolaou and co-workers.[7]

(1)

Dehydration.

Various secondary and tertiary alcohols can be efficiently dehydrated to their corresponding alkenes by the action of silver perchlorate in refluxing benzene,[8] as a milder alternative to treatment with strong acid. It has also been demonstrated that α-hydroxy thioacetals[9] (eq 3) and α-hydroxy ketones (eq 4)[10] are easily dehydrated to cyclopentenones by this reagent in the presence of water and under anhydrous conditions, respectively. In the investigation of α-hydroxy thioacetals, silver perchlorate was demonstrated to be a very potent reagent for the cleavage of thioacetals to ketones.

Glycosylation.

Silver perchlorate has been employed in a large variety of ways to form glycosidic linkages.[1c,d] In concert with various Lewis acids,[11,12] silver perchlorate catalyzes the glycosylation of 1-*O*-acetyl-D-glucose to produce a glucoside with a high degree of stereoselectivity (eq 5). Similar success has been achieved in both the stoichiometric and catalytic coupling of glycosyl fluorides,[13-22] dimethylphosphothionates,[23] and imidazolylcarbonyls[24,25] with various silver perchlorate systems.

(1)

Rearrangement and Electrocyclic Reactions.

Rearrangements in a wide range of strained molecules can be triggered by silver perchlorate.[1a,b] Bicyclobutanes are readily transformed into butadienes[26,27] in high yield, as evidenced in eq 6; cyclopropanes, particularly those in quadricyclane structures, display similar reactivity (eq 7).[28-30] Padwa et al.[31] have demonstrated that cyclopropenes can be manipulated by Ag^+ into interesting structures (eq 8). Silver perchlorate has also been implemented in the rearrangement of propargyl acetates to allenes.[32] Hiyama[33] used a modification of this procedure to access protected substituted furanones (eq 9) that are complementary to those formed by the mercury-catalyzed process. Finally, 2-(trimethylsiloxy)allyl cations have been generated in the presence of silver perchlorate and furan to generate 4-pyrones via a [3 + 4] cycloaddition process (eq 10).[34]

(8)

(9)

(10)

Solvolysis of Halides.

Wynberg[35] and colleagues have observed an interesting quasi-Favorskii rearrangement when they treated 4-bromoadamantanone with silver perchlorate in acetone-water (eq 11); solvolysis with retention is observed, however, in the case of *trans*,*trans*-2-bromodecalin in refluxing acetonitrile (eq 12).[36] Finally, Reese et al.[37] have examined the silver perchlorate-facilitated methanolysis of dihalocarbene adducts in the context of synthetic routes to functionalized medium-ring cycloalkanes.

Silver(I) Phosphate

Ag_3PO_4

[7784-09-0] · Ag_3O_4P · Silver(I) Phosphate · (MW 418.58)

(basic halophilic salt capable of accelerating the rate of palladium-catalyzed Heck reactions,[1,2] exhibiting large effects on enantio- or diastereoselectivity, and suppressing product alkene isomerization[3,4])

Physical Data: mp 849 °C; *d* 6.37 g cm^{-3}.

Solubility: slightly sol H_2O, acetic acid; freely sol nitric acid; ammonia.

Form Supplied in: yellow, odorless powder.

Handling, Storage, and Precautions: protect from light.

Palladium-Catalyzed Heck Reactions.

Rate Enhancement.

The rate of Heck reactions of aryl or alkenyl halides is typically increased upon addition of silver salts with nonnucleophilic or weakly nucleophilic counterions, including NO_3^-, OTf^-, CO_3^{2-}, OAc^-, and PO_4^{3-}. Silver phosphate is among the most effective of these salts, and its relative efficiency has been attributed to the basicity of the anion. Its role is likely two-fold. First, the Ag^+ likely abstracts the halide from the Pd^{II} complex which is generated by oxidative addition of the aryl or alkenyl halide. Halide abstraction produces a cationic Pd^{II} complex which binds more efficiently to the alkene which is inserted in the next step of the process.[1,2] Secondly, the PO_4^{3-} is an efficient base for scavenging the proton generated by the β-hydride elimination which terminates the process.

Suppression of Product Isomerization.

Alkene isomerization is frequently a problem in Heck reactions and is undoubtedly caused by readdition-elimination of a palladium hydride species to the product alkene. The removal of the hydrohalic acid by silver phosphate prevents such a readdition and thus effectively suppresses alkene isomerization (eq 1). Silver phosphate is typically the most effective silver salt in the suppression of alkene isomerization.[3,4]

Ag_3PO_4	74% (*S*) 79-81% ee	8%
1,2,2,6,6-pentamethylpiperidine	45% (*R*) 89-95% ee	44%

Effect on Diastereoselectivity.

The diastereoselectivity of Heck reactions can be markedly affected by the presence of silver phosphate (eqs 2 and 3). Such an effect was attributed to coordination of a remote alkene to the cationic palladium complex generated in a silver phosphate-promoted cyclization.[5]

(3)

Effect on Enantioselectivity.

Silver phosphate has been used in the catalytic asymmetric synthesis of *cis*-hydrindanes[6] and *cis*-decalins[7,8] by Heck reactions (eqs 4 and 5). Enantioselectivities with silver phosphate generally exceed those of other silver salts and of non-silver-catalyzed reactions. In one study (eq 1), the addition of silver phosphate completely reversed the absolute stereochemistry of the products with respect to the enantioselectivity observed in the non-silver-catalyzed reaction. Less basic silver salts afforded virtually no asymmetric induction in this study.[4]

Silver(I) Tetrafluoroborate

$AgBF_4$

[14104-20-2] · $AgBF_4$ · Silver(I) Tetrafluoroborate · (MW 194.68)

(mild Lewis acid with a high affinity for organic halides)

Physical Data: mp 200 °C (dec).

Solubility: sol benzene, toluene, nitromethane, diethyl ether, water.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: contents of Ag can be assayed conveniently by volumetric titration of Ag^I.

Preparative Method: can be prepared by reacting ***Silver(I) Fluoride*** with ***Boron Trifluoride*** in nitromethane.[1]

Handling, Storage, and Precautions: should be protected from light and moisture; very hygroscopic.

Introduction.

This reagent has replaced ***Silver(I) Perchlorate*** to a large extent because of the sensitivity of perchlorates.

Activation of Acyl Chlorides.

In several cases, $AgBF_4$ has been used to increase the reactivity of acyl chlorides towards nucleophiles.[2] For example, *N*-acylammonium salts were prepared for the first time by the reaction of a tertiary amine and an acyl chloride in the presence of $AgBF_4$ (eq 1).[3]

(1)

Nucleophilic Substitution on Alkyl Halides by Heteroatoms.

A number of more or less activated alkyl halides, such as benzyl halides[4] and allyl halides,[5] undergo substitution reactions mediated by $AgBF_4$ in the presence of a heteroatom nucleophile. For example, treatment of pentamethylcyclopentadienyl bromide with $AgBF_4$ in the presence of a nucleophile gives the corresponding substituted product (eq 2). Thiols, amines, and alcohols have been used as nucleophiles.[6]

(2)

Adenine analogs are prepared stereoselectively from cyclopentene derivatives using a two-step procedure (eq 3). The reaction probably involves a seleniranium salt as an intermediate.[7]

(3)

Intramolecular substitutions mediated by Ag^+ do not seem to require activated halides.[8] For example, o-chloro amides react with $AgBF_4$, giving products from intramolecular attack of the amide oxygen. Depending on the structure of the amide, imino lactones,[9] imino lactonium salts,[10] or lactone hydrazones (eq 4)[11] are obtained as products. Fluorination of α-bromo ketones using $AgBF_4$ has also been reported.[12]

(4)

Nucleophilic Aromatic Substitution.

In one case, it has been reported that $AgBF_4$ promotes the nucleophilic substitution of an aromatic chloride (eq 5).[13] This is not due to activation of the halide, but apparently to suppression of halide-promoted decomplexation of the arene-manganese derivative.

Carbon-Carbon Bond Formation via Cationic Intermediates.

In analogy with the heteroatom substitutions described above, certain aliphatic halides undergo substitution reactions with carbon nucleophiles promoted by $AgBF_4$. For example, Eschenmoser and co-workers used $AgBF_4$ in order to transform α-chloro nitrones into 1,3-dipoles which react with ordinary alkenes in a cycloaddition manner (eq 6).[14]

Livinghouse and co-workers have shown that acylnitrilium ions, prepared from isocyanides and an acid chloride followed by treatment with $AgBF_4$, are useful intermediates in the synthesis of nitrogen-containing heterocycles (eq 7).[15]

In certain cases, allylsilanes[16] and trimethylsilyl enol ethers[17] react with alkyl halides with the formation of a new carbon-carbon bond. α-Bromo imidates[18] (eq 8) and β-chloro imines[19] have been reported to undergo electrophilic aromatic substitution on relatively electron-rich aromatics in the presence of $AgBF_4$.

Synthesis via Iminium Ions.

α-Cyano amines react with $AgBF_4$ with the formation of an intermediate iminium ion.[20] This has been used synthetically as a method for removal of the cyano group either by a consecutive reduction[21,22] to the amine (eq 9) or by elimination to the imine[23] or enamine.[24]

Rearrangements.

A number of strained alkyl and/or reactive halides, such as cyclopropyl[25] and bicyclic[26,27] chlorides, rearrange on treatment with $AgBF_4$. For example, β-bromotetrahydropyrans rearrange to tetrahydrofurans stereoselectively on treatment with $AgBF_4$ (eq 10).[28] Other examples include the rearrangement of α-haloalkyl aryl ketones into arylacetic acid derivatives,[29] and the rearrangement of α-haloalkylsilanes upon treatment with $AgBF_4$.[30]

In the presence of strained hydrocarbons, $AgBF_4$ functions as a mild Lewis acid and causes rearrangements.[31-33] For example, the tricyclic hydrocarbon (**1**) rearranges upon treatment with a catalytic amount of $AgBF_4$ to the less strained hydrocarbon (**2**) (eq 11).[34]

Numerous examples include the rearrangement of propargyl esters into allenyl esters (see also ***Silver(I) Trifluoromethanesulfonate***)[35] or to dihydrofurans,[36] the Claisen rearrangement of aryl allenylmethyl ethers,[37] and the rearrangement of silyloxycyclopropanes (eq 12, also effected by ***Copper(II) Tetrafluoroborate***).[38]

(12)

Activation of Thiol Esters.

Pyridyl thiol esters are converted into esters on treatment with $AgBF_4$ and an alcohol.[39] Acylation of alkynylsilanes can also be carried out using thiol esters in the presence of $AgBF_4$.[40]

Alkylation of Thioethers.

Thioethers can be methylated by ***Iodomethane*** in the presence of $AgBF_4$.[41] Benzylation of thioethers in the presence of $AgBF_4$ has also been reported.[42]

Electrophilic Aromatic Substitution.

Electrophilic nitration using a combination of NO_2Cl and $AgBF_4$ has been reported.[43] Conversion of arylsilanes into iodides and bromides has been achieved using a combination of the halogen and $AgBF_4$ (eq 13).[44]

(13)

Catalysis of Cycloadditions.

Addition of catalytic amounts of $AgBF_4$ greatly increases the selectivity of [2 + 4] cycloadditions of benzyne.[45]

Related Reagents.

Dimethyl Sulfoxide-Silver Tetrafluoroborate.

Silver(I) *p*-Toluenesulfonate

[16836-95-6] · $C_7H_7AgO_3S$ · Silver(I) *p*-Toluenesulfonate · (MW 279.08)

(mild Lewis acid with a high affinity for organic halides)

Solubility: sol acetonitrile, diethyl ether, water.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: contents of Ag can be assayed conveniently by volumetric titration of Ag^I.

Preparative Method: can be prepared by mixing aqueous solutions of ***Silver(I) Nitrate*** and sodium tosylate and filtering off the precipitate.

Handling, Storage, and Precautions: should be protected from light.

Conversion of Alkyl Halides into Tosylates.

Treatment of primary alkyl halides, in most cases bromides and iodides, with silver tosylate in acetonitrile, gives good yields of the corresponding tosylates.[1,2] Tertiary and benzylic tosylates, even though they are very prone to dissociate, have been prepared using a similar procedure.[3]

Solvolysis of Reactive Halides.

In analogy with other silver(I) salts, this reagent has been used for solvolysis of reactive bromides. Thus treatment of bicyclic geminal dibromocyclopropanes leads to ring-enlarged products (eq 1). The stereoselectivity observed indicates that a concerted electrocyclic ring opening is involved.[4] Analogously, benzylic bromides have been shown to give styrenes on treatment with AgOTs in dichloromethane.[5]

(1)

Synthesis via Benzeneselenenyl Tosylate.

Treatment of ***Benzeneselenenyl Chloride*** with AgOTs in acetonitrile gives the unstable benzeneselenenyl tosylate. This reagent (prepared in situ) adds to alkynes to give β-(phenylseleno)vinyl tosylates (eq 2).[6]

Silver(I) Trifluoroacetate

$AgOCOCF_3$

[2966-50-9] · $C_2AgF_3O_2$ · Silver(I) Trifluoroacetate · (MW 220.89)

(mild Lewis acid with a high affinity for aliphatic halides)

Physical Data: mp 257-269 °C (dec).

Solubility: sol benzene, diethyl ether, water.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: contents of Ag can be assayed conveniently by volumetric titration of Ag^I.

Preparative Method: can be prepared by extraction of an aqueous solution of ***Silver(I) Nitrate*** and $NaOCOCF_3$ with ether.[1]

Handling, Storage, and Precautions: should be protected from light.

Solvolysis of Reactive Halides.

Like other silver(I) salts, this reagent has been used for solvolysis of reactive halides. Thus treatment of methoxyallyl bromide with $AgOCOCF_3$ yields the corresponding allyl cation which can be captured as its cycloadduct with furan (eq 1).[2]

(1)

Geminal dibromocyclopropanes, as well as dibromocyclobutanes, are easily hydrolyzed using this reagent.[3,4] In the case of substrates containing a side-chain with a nucleophilic hydroxy or carboxylic acid group, products from ring opening of the cyclopropane followed by nucleophilic ring closure (eq 2) have been observed.[5]

(2)

Alkylation of Silyl Enol Ethers.

Primary and secondary iodides,[6] as well as allylic bromides,[7] react with silyl enol ethers in the presence of $AgOCOCF_3$ to give products of alkylation (eq 3). In the case of 2-trimethylsilyloxyfuran, exclusive attack on the 5-position is observed (eq 4).[8,9]

(3)

(4)

Activation of Thiol Esters.

Thiol esters can be converted into *O*-esters on treatment with the corresponding alcohol and $AgOCOCF_3$, $HgOCOCF_3$, or copper salts (eq 5).[10] Similarly, β-keto thioesters react with amines in the presence of $AgOCOCF_3$ to give β-keto amides (eq 6).[11]

(5)

(6)

Rearrangements of Alkynes.

Propargylic esters rearrange to 1,3-dienyl esters in the presence of a catalytic amount of $AgOCOCF_3$ (eq 7).[12,13] For similar transformations, see ***Silver(I) Tetrafluoroborate***.

(7)

Oxidation of Dihydrazones.

Newman and Reid found that $AgOCOCF_3$ is an excellent reagent for the oxidation of aromatic dihydrazones into 1,2-diarylacetylenes (eq 8).[14]

Silver(I) Trifluoromethanesulfonate

$AgOSO_2CF_3$

[2923-28-6] · $CAgF_3O_3S$ · Silver(I) Trifluoromethanesulfonate · (MW 256.95)

(reactive triflating agent and source of soluble silver ions useful for formation of electrophilic onium species,[1] and promotion of Friedel-Crafts,[2] nucleophile-alkene cyclization,[3] and esterification[4] reactions)

Alternate Name: silver triflate.

Physical Data: mp 356 °C.

Solubility: sol typical organic solvents.

Form Supplied in: white solid; widely available.

Preparative Method: can be prepared from the barium salt via treatment with dil H_2SO_4 followed by neutralization with Ag_2CO_3.[5]

Handling, Storage, and Precautions: light sensitive; irritant. Use in a fume hood.

Oxonium (Iminium) Reactions.

Oxygen- and nitrogen-containing molecules bearing an α-nucleofuge such as a halide or sulfur are converted by AgOTf to highly electrophilic onium (eq 1)[1] or iminium (eq 2)[6] species. The intermediacy of a planar cation is substantiated by the formation of the same diastereomer from either substrate isomer in some cyclization reactions (eq 1).

(1)

(2)

This reaction type has enjoyed wide application in carbohydrate chemistry, as anomeric carbons can be easily functionalized with high stereospecificity by silyl enol ethers (eq 3, R´ = Ph,[7] H[8]) and other nucleophiles.

(3)

R = Bn

R' = Ph, 88%
R' = H, 81%

Friedel-Crafts (and Other Aromatic Functionalization) Reactions.

When treated with AgOTf, alkyl,[2] acyl (eq 4),[9] and sulfonyl[10] halides are converted to extremely electrophilic triflate species that react rapidly with even deactivated[11] aromatic rings in the absence of catalysis. Benzylic chloroformates participate similarly (eq 5).[12] Aromatic rings are also efficiently vinylated[13] and iodinated[14] via AgOTf-promoted processes.

(4)

(5)

Ar = *p*-$MeOC_6H_4$-

Miscellaneous Reactions.

AgOTf induces a highly diastereoselective cyclization of amino ketenes wherein asymmetry is induced by an adjacent stereogenic center and is dependent upon silver concentration (eq 6).[3] Acetylenic oxy-Cope rearrangements are also facilitated by AgOTf (eq 7),[15] and a mild, high-yield esterification utilizes AgOTf in the presence of ***Titanium(IV) Chloride*** (eq 8).[4]

Singlet Oxygen

[7782-44-7] · O_2 · Singlet Oxygen · (MW 32.00)

(electrophilic oxidizing agent for oxygenation of cisoid 1,3-dienes, many types of heterocyclic systems, enamines, alkenes containing allylic hydrogen atoms, sulfides, carbon-phosphorus double bonds, and other electron-rich unsaturated organic compounds)

Physical Data: singlet oxygen ($^1O_2$) is the first excited electronic state of molecular oxygen ($^1\Delta_g$), lying 22.4 kcal mol^{-1} above the ground state triplet. The second singlet state (^{1}&SSigma;+g), 37 kcal mol^{-1} above the ground state, is relatively short-lived in solution (10^{-12} s) due to a rapid spin-allowed transition to the longer-lived (10^{-3}-10^{-6} s) first excited state. Because of the short lifetime of the ^{1}&SSigma;+g state, the more stable singlet oxygen species ($^1\Delta_g$) is considered to be the reactive intermediate in the oxygenation of organic compounds in solution.[1]

Solubility: sol aqueous and organic solvents.

Form Supplied in: singlet oxygen is an unstable, short-lived species and must be prepared in situ or immediately prior to use.

Preparative Methods: among the methods for generating singlet oxygen in solution are: (a) the dye-sensitized photooxidation of triplet oxygen;[2] (b) the decomposition of phosphite ozonides;[3] (c) the decomposition of transannular peroxides such as 9,10-diphenylanthracene peroxide;[4] (d) the reaction of ***Hydrogen Peroxide*** with ***Sodium Hypochlorite***;[5,6] and (e) subjecting gaseous oxygen to electrodeless discharge.[7] In the following section, the procedures for generating singlet oxygen by the methods (a)-(d) above are discussed, and some typical reactions of singlet oxygen with organic compounds are reviewed.

Handling, Storage, and Precautions: the initial peroxidic products formed in $^1O_2$ reactions usually undergo decomposition or rearrangement under the conditions of workup, but in some cases (certain transannular peroxides or dioxetanes) they may remain in the reaction mixture as potentially explosive materials. Unless the peroxides are sought as reaction products, they may be deoxygenated by the action of ***Dimethyl Sulfide***, diphenyl sulfide, or ***Triphenylphosphine***.

Preparative Methods.

Generation by Dye-Sensitized Photooxygenation.[2]

The most common method for generating $^1O_2$ in solution is the dye-sensitized photochemical excitation of triplet oxygen. The mechanism for generating $^1O_2$ in this way involves the excitation of an appropriate dye with visible light to form the corresponding excited singlet state. Rapid intersystem crossing generates the excited triplet state of the sensitizer (E_T > 22.4 kcal mol^{-1}) which undergoes energy transfer with triplet oxygen to form singlet oxygen, regenerating the ground state of the sensitizer (eq 1). Among the sensitizers which can be utilized in solution are methylene blue, Rose Bengal, eosin yellow, chlorophyll, riboflavin, zinc tetraphenylporphyrin, bis-naphthalenothiophene, erythrosin B, and hematoporphyrin. In addition to the soluble, homogeneous sensitizers, polymer-bound dyes such as Rose Bengal have been used for the photochemical generation of $^1O_2$.[8]

$$\text{Sens} \xrightarrow{h\nu} {}^1(\text{Sens}^*) \xrightarrow{\text{ISC}} {}^3(\text{Sens}^*) \xrightarrow{{}^3O_2} {}^1O_2 + \text{Sens} \quad (1)$$

Singlet oxygen may be generated in a wide range of solvents, the choice of solvent being dictated by the solubility of substrate and sensitizer and by solvent properties that influence ease of workup. The lifetime of $^1O_2$ varies from 2 µs in H_2O to approximately 700 µs in CCl_4 (Table 1) and is considerably longer when the solvent is deuterated (the lifetime of $^1O_2$ is almost always increased by a factor of ten when the solvent is perdeuterated).[9]

Table 1 Lifetimes of Singlet Oxygen in Various Solvents[9]

Solvent	Lifetime (ms)	Solvent	Lifetime (ms)
H_2O	2	MeCN	30
MeOH	7	$CHCl_3$	60
EtOH	12	CS_2	200
C_6H_{12}	17	$CDCl_3$	300
D_2O	20	C_6F_6	600
C_6H_6	24	CCl_4	700
MeCOMe	26	Freon-11	1000

The light sources used are generally high intensity lamps which emit light in the visible range. Sun lamps have been employed in certain instances but they may bring about competing UV-promoted reactions and rearrangements. Among the lamps used as light sources are Sylvania 500 W tungsten halogen,[10] Osram-Vialox 250 W,[11] 500 W Halogen-Argaphoto,[12] 500 W Toshiba JD,[13] 200 W halogen,[14] 650 W tungsten halogen,[15] 100 W tungsten halogen,[16] and 500 W high pressure sodium.[17]

Generation from Phosphite Ozonides.[3]

Triphenyl Phosphite is treated with ***Ozone*** at -78 °C (dry ice-acetone) in methylene chloride until the blue color of excess ozone is observed. Ozonization is then discontinued and the solution is purged with dry nitrogen to remove the excess oxidant. A cold solution of the acceptor in methylene chloride is then added, and mixing is effected by the nitrogen stream. The -78 °C bath is then removed and replaced with a -25 °C bath (ice-methanol). Alternatively, the reaction mixture is permitted to warm to rt and then worked up by concentration and chromatography.

Generation by the Decomposition of 9,10-Diphenylanthracene Endoperoxide. Oxidation of an Oxazole to a Triamide.

In contrast to dialkyl peroxides, which usually undergo oxygen-oxygen bond cleavage on pyrolysis, many aromatic endoperoxides break down on heating with release of oxygen in the singlet state.[18] Among the available endoperoxides, 9,10-diphenylanthracene peroxide (**1**) has been found to be a particularly efficient donor of $^1O_2$ in this type of decomposition. It can easily be prepared as a stable product (dec 180-181 °C, mp 254 °C) by irradiation of a cold solution of 9,10-diphenylanthracene in carbon disulfide for 48 h in a stream of oxygen using a 275 W Sylvania RS lamp.[19]

(1) DPAP

A typical singlet oxygen reaction using this peroxide is illustrated in the conversion of 2,5-diphenyl-4-methyloxazole to *N*-acetyldibenzamide (eq 2).[18] In this oxidation, an anhydrous benzene solution containing the peroxide and the oxazole is stirred at reflux temperature in the dark for 94 h under a positive pressure of nitrogen. Removal of benzene and chromatography on silica gel yields the triamide (92%), as well as some diamide formed during chromatography, in addition to 9,10-diphenylanthracene.[4]

Generation of $^1O_2$ by Hypochlorite-Hydrogen Peroxide Oxygenation.[5]

In this procedure, illustrated by the conversion of 2,3-dimethylbutene to the allylic hydroperoxide (eq 3), a methanolic solution of the substrate is treated with 3 equiv of 30% ***Hydrogen Peroxide*** and stirred at 10 °C. To this mixture, aqueous ***Sodium Hypochlorite*** is slowly added (2.5 equiv). The solution is then diluted with water, extracted with ether, and worked up.

Oxygenations with $^1O_2$.

Singlet oxygen undergoes three classes of reaction with alkenes: an ene type of reaction forming allylic hydroperoxides; 1,4-cycloaddition with cisoid 1,3-dienes; and 1,2-cycloaddition with electron-rich or strained alkenes. In addition, $^1O_2$ reactions take place with many types of heterocyclic compounds including furans, pyrroles, oxazoles, indoles, imidazoles, and thiophenes.[20,21] Other types of $^1O_2$ reaction take place with sulfides, carbon-phosphorus double bonds, and electron-rich aromatic systems. In many cases, competition exists between different modes of oxidation, as in the reaction of dihydropyran with $^1O_2$ (eq 4), which takes place either by 1,2-dioxetane formation and subsequent cleavage, or by an ene reaction forming a hydroperoxide which undergoes O-O bond fission by a β-elimination. In this case, it is found that the ratio of products (**2**) to (**3**) varies over a 58-fold range depending on the solvent used (Table 2), with polar solvents favoring 1,2-dioxetane formation over the ene reaction.[22]

Table 2 Dependence of Reaction Mode on Solvent in the $^1O_2$ Oxidation of Dihydropyran

Solvent	Product ratio (**2**)/(**3**)
Benzene	0.094
Acetone	0.50
Methylene chloride	2.67
Acetonitrile	5.51

The Singlet Oxygen Ene Reaction.

The reaction of alkenes containing at least one allylic hydrogen with singlet oxygen, yielding a hydroperoxide with accompanying shift of the double bond, bears a close resemblance to the Alder ene reaction (eq 5). This ene type of oxidation has been extensively used in synthesis. Reduction of the allylic hydroperoxide yields the corresponding allylic alcohol. An analogous reaction of enol silyl ethers yielding silylperoxy esters is assumed to take place by the same mechanism (eq 6).[23] Formation of allylic hydroperoxides is not stereoselective, as is shown by the intermediates in the garrya and atisine alkaloid syntheses (eqs 7 and 8).[24]

(5)

(6)

(7)

(8)

The photooxygenation of Δ^9-octalin followed by reduction with hydrazine yields $\Delta^{1(9)}$-10-octalol, a key intermediate in the synthesis of *trans*-cyclodecenone (eq 9).[25] The ene reaction has also been used for the contrathermodynamic isomerization of an alkene (eq 10)[26] and in the formation of allylic alcohols for later conversion to α,β-unsaturated ketones (eq 11).[27]

(9)

(10)

(11)

An interesting use of the ene $^1O_2$ reaction in conjunction with the Diels-Alder type of $^1O_2$ addition is found in the dye-sensitized photooxidation of neoabietic acid.[28] The first step involves an ene reaction at the more highly substituted double bond, generating a hydroperoxide along with the shift of the double bond to form a *cis*-1,3-diene. The second-stage [2 + 4] addition yields a transannular peroxide which undergoes a β-elimination and reduction to form the product (eq 12).

(12)

In the final steps of a total synthesis of tetracycline, the anhydro derivative is converted to a hydroperoxide in high yield by a singlet oxygen addition in the ene mode (eq 13). The reaction is very sensitive to overoxidation and succeeds only when the dye-sensitized photooxidation is terminated after a few minutes.[29]

(13)

1,4-Cycloaddition.

The reaction of singlet oxygen with cisoid 1,3-dienes takes place in both carbocyclic and heterocyclic systems. In general, the formation of 1,4-cycloaddition products from 1,3-dienes is the hallmark of singlet oxygen reactivity, in contrast to other less well-defined oxidation processes effected by oxygen in the ground state. The early synthesis of (±)-ascaridol by the dye-sensitized photooxygenation of α-terpinene is a classic case of 1,4-addition by singlet oxygen (eq 14).[30] The Schenck synthesis of cantharidine[31] also makes use of an endoperoxide formed by a Diels-Alder type cycloaddition of singlet oxygen (eq 15). In another application, the formation of bis-epoxides by thermolysis of 1,4-endoperoxides generated in a singlet oxygen addition is employed in the synthesis of (±)-crotepoxide (eq 16).[32]

(14)

(15)

(16)

Furan photooxidation by 1,4-cycloaddition of $^1O_2$ has been widely used as a means of generating carbonyl compounds from transannular peroxide intermediates. In an early example, 2-furfural was converted by $^1O_2$ to the unsaturated lactone intermediate (eq 17) in a synthesis of camptothecin.[33] Likewise, oxidation of 3-methyl-2-furoic acid yields the corresponding methyl derivative used as a key component in a synthesis of (±)-strigol (eq 18).[34] These transformations most probably take place by solvolysis of the intermediate endoperoxide followed by fragmentation, as shown in eq 19. Examples have been reported of singlet oxygen reactions with styrene derivatives where a benzene ring acts as part of a 1,3-diene system (eq 20).[35,36]

(17)

A recent example of 1,4-addition of singlet oxygen to a pyrrole involves the dye-sensitized photooxidation of 2-carboxy-4-methoxy-5-(methoxycarbonyl)-1-methylpyrrole (eq 21). The intermediate endoperoxide undergoes fragmentation by decarboxylation and cleavage of the O-O bond to give 5-hydroxy-4-methoxy-5-(methoxycarbonyl)-1-methyl-3-pyrrolin-2-one).[37]

Addition of Singlet Oxygen to Alkenes Activated by Electron-Releasing Groups.

The addition of singlet oxygen to alkenes occurs in the presence of amino or alkoxyl groups in the absence of active allylic hydrogens in the same molecule. The addition takes place stereospecifically by *cis* addition to form dioxetanes as isolable products. These, in turn, undergo thermolysis to form electronically excited carbonyl compounds with accompanying chemiluminescence. Thus photooxidation of 1,1,2,2-tetramethyoxyethylene sensitized by either zinc tetraphenylporphyrin or dinaphthalenothiophene proceeds smoothly to give an isolable clear, pale-yellow liquid shown to be the tetramethoxydioxetane (eq 22).[38] On the other hand, the crystalline *cis*-dioxetane, formed on dye-sensitized photooxidation of *cis*-diethoxyethylene in fluorotrichloromethane at -78 °C under irradiation with a 500 W lamp for 25 min, explodes on warming to rt (eq 23).[39]

Reactions of Enamines with Singlet Oxygen.

Reactions of enamines with $^1O_2$ take place readily to form the carbonyl products expected from the cleavage of dioxetane intermediates. In the case of the piperidine enamine of methyl isopropyl ketone, the reaction is carried out in benzene using zinc tetraphenylporphyrin as sensitizer (eq 24).[40] In related work, photooxygenation of the 22-morpholine enamine of 3-oxobisnor-4-cholen-22-al in DMF at 15 °C using Rose Bengal as sensitizer yields a quantitative yield of progesterone (eq 25).[41] Likewise, $^1O_2$ cleavage of the highly electron-rich enamines formed from the silyl enol ethers of azetidinecarboxylic esters provides a route to β-lactams (eq 26).[42]

(25)

(26)

Reactions of Enols with $^1O_2$.

As electron-rich alkenes, enols react with singlet oxygen along the lines of the ene reaction to give unstable intermediate hydroperoxides which undergo further transformations. The reactions are enhanced by the presence of fluoride ion, presumably by the formation of a strong hydrogen bond between the enol-OH and the fluoride.[43] Thus 1,3-cyclohexanedione reacts with $^1O_2$ in the presence of fluoride ion to give pyrogallol (eq 27). 4-Hydroxycoumarin, which is normally relatively inert toward $^1O_2$, readily undergoes oxygen uptake with $^1O_2$ in the presence of fluoride ion (eq 28).

(27)

(28)

While it has generally been assumed that alkenes with electron-withdrawing groups are inert to $^1O_2$, it has recently been shown that α,β-unsaturated ketones which are constrained in the *s-cis* conformation are rapidly oxidized by $^1O_2$. Systems which prefer the *s-trans* conformation react slowly or not at all.[44,45] For example, compound (**4**) yields 88% of the hydroperoxide (eq 29) while compound (**5**) shows no reaction toward $^1O_2$. The difference is accounted for in terms of an initial [4 + 2] cycloaddition of $^1O_2$ to form a 1,2,3-trioxine (eq 30),[44] which then undergoes further transformations.

(29)

(4)

(5)

(30)

Oxidation of Sulfides.

Sulfides react with singlet oxygen to form sulfoxides and sulfones.[46-49] The reaction takes place through intermediate persulfoxides. The rate of uptake of $^1O_2$ appears to be relatively independent of solvent and temperature. Other reaction paths have been observed. Thus although the $^1O_2$ oxidation of the linear sulfide yields the expected mixture of sulfoxide and sulfone (eq 31), oxidation of the thiazolidine with singlet oxygen, followed by deoxygenation with Me_2S or Ph_3P, gives a quantitative yield of the product of α-hydroxylation (eq 32). Formation of this alcohol is considered to take place by a Pummerer-type of rearrangement of an intermediate persulfoxide.[50]

(31)

(32)

Cleavage of Carbon-Phosphorus Double Bonds by Singlet Oxygen.

Singlet oxygen cleaves phosphorus ylides to form carbonyl compounds and the corresponding phosphine oxide (eq 33).[51] The reported procedure involves dye-sensitized photooxidation of the phosphorane in a solvent such as chloroform, benzene, or methanol using *meso*-tetraphenylporphyrin or Rose Bengal as sensitizer with irradiation from a 500 W tungsten filament lamp while oxygen is bubbled through the solution. This method has recently been employed in one of the procedures for oxidizing phosphoranes to tricarbonyl compounds (eq 34).[52]

(33)

(34)

Trapping Dioxetanes and Other Peroxidic Singlet Oxygen Oxidation Products.

In certain cases, dioxetane intermediates and other peroxidic species may be deoxygenated by reaction with diphenyl sulfide, a species which is unreactive toward $^1O_2$.[48] As an example,[53] the dye-sensitized photooxygenation of tetraphenylimidazole normally yields the dibenzoyl derivative in nearly quantitative yield, presumably through the dioxetane (eq 35). In the presence of diphenyl sulfide, a product of rearrangement is also formed along with diphenyl sulfoxide. Other studies on trapping agents for peroxidic intermediates have included the use of pinacolone for perepoxides[54] and dimethyl sulfide or triphenylphosphine for persulfoxides.[55]

(35)

Sensitivity of $^1O_2$ Reactions to the Environment.

The reactions of singlet oxygen with organic substrates are very sensitive to the experimental environment. Temperature, reaction time, substituents, solvent, and dissolved solutes may all affect the oxidations, resulting in mixtures of products of varied composition. This phenomenon is well illustrated in the studies on the sensitized photooxidation of a 5,6-disubstituted 3,4-dihydro-2*H*-pyran, in which solvent effects lead to widely varying product distributions (eq 36).[56] Table 3 illustrates these effects.

Sodium[1]

Na

[7440-23-5] · Na · Sodium · (MW 22.99)

(powerful one-electron reducing agent for most functional groups;[1] reductively couples ketones and esters to unsaturated carbon atoms;[2] reductively eliminates and couples halogens and other groups; can be used to generate alkoxides)

Physical Data: mp 97.8 °C; *d* 0.968 g cm^{-3}.

Solubility: sol liquid NH_3; slightly sol ethereal solvents; dec in alcohols; reacts violently in H_2O.

Form Supplied in: silver-white or gray solid in brick, stick, or ingot form; more commonly as 3-8 mm spheres or as a dispersion in various inert oils.

Purification: surface oxide can be removed by heating in toluene;[3] oxide impurities can usually be ignored.

Handling, Storage, and Precautions: the dry solid quickly oxidizes when exposed to air and in very moist air is potentially flammable. The highly corrosive sodium vapor ignites spontaneously in air, and is a severe irritant to eyes, skin, and mucous membranes. Utmost care should be taken to keep sodium away from halogenated solvents, oxidants, and aqueous mineral acids. Fires should be quenched with a dry powder such as Na_2CO_3, NaCl, or NaF; water, CO_2, Halon, and silica gel should be avoided. Excess sodium is best disposed of by slow introduction into a flask of isopropanol, possibly containing 1% water, taking care to vent liberated H_2, and neutralizing the resulting solution with aqueous acid. Sodium stored under oil is best weighed by rinsing freshly cut pieces with hexane and after evaporation adding to a tared beaker containing hexane.

Reaction Conditions.

Sodium, along with the other commonly used alkali metals ***Lithium*** and ***Potassium***, is an extremely powerful one-electron reductant. Historically, solutions of sodium in ammonia have been used to reduce a wide variety of functional groups (see also ***Sodium-Ammonia*** for some of these transformations, particularly the Birch reduction of aromatic rings).[4] These reductions are usually carried out in the presence of proton donors, normally simple alcohols or NH_4Cl, though occasionally these are added prior to workup. Many reductions are performed with solutions of sodium in refluxing alcohols; here a large excess of sodium is often required due to its gradual decomposition to alkoxides and H_2. It is sometimes simpler to add a mixture of alcohol and substrate to a dispersion of sodium in an inert solvent such as toluene. HMPA is also occasionally employed as a solvent;[5] solutions of sodium in HMPA behave similarly to those in ammonia.[6] While sodium is insoluble in solvents such as DME or THF, naphthalene is usually included, and a green solution of the ***Sodium Naphthalenide*** radical anion forms.[7] Though the reduction potential of this system is similar to that of sodium in other solvents (a half-wave potential of -2.5 V[8] vs. -2.96 V in HMPA[6b] and -2.59 V in NH_3[1b]), side reactions are often minimized, and reductions are sometimes titrated to color end-point. Other additives such as anthracene and benzophenone result in solutions with decreased, more selective, reducing power, though this has been rarely exploited.[8]

Reduction of Unsaturated Bonds.

The classical reduction of ketones with sodium in alcohol, along with the mechanistically similar reduction in ammonia with added proton donors, still finds use in certain systems where the desired stereochemistry cannot be generated by metal hydrides (see also ***Lithium***).[1d-g] The ammonia system is preferred, minimizing epimerization of ketones and equilibration of product alcohols. NH_4Cl has been recommended as proton donor to suppress hydrogen transfer,[9] though this requires a large excess of sodium;[10] using several equivalents of a primary alcohol also minimizes this side reaction.[11] Alcohols, ethers, amines, carboxylic acids, and isolated internal double bonds are unaffected, but most other functional groups have reduction potentials less negative than aliphatic ketones. Aromatic ketones and α-heteroatom-substituted ketones are generally unsuitable substrates for these reductions.

Reductions are kinetically controlled, though the literature contains several mistaken assumptions on this point; stereochemistry is determined by pyramidalization of the ketyl and subsequent carbanion intermediates, and prediction of the stereochemical result is in

most cases extremely difficult. Study of certain systems does allow a few general remarks to be made. Unhindered cyclohexanones usually give larger equatorial:axial ratios than can be obtained with metal hydrides or by equilibration.[12] Generation of equatorial alcohols from hindered cyclohexanones often requires the use of dissolving metals, while metal hydrides can give exclusively the axial product (eqs 1 and 2).[13] Bicyclo[2.2.1]heptan-2-ones always provide an excess of the *endo*-alcohol (eq 3).[14,15]

(1)

(2)

(3)

Imines are reduced to amines in good yield by sodium in alcohols, probably through a similar mechanism. In the absence of proton donors, reductive dimerization dominates.[16] 1,3-Diimines, which exist as tautomeric enamino imine mixtures, are reduced to diastereomeric mixtures of diamines (eq 4).[17] Allylic imines have been reduced to alkenes.[18] Reduction of oximes by sodium in alcohol is particularly useful,[19] since ***Lithium Aluminum Hydride*** can produce Beckmann rearrangements or aziridines.[20,21] Bicyclo[2.2.1]heptan-2-one and tricyclo[2.2.1.0^{2,6}]heptan-3-one oxime reductions yield predominantly *endo*-amines (eq 5).[21,22]

(4)

The reduction of esters to alcohols with sodium in alcohol (Bouveault-Blanc reduction)[23] has been all but supplanted by the use of metal hydrides. Where an ester must be reduced in the presence of an acid, an improved procedure run in ammonia can be used effectively (eq 6).[24]

Dissolving metal reductions of α,β-unsaturated carbonyl compounds are almost always performed with lithium in ammonia (see ***Lithium***),[1d] though sodium is occasionally used without any particular change in result. Selected examples of enone reduction with sodium in HMPA have been examined;[6b,25] these are most notable for the fact that they tend to produce product mixtures enriched in the less stable epimer, compared to reactions run in ammonia (eq 7).[25a,1e]

The reduction of internal acyclic alkynes to *trans*-alkenes by sodium in ammonia is well known.[1b] Complications in reducing terminal alkynes result from deprotonation by $NaNH_2$, formed in situ. This can be exploited by addition of an equivalent of $NaNH_2$,[26] or overcome by addition of ammonium salts.[27] Medium-ring cyclic alkynes often give mixtures of *cis*- and *trans*-alkenes, resulting from partial isomerization by $NaNH_2$ to allenes,[28] which in turn give *cis*/*trans* mixtures dependent on product stability and the presence or absence of proton donors.[29] Sodium in HMPA/*t*-BuOH has been shown to reduce alkynes;[30] internal monoalkenes, inert under most conditions, give near-equilibrium mixtures of alkanes with this system (eqs 8 and 9).[31] Conjugated dienes are reduced via a *cis*-radical anion,[32] while, with lithium, *trans*-dianions may play a role. Dimerization and regioisomer formation usually preclude the use of sodium, though exceptions exist.[33] A few reports of homoconjugated diene reduction have appeared.[34]

(9)

73:27

Pinacol Coupling Reactions.

In the absence of proton donors, reductions of carbonyl compounds often lead to significant amounts of reductively coupled products, but the intentional pinacol coupling of ketones with sodium in inert solvents is typically a low-yielding, unselective process. Milder conditions utilize lanthanoids and low-valent transition metals, particularly titanium.[35] Sodium is used only in cases where no other functional groups are present.[36] Sodium is often employed in related intramolecular couplings with unsaturated carbon-carbon bonds, forming five- and six-membered rings regio- and (often) stereoselectively.[37] Ketyls cyclize onto allylic systems with *anti* displacement (eqs 10 and 11).[38] Transannular cyclizations have also been demonstrated.[39] Alkynes are cyclized similarly (eq 12),[40] usually with ***Sodium Naphthalenide***.[41] With allenes, the *exo* closure product is obtained (eq 13),[42] though prolonged reaction can scramble the position of the resulting double bond.[43]

(10)

(11)

(12)

(13)

Acyloin Couplings.

Reductions of esters under aprotic conditions, usually refluxing toluene or xylene, result in α-hydroxy ketones, also called acyloins.[2] ***Sodium-Potassium Alloy*** alloy is also used and allows reaction at lower temperatures. Rigorous exclusion of oxygen during reaction and workup is essential. Base-catalyzed side reactions are suppressed by the coaddition of substrate and ***Chlorotrimethylsilane***, so as to trap the enediolate and alkoxide products, though good yields can sometimes be obtained regardless.[2,44] Workup is greatly simplified, and the acyloins can be freed by treatment with aqueous acid or deoxygenated methanol. Couplings can be performed on esters with leaving groups at the β-position (eq 14),[45] resulting in a useful cyclopropanone hemiacetal synthesis (eq 15).[46]

(14)

(15)

Intramolecular acyloin couplings are an enormously successful method for forming four-membered rings.[47] Highly strained products can undergo subsequent thermal ring opening (eq 16); Na/K is sometimes more effective in these cases. Hindered diesters can undergo α,α-bond cleavage prior to reduction.[2] Five- and six-membered rings are routinely generated, often without employing TMSCl. Larger rings, more difficult to form by other methods, are also closed in good yields,[48] including several polycyclic frameworks (eq 17).[49] Rings containing 12, 24, and 42 carbon atoms,[50] paracyclophanes, and rings containing N, O, S, and Si atoms have been formed.[51]

(16)

(17)

Reduction of Saturated Bonds.

Typical Birch reduction conditions dehalogenate aryl, vinyl, bridgehead, and cyclopropyl halides, though side reactions are often

troublesome.[52] Alkyl fluorides are not reduced by sodium under any conditions, requiring a K/crown ether system.[53] Sodium in alcohol/THF is an effective substitute for Birch conditions;[54,55] these conditions can also reduce simple alkyl halides (eq 18).[36b] A simpler procedure employing refluxing ethanol is superior in some cases (eq 19).[56]

(18)

(19)

Alcohols are usually derivatized and reduced with metal hydrides, though other methods have received attention.[57] Among dissolving metal techniques, lithium or potassium in amines are most often used to hydrogenolyze various esters. Sodium in HMPA gives nearly quantitative yields of alkanes from tertiary esters.[58] Sodium in ammonia can cleave alkyl mesylates (eq 20),[59] while phosphate esters or mesylates of phenols are similarly reduced to aromatic hydrocarbons.[60] Like metal hydrides, sodium in ammonia cleaves epoxides to give the more substituted alcohols, with the exception of aryl-substituted epoxides (eq 21).[61] Lithium and second-row metals, particularly calcium, are also effective for epoxide cleavages.

(20)

(21)

Most other aliphatic ethers are inert to dissolving metals, but benzyl ethers (as well as esters, amines, and thioethers) are readily debenzylated by sodium in ammonia. This is a common deprotection method in peptide and carbohydrate chemistry.[62] Substituted trityl ethers have been used to protect hydroxyl groups in nucleotides. The differing reduction potentials for the *p*-methoxytrityl[63] and α-naphthyldiphenylmethyl[64] groups allow for selective deprotection using sodium/aromatic hydrocarbon systems (eqs 22 and 23). Simple phenyl ethers are cleaved by sodium only with great difficulty.

(22)

(23)

While many desulfurizations by alkali metals are known,[65] use of sodium is generally restricted to alkyl aryl thioethers. These are cleaved in the presence of aryl ethers by sodium in HMPA.[66] Phenyl thioethers are more often cleaved in refluxing alcohols (eq 24).[67] By substituting TMSCl for the proton source, alkyl or vinyl silanes can be isolated (eq 25).[68] Sodium in ammonia has been used in a deoxy sugar synthesis where more typical reagents (***Raney Nickel***, ***Nickel Boride***, ***Tri-n-butylstannane***) fail.[69]

(24)

(25)

Sulfones are hydrogenolyzed by sodium in ethanol.[70] This method is again most often used where commonly preferred methods fail (eq 26),[71] and includes a rare application to an α-substituted carboxylic acid (eq 27).[72] Aryl sulfonamides are readily cleaved to amines with sodium naphthalenide and ***Sodium Anthracenide***.[73] Tosylates[74,62] and *N*-tosylsulfoximines[75] are similarly reduced to alcohols and sulfoximines, respectively.

Reductive decyanation is effectively performed with sodium in ammonia.[76] This method complements ***Sodium Borohydride***, which is sometimes ineffective with α-amino nitrile substrates and provides products with inversion of configuration (eq 28).[77] An alternative method employing sodium or preferably potassium in HMPA/*t*-BuOH also smoothly removes nitriles.[78] Isocyanides are reduced to hydrocarbons, providing an effective deamination method (eq 29).[79] Rearrangements are largely avoided but, with acyclic substrates, loss of optical activity results. Finally, one last common application of the sodium/ammonia system is the reductive cleavage of acylated N-N bonds (eq 30).[80]

Reductive Eliminations.

When a leaving group is situated adjacent to a reducible functionality, elimination results. It is generally agreed that at the site of the initially reduced carbon atom, an anion is generated which then displaces the leaving group. Highly strained alkenes have been generated in this way. Usually *vic*-dihalides are the immediate precursor (eq 31),[81] though *vic*-dimesylates have also been used.[82] Alkenes have also been generated from *vic*-dinitriles[83] and more exotic combinations of functional groups.[84] Fragmentations of β-chloro ethers,[85] β,γ-epoxy nitriles,[86] and β-hydroxy nitriles[87] have also been demonstrated, the last undergoing subsequent double bond reduction (eqs 32-34).

(31)

(32)

(33)

(34)

Wurtz Reaction.

The classical intermolecular coupling of halides with sodium, mechanistically related to the eliminations noted above, is of limited use.

Cross couplings lead to mixtures of desired and homocoupled products, while dimerizations are of little synthetic value. Magnesium, lithium, and copper reagents are normally employed here.[88] Intramolecular couplings frequently employ sodium, however. Ring closure to form [2.2]phanes is effective when tetraphenylethylene (TPE) is used catalytically (eq 35).[89] Greatest utility is found in the formation of cyclopropanes (eq 36),[90] and to a lesser extent cyclobutanes (eq 37),[91] where ***Zinc*** is preferred.

(35)

(36)

(37)

Use as a Base.

Sodium reacts slowly with alcohols to give solutions of alkoxides. While sodium alkoxides are far more commonly generated by ***Sodium Hydride***, or obtained commercially, the older method is still occasionally used. The protic Bamford-Stevens reaction uses sodium to generate alkoxides from ***Ethylene Glycol***, present as solvent.[92] Sodium methoxide can be substituted, but the original conditions are usually employed. Regioselectivity can be a problem; while the more substituted regioisomer usually predominates, prediction is difficult.[93] Rearrangements of cationic intermediates also limit its use, though many successful examples of this reaction do exist (eq 38).[94]

(38)

Related Reagents.

Sodium-Alcohol; ***Sodium-Alumina***; ***Sodium-Ammonia***.

Sodium-Alcohol[1]

Na-ROH

(Na)

[7440-23-5] · Na · Sodium-Alcohol · (MW 22.99)

(reducing agent for esters, amides, ketones, oximes, nitriles, sulfonamides, aromatic hydrocarbons, certain alkenes, ethers, and carbon-halogen bonds; moderately strong base)

Physical Data: Na: mp 97.5 °C; bp 880 °C; *d* 0.97 g cm^{-3}. EtOH: mp -117.3 °C; bp 78.5 °C; *d* 0.7893 g cm^{-3}.

Form Supplied in: Na: silvery white, soft metal. EtOH and other alcohols: liquid. *Drying:* absolute ethanol can usually be employed without further drying. Most other common alcohols can be dried by storing over anhydrous calcium sulfate followed by distillation.

Handling, Storage, and Precautions: ***Sodium*** metal is a water-reactive, flammable solid. In case of contact with water, the heat of the reaction is usually sufficient to ignite the product hydrogen. Ethanol and other alcohols likely to be encountered in these reductions are flammable liquids. Use in a fume hood.

Reduction of Esters and Carboxamides.

Though often replaced by the use of more modern hydride reagents, the Bouveault-Blanc reduction has long been known to convert esters to alcohols by refluxing the former reagents with sodium in alcohols.[2] For example, ethyl hydrocinnamate is converted to hydrocinnamyl alcohol in good yields (eq 1).[2] Numerous examples of reductions of mono-[3] and diesters[4] can be found in the literature. The major improvement in the procedure over the years has been the use of stoichiometric amounts of ester, alcohol, and toluene or xylene added to sodium in xylene.[5] Treatment of unsaturated esters with sodium in alcohols reduces conjugated double bonds[2] but not unconjugated alkenes (eq 2).[6] Less common have been reductions of carboxamides to amines by sodium in alcohols. For example, a number of primary, secondary, and tertiary amides have been reduced to their corresponding amines in good yields by sodium in propanol.[7]

(1)

(2)

Reduction of Ketones and Derivatives.

Aliphatic ketones and phenones are readily converted to alcohols by sodium in alcohols,[8] as illustrated by the thermodynamically controlled reduction shown in eq 3, which forms part of a recently described synthesis of taxol and its analogs.[8d]

Reduction by sodium in alcohols of α,β-unsaturated ketones affords saturated alcohols (eq 4),[9] while similar reductions of diaryl ketones give methylene derivatives (eq 5).[10]

Oximes are conveniently converted to amines by sodium in alcohols.[11] For example, the oxime of 2-phenylcyclohexanone is reduced by sodium in ethanol to the corresponding amine in quantitative yield (eq 6).[11b] The use of higher molecular weight alcohols has been reported to afford better yields of products.[11d]

Reduction of Nitriles.

Aliphatic nitriles are also reduced to amines in satisfactory yields by sodium in *n*-butyl alcohol[12a] or ethanol and toluene (eq 7).[12b]

Reduction of Sulfonamides.

Both aliphatic and aromatic sulfonamides are converted to sulfinic acids and amines by sodium in isopentyl alcohol.[13] This reduction has been employed in the preparation of azetidine (eq 8).[13b]

(8)

Reduction of Aromatic Hydrocarbons.

Naphthalene and higher aromatic hydrocarbons, as well as certain amino, ether, and carboxyl derivatives, are reduced to more saturated derivatives by sodium in numerous alcohols.[1a,14] Thus while naphthalene itself is converted by sodium in ethanol and benzene to the 1,4-dihydro derivative,[14b] β-naphthylamine and β-alkoxynaphthalenes are reduced to tetrahydro-β-naphthylamine (eq 9)[14a] and β-tetralone (eq 10),[14c,d] respectively.

(9)

(10)

Interestingly, sodium/isopentyl alcohol reduction of salicylic acid gives pimelic acid (eq 11).[14e] In the case of biphenyl substituted with a carboxyl group on one ring and a methoxy group on the other, the ring bearing the carboxyl group is converted to its hexahydro derivative (eq 12).[14f]

(11)

(12)

Pyridine derivatives are also reduced by sodium in ethanol[15] or in pentyl alcohol.[11b] For example, benzo[*f*]quinoline is converted to the *trans*-amine (eq 13).[11b]

(13)

Reduction of Alkenes.

Perhaps surprisingly, numerous examples of alkenes conjugated with aromatic rings have been converted to alkanes by sodium in alcohols.[1a] For example, cinnamyl alcohol is conveniently reduced by this method (eq 14).[16]

(14)

Cleavage of Ethers.

4-Phenyl-*m*-dioxane has been reduced to 3-phenyl-1-propanol by sodium in isobutyl alcohol.[17] Similar examples include demethoxylations of methyl aryl ethers (eq 15)[18a,b] and debenzylations of benzyl derivatives of certain sugars.[18c]

(15)

Reduction of Carbon-Halogen Bonds.

gem-Dibromides are reduced by sodium in wet methanol to the parent hydrocarbons (eqs 16 and 17).[19] Both vinylic and allylic chlorides, but not methyl ether moieties, are similarly reduced by sodium in *t*-butyl alcohol and THF (eq 18).[20]

Sodium-Alumina

Na/Al_2O_3

(Na)

[7440-23-5] · Na · Sodium-Alumina · (MW 22.99) (Al_2O_3)

[1344-28-1] · Al_2O_3 · Sodium-Alumina · (MW 101.96)

(isomerization of alkenes;[1] isomerization of amines;[2] a form of high surface area sodium metal[3])

Physical Data: sodium: mp 97.8 °C; *d* 0.968 g cm^{-3}. Alumina: *d* 3.97 g cm^{-3}.

Preparative Method: basic ***Alumina*** is dried at 150-200 °C and vigorously stirred with ***Sodium*** metal under an inert atmosphere until cool. The 2-10% sodium on alumina mixtures (as typically used for alkene isomerization) are free flowing, nonpyrophoric solids ranging from bright to dark gray; the color intensity markedly increases with increasing metal content.[1,4-6]

Handling, Storage, and Precautions: sodium metal reacts violently with water to produce flammable H_2 gas. High sodium-containing Na/Al_2O_3 catalysts may be pyrophoric. In case of fire, do not expose to water, CO_2, or vaporizable liquids. The activity of the catalyst is lost upon exposure to air or moisture.

Alkene Isomerization.

Isomerization of alkenes may be accomplished under mild conditions. Thus methylenecyclobutane is converted to methylcyclobutene in nearly quantitative yield, avoiding the formation of isoprene, common with higher temperature routes (eq 1).[4] Both 1-butene and 1-pentene have been isomerized to the internal alkene with this catalyst.[5,7] The system operates under kinetic control, favoring the initial formation of the *cis*-isomer over the *trans*-isomer (eq 2). When cyclic dialkenes are treated with Na/Al_2O_3, dehydrogenation can follow the reversible C=C bond shift (eq 3).[1] More forcing conditions can cause skeletal rearrangement (eq 4).[1]

(1)

(2)

Miscellaneous Uses.

This catalyst has also been used to racemize optically active benzyl amines.[2] Na/Al_2O_3 has also been used as a sodium metal source in the large scale preparation of sodium cyclopentadienide.[3] Recently, this method has been abandoned for the use of oil-free ***Sodium Hydride***, avoiding the need to filter Al_2O_3 from the product.[8]

Sodium Aluminum Hydride

$NaAlH_4$

[13770-96-2] · AlH_4Na · Sodium Aluminum Hydride · (MW 54.01)

(reducing agent similar in activity to $LiAlH_4$;[1] deoxygenative dimerization of carbonyls and alcohols;[11a] hydroalumination of alkenes and alkynes[11b])

Physical Data: mp 180-183 °C (dec with evolution of H_2); *d* 1.28 g cm^{-3}.

Solubility: sol THF, DME, diglyme; insol ether, hydrocarbons.

Form Supplied in: white crystalline solid.

Analysis of Reagent Purity: iodometric titration;[10b] H content determined by gas evolution analysis; Al content determined by EDTA-$Zn(OAc)_2$ back titration at pH 4 using dithizone as an indicator.[9a]

Purification: recrystallization from a THF-benzene solvent mixture by addition of benzene, followed by partial removal of the solvent under vacuum. The white solid is collected and dried under vacuum before dissolving in freshly distilled THF.

Handling, Storage, and Precautions: severe fire and explosion hazard in contact with oxidizing agents and water, forms caustic and irritant compounds; stable in dry air at room temperature. Solutions in THF or diglyme appear to be stable for at least several months if not exposed to air. To preserve reactivity it is best to store wet with toluene than to store dry. Use in a fume hood.

Functional Group Reductions.

This reagent reduces aldehydes, ketones, carboxylic acids, esters, and acid chlorides to give alcohols. Amides, nitriles, and aliphatic nitro compounds give amines. Aromatic nitro compounds yield azo compounds. Yields are usually within 10% of those reported for ***Lithium Aluminum Hydride***.[1] $NaAlH_4$ is about 10-11 times less reactive than $LiAlH_4$ in the reduction of ketones.[2] Heterogenous reductions of esters in diethyl ether, benzene, toluene, or heptane give good yields of the alcohols.[1a,3] Hydrogenolysis of alkyl halides occurs at a rate considerably slower than with $LiAlH_4$.[1,4a,b] Aromatic iodides and bromides are readily reduced in THF but diglyme is a better solvent for chlorides.[4c] Ethers and double and triple bonds are normally stable to this reagent. Under controlled conditions, the reaction with esters, dialkylamides, and aromatic nitriles can provide aldehydes in good yields.[5] Aliphatic nitriles proceed mainly to the amines with only 15-25% yield of the aldehydes. Best yields are obtained by inverse addition of the hydride at low temperatures. Certain lactones can be partially reduced.[6a] Phthalic anhydrides are sluggishly converted to the lactones and substituent effects on regioselectivity have been studied.[6b] Quaternary pyridinium iodides are reduced to piperidines.[7] Reduction of *N*-cyclopropylimines gives the cyclopropylamines as well as the *n*-propylamines resulting from ring cleavage.[8]

Stereoselective Reductions.

$NaAlH_4$ gives a slightly smaller extent of axial addition to 4-*t*-butylcyclohexanone than is observed for $LiAlH_4$ (88% and 92%, respectively).[9] The stereochemical features of a number of ketone reductions by this reagent have been examined.[9,10] Greater degrees of stereoselectivity are generally found with $LiAlH_4$. In the case of cyclic α-amino ketones, larger amounts of *trans*-isomers are produced compared to $LiAlH_4$ (eq 1).[10d-f]

Deoxygenative Dimerization Reactions.

In the presence of $NaAlH_4/NbCl_5$, aromatic carbonyl compounds undergo deoxygenative dimerization to yield alkenes (56-99%).[11a] Purely aliphatic carbonyls give trace to low yields of alkenes. Allylic and benzylic alcohols form symmetrical coupling products (eq 2). Allylic rearrangements occur in some cases. Under these conditions, epoxides can be deoxygenated to give the corresponding alkenes.

Hydrometalation.

Internal alkynes are converted to (*Z*)-alkenes with high stereoselectivities (>20:1) using the $NaAlH_4/NbCl_5$ system.[11a] Terminal alkenes and internal alkynes are reduced rapidly and in high yield by $NaAlH_4$ in the presence of a catalytic amount of ***Dichlorobis(cyclopentadienyl)titanium***.[11b] The reduction of 2-alkyn-1-ols by $NaAlH_4$ via a cyclic alanate provides β- or γ-substituted allyl alcohols, depending on the solvent and the electronic character of the substituent.[12]

Sodium Amalgam

Na(Hg)

[11110-52-4] · Na · Sodium Amalgam · (MW 22.99)

(used in the preparation of alkenes and alkynes; to reductively cleave C-S and N-O bonds; for the reductive cleavage of quaternary phosphonium and arsonium salts; selective dehalogenation of aryl halides; also for the reduction of a variety of other functional groups)

Physical Data: the consistency and mp vary with the sodium content; 1.2% sodium is a semisolid at room temperature and melts completely at 50 °C; 5.4% sodium melts above 360 °C.

Solubility: sodium amalgams are decomposed by water but more slowly than sodium.

Form Supplied in: crushed solid; limited commercial availability.

Analysis of Reagent Purity: the amalgam can be analyzed for sodium by titration with 0.1 N sulfuric or hydrochloric acid.

Preparative Methods: several procedures for the preparation of sodium amalgam have been reported.[1-4] Amalgams containing 2-6% sodium are the most commonly employed for synthetic work. The safest and most convenient procedure for the preparation of 2% sodium amalgam is the addition of ***Mercury(0)*** to ribbons of ***Sodium*** metal.[5,6] No external heating is required with this protocol. The resulting solid can be crushed and stored indefinitely in a tightly stoppered container.

Handling, Storage, and Precautions: moisture sensitive; keep tightly closed.

Alkyne Synthesis.

Reductive cleavage of the triflate salts of vinyl phosphonium triflates with 2% sodium amalgam affords pure alkynes in good to excellent yield (eqs 1 and 2).[7] This represents a significant improvement in yield and purity over the method involving thermal cleavage of acyl ylides. The highest yields are obtained when one group is aryl (eq 2). Alkynes are also obtained in respectable yields by the reductive elimination of enol phosphates of β-oxo sulfones with the reagent (6%) in DMSO-THF (eq 3).[8]

(3)

Longer reaction times are required for nonconjugated enol phosphates. Aromatic *cis*- and *trans*-enediol diesters are reported to give the corresponding diaryl alkynes in modest yield by reductive elimination with the reagent (eq 4).[9] This procedure has been modified to provide for a one-pot operation in which 4 equiv of an aromatic acyl chloride is treated with an excess of the reagent in ether.[9]

(4)

Alkene Synthesis.

The preparation of *trans*-alkenes from the reaction of β-alkoxy or acyloxy sulfones with sodium amalgam has been reported (eq 5).[10] Trisubstituted and tetrasubstituted precursors generally give disappointing results. Stereoselective introduction of the double bond in a total synthesis of diumycinol was accomplished with this method (eq 6).[11] This protocol is effective when other standard conditions fail.

(5)

(6)

Desulfurization.[12-17]

This reaction has perhaps found the widest use of the reagent. The value of sulfides, sulfoxides, and sulfones in organic synthesis is increased by the ease with which their removal is accomplished. For example, sulfones are conveniently hydrogenolyzed with 6% reagent in boiling ethanol (eq 7).[12] The use of disodium hydrogen phosphate is recommended as a buffer with the reagent in some applications with allylic sulfones and β-keto sulfides (eqs 8 and 9).[15]

(7)

(8)

(9)

Desulfonylation of unsaturated α,β-unsaturated acetals with the reagent in buffered methanolic medium gives the reduced products as a mixture of isomers (eq 10).[17] Hydrolysis of the mixture affords the desired α,β-unsaturated ketone as the major product. β-Hydroxynitriles have been prepared in good yield and with retention of stereochemistry by the action of the 2% reagent in wet THF on sulfonylisoxazolines (eqs 11 and 12).[18] The addition of aqueous phosphate buffer is sometimes required to prevent further hydrogenolysis (eq 12).

(10)

(11)

(12)

Enantiomerically pure 4,5-dihydroisoxazoles are available by selective desulfurization of 3-*p*-tolylsulfinylmethyl-4,5-dihydroisoxazoles with the reagent in a buffered medium (eq 13).[19] Further treatment of the products with ***Raney Nickel*** affords the corresponding amino alcohols. Selective desulfurization of methyl 3,4,6-tri-*O*-benzyl-2-*O*-(methylsulfonyl)-α-D-mannopyranoside derivatives was accomplished with 6-7% reagent in 2-propanol and ether (eq 14).[20] Treatment with ***Nickel*** in ethanol, ***Sodium Naphthalenide*** in THF, or ***Sodium-Ammonia*** resulted in removal of the benzyl groups as well.

(13)

(14)

N-O Bond Hydrogenolysis.

Reductive cleavage of N-O bonds is easily accomplished with the reagent (eqs 15 and 16). Keck reported the facile hydrogenolysis of the intramolecular Diels-Alder acyl-nitroso cycloadduct with excess reagent in a buffered alcoholic medium to yield a hydroxy lactam (eq 15).[21] Similarly, Jager subjected dihydroisoxazoles to hydrogenolysis with 6% sodium amalgam to afford the corresponding 1,3-amino alcohols (eq 16).[22] The *syn* and *anti* stereoselectivity is reported to be lower with this reagent than with ***Lithium Aluminum Hydride***. This method of N-O bond reduction is less common than those using either ***Aluminum Amalgam*** or LAH.

(15)

Reductive Cleavage of Quaternary Phosphonium and Arsonium Salts.

Reductive cleavage of achiral and optically active quaternary and phosphonium salts with the reagent affords tertiary phosphines and arsines in high yields and with retention of configuration (eq 17).[23]

Selective reductive cleavage of the *t*-butyl group occurs in substrates containing both the *t*-butyl and benzyl substituents. The present method is reported to be superior to the conventional cathodic cleavage. Emde degradation of the quaternary ammonium chloride succeeds where the Hofmann method is unsuccessful (eq 18).[24] In a similar fashion, hemimellitene was prepared by treating an aqueous suspension of the benzyltrimethylammonium iodide with a large excess of the reagent (eq 19).[3]

Dehalogenation of Aryl Halides.

Selective dehalogenation of aryl halides with the reagent in liquid ammonia has been found (eqs 20 and 21).[25]

(21)

Reduction of Miscellaneous Functional Groups.

Many additional functional groups react readily with the reagent to afford, in generally good yields, the corresponding reduced products. For example, phthalic acid reacts with the 3% reagent to yield *trans*-1,2-dihydrophthalic acid in good yield (eq 22).[4] α,β-Unsaturated carboxylic acids are also readily reduced by the reagent. Thus cinnamic acid is reduced to hydrocinnamic acid with 2.5% reagent in aqueous base (eq 23).[4]

(22)

(23)

The product from the condensation of vanillin and creatinine is reduced by 3% reagent in water (eq 24).[26] Xanthone was reduced to xanthydrol with the reagent in ethanol (eq 25).[1] Triphenylchloromethane is converted to triphenylmethylsodium by action of the 1% reagent (eq 26).[2] Oximes are reduced to primary amines with the 2.5% reagent with acetic acid in ethanol (eq 27).[27] One of the oldest applications of sodium amalgam involves the reduction of aldonolactones to aldoses (eq 28).[28]

(24)

(25)

(26)

(27)

(28)

Other Applications.

Several recent useful miscellaneous applications have been reported. They include the use of the 3% reagent for the reduction of 1-ethyl-4-methoxycarbonylpyridinium iodide in acetonitrile to produce a stable radical (eq 29);[29] the use of the reagent as a catalyst to initiate aromatic radical nucleophilic substitution reactions;[30] and the use of the reagent for the preparation of novel titanium catalysts for the stereoselective cyclization of diynes to (*E*,*E*)-exocyclic dienes.[31]

Sodium Amide

$NaNH_2$

[7782-92-5] · H_2NNa · Sodium Amide · (MW 39.02)

(strong base;[3] strong nucleophile[3b])

Alternate Name: sodamide.

Physical Data: mp 210 °C; bp 400 °C/760 mmHg.

Solubility: sol liq ammonia (~1 mol L^{-1} at -33 °C).[1]

Form Supplied in: commercially available as a powder; easily prepared in the laboratory.

Preparative Methods: combination of ***Ammonia***, small quantities of an iron(III) salt, and ***Sodium*** leads to formation of a black catalyst, whereupon the remainder of the sodium is added. Published procedures differ in details.[2]

Handling, Storage, and Precautions: flammable; corrosive; when opened to air, decomposes and forms a potentially explosive yellow byproduct.[1]

Reaction as a Base.

Sodamide often serves as a base to generate reactive anions.[3] In DMSO in the presence of various bases, including sodamide, carbohydrates are benzylated in good yield with ***Benzyl Chloride***.[3a] Reaction of (**1**) and (**2**) in the presence[3b] of sodamide gives (**3**) (eq 1). Sodamide is effective in generating the acetonitrile anion for reaction with sulfines.[4] Deprotonation of phenylacetic esters in the presence of sodamide allows aldol reaction with benzaldehyde derivatives to afford 2,3-diaryl-3-hydroxypropionic acids.[5] Similarly, reaction of acetophenone and ethyl chloroacetate (eq 2) gives the Darzens' product (**4**).[6] Treatment of primary anilines and cyanopyridines with sodamide leads to good yields of carboxamidines.[7] Oxygenation of hindered 4-alkylphenols in the presence of sodamide provides a convenient source of quinols.[8]

(1)

(2)

Sodamide in THF with boric acid neutralization has proven effective for the deconjugation of conjugated unsaturated steroids.[9] The

presence of sodamide in liquid ammonia at low temperature facilitates interconversion of 1,4- and 1,3-cyclohexadienes.[10] Deprotonation of 2-bromothiophenes and 2-halothianaphthalenes affords the 3-halo isomers via a series of complex equilibria.[11] Cyclopropenes, which possess an acidity comparable to alkynes, are rapidly metalated by sodamide (and other alkali amides) to produce reactive intermediates for alkylation.[12] Selective deprotonation occurs with a wide variety of acidic methyl, methylene, and methine hydrogens adjacent to carbonyls or attached to heterocycles. For example, 2,4-lutidine (**5**) undergoes deprotonation (eq 3) to (**6**) followed by reaction with ethyl benzoate to yield (**7**).[13a] Deprotonation followed by reaction with electrophiles is a powerful method for generating complex carbon skeletons.[13] Examination of the role of bases, including sodamide, on the stereochemistry (including isomerization) of products formed in the Michael reaction has been reported.[14] In the racemization of the single stereogenic center in nicotine, sodamide was inferior to ***Potassium t-Butoxide***.[15]

Dianion Generation.

Numerous early investigations into dianion chemistry[16] employed sodamide as the base. Conversion of the simple heterocycle (**8**) into the corresponding dianion with sodamide in liquid ammonia followed by reaction with benzonitrile (eq 4) led to an interesting rearrangement product (**9**).[17] β-Dicarbonyl dianions are routinely prepared by reaction with sodamide. These strongly nucleophilic species undergo regioselective alkylation (eq 5) by reaction of disodioacetylacetone (**10**) (much more soluble in liquid ammonia than its dipotassium counterpart[16a]) with 11-bromoundecanoic acid to give (**11**)[18] and reaction of (**10**) (eq 6) with diphenyliodonium chloride to yield (**12**).[19]

Elimination Reactions.

Sodamide's utility as a reagent for elimination reactions is illustrated by the following selected examples. Methiodide (**13**) undergoes facile loss of HI and diethylmethylamine to generate methyl vinyl ketone.[20] Five isomeric alkenes and a cyclopropane result from treatment of 2-benzyl-3-phenylpropyltrimethylammonium iodide with sodamide.[21] Upon reaction with sodamide, various thioamides eliminate hydrogen sulfide to form ynamines in fair yield.[22] In the presence of sodamide, *cis*-1,4-dichloro-2-butene (**14**) yields mainly *trans*-1-chloro-1,3-butadiene (**15**) (eq 7) while *trans*-1,4-dichloro-2-butene gives a preponderence of *cis*-1-chloro-1,3-butadiene (**16**) (eq 8).[23] Upon warming a mixture of methallyl chloride (**17**) and sodamide (eq 9), there is formed methylenecyclopropane (**18**) and 1-methylcyclopropene (**19**).[24] Sodamide, ***Sodium Hydride***, and ***Sodium Methoxide*** all have utility in the Bamford-Stevens reaction for the conversion of tosylhydrazones into alkenes.[25]

(13)

(7)

(14) **(15)**

(8)

(16)

(9)

(17) **(18)** **(19)**

Preparation of Alkynes.

Sodamide-mediated elimination of one or two moles of HX from a suitable substrate is a classical method for the synthesis of alkynes. For example, β-bromostyrene with sodamide in liquid ammonia provides an excellent source of phenylacetylene.[26] Cyclohexylpropyne (**21**) can be generated by reaction (eq 10) of vinyl bromide (**20**) with 3 equiv (excess) of sodamide.[27] Oleic acid (**22**) can be transformed into stearolic acid (**23**) by a straightforward sequence (eq 11) involving bromination followed by reaction with excess sodamide.[28] Similar methodology has been employed to synthesize many other alkynes.[29] Dehydrohalogenation with concomitant ether cleavage provides an efficient route to complex alkynes. For example, reaction of (**24**) with sodamide (eq 12) provides the hydroxylic terminal pentyne (**25**).[29j] Alkyne-allene isomerization has been accomplished with sodamide.[30]

(20) (21) (10)

(22) (23) (11)

(24) (25) (12)

Aryne Chemistry.

Among the many existing methods for the generation of arynes,[31] reaction of a halobenzene derivative with sodamide (as in the example (eq 13) of (**26**) going to (**27**)[32a]) is a commonly employed procedure.[32] The highly reactive intermediate arynes can be made to undergo reaction with nucleophiles other than amide anion. Thus bromobenzene (**28**) is converted (eq 14) into aryl sulfide (**29**).[33a] Sodamide-generated arynes have also been reacted with more complex species,[34] as illustrated by the transformation (eq 15) of (**30**) into (**31**) followed by cyclization to (**32**).[34a] Intramolecular benzyne reactions involving sodamide have been used successfully in the synthesis of aporphine alkaloids.[35]

(26) (27) (13)

(28) (29) (14)

(30) (31) (32) (15)

Generation of Ylides.

Sodamide is a common base for the generation of ylides in the Wittig reaction.[36] The commercially available instant ylide consists[37a] of a 1:1 stoichiometric mixture of ***Methyltriphenylphosphonium Bromide*** and sodium amide (eq 16).[37b]

(16)

Reaction as a Nucleophile.

Nucleophilic addition reactions are a major feature of sodamide chemistry. Addition followed by intramolecular attack provides a convenient methodology for the construction of unusual adducts.[38] Sodamide, sodamide/potassamide mixtures, and other alkali metal amides have been found to catalyze the amination of alkenes.[39] The Chichibabin reaction and its variants[40] provide a useful route to numerous substituted heterocycles. The addition-elimination reaction of sodamide on a heterocyclic substrate is nicely illustrated by the transformation (eq 17) of (**33**) into 6-methylisocytosine (**34**).[41] Nucleophilic addition reactions to nitro-substituted aromatic substrates have been observed.[42] Also intriguing are the various reaction pathways observed for heterocycles containing an appended trifluoromethyl group.[43] Photochemically assisted additions of sodamide have been reported (eq 18).[44] Sodamide is also an effective reagent for accomplishing *N*-dealkylations (eq 19)[45a] and *N*-deacylations.[45b]

(19)

Cleavage and Rearrangement.

Sodamide is involved in many cleavage and rearrangement reactions. Cleavage reactions,[46] with specific reference to the Haller-Bauer reaction,[47] exemplified by (**35**) going to (**36**) (eq 20),[47d] are a convenient synthetic transform. It is significant that the addition of ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO) permits the Haller-Bauer reaction to be performed with commercial sodamide.[47d] Rearrangement reactions involving sodamide are well-known,[48] with several being common name reactions such as the Truce-Stiles,[49] the Sommelet-Hauser,[50a] and the Stevens[50a] reactions. A typical Sommelet-Hauser rearrangement is illustrated by (**37**) going to (**38**) (eq 21).[50b] Vinylpyridines undergo polymerization in sodamide/liquid ammonia.[51]

(35) (36)

(20)

(37) (38)

(21)

In recent years, sodamide has been combined with other bases (especially with alkali metal *t*-butoxides) to create a whole family of so-called complex bases with exceptional properties (see ***Sodium Amide-Sodium t-Butoxide***).[52] Typical applications of these bases are in the *syn* elimination depicted[52d] by (**39**) going to (**40**) and (**41**) (eq 22) and the carbanion alkylation involving the conversion of (**42**) to (**43**) (eq 23).[52f]

Sodium Amide-Sodium *t*-Butoxide[1]

$NaNH_2$-RONa

($NaNH_2$)

[7782-92-5] · H_2NNa · Sodium Amide-Sodium *t*-Butoxide · (MW 39.02) (R = *t*-Bu)

[865-48-5] · C_4H_9NaO · Sodium Amide-Sodium *t*-Butoxide · (MW 96.12) (R = $Et(OCH_2CH_2)_2$)

[52382-21-5] · $C_6H_{13}NaO_3$ · Sodium Amide-Sodium Ethoxyethoxyethoxide · (MW 156.18)

(strong bases, very efficient for *syn* eliminations of organic halides, useful in aromatic, heteroaromatic, and cycloalkenyl elimination-addition reactions; initiate anionic polymerizations)

Physical Data: sodium amide complex bases have not been characterized structurally. They are generated in situ, or commercial preparations are used as received. They are white or light yellow suspensions in the reaction solvent.

Solubility: poorly sol THF or DME.

Preparative Methods: complex bases $NaNH_2$-RONa (2:1) are conveniently prepared by the reaction of an alcohol (ROH, 1 equiv) with $NaNH_2$ (3 equiv) in ethereal solvents (THF, DME, etc.) or in hydrocarbons; *t*-BuOH and $Et(OCH_2CH_2)_2OH$ are distilled from sodium. Complex bases (2:1) contain 2 equiv $NaNH_2$ and 1 equiv RONa (activating agent).

Form Supplied in: suspensions in THF: NABUT (~0.8 mol L^{-1}, *d* 0.915-0.920 g mL^{-1}); NAMEDEG (~0.7 mol L^{-1}, *d* 0.928-0.933 g mL^{-1}).

Handling, Storage, and Precautions: complex bases must be handled and stored under inert atmosphere (N_2 or Ar). Hydrolysis is performed by slow addition of cold water.

Proton Abstractions.

Complex bases $NaNH_2$-RONa (2:1) abstract protons from very weak organic acids. Condensation of the resulting carbanions with electrophiles takes place in excellent yields, as exemplified in eq 1.[2]

(1)

Complex bases strongly favor monoalkylation of activated methylenes, a property used to perform monoalkylation of carboxylic acid derivatives on an industrial scale.[3]

$NaNH_2$-*t*-BuONa or $NaNH_2$-$Et(OCH_2CH_2)_2ONa$ (the strongest of the sodium amide-containing complex bases) may conveniently replace

organolithium reagents or lithium amides in the synthesis of diazaphospholanes[4] as well as in the thiomethylation of ketones (eq 2).[5]

(2)

Elimination Reactions.

Complex bases are efficient in usual elimination reactions and they conveniently replace more expensive and/or less accessible bases. Thus $NaNH_2$-*t*-BuONa may be used instead of ***Potassium Amide*** in the preparation of methylenecyclopropane (eq 3).[2b]

(3)

The complex base $NaNH_2$-*t*-BuONa (2:1) promotes *syn* eliminations under mild conditions (eq 4).[6]

(4)

The poorer leaving group is preferentially eliminated in reactions of *trans*-dihalocyclohexanes with $NaNH_2$-*t*-BuONa (1:1).[7] Advantage may be gained from the strong propensity of $NaNH_2$-*t*-BuONa (2:1) to effect *syn* eliminations in the synthesis of linear[8] and cyclic alkynes.[9]

Elimination-Addition Reactions.

Nucleophilic arynic substitutions may be performed in etheral solvents such as THF or DME due to the facile generation of arynes from aryl halides and $NaNH_2$-*t*-BuONa or $NaNH_2$-Et$(OCH_2CH_2)_2$ONa. Such reactions are more convenient than condensations usually performed in liquid NH_3 and the scope of applications is more extended.

Thus amines and sodium thiolates are condensed with aryl halides (including fluorides) under mild conditions and in very good yields, as exemplified in eq 5.[10]

(5)

Such reactions may be also performed with polyhalogenobenzenes[11] and used in the synthesis of nitrogen containing heterocycles (eq 6).[11d]

(6)

Use of the complex base $NaNH_2$-$Et(OCH_2CH_2)_2ONa$ provides a good solution to the difficult monoarylation of nitriles (eq 7).[12]

(7)

Arynic condensations of ketone enolates which cannot be performed in the presence of sodium amide alone, are easily performed with $NaNH_2$-*t*-BuONa. Thus 1,2-diketone monoacetals are condensed with bromobenzene to give benzocyclobutenol derivatives in good yields (eq 8).[5b,13]

(8)

In the same way, one-step syntheses of naphthalenes, tetralones, indanones, and dihydronaphthocyclobutenols are easily performed via arynic condensation of α,β-unsaturated ketone enolates with aryl halides in the presence of $NaNH_2$-*t*-BuONa.[14]

$NaNH_2$-*t*-BuONa is also an efficient reagent for generating cyclopropabenzynes (eq 9),[15] while classical conditions in liquid NH_3 are unsuccessful.

(9)

$NaNH_2$-*t*-BuONa easily generates pyrid-3-yne, allowing hetarynic condensations with nucleophiles.[16]

Finally, strained cycloalkynes and cycloalka-1,2-dienes are generated under mild conditions from the corresponding 1-halocycloalkenes and $NaNH_2$-*t*-BuONa and condensed with nucleophiles (eq 10).[17]

(10)

Such reactions have found a large number of extensions and applications.[1b,d,18]

Anionic Polymerizations.

The complex bases $NaNH_2$-*t*-BuONa and $NaNH_2$-Et$(OCH_2CH_2)_2$ONa are very efficient in initiating anionic polymerizations of acrylic and methacrylic derivatives as well as styrene and vinylpyridine.[1c] These reactions can be performed in solution or in the absence of solvent.

Sodium-Ammonia[1]

Na-NH_3

(Na)

[7440-23-5] · Na · Sodium-Ammonia · (MW 22.99) (NH_3)

[7664-41-7] · H_3N · Sodium-Ammonia · (MW 17.04)

(strong reducing agent; reduces polyunsaturated hydrocarbons, carbonyl compounds, and other electron acceptors by electron transfer; strongly basic medium)

Physical Data: sodium: mp 97.8 °C; *d* 0.968 g cm^{-3}. Ammonia: mp -77.7 °C; bp -33.4 °C.

Solubility: sodium is soluble to the extent of 25 g in 100 g ammonia at -33 °C.

Form Supplied in: sodium: flammable, metallic solid. Ammonia: compressed gas.

Purification: sodium: by melting and removal of oxide shell.[2] Ammonia: by distillation from alkali metal solutions or passage through a drying tube containing barium oxide.[1o]

Handling, Storage, and Precautions: ***Sodium*** reacts violently with water (frequently explosively) and many other protic or halogenated solvents. While it is best handled under an inert atmosphere, it is usually stored under oil and common practice is to rinse the metal with hydrocarbon solvent and weigh it in air. ***Ammonia*** is a corrosive gas with a pungent odor, and must be handled in a good fume hood.

Sodium-Ammonia Solutions.

Sodium dissolves in liquid, anhydrous ammonia to form a deep-blue solution.[3] At high concentrations, the solution separates into two liquid phases: the more dilute lower phase retains the deep-blue color while the upper phase has a metallic bronze appearance. Sodium reacts slowly with ammonia to produce sodium amide and hydrogen (eq 1), and this reaction is catalyzed by metals such as iron, cobalt, and nickel. The addition of trace amounts of iron salts to sodium-ammonia solutions is a convenient method for the preparation of ***Sodium Amide***. Sodium-ammonia solution serves as an excellent reducing agent, with a half-wave potential of -2.59 V at -50 °C.[1f]

$$Na + NH_3 \longrightarrow NaNH_2 + 1/2\ H_2 \qquad (1)$$

Birch Reduction of Aromatic Rings.

A major use of the sodium-ammonia reagent is the Birch reduction of aromatic rings to cyclohexadienes or sometimes higher levels of unsaturation.[1,4,5] With benzene and less reactive aromatics (electron donor substituents), a proton donor is necessary and alcohols such as ethanol and *t*-butyl alcohol are commonly used. With more reactive aromatics (electron-withdrawing substituents and polynuclear aromatics), alcohols are generally unnecessary and are often deleterious.[1n] The kinetically controlled regiochemistry[6] affords 1,4-dihydroaromatics (1,4-cyclohexadienes), with preference for the regioisomer with the maximum number of alkyl and/or alkoxy groups located on the remaining double bonds (i.e. the Birch rule).[1h,7] Due to the limited solubility of many aromatic compounds in ammonia, cosolvents are often included in amounts of 25-35% relative to the volume of ammonia. While the most common cosolvents are ethers, such as diethyl ether and THF, protic solvents are sometimes used as both cosolvent and proton source. The range of metal concentrations is usually 0.1-0.5 g metal per 100 mL of ammonia, and highly concentrated solutions producing so-called metallic or bronze phases are generally avoided for Birch reductions.

Benzenes containing alkyl or ether substituents, especially where these substituents may be attached to vinyl positions in the product, are reduced in high yields by sodium-ammonia solution in the presence of ethanol or *t*-butyl alcohol (eq 2).[8] The reduced ethers are useful in synthesis since subsequent acid hydrolysis leads to either nonconjugated or conjugated ketones; alternatively, products may be used directly in Diels-Alder reactions without hydrolysis (eq 3).[9]

(2)

(3)

In cases where this substitution pattern does not apply, however, reduction may be more difficult. For example, while 6-methoxytetralin is reduced smoothly by sodium-ammonia (eq 4), 5-methoxytetralin requires the use of ***Lithium*** with the alcohol added last (eq 5).[5a,10,11] This latter procedure is known as the Wilds and Nelson modification,[11] and is useful for less reactive substrates.

(4)

(5)

In polynuclear aromatics, regiochemistry generally follows protonation at the positions bearing the highest coefficients in the HOMO of the anionic intermediates, with sometimes little influence from substituents.[1g,m] Both anthracene (eq 6) and naphthalene (see below) are reduced in nearly quantitative yields by sodium-ammonia solution, provided that highly acidic quenching agents such as water or ammonium chloride are used rather than alcohols. However, some reductions of polynuclear aromatics are hard to control even under these conditions, and iron salts have been used to keep the reaction to a single stage. Such is the case with chrysene (eq 7) and phenanthrene.[1o]

(6)

Sodium vs. Lithium.

While sodium and lithium are the most commonly employed metals in Birch reduction (and ***Potassium*** to a lesser extent), the choice between these two metals is not always obvious due to the relative lack of comparison data. Although lithium is the most reactive due to its greater heat of solvation of the cation, its reactivity relative to sodium has probably been overestimated. Early experiments with sodium-ammonia solutions containing impurities in either the metal or ammonia probably showed diminished reactivity due to the greater sensitivity of sodium to amide formation catalyzed by trace contaminants.[1f] Thus metal selection may be based on expense, reactivity, or demonstrated superiority with a particular substrate. With very small scale reactions, the higher atomic weight of sodium may make it more practical due to accuracy in weighing. Lithium is the metal of choice when greater reactivity is required, but greater reactivity can sometimes lead to overreduction, whereupon sodium becomes the reagent of choice.

In many cases (eq 8)[12,13] the results are comparable with either metal. However, a comparison of the two metals in the reduction of naphthalene[14] shows best results with sodium at low temperatures (eq 9). At higher temperatures, and especially with lithium, protonation of the intermediates and subsequent isomerization of the 1,4-dihydro product to the 1,2-dihydro isomer leads to appreciable overreduction. The reductive methylation of naphthalene shows even greater differences between the metals, with lithium affording monoalkylation (95%) and sodium dialkylation (93%).[14,15] This is due to a second alkylation via proton abstraction by amide ion during the alkylation step, a process that does not occur with lithium due to the relative lack of solubility of lithium amide in ammonia as compared to sodium amide. Similar results are observed for biphenyl, where lithium provides 99% monomethylation and sodium leads to 40% dimethylation with 10% trimethylation.[16]

$M = Li, R^1 = CH_2CHMeOH, R^2 = R^3 = H, 89\%$
$M = Na, R^1 = Me, R^2 = OH, R^3 = Et, 87\%$

M = Li, -33 °C	40%	55%
M = Li, -78 °C	81%	14%
M = Na, -33 °C	83%	17%
M = Na, -78 °C	96%	2%

Regioselectivity and Stereoselectivity.

The regiochemistry of Birch reduction is generally driven by electron densities in the radical anions, dianions, and monoanions that serve as intermediates in the reaction. An attempt has been made to control regiochemistry by use of trimethylsilyl substituents.[17] For example, while 1-methylnaphthalene reduces exclusively in the unsubstituted ring, 1-methyl-4-trimethylsilylnaphthalene reduces in the silylated ring, and subsequent removal of the silyl group affords a misoriented Birch product (eq 10).

Excellent diastereoselectivities have been accomplished in the reductive methylation of benzoic acids where L-proline has been introduced as a chiral auxiliary (eq 11).[18] Results with a variety of derivatives appear to give comparable results with sodium, lithium, or potassium.

(11)

Reduction of Carbonyl Functions.

The sodium-ammonia reduction of cyclic aliphatic ketones has some utility for the preparation of the more stable epimeric alcohols (such as 11α-hydroxy steroids) derived from sterically hindered ketones.[11,m] In other cases, product mixtures resemble those obtained with reagents such as borohydride. Similarly, esters may be reduced (Bouveault-Blanc reduction), but there is little advantage except with monoesters of diacids where the acid carbonyl remains unreduced (eq 12).[19] Carboxamides are reduced by sodium-ammonia, often affording rather good results, as illustrated with the L-asparagine derivative (eq 13).

