Tetra-*n*-butylammonium Iodide[1]

***n*-Bu_4NI**

[311-28-4] · $C_{16}H_{36}IN$ · Tetra-*n*-butylammonium Iodide · (MW 369.43)

(phase-transfer catalyst;[1] ether cleavage;[1] alkyl iodide formation;[1] salt effects[1])

Physical Data: mp 148 °C.

Solubility: sol EtOH, H_2O.

Form Supplied in: anhydrous white solid.

Analysis of Reagent Purity: tetraalkylammonium salts can be titrated with potassium 3,5-di-*t*-butyl-2-hydroxybenzenesulfonate and iron(III) chloride.[1a]

Purification: crystallize from toluene-petroleum ether, CH_2Cl_2-petroleum ether (or hexane), acetone, ethyl acetate, EtOH-ethyl ether, aq EtOH, or H_2O. The solid is then dried at 90 °C under high vacuum for 2 d.[2]

Handling, Storage, and Precautions: highly hygroscopic solid.

Phase-Transfer Catalyst.

Although Bu_4NI is not as widely used as ***Tetra-n-butylammonium Bromide***, it is often used in phase-transfer reactions. It was shown to promote several *N*-alkylation reactions[3] of heterocycles such as pyrroles[4] and of amides[5,6] (eq 1).

(1)

It has also been used in phase-transfer carbene-mediated cyclopropanation reactions,[7] metal-catalyzed carbonylation reactions of organic halides,[8,9] and Wittig alkenation reactions.[10]

Several *O*-alkylation reactions[11] were shown to proceed much faster if Bu_4NI was added to the reaction mixture. One particularly interesting case is the benzylation of diethyl tartrate in which addition of a catalytic amount of Bu_4NI was shown to be essential for obtaining high yield of the desired product (eq 2).[12]

(2)

A mixture of ***Zinc Chloride*** and Bu_4NI catalyzes the synthesis of cyclic carbonates from oxiranes and carbon dioxide at rt and atmospheric pressure.[13]

Ether Cleavage.

Methyl, allyl, and benzyl ethers derived from alcohols and phenols are regioselectively cleaved by a mixture of Bu_4NI and a Lewis acid (***Boron Trifluoride Etherate***[14] or ***Aluminum Iodide***[15]).

Alkyl and Vinyl Iodide.

Bu_4NI can also be used as a source of iodide for nucleophilic displacement reactions. Neopentyl iodides can be prepared via S_N2 displacement of the corresponding triflate (eq 3).[16] Alkenyliodonium tetrafluoroborates can be converted to vinyl iodides upon treatment with Bu_4NI (eqs 4 and 5).[17]

Tetra-*n*-butylammonium Periodate

***n*-Bu_4NIO_4**

[65201-77-6] · $C_{16}H_{36}INO_4$ · Tetra-*n*-butylammonium Periodate · (MW 433.43)

(oxidation of sulfides,[1] phenacyl bromides,[1] benzyl halides,[3] phosphites;[7] oxidative decarboxylation;[1] co-oxidant in metal-catalyzed oxidation[1b,5,8])

Physical Data: mp 158-159 °C.

Solubility: sol CH_2Cl_2, $CHCl_3$, benzene, DMSO; insol H_2O, alcohol.

Form Supplied in: white crystalline solid; readily available.

Handling, Storage, and Precautions: tetrabutylammonium periodate is best stored in the dark because it readily turns yellow on exposure to light. There is no loss of oxidizing power on prolonged storage.

Introduction.

Due to its ease of preparation[1] and its solubility in common organic solvents, tetrabutylammonium periodate (**1**) is a useful reagent for the oxidation of organic compounds under homogeneous reaction conditions.

Oxidation of Sulfides to Sulfoxides.[1]

Treatment of sulfides with (**1**) in refluxing $CHCl_3$ selectively provided the sulfoxides in good yields.[1a] Thus, oxidation of methyl *p*-methylphenyl sulfide gave the corresponding sulfoxide in 86% yield. An advantage of this method is that the sulfoxides are readily isolated by simple filtration through a column of silica gel. Oxidant (**1**) and catalytic amounts of *meso*-tetraphenyporphyrinatoiron(III) chloride (**2**) have been found to be effective for the selective oxidation of sulfides to sulfoxides (eq 1).[1b] Sulfides that usually resist oxidation, such as *p*-nitrophenyl phenyl sulfide and di-*t*-butyl sulfide, are also efficiently oxidized to the corresponding sulfoxides. Alkenic bonds are tolerated under the reaction conditions.

(1)

Oxidative Cleavage of Carbonyl Compounds.

α-Hydroxy carboxylic acids are efficiently oxidized to the aldehydes by treatment with (**1**) in refluxing $CHCl_3$ (eq 2).[1a] Reaction times were found to be shorter than the usual ***Sodium Periodate*** method, which required extended reaction times.

(2)

$R = C_{14}H_{29}$, 90%; Ph, 86%

Benzaldehyde derivatives were also obtained in good yields by the oxidative decarboxylation of arylacetic acids with (**1**) in refluxing 1,4-dioxane.[2] This method was found to be better than the hypochlorite route, which gave over-oxidation products. Treatment of phenacyl bromides with (**1**) in refluxing 1,4-dioxane gave good yields of the corresponding benzoic acids (eq 3).[1a] This oxidation was found to be specific for phenacyl bromides since chloroacetone was not oxidized under the same reaction conditions.

(3)

Other Applications.

Benzyl halides are efficiently converted to benzaldehydes by treatment with (**1**) in refluxing 1,4-dioxane.[3] This oxidation was found to be specific for benzyl halides since compounds such as phenethyl bromide were not oxidized under the same conditions. Oxidant (**1**) has also been shown to be effective for the oxidative cleavage of stannylene derivatives of 1,2-glycols to give high yields of the aldehydes.[4] It was also shown that allylic and benzylic alcohols were oxidized to the corresponding aldehydes by the use of (**1**) and catalytic amounts of either *trans*-$[RuO_2(py)_4][BF_4]_2.H_2O$ (**3**) or *trans*-$[Ru_2O_6(py)_4]$ in CH_2Cl_2 at rt.[5] For example, piperonyl alcohol was oxidized using (**1**) in the presence of (**3**) to give a 99% yield of piperonal. Phenols have been subjected to (**1**) in CH_2Cl_2 at rt to afford good yields of quinones.[6] In the synthesis of oligodeoxynucleotides via the phosphite triester route, oxidant (**1**) was found to be useful for the oxidation of a dinucleoside phosphite to a dinucleoside phosphate under neutral, nonaqueous conditions.[7] The use of a catalytic amount of *meso*-tetraphenylporphyrinatomanganese(III) chloride (**4**) and (**1**), in the presence of 1 equiv of ***Imidazole***, was found[8] to be highly effective for the oxidative desulfurization and deselenation at pentavalent phosphorus (eq 4). The use of (**1**) alone only gave low yields of products.

Tetra-*n*-butylammonium Permanganate

***n*-Bu_4NMnO_4**

[35638-41-6] · $C_{16}H_{36}MnNO_4$ · Tetra-*n*-butylammonium Permanganate · (MW 361.47)

(used for the oxidation of polycyclic alkanes,[1] arenes,[1,2] alkenes,[2,3] alcohols,[2,4] and aldehydes[2])

Physical Data: 98 °C (dec).[5]

Form Supplied in: purple solid.

Solubility: sol 0.417 M in CH_2Cl_2, 3.44 × 10^{-4} M in toluene, 2.96 × 10^{-5} M in CCl_4, 2.10 × 10^{-3} M in H_2O; dec $CHCl_3$.[5]

Analysis of Reagent Purity: ε = 2530 ± 30 L mol^{-1} cm^{-1} at 526 nm.[5] IR (KBr) 3420, 2970, 2870, 1470, 1370, 910 cm^{-1}. NMR (CD_2Cl_2) δ 0.35, 0.80, 2.70 ppm.

Preparative Methods: ***Potassium Permanganate*** (3.16 g, dissolved in a minimum of water) is added with stirring to tetra-*n*-butylammonium chloride (6.44 g, dissolved in 200 mL of water) and the purple precipitate collected and washed with water; yields 6.43 g (89%) after drying under vacuum in the presence of P_2O_5.[6]

Purification: recrystallize by dissolving the reagent in a 2:1 solution of CCl_4 and CH_2Cl_2 and drawing a stream of dry air over the mixture to slowly evaporate the solvent. The crystalline product which forms is collected and washed with pentane. It decomposes with ignition at 101 °C when heated in a melting-point tube. The melting point obtained using thermal differential analysis is 98 °C. Highly purified material is not required for most synthetic procedures.

Handling, Storage, and Precautions: oxidant; small quantities may be stored in glass vessels at or below rt. One report states that a violent ignition occurred when 2 g of tetra-*n*-butylammonium permanganate was being weighed onto a glassine paper.[2] Precautions should, therefore, be taken when handling this reagent.

Oxidation of Polycyclic Hydrocarbons.

As illustrated by the following reactions, this reagent shows a substantial preference for the oxidation of tertiary C-H bonds to alcohols as compared to secondary C-H bonds to ketones (eq 1).[1]

(1)

Oxidation of Arenes.

The oxidation of benzylic methyl groups yields carboxylic acids (eq 2),[2] while more elaborate side chains give alcohols or ketones, depending on the extent of substitution in the benzylic position (eqs 3 and 4).[1]

(2)

(3)

(4)

Oxidation of Alkenes.

Alkenes are either cleaved[2] or converted into 1,2-diols by tetra-*n*-butylammonium permanganate (eqs 5 and 6).

(5)

(6)

Fc = ferrocenyl

Oxidation of Alcohols.

Primary alcohols are oxidized to carboxylic acids[2] and secondary alcohols to ketones[2,4] by this reagent (eqs 7-9).

(7)

(8)

(9)

Fc = ferrocenyl
R = methyl, isopropyl, methoxy or aryl

Oxidation of Aldehydes.

Substituted benzaldehydes are oxidized to the corresponding benzoic acids in good yield.

Other Reactions.

Tetra-*n*-butylammonium permanganate has also been used as an oxidant in certain inorganic syntheses.[7] The reactions of tetra-*n*-butylammonium permanganate are very similar to those of other quaternary ammonium and phosphonium permanganates such as ***Benzyltriethylammonium Permanganate*** and ***Methyltriphenylphosphonium Permanganate***. Similar reactions can also be carried out more simply by use of phase-transfer processes which are described under ***Potassium Permanganate***.

Tetra-*n*-butylammonium Tribromide

***n*-Bu_4NBr_3**

[38932-80-8] · $C_{12}H_{36}Br_3N$ · Tetra-*n*-butylammonium Tribromide · (MW 482.23)

(mild and efficient brominating agent; useful for synthesis of vicinal dibromides from alkenes and alkynes; synthesis of α-bromo acetals; determination of multiple bonds; oxidation in nonaqueous medium)

Alternate Name: $TBABr_3$.

Physical Data: mp 84 °C (76 °C when crude); λ_{max} (MeCN): 268 nm (67 000), λ 380 nm (810).

Solubility: insol H_2O; sol anhydrous acetic acid (50 g/100 mL), MeCN (300 g/100 mL), $CHCl_3$, trichloroethylene (10 g/100 mL), THF, dioxane; very sol DMF, DMSO; slightly sol alcohols; sol acetone with slow reaction, giving lachrymatory solution.

Form Supplied in: anhydrous, orange nonhygroscopic stable solid; purity more than 98%; stable bromine degree (1 g = 2.07 mequiv Br_2). Red crystals when recrystallized from DMF solution.

Handling, Storage, and Precautions: avoid washing reaction vessels with acetone prior to using with this reagent. Should be handled in a fume hood.

Bromination of Alkenes.

The application of pyridinium, quinolinium, or trimethylphenylammonium tribromide as brominating reagents is known but little used.[1] Tetra-*n*-butylammonium tribromide allows easy double bond bromination under mild conditions and with very good yields (Table 1).[2] For example, an equimolar amount of $TBABr_3$ is slowly added to a solution of alkene in $CHCl_3$ to give, after solvent evaporation, a residue which is washed with 5% aqueous $Na_2S_2O_3$ solution and ethanol, and then filtered and recrystallized. Yields are generally in the range 85-95%.

		15

Bromination of Alkynes.

The bromination of alkynes is usually difficult and gives mixtures of products.[3] The use of $TBABr_3$ in CCl_4, at rt leads to the (*E*) isomer of 1,2-dibromo alkenes in high yields (85-95%) (Table 2).[4]

Synthesis of α-Bromo Acetals.

α-Bromo acetals are useful reagents for the synthesis of α,β-unsaturated ketones.[5] These derivatives are usually prepared in two steps including

bromination.[5,6] and yields are often poor. $TBABr_3$ is a convenient reagent which gives α-bromo acetals from ketones when used with ethylene glycol.[2] Thus, to a solution of 120 mL of dry ethylene glycol and 0.1 mol of ketone is added an equimolar amount of $TBABr_3$ until the red solution turns yellow (generally 6-10 h). The mixture is then poured into 70 mL of pentane, 70 mL of 10% Na_2CO_3 and 20 mL of 5% aqueous $Na_2S_2O_3$. The organic phase is separated, water washed, dried (Na_2SO_4), and concentrated. The desired α-bromo acetals are obtained in yields of 75-80% (Table 3).

Table 3 Synthesis of α-Bromo Acetals

Ketone	α-Bromo Acetal	Reaction time (h)
		6
		8
		8

Oxidizing Bromination.

4-Bromo-1,1-diphenylbuten-3-one can be prepared in a one-pot synthesis from 1,1-diphenyl-3-ethylenedioxy-1-butanol by the action of $TBABr_3$ in dry $CHCl_3$.[7]

Regioselective Bromination of Aromatic Amines.

The reaction of $TBABr_3$ with aminopyridine and aromatic amines $PhNR^1R^2$ (R^1 = H, Me, Ph, Cy; R^2 = H; R^1 = R^2 = Et) in an aprotic and nonbasic solvent at 20 °C gives exclusively the *para*-brominated compounds in high yields (95%).[8]

Selective Bromination of Phenols.

Phenols were brominated in the *para* position (95%) using $TBABr_3$ in chloroform (or in the *ortho* position if the *para* position was substituted).[8a,9]

Determination of Unsaturation Number.

A method for the determination of the unsaturation number in organic compounds is based on bromination with $TBABr_3$ in nonpolar media followed by electrochemical monitoring of Br_3^-.[10]

Tetra-*n*-butylammonium Tricarbonylnitrosylferrate

***n*-$Bu_4N^+[Fe(CO)_3(NO)]^-$**

[96206-23-4] · $C_{19}H_{36}FeN_2O_4$ · Tetra-*n*-butylammonium Tricarbonylnitrosylferrate · (MW 412.42)

(nucleophilic source of iron;[1] mediates electrophilic allylation;[2] can mediate nucleophilic allylation;[2] carbonylation reagent[3])

Physical Data: mp 56-56.5 °C.

Solubility: sol conventional organic solvents such as benzene and THF.

Preparative Method: prepared in 84% yield by the addition of a benzene solution of ***Pentacarbonyliron*** (15 mmol in 5 mL) to a mixture of ***Sodium Nitrite*** (15 mmol) and ***Tetra-n-butylammonium Bromide*** (15 mmol) in water, stirring for 3 h, and separation and concentration of the benzene layer.[1]

Handling, Storage, and Precautions: is less susceptible than sodium tricarbonylnitrosylferrate to air or moisture, allowing handling in the open atmosphere. Storage under inert atmosphere in a glove box is recommended.

Allylic Alkylation.

Tetrabutylammonium tricarbonylnitrosylferrate catalyzes the allylation of malonate anion by allyl carbonates.[1] The reagent serves as a more air-stable substitute (albeit less reactive[5]) for sodium tricarbonylnitrosylferrate. Allylation occurs predominantly without allyl migration, and with a high degree of retention of configuration at a chiral center of the allyl unit (eq 1).[4] Typical conditions employ sodium diethyl malonate (2 equiv), $Bu_4N[Fe(CO)_3(NO)]$ (25 mol %), and the allyl carbonate in THF at reflux under a CO atmosphere. The reaction is thought to proceed by two successive S_N2 reactions, and an η^1-allyliron intermediate.

Using stoichiometric amounts of $Bu_4N[Fe(CO)_3(NO)]$, a wider variety of stabilized carbanions (anions of malonates, β-keto esters, dicyanomethane) and enamines have been allylated by allylic halides or mesylates, via an isolated η^3-allyliron intermediate.[2,6] The reaction has been applied to 2-trimethylsiloxyallyl halides and 3-trimethylsiloxyallyl halides to give 1,4-dicarbonyl compounds and 1,5-dicarbonyl compounds, respectively (eq 2).[7] In the stoichiometric reactions, nucleophilic attack is predominantly at the less substituted side of the allyl unit, and *anti* to the face of the allyl unit bearing the iron residue.

The η^3-allyliron complexes formed from $Bu_4N[Fe(CO)_3(NO)]$ and allyl halides may also function as nucleophiles with allyl or propargyl halides or acid chlorides.[2] The 1-silyloxyallyliron complexes (formed from 3-trimethylsilyloxyallyl iodides) also react in this fashion with allyl or propargyl halides to afford β-allyl or propargyl ketones or esters upon workup, thereby serving as nucleophilic homoenolate equivalents.[6] In these cases the prior addition of ***Triphenyl Phosphite*** gives enhanced yields (eq 3). Regiochemistry of attack is predominantly at the less substituted end of the allyl halide, and attack by the allyl halide is *syn* to iron.

Carbonylation.

Alkyl halides are carbonylated by stoichiometric amounts of $Bu_4N[Fe(CO)_3(NO)]$ in the presence of ***Carbon Monoxide*** (eq 4).[3] Primary benzyl halides react much more efficiently than secondary benzylic ones. Formation of aldehydes may compete in the case of alkyl halides. Allylic halides may be carbonylated in a two-step process featuring the addition of diphos (***1,2-Bis(diphenylphosphino)ethane***) with $Bu_4N[Fe(CO)_3(NO)]$ in the initial step.

Tetracarbonylcyclopentadienylvanadium[1]

$CpV(CO)_4$

[12108-04-2] · $C_9H_5O_4V$ · Tetracarbonylcyclopentadienylvanadium · (MW 228.08)

(catalyst for stereoselective alkene oxidation;[1e,3] forms an anionic hydride complex which reduces dibromides;[4] reacts with alkynes to form cyclic ketones[1a,5])

Physical Data: mp 139 °C.[1a]

Solubility: sol benzene, 1,2-dichloroethane, THF; slightly sol hexane.

Form Supplied in: orange air-sensitive solid.

Analysis of Reagent Purity: IR, NMR.[2]

Purification: sublimation at 80-100 °C/0.5 mmHg.[1a]

Handling, Storage, and Precautions: store and handle under an inert atmosphere.

Alkene Oxidation.

$CpV(CO)_4$ catalyzes the stereoselective oxidation of cyclohexene by molecular oxygen to form *cis*-1,2-epoxycyclohexane-3-ol with 99% stereoselectivity.[3a] The yields are good at low conversion rates (e.g. 65% at 10% conversion) and are reasonable at higher conversion rates (eq 1).

(1)

$CpV(CO)_4$ has also been reported to catalyze the epoxidation of (*Z*)-cyclooct-2-en-1-ol with ***t-Butyl Hydroperoxide***, giving predominantly the *cis*-epoxy alcohol (eq 2).[3b]

(2)

Reduction of Organic Halides.

The anionic hydride, generated from $CpV(CO)_4$ and ***Sodium*** metal followed by a water quench, has been reported to replace halogen by hydrogen in alkyl, acyl, and vinyl halides by an apparent free radical mechanism (Table 1).[4]

Table 1 Reduction of Organic Halides by $PPN^+ [CpV(CO)_3H]^-$

$$CpV(CO)_4 \xrightarrow[3.\ PPN^+Cl^-]{1.\ Na,\ THF;\ 2.\ H_2O} PPN^+[CpV(CO)_3H]^- \xrightarrow[25\ °C]{R\text{-}X} RH$$

Substrate	Product	Time (h)	Yield (%)
$C_8H_{17}Br$	C_8H_{18}	4	75
		0.5	95
		1	95
BnCOCl	BnCHO	<0.1	100
PhCH=CHBr	$PhCH{=}CH_2$	5	46

Alkyne-CO Cooligomerization.

The interaction of $CpV(CO)_4$ with alkynes has been shown to give cyclic ketone products where either one or two CO ligands are incorporated into the organic product. Cyclopentadienones, quinones, and tropones have all been observed as products in these reactions, with the product ratios being dependent upon the reaction conditions and the identity of the substituents on the alkyne. An example of the dependency of the reaction on the alkyne substitution is shown by the contrasting results shown in eqs 3 and 4. The thermal reaction of diphenylacetylene with $CpV(CO)_4$ gives tetraphenylcyclopentadienone as the major organic product (eq 3), while perfluorodiphenylacetylene gives perfluorotetraphenylquinone as the major organic product (eq 4).[5]

$$CpV(CO)_4 + 2\ PhC{\equiv}CPh \xrightarrow[\text{reflux, 12 h; 46\%}]{\text{toluene}} \text{(Ph}_4\text{-cyclopentadienone)} \quad (3)$$

$$CpV(CO)_4 + 2\ C_6F_5C{\equiv}CC_6F_5 \xrightarrow[\text{reflux, 12 h; 61\%}]{\text{toluene}} \text{(}(C_6F_5)_4\text{-quinone)} \quad (4)$$

Tetracarbonyl(di-μ-chloro)dirhodium

[14523-22-9] · $C_4Cl_2O_4Rh_2$ · Tetracarbonyl(di-μ-chloro)dirhodium · (MW 388.76)

(catalyst or catalyst precursor for rearrangement of strained rings;[1] carbonylative ring expansion;[2] carbonylative coupling of organometallics;[3] hydroformylation;[4] silylformylation[5])

Physical Data: mp 124 °C; sublimes 80 °C/1 mmHg.

Solubility: sol most organic solvents; slightly sol saturated hydrocarbons.

Form Supplied in: red or orange solid; widely available.

Purification: recryst from hexanes.

Handling, Storage, and Precautions: stable in dry air but should be protected from moisture. Solutions decompose in air; solvents should be deoxygenated before dissolving reagent.

Rearrangement of Strained Rings.

Rearrangements of many strained polycyclic hydrocarbons have been carried out with $[Rh(CO)_2(\mu\text{-}Cl)]_2$, but most of these hold more mechanistic interest than synthetic utility.[6] On the other hand, rearrangements of three-membered rings have proven more generally useful. Thermolysis of alkoxy- or siloxycyclopropanes with catalytic $[Rh(CO)_2(\mu\text{-}Cl)]_2$ gives enol ethers,[1a,b] although stereoselectivity is slight (eq 1). Catalyzed rearrangement of 3-acylcyclopropenes yields substituted furans in a regioselective manner (eq 2).[1c,2a] When the reaction is carried out under CO, these same substrates are rearranged with carbonylation to give α-pyrones (eq 3).[2a] In a similar way, vinyl cyclopropenes are carbonylated to give phenols.[2a] Carbonylative ring expansion of aryl aziridines occurs stereo- and regiospecifically to give β-lactams (eq 4); however, the reaction fails in the absence of the aryl substituent.[2b] Cyclopropene (**1**) reacts with 1-hexyne to give oxepin (**2**) in the presence of $[Rh(CO)_2Cl]_2$, which then was isomerized with acid to phenol (**3**) (eq 5) in near quantitative yield.[11]

(1)

(*E*):(*Z*) = 70:30

(2)

Organometallic Coupling.

The $[Rh(CO)_2(\mu\text{-}Cl)]_2$-catalyzed carbonylative coupling of vinylmercury(II) chlorides provides an efficient synthesis of symmetric divinyl ketones (eq 6).[3a] Arylmercury(II) chlorides or triarylbismuthines[3b] are coupled to give diaryl ketones, while in the absence of CO the mercury reagents are directly coupled to 1,3-dienes and biaryls.[7]

Hydroformylation of Alkenes.

$[Rh(CO)_2(\mu\text{-}Cl)]_2$ is a common catalyst precursor for hydroformylation in the presence of phosphine or phosphite ligands.[4a,b] These reactions are not often used in synthetic schemes because regioselectivity can be poor and alkene isomerization and hydrogenation can

interfere. Nevertheless, with some functionalized alkenes, useful selectivity can be achieved,[4a,c] including modest enantioselectivity (eq 7).[4b,d]

(7)

Silylformylation.

In reactions related to hydroformylation, $[Rh(CO)_2(\mu\text{-}Cl)]_2$ catalyzes the addition of hydrosilanes and CO to enamines, giving silyl enol ethers (eq 8).[5a] Hydrolysis provides α-siloxy ketones. β-Siloxy aldehydes arise stereospecifically from the ring-opening silylformylation of epoxides (eq 9).[5b] As in many of the reactions catalyzed by $[Rh(CO)_2(\mu\text{-}Cl)]_2$, other Rh^I catalysts such as $[Rh(cod)(\mu\text{-}Cl)]_2$ and $Rh(CO)_2(acac)$ can also be used.

(8)

(9)

Catalytic Hydrogenation of Alkenes.

Alkenes are catalytically hydrogenated to alkanes with $[Rh(CO)_2Cl]_2$. The reagent is usually bound to either alumina[8] or phosphine-functionalized polystyrene,[9] although $[[Rh(CO)_2Cl]_2$ has also been used as a heterogeneous catalyst. *trans*-1,3-Pentadiene, for example, has been reduced regiospecifically at the terminal double bond in good yield.[10]

Related Reagents.

Chlorotris(triphenylphosphine)rhodium(I).

Tetracarbonylnickel[1]

$Ni(CO)_4$

[13463-39-3] · C_4NiO_4 · Tetracarbonylnickel · (MW 170.73)

(oxidation of aryl halides and alkynes; oxidative addition of alkyl and aryl halides; rearrangement and cyclization; carbonylation)

Physical Data: mp -25 °C; bp 43 °C; *d* 1.32 g cm^{-3}; based on calorimetry, the average Ni-C bond strength is 35 kcal mol^{-1}; bond distances Ni-C 1.82 Å and C-O 1.15 Å.

Solubility: insol H_2O; sol most organic solvents.

Form Supplied in: colorless liquid in a lecture bottle or in a cylinder, usually under CO pressure.

Analysis of Reagent Purity: IR spectrum, ν_{CO} = 2040 cm^{-1}; ^{13}C NMR spectrum, δ = 193 ppm; UV spectrum, λ_{max} = 206 nm (ε = 10^5).

Preparative Method: formed from finely divided ***Nickel*** and ***Carbon Monoxide*** gas to give a four-coordinate d^{10} metal complex, with tetrahedral geometry, that satisfies the 18-electron rule.

Handling, Storage, and Precautions: toxic; flammable in air; must be used in a well ventilated fume hood and kept under an inert atmosphere.

Oxidation Reactions.

Upon reaction of $Ni(CO)_4$ with ***Chlorine***, ***Bromine***, or ***Iodine***, the carbonyls are released as carbon monoxide gas and the nickel is oxidized, generating NiX_2 (eq 1). This reaction proves to be a very efficient method for the destruction of excess $Ni(CO)_4$ at the end of a reaction sequence. For example, simply pouring the reaction mixture into a flask containing solid I_2 or by adding an I_2 solution to the reaction mixture, CO gas evolves and the nickel forms NiI_2, which is water soluble.[1]

$$Ni(CO)_4 + X_2 \longrightarrow CO + NiX_2 \qquad (1)$$

A second method for quenching unreacted $Ni(CO)_4$ is to sweep all volatile compounds out of the reaction flask with a stream of nitrogen or argon gas. These volatile compounds are collected in a cold trap and then quenched with ***Nitric Acid***. As with the halogens, the HNO_3 will oxidize the $Ni(CO)_4$, generating carbon monoxide gas and a water-soluble nickel complex.

Reduction Reaction.

The reaction between $Ni(CO)_4$ and an alkali metal, a metal amalgam, or a metal hydroxide generates anionic nickel carbonyl clusters. The major two products are $Ni_5(CO)_{12}^{2-}$ and $Ni_6(CO)_{12}^{2-}$, with the ratio being dependent upon the reaction conditions used.[2] These clusters react with aryl halides[3] (or alkynes[4]) to generate benzoic acid derivatives (eq 2).

$$Ni(CO)_4 + OH^- \longrightarrow Ni_5(CO)_{12}^{2-} \xrightarrow[88\%]{PhBr} PhCO_2H \qquad (2)$$

Nucleophilic Attack.

There are two sites for nucleophilic attack in $Ni(CO)_4$. The first is one of the coordinated carbonyl ligands and the second is the nickel itself, but this can occur only if one of the ligands first dissociates.

Unlike the reaction with hydroxide mentioned above, in the reaction of $Ni(CO)_4$ with a nucleophile such as methoxide, a dialkyl amide, or an alkyllithium, the carbonyl is attacked to give a nickel acylate complex (eq 3). Because these complexes are discussed under ***Lithium Tricarbonyl(n-pentanoyl)nickelate***, it will only briefly be mentioned here that nickel acylate complexes are very air- and water-sensitive, and they react with both alkyl and vinyl halides to form esters, amides, and ketones, respectively.[5-7]

(3)

Poorer nucleophiles do not attack one of the carbonyls. Instead, they coordinate to $Ni(CO)_3$, which is formed readily by the thermal or photochemical dissociation of a carbonyl ligand from the $Ni(CO)_4$.[8] As a specific example, the reaction of $Ni(CO)_4$ with a phosphine (PR_3) is first order in nickel complex and zero order in phosphine.[9] This suggests rate-limiting dissociation of a carbonyl ligand followed by a rapid attack on the $Ni(CO)_3$ by the phosphine (eq 4).

(4)

If an excess of phosphine is used, the $Ni(CO)_3(PR_3)$ complex will react in a similar manner to generate $Ni(CO)_2(PR_3)_2$. Due to the increase in back-bonding from the metal into the π^* orbital of the carbonyl as the number of phosphine ligands increases, removal of a third carbonyl and formation of $Ni(CO)(PR_3)_3$ does not occur.

Halide ions will also react with $Ni(CO)_4$ to form halide-$Ni(CO)_3$ anionic complexes.[8,10] The order of nucleophilicity of the halides is the standard order of $I^- > Br^- > Cl^-$. It is believed that a halide-$Ni(CO)_3$ anionic complex is the actual species which reacts with the acid chloride in the lactone synthesis shown in eq (5).[10]

(5)

Oxidative Addition Reactions.

$Ni(CO)_4$, or more specifically $Ni(CO)_3$, will react with alkyl halides in an oxidative addition reaction. (There are a large number of examples of Ni^0 complexes other than $Ni(CO)_4$ undergoing oxidative addition reactions;[1] however, they will not be covered here.) One of the more common reactions of this type is the reaction of $Ni(CO)_4$ with an allyl bromide derivative to form a π-allyl nickel complex (eq 6). These complexes, unlike the analogous palladium complexes, are nucleophilic.[11] In addition, the allyl groups can couple to form a 1,5-hexadiene derivative. For more of the chemistry of allyl nickel complexes, see ***Bis(allyl)di-μ-bromodinickel***.

(6)

The reaction of an aryl iodide with $Ni(CO)_4$ generates a 1,2-diketone when THF is used as the solvent, and an ester when methanol is used as the solvent (eq 7). The exact mechanism of this reaction is not known, but a benzoyl-nickel complex has been proposed as a likely intermediate. The reaction of this intermediate with another intermediate forms the diketone or with the alcohol forms the ester.[12]

(7)

Similarly, the reaction of an alkyl or vinyl halide with an excess of an alkoxide (RO^-) and $Ni(CO)_4$ in an alcohol solvent at refluxing temperature, generates the corresponding ester in high yield (eq 8). In contrast to the previous reaction, it is speculated that the mechanism involves initial formation of a nickel acylate complex, followed by reaction of the acylate complex with the alkyl or vinyl halide.[6] However, a mechanism in which the nickel carbonyl reacts with the alkyl or vinyl halide to form an acyl nickel complex, and then this is quenched by the alkoxide, cannot be excluded.

(8)

This general type of reaction also can be performed in the presence of an amine to form an amide as the final organic product (eq 9).[6]

(9)

Intramolecular variations of these two reactions have led to the syntheses of α-methylene lactones and β-lactams. Specifically, the reaction of nickel tetracarbonyl with a molecule possessing a vinyl halide on one end and an alcohol on the other, in refluxing THF with or without added base, can generate a five- or six-membered α-methylene lactone in good yield (eq 10).[13]

(10)

An aziridine, which is first ring-opened with ***Lithium Iodide***, reacts with nickel tetracarbonyl in a similar cyclization reaction to generate a β-lactam (eq 11).[14]

(11)

These two steps must be done individually because, as discussed above, iodide and nickel carbonyl readily react with each other. Because

the first step is an S_N2 reaction, the less substituted carbon-nitrogen bond is carbonylated. This result is complementary to the use of a rhodium complex for the conversion of an aziridine to a β-lactam. In that reaction it is always the more substituted C-N bond which is carbonylated.[15] In addition, it has been shown that when a 2,3-disubstituted aziridine is the starting material, the product β-lactam is generated with retention of stereochemistry.

The oxidative addition of nickel tetracarbonyl has been shown to be an effective method for the formation of an alkene by the removal of two halogens which are *cis*. For example, a *cis*-1,2-dichlorocyclobutane derivative upon reaction with nickel carbonyl generates the corresponding cyclobutene (eq 12).[16] This reaction is compatible with a large variety of R groups; however, the chlorines must be attached to carbon atoms which contain electron-withdrawing groups. If the methoxycarbonyl groups are replaced by electron donors, the starting material is stable to the reaction conditions.[17]

(12)

R = Et, 87%

Rearrangement and Cyclization Reactions.

Nickel carbonyl will catalyze the rearrangement of a vinylcyclobutene to a cyclohexadiene derivative (eq 13).[17] Although a reactive intermediate has not been observed, based upon deuterium-labeling studies, it has been determined that the reaction is unimolecular and that it is the 2,3-bond (and not the 3,4-bond) which is cleaved.

(13)

Nickel tetracarbonyl has initiated a variety of other ring-formation reactions, including the lactone synthesis shown in eq 5.[10] Another is the reaction between an allyl bromide and an alkyne to generate a cyclopentenone derivative (eq 14).[18]

(14)

This reaction is not restricted to allyl bromide itself. A large variety of allyl bromide derivatives have been used, including cyclic derivatives which generate products containing either fused bicyclic or spirocyclic ring systems. In all cases the cyclization reaction gives the five-membered ring rather than the six-membered ring. The alkyne component does not have to be symmetrical. Acetylene itself, terminal alkynes, and unsymmetrical disubstituted alkynes work well. Although the exact mechanism of this reaction is not known, it has been proposed that initially an allyl-nickel complex is formed, followed by alkyne insertion, then carbonyl insertion, and finally ring closure to produce the five-membered ring.[19]

Carbonylation Reactions.

In the absence of any added allyl bromide, an alkyne and nickel carbonyl will react in methanol (excess HCl also is added to this reaction to increase the rate) to give an α,β-unsaturated ester in good yield (eq 15).[20]

(15)

In addition, it is possible to carbonylate alkenes. This reaction proceeds at a faster rate when the double bond is incorporated into a strained ring system, but almost any alkene will work. 1,5-Hexadiene can be carbonylated to give a *cis*/*trans* mixture of 2,5-dimethylcyclopentanone, as the major product, in good yield (eq 16). Some of the methylcyclohexanone also is generated.[21]

(16)

A substituted dibromocyclopropane, but not the corresponding monobromocyclopropane, can be carbonylated with nickel carbonyl using DMF as the solvent to generate an ester, when the reaction is done in the presence of an alcohol, or an amide, when the reaction is done in the presence of a secondary amine. A large variety of R groups are compatible with these reaction conditions.[22] Where applicable, a *cis*/*trans* mixture of products usually results (eq 17).

(17)

If one of the R groups is H and the other is CH_2Cl, ring opening of the cyclopropane occurs concomitantly with the carbonylation, again to generate either the ester or the amide (eq 18).[23]

Tetrachlorocyclopentadienone

[4723-74-4] · C_5Cl_4O · Tetrachlorocyclopentadienone · (MW 217.85)

(highly reactive diene for Diels-Alder reactions)

Physical Data: unstable as the monomer; matrix-isolated IR spectrum has been recorded.[1]

Form Supplied in: must be prepared in situ.

Preparative Methods: conveniently generated in the presence of dienophiles, starting from hexachlorocyclopentadiene. Treatment of this material with concentrated ***Sulfuric Acid*** at 80 °C affords in good yield the pentachlorocyclopentenone,[2] which is readily dehydrohalogenated with either sodium acetate in MeCN or ***Sodium Iodide*** in 1,2-dimethoxyethane (eq 1).[3]

(1)

Reactive Diene.

The utility of tetrachlorocyclopentadienone as a reactive diene has received very little attention. The reagent has only rarely been employed as a trap for dienophiles. Dietsche reported the first Diels-Alder reactions of the reagent with norbornadiene and cyclopentadiene in yields of 80% and 60%, respectively (eqs 2 and 3).[3] The norbornadiene cycloadduct undergoes thermal extrusion of carbon monoxide and subsequent retro-Diels-Alder reaction to give the 1,2,3,4-tetrachlorobenzene (eq 4). Maleic anhydride, acrylonitrile, and less reactive dienophiles such as cyclopentene, cyclohexene, norbornene, and phenylacetylene all fail to react with the reagent; dimerization presumably occurs preferentially.

(2)

(3)

(4)

Fray reported the Diels-Alder reaction of the reagent with acenaphthylene to afford the *endo* and *exo* cycloadducts in a ratio of 4.2:1 (eq 5).[4] Reinvestigation of the reaction with cyclopentadiene gave as the major products the *endo*- and *exo*- adducts in a ratio of about 170:1, along with the Cope-rearranged derivative (eq 6).

Because of the propensity to dimerize, the reagent is more commonly employed as its dimethyl acetal.[2]

Related Reagents.

Cyclopentadiene; ***2,5-Bis(methoxycarbonyl)-3,4-diphenylcyclopentadienone***; ***5,5-Dimethoxy-1,2,3,4-tetrachlorocyclopentadiene***; ***Tetrachlorocyclopentadienone Ethylene Acetal***; ***Tetraphenylcyclopentadienone***.

Tetrachlorocyclopentadienone Ethylene Acetal[1]

[2082-08-8] · $C_7H_4Cl_4O_2$ · Tetrachlorocyclopentadienone Ethylene Acetal · (MW 261.91)

(Diels-Alder adduct formation;[1-3] employed in the synthesis of condensed polycyclic systems[4,5])

Alternate Name: 6,7,8,9-tetrachloro-2,5-dioxaspiro[4.4]nona-6,8-diene.

Physical Data: mp 65-67 °C; bp 78-80 °C/0.13 mmHg.

Solubility: insol H_2O; sol ether, alcohol, acetone; slightly sol hexane.

Form Supplied in: not available commercially; can be made before use and stored.

Preparative Method: the title reagent can be prepared from hexachlorocyclopentadiene, ***Ethylene Glycol***, and ***Potassium Hydroxide***.

Purification: by distillation followed by recrystallization from ether-pentane.[1]

Handling, Storage, and Precautions: dimerizes in solution within a few months at 0 °C and within 1 h at 100 °C. It is stable for at least 1 year when stored at 0 °C. It is carcinogenic and should be handled in a fume hood.

Diels-Alder Reactions.

The principle use of the title reagent is as a diene in [4 + 2] cycloaddition reactions. It provides 1:1 adducts as shown in eq 1 with dienophiles such as ***Maleic Anhydride***, 2-butene-1,4-diol, ***2,5-Dihydro-2,5-dimethoxyfuran***, allyl alcohol, methyl maleate, indene, ***Vinyl Acetate***, 3-thiolen-2-one,[3a] vinylcyclopropane,[3b] 1,1-diphenyl-2-vinylcyclopropane,[3b] cyclopropene,[3c] 1-methylcyclopropene,[3c] phenylacetylene,[2b] diallylamine, ***Cyclopentadiene***, *cis,cis*-cycloocta-1,3-diene, *cis,cis*-cycloocta-1,5-diene, and cyclooctadeca-1,5,9-triene.[1c] It is notable that reactions occur with both electron-rich and electron-deficient dienophiles. Other alkenes that react with the title reagent include norbornadiene,[5d] 7-*t*-butoxy norbornadiene,[6] cycloheptatriene, tropone, and *p*-benzoquinone.[7] Several of the polyenes afford 2:1 cycloadducts.

(1)

Cycloadducts with properly selected dienophiles can lead to structures of potential interest by unmasking and manipulating the carbonyl group, and using the chlorides as precursors for other functional groups of interest.[4] For example, the title reagent has been used as a starting material in syntheses of condensed polycyclic systems, as shown in eqs 2 and 3.[5]

(2)

(3)

Miscellaneous Reactions.

The reaction of nitrosobenzene with the title reagent has been reported to give *N*-phenyldichloromaleimide and the unsaturated lactam shown in eq 4.[8] The mass spectra of Diels-Alder adducts of alkenes with the title reagent are much simpler than the spectra of other derivatives, and have been used to determine double bond position and alkene geometry.[9]

Tetrachloro(η^5-cyclopentadienyl)niobium-Magnesium[1]

($CpNbCl_4$)

[33114-15-7] · $C_5H_5Cl_4Nb$ · Tetrachloro(η^5-cyclopentadienyl)niobium-Magnesium · (MW 299.81) (Mg)

[7439-95-4] · Mg · Tetrachloro(η^5-cyclopentadienyl)niobium-Magnesium · (MW 24.31)

(catalyst for cyclotrimerization of alkynes[1])

Solubility: sol THF.

Preparative Method: generated, in situ, from $CpNbCl_4$ and ***Magnesium***.

Handling, Storage, and Precautions: is prepared and used under an inert atmosphere of nitrogen or argon.[1] Use in a fume hood.

Cyclotrimerization.

It has been demonstrated[1] that catalytic amounts of $CpNbCl_4$-Mg (i.e. 1 mol %) will effect the cyclotrimerization of terminal alkynes. A mixture of 1,3,5- and 1,2,4-trisubstituted benzenes are obtained as products, with the 1,3,5-trisubstituted isomer being slightly favored (eq 1; Table 1). The reaction proceeds in 83-91% yield with aryl- and alkyl-substituted alkynes; trimethylsilylacetylene, however, does not react. In contrast to the reaction with terminal alkynes, internal alkynes do not undergo cyclotrimerization or polymerization when treated with catalytic amounts of $CpNbCl_4$-Mg.

Table 1 Cyclotrimerization of Terminal Alkynes (eq 1)

R	Yield (%)	Ratio (**1**):(**2**)
Ph	90	7
Bu	91	1.2
$(CH_2)_3OTBDMS$	95	1.2
$(CH_2)_2OCO$-*i*-Bu	83	1.2

Alkyne-Diyne Annulation.

$CpNbCl_4$-Mg catalyzes an annulation reaction between diynes and internal alkynes or sterically hindered terminal alkynes (eqs 2 and 3). These annulations, which lead to indanane ring systems, are conducted at 50 °C with 0.35 equiv of $CpNbCl_4$-Mg. Higher reaction temperatures are required because of the less reactive alkyne component, and greater than catalytic amounts of niobium are needed due to decomposition of the niobium intermediates at the higher temperature.

Tetrachlorocyclopropene[1]

[6262-42-6] · C_3Cl_4 · Tetrachlorocyclopropene · (MW 177.83)

(versatile synthetic building block, based on its ability to react as a cyclopropenium cation,[2] a vinylcarbene,[3] or a dienophile[4])

Physical Data: bp 130-133 °C; *d* 1.450 g cm^{-3}.

Solubility: sol common organic solvents; undergoes ring opening in H_2O at 25 °C and in alcohols at 50-80 °C.[5]

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: GC, IR.[5]

Preparative Method: from ***Sodium Trichloroacetate*** and ***Trichloroethylene***.[6]

Handling, Storage, and Precautions: lacrymator; must be stored at 4 °C in the absence of moisture; use in a fume hood.

Cyclopropenium Cations.

Tetrachlorocyclopropene (**1**) is widely used as an entry to cyclopropenium cation chemistry. Thus, upon treatment with ***Aluminum Chloride***, (**1**) readily forms the trichlorocyclopropenium salt (**2**) in virtually quantitative yield,[7] which can further be converted to a variety of cyclopropenium cations (**3**) (eq 1).[2] Compound (**2**) has been the starting point for the synthesis of a broad variety of heterocycles, e.g. benzimidazoles or 1,5-benzodiazepines,[8] 2-azacalicenium salts,[9] or indolizines.[10]

Treatment of (**2**) with arenes and subsequent hydrolysis with alcohols gives rise to arylpropiolates (**4**) in good to excellent yields (eq 2).[11]

The transformation of (**2**) to substituted cyclopropenones opens up another wide field in synthetic chemistry. For example, vinyl-substituted cyclopropenones derived from (**2**) have been proven to be excellent precursors to α-methylene-γ-butyrolactones.[12]

Another important application of (**2**) was demonstrated with the synthesis of the dialkynyl-substituted cyclopropenone (**5**), which was envisaged as a precursor to new allotropic forms of carbon such as C_{18}, C_{24}, or C_{30}, respectively (eq 3).[13] Moreover, (**5**) can easily be converted to the enediyne (**6**),[13] a structure element which plays a pivotal role in the chemistry of the esperamicin/calicheamicin class of anticancer drugs.[14]

Diarylcyclopropenones (**7**), also readily obtained from (**2**), can be decarbonylated to symmetrically or unsymmetrically substituted alkynes (**8**) in high yields (eq 4).[15]

Vinylcarbenes.

Reagent (**1**) undergoes thermal ring opening to perchlorovinylcarbene (**9**), which is efficiently trapped with a large number of alkenes to form 1-chloro-1-trichlorovinylcyclopropanes (**10**).[3] From these intermediates, ethynylcyclopropanes (**11**) as well as cyclopropylideneacetates (**12**) are readily available (eq 5), which have been widely used in natural and nonnatural product synthesis,[16] including α- and β-amino acids,[16d,e] and β-lactams.[16f]

(5)

Cycloadditions.

Reagent (**1**) can react as an electron-poor dienophile in [4 + 2] cycloadditions to yield bicyclo[4.1.0]heptene derivatives (**13**) (eq 6) allowing, for example, the synthesis of tropolones[17] or triafulvalenes.[18] The stereochemical course of such cycloadditions has been investigated.[4]

Tetrachlorosilane

[10026-04-7] · Cl_4S_2 · Tetrachlorosilane · (MW 169.89)

(precursor of chlorotrialkylsilanes; Lewis acid catalyst)

Physical Data: mp -70 °C; bp 57.6 °C; *d* 1.483 g cm^{-3}.

Solubility: sol benzene, ether, chloroform, petroleum ether, dichloromethane.

Form Supplied in: neat as clear colorless liquid; as 1.0 M solution in dichloromethane.

Handling, Storage, and Precautions: the neat liquid and solutions react violently with water and protic solvents to produce HCl gas. The neat reagent reacts violently and/or explosively with DMSO and DMF. Avoid contact with metals, strong bases, strong acids, and glass. Corrosive; stench; handle and store under N_2; store cool. Use in a fume hood.

Chlorosilane Precursor.

Tetrachlorosilane serves as a useful precursor to tri-, di-, and monosilyl chlorides.[1] Substitution by metal alkoxides and phenoxides,[2] as well as alkyl, vinyl,[3] and aryl organometal nucleophiles, have been reported (eqs 1 and 2). An extremely hindered chlorosilane has been prepared from tri-*t*-butylphenoxide and tetrachlorosilane.[4]

$$2\,ROH + 2\,MeLi \xrightarrow{SiCl_4} (RO)_2SiCl_2 \qquad (1)$$

R = alkyl, aryl

(2)

Treatment of tetrachlorosilane with 4 equiv of a propargyl Grignard reagent afforded, after zirconocene-promoted cyclization and sulfurization, a spiro-fused tetracyclic compound which serves as a precursor to orthogonally fused conducting polymers (eq 3).[5]

Coupling Reagent for Amide Formation.

Tetrachlorosilane in pyridine has been shown to facilitate amide formation from carboxylic acids and alkyl and aryl amines (eq 4).[6]

Acetal and Thioacetal Formation.

Tetrachlorosilane has been shown to convert α,β-unsaturated ketones, in the presence of ethylene glycol, to β-chloro acetals (eq 5).[7] Similarly, a propargyl ketone was transformed into the corresponding β,β-dichloro acetal under the same conditions (eq 6).

(6)

Dithioacetals of aryl aldehydes are efficiently formed upon treatment with 2 equiv of thiol in the presence of tetrachlorosilane (eq 7).[8] Aryl ketones (e.g. acetophenone or benzophenone) were not converted under the reaction conditions, while treatment of aliphatic ketones with tetrachlorosilane and dimercaptoethane resulted in some vinyl sulfide byproduct, as well as the desired dithioacetal (eq 8).

(7)

(8)

Cyclization Promoter.

Tetrachlorosilane was the Lewis acid promoter of choice for a critical cyclization step towards the synthesis of the alkaloids julandine and ipalbidine (eq 9).[9] Other Lewis acids evaluated were $TiCl_4$, $SnCl_4$, $BF_3.Et_2O$, $ZrCl_4$, $AlCl_3$, and $FeCl_3$. Tetrachlorosilane, and several other Lewis acids, were evaluated as promoters for Fischer indole synthesis reactions.[10]

(9)

Disulfide Bond Formation.

In conjunction with diphenyl sulfoxide, tetrachlorosilane in trifluoroacetic acid (TFA) has been shown to effectively facilitate disulfide bond formation in the synthesis of cystine-containing peptides.[11,12] As shown in eq 10, the tetrachlorosilane-diphenyl sulfoxide-TFA system serves to activate the protected SH moiety of cysteine residue side-chains in peptides to afford, after nucleophilic attack of a second protected cysteine thiol, a disulfide bridge. A number of S-protecting groups were employed in the study, including acetamidomethyl (Acm), trimethylacetamidomethyl (Tacm), benzamidomethyl (Bam), *t*-butyl, isopropyl, 4-methoxybenzyl, 4-methylbenzyl, and 4-nitrobenzyl. Similarly, methyltrichlorosilane can be used in place of tetrachlorosilane to effect this transformation and, due to its ease of handling relative to tetrachlorosilane, is recommended by the authors.

The chlorosilane-diphenyl sulfoxide oxidation system is operationally superior to both air and iodine, which are also used to facilitate peptide disulfide bond formation, due to shorter reaction times and improved regio- and chemoselectivity.

Friedel-Crafts Acylation Catalyst.

Tetrachlorosilane-***Silver(I) Perchlorate*** has been employed as a catalyst to effect the Friedel-Crafts acylation of anisole by hexanoic acid anhydride (eq 11).[13] Other Lewis acids used in combination with $AgClO_4$ which were evaluated in the study and shown to be as effective or better than $SiCl_4$ were $GaCl_4$, $GeCl_4$, $SnCl_4$, BCl_3, and $AlCl_3$. Lewis acids which were not as effective as $SiCl_4$ for this application were $InCl_3$, $SbCl_5$, $TiCl_4$, $ZrCl_4$, and $HfCl_4$.

Tetrachlorotris[bis(1,4-diphenylphosphino)butane]diruthenium

$Ru_2Cl_4(dppb)_3$

[55669-36-8] · $C_{84}H_{84}Cl_4P_6Ru_2$ · Tetrachlorotris[bis(1,4-diphenylphosphino)butane]diruthenium · (MW 1623.44)

(a regioselective hydrogenation and dehydrogenation catalyst for the formation of lactones)

Physical Data: mp 186 °C.[1]

Form Supplied in: light-green solid.[1]

Solubility: insol alcohol, ethyl ether; sol CH_2Cl_2, chlorobenzene.[1]

Preparative Methods: $K_2[RuCl_5(H_2O)]$ (1 mmol) in 2 mL of water is added to a hot ethanolic solution (100 mL) of 1,4-bis(diphenylphosphino)butane (dppb) (4 mmol), and the mixture refluxed for 3 h. The resulting light-green precipitate is washed with diethyl ether and extracted with chlorobenzene. The soluble fraction is crystallized repeatedly from chlorobenzene-diethyl ether.[1]

Handling, Storage, and Precautions: should be handled and stored under an inert atmosphere.

Regioselective Hydrogenation Reactions.

Catalytic amounts of tetrachlorotris[bis(1,4-diphenylphosphino)butane]diruthenium (**1**) have been used to regioselectively hydrogenate unsymmetrically substituted cyclic anhydrides to the corresponding lactones. These reactions have been carried out using as little as 2 mol % of (**1**) with both high regioselectivity and isolated yields (eq 1).[2]

(1)

Attempts to reduce the anhydride of eq 1 with ***Lithium Tri-t-butoxyaluminum Hydride*** resulted in low chemical yields and poor regioselectivity. Use of ***Lithium Aluminum Hydride*** and ***Sodium Borohydride*** resulted in reduction of the more sterically hindered carbonyl group.[2]

Regioselective Dehydration Reactions.

Compound (**1**) also catalyzes the dehydrogenation of α,o-diols to lactones with the use of alkenic hydrogen acceptors (eq 2).[3] This system has several advantages over other reagents and catalysts that could be used in these reactions: it is highly regioselective, can be used catalytically, is less expensive than Ag^{I}, is less toxic than Cr^{VI}, and is safer than peroxides.

(2)

These hydrogenation and dehydrogenation reactions are sensitive to the size and location of substituents.[3b] With hydrogenations, bulky substituents α to the anhydride give the highest regioselectivity, while with dehydrogenations, bulky substituents β to an alcohol give the highest regioselectivity. Another study has shown that other ruthenium catalysts, e.g. ***Dihydridotetrakis(triphenylphosphine)ruthenium(II)***, can be comparable and in several cases exceed compound (**1**) in both regioselectivity and yield in catalytic dehydrogenations.[3a]

Tetracyanoethylene[1]

[670-54-2] · C_6N_4 · Tetracyanoethylene · (MW 128.10)

(highly electron-deficient and strongly electrophilic reagent; principal reaction types are addition to its double bond and replacement of the cyano group;[1] forms complexes with organometallic reagents[2])

Alternate Name: TCNE.

Physical Data: mp 200-202 °C (sealed capillary); bp 223 °C/760 mmHg; sublimes at 130 °C/5 mmHg or 60-65 °C/0.2 mmHg.

Form Supplied in: colorless crystals.

Preparative Methods: the preferred synthetic preparation of TCNE involves the debromination of the KBr complex of dibromomalononitrile with Cu powder in boiling benzene (62% yield).[3]

Purification: recrystallize from 1,2-dichloroethane or chlorobenzene, followed by sublimation (130 °C/5 mmHg).

Handling, Storage, and Precautions: extremely toxic and irritant.[4] It must be handled in a well ventilated hood, with rubber gloves, due to appreciable vapor pressure of the reagent at room temperature; sensitive to moist air.

Addition Reactions.

TCNE can be reduced to tetracyanoethane by a variety of reagents (H_2/Pd, HI, H_2S, thiols, $HSCH_2CO_2H$). It was found that, as hydrogen donors, several benzyl alcohols[5] and hydroheterocycles[6] could be dehydrogenated by TCNE (Scheme 1).

Scheme 1

The chlorination of TCNE leads to the formation of 1,2-dichlorocyanoethane (Scheme 1).[7]

TCNE reacts readily with sulfurous acid to give 1,1,2,2-tetracyanosulfonic acid, of which a number of salts have been reported (Scheme 1).[8]

Diazomethane reacts with TCNE to give a pyrazoline which splits off a molecule of nitrogen to give 1,1,2,2-tetracyanocyclopropane (Scheme 1).[9]

The α-cyanoisopropyl radical reacts with TCNE to give 2,3,3,4,4,5-hexacyano-2,5-dimethylhexane (Scheme 1).[8]

The allene tetramer 1,3,5,7-tetramethylenecyclooctane undergoes an unusual 1,7-addition of TCNE to give 3,3,4,4-tetracyano-8,11-dimethylenetricyclo[4.3.3.0]dodecane (Scheme 1).[10]

TCNE adds to ketones containing an α-hydrogen to give tetracyanopropyl ketones (Scheme 1).[8] It is an acid-catalyzed Michael-type addition. However, the reaction of other active methylene compounds with TCNE depends on the basicity of the reaction medium.[11] Thus the reaction of TCNE with 2,4-pentanedione can give different products (Scheme 2).[12] TCNE can also react with cyclic ketones.[1b]

Scheme 2

The oxidation of TCNE with aqueous ***Hydrogen Peroxide*** is the method of choice for the synthesis of tetracyanoethylene oxide (TCNEO) (Scheme 1).[13] The reaction of TCNEO with alkenes proceeds via a 1,3-dipolar cycloaddition pathway.[14] TCNEO can also react with nucleophilic reagents[15] (dialkyl sulfide,[16] nitrogenated tertiary aromatic bases,[14e,15,17] diphenylcyclopropenone, diphenylcyclopropenenethione,[18] or thiophene[19] (Scheme 3).

Scheme 3

Synthesis of Heterocycles.

TCNE has proven to be a useful starting material for the synthesis of five- or six-membered heterocycles, including thiophenes, pyrroles,[20] isoxazoles, pyrazoles, pyridines, and pyrimidines.[21] The required reaction partner can be an enolic ketone, amine, imine, hydrazone, or an α,β-unsaturated azo compound. The reaction generally proceeds via a Diels-Alder or 1,3-dipolar cycloaddition. The reaction of TCNE with acyclic ketones yields either 4*H*-pyrans[12] or dihydropyrroles;[22] enolic 1,3-cyclohexanediones with TCNE also produce pyran derivatives.[23] Substituted pyrimidines are obtained from the reaction of barbituric acid with TCNE, and pyrazolopyridines are obtained from aminopyrazoles.[24] Cyclization of 1,1,2,2-tetracyanoethane with substituted azomethines leads to dihydropyrrole or pyrrole derivatives.

Replacement Reactions.

Tricyanovinylation occurs at either the N atom (aliphatic amines) (eq 1) or the *para* position (aromatic amines) (eq 2).[25] (Tricyanovinyl)amines have found widespread interest because of their optical[26] and dyeing[25] properties, and their ability to yield charge-transfer complexes with donors and acceptors.[27] Hassan recently reported that TCNE also forms another tricyanovinylation product, $(PhCH_2)_2NC_6H_4C(CN)=C(CN)_2$, with *N*,*N*-dibenzylaniline.[28]

An example of retrograde Michael addition reaction is illustrated by 2*H*,3*H*-thieno[3,2-*b*]pyrrol-3-one. Instead of the expected tricyanovinyl derivative, 2-dicyanomethylene-2*H*,3*H*-thieno[3,2-*b*]pyrrol-3-one was obtained (eq 3).[29]

Cycloaddition Reactions.

Diels-Alder and Related [4 + 2] Cycloaddition Reactions.

TCNE is a reactive dienophile and undergoes Diels-Alder type cycloadditions with conjugated dienes. The Diels-Alder reaction of TCNE occurs even with sluggish dienes such as 2-vinylnaphthalene, spontaneously and rapidly, without added catalyst or external heat.[8]

The regiochemistry of concerted, thermal cycloadditions is not fully understood, and the stereoselectivity involves either a torsional preference or π-facial attack on the diene entering the [4 + 2] cycloaddition.[30]

Recently, Fessner et al. have investigated the π-facial diastereoselectivity in the Diels-Alder reaction by studying the directing influence of proximate unsaturation.[31] They used the model dienes (**1**) and (**2**) to differentiate the regioselectivity observed with various dienophiles. Based on steric and electronic considerations, (**1**) is expected to yield the *endo-syn* (*syn* with respect to the four-membered ring) adduct and (**2**) the *endo-anti* product with various dienophiles. Dienophiles such as maleic anhydride and *p*-benzoquinone gave the expected *syn* and *anti* cycloadducts with (**1**) and (**2**), respectively. However, TCNE predominantly gave the *syn* product with both (**1**) and (**2**). The authors attribute this to an *anti* preorienting charge-transfer complex involving the electron-depleted orthogonal π-bonds of the dienophile and the suitably oriented π-moieties of (**2**).

(1)

(2)

Porter et al. have investigated the cycloaddition reactions of TCNE with 3-vinylindene, 3-vinylbenzo[*b*]thiophene, and 3-vinylindole.[32] The normal [4 + 2] Diels-Alder cycloaddition reaction is observed with the unsubstituted compounds. However, alkylation of the diene can alter the course of the reaction. Thus (**3**) and (**4**) yield the [2 + 2] cycloadduct (**5**) on reaction with TCNE and a rearrangement accompanies the cycloaddition of TCNE to 2-methyl-3-vinylbenzo[*b*]thiophene (**6**) to give adduct (**7**) (eqs 4 and 5).

(4)

(3) R = Me, X = S
(4) R = H, X = NMe

(5)

(5)

(6) **(7)**

Pindur et al. have demonstrated the versatility of [4 + 2] cycloaddition and elimination processes of TCNE in their studies of the addition reactions such as 1,4-cycloaddition, cycloreversion, sigmatropic rearrangements, and elimination processes of TCNE with dimethylpyrano[3,4-*b*]indol-3-one and 1-methylpyrido[3,4-*b*]indol-3-one.[33] Pindur et al. have also studied the stereoselectivity and regioselectivity of the Diels-Alder reaction of TCNE with (*E*/*Z*)-2-methoxy-substituted 3-vinylindoles. TCNE reacted with (*Z*)-(**8**) to produce (**9a**):(**10**) in a 1:1 ratio and with (*E*)-(**8**) to give (**9b**):(**10**) in a 1:1 ratio.[34]

(8) **(9a)** β-OMe **(10)**
(9b) α-OMe

Homo-Diels-Alder Reaction.

The cycloaddition of dienophiles to bridged 1,4-dienes with interrupted conjugation (homo DA reaction) is a useful synthetic reaction for the preparation of tetracyclic compounds (eq 6).[35]

(6)

Alder Ene Reaction.

The ene reaction is the indirect, substituting addition of a compound having a double bond (enophile) to an alkene possessing an allylic hydrogen atom (ene).[36] Trimethyl-substituted isodicyclopentadiene reacts readily with TCNE in an ene reaction involving a zwitterionic intermediate when the reaction is performed in ethyl acetate. However, TCNE adds to isodicyclopentadiene in refluxing xylene to produce the [4 + 2] cycloadduct in 51% yield.[37]

Thermal [2 + 2] Cycloaddition.

It is well established that TCNE undergoes nonconcerted, ionic, thermal, [2 + 2] cycloaddition reactions with electron-rich alkenes (eq 7).[38] The reaction is believed to involve a zwitterion and not a biradical intermediate. This is supported by strong dependency on solvent polarity,[38c] incomplete stereochemistry,[39] and trapping of the zwitterion with alcohol to form an acetal.[40]

(7)

Other Cycloadditions.

Cyclopropylethylene derivatives have been found to undergo facile cycloadditions with TCNE to form either cyclobutane[41] or cyclopentane derivatives. This thermal, ring-opening cycloaddition was reviewed in 1984.[42]

The reaction of TCNE with substituted 1,3-butadienes leads to competing [4 + 2] and [2 + 2] cycloadditions. The regioselectivity of the reaction depends on substitution of both diene termini, and on solvent polarity. 2,7-Dimethyl-2,4,6-octatriene undergoes cycloaddition with TCNE to give not only the expected Diels-Alder adduct but also the [2 + 2] cycloadduct. Formation of the latter adduct is favored by more polar solvents. The less-substituted 2-methyl-2,4,6-octatriene gives only the [4 + 2] cycloadduct (eq 8).[43]

TCNE can react with [4]annulenes, fulvenes, bullvalenes, and cyclooctatetraenes.[1d]

Photochemical Reactions.

Brief reviews on the photochemical reactions of organic compounds in the presence of TCNE are available.[1e,44] The photocycloaddition of alkenes to benzenoids gives a variety of products. Such electron-poor alkenes as α,β-unsaturated acid derivatives generally give [2 + 2] cycloadducts.[45]

Additional cycloaddition type reactions have been described (cycloaddition with aromatic hydrocarbons, cyclophanes, mesoionic compounds, heterocyclic compounds, and stereoselective addition with exocyclic dienes).[1e]

Organometallic Reactions.

With organometallics, TCNE shows interesting properties such as insertion into metal-hydrogen, metal-carbon, and even metal-metal bonds.

Reactions with Main Group Organometallics.

The reaction of TCNE with the main group organometallic compounds generally proceeds by pathways involving the formation of charge-transfer complexes or fragmentation products. Formation of cycloadducts can also be observed.[46] A review on TCNE charge-transfer complexes of phenyl derivatives of silicon, germanium, tin, and lead has been published.[46b]

It has been found that σ-electrons of low ionization energy, such as the Si-Si and Ge-Ge bonds, can be donated to certain π-acceptors, such as TCNE. Charge-transfer complexes of silicon and germanium with TCNE include polymethylpolysilanes,[47] bimetallic compounds $[(Et_3Ge)_2Hg]$,[48] methylphenylsilanes,[49] aryltrisilanes,[50] phenylsilacyclobutanes,[51] 1,2-disilacycloalkanes,[52] silacyclopentenes,[53] cyclopolysilanes,[54] silatranes,[55] trimethylsilyl-substituted benzene,[56] naphthalene, anthracene, and phenanthrene derivatives,[56b] phenylsilanes[57] and -germanes,[57,58] benzylsilanes and -germanes,[59] silicon-containing ethers,[60] and peralkylcyclopropylsilanes.[61] Furans and thiophene containing silyl,[62] germyl, stannyl, and plumbyl have also been examined.[62b]

Reactions of tetraalkyl organometallics derived from silicon, germanium, tin, and lead with TCNE have been described and involve fragmentation of cation radicals following electron transfer.[63]

The Diels-Alder cycloaddition of TCNE to organometallics derived from silicon, germanium, tin, and mercury is not common but has been described.[64] Moreover, the reaction products are not easy to predict.

Reactions with Metallocenes.

Iron metallocenes are regarded as π-bases of high reactivity. They are able to form charge-transfer complexes with TCNE (π-acid) in which the π-cyclopentadienyl rings or the metal can act as an electron donor (eq 9). These complexes have been shown to have a benzenoid structure.[65] In some cases the TCNE radical-anion salt is obtained (complete electron transfer occurs).[66] Neither ruthenocene nor osmocene form stable complexes with TCNE. However, it can proceed smoothly under photochemical activation.[67] Substituted vinylferrocenes react readily with TCNE in a [2 + 2] cycloaddition type reaction.[68]

(9)

Reaction with Metal-Coordinated Alkenes and Alkynes.

The electrophile TCNE may act either as a one-electron oxidant towards organotransition metal complexes (eq 10),[69] or undergo a variety of reactions such as metal-carbon insertion (eq 11)[70] and [2 + 2] cycloaddition to coordinated polyalkenes (eq 12).[71]

$$Cr(CO)_2(POMe_3)(\eta^6\text{-}C_6Me_6) + TCNE \xrightarrow{CH_2Cl_2,\ rt} Cr(CO)_2(TCNE)(\eta^6\text{-}C_6Me_6) \qquad (10)$$

$$Ru(CO)_2(POMe_3)[H_2C{=}C(Me)\text{-}(Me)C{=}CH_2] + TCNE \xrightarrow{CH_2Cl_2}$$

(11)

(12)

Additional applications of TCNE in organometallic chemistry include platinum-family complexes with TCNE,[2,72] reactions of tricarbonyliron complexes with TCNE,[2] and diverse behavior of TCNE towards transition metal-carbon σ-bonded complexes.[2]

Tetraethylammonium Cyanide

$R_4N^+CN^-$

(R = Et)

[13435-20-6] · $C_9H_{20}N_2$ · Tetraethylammonium Cyanide · (MW 156.31) (R = *n*-Bu)

[10442-39-4] · $C_{17}H_{36}N_2$ · Tetrabutylammonium Cyanide · (MW 268.55)

(nitrile synthesis; asymmetric cyanohydrin synthesis; catalyst)

Physical Data: R = Et, mp 250 °C; R = *n*-Bu, mp 82-85 °C.

Form Supplied in: white powders, commercially available.

Handling, Storage, and Precautions: highly toxic, irritant solids; very hygroscopic and light sensitive; keep container tightly closed, store in dry and dark area. Use only in chemical fume hood. Incompatible with strong acids and bases. Thermal decomposition may produce hydrogen cyanide.

Nitrile Synthesis.

Primary, secondary, neopentyl, benzylic, and allylic halides are readily converted into the corresponding nitriles by reaction with Et_4NCN in polar aprotic solvents (eq 1).[1,2] The workup of the reaction is simple, since the solvent is removed, and the nitrile is dissolved in ether and filtered from the quaternary ammonium halide byproduct which precipitates out. The same reaction applies to acyl or thioacyl halides, while dihalides furnish dinitriles (eq 2).[1]

(1)

(2)

Aromatic or heteroaromatic halides are less reactive, but their trimethylammonio derivatives react with Et_4NCN under very mild conditions yielding nitriles. In this way, chloropyrimidines and chloroquinazolines are converted smoothly into their carbonitriles (eq 3).[3] The same conditions are applied for the conversion of 6-chloropurines to 6-cyanopurines.[4] Treatment of α-halo ketones with Et_4NCN in CH_2Cl_2 furnishes oxiranecarbonitriles (eq 4)[2] which, under more vigorous conditions, especially with the presence of Et_4NBr, furnish β-keto nitriles (eq 4).

Both methoxymethyl (MOM) and (2-methoxyethoxy)methyl (MEM) ethers are directly converted into cyanomethyl ethers by sequental treatment with ***Bromodimethylborane*** and Bu_4NCN in CH_2Cl_2 at -78 °C (eq 5).[5] The reaction conditions are applicable for the preparation of primary, secondary, or tertiary cyanomethyl ethers, which are being used as excellent acyl anion equivalents in intramolecular alkylation reactions.[6]

Treatment of *trans*-octahydro-8α-tosyloxymethyl-2(1*H*)-naphthalenone derivatives with Bu_4NCN in THF results in the formation of the nitrile and the simultanous ring closure, yielding the corresponding (4α)-1α-cyano-11-oxatricyclo[7.2.1.0]dodecane derivative (eq 6).[7]

Asymmetric Cyanohydrin Synthesis.

Reaction of racemic or optically active π aldehyde-rhenium Lewis acid complexes $[CpRe(NO)(PPh_3)(\eta^2\text{-}O{=}CHR)]^+ BF_4^-$ with Et_4NCN in CH_2Cl_2 at -80 °C gives cyanohydrin alkoxide complexes, which by treatment with MTPA-Cl and DMAP in C_6H_6 furnish the optically active Mosher esters of the cyanohydrins (eq 7).[8] Analogous reactions of racemic σ methyl ketone complexes leading to the corresponding optically active cyanohydrins are also reported.[8]

(7)

Use as a Catalyst.

Et_4NCN is formed in situ during the phase transfer catalyzed displacement reactions of alkyl halides (or methansulfonates) with cyanide anion (eq 8).[9]

(8)

The complex $Bu_4NCu(CN)_2$ (prepared as a colorless solid by treatment of a slurry of ***Copper(I) Cyanide*** in MeOH with a solution of 1 equiv of Bu_4NCN in MeOH at rt under N_2 and evaporation of the resulting solution to dryness) is used as catalyst for the coupling of vinyllithium components with OBO ester iodides (eq 9).[10]

Benzyltrimethylammonium Cyanide.

This related quaternary ammonium cyanide reagent is prepared by dissolving equimolar amounts of $BnNMe_3Cl$ and NaCN in water.[11] It is used for the transformation of alkyl halides to nitriles in aqueous solution. The reaction proceeds in the absence of any organic solvent, and the ammonium salt serves not only as a cyanide source, but also as a surface active agent, thus promoting the reaction rate (eq 10).[12]

Related Reagents.

Acetone Cyanohydrin; ***t-Butyldimethylsilyl Cyanide***; ***Cyanotrimethylsilane***; ***Diethylaluminum Cyanide***; ***Hydrogen Cyanide***; ***Potassium Cyanide***; ***Sodium Cyanide***.

Tetraethylammonium Periodate

Et_4NIO_4

[5492-69-3] · $C_8H_{20}INO_4$ · Tetraethylammonium Periodate · (MW 321.19)

(oxidizing agent used for generating nitroso compounds from hydroxamic acids,[1] *N*-hydroxycarbamic esters,[2] and *N*-hydroxyureas[3])

Physical Data: mp 176-177 °C.

Solubility: sol H_2O, $MeCO_2H$, acetone, pyridine, CH_2Cl_2; slightly sol alcohol; insol ethyl acetate, Et_2O, benzene.

Preparative Methods: a solution of periodic acid (H_5IO_6) (7.72 g, 0.034 mol) in water (20 mL) was added slowly to a cooled solution of 25% tetraethylammonium hydroxide (20 mL, 0.034 mol). The resulting solution was evaporated under reduced pressure, the solid residue was extracted with hot *t*-butyl alcohol, and the product was precipitated by addition of diisopropyl ether. Recrystallization from *t*-butyl alcohol yielded a white solid (8.5 g, 82%).[4a] **Caution**: a safety shield should be used since any excess H_5IO_6 present may explode violently during concentration of the aqueous solution and extraction of the crude salt.[4b]

Handling, Storage, and Precautions: the reagent is stable and is best stored in a desiccator in the dark.

Oxidizing Agent.

Tetraethylammonium periodate has similar oxidizing properties to ***Sodium Periodate*** but has the advantage that reactions can be conducted in nonaqueous media and its greater solubility in water may be useful in cases where the use of relatively less soluble periodate salts is problematic.[4] Tetraethylammonium periodate has been used mainly for the oxidation of derivatives of hydroxylamines to yield nitroso compounds. It has been reported[4] that stable nitroso compounds have been obtained from the oxidation of *N*-*t*-alkylhydroxylamines. Tetraethylammonium periodate was found to be a mild oxidant for the selective oxidation of hydroxamic acids,[1] *N*-hydroxycarbamic esters,[2] and *N*-hydroxy ureas[3] in the presence of conjugated dienes (eqs 1-3). The highly reactive nitroso intermediates that were formed readily undergo Diels-Alder cycloaddition to the dienes to give synthetically useful cycloadducts. Further, it was demonstrated[5] that cycloadducts of type (**1**) serve as a good source of highly reactive, transient nitroso species; they undergo facile retro-Diels-Alder reactions on heating to regenerate the nitroso intermediate and 9,10-dimethylanthracene. This method for the regeneration of the nitroso compound has been exploited in inter- and intramolecular nitroso-ene reactions.[5]

(1)

(2)

(3)

The generation of nitroso intermediates and trapping of these species by conjugated dienes has found application in natural product synthesis.[6,7] For example, in the stereospecific synthesis of tabtoxin,[6] the key stereochemical defining step involved the cycloaddition of benzyl nitrosoformate, generated in situ by Et_4NIO_4 oxidation of benzyl *N*-hydroxycarbamate, with ethyl 1,3-cyclohexadienecarboxylate (eq 4).

Tetraethyl Pyrophosphate

[21646-99-1] · $C_8H_{20}O_5P_2$ · Tetraethyl Pyrophosphate · (MW 258.22)

(peptide synthesis; phosphonylation of ketones, aldehydes, and perfluoroalkyl iodides)

Alternate Name: TEPP.

Physical Data: bp 79-81 °C/0.15 mmHg; *d* 1.057 g cm^{-3}; n_D 1.434.

Solubility: sol acetonitrile, 1,1,2-trichloro-1,2,2-trifluoroethane.

Form Supplied in: colorless liquid; commercially available.

Preparative Methods: the most convenient method involves the reaction of diethyl phosphite with diethyl phosphorochloridite. Diethyl phosphorochloridite (223 g) is added rapidly to a solution of diethyl phosphite (138 g) and triethylamine (101 g) in benzene (200 ml). The mixture is filtered and the benzene removed by distillation at reduced pressure. The product is isolated by further distillation at reduced pressure (79-81 °C/0.15 mmHg) in 41% yield.

Analysis of Reagent Purity: product purity is assessed by refractive index.

Handling, Storage, and Precautions: protect from moisture; irritant; handle in a fume hood.

Peptide Formation.[1]

Tetraethyl pyrophosphite will react with amino acids at either the free amine (eq 1) to give amidophosphites, or at the free carboxylic acid (eq 2) to give mixed anhydrides, and both are activated for peptide formation. ***Diethyl Phosphonite*** is a good solvent for amino acids and peptides and so the most convenient procedure for peptide formation involves heating an *N*-protected amino acid with an amino acid ester (eq 3) with an excess of TEPP in diethyl phosphite solution. If the amino acid ester is used as the HCl salt, addition of ***Triethylamine*** is advantageous. The product is precipitated by the addition of water or an organic solvent. No racemization has been observed in this procedure with dipeptide formation; however, variable amounts of racemization are observed in tripeptide formation where Cbz protecting groups are used. TEPP has been successfully used in the synthesis of important medium sized peptides, e.g. oxytocin.[2]

(1)

(2)

(3)

Phosphonylation.

Tetraethyl pyrophosphite can function as both an electrophile and a nucleophile. The electrophilic behavior is exemplified by the formation of mixed anhydrides from carboxylic acids (eq 4).[3] TEPP shows a nucleophilic character in reaction with carbonyl compounds. Addition of TEPP to aldehydes and ketones (eq 5)[4-6] gives phosphonium alkoxide intermediates, which undergo an intramolecular transfer of phosphite yielding mixed phosphonate-phosphite adducts. A further equivalent of carbonyl reportedly results in further oxidation to phosphonate-phosphate adducts.

(4)

(5)

Reaction of perfluoroalkyl iodides with TEPP and ***1,1-Di-t-butyl Peroxide*** in 1,1,2-trichloro-1,2,2-trifluoroethane gives diethyl phosphonites, which on oxidation with ***t-Butyl Hydroperoxide*** form diethyl perfluoroalkylphosphonates in good yield (eq 6).[7,8] The standard Arbuzov reaction is not generally applicable to fluoroalkyl phosphonates.

Tetrafluoroboric Acid

BF_4H

[16872-11-0] · BF_4H · Tetrafluoroboric Acid · (MW 87.82) ($HBF_4.OMe_2$)

[67969-83-9] · $C_2H_7BF_4O$ · Tetrafluoroboric Acid Dimethyl Etherate · (MW 133.90) ($HBF_4.OEt_2$)

[67969-82-8] · $C_4H_{11}BF_4O$ · Tetrafluoroboric Acid Diethyl Etherate · (MW 161.96)

(strong acid with pK_a = -0.44[1] and a noncoordinating counterion[2])

Solubility: sol H_2O, alcohols and ethers.

Form Supplied in: 48% aq solution; diethyl ether complex; dimethyl ether complex.

Purification: commercial 50% solutions can be concentrated by evaporation at 50-60 °C/5 mmHg to give a residue of 11 N total acidity. Water can also be removed by slow addition to ice-cold acetic anhydride (dangerously exothermic reaction: caution is advised!).[3]

Handling, Storage, and Precautions: storage in glass containers is not recommended, although dilute solutions can be used in glass containers over short periods. Poisonous: causes burns to eyes, skin, and mucous membranes and may be fatal if ingested. Use in a fume hood with safety goggles and chemically resistant gloves and clothing. Incompatible with cyanides and strong bases: decomposes to form HF.

General Considerations.

Tetrafluoroboric acid is a useful strong Brønsted acid with a nonnucleophilic counterion. Its solubility in polar organic solvents makes it a useful strong acid under nonaqueous conditions.

Preparation of Arenediazonium Tetrafluoroborates.

Arenediazonium salts can be precipitated as their tetrafluoroborate salts by addition of a cold solution of HBF_4 to a solution of the initial arenediazonium chloride. 4-Methoxybenzenediazonium tetrafluoroborate is thus obtained in 94-98% yield. The arylamine can be diazotized with ***Sodium Nitrite*** in the presence of HBF_4, and the diazonium fluoroborate then precipitates directly. 3-Nitroaniline, when treated in this manner, provides a 90-97% yield of 3-nitrobenzenediazonium tetrafluoroborate (eq 1).[4] Diazotizations of arylamines and heteroarylamines in organic solvents can be conveniently conducted using $HBF_4.OEt_2$ and alkyl nitrites.[5]

(1)

Protecting-Group Manipulations.

A preparation of monoesters of glutamic and aspartic acids using $HBF_4.OEt_2$ as a catalyst has been developed. The diesters are generally side products when other acids are used, but $HBF_4.OEt_2$ appears to suppress the diesterification. Thus L-glutamic acid γ-benzyl ester was obtained in 94% yield by treatment of the carboxylic acid in BnOH with the $HBF_4.OEt_2$ catalyst and a drying agent.[6]

When di-*t*-butyl carbonate is treated with DMAP.HBF_4, water-soluble Boc-pyridinium tetrafluoroborate is formed.[36] This reagent installs the Boc protecting group onto amino acids in aqueous NaOH. Thus L-proline is converted to its *N*-Boc derivative in nearly quantitative yield in 10 min.

Carbohydrate protection and deprotection reactions are amenable to HBF_4 catalysis; aqueous HBF_4 and $HBF_4.OEt_2$ are complementary in these applications. Transacetalization with benzaldehyde dimethyl acetal and ethereal HBF_4 gives a monobenzylidene product without disturbing the isopropylidene and trityl groups of the substrate (eq 2). Aqueous HBF_4 is useful in selective deprotection reactions, cleaving a trityl group in the presence of other acid-sensitive functionality (eq 3).[7]

(2)

(3)

Recently developed in solid-phase peptide synthesis is the use of HBF_4/thioanisole/*m*-cresol as a general deprotection reagent. Most commonly used groups are cleaved from termini or side chain functionality under mild conditions (1 M HBF_4, 4 °C, 30-60 min) in very high yields. Human glucagon (a 29 residue peptide) has been synthesized as a demonstration of the effectiveness of the method,[8] which has been successful in both solid-phase and solution-phase syntheses.[9]

General Acid Catalysis.

HBF_4 is a versatile acid catalyst which is applicable to many typical acid-catalyzed reactions. Some adducts obtained upon reaction of cyclopropyl phenyl sulfide anion with carbonyl compounds can be rearranged to cyclobutanones under the catalytic influence of HBF_4 (eq 4), although different acids have been required for other substrates.[10] Acid-catalyzed rearrangement of 2-cyclopropylphenyl phenyl ether or sulfide with HBF_4 has been reported (eq 5).[11]

(4)

(5)

Acid-catalyzed oxidation of epoxides with $HBF_4.OMe_2$/DMSO results in the formation of α-hydroxy ketones (eq 6).[12] This procedure in an acidic medium complements the α-hydroxylation of ketone enolates under strongly basic conditions.

(6)

An intramolecular alkylation of a diazomethyl ketone was achieved with catalysis by HBF_4, providing an angularly fused cyclopentanone hydrofluorene (eq 7).[13]

(7)

Other catalytic applications of HBF_4 include alkene isomerizations,[14] alkylation of alcohols with diazoalkanes,[15] preparations of substituted pyridines,[16] hydrolysis of α-hydroxyketene or α-(methylthio)ketene thioacetals to α,β-unsaturated thioesters,[17] and terpene formation from isoprenic precursors.[18]

Preparation of Annulated Triazolones.

Cyclization of the isocyanate in eq 8 in the presence of HBF_4 affords an oxotriazolium tetrafluoroborate, which then rearranges to form a 1,5-heteroannulated 1,2-dihydro-2-phenyl-3*H*-1,2,4-triazol-3-one (eq 8).[19]

Carbenium Tetrafluoroborate Preparation.

4,6,8-Trimethylazulene is converted by ethereal HBF_4 into 4,6,8-trimethylazulenium tetrafluoroborate.[20] A convenient preparation of tropylium tetrafluoroborate employs HBF_4 to precipitate the product from a solution of the double salt $[C_7H_7]PCl_6.[C_7H_7]Cl$ in ethanol (eq 9). An indefinitely stable, nonhygroscopic, and nonexplosive white solid is obtained, a distinct advantage of a fluoroborate salt.[21]

The formyl cation equivalent 1,3-benzodithiolylium tetrafluoroborate can be made in 94% yield by treatment of a dithioorthoformate with HBF_4/Ac_2O (eq 10).[22] 2-Deuterio-1,3-benzothiolylium tetrafluoroborate prepared by this method has been used to produce 1-deuterioaldehydes by homologation.[23] An analogous preparation of a similar formyl cation equivalent, 1,3-dithiolan-2-ylium tetrafluoroborate, employs $HBF_4.OEt_2$ (eq 11) to provide the intermediate salt. Subsequent reaction with a silyl enol ether forms a masked 2-formylcyclohexanone in high yield (eq 11).

(11)

Ethynylfluorenylium dyes can be obtained by treatment of appropriate tertiary alcohols with HBF_4 (eq 12).[24]

(12)

In addition to the aforementioned carbenium ions and diazonium ions, numerous other organic cations can be obtained as their fluoroborate salts by treatment of appropriate precursors with HBF_4.[25]

Dimerization of Carbodiimides.

Treatment of alkyl carbodiimides with anhydrous $HBF_4.OEt_2$ in CH_2Cl_2 results in rapid dimerization to tetrafluoroborate salts in 95% yield (eq 13). Basification converts the salts to diazetidines.[26] In the same work, aryl carbodiimides undergo a similar reaction, but substituted quinazolines are obtained.

Mercury(II) Oxide/Tetrafluoroboric Acid.

Yellow ***Mercury(II) Oxide*** is added to 48% aqueous HBF_4 to yield, upon solvent removal, $HgO.2HBF_4$ as a hygroscopic white solid.[27] This reagent is useful in applications involving mercuration of alkenes, including diamination of alkenes and preparation of *trans*-cinnamyl ethers from allylbenzene.[28] Alkylations of carboxylic acids[29] and alcohols[30] with alkyl halides are also facilitated by $HgO.2HBF_4$. Mercury(II) oxide and HBF_4 in alcohol effected mild solvolysis of 2-hydroxytrithioorthoesters to yield α-hydroxycarboxylic esters in high yield.[31] See also ***Mercury(II) Oxide-Tetrafluoroboric Acid***.

Preparation of a Useful Hypervalent Iodine Reagent.

When treated with $HBF_4.OMe_2$ at low temperatures, ***Iodosylbenzene*** reacts with silyl enol ethers to form a hypervalent iodine adduct capable of useful carbon-carbon bond formation reactions with alkenes (eq 14).[32]

Synthesis of Cationic Organometallic Complexes.

Tetrafluoroborate is frequently encountered as the counterion in cationic organometallic compounds; its lack of nucleophilic reactivity makes HBF_4 and its etherates ideal reagents for delivery of protons without side reactions. The poorly coordinating conjugate base of HBF_4 allows substrates greater opportunity to bind to metals in organometallic reactions requiring the presence of acids.[33]

Propargylium complexes of cobalt, obtained by treatment of propargylic alcohols with $HBF_4.OEt_2$, have been studied with regard to their selectivity as alkylating agents. *N*-Acetyl-3,4-dimethoxyphenethylamine undergoes selective aromatic substitution, whereas the unprotected amine undergoes *N*,*N*-dialkylation but not aromatic substitution (eq 15).[34]

Oxidation.

In a reaction proposed as a model for substrate reactions at metal-sulfur centers of enzymes, HBF_4 apparently functions as an oxidizing agent in a two-electron oxidation of a ruthenium benzenedithiolate complex (eq 16).[35]

(3*R*,*cis*)

[123808-97-9]

(chiral template for synthesis of enantiomerically pure cyclopropanes, cyclobutanes, cyclopentenones, pyrrolidines, pyrrolidinones, and α,α-disubstituted γ-keto acids[1])

Physical Data: bp 76-80 °C/0.05 mmHg; $[\alpha]_D$ 95.5°.

Preparative Methods: the richly functionalized chiral bicyclic lactam is easily procured by condensation of commercially available (*S*)-valinol and levulinic acid in 86% yield (eq 1).[2] Similar bicyclic lactams have been prepared from other amino alcohols.[3] These bicyclic lactams have served as precursors to a variety of enantiomerically pure compounds that possess quaternary stereocenters. An extensive review on the utility of chiral, nonracemic bicyclic lactams is available.[1]

General Considerations.

The title reagent can be sequentially alkylated α to the carbonyl group in a stereocontrolled fashion (eq 2).[1] Lithiation of the parent bicyclic lactam with ***s-Butyllithium*** and reaction with an alkyl halide affords the monoalkylated product. The epimeric mixture is treated again with *s*-BuLi and a second alkyl halide to give the dialkylated bicyclic lactam. The initial epimeric mixture is used directly in the second alkylation since this step proceeds via a planar enolate. It is the second alkylation that dictates the final diastereomeric ratio. The opposite stereochemistry at C-6 can be obtained by inverting the order of electrophile addition.

(2)

Reduction and hydrolysis of the bicyclic lactam followed by aldol cyclization affords enantiomerically pure 4,4-dialkyl-2-cyclopentenones (eq 3).[2,4]

(3)

More highly functionalized cyclopentenones can be accessed by organolithium addition to the carbonyl group instead of hydride reduction with ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Red-Al).[5]

α-Substituted γ-keto acids, upon condensation with β-amino alcohols, afford bicyclic lactams containing α-substitutents such as aryl groups. In this case, only one metalation-alkylation sequence is required to form the chiral, nonracemic α,α-disubstituted bicyclic lactam (eq 4).[4b]

The angular 7a-phenyl bicyclic lactam can be prepared by the cyclocondensation of 3-benzoylpropionic acid and (*S*)-valinol in 85% yield.[6] Dialkylation of this lactam also affords cleanly the α,α-disubstituted compound. Lactam hydrolysis releases chiral, nonracemic α,α-disubstituted γ-keto carboxylic esters (or acids) (eq 5) and 3,3-disubstituted dihydronaphthalenes may be obtained via cyclization.[6]

When the bicyclic lactam is substituted with a 3-hydroxypropyl group in the 6-position, acidic hydrolysis gives a bridged bicyclic acetal lactone (eq 6).[7]

An α-(4-bromobutyl) group can be used as a latent organolithium species by means of bromine-lithium exchange. Intramolecular addition of the organometallic tether to the carbonyl group, followed by lactam hydrolysis and aldol cyclization, affords enantiomerically pure hydrinden-2-ones (eq 7).[8]

α,β-Unsaturation may be introduced into the bicyclic lactams by standard α-selenation-oxidation methodology. The lactam can now behave as a chiral enone in photochemical [2 + 2] cycloadditions. The lactam moiety can be easily detached owing to its amide and aminal features; thus chiral, nonracemic cyclobutanes are obtained upon hydrolysis (eq 8).[9]

These unsaturated, bicyclic lactams are also precursors to a variety of chiral nonracemic cyclopropanes. Treatment of the parent α,β-unsaturated lactam with ***Dimethylsulfoxonium Methylide*** generates the *endo* cyclopropanated adduct (eq 9).[3b,10]

(9)

Diels-Alder cycloadditions occur on the *endo* face when the unsaturated bicyclic lactam is treated with 1,3-dienes such as ***Isoprene*** (eq 10).[11] Ester reduction followed by organolithium addition to the lactam carbonyl group and subsequent hydrolysis affords a variety of enantiopure functionalized cyclohexenes.[11]

(10)

Cyclopropyl-containing carbocycles can be prepared from the initial [4 + 2] cycloadducts by an *N*-acyliminium ion-enamide rearrangement. The unsaturated bicyclic lactam also undergoes 1,3-dipolar cycloadditions with azomethine ylides.[12] Reduction of the bicyclic lactam with alane followed by hydrogenation affords enantiomerically pure 2-substituted pyrrolidines (eq 11).[13]

(11)

5,5-Disubstituted pyrrolidinones are formed when the bicyclic lactam is treated with ***Allyltrimethylsilane/Titanium(IV) Chloride***. The remaining phenylglycinol moiety is cleaved with Li/NH_3 (see ***Lithium Amide***) (eq 12).[14] Further reduction with ***Lithium Aluminum Hydride*** affords 2,2-disubstituted pyrrolidines.

(12)

Reduction with ***Triethylsilane*** allows for the formation of enantiomerically pure 5-substituted pyrrolidinones and 2-substituted pyrrolidines in the same manner.[15]

Conjugate addition of organocuprates to the unsaturated bicyclic lactams (see above) affords rapid access to chiral, nonracemic 3- and 4-substituted pyrrolidines[16] and *trans*-2,3-disubstituted pyrrolidines.[17]

Tetrahydro-1-methyl-3,3-diphenyl-1*H*,3*H*-pyrrolo[1,2-*c*][1,3,2]oxazaborole[1]

(*S*)

[112022-81-8] · $C_{18}H_{20}BNO$ · Tetrahydro-1-methyl-3,3-diphenyl-1*H*,3*H*-pyrrolo[1,2-*c*][1,3,2]oxazaborole · (MW 277.20) (.BH_3)

[112022-90-9] (*R*)

[112022-83-0]

(one of many chiral oxazaborolidines/chiral Lewis acids useful as enantioselective catalysts for the reduction of prochiral ketones,[1-3] imines,[4] and oximes,[2e,f,5] and the reduction of 2-pyranones to afford chiral biaryls;[6] other chiral oxazaborolidines have been used for the addition of diethylzinc to aldehydes,[7] asymmetric hydroboration,[8a,b] the Diels-Alder reaction,[9-11] and the aldol reaction[12,13])

Physical Data: mp 79-81 °C.

Solubility: very sol THF, CH_2Cl_2, toluene.

Preparative Methods: see text.

Purification: Kugelrohr distillation (50 °C/0.001 mbar)

Handling, Storage, and Precautions: the free oxazaborolidine must be rigorously protected from exposure to moisture. The crystalline borane complex is more stable, and is the preferred form to handle and store this catalyst.

Enantioselective Ketone Reduction.

The major application of chiral oxazaborolidines has been the stoichiometric (as the oxazaborolidine-borane complex) (eq 1) and catalytic (in the presence of a stoichiometric borane source) (eq 2) enantioselective reduction of prochiral ketones.[1] These asymmetric catalysts work best for the reduction of aryl alkyl ketones, often providing very high (>95% ee) levels of enantioselectivity.

(1)

(2)

Following from the work of Itsuno[2] and Corey,[3] over 75 chiral oxazaborolidine catalysts have been reported for the reduction of prochiral ketones [(**1**),[2,3a,14,15a,e,f,16d-f,17b] (**2**),[16d,18b] (**3**),[3,6,19b-e,20,21,26c] (**4**),[16a] (**5**),[1b,16c,22] (**6**),[22b] (**7**),[3d,18a] (**8**),[16b] (**9**),[23] (**10**),[24] (**11**),[24] (**12**),[19a]]. Oxazaborolidines derived from proline (**3**) (see ***α,α-Diphenyl-2-pyrrolidinemethanol***) and valine (**1**; R^4 = *i*-Pr) (see ***2-Amino-3-methyl-1,1-diphenyl-1-butanol***) have received the most attention.

(10)

(11)

(12)

Unsubstituted (B-H) oxazaborolidines (**16**) are prepared from a chiral β-amino alcohol (**13**) and a source of borane (***Diborane***, ***Borane-Tetrahydrofuran***, ***Borane-Dimethyl Sulfide***, or $H_3B.NMe_3$) via a multistep process (eq 3). Formation of the initial amine-borane complex (**14**) is generally exothermic, and this intermediate can often be isolated. Gentle heating with the loss of one mole of hydrogen results in the formation of (**15**). Continued heating with the loss of a second mole of hydrogen then affords oxazaborolidine (**16**). When R^4 and R^5 are connected, forming a four- or five-membered ring, more forcing conditions (70-75 °C, 1.7 bar, 48-72 h) are required to effect this conversion due to the additional ring strain. [*Caution*: under these conditions, borane or diborane in the vapor phase can begin to decompose.[25]] Finally, additional borane is added to afford the oxazaborolidine-borane complex (**17**).

(3)

Free oxazaborolidine (**16**), by itself, will not reduce ketones. Furthermore, (**16**) is not particularly stable, reacting with moisture (H_2O), air (O_2), unreacted amino alcohol, other alcohols,[8c] or, depending on the substituents, with itself to form various dimers.[3a,8c,d,15d,26,27a] This instability is due to the strain of a partial double bond between nitrogen and boron (eq 4). Formation of the oxazaborolidine-borane complex (**17**) tends to release some of this strain. As such, (**16**) and (**17**) are generally prepared and used in situ without isolation; in many cases, they have not been fully characterized.[17c]

(4)

Oxazaborolidines substituted at boron (**1**; R^1 = alkyl, aryl) are prepared from a chiral β-amino alcohol and the corresponding boronic acid in a two-step process (eq 5).[3b,9] Heat and an efficient method of water removal (i.e. azeotropic distillation, molecular sieves) are required to drive the second step. When R^4 and R^5 are connected, more forcing conditions are necessary, both to complete the second step and to prevent the intermediate from proceeding to an alternate disproportionation product.[21] Alternative procedures using bis(diethylamino)phenylborane (eq 6),[26a,b] trisubstituted boroxines (eq 7),[21,27] and ethyl or butyl bis(trifluoroethyl)boronate esters (eq 8)[19e] have been developed to circumvent these problems. The substituted oxazaborolidines are more stable than unsubstituted (B-H) oxazaborolidines (i.e. they can be handled in the presence of air, and do not form dimers), but are still prone to decomposition by moisture (H_2O).[21] In many cases the substituted oxazaborolidines have been isolated, purified, and characterized.

(18)

(8)

Substituted oxazaborolidines also react with borane (B_2H_6, $H_3B.THF$, or $H_3B.SMe_2$) to form an oxazaborolidine-borane complex (**19**) (eq 9).[3b,27] The oxazaborolidine-borane complex, by releasing the strain of the partial double bond between the ring boron and nitrogen, is more stable than the free oxazaborolidine, and in many cases exists as a stable crystalline solid.[21c,27,28]

(9)

(19)

The oxazaborolidine-borane complex (**19**) can be used stoichiometrically (eq 1) or catalytically (eq 10) for the enantioselective reduction of prochiral ketones.[27a] When used catalytically, the oxazaborolidine-borane complex (**19**) is the second intermediate in the catalytic cycle (eq 10) proposed to explain the behavior of the oxazaborolidine catalyst.[3a,29] Subsequent coordination between the Lewis acidic ring boron and the carbonyl oxygen activates the ketone toward reduction. Intramolecular hydride transfer from the BH_3 coordinated to the ring nitrogen then occurs via a six-membered ring chair transition state.[17b,27a,30] Following hydride transfer, the alkoxy-BH_2 dissociates, and oxazaborolidine (**1**) is free to begin the cycle again. The diastereomeric transition state model (**20**), leading to the enantiomeric carbinol product, is disfavored due to unfavorable 1,3-diaxial steric interactions between R_L and R^1. Additional work will be required to better understand the catalytic cycle and the intermediates involved to further improve the oxazaborolidine catalysts. The behavior of the catalysts has been the subject of molecular orbital calculations in a series of 12 papers.[31] It should be noted, however, that not all of the results and conclusions are supported by experimental observations.

(10)

Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole

(20)

The enantioselectivities reported for the reduction of acetophenone and 1-tetralone using several representative chiral (4*S*)-oxazaborolidine catalysts are summarized in Table 1. The oxazaborolidines derived from (*S*)-azetidinecarboxylic acid and (*S*)-proline provide the best results. It is interesting to note the reversal in enantioselectivity going from catalyst (**5a**) to (**6a**).

Table 1 Chiral Oxazaborolidine Catalyzed Reduction of Acetophenone and 1-Tetralone

Catalyst	R^1	R^2,R^3	R^4 (mol %)	Catalyst (ee %)	Acetophenone (ee %)	1-Tetralone
(1a)[3a]	H	Ph	*i*-Pr	10	94.7 (*R*)

(12a)[19a]	Me	Ph		10	97.5 (*R*)	95.3 (*R*)

Oxazaborolidine catalyzed reductions are generally performed in an aprotic solvent, such as dichloromethane, THF, or toluene. When the reactions are run in a Lewis basic solvent, such as THF, the solvent competes with the oxazaborolidine to complex with the borane, which can have an effect on the enantioselectivity and/or rate of the reaction.[27a] The solubility of the oxazaborolidine-borane complex can be the limiting factor for reactions run in toluene, although this problem has been circumvented by using oxazaborolidines with more lipophilic substituents (R^1 = *n*-Bu; R^2, R^3 = 2-naphthyl).[19b-d] We have found dichloromethane to be the best overall solvent for these reactions.[27a]

The reactions are typically performed using $H_3B.THF$, $H_3B.SMe_2$, or ***Catecholborane***[19d] as the hydride source. When using $H_3B.THF$ or $H_3B.SMe_2$, two of the three hydrides are effectively utilized.[27a] This is only true for reactions run at temperatures greater than -40 °C. At lower temperatures,

only one hydride is transferred at a reasonable rate. When two hydrides are used, there is some evidence that the enantioselectivity for transfer of the second hydride is different, and may in fact be lower.[27a] Whether this implies that an alternative catalytic cycle operates, whereby the alkoxy-BH_2 intermediate generated during the first hydride transfer remains coordinated to the oxazaborolidine, and then transfers the second hydride (with a different degree of enantioselectivity), or that some other intermediate present is active, but not as an enantioselective reducing agent, will require further investigation. In any event, the amount of BH_3 used should be at least 0.5 mole per mole of ketone plus an amount equal to the oxazaborolidine catalyst, with the possibility that 1 mole per mole provides slightly higher enantioselectivity. When catecholborane is used as the hydride source, a 50-100% excess of this reagent is used.

The mode of addition and the reaction temperature both affect the enantioselectivity of the reaction. The best results are obtained when the ketone is added slowly to a solution of the oxazaborolidine (or oxazaborolidine-borane complex) and the borane source, at as low a temperature that provides a reasonable reaction rate.[27a] This is in contrast to a previous report that indicated that oxazaborolidine-catalyzed reductions lose stereoselectivity at lower temperatures.[19d] With unsubstituted (R^1 = H) oxazaborolidines, higher temperatures may be required due to incomplete formation of the catalyst, the presence of dimers, and/or other intermediates.[26c]

In their role as enantioselective catalysts for the reduction of prochiral ketones, chiral oxazaborolidines have been used for the preparation of prostaglandins,[3a] PAF antagonists,[3a] a key intermediate of ginkgolide B,[32a] bilobalide,[32b] a key intermediate of forskolin,[32c] (*R*)- and (*S*)-fluoxetine,[32d] (*R*)- and (*S*)-isopreterenol,[19c] vitamin D analogs,[33] the carbonic anhydrase inhibitor MK-0417,[21b] the dopamine D1 agonist A-77636,[20b] taxol,[34] the LTD_4 antagonists L-695,499 and L-699,392,[35] the β-adrenergic agonist CL 316,243,[36] and the antiarrhythmic MK-0499.[37] They have also been used for the synthesis of chiral amines,[38,39] α-hydroxy acids,[19d,40a] benzylic thiols,[40c] the enantioselective reduction of trihalomethyl ketones,[40a,b,d] and ketones containing various heteroatoms.[17a,21b,27a,35,37]

Enantioselective Reduction of Imines and Ketoxime *O*-Ethers.

In addition to the reduction of prochiral ketones, chiral oxazaborolidines have been employed as enantioselective reagents and catalysts for the reduction of imines (eq 11)[4,23] and ketoxime *O*-ethers (eq 12)[2e,f,5] to give chiral amines. It is interesting to note that the enantioselectivity for the reduction of ketoxime *O*-ethers is opposite that of ketones and imines. For more information, see ***2-Amino-3-methyl-1,1-diphenyl-1-butanol***.

(11)

(12)

Enantioselective Addition of Diethylzinc to Aldehydes.

Oxazaborolidines derived from ephedrine have been used to catalyze the addition of ***Diethylzinc*** to aldehydes (eq 13).[7] Both the rate and enantioselectivity are optimized when R^1 = H. Aromatic aldehydes generally react faster than aliphatic aldehydes, and the enantioselectivity for aromatic aldehydes is good to excellent (86-96% ee).

Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole

(13)

Other Applications.

Chiral oxazaborolidines derived from ephedrine have also been used in asymmetric hydroborations,[8a,b] and as reagents to determine the enantiomeric purity of secondary alcohols.[8c] Chiral 1,3,2-oxazaborolidin-5-ones derived from amino acids have been used as asymmetric catalysts for the Diels-Alder reaction,[9-11] and the aldol reaction.[12,13]

Related Reagents.

2-Amino-3-methyl-1,1-diphenyl-1-butanol; ***α,α-Diphenyl-2-pyrrolidinemethanol***; ***Ephedrine-borane***; ***Norephedrine-Borane***.

1-(Tetrahydropyranyloxy)cyclopropanecarbaldehyde[1]

(R = THP)

[83606-32-0] · $C_9H_{14}O_3$ · 1-(Tetrahydropyranyloxy)cyclopropanecarbaldehyde · (MW 170.23) (R = TBDMS)

[90660-09-6] · $C_{10}H_{20}O_2Si$ · 1-(*t*-Butyldimethylsilyloxy)cyclopropanecarbaldehyde · (MW 200.39)

(1-hydroxycyclopropanecarbaldehyde derivatives provide readily 1-donor substituted vinylcyclopropanes, which can undergo ring expansions selectively to four- to eight-membered rings)

Solubility: sol usual organic solvents (ether, THF, CH_2Cl_2).

Purification: by chromatography on silica gel.

Preparative Methods: acyloin condensation of succinic esters by ***Sodium*** in the presence of ***Chlorotrimethylsilane*** provides 1,2-disilyloxycyclobutene.[2] One-pot bromination in CH_2Cl_2 at -10 °C and addition of ice-water gives the 1-hydroxycyclopropanecarboxylic acid.[3] Successive esterification (MeOH, ***Thionyl Chloride***), *O*-protection (***3,4-Dihydro-2H-pyran***, ***Pyridinium p-Toluenesulfonate***.[4] or ***t-Butyldimethylchlorosilane***[5]), reduction with ***Lithium Aluminum Hydride***, and finally oxidation with ***Pyridinium Dichromate***,[6] ***Pyridinium Chlorochromate***,[7] or ***Dimethyl Sulfoxide-Oxalyl Chloride***[8] produce the expected aldehyde in high yields (eq 1).[3b,9]

Other routes involve cyclopropanone cyanohydrin as intermediate,[10] or ring closure of 2-chloropropionaldehyde cyanohydrin ethoxyethyl ether with ***Sodium Hexamethyldisilazide***.[11]

Optically active (1*S*,2*R*)- and (1*R*,2*S*)-1-*t*-butyldimethylsilyloxy 2-methylcyclopropanecarbaldehydes (>95% ee) have been prepared by acyloin cyclization of (*R*)- and (*S*)-dimethyl 2-methylsuccinate obtained by enzymatic resolution.[12]

Handling, Storage, and Precautions: must be stored in the absence of oxygen to avoid oxidation into cyclopropanecarboxylic acid. Cleavage of the protective group leads to 2-hydroxycyclobutanone.[1]

Ring Expansions to 2-Vinylcyclobutanones.

Addition of ***Vinylmagnesium Bromide*** and deprotection (PPTS, EtOH)[13] lead to 1-(1-hydroxycyclopropyl)allyl alcohol, which undergoes quantitative C_3 -> C_4 ring expansion to 2-vinylcyclobutanone upon addition of a catalytic amount of ***Boron Trifluoride Etherate*** (eq 2).[3b]

(2)

This rearrangement provides a new synthesis of 2-vinylcyclobutanones;[3b,13,14] these versatile building blocks can undergo further ring expansions leading to five-, six-, or eight-membered ring derivatives in acid, base, thermally, or photochemically induced ring rearrangements.[1b]

Optically active 2-vinylcyclobutanones have been prepared by regio- and stereoselective rearrangement and used in the total synthesis of natural γ-lactones (eq 3).[12]

(3)

2-Alkynylcyclobutanones have been also obtained from ring expansion induced by ***Lithium Chloride***.[9b]

C_3 -> C_5 Ring Expansions to Silylated Cyclopentanone Enol Ethers.

Alkenations of the aldehyde (Wittig reaction or successive aldolization and dehydration) provide, after cleavage of the THP group[4] and *O*-silylation,[15] 1-silyloxyvinylcyclopropane derivatives which undergo the thermal vinylcyclopropane-cyclopentane rearrangement[16] to cyclopentanone silyl enol ethers, regioselectively, either on heating neat in a sealed tube or by flash vacuum thermolysis (FVT) (eqs 4-6).

(4)

R = H, 100%; C_5H_{11}, 96%

(5)

(6)

Total syntheses of *cis*-jasmone and dihydrojasmone[9a] (important raw material as a perfume ingredient), dicranenone A[17] (a new antimicrobial fatty acid containing a cyclopentanone ring), and the spirovetivane framework[9c] (found in sesquiterpenes of the spirovetivane and acorane class) have been performed by the thermal ring enlargement of these readily available vinylcyclopropanes.

Other recent applications of this aldehyde involve the synthesis of eicosanoid compounds[18] (5-lipoxygenase inhibitors), the enantioselective total syntheses of (*R*)-(+)-dodecan-5-olide, and (*S*)-(+)- and (*R*)-(-)-dihydrofuran-2(3*H*)-ones.[19]

Related Reagents.

3-Tetrahydropyranyloxy-1-propyne

[6089-04-9] · $C_8H_{12}O_2$ · 3-Tetrahydropyranyloxy-1-propyne · (MW 140.20)

(lithium derivative useful as a synthon for preparation of substituted propargylic alcohols;[1] preparation of α-allenic alcohols;[2] synthesis of *trans*-allylic alcohols[3])

Alternate Name: tetrahydro-2-(2-propynyloxy)-2*H*-pyran.

Physical Data: bp 63-65 °C/9 mmHg, 47-50 °C/3.5-5 mmHg; *d* 0.997 g cm^{-3}.

Solubility: insol H_2O; sol benzene, chloroform, 1,2-dichloroethane, ethanol, ether, acetone, dioxane, THF.

Form Supplied in: colorless liquid; commercially available.

Purification: dried over sodium carbonate and distilled under reduced pressure.

Handling, Storage, and Precautions: combustible liquid; harmful if inhaled, or absorbed through skin; causes severe irritation. The THP ether is stable to base but is hydrolyzed by acids or magnesium sulfate, and should be stored under nitrogen in the refrigerator.

Synthesis of Substituted Propargylic Alcohols.

The 2-tetrahydropyranyl (THP) ether of propargyl alcohol can be metalated to form the lithium or magnesium acetylide, which reacts with various electrophiles (eqs 1-7)[1] such as alkyl tosylates,[4] alkyl halides,[5] oxiranes,[6] chloroformates,[7] orthoformates,[8] aldehydes,[9] and ketones.[10] The products have been used to synthesize juvenile hormone (JH-I) (eq 1)[4] and other natural products (eqs 2 and 3).[5,6] Hydroxyalkynoates and protected alkynals are obtained by reactions with chloroformate and orthoformate (eqs 4 and 5).[7,8] Reactions of lithiated propargyl THP ether with ketones or aldehydes provide 2-butyne-1,4-diol derivatives,[9-13] as exemplified in synthetic routes toward (±)-eupenoxide (eq 6)[11] and a benzoquinone (eq 7).[12] Coupling reactions with vinyl halides provide precursors of enediynes (eq 8).[13]

(±)-Eupenoxide

Reduction of the resulting 2-butyne-1,4-diol mono-THP ethers with ***Lithium Aluminum Hydride*** gives α-allenic alcohols (eq 9).[2,14,15] In contrast, Birch reduction of similar substrates gives *trans*-2-butene-1,4-diol mono-THP ethers (e.g. eq 10).[9] Reaction with cuprates affords a mixture of alkylated allenyl and propargyl alcohols (eq 11).[16]

Synthesis of *trans*-Allylic Alcohols via Organotin Reagent.

Radical mediated hydrostannylation of propargyl THP ether gives a vinylstannane which serves as a precursor to the corresponding alkenyllithium reagent (eq 12).[3] The corresponding organocopper compound undergoes conjugate addition to cyclopentenones through a mixed cuprate; this sequence has been applied to the synthesis of 11-deoxyprostaglandin E_2 (eq 13).[3] Cyclic 1,5-dienes are obtained by alkylation of the lithium reagent with α,o-dibromoalkanes followed by deprotection, bromination, and reductive coupling with ***Tetracarbonylnickel*** (eq 13).[3,17]

3-Tetrahydropyranyloxy-1-trimethylsilyl-1-propyne[1]

[36551-06-1] · $C_{11}H_{20}O_2Si$ · 3-Tetrahydropyranyloxy-1-trimethylsilyl-1-propyne · (MW 212.40)

(metal derivative is used for 1-alkoxypropargylation;[2,3] used in synthesis of functionalized vinylsilanes[4])

Physical Data: bp 108 °C/11 mmHg; *n*20D 1.4630.[2]

Solubility: sol THF, ether, and most organic solvents.

Preparative Methods: from 2-propynol via tetrahydropyranyl ether formation, deprotonation, and trimethylsilylation;[2,5,6] from 3-trimethylsilylpropynol via tetrahydropyranyl ether formation.[4]

Handling, Storage, and Precautions: store in the absence of air and moisture.

Alkoxypropargylation.

The ambident character of the propargylic anion, which may be in equilibrium with the allenic form, is responsible for its limited use in synthesis. In general the structure and reactivity of the ambident anion depend on the nature of the substrate, the counter cation, and the solvent.[7,8] There is also an *erythro-threo* stereoselectivity problem when alkylated propargylic anions react with aldehydes or unsymmetrical ketones. In contrast, the zinc and titanium reagents derived from the title compound possess the allenic structure and, upon reaction with aldehydes, lead almost exclusively to the β-acetylenic alcohol (eq 1), presumably by a chelate transition state (S_Ei' process).[3,5] The reaction also leads preferentially to the *erythro* diastereomer. The stereoselectivity is highest with titanium as the metal and THF as the solvent.[6,9]

Whereas the titanium reagent is not reactive towards ketones, the zinc derivative has been found to react even with sterically encumbered ketones, such as 17-keto steroids, to yield the β-acetylenic alcohol in good yield (75%).[2]

Synthesis of Vinylsilanes.

The title compound can be used in reductive alkylation sequences for the synthesis of functionalized vinylsilanes with high isomeric purity (eq 2). One sequence consists of a regioselective *cis*-hydroboration, transmetalation, and carbodemetalation.[4,10] In another sequence, ***Diisobutylaluminum Hydride*** reduction-bromination leads to brominated vinylsilanes,[11] which can be further transformed via halogen-metal exchange, followed by reaction with iodides,[12] or with aldehydes and ketones.[13]

Tetrakis(acetonitrile)copper(I) Perchlorate

$(MeCN)_4Cu^+ ClO_4^-$

[14057-91-1] · $C_8H_{12}ClCuN_4O_4$ · Tetrakis(acetonitrile)copper(I) Perchlorate · (MW 327.24)

(catalyst for Ullmann reaction,[1] cyclopropanation,[4,5] ring expansions of cyclic and cyclopropyl ketones,[2,3] aziridine formation;[7] precursor of other complex catalysts[6])

Physical Data: white crystals that decompose slowly in moist air;[9] mp 164-166 °C;[9] IR ν 2270 (CN), 1092, 622 (ClO_4^-) cm^{-1}.[10]

Solubility: sol toluene, CH_2Cl_2, MeCN.

Form Supplied in: prepared as needed.

Analysis of Reagent Purity: gravimetric determination[9] or EDTA titration[10] of Cu; perchlorate analysis via the tetraphenylarsonium salt.[10]

Preparative Methods: several available, e.g. modification of the known hexafluorophosphate procedure,[11] reaction of ***Copper(I) Oxide*** and ***Acetonitrile*** in perchloric acid,[12] the combination of $CuClO_4$ and MeCN in 2-butanol,[10] and refluxing $Cu(ClO_4)_2$ in MeCN with excess copper powder[9] or turnings.[2]

Purification: can be recryst from MeCN and dried under nitrogen in vacuo at 80 °C for 12 h.[13,14]

Handling, Storage, and Precautions: irritant; moisture sensitive; handle under inert atmosphere. Occasional mild explosions have been reported with dry organic perchlorate salts.[10] Use in a fume hood.

Ullmann Condensation Catalyst.

The title reagent eliminates the induction period in the Ullmann condensation reaction of 1-bromoanthraquinone with 2-aminoethanol. The Cu^I catalyst is first oxidized to a Cu^{II} species by electron transfer from Cu^I to the haloanthraquinone; this Cu^{II} species increases the catalytic activity of the Cu^I catalyst (eq 1).[1]

Ring Expansions of Ketones.

The reagent can react with the adducts formed from acyclic or cyclic cyclopropyl ketones and tris(methylthio)methyllithium (see ***Tris(methylthio)methane***); the products have been rationalized via the intervention of epoxide intermediates.[2,3] With acyclic cyclopropyl ketones, C-O epoxide bond cleavage occurs selectively, leading to a cyclopropylcarbinyl carbocation intermediate and subsequent thiomethyl group migration. With more sterically restricted substrates (eq 2), alternative C-O bond cleavage competes.[2]

Cyclopropanations.

$Cu(MeCN)_4ClO_4$ can catalyze the cyclopropanation of tetramethylethylene (TME) with ***Ethyl Diazoacetate*** (EDA).[4] High TME/EDA and EDA/catalyst ratios, longer addition periods, and high reaction temperatures increase the product yield.

The reagent has been used to synthesize bis(oxazoline)copper(I) complexes that exhibit high enantioselectivity (up to 94% ee) in the catalytic cyclopropanations of trisubstituted and unsymmetrical *cis*-1,2-disubstituted alkenes.[5] The use of diazoacetates with steric bulk (e.g. R = (-)-menthyl, dicyclohexylmethyl, di- and trimethylpentyl) (eq 3) gives *trans:cis* product ratios as high as 99:1.

Aziridination Catalyst.

Using PhI=NTs as a nitrene precursor, alkenes are converted to aziridines with $Cu(MeCN)_4ClO_4$ as catalyst (eq 4).[7]

Other Reactions.

This copper(I) complex can serve as the precursor of other synthetically useful catalysts. For example, the addition reaction of tetrachloromethane to 1,5-hexadiene is catalyzed by a copper(I)-butylamine complex[6] prepared from the title reagent. $Cu(MeCN)_4ClO_4$ also catalyzes the intramolecular cycloadditions of ketones with nitrogen heterocycles bearing α-carbonitrile functionality, as illustrated with pyridine-2-carbonitrile (pyCN) (eq 5).[8]

Related Reagents.

Tetrakis(acetonitrile)copper(I) Tetrafluoroborate; ***Tetrakis(pyridine)copper(I) Perchlorate***.

Tetrakis(acetonitrile)copper(I) Tetrafluoroborate

$(MeCN)_4Cu^+ BF_4^-$

[15418-29-8] · $C_8H_{12}BCuF_4N_4$ · Tetrakis(acetonitrile)copper(I) Tetrafluoroborate · (MW 314.60)

(catalyst in Diels-Alder[3] and Ullmann[5] reactions, intramolecular aromatic annulations,[6,7] ring expansions in steroids[8])

Physical Data: white crystals that decompose slowly in moist air[9] to a greenish solid;[10] mp 159-161 °C, dec 270 °C[9] (161-171 °C, sealed tube;[10] 167-169 °C with decomposition[11]); *d* 1.466 g cm^{-3};[10] IR ν 2270, 2290 (CN) cm^{-1}.[9]

Solubility: sol toluene, CH_2Cl_2, MeCN.

Form Supplied in: prepared as needed.

Analysis of Reagent Purity: gravimetric determination of Cu.[9]

Preparative Methods: several available, e.g. modification of the known hexafluorophosphate procedure,[12] addition of ***Acetonitrile*** to the $CuBF_4$-toluene complex,[10] and treatment of ***Copper(I) Oxide*** with ***Boron Trifluoride Etherate*** in MeCN.[11]

Purification: can be recryst from hot MeCN and dried in vacuo at 80 °C for 12 h.[13]

Handling, Storage, and Precautions: irritant; moisture sensitive; handle under inert atmosphere. Use in a fume hood.

Precursor of Redox Catalysts.

Autoxidation of $Cu(MeCN)_4BF_4$ in DMSO, followed by treatment with dioxane, gave $[Cu_2(O)(DMSO)_4(dioxane)]^{2+}$ $2BF_4^-$, a versatile redox catalyst which promotes the oxidation of 2,6-xylenol, benzoin, and 3,5-di-*t*-butylcatechol to poly(2,6-dimethyl-1,4-phenylene ether), benzil, and 3,5-di-*t*-butyl-*o*-benzoquinone, respectively (eq 1).[1,2,4]

Catalyst for Organic Reactions.

The reagent $Cu(MeCN)_4BF_4$ catalyzes the Diels-Alder reactions of acrylic monomers with furan (eq 2).[3] Lewis acids such as $FeCl_3$, $SnCl_4$, and $ZnCl_2$ led to polymeric products. Many strongly activated dienophiles which are unreactive toward furan in the presence of $Cu(BF_4)_2$-hydroquinone, successfully reacted using the acetonitrile complex. Reactions can be performed at comparatively low temperature (34 °C) without the need for high-pressure apparatus.

(2)

The title reagent is also responsible for the catalysis of the Ullmann amination of halogenoarenes, the replacement of halogen attached to aromatic nuclei by amines (or ammonia) in the presence of copper salts.[5] Electron-transfer processes and radical formation are mechanisms suggested in discussion of amination and other copper-assisted nucleophilic aromatic substitutions (also see ***Tetrakis(acetonitrile)copper(I) Perchlorate***).

Aromatic Annulation.

As a Lewis acid, $Cu(MeCN)_4BF_4$ promotes cyclization of o-aryl-1,1,1-tris(phenylthio)alkanes, e.g. 4-(*m*-methoxyphenyl)-1,1,1-tris(phenylthio)butane, to the corresponding tetralone in high yield (eq 3).[6] The analogous tris(phenylthio)propane gave uncyclized phenylthio ketone, albeit in 90% yield. ***Silver(I) Trifluoromethanesulfonate*** (and other Lewis acids) gave somewhat lower yields.

(3)

$Cu(MeCN)_4BF_4$ (in stoichiometric amounts) allows propargyl derivatives of phenylenediamine to undergo cyclization and aromatization to the quinoxaline (eq 4).[7] Attempted intramolecular amination using I_2-THF, CuI-toluene, and bis(collidine)bromonium perchlorate-toluene was unsuccessful.

(4)

Steroidal Ring Expansions.

When used in the acid-catalyzed ring expansion reaction of α-hydroxy dithioacetal derivatives of 3-hydroxy-3-acetyl-14α-methyl-4-nor-5α- and -5β-cholest-8-ene (eq 5),[8] exclusive migration of a secondary carbon atom results in the formation of 3,14α-dimethyl-4-oxo steroids. $Cu(MeCN)_4BF_4$ gave the best results compared with $TiCl_4$ and $HgCl_2$-BF_3 etherate.

$R^1 = R^2 = SEt$

Tetrakis(acetonitrile)palladium Tetrafluoroborate

$[Pd(MeCN)_4](BF_4)_2$

[21797-13-7] · $C_8H_{12}B_2F_8N_4Pd$ · Tetrakis(acetonitrile)palladium Tetrafluoroborate · (MW 444.28)

(catalyst for isomerization and rearrangement of alkenes[1] and strained carbocycles,[1,2] polymerization of vinyl monomers[1,2] and reagent for preparation of more stable Pd^{2+} complexes[3])

Physical Data: yellow to bright yellow solid; mp 230 °C (dec).

Solubility: sol polar solvents such as MeCN, $MeNO_2$; insol less polar solvents.

Preparative Methods: commercially available but it is easily prepared from either spongy palladium metal[4,5] or ***Palladium(II) Chloride***.[5b,6]

Handling, Storage, and Precautions: air and moisture sensitive.

Double Bond Isomerization and Skeletal Rearrangements.

Double bond isomerizations catalyzed by $[Pd(MeCN)_4](BF_4)_2$ occur mostly at room temperature. Most often, the thermodynamically most stable alkene predominates,[1] but an example has been noted where the product ratio is kinetically controlled (eq 1).[7] The efficacy of this electrophilic catalyst in isomerizations is illustrated by fast skeletal rearrangements of alkenes (eq 2),[1,5b] substituted cyclopropanes (eq 3),[1,5b] and cyclopropenes (eq 4)[5b] at 25 °C.

Oligomerization and Polymerization of Vinyl Compounds.

$[Pd(MeCN)_4](BF_4)_2$ has been found to be a very effective catalyst for highly regioselective dimerization of acrylic esters (eq 5) in the presence of ***Lithium Tetrafluoroborate***.[8] It catalyzes the polymerization of vinyl monomers and alkynes at room temperature.[1,5b,9] In the polymerization of norbornene (eq 6)[2,5b,9] and norbornadiene[5b,9] by this catalyst, the bicyclic structure is retained intact. Both cationic[1,5b] and insertion[2] mechanisms have been suggested for these Pd^{2+}-catalyzed processes.

In the presence of ligands which bind more strongly to palladium than MeCN, $[Pd(MeCN)_4](BF_4)_2$ catalyzes the copolymerization of CO with alkenes. The addition of two styrene molecules to CO is highly regiospecific when a solution of this catalyst and styrene in THF is placed under CO and H_2 pressure in the presence of 1,3-diphenylphosphinopropane (dppp) (eq 7).[10] Similarly, CO and ethylene give a polyketone when treated with $[Pd(MeCN)_4](BF_4)_2$ in the presence of a phosphine ligand at room temperature.[11] Cotelomerization of CO_2 with butadiene using the same catalyst and other ligand additives has been reported to give δ-lactones with high selectivity.[12]

Preparation of More Stable Pd^{2+} Complexes.

Because of the lability of the acetonitrile ligands of $[Pd(MeCN)_4](BF_4)_2$, other cationic and neutral Pd^{2+} complexes are conveniently prepared from it either in a separate step[3] or in situ.[10-12]

Tetrakis(pyridine)cobalt(II) Dichromate[1]

$(py)_4Co(HCrO_4)_2$

[139033-95-7] · $C_{20}H_{22}CoCr_2N_4O_8$ · Tetrakis(pyridine)cobalt(II) Dichromate · (MW 609.39)

(oxidizing agent for many functional groups;[1,2,5] dehydrogenative aromatization agent of five-membered N-heterocyclic compounds[6,7])

Alternate Names: TPCD; tetrakis(pyridine)cobalt (II) bis(chromate).

Physical Data: dec. 307 °C

Solubility: sol DMF, DMSO, AcOH, hot H_2O; insol acetone, Et_2O, dichloromethane.

Form Supplied in: deep brown or black crystals; commercially available.

Preparative Methods: to a solution of ***Chromium(VI) Oxide*** (2 equiv) and ***Cobalt(II) Acetate*** (1 equiv) in H_2O is added ***Pyridine*** (4 equiv) at 60 °C. TPCD is collected as brown-colored crystals and washed with acetone. After drying under vacuum, it is available for use.

Handling, Storage, and Precautions: the dry crystals are nonhygroscopic and air stable. The sample stored in a brown-colored bottle under nitrogen over one year will keep its original activity. The reagent should not be heated above its decomposition point without solvent.

Oxidation of Alcohols, Halides, and Amines.[1]

As a neutral Cr^{VI} complex, TPCD oxidizes primary and secondary alcohols, benzylic halides, and benzylamines to their corresponding aldehydes and ketones under essentially neutral conditions. It is very suitable for oxidation of some alcohols with acid-sensitivity and limited solubility (eq 1), for benzylic halides bearing electron-withdrawing substituents (eq 2), and for non-tertiary benzylic amines (eq 3); tertiary amines and quaternary ammonium salts are unaffected by TPCD.

Oxidation of Oxime Compounds.

The behavior of oxime compounds is different and depends on the solvent used. Hence, aromatic aldoximes are converted smoothly into nitriles in DMF or carboxylic acids in aq HOAc (eq 4),[2] in which the dehydro dimer of aldoxime (i.e. a bis-nitrone) is identified as an intermediate. Benzaldoxime dehydro dimer can be trapped by ***Methyl Acrylate*** to yield a 1,3-cycloaddition product.[3] When chalcone oxime is warmed with TPCD at 60 °C, within 1 min an intramolecular 1,3-cycloaddition occurs to give 3,5-diphenylisoxazole (eq 5).[4]

Oxidation of Hydrazides and Hydrazones.

Under the influence of Co^{II}, the behavior of TPCD, as expected, is different from that of other Cr^{VI}-based oxidants. Thus, it can effect the cleavage of hydrazides selectively to generate their acids in the presence of ester or amide groups (eq 6). It also converts benzil dihydrazones into diphenylacetylene derivatives in excellent yields, whereas 1,2-cyclodecanedione dihydrazone affords an 18% yield of cyclodecyne (eq 7).[5]

Oxidation of Pyridinium and Related Heterocyclic Ylides.

In the presence of TPCD, derivatives of *N*-acylpyridinium bromides are converted into 1,2,3-triacylindolizines according to a 1,5-dipolar cycloaddition mechanism (eq 8).[6] 1,3-Dipolar cycloaddition of *N*-phenacylpyridinium bromide with alkenes can be accomplished to give the aromatic indolizines in one step (eq 9).[7] Both of these reactions appear to proceed by a dipolar cycloaddition first, followed by a dehydrogenative aromatization. Co^{III} may be regarded as a real oxidant and Cr^{VI} as a reoxidant in these cases.

Tetrakis(pyridine)copper(I) Perchlorate

$(py)_4Cu^+ ClO_4^-$

[21465-66-7] · $C_{20}H_{20}ClCuN_4O_4$ · Tetrakis(pyridine)copper(I) Perchlorate · (MW 479.44)

(catalyst for the decomposition of diazonium salts)

Physical Data: light yellow crystals;[2,7] *d* 1.47 g cm^{-3};[7] IR ν 1085 (ClO_4^-), 616 (py) cm^{-1}.[2,8]

Solubility: sol pyridine, MeCN.

Form Supplied in: prepared as needed.

Analysis of Reagent Purity: iodometric determination of Cu.[2]

Preparative Methods: conveniently prepared from the tetrakis(acetonitrile) complex[1] by reaction with ***Pyridine*** in a 1:4 molar ratio under nitrogen.[2]

Purification: drying in vacuo at rt.

Handling, Storage, and Precautions: irritant; moisture sensitive; handle under inert atmosphere. Occasional mild explosions have been reported with dry organic perchlorate salts.[9] Use in a fume hood.

Decomposition of Aryl Diazonium Salts.

The homolytic decomposition of aryl diazonium salts can be catalyzed effectively by copper(I) salts. For example, ***Copper(I) Oxide*** accelerates homolytic carbon-nitrogen bond scission and eliminates the competitive heterolytic pathway in the decomposition of 2-diazobenzophenone tetrafluoroborate at 45 °C.[5,6] However, Cu_2O has the disadvantage of being effective only in highly acidic media, due to its insolubility in neutral water. The title reagent was shown[3,4] to be an effective catalyst for diazonium salt decomposition in less acidic media (pH = 6.2). Similar complexes, e.g. ***Tetrakis(acetonitrile)copper(I) Perchlorate*** and ***Tetrakis(acetonitrile)copper(I) Tetrafluoroborate***, disproportionated to Cu^{II} species too rapidly to be useful; nitrate complexes were too unstable to react with the diazonium salt. Many common cuprous salts, as well as CuH, failed to catalyze the reaction.[3]

The nature and concentration of the copper complexes significantly affect the distribution of products shown in eq 1. In the presence of Cu^{II} ions, high yields of 2-hydroxybenzophenone (**1**) could be obtained; with hydrogen-donating solvents such as ethanol, the major product was benzophenone (**2**). A similar heterocyclic amine complex, tris(2-picoline)copper(I) perchlorate, also proved useful as a catalyst, giving a dibenzoylbiphenyl dimer and 9-fluorenone (**3**) as the major products.

A kinetic study showed the relative rate constants for reduction, phenol formation, and cyclization of the intermediate radical to be 4, 2, and 1, respectively; in solutions containing 15% or more dioxane, however, the rate constant for phenol formation is drastically reduced by micelle formation. A pH-dependent competition between dimerization and cyclization was also observed.[4]

Tetrakis(trichlorophosphine)nickel(0)[1]

$Ni(PCl_3)_4$

[36421-86-0] · $Cl_{12}NiP_4$ · Tetrakis(trichlorophosphine)nickel(0) · (MW 607.97)

(source of nickel(0) useful for the cyclotetramerization of alkynes[2])

Physical Data: thermochromic crystalline solid that is pale yellow at rt and white at temperatures below -30 °C; mp 120 °C (dec).

Solubility: readily sol benzene, cyclohexane, chloroform, CCl_4, pentane

Analysis of Reagent Purity: ^{31}P NMR: 171.8 ppm (downfield from H_3PO_4).[3] IR (Nujol): 325s, 500s, 570s, 805m, 870m cm^{-1}.[4]

Preparative Methods: the original preparation involved addition of excess ***Phosphorus(III) Chloride*** to ***Tetracarbonylnickel*** (caution: extremely toxic, volatile), whereupon CO was immediately evolved. The reaction was completed by heating the pale-yellow solution to reflux. Distillation removed most of the remaining PCl_3. The pot residue was dissolved in pentane at rt and the resulting solution cooled to -60 °C to crystallize the product as fine crystals, which were dried on a porous plate. Two recrystallizations were sufficient to remove all PCl_3 and gave an 80% yield of $Ni(PCl_3)_4$. All manipulations were carried out under inert atmosphere.[5] The complex may also be prepared by reaction of PCl_3 with $Ni(allyl)_2$.[6]

Handling, Storage, and Precautions: the flammable crystalline solid is stable in air but highly oxygen sensitive in solution. Special inert-atmosphere techniques must be used.[7] Should be stored at 0 °C.

Cyclotetramerization of Alkynes.

The methyl and ethyl esters of propiolic acid can be cyclotetramerized in the presence of catalytic $Ni(PCl_3)_4$ to form cyclooctatetraenes (**1**) (eq 1).[2] For the methyl ester, the remaining product (17%) is the trimerization product (**2**). For the ethyl ester, the selectivity favoring cyclotetramerization reverses, and trimerization accounts for 72% of the product. Attempts to cyclotetramerize a wide variety of other alkynes were unsuccessful. Although the scope of this reaction is extremely limited, $Ni(PCl_3)_4$ is one of only very few compounds that are able to catalyze the cyclotetramerization of substituted alkynes.[8] The order of reactivity of several such catalysts is $Ni(PCl_3)_4$ > $Ni(PF_3)_4$ >> $Ni(PBr_3)_4$ &AApprox; $Ni(PhPCl_2)_4$.

(1) **(2)**

R = Me, 66% 83:17
R = Et, 73% 28:72

Other Uses.

The polymerization of butadiene has been described using a three-component system made up of $Ni(PCl_3)_4$, ***Titanium(IV) Chloride*** and ***Aluminum Chloride***.[9]

Tetrakis(triethyl phosphite)nickel(0)

$[(EtO)_3P]_4Ni$

[14839-39-5] · $C_{24}H_{60}NiO_{12}P_4$ · Tetrakis(triethyl phosphite)nickel(0) · (MW 723.41)

(catalyst for allylic alkylation;[1] cycloadditions;[2] alkene isomerization;[3] aldol reaction[4])

Physical Data: mp 108 °C; white crystals.

Solubility: sol THF, toluene.