(12)

(13)

The most common use of sodium-ammonia reagent for the reduction of carbonyl compounds is the reduction of α,β-unsaturated ketones, and an extensive list of examples has been provided by Caine.[1k] Of special interest are bicycloalkenones, where the α,β-double bond is exocyclic to the second ring (eq 14).[20] In these cases, stereochemistry is dictated by the protonation at the β-position, and the most favored transition states are those involving protonation of an axial anionic center; this most often results in the formation of *trans* products, although the stereochemistry can be reversed by 6β- and 7α-substituents. α,β-Unsaturated acids and esters can also be reduced, and reductive alkylation can be achieved by adding alkylating agents before the protic quench. However, Li and K have more often been used for the latter process.

(14)

Reductive Cleavage.

The sodium-ammonia reagent is effective in cleaving a variety of bonds including carbon-carbon (especially when strained), carbon-sulfur, carbon-nitrogen (especially positively charged nitrogen), and carbon-halogen; also allylic and benzylic alcohols, ethers and esters, epoxides, and many phenol ethers. While most halides are cleaved, vinyl halides are cleaved stereospecifically (eqs 15 and 16).[21,22]

(15)

(16)

Cleavage of the hydrazine derivative in eq 17 represents an especially useful application since ***Zinc-Acetic Acid***, ***Aluminum Amalgam***, and ***Raney Nickel*** all give no reduction.[23] An interesting example of carbon-carbon bond cleavage is provided by an important step in the synthesis of (C_2)-dioxa-C_{20}-octaquinane (eq 18),[24] and sulfur-sulfur bond cleavage is illustrated with the mercaptosulfinate synthon shown in eq 19.[25] In the latter example, both sodium hydride and ***Sodium Borohydride*** gave poor results.

(17)

(18)

(19)

Reduction of Alkenes and Alkynes.

Conjugated polyenes are reduced by sodium-ammonia, although complications such as dimerization generally limit good results to cyclic systems and styrenes.[1f] The reduction of alkynes to *trans*-alkenes is well-known,[1f,h] the stereochemistry presumably resulting from the *trans* nature of the intermediate radical anion. Terminal alkynes can be protected by removal of the acidic proton by sodium amide, allowing synthetically useful strategies (eq 20).[26]

Sodium Anthracenide

[12261-48-2] · $C_{14}H_{10}Na$ · Sodium Anthracenide · (MW 201.23)

(reductive cleavage of N-S,[1,2] O-S,[3] O-P,[4] and C-O[5-7] bonds)

Solubility: sol THF, DME, HMPA.

Preparative Methods: a 0.1 M solution of the reagent in THF (or DME) is prepared by stirring sodium metal (1.0 equiv) and anthracene (1.1 equiv) in anhydrous solvent for 24 h under an argon atmosphere.[2] The resulting solution exhibits the characteristic dark green color of the radical anion. The preparation time can be significantly reduced by ultrasound irradiation of the reaction.[1,8]

Handling, Storage, and Precautions: sodium anthracenide is both air- and moisture-sensitive. However, stock solutions of the reagent are stable for several weeks at rt when stored under an argon atmosphere. The reagent is flammable and should be handled with care. Excess reagent can be neutralized by the slow addition of isopropyl alcohol.

Reductive N-S Cleavage.

Sulfoximines unsubstituted at nitrogen are readily prepared by the titration of *N*-tosylsulfoximines with sodium anthracenide (eq 1).[1] Alternative reagents employed to cleave the tosyl group (e.g. ***Sulfuric Acid***, *h*υ, and ***Sodium-Ammonia***) are less efficient (yields of 7-60% in eq 1).

(1)

Secondary arenesulfonamides are reductively cleaved by sodium anthracenide to provide the corresponding amines.[2] *N*-Arenesulfonyl aziridines can be reduced to free aziridines without concomitant homolytic ring opening (eq 2).[2c] Primary arene- and methanesulfonamides are deprotonated, rather than reduced.

(2)

Reductive O-S Bond Cleavage.

Sodium anthracenide converts arene mesylates to the corresponding phenols (eq 3).[3] More powerful reducing agents such as ***Sodium Naphthalenide*** and Na/NH_3 tend to produce competitive C-O bond cleavage.

Reductive O-P Bond Cleavage.

Aromatic phosphate esters are reduced to the corresponding phenols upon treatment with sodium anthracenide (eq 4).[4] Extensive C-O bond cleavage can occur with sodium naphthalenide or Na/NH_3.

Reductive C-O Bond Cleavage.

The α-naphthyldiphenylmethyl group is selectively cleaved by sodium anthracenide in the presence of the *p*-methoxytrityl protecting group (eq 5).[5] No discrimination between the triarylmethyl ethers is observed with sodium naphthalenide. The order of reactivity is reversed for hydrolytic (aqueous acid) deprotection.

The dimesylates of vicinal diols are efficiently reduced to the corresponding alkenes upon treatment with sodium anthracenide (eq 6).[6] In acyclic substrates, the product contains a mixture of alkene isomers.

(6)

The reductive cleavage of a cyclic ether to an alcohol with sodium anthracenide has been reported (eq 7). The enone moiety is undisturbed.[7]

(7)

Related Reagents.

Sodium Phenanthrenide.

Sodium Azide[1]

NaN_3

[26628-22-8] · N_3Na · Sodium Azide · (MW 65.02)

(nucleophilic azide source for organoazide preparation;[2] precursor to reagents such as hydrazoic acid,[3] halogen azides,[4] trimethylsilyl azide,[5] tosyl azide,[6] and diphenyl phosphorazidate[7])

Physical Data: dec ca. 300 °C; *d* 1.850 g cm^{-3}.

Solubility: sol water (39 g/100 g at 0 °C, 55 g/100 g 100 °C); slightly sol alcohol; insol ether.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: while relatively insensitive to impact, the solid can decompose explosively above its melting point. It forms highly explosive azides with metals such as Cu, Pb, Hg, Ag, Au, their alloys and compounds, and reacts with acids to form hydrazoic acid (HN_3) which is a toxic, spontaneously explosive gas. Explosive *gem*-diazides can be formed in CH_2Cl_2 or other chlorinated solvents and shock or heat sensitive metal azidothioformates in CS_2. All work with NaN_3 and other azides should be conducted on a very small scale behind a shield, in a fume hood. Excess NaN_3 on flasks, paper, etc. can be destroyed in a fume hood by soaking with acidified ***Sodium Nitrite*** or by oxidation with ***Cerium(IV) Ammonium Nitrate***.[8]

Introduction.

The reaction of NaN_3 with I_2 (releasing N_2) is catalyzed by thiols and thiones and this has been used as a spot test for such compounds.[9] NaN_3 has been used to assess the interactions between charged sites in myoglobin.[10]

Preparation of Organic Azides.

Organic azides can be reduced readily to amines, utilized for amine, azide or diazo transfer, act as nitrene or nitrenium precursors, and undergo Curtius and Schmidt rearrangements, cycloadditions and Staudinger reactions.[1b] They are prepared most often by nucleophilic displacement of a leaving group by azide ion (commonly NaN_3) (eq 1). Various leaving groups have been used, including halides, sulfonates (mainly OTs, OMs, or OTf, although brosylates[11] and nosylates[12] have been employed), sulfites,[13] and anhydrides.[14] Displacement of allylic acetates (and related species),[15] with ***Tetrakis(triphenylphosphine)palladium(0)*** as catalyst, and groups such as nitro,[16] phosphine sulfides (from thiaphosphonium species),[17] and phenylseleninates[18] has been reported.

$$R\text{-}X + NaN_3 \longrightarrow R\text{-}N_3 \qquad (1)$$

Eliminative azidation to form α-azidovinyl ketones occurs on NaN_3 treatment of some dibromo ketones (eq 2).[19] This approach also works well for the preparation of α-azidostyrenes from styrene.[20] Usually, *gem*-dihalo compounds react with NaN_3 to give *gem*-diazides;[21] however, an unusual nitrile formation has been reported (eq 3) under these conditions.[22] An interesting, stereospecific, solvent-dependent, azide-induced ring opening reaction of a dioxaphospholane has been observed (eq 4).[23]

(2)

(3)

(4)

Displacements can occur at the carbon atom of alkyl (primary, or secondary; tertiary requires ***Zinc Chloride*** or ***Zinc Iodide*** catalysis[24]), allyl, benzyl, acyl,[25] activated vinyl,[26] aryl,[27] or heteroaryl[28] species, and aryl diazonium salts (ArN_2^+, from $ArNH_2/HNO_2$),[29] or at the heteroatom of, amongst others, organosulfonyl, silyl and phosphoryl halides. Of the latter, ***p-Toluenesulfonyl Azide*** ($PTSN_3$),[6] ***Azidotrimethylsilane*** ($TMSN_3$),[5] and ***Diphenyl Phosphorazidate***, $(PhO)_2P(O)N_3$ (DPPA),[7] are the most common and the last two are commercially available.

Nucleophilic azide ion displacements are enhanced by polar, aprotic solvents (e.g. DMSO) with which high yield, aryl halide displacement to form even mononitrophenyl azides can occur.[27] Phase-transfer catalysis[30] (permitting the use of less polar solvents) or ultrasonication (for activated primary halides)[31] has also been used. Under such conditions, S_N2 inversion of configuration occurs and this has been observed also for alcohols under Mitsunobu conditions (***Triphenylphosphine***, ***Diethyl Azodicarboxylate***, HN_3).[32] Retention is possible where a neighboring group is present.[33]

Tertiary alcohols are converted directly to azides using NaN_3/***Sulfuric Acid*** or HN_3/***Boron Trifluoride*** or ***Titanium(IV) Chloride*** (eq 5),[34] and the carboxylic acid to acyl azide transformation (often en route to Curtius rearrangements to isocyanates) occurs with DPPA[7,1b] or via activation with DMF/***Thionyl Chloride***.[35]

(5)

NaN_3 reacts with epoxides at 25-30 °C (pH 6-7) to give azido alcohols.[36] Usually, inversion of stereochemistry takes place and attack at the least hindered site is preferred. The regio- and stereoselectivity of the reaction can often be enhanced by using $TMSN_3$ with a Lewis acid.[37] High selectivity was shown by NaN_3 on a calcium cation-exchanged Y-type zeolite (CaY) (eq 6),[38] but less so with NaN_3 on silica or alumina or the NaN_3/NH_4Cl system. $NaN_3/ZnCl_2$ gave lower yields than $TMSN_3/BF_3.OEt_2$ for the ring opening of 1,2-

epoxysilanes;[39a] selective azide opening at the site of silyl substitution has been reported.[39b] With a $PhSO_2$ group attached to the epoxide, azidation-elimination occurs to form the corresponding azidoaldehydes.[40] Reaction of the epoxy ester (**1**) with NaN_3 under more vigorous conditions gave (**2**) in 60% yield (eq 6).[41]

(6)

(1) **(2)**

Hydrazoic acid (HN_3; NaN_3/H^+) reacts with alkenes to form azidoalkanes.[42] Alkenes bearing a phenyl group or two geminal alkyl groups require a Lewis acid ($TiCl_4$ is best). Mono- or 1,2-dialkyl alkenes do not react and Michael additions occur with α,β-unsaturated alkenes.[26b] Enol ethers and silylenol ethers give azido ethers[42] and a similar process occurs with ***Trifluoroacetic Acid*** catalysis[43] or from acetals[44] or aldehydes with $TMSN_3$.[43] Interestingly, $TiCl_4$-catalyzed HN_3 addition to silyl enol ethers in the presence of primary or secondary alcohols gives the azido ethers shown (eq 7).[42] Recently, it has been found that (**3**) reacts with NaN_3/CAN to form the α-azido ketone (**4**) (eq 8).[45]

(7)

(8)

(3) **(4)**

Other oxidative double bond azidations have been reported. Thus an azidohydrin was formed from pregnenolone acetate and chromyl azide (NaN_3, ***Chromium(VI) Oxide***)[46] and steroidal dienones reacted with $TMSN_3$/***Lead(IV) Acetate***[47] to give diazido compounds. Vicinal diazides also result from alkenes and Fe^{III},[48] ***Manganese(III) Acetate*** (eq 9),[49] or ***Iodosylbenzene*** and NaN_3.[50] Anti-Markovnikov selenoazido products were prepared from the reaction of azide ion with alkenes and ***(Diacetoxyiodo)benzene***/***Diphenyl Diselenide*** (eq 10);[51] α-keto azides (with $TMSN_3$) are formed without PhSeSePh.[52]

(9)

(10)

Azide ion (or congener) attack upon nonconjugated alkenes is aided by the use of ***Dimethyl(methylthio)sulfonium Tetrafluoroborate***.[53] *Trans* products are obtained and, in general, the amount of anti-Markovnikov product increases with increased azide nucleophilicity, and vice versa. Monosubstituted alkenes favor anti-Markovnikov addition, whereas the opposite occurs with trisubstitution. 1,1-Disubstituted alkenes can give either orientation.

Schmidt Reactions.[54]

This term is used for several transformations, general examples of which are shown in eqs 11 and 12. The former is used infrequently due to the drastic conditions required compared to the analogous Curtius and Hoffmann rearrangements and the discovery that DPPA effects the transformation under mild conditions.[7,1b] $TMSN_3$ has been used frequently.

$$RCO_2H \xrightarrow[H^+]{NaN_3} RNH_2 \qquad (11)$$

$$RCOR \xrightarrow[H^+]{NaN_3} RCONHR \qquad (12)$$

The ketone to amide transformation (eq 12) is still of considerable utility (with the provisos regarding the hazards associated with HN_3) and various acids have been employed, including H_2SO_4 (the most common), ***Polyphosphoric Acid***, and ***Methanesulfonic Acid***. With an unsymmetrical ketone a mixture of amide products can result although preferential migration of an aryl group (over alkyl) has been reported. In one case, the amount of aryl migration product (**6**) (R = H, 75%) was greater (80%) starting from the 7-nitroketone (**5**) (R = NO_2) and lower (70%) from the 7-amino species (**5**) (R = NH_2) (eq 13).[55] Aldehydes usually give nitriles under Schmidt conditions.[56]

Curtius Reaction.[57]

The Curtius reaction involves conversion of an acid chloride (or anhydride) to an isocyanate (eq 14). Trapping of the isocyanate is possible in the presence of a nucleophile. Some cyclic anhydrides react to give isocyanates which can cyclize subsequently.

$$RCOCl \xrightarrow[2.\ \Delta]{1.\ NaN_3 \text{ or } TMSN_3} RNCO \qquad (14)$$

Preparation of Heterocycles.

As mentioned, heterocycles can be obtained via Schmidt or Curtius reactions. In addition, organic azides react with alkenes to form triazolines (triazoles from alkynes), aziridines, or other heterocycles.[58] In situ triazoline generation and subsequent cleavage can lead to other heterocycles (see eq 15).[59] Reaction of NaN_3 with other α,β-unsaturated alkenes (or alkynes) provides different heterocycles dependent on the substituents. Such reactions are too numerous to mention in detail and only selected examples are shown in eqs 16-18.[60-62]

(15)

(16)

(17)

(18)

A useful tetrazole preparation is the addition of NaN_3 (under acidic conditions) to nitriles.[63] Similar processes occur with ***Tri-n-butyltin Azide*** or $TMSN_3$.[64]

Related Reagents.

Azidotrimethylsilane; ***N-Bromosuccinimide-Sodium Azide***; ***Hydrazoic Acid***.

(formation of saturated and unsaturated sulfones;[2] synthesis of thiosulfonates;[3] preparation of *p*-tolylsulfonyldiazomethane[4] and *p*-tolylsulfonylmethyl isocyanide[5])

Physical Data: (**1**) mp >300 °C; (**2**) mp >300 °C.

Solubility: sol H_2O.

Form Supplied in: white solids; widely available.

Analysis of Reagent Purity: (**1**) 97-98% purity; (**2**) 97-98% purity containing 9-18% H_2O; anhydrous reagent commercially available.

Handling, Storage, and Precautions: both sodium sulfinates can be dried in a vacuum oven at 140 °C overnight to remove the water of hydration.

Preparation of Sulfones.

Sodium benzenesulfinate (**1**) and sodium *p*-toluenesulfinate (**2**) are ambident nucleophiles that react with soft electrophiles, such as alkyl halides, to form sulfones as the major product. Hard electrophiles, such as diazomethane, react to yield predominantly sulfinic esters, although substantial quantities of sulfone may be produced (eq 1).[6,7] (Sulfinic esters are best produced by alternate procedures; see ***Methyl Benzenesulfinate***.) The amount of sulfinic ester impurity, typical in the preparation of a sulfone, can be reduced greatly by performing the alkylation under phase-transfer conditions,[8] or by preforming the tetrabutylammonium sulfinate salt.[9] Numerous reactions of arenesulfinates with simple electrophiles to form sulfones have been reported in the early literature.[10]

(1)

Aryl alkyl sulfones can readily form α-sulfonyl carbanions by treatment with Grignard reagents or alkyllithium reagents;[11,12] other bases that have been used include ***Lithium Diisopropylamide***, ***Lithium Amide*** and ***Sodium Amide***, ***Sodium Hydride***, and potassium alkoxides.[11] Reagent (**2**) has been used to introduce a sulfone as an activating group for the Michael addition of a benzyl group to

acrylonitrile; the sulfonyl group was removed easily by reductive cleavage with ***Sodium Amalgam*** (eq 2).[13]

Reagent (**2**) can add to α,β-unsaturated ketones in the presence of AcOH to form γ-oxo sulfones.[14] These intermediates are useful for the β-alkylation of α,β-unsaturated ketones since the sulfonyl group can be eliminated easily with base to reform the double bond (eq 3).

Allylic sulfones are useful synthetic intermediates that can be prepared from either (**1**) or (**2**) and a variety of allylic starting materials.[15] Allylic nitro compounds undergo denitro-sulfonylation in the presence of (**1**)/AcOH,[16] or in the presence of ***Tetrakis(triphenylphosphine)palladium(0)***;[17,18] the latter reaction occurs with high regioselectivity to afford the product from direct displacement of the nitro group (eq 4).

Allylic bromides reportedly react with (**1**) or (**2**) to form sulfones via a classical S_N2' mechanism, but equilibrate to the more thermodynamically stable compound in the presence of catalytic amounts of the same sulfinate.[19] A general synthesis of 1,5-dienes via coupling of an allylic halide and an allylic sulfone followed by reductive cleavage of the sulfone has been reported (eq 5).[20] In this account, ***Lithium-Ethylamine*** was found to be preferred to Na(Hg) for removal of the sulfonyl group, since the use of Na(Hg) resulted in

double-bond migration.

Unsaturated sulfones can be prepared via iodosulfonylation of alkenes and conjugated dienes with (**1**) or (**2**) in the presence of ***Iodine***.[21,22] Alkenes react stereospecifically with (**1**)/I_2 to form 2-iodo sulfones, while 1,3-dienes react to form δ-iodo allylic sulfones. The iodo functionality can be substituted by various nucleophiles or undergo dehydrohalogenation to form allylic sulfones or 1-sulfonyl-1,3-dienes, respectively (eq 6).

Alternatively, addition of (**1**) to a 1,3-diene in the presence of ***Mercury(II) Chloride*** results in the formation of 2-(phenylsulfonyl)-1,3-dienes (eq 7).[23] These versatile intermediates can participate in Michael-type additions and cycloaddition reactions.[24-26]

(7)

Substituted vinyl sulfones also may be prepared by addition of (**1**) to alkynyl esters in the presence of ***Boric Acid*** (eq 8).[27] These vinyl sulfones serve as excellent dienophiles in Diels-Alder reactions, containing useful functionality for further transformation.[28] In general, vinyl sulfones serve as valuable synthetic intermediates.[29]

(8)

Catalytic quantities of (**1**) have also been used in a highly efficient [3 + 2] cyclization-elimination reaction of (phenylsulfonyl)allene in the presence of α,β-unsaturated compounds to produce cyclopentenyl-substituted sulfones; other nucleophiles such as cyanide or nitrite will work as well (eq 9).[30]

(9)

Preparation of Thiosulfonates.

(**1**) or (**2**) react with elemental sulfur in various amines or liquid ammonia to produce thiosulfonate salts.[3] These salts can be alkylated to form thiosulfonate esters in good yield (eq 10); these compounds are useful sulfenylating agents (eq 11).[31]

Preparation of *p*-Tolylsulfonyldiazomethane.

(**2**) has been used for preparing *p*-tolylsulfonyldiazomethane,[4] a useful reagent for the synthesis of trisubstituted-methane derivatives,[32] and the conversion of allylic alcohols to homoallylic alcohols.[33] This α-diazo sulfone also reacts with alkenes to provide sulfonyl-substituted cyclopropanes (eq 12).[32,34]

Preparation of *p*-Tolylsulfonylmethyl Isocyanide.

(**2**) also has been utilized for the preparation of ***p-Tolylsulfonylmethyl Isocyanide*** (TosMIC),[5] a useful reagent for the formation of various azole ring systems.[35] Base-induced addition of the C-N=C moiety into the C=O functionality of an aldehyde, for example, produces oxazoles in excellent yield (eq 13).[36] Other ring systems such as imidazoles, thiazoles, pyrroles, and 1,2,4-triazoles can be manufactured via reaction with C=S-, C=C-, C=O-, and N=N-containing substrates, respectively. This reagent also has been utilized for the conversion of ketones into cyanides,[37] and the synthesis of α-hydroxy aldehydes.[35]

Sodium Benzylate

[20194-18-7] · C_7H_7NaO · Sodium Benzylate · (MW 130.13)

(nucleophilic metal alkoxide; infrequently used as the base in Favorskii rearrangements[1])

Solubility: the saturated solution in benzyl alcohol is 3.6 M.[1]

Preparative Methods: usually formed in situ by the reaction of sodium with neat benzyl alcohol[1] or by the reaction of NaH with 1.0 equiv of benzyl alcohol in an ethereal solvent.[2,3]

Handling, Storage, and Precautions: use the same precautions as for other alkali metal alkoxides (e.g. ***Potassium t-Butoxide***); avoid contact of the neat salt or solutions with the eyes, skin, and clothing; carry out preparation and conduct reactions under an inert nitrogen or argon atmosphere. Use in a fume hood.

Substitution and Transesterification Reactions.

$PhCH_2ONa$ is a useful nucleophile in S_N2 reactions of alkyl halides (eq 1).[2] It reacts with acid chlorides to give benzyl esters and participates in transesterification reactions with esters and thioesters. Thiophenyl carbamates are converted into benzyl carbamates with the reagent (eq 2).[4] The reagent also effects slow desilylation of TBDMS-protected alcohols;[4] the low yield of the product in eq 2 is attributable to partial desilylation of TBDMS-protected 3´- and 5´-hydroxyl groups.[4]

The reagent is capable of effecting demesylation of certain mesylate esters by attacking at the sulfur atom and displacing the alkoxide group with retention of configuration, rather than attacking at the carbon atom and displacing the mesylate group (eq 3).[5] Such reactions are termed S_N2S-type reactions.[6]

(3)

The reagent acts as a nucleophile in nucleophilic aromatic substitution reactions. The reaction of the 2,6-diacid chloride of 4-chloropyridine with excess $PhCH_2ONa$, which first yields the 2,6-dibenzyloxycarbonyl derivative of 4-benzyloxypyridine, provides an example (eq 4).[7] $PhCH_2ONa$ displaces the chlorine of 3-phenyl-5-chloroisoxazole to give the 5-benzyloxy compound (eq 5).[8] An *ipso* nucleophilic aromatic substitution reaction is also involved in the $PhCH_2ONa$-induced cleavage reactions of the methylenedioxy rings of various aromatic compounds containing appropriately located electron-withdrawing groups in $PhCH_2OH$/DMSO.[9]

(4)

(5)

Addition Reactions.

$PhCH_2ONa$ undergoes conjugate addition to α,β-unsaturated methyl esters and simultaneously exchanges methoxy groups with benzyloxy groups to form benzyl esters. The reaction illustrated in eq 6 is somewhat stereoselective.[10] The conjugate addition reaction occurs more slowly with $PhCH_2ONa$ than with ***Sodium Methoxide*** or ***Sodium Ethoxide***. The strained α-chloro-α,β-unsaturated ester shown in eq 7 also undergoes conjugate addition and ester exchange with the reagent in $PhCH_2OH$.[11] A lower yield was obtained using $PhCH_2OK$ as the nucleophile.[11]

(6)

(7)

α,β-Unsaturated nitro compounds yield conjugate addition products upon reaction with $PhCH_2ONa$ in THF. Quenching of the nitronate anion with acetic acid at low temperature yields *anti* β-benzyloxy nitro compounds stereoselectively (eq 8).[3] $PhCH_2OLi$ and $PhCH_2OK$ additions occur with the same degree of stereoselectivity as $PhCH_2ONa$, but the yields of adducts are somewhat lower. Catalytic reduction of the nitro group and hydrogenolysis of the benzyloxy group yields the corresponding β-amino alcohols.[3]

(8)

Favorskii Rearrangements.

The lower molecular weight alkoxides such as MeONa and EtONa are generally employed for the Favorskii rearrangement of α-halo ketones to esters.[12] However, when used as a suspension in Et_2O, $PhCH_2ONa$ is more effective than MeONa, EtONa, or *i*-PrONa for the stereospecific rearrangement of *cis*- and *trans*-1-acetyl-1-chloro-2-methylcyclohexane to the corresponding benzyl esters, in which the new carbon-carbon bond has the opposite configuration to the departing halogen.[1] A solution of the base in DME is highly effective for the stereospecific rearrangement of *cis*-1-acetyl-1-chloro-2-*p*-methoxyphenylcyclohexane into the corresponding benzyl ester (eq 9).[13]

Related Reagents.

Lithium t-Butoxide; ***Potassium t-Butoxide***; ***Sodium Ethoxide***; ***Sodium Methoxide***.

Sodium Bis(dimethylglyoximato)(pyridine)cobaltate[1]

[75699-52-4] · $C_{13}H_{19}CoN_5NaO_4$ · Sodium Bis(dimethylglyoximato)(pyridine)cobaltate · (MW 391.29)

(supernucleophilic cobalt complex;[1] reagent for preparation of alkylbis(dimethylglyoximato)(pyridine)cobalt(III) complexes (alkylcobaloximes)[2] and for formation of metal-cobalt bonds;[3] reducing agent; reagent for reductive formation of carbon-carbon bonds,[4] initializing ring expansions from cyclic halomethyl derivatives[5] and cleavage of *N*-terminal protecting groups of peptides[6])

Alternate Name: sodium cobaloxime(I).

Physical Data: dark purple to brown solid; no melting point has been reported; UV/vis in methanol: λ_{max} = 641, 550, 458 nm.

Solubility: sol oxygen-free alcohols (ethanol, methanol), pyridine; insol ethers (THF, diethyl ether).

Preparative Methods: the reagent is prepared in situ from ***Cobalt(II) Chloride***, butane-2,3-dione dioxime (dimethylglyoxime, $dmgH_2$), ***Pyridine***, ***Sodium Hydroxide*** and ***Sodium Borohydride*** in methanol at temperatures between -78 °C and rt. Addition of triethanolamine and its hydrochloride buffers solutions for base-labile alkylating reagents. Pyridine can be replaced by other heterocyclic nonreducible bases such as substituted pyridines, phosphines, anilines, imidazoles, trialkylamines, thioethers, arsines, or stibines. Water is an especially useful leaving group in alkylcobaloximes(III) for axial ligand exchange as it can fine tune the reactivity or solubility of the cobalt complex.[7]

Another convenient preparation of cobaloximes(I) uses cobalt(II) chloride, dimethylglyoxime, and an excess of sodium hydroxide. The strong basic reaction conditions lead to disproportionation of cobaloxime(II) to cobaloxime(I) and cobaloxime(III), both as their aqua complexes. Alkylation of the nucleophilic cobaloxime(I) with nonbase-labile alkyl halides or sulfonates yields alkylbis(dimethylglyoximato)(aqua)cobalt(III).[8] Alkylaqua complexes of cobalt(III) are more soluble in alcohols or water than their pyridine derivatives, and thus are well suited for introducing any ligand which is more prone to bind to coordinated cobalt(III) than water (the latter property is in general well correlated with the nucleophilicity of the axial ligand in question) (eq 1).

The reagent can also be synthesized by alkali borohydride or alkali amalgam reduction of previously isolated and recrystallized halogenocobaloximes(III).[9] This process is of interest whenever high purity cobaloxime(I) solutions are needed. Some applications of cobaloxime(I) require nonbasic conditions. Thus reacting cyanoethylcobaloxime with potassium *t*-butoxide leads to acrylonitrile elimination and potassium cobaloxime(I)[10] (eq 2).

Handling, Storage, and Precautions: extremely air- and acid-sensitive; the reagent should be used as prepared in oxygen-free solutions at temperatures between -78 °C and rt by adding oxygen-free alkyl halides or sulfonates. Solid reagents, i.e. alkylating reagents, should be dissolved in acetone for best results, with halogenated solvents, i.e. carbon tetrachloride or methylene chloride, being avoided as they lead to the immediate formation of chloromethylbis(dimethylglyoximato)(pyridine)cobalt(III).[2e]

Cobalt is the catalytic center of vitamin B_{12} and therefore an essential trace element. However, care should be taken while handling inorganic cobalt(II) salts because they are potential carcinogens on parenteral application (i.e. bypassing the digestive system). Use in a fume hood.

Alkylcobaloximes(III).

Alkylation of supernucleophilic sodium cobaloxime(I) has been reported for a variety of primary and secondary alkyl halides,[2a,b] sulfonates,[2c] epoxides,[2d] electron-deficient alkenes,[2e] or perfluoroalkyl iodides.[2f] Sodium cobaloxime(I) adds in a Michael fashion to acrylic acid derivatives or acrylonitrile (eq 3).

(3)

Hydridocobaloxime can be prepared from cobaloxime(II) or sodium cobaloxime(I) under a hydrogen atmosphere. Hydridocobaloxime adds to α,β-unsaturated carbonyl compounds or aryl substituted alkynes with the opposite regioselectivity of that of sodium cobaloxime. This process can be used for selective isotope labeling (eq 4),[11] when the reaction is carried out in deuterated media under a deuterium atmosphere.

(4)

The stereochemistry of the alkylation reaction is largely governed by the substrate. Kinetic data indicates an S_N2 mechanism operating for simple primary and secondary alkyl bromides.[1] In other cases, reaction pathways are derived from product distributions via S_N2 reactions, e.g. for 4-substituted *t*-butylcyclohexanes (eq 5)[12] and SET reactions of glycosyl halides showing either selective[13a] or nonselective[13b] substitution of the halide (eq 6).

Glycosyl cobaloximes have been employed as building blocks for KDO[13a] and as precursors for amino sugars.[13c] Tertiary alkyl cobaloximes(III) are limited to a few examples, but bridgehead positions are favorable sites for stable tertiary alkyl cobaloxime(III). A synthesis has been designed which takes advantage of the labile intermediate tertiary cobaloxime in the ring expansion of iodomethyl penicillin to a 3:2 mixture of exomethylene cepham to Δ^2-cephem (eq 7).[5]

Vinyl triflates react with sodium cobaloxime(I) within 10 min at 0 °C in aqueous methanol to yield vinyl cobaloximes(III) (eq 8). Transformation of isomeric (*E*)- and (*Z*)-vinyl triflates results in stereoconvergence. Application of this methodology to alkynylvinyl triflates leads to σ-butatrienyl- (eq 9) and σ-enynylcobaloximes(III)[14]

Although arylation of halogenocobaloximes(III) by Grignard reagents is the method of choice for the synthesis of aryl cobaloximes, successful reactions of aryl bromides and cobaloxime(I) have been reported. An electron-withdrawing group in the *para* position (CF_3, CO_2Me) is

required. Bromobenzene is unreactive (eq 10).[15]

(10)

$X = CF_3, CO_2Me$

Sodium Bis(2-methoxyethoxy)aluminum Hydride[1]

$NaAlH_2(OCH_2CH_2OMe)_2$

[22722-98-1] · $C_6H_{16}AlNaO_4$ · Sodium Bis(2-methoxyethoxy)aluminum Hydride · (MW 202.19)

(reducing agent for many functional groups;[1] methylation reagent for aryl-activated compounds;[19] can function as a base;[21] can hydroaluminate alkenes and alkynes[22])

Alternate Names: SMEAH, Red-Al®, Vitride.

Physical Data: fp 4 °C (3.4 M toluene solution); *d* 1.036 g cm^{-3} (3.4 M toluene solution), *d* 1.122 g cm^{-3} (solid); highly viscous liquid at rt; thermally stable up to 205 °C, upon which vigorous decomposition starts.

Solubility: sol aromatic hydrocarbons, ether, THF, DME; insol aliphatic hydrocarbons.

Form Supplied in: 3.4 M solution in toluene. 145 g contains 1 mol of active hydride. The pure compound is a slightly yellow, glassy solid.

Analysis of Reagent Purity: concentration can be determined by iodometric titration.

Handling, Storage, and Precautions: highly flammable; moisture sensitive; reacts less strongly with H_2O than $LiAlH_4$; potent skin irritant. Use in a fume hood.

Functional Group Reductions.

SMEAH has reducing properties fully comparable to ***Lithium Aluminum Hydride***, making it a valuable alternative reducing reagent.[1,2] Some practical advantages of SMEAH are that it does not ignite when exposed to moist air or O_2, has greater solubility in aromatic solvents and ethers, and reactions can be carried out at higher temperatures (up to 200 °C). Carboxylic esters, acids, acid chlorides, anhydrides, aldehydes, and ketones are efficiently converted to the alcohol. Cyclic anhydrides and lactones yield diols. Carboxylic esters are not reduced at -78 °C and *t*-Bu and Ph esters are generally stable to SMEAH at low temperature.

Nitriles, amides, imines, azido compounds, nitro compounds, isocyanates, urethanes, sulfonamides, oximes, lactams, and imides can be reduced to the amine. The formation of aziridines can complete with simple reduction of ketoximes and their *O*-alkyl derivatives. Nitroarenes form azoxyarenes, azoarenes, or hydrazoarenes depending on reaction conditions.[3]

Alkanesulfonates can be converted to alkanes or to alcohols. Phosphate esters afford the alcohol.[4] Some epoxides can be reduced to the alcohol (temperatures above 0 °C are required). Disulfides give thiols while sulfoxides yield sulfides. Sulfones are generally inert or give low yields of sulfides. Haloalkanes, haloarenes, and organosilicon halides undergo hydrogenolysis to the alkane, arene, and silane, respectively.[5] Benzylic aldehydes or alcohols, aryl alkyl or diaryl ketones, and aryl acids containing strong electron donating groups in the *ortho* or *para* position also undergo hydrogenolysis at 120-140 °C.[6] Acetals are usually stable toward hydrogenolysis or elimination at 0-20 °C, except in the presence of a conjugated double bond and bromide (eq 1)[7a] or in certain quinone monoacetal systems.[6b]

Partial Reductions.

Low-temperature conditions or the use of alcohol or amine-modified SMEAH have proven especially valuable for partial functional group reductions.[1,2] Carboxylic esters, nitriles, and amides can be reduced to the aldehyde at low temperatures. The morpholine or *N*-methylpiperazine modified reagent also yields aldehydes at -55 to 0 °C.[8,9] Lactones are converted to lactols by unmodified SMEAH at -70 °C[2b] or with the EtOH, pyridine, or *i*-PrOH modified reagent at 0 °C. *N*-Substituted cyclic imides provide hydroxylactams upon reduction at -78 °C.[10] It is the reagent of choice for the reduction of Cp_2ZrCl_2 to Cp_2ZrClH.[11]

Selective Reductions.

Vinylogous amides have been selectively reduced to the β-ketoamine (eq 2).[12a] SMEAH is superior to $LiAlH_4$ for the reduction of acetal-protected cyanohydrins to the aldehyde.[12b] It chemoselectively reduces α-formyl ketones to the α-hydroxymethyl ketone.[12c] Lactones are stable in the presence of ketone or aldehyde functionality at low temperatures. SMEAH modified by alcohols or in pyridine solvent selectively reduces lactones in the presence of an amide or ester.[13a] Ester groups in amidoesters undergo selective reduction at 0 °C and short reaction times.[13b] SMEAH gives higher yields than $LiAlH_4$ in the reduction of some hydroxy-substituted carbonyl compounds (eq 3).[13c] 5,5-Disubstituted hydantoins are selectively reduced at the 4-position[13d] and keto aldehydes have been cleanly reduced to the keto alcohol.[13e] Optically active α-alkoxy carboxamides have been reduced to the α-alkoxy aldehydes without racemization.[13f]

1,2-vs. 1,4-Reductions.

The structure of the enone, solvent, relative initial concentrations, temperature, and softness or hardness of the hydride reagent all play a role in controlling the mode of addition to enone systems. SMEAH typically acts as a hard hydride, favoring 1,2-addition in these reactions. High yields of the allylic alcohol have been reported by inverse addition of the hydride to aliphatic or alicyclic α,β-unsaturated aldehydes and esters.[14a,b] It favors 1,2-addition to cyclic α-enones and is the reagent of choice for the low-temperature reduction of enol esters of alicyclic 1,3-diketones (eq 4).[14c] Alkyl esters are not reduced under these conditions. The SMEAH/CuBr/2-butanol reagent is extremely efficient for 1,4-reduction.[15] Nitrile and ester functions are stable under the conditions of the conjugate reduction, while aldehydes, ketones, and bromides are attacked by the complex.

(4)

$R = (CH_2)_6CO_2Me$
$R' = i\text{-Pr, PhCO, ArSO}_2$

Stereoselective Reductions.

The stereochemistry of reductions often varies, depending on the solvent. A possible factor is the degree of solvation. In some cases, complete reversal of stereochemistry has been observed by using SMEAH in benzene versus THF.[1] In comparison to other reducing agents, SMEAH often shows stereoselectivity opposite to that of $LiAlH_4$, ***Sodium Borohydride***, or lithium trialkoxyaluminum hydrides. Unsymmetrical epoxides are attacked preferentially at the least-substituted carbon atom to give the more highly substituted alcohol as the major product.[16a] Exceptionally high regioselectivity in the reduction of α,β-epoxy alcohols to the 1,3-diol has been observed (eq 5).[16b-e] Substituents at the α-carbon reverses the selectivity and decreases the reaction rate. The reduction of α-silyloxy ketones produces *syn*-vicinal diols with high levels of diastereoselectivity.[16f,g]

(5)

SMEAH reacts with bridged bicyclic ketones from the less hindered side of the carbonyl.[17a] Reduction of *gem*-dihalocyclopropanes gives *anti*-monohalides as the major product.[17b] It reduces α-alkynic alcohols to *trans*-allylic alcohols with high selectivity.[18a-d] Alkynyl ethers give almost exclusively *O*-alkyl enol ethers with the (*E*) configuration with SMEAH, but with alcohol-modified SMEAH reagent (*Z*)-enol ethers are obtained (eq 6).[18e]

(6)

R = alkyl
R^1, R^2 = alkyl, alicyclic

Methylation Reagent.

The reduction of aryl-conjugated double bonds yields selective methylation at the more highly arylated carbon atom.[19] The Me group originates from the hydride OMe group. Aryl-activated alkanes undergo methylation by this reagent. Diaryl and condensed aromatic ketones undergo hydrogenolysis and subsequent methylation at the benzylic carbon.

Reductive Cleavage of Ethers.

Ethers are usually stable at temperatures below 100 °C. At higher temperatures, cleavage of the ether linkage occurs. SMEAH is a useful reagent for debenzylation and deallylation of aryl benzyl and aryl allyl ethers (eq 7).[20] The reaction is enhanced by a vicinal methoxy group. This method is recommended for debenzylation and deallylation of phenolic ethers that are labile to acid or catalytic hydrogenolysis.

(7)

Use as a Base.

SMEAH can act as a strong base. It is known to promote isomerization and dehydrogenation of aromatic hydrocarbons by a base-catalyzed reaction.[21a,b] The Stevens rearrangement of berbine methiodide affords the spiroisoquinoline derivative in high yield.[21c]

Hydroalumination Reagent.

Double and triple bonds undergo catalytic hydroalumination with a number of aluminum hydride reagents.[22] The effectiveness of SMEAH in this reaction is comparable to that of $LiAlH_4$, $NaAlH_4$, $NaAlHMe_3$, $LiAlH_2(NR_2)_2$, or $NaAlH_2(NR_2)_2$.

Related Reagents.

Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride.

Sodium Bismuthate[1]

$NaBiO_3$

[12232-99-4] · $BiNaO_3$ · Sodium Bismuthate · (MW 279.97)

(selective oxidant for cleavage of 1,2-diols[1])

Physical Data: somewhat uncertain composition corresponding to around 85% $NaBiO_3$.

Solubility: insoluble in common solvents.

Form Supplied in: amorphous powder.

Oxidative Cleavage.

Sodium bismuthate is a selective reagent for the oxidative cleavage of 1,2-diols, somewhat similar in scope to periodate or ***Lead(IV) Acetate***.[1] The reagent, an insoluble powder, is used as a suspension in aqueous or organic solvents, normally acidified with ***Acetic Acid*** or ***Phosphoric Acid***. The color and reactivity of commercial samples is somewhat variable. 1,2-Diols are rapidly cleaved to the corresponding carbonyl compounds by sodium bismuthate at moderate temperatures. Like lead tetraacetate but unlike periodate, sodium bismuthate also cleaves α-hydroxy carboxylic acids and some α-hydroxy ketones.[2,3] The general cleavage reactions of sodium bismuthate include the transformations of eqs 1-3 (R = H or alkyl).

Sodium bismuthate is sometimes preferred to lead tetraacetate because anhydrous conditions are not required for its use. The diol fission reactions of sodium bismuthate are carried out in an excess of acetic or phosphoric acid. When acetic acid is used, a reddish brown suspension, assumed to be bismuth(V) oxide, is formed initially and gradually disappears as the reaction proceeds, leaving a solution of bismuth triacetate. When the reagent is used in combination with phosphoric acid, an orange yellow suspension of unknown composition forms initially. As the oxidation takes place, this gives way to a white precipitate

of bismuth triphosphate.

Even analytical-grade samples of sodium bismuthate display an oxidizing capacity which corresponds to about 85% $NaBiO_3$. Reactions may be carried out in 100% or aqueous acetic acid at, or slightly above, room temperature. A clear colorless solution remains when reaction is complete. Bismuth may be conveniently removed from the reaction by precipitation as the phosphate. Complete reaction may take from a few minutes to several hours.

One application of sodium bismuthate which has received considerable attention is the analytical determination of urinary corticosteroids.[4] This technique relies on the selective cleavage of the corticosteroid side chain. Analysis of the reaction products for 17-keto steroids and formaldehyde is then used to identify the corticosteroids originally present.

Other Oxidations.

Various other oxidation reactions of sodium bismuthate have been studied in addition to 1,2-diol and related cleavage processes. The reagent has been studied, although not widely used, for the oxidation of phenols. Either radical coupling products (typical of one-electron oxidation) or quinonoid products (typical of two-electron oxidation) may be formed, depending on the reaction conditions.

Sodium Borohydride

$NaBH_4$

[16940-66-2] · BH_4Na · Sodium Borohydride · (MW 37.84)

(reducing agent for aldehydes and ketones, and many other functional groups in the presence of additives[1])

Physical Data: mp 400 °C; *d* 1.0740 g cm^{-3}.

Solubility: sol H_2O (stable at pH 14, rapidly decomposes at neutral or acidic pH); sol MeOH (13 g/100 mL)[1b], and EtOH (3.16 g/100mL),[1b] but decomposes to borates; sol polyethylene glycol (PEG),[2a] sol and stable in *i*-PrOH (0.37 g/100 mL)[3] and diglyme (5.15 g/100 mL);[1b] insol ether;[1b] slightly sol THF.[1c]

Form Supplied in: colorless solid in powder or pellets; supported on silica gel or on basic alumina; 0.5 M solution in diglyme; 2.0 M solution in triglyme; 12 wt % solution in 14 M aqueous NaOH. Typical impurities are sodium methoxide and sodium hydroxide.

Analysis of Reagent Purity: can be assessed by hydrogen evolution.[4]

Purification: crystallize from diglyme[3] or isopropylamine.[4]

Handling, Storage, and Precautions: harmful if inhaled or absorbed through skin. It is decomposed rapidly and exothermically by water, especially if acid solutions are used. This decomposition forms toxic diborane gas and flammable/explosive hydrogen gas, and thus must be carried out under a hood. Solutions in DMF can undergo runaway thermal reactions, resulting in violent decompositions.[5] The addition of supported noble metal catalysts to solutions of $NaBH_4$ can result in ignition of liberated hydrogen gas.[5]

Reduction of Aldehydes and Ketones.

Sodium borohydride is a mild and chemoselective reducing agent for the carbonyl function. At 25 °C in hydroxylic solvents it rapidly reduces aldehydes and ketones, but it is essentially inert to other functional groups such as epoxides, esters, lactones, carboxylic acid salts, nitriles, and nitro groups. Acyl halides, of course, react with the solvent.[1a] The simplicity of use, the low cost, and the high chemoselectivity make it one of the best reagents for this reaction. Ethanol and methanol are usually employed as solvents, the former having the advantage of permitting reductions in homogeneous solutions with relatively little loss of reagent through the side reaction with the solvent.[1a] Aprotic solvents such as diglyme greatly decrease the reaction rates.[1a] On the other hand, $NaBH_4$ in polyethylene glycol (PEG) shows a reactivity similar to that observed in EtOH.[2a] Although the full details of the mechanism of ketone reduction by $NaBH_4$ remain to be established,[6] it has been demonstrated that all four hydrogen atoms can be transferred. Moreover, the rate of reduction was shown to slightly increase when the hydrogens on boron are replaced by alkoxy groups.[1a,c,d] However, especially when $NaBH_4$ is used in MeOH, an excess of reagent has to be used in order to circumvent the competitive borate formation by reaction with the solvent. Ketone reduction has been accelerated under phase-transfer conditions[7] or in the presence of HMPA supported on a polystyrene-type resin.[8]

The isolation of products is usually accomplished by diluting the reaction mixture with water, making it slightly acidic to destroy any excess hydride, and then extracting the organic product from the aqueous solution containing boric acid and its salts.

Kinetic examination of the reduction of benzaldehyde and acetophenone in isopropyl alcohol indicated a rate ratio of 400:1.[1a] Thus it is in principle possible to reduce an aldehyde in the presence of a ketone.[9a] Best results (>95% chemoselectivity) have been obtained using a mixed solvent system (EtOH-CH_2Cl_2 3:7) and performing the reduction at -78 °C,[9a] or by employing an anionic exchange resin in borohydride form.[10] This reagent can also discriminate between aromatic and aliphatic aldehydes. On the other hand, reduction of ketones in the presence of aldehydes can be performed by $NaBH_4$-***Cerium(III) Chloride***. $NaBH_4$ in MeOH-CH_2Cl_2 (1:1) at -78 °C reduces ketones in the presence of conjugated enones and aldehydes in the presence of conjugated enals.[9]

Conjugate Reductions.

$NaBH_4$ usually tends to reduce α,β-unsaturated ketones in the 1,4-sense,[1d] affording mixtures of saturated alcohol and ketone. In alcoholic solvents, saturated β-alkoxy alcohols can be formed as byproducts via conjugate addition of the solvent.[11] The selectivity is not always high. For example, while cyclopentenone is reduced only in the conjugate fashion, cyclohexenone affords a 59:41 ratio of allylic alcohol and saturated alcohol.[1d] Increasing steric hindrance on the enone increases 1,2-attack.[11] Aldehydes undergo more 1,2-reduction than the corresponding ketones.[1c,1d] The use of pyridine as solvent may be advantageous in increasing the selectivity for 1,4-reduction, as exemplified (eq 1) by the reduction of (*R*)-carvone to dihydrocarveols and (in minor amounts) dihydrocarvone.[12]

Trialkyl borohydrides such as ***Lithium Tri-s-butylborohydride*** and ***Potassium Tri-s-butylborohydride*** are superior reagents for the chemoselective 1,4-reduction of enones. On the other hand, 1,2-reduction can be obtained by using $NaBH_4$ in the mixed solvent MeOH-THF (1:9),[13] or with $NaBH_4$ in combination with $CeCl_3$ or other lanthanide salts.[14]

$NaBH_4$ in alcoholic solvents has been used for the conjugate reduction of α,β-unsaturated esters,[15] including cinnamates and alkylidenemalonates, without affecting the alkoxycarbonyl group. Conjugate nitroalkenes have been reduced to the corresponding nitroalkanes.[16] Saturated hydroxylamines are obtained by reducing nitroalkenes with the ***Borane-Tetrahydrofuran*** complex in the presence of catalytic amounts of $NaBH_4$, or by using a combination of $NaBH_4$ and ***Boron Trifluoride Etherate*** in 1:1.5 molar ratio.[17] Extended reaction can lead also to the saturated amines.[17]

Reduction of Carboxylic Acid Derivatives.

The reduction of carboxylic esters[1c,1d] by $NaBH_4$ is usually slow, but can be performed by the use of excess reagent in methanol or ethanol[18] at room temperature or higher. The solvent must correspond to the ester group, since $NaBH_4$ catalyzes ester interchange. This transformation can also be achieved at 65-80 °C in *t*-BuOH[19] or polyethylene glycol.[2b] Although the slow rate and the need to use excess reagent makes other stronger complex hydrides such as ***Lithium Borohydride*** or ***Lithium Aluminum Hydride*** best suited for this reaction, in particular cases the use of $NaBH_4$ allows interesting selectivity: see, for example, the reduction of eq 2,[20] where the β-lactam remains unaffected, or of eq 3,[21] where the epoxide and the cyano group do not react.

Borohydrides cannot be used for the reduction of α,β-unsaturated esters to allylic alcohols since the conjugate reduction is faster.[18b] The reactivity of $NaBH_4$ toward esters has been enhanced with various additives. For example, the system $NaBH_4$-$CaCl_2$ (2:1) shows a reactivity similar to $LiBH_4$.[18b] Esters have also been reduced with $NaBH_4$-***Zinc Chloride*** in the presence of a tertiary amine,[22] or with $NaBH_4$-***Copper(II) Sulfate***. The latter system reduces selectively aliphatic esters in the presence of aromatic esters of amides.[23] Finally,

esters have also been reduced with $NaBH_4$-***Iodine***.[24a] In this case the reaction seems to proceed through diborane formation, and so it cannot be used for substrates containing an alkenic double bond. A related methodology, employing ***Borane-Dimethyl Sulfide*** in the presence of catalytic $NaBH_4$,[25] is particularly useful for the regioselective reduction of α-hydroxy esters, as exemplified by the conversion of (*S*)-diethyl malate into the vicinal diol (eq 4).

Lactones are only slowly reduced by $NaBH_4$ in alcohol solvents at 25 °C, unless the carbonyl is flanked by an α-heteroatom functionality.[1d] Sugar lactones are reduced to the diol when the reduction is carried out in water at neutral pH, or to the lactol when the reaction is performed at lower (~3) pH.[26] Thiol esters are more reactive and are reduced to primary alcohols with $NaBH_4$ in EtOH, without reduction of ester substituents.[27]

Carboxylic acids are not reduced by $NaBH_4$. The conversion into primary alcohols can be achieved by using $NaBH_4$ in combination with powerful Lewis acids,[1k,28] ***Sulfuric Acid***,[28] ***Catechol***,[24b] ***Trifluoroacetic Acid***,[24b] or I_2.[24a] In these cases the actual reacting species is a borane, and thus hydroboration of double bonds present in the substrate can be a serious side reaction. Alternatively, the carboxylic acids can be transformed into activated derivatives,[29] such as carboxymethyleneiminium salts[29a] or mixed anhydrides,[29b] followed by reduction with $NaBH_4$ at low temperature. These methodologies tolerate the presence of double bonds, even if conjugated to the carboxyl.[29a]

Nitriles are, with few exceptions,[21] not reduced by $NaBH_4$.[1k] Sulfurated $NaBH_4$,[30] prepared by the reaction of sodium borohydride with sulfur in THF, is somewhat more reactive than $NaBH_4$, and reduces aromatic nitriles (but not aliphatic ones) to amines in refluxing THF. Further activation has been realized by using the ***Cobalt Boride*** system, ($NaBH_4$-$CoCl_2$) which appears to be one of the best methods for the reduction of nitriles to primary amines. More recently it has been found that ***Zirconium(IV) Chloride***,[31] Et_2SeBr_2,[32] $CuSO_4$,[23] ***Chlorotrimethylsilane***,[33] and I_2[24a] are also efficient activators for this transformation. The $NaBH_4$-Et_2SeBr_2 reagent allows the selective reduction of nitriles in the presence of esters or nitro groups, which are readily reduced by $NaBH_4$-$CoCl_2$.

$NaBH_4$ in alcoholic solvents does not reduce amides.[1a,1c-d] However, under more forcing conditions ($NaBH_4$ in pyridine at reflux), reduction of tertiary amides to the corresponding amines can be achieved.[32] Secondary amides are inert, while primary amides are dehydrated to give nitriles. Also, $NaBH_4$-Et_2SeBr_2 is specific for tertiary amides.[32] Reagent combinations which show enhanced reactivity, and which are thus employable for all three types of amides, are $NaBH_4$-$CoCl_2$, $NaBH_4$ in the presence of strong acids[34] (e.g. ***Methanesulfonic Acid*** or ***Titanium(IV) Chloride***) in DMF or DME, $NaBH_4$-Me_3SiCl,[33] and $NaBH_4$-I_2.[24a]

An indirect method for the reduction of amides to amines by $NaBH_4$ (applicable only to tertiary amides) involves conversion into a Vilsmeier complex [$(R_2N{=}C(Cl)R)^+Cl^-$], by treatment with ***Phosphorus Oxychloride***, followed by its reduction.[35] In a related methodology, primary or secondary (also cyclic) amides are first converted into ethyl imidates by the action of ***Triethyloxonium Tetrafluoroborate***, and the latter reduced to amines with $NaBH_4$ in EtOH or, better, with $NaBH_4$-***Tin(IV) Chloride*** in Et_2O.[36]

In addition to the above-quoted methods, tertiary δ-lactams have been reduced to the corresponding cyclic amines by dropwise addition of MeOH to the refluxing mixture of $NaBH_4$ and substrate in *t*-BuOH,[37] or by using trifluoroethanol as solvent.[38] This reaction was applied during a synthesis of indolizidine alkaloid swainsonine for the reduction of lactam (**1**) to amine (**2**) (eq 5).[38]

Acyl chlorides can be reduced to primary alcohols by reduction in aprotic solvents such as PEG,[2a] or using $NaBH_4$-***Alumina*** in Et_2O.[39] More synthetically useful is the partial reduction to the aldehydic stage, which can be achieved by using a stoichiometric amount of the reagent at -70 °C in DMF-THF,[40] with the system $NaBH_4$-***Cadmium Chloride***-DMF,[41] or with ***Bis(triphenylphosphine)copper(I) Borohydride***.

Alternative methodologies for the indirect reduction of carboxylic derivatives employ as intermediates 2-substituted 1,3-benzoxathiolium tetrafluoborates (prepared from carboxylic acids, acyl chlorides, anhydrides, or esters)[42] and dihydro-1,3-thiazines or dihydro-1,3-oxazines (best prepared from nitriles).[43] These compounds are smoothly reduced by $NaBH_4$, to give acetal-like adducts, easily transformable into the corresponding aldehydes by acidic hydrolysis. Conversion of primary amides into the *N*-acylpyrrole derivative by reaction with 1,4-dichloro-1,4-dimethoxybutane in the presence of a cationic exchange resin, followed by $NaBH_4$ reduction, furnished the corresponding aldehydes.[44]

Cyclic anhydrides are reduced by $NaBH_4$ to lactones in moderate to good yields. Hydride attack occurs principally at the carbonyl group adjacent to the more highly substituted carbon atom.[45] Cyclic imides are more reactive than amides and can be reduced to the corresponding α´-hydroxylactams by using methanolic or ethanolic $NaBH_4$ in the presence of HCl as buffering agent.[1c] These products are important as precursors for *N*-acyliminium salts. The carbonyl adjacent to the most substituted carbon is usually preferentially reduced[46] (see ***Cobalt Boride***). *N*-Alkylphthalimides may be reduced with $NaBH_4$ in 2-propanol to give an open-chain hydroxy-amide which, upon treatment with AcOH, cyclizes to give phthalide (a lactone) and the free amine. This method represents a convenient procedure for releasing amines from phthalimides under nonbasic conditions.[47]

Reduction of C=N Double Bonds.

The C=N double bond of imines is generally less reactive than the carbonyl C=O toward reduction with complex hydrides. However, imines may be reduced by $NaBH_4$ in alcoholic solvents under neutral conditions at temperatures ranging from 0 °C to that of the refluxing solvent.[1c,1d,48] Protonation or complexation with a Lewis acid of the imino nitrogen dramatically increases the rate of reduction.[1i] Thus $NaBH_4$ in AcOH (see ***Sodium Triacetoxyborohydride***) or in other carboxylic acids is an efficient reagent for this transformation (although the reagent of choice is probably ***Sodium Cyanoborohydride***). Imines are also reduced by ***Cobalt Boride***, $NaBH_4$-***Nickel(II) Chloride***, and $NaBH_4$-$ZrCl_4$.[31] Imine formation, followed by in situ reduction, has been used as a method for synthesis of unsymmetrical secondary amines.[48] Once again, $Na(CN)BH_3$ represents the best reagent.[1c,1d,48] However, this transformation was realized also with $NaBH_4$,[48,49] either by treating the amine with excess aqueous formaldehyde followed by $NaBH_4$ in MeOH, or $NaBH_4$-CF_3CO_2H, or through direct reaction of the amine with the $NaBH_4$-carboxylic acid system. In the latter case, part of the acid is first reduced in situ to the aldehyde, which then forms an imine. The real reagent involved is $NaB(OCOR)_3H$ (see ***Sodium Triacetoxyborohydride***). Reaction of an amine with glutaric aldehyde and $NaBH_4$ in the presence of H_2SO_4 represents a good method for the synthesis of *N*-substituted piperidines.[49c] Like protonated imines, iminium salts are readily reduced by $NaBH_4$ in alcoholic media.[1c,50] *N*-Silylimines are more reactive than *N*-alkylimines. Thus α-amino esters can be obtained by reduction of *N*-silylimino esters.[51] α,β-Unsaturated imines are reduced by $NaBH_4$ in alcoholic solvents in the 1,2-mode to give allylic amines.[52] Enamines are transformed into saturated amines by reduction with $NaBH_4$ in alcoholic media.[48,53]

The reduction of oximes and oxime ethers is considerably more difficult and cannot be realized with $NaBH_4$ alone. Effective reagent combinations for the reduction of oximes include sulfurated $NaBH_4$,[30] $NaBH_4$-$NiCl_2$, $NaBH_4$-$ZrCl_4$,[31] $NaBH_4$-MoO_3,[54] $NaBH_4$-$TiCl_4$,[55] and $NaBH_4$-***Titanium(III) Chloride***.[56] In all cases the main product is the corresponding primary amine. $NaBH_4$-$ZrCl_4$ is efficient also for the reduction of oxime ethers. $NaBH_4$-MoO_3 reduces oximes without affecting double bonds, while $NaBH_4$-$NiCl_2$ reduces both functional groups. The reduction with $NaBH_4$-$TiCl_3$ in buffered (pH 7) aqueous media has been used for the chemoselective reduction of α-oximino esters to give α-amino esters (eq 6).[56]

(6)

$NaBH_4$ reduces hydrazones only when they are *N*,*N*-dialkyl substituted. The reaction is slow and yields are not usually satisfactory.[57] More synthetically useful is the reduction of *N*-*p*-tosylhydrazones to give hydrocarbons,[1c,1d,58] which has been carried out with $NaBH_4$ in refluxing MeOH, dioxane, or THF.[58] Since *N*-*p*-tosylhydrazones are easily prepared from aldehydes or ketones, the overall sequence represents a mild method for carbonyl deoxygenation. α,β-Unsaturated tosylhydrazones show a different behavior yielding, in MeOH, the allylic (or benzylic) methyl ethers.[58c] The reduction of tosylhydrazones with $NaBH_4$ is not compatible with ester groups, which are

readily reduced under these conditions. More selective reagents for this reduction are $NaBH(OAc)_3$ and $NaCNBH_3$.

Reduction of Halides, Sulfonates, and Epoxides.

The reduction of alkyl halides or sulfonates by $NaBH_4$ is not an easy reaction.[1d] It is best performed in polar aprotic solvents[59] such as DMSO, sulfolane, HMPA, DMF, diglyme, or PEG (polyethylene glycol),[2a] at temperatures between 60 °C and 100 °C (unless for highly reactive substrates), or under phase-transfer conditions.[60a] The mechanism is believed to be S_N2 (I > Br > Cl and primary > secondary). Although the more nucleophilic ***Lithium Triethylborohydride*** seems better suited for these reductions,[59b] the lower cost of $NaBH_4$ and the higher chemoselectivity (for example esters, nitriles, and sulfones can survive)[59a] makes it a useful alternative. Also, some secondary and tertiary alkyl halides, capable of forming relatively stable carbocations, for example benzhydryl chloride, may be reduced by $NaBH_4$. In this case the mechanism is different (via a carbocation) and the reaction is accelerated by water.[59a,b] Primary, secondary, and even aryl iodides and bromides[1d] have been reduced in good yields by $NaBH_4$ under the catalysis of soluble polyethylene- or polystyrene-bound tin halides (PE-$Sn(Bu)_2Cl$ or PS-$Sn(Bu)_2Cl$).[61] Aryl bromides and iodides have also been reduced with $NaBH_4$-***Copper(I) Chloride*** in MeOH.[62]

$NaBH_4$ reduces epoxides only sluggishly.[1d] Aryl-substituted and terminal epoxides can be reduced by slow addition of MeOH to a refluxing mixture of epoxide and $NaBH_4$ in *t*-BuOH,[63] or by $NaBH_4$ in polyethylene glycol.[2b] The reaction is regioselective (attack takes place on the less substituted carbon), and chemoselective (nitriles, carboxylic acids, and nitro groups are left intact).[63] The opposite regioselectivity was realized by the $NaBH_4$-catalyzed reduction with diborane.[64]

Other Reductions.

Aromatic and aliphatic nitro compounds are not reduced to amines by $NaBH_4$ in the absence of an activator.[1d] The $NaBH_4$-$NiCl_2$ system (see ***Nickel Boride***) is a good reagent combination for this reaction, being effective also for primary and secondary aliphatic compounds. Other additives that permit $NaBH_4$ reduction are $SnCl_2$,[65] Me_3SiCl,[33] $CoCl_2$ (see ***Cobalt Boride***), and MoO_3 (only for aromatic compounds),[66] Cu^{2+} salts (for aromatic and tertiary aliphatic),[23,67] and ***Palladium on Carbon*** (good for both aromatic and aliphatic).[68] Also, sulfurated $NaBH_4$[30] is an effective and mild reducing agent for aromatic nitro groups. In the presence of catalytic selenium or tellurium, $NaBH_4$ reduces nitroarenes to the corresponding *N*-arylhydroxylamines.[69]

The reduction of azides to amines proceeds in low yield under usual conditions, but it can be performed efficiently under phase-transfer conditions,[60b] using $NaBH_4$ supported on an ion-exchange resin,[70] or using a THF-MeOH mixed solvent (this last method is well suited only for aromatic azides).[71]

Tertiary alcohols or other carbinols capable of forming a stable carbocation have been deoxygenated by treatment with $NaBH_4$ and CF_3CO_2H or $NaBH_4$-CF_3SO_3H.[72] Under the same conditions,[72] or with $NaBH_4$-***Aluminum Chloride***,[73] diaryl ketones have also been deoxygenated.

Cyano groups α to a nitrogen atom can be replaced smoothly by hydrogen upon reaction with $NaBH_4$.[74] Since α-cyano derivatives of trisubstituted amines can be easily alkylated with electrophilic agents, the α-aminonitrile functionality can be used as a latent α-amino anion,[74a] as exemplified by eq 7 which shows the synthesis of ephedrine from a protected aminonitrile. The reduction, proceeding with concurrent benzoyl group removal, is only moderately stereoselective (77:23).

(7)

Primary amines have been deaminated in good yields through reduction of the corresponding bis(sulfonimides) with $NaBH_4$ in HMPA at 150-175 °C.[75] $NaBH_4$ reduction of ozonides is rapid at -78 °C and allows the one-pot degradation of double bonds to alcohols[1b] (see also ***Ozone***). The reduction of organomercury(II) halides (see also ***Mercury(II) Acetate***) is an important step in the functionalization of double bonds via oxymercuration-or amidomercuration-reduction. This reduction, which proceeds through a radical mechanism, is not stereospecific, but it can be in some cases diastereoselective.[76] In the presence of ***Rhodium(III) Chloride*** in EtOH, $NaBH_4$ completely saturates arenes.[77] $NaBH_4$ has also been employed for the reduction of quinones,[78] sulfoxides (in combination with ***Aluminum Iodide***[79]

or Me_3SiCl[33]), and sulfones (with Me_3SiCl),[33] although it does not appear to be the reagent of choice for these reductions. Finally, $NaBH_4$ was used for the reduction of various heterocyclic systems (pyridines, pyridinium salts, indoles, benzofurans, oxazolines, and so on).[1c,1d,48,80] The discussion of these reductions is beyond the scope of this article.

Diastereoselective Reductions.

$NaBH_4$, like other small complex hydrides ($LiBH_4$ and $LiAlH_4$), shows an intrinsic preference for axial attack on cyclohexanones,[1c,1d,81] as exemplified by the reduction of 4-*t*-butylcyclohexanone (eq 8).[81a] This preference, which is due to stereoelectronic reasons,[82] can be counterbalanced by steric biases. For example, in 3,3,5-trimethylcyclohexanone, where a β-axial substituent is present, the stereoselectivity is nearly completely lost (eq 9).[81a]

Also, in 2-methylcyclopentanone[81c] the attack takes place from the more hindered side, forming the *trans* isomer (dr = 74:26). In norcamphor,[81a] both stereoelectronic and steric effects favor *exo* attack, forming the *endo* alcohol in 84:16 diastereoisomeric ratio. In camphor, however, the steric bias given by one of the two methyls on the bridge brings about an inversion of stereoselectivity toward the *exo* alcohol.[81a]

The stereoselectivity for equatorial alcohols has been enhanced by using the system $NaBH_4$-***Cerium(III) Chloride***, which has an even higher propensity for attack from the more hindered side,[83] or by precomplexing the ketone on ***Montmorillonite K10*** clay.[84] On the other hand, bulky trialkylborohydrides (see ***Lithium Tri-s-butylborohydride***) are best suited for synthesis of the axial alcohol through attack from the less hindered face.

$NaBH_4$ does not seem to be the best reagent for the stereoselective reduction of chiral unfunctionalized acyclic ketones. Bulky complex hydrides such as $Li(s\text{-}Bu)_3BH$ usually afford better results.[1c,1d] When a heteroatom is present in the α- or β-position, the stereochemical course of the reduction depends also on the possible intervention of a cyclic chelated transition state. Also, in this case other complex hydrides are often better suited for favoring chelation (see ***Zinc Borohydride***). Nevertheless, cases are known[85] where excellent degrees of stereoselection have been achieved with the simpler and less expensive $NaBH_4$. Some examples are shown in eqs 10-15.

(11)

(12)

(13)

(14)

(15)

The stereoselective formation of *anti* adduct (**4**) in the reduction of ketone (**3**) was explained through the intervention of a chelate involving the methoxy group,[85a] although there is some debate on what the acidic species is that is coordinated (probably Na^+). A chelated transition state is probably the cause of the stereoselective formation of *anti* product (**6**) from (**5**).[85b] Methylation of the NH group indeed provokes a decrease of stereoselection. On the other hand, when appropriate protecting groups that disfavor chelation are placed on the heteroatom, the reduction proceeds by way of the Felkin model where the heteroatomic substituent plays the role of large group, and *syn* adducts are formed preferentially. This is the case of α-dibenzylamino ketones (eqs 12 and 13)[85c,d] and of the α-silyloxy ketone of eq 14.[85e] Finally, the sulfonium salt of eq 15 gives, with exce llent stereocontrol, the *anti* alcohol.[85f] This result was explained by a transition state where the S^+ and carbonyl oxygen are close due to a charge attraction.

The reduction of a diastereomeric mixture of enantiomerically pure β-keto sulfoxides (**7**) furnished one of the four possible isomers with good overall stereoselectivity (90%), when carried out under conditions which favor epimerization of the α chiral center (eq 16). This outcome derives from a chelation-controlled reduction (involving the sulfoxide oxygen) coupled with a kinetic resolution of the two

diastereoisomers of (7).[86]

The reduction of cyclic imines and oximes follows a trend similar to that of corresponding ketones. However, the tendency for attack from the most hindered side is in these cases attenuated.[1c,1d,57,87] In the case of oximes, while $NaBH_4$-MoO_3 attacks from the axial side, $NaBH_4$-$NiCl_2$ attacks from the equatorial side.[88] An example of diastereoselective reduction of acyclic chiral imines is represented by the one-pot transformation of α-alkoxy or α,β-epoxynitriles into *anti* vicinal amino alcohols (eq 17) or epoxyamines. The outcome of these reductions was explained on the basis of a cyclic chelated transition state.[89]

Enantioselective Reductions.

$NaBH_4$ has been employed with less success than $LiAlH_4$ or BH_3 in enantioselective ketone reductions.[1d,90,91] Low to moderate ee values have been obtained in the asymmetric reduction of ketones with chiral phase-transfer catalysts, chiral crown ethers,[91a] β-cyclodextrin,[91b] and bovine serum albumin.[91c] On the other hand, good results have been realized in the reduction of propiophenone with $NaBH_4$ in the presence of isobutyric acid and of diisopropylidene-D-glucofuranose (ee = 85%),[91d] or in the reduction of α-keto esters and β-keto esters with $NaBH_4$-L-tartaric acid (ee &egt;86%).[91e]

Very high ee values have been obtained in the asymmetric conjugate reduction of α,β-unsaturated esters and amides with $NaBH_4$ in the presence of a chiral semicorrin (a bidentate nitrogen ligand) cobalt catalyst.[92] Good to excellent ee values were realized in the reduction of oxime ethers with $NaBH_4$-$ZrCl_4$ in the presence of a chiral 1,2-amino alcohol.[93]

Sodium Bromate

$NaBrO_3$

[7789-38-0] · $BrNaO_3$ · Sodium Bromate · (MW 150.89)

(in combination with CAN, oxidizes alcohols to carbonyl compounds;[1] oxidizes other functional groups; promotes oxidative cleavage of ethers[2])

Physical Data: mp about 381 °C decomposing with evolution of oxygen; *d* 3.34 g cm^{-3}.

Solubility: sol 2.5 parts water, 1.1 parts boiling water; almost insol alcohol; sodium bromate is more soluble in water than potassium bromate.

Form Supplied in: colorless crystals or white granules or powder; widely available. *Drying:* for analytical work dry at 100-110 °C for 1 h.

Handling, Storage, and Precautions: sodium bromate is a strong oxidizing agent (standard potential is 1.44 V); toxicity is low; should be kept from contact with mineral acids and organic compounds during storage.

Oxidation of Alcohols.

Sodium bromate, when used with catalytic amounts of cerium(IV) salts, oxidized arylmethanols to the corresponding ketones and aldehydes (eq 1).[3] The sodium bromate serves to continuously replenish the more expensive oxidant, ***Cerium(IV) Ammonium Nitrate*** (CAN).

(1)

Sodium bromate was superior to other oxidants in the transition metal-catalyzed oxidation of alcohols to carbonyl compounds.[1] Primary alcohols were recovered practically unchanged. Selective oxidations were observed in mixed primary/secondary alcohol systems (eq 2). However, alkenic moieties even several carbon atoms removed from the hydroxyl group interrupted the oxidation.[1] Oxidations using polymer-supported Ce^{IV}, which are not affected by the alkene moiety in the substrate, provide a useful extension of this method.[4]

(2)

Secondary alcohols could also be oxidized using ruthenium derivatives in combination with sodium bromite.[1] Oxidation of primary alcohols to aldehydes could be achieved without overoxidation using sodium bromate and dodecacarbonyltriruthenium(0) or sodium bromate and buffered ***Ruthenium(III) Chloride***.[1] Metal-catalyzed oxidation technology has recently been reviewed.[5] Secondary alcohols are oxidized to ketones with ***Sodium Bromite*** in aqueous acetic acid in the absence of a metal catalyst.[6] Oxidative esterification of primary alcohols to the corresponding ester occurs in good yield with sodium bromite.[6]

Oxidation of hydroquinone derivatives to produce the quinones has been reported with sodium bromate in acetic acid.[7] Oxidations of hydroquinones using sodium bromate and CAN in the solid state[8] and in solution[9] have also been reported (eq 3).

(3)

Oxidation of Other Functional Groups.

The oxidation of sulfides to sulfoxides has been reviewed.[10] A mixture of sodium bromate and bromide in hydrochloric acid solution, which generates a solution of bromine, oxidized sulfides to the sulfoxides.[11] ***Potassium Bromate*** in the absence of added bromide also oxidized thiophenol to diphenyl disulfide or benzenesulfonic acid depending on the conditions.[12] 4,4-Dinitrodiphenyl sulfide was oxidized to the sulfone in excellent yield.[12]

Catalytic amounts of CAN and sodium bromate have been shown to oxidize diaryl sulfides and dialkyl sulfides to the corresponding sulfoxide without overoxidation to the sulfone.[9] In contrast, using CAN alone, dialkyl sulfides were found to undergo the Pummerer rearrangement.[13] Sodium bromite also oxidizes alkyl and aryl sulfides to the sulfoxide.[6]

Catalytic ring opening of epoxides has been reported using polymer-supported cerium(IV) catalysts (eq 4).[14] A mixture of sodium bromate in nitric acid is used to regenerate the catalytic activity. Potassium bromate also oxidizes dialkylhydrazine derivatives to the tetraalkyltetrazenes.[15] Benzaldehyde has been oxidized to benzoic acid using potassium bromate.[16] However, sodium bromate and CAN were not effective for the oxidation of 1,4-dihydropyridines to the pyridine derivatives.[17]

(4)

Oxidative Cleavage of Ethers.[18]

Methyl, ethyl, trimethylsilyl, and *t*-butyldimethylsilyl ethers readily undergo oxidative cleavage to afford the corresponding carbonyl compounds with a catalytic amount of CAN and a molar equivalent of sodium bromate (eq 5).[2] The reaction proceeds smoothly in refluxing aqueous acetonitrile. The reactivity of sodium bromate and CAN approaches that of Jones/KF (see ***Chromic Acid***) and PDC/Me_3SiCl/CH_2Cl_2 (see ***Pyridinium Dichromate***) for the oxidative deprotection and oxidation of alcohols.[18] The selectivity of $NaBrO_3$/CAN for the oxidation of alcohols in the presence of silyl ethers, or the selective oxidation of primary or secondary silyl ethers, has not been extensively explored.[18]

(5)

A selective oxidation of a primary alcohol in the presence of a *t*-butyldimethylsiloxy group has been reported with sodium bromite.[19]

Related Reagents.

Cerium(IV) Ammonium Nitrate-Sodium Bromate.

Sodium Bromide

NaBr

[7647-15-6] · BrNa · Sodium Bromide · (MW 102.89)

(source of bromide ion as nucleophile; precursor to bromine electrophiles)

Physical Data: mp 755 °C; *d* 3.21 g cm^{-3}.

Solubility: very sol water; sol methanol, ethanol.

Form Supplied in: colorless, odorless crystals, granules, or powder. *Drying:* is hygroscopic and should be dried at 140 °C for applications that require the anhydrous salt.

Handling, Storage, and Precautions: should be taken directly from the oven when dryness is required. NaBr is of low toxicity.

Source of Bromide Nucleophile.

Sodium bromide is an inexpensive source of bromide anion for service as a nucleophile or nucleophilic catalyst. In alcoholic and dipolar aprotic solvents, NaBr converts the sulfonate esters of primary and secondary alcohols to the corresponding alkyl bromides.[1] Sodium bromide cleanly converts primary alkyl chlorides to bromides, provided that a large excess of ethyl bromide or dibromomethane is added as a chloride ion scavenger.[2] In the presence of Dowex-50 ion exchange resin, NaBr opens epoxides to bromohydrins.[3] ***Bromotrimethylsilane*** can be generated in situ from ***Chlorotrimethylsilane*** and NaBr, and then used to convert aldehydes and ketones to silyl enol ethers under mild conditions with significant regio- and stereoselectivity.[4]

Precursor to Bromine Electrophiles.

Chemical or electrochemical oxidation of sodium bromide generates reactive electrophilic bromine species, which can effect a variety of useful transformations. A mixture of NaBr and ***Peracetic Acid*** oxidizes secondary alcohols to ketones, primary benzylic alcohols to aldehydes, primary aliphatic alcohols to dimeric esters, and α,o-diols to lactones.[5] The reaction conditions, which appear to involve the formation of acetyl hypobromite, provide an inexpensive and less toxic alternative to chromium oxidants. By combining NaBr and $NaBrO_2$, it is possible to generate hypobromite ion without using elemental bromine. This mixture of salts effects the Hofmann degradation of primary amides to generate amines and promotes the bromoform reaction of methyl ketones to generate carboxylic acids.[6] Organoboranes are brominolyzed to bromoalkanes or bromoalkenes upon treatment with bromine

chloride, which can be generated by reaction of NaBr with ***Chlorine***, ***Chloramine-T***, or ***N-Chlorosuccinimide***.[7] This procedure allows the preparation of radiobrominated organic compounds from radioactive NaBr. Sodium bromide is useful as an electrolyte in electrochemical oxidations, generating electrophilic bromine species which can react with organic substrates. Under suitable conditions, alkenes are epoxidized,[8] alcohols are oxidized,[9] and methyl ketones are converted to methyl esters.[10]

Miscellaneous Uses.

Raney Nickel modified with tartaric acid and NaBr is an inexpensive catalyst, suitable for the large-scale reduction of methyl ketones and 1,3-dicarbonyl compounds to optically active alcohols in moderate enantiomeric excesses.[11]

Sodium Bromite[1]

$NaBrO_2$

[7486-26-2] · $BrNaO_2$ · Sodium Bromite · (MW 134.89)

(selective oxidant; oxidizes secondary in preference to primary alcohols, and α,o-diols to lactones; sulfides oxidized to sulfoxides; can be used for Hofmann degradation)

Solubility: sol H_2O (28 g/100 mL at 0 °C; 91 g/100 mL at 100 °C); insol most organic solvents.

Form Supplied in: aqueous solution.

Analysis of Reagent Purity: titration with Na_3AsO_3.

Preparative Methods: the commercial reagent is concentrated under reduced pressure below -30 °C to produce the trihydrate. Anhydrous material is obtained by crystallization from aqueous 2N NaOH followed by drying (20 °C/5 mmHg).

Purification: crystallization as above.

Handling, Storage, and Precautions: refrigerate, thermally labile; handle in a fume hood.

Oxidation of Alcohols.

Sodium bromite oxidizes a range of secondary alcohols to the corresponding ketones (eq 1) in aqueous acetic acid.[2] If the reagent is used in the presence of ***Alumina***, other solvents can be used, in particular dichloromethane, thereby simplifying product isolation (eq 2).[3] Selective oxidation of a primary-secondary diol results in the formation of the hydroxy ketone (eq 3),[2] whereas oxidation of a primary alcohol produces the ester rather than the corresponding aldehyde (eq 4).[4] Following this pattern of reactivity, α,o-diols give good yields of lactones (eq 5).[4]

(1)

(2)

(3)

(4)

(5)

A catalytic quantity of metals and metal salts (such as Cu, Cu^{2+}, Fe^{3+}, Al^{3+}) has been reported to improve the oxidation of various types of alcohols to ketones, lactones, and diones.[5] Sodium bromite has been used as the stoichiometric oxidant in oxidations of alcohols catalyzed by *N*-oxyl compounds such as (**1**), conditions which allow for the oxidation of primary alcohols to aldehydes (eqs 6 and 7) or acids depending on the conditions (eq 8).[6] Primary alcohols are oxidized in preference to secondary alcohols (eq 9).

(1)

(6)

(7)

(8)

(9)

Oxidation of Sulfides to Sulfoxides.

The oxidation of sulfides to sulfoxides with sodium bromite is often highly selective, with little or no sulfone being produced, and it is possible to avoid oxidation of other potentially reactive functional groups (eqs 10 and 11).[2] This oxidation can be performed very effectively in the presence of wet ***Montmorillonite K10*** (eq 12).[7]

(10)

(11)

(12)

Other Applications.

Sodium bromite has been used for a number of other oxidations, including the generation of nitrile oxides for dipolar cycloadditions (eq 13),[8] the conversion of alkenes to α-bromo ketones (eq 14),[9] the preparation of *N*-bromoamides (eq 15),[10] and the Hofmann degradation (eq 16).[11]

Sodium Carbonate

Na_2CO_3

[497-19-8] · CNa_2O_3 · Sodium Carbonate · (MW 105.99)

(widely used base)

Physical Data: mp 851 °C; *d* 2.532 g cm^{-3}.

Solubility: sol glycerol, water.

Form Supplied in: white powder.

Handling, Storage, and Precautions: moderately toxic; severe irritant; noncombustible; stable; decomposition occurs slowly above 400 °C to give carbon dioxide and sodium oxide; incompatible with strong acids and aluminum; hygroscopic.

Selective Hydrolysis.

Cyanoethylated β-keto esters can be hydrolyzed with aqueous sodium carbonate to the corresponding δ-keto nitrile (eq 1).[1] The use of sodium hydroxide in this reaction leads to hydrolysis of the nitrile, affording the keto acid.

(1)

The selective hydrolysis of esters in the presence of acetyl-protected amines can be achieved with aqueous sodium carbonate (eq 2).[2]

(2)

McFadyen-Stevens Reduction.

The decomposition of sulfonylhydrazines to aldehydes was achieved using sodium carbonate as base. The sulfonylhydrazine was heated in ethylene glycol to 150 °C, and 4-6 equiv of sodium carbonate added. The reaction is complete in approximately 30 s. This reaction has been applied to the formation of aromatic,[3] heterocyclic,[3] and aliphatic aldehydes (eq 3).[4]

Carbon-Carbon Bond Forming Reactions.

The reaction of β-keto esters with α,β-unsaturated aldehydes in the presence of sodium carbonate and a phase-transfer catalyst afforded the Michael addition product (eq 4).[5] The use of sodium hydroxide in this reaction led to substantial decomposition.

This methodology was used to prepare 3-oxo-5-phenyl-1-cyclohexene from ethyl acetoacetate and cinnamic acid (eq 5).[5] Under the same conditions, β-cyano esters and α,β-unsaturated aldehydes undergo Knoevenagel condensation (eq 6).[5]

Hydrogenation.

Sodium carbonate is an effective acid scavenger for hydrogenations. The hydrogenation of *m*-nitro-*O*-benzoylmandelate with ***Raney Nickel*** and sodium carbonate in ethanol at 180 °C afforded the ethyl ester of *m*-aminophenylacetic acid (eq 7).[6] Other bases were found to be less effective in removing the benzoic acid, resulting in slow and incomplete reactions. Sodium carbonate is also used in the sodium hydrophosphite hydrogenations of many functional groups.[7]

(7)

Synthesis of Phenyliodonium β-Diketonates.

β-Diketones react with ***(Diacetoxyiodo)benzene*** in the presence of sodium carbonate to afford phenyliodonium β-diketonates (eq 8).[8] Ozonolysis of the phenyliodonium β-diketonates provides an efficient synthesis of triketones.

(8)

Other Applications.

Sodium carbonate is used in the alkylation of amines,[9] debromination,[10] hydrolysis,[11] imidazoline synthesis,[12] as a buffer,[13] and a neutralization agent.[14]

Related Reagents.

Barium Hydroxide; ***Cadmium Carbonate***; ***Calcium Carbonate***; ***Cesium Carbonate***; ***Lithium Carbonate***; ***Potassium Carbonate***; ***Potassium Hydroxide***; ***Sodium Hydroxide***.

Giba-Geigy, Summit, NJ, USA

Sodium Chlorite[1]

$NaClO_2$

[7758-19-2] · $ClNaO_2$ · Sodium Chlorite · (MW 90.44)

(mild and selective reagent for the oxidation of all types of aldehydes to carboxylic acids at room temperature[16,17])

Physical Data: mp 180-200 °C (dec).

Solubility: 39 g/100 ml H_2O (17 °C); slightly sol MeOH.

Form Supplied in: white solid; widely available as technical grade material (ca. 80%; the rest is mainly NaCl).

Analysis of Reagent Purity: iodometric titration at pH 2.

Purification: technical grade material can be used as received. Crystallization from H_2O gives $NaClO_2.3H_2O$ which dehydrates at >37 °C.

Handling, Storage, and Precautions: decomposition at >175 °C is highly exothermic. The reagent is not shock sensitive unless contaminated with organic materials. Causes severe irritation or burns to skin and eyes. Acute oral LD_{50} 180 mg kg^{-1} (rat, 80% assay material).

Oxidation of Aldehydes to Carboxylic Acids.

First employed in cellulose chemistry,[2] the reagent is now widely used for the oxidation of saturated,[3-8] α,β-unsaturated,[9-15] aromatic,[8,13,16,17] and heteroaromatic[13] aldehydes to the corresponding carboxylic acids (eq 1). The high yields, selectivity, mild conditions, and ease of workup make this the method of choice for most RCHO to RCO_2H conversions. For example, with allylic primary alcohols[13] it is advantageous to carry out a two-step $MnO_2/NaClO_2$ process instead of a direct oxidation using Cr^{VI} or Ag^{I} because of higher purity and yield. The hypochlorite formed (eq 1) may interfere with the substrate or the product, or react with the reagent to give ClO_2 (eq 2), which also may have an adverse effect.

$$RCHO + HClO_2 \longrightarrow RCO_2H + HOCl \qquad (1)$$

$$HOCl + 2\,ClO_2^- \longrightarrow 2\,ClO_2 + Cl^- + OH^- \qquad (2)$$

To eliminate the various unwanted positive Cl species present, the reaction is therefore usually conducted in the presence of a scavenger (Table 1). The use of resorcinol has the drawback that the byproduct formed (4-chlororesorcinol) must be removed from the carboxylic acid in a separate step.

Table 1 The Reported Areas of Applicability and Functional Group Tolerances or Incompatibilities of Various ClO_2 Oxidation Procedures[a]

	Cl scavenger					
	H_2NSO_3H	Resor-cinol	$Me_2C=CHMe$	H_2O_2	DMSO	None
R CHO		(+)[3]	(+)[4 7]			(+)[8]
C=C CHO	(-)[15]	(+)[9,10]	(+)[11 14]	(+)[15]	(+)[15]	(-)[8]
C° C CHO, Het CHO				(+)[15,b]

Isolated C=C		yes[10]	yes[7,23]	no[15]		
Conj. diene; acetal			yes[7]			
Cyclopropane			yes[23]			
s-OH		yes[9]	yes[7]			no[18]
R_2CH N_3			yes[19]			
p-HO Ar	yes[16,17]	yes[16]		no[15]	yes[15]	yes[8]
o-HO Ar	yes[17]			no[15]	yes[8]	no[8]
p-H_2N- or *p*-MeS Ar				no[15]		
MOM ether			yes[5]			
$PhCH_2$ ether		yes[3]	yes[12]			
TBDMS ether			yes[11,12]			
Allyl ether			yes[11]			
Ester		yes[3,9]	yes[4,7,14]			
Epoxy			yes[4]			
a-Boc-NH ester			yes[6]			
Ketone	yes[17]	yes[9]				yes[8]
b-Lactam, $ArNO_2$		yes[3]				

[a] (+) oxidized in good yield; (-) not oxidized or decomposes; 'yes' = compatible functionality; 'no' = functionality oxidized or compound decomposes. [b] Not pyrrole.

The alkene double bond is retained in oxidations of unsaturated alcohols. In an enantiospecific synthesis[19] of L-amino acids in >92% ee, intermediate chloroboronic esters (obtained from the alkyl Grignards) were directly oxidized to the acids, thus circumventing the problematic

prior conversion to the aldehydes (eq 3).

(3)

Other Oxidations.

Dithiocarbamates are oxidized to isothiocyanates,[20] ArSMe to ArSOMe,[21] RCH_2NO_2 to RCHO, and $R_2CH\text{-}NO_2$ to R_2CO (eq 4).[22]

Sodium Chlorodifluoroacetate

[1895-39-2] · $C_2ClF_2NaO_2$ · Sodium Chlorodifluoroacetate · (MW 152.46)

(generation of difluorocarbene and the synthesis of difluorocyclopropanes and difluoroalkenes)

Physical Data: mp 196-198 °C.

Solubility: sol DME, diglyme (0.60 g mL^{-1}), triglyme, DMF.

Preparative Methods: the salt is prepared by careful neutralization of 130.5 g (1.0 mol) of chlorodifluoroacetic acid in 300 mL of Et_2O with 53 g (0.5 mol) of anhydrous Na_2CO_3. The Et_2O and water are removed under reduced pressure. The salt is then dried in a vacuum desiccator over P_2O_5.[1]

Handling, Storage, and Precautions: is an irritant and is hygroscopic.

Cyclopropanation.