Preparative Methods: easily synthesized by the reaction of ***Triethyl Phosphite***, ***Nickel(II) Chloride***, and Et_2NH.[5]

Handling, Storage, and Precautions: is a cancer suspect agent; air sensitive; reacts with halogenated solvents; should be handled using Schlenk or glovebox techniques.

Allylic Alkylation.

Alkylation of allylic carbonates by 1,3-dicarbonyl compounds under neutral conditions is catalyzed by $[(EtO)_3P]_4Ni$ (eq 1).[1] Alkenyl allyl carbonates undergo an intramolecular decarbonylative allylation with $[(EtO)_3P]_4Ni$ (eq 2).[6]

(1)

(2)

Cycloaddition Reactions.

The cycloaddition of trimethylenemethane intermediates to imines is catalyzed by $[(EtO)_3P]_4Ni$ to form 4-methylenepyrrolidines (eq 3).[2]

Alkene Isomerization.

$[(EtO)_3P]_4Ni$ catalyzes the isomerization of 1-pentene to a mixture of *cis*- and *trans*-2-pentene (eq 4).[3] At 35 °C, an equilibrium mixture (3:1:1) of *trans*-2-pentene, *cis*-2-pentene, and 1-pentene is formed.

Aldol Reaction.

The reaction of aldehydes with β-keto allyl esters is catalyzed by $[(EtO)_3P]_4Ni$ to form β-hydroxy ketones (eq 5).[4]

Tetrakis(triisopropyl phosphite)nickel(0)

$[(i\text{-PrO})_3P]_4Ni$

[36700-07-9] · $C_{36}H_{84}NiO_{12}P_4$ · Tetrakis(triisopropyl phosphite)nickel(0) · (MW 891.77)

(catalyst for hydrazone[1] and alkyne allylation,[2] allyl ester rearrangements,[3] alkene cyclodimerization,[4] and amination[5])

Physical Data: mp 187 °C.

Preparative Methods: most conveniently synthesized by the reaction of ***Bis(1,5-cyclooctadiene)nickel(0)*** with ***Triisopropyl Phosphite***.[6]

Handling, Storage, and Precautions: is a cancer suspect agent; air sensitive; should be handled using Schlenk or glove box techniques. Use in a fume hood.

Catalytic Allylation.

$[(i\text{-PrO})_3P]_4Ni$ efficiently catalyzes the allylation of alkynes and phenylhydrazones with allyl esters. The reaction of phenylhydrazones with allyl acetate using 5 mol % $[(i\text{-PrO})_3P]_4Ni$ produces azo compounds (eq 1).[1] $[(i\text{-PrO})_3P]_4Ni$ was superior to Ni^0 complexes of other alkyl and aryl phosphites.

Alkynes react with allyl but-3-enoate in the presence of 2 mol % $[(i\text{-PrO})_3P]_4Ni$ at room temperature to form nonconjugated eneynes in high yield (eq 2).[2] $[(i\text{-PrO})_3P]_4Ni$ was determined to be the optimum catalyst for this transformation.

Allyl Ester Rearrangement.

In the absence of alkynes, allyl but-3-enoate is rearranged by $[(i\text{-PrO})_3P]_4Ni$ to a mixture of isomeric heptadienoic acids (eq 3).[3] A 2:1 ratio of isomeric carboxylic acids was formed with $[(i\text{-PrO})_3P]_4Ni$. For comparison, ***Tetrakis(triethyl phosphite)nickel(0)*** gave a 0.8:1 mixture.

Cyclodimerization Reactions.

Dihydroindoles can be prepared by the dimerization of dipropargylamines with alkynes using catalytic amounts of $[(i\text{-PrO})_3P]_4Ni$ (eq 4).[4] Norbornadiene derivatives can be cyclodimerized with allyl acetate in the presence of $[(i\text{-PrO})_3P]_4Ni$ to give tricyclononane products (eq 5).[7]

Amination Reactions.

Addition of amines to vinylcyclopropanes is catalyzed by $[(i\text{-PrO})_3P]_4Ni$ to give acyclic allylic amines (eq 6).[5] This reaction is also catalyzed by ***Tetrakis(triphenylphosphine)palladium(0)*** in comparable yield. The reaction of amines with vinyl lactones gave allylamino carboxylic acids.

Tetrakis(triisopropyl phosphite)palladium(0)

$[(i\text{-PrO})_3P]_4Pd$

[82838-61-7] · $C_{36}H_{84}O_{12}P_4Pd$ · Tetrakis(triisopropyl phosphite)palladium(0) · (MW 939.50)

(catalyst for [4 + 3] and [3 + 2] cycloaddition reactions[1] and nucleophilic additions[2])

Preparative Methods: has only been generated in situ from the reaction of ***Palladium(II) Acetate*** with 2 equiv ***n-Butyllithium*** and 4 equiv ***Triisopropyl Phosphite*** in THF.[2] No reports of the characterization or isolation of $[(i\text{-PrO})_3P]_4Pd$ have appeared.

Handling, Storage, and Precautions: solutions of $[(i\text{-PrO})_3P]_4Pd$ should be generated and used under an argon or nitrogen atmosphere. Use in a fume hood.

Cycloaddition Reactions.

$[(i\text{-PrO})_3P]_4Pd$ has been predominantly utilized in catalytic cycloaddition reactions which involve palladium-trimethylenemethane intermediates. The [3 + 2] cycloaddition of dimethyl 2,3-bicyclo[2.2.1]heptanedicarboxylate with 2-((trimethylsilyl)methyl)allyl iodide gave a single methylenecyclopentene isomer in 63% yield (eq 1).[3] For this particular cycloaddition, $[(i\text{-PrO})_3P]_4Pd$ was reported to be the preferred reagent. Under similar conditions, pyrones undergo selective [4 + 3] cycloaddition to give methyleneoxabicyclononenones (eq 2).[4]

In cycloadditions which involve acyclic dienes, a competition has been observed for formation of five- and seven-membered rings. The reaction of dimethyl (*E*,*E*)-muconate with 2-((trimethylsilyl)methyl)allyl acetate in the presence of a catalytic amount of $[(i\text{-PrO})_3P]_4Pd$ gave a 1.1:1 ratio of methylenecyclopentene and methylenecycloheptene products in 89% combined yield (eq 3).[1] For comparison, ***Tetrakis(triphenylphosphine)palladium(0)*** + ***1,2-Bis(diphenylphosphino)ethane*** in dioxane gave increased selectivity for methylenecyclopentene (3.8:1). Product ratios were also found to be dependent upon diene stereochemistry. The reaction of dimethyl (*Z*,*E*)-muconate with 2-((trimethylsilyl)methyl)allyl acetate using $[(i\text{-PrO})_3P]_4Pd$ gave only cyclopentene products.

Nucleophilic Additions.

[(i-PrO)$_3$P]$_4$Pd has also been used as a catalyst for nucleophilic addition with high stereo- and regioselectivity. Addition of adenine to epoxides produced a single isomer in 90% yield (eq 4).[1]

$Ni(PPh_3)_4$

[15133-82-1] · $C_{72}H_{60}NiP_4$ · Tetrakis(triphenylphosphine)nickel(0) · (MW 1107.89)

(a source of nickel(0) useful for coupling reactions of organic halides,[2] and the cyclooligomerization of cumulenes[3])

Physical Data: mp 123-128 °C (N_2).

Solubility: sol DMF, DMA, THF, acetonitrile, benzene; slightly sol Et_2O; very slightly sol *n*-heptane, EtOH.

Form Supplied in: widely available as a red powder of greater than 98% purity.

Preparative Methods: the standard preparation involves the reduction of ***Nickel(II) Acetylacetonate*** with ***Triethylaluminum*** in the presence of ***Triphenylphosphine***. To 21.3 g of anhydrous $Ni(acac)_2$ and 125 g PPh_3 in 800 mL of Et_2O under N_2 at 0 °C is slowly added 28.0 g Et_3Al. The reddish-brown precipitate is collected, washed with Et_2O, and twice dissolved in benzene and reprecipitated by the addition of *n*-heptane to give about 50 g (55%) of $Ni(PPh_3)_4$.[4]

Handling, Storage, and Precautions: highly oxygen sensitive. Special inert-atmosphere techniques must be used.[5] Should be stored at 0 °C. Cancer suspect agent.

Coupling Reactions of Organic Halides.

The zerovalent nickel complex $Ni(PPh_3)_4$ reacts with organic halides by oxidative addition into the carbon-halogen bonds to give organonickel(II) intermediates.[6] These intermediates, which are typically not isolated, can react with a variety of nucleophilic reagents to replace the original halide with another group.[2] With a catalytic amount of $Ni(PPh_3)_4$, aryl halides react with halide salts to give halogen exchange,[7] and with MgH_2 to give hydrogenation.[8] Aryl halides and triflates react with cyanide salts to give nitriles.[9] Aryl bromides and iodides both work well as substrates, and many functional groups are tolerated. However, *o*-substituents tend to slow the reactions down and give lower yields. Oxidative addition to benzylic halides occurs with racemization.[6a] Insertion of an alkene into the organonickel intermediate leads to overall coupling via a β-hydride elimination pathway.[10] This type of reaction has been utilized intramolecularly in the synthesis of indole and oxindole derivatives (eq 1).[11] The organonickel intermediate derived from MeI and $Ni(PPh_3)_4$ can be used for the regioselective alkylation of epoxides.[12]

Homocoupling of aryl and alkenyl halides can occur with stoichiometric amounts of nickel(0) (see ***Bis(1,5-cyclooctadiene)nickel(0)***),[13] or catalytically in the presence of an added reducing agent such as zinc (see ***Tris(triphenylphosphine)nickel(0)***).[14] $Ni(PPh_3)_4$ has been used for the homocoupling of 2-halopyridines,[15] and α-halo ketones.[16] Cross coupling of distinct aryl halides by this method is generally not efficient due to extensive symmetrical coupling. Intramolecular couplings of bis(aryl halides), however, do not suffer from this limitation and give cyclized products.[17] These couplings work well for many different tether lengths (eq 2) and this strategy was utilized in the synthesis of the macrocyclic ketone alnusone.[18] The mild conditions of this reaction permit a wide variety of functional groups to be present without concern for the formation of byproducts or decomposition. This is in contrast to the copper catalyzed Ullmann reaction, which often requires harsh thermal conditions (>200 °C).[19]

$n = 2$, 81%; 3, 83%; 4, 76%; 5, 85%; 6, 38%

Coupling Reactions with Organometallic Compounds.

The cross-coupling of aryl and alkenyl halides may be effected by the reaction of organometallic reagents with organic halides in the presence of $Ni(PPh_3)_4$. As before, oxidative addition of Ni^0 to the organic halide is the initial step in the mechanism. The transiently formed organonickel intermediate can then accept an organic group from the added metal reagent through ligand substitution, which leads, upon reductive elimination, to replacement of the original halide with this new group and regeneration of a catalytic nickel(0) species. While initial studies in this area were confined to highly reactive organomagnesium and -lithium reagents,[20] which limited their applicability in synthesis, more recent studies have shown that organic complexes of aluminum, zinc, and zirconium, among others, are all active for the coupling reaction.[21]

Recent uses of Grignard reagents in the presence of $Ni(PPh_3)_4$ include the reaction with trichloroethylene to give 1,1-dichloroalkenes,[22] with 1,2-dichloroethylenes to stereoselectively produce vinyl chlorides,[23] and with phenolic ethers to give arenes,[24] and the reaction of $TMSCH_2MgCl$ with vinyl iodides to give allyl silanes.[25] In addition, lithium enolates have been coupled with aryl halides inter- and intramolecularly.[26]

Alkenylalanes readily couple with aryl and alkenyl halides in the presence of $Ni(PPh_3)_4$ to give styrene and butadiene derivatives in good yields (eq 3).[21] *Trans*-alkenylalanes, which are readily obtainable by the carboalumination of alkynes, couple with retention of configuration at the double bond to provide an efficient route to *trans*-alkenes.[27] (*E*)-1,2-Dichloroethene was coupled with an alkenylalane to give a 1-chloro-(*E*,*E*)-1,3-diene in 80% yield.[28]

Alkenylzirconium reagents are similar to alkenylalanes in that they can be easily prepared by carbometalation of alkynes. They may be coupled with aryl, alkenyl, and alkynyl halides (eq 3).[21] The coupling is facilitated by the presence of added salts containing Zn or Cd such as ***Zinc Chloride***.[29]

(3)

R = Al(*i*-Bu)$_2$, 91%; $ZrCp_2Cl$, 96%

Arylzinc compounds have also been reacted with aryl halides in good yields with very little homocoupling.[30] This mild coupling method was used with great success in the synthesis of a bisbenzocyclooctadiene lignan, steganone (eq 4).[31] Alkylzincs formed from the Reformatsky reagent also react with aryl halides to give arylacetic acid esters.[32] Benzylzinc compounds react with alkenyl halides in a similar fashion; however, palladium catalysts were found to be more suitable for this reaction due to extensive isomerization to the

conjugated isomers in the presence of nickel.[33] Knochel's (dialkoxyboryl)methylzinc reagents have also been coupled with greater success using palladium catalysts.[34]

(4)

In general, the coupling reactions of aryl halides may be catalyzed with similar efficiency by palladium catalysts such as ***Tetrakis(triphenylphosphine)palladium(0)*** or $Cl_2Pd(PPh_3)_2$-***Diisobutylaluminum Hydride***. The nickel catalysts tend to be slightly more reactive, however, easily entering into reactions with both organic iodides and bromides, while the palladium catalysts sometimes require activated bromides to react.[30a] In the case of alkenyl halides, the nickel catalysts have shown slight (<=10%) stereochemical scrambling when coupled with alkenylalanes, whereas with the palladium catalysts the stereochemical integrity is &egt;97%.[27b] Palladium catalysts also have the added advantage that they are compatible with the nitro group, which nullifies the catalytic activity of the nickel(0) complexes,[30a] and coupling with boranes is possible.[35]

Cyclooligomerization of Cumulenes.

$Ni(PPh_3)_4$ reacts catalytically with cumulenes via a [2 + 2] cycloaddition to give [4]radialenes[36] and in a [2 + 2 + 2] fashion to give [6]radialenes. The choice of solvent affects the selectivity of some reactions, with benzene providing dimers and DMF leading primarily to the trimeric products.[37] Several extremely strained cyclobutanes have been prepared by this method.[38] Interestingly, the cumulene starting materials (**3**) can be prepared by the Ni^0 mediated coupling of 1,1-dihaloalkenes (**1**) and the subsequent Ni^0 catalyzed elimination of the 2,3-dihalo-1,3-butadiene products (**2**). Thus [4]radialenes (**4**) may be prepared in one step from 1,1-dihaloalkenes (**1**) (eq 5).[39]

(4)

(5)

Other Uses.

Terminal alkenes may be prepared by the oxidative addition of primary halides to $Ni(PPh_3)_4$ followed by β-hydride elimination.[40] Cyclopropanation of electron-deficient alkenes is possible by the reaction of the complex with *gem*-dibromides or diazoalkanes.[41] Methylenecyclopropane is linearly trimerized selectively in the presence of this catalyst.[42] Tethered diynes react inter- and intramolecularly with alkynes in [2 + 2 + 2] cycloadditions to give tetralins (eq 6).[43]

Tetrakis(triphenylphosphine)palladium(0)[1]

$Pd(PPh_3)_4$

[14221-01-3] · $C_{72}H_{60}P_4Pd$ · Tetrakis(triphenylphosphine)palladium(0) · (MW 1155.62)

(catalyzes carbon-carbon bond formation of organometallics with a wide variety of electrophiles;[2] in combination with other reagents, catalyzes the reduction of a variety of functional groups;[3] catalyzes carbon-metal (Sn, Si) bond formation;[4] catalyzes deprotection of the allyloxycarbonyl group[5])

Physical Data: mp has been reported to vary between 100-116 °C (dec) and is not a good indication of purity.

Solubility: insol saturated hydrocarbons; moderately sol many other organic solvents including $CHCl_3$, DME, THF, DMF, PhMe, benzene.

Form Supplied in: yellow, crystalline solid from various sources. The quality of batches from the same source have been noted to be highly variable and can dramatically alter the expected reactivity.

Preparative Methods: readily prepared by the reduction of $PdCl_2(Ph_3P)_2$[6] with ***Hydrazine*** or by the reaction of ***Tris(dibenzylideneacetone)dipalladium*** with ***Triphenylphosphine***.[7]

Handling, Storage, and Precautions: is air and light sensitive and should be stored in an inert atmosphere in the absence of light. It can be handled for short periods quickly in the air but best results are achieved by handling in a glove box or glove bag under argon or nitrogen.

Direct Carbon-Carbon Bond Formation.

One of the most attractive features of $Pd(Ph_3P)_4$ is its ability to catalyze carbon-carbon bond formation under mild conditions by the cross-coupling of organometallic (typically organoaluminum,[2e] -boron,[2f] -copper, -magnesium, -tin,[2b-d] or -zinc[2e] reagents) and unsaturated electrophilic partners (halides or sulfonates such as trifluoromethanesulfonates[2d] (triflates)). Although $Pd(Ph_3P)_4$ is the catalyst of choice in many of these reactions, numerous other Pd^0 and Pd^{II} catalysts have been used successfully.

Symmetrical or unsymmetrical biaryls are efficiently produced by the $Pd(Ph_3P)_4$ catalyzed cross-coupling of aryl halides or aryl triflates (I, Br > OTf in terms of rate of reaction[8a]) with a variety of metalated aromatics such as arylboronic acids,[8] arylstannanes,[9] aryl Grignards[10] and arylzincs[11] (eqs 1 and 2). Reactions employing $ArB(OH)_2$ are carried out in aqueous base (2M Na_2CO_3 or K_3PO_4) while the remainder are conducted under anhydrous conditions. A recent report documents the reaction of $ArB(OR)_2$ with ArBr under nonaqueous conditions in the presence of ***Thallium(I) Carbonate***.[8c] Reactions employing ArOTf and $ArSnR_3$ as coupling partners require greater than stoichiometric amounts of ***Lithium Chloride***.[9a,b] Acceleration of the reaction rate has been noted in the coupling of $ArSnMe_3$ and either ArOTf or ArBr/I by the addition of catalytic ***Copper(I) Bromide***[9c] or stoichiometric ***Silver(I) Oxide***,[9f] respectively. In many cases, one or both of the aromatic species can be heteroaromatic such as pyridine, furan, thiophene, quinoline, oxazole, thiazole, or indole.[8e,9f,g,11] Symmetrical biaryls have been prepared in excellent yields by the $Pd(Ph_3P)_4$-catalyzed homocoupling of ArBr/I under phase transfer conditions.[12]

(1)

M = MgBr, X = I 70%
M = ZnCl, X = OSO_2F 95%

In a similar manner, $Pd(Ph_3P)_4$ catalyzes the cross-coupling of metalated alkenes, such as vinylaluminum reagents,[13] vinylboronates or -boronic acids,[8d,14] vinylstannanes,[15] vinylsilanes,[16] vinylzincs or -zirconates,[17] vinylcuprates[18] or -copper reagents[19] and vinyl Grignards[20] with vinyl halides (I, Br), triflates, or phosphates to form 1,3-dienes (eq 3). Vinylallenes,[17f] dienyl sulfides,[14h] and dienyl ethers[17d] have also been prepared using this strategy. In most instances the dienes are formed with retention of double bond geometry in both reacting partners.[14g] However, the formation of (*E*,*Z*)- and (*Z*,*Z*)-diene combinations has been documented to suffer from poor reaction yields or scrambling of alkene geometry in some cases (eq 4).[14a,b,18-20] A dramatic rate enhancement has been noted in the coupling of vinyl iodides with vinylboronic acids by replacing the aqueous bases that are normally used (NaOEt or NaOH) with ***Thallium(I) Hydroxide***[14f,i] or ***Thallium(I) Carbonate***.[21] LiCl[15a,c] is required when vinyl triflates are used in coupling reactions with vinylstannanes. Intramolecular versions of the vinylstannane-vinyl triflate coupling have been reported[22] and the necessity of adding LiCl in these reactions has been debated.[22a] 1,3-Dienes have been prepared via the $Pd(Ph_3P)_4$-catalyzed reaction between allylic alcohols and aldehydes in the presence of ***Phenyl Isocyanate*** and ***Tri-n-butylphosphine*** (eq 5).[23] (*E*/*E*):(*E*/*Z*) ratios range from 1:1 to 4:1.

$R^1 = Hex$, $X = Br$; $M = B(DOB)$, $R^2 = Bu$ 86%
$R^1 = Bu$, $X = I$; $M = ZrCp_2Cl$, $R^2 = Hex$ 93%

$R^1 = Bu$, $X = Br$; $M = B(sia)_2$, $R^2 = Hex$ 49%
$R^1 = t\text{-}Bu$, $X = I$; $M = Cu \cdot MgCl_2$, $R^2 = Pent$ 53%

Similar cross-coupling procedures have been used to prepare styrenes by the reaction of metalated aromatics with vinyl halides/triflates[11d,24] or, conversely, metalated alkenes with aromatic halides/triflates[9b,16,25] in the presence of $Pd(Ph_3P)_4$ (eq 6). Typically, ArCl are poor substrates in $Pd(PPh_3)_4$-catalyzed coupling reactions. However, by forming the chromium tricarbonyl complex of the aryl chloride, a facile coupling reaction with vinylstannanes can be achieved (eq 7).[26]

(6)

(7)

Enynes and arenynes are available from the $Pd(Ph_3P)_4$-catalyzed coupling of metalated alkynes (Mg,[20] Al,[13,27] Zn,[17f,28] Sn[15a,b,29]) with vinyl or aryl halides, triflates or phosphates (eq 8). Alternatively, 1-haloalkynes and metalated alkenes (B[14c] or Zn[11a,17a]) can be utilized in similar procedures.

(8)

Enynes and arenynes can also be prepared by the $Pd(Ph_3P)_4$-catalyzed reaction between vinyl halides (I, Br, or Cl) and 1-alkynes in the presence of ***Copper(I) Iodide*** and an amine base such as RNH_2 (R = Bu, Pr), Et_2NH, or Et_3N.[30] A modified procedure employing aqueous base under phase transfer conditions has also been described (eq 9).[31] The arenyne products derived from such coupling reactions provide ready access to substituted indoles (eq 10).[29c,30d]

(9)

(10)

$Pd(Ph_3P)_4$ catalyzes the coupling of simple alkyl metals and vinyl halides (Br, I) or triflates to form substituted alkenes (eq 11). Alkylboron,[32] alkyl Grignard,[20,33] alkylzinc,[34] and alkylaluminum[13] reagents have been particularly useful in this regard. A variety of functional groups on either reacting partner are tolerated and the reaction proceeds with retention of alkene geometry (usually >98%),

providing stereochemically pure, highly substituted alkenes. For example, allylsilanes (eq 12)[35] and vinylcyclopropanes (eq 13)[36] have been prepared employing ***Trimethylsilylmethylmagnesium Chloride*** and cyclopropylzinc chloride, respectively, as the organometallic partner.

(11)

(12)

(13)

Ketones are obtained by the $Pd(Ph_3P)_4$-catalyzed coupling of acid chlorides with organometallic reagents (eq 14). Organozinc[37] and organocopper[38] reagents have been used most successfully, while other reports document the utility of R_4Pb (R = Bu, Et),[39] R_4Sn (R = Me, Bu, Ph),[40] and R_2Hg (R = Et, Ph)[41] reagents in this reaction. For those cases in which the organometallic reagent is alkenic, complete retention of alkene geometry is observed (see eq 14). In addition, the formation of tertiary alcohols is not observed under the conditions employed. A modified procedure that substitutes alkyl chloroformates for acid chlorides leads to an efficient preparation of esters (eq 15).[37b,38] In a related reaction, $Pd(Ph_3P)_4$ catalyzes the coupling reaction between substituted aryl- or alkylsulfonyl chlorides and vinyl- or allylstannanes, providing a general route to sulfones (eq 16).[42]

(14)

(15)

(16)

The $Pd(Ph_3P)_4$-catalyzed reaction of various allylic electrophiles with carbon-based nucleophiles is a very useful method for the formation of C-C bonds under relatively mild conditions (eq 17) and has been extensively reviewed elsewhere.[2a,43] The most commonly used electrophilic substrates for $Pd(Ph_3P)_4$-catalyzed allylic substitution reactions are allylic esters, carbonates, phosphates, carbamates, halides, sulfones, and epoxides. More recently, allylic alcohols themselves have been demonstrated to be useful substrates.[44] Commonly employed nucleophiles include soft stabilized carbanions such as malonate and, to a lesser extent, a variety of organometallic reagents (Al, Grignards, Sn, Zn, Zr). A few selected examples begin to illustrate the scope of this reaction in terms of the general patterns of reactivity with respect to regioselectivity (eqs 18 and 19) and stereoselectivity (eqs 17 and 18). It should be noted that a variety of other Pd catalysts (including ***Palladium(II) Acetate-1,2-Bis(diphenylphosphino)ethane*** and ***Bis(dibenzylideneacetone)palladium(0)***) have been shown to be useful in these alkylations. In addition, certain nitrogen-, sulfur-, and oxygen-based reagents are suitable nucleophilic substrates. The utility of some of these latter reagents are covered in subsequent sections.

(17)

(18)

(19)

Aldehydes and α-bromo ketones or esters are efficiently coupled in an aldol reaction in the presence of ***Diethylaluminum Chloride-Tri-n-butylstannyllithium*** (or ***Tin(II) Chloride***) and catalytic $Pd(Ph_3P)_4$, providing β-hydroxy ketones or esters (eq 20).[45]

(20)

Carbonylative Carbon-Carbon Bond Formation.

A general, mild (50 °C), and high yielding conversion of halides and triflates into aldehydes via $Pd(Ph_3P)_4$-catalyzed carbonylation (1-3

atm CO) in the presence of ***Tri-n-butylstannane*** has been described (eq 21).[46] The range of usable substrates is extensive and includes ArI, benzyl and allyl halides, and vinyl iodides and triflates. The reaction has been extended to include ArBr by carrying out the carbonylation at 80 °C under pressure (50 atm CO), using poly(methylhydrosiloxane) (PMHS) instead of tin hydride.[47]

(21)

$Pd(Ph_3P)_4$ catalyzes the carbonylation of benzyl[48a] and vinyl[48b] bromides under phase transfer conditions in the presence of hydroxide to form the corresponding carboxylic acids. A wide variety of substitution is tolerated and the products are formed in moderate to excellent yield at room temperature and at normal pressure (1 atm CO). Extension of the reaction to the formation of esters from aryl, alkyl, and vinyl bromides has been described.[49] These transformations usually require a co-catalyst system of $Pd(Ph_3P)_4$ and $[(1,5\text{-cyclohexadiene})RhCl]_2$ in the presence of either $M(OR)_4$ (M = Ti, Zr) or $M(OR)_3$ (M = B, Al) (eq 22).

(22)

Vinyl triflates serve as substrates for $Pd(Ph_3P)_4$-catalyzed carbonylation and have been converted into the corresponding esters[50] or ketones[15c,51] (eq 23).

(23)

Aromatic and Vinyl Nitriles.

Aromatic halides (Br, I) have been converted into nitriles in excellent yields by $Pd(Ph_3P)_4$ catalysis in the presence of ***Sodium Cyanide/Alumina***,[52] ***Potassium Cyanide***,[53] or ***Cyanotrimethylsilane***[54] (eq 24). While the latter two procedures require the use of ArI as substrates, a more extensive range of substituents are tolerated than the alternative method employing ArBr. A $Pd(Ph_3P)_4$-catalyzed extrusion of CO from aromatic and heteroaromatic acyl cyanides (readily available from cyanohydrins) at 120 °C provides aryl nitriles in excellent yields (eq 25).[55]

(24)

(25)

Similarly, vinyl halides (Br, Cl) provide vinyl nitriles upon treatment with $Pd(Ph_3P)_4$/***Potassium Cyanide/18-Crown-6***.[56]

Carbon-Heteroatom (N, S, O, Sn, Si, Se, P) Bond Formation.

Primary and secondary amines (but not ammonia) undergo reaction with allylic acetates,[57] halides,[58] phosphates,[59] and nitro compounds[60] in the presence of $Pd(Ph_3P)_4$ to provide the corresponding allylic amines (eq 26). A variety of ammonia equivalents have been demonstrated to be useful in this $Pd(Ph_3P)_4$-catalyzed alkylation, including 4,4´-dimethoxybenzhydrylamine,[57c] NaNHTs,[58] and NaN_3[61] (eq 26). Both allylic phosphates and chlorides react faster than the corresponding acetates[58,59a] and (*Z*)-alkenes are isomerized to the (*E*)-isomers.[57a,59a] The use of primary amines as nucleophiles in the synthesis of secondary allyl amines is sometimes problematic since the amine that is formed undergoes further alkylation to form the tertiary amine. Thus hydroxylamines have been shown to be useful primary amine equivalents (eq 27) since the reaction products are easily reduced to secondary amines.[59b]

(26)

$X = PO(OEt)_2$, $Nu = NEt_2$ 68%
$X = Ac$, $Nu = N_3$ 88%

(27)

Allyl sulfones can be obtained by the $Pd(Ph_3P)_4$-catalyzed reaction of allylic acetates[62] and allylic nitro compounds[63,64] with $NaSO_2Ar$ (eq 28). $Pd(Ph_3P)_4$ also catalyzes the addition of HOAc to vinyl epoxides, providing a facile entry into 1,4-hydroxy acetates.[65]

(28)

Aryl halides (Br, I) have been converted in good yields into the corresponding arylstannanes or -silanes by treatment with R_6Sn_2 (R = Bu, Me)[4,66] or ***Hexamethyldisilane***,[67] respectively, in the presence of catalytic $Pd(Ph_3P)_4$ (eq 29). Aryl[9a,b] and vinyl[15b,68] triflates produce aryl- and vinylstannanes under similar conditions, provided ***Hexamethyldistannane*** and LiCl are used as co-reactants. In some cases, the presence of additional Ph_3P has been observed to improve yields.[68] By using the $(Ph_3Sn)_2Zn$-TMEDA complex, vinyl halides can also be converted into vinylstannanes.[69]

(29)

Acyltrimethylstannanes can be prepared in moderate yields by the treatment of acid chlorides with Me_6Sn_2 and catalytic $Pd(Ph_3P)_4$ in refluxing THF.[70c] However, $Pd(Ph_3P)_2Cl_2$ is a superior catalyst for this transformation when using sterically bulky or electron-poor acyl halides.

$Pd(Ph_3P)_4$ catalyzes the addition of R_6Sn_2,[70] R_6Si_2,[71] Ph_2S_2, and ***Diphenyl Diselenide***[72] across the triple bond of 1-alkynes to provide the respective (*Z*)-1,2-addition products (eq 30). The (*Z*)-distannanes can be partially isomerized to the (*E*)-isomers by photolysis.[70] The reaction cannot be extended to include internal alkynes containing alkyl substituents, but allenes do undergo 1,2-addition of disilane[73] and ditin.[74] In a similar fashion, $Pd(PPh_3)_4$ catalyzes the regio- and stereospecific addition of $R_3Sn\text{-}SiR_3$ to 1-alkynes, the (*Z*)-1-silyl-2-stannylalkene isomers being the sole products (eq 30).[75]

(30)

M = N = SPh	79%
M = N = $SnBu_3$	59%
M = $SnMe_3$, N = TMS	51%

α,β-Acetylenic esters react with R_6Sn_2 in the presence of $Pd(Ph_3P)_4$ at room temperature to provide only the (*Z*)-2,3-distannylalkenoates (eq 31).[76] When heated to 75-95 °C, clean isomerization to the (*E*)-isomers is observed. The corresponding amides are also useful substrates but provide either the (*E*)-isomers directly or (*E*/*Z*)-distannane mixtures.[76] Surprisingly, under similar reaction conditions, α,β-alkynic aldehydes and ketones form (*Z*)-β-stannyl enals and enones in excellent yields (eq 32).[77]

(31)

R = Me, TBDMSOCH$_2$

(32)

P = TBDMS X = H, 87%; Me, 90%

The $Pd(Ph_3P)_4$-catalyzed hydrostannylation of 1-alkynes with R_3SnH provides mixtures of vinylstannane regio- and stereoisomers, the ratios depending upon the nature of the alkyne substituents and the R group of the tin reagent.[78] In general, when using alkyl-substituted 1-alkynes, ***Triphenylstannane*** provides (*E*)-1-stannylalkenes[78a] as the major products, while 2-stannylalkenes are obtained predominantly with $(Bu_3Sn)_2Zn$[78c] (eq 33). The $Pd(Ph_3P)_4$ mediated *cis* addition of $R_3Sn\text{-}H$ across symmetrical internal alkynes has also been demonstrated to be generally high yielding.[78b] The hydrostannylation of α,β-unsaturated nitriles with $Bu_3SnH/Pd(Ph_3P)_4$ is regioselective, providing α-stannyl nitriles as the sole products.[79]

The $Pd(Ph_3P)_4$-mediated preparation of allyl- and benzylstannanes has been achieved by treatment of allylic acetates with $Et_2AlSnBu_3$[80] or by reacting benzyl halides (Br, Cl) with R_6Sn_2.[66c] In a similar fashion, allyl- and benzylsilanes are prepared by the $Pd(Ph_3P)_4$-catalyzed reaction of R_6Si_2 with allylic halides[81] and benzyl halides,[4] respectively. Allylstannanes have also been prepared by the addition of Bu_3SnH to 1,3-dienes in the presence of $Pd(Ph_3P)_4$ (eq 34).[82]

Dialkyl aryl- and vinylphosphonates ($RPO(OR')_2$) are readily prepared in excellent yields by the reaction of aryl or vinyl bromides, respectively, with dialkyl phosphite ($HPO(OR')_2$) in the presence of catalytic $Pd(Ph_3P)_4$ and Et_3N.[83] In a related process, unsymmetrical alkyl diarylphosphinates (ArPhPO(OR)) are obtained in good yields, regardless of aromatic substitution, by the $Pd(Ph_3P)_4$-catalyzed coupling reaction between aryl bromides and alkyl benzenephosphonites (HPhPO(OR)).[84]

Oxidation Reactions.

α-Bromo ketones are dehydrobrominated to produce enones in low to good yields, especially when the products are phenolic, by treatment with stoichiometric $Pd(Ph_3P)_4$ in hot benzene.[85] Primary and secondary alcohols are oxidized in the presence of PhBr, base (NaH or K_2CO_3) and $Pd(Ph_3P)_4$ as catalyst to the corresponding aldehydes or ketones.[86] The practical advantages of these methods to alternative strategies have yet to be demonstrated.

Reduction Reactions.

At elevated temperatures (100-110 °C), ArBr and ArI are reduced to ArH in the presence of catalytic $Pd(Ph_3P)_4$ and reducing agents such as HCO_2Na (eq 35),[3,87] NaOMe,[88] and PMHS/Bu_3N.[3] Aldehydes, ketones, esters, acids, and nitro substituents are unaffected. ArCl are poor substrates unless the aromatic nucleus is substituted with NO_2.[88] ArOTf are reduced in poorer yield under similar conditions; $Pd(OAc)_2$ and $Pd(Ph_3P)_2Cl_2$ are superior catalysts with these substrates.[89] A limited number of examples of the $Pd(PPh_3)_4$-catalyzed reduction of vinyl bromides and triflates to alkenes in the presence of HCO_2Na[3] and Bu_3SnH,[15a,b] respectively, have been described.

$Pd(Ph_3P)_4$ catalyzes the reductive displacement of a variety of allylic substituents with hydride transfer reagents. Allylic acetates are reduced to simple alkenes in the presence of ***Sodium Cyanoborohydride***,[90] PMHS,[91] ***Samarium(II) Iodide***/*i*-PrOH,[92] or Bu_3SnH[93] (eq 36). $Bu_3SnH/Pd(Ph_3P)_4$ also reduces allylic amines[93] and thiocarbamates.[94] All of these reductive procedures are accompanied by positional and/or geometrical isomerization of the alkene to an extent dependent upon the substrate structure. Interestingly, the $Pd(Ph_3P)_4$-catalyzed reduction of allylic sulfones with ***Sodium Borohydride*** is high yielding with no double bond positional isomerization observed.[95] By using a more bulky reducing agent, ***Lithium Triethylborohydride***, a range of allylic groups, such as methyl, phenyl, and silyl ethers, sulfides, sulfones, selenides, and chlorides, are reduced to alkenes in the presence of $Pd(Ph_3P)_4$ and excess Ph_3P with little or no loss of alkene regio- or stereochemistry (eq 37).[96] An interesting $Pd(Ph_3P)_4$-catalyzed reduction of allylic acetates, tosylates, and chlorides to the

corresponding alkenes has been described that uses *n*-BuZnCl as the hydride source.[97] This procedure proceeds with high levels of regio- and stereospecificity, but the scope has yet to be explored.

Acid chlorides[98] and acyl selenides[99] are efficiently reduced in the presence of Bu_3SnH under $Pd(Ph_3P)_4$ catalysis to provide the corresponding aldehydes in good to excellent yields without the formation of ester or alcohol byproducts (eq 38). A wide variety of substrate substituents, such as alkenes, nitriles, bromides, and nitro groups, are tolerated.

The conjugate reduction of α,β-unsaturated ketones and aldehydes to the saturated analogs can be accomplished in the presence of $Pd(Ph_3P)_4$ and hydride transfer reagents such as Bu_3SnH[100] or mixed systems of Bu_3SnH/HOAc or $Bu_3SnH/ZnCl_2$.[79] A potentially more versatile, general, and selective reduction procedure involves a three-component system of $Pd(Ph_3P)_4/Ph_2SiH_2/ZnCl_2$ (eq 39).[101] α,β-Unsaturated esters and nitriles are untouched using this latter method.

α-Bromo ketones are reductively debrominated to the parent ketones in the presence of $Pd(Ph_3P)_4$ and Ph_2SiH_2/K_2CO_3 at room temperature.[102] However, ***Hexacarbonylmolybdenum*** appears to be a superior catalyst for this conversion. Reductive debromination of α-bromo ketones, acids, and nitriles can also be accomplished by $Pd(Ph_3P)_4$ catalysis using PMHS/Bn_3N,[87b] HCO_2Na,[87b] or Me_6Si_2[103] as hydrogen donors but under much more drastic conditions (110-170 °C).

Removal of Allyloxycarbonyl (Aloc) and Allyl Protecting Groups.

The allyloxycarbonyl protecting group[5] has been used extensively for the protection of a variety of alcohols[104] and amines,[105] including the amines of nucleotide bases,[106] *N*-terminal amines of amino acids and peptides,[107] and amino sugars.[108] $Pd(Ph_3P)_4$ mediates the high

yielding removal of the Aloc group in the presence of nucleophilic allyl scavengers (eq 40) such as Bu_3SnH, 2-ethylhexanoic acid, dimedone, malonate, ***Ammonium Formate***, ***N-Hydroxysuccinimide***, and various amines including ***Morpholine*** and ***Pyrrolidine***. The deprotections are effected at or below room temperature, often in the presence of excess Ph_3P. The mild conditions used in these procedures leave most of the common N or O protecting groups intact, including Boc, TBDMS, MMT, DMT, and carbonates.

(40)

The $Pd(Ph_3P)_4$-catalyzed removal of the *O*-allyl protecting group has been described for a number of systems.[5] For example, allyl esters are efficiently cleaved to the parent acid in chemically sensitive systems such as penicillins[105,109] and glycopeptides.[110] The internucleotide phosphate linkage, protected as the allyl phospho(III)triester, remains intact upon deprotection under $Pd(Ph_3P)_4$ catalysis.[111] Allyl ethers that protect the anomeric hydroxy in carbohydrates (mono- and disaccharides) are efficiently removed under $Pd(Ph_3P)_4$ catalysis in hot (80 °C) HOAc.[112]

Rearrangements, Isomerizations and Eliminations.

$Pd(Ph_3P)_4$ catalyzes several [3,3]-sigmatropic rearrangements including those of *O*-allyl phosphoro- and phosphonothionates to the corresponding *S*-allyl thiolates (eq 41)[113] and allylic *N*-phenylformimidates to *N*-allyl-*N*-phenylformamides (eq 42).[114] The 3-aza-Cope rearrangement of *N*-allylenamines to γ,δ-unsaturated imines (eq 43)[115] and a Claisen rearrangement but with no allyl inversion[116] have also been described. In general, these $Pd(Ph_3P)_4$-catalyzed rearrangements provide compounds that are either not accessible via thermal reactions or are produced only under much more forcing reaction conditions. For those cases in which the allyl moiety contains substituents that may lead to regioisomers upon rearrangement, the less substituted isomer is usually favoured[113,115] (see eq 41), although exceptions are known.[114]

(41)

(42)

(43)

$Pd(Ph_3P)_4$ catalyzes stereoselective, intramolecular metallo-ene reactions of acetoxydienes in HOAc, efficiently generating a range of cyclic 1,4-dienes (eq 44).[117] The reactions proceed in good to excellent yields and have been extended to include the preparation of pyrrolidines, piperidines, and tetrahydrofurans by incorporating N and O atoms into the bridge that tethers the reactive alkenes.

(44)

$X = C(CO_2Me)_2$, 52% 10:90
$X = NCOCF_3$, 67% 28:72

The isomerization of allylic acetates is a useful method for allylic oxygen interconversion. Although these reactions are typically carried out in the presence of Pd^{II} catalysts such as $Pd(OAc)_2$, $Pd(Ph_3P)_4$ has proven to be useful in the 1,3-rearrangement of α-cyanoallylic acetates to γ-acetoxy-α,β-unsaturated nitriles (eq 45).[118] These compounds are conveniently transformed into furans.

(45)

Several 1,3-diene syntheses involving elimination reactions that are catalyzed by $Pd(Ph_3P)_4$ have been reported. The first involves the Et_3N mediated elimination of HOAc from allylic acetates in refluxing THF.[119] A complementary procedure involves the $Pd(Ph_3P)_4$ catalyzed decarboxylative elimination of β-acetoxycarboxylic acids (eq 46).[120] The substrates are easily prepared by the condensation of enals and carboxylate enolates; irrespective of the diastereomeric mixture, (*E*)-alkenes are formed in a highly stereocontrolled manner. The geometry of the double bond present in the enal precursor remains unaffected in the elimination and the reaction is applicable to the formation of 1,3-cyclohexadienes.

(46)

Monoepoxides of simple cyclic 1,3-dienes are smoothly converted in good yield to β,γ-unsaturated ketones in the presence of $Pd(Ph_3P)_4$ catalyst (eq 47).[121] Other vinyl epoxides, such as those in open chains or in cyclic systems in which the double bond is not in the ring, are converted under similar conditions into dienols.

(47)

A mixture of $Pd(Ph_3P)_4$/dppe catalyzes the transformation of α,β-epoxy ketones, readily available via several methods, into β-diketones (eq 48).[122] The reaction is applicable to both cyclic and acyclic compounds, although epoxy ketones bearing an α-alkyl group are poor substrates.

Tetrakis(triphenyl phosphite)nickel(0)

$[(PhO)_3P]_4Ni$

[14221-00-2] · $C_{72}H_{60}NiO_{12}P_4$ · Tetrakis(triphenyl phosphite)nickel(0) · (MW 1299.89)

(catalyst for alkene and alkyne hydrocyanation[1]; styrene dimerization[2])

Physical Data: mp 145 °C (dec).

Solubility: sol THF, toluene.

Form Supplied in: commercially available solid.

Preparative Methods: can be prepared by treating ***Nickel(II) Acetylacetonate*** with ***Sodium Borohydride*** and ***Triphenyl Phosphite***.[3]

Handling, Storage, and Precautions: is a cancer suspect agent; is air sensitive and should be handled using Schlenk or glove-box techniques.

Hydrocyanation of Alkenes and Alkynes.

Hydrocyanation of 1,3-cyclohexadiene is catalyzed by $[(PhO)_3P]_4Ni$ (eq 1).[1] Silylalkynes are hydrocyanated by $[(PhO)_3P]_4Ni$ to give isomeric mixtures of α- and β-silylacrylonitriles.[4] When the bulky Ph_3Si substituent is employed, regiospecific formation of the β-silylacrylonitrile occurs (eq 2). Smaller silyl substituents and alkyl groups give increased amounts of the α-silyl isomer. Aminoalkynes and alkynols have also been hydrocyanated to similar mixtures of acrylonitriles.[5,6]

(1)

(2)

Styrene Dimerization.

$[(PhO)_3P]_4Ni$, in the presence of ***Trifluoroacetic Acid***, catalyzes the dimerization of styrene (eq 3). The reaction forms only the linear dimer with (*E*):(*Z*) = 5.4.

α-Tetralyl Hydroperoxide[1]

[771-29-9] · $C_{10}H_{12}O_2$ · α-Tetralyl Hydroperoxide · (MW 164.22)

(weak electrophile which delivers oxygen to alkenes when activated by Lewis acids[2])

Alternate Names: tetralin hydroperoxide; THPO; 1,2,3,4-tetrahydro-1-naphthalenyl hydroperoxide.

Physical Data: mp 54-54.5 °C.

Solubility: sol toluene, cyclohexane, $CHCl_3$.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: assay using iodometry.[3]

Preparative Methods: oxygen is passed through pure tetralin maintained at 70 °C until the peroxide content of the reaction mixture is 25-30% (24-48 h). Unreacted tetralin is separated by fractional distillation in an all-glass apparatus in high vacuum (0.2-0.4 mmHg); the pot temperature is not allowed to exceed 70 °C. Crystallization of the pot residue from toluene furnishes THPO (**1**) in 44-57% yield.[4]

Purification: by recrystallization from toluene.

Handling, Storage, and Precautions: remains colorless without appreciable decrease in active oxygen for several months if stored in the dark at or below 0 °C. Since the reagent is a peroxide it is potentially explosive and care is required in handling it (use safety shield). During workup, check for peroxides before solvent removal.

Functional Group Oxidations.

When THPO (**1**) is heated in the presence of cyclohexyl metaborate (CHMB) (**2**) it undergoes facile decomposition at 80 °C.[2] This system (THPO-CHMB) epoxidizes alkenes in high yields. For example, 1-methylcyclohexene (**3**) is thus epoxidized in quantitative yield (eq 1).[2] Epoxidation of *cis*-2-octene at 80 °C furnishes only *cis*-2,3-epoxyoctane in almost quantitative yield. Competitive epoxidations of alkenes have been

studied. It has been observed that the rate of epoxidation increases with the degree of substitution; trisubstituted alkenes react faster than disubstituted alkenes. The reactivity pattern is comparable to that of organic peroxy acids. It has been suggested that the epoxidation proceeds through the transition state (**4**).[2]

(2)

(1)

(3)

(4)

When cyclodecyne was heated with THPO-CHMB in cyclohexane (reflux, 24 h), a mixture of (**5**), (**6**), and (**7**) was obtained in a 47:23:31 ratio.[5] Similar results are obtained when cyclodecyne is reacted with ***m-Chloroperbenzoic Acid***.

(5)

(6)

(7)

Asymmetric epoxidation of the allyl alcohol (**8**) has been carried out with six different peroxides at -20 °C with L-(+)-DIPT/***Titanium Tetraisopropoxide*** as catalyst; the yields and ee of the resulting epoxy alcohol (**9**) have been determined.[6] Best results are obtained with ***t-Butyl Hydroperoxide*** (TBHP), which furnishes (**9**) having 90% ee in 45-50% yields. When THPO is used, (**9**) is obtained in 35% yield but the ee of the product is only 14%.

(8)

(9)

For preparing epoxides from alkenes lacking directing groups, the widely used reagents are TBHP/Mo[7] and *m*-CPBA.

Other Applications.

2-Thienol (**10**) has been prepared in 10% yield by reacting 2-thienyllithium with THPO;[8a] the same procedure applied to phenyllithium furnishes phenol in 75% yield. THPO oxidation of β-carotene in $CHCl_3$ at rt for 20-22 h furnishes a number of allylic oxidation products, including 4,4´-dihydroxycarotene (**11**) and 4,4´-dioxocarotene (**12**).[8b]

Tetramethoxycarbonylpalladacyclopentadiene

[35279-80-2] · $C_{12}H_{12}O_8Pd$ · Tetramethoxycarbonylpalladacyclopentadiene · (MW 390.66)

(catalyst for intramolecular enyne cyclizations,[1] [2 + 2 + 2] cycloadditions,[1] allene-alkyne cross-condensations,[2] and enyne metatheses[3])

Alternate Name: [1,2,3,4-tetrakis(methoxycarbonyl)-1,3-butadien-1,4-diyl]palladium.

Physical Data: 170 °C (dec); brown, microcrystalline complex which exists as a polymeric structure.[4]

Solubility: very sol complexing solvents (phosphines, benzonitrile); sparingly sol noncomplexing solvents,[4] but will dissolve in benzene and 1,2-dichloroethane upon addition of one equivalent of a phosphine.[1]

Analysis of Reagent Purity: ^{1}H NMR (PhCN) δ 6.23 (s, 6H), 6.34 (s, 6H).[4]

Preparative Methods: synthesized from ***Dimethyl Acetylenedicarboxylate*** and ***Tris(dibenzylideneacetone)dipalladium*** in virtually quantitative yield.[4] The active complex is usually generated by addition of a phosphine ligand to break up the insoluble polymer.[1]

Intramolecular Enyne Cyclization.

In an attempt to observe intermediates in the Pd^{2+} catalyzed cyclization of 1,6-enynes, the title reagent (**1**) was used as an electron-deficient catalyst; an intramolecular carbometalation and subsequent cyclization were observed (eq 1).[1]

[2 + 2 + 2] Cycloaddition.

When cyclization of a 1,6-enyne was performed in the presence of an acetylene, a [2 + 2 + 2] cycloaddition resulted (eq 2).[1] Further experimentation supported a [2 + 2 + 2] cyclization mechanism rather than a Diels-Alder reaction.[1]

Allene-Alkyne Cross-Condensation.

When (**1**) is exposed to a combination of an allene and an alkyne, a cross-condensation occurs.[2] Regio- and stereocontrol can be obtained by an appropriate choice of ligand (eq 3). Even sterically hindered allenes can be used (eq 4).[2]

(A)	9%	47%	44%
(B)	42%	37%	21%
(C)	83%	17%	0%

(A) = tris(2,4,6-trimethoxyphenyl)phosphine, 64%
(B) = tris(2,6-dimethoxyphenyl)phosphine, 62%
(C) = triphenylphosphine, 48%

Intramolecular Enyne Metathesis.

By changing the CO_2Me groups to $CO_2CH_2CF_3$ ($TCPC^{TFE}$) or $CO_2CH_2CF_2CF_2CF_3$ ($TCPC^{HFB}$) groups, one obtains a catalyst that effects intramolecular enyne metatheses, accomplishing the installation of a bridgehead alkene within a bridged bicycle (eq 5).[3] The difference in reactivity between (**1**) and $TCPC^{TFE}$ or $TCPC^{HFB}$, shown in eq 6, demonstrates the synthetic utility of this type of catalyst.[3]

Tetramethoxyethylene[1]

[1069-12-1] · $C_6H_{12}O_4$ · Tetramethoxyethylene · (MW 148.18)

(strong electron-rich ketene acetal which reacts as an oxalyl dication equivalent with a variety of electrophiles).

Physical Data: bp 48 °C/15 mmHg.

Preparative Methods: the best preparative method is from (*p*-chlorophenoxy)dimethoxymethane and ***Sodium Hydride*** (eq 1).[2] This method is also applicable for other tetraalkoxy analogs.

Handling, Storage, and Precautions: the compound should be stored in dry, base-rinsed vessels under nitrogen.

Introduction.

Tetramethoxyethylene, as a very electron-rich alkene, belongs to the class of ketene acetals. Due to its symmetrical electron distribution, its reactivity is generally somewhat lower than the more polarized ketene acetals, e.g. the 1,1-dialkoxyalkenes. The general reactivity towards electrophiles was first explored by Hoffmann et al.[1a] A variety of cationic species such as diazonium salts add to tetramethoxyethylene to yield substituted methyl dimethoxyacetates (eq 2).

Dihalocarbenes add to give 1,1-dihalotetramethoxycyclopropanes, which upon reaction with ***n-Butyllithium*** are converted into the electron-rich tetramethoxyallene (eq 3).

The most important applications are in the field of cycloadditions.[1c] Generally these reactions occur with fewer side products than those of the 1,1-dialkoxyalkenes and the cycloadducts obtained are more stable.

[2 + 2] Cycloadditions.

With a variety of electron-poor alkenes, tetramethoxyethylene reacts to give tetramethoxycyclobutanes.[3] These higly oxygenated cyclobutanes are valuable precursors for the synthesis of α,α-dimethoxy esters,[4] 1-cyano-2-aryl-3,3,4,4-tetramethoxycyclobutenes,[5] 1-cyano-2-arylcyclobutenediones,[6] and 1,1,4,4-tetramethoxybuta-1,3-dienes (eq 4).[7]

(4)

With aldehydes in the presence of Lewis acids, 2,2,3,3-tetramethoxyoxetanes are formed in good yields (eq 5).[8] These can be easily hydrolyzed to α,α-dimethoxy-β-hydroxy esters.

(5)

Under the influence of Lewis acids, α,β-unsaturated carbonyl compounds yield either cyclobutanes or oxetanes depending on the structure of the α,β-unsaturated carbonyl compound (eq 6).[1c,9] These reactions can also be performed at high pressure without Lewis acids.

(6)

The thermal reaction with ketene yields mixtures of 2,2,3,3-tetramethoxycyclobutanone and 2,2,3,3-tetramethoxy-4-methyleneoxetane.[10] In the presence of Lewis acids the oxetane is selectively formed.[1c] The cycloadducts from tetraalkoxyethylenes and ketenes have been applied effectively in the synthesis of 1,2-substituted tetramethoxycyclobutenes, 1-substituted 4-oxotrimethoxycyclobutenes, and squaric acid.[11]

Other Cycloadditions.[1c]

Diels-Alder adducts are only obtained from electron-poor dienes or α,β-unsaturated carbonyl compounds having a preferred cisoid conformation. Epoxides behave like 1,3-dipoles when adding to tetramethoxyethylene in the presence of Lewis acids to give 2,2,3,3-tetramethoxy(tetrahydrofurans). Diaryl α-diketones yield [4 + 2] cycloadducts with tetramethoxyethylene (eq 7), whereas electronically asymmetric ketene acetals give oxetanes and bis-oxetanes.

(7)

An inverse demand Diels-Alder reaction is also reported with dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate (eq 8).[1a]

1,1,1,3-Tetramethoxypropane

[77197-59-2] · $C_7H_{16}O_4$ · 1,1,1,3-Tetramethoxypropane · (MW 164.23)

(furnishes methyl α-substituted acrylates from allylic alcohols via Claisen orthoester rearrangement and β-elimination[1-5])

Physical Data: bp 89-90 °C/20 mmHg.[1]

Solubility: CCl_4, organic solvents.

Handling, Storage, and Precautions: keep away from moisture; use in a fume hood.

General Discussion.

1,1,1,3-Tetramethoxypropane (**1**) is prepared[1] from β-methoxypropionitrile[6] by the Pinner reaction.[7] It has been used as a synthon for the preparation of methyl α-substituted acrylates via Claisen orthoester rearrangement[8] with allylic alcohols followed by β-elimination of methanol with base. Claisen orthoester rearrangement of allylic alcohols (**2**)-(**4**) with excess (**1**) and a catalytic amount of 2,4,6-trimethylbenzoic acid gave the esters (**5**)-(**7**).[1] Treatment of these esters with one equivalent of ***Potassium t-Butoxide*** in THF (0 °C, 10 min) gave the α-substituted acrylates (**8**)-(**10**).[1]

Tetramethylammonium Bromide[1]

Me_4NBr

[64-20-0] · $C_4H_{12}BrN$ · Tetramethylammonium Bromide · (MW 154.07)

(phase transfer catalyst; source of nucleophilic bromide; cleavage of cyclopropane; salt effects)

Physical Data: mp 230 °C (dec) bp 360 °C (sub. vac.); *d* 1.56 g cm^{-3}.

Solubility: sol H_2O, MeOH.

Form Supplied in: white solid; commercially available.

Analysis of Reagent Purity: tetraalkylammonium salts can be titrated with potassium 3,5-di-*t*-butyl-2-hydroxybenzenesulfonate and iron(III) chloride.[1a]

Purification: the commercially available compound can be recrystallized from EtOH, EtOH-diethyl ether, MeOH-acetone, H_2O, or acetone-EtOH (4:1). It is then dried at 110 °C under reduced pressure for 24 h.

Phase Transfer Catalyst.

It has been generally observed that Me_4NBr is one of the least effective ammonium salts for phase transfer catalysis. A number of studies have shown that increasing the size of the alkyl groups on the nitrogen is generally beneficial for the promotion of phase transfer reactions by ammonium salts. For example, this salt was shown to be inferior to $BuNEt_3Br$ in the *O*- and *C*-alkylation of aryl ketones (eq 1),[2] to ***Tetra-n-butylammonium Iodide*** in the Horner-Emmons alkenation of aldehydes (eq 2),[3] to $(C_8H_{17})_3NMeCl$ in the *S*-alkylation of thiophenol,[4] to Et_4NBr in the oxybromination of aromatic compounds,[5] and to ***Tetra-n-butylammonium Bromide*** and Bu_4PBr in the alkylation of K_2CO_3.[6] Me_4NBr was a very effective phase transfer catalyst for the *N*-alkylation of aromatic heterocyclic compounds (eq 3).[7]

Me_4NBr	21%
$BuNEt_3Br$	100%
Et_4NBr	85%

Me_4NBr	77:23
Bu_4NBr	88:19
Et_4NI	83:17

Nucleophilic Opening of Cyclopropyl Ketones.

In combination with acetyl methanesulfonate, Me_4NBr was shown to promote the efficient cleavage of cyclopropyl ketones to produce γ-bromovinyl esters (eqs 4 and 5).[8]

Tetramethylammonium Dimethyl Phosphate

[756-77-4] · $C_6H_{18}NO_4P$ · Tetramethylammonium Dimethyl Phosphate · (MW 199.22)

(dehydrobromination of bromo ketones, bromo aldehydes, and bromoalkanes)

Physical Data: mp 215 °C.

Solubility: sol acetonitrile, DMF, HMPA.

Preparative Methods: prepared[1,2] by reacting an excess of ***Trimethylamine*** (139 g) with ***Trimethyl Phosphate*** (210 g) in acetone solution (400 g) in a sealed glass reactor at ambient temperature. The crystalline product is recovered by filtration in greater than 90% yield.

Analysis of Reagent Purity: the purity is assessed by mp.

Handling, Storage, and Precautions: no data available.

Elimination of Hydrogen Bromide.

Steroidal α-bromo ketones undergo elimination of HBr with tetramethylammonium dimethyl phosphate (**1**) in acetonitrile or DMF at 110 to 150 °C (eq 1) in an autoclave to give α,β-unsaturated ketones in 45-60% yields.[3] Alternative procedures, for example ***Lithium Chloride***/***Lithium Carbonate*** in DMF, are reported to give superior yields.[4]

Reaction of less complex α-bromo ketones with (**1**) leads to variable results. 2-Bromocyclopentanone yields exclusively 2-cyclopentenone (60%), whereas 2-bromocyclohexanone and 2-bromocycloheptanone (eq 2) give mixtures of α,β-unsaturated ketones and ketophosphates.[5,6] Additional α-substitution causes elimination to become the predominant pathway; thus 2-bromo-2-methylcyclohexanone gives 2-methyl-2-cyclohexenone in 62% yield.

Reaction of (**1**) with α-bromo aldehydes[2] leads predominantly to α-aldophosphates, whereas α-alkyl substituted α-bromo aldehydes[7] give α,β-unsaturated aldehydes by elimination (eq 3). The reaction of alkyl bromides is exemplified by 2-bromopentane in DMF, which forms (*E*)- and (*Z*)-2-pentene, 1-pentene (total alkene 42%), and 2-pentyl dimethyl phosphate (19%).[8]

Surprisingly, the steroidal diaxial dibromide (eq 4) gave a quantitative mixture of the $\Delta^{5,7}$-diene and the $\Delta^{4,6}$-diene (1.3:1) upon treatment with (**1**) in HMPA at 130 °C.[9]

Tetramethylammonium Hydroxide

$Me_4N^+OH^-$

[75-59-2] · $C_4H_{13}NO$ · Tetramethylammonium Hydroxide · (MW 91.18)

(conversion of hydroperoxyoxiranes to hydroxyalkyl-1,2-dioxetanes; catalyst for transesterification of carboxylic acids; synthesis of phosphorylating agent)

Physical Data: dependent on form supplied in, e.g. 10% aqueous solution has *n*20D 1.3521 and *d* 1.006 g cm^{-3}.

Solubility: sol MeOH, H_2O.

Form Supplied in: commercially available as a solution in water or methanol, or in solid form as the pentahydrate.

Preparative Methods: 1. By heating trimethylacetonylammonium bromide ($MeCOCH_2{+}NMe_3\ Br^-$) to 195-200 °C. The free base is obtained by treating the bromide with warm water.[1] 2. Prepared as a solution in water by electrolysis of tetramethylammonium iodide (at anode), ammonium hydroxide (at cathode), and water (central compartment) in a three-compartment cell.[2] 3. By an ion-exchange method using AV-17 and Me_4NX (X = Cl, Br, I).[3] 4. By treatment of tetramethylammonium iodide with freshly prepared silver(I) oxide in water at 50 °C.[4]

Handling, Storage, and Precautions: decomposes on distillation; stored as solution. It is a very strong base, readily absorbing carbon dioxide from the air. Keep container well closed. Solution is flammable and causes burns.

General Discussion.

Hydroperoxyoxiranes (**2**) are converted to the 3α-hydroxyalkyl-1,2-dioxetanes (**3**) by treatment with tetramethylammonium hydroxide in a two-phase water/diethyl ether medium (eq 1).[5]

Tetramethylammonium hydroxide in methanol is used to catalyze the transesterification of carboxylic acids. The methyl esters are formed on pyrolysis of the corresponding tetramethylammonium salt when injected into a gas chromatographic unit[6] (methyl esters are popular derivatives for the gas chromatogaphic analysis of fatty acids[7]).

Aqueous solutions of quaternary ammonium hydroxides were used as initiators for the anionic homogeneous polymerization of

acrylonitrile and methylacrylonitrile in DMF.[8]

Aqueous tetramethylammonium hydroxide reacts with di-*t*-butyl phosphite to give tetramethylammonium *t*-butyl hydrogen phosphite (**4**). This is a convenient phosphorylating agent for organic halides. It reacts easily with alkyl iodides and some alkyl bromides in boiling acetone, affording the corresponding alkyl *t*-butyl phosphites (**5**). Treatment with ***Trifluoroacetic Acid*** at room temperature yields monoalkyl hydrogen phosphites (**6**).[9]

Tetramethylammonium Triacetoxyborohydride

$R_4N(AcO)_3BH$

(R = Me)

[109704-53-2] · $C_{10}H_{22}BNO_6$ · Tetramethylammonium Triacetoxyborohydride · (MW 263.14) (R = Bu)

[83722-99-0] · $C_{22}H_{46}BN0_6$ · Tetramethylammonium Triacetoxyborohydride · (MW 431.50)

(reducing agent for the regio- and stereoselective reduction of β-hydroxy ketones, amides, and oximino ethers)[1]

Alternate Name: TABH.

Physical Data: mp 96-98 °C.

Solubility: sol range of organic solvents including CH_2Cl_2, $CHCl_3$, MeCN.

Form Supplied in: hygroscopic white powder; commercially available.

Preparative Methods: experimental procedures are available (eqs 1 and 2).[5a,6]

$$Me_4NOH + NaBH_4 \longrightarrow Me_4NBH_4 \quad (1)$$

$$Me_4NBH_4 + AcOH \longrightarrow Me_4N(AcO)_3BH \quad (2)$$

Purification: recrystallized from CH_2Cl_2-EtOAc.[5a]

Handling, Storage, and Precautions: moisture sensitive; irritant. Stable at 25 °C. Handle in a well ventilated fume hood.

Selective Reduction of Aldehydes.

Tetra-*n*-butylammonium triacetoxyborohydride ($Bu_4N(AcO)_3BH$) reduces aldehydes selectively in the presence of ketones (eq 3).[2] β-Keto aldehydes are reduced to afford the corresponding 1,3-diol adduct; none of the derived primary β-hydroxy ketone is generated. It is proposed that the aldehyde carbonyl group is reduced first and the resulting hydroxyl group directs the delivery of hydride to the ketone site (eq 4).[3]

(3)

(4)

Similar observations have been reported with ***Sodium Triacetoxyborohydride***.[4] As shown in eq 5, reduction of a cyclic ketone containing a properly disposed hydroxyl function (for hydride delivery) proceeds to afford the derived equatorial alcohol with high diastereoselectivity. In

contrast, an equal mixture of axial and equatorial alcohols are obtained when ***Sodium Borohydride*** is employed as the reducing agent.

(5)

Directed Reduction of β-Hydroxy Ketones.

Evans has reported that TABH may be employed to effect the stereoselective reduction of β-hydroxy ketones.[5] Several reducing agents under a variety of conditions have been examined (eq 6 and Table 1). The reactivity and selectivity with TABH in AcOH/MeCN are superior to other solvent systems. The presence of HOAc is essential to reaction efficiency, as the protic acid catalyzes the rate determining association between the boron reagent and the resident substrate heteroatom.[5b] Acetonitrile is required since the reduction process may then be performed at lower temperatures without freezing of the reaction mixture; reduced temperatures are critical to obtaining high levels of stereoinduction.

(6)

Table 1 Diastereoselective Directed Reduction of b-Hydroxy Ketones by Various Borohydrides

Hydride	Solvent	Time	Temp (°C)	Ratio (*anti*:*syn*)
$NaBH_4$	AcOH	30 min	25	80:20
$Na(AcO)_3BH$	AcOH	15 min	25	84:16
Me_4NBH_4	AcOH	30 min	25	92:8
$Me_4N(AcO)_3BH$	AcOH	15 min	25	92:8
$Me_4N(AcO)_3BH$	AcOH/MeCN	5 h	- 40	95:5

As illustrated in the directed reductions shown in eqs 7 and 8, the level and sense of diastereoselectivity is independent of the local chirality within the substrate molecule.

(7)

ds 50:1

(8)

ds 50:1

Eqs 9 and 10 illustrate two additional important points with regard to the directed borohydride reduction: (1) the hydroxyl unit of an enol function may serve as the directing group (eq 9); (2) the stereoselective intramolecular hydride delivery may be relayed to effect generation of multiple stereogenic sites within an acyclic chain (eq 10).

(9)

ds 92:8

(10)

one stereoisomer

Directed Reduction of Oximino Ethers.

Substrates with β-Hydroxy Substitution.

Stereocontrolled reduction of β-hydroxy oximino ethers has been reported by Williams.[6] Eqs 11 and 12 indicate that whereas (*E*) substrates are

reduced selectively, (*Z*) adducts react with TABH with inferior levels of stereoinduction. As illustrated in eqs 13-16, the stereochemical outcome of reduction of (*E*) oxime ethers is insensitive to the substrate local chirality, whereas the corresponding (*Z*) isomers afford β-hydroxy amines with high selectivity. However, in the latter instance the identity of the major isomer depends on the configuration of the α stereogenic center (eqs 13 and 14). Within the same context, with substrates containing a primary hydroxyl group, the α stereogenic center induces the preferred formation of the *syn* stereoisomer (eq 17). A mechanism-based understanding of the trends in stereoselectivity shown is not yet available.

(16)

(17)

Substrates with α-Hydroxy Substitution.

Reductions of α-hydroxy oximino ethers with TABH provide *syn*-1,2-hydroxyamines with high diastereoselectivity (eq 18).[7] The observed stereochemical trend complements the previously observed *anti* selectivity achieved with ***Lithium Aluminum Hydride*** (LAH) or ***Diisobutylaluminum Hydride*** (DIBAL)[8] as reducing agents, or when Pd-catalyzed stereoselective hydrogenation is employed.[9] Unlike the case with β-alkoxy oximino ethers (eqs 11-17), neither the stereochemistry at the nitrogen (*E* vs. *Z*) nor that of the methyl group at the β-position has any effect on the stereochemical outcome of the reduction (e.g. eq 19).

(18)

(19)

Directed Reduction of Imides.

As shown in Table 2 and eq 20, imides may undergo directed selective reduction with TABH.[10] The superior levels of stereochemistry obtained with the title borohydride, as opposed to LAH or ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Red-Al), may be attributed to the ability of TABH to undergo reduction through the directed pathway exclusively. It is noteworthy that upon protection of the hydroxyl group, no reaction is obtained with TABH. Reduction of the silyl ether with lithium ***Lithium Tri-s-butylborohydride*** (L-Selectride) proceeds with the opposite sense of stereochemical control.

(20)

Table 2 Diastereoselective Directed Reduction of Imides

R¢	Hydride reagent	Yield (%)	(*R*):(*S*)
	LAH	75	61:39
H	Red-Al	80	82:18
	$Me_4N(OAc)_3BH$	63	>99:1
t-$BuMe_2Si$	L-Selectride	98	<1:99
	$Me_4N(OAc)_3BH$	No reaction	

Applications in Synthesis.

The ability of TABH and the corresponding sodium salt to participate in substrate-directed reductions with high levels of diastereoselection renders these reagents as attractive tools in the synthesis of complex molecules. For example, as illustrated in eq 21 in the synthesis of (-)-rocaglamide,[11] the α-hydroxyl group strictly controls (>95%) the stereochemical outcome of the ketone reduction with TABH as the reducing agent. In contrast, hydrogenation (***Palladium(II) Hydroxide*** as catalyst) of the same substrate affords only a 2:1 mixture of isomers. In the total synthesis of (+)-lepicidin A (eq 22), a highly selective β-hydroxy ketone reduction has been achieved (10:1).[12] Stereoselective and directed reductions of β-hydroxy ketones have been employed in the synthesis of subunits of several medicinally important natural products, such as bryostatin I and II, in addition to mevinic acids, compactin, and mevinolin (eq 23, 93% yield, 13:1 selectivity).[13]

Tetramethylammonium Tribromide

$Me_4N^+Br_3^-$

[15625-56-6] · $C_4H_{12}Br_3N$ · Tetramethylammonium Tribromide · (MW 313.87)

(mild brominating agent)

Physical Data: mp 118-119 °C.

Solubility: slightly sol H_2O, alcohols, other organic solvents; slowly dissolves in acetone, reacting to form a lachrymatory solution.

Form Supplied in: anhydrous orange powder.

Preparative Methods: tetraalkylammonium salts that have poor stability can be freshly prepared by the procedure in eq 1. Stoichiometric amounts of tetraalkylammonium (methyl, ethyl, butyl…) bromide and sodium bromide are dissolved into hot water (1 L/mol of sodium bromide) and concd nitric acid (2.2 mol/mol NaBr) is slowly added with stirring. The reaction starts after few min and can be quite exothermic. When the temperature of the mixture returns to rt, the orange precipitate is filtered, washed with ethanol and ether, and dried.

$$2\ NaBr + R_4NBr + 4\ HNO_3 \longrightarrow R_4NBr_3 + 2\ NO_2 + 2\ H_2O + 2\ NaNO_3 \quad (1)$$

Purification: by recrystallization from glacial acetic acid.

Handling, Storage, and Precautions: this hygroscopic solid should be stored under dry conditions. Purity more than 98%; stable bromine degree (1 g = 3.18 mequiv Br_2) when correctly handled. Avoid washing reaction vessels with acetone. Less toxic than bromine, but handle in a fume hood.

Bromination of Alkenes.

Application of tetramethylammonium tribromide as a brominating reagent is well known.[1] Tetramethylammonium tribromide allows double bond bromination under mild conditions and with good yields, and in some cases permits the bromination of aryl compounds at the α-position.[2] Cyclohexene leads to 1,2-dibromocyclohexane; toluene gives benzyl bromide. The bromination of fluorene and methylnaphthalene has also been reported.

1,1,3,3-Tetramethylbutyl Isocyanide[1]

[14542-93-9] · $C_9H_{10}N$ · 1,1,3,3-Tetramethylbutyl Isocyanide · (MW 139.26)

(adds organometallic reagents to give α-metalloaldimines; synthetically useful acyl anion equivalent[2])

Alternate Name: isooctyl isocyanide; 2-isocyano-2,4,4-trimethylpentane; TMBI.

Physical Data: bp 55-57 °C/11 mmHg; *n*20D 1.4220; *d* 0.794 g cm^{-3}.

Solubility: insol water; sol common organic solvents.

Form Supplied in: colorless liquid, commercially available.

Analysis of Reagent Purity: IR ν = 2130 cm^{-1}; ^1H NMR (neat) δ 1.08 (*s*, 9H), 1.43 (t, $J_{^{14}N-H}$ = 2 Hz, 6H) 1.58 (t, $J_{^{14}N-H}$ = 2.3 Hz, 2H).

Preparative Methods: readily available in two steps from 1,1,3,3-tetramethylbutylamine, which is formylated with ***Formic Acid*** (86-90%) followed by dehydration with ***Dimethylchloromethyleneammonium Chloride*** (Vilsmeier reagent).[3]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: unlike other isocyanides 1,1,3,3-tetramethylbutyl isocyanide is not malodorous, though its sweetish pine odor may become unpleasant after continued inhalation. Since some isocyanides are presumed to be toxic,[4] appropriate precautions are recommended.

Addition of Organometallic Reagents.

Organolithium, Grignard, organocopper, and organozinc reagents add to the NC function of isocyanides that do not possess α-hydrogen atoms to give α-addition products. The α-metalloaldimines formed are useful synthetic equivalents[5] for acyl anions, which are notoriously difficult to prepare.[6] Reaction of α-metalloaldimines with electrophiles followed by hydrolysis of the imine introduces the acyl moiety into the product (eq 1).

(1)

1,1,3,3-Tetramethylbutyl isocyanide has several advantages over other isocyanides without α-hydrogens.[7] It is easy to prepare from inexpensive starting materials and is not malodorous. Aromatic isocyanides, which could also be considered as precursors to α-metalloaldimines, tend to oligomerize and arylalkyl isocyanides do not form sufficiently stable α-metalloaldimines.

α-Lithioaldimines are generally prepared by addition of organolithium reagents to a solution of 1,1,3,3-tetramethylbutyl isocyanide in ether at

0 °C.[2,7] Aliphatic organolithium reagents add rapidly to produce excellent yields of the products. Aromatic organolithiums usually give lower yields. Grignard reagents also tend to give somewhat lower yields,[2,7] but their use may sometimes be more expedient when organolithiums are not readily available. Anions generated from C-H acids of pK_a < 30 do not add to 1,1,3,3-tetramethylbutyl isocyanide. Reaction with the substituted cyclopropyllithium shown leads to a substituted cyclobutanone as the main product (eq 2).[8]

(2)

Preparation of Aldehydes and 1-Deuterio Aldehydes.

While simple protonation of metalloaldimines followed by hydrolysis of the imine provides a facile procedure for the preparation of aldehydes,[2,7] from a synthetic point of view it is much more interesting to utilize this reaction to prepare 1-deuterioaldehydes by using D_2O as a quenching agent (eq 3).[2,3,7]

(3)

Yields and deuterium incorporation are higher with organolithiums than with Grignard reagents (Table 1). The products are conveniently isolated by steam distillation from oxalic acid solution.

Table 1 Synthesis of 1-Deuterated Aldehydes from 1,1,3,3-Tetramethylbutyl Isocyanide and Organometallic Reagents

RM	Yield (%)	Deuterium (%)
s-BuLi	92	98
t-BuLi	92	98
s-BuMgBr	67	96
Benzyl MgBr	63	80
Cyclopentyl MgBr	66	89

Reactions with Other Electrophiles.

α-Metalloaldimines react smoothly with ***Carbon Dioxide*** to give, after hydrolysis, α-keto acids (eq 4).[2,7] Similar reaction with ***Ethyl Chloroformate*** leads to α-keto esters.[2]

(4)

Alkylation can be performed with primary halides, which leads to unsymmetrical ketones (eq 5).[7b] Benzylic and allylic halides do not give synthetically useful reactions, whereas secondary halides undergo elimination. In the latter case, dialkylchloroboranes were successfully used to overcome this difficulty (demonstrated for *t*-butyl isocyanide).[9]

(5)

Addition to nonenolizable aldehydes proceeds smoothly to give, after hydrolysis, α-hydroxy ketones (eq 6), whereas ***Propylene Oxide*** yields β-hydroxy ketones (eq 7) virtually without dehydration.[2,7b]

(6)

(7)

The mechanism of the reaction with aldehydes has been studied in more detail.[10] It was found that, whereas α-metalloaldimines add to acrolein in a 1,2 fashion, a 1,4-Michael-type addition occurs with ***Methyl Acrylate***.[10]

Reaction of metalloaldimines with ***Chlorotrimethylsilane*** constitutes a simple route to acylsilanes, though the yield is somewhat low due to the difficulties with selective hydrolysis of the intermediate imine (eq 8).[2,7b]

(8)

Coupling of Lithium Aldimines with Aryl, Vinyl, and Alkynyl Halides.

In a reaction unique among acyl anion equivalents, lithium aldimine generated from 1,1,3,3-tetramethylbutyl isocyanide and ***t-Butyllithium***[2] couples with aryl, vinyl, and alkynyl halides to give, after hydrolysis, the corresponding ketones (eqs 9-11).[11]

(9)

(10)

(11)

Aryl halides like iodo- or bromobenzene (but not chlorobenzene) give excellent yields of ketones. This interesting reaction is believed to proceed by halogen-metal exchange to give imidoyl halides and organolithium reagents, which in turn couple to give the product.[11]

Dissociation of Metalloaldimines.

Lithium aldimines are relatively stable; very little dissociation is observed in their reactions. However, their conversion to copper derivatives accelerates the dissociation.[12] Good yields of nitriles are found only when tertiary alkyllithium reagents are used to generate the lithium aldimine (eq 12).

1,1,3,3-Tetramethyldisilazane

$(HMe_2Si)_2NH$

[15933-59-2] · $C_4H_{15}NSi_2$ · 1,1,3,3-Tetramethyldisilazane · (MW 133.38)

(intramolecular hydrosilation of allyl alcohols, homoallyl alcohols, and homopropargyl alcohols for the regio- and stereoselective synthesis of polyols)

Physical Data: bp 99-100 °C; *n*20D 1.4040; *d* 0.752 g cm^{-3}.

Solubility: common organic solvents.

Form Supplied in: neat liquid.

Handling, Storage, and Precautions: moisture sensitive but no special precautions necessary for handling in the air for a short period of time. May be stored under nitrogen in a tightly capped bottle in a refrigerator. Use in a fume hood.

Intramolecular Hydrosilation.[1,2]

Allyl and homoallyl alcohols are transformed into 1,3-diols in a highly regio- and stereoselective fashion via intramolecular hydrosilation followed by oxidative cleavage of the silicon-carbon bonds by ***Hydrogen Peroxide***, which proceeds with complete retention of configuration at carbon (eqs 1 and 2).[3,4]

Thus, an alcohol is converted into a hydrodimethylsilyl ether by treatment with 1,1,3,3-tetramethyldisilazane in the absence or presence of a catalytic amount of ammonium chloride as a promoter. The ammonia produced in this reaction and the excess disilazane must be removed prior to the hydrosilation step (see also ***Chlorodimethylsilane*** and ***N,N-Diethylaminodimethylsilane***. The intramolecular hydrosilation can be achieved by using a platinum or rhodium catalyst (<=1 mol %) such as acidic $H_2PtCl_6.6H_2O$ in *i*-PrOH (Speier's catalyst) or THF, neutral $Pt[\{(CH_2{=}CH)Me_2Si\}_2O]_2$ in xylene, or ***Chlorotris(triphenylphosphine)rhodium(I)*** (Wilkinson's catalyst). After the reaction, the catalyst, which causes a rapid decomposition of hydrogen peroxide in the subsequent oxidation step, must be removed by stirring the mixture with crystalline EDTA.2Na or activated carbon followed by filtration.[2] The oxidative cleavage of the organosilane intermediate usually proceeds smoothly at room temperature under the standard conditions shown in the following examples.

The reaction of terminal allyl alcohols proceeds in a 5-*endo* fashion to give five-membered ring compounds regioselectively and stereoselectively. Subsequent oxidation affords 2,3-*syn*-1,3-diols preferentially, regardless of the nature of the catalyst (eq 1).[5] The stereoselectivity increases with increased bulkiness of the allylic substituent R^1 and the nature of the alkene substituent R^2 (see below).[5] 5-*Exo* type cyclization occurs with homoallyl alcohols to form five-membered heterocycles and 1,3-diols after oxidation. Two chiral centers are produced in this reaction. The 2,3-relationship (*anti*) is controlled by the allylic substituent, while the 3,4-relationship is determined by the stereochemistry of the alkene; the hydrosilation occurs by *cis* addition of Si-H to the alkene (eq 2).[5b]

This methodology has been applied to the construction of a variety of stereoisomers of polypropionate skeletons, as exemplified by the formation of a tetraol from a symmetrical bis-allyl alcohol by a sequence involving three intramolecular hydrosilation-oxidation steps (eq 3).[5b]

(3)

Extremely high stereoselectivity has been attained in the intramolecular hydrosilation of α-hydroxy enol ethers, leading to 1,2,3-triol derivatives with 2,3-*syn* stereochemistry (eq 4).[6] It has been pointed out, however, that the stereoselectivity largely depends upon the nature of the catalyst, Pt or Rh, and the presence or absence of the disilazane in the Pt case (eq 5).[7]

catalyst

$Pt[\{CH_2{=}CH)Me_2Si\}_2O]_2$, 72% 16:84

Rh(acac)(1,5-cod), 61%	>95:<5

The intramolecular hydrosilation of homopropargyl alcohols also proceeds in a 5-*exo* manner to form five-membered cyclic vinylsilanes exclusively. Subsequent oxidation affords a β-hydroxy ketone (eq 6).[8] The vinylsilane also undergoes a Pd-catalyzed cross-coupling reaction with aryl or alkenyl halides stereoselectively (eq 6).[9] The intramolecular hydrosilation thus provides an efficient methodology for the regio- and/or stereoselective functionalization and carbon-carbon bond formation of the alkyne moiety in homopropargyl alcohol.

While the five-membered cyclic alkoxysilane moiety has been found to tolerate a wide range of chemical transformations (OsO_4 oxidation, Swern oxidation, Horner-Emmons alkenation, protection conditions such as Tr/py$^+$ BF_4^- and MeI/NaH, and catalytic hydrogenation), the carbon-silicon bond can be cleaved efficiently by ***Tetra-n-butylammonium Fluoride*** in DMF (eq 7).[10]

The intramolecular hydrosilation of allyl alcohols containing an ester group at the terminal carbon proceeds in a 5-*endo* fashion to form the five-membered cyclic products with modest stereoselectivity. The silyl group α to the carbonyl group is readily cleaved by a fluoride ion in protic solvents (eq 8).[11]

Catalytic asymmetric intramolecular hydrosilation of allyl alcohols has been achieved by using ***Chlorodiphenylsilane***[12] or 1-chloro-1-silacyclohexane[13] as the silylating agent.

Physical Data: bp 121 °C; *d* 0.781 g cm^{-3}.

Solubility: very sol water, most organic solvents.

Form Supplied in: colorless liquid, typically of 99% purity as obtained commercially. *Drying:* for uses in conjunction with organometallic reagents, moisture exclusion is necessary. Removal of water is best achieved by refluxing over lithium aluminum hydride or calcium hydride for 2 h under nitrogen and distilling immediately prior to use.

Handling, Storage, and Precautions: TMEDA should be used directly after distilling. However, it may be stored under nitrogen and transferred by using a syringe and septum cap as required. For most applications the amine is removed during aqueous workup simply by washing with water owing to its high water solubility. Use in a fume hood.

Lithiation of Difficult Substrates.

TMEDA, through an erstwhile perception of enhanced chelating ability,[1b] but more likely through presentation of a more labile environment, activates organolithium reagents.[1i] ***n-Butyllithium*** forms hexamers in hexane but in the presence of TMEDA exists as a solvated tetramer.[2] Thus the use of the *n*-butyllithium/TMEDA complex in hexane[3] effects the dilithiation of ***Furan*** and thiophene,[4] and lithiation of benzene,[5] in high yields. The allylic deprotonation of unactivated alkenes is normally difficult to achieve with BuLi alone. However, in the presence of TMEDA, propene is monolithiated or dilithiated in the allylic position,[6] and limonene is selectively lithiated at C-10.[7] The resulting allylic carbanion and electrophiles such as ***Paraformaldehyde*** give functionalized products (eq 1).[8]

However, when vinylic metalation is desired, competing allylic deprotonation may occur. In general, thermodynamic acidity and the kinetic preference for vinylic deprotonation of cyclic alkenes decrease with increasing ring size.[1h] The stable alkane-soluble reagent ***n-Butyllithium-Potassium t-Butoxide***-TMEDA in hexane[9] metalates ***Ethylene*** with potassium[10] and effects selective vinylic deprotonation of cyclopentene (eq 2),[11] cyclobutene,[12] norbornene, and norbornadiene.[10]

(2)

N-Alkyl- and *N*-arylpyrroles are readily α-lithiated.[1c] For example, *N*-methylpyrrole is deprotonated with ***Ethyllithium***/TMEDA and the lithiated product has been treated with ***Carbon Dioxide*** to give the corresponding carboxylic acid in 70% yield (eq 3).[13]

(3)

Numerous examples exist in which TMEDA not only facilitates the lithiation of aromatic and heteroaromatic substrates but also controls the regioselectivity of lithiation.[1c] While tertiary benzamides are susceptible to nucleophilic attack by *n*-butyllithium to give aryl butyl ketones, the use of ***s-Butyllithium***/TMEDA in THF at -78 °C provides the synthetically useful *ortho* metalated tertiary benzamide which may be treated with a large variety of electrophiles (eq 4).[1d,14] Even with compounds having a second more acidic site the above conditions allow *ortho* lithiation to take place under kinetic control. Thus a *p*-toluamide is *ortho* lithiated with *s*-butyllithium/TMEDA in THF at -78 °C, but when ***Lithium Diisopropylamide*** is used as the base in THF at 0 °C the thermodynamically favored benzyllithium species is obtained (eq 5).[15] The very marked influence of TMEDA on the lithiation of naphthyl methyl ether in hydrocarbon solvents is dramatically illustrated in the example in eq 6.[16]

(5)

(6)

R = Bu, hexane/TMEDA	>99.3:<0.3	60%
R = *t*-Bu, cyclohexane	1:99	35%

The use of the *s*-butyllithium/TMEDA system in THF at -78 °C is widely employed for the lithiation of amide and thioamide derivatives adjacent to nitrogen.[1f] The resulting lithiated species undergo reaction with a variety of electrophiles such as aldehydes and ketones[17a] and dihalides (eq 7).[17b]

Ligand for Crystallographic Studies.

TMEDA markedly facilitates the isolation of otherwise inaccessible crystalline organolithium reagents suitable for structural determination by X-ray crystallographic means.[18] In most cases, bidentate binding of the TMEDA ligand to the lithium ion is observed.

Control of Regioselectivity and Stereoselectivity.

The recognition by Ireland and co-workers[19] that ***Hexamethylphosphoric Triamide*** has a profound effect on the stereochemistry of lithium enolates has led to the examination of the effects of other additives, as the ability to control enolate stereochemistry is of utmost importance for the stereochemical outcome of aldol reactions. Kinetic deprotonation of 3-pentanone with ***Lithium 2,2,6,6-Tetramethylpiperidide*** at 0 °C in THF containing varying amounts of HMPA or TMEDA was found to give predominantly the (*Z*)-enolate at a base:ketone:additive ratio of ca. 1:1:1, whereas with a base:ketone:additive ratio 1:0.25:1, formation of the (*E*)-enolate was favored (Table 1).[20] This remarkable result contrasts with those cases where HMPA:base ratios were varied towards larger amounts of HMPA, which favored formation of the (*Z*)-enolate.[21]

Table 1 Deprotonation of 3-Pentanone with LiTMP (1.0 mmol) in THF at 0 °C in the Presence of TMEDA or HMPA[19]

3-Pentanone (mmol)	TMEDA (mmol)	HMPA (mmol)	(*E*)-Enolate	(*Z*)-Enolate	Total % yield of silyl enol ether derivatives
0.9	1.0		17	83	70
0.45	1.0		91	9	90
0.25	1.0		95	5	70
0.9		1.0	8	92	89
0.45		1.0	65	35	75
0.25		1.0	66	34	80

However, TMEDA unlike HMPA, does not cause flow over from a carbonyl to conjugate addition manifold for many lithiated systems. For example, lithiated allylic sulfides undergo conjugate (or 1,4) addition to cyclopent-2-enone in the presence of HMPA (see ***Allyl Phenyl Sulfide***), but in the presence of TMEDA, carbonyl addition only is observed.[22] The perception that TMEDA is unable to form solvent-separated ion pairs required for conjugate addition in this case now requires reevaluation.[1j,23] In the reaction of lithio α-trimethylsilylmethyl phenyl sulfide with cyclohexenone, HMPA promotes predominant conjugate addition, whereas TMEDA has little effect on the normal carbonyl addition pathway taken in THF alone (eq 8).[24]

(8)

Likewise, TMEDA in THF has little effect on the stereochemical outcome of the Horner-Wittig reaction of lithiated ethyldiphenylphosphine oxide with benzaldehyde in THF at low temperature compared to the reaction in THF alone: a very slight enhancement in favor of the *erythro* (*anti*) hydroxy phosphine oxide intermediate (*erythro*:*threo* from 85:15 to 88:12), thus leading to slightly enhanced (*Z*)-alkene formation, is observed. By contrast, a reaction in ether alone provides less of the *erythro* product (*erythro*:*threo* 60:40).[25] These examples serve to emphasize current thought that TMEDA is not a good chelating agent for lithium in relation to THF itself.[1i] It is noteworthy that the substitution of methyl in TMEDA by chiral binaphthylmethyl ligands generates a reagent which efficiently catalyzes asymmetric addition of butyllithium to benzaldehyde in ether at low temperature (eq 9).[26]

(9)

Butylmagnesium bromide in THF in the presence of excess TMEDA undergoes addition to a chiral crotonamide derivative to give the conjugate adduct in modest diastereomeric excess (67%) compared with 16% in the absence of TMEDA.[27] On the other hand, diastereoselection in the alkylation of enolates of chiral diamides derived from piperazines in THF containing TMEDA was minimal, with better results being provided by HMPA.[28]

Stabilization and Activation of Organometallic Reagents.

The development and use of organocopper reagents as nucleophiles in the conjugate addition to enones is an important area of organic synthesis. It has been found that the reactivity of aryl- and alkylcopper reagents is dramatically improved through the use of ***Chlorotrimethylsilane*** and TMEDA.[29] The TMEDA not only stabilizes and solubilizes the organocopper reagent but also facilitates the trapping of the resulting enolates, thereby affording silyl enol ethers in excellent yields.[29a] Such a role is also played by HMPA[30] and ***4-Dimethylaminopyridine***.[30b] However, the low toxicity and cost of TMEDA makes it an attractive alternative. Conjugate addition of ***Lithium Di-n-butylcuprate*** to methyl 2-butynoate in diethyl ether provides a 74:26 mixture of (*E*)- and (*Z*)-alkylated enoates, whereas in the presence of TMEDA this ratio increases to 97:3. Stereoselectivity of the conjugate addition of the copper reagent derived from butylmagnesium bromide and ***Copper(I) Iodide*** to ethyl pentynoate in diethyl ether is also enhanced when TMEDA or pyrrolidone are used as additives, to give the (*E*)- and (*Z*)-enoates in a ratio of 99:1. In contrast, the use of HMPA affords a selectivity

of only 78:22 for the (*E*)-isomer.[31]

The preparation of a trifluoromethylvinyl anion equivalent has been described in which the vinyl bromide is converted into the zinc reagent with ***Zinc/Silver Couple*** in the presence of TMEDA. The conversion proceeds very cleanly to afford a thermally stable vinylzinc bromide-TMEDA complex which can undergo reactions with electrophiles. TMEDA is essential for the conversion (eq 10).[32]

(10)

The intramolecular insertion of unactivated alkenes into carbon-lithium bonds to give cycloalkylmethyllithium compounds provides a high-yielding alternative to analogous radical cyclizations.[1g,33] In many cases the addition of Lewis bases such as TMEDA increases the rate of cyclization[1g,33] and dramatically improves those cyclizations which are otherwise sluggish at room temperature (eq 11).[34]

(11)

TMEDA (2 equiv)	68%	31%
no TMEDA	6%	93%

Open chain allylic alcohols add organolithium reagents in the presence of TMEDA. The reactions are regio- and stereoselective; the suggestion is made that the TMEDA complexes the alkoxide lithium counterion, allowing the alkoxide to orientate the incoming organolithium reagent and stabilize the resulting intermediate (eq 12).[35]

(12)

threo:*erytho* = >50:1

Inorganic Complexes useful in Organometallic Reactions and Organic Synthesis.

The complexing properties of TMEDA have made it possible to prepare and handle salts which are otherwise air and moisture sensitive. Thus ***Zinc Chloride*** in the presence of one equivalent of TMEDA forms a crystalline air stable solid, $ZnCl_2$.TMEDA,[36] which with three equivalents of an alkyllithium reagent is converted into trialkylzinclithium. Likewise, CuI and TMEDA react to form the CuI.TMEDA complex,[29] a stable solid which is used for the preparation of stabilized organocopper reagents. The rate of Cu^I-catalyzed oxidative coupling of terminal alkynes in the presence of oxygen to form diynes is considerably increased by using TMEDA as a solubilizing agent for ***Copper(I) Chloride***.[37] Magnesium hydride, rapidly acquiring widespread recognition as a versatile reducing agent (see ***Magnesium Hydride-Copper(I) Iodide***), is prepared from phenylsilane and ***Dibutylmagnesium*** in the presence of TMEDA to give a very active THF-soluble complex free of halide or impurities derived from the usual reducing agents such as ***Lithium Aluminum Hydride***.[38] TMEDA (see also ***1,4-Diazabicyclo[2.2.2]octane***) forms insoluble adducts with boranes and alanes. In particular, the formation of air-stable adducts with monoalkyl boranes is of synthetic usefulness. The free monoalkyl borane may be regenerated by treating the adduct with ***Boron Trifluoride Etherate*** in THF and filtering off the newly formed TMEDA.$2BF_3$ precipitate.[1e]

Base Catalyzed Reactions.

TMEDA can be monoprotonated (pK_a 8.97) and diprotonated (pK_a 5.85).[39] Titanium enolate formation from ketones and acid derivatives has been achieved by using ***Titanium(IV) Chloride*** and tertiary amines including TMEDA in dichloromethane at 0 °C.[40] The reactive species, which is likely to be a complex with the tertiary amine, undergoes aldol reaction with aldehydes to form *syn* adducts with high stereoselectivity (eq 13).

(13)

In the case of TMEDA, stereoselection in favor of the *syn* product (98:2) is enhanced over that achieved with ***Diisopropylethylamine*** (94:6).[40] Along with bases such as ***Triethylamine*** and ethylisopropylamine, TMEDA facilitates the preparation of cyanohydrin trimethylsilyl ethers from aldehydes and ***Cyanotrimethylsilane***.[41] It has been suggested that coordination by nitrogen induces formation of an active hypervalent cyanation intermediate from cyanotrimethylsilane. The conjugate addition of thiols to enones has been successfully catalyzed by using TMEDA in methanol at room temperature, as exemplified by the reaction of 10-mercaptoisoborneol and 4-*t*-butoxycyclopentenone (eq 14).[42] In this case the relative mildness of the reaction conditions prevents subsequent elimination of *t*-butoxide from occurring to give the unwanted enone.

(14)

Related Reagents.

Hexamethylphosphoric Triamide; ***N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine***; ***Potassium Hydride-s-Butyllithium-N,N,N´,N´-Tetramethylethylenediamine***; ***(-)-Sparteine***.

1,1,3,3-Tetramethylguanidine

[80-70-6] · $C_5H_{13}N_3$ · 1,1,3,3-Tetramethylguanidine · (MW 115.21)

(strong base used to generate diazo compounds, protected 3β-substituted steroids, amino acid derivatives without racemization, α-nitroalkyl anions, β-glycosylated phenols, amides from acid chlorides; for the selective cleavage of Cbz groups; for cleavage of peptides from a resin; for the catalysis of conjugate addition reactions, as an azide counterion in asymmetric synthesis; for the catalysis of silylation reactions; for the conversion of ketone hydrazones to vinyl iodides)

Alternate Name: TMG.

Physical Data: bp 165 °C, 52-54 °C/11 mmHg; mp 60 °C; *d* 0.918 g cm^{-3}.

Solubility: freely sol most organic solvents; sol water.

Purification: distillation in vacuo.

Handling, Storage, and Precautions: this liquid is corrosive. It is harmful if swallowed, inhaled, or absorbed through the skin. It should be handled in a fume hood; the handler should wear chemical safety goggles, rubber gloves, and a respirator. Bottles of the liquid should be flushed with an inert atmosphere such as nitrogen or argon to minimize exposure to carbon dioxide.

Diazodiphenylmethane Preparation.

1,1,3,3-Tetramethylguanidine is the base of choice for use in the preparation of ***Diphenyldiazomethane*** from the corresponding ketone hydrazone (eq 1).[1]

(1)

Base	Yield (%)

*Transesterification byproducts

*Transesterification byproducts

Amino Acid Derivatives without Racemization.

TMG readily forms soluble salts with numerous amino acids, thus facilitating many reactions. The variety of amino acid derivatives prepared without racemization include *N*-Boc from ***t-Butyl Azidoformate***[3] or from *t*-butyl phenyl carbonate,[4] *N*-trifluoroacetyl,[5] and peptide coupling products (eq 3).[6,7]

(3)

Insoluble amino acids such as taurine are converted to γ-L-glutamyl taurine with TMG as base (eq 4).[8]

(4)

α-Nitroalkyl Anion Formation.

TMG is often chosen as the basic catalyst for conjugate additions of nitromethane. An early report[9] cited isolation of monomeric addition products to unsaturated esters as a key result (eq 5). Highly selective additions of nitromethane to levoglucosenone afford excellent yields of condensation products (eq 6).[10]

Addition of nitromethane to 4-oxygenated 2-substituted cyclopent-2-enones provides a facile entry to prostaglandin intermediates (eq 7).[11] Precursors of γ-aminobutyric acid analogs are readily available in good yield from nitromethane additions to 2-alkenoic esters (eq 8).[12]

With more hindered nitroalkanes, ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) is required as base for high yields of Michael products (eq 9).[13]

Amides from Acid Chlorides.

For the preparation of chiral, nonracemic C_2-symmetrical pyrrolidine-derived auxiliaries, TMG is the base of choice (eq 12).[16]

(12)

Selective Cleavage of Z Groups.

Selective removal of a primary benzyloxycarbonyl (Cbz, Z) group in the presence of both primary *t*-butoxycarbonyl (Boc) and secondary Z groups gives primary amines by TMG-catalyzed methanolysis (eq 13).[17,18]

Cleavage of Peptides from a Resin.

TMG-catalyzed elimination effects removal of protected peptides from a 2-[4-(hydroxymethyl)phenylacetoxy]propionyl resin (eq 14).[19]

Catalysis of Conjugate Addition Reactions.

Thiol addition to α,β-unsaturated nitroalkenes, in the presence of ***Formaldehyde***, leads to precursors of allyl alcohols in high yields (88-97%) (eq 15).[20] Conjugate addition of hydroxylamine to β-alkoxy acrylonitrile derivatives provides an entry to 4-thiocarbamoyl-5-aminoisoxazoles (eq 16).[21] Conjugate addition of benzyl alcohol catalyzed by TMG provides an adduct with no racemization noted at the initial stereocenter (eq 17).[22]

(16)

(17)

A practical synthesis of (-)-huperzine A utilizes TMG as the base in a key step involving the assemblage of the tricyclic intermediate (eq 18).[23,24] Enantioselective synthesis of α-allokainoic acid uses tandem conjugate additions catalyzed by TMG (eq 19).[25]

Azide Counterion in Asymmetric Synthesis.

In the asymmetric synthesis of α-amino acids via the electrophilic azidation of chiral nonracemic imide enolates, stereospecific bromide

displacement by tetramethylguanidinium azide was a high yielding step (eq 20).[26,27]

(20)

Tetramethyl Orthocarbonate

$C(OMe)_4$

[1850-14-2] · $C_5H_{12}O_4$ · Tetramethyl Orthocarbonate · (MW 136.17)

(CO_2 fixation; formation of orthocarbonates from diols; electrophilic introduction of an ester functionality)

Alternate Names: tetramethoxymethane; methyl orthocarbonate.

Physical Data: mp -5.5 °C; bp 114 °C; n_D 1.3864; *d* 1.023 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Preparative Methods: has been prepared by heating a solution of ***Sodium Methoxide*** in methanol with chloropicrin,[1] ***Trichloroacetonitrile***,[2] or thiocarbonyl perchlorate;[1] the best yields have been obtained with the perchlorate. Alternatively, disodium hexamethoxystannate (prepared in situ from sodium methoxide and tetrachlorostannane) can be refluxed with ***Carbon Disulfide*** in methanol to form the orthocarbonate.[3]

Handling, Storage, and Precautions: flammable; moisture sensitive.

Cyanation.

Replacement of one of the methoxy groups of tetramethyl orthocarbonate with a cyano group can be efficiently accomplished by treatment with ***Cyanotrimethylsilane*** in the presence of a Lewis acid such as ***Iron(III) Chloride***,[4] ***Tin(II) Chloride***,[5] or ***Tin(IV) Chloride*** (eq 1).[6]

$$C(OMe)_4 + TMSCN \xrightarrow[69\text{-}83\%]{\text{Lewis acid}} C(OMe)_3CN \qquad (1)$$

CO_2 Fixation.

The title reagent has been employed in the fixation reaction of CO_2 with diethylamine, providing excellent yields of the methyl carbamate (eq 2).[7]

$$Et_2NH + CO_2\ (40\ atm) + C(OMe)_4 \xrightarrow{120\ °C} Et_2NCO_2Me \qquad (2)$$

Protection of Diols.

Tetramethyl orthocarbonate can be used to protect ribonucleosides as their 2´,3´-orthocarbonates, which are stable to basic conditions. The orthocarbonate may also be transformed, under aqueous acidic conditions, into an acid-stable cyclic carbonate protecting group (eq 3).[8]

Spiroorthocarbonates.

The acid-catalyzed reaction of tetramethyl orthocarbonate with 2 equiv of a diol at 110 °C affords symmetrical spiroorthocarbonates. Their unsymmetrical counterparts can be prepared via a two-step procedure (eq 4).[9]

Formation of Thiiranes.

Conversion of 2-mercaptoalcohols to thiiranes can be accomplished with tetramethyl orthocarbonate in the presence of ***p-Toluenesulfonic Acid*** (eq 5).[10]

Alkylation.

Tetramethyl orthocarbonate can be used as an electrophile to introduce an ester functionality (eq 6).[11]

2,2,6,6-Tetramethylpiperidine

[768-66-1] · $C_9H_{19}N$ · 2,2,6,6-Tetramethylpiperidine · (MW 141.29)

(hindered secondary amine used in preparing metallo-amide bases; selective generation of silylketene acetals)

Alternate Name: TMP.

Physical Data: bp 155.5-156.5 °C; fp 24 °C; *d* 0.837 g cm^{-3}.

Solubility: sol most organic solvents.

Purification: by distillation.

Handling, Storage, and Precautions: liquid is corrosive and flammable. Bottles of 2,2,6,6-tetramethylpiperidine should be flushed with nitrogen or argon to prevent exposure to carbon dioxide. The vapors are harmful and care should be taken to avoid absorption through the skin. Use in a fume hood.

Silylketene Acetal Preparations.

This reagent finds utility in the selective preparation of (*Z*)-silylketene acetals from simple alkyl esters and ***Triethylsilyl Perchlorate*** under kinetic conditions.[1] In a comparison with ***Triethylamine*** and ***Diisopropylethylamine*** (DIPEA), 2,2,6,6-tetramethylpiperidine was found to be the superior base for generating the (*Z*)-silylketene acetal of isopropyl propanoate using triethylsilyl perchlorate in $CHCl_3$ at -70 °C (eq 1). Isomerization (equilibration) is not observed under these reaction conditions (see ***Diisopropylethylamine*** for discussion on similar base-controlled generation of boron enolates).

(1)

Amine base	(*E*):(*Z*) ratio
Triethylamine	37:63
DIPEA	10:90
TMP	3:97

Amide Base Preparation.

The hindered base can easily be converted to stronger metallo-amide bases while retaining nonnucleophilic character. Treatment of TMP with organolithium reagents generates ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LTMP),[2] which finds application in synthesis when a strong base (LTMP, pK_a &AApprox; 37.3)[3] is required.[4] However, LTMP has been shown to be somewhat nucleophilic. Treatment of the trifluoromethylamidine (**1**) with a five-fold excess of LTMP in benzene at 50 °C[5] affords the 4-substituted quinazoline (**2**) in 36% yield.

The mechanism involves sequential addition of multiple equivalents of LTMP (eq 2).[6]

TMP generates, when treated with 1 equiv of ***Ethylmagnesium Bromide*** or 0.5 equiv of ***Dibutylmagnesium*** in refluxing THF, the amido-Grignard reagent *N*-(bromomagnesio)-2,2,6,6-tetramethylpiperidide (TMPMgBr) and the magnesium amide base bis(2,2,6,6-tetramethylpiperidino)magnesium ($(TMP)_2Mg$), respectively. The TMPMgBr base finds use in selective enolate formation,[7] while the bis magnesium base, $(TMP)_2Mg$, succeeds at *ortho* metalation by magnesium of benzamides (eq 3) and aromatic esters (eq 4).[8]

LTMP can be converted to dialkylaluminum amides (e.g. ***Diethylaluminum 2,2,6,6-Tetramethylpiperidide***) by treatment with

dialkylaluminum chloride in toluene. Reaction of LTMP with diisobutylaluminum chloride yields diisobutylaluminum 2,2,6,6-tetramethylpiperidide (*i*-Bu_2AlTMP), which has utility in the diastereoselective cleavage of acetals to chiral nonracemic enol ethers (eq 5).[9]

Proton Abstraction.

The nonnucleophilic character of the base TMP makes it an ideal choice in alkylations involving reactive electrophiles. This is evident in the cycloaddition reaction between the trithiadiazepine (**3**) and the highly reactive 1,3-diphenylisobenzofuran involving the intermediacy of the base-induced hetaryne (**4**) (eq 6).[10] Use of TMP in the reaction gives the cycloaddition product (**6**), whereas use of a more nucleophilic base, ***Morpholine***, results in the morpholino derivative (**5**) as the major product. However, when the hetaryne (**4**) reacts with a less reactive diene, such as tetraphenylcyclopentadienone, the major isolated product is the tetramethylpiperdino derivative (**5**) (NR_2 = TMP).[11]

R_2NH	Yield (%) (5)	(6)
Morpholine	74	3
Diisopropylamine	54	11
TMP	0	76

Though TMP is considered nonnucleophilic, it can be alkylated (eq 7)[12] and sulfenylated.[13] Chlorination, using sodium dichloroisocyanurate, leads to *N*-chloro-2,2,6,6-tetramethylpiperidine,[14] which has found limited use in regiospecific chlorinations.[15] Also, treatment of TMP with trifluoroamine oxide produces the *N*-fluoro and *N*-nitroso derivatives,[16] while treatment with ***N,O-***

Bis(trimethylsilyl)acetamide and ***Methyl Chloroformate*** affords the methyl carbamate derivative in 65% yield.[17] The reaction of TMP with diethyl phosphonomethyltriflate in ether at 0 °C for just 30 min leads to the *N*-(diethyl phosphonomethyl)-TMP derivative in excellent yield (eq 7).[18]

(7)

Oxidation.

N-Hydroxy-2,2,6,6-tetramethylpiperidine is oxidatively converted to the stable nitroxyl radical ***2,2,6,6-Tetramethylpiperidin-1-oxyl***,[19] which is useful as a spin label or trap, and a catalyst for selective oxidation of alcohols.[20]

2,2,6,6-Tetramethylpiperidin-1-oxyl[1]

[2564-83-2] · $C_9H_{18}NO$ · 2,2,6,6-Tetramethylpiperidin-1-oxyl · (MW 156.28)

(oxidizing agent for the conversion of primary alcohols to aldehydes[2,3] or carboxylic acids,[2] of secondary alcohols to ketones,[2] and of diols to lactones or hydroxy aldehydes[4])

Alternate Name: TEMPO.

Physical Data: mp 40.0 °C; fp 67 °C.

Solubility: sol all organic solvents and 0.03 mol L^{-1} in H_2O at 25 °C.

Form Supplied in: red orange solid; commercially available.

Analysis of Reagent Purity: IR (Nujol) 1330, 1180, 1060, 975, 950 cm^{-1};[5] UV-Vis, λ (ε) = heptane, 470 nm (10.5), dioxane, 465 nm (10.4), 240-242 nm (2030).[5]

Purification: sublimation.[6]

Handling, Storage, and Precautions: TEMPO is a toxic substance, and a severe irritant which is readily absorbed through the skin.[7] Its toxicity is probably related to the formation of hydroxylamine metabolites.[8]

Oxammonium Salts.

Oxammonium salts (**2**) can be prepared in situ by oxidation of the nitroxide (**1**).[1e] There is evidence that the oxoammonium ion (**2**) is actually the product of an acid-catalyzed disproportionation between two nitroxide molecules (**1**), which produces one oxoammonium ion (**2**) and one hydroxylamine molecule (**3**).[1e] Peracids, for instance, do not oxidize nitroxides to oxoammonium ions, yet do act as the secondary oxidant. The chemical stability of (**2**) depends on the counterion, and this can be easily exchanged; the chloride salt is not very stable. The oxammonium salt is the active species in the oxidation of primary and secondary alcohols to carbonyl derivatives and can be used in stoichiometric or catalytic fashion.[1e] Catalytic procedures require a co-oxidant such as ***Copper(II) Chloride***-O_2,[9] peroxy acids,[10] electrooxidation,[11] or ***Sodium Hypochlorite***.[2-4] Oxammonium salts can be titrated iodometrically.[1e]

It has been proposed that (**2**) reacts with alcohols, forming carbonyl derivatives and hydroxylamine (**3**).

Oxidation of Alcohols.[2,3,7]

Primary alcohols are converted into aldehydes by the following catalytic system: 0.01-0.002 equiv of TEMPO (or its 4-methoxy derivative), 0.05 equiv of KBr as co-catalyst, and aqueous NaOCl buffered at pH 8.5-9.5 in a CH_2Cl_2/H_2O two-phase system. At this pH, HOCl is the co-oxidant and in the presence of KBr it is likely transformed into HOBr which is more efficient in the oxidation of (**1**) to (**2**). The reaction is exothermic. For reactions carried out on a 1-10 mmol scale the temperature can be easily maintained at 0 °C and conversion is complete in few minutes. On a larger scale, a very efficient cooling system is required. A compromise is to maintain the temperature in the range 10-15 °C with an ice bath; note that higher temperatures lead to fast decomposition of the catalyst. The pH is buffered by adding the appropriate amount of $NaHCO_3$ to the aqueous NaOCl. $NaH_2PO_4.2H_2O$ and $Na_2HPO_4.2H_2O$ have been used as alternatives.[12]

Oxidation of secondary alcohols similarly affords ketones. The oxidation can be applied to saturated alkyl and aryl-alkyl substrates; relatively unstable protecting groups such as acetonide derivatives of diols are not affected. Side reactions occur with substrates with isolated and conjugated double bonds, leading to lower yields. The reaction rates are markedly decreased by the presence of electron-donor groups in the aromatic ring of benzyl alcohol, but they can be speeded up by addition of catalytic amounts of quaternary ammonium salts (Q^+X^-). At the pH of commercial bleach (12.7), reactions are very slow. At lower pH, HOCl is distributed between the aqueous and the organic phase, thus making the phase transfer catalyst unnecessary. Optically active alcohols afford the corresponding aldehydes in good yields and high enantiomeric purity (eq 1).[3,13]

(1)

Oxidation of Diols.

Diols are easily oxidized with this reagent; the nature of the products depends on the amount of oxidant used, the difference in oxidation rates of primary vs. secondary alcohols, the presence of Q^+X^-, and on the relative distance between the OH groups in the aliphatic chain. Under the reaction conditions reported above, primary-secondary diols afford hydroxy or keto aldehydes. In the presence of a catalytic amount of Q^+X^-, primary-secondary diols lead to ketocarboxylic acids. Selectivity in these oxidations also depends on the substituents on the 2,2,6,6-tetramethylpiperidine ring.[14]

Lactones are obtained from 1,4- and 1,5-diols, whereas α,o-diols give unresolvable mixtures of polymeric products.[4] Oxidation of hydrophilic 1,4- and 1,5-diols to γ- and δ-lactones and of hydrophilic alcohols to aldehydes is best conducted using CH_2Cl_2/solid LiOCl in the presence of solid $NaHCO_3$. Commercial LiOCl contains 7% of H_2O so that reaction conditions are those of a pseudo solid-liquid system.[4]

Oxidation of Primary Alcohols and Aldehydes to Carboxylic Acids.[2]

The addition of catalytic amounts of quaternary salt to the oxidizing system leads to the fast and direct formation of carboxylic acids. This oxidation requires the presence, in the organic phase, of ClO^- and/or BrO^- anions which behave as strong bases. Again, electron-donor groups in benzyl alcohol or aromatic aldehydes strongly lower the reaction rates.

Tetramethylstannane[1]

Me_4Sn

[594-27-4] · $C_4H_{12}Sn$ · Tetramethylstannane · (MW 178.87)

(weak nucleophile which reacts with Brønsted and Lewis acids;[2] source of trimethyltin halides;[3] commonly used in Stille coupling[4])

Alternate Name: tetramethyltin.

Physical Data: bp 74-75 °C/760 mmHg; mp -55 °C; *d* 1.315 g cm^{-3}.

Solubility: sol common organic solvents; insol H_2O.

Form Supplied in: widely available as a neat liquid.

Preparative Methods: synthesized by the reaction of methylmagnesium iodide with $SnCl_4$ in Et_2O or THF.[5] Use of higher boiling and/or less Lewis basic solvents, such as toluene or Bu_2O, lessens the need for Vigreux distillation of the product.[6]

Analysis of Reagent Purity: shows one peak in the GC. ^1H NMR (δ 0.1, $J_{H\text{-}^{117}Sn}$ 54.0 Hz, $J_{H\text{-}^{119}Sn}$ 51.0 Hz), ^{13}C NMR (δ -9.5), and ^{119}Sn NMR (Me_4Sn is the common standard) can also be informative.

Purification: commercial tetramethyltin is typically obtained as a colorless oil and is used without further purification. Tetramethyltin is a good solvent for silicone grease;[6b] contamination should be avoided.

Handling, Storage, and Precautions: is an air and water stable oil. Tetramethyltin has a high vapor pressure and containers should be well sealed before storage. Organostannanes are toxic and should only be used in a well ventilated hood. All glassware should be rinsed in a KOH/EtOH bath during cleaning.

Palladium-Mediated Cross-Coupling Reactions (Stille Coupling and Related Reactions).

Tetramethyltin acts as a nucleophile in palladium-mediated cross coupling with electrophiles.[4] The coupling is general for halides with sp or sp^2 centers at or adjacent to the electrophilic center. Aryl and heteroaryl halides (eq 1),[7-9] acid chlorides (eq 2),[10] imidoyl chlorides (eq 3),[11] and some β-ketovinyl iodides (eq 4)[12] have been shown to couple with tetramethyltin. Selectivity for substitution of aryl iodides over aryl chlorides is normally observed.[13] The reaction has been found to be of particular use for the alkylation of the base moiety of nucleosides (eq 5).[14] A variety of Pd^0 and Pd^{II} catalysts may be used to mediate the cross coupling. Variation of the stabilizing ligand from PPh_3 to $(2\text{-furyl})_3P$ (PFu_3) or $AsPh_3$ appears to have little effect on the rate of the reaction.[8] Reactions run at or above the boiling point of tetramethyltin often require use of a sealed flask. Workup is facilitated because the trimethyltin halide byproduct is water soluble.

Vinyl and aryl triflates (eq 6) have also proven to be valuable electrophiles in palladium-mediated cross coupling with tetramethyltin.[15,16] An excess of ***Lithium Chloride*** is typically required for the successful coupling. The reaction has found particular value in the synthesis of cephalosporin analogs (eq 7).[17] Palladium catalysts also mediate the cross coupling of tetramethyltin with arylboronic acids,[18] arenediazonium salts,[19] and arylthallium compounds.[20]

(6)

(7)

When conducted under 1-3 atm of carbon monoxide, cross coupling of tetramethyltin with aryl iodides,[21] aryl triflates,[22] and vinyl triflates (eq 8)[23] affords the corresponding methyl ketone. LiCl is typically not required for the reaction to proceed. Occasionally, carbonylative coupling is accelerated by the addition of 1 equiv of anhydrous ***Zinc Chloride***, presumably due to transmetalation to a methylzinc complex. ***Dicarbonylbis(triphenylphosphine)nickel(0)***, a more robust catalyst, has also been reported to mediate a carbonylative coupling.[24]

(8)

Reaction with Brønsted and Lewis Acids.

Tetramethyltin reacts with Brønsted and Lewis acids through either homolytic or heterolytic pathways to cleave a methyl-tin bond. Though reaction of ***Mercury(II) Chloride*** with tetramethyltin has been used to generate ***Chlorotrimethylstannane*** and dichlorodimethylstannane,[25] disproportionation is a better route to these compounds. Direct nucleophilic reaction of tetramethyltin with Lewis acids has been effectively utilized to methylate haloboranes (eq 9),[26] thionyl chloride,[27] and antimony halides.[28]

(9)

Disproportionation.

Disproportionation of tetramethyltin with ***Tin(IV) Chloride*** in the absence of solvent provides a simple, quantitative, and relatively inexpensive route to chlorotrimethylstannane.[3]

Related Reagents.

Tungsten(VI) Chloride-Tetramethylstannane.

(*S*)-(+)-2-(2,4,5,7-Tetranitro-9-fluorenylideneaminooxy)propionic Acid

(*S*)-(+)

[50996-73-1] · $C_{16}H_9N_5O_{11}$ · (*S*)-(+)-2-(2,4,5,7-Tetranitro-9-fluorenylideneaminooxy)propionic Acid · (MW 447.30) (*R*)-(-)

[50874-31-2]

(used as a π-acidic resolving agent for racemic π-bases, especially carbohelicenes[1] and heterohelicenes,[1a,2] and also for resolving certain types of amines[3])

Alternate Name: TAPA.

Physical Data: mp 195 °C (dec.); $[\alpha]^{25}$ +92° (*c* = 1.6, dioxane).

Solubility: sol $CHCl_3$, dioxane, hot acetic acid; slightly sol CH_2Cl_2, toluene.

Form Supplied in: available as the neat solid.

Analysis of Reagent Purity: NMR,[4] mp, [α].

Preparative Methods: prepared from acetone oxime, ethyl 2-bromopropionate, and 2,4,5,7-tetranitrofluorenone.[4] The intermediate racemic 2-(isopropylideneaminooxy)propionic acid is resolved with ***(1R,2S)-Ephedrine***.

Handling, Storage, and Precautions: should be stored under protection from light. No reported toxicity.

Resolving Agent for π-Bases.

The title reagent was originally designed as an agent for resolving hexahelicene, through formation of diastereomeric charge-transfer complexes.[5] It has subsequently been used for resolution of several different types of chiral, racemic π-bases not containing any of the functional groups usually needed to effect resolution by conventional reagents. Carbohelicenes[1] and heterohelicenes (e.g. **1**),[1a,2] [2,2]paracyclophanes,[6] naphthalenophanes,[7] highly substituted alkenes,[8] derivatives of polycyclic aromatic hydrocarbons (e.g. **2**),[9] porphyrin derivatives,[10] an alkyl aryl ether,[11] and an α-aryl ester[11] have been successfully resolved using this reagent, either by chromatographic separation on columns coated with TAPA or by fractional crystallization. Analytical determination of the enantiomeric purity of hexahelicene and several of its derivatives is also possible using HPLC.[12]

(1)

(2)

Resolution of helicenes has been effected using chromatography on other types of chiral stationary phases, including columns derivatized with analogs of TAPA containing larger alkyl groups at the stereocenter, but TAPA is generally the most effective agent.[1]

Resolving Agent for Certain Types of Amines.

TAPA has also been used as resolving agent for some amines that formed either unstable, insoluble, or noncrystalline salts with common resolving acids. Compounds (**3**) and (**4**) were among those resolved with TAPA, whereas camphor-10-sulfonic acid, 3-bromo-8-camphorsulfonic acid, *O*,*O*-di-*p*-toluoyl-(+)-tartaric acid, (+)-tartaric acid, and (+)-camphoric acid could not be used.[3]

Tetraphenylcyclopentadienone[1]

[479-33-4] · $C_{29}H_{20}O$ · Tetraphenylcyclopentadienone · (MW 384.49)

(reactive diene for Diels-Alder reactions)

Alternate Names: tetracyclone; cyclone.

Physical Data: mp 217-220 °C.

Solubility: soluble in ethanol, benzene, xylene, acetic acid.

Form Supplied in: black-violet crystalline solid; commercially available. *Drying:* may be recrystallized from ethanol-benzene.

Handling, Storage, and Precautions: no special precautions; follow manufacturer's label instructions.

General Discussion.

Tetraphenylcyclopentadienone is readily prepared in high yield by the condensation of benzil with dibenzyl ketone under basic catalysis.[2] Less commonly, the reagent has been prepared from the alkaline ***Potassium Ferricyanide*** oxidation of 2,4,5,6-tetraphenyl resorcinol in modest yield.[3] The reagent is most frequently employed as a reactive diene in the Diels-Alder reaction with a large number of vinylic and alkynic dienophiles, especially arynes (eq 1).[1,4] This subject has been reviewed.[1]

(1)

The reaction can be followed visually by the disappearance of the characteristic intense purple color. Depending on the reaction conditions, the initial cycloadduct may retain the carbonyl bridge (eq 2).[5,6]

With alkyne dienophiles, loss of CO is universal. The reaction of the reagent with ***Dimethyl Acetylenedicarboxylate*** has been studied extensively in a wide range of solvents (eq 3).[5]

Less common reactions involving the reagent have also been reported. For example, treatment of the cyclooctyne-silver nitrate complex with the reagent affords the decarbonylated cycloadduct in high yield.[7] Reaction of the *O*-tosylhydroxylamine of the reagent with aryl Grignard or lithium nucleophiles gives the corresponding imine, which is converted to the arylamine by treatment with excess ***Hydroxylamine*** in aqueous pyridine.[8] Reduction of the reagent with ***Lithium Aluminum Hydride*** and ***Aluminum Chloride*** (1:1) in ether affords the useful diene tetraphenylcyclopentadiene in excellent yield.[9] The reagent has been used as a scavenger for singlet oxygen.[10]

Related Reagents.

Tetrachlorocyclopentadienone.

Tetraphenylcyclopentadienone Oxime *O*-Tosylate

[91550-25-3] · $C_{36}H_{27}NO_3S$ · Tetraphenylcyclopentadienone Oxime *O*-Tosylate · (MW 553.71)

(electrophilic aminating reagent for Grignard reagents[1])

Solubility: sol ether, THF.

Preparative Methods: ***Tetraphenylcyclopentadienone*** (commercially available) reacts with ***Hydroxylamine*** in pyridine to yield the corresponding oxime,[2] and the oxime reacts with ***p-Toluenesulfonyl Chloride*** in an acetone-H_2O basic solution to yield the oxime tosylate.[3]

Electrophilic Amination.

The addition of organometallic reagents to oximes[4] has found limited applicability due to their low electrophilicity and α-deprotonation requiring the use of a considerable excess of organometallic reagent (eq 1). There are various scattered reports of reactions of Grignard reagents and organolithiums with oximes that furnish amines, amino acids, aziridines, β-amino alcohols, and other products.[5] Ketoximes and their *O*-substituted derivatives can also serve as electrophilic aminating reagents for Grignard reagents and organolithiums (eq 2).[5] So far, acetoxime,[6,7] butanone oxime,[6] cyclohexanone oxime,[8] benzaldoxime,[9] isobutyrophenone oxime,[10] ***Acetoxime O-(2,4,6-trimethylphenyl)sulfonate***,[11] and tetraphenylcyclopentadienone oxime *O*-tosylate[1] have been used for amination of Grignard reagents and organolithiums.

(1)

(2)

Tetraphenylcyclopentadienone oxime *O*-tosylate reacts with aryl Grignards and lithiums to give the corresponding imines in good to excellent yields, which are then converted to arylamines by reaction with excess hydroxylamine (eq 3).[3]

A typical experimental procedure is as follows. The aminating reagent (1 equiv) is added to the aryl Grignard reagent (7 equiv) in THF at -78 °C and the mixture is stirred at -78 °C for 45-90 min. The imine is extracted with benzene, crystallized from benzene-heptane (1:3), and then stirred at rt for 2 h with excess hydroxylamine in aqueous pyridine. The oxime is precipitated on acidification, and, following base treatment, the amine is isolated. Alkyllithiums and Grignard reagents have also been reported to react with the tosylate to yield the corresponding imine, but yields have not been reported.

Significant features of this method are the good yields of aryl amines compared to those obtained by the use of other ketoximes as electrophilic aminating reagents, and the mode of the activating the aminating reagent *O*-tosylhydroxylamine by attacking an auxiliary group (tetraphenylcyclopentadienyl moiety), which then can be removed and efficiently recycled through the sequence.

Tetra-*n*-propylammonium Perruthenate[1]

$Pr_4N^+RuO_4^-$

[114615-82-6] · $C_{12}H_{28}NO_4Ru$ · Tetra-*n*-propylammonium Perruthenate · (MW 351.48)

(mild oxidant for conversion of multifunctionalized alcohols to aldehydes and ketones;[1] can selectively oxidize primary-secondary diols to lactones;[2] can cleave carbon-carbon bonds of 1,2-diols[3])

Alternate Name: TPAP.

Physical Data: mp 165 °C (dec).

Solubility: sol CH_2Cl_2, and MeCN; partially sol C_6H_6.

Form Supplied in: dark green solid; commercially available.

Analysis of Reagent Purity: microanalysis.

Handling, Storage, and Precautions: stable at room temperature and may be stored for long periods of time without significant decomposition, especially if kept refrigerated in the dark. The reagent should not be heated neat, as small quantities decompose with flame at 150-160 °C in air.

General Procedures.

TPAP is a convenient, mild, neutral and selective oxidant of primary alcohols to aldehydes and secondary alcohols to ketones.[1] These reactions are carried out with catalytic TPAP at rt in the presence of stoichiometric or excess ***N-Methylmorpholine N-Oxide*** (NMO) as a cooxidant. A kinetic study with 2-propanol as the substrate has shown that these oxidations are strongly autocatalytic.[4] Turnovers of up to 250 are obtainable if activated powdered molecular sieves are introduced to remove both the water formed during oxidations and the water of crystallization of the NMO. Solvents commonly employed are dichloromethane and acetonitrile, or combinations of these. This reagent also works well on a small scale where other methods, such as those employing activated ***Dimethyl Sulfoxide*** reagents, are inconvenient.[1] For large scale oxidations it is necessary to moderate these reactions by cooling and by slow portionwise addition of the TPAP. To achieve full conversion on a large scale, the NMO should be predried (by first treating an organic solution of NMO with anhydrous magnesium sulfate) and the use of 10% acetonitrile-dichloromethane as solvent is recommended.[1]

Oxidation of Primary Alcohols.

Primary alcohols can be oxidized in the presence of a variety of functional groups, including tetrahydropyranyl ethers (eq 1),[1,5] epoxides (eq 2),[1,6] acetals (eq 3),[1,7] silyl ethers,[1,8] peroxides,[9] lactones,[1,10] alkenes,[1,11] alkynes,[1,12] esters,[1,13] amides,[1,14] sulfones,[1] and indoles.[10] Oxidation of substrates with labile α-centers proceeds without epimerization.[1]

(1)

(2)

(3)

Oxidation of Secondary Alcohols.

In a similar fashion, multifunctional secondary alcohols are oxidized to ketones (eqs 4 and 5)[9,15] in good yields.[1,5-14]

(4)

(5)

A particularly hindered secondary alcohol (an intermediate in the latter stages of the synthesis of tetronolide) resisted oxidation with activated DMSO, ***Pyridinium Chlorochromate***, and activated ***Manganese Dioxide***, yet stoichiometric TPAP afforded the ketone in 81% yield.[16]

Allylic Alcohols.

These alcohols are successfully oxidized to the corresponding enones and enals (eq 6).[1,17]

(6)

Oxidation of a primary allylic alcohol over a secondary allylic alcohol has been achieved.[18] Oxidation of the homoallylic alcohol of cholesterol by TPAP and NMO under ultrasonication conditions gives the dienone cholest-4-ene-3,6-dione in 80% yield.[19] This oxidation was subsequently carried out in the presence of a labile TBDMS enol ether group which remained intact, while with both PCC and activated DMSO this protecting group did not survive.[19] Oxidation of homopropargylic alcohols leads to allenones, as with other common oxidants.[20]

Lactols.

Oxidations of lactols to lactones are facile and high yielding; several examples have been reported in the literature (eq 7).[1,21]

(7)

Selective Oxidations.

The selective oxidation of 1,4 and 1,5 primary-secondary diols to lactones is a valuable application of this reagent.[2] Few general mild reagents for the chemoselective oxidation to the hydroxy aldehyde are available.[22] The most widely known reagents are Pt and O_2, and ***Dihydridotetrakis(triphenylphosphine)ruthenium(II)***.[22] Hydroxy aldehydes, in their lactol form, are then oxidized further to lactones. The use of TPAP is advantageous in that it is commercially available, employs mild catalytic reaction conditions, and reacts with high selectivity in unsymmetrical cases (eq 8).[2] Lactones have also been formed from primary-tertiary diols.[23]

(8)

Functional Group Compatibility.

The neutral conditions of these oxidations have been utilized to provide improved yields with acid sensitive substrates compared to the well established Swern method (eqs 9, 10).[1,16]

(9)

(10)

Highly sensitive alcohols have also been oxidized, albeit in low yield, when most other conventional methods, such as Dess-Martin periodinane (***1,1,1-Triacetoxy-1,1-dihydro-1,2-benziodoxol-3(1H)-one***),[24] PCC, ***Pyridinium Dichromate***, and DMSO activated with ***Sulfur Trioxide-Pyridine*** have failed (eq 10).[25]

Oxidative Cleavage Reactions.

Among the numerous methods for 1,2-diol cleavage there exist only a few that involve catalytic ruthenium reagents, for example ***Ruthenium(III) Chloride*** with ***Sodium Periodate***.[22] Attempted selective monooxidation of a 1,2-diol to the hydroxy aldehyde with catalytic TPAP and NMO resulted in carbon-carbon bond cleavage to provide the aldehyde (eq 11).[3] Furthermore, attempted oxidation of an anomeric α-hydroxy ester failed; instead, in this case decarboxylation/decarbonylation and formation of the lactone was observed (eq 12). However, ***Dimethyl Sulfoxide-Acetic Anhydride*** provided the required α-dicarbonyl unit.[26] Retro-aldol fragmentations can also be a problem.[27]

(11)

(12)

Heteroatom Oxidation.

Thus far, TPAP has only been used to oxidize sulfur. Oxidation of an oxothiazolidine *S*-oxide to the corresponding *S,S*-dioxide gave only poor results in comparison to the standard RuO_2 with $NaIO_4$ conditions.[28] However, oxidation of sulfides to sulfones in the presence of isolated double bonds has been investigated. The yields with TPAP/NMO range from 61-99% which are higher than to those obtained with ***m-Chloroperbenzoic Acid***, ***Potassium Monoperoxysulfate*** (Oxone®), or ***Hydrogen Peroxide-Acetic Acid***.[29]

Tetravinylstannane[1]

$(CH_2{=}CH)_4Sn$

[1112-56-7] · $C_8H_{12}Sn$ · Tetravinylstannane · (MW 226.91)

(vinyllithium precursor;[2] vinyl nucleophile source for Stille coupling[3])

Alternate Name: tetravinyltin.

Physical Data: bp 55-57 °C/17 mmHg, 67-70 °C/28 mmHg.

Solubility: sol common organic solvents; insol H_2O.

Form Supplied in: available as a neat liquid. Major impurities are tin chlorides.

Preparative Methods: synthesized by the reaction of ***Vinylmagnesium Bromide*** with ***Tin(IV) Chloride*** in THF.[4]

Analysis of Reagent Purity: shows one spot in the TLC (hexane) and one peak in the GC. ^1H NMR (C_6D_6) can also be informative.

Purification: commercial tetravinyltin is commonly used without further purification. Large quantities are purified by fractional distillation. Smaller amounts may be filtered through a plug of silica.

Handling, Storage, and Precautions: is an air and water stable oil. No unusual storage precautions are required. Organostannanes are toxic and should only be used in a well ventilated hood. All glassware should be rinsed in a KOH/EtOH bath during cleaning.

Vinyllithium.

The primary use of tetravinyltin is for the generation of vinyllithium. There are three common methods used to form vinyllithium. Treatment of a pentane solution of tetravinyltin with 2.0-2.5 equiv of ***n-Butyllithium*** in pentane initiates an exchange reaction which is driven by the precipitation of solid vinyllithium.[2] Removal of solvent by syringe or filtration, followed by washing the vinyllithium and dissolution in Et_2O, affords a solution of vinyllithium which is stable for long periods if stored under an inert atmosphere. An excess of tetravinyltin is employed because the exchange reaction will not proceed to completion.[2] Ethereal vinyllithium solutions are stable for several months at 0 °C. A subsequent study using *n*-BuLi in hexane has shown that the vinyllithium solution can be contaminated with small amounts (<2%) of *n*-BuLi, *n*-hexyllithium, and Bu_4Sn.[5] Vinyllithium formed in this manner has been reacted with 1-chloro-2-methylcyclohexene to afford a substituted bicyclo[4.1.0]heptane (eq 1).[4]

Formation of solid vinyllithium can be avoided by treatment of an Et_2O solution of tetravinyltin with 4 equiv of ***Phenyllithium***.[2] Removal of tetraphenyltin by filtration affords a solution of vinyllithium, which also contains LiBr from the PhLi preparation and trace levels of Ph_4Sn (Ph_4Sn is soluble in Et_2O at 0.0010 g mL^{-1} at 20 °C). Vinyllithium generated in this manner has been reacted with a

sulfonyldihydroisoxazole to afford the vinyldihydroisoxazole (eq 2).[6] Use of Vinylmagnesium bromide afforded the product in low yield.

More recently, vinyllithium has been generated by the reaction of tetravinyltin with either 4 equiv of *n*-BuLi in THF[7] or 4 equiv of ***Methyllithium*** in Et_2O,[8] obviating the need for filtration. Tetraalkylstannanes must not interfere with the ensuing steps. This approach has been used to generate lithium vinyltellurolate[7] and vinylcyanocuprate.[8] Reaction of vinyllithium generated in this manner with 1-naphthyloxazoline afforded, after acid quench, the *trans*-dihydronaphthalene (eq 3).[9]

Palladium-Mediated Cross-Coupling Reactions (Stille Reaction).