The thermal decomposition of sodium chlorodifluoroacetate produces difluorocarbene, which will react with alkenes to form the difluorocyclopropane. Cyclohexene reacts (eq 1) with the carbene to form the difluorocyclopropane in 11% yield.[2]

(1)

There are times when a change from the sodium salt to the lithium salt results in a higher yield of the cyclopropane (eq 2). In addition to the higher yields, the reaction with the lithium salt was also reported to be cleaner. No stereochemistry for the products of this reaction was reported.[3]

(2)

M = Na^+, 26 %; Li^+, 51%

A change from sodium to lithium can also alter the course of the reaction. The reaction of an *o*-quinone (eq 3) with the sodium salt produces the carbonate, while the lithium salt provides the hydroxy ketone. The exact reason for the different paths followed by the two salts is not known for certain. One explanation was that the sodium salt produced the difluorocarbene directly by a one-step α-elimination and then the carbene underwent a 1,4-addition to the *o*-quinone. The carbonate was then produced by hydrolysis, which would require only 0.05% water to be present in the diglyme.[4]

(3)

A 1,4-addition had been previously observed in the reaction of a *cisoid* β-methoxy enone (eq 4). This reaction affords the 1,4-adduct as a mixture of 3´-methoxy isomers.[5]

(4)

Transoid enones produce the cyclopropane derivatives. The α,β-unsaturated ketone (eq 5) only underwent addition at a temperature of 150 °C, even though the salt was observed to decompose at 125 °C.[6] In the case of a trienone (eq 6), the reaction selectively took place at the carbon-carbon double bond furthest removed from the carbonyl.[7]

(5)

(6)

Similar regiospecificity has been seen in the reaction of a dienone (eq 7) from the prostaglandin area. Again, reaction at the more remote double bond was observed. The reaction was not stereoselective in this case, providing a mixture of stereoisomeric cyclopropanes.[8]

(7)

A mixture of cyclopropanes was also observed for the reaction of a diene lactone with the sodium salt in triglyme (eq 8). Cyclopropanation of the more remote double bond is again preferred.[9]

(8)

The selective difluorocyclopropanation of an α-methylene lactone over an unsaturated ketone was also achieved by reaction with sodium chlorodifluoroacetate. Helenalin acetate (eq 9) afforded a mixture of three products, all resulting from cyclopropanation of the α-methylene group.[10]

(9)

Enol acetates will react with difluorocarbene. The enol acetate of diisobutyl ketone (eq 10) leads to the formation of an unspecified 2:1 mixture of acetoxy difluorocyclopropanes.[11] The enol acetate (eq 11) was selectively cyclopropanated over the 5,6-double bond by controlling the amount of the sodium salt used (~10 mol equiv). The yield in this reaction was 34%, with 53% of the starting enol acetate being recovered.[12]

(10)

(11)

Silyl enol ethers react readily with difluorocarbene. In the case of an α,α-difluoro ketone, the enol acetate was unreactive toward difluorocarbene generated by thermal decomposition of the salt. The trimethylsilyl enol ether reacted rapidly with the carbene to produce the trimethylsilyloxycyclopropane (eq 12). Some of the enol ether underwent hydrolysis to return the ketone under the reaction conditions. The *t*-butyldimethylsilyl enol ether was stable to hydrolysis but reacted at a much slower rate that the trimethylsilyl enol ether.[13]

(12)

A comparison of methods for difluorocarbene formation has shown the thermal decomposition of the salt to be one of the two most effective for the cyclopropanation of butyl (*Z*)-propenyl ether (eq 13). The reaction of the enol ether and 2 equiv of the salt in triglyme at 165 °C for 0.5 h results in a 42% yield of the cyclopropane. The *cis* relationship of the groups on the double bond appears to be maintained in the final product. By using 4 equiv of the salt, the yield could be raised to 53%. The only method found to be superior in terms of yield was the fluoride ion-induced decomposition of (bromodifluoromethyl)triphenylphosphonium bromide.[14]

(13)

Wittig Alkenation.

In the presence of ***Triphenylphosphine***, sodium chlorodifluoroacetate produces the intermediate difluoro ylide. Treatment of benzaldehyde (eq 14) with this reagent combination delivers the difluoroalkene in 74% yield.[15] The reaction reportedly does not work well for ketones when triphenylphosphine is used. Substitution of ***Tri-n-butylphosphine*** and changing the solvent to *N*-

methylpyrrolidone allows cyclohexanone (eq 15) to be transformed in 46% yield to the difluoroalkene.[16]

(14)

(15)

With fluorines on the α-carbon of the carbonyl, the reaction with the salt and triphenylphosphine in DME provides the perfluoroalkenes in good yield. Treatment of 2,2,2-trifluoroacetophenone under these conditions affords the alkene (eq 16) in 68% yield.[1] Changing solvents to DMF causes a dramatic increase in the rate of decomposition of the salt. It also results in an improvement in yield to 84%.[17]

(16)

DME, 3 h	68%
DMF, 0.5 h	84%

When the perfluoroalkyl chain of the ketone is two or more carbons, fluoride ion-catalyzed rearrangement of the initially produced alkene can occur (eq 17). In these cases, the use of the lithium salt is recommended in order to suppress rearrangement.[18]

(17)

M = Na^+, 6.5 h	42%	2%
M = Na^+, 20 h	6%	54%
M = Li^+, 0.5 h	48%	0%

Miscellaneous.

The acyl hypochlorite of chlorodifluoroacetic acid can be prepared by reaction of the sodium salt and Cl-F at low temperature.[19] A substitution product has been isolated from the reaction of a tungsten dihydride with the salt.[20] The crystal structures of the products from the reaction of Vaska's complex, $IrCl(CO)(PPh_3)_2$, with the salt have also been reported.[21] An iridobetaine intermediate has been proposed to account for the observed products.[21c]

Sodium Cyanide[1]

NaCN

[143-33-9] · CNNa · Sodium Cyanide · (MW 49.01)

(preparation of nitriles,[2] cyanohydrins,[3] α-amino nitriles,[4] methyleneamino acetonitriles;[5] catalyst for benzoin condensation[6])

Physical Data: mp 563.7 °C; vp_1 1.0 mmHg (817 °C).

Solubility: sol water; slightly sol ethanol; the aq soln is strongly alkaline and rapidly decomposes.

Form Supplied in: white powder with chunks; widely available.

Purification: Perrin and Armarego[7] for general procedure.

Handling, Storage, and Precautions: highly toxic; severe eye irritant; hygroscopic; readily absorbed through skin. Avoid breathing dust particles. Can be fatal if inhaled, swallowed, or absorbed through skin. Exposure can cause lung irritation and cyanosis (orl-hmn LDLo: 2857 μg kg^{-1}; orl-rat LD_{50}: 6440 μg kg^{-1}). Store in a dry area; use only in a fume hood. Incompatible with acids, strong oxidizing agents, and carbon dioxide. May decompose on exposure to moist air or water. Thermal decomposition produces toxic fumes of hydrogen cyanide, carbon monoxide, carbon dioxide, and nitrogen oxides.

Nitrile Synthesis.

Nitriles can be readily prepared from activated alcohols and halides by treatment with NaCN in an appropriate solvent. The reactivity of NaCN closely parallels ***Potassium Cyanide*** and the review of the latter reagent should also be considered for general reaction conditions. A difference in reactivity, however, was observed in the reaction of NaCN with alkyl chlorides in DMSO.[8] Increased yields and lower reaction times were seen for NaCN compared to KCN (eq 1). The conversion of alkyl bromides to nitriles using NaCN is accomplished under phase-transfer conditions employing primary, secondary, or tertiary amines as catalysts.[9]

$$\text{BuCl} \xrightarrow[93\%]{\text{NaCN, DMSO}\ 140\ ^\circ\text{C}} \text{BuCN} \qquad (1)$$

NaCN has also proved to be the most favorable reagent for the preparation of sodium dicyanocuprate. The cyanocuprate generated in situ reacts readily with vinyl and aryl halides to afford the corresponding nitrile (eq 2).[10] Aryl cyanation can also be effected with NaCN in the presence of catalytic ***Tetrakis(triphenylphosphine)palladium(0)***.[11] This method requires the use of neutral ***Alumina*** either as a support for NaCN or as a cocatalyst.

(2)

Aldehydes can be converted to nitriles by treating the *N*-tosyl imines with NaCN in HMPA (eq 3).[12] Tetrahydropyranyl ethers have also been shown to react with NaCN in the presence of ***Triphenylphosphine Dibromide*** to yield a nitrile (eq 4).[13]

(3)

(4)

The reaction of NaCN with aryl nickel compounds also provides a facile route to aromatic nitriles in high yields (eq 5).[14]

(5)

Cyanohydrin Synthesis.

Cyanohydrins are versatile synthetic intermediates which can be prepared by the reaction of NaCN with aldehydes, although benzoin condensations often compete. The reactions of NaCN with ketones,[15] acid chlorides,[16] and epoxides[17] are much more general. A novel preparation of aryl cyanohydrin esters involves treatment of an acid chloride with NaCN, ***Sodium Borohydride***, and catalytic ***Tetra-n-butylammonium Bromide*** (eq 6).[18] The cyanohydrin anion generated by reduction of the acyl cyanide is immediately captured by any anhydrides or acid chlorides present.

(6)

α-Amino Nitriles.

Cyclopropane hemiacetals can undergo a one-pot modified Strecker synthesis under sonication to provide α-amino nitriles (eq 7).[19] The reaction is high yielding and does not suffer significant polymerization or ring-opening side reactions. Since the cyanide group is easily hydrolyzed to the acid, this is a convenient method for the preparation of α-amino acids.

(7)

Acyl Cyanides.

α-Cyanoalkyl aryl ketones can be obtained from arylhydrazones by heterogeneous reaction with aq NaCN, an inert organic solvent, and acetic acid in the presence of air with catalytic quaternary ammonium salts (eq 8).[20] Air oxidation of the initial adduct is followed by alkaline-induced decomposition affording the α-cyanoalkyl ketone.

(8)

Ring Opening/Forming.

NaCN in DMSO has been used to nucleophilically open geminally activated cyclopropanes (eq 9).[21] Conversely, the reaction of NaCN on a dimethylene heptanedionate yields a cyano-oxobicyclo[3.2.1]octanecarboxylate via a novel double-ring closure (eq 10).[22]

(9)

(10)

Reducing Agent.

Deethoxycarbonylation of geminal diesters can be effected with NaCN in DMSO (eq 11).[23] The same reaction in HMPA can selectively cleave methyl esters in the presence of ethyl esters.[24]

(11)

The reaction of benzil with NaCN in DMSO has been shown to produce a *trans*-α,α´-stilbenediol dibenzoate (eq 12).[25] The proposed mechanism assumes cleavage of the central C-C bond in benzil, generating a resonance stabilized carbanion. In the presence of a proton donor this carbanion is forced to attack a second benzil molecule, forming the stilbene product.

(12)

NaCN has also been used in the desulfurization of dialkyl disulfides in DMSO or DMF to give the corresponding monosulfide (eq 13).[26] Under similar conditions, thiophenols react with NaCN to afford methyl thioethers (eq 14).

(13)

(14)

Oxidations.

The oxidation of α,β-unsaturated aldehydes to the corresponding methyl esters can be accomplished with NaCN (eq 15).[27] The cyanohydrin generated in situ is susceptible to further oxidation by ***Manganese Dioxide*** to an acyl cyanide, leading finally in an alcoholic medium to an ester. Aside from the simplicity and convenience of this procedure, the high yield and lack of *cis-trans* isomerization of the α,β-alkenic linkage is also noteworthy compared to traditional methods such as ***Silver(I) Oxide*** oxidation.

Sodium Cyanoborohydride[1]

$NaBH_3CN$

[25895-60-7] · CH_3BNNa · Sodium Cyanoborohydride · (MW 62.85)

(selective, mild reducing reagent for reductive aminations of aldehydes and ketones, reductions of imines, iminium ions, oximes and oxime derivatives, hydrazones, enamines; reductive deoxygenation of carbonyls via sulfonyl hydrazones, reductions of aldehydes and ketones, polarized alkenes, alkyl halides, epoxides, acetals, and allylic ester groups)

Physical Data: white, hygroscopic solid, mp 240-242 °C (dec).

Solubility: sol most polar solvents (e.g. MeOH, EtOH, H_2O, carboxylic acids) and polar aprotic solvents (e.g. HMPA, DMSO, DMF, sulfolane, THF, diglyme); insol nonpolar solvents (e.g. ether, CH_2Cl_2, benzene, hexane).

Form Supplied in: widely available; the corresponding deuterated (or tritiated) reagent is available via acid-catalyzed exchange with D_2O (or T_2O).[1a,2]

Handling, Storage, and Precautions: store under dry N_2 or Ar.

Functional Group Reductions: General.

The chemoselectivity available with $NaBH_3CN$ is remarkably dependent on solvent and pH. Under neutral or slightly acidic conditions (pH > 5), only iminium ions are reduced in protic and ether (e.g. THF) solvents.[2] Most other functional groups including aldehydes, ketones, esters, lactones, amides, nitro groups, halides, and epoxides are inert under these conditions.

Reductive Aminations.

The relative inertness of aldehydes and ketones toward $NaBH_3CN$ at pH > 5 allows reductive aminations with amine and amine derivatives (usually in MeOH) via in situ generation of iminium ions which are then reduced to amines (eqs 1 and 2).[2-4] This protocol is compatible with most other functional groups, can be used to prepare N-heterocycles with stereochemical control (eqs 3 and 4),[5,6] and serves as a methylation process using CH_2O as the aldehyde (eq 5).[7,8] For difficult cases (e.g. aromatic amines, hindered and trifluoromethyl ketones), yields may be greatly improved by prior treatment of the carbonyl and amine with ***Titanium(IV) Chloride*** (eq 6)[9] or ***Titanium Tetraisopropoxide***.[10a] A reagent system prepared from $NaBH_3CN$ and ***Zinc Chloride*** also is also effective for reductive aminations[10b] (see also ***Sodium Triacetoxyborohydride*** and ***Tetra-n-butylammonium Cyanoborohydride***).

(4)

(5)

(6)

Reductions of Imines and Derivatives.

Preformed imines (eq 7),[2,11,12] iminium ions (eq 8),[2,11,13] oximes (eq 9),[2,14] oxime derivatives (eqs 10 and 11),[15,16] hydrazones (eq 12),[17] and other *N*-heterosubstituted imines (eqs 13 and 14)[18,19] are reduced to the corresponding amine derivatives by $NaBH_3CN$, usually in acidic media (see also ***Lithium Aluminum Hydride*** and ***Sodium Borohydride***).

(7)

(8)

(9)

(10)

Also under acidic conditions, enamines are reduced to amines via iminium ions by $NaBH_3CN$ (eq 15).[2,20] This type of conversion is also effected with $NaBH_3CN/ZnCl_2$.[10b] Pyridines and related nitrogen heterocycles are reduced by $NaBH_3CN/H^+$ to di- or tetrahydro derivatives (eq 16).[1e,21] Likewise, pyridinium and related salts (e.g. quinolinium, isoquinolinium) are reduced. With 4-substituted derivatives, 1,2,5,6-tetrahydropyridine products are produced (eq 17).[22]

(16)

(17)

Reductive Deoxygenation of Aldehydes and Ketones.[23,24]

p-Toluenesulfonylhydrazones (tosylhydrazones), generated in situ from unhindered aliphatic aldehydes and ketones and tosylhydrazine, are reduced by $NaBH_3CN$ in slightly acidic DMF/sulfolane (ca. 100-110 °C) to hydrocarbons via diazene intermediates (eq 18).[24] With hindered examples the tosylhydrazones must be preformed and large excesses (5-10×) of $NaBH_3CN$ used in more acidic media (e.g. pH < 4) (eq 19).[24,25] Likewise, aryl tosylhydrazones are nearly inert to the reagent, but exceptions are known.[26] Reduction of tosylhydrazones to hydrocarbons also occurs with $NaBH_3CN/ZnCl_2$ in refluxing MeOH. This combination also gives poor yields with aryl systems.[10b]

(18)

(19)

Reductive deoxygenation of most α,β-unsaturated tosylhydrazones with $NaBH_3CN$ cleanly affords alkenes in which the double bond migrates to the former tosylhydrazone carbon (eq 20).[24,27,28] However, the process gives mixtures of alkenes and alkanes with cyclohexenones[27] (see also ***Bis(triphenylphosphine)copper(I) Borohydride***, ***Catecholborane*** and ***Sodium Borohydride***).

(20)

Reduction of Other π-Bonded Functional Groups.

In acidic media (i.e. pH < 4), aldehydes and ketones are selectively reduced to alcohols (eq 21).[2a,28] α,β-Unsaturated ketones are reduced primarily to allylic alcohols (eq 22)[29] except cyclohexenones, which give mixtures of allylic and saturated alcohols. Allylic ethers are also produced concomitantly with substrates further conjugated with aryl rings.[29]

(21)

(22)

The combination of $NaBH_3CN/ZnCl_2$ in ether also reduces aldehydes and ketones to alcohols.[10b] With 5% H_2O present, cyclohexanones are selectively reduced in the presence of aliphatic derivatives.[30a] With $NaBH_3CN$/***Zinc Iodide***, however, aryl aldehydes and ketones are

converted to aryl alkanes.[30b]

While isolated alkenes are inert toward $NaBH_3CN$, highly polarized double bonds (i.e. containing an attached nitro or two other electron-withdrawing groups) are reduced to hydrocarbons in acidic EtOH (eq 23).[31,32] Reductions of iron carbonyl-alkene complexes to the corresponding alkyl complexes also occurs readily with $NaBH_3CN$ in MeCN.[33]

Nitriles are inert toward $NaBH_3CN$ even under strongly acidic conditions. However, methylation with $Me_2Br^+SbF_6^-$ and subsequent reduction with $NaBH_3CN$ affords the corresponding methylamine (eq 24).[34]

Reduction of σ-Bonded Functional Groups.

In S_N2 rate enhancing polar aprotic solvents (e.g. HMPA, DMSO), primary and secondary alkyl, benzylic and allylic halides, sulfonate esters (eqs 25 and 26),[35a] and quaternary ammonium salts[36] are reduced to hydrocarbons. As expected for an S_N2-type process, the order of reactivity is I > Br, RSO_3 > Cl.[35a] In addition, primary alcohols are reduced to hydrocarbons via in situ conversion to iodides with ***Methyltriphenoxyphosphonium Iodide*** (MTPI) and subsequent reduction (eq 27).[35a,37] On the other hand, the combinations $NaBH_3CN$/***Tin(II) Chloride***[38a] or $NaBH_3CN/ZnCl_2$[38b] reduce tertiary, allylic, and benzylic halides but are inert toward primary, secondary, and aryl derivatives (eq 28)[38] (see also ***Lithium Aluminum Hydride***, ***Lithium Tri-s-butylborohydride*** and ***Sodium Borohydride***).

(25)

(26)

(27)

(28)

In the presence of ***Boron Trifluoride Etherate***, $NaBH_3CN$ reduces epoxides to alcohols[39] with attack of hydride at the site best able to accommodate a carbocation. Epoxide opening occurs primarily *anti* (eq 29).[39] Acetals are also reduced to ethers by $NaBH_3CN$ in acetic media (eq 30).[40]

(29)

(30)

Allylic groups that are normally not displaced by hydrides (e.g. carboxylates, ethers) are effectively activated via Pd^0 complexation to give π-allyl complexes which are reduced by $NaBH_3CN$ to alkenes (eq 31).[41]

Sodium Dicarbonylcyclopentadienylferrate

[12152-20-4; 12107-09-4] · $C_7H_5FeNaO_2$ · Sodium Dicarbonylcyclopentadienylferrate · (MW 199.96)

(nucleophilic source of iron;[1] precursor to iron alkene complexes;[1] precursor to η^1-allyliron and η^1-propargyliron complexes; precursor to acyliron complexes;[2] precursor to iron carbenes;[3] with subsequent oxidation will carbonylate alkyl halides or sulfonates[4])

Solubility: sol ethereal organic solvents (Et_2O, THF).

Preparative Methods: to ***Mercury(0)*** (70 mL) stirring under nitrogen in a 500 mL flask with a stopcock in the bottom is slowly added ***Sodium*** metal (7.2 g), cut into small pieces, under a strong flow of nitrogen. The resulting amalgam is cooled to room temperature, and THF (100 mL) is added, followed by ***Bis(dicarbonylcyclopentadienyliron)*** (35.4 g, 0.1 mol). The mixture is stirred for 40 min, and the mercury is drained through the stopcock. The resulting $Na[Fe(CO)_2Cp]$ is used without further purification.[5] An alternative preparation using sodium dispersion in THF at reflux has also been reported.[6]

Handling, Storage, and Precautions: generally prepared and used immediately; it is destroyed by protic solvents.

Organoiron Reagents.

The reagent, NaFp (the $[Fe(CO)_2Cp]$ unit is commonly abbreviated Fp), is a highly nucleophilic source of iron which readily substitutes alkyl halides or pseudohalides.[7] The reaction occurs with inversion at a chiral center, and substrate reactivity, as well as yields, are as expected for S_N2 substitutions (primary > secondary >> tertiary). Benzyl and allyl halides also react easily (eq 1), while propargyl substrates give the expected propargyl-Fp complexes if the remote alkyne terminus is substituted (eq 2)[7b] and σ-bonded iron allenes (by formal S_N2') if unsubstituted (eq 3).[7c] Epoxides react readily but undergo subsequent rearrangement. Acid chlorides or anhydrides are attacked by NaFp to give useful yields of acyl iron complexes (eq 4).[8] β-Chloroenones undergo addition-elimination with NaFp to afford β-Fp enones.[9]

Iron Alkene Complexes.[1]

Epoxides suffer nucleophilic attack by NaFp, and give cationic iron alkene complexes upon protonation with strong acid. Iodide ion in acetone liberates the free alkene, giving an overall stereospecifically *syn* reduction of epoxides (eq 5). Pyrolysis of the iron alkoxide intermediate gives the other alkene isomer (eq 6), allowing access to either isomer from one epoxide. Stereospecificity is high for diaryl or dialkyl epoxides, but isomeric mixtures are obtained in the preparation of enones.[10]

The cationic enone-iron complexes made by the above procedure undergo highly regioselective β-nucleophilic attack. They have been shown to be reactive as Michael acceptors with enolates or silyl enol ethers and may serve as Robinson ring annulation precursors (eq 7).[11]

The attack of NaFp upon α-bromo acetals, followed by acid- or trityl cation-induced loss of alkoxide, gives cationic Fp-vinyl ether

complexes (eq 8).[12,13] These compounds react with enolates α to the alkoxy unit, regardless of additional substituents; subsequent treatment with strong acid and iodide ion gives overall vinylation of the enolate.[13] The complex of ethyl α-ethoxyacrylate (**1**) serves in a closely analogous manner in the three step synthesis of α-methylene-γ-lactones (eq 9).[13b]

Alkene Synthesis.

Aliphatic alkyl halides or pseudohalides may be converted into alkenes by a three-step process involving nucleophilic substitution by NaFp, hydride abstraction by ***Triphenylcarbenium Tetrafluoroborate***, and ***Sodium Iodide***-induced decomposition of the iron alkene (eq 10). Hydride abstraction is selective, such that both 1-haloalkenes and 2-haloalkenes normally afford terminal alkenes; 3-haloalkenes normally give (*Z*)-alkenes as products, but yields are modest.[14]

η^1-Allyliron Complexes.

η^1-Allyliron complexes, prepared by the nucleophilic substitution of NaFp on allyl halides or pseudohalides, are nucleophilic allylation reagents for aldehydes, ketones, and acid chlorides in the presence of Lewis acids (eq 11).[15]

(11)

They are reactive with a variety of other cationic species, including strong acids, and this route has been employed for the preparation of more complex alkene-Fp cations.[7b] Reaction occurs at the end of the allyl unit remote from iron; this fact has been used to convert allyl alcohols to terminal alkenes through the intermediacy of Fp-allyl complexes (eq 12).[16]

(12)

η^1-Allyliron and η^1-propargyliron complexes, as well the Fp-allene complex, react with electron-deficient alkenes in a stepwise [3 + 2] cycloaddition; the result is a cyclopentane or cyclopentene ring annulation (eq 13). The most reactive substrates include α,β-unsaturated esters or nitriles possessing two electron-withdrawing groups, whereas simple enones will react in the presence of a Lewis acid.[7b,17,18] Heteroatom-based double-bonded systems such as isocyanates, hexafluoroacetone, *N*-sulfonylurethane, and S_2O (generated in situ)[19] participate in these cycloadditions, but the resulting Fe-C bond usually has not been further manipulated (S_2O adduct excepted). Also reactive is the uncomplexed double bond of tropyliumiron tricarbonyls, which ultimately form the fused 5,7 ring systems of hydroazulenes (eq 14).[20]

(13)

(14)

Acyliron Complexes.

α,β-Enoyl-Fp complexes, available by NaFp attack on acid chlorides (eq 4), are susceptible to conjugate addition by amine or thiol nucleophiles. The amine adducts may be oxidatively demetalated to give β-lactams (eq 15).[21] Allylstannanes react with α,β-enoyl-Fp complexes in a highly regio- and stereoselective [3 + 2] cycloaddition (eq 16).[2] The tin residue of the product is invariably *trans* to the acyliron function, whereas either *cis* or *trans* crotylstannanes result in a methyl function *trans* to the tin unit. Subsequent conversion of the acyliron function to an ester and conversion of the tin unit to a hydroxy group gives moderate overall yields of cyclopentanes which may be quite highly functionalized. The use of dimethoxycarbenium tetrafluoroborate instead of ***Aluminum Chloride*** results in conjugate addition without cyclization.[2]

(15)

(16)

The chiral acyl-Fe(CO)(PR_3)Cp complexes are not generally accessible by phosphine substitution of acyl-Fp complexes (see ***(S)-Aceto(carbonyl)(cyclopentadienyl)-(triphenylphosphine)iron***). The nicotinyl or dihydronicotinyl acyliron substrates do substitute phosphine ligands successfully, however, and complexes such as (**2**) prepared in this manner have been shown to be useful in the enantioselective reduction of ethyl benzoylformate to ethyl mandelate.[22]

(2)

Iron Carbene Reagents.[2]

NaFp reacts with α-chloro ethers and α-chloro thioethers to afford α-methoxy- or α-alkylthioalkyliron complexes (**3**), respectively (eq 17).[23-26] Acyliron complexes undergo an *O*-methylation-reduction sequence which also gives (**3**; R = OMe) (eq 18). Alternatively, the reaction of NaFp with aldehydes, followed by *O*-silylation, gives α-trimethylsiloxyalkyliron complexes (**3**; X = $OSiMe_3$) (eq 19).[27] When treated with protic or (more often) Lewis acids, these compounds (**3**) are converted to cationic iron carbene complexes (**4**) (eq 20), which in turn react with alkenes to form cyclopropanes.

$$Na[Fe(CO)_2Cp] + ClCH(R)X \longrightarrow Cp(CO)_2FeCH(R)X \qquad (17)$$

(3) X = OMe, SMe, SPh

Addition to the alkene is stereospecifically *cis* with respect to alkene geometry. The α-methoxyalkyliron and trimethylsiloxyalkyliron complexes are the most reactive and the most stereoselective at any newly formed chiral centers; substituents on the carbene normally enter *cis* with respect to alkene substituents (&egt;4:1) (eq 21). The α-alkylthioalkyliron complexes (X = SMe, SPh) are less *cis* stereoselective, but are more suitable for transfer of a methylene group (R = H) (eq 22). For intermolecular cases, yields are best for methyl-, aryl-, or cyclopropyl-substituted carbenes;[28] vinyl substituents give lower yields, and *n*-alkyl- or dialkyl-substituted carbenes, regardless of precursor, do not give synthetically useful yields. Intramolecular cyclopropanations have also been reported, but yields are variable and both C-H insertion and cationic cyclization may compete.[29]

Iron carbenes with α-bridgehead carbon atoms decompose by alkyl group migration to give bridgehead alkene-iron complexes, provided the alkene strain is below 88 kJ mol^{-1}. The decomplexed alkene was isolated in one case (eq 23).[30]

Carbonylation.

Substitution of alkyl halides or sulfonates by NaFp, followed by oxidative carbonyl insertion by Br_2 in methanol, gives good yields of carbonylation products (eq 24). The use of NaFp allows milder reaction conditions to be used relative to ***Sodium Tetracarbonylcobaltate***, and ethers, esters, and free hydroxyl groups are tolerated.[3] Although applied synthetically for primary halides or pseudohalides, secondary substrates give overall inversion of configuration.[31] Carbonyl insertion is also induced by the addition of a ligand, most commonly PPh_3; this route is the one of choice for the preparation of racemic acetyl(carbonyl)cyclopentadienyl(triphenylphosphine)iron (eq 25).[32]

Sodium Dichlorofluoroacetate

[2837-90-3] · $C_2Cl_2FNaO_2$ · Sodium Dichlorofluoroacetate · (MW 168.91)

(reagent for generation of chlorofluorocarbene and the synthesis of chlorofluorocyclopropanes and chlorofluoroalkenes)

Solubility: sol DME, diglyme, triglyme, *N*-methylpyrrolidone.

Preparative Methods: prepared by careful neutralization of 80 g (0.54 mol) of dichlorofluoroacetic acid in 150 mL of Et_2O with 29 g of anhydrous Na_2CO_3. The Et_2O and water are removed under reduced pressure. The salt is then dried overnight at 50 °C at a pressure of less than 4 mmHg.[1]

Handling, Storage, and Precautions: is an irritant and is hygroscopic.

Wittig Reactions.

The thermal decomposition of sodium dichlorofluoroacetate in the presence of ***Triphenylphosphine*** and benzaldehyde in triglyme results in the formation of a mixture of (*E*)- and (*Z*)-chlorofluoroalkenes in 49% yield (eq 1). A ratio of triphenylphosphine:sodium salt:carbonyl of 1.5:1.5:1.0 is recommended. The choice of solvent had little effect on the ratio of alkene isomers obtained. However, in terms of overall yield, triglyme was the solvent of choice. Simple ketones generally do not react well under these conditions, the exceptions being when there are fluorine substituents on the α-carbon (eq 2).[1]

(1)

(2)

Substitution of ***Tri-n-butylphosphine*** for triphenylphosphine produced a less stable but more reactive ylide that was capable of reacting with cyclopentanone (eq 3). The yield in the cyclopentanone reaction was comparable to the haloform method of carbene formation and subsequent ylide generation. In general, the yields of chlorofluoroalkenes using the decarboxylation method for generating chlorofluorocarbene were superior to the haloform method.

(3)

Cyclopropanation.

The reaction of tetramethylethylene with the sodium salt in triglyme at 85 °C leads to the formation of the chlorofluorocyclopropane in 37% yield (eq 4). In the presence of triphenylphosphine, no cyclopropane was observed. Tetramethylethylene and triphenylphosphine have been shown to be comparable in reactivity toward chlorofluorocarbene generated using the haloform method. Thus it appears that the carbene may not be the precursor for the ylide in the decarboxylation method.[1]

Sodium Dichromate[1]

[7778-12-0] · $Cr_2Na_2O_7$ · Sodium Dichromate · (MW 298.02)

(reagent for oxidizing alkylaromatics to carboxylic acids, oxidizing benzylic methylene groups to carbonyl groups, oxidizing alkenes to form α,β-unsaturated compounds, and for converting alcohols to carbonyl compounds)

Physical Data: mp (loses $2H_2O$ at 100 °C) 356.7 °C (anhydr); d = 2.52 g cm^{-3}.[13]

Solubility: sol H_2O (238 g/100 mL at 0 °C), acetic acid, DMSO.

Form Supplied in: red crystals.

Handling, Storage, and Precautions: highly toxic and a cancer suspect agent. All chromium(VI) reagents must be handled with care in a fume hood. The mutagenicity of Cr^{VI} compounds is well documented.[2]

Introduction.

Sodium dichromate, which contains three oxygen equivalents per mol, has a wide range of oxidizing powers which are dependent on the solvent systems and experimental conditions.

Oxidation of Alkylaromatics to Carboxylic Acids.

Aqueous sodium dichromate selectively oxidizes arylmethanes and heteroarylmethanes to the corresponding carboxylic acids in excellent yields.[3] For example, 1-methylnaphthalene is oxidized to 1-naphthoic acid in 95% yield (eq 1). Aromatic dicarboxylic acids are also available from dialkyl-substituted aromatic nuclei. In general, the lower the pH the more likely is attack on the aromatic nucleus.

(1)

Oxidation of Benzylic Methylene Groups to Carbonyl Groups.

Sodium dichromate in acetic acid oxidizes 3-ethyl-2,6-dimethylpyrazine to 3-acetyl-2,6-dimethylpyrazine (57%).[4] The heterocyclic ring is essentially destroyed under these experimental conditions. 2-Acetylfluorene is oxidized to the fluorene-2-carboxylic acid by sodium dichromate in acetic anhydride/acetic acid (eq 2)[5] and acenaphthene is converted to acenaphthenequinone with sodium dichromate in anhydrous acetic acid in the presence of cerium(IV) acetate catalyst (eq 3).[6] The octahydrophenanthrene derivative (**1**), an intermediate in the synthesis of morphine analogs, is oxidized to the benzylic ketone by sodium dichromate in sulfuric acid (eq 4).[7]

(2)

(3)

(4)

(1)

Allylic Oxidation of Alkenes to α,β-Unsaturated Compounds.

Sodium dichromate, ***Dipyridine Chromium(VI) Oxide*** (Collins reagent), ***Chromium(VI) Oxide-3,5-Dimethylpyrazole*** (DMP/CrO_3), ***Di-t-butyl Chromate***, and sodium chromate are very useful for oxidizing polycyclic alkenes, especially terpenes and steroids, to α,β-unsaturated compounds. Limitations may include side reactions such as cleavage of the carbon-carbon double bond and lack of regiochemistry in the oxidation. Sodium dichromate in acetic acid oxidizes methyl acetyloleanolate to the 11-keto derivative (eq 5).[8]

Oxidation of Alcohols to Carbonyl Compounds.

Primary alcohols are oxidized to aldehydes in excellent yields by ***Chromium(VI) Oxide-Silica Gel***, chromium(VI) oxide/graphite, chromium(VI) oxide/Kieselguhr, and other chromium oxidants. Primary alcohols are oxidized to aldehydes, acids, and esters by sodium dichromate.[9-13] Removal of the low molecular weight aldehyde as fast as it is formed increases the yield.[9,10] α,β-Unsaturated aldehydes may be prepared (35-50%) by stirring the α,β-unsaturated alcohols in aqueous sulfuric acid with sodium dichromate, followed by extraction of the product.[14-16] Benzyl alcohols are oxidized to aromatic aldehydes in good to excellent yields.[17] 4-Hydroxymethyl-3-methyl-5-phenylisoxazoles are oxidized to 3-methyl-5-phenylisoxazole-4-carbaldehydes by sodium dichromate in sulfuric acid/DMSO (eq 6).[18] Sodium dichromate in DMSO containing small amounts of sulfuric acid oxidizes primary and secondary saturated, allylic, and benzylic alcohols to carbonyl compounds (80-90%).[19]

Oxidation of Secondary Alcohols to Ketones.

Secondary alcohols are generally oxidized by sodium dichromate to ketones in excellent yields.[19-22] A two-phase procedure using sodium dichromate, acetic acid, and benzene oxidized a *cis*/*trans* mixture of 1,5-dihydroxydecalins to a *cis*/*trans* mixture of decalin-1,5-diones (71-76%).[23] This system oxidizes 2,5,5-trimethylcyclohex-2-en-1-ol to 2,5,5-trimethylcyclohex-2-en-1-one in 91% yield.[24] A two-phase system of sodium dichromate, sulfuric acid, water, and ether oxidizes (-)-menthol to (-)-menthone in 97% yield.[25,26] The latter procedure has been used for the selective oxidation of steroidal 16β,20α-diols to 16-keto-20α-ols.[27] Dichloromethane has also been used as the organic phase in the sodium dichromate/sulfuric acid oxidation of a *cis*/*trans* mixture of 2-cyclopentene-1,4-diol to the 2-cyclopentene-1,4-dione.[28] The organic phase protects the product from undesirable side reactions such as oxidation and epimerization. Of the three organic solvents, ethyl ether appears to be the one of choice owing to the ease of product isolation. Other examples of the two-phase sodium dichromate oxidation of alcohols are shown in eqs 7 and 8.[29] Addition of a phase-transfer catalyst improves the two-phase transfer procedures.[30,31]

(7)

(8)

Other Applications.

Sodium dichromate in aqueous sulfuric acid oxidizes phenols, anilines, and aminophenols to *p*-quinones.[32,33] 3-Iodo-4-aminophenol is oxidized to 2-iodobenzoquinone in 95% yield. Sodium dichromate in acetic acid/sulfuric acid oxidizes phenols with an alkyl group *para* to the oxygen function to quinones and coupling products (eq 9).[34] The minor product arises from oxidative elimination of the tertiary alkyl group from the *para* position. Sodium dichromate in acetic acid, sulfuric acid, and water (Kiliani reagent)[35,36] oxidizes the triol digitogenin to digitogenic acid (a 13-keto-2,3-dioic acid).[35]

(9)

Borinate esters derived from the hydroboration of homoallylic alcohols were oxidized with sodium dichromate in aqueous sulfuric acid to racemic and enantiomeric γ-butyrolactones (2-oxotetrahydrofurans).[37] Hydroboration of 1-alkyl- and 1-aryl-1-indenes followed by sodium dichromate oxidation leads to the corresponding 1-alkyl- and 1-aryl-2-indanones (70-80%).[38]

Sodium *O,O*-Diethyl Phosphorotelluroate

[65857-68-3] · $C_4H_{10}NaO_3PTe$ · Sodium *O,O*-Diethyl Phosphorotelluroate · (MW 287.69)

(deoxygenation of epoxides,[1] dehalogenation of α-bromo and α-chloro ketones,[2] debromination of vicinal dibromides,[3] and for use in the preparation of sulfones[4])

Physical Data: white solid;[1] NMR data (^{31}P and ^{1}H) have been reported.[1]

Solubility: sol ethanol, tetrahydrofuran.[1]

Preparative Methods: [1] generated in situ by addition of ethanolic sodium diethyl phosphite to metallic tellurium. When made separately, the reagent is best formed in THF. This solvent can then be replaced by ethanol, which is the best solvent for epoxide deoxygenation.

Handling, Storage, and Precautions: the reagent is extremely air sensitive and is preferably made just before use or, more simply, generated in situ.[1]

Deoxygenation of Epoxides.[1]

Sodium *O,O*-diethyl phosphorotelluroate and the lithium salt, which is more reactive, deoxygenates epoxides to the corresponding alkenes. The reaction occurs in ethanol solution but in THF is too slow to be useful. Reaction takes place most easily with terminal epoxides and it can be run for these cases, as well as for certain others, by using much less than a stoichiometric amount (e.g. 2-20 mol %) of tellurium. For such experiments, sodium diethyl phosphite is added to a stirred mixture of the epoxide, ***Tellurium***, and ethanol. When used stoichiometrically, the reagent is made in THF, and the solvent is evaporated and replaced by ethanol. The deoxygenation is stereospecific and epoxides derived from (*Z*)-alkenes are more reactive than those from (*E*)-alkenes. Reaction occurs more easily with cyclohexene oxide than with cyclopentene oxide. Typical deoxygenations are shown in eqs 1-4.

(1)

Dehalogenation of α-Bromo and α-Chloro Ketones.[2]

α-Bromo and α-chloro ketones, on treatment with sodium *O,O*-diethyl phosphorotelluroate in ethanol or THF, are converted into the parent ketone. Reaction proceeds in the temperature range 25-80 °C and reaction times vary from 45 min to 15 h. For highest yields, a stoichiometric amount of reagent is best, but a catalytic amount of tellurium and a stoichiometric amount of sodium diethyl phosphite can also be used. The catalytic mode is possible because sodium *O,O*-diethyl phosphate reacts only slowly with α-bromo ketones, but rapidly with tellurium, and the reagent itself reacts rapidly with α-halo ketones. The selenium analog, sodium *O,O*-diethyl phosphoroselenoate, does not appear to dehalogenate α-bromo ketones,[2] the selenium atom merely being alkylated. Typical results with the tellurium reagent are shown in eqs 5 and 6.

Debromination of Vicinal Dibromides.[3]

Vicinal dibromides are converted (2.5-10 h at rt; 64-88% yields) into the corresponding alkenes by treatment in ethanol with sodium diethyl phosphite and a catalytic amount of tellurium (eqs 7 and 8). The alkene geometry corresponds to removal of the bromine from an antiperiplanar conformation.

Formation of α,β-Unsaturated Ketones.[4]

2-Bromoacetophenone has been converted into a series of α,β-unsaturated ketones (eq 9) by treatment with an aldehyde in ethanol in the presence of sodium *O,O*-diethyl phosphorotelluroate (77-93% yield).

Conversion of Arenesulfonyl Chlorides into Sulfones.[5]

Aryl sulfonyl chlorides are converted by sodium *O,O*-diethyl phosphorotelluroate into the corresponding sodium sulfinates. These then react in situ with alkyl halides to afford sulfones in 77-94% yield (eq 10).

Related Reagents.

Chromium(II) Chloride; ***Chromium(II) Sulfate***; ***Diphenylphosphine***; ***3-Methyl-2-selenoxobenzothiazole***; ***Sodium Dicarbonylcyclopentadienylferrate***; ***Sodium Iodide***; ***Sodium Nitrite***; ***Sodium Selenide***; ***Tellurium***; ***Tetrakis(triphenylphosphine)palladium(0)***; ***Tin(II) Chloride***; ***Tungsten(VI) Chloride-n-Butyllithium***; ***Zinc/Copper Couple***.

Sodium 4,6-Diphenyl-1-oxido-2-pyridone

[65218-74-8] · $C_{17}H_{12}NNaO_2$ · Sodium 4,6-Diphenyl-1-oxido-2-pyridone · (MW 285.29)

(nonhydrolytic conversion of alkyl and benzyl halides to aldehydes and ketones)

Alternate Name: pyridona.

Physical Data: white solid, mp 299-301 °C.

Solubility: sol methanol, DMF, ethanol.

Preparative Methods: the reagent is not commercially available. It can be synthesized by treatment of ethyl benzoylacetate with ***Sulfuric Acid*** to give 4,6-diphenyl-2-pyrone,[1] which is converted by reaction with ***Hydroxylamine*** followed by base to the title compound (eq 1).[2,3]

Purification: the salt is used without purification. The *N*-hydroxy precursor, mp 162 °C, is recrystallized from benzene light petroleum.

Analysis of Reagent Purity: ^{1}H NMR (DMSO-d_6) δ (ppm) 6.4 (1H, s), 6.5 (1H, s), 7.5 (10H, m).

Handling, Storage, and Precautions: store protected from moisture.

Oxidation of Alkyl and Benzyl Halides.

A disadvantage of most of the methods of accomplishing this transformation[4] (e.g. the Kröhnke and Kornblum oxidations) is the need for strongly hydrolytic conditions which may be deleterious to sensitive functionality. Furthermore, many of these alternative methods are limited to activated (allylic or benzylic) halides. The reaction employing pyridona developed by Katritzky et al. avoids these problems.[3,5-7] This oxidation takes place in two steps. First, the halide and title reagent are allowed to react together in a solvent (usually DMF but also MeOH and EtOH), giving the *N*-alkoxy-2-pyridone derivative. On thermolysis or photolysis, this compound then undergoes homolytic decomposition to the carbonyl compound and the 2-pyridone (eq 2).

As can be seen from Table 1, the reaction proceeds very smoothly for benzylic halides. For certain aliphatic halides a significant amount of the alcohol is produced as a byproduct in the second step.

Table 1 Conversion of Halides to Carbonyl Compounds using Pyridona

R	R¢	X	Yield, 1st step (%)	Yield, D (%)	Temp (°C)	Yield, hn (%)
Ph	H	Br	94	73	200	80
4-$NO_2C_6H_4$	H	Br	99	79	190	53
2,4,6-$(NO_2)_3C_6H_2$	H	Cl	72	93	140	
Pr	H	Br	94	59	240	
C_7H_{15}	H	I	94	37[a]	240	47
MeCH=CH	H	Cl	96	53	200	
Me	CH_3	Br	94	32	220	
Bn	H	Br	99	49	220	30

[a] 13% alcohol isolated.

The thermolysis is usually performed neat, and the carbonyl compound is obtained as it is formed by distillation from the reaction mixture. The alternative photolysis procedure is conducted with a medium-pressure mercury lamp through a pyrex filter, usually in ethyl acetate or benzene (eq 3). A limitation of the method is the further fragmentation of certain substrates.[6]

The oxidation may be performed with comparable results with the alternative reagents (**1**) and (**2**).[8]

Sodium Diselenide[1]

Na_2Se_2

[39775-49-0] · Na_2Se_2 · Sodium Diselenide · (MW 203.90)

(nucleophilic agent for synthesis of organic diselenides[1,2])

Alternate Name: disodium diselenide.

Physical Data: mp about 495 °C.

Solubility: readily sol water, forming a red solution which easily decomposes on contact with air, separating selenium; sol ethanol, liquid ammonia; sparingly sol THF.

Form Supplied in: dull gray-black, microcrystalline material; used in solution or suspension without isolation.

Preparative Methods: heat equimolar amounts of ***Sodium*** and ***Selenium*** under nitrogen at 500 °C, or reduce Se with Na in liquid ammonia.[4] ***Sodium Hydroxymethanesulfinate*** (rongalite) in water[5] and ***Sodium Borohydride*** in water or ethanol[6] are used as reducing agents. ***Hydrazine*** in aqueous alkali also reduces Se, giving Na_2Se_2 or K_2Se_2 solutions as a source of Se_2^{2-}.[7,8] A combination of electrochemical reduction of Se and ultrasound will produce the Se_2^{2-} anion in THF, acetonitrile, or DMF.[9] A suspension of Na_2Se_2 (or K_2Se_2) can be produced in high-boiling polar aprotic solvents, such as DMF, HMPA, or NMP by the direct reaction of selenium powder with sodium or ***Potassium***.[10] A similar reduction in THF, carried out in the presence of catalytic amounts of naphthalene, is the best way to prepare of a suspension of Na_2Se_2 or K_2Se_2 in this solvent.[2]

Handling, Storage, and Precautions: very hygroscopic; decomposes in moist air, turning red. It should be used as prepared without isolation. Use in a fume hood.

Synthesis of Diselenides.

The diselenide anion Se_2^{2-} derived from Na_2Se_2 or K_2Se_2 is an excellent nucleophilic agent used for the synthesis of dialkyl diselenides from alkyl halides or sulfates.[2,4-8,11] The alkylating agent is added directly to the alkali metal diselenide solution or suspension and the dialkyl diselenide is formed, usually in high yield (eq 1).[2] Nucleophilic aromatic substitution with the Se_2^{2-} anion is achieved on activated aromatic halides, such as 2-nitrochlorobenzene (eq 2).[12]

Sodium Disulfide[1]

Na_2S_2

[22868-13-9] · Na_2S_2 · Sodium Disulfide · (MW 110.12)

(nucleophilic agent for synthesis of organic disulfides and selective reducing reagent for the nitro group[1-3])

Alternate Name: disodium disulfide.

Physical Data: mp about 495 °C; *d* 2.01 g cm^{-3}.

Solubility: readily sol water; sol ethanol.

Form Supplied in: light yellow, microcrystalline, very hygroscopic powder; gradually darkens on heating. $N_2S_2.6H_2O$, cream colored needles. Alkali metal disulfides are not commercially available.

Preparative Methods: Na_2S_2 preparations are cumbersome and sometimes afford mixtures containing the polysulfides Na_2S_4 and Na_2S_5. They involve reduction of ***Sulfur*** with ***Sodium*** in liquid ammonia,[4] heating Na with S in a vacuum at 500 °C,[4] or heating Na_2S_4 with Na in absolute ethanol under inert gas.[4,5] Na_2S_2 is formed in situ by heating the aqueous or alcoholic ***Sodium Sulfide*** solution with elemental sulfur.[6-9]

Handling, Storage, and Precautions: can be stored for a limited period under anhydrous and oxygen-free conditions, but generally it is used directly as prepared as the aqueous or ethanolic solution.

Organic Disulfides Formation.

Alkylation of Na_2S_2 with alkyl halides or sulfonates is a good synthesis of symmetrical disulfides.[1,2,9-11] For example, when 1-bromopentane is treated with Na_2S_2 (generated in situ from Na_2S and S), bis(*n*-pentyl) disulfide is formed in satisfactory yield (eq 1).[12]

(1)

Activated aryl halides treated with Na_2S_2 produce disulfides in high yields and numerous examples, among them the preparation of bis(2-nitrophenyl) disulfide (eq 2), have been reported.[1,2,13]

(2)

The Sandmeyer-type displacement of the diazonium group by S^{2-} anion gives aryl disulfides. Reaction of this type is used for synthesis of thiosalicyclic acid (eq 3).[6] Although many arenediazonium salts arylate Na_2S_2, one should beware of possible explosions, probably caused by an accumulation of diazosulfides.[1,2]

Selective Reduction of Nitro Groups.

Na_2S_2 is a useful reducing reagent for the nitro group in the presence of other functional groups. It is used for selective reduction of 3-nitrobenzonitrile to 3-aminobenzonitrile, and of one nitro group in 4,6-diamino-1,3-dinitrobenzene (eq 4).[7] The reaction of 4-nitrotoluene with Na_2S_2 and polysulfides, generated in situ from Na_2S and S, involves an interesting disproportionation. The methyl group is oxidized to formyl, and the nitro group is reduced to NH_2. Finally, 4-aminobenzaldehyde is obtained as a product (eq 5).[8]

Sodium Dithionite[1]

$Na_2S_2O_4$

[7775-14-6] · $Na_2O_4S_2$ · Sodium Dithionite · (MW 174.12)

(versatile reagent for reduction of aldehydes,[2] ketones,[2-6] unsaturated conjugated ketones,[7,8] quinones,[9-10] diunsaturated acids,[11] azo,[12] nitro,[13] and nitroso compounds,[14,15] imines,[16] oximes,[17] tropylium salts,[18] pyridinium salts,[19] pyrazine,[20] and vinyl sulfones;[21] intramolecular Marschalk cyclizations,[22,23] dehalogenation of *vic* dibromides[24] and α-halo ketones,[25] Claisen rearrangement of allyloxyanthraquinones[26] and for the synthesis of 8-arylaminopurines[27,28])

Alternate Name: sodium hydrosulfite.

Physical Data: mp 52 °C (dec).

Solubility: very sol water; sol alcohol.

Form Supplied in: white or gray-white crystalline powder.

Preparative Methods: by the action of ***Sulfur Dioxide*** on ***Sodium Amalgam*** in alcoholic solution.[29,30]

Handling, Storage, and Precautions: flammable; moisture sensitive.

Reduction of Aldehydes and Ketones.[2]

Sodium dithionite is an alternative and less expensive reducing agent than metal hydrides. The reactions are performed in water for soluble substrates, otherwise a 50:50 mixture of water and dioxane or DMF can be used; sodium bicarbonate is added to keep the reaction mixture basic. Examples are hexanal to 1-hexanol (67%), benzaldehyde to benzyl alcohol (84%), cyclohexanone to cyclohexanol (80%),[3] and acetophenone to α-hydroxyethylbenzene (94%).[2] Reduction of methylcyclohexanones by $Na_2S_2O_4$ in benzene-water using adogen (commercial mixture of methyl trialkyl C_8-C_{10} ammonium chloride) as a phase-transfer agent afforded good yields of isomeric mixtures of the corresponding methylcyclohexanols.[3] Reduction using $Na_2S_2O_4$ proceeds with stereoselectivity[4-6] similar to that obtained with metal hydrides (***Sodium Borohydride***) and opposite to dissolving metals reductions, e.g. the reductions of 3α-hydroxy-7-keto-5β-cholanic acid to diols (eq 1).

Na, 100%	85:15
K, 100%	94:6
$Na_2S_2O_4$, 100%	4:96
$NaBH_4$, 100%	6:94

Regiospecific Reduction of Unsaturated Conjugated Ketones.[7,8]

Exclusive reduction of conjugated carbon-carbon double bonds is achieved with $Na_2S_2O_4$ to afford the corresponding saturated carbonyl compound. A two-phase (benzene-water) system using adogen as the phase-transfer catalyst is used. The isolated carbon-carbon double bond remains unaffected. No alcohols are detectable (eqs 2-4).

Quinones to Hydroquinones.[9]

Most quinones are reduced by sodium dithionite to hydroquinones. Naphthacenequinone and higher linear benzologs are exceptional in that they are not reduced by alkaline sodium dithionite.[10] Sodium dithionite reduces anthraquinone to anthrone.

Conjugated Diunsaturated Acids (and Esters) to Monounsaturated Acids (and Esters).[11]

α,β;γ,δ-Unsaturated acids are reduced by $Na_2S_2O_4$ in an alkaline medium (NaOH or $NaHCO_3$) to a mixture of (*Z*)- and (*E*)-β,γ-unsaturated acids (and esters) (40-75% yield) (eq 5).

Azo to Amine.[12]

Azobenzene is reduced to aniline by sodium dithionite. This reaction is used to introduce an amino group into a phenolic compound by first coupling with an aromatic diazonium salt and then reducing the resulting hydroxyazo derivatives with $Na_2S_2O_4$, e.g. 2- and 4-amino-1-naphthols can be prepared from 1-naphthol.

Nitro to Amine.[13]

Various aromatic nitro compounds are reduced conveniently to the corresponding aniline derivatives with sodium dithionite using dioctyl viologen as an electron-transfer catalyst in a two-phase system (CH_2Cl_2-H_2O), e.g. 1-nitronaphthalene to 1-naphthylamine.

Nitroso to Amine.

Nitroso compounds are reduced to amines by sodium dithionite, e.g. nitrosouracil to diaminouracil (eq 6).[14] Reduction of *N*-nitrosodibenzylamine[15] with $Na_2S_2O_4$ is accompanied by liberation of N_2 and rearrangement to dibenzyl. Mixed benzylaryl or diaryl-*N*-nitrosoamines are reduced to hydrazines (eq 7).

Imines to Amines.

Sodium dithionite in DMF reduces imines[16] to *N*-alkylamines at 110 °C with yields ranging from 40 to 73%. Heating *N*-cyclohexyldibenzylamine, sodium dithionite, and $NaHCO_3$ in DMF for 30 min at 110 °C gives 73% benzylcyclohexylamine.

Oximes to Amines.[17]

Oximes are readily reduced to amines by sodium dithionite. Substituted phenylethylamines are key intermediates required for the synthesis of isoquinoline derivatives. They are readily obtained from aryl alkyl ketones by nitrosation of the alkyl group followed by the reduction of the resulting oxime derivatives by sodium dithionite (eq 8).

(8)

Cleavage of Oximes.[16]

Both aldehydes and ketones are regenerated from their oxime derivatives with aqueous sodium dithionite either alone or in the presence of Na_2CO_3 at 25 °C, e.g. cyclohexanone oxime to cyclohexanone (95%) and benzaldehyde oxime to benzaldehyde (96%).

Reduction of Tropylium and Cyclopropenium Halides.[18]

$Na_2S_2O_4$ in acetonitrile at 25 °C reduces the tropylium halides to ditropyl (eq 9) and triphenylcyclopropenium halides to bicyclopropenyl sulfones (eq 10).

(9)

(10)

R = H, Ph

Reduction of Pyridinium Salt.[19]

Sodium dithionite has been extensively used for the reduction of *N*-methylpyridinium-3-carboxamide to *N*-methyl-1,4-dihydropyridine-3-carboxamide (eq 11), which is a model of reduced dihydrophosphopyridine nucleotide (DPNH).

(11)

Reduction of Pyrazine Derivatives.[20]

2,3,5,6-Tetraethoxycarbonyl-1,4-dihydropyrazine is prepared from 2,3,5,6-tetraethoxycarbonylpyrazine using sodium dithionite as

reducing agent (eq 12). It is a more convenient and simpler method than catalytic hydrogenation and no saponification of esters occurred during this reduction process.

(12)

Reduction of Vinyl Sulfone.

An insect phermone, (*Z*)-8-dodecenyl 1-acetate,[21] is readily obtained by the reduction of corresponding vinyl sulfone in aqueous ethanol with retention of configuration (eq 13). The mechanism involves the Michael addition of SO_2^- to the vinylic sulfone, accompanied by protonation and expulsion of SO_2 and sulfinate ion to give the alkene.

(13)

Intramolecular Marschalk Cyclization.[22,23]

This cyclization reaction is a key step in the total synthesis of daunomycinone, the aglycon of an anthracycline antibiotic. Treatment of the anthraquinone derivative with sodium dithionite and sodium hydroxide in dioxane at 25-90 °C gives the anticipated cyclized product in 52% yield (eq 14).

(14)

Dehalogenation of *vic*-Dibromides, α-Bromo and α-Chloro Ketones.

Vicinal dibromides are debrominated[24] with $Na_2S_2O_4$ in DMF (140-145 °C). The yields are moderate to high but the reaction is not

stereospecific. Both *meso*- and (±)-2,3-dibromobutane give 1:1 mixtures of *cis*- and *trans*-2-butene. The dehalogenation[25] of α-bromo or α-chloro ketones can be effected with $Na_2S_2O_4$ in aqueous DMF at 25-90 °C in yields of 50-95%. The rate can be enhanced by addition of $NaHCO_3$.[25]

Claisen Rearrangement of Allyloxyanthraquinone.[26]

1-Allyloxyanthraquinones rearrange to 1-hydroxy-2-allylanthraquinones in high yields when heated in DMF-H_2O containing 1.3-1.8 equiv $Na_2S_2O_4$. 1,4-Bis(allyloxy)anthraquinone rearranges slowly under these conditions, but more readily if 4 equiv NaOH is added (eq 15).

Synthesis of 8-Arylaminotheophyllines.[27,28]

Treatment of 5-arylazo-1,3-dimethyl-6-ethoxymethyleneaminouracil with $Na_2S_2O_4$ in formic acid gives 8-arylaminotheophyllines (eq 16). The key intermediates required for this reaction are prepared by reaction of the appropriate 6-amino-5-arylazo-1,3-dimethyluracils with a mixture of ***Triethyl Orthoformate*** and DMF at 180 °C for 5 h.

Sodium Dodecyl Sulfate

[151-21-3] · $C_{12}H_{25}NaO_4S$ · Sodium Dodecyl Sulfate · (MW 288.38)

(used in surfactant-based reaction media)

Alternate Names: SDS; sodium lauryl sulfate; SLS.

Physical Data: mp 204-207 °C.

Solubility: sol H_2O; insol Et_2O; critical micelle concentration (CMC) in H_2O (25 °C) = 8.1 mM.[1]

Form Supplied in: colorless or white solid.

Analysis of Reagent Purity: commercially available sodium dodecyl sulfate generally contains 1-dodecanol,[2] which yields a minimum at the CMC in plots of surface tension vs. concentration. The presence of 1-dodecanol can be detected by an HPLC method.[3] Impurities can also include surfactant homologs and electrolytes,[2] which yield low surface tension values above the CMC.

Preparative Methods: by sulfation of 1-dodecanol with ***Sulfur Trioxide***, followed by neutralization of the resultant dodecylsulfuric acid with ***Sodium Hydroxide***.[4]

Purification: recrystallization from H_2O and EtOH.[5]

Handling, Storage, and Precautions: harmful if inhaled or swallowed and is irritating to the eyes and skin; should be stored under nitrogen.[2b]

General Considerations.

In H_2O, SDS forms micelles above its CMC. Aqueous micellar solutions solubilize neutral organic compounds that would otherwise be insoluble in H_2O alone. Synthetic applications of micellar SDS have generally involved its ability to solubilize simultaneously both H_2O-insoluble organic substrates and H_2O-soluble (inorganic) reagents, and thus to facilitate their reactions under homogeneous conditions. An organic compound with even modest polarity is normally solubilized within a micelle in a preferred time-averaged orientation with the polar portion near or at the micelle-H_2O interface and the nonpolar portion directed into the micelle's hydrocarbon interior. In several of the examples given below, regioselectivity has resulted from these orientational effects. The features and principles of micellar catalysis have been reviewed,[6] including coulombic attraction and repulsion of ionic reagents from charged micelle-H_2O interfaces. SDS can also be used to form microemulsions, which are isotropic, optically transparent dispersions of oil (hydrocarbon) in water or water in oil. Microemulsions are formed from specific proportions of a surfactant, a cosurfactant (usually a low molecular weight alcohol), H_2O, and a hydrocarbon. Compared to aqueous micellar solutions, microemulsions can solubilize greater amounts of H_2O-insoluble organic compounds and thus offer greater reaction capacity.

Electrophilic Aromatic Substitution.

Micellar SDS has been used as a reaction medium for the chlorination and bromination of alkyl phenyl ethers[4,5a,7] and phenol[7b,8] by several halogenating agents (eq 1). Compared to reactions in H_2O alone, the *para*:*ortho* product ratio increased for pentyl, nonyl, and dodecyl phenyl ether, and decreased for anisole. Enhanced *ortho* relative to *para* substitution was obtained with phenol. In each case the observed regioselectivity derived at least in part from alignment of the substrate at the micelle-H_2O interface and resultant differential steric shielding of the *para* and *ortho* positions by the micelle superstructure.

Electrophilic Addition to Alkenes.

Hydroxy- and alkoxymercurations of alkenes have been performed in micellar SDS.[9] Hydroxymercuration of (**1**) with ***Mercury(II) Acetate***, followed by reduction with ***Sodium Borohydride***, gave a greatly enhanced yield of (**2**) in micellar SDS (90%) relative to that obtained in THF-H_2O (20-25%) (eq 2).[9a] Also, the reactions of (**1**) and the related limonene[9a] gave greater cyclic ether:diol product ratios in the SDS environment than in aq THF. Both the enhanced yields and ratios were attributed to anisotropic solubilization of the alkylmercurial intermediate in a relatively H_2O-poor micellar microenvironment. The hydroxymercuration of an aromatic diene, *p*-diallylbenzene, did not display enhanced chemoselectivity (mono vs. diol formation) in micellar SDS relative to THF-H_2O.[9b] This result suggests that the micellar solubilization sites of aromatic substrates and reaction intermediates are more H_2O-rich than those of aliphatic systems.

Alkoxymercuration of 1-octene in micellar SDS by added primary alcohols gave 2-octyl alkyl ethers.[9b] Thus when a given alcohol cannot be employed as both the reactant and solvent in the alkoxymercuration of an alkene, the use of micellar SDS-alcohol could be an attractive option.

Oxidation and Reduction.

Hypochlorite oxidations of alcohols to aldehydes and acids and of primary amines to nitriles have been performed in micellar SDS.[10,11] A microemulsion composed of SDS, 1-butanol, H_2O, and cyclohexane has been used for the very rapid oxidation of ethyl 2-chloroethyl sulfide to the corresponding sulfone by hypochlorite.[12] SDS has been used as a catalyst in the oxidations of 3,6-dimethoxydurene and xylenes by ***Cerium(IV) Ammonium Nitrate*** under two-phase conditions.[13] Selective reductions of α,β-unsaturated aldehydes and ketones have been performed with $NaBH_4$ in micellar SDS.[14] Compared to reactions in EtOH and H_2O, greater fractions of unsaturated alcohols were obtained, relative to saturated alcohols.

Cyclization.

The acid-catalyzed cyclization of (+)-citronellal (**3**) in H_2O gives diols (**4**) and (**5**) (2:1 ratio) as the major products (eq 3).[15a] In micellar SDS, the product ratio increases to 5:1 and the rate of cyclization also increases.[15a] The product and rate effects in micellar SDS are consistent with orientational effects for reactive conformations of (**3**) at the micelle-H_2O interface. Furthermore, the cyclization can be performed in micellar SDS with concentrations of (**3**) far above its solubility in H_2O alone. Micellar SDS significantly altered the ratio of acyclic to cyclic alcohol products in the acid-catalyzed solvolysis of linalyl acetate.[15b]

In micellar SDS and vesicular dipalmitoylphosphatidylcholine (DPPC), the aggregate-H_2O interfaces induce stereoselectivity in the radical cyclization of bromohydrin (**6**) (eq 4).[16] In C_6H_6 and pH 10 buffer the (**7**):(**8**) ratios are 0.77 and 1.03, respectively, whereas in the pH 10 buffer with SDS and DPPC the (**7**):(**8**) ratios are 2.29 and 2.39, respectively. These results are consistent with differential stabilization at the aggregate-H_2O interfaces of the diastereomeric transition states leading to (**7**) and (**8**).

Miscellaneous.

Diazonium ion (**10**), formed from amine (**9**) (eq 5), in the presence of H_3PO_2 gives (**11**) with, and (**12**) without, micellar SDS.[17]

(11)

(12)

There have been many other reports of reactions of organic substrates performed in micellar SDS under conditions that would not be synthetically useful.[6] Generally, the focus of these studies has been kinetics and/or regio- and stereoselectivity. However, the clear potential exists for the application of their results to organic synthesis. The conditions under which SDS undergoes acid- and base-catalyzed hydrolyses (eq 6) are generally more severe than those used in reactions performed in micellar SDS;[18] thus the hydrolysis of SDS can usually be neglected.

(6)

Synthetic Application of Other Surfactants.

In most cases, other anionic surfactants would be expected to offer results comparable to those obtained above with SDS. Cationic surfactants such as hexadecyltrimethylammonium bromide catalyze reactions involving anionic reagents.[6] In general, the isolation of organic products from surfactant-based reaction media can be facilitated by the use of cleavable surfactants.[19] A cleavable surfactant can be converted into nonsurfactant products after its use in a surfactant-based reaction solvent, thereby eliminating problems resulting from the presence of a surfactant during workup, such as the formation of persistent emulsions.

Sodium Ethoxide[1]

NaOEt

[141-52-6] · C_2H_5NaO · Sodium Ethoxide · (MW 68.06)

(used as a base for the α-deprotonation of carbonyl-containing compounds for subsequent intermolecular[2] or intramolecular[1f] condensations, displacements,[3] or skeletal rearrangements,[1d,4] arylacetonitriles,[5] nitro-containing aliphatic compounds,[6] sulfonium salts,[3j,7] for the dehydration of carbinolamines[8] and for dehydrohalogenation,[1b,9] for the *N*-deprotonation of amides,[10a-d] tosylamines,[10e] amine hydrochlorides[1c] or toluenesulfonates,[10f] cyanamide,[10g] and the *S*-deprotonations of sulfides,[1c,11] often followed by cyclizations;[1c,10b,10g,11] can be used as a nucleophile in *ipso* substitution reactions of vinyl sulfides,[12a] aromatic halides,[12b-i] sometimes catalyzed by copper[12c] or palladium,[12h,i] aryl sulfones,[12j] and aromatic nitro compounds,[12k] in the Williamson ether synthesis,[13a-c] in displacements of halo,[13d-h] nitro,[13e] thiooxy,[13g,h] and phenoxy[13g] groups from dichloromethane and chloroform analogs, in a novel transesterification-conjugate addition protocol of acrylic esters,[14] with α-nitro epoxides to form α-ethoxy ketones,[15] in the nucleophilic attack on nitriles[1e,16] and polyhaloalkenes,[17] in reaction with chlorodiphenylphosphine to form Arbuzov precursors,[18] and with Grignard reagents to form organomagnesium ethoxides[19])

Physical Data: mp >300 °C.

Solubility: sol ethanol, diethyl ether.

Form Supplied in: white or yellowish powder or as 21 wt % solution in ethanol; widely available.

Preparative Methods: it is often necessary to prepare sodium ethoxide immediately prior to its use. Preparation of a 6-10% solution in ethanol: to commercial absolute ethanol is added the required amount of ***Sodium*** in lumps or slices with or without stirring and with or without a nitrogen atmosphere and the solution is cooled or heated as required until the metal is dissolved. The evolved hydrogen should be vented into a hood. Addition of ethanol to sodium is also reported. Alcohol-free reagent can also be prepared.[1a]

Handling, Storage, and Precautions: is a hygroscopic, flammable, corrosive, and toxic solid which will decompose upon exposure to air. The solid or solution reagent should be tightly sealed under an inert atmosphere in a dark bottle.

General Discussion.

Kinetic studies of the proton transfer reaction between bis(4-nitrophenyl)methane and alkoxide base systems reveal that sodium ethoxide is a kinetically faster (k_H = 2.16 M^{-1} s^{-1}) base than either sodium isopropoxide (k_H = 0.280 M^{-1} s^{-1}) or sodium *t*-butoxide (k_H = 1.05 M^{-1} s^{-1}) (eq 1).[20a] Reaction between alkali alkoxides and *p*-nitrophenyl methanesulfonate have revealed the following order of reactivity: LiOEt< NaOEt < CsOEt &AApprox; KOEt &AApprox; KOEt + 18-crown-6 < KOEt + [2.2.2]cryptand.[20b]

$$Ar_2CH_2 + RONa \rightleftharpoons Ar_2CHNa + ROH \qquad (1)$$

Condensations of esters with the enolate of acetone can be effected using sodium ethoxide as a base to yield products such as acetylacetone[2a] and the precursor to chelidonic acid depicted in eq 2.[2b] The corresponding enolates of methyl aryl ketones can similarly be utilized.[2c,1f]

(2)

Condensation of the sodium ethoxide-generated enolate of cyclohexanone with ethyl formate yields 2-hydroxymethylenecyclohexanone which, upon treatment with hydrazine monohydrate, forms indazole in excellent yield (eq 3).[2d]

(3)

Sodium ethoxide is often the base of choice in the α-acylation[2e-i] and alkylation[3h] of esters. Interesting intramolecular cyclizations sometimes follow in good yield (eq 4).

(4)

Alkylation of malonate esters through the intermediacy of enolates generated using sodium ethoxide is quite common.[3] Subsequent decarboxylation to the carboxylic acid can then be induced, as depicted in eq 5.[3d]

Sodium ethoxide and ***Sodium Hydroxide*** have both proven effective in the cyclopropanation of various γ,δ-epoxy ketones, as illustrated in eq 6. Adducts are generated in good to excellent yields.[4]

Deprotonation α to nitriles has been found to be strongly influenced by the purity of the sodium ethoxide used[5a] and can be done selectively over α-deprotonation of an ester.[5b] Reactions with aromatic aldehydes lead to condensation adducts (eq 7).[5c]

Deprotonations α to nitro functionalities have been found to proceed with greater ease using sodium ethoxide rather than ***Sodium Methoxide***.[6] The in situ generated anion of 2-nitropropane transforms a benzylic bromide to its aromatic aldehyde derivative in good yield (eq 8).[7a]

Sodium ethoxide serves as a multipurpose base to generate both the ylide of dimethyl-2-propynylsulfonium bromide and the anion of acetylacetone in the synthesis of 3-acetyl-2,4-dimethylfuran illustrated in eq 9.[3j] The intermediacy of an allene has been suggested.[7b]

(9)

Sodium ethoxide both dehydrates and nucleophilically assists in the deacylation of the carbinolamine intermediate depicted in eq 10.[8] Furthermore, sodium ethoxide-mediated dehydrohalogenation in DMSO solvent has been achieved in excellent yield (eq 11).[1b,9]

(10)

(11)

Heteroatom deprotonations using sodium ethoxide as the base are also quite common. Sodium ethoxide serves as an effective base when the nitrogen of cyanoacetamide must be condensed on an ester. Subsequent intramolecular cyclization proceeding via α-deprotonation to the nitrile leads to excellent yield of the dicyanoglutarimide shown in eq 12.[10a]

(12)

Other *N*-deprotonations include that of urea,[10b] thiourea,[10c] succinimide,[10d] tosylamines,[10e] cysteamine hydrochloride (eq 13),[1c] ribofuranosylamine toluenesulfonate,[10f] and cyanamide (eq 14).[10g] Similarly, *S*-deprotonations of sulfides (eq 13)[1c,11] have been reported. Often, adducts can be used in subsequent cyclizations.[1c,10b,g,11]

The synthesis of 6,6-dialkoxyfulvenes from 6,6-bis(methylthio)fulvene has been reported in good yield via treatment with sodium ethoxide or related nucleophiles, followed by thermolysis (eq 15).[12a]

Addition of a large excess of sodium ethoxide or methoxide to 11-chloro[5]metacyclophanes leads to good yields of *ipso* alkoxy-substituted adducts.[12b] Sodium ethoxide proves to be the fastest of a series of nucleophiles in *ipso* substitution reactions of aromatic bromides employing a ***Copper(I) Bromide*** catalyst (eq 16). Once again, purity of alkoxide seems to be important.[12c] Substitution of aryl iodides is also known.[12d]

Ipso ethoxy substitutions of halo-pyrimidines,[10g] -purines (eq 17),[12e] -thiophenes,[12c,f] -furans,[12c] and -triazines[12g] using sodium ethoxide have

also been reported in good yield.

Aryl iodides, vinyl bromides, and tricarbonyl(chloroarene)chromium complexes have been found to react under mild conditions with sodium alkoxides in the presence of catalytic dichlorobis(triphenylphosphine)palladium(II) (see ***Palladium(II) Chloride***) to afford the corresponding benzoate esters as the major products (eq 18).[12h,i] It has been rationalized that the higher base strength of sodium ethoxide compared to that of sodium methoxide allows the former to successfully decarbonylate ethyl formate, whereas the latter proves more sluggish, yielding poorer results.

Ipso substitution of 2- and 4-pyridyl sulfones is also possible using a variety of nucleophiles, including sodium ethoxide. The sulfone moiety is preferentially displaced over a chlorine substituent also present on the aromatic ring (eq 19). The same reaction utilizing sulfoxides gives mixed results, while sulfides fail to react.[12j]

It has been suggested that displacement of the nitro group of the radical anion of *p*-nitrobenzophenone by sodium ethoxide is followed by chain transfer from the resulting *p*-ethoxybenzophenone radical, resulting in the adduct pictured in eq 20.[12k]

Sodium ethoxide is frequently employed as the nucleophile in the Williamson ether synthesis,[13a-c] as illustrated in eq 21. Furthermore, polydisplacements of halo,[13d-h] nitro,[13e] thiooxy,[13g,h] and phenoxy[13g] groups of dichloromethane and chloroform analogs have been realized by the use of sodium ethoxide as the nucleophile. This methodology has been used in the syntheses of ethyl orthocarbonate (eq 22) and ethyl diethoxyacetate (eq 23) in moderate to good yields.

Sodium ethoxide has been employed for a transesterification-conjugate addition protocol, which takes advantage of the *syn*-selective addition of sodium alkoxides to acrylic esters such as the one depicted in eq 24.[14]

An interesting synthesis of α-ethoxy ketones employs nucleophilic reaction of sodium ethoxide with α-nitro epoxides. The reaction appears to be quite general and a variety of nucleophiles may be employed (eq 25).[15]

(25)

Nucleophilic attack of sodium ethoxide on 3,4- or 2,3-cyanomethyl cyanopyridines followed by cyclization provides access to amino alkoxy naphthyridines (eq 26).[1e,16] The reaction is believed to proceed through an imidate intermediate.[16a] Unfortunately, treatment of the analogous carbocyclic 2-cyanobenzyl cyanides under similar conditions leads to dimerization of starting material, and cyclization must be achieved under acidic conditions.[16b]

(26)

Sodium ethoxide is also known to nucleophilically add to polyhaloalkenes with preferential attack on the methylene with the highest degree of fluorine substitution (eqs 27 and 28).[17] Excess nucleophile unveils an ethyl ester (eq 28).

(27)

(28)

80-85%

Reaction of sodium ethoxide with chlorodiphenylphosphine provides access to Arbuzov precursors, which can be further reacted with suitable electrophiles to form phosphine oxides (eq 29).[18]

(29)

Treatment of Grignard reagents (RMgBr) with sodium ethoxide offers a synthetic route to organomagnesium ethoxides (RMgOEt).[19] No yields are reported for this reaction.

Related Reagents.

Potassium t-Butoxide; ***Potassium 2-Methyl-2-butoxide***; ***Sodium Hydroxide***; ***Sodium Methoxide***.

Sodium Fluoride[1]

NaF

[7681-49-4] · FNa · Sodium Fluoride · (MW 41.99)

(halogen replacement by fluorine)

Physical Data: mp 993 °C; *d* 2.56 g cm^{-3}.

Solubility: sol 42.2 g L^{-1} H_2O; sol HF; insol EtOH.

Form Supplied in: white solid, widely available.

Handling, Storage, and Precautions: moderately toxic with LD_{50} = 0.18 g kg^{-1} in rats. People are severely affected after injesting less than one gram of NaF.

Introduction.

Although NaF can be used to replace other halogens with fluorine, ***Potassium Fluoride*** is the research chemist's reagent of choice because NaF is less efficient and much less soluble in commonly used solvents. This is not meant to imply that NaF is ineffective. Where the previously listed disadvantages are not critical, NaF is less hygroscopic and cheaper.[2] In general, laboratory syntheses use KF and, upon scaleup to a plant procedure, NaF is substituted if possible.

Displacement of Halogen with Sodium Fluoride.

Traditionally, compounds containing a reactive chlorine bonded to carbon, sulfur, or phosphorus can be converted to the corresponding fluorides with NaF in tetramethylene sulfone, MeCN, or DMF, as shown in Table 1.[1] Pentachloropyridine and NaF in tetramethylene sulfone gave 3,5-dichlorotrifluoropyridine.[3] In a similar way, 2,4,6-trifluoro-1,3,5-triazine can be formed from the trichloro- or a mixture of chloro- and fluoro-1,3,5-triazines.[4] The rate and efficiency of the reaction can be improved by the addition of a phase-transfer catalyst. This is illustrated by the conversion of benzyl halides to benzyl fluoride or carboxylic acid halides to carboxylic acid fluorides.[5]

Table 1 Conversion of Organic Chlorides to Fluorides with NaF and Tetramethylene Sulfone.

Reactant	Product	Conversion to fluoride (%)
CCl_3SCl	CF_3SCl	47
$ClCH_2OMe$	FCH_2OMe	47
$ClCO_2Me$	FCO_2Me	33
$(COCl)_2$	$(COF)_2$	60
MeCOCl	MeCOF	48
PhCOCl	PhCOF	62
$SOCl_2$	SOF_2	77
SO_2Cl_2	SO_2F_2	85
$PhPSCl_2$	$PhPSF_2$	65

Although a halomethyl ether can be converted to a fluoromethyl ether (Table 1), an unusual reaction incorporates the use of NaF, with the reactant and product as the solvent, under supercritical reaction conditions, to displace halogen with fluoride (eqs 1 and 2). KF is equally effective.[6]

(1)

(2)

Generally speaking, the choice of NaF in place of KF is based on economics. There is no cited synthetic advantage of NaF over KF other than that NaF is easier to obtain and maintain in the anhydrous state.

Sodium Hexamethyldisilazide[1]

$NaN(SiMe_3)_2$

[1070-89-9] · $C_6H_{18}NNaSi_2$ · Sodium Hexamethyldisilazide · (MW 183.42)

(useful as a sterically hindered base and as a nucleophile)

Alternate Names: NaHMDS; sodium bis(trimethylsilyl)amide.

Physical Data: mp 171-175 °C; bp 170 °C/2 mmHg.

Solubility: sol THF, ether, benzene, toluene.[1]

Form Supplied in: (a) off-white powder (95%); (b) solution in THF (1.0 M); (c) solution in toluene (0.6 M).

Analysis of Reagent Purity: THF solutions of the reagent may be titrated using 4-phenylbenzylidenebenzylamine as an indicator.[2]

Handling, Storage, and Precautions: the dry solid and solutions are flammable and must be stored in the absence of moisture. These should be handled and stored under a nitrogen atmosphere. Use in a fume hood.

Introduction.

Sodium bis(trimethylsilyl)amide is a synthetically useful reagent in that it combines both high basicity[3] and nucleophilicity,[4] each of which may be exploited for useful organic transformations such as selective formation of enolates,[5] preparation of Wittig reagents,[6] formation of acyl anion equivalents,[7] and the generation of carbenoid species.[8] As a nucleophile, it has been used as a nitrogen source for the preparation of primary amines.[9,10]

Sterically Hindered Base for Enolate Formation.

Like other metal dialkylamide bases, sodium bis(trimethylsilyl)amide is sufficiently basic to deprotonate carbonyl-activated carbon acids[5] and is sterically hindered, allowing good initial kinetic vs. thermodynamic deprotonation ratios.[11] The presence of the sodium counterion also allows for subsequent equilibration to the thermodynamically more stable enolate.[5f] More recently, this base has been used in the stereoselective generation of enolates for subsequent alkylation or oxidation in asymmetric syntheses.[12] As shown in eq 1, NaHMDS was used to selectively generate a (*Z*)-enolate; alkylation with ***Iodomethane*** proceeded with excellent diastereoselectivity.[12a] In this case, use of the sodium enolate was preferred as it was more reactive than the corresponding lithium enolate at lower temperatures.

The reagent has been used for the enolization of carbonyl compounds in a number of syntheses.[13] For ketones and aldehydes which do not have enolizable protons, NaHMDS may be used to prepare the corresponding TMS-imine.[14]

Generation of Ylides for Wittig Reactions.

In the Wittig reaction, salt-free conditions have been shown to improve (*Z*):(*E*) ratios of the alkenes which are prepared.[15] NaHMDS has been shown to be a good base for generating ylides under lithium-salt-free conditions.[6] It has been used in a number of syntheses to selectively prepare (*Z*)-alkenes.[16] Ylides generated under these conditions have been shown to undergo other ylide reactions such as *C*-acylations of thiolesters and inter- and intramolecular cyclization.[6] Although Wittig-based syntheses of vinyl halides exist,[17] NaHMDS has been shown to be the base of choice for the generation of iodomethylenetriphenylphosphorane for the stereoselective synthesis of (*Z*)-1-iodoalkenes from aldehydes and ketones (eq 2).[18]

NaHMDS has been shown to be the necessary base for the generation of the ylide anion of sodium cyanotriphenylphosphoranylidenemethanide, which may be alkylated with various electrophiles and in turn used as an ylide to react with carbonyl compounds.[19] NaHMDS was used as the base of choice in a Horner-Emmons-Wadsworth-based synthesis of terminal conjugated enynes.[20]

Intramolecular Alkylation via Protected Cyanohydrins (Acyl Anion Equivalents).

Although NaHMDS was not the base of choice for the generation of protected cyanohydrin acyl carbanion equivalents in the original references,[21] it has been shown to be an important reagent for intramolecular alkylation using this strategy (eqs 3 and 4).[7,22] The advantages of this reagent are (a) that it allows high yields of intramolecularly cyclized products with little intermolecular alkylation and (b) the carbanion produced in this manner acts only as a nucleophile without isomerization of double bonds α,β to the anion or other existing double bonds in the molecule. Small and medium rings as well as macrocycles[22a] have been reported using this methodology (eqs 3 and 4).

(3)

(4)

Generation of Carbenoid Species.

Metal bis(trimethylsilyl)amides may be used to effect α-eliminations.[23] It is proposed that these nucleophilic agents undergo a hydrogen-metal exchange reaction with polyhalomethanes to give stable carbenoid species.[23b] NaHMDS has been used to generate carbenoid species which have been used in a one-step synthesis of monobromocyclopropanes (eqs 5 and 6).[23c,d] NaHMDS has been shown to give better yields than the corresponding lithium or potassium amides in this reaction.

(5)

(6)

A similar study which evaluated the use of NaHMDS versus ***n-Butyllithium*** for the generation of the active carbenoid species from 1,1-dichloroethane and subsequent reaction with alkenes, forming 1-chloro-1-methylcyclopropanes, suggested that the amide gave very similar results to those with *n*-butyllithium.[24]

In an initial report, the carbenoid species formed by the treatment of diiodomethane with NaHMDS was shown to react as a nucleophile, displacing primary halides and leading to a synthesis of 1,1-diiodoalkanes; this is formally a 1,1-diiodomethylene homologation (eq 7).[25] This methodology is limited in that electrophiles which contain functionality that allows facile E2 elimination (i.e. allyl) form a mixture of the desired 1,1-diiodo compound and the iododiene. In the case of ***Allyl Bromide***, addition of 2 equiv of the sodium reagent allows isolation of the iododiene as the major product.

(7)

Synthesis of Primary Amines.

The nucleophilic properties of this reagent may be utilized in the S_N2 displacement of primary alkyl bromides, iodides, and tosylates to form bis(trimethylsilyl)amines (**1**) (eq 8).[9a] HCl hydrolysis of (**1**) allows isolation of the corresponding hydrochloride salt of the amine, which may be readily separated from the byproduct, bis(trimethylsilyl) ether. In one example a secondary allylic bromide also underwent the conversion with good yield.

(8)

Aminomethylation.

NaHMDS may be used as the nitrogen source in a general method for the addition of an aminomethyl group (eq 9).[10] The reagent is allowed to react with chloromethyl methyl ether, forming the intermediate aminoether. Addition of Grignard reagents to this compound allows the displacement of the methoxy group, leaving the bis(trimethylsilyl)-protected amines. Acidic hydrolysis of these allows

isolation of the hydrochloride salt of the corresponding amine in good yields.

Sodium Hydrazide[1]

$NaHNNH_2$

[16657-57-1] · H_3N_2Na · Sodium Hydrazide · (MW 54.04)

(capable of nucleophilic addition to alkenes,[2] alkynes,[3] and nitriles[4] to give hydrazines, hydrazones, or amidrazones; reacts by nucleophilic substitution with electrophilic heteroarenes[5] to give hydrazines[5] or amines[6] and with benzene halides[7] or benzene sulfonates[8] to give hydrazines; reacts with 1,3-dienes in presence of hydrazine to give dehydrogenated hydrazine derivatives;[9] further reaction modes include reduction of unsaturated hydrocarbons[10] and reductive dehalogenation,[11] cleavage of C=C double bonds affording a hydrocarbon and a hydrazone,[12] and selective cleavage of tertiary amide bonds[13])

Physical Data: IR spectrum.[14]

Solubility: moderately sol H_2NNH_2, liquid NH_3.

Preparative Methods: obtained as a suspension of pale yellow crystals by action of ***Sodium Amide*** on anhydrous ***Hydrazine*** under pure N_2 at rt in ether or at -33 °C in liquid NH_3 in a special apparatus.[2a] The method of preparation using Na/H_2NNH_2 often leads to explosion, even if O_2 is strictly excluded.[15]

Handling, Storage, and Precautions: **explodes violently and regularly** in contact with O_2; storage is not recommended. A protective plexiglass screen (thickness 1 cm) is absolutely necessary in front of the apparatus as $NaHNNH_2$ is prepared and reacted. In reactions with organic compounds, moderate heating (max 60 °C) is allowed. Hydrolysis of the reaction mixture is possible by very slow addition (avoidance of local overheating) of water under ice-cooling. Use in a fume hood.

Nucleophilic Addition.

The high tendency of $NaHNNH_2$ to add by a special mechanism[2a] to unsaturated organic compounds enables the transformation of alkenes such as styrene[2] to alkyl hydrazines, of alkynes[3] to hydrazones, and of nitriles[4] to amidrazones at low temperatures in ether (eqs 1-5). For the reaction of eq 1, only a catalytic amount of $NaHNNH_2$ is necessary.

(1)

(2)

(3)

(4)

(5)

Nucleophilic Substitution.

$NaHNNH_2$ reacts with electrophilic heteroarenes such as pyridine[5a] and isoquinoline[5b,5c] by substitution of hydrogen. In ether, reactions in the presence of H_2NNH_2 produce mono(heteroaryl)hydrazines, whereas in the absence of H_2NNH_2, *N,N′*-bis(heteroaryl)hydrazines are generated (eqs 6 and 7). In the case of acridine and phenanthridine the substitution product is an amino heteroarene.[6] Treating *p*-tolyl halides[7] with $NaHNNH_2/H_2NNH_2$ yields tolyl hydrazines by an addition-elimination mechanism (eq 8) or aryne mechanism (eq 9). Sodium *p*-tolylsulfonate[8] reacts under the same conditions to give *p*-tolylhydrazine.

(6)

(7)

(8)

(9)

Oxidative Hydrazination.

Hydrazination with subsequent dehydrogenation to give azines or pyrazoles occurs by simultaneous action of $NaHNNH_2$ and H_2NNH_2 in ether on 1,3-dienes (eqs 10 and 11).[9]

Reduction and Reductive Hydrazination.

Treatment of unsaturated hydrocarbons (e.g. stilbene), unsaturated nitrogen compounds, or polycyclic arenes with $NaHNNH_2/H_2NNH_2$ leads frequently to reduction of the substrate[10] (e.g. eq 12). The initially formed $NaHNNH_2$ adduct is believed to eliminate sodium diimide in these cases. Naphthalene is reduced to the 1,2-dihydro derivative, which affords 2-hydrazino-1,2,3,4-tetrahydronaphthaline[2b] by addition of $NaHNNH_2$ (eq 13). A further type of reduction is reductive dehalogenation.[11]

Alkene Hydrazidolysis.

$NaHNNH_2$ is capable of cleaving C=C double bonds[12] which are activated by an adjacent aryl residue (eq 14). This reaction is analogous to the reaction of aldehydes and ketones with H_2NNH_2 to give H_2O and a hydrazone. By subsequent treatment of the hydrazone of eq 14 with aq acid, a formal hydrolysis (eq 15) of a C=C double bond is achieved. Alternatively, subsequent treatment of the hydrazone with NaOH under Wolff-Kishner conditions gives rise to formal reductive cleavage (eq 16).

(14)

(15)

(16)

A related cleavage reaction (eq 17)[12c] was observed by reacting 2 equiv $NaHNNH_2$ with β-halogen phenylalkanes in the presence of hydrazine.

(17)

Regiospecific or Regioselective Peptide Hydrazidolysis.

In the presence of hydrazine, $NaNHNH_2$ cleaves tertiary amide groups, whereas secondary and primary amide groups (which form

mesomeric anions) are stable under these conditions. This allows a quantitative regiospecific hydrolysis of diglycyl-L-proline (eq 18).[13] By reacting $NaHNNH_2/H_2NNH_2$ with insulin, which contains only one tertiary amide bond, selective fission was possible to give the peptide Pro-Lys-Ala-CO_2H (ca. 70%).

Sodium Hydride[1]

NaH

[7646-69-7] · HNa · Sodium Hydride · (MW 24.00)

(used as a base for the deprotonation of alcohols, phenols, amides (NH), ketones, esters, and stannanes; used as a reducing agent for disulfides, disilanes, azides, and isoquinolines)

Physical Data: mp 800 °C (dec); *d* 1.396 g cm^{-3}.

Solubility: decomposes in water; insol all organic solvents; insol liq NH_3; sol molten sodium.

Form Supplied in: free-flowing gray powder (95% dry hydride); gray powder dispersed in mineral oil.

Handling, Storage, and Precautions: the dispersion is a solid and may be handled in the air. The mineral oil may be removed from the dispersion by stirring with pentane, then allowing the hydride to settle. The pentane/mineral oil supernatant may be pipetted off, but care should be exercised to quench carefully any hydride in the supernatant with a small amount of an alcohol before disposal. The dry powder should only be handled in an inert atmosphere.