Tetravinyltin has occasionally been used as a nucleophile in palladium-mediated cross-coupling reactions with acid chlorides,[10] bromo- and iodonucleosides (eq 4),[11,12] and iodoglycals.[13] Because only one vinyl equiv is transferred per tin, vinyltrimethyltin or ***Vinyltributylstannane*** are more commonly utilized in cross-coupling reactions.[3]

(4)

Protolytic and Halogenolytic Cleavage.

Tetravinyltin reacts once with I_2 to give vinyl iodide and trivinyltin iodide.[14] Similarly, reaction with aqueous HCl affords ethylene and trivinyltin chloride.[15]

Thallium[1]

[7440-28-0] · Tl · Thallium · (MW 204.38)

(reducing agent, coupling agent)

Physical Data: mp 303 °C, bp 1437 °C, *d* 11.85 g cm^{-3}.

Solubility: insol organic solvents.

Form Supplied in: bluish-white very soft metal, packaged under water; widely available.

Handling, Storage, and Precautions: oxidizes superficially in air, forming a coating of thallium oxide. All thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium is a very soft, abundant, and inexpensive metal. Like a variety of other metals, the utility of thallium in Ullmann-like coupling reactions has been explored. Inactivated thallium metal is very inefficient in coupling reactions of aryl halides. For example, reaction of bromobenzene with thallium under reflux produces <5% of biphenyl (eq 1).[2] The use of mossy or pyrophoric thallium in these coupling reactions does not lead to improvement in yields of the biaryls.

$$2\ ArBr + 2\ Tl \longrightarrow \underset{<5\%}{ArAr} + 2\ TlBr \qquad (1)$$

The use of an activated form of thallium in the preparation of trialkylthalliums from alkyl iodides has been reported (eq 2).[3] The activated thallium was prepared by reduction of thallium(I) chloride with ***Potassium*** in boiling *m*-xylene.

$$Tl + RI \longrightarrow R_3Tl \xrightarrow{HCl} R_2TlCl \qquad (2)$$

Metallic thallium is useful in converting aromatic nitro compounds to azoxy compounds (eq 3).[4] In this reaction, thallium is believed to act as a reducing agent and thallium oxide is the byproduct.

(3)

R = H, 76%; 2-Me, 73%; 3-Me, 77%; 4-Me, 77%; 3-OMe, 80%; 2-Cl, 86%; 3-Cl, 84%; 4-F, 89%

The preparation of azoxy compounds by this route is very efficient and simple. The yields range from good to excellent and a variety of substrates can be used. Aromatic nitro compounds with electron-withdrawing substituents and substrates containing acidic hydrogens such

as OH and NH_2 fail to give azoxy compounds. Bromo- and iodo-substituted nitrobenzenes gave complex products. An interesting coupling reaction using 2,4-dichloronitrobenzene was also reported in this study.[4] This reaction gives a high yield of 2,2´,4,4´-tetrachloroazobenzene as the product (eq 4).

Thallium(I) Acetate

TlOAc

[563-68-8] · $C_2H_3O_2Tl$ · Thallium(I) Acetate · (MW 263.43)

(inexpensive and stable substitute for Ag^IOAc for iodocarboxylation;[1] stereoselective vicinal diol synthesis;[2] kinetically controlled iodolactonization[3])

Physical Data: mp 110 °C; *d* 3.68 g cm^{-3}.

Solubility: sol water, alcohol, acetic acid.

Form Supplied in: silk-white crystals; widely available.

Handling, Storage, and Precautions: thallium reagents are extremely toxic. The reactions should be carried out in a well-ventilated fume hood, and rubber gloves should be worn. Thallium(I) acetate is reported as a human poison by unspecified routes.[4]

Iodocarboxylation.

As an inexpensive and stable substitute for ***Silver(I) Acetate***, Tl^IOAc reacts with stoichiometric amounts of alkenes and ***Iodine*** in acetic acid to produce *trans*-α-iodoacetates in high yields (eq 1).[1] The reaction can be carried out in a nonhomogeneous system using benzene or CH_2Cl_2 as a solvent, where more than two equiv of the thallium salt are required. This reaction is not highly regioselective for trisubstituted alkenes,[5,6] and no addition was observed for electron-poor alkenes such as methyl cinnamate.[7] When enol acetates are used as alkenes, the corresponding α-iodo ketones are formed (eq 2).[8] This reaction is a mild alternative to the ***N-Iodosuccinimide*** procedure for α-iodination of ketones.

(1)

(2)

Thallium acetate can be used in the Prevost reaction[9] (dry) and in the Woodward modification[10] (wet) for stereoselective vicinal diol formation. *trans*-1,2-Diacetoxycyclohexane is obtained when a mixture of TlOAc, I_2, and cyclohexene (a stoichiometric ratio of 2:1:1) is heated at reflux in anhydrous acetic acid.[2] After hydrolysis of the acetyl groups, *trans*-1,2-cyclohexanediol is obtained in 65-70% yields (eq 3). In the Woodward modification the reaction mixture is heated at reflux in aqueous acetic acid to afford *cis*-hydroxyacetate, which, upon hydrolysis, produces *cis*-1,2-cyclohexanediol in 70-75% yields (eq 4).[2]

(3)

(4)

Intramolecular iodocarboxylation of unsaturated carboxylic acids in the presence of a stoichiometric amount of TlOAc in CH_2Cl_2 leads to iodolactones in high yields (eq 5).[3] The kinetically controlled product is formed under neutral and nonaqueous conditions.

(5)

As a Catalyst or an Additive.

TlOAc catalyzes the formation of isothiocyanates from isocyanides and disulfides (eq 6).[11] Various isocyanides can be used in this reaction, and the best yields are obtained with dibenzoyl disulfide. The reactions are carried out at 61-85 °C in various solvents such as $CHCl_3$, toluene, cyclohexane, EtOH, and dioxane. TlOAc also catalyzes rearrangements of ten-membered-ring allenes to tricyclic compounds in acetic acid at room temperature (eq 7).[12] The double bond at C-5-C-6 is required for the rearrangement to occur.

(6)

(7)

TlOAc promotes palladium-catalyzed intramolecular cyclization-carbonylation of properly substituted aromatic iodides (eq 8).[13] When ***Triethylamine*** is used as the base instead of TlOAc, a low yield of cyclization-carbonylation product is obtained, which is accompanied by the product derived from the direct carbonylation process. Besides the above examples, bromination of benzene or toluene and selective *ortho*-iodination of phenols mediated by TlOAc were reported.[14,7]

Thallium(III) Acetate

$Tl(OAc)_3$

[2570-63-0] · $C_6H_9O_6Tl$ · Thallium(III) Acetate · (MW 381.53)

(oxidation of alkenes[4] and alkynes;[5] oxidation of conjugated dienes;[7] hydroxylation of double bonds;[11] cleavage of cyclopropane rings;[15] oxidation of enamines;[18] oxidative rearrangements;[20,21,23] bromination of aromatic compounds;[24] oxidation of thiols[25] and *p*-toluenesulfonylhydrazones;[26] formation of acyloxy carboxylic acids;[27] oxidative cyclizations[28])

Physical Data: mp 195 °C.

Solubility: sol hot acetic acid, alcohols, H_2O.

Form Supplied in: white solid; commercially available (98.6%). *Drying:* dry over P_2O_5.

Preparative Methods: was first described by Meyer and Goldschmidt[1] in 1903. It can also be prepared[2] by dissolving thallium(III) oxide in acetic acid and acetic anhydride and stirring at 80-90 °C. The solution is filtered, cooled and the product obtained is recrystallized.

Purification: use after crystallization from acetic acid for best results.

Handling, Storage, and Precautions: remains stable for long periods if kept in a well-sealed desiccator and away from light. It is extremely poisonous. Use in a fume hood.

Oxidation of Alkenes and Alkynes.

It was expressed by Kabbe[3] that thallium(III) acetate as an oxidizing agent occupies an important place between ***Lead(IV) Acetate*** and ***Mercury(II) Acetate***. Oxidation[4] of cyclohexene (**1**) with thallium(III) acetate in acetic acid at rt (several days) yields *cis*/*trans* diacetates (**2**) and (**3**) (40-50%), ring contracted diacetate (**4**) and aldehyde (**5**) (50-60%), and allylic oxidation product (**6**) (2-3%) (eq 1). In dry solvent the *trans*-diacetate (**2**) is obtained in major yield (88%), whereas in moist solvent the *cis*-diacetate (**3**) (81%) predominates. It has been observed that similar oxidation with lead(IV) acetate yields the same five products but the yield of allylic acetate (**6**) is increased by 37% whereas the oxidation carried out with mercury(II) acetate affords exclusively the allylic acetate (**6**). It has been observed[5] that terminal alkynes (**7**) react with thallium(III) acetate in acetic acid or chloroform at 0-20 °C to give a new type of oxythallation adduct (**8**), which on being heated with one equivalent of thallium(III) acetate can be converted to methyl ketone (**9**) (eq 2). Although this procedure for the preparation of ketones was reported[6] previously, the intermediates were not isolated at that time.

(1)

(2)

Oxidation of Conjugated Dienes.

Conjugated dienes (isoprene, 1,3-butadiene, 2,3-dimethyl-1,3-butadiene, etc.) react with thallium(III) acetate in acetic acid at 10-65 °C (0.5-15 h) to give an isomeric mixture (1,2 and 1,4) of the corresponding diacetoxyalkenes in 10-72% yield.[7] All the dienes studied except 1,3-cyclopentadiene afford the 1,2-addition adduct predominantly. The reaction of 2,3-dimethyl-1,3-butadiene (**10**) with thallium(III) acetate has been reported to give the 1,2-addition product (**11**) in good yield and the 1,4-addition product (**12**) in inferior yield (eq 3). In the oxymercuration of dienes with mercury(II) acetate the formation of 1,4-addition products has not been reported.[8] The reaction of diene (**13**) with thallium(III) acetate has been described (eq 4).[9] The resulting product on alkaline hydrolysis has been found to yield alcohols (**14**), (**15**), (**16**), (**17**), and (**18**). The alcohols (**15**) and (**16**) have been utilized for the synthesis of drimane sesquiterpenes. It is worthwhile to mention that the conjugated dienes also undergo *cis* addition[10] with ***Thallium(III) Trifluoroacetate***.

(3)

Hydroxylation of Double Bonds.

The stereoselective *cis* hydroxylation of unsaturated steroids such as (**19**) has been effected[11] with thallium(III) acetate in acetic acid. In addition to the *cis*-glycol monoacetates (**20**) and (**21**) (76%), small amounts of *cis*-diacetate (**22**) (7%) and *trans*-glycol monoacetates are obtained (eq 5). The alkaline hydrolysis of monoacetates (**20**) and (**21**) affords the triol (**23**). A number of steroidal alkenes have been hydroxylated with this reagent. This constitutes a convenient procedure for the *cis* hydroxylation of double bonds which have been effected with other procedures.[12-14]

(5)

Cleavage of Cyclopropanes.

The phenylcyclopropane (**24**) undergoes cleavage[15] with thallium(III) acetate in acetic acid, yielding mainly diacetoxypropane (**25**) (92%) and a small amount of *trans*-cinnamyl acetate (**26**) (8%) (eq 6). The reaction can also be effected with thallium(III) oxide because under the reaction conditions it is converted to thallium(III) acetate and thus the use of the moisture sensitive thallium(III) acetate can be avoided. The same cleavage reaction when effected with lead(IV) acetate[16] yields the same products (**25**) (63%) and (**26**) (5%) along with another diacetate (**27**) (32%).

(6)

The formation of the products (**25**) and (**26**) can be accounted for as a result of the cleavage of C-1-C-2, whereas the cleavage of bond C-2-

C-3 yields the diacetate (**27**). It is important to note that the cleavage of cyclopropane with thallium(III) acetate, which requires 120 h at 75 °C for completion, can be effected with lead(IV) acetate in 10 h.

The cyclopropane ring of methyl *ent*-trachyloban-19-oate (**28**) undergoes an interesting cleavage[17] with thallium(III) acetate in acetic acid, affording four products (**29**), (**30**), (**31**), and (**32**) (eq 7).

(7)

Oxidation of Enamines.

The oxidation of various enamines with thallium(III) acetate at rt in glacial acetic acid or chloroform followed by hydrolysis gives α-acetoxy derivatives of the parent ketone.[18] Thus morpholinocyclohexene (**33**) was converted to 2-acetoxycyclohexanone (**34**) in 70% yield (eq 8). The same reaction can also be carried out on a combination of cyclohexene and morpholine (in situ generation of enamine) and this gives a superior yield (77%). The yield was lower when the pyrrolidine enamine, instead of morpholine enamine, was used. The yield of α-acetoxy ketone is superior to that obtained by direct oxidation of ketones with thallium(III) acetate or lead(IV) acetate. This particular reaction is of preparative value. It has received application in the synthesis of antitumor alkaloids of the vinblastine group.[19] It is necessary to point out that the synthetic utility of this oxidation reaction depends on the use of the equivalent amount of the reaction components.

(8)

Oxidation of Ketones.

A number of cyclic ketones, specially steroidal ketones, have been subjected to oxidation by thallium(III) acetate in acetic acid. Three types of reactions have been noted during the oxythallation of ketones,[20] namely acetoxylation, dehydrogenation, and ring contraction. The ketone (**35**) on treatment with thallium(III) acetate in acetic acid yields the dienone (**36**) and acetoxy derivative (**37**) in 23% and 30% yields, respectively (eq 9). Both products presumably arise from the same thallium adduct (A). The ketone (**38**) on similar treatment affords the ketone (**39**) and the ring contracted acid (**40**) (eq 10). The ketone (**39**) probably arises from a thallium enolate (B).

The oxidation of α,β-unsaturated ketones (**41**), (**42**), and (**43**) with thallium(III) acetate in acetic acid yields only the dienones (**44**), (**45**), and (**46**), respectively (eqs 11-13).[21] The formation of other products, as in the case of steroidal ketones, is not observed. The oxidation of these ketones with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** (DDQ) gives better yields of the dienone, whereas little improvement in the yield of the dienones is observed when the oxidation reaction is repeated with benzeneseleninic anhydride (BSA) (see ***Benzeneseleninic Acid***). These experiments indicate that the potential of thallium(III) acetate is similar to that of DDQ or BSA.

(41) (44) (11)

(42) (45) (12)

(43) (46) (13)

Oxidative Rearrangements.

Molecular rearrangement has also been observed during oxidation reactions with thallium(III) acetate in acetic acid or methanol. The 3β-acetoxypregn-5-en-20-one (**47**) undergoes Wagner-Meerwein rearrangement with thallium(III) acetate in acetic acid yielding the product (**48**)[20] as a result of attack on the more stable $\Delta^{17,20}$-enol (eq 14). This is in contrast to the kinetically controlled acetoxylation at C-21 in reaction with lead(IV) acetate.[22] The chalcone (**49**) on treatment with thallium(III) acetate in boiling methanol yields the isoflavone (**50**) (eq 15).[23] This finding proves that thallic acid induced rearrangement involves exclusively 1,2-aryl migration and thus demonstrates the direct utilization of chalcones rather than flavanones in isoflavone biosynthesis.

(47) (48) (14)

A very interesting rearrangement of the ketone (**51**) was observed with thallium(III) acetate in acetic acid.[21] Instead of the expected dienone (**52**), the catechol derivative (**53**) was obtained (eq 16). This transformation probably involves three processes: (i) acetylation, (ii) dehydrogenation, and (iii) aromatization. A combination of two effects, steric and inductive, is probably responsible for the angular methyl migration and aromatization sequence. The presence of the C-4 methyl group plays an important role in this rearrangement. A similar rearrangement does not occur in the absence of the C-4 methyl group.

Preparation of Aromatic Bromides.

A mixture of thallium(III) acetate and ***Bromine*** in CCl_4 is a mild and effective reagent for the bromination of aromatic compounds.[24] In addition to experimental simplicity, the reaction is remarkable in that a single pure monobromo isomer is generally obtained and this is the special advantage that the reaction possesses over the vast majority of electrophilic halogenation reactions. Exclusive *p*-substitution is observed with almost all monosubstituted benzenes. It should be noted that electron-withdrawing groups inhibit the bromination of monosubstituted benzenes. The present method is particularly useful for the preparation of bromides for sensitive substrates such as 9-bromoanthracene (**55**) (eq 17), 2-bromobiphenylene (**57**) (eq 18), and 2-bromofluorene (**59**) (eq 19) from anthracene (**54**), biphenylene (**56**), and fluorene (**58**), respectively. It is concluded from experimental results that the reaction involves bromination by molecular bromine catalyzed by either thallium(III) bromide or thallium(III) acetate.

(17)

(54) (55)

(18)

(56) (57)

(19)

(58) (59)

Thiols to Disulfides.

A number of thiols undergo oxidation by thallium(III) acetate in chloroform.[25] As an oxidizing agent, thallium(III) acetate is more effective than lead(IV) acetate or mercury(II) acetate. The conversion of thiols (**60**) and (**61**) to disulfides. (**62**) and (**63**), respectively, are the typical examples of this oxidation (eqs 20, 21).

(20)

(60) (62)

(21)

(61) (63)

Oxidation of *p*-Toluenesulfonylhydrazones.

Thallium(III) acetate in acetic acid is useful for the regeneration of both aldehydes and ketones from tosylhydrazones.[26] The cleavage can be effected at room temperature in the case of aldehydes, but reflux temperature is required for ketones. The reagent can also be used for the regeneration of ketones from semicarbazones. The reaction requires reflux temperature and acetoxylation is a side reaction. The reactivity of thallium(III) acetate has been compared with lead(IV) acetate and mercury(II) acetate.[26]

α-Acyloxy Carboxylic Acids.

Thallium(III) acetate has been found to react with a number of aliphatic carboxylic acids, yielding α-acyloxy carboxylic acids.[27] Thus acetic acid (**64**) gives acetoxyacetic acid (**65**) (eq 22). α-Acyloxy carboxylic acids can be hydrolyzed to α-hydroxy acids.

(22)

Oxidative Cyclization.

Thallium(III) acetate has played an important role in oxidative cyclizations of *o*-hydroxyphenyl or *o*-methoxyphenyl ketones, yielding benzofuran compounds.[28] Thus the ketones (**66**) and (**68**) are converted to benzofurans (**67**) and (**69**), respectively, on heating at 75-85 °C with thallium(III) acetate (3 equiv) in acetic acid (eqs 23, 24). Ketones monosubstituted at the α-carbon give good yields (65-84%), while the unsubstituted and disubstituted ketones give lower yields.

(23)

(24)

Homoallylic alcohols undergo cyclization, resulting in the formation of tetrahydrofurans.[29] Thus the alcohol (**70**) is converted to tetrahydrofuran (**71**) by stirring with thallium(III) acetate at rt (eq 25). It was reported[30] that various substituted 4-alkenols undergo electrophilic cyclization with thallium(III) acetate, affording a convenient procedure for the synthesis of *trans*-disubstituted furans. Thus the alkenol (**72**) produces disubstituted furan (**73**) in 60-80% yield (eq 26) with only traces of *cis*-isomer or a tetrahydropyranyl regioisomer. The same reaction using lead(IV) acetate gives (**73**) in only 31% yield.

(25)

(26)

(72) (73)

Several years ago it was reported[31] that ethylene reacts with acetylacetone in acetic acid containing thallium(III) acetate and perchloric acid to yield the furan derivative (**74**) (eq 27). Similarly, styrene also gives furan derivatives.

Thallium(III) Acetate-Bromine[1]

$Tl(OAc)_3$-Br_2

[2570-63-0] · $C_6H_9O_6Tl$ · Thallium(III) Acetate-Bromine · (MW 381.53)

[7726-95-6] · Br_2 · Thallium(III) Acetate-Bromine · (MW 159.80)

(brominating agent)

Physical Data: see entries ***Thallium(III) Acetate*** and ***Bromine***.

Form Supplied in: generated in situ by simple admixture of the two commercially available components.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

A mixture of thallium(III) acetate and bromine has been shown to be a superior reagent for the bromination of aromatic compounds (eq 1, Table 1).[2] When care is taken to control the rate of addition of the bromine solution, use of this system results in good selectivity, giving the monobrominated product in very good yields. It has also been shown to be especially useful for the preparation of 9-bromoanthracene, 2-bromobiphenylene, and 2-bromofluorene, compounds otherwise difficult to obtain using conventional bromination methods. Although this methodology has been used successfully on a wide variety of aromatic substrates, it is not suitable for those with strongly deactivating groups on the aromatic ring; if a readily oxidized group is present (e.g. benzyl alcohol or benzaldehyde), oxidation at this site competes with the substitution reaction (see, however, entry 5 in Table 1). Earlier researchers postulated that the reason for the good regioselectivity was the formation of a Tl^{III}-bromine-arene complex whose steric demands regulated the position of the bromine. However, further work[3] demonstrated that excellent regioselectivity results even in the presence of competing steric requirements (eq 2). Thus it was concluded that this reaction provides a demonstration of remarkable electronic control, not steric governance.

Other thallium reagents have also been used synthetically in conjunction with elemental bromine. For example, there have been several examples of the use of thallium(I) reagents with bromine to affect a Hunsdieker reaction (eq 3).[4] The transformation begins with the conversion of the carboxylic acid to the thallium salt, which is then treated with a solution of bromine in carbon tetrachloride to accomplish the bromodecarboxylation. The reaction is successful only for primary carboxylic acids. It is interesting to note that a thallium(III) species is involved in the reaction; it has been determined[5] that 1.1 equiv of bromine is used to convert the thallium carboxylate to a Tl^{III} carboxylate dibromide, which is then converted to the alkyl bromide product upon treatment with an additional 0.5 mol bromine.

Thallium(I) Acetate-Iodine

TlOAc-I_2

[563-68-8] · $C_2H_3O_2Tl$ · Thallium(I) Acetate-Iodine · (MW 263.43)

[7553-56-2] · I_2 · Thallium(I) Acetate-Iodine · (MW 253.80)

(preparation of *vic*-iodoacetates for Prevost (dry) and Woodward-Prevost (wet) conversion of alkenes into *trans*- and *cis*-diols;[1] for iodolactonizations,[2] iodination of phenols,[3] formation of α-iodo ketones[4])

Physical Data: TlOAc: mp 131 °C; *d* 3.76 g cm^{-3}. I_2: mp 113.5 °C; bp 184.35 °C; *d* 4.93 g cm^{-3}.

Solubility: TlOAc: v sol cold H_2O, EtOH, $CHCl_3$; insol acetone. I_2: sparingly sol hot H_2O (0.078 g/100 mL); sol ether (20.6 g/100 mL), EtOH (20.5 g/100 mL).

Preparative Methods: prepared in situ by heating ***Thallium(I) Acetate*** (2 equiv) with dry acetic acid under reflux for 1 h, and then treating the cooled mixture with the alkene (1 equiv) and ***Iodine*** (1 equiv). The resulting suspension is stirred and heated at reflux, filtered from yellow thallium(I) iodide, and worked up[1] to give the *vic*-diol ester. Alternatively, a dichloromethane solution of iodine (1 equiv) is added dropwise to a stirred suspension of thallium(I) acetate (1 equiv) in dichloromethane containing the alkene (1 equiv) and the mixture worked up to give the *vic*-iodocarboxylate.

Handling, Storage, and Precautions: thallium salts are extremely toxic and thus great care must be taken in their use and disposal. All operations should be carried out in an efficient fume hood, and rubber gloves should be worn. Dispose of thallium wastes carefully.[5-8]

α-Iodocarboxylations.

The reaction of an alkene with iodine and thallium(I) acetate in the ratio 1:1:1.2 in acetic acid at room temperature gives the *trans*-α-iodoacetate, generally in yields of 85-89% (eq 1). Thallium(I) benzoate in benzene can also be used.[1,2]

(1)

Since the iodocarboxylates can be transformed into appropriate derivatives of either *syn*- or *anti*-diols by suitable choice of conditions for solvolysis, the reaction provides an inexpensive alternative to the Prevost reaction,[9] which uses silver(I) carboxylates. Thus solvolysis of a *trans*-iodoacetate in wet acetic acid gives the corresponding *cis*-hydroxyacetate; *trans*-diacetates are obtained by solvolysis in dry acetic acid with added sodium acetate. Unlike silver(I) carboxylates, thallium(I) carboxylates are readily prepared in high yield as crystalline solids and they do not induce solvolysis at room temperature.[2,10] With the exception of 3-phenylpropene, reactions with unsymmetrical alicyclic alkenes are regioselective, addition occurring in the Markovnikov orientation (eq 2).

(2)

Marked differences exist between the modes of reaction of thallium(I) carboxylates and silver(I) carboxylates. No reaction occurs between the thallium(I) carboxylate, iodine, and an alkene unless all three are present, in contrast to the silver(I)-mediated systems where prior formation of the Simonini complex between the acyl hypoiodite, the silver carboxylate, and iodine is the case. Thus it has been suggested that an iodonium ion is formed from the interaction of a thallium(I) species and an alkene-iodine π-complex (eq 3), which gives the iodocarboxylate that then reacts by a normal Woodward or Woodward-Prevost mechanism.[1]

Reaction of thallium(I) acetate-iodine with 1-methylcyclohexene in wet acetic acid at 20 °C gives a *trans*-iodoacetate as the major product, but also affords a significant amount of regioisomer (eq 4), indicating that the high regioselectivity observed for acyclic compounds does not apply to substituted carbocycles.[11] Likewise, 3-*t*-butylcyclohexene gives a mixture (ca. 3:1) of stereoisomeric iodoacetates (eq 5).[12]

These results can be explained based on the assumption that two stereoisomeric iodonium ions are formed in a reversible pre-equilibrium, which then react at rates dependent on steric and conformational factors.

Substituted cyclopropanes (e.g. phenylcyclopropane) react with thallium(I) acetate-iodine less readily than alkenes, but give ring opened 1,3-disubstituted propanes as the major products, and in some cases products from solvolysis of intermediate iodoacetates (eq 6).[13]

Neighboring groups influence the course of reactions by taking part in rearrangements which typically involve carbocationic intermediates.[14]

The *trans vic*-iodoesters formed from alkenes are readily converted into *cis*-hydroxyesters by oxidative displacement with ***m-Chloroperbenzoic Acid*** (eq 7).[15]

(7)

Unlike iodine(I) acetate (prepared from iodine(I) chloride and ***Silver(I) Acetate***) which oxidatively cleaves *vic*-diols rapidly and in high yield at 20 °C, thallium(I) acetate and iodine(I) chloride has no effect.[16]

Iodolactonizations.

Addition of iodine in ether to a suspension of an unsaturated thallium(I) carboxylate in ether at room temperature using a stoichiometric ratio of 1:1 gives high yields of iodolactones.[17] Addition to β,γ-unsaturated acids can in appropriate cases give β-lactones as the products of reaction under kinetic control. Rearrangement then gives the isomeric γ-lactone (eq 8). Using thallium(I) acetate and iodine in a nonpolar solvent at 0 °C gives even better yields of the lactones (eq 8).[18] This reaction has been extended to bromolactonization using ***Thallium(I) Carbonate*** and bromine.[19]

(8)

Iodination of Phenols.

Iodination of activated phenols with thallium(I) acetate-iodine using a ratio of 1:1:1.2 gives selective *ortho*-iodination (eq 9).[3] Use of dichloromethane as the solvent rather than acetic acid results in increased solubility of the iodine and facilitates workup since neutralization of the acetic acid is no longer necessary.

(9)

Formation of α-iodo Ketones.

Treatment of enol acetates with thallium(I) acetate-iodine affords high yields of α-iodo ketones (eq 10).[4] The α-iodo ketones are probably formed via an acetoxyiodonium ion by a pathway similar to that for iodocarboxylations of alkenes.

Thallium(I) Bromide[1]

TlBr

[7789-40-4] · BrTl · Thallium(I) Bromide · (MW 284.28)

(Lewis acid; reagent for coupling and bromination)

Physical Data: mp 480 °C.

Solubility: sol 2360 parts water.

Form Supplied in: pale yellow crystalline powder; commercially available.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

The primary utility of thallium(I) bromide is in Ullmann-like coupling reactions of aryl and alkyl Grignard reagents. A very practical method for the synthesis of biaryls from aryl Grignards using TlBr as a reagent has been developed (eq 1).[2] These reactions are operationally simple and proceed in good to high yields, thus providing a good alternative to similar coupling reactions mediated by other metals. The optimal ratio of thallium bromide to aryl Grignard reagent was found to be 1:1.5. Thallium bromide is regenerated during the coupling reaction. Coupling of two different aryl Grignards with thallium bromide provides all three possible biphenyls. The unsymmetrical biphenyl is generally the major product but the formation of multiple products makes this process of marginal utility. The coupling reaction of 3- and 4-substituted aryl Grignards provide the corresponding biphenyls in good yields. The only drawback to the reaction is that *ortho*-substituted aryl Grignards give no coupling products.

(1)

R = H, 85%; 4-Me, 83%; 4-OMe, 99%
4-Cl, 73%; 4-F, 73%; 3-Me, 85%

This reaction has been extended to secondary aliphatic bromides.[3] The reactions proceed only in moderate yields (eq 2). Similar reactions with primary aliphatic Grignards give only traces of the coupled products.

(2)

R = cyclohexyl, 58%; cyclopentyl, 56%; 2-pentyl, 50%

Thallium(I) bromide serves as a catalyst for nuclear bromination of aromatic compounds (eq 3).[4] For example, benzene can be converted to bromobenzene in moderate yields. Similarly, toluene reacts to produce a mixture of *o*- and *p*-bromotoluene, and the product resulting from benzylic bromination was not observed. These brominations proceed more effectively with Tl^{III} salts as compared to Tl^{I} salts.

Triorganothallium derivatives are useful reagents in organic synthesis. The utility of this reagent in ketone synthesis has been reported.[5] Thallium(I) bromide serves as a precursor for the preparation of triorganothallium reagents. Two methods for the preparation of this reagent are illustrated in eqs 4 and 5.[5,6]

Related Reagents.

Thallium(III) Acetate-Bromine.

Thallium(I) Carbonate[1]

Tl_2CO_3

[6533-73-9] · CO_3Tl_2 · Thallium(I) Carbonate · (MW 468.77)

(base; promoter of coupling reactions)

Physical Data: mp 272 °C; *d* 7.110 g cm^{-3}.

Solubility: sol 24 parts water; 3.7 parts boiling water; sol typical organic solvents; insol alcohol.

Form Supplied in: white solid; commercially available. *Drying:* decomposes on heating.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium carbonate exhibits a variety of interesting applications. The most important of these is the use of thallium carbonate in the Suzuki palladium-catalyzed cross-coupling reaction of alkylboronic esters.[2] As shown in eq 1, the coupling reaction occurs in high yield to give the hydrocarbon product. ***Thallium(I) Hydroxide*** can also be used as the base for this valuable transformation, but thallium carbonate offers the advantage of nonaqueous conditions.

Thallium carbonate has also been used to generate thallium carboxylates, which are then transformed to the alkyl bromide in a thallium version of the Hunsdieker reaction (eq 2).[3] These researchers found that the carbonate was a better reagent than thallium ethoxide for preparing the thallium carboxylates, due to its increased stability.

Both thallium carbonate and ***Thallium(III) Nitrate*** have been examined as additives for promotion of a palladium-catalyzed tandem cyclization-anion capture protocol (eq 3).[4] The presence of this particular additive affects the ratio of the cyclized product (**2**) to the direct capture product (**1**).

The use of thallium carbonate to generate macrocyclic lactones has been investigated,[5] as shown in eq 4. While the thallium salt did effectively promote the ring closure, it was found that ***Cesium Carbonate*** was a superior reagent in this regard.

Thallium carbonate has been utilized in transesterifications with the sensitive epoxy alcohol 2,3-epoxypropanol (eq 5).[6] It was found that thallium salts could mediate the transesterification without accompanying decomposition of the epoxypropanol. A very wide range of thallium salts (both Tl^{I} and Tl^{III}) was examined. There was no significant difference in the outcome of the reaction among the various salts.

Thallium carbonate is also used in the preparation of thallium zeolite, an insoluble promoter for *O*-glycosylation reactions.[7] The zeolite is prepared by stirring 4&AAring; molecular sieves with thallium carbonate in water, followed by washing with water, then acetone, and drying at 190 °C. The glycosylation reaction, using a fourfold excess of the zeolite, proceeds smoothly in 30-90% yields, with the thallium zeolite behaving similarly to Ag, Co, and Cd zeolites.

Thallium(I) Cyclopentadienide[1]

[34822-90-9] · C_5H_5Tl · Thallium(I) Cyclopentadienide · (MW 269.48)

(cyclopentadienyl ligand)

Physical Data: mp >300 °C.

Solubility: sol organic solvents.

Form Supplied in: light yellow solid readily prepared from thallium hydroxide and dicyclopentadiene;[2] commercially available. *Drying:* purified by sublimation.

Handling, Storage, and Precautions: stable for several months if stored under nitrogen in a Schlenk flask kept in the dark. All thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium(I) cyclopentadienide is a versatile reagent for the introduction of the cyclopentadienyl ligand into metal complexes.[3] For example, a novel iridium sandwich complex was prepared in 37% yield starting from TlCp (eq 1).[4]

(1)

Monosubstituted cyclopentadienes can be readily prepared from the reaction of TlCp and alkylating agents. This reagent is superior compared to lithium or sodium cyclopentadienide, since isomerization of the resultant monosubstituted cyclopentadiene is minimal. Additionally, product isolation is very simple since the thallium halide byproduct is very insoluble in organic solvents. In a synthesis of prostaglandins, monosubstituted cyclopentadienes were prepared using thallium cyclopentadienide (eq 2).[5] The same strategy has been used by others to prepare several 5-substituted 1,3-cyclopentadienes cleanly.[6]

(2)

TlCp is also a convenient precursor for the preparation of 5-halo-1,3-cyclopentadiene (eq 3)[7] and 5-heteroatom-substituted 1,3-cyclopentadiene (eq 4).[8]

(3)

X = Br, Cl

(4)

X = S, Se

TlCp reacts with acyl iodides to provide 1-acyl-1,3-cyclopentadienes in good yields (eq 5).[9] The product dienes were used in an ensuing Diels-Alder reaction without isolation. The corresponding reaction with acid chlorides was too slow to be of practical utility.

(5)

R = Me, C_7H_{15}, *i*-Pr, *t*-Bu

TlCp reacts with electron-deficient alkenes such as ***Tetracyanoethylene*** by an addition-elimination pathway to produce an ionic thallium(I) salt (eq 6).[10]

Thallium(I) Hydroxide[1]

TlOH

[4310-83-4] · HOTl · Thallium(I) Hydroxide · (MW 221.39) (.H_2O)

[12026-06-1]

(base; additive for cross-coupling reactions)

Physical Data: mp 139 °C (dec).

Solubility: sol water, ethanol.

Form Supplied in: yellow needles; commercially available. *Drying:* decomposes on heating.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium hydroxide has been found to be an especially useful base for the enhancement of the Suzuki cross-coupling of alkyl boronic acids and esters with vinyl and aryl halides.[2] This thallium hydroxide-mediated transmetalation has been used for the preparation of a key diene in the synthesis of palytoxin (eq 1).[3] The use of TlOH instead of ***Potassium Hydroxide*** resulted in a dramatic 1000-fold rate enhancement.

(1)

This method was also successfully used as a diene preparation in an approach to the bottom half of chlorothricolide (eq 2).[4] The yield of this transformation was considerably improved by the use of thallium hydroxide (cf. 55% for ***Sodium Hydroxide***). It is interesting to note that the boronic acid ester was used in this transformation. Like Suzuki,[2] these researchers found the ester gave better results. However, in subsequent work[4b] it was determined that the boronic acid gave optimal results, presumably due to ease in purification of the acid derivatives.

(2)

Thallium hydroxide has been used in the preparation of thallium(I) salts of β-keto esters.[5] These thallium salts are subsequently condensed with various electrophiles to obtain useful adducts (eq 3).

(3)

Thallium hydroxide has also been studied in the condensation of ***Formaldehyde*** with α-hydroxy ketones, and found to be better than calcium hydroxide in terms of solubility and catalytic action.[6]

Thallium(I) 2-Methyl-2-propanethiolate

t-BuSTl

[56393-79-4] · C_4H_9STl · Thallium(I) 2-Methyl-2-propanethiolate · (MW 293.58)

(nucleophile; reagent for preparation of thiol esters)

Physical Data: mp 170-175 °C (dec).

Solubility: sol organic solvents.

Form Supplied in: bright yellow solid. *Drying:* can be dried under vacuum.

Preparative Methods: can be readily prepared starting from *t*-butyl thiol and thallium(I) ethoxide.[1]

Handling, Storage, and Precautions: the compound should be stored in a dark bottle under argon. All thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium 2-methyl-2-propanethiolate is a convenient nucleophile for the preparation of thiol esters.[2] The thiol esters can be prepared starting from either acid chlorides (eq 1) or diethyl phosphates (eqs 2 and 3) and *t*-BuSTl.[3] The reaction conditions are simple, proceed in good yields, and the workup procedure is straightforward.

(1)

(2)

(3)

Due to the thermal instability of the diethyl phosphates, the preparation of thiol esters from this starting material is most efficient with thallium thiolates. Reactions with sodium and potassium thiolates in place of thallium give unsatisfactory results. The superiority of

thallium thiolates can be attributed to their ease of preparation and solubility in aprotic solvents.

Thallium 2-methyl-2-propanethiolate can also be used for the formation of metal-sulfur bonds.[1b,4] An example of this type of transformation in the formation of a tungsten-sulfur bond is shown in eq 4.

(4)

Related Reagents.

Thallium(I) 1-Propanethiolate.

Thallium(III) Nitrate Trihydrate[1]

$Tl(NO_3)_3.3H_2O$

[13453-38-8] · N_3O_9Tl · Thallium(III) Nitrate · (MW 444.47)

(oxidizing agent; Lewis acid for alkene cyclization)

Alternate Name: TTN.

Physical Data: mp 102-105 °C.

Solubility: sol water, organic solvents.

Form Supplied in: moist white crystals, hygroscopic; widely available. *Drying:* compound decomposes on heating.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

Oxidations.

Thallium trinitrate is a powerful oxidant. A variety of substituted phenols undergo oxidation using TTN to provide quinones.[2] For example, hydroquinones are oxidized to quinones in good yields. *p*-Alkoxyphenols are oxidized to *p*-quinone acetals in good yields by TTN in methanol (eq 1). Similarly, naphthols are oxidized to naphthoquinones using TTN. This oxidation proceeds in higher yields if TTN on ***Celite*** is used as the oxidant.[3]

(1)

R = H, 97%; Cl, 97%; Br, 91%; Me, 87%

Chalcones are oxidized under acidic conditions to 1,2-diketones using three equivalents of TTN (eq 2).[4]

(2)

Ar = Ar' = Ph, 61%
Ar = 4-BrC_6H_4, Ar' = Ph, 55%
Ar = Ph, Ar' = 4'-BrC_6H_4, 70%
Ar = Ph, Ar' = 4'-MeC_6H_4, 49%
Ar = Ph, Ar' = 4'-$MeOC_6H_4$, 49%

TTN is a trihydrate and generally reactions with it are carried out under fairly acidic conditions. TTN oxidations in methanol as a solvent are also strongly acidic, since nitric acid is produced as a byproduct. Reactions that fail or proceed poorly with TTN (TTN in methanol or acetic acid), or where the substrates are acid sensitive, can be promoted by using a 1:1 mixture of methanol and trimethyl orthoformate (TMOF) (see ***Triethyl Orthoformate***) or neat TMOF as solvent. Oxidation of cinnamaldehyde with TTN in methanol proceeds very slowly and produces seven products. On the other hand, cinnamaldehydes are rearranged to aryl malondialdehyde tetramethyl acetals in good yields on treatment with TTN in 1:1 MeOH-TMOF (eq 3).[5]

(3)

$R^1 = R^2 = H$, 79%
$R^1 = 4\text{-MeO}$, $R^2 = H$, 84%
$R^1 = 4\text{-}NO_2$, $R^2 = H$, 63%
$R^1 = H$, $R^2 = Me$, 83%
$R^1 = 3\text{-}NO_2$, $R^2 = Me$, 50%

TTN adsorbed on ***Montmorillonite K10*** is an effective reagent for the conversion of ketones to rearranged esters. For example, acetophenone is readily converted to phenylacetate on treatment with TTN/K-10 reagent (eq 4).[6] Supported TTN reagents are practical, since product isolation from the insoluble inorganic byproducts is simple.

(4)

R	TTN, MeOH, $HClO_4$	TTN/K-10
H	84%	86%
F	44%	88%
Me	86%	84%
Br	35%	89%

Alkene Oxidation.

Simple alkenes are converted to aldehydes or ketones in good yields using TTN. These reactions proceed with migration of the higher migratory aptitude substituent.[7] The preparation of arylacetaldehyde dimethyl acetals by oxidative rearrangement of substituted styrenes using TTN proceeds in good yields (eq 5). The reaction proceeds through the exclusive migration of the aryl substituent and the yields are higher if TTN supported on K-10 is used as the oxidant.[1b,6b]

(5)

R	TTN, MeOH	TTN/K-10
H	85%	92%
F	27%	79%
OMe	64%	81%
Br	30%	76%

Cycloalkenes provide ring contracted aldehydes on oxidation with TTN under acidic conditions. Corey and Ravindranathan have used this methodology to prepare a key prostaglandin intermediate (eq 6).[8] Similarly, enol ethers also undergo oxidative ring contraction on treatment with TTN (eq 7).[9] If methanol is used as the solvent, the corresponding acetals are formed as the products.[10] In contrast to the ring contractive oxidation of monocycloalkenes, bicyclic alkenes furnish nitrate esters on treatment with TTN.[11] Exocyclic alkenes furnish ring enlarged ketones on oxidation with TTN (see ***Thallium(III) Perchlorate*** for similar reactions).[12]

(6)

(7)

Diarylalkynes are converted to 1,2-diketones using two equivalents of TTN (eq 8) and terminal alkynes are oxidized to carboxylic acids (eq 9).[13]

(8)

(9)

$R = C_6H_{13}$, 80%; C_5H_{11}, 55%

TTN can be used for electrophilic cyclizations of polyalkenes.[14] The oxythallative cyclization of elemol acetate using TTN in acetic acid produces a guaiene diol after ***Lithium Aluminum Hydride*** reduction (eq 10).[15] In contrast, ***Mercury(II) Acetate*** mediated cyclization of elemol produces the unrearranged cryptomeridiol.

(10)

Allylations Using Allysilanes and TTN.

Aromatic compounds are allylated using allylsilanes and TTN, but in poor yield.[16] Allylsilanes are converted to allylic ethers (eq 11),[17] *N*-allylic amides (eq 12),[18] and allylic nitrates[19] on treatment with TTN and the appropriate nucleophile.

(11)

(12)

Functional Group Interconversions.

TTN finds utility in a variety of functional group interconversions. Phenols are readily converted to anilines using TTN.[20] Sulfides and selenides are converted to sulfoxides (eq 13) and selenoxides, respectively, on oxidation with TTN.[21] Other transformations include the preparation of allene esters from α-alkyl-β-keto esters (eq 14),[22] carbamates from isocyanides (eq 15),[23] and lactones from γ,δ-unsaturated acids.[24]

(13)

R = Et, 85%; Pr, 92%; Bu, 94%; Ph, 82%

(14)

(15)

R = $EtOCOCH_2$, 84%; Cy, 90%; *t*-Bu, 35%; Ph, 93%; 4-MeC_6H_4, 85%

TTN has been used to selectively deprotect bisthioacetals to give monothioacetals (eq 16).[25] Simple thioacetals can also be deprotected using TTN. Oximes are converted to aldehydes or ketones in high yields on treatment with TTN in methanol at rt (eq 17).[26]

Thallium(III) Perchlorate Hexahydrate

$Tl(ClO_4)_3.6H_2O$

[15596-83-5] · $Cl_3O_{12}Tl$ · Thallium(III) Perchlorate · (MW 610.85)

(oxidizing agent; mild Lewis acid for alkene cyclization)

Physical Data: melts with decomposition.

Solubility: sol water.

Form Supplied in: colorless hygroscopic crystals; widely available. *Drying:* compound decomposes on heating.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. All perchlorates are potentially explosive and appropriate care should be exercised. Use in a fume hood.

Oxidations.

Thallium perchlorate is an efficient oxidizing agent. It converts *p*-alkylphenols to the corresponding *p*-quinols in high yields.[1] Oxidation of 5-hydroxyindan to 6-hydroxybicyclo[4.3.0]nona-1,4-dien-3-one can be achieved in 80% yield by a biphasic reaction using methylene chloride and aqueous thallium perchlorate solution at low temperatures (eq 1).

(1)

Alternatively, oxidation of *p*-alkylphenols using higher concentrations of perchloric acid at rt provides 2-substituted hydroquinones by a dienone-phenol rearrangement. The hydroquinones are further oxidized to substituted benzoquinones (eq 2).[2]

(2)

R = Me, 70%; CH_2CH_2OAc, 66%

A selective and remote oxidation of estrone using thallium perchlorate has been reported (eq 3).[3] Oxidation of estrone provides the 11-keto-*p*-quinol (**1**) as the major product, along with lesser amounts of (**2**). This is in contrast to oxidation with ***Thallium(III) Trifluoroacetate***, where (**2**) is formed as the sole product.[4]

Enol ethers of alkyl aryl ketones are oxidized very selectively to 2-aryl alkanoates using thallium perchlorate (eq 4).[5] Similar oxidations can also be achieved using other thallium(III) salts such as ***Thallium(III) Nitrate***, ***Thallium(III) Sulfate***, and ***Thallium(III) Acetate***.

Reactions with Alkenes.

Thallium perchlorate has been effectively used for ring-expansion of cyclic ketones.[6] The sequence involves the formation of exocyclic alkenes from the ketone by a Wittig reaction, followed by oxidation using thallium perchlorate (eq 5). The ring expansion is most effective when the double bond is exocyclic to four- or five-membered rings.

Polyalkenes can cyclize on treatment with thallium perchlorate. For example, geraniol reacts with thallium perchlorate to provide three carbocyclic products (eq 6).[7] The reaction is noteworthy since cyclization yields the five-membered carbocycle predominantly.

In contrast to its geometrical isomer geraniol, nerol reacts with thallium perchlorate to furnish two isomeric oxabicyclo[3.2.1]octanes and four diastereomeric dioxabicyclo[3.3.1]nonanes (eq 7).[8]

Citral also undergoes a similar cyclization on treatment with thallium perchlorate, yielding diastereomeric dioxabicyclo[3.2.1]octanes (eq 8).[9]

Thallium(I) 1-Propanethiolate

***n*-PrSTl**

[58587-01-2] · C_3H_7STl · Thallium(I) 1-Propanethiolate · (MW 279.55)

(nucleophile; reagent for preparation of thiol esters)

Solubility: sol in organic solvents.

Form Supplied in: can be readily prepared in situ. *Drying:* can be dried under vacuum.

Preparative Methods: can be readily prepared starting from 1-propanethiol and thallium(I) ethoxide.[1]

Handling, Storage, and Precautions: the compound should be stored in a dark bottle under argon. All thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium-1-propanethiolate is a convenient nucleophile for the preparation of thiol esters (see also ***Thallium(I) 2-Methyl-2-propanethiolate***).[2] The thiol esters can be prepared starting from diethyl phosphates and thallium 1-propanethiolate (eqs 1-3).[3] The reaction conditions are simple, proceed in good yields, and the workup procedure is straightforward.

(1)

(2)

(3)

As indicated in the case of *t*-BuSTl, the preparation of thiol esters from diethyl phosphates and thallium 1-propanethiolate is the most efficient. Reactions with sodium and potassium thiolates in place of thallium can give unsatisfactory results. The superiority of thallium 1-propanethiolate can be attributed to the ease of preparation and solubility in aprotic solvents.

Thallium 1-propanethiolate can also be used for the formation of metal-sulfur bonds.[1,4] An example of this type of transformation in the formation of molybdenum-sulfur bond is shown in eq 4.

Thallium(III) Sulfate[1]

$Tl_2(SO_4)_3$

[16222-66-5] · $O_{12}S_3Tl_2$ · Thallium(III) Sulfate · (MW 696.97)

(oxidizing agent)

Physical Data: mp 102-105 °C.

Solubility: sol water, organic solvents.

Form Supplied in: generally prepared in situ; commercially available.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium(III) sulfate is a versatile oxidant, although most reports have been in kinetic and mechanistic studies of thallium(III) salts in general. The reagent is usually formed in situ by dissolving another thallium compound (e.g. ***Thallium(I) Hydroxide*** or Tl_2O_3) in sulfuric acid. Thus formed, thallium(III) sulfate has been used to oxidize both alkenes and aliphatic ketones. In the latter case, α-hydroxy ketones result.[2] The oxidation of alkenes can result in either vicinal diols or carbonyl compounds. Oxidation of ethylene by thallium(III) sulfate has been investigated[3] from a mechanistic viewpoint. In a kinetic study,[4] the oxidation of methylpentenes with this reagent was reported (eq 1). Good yields of a mixture of the carbonyl product and the vicinal diol were obtained.

(1)

The oxidation of cyclohexenes with thallium sulfate has also been studied.[5] Thus thallium(III) sulfate oxidation of *t*-butylcyclohexene provides primarily the *trans*-diol (**1**) with lesser amounts of the isomeric byproducts shown (eq 2).

An interesting variation of alkene oxidation by thallium(III) sulfate has been demonstrated in a preparation of 3-chromanols (eq 3).[6] The alkylthallium salt postulated as an intermediate in the oxidation is susceptible to intramolecular attack by the aromatic ring, thus forming the ether. In the case of R = NO_2, the aromatic ring was sufficiently deactivated by the nitro group to prevent cyclization, resulting in a mixture of the methyl ketone (**2**) and the diol (**3**) (eq 4).

Thallium(III) Trifluoroacetate[1]

$Tl(OCOCF_3)_3$

[23586-53-0] · $C_6F_9O_6Tl$ · Thallium(III) Trifluoroacetate · (MW 543.44)

(oxidizing agent; thallating agent; Lewis acid; reagent for dethioacetalization)

Alternate Name: TTFA.

Physical Data: mp 100 °C (dec).

Solubility: sol water, organic solvents.

Form Supplied in: moist white crystals, hygroscopic; widely available. *Drying:* decomposes on heating.

Preparative Method: readily prepared by refluxing a suspension of thallium(III) oxide with ***Trifluoroacetic Acid*** (TFA).[2]

Handling, Storage, and Precautions: water sensitive solid. All thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

Thallation.

Thallium trifluoroacetate is the most versatile of all the thallium reagents. It has seen extensive utility in a variety of organic transformations.[1] The solution of TTFA in TFA is a potent thallating reagent. Aromatic compounds react with TTFA to provide thallated aromatics (eq 1). As is the case with other electrophilic aromatic substitution reactions, thallation is most efficient with electron-rich aromatics. Other methods are now available for the preparation of thallated aromatics using TTFA.[3] Generally, the thallated intermediates are not isolated, but are transformed to a variety of compounds in a subsequent reaction with nucleophiles.

(1)

Thallation of substituted aromatics with TTFA is highly regioselective, depending on the nature of the substituent and reaction conditions. The reaction is reversible, requires a moderately large activation energy, and has large steric constraints. The electrophilic character of TTFA can be increased by the addition of Lewis acids such as ***Boron Trifluoride*** or ***Antimony(V) Fluoride***.[4] Thallation of substituted aromatics (nonheteroatom substituents) under kinetic control (short reaction times) yields the *para*-thallated product, illustrating the steric requirements of the reaction. The *meta*-thallated product can be obtained by conducting the reaction in refluxing TFA (eq 2).[5]

(2)

Thallation of aromatics possessing heteroatom-containing substituents (CO_2R, CO_2H, OR, CH_2OH, etc.) shows a different type of regioselectivity, providing the *ortho*-thallated product (eq 3).[6] This selectivity has been rationalized as intramolecular delivery of the thallium electrophile. The monothallated species generally deactivates the ring toward further thallation.

(3)

Anisole can be polythallated using excess TTFA in TFA (eq 4).[7] The thallated intermediate can be converted to the corresponding iodo compound on treatment with ***Sodium Iodide***.

(4)

Electrophilic thallations are not restricted to aromatic compounds. Heterocyclic compounds, such as thiophenes, furans, and indoles, undergo thallations cleanly.[8] These thallated intermediates can also be treated with nucleophiles to provide substituted heterocycles.

ipso-Displacements.

The thallated aromatics are useful in the preparation of a variety of substituted compounds. The reaction involves treatment of the thallated intermediates with nucleophiles, alkenes, arenes, and cations.[1] The introduction of the nucleophile takes place with very high selectivity: the nucleophile occupies the same position as the thallium (*ipso* substitution) (eq 5) (see ***Phenylthallium Bis(trifluoroacetate)*** for examples).

(5)

Nu = OH, F, Cl, Br, I, SCN, CN, SeCN, NO_2, Alkyl, SH, etc

Preparation of aryl fluorides from thallated aromatics has been attempted by several researchers with mixed results.[9] Only Taylor et al.[9b] have been successful, using the three-step method (including the preparation of the arylthallium bis(trifluoroacetate)) shown in eq 6. While

Taylor's method is less complicated than the Balz-Schiemann method of preparing fluoride compounds, it is limited to those aromatic substrates that do not contain electron-withdrawing groups, or oxygen or nitrogen functionality.

(6)

Phenols are also readily accessed via this methodology. Arylthallium bis(trifluoroacetate) salts can be oxidized in a single step to phenols, as shown in eq 7.[10] An interesting alternative which combines both boron and thallium chemistry has been developed whereby the arylthallium compound is treated with diborane to provide the arylboronic acid.[11] Oxidation of the boronic acid under standard conditions (eq 8) yields the phenol.

(7)

(8)

Thallation of substituted arenes provides entry into indoles under notably mild conditions (eqs 9 and 10).[12,13]

(9)

(10)

Silyl enol ethers have been treated with tolylthallium bis(trifluoroacetate) to generate the novel α-metallo ketones shown in eq 11.[14] These compounds are enolate equivalents in titanium-mediated aldol condensations.

(11)

Oxidations.

TTFA is a very useful oxidant. Simple alkenes undergo oxidation when treated with thallium(III) salts. The reaction proceeds by an initial oxythallation of the alkene followed by dethallation to give the oxidation product and thallium(I). The intermediate thallium(III) salts are not generally isolated. The oxidation products are glycols, their mono- and diesters, aldehydes, ketones, and epoxides, and the reaction generally involves the migration of a substituent. The product distribution is dependent on reaction conditions and the nature of the thallium(III) salt. An illustration of the use of TTFA in alkene oxidation is shown in eq 12.[15] The reagent of choice for alkene oxidations is, however, ***Thallium(III) Nitrate***.

(12)

Acyclic conjugated dienes react with TTFA to provide 1,2-diacetoxyalkenes in low yields.[16] This is in contrast to ***Thallium(III) Acetate***, which provides both 1,2- and 1,4-addition products.[17] On the other hand, reaction of cyclic dienes with TTFA provides both the 1,2- and 1,4-addition products with *cis* stereochemistry (eq 13). Oxidation of nonconjugated dienes with TTFA is also possible. An example of this methodology in the transannular cyclization of 1,5-cyclooctadiene is shown in eq 14.[18]

(13)

59:41

(14)

3:2

Efficient routes have been developed for the preparation of *p*-quinones from a variety of aromatic substrates.[19] For example, substituted 4-*t*-butylphenols can be converted to quinones in good yields (eq 15). Similarly, hydroquinones, 4-aminophenols, and 4-halophenols can be converted to *p*-quinones in good yields (eq 16).

(15)

$R^1 = Br, R^2 = H$; 57%
$R^1 = Br, R^2 = Me$; 89%
$R^1 = I, R^2 = t\text{-}Bu$; 87%
$R^1 = Me, R^2 = Me$; 88%

(16)

$R^1 = R^2 = H, X = OH$; 68%
$R^1 = Me, R^2 = H, X = OH$; 77%
$R^1 = Ph, R^2 = H, X = OH$; 73%
$R^1 = R^2 = H, X = NH_2$; 88%
$R^1 = R^2 = Br, X = NH_2$; 81%
$R^1 = R^2 = X = Br$; 77%

Thallated aromatics also undergo oxidation with ***Trifluoroperacetic Acid*** to provide quinones (eq 17). The reaction proceeds with the migration of an R group or by elimination of hydrogen halide (R^1 = halogen).[20]

(17)

$R^1 = R^2 = R^3 = R^4 = H$; 65%
$R^1 = Me$, $R^2 = R^3 = H$, $R^4 = Me$; 68%
$R^1 = Cl$, $R^2 = R^3 = R^4 = H$; 42%
$R^1 = OMe$, $R^2 = R^3 = R^4 = H$; 61%

Methoxy-substituted phenylpropanoic acids undergo oxidation with 2 equiv TTFA to provide *p*-quinones (eq 18).[21] The reaction involves a one-electron oxidation to form a radical cation, followed by trapping of the intermediate with the carboxyl group and subsequent oxidation to the quinone by the second equivalent of TTFA.

(18)

TTFA has found extensive utility in intramolecular oxidative phenolic coupling reactions and has been elegantly used in the synthesis of many natural products. This coupling strategy, which mimics the biosynthesis of these natural products, provides a laboratory analog of this important reaction. In these reactions, TTFA functions as a two-electron oxidant. The *ortho-para* coupling strategy in the synthesis of a precursor for racemic oxocrinine is shown in eq 19.[22]

(19)

The major problems associated with this type of coupling reaction are regioselectivity, oxidation of other functional groups, and low yields. A solution to the above problems has been presented in the synthesis of narwedine by the use of a palladacycle to direct the mode of cyclization and to protect the oxidizable functional groups (eq 20).[23] The reaction furnishes a 51% yield of narwedine.

Oxidative dimerization reactions of cinnamic acids have been explored. The reaction proceeds in the presence of ***Boron Trifluoride Etherate*** to provide fused bislactones (eq 21).[24]

TTFA can be effectively used for both inter- and intramolecular biaryl coupling reactions (Ullmann-type couplings). An example of an intermolecular coupling reaction is illustrated in eq 22.[25] (for similar biaryl coupling reactions with TTFA and palladium catalysis, see ***Thallium(III) Trifluoroacetate--Palladium(II) Acetate***). The details of the various reaction conditions for this coupling reaction have been determined.[25] The coupling reactions work well with moderately electron-rich aryls and poorly with electron-poor aryls. Modification of the reaction conditions for coupling of highly electron-rich aryls has also been reported.[26]

Intramolecular biaryl coupling reactions using TTFA also proceed in a facile fashion. An example of this methodology in the synthesis of the aporphine alkaloid ocoteine is shown in eq 23.[27] TTFA is a superior reagent to ***Vanadyl Trifluoride*** in this type of coupling, since the latter reagent generally gives *O*-demethylated compounds.

(23)

An interesting example of the biaryl coupling reaction in the synthesis of macrocyclic lactones has been reported (eq 24).[28] Other examples of oxidative biaryl coupling reactions include the synthesis of lignan natural products.[29]

(24)

Miscellaneous.

Aromatic compounds are allylated using allylsilanes and TTFA.[30] Allylsilanes are converted to allyl ethers,[31] *N*-allyl amides,[32] and allyl nitrates[33] on treatment with TTFA and the appropriate nucleophile. The soft Lewis acid properties of TTFA can be effectively applied in the deprotection reactions of sulfur-containing compounds. Thioacetals can be deprotected to form the corresponding carbonyl compounds in high yields (eq 25).[34]

(25)

R = Ph, R^1 = Me; 84%
R = R^1 = Ph; 95%
R = Ph, R^1 = H; 83%

TTFA has also been used for the deprotection of sulfur protecting groups in cysteines and subsequently as an oxidant to yield cystines (eq 26).[35] The reaction has been extended to intramolecular disulfide bond formation in cystine-containing peptides. The reaction employs very mild conditions and proceeds in high yields without the problems associated with other oxidants such as iodine.

(26)

R = adamantyl, 80%; Bn, 0%; *t*-Bu, 80%; trityl, 87%

Thallium(III) Trifluoroacetate--Palladium(II) Acetate[1]

$Tl(OCOCF_3)_3$-$Pd(OAc)_2$

[23586-53-0] · $C_6F_9O_6Tl$ · Thallium(III) Trifluoroacetate--Palladium(II) Acetate · (MW 543.44)

[3375-31-3] · $C_4H_6O_4Pd$ · Thallium(III) Trifluoroacetate--Palladium(II) Acetate · (MW 224.52)

(catalyst for aryl couping, carbonylation, and alkenation)

Physical Data: see entries ***Thallium(III) Trifluoroacetate*** and ***Palladium(II) Acetate***.

Solubility: sol common organic solvents; limited sol hexane.

Form Supplied in: white solid ($Tl(OCOCF_3)_3$); orange-brown solid ($Pd(OAc)_2$); commercially available.

Handling, Storage, and Precautions: all thallium compounds are extremely toxic to inhalation, skin contact, and ingestion. Toxicity is cumulative. Extreme caution should be used when handling these materials. Use in a fume hood.

General Discussion.

Thallium(III) salts are efficient reagents for the conversion of aryls to biaryls under mild conditions.[2] The major drawback of these reactions is the requirement of at least one electron-donating substituent on the aromatic ring. A practical alternative for the preparation of biaryls containing both electron-donating and mild electron-withdrawing groups has been developed.[3] The reaction involves the coupling of arylthallium bis(trifluoroacetates) in the presence of catalytic palladium(II) acetate (eq 1).

(1)

R	Temp. (°C)	Yield (%)
H	65	64
Me	105	93
OMe	50	79
Cl	105	66
F	70	86

The reaction proceeds in good to high yields, with thallium(III) functioning as a reoxidant for palladium. These reactions are homogeneous and product isolation is simple. Lithium tetrachloropalladate has been used as the catalyst in similar coupling

reactions to produce good yields of biaryls (eq 2).[4] It is interesting to note that the palladium(II) acetate-catalyzed reaction with chlorobenzene gives a higher yield of the biphenyl as compared to the reaction with lithium tetrachloropalladate (66% vs. 20%).

(2)

R = H, 88%; Me, 97%; OMe, 89%; Cl, 20%; *t*-Bu, 72%

A tandem thallation-carbonylation process has been developed for arenes en route to aromatic esters, phthalides, anhydrides, imides, and 3,4-dihydroisocoumarins.[5] The reaction involves the carbonylation of arylthallium bis(trifluoroacetates) in the presence of catalytic ***Palladium(II) Chloride***, ***Carbon Monoxide***, and ***Lithium Chloride*** at room temperature and atmospheric pressure. The preparation of a variety of esters and phthalides are shown in eqs 3 and 4, respectively.

(3)

R = H, 55%; F, 42%; OMe, 62%; *t*-Bu, 80%

(4)

X = H, 18%; OMe, 47%; OH, 95%; Cl, 45%

Palladium(II)-catalyzed alkenation of arylthallium bis(trifluoroacetates) has been explored by several groups.[6] An interesting Heck-type alkenation of arylthallium bis(trifluoroacetate) with ***Methyl Vinyl Ketone*** has been reported.[7] This reaction uses lithium tetrachloropalladate as the catalyst and proceeds under mild reaction conditions (eq 5).

(5)

R = H, 98%; Me, 97%

Thexylborane[1]

[3688-24-2] · $C_6H_{15}B$ · Thexylborane · (MW 98.02)

(readily available monoalkylborane useful for regioselective hydroboration of alkenes and dienes; thexylalkylboranes and thexyldialkylboranes are useful intermediates for the synthesis of unsymmetrical ketones, cyclic ketones, *trans* disubstituted alkenes, conjugated dienes, and diols[1])

Alternate Name: (1,1,2-trimethylpropyl)borane.

Physical Data: generally prepared in situ; dimeric in THF. It can be isolated as a liquid, mp -34.7 to -32.3 °C.[2]

Solubility: sol ether, hydrocarbon, and halocarbon solvents; THF is generally the solvent of choice; reacts rapidly with protic solvents.[1a]

Form Supplied in: not commercially available.

Analysis of Reagent Purity: analyzed by NMR and IR spectroscopy and by hydrogen evolution upon reaction with methanol.[1a,3]

Preparative Method: most conveniently prepared from ***Borane-Tetrahydrofuran*** and 2,3-dimethyl-2-butene in THF (eq 1).[1a,2]

Handling, Storage, and Precautions: very reactive with oxygen and moisture; must be handled using standard techniques for handling air-sensitive materials.[3] The reagent is reported to be stable for at least a week when stored at 0 °C in THF solution under N_2.[1a] However, at rt the boron atom slowly migrates from the tertiary position to the primary (3% in 8 days).[4] Use in a fume hood.

Hydroboration of Alkenes.

Reactions of alkenes with thexylborane have been extensively studied and several reviews have appeared.[1] Thexylborane ($ThxBH_2$) in THF reacts with 2 equiv of relatively unhindered alkenes to form thexyldialkylboranes. The regioselectivity in the hydroboration of alkenes with thexylborane is similar to that of borane in THF. For example, hydroboration of 2 equiv of 1-hexene with thexylborane followed by oxidation produces a 95:5 mixture of 1-hexanol and 2-hexanol. Hydroboration of a terminal monosubstituted alkene with thexylborane in a 1:1 ratio gives a mixture of both the thexylmonoalkylborane and thexyldialkylborane. (Preparation of thexylmonoalkylboranes from monosubstituted alkenes can be accomplished using ***Chloro(thexyl)borane-Dimethyl Sulfide***). With most disubstituted and some trisubstituted alkenes, it is possible to prepare the corresponding thexylmonoalkylborane by treating 1 equiv of the alkene with thexylborane at -20 to -25 °C.[5] Thexylmonoalkylboranes can hydroborate relatively unhindered alkenes to form thexyldialkylboranes containing two different alkyl groups (eq 2).[6]

(2)

Hydroboration of a hindered alkene with either thexylborane or thexylmonoalkylborane is slow and is accompanied by dehydroboration of the thexylmonoalkylborane, producing a monoalkylborane and 2,3-dimethyl-2-butene. Lower reaction temperatures and the presence of excess 2,3-dimethyl-2-butene in the reaction may reduce the amount of dehydroboration.[6] Sterically hindered alkenes can be hydroborated under high pressure (6000 atm) to produce highly hindered trialkylboranes, such as trithexylborane,[7] but this procedure does not appear to be practical for synthetic purposes.

Mixed thexyldialkylboranes have also been prepared by treating thexylborane consecutively with different halomagnesium or lithium dialkylcuprates.[8] This procedure offers the advantage of being able to introduce methyl or aryl groups onto the boron atom.

The hydroboration of either terminal or internal alkynes with thexylborane in a 2:1 ratio gives good yields of the expected thexyldialkenylboranes, but the reaction of thexylborane with 1 equiv of a terminal alkyne is reported to give at most 20% of the thexylalkenylborane.[1a,4]

Complete dehydroboration of the thexyl group in thexylmonoalkylboranes can be achieved by treating thexylmonoalkylboranes with a fourfold excess of ***Triethylamine***.[5] This reaction provides a general method for the synthesis of monoalkylboranes as the triethylamine complexes. More recently, it has been found that thexylborane-triethylamine or thexylborane-***N,N,N´,N´-Tetramethylethylenediamine*** adducts can be used to hydroborate hindered alkenes directly (with concomitant loss of the thexyl group as 2,3-dimethyl-2-butene) to give the monoalkylborane-amine adducts.[9] ***Monoisopinocampheylborane***, a useful chiral hydroborating reagent, can be prepared by this reaction.[10]

Thexylborane is the reagent of choice for the hydroboration of dienes to form *B*-thexylboracyclanes (eq 3)[11] since the reaction of borane with dienes tends to give polymeric products.[12] Stereoselective cyclic hydroboration of dienes by thexylborane has been employed to prepare acyclic diols with 1,3-, 1,4-, and 1,5-asymmetric induction (eq 4).[13] In the cyclic hydroboration of appropriately substituted 1,5-dienes to yield 1,5-diols, 1,2-asymmetric induction was employed as a key step (eq 5) in the synthesis of the Prelog-Djerassi lactone.[14]

(3)

Cyclic hydroboration of allyl vinyl ethers provides a highly stereoselective synthesis of 1,3-diols with *syn* stereochemistry (eq 6).[15] The *syn* stereoselectivity observed in the cyclic hydroboration of allyl vinyl ethers is opposite to the stereoselectivity observed in the acyclic hydroboration of allylic alcohols (see eq 9).[18] Remote stereocontrol in the hydroboration-reduction of enones with thexylborane has also been reported (eq 7).[16] This reaction is proposed to occur by a rapid hydroboration of the carbon-carbon double bond followed by an intramolecular reduction of the carbonyl group by the intermediate dialkylborane.

(7)

Acyclic diastereoselection in the hydroboration of alkenes has been reported by several groups. Evans and co-workers[17] observed high levels of 1,3-asymmetric induction in the hydroboration of a number of terminal alkenes bearing substituents at the 2-position of the alkene and a proximal chiral center, as illustrated in eq 8. These workers concluded that the diastereoselection is directed primarily by the nearest chiral center in each of the substrates, and they proposed a transition state model to account for the observed diastereoselectivity. The hydroboration of acyclic secondary allylic alcohols with thexylborane, yielding 1,3-diols with high *anti* (or *threo*) diastereoselection, has also been reported (eq 9).[18] The diastereoselection observed in this reaction does not require the use of a protecting group on the allylic alcohol. Thexylborane proves to be the hydroboration reagent of choice for reaction with trisubstituted alkenes, but terminal alkenes give higher diastereoselection with the more sterically demanding reagents ***9-Borabicyclo[3.3.1]nonane*** or ***Dicyclohexylborane***.

(8)

Selective Functional Group Reductions.

The selective reduction of functional groups by thexylborane has been reported,[19a] and the relative reactivity of thexylborane with common functional groups has been compared to that of other borane reagents (***Diborane***, ***Disiamylborane***, and thexylchloroborane-dimethyl sulfide).[19] Acidic hydrogens in -OH, -CO_2H, and -SO_3H groups react at moderate to rapid rates with thexylborane with the evolution of hydrogen. Aldehydes generally react rapidly with thexylborane yielding alcohols after hydrolysis. However, ketones and most other carbonyl groups react only slowly with thexylborane. Carboxylic acids can be reduced to aldehydes by 2.5 equiv of thexylborane, but ***Chloro(thexyl)borane-Dimethyl Sulfide*** is the borane reagent of choice for this transformation. Nitriles, oximes, epoxides, and aromatic nitro compounds are reduced only slowly, and alkyl nitro compounds, disulfides, sulfones, and tosylates do not react with thexylborane.

Use of Thexyldialkylboranes in Synthesis.

Thexyldialkylboranes are particularly useful in synthetic reaction sequences due to the availability of a variety of these compounds and the low migratory aptitude of the tertiary thexyl group in most rearrangement reactions. Several reviews of the role of boron in synthesis have appeared.[1,2,20]

Synthesis of Ketones.

Reaction of thexyldialkylboranes with ***Carbon Monoxide*** in the presence of water followed by oxidation provides a novel route to the synthesis of ketones (eq 10).[21] Yields in this reaction are generally in the 50-80% range. The observed migratory aptitude for the alkyl groups is: primary > secondary >> tertiary. Cyclic ketones can be prepared from dienes by cyclic hydroboration with thexylborane followed by carbonylation and oxidation (eq 11).[22] This annulation procedure stereoselectively provides the *trans*-ring fusion in both the indanone and decalone systems. This methodology has been successfully employed in the stereospecific annulation of 1,5-diene substrates to form the *trans*-hydroazulene nucleus.[23]

(11)

An alternate procedure to convert thexyldialkylboranes into ketones via an intermediate cyanoborate has been reported (eq 12)[24] which avoids the use of carbon monoxide under high pressure. Yields are quite good, generally >75%, and no special equipment is required for the reaction. This procedure has been employed in the synthesis of the heterocyclic ring system of δ-coniceine (**1**) (eq 13).[25]

(12)

(13)

(1)

Synthesis of Alkenes.

The stereoselective synthesis of (*E*)-disubstituted alkenes[26] can be carried out by treating a thexylmonoalkylborane (**2**) with a 1-bromo-1-alkyne to yield the intermediate thexylalkyl(1-bromo-1-alkenyl)borane (**3**), which is then treated with ***Sodium Methoxide*** to induce a stereospecific rearrangement of the alkyl group (R^1) from boron to carbon. Stereospecific protonolysis of the resulting intermediate (**4**) provides the (*E*)-alkene in high isomeric purity and good to excellent yield (eq 14).

Trisubstituted alkenes can be synthesized[27] by first treating a thexyldialkylborane (**5**) with an alkynyllithium to yield a thexyldialkylalkynylborate (**6**), which is then alkylated with migration of an alkyl group from boron to carbon to give the thexylalkylvinylboranes (**7** and **8**) (eq 15). After acid hydrolysis, the trisubstituted alkenes (**9** and **10**) are obtained in >70% yield in a ratio of about 9:1. The major product (**9**) in all cases is the isomer in which the migrating group (R^1) and the group introduced by alkylation (R^3) are *cis* to each other. Various alkylating agents are effective in this reaction including primary alkyl iodides, benzyl and allyl bromides, ***Dimethyl Sulfate***, and ***Triethyloxonium Tetrafluoroborate***.

Synthesis of Dienes.

Thexylborane reacts with 2 equiv of 1-alkyne to give the corresponding thexyldialkenylborane (**11**) in good yield (eq 16).[4] However, when (**11**) is treated with ***Sodium Hydroxide*** and ***Iodine*** to induce rearrangement, an almost equal mixture of the desired (*E*,*Z*)-diene (**12**) and alkene (**13**) results where either the alkenyl group or the thexyl group migrates with approximately equal facility.[28] This problem can be surmounted by selectively oxidizing the thexyl group in the thexyldialkenylborane (**11**) with ***Trimethylamine N-Oxide*** before the reaction with iodine and sodium methoxide.[28] This procedure appears to be useful only for the synthesis of symmetrical (*E*,*Z*)-dienes (**12**) due to the difficulty in preparing unsymmetrical thexyldialkenylboranes in a stepwise hydroboration sequence from two different 1-alkynes.

However, thexylborane will react with 1-chloro-1-alkynes and 1-bromo-1-alkynes (but not with 1-iodo-1-alkynes) to give thexyl(1-haloalkenyl)boranes (**14**) in high yield (eq 18).[29] This observation enabled the development of a general and highly stereospecific synthesis of conjugated (*E*,*E*)-dienes. The borane (**14**) reacts stereoselectively with a 1-alkyne to give the thexyldialkenylborane (**15**), which is then treated with sodium methoxide to produce (**16**). Compound (**16**) is protonolyzed with refluxing isobutyric acid to give the (*E*,*E*)-diene (**17**) in 53-63% yield and >98% isomeric purity.[29] The intermediate (**16**) is also transformed into the (*E*)-enone (**18**) in 50% yield by oxidation with ***Hydrogen Peroxide*** and NaOAc (eq 19).[29]

(17)

(19)

A stereoselective synthesis of 1,2,3-butatrienes was also developed based on the reaction of thexylborane with 1-halo-1-alkynes. In this synthesis, 2 equiv of a 1-iodo-1-alkyne react with thexylborane to give the thexyldialkenylborane (**19**) that rearranges to the 1,2,3-butatriene (**21**) upon treatment with 2 equiv of sodium methoxide (eq 20).[29b,30] Although the yields of (**21**) are only moderate (47%, R = butyl; 29%, R = cyclohexyl), the products are of high isomeric purity.

(20)

Synthesis of Carboxylic Acids.

A convenient procedure for the direct oxidation of organoboranes from terminal alkenes to carboxylic acids has been reported.[31] The oxidation gives high yields with a number of different organoboranes derived from a variety of borane reagents including thexylborane. Several different oxidizing agents (***Pyridinium Dichromate***, ***Sodium Dichromate*** in aqueous H_2SO_4, and ***Chromium(VI) Oxide*** in 90% aqueous acetic acid) are effective for the reaction. For example, 2-methyl-1-pentene is converted to 2-methylpentanoic acid in 86% yield (eq 21).

(21)

1,3-Thiazolidine-2-thione[1]

[96-53-7] · $C_3H_5NS_2$ · 1,3-Thiazolidine-2-thione · (MW 119.23)

(activating group for carboxylic acids;[1] 3-acyl derivatives can be reduced to aldehydes,[2,3] used in peptide synthesis,[4] or selectively aminolyzed[1,5,6])

Physical Data: mp 106-107 °C.

Solubility: sol acetone, ethanol, water; moderately sol benzene.

Preparative Method: readily synthesized from ***Carbon Disulfide*** and aminoethyl hydrogen sulfate.[7]

Handling, Storage, and Precautions: the solid is quite stable and fairly resistant to hydrolysis. Thiazolidinethione derivatives show a wide variety of biological activity, and should be treated with due caution.

3-Acylthiazolidine-2-thiones.

The reaction between 1,3-thiazolidine-2-thione and either carboxylic acids or acyl halides produces a useful amide intermediate (eq 1) which can subsequently be transformed into a variety of compounds. The amide linkage in 3-acylthiazolidone-2-thiones (ATTs) is more reactive than usual, and is susceptible to attack by a variety of nucleophiles. The yellow colour of the 3-acyl intermediate also allows easy monitoring of the progress of subsequent transformations. Synthesis of ATTs in useful yields (70-80%) can be achieved by the condensation of a carboxylic acid and 1,3-thiazolidine-2-thione in the presence of either ***1,3-Dicyclohexylcarbodiimide*** or ***2-Chloro-1-methylpyridinium Iodide***.[2,3] Higher yields (80-97%) are obtained by using an acyl chloride with ***Triethylamine***, or by employing the thallium salt of 1,3-thiazolidine-2-thione.[3]

(1)

Aldehydes are generated by the action of ***Diisobutylaluminum Hydride*** on ATTs in moderate to good yield (54-93%).[2,3] One advantage of this route is that the intermediate reduced complex (unlike in many similar reductions) is stable towards excess DIBAL, and so over-reduction is not a problem. Similarly, treatment with ***Sodium Borohydride*** results in the formation of alcohols in high yield, even in the presence of another amide or ester functionality. Amides are produced from the reaction between amines and ATTs under mild conditions (25 °C, THF or CH_2Cl_2), often in almost quantitative yield.[1,5,6] The reaction is quite sensitive to the electronic and steric environment of the amine, allowing useful selectivities to be achieved when there is possible competition for amide formation. Hydroxy and thio functionality does not interfere in this reaction. The order of reactivity of various amines is: aliphatic > aromatic; RCH_2NH_2 > R_2CHNH_2 >> R_3CNH_2; RNH_2 &egt; R_2NH. This selectivity is used in the synthesis of maytenine (eq 2).[5] Macrolactams with ring sizes up to 50 atoms have also been constructed using this method.[6] The reaction can also be extended to include peptide synthesis using Cbz- or Boc-protected amino acids.[4] The yellow color of the ATT intermediate means that the extent of the reaction can be followed easily. No racemization of the amino acids is detected in the final peptides and overall yields are in the range 50-75%; the poorest step is the initial formation of the ATT-amino acid intermediate.

Chiral analogs of 1,3-thiazolidine-2-thione have been used to control asymmetric induction in a variety of reactions, including aldol condensations.[8]

Thioanisole

[100-68-5] · C_7H_8S · Thioanisole · (MW 124.22)

(preparation of phenylthiomethyllithium[1-3] and (2-lithiophenylthio)methyllithium;[2] deprotection of aromatic methyl ethers;[9] deprotection of *N*-benzyloxycarbonyl groups;[10] cleavage of epoxides;[11] oxidation of diols to hydroxy ketones[12])

Physical Data: bp 188 °C.

Form Supplied in: colorless liquid; commercially available.

Handling, Storage, and Precautions: stench; handle in a fume hood.

Phenylthiomethyllithium.

Thioanisole (**1**) can be efficiently monometalated by treatment with ***Phenyllithium***,[1] ***n-Butyllithium*** and DABCO,[1] *n*-butyllithium and TMEDA,[2] or ***t-Butyllithium*** and HMPA[3] to afford phenylthiomethyllithium (**2**) which reacts smoothly with primary and secondary alkyl halides, leading to alkylaryl sulfides (eq 1).[1,2]

Treatment of phenylthiomethyllithium (**2**) with ketones produces (phenylthiomethyl)carbinols (eq 2), which can be dehydrated to vinyl sulfides[1] or converted to alkenes, either directly[4] or via the corresponding benzoate esters.[5]

(2)

In the case of cyclic α,β-unsaturated ketones, exclusive 1,2-addition of phenylthiomethyllithium (**2**) occurs to provide tertiary allylic alcohols which can undergo oxidative allylic transposition to afford 3-(phenylthio)methyl α,β-unsaturated ketones (eq 3).[6]

(3)

A one-pot synthesis of substituted cyclopent-2-en-1-ones relies on the addition of phenylthiomethyllithium (**2**) to ethyl 2-chloro-2,3-dialkylbut-3-enoate esters, followed by sulfur-assisted S_N2' displacement of chloride ion and [1,2]-sigmatropic rearrangement of the resultant ylide (eq 4).[7] This procedure has been applied to the synthesis of *cis*-jasmone and dihydrojasmone.[7]

(4)

(2-Lithiophenylthio)methyllithium.

When thioanisole (**1**) is treated with 2.2 equiv of *n*-butyllithium and TMEDA, dimetalation occurs to give (2-lithiophenylthio)methyllithium.[2,8] The latter compound can be dialkylated, diacylated, dicarboxylated, or disilylated (eq 5).[2] Monoacylation of (2-lithiophenylthio)methyllithium is followed by intramolecular cyclization, leading to benzothiophenes after dehydration (eq 6).[8]

Deprotection of Aromatic Methyl Ethers and *N*-Benzyloxycarbonyl Groups.

In combination with ***Trifluoromethanesulfonic Acid***, thioanisole (**1**) effects the demethylation of *O*-methyltyrosine (eq 7).[9] Similarly, ***Trifluoroacetic Acid*** and thioanisole (**1**) remove the *N*-benzyloxycarbonyl (*N*-Cbz) group from the amino terminus of peptides (eq 8).[10]

Epoxide Cleavage and Oxidation of Diols.

The chlorosulfonium salt, formed when thioanisole (**1**) is reacted with ***Chlorine***, causes ring opening of epoxides to give α-chloro sulfoxonium salts which can be converted to α-chloro alcohols or α-chloro ketones (eq 9).[11] When 1,2-diols are treated with the thioanisole (**1**)-chlorine complex, oxidation to α-hydroxy ketones takes place (eq 10).[12]

1,1´-Thiocarbonyldiimidazole[1]

[6160-65-2] · $C_7H_6N_4S$ · 1,1´-Thiocarbonyldiimidazole · (MW 178.24)

(conversion of vicinal diols to alkenes;[1] deoxygenation of alcohols;[13] thiocarbonyl transfer agent[29])

Alternate Name: TCDI.

Physical Data: mp 101-103 °C.

Solubility: sol many organic solvents including THF, CH_2Cl_2, toluene.

Form Supplied in: yellow solid; 90% pure or >97% pure.

Preparative Methods: prepared by the reaction of ***Thiophosgene*** with 2 equiv of ***Imidazole***.

Purification: can be recrystallized from THF to give yellow crystals; can also be sublimed.

Handling, Storage, and Precautions: very hygroscopic; should be reacted and stored in a dry atmosphere.

Alkene Synthesis.

The Corey-Winter alkene synthesis is an effective method for the deoxygenation of vicinal diols.[1,2] The method involves formation of a 1,3-dioxolane-2-thione [cyclic thionocarbonate (or thiocarbonate)] by treatment of a vicinal diol with TCDI. Decomposition of the thionocarbonate, usually with a phosphorus compound, affords the alkene (eq 1).[3] The breakdown of the thionocarbonate occurs in a stereospecific sense; details of investigations into the mechanism have been summarized.[1]

The conditions required for the introduction of the thiocarbonyl group vary greatly, depending on the structure of the diol.[1,4] The thionocarbonate may also be prepared without TCDI. The reaction of vicinal diols with thiophosgene/DMAP/CH_2Cl_2/0 °C,[5] with base/CS_2/MeI/heat,[1] or with 1,1´-thiocarbonyl-2,2´-pyridone/toluene/110 °C[6] also provides thionocarbonates. Along with phosphines and phosphites, other reagents can decompose the thionocarbonates, but not always in a stereospecific manner. The Corey-Hopkins reagent 1,3-dimethyl-2-phenyl-1,3,2-diazaphospholidine,[5] along with ***Raney Nickel***[7] and ***Bis(1,5-cyclooctadiene)nickel(0)***,[8] affords products of stereospecific *cis*-elimination, while the alkyl iodide/***Zinc*** combination[9] and ***Pentacarbonyliron***[10] yield products of nonstereospecific elimination or unknown stereochemistry.

The Corey-Winter synthesis has proved useful for the generation of a large number of structurally interesting alkenes,[1] including some unstable alkenes that must be captured in situ (eq 2).[4]

The method has found its niche in the chemistry of sugars. Their polyhydroxylated nature make them excellent substrates provided the by-standing hydroxyls are protected (eq 3).[11] The 2´- and 3´-oxygens of nucleosides are readily are removed under the Corey-Winter conditions.[12]

(3)

Radical Chemistry.

Treatment of secondary alcohols with 1 equiv of TCDI affords an imidazole-1-thiocarbonyl derivative (imidazolide), which can be reduced to a CH_2 unit under ***Tri-n-butylstannane*** (TBTH) radical chain reaction conditions.[13,14] The deoxygenation of secondary alcohols by way of an imidazolide or other thiocarbonyl derivative is called the Barton-McCombie reaction (eq 4).[6,14] Since imidazolide formation (TCDI, reflux, 65 °C) and the subsequent radical chemistry are done under neutral or near-neutral conditions, the overall reduction is tolerant of the presence of many sorts of functional groups. Furthermore, the low solvation requirements of radical species permits deoxygenation in sterically congested environments (eq 5).[15]

(4)

The mechanism of the radical attack at the thiocarbonyl group and the ensuing breakdown has been outlined elsewhere.[13,14] Some groups have studied the comparative chemistries of the possible thiocarbonyl derivatives, with no particularly obvious trends arising.[13,16,17] There are numerous reports of the deoxygenation of carbohydrates[13,16,18] and related polyhydroxylated species.[14,17,19,20] In one instance of amino glycoside deoxygenation, the C(3´)-OH group can be selectively functionalized with TCDI, while the C(5)-OH group is unaffected and the radical reduction proceeds without protection of the C(5)-OH group (eq 6).[20]

Reduction of tertiary alcohols is not recommended due to the instability of the tertiary imidazolide, although, as an alternative, a thioformaldehyde version has been developed.[21] Imidazolides from primary alcohols do not respond well to the same conditions as the secondary systems, but performing the radical chemistry at 130-150 °C can lead to deoxygenation.[22] As an alternative to the high-temperature radical chemistry, the imidazolide can be converted by methanolysis to a thiocarbonate which can be reduced at room temperature (Et_3B, TBTH, benzene).[23] Tin hydride treatment of thionocarbonates derived from primary/secondary diols affords, after base exposure, the product of selective reduction of the secondary site, leaving the primary hydroxyl (eq 7).[14,24] The approach has also been successfully applied to 1,3-diols.[24,25]

(7)

Since the reduction method proceeds via radical chemistry, the intermediate radicals are prone to bimolecular chemistry and unimolecular reactions such as rearrangements or β-scission, if suitable functionality is proximal.[14] Indeed, the imidazolides have been employed as radical precursors when rearrangement is the desired result.[14]

Thiocarbonyl Transfer.

While virtually all uses of TCDI involve a thiocarbonyl transfer reaction, this section covers those uses of the thiocarbonyl transfer that do not lead to radical chemistry or alkene syntheses. TCDI has been used for the simple placement of a thiocarbonyl group between two nucleophilic atoms of one[26] or two molecules.[27] An alcohol which has been converted to an imidazolide is a reactive functionality for coupling reactions,[28] for sigmatropic rearrangements,[29] and for elimination (eq 8).[30] The TCDI alternative 1,1´-thiocarbonyl-2,2´-pyridone[6] seems to be an excellent thiocarbonyl transfer agent.

Thiocyanogen[1]

$(SCN)_2$

[505-14-6] · $C_2N_2S_2$ · Thiocyanogen · (MW 116.18)

(mono- or dithiocyanation of organic compounds by electrophilic or radical chemistry[1])

Physical Data: mp -3 to -2 °C.

Solubility: sol alcohol, CS_2, benzene, ether, acetic acid, halogenated solvents.

Preparative Methods: prepared for reaction in various solvents by treating dry $Pb(SCN)_2$ with ***Bromine*** at rt, sometimes followed by filtration in an inert atmosphere. It can also be obtained by reacting ***Potassium Thiocyanate*** and Br_2 at -70 °C or by the electrolysis of alkali or ammonium thiocyanates.

Handling, Storage, and Precautions: the neat material is explosive at >20 °C. Stable in acetic acid/anhydride as 0.1 M solution over 8 days. Use of polar protic solvents, including the stabilizing EtOH in $CHCl_3$, may give erratic results and lower yields. Electrophilic reactions should be carried out in the dark or under diffuse light conditions. Use under N_2 or Ar.

Substitution.

The electrophilic reactivity of the pseudohalogen thiocyanogen lies between those of ***Bromine*** and ***Iodine***. Therefore, in reactions with aromatic compounds, anilines and phenols readily undergo *para* thiocyanation, but less activated aryl rings require a Friedel-Crafts catalyst.[1] Polyaromatic species such as anthracene react readily with thiocyanogen, and the reaction may give a dithiocyanato derivative.[1] Electron-rich heteroaromatic species such as pyrroles undergo thiocyanation readily (eq 1),[1,2] but thiocyanation of thiophene requires a catalyst. Numerous other heterocycles react with thiocyanogen.[1] *Ipso* substitution of silylated aromatics is also possible (eq 2).[3] The polarization of thiocyanogen and the electrophilic nature of the mechanism prevent formation of any isothiocyanato compounds, products which may arise from nucleophilic substitution reactions with a metal thiocyanate.[1]

(1)

(2)

Other nucleophiles also attack thiocyanogen to effect substitution. Thiocyanation occurs at the nitrogen of primary and secondary amines,[4] at the sulfur of divalent sulfur compounds[1] and sulfinate anions,[5] and at the carbon of enols,[1] some enamines,[6] and related nucleophiles.[1] Organomercury compounds undergo thiocyanation at their metalated site.[1] Grignard reagents do not tend to react well,[1] but the reaction of organolithiums with $Zn(SCN)_2$ and then ***N-Chlorosuccinimide*** affords the corresponding thiocyanate.[7] Radical chain substitution proceeds well with primary and secondary benzylic hydrogens of phenyl alkanes. The reaction of tertiary benzylic hydrogens affords significant

isothiocyanate.[8]

Electrophilic Addition.

Thiocyanogen may add across the π-bond of alkenes or alkynes by an electrophilic or radical mechanism. The electrophilic mechanism is similar to the electrophilic halogenation of alkenes: an initially formed cyanosulfonium ion (**1**) is attacked by thiocyanate or solvent to complete the addition process. Hence additions to simple alkenes occur with *trans* stereospecificity and no regiospecificity. On the other hand, with aryl alkenes the intermediate is not cyclic (**2**) and the overall addition occurs with regiospecificity but not stereospecificity.[1]

(1)

(2)

The interference of radical species is troublesome in the addition reaction. Other problems may occur through the formation of isothiocyanato thiocyanates which originate from nucleophilic attack on the intermediate cation by the nitrogen of the thiocyanate ion. The best yields of α,β-dithiocyanates are obtained when the reactions are performed (i) in the dark or with a radical inhibitor present (up to 15 mol %),[9] (ii) with a metal or metal salt present,[9,10] (iii) with a filtered thiocyanogen solution,[9,10] and (iv) in polar or dipolar aprotic solvent[9] (eq 3).[10] A radical chain mechanism is also suitable for the synthesis of α,β-dithiocyanates from simple alkenes.[1,11] The addition of thiocyanogen across alkynes should be done under radical conditions; the *trans*-isomer usually predominates.[12] In all addition reactions of thiocyanogen with alkenes or alkynes, prolonged stirring may lead to the thermodynamically more stable isothiocyanate isomers.[1,12]

Thiolacetic Acid

[507-09-5] · C_2H_4OS · Thiolacetic Acid · (MW 76.13)

(addition to α,β-unsaturated carbonyl compounds; radical additions to alkenes and alkynes; chiral dithioacetal formation; selective acylating agent; S_N2 substitutions to make thiolesters)

Physical Data: bp 88-91.5 °C; *d* 1.065 g cm^{-3}.

Solubility: sol hot H_2O, alcohol.

Form Supplied in: light yellow liquid (impurity: acetic acid).

Purification: fractional distillation.

Handling, Storage, and Precautions: use only in fume hood. Wear protective clothing such as safety goggles and chemical-resistant gloves. Harmful if swallowed, inhaled, or absorbed through the skin. Corrosive. Lachrymator. Flammable. Stench. May develop pressure. Refrigerate. Forms explosive mixtures in air. Vapor may travel considerable distance to source of ignition and flash back. Incompatible with oxidizing agents and strong bases.

Conjugate Addition to α,β-Unsaturated Carbonyl Compounds.

The addition of thiolacetic acid to α,β-unsaturated aldehydes, ketones, and carboxylic acids and their derivatives occurs at the β-position, regardless of whether the mechanism is radical or ionic in nature.[1] Stereoselective addition to the less hindered face of the double bond is observed in cases in which there is an inherent facial preference. A representative example is the addition of thiolacetic acid to a $\Delta^{1,2}$-3-oxo steroid (**1**) to give the product in which the acylthio substituent is in the α-configuration (eq 1).[2]

(1)

(1)

A more recent example by Bartmann[3] is the addition of thiolacetic acid to the unsaturated lactone (**2**) to give exclusively the (*R*) configuration at the newly formed stereogenic center (eq 2). The enoate double bond undergoes reaction preferentially to the conjugated diene portion of the molecule, but with longer reaction times and an excess of reagent (25 °C, 2 days, 1.7 equiv MeCOSH, 0.2 equiv Et_3N), the 1,4-addition products (**3**) and (**4**) are also obtained.

(2)

(3) (4)

Asymmetric induction in the addition of thiolacetic acid to cyclic and acyclic enones and to α,β-unsaturated mono- and diesters has been investigated by Gawronski and co-workers.[4] Of the catalysts studied, the cinchona alkaloids are the most effective. The enantiomeric excess in the reaction of thiolacetic acid with cyclohexenone increases from the 50% to the 60% range with variations of catalyst structure and concentration (eq 3).[4a,4c] It was also found that under standard conditions (1 mol % cinchonine), alteration of the thiolacid structure improves enantiomeric excesses, with cyclohexanethiolcarboxylic acid and *t*-butyl thiolcarboxylic acid giving the highest ee's (68% and 64%, respectively).

(3)

catalyst	mol %	% ee
11-thiobenzyl cinchonine	1.0	61 *(S)*
11-thiobenzyl quinidine	1.0	59.5 *(S)*
cinchonine	2.0	58 *(S)*
cinchonine	5.0	61 *(S)*

Acyclic enals and enones which differ in conformation due to steric demands of the ketone alkyl group give products with different absolute configurations at the newly formed stereogenic center.[4d] Thus cinnamaldehyde (**5a**), which exists predominantly in the *s-trans* conformation, gives the (*S*)-product due to *si*-face attack on the alkene, while benzylideneacetophenone (**5b**) in the *s-cis* conformation gives the (*R*)-product of *re*-face attack (eqs 4 and 5).

(4)

(5)

Although absolute configurations can be assigned using circular dichroism, enantiomeric excesses cannot be determined due to product degradation during acetal formation (for a description of this method of determining ee's, see Wynberg.[22]) The stereochemical outcome of these reactions is rationalized by the transition state complex of enone, thiolacetic acid, and cinchonine in which the cinchonine is in the preferred *gauche* conformation and is hydrogen-bonded to the enone carbonyl group. Thiolacetate and protonated quinuclidine base form an ion pair, and the *si*- and *re*-face attacks of *s-trans* and *s-cis* enones, respectively, can be visualized (eq 6).

(6)

α,β-Unsaturated mono- and diesters are also subject to asymmetric addition of thiolacetic acid in the presence of cinchona catalysts, but to a lesser degree.[4b] Derivatives of 2-methylpropenoic acid are used in the monoester cases, and best results are obtained with *S*-alkyl thiolesters, which give only a 27% enantiomeric excess (eq 7). In the diester cases, the degree of asymmetric induction is difficult to ascertain due to *cis*/*trans* isomerization of the substrates. Qualitatively, however, these results indicate that *cis*-butenedioates enhance the ee's of products and that small alkoxy substituents (such as OEt) result in higher diastereoselectivity of the addition to the *cis*/*trans* isomers. It should be noted that asymmetric induction of chirally derivatized α,β-unsaturated mono- and diesters has been attempted by Yoshihara et al.,[5] but gives poor results in comparison to Gawronski's work. Using (-)-menthol as a chiral auxiliary, enantiomeric excesses of 15-18% for monoesters and 12% for diesters are obtained in the best cases.

(7)

Thiolacetic acid has also been utilized as an enone protecting group.[6] Although few addition products in this study are formed in good yields, an interesting example is the protection of the dienone macrolide (**6**) (eq 8), which does give a good yield of the (11*S*)-11-acetylthio derivative (**7**), along with 3% of the (11*R*) derivative and 16% of recovered (**6**). It is interesting to note that in no instance is addition to the terminal position of the dienone observed. Deprotection of (**7**) with ***Tetra-n-butylammonium Fluoride*** to regenerate the dienone presumably occurs smoothly, although no yield is given.

(8)

Radical Additions to Alkenes and Alkynes.

Thiolacetic acid typically adds to unsymmetrical alkenes in an anti-Markovnikov sense,[7] although exceptions have been noted in cases in which the anti-Markovnikov intermediate C-radical is less stable than the Markovnikov C-radical.[8] The addition of thiolacetic acid to cyclic alkenes is stereoselective,[7] with *trans* addition to obtain the *cis* product preferred over *cis* addition to obtain the *trans* product in additions to both cyclohexenes and cyclopentenes (eq 9).[9]

(9)

$n = 1$	71% *cis*	29% *trans*
$n = 2$	83% *cis*	17% *trans*

The addition of thiolacetic acid to acyclic alkenes is generally nonstereoselective, but attempts have been made to induce asymmetry through the use of chiral additives.[10] In the presence of (-)-menthol or deoxycholic acid (DCA) and ***Azobisisobutyronitrile*** (AIBN), 2-octene gives addition products (**8**) and (**9**) (eq 10) with ee's of 28% with (-)-menthol and 7% with DCA for compound (**8**). Although the absolute configuration of (**8**) was determined to be (*S*), no such determination was made for (**9**), and no ee's for (**9**) were reported.

(10)

(8) **(9)**

chiral additive	**(8)**	**(9)**
(-)-menthol	45% (28% ee)	40%
DCA	40% (7% ee)	38%

Radical addition of thiolacetic acid to alkenes is the key step in a preparation of alkanesulfonic acids developed by Swern and co-workers (eq 11).[11] This method is nonideal for complex or sensitive substrates, however, and a much milder method has been reported by Musicki (eq 12)[12] which employs α-lithio sulfonates. Subsequent hydrolysis of the sulfonate ester (**10**) gives the sulfonate (**11**), which can then be coupled with other ribose units.

(11)

(10)

(12)

(11)

Thiolacetic acid adds readily to alkynes to give mono- and bis-adducts. If the alkyne is monosubstituted, anti-Markovnikov regioselectivity is observed in the monoadduct. Varying yields of both the mono- and bis-products are obtained, depending on the structure of the alkynyl substrate and the amount of thiolacetic acid added, and yields are often improved by the addition of initiators, such as peroxide.[13,1b] Monoadducts can be further transformed into aldehyde equivalents such as semicarbazones (**12**) (eq 13), which are synthetically useful intermediates.

(13)

(12) 57%

A more recent method that is much milder and potentially more useful is the conversion of ethynyl carbinols into α,β-unsaturated aldehydes via a two-step Meyer-Schuster rearrangement (eq 14).[14] This method employs ***Thiophenol*** rather than thiolacetic acid. The (*E*/*Z*) ratio of the α,β-unsaturated aldehyde products range from 94/6 to 66/34, depending on the reaction conditions.

Use in the Formation of Chiral Dithioacetals.

Mixed acyl dithioacetals (**13**) have been prepared in good yield by the reaction of an aldehyde, a thiol, and thiolacetic acid in the presence of an acid catalyst (eq 15).[15a] These compounds can then be hydrolyzed and alkylated to give chiral dithioacetals (**14**), which are key functional groups in a series of potent and specific leukotriene D_4 antagonists developed by Gauthier et al.[15] Highest yields of the acyldithioacetals (**13**) are obtained with ***Zinc Iodide*** as the catalyst in refluxing dichloromethane for 2 h (86-91%). Deacylation with ***Potassium Carbonate***, ***Sodium Methoxide***, or ***Methyllithium***, followed by alkylation at low temperature (-10 to -80 °C), gives chiral dithioacetals (**14**) in good yield (86-97%). As an extension of this method, optically active dithioacetals can be prepared by use of a chiral thiolacid which renders the intermediate acyl dithioacetals diastereomeric and, thus, separable. Each diastereomer can then be further reacted to yield an optically active dithioacetal (**14**) with no loss of configurational purity.[15b,c]

As an Acylating Agent.

Thiolacetic acid is not generally used as an acylating agent. It has been employed to acylate aromatic amines[16] and thiols,[17a,b] but in these cases there is no distinct advantage of thiolacetic acid over more commonly used acylating agents such as acid chlorides and anhydrides. Thiolacetic acid has the capability, however, of selectively acylating certain functional groups in the presence of others. For example, van Montagu et al.[18] selectively acylated the primary amino group of a cytidine moiety in the presence of a primary alcohol (eq 16). Acylation of alcohols will occur but typically requires forcing conditions. This is a common side reaction when thiolacetic acid is employed in 1,4-addition to enones containing alcohol groups.[2,5] Chemoselective reductive acylation of azides has also been observed with thiolacetic acid (eq 17).[19]

(17)

S_N2 Substitutions of Halides and Activated Alcohols.

Just as in the case of carboxylic acids, thiolacetic acid can be successfully used to effect Mitsunobu-type substitutions of secondary alcohols to give thioesters with inversion of configuration at the carbinol center (eq 18).[20] S_N2 substitution by thiolacetic acid of α-glycosides, activated at the anomeric position, has been observed by several groups (eqs 19 and 20).[21] In all cases, the β-thioglycoside product predominates.

Thionocarbonates[1]

(method used for the deoxygenation of alcohols;[6] conversion of vicinal diols to alkenes;[3] undergo cyclizations,[3g] radical allylation,[6e] rearrangements[12])

Solubility: sol methanol, ethanol, most organic solvents.

Preparative Methods: see text.

Purification: chromatography or distillation where appropriate.

Definition.

Thionocarbonates are a class of chemical compounds having the general structure shown. There are two further classifications of this general structure: *cyclic*, where the two carbons are connected directly or via a carbon or heteroatom chain; and *acyclic*, where the two carbons are not connected. These compounds exhibit a wide range of activity, allowing the chemist to deoxygenate alcohols or to convert vicinal diols to alkenes (Corey-Winter reaction). In addition, thionocarbonates undergo cyclizations, rearrangements, and radical allylations.

Synthesis.

There are a wide variety of methods for preparing thionocarbonates. They are usually catered to fit the specific substrate and can vary widely with regard to pH, solvent, and temperature constraints. Cyclic thionocarbonates can be prepared by one of three general methods:

- 1)Vicinal diols can be reacted with ***1,1´-Thiocarbonyldiimidazole*** (TCDI) in a suitable solvent such as methylene chloride, acetone, or xylene. Temperatures vary from ambient to reflux. In one case, pyridine was added to facilitate formation of the thionocarbonate. Yields vary widely but in general are good.[2] This method is especially useful with acid sensitive substrates. Unfortunately, this method is unsatisfactory for large scale preparations due to the high cost of TCDI.[3]
- 2)***Thiophosgene*** reacts with diols in the presence of a base such as ***4-Dimethylaminopyridine*** (DMAP) to give thionocarbonates. The solvent is usually dichloromethane but can vary, depending on the substrate. Reaction temperatures vary also (0 °C to room temperature), as do yields (ca. 80%). Care must be taken in handling thiophosgene as it is highly toxic.[4]
- 3)Cyclic thionocarbonates have also been prepared by reaction of the diol with a base (***n-Butyllithium***, ***Sodium Hydride***, etc.) followed by quenching with ***Carbon Disulfide*** then ***Iodomethane***. Reaction temperatures and solvents vary according to the substrate. Reported yields are generally poor (<40%).[5]

Acyclic thionocarbonates are prepared by reaction of an alcohol with an aryl chlorothioformate (aryl = Ph, 4-FC_6H_4, C_6F_5, 2,4,6-$Cl_3C_6H_2$). Solvents that are used include acetonitrile, methylene chloride, THF, pyridine, and acetone. A base is also added (pyridine, DMAP, *n*-BuLi). Temperatures vary widely, as do yields (40-100%).[6]

Alkene Synthesis.

The conversion of vicinal diols to alkenes via the thionocarbonates is commonly known as the Corey-Winter reaction.[3c] As originally reported, cyclic thionocarbonates are treated with a trialkyl phosphite to give the alkene via *cis* elimination (eq 1). It was originally postulated that the reaction proceeds through a concerted cycloelimination mechanism,[3a] but evidence has also been presented supporting a carbene intermediate which decomposes to give CO_2 and the alkene.[7] Yields are generally high (>90% in some cases). A wide variety of substrates have been synthesized using this protocol, but it appears especially useful in the synthesis of highly strained alkenes.

(1)

Other procedures have been identified to effect the elimination of the thionocarbonate to give an alkene. ***Pentacarbonyliron***,[8] ***Bis(1,5-cyclooctadiene)nickel(0)***,[9] and diazaphosphonolides (**1**)[4c] have been used in lieu of trialkyl phosphites. This procedure has been utilized by Paquette in the synthesis of cyclobutenes[3b,d] and $(CH)_{12}$ hydrocarbons,[4d] Ireland in the lasolocid A synthesis,[3e] and Barton in a synthesis of conduritol-B peracetate.[4b]

(1)

Vedejs and Wu reported manipulation problems with (**1**). This led to the development of a less direct conversion involving treatment with an alkyl halide (R = Me, *i*-Pr) followed by reductive elimination when treated with ***Magnesium Amalgam*** (eq 2).[2]

(2)

Alkenes have been introduced into monohydroxy alcohols using acyclic thionocarbonates. Eq 3 shows how a double bond is introduced by refluxing the phenylthioformate in xylene. This provides a key intermediate in the synthesis of pyrrolo[1,4]benzodiazepine antibiotics.[6i] Similar transformations have been accomplished with different conditions such as thermolysis[6h] or radical elimination[6g] of an acyclic thionocarbonate.

(3)

Deoxygenation.

Thionocarbonates provide a useful avenue for removal of hydroxyl groups from certain substrates. Typically, the thionocarbonate is treated with R_3SnH in the presence of a radical initiator (***Azobisisobutyronitrile*** or ***Dibenzoyl Peroxide***). Other hydrogen donors have been utilized including Ph_2SiH_2 and ***Tris(trimethylsilyl)silane***.[10] The reactions are run in refluxing toluene or xylene. Sugars are easily deoxygenated via this protocol[6a,b,d,j,k] and Martin et al. used this method in the preparation of difluoroalkylphosphonates.[11] One interesting observation was made during the deoxygenation of vicinal bromo thionocarbonates. In this case, treatment with Bu_3SnH/AIBN/toluene (reflux) gives the alkene (eq 4).[6a]

(4)

Other Reactions.

Medium-ring cyclic thionocarbonates undergo [3,3]-sigmatropic rearrangements to give cyclic thiolcarbonates on treatment with base (eq 5) (70-80%).[12] A similar rearrangement allows the conversion of an alcohol to a thiol (eq 6).[3f]

(5)

(6)

Radical cyclizations have been observed when thionocarbonates have been treated with ***Tri-n-butylstannane*** (eq 7 AIBN/toluene; 60%).[3g] Allyl groups have been introduced via the Keck procedure (***Allyltributylstannane***/AIBN/toluene). This is particularly useful in the synthesis of nucleosides (eq 8) (50-74%).[6e]

2-Thiono-1,3-dioxol-4-ene

[37635-87-3] · $C_3H_2O_2S$ · 2-Thiono-1,3-dioxol-4-ene · (MW 102.12)

(dienophile in Diels-Alder reactions;[1] acetylene equivalent in cycloaddition reactions;[2] source of ketene;[3] forms dication dichalcogenides with strong Lewis acids[4])

Alternate Name: vinylene thionocarbonate.

Physical Data: mp 48 °C; bp 60-70 °C/0.2 mmHg.

Solubility: sol acetonitrile, benzene, carbon tetrachloride, dichloromethane, toluene; insol hexane.

Form Supplied in: not commercially available.

Preparative Method: prepared by reaction of ***Phosphorus(V) Sulfide*** with ***Vinylene Carbonate***.[1]

Purification: recrystallization from benzene-hexane gives white crystals; sublimation at 120 °C generates long white needles.

Handling, Storage, and Precautions: material is apparently stable.

Cyclization with Dienes.

The reaction of 2-thiono-1,3-dioxol-4-ene with anthracene at elevated temperatures leads to the production of the bicyclic adduct (**1**) (eq 1).[1,2] No other dienes have been reported to cyclize with this reagent. Diels-Alder adducts could be treated with phosphines to effect a Corey-Winter alkenation, which would render the reagent an acetylene equivalent.

(1)

(1)

Synthesis of Ketene.

Photolysis (270 nm) of 2-thiono-1,3-dioxol-4-ene results in the quantitative formation of ketene via Wolff rearrangement of the corresponding α-ketocarbenes (eq 2).[3] Substituted dioxolenes can also be used in this fashion to generate substituted ketenes (eq 3). This serves as a convenient alternative to the use of α-diazo ketones in the generation of ketenes.

(2)

(3)

Preparation of Dication Dichalcogenides.

Treatment of 2-thiono-1,3-dioxol-4-ene with ***Trifluoromethanesulfonic Anhydride*** leads to the formation of the corresponding dimeric dication (eq 4).[4] Hydrolysis of this stable dication with aqueous base generates equimolar amounts of both vinylene carbonate and vinylene thionocarbonate.[4]

Thionyl Bromide[1]

$SOBr_2$

[507-16-4] · Br_2OS · Thionyl Bromide · (MW 207.87)

(brominating agent for alcohols, carboxylic acids, alkenes, and ketones)

Physical Data: mp -52 °C; bp 68 °C/40 mmHg; *d* 2.688 g cm^{-3}.

Solubility: sol benzene, chloroform, carbon tetrachloride.

Form Supplied in: commercially available.

Handling, Storage, and Precautions: less stable than thionyl chloride and will slowly decompose, even in a stoppered container. Stable if kept dry, but reacts violently with water. Extremely destructive to tissue of mucous membranes, upper respiratory tract, eyes, and skin. Reacts vigorously with acetone to form a lachrymator. Should be handled in a fume hood.

Thionyl bromide is considerably more reactive than ***Thionyl Chloride*** and is more difficult to use.[2] Unlike thionyl chloride, whose reactions are often carried out in pyridine, thionyl bromide undergoes a reaction with this solvent to form a nonreactive salt (eq 1).[3]

(1)

Preparation of Acid Bromides from Carboxylic Acids.

Although not often used, thionyl bromide can convert a simple organic acid to the acid bromide.[4] When the acid is an α,β-unsaturated acid, addition of bromine across the double bond occurs, generally in quantitative yield (eqs 2 and 3).

(2)

(3)

For simple aliphatic acids, formation of the acid bromide is a high yield reaction (eq 4). Simple aromatic carboxylic acids also form the acid bromides in good yield.

(4)

R = Me, 85%; Et, 90%; Pr, 92%; Bu, 90%

Thionyl bromide can function as a dehydrating agent for suitably positioned dicarboxylic acids (eq 5).

(5)

Preparation of Bromides from Alcohols.

In the ribonucleotide series, specific OH replacement has been noted (eq 6).[5] Other examples of the transformation of OH to Br are illustrated in eqs 7 and 8.[6,7] Conversion of an alcohol to a dibromo derivative has been reported (eq 9).[8]

(6)

(7)

62 g 82 g

(8)

(9)

Bromination α to a Carbonyl Group.

Aromatic ketones with active methylene protons can be brominated with thionyl bromide. There is an example of dibromination of a methyl ketone (eq 10).[8] Propiophenone gives a mixture of α-bromopropiophenone and α-bromo-α-methylpropiophenone. The reaction with unsaturated ketones gives addition to the double bond (eq 11).[9]

(10)

(11)

Preparation of *N*-(1-Bromoalkyl)heteroarylium Salts.

A general reaction is given in eq 12.[10]

Thionyl Chloride[1]

$SOCl_2$

[7719-09-7] · Cl_2OS · Thionyl Chloride · (MW 118.97)

(chlorination of alcohols,[2] carboxylic acids,[3] and sulfonic acids;[4] dehydration of amides;[5] formation of imidoyl chlorides,[6] sulfur-containing heterocycles,[7] and the Vilsmeier reagent)

Physical Data: [8] bp 76 °C; *d* 1.631 g cm^{-3}.

Solubility: sol ethers, hydrocarbons, halogenated hydrocarbons; reacts with water, protic solvents, DMF, DMSO.

Form Supplied in: colorless to yellow liquid.

Purification: impurities cause formation of yellow or red colors. Iron contamination can cause a black color. Fractional distillation, either directly[9] or from triphenyl phosphite[10] or quinoline and linseed oil,[11] has been recommended.

Handling, Storage, and Precautions: very corrosive and reactive; the vapor and liquid are irritating to the eyes, mucous membranes, and skin. Protective gloves should be worn when handling to avoid skin contact. Thionyl chloride should be stored in glass containers at ambient temperature and protected from moisture. It reacts with water to liberate the toxic gases HCl and SO_2. Since most reactions using $SOCl_2$ evolve these gases, they should be performed only in well-ventilated hoods. Above 140 °C, $SOCl_2$ decomposes to Cl_2, SO_2, and S_2Cl_2. Iron and/or zinc contamination may cause catastrophic decomposition.[12]

Chlorides from Alcohols.

Thionyl chloride reacts with primary, secondary, and tertiary alcohols to form chlorosulfite esters (eq 1) which can be isolated.[13] The fate of these esters depends on the reaction conditions, especially the stoichiometry, solvent, and base. If 2 equiv of alcohol and pyridine are used relative to thionyl chloride, dialkyl sulfites may be isolated (eq 2).[14]

$$ROH + SOCl_2 \longrightarrow ROSOCl + HCl \qquad (1)$$

$$2\,BuOH + SOCl_2 \xrightarrow[77\text{-}84\%]{py} BuOSO_2Bu \qquad (2)$$

When thionyl chloride is in excess, or when alkyl chlorosulfites are treated with thionyl chloride,[15] alkyl chlorides are produced and the byproducts are HCl and SO_2. The mechanism of this reaction may be S_N1, S_N2, S_Ni, or S_N2' (with allylic or propargylic alcohols). In the absence of base the S_Ni mechanism operates; retention of configuration is observed in the alkyl chloride (eq 3).[16] Considerable ionic character may be involved in this process and small amounts of elimination or rearrangement are common as side reactions.[17]

(3)

Thus, simple heating of the alcohol with thionyl chloride alone is often the preferred method for retaining the configuration of the alcohol

in the chloride. Alternatively, use of amine bases, most commonly ***Pyridine***,[18] results in a shift in the mechanism to S_N2 (eq 4) and consequently overall inversion. Excess pyridine may cause dehydrochlorination or alkylation of the base. If inversion of the substrate is desired or the stereochemical outcome need not be controlled, the use of pyridine or other amine base is recommended since the resulting high chloride concentrations minimize rearrangements and eliminations.[19,17a] Alternatively, catalysis of the chlorination by ***Hexamethylphosphoric Triamide*** results in inversion.[20] With allylic substrates, rearranged products generally predominate, especially in nonpolar solvents.[21] Use of ***Tri-n-butylamine*** as the base can result in unrearranged allylic products.[22]

(4)

Representative procedures are available for the chlorination of tetrahydrofurfuryl alcohol,[23] benzoin,[24] and ethyl mandelate.[25] The use of thionyl chloride for this transformation usually gives less rearrangement and elimination than conc HCl, PCl_3, or PCl_5. For compounds which are acid-sensitive, ***Triphenylphosphine-Carbon Tetrachloride*** may be used.

Carboxylic Acid Chlorides from Acids.

Thionyl chloride has been the most widely used reagent for the preparation of acid chlorides. Carboxylic anhydrides also react with $SOCl_2$, giving 2 equiv of the acid chloride.[26] The procedure normally involves heating the carboxylic acid with a slight to large excess of $SOCl_2$ in an inert solvent or with $SOCl_2$ itself as the solvent. Operation at the boiling point of the solvent speeds removal of the byproducts, HCl and SO_2. The ease of removal of the byproducts is the chief advantage of $SOCl_2$ over PCl_5 and PCl_3. This simple procedure gives good yields of the acid chlorides of butyric,[27] cinnamic,[28] and adipic acid.[29] The reactions are first order in each reactant and electron-withdrawing groups on the acid decrease the rate.[30] Several agents have been developed for the catalysis of this reaction. Pyridine was historically the most common; its presumed mode of action is to ensure the presence of soluble chloride (as ***Pyridinium Chloride***) which reacts with the intermediate as shown in eq 5. Catalytic pyridine ensures that the chlorination of certain diacids such as succinic acid proceeds completely to the diacid chloride rather than stopping at the anhydride.[31] The preparation of aromatic acid chlorides also commonly uses pyridine as a catalyst (eq 6).[32] Trichloroacetic acid, which is unreactive toward thionyl chloride alone, is chlorinated by the use of pyridine catalyst.[33]

(5)

(6)

N,N-Dimethylformamide is a particularly effective catalyst for the formation of acid chlorides with $SOCl_2$ and is now commonly the catalyst of choice.[34] The chloromethyleneiminium chloride intermediate is the active chlorinating species (see ***Dimethylchloromethyleneammonium Chloride***).

Esters of amino acids may be produced directly from the amino acid, alcohol, and thionyl chloride. One procedure involves the sequential addition of thionyl chloride and then the acid to chilled methanol.[35] Alternatively, benzyl esters have been prepared by the slow addition of $SOCl_2$ to a suspension of the amino acid in benzyl alcohol at 5 °C.[36]

For the formation of acid chlorides, the competing reactions of concern are α-oxidation and acid-catalyzed degradation. The use of solid

Sodium Carbonate in the reaction mixture can minimize the latter for some compounds.[37] As shown in eq 7, even simple carboxylic acids with enolizable hydrogens α to the carboxylic functionality are subject to oxidation under standard chlorinating conditions.[38] Since the unoxidized acid chloride is the precursor to the sulfenyl chloride, careful attention to stoichiometry and reaction time can effectively minimize this problem.

Sulfonyl and Sulfinyl Chlorides from Sulfonic and Sulfinic Acids.

Alkyl or arylsulfonyl chlorides are prepared by heating the acid with thionyl chloride; DMF catalyzes this reaction. (+)-Camphorsulfonyl chloride is produced in 99% yield without a catalyst.[39] Use of the salts of sulfinic acids minimizes their oxidation; *p*-toluenesulfinyl chloride is produced in about 70% yield from sodium *p*-toluenesulfinate dihydrate with excess thionyl chloride.[40] ***Phosphorus(V) Chloride*** is more commonly used for this transformation.

Nitriles and Isocyanides via Amide Dehydration.

Thionyl chloride dehydrates primary amides to form nitriles (eq 8); for example, 2-ethylhexanonitrile is produced in about 90% yield by heating with $SOCl_2$ in benzene.[41] Substituted benzonitriles are readily produced from benzamides.[42] These reactions may also be catalyzed by DMF.[43] *N*-Alkylformamides may be dehydrated to isocyanides.[44]

Reactions with Secondary Amides.

Treatment of *N*-alkyl or *N*-aryl secondary amides with thionyl chloride in an inert solvent such as methylene chloride results in the formation of imidoyl chlorides (eq 9).[45] Upon heating, the imidoyl chlorides from *N*-alkylamides undergo scission to generate nitriles and alkyl chlorides via the von Braun degradation (eq 10).[46]

Reactions with Aldehydes and Ketones.

Aromatic or α,β-unsaturated aldehydes or their bisulfite addition compounds are converted to *gem*-dichlorides by treatment with $SOCl_2$, either neat or in an inert solvent such as nitromethane (eq 11).[47] This process is readily catalyzed by HMPA.[48] Thionyl chloride may be preferred over the more commonly used PCl_5 if removal of byproducts is problematic with the latter reagent.

Carbonyl compounds or nitriles[49] with α-hydrogens may be oxidized at this position by thionyl chloride. This reaction appears more often as a troublesome side reaction than a useful synthetic procedure. Nitriles with one α-hydrogen produce α-cyanosulfinyl chlorides (eq 12) while those with two α-hydrogens give moderate yields of α-chloro-α-cyanosulfinyl chlorides.[50]

Oxidation of Activated C-H Bonds.

As shown in eq 13, extensive oxidation adjacent to carbonyl groups is possible with $SOCl_2$ under relatively mild conditions.[51] The process often stops after formation of the α-chlorosulfenyl chloride. Remarkably, these may be easily hydrolyzed back to the carbonyl compounds from which they were derived.[52] Alternatively, they may be treated with a secondary amine such as morpholine followed by hydrolysis to yield the α-dicarbonyl compound. Similar oxidation of acid derivatives during acid chloride formation is possible (see above).

Methyl groups attached to benzenoid rings may be oxidized by $SOCl_2$ without added catalysts. The range of reactivity is large and not well understood; the products may be monochlorinated or further oxidation to the trichloromethyl aromatic system is possible.[53] 2-Methylpyrroles are similarly oxidized.[54] In systems with vicinal methyl and carboxylic acid groups, both oxidation of the methyl group and cyclization to a γ-thiolactone can occur.[55] In conjunction with radical initiators, $SOCl_2$ can chlorinate alkanes.[56] Aryl methyl ethers can be oxidized on the aromatic ring to give arylsulfenyl chlorides which may undergo further reactions.[57] This latter process, which presumably occurs via electrophilic aromatic substitution, is another potential serious side reaction for active substrates.

Rearrangement Reactions.

Thionyl chloride can act as the dehydrating agent in the Beckman[58] and Lossen rearrangements[59] and promotes the Pummerer rearrangement.[60]

Synthesis of Heterocyclic Compounds.

Thionyl chloride and pyridine at elevated temperatures convert diarylalkenes, styrenes, and cinnamic acids to benzo[*b*]thiophenes[61] and adipic acid to 2,5-bis(chlorocarbonyl)thiophene.[62] Additional heterocycles which have been prepared include thiazolo[3,2-*a*]indol-3(2*H*)-ones,[63] oxazolo[5,4-*d*]pyrimidines,[64] and 1,2,3-thiadiazoles.[65] Treatment of 1,2-diamino aromatic compounds with thionyl chloride gives good yields of fused 1,2,5-thiadiazoles.[66]

Other Applications.

Thionyl chloride has been used to convert epoxides to vicinal dichlorides[67] and for the preparation of dialkyl sulfides from Grignard reagents.[68] Phenols react with $SOCl_2$ to produce aryl chlorosulfites and diaryl sulfites[69] or nuclear substitution products. As shown in eq 14, ***Aluminum Chloride*** catalysis yields symmetric sulfoxides, while in the absence of Lewis acids, aromatic thiosulfonates are the principal products.[70] Primary amines, especially aromatic ones, react with $SOCl_2$ to produce *N*-sulfinylamines, which are potent enophiles and useful precursors to some heterocyclic compounds.[71]

Related Reagents.

1,1´-Thionylimidazole[1]

[3005-50-3] · $C_6H_6N_4OS$ · 1,1´-Thionylimidazole · (MW 182.23)

(forms *N*-acylimidazolides[1] used to synthesize amides, peptides,[2] esters,[3] and ketones;[4] synthesis of symmetrical sulfoxides,[5] inorganic esters,[6] and *N*-alkylimidazoles[7])

Alternate Names: N,N´-thionylimidazole; *N,N´*-thionyldiimidazole; TDI.

Physical Data: mp 78-79 °C.

Solubility: sol THF, CH_2Cl_2, toluene.

Form Supplied in: not commercially available; usually used in THF solution.

Analysis of Reagent Purity: usual preparations are used immediately without analysis.

Preparative Method: the reagent is prepared by reacting ***Thionyl Chloride*** with 4 equiv of ***Imidazole*** in anhydrous THF at 0 °C. The precipitated imidazole hydrochloride is filtered and the solution is pure enough to use.[8]

Purification: filter to remove imidazole hydrochloride. Analytically pure samples have been prepared by reaction of thionyl chloride and ***N-(Trimethylsilyl)imidazole***.[9]

Handling, Storage, and Precautions: extremely hygroscopic; reacts exothermically with water and alcohols. Store as a solution in THF or CH_2Cl_2 under dry N_2.[8b] Use in a fume hood.

N-Acylimidazolides.

N,N´-Thionylimidazole reacts with carboxylic acids to form *N*-acylimidazolides (eq 1) that readily acylate amines, amino acids, or alcohols.[1] The products are readily purified since the byproducts, imidazole and SO_2, are easily removed. ***N,N´-Carbonyldiimidazole*** (CDI) is another useful reagent for formation of *N*-acylimidazolides. TDI is used less frequently for formation of *N*-acylimidazolides because of its high reactivity; also, CDI is commercially available and easier to handle. Most reported transformations from *N*-acylimidazolides involve CDI; however, TDI should give similar results.

Peptide Coupling Reagent.

N-Acylimidazolides are useful acylating intermediates in peptide synthesis (eq 2).[2] These are direct couplings where the amine and acid components are premixed in solution. There are only a few examples of peptides being synthesized with this reagent. Therefore it is not known what limitations exist, such as extent of racemization, ease of handling, etc. Comparisons with many of the well-known peptide coupling reagents (e.g. ***1,3-Dicyclohexylcarbodiimide***) have not been published. CDI is used more frequently if the imidazolide intermediate is desired because of its ease of handling.

Ester Formation.

N-acylimidazolides react with alcohols very fast in the presence of catalytic amounts of the alkoxide (eq 3).[3] With this method the methyl ester of vitamin A has been obtained in 91% yield.[3]

Ketones.

N-Acylimidazolides react with Grignard reagents to give ketones in good yields.[4] A comparison of *N*-acylimidazolides and mixed acid anhydrides in Grignard reactions indicates that the imidazolides result in higher yields (eq 4).[10] There are many procedures for reacting Grignard reagents with activated carboxylic acids to give ketones. Other reagents used with varying degrees of success are acid chlorides (e.g. ***Ethyl Chloroformate***), nitriles, and 2-pyridylthiol esters (e.g. ***2-Thiopyridyl Chloroformate***).[11]

(4)

R	Anhydride	Imidazolide
Et	57	68
Pr	57	74
C_6H_{13}	62	74
Ph	0	79

Symmetrical Sulfoxides.

Thionylimidazole reacts directly with Grignard reagents resulting in symmetrical sulfoxides in reasonable yields (eq 5).[5] This method offers an easy workup and purification since the main byproduct is imidazole.

(5)

Inorganic Ester Formation.

Phenols and alcohols react exothermically with TDI to give sulfonic acid diesters in high yield (eq 6).[6]

(6)

N-Alkylimidazoles.

Thionylimidazole has found great utility in the synthesis of *N*-alkylimidazoles.[7] Tertiary alcohols react with TDI to form monosulfonic ester imidazolides that rearrange to transfer the imidazole to the tertiary carbon (eq 7).[12] The products are also obtained by treatment of the trityl chloride with imidazole; however, comparison of the two procedures is not possible as yields were not reported.[12]

This imidazole transfer reaction occurs readily with *o*-hydroxybenzyl alcohols, giving the imidazole from a primary or secondary alcohol (eq 8).[7] It is thought that the *o*-hydroxy group contributes to the facile transfer of the imidazole. Similarly, *o*-amines promote the transfer of the imidazole. Carbonyl diimidazole also works in this imidazole transfer reaction, but it usually gives lower yields of the desired product.[7]

This imidazole transfer reaction works with ketones as well; however, in this case two products, the mono- and diimidazoles, are obtained (eq 9).[13] Increasing the temperature does not change the product ratio or yield. Some examples contain hydrogen-bonding groups on the ring, but this does not modify the product ratio or yield either. CDI gives similar results in most cases. This imidazole transfer reaction does not work with aldehydes under these conditions.[13]

Thiophenol

PhSH

[109-98-5] · C_6H_6S · Thiophenol · (MW 110.19)

(precursor of the thiophenoxy radical, which adds to alkenes and alkynes, initiating cyclizations; *cis*/*trans* alkene isomerization; synthesis of vinyl sulfides, alkyllithiums, pyridines; transacetalization; Michael addition)

Physical Data: mp -15 °C; bp 169 °C, 46.4 °C/4 mmHg; n^{20} 1.5893; d^{20} 1.0766 g cm^{-3}.

Solubility: sol alcohol, ether, benzene, methylene chloride.

Form Supplied in: liquid; commercially available.

Handling, Storage, and Precautions: handle under an inert atmosphere as oxygen causes oxidation to the disulfide. This may accelerated in the presence of base. Stench reminiscent of garlic. Very toxic. Handle only in an efficient fume hood.

Radical Reactions.

Thiophenol is best known as a hydrogen atom source or radical initiator in radical reactions. Vinylcyclopropanes can undergo a radical-induced rearrangement (eq 1).[1] In this example, addition of the thiophenoxy radical to the alkenic terminus is followed by opening of the cyclopropane ring; this radical may then add to another alkene to give a radical primed to undergo a 5-*exo-trig* closure onto the remaining alkene. The dienylic cyclopropane can undergo a similar reaction but instead the radical can also undergo cyclization without an added alkene (eq 2).[2] As in most radical cyclizations, formation of five-membered carbocyclic rings is generally favored.

(1)

(2)

Alkynes separated from an alkene by a three-carbon tether are similarly prone to cyclize on treatment with thiophenol.[3] This reaction is initiated by addition of the thiyl radical to the alkyne to form a vinyl radical which then closes (eq 3). The cyclization in this case must compete with hydrogen atom abstraction, resulting in low yields. The alkyne addition to form a vinyl sulfide without the cyclization is also known, wherein thiophenol adds across the triple bond of an alkyne in the presence of ***Triethylborane*** as radical initiator to form a vinyl sulfide (eq 4) (see below for other routes to vinyl sulfides and for another application of this reaction).[4]

(3)

(4)

Another very common usage of thiophenol is to change the *cis*/*trans* isomer ratio of alkenes to favor the *trans* configuration (eq 5).[5]

(5)

Vinyl Sulfides.

A useful application of thiophenol is as an in situ source of ***Benzenesulfenyl Chloride*** (generated from thiophenol and ***N-Chlorosuccinimide*** or ***Sulfuryl Chloride***).[6] This can add electrophilically across alkenes to generate vicinal chloro sulfides (eq 6). Subsequent elimination of HCl using ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** or ***Sodium Carbonate*** provides vinyl sulfides which are useful as precursors to sulfones (by oxidation) and to vinyllithiums (see below), or as synthetic equivalents to enols.[7] An alternative route towards cyclic vinyl sulfides involves ***Montmorillonite K10*** catalysis (eq 7) and cyclic ketones.

Alkylation; Alkyllithiums.

Thiophenol is also the precursor of choice to make alkyl phenyl sulfides by nucleophilic substitution of an alkyl halide. These have recently become popular precursors to complex alkyllithiums via reductive lithiation of phenyl sulfides (eq 8). These reactions are generally done in THF, utilizing ***Lithium Naphthalenide***,[8] ***Lithium 1-(Dimethylamino)naphthalenide***,[9] or ***Lithium 4,4´-Di-t-butylbiphenylide***.[10]

Conjugate Additions.

The nucleophilic properties of thiophenoxide are also apparent in Michael reactions. Thiophenoxide is easily formed in the presence of ***Triethylamine*** (eq 9) and adds to α,β-unsaturated enones and enoates[11] with equal ease and in high yield. It has been used as a key reagent in the synthesis of butenolides from γ-hydroxy α,β-unsaturated enoates[12] (eq 10).

Michael addition to activated acetylene derivatives, such as propiolate esters, may also be carried out with subsequent trapping by electrophiles such as benzaldehyde (eq 11).[13]

(11)

Pyridine Synthesis.

Thiophenol also shows some utility in the synthesis of a wide variety of substituted pyridines from acyclic precursors (eq 12) in overall yields of 45-60%. In this example, treatment of thiophenol with ***Methyl Vinyl Ketone*** to obtain the Michael adduct, followed by condensation with a ketone enolate (made with ***Lithium Diisopropylamide***) and dehydration with ***Thionyl Chloride***, provides the 4-(phenylthio) enone. Oxidation to the sulfoxide, Pummerer rearrangement, and treatment with ***Ammonia*** provide the pyridine.[14]

(12)

Thioacetals and Glycosides.

It is also possible to take advantage of the nucleophilicity of thiophenol to carry out transacetalizations. These are done in the presence of a Lewis acid. In examples such as MOM ethers this provides a net deprotection, as shown recently in the final step of Corey's synthesis of gingkolide A (eq 13).[15] The resulting coproduct is a useful reagent in its own right, shown by Livinghouse to be a formyl anion equivalent.[16] Thiophenol's main use in this area, however, is in the synthesis of thioglycosides. Acid-catalyzed transacetalization of either the acetyl glycoside[17] or the hemiacetal can provide the required 2-thiopyran ring (eq 14). Lewis acid-catalyzed synthesis must have an oxygen acceptor in the system to work, an example being ***Zinc Chloride*** with ***Phosphorus Oxychloride***[18] or ***Trimethylsilyl Trifluoromethanesulfonate***.[19]

(13)

(14)

Other Applications.

Thiophenol can also be utilized in the transformation of acetylenic alcohols to unsaturated aldehydes with allylic transposition (eq 15).[20] The reaction begins with treatment of an acetylenic alcohol with thiophenol to obtain a vinyl sulfide in a radical-induced reaction (see above). Acid-catalyzed hydrolysis then provides a homologated α,β-unsaturated aldehyde.

(15)

An interesting photochemical application of thiophenol is in the cleavage of β-phenylthio alcohols (available from reaction of epoxides with thiophenol). Irradiation of these alcohols at 350 nm using benzophenone as sensitizer causes cleavage of the central bond and formation of the ketone in good yield (eq 16).[21]

Thiophenol-Azobisisobutyronitrile

(PhSH)

[108-98-5] · C_6H_6S · Thiophenol-Azobisisobutyronitrile · (MW 110.19) (AIBN)

[78-67-1] · $C_8H_{12}N_4$ · Thiophenol-Azobisisobutyronitrile · (MW 136.22)

(preparation of benzenethiyl radicals with subsequent use in radical addition reactions of thiophenol to alkenes and alkynes;[1-4] alkene isomerizations[5])

Preparative Methods: prepared from ***Thiophenol*** and ***Azobisisobutyronitrile***, both of which are commercially available.