Sodium hydride dust is a severe irritant and all operations should be done in a fume hood, under a dry atmosphere. Sodium hydride is stable in dry air at temperatures of up to 230 °C before ignition occurs; in moist air, however, the hydride rapidly decomposes, and if the material is a very fine powder, spontaneous ignition can occur as a result of the heat evolved from the hydrolysis reaction. Sodium hydride reacts more violently with water than sodium metal (eq 1); the heat of reaction usually causes hydrogen ignition.

$$NaH + H_2O \longrightarrow NaOH + H_2 \qquad (1)$$

Introduction.

The following is arranged by reaction type: NaH acting as a base on oxygen, nitrogen, germanium/silicon, and carbon acids, and as a reducing agent.

Oxygen Acids (Alcohol Deprotonation).

Sodium hydride may be used as a base in the Williamson ether synthesis in neat benzyl chloride,[2] in DMSO,[3] or in THF (eq 2).[4] Phenols may also be deprotonated and alkylated in THF.[4b]

$$Ph_3COH + NaH + MeI \xrightarrow[85\%]{THF} Ph_3COMe \qquad (2)$$

Curiously, tertiary propargylic alcohols may be alkylated in preference to either axial or equatorial secondary alcohols, using sodium hydride in DMF (eq 3).[5]

Sodium hydride in DMF is also used to deprotonate carbohydrate derivatives, for methylation or benzylation (eq 4).[6]

Unstable benzyl tosylates may be made by deprotonation of benzyl alcohols and acylation with ***p-Toluenesulfonyl Chloride*** (eq 5).[7]

An interesting conformational effect is seen when *p-t*-butylcalix[4]arene is tetraethylated. When ***Potassium Hydride*** is used as the base, the partial cone conformation predominates (i.e. one of the aryl groups is inverted), whereas with sodium hydride, the cone is produced exclusively (eq 6).[8]

Deprotonation of vinylsilane-allylic alcohols using sodium hydride in HMPA is followed by an essentially quantitative C -> O silicon migration (eq 7).[9]

Nitrogen Acids.

Sodium hydride in DMSO, HMPA, NMP, or DMA assists the transamination of esters (eq 8).[10]

Acyl amino acids and peptides may be alkylated on nitrogen using sodium hydride, with no racemization (eq 9).[11] A slight change of reaction conditions allows simultaneous esterification.[12]

A similar intramolecular alkylation has been used to make β-lactams (eq 10).[13]

Germanium/Silicon Acids.

Germanium-hydrogen and silicon-hydrogen bonds are quantitatively cleaved with sodium hydride in ethereal solvents (eq 11).[14]

Carbon Acids.

Active methylene compounds, such as malonates and β-keto esters, can be deprotonated with sodium hydride and alkylated on carbon (eqs 12 and 13).[15] Alkylation of Reissert anions is also facile with sodium hydride (eq 14).[16]

(12)

(13)

(14)

Normally, sodium enolates of ketones alkylate on oxygen. A superactive form of sodium hydride is formed when butylsodium is reduced with hydrogen; superactive sodium hydride is an excellent base for essentially quantitative deprotonation of ketones, trapped as their silyl ethers.[17] For example, cyclododecanone is converted to its enol ether (containing a hyperstable double bond) in 92% yield (eq 15).

(15)

More commonly, sodium hydride is used as a base for carbonyl condensation reactions. For example, Claisen condensations of ethyl acetate[18] and ethyl isovalerate[19] are effected by sodium hydride. Condensations of cyclohexanone with methyl benzoate[19] and ethyl formate (eq 16)[20] are also facile.[21] Sodium hydride can also doubly deprotonate β-diketones, allowing acylation at the less acidic site (eq 17).[22]

(16)

(17)

An undergraduate experiment using sodium hydride involves the crossed condensation of ethyl acetate and dimethyl phthalate (eq 18).[23] Sodium hydride is also effective as a base in the Stobbe condensation[24] and the Darzens condensation.[25] It is also effective in a stereoselective intramolecular Michael reaction (eq 19).[26]

(18)

(19)

The Dieckmann condensation of esters[27] and thioesters[28] is mediated by sodium hydride (eq 20). Conditions for the latter are significantly more mild than for the former, and the yields are higher.

(20)

Sodium hydride may be used to cleave formate esters and formanilides (eqs 21 and 22).[29] The mechanism apparently involves removal of the formyl proton and loss of carbon monoxide.

(21)

(22)

Dehydrohalogenation with sodium hydride is a means of making methylenecyclopropanes (eq 23).[30]

(23)

Enolate formation apparently accelerates the Diels-Alder cycloaddition/cycloreversion, shown in eq 24, which occurs at room temperature.[31]

(24)

An unusual cyclization of *N*-allyl-α,β-unsaturated amides is mediated by sodium hydride in refluxing xylene (eq 25).[32] The reaction is thought to proceed by intramolecular 1,4-addition of the dianion shown.

(25)

Reductions.

The sodium salt of trimethylsilane is produced quantitatively by reduction of hexamethyldisilane with sodium hydride (eq 26).[33]

(26)

Sodium hydride in DMSO is an effective medium for the reduction of disulfide bonds in proteins under aprotic conditions.[34] When the molar ratio of hydride to 1/2 cystine residues exceeds 2:1, essentially complete reduction of the disulfide bonds of bovine serum albumin is achieved.

Azides are reduced to amines by sodium hydride, although the yields are moderate (eq 27).[35] Sodium hydride also reduces isoquinoline to 1,2-dihydroisoquinoline in good yield (eq 28).[36]

Sodium Hydride-Copper(II) Acetate-Sodium *t*-Pentoxide

NaH + $Cu(OAc)_2$ + NaO-*t*-C_5H_{11}

(NaH)

[7646-69-7] · HNa · Sodium Hydride-Copper(II) Acetate-Sodium *t*-Pentoxide · (MW 24.00) ($Cu(OAc)_2$)

[142-71-2] · $C_4H_6CuO_4$ · Sodium Hydride-Copper(II) Acetate-Sodium *t*-Pentoxide · (MW 181.65) (NaO-*t*-C_5H_{11})

[14593-46-5] · $C_5H_{11}NaO$ · Sodium Hydride-Copper(II) Acetate-Sodium *t*-Pentoxide · (MW 110.15)

(a complex reducing agent (CRA) that converts aromatic halides to hydrocarbons; can act as a coupling agent[1,2])

Physical Data: see ***Sodium Hydride*** and ***Copper(II) Acetate***; the *t*-pentoxide salt is prepared in situ.

Solubility: sol THF, DME.

Preparative Methods: from NaH, *t*-pentanol, and $Cu(OAc)_2$ in THF. Addition of *t*-pentanol begins at 40 °C, as it is very important not to exceed 45 °C throughout the process. After 3 h of stirring at 45 °C, the catalyst is ready for use.[3,4]

Handling, Storage, and Precautions: store under argon in airtight bottles; moisture sensitive. Use in a fume hood.

Reduction of Aromatic Halides.

The title reagent is an example of a series of complex reducing agents (CRAs) obtained by treating NaH and an alcohol (in this case, *t*-pentanol) with a metallic acetate salt (in this case, copper(II) acetate). These CRAs exhibit reducing abilities which can be varied by changing the solvent, the alkoxide, or the reaction temperature. In eq 1, reduction of 1-bromonaphthalene to the hydrocarbon is accompanied by coupling to produce 1,1´-binaphthyl.

Both THF and DME can be used as solvent. In THF, reaction after 17 h yielded 60-65% naphthalene and 20% 1,1´-binaphthyl. In DME, after 20 h, 80-85% naphthalene and 5-10% 1,1´-binaphthyl were formed. With other salts ($Co(OAc)_2$, $Ni(OAc)_2$, $Zn(OAc)_2$), hydrocarbon yields were 85-95% within 5 min-2 h, with no coupling product observed.

Reduction of Primary Alkyl Halides.

The reagent was not effective in the reduction of primary alkyl halides. When reacted with *n*-octyl bromide, it afforded mainly 1-octene along with small amounts (5-20%) of octane.

Sodium Hydride-Nickel(II) Acetate-Sodium *t*-Pentoxide

$NaH + Ni(OAc)_2 + NaO\text{-}t\text{-}C_5H_{11}$

(NaH)

[7646-69-7] · HNa · Sodium Hydride-Nickel(II) Acetate-Sodium *t*-Pentoxide · (MW 24.00) ($Ni(OAc)_2.4H_2O$)

[6018-89-9] · $C_4H_{14}NiO_8$ · Sodium Hydride-Nickel(II) Acetate-Sodium *t*-Pentoxide · (MW 248.87) ($NaO\text{-}t\text{-}C_5H_{11}$)

[14593-46-5] · $C_5H_{11}NaO$ · Sodium Hydride-Nickel(II) Acetate-Sodium *t*-Pentoxide · (MW 110.15)

(highly active and selective nickel hydrogenation catalyst at atmospheric pressure; allows semihydrogenation of alkynes to *cis*-alkenes[1,2] and stereoselective reduction of ketones[9])

Physical Data: see ***Sodium Hydride*** and ***Nickel(II) Acetate***; the *t*-pentoxide salt is prepared in situ.

Solubility: sol THF, DME.

Preparative Methods: the nickel catalyst (referred to as NiC) is easily prepared by addition of the alcohol, the sodium salt of which has been chosen as an activating agent (in this case, sodium *t*-pentoxide), to a stirred suspension of $Ni(OAc)_2$ and a calculated excess of NaH in THF at 45 °C. Before hydrogenation, EtOH is used to wash NiC to eliminate excess soluble alkoxide.

Handling, Storage, and Precautions: when long storage is required, the excess sodium hydride must not be neutralized, but rather destroyed before use in hydrogenation. Simple washing with EtOH can eliminate excess alkoxide. Store under argon. Use in a fume hood.

Hydrogenation.

It was observed that, at room temperature and atmospheric pressure, alkenes and alkynes could be reduced to alkanes and *cis*-alkenes, respectively, over this NiC catalyst. Until most of the alkyne is converted to the alkene, only minor amounts of alkane are formed, even when further hydrogenation of the alkene is the faster reaction.[1,2] It was also found that NiC could promote hydrogenation of carbonyl compounds under ambient conditions. In reductions of ethylenic unsaturations, NiC catalysts are very sensitive to steric hindrance about the carbonyl groups (eqs 1-4).[3]

(1)

3α:3β = 67:33

(2)

5α:5β = 13:87

Other Reductions.

NiC can also be activated by ***Chlorotrimethylsilane***; selective reduction of polyunsaturated ketones is easily performed with this reagent.[4] NiC is useful in desulfurizing organic compounds such as sulfur-containing heteroaromatic substrates, aryl thioethers, dithioacetals, sulfoxides, and sulfones.[5,8] NiC combined with 2,2´-bipyridine (the nickel complex reducing agent NiCRA-bipy) is also very efficient in the desulfurization of organic compounds.[8]

Homocoupling of aryl bromides and chlorides is effected with NiCRA-bipy; the presence of alkali iodides improves the procedure. Yields are very high; however, a number of functional groups in the substrate may cause loss of reactivity.[6] NiCRA-bipy is the first nickel-containing reagent that allows Ullmann-type cross-coupling to occur in good yield and under mild conditions.[7]

NiCRAs and other metal complex reducing agents are among the reagents known for epimerization of alcohols. By varying the metal used, and by using additives such as ***Magnesium Bromide*** or Me_3SiCl, preferential formation of axial and equatorial alcohols from ketones is achieved. NiCRAs may be used to transform a given alcohol into its thermodynamically less stable epimer.[9] This method, complementary to the familiar Meerwein-Ponndorf-Verley-Oppenauer and Raney nickel processes, employs substrate-activated agents ((SA)NiCRA) or other additives (eq 5) (DMHDNa = sodium salt of 2,5-dimethylhexane-2,5-diol).

Sodium Hydride-Palladium(II) Acetate-Sodium *t*-Pentoxide

NaH + $Pd(OAc)_2$ + NaO-*t*-C_5H_{11}

(NaH)

[7646-69-7] · HNa · Sodium Hydride-Palladium(II) Acetate-Sodium *t*-Pentoxide · (MW 24.00) ($Pd(OAc)_2$)

[3375-31-3] · $C_4H_6O_4Pd$ · Sodium Hydride-Palladium(II) Acetate-Sodium *t*-Pentoxide · (MW 224.52) (NaO-*t*-C_5H_{11})

[14593-46-5] · $C_5H_{11}NaO$ · Sodium Hydride-Palladium(II) Acetate-Sodium *t*-Pentoxide · (MW 110.15)

(complex reducing agent; reduction of aromatic halides;[1] self-terminating semihydrogenation of alkynes[2])

Physical Data: see ***Sodium Hydride*** and ***Palladium(II) Acetate***; the *t*-pentoxide salt is prepared in situ.

Solubility: sol THF, DME, ethanol, hydrocarbon solvents.

Preparative Methods: from NaH, *t*-pentanol, and $Pd(OAc)_2$ in THF. Add the *t*-pentanol at 40 °C, as it is very important not to exceed 45 °C throughout the process. After 3 h of stirring at 45 °C, the catalyst is ready for use.[1,3,4]

Handling, Storage, and Precautions: store under argon in air-tight bottles; moisture sensitive; use in a fume hood.

Reduction of Aromatic Halides.

The reagent can be an effective reducing agent for converting aromatic halides to the corresponding hydrocarbons, as illustrated by the bromonaphthalenes (eq 1).[1] Both THF and DME can be used as solvent with a reaction temperature of 63 °C. With THF, the reaction time is 5 min (90-95% yield); with DME, the reaction time increases to 30 min (85-90% yield).

(1)

Self-Terminating Semihydrogenation of Alkynes.

This palladium complex reducing agent (Pd CRA) allows semihydrogenation of alkynes to *cis*-alkenes at atmospheric pressure. For the semihydrogenation of monosubstituted alkynes, reactions must be conducted in solvents such as hexane or octane, whereas the semihydrogenation of disubstituted alkynes are conducted in ethanol, ethanol/hydrocarbon mixtures, or ethanol/THF mixtures. Moreover, in all cases, the presence of ***Quinoline*** as a catalyst modifier was necessary (eq 2).[2]

Related Reagents.

Nickel Complex Reducing Agents; ***Sodium Hydride***; ***Sodium Hydride-Copper(II) Acetate-Sodium t-Pentoxide***; ***Sodium Hydride-Nickel(II) Acetate-Sodium t-Pentoxide***; ***Zinc Complex Reducing Agents***.

Sodium Hydrogen Selenide[1]

NaHSe

[12095-50-5] · HNaSe · Sodium Hydrogen Selenide · (MW 102.96)

(nucleophilic agent for introduction of selenium by substitution reactions; mild reducing agent[1])

Solubility: sol water, ethanol.

Form Supplied in: white crystals; very unstable in moist air.

Preparative Methods: reaction of ***Hydrogen Selenide*** with ***Sodium Ethoxide*** in anhydrous conditions under nitrogen.[2] Aqueous or ethanolic solutions of NaHSe can be prepared by treatment of NaOEt, NaOH, or Na_2CO_3 solutions with H_2Se.[3-5] The most convenient procedure involves reduction of ***Selenium*** with ***Sodium Borohydride***.[6] It allows the rapid and easy preparation of NaHSe without the necessity of generating dangerously toxic H_2Se. A suspension of NaHSe in DMF is produced similarly.[7]

Handling, Storage, and Precautions: unstable compound; decomposes in moist air with the formation of polyselenides and precipitation of Se. It should be used directly as prepared in solution or suspension without isolation. Use in a fume hood.

Introduction of Se.

NaHSe reacts with acyl chlorides to give diacyl diselenides after oxidation (eq 1).[3] Aromatic aldehydes are converted into benzyl diselenides when treated with NaHSe in the presence of ***Piperidine*** hydrochloride followed by reduction with $NaBH_4$.[8]

Selenoamides can be obtained from thioamides treated with NaHSe,[9] whereas tetrasubstituted selenoureas are prepared by the reaction of NaHSe with methylthiouronium salts (eq 2).[5] An efficient method for synthesis of selenoesters consists in transforming *N*,*N*-dimethylamides into *N*,*N*-dimethylimidoyl chlorides and treatment of these with NaHSe in ethanol (eq 3).[10] Selenoformates are also prepared in this way.[11] Carboxylic esters are easily cleaved into carboxylic acids and selenols by treatment with NaHSe in DMF or EtOH.[7,12] Alkyl halides react with NaHSe to form selenides (eq 4)[6] or selenols.[13]

(2)

(3)

(4)

Reducing Reagent.

NaHSe functions as an efficient agent for reductive elimination of vicinal dihalides. Chalcone dibromides undergo debromination when treated with NaHSe in boiling ethanol to give chalcones in 53-65% yield.[14] NaHSe has been shown to be an effective reagent for reduction of alkyl, aryl, aralkyl, and functionally substituted disulfides to thiols under mild conditions in protic solvents.[15]

Related Reagents.

Hydrogen Selenide; ***Lithium Selenide***; ***Sodium Selenide***.

Sodium Hydrogen Sulfide

NaSH

(anhyd)

[16721-80-5] · HNaS · Sodium Hydrogen Sulfide · (MW 56.07) (hydrate)

[140650-84-6]

(a nucleophile and reducing agent derived from H_2S; a reagent for the synthesis of thiols[1] and other divalent sulfur compounds,[2] including thiocarbonyl derivatives;[3] reduces aromatic nitro groups to amines[4])

Physical Data: mp (hydrate) 52-54 °C; anhyd, 350 °C; *d* 1.79 g cm^{-3}; pK_a (HS^- &ibond; S^{2-} + H^+) 14.15.

Solubility: v sol H_2O; sol EtOH, DMF (colored solution).

Form Supplied in: yellow chips ($NaSH.xH_2O$, may be principally $NaSH.2H_2O$); also available anhydrous; may contain Na_2S, $Na_2S_2O_3$ Na_2CO_3.

Analysis of Reagent Purity: iodometric titration.[5]

Preparative Methods: saturation of ethanolic ***Sodium Hydroxide*** with ***Hydrogen Sulfide***;[5] anhydrous NaSH is obtained by precipitation with ether. Saturation with H_2S shifts the equilibrium, 2NaSH &ibond; Na_2S + H_2S, to the left, as does operation in a solvent less polar than water or addition of $NaHCO_3$ to Na_2S.

Handling, Storage, and Precautions: store in cool, dry place under nitrogen. Exposure to air forms $Na_2S_2O_4$ and Na_2CO_3; very hygroscopic. Flammable; produces SO_2 on combustion. Stench. A reducing agent. Incompatible with acids (produces H_2S), with strong oxidizing agents, and with Zn, Al, and Cu. Corrosive (NaSH + H_2O &ibond; NaOH + H_2S). Use in a well-ventilated fume hood. Toxicity like that of Na_2S. Extremely destructive to mucous membranes, eyes, upper respiratory tract, and skin. Can cause blindness; inhalation can be fatal. Decontamination with $FeCl_3$ (production of insoluble iron sulfides).

Thiols.[1]

Treatment of halides, sulfonate esters, epoxides (eq 1),[6a] and aziridines with NaSH yields thiols. Saturation with H_2S helps to prevent sulfide formation. Near quantitative yields of thiols are obtained from primary alkyl bromides in DMSO.[6b] Primary substrates are best; tertiary substrates undergo elimination reactions. Aliphatic thiols are readily desulfurized by ***Raney Nickel***, thus providing a method for reduction of alcohols to alkanes (eq 2).[7] Activated aromatic or heteroaromatic halides (eq 3)[8] also are satisfactory, but nitro groups and cyano groups are likely to be incompatible due to reduction (or substitution) and addition reactions, respectively. Michael additions of SH^- to activated double and triple bonds also yield thiols or thiolates; sulfides may be obtained by further reaction of the thiolate (eq 4).[9] Thiol acids (RCOSH) are obtained from NaSH and acid chlorides or anhydrides (eq 5).[10]

Thioethers (Sulfides).[2]

Sodium sulfide and sodium thiolates are more commonly used to prepare thioethers (eq 4), but NaSH has been applied to the synthesis of heterocyclic compounds of sulfur. Both the facile addition of NaSH to alkynic bonds[9a,11] and its desilylating ability are exemplified in eq 6.[11a] The addition of NaSH in liquid NH_3 to phenylacetylene gave both (*Z*,*Z*)- and (*E*,*Z*)-distyryl sulfide (in a ratio of 2.5:1), unlike $Na_2S.9H_2O$ which gave principally the (*Z*,*Z*) isomer (ratio 20:1).[11d]

Thiocarbonyl Compounds.[3]

Addition of NaSH to iminium salts (Vilsmeier intermediates) (eq 7)[12] and related compounds[13] results in introduction of the thiocarbonyl group. Thioamides are obtained by addition to the triple bond of nitriles.

Reductions.

Aromatic, but not aliphatic, nitro groups are reduced by NaSH to amino groups,[4,14] often selectively,[15] as shown in eq 8. Favorable steric factors and the presence of an *ortho* phenolic hydroxyl group facilitate the reduction of one nitro group in preference to others. Further reductions are the dehalogenation of α-halo ketones and α-halo esters mediated by ***Tin(II) Chloride***[16] and the conversion of ArN=NAr to $ArNH_2$[17] (a nitro group is reduced preferentially[18]).

Miscellaneous.

Anti debromination of *gem*-dibromides by NaSH (or Na_2S) yields alkenes (eq 9).[19] 2-Pyranthiones are isomerized to 2-thiopyrones by NaSH.[20] A solution of NaSH at pH 8 selectively removes the acetyl group from menthyl *O*-acetylmandelate.[21]

Sodium Hydroxide[1]

NaOH

[1310-73-2] · HNaO · Sodium Hydroxide · (MW 40.00)

(inorganic source of hydroxide ion for the saponification of carboxylic acid derivatives;[3,4] alkylation of phenols,[7] alcohols,[13] aldehydes,[18] and ketones;[19] transformation of amides to amines,[11] generation of dichlorocarbenes;[22] also useful for removing water from amines[27])

Physical Data: mp 318.4 °C; *d* 2.13 g cm^{-3}.

Solubility: in water: 0.42 g mL^{-1} at 0 °C; 3.47 g mL^{-1} at 100 °C.

Form Supplied in: pellets or standard aqueous solutions of variable concentrations.

Purification: dissolve in dry ethanol, 100 g L^{-1}, filter solution through a fine frit. Concentrate the solution under vacuum until a thick slurry is formed. Place slurry on a coarse sintered-glass disk, remove mother liquor and wash several times with dry ethanol. Vacuum dry crystals with mild heating for 30 h to give fine white powder.

Handling, Storage, and Precautions: hygroscopic; keep in a sealed container in a dry environment. Keep away from flame. Avoid contact and ingestion.

Hydrolysis of Carboxylic Acid Derivatives.

The hydrolysis of esters, amides, nitriles, and ureas to the corresponding carboxylic acid can be accomplished with NaOH as hydroxide source, although milder methodology is available.[2] Ester hydrolysis is typically carried out in combinations of 1 N NaOH and either ethanol or methanol.[3] The hydrolysis of amides, nitriles and ureas is usually accomplished using excess NaOH in refluxing ethylene glycol with trace amounts of water.[4]

Dehydration of Sulfoxides and Selenoxides.

Thiophenes and selenophenes can be generated by the dehydration of the corresponding sulfoxides[5] and selenoxides[6] using 40% and 50% NaOH (aq), respectively.

Alkylation Reactions.

The NaOH-promoted conversion of phenols and carboxylic acids to their corresponding ethers[7] and esters[8] is accomplished in almost quantitative yield when excess ***Hexamethylphosphoric Triamide*** (HMPA) is added. The procedure calls for substrate, alkylating agent, 25% NaOH (aq), and HMPA to be combined at room temperature (eq 1).

(1)

Phenols can be methylated with dimethyl sulfate,[9] and epoxides can be derived from halohydrins[10] using NaOH to generate the phenolate and alcoholate anions.

Conversion of Amides to Amines.

The conversion of amides to amines containing one less carbon, the Hoffman reaction, is accomplished by the combination of bromine (or chlorine) with NaOH followed by heating (eq 2).[11] The reaction works well with aliphatic, aryl, and heterocyclic amides. The reaction can also be carried out in alcohol solutions, and the resulting urethane hydrolyzed in a subsequent step.

(2)

Phase-Transfer-Catalyzed Alkylation Reactions.

The use of phase-transfer-catalyzed two-phase reactions introduces hydroxide ion into organic solvent.[12] Under these conditions, hydroxide acts as a powerful base that efficiently promotes many transformations. Phase-transfer methodology is superior to the traditional Williamson synthesis of ethers (eq 3).[13]

(3)

Reaction conditions consist of a fivefold excess of 50% NaOH (aq), alcohol, excess alkyl chloride, and 3-5 mol % tetrabutylammonium bisulfate (TBAB). This method does not work with secondary alkyl halides but was successful with secondary alcohols. Alcohols can also be methylated under phase-transfer conditions using ***Dimethyl Sulfate***, 50% NaOH (aq), alcohol, and ***Tetra-n-butylammonium Iodide*** (TBAI) with methylene chloride or petroleum ether as the second phase.[14] This method works well for primary alcohols, is sluggish for secondary alcohols, and works not at all for tertiary alcohols. The use of a chiral phase-transfer catalyst gave alkylation of racemic alcohols[15] and ring closure of racemic chlorohydrins[16] with only moderate enantiomeric excess. Diphenylphosphinic hydrazide was alkylated in high yield using a mixture of solid K_2CO_3, NaOH, and tetra-*n*-butylammonium sulfate in boiling benzene.[17]

The combination of TBAI and 50% NaOH (aq) promotes aldehyde alkylation in modest yield.[18] The use of *N*-benzylcinchonine salts as phase-transfer catalysts results in excellent yield and good enantioselectivity in the alkylation of indonanes (eq 4).[19]

Phase-Transfer-Catalyzed Ylide Chemistry.

Wittig reactions can be done by combining 50% NaOH (aq), TBAI, a phosphonium salt, and a ketone in CH_2Cl_2. Benzylic phosphonium salts are converted to alkenes in good yields, but no stereoselectivity is observed (eq 5).[20]

Similarly, trimethylsulfonium iodide (eq 6) and trimethyloxosulfonium iodide (eq 7) are converted to the corresponding sulfur ylides.[21]

Phase-Transfer-Catalyzed Carbene Chemistry.

Dichlorocarbene can be generated from chloroform using 50% NaOH (aq) with 1-5% phase-transfer catalyst. This methodology can be used for dichlorocyclopropanation (eq 8),[22] C-H insertion (eq 9)[23] and the conversion of primary amines into isocyanides.[24]

Micelles have been shown to give increased yields compared to tetraalkylammonium salt phase-transfer catalysts.[25] Similiar reactions can be done using bromoform, but the ease with which dibromocarbene undergoes hydrolysis makes this methodology less useful than the generation of dichlorocarbene.[26]

Sodium Hydroxymethanesulfinate

[149-44-0] · CH_3NaO_3S · Sodium Hydroxymethanesulfinate · (MW 118.10) (dihydrate)

[6035-47-8] · CH_7NaO_5S · Sodium Hydroxymethanesulfinate · (MW 154.14) (Zn salt)

[24887-06-7]

(reducing agent for elemental selenium and tellurium, diselenides, α-halo ketones, and aromatic aldehydes; yields symmetrical sulfones with primary halides and with Michael acceptors; a source of SO_2^-&bdot; and SO_2^{2-})

Alternate Names: Rongalite; sodium formaldehyde sulfoxylate.

Physical Data: mp (dihydrate) 64.5 °C; *d* 1.75 g cm^{-3}.

Solubility: v sol H_2O; sol aq EtOH, formamide, DMSO; sl sol DMF; insol abs EtOH, ether, CS_2, benzene.

Form Supplied in: the white, crystalline dihydrate is available commercially with a purity of 90% or greater. May contain up to 5% Na_2SO_3 or $NaHSO_3$.

Analysis of Reagent Purity: iodometric titration.[1]

Purification: recrystallization from H_2O and vacuum drying.

Handling, Storage, and Precautions: thermally unstable ($2HOCH_2SO_2Na$ -> $2CH_2O + Na_2SO_3 + S + H_2O$). Slowly decomposes in air. Above 80 °C in air the odor of hydrogen sulfide becomes apparent. Keep refrigerated and airtight. Hygroscopic. In aqueous solutions the decomposition products include $HOCH_2SO_3Na$, Na_2SO_3, $Na_2S_2O_3$, HCO_2Na, H_2S, CH_2O. Stability is greatest between pH 6 and 9. Low toxicity (oral LD_{50} (mouse) 4 g kg^{-1}). Can be handled without unusual precautions. Incompatible with oxidizing agents and acids.

Reduction of Se and Te.

Elemental ***Selenium***[2] and ***Tellurium***[2a,3] are reduced by Rongalite to ***Sodium Selenide*** and ***Sodium Telluride***. Colored solutions are common and indicate the presence of Na_2Se_n (red-brown) or Na_2Te_n (red-purple), probably existing mainly as Na_2Se_2 and Na_2Te_2. Solutions of Na_2Te_n obtained from Rongalite are capable of converting tosylates of primary, optically active glycidols to optically active secondary and tertiary allylic alcohols; however, these same solutions perform sluggishly with secondary tosylates, for which solutions of telluride ions produced via reduction with a borohydride are required.[4] It is suggested that borane byproducts in the reduction of Te with borohydrides catalyze the telluride reaction with the sterically more hindered secondary tosylates.

Reductions of Organic Compounds.

Reductions performed by Rongalite are sensitive to solvent, temperature, and the presence or absence of base. The reduction of diselenides is a useful method of producing selenide anions (RSe^-) in situ for further reaction with electrophilic reagents (eq 1).[5] The reductive dehalogenation of phenacyl chlorides and bromides occurs smoothly, but aliphatic analogs are less reactive.[6] The addition of a nucleophilic catalyst (***Sodium Iodide***) in the reduction of phenacyl chloride under anhydrous conditions gives the symmetrical 1,4-dione as the major product instead of acetophenone (eq 2).[6b] 2,4-Dinitrobenzyl bromide yields 2,4-dinitrotoluene; perfluorinated aromatic and aliphatic iodides (Ar_FI, R_FI) are reduced to Ar_FH and R_FH by Rongalite.[7] Reduction of aromatic aldehydes to benzyl alcohols (60-77%)[8] and benzils to benzoins (62-75%)[8,9] occurs best in DMF solvent at 100 °C. Simple ketones are reduced very slowly, and cyano groups are unaffected. 7,7,8,8-Tetracyanoquinodimethane, fumaronitrile, and fumaric acid are reduced to *p*-phenylenedimalononitrile (71%),

succinodinitrile (49%), and succinic acid (no yield given), respectively.[10] Rongalite is used widely in the reduction of vat dyes.

Sulfones and Sulfinates.

Symmetrical sulfones are obtained by treatment of primary halides with Rongalite, presumably by way of intermediate sulfinate salts. Benzyl halides give the best yields (45-88%) (eq 3);[6b,11] di-*n*-butyl sulfone is obtained from *n*-butyl bromide (46%), thiacyclohexane 1,1-dioxide from 1,5-dibromopentane (43%), and diallyl sulfone from allyl bromide (20%).[6b] Phenacyl halides yield sulfones when the reaction is conducted in the presence of ***Sulfur Dioxide*** (eq 4).[6b] When α,α´-dibromo-*o*-xylene is treated with a slurry of Rongalite in DMF at 0-25 °C, a cyclic sulfinate (sultine) is obtained. If sulfur dioxide is passed through the reaction mixture at 70 °C, the cyclic sulfone is obtained (eq 5).[12] Sulfones are also obtained by the reaction of Rongalite via SO_2^{2-} or HSO_2^- with activated double bonds. Mannich bases[13] and α,β-unsaturated carbonyl, nitrile, sulfonyl, or pyridyl derivatives yield symmetrical sulfones (eq 6).[14] Treatment of anilines with Rongalite, ***Formaldehyde***, and concentrated aqueous HCl produces *p*-aminobenzyl sulfones.[15] Sodium sulfinates (R_FSO_2Na) are isolated in the reaction of perfluorinated alkyl iodides (R_FI) with Rongalite in acetonitrile or DMF; reduction to R_FH occurs in ethanol or dioxane.[7b,16]

Perfluoroalkylation Reactions.

Perfluoroalkyl radicals are generated from perfluoroalkyl iodides or bromides and the anion radical, SO_2^-&bdot;, obtained from Rongalite. Additions of the perfluoroalkyl radicals to disulfides (eq 7),[17] pyridines,[18] coumarins (eq 8),[19] and other alkenes[20] give good yields of perfluoroalkyl derivatives. Cyano, amino, and ester groups are unaffected.

Miscellaneous.

The hydrolysis of primary perfluoroalkyl iodides or bromides with Rongalite-$NaHCO_3$ in aqueous DMF or DMSO gives perfluoro carboxylates (51-86%).[21]

Related Reagents.

Sodium Dithionite.

Sodium Hypochlorite[1]

NaOCl

[7681-52-9] · ClNaO · Sodium Hypochlorite · (MW 74.44)

(versatile and easily handled oxidizing agent;[1] can oxidize alcohols,[2] aldehydes,[3] electron deficient alkenes,[4] amines,[5] and transition metal catalysts;[6] reagent for *N*-chlorination,[7] oxidative coupling,[8] and degradation reactions[9])

Physical Data: most commonly used in aqueous solution; $NaOCl.5H_2O$: mp 18 °C.

Solubility: pentahydrate: 293 g L^{-1} in H_2O (0 °C).

Form Supplied in: commercially available as aqueous solutions with 5.25-12.5% available oxidant (w/v) (0.74-1.75 M). Concentration is expressed in % available chlorine, since half of the chlorine in bleach is present as NaCl. The pH of commercial bleach is typically 11-12.5, and it may be adjusted and buffered.[6a]

Analysis of Reagent Purity: active oxidant may be assayed by iodometric[10] or potentiometric[11] titration.

Preparative Methods: solutions may be generated in situ by passing ***Chlorine*** gas through aq ***Sodium Hydroxide*** solution,[12] or electrochemically.[13]

Purification: commercial solutions are generally used without purification.

Handling, Storage, and Precautions: higher concentration sodium hypochlorite (12.5%), sometimes referred to as swimming pool chlorine, tends to decrease in concentration by 20% per month upon storage and therefore should be titrated prior to use.[1b] The concentration of oxidant in household bleach (5.25%) tends to remain constant upon prolonged storage; titration is generally not necessary with brand names (e.g. Clorox®). Solid NaOCl is explosive as the pentahydrate or the anhydride, and therefore it is very rarely employed in those forms. Aqueous solutions are very stable. Bleach is a household item, and it is quite easy and safe to handle. Still, it is a strong oxidant, and precaution should be taken to avoid prolonged skin exposure or inhalation.[14] May react violently with NH_3.

Composition of Aqueous Solution as a Function of pH.

The equilibrium composition of aqueous solutions of NaOCl is pH-dependent (eqs 1 and 2), and so pH control can be a critical consideration in many oxidation and chlorination reactions. Under strongly alkaline conditions (pH > 12), OCl^- is the predominant form of positive chlorine. Because hypochlorite ion is insoluble in organic solvents, phase transfer catalysts are needed at this pH to effect oxidation reactions in biphasic media.[15] In general, tetraalkylammonium salts have been the phase-transfer catalysts of choice for such applications. Below pH 11, the equilibrium amount of HOCl becomes significant,[6a] and this form of positive chlorine is soluble in polar organic solvents such as CH_2Cl_2. No phase-transfer catalyst is necessary to effect oxidation of substrates or catalysts dissolved in the organic phase of biphasic reactions in the pH range 10-11.[6a] Below pH 10, molecular chlorine becomes a significant component of aqueous bleach solutions, and the reactivity of these solutions can be attributed to that of Cl_2.[1b]

$$ClO^- + Cl^- + H_2O \rightleftharpoons Cl_2 + 2\,OH^- \qquad (1)$$

$$ClO^- + H_2O \rightleftharpoons HOCl + OH^- \qquad (2)$$

Oxidation of Alcohols.

Oxidation of alcohols by NaOCl can be effected under a variety of conditions, and useful yields and selectivities are attainable for

conversion of primary alcohols to aldehydes or carboxylic acids, or of secondary alcohols to ketones. The advantages of NaOCl oxidations over methods that employ stoichiometric Cr^{VI} include simplified waste disposal and lower toxicity and cost. The earliest application of NaOCl as a practical synthetic reagent for alcohol oxidation involved its use in a two-phase system with a phase-transfer catalyst,[16] or in association with ***Ruthenium(VIII) Oxide***.[17] More recently, two improved methods for bleach-mediated oxidation of alcohols have been developed, one of which employs acetic acid as solvent in a monophasic system,[18] and the other uses catalytic amounts of ***2,2,6,6-Tetramethylpiperidin-1-oxyl*** (TEMPO) in a buffered biphasic medium.[2b] These variants are highly complementary and can offer significant advantages over alternative methods for alcohol oxidation.

Secondary alcohols are cleanly oxidized to ketones with NaOCl in acetic acid in the absence of added catalyst (eq 3).[18] Either swimming pool chlorine or household laundry bleach can be used with similar success.[19] Excess hypochlorite is quenched with sodium bisulfite, and essentially pure ketone is obtained simply by extraction of the product into dichloromethane or ether.

(3)

Under these conditions, secondary alcohols can be oxidized in the presence of primary alcohols with essentially absolute selectivity (eq 4).[20] No epimerization is observed in the oxidation of alcohols bearing β-stereocenters (eq 5). Kinetic studies have led to the proposal that molecular chlorine is the active oxidant under conditions of low pH such as those employed for these reactions.[21]

(4)

(5)

Primary and secondary alcohols can be oxidized by oxoammonium salts;[22] hypochlorite oxidation of the reduced nitroxyl radical regenerates the active oxoammonium salt. Thus the nitroxyl radical agent TEMPO can be employed as an alcohol oxidation catalyst, with NaOCl as the stoichiometric oxidant.[2b] This protocol has rapidly achieved widespread use due to its selectivity, ease of application, and versatility. A biphasic system is employed consisting of CH_2Cl_2 or toluene as the organic phase, and commercial bleach buffered to pH ~9 with $NaHCO_3$ and containing substoichiometric levels of KBr or NaBr (eq 6).[23] Reaction times are longer in the absence of bromide salts, indicating that HOBr is the agent that oxidizes TEMPO to the nitrosonium ion. Without added phase transfer catalyst, primary alcohols are oxidized with excellent selectivity to the corresponding aldehydes.[24] High stirring rates (>1000 rpm) help to minimize overoxidation to the carboxylic acid.[23] The stereospecificity of TEMPO-catalyzed oxidations of primary alcohols bearing β-stereocenters has been investigated in detail, and it is absolute in all cases reported thus far (eqs 7-9).[23,24]

Although both primary and secondary alcohols are oxidized with this catalyst system, moderate-to-good selectivity for the primary position is obtained in oxidation of diols (eq 10).[25] The diol must have nearly complete solubility in the organic phase for these oxidations to occur cleanly. This selectivity for primary alcohols is in direct contrast with monophasic NaOCl oxidations in acetic acid (see above). Thus, proper choice of reaction conditions allows selective oxidation by NaOCl of either or both the primary or the secondary carbinol in diols.

(10)

Molecular chlorine generated from NaOCl appears to have a detrimental effect on the oxidizing power of the *N*-oxoammonium salt in these reactions.[26] A similar protocol to the one described above, but using ***Sodium Bromite*** ($NaBrO_2$) in place of NaOCl may be superior in this context. Despite this caveat, there is ample precedent for the successful application of the NaOCl/TEMPO system with a variety of substrates, and the use of commercial bleach solutions has significant practical advantages.

For further discussion of this oxidizing system, see: ***2,2,6,6-Tetramethylpiperidin-1-oxyl***. See also ***Dimethyl Sulfoxide-Oxalyl Chloride***, ***Pyridinium Chlorochromate***, ***Pyridinium Dichromate***, ***Potassium Permanganate***, ***Dipyridine Chromium(VI) Oxide***, and ***Tetra-n-propylammonium Perruthenate***.

Oxidation of Primary Alcohols to Carboxylic Acids.

Simple incorporation of a tetraalkylammonium chloride phase-transfer catalyst (PTC) to the catalyst recipe outlined above for aldehyde synthesis leads to a useful protocol for oxidation of primary alcohols to the corresponding carboxylic acids (eq 11).[2b] Similar selectivity for primary alcohols over secondary alcohols is observed as in the absence of PTC.[25] This has been exploited in the oxidation of unprotected monosaccharide derivatives to the corresponding uronic acids (eq 12).[27]

(11)

(12)

The mildness of the oxidizing medium in TEMPO-catalyzed oxidations by NaOCl is illustrated by the high yield oxidation of (2-hydroxyethyl)spiropentane to the corresponding acid (eq 13).[28] Jones oxidation conditions lead to extensive decomposition of the

spiropentane residue of the same substrate.

See also: ***Chromium(VI) Oxide***, ***Potassium Dichromate***, ***Potassium Permanganate***, and ***Oxygen-Platinum Catalyst***.

Oxidation of Aldehydes.

Sodium hypochlorite oxidizes aromatic aldehydes to the corresponding acids in the presence of a phase-transfer catalyst.[3] Best results are obtained at pH 9-10 with Bu_4NHSO_4 as phase-transfer catalyst (eq 14). In this pH regime, HOCl is present in significant concentrations, and phase-transfer catalysts are generally not necessary.[6a] It has been suggested that in this system, however, the phase-transfer catalyst helps to solubilize HOCl in the organic phase through hydrogen bonding.[3] Direct oxidation of aliphatic and aromatic aldehydes to the corresponding methyl esters is accomplished with methanol in acetic acid and 1-2 equiv of NaOCl.[20] This reaction, which affords esters in moderate-to-good yield, probably proceeds via oxidation of equilibrium concentrations of methyl hemiacetals. Poor results are obtained with electron-rich aromatic aldehydes and unsaturated aldehydes, each of which undergo competitive chlorination.[20]

(14)

See also: ***Potassium Permanganate***, ***Ozone***, and ***N-Bromosuccinimide***.

Epoxidation.

Sodium hypochlorite is an effective, although infrequently utilized, reagent for epoxidation of enones and polycyclic arenes. Careful control of pH is necessary for good yields in these reactions. Polycyclic aromatics can be oxidized to epoxides at pH 8-9 (eq 15).[29] Phenanthridine is oxidized to the corresponding lactam, presumably via an oxaziridine intermediate (eq 16), without formation of *N*-oxide.[29] The optimum pH for this reaction is 8-9, and phase transfer catalysts are required.

(15)

(16)

Enones,[4,30] particularly chalcones,[31] also react with sodium hypochlorite to form epoxides (eqs 17-19). These reactions generally exhibit

a strong dependence on the pH of the aqueous phase; chlorination reactions can be competitive.[30a] The mechanism for these reactions has been proposed to involve production of the ClO**.** radical species; this proposal was made on the basis of data from the chlorination of hydrocarbons, selectivity of epoxidation reactions, and Hammett ρ values for the chlorination of toluene.[32]

(17)

(18)

(19)

Other Oxidation Reactions.

Several other substrate classes also undergo oxidation reactions with sodium hypochlorite. Diketones may be oxidatively cleaved to give the corresponding diacids (eq 20).[33] Oxidation of hydroquinones and catechols[34] and oxidative cyclization of phenols (eq 21)[8] have also been realized.

(20)

Oxidative Degradation.

Treatment of carboxylic acids with sodium hypochlorite can lead to decarboxylation to afford aldehydes with one less carbon atom (eq 22).[35] The mechanism of this reaction is likely to involve methylene oxidation to the chloride or the alcohol followed by decarboxylation and oxidation to the aldehyde. This method has primarily been applied to sugar degradation (eq 23).[9,36]

Reaction with Amines.

Reactions of sodium hypochlorite with amines can yield ketones, cyclization products, or, in the case of amino acids, degradation products. The mechanism of each of these processes involves initial *N*-chlorination.[37] Chlorinated intermediates have been identified spectroscopically, and in some cases isolated, providing access to chlorination products as well. Treatment of aliphatic amines under phase transfer conditions yields ketones or nitriles.[15,16a] The initial product is the *N*-chloro imine, with the carbonyl being released upon hydrolytic workup (eq 24).

Reaction of α- or β-amino acids with NaOCl leads to the corresponding aldehyde or methyl ketone containing one less carbon.[38] The mechanism postulated for this Strecker-type degradation of amino acids again involves *N*-chlorination, followed by decarboxylation to

yield the imines. Aldehydes and ketones are released by hydrolysis (eq 25).[39] This method has been applied to degradation of α-methyl DOPA (eq 26).[40]

(25)

(26)

Oxidative Cyclization of Amines.

Treatment of nitro anilines with sodium hypochlorite under alkaline conditions affords benzofuroxans as cyclization products (eq 27).[41] Spectroscopic evidence suggests an initial chlorination of the amino group, followed by cyclization. In addition, chlorinated intermediates have been prepared independently and submitted to the reaction conditions to show that cyclization products are formed.[37] The cyclization reaction requires addition of base, as azo products are formed at neutral pH. Oxadiazoles (eq 28)[42] and chlorodiazirines (eq 29)[43] are also formed by oxidative cyclization in moderate-to-good yields. The key intermediate for both of these reactions is also proposed to be an *N*-chloro imine.

(27)

(28)

Amine Coupling Reactions.

Hydrazines[44] and alkylhydrazines (eq 30)[45] are formed by the action of bleach and amines. Azoethanes are toxic, and therefore care should be taken in their production and handling.

Chlorination.

Several types of organic nucleophiles undergo reaction with sodium hypochlorite to afford chlorination products. *N*-Chlorination of primary and secondary amines is a representative and widely-used example of this reaction class (eq 31).[46] Either mono- or dichlorinated products can be obtained selectively through control of the relative stoichiometry of the amine and NaOCl.[47] A two-step chlorine-shuttle pathway for the selective chlorination of electron-rich aromatics has been developed which relies on initial *N*-chlorination with NaOCl.[46] Intramolecular cyclization of amines via the Hofmann-Loffler reaction may also be accomplished by effecting the requisite *N*-halogenation with NaOCl (eq 32).[48]

(32)

Chlorination of indoles (eq 33),[7,49] amides, and ureas[50] occurs at the nitrogen center, while oximes[51] are chlorinated at carbon. Selective chlorination of nicotinic acids (eq 34),[52] chromones,[53] and polymers[54] has also been achieved. Substitution of chlorine for other halides occurs upon treatment of certain aromatic halides with sodium hypochlorite solution.[55]

Sodium Hypochlorite-*N,N´*-Bis(3,5-di-*t*-butylsalicylidene)-1,2-cyclohexanediaminomanganese(III) Chloride[1]

(NaOCl)

[7681-52-9] · ClNaO · Sodium Hypochlorite-*N,N´*-Bis(3,5-di-*t*-butylsalicylidene)-1,2-cyclohexanediaminomanganese(III) Chloride · (MW 74.44) (*R,R*)-(**1**)

[138124-32-0] · $C_{36}H_{52}ClMnN_2O_2$ · Sodium Hypochlorite-*N,N´*-Bis(3,5-di-*t*-butylsalicylidene)-1,2-cyclohexanediaminomanganese(III) Chloride · (MW 635.29) (*S,S*)-(**1**)

[135620-04-1]

(catalytic system for enantioselective epoxidation of unfunctionalized alkenes[2])

Physical Data: NaOCl: see ***Sodium Hypochlorite***. (**1**): mp 330-332 °C.

Solubility: (**1**) freely sol CH_2Cl_2, *t*-butyl methyl ether, acetonitrile, ethyl acetate.

Form Supplied in: both enantiomers of (**1**) are commercially available as brown powders, 98%; synthetic preparations may contain up to one solvated molecule of ethanol or DMF for each manganese.

Analysis of Reagent Purity: (salen)Mn^{III} complexes are paramagnetic and do not provide readily interpretable NMR data. (**1**): R_f = 0.63 (SiO_2, ethanol); purity may be established by elemental analysis.

Preparative Methods: over 100 chiral manganese(III) salen complexes have been reported;[1] the general procedure for their preparation involves condensation of a 1,2-diamine with 2 equiv of a salicylaldehyde derivative, followed by addition of $Mn(OAc)_2$ in the presence of air.[3] Yields of (salen)Mn^{III} complexes usually exceed 90%.

Purification: (**1**) can be recrystallized from toluene or CH_2Cl_2/heptane. The solvent content of (**1**) and related complexes does not influence their effectiveness as epoxidation catalysts,[4] but heating to >80 °C for 3 h under vacuum results in liberation of solvated molecules.

Handling, Storage, and Precautions: (**1**) is sensitive to acid, but indefinitely stable to air, moisture, and light.

Epoxidation Method.

Epoxidation of a variety of conjugated and nonconjugated alkenes may be effected in a biphasic reaction system consisting of aqueous bleach at pH &egt; 9.5 and an organic phase bearing catalytic levels of a soluble manganese(III) complex.[4,5] The ideal pH range appears to be 10.5-11.5 for most applications, with nonwater-miscible solvents such as CH_2Cl_2, *t*-butyl methyl ether, or ethyl acetate as the organic solvent. At pH <= 11.5, no phase transfer catalysts are necessary for epoxidation to occur, due to the presence of significant equilibrium concentrations of HOCl.[5] At low pH, equilibrium levels of Cl_2 can produce chlorinated byproducts. Reactions with alkenes are carried out in air, without the need for precautions to exclude moisture or trace impurities. The substrate and catalyst are dissolved in the organic solvent and combined with the bleach solution at 0 °C or room temperature. Catalyst turnover numbers and product yields may be improved in the epoxidation of certain substrates by the addition of substoichiometric levels of a pyridine *N*-oxide derivative (Table 1).[3a,6] Isolation of the epoxide is accomplished by separation of the organic phase and purification by distillation, crystallization, or chromatography.

Table 1 Asymmetric Epoxidation of Representative Alkenes by Catalyst **(1)**

Alkene	*N*-Oxide[a] (mol %)	**(1)** (mol %)	Yield (%)	ee of major epoxide (%)
	0	4	84[b]	92
	20	4	67	86
	0	2	87	98
	0	1	80	88
	0	4	65[c]	98
	20	15	63	94
	20	8	67[d]	97

[a]*N*-Oxide employed is 4-phenylpyridine *N*-oxide. [b]Isolated yield of epoxide mixture (*cis*:*trans* = 11.5:1). [c]Isolated yield of epoxide mixture (*cis*:*trans* = 1:5.2). [d]Isolated yield of epoxide mixture (*cis*:*trans* = 5:1).

Substrate Scope.

Best results in the (salen)Mn^{III}-catalyzed epoxidation reaction have been obtained with *cis*-disubstituted, conjugated alkenes (Table 1). Epoxidation of 2,2-dimethylchromene derivatives occurs with especially high selectivity (&egt;97% ee).[7] *trans*-Disubstituted alkenes are epoxidized with low selectivity (20-50% ee), as are simple alkyl-substituted alkenes.

Mechanistic Considerations.

A stepwise mechanism involving a nonpolar intermediate has been proposed for the oxygen atom transfer event in (salen)Mn^{III}-catalyzed epoxidations (eq 1).[6a,8] Consistent with this proposal, acyclic *cis*-alkenes afford mixtures of *cis*- and *trans*-epoxides, and conjugated alkenes are 1-2 orders of magnitude times more reactive than isolated alkenes.[1] In the case of dienes and enynes, the *trans*-epoxide can in fact constitute the major product.[7]

In the case of 1,2-disubstituted alkenes, the nonstereospecificity of the epoxidation reaction results in formation of diastereomeric epoxides. In contrast, for terminal alkenes the *trans* pathway results in partitioning to enantiomers. Thus, diminished enantioselectivity observed in the epoxidation of terminal alkenes such as styrene (50-70% ee) relative to sterically similar *cis*-disubstituted alkenes can be attributed to enantiomeric leakage due to the *trans* pathway. Suppression of this pathway has not been accomplished successfully, and synthetically useful enantioselectivities with terminal alkenes have not yet been achieved using the chiral (salen)Mn^{III} systems.

Sodium Hypophosphite

NaH_2PO_2

[7681-53-0] · H_2NaO_2P · Sodium Hypophosphite · (MW 87.98)

(source of hydrogen in heterogeneous catalytic transfer reductions;[1-10] synthesis of phosphonous acids via hydrophosphorylation of terminal alkenes[11])

Physical Data: decomposes upon strong heating with release of phosphine, which is highly flammable in air.

Solubility: sol water, alcohol; insol ether.

Form Supplied in: monohydrate, white solid.

Handling, Storage, and Precautions: explodes when triturated with chlorates or other oxidizing agents.

Functional Group Reductions.

Sodium hypophosphite is a very effective and mild hydrogen-transfer reagent capable of reducing a wide range of functional groups when utilized with the appropriate catalyst. The reductions of aldehydes to alcohols,[1] alkynes to alkenes,[2] azides to amines,[1] benzoquinones to dihydrobenzoquinones,[3] epoxides to alcohols,[1] alkyl or aryl halides to alkanes or arenes,[1,4] ketones to alcohols,[1] nitriles to aldehydes,[5] nitroalkenes to oximes,[6] nitroarenes to aryl amines,[7] *N*-oxides to amines,[1] alkenes to alkanes,[8] oximes to ketones,[1,9] and phenols to arenes,[10] as well as the hydrogenolysis of benzylic ethers,[1] have all been effected. Reactions have been carried out in solvent systems ranging from aqueous to anhydrous organic solvents, typically at elevated temperatures (50-75 °C), with excess sodium hypophosphite and most often ***Palladium on Carbon*** as the catalyst. Reaction workup generally involves filtration of the catalyst, extraction if appropriate, and removal of solvent.

Studies on polyfunctional molecules have shown the reduction to be tunable; while treatment of cinnamonitrile (**1**) with sodium hypophosphite and 5% Pd/C yields 87% of dihydrocinnamonitrile (**2**),[1] reduction with sodium hypophosphite and ***Raney Nickel*** gives only cinnamaldehyde (**3**)[5] (eq 1). A more profound demonstration of selectivity is seen in the conversion of (**4**) to (**5**) (eq 2), intermediates in the synthesis of (+)-pilocarpine.[5b]

Hydrophosphorylation of Alkenes.

Terminal alkenes (**6**), when treated with sodium hypophosphite in the presence of ***Azobisisobutyronitrile***, yield phosphonous acids (**7**) (eq 3).[11]

Sodium Iodide[1]

NaI

[7681-82-5] · INa · Sodium Iodide · (MW 149.89)

(source of iodide ion for nucleophilic displacement reactions in the preparation of alkyl iodides[4-10] and aryl iodides[11-13] from halides and sulfonates; in combination with Zn, reduces sulfonates;[14,15] converts *vic*-dihalides and *vic*-disulfonates to alkenes;[16-20] dehalogenates α-halo ketones[21-23] and α-bromo enones;[27] converts acyl chlorides to acyl iodides;[24] cleaves aryl methyl[25,26] and some dialkyl ethers;[27-32] deoxygenates epoxides;[31] in combination with TMSCl/MeCN, generates TMSI in situ;[33-35] catalyzes phosphorylations;[36] reduces ene dicarbonyl compounds;[37] converts acetylenic ketones to vinyl iodides;[38] in combination with TMSCl/MeCN/0.5 H_2O, generates anhydrous HI;[40] with various co-reagents, reduces sulfoxides[41-43] and *N*-oxides;[43a,44,45] with oxidizing agents, iodinates organoboranes,[46] phenols,[47,48] and aromatic compounds[49])

Physical Data: mp 661 °C; bp 1304 °C; *d* 3.667 g cm^{-3}.

Solubility: very sol cold H_2O (184 g/100 mL, 25 °C), hot H_2O (302 g/100 mL, 100 °C), alcohol (42.57 g/100 mL, 25 °C), acetone (39.9 g/100 mL, 25 °C); sol glycerin.[2] Also sol acetic acid, acetonitrile, DMF, DMSO, formic acid, HMPA, methyl ethyl ketone.

Form Supplied in: white solid (crystalline, granular, or powder); widely available. *Drying:* can be dried under vacuum at 70 °C.[3]

Handling, Storage, and Precautions: deliquescent in moist air (gradually absorbs up to ca. 5% (0.5 mol) H_2O in air), and upon long exposure to air will turn brown due to liberation of iodine; storage in a dry or inert atmosphere is recommended.

Introduction.

Sodium iodide and potassium iodide are used in organic synthesis as sources of iodide. NaI is more commonly used due to greater solubility in organic solvents and slightly lower cost. Tetraalkylammonium iodides have also been used as organic-soluble sources of iodide. See also ***Potassium Iodide*** and ***Tetra-n-butylammonium Iodide***.

Displacement Reactions.

NaI reacts with alkyl chlorides, bromides, and sulfonates (e.g. mesylates and tosylates[4]) to provide the corresponding alkyl iodides.[5] The conversion of alkyl halides to iodides using NaI in acetone is known as the Finkelstein reaction.[6] Though usually an S_N2 displacement, radicals have been implicated in some cases.[6b] Displacement reactions using NaI are numerous in the literature, and representative examples (eqs 1 and 2)[7,8] are shown below. In some cases the iodo compound is not isolated but reacts with another nucleophile present (eq 3).[9] NaI has been used catalytically in such reactions.[10]

(1)

(2)

(3)

NaI reacts with electron-deficient aryl halides in a formal S_NAr reaction (e.g. with 2,4-dinitrochlorobenzene)[11] to give aryl iodides; however, with aryl diazonium compounds the reaction proceeds via electron transfer and involves an aryl radical.[12] The latter process has been applied to the Pschorr phenanthrene synthesis[13] (eq 4).[13b]

(4)

R = CH_2Ph	20%	45%
R = SO_2Ph	few %	71%

Reductive Cleavage of Sulfonates.

NaI/***Zinc*** has been used to reduce alkyl tosylates and mesylates to the corresponding alkanes (eq 5).[14] This procedure complements ***Lithium Aluminum Hydride*** reductions of sulfonates since, in some cases, $LiAlH_4$ produces both the alkane and the alcohol. However, with secondary mesylates and tosylates a large amount of the alkene elimination product is often obtained using NaI/Zn. NaI/Zn/D_2O (or T_2O) in dimethoxyethane has been used to replace primary and secondary hydroxyl groups with deuterium (or tritium).[15]

Conversion of *vic*-Halides and *vic*-Sulfonates to Alkenes.

NaI reacts with *vic*-dibromides, *vic*-bromochlorides, and *vic*-dichlorides to give the corresponding alkenes.[16] This reaction can be utilized for alkene *cis*/*trans* isomerization (eq 6).[17] *vic*-Bromochlorides and *vic*-dichlorides give predominantly *cis*-products while dibromides give predominantly *trans*-alkenes. *vic*-Dimesylates[17] and *vic*-ditosylates[18,19] also give alkenes when treated with sodium iodide, via initial displacement of one sulfonate group followed by attack of iodide on the iodine of the *vic*-iodosulfonate. This reaction has been carried out under phase-transfer conditions.[20]

Dehalogenation of α-Halo Ketones.

NaI will reductively dehalogenate some α-halo ketones in acidic aqueous THF or dioxane (eq 7)[21] or in AcOH.[22] This reaction may not be general for all α-halo ketones.[21] NaI/***Sulfur Trioxide-Pyridine*** in acetonitrile has also been used to carry out this transformation.[23]

Preparation of Acyl Iodides.

NaI reacts with acyl chlorides in anhydrous acetonitrile to give acyl iodides in high yield.[24] Diacyl diiodides[24b] and iodoformates[24c] have

also been prepared in this fashion.

Demethylation of Aryl Methyl Ethers.

NaI reacts with aryl methyl ethers in acetic or formic acid to give the corresponding phenolic derivatives and methyl iodide.[25] In one study, KI was found to give slightly higher yields (eq 8).[26] See also NaI/Me_3SiCl/MeCN below.

(8)

Other Ether Cleavage Reactions.

NaI/***Boron Trifluoride Etherate*** cleaves some alkyl ethers[27] and acetals,[27b] and converts keto epoxides to enones.[27c] Some primary and secondary alkyl methyl ethers are cleaved by NaI/***Boron Tribromide***/***15-Crown-5*** in CH_2Cl_2.[28] Cyclic (e.g. THF and THP) and acyclic dialkyl ethers are cleaved at the less substituted carbon by NaI in the presence of acyl chlorides.[29] For example, 2-methyltetrahydrofuran gives the pivalate derivative of 5-iodo-2-pentanol when treated with NaI/*t*-BuCOCl in acetonitrile. Similarly, 2-iodoethyl esters are produced from acyl chlorides, ***Ethylene Oxide***, and NaI (eq 9).[30] NaI/***Trifluoroacetic Anhydride*** has been used to deoxygenate epoxides with retention of configuration: trifluoroacetyl iodide is generated in situ and reacts with the epoxide in the presence of NaI to give a *vic*-iodo trifluoroacetate, which decomposes in the presence of excess NaI to give the alkene.[31] NaI/NaOAc has been reported to reduce α,β-epoxy ketoses to β-hydroxy ketoses, presumably via the α-iodo-β-hydroxy ketone (eq 10).[32]

(9)

(10)

In Situ Generation of Trimethylsilyl Iodide.

NaI/***Chlorotrimethylsilane***/MeCN has been widely used as a convenient substitute for ***Iodotrimethylsilane***.[33-35] For example, this reagent removes benzylic hydroxyl groups,[34] cleaves methoxyethoxymethyl (MEM),[35] aryl methyl, and aryl ethyl ethers, deoxygenates sulfoxides (and *N*-oxides in the presence of zinc), converts some alcohols to iodides, and dehalogenates α-halo ketones.[33a]

Catalysis of Phosphorylation.

NaI catalyzes the phosphorylation of nucleosides by chlorophosphates, pyrophosphates, and triazolides.[36] The rate of phosphorylation is greatly enhanced by addition of 1 or 2 equiv of NaI. For example, 3´-*O*-benzoylthymidine is phosphorylated over 10 times faster with

Diethyl Phosphorochloridate when 1 equiv of NaI is added, and over 300 times faster when 2 equiv of NaI are added.

1,4-Addition to α,β-Unsaturated Carbonyl Compounds.

NaI has been used to reduce the carbon-carbon double bond of 2-ene-1,4-dicarbonyl compounds, presumably via conjugate addition of iodide followed by reduction of the newly formed α-iodo carbonyl compound (eq 11).[37] The reaction is specific to 1,4-diketones or keto aldehydes, and fails with 1,4-diacids, 1,4-diesters, and α,β-unsaturated monocarbonyl compounds. However, NaI apparently does add to enones under some conditions since NaI/BF_3.OEt_2 dehalogenates α-bromo enones (via the *vic*-bromoiodide).[27c] Furthermore, NaI in TFA reacts with α,β-acetylenic ketones to give (*E*)-β-iodovinyl ketones, while NaI in AcOH gives predominantly the (*Z*)-isomer (eq 12).[38] The reaction tolerates both terminal and substituted alkynes.

(11)

(12)

NaI, TFA	30 min	-	95%
NaI, AcOH	30 min	70%	17%
NaI, AcOH	21 h	-	94%

Conversion of Allylic, Benzylic, and Tertiary Alcohols to Iodides.

NaI/BF_3.OEt_2 in acetonitrile converts allylic, benzylic, and tertiary alcohols to iodides in good yield.[39,40] NaI/Me_3SiCl/MeCN/0.5 H_2O (anhydrous HI) has been used to convert allylic alcohols to allylic iodides, with allylic rearrangement if the alcohol is secondary or tertiary.[40]

Reduction of Sulfoxides.

NaI/$(CF_3CO)_2O$ in acetone,[41] NaI/BF_3.OEt_2 in acetonitrile,[42] NaI/I_2/***Hexamethylphosphorous Triamide*** in acetonitrile,[43a] NaI/***Oxalyl Chloride*** in acetonitrile,[43b] NaI/Me_3SiCl in acetonitrile,[43c] NaI/I_2/Me_2NEt.SO_3 in acetonitrile,[43d] and NaI/pyridine.SO_3 in acetonitrile[43d] all reduce sulfoxides to sulfides in high yield.

Reduction of *N*-Oxides and Nitrones.

NaI/$(CF_3CO)_2O$ in acetonitrile deoxygenates various heteroaromatic *N*-oxides and nitrones in very high yield.[44] NaI/pyridine.SO_3 deoxygenates di-*N*-oxides of quinoxalines and phenazines.[45] NaI/I_2/$(Me_2N)_3P$ in acetonitrile deoxygenates azoxides.[43a]

Iodinations of Phenols and Organoboranes.

NaI/***Chloramine-T*** has been used as an in situ source of ***Iodine Monochloride*** for iodinations of organoboranes[46] and phenols.[47] For example, methyl 5-iodosalicylate is prepared from methyl salicylate in 78% yield.[47] Iodinated carbohydrates have been prepared via iodination of organoboranes (eq 13).[46b] Recently, NaI/***Sodium Hypochlorite*** in methanol has been used to iodinate phenols in high yield with good regioselectivity.[48] The yield and regioselectivity with phenol (80% *para*, 10% *ortho*, 4% *ortho,para*) are different than those obtained with ICl or NaI/Chloramine-T. Simple aromatic hydrocarbons are iodinated with NaI/O_2/cat. ***Nitrosonium Tetrafluoroborate*** in

CH_2Cl_2/TFA.[49] This iodination fails with electron-deficient aromatics.

Related Reagents.

Sodium Iodide-Copper; ***Trifluoroacetic Anhydride-Sodium Iodide***.

(NaI)

[7681-82-5] · INa · Sodium Iodide-Copper · (MW 149.89) (Cu)

[7440-50-8] · Cu · Sodium Iodide-Copper · (MW 63.55)

(mild two-electron reductant, capable of generating weakly electrophilic sodium oxyallyl cations from α,α´-dibromo ketones; capture of nucleophilic 1,3-dienes affords seven-membered unsaturated ketones)

Physical Data: NaI: mp 661 °C; bp 1304 °C; *d* 3.67 g cm^{-3}.

Solubility: NaI: sol water, alcohol, acetone, acetonitrile.

Form Supplied in: NaI: white odorless, deliquescent crystals or granules. *Drying:* sodium iodide (together with commercially available copper powder) is dried in a flame-dried reaction flask for 3 h at 150 °C under reduced pressure (oil pump).

Handling, Storage, and Precautions: NaI: gradually absorbs up to ca. 5% (0.5 mol) moisture when exposed to air. Slowly becomes brown in air due to liberation of iodine. Keep well closed and protected from light.

Sodium Oxyallyl Intermediates.

Sodium oxyallyl cations, conveniently generated from α,α´-dibromo ketones and anhydrous ***Sodium Iodide*** in the presence of ***Copper*** powder in anhydrous acetonitrile, are weak and selective electrophilic intermediates, which combine with nucleophilic 1,3-dienes to give 4-cycloheptenones. Iodide ion (2 equiv) functions as a two-electron reductant. Molecular iodine liberated during the reaction (eq 1) is removed efficiently by metallic copper powder (eq 2), while the reaction solution assumes a characteristic oatmeal color.[1-3]

$$2\,I^- \longrightarrow I_2 + 2\,e^- \qquad (1)$$

$$I_2 + 2\,Cu \longrightarrow 2\,CuI \qquad (2)$$

The mode of workup is important, in order to avoid decomposition of sensitive cycloadducts. The reaction mixture is cooled, and remaining copper and sodium salts are suction filtered. Filtration through silica gel is also helpful at this stage. Usually, the acetonitrile mother liquor (which can be concentrated further under reduced pressure at 0 °C) contains dissolved CuHal and is taken up in ice-cooled dichloromethane. The combined organic phase is washed with ice-cold ammonia, until the blue color disappears. (In aqueous solution, Cu^I disproportionates: 2 Cu^I -> Cu + Cu^{II}; the reaction is driven by complexation of Cu^{II} with NH_3). Standard workup (evaporation of solvent, chromatography on silica gel, and, in the case of the major α,α-configurated stereoisomer, crystallization) affords the oxa-bridged seven-membered ketone (eq 3).[2] Among cyclic dienes, ***Furan*** (bp 31 °C) is especially useful, because it can be used in excess without problems, serves as a solvent for the α,α´-dibromo ketone, and is removed easily on workup.

In place of furan (eq 3), other cyclic dienes have been reacted with ***2,4-Dibromo-3-pentanone*** (**1**), including ***Cyclopentadiene***, ***6,6-Dimethylfulvene***, and 6-acetoxyfulvene.[4] These give (**2**), (**3**), and (**4**), respectively; only the major stereoisomer with α,α-configured dimethyl groups is shown. The bicyclic dione (**5**), the hypothetical adduct of cyclopentadienone, has been prepared by hydrolysis and oxidation of 8-acetoxymethylene-2,4-dimethylbicyclo[3.2.1]oct-6-en-3-one (**4**) (eq 4)[4] (the minor stereoisomer is α,β-configurated in this case).

α-Alkylated 2,6-dibromocyclohexanones and NaI/Cu also enter into reductive intermolecular cyclodehalogenation, giving unsaturated tricyclic ketones.[5,6] The preparation of 1-isopropyl-7-methyl-11-oxatricyclo[4.3.1.1^{2,5}]undec-3-en-10-one (**6**) from furan and α,α´-dibromomenthone has been optimized.[6,7]

5.5 g isolated

The reaction of dibromo ketones derived from (5*R*)- and (5*S*)-menthone affords enantiomerically pure tricyclic compounds (eqs 5 and 6).[3]

(5)

(6)

For cycloadditions with ***Cyclopentadiene***, it is advantageous to precool the cyclopentadiene to -78 °C and to add it slowly by syringe to the reaction mixture, synchronously with the α,α´-dibromo ketone which is added with another syringe.[5] Other tricyclic compounds (**7**) and (**8**) have been prepared in similar fashion.[5,7,8]

(7)
$n = 1$, 25%
$n = 2$, 21%
$n = 3$, 13%

(8) 25%

The series of cycloadducts (**9**)-(**11**) derived from 2,6-dibromo-2,6-dimethylcyclohexanone is of interest, because the ketone is flanked by two quaternary carbon atoms.[5,6]

(9) 22%

(10) 18%

(11) 23%

Starting from the acyclic ditertiary dibromo ketone (**12**) and the secondary-tertiary dibromo ketone (**13**), the furan and cyclopentadiene adducts are accessible in good yield (eqs 7 and 8). In these cases the NaI/Cu procedure is the recommended alternative[9] to the ***Zinc/Copper Couple*** and the ***Nonacarbonyldiiron*** procedures, which have been used more frequently in the past.[3,10,11]

(7)

(12)

Z = O, 50%, 2.70 g
Z = CH_2, 37%, 1.98 g

(8)

(13)

Z = CH_2, 70%, 17.2 g; α:β = 19:1

Pyrroles and alkylated pyrroles afford unsaturated β-amino ketones (**14**)-(**16**) (bicyclic Mannich bases) in a simple one-pot procedure.[12,13] Temporary tethering of the sodium cation by the ethoxycarbonyl group of the pyrrole is thought to facilitate the formation of the azabicyclic compound (**16**), which has been obtained in high isolated yield.[13] From the point of view of substitution pattern, the oxyallyl cation route to 6,7-dehydrotropinones complements the well-known synthesis of the alkaloid (±)-tropinone (*N*-methyl-9-azabicyclo[3.2.1]octan-3-one) by Robinson[14a] and Schöpf.[14b,15]

Reaction of ***Isoprene*** with the isoprenoid primary-tertiary α,α´-dibromo ketone (**17**) affords monoterpenoid ethers on extractive workup. Claisen rearrangement of the major isomer at higher temperature (E_a = 33.6 kcal mol^{-1}) yields 2,2,4-trimethyl-4-cycloheptenone, while the minor ether gives karahanaenone (eq 9).[20a] The two isomeric seven-membered ketones are obtained directly and more easily from isoprene

and more electrophilic isoprenoid metal oxyallyl cation intermediates.[3,20b]

(9)

In summary, NaI/Cu in acetonitrile is a simple and inexpensive reagent that allows the generation of sodium oxyallyl cation intermediates from a number of α,α´-dibromo ketones, as exemplified by the disecondary (**1**), ditertiary (**12**), and secondary-tertiary (**13**) dibromo ketones. These intermediates have been trapped with nucleophilic dienes to give seven-membered rings. For structurally and electronically more demanding cycloadditions, other methods for generating allyl cations are required. Frequently, but not necessarily, a preformed allylic halide or ester, with a donor substituent at the central allyl carbon atom, is treated with a Lewis acid in the presence of the diene at low temperature.[21-24] In all cases, the electrophilicity of the allyl cation and, equally important, its hidden nucleophilicity (cf. stepwise class B reactions[3]) must be tailored carefully to match the reactivity of the diene.

Acyl Iodides and Related Derivatives.

Sodium iodide in acetonitrile (in the presence or absence of copper powder) is the reagent of choice for preparing acyl iodides from acyl chlorides (eq 10) A wide variety of acyl chlorides react in excellent yield, including sterically hindered pivaloyl chloride (80%), adamantanecarbonyl chloride (93%), and aromatic derivatives. The reaction is monitored by precipitation of sodium chloride. Acyl iodides are surprisingly lipophilic, due to the large iodine atom, and are isolated by continuous extraction from the mother liquor with pentane, using the low temperature reactor-extractor[25] (cf. eq 9). The structure of the acyl iodides is indicated by the diagnostic ^{13}C NMR upfield shift of the iodocarbonyl atom (heavy atom effect).[25]

(10)

Using the same methodology, Hoffmann and his co-workers have also prepared dicarboxylic acid iodides. For example, hexanedioyl diiodide (from the dichloride of adipic acid) has been isolated as heavy, snow-white crystals by extraction into pentane. When exposed to air the compound is oxidized readily, first turning yellow and then brown with simultaneous fuming.[26] Under the same conditions,

chloroformates have been converted into iodoformic esters.[27]

Sodium Pentacarbonylmanganate[1,2]

$NaMn(CO)_5$

[$NaMn(CO)_5$]

[13859-41-1] · C_5MnNaO_5 · Sodium Pentacarbonylmanganate · (MW 217.98) [$LiMn(CO)_5$]

[15689-01-7] · C_5LiMnO_5 · Lithium Pentacarbonylmanganate · (MW 201.93) [$(Ph_3P)_2N$][$Mn(CO)_5$]

[52542-59-3] · $C_{41}H_{30}MnNO_5P_2$ · Bis(triphenylphosphoranylidene)ammonium Pentacarbonylmanganate · (MW 733.60) [$Mn(CO)_5$]$^-$

[14971-26-7]

(strong nucleophile for the preparation of alkyl-, acyl-, and silylmanganese compounds[1,2])

Physical Data: gray or white powder when dried; usually prepared and used as cloudy gray-green solution in THF.

Solubility: Na, K, and Li salts: sol THF. PPN salt: very sol THF, CH_2Cl_2; sparingly sol benzene, diethyl ether; insol hexane.

Form Supplied in: not commercially available

Analysis of Reagent Purity: IR: M[$Mn(CO)_5$][3,4] (M = Na, Li, K; THF, cm^{-1}) 1897 ± 1 (s), 1862 ± 1 (s). PPN[$Mn(CO)_5$][5] (nujol, cm^{-1}) 1892 (s), 1856 (s), 1839 (m).

Preparative Methods: reduction of ***Decacarbonyldimanganese*** with ***Sodium Amalgam*** in THF (eq 1);[6-8] the resulting solution is contaminated with approximately 10% $(CO)_5Mn$-Hg-$Mn(CO)_5$.[7] Use of ***Sodium-Potassium Alloy*** ($NaK_{2.8}$) provides mostly K[$Mn(CO)_5$].[4] Treatment of $Mn_2(CO)_{10}$ with 2.5 equiv ***Lithium Triethylborohydride*** in THF affords clean Li[$Mn(CO)_5$] (eq 2).[3] The potassium salt may be prepared similarly with ***Potassium Tri-s-butylborohydride*** (eq 3).[3]

$$Mn_2(CO)_{10} + 2\ Na/Hg \xrightarrow{THF,\ rt} Na[Mn(CO)_5] \qquad (1)$$

$$Mn_2(CO)_{10} + 2.5\ LiBEt_3H \xrightarrow{THF,\ 0\ ^\circ C} Li[Mn(CO)_5] \qquad (2)$$

$$Mn_2(CO)_{10} + 2.5\ KB(s\text{-}Bu)_3H \xrightarrow{THF,\ 0\ ^\circ C} K[Mn(CO)_5] \qquad (3)$$

Purification: usually used without purification; the PPN salt (PPN = $[(Ph_3P)_2N]^+$) may be obtained as large yellow crystals by treatment with PPNCl and recrystallization from THF and petroleum ether.[3-5]

Handling, Storage, and Precautions: solutions of the pentacarbonylmanganate anion decompose rapidly upon exposure to air or moisture, and are usually used immediately after generation. The PPN salt may be handled in air in the solid state, but darkens after several days exposure. Use in a fume hood.

Reactions with Electrophiles.

$[Mn(CO)_5]^-$ is highly nucleophilic, reacting at the metal center with a variety of electrophiles (eq 4). Most important are reactions with

alkyl, acyl, and silyl halides,[1-3,9-11] giving organomanganese complexes that undergo subsequent insertion or decarbonylation reactions (see also ***Pentacarbonylmethylmanganese***, ***Pentacarbonylphenylmanganese***, and ***Pentacarbonyl(trimethylsilyl)manganese***). $[Mn(CO)_5]^-$ also reacts cleanly with elemental iodine,[6] Sn and Ge halides,[5] $TlNO_3$ (giving $Tl[Mn(CO)_5]_3$),[12] and strongly electron-deficient vinyl halides.[13,14]

Generation of Ketenes.

Reaction of α-bromoacyl halides with $[PPN][Mn(CO)_5]$ in chloroform comprises a convenient method for the generation of pure solutions of ketenes (eq 5).[15]

Sodium Methoxide

NaOMe

[124-41-4] · CH_3NaO · Sodium Methoxide · (MW 54.03)

(highly basic solid capable of catalyzing numerous reactions, including condensations, dehydrohalogenations, and other base-catalyzed mechanisms; also acts as a nucleophile in S_N2 and S_NAr reactions)

Physical Data: mp >300 °C.

Solubility: sol methanol, ethanol, pentane, and DMSO, as well as a wide variety of other solvents; insol hydrocarbon solvents.

Form Supplied in: widely available commercially as a free flowing white powder of 95% purity.

Handling, Storage, and Precautions: flammable solid which spontaneously combusts at 70-80 °C; corrosive; sensitive to and may decompose upon contact with air and moisture; harmful if swallowed, inhaled, or absorbed through the skin; store in a cool, dry place. Capable of creating a dust explosion; keep away from heat, sparks, and flame; incompatible with chlorinated solvents; reacts violently with water and acids.

Basicity of Sodium Methoxide.

The basicity of sodium methoxide is highly dependent on the solvent medium. Solvation and separation of the sodium cation from the methoxide anion affects base strength,[1] as does the degree of hydrogen bonding between the solvent and methoxide ion. Base strength and rates of base-catalyzed reactions may increase by several orders of magnitude in going from a polar protic solvent like methanol to a polar aprotic solvent like DMSO[1,2] (see ***Potassium Methoxide-Dimethyl Sulfoxide***). In comparison to other metalmethoxides, the basicity of sodium methoxide in methanol is greater than that of lithium methoxide but less than that of potassium methoxide.[3] The same basicity order has also been found for solutions of the metal methoxides in DMSO.[1]

Uses as a Base.

Sodium methoxide is the preferred base in the Kolbe electrolytic coupling reaction in methanol.[4] Methoxide ion is generated at the cathode, so only catalytic amounts of NaOMe are required.[5] Sodium methoxide is the preferred base here because of its low cost and the low cost of methanol from which the methoxide is regenerated. Tashiro and co-workers[6] have used the Kolbe electrolysis to synthesize 4-phenylbutyric acid (eq 1). Sodium methoxide has also found use as the preferred base for forming dichlorocarbene from ***Ethyl Trichloroacetate***.[4] An example is the reaction with dihydropyran (eq 2).[7]

(1)

(2)

As a base, sodium methoxide may also perform dehydrohalogenation reactions. Benzalacetophenone dibromide may be treated in this way with sodium methoxide (eq 3).[8] The mechanism of this reaction involves first the nucleophilic displacement of bromide,[4] followed by E2 elimination.[4] Acid hydrolysis then gives dibenzoylmethane.[8] Sodium methoxide also catalyzes the Favorskii rearrangement (eq 4). The first step of the reaction is dehydrochlorination, followed by S_N2 attack of methoxide on the bicyclic intermediate.[9] These examples illustrate one drawback of using sodium methoxide as a base for dehydrohalogenation, namely that NaOMe may also act as a nucleophile, often causing a competition between E2 and S_N2 reactions. Sodium methoxide is not as efficient for E2 reactions as a sterically bulky base might be (see ***Potassium t-Butoxide***).

(3)

(4)

Sodium methoxide is a basic condensation catalyst typically employed in the aldol condensation reaction as a means of generating the enolate (eq 5).[10] Metal hydroxides do not have sufficient base strength to convert a substantial fraction of the aldehyde or ketone to the enolate, so the equilibrium lies far to the left.[10] For condensation reactions that are difficult to drive forward, as in the condensation of ketones, a stronger base must be used, such as ***Lithium Diisopropylamide***. Although NaOMe is not as strong as LDA in generating the enolate, it has the advantages of lower cost, longer shelf life, and ease of handling, storage, and preparation.[10] It is also used in the Robinson annulation reaction (eq 6).[10] Sodium methoxide has been used to catalyze the condensation of γ-butyrolactone as the first step in the synthesis of dicyclopropyl ketone (eq 7).[11]

(5)

(6)

(7)

Seus and Wilson have used sodium methoxide as the basic catalyst for synthesis of stilbene, 2-stilbazole, 2-styrylfuran, and 2-styrylthiophene (eq 8).[12] This method of synthesis provides good yields (75-85%) of the *trans*-alkenes, and is a more convenient procedure than the Wittig alkene synthesis.[12] Sodium methoxide has also been used to condense methyl *N,N*-dimethylsebacamate to give *N,N,N´,N´*-tetramethyl-9-methoxycarbonyl-10-oxononadecanediamide, which, after further processing, yields nonadecanoic acid (eq 9).[13]

(8)

Ar = Ph, 2-pyridyl, 2-furyl, 2-thienyl

(9)

Sodium methoxide has found use as a condensation catalyst for a particularly interesting category of reactions, namely the synthesis of various heterocycles.[4] For example, 2-amino-4-anilino-6-chloromethyltriazine may be synthesized from phenylbiguanide hydrochloride and ethyl chloroacetate in one step (eq 10).[14] Also, 2-thio-6-methyluracil may be synthesized in a similar reaction from ***Ethyl Acetoacetate*** and ***Thiourea*** (eq 11).[15] A final example is the condensation of ***Urea*** and ***Diethyl Oxalate*** to generate parabanic acid (eq 12).[16]

(10)

(11)

(12)

Carbanion Formation.

Sodium methoxide is also useful for generating carbanions. The synthesis of anthraquinones provides an example (eq 13).[17] Sodium methoxide in HMPA is also capable of cleaving carbon-silicon bonds, resulting in a carbanion (eq 14) that is useful in the synthesis of alkenes.[18] When the carbanion is reacted with a carbonyl compound, the alkene results (eq 15).

Nucleophile.

Sodium methoxide solvates to produce a relatively small nucleophile. As previously shown, it may displace halogens from an sp^3 carbon in a typical S_N2 reaction. A wide variety of such methoxylations are possible.[19] One interesting use of sodium methoxide as a nucleophile is in the synthesis of secondary amines from aminosilanes.[20] Typical methods of secondary amine synthesis involve reaction of ammonia or a primary amine with an alkyl halide. This method, however, is not highly selective since the alkylation of the ammonia or amine will not stop at the secondary amine stage and will proceed to yield tertiary amines. Ando and Tsumaki have reported a simple and selective synthesis of secondary amines[20] in which nucleophilic attack of methoxide on the silicon atom of the aminosilane is the first step (eq 16), followed by nucleophilic attack of the amide anion on the alkyl halide of choice (eq 17).

Sodium methoxide is also used as a nucleophile in the simple and efficient synthesis of phloroglucinol from 1,3,5-tribromobenzene (eq 18).[21] Nucleophilic attack of methoxide proceeds by an S_NAr mechanism, and the trimethoxybenzene is then hydrolyzed to give a high yield (~80%) of phloroglucinol.[21] This method has the advantage over the old synthesis in that only two steps are required and no toxic

wastes are produced. Sodium methoxide may also be employed in nucleophilic aromatic substitution reactions to synthesize phenols, anisoles, and methoxyphenols from unactivated aryl halides (eq 19)[22] or 3,5-dinitroanisole from 1,3,5-trinitrobenzene (eq 20).[23]

(18)

(19)

(20)

Other Reactions.

Sodium methoxide may be used to perform selective dealkylation of bis(alkylthio)benzenes.[24,25] Depending on whether sodium methoxide or sodium methanethiolate is used, removal of either the more branched or the less branched alkyl group is possible. If sodium methanethiolate is used, then the less highly substituted alkyl group is eliminated (eq 21). The postulated mechanism[24] for this involves the methanethiolate anion (which is a much better nucleophile than the methoxide anion) attacking the less highly substituted alkyl group in an S_N2 reaction to displace the substituted phenyl group.[24] If sodium methoxide is used, however, then the more highly substituted alkyl group is removed in an elimination reaction, which produces propene and the thiolate with the less substituted alkyl group (eq 22).[24] The reaction may be performed in HMPA[24] or DMF.[25]

(21)

(22)

Another interesting reaction performed by sodium methoxide is the methylation of fluorene. Heating a mixture of fluorene, methanol, and sodium methoxide together in a bomb results in the formation of 9-methylfluorene (eq 23).[26]

Sodium Methylsulfinylmethylide[1]

NaDMSO

[15590-23-5] · C_2H_5NaOS · Sodium Methylsulfinylmethylide · (MW 100.13)

(strong base and nucleophile; very useful for the introduction of the methylsulfinylmethyl group[1])

Alternate Names: sodium dimsylate; dimsylsodium.

Solubility: sol DMSO.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: titration with formanilide using triphenylmethane as indicator.[2]

Preparative Method: prepared by the reaction of ***Sodium Hydride*** with ***Dimethyl Sulfoxide*** for 1 h at 70 °C. ***Sodium Amide*** may also be used as base.[3]

Handling, Storage, and Precautions: this reagent is not exceptionally stable over long periods of time. Modifications in preparation and storage have led to an increased shelf life.[4] However, it is probably best prepared as needed and used quickly. Hydrogen is emitted during the preparation of this reagent and decomposition occurs at elevated temperatures.[5] Due caution should be exercised in the preparation, particularly on a large scale. Reports have been made of explosions during the large scale preparation of this reagent or its attempted isolation.[1,6]

Introduction.

The pK_a of DMSO is 35. Consequently, one might expect its conjugate base to be a potent Brønsted base and this is indeed the case. In addition to the sodium salt, both the lithium and potassium salts of DMSO have found widespread use in synthesis (see ***Lithium Methylsulfinylmethylide*** and ***Potassium Methylsulfinylmethylide***). After its introduction by Corey,[2] explorations of the chemistry of sodium methylsulfinylmethylide (NaDMSO) blossomed and are summarized nicely in two reviews.[1]

Sodium Methylsulfinylmethylide as Base.

Generation of Ylides.

NaDMSO as a solution in DMSO has been used extensively in the preparation of phosphorus and sulfur ylides.[1,7,8] This medium is often the one of choice for the generation and reaction of Wittig reagents (eq 1).[7,9] A less common application of Wittig reagents generated with NaDMSO is in an oxidative coupling of a bis-ylide to form a cyclic alkene (eq 2).[10]

(1)

The methylene transfer reagents ***Dimethylsulfonium Methylide*** and ***Dimethylsulfoxonium Methylide*** are conveniently generated with NaDMSO in DMSO.[11] These and other sulfonium ylides are useful in the synthesis of epoxides and cyclopropanes (eqs 3 and 4).[8,11] Also intriguing is the use of dimethyloxosulfoxonium methylide to give dienes (eq 5).[12]

Diaminosulfonium salts can be deprotonated with NaDMSO to give rearrangement products or epoxides upon reaction with aldehydes (eq 6).[13] A variety of ammonium ylides have been generated using NaDMSO.[14,15] These species are disposed to undergo Wittig, Stevens, or Sommelet-Hauser rearrangements, depending on their specific constitution (eqs 7 and 8). Changes in base and other reaction conditions can change product distributions.[14a,b]

(6)

(7)

(8)

Eliminations.

Elimination reactions using NaDMSO have apparently not been extensively investigated, although the use of metal alkoxides in DMSO has received considerable attention.[16] Whether the active agent in such mixtures is NaDMSO is not clear. Eliminations clearly mediated by NaDMSO are known.[17] For example, treatment of (**1**) with NaDMSO at 25 °C gives the elimination product (**2**) in 91% yield (eq 9).[17a] Longer reaction times result in addition of DMSO to the newly formed double bond. Heating results in isolation of a dealkylation product (**4**), a clear example of the diverse reactivity associated with NaDMSO. Alkynes are generated by the reaction of 1,2-dibromoalkanes with excess NaDMSO.[18] Aryl halides can give benzynes in the presence of NaDMSO (eq 10).[19] Further, addition of DMSO is possible, leading to a unique mode of functionalization (eq 11).[19c]

(11)

Rearrangements.

NaDMSO has been used to promote double bond isomerization, leading to aromatization in the case shown (eq 12).[20] An anionotropic rearrangement of a cyclohexadienone to a substituted hydroquinone has been reported (eq 13).[21] The use of NaDMSO in DMSO has been described as an optimal choice for executing the carbanion accelerated Claisen rearrangement (eq 14).[22] Grob-type fragmentations mediated by NaDMSO have been used in total synthesis (eq 15).[23]

(12)

(13)

(14)

(15)

Anion Alkylation and Acylation.

NaDMSO has been used as a base to create new anions or carbanions, which then can be functionalized via normal alkylation or acylation procedures. Intramolecular aminolysis of an ester mediated by NaDMSO has been reported (eq 16).[24] A tandem double Michael-Dieckmann condensation leading to a complex tricyclic structure has been developed (eq 17).[25] Generation of a ketone enolate with NaDMSO followed by an intramolecular alkylation has been a part of a number of total syntheses.[26] Alkylations of sulfoximine and sulfone (Ramberg-Bäcklund rearrangement) carbanions derived from NaDMSO are known.[27] The intramolecular oxidative coupling of nitro-stabilized carbanions can lead to highly functionalized cyclopropanes which are potentially useful as high energy materials (eq 18).[28]

(16)

(17)

(18)

Ether Synthesis.

The application of NaDMSO to the Williamson ether synthesis has been documented.[29] The potential for alkoxide fragmentation exists and some discretion must be exercised in using this base for ether formation.[30] An intramolecular version of the Williamson reaction mediated by NaDMSO leads to an oxetane in high yield.[31] The preparation of otherwise difficulty accessible xanthates has been realized using NaDMSO.[32] Very common is the modification of oligo- and polysaccharides via Williamson ether synthesis (Hokomori reaction) to facilitate handling and analysis of these compounds.[33] Other hydroxylic polymers can also be functionalized in this way.[34]

Sodium Methylsulfinylmethylide as Nucleophile.

Reactions with Esters.

Perhaps one of the most useful reactions of NaDMSO is its condensation with esters to produce β-keto sulfoxides. The rich chemistry of these difunctional compounds makes accessible a wide variety of other organic compounds.[1,35] One of the most straightforward applications of NaDMSO is the synthesis of methyl ketones from esters (eq 19).[36] Thermal elimination of methylsulfenic acid after alkylation leads to α,β-unsaturated ketones (eq 20).[37] Among the wide variety of possible transformations of β-keto sulfoxides, another which stands out is the Pummerer reaction, which allows for the formation of carbon-carbon bonds via an umpolung of the reactivity adjacent to the carbonyl group (eq 21).[38] A synthesis of ninhydrin was developed based on this type of chemistry.[38c] Methacrylate polymers have been modified by reaction with NaDMSO.[39]

(19)

(20)

(21)

Reactions with Aldehydes and Ketones.

The reaction of nonenolizable ketones and aldehydes with NaDMSO generally proceeds smoothly to give β-hydroxy sulfoxides.[1] The chemistry of the latter is not as rich as that of β-keto sulfoxides, to which they can be converted. However, dehydration leads efficiently to α,β-unsaturated sulfoxides which can be transformed to the corresponding sulfides or sulfones.[40] A one-pot procedure using ***Sodium*** metal to produce NaDMSO and serve as a reductant leads to α,β-unsaturated sulfides directly.[41] Interestingly, a dianion of DMSO can be prepared from the reaction of DMSO with 2.2 equiv of $NaNH_2$. Reaction with benzophenone gives the expected adduct, albeit in only modest yield (eq 22).[3] A unique synthesis of 3-phenylindole based upon the reaction of NaDMSO with 2-aminobenzophenone has been reported (eq 23).[42]

(22)

(23)

Enolizable ketones and aldehydes often give enolates upon reaction with NaDMSO as well as the expected addition products, limiting the utility of the reagent with these systems. Several unusual reactions of NaDMSO with enolizable ketones have been reported. For example, treatment of 4-heptanone with NaDMSO at elevated temperatures results in diene formation (eq 24).[43] Similarly, the reaction of cyclopentanone with NaDMSO gives a diene resulting from condensation followed by nucleophilic addition of NaDMSO and fragmentation (eq 25).[44]

(24)

(25)

Reactions with Imines and Related Compounds.

The reaction of imines with NaDMSO has not been extensively studied.[2] However, several interesting applications with heterocycles at least formally possessing imine functional groups have been reported. Treatment of 1-methylquinoline with excess NaDMSO results in a tandem 1,4-1,2 addition to give a unique β-amino sulfoxide (eq 26).[45] A mechanistically intriguing synthesis of phenanthrene is the result of the reaction of a benzoquinoline *N*-oxide with NaDMSO (eq 27).[46] Finally, a synthesis of dibenzo[*a*,*f*]quinolizines has been developed based on the addition of NaDMSO to an imine followed by trapping of the resulting amide with a pendant benzyne (eq 28).[47]

(26)

(27)

(28)

Reactions with Alkenes and Alkynes.

The reaction of NaDMSO with alkenes or alkynes conjugated to an aryl ring or alkene is well known.[1] 1,1-Diphenylethene gives a 1:1 addition product in quantitative yield upon reaction with NaDMSO.[48] From a synthetic perspective, one of the most useful of these reactions is the alkylation, especially the methylation, of stilbenes (eq 29).[49] This occurs by initial attack of NaDMSO on the unsaturated system followed by the elimination of methanesulfenic acid and isomerization. Dienes and other polyenes are subject to the same type of chemistry, but yields are modest and isomer formation can be a problem (eq 30).[50] Reaction of NaDMSO with diphenylacetylene can lead to either simple addition products or those based on an addition-elimination sequence, depending on the reaction conditions (eq 31).[51] Addition of NaDMSO to unsaturated systems has been used in polymer synthesis.[52]

(29)

(30)

(31)

Reactions with Aromatics.

The reactions of NaDMSO with aromatic electrophiles can be categorized as occurring through either benzyne or addition-elimination mechanisms. Reaction of NaDMSO with chlorobenzene gives a mixture of sulfoxides, presumably via a benzyne intermediate (eq 32).[53] This chemistry has been used in the modification of polystyrenes.[54] Various fluoroaromatics react with NaDMSO to produce substitution products via addition-elimination (eq 33).[55] A variety of condensed aromatics (e.g. anthracene) undergo methylation analogous to that of stilbene upon reaction with NaDMSO (eq 34).[56]

(32)

(33)

(34)

Reactions with Halides and Related Compounds.

Alkylation of NaDMSO with primary halides and tosylates results in the formation of the expected sulfoxides.[57] However, reaction with benzyl chloride gives stilbene as the major product, suggesting that the basicity of NaDMSO must be considered even with reactive electrophiles.[2] More hindered systems favor elimination. 1,2,5,6-Tetrabromocyclooctane debrominates to 1,5-cyclooctadiene upon reaction with NaDMSO (eq 35).[58] With ***Potassium t-Butoxide*** in DMSO the major product is one of elimination, namely cyclooctatetraene. Monodebromination also occurs with *gem*-dibromocyclopropanes.[59] In a process which presumably proceeds via S_N2 substitution, reaction of imidates with NaDMSO leads to amides (eq 36).[60]

(35)

(36)

Reactions with Epoxides.

The reaction of NaDMSO with epoxides does not appear to have been widely investigated. Nevertheless, some synthetically useful transformations have been documented. Ring opening with NaDMSO followed by thermal alkene formation was developed as a route to an optically pure secondary allylic alcohol (eq 37).[61] A related transformation involves the reaction of trimethylsilyl-substituted epoxides (eq 38).[62] Ring opening at the TMS-substituted carbon, followed by desilylation and sulfenate elimination, leads to allyl alcohols in good yield in a one-pot process.

(37)

(38)

Reactions with Phosphorus and Sulfur Electrophiles.

A one-pot synthesis of α,β-unsaturated sulfoxides begins with the reaction of NaDMSO with ***Diethyl Phosphorochloridate*** to give a Horner-Emmons reagent which reacts with aldehydes in an efficient manner (eq 39).[63] Bis-sulfoxides are prepared by the reaction of NaDMSO and a diastereomerically pure methyl sulfinate ester.[64] Some kinetic resolution is observed in this reaction. The thiophilic addition of NaDMSO to sulfines also leads to bis-sulfoxides (eq 40).[65]

Sodium Naphthalenide

[3481-12-7] · $C_{10}H_8Na$ · Sodium Naphthalenide · (MW 151.17)

(one-electron donor promoting ketyl-alkene[3] and ketyl-alkyne[2] radical cyclizations; facilitates coupling of ketone[4] and thiocarbonyl[5] functionalities; removes mesylate, tosylate, and benzyl protecting groups[11,13-15] to generate the corresponding alkene or alcohol)

Solubility: sol diethyl ether, THF; forms complexes with diethyl ether and THF.

Preparative Method: typically prepared from the reduction of naphthalene by ***Sodium*** metal in THF solvent.[1]

Handling, Storage, and Precautions: stability is a matter of contention.[1] THF apparently contributes substantially to the stability of the complex by solvating the resulting ion pairs.

Reductive Cyclization.

Sodium naphthalenide is a good electron donor and promotes the reductive cyclization of steroidal acetylenic ketones in high yield (eq 1).[2] The resulting allylic alcohol is the only observed product and no overreduction occurs as with more powerful reducing agents.

Similarly, radical cyclization of an alkenyl aldehyde with sodium naphthalenide provides the product resulting from 5-*exo* ring closure in moderate yield. This method has been utilized in the synthesis of a key intermediate leading to α-cuparenone, which presents a challenge synthetically because of the steric congestion around the cyclopentane ring (eq 2).[3]

Ketone and Thiocarbonyl Coupling.

More recently, sodium naphthalenide in conjunction with ***Titanium(IV) Chloride*** has been used to perform a McMurry-like coupling reaction in an intramolecular process, providing a bicyclic structure in good yield (eq 3).[4]

(3)

Sodium naphthalenide further provides a method for the bridging of macrocycles. Nicolaou has recently used this method in the preparation of *cis*- and *trans*-fused oxabicyclic and oxapolycyclic systems, which are common structural components of marine and other natural products (eq 4).[5] This process is thought to proceed by initial electon transfer to the thiocarbonyl group of the macrodithionolide system generating the radical anion; this initiates a sequence leading to the bridged product which is quenched with methyl iodide to generate the more stable disulfide. The disulfide may then be further transformed chemically to either the *cis*- or *trans*-fused polycycle.

(4)

Reduction of Epoxides.

The ability to relocate the allylic alcohol moiety within a molecule is another synthetic strategy for which sodium naphthalenide has been found useful. This ability is demonstrated in the transformation of geraniol to linalool (eq 5) by epoxidation of the allylic alcohol, mesylation, and subsequent treatment with sodium naphthalenide to produce the allylic alcohol in good yield.[6] Similarly, this method has been utilized in the synthesis of isocarbacyclin, a therapeutic agent for cardiovascular disease. Treatment of the epoxidized and protected allylic alcohol with sodium naphthalenide provides the desired allylic alcohol with the exocyclic double bond as a mixture of diastereomers (eq 6).[7] Apparently, the *t*-butyldimethylsilyl ether is unaffected under these reaction conditions.

(5)

Sodium naphthalenide with ***N,N,N´,N´-Tetramethylethylenediamine*** effects a carbon-carbon bond-forming reaction between carboxylic acids and conjugated alkenes (eq 7) to produce the substituted carboxylic acid in moderate yield.[8,9] This method has been utilized in the preparation of dihydrolavandulol (eq 8) in fair yield.[8]

Treatment of benzimidazoline-2-thione with alkyl halide and sodium naphthalenide in THF affords the 1-alkyl-2-(alkylthio)benzimidazoles in excellent yield. These substrates may be further transformed by additional sodium naphthalenide to provide the 1-alkylbenzimidazoline-2-thiones in high yield (eq 9).[10] Thus, sodium naphthalenide provides an alternative to other known methods which generally proceed in much lower yield and require longer reaction times and more vigorous reaction conditions.

R	(1) (%)	(2) (%)
Me	97	88
Et	100	94
Allyl	100	92
Benzyl	100	93

Protecting Group Removal; Alkene Formation.

Sodium naphthalenide also facilitates the removal of protecting groups. It has been utilized in the debenzylation of nucleosides (eq 10).[11] Sodium naphthalenide also effects the reductive cleavage of toluenesulfonates. Both menthyl tosylate and bridged bicyclic tosylates are quantitatively reduced under mild reaction conditions (eqs 11 and 12).

(12)

Cyanohydrins with α-methyl thiomethyl ether or α-methyl thiomethyl sulfone substituents are converted regio- and stereospecifically to the corresponding alkenes (eqs 13 and 14).[12] The *cis*-substituted cyanohydrin undergoes elimination to generate the *cis*-alkene while the *trans*-substituted cyanohydrin provides the *trans*-alkene upon treatment with sodium naphthalenide/HMPA. This provides an excellent method for the preparation of either *cis*- or *trans*-alkenes in large ring systems.

(13)

R = H, 85%; Me, 74%
R' = CH_2SMe or CH_2SO_2Me

(14)

R = H, 60%; Me, 83%
R' = CH_2SMe or CH_2SO_2Me

Treatment of methanesulfonates of vicinal diols with sodium naphthalenide in THF or DME results in the rapid and high conversion to the alkene (eqs 15 and 16).[13] Although the reaction is highly regiospecific, the more stable alkene generally predominates in close to the equilibrium ratio. This method has recently been utilized in the synthesis of (±)-20-deethylcatharanthine (eq 17) in which the diol is converted to the dimesylate followed by subsequent treatment with sodium naphthalenide, providing the desired alkaloid analog in good yield.[14]

(15)

(16)

(17)

Similar conversion of the bicyclic vicinal diol to the dimesylate followed by treatment with sodium naphthalenide provides an efficient strategy for the deoxygenation of the vicinal diol to form an immediate precursor to the natural product (+)-(1*S*,5*R*,7S)-exobrevicomin (eq 18).[15] This method provides significantly higher yield than xanthate formation followed by reduction with ***Tri-n-butylstannane***.

(18)

Sodium naphthalenide further affords a useful procedure for the conversion of cyclic sulfates into alkenes, providing an efficient synthesis of deoxygenated vicinal diols (eq 19).[16] This reaction is highly regiospecific but, in examples where (*E*)/(*Z*) isomerization is possible, the thermodynamically preferred alkene predominates. Additionally, carbonyl functionalities and other easily reduced species are incompatible with these reaction conditions.

Sodium Nitrite[1]

$NaNO_2$

[7632-00-0] · $NNaO_2$ · Sodium Nitrite · (MW 69.00)

(diazotization of primary aliphatic and aromatic amines;[1] *N*- and *C*-nitrosating agent;[2,3] reacts with alkyl halides to form aliphatic nitro compounds[4])

Physical Data: mp 271 °C; dec. above 320 °C; *d* 2.17 g cm^{-3}.

Solubility: very sol water (0.815 g mL^{-1}, 15 °C); sol DMSO, DMF; slightly sol Et_2O, MeOH, EtOH.

Form Supplied in: white crystalline, hygroscopic solid; reagent grade 97%+; widely available.

Handling, Storage, and Precautions: should be kept dry in tightly closed containers. Nitrites undergo slow oxidation to the nitrate in air. Aqueous solutions of $NaNO_2$, which are alkaline (ca. pH 9), are unstable on prolonged storage and should be made up fresh prior to use. $NaNO_2$ decomposes in the presence of weak acids with the evolution of brown fumes of N_2O_3. Since $NaNO_2$ is classified as toxic, oral ingestion should be avoided.

Introduction.

In many synthetic applications, $NaNO_2$ is used as a convenient precursor of the unstable nitrous acid HONO which is generated in situ on treatment with a variety of mineral and carboxylic acids. Reactions involving HONO are complex because, in solution, it exists in equilibrium with a variety of other reactive species, including N_2O_3, nitrosyl halides, and the nitrosonium ion ON^+. Although $LiNO_2$ and KNO_2 will also react in a similar fashion to the sodium salt, the latter is preferred on the basis of price and availability. Diazotization and nitrosation reactions can also be carried out using a variety of reagents including ***Nitrosyl Chloride*** and alkyl nitrites.

Reactions with Amines and Related Compounds.

In such reactions, a solution or suspension of the amine in dilute hydrochloric acid (2.5 molar equiv per mole of amine) is treated with a molar equiv of $NaNO_2$ solution at 0-10 °C. Reactions are normally rapid and in many cases quantitative.[1] The reaction outcome depends markedly on the nature of the amine. With primary aliphatic amines, the reaction (usually described as diazotization) produces the corresponding diazonium ion (**1**) as the first significant intermediate. This can subsequently eliminate either a molecule of nitrogen to generate a carbocation, or H^+ to give a diazoalkane (eq 1).[5] In the diazotization of simple primary aliphatic amines with sodium nitrite in dilute mineral acid, the former process predominates resulting in rapid evolution of N_2, an observation which forms the basis for the characteristic chemical test for primary aliphatic amines.

Cycloalkylamines (ring sizes C_4 and C_6-C_8) can undergo ring contraction on diazotization (eq 2); conversely, cycloalkylmethylamines (ring sizes C_3-C_8) undergo ring expansion under similar conditions (Demjanov rearrangement) (eq 3).[6] Ring expansions of certain

alkanolamines (ring sizes C_4-C_8) also occur on diazotization, affording cyclic ketones (Tiffeneau-Demjanov rearrangement) (eq 4).[7] Product yields from the latter reaction are generally superior to those from the corresponding simple Demjanov rearrangements.

(2)

(3)

(4)

Diazotization of amino acids using $NaNO_2$ in HCl affords the corresponding α-chloro carboxylic acids in moderate yield and with almost complete retention of configuration (95-98% ee) (eq 5).[8] Analogous deamination/halogenation transformations have also been effected on 6β-aminopenicillanic acid (**2**) with inversion of configuration.[9] In the presence of ***Bromine***, the corresponding geminal dibromide (ca. 30%) is obtained;[10] yields can be increased to 80% if a two-phase solvent system is used (eq 6).[11] The *S*,*S*-dioxide derivative of (**2**) affords the corresponding geminal dibromide in good yield and high purity with methanol, rather than water, as solvent.[12]

(5)

(6)

When primary aliphatic amines with strongly electron-withdrawing substituents attached to the amino carbon atom are diazotized, the corresponding diazoalkanes can be isolated.[5,13] Diazotization of 2,2,2-trifluoroethylamine affords the corresponding diazoalkane in 70% yield.[14] Treatment of glycine ethyl ester hydrochloride with sodium nitrite in dilute sulfuric acid affords the important synthetic intermediate ***Ethyl Diazoacetate*** (eq 7).[15] The benzyl ester of acid (**2**) has also been transformed into the corresponding α-diazo derivative using sodium nitrite in aqueous acetone.[16] Attempted diazotization of 2-aminocyclohexanone results in deamination and

rearrangement to cyclopentanecarboxylic acid (57%).[17]

(7)

Primary aromatic amines readily undergo diazotization to give the corresponding diazonium salts, which are generally stable in solution at temperatures below 0 °C.[1] These are important intermediates in electrophilic aromatic substitution reactions, e.g. the formation of azo dyes, and a variety of coupling/displacement reactions including the Sandmeyer, Balz-Schiemann, and Gomberg reactions. Amines with strongly acidic groups are best diazotized by the slow addition of a solution of the amine and $NaNO_2$ in dilute alkali to the acid with vigorous stirring.[1a] To avoid hydrolysis of the diazonium salt, amines with strongly electron-withdrawing groups should be diazotized in concentrated acid.[1a,18] The transformation of aromatic 1,2-diamines to bis-diazonium salts should also be carried out in concentrated acid. In dilute or weak acid, the mono-diazonium ions derived from 1,2-phenylenediamines cyclize to give 1,2,3-benzotriazoles (eq 8).[1a,b,19] By analogy, diazotization of *p*-nitro-*o*-toluidine affords 5-nitroindazole under similar conditions.[20]

(8)

Treatment of diazonium salts, preferably the tetrafluoroborates, with $NaNO_2$ in the presence of a Cu^I catalyst at pH > 7 results in the formation of the corresponding aromatic nitro compounds (cf. the Sandmeyer reaction).[21] For analogous reactions involving amines with strongly electron-withdrawing groups, a Cu^I catalyst is not required.[22]

Heteroaromatic amines also undergo diazotization on treatment with sodium nitrite in acid; for example, 3-aminopyridines give isolable diazonium salts whereas the 2- and 4-derivatives afford either the corresponding pyridones in dilute acid[23] or halopyridines in concentrated HCl or HBr (eq 9).[24] Diazotization of 2-aminopyrimidine in concentrated HCl produces 2-chloropyrimidine.[25]

(9)

Treatment of secondary dialkyl-, diaryl-, and alkylarylamines with sodium nitrite in mineral acid with gentle heating usually results in the formation of the corresponding *N*-nitrosamines which, being unable to lose a proton, are comparatively stable to further reaction (eq 10).[2,26] Secondary amides will also undergo *N*-nitrosation.[27]

(10)

Although erroneously considered to be inert towards nitrosation,[28] tertiary amines do undergo nitrosative dealkylation when treated with $NaNO_2$ in aqueous acetic acid at 90 °C to give mixtures of products including dialkyl-*N*-nitrosamines, carbonyl compounds, and nitrous oxide (eq 11).[29] A diterpenylalkanolamine was found to lose a terpenyl substituent selectively on nitrosation with $NaNO_2$ in acetic acid.[30]

Nitrosation of hydrazine derivatives using $NaNO_2$ in acid solution provides a convenient method of preparing the corresponding azide derivatives.[31] For example, phenyl azide can be prepared by treating a suspension of phenylhydrazine hydrochloride in dilute HCl with $NaNO_2$ at 0 °C in a two-phase water/ether system (eq 12).[32] Highly substituted hydrazines undergo nitrosative dealkylation in an analogous fashion to give tertiary amines.[33] Hydrazinium salts, derived from *N*,*N*-dimethylhydrazine and an alkyl halide, are deaminated on treatment with $NaNO_2$ in HCl (4 M) to yield tertiary amines (eq 13).[34] Like simple hydrazines, hydrazides can be converted into the corresponding acyl azides by reaction with $NaNO_2$ in dilute HCl at low temperature.[31,35]

C-Nitrosation Reactions.

Aliphatic carbon centers in alkanes do not readily undergo *C*-nitrosation with nitrous acid unless activated by an electron-withdrawing substituent such as acyl, aroyl, carbonyl, carboxyl, nitro, cyano, imino, or aryl.[3] The usual products are *C*-nitrosamines or oximes, depending on the degree of substitution at the carbon center in question (eq 14). Detailed procedures have been reported for the preparation of the oximes derived from the active methylene compounds ***Ethyl Acetoacetate*** and ***Diethyl Malonate***.[36,37] The unstable β-chloro- and bromopyruvaldoximes have been obtained by treatment of the appropriate γ-haloacetoacetyl chlorides with $NaNO_2$ in ether-water via a reaction sequence which involves hydrolysis and nitrosation of the resulting β-keto acid followed by decarboxylation.[38]

Although gaseous NOCl is generally the reagent of choice for the direct nitrosation of alkenes, the simultaneous addition of concentrated solutions of $NaNO_2$ and hydrochloric acid to limonene in isopropanol (t < 10 °C) affords the corresponding chloro oxime in good yield (eq 15).[39] The rate of nitrosation of alkenes using $NaNO_2$ and aqueous hydrochloric acid can be accelerated to a significant extent by bromide and chloride ions.[40] Tetracyclone undergoes *cis*-dihydroxylation on treatment with $NaNO_2$ in acetic acid; the reaction is thought to proceed via a cycloaddition of N_2O_3 to one of the double bonds (eq 16).[41a] Under similar conditions, methyl methacrylate and tricyclone are nitrated at unsubstituted sp^2 carbon centers, and 2,5-disubstituted furans ring open to unsaturated diketones.[41b] Isopropylidene and terpene alkenes undergo dehydromethylation to give alkynes in moderate to good yield on reaction with $NaNO_2$ in acetic acid; the reaction is complex and the Me group is lost as CO_2 (eq 17).[42] Mucobromic acid in ethanol is transformed to the sodium

salt of nitromalonaldehyde, a useful building block for the synthesis of pyrimidines, by the action of aqueous $NaNO_2$.[43]

(15)

(16)

(17)

Nitrosation of phenols using $NaNO_2$ in hydrochloric acid generally results in formation of the corresponding nitroso compound.[44] Thus, for example, phenol yields 4-nitrosophenol, together with a small quantity of the 2-isomer (ca. 10%) (eq 18),[44] and 2-naphthol produces 1-nitroso-2-naphthol.[45] Treatment of phenols with buffered nitrous acid ($NaNO_2$ in large excess compared to HCl) in aqueous acetone results in the formation of diazonium salts.[46]

(18)

Although anisole and diphenyl ether are readily nitrosated, they both give rise to 4-nitrosophenol.[47] 4-Nitrosoanisole is, however, obtained in 57% yield from anisole if the nitrosation reaction is carried out in CH_2Cl_2/CF_3CO_2H under argon at 0 °C.[48] Nitration of simple aromatic compounds is reported to be readily achieved by reaction with $NaNO_2$ in ***Trifluoroacetic Acid*** at 25 °C; isomer ratios are similar to those expected from electrophilic aromatic substitution reactions.[49] Hydroquinones are conveniently oxidized to quinones by excess $NaNO_2$ in acetic acid.[50] Reaction of 2,3,5-trisubstituted pyrroles and 3,5-disubstituted pyrazoles with buffered nitrous acid gives rise to diazo compounds.[51]

Oxidation Reactions.

$NaNO_2$ in various acidic media, including dilute HCl, acetic acid, and CF_3CO_2H, oxidatively cleaves C=N bonds in oximes,[52] semicarbazones,[53] and hydrazones,[54,55] thereby regenerating the carbonyl group under mild reaction conditions (eq 19). 2,4-Dinitrophenylhydrazones, which are normally resistant to hydrolysis, are transformed to carbonyl compounds in ca. 80% yield.[55] Reaction of secondary or tertiary thioamides with $NaNO_2$ in HCl (4 M) affords the corresponding amides in good yield (70-90%).[56]

(19)

α-Nitro esters[57] and sulfones[58] are readily converted into their respective α-oximino derivatives on reaction with $NaNO_2$ in aqueous ethanol and DMF, respectively. Reactions between secondary aliphatic nitro compounds and mixtures of $NaNO_2$ and alkyl nitrites give ketones in good yield;[59] with primary aliphatic nitro compounds, carboxylic acids are obtained in low yield.[60] Carboxylic acids can undergo oxidative decarboxylation with concomitant formation of cyano compounds (50-70%) on treatment with a mixture of $NaNO_2$ and ***Trifluoroacetic Anhydride*** (1:3) in CF_3CO_2H.[61] Benzylic alcohols can be oxidized to aldehydes with $NaNO_2$ in aqueous CF_3CO_2H.[62] Diazotization of benzylamine with $NaNO_2/CF_3CO_2H$ in dry DMSO at 100 °C results in the formation of benzaldehyde (60-80%); poorer yields are obtained from the analogous isoamyl nitrite reaction.[63]

Nitroalkanes and Nitrite Esters.

Since the nitrite ion is bidentate, nucleophilic displacement reactions with alkyl halides can take place through either nitrogen or oxygen to give nitro compounds or nitrite esters respectively (eq 20). $NaNO_2$ in either DMF or DMSO reacts readily with primary and secondary alkyl bromides or iodides to yield the corresponding nitro compounds; ***Silver(I) Nitrite*** gives better yields with primary alkyl halides.[64] It is important that significant quantities of both the nitrite and the halide are in solution or the reaction does not take place. Secondary nitrosation reactions can be minimized by the addition of a nitrite scavenger such as phloroglucinol.

(20)

Simple alkyl nitrites can be prepared by direct esterification of the appropriate alcohol with aqueous $NaNO_2$ in sulfuric acid at 0 °C. The preparations of methyl,[65] ethyl,[66] and butyl nitrites[67] have been described in detail. ***Isopentyl Nitrite*** is obtained in high yield by treatment of a mixture of the alcohol and $NaNO_2$ with aluminum sulfate.[68] Propargyl bromides have been transformed into 3-nitroisoxazoles (20-60%) using $NaNO_2$ in DMF (eq 21).[69]

(21)

Fremy's Salt.

Potassium Nitrosodisulfonate, a useful reagent for the selective oxidation of phenols and aromatic amines to quinones (Teuber reaction), has been prepared by the reaction of $NaNO_2$ with $NaHSO_3$ and SO_3 followed by electrolysis using a stainless steel anode in alkaline solution.[70] Fremy's salt has also been generated in situ as a marker in ESR spectroscopy by bubbling O_2 through an equimolar mixture of $NaNO_2$ and $NaHSO_3$ in alkaline solution (pH 9).[71]

Sodium Octacarbonylhydridodiferrate

$NaHFe_2(CO)_8$

[60308-01-2] · $C_8HFe_2NaO_8$ · Sodium Octacarbonylhydridodiferrate · (MW 359.78)

(reduction of α,β-unsaturated carbonyl compounds)

Physical Data: X-ray structure of the $HFe_2(CO)_8^-$ ion as the PPN^+ salt has been reported.[1]

Solubility: sol THF.

Form Supplied in: prepared as a solution in THF; not commercially available.

Analysis of Reagent Purity: IR (THF) 1987 (s), 1940 (s), 1880 (s), 1852 (s), 1770 (m) and 1730 cm^{-1} (w); ^1H NMR (THF, C_6D_6) δ -8.47 (32 °C).

Preparative Method: $Na_2Fe_2(CO)_8$ (0.764 g, 2.00 mmol)[2] is taken into a test tube equipped with a magnetic stir bar. With a pipet, 20 mL of dry THF is added; 0.112 mL of HOAc (2.00 mmol) is then added and the test tube is sealed with a serum stopper, removed from the dry box, and immediately placed in an ice bath. The sample is centrifuged for 5-10 min. This procedure gives about 12-13 mL of a yellow-brown homogeneous 0.10 M $NaHFe_2(CO)_8$ solution.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture; solutions in THF slowly decompose at ambient temperature; the solutions are stable for a few days in a -22 °C freezer.

Reaction with CO and Ph_3P.

Added ***Carbon Monoxide*** cleaves the metal-metal bond in $NaHFe_2(CO)_8$ and forms the products shown in eq 1. The addition of other ligands such as ***Triphenylphosphine*** to $NaHFe_2(CO)_8$ in THF also results in iron-iron bond cleavage. The reaction gives significant amounts of $NaHFe(CO)_4$, $Fe(CO)_3(Ph_3P)_2$, $Fe(CO)_5$, and some $Fe(CO)_4Ph_3P$, but not $NaHFe(CO)_3Ph_3P$. The reaction stoichiometry, precise to ±15%, is shown in eq 2.

$$NaHFe_2(CO)_8 + CO \xrightarrow{THF} NaHFe(CO)_4 + Fe(CO)_5 \quad (1)$$

$$NaHFe_2(CO)_8 + Ph_3P \xrightarrow[25\ °C]{THF} NaHFe(CO)_4 + 0.4\ Fe(CO)_5 + 0.4\ Fe(CO)_3(Ph_3P)_2 + 0.2\ Fe(CO)_4Ph_3P \quad (2)$$

Reaction with MeCOCl.

The addition of ***Acetyl Chloride*** to $NaHFe_2(CO)_8$ in THF gives 18% of acetoxymethylenediiron heptacarbonyl and 20-25% acetaldehyde (eq 3).[3]

Selective Reductions.

A solution of $NaHFe_2(CO)_8$ and HOAc in THF reduces the alkenic bond in α,β-unsaturated carbonyl compounds in high yield.[2] The double bonds in unsaturated esters, ketones, aldehydes, nitriles, amides, and lactones are all reduced without concurrent carbonyl reductions, demonstrating the mild conditions of these reductions. Carvone is reduced without isomerization or concurrent reduction of the isopropenyl group (eq 4). This is in contrast to Wilkinson's catalyst[4] (***Chlorotris(triphenylphosphine)rhodium(I)***), which preferentially hydrogenates the isopropenyl group in carvone.

$\Delta^{1,9}$-2-Octalone is reduced to 2-decalone with a *cis*:*trans* ratio of 4:1 (eq 5). The selectivity is better than that of Noyori's reduction[5] based on ***Pentacarbonyliron*** and NaOH in methanol, which yields products with a *cis*:*trans* ratio of 1:2. A bulky substrate such as testosterone is also reduced with a *cis*:*trans* ratio of 10:1 (eq 6). However, the yield of this reaction is poor.

Except for exceptionally active substrates like ***Dimethyl Maleate*** and mesityl oxide, 2 or more equiv of $NaHFe_2(CO)_8$ are required to reduce 1 equiv of substrate. Compared to acetic acid, the weak, insoluble acid NH_4Cl increases yields, while the stronger acid ***Trichloroacetic Acid*** decreases yields. This reagent is a better reducing agent for the alkenic bond in α,β-unsaturated carbonyl compounds than ***Sodium Borohydride***, which is limited primarily to double bonds activated by two carbonyls.[6] The reagent also has the advantage of greater selectivity and mildness over heterogeneous hydrogenation.[7]

Sodium Perborate

$NaBO_3.4H_2O$

[10486-00-7] · BH_8NaO_7 · Sodium Perborate · (MW 153.88)

(oxidizing agent for a variety of functional groups)

Physical Data: mp 60 °C (dec.); bulk density 0.74-0.82 g cm^{-3}.

Solubility: sol water (~23 g L^{-1} at 20 °C, ~37 g L^{-1} at 30 °C; pH of 1% solution ~10.4); sol acetic acid, lower alcohols.

Form Supplied in: colorless, crystalline, odorless, free-flowing powder; widely available; 96% minimum sodium perborate tetrahydrate; 10% minimum available oxygen.

Handling, Storage, and Precautions: safe when handled correctly. It should be stored in a cool, dry place (below 40 °C) protected from direct heat and humidity.

Sodium perborate tetrahydrate, $NaBO_3.4H_2O$, has the 1,4-diboratetraoxane structure (**1**). This structure is disrupted in polar protic solvents such as water, alcohols, and carboxylic acids, and various types of oxidizing species can be generated, from the perhydroxyl anion to protonated perboric acid, depending on the pH. The reagent is most commonly used in acetic acid at temperatures between ambient and 60 °C; peracetic acid is produced at appreciable rates at higher temperatures. Detailed mechanisms for the various perborate oxidations have yet to be established. In most of its applications, sodium perborate is recommended as a cheap, safe, and convenient alternative to oxidants such as ***Hydrogen Peroxide***, ***Peracetic Acid*** and ***m-Chloroperbenzoic Acid***, especially for large scale operations.

(1)

Functional Group Oxidations.

Sulfur and Selenium.

Thiols (RSH) and selenols (RSeH) are smoothly oxidized in high yield to disulfides (RSSR) and diselenides (RSeSeR).[1] Many sulfides, including a range of heterocyclic sulfur compounds, have been oxidized cleanly to sulfones with excess reagent (eq 1).[2-5] Conversion of sulfides into sulfoxides also proceeds in high yield when 1 equiv of oxidant is used, although in most cases small amounts of sulfones are also formed.[2,6] Chiral sulfoxides are obtained from appropriate precursors (eq 2).[7] Oxidation at sulfur and selenium is faster than at most other functional groups and hence it is not usually necessary to protect amino, hydroxyl, or alkenic centers. In the presence of ***Acetic Anhydride***, sodium perborate is an effective reagent for the preparation of α,β-unsaturated carbonyl compounds by oxidative deselenylation of α-phenylselenocarbonyl derivatives (eq 3).[8]

(1)

(2)

(3)

Nitrogen.

Oxidation of π-deficient azines (substituted pyridines, pyrazines, and quinolines; isoquinoline) with sodium perborate in acetic acid gives good yields of the corresponding *N*-oxides.[5,9] The reactions of anilines are particularly interesting. Depending on the reaction conditions, they can be converted into the corresponding azo,[10-12] azoxy,[13] or nitro[2,14] compounds (eq 4). The latter transformation is particularly useful for anilines which contain powerful electron-withdrawing groups in the *ortho* or *para* positions (eq 5).[2] Excellent yields are obtained of products which are very difficult, or impossible, to prepare by standard aromatic substitution reactions. Primary aliphatic amines are oxidised to *C*-nitroso compounds[15] (isolated in good yield as the dimers), while oximes give moderate yields of the corresponding nitro compounds.[16] *N*,*N*-Dialkylhydrazones are cleaved to the ketones in good to excellent yield.[2,17]

(4)

(5)

X = 4-CF_3, 86%; 2-O_2N, 76%; 4-NC, 91%

Alkenes and Alkynes.

Most types of alkenes react rather sluggishly with sodium perborate in acetic acid and this process is of little use for epoxidation. A mixture of the perborate with acetic anhydride, however, apparently generates peroxybis(diacetoxyborane), $(AcO)_2B\text{-}O\text{-}O\text{-}B(OAc)_2$, which does epoxidize alkenes in good yield (eq 6).[18] Use of the same reagent system with ***Sulfuric Acid*** catalysis gives 1,2-diol monoacetates (eq 7). Similar types of products are obtained from a series of α-substituted styrenes with perborate in acetic acid (eq 8),[19] while terminal alkynes give 1-acetoxyalkan-2-ones with added ***Mercury(II) Acetate*** as catalyst.[20] Epoxidation of α,β-unsaturated ketones can be effected in excellent yield either under phase-transfer conditions[21] or simply by using sodium perborate in a two phase water-THF system (eq 9).[22] Epoxidation of quinones has been described,[23] but in most cases yields are low.

(6)

(7)

(8)

(9)

Alcohols, Aldehydes, Ketones, Phenols, and Nitriles.

Simple alcohols react only very slowly with sodium perborate and, as indicated below, aqueous alcohol serves as a very suitable solvent for the hydration of nitriles. Benzylic alcohols are oxidized to aldehydes, ketones, and/or carboxylic acids only at temperatures higher than 60 °C.[24] α-Hydroxy acids are oxidized to ketones or carboxylic acids, 1,2-diols are cleaved to acids and ketones, and α-diketones also give carboxylic acids.[25] Room temperature Baeyer-Villiger oxidation of ketones proceeds smoothly (eq 10),[2] while perborate/acetic acid at 45-50 °C is an excellent reagent for the high yield oxidation of a wide range of aromatic aldehydes to the corresponding carboxylic acids.[5,26] Hydroquinones and certain highly substituted phenols are oxidized in good yield to quinones.[2] The phenol oxidations may involve initial electrophilic hydroxylation of the electron-rich rings.[11,27] Although not formally an oxidation, the hydration of nitriles by perborate is a clean and high yielding reaction.[5,28,29] Interestingly, there is no reaction when acetic acid is used as solvent, but use of water, aqueous methanol, or a water-dioxane system gives excellent results.

(10)

Boron, Iodine, Phosphorus.

Trialkyl- and triarylboranes are efficiently converted into alcohols and phenols on treatment at room temperature with sodium perborate in a water-THF system.[30,31] Oxidation at boron is even faster than oxidation at sulfur (eq 11), and the perborate oxidation is as good as, or better than, the conventional peroxide/base procedure. It is particularly useful for the clean, high yield conversion of alkenylboranes into aldehydes and ketones.[32] Iodoarenes are readily oxidised by sodium perborate. Use of acetic acid as solvent gives good yields of (diacetoxyiodo)arenes (eq 12),[5] while (dichloroiodo)arenes, $ArICl_2$, are obtained in 60-98% yield when hydrochloric acid is used.[33] Sodium perborate has been recommended as a viable alternative to hydrogen peroxide for the large scale oxidative decomposition of toxic organophosphorus ester wastes.[34-36]

Sodium Periodate[1]

$NaIO_4$

[7790-28-5] · $INaO_4$ · Sodium Periodate · (MW 213.89)

(oxidative cleavage of 1,2-diols;[2] oxidation of sulfides,[3] selenides,[4] phenols,[5] indoles,[6] and tetrahydro-β-carbolines[7])

Alternate Name: sodium metaperiodate.

Physical Data: mp 300 °C (dec); specific gravity 3.865.

Solubility: sol H_2O (14.4 g/100 mL H_2O at 25 °C; 38.9 g/100 mL at 51.5 °C), H_2SO_4, HNO_3, acetic acid; insol organic solvents.

Form Supplied in: colorless to white tetragonal, efflorescent crystals; readily available.

Handling, Storage, and Precautions: irritant; gloves and safety goggles should be worn when handling this oxidant; avoid inhalation of dust and avoid contact of oxidant with combustible matter.

Introduction.

Sodium periodate is widely used for the oxidation of a variety of organic substrates and as a cooxidant in other oxidation reactions (see ***Sodium Periodate-Osmium Tetroxide*** and ***Sodium Periodate-Potassium Permanganate***).[8] The $NaIO_4$ oxidation is usually conducted in water; however, for organic substrates that are insoluble in water, an organic cosolvent (e.g. MeOH, 95% EtOH, 1,4-dioxane, acetone, MeCN) is used. Alternatively, the oxidation can be conducted either with phase-transfer catalysis (PTC) using quaternary ammonium[5] or phosphonium[9] salts in a two-phase system, or in an organic solvent if the oxidant is first coated on an inert support.[10]

Oxidative Cleavage of 1,2-Diols.

$NaIO_4$ is widely used for the oxidative cleavage[2] of a variety of 1,2-diols to yield aldehydes or ketones (eq 1). In this respect, it complements the ***Lead(IV) Acetate*** method for oxidation. 1,2-Diols have been shown to be chemoselectively cleaved by $NaIO_4$ in the presence of a sulfide group.[11] $NaIO_4$ coated on wet silica gel efficiently oxidizes 1,2-diols to the aldehydes (eq 2).[10a] This method is particularly useful for the preparation of aldehydes which readily form hydrates, and it is also convenient to conduct because isolation of the product involves simple filtration of the reaction mixture and evaporation.

(1)

(2)

Oxidation of Sulfides to Sulfoxides.

The selective oxidation of sulfides to sulfoxides is an important transformation because sulfoxides are useful intermediates in synthesis.[12] The reaction is conducted using an equimolar amount of $NaIO_4$ in aqueous methanol at 0 °C (eq 3).[3] Higher reaction temperatures or the use of an excess of $NaIO_4$ result in overoxidation to give sulfones. $NaIO_4$ supported on acidic alumina (eq 4)[10b,c] or silica gel[10d] is effective for the selective oxidation of sulfides, at ambient temperature, to afford good yields of sulfoxides. Phase transfer-catalyzed $NaIO_4$ oxidation of sulfides also results in the selective formation of sulfoxides.[9]

(3)

(4)

α-Phosphoryl sulfoxides, useful for the preparation of vinylic sulfoxides,[13] are prepared in high yields by the oxidation of α-phosphoryl sulfides using $NaIO_4$.[14] Vinylic sulfoxides can also be prepared in good yields by the oxidation of vinylic sulfides using $NaIO_4$ (eq 5).[15] Poor yields of sulfoxides are obtained in the $NaIO_4$ oxidation of acetylenic sulfides.[15a]

(5)

2-Substituted 1,3-dithianes are stereoselectively oxidized to the *trans*-1-oxide by $NaIO_4$ at low temperatures.[16] Dimethyl dithioacetals of aldehydes and ketones suffer $NaIO_4$-mediated hydrolysis to give carbonyl compounds.[17] This method could be useful for the deprotection of dimethyl dithioacetals. Oxidation of dithioethers such as 1,4-dithiacycloheptane using $NaIO_4$ at 0 °C furnishes the 1-oxide in modest yield.[18] The use of ***m-Chloroperbenzoic Acid*** for this oxidation leads to an appreciable amount of the 1,4-dioxide. Oxidation of a naphtho-1,5-dithiocin using an excess of $NaIO_4$ at rt results in a high yield of the *cis*-1,5-dioxide.[19] The sulfide unit in thiosulfoxides is selectively oxidized to the *S,S*-dioxide in good yields using an equimolar amount of $NaIO_4$ at 0 °C.[20] Unsymmetrical thiosulfinic *S*-esters are efficiently converted to the thiosulfonic *S*-esters, without concomitant cleavage of the S-S bond, by $NaIO_4$ oxidation.[21] $NaIO_4$ is effective for the selective oxidation of the sulfide moiety in (**1**) to the sulfoxide in the presence of a disulfide linkage (eq 6).[22] Other oxidants such as CrO_3 in acetic acid, H_2O_2, and *m*-CPBA, which are useful for the oxidation of simple sulfides, only cause the decomposition of (**1**).

Oxidation of Selenides to Selenoxides.

Diaryl, dialkyl, and aryl alkyl selenides are oxidized[4] to the corresponding selenoxides in high yields using a slight excess of $NaIO_4$ at 0 °C (eq 7).[4a] The presence of an electron-withdrawing substituent in diaryl selenides inhibits the oxidation of the selenium center. Vinylic selenides can be oxidized[23] with $NaIO_4$ to give high yields of vinylic selenoxides (eq 8).[23a] In contrast, oxidation with ***Hydrogen Peroxide*** results in the cleavage of the double bond to give carboxylic acids. The oxidation of organoselenides possessing β-hydrogens results in the formation of highly unstable organoselenoxides that undergo facile *syn* elimination, often at room temperature, to give alkenes (eq 9).[24,25] Such a process constitutes a useful method for the introduction of a double bond into organic molecules.

Oxidation of Phenols and Its Derivatives.

Dihydroxybenzenes are oxidized to give high yields of the corresponding quinones using $NaIO_4$ supported on silica gel (eq 10)[10a] or under PTC (see also ***Tetra-n-butylammonium Periodate***).[5] Treatment of *p*-hydroxybenzyl alcohol with $NaIO_4$ in aqueous acetic acid results in the formation of *p*-benzoquinone, albeit in low yield (23%).[26] On the other hand, *o*-(hydroxymethyl)phenols possessing at least one bulky group at the C-4 position are efficiently oxidized to give spiroepoxy-2,4-cyclohexadienones (eq 11).[27] In the absence of a bulky group, self-dimerization of the spiroepoxycyclohexadienone via Diels-Alder reaction occurs. In the case of *o*-(hydroxymethyl)phenols that are substituted with one or two aryl groups at the benzylic carbon, a novel oxidative rearrangement occurs to yield benzylidene protected catechols in modest yields (eq 12).[28] However, this oxidative rearrangement is only successful if substituents are present in the C-2 and C-4 positions of the phenol unit, because oxidation of α-(2-hydroxyphenyl)benzyl alcohol only results in the formation of a dimer.

(10)

(11)

(12)

Oxidation of Indoles and Tetrahydro-β-Carbolines.

The indolic double bond in 2,3-dialkyl- and 3-alkylindoles is readily oxidized by 2 mole equiv of $NaIO_4$ at room temperature to give *o*-amidoacetophenone derivatives in good yields (eq 13).[6] However, the oxidation of 2,3-diphenylindole under the same conditions results in a lower yield of the oxidative cleavage product.[29] Interestingly, the oxidation of 2-alkylindoles results in the formation of a mixture of products comprised of indoxyl derivatives.[29] Tetrahydrocarbazoles are also efficiently oxidized by $NaIO_4$ to afford benzocyclononene-2,7-dione derivatives.[6] Tetrahydro-β-carbolines have also been subjected to $NaIO_4$ oxidation.[7] Thus, in the oxidation of the tetrahydro-β-carboline-3-carboxylates, the type of product that is formed depends upon the degree of substitution at C-1 of the starting material (eqs 14 and 15).[7a]

(13)

(14)

(15)

Other Applications.

1,3-Cyclohexanedione and its 3-substituted derivatives are oxidized with $NaIO_4$, with concomitant loss of the C-2 carbon unit, to give glutaric acid in good yields.[30] 1,3-Cyclopentanediones react more slowly under the same conditions, and aromatic diketones such as 1,3-indandione give poor yields of the dicarboxylic acid product. α-Hydroxy carboxylic acids undergo oxidative decarboxylation to give aldehydes (eq 16)[31] upon treatment with aqueous $NaIO_4$; however, long reaction times are required. The use of PTC[9] or Bu_4NIO_4 allows for shorter reaction times without adversely affecting the yield. The oxidation of hydrazine with $NaIO_4$ in the presence of trace amounts of aqueous ***Copper(II) Sulfate*** and ***Acetic Acid*** results in the formation of ***Diimide***. The in situ generation of diimide by this method has been successfully applied to a one-pot procedure for the reduction of alkenes (eq 17).[32]

(16)

(17)

A secondary amide is obtained by selective oxidation of a tertiary carbon center in adamantane with $NaIO_4$ in the presence of iron(III) perchlorate in acetonitrile (eq 18).[33] Dimethylhydrazones undergo periodate induced hydrolysis, at pH 7, to give carbonyl compounds in high yields (eq 19).[34] However, these conditions are unsuitable for the hydrolysis of dimethylhydrazones derived from aromatic or α,β-unsaturated aldehydes because mixtures of aldehydes and nitriles are formed.

(18)

(19)

Acylphosphoranes are oxidized to α,β-dicarbonyl compounds in fair yields using aqueous $NaIO_4$ (eq 20).[35] This method complements other methods such as the ***Potassium Permanganate***[36a] or ***Ruthenium(VIII) Oxide*** oxidation[36b] of alkynes. $NaIO_4$ is also used for the oxidation of hydroxamic acids and *N*-hydroxycarbamic esters at pH 6 to generate highly reactive nitroso compounds.[37] The oxidations are usually conducted in the presence of conjugated dienes so that the nitroso intermediates are trapped as their Diels-Alder cycloadducts (eq 21).

Sodium Periodate-Osmium Tetroxide[1,2]

$NaIO_4$-OsO_4

($NaIO_4$)

[7790-28-5] · $INaO_4$ · Sodium Periodate-Osmium Tetroxide · (MW 213.89) (OsO_4)

[20816-12-0] · O_4Os · Sodium Periodate-Osmium Tetroxide · (MW 254.20)

(oxidizing agent for oxidative cleavage of carbon-carbon double bonds[3] to give aldehydes and ketones)

Physical Data: $NaIO_4$: mp 300 °C (dec); specific gravity 3.865. OsO_4: bp 130 °C; mp 40 °C; specific gravity 4.900 at 22 °C.

Solubility: $NaIO_4$: sol H_2O (14.4 g/100 mL H_2O at 25 °C; 38.9 g/100 mL at 51.5 °C), H_2SO_4, HNO_3, acetic acid; insol organic solvents. OsO_4: sol alcohol, Et_2O, benzene, CCl_4, NH_3, $POCl_3$, H_2O (25%).

Form Supplied in: $NaIO_4$: colorless to white tetragonal, efflorescent crystals. OsO_4: colorless to pale yellow crystals contained in ampules. Both reagents are readily available.

Handling, Storage, and Precautions: $NaIO_4$: irritant; gloves and safety goggles should be worn when handling this oxidant; avoid inhalation of dust and avoid contact of oxidant with combustible matter. OsO_4: acrid, chlorine-like odor; irritant; highly corrosive; causes burns to skin, eyes, and respiratory tract; gloves and safety goggles must be worn and this reagent must be handled in a well ventilated fume hood.

Introduction.

In 1956, Lemieux, Johnson, and co-workers first described[3] the use of sodium periodate-osmium tetroxide for the direct oxidation of alkenic bonds to give carbonyl compounds. This reaction combines the hydroxylating properties of ***Osmium Tetroxide*** with the glycol cleavage capabilities of ***Sodium Periodate***. Additionally, sodium periodate serves to regenerate osmium tetroxide during the reaction, thereby permitting the use of only catalytic amounts of the expensive and toxic osmium tetroxide. This oxidation complements the classical method of ozonization of double bonds followed by reductive cleavage. The reaction is usually carried out in a mixed aqueous solvent system such as aqueous dioxane, aqueous THF, aqueous acetone, or aqueous DME. Water is required in this reaction for the hydrolysis of the intermediate osmate ester. In reactions where the carbonyl products are prone to self-condensation, the use of the ether-water system is found to be highly satisfactory.

Oxidative Cleavage of Double Bonds to Give Carbonyl Compounds.

The oxidation of acyclic alkenes and stilbene in aqueous 1,4-dioxane using sodium periodate in the presence of catalytic amounts of osmium tetroxide ($NaIO_4$-cat. OsO_4) yields the corresponding aldehydes in good yields (eqs 1 and 2).[3,4] In contrast, the oxidation of cyclohexene under the same conditions gives only a low yield of adipaldehyde. The low yield is attributed to the tendency of adipaldehyde to undergo self-condensation. The use of an ether-water system for the oxidation circumvents this problem. Under the modified conditions, the oxidation of cyclohexene gives a good yield of adipaldehyde (eq 3).[3] Similarly, cyclopentene is oxidized to afford glutaraldehyde in good yield. 1-Methylcyclohexene, however, is oxidized very slowly under the optimum conditions found for cyclohexene; only a small amount of an uncharacterized carbonyl compound is obtained. Nevertheless, this outcome suggests that $NaIO_4$-cat. OsO_4 can be employed for the selective cleavage of unhindered double bonds in the presence of hindered ones. This type of selective oxidation is effectively applied to the cleavage of a vinyl group in the presence of a more hindered alkenic bond in the etorphine ring system (eq 4).[5]

(1)

(2)

(3)

(4)

Alkenic compounds are rapidly and efficiently cleaved to carbonyl compounds using $NaIO_4$ in the presence of polymer-supported OsO_4 (P-OsO_4) (eqs 5 and 6).[6] Cyclohexene is oxidized to give a fairly good yield of adipaldehyde (eq 7). This provides a useful alternative to oxidation in the ether-water system[3] alluded to earlier. α,β-Unsaturated carbonyl compounds are oxidized at the double bond to give aldehydes in good yields (eq 8). A notable feature of this method[6] is that a particular oxidation can be easily repeated, at least 10 times, by simply adding new portions of substrate and sodium periodate.

(5)

(6)

(7)

(8)

The double bond in alkyl, cycloalkylmethyl, and arylmethyl allyl ethers can be oxidatively cleaved using $NaIO_4$-cat. OsO_4. The oxidation of (**1**) in aqueous dioxane containing trace amounts of acetic acid affords a good yield of the benzyloxy aldehyde (eq 9).[7] On the other hand, oxidation of similar systems[8] in aqueous dioxane results in only low yields of aldehydes. Higher yields are obtained when the oxidation is carried out using the ether-water system (eq 10).

(1)

(9)

(10)

Allylic alcohols are oxidized using $NaIO_4$-cat. OsO_4, with concomitant loss of two carbon units, to furnish good yields of the expected aldehyde (eq 11).[9] The double bond in hydroxy alkenes, such as in (*R*)-(+)-citronellol, is selectively oxidized to give the corresponding hydroxy aldehydes which, upon subsequent Wittig alkenation, give the α,β-unsaturated esters (eq 12).[10]

(11)

(12)

The oxidation of γ,δ-unsaturated carbonyl substrates using $NaIO_4$-cat. OsO_4 is a practical method for the preparation of synthetically useful 1,4-dicarbonyl compounds.[11] For example, oxidation of the double bond of the allyl moiety in (**2**) yields the aldehyde in good yield (eq 13).[11a] Subsequent base-catalyzed aldol condensation of the keto aldehyde furnishes the spirocyclopentenone derivative, albeit in low yield. Such a protocol has been employed for the preparation of key cyclopentenone intermediates used in natural products synthesis, e.g. in the syntheses of phytuberin (eq 14),[12] aphidicolin (eq 15),[13] and bakkenolide (eq 16).[14]

(13

(14)

(15)

(16)

The 1-methylvinyl group can be used as a latent acetyl unit in synthesis. This is exemplified in the synthesis of a key intermediate required for the construction of the polyether antibiotic carbamonensin (eq 17).[15] The acetyl group is subsequently utilized for the stereospecific installation of the acetate moiety via Baeyer-Villiger oxidation. Double bonds present in polyoxygenated systems have also been efficiently oxidized to the aldehydes in high yields (eq 18).[9]

(17)

(18)

The reaction conditions used for the $NaIO_4$-cat. OsO_4 oxidation are mild and this permits the oxidation of double bonds in the presence of acid or base labile groups such as the ester (eq 19),[11b] carbamate, acetal (eq 20),[16] silyl ether (eq 21),[17] and carbonate (eq 22)[18] functions.

(19)

(20)

(21)

(22)

Cyclobutanones have been prepared from alkylidene- or arylidenecyclobutanes via the $NaIO_4$-cat. OsO_4 oxidation.[19] The oxidation of benzylidenecyclobutane with $NaIO_4$-cat. OsO_4 gives cyclobutanone, albeit in low yields (17%).[19a] This outcome, however, is better than the ozonolysis method, which does not yield any cyclobutanone. The $NaIO_4$-cat. OsO_4 oxidation of 3-methylenecyclobutanecarboxylic acid is more successful and a good yield of 3-oxocyclobutanecarboxylic acid is obtained (eq 23).[19b] This protocol for the preparation of cyclobutanone from methylenecyclobutane has been used in natural product synthesis (eq 24).[20]

(23)

(24)

Alkenic bonds in heterocyclic molecules have also been oxidatively cleaved using $NaIO_4$-cat. OsO_4. Oxidation of the methylenecyclobutane moiety in the 2-quinolone derivative affords a good yield of the cyclobutanone derivative (eq 25).[21] 1-Substituted 2-nitroimidazole-5-carbaldehydes are prepared in useful yields by the action of $NaIO_4$-cat. OsO_4 on 5-vinylimidazole precursors (eq 26).[22] This method is better than the two-step procedure, namely, ***Potassium Permanganate*** hydroxylation followed by $NaIO_4$ oxidation of the 1,2-diol, which gives a lower yield of the product. Previous attempts to prepare 2-nitroimidazole-5-carbaldehydes such as by the ozonolysis of 5-vinylimidazoles and by the direct oxidation of 5-methyl-2-nitroimidazoles with CAN or SeO_2 were unsuccessful. $NaIO_4$-cat. OsO_4 is effective for the oxidation of double bonds in 2-azetidinone derivatives to give a good yield of the co rresponding aldehydes (eq 27).[23]

(25)

(26)

(27)

Other Applications.

$NaIO_4$-cat. OsO_4 is a mild oxidizing agent and does not oxidize aryl groups. However, pyrene has been oxidized using $NaIO_4$-cat. OsO_4 to afford two major products arising from oxidation at the 4,5-double bond (eq 28).[24] The use of OsO_4-H_2O_2 gives only a low yield of the 4,5-quinone and most of the starting material is recovered. RuO_2-$NaIO_4$ oxidation is less specific and a mixture of products, resulting from attack at positions other than the 4,5-double bond, is obtained.

Sodium Periodate-Potassium Permanganate

$NaIO_4$-$KMnO_4$

($NaIO_4$)

[7790-28-5] · $INaO_4$ · Sodium Periodate-Potassium Permanganate · (MW 213.89) ($KMnO_4$)

[7722-64-7] · $KMnO_4$ · Sodium Periodate-Potassium Permanganate · (MW 158.04)

(oxidant for the cleavage of carbon-carbon double bonds[1])

Physical Data: $NaIO_4$: mp 300 °C (dec); specific gravity 3.865. $KMnO_4$: mp 240 °C (dec); specific gravity 2.703.

Solubility: $NaIO_4$: sol H_2SO_4, HNO_3, $MeCO_2H$, hot water; slightly sol cold water. $KMnO_4$: sol MeOH, acetone, hot water; slightly sol cold water.

Form Supplied in: $NaIO_4$: white to colorless efflorescent solid. $KMnO_4$: dark purple crystals. Both reagents are widely available and can be used as supplied.

Handling, Storage, and Precautions: gloves and safety goggles must be worn during handling; avoid inhalation of dust and contact with combustible matter.

Introduction.

The oxidative cleavage of carbon-carbon double bonds to give carboxylic acids using a catalytic amount of ***Potassium Permanganate*** in the presence of ***Sodium Periodate*** was first reported by Lemieux and von Rudloff.[2] The reaction is usually carried out under buffered reaction conditions and, depending on the pH of the solution, either a 1,2-diol (at pH 9-10) or a 1,2-ketol (at pH 7-8) is initially formed. Oxidative cleavage of either of these intermediates by periodate yields the corresponding aldehyde, which is oxidized by permanganate to give the carboxylic acid. Permanganate is continually being regenerated from its reduced state (manganate) by the periodate. The reaction can be carried out in an aqueous medium or in mixed solvents (e.g. *t*-BuOH-H_2O, pyridine-H_2O) and proceeds optimally in the pH range between 7 and 10. Ketones and esters are not oxidized by $NaIO_4$-$KMnO_4$, whereas alcohols are oxidized slowly to carboxylic acids. Acyclic and cyclic alkenes are efficiently oxidized by $NaIO_4$-$KMnO_4$ to the carboxylic acids (eqs 1 and 2).[1,3] α,β-Unsaturated ketones are oxidized smoothly to give keto acids with loss of one carbon atom (eq 3).[4]

(1)

(2)

Double bonds located in the side chain of a ring are more easily oxidized than those situated in the ring (eq 4).[5] Also, double bonds in hydroxy alkenes can be selectively cleaved in the presence of a hydroxyl group.[5b,c] Thus (*R*)-(+)-citronellol is oxidized with $NaIO_4$-$KMnO_4$ to give (*R*)-(+)-6-hydroxy-4-methylhexanoic acid (eq 5).[5c] The oxidation of cyclic conjugated dienes[6] with $NaIO_4$-$KMnO_4$ can lead to products arising from hydroxylation[7] and epoxidation[5a] of the double bonds, as well as the expected oxidative cleavage of the double bonds (eq 6).[7a]

Sodium Permanganate

$NaMnO_4.H_2O$

[10101-50-5] · H_2MnNaO_5 · Sodium Permanganate · (MW 159.95)

(oxidant; capable of converting secondary alcohols into ketones, primary alcohols and aldehydes into carboxylic acids, sulfides into sulfones, and amines into the corresponding nitro compounds; less effective oxidant for unsaturated alcohols; unreactive toward alkanes, alkenes, alkynes, and epoxides)

Physical Data: solid; decomposes with evolution of oxygen at 170 °C; *d* 2.46 g cm^{-3}.

Solubility: sol water; insol hexane.

Form Supplied in: purple solid; commercially available.

Handling, Storage, and Precautions: oxidant; store in glass vessel at rt.

Introduction.

When dissolved in water, the chemical properities of sodium permanganate are very similar to those of ***Potassium Permanganate***; when used heterogeneously, it is a slightly less reactive oxidant than ***Copper(II) Permanganate*** heptahydrate. In common with $Cu(MnO_4)_2$, anhydrous sodium permanganate is not a good heterogeneous oxidant.

Oxidation of Alcohols.

When 3 mmol of an alcohol in 15 mL of hexane is stirred with 1.92 g (12 mmol) of $NaMnO_4.H_2O$ at reflux for 2.5 h, the resulting ketone or carboxylic acid can be easily isolated by filtering the mixture and flash evaporating the solvent.[1] The yields for allylic alcohols are lower. Typical examples of this oxidation are shown in eqs 1-4.

(1)

(2)

(3)

(4)

Oxidation of Sulfides.

Dialkyl sulfides are converted to the corresponding sulfones under similar conditions (eq 5).[1]

Sodium Phenanthrenide

[96229-74-2] · $C_{14}H_{10}Na$ · Sodium Phenanthrenide · (MW 201.23)

(dehalogenation of vicinal dichlorides[1])

Solubility: sol THF

Preparative Method: prepared by adding 1.0 equiv of ***Sodium*** to a solution of 1.1 equiv of phenanthrene in dry THF. The resulting dark-green solution is stirred for 18 h at rt.[1]

Handling, Storage, and Precautions: should be used as prepared, under anhydrous conditions; the dry solid and solutions are flammable.

Dehalogenation Agent.

Sodium phenanthrenide is a useful reagent for the dehalogenation of vicinal dichlorides, resulting in the formation of alkenes. An isomeric mixture of *cis*- and *trans-exo,exo*-3,4-dichlorotetracyclo[4.4.2.0^{2,5}.0^{7,10}]dodeca-8,11-diene is easily converted to *exo,exo*-tetracyclo[4.4.2.0^{2,5}.0^{7,10}]dodecatriene in the presence of sodium phenanthrenide in THF (eq 1).[1]

(1)

In addition to sodium phenanthrenide, disodium phenanthrenide,[2] zinc metal,[3] chromium dichloride,[4] titanium trichloride/lithium aluminum hydride,[5] sodium sulfide nonahydrate,[6] and activated nickel complexes[7] have also been employed in dehalogenations of 1,2-dihalides.

Related Reagents.

Chromium(II) Chloride; ***Disodium Phenanthrenide***; ***Lithium 4,4´-Di-t-butylbiphenylide***; ***Lithium Naphthalenide***; ***Potassium Naphthalenide***; ***Sodium Anthracenide***; ***Sodium Naphthalenide***; ***Sodium Sulfide***; ***Titanium(III) Chloride-Lithium Aluminum Hydride***; ***Zinc***.

Sodium-Potassium Alloy

Na-K

[11135-81-2] · KNa · Sodium-Potassium Alloy · (MW 62.09)

(preparation of organopotassium compounds;[1] in combination with TMSCl, greatly enhances acyloin condensations;[2] dehalogenation of dihalides;[3] preparation of γ, δ-unsaturated alcohols via fragmentation of γ-halo ketones;[4] in combination with crown ethers is a useful reducing agent for alkynes[5,6] and alkyl fluorides[7,8])

Physical Data: mp -11 °C.

Form Supplied in: available in two alloy forms: 56% K, 44% Na; 78% K, 22% Na.

Preparative Method: can be prepared by mixing 1 part ***Sodium*** and 5 parts ***Potassium*** (by weight) in refluxing xylene until melted. The melt is then carefully mixed with a glass stirring rod, keeping the alloy in one large globule. Upon cooling to room temperature, the alloy will remain liquid and can easily be transferred via a glass pipet.[1]

Handling, Storage, and Precautions: flammable solid; handle under inert atmosphere.

Organopotassium Compounds.

Potassium derivatives can be generated from a number of organic substrates via the action of Na-K alloy (eqs 1-3).[1] The generated organopotassium adducts are soluble and stable in anhydrous diethyl ether. Similarly, the treatment of either organosodium or organolithium compounds with Na-K alloy results in the more reactive organopotassium species.

(1)

(2)

(3)

Acyloin Condensation.

The combination of ***Chlorotrimethylsilane*** (TMSCl) with Na-K alloy greatly facilitates the acyloin condensation.[2] This action results in smooth conversion of diesters to disiloxenes (eqs 4 and 5). Sodium metal can also be used, with similar results, to facilitate the acyloin condensation.

(4)

(5)

Dehalogenations.

Sodium-potassium alloy is also useful in the dehalogenation of dihalides. Sodium-potassium alloy in ethanol reacts with 1,4-dibromobicyclo[2.2.2]octane to give the Grob fragmentation product, 1,4-dimethylenecyclohexane (eq 6). However, the use of an inert solvent such as cyclohexane affords bicyclo[2.2.2]octane in modest yield (eq 7).[3]

(6)

(7)

Fragmentation of γ-Halo Ketones.

The reaction of γ-halo ketones with Na-K alloy in anhydrous ether gives rise to products where 1,4-reductive elimination of halide proceeds with cleavage of the 2,3 carbon-carbon bond.[4] Under these conditions, 1-chloroadamantan-4-one is converted to 7-methylbicyclo[3.3.1]nonan-2-ol (eq 8).

(8)

Reduction of Multiple Bonds.

The dissolving metal reduction of alkynes typically involves an alkali metal in liquid ammonia.[5] However, it has been demonstrated that dissolving metal reductions utilizing *t*-butyl alcohol and Na-K alloy in THF with catalytic amounts of ***18-Crown-6*** proceed smoothly.[6] The solubility of alkali metals in THF can be greatly increased with the aid of an appropriate crown ether or cryptate. Thus 4-octyne can be reduced to the corresponding octene (3:1 mixture of *trans*:*cis*) (eq 9).

(9)

Reduction of Alkyl Fluorides.

The reductive cleavage of unactivated C-F bonds is a difficult transformation in organic synthesis. The carbon-fluorine bond is known to strongly resist the usual reductive conditions.[7] However, the use of sodium-potassium alloy and ***Dicyclohexano-18-crown-6*** in diglyme is effective in the reductive cleavage of unactivated carbon-fluorine bonds.[8] Thus 3β-fluorocholest-5-ene is successfully reduced to cholest-5-ene in high yield (eq 10).

Related Reagents.

Sodium Phenanthrenide.

Sodium Selenide[1]

Na_2Se

[1313-85-5] · Na_2Se · Sodium Selenide · (MW 124.94)

(nucleophilic agent for synthesis of organic selenides[1])

Physical Data: mp 845 °C; *d* 2.58 g cm^{-3}.

Solubility: readily sol water; sol ethanol, liquid ammonia; sparingly sol THF.

Form Supplied in: white, fine hygroscopic crystals.

Preparative Methods: prepared by reduction of ***Selenium*** with ***Sodium*** (molar ratio 1:2) in liquid ammonia. It can be used in solution[2b,c] or isolated by evaporation of ammonia.[2a] In aqueous medium, Na_2Se is obtained by reduction of Se with ***Sodium Hydroxymethanesulfinate*** (rongalite)[3] or by reduction of Na_2Se_2 with ***Sodium Dithionite***.[4] Na_2Se (or K_2Se) can also be produced by the direct reaction of Se with Na (or K) in high-boiling, polar, aprotic solvents, such as DMF, HMPA, and NMP[5] or in THF in the presence of naphthalene as a catalyst.[6] A combination of electrochemical reduction and ultrasound is used to produce the Se^{2-} anion in THF, DMF, and acetonitrile.[7]

Handling, Storage, and Precautions: hygroscopic crystals; rapidly turns red in moist air because of the formation of polyselenides and separation of Se. From water solution, red Se separates rapidly on contact with air. It can be stored under anhydrous and oxygen-free conditions, although usually it is used as prepared without isolation. Use in a fume hood.

Sodium and potassium selenides are good nucleophiles for the synthesis of dialkyl selenides from alkyl halides or sulfates.[2b,3,4,7] The alkylating agent is added directly to Na_2Se (or K_2Se) in solution or suspension (eq 1).[7] Aliphatic diacyl selenides are obtained in 58-90% yield from the reaction of acyl chlorides with Na_2Se suspended in ethyl ether.[8]

$$\mathrm{Se} + 2\,\mathrm{Na} \xrightarrow[\mathrm{N_2,\ rt,\ 4\ h}]{\mathrm{THF,\ naphthalene\ (cat)}} \mathrm{Na_2Se} \xrightarrow[\mathrm{reflux,\ 4\ h}]{\mathrm{PhCH_2CH_2Br,\ THF}} \underset{78\%}{(\mathrm{PhCH_2CH_2})_2\mathrm{Se}} \qquad (1)$$

A general method for the preparation of symmetrical diaryl selenides involves treatment of arenediazonium salts with Na_2Se or K_2Se,[9] or with sodium or potassium polyselenide (Na_2Se_x or K_2Se_x) produced by heating elemental Se with NaOH (or KOH) (eq 2).[1b,10] Bis(nitroaryl) selenides are prepared in a similar way from nitroaryl halides.[1b,11]

$$\mathrm{Se} \xrightarrow[\mathrm{2.\ H_2O}]{\mathrm{1.\ KOH,\ \Delta}} \mathrm{K_2Se_x} \xrightarrow[\mathrm{H_2O}]{\mathrm{PhN_2Cl}} \underset{86\%}{\mathrm{PhSePh}} \qquad (2)$$

Diphenyl selenide is formed from Na_2Se and iodobenzene in liquid ammonia under photochemical activation. This selenide is easily reduced to the benzeneselenolate anion ($PhSe^-$) by addition of an excess of Na, and this provides a route to aryl methyl selenides (when ***Iodomethane*** is added) and unsymmetrical diaryl selenides (by photostimulated reaction with aryl iodides).[2c]

Sodium selenide is also used in the synthesis of divinyl selenides. Alkylation with diethyl iodomethylphosphate forms a selenide which gives bis(2-phenylvinyl) selenide by Horner-Wittig reaction with benzaldehyde (eq 3).[12] Treatment of *N*-phenyldichloroimine with Na_2Se gives phenyl isoselenocyanate.[13]

Related Reagents.

Hydrogen Selenide; ***Lithium Selenide***; ***Sodium Sulfide***.

Sodium Sulfide[1]

$Na_2S.9H_2O$

(nonahydrate)

[1313-84-4] · $H_{18}Na_2O_9S$ · Sodium Sulfide · (MW 240.18) (anhydrous)

[1313-82-2] · Na_2S · Sodium Sulfide · (MW 78.05)

(nucleophile and reducing agent derived from H_2S; reagent for the synthesis of thiols,[2] thioethers,[3] and disulfides;[4] reduces aromatic nitro compounds to amines[5])

Physical Data: mp ~50 °C (hydrate, loses most of its water below 100 °C); mp 1180 ± 10 °C (pure Na_2S); *d* 1.43 g cm^{-3} (anhydrous 1.86 g cm^{-3}); E_0 (S^{2-} -> S + 2e) +0.48 V.

Solubility: v sol cold and hot water; somewhat sol methanol, ethanol; insol acetone, benzene, ether.

Form Supplied in: colorless or pale yellow crystalline solid. May contain NaSH and small amounts of $Na_2S_2O_3$, Na_2SO_3, NaOH, Na_2CO_3, NaCl, $Na_2S_2O_4$, and Na_2SO_4. Also available as essentially anhydrous fused chips of 60% Na_2S. The form used in synthesis is not always specified. A pentahydrate is also known.

Analysis of Reagent Purity: titration methods (e.g. iodometric) are available.

Handling, Storage, and Precautions: light (discolors) and air sensitive. Produces H_2S on exposure to air. Corrosive; flammable; deliquescent. Refrigerate. Incompatible with oxidizing agents and strong acids. Destructive of mucous membranes, eyes, skin. Absorbed through the skin. Inhalation can be fatal. Use a well-ventilated hood, goggles, and gloves.

Preparation of Na_2S_2, Na_2S_x.

Refluxing sodium sulfide with elemental ***Sulfur*** in 95% ethanol or aqueous sodium hydroxide yields solutions of ***Sodium Disulfide***, Na_2S_3, and Na_2S_x.[6]

Thiols.

Although treatment of halides, epoxides, aziridines, and sulfonate esters with ***Sodium Hydrogen Sulfide*** or ***Potassium Hydrogen Sulfide*** is usually more advantageous (Na_2S often gives the thioether), the use of Na_2S_2 followed by reduction of the disulfide has found application (eq 1).[6b,d] Sulfide or disulfide ions can cleave a disulfide to a thiolate ion,[7] and nitro aromatic halides have been observed to yield the thiolate under conditions in which Na_2S_2 may be formed from Na_2S.[7b] Best results are obtained at room temperature with anhydrous Na_2S, in DMF or DMSO (eq 2).[8a] Reduction of the nitro group[8b] does not occur. What appears to be a direct synthesis of a thiol via $Na_2S.9H_2O$ occurs in the formation of 6-mercaptopteridine (84% yield) from 6-chloropteridine,[9a] and 3-aryl-1,2,3,4-thiatriazolium-5-thiolates (30-34% yields) from 5-ethoxy-3-aryl-1,2,3,4-thiatriazolium tetrafluoroborates.[9b] Na_2S cleaves thiocyanates to the thiols.[10] Tertiary thiols are obtained from tertiary nitro compounds by treatment with Na_2S_x (Na_2S + S) in DMSO (eq 3),[11] but the reaction is limited to tertiary derivatives. Addition of ***Methanethiol*** to acetaldehyde in the presence of Na_2S gives the dithiohemiacetal in 38% yield.[12]

(1)

(2)

(3)

85%

Thioethers (Sulfides).

Symmetrical primary and secondary acyclic thioethers are obtained from the corresponding halide, sulfonate, or sulfate ester.[13] Oxiranes and aziridines are also useful substrates but ***Hydrogen Sulfide***, NaSH, and KSH are more commonly used with this class of compound.[3] Secondary starting materials may yield some alkene, particularly if Na_2S is prepared in situ from H_2S and alkali. The yield of di-*n*-octyl sulfide from *n*-octyl bromide is increased from 20% to 97% when Na_2S is supported on neutral ***Alumina***.[14] The use of phase-transfer catalysis is beneficial.[15] In the absence of catalyst, the yield of bis(3-penten-2-yl) sulfide from 4-chloro-2-pentene and $Na_2S.9H_2O$ is 14%; in the presence of polyglycol or ***Tetra-n-butylammonium Bromide*** it is 98% and 94%, respectively (eq 4).[15a] The α-trimethylsilyl sulfide (**1**) is a source of the useful $MeSCH_2^-$ synthon (eq 5),[16] ***Bis(trimethylsilyl) Sulfide*** is available (96% yield) by treatment of ***Chlorotrimethylsilane*** with anhydrous Na_2S at 240 °C in a sealed tube.[17a] Treatment of this silyl sulfide[17b] with ***Methyllithium*** yields highly active Li_2S that is useful in the synthesis of six- to twelve-membered sulfur heterocycles without the need for high dilution techniques.[17c] Addition of the sulfide anion to Michael acceptors such as acrylonitrile is another route to acyclic sulfides.[18]

(4)

(5)

Cyclic sulfides in small to large ring sizes are readily obtained from dihalides, bissulfonates, or other compounds that are capable of reacting with Na_2S at two sites with formation of a ring. The formation of thiiranes[19] from 1,2-dihalides and Na_2S frequently fails due to polymerization or elimination to the alkene. However, use of α-halo or thiocyanato thiocyanates or disulfides with Na_2S can circumvent this limitation (eq 6).[19,20] Thietanes are conveniently prepared from 1,3-dihalides and related compounds (eq 7).[21] Cyclizations involving mesylates or tosylates are conducted under anhydrous conditions to avoid hydrolysis.[22] Even the cyclization of 1,4-dichlorobutane to thiolane gives better yields if fused 60% Na_2S is used instead of the nonahydrate.[23] Examples of the synthesis of five- and six-membered sulfur heterocycles are shown in eqs 8-10.[24-26] The dithiin synthesis in eq 11 demonstrates the ability of sulfide ion to add to an acetylenic bond.[27] Macrocyclic sulfides are readily prepared (eq 12).[28]

(6)

(7)

(8)

(9)

(10)

(11)

(12)

Aryl sulfides are obtained by S_NAr-type reactions of sulfide ion with activated aryl halides;[3] a nitro group also may be displaced,[29a] even in preference to halogen.[29b] Phase transfer catalysts, including crown ethers, are useful (eq 13).[30] The yields in the substitution reaction are sensitive to the medium. The yield of sulfide from 4-chlorobenzonitrile is 99% in DMF but only 14% in toluene.[30] In ethanol, 2,4-dinitrochlorobenzene yields the sulfide (79%) with $Na_2S.9H_2O$ and the disulfide when the same reaction is done in the presence of elemental sulfur.[31] It should be noted that nitro groups may be reduced by sulfide or polysulfide ions.[5]

(13)

Di- and Polysulfides.

These are derived from Na_2S_2 (or Li_2S_2, Na_2S_x) and halides (or their equivalents) (eq 14)[4,6a,c-e,32,33] or aryl diazonium salts (eq 1).[6b] With some substrates, especially those that contain sulfur, Na_2S itself may be used (eq 15).[33]

(14)

(15)

Reductions.

Sodium sulfide and polysulfides are better reducing agents than H_2S and have been widely used in the reduction of aromatic nitro groups to amino groups (the Zinin reaction).[5,6c,f,7c,34] The reduction can be selective for one nitro group of several. In the reduction shown in eq 16, Na_2S reduces the *o*-nitro group whereas ***Tin(II) Chloride*** reduces the *p*-nitro group.[34a] The Zinin reaction is especially useful in the presence of groups sensitive to acid that preclude the use of a metal-acid reducing reagent. Aliphatic nitro groups are unreactive (eq 17),[35] although elimination of nitrous acid has been observed with tertiary aliphatic derivatives. Differences are observed depending on whether $Na_2S.9H_2O$ or anhydrous Na_2S is used. Treatment of *p*-nitrotoluene with Na_2S_x-NaOH results in a remarkable oxidation-reduction reaction (eq 18).[6c,36] Partial reduction of 2,2´-dinitrobiphenyl by Na_2S gives a benzocinnoline (eq 19),[37a] whereas Na_2S_x gives the monoamino derivative.[37b] Refluxing 2-nitro-4,5-dimethoxybenzophenone with methanolic sodium sulfide yields the anthranil (**2**) (eq 20).[37c] A quinone dioxime is reduced to the diamine by $Na_2S.9H_2O$,[38] and nitrite esters are reduced to alcohols.[39] In β-nitrostyrenes, the nitro group is replaced by hydrogen on treatment with $Na_2S.9H_2O$-PhSH.[40] Other functionalities that are reduced by Na_2S are as follows (product in parentheses): nitroxide (amine),[41] chlorosulfonyl (sulfinic acid),[42] disulfide (thiol),[20,43] α-halo (with $SnCl_2$) and α-phenylthio ketones (ketone),[44] aldehydes (alcohols; requires Na_2S-Al_2O_3 which does not reduce nitro groups, ketones, or esters) (eq 21),[45] carbon-Hg bonds (hydrocarbon) (elimination may be a serious side reaction) (eq 22),[46] tetravalent tellurium- and selenium-halogen bonds (divalent tellurides, selenides) (eq 23).[47]

Miscellaneous.

Na_2S has been used in the synthesis of thiocarbonyl compounds, but H_2S is more widely applicable. A combination of $Na_2S.9H_2O$ and H_2S with a phase-transfer catalyst converts nitriles to thioamides (46-98% yields),[48] and the combination of Na_2S with ***Phosphorus(V) Sulfide***, which performs the same transformation, is notable in that a nitro group is not reduced (eq 24).[49] A convenient isothiazole synthesis uses thioenaminones obtained by addition of $Na_2S.9H_2O$ to ArC(Cl)=CHCH=+NMe_2 ClO_4^-.[50] A cyclopropenethione is obtained by addition of Na_2S to a chlorocyclopropenium salt,[51a] a thioester by addition to a dialkoxy carbocation,[51b] and 4*H*-thiopyran-4-thiones by addition to 6a-thiathiophthenes.[51c] The usefulness of ***2-Chloroacrylonitrile*** as a dienophile is enhanced by the conversion of the chloro nitrile adducts to ketones by $Na_2S.9H_2O$, which is superior to KOH (eq 25).[52] A thioketone is presumed to be an intermediate. This renders 2-chloroacrylonitrile into a dienophilic ketene equivalent. An improved synthesis of ***Sodium Trithiocarbonate*** utilizes a phase-transfer catalyst in the reaction of $Na_2S.9H_2O$ with CS_2.[53] Sodium sulfide also has been used to effect elimination reactions from 1,2-dihalides (*anti*),[54] 1,2-dinitro compounds,[55a] β-halo tellurium(IV) derivatives (*anti*),[55b] and β-nitro sulfones,[55c] and to assist in hydration of alkynes.[56] Carboxylic acids protected as their cyanomethyl[57a] or 4-chlorobutyl[57b] esters are readily deprotected by treatment with Na_2S, thus avoiding strongly acidic or basic conditions (eq 26).

Sodium Telluride[1]

Na_2Te

(Na_2Te)

[12034-41-2] · Na_2Te · Sodium Telluride · (MW 173.58) (NaHTe)

[65312-92-7] · HNaTe · Sodium Hydrogen Telluride · (MW 151.60) (Li_2Te)

[12136-59-3] · Li_2Te · Lithium Telluride · (MW 141.48) (K_2Te)

[12142-40-4] · K_2Te · Potassium Telluride · (MW 205.80)

(telluride ion and its conjugate acid, TeH^-, are reducing agents and powerful nucleophiles that accomplish nucleophilic reductions;[2] reduction of nitro groups,[3] *N*-oxides,[4] imines,[5] azides,[6] enones,[7] alkenes,[7b,8] α,β-epoxy ketones,[9] and carbon-halogen[10] or carbon-sulfur[11] bonds; conversion of optically active glycidyl sulfonate esters to allylic alcohols;[2] ester cleavage;[12] reductive alkylation of amines;[13] Reformatsky reaction;[14] synthesis of tellurium compounds[1b])

Physical Data: mp 953 °C (dec); *d* 2.90 g cm^{-3}; pK_a (HTe^{-}&b;&ibond; $H^+ + Te^{2-}$) 10.8; E_0 (Te^{2-} -> Te + 2e) +0.95 to 1.14 V.

Solubility: sol H_2O; insol. THF; purple solutions of sodium polytellurides (Na_2Te_n) occur in H_2O, THF, DMF, and methanol.

Preparative Methods: prepared[1b,e] in situ (often as a suspension) by reduction of elemental ***Tellurium*** with ***Sodium Hydroxymethanesulfinate*** ($HOCH_2SO_2Na$) in aqueous base, ***Sodium Borohydride*** in protic or dipolar aprotic (DMF) solvents,[1f] ***Lithium Triethylborohydride*** in THF, ***Thiourea Dioxide*** in aqueous basic THF, ***Sodium Hydride*** in dipolar aprotic solvents, ***Sodium*** in liquid ammonia or DMF, aqueous ***Sodium Dithionite***, ***Sodium Naphthalenide*** in THF, or ***Hydrazine*** hydrate in aqueous base or in DMF, or by electrolysis of elemental tellurium. Often, only catalytic amounts of tellurium are required in the reductions of various organic compounds. Buffering solutions of Na_2Te with acetic acid provides NaTeH. The latter also is obtained by decreasing the amount of $NaBH_4$ in reduction with that reagent.

Handling, Storage, and Precautions: sodium telluride is a white, crystalline, hygroscopic solid that decomposes to elemental tellurium on exposure to air. Traces of oxygen immediately produce pink to purple solutions of polytelluride anions that are not necessarily harmful for subsequent use. Operation in an inert atmosphere is essential, and degassing of solvents is advised. Avoid strong acids that produce noxious ***Hydrogen Telluride***. The reaction with oxidizing agents may be highly exothermic. All reactions should be carried out in a good fume hood to avoid exposure to possible toxic and malodorous organic tellurium products or byproducts. Decontamination of apparatus or spills is effected by treatment with oxidants such as Chlorox or hydrogen peroxide.

Reductions.

Aromatic mono- and polynitro compounds are reduced to amines by catalytic amounts of Na_2Te (eq 1).[3a] The method is useful when acid sensitive groups are present and is said to give fewer side reactions than does ***Sodium Sulfide***. Use of NaH in DMF to reduce Te gives azobenzenes,[3a,b] and use of sodium borohydride gives arylhydroxylamines.[3c] Sodium hydrogen telluride produces azoxybenzene derivatives.[3e] The latter reagent also reduces amine oxides[4] and imines[5] to the free amines. Sulfoxides are difficult to reduce and phosphine oxides are inert.[4c] The in situ formation and reduction of imines by NaTeH is a variation of the reductive alkylation of amines (eq 2).[13] Reductions of imines may proceed via iminium salts and are pH sensitive.[5b] At pH 6, *N*-methylpyridinium iodide is reduced to *N*-methylpiperidine, whereas at pH 10-11 a 2:1 mixture of *N*-methyl-1,2- and -1,4-dihydropyridine is obtained. Azides are selectively reduced to amines by NaTeH,[6] thus providing a useful synthesis for the pyrazine (**1**) (eq 3),[6a] but the method is not applicable to primary azido ketones. For the selective reduction of the double bond of enones[7] and of certain α,β-unsaturated sulfones,[11a,15] NaTeH is superior to Na_2Te (eq 4).[7c] In the sulfone case, reduction of the carbon-sulfur bond may occur (eq 5).[15] The triple bond of dimethyl acetylenedicarboxylate and of methyl phenylpropiolate is reduced partially.[16] Carbon-carbon double bonds conjugated with aromatic systems are reduced by NaTeH (and also PhTeH).[7b,8] Addition of HTe^- to an isolated, unconjugated double bond followed by reduction with ***Nickel Boride*** effects the reduction of alkenes.[17a]

One carbonyl group in 1,2-diketones is reduced to the alcohol,[4c] and aromatic thioketones are reduced to the alkane.[3a] Aromatic aldehydes and ketones are reduced to alcohols (34-89% yields) by Na_2Te (Te, NaH) in ***1-Methyl-2-pyrrolidinone*** (NMP).[17b] Other groups that are reduced are as follows: the carbon-carbon bond of certain *C*-allyl compounds,[18] the α-carbon-oxygen bond of α,β-epoxy ketones (eq 6),[9] carbon-sulfur bonds of sulfides and sulfones (eqs 5, 7 and 8),[11,15b,19] the carbon-nitrogen bond of tertiary nitro compounds,[20] *gem*-diamino compounds,[21] and carbamate esters,[22] carbon-halogen bonds,[10] sulfonyl chlorides (to the sulfinate anion),[23] and the sulfur-sulfur bond of disulfides and thiosulfates.[24]

The reduction of α-halo carbonyl compounds leads to a variant of the Reformatsky reaction (eq 9).[14] Wurtz-type couplings have been

observed with halides.[25] The reduction of optically active glycidyl tosylates and mesylates (obtained via a Sharpless asymmetric epoxidation) by Na_2Te to allylic alcohols is accompanied by a transposition of the hydroxy function and the former double bond that enables the synthesis of optically active secondary and tertiary allylic alcohols without the necessity of a resolution (eq 10).[2] Epichlorohydrins are transformed to allylic alcohols by treatment with telluride ion.[26] Simple epoxides may be reduced to alkenes by a two-step procedure involving nucleophilic opening of the epoxide by NaTeH to a β-hydroxy tellurol and conversion of the alcohol function to a tosylate which, in the presence of pyridine, decomposes to the alkene and elemental tellurium.[27]

Deprotection of Functional Groups.

Deprotection of various esters to yield carboxylic acids is effected with either Na_2Te or NaTeH.[12,28] β-Halo alkyl esters are especially reactive (eq 11);[12a,b,28c] methyl, ethyl, phenacyl,[12d,28a] and allyl esters[12c] also are dealkylated readily. Phenols protected as acetate, benzoate,[28b] carbonate,[29] or chloroacetate[28c] esters or as allyl ethers[12c] can be regenerated. Amines have been freed from quaternary ammonium salts,[27] and diols, from cyclic acetals.[30]

Heterocyclic Compounds.[31]

Addition of telluride ion to the triple bonds of 1,3-dialkynes such as 1,4-bis(trimethylsilyl)-1,3-butadiyne is a convenient synthesis of tellurophenes (eq 12);[32] six-membered ring systems containing tellurium can likewise be obtained from the appropriate dialkyne.[33] A tellurophene synthesis (eq 13) that involves reaction of telluride ion with an acetylenic epichlorohydrin is related to the nucleophilic reduction-transposition reaction exemplified in eq 10.[34]

Tellurols and Tellurides.[35]

Reactions of Na_2Te and NaTeH with organic halides have found limited use in the synthesis of sodium salts of tellurols. However, a wide variety of symmetrical tellurides are obtained from halides, alkynes, and related compounds with Na_2Te (eqs 14 and 15).[36a-d] Tellurocarboxylates, $RCOTe^-$, are obtained from the acid chloride.[36e]

Miscellaneous.

Elimination reactions yielding alkenes are observed when the following are treated with NaTeH or Na_2Te: 1,2-dihalides,[8b,37] 1,2-dinitroalkanes,[3e] β-nitro sulfones,[38] and β-bromo azides.[6a] Conversion of an alcohol to a benzyl ether has been accomplished by addition of NaTeH to an iminium ester derivative of the alcohol.[39a,b] Lithium telluride is used in the preparation of $(Bu_3Sn)_2Te$ (from Bu_3SnCl) which is an intermediate for $(Me_2Al)_2Te$, useful in the synthesis of highly reactive telluroaldehydes and telluroketones.[40]

Related Reagents.