Synthesis of Sulfide Derivatives from Alkenes.

Thermally induced decomposition of AIBN to cyanopropyl radicals initiates hydrogen abstraction from thiophenol in the title reagent system to give benzenethiyl radicals. Kinetic studies involving the addition of the thiol radical to 1,4-divinylbenzene (eq 1), using a catalytic amount of AIBN, demonstrate that the sulfide-containing styrene monomer can be prepared in high yield by carrying out the reaction at 60 °C with an equimolar ratio of thiophenol and the alkene.[1] More vigorous reaction conditions (170 °C) are necessary, however, in the thio radical addition to triethoxyvinylsilane (eq 2), since no reaction takes place even on prolonged heating at 100-110 °C.[2]

(1)

(2)

Synthesis of Vinyl Sulfides from Alkynes.

The AIBN radical-initiated addition reaction of thiophenol to the terminal alkyne of a ynoic acid (eq 3) derivative provides the corresponding vinyl sulfide intermediate used in the synthesis of cyclohexanone derivatives.[3] This process has also been used in the synthesis of a chiral diene (eq 4) from an enyne precursor, a key intermediate in the enantiospecific total synthesis of (+)-compactin.[4]

Thiophenol-Mediated Alkene Inversion.

trans-Substituted alkenes containing a quarternary carbon center adjacent to the double bond are difficult to prepare by standard techniques, such as the Wittig reaction or by chemical reduction of the corresponding alkyne. However, they have been prepared by isomerizing the readily available *cis*-alkene using thiophenol-AIBN (eq 5).[5]

Heterocyclic Synthesis.

The reaction of 1,2,3-benzothiadiazole with PhSH/AIBN in refluxing EtOAc provides a mixture of products including dibenzo[*c*,*e*]-*o*-dithiin (**1**), thianthrene (**2**), and 2-(phenylthio)diphenyl disulfide (**3**).[6]

Thiophosgene[1]

[463-71-8] · CCl_2S · Thiophosgene · (MW 114.98)

(very electrophilic reagent capable of forming isothiocyanates with amines;[1] used in forming various heterocycles;[12] in combination with phosphorus reagents, capable of forming *cis*- and *trans*-alkenes from cyclic thiocarbonates (Corey-Winter alkenation);[22] dienophile in Diels-Alder reactions[25])

Physical Data: bp 73 °C; *d* 1.508 g cm^{-3}.

Solubility: sol most organic solvents; decomposes in H_2O and alcoholic solvents.

Form Supplied in: red-orange liquid; widely available.

Handling, Storage, and Precautions: wear appropriate safety equipment. Use only in a chemical fume hood; keep container tightly closed; unpleasant odor. Moisture sensitive; store under nitrogen; refrigerate. Highly toxic; may be fatal if inhaled, swallowed, or absorbed through skin; corrosive; lachrymator.

Reactions with Nitrogen Nucleophiles.

Thiophosgene has most commonly been used to convert primary aliphatic and aromatic amines (eq 1) into isothiocyanates[2,3] and thioureas (eq 2).[4,5] Secondary amines have been converted to aminothiocarbonyl chlorides,[6] *N*,*N*-disubstituted thiocarbamates,[7] and thioureas (eq 3).[8] Tertiary amines can be transformed to thiocarbamoyl chlorides[9] and isothiocyanato acid chlorides.[10]

(1)

(2)

(3)

Primary amines react selectively with thiophosgene in the presence of other reactive functional groups (OH, NH, CO_2H, CONH, SO_3H, or SH), situated far from the reacting amine, to form isothiocyanates (eq 4).[11] However, reactive functional groups present in the vicinity of the reactive amino group interact with the thiophosgene or the isothiocyanate generated in situ to afford a wide variety of heterocycles.[4,11a,12] Examples include formation of heterocyclic thiones (eq 5)[13] and benzoxazines (eq 6).[14]

(4)

(5)

(6)

The reaction of primary amides with thiophosgene may yield the corresponding isothiocyanate[15] or a nitrile and a thione, depending on the reaction conditions.[16] Also, subjecting thioureas and thioamides to thiophosgene followed by hydrolysis is a useful way to prepare the corresponding ureas and amides.[17] Ketimines which do not have a β-hydrogen atom react with thiophosgene to give α-chloroalkyl isothiocyanates, while those carrying a β-hydrogen give α-alkenyl isothiocyanates.[18] A number of fused 2*H*-1,3-oxazine-2-thiones have

been prepared by reacting 1,2-hydroximines with thiophosgene.[19] *N*-Isothiocyanato amines are prepared by reacting hydrazines with thiophosgene.[20]

Reactions with Oxygen Nucleophiles.

In the presence of thiophosgene, alcohols and phenols have been converted into chlorothioformates[21] which can be useful precursors of thiocarbonates, thiocarbamates, and dithiocarbonates.[1] Diols have been shown to form cyclic thiocarbonates. Specifically, 1,2-diols have been transformed into cyclic thiocarbonates which can be further transformed stereospecifically to *cis*- or *trans*-alkenes (eq 7).[22]

(7)

Reactions with Sulfur Nucleophiles.

Thiols have been converted to chlorodithioformates (eq 8),[23] trithiocarbonates,[24] and cyclic thiones[12] in the presence of thiophosgene, depending on the reaction conditions.

(8)

Miscellaneous Reactions.

Thiophosgene has been used as a dienophile in the Diels-Alder reaction.[25] Examples include the synthesis of thiopyranones (eq 9)[26] and bicyclic systems (eq 10).[27] [2 + 2] Cycloaddition reactions have also been achieved with thiophosgene.[28] Thiiranes have been prepared from diazo compounds,[29] and thioketenylidenetriphenylphosphorane from methylenetriphenylphosphorane,[30] when combined with thiophosgene.

Thiophosphoryl Chloride

[3982-91-0] · Cl_3PS · Thiophosphoryl Chloride · (MW 169.39)

(thionation of amides; thiophosphorylating agent for alcohols, amines, diols, amino alcohols, diamines, etc.)

Physical Data: mp -35 °C; bp 125 °C; n_D 1.550; *d* 1.668 g cm^{-3}.

Solubility: sol benzene; CCl_4, $CHCl_3$, CS_2; reacts with alcohols and amines.

Form Supplied in: liquid; widely available.

Analysis of Reagent Purity: ^{31}P NMR.

Purification: distillation.[1]

Handling, Storage, and Precautions: highly toxic; corrosive, undergoes slow hydrolysis when exposed to moisture. Must handled in a fume hood and reactions performed under a dry, inert atmosphere.

Thionation of Tertiary Amides.[2]

Thiophosphoryl chloride and its *N,N*-dimethylamide derivatives (eq 1)[3] react with amides at elevated temperature to give thioamides in good yield. The reaction is run in an excess of the thiophosphorus compounds. The most efficient of the thionating agents examined is *N,N,N´,N´*-tetramethylamidophosphonothioic chloride.

(1)

Thiophosphorylation.

Thiophosphoryl chloride will thiophosphorylate amines,[3] alcohols,[4] amino alcohols,[5] diols,[6] and diamines.[7] The rate of reaction decreases as each chlorine atom in replaced; thus it is possible to replace each chlorine atom with a different substituent under controlled reaction conditions. Thiophosphoryl derivatives of chiral amino alcohols have been studied extensively as stereochemical probes for the stepwise hydrolyses and alcoholysis of thiophosphates (eq 2), which can lead to the formation of nonracemic chiral thiophosphates.[8] They have also been used as chiral derivatizing agents for the NMR analysis of chiral alcohols and amines.[9]

2-Thiopyridyl Chloroformate[1]

[73371-99-0] · C_6H_4ClNOS · 2-Thiopyridyl Chloroformate · (MW 173.63)

(convenient preparation of 2-pyridylthiol esters;[2] subsequent transformation into lactones,[3] peptides,[4] and ketones[5])

Physical Data: ^1H NMR ($CDCl_3$) δ 8.64 m (1H), 7.75 m (2H), 7.38 m (1H).

Solubility: sol CH_2Cl_2, ether.

Form Supplied in: colorless oil; main impurity is bis(thiopyridyl) carbonate; not commercially available.

Analysis of Reagent Purity: IR (CH_2Cl_2) 1765 cm^{-1} (C=O); main impurity: IR (CH_2Cl_2) 1715 cm^{-1} (C=O).

Preparative Method: ***Phosgene*** (5 equiv) in toluene and CH_2Cl_2 is cooled to 0 °C. Dropwise addition (5 min) of a CH_2Cl_2 solution of ***Triethylamine*** (slight excess) and ***2-Pyridinethiol*** is followed by stirring for 10 min. After removal of excess phosgene and CH_2Cl_2 in vacuo, hexane is added and the resulting precipitate is filtered. After concentration of the combined filtrates, the colorless oil (96%) is dissolved in CH_2Cl_2 and stored at -25 °C.

Handling, Storage, and Precautions: very unstable to water and silica gel; however, it can be handled in air. It is stable for one month if stored at -25 °C. Since phosgene is used in preparing this reagent, preparation should be in a working fume hood and extreme caution is required.

Preparation of 2-Pyridylthiol Esters.

2-Pyridylthiol esters are formed by treating a carboxylic acid with 2-thiopyridyl chloroformate under extremely mild conditions (eq 1).[2] The $Et_3N.HCl$ is removed by filtration or by washing with cold aqueous acid and base. After thorough drying, the thiol esters are generally pure enough to use in many synthetic applications.

There are several other reagents for preparing 2-pyridylthiol esters. ***1,3-Dicyclohexylcarbodiimide***[4] generally gives lower yields of the thiol ester and removal of the dicyclohexylurea can be difficult. Treating an acid chloride with thallium(I) 2-pyridinethiolate[6] has been

used, but thallium salts are toxic. The method used most frequently before the introduction of 2-thiopyridyl chloroformate involves reacting a carboxylic acid with ***Triphenylphosphine*** and ***2,2´-Dipyridyl Disulfide***.[7] This procedure suffers from the necessity of removing 2-pyridinethiol and triphenylphosphine oxide by chromatography, which precludes preparing large batches of the thiol esters since there can be a loss of product by reaction with the silica gel. 2-Thiopyridyl chloroformate provides access to many reported synthetic transformations. In some of these reports, the thiol ester has been prepared by other methods. However, use of 2-thiopyridyl chloroformate should make these transformations even more accessible.

Lactone Formation.

There are several examples of the synthesis of lactones with 2-pyridylthiol esters.[3] Since this is a facile reaction, reasonable yields of complex macrocycles are obtained (eq 2).[8] The pyridine nitrogen may provide anchimeric assistance for the approaching nucleophile, thus facilitating the acylation.[3]

Ester Formation.

2-Pyridylthiol esters acylate lysophosphatidylcholines rapidly when catalyzed by silver ion, giving mixed-chain phosphatidylcholines in high yields and isomeric purity (eq 3).[9] The main advantages of this procedure over the usual ***4-Dimethylaminopyridine*** catalyzed acylation with acid anhydrides[10] are that less acylating reagent is required to give high yields and rearrangement of the fatty acids is minimized. The main disadvantage is the sensitivity of the 2-pyridylthiol ester to water.

Peptide Coupling.

These thiol esters have been used in the synthesis of several dipeptides. Many of the examples involve highly sterically hindered amino acids and result in very good yields and high optical purity (eq 4).[4] There are many useful active esters for peptide coupling, such as ***Pentafluorophenol***, ***p-Nitrophenol***, and ***N-Hydroxysuccinimide***. However, these do not work as well with the hindered amino acids shown in eq 4. Additionally, there are many direct coupling procedures; therefore the 2-pyridylthiol esters have not been used frequently.

(4)

Ketones.

Reaction of 2-pyridylthiol esters with Grignard reagents occurs rapidly to give ketones in almost quantitative yields (eq 5).[5] In all studies, less than 1% of the tertiary alcohol is observed. This procedure works reasonably well with a suitably protected amino acid to give the ketone (eq 6).[11] Phthaloyl protection of the amine is required since esters with amide NH groups decompose when treated with Grignard reagents.[11]

(5)

(6)

Preparation of thiol esters of highly elaborated phosphoranes with thiopyridyl chloroformate has been reported. Treatment of the thiol ester with an aryl Grignard reagent gives the corresponding ketone without epimerization of the chiral centers (eq 7).[12] There are many

procedures for reacting Grignard reagents with activated carboxylic acids to give ketones. Other reagents used with varying degrees of success include acid chlorides, nitriles, acid anhydrides, and *N*-acylimidazolides (e.g. ***N,N´-Carbonyldiimidazole***, ***1,1´-Thionylimidazole***).[13] Many of these give higher yields of the tertiary alcohol. However, treating acid chlorides with Grignard reagents at -78 °C gives better results,[14] so this may be an alternative to the thiol esters.

Thiourea

[62-56-6] · CH_4N_2S · Thiourea · (MW 76.14)

(reduction of endoperoxides and ozonides; nucleophilic H_2S equivalents; aminothiazole, pyrimidine, and episulfide synthesis; precursor of formamidinesulfinic acid)

Physical Data: mp 182 °C; *d* 1.405 g cm^{-3}.

Solubility: sol water, alcohol.

Form Supplied in: solid; commercially available.

Handling, Storage, and Precautions: liable to hydrolysis with generation of hydrogen sulfide. Powder is therefore toxic as well as malodorous. Should be used only with adequate ventilation. Use in a fume hood.

Reduction of Peroxides.

One of the more common uses of thiourea is in the reduction of peroxides to the alcohols. Examples include the reduction of cyclopentadiene endoperoxide[1] to form the corresponding diol (eq 1) and the reduction of ozonides[2] to the corresponding carbonyl compounds (eq 2) with a minimum of expense or odor.

(1)

(2)

Isothiuronium Salts.

Another use of thiourea is related to its synthetic equivalence to ***Hydrogen Sulfide***. Reaction with an alkyl halide or sulfonate via the sulfur of thiourea provides the isothiuronium salt (eq 3). This alternative provides an advantage over the use of hydrogen sulfide in that it avoids formation of dialkyl sulfides. Alkaline hydrolysis of the isothiuronium salt provides the thiol;[3] aqueous chlorination can provide the sulfonyl chloride.[4] Alternatively, the sulfur fragment may be easily displaced with an amine in a synthesis of substituted guanidines (eq 4).[5]

(3)

(4)

Heterocycle Synthesis.

A major use of thiourea is in the construction of heterocycles. Aminothiazoles can be synthesized by the Hantzsch synthesis wherein an α-halo carbonyl compound is treated with thiourea.[6a,b] The reaction of the carbonyl with one of the thiourea nitrogens to form the imine is the first step of the synthesis. Upon further heating, the sulfur displaces the halide with cyclization (eq 5). Pyrimidines are made by reaction of thiourea with β-dicarbonyl compounds[7a,b] via an initial attack by a thiourea nitrogen on a carbonyl, followed by cyclization and tautomerization (eq 6). Thiourea is the key reagent for the synthesis of episulfides[8a,b] from the corresponding epoxides, in one step and in synthetically useful yield (eq 7).

(5)

(6)

(7)

Lastly, thiourea and ***Hydrogen Peroxide*** are the starting materials for synthesis of ***Thiourea Dioxide*** (eq 8)[9] a mild reducing agent commonly used in the reduction of ketones to secondary alcohols.[10]

Thiourea Dioxide[1]

$NH_2C(=NH)SO_2H$

[1758-73-2] · $CH_4N_2O_2S$ · Thiourea Dioxide · (MW 108.14)

(convenient and economical reducing agent for obtaining secondary alcohols from aliphatic,[2] alicyclic,[2] aromatic,[2] heterocyclic,[2] and steroidal ketones;[3] efficient reducing agent for the conversion of disulfides to thiols,[4] of *N*-tosylsulfilimines to sulfides,[4] of sulfoxides to sulfides,[5] and of halides and oxides of organotellurium and organoselenium to tellurides and selenides;[6] synthesis of substituted imidazoles[7])

Alternate Names: TUD; formamidinesulfinic acid; aminoiminomethanesulfinic acid.

Physical Data: mp 144 °C (dec).

Solubility: partially sol cold water; insol in organic solvents.

Preparative Method: prepared by oxidation of ***Thiourea*** with ***Hydrogen Peroxide***.[8]

Handling, Storage, and Precautions: moisture sensitive.

Reduction of Ketones to Secondary Alcohols.[2]

A variety of ketones are reduced by TUD, in an aqueous ethanolic solution in the presence of NaOH, to the corresponding secondary alcohol in good yield. Generally, reduction of ketones requires 1-3 equiv of TUD and 2-6 equiv of NaOH; for example, dipropyl ketone gives heptan-4-ol (74%), benzophenone gives benzhydrol (100%), and 3-pyridyl phenyl ketone gives 3-pyridylphenylmethanol (100%). From the reaction mixture, almost theoretical amounts of the byproducts, sodium bisulfite and urea, are obtained.

Steroidal Ketones.[3]

Using TUD, in the presence of an alkoxide in alcohol, steroidal ketones are reduced to the corresponding secondary alcohols. The reduction proceeds satisfactorily in the case of 3- and 6-keto steroids.[3] Steroidal diketones having a 20-oxo group do not undergo reduction with TUD. The results obtained from TUD, metal-alcohol (Bouveault-Blanc), and ***Lithium Aluminum Hydride*** reductions are compared in Table 1. With all three reducing agents, 5α-cholestan-3-one gives the equatorial isomer as the major product. With 3β-hydroxy-5α-cholestan-3-one, TUD favors α-attack to produce predominantly the axial isomer.

Table 1 Comparison between TUD, Metal Alcohol and $LiAlH_4$ Reductions

Substrate	Products	Yield (%)		
		TUD	Na ROH	$LiAlH_4$
5a-Cholestan-3-one	3a-ol	10		10
	3b-ol	90	100	90
3b-Hydroxy-5a-cholestan-6-one	3b,6a-diol	16	95	33
	3b,6b-diol	84	5	67

Reduction of Disulfides and of *N*-Tosylsulfilimines.[4]

Disulfides and *N*-tosylsulfilimines are transformed into the corresponding thiols and sulfides (eq 1), respectively. For example, dibutyl disulfide is reduced to butanethiol (90%) and diphenyl disulfide to thiophenol (77%). The reactions are carried out under phase transfer conditions in the presence of a catalyst such as ***Tri-n-butylhexadecylphosphonium Bromide***.

(1)

R^1	R^2	Yield (%)
Ph	Me	93
Bn	Me	68
Bn	Ph	83
Bn	Bn	67

Reduction of Sulfoxides.[5]

Sulfoxides are reduced to the corresponding sulfides by TUD in the presence of ***Iodine***; for example, dibutyl sulfoxide gives dibutyl sulfide (89%) and diphenyl sulfoxide gives diphenyl sulfide (95%). The reaction is generally carried out by adding sulfoxides and iodine to a suspension of TUD in acetonitrile and then refluxing the mixture for a short time.

Reduction of Organoselenium and -tellurium Halides and Oxides.[6]

TUD reduces aryltellurium trihalides to diaryl ditellurides (eq 2) and diorganyltellurium dihalides and telluroxides to diorganyl tellurides (eq 3) in high yield. The corresponding selenium compounds are reduced similarly. Some examples are given in Table 2. The reduction is performed by premixing the substrate and 2 N NaOH at room temperature for 15 min prior to the addition of TUD in petroleum ether.

$$ArMX_3 \xrightarrow[25\ °C]{NaOH,\ H_2O} [ArMO_2^-] \xrightarrow{TUD} (ArM)_2 \qquad (2)$$

M = Te, Se

$$R_2MX_2 \xrightarrow[25\ °C]{NaOH,\ H_2O} [RM(O)R] \xrightarrow{TUD} RMR \qquad (3)$$

Table 2 Reduction of Organotellurium and Organoselenium Halides and Oxides by TUD

Starting material	Product	Yield (%)
$PhTeCl_3$	$(PhTe)_2$	92
$(C_{12}H_{25})_2TeCl_2$	$(C_{12}H_{25})_2Te$	86
PhTe(O)Bu	PhTeBu	77
$PhSeBr_3$	$(PhSe)_2$	93
Ph_2SeCl_2	PhSePh	92
Ph_2SeO	PhSePh	90

Reaction of Acylvinylphosphonium Halides with TUD.[7]

Triphenyl-β-acetylvinylphosphonium halides (X = Cl, Br) react with TUD (in DMSO) in the presence of base (***Sodium Hydride***) to give the imidazolylphosphonium salts in high yield (eq 4). These imidazolyl halides can be readily converted to multifunctional imidazoles with quantitative recovery of PPh_3; for example, 4-methyl-(5-methylimidazolyl)triphenylphosphonium halide, on treatment with NaOMe in MeOH, affords 5-methyl-4-methoxymethylimidazole.

Tin[1]

Sn

[7440-31-5] · Sn · Tin · (MW 118.71)

(with HCl, reduces a variety of functional groups;[2] stereoselective allylation of carbonyl compounds;[3] in situ generation of tin enolates for directed aldol reactions[4])

Physical Data: mp 232 °C; bp ~2270 °C; *d* 7.31 g cm^{-3}.

Solubility: insol water, organic solvents; reacts with mineral acids.

Form Supplied in: foil, moss, powder, granules, shot, and wire.

Preparative Methods: activated form is prepared from ***Tin(II) Chloride*** in THF by reduction with ***Lithium Aluminum Hydride***[5] or ***Potassium*** metal;[6] tin amalgam is prepared from ***Mercury(II) Chloride*** and 30-mesh Sn in water;[7] tin-copper couple is prepared from ***Copper(II) Acetate*** and 30-mesh tin in acetic acid.[8]

Handling, Storage, and Precautions: incompatible with strong acids and strong oxidizing agents; powdered form is air and moisture sensitive and should not be inhaled or contacted with the eyes or skin; amalgam is stored under water; tin-copper couple is stored under ether.

Functional Group Reductions.

The use of tin and ***Hydrochloric Acid*** is a classical method for the reduction of a variety of functional groups.[2] However this procedure has decreased in importance since the development of catalytic hydrogenation and of metal hydride reducing agents, and the harsh reaction conditions (strong acids and high temperatures) are often incompatible with other functional groups. Many reductions effected by tin are more conveniently carried out with ***Tin(II) Chloride***, which is soluble in some organic solvents. Nevertheless, the method is still used, most notably for the reduction of aromatic nitro compounds to amines, for which metal hydrides are less effective (see ***Lithium Aluminum Hydride***). Representative examples of standard procedures which utilize Sn/HCl include the reductions of 2,6-dibromo-4-nitrophenol to the aminophenol,[9] 2,4,6-trinitrobenzoic acid to the triamine (eq 1),[10] and nitrobarbituric acid to the amine (uramil).[11] Aromatic nitro group reductions with tin and hydrochloric acid have been employed in the preparation of functionalized paracyclophanes[12] and hemispherands.[13] 8-Nitroquinolines have been reduced to the corresponding amines with a combination of tin and tin(II) chloride.[14] In some cases the generated amines undergo further reactions (eq 2).[15]

(1)

(2)

Sterically hindered aliphatic vicinal diamines have recently been prepared by Sn/HCl reductions of the corresponding 1,2-dinitro compounds (eq 3).[16] Under the same conditions, a geminal dinitro compound is reported to give the corresponding oxime (eq 4).[16] *N*-Nitrosamines are reduced by tin and HCl to the denitrosated amines (eq 5),[17] whereas the corresponding ***Zinc*** reduction produces the hydrazines.

(3)

(4)

(5)

Examples of reductions of other functional groups by tin and HCl include the reduction of isoquinoline methiodides,[18] of tetrahydrocarbazole to hexahydrocarbazole,[19] and of 5-(chloromethyl)uracil to thymine (eq 6),[20] the selective debromination of 1,6-dibromo-2-naphthol (eq 7),[21] and the reduction of anisoin to deoxyanisoin,[22] of anthraquinone to anthrone (eq 8),[23] and of benzaldehydes to stilbenes.[24]

(6)

(7)

(8)

Tin amalgam and hydrochloric acid is useful for the selective reduction of the double bond of conjugated enediones in high yield (eq 9)[7] and for the controlled reduction of benzils to either benzoins or deoxybenzoins.[25] Tin amalgam in ***Acetic Acid*** also reduces benzoquinones to hydroquinones.[7,26]

(9)

Tin reductions have also been used for the conversion of arylsulfonyl chlorides to the corresponding thiols[27] and for the preparation of ***Thiophosgene*** from thiocarbonyl perchloride.[28] Metallic tin has recently been used for the in situ generation of low-valent bismuth and titanium species that catalyze cyclizations to 3-hydroxycephems (eq 10).[29] A tin-copper couple has been used for the selective debromination of activated dibromides (eq 11),[8] in cases where the more commonly employed ***Zinc/Copper Couple*** leads to overreduction.

(10)

(11)

Barbier-Type Allylations and Related Reactions.

The reaction of carbonyl compounds with allylmetal reagents to give homoallylic alcohols is an extremely important reaction in organic synthesis.[3,30] Metallic tin can be used for the in situ generation of diallyltin dihalides for subsequent reaction with aldehydes or ketones in good yield (eq 12).[31] The procedure is considerably more convenient than that involving isolation of allyltin intermediates and can be carried out in the presence of water.[32] Moderate asymmetric induction is observed when the reaction is carried out in the presence of monosodium (+)-diethyl tartrate.[33] The yields are improved by sonication[34] and this procedure has recently been applied to chain extensions of carbohydrates.[35] The reaction can be made catalytic by electrochemical regeneration of the tin reagent.[36]

(12)

A further improvement involves performing the reaction in the presence of ***Aluminum*** powder in a THF-water mixture.[32] Under these conditions, allyl chloride also reacts[37] and yields are improved for reactions of substituted allyl halides. In such cases the

diastereoselectivity is dependent on the specific reactants and reaction conditions. For example the Sn/Al reaction of benzaldehyde with crotyl bromide gives the *syn* diastereoisomer as the major product (eq 13),[32] whereas reaction with cinnamyl chloride occurs with exclusive *anti* selectivity (eq 14).[38] Under the same conditions cinnamyl chloride reacts with enals by exclusive 1,2-regioselective addition and complete *anti* diastereoselectivity and with 2-phenylpropanal with moderate Cram selectivity (eq 15).[38] These reactions are compatible with a variety of other functional groups,[32,39,40] although in some cases these may induce further reactions (eq 16).[40] A mechanistic study of the tin-promoted reactions of allylic iodides with benzaldehydes has recently been reported.[41] It has also recently been shown that allylic alcohols undergo similar reactions with metallic tin in the presence of ***Chlorotrimethylsilane*** and ***Sodium Iodide***.[42] Under these conditions, substituted allylic alcohols undergo carbon-carbon bond formation to the less substituted allylic carbon.[42]

(13)

(14)

(15)

(16)

The Sn/Al procedure has been further extended to the reactions of propargylic halides and such reactions can give both alkynic and allenic products, depending on the reaction conditions (eq 17).[43] The direct reaction of metallic tin with simple alkyl halides to give dialkyltin dihalides is an industrially important reaction and is usually restricted to the reactions of alkyl iodides.[44] More recently, a phase-transfer catalyzed procedure has been developed that facilitates reactions of alkyl bromides and chlorides.[45]

Tin Enolates.

Tin enolates are useful intermediates for use in directed aldol reactions.[4,46] Tin(II) enolates are usually prepared[47] by reaction of enolizable ketones with ***Tin(II) Trifluoromethanesulfonate***, but can also be prepared from reactions of α-bromocarbonyl compounds with activated metallic tin. Such enolates react with aldehydes and ketones under mild conditions to give aldols, generally in high yield (eq 18).[48] With α-substituted enolates high *syn* selectivity is observed (eq 19);[48] this is the opposite selectivity to that found with tin(IV) enolates. It has recently been shown that such reactions can be carried out in aqueous media with unactivated tin powder, but that under these conditions the metal enolate is probably not involved; a single-electron-transfer mechanism has been suggested.[49] In a related reaction, metallic tin has been used to generate a highly functionalized tin(II) enolate for alkylation of an azetidinone as part of a carbapenam synthesis (eq 20).[50]

β:α = 3:1

Tin(II) ester enolates can also be prepared by reaction of α-bromo carboxylic acid esters for Reformatsky-type reactions under very mild conditions (eq 21).[5] Reaction of an α-diketone or α-keto aldehyde with activated metallic tin produces a tin(II) enediolate that reacts with aldehydes to produce α,β-dihydroxy ketones in high yield (eq 22).[51] The diastereoselectivity of this reaction can is controlled by the addition of hexafluorobenzene.

Tin(II) Bromide

$SnBr_2$

[10031-24-0] · Br_2Sn · Tin(II) Bromide · (MW 278.51)

(mild Lewis acid used in halogenative allylation and Friedel-Crafts allylation; synthesis of α-nucleosides; α-methylation of ketones; reduction of acetals and aromatic nitro compounds; reductive dimerization of imines)

Alternate Name: stannous bromide.

Physical Data: mp 215.5 °C; bp 620 °C; *d* 5.1 g cm^{-3}.

Solubility: sol water (85.2 g/100 mL at 0 °C, 222.5 g/100 mL at 100 °C), alcohol, ether, acetone.

Form Supplied in: pale yellow rhombic crystals; commercially available.

Handling, Storage, and Precautions: corrosive and moisture sensitive; should be stored in a tightly closed container protected from light.

Allylations.

Oriyama[1] has shown that aromatic acetals can be converted in 63-87% yield to α-allylbenzyl bromides utilizing ***Allyltrimethylsilane*** and a catalytic amount of $SnBr_2$ in combination with excess ***Acetyl Bromide*** (eq 1). This reaction works equally well with $SnCl_2$ and ***Acetyl Chloride*** to yield the corresponding α-allylbenzyl chlorides. The Friedel-Crafts allylation of anisole with allylic bromides catalyzed by $SnBr_2$ has also been reported (eq 2).[2]

α-Methylene Ketones.

Silyl enol ethers react with ***Bromomethyl Methyl Ether*** in the presence of a catalytic amount of $SnBr_2$ to yield α-bromomethyl ketones. The α-bromomethyl ketones can be isolated or converted in a one-pot procedure to α-methylene ketones by treatment with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (eq 3).[3] Other tin halides such as ***Tin(II) Fluoride*** and ***Tin(II) Chloride*** can be used successfully in the reaction. This one-pot procedure is a convenient method for the introduction of α-methylene groups to ketones. Other methods such as the introduction of dialkylaminomethyl[4] or arylthiomethyl[5] groups α to a ketone, followed by activation and elimination, are two-step procedures. This methodology has been used in the synthesis of the antitumor antibiotic sarkomycin (**1**) (eq 4).

Reductive Dimerization of Imines.

The reductive dimerization of *N*-alkyl imines to vicinal diamines can be effected in 62-90% yields with ***Aluminum*** and a catalytic amount of a Sn^{II} or Pb^{II} salt in the presence of ***Trifluoroacetic Acid*** or ***Aluminum Bromide*** (eq 5).[6] The $PbBr_2$/Al bimetal redox system is the best combination although $SnBr_2$/Al is also effective. The reaction works best on both substituted and unsubstituted aromatic imines; however, aliphatic and aromatic ketimines will undergo reductive dimerization under refluxing conditions. This method produces slightly better yields than two other recently developed methods for the preparation of vicinal diamines, namely the niobium(IV) promoted dimerization of *N*-trimethylsilylimines[7] and the reductive dimerization of *N*-alkylbenzylimines with titanium(0).[8]

Nucleosides from Acyclic Epoxy Aldehydes.

Acyclic epoxy aldehydes undergo an addition-cyclization process with the tin(II) salts of nucleoside bases in the presence of $SnBr_2$ to yield nucleosides having predominately the α configuration (eq 6).[9] This methodology can be used to prepare stereoselectively 2´-deoxyribonucleosides that are difficult to prepare by other means.

(6)

Reductions.

Aromatic acetals can be reductively halogenated in high yield to give benzylic bromides[1] by employing a catalytic amount of $SnBr_2$ in the presence of ***Triethylsilane*** and excess acetyl bromide. The intermediate bromides can be further reduced with ***Lithium Aluminum Hydride*** or ***Tri-n-butylstannane*** to the corresponding hydrocarbon (eq 7).[10] This methodology has been extended to the reduction of aliphatic and aromatic ketone acetals; however, the product may be contaminated with small amounts of alkene as a byproduct (eq 8). This three-step conversion of ketones and aldehydes to the corresponding alkanes represents a mild and convenient alternative to the Wolff-Kishner and Clemmensen reductions.

(7)

(8)

It has been reported that *m*-bromobenzaldehyde can be prepared by reduction of *m*-nitrobenzaldehyde with $SnBr_2$/HCl, followed by diazotization of the resulting aminoaldehyde with ***Sodium Nitrite***, and treatment of the diazonium ion solution with ***Copper(I) Bromide***/HBr (eq 9).[11] The use of $SnBr_2$ is important in the reduction step because substitution of $SnCl_2$ leads to a product mixture containing up to 20% of *m*-chlorobenzaldehyde.

Tin(II) Chloride

$SnCl_2$

[7772-99-8] · Cl_2Sn · Tin(II) Chloride · (MW 189.61)

(reducing agent for many functional groups; carbonyl allylation; Lewis acid catalyst in C-C bond-forming reactions; catalyst with $AgClO_4$ for the synthesis of α-glycosides; synthesis of alkenes, dienes, *cis*-vinyloxiranes, and allylic selenides; deoxygenation of 1,4-endoperoxides; protection of carboxylic acids as 1,3-dithianes; selective *p*-methoxybenzyl ether cleavage reagent; additive in hydroformylation and carbonylation reactions[1])

Alternate Name: stannous chloride.

Physical Data: mp 246.8 °C; bp 623 °C; *d* 3.95 g cm^{-3}.

Solubility: insol xylenes; sol water, ethanol, acetone, diethyl ether, methyl acrylate, methyl ethyl ketone, isobutyl alcohol.

Form Supplied in: white crystalline solid; widely available.

Preparative Methods: analytical reagent grade tin(II) chloride is prepared by adding the dihydrate to a vigorously stirred solution of acetic anhydride (120 g salt per 100 g anhydride). After ca. one hour, the anhydrous $SnCl_2$ is filtered on a dry sintered glass or Buchner funnel, washed free from acetic acid with dry Et_2O, and dried in vacuo. It is best stored in a sealed container.[2]

Functional Group Reductions.

$SnCl_2$ is an effective reducing agent under acidic conditions.[3] $SnCl_2$ selectively reduces aromatic nitro compounds under nonacidic and nonaqueous conditions. Nearly quantitative yields of arylamines are obtained by using $SnCl_2.2H_2O$ in ethanol or ethyl acetate, or anhydrous $SnCl_2$ in alcohol at 70 °C. Under these conditions, other reducible or acid sensitive groups such as ketones, esters, nitriles, halogen, oximes, and alkenes are unaffected (eq 1).[4]

(1)

R = H, Cl, OH, CO_2H, CHO, OMe, CO_2R, OAc

$SnCl_2$ is used in the reduction of nitriles to aldehydes.[5] For example, treatment of the nitrile (**1**) with hydrochloric acid generates the intermediate (**2**). This is reduced with anhydrous $SnCl_2$ to (**3**), which precipitates as a complex with $SnCl_4$ and is then hydrolyzed to the aldehyde (**4**) (eq 2).[2] This protocol, known as the Stephen reaction, is most successful with aromatic nitriles, but it has been reported for aliphatic nitriles with up to six carbons. An alternative procedure in which (**2**) is obtained from the *N*-phenylamide, ArCONHPh, by treatment with ***Phosphorus(V) Chloride*** is known as the Sonn-Müller method.[6] Carboxylic acids can be prepared by reduction of cyanosilyl ethers (**5**) with $SnCl_2$ in AcOH and HCl (eq 3).[7]

Organic azides are reduced by $SnCl_2$ in methanol to the corresponding amines in 85-98% yield.[8] For less reactive azides, it is necessary to initiate the reaction by adding catalytic amounts of ***Aluminum Chloride***

α-Halo ketones are hydrodehalogenated to the corresponding ketones in good yield using $SnCl_2$ in combination with a variety of additives, e.g. sodium halides (chloride, bromide, iodide) and pseudohalides (thiocyanate, cyanate, chloride),[9] sulfur compounds (NaSH, Na_2S, $NaHSO_3$, Na_2SO_3), and aromatic compounds (benzene, pyridine, aniline) (eq 4).[10] $SnCl_2$ is more effective than other metal halides, such as $SnCl_4$, $FeCl_2$, $AlCl_3$, and $CrCl_3$.

(4)

X = Cl, Br; Y = Cl, Br, I, SCN, OCN, ClO_2, HS, HSO_3, NO_2

Treatment of an α-bromo carbonyl compound with $SnCl_2$ and ***Diethylaluminum Chloride*** effects dehydrohalogenation with formation of an aluminum enolate, which can react with an aldehyde or ketone to give the β-hydroxy carbonyl compound in 61-95% yield, in a modification of the Reformatsky reaction (eq 5).[11] Catalytic quantities of ***Tetrakis(triphenylphosphine)palladium(0)*** promote the reduction and improve the yield of the desired aldol adducts.

(5)

The reagent prepared from ***Sodium Cyanoborohydride*** and $SnCl_2$ in a 2:1 ratio will reduce tertiary, allyl, and benzyl halides in good yields and is thus comparable to $NaBH_3CN$-$ZnCl_2$. However, other functional groups such as aldehydes, ketones, and acid chlorides are reduced to alcohols. Esters and amides are unaffected.[12]

Carbonyl Reduction.

Asymmetric reduction of prochiral ketones,[13] α-, β-, and γ-keto esters,[14] and prochiral hydroxy ketones[15] can be achieved with a reagent prepared from $SnCl_2$ and ***Diisobutylaluminum Hydride***, in the presence of a chiral diamine derived from (*S*)-proline (eq 6).

(6)

R^1	R^2	Yield (%)	ee (%)
Bn	Me	71	78
Ph	Me	80	76
Ph	Et	74	74
Ph	CH_2OMEM	81	91
Ph	CO_2MEM	82	89
Me	CO_2MOM	60	48

β-Diketo Ester Synthesis.

Aldehydes are efficiently converted to β-diketo esters in 50-90% yield by addition of ***Ethyl Diazoacetate*** in the presence of $SnCl_2$ (eq 7). Although the reaction can be effected by a variety of Lewis acids, $SnCl_2$, BF_3, and $GeCl_2$ are the most effective.[16]

(7)

Treatment of a number of trisubstituted alkenes with ***Ozone*** followed by the addition of $SnCl_2$ and ethyl diazoacetate affords the β-diketo esters in 47-90% yield (eq 8). For monosubstituted alkenes to be successful, they must first be treated with ozone in the presence of methanol to generate methoxy hydroperoxides, which can subsequently be reduced to the β-diketo esters in 47-74% yield.[17] 1,3-Diketones can be prepared in 42-90% yield by $SnCl_2$-catalyzed reaction of α-diazo ketones with aldehydes (eq 9).[18]

(8)

(9)

Diastereoselective Carbonyl Allylation.

High regio- and diastereoselectivity can be achieved in the reaction of cinnamyl chloride with aldehydes using $SnCl_2$ and ***Aluminum***.[19] The reaction proceeds through zerovalent tin and affords the *anti*-adducts with high selectivity (eq 10). Under the same conditions, enals provide 1,2-adducts.

(10)

$SnCl_2$ acts as a reducing agent in the allylation of carbonyl compounds using allylic alcohols and Pd^0; this reaction proceeds through a π-allylpalladium complex (eq 11). The order of reactivity of allylating agents is allylic carbonate > allylic alcohol > allylic acetate, and that of carbonyl compounds is aldehyde > ketone. High regioselectivity is obtained in polar solvents such as DMF, DMI (1,3-dimethyl-2-imidazolidone), and DMSO, where the carbonyl compound attacks the more substituted allylic position of the π-allylpalladium complex.

(11)

Diastereocontrol in the Pd-catalyzed carbonyl allylation of allylic alcohols with $SnCl_2$ is dependent on the nature of the solvent. Use of DMSO at 25 °C affords the *syn*-adduct, while *anti* selection is found in THF, DMF, and DMI. The addition of water in any solvent accelerates the rate of the reaction and enhances both regioselectivity and diastereoselectivity (eq 12). For reactions in DMSO-H_2O, the ratio of *syn*:*anti* products can be controlled by the amount of water added to the reaction.[20] SnF_2 and $Sn(OAc)_2$ cannot replace $SnCl_2$ in this allylation reaction.

(12)

R^1	R^2	Solvent	Yield (%)	*syn*:*anti*
Me	*p*-$MeO_2CC_6H_4$	DMSO-H_2O	90	77:23
Me	*p*-$MeO_2CC_6H_4$	DMF	99	22:78
Pr	Ph	THF-H_2O	82	20:80
Pr	Ph	DMSO-H_2O	83	70:30
Me	Ph	THF	81	9:91
Me	Ph	DMSO	34	65:35

This reaction has been extended to the synthesis of α-methylene-γ-hydroxy lactones by allylation of carbonyl compounds with ethyl α-(hydroxymethyl)acrylate in DMI/H_2O (eq 13).[21] When the hydroxymethyl group bears an alkyl substituent, the product is obtained with high *syn* selectivity (eq 14).

(13)

(14)

C-C Bond Formation.

Acetals, aldehydes, orthoesters, and α,β-unsaturated ketones are sufficiently activated by a combination of $SnCl_2$ and ***Chlorotrimethylsilane***[22] or $SnCl_2$ and trityl chloride[23] to react with silyl enol ethers to give the corresponding addition products in 70-97% yield (eq 15). These reagents are also effective in facilitating the reaction of activated alkenes, such as 3,4-dihydro-2*H*-pyran, vinyl ethers, and styrene, with acetals to afford the corresponding adducts in 55-85% yield under extremely mild conditions.[24] $SnCl_2$ facilitates the workup in the ***Titanium(IV) Chloride***-catalyzed reaction of aldehydes with silyl enol ethers by inhibiting β-elimination and formation of polymers (eq 16).[25]

(15)

(16)

α-Glycosidation.[26]

α-Glycosides are formed predominantly by reaction of an alcohol with 2,3,4,6-tetra-*O*-benzyl-β-glucosyl fluoride in the presence of ***Tin(II) Chloride-Silver(I) Perchlorate*** (eq 17).

Alkenes and (*E*)-1,3-Dienes.

vic-Dinitro compounds can be denitrated to yield alkenes using either anhydrous $SnCl_2$ or the dihydrate. This method fails for aliphatic *vic*-dinitro compounds.[27] Alkenes can also be obtained in good yield from the *vic*-dibromo compounds using $SnCl_2$ and DIBAL (eq 18).[16]

Reaction of a variety of aldehydes with 1-bromo-3-iodopropene in the presence of 2 equiv of $SnCl_2$ yields the corresponding (*E*)-1,3-dienes in 40-70% yield (eq 19).[28] When an enal is employed a terminal conjugated triene is obtained. Treatment of 1-chloro-3-iodopropene with 1 equiv of $SnCl_2$ in DMF, and reaction with an aldehyde followed by NaOMe yieldes *cis*-vinyloxiranes in 51-53% yield (eq 20).[29]

Propargylic iodides form an adduct with $SnCl_2$, which can react with aldehydes to form a mixture of α-hydroxy allenes and β-hydroxy alkynes, in which the former usually predominates. DMI is the preferred solvent (eq 21).[30]

Deoxygenation of 1,4-Endoperoxides of 1,3-Dienes.[31]

1,4-Endoperoxides are converted to the corresponding 1,3-dienes in 15-70% yield using $SnCl_2$ (eq 22).

Rearrangements of 2-Hydroxy-3-trimethylsilylpropyl Selenides.[32]

Addition of ***Trimethylsilylmethyllithium*** to α-phenylseleno aldehydes generates 2-hydroxy-3-trimethylsilylpropyl selenides which rearrange in the presence of $SnCl_2$ to allylic selenides (eq 23).

Direct Conversion of Carboxylic Acids into 1,3-Dithianes.[33]

Reactions of carboxylic acids with 1,3,2-dithiaborinane-dimethyl sulfide in the presence of $SnCl_2$ in THF affords the corresponding 1,3-dithianes in high yields. This method is also sufficient to distinguish between carboxylic acids and isolated double bonds (eq 24).

Deprotection.[34]

p-Methoxybenzyl (PMB) ethers can be cleaved selectively in the presence of benzyl ethers by employing TMSCl/anisole and a catalytic amount of $SnCl_2$ (eq 25).

Related Reagents.

Cerium(III) Chloride-Tin(II) Chloride; ***Dichlorobis(triphenylphosphine)platinum(II)-Tin(II) Chloride***.

Tin(IV) Chloride

$SnCl_4$

[7646-78-8] · Cl_4Sn · Tin(IV) Chloride · (MW 260.51)

(strong Lewis acid used to promote nucleophilic additions, pericyclic reactions, and cationic rearrangements; chlorination reagent)

Alternate Name: stannic chloride.

Physical Data: colorless liquid; mp -33 °C; bp 114.1 °C; *d* 2.226 g cm^{-3}.

Solubility: reacts violently with water; sol cold H_2O; dec hot H_2O; sol alcohol, Et_2O, CCl_4, benzene, toluene, acetone.

Form Supplied in: colorless liquid; 1 M soln in CH_2Cl_2 or heptane; widely available.

Purification: reflux with mercury or P_2O_5 for several hours, then distill under reduced nitrogen pressure into receiver with P_2O_5. Redistill. Typical impurities: hydrates.

Handling, Storage, and Precautions: hygroscopic; should be stored in a glove box or over P_2O_5 to minimize exposure to moisture. Containers should be flushed with N_2 or Ar and tightly sealed. Perform all manipulations under N_2 or Ar. Solvating with H_2O liberates much heat. Use in a fume hood.

Introduction.

$SnCl_4$ is used extensively in organic synthesis as a Lewis acid for enhancing a variety of reactions. $SnCl_4$ is classified as a strong Lewis acid according to HSAB theory, and therefore interacts preferentially with hard oxygen and nitrogen bases. Six-coordinate 1:2 species and 1:1 chelates are the most stable coordination complexes, although 1:1 five-coordinate species are also possible.[1] $SnCl_4$ can be used in stoichiometric amounts, in which case it is considered a promoter, or in substoichiometric amounts as a catalyst, depending upon the nature of the reaction. $SnCl_4$ is an attractive alternative to boron, aluminum, and titanium Lewis acids because it is monomeric, highly soluble in organic solvents, and relatively easy to handle. $SnCl_4$ and $TiCl_4$ are among the most common Lewis acids employed in chelation control strategies for asymmetric induction. However, $SnCl_4$ is not often the Lewis acid of choice for optimum selectivities and yields.

$SnCl_4$ is also the principal source for alkyltin chlorides, R_nSnCl_{4-n}.[2] Allyltrialkyltin reagents react with $SnCl_4$ to produce allyltrichlorotin species through an S_E2' pathway (eq 1).[3] Silyl enol ethers react with $SnCl_4$ to give α-trichlorotin ketones (eq 2).[4] Transmetalation or metathesis reactions of this type are competing pathways to nucleophilic addition reactions where $SnCl_4$ is present as an external Lewis acid. As a consequence, four important experimental variables must be considered when using $SnCl_4$ as a promoter: (1) the stoichiometry between the substrate and the Lewis acid; (2) the reaction temperature; (3) the nature of the Lewis base site(s) in the substrate; and (4) the order of addition. These variables influence the reaction pathway and product distribution.[5]

Nucleophilic Additions to Aldehydes.

$SnCl_4$ is effective in promoting the addition of nucleophiles to simple aldehydes. Among the most synthetically useful additions are allylstannane and -silane additions. The product distribution in the stannane reactions can be influenced by the order of addition, stoichiometry, and reaction temperature. The *anti* geometry of the tin-aldehyde complex is favored due to steric interactions. Furthermore, the six-coordinate 2:1 complex is most likely the reactive intermediate in these systems. The use of crotylstannanes provides evidence for competing transmetalation reaction pathways (eq 3).[6] Superior selectivities are provided by ***Titanium(IV) Chloride***.

The presence of additional Lewis base sites within the molecule can result in the formation of chelates with $SnCl_4$ or $TiCl_4$, which can lead to 1,2- or 1,3-asymmetric induction with the appropriate substitution at the C-2 or C-3 centers. NMR studies have provided a basis for explaining the levels of diastereofacial selectivity observed in nucleophilic additions to Lewis acid chelates of β-alkoxy aldehydes with substitution at the C-2 or C-3 positions.[7] These studies reveal that $SnCl_4$ chelates are dynamically unstable when substrates are sterically crowded at the alkoxy center, thus enhancing the formation of 2:1 complexes and/or competing metathesis pathways. Furthermore, for β-siloxy aldehydes, the 2:1 $SnCl_4$ complex is formed preferentially over the corresponding chelate.[8]

Mukaiyama Aldol Additions.

Lewis acid-promoted additions of a chiral aldehyde to a silyl enol ether or silyl ketene acetal (the Mukaiyama[9] aldol addition) occurs with good diastereofacial selectivity.[10] The reaction has been investigated with nonheterosubstituted aldehydes, α- and β-alkoxy aldehydes,[11] α- and β-amino aldehydes,[12] and thio-substituted aldehydes.[13] High diastereoselectivity is observed in the $SnCl_4$- or $TiCl_4$-promoted aldol addition of silyl enol ethers to α- and β-alkoxy aldehydes. Prior chelation of the aldehyde before addition of the enol silane is important because certain enol silanes interact with $SnCl_4$ to produce α-trichlorostannyl ketones, which provide lower selectivity.[14] Simple diastereoselectivity is independent of the geometry of the enol silane, and the reaction does not proceed through prior Si-Ti or Si-Sn exchange. Good *anti* selectivities (up to 98:2) are obtained in the $SnCl_4$-promoted reactions of chiral α-thio-substituted aldehydes only with α-phenylthio-substituted aldehydes (eq 4). Stereorandom results are obtained with $SnCl_4$ when other alkylthio-substituted aldehydes, such as α-isopropylthio-substituted aldehydes, are used. ***Boron Trifluoride Etherate*** catalysis gives better *anti* selectivities than $SnCl_4$ for aldehydes with smaller alkylthio substituents. Excellent *syn* selectivities are obtained for α-thio-substituted aldehydes with $TiCl_4$.

Additions to Nitriles.

$SnCl_4$-promoted addition of malonates and bromomalonates to simple nitriles (not electron deficient) gives α,β-dehydro-β-amino acid derivatives (eq 5).[15] $SnCl_4$ is the Lewis acid of choice for the condensation of aroyl chlorides with sodium isocyanate, affording aroyl isocyanates in 70-85% yields.[16] Nonaromatic acyl chlorides react under more variable reaction conditions.

Hydrochlorination of Allenic Ketones.

$SnCl_4$ is also a source for generating chloride anions which form new carbon-chlorine bonds. This occurs through a ligand exchange pathway which has been exploited in the formation of β-chloro enones from conjugated allenic ketones (eq 6).[17] Yields range from 36-82% with complete selectivity for the *trans* geometry. A variety of substituents (R^1, R^2) can be tolerated including aryl, rings, and alkoxymethyl groups (R^1).

Glycosylations.

The reaction of glycofuranosides having a free hydroxyl group at C-2 with functionalized organosilanes, in the presence of $SnCl_4$, provides *C*-glycosyl compounds in high stereoselectivity (eq 7).[18] Organosilanes such as 4-(chlorodimethylsilyl)toluene, chlorodimethylvinylsilane, ***Allyltrimethylsilane***, and allylchlorodimethylsilane are effective reagents. The presence of a leaving group on the silane is essential for good selectivity since the reaction proceeds intramolecularly through a 2-*O*-organosilyl glycoside. The availability of furanosides in the ribo, xylo, and arabino series make this reaction valuable for the stereoselective synthesis of *C*-furanosides. Regioselective glycosylation of nitrogen-containing heterocycles is also effectively promoted by $SnCl_4$, and has been used in the synthesis of pentostatin-like nucleosides, such as (**1**).[19]

(1)

Selective De-*O*-benzylation.

Regioselective de-*O*-benzylation of polyols and perbenzylated sugars is achieved with organotin reagents or other Lewis acids.[20,21] The equatorial *O*-benzyl group of 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-mannopyranose is selectively cleaved by $SnCl_4$ or $TiCl_4$ (eq 8).[2] The equatorial *O*-benzyl group is also selectively cleaved when one of the axial *O*-benzyl groups is replaced by an *O*-methyl group. The 2-*O*-benzyl group of 1,2,3-tris(benzyloxy)propane is selectively cleaved (eq 9), but no debenzylation is observed with 1,2-bis(benzyloxy)ethane.

$SnCl_4$	92%	5%
$TiCl_4$	77%	19%

(9)

Rearrangement of Allylic Acetals.

Lewis acid-promoted ($SnCl_4$ or ***Diethylaluminum Chloride***) rearrangements of allylic acetals provide substituted tetrahydrofurans.[22] Upon addition of Lewis acid, (**2**) rearranges to the *all-cis* furan (**3**) (eq 10). No racemization is observed with optically active allylic acetals; however, addition of KOH completely epimerizes the furan-carbonyl bond, as does quenching at room temperature. Acetals successfully undergo similar rearrangement provided the alkene is substituted. Completely substituted tetrahydrofurans are synthesized stereoselectively (>97% ee) by the rearrangement of disubstituted allyl acetals (eq 11). This reaction is related to the acid-catalyzed rearrangements of 5-methyl-5-vinyloxazolidines to 3-acetylpyrrolidines, which involves an aza-Cope rearrangement and Mannich cyclization.[23]

(10)

(11)

The rearrangement is also useful for furan annulations, through enlargement of the starting carbocycle.[24] Thus addition of $SnCl_4$ to either diastereomer of the allylic acetal (**4**) produces the *cis*-fused cycloheptatetrahydrofuran (**5**) in 48-76% yield (eq 12). Acetals derived from *trans*-diols rearrange to the same *cis*-fused bicyclics in higher yield. The stereochemistry of a terminal alkene is transmitted to the C-3 carbon of the bicyclic products (eq 13). Rearrangements of acetals require substitution at the internal alkene carbon.

(12)

(13)

α-*t*-Alkylations.

$SnCl_4$-promoted α-*t*-alkylations of alkenyl β-dicarbonyl compounds is a particularly useful cyclization reaction.[25] Cyclization occurs through initial formation of a stannyl enol ether, followed by protonation of the alkene to form a carbocation which undergoes subsequent closure (eq 14). The analogous α-*s*-alkylation reactions are best catalyzed by other Lewis acids.

This reaction is useful for cyclizations involving 6-*endo*-trigonal (eq 14) and allowed 7-*endo* trigonal processes (eq 15), but not for those involving 5-*endo* trigonal processes (eq 16). These observations are consistent with the Baldwin rules.

Reactions involving 4- and 6-*exo* trigonal cyclizations result in poor yields or undesired products, while those involving 5-*exo* trigonal cyclizations produce higher yields (eq 17). This synthetic strategy can also be used to form bicyclic and spiro compounds (eqs 18 and 19).

(17)

(18)

(19)

Alkene Cyclizations.

Cationic cyclizations of polyenes, containing initiating groups such as cyclic acetals, are promoted by $SnCl_4$ and have been utilized in the synthesis of *cis*- and *trans*-decalins, *cis*- and *trans*-octalins, and tri- and tetracyclic terpenoids and steroids.[26] In most instances, *all-trans*-alkenes yield products with *trans,anti,trans* stereochemistry (eq 20), while *cis*-alkenes lead to *syn* stereochemistry at the newly formed ring junctions. The stereoselectivity of polyene cyclizations are often greatly diminished when the terminating alkene is a vinyl group rather than an isopropenyl group. Acyclic compounds which contain terminal acyclic acetals and alkenes or vinylsilanes can be cyclized in a similar fashion to yield eight- and nine-membered cyclic ethers (eq 21).[27]

(20)

(21)

$R^1 = H$, TMS; $R^2 = (CH_2)_2OMe$

The analogous cyclization of chiral imines occurs in high yields (75-85%) with good asymmetric induction (36-65% ee).[28] For example, the cyclization of aldimine (**6**), derived from methyl citronellal, using $SnCl_4$ affords only the *trans*-substituted aminocyclohexane (**7**) in high yield (eq 22). *Exo* products are formed exclusively or preferentially over the thermodynamically favored *endo* products.

(22)

(6) **(7)**

$SnCl_4$-induced cyclizations between alkenes and enol acetates result in cycloalkanes or bicycloalkanes in high yield (eq 23). It is interesting to note that the TMSOTf-catalyzed reaction can yield fused products rather than bicyclo products. Alkenic carboxylic esters, allylic alcohols, sulfones, and sulfonate esters are also cyclized in the presence of $SnCl_4$; however, alkenic oxiranes often cyclize in poor yield.[26a]

(23)

$SnCl_4$ is also effective in the opening of cyclopropane rings to produce cationic intermediates useful in cyclization reactions. For example, the cyclization of aryl cyclopropyl ketones to form aryl tetralones, precursors of aryl lignan lactones and aryl naphthalene lignans, is mediated by $SnCl_4$ (eq 24).[29] The reaction is successful in nitromethane, but not in benzene or methylene chloride. Analogous cyclizations with epoxides result in very low yields (2-5%).

Polymerization.

Cationic polymerizations are catalyzed by $SnCl_4$ and other Lewis acids (eq 25). Propagation is based upon the formation of a cationic species upon complexation with $SnCl_4$.[30] Radical pathways are also possible for polymer propagation.[31]

Diels-Alder Reactions.

Diels-Alder reactions are enhanced through the complexation of dienophiles or dienes by Lewis acids.[32] Furthermore, Lewis acids have been successfully employed in asymmetric Diels-Alder additions.[33] Although $SnCl_4$ is a useful Lewis acid in Diels-Alder reactions, in most instances titanium or aluminum Lewis acids provide higher yields and/or selectivities. The stereoselectivity in Lewis acid-promoted Diels-Alder reactions between chiral α,β-unsaturated *N*-acyloxazolidinones shows unexpected selectivities as a function of the Lewis acid (eq 26).[34] Optimum selectivity is expected for chelated intermediates, yet both $SnCl_4$ and $TiCl_4$ perform poorly relative to Et_2AlCl (1.4 equiv). The formation of the $SnCl_4$-*N*-acyloxazolidinone chelate has been confirmed by solution NMR studies.[35] These data suggest that other factors such as the steric bulk associated with complexes may contribute to stereoselectivity.

Lewis acid	conv %	Σ*endo*:Σ*exo*	*endo* I:*endo* II
1.1 equiv $SnCl_4$	70	14.9	3.1
1.1 equiv $TiCl_4$	100	9.9	2.7
1.4 equiv Et_2AlCl	100	50.0	17

In Lewis acid-promoted Diels-Alder reactions of cyclopentadiene with the acrylate of (*S*)-ethyl lactate, good diastereofacial and *endo*/*exo* selectivity are obtained with $SnCl_4$ (84:16; *endo*/*exo* = 18:1) and $TiCl_4$ (85:15; *endo*/*exo* = 16:1).[36] It is interesting to note that boron, aluminum, and zirconium Lewis acids give the opposite diastereofacial selectivity (33:67 to 48:52). Competing polymerization of the diene is observed in methylene chloride, particularly with $TiCl_4$, but not in solvent mixtures containing *n*-hexane.

Cycloalkenones generally perform poorly as dienophiles in Diels-Alder reactions but their reactivity can be enhanced by Lewis acids.[37] $SnCl_4$ is effective in promoting the Diels-Alder reaction between simple 1,3-butadienes, such as isoprene and piperylene, and cyclopentenone esters. For example, the $SnCl_4$-promoted cycloaddition between (**8**) and isoprene is completely regioselective, providing the substituted indene in 86% yield (eq 27).[38] However, cycloaddition does not occur in the presence of $SnCl_4$ when the diene contains an oxygen-bearing substituent such as an alkoxy or siloxy group. In these cases, as is generally true for the Diels-Alder reactions of cycloalkenones, other Lewis acids are more effective. For example, $SnCl_4$-promotion of the cycloaddition between (**8**) and 3-methyl-2-(*t*-butyldimethylsiloxy)butadiene yields 37% of the desired product, while ***Zinc Chloride*** provides a 90% yield. When furan or 2-methyl-1-alkylsiloxybutadiene are utilized as dienes, only decomposition of the starting material is observed with $SnCl_4$.

(27)

The Lewis acid-promoted Diels-Alder reaction has been employed in the assembly of steroid skeletons.[39] The cycloaddition reaction between a substituted bicyclic diene and 2,6-dimethylbenzoquinone produces two stereoisomers in a 1:5 ratio with a yield of 83% when $SnCl_4$ is used in acetonitrile. $TiCl_4$ provides slightly higher selectivities (1:8) but lower yield (70%) (eq 28).

(28)

When the dienophile *N*-α-methylbenzylmaleimide (**9**) is reacted with 2-*t*-butyl-1,3-butadiene in the presence of Lewis acids, cycloadducts (**10**) and (**11**) are formed (eq 29).[40] While $SnCl_4$ provides (**10**) and (**11**) in a 5:1 ratio, $TiCl_4$ and $EtAlCl_2$ both provide a 15:1 ratio. Polymerization of the diene competes with adduct formation under all conditions.

(29)

[4 + 3] Cycloadditions.

Oxyallyl cations,[41] which react as C_3 rather than C_2 components in cyclization reactions, are generated by the addition of $SnCl_4$ to substrates which contain silyl enol ethers which are conjugated with a carbonyl moiety. Thus 2-(trimethylsiloxy)propenal undergoes cyclization with cyclopentadiene or furan (eq 30).[42] Substituted 1,1-dimethoxyacetones also form these intermediates and undergo subsequent cyclizations (eq 31).[43] This method complements the usual synthesis of oxyallyl cations involving reductive elimination of halogens from halogenated ketones or electronically equivalent structures.[44]

(30)

(31)

[3 + 2] Cycloadditions.

Lewis acid-mediated [3 + 2] cycloadditions of oxazoles and aldehydes or diethyl ketomalonate have been observed using organoaluminum and Sn^{IV} Lewis acids.[45] The reactions are highly regioselective, with stereoselectivity extremely dependent upon Lewis acid (eq 32). For example, the (BINOL)AlMe-promoted reaction between benzaldehyde and the oxazole (**12**) provides the oxazoline with a *cis*/*trans* ratio of 98:2. The selectivity is reversed with $SnCl_4$ which provides a *cis*/*trans* ratio of 15:85. *trans*-5-Substituted 4-alkoxycarbonyl-2-oxazolines are synthesized under thermodynamic conditions in the aldol reaction of isocyanoacetates with aldehydes.[46]

(32)

[2 + 2] Cycloadditions.

The regioselectivity in the cycloaddition reactions of 2-alkoxy-5-allyl-1,4-benzoquinones with styrenes is controlled by the choice of Ti^{IV} or $SnCl_4$ Lewis acids (eq 33).[47] The use of an excess of $TiCl_4$ or mixtures of $TiCl_4$ and $Ti(O\text{-}i\text{-}Pr)_4$ produces cyclobutane (**13**) as the major or exclusive product, while $SnCl_4$ promotion with one equivalent of Lewis acid results in the formation of (**14**) only. These reactions represent a classic example of the mechanistic variability often associated with seemingly modest changes in Lewis acid.

(33)

Ene Reactions.

The Lewis acid-catalyzed ene reaction is synthetically useful methodology for forming new carbon-carbon bonds.[48] Ene reactions utilizing reactive enophiles such as formaldehyde and chloral can be promoted by $SnCl_4$. $SnCl_4$ also enhances intramolecular ene reactions, such as the cyclization of (**15**) which produces the α-hydroxy δ-lactone in 85% yield (eq 34).[49] The ene cyclization of citronellal to give isopulegol has also been reported.[50] Proton scavenging aluminum Lewis acids such as $RAlCl_2$ are most often used in ene reactions to eliminate proton-induced side reactions.

Tin(II) Chloride-Silver(I) Perchlorate[1]

$SnCl_2$-$AgClO_4$

($SnCl_2$)

[7772-99-8] · Cl_2Sn · Tin(II) Chloride-Silver(I) Perchlorate · (MW 189.61) ($AgClO_4$)

[14242-05-8] · $AgClO_4$ · Tin(II) Chloride-Silver(I) Perchlorate · (MW 207.32)

(glycosylation promoter;[2] activates glycosyl fluoride[2])

Physical Data: $SnCl_2$: bp 247 °C; *d* 3.95 g cm^{-3}. $AgClO_4$: dec 486 °C; *d* 2.806 g cm^{-3} (25 °C).

Solubility: $SnCl_2$: sol H_2O, ethanol, acetone, ether. $AgClO_4$: sol water.

Form Supplied in: $SnCl_2$ (anhydrous): white solid; widely available. $AgClO_4$: widely available as a hydrated form.
Drying: anhydrous $SnCl_2$ is dried for 1 h at 100 °C under reduced pressure (ca. 0.5 mmHg). Commercially available $AgClO_4.H_2O$ is dissolved in benzene and the solution is refluxed for 6 h using Dean-Stark equipment (water is separated as the benzene azeotrope). After cooling and filtration, crude anhydrous $AgClO_4$ is recrystallized from benzene and dried at room temperature for 24 h.

Preparative Methods: the ***Tin(II) Chloride-Silver(I) Perchlorate*** reagent is usually prepared in situ by mixing an equimolar amount of $SnCl_2$ and $AgClO_4$ in an appropriate solvent such as Et_2O.

Handling, Storage, and Precautions: anhydrous $SnCl_2$ and $AgClO_4$ are handled and stored under an argon atmosphere. Anhydrous $AgClO_4$ explodes readily when struck or heated.

Promoter for Stereoselective Glycosylations.

Combined use of tin(II) chloride ($SnCl_2$) and silver perchlorate ($AgClO_4$) effectively promotes the stereoselective glycosylation reaction of glucosyl fluorides with hydroxy compounds. α-Glucopyranosides are predominantly prepared by the reaction of 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl fluoride (**1**) with various hydroxy compounds, including sterically hindered ones (eq 1).[2,3]

Under the same reaction conditions, a β-ribofuranoside is obtained as a major product from 2,3,5-tri-*O*-benzyl-β-D-ribofuranosyl fluoride (**2**). α-Ribofuranosides are prepared when $SnCl_2$ is combined with ***Triphenylmethyl Perchlorate*** ($TrClO_4$) instead of $AgClO_4$ (eq 2).[4]

Although the precise structure of an active species generated from $SnCl_2$ and $AgClO_4$ is not clear, formation of $SnCl(ClO_4)$ or $Sn(ClO_4)_2$ is postulated. On the other hand, combination of ***Dichlorobis(cyclopentadienyl)hafnium*** and 2 equiv $AgClO_4$ is reported to form $Cp_2Hf(ClO_4)_2$, which is effective in the β-selective glycosylation of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl fluoride (**3**) (eq 3).[5] In this case, use of 2 equiv of $AgClO_4$ gives better results than those obtained by use of 1 equiv.[5d] Some other examples of stereoselective glycosylations of glycosyl fluorides using other activators such as SiF_4,[6] TMSOTf,[7] $BF_3.OEt_2$,[8,9] TiF_4,[10] Tf_2O,[11] and Me_2GaCl[12] have also been reported.

While more than stoichiometric amounts of promoters are required in the above examples, catalytic reactions are realized by using ***Tin(IV) Chloride***-$AgClO_4$. In the presence of a catalytic amount of $SnCl_4$-$AgClO_4$, 1-*O*-acetyl-2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (**4**) reacts with alcohol trimethylsilyl ethers to afford the corresponding α-glucopyranosides in high yields (eq 4).[13] Other examples of the preparation of β-glucosides[14] and α-[15] and β-2-amino-2-deoxyglycosides[16] have also been reported.