Sodium Tetraborate

$Na_2B_4O_7$

[1330-43-4] · $B_4Na_2O_7$ · Sodium Tetraborate · (MW 201.22) (decahydrate)

[1303-96-4]

(source of boric acid at low concentration in aq soln;[1] desilylation of trimethylsilyl alkynones[2])

Physical Data: mp 743 °C, 720 °C, 663 °C (α, β, and γ crystals); bp 1575 °C; *d* 2.367 g cm^{-3}.

Solubility: slowly sol water (1 g in 91 mL at 0 °C; 1 g in 11.4 mL at 40 °C); sol methanol, ethylene glycol.

Form Supplied in: powder or glasslike plates that turn opaque on exposure to air. Commonly supplied as the decahydrate (borax). However, borax is insoluble in alcohol.

Handling, Storage, and Precautions: hygroscopic; absorbs water up to 300 °C; dehydrates completely at 700 °C. Slow decomposition will occur above 900 °C. Eye, skin, and upper respiratory tract irritant. Incompatible with strong oxidizing agents.

Introduction.

$Na_2B_4O_7$ is most commonly available as its decahydrate (borax) and is sometimes referred to as fused borax. Below 10% relative humidity, borax will irreversibly decompose to the dihydrate (metakernite); between 10-50% relative humidity there is reversible decomposition to the pentahydrate (tincalconite).[3] In aqueous solution, $Na_2B_4O_7$ dissociates into a number of different boron species depending upon the pH, temperature, concentration of boron, and concentration of any added salt.[1] At low concentration (i.e. [B] < 0.025 M), $Na_2B_4O_7$ dissociates exclusively into ***Boric Acid***, $[B(OH)_3]$, and monoborate ion, $[B(OH)_4^-]$, to yield an alkaline solution that buffers around pH 9.[4] At higher boron concentrations, polyborates predominate.[1]

Desilylation.

The high yields and low cost make $Na_2B_4O_7$ an attractive reagent for the desilylation of trimethylsilyl alkynones to yield monosubstituted alkynes (eq 1).[2,5]

(1)

Nef Reaction.

The original Nef reaction involves hydrolysis of the conjugate base of a primary or secondary nitro compound to the corresponding aldehyde or ketone with ***Sulfuric Acid***.[6] Many alternatives exist for carrying out this reaction. One approach is to oxidize the conjugate base.[6] When an alkaline ***Potassium Permanganate*** solution is used, it has been shown that addition of $Na_2B_4O_7$ will improve yields (eq 2).[7]

R = alkyl, aryl containing acid sensitive functionalities

Substitution and Addition.

$Na_2B_4O_7$ in methanol creates a mild source of methoxide ion for carrying out stereoselective substitutions α to a carbonyl function (eq 3).[8,9]

$Na_2B_4O_7$ affects the reactivity of α,β-unsaturated esters in two ways: (i) suppression of 1,2 attack;[10] and (ii) enhancement of 1,4 addition especially by thioalkanes.[11] The combined effects have been used succesfully as a method to selectively reduce isolated alkenes in the presence of conjugated alkenes (eq 4).[12]

Protecting Group For Vicinal Diols.

The ability of $Na_2B_4O_7$ to complex with vicinal diols provides a convenient protecting group that can be easily removed under acidic conditions.[13] The selective methylation of methyl gallate illustrates the simplicity of the method (eq 5).[14]

[38991-21-8] · C_4CoO_4Tl · Thallium Tetracarbonylcobaltate · (MW 375.35) ($[CuCo(CO)_4]_4$)

[94024-70-1] · $C_{16}Co_4Cu_4O_{16}$ · Tetracopper Tetrakis(tetracarbonylcobaltate) · (MW 938.08)

(catalyst for carboxylation reactions of alkyl,[46] benzyl,[49] aryl,[55] and vinyl halides;[55] reagent for single and double carbonylation of benzyl halides[17a,b] and alkene oxides;[65] mediates butenolide synthesis from alkynes and acid chlorides;[73] mediates alkyl halide hydrogenolysis,[77] coupling of *gem*-dihalides to give tetrasubstituted alkenes,[5b] formation of symmetrical ketones,[80] formation of alkylcobalt tetracarbonyl complexes and alkylidynetricobalt nonacarbonyl complexes;[82,84] the conjugate acid, $HCo(CO)_4$, is the true hydroformylation catalyst;[31] $HCo(CO)_4$ is also a reagent for hydrogenation of alkenes conjugated to aldehydes,[108a] ketones,[111a] or arenes[111a] and for alkene isomerization;[93b,c] $HCo(CO)_4$ is an effective acid catalyst for a variety of organic transformations; tetracarbonylcobaltate with a range of counter ions mediates an array of organic transformations)

Physical Data: white solid. No other documented literature values. The $Co(CO)_4^-$ anion has a distorted tetrahedral structure.[1]

Solubility: sol heptane, hexane, benzene, toluene, dichloromethane, THF, ether; alcohols are the most effective solvents for reactions of the title compound.

Form Supplied in: off-white powder; commercially available.

Analysis of Reagent Purity: IR;[2] ^{59}Co NQR;[3] Raman.[2f,g]

Preparative Methods: conveniently prepared in a variety of ways.[4] Reacting ***Octacarbonyldicobalt*** with ***Sodium Amalgam*** (1%) in THF,[5] ether,[6] hexane,[7] or benzene[8] under N_2 or CO gives $NaCo(CO)_4$ in up to 94% yield.[8] High yields can also be achieved using alternative reducing agents with $Co_2(CO)_8$ under mild conditions. ***Sodium Hydride*** (98% yield),[9] ***Sodium Naphthalenide*** (90% yield),[10] ***Sodium-Potassium Alloy*** (product isolated as the Ph_3Sn derivative in 96% yield),[11] and ***Sodium-Ammonia*** (95% yield)[12] have all been used to prepare the required anion. Octacarbonyl(mercury)dicobalt ($Hg[Co(CO)_4]_2$) (see also ***Octacarbonyl(zinc)dicobalt***) has also been efficiently used as the $Co(CO)_4$ source with either Na(Hg)[7] or aqueous ***Sodium Sulfide***.[13] When required under stringently dry and deoxygenated conditions, $NaCo(CO)_4$ is most conveniently and rapidly formed from $Co_2(CO)_8$ with ***Sodium Hydroxide*** in dry THF under N_2.[14] Furthermore, this technique does not require the preformation or handling of Na(Hg) or $Hg[Co(CO)_4]_2$. Less widely used methods involving electrochemical[15] or photochemical techniques[16] have also been reported. In addition to the techniques already described, $NaCo(CO)_4$ is commonly prepared in situ either from $Co_2(CO)_8$ under basic phase-transfer conditions[17] or under reductive conditions from simple cobalt salts and CO (e.g. $CoCl_2/NaBH_4$,[18] $CoBr_2$/Na naphthalenide,[19] and $Co(acac)_2$/Na naphthalenide[20]).

The potassium, lithium, and thallium analogs, $KCo(CO)_4$[13,14] (IR[2i,j]), $LiCo(CO)_4$[14] (white crystalline solid, IR[2h-j]), and $TlCo(CO)_4$[21-23] (recrystallized from H_2O,[21] volatile, air-sensitive,[22] bright yellow crystalline solid, mp 120-130 °C (dec),[21] IR,[21] MS,[21] X-ray structure[23]), are also available by similar techniques, as well as by alternative routes using KH,[24] K- and L-Selectride,[25] C_8K,[26] and Li wire in THF with $Co_2(CO)_8$.[27] It is also worth noting that an efficient aqueous, low-pressure

synthesis of the potassium species has been reported from simple cobalt halides, KOH, and KCN in the presence of CO.[28] This procedure is more convenient than a similar earlier synthesis from $Co(NO_3)_2$.[29] In addition to the species already mentioned, the copper analog, $CuCo(CO)_4$, exists as an orange-red crystalline tetramer (X-ray structure[30]) and is readily synthesized from $NaCo(CO)_4$ and CuCl.[30]

Tetracarbonylhydridocobalt,[31] $HCo(CO)_4$, (hydrogen tetracarbonylcobaltate, cobalt tetracarbonyl hydride, cobalt hydrocarbonyl; white to light yellow solid or liquid; mp -33 °C;[28a,29,32] bp 10 °C (estimate),[33] bp 47 °C;[34] decomposes thermally to $Co_2(CO)_8$ and H_2;[29,32,35] intolerable odor;[29] sol hexane, toluene, ethanol; sparingly sol in H_2O; IR,[36] ^1H NMR,[1h,37] ^{59}Co NQR,[3] MS;[38] X-ray structure,[39] central Co surrounded tetrahedrally by four CO groups with H lying in one face of the tetrahedron and bonded to three CO groups[39,40]) is the conjugate acid of the title compound and will also be discussed here. The metal hydride is not readily available commercially but is prepared by a variety of techniques with and without the requirement for high gas pressures. Methods where CO and H_2 pressure are not required include reaction of salts containing the $Co(CO)_4^-$ anion (usually the readily prepared pyridinium salt) with protic acids[40a] or the similar reaction of acid with the disproportionation product of $Co_2(CO)_8$ with DMF under 1 atm of CO.[41] A further simple route to $HCo(CO)_4$ is by reaction of preformed $KCo(CO)_4$ with HCl.[28a,29,32] In a much less common route, reaction of a range of other transition metal hydrides with $Co_2(CO)_8$ yields the cobalt hydride.[36l] Routes to $HCo(CO)_4$ from common cobalt salts are available but require high pressures (approx. 200 atm) of CO with, in most cases, H_2.[33,40a,42] Similarly, $Co_2(CO)_8$ can be converted to $HCo(CO)_4$ under CO/H_2 pressure at elevated temperatures.[43] An electrochemical route from $Co(acac)_2$ at milder CO/H_2 pressures has also been reported.[44] Yields in the higher pressure reactions are generally lower than the atmospheric pressure reactions and offer no obvious advantage. General purification techniques for $HCo(CO)_4$ are given by Moore et al.[45]

Handling, Storage, and Precautions: the title compound decomposes readily in air. Can be handled and stored as a solid or solution in the organic solvents quoted above under inert gas (argon or nitrogen). The conjugate acid, $HCo(CO)_4$, is an unpleasantly odorous gas at room temperature with a toxicity predicted as being equivalent to that of $Ni(CO)_4$.[29] This material is usually prepared as required.

Carboxylation and Related Reactions.

Carboxylation of halogen compounds with $Co_2(CO)_8$, which is considered to involve $^-Co(CO)_4$, is well known and is discussed elsewhere (see ***Octacarbonyldicobalt***). Additionally, the reaction of alkyl halides, sulfates, or sulfonates and carbon monoxide (atmospheric pressure) in alcohol solution in the presence of base with a catalytic amount of $NaCo(CO)_4$ gives alkoxycarbonylation in good yields (eqs 1 and 2).[46] The initially formed alkylcobalt tetracarbonyl undergoes carbon monoxide addition to form the acylcobalt tetracarbonyl and finally gives the ester by alcoholysis.[47] When the reactions are carried out at 50 °C or below, only the expected ester, where the halogen has been directly replaced by the methoxycarbonyl group, is obtained. Therefore, at low temperatures, the mixture of isomers formed by the analogous $Co_2(CO)_8$ carboxylation is avoided. Further studies have shown that isomerization of acylcobalt carbonyls is possible and is dependent on solvent, atmosphere, and the acyl group structure.[28b,48]

(1)

(2)

Benzyl halides also undergo carboxylation reactions under both homogeneous (eq 3)[49] and phase-transfer conditions (PTC) (eq 4).[17a,b,50] Anion-exchange resins have also been used effectively, in a similar way to PTC, to heterogenize the cobaltate anion.[51] Additionally, the tetracarbonylcobaltate anion has been prepared in situ from simple cobalt salts and CO under reductive conditions, and reacted with benzyl halides to give the products of both carboxylation and carbonylation/cyclization in good yields (eqs 5 and 6).[18-20,52]

(3)

(4)

(5)

(6)

Following the initially reported reactions, PTC have been used extensively in reactions involving the tetracarbonylcobaltate anion.[17c,53] Under such conditions the Co anion is considered to be more nucleophilic than under more conventional techniques[50b] and, in carboxylation reactions, the PTC allow the product and catalyst to be easily separated in the aqueous and organic phase respectively.[54] Furthermore, in most cases when PTC are used, the $(CO)_4Co^-$ is generated in situ from $Co_2(CO)_8$ and base under a CO atmosphere. The efficiency of the phase-transfer techniques is illustrated by the carboxylation of aryl and vinyl halides (eqs 7 and 8).[55] Subsequently, the carboxylation of vinyl, aryl, and heteroaryl halides, using a variety of techniques for the generation and reaction of the tetracarbonylcobaltate anion, have been reported. These include the in situ preparation of activated alkyltetracarbonylcobalt complexes,[20,56] the similarly prepared Co/complex reducing agent/CO (CoCRACO) system,[9,57] and the more routine use of $KCo(CO)_4$.[58]

(7)

(8)

The products of double CO insertion can also predominate in the two-phase system. This is illustrated by the reaction of (1-

bromoethyl)benzene (eq 9)[17a,b] in *t*-pentyl alcohol (cf. Alper and Des Abbayes[50b]). The distribution of single and double carbonylation products is dependent on solvent,[17a,b,50b] aromatic substitution,[59] and, remarkably, the stirring speed of the reaction.[59] Furthermore, when aromatic hydrocarbons replace alcoholic solvents under PTC, the products of benzyl coupling predominate (eq 10).[17a,b]

(9)

(10)

In a further variation to the phase-transfer techniques already presented, aryl methyl ketones result when the reactions are carried out in the presence of an excess of ***Iodomethane*** (eq 11).[60] When the cobaltate anion is generated in a homogeneous mixture, carboxylic acids or α-keto acids, the products of double carbonylation, result.[61] Again, the product distribution is both solvent and base dependent.[61,62] When the tetracarbonylcobaltate anion is generated in situ from $CoCl_2$, the α-keto acids again predominate, even when an excess of MeI is used (eq 12).[63]

(11)

In an extension of the photostimulated phase-transfer studies, it has been shown that benzolactones and lactams can be prepared (eqs 13 and 14)[58] using techniques which compare favorably with the equivalent Pd methods.[64] Again, activated alkyltetracarbonylcobalt complexes, prepared in situ have been used to prepare similar products.[56]

In a similar fashion to $Co_2(CO)_8$ (see ***Octacarbonyldicobalt***), despite low yields being common, regioselective carboxylation of epoxides can be achieved using $NaCo(CO)_4$.[65] The yields are improved in a number of specific examples (e.g. eq 15)[66] or, alternatively, by either employing $KCo(CO)_4$[67] or by the in situ formation of the cobaltate anion from $Co_2(CO)_8$ and K_2CO_3 under a CO atmosphere.[68] Again, under PTC, double CO insertion products can result. To date, this type of reaction is only known for styrene oxides in the presence of methyl iodide (eq 16).[69] Alternatively, under similar conditions, styrene sulfides simply give the products of single CO insertion.[70] It should also be noted here that, under certain conditions, $NaCo(CO)_4$ (and $Co_2(CO)_8$) can deoxygenate epoxides to give the alkenic products with good stereoselectivity.[71]

Alkoxycarbonylation of allyl acetates with $NaCo(CO)_4$, in combination with Pd, has also been demonstrated. Here, the cobaltate anion attacks the initially formed (π-allyl)palladium species and, following CO insertion and methanolysis, gives the corresponding ester (eq 17).[72]

In studies which follow on from the original Co-catalyzed formation of butenolides from acylcobalt tetracarbonyls and alkynes,[47a,73] acid chlorides have been used with stoichiometric quantities of $NaCo(CO)_4$ to form the acylcobalt species in situ which, in turn, react with disubstituted alkynes to give 3,4,5-trisubstituted 3-buten-2-olides.[74] Unsymmetrically substituted alkynes where the substituents are sterically similar give rise to mixtures of regioisomers. In contrast, 2,2-dimethyl-3-pentyne undergoes reaction with propionyl chloride and $NaCo(CO)_4$ to give predominantly one regioisomer (eq 18). Under these conditions, terminal alkynes do not react cleanly. However, in a similar transformation this is overcome by the use of mild PTC.[75] Furthermore, butadienolides are also available using the title compound when acid chlorides which contain a leaving group in the α-position (e.g. chloroacetyl chloride) (eq 19)[76] are employed.

Other $NaCo(CO)_4$-Mediated Reactions.

In contrast to the carboxylation reactions, which occur when the cobaltate anion is either formed or simply used under basic conditions, hydrodehalogenation can be achieved in the presence of acid (eq 20) (anion formed in situ).[77] The yields of the hydrogenated products are often poor. Additionally, the reaction rate depends on the structure of the alkyl halide, and the hydrogenolysis of the C-X bond is often accompanied by aldehyde formation.

Coupling of *gem*-dihalides has also been achieved using the title compound to produce tetrasubstituted alkenes in good yield (eq 21).[5b] ***Octacarbonyldicobalt*** also mediates this reaction in comparable yield, whilst the related metal-cobalt carbonyl species $Hg[Co(CO)_4]_2$ (see ***Octacarbonyl(zinc)dicobalt***) is effective when UV irradiation is employed.[5b] In a related reaction, vicinal dihalides are dehalogenated using $NaCo(CO)_4$ (eq 22) or $Co_2(CO)_8$.[5b]

In a transformation which is complementary to the synthesis of symmetrical diaryl ketones using $Hg[Co(CO)_4]_2$,[78] dialkyl ketones can be

formed by the reaction of $NaCo(CO)_4$ (formed in situ[19]) with a dialkyl-BI species[79] followed by basic oxidative workup.[80] This procedure is illustrated for the formation of di-*n*-octyl ketone (eq 23).

(23)

In an isolated example, $NaCo(CO)_4$ (in combination with $Co(NO)_2Cl$) has been shown to catalyze the dimerization of butadiene to afford 4-vinylcyclohexene (eq 24).[81] On the other hand, the alternative sodium-metal species, $Na[Fe(CO)_3NO]$, with various metal halides, mediates this transformation more efficiently in up to 100% yield under similar reaction conditions.[81]

(24)

Alkylcobalt tetracarbonyl complexes, $RCo(CO)_4$, are readily formed from the tetracarbonylcobaltate anion and organic halides or tosylates. These species readily insert CO under mild conditions to give the corresponding acylcobalt complexes, $RCOCo(CO)_4$. The acylcobalt species react readily with 1,3-dienes to give (π-allyl)cobalt complexes by insertion of the diene into the Co-acyl bond. In turn, when these complexes are treated with base, acyl dienes result.[82] Phase-transfer techniques have also been used in this area.[75] These transformations are illustrated by the last step of a one-pot reaction sequence in which the acyl(π-allyl)cobalt complex (**1**) reacts with a stabilized carbanion to give 1,4-acylation/alkylation products from 1,3-dienes (eq 25).[83]

(25)

Alkylidynetricobalt Nonacarbonyl Complexes.[4b,5a,84]

Trinuclear compounds of the general structure $RCH_2C[Co_3(CO)_9]$ are formed directly from $Co_2(CO)_8$ with terminal alkynes at 85 °C[85] or by reaction of the terminal alkyne complex (RC&tbond;CH)$[Co_2(CO)_6]$ with H_2SO_4 in MeOH.[86] More general syntheses of trinuclear alkylidyne complexes of general structure $RCCo_3(CO)_9$ are available by treating trihalomethane derivatives of type RCX_3 with $Co_2(CO)_8$ or $Co_4(CO)_{12}$.[4b,87] The significance of the tetracarbonylcobaltate anion in the latter synthetic strategy has been supported by the preparation of $MeCCo_3(CO)_9$ from $NaCo(CO)_4$ and $MeCCl_3$ in refluxing THF.[4b] Furthermore, fluorinated tricobalt complexes of the type $RC[Co_3(CO)_9]$, where R = F, CF_3, CF_3CF_2, and CHF_2, have been prepared by the reaction of fluoroalkyltetracarbonylcobalt compounds with $NaCo(CO)_4$ (e.g. eq 26).[88] The fluoroalkyl complexes are themselves conveniently prepared by treatment of the corresponding fluorinated acid chloride with $NaCo(CO)_4$.[5a,27,89]

Three other routes to complexes of the general structure $RC[Co_3(CO)_9]$ are worth noting. In the first, $NaCo(CO)_4$ reacts with ***N-Dichloromethylene-N,N-dimethyliminium Chloride*** to give the complex where R = NMe_2 in good yield.[90] In the second example, $TlCo(CO)_4$ is reacted with CCl_4 in benzene to give the compound where R = Cl.[91] Lastly, PTC have been employed with $Co_2(CO)_8$ to generate the anion in situ and prepared a number of complexes from trihalomethane derivatives.[92] Alkylidynetricobalt nonacarbonyl complexes are deep violet/purple crystalline compounds which are soluble in organic solvents (insoluble in H_2O) and appear to be some of the most air-stable of all cobalt carbonyl derivatives.[4b] The chemistry of these compounds is reviewed by Seyferth.[84a]

Reactions of the Conjugate Acid, Tetracarbonylhydrocobalt, $HCo(CO)_4$.

In the hydroformylation reaction of alkenes with $Co_2(CO)_8$, CO, and H_2, it has been demonstrated that the true catalyst is $HCo(CO)_4$.[31,41a,43,93] Hydroformylation reactions catalyzed by cobalt are covered elsewhere (see ***Octacarbonyldicobalt***). Nonetheless, by using the title compound (and its deuterium equivalent), it has been shown that this transformation is a *cis* process.[94] Further studies have also shown that, with catalytic hydroformylation, the reaction rate is increased by the addition of organic bases[95] (e.g. pyridine, quinoline, or Et_3N) or oxygenated compounds (e.g. ketones or alcohols).[96] Under stoichiometric conditions using $HCo(CO)_4$, the reaction rate and yield are increased and the isomerization of excess alkene is greatly reduced by the addition of benzonitrile.[97] Alternative nucleophiles have been shown to be less effective in promoting hydroformylation. Additionally, product ratios have been optimized using modified catalysts; for example, phosphine ligands enhance straight-chain products.[98] Hydrogenation reactions are also possible when $HCo(CO)_4$ is reacted with alkenes (see below). However, it should be noted that mixtures of hydrogenation and hydroformylation products can result, with product ratios being dependent on both reaction atmosphere composition and pressure,[99] as well as on temperature and catalyst activator.[100]

As with $Co_2(CO)_8$ and $NaCo(CO)_4$, the hydrocobalt species is also known to mediate the hydroformylation of alkene oxides to give β-hydroxy aldehydes.[96,101] Furthermore, these reactions are accelerated by addition of small amounts of inorganic salts, the best of those used being ***Copper(I) Oxide***.[102] In related examples, $HCo(CO)_4$ has been shown to react with aziridines with CO insertion to give β-aminoacyl complexes.[103] More recently, the alkoxycarbonylation of vinylsilanes has been significantly improved. When compared to previous examples,[104] the hydroesterification reactions can be performed with Co catalysis and display high α-stereoselectivity[105] (cf. the use of Pd catalysis for β-selectivity). Again, stoichiometric quantities of $HCo(CO)_4$ are active in this process. In one final carbonylation related example, the rarely used Co-mediated homologation of alcohols (see ***Octacarbonyldicobalt***), the active species is believed to be $HCo(CO)_4/^-Co(CO)_4$.[106]

When catalytic hydroformylation is performed at elevated temperatures (approx. 185 °C), the aldehydes are believed to be reduced under the reaction conditions and alcohols are isolated as the principal products.[107] On the other hand, when reactions are performed using $HCo(CO)_4$ under stoichiometric conditions, aldehydes are only reduced very slowly and in low overall yield.[108] Indeed, in only a limited number of cases have stoichiometric reductions of carbonyl groups been successfully performed using mononuclear Co complexes[109] (e.g. formaldehyde in eq 27).[110]

In contrast to the reduction of carbonyl groups, double bonds conjugated to aldehydes,[108a,111] ketones,[111a,112] or arenes[111a,113] are readily reduced under mild stoichiometric conditions (cf. less mild catalytic conditions).[114] Two illustrative examples are shown in eqs 28 and 29.[108a,113a] Hydrogenation using $HCo(CO)_4$[31,93d,115] has been shown, like the similar hydroformylation, to be a *cis* process[113h,i] and proceeds under H_2, N_2, or CO atmospheres. Reaction rates under CO, which retards the breakdown of $HCo(CO)_4$, are faster.[108,111a,113a] With only one recorded exception,[116] α,β-unsaturated esters undergo hydroformylation in preference to hydrogenation.

(28)

(29)

Cobalt-catalyzed dihydroformylation of conjugated butadienes is not successful, especially when compared to the substantial yields which can be achieved with Rh catalysts.[117] Normally with $HCo(CO)_4$ as the reactive species, butadienes are hydrogenated to butenes which then undergo hydroformylation or alkoxycarbonylation to give C_5 products.[115b,118] Reactions of conjugated dialkenes with $HCo(CO)_4$ can also readily give π-methallyl complexes.[119] Furthermore, it has been demonstrated that $HCo(CO)_4$ readily isomerizes alkenes to give more highly substituted double bonds.[93b,c,111b,115b,120] Tetrasubstituted allenes give mixtures of both isomerized and hydrogenated products when treated with $HCo(CO)_4$.[121]

At elevated temperatures (180-220 °C), $HCo(CO)_4$ catalyzes the hydrogenolysis of diaryl glycols to diarylethanes with high selectivity.[93a,122] Additionally, in contrast to $Co_2(CO)_8$ which in reaction with acetylene gives fumaric, acrylic, and succinic acid esters under hydroformylation conditions,[123] $HCo(CO)_4$ simply gives the acetylenehexacarbonyldicobalt complex under similar conditions.[124]

Despite being often termed as a cobalt hydride, $HCo(CO)_4$ is a stronger acid than $MeSO_3H$ and 2,4,6-trinitrophenol and all other transition metal hydrides which have been examined, and is comparable in acid strength with HCl and HNO_3[33,36a,k,45,125] (pK_a 8.3 in MeCN,[45] bond dissociation energy 280 kJ mol^{-1} [126]). It is also mildly reducing in character.[127] In terms of organic synthesis, the acidic Co hydride has been utilized to mediate a number of acid-catalyzed reactions including the pinacol rearrangement to pinacolone,[128] the formation and hydrolysis of acetals,[129] the homologation of alcohols,[130] and the reactions of vinyl ethers,[131] as well as the course of the reaction of $HCo(CO)_4$ itself with cyclohexene oxide.[132] Finally, in an isolated series of examples, $HCo(CO)_4$ has been shown to mediate the cyclization and coupling of aryl imines with vinyl ethers.[133] Electron-releasing substituents favor formation of the quinoline products (e.g. eq 30) but, in other examples, mixtures of products often result. When THF is used as solvent, only the quinoline products result, albeit with a drop in yield.

Tetracarbonylcobaltate with Alternative Counter Ions.

When the tetracarbonylcobaltate moiety is combined with counter ions other than Na^+ (Li^+, K^+, Tl^+) or H, a considerable variety of reactivity has been observed. In the simplest example, where the counter ion is the pyridinium ion, $C_5H_5NH^+$, higher catalytic activities in reactions involving CO, e.g. hydroformylation and hydrocarboxylation, are observed.[134] When readily formed[135] ytterbium/cobalt

clusters, such as $Cp_2YbCo(CO)_4$, are used under hydroformylation conditions, compared to $Co_2(CO)_8$ a considerably higher conversion of starting alkene into aldehydes results.[136] Similar processes using lutetium[137] and uranium[138] have also been reported.

With other counter ions, reactions which have not been reported with the simple cobaltate systems have been observed. In the first example, the results can be directly compared with the $NaCo(CO)_4$ carboxylation of epoxides. When cobalt hexaalcohol counter ions are used as the reagents, ketones are formed in good yields.[139] The methanol (eq 31) and isopropyl alcohol complexes have been used to give comparable yields of products. A similar reaction using $Sn[Co(CO)_4]_4$ under high CO pressure has also been reported.[140]

(31)

Another reaction which can readily be compared with those of other Co species, in particular $CpCo(CO)_2$, $Co_2(CO)_8$, and $Hg[Co(CO)_4]_2$, is the cyclotrimerization of alkynes using $[Ph_3PC_5H_4Co(CO)_2]^+$ $[Co(CO)_4]^-$.[141] This complex is readily formed by reaction of $Co_2(CO)_8$ and triphenylphosphinocyclopentadienide (Cp^--PPh_3^+) and is reacted in refluxing THF to give good yields of aromatic products (e.g. eq 32).

(32)

Novel silyl carbocyclization reactions with double CO incorporation have been observed[142] using $(t\text{-BuNC})_4RhCo(CO)_4$[143] as catalyst. When dipropargylallylamines are reacted with this catalyst, the main product (**2**) is accompanied by a small amount of a single CO incorporation product (**3**) (eq 33). When $Rh_4(CO)_{12}$ is used as the catalyst (at ambient CO pressure), ketone (**3**) is the sole product (81%). Cyclopentenone formation can also be achieved using the same Rh/Co catalyst (eq 34).[142] Alternative Rh and Rh/Co catalysts have also been reported for this latter cyclization. Mixed Rh/Co complexes also catalyze silylcarbonylation (the Si version of hydroformylation) and hydrosilylation of alkynes,[144] as well as the synthesis of 2-arylethanols from benzyl halides.[145]

(33)

(2) 62% **(3)** <2%

(34)

When the tetracarbonylcobaltate anion was being studied as a potential desulfurization agent, it was found that tetraarylethylenes are formed as the principal organic products from reaction of $(Ph_3P)_2N^+\ ^-Co(CO)_4$ with thioketones (eq 35).[146] The same study showed that higher yields in this reaction can be achieved by using $Co_2(CO)_8$ and that desulfurization to give hydrocarbons can be realized by using the $HFe(CO)_4^-$ anion.

(35)

The structurally simple ammonium tetracarbonylcobalt species, $NH_4Co(CO)_4$, is formed by reaction of $HCo(CO)_4$ with ammonia and reacts with aromatic aldehydes to give aromatic imines.[147] Finally, it is also worth noting that the tin tetracobaltate species, $Sn[Co(CO)_4]_4$, is an active catalyst for the hydrolysis of carbonates[148] (as is $Co_2(CO)_8$) and for hydroformylation and acetalization reactions.[149]

Sodium Tetracarbonylhydridoferrate

$NaHFe(CO)_4$

[53558-55-7] · $C_4HFeNaO_4$ · Sodium Tetracarbonylhydridoferrate · (MW 191.89)

(alkylation of carbonyl compounds and amines with aldehydes; reduction of α,β-unsaturated carbonyl compounds, enamines, and nitro compounds; carbonylation of alkenes)

Physical Data: X-ray structure of the $HFe(CO)_4^-$ ion as the PPN^+ salt has been reported.[1]

Solubility: sol THF, ethanol, methanol.

Form Supplied in: prepared as a solution in THF or in methanol.

Analysis of Reagent Purity: IR (THF) 1997 (m), 1903 (sh), 1878 (s), 1851 (sh) cm^{-1}; ^1H NMR (THF, C_6D_6) δ -8.74 (32 °C).

Preparative Methods: Method A. To a stirred suspension of ***Sodium Amalgam*** (100 g of mercury and 0.76 g of sodium) in dry THF (50 mL), ***Pentacarbonyliron*** (1.5 mL, 11 mmol) is added dropwise under argon. The mixture is stirred for 2 h at room temperature, and the excess of amalgam is removed through a sidearm. The suspension is treated with water (0.2 mL, 11 mmol) and the resulting $NaHFe(CO)_4$ is used immediately. Method B. To a stirred solution of ***Sodium Hydroxide*** (33 mmol) in methanol (50 mL), pentacarbonyliron (1.5 mL, 11 mmol) is added under nitrogen or argon. The mixture is stirred for 2 h under reflux and the resulting solution of $NaHFe(CO)_4$ is used immediately. The corresponding potassium salt of $HFe(CO)_4^-$ is prepared similarly from ***Potassium Hydroxide***.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2).

Dimerization.

When the light yellow aqueous solution of $NaHFe(CO)_4$ is allowed to stand for a few days, it becomes dark red due to the formation of a dimeric anion (eq 1). The dimer slowly gives off hydrogen and forms a dinuclear iron carbonyl anion.[2]

Reaction with Acetylene.

Reaction of an alkaline aqueous solution of $HFe(CO)_4^-$ with acetylene followed by acidic workup provides $H_2[HC{=}CHFe_2(CO)_8]$.[3] The structure of the complex has been determined on the basis of chemical and spectroscopic evidence.[3,4] Analogous complexes are obtained from propyne and 2-butyne by essentially similar methods.[4] In an aprotic solvent such as methylene chloride, the $HFe(CO)_4^-$ ion (prepared as $[N(PPh_3)_2][FeH(CO)_4]$ from $KHFe(CO)_4$ and bis(triphenylphosphine)iminium chloride in methanol) reacts with methyl propiolate, dimethyl acetylenedicarboxylate, ethynyl methyl ketone, and propiolaldehyde to give (η^3-acryloyl)tricarbonylferrates by *trans* addition of the hydride to the acetylenic bond (eq 2).[5]

Alkylation of Carbonyl Compounds and Amines with Aldehydes.

Treatment of an aldehyde or a ketone with formaldehyde in the presence of $HFe(CO)_4^-$ in ethanol or water results in reductive methylation of the carbonyl compounds in high yield (eq 3).[6] The reaction also occurs with carbonyl compounds and alkyl, aryl, and heterocyclic aldehydes in the presence of $HFe(CO)_4^-$ to provide a variety of substituted carbonyl compounds.[7]

Indole can also be reductively alkylated or arylated in the 3-position by aliphatic or aromatic aldehydes using the same procedure (eq 4).[8] The facile alkylation and arylation of primary and secondary amines and of ammonia by aldehydes in the presence of $HFe(CO)_4^-$ has also been reported (eq 5).[9] A practical advantage of this method is the possibility of obtaining a predominantly mono- or dialkyl derivative by using a 1:1:1 or 1:2:2 molar ratio of amine, aldehyde, and $HFe(CO)_4^-$, respectively.

R^1, R^2 = H, alkyl, aryl, part of a ring
R^3 = H, alkyl, aryl

Reduction of α,β-Unsaturated Carbonyl Compounds.

Treatment of unsaturated carbonyl derivatives (ketones, aldehydes, esters, lactones, nitriles) with $HFe(CO)_4^-$, generated in situ from iron pentacarbonyl and NaOH in methanol, gives the corresponding saturated derivatives in high yield.[10] The method is very mild and possesses the following characteristics: (1) overreduction of the ketonic groups is negligible; (2) ester functions are not reduced; (3) reductive coupling of ketones to pinacols, frequently encountered with Birch conditions, is not observed; (4) no skeletal rearrangement, often observed during Clemmensen reduction, takes place; (5) phenyl and furyl groups are not affected; and (6) the rate of reduction is influenced by steric environments around double bonds; reduction is slower for a sterically hindered double bond. As to the stereochemistry of the reduction, cholest-4-en-3-one is converted selectively into the corresponding 5β-cholestanone having *cis* stereochemistry (eq 6), whereas $\Delta^{1,9}$-2-octalone is reduced to afford a stereoisomeric mixture of 2-decalones (eq 7).

(6)

(7)

cis:*trans* = 37:63

In an aprotic solvent under ambient conditions, α,β-unsaturated esters selectively insert into the hydrogen-iron bond of $HFe(CO)_4^-$

(prepared by protonation of $Na_2[Fe(CO)_4]$ in THF with 1 equiv of acetic acid) to give alkyl-iron complexes (eq 8). On treatment with alkyl iodide, the alkyl complexes give the corresponding hydroacylated products (eq 8).[11]

The $HFe(CO)_4^-$ derivatives prepared from triethylenediamine (33 mol), deionized water (33 mmol), and pentacarbonyliron (11 mmol) are effective in reducing α,β-unsaturated carbonyl compounds to the saturated alcohols.[12] With prochiral compounds the reaction proceeds stereospecifically. For example, $HFe(CO)_4^-$, generated in situ in THF, reacts with (+)-carvone at 60 °C for 9 days under an argon atmosphere to give (-)-neodihydrocarveol in almost quantitative yield (eq 9). Similarly, (+)-neodihydrocarveol is obtained exclusively from (-)-carvone.

Reduction of Enamines and Nitro Compounds.

Enamines are converted to the corresponding saturated tertiary amines.[13] For example, enamines such as *N*-(1-cyclohexenyl)morpholine, *N*-(1-phenylvinyl)morpholine, and *N*-(2-methyl-1-propenyl)piperidine readily react with an alcoholic solution of $HFe(CO)_4^-$ with the absorption of CO at room temperature to give the corresponding amines in high yield (eqs 10-12).

An application of $HFe(CO)_4^-$ as a reducing reagent in the preparation of primary amines from nitro compounds, mainly substituted

nitrobenzenes, has also been reported (eq 13).[14] The reduction is exothermic and gives the corresponding amines in excellent yields. The ferrate has also high reactivity for nitrosobenzene and moderate reactivity for azobenzene.[14] Nitrocyclohexane reacts slowly to provide cyclohexylamine in good yield.[14]

Y = Cl, Me, CO_2H, OH, NH_2

Carbonylation of Alkenes.[15]

$HFe(CO)_4^-$ reacts with ethyl acrylate at 40-70 °C under an atmosphere of carbon monoxide to give methylmalonate in high yield after treatment of the reaction mixture with alcoholic iodine and hydrogen chloride solutions (eq 14). Both crotonate and 3-butenoate give ethylmalonate as a major product and methylsuccinate and glutarate as minor ones (eq 15). Styrene, on treatment with iron ferrate under CO, yields two isomeric aldehydes, α- and β-phenylpropionaldehyde (eq 16). Ethyl caproate and enanthate are obtained from 1-pentene and 1-hexene, respectively, in poor yield.

Other Reactions.

The reaction of $HFe(CO)_4^-$ with [$M(CO)_3$(α-diimine)Br] yields novel heterodinuclear hydride species (eq 17).[16] The structure of these bimetallic compounds has been determined by X-ray crystallography. The $HFe(CO)_4^-$ anion is also an effective catalyst for the steam gasification of Miike coal.[17] It is also used for hydrodimerization of acrylonitrile to provide adiponitrile.[18] With $Na_2S.9H_2O$, it provides iron carbonyl sulfide clusters.[19]

Related Reagents.

Potassium tetracarbonylhydridoferrate is prepared and used in a similar fashion to the sodium salt.[6,9,20,21] Tetramethylammonium tetracarbonylhydridoferrate is readily prepared by reaction of pentacarbonyliron with KOH and Me_4NBr in aqueous solution. Similar transformations may be performed with this reagent, including high yielding reduction of acid chlorides to aldehydes.[22]

Sodium Tetrachloroaluminate[1]

$NaAlCl_4$

[7784-16-9] · $AlCl_4Na$ · Sodium Tetrachloroaluminate · (MW 191.77)

(dehydrating and dehydrogenating agent; Friedel-Crafts acylating agent)

Alternate Name: sodium aluminum chloride.

Physical Data: mp 100-150 °C, depending on composition. The initial melting point depends on the ratio of NaCl to $AlCl_3$ and on the coarseness of the mixture. Once the mixture has melted, the temperature may be lowered, with solidification beginning about 100 °C. The 1:2 (NaCl-$AlCl_3$) mixture is a strong Lewis acid because it contains excess $AlCl_3$. The 1:1 mixture is much less acidic.

Solubility: used as a solvent itself; appears to dissolve compounds with nucleophilic groups (carbonyl, hydroxyl); incompatible with water.

Form Supplied in: not supplied commercially, but easily formed from NaCl and $AlCl_3$ in the heated reaction vessel. The reagent can be prepared in advance and stored.[2]

Analysis of Reagent Purity: can be done electrochemically,[1] but this is rarely necessary. The purity of the reagent depends entirely on the purity of the NaCl and $AlCl_3$ used. In the 1:1 melt, excess $AlCl_3$ markedly changes the acidity of the reagent, but excess NaCl has little effect on the acidity. The properties of the 1:2 reagent (excess $AlCl_3$) do not change greatly with small differences in composition.

Handling, Storage, and Precautions: similar to ***Aluminum Chloride***, except that the molten salt is capable of producing thermal burns, as well as severe burns from $AlCl_3$. The melt may spatter when organic reagents are added, and spattering is common when the reaction mixture is poured over ice. HCl fumes are evolved during most reactions, and large amounts of HCl are evolved when the mixture is poured over ice. Use in a fume hood.

Friedel-Crafts Acylation.

In the presence of sodium tetrachloroaluminate, acids acylate activated aromatic rings (eq 1).[3] Yields of ketones from these acylations are often best with intramolecular reactions (eq 2).[3,4] Anhydrides also can be used as acylating reagents (eq 3).[5,6]

Acylation can also take place via the Fries rearrangement (eq 4).[3] A seven-membered ring can be formed by cyclodehydration (eq 5).[3,7] Aryl vinyl ketones may isomerize to give products resulting from aromatic substitution (eq 6).[3]

The reagent promotes the cyclization of *N*,*N*′-diphenylmalonamide by a cyclodeamination that may proceed via a ketene intermediate (eq 7).[8,9] Sodium tetrachloroaluminate dehydrates simple amides to nitriles (eq 8).[2]

The Scholl reaction, an aromatic cyclodehydrogenation known to take place with aluminum chloride,[10] also takes place with sodium tetrachloroaluminate. Examples are known using polynuclear aromatics (eq 9),[11] benzophenones (eq 10),[12] quinazolines,[13] and benzothiophene-based heterohelicenes.[14]

Sodium Tetrachloroaurate(III)

$NaAuCl_4.2H_2O$

($NaAuCl_4.2H_2O$)

[13874-02-7] · $AuCl_4H_4NaO_2$ · Sodium Tetrachloroaurate(III) · (MW 397.80) ($NaAuCl_4$)

[15189-51-2] · $AuCl_4Na$ · Sodium Tetrachloroaurate(III) · (MW 361.76) ($KAuCl_4$)

[13682-61-6] · $AuCl_4K$ · Potassium Tetrachloroaurate(III) · (MW 377.87) ($HAuCl_4$)

[16903-35-8] · $AuCl_4H$ · Hydrogen Tetrachloroaurate(III) · (MW 339.78)

(catalyst precursor for the hydrochlorination of acetylene,[1] oxidation of sulfides,[2] and the synthesis of isoxazoles[3])

Physical Data: mp 100 °C (dec).

Solubility: sol water, alcohols; sparingly sol diethyl ether.

Form Supplied in: golden-yellow crystalline solid.

Preparative Method: prepared from $HAuCl_4$ (which is formed when $AuCl_3$ is dissolved in HCl or when Au is dissolved in aqua regia) and NaCl to give orange-yellow crystals.

Handling, Storage, and Precautions: air stable.

Hydrochlorination.

Addition of hydrogen chloride to acetylene to afford vinyl chloride (eq 1) is a well established industrial process, currently accounting for 6% of the total world production of this versatile monomer. Although the industrial process utilizes ***Mercury(II) Chloride*** as the catalyst source,[4] recent work demonstrates that gold(III) catalysts can also be employed for this transformation.[1] Catalysts comprised of $HAuCl_4$ supported on activated carbon are particularly active.

Oxidation of Sulfides.

Sulfoxides are important intermediates in organic synthesis and recent work has focused on improving their method of preparation.[5] While it is well known that gold(III) halides oxidize organic sulfides to sulfoxides and sulfones,[6-8] early work was stoichiometric in gold. More recently, studies have shown that $AuCl_4^-$ can be employed in catalytic amounts

under phase-transfer conditions to affect this reaction (eq 2). Oxidation under these conditions takes place selectively at the sulfur atom even in the presence of other oxidizable moieties such as vinyl, tertiary amino, hydroxy, and diol groups.

(2)

Reactions with unsymmetric disulfides are completely regiospecific, affording monosulfoxides where the more reactive sulfur has been oxidized. Symmetric disulfides afford monosulfoxides upon oxidation in higher yields than those obtained using traditional oxidizing agents such as ***Bromine***.[6] The greater activity of the analogous tetrabromoaurate(III) catalyst is exemplified in the oxidation of hindered dialkyl sulfides and aryl alkyl sulfides, as well as diaryl sulfides, which are not readily oxidized under mild conditions using $AuCl_4^-$.[7] In a related study, a number of gold complexes were found to catalyze the oxidation of carbon monoxide at low temperatures.[8]

Synthesis of Isoxazoles.

Terminal alkynes react with nitric acid under biphasic conditions and in the presence of a catalytic amount of $TBA^+AuCl_4^-$ to give 3,5-disubstituted isoxazoles (eq 3).[3] There appears to be no limitations on the nature of the R group and yields of isolated products range from 35-50%. Poor results are obtained using different metal chloride catalysts, and a biphasic system of nitromethane/water seems to be unique in promoting this transformation.

Sodium Thiocyanate[1]

NaSCN

[540-72-7] · CNNaS · Sodium Thiocyanate · (MW 81.08)

(thiocyanation or isothiocyanation of organic compounds;[1] with a metal salt, reduces α-halo ketones to ketones[13])

Physical Data: mp 287 °C.

Solubility: v sol H_2O (139 g/100 mL at 21 °C); sol acetone, EtOH; partially sol CH_2Cl_2.

Form Supplied in: colorless to white deliquescent crystals; widely available.

Purification: recrystallization from water, MeCN, or MeOH, followed by washing with ether and drying at 130 °C.

Handling, Storage, and Precautions: contact with acids liberates toxic gas. Keep container well sealed during storage.

General Discussion.

Sodium thiocyanate is primarily a reagent for the thiocyanation or isothiocyanation of organic compounds by nucleophilic chemistry. It acts as a thiocyanating agent by nucleophilic attack via its sulfur while attachment by nitrogen affords isothiocyanates.[1] The ambident character of thiocyanate ion is explained in more detail in the description of ***Potassium Thiocyanate***. Sodium thiocyanate is not often employed for the thiocyanation of organic compounds, although there are some instances of its use.[1] It is preferred over KSCN for the formation of PhSeSCN from PhSeCl,[2] but TMSNCS is the best reagent since the product is not contaminated with thiocyanate ion residues.[3] NaSCN has been employed to introduce a thiocyanate group into a nitroxyl spin label (eq 1).[4] NaSCN is rarely utilized for the thiocyanation of saccharides; potassium, ammonium, silver, and lead thiocyanates are employed instead.[5]

(1)

The primary use of sodium thiocyanate is as a reagent for the isothiocyanation of unsaturated compounds. For instance, the reaction of alkyl carbonochloridothioates with NaSCN followed by an alcohol quench affords *O,O*-dialkyl imidodithiocarbonothioates via an intermediate isothiocyanate. KSCN and NH_4SCN give lower yields (eq 2).[6] The identity of the base is also important in these and related isothiocyanate syntheses.[6,7]

M = Na, 79%; K, 64%; NH_4, 40%

In addition to alkoxycarbonyl halides, compounds such as imidoyl chlorides[8] and aminocarbonyl chlorides[9] react with NaSCN to afford isothiocyanates; in many cases, the isothiocyanates are intermediates on the path to substituted thioureas (eq 3). The reaction of NaSCN with imidoyl chlorides attached to a phosphonium salt affords substituted thioimidazolones by nitrogen attack and cyclization.[10] Thioacyl halides may give the isothiocyanate or the thiocyanate, depending on the reaction conditions.[1,11] In some instances, the organic thiocyanate can be converted to the isothiocyanate by thermolysis.[1]

The reaction of 2 equiv of NaSCN with aryl and alkyl dichloromethyl disulfides is an effective means of synthesizing 2-alkyl(aryl)thio-4λ^4-[1,2,4]dithiazolo[1,5-*b*][1,2,4]dithiazoles (eq 4).[12]

NaSCN is one of a collection of pseudohalides or halides that has been used in conjunction with a metal halide for the reductive dehalogenation of α-halo ketones (eq 5).[13] NaSCN does not seem to have any particular advantage over the other reagents; all achieve the reduction in >90% yield.

Sodium Thiosulfate[1]

$Na_2S_2O_3$

($Na_2S_2O_3$)

[7772-98-7] · $Na_2O_3S_2$ · Sodium Thiosulfate · (MW 158.12) ($Na_2S_2O_3.5H_2O$)

[10102-17-7] · $H_{10}Na_2O_8S_2$ · Sodium Thiosulfate · (MW 248.22)

(general reducing agent; reagent for nucleophilic introduction of sulfur[2])

Physical Data: mp (pentahydrate) 40-45 °C; *d* 1.73 g cm^{-3}.

Solubility: insol alcohol; v sol water.

Form Supplied in: both the pentahydrate and anhydrous form are widely available as white solids.

Handling, Storage, and Precautions: reported to be an irritant. The anhydrous form is hygroscopic.

Functional Group Reductions.

$Na_2S_2O_3$ is a sufficiently powerful reducing agent to effect a number of useful synthetic transformations. Vicinal dibromides are efficiently dehalogenated to the corresponding alkenes in warm DMSO.[3] Anilines are obtained by reduction of aryl nitroso compounds[4] or aryl azides,[5] and nitrosamides can be reduced to amides.[6] Peroxides are reduced to the corresponding alcohols[7] when exposed to aqueous $Na_2S_2O_3$, and reductive workup of an ozonolysis with NaI/$Na_2S_2O_3$ has been employed in the isolation of a ketone.[8] Saturation of activated alkenes by $Na_2S_2O_3$ has been reported, including the reduction of a quinone[9] and of 1,2-dibenzoylethylene.[10]

Introduction of Sulfur.

Nucleophilic attack by thiosulfate on alkyl halides results in the formation of *S*-alkyl thiosulfates, commonly known as Bunte salts. Extensive reviews on the preparation and classical reactions of Bunte salts have appeared.[2] In addition to alkyl halides, thiosulfate has been reported to add to epoxides,[2b] oxetanes,[11] activated alkenes,[2b] and even acylaziridines.[12] Probably the most well-known classical application of Bunte salts is their conversion to thiols, which can be accomplished via acidic hydrolysis[13] or reduction.[11] Extension of this methodology to the synthesis of aryl thiols is possible by the addition of $Na_2S_2O_3$ to quinones (eq 1).[14] When the hydrolysis is performed under oxidative conditions, sulfonic acids or sulfonyl chlorides are obtained.[2,15]

(1)

Much of the useful chemistry of Bunte salts results from the leaving group potential of the sulfite moiety. Nucleophilic displacement by thiolates results in the synthesis of unsymmetrical disulfides (eq 2).[16] In a mechanistically similar manner, symmetrical trisulfides are available by the reaction of Bunte salts with sodium sulfide.[17]

(2)

The sulfite group of Bunte salts may also function as a leaving group via an E2 elimination, comprising a convenient and mild method for generating thiocarbonyl compounds. This reaction was first noted when the carbamoyl derivatives $RNHCOCH_2SSO_3Na$ were reacted with primary and secondary amines R'_2NH, affording thiooxamides $RNHCOCSNR'_2$.[18] Dimerization of the reactive thiocarbonyl intermediates to 1,3-dithietanes has also been observed.[19] The thiocarbonyl group is a good dienophile and will trap 1,3-dienes at low temperatures.[20] The resulting cycloadducts can be rearranged stereoselectively under basic conditions to cyclopentenyl sulfides (eq 3).[21]

Sodium Triacetoxyborohydride[1]

$NaBH(OAc)_3$

[56553-60-7] · $C_6H_{10}BNaO_6$ · Sodium Triacetoxyborohydride · (MW 211.96)

(the prototype of a class of $NaBH(OCOR)_3$ reagents that are selective reducing agents for a number of functional groups[1] and heterocycles;[1] alkylation of amines;[1-4] hydroboration[1])

Physical Data: mp 116-120 °C (dec); the related $NaBH_3OAc$ has not been fully characterized.

Solubility: $NaBH(OAc)_3$ and related acyloxyborohydrides are rapidly destroyed by H_2O and protic solvents; H_2 is liberated. Cosolvents that have been employed are benzene, toluene, THF, dioxane, CH_2Cl_2, $ClCH_2CH_2Cl$.

Form Supplied in: $NaBH(OAc)_3$ and the related ***Tetramethylammonium Triacetoxyborohydride*** are commercially available as colorless powders.

Preparative Method: $NaBH(OAc)_3$ and $NaBH_3OAc$ can be easily prepared in situ from the appropriate amount of acetic acid and $NaBH_4$.

Analysis of Reagent Purity: $NaBH(OAc)_3$ has been characterized by elemental analysis, IR, and ^1H, ^{13}C, and ^{11}B NMR.

Handling, Storage, and Precautions: because H_2 is liberated during the preparation of these reagents, all handling and storage of acyloxyborohydrides should take place under an inert atmosphere.

Functional Group Reductions.

$NaBH(OAc)_3$ selectively reduces aldehydes but not ketones[5,6] (eqs 1 and 2),[7,8] even with excess reagent. However, α- and β-hydroxy ketones are reduced to the *anti*-diols by hydroxy-directed hydride delivery[6,9,10] (eqs 3 and 4).[11,12] Diastereoselectivities are generally excellent, although $Me_4NBH(OAc)_3$ seems to be a superior reagent in this regard.[9] Several recent examples of $NaBH(OAc)_3$ in the stereoselective reduction of hydroxy ketones attest to the power of this reagent.[13]

(1)

(2)

(3)

anti:*syn* = >30:1

(4)

The hydroxy-directed $NaBH(OAc)_3$ reduction of an imide has been described.[14] The more reactive $NaBH_3OAc$ reduces enones to allylic alcohols,[15] and some ketones can be reduced to alcohols with ***Sodium Borohydride***-tartaric acid.[16] The combination of $NaBH_4$ or ***Sodium Cyanoborohydride-Acetic Acid*** serves to deoxygenate tricarbonyl systems (eq 5)[17] and tosylhydrazones of ketones and aldehydes (eq 6).[18] Primary and secondary amides are reduced to amines by the action of $NaBH_3OAc$ (eq 7),[19,20] while tertiary amides require ***Sodium Trifluoroacetoxyborohydride***.

(5)

(6)

(7)

Amine Alkylation (Reductive Amination).

By a pathway that may involve the generation of free aldehyde, the combination of $NaBH_4$ and carboxylic acids is capable of *N*-alkylation of amines.[1-4] Recent examples abound (eqs 8-11). At lower temperature, monoalkylation is generally observed (eq 8),[21] while at 50-55 °C, primary and secondary amines are converted into tertiary amines (eqs 9 and 10).[22,23] Neat carboxylic acid (eqs 8 and 9) or a cosolvent (eq 10) may be used. In the latter event, solid carboxylic acids function well (eq 11).[24] ***Formic Acid*** may be employed for *N*-methylation.[1,25] A useful variation is the reductive amination of aldehydes and ketones (eqs 12-14),[1,26-29] a method which is claimed to be superior to that using $NaBH_3CN$-MeOH.[26] ***Paraformaldehyde*** serves as a convenient source of HCHO for *N*-methylation in this protocol.[30,31]

Carboxylic acids are reduced to alcohols with $NaBH_4$ in THF,[32] although the use of CF_3CO_2H in this regard is superior, and there is one report of an ester reduction to a primary alcohol with $NaBH_4$-HOAc.[33]

Enamine, Imine, Iminium Ion, and Enamide Reduction.

The first reported use of $NaBH_4$-HOAc was in the reduction of dienamines,[34] and this application has found extensive use in synthesis[1] (eqs 15-19).[35-39]

(19)

Indole Reduction.

Indole is smoothly reduced to indoline under the influence of $NaBH_3CN$-HOAc;[2] the reaction is quite general[1,40] and has been employed often (eqs 20-22),[41-43] especially in the synthesis of CC-1065, PDE, and analogs where only the more basic indole ring is reduced (eq 23).[44,45] *N*-Substituted indoles are reduced to indolines with $NaBH_4$-HOAc,[1,2] and the action of $NaBH_4$-RCO_2H on *N*-unsubstituted indoles affords *N*-alkylindolines by *N*-alkylation of the initially formed indoline.[1,2]

(20)

(21)

(22)

(23)

Reduction of Other Heterocycles.

Quinolines and isoquinolines are reduced to the corresponding tetrahydro derivatives with $NaBH_3CN$ or $NaBH_4$-RCO_2H, the latter combination affording the *N*-alkylated compounds.[1,46] Related heterocycles have been subjected to this protocol (eqs 24 and 25).[47]

The reduction of pyrylium salts (eq 26),[48] the reductive cleavage of benzoxazoles (eq 27)[49] and of saturated nitrogen heterocycles (eqs 28 and 29),[1,50,51] and the reduction of other π-deficient nitrogen heterocycles[1] are known.

(27)

(28)

trans:*cis* = 6:1

(29)

R = H, 61%; Et, 34%

Reduction of Oximes.

Oximes can be alkylated or reduced, depending on whether $NaBH_4$ or $NaBH_3CN$ is employed, to give hydroxylamines[1,52] (eqs 30 and 31).[52,53] Oxime ethers are also reduced under these conditions,[1,54] and the hydroxy-directed reduction of oxime ethers has been reported using $Me_4NBH(OAc)_3$.[55] Nitriles are converted into primary amines by the tandem action of acyloxyborohydrides and alkyllithium reagents (eq 32).[56]

(30)

(31)

(32)

Hydroboration of Alkenes.

The second reported reaction of acyloxyborohydrides was the hydroboration of alkenes,[1,57] and this reaction has been further refined.[58] In a similar vein, the reduction of organomercurials by $NaBH(OAc)_3$ has been described.[59]

Related Reagents.

Sodium Trichloroacetate

$Cl_3C\text{-}CO_2Na$

[650-51-1] · $C_2Cl_3NaO_2$ · Sodium Trichloroacetate · (MW 185.36)

(generation of the trichloromethyl anion and dichlorocarbene)

Physical Data: mp >300 °C.

Solubility: sol DME, diglyme.

Preparative Method: a methanol solution of ***Trichloroacetic Acid*** is neutralized with freshly prepared ***Sodium Methoxide*** to the phenolphthalein end point while keeping the temperature below 20 °C. The methanol is removed on the rotary evaporator at 20 °C. The salt is then dried in a vacuum oven at 50 °C for 20 h. The yield is nearly quantitative.[1]

Handling, Storage, and Precautions: is an irritant and is hygroscopic.

Cyclopropanations.

It was discovered that dichlorocarbene could be generated under essentially neutral conditions by heating a solution of sodium trichloroacetate. If this was done in the presence of an alkene, the corresponding dichlorocyclopropane was obtained (eqs 1 and 2). Cyclohexene and cycloheptatriene yielded the cyclopropyl derivatives in 65% and 47% yield, respectively.[2]

(1)

(2)

This was found to be the preferred method for the cyclopropanation of ***Trichloroethylene*** (eq 3). Although the yield was modest (22%), this was counterbalanced by the overall simplicity of the method.[3] This yield was later improved to 47% by reducing the amount of ***1,1-Dimethoxyethane*** (DME) used in the reaction by one half. The reduction in the amount of DME slowed the decomposition of the salt and cut down on the byproducts produced from the reaction of DME with dichlorocarbene. Hundreds of grams of the cyclopropane can be prepared in this way.[4]

(3)

Another modification in the way the reaction can be run is to use a combination of tetrachloroethylene, which is very unreactive,[5] and DME. By using a 10:2.5 ratio of tetrachloroethylene:DME, the entire amount of the salt could be added at the start rather than in portions. In this solvent mixture, only a portion of the salt dissolves. This helps control the rate of CO_2 evolution and hence the rate of carbene formation. Under these conditions, the yield of the *cis*-biscyclopropyl derivative of 1,5-cyclooctadiene (eq 4) rose to 62%. A small amount of the *trans*-bis-adduct was also formed, but was easily removed by recrystallization. If the solvent was tetrachloroethylene alone, none of the desired product was formed.[6]

(4)

Allene reacts with dichlorocarbene generated from the salt to afford the methylenecyclopropane derivative (eq 5).[7]

(5)

In an attempted cyclopropanation of ***Bis(trimethylsilyl)acetylene*** with sodium trichloroacetate (eq 6), the cyclobutenone was produced instead of the cyclopropane. The reaction with ***Phenyl(trichloromethyl)mercury*** resulted in ill-defined material.[8]

(6)

An effort to prepare diaziridines from azodicarboxylates and dichlorocarbene was thwarted by a rearrangement. The reaction of ***Diethyl Azodicarboxylate*** with sodium trichloroacetate in refluxing DME (eq 7) produced the rearranged compound in 69% yield. The same reaction with $PhHgCCl_2Br$ as the carbene precursor provided the same compound in 87% yield.[9]

(7)

The use of phase transfer conditions can provide an effective set of reaction conditions in some cyclopropanation reactions, with tetraheptylammonium bromide and Aliquat® 336 being the most effective.[10] In addition, crown ethers were found to accelerate the loss of CO_2, but at the same time result in somewhat lower yields.[11]

Insertion Reactions.

Dichlorocarbene has been shown to be capable of inserting into a C-H bond of alkyl-substituted aromatics. Thus the reaction of cumene with sodium trichloroacetate (eq 8) in refluxing DME resulted in a 33% yield of β,β-dichloro-*t*-butylbenzene. Only a 0.5% yield of insertion product was obtained if the dichlorocarbene was formed using ***Chloroform*/*Potassium t-Butoxide***.[12] Prior to this, halocarbenes were not known to attack C-H bonds.

(8)

The insertion into Si-H is also possible. Treatment of ***Triethylsilane*** with sodium trichloroacetate affords the dichloromethylsilane (eq 9) in 32% yield.[13] The insertion of dichlorocarbene into the Si-H bond occurs with retention of configuration at silicon. The reaction of (+)-α-naphthylphenylmethylsilane (eq 10) with sodium trichloroacetate in the presence of ***18-Crown-6*** produces (+)-α-naphthylphenylmethyldichloromethylsilane in 70% yield.[14]

(9)

(10)

Trichloromethyl Anion.

The reaction of the tricyclic anhydride with sodium trichloroacetate did not result in any dichlorocyclopropane formation. Instead, the product from the addition of the trichloromethyl anion to the anhydride was produced (eq 11).[1] The reaction of aldehydes (eq 12) and acid chlorides (eq 13) under these conditions also affords products resulting from the reaction of the trichloromethyl anion.[15] The yields for these later two processes were not as good as for the reaction with the anhydride. The presence of the anhydride was found to accelerate the decomposition of the salt.

(11)

(12)

(13)

Miscellaneous.

Sodium trichloroacetate has been employed in the syntheses of trimethylsilyl trichloroacetate[16] and *t*-butyldimethylsilyl trichloroacetate.[17] The trimethylsilyl derivative was prepared from the salt and the silyl chloride in 83% yield in benzene using 18-crown-6 as the catalyst (eq 14). The *t*-butyldimethylsilyl compound was formed in 83% yield in an uncatalyzed reaction between the salt and the silyl chloride in THF (eq 15). These two reagents have found use for the introduction of silyl-protecting groups.[17,18] The trimethylsilyl trichloroacetate has also found application in a simple procedure for the preparation of Mosher's acid.[16]

(14)

(15)

Dichlorocarbene has been found to mediate carbon-carbon bond formation in the coupling of benzazoles to bis-benzazoles. The yields of the bis-benzazoles were identical using either the sodium trichloroacetate method (eq 16) or the ***Chloroform***/***Sodium Hydroxide***/phase transfer method to generate dichlorocarbene.[19]

(16)

X = NMe, 30%; S, 60%; O, 24%

In a ring-expansion route for the preparation of [6](2,4)pyridinophanes, the bicyclic pyrrole was heated with sodium trichloroacetate in DME (eq 17) to provide the pyridinophane in 28% yield. An analogous reaction with phenyl(bromodichloromethyl)mercury as the source of dichlorocarbene produced the same compound but only in 20% yield.[20]

Sodium Triethylborohydride-Iron(II) Chloride

$NaEt_3BH$-$FeCl_2$

($NaEt_3BH$)

[17979-81-6] · $C_6H_{16}BNa$ · Sodium Triethylborohydride-Iron(II) Chloride · (MW 122.02) ($FeCl_2$)

[7758-94-3] · Cl_2Fe · Sodium Triethylborohydride-Iron(II) Chloride · (MW 126.75)

(reducing agent for thiols;[1] can dimerize diaryl thioketones[2])

Form Supplied in: ***Iron(II) Chloride*** is supplied in anhydrous form as a white powder. Sodium triethylborohydride is available as a 1 M solution in diethyl ether, THF, or toluene.

Desulfurization.

Thiols may be desulfurized to their parent hydrocarbons by the action of a mixture of $FeCl_2$ and $NaEt_3BH$ (eq 1). Normally, a solution of the thiol (1.5 mmol) in THF (2-3 mL) is added to anhydrous $FeCl_2$ (3.0 mmol) in THF (2 mL). THF (8 mL) is added, and after stirring for a short time period, the solution is added to a 1 M solution of $NaEt_3BH$ (6 mmol) in THF at -78 °C. An option exists where the $NaEt_3BH$ mixed with ***Alumina*** allows room temperature reactions and a more convenient reaction workup,[2] but results in some cases in increased amounts of dimerization side products.

(1)

Dimerization of Diaryl Thioketones.

Diaryl thioketones undergo dimerization to tetraarylalkenes by $NaEt_3BH$-$FeCl_2$ on alumina (eq 2).[2] These heterogeneous conditions give results superior to the homogeneous ones, where a significant amount of reduction to the diarylalkane competes with the desired reaction.

Sodium Trifluoroacetoxyborohydride[1]

$NaBH_3OCOCF_3$

[61666-40-8] · $C_2H_3BF_3NaO_2$ · Sodium Trifluoroacetoxyborohydride · (MW 149.85)

(a very selective reducing agent for the reduction of nitriles and amides to amines;[1] may serve as a source of trifluoroacetaldehyde or its equivalent[2])

Solubility: the reagent is rapidly destroyed by H_2O and protic solvents; H_2 is liberated. Common cosolvents for the reactions of this reagent are CH_2Cl_2, THF, toluene, and Et_2O.

Form Supplied in: not commercially available.

Preparative Methods: normally prepared in situ by the reaction of the appropriate amount of ***Trifluoroacetic Acid*** with ***Sodium Borohydride***.[1]

Analysis of Reagent Purity: has not been characterized.

Handling, Storage, and Precautions: the preparation of and all reactions involving this reagent should be conducted under an inert atmosphere because H_2 may be liberated; this is particularly true when $NaBH_4$ powder is used.

Functional Group Reductions.

The combination of strong acid and hydride donor yields a unique and powerful reagent for the reduction of nitriles and amides to amines. The related though less reactive ***Sodium Tris(trifluoroacetoxy)borohydride*** effects the deoxygenation of benzylic alcohols and aryl ketones, the reduction of imines, enamines, oximes, and related double bonds, and the reduction of heterocycles (indoles, pyrroles, and some π-deficient heterocyclic systems). In some of these examples the active reagent may be $NaBH_3OCOCF_3$.

Whereas nitriles and amides are unaffected by $NaBH(OCOCF_3)_3$ ($NaBH_4$ in excess CF_3CO_2H), the action of $NaBH_3OCOCF_3$ on these functional groups leads to amines[3] (eqs 1-7).[4-10] Noteworthy is the survival of the 1,2-oxazine carbamate (eq 3),[6] the diaryl ketone (eq 4),[7] the Boc protecting groups (eq 5),[8] and the diaryl carbinol (eq 7).[10] Thus $NaBH(OCOCF_3)_3$ (in CF_3CO_2H) reduces diaryl carbinols but not amides, while $NaBH_3OCOCF_3$ reduces amides but not diaryl carbinols!

(3)

(4)

(5)

(6)

(7)

Carboxylic acids can be reduced to primary alcohols with $NaBH_3OCOCF_3$.[11]

Sodium Trimethoxyborohydride[1]

$NaBH(OMe)_3$

[16940-17-3] · $C_3H_{10}BNaO_3$ · Sodium Trimethoxyborohydride · (MW 127.93)

(reducing agent for various functional groups;[1,2] dehalogenates vicinal dihalides;[3] assists in coupling of electron-deficient alkenes with organomercurials[4])

Alternate Name: sodium hydrotrimethoxyborate

Physical Data: mp 230 °C (disproportionates).

Solubility: sol isopropylamine, pyridine, morpholine, dioxane, diglyme, and THF,[5] as well as HMPA[2c,d] and methylene chloride.[2c-e] However, it disproportionates rapidly in diglyme to $NaBH_4$ (soln) and $NaB(OMe)_4$ (ppt) or in THF to $NaBH_4$ (ppt) and $NaB(OMe)_4$ (soln).[6] Also, methanol reacts with $NaBH_4$ in THF only to a limited extent, with initially formed methoxyborohydrides disproportionating rapidly to $NaBH_4$ and $NaB(OMe)_4$ and contributing to solubilization of the otherwise insoluble $NaBH_4$.[7] Thus, disproportionation products may account for some reductions attributed to $NaBH(OMe)_3$.

Form Supplied in: white solid.

Preparative Methods: reaction of suitably active ***Sodium Hydride*** with ***Trimethyl Borate*** at reflux;[8] addition of $(MeO)_3B$ to a suspension of NaH in refluxing THF.[2a]

Handling, Storage, and Precautions: the solid material is stable in dry air. It reacts rapidly with strong acids and slowly with water and some alcohols. It is considered relatively safe.

Functional Group Reductions.

The reagent reduces various functional groups.[2a] With diethyl ether as solvent, aldehydes, ketones, acid chlorides, and acid anhydrides are readily reduced to alcohols at 35 °C. Esters and nitriles are more slowly reduced, even at 100-140 °C (dibutyl ether solvent). Carboxylic acids and carboxylates are not affected and nor are alkenes, even those in conjugation with carbonyl groups. The nitro group undergoes reaction at 140 °C but the nature of the product was not investigated. An acyl chloride may be reduced to an aldehyde selectively at -80 °C.[2b]

In HMPA at 70 °C, reductive displacement of halides and sulfonates occurs (***Sodium Borohydride*** gives better results in most cases).[2c,d] Quantum yields in photodechlorination of chlorotoluenes are enhanced by $NaBH(OMe)_3$ or $NaBH_4$.[2e] Birch-type reduction occurs on reaction with cation radicals generated by photoelectron transfer between aromatic hydrocarbons and electron acceptors.[2f]

Selective Reductions.

Conjugated nitroalkenes are reduced to the corresponding nitroalkanes, with accompanying addition of the original reduction products to the parent nitroalkenes to form salts of the corresponding 1,3-dinitroalkanes (eq 1).[9] In most cases, comparable results are obtained with ***Lithium Borohydride***, $NaBH_4$, and ***Lithium Aluminum Hydride***.

One of two ester functions is reduced selectively (eq 2), since relative rates are primary > secondary > tertiary.[10] Ketones are reduced selectively in the presence of conjugated enones, as demonstrated for conversion of androst-4-ene-3,17-dione to testosterone (eq 3).[11]

Iodide is displaced selectively in the presence of chloride for some 1-chloro-2-iodoperfluorocycloalkenes (eq 4).[12] Even in the most reactive case (n = 1, yield 72%) there is unreacted starting material, and yields diminish with increasing n.

Stereoselective Reductions.

Stereoselectivity is reported in the reduction of some ketones.[13] An example for which in situ formation of $NaBH(OMe)_3$ is postulated[13d] may involve disproportionation.[7] Better selectivity is usually obtained using other hydrides, most of which also are not prone to disproportionation. In stereoselective demercuration, superior results are obtained with $NaBH_4$.[14]

Dehalogenation of Vicinal Dihalides.

While this is not a highly useful synthetic reaction, it is noted that $NaBH(OMe)_3$ gives good results in some cases.[3] For example, 5α,6β-dibromocholestan-3β-ol is converted to cholesterol (diglyme, 24 h, 25 °C, 80%).

Coupling of Alkylmercury(II) Salts with Electron-Deficient Alkenes.

Methoxyalkylmercury(II) chlorides, generated from the corresponding alkenes or cyclopropanes, add to various electron-deficient alkenes in the presence of $NaBH(OMe)_3$ (eqs 5 and 6).[4a,b]

(5)

(6)

X = OMe, 76%
X = H, 80%

Yields are improved for coupling with acrylates if a 1:1 ***Mercury(II) Oxide-Mercury(II) Acetate*** mixture is used for mercuration, with the entire sequence carried out in a single flask.[4c,d] The electron-rich alkene may contain a nucleophilic neighboring group (eq 7).[4d] Enones containing isolated double bonds are converted to mercurial enones, which may then undergo reductive cyclization (eq 8).[4e]

(7)

(8)

Related Reagents.

Lithium Borohydride; ***Lithium Tri-t-butoxyaluminum Hydride***; ***Mercury(II) Acetate-Sodium Trimethoxyborohydride***; ***Sodium Borohydride***.

Sodium Tris(trifluoroacetoxy)borohydride[1]

$NaBH(OCOCF_3)_3$

[76791-24-7] · $C_6HBF_9NaO_6$ · Sodium Tris(trifluoroacetoxy)borohydride · (MW 373.87)

(a reducing agent for many different functional groups and heterocycles;[1] can serve as a source of trifluoroacetaldehyde or its equivalent;[2] is similar to other ionic hydrogenation methods in the facile reduction of benzylic systems[3])

Physical Data: mp 64-66 °C.[4]

Solubility: is rapidly destroyed by H_2O and protic solvents; H_2 is liberated. Common cosolvents for the reactions of this reagent are CH_2Cl_2, THF, toluene, and Et_2O.

Form Supplied in: not commercially available.

Preparative Methods: normally prepared in situ by the reaction of excess ***Trifluoroacetic Acid*** with ***Sodium Borohydride***.[1,4]

Analysis of Reagent Purity: has been characterized by elemental analysis and IR.[4]

Handling, Storage, and Precautions: the preparation of and all reactions involving this reagent should be conducted under an inert atmosphere because H_2 may be liberated; this is particularly true when $NaBH_4$ powder is used; $NaBH_4$ pellets are particularly convenient and safe to use for the preparation of $NaBH(OCOCF_3)_3$.

Functional Group Reductions.

The combination of strong acid and hydride donor provides a unique and powerful reagent for the deoxygenation of benzylic alcohols and aryl ketones, the reduction of imines, enamines, oximes, and related double bonds, and the reduction of heterocycles (indoles, pyrroles, and some π-deficient heterocyclic systems). The deoxygenation of benzylic alcohols via carbocations is limited to diarylcarbinols,[3,5] triarylcarbinols,[3] and a few activated monobenzylic systems (eqs 1-3),[6] but a wide range of functional groups is tolerated by the reaction conditions. Generally, excess CF_3CO_2H is employed and, in these cases, the reducing species is assumed to be $NaBH(OCOCF_3)_3$,[2,3] although in some cases ***Sodium Trifluoroacetoxyborohydride*** may be involved.[5,6] Recent examples abound.[7]

(1)

(2)

(3)

Diaryl ketones and a few aryl ketones are deoxygenated by $NaBH_4$ in CF_3CO_2H and a wide range of functional groups may be present in the substrate (CO_2Me, CN, NO_2, halogen, CO_2H, CONHPh, NMe_2, OMe).[8] Some examples are shown (eqs 4-8).[9]

(4)

(5)

(6)

(7)

(8)

1,1-Diphenylethylene is reduced to 1,1-diphenylethane in 93% yield,[3] presumably via the carbocation.

Whereas indoles containing a second, basic nitrogen are normally not reduced by ***Sodium Triacetoxyborohydride***, they are reduced by the combination $NaBH_4$ or ***Sodium Cyanoborohydride*** and CF_3CO_2H (eqs 9-11).[10-12]

(9)

(10)

(11)

The combination of $NaBH_3CN$-CF_3CO_2H, which smoothly reduces even deactivated indole rings (eqs 10 and 11),[11] also reduces some pyrroles (eqs 12 and 13).[13]

(12)

(13)

Benzylic acetals are reductively cleaved with $NaBH_3CN$-CF_3CO_2H[14,15] (eq 14),[15] as are arene 1,4-oxides[16] and ozonides.[17]

(14)

Iminium ions, whether generated from imines, enamines, or carbinol amines, are readily reduced by $NaBH_4$-CF_3CO_2H (eqs 15-18).[18-21]

(15)

(16)

(17)

(18)

Oximes are also reduced to amines (eqs 19 and 20).[22-24]

(19)

(20)

The *N*-trifluoroethylation of amines occurs with $NaBH_4$-CF_3CO_2H (eq 21),[25] presumably via CF_3CHO or its equivalent,[1,2] and has been observed by several groups.[1] CF_3CO_2H can serve as a useful medium for the $NaBH_4$-***Paraformaldehyde*** methylation of amines (eq 22).[26]

(21)

(22)

In a reaction (Baeyer condensation) reminiscent of the classic DDT synthesis, the combination $NaBH_4$-CF_3CO_2H leads to the formation of bis-arenes (eqs 23 and 24).[2,25]

(23)

(24)

A few π-deficient heterocycles, such as quinoxaline (eq 25)[27] and pyrido[2,3-*b*]pyrazine (eq 26),[27] are reduced by $NaBH_4$-CF_3CO_2H.

Sodium Trithiocarbonate[1]

[534-18-9] · CNa_2S_3 · Sodium Trithiocarbonate · (MW 154.20)

(converts alkyl chlorides into thiols;[1] 1,2- or 1,3-dihaloalkanes or dimesylates into cyclic trithiocarbonates[2] or into alkenes;[3] reductively removes chloroethyl ester protecting groups;[4] effective for demercuration[5])

Preparative Method: a 33% aqueous solution is prepared from ***Sodium Sulfide*** and ***Carbon Disulfide*** in H_2O.

Alkyl chlorides can be treated with sodium trithiocarbonate followed by an acidic workup to prepare the corresponding thiol (eq 1).[1a] This methodology was applicable to simple alkyl chlorides (eq 2)[1b] and to β-alkoxy chlorides (eq 3).[1a] It was noted that this method was superior to direct substitution with NH_4SH.

(1)

(2)

(3)

Sodium trithiocarbonate can be reacted with ***Chloroacetonitrile*** with liberation of carbon disulfide (eq 4).[6] The mercaptoacetonitrile could be reacted further with acid chlorides, providing cyanomethyl thioesters.

Thioureas have been prepared by reaction of sodium trithiocarbonate, ***2-Chloro-1-methylpyridinium Iodide*** and two equivalents of the appropriate amine.[7] The bis(pyridinium) thiocarbonate intermediate is activated toward nucleophilic attack (eq 5). The authors point out that other methods suffer from severe conditions and toxic reagents (e.g. ***Thiophosgene***). Sterically hindered amines, such as 2,6-dimethylaniline, were accommodated as well.

Chloroethyl esters, when treated with sodium trithiocarbonate, are reductively deprotected to liberate the carboxylic acid.[4]

Preparation of Cyclic Trithiocarbonates.

Cyclic trithiocarbonates are important intermediates en route to insecticides and other biologically active compounds.[8] These compounds can be synthesized by a double nucleophilic addition of sodium trithiocarbonate and 1,2- or 1,3-bis(mesylates)[2a] or halides (eqs 6 and 7).[2b] It was found that the reactions of the dibromide compounds were best performed under phase-transfer catalysis with trioctylmethylammonium chloride. In general, the yields were better for five-membered ring formation than for six-membered rings. One limitation for five-membered rings was that R^1 and R^2 need be alkyl groups. When R^1 and R^2 were phenyl or methoxycarbonyl groups, alkenes were isolated in excellent yields by a single electron transfer mechanism.[3]

(6)

R^1	R^2	X	Temp (°C)	Time (h)	Cat (equiv)	Yield (%)
H	H	Br	60	8	0	84
H	H	Br	60	8	0.08	97
H	H	SH	80	2	0	90
Me	H	Br	60	20	0.08	81
Me	Me	Br	60	25	0.08	10

(7)

R^1	R^2	X	Temp (°C)	Time (h)	Yield (%)
H	H	Br	60	1	7
H	H	SH	100	3	45
Me	H	Br	60	5	66
Me	Me	Br	60	20	31

Cyclic trithiocarbonates have been selectively reduced to the dithiol or the thioacetal depending on the choice of reducing agent (eq 8).[9] Thus reduction with ***Lithium Aluminum Hydride*** in toluene at 110 °C provided good yields of the dithiol whereas if ***Diisobutylaluminum Hydride*** was employed, the thioacetal was isolated. The trithiocarbonate could also be desulfurized with aqueous ***Mercury(II) Acetate*** to provide the 1,3-dithiole-2-thione (eq 9).[10]

(8)

n	hydride		
1	LAH	86%	0%
1	DIB AL	0%	59%
2	LAH	37%	0%
2	DIB AL	0%	67%

(9)

Demercuration.

A synthetic sequence en route to propionate natural products utilized the regio- and stereoselective oxymercuration[11] of stereodefined enoates. The success of this method hinged upon the stereoselective removal of mercury (eq 10).[5] Previous methods (e.g. ***Sodium Borohydride*** and ***Sodium Sulfide***)[12] gave poor diastereomeric ratios. In this system it was determined that sodium borohydride favored formation of the *threo* isomer and the dithiol reagents gave preferentially the *erythro* product. Sodium trithiocarbonate was slightly less efficient than ***1,3-Propanedithiol*** both in terms of yield and selectivity.

(-)-Sparteine[1]

[90-39-1] · $C_{15}H_{26}N_2$ · (-)-Sparteine · (MW 234.43) (sulfate pentahydrate)

[6160-12-9] · $C_{15}H_{38}N_2O_9S$ · (-)-Sparteine · (MW 422.62)

(reagent for chiral modification of organo-lithium, -magnesium, and -zinc reagents[1,2])

Alternate Name: [(7*S*)-(7α,7aα,14α,14aβ)]-dodecahydro-7,14-methano-2*H*,6*H*-dipyrido[1,2-*a*:1´,2´-*e*][1,5]diazocine.

Physical Data: bp 137-138 °C/1 mm Hg; *d* 1.02 g cm^{-3}; $[\alpha]^{20}_D$ -17.5° (*c* = 2, EtOH). X-Ray structures of several complexes of metal salts,[3] alkyllithium derivatives,[4] and of allylpalladium[5] and studies on the conformation in solution[6] and a NMR study on the structure of the 2-propyllithium-ether-(-)-sparteine complex[7] have been reported.

Solubility: 0.3 g/100 ml H_2O at 20 °C; sol ether, hexane.

Form Supplied in: free base: colorless viscous fluid.

Handling, Storage, and Precautions: highly toxic in the digestive tract. Keep in refrigerator at 0 °C. Moderately hygroscopic; dehydration by drying an ethereal solution over ***Calcium Hydride***. Is easily recovered by extraction of alkaline aqueous solutions. Use in a fume hood.

Chiral Modification of Achiral Organometallic Reagents.

The addition of ***n-Butyllithium*** or ***Ethylmagnesium Bromide*** to aldehydes or ketones in the presence of (-)- sparteine resulted in the formation of optically active secondary or tertiary alcohols with 20% ee or lower.[8] Optically active acyl sulfoxides (<=15% ee) were obtained by acylation of ***p-Tolylsulfinylmethyllithium***.[9] The asymmetric Reformatsky reaction of ethyl bromoacetate with benzaldehyde proceeds with 95% ee,[10] in an exceptional case (eq 1).[11]

Equilibration of Configurationally Labile Organolithium Reagents.

The equilibration of diastereomeric pairs of alkyllithium-(-)-sparteine complexes and trapping by achiral electrophiles gives enantioenriched products. Examples are α-(*N*,*N*-diisopropylcarbamoyloxy)benzyllithium in ether,[12] not in THF,[13] 1-phenylethyllithium,[8a] and the dilithium salt of *N*-methyl-3-phenylpropanoic acid amide (eq 2).[14]

The deprotonation[15] of (*E*)-2-butenyl *N*,*N*-diisopropylcarbamate leads to (1*S*,2*E*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-2-butenyllithium-(-)-sparteine[16] with &egt;90% de after crystallization, combined with a second-order asymmetric transformation (eq 3).[4d] It has been applied in the enantioselective synthesis of γ-lactones,[16] such as (+)-eldanolide (eq 3),[17] dihydroavermectin B_{1b},[18] and doubly branched sugar analogs.[19]

62%, >97% ds, 92% ee

Generation of Enantioenriched, Configurationally Stable Organolithium Reagents.[15,20]

(1*S*,2*E*)-1-(*N*,*N*-Diisopropylcarbamoyloxy)-1-methyl-2-butenyllithium-(-)-sparteine is configurationally stable in solution and is obtained by kinetic resolution of the racemic 2-alkenyl carbamate by *n*-butyllithium-(-)-sparteine with &egt;80% de (eq 4).[21] The enantioenriched allylstannane, obtained on γ-stannylation, was used as chiral homoenolate reagent.[21a] The methoxycarbonylation (α, inversion) yields enantioenriched 3-alkenoates.[21b]

Alkyl carbamates, derived from 2,2,4,4-tetramethyl-1,3-oxazolidine (R-CH_2-OCby), are deprotonated by ***s-Butyllithium***-(-)-sparteine with differentiation between the enantiotopic protons (eq 5).[22,20] The pro-*S* proton is removed with high stereoselectivity and reliability, and, subsequently, stereospecifically substituted by electrophiles with stereoretention to give enantiomerically enriched secondary alcohols (&egt;95% ee) after deprotection.[22b]

(5)

R = alkyl, Bn_2NCH_2, $Bn_2N(CH_2)_2$, $CbyOCH_2CH_2$

The ee values in the enantioselective deprotonation are independent of the size of the attached alkyl residue. The method tolerates several substituents, e.g. 2-[23] or 3-dibenzylamino,[24] 3- or 4-(*N*,*N*-dialkylcarbamoyloxy),[25] or 4-TBDMSO.[25a] Essentially enantiopure 2-hydroxy acids,[22a] β-amino alkanols,[24] γ-amino alkanols,[23] cyclopropyl carbamates,[25a] and 2-hydroxy-4-butanolides[25a] were obtained. Extraordinary high (>70) kinetic H/D isotope effects were observed in the deprotonation of chiral 1-deuteroalkyl carbamates.[26] Kinetic resolution of racemic alkyl carbamates was achieved.[27]

N-Boc-pyrrolidines are similarly deprotonated and furnish enantioenriched 2-substituted pyrrolidines (eq 6).[28]

(6)

Further Applications.

Chiral 1,1-diaryl-2-propynols are resolved by mutual crystallization with (-)-sparteine.[29] Low ee values were achieved in Pd-mediated alkylations.[30] Numerous attempts at enantioselective, alkyllithium-catalyzed polymerizations of alkenes in the presence of (-)-sparteine have been reported.[31]

Related Reagents.

(+)-Sparteine (pachycarpine[32]) is best prepared by resolution of (±)-sparteine, obtained from *rac*-lupanine[33] or by total synthesis[34] with (-)-10-camphorsulfonic acid.[35]

Spiro{bicyclo[4.2.0]octa-1,3,5-triene-7,2´-[1,3]-dioxolan}-8-one[1]

[6383-64-8] · $C_{10}H_8O_3$ · Spiro{bicyclo[4.2.0]octa-1,3,5-triene-7,2´-[1,3]-dioxolan}-8-one · (MW 176.18)

(serves as a 1,4-dipole synthon for synthesis of anthraquinone-related ring systems[2])

Physical Data: mp 109-112 °C.

Preparative Methods: this simple monoethylene acetal of benzocyclobutenedione[3] may be prepared by reaction of the parent dione with ***Ethylene Glycol*** in benzene with a trace of ***p-Toluenesulfonic Acid*** and azeotropic removal of water,[1] or by a three-step method that is essentially a silicon analog of the Kornblum oxidation (eq 1).[4] The latter approach affords control over acetal regiochemistry in systems with unsymmetrical substitution on the aromatic ring.

Purification: crystallizes from benzene-hexane; slightly yellow needles.

Annulation Reactions.

Reaction with lithiated quinone bisacetals affords anthraquinone-related structures (eq 2).[2] Studies support a stepwise rather than a concerted mechanism for this 1,4-dipole-type annulation.[5] Thus reaction with a highly functionalized lithioquinone bisacetal followed by hydrolysis and demethylation steps gave the 7-*O*-methyl epimer of the anthracycline aglycons 4-demethoxydaunomycinone (R = H) or daunomycinone (R = OMe) (eq 3).[4] A related strategy was used in a synthesis of α-citromycinone,[6] although the annulation yield was only 30%.

(2)

(3)

R = H, 62%; R = OMe, 56%

This method has also been used in an approach to the tetracycline antibiotics,[7] giving an annulation adduct which, after addition of ***Methyllithium***, showed the correct relative configuration at key eventual positions of the tetracycline ring system (eq 4).

(4)

Ring Expansion.

Reaction with 1-lithioalkynes affords 1,2-adducts which undergo palladium triflate-catalyzed ring expansion to (*Z*)-2-alkylideneindan-1,3-dione monoacetals (eq 5),[8] a methodology that has been used in the synthesis of a benzo analog of the antiviral agent abikoviromycin.[9]

Squaric Acid[1]

[2892-51-5] · $C_4H_2O_4$ · Squaric Acid · (MW 114.06)

(synthesis of cyclobutenediones, quinones, and hydroquinones[1])

Alternate Name: 3,4-dihydroxy-3-cyclobutene-1,2-dione.

Physical Data: mp >300 °C.

Solubility: sol H_2O.

Form Supplied in: white crystals.

Analysis of Reagent Purity: IR ν 2326 (OH), 1818 (C=O), 1639 (C=C) cm^{-1}.

Handling, Storage, and Precautions: the crystals should be handled with gloves.

Dichlorocyclobutenedione.

Treatment of squaric acid (**1**) with ***Thionyl Chloride*** and a trace amount of ***N,N-Dimethylformamide*** affords dichlorocyclobutenedione (DCCB) (**2**) (eq 1).[2]

(1)

DCCB (**2**) reacts with nucleophiles by displacement of the chlorine atoms.[1d] For example, reaction of (**2**) with 2-nitroaniline in a solution of *o*-dichlorobenzene at 150 °C for 40 min affords diaminocyclobutenedione (**3**) (eq 2).[3]

(2)

DCCB reacts similarly with ***Sodium Azide*** at 0 °C to afford chlorocyanoketene,[4] with cyanamides[5] and carbodiimides[6] to afford carboxyimidoyl chlorides, with thiols to afford dithiocyclobutenediones,[7] with tertiary amines, phosphines, arsines, and thioethers to afford betaines,[8] and with carbonylmetallates to afford metallocyclobutenediones.[9]

DCCB also reacts with carbon nucleophiles. For example, treatment with ***Aluminum Chloride*** in benzene affords diphenylcyclobutenedione (**4**) (eq 3).[10] Furthermore, (**2**) reacts with ***Tetrakis(triphenylphosphine)palladium(0)*** and alkynylstannanes to give dialkynylcyclobutenediones in 11-70% yield.[11]

(3)

Dialkoxycyclobutenediones.

Treatment of squaric acid (**1**) with ***Sodium Hydroxide*** followed by ***Silver(I) Nitrate*** affords disilver salt (**5**) (eq 4); this reacts with ***Iodomethane*** to give dimethyl squarate (DMS) (**6a**).[12] Similarly, treatment of (**5**) with *t*-butyl chloride affords di-*t*-butyl squarate (**6b**).[13]

(4)

Other esters can be prepared by refluxing a solution of squaric acid in the appropriate alcoholic solvent.[12] A specific example is given in eq 5, showing the formation of diisopropyl squarate (DIPS) (**7**).[14]

(5)

Cyclobutenediones.

Dialkoxysquarates can be converted to a wide variety of other cyclobutenediones. For example, treatment of (**7**) with ***Methyllithium*** yields methyl adduct (**8**) (eq 6). The crude material is then subjected to acidic hydrolysis to afford dione (**9**) in 89% overall yield.[14] Alternatively, this transformation can be accomplished in a one-pot procedure with comparable yields by treatment of the intermediate lithium alkoxide with ***Trifluoroacetic Anhydride*** followed by an aqueous extraction.[15]

Disubstituted cyclobutenediones can be made by the following procedure. First, a 4-hydroxycyclobutenone such as (**8**) is silylated with ***4-Dimethylaminopyridine*** and ***t-Butyldimethylchlorosilane*** (eq 7).[14] Then, a second lithium reagent is added (e.g. ***n-Butyllithium***) followed by acidic hydrolysis of the crude material to afford dione (**10**) in 79% yield.

The two carbonyl groups of cyclobutenediones can be differentiated by forming a monoacetal. One such method produces cyclobutenedione ethylene acetal.[16] Another method is described in eq 8. Acetal (**11**) is made from DMS (**6a**) by the addition of ***Phenyllithium*** followed by treatment with TFAA and MeOH. A second lithium reagent (e.g. MeLi) is then added; addition of TFAA and aqueous extraction affords disubstituted acetal (**12**).[17]

In eq 9, DIPS is treated with *n*-$Bu_3SnSiMe_3$ and a catalytic amount of *n*-Bu_4NCN to afford dione (**13**).[18] Stannylcyclobutenediones are versatile intermediates for the synthesis of other cyclobutenediones, utilizing palladium-catalyzed coupling reactions.[19]

Quinones and Aromatic Compounds.

Lithium anions add to cyclobutenediones and cyclobutenedione monoacetals to afford 4-alkynyl-, 4-aryl-, and 4-alkenylcyclobutenones. When heated, these compounds rearrange to give quinones or related aromatic compounds.[20] The reaction is general and is limited only by the availability of the starting cyclobutenedione. For example, eq 10 depicts the thermolysis of 4-alkynylcyclobutenone (**14**), which was made by the addition of the lithium salt of benzylacetylene to 3-butyl-4-methoxycyclobutenedione, to produce quinone (**15**).[20a] Upon heating, 4-arylcyclobutenone (**16**), which was made from acetal (**12**) by addition of PhLi followed by hydrolysis with HCl, rearranges to afford naphthoquinone (**17**) after oxidation in 70% yield from (**12**) (eq 11).[17] Finally, 4-alkenylcyclobutenone (**18**) is thermolyzed to afford coenzyme Q_0 (**19**) after oxidation (eq 12).[20d]

(10)

(14) (15)

(11)

(16) (17)

(12)

(18) (19)

Besides the methods described above, another regioselective route to 2,3-disubstituted furano- and naphthoquinones has been developed,[21] as illustrated in eq 13. Cyclobutenone (**20**) is made from 2-methyl-3-isopropoxy-4-methoxy-4-(2-methoxyphenyl)-3-cyclobutenone by reduction with ***Lithium Aluminum Hydride*** followed by treatment with TFAA and aqueous extraction in 54% yield. Thermolysis of (**20**) then produces naphthoquinone (**21**).

(13)

(20) (21)

A number of unusual classes of quinones are available by the rearrangement of 4-alkynylcyclobutenones. For example, thermolysis of cyclobutenone (**22**) affords silylquinone (**23**) (eq 14).[20a,22] Analogously, thermolysis of cyclobutenones in the presence of ***Tri-n-butyl(methoxy)stannane*** provides stannylquinones in good yields (eq 15).[23]

(14)

(15)

Cyclobutenone ring expansions have been employed as key steps in the synthesis of a variety of natural products and biologically active molecules such as isoarnebifuranone,[24] nanaomycin D,[24,25] mycophenolic acid,[26] Δ^6-tetrahydrocannabinol,[27] danshenxinkun B,[28] terreic acid,[29] perezone and isoperezone,[29,30] lonapalene,[31] and khellin.[32]

Alkylidenecyclopentenediones.

Treatment of cyclobutenones with ***Palladium(II) Trifluoroacetate*** triggers a ring expansion to alkylidenecyclopentenediones.[33] For example, eq 16 shows the rearrangement of cyclobutenone (**24**). The palladium intermediate can be efficiently trapped with ***N-Bromosuccinimide*** to afford vinyl bromide (**25**) in 77% yield.

Succindialdehyde

[638-37-9] · $C_4H_6O_2$ · Succindialdehyde · (MW 86.10)

(useful annulating reagent for constructing heterocycles)

Alternate Name: butanedial.

Physical Data: oil, bp 62 °C/14 mmHg.

Solubility: v sol water, alcohol, ether.

Preparative Methods: easily made by acidic hydrolysis of its stable, commercially available synthetic equivalent ***2,5-Dimethoxytetrahydrofuran*** (or its diethoxy analog), followed by extraction with ether and distillation (eq 1).[1]

Handling, Storage, and Precautions: succindialdehyde rapidly polymerizes and has to be used immediately after distillation. Use in a fume hood.

Annulations.

Succindialdehyde is largely used as an annulating agent in the synthesis of pyrrole and pyrrolidine derivatives. Use of 2,5-dimethoxytetrahydrofuran as a precursor of the dialdehyde may be preferred in some instances. A familiar example is the Robinson-Schöpf cyclization (eq 2)[2] (for similar reactions see also ***Glutaraldehyde***).

Using the same methodology, 2,5-dicyanopyrrolidines can be prepared with cyanide as nucleophile (eq 3); in this example,

succindialdehyde is used as its bis-sodium bisulfite adduct.[3]

Pyrrolidines are formed by reductive alkylation (eq 4),[4] whereas in the absence of any nucleophilic reagent the double condensation of succindialdehyde with a primary amine gives a pyrrole (eq 5).[5]

Succindialdehyde can also be considered as a linear C_4 unit useful in the synthesis of natural products. It has been used as starting material in the synthesis of squalene;[6] the first step consists of the addition of a Grignard reagent to both aldehyde functions (eq 6).

The diol thus obtained can be cyclized to give a 2,5-dialkyltetrahydrofuran, as in the example (eq 7) using Mitsunobu conditions.[7]

Succindialdehyde has also proved useful in the synthesis of the anthracycline skeleton (eq 8) via two aldol-type reactions.[8]

A formal phenyl homologation can be achieved by the double aldol condensation of phthalaldehyde with succindialdehyde. In this example, succindialdehyde is generated in situ from 2,5-dimethoxytetrahydrofuran (eq 9).[9]

Related Reagents.

Diethyl Succinate; ***Malondialdehyde***.

Succinic Anhydride

[108-30-5] · $C_4H_4O_3$ · Succinic Anhydride · (MW 100.08)

(acylation reactions,[1-8] lactone synthesis,[9-14] Reformatsky reaction[15])

Alternate Names: succinic acid anhydride; butanedioic anhydride; dihydro-2,5-furandione; succinyl anhydride.

Physical Data: mp 119-120 °C; bp 261 °C; vapor density 3.5; vapor pressure 1 mmHg (92 °C).

Form Supplied in: colorless needles or white flakes.

Solubility: slightly sol water; sol toluene (10.0 g L^{-1} at 30 °C).

Handling, Storage, and Precautions: use only in a chemical fume hood; severe eye irritant; moisture sensitive; store in cool dry place.

Acylation Reactions.

N- and *O*-Acylation.

Succinic anhydride (**1**) is a reactive acylating agent and reacts rapidly with amines. For alcohols, procedures often call for use of ***Pyridine*** or ***4-Dimethylaminopyridine*** as catalyst. The *N*-acylation reaction has been extensively used for the synthesis of chiral succinimides (eq 1),[1a] which are important intermediates in asymmetric synthesis.[1] The *O*-acylation has been widely employed as a facile method for enzymatic resolution of racemic alcohols (eq 2).[2]

(1)

Acylation of Organometallic Agents.

γ-Keto acids can be obtained in good yield by reaction of organomanganese(II) compounds with (**1**) (eq 3).[3]

The keto acid intermediate in the khellin total synthesis was readily prepared by addition of (**1**) to the dianion of 3-furoic acid (eq 4).[4] The anion derived from diphenylmethane reacts with (**1**) to form the diphenylmethyl ketone in 63% yield.[5]

(4)

Acylation of Ketone Enolates.

Aryl 1,3-diketones have been prepared in good yields by quenching the enolate of an aryl methyl ketone with (**1**) (eq 5).[6]

(5)

Friedel-Crafts Acylation.

Alkenes[7] and aromatic[8] compounds react with (**1**) in the presence of Lewis acid catalysts to give various succinoylation products,[8c] which are useful synthetic intermediates. Selected examples are shown in eqs 6 and 7.[7a,8a]

(6)

(7)

Lactone Synthesis.

Reduction.

Anhydride (**1**) can be reduced to give γ-butyrolactone by metal oxide catalysts[9a] by catalytic hydrogenation,[9b] and by ***Sodium Borohydride***.[10a] Similar reductions of unsymmetrical succinic anhydrides by hydrogenation $[Ru(PPh_3)_3Cl_2]$,[10b] sodium borohydride,[10a,c] or ***Lithium Aluminum Hydride***[10d] often occur selectively at the more hindered carbonyl group, although some exceptions have been reported.[10e]

Spirolactone Synthesis.

Diaddition of Grignard reagents to (**1**) gives spirolactones in good yield.[11] The reaction has been applied to the preparation of a key intermediate in the synthesis of cubebene (eq 8).[11c] Monoaddition of cerium 3-cerio propoxide to (**1**) gives the oxaspirolactone (eq 9).[12]

(8)

Condensation with Aldehydes and Ketones.

The enolate of (**1**) can be successfully prepared by treatment of (**1**) with a sterically hindered alkoxide, lithium 1,1-bis(trimethylsilyl)-3-methyl-1-butoxide, in THF at -78 °C. The enolate readily reacts with aldehydes and ketones to give γ-butyrolactones (eq 10).[13]

Wittig Reaction.

Enol lactones can be prepared by the Wittig reaction between stabilized phosphoranes and (**1**) (eq 11).[14]

Reformatsky Reaction.

Electrolysis of ethyl 2-bromo-2-methylpropanoate in the presence of (**1**) in DMF gave 1-ethyl 3-oxo-2,2-dimethylhexanedioate in 65% yield (eq 12).[15] This electrochemically assisted procedure circumvented both the problems of zinc activation and the difficulty associated with the uncontrollable exothermic course of the normal Reformatsky reaction of cyclic carboxylic anhydrides.

Vinyl Ether Synthesis.

Use of (**1**) as a methanol scavenger, provides an improved procedure for the preparation of vinyl ethers.[16] The method has been used for the synthesis of spiro vinyl ethers (eq 13).[16b]

Succinimide[1]

[123-56-8] · $C_4H_5NO_2$ · Succinimide · (MW 99.10)

(building block for synthesis of other heterocyclic compounds, especially via *N*-acyliminium cyclizations[2])

Physical Data: mp 126-127 °C; bp 287-288 °C (slight decomposition); *d* 1.418 g cm^{-3}; dipole moment 1.54 D (dioxane, 20 °C); pK_a 9.656 (H_2O, 25 °C).

Solubility: sol H_2O (1 g/3 mL at 20 °C; 1 g/0.7 mL at bp), ethanol (1 g/24 mL at 20 °C; 1 g/5 mL at 60 °C); insol ether, chloroform.

Form Supplied in: white solid.

Handling, Storage, and Precautions: may be harmful by inhalation, ingestion, or skin absorption; may cause irritation. Use in a fume hood.

Reactions at the Nitrogen Atom.

The most widely used method for direct *N*-alkylation of succinimide is the Mitsunobu condensation[3] with primary[4] or secondary[5] alcohols under the influence of ***Triphenylphosphine*** and dialkyl azodicarboxylates (eq 1).[4] The extraction and purification steps are often tedious, on account of Ph_3PO and $RO_2CNHNHCO_2R$, formed in the reaction. Therefore, reaction of alkali metal salts of succinimide with primary halides or sulfonates is usually more convenient in cases where the electrophile does not give side reactions with the basic substrate (eq 2).[6] The alkali metal salt can be prepared by reaction of ***Sodium Methoxide*** in MeOH, or ***Potassium t-Butoxide*** in *t*-BuOH, and can also be generated from the alkali metal hydride in DMF or HMPA, without isolation of the salt. Solid-liquid phase-transfer catalysis (***Potassium Carbonate***, 0.1 equiv ***18-Crown-6***, reflux in benzene or toluene)[7] is also used for *N*-alkylation of succinimide in high yield. Addition of 0.1 equiv of ***Potassium Iodide*** increases the reaction rate for less reactive halides.

(1)

N-Alkenyl and *N*-alkynylsuccinimides are important intermediates in the synthesis of other heterocyclic compounds. Upon partial reduction (***Sodium Borohydride***, EtOH, H^+) to the hydroxylactam and treatment with acid, an *N*-acyliminium cyclization occurs (eq 3).[2]

The ***Copper(I) Iodide*** promoted reaction of potassium succinimide with a vinyl bromide in an aprotic solvent affords the *N*-vinyl derivative (eq 4).[8] *N*-Alkoxycarbonyl derivatives can be prepared with the corresponding alkyl chloroformate (eq 5).[9]

Reactions at the Carbonyl Group.

Addition of Grignard reagents (3 equiv; or first 1 equiv of MeMgCl and then 2 equiv of the more expensive reagent) provides hydroxylactams,[10] which can be reduced with ***Sodium Cyanoborohydride*** at pH 3 to the 5-alkylpyrrolidinone (eq 6).[10a]

For intermolecular Wittig reactions of succinimide with stabilized phosphoranes, high temperatures are necessary and yields are poor.[11]

The intramolecular reaction proceeds somewhat better and can be applied to the synthesis of pyrrolizidine derivatives. *N*-Alkylation of sodium succinimide with bromophosphorane (**1**) and subsequent intramolecular Wittig reaction affords the pyrrolizidinedione (**2**) (eq 7).[12] Another pyrrolizidine compound is obtained upon reaction of sodium succinimide with cyclopropyl derivative (**3**). The reaction presumably proceeds via nucleophilic opening of the activated cyclopropane ring, leading to a stabilized ylide which then undergoes an intramolecular Wittig reaction (eq 8).[13]

Reactions at the α-Methylene Position.

Upon reaction of the dipotassium or disodium salt of succinimide with electrophiles, such as ***Benzyl Chloride***, benzophenone, or methyl benzoate, 2-substituted succinimide derivatives are obtained in moderate yields (eq 9).[14]

Related Reagents.

Glutarimide; ***Phthalimide***.

Sulfamide[1]

(R = H)

[7803-58-9] · $H_4N_2O_2S$ · Sulfamide · (MW 96.13) (R = Et)

[6104-21-8] · $C_4H_{12}N_2O_2S$ · *N,N´*-Diethylsulfamide · (MW 152.25) (R = *n*-Pr)

[19757-10-9] · $C_6H_{16}N_2O_2S$ · *N,N´*-Dipropylsulfamide · (MW 180.31) (R = *t*-Bu)

[13952-67-5] · $C_8H_{20}N_2O_2S$ · *N,N´*-Di-*t*-butylsulfamide · (MW 208.37) (R = $NO_2C_6H_4$)

[19757-13-2] · $C_{12}H_{10}N_4O_6S$ · *N,N´*-Bis(4-nitrophenyl)sulfamide · (MW 338.33)

(useful for synthesis of substituted 1,2,6-thiadiazine 1,1-dioxides,[3] 1,2,5-thiadiazolidine 1,1-dioxides,[7] sulfamoylamidines,[11] and nitriles[12])

Physical Data: R = H, mp 93 °C, dipole moment 3.9 D; R = Et, mp 67 °C; R = *n*-Pr, mp 118 °C; R = *t*-Bu, mp 140 °C; R = $NO_2C_6H_4$, mp 197 °C.

Solubility: R = H, freely sol water, hot alcohol, acetone; more acidic than urea, and can act as a dibasic acid.

Preparative Methods: N,N´-diethylsulfamide is prepared by addition of a solution of ***Sulfuryl Chloride*** (0.889 mol) in petroleum ether, at -30 °C, to a mixture of ethylamine (2.2 mol) and ***Pyridine*** (1.76 mol) in petroleum ether. Stirring at rt followed by acidic workup affords *N,N´*-diethylsulfamide (45% yield). Large alkyl (C_3 to C_6) sulfamides are prepared by addition of a solution of an alkylamine (2.5 mol) in chloroform to a mixture of pyridine (4 mol) and sulfuryl chloride (1 mol) in chloroform at -5 °C. Similar workup as above gives *N,N´*-dialkylsulfamides in 58-69% yield.[1,2]

Handling, Storage, and Precautions: use in a fume hood.

General Discussion.

Sulfamide reacts with 1,3-diketones (eq 1)[3] and β-amino α,β-unsaturated ketones (eq 2)[4] to provide substituted 2*H*-1,2,6-thiadiazine 1,1-dioxides. The reaction of sulfamide with ***Malononitrile*** (eq 3)[5] or cyanogen (eq 4)[6] under acid catalysis yields 3,5-diamino-4*H*-1,2,6-thiadiazine 1,1-dioxides or 3,4-diamino-1,2,5-thiadiazole 1,1-dioxide. 3-Imino-4-substituted 1,2,5-thiadiazolidines[7] can be prepared from sulfamide, aldehydes, and metal cyanides (eq 5).

(1)

R = Me, Ph, *t*-Bu (2)

(3)

(4)

(5)

R	Yield (%)
hexyl	40
4-methoxyphenyl	62
2-pyrrolyl	12

N,*N*′-Cyclic sulfamides are synthesized by heating sulfamide with 1,2- or 1,3-diamines in pyridine or diglyme solvent (eqs 6 and 7).[8,9] Reaction temperature is an important factor in this cyclization, because at lower temperature uncyclized products may be obtained (eq 6).[8]

(6)

(7)

Sulfamide can be used to form eight-membered heterocyclic compounds[10] and the very toxic tetramethylenedisulfotetramine (eqs 8 and 9).[11]

(8)

(9)

N-Sulfamoylamidines,[12] nitriles,[13] and azoalkanes[2] have been prepared by using sulfamide or substituted sulfamides (eqs 10-12).

Related Reagents.

Sulfuryl Chloride; ***N,N´-Sulfuryldiimidazole***.

Sulfene[1]

$H_2C{=}SO_2$

[917-73-7] · CH_2O_2S · Sulfene · (MW 78.10)

(reactive intermediate used for sulfonations and as a partner in [2 + 2], [3 + 2], [4 + 2], [8 + 2], and 1,3-dipolar cycloaddition reactions)

Solubility: sol CH_2Cl_2, THF, Et_2O, MeCN.

Preparative Methods: prepared in situ by reaction of ***Methanesulfonyl Chloride*** and ***Triethylamine*** in a solvent such CH_2Cl_2. The sulfonyl chloride is usually added slowly to a solution of the substrate and Et_3N.[2] Alternatively, sulfene can be generated by the action of fluoride ion on 1-(trimethylsilyl)methanesulfonyl chloride (see ***(Trimethylsilyl)methanesulfonyl Chloride-Cesium Fluoride***). This method has advantages over the amine method when reagents either have a low reactivity with sulfene or high reactivity with the amine.[3]

Handling, Storage, and Precautions: unstable at rt. It has been observed by IR after trapping at -196 °C.[4] The methanesulfonyl chloride commonly used to generate sulfene is toxic, corrosive, a lachrymator, and moisture sensitive. Use in a fume hood.

Sulfonations.

Although sulfene is not stable, it is still useful for the preparation of methanesulfonate esters and other sulfonyl compounds. It will react with H_2O, alcohols, amines, thiols, sulfonamides, imides, and oximes[1a] The most common use of sulfene is in the synthesis of mesylate esters of hydroxy compounds. These esters are typically prepared via the amine method (eq 1). These conditions will allow for the preparation of reactive mesylates provided the temperature is held at 0 °C.[2]

(1)

[2 + 2] Cycloadditions.

The simultaneous discovery that sulfene will undergo cycloaddition with an enamine was one of the first hints at its existence. The reaction with cyclohexanone enamine produced the four-membered ring sulfone (eq 2).[5] The acyclic enamine from propionaldehyde also formed the cyclic sulfone (eq 3).[6]

(2)

(3)

There is no observed stereoselectivity in the reaction of sulfene with enamines of 4-*t*-butylcyclohexanone. This reaction produces a nearly 1:1 mixture of the two diastereomers (eq 4).[7]

(4)

An investigation of asymmetric induction in the sulfene-enamine condensation with an enamine derived from propionaldehyde and (*R*)-2-methylpyrrolidine was conducted. Following Hofmann elimination, the thiete 1,1-dioxide (eq 5) was obtained in 25% ee. The use of (*R*)-(+)-methyl-α-phenethylamine resulted in an opposite sense of induction but the product only had a 6% ee. Attempts to induce asymmetry by using an optically active tertiary amine to generate sulfene were unsuccessful.[8]

(5)

[4 + 2] Cycloadditions.

Sulfene generated using the amine protocol does not undergo reaction with simple alkenes or dienes. However, when cyclopentadiene was reacted with sulfene prepared using the newly developed fluorodesilylation method, the [4 + 2] cycloadduct was obtained in 64% yield (eq 6).[3] The use of the sulfonic anhydride instead of the chloride gave a 75% yield of the cycloadduct.

(6)

Miscellaneous.

Recently, an interesting reaction of sulfene with citreamicin η produced the cyclic β-hydroxy sulfonate in addition to forming the mesylate of the hydroxymethyl group (eq 7).[9] A similar result was observed earlier in an attempt to mesylate the α-hydroxy ketone (eq 8). Instead of stopping at the simple mesylate, the intermediate reacted further to afford the unsaturated sultone.[10]

(7)

(8)

Related Reagents.

(Trimethylsilyl)methanesulfonyl Chloride-Cesium Fluoride.

N-Sulfinyl-*p*-toluenesulfonamide[1]

[4104-47-6] · $C_7H_7NO_3S_2$ · *N*-Sulfinyl-*p*-toluenesulfonamide · (MW 217.29)

(used to generate electrophilic *N*-tosyl aldimines;[4-7] can act as an enophile in ene reactions[2,8] and as a dienophile in Diels-Alder reactions;[10,11] participates in Wittig-type reactions[17])

Alternate Name: 4-methyl-*N*-sulfinylbenzenesulfonamide.

Physical Data: mp 53 °C; bp 130-140 °C/0.06 mmHg.

Solubility: sol benzene, toluene, halogenated solvents.

Form Supplied in: bright yellow solid; commercially available.

Preparative Methods: the most common method of preparing *N*-sulfinyl-*p*-toluenesulfonamide (TsNSO) (**1**) is by heating *p*-toluenesulfonamide with excess ***Thionyl Chloride*** in benzene (eq 1).[2]

An alternative procedure is the treatment of *p*-toluenesulfonamide with *N*-chlorosulfinylimidazole, which is derived from thionyl chloride and ***Imidazole*** (eq 2).[3] The latter method benefits from shorter reaction times and better yields.

Handling, Storage, and Precautions: should be weighed out in a glove bag or dry box, since it readily hydrolyzes to *p*-toluenesulfonamide. Can be prepared just prior to use and used in situ or stored for extended periods of time in an inert environment.

Formation of *N*-Tosyl Aldimines.

A number of years ago it was reported by Kresze that nonenolizable aldehydes could be converted to the corresponding *N*-tosylimine using the title reagent (**1**) in the presence of a Lewis acid.[4] Recently, it has been shown that this transformation can also be effected with enolizable aldehydes both under Lewis acid catalysis at low temperature and thermally.[5] Thus treatment of propionaldehyde with (**1**) leads to the *N*-tosyl aldimine (**2**) or its Lewis acid complex (eq 3).

(3)

The imines (**2**) can be trapped in situ with 1,3 dienes,[5a] organometallic reagents,[5b] allyl silanes,[5c] or reduced with ***Triethylsilane*** (eq 3).[5d] Vinyl silanes also add intramolecularly to *N*-tosylimines in the presence of ***Boron Trifluoride Etherate*** or ***Tin(IV) Chloride*** to give cyclohexenylsulfonamides (eq 4).[6]

(4)

Intramolecular ene-like reactions of Lewis acid complexed *N*-tosyliminium intermediates can be effected to afford cyclization products, presumably via a cationic, stepwise pathway (eq 5).[7]

Ene Reaction.

The ene reaction of (**1**) and β-pinene in benzene at rt to give the *N*-tosylsulfinamide (**3**) (eq 6)[2a] is reversible under these conditions and has been exploited specifically to introduce deuterium into the allylic position of an alkene.

A more reactive *N*-sulfinyl compound, *N*-sulfinylnonafluorobutanesulfonamide, undergoes intermolecular ene reactions with alkenes over 10^3 times faster than the corresponding tosyl derivative (eq 7).[8]

In addition, this perfluoro-*N*-sulfinyl compound undergoes thermal, intermolecular ene reactions with 1-aryl-2-alkanones under neutral conditions to give *N*-sulfinyl-2-oxoalkanesulfonamides in high yields (eq 8).[8a,9]

Diels-Alder Reactions.

N-Sulfinyl compound (**1**) is an effective dienophile in the regioselective [4 + 2] cycloaddition of unsymmetrical dienes.[1b,10,11] For example, 2-substituted dienes were found to yield only 5-substituted dihydrothiazine oxides (eq 9). The cycloaddition of (**1**) with simple 1-substituted 1,3-dienes is often dependent on the reaction temperature. At low temperatures, 3-substituted dihydrothiazine oxides are usually formed as kinetic products, but at higher temperatures the more stable 6-substituted heterocycles are produced (eq 10).[12]

(9)

R = Ph, Cl, Me

R = Ph, *p*-$NO_2C_6H_4$, *p*-$MeOC_6H_4$, Me

(10)

The dihydrothiazine oxides derived from this hetero Diels-Alder process are valuable synthetic intermediates in constructing homoallylic amines and vicinal amino alcohols in a stereorational manner.[11] For instance, in a system involving the diastereoselective synthesis of unsaturated acyclic amines, (**1**) was combined with (*E*,*E*)-tetramethylbutadiene to give cycloadduct (**4**), whereupon hydrolysis and retro-ene loss of SO_2 via a rigid chair-like transition state afforded exclusively the (*E*)-homoallylic amine derivative (**5**) (eq 11).[11,13] Similarly, (*E*,*Z*)-tetramethylbutadiene produced 3,6-dihydrothiazine oxide (**6**), which was hydrolyzed to give (*E*)-homoallylic sulfonamide (**7**).

In a related system involving the diastereoselective synthesis of unsaturated vicinal amino alcohols, the Diels-Alder cycloaddition of (*E*,*E*)-hexadiene with benzyl *N*-sulfinylcarbamate[14] gave a 15:1 mixture of epimeric adducts (eq 12). Ring opening of these cycloadducts with ***Phenylmagnesium Bromide***, followed by the [2,3]-sigmatropic rearrangement of the intermediate allylic sulfoxide in the presence of trimethyl phosphite, yielded the (*E*)-*threo* vicinal amino alcohol derivative (**8**). Similarly, (*E*,*Z*)-hexadiene underwent the *N*-sulfinyl Diels-Alder reaction and subsequent steps to give the (*E*)-*erythro* hydroxy carbamate (**9**) exclusively.

The chiral *N*-sulfinyl carbamate prepared from (+)-camphor (eq 13)[15] displayed high enantioselectivity in the ***Titanium(IV) Chloride*** catalyzed [4 + 2] cycloaddition with 1,3-cyclohexadiene, affording only one cycloadduct. The stereochemistry of compound (**12**) can be rationalized by a cycloaddition occurring through either conformer (**10**) via an *endo* transition state or conformer (**11**) by an *exo* transition state. High levels of asymmetric induction have also been reported in the cycloaddition reactions of *N*-sulfinylcarbamates derived from the chiral auxiliary 8-phenylmenthol.[16]

(13)

(12) 75%

Wittig-Type Reaction.

TsNSO undergoes an interesting Wittig-type reaction with triphenylphosphonium fluorenylide to afford thione *S*-imides in good yields (eq 14).[17]

3-Sulfolene[1]

[77-79-2] · $C_4H_6O_2S$ · 3-Sulfolene · (MW 118.17)

(solid source of butadiene and substituted butadienes used in Diels-Alder reactions;[3] undergoes ready addition reactions and alkylation/aldol reactions[21])

Alternate Names: butadiene sulfone; 2,5-dihydrothiophene 1,1-dioxide.

Physical Data: mp 65 °C; dec above ca. 110 °C.

Solubility: sol water, organic solvents.

Form Supplied in: white solid, widely available.

Handling, Storage, and Precautions: nonflammable and nonhygroscopic, odorless, and indefinitely stable; skin irritant and under investigation as a potential carcinogen[2] (RTECS #XM9100000).

Introduction.

3-Sulfolene (**1**) is a convenient solid source for in situ generation of ***1,3-Butadiene***, for example in Diels-Alder reactions (eq 1).[3] It affords ***Sulfur Dioxide*** and butadiene by a concerted disrotatory[4-6] thermal process. The liberated SO_2 may cause acid-catalyzed reactions (eq 2).[7]

(1)

(2)

(a) butadiene, toluene, 110 °C 45%, 96% de, 99% ee
(b) **(1)**, toluene, 110 °C 77%, 73% de, 72% ee

Under mildly basic conditions, equilibrium is established between the 2-isomer (42%) and 3-isomer (58%).[8,9] For substituted rings, the equilibrium concentrations are strongly substituent dependent. Sulfolene serves as a platform for preparing conjugated dienes (eq 3)[10] by

substitution followed by SO_2 elimination. Very sensitive conjugated dienes such as those of the dendralene type (eq 7)[11] can be prepared in this manner.

Additions to C=C.

Typical electrophilic additions occur readily. The dibromo derivative is a convenient source of the very reactive thiophene dioxide (eq 4).[12]

PhSX and PhSeX give *trans* additions and oxidative removal of PhSeOH affords the substituted 3-sulfolene (eq 5).[13] Dienes such as 2,3-bis(phenylthio)butadiene have been prepared by manipulation of the addition products.[14] Products of peracid oxidation or carbene or nitrene addition afford divinyl ethers, 1,4-dienes,[15] divinylamines,[16] or cyclobutenes[17] by thermal extrusion of SO_2 (eq 6).

(6)

X = CH, N, O

The epoxides are often elaborated further to regenerate a substituted 3-sulfolene (eq 7).

(7)

Apparently anomalous nucleophilic additions actually proceed by prior isomerization to the vinyl sulfone (2-sulfolene) (eq 8). Other processes are also affected by this tautomerism.[8]

(8)

Alkylations and Aldol Reactions.

Substituted (**1**) can be obtained by addition of SO_2 to dienes or nucleophiles to thiophene dioxides,[1] by alkylations of anions derived from (**1**), or by peracid oxidation of substituted 2,5-dihydrothiophenes which occurs regioselectively at sulfur (eq 9).[18,19] The alkyl-substituted dihydrothiophenes are best prepared from vinylphosphonium salts,[18,19] while functionalized systems can be prepared using vinyl phosphonates.[20]

Deprotonation to form a delocalized carbanion occurs under basic conditions. Reactions with electrophiles usually occur α to the sulfone (eq 3) to afford the 2-substituted 3-sulfolene,[21] but electronic and steric effects of existing substituents strongly affect the alkylation regioselectivity.[22] Equilibration with D_2O affords the 2,2,5,5-tetradeutero derivative,[23] which is a convenient source of specifically deuterated butadiene-d_4. This has been used in syntheses of deuterated anthracenes[24] and cyclohexenes,[25] etc. Dialkylation preferentially proceeds to give the 2,5-disubstituted isomer.[26,27] The presence of a 2-trimethylsilyl or -stannyl substituent can be used advantageously to access the 2-monosubstituted or the 2,2-disubstituted system which may be spiro in nature (eq 10).[26,28]

The alkylation stereochemistry controls the geometry of the diene and ultimately the stereochemistry of the Diels-Alder product. The *trans* 2,5-disubstituted isomer is formed fastest but the *cis* isomer is more stable and its thermal decomposition to the (*E*,*E*)-diene is faster than that of the isomeric *trans* isomer to the (*E*,*Z*)-diene. Therefore by heating the *trans* isomer in the presence or absence of small amounts of base, either the (*E*,*E*)- or the (*E*,*Z*)-dienes can be obtained selectively (eq 11).[27]

Other methodologies have been used to obtain the *cis* isomer (e.g. eq 12)[29]

Aldol reactions and acylations[30] occur at the 2-position. Aldol condensations with various heterocyclic aldehydes occur in low yields (ca. 10%), but the products have been used as precursors to conducting polymers (eq 13).[31]

John M. McIntosh

o-Sulfoperbenzoic Acid

[31652-18-3] · $C_7H_6O_6S$ · *o*-Sulfoperbenzoic Acid · (MW 218.20)

(electrophilic reagent which delivers oxygen to alkenes[1])

Solubility: sol water and aqueous acetone.

Form Supplied in: not available commercially.

Analysis of Reagent Purity: iodometry.[2]

Preparative Method: o-sulfobenzoic anhydride and ***Hydrogen Peroxide*** (30%; 1.3 equiv) react in acetone at -4 to 0 °C to furnish *o*-sulfoperbenzoic acid (**1**) in 65-75% yield (eq 1).

Handling, Storage, and Precautions: an aqueous acetone solution of the reagent is quite stable at rt and loss of active oxygen amounts to 1-2% per week. Since the reagent is a peroxide and potentially explosive, care is required in carrying out reactions with it. During workup, check for peroxides before solvent removal.

Anti Hydroxylation of Alkenes.

Reaction of a peroxycarboxylic acid (RCO_3H) with an alkene (**2**) is *syn* stereospecific;[3] the product is the epoxide (**3**) (eq 2). Under favorable conditions (pH of the reaction medium, temperature) the initially formed epoxide (**3**) undergoes *trans* ring opening due to reaction with RCO_2H and furnishes the diol monoester (**4**) or (**5**) (or a mixture of **4** and **5**); saponification of the diol monoester gives the diol (**6**). Peroxyformic acid (H_2O_2/***Formic Acid***) and ***Trifluoroperacetic Acid*** (TFPAA) are the peroxy acids which are normally used to effect the *anti* hydroxylation of alkenes (**2** -> **6**). *Anti* addition of hydroxyl groups to alkenes can also be effected by Prevost reaction, which involves treating an alkene with one equivalent of ***Iodine*** and two equivalents of the silver salt of a carboxylic acid; the monoester of the diol which is obtained is saponified.[4]

(2)

When an alkene is reacted with the peroxy acid (**1**) in aqueous acetone, the *anti* hydroxylation product is obtained directly. Cyclohexene (**8**) is converted to the *trans*-diol (**9**) (eq 3). Reagent (**1**) has been used for the synthesis of (±) γ-rhodomycinone (**11**) via *trans* hydroxylation of the alkene (**10**) (eq 4).[5]

(3)

(8) (9)

(10)

(4)

(11)

It is of interest to note that the electron-deficient alkene maleic acid has been hydroxylated to furnish tartaric acid in 80% yield. Phenylglyceric acid has been similarly prepared from cinnamic acid.

When one of the groups (R^1,R^2,R^3,R^4) attached to the epoxide ring in (**3**) is capable of stabilizing a positive charge on the neighboring carbon, the epoxide can undergo *cis* ring opening.[6]

Epoxidation of Alkenes.

Epoxides have been isolated by reacting alkenes with the peroxy acid (**1**) in the presence of a solid buffer such as ***Sodium Carbonate***. Epoxides have been prepared from α-terpineol and cholesterol in 82% and 89% yields, respectively.

Baeyer-Villiger Reaction.

Baeyer-Villiger reaction of cyclohexanone takes place readily at 0 °C with (**1**) (4-6 h) to furnish hexanolide in 80% yield. Peracid (**1**) did not react with the ketone (**12**) and 4,4-dimethylcholestan-3-one. Reaction of (**12**) with ***Peracetic Acid-Boron Trifluoride Etherate*** furnished the lactone (**13**) in 36% yield.[7]

Sulfur[1]

[7704-34-9] · S · Sulfur · (MW 32.07)

(mild oxidizing agent used for the Willgerodt reaction[2] and dehydrogenation of various organic compounds;[3] its most recent use has been for the in situ generation of carbonyl sulfide[4] from CO for the synthesis of thiocarbamates[5] and other derivatives)

Physical Data: mp 119 °C; bp 444.6 °C; *d* 2.07 g cm^{-3}.

Solubility: insol water; slightly sol alcohol, ether; sol carbon disulfide, benzene, toluene.

Form Supplied in: powder, flakes.

Handling, Storage, and Precautions: store in a closed bottle at ambient temperatures. Chronic inhalation of dust can cause irritation of the mucous membranes.

Willgerodt Reaction.

The first reaction of this type was carried out by Willgerodt[6] on 1-acetylnaphthalene to give what was later identified as 1-naphthylacetamide (eq 1).[7] This was accomplished by using an ammonium polysulfide solution in a sealed tube at 210-230 °C for 3 or 4 days. The corresponding acid salt always accompanied the amide. Another limitation is that the harsh conditions used in the original procedure gave yields of only 20-50%.

(1)

The Kindler[8] modification of the reaction allows this to be carried out under anhydrous conditions at lower temperatures. The thioamide can be isolated and then hydrolyzed to the acid or reduced to the amine. Even with this important change, the reaction saw little application because it had to be carried out in an autoclave as in eq 2.[9]

(2)

The adoption of ***Morpholine*** as both the solvent and base led to a procedure that could be used at ambient pressure (eq 3).[10a] With the relatively mild temperatures (bp 129 °C), certain functionalities on the aryl ring like nitro, amino, hydroxy, and acetoxy groups can tolerate these conditions.[10b]

(3)

The original Willgerodt conditions found a use in converting aliphatic aldehydes and ketones to the amides in poor to moderate yields (eqs 4-7).[11]

(4)

(5)

(6)

(7)

This reaction can also be applied to unconventional substrates for conversion into thioamides (eq 8).[12] It was found that methylphenylcarbinol, β-phenylethyl alcohol, β-phenylethyl acetate, and methylbenzylcarbinol failed to give appreciable amounts of amide when heated with a typical Willgerodt reagent at 160 °C. Unexpected results were seen with β-substituted acrylic acids (eqs 9 and 10).[13] Apparently, the carboxyl group was eliminated to give an amide with one less carbon atom.

(8)

(9)

(10)

Other functionalities were found to allow the Willgerodt reaction to work on substrates that yield phenylacetamide in an attempt to elucidate the mechanism.[14] Poor to good yields were obtained. A thorough review of this reaction was written by Carmack and Spielman in 1946.[15]

Dehydrogenation.

This reaction is another important use of elemental sulfur in organic chemistry. Sulfur is the reagent of choice for the dehydrogenation of hydroaromatic compounds because it is simpler than ***Selenium*** and may be preferred over selenium or catalytic dehydrogenation. The following example is from a systematic study that compared the three methods (eq 11).[16]

(11)

S	230-240 °C	+	-
Pd/C	260-280 °C	+	+
Se	330-350 °C	-	+

The dehydrogenation of aromatizable hydrocarbons works well enough to have been incorporated into an undergraduate experiment (eq 12).[17]

In this experiment it was necessary to use less than the theoretical amount of sulfur because the brilliantly blue product, guaiazulene, reacts with sulfur to form an intractable brown product.

More complex structures can be selectively dehydrogenated to give fair yields of products, as the example from Haede et al. illustrates (eq 13).[18]

Other heterocycles are good substrates for the dehydrogenation reaction (eqs 14-18).[19-23]

(15)

(16)

(17)

(18)

Carbonyl Sulfide Generation.

The use of ***Carbon Monoxide*** and sulfur leads to the generation of carbonyl sulfide (***Carbon Oxysulfide***), which is electrophilic enough to be attacked by nucleophiles present in the reaction mixture. A new synthesis of ureas based upon this intermediate was put forth (eq 19).[24] This reaction starts out with each of the reactants in a different phase, liquid, gas, and solid, respectively. This simplifies the industrial process, and the in situ oxidation of carbon monoxide leads to a ***Phosgene*** synthon without the formation of ammonium salts as byproducts. In an experiment using only ***Ammonia***, carbon monoxide, and sulfur in methanol, Franz and Applegath[25] found carbonyl sulfide making up about 30% of the product gases when the reaction was run at 150 °C. Ammonium thiocarbamate was obtained in large quantities when the temperature of the reaction was held overnight at 25-30 °C with 700 psi of CO. The isocyanate group was detected by IR in an alcoholic solution of ammonium thiocarbamate (eq 20). This method has also been used to synthesize unsymmetrical ureas, with the authors postulating that aryl isocyanates are formed first which then react with primary or secondary alkyl amines to give the 1-aryl-3-alkyl- or 1-aryl-3-dialkylureas in good yield (eq 21).[26]

(19)

This sulfur-assisted carbonylation has also been applied to the synthesis of 4-hydroxycoumarins,[27] which entails the direct formation of a C-C bond without a transition metal catalyst (eq 22).

This reaction has also been applied to the synthesis of *S*-alkyl carbonothioates, which requires the use of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** and an alkylating agent (eq 23).[28]

Application to the synthesis of carbonates has been accomplished by inclusion of a stoichiometric amount of ***Copper(II) Chloride*** in the second step (eq 24).[29]

More complex heterocycles like 4-alkylidene-2-oxo-1,3-oxathiolanes have been synthesized by a related method (eq 25).[30]

The same group has developed a variation of this technique which provides the *S*,*S*-dialkyl dithiocarbonates from water, sulfur, carbon monoxide, and alkyl halides.[31] The use of a catalytic amount of selenium provides a synthesis of *S*-alkyl thiocarbamates from amines, carbon monoxide, sulfur, and alkyl halides that can be carried out under ambient pressure (eqs 26 and 27).[32] The intermediate (**1**) can undergo decomposition to carbonyl selenide which then undergoes facile exchange with sulfur to give carbonyl sulfide, which will then react as usual. At higher pressures of CO (10 atm) and 1 mol % selenium these authors can synthesize *S*-alkyl carbonothioates.[33]

Sulfide and Polysulfide-Derived Reactions.

The largest and broadest application of sulfur in organic synthesis is in the generation of sulfides and polysulfides from elemental sulfur. These polysulfides can act as nucleophiles, reductants, and oxidants. A brief survey of these various aspects of sulfides and polysulfides is in order.

Elemental sulfur is believed to dissociate in liquid ammonia according to the following series of equations (eq 28).

(28)

Sato obtained a mixture of products upon attempted reduction of 4-nitrotoluene in liquid ammonia (eq 29).[34]

(29)

The use of sulfur as an oxidant is more common and several examples exist. The oxidation of aromatic sulfinates with elemental sulfur in amines gives thiosulfonates almost quantitatively.[35] Oxidation of benzylic carbons to aldehydes is observed with 4-nitrotoluene in a water-ethanol solvent at reflux (eq 30).[36] The oxidation of both methyl groups of *m*- and *p*-xylene gave high yields of isophthalic and terephthalic acids in 87 and 96% yields, respectively (eqs 31 and 32).[37]

(30)

(31)

(32)

Strong nucleophiles are generated upon the reaction of excess ammonia and elemental sulfur. These have been used to prepare arenesulfinamides from *S*-(4-nitrophenyl) *S*-substituted phenyl sulfoximides (eq 33).[38] The same conversion has been accomplished using 4-nitrophenyl substituted phenyl sulfoxides.[39]

(33)

The generation of anhydrous lithium sulfide is easily accomplished by reaction of two equivalents of ***Lithium Triethylborohydride*** with sulfur in THF at room temperature. This reacts well with a variety of electrophiles that require strictly anhydrous conditions to give good yields of products. The alkali metal disulfides are not commercially available and the methods for their preparation [Li^0, NH_3(l)] are difficult and give mixtures of polysulfide salts. The reaction of one equivalent of the hydride reagent with sulfur yields the lithium disulfide which gives high yields of disulfide products.[40] More recently a phase transfer catalytic method of generating the disulfide in a water/chloroform mixture has been used with electrophiles that can tolerate the presence of water (eq 34).[41]

(34)

When sulfur reacts with ***Sodium Borohydride*** in an appropriate solvent such as THF, the sulfurated hydride $NaBH_2S_3$ is formed. The reagent is most useful for its special reactivity and not necessarily as a sulfurating agent (eqs 35 and 36). A synopsis of its range of reactions was published more than 20 years ago.[42]

(35)

Miscellaneous Reactions.

Sulfur will react with organometallic reagents to replace a metal-carbon bond with a sulfur-carbon bond. Since sulfur is divalent, a thiolate results which is generally not useful. In some cases, however, the thiolate is essential for further reactivity. The utility of lithium thioalkynolates in the synthesis of alkenes is outlined below (eqs 37 and 38).[43]

Using the same intermediate alkynylthiolates, one can prepare thioamides (eq 39).[44] This sequence works for selenium derivatives as well.

A tetrahydrothiophene synthesis was accomplished by treating the carboalumination product of ***Triethylaluminum*** and terminal alkenes with sulfur (eq 40).[45]

Diazo compounds react with sulfur to give thioketones. Monothioanthraquinones can be synthesized from the reaction of 10-diazoanthrones with sulfur in DMF at 130-150 °C (eq 41).[46]

Sulfur is less reactive towards carbenes than selenium and so selenium is used in a catalytic fashion first to react with carbene-like compounds (isocyanides in this case), and then sulfur replaces the selenium to give an isothiocyanate (eq 42).[47] Using this method, cyclohexyl isothiocyanate was synthesized in 89% yield using 5 mol % of Se and 1.2 equiv of S. The reaction could be run with 0.5 mol % Se with only a modest lengthening of the reaction time.

(42)

An unusual aspect of sulfur chemistry is the reaction of alkenes with elemental sulfur (eqs 43 and 44). The reaction of sulfur with norbornene in the presence of ammonia in DMF at 110 °C results in a selective and stereospecific sulfuration.[48] The *exo*-3,4,5-trithiatricyclo[5.2.1.0^{2,6}]decane forms in about 86% yield.

(43)

(44)

Sulfur has also been used to oxidize inorganic compounds to increase their electrophilic nature. A simple synthesis of ***Triphenylphosphine*** that does not rely on organometallic reagents has been published by Olah (eq 45).[49] This Friedel-Crafts reaction fails with ***Phosphorus(III) Chloride*** as well as its corresponding oxide. There exists an unfavorable disproportionation between triphenylphosphine, diphenylchlorophosphine, and phenyldichlorophosphine. The oxychloride does not give the triphenylphosphine oxide. The phosphorus sulfochloride gives the corresponding triphenylphosphine sulfide, which is easily reduced.

(45)

Olah also used ***Trifluoromethanesulfonic Acid*** catalysis for the electrophilic sulfuration of cycloalkanes.[50] Elemental sulfur was heated in a stainless steel autoclave with excess cyclopentane in triflic acid at 150 °C for 12 h. This gave dicyclopentyl sulfide in 46% isolated yield (eq 46).

Sulfur Dichloride

[10545-99-0] · Cl_2S · Sulfur Dichloride · (MW 102.97)

(electrophilic addition to alkenes and dienes;[1] synthesis of heterocycles from eneimines and nitriles;[2] and electrophile for the synthesis of sulfides[3])

Physical Data: mp -121 °C; bp 59 °C; *d* (20 °C) 1.621 g cm^{-3}; *n*20D 1.5570.

Solubility: sol dichloromethane, *n*-hexane, CCl_4, benzene; reacts violently with H_2O, acetone, DMSO, DMF.

Form Supplied in: dark-red liquid. Techgrade (80%), major impurity is S_2Cl_2. Also 1.0 M in CH_2Cl_2. Very pungent, chlorine-like odor. Readily decomposes to S_2Cl_2 and Cl_2.

Preparative Methods: can be synthesized from $S_{(5)}$ or S_2Cl_2.[4]

Purification: pure SCl_2 can be obtained from ***Disulfur Dichloride*** and ***Chlorine*** by distillation from ***Phosphorus(III) Chloride***.

Handling, Storage, and Precautions: distilled SCl_2 is stable for a few days in glass with a few drops of PCl_3. Air and H_2O sensitive. Incompatible with acids, bases, alcohols, plastics, amines. Avoid contact with metals. Corrosive; lachrymator. Harmful if swallowed, inhaled, or absorbed through the skin. Inhalation can be fatal. Possible carcinogen.

Electrophilic Addition to Dienes.

Sulfur dichloride is an extremely reactive electrophile towards alkenes. Under dilute conditions, sulfur dichloride reacts with unconjugated dienes (eq 1) to give dichloro sulfur-bridged bicyclic compounds.[1a-c,5]

The proposed 1,2-episulfonium ion intermediate (eq 2) explains the selectivity of chlorine addition and their high lability. Yields for the addition of SCl_2 to dienes[1] and for subsequent halide displacements are closely tied to how readily the sterically demanding 1,2-episulfonium ion is formed.[6,7]

Common transformations of the SCl_2-diene addition products are chloride replacement,[6a] chloride displacement to form episulfides,[6b,7a] and oxidation of the sulfide bridge to a sulfone bridge.[1] In a few cases, the addition of SCl_2 has been extended to conjugated dienes.[8]

The reactivity of sulfur dichloride towards alkenes is exploited in the synthesis of thiaalkanams and thiaisoalkanams in which SCl_2 is used as a sulfur transfer agent to nonconjugated diene systems (eq 3).

(3)

Select examples of five and seven-membered sulfur-nitrogen heterocycles can be synthesized in modest yield.[9,10]

Reaction with Unsaturated Heteroatom Functionality.

Lewis acid catalysis of sulfur dichloride additions to nitriles leads to the formation of 1,2,4-thiadiazoles.[2] As seen in eq 4, a major side reaction of this process is the chlorination of the aromatic substituents.

(4)

Lewis acid catalysts for this reaction are ***Tin(IV) Chloride***, ***Aluminum Chloride***, ***Iron(III) Chloride*** and ***Antimony(V) Chloride***. Nitriles with α-hydrogens do not yield any thiadiazole product, but rather give disulfur species from deprotonation (eq 5).[2]

(5)

Conjugated imines such as 1-*t*-butyl-4-phenyl-1-aza-1,3-butadiene react with 0.5 equiv of sulfur dichloride to give isothiazoles[11] in high yield, 86-91%, based on sulfur (eq 6). Spectroscopic evidence verifies that two equivalents of the imine are required to form the 2:1 salt intermediate before cyclization.

Unlike 1-azadienes, 2-azadienes react with high yields in a 1:1 molar ratio and show no spectroscopic evidence of a 2:1 salt intermediate (eq 7).

Miscellaneous Applications.

Other applications include the synthesis of dialkynyl sulfides, (RC&tbond;C)S,[12] the heterocyclic adducts of alkynes,[13] the synthesis of novel macrocyclic polysulfur compounds,[13b] and one-pot syntheses of benzothiophenes.[14] Considerable literature has also been devoted to the formation of episulfides from hindered alkenes,[15] with limited success (see also ***Disulfur Dichloride***).

Sulfur Dioxide

O=S=O

[7446-09-5] · O_2S · Sulfur Dioxide · (MW 64.07)

(reacts with 1,3-dienes in reversible cheletropic addition;[2,3] SO_2 extrusion from 2,5-dihydrothiophene 1,1-dioxides generates 1,3-dienes,[9,10] *o*-quinodimethanes;[4,5] inserts into carbon-metal bonds;[14-16] reacts with ylides to give heterocycles;[17,18] electrophilic promoter of Mannich reactions;[20,21] catalyst for isomerization of alkenes,[24] dienes,[22,23] and nitrile oxides;[25] involved in sulfonic acid[26] and sulfonyl chloride synthesis;[27] reacts with Wittig reagents or α-silyl carbanions to give sulfines;[28,29] reacts with polyenes,[30,31] cyclopropanes;[32] reduces pyridine *N*-oxides[36] and ozonides;[37] solvent for superacid-promoted reactions[41])

Physical Data: [1] mp -75.5 °C; bp -10.0 °C; *d* (liquid) 1.434 g cm^{-3} at 0 °C; *d* (vapor, 0 °C) 2.264 g cm^{-3}.

Solubility: sol H_2O, alcohol, acetic acid, sulfuric acid, benzene, acetonitrile.

Form Supplied in: colorless liquid or pungent, nonflammable gas; supplied in small cylinders; widely available.

Handling, Storage, and Precautions: corrosive irritant to respiratory system, skin, eyes; mildly toxic by inhalation; teratogenic; reacts violently with numerous substances; use only in well-ventilated fume hood.[1]

Reversible Cheletropic Addition of SO_2 to 1,3-Dienes and Analogs.

Much of the chemistry of SO_2 involves its reversible cheletropic addition to 1,3-dienes to give 2,5-dihydrothiophene 1,1-dioxides (sulfolenes) (eq 1).[2] Much less commonly observed is the alternative, hetero-Diels-Alder cycloaddition mode, also reversible, leading to the sultine (sulfinic ester) structure.[3] At low temperature this latter mode can be kinetically favored with reactive 1,3-dienes, but the cheletropic addition is generally favored thermodynamically.[3]

(1)

Trapping and regeneration of reactive *o*-quinodimethanes via cheletropic addition and extrusion of SO_2 has proven useful in heterocyclic (eqs 2 and 3)[4] and carbocyclic systems (eq 4).[5] Thermal extrusion of SO_2 from the cyclic sulfones yielded the reactive *o*-quinodimethanes, which were trapped with various dienophiles.

(2)

(3)

(4)

Linear cheletropic addition of SO_2 to conjugated diallenes affords 2,5-bis(alkylidene)-2,5-dihydrothiophene 1,1-dioxides via the disrotatory process shown (eq 5).[6]

(5)

Similarly, addition of SO_2 to 3-methyl-1,2,4-pentatrienyl-1-phosphonate (eq 6)[7] or 5-methyl-1,3,4-hexatrienyl-3-phosphonate esters (eq 7)[8] affords the corresponding phosphorylated alkylidene-2,5-dihydrothiophene 1,1-dioxides.

(6)

(7)

Chemical separation of a mixture of 1,3-diene geometric isomers was accomplished by selective cheletropic addition of SO_2 to the *trans* diastereomer (eq 8).[9] Chromatographic purification of the dihydrothiophene and thermolysis cleanly afforded *trans*-9,11-dodecadien-1-yl acetate, a sex pheromone of the female red bollworm moth.

(8)

An elaboration of this tactic is shown in eq 9 for the synthesis of (*E*)-1-substituted 1,3-dienes and (*E*,*E*)-1,4-disubstituted 1,3-dienes.[10] The tricyclic sulfone (**1**) can be metalated and alkylated once or twice, giving (**2**) or (**3**), respectively. Thermolysis in the gas phase at 650 °C resulted in sequential loss of cyclopentadiene and SO_2 to provide the dienes in 91-98% isomeric purity.

(9)

Acyclic Sulfone Synthesis.

Addition of Grignard and organolithium reagents to SO_2 is known to produce salts of sulfinic acids.[11] An example extending this to the enolate derived from camphor is shown in eq 10.[12] The intermediate β-keto sulfinate was alkylated to afford the β-keto sulfone shown in

modest yield.

(10)

A high yield synthesis of diphenyl sulfone results from the phenylation of SO_2 with pentaphenylbismuth (eq 11),[13a] which proceeds more readily than the corresponding reaction with ***Triphenylbismuthine***.[13b]

(11)

Insertion of SO_2 into Carbon-Metal Bonds.

Sulfur dioxide inserts into cyclohex-2-enylstannanes in chloroform via a *syn* S_E' process (eqs 12 and 13).[14] The γ-*syn* stereospecificity is lost upon changing the solvent to methanol.

(12)

(13)

The bis(η^1,η^3-allyl)palladium phosphine complex in eq 14 inserts SO_2 to provide the *S*-sulfinate derivative, which undergoes reductive elimination to a 1:1 mixture of diallyl and allyl 2-propenyl sulfone upon treatment with ***Carbon Monoxide***.[15]

Triethylaluminum etherate reacts with SO_2 to afford the aluminum salt of ethylsulfinic acid (eq 15).[16]

Heterocycle Synthesis.

Combination of a dihaloketene, a Schiff base and SO_2 to give 5,5-dihalo-4-oxo-1,3-thiazolidine 1,1-dioxides is exemplified in eq 16.[17] These products can be dehalogenated or heated to extrude SO_2, yielding β-lactams.

Generation of a thiocarbonyl ylide in liquid SO_2 from a Δ^3-1,3,4-thiadiazoline results in a regioselective 1,3-dipolar cycloaddition, giving 1,2,4-oxadithiolane 2-oxides (eq 17).[18]

Reaction of the functionalized formamidine in eq 18 with SO_2 in the presence of ***Triethylamine*** affords the 1,2,4-oxathiazole 2-oxide shown.[19]

Use of SO_2 in Mannich Reactions.

Treatment of 2,5-dimethylphenol with SO_2 apparently allows the formation of a half-sulfite ester (eq 19). Addition of an aminol ether affords selective *o*-aminoalkylation.[20] Without SO_2, the major pathway of Mannich reaction with 2,5-dimethylphenol leads to the *p*-amino-alkylation product.

Sulfur dioxide serves as an electrophilic reagent for activating bis(dialkylamino)methanes or alkoxy(dialkylamino)methanes for Mannich reactions with 2-methylfuran (eq 20), *N*-methylpyrrole (eq 21), and indole (eq 22).[21] Dipolar adducts of SO_2 and the bis(amino)methane or alkoxyaminomethane reagents are proposed as intermediates, rather than free iminium salts.

(22)

Isomerization of Dienes, Alkenes, and Nitrile Oxides by SO_2.

Treatment of ergosterol acetate with SO_2 in pyridine causes rearrangement of the 5,7-diene to the 6,8(14)-diene isomer (eq 23).[22] This result is fundamentally different from related sterol diene rearrangements catalyzed by acid. A consistent rationale for this SO_2-induced isomerization is shown.

(23)

Addition of SO_2 to (5*Z*)- and (5*E*)-vitamin D_3 (**4**) yields the sulfolene derivatives (**5**) (eq 24).[23] Thermal extrusion of SO_2 from (**5**) affords isotachysterol$_3$ (**6**), alone or mixed with isovitamin D_3 (**7**). Treatment of sulfone (**5**) with methanolic ***Potassium Hydroxide*** or ***Alumina*** results in the formation of (5*E*)-vitamin D_3.

Regiospecific alkene isomerization has been effected by SO_2 with a variety of acyclic and cyclic alkenes, including β-pinene (eq 25) and methylenecyclohexane (eq 26).[24a] The sequence of steps presented in eq 26 has been advanced to rationalize the process. Interestingly, if the reaction is attempted in the presence of D_2O, alkene migration is completely suppressed, and all allylic hydrogens in the substrate alkene are exchanged for deuterium.[24b]

SO_2 catalyzes the conversion of nitrile oxides to isocyanates via a dipolar cycloaddition followed by regioisomeric loss of SO_2 and rearrangement (eq 27).[25] The intermediate 1,3,2,4-dioxathiazole 2-oxides can be isolated, or converted to hydroxamic acids upon hydrolysis.

Sulfonic Acid and Sulfonyl Chloride Synthesis.

Condensation of benzimidazole with SO_2 and an aldehyde or ketone results in the formation of benzimidazoylalkylsulfonic acids (eq 28).[26]

A wide variety of substituted anilines, especially those with electron-withdrawing substituents, can be converted to substituted arenesulfonyl

chlorides via their diazonium salts (eq 29).[27]

(29)

Synthesis of Sulfines.

Reaction of SO_2 with fluorenylidene-triphenylphosphorane in benzene gave the corresponding sulfine (eq 30).[28] In a related fashion, reaction of SO_2 with an α-silyl carbanion leads to the sulfine product (eq 31).[29] Thus alkylidenation of SO_2 is possible with Wittig or Peterson reagents.

(30)

(31)

Miscellaneous Addition Reactions of SO_2.

A 1,6-addition of SO_2 to *cis*-3-hexatriene gives 2,7-dihydrothiepin 1,1-dioxide in high yield (eq 32).[30] Fully unsaturated thiepin dioxides can be elaborated from this and analogous triene-SO_2 adducts, or the triene can be regenerated by thermolysis.

(32)

A cyclo(copolymerization) between dimethyldiallylammonium chloride and SO_2 afforded a 3:1 mixture of the 10- and 20-membered macrocycles containing pyrrolidinium and sulfonyl groups (eq 33).[31]

Aryl-substituted cyclopropanes undergo γ-sultine formation when treated with SO_2 in protic acid. The ring opening is regioselective, but the substituted 1,2-oxathiolane 2-oxides are formed as mixtures of diastereomers (eq 34).[32]

(34)

Bicyclo[5.1.0]octa-2,5-diene reacts with dry SO_2 at 150 °C in toluene to afford a moderate yield of the bicyclic sulfone shown (eq 35).[33]

(35)

Photoaddition of 4,5-pyrenedione and SO_2 proceeds to give the cyclic sulfate (eq 36) in high yield.[34]

(36)

Cheletropic [$_{\pi}2_s + {}_{\pi}2_s + {}_{o}2_s$] addition of SO_2 to norbornadiene provides a nearly quantitative yield of the tetracyclic sulfone in eq 37.[35] Of several homoconjugated dienes examined, only norbornadiene exhibited this mode of reactivity.

(37)

Miscellaneous Reactions of SO_2.

Two examples of SO_2 serving as a reductant are illustrated in eqs 38 and 39. Pyridine *N*-oxides are deoxygenated under mild conditions in moderate yields.[36] The ozonide derived from sulfolene (itself a product of SO_2 plus butadiene) is reduced by SO_2 to afford the acetal. Treatment of this with ammonium chloride gives 4*H*-1,4-thiazine 1,1-dioxide (eq 39).[37]

(38)

(39)

Vinyldiazomethane reacts with SO_2 leading, via the presumed *cis*-divinyl episulfone intermediate, to the dihydrothiepin 1,1-dioxide through a Cope rearrangement (eq 40).[38]

(40)

Sulfur dioxide also serves as an electrophilic agent for the conversion of orthoesters to esters and dialkyl sulfites. For example, ***Triethyl***

Orthoacetate gives only ethyl acetate and diethyl sulfite as products upon treatment with SO_2 (eq 41).[39]

Formation of dithioacetals and *O*,*S*-acetals from ketones and aldehydes can be catalyzed by SO_2, with yields comparable or superior to protic catalysts.[40] Finally, liquid SO_2 has served as a solvent for a variety of superacid-mediated cyclization, rearrangement, and sulfinylation reactions.[41]

Related Reagents.

Copper(I) Chloride-Sulfur Dioxide.

Sulfuric Acid[1]

H_2SO_4

[7664-93-9] · H_2O_4S · Sulfuric Acid · (MW 98.09)

(widely used protic acid solvent and catalyst;[1] can oxidize aliphatic and aromatic hydrocarbons;[1d] can sulfonate aromatic rings[1b])

Physical Data: mp 3 °C (98% sulfuric acid); bp 290+ °C; *d* 1.841 g cm^{-3} (96-98% sulfuric acid).

Solubility: sol water.

Form Supplied in: liquid sold in aqueous solutions of concentrations 78, 93, 95-98, 99, 100 wt %. Sulfuric acid (fuming) contains 18-24% free ***Sulfur Trioxide***.

Preparative Method: 100% sulfuric acid can be prepared by adding 95-98% sulfuric acid (concentrated sulfuric acid) to fuming sulfuric acid.[2]

Protic Acid Solvent and Catalyst.[3]

Sulfuric acid is an inexpensive, easily handled protic acid, solvent, and catalyst. Typical workup procedures for reactions in H_2SO_4 involve aqueous dilution prior to product separation.

Hydrolyses.

Nitroalkanes are readily available and their hydrolysis is an important synthetic tool. Hydrolysis of primary nitroalkanes with H_2SO_4, the most effective catalyst, gives carboxylic acids.[4] The salts of primary or secondary nitroalkanes, when hydrolyzed with H_2SO_4, form aldehydes or ketones (also see ***Titanium(III) Chloride***).[5] This reaction has been applied to β,γ-unsaturated nitroalkenes as a mild route to α,β-unsaturated aldehydes.[5c] An improved two-layer method treats the nitronate anion with H_2SO_4 in pentane; the product aldehyde dissolves in pentane and avoids contact with acid.[5d]

Vinyl halides are hydrolyzed by H_2SO_4 in the Wichterle reaction, a route to 1,5-diketones in which 1,3-dichloro-*cis*-2-butene serves as a methyl vinyl ketone equivalent.[6] The hydrolysis can be controlled to avoid acid-catalyzed aldol condensation (see condensations, below).[7]

Sulfuric acid is a useful catalyst for cleavage of protecting groups,[8] and has been used to cleave TBDMS protecting groups in the presence of TBDPS groups.[9] A useful method for resolution of chiral ketones involves formation and separation of chiral hydrazones followed by hydrolysis with 10% H_2SO_4.[10]

Hydrations.

Alkyne hydration generally involves mercury(II) ion catalysts.[1b] However, H_2SO_4 hydrates the alkyne (**1**) and also catalyzes a subsequent regio- and stereoselective cyclopentanone annulation via the Nazarov cyclization (eq 1).[11] Nitriles can be selectively hydrated to amides using strong H_2SO_4.[12]

(1)

64% 10% (1)

Additions.[1a,b]

The Ritter reaction, in which nitriles add to alkenes in conc H_2SO_4, is a useful procedure for preparation of amides of *t*-alkylcarbinamines.[1b] As applied to the *threo* α-halo alcohol (**2**), retention of stereochemistry is observed (eq 2).[13] H_2SO_4 catalyzes carbonylation of α,β-unsaturated aldehydes in a general synthesis of 3,4-dialkyl-2(5*H*)-furanones (eq 3).[14] Michael additions to conjugated ketones are catalyzed by H_2SO_4 (see condensations, below).[7]

(2) (2)

(3)

Sulfuric acid catalyzes the regioselective methoxybromination of α,β-unsaturated carbonyl compounds with ***N-Bromosuccinimide*** (eq 4); ***Boron Trifluoride***, ***Acetic Acid***, and ***Phosphoric Acid*** were unsatisfactory catalysts.[15] Sensitivity to acid catalyst was also noted in the intramolecular diazo ketone cyclization of β,γ-unsaturated diazomethyl ketone (**3**) (eq 5); H_2SO_4 gave a rearrangement product (**4**).[16]

(4)

Dehydrations and β-Eliminations.[1b]

Useful stereospecific H_2SO_4-catalyzed *anti* elimination of *threo*-β-hydroxyalkylsilanes is stereoselective for the *cis*-alkene, while ***Potassium Hydride*** mediated *syn* elimination affords selectively *trans*-alkenes (eq 6).[17]

Electrophilic Substitutions.[1a]

Sulfuric acid catalyzes nitration of aromatic carbocycles[1a,b] and heterocycles.[18] Benzenes with *meta*-directing groups can be alkylated by primary and secondary alcohols in H_2SO_4, ***Polyphosphoric Acid***, or 85% phosphoric acid; even nitrobenzene can be alkylated by ethanol.[19] H_2SO_4 catalyzes the α-amidoalkylation reaction[20] and is especially useful for Friedel-Craft ketone synthesis using anhydrides.[1a] For acylations with acids, PPA avoids charring, sulfonation, and ester cleavage and is generally a preferred reagent (***Hydrogen Fluoride*** and ***Trifluoromethanesulfonic Acid***).[21] Keto acids and phenol react selectively to give phenolic esters with PPA, but ring substitution products with H_2SO_4.[22]

The utility of H_2SO_4 as a catalyst for the substitution of alkanes is evidenced in the formation of carboxylic acids by *trans* carboxylation (eq 7);[23] the hydrocarbon must have a tertiary hydrogen and the acid source for CO must be a tertiary alkyl acid.

(7)

Carbonyl Reactions.[1a,b]

H_2SO_4 is considerably more effective than ***p-Toluenesulfonic Acid*** for conversion of anthrone to 9-alkoxyanthracenes.[24] A practical procedure for regioselective formation of pyridoxine dimethyl acetal which replaces anhydrous TsOH utilizes 96% H_2SO_4 (eq 8).[25]

(8)

H_2SO_4 catalyzes esterification of highly hindered aromatic acids,[1b] and it catalyzes the formation of *N*-acylamides from acid anhydrides and amides.[26] A rapid esterification procedure involves reaction of primary, secondary, or tertiary alcohols with acids in H_2SO_4 using ultrasound.[27]

Condensations.

Sulfuric acid is a useful reagent for the synthesis of heterocycles by dehydrative cyclization.[18,28] Yields in the Skraup quinoline synthesis, which utilizes sulfuric acid as the condensing agent, are remarkably sensitive to H_2SO_4 concentration.[29]

Sulfuric acid-catalyzed aldol condensations of 1,5-diketones in H_2SO_4 are under thermodynamical control[30] and products may differ from those of base-catalyzed reactions (eqs 9 and 10).[7,31,32]

(9)

(10)

Rearrangements.

The choice of acid catalyst can influence skeletal rearrangements; for example, H_2SO_4 and H_3PO_4 can afford different products in polyene cyclizations (eq 11).[33] The reductive rearrangement of alcohol (**5**) gave different products in H_2SO_4 and H_3PO_4 (eq 12).[34]

(11)

(12)

For functional group isomerizations, H_2SO_4 is useful in the Beckmann rearrangement of oximes and the Hofmann-Loffler-Freytag reaction of *N*-haloamines and amides.[1b] H_2SO_4 is superior to BF_3 in the isomerization of α-epoxycyclopentanones to α-hydroxycyclopentenones (eq 13).[35] The formation of 2-oxoadamantane from bicyclo[3.3.1]nonane-2,6-diol is highly sensitive to acid concentration and requires 95% H_2SO_4 for optimum yield.[36]

(13)

Choice and strength of acid catalyst can have regiochemical consequences. H_2SO_4-catalyzed Wallach rearrangement of azoxybenzenes provides mainly *p*-hydroxyazobenzenes, while ***Antimony(V) Chloride*** gives mainly *ortho* products.[37] Regiochemistry in the Schmidt reaction of ketones can be dependent upon H_2SO_4 concentration (eq 14).[38]

(14)

H_2SO_4 can catalyze stereochemical isomerizations (eq 15); thermodynamic conditions afforded *cis*-lactone (**6**); the diastereomeric *cis*-lactone is formed under kinetic control with ***Formic Acid*** or ***Tin(IV) Chloride***.[39] If a chiral center is present, enantioselective allylic alcohol rearrangement[40] and enantioselective alkene cyclization can be catalyzed by H_2SO_4 (eq 16).[41]

(15)

(6)

(16)

Catalyzed Oxidations.[1b]

Sulfuric acid is the catalyst of choice for ***m-Chloroperbenzoic Acid*** oxidation of unreactive 11-keto steroids,[42] and it catalyzes the $NaBO_3$ oxidation of alkenes in Ac_2O to *trans*-diols.[43]

Dehydrogenation.

H_2SO_4 acts as solvent, catalyst, and selective oxidizing agent in the formation of 2-pyridones from cyclic cyano ketones (eq 17).[44] Aromatization of unsaturated carbocyclic rings can be effected using H_2SO_4 and heat,[1d] and α-alkylcyclohexanones can be converted to *o*-alkylphenyl acetates by reaction using H_2SO_4 (eq 18).[45] Intermolecular dehydrogenation of an aminonaphthalene to a biphenyl occurs

with 66% H_2SO_4 (eq 19).[46]

(17)

(18)

(19)

Hydroxylation.

Hydroxylation of nitro and hydroxyl-substituted fused aromatic rings can be effected with sulfuric acid under forcing conditions.[1d] Adamantanone has been prepared from adamantane using 98% H_2SO_4 as oxidant.[47]

Sulfonation.

Sulfonation of β-carbolines occurs in concentrated H_2SO_4; pyrrole, indole, and carbazole do not sulfonate under the conditions.[48]

Formation of Reducing Agents.

An easily scaled-up method to convert amino acids to amino alcohols without affecting *N*-tosyl or *N*-Cbz groups uses H_2SO_4/***Sodium Borohydride*** (see also ***Aluminum Hydride***).[49]

Sulfur Tetrafluoride[1]

[7783-60-0] · F_4S · Sulfur Tetrafluoride · (MW 108.07)

(fluorinating agent for many functional groups;[1] can form other fluorinating agents[1])

Physical Data: mp -121.0 °C; bp -38 °C; *d* (liq, -78 °C) 1.95 g cm^{-3}, *d* (solid, -183 °C) 2.349 g cm^{-3}.

Solubility: sol benzene.

Form Supplied in: colorless gas.

Handling, Storage, and Precautions: is about as toxic as phosgene. It is also a strong irritant and a corrosive agent that should be handled with utmost care in a well-ventilated fume hood. Sulfur tetrafluoride reacts violently with water. The reagent can be handled in a well-dried Pyrex glass apparatus up to about 30 °C with only nominal attack. Stainless steel, copper, and nickel are all inert to SF_4 at both ordinary and elevated temperatures. First-aid treatment of hydrogen fluoride burns has been described.[2] A reactor design for safe, routine handling of SF_4 and HF is available.[3]

Introduction.

Sulfur tetrafluoride is one of the more common fluorinating agents. It converts hydroxyl, carbonyl, and carboxylic groups into mono-, di-, and trifluoromethyl groups, respectively (eq 1).

(1)

Fluorination of Alcohols.

Sulfur tetrafluoride is suitable for fluorination of alcohols in high yield, provided that the alcohols are roughly equal to or greater than tropolone in acidity (pK_a = 6.42).[1a] Decomposition is often a problem during SF_4 fluorination of aliphatic alcohols and various alternative fluorinating agents have been introduced, e.g. ***N,N-Diethylaminosulfur Trifluoride*** (DAST),[4] SeF_4-pyridine,[5] and HF.amine (see ***Hydrogen Fluoride***) reagents.[6]

(2-Furyl)methanol and 2-phenylethanol react with SF_4 at -50 °C in the presence of ***Triethylamine*** or ***Pyridine*** in CH_2Cl_2 or cyclohexane to give (2-fluoromethyl)furan and 2-fluoro-1-phenylethane, respectively (eqs 2 and 3).[7]

(2)

(3)

Fluorination of vicinal diols such as ethanediol and 1,2-propanediol under mild conditions leads to the formation of 2-fluoro fluorosulfites, which are readily hydrolyzed to give the respective fluorohydrins (eqs 4 and 5).[8] A different pattern is observed in the reaction of 3,3,3-trifluoro-1,2-propanediol with SF_4 (eq 6).

(4)

(5)

(6)

Selective substitution of the hydroxyl group by fluorine can also be realized in the reactions of SF_4 with 1,3- and 1,4-diols (eqs 7 and 8).[9]

(7)

(8)

Reaction of glycerol with SF_4 in anhydrous HF under mild conditions leads unexpectedly to 3-fluoro-1,2-propylene sulfite (eq 9).[10] Treatment of *myo*-inositol with SF_4 and anhydrous HF yields a novel compound, the cyclic sulfite ester of 2β,3β-difluoro-7-oxabicyclo[2.2.1]heptane-5α,6α-diol (eq 10).[11]

(9)

(10)

Fluorination of Aldehydes and Ketones.

Aldehydes lacking α-hydrogens react with SF_4 at high temperatures (150-200 °C) to afford *gem*-difluoride compounds (eq 11).[1a] Aldehydes possessing α-hydrogen atoms can be fluorinated by SF_4 at lower temperatures (to prevent decomposition) and yields of the resulting difluorides are generally low (eq 12).[1a]

(11)

(12)

Fluorination of ketones by SF_4 is exemplified as shown in eq 13.[12] Either one or both carbonyl groups can be converted into difluoromethylene by the control of reaction temperature and time.

(13)

Aliphatic β-diketones react with SF_4 to form the corresponding di- and tetrafluoro derivatives and also compounds containing double and triple carbon-carbon bonds (eq 14).[13]

(14)

Fluorination of Carboxylic Acids.

Aliphatic carboxylic acids react with SF_4 at low temperature to give 1,1,1-trifluoroalkanes as well as the unexpected α,α,α´,α´-tetrafluoroalkyl ethers (eq 15).[1b] The yields of tetrafluoroalkyl ethers depend primarily on their stability in the reaction medium because they are subject to protolytic decomposition by HF (eq 16).

Sulfur tetrafluoride fluorination of aromatic carboxylic acids is the method of choice for introducing the trifluoromethyl substituent (eqs 17-19).[1b,14]

Preparation of Other Fluorinating Agents.

Sulfur tetrafluoride is used to prepare a very useful fluorinating agent, ***N,N-Diethylaminosulfur Trifluoride*** (DAST) (eq 20).[1b]

DAST is a convenient reagent to replace the hydroxyl group and carbonyl oxygen of aldehydes or ketones with one and two fluorine atoms, respectively.

Sulfur Trioxide[1]

[7446-11-9] · O_3S · Sulfur Trioxide · (MW 80.07)

(highly reactive electrophilic agent for replacing (i) a hydrogen atom or other substituent bonded to carbon by an SO_3H or derived sulfo group, forming a carbon-sulfur bond (called sulfonation), (ii) a hydrogen atom bonded to oxygen by an SO_3H group, forming an oxygen-sulfur bond (called sulfation or *O*-sulfonation, and (iii) a hydrogen atom bonded to nitrogen by an SO_3H group, forming a nitrogen-sulfur bond (called sulfamation or *N*-sulfonation);[1a,1b] reagent for cycloaddition to carbon-carbon double bonds;[1a,2] moderate oxidizing agent[3])

Physical Data: mp 16.8 °C; bp 44.7 °C; *d* 1.970 g cm^{-3}.

Solubility: miscible in all proportions with liquid SO_2; sol dichloromethane, chloroform, carbon tetrachloride, 1,1,1-trichloroethane (some react slowly with SO_3, e.g. CCl_4 yields phosgene);[4] SO_3 in dilute solution (<=10 mol %) in SO_2, CCl_3F, and CCl_4 is present as monomer; at higher concentrations the cyclic trimer is also present;[5] sol nitromethane (reacts at 0-15 °C slowly, and at 25-40 °C sometimes violently to give nitromethanesulfonic acid and other compounds);[6] modestly sol 1,4-dioxane; the resulting complex is unstable;[7,8] the solid adduct can decompose violently on standing for some time at rt;[9] reacts violently with water.

Form Supplied in: liquid/solid, containing 1% of stabilizer to prevent polymerization, in sealed glass container.

Handling, Storage, and Precautions: in the absence of a suitable stabilizer, SO_3 shows a strong tendency to polymerize when exposed even to traces of moisture. Use in a fume hood. Keep the container of SO_3 tightly closed and dry. Upon handling open to air, the liquid gives off fumes of a sulfur trioxide-sulfuric acid spray! Reacts violently with water. Causes burns to the skin; is very toxic by inhalation and if swallowed. Contact with combustible material may cause fire. Wear eye and face protection and suitable protective clothing. In case of contact with eyes, rinse immediately with plenty of water, immediately remove all contaminated clothing and seek medical advice.

Organic Sulfur Trioxide Reagents.

Apart from SO_3 and its less reactive addition compounds, formed with suitable Lewis bases[10] such as ***Pyridine***,[11] ***Trimethylamine***,[12] ***Dimethyl Sulfide***,[13] sulfolane,[14] ***Triphenylphosphine***,[15,16] triphenylbismuthine,[16] triphenylphosphine oxide,[17] tricylohexyl-[16] and trimethylphosphine oxide,[17] triethyl phosphate,[18] ***Dimethyl Sulfoxide***,[19] ***N,N-Dimethylformamide***,[20] ***Nitromethane***,[21] 1,4-dioxane,[1a-d] and 1,4-oxathiane,[22] there is a class of sulfonating sulfate ester reagents, e.g. dimethyl polysulfate ($MeOSO_2(OSO_2)_nOMe$)[23] and trimethylsilyl chlorosulfate.[24,25] There are also the protic sulfonating reagents, concentrated aqueous and fuming ***Sulfuric Acid***, and ***Fluorosulfuric Acid***, ***Chlorosulfonic Acid***, and acetylsulfuric acid.[1d] The reactivity order of the Lewis base complexes of SO_3 varies strongly. On the basis of direct experimental evidence[26] and of relative $pK_{B\text{-}SO_3}$[27] and pK_{BH^+}[28] values, the sulfonation reactivity is suggested to increase in the order trimethylamine-SO_3 < ***Sulfur Trioxide-Pyridine***, DMSO-SO_3 < *N,N*-dimethylformamide-SO_3, ***Trimethyl Phosphate***-SO_3 < ***Sulfur Trioxide-1,4-Dioxane*** < sulfolane-SO_3, nitromethane-SO_3.

Aromatic Sulfonation.

Reaction of an arene (ArH) with SO_3 leads to sulfonation with formation of arenesulfonic acids ($ArSO_3H$). Mechanistically two different stages can be recognized, viz. primary and secondary sulfonation.[1f,29,30] In the primary stage, arenepyrosulfonic acids (ArS_2O_6H) are formed. A pyrosulfonic acid is a mixed anhydride, liable to disproportionate to give arenesulfonic anhydride and $H_2S_2O_7$.[30b,31-34] Working up the reaction mixture with water and heating the resulting aqueous mixture to reflux for 15 min leads to complete hydrolysis of the pyrosulfonic acids and sulfonic anhydrides to the corresponding arenesulfonic acids.[31] Sulfonylation to give diaryl sulfones is another possible complication in reaction of arenes with SO_3, especially when using deactivated arenes at high concentrations.[1f]

The steric requirements of a sulfonic acid group are very similar to those of a *t*-butyl group and prevent sulfonation *ortho* to a *t*-butyl group. Sulfonation of *t*-butylbenzene with SO_3 gives 98% of the 4-sulfonic acid (4-S), and that of *m*-di-*t*-butylbenzene gives 98% of the 5-S.[35] Reaction of *p*-di-*t*-butylbenzene with SO_3 in CCl_3F yields 58% of *p*-*t*-butylbenzenesulfonic acid by direct sulfo-de-*t*-butylation.[35]

Sulfonic acid isomer distribution data for the SO_3 sulfonation are available for alkylbenzenes[36] and their halogeno derivatives;[37] phenol and anisole,[31,38] and their methyl,[38,39] halogeno,[38,40] and hydroxy and methoxy derivatives;[32,41] and naphthalene,[36] and its methyl,[42] and hydroxy and methoxy derivatives.[34,43] SO_3 sulfonation isomer distribution data are also available for a number of polycyclic aromatic hydrocarbons and 1,6-methano[10]annulenes, including some alkyl derivatives.[36]

Deviating Sulfonation Behavior of 9-Alkylanthracenes.

Reaction of 9-methylanthracene with SO_3 in dioxane leads exclusively to methyl sulfonation to give sulfonic acid (**1**) quantitatively.[44] Under comparable conditions, 9-*t*-butylanthracene gives δ-sultone (**2**).[45a] Sulfonation of 9-pentylanthracene gives predominantly sulfonic acid (**3**) with some (**4**).[45b] The α-alkenyl-γ-sulfonic acid (**3**) is formed via the corresponding 9-alkenylanthracene as an intermediate.[45c]

(1) R = H
(4) R = Bu

(2)

(3)

Positional Selectivity.

Judging from the data for toluene,[46] *o*-xylene,[47] 1-methylnaphthalene,[42a,48] phenol,[38,49] anisole,[38,49] and 2,3-dihydrobenzofuran[50] and -pyran,[50] the positional selectivity is significantly greater for sulfonation with SO_3 than with sulfuric acid containing 90 wt % H_2SO_4.

For the sulfonation of an (alkyl)arene with SO_3 in differing solvents, the variation in the isomer distribution is limited.[14,51] With phenol and anisole the *ortho*:*para* sulfonation ratio is significantly larger when using CH_2Cl_2 than the complex-forming solvents nitromethane and dioxane.[31] With CH_2Cl_2 the SO_3 forms instead a complex with the C(sp^2) oxygen of the substrate which, as result of intramolecular transfer of SO_3, leads to enhanced *ortho* sulfonation. With substituted phenols and anilines, subject to the positions of the other substituents, the positional selectivity changes very significantly on varying the [SO_3]:[substrate] from <=1.0 to &egt;4.0 (Table 1).

Table 1 Sulfonation of Phenol and Aniline Derivatives in Nitromethane at 0 °C

Substrate[a]	SO_3 (equiv)	Product mixture composition (%)[a]
2-MeO-P[41]	1.0	4-S (76) 5-S (24)
	4.0	(19) (81)
	4.0[b]	(<2) (>98)
3,5-Me_2-P[39]	0.9	2-S (89) 4-S (11)
	4.0	(25) (75)
2,6-Me_2-P[40b]	0.9	3-S (<2) 4-S (>98)
	6.0	(77) (23)
2,6-Me_2-A[40b]	1.0	3-S (<2) 4-S (>98)
	8.0	(87) (13)

[a] P, A, and S stand for phenol, aniline, and SO_3H, respectively.
[b] Reversed addition

As for the phenol derivatives, this illustrates the importance of the initial sulfation equilibrium (k_1, k_{-1}) (eq 1). Applying <=1.0 equiv SO_3 the effective substrate species being sulfonated is the hydroxyarene H-Ar-OH (k_2), the OH substituent of which is strongly activating and *para* directing, whereas on using a large excess of SO_3 the entity undergoing sulfonation is the corresponding aryl hydrogen sulfate H-Ar-OSO_3H (k_3), the OSO_3H substituent being deactivating and *para* (+ *ortho*) directing. This may accordingly lead to a different substitution pattern. The sulfation equilibrium (k_1, k_{-1}) constant is temperature dependent. Phenol with 1.0 equiv SO_3 in nitromethane at -35 °C is rapidly sulfated to give phenyl hydrogen sulfate quantitatively, which at &egt;0 °C isomerizes to phenol-4-S as the only eventual product.[38] The increase of both the 2- to 3-S ratio in the reaction of *p*-methoxyphenol with 1.5 equiv SO_3,[41] and the 2- to 4-S ratio in the reaction of 1-naphthol with 1.0 equiv SO_3[43a] with increasing reaction temperature, were ascribed to the increase in the k_{-1}/k_1 ratio.

Sulfonation of Unsaturated Aliphatic Compounds.

Sulfur trioxide reacts vigorously with linear[52] and branched[53] alkenes to give rise to β-sultones as the primary sulfonation products.[1a,1b,2] Since neat SO_3 is too reactive, complexes of SO_3 with dioxane[8] or pyridine[11] are used to moderate the sulfonation reaction. The formation of β-sultone is stereo- (*syn*) and regioselective, obeying Markovnikov's rule. However, these β-sultones are thermally unstable at rt and their rearrangement leads to complex mixtures of alkenesulfonic acids and γ- and δ-sultones. Yields of the isolated alkenesulfonic acids (eq 2)[54] and sultones (eq 3)[53] vary considerably with the alkene structure and reaction conditions. Halogenated,[1h] in particular fluorinated,[1i] ethylenes react with SO_3 to give relatively stable halogenated β-sultones. This cycloaddition of SO_3 at the double bond proceeds in a regioselective way (eq 4).[55]

(2)

(3)

(4)

Reaction of an alkene with an excess of SO_3 gives a cyclic sulfonate-sulfate anhydride, also referred to as carbyl sulfate or pyrosulfate (eq 5).[56] This carbyl sulfate is formed by a slow insertion of SO_3 into the intermediate β-sultone.[52a] The complex of sulfur trioxide with dimethyl sulfide reacts with alkenes and alkynes to afford sulfobetaines in good yields (eq 6).[13,57] These sulfobetaines are produced by nucleophilic attack of the dimethyl sulfide on the initially formed β-sultones.

(5)

R = H, 94%; Me, 94%; 2,6-$Cl_2C_6H_3$, 96%

(6)

Conjugated dienes are sulfonated by sulfur trioxide reagents to give β-unsaturated δ-sultones (eq 7). The yields vary strongly; they increase with the number of alkyl substituents at the 2- and 3-positions of the alkadiene.[58]

(7)

Functionalized alkenes containing a phenyl or carboxylic acid group at appropriate distance from the double bond undergo intramolecular cyclization during the sulfonation.[59] On reaction of (*E*)-4-hexenoic acid[59a] with SO_3 a sulfo-δ-lactone is formed (eq 8), and a Friedel-Crafts type cyclization is observed on sulfonation of (*E*)-5-phenyl-2-pentene[59b] (eq 9); both cyclizations proceed quantitatively and stereospecifically.

(8)

(9)

Sulfonation of Saturated Aliphatic Compounds.

Sulfur trioxide reacts with aliphatic acids[60] or esters[61] to give, initially, insertion of SO_3 into the carboxylic acid or ester group, followed by sulfonation at the α-carbon (eq 10). Reactions of aldehydes and ketones with SO_3 also afford the α-sulfonated products.[62]

(10)

R^1 = H, alkyl; R^2 = H, alkyl

It should be noted that sulfonation of linear alkylbenzenes, linear long-chain α-alkenes, and fatty esters and the sulfation of fatty alcohols by SO_3-air mixtures are widely applied processes in industry for the production of surfactants.[63]

Related Reagents.

Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine; ***Sulfur Trioxide-1,4-Dioxane***; ***Sulfur Trioxide-Pyridine***.

Sulfur Trioxide-1,4-Dioxane[1]

(*x* unspecified)

[54287-50-2] (*x* = 1)

[20769-58-8; 35346-47-5] · $C_4H_8O_5S$ · Sulfur Trioxide-1,4-Dioxane · (MW 168.19) (*x* = 2)

[52922-31-3] · $C_4H_8O_8S_2$ · Sulfur Trioxide-1,4-Dioxane · (MW 248.26) (*x* = 3)

[52922-32-4] · $C_4H_8O_{11}S_3$ · Sulfur Trioxide-1,4-Dioxane · (MW 328.33)

(useful for effecting Beckmann rearrangements;[8] sulfonation of alkenes[11] and arenes[16])

Physical Data: mp 75 °C,[2] but almost never isolated.

Solubility: generated as a solution in dioxane, with or without other solvents.

Preparative Methods: the *Organic Synthesis* procedure[2] involves reaction of ***Sulfur Trioxide*** (as Sulfan B) with dioxane in 1,2-dichloroethane. The complex precipitates and is used immediately. An alternate procedure involves treatment of dioxane with $ClSO_3TMS$,[3] itself prepared by reaction of ***Chlorotrimethylsilane*** and ***Chlorosulfonic Acid***.[4]

Handling, Storage, and Precautions: reacts vigorously with water, alcohols, etc. It has been reported to decompose violently upon standing at rt[2] or upon heating to 75 °C.[5] The chemistry is essentially that of SO_3 with some attenuation in reactivity. Safety precautions in the handling of SO_3, which can be an unexpectedly strong oxidant, should be followed.[1c]

General.

Sulfur trioxide forms addition complexes of varying stability and reactivity with Lewis bases. The stronger the base, the more stable and less reactive is the complex. The reactions of these complexes are essentially those of SO_3 and so it is possible to tune the reactivity of SO_3 to suit the reaction or substrate of interest. Frequently used bases, in order of decreasing reactivity of their SO_3 complexes, are ***N,N-Dimethylformamide***, 1,4-dioxane, ***Pyridine***, and ***Trimethylamine***.[1c] The dioxane adducts are hydrolyzed instantly in cold water, whereas the pyridine adduct is stable in aqueous solution. Dioxane-SO_3 adducts with the stoichiometry of 1:1, 1:2, 1:3, and 1:4 have all been identified. The second and third equivalents of SO_3 in the 1:2 and 1:3 complexes are much more reactive than the first. The following paragraphs refer specifically to the 1:1 complex.

Sulfation Reactions.

Reactions of alcohols proceed with extraordinary ease.[1c] When aromatic nuclei are present, simple control of stoichiometry is sufficient to prevent aromatic substitution. In many cases, reaction of the dioxane-SO_3 complex with amines (sulfamation) is too vigorous to be convenient and a tamer (pyridine-SO_3) complex is preferable. The OH group undergoing sulfation may be part of

another group, e.g. an oxime.[6,7] The oxime-*O*-sulfonate may occasionally be isolated, but more commonly is directly transformed into the amide (Beckmann rearrangement) by heating (eq 1).[8]

(1)

Sulfonation of Alkenes.

Alkenes undergo sulfonation. The initial product is the cyclic β-sultone which is formed by a concerted mechanism[9] and stereospecifically.[10] These are rapidly hydrolyzed in the presence of water or alcohols. Products range from 2-hydroxysulfonic acids to vinyl or allyl sulfonic acids (eq 2).[1c,11-13]

(2)

Sulfonation of Carbonyl Compounds.

Carboxylic acids form acyl sulfates which rearrange into α-sulfo acids. Similarly, aldehydes and ketones sulfonate in the α-position.[14] Aryl-substituted alkanoic acids sulfonate α to the acid without aromatic substitution. This is contrary to their reaction with ***Sulfuric Acid***, which affords ring-sulfonated products.

Sulfonation of Aromatic Compounds.

Cerfontain and co-workers have published many papers dealing with the mechanism of this reaction.[1b,15] Benzene and its derivatives do not react unless highly activated. Polycyclic aromatics react via sultones which may be isolated or may open to give sulfonic acids. For example, anthracene affords the 9-sulfonic acid;[16] 9-alkylanthracenes afford principally side-chain sulfonated materials,[17] whereas alkyl substitution on ring A leads to sultones whose structures depend on the substitution pattern (eq 3).[18] The isomeric composition of the sulfonic acid products may differ substantially from that obtained using sulfuric acid. Dioxane-SO_3 is the reagent of choice for the sulfonation of moderately acid-sensitive aromatics (e.g. thiophene),[19] but it is still too reactive to use with ***Furan*** and pyrrole. The patent literature is replete with references to sulfonation of various polymers using SO_3 in various for ms, but this is beyond the scope of this report.

Related Reagents.

Sulfur Trioxide; ***Sulfur Trioxide-Pyridine***.

John M. McIntosh

University of Windsor, Ontario, Canada

Sulfur Trioxide-Pyridine

[26412-87-3] · $C_5H_5NO_3S$ · Sulfur Trioxide-Pyridine · (MW 159.18)

(forms sulfate esters which can be displaced with hydride; useful in displacement reactions of allylic alcohols which cannot be converted to halides; used with DMSO for oxidation of alcohols)

Physical Data: mp 175 °C.

Solubility: sol DMSO; slightly sol ether, $CHCl_3$, CCl_4.

Form Supplied in: crystalline white solid; widely available.

Preparative Methods: reaction of ***Chlorosulfonic Acid*** and ***Pyridine*** in $CHCl_3$[1a,b] or reaction of ***Sulfur Trioxide*** and pyridine.[1c]

Handling, Storage, and Precautions: corrosive; reacts quantitatively with hot H_2O to give pyridine and sulfuric acid. Use in a fume hood.

General Discussion.

Addition of the title complex to farnesol (**1**) in THF at 0 °C and stirring of the suspension results in formation of the sulfate (**2**) (eq 1). Addition of ***Lithium Aluminum Hydride*** in THF then gives the hydrocarbon (**3**) (eq 2). [2a] Other alcohols are converted similarly.[2] Reaction with glucose gave glucose-6-sulfate (**4**) isolated as the barium salt (eq 3).[3a] Sulfonation of indole occurs on treatment with the reagent (eq 4).[3b]

(1)

Related Reagents.

Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine; ***Sulfur Trioxide***; ***Sulfur Trioxide-1,4-Dioxane***.

Sulfuryl Chloride

SO_2Cl_2

[7791-25-5] · Cl_2O_2S · Sulfuryl Chloride · (MW 134.97)

(widely used chlorinating agent;[1] oxidizing agent;[32] dehydrating agent;[30] esterification catalyst[31])

Physical Data: bp 68-70 °C.

Solubility: miscible with most organic solvents.

Form Supplied in: commercially available in 97-98% purity.

Analysis of Reagent Purity: bp.

Purification: fractional distillation.

Handling, Storage, and Precautions: is highly toxic, corrosive, and acts as a lachrymator. It reacts violently with water to liberate hydrogen chloride gas. Sulfuryl chloride is incompatible with DMSO, DMF, and ethers. This reagent should only be handled in a chemical fume hood using proper protective equipment.

Chlorination of Alkanes.

Hydrocarbons can be chlorinated using sulfuryl chloride by either radical or ionic processes. In the radical mediated process developed by Kharasch and Brown,[1] a mixture containing an excess of the alkane with sulfuryl chloride and a catalytic amount of ***Dibenzoyl Peroxide*** in a suitable solvent such as carbon tetrachloride is heated, initiating chlorination and concomitant evolution of hydrogen chloride and sulfur dioxide. With simple alkanes a mixture of positional isomers is obtained.

Radical chlorination of benzylic positions using sulfuryl chloride proceeds with good selectivity over less activated sites of reaction (eq 1).[1] This reaction can be facilitated by transition metal complexes[2] or zeolites.[3]

Certain substituted alkanes can also be selectively chlorinated by this method.[4] A good example is Lampman and Aumiller's synthesis of 3-chlorocyclobutanecarboxylic acid (eq 2).[5]

Ionic chlorination of alkanes can be accomplished by heating a mixture of alkane and excess sulfuryl chloride in sulfolane (eq 3).[6] In these chlorinations the reaction mixture is shielded from light to prevent the initiation of radical processes. Since alkanes are more readily chlorinated by this method than sulfolane, competing solvent chlorination is not a problem.

Reactions with Alkenes.

Alkenes react exothermically with sulfuryl chloride to give vicinal dichlorides in generally good yields (eq 4).[7]

A mixture of sulfuryl chloride and *N*-methylpyrrolidine can be used to convert styrene into styrylsulfonyl chloride (eq 5).[8]

β-Chloro methyl sulfides are produced by the action of ***Dimethyl Sulfide***/sulfuryl chloride/***Dimethyl Sulfoxide*** in acetonitrile on alkenes (eq 6).[9] It is thought that this reagent combination generates methanesulfenyl chloride, which undergoes exclusive *trans* addition to the alkenes. The initially formed anti-Markovnikov adducts slowly rearrange to Markovnikov products.

(6)

Chlorination of Epoxides.

Sulfuryl chloride reacts with cyclohexene oxide and ***Pyridine*** in refluxing chloroform to give 99% *cis*-1,2-dichlorocyclohexane in 70% yield.[10]

Chlorination of Alkynes.

Many alkynes react with this reagent via a homolytic pathway to give the corresponding (*E*)- and (*Z*)-dichloroalkenes in good to moderate yields.[11] The ratio of isomers obtained is kinetically controlled and varies depending on the relative size of the alkyne substituents.

Chlorination of Aromatics.

Sulfuryl chloride reacts with aromatic derivatives under mild conditions to afford ring chlorinated products.[12] For example, ethyl 4-hydroxybenzoate reacts at both the 3- and 5-positions when heated with excess sulfuryl chloride. Ester hydrolysis followed by decarboxylation gives 2,6-dichlorophenol (eq 7).[13]

(7)

Regioselective *para*-monochlorination of various phenols has been accomplished using sulfuryl chloride in combination with either ***Aluminum Chloride*** or ***Iron(III) Chloride*** as catalyst.[14]

Thiophenes react with sulfuryl chloride to give 2- or 5-chlorinated products with high selectivity.[15] This reagent has been applied with excellent results to the chlorination of 2-thienylamines. For example, the antihistamine methapyrilene can be converted to chlorothen in 84% yield (eq 8).[16]

(8)

Aromatic hydrocarbons can be perchlorinated using a reagent composed of sulfur monochloride (5 g), sulfuryl chloride (850 mL), and aluminum trichloride (2.5 g).[17] This reagent combination has been used to prepare highly strained aromatic chlorocarbons, including perchlorotoluene, perchloro-*p*-xylene, and perchlorophenanthrene.

α-Chlorination of Active Methylene Compounds.

Ketones are selectively chlorinated at the α-position with sulfuryl chloride to form products consistent with reaction between the reagent and the thermodynamic enol.[18] For example, only 2-chloro-2-methylcyclohexanone is obtained from 2-methylcyclohexanone (eq 9).[19] Direct chlorination of this ketone with ***Chlorine*** gives mixtures of chloro compounds.[20]

(9)

Many other activated methylene compounds can be α-chlorinated with sulfuryl chloride. Examples include the conversion of ***Ethyl Acetoacetate*** to ethyl 2-chloroacetoacetate in 93-97% yield;[21] the chlorination of pyruvic acid in 96-98% yield;[22] the α-chlorination of ε-benzoylaminocaproic acid;[23] and the transformation of *N*-benzoyl-ε-caprolactam to *N*-benzoyl-α-chloro-ε-caprolactam in 89% yield.[24] Aldehydes react with this reagent to give α-chlorinated products that often react further to form cyclic ether trimers and linear polyethers.[25,26]

4-Ene-3-oxo-steroids react with excess sulfuryl chloride in pyridine solution cleanly to give 4-chloro-4-ene-3-oxo-steroids (eq 10).[27] When testosterone acetate is treated with excess sulfuryl chloride in anhydrous ether, 2α,6β-dichlorotestosterone acetate is obtained as the major product.[28]

(10)

Conversion of Alcohols to Chlorides.

Kozikowski and Lee[29] report that secondary alcohols can be converted to chlorides with retention of configuration via methyl xanthate formation followed by reaction with sulfuryl chloride (eq 11).

(11)

Dehydrating Agent.

A combination of sulfuryl chloride and pyridine is useful as a dehydrating reagent in the synthesis of shikimic acid derivatives (eq 12).[30]

(12)

Esterification Catalyst.

Sulfuryl chloride catalyzes formation of methyl and benzyl esters of *N*-acylated amino acids and peptides at room temperature in yields ranging from 48-98% without causing racemization.[31]

Oxidation of Pyrroles.

This reagent is used to oxidize the methyl group at the 5-position of alkyl 3,4-dialkyl-5-methyl-2-pyrrolecarboxylates. Depending on reaction conditions, one can obtain either the ester (eq 13),[32] the carboxylic acid,[33] the aldehyde,[34] or the dichloromethyl derivative.[35]

(13)

Reactions with Sulfides.

Sulfuryl chloride reacts with methyl sulfides to give chloromethyl sulfide derivatives (eq 14).[36]

(14)

With α-methylthioalkyl ethers, the corresponding α-chloroalkyl ethers are obtained in high yields.[37] Similarly, α-chloroalkyl esters are obtained from α-phenylthioalkyl esters (eq 15).[38] Styrene is added to remove the benzenesulfenyl chloride that is also formed in the reaction.

(15)

The facile α-chlorination of sulfides by sulfuryl chloride[39] has been used as a means of dehydrogenating 2,5-dihydrothiophenes.[40] This reaction is successfully employed in the commercial synthesis of the artificial sweetener thiophenesaccharin (eq 16).[41]

(16)

A reaction sequence involving α-chlorination of dibenzyl sulfides followed by a Ramberg-Bäcklund-like extrusion of sulfur produces diarylethylenes (eq 17).[42]

(17)

3-Phenylthio-2-azetidinones are converted to 3-chloro-3-phenylthio-2-azetidinones in 78-95% yield via a Pummerer-type mechanism. Hydrolysis by moist silica gel in the presence of catalytic ***Zinc Chloride*** provides the α-keto-β-lactams in 85-90% yield (eq 18).[43]

(18)

When alkyl sulfides are treated with sulfuryl chloride at -78 °C, the intermediate chlorosulfonium salts thought to be involved in formation of α-chloro sulfides can be hydrolyzed by treatment with ethanol at -70 °C and then at 25 °C to provide sulfoxides in high yield (eq 19).[44] Alternatively, the oxidation can be performed by dropwise addition of sulfuryl chloride to a stirred mixture of the sulfide and wet silica gel in dichloromethane.[45] The latter method has also been recommended as a convenient means of thioacetal oxidative cleavage, giving the carbonyl compounds in nearly quantitative yields.[46]

(19)

Reaction of benzyl thioethers with sulfuryl chloride can result in cleavage to form sulfenyl chlorides and benzyl chlorides. An example is Kharasch and Langford's preparation of 2,4-dinitrobenzenesulfenyl chloride (eq 20).[47]

(20)

Reaction with Thiols, Disulfides, and Thioesters.

Sulfinyl chlorides can be conveniently prepared in high yield by the action of sulfuryl chloride in acetic acid on disulfides (eq 21)[48] or thiols[49] at low temperature. Similarly, thioesters are rapidly converted to sulfinyl chlorides in high yields by sulfuryl chloride in acetic anhydride at -10 °C.[50]

(21)

Similarly, sulfenyl chlorides can be prepared from disulfides in carbon tetrachloride[51] and from thiols in pentane by treatment with sulfuryl chloride[52] in the presence of ***Triethylamine***. The reaction of thioesters with sulfuryl chloride in carbon tetrachloride has been used in the synthesis of optically active sulfenyl chlorides (eq 22).[53]

(22)

Chlorination of Sulfoxides.

Sulfoxides are rapidly α-monochlorinated by sulfuryl chloride at -78 to 0 °C in dichloromethane containing CaO.[54] Longer reaction times lead to α,α-dichlorination. Sulfoxides with two available sites of reaction undergo selective chlorination to form the more highly substituted chlorides. α-Chlorination of sulfoxides can also be effected using SO_2Cl_2/pyridine/CH_2Cl_2.[55]

α,β-Unsaturated Ester Synthesis.

β-Hydroxy sulfoxides react with sulfuryl chloride to form alkenes. This reaction has been used to synthesize α,β-unsaturated esters (eq 23).[56] The products obtained from aldehydes in this synthesis have the (*E*) configuration, whereas ethyl methyl ketone gives a 1:1 mixture of geometric isomers.

(23)

Chlorination of Sulfones.

Unlike the reaction with sulfides and sulfoxides, chlorination of sulfones using sulfuryl chloride is slow and occurs mostly at β-, γ-, and δ-positions. Sulfolane is quantitatively converted to β-chlorosulfolane (eq 24).[57]

(24)

Synthesis of Sulfonyl Chlorides and Sulfamides.

Alkyllithiums react with sulfuryl chloride in pentane at -65 to -20 °C to give sulfonyl chlorides in moderate yields.[58] Aromatic sulfonyl chlorides can be prepared from aryllithiums by reaction with sulfur dioxide to form the sulfinate salts followed by oxidation with sulfuryl chloride (eq 25).[59]

(25)

Sulfuryl chloride oxidizes thiols to sulfonyl chlorides in the presence of potassium nitrate or ***Silver(I) Nitrate*** in ***Acetonitrile*** at 0 °C (eq 26).[60] This transformation probably occurs via initial formation of the sulfenyl chloride followed by conversion to a sulfenyl nitrate and further oxidation.

(26)

N-Monoalkyl amidosulfonyl chlorides are produced by the reaction of this reagent with primary amine hydrochlorides in refluxing acetonitrile with an appropriate Lewis acid (eq 27).[61]

(27)

Treatment of alkylamines[62] or anilines[63] in pyridine with sulfonyl chloride results in formation of the corresponding sulfamides (eq 28).

(28)

Synthesis of 2-Aminobenzothiazoles.

Phenylthioureas react with sulfuryl chloride to give 2-aminobenzothiazoles (eq 29).[64]

Other Transformations.

Sulfuryl chloride can be used to prepare *n*-butyl sulfate by heating the reagent with 2 equiv of *n*-butyl sulfite and removing the *n*-butyl chloride formed by distillation.[65]

Sulfuryl chloride oxidizes benzoin to benzil via a cyclic dienol ester that decomposes to extrude sulfur dioxide.[66]

N,N´-Sulfuryldiimidazole[1]

[7189-69-7] · $C_6H_6N_4O_2S$ · *N,N´*-Sulfuryldiimidazole · (MW 198.23)

(reagent for the generation of imidazolylsulfonates which function as leaving groups in S_N2 displacement reactions)

Physical Data: stable crystalline solid, mp 141 °C.

Preparative Method: can be prepared from the reaction of ***Imidazole*** and ***Sulfuryl Chloride*** in THF at ambient temperature.[2]

Purification: recrystallized from ethanol.

Amide Exchange.[3]

In general, tetrasubstituted sulfamides tend to be very unreactive. However, *N,N´*-sulfuryldiimidazole was demonstrated to undergo amide exchange with subsequent rearrangement (eq 1).

Nucleophilic Displacement Reactions.[4]

Primary and secondary alcohols can be converted to their imidazolylsulfonate esters via the reaction of the corresponding alkoxides (***Sodium Hydride***, ***N,N-Dimethylformamide***) with *N,N´*-sulfuryldiimidazole. Alternatively, the alkoxides were prepared from the action of ***Tetra-n-butylammonium Fluoride*** upon the corresponding trimethylsilyl ethers. Subsequent heating with the title compound in THF at reflux afforded the desired imidazylates. The primary imidazolylsulfonates reacted with azide, fluoride, and iodide at room temperature to provide the displacement products in high yield (eq 2).

(2)

a) X = I, 81%
b) X = F, 75%
c) X = N_3, 81%

Nucleophilic displacements at the C-2 and C-3 positions of glucopyranosides proved to be equally facile when proceeding through the intermediacy of the imidazylates. Reactions at C-2 have previously been difficult or impossible to effect by other means (eqs 3 and 4).[5,6]

(3)

a) X = Cl, 78%; I, 82%
b) X = N_3, 89%
c) X = OBz, 85%

Subsequent reduction of the iodides with ***Tri-n-butylstannane*** and ***Azobisisobutyronitrile*** afforded the deoxyglycosides in good yields.

Cyclic Sulfates.[7]

Cyclic sulfate formation followed by treatment with fluoride ion and subsequent acid hydrolysis provided the fluorinated glucose derivative (eq 5).

Eliminations.[4]

Alcohol-derived imidazolylsulfonates gave elimination products upon heating with ***Tetra-n-butylammonium Iodide*** in toluene at reflux (eq 6).

Tellurium[1]

[13494-80-9] · Te · Tellurium · (MW 127.60)

(*N*-tosylimine synthesis;[5] catalyst for synthesis of alkenes,[6,7] ureas,[8] isothiocyanates,[9] and for reduction of various functional groups[3])

Physical Data: mp 449.8 °C; bp 1390 °C; *d* 6.25 g cm^{-3}.

Solubility: insol any solvent unless tellurium reacts with it.

Form Supplied in: powder, pieces, or ingot.

Preparative Methods: amorphous form of tellurium can be obtained by reduction of tellurous acid (H_2TeO_3) with ***Sulfur Dioxide*** or ***Hydrazine*** hydrate as brown to gray powder.

Handling, Storage, and Precautions: storage under inert atmosphere is recommended since tellurium is oxidized gradually in air at room temperature. Use in a fume hood.

Synthesis of Organotellurium Compounds.[1c,d,2]

Elemental tellurium reacts with organolithium, -sodium, and Grignard reagents to form RTeM (M = Li, Na, MgX) at room temperature. This reaction and reduction of tellurium to its dianion (see below) provide a convenient synthetic route to a variety of organotellurium compounds by combination with appropriate subsequent reactions, as exemplified in eq 1. Tellurium also directly reacts with some organic halides to give diorganyltellurium dihalides, but the synthetic utility of this reaction is limited to the use of alkyl iodides or to the formation of cyclic tellurides from dihaloalkanes.

Selective Reduction.[2,3]

Among several methods which have been developed for the reduction of elemental tellurium to its dianion species, synthetically the most convenient are ***Sodium Borohydride*** in EtOH,[2a] ***Lithium Triethylborohydride*** in THF,[2b] rongalite-C (***Sodium***

Hydroxymethanesulfinate) in H_2O,[2c] ***Sodium Hydride*** in DMF[2d] or NMP.[2e] Salts of hydrogen telluride which can be formed (frequently referred to as M_2Te or MTeH where M = Li or Na, see ***Hydrogen Telluride*** and ***Sodium Telluride***) reduce aromatic aldehydes, C-C double bonds conjugated with carbonyl or aryl groups, imines and iminium salts, enamines, thiocarbonyls, epoxides, and a variety of nitrogen-containing functional groups.[3] They also facilitate dehalogenation, desulfurization, desulfonylation, dealkylation or deacylation of carboxylates, deallylation of allylic ethers, etc. Metallic tellurium also reacts with sodium diethyl phosphite in EtOH or THF to give ***Sodium O,O-Diethyl Phosphorotelluroate***, which acts as a reducing agent in a similar manner.[4] These tellurium reagents regenerate elemental tellurium after the reaction, and some reductions have been performed successfully by the use of a catalytic amount of tellurium.

Synthesis of *N*-Tosylimines.[5]

N-Tosylimines have been prepared in excellent yields from aldehydes, ***Chloramine-T***, and 0.5 mol equiv of tellurium (eq 2). This reaction is proposed to involve [2 + 2] cycloaddition of an aldehyde with *N,N´*-ditosyltellurodiimide generated in situ and subsequent cycloreversion.

$$\mathrm{RCHO} + \mathrm{TsN(Cl)Na} \xrightarrow[\text{84-100\%}]{\text{Te, toluene, reflux}} \mathrm{RCH{=}NTs} \qquad (2)$$

Alkene Synthesis by Tellurium-Catalyzed Homocoupling.

Wittig reagents[6] and benzenesulfonylbenzyllithiums[7] undergo homocoupling to yield alkenes in the presence of a catalytic amount of tellurium (eqs 3 and 4). The intermediacy of tellurocarbonyl compounds in the former case was evidenced by the successful trapping with dienes to give telluracyclohexenes.

$$\mathrm{Ph_3P{=}CHPh} \xrightarrow[\text{61\%}]{\text{Te (10 mol\%), toluene, 100 °C, 6 h}} \textit{trans}\text{-PhCH=CHPh} \qquad (3)$$

$$(\mathrm{PhSO_2})\mathrm{PhCHLi} \xrightarrow[\text{90\%}]{\text{Te (ca. 20 mol\%), THF, 25 °C, 3 h}} \underset{(E):(Z) = 80:20}{\mathrm{PhCH{=}CHPh}} \qquad (4)$$

Urea Synthesis by Tellurium-Catalyzed Carbonylation of Amines.[8]

Primary amines are carbonylated with ***Carbon Monoxide*** using tellurium as catalyst to give an equimolar amount of the urea and hydrogen along with formamides (eq 5). Addition of nitrobenzene in the reaction media affords aniline and suppresses the generation of hydrogen and formamides.

$$\underset{\text{100 mmol}}{\mathrm{BuNH_2}} + \underset{\text{30 kg cm}^{-2}}{\mathrm{CO}} \xrightarrow[\text{140 °C, 72 h}]{\text{Te (1 mmol)}} \underset{\text{22.0 mmol}}{\mathrm{(BuNH)_2CO}} + \underset{\text{21.0 mmol}}{\mathrm{H_2}} + \underset{\text{51.8 mmol}}{\mathrm{BuNHCHO}} \qquad (5)$$

Tellurium-Catalyzed Isothiocyanate Synthesis.[9]

Tellurium, like ***Selenium***, catalyzes the synthesis of isothiocyanates from isocyanides and ***Sulfur*** in the presence of a tertiary amine such as ***Triethylamine***, but much more efficiently (eq 6). This reaction is proposed to proceed via isotellurocyanate intermediates.

Tellurium(IV) Chloride[1]

$TeCl_4$

[65829-99-4] · Cl_4Te · Tellurium(IV) Chloride · (MW 269.40)

(for carbon-carbon bond-forming reactions and functional group manipulation via telluration; Lewis acid for thioacetalization/deacetalization and rearrangements; chlorinating agent)

Physical Data: mp 224 °C; bp 390 °C/755 mmHg; *d* 3.01 g cm^{-3}.

Solubility: insol cyclohexane, hexanes, methylene chloride, chloroform; sol acetonitrile, DMSO, DMF; slightly sol ether, benzene.

Form Supplied in: pale yellow solid; widely available.

Purification: distillation, or, more conveniently, sublimation (200 °C/0.1 mmHg).

Handling, Storage, and Precautions: readily hydrolyzed by water and must be handled and stored in the absence of moisture. The toxicity of tellurium and organotellurium compounds is little investigated. Use in a fume hood.

Carbon-Carbon Bond-Forming Reactions.

Many aromatic compounds undergo electrophilic aromatic substitution with $TeCl_4$ to yield aryltellurium trichlorides and diaryltellurium dichlorides.[2] These compounds can be converted into symmetrical biaryls by treatment with degassed ***Raney Nickel*** in high-boiling ether solvents (eq 1).[3,4] On treatment with ***Tetracarbonylnickel***[5] or ***Carbon Monoxide*** in the presence of a palladium(II) salt,[6] the organotellurium compounds are carbonylated to give benzoic acid derivatives. When $TeCl_4$ is allowed to react with four equiv of 1-alkynyllithium reagents, 1,3-diynes are formed,[7] probably via reductive coupling[8] from intermediate tetrakis(1-alkynyl)tellurium species.

(1)

Functional Group Manipulations.

Tellurium(IV) chloride readily adds to a variety of alkenic substrates to produce β-chloroalkyltellurium trichlorides. In the presence of a radical scavenger, the addition is highly *syn* specific.[9] The *anti* specific ***Sodium Sulfide***-induced elimination of tellurium from this compound has been used for the mild inversion of alkenes (eq 2). $TeCl_4$ undergoes a diastereospecific 1,3-addition to α-substituted allylic esters with 1,2-migration of the acyloxy group.[10] After hydrodetelluration (Raney Ni) and alkaline hydrolysis/ring closure of the resulting chlorohydrin ester, epoxides are formed (eq 3).

(2)

(Z):(E) = 97:3

(3)

The reaction of alkenes with $TeCl_4$ and lithium acetate in acetic acid at 120 °C affords products of *syn* diacetoxylation of the double bond.[11] This reaction probably proceeds via *anti* acetoxytellurination followed by acetate-induced cleavage of the C-Te bond with inversion of configuration. The replacement of an alkyl-, alkenyl- or aryl-bound $TeCl_3$ group by chlorine can be induced by heat, light, or oxidation to give *cis*-1,2-dichloroalkanes, *cis*-1,2-dichloroalkenes, and aryl chlorides, respectively.[12]

Lewis Acid Properties.

Aldehydes and ketones react with alkanethiols in the presence of a catalytic amount of $TeCl_4$ to form dithioacetals in good yields. In the presence of a stoichiometric amount of the tellurium reagent, dithioacetals and acetals are easily cleaved by the reagent to regenerate the carbonyl compounds (eq 4).[13,14]

(4)

When the deprotection procedure is applied to five-membered cyclic thioacetals, a facile ring enlargement takes place to give a dihydro-1,4-dithiin.[15] $TeCl_4$ catalyzes the oligomerization of phenylethylenes and benzyl chlorides.[16] Cycloheptatrienes undergo rearrangement with chlorination to give benzyl chlorides in the presence of $TeCl_4$.[17] Alcohols are converted to the corresponding alkyl chlorides when treated with $TeCl_4$ in nonpolar solvents. In aromatic solvents, the tellurium compound acts as a Friedel-Crafts catalyst to give alkylbenzene derivatives.[18] When treated with $TeCl_4$, silyloxycyclopropanes afford β-oxyalkyltellurium trichlorides in high yields.[19] On treatment with ***Dimethyl Sulfoxide*** or amine bases, dehydrotelluration occurs to give α-methylene ketones (eq 5).

Chlorinating Agent.

Unsaturated or halogenated cyclic or polycyclic hydrocarbons are readily aromatized when heated with $TeCl_4$ at elevated temperature (ca. 80 °C).[20] Chlorinated intermediates were proposed in the reaction. Aromatic compounds are chlorinated by $TeCl_4$[21] and β-ketonitroalkanes are both chlorinated and partly deoxygenated to give α-(hydroxyimino)-α-chloro ketones. The nitriloxides resulting from the latter compounds react with stilbenes to form isoxazolines.[22] It has been reported that the formation of oxamide derivatives, RNHC(O)C(O)NHR, from isocyanides, RNC, in the presence of $TeCl_4$ involves initial insertion of the isocyanide into the Te-Cl bond.[23]

Tetraacetyl Diborate[1]

$(AcO)_2BOB(OAc)_2$

[5187-37-1] · $C_8H_{12}B_2O_9$ · Tetraacetyl Diborate · (MW 273.82) ($B(OAc)_3$)

[4887-24-5]

(selective acetylating agent for aromatic polyhydroxycarbonyl compounds;[1-3] mild Lewis acid for Diels-Alder reactions of hydroxyquinones[4])

Alternate Names: TADB; boron triacetate; boroacetic anhydride; pyroboroacetate; oxybis(diacetoxyborane).

Physical Data: mp 150-152 °C (sealed tube),[3] 146-147 °C.[5]

Solubility: nearly insol petroleum ether, CCl_4, CS_2, Et_2O; especially sol dry warm benzene, EtOAc, ethylene bromide, and nitrobenzene (can be recrystallized from these solvents).[3]

Preparative Methods: a mixture of 31 g (0.50 mol) of ***Boric Acid*** and 165 mL (1.75 mol) of ***Acetic Anhydride*** is heated slowly with an oil bath under N_2 in a flask equipped with a reflux condenser and a magnetic stirrer. At about 70 °C a vigorous exotherm (CAUTION) occurs and the reaction mixture becomes a clear solution which, upon cooling, deposits crystals of TADB. The supernatant is drawn off and the crystals either washed with dry ether or recrystallized from 200 mL $CHCl_3$/benzene.[5]

Handling, Storage, and Precautions: moisture sensitive.

Structure.

There is some controversy[1,6] whether the mixed anhydride of boric and acetic acid has the structure $(AcO)_2BOB(OAc)_2$ (TADB) or $B(OAc)_3$. The material normally obtained from the reaction of boric acid (H_3BO_3) and acetic anhydride is $(AcO)_2BOB(OAc)_2$, at least in the crystalline state (mp ~150-152 °C).[5,6] Even when prepared under conditions (BH_3 + 3 HOAc) that might be expected to give $B(OAc)_3$,[5,7] the crystalline material isolated is TADB.[5] There is an early report[8] of the preparation of $B(OAc)_3$, mp 121 °C, from boric anhydride (B_2O_3) and Ac_2O. Since TADB is normally employed in excess, the constitution in solution (and the exact molecular weight) is somewhat immaterial to its use.

Selective Acetylation.

The use of TADB/acetic anhydride to acetylate selected hydroxy groups of polyhydroxyquinones was introduced by Dimroth.[2,3] Thus treatment of alizarin (**1**) with a hot mixture of TADB and Ac_2O gives, after workup with cold water, monoacetate (**2**).[2] The reaction proceeds by way of boroacetate complex (**3**), which after acetylation to (**4**) is hydrolyzed to (**2**). Selective preparation of (**6**) from purpurin (**5**) was achieved analogously.[2] If a carbonyl is flanked by two *peri* hydroxyls, only one is protected from acetylation.[2] Thus treatment of (**7**) with TADB/Ac_2O affords (**8**) after hydrolytic workup.[2] Selective monoacetylation of xanthone (**9**) to (**10**) was accomplished similarly.[9] That the product from eq 1 forms a boroacetate derivative was taken as conclusive proof that it possesses structure (**11**) rather than (**12**).[10] In the absence of a flanking carbonyl, a phenol group is not protected from acetylation: reaction of (**13**) with TADB/Ac_2O gives diacetate (**14**).[3] Other compounds or functional group combinations that give boroacetate complexes include salicyclic acid, 8-hydroxyquinoline, *peri*-aminoquinones, and *o*-hydroxyaryl ketones.[1,3]

Diels-Alder Reaction Catalysis.

TADB has seen considerable recent use as a catalyst in the Diels-Alder reactions of *peri*-hydroxylated quinones.[4] In addition to usually accelerating[4,11,12] the rate of reaction, it has been employed to advantage to enhance regioselectivity. Thus in the absence of catalyst, (**15**) reacts with (**17**) to give a 45:55 ratio of (**18**) to (**19**).[4] When (**15**) and (**17**) react in the presence of 2 equiv of TADB (via **20**), the ratio of (**18**) to (**19**) is >19:1.[4] In general, with TADB the carbonyl *peri* to the hydroxyl becomes the regiochemical director. Regiochemical control is best achieved with highly polarized dienes;[4] however, in some[11,12] (but not all)[4] cases even ***Isoprene*** reacts with considerable regioselectivity. A frontier molecular orbital explanation for the regiochemical outcome induced by TADB has been advanced.[13] It is to be noted that other Lewis acids can sometimes give a reversal of regiochemistry:[4,11,12] in the absence of catalyst, (**16**) and (**17**) react to give a 40:60 ratio of (**21**) and (**22**), but with 0.5 equiv of ***Magnesium Iodide*** the ratio is 1:>19.[4]

(15) R = H
(16) R = Me

(17)

(2)

(18) R = H
(21) R = Me

(19) R = H
(22) R = Me

(20)

One of the other virtues of TADB is its relatively noncorrosive nature which, for example, renders it compatible with dienes destroyed by Lewis acids such as ***Boron Trifluoride Etherate***.[4,11] Regiospecific TADB-catalyzed Diels-Alder reactions have been featured in the syntheses of (±)-bostrycin (**23**)[14] (this paper contains experimental details), (±)-altersolanol B (**24**),[15] (±)-ochromycinone (**25**),[16] and (±)-epirubigenone B1 (**26**).[17]

(23)

(24)

(25) $R^1 = H$, $R^2 = R^3 = O$

(26) $R^1 = Me$, $R^2 = H$, $R^3 = OH$

(30)

In the presence of TADB the Diels-Alder reaction between (**27**) and (**28**) proceeds with complete (&egt;98%) facial (and regio-) selectivity (eq 3).[18] Chiral analogs[19,20] (e.g. **30**[19]) of the borate complexes have been used for asymmetric Diels-Alder reactions, including one in an enantioselective synthesis of (-)-bostrycin (**23**).[19] Quinizarin (**31**) does not exhibit any tendency to undergo a Diels-Alder reaction by way of its putative tautomer (**32**) (eq 4),[21] but in the presence of TADB cycloaddition occurs.[22] 1,4-Diaminoanthraquinone behaves similarly.[22] The boroacetate complex of (**32**) also acts as a dipolarophile.[23]

(29)

(4)

(31) (32)

Miscellaneous.

TADB has been used for the selective cleavage of cyclic ethers, e.g. (**33**) -> (**34**) (eq 5).[7] In the synthesis of (**26**), TADB was enlisted to aromatize the B ring in (**35**) when acidic and basic treatment gave (**36**).[17]

Tetraallylstannane[1]

[7393-43-3] · $C_{12}H_{20}Sn$ · Tetraallylstannane · (MW 283.03)

(allyllithium precursor;[2] allyl nucleophile for allyl transfer reactions[3] and Stille coupling[4])

Alternate Name: tetraallyltin.

Physical Data: bp 69-70 °C/1.5 mmHg, 87-88 °C/4 mmHg; *d* 1.179 g cm^{-3}.

Solubility: sol common organic solvents; insol H_2O.

Form Supplied in: widely available as a neat liquid. Major impurities are tin chlorides.

Preparative Methods: synthesized by the reaction of ***Allylmagnesium Bromide*** with ***Tin(IV) Chloride*** in THF.[5]

Analysis of Reagent Purity: shows one spot in the TLC (hexane) and one peak in the GC. ^1H NMR (C_6D_6) can also be informative.

Purification: pure tetraallyltin is a colorless oil. Commercial tetraallyltin is typically obtained as a slightly yellow oil and used without further purification. Large quantities are purified by fractional distillation. Smaller amounts may be filtered through a plug of silica.

Handling, Storage, and Precautions: is an air and water stable oil. No unusual storage precautions are required. Organostannanes are toxic and should only be used in a well ventilated hood. All glassware should be rinsed in a KOH/EtOH bath during cleaning.

Allyllithium.

Allyllithium is formed from transmetalation of tetraallyltin with alkyllithiums. Treatment of a hexane or pentane solution of tetraallyltin with 2.0 equiv of ***n-Butyllithium*** initiates an exchange reaction which is driven by the precipitation of solid allyllithium.[2,6] Removal of solvent by syringe or filtration, followed by washing the allyllithium and dissolution in Et_2O, affords a solution of allyllithium which is stable for long periods if stored under an inert atmosphere. An excess of tetraallyltin is employed because transmetalation is an equilibrium reaction which will not proceed to completion.[2] Ethereal allyllithium solutions are stable for several months at 0 °C. Because of the need to filter solid allyllithium, this approach has been used only sparingly.

Formation of solid allyllithium can be avoided by treatment of an Et_2O solution of tetraallyltin with 4 equiv of ***Phenyllithium***.[2] Removal of tetraphenyltin by filtration (filtration is optional) affords a solution of allyllithium, which also contains LiBr from the PhLi preparation and trace levels of Ph_4Sn (Ph_4Sn is soluble in Et_2O at 0.0010 g mL^{-1} at 20 °C). Allyllithium generated in this manner undergoes conjugate addition with vinyl sulfones in the presence of ***Potassium t-Butoxide*** to give the β-allyl sulfone (eq 1).[7]

(1)

A solution of allyllithium has also been generated by the reaction of tetraallyltin with 4 equiv of ***Methyllithium*** in Et_2O.[8] Tetraalkylstannanes must not interfere with the ensuing steps. Reaction of allyllithium generated in this manner with 1-naphthyloxazoline afforded, after acid quench, the *trans*-dihydronaphthalene (eq 2).[8]

(2)

Disproportionation of tetraallyltin with $SnCl_4$ affords a route to allyltin chlorides.[9]

Allyl Transfer Reactions.

Tetraallyltin is a gentle nucleophile capable of transferring one allyl group to ketones, epoxides, and other reactive electrophiles (eq 3).[3] Nucleophilicity can be enhanced by reaction in the presence of fluoride,[10] or BF_3.[11] Because only one allyl moiety is transferred, ***Allyltributylstannane*** or trimethylallyltin is more commonly used in this reaction.

Palladium-Mediated Cross-Coupling Reactions (the Stille Reaction).

Tetraallyltin acts as a nucleophile in palladium-mediated cross-coupling reactions (eq 4).[12] Because the triallyltin halide byproduct is unreactive, tributylallyltin or trimethylallyltin is more commonly used in this reaction. In an interesting variation, treatment of α-halo ketones with ***Tetravinylstannane*** in the presence of catalytic ***Benzylchlorobis(triphenylphosphine)palladium(II)*** affords allyl epoxides (eq 5).[13]

1,1,3,3-Tetrabromoacetone[1]

$(CHBr_2)_2CO$

[22612-89-1] · $C_3H_2Br_4O$ · 1,1,3,3-Tetrabromoacetone · (MW 373.65)

(a good source of the 1,3-dibromooxyallyl cation, a synthetic equivalent of the oxyallyl cation; especially useful for [4 + 3] cycloadditions[1])

Alternate Name: 1,1,3,3-tetrabromopropanone.

Physical Data: bp 129-130 °C;[7] mp 37-38 °C.

Solubility: sol moderately polar to polar organic solvents.

Form Supplied in: not commercially available and should be prepared as needed.[2]

Analysis of Reagent Purity: assay by NMR.[2]

Handling, Storage, and Precautions: powerful lachrymator; use in a fume hood. If contact with the skin occurs the affected area should be thoroughly washed with soap followed by a solution of sodium bicarbonate.[3]

[4 + 3] Cycloadditions.

The chemistry of 1,1,3,3-tetrabromoacetone (**1**) is dominated by its ability to form oxyallylic cation (**2**) and related species under a variety of conditions (eq 1). This intermediate has been exploited essentially exclusively as a dienophile in [4 + 3] cycloadditions with dienes, in which it serves as an equivalent of the elusive parent oxyallyl (**3**).[1] 1,1,3,3-Tetrabromoacetone serves as a prototype for other polyhalogenated ketones which exhibit similar chemistry.

(1) (2) (3) (1)

A number of reagents have been utilized to effect the conversion of (**1**) to (**2**). These include ***Diethylzinc***,[4] ***Nonacarbonyldiiron***,[1d] ***Pentacarbonyliron***,[1c,5] zinc/triethyl borate,[6] ***Zinc/Copper Couple***,[7] and ***Zinc/Silver Couple***.[8] The nature of these reagents precludes the formation of (**2**) in free form and suggests the inclusion of metal counterions which can be expected to attenuate the reactivity of (**2**) in combination with solvent and other effects. It is important to note that 1,3-dibromoacetone has not been successfully used to directly access (**3**).[1c]

The majority of [4 + 3] cycloadditions using (**2**) have involved furans as reaction partners. The reaction of (**2**) with furan to form 8-oxabicyclo[3.2.1]-6-octen-3-one (**4**) is illustrative (eq 2). Nearly all the aforementioned reagents have been used to generate (**2**) for this reaction. Some of the reactions have been conducted quite successfully on a large scale (Table 1).[4,6,8-10] The initial cycloadducts contain bromine, which is removed using a reductive debromination with zinc/copper couple.

Table 1 Formation of (**3**) from Furan

Reagent	Furan (equiv)	Yield (%)
Et_2Zn[4]	20	57
$Zn/B(OEt)_3$[6,9]	2	54
$Fe_2(CO)_9$[10]	55	63
Zn/Ag[8]	10	55 65

Adducts derived from (**2**) and various furans have been used in the synthesis of analogs of thromboxane,[8] cocaine,[11] and muscarine,[12] among others. A general synthesis of tropanes from such cycloadducts has been developed.[13] For example, nezukone (**6**) could be prepared in fair overall yield in three steps from cycloadduct (**5**) (eq 3).

Among the most interesting and important applications of cycloadducts derived from (**2**) has been the synthesis of a family of structurally diverse ribo-C-nucleosides.[14] Examples include (**7**)-(**9**), all of which are ultimately derived from (**1**) and the appropriate furan.[14]

(7)

(8)

(9)

Oxyallyl (**2**) has also been used in reactions with pyrroles to produce analogs of tropane alkaloids (eq 4).[4,7] Trapping with dienes such as ***Cyclopentadiene***[5,6,9,15] and substituted anthracenes[16] has been studied as well (eqs 5 and 6).

(1)

(4)

(1)

(5)

(1)

(6)

Other Routes to Equivalents of (3).

Several synthetic routes to equivalents of (**3**) are known. 2-Methoxy-3-bromopropene, for example, undergoes a reaction with ***Furan*** in the presence of silver ion to give (**4**) in low yield (eq 7).[17] Presumably, the cation (**10**) is an intermediate. This intermediate is so reactive that it even gives [4 + 3] cycloaddition products with benzene.[18]

(7)

The reaction of the trimethylsilyl enol ether of 1,3-dichloroacetone (**11**) with furan in the presence of ***Silver(I) Perchlorate*** gave an 80% yield of a mixture of cycloadducts (eq 8).[19] These could undoubtedly be converted to (**3**) via reductive dehalogenation. While the use of silver salts makes this process expensive, the ready availability of (**11**) renders this method attractive.

(8)

Finally, tetrachloro- and pentachloroacetone have been shown to give rise to oxyallylic cations capable of [4 + 3] cycloaddition with furan. ***Triethylamine*** in methanol, triethylamine or sodium trifluoroethoxide in trifluoroethanol/furan, and triethylamine in ethereal lithium perchlorate have been used in this reaction (eqs 9 and 10).[20] The cycloadducts in these cases could be dehalogenated to (**4**). This approach has been recognized as particularly convenient, since tetrachloroacetone is more easily handled than (**1**).[1b]

(9)

(10)

Favorsky Rearrangement.

Treatment of (**1**) with 1 M sodium bicarbonate resulted in a Favorsky rearrangement to yield β,β-dibromoacrylic acid in good yield (eq 11).[21]

(1) (11)

Related Reagents.

2,4-Dibromo-3-pentanone; ***Diethylzinc***; ***2-Methoxyallyl Bromide***; ***Zinc/Copper Couple***; ***Zinc/Silver Couple***.

2,4,4,6-Tetrabromo-2,5-cyclohexadienone[1]

[20244-61-5] · $C_6H_2Br_4O$ · 2,4,4,6-Tetrabromo-2,5-cyclohexadienone · (MW 409.68)

(selective bromination of polyalkenes;[2-4] monobromination of phenols,[5,6] unprotected arylamines,[7,8] and aza heterocycles;[9] oxidation of thiols to disulfides;[10] synthesis of α´-bromo-α,β-unsaturated ketones;[11] electron acceptor in photosensitization reactions;[12] cyclization of alkenols[3,13])

Alternate Name: TBCHD.

Physical Data: mp 125-130 °C (dec).

Solubility: sol CH_2Cl_2, Et_2O, $CHCl_3$, $MeNO_2$, MeOH.

Form Supplied in: crystalline material; commercially available.

Preparative Methods: bromination of 2,4,6-tribromophenol with ***Bromine*** in acetic acid in the presence of sodium acetate (eq 1).[6,7,8,14]

Analysis of Reagent Purity: ^{1}H NMR.

Handling, Storage, and Precautions: the reagent should be kept in a dark vessel, well-protected from light.

Brominative Cyclization of Polyalkenes.

Electrophilic bromination of 1,5-dienes with 2,4,4,6-tetrabromo-2,5-cyclohexadienone results in the formation of brominated six-membered carbocycles. This brominative cyclization does not always proceed in good yield, but has been used for the biomimetic construction of marine natural products.[15] Nerolidol thus reacts with TBCHD to give the monocyclic sesquiterpenes α- and β-snyderol (from the red algae *Laurencia* species) in low yield (eq 2).[2,4] When used as solvent, acetonitrile may participate in the reaction, depending upon the temperature.[16] In a similar fashion, brominative cyclization of methyl farnesate has been used in the total synthesis of acoratriene (eq 3)[16] and 10-bromo-α-chamigrene.[17]

In contrast, geranyl acetate,[17] carvone,[18] and farnesyl cyanide[18] undergo selective bromination to the dibromo adducts with TBCHD (e.g. eq 4). Natural products from *Desmia hornemanni* have been synthesized by bromination of myrcene,[19] and the synthesis of isoconcinndiol has been achieved in a fashion similar to that outlined above.[20]

Monobromination of Phenols, Arylamines, and Aza Heterocycles.

Phenols are selectively monobrominated at the *ortho* position by TBCHD.[5,6] Phenol is brominated in CCl_4 to give a 87:13 ratio of *o*-bromo- and *p*-bromophenol (95% yield).[5] Estradiol is brominated at the 2- and 4-positions.[21] Of more potential use is the selective monobromination of anilines at the *para* position (eq 5);[5,7,8,22,28] the following arylamines have been brominated in this fashion: aniline (92%), *N*-methylaniline (94%), *N*,*N*-dimethylaniline (91%), *o*-toluidine (88%), *m*-toluidine (90%), 2,3-dimethylaniline (91%), 2-chloroaniline (86%), 3-chloroaniline (86%), 3-bromoaniline (82%), 2-nitroaniline (91%), *o*-anisidine (85%), 2-aminopyridine (75%), 2-*N*,*N*-dimethylaminopyridine (70%), and 3-*N*,*N*-dimethylaminopyridine (60%). Monobromination of ***Imidazole***, ***N-Methylimidazole*** and indole has also been achieved with TBCHD (eq 6).[9]

Oxidation of Thiols to Disulfides.

Thiols (as their sodium salts) are oxidized by TBCHD to give disulfides (eq 7).[10] The use of benzene as solvent is particularly recommended as all byproducts are then easily removed as insoluble precipitates. The reagent behaves as an oxidizing agent towards sulfides, converting them into sulfoxides.[23]

(7)

R = Pr, Bu, Ph, *o*-MeC$_6$H$_4$

Selective α´-Bromination of α,β-Unsaturated Ketones.

Monobromination of α,β-unsaturated ketones at the α´-position without affecting the double bond was performed with TBCHD (eqs 8 and 9).[11,29] The rate of the reaction is very slow, but can be enhanced by the addition of a catalytic amount of gaseous ***Hydrogen Chloride*** or ***Hydrogen Bromide***.

(8)

(9)

Electron Acceptor in Photosensitization Reactions.

TBCHD is an electron acceptor in the photosensitized oxidation of unsaturated substrates, e.g. alkynes,[12] stilbene,[12] tetraphenylethylene,[12] α-methylstyrene,[12] dioxenes,[24] and 2,3,5,6-tetraphenyl-*p*-dioxin.[24]

Cyclization of Alkenols.

Cyclization of alkenols with TBCHD gives brominated tetrahydropyrans accompanied by minor amounts of brominated tetrahydrofurans (eq 10).[3,13,25] This reaction has been used for the synthesis of (±)-incensole from (±)-mukulol. In addition, this methodology allows the stereospecific construction of *trans*-2,5-disubstituted tetrahydrofurans by the cyclization of γ,δ-unsaturated alcohols to 3-bromotetrahydropyrans followed by silver-induced ring contraction (eq 11).[13]

Allylic Bromination and Synthesis of Spiroisoxazolines.

Allylic brominations of cephem derivatives have been achieved with the dienone reagent under irradiation (eq 12).[26] Spiroisoxazolines are formed by oxidative cyclization of *o*-hydroxybenzyl oximes. This methodology was used in the synthesis of the sponge metabolite *cis,cis*-aerothionine (eq 13).[27]

cis,cis-Aerothionine

Tetra-*n*-butylammonium Acetate

***n*-Bu_4NOAc**

[10534-59-5] · $C_{18}H_{39}NO_2$ · Tetra-*n*-butylammonium Acetate · (MW 301.58)

(nucleophile for S_N2 displacement of sulfonates[1] and allylic halides;[2] mild, soluble base for reduction of tosylhydrazones with catecholborane[3])

Physical Data: mp 114-115 °C (Alfa), 95-98 °C (Aldrich).

Solubility: sol most polar organic solvents (MeCN, acetone, CH_2Cl_2, EtOH); slightly sol benzene.

Form Supplied in: white crystalline solid; widely available.

Purification: recrystallization from a minimum amount of methanol (mp 114-115 °C) or, alternatively, filtration of a benzene solution through basic alumina (activity I) and recrystallization from 5:4:2 benzene-pentane-ethyl acetate at -25 °C (mp 95-98 °C).

Handling, Storage, and Precautions: irritant, hygroscopic; protect from moisture.

Synthesis of Acetate Esters via S_N2 Displacements.

This reagent is an excellent source of nucleophilic acetate ion for S_N2 substitution reactions. Tetraethylammonium acetate functions in a similar fashion. Equatorial steroidal tosylates are displaced to give axial acetates upon treatment with tetra-*n*-butylammonium acetate in refluxing acetone (eq 1).[4] The use of benzene, instead of acetone, results in clean inversion of deuterated *endo*-norbornyl sulfonates without isotopic rearrangement[5] (eq 2).[1] This process may also be carried out in molten reagent (eq 3).[6]

3-Bromomethyl-2-thiacephem derivatives are converted to allylic acetates in excellent yield (eq 4).[2] The use of AcOH as solvent prevents double bond isomerization for related Δ^3-3-bromomethylcephems.[7]

(4)

Other Applications.

The solubility of tetra-*n*-butylammonium acetate in organic solvents makes it an effective replacement for NaOAc. Tetra-*n*-butylammonium acetate is superior to NaOAc for the deoxygenation of aldehydes and ketones by reduction of the corresponding tosylhydrazones with catecholborane (eq 5).[3]

(5)

Use of tetra-*n*-butylammonium acetate in the electrochemical reduction of some *o*-bis(phenylsulfonyl)benzene derivatives affords good yields of dibenzothiophene 5,5-dioxides.[8] Photolysis of 1,2,4,5-tetracyanobenzene in the presence of tetra-*n*-butylammonium acetate yields bis(2,4,5-tricyanophenyl)methane.[9] The reaction between tetra-*n*-butylammonium carboxylates and ***p-Toluenesulfonyl Chloride*** produces mixed *p*-toluenesulfonic carboxylic anhydrides,[10] an alternative to chloroformates.

Tetra-*n*-butylammonium acetate promotes an unexpected elimination of a bromohydrin acetate to produce an alkene.[11] The reagent is also an effective catalyst for the phosphorylation of alcohols by cyclic enediol phosphates in aprotic solvents,[12] as well as for anionic polymerization.[13]

Tetra-*n*-butylammonium Borohydride

***n*-Bu_4NBH_4**

[33725-74-5] · $C_{16}H_{40}BN$ · Tetra-*n*-butylammonium Borohydride · (MW 257.38)

(selective reducing agent for aldehydes and ketones;[1] soluble in nonaqueous media)

Physical Data: mp 123-128 °C.

Solubility: readily sol CH_2Cl_2, $CHCl_3$; moderately sol benzene; relatively insol ether solvents, H_2O.

Form Supplied in: colorless crystalline solid; commercially available.

Preparative Methods: can be prepared by the reaction between ***Sodium Borohydride*** and tetrabutylammonium chloride.[2] The reagent can also be prepared from the less expensive ***Tetra-n-butylammonium Iodide*** by ion exchange.[1]

Purification: recrystallization from ethyl acetate followed by careful drying under vacuum at 50-60 °C.

Handling, Storage, and Precautions: crystalline samples showed no loss of active hydrogen after storage at rt for more than 1 year.[1] As with other borohydrides, the material reacts rapidly with aqueous acids to produce hydrogen (and, potentially, borane).[2] Use in a fume hood.

General Considerations.

Tetrabutylammonium borohydride, by virtue of its high solubility in organic solvents such as CH_2Cl_2, permits the reduction of aldehydes and ketones to be carried out in high yields in aprotic solvents. The general reactivity of the reagent is analogous to that of sodium borohydride in aqueous or alcoholic media, and reductions are highly selective for the carbonyl groups of aldehydes and ketones relative to unconjugated carbon-carbon multiple bonds. At rt, acid chlorides are reduced very rapidly, aldehydes and ketones are reduced at convenient rates (with half-times of a few hours), and esters are reduced quite slowly. The solubility properties[1,4] of this compound relative to that of other quaternary ammonium borohydrides make it an excellent reagent for reductions of aldehydes and ketones, which sometimes exhibit poor solubility in the protic solvents needed for sodium borohydride reductions.

The tetrabutylammonium reagent is considerably easier to handle and purify[2] than the tetraethylammonium salt, because it is less hygroscopic and is more soluble in organic solvents (although the greater water solubility of most tetraethylammonium salts can facilitate workup of reductions with the latter derivatives). Tetrabutylammonium borohydride was first used to prepare solutions of ***Diborane*** in CH_2Cl_2[2] and was then found to be a mild and selective reagent for the reduction of dioxolenium ions.[5] Subsequently, the reductions were extended to carbonyl reductions in aprotic solvents. Related reductions were reported using ***Tetra-n-butylammonium Cyanoborohydride*** in ***Hexamethylphosphoric Triamide***.[6]

The reactivity of tetrabutylammonium borohydride decreases along the sequence acid chlorides > aldehydes > ketones > esters. The extremes are illustrated by ***Benzoyl Chloride*** (**1**), which is reduced rapidly, even at -78 °C (eq 1),[1] and ethyl laurate (**2**), which undergoes only 25% reduction after 4 d at 25 °C (eq 2).[1]

Aldehydes and ketones undergo reduction at 25 °C at convenient rates, which vary with respect to the steric bulk of the substituents. While the reduction of unhindered aldehydes proceeds readily and nearly to completion with only 1 equiv of tetrabutylammonium borohydride, it was found preferable to use 4 equiv of the reducing agent as a general procedure for ketones, where the reaction is otherwise inconveniently slow or does not proceed to completion. The typical reaction time of 2 d for ketone reduction (rt, CH_2Cl_2) can be decreased to several hours if the reduction is carried out at the higher temperature of refluxing $CHCl_3$.[1]

A typical reduction is accomplished by allowing a CH_2Cl_2 solution of the carbonyl derivative (1 M) and tetrabutylammonium borohydride (0.4-1 M) to stand in a stoppered vessel at rt for 0.25-48 h. The reaction mixture is then quenched by stirring for 2 h with alkaline, aqueous ***Hydrogen Peroxide*** (2 vol of 3% hydrogen peroxide and 1 vol of 10% NaOH). After drying the organic layer and evaporating the solvent at reduced pressure, insoluble ammonium salts can be removed by dissolving the crude product in Et_2O and filtering the solution through a short column of alumina. The use of aqueous hydrogen peroxide in the workup not only serves to destroy any unreacted hydride, but also facilitates the hydrolysis of the borate esters formed in the reduction.[7] If this step is omitted, much lower yields result. In order to destroy any peroxides that may have formed during workup, a CH_2Cl_2 solution of the product is washed with aqueous sodium sulfite prior to distillation.

Selective Reductions.

Only the keto group of methyl 3-benzoylpropionate (**3**) was reduced, and the corresponding lactone (formed spontaneously during distillation of the product) was obtained (eq 3).[1]

On the other hand, the reactivity differences of aldehyde and ketone carbonyl groups do not appear to be sufficient to allow selective reduction. Although the aldehyde is reduced preferentially, the product distribution in the following example is only 80:20 at best (eq 4).[3]

Although diborane is probably formed during the reduction of ketones, hydroboration of the carbon-carbon double bond in 6-methyl-5-hepten-2-one was not observed, and the unsaturated alcohol was isolated in good yield.[1] As with other borohydride reductions,[8,9] there is evidence that the reaction can be assisted by electrophilic catalysis. While not a prerequisite for reduction, the addition of an equivalent amount of ethanol results in an approximate twofold increase in the rate of reduction of cyclohexanone by tetrabutylammonium borohydride in CH_2Cl_2.[1] The identity of the actual reducing agent in reductions performed with Bu_4NBH_4 in CH_2Cl_2 is uncertain. The ability of Bu_4NBH_4 to reduce certain functional groups, such as the cyano group of nitriles,[10] might be due to the presence of diborane in CH_2Cl_2 solutions of this reagent. However, the exact nature of the species present in CH_2Cl_2 solutions of Bu_4NBH_4 is unknown. These solutions are probably complex since it is known[11] that heptahydrodiborate ion ($B_2H_7^-$) is produced in solutions which contain borohydride ion (from Bu_4NBH_4) and diborane.

Tetrabutylammonium borohydride has also been used effectively in aprotic solvents for the reduction of indoles to idolines[12] and for the selective 1,4-reduction of α,β-unsaturated cyclic ketones.[13] Other reports of the use of this reagent that may be of relevance for organic synthesis include deoxy sugar synthesis (in an S_N2 reduction),[14] reduction of thiol esters,[15] stereoselective synthesis of indanols from 2-methyl-2-aryl-1-indanones,[16] preparation of methylboronic acid and trimethylboroxin,[17] the use of borohydrides on solid supports,[18] and synthesis of organic selenides and tellurides.[19]

Related Reagents.

Diborane; ***Sodium Borohydride***; ***Tetra-n-butylammonium Cyanoborohydride***.

***n*-Bu$_4$NBr**

[1643-19-2] · $C_{16}H_{36}BrN$ · Tetra-*n*-butylammonium Bromide · (MW 322.43)

(phase-transfer catalyst;[1] source of nucleophilic bromide[1])

Physical Data: mp 103-104 °C.

Solubility: sol H_2O, 1% aq NaOH, CH_2Cl_2, EtOH; slightly sol toluene; insol 20% aq NaOH.

Form Supplied in: anhydrous white solid.

Analysis of Reagent Purity: tetraalkylammonium salts can be titrated with potassium 3,5-di-*t*-butyl-2-hydroxybenzenesulfonate and iron(III) chloride.[1a]

Preparative Methods: several methods are available to recover the quaternary ammonium ion efficiently.[1a]

Purification: all manipulations should be carried out in a dry-box. The salt can be crystallized from benzene (5 mL g^{-1}) at 80 °C by adding 3 vol of hot hexane and allowing to cool. It can also be purified by precipitation of a saturated solution in dry CCl_4 by addition of cyclohexane or by crystallization from a mixture CH_2Cl_2-Et_2O. After filtration, the solid is further dried by heating at 75 °C under vacuo (0.1 mmHg) in the presence of P_2O_5.[2]

Handling, Storage, and Precautions: highly hygroscopic; if used in a reaction requiring anhydrous conditions, it should be manipulated in a glove-bag or in a dry-box.

Catalyst for C-X Bond Formation.

Tetrabutylammonium bromide is undoubtedly one of the most widely used phase-transfer catalysts. It combines the lipophilicity required for an efficient phase-transfer catalyst with the hydrophilicity necessary for efficient catalyst recovery. It has been successfully used in the liquid-liquid or solid-liquid phase-transfer alkylation of the NH groups of anilines,[3] amides,[4] lactams,[5] sulfonamides,[6] and other nitrogen heterocyclic compounds.[7] Sulfur[8] and oxygen-containing functional groups[9] can also be smoothly alkylated under phase-transfer conditions. Several *S*-alkylthioacridines have been prepared by liquid-liquid[10] or solid-liquid[11] phase-transfer catalysis (eq 1).

(1)

Carboxylic acids[12] and phenols[13] can also be alkylated in the presence of tetrabutylammonium bromide. Macrolides can be synthesized by an intramolecular S_N2 reaction of a bromo ester via simulated high dilution conditions (eq 2).[14]

(2)

Bu_4NBr is also very effective in promoting nucleophilic aromatic substitution reactions to produce aryl thio esters,[15] aryl ethers,[16] and *N*-arylbenzodiazepines.[17] Some glycosylations were shown to be efficient only in the presence of Bu_4NBr.[18]

Catalyst for Oxidation Reactions.

Phase-transfer oxidation of alcohols to acids,[19] alkenes to carboxylic acids,[18] sulfides to sulfones,[20] and sulfilimines to sulfoximines[21] have also been carried out in the presence of tetrabutylammonium bromide along with an oxidizing reagent.

Catalyst for C-C Bond Formation.

The presence of Bu_4NBr was shown to be essential in a number of carbon-carbon bond-forming reactions, such as the alkylation of allyl sulfones[22] and of ***Malononitrile***,[23] and in the lead-promoted Barbier-type reaction of propargyl bromide with aldehydes.[24] It has also been used in the efficient synthesis of racemic α-alkyl and α,α-dialkyl α-amino acids by phase-transfer alkylation of Schiff bases (eq 3).[25]

(3)

The presence of Bu_4NBr was shown to be necessary to increase the efficiency of some carbon-carbon double bond forming reactions such as Heck-type couplings,[26] dehydrohalogenations,[27] and Horner-Emmons-Wittig reactions.[28]

Alkyl and Alkenyl Bromides.

Bu_4NBr can be used as a powerful source of bromide for nucleophilic displacement reactions of triflates[29] and iodonium salts.[30]

Tetra-*n*-butylammonium Chlorochromate[1]

***n*-Bu$_4$N(ClCrO$_3$)**

[54712-57-1] · $C_{16}H_{36}ClCrNO_3$ · Tetra-*n*-butylammonium Chlorochromate · (MW 377.98)

(mild and selective oxidizing agent for benzylic and allylic alcohols;[2] can oxidize thiols[2])

Alternate Name: TBACC.

Physical Data: mp 184-185 °C.

Solubility: sol ethyl acetate, THF, $CHCl_3$, CH_2Cl_2.

Form Supplied in: orange crystalline solid; widely available.

Handling, Storage, and Precautions: the dry solid is nonhygroscopic, but must be stored in the absence of light, since it slowly darkens within weeks, although without losing its oxidizing power. Reaction solvents must be anhydrous and free of reducing impurities. Tetrabutylammonium chlorochromate is reported to be a toxic agent. Use in a fume hood.

Oxidation of Benzylic and Allylic Alcohols.

As is well known, the oxidizing power of heterocycle-chlorochromate salts is inversely proportional to the basicity of the amine counterpart of the chlorochromate anion. Consequently, tetrabutylammonium chlorochromate is described as a neutral, mild, and selective oxidant for benzylic and allylic alcohols. The reagent (3 equiv) very slowly oxidizes these alcohols into the corresponding carbonyl compounds at rt in 68-88% yield (eqs 1-3).[2a] No (*E*)/(*Z*) isomerization is generally observed.

(1)

(2)

(3)

In refluxing chloroform, the oxidation of benzylic and allylic alcohols is achieved in a reasonable period of time (1-24 h) and in good yields. Using 3 equiv of oxidant, saturated aliphatic alcohols are oxidized to a minimum extent both at rt and in refluxing chloroform. For example, treatment of 1-phenyl-1,3-propanediol with TBACC at 70 °C for 1 h affords 3-hydroxy-1-phenyl-1-propanone in 52% yield (eq 4).[2]

(4)

With a large excess of oxidant (6 equiv), primary and secondary aliphatic alcohols can be oxidized slowly in refluxing chloroform to carbonyl compounds in 50-75% yields.[2a]

Oxidation of Thiols.

TBACC can rapidly perform oxidative coupling of thiols to disulfides in good yield. The reaction can be applied to both alkanethiols and arenethiols, and appears to be superior to ***Pyridinium Chlorochromate*** for this transformation (eq 5).[2]

Tetra-*n*-butylammonium Cyanoborohydride[1]

***n*-Bu$_4$NBH$_3$CN**

[43064-96-6] · $C_{17}H_{39}BN_2$ · Tetra-*n*-butylammonium Cyanoborohydride · (MW 282.39)

(selective, mild reducing reagent for aldehydes, conjugated aldehydes and ketones, alkyl iodides and bromides; useful for reductive aminations of aldehydes and ketones in nonpolar solvents)

Alternate Name: TBAC.

Physical Data: mp 144-145 °C.

Solubility: sol most polar (e.g. alcohols, carboxylic acids), polar aprotic (e.g. HMPA, DMSO, DMF), and nonpolar (e.g. CH_2Cl_2, benzene, hexane) solvents; sparingly sol H_2O, ether.

Form Supplied in: white, nonhydroscopic solid; commercially available.

Preparative Methods: from *n*-Bu$_4$NHSO$_4$ suspended in H_2O, treated with ***Sodium Hydroxide*** and ***Sodium Cyanoborohydride***, and extracted into CH_2Cl_2; recrystallized from ethyl acetate. Other tetraalkylammonium derivatives are available[3a] (including polymer-supported)[3b] or can be generated in situ from $NaBH_3CN$ and Aliquat 336.[3c]

Functional Group Reductions.

Under neutral conditions in HMPA at ambient temperature, only primary alkyl iodides and allylic bromides are efficiently reduced with TBAC. Most other functional groups, including aldehydes, ketones, esters, amides, nitro groups, and epoxides, are inert. At higher temperatures (e.g. 70-100 °C), benzylic halides, primary and secondary bromides, and naphthalenic iodides and bromides are also reduced (Table 1).[4]

Table 1 Reductions of Alkyl Halides with TBAC in HMPA

Compound	Temp. (°C)	Time (h)	Product	Yield (%)
$Me(CH_2)_9I$	25	21	$Me(CH_2)_8Me$	81
$Me(CH_2)_9Br$	80	24	$Me(CH_2)_8Me$	89
$PhCH{=}CHCH_2Br$	25	3	PhCH=CHMe	64
2,6-$Cl_2C_6H_3CH_2Cl$	70	17	2,6-$Cl_2C_6H_3Me$	91
PhCHBrMe	70	5.25	$PhCH_2Me$	78
1-Bromonaphthalene	100	66	Naphthalene	99

In acidic media, TBAC reduces aldehydes and ketones to alcohols (eqs 1 and 2). However, the greater susceptibility of aldehydes allows selective reductions in the presence of ketones (and halides) at low acid concentrations (eq 3).[1a,5] Alicyclic α,β-unsaturated and α,β-alkynic carbonyls are reduced to allylic and propargylic alcohols, respectively, in acidic media (eq 4).[2]

(1)

(2)

(3)

(4)

TBAC is effective for reductive aminations of aldehydes and ketones in nonpolar media including CH_2Cl_2, hexane, THF, and benzene (eq 5).[3c] Alternatively, the combination of ***Sodium Cyanoborohydride*** and Aliquat 336 (methyltrialkylammonium chloride) may be used to generate tetraalkylammonium cyanoborohydride in situ for reductive aminations (eq 6).[3c]

(5)

The excellent chemoselectivity available recommends this reagent for reduction of primary alkyl iodides and benzylic bromides at ambient temperature in HMPA since virtually no other functional groups are affected. At higher temperatures, other halides are also reduced chemoselectively. Comparison between TBAC and other cyanoborohydrides (particularly $NaBH_3CN$) for halide reductions is provided by Hutchins.[4] In acidic media, effective chemoselective reductions of aldehydes in the presence of ketones may be obtained.

TBAC allows reductive aminations in nonpolar solvents as an alternative to $NaBH_3CN$, which is used in polar solvents.

Tetra-*n*-butylammonium Dichlorocuprate(I)[1]

***n*-$Bu_4N^+CuCl_2^-$**

[39926-94-8] · $C_{16}H_{36}Cl_2CuN$ · Tetra-*n*-butylammonium Dichlorocuprate(I) · (MW 376.92)

(homogeneous catalyst for rearrangement of propargyl chlorides to allenyl chlorides;[2] reagent for halogen exchange of halonitrobenzenes[1])

Alternate Name: copper(I) chloride-tetra-*n*-butylammonium chloride.

Physical Data: mp 71-72 °C.

Solubility: sol haloalkanes, haloarenes, ketones, and other polar solvents; poorly sol alkanes.

Preparative Methods: in situ complexation of freshly prepared ***Copper(I) Chloride*** by tetrabutylammonium chloride in appropriate solvent (acetone, chloroform, etc.);[2] pure material can best be prepared by reduction of ***Copper(II) Sulfate*** pentahydrate in aqueous solution with sodium sulfite or ascorbic acid in the presence of tetrabutylammonium hydrogen sulfate and sodium chloride, in the molar ratio 1:2:1:4. The resulting dichlorocuprate salt is extracted into CH_2Cl_2 and may be purified by recrystallization.[3]

Purification: the CH_2Cl_2 solution of the reagent may be dried, the solvent evaporated, and the residue recrystallized from ethyl acetate to yield colorless crystalline rhombic plates.

Handling, Storage, and Precautions: the solid cuprate salt is stable to short-term exposure to air, but should be used immediately or stored under an inert atmosphere.

Chloride Source.

The purified, solid copper(I) chloride-tetrabutylammonium chloride complex has been shown by X-ray crystallography to consist of monomeric, linear $CuCl_2^-$ ions,[4] and is thus best described as tetrabutylammonium dichlorocuprate(I). The reagent appears to function as a source of nucleophilic chloride soluble in common organic solvents. The exact role of the copper(I) is unclear, but the reactivity of the dichlorocuprate does not appear to be a simple extension of that of the chloride ion alone. The nucleophilic reactivity is strongly enhanced over that of tetrabutylammonium chloride alone in the same solvents,[1] and it seems likely that the dichlorocuprate ion coordinates with the substrate during reaction.

The reagent provides a mild alternative to the mixtures of solid and dissolved copper(I) chloride in concentrated hydrochloric acid commonly used to effect rearrangement of propargyl chlorides to the isomeric allenyl chlorides and to effect halogen exchange in activated aryl halides. It is particularly useful where a strongly acidic reaction medium is undesirable, or in kinetic studies in which it is necessary to know the exact concentration of

dichlorocuprate ion.

Use of this reagent promoted rearrangement of a propargyl chloride to the isomeric allene with a high degree of *anti* stereospecificity (eq 1).[2]

(1)

The purified dichlorocuprate reagent was used in kinetic studies of the halogen exchange reaction of 3-bromo-2-halonitrobenzenes (eq 2).[1,5]

(2)

Both chlorides of the dichlorocuprate are kinetically active, and the observed rate expression was first order in both substrate and chloride ion. Under the conditions of the kinetic study in chlorobenzene solution, the substitution was approximately 90% complete after 5 h, and >99% complete after 24 h reaction time. The 3-bromo-2-chloronitrobenzene product was not reactive with tetrabutylammonium dibromocuprate and tetrabutylammonium diiodocuprate; hence, the above reaction was not reversible. However, 2,3-dibromonitrobenzene and 2-iodo-3-bromonitrobenzene underwent reversible substitutions with the latter two dihalocuprates. Reaction rates for substitution of 2,3-dibromonitrobenzene by tetrabutylammonium dichlorocuprate are enhanced in aqueous DMSO.[5]

Related Reagents.

Tetra-*n*-butylammonium Fluoride[1]

***n*-Bu$_4$NF**

(TBAF)

[429-41-4] · $C_{16}H_{36}FN$ · Tetra-*n*-butylammonium Fluoride · (MW 261.53) (TBAF.3H_2O)

[87749-50-6] · $C_{16}H_{42}FNO_3$ · Tetra-*n*-butylammonium Fluoride · (MW 315.59) (TBAF.*x*H_2O)

[22206-57-1]

(can be used for most fluoride-assisted reactions; deprotection of silyl groups;[1e] desilylation;[2,3] fluorination;[4] used as a base[5,6])

Alternate Name: TBAF.

Physical Data: TBAF.*x*H_2O: mp 62-63 °C.

Solubility: sol H_2O, THF, MeCN.

Form Supplied in: trihydrate, 1.0 M solution in THF, and 75 wt % solution in water.

Preparative Method: aqueous ***Hydrofluoric Acid*** is passed through an Amberlite IRA 410 OH column, followed by an aqueous solution of ***Tetra-n-butylammonium Bromide***. After the resin is washed with water, the combined water fractions are repeatedly evaporated until no water is present. Tetrabutylammonium fluoride is collected as an oil in quantitative yield.

Handling, Storage, and Precautions: use in a fume hood.

Deprotection of Silyl Groups.

Tetrabutylammonium fluoride has been used widely as a reagent for the efficient cleavage of various silyl protecting groups such as *O*-silyls of nucleosides,[7,8] pyrophosphate,[9] *N*-silyls,[10,11] CO_2-silyl, and *S*-silyl derivatives.[1e] These reactions are often carried out under very mild conditions in excellent yields. Thus it has been used in the synthesis of base-sensitive chlorohydrins (eq 1)[12] and β-lactams.[10,13] 2-(Trimethylsilyl)ethoxymethyl groups can also be effectively removed from various substrates (eq 2).[14-18] Silyl ethers can be converted to esters in one pot when they are treated with TBAF, followed by exposure to acyl chlorides[19,20] or anhydride[21] in the presence of base (eq 3). Treatment of triisopropylsilyl enol ethers with ***Iodosylbenzene***/***Azidotrimethylsilane***, followed by desilylation and elimination with TBAF, gives good yields of the α,β-unsaturated ketones (eq 4).[22,23]

(1)

(2)

(3)

(4)

Cyclobutanone alkyl silyl acetals, obtained from [2 + 2] cycloadditions, can be deprotected with 1 equiv of TBAF in THF to give the open-chain cyano esters in excellent yields (eq 5).[24] When 4-chloro-2-cyanocyclobutane alkyl silyl acetals are used as substrates for this reaction, (*E*/*Z*) mixtures of 2-cyanocyclopropanecarboxylates are obtained by an intramolecular cyclization (eq 6).

(5)

(6)

11-Membered pyrrolizidine dilactones have been synthesized by treating a trimethylsilylethyl ester with TBAF in MeCN to form an anion, which then undergoes cyclization by displacement of the mesylate.

Desilylation Reagent.

Cleavage of carbon-silicon bonds with fluoride has been studied very extensively. TBAF is a very powerful reagent for desilylation of a wide range of silicon-containing compounds, such as vinylsilanes,[2,25,26] alkynylsilanes,[23,27] arylsilanes,[28,29] acylsilanes,[30] β-silyl sulfones,[31-33] and other silane derivatives.[3,34-37] It appears that cleavage of sp-C-Si bonds is more facile than that of sp^2-C-Si and sp^3-C-Si bonds and that substituted groups, such as phenyl and alkoxyl, can often facilitate cleavage. A dimethylphenylsilyl group can be removed from a vinyl carbon by TBAF with retention of the alkene stereochemistry (eq 7).[2] This method has been applied to the synthesis of

terminal conjugated trienes (eqs 8 and 9).[38] The five-membered siloxanes can be desilylated with 3 equiv of TBAF in DMF and this protodesilylation is very sensitive to subtle structure changes (eq 10).[39]

(7)

(8)

(9)

(10)

The anions, generated in situ by desilylation of silylacetylenes,[40,41] allylsilanes,[42-44] propargylsilanes,[45] α-silyloxetanones,[46] bis(trimethylsilylmethyl) sulfides,[47] and other silane derivatives,[48-51] can undergo nucleophilic addition to ketones and aldehydes (eq 11).[52] *N*-(*C*,*C*-bis(trimethylsilyl)methyl) amido derivatives can add to aldehydes followed by Peterson alkenation to form acyl enamines.[48,53] Treatment of 2-trimethylsilyl-1,3-dithianes can generate dithianyl anions, which are capable of carbocyclization via direct addition to carbonyl or Michael addition (eq 12). The fluoride-catalyzed Michael additions are more general than Lewis acid-catalyzed reactions and proceed well even for those compounds with enolizable protons and/or severe steric hindrance (eq 13).[54,55]

(11)

(12)

(13)

Direct fluoride-induced trifluoromethylation of α-keto esters (eq 14),[56] ketones,[57] aldehydes,[58,59] and sulfoxides[59] have been reported using ***Trifluoromethyltrimethylsilane*** with TBAF in THF.

(14)

Desilylation of some compounds can generate very reactive species such as benzynes,[60] pyridynes,[61] xylylenes,[62,63] and benzofuran-2,3-xylylenes.[64] 1,4-Elimination of *o*-(α-trimethylsilylalkyl)benzyltrimethylammonium halides with TBAF in acetonitrile generates *o*-xylylenes, which undergo intermolecular and intramolecular cycloadditions (eq 15).[62-64] Treatment of α-silyl disulfides with ***Cesium Fluoride*** or TBAF forms thioaldehydes, which have been trapped by cycloaddition with cyclopentadiene (eq 16).[65]

(15)

Use as a Base.

TBAF has been widely used for a variety of base-catalyzed reactions such as alkylation,[66] elimination,[67] halogenation,[68] Michael addition,[69-71] aldol condensation, and intramolecular cyclizations.[5,72-74] It is especially useful when other inorganic bases face solubility problems in organic solvents. The reactions are usually carried out below 100 °C due to the low thermal stability of TBAF.[1e]

TBAF is very useful for alkylation of nucleic acid derivatives. Methylation[75] or benzylation[66] of uracil gives almost quantitative yields of alkylated product when using alkyl bromides, dialkyl sulfates (eq 17), trialkyl phosphates, or alkyl chlorides with TBAF. Alkylation of the thiol anions generated from deprotection by 1,2-dibromoethane produces interesting tetrachalcogenofulvalenes.[14] Under phase-transfer conditions, selective mono- and dialkylations of malononitrile have been achieved by using neat TBAF with ***Potassium Carbonate*** or ***Potassium t-Butoxide*** and controlling the amount of alkyl bromides or iodides used (eqs 18 and 19).[76]

Enol silyl ethers react with aldehydes with a catalytic amount of TBAF to give the aldol silyl ethers in good yields. These reactions generally proceed under very mild conditions and within shorter periods of time than conventional strong acidic or basic conditions. The

products from 4-*t*-butyl-1-methyl-2-(trimethylsilyloxy)cyclohexene and benzaldehyde show very good axial selectivity and a little *anti-syn* selectivity (eq 20).[77] The aldol condensation of ketones and aldehydes can be achieved in one pot when ethyl (trimethylsilyl)acetate is used as a silylation agent with TBAF (eq 21).

(20)

(21)

Silyl nitronates undergo aldol condensation with aldehydes in the presence of a catalytic amount of anhydrous TBAF to form highly diastereoselective *erythro* products, which can be elaborated to give synthetically useful 1,2-amino alcohols (eq 22).[6,78] A one-pot procedure has been developed for direct aldol condensation of nitroalkanes with aldehydes by using TBAF trihydrate with ***Triethylamine*** and ***t-Butyldimethylchlorosilane***.[79] It appears that silyl nitronates are not reactive intermediates in this case, and the reactions proceed by a different mechanism.

(22)

Miscellaneous.

Fluoride ion from anhydrous TBAF undergoes nucleophilic displacement of tosylates,[4,80] halides,[80] and aryl nitro compounds[81] to give fluorinated products. When used with ***N-Bromosuccinimide***, bromofluorination products are obtained.[82]

Several important peptide-protecting groups such as 9-fluorenylmethyloxycarbonyl,[83] benzyl,[84] 4-nitrobenzyl,[85] 2,2,2-trichloroethyl,[85] and acetonyl (eq 23)[86] can be removed by TBAF under mild conditions.

Tetra-*n*-butylammonium Fluoride (Supported)[1]

***n*-Bu$_4$NF**

[429-41-4] · $C_{16}H_{36}FN$ · Tetra-*n*-butylammonium Fluoride (Supported) · (MW 261.53)

(can be used for most fluoride-assisted reactions;[1] deprotection of silyl groups;[2] catalysis of Michael addition;[1] alkylation;[3] desilylation;[4] fluorination[5])

Alternate Name: TBAF.

Form Supplied in: on alumina; on silica gel.

Handling, Storage, and Precautions: TBAF/SiO_2 is nonhygroscopic and an air-stable material. Contact with skin may cause irritation.

Desilylation Reagent.

Tetra-n-butylammonium Fluoride is very hygroscopic and absorbed water can greatly effect the reactivity. TBAF/SiO_2 is a nonhygroscopic fluoride ion source, which is also very effective for most fluoride-assisted reactions. Desilylations of allyl, benzyl, and heteroaryl silanes generate carbanions, which undergo nucleophilic addition to an electrophilic center.[4,6] The benzothiazolyl carbanion obtained from treatment of benzothiazolylsilanes with TBAF/SiO_2 or ***Cesium Fluoride*** adds to benzaldehyde to give alcohols (eq 1). When cyclohexen-2-one is used as an electrophile, the 1,4-Michael addition product is obtained in reasonable yield (eq 2). δ-Valerolactone can be opened under these reaction conditions to give the corresponding keto alcohols (eq 3).

(1)

(2)

(3)

By using TBAF/SiO_2 or CsF as catalysts with allylsilanes, different products from addition to cyclohexen-2-one have been obtained (eqs 4 and 5). The α-chloroallyl anion made from α-trimethylsilylallyl chloride with TBAF/SiO_2 adds to benzaldehyde with little regioselectivity (eq 6).[7]

(4)

(5)

(6)

TBAF/SiO_2 is also effective for deprotecting silyl groups. TBDMS groups of *N*-silylated β-sultam derivatives can be removed by TBAF/SiO_2 using very mild conditions in good yields (eq 7).[2]

(7)

Fluoride- and Lewis acid-catalyzed intramolecular cyclization of alkylidene 1,3-dioxo compounds with an allylsilane moiety has been observed. It is possible that fluoride cleaves the allylic C-Si bond to give an allylic anion which adds to carbonyl compounds, or more likely, a hypervalent silyl anion is formed as an intermediate (eq 8).[8]

(8)

Fluorination.

Activated nitro groups can be displaced by the fluoride of TBAF or TBAF/SiO_2. This reaction can provide some very useful fluoroaromatic compounds with a very short synthesis. Heating 1-nitrobenzo[*c*]cinnoline with TBAF/SiO_2 in decalin for several hours gave 1-fluorobenzo[*c*]cinnoline in reasonable yield (eq 9).[5]

(9)

Use as a Base.

TBAF/SiO_2 is an effective and convenient reagent for catalyzing Michael addition, oxidation, sulfenylation, and alkylation. Nitromethane (eq 10) and PhSH (eq 11) undergo Michael addition very smoothly at rt within a few hours.[1] When a large excess of reagent was used, esterification of acetic acid was achieved (eq 12).

(10)

(11)

(12)

TBAF/Al_2O_3 is more effective than KF/Al_2O_3 and CsF/Al_2O_3 for methylation of phenol. The reactions are usually complete within a short period of time in quantitative yields (eq 13).[3]

(13)

When using ***Ethyl Trimethylsilylacetate*** (ETSA) as a silylating agent and TBAF/SiO_2 as a catalyst, regioselective formation of silyl enol ethers has been achieved. 2-Methylcyclohexanone is converted to two silyl enol ether isomers where the kinetic product is predominant (eq 14). Exclusive kinetic product with high (*Z*) selectivity has been achieved on 2-methylpentan-3-one (eq 15). These reaction conditions can also be used to silylate alcohols with longer reaction times (eq 16).

Tetra-*n*-butylammonium Hydroxide

***n*-Bu$_4$NOH**

[2052-49-5] · $C_{16}H_{37}NO$ · Tetra-*n*-butylammonium Hydroxide · (MW 259.54)

(quaternary ammonium salt; strong base; phase-transfer catalyst[1])

Alternate Name: TBAH.

Solubility: sol most organic solvents (alcohols, hydrocarbons, aromatics, halogenated solvents), H_2O.

Form Supplied in: 40 wt % solution in H_2O; 1.0 M solution in MeOH. A typical impurity is tributylamine.

Analysis of Reagent Purity: aqueous titration with HCl versus phenolphthalein;[2] nonaqueous titration with benzoic acid in pyridine and thymol blue indicator.[3]

Preparative Method: prepared in situ from ammonium halides.[2]

Handling, Storage, and Precautions: methanol solution is hygroscopic; highly toxic; may decompose on heating.[4]

Alkylations.

Tetrabutylammonium hydroxide (**1**) has been used to effect a variety of organic transformations. A strongly basic catalyst, (**1**) was able to promote alkylation (eq 1)[5] and arylation[6] of nitroalkanes under phase-transfer conditions. The intermediate tetrabutylammonium *aci*-nitronates generated were more reactive than the corresponding lithium salts.

The monoalkylation of cyanomethanephosphonic diamides was reported to occur with high selectivity and good yield (eq 2).[7] Strong amide bases or ***Sodium Hydride*** led to formation of mixtures of mono- and dialkylation products. Alkylations of other active hydrogen compounds have been studied.[8]

The selective monobenzylation of an indole nitrogen under phase-transfer conditions proceeds in better than 95% yield for a variety of substrates (eq 3).[9] The reaction is procedurally simple when compared to the alkylation of the dianion normally generated under

anhydrous conditions with ***n-Butyllithium*** (***Hexamethylphosphoric Triamide***, THF, 0 °C), which produces only a 60% yield of product.

(3)

An extension of this chemistry is seen in the intramolecular alkylations of nitrogen which have been reported in the preparation of dihydropyridones (eq 4).[10]

(4)

Tetrabutylammonium hydroxide has also been used in the Robinson annulation of dihydrocarvone with ***Methyl Vinyl Ketone*** in 63% yield, which is reported to improve upon other methods.[11] Dehydration does not occur in the reaction and workup is simplified (eq 5). Similarly, intramolecular Horner-Emmons closure of an activated phosphono ester was used in the synthesis of (±)-silphinene (eq 6).[12]

(5)

(6)

Dehydrations.

Vicinal dihydro diols of polycyclic aromatic hydrocarbons such as the benzo[*a*]pyrene derivative (**2**) were dehydrated under mild conditions by treatment with TBAH in methanol (eq 7).[13] Alkali hydroxides did not effect the reaction in these cases without a catalyst present (crown ether or ammonium salt), and methanol was necessary as solvent. The regioselectivity for the dehydration (**3:4** = 13:87) was opposite to that from a ***Phosphoric Acid***-catalyzed dehydration (**3:4** = 97:3). The base-catalyzed reaction did not proceed for substrates which lacked aromatization capability. A patent has been obtained for the monodehydration of a fluorinated dihydroxybenzene under similar conditions.[14]

Carbenes.

The reaction of (**1**) with ***Chloroform*** under phase-transfer conditions is a good method for generating dichlorocarbene.[1c] This reaction was used to cleanly generate aldehyde (**6**) from dehydronuciferene (**5**), which is nucleophilic enough to attack dichlorocarbene (eq 8).[15] In contrast, compound (**5**) could not be alkylated with ***Iodomethane***.

A phase-transfer reaction mediated by tetrabutylammonium hydroxide was found to be most suitable for the halo lactonization of alkynoic acids to prepare halo enol lactones (eq 9).[16] The reaction was carried out with halosuccinimides in the presence of catalytic TBAH, and yields of 70-93% were obtained.