Tin(IV) Chloride-Zinc Chloride[1]

$SnCl_4$-$ZnCl_2$

($SnCl_4$)

[7646-78-8] · Cl_4Sn · Tin(IV) Chloride-Zinc Chloride · (MW 260.51) ($ZnCl_2$)

[7646-85-7] · Cl_2Zn · Tin(IV) Chloride-Zinc Chloride · (MW 136.29)

(catalyst for bond formation between silyl nucleophiles and carbonyl groups or enones[1])

Physical Data: $SnCl_4$: mp -33 °C; bp 114.1 °C; *d* 2.226 g cm^{-3}; $ZnCl_2$: mp ca. 290 °C; bp 732 °C.

Solubility: both reagents react violently with water. $SnCl_4$: sol cold H_2O; dec hot H_2O; sol alcohol, ether, CCl_4, benzene, toluene, acetone. $ZnCl_2$: sol H_2O (432 g/100 g at 25 °C, 614 g/100 g at 100 °C); 2% HCl (4 g/1 mL); alcohol (1 g/1.3 mL); glycerol (1 g/2 mL); freely sol acetone.

Form Supplied in: blend not commercially available. Anhydrous $SnCl_4$: colorless liquid; 1 M soln CH_2Cl_2 or heptane; widely available. Anhydrous $ZnCl_2$: white, odorless granules, lumps, or rods; 1 M soln in Et_2O, 0.5 M soln in THF; widely available.

Purification: $SnCl_4$: heat to reflux with mercury or P_2O_5 for several hours, then distil under reduced nitrogen pressure into receiver with P_2O_5. Redistil. Typical impurities: hydrates. $ZnCl_2$: heat to reflux in dioxane (100 g/800 mL) with zinc dust (10 g), filter hot, and cool to precipitate $ZnCl_2$. Crystallize from dioxane. Impurities: H_2O, zinc oxychloride.

Handling, Storage, and Precautions: both reagents are hygroscopic and should be stored in a glove box or over P_2O_5 to minimize exposure to moisture. Containers should be flushed with N_2 or Ar and tightly sealed. Perform all manipulations under N_2 or Ar. Solvating $SnCl_4$ with H_2O is highly exothermic. Use in a fume hood.

Introduction.

The ***Tin(IV) Chloride-Zinc Chloride*** blend[1] is one of many Lewis acid blends, such as $Sn(OTf)_2$-Bu_3SnF,[2] $SnCl_4$-$Sn(OTf)_2$,[3] $SbCl_5$-$Sn(OTf)_2$,[4] TMSCl-$SnCl_2$,[5] TrCl-$SnCl_2$ (Tr = trityl),[6] SnO-TMSOTf,[7] and $GaCl_3$-$AgClO_4$,[8] which are effective catalysts in carbon-carbon bond forming reactions. The active catalyst is believed to be ^+ZnCl-$SnCl_5^-$ which is formed prior to the addition of organic reactants. Single Lewis acids ($SnCl_4$, $TiCl_4$, etc.) promote these reactions, but do not catalyze them.[9]

Ethynylation of Acetals and Aldehydes.[1]

The $SnCl_4$-$ZnCl_2$ blend is the most useful catalyst (10 mol %) for the preparation of secondary propargylic ethers from 1-trimethylsilyl-1-alkynes and acetals (eq 1).[1] Conventional promoters such as TrCl-$SnCl_2$ and TMSCl-$SnCl_2$ are not effective, and Sn^{II}-Sn^{IV}, Sn^{II}-Ti^{IV}, and Zn^{II}-Ti^{IV} blends provide lower yields. Moderate yields (29-53%) are obtained for acetals with large alkoxy groups (R^2); however, cyclic acetals, such as 1,3-dioxolane, do not react. Aromatic and conjugated dimethyl acetals provide dipropargyl derivatives as side products. Ethynylation of aldehydes is accomplished by forming intermediate hemiacetal-like compounds from aldehydes and alkoxytrimethylsilanes in the presence of the Lewis acid blend. These intermediates then undergo reaction with 1-trimethylsilyl-1-alkynes to form the desired secondary propargylic ethers (eq 2).

Allylation of Secondary Propargylic Ethers and Aldehydes.[1]

Propargylic ethers are allylated by ***Allyltrimethylsilane*** in the presence of the $SnCl_4$-$ZnCl_2$ blend (eq 3). Thus acetals can be transformed to 1,5-enynes in one pot with sequential nucleophilic additions. The blend also catalyzes the allylation of aldehydes by allyltrimethylsilane, yielding homoallylic alcohols in good yields (61-74%).

Aldol and Michael Reactions.[1]

The $SnCl_4$-$ZnCl_2$ blend is an effective catalyst in the aldol reaction of silyl enol ethers with aldehydes (eq 4), acetals (eq 5), or ketones. The product *anti*/*syn* ratios are variable (32:69 to 89:11). The blend also catalyzes the Michael addition of silyl enol ethers with α,β-unsaturated ketones (eq 6), yielding alkylation products (84-100%) with *anti* selectivity (*anti*/*syn* = 55:45 to 87:23)

Tin(II) Fluoride[1]

SnF_2

[7783-47-3] · F_2Sn · Tin(II) Fluoride · (MW 156.71)

(Knoevenagel[2] and aldol-type[3] catalyst; oxidative addition to carbon-halogen bonds;[4,5] stereocontrolled [3 + *n*] (*n* = 3, 4, or 5) annulations;[6,8,9] conversion of allylic phosphonates to allyltin intermediates[7])

Alternate Name: stannous fluoride.

Physical Data: mp 213 °C, 219.5 °C; bp 850 °C; *d* 4.570 g cm^{-3}.

Solubility: v sol water (>30% w/w); sol aq potassium hydroxide, fluoride solutions, mineral acids. Readily dissolves in donor solvents such as acetone, ethyl acetate, or pyridine, forming presumed pyramidal (&PPsi;-tetrahedral) complexes.

Form Supplied in: white, monoclinic crystals; widely available.

Handling, Storage, and Precautions: slowly hydrolyzes in water to SnO. Converts to $SnOF_2$ upon exposure to air. Stable in aq mineral acids. Aq solutions are readily oxidized (catalyzed by light). Fluoride solutions react with SnF_2, providing SnF_3^- (p*K* = 10) which absorbs oxygen but does not oxidize. Containers of SnF_2 should be stored under a dry, inert atmosphere. LD_{50} 128.4 mg/kg (mouse), 188.2 mg/kg (rat).

Knoevenagel Condensations.

Among 14 metallic fluorides, Lelean[2] has shown that tin(II) fluoride is a superior catalyst in the Knoevenagel condensation of a tetrahydropyrimidine with 2-thiophenecarbaldehyde in methylcyclohexane at reflux (eq 1). Complete conversion (based upon the amount of water formed) is observed with only 9.3 mol % of catalyst.

Oxidative Addition to Carbon-Halogen Bonds.

Tin(II) fluoride undergoes oxidative insertion with α,α-dibromoacetophenone derivatives (eq 2) (R^1 = Me, Et), affording the tin enolate which undergoes addition to aliphatic and aromatic aldehydes (R^2 = $PhCH_2CH_2$, Ph, *n*-C_8H_{17}, *p*-ClC_6H_4) at -45 °C. Treatment of the aldol intermediate with ***Cesium Fluoride*** (or ***Triethylamine***) promotes closure to the α,β-epoxy ketone in 52-81% yields.[3]

(2)

Mukaiyama[4] has shown that ***Allyl Iodide*** reacts with SnF_2 to give an allyltin species (eq 3) which adds to aldehydes (R^1 = $PhCH_2CH_2$, PhCH=CH, Ph) to give an intermediate which, in turn, can be trapped with acid chlorides (R^2 = Me, $PhCH_2CH_2$), affording esters of homoallylic alcohols.

(3)

This methodology has been applied to a four-pot synthesis of 2-deoxy-D-ribose (eq 4).[4] Allylation/trapping of 1,2-*O*-isopropylidene-D-glyceraldehyde with phenoxyacetyl chloride gives a 78% yield of the *erythro*-homoallylic alcohol (admixed with 19% of the *threo*-isomer). Cleavage of the phenoxyacetyl group with ***Ammonia*** affords the acetonide in 71% yield. Hydrolysis then gives the triol in 95% yield, and this affords 2-deoxy-D-ribose in 75% yield after ozonolysis with a reductive workup.

(4)

In a similar manner, reaction of ***Carbon Tetrabromide*** with SnF_2 in DMSO at 25 °C gives an intermediate which adds to aldehydes (R = Ph, 1-furyl, $PhCH_2CH_2$, *n*-C_8H_{17}, PhCH=CH, PhCO, PhCH(Me)), affording the corresponding tribromoethanols in 46-80% yields (eq 5).

(5)

Tribromoethanols are useful precursors of α-hydroxy carboxylic acids and have been employed in the synthesis of 2,3-diacetyl-D-erythronolactone[5] from 1,2-*O*-isopropylidene-D-glyceraldehyde (eq 6).

(6)

Stereocontrolled [3 + *n*] (*n* = 3, 4, or 5) Annulations.[6,8,9]

Molander reports the stereocontrolled synthesis of cyclopentanoids[6] (eq 7) using a 1,2-dicarbonyl component and a 1,3-dianion synthon derived from the treatment of 3-halo-2-[(trimethylsilyl)methyl]propenes (X = I, Br) with SnF_2 in THF at 25 °C. Several 1,2-diketones (R, R^1 = Me, Et, Ph, *n*-Pr, $Cl(CH_2)_4$, $-(CH_2)_4-$; 0% for R = R^1 = Ph) afford the *cis*-diols.

(7)

SnF_2 appears unique for this annulation. After generation of the allylstannane, the Sn^{4+} serves as a Lewis acid catalyst and provides internal chelation. The fluoride counterion is an ideal nucleophile for the activation of the allylsilane. The high stereoselectivity (25:1 to 75:1) is attributed to chelation (eq 8).[6]

(8)

Reaction of an asymmetrically substituted 1,2-dione with the allylstannane as described above gives predominantly the diastereomer predicted by the Felkin-Ahn model (eq 9).[6]

(9)

Cyclohexanediols are prepared in approximately 20-60% yields (diastereomeric ratios from 4:1 to 50:1) by a [3 + 3] annulation using α,β-epoxy aldehydes (R = alkyl, H) as the dielectrophilic partner (eq 10).[8] The high degree of stereoselectivity and the lack of appreciable [3 + 2] annulation is attributed to internal chelation and an internal *trans*-diaxial epoxide opening (eq 11).[8]

(10)

(11)

Annulations with 1,4-dicarbonyl or 1,5-dicarbonyl substrates (R = aryl, aliphatic) give seven- and eight-membered ethers in high yields (eqs 12 and 13).[9] The ethers are obtained since the initial adduct may form an internal acetal (eq 14).[9]

(12)

(13)

(14)

Allylations of Aldehydes with Allylic Phosphonates.

Allylic phosphonates (R = H or Me) react with $Et_2AlSnClF_3$ (formed in situ with SnF_2 and ***Diethylaluminum Chloride*** with a catalytic amount of ***Tetrakis(triphenylphosphine)palladium(0)***), giving an allyltin reagent which adds to benzaldehyde or hexanal in high yields (eq 15).[7] The *syn*/*anti* selectivities of the homoallylic alcohols range from 25/75 to 55/45.

Tin(II) Trifluoromethanesulfonate

$Sn(OTf)_2$

[62086-04-8] · $C_2F_6O_6S_2Sn$ · Tin(II) Trifluoromethanesulfonate · (MW 416.87)

(mild Lewis acid used primarily for the generation of tin(II) enolates for stereoselective aldol and Michael reactions;[1] [2,3]-Wittig and Ireland-Claisen rearrangements;[2] addition of tin(II) acetylides to aldehydes;[3] asymmetric allylation of aldehydes[4])

Physical Data: mp >300 °C.

Form Supplied in: fine white powder.[5]

Purification: can be purified by washing with diethyl ether.[6]

Handling, Storage, and Precautions: moisture and air sensitive; all handling and storage should be done under nitrogen.

Aldol Reaction.

Mukaiyama has developed the use of tin(II) triflate in diastereoselective and enantioselective aldol-type reactions.[1,7] Initially, the stereoselective aldol reactions were demonstrated using a stoichiometric amount of tin(II) triflate.[8] The reaction between 3-acylthiazolidine-2-thione and 3-phenylpropionaldehyde is a representative example of a diastereoselective *syn*-aldol synthesis (eq 1).

Enantioselective aldol-type reactions have been achieved by addition of a chiral diamine to the reaction mixture.[9] Specifically, addition of (*S*)-1-methyl-2-[(piperidin-1-ylmethyl]pyrrolidine to the reaction of 3-acetylthiazolidine-2-thione and 3-phenylpropionaldehyde provides the *syn*-aldol with greater than 90% ee (eq 2).

Reactions of ketene silyl acetals with various aldehydes in the presence of a stoichiometric amount of a tin(II) triflate-tin(IV) additive-chiral diamine complex have also been performed with excellent enantioselectivity (eq 3).[10]

Stereoselective aldol reactions using a catalytic amount of tin(II) triflate have been developed. The diastereoselective reaction between ***Methyl Vinyl Ketone*** and benzaldehyde first demonstrated the usefulness of tin(II) triflate as a catalyst (eq 4).[1]

The development of catalytic enantioselective reactions of silyl enol ethers with aliphatic, aromatic, alkynic, and α,β-unsaturated aldehydes has broadened the scope of this catalytic process (eqs 5-7).[7a,b]

In addition, Mukaiyama has shown that the stereochemistry of these reactions is controlled by the tin(II) triflate-tin(IV) additive-chiral diamine complex and is therefore independent of the chirality of the aldehyde (eqs 8 and 9).[7b,11]

Michael Reaction.

The development of catalytic aldol-type reactions led to the discovery of a tin(II) triflate-catalyzed asymmetric Michael reaction.[1] Specifically, tin(II) enolates, prepared in situ from silyl enethiolates with catalytic amounts of tin(II) triflate and a chiral diamine, react with various α,β-unsaturated ketones to give chiral Michael adducts with 40-70% ee (eq 10).[12] Previously, asymmetric Michael reactions of tin(II) enolates with enones had been demonstrated in stoichiometric systems (eq 11).[13]

(10)

(11)

[2,3]-Wittig Rearrangements.

Tin(II) enolates, generated from allylic glycolate esters and tin(II) triflate in the presence of ***Diisopropylethylamine***, undergo [2,3]-Wittig rearrangements upon warming to room temperature (eq 12).[2a] The corresponding boron enolates of the esters rearrange in a similar manner but with less stereoselectivity.

Ireland-Claisen Rearrangement.

An isolated case of an α-alkoxy ester rearranging via a tin(II) enolate has been reported (eq 13).[2b]

Addition of 1-Alkynes to Aldehydes.

In the presence of a stoichiometric amount of tin(II) triflate, 1-alkynes react with aldehydes and ketones to give alkynic alcohols in 57-91% yield (eq 14).[3] The mechanism of this reaction is, at present, unclear. It has been proposed that the tin(II) triflate reacts with the alkyne to form a tin acetylide which adds to the aldehyde.

Asymmetric Allylation.

Mukaiyama has designed a chiral allylating agent consisting of an allyldialkylaluminum and a chiral diamine chelated to tin(II) triflate. The reaction of this agent with various aldehydes gives corresponding homoallylic alcohols with good to excellent enantioselectivity (eq 15).[4] Other tin(II) compounds ($SnCl_2$, $SnBr_2$, SnF_2, $Sn(OAc)_2$) react in this system to give the homoallylic alcohols in good yield but with virtually no enantioselectivity.

Titanium[1]

Ti

[7440-32-6] · Ti · Titanium · (MW 47.88)

(low-valent titanium, i.e. Ti^0/Ti^I, can be generated from a variety of sources and is used for the inter- and intramolecular reductive coupling of carbonyl and dicarbonyl compounds, imines, and iminium species, and for reductive elimination reactions and reductions)

Physical Data: mp 1677 °C; *d* (α-form) 4.506 g cm^{-3}.

Solubility: unknown but presumably low in most organic solvents. THF and DME appear to be the favored solvents for reactions involving low-valent titanium.

Form Supplied in: a 4:1 ball-milled mixture of $TiCl_3$ and $LiAlH_4$ is available commercially and serves as a precursor to the McMurry reagent (see ***Titanium(III) Chloride-Lithium Aluminum Hydride***). Low-valent titanium can be generated in situ from a variety of other sources as discussed below.

Preparative Methods: low-valent titanium reagents, including Ti^0, can be generated by in situ reduction of Ti^I-Ti^{IV} chlorides. At least a dozen commonly used procedures have been reported including those involving $TiCl_3$/Zn,[2] $TiCl_3$/Mg,[3] $TiCl_3/LiAlH_4$,[4] $TiCl_3$/K,[5] $TiCl_3$/Li,[6] $TiCl_3$/Zn(Cu),[5] $TiCl_3/C_8K$,[7] $CpTiCl_3/LiAlH_4$,[8] $TiCl_4$/Zn,[9] $TiCl_4/Al/AlCl_3$,[8] and $TiCl_4$/Mg(Hg).[8,10] Whether a Ti^0 or a Ti^I species is generated is dependent upon various factors, including the particular reagent combination used and the titanium chloride to reductant ratio employed.

Handling, Storage, and Precautions: most commonly, low-valent titanium species are prepared under an inert atmosphere (nitrogen or argon) immediately prior to use. Presumably, the reagent is pyrophoric although this property may be due to the residual reducing agent used in the preparation process and may not be an inherent property of Ti^0/Ti^I itself. The reagent is moisture sensitive.

Inter- and Intramolecular Coupling of Carbonyl and Dicarbonyl Compounds.

The capacity of low-valent titanium species to effect reductive couplings was reported in 1973-1974 by several independent groups,[1,3,9] but McMurry and his co-workers have exploited such processes most extensively. A number of excellent reviews[1] are available on this and related topics. McMurry has now developed[11] an optimized procedure involving a combination of the $TiCl_3$/dimethoxyethane solvate $TiCl_3(DME)_{1.5}$ and ***Zinc/Copper Couple***. Thus coupling of diisopropyl ketone with the $TiCl_3(DME)_{1.5}$/Zn(Cu) reagent gives an 87% yield of the expected alkene (eq 1). A 4:1 ratio of $TiCl_3(DME)_{1.5}$ to carbonyl compound appears to give the best results. When the same conversion is effected using $TiCl_3/LiAlH_4$ and $TiCl_3$/Zn(Cu), yields of 12% and 37%, respectively, are obtained. Cross coupling of different carbonyl compounds to produce unsymmetrical alkenes can be effected in acceptable yield if one of the components, often acetone, is used in excess.[10] The coupling conditions have proven to be compatible with a variety of other potentially reducible functional groups including carboxylate and sulfonate esters,[12] as well as halides.[13]

(1)

Intramolecular couplings of dicarbonyl compounds (including diketones, dialdehydes and keto esters) can be effected very efficiently with low-valent titanium (eq 2) and such processes have been exploited extensively in the synthesis of a number of natural products[1] and various novel hydrocarbons[1] (see ***Titanium(III) Chloride-Zinc/Copper Couple*** for examples).

(2)

The geometry (*E* or *Z*) about the alkene double bond being formed in these so-called McMurry reactions is apparently controlled by thermodynamic factors. When the energy difference between the (*E*)- and (*Z*)-alkenes exceeds 4-5 kcal mol^{-1} the former isomer is formed preferentially.[14] However, coupling of alkyl aryl ketones affords the (*Z*)-alkene preferentially, perhaps because of π-complexation between the phenyl rings and Ti^0.[15] The mechanism proposed (eq 3)[1,16] to account for these conversions involves initial pinacolic-type coupling followed by successive elimination of 2 equiv of Ti=O to produce the observed products. When short reaction times and low temperatures are used, pinacols can be isolated. If such species are resubjected to the normal coupling conditions, deoxygenation occurs and the expected alkene results. Interestingly, when stereochemically pure pinacols are subjected to reaction with low-valent titanium reagents, then mixtures of (*E*)- and (*Z*)-alkenes are produced although some stereochemistry is preserved.[1a]

(3)

The reductive coupling of imines and related iminium species to give *vic*-diamines can be effected by low-valent titanium species.[17-19] In those cases where it is relevant, low to modest diastereoselectivities are observed (eq 4). Allylic alcohols, benzylic alcohols, and benzylic halides all undergo reductive coupling in the presence of certain low-valent titanium reagents (see ***Titanium(III) Chloride-Lithium Aluminum Hydride***).

(4)

Reductive Eliminations.

vic-Dibromides,[20,21] bromohydrins,[22,23] epoxides,[22,24-27] hydroxy sulfides,[28-30] and allylic diols,[31-34] as well as 1,2-diols (pinacols), undergo reductive elimination on exposure to various low-valent titanium species, resulting in the formation of the corresponding alkene or 1,3-alkadiene. The dithioacetals of various acyloins also suffer reductive elimination upon treatment with Ti^0, thereby affording vinyl

sulfides.[35]

Reductions.

Various reductions can be effected with Ti^0/Ti^I species. Thus enol phosphates are converted into the corresponding alkenes[36] while analogous reduction of aryl phosphates[37] provides a useful protocol for the deoxygenation of phenols. Acyl, vinyl, and alkyl halides, as well as dithioacetals, can all be converted into the corresponding hydrocarbon on exposure to various sources of low-valent titanium,[38-41] while both nitriles[42] and isocyanides[43] suffer reductive removal of the -CN and -NC groups, respectively. Reduction (net addition of the elements of H_2) of both isolated[44-46] and conjugated[47,48] double bonds can also be accomplished with low-valent titanium.

University of Melbourne, Parkville, Victoria, Australia

Titanium(IV) Chloride

[7550-45-0] · Cl_4Ti · Titanium(IV) Chloride · (MW 189.68)

(Lewis acid catalyst;[52] affects stereochemical course in cycloaddition[38,39] and aldol reactions;[4-17] electrophilic substitutions;[55] powerful dehydrating agent; when reduced to low-valent state, effects C-C bond formation by reductive coupling;[7-9] reduction of functional groups[81])

Physical Data: mp -24 °C, bp 136.4 °C, *d* 1.726 g cm^{-3}.

Solubility: sol THF, toluene, CH_2Cl_2.

Form Supplied in: neat as colorless liquid; solution in CH_2Cl_2; solution in toluene; $TiCl_4$.2THF *[31011-57-1]*.

Preparative Methods: see Perrin et al.[1]

Purification: reflux with mercury or a small amount of pure copper turnings and distill under N_2 in an all-glass system. Organic material can be removed by adding aluminum chloride hexahydrate as a slurry with an equal amount of water (ca. 2% weight of the amount of $TiCl_4$), refluxing the mixture for 2-6 h while bubbling in Cl_2 which is subsequently removed by a stream of dry air, before the $TiCl_4$ is distilled, refluxed with copper, and distilled again. Volatile impurities can be removed using a technique of freezing, pumping, and melting.[2]

Handling, Storage, and Precautions: moisture sensitive; reacts violently, almost explosively, with water; highly flammable; toxic if inhaled or swallowed; causes burns on contact with skin; use in a fume hood.

General Discussion.

$TiCl_4$ is a strong Lewis acid and is used as such in organic reactions. It has high affinity for oxygenated organic molecules and possesses a powerful dehydrating ability. Low-valent titanium, from the reduction of $TiCl_4$ by metal or metal hydrides, is used for reductive coupling reactions and for reduction of functional groups.

Carbon-carbon bond formation by reductive coupling of ketones by low-valent titanium leads to vicinal diols and alkenes, as does coupling using low-valent reagents from ***Titanium(III) Chloride***. Reviews are available on the preparation and reactions of low-valent titanium.[3-6] The reagent from ***Titanium(IV) Chloride-Zinc*** in THF or dioxane in the presence of pyridine transforms ketones into tetrasubstituted alkenes. Unsymmetrical ketones yield (*E*)/(*Z*)-isomer mixtures (eq 1). Strongly hindered ketones react slowly and may preferentially be reduced to alcohols.[7] Reductive coupling of diketo sulfides yields 2,5-dihydrothiophenes (eq 2).[8] The macrocyclic porphycene has been obtained, albeit in low yield, by McMurry coupling of diformylbipyrrole (eq 3).[9] Aldimines are reductively coupled in a reaction analogous to the reaction of carbonyl compounds. The product is a 1:1 mixture of *meso*- and (±)-isomers (eq 4).[10]

(1)

(2)

Methylenation of aldehydes and ketones results from reactions with the complex from $TiCl_4$-Zn and ***Diiodomethane*** or ***Dibromomethane*** (eq 5). The reagent can be used for methylenation of enolizable oxo compounds.[6] Recommended modifications to the reagent have been reported.[11] In keto aldehydes, selective methenylation of the keto group results when the aldehyde is precomplexed with ***Titanium Tetrakis(diethylamide)***. Chemoselective methenylation of the aldehyde function is possible by direct use of CH_2I_2/Zn/***Titanium Tetraisopropoxide*** (eq 6).[12] Cyclopropanation to *gem*-dihalocyclopropanes uses ***Lithium Aluminum Hydride-Titanium(IV) Chloride***. The exclusion of a strong base, as frequently used in alternative procedures, is an advantage (eq 7).[13] Allylation of imines has been effected by low-valent titanium species generated from $TiCl_4$ and ***Aluminum*** foil (eq 8).[14]

(8)

$TiCl_4$ is a powerful activator of carbonyl groups and promotes nucleophilic attack by a silyl enol ether. The product is a titanium salt of an aldol which, on hydrolysis, yields a β-hydroxy ketone. $TiCl_4$ is generally the best catalyst for this reaction. The temperature range for reactions with ketones is normally 0-20 °C; aldehydes react even at -78 °C, which allows for chemoselectivity (eq 9).[15] In α- or β-alkoxy aldehydes, the aldol reaction can proceed with high 1,2- or 1,3-asymmetric induction. With the nonchelating Lewis acid ***Boron Trifluoride Etherate***, the diastereoselectivity may be opposite to that obtained for the chelating $TiCl_4$ or ***Tin(IV) Chloride*** (eq 10).[16]

(9)

(10)

$TiCl_4$,	85%	>95:5
BF_3		10:90

Titanium enolates are generally prepared by transmetalation of alkali-metal enolates but may also arise as structural parts of intermediates in $TiCl_4$-promoted reactions. This is illustrated in a stereoselective alkylation using an oxazolidinone as a chiral auxiliary (eq 11). The enolate, or its ate complex, may be the intermediate in the reaction.[17]

(11)

The stereoselectivity in $TiCl_4$-promoted reaction of silyl ketene acetals with aldehydes may be improved by addition of ***Triphenylphosphine*** (eq 12).[18] Enol ethers, as well as enol acetates, can be the nucleophile (eqs 13 and 14).[19] 2-Acetoxyfuran, in analogy to vinyl acetates, reacts with aldehydes to furnish 4-substituted butenolides under the influence of $TiCl_4$ (eq 15).[20]

(12)

(13)

(14)

(15)

Silyl enol ethers react with acetals at -78 °C to form β-alkoxy ketones.[21] In intramolecular reactions, six-, seven-, and eight-membered rings are formed.[22] With 1,3-dioxolanes (acetals), 1-2 equiv of $TiCl_4$ leads to pyranone formation (eq 16), whereas no cyclization products are obtained with $SnCl_4$ or $ZnCl_2$.[23]

(16)

Alkynyltributyltin compounds react with steroidal aldehydes. In the presence of $TiCl_4$ the reaction gives 9:1 diastereoselectivity (eq 17). Reactions of alkynylmetals with chiral aldehydes generally show only slight diastereoselectivity.[24] With silyloxyacetylenes and aldehydes, α,β-unsaturated carboxylic acid esters are formed with high (*E*) selectivity (eq 18).[25]

(17)

(18)

Allylsilanes are regiospecific in their Lewis acid-catalyzed reactions, the electrophile bonding to the terminus of the allyl unit remote from the silyl group (eq 19).[26,27] Allylstannanes are less reliable in this respect.[26,28] The example in eq 19 illustrates regioselectivity.[29] On extended conjugation the reaction takes place at the terminus of the extended system (eq 20).[30]

(19)

(20)

Intramolecular reactions work well, both for allylstannanes and allylsilanes. An epoxide can be the electrophile. Opening of the epoxide with allylic attack gives the cyclic product (eq 21). $TiCl_4$ is superior to $Ti(O\text{-}i\text{-}Pr)_4$, $SnCl_4$, and ***Aluminum Chloride***, the other Lewis acids tested in the cyclization reaction. The reaction is stereospecific.[31]

(21)

Stereochemical aspects in these $TiCl_4$-promoted reactions have been covered in reviews.[26,27] Acetals are very good electrophiles for allylsilanes, and may be better than the parent oxo compounds because the products are less prone to further reaction; intramolecular reactions are facile.[26,32] In the unsymmetrical acetal in eq 22, the methoxyethoxy group departs selectively because of chelation to the Lewis acid.[33]

(22)

The $TiCl_4$-mediated addition of allenylsilanes to aldehydes and ketones provides a general, regiocontrolled route to a wide variety of substituted homopropargylic alcohols. With acetals, corresponding ethers are formed (eq 23).[34] Allenylation of acetals results from the reaction of propargylsilanes with acetals. The products are α-allenyl ethers (eq 24).[35]

(23)

(24)

Homoallylamines are formed in $TiCl_4$- or $BF_3.OEt_2$-mediated reactions between allylstannanes and aldimines. Crotyltributyltin gives mainly *syn*-β-methyl homoallylamines under optimal conditions (eq 25).[36]

(25)

Diastereoselective Mannich reactions may result with $TiCl_4$ as adjuvant (eq 26); transmetalation of the initial lithium alkoxide adduct and displacement by a lithium enolate gives a diastereoselectivity of 78%.[37]

(26)

Lewis acid catalysis increases the reactivity of dienophiles in Diels-Alder reactions by complexing to basic sites on the dienophile. In aldehydes, complexation takes place via the lone pair on the carbonyl oxygen. The stereochemistry is strongly influenced by the Lewis acids.[38] Under chelating conditions, when α-alkoxy aldehydes are used, the prevalent products from $TiCl_4$ catalysis have *cis* configuration (eqs 27 and 28). Stereochemical aspects of pericyclic pathways or passage through aldol type intermediates have been summarized and discussed.[38,39]

(27)

(28)

Ketene silyl acetals can be dimerized to succinates on treatment with $TiCl_4$ in CH_2Cl_2 (eq 29). No reaction occurs with $TiCl_3$, nor are other metal salts efficient.[40] β-Amino esters are formed in the presence of Schiff bases (eq 30).[41]

(29)

(30)

Cycloaddition of alkenes to quinones is effected by Ti^{IV} derivatives. The composition of the Ti^{IV} adjuvant largely controls the type of cycloadduct. $TiCl_4$ favors [3 + 2] cycloaddition; [2 + 2] cycloaddition requires a mixed $TiCl_4$-Ti(O-*i*-Pr)$_4$ catalyst (eq 31).[42]

(31)

The $TiCl_4$-promoted Michael reaction proceeds under very mild conditions (-78 °C); this suppresses side-reactions and 1,5-dicarbonyl compounds are formed in good yields.[3] For $TiCl_4$-sensitive compounds, a mixture of $TiCl_4$ and Ti(O-*i*-Pr)$_4$ is used. From silyl enol ethers and α,β-unsaturated ketones, 1,5-dicarbonyl compounds are formed (eq 32).[3] The reaction also proceeds for α,β-unsaturated acetals.[43] Silylketene acetals react with α,β-unsaturated ketones or their acetals to form δ-oxo esters (eq 33).[44]

(32)

Conjugate addition of allylsilanes to enones results in regiospecific introduction of the allyl group (eq 34).[45] The reaction can be intramolecular (eq 35).[46] $TiCl_4$ or $SnCl_4$ activates nitro alkenes for Michael addition with silyl enol ethers or ketene silyl acetals. The silyl nitronate product is hydrolyzed to a 1,4-diketone or γ-keto ester (eq 36).[47]

Conjugate propynylation of enones results from $TiCl_4$-mediated addition of allenylstannanes. Other Lewis acids are ineffective in this reaction (eq 37).[48]

The 3,4-dichloro derivative of squaric acid, on $TiCl_4$-catalysis, reacts with silyl enol ethers or allylsilanes to form 1,2- or 1,4-adducts depending on the substitution. The 3,4-diethoxy derivative, however, adds silyl enol ethers in a 1,4-fashion; the adduct subsequently eliminates the ethoxy group (eq 38).[49]

(38)

The Knoevenagel reaction with $TiCl_4$ and a tertiary base (eq 39) is recommended over methods which rely on strongly basic conditions.[50] The $TiCl_4$-procedure at low temperature is suitable for base-sensitive substrates.[51]

(39)

$TiCl_4$, as a Lewis acid, is used as a catalyst in Friedel-Crafts reactions. $AlCl_3$, $SnCl_4$, and $BF_3.OEt_2$ are more commonly used Friedel-Crafts catalysts for reactions with arenes.[52] Use of $TiCl_4$ as catalyst in the preparation of aromatic aldehydes is shown in eq 40.[53]

(40)

The formylation reaction can be used to prepare (*E*)-α,β-unsaturated aldehydes from vinylsilanes by *ipso* substitution (eq 41).[54] Regioselectivity in alkylation reactions may depend on the Lewis catalyst. In a fluorene, regioselective 1,8-chloromethylation results with $TiCl_4$ (eq 42).[55] $TiCl_4$ activates nitroalkenes for electrophilic substitution into arenes. The intermediate is hydrolyzed to the oxoalkylated product (eq 43).[56]

(41)

(42)

(43)

$TiCl_4$ is generally a good catalyst for Friedel-Crafts acylation of activated alkenes. In the acylation of pyrrolidine-2,4-diones, particularly with unsaturated acyl substrates, $TiCl_4$ is superior to $SnCl_4$ and $BF_3.OEt_2$ (eq 44).[57]

(44)

The ready *ipso* substitution of a silyl group favors substitution rather than addition of electrophiles in alkenylsilanes.[58] Direct acylation of isobutene is not satisfactory, but the acylation is successful on silyl derivatives (eq 45).[59] Intramolecular acylation of alkenylsilanes leads to cyclic products. Even (*E*)-silylalkenes have been cyclized to enones (eq 46).[60]

(45)

(46)

In analogy to the acylation reactions, vinylsilanes can be alkylated by *ipso* substitution. In the example in eq 47, the MEM group is activated as leaving group by metal complexation[61] The silyl group in allylsilanes directs the incoming electrophile to the allylic γ-carbon (eq 48). $TiCl_4$ is one of several Lewis acids used for catalysis in acylations.[58] The same reaction is seen in allylsilanes with extended conjugation.[62] Eq 49 shows the $TiCl_4$-catalyzed alkylation of an allylsilane.[63]

(47)

(48)

(49)

$TiCl_4$ is a useful catalyst for the Fries rearrangement of phenol esters to *o*- or *p*-hydroxy ketones (eq 50). $TiCl_4$ is a cleaner catalyst than the more frequently used $AlCl_3$, which may cause alkyl migrations.[64]

$TiCl_4$ is both a strong Lewis acid and a powerful dehydrating agent, and hence useful as a water scavenger in the synthesis of enamines. It is particularly useful for the preparation of enamines of acyclic ketones. It is recommended that $TiCl_4$ is complexed with the amine before addition of the ketone.[65] Highly sterically hindered enamines are available by this method (eq 51).[66] Primary amines generally react very slowly with aromatic ketones to form imines. $TiCl_4$ is a good catalyst (eq 52).[67]

$TiCl_4$ with a tertiary base provides mild conditions for dehydration of both aldoximes and primary acid amides to form nitriles.[68] Vinyl sulfides are formed from oxo compounds using $TiCl_4$ and a tertiary amine.[3] $TiCl_4$ activates carbon-carbon double bonds for thiol addition (eq 53).[3]

$TiCl_4$ mediates thioacetalization of aldehydes and ketones with alkanethiols or alkanedithiols in yields >90%. The reaction is satisfactory also for readily enolizable oxo compounds.[69] γ-Lactols, which are generally more stable than acyclic analogs, are amenable to dithiol cleavage (eq 54).[70]

α-Hydroxy amides are formed in a reaction involving an isocyanide, $TiCl_4$, and an aldehyde or a ketone (eq 55).[71] Vinyl chlorides undergo ready hydrolysis on combined use of $TiCl_4$ and MeOH-H_2O (eq 56).[72] $TiCl_4$-mediated hydrolysis of vinyl sulfides is a good preparative route to ketones.[3,73]

(55)

(56)

Low-valent titanium can be used to reduce sulfides and haloarenes to the corresponding hydrocarbons (eq 57).[3,74] Low-valent titanium, prepared from $TiCl_4$ and ***Magnesium Amalgam***, will reduce nitroarenes to amines in THF/*t*-BuOH at 0 °C without affecting halo, cyano, and ester groups.[75] $SnCl_2.2H_2O$ is an alternative reagent for nitro group reduction.[76]

(57)

Deoxygenation of sulfoxides is a rapid reaction using $[TiCl_2]$ formed in situ by reduction of $TiCl_4$ with Zn dust in CH_2Cl_2 or Et_2O at rt, with yields in the range 85-90%.[77] For deoxygenation of *N*-oxides of pyridine-based heterocycles, a reagent prepared from $TiCl_4$-$NaBH_4$ (1:2) in DME has been described.[78] Carboxylic acids can be reduced to primary alcohols by $TiCl_4$-$NaBH_4$ (ratio 1:3). For reduction of amides and lactams the optimum molar ratio is 1:2.[79]

Several low-valent metal species have been found active in reductive elimination of vicinal dibromides to the corresponding alkenes. In most cases, e.g. with $TiCl_4$-LAH and $TiCl_4$-Zn, the reactions proceed through predominant *anti* elimination to yield alkenes with high isomeric purity.[80] The low-valent titanium reagent obtained from $TiCl_4$-LAH (ca. 2:1) will saturate the double bond of enedicarboxylates in the presence of triethylamine (eq 58).[81]

Titanium(III) Chloride

[7705-07-9] · Cl_3Ti · Titanium(III) Chloride · (MW 154.23)

(aqueous functional group reducing agent; after reducing to low-valent species, reductive coupling reagent of carbonyls to vicinal diols and alkenes)

Physical Data: mp 440 °C (dec); *d* 2.640 g cm^{-3}.

Solubility: sol water, alcohol; insol diethyl ether, $CHCl_3$, CCl_4, CS_2, benzene.

Form Supplied in: dark red-violet solid; dimethoxyethane complex, $TiCl_3$.1.5DME *[18557-31-8]*, solution in CH_2Cl_2/THF, solution in hydrochloric acid.

Purification: sublimation of solid at 1 mmHg.[1b]

Analysis of Reagent Purity: aqueous solutions of $TiCl_3$ can be titrated against 0.1 N cerium(IV) sulfate.[2]

Handling, Storage, and Precautions: dry powder is pyrophoric in air; moisture sensitive; reacts violently with water, and causes skin burns. Heating in vacuo over ca. 450 °C gives $TiCl_2$ and $TiCl_4$. Use in a fume hood and in a dry box under inert atmosphere. $TiCl_3.(DME)_{1.5}$ is air sensitive, but can be stored indefinitely under Ar at room temp. Reactions involving low-valent titanium should be run under argon.[1]

Introduction.

The low-valent titanium species (Ti^0/Ti^I) generated from $TiCl_3$ are very useful for reductive coupling of aldehydes and ketones to give vicinal diols and further to alkenes. Aqueous $TiCl_3$ is used for the reduction of various functional groups (-SO, $-NO_2$, -NHOR, -X).

Reductive Coupling.[3-8]

The reagent composition of the low-valent species (Ti^0/Ti^I) to be used in the coupling reaction depends on the reducing conditions for its generation. $TiCl_3$ and ***Lithium Aluminum Hydride*** in a 1:0.6 molar ratio produces a Ti^0 species, and the molar ratio 1:0.5 a Ti^I species.[4] Other reducing agents such as ***Lithium***,[9,10] ***Sodium***,[9] ***Potassium-Graphite*** (C_8K),[11] ***Magnesium***,[9,12,13] ***Zinc/Copper Couple***[12] and Rieke titanium have been applied to $TiCl_3$.[14] Low-valent titanium species can also be obtained from ***Titanium(IV) Chloride*** by similar reductive procedures.[4] THF is usually the preferred solvent in the reductive coupling reactions, although other solvents such as dioxane or dimethoxyethane have also been used. The reaction should be performed under argon. The reagents and solvents must be pure and absolutely dry, since traces of oxidation or hydrolysis products can interfere. Variable yields in closely related reactions, and reactions difficult to reproduce, have been ascribed to aged and ineffective batches of $TiCl_3$. The variable nature of $TiCl_3$ samples is overcome by prior conversion of $TiCl_3$ into a dimethoxyethane complex, $TiCl_3.(DME)_{1.5}$. The complex is readily purified by crystallization.[7] According to McMurry et al., the optimized titanium reagent for the reductive carbonyl coupling is prepared by the Zn/Cu couple reduction of $TiCl_3.(DME)_{1.5}$.[7]

Mechanism of Carbonyl Coupling.

The reducing metal adds an electron to the oxo group and the anion radical dimerizes in a pinacol reaction (eq 1). The intermediate pinacols can be isolated at low temperature (0 °C), and are dehydroxylated at higher temperature (60 °C) to alkenes on the surface of zero-valent titanium particles.[7] For the reductive pinacol formation, ***Samarium(II) Iodide*** is an alternative.[15]

Intermolecular Coupling.

The reaction is most suitable for the preparation of symmetrical alkenes by joining two of the same carbonyl compounds, and is an excellent method for coupling of aliphatic carbonyl compounds (eq 2).[8] It is also an effective method for the synthesis of highly strained alkenes (eqs 3 and 4).[16]

Mixed Coupling.

A mixture of two different carbonyl compounds will generally react to afford a nearly statistical mixture of alkenes. However, by applying an excess of one carbonyl compound, mixed couplings can be synthetically useful (eq 5).[17]

Intramolecular Coupling.

Coupling of α,o-dicarbonyl compounds gives cycloalkenes (eq 6).[7] Difficult intramolecular couplings leading to medium- and large-ring cycloalkenes require a lengthy addition time to achieve high dilution, and the use of 4 or more equiv of titanium per carbonyl group.

Keto-ester couplings work well for five- to seven-membered ring formation. The product is the corresponding ketone.[18] Functional group compatibility includes acetal, alcohol, alkene, alkylsilane, amine, ether, halide, sulfide, and vinylsilane; incompatible are allylic alcohol, 1,2-diol, epoxide, halohydrin, α-halo ketone, nitro group, oxime, and sulfoxide.[3]

Reductions.[6]

Aqueous $TiCl_3$ is a very useful reagent for the reduction of oximes to imines. The imines are rapidly hydrolyzed to carbonyl derivatives at low pH, and the overall reaction is a mild, rapid, and efficient deoximation procedure.[19] Cr^{II} [20] and V^{II} [21] reagents have also been used for this purpose. The usefulness is exemplified by a synthesis of a vicinal tricarbonyl system via an oxime which is readily available by nitrosation of the 1,3-dioxo derivative (eq 7).[22]

The reaction with α-hydroxyimino-β-keto esters may also lead to pyrazine formation.[23] With added ***Sodium Borohydride***, amine formation has been used in the synthesis of α-amino acids.[24] By analogy to the oxime reduction, aliphatic nitro compounds are transformed into carbonyl derivatives. Reduction of the nitro group gives the corresponding nitroso derivative, with subsequent tautomerism to the oxime which reacts further as above (eq 8).[25]

Aromatic and heteroaromatic nitro compounds are also reduced to amines under mild conditions.[26] Buffered aqueous $TiCl_3$ can also be used to reduce hydroxamic acids, cyclic or acyclic (eq 9).[27] The ready cleavage of N-O bonds is attributed in part to titanium's high affinity for oxygen. Accordingly, sulfoxides are also deoxygenated cleanly and in high yields to the corresponding sulfides.[28]

(9)

α-Halo ketones are dehalogenated by $TiCl_3$.[29] A number of reductive transition metal complexes,[30] as well as SmI_2,[31] possess this ability. $TiCl_3$ is commercially available and therefore a convenient reagent. Halogen atoms in aromatics can also be removed by aqueous $TiCl_3$. Both halo- and cyanopyridines are reduced to pyridines with aqueous $TiCl_3$,[32] which should find wide application in heterocyclic chemistry (eq 10).

(10)

Highly electrophilic and polarized carbon-carbon double bonds can also be reduced with aqueous $TiCl_3$ (eq 11).[33]

(11)

Related Reagents.

Niobium(V) Chloride-Zinc; ***Samarium(II) Iodide***; ***Titanium(III) Chloride-Potassium***; ***Titanium(III) Chloride-Lithium Aluminum Hydride***; ***Titanium(III) Chloride-Zinc/Copper Couple***.

Titanium(IV) Chloride-Diazabicyclo[5.4.0]undec-7-ene

($TiCl_4$)

[7550-45-0] · Cl_4Ti · Titanium(IV) Chloride-Diazabicyclo[5.4.0]undec-7-ene · (MW 189.68) (DBU)

[6674-22-2] · $C_9H_{16}N_2$ · Titanium(IV) Chloride-Diazabicyclo[5.4.0]undec-7-ene · (MW 152.27)

(combination of reagents which allows the opening of epoxides to give chlorohydrins in the presence of acid labile groups[1])

Physical Data: see ***Titanium(IV) Chloride*** and ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.

Solubility: $TiCl_4$: sol aromatic hydrocarbons, ether, THF, dioxane, chlorohydrocarbons. DBU: sol ethers, chlorohydrocarbons, aromatic solvents.

Form Supplied in: $TiCl_4$: colorless liquid, or as a crystalline complex with THF. DBU: colorless liquid.

Preparative Methods: DBU (2 equiv) is added to a solution of the epoxide in dichloromethane. The mixture is cooled to -78 °C. $TiCl_4$ (1 equiv) is then added and the mixture allowed to warm to rt.

Handling, Storage, and Precautions: $TiCl_4$ is corrosive and moisture sensitive. DBU is a flammable liquid. The combination reagent is moisture sensitive and reactions are best performed under a dry inert atmosphere. Solvents should be dried before use.

Preparation of Chlorohydrins.

Epoxides are treated with the reagent to give chlorohydrins.[1] Mono- and disubstituted epoxides are converted in excellent yields (eq 1). Trisubstituted epoxides give moderate yields. The regiochemical outcome is such that the chlorine is added to the more stabilized carbocation center and the stereochemistry is that of a *trans* opening of the epoxide. The chlorohydrin (**2**) obtained from (-)-dihydrogeraniol epoxide (**1**) could be converted back to the epoxide without loss of optical activity (eq 2).[1] The presence of DBU is essential for the survival of acid-sensitive groups such as acetals. ***4-Dimethylaminopyridine*** has been used as an alternative to DBU but the yields are lower.

Titanium(III) Chloride-Potassium[1]

$TiCl_3$-K

($TiCl_3$)

[7705-07-9] · Cl_3Ti · Titanium(III) Chloride-Potassium · (MW 154.23) (K)

[7440-09-7] · K · Titanium(III) Chloride-Potassium · (MW 39.10)

(combination of reagents used for the in situ generation of highly oxophilic low-valent titanium species[2] which are used to effect the reductive coupling of carbonyl groups[2] (McMurry coupling) and reductive deoxygenations[3])

Physical Data: see ***Titanium(III) Chloride*** and ***Potassium***.

Solubility: $TiCl_3$: sol alcohol, hydrochloric acid; v. slightly sol DME, THF. K: insol DME, THF.

Form Supplied in: $TiCl_3$: violet, air-sensitive solid. K: metal under paraffin.

Preparative Methods: potassium metal (3.2 equiv) is washed with hexane and added to a slurry of titanium(III) chloride (1 equiv) in THF at rt under an inert atmosphere. The mixture is heated under reflux for 1 h, during which time the reaction mixture turns black. The mixture is cooled to rt and is then ready for the addition of the reaction substrates.

Handling, Storage, and Precautions: care is required when handling potassium because it reacts violently with water and protic solvents, liberating highly flammable gases which are readily ignited. Titanium(III) chloride should be stored and used under argon, preferably in a glove bag or box. The low-valent titanium reagent is sensitive to air and moisture; therefore to obtain good yields, it must be freshly prepared. All reactions should be performed under argon. If excess reagent is used, it should be quenched prior to workup by the cautious addition of methanol. Alternatively, if the use of methanol is incompatible with the products, the reaction mixture may be filtered carefully through a pad of Celite; care must be taken as the residues collected may be pyrophoric. All solvents must be dried and preferably deoxygenated or degassed before use.

Coupling of Aldehydes and Ketones.

Reduction of $TiCl_3$ with 3 equiv of potassium gives a Ti^0 species which is used in the reductive coupling (McMurry coupling) of carbonyl compounds (eq 1). Other less hazardous methods exist for the generation of Ti^0, e.g. ***Titanium(III) Chloride-Zinc/Copper Couple*** or $TiCl_3$/Li, but the reagent generated from potassium gives the most consistent results and the highest yields when coupling aliphatic aldehydes and ketones.[4] When aldehydes or nonsymmetrical ketones are coupled, the (*E*)-alkene product predominates. Even with the highly hindered 1-methyl-2-adamantanone, coupling could be achieved in 52% yield (eq 2).[5] The recently reported generation of Ti^0 from the $TiCl_3(DME)_{1.5}$ solvate and ***Zinc/Copper Couple***[6] is likely to be the reagent of choice in future. It gives good to excellent yields, while avoiding the hazards associated with the use of potassium.

(1)

(2)

The mechanism of the McMurry coupling has been studied.[7] The reaction proceeds via a pinacol coupling and subsequent deoxygenation. Using the title reagent, it is only possible to isolate good yields of the pinacol product when the formation of the alkene is disfavored, e.g. in compound (**1**),[8] where the double bond would have to be formed at a strained bridgehead (eq 3). A wide range of functionality is compatible with carbonyl coupling,[1a] although allylic alcohols, epoxides, oximes, sulfoxides, and nitro groups are not.

(1)

Gibberellic acid (3)

The reagent has been modified by the use of ***Potassium-Graphite*** as the reducing partner,[9,10] with the Ti^0 being formed on the surface of the graphite. Again, 3 equiv of potassium are generally used, although the cyclization of (**2**) to (**3**) was optimized using 2 equiv of potassium (eq 4).[11] Formally, this requires a Ti^I species for the coupling. The reaction was highly specific: no epimerization was noted at C-8a, nor was there any loss of the acetal.

(2) **(3)**

Compactin (4)

Coupling of Esters and Amides.

The Ti^0 on graphite reagent facilitates the intramolecular coupling of ketones to esters,[10] yielding enol ethers which subsequently hydrolyze to ketones (eq 5). This type of reaction has also found use in the synthesis of furans and benzofurans by the coupling of *O*-benzoyl derivatives of 1,3-dicarbonyl compounds (eq 6);[12] yields are improved by further aromatic substituents. Indoles may be prepared by analogous methods (eq 7).[12]

(5)

(6)

R = Ph, 92%; Me, 58%

(7)

Deoxygenations.

As the McMurry coupling proceeds via the pinacol, it is not surprising that Ti^0 is capable of converting 1,2-diols to alkenes in good to excellent yields. In addition to diols, $TiCl_3$/K also converts 1-phenylthio-2-benzoyloxyethanes to alkenes (eq 8).[13] Deoxygenation of phenols and enolizable ketones is achieved via the *O*-phosphate derivative (eqs 9 and 10).[3]

(8)

Miscellaneous Reductions.

The Ti^0 produced by the title reagents can be expected to perform the transformations achieved by Ti^0 generated from other reagents, e.g. coupling of thiocarbonyls to alkenes or allylic alcohols to 1,5-dienes. However, in these cases the use of potassium is not justified.

Titanium(IV) Chloride-2,2,6,6-Tetramethylpiperidine

($TiCl_4$)

[7550-45-0] · Cl_4Ti · Titanium(IV) Chloride-2,2,6,6-Tetramethylpiperidine · (MW 189.68) (TMP)

[768-66-1] · $C_9H_{19}N$ · Titanium(IV) Chloride-2,2,6,6-Tetramethylpiperidine · (MW 141.29)

(oxophilic Lewis acid for the intramolecular cyclization of unsaturated (*Z*)-allylic alcohols[1])

Physical Data: see ***Titanium(IV) Chloride*** and ***2,2,6,6-Tetramethylpiperidine***.

Solubility: $TiCl_4$: sol aromatic hydrocarbons, ether, THF, dioxane, chlorohydrocarbons. TMP: sol acid, ethers, chlorohydrocarbons, aromatic solvents.

Form Supplied in: $TiCl_4$: colorless liquid, or as a crystalline complex with THF. TMP: colorless liquid.

Preparative Methods: TMP (1.5 equiv) is added to a solution of $TiCl_4$ (1.5 equiv) in dichloromethane at 0 °C. It is assumed that a complex, analogous to the $TiCl_4$-*N*-methylaniline complex,[1,2] is formed. The mixture is then cooled to -23 °C and the (*Z*)-allylic alcohol added.

Handling, Storage, and Precautions: $TiCl_4$ is corrosive and moisture-sensitive. TMP is a flammable liquid which should be stored in colored glass. The reagent will be moisture sensitive so the reactions are best performed under a dry inert atmosphere. Solvents should be dried before use.

Cyclization of Unsaturated (*Z*)-Allylic Alcohols.

Nerol has been cyclized using $TiCl_4$-TMP to give the chloroisopropylcyclohexene shown (eq 1).[1] Use of $TiCl_4$ alone gave a complex mixture. The use of *N*-methylaniline in place of TMP gave (**1**) in 67%; this latter reagent has been much more widely used. By analogy, (*E*)-allylic alcohols could be expected to give the allylic halide, as could (*Z*)-allylic alcohols lacking further suitably disposed alkenic bonds.

Titanium(IV) Chloride-Triethylaluminum[1]

$TiCl_4$-$AlEt_3$

($TiCl_4$)

[7550-45-0] · Cl_4Ti · Titanium(IV) Chloride-Triethylaluminum · (MW 189.68) ($AlEt_3$)

[97-93-8] · $C_6H_{15}Al$ · Titanium(IV) Chloride-Triethylaluminum · (MW 114.19)

(alkene polymerization and/or oligomerization catalyst;[1] alkyne polymerization, oligomerization, and/or trimerization catalyst;[2] cationic polymerization catalyst for aldehydes, epoxides; alkylation of alkenes[3])

Physical Data: see ***Titanium(IV) Chloride*** and ***Triethylaluminum***.

Form Supplied in: $TiCl_4$: colorless (occasionally pale yellow) liquid; 1.0 M solution in dichloromethane or toluene; widely available. $AlEt_3$: colorless liquid; 1.0 M hexane solution; 25 wt % toluene solution; widely available.

Purification: reflux $TiCl_4$ with mercury or a small amount of pure copper turnings to remove the last traces of light color (due to $FeCl_3$ and VCl_4), then distil under nitrogen in an all-glass system, taking precautions to exclude moisture.[4] Distil $AlEt_3$ under vacuum in a column containing a heated nichrome spiral.[5]

Handling, Storage, and Precautions: $TiCl_4$ is moisture sensitive; fumes in air; an irritant to eyes and respiratory tract. $AlEt_3$ is flammable in air; should be kept away from water, and stored under an inert atmosphere. Use in a fume hood.

Polymerization of Ethylene, Propylene or Other α-Alkenes.

The Ziegler-Natta catalyst[6] is one of the most widely used organometallic catalysts. This type of catalyst has made it possible to obtain linear polyethylene and isotactic polypropylene under mild reaction conditions (eq 1).

(1)

The recent development of $MgCl_2$-supported catalysts has been a major breakthrough in the production of polyalkenes.[7] By the addition of other components (Lewis bases as internal and external electron donors), high isotacticity as well as high activity can be achieved.[8] $TiCl_4/AlEt_3$ without the Lewis base may be used for polyethylene synthesis or the polymerization of other monomers, but not for the preparation of isotactic polypropylene because of their low stereospecificity. When stereospecific poly(α-alkene) is the desired product, the following five components are basically used as catalyst: (1) transition metal compounds, typically $TiCl_4$; (2) a solid support ($MgCl_2$ is the most commonly reported); (3) an internal Lewis base, typically aromatic esters such as ethyl benzoate and dialkyl phthalate; (4) organoaluminum compounds (so-called cocatalyst), typically $AlEt_3$; and (5) an external Lewis base, such as aromatic esters, phenylalkoxysilanes, and ***2,2,6,6-Tetramethylpiperidine***. Although many variations are possible for this catalyst system, this article will describe only some typical examples.

Practical procedures for the preparation of a solid catalyst ($MgCl_2$-supported $TiCl_4$ with an internal Lewis base) can be found in a number of patents and in the literature. An outline of a typical procedure is as follows. Anhydrous $MgCl_2$ is mechanically co-milled with ethyl benzoate for 10-100 h and rinsed out of the mill with heptane. The solid support is suspended in a heptane solution of $TiCl_4$ and stirred for several hours at 80-100 °C. The solid is filtered and washed with hydrocarbons to remove unreacted $TiCl_4$ and dried. The content of Ti in the solid catalyst is ca. 2-5 wt %.

Polymerization is often carried out under atmospheric pressure in propylene-saturated heptane at 40-60 °C. After an external Lewis base is added, polymerization is started by adding organoaluminum compounds such as $AlEt_3$. The solvent and inert gas should be purified carefully since contamination by a slight amount of oxygen or water may affect not only the activity of the catalyst, but also the microstructure of polymers obtained. A variety of supports and their preparation methods have also been investigated. Some examples of the polymerization of propylene are shown in Table 1. Extensive investigations have also been performed for the polymerization of higher α-alkenes.[9]

Table 1 Polymerization of Propylene Catalyzed by $TiCl_4/AlEt_3$

Support	Internal Lewis base	External Lewis base	Al/Ti	Polymn. temp. (°C)	Activity[a]	I.I[b] (%)
$MgCl_2$	Ethyl benzoate[10]	Ethyl benzoate	20	rt	2.7	94
$MgCl_2$	Dibutyl phthalate[11]	$Ph_2C(OMe)_2$	140	70	4.5 6[c]	97 98
$MgCl_2$	Diisobutyl phthalate[12]	$Ph_2Si(OMe)_2$	200	60	7.0	98.5

[a] Grams of polypropylene per gram of Ti per hour. [b] Isotactic index: insoluble part of polymers in heptane which gives an index of isotacticity of obtained polymers. [c] Productivity (grams of polypropylene per gram of Ti). [d] TMP = 2,2,6,6-tetramethylpiperidine. [e] Prepared from homogeneous solution.

γ-$TiCl_3/AlEt_2Cl$, as well as $TiCl_4/AlEt_3$, is also known as a stereospecific catalyst. In the case of $TiCl_3$, a less stereoregular polymer is obtained with $AlEt_3$.[17] Many other metals, such as vanadium,[18] chromium,[19] etc., are also used as catalysts. A comparison of the Ti catalyst with Cr and V is shown in Table 2.

Table 2 Polymerization of Propylene with Various Metal Catalysts[20]

Catalyst				Polymerization			
Type	Amount of metal[a] (mmol)	Amount of $AlEt_3$ (mmol)	Monomer (mol L^{-1})	Temp. (°C)	Time (min)	Yield (g)	Activity[e]
$MgCl_2/TiCl_4$	2.46	0.51	0.27	50	20	1.89	48.3
UC-Cr[b]	142	0	0.22	60	60	3.28	0.45

[a] Metal = T, Cr, V. [b] Chromocene supported on silica. [c] Phillips CrO_3 supported on silica/alumina. [d] Gas-phase polymerization at 20 psi pressure. [e] kg of polymer per gram of metal per hour.

In the copolymerization of ethylene and α-alkenes, the distribution and sequence of each unit in the polymer chain should be considered. It is known that the presence of an α-alkene enhances the activity of the catalyst for ethylene polymerization.[21] Some examples of copolymerization are summarized in Table 3. It is commonly believed that the oxidation state of Ti at the active site is Ti^{III}. It is important for copolymerization because Ti^{III} is effective for polymerization both of ethylene and other α-alkenes, while Ti^{II} can polymerize only ethylene.[22] The existence of Ti^{II} in the catalyst system causes a mixture of copolymer and ethylene homopolymer to be formed.

Table 3 Copolymerization of a-Alkenes

Support	Internal Lewis base	External Lewis base	Monomers M_1 M_2	Polymn. temp. (°C)	Activity[a]	r_1, r_2
$MgCl_2$	Ethyl benzoate		Ethylene propylene[23]	50	58	$r_1 = 11.9$, $r_2 = 0.18$
$MgCl_2$	Dioctyl phthalate	$PhSi(OEt)_3$	Ethylene propylene[24]	60	1.7	$r_1 \cdot r_2 = 2.5$
No support			Ethylene 1-butene[25]	80		$r_1 \cdot r_2 = 0.6$ 1.1
MgH_2			Ethylene 1-hexene[26]			$r_1 = 29$ 62, $r_2 = 0.008$ 0.02
$SiO_2/EtMgCl$			Ethylene 1-hexene[27]	50	3.6 8.4	$r_1 = 26$ 53
$MgCl_2$	Diisobutyl phthalate	TMP[b] or $PhSi(OMe)_3$	Propylene 1-butene[28]	15	20 30[c]	$r_1 \cdot r_2 = 1.2$ 1.5

[a] kg of polymer per gram of Ti per hour. [b] TMP = 2,2,6,6-tetramethylpiperidine. [c] Grams of polymer per gram of catalyst.

Polymerization of Conjugated Dienes.

$TiCl_4/AlEt_3$ with a nickel catalyst is effective for the preparation of *cis*-1,4-polybutadiene.[29] *trans*-1,4-Polybutadiene can be obtained with the $TiCl_4/VCl_4/AlEt_3$ system (eq 2).[30]

Various transition metal catalysts other than titanium catalysts can also be used. A cobalt catalyst with $AlEt_3$ and $AlEt_2Cl$ gives 1,2-polybutadiene and *cis*-1,4-polybutadiene, respectively.[31] For the polymerization of isoprene, the combination $TiCl_4/AlEt_3$ gives *cis*-1,4-polymer,[32] while ***Vanadium(IV) Chloride***/$AlEt_3$[33] and $V(acac)_3/AlEt_3$[34] give *trans*-1,4-polymer and 3,4-polymer, respectively. Other substituted[35] or cyclic[36] dienes can also be polymerized with Ziegler-Natta catalysts. The $TiCl_4/AlEt_3$/phosgene system affords a random copolymer of butadiene and propylene.[37] Copolymerization of ethylene-butadiene with titanium has also been investigated.[38]

Polymerization of Other Vinyl Compounds.

Titanium-catalyzed polymerization of other vinyl compounds, such as internal alkenes,[39] cyclic alkenes, allenes,[40] and those with functional groups, have been investigated. Three modes of polymerization are known for norbornenes[41] and its derivatives:[42] a vinyl polymerization and two types of ring-opening polymerization providing polymers with *trans* and *cis* double bonds (eq 3).

Cycloalkenes show a similar behavior in their polymerization.[43] The mechanism of ring-opening polymerization is explained by metathesis at the catalyst metal.[44] Some examples have been reported on vinyl monomers with functional groups such as alkyl acrylates,[45] vinyl chloride,[46] vinylidene fluoride,[47] vinyl acetate,[48] etc.

Polymerization and Oligomerization of Alkynes.[2,49]

Although a variety of methods for the preparation of conjugated polyacetylene is known, Ziegler-Natta catalysts are the most suitable for obtaining polyacetylene film (eq 4).

$Ti(OBu)_4/AlEt_3$ provides a good film of polyacetylene on the surface of a catalyst solution.[50] In this method, a concentrated solution of $AlEt_3$ is needed. Since it can ignite easily in air, the concentrated solution should be handled carefully under an inert atmosphere. Acetylene gas is also potentially explosive. Trimerization of acetylene often competes with polymerization to give benzene (eq 4).[51] A combination of titanium compounds and ***n-Butyllithium*** is also a good catalyst system for the formation of polyene.[52] It is known that the polymerization of mono- and disubstituted acetylene is catalyzed by Group 5 or 6 metal systems[53] rather than titanium. Some substituted alkynes, such as phenylacetylene,[54] phenoxyacetylene,[55] trimethylsilylacetylene,[56] and dihaloacetylene,[57] can be polymerized or oligomerized by Ti catalysts.

Polymerization and Oligomerization of Other Compounds.

Various other kinds of compounds can be polymerized or oligomerized by the $TiCl_4/AlEt_3$ catalyst system. Ring-opening polymerization of cyclopropanes proceeds in the presence of $TiCl_4$ as well as ***Tungsten(VI) Chloride*** or ***Tin(IV) Chloride***.[58] Cyclic ethers such as trioxane[59] and propylene oxide[60] also undergo ring-opening polymerization to afford polyethers. Some bifunctional compounds, such as *o*-phthalaldehyde,[61] malealdehyde,[62] and succinonitrile[63] afford cyclopolymerization products.

Miscellaneous Reactions Yielding Small Molecules.

Some synthetic reactions which give small molecules are known. Cyclotrimerization of butadiene gives 1,5,9-cyclodecatriene.[64] Cross-cyclodimerization of ethylene and butadiene proceeds catalytically to afford vinylcyclobutane (eq 5).[65]

(5)

Alkylation of alkenes with organoaluminum reagents is catalyzed by titanium salts to give organoaluminum compounds.[3,66] $AlEt_2Cl$ rather than $AlEt_3$ usually gives better results (eq 6).

Titanium(IV) Chloride-Zinc

$TiCl_4$-Zn

($TiCl_4$)

[7550-45-0] · Cl_4Ti · Titanium(IV) Chloride-Zinc · (MW 189.68) (Zn)

[7440-66-6] · Zn · Titanium(IV) Chloride-Zinc · (MW 65.39)

(combination of reagents which generates a divalent titanium chloride species: an oxophilic reducing agent used for carbonyl couplings[1] and reduction of sulfoxides,[2] etc.)

Physical Data: see ***Titanium(IV) Chloride*** and ***Zinc***.

Solubility: $TiCl_4$: sol aromatic hydrocarbons, ether, THF, dioxane, chlorohydrocarbons. Zinc: insol organic solvents.

Form Supplied in: $TiCl_4$: colorless liquid, or as a crystalline complex with THF; also supplied as solutions in toluene or dichloromethane. Zinc: metallic grey powder.

Preparative Methods: zinc powder (3 equiv) is added slowly to a mixture of the reagent(s) and $TiCl_4$ (1.5 equiv) in THF at -10 °C under argon. The mixture is then heated to the required temperature for an appropriate time.

Handling, Storage, and Precautions: $TiCl_4$ is corrosive and moisture sensitive. Zinc powder will react with water, liberating flammable gases and may spontaneously ignite in air. $TiCl_2$ is moisture and oxygen-sensitive and all reagents and reaction mixtures should therefore be handled under a dry inert atmosphere. Solvents should be dried before use.

Coupling of Aldehydes and Ketones.

Mukaiyama et al. reported that the reagent can be used to effect pinacol couplings (THF, rt, 2 h) or, under more forcing conditions, to give alkenes (THF or dioxane, reflux, >4 h; McMurry coupling).[1] When aldehydes or nonsymmetrical ketones are coupled, the stereochemistry about the new double bond is predominantly (*E*) (eq 1).

(1)

Alicyclic ketones are also coupled in high yields, although longer reaction times are required (eq 2).[3]

(2)

Intramolecular couplings have been used to prepare cembrane-type diterpenes,[4,5] e.g. isosarcophytol A (eq 3), thiophenes,[6] and 2,5-dihydrothiophenes (eq 4).[7]

(3)

(4)

Other Reductive Coupling Reactions.

Ketones have been shown to couple intramolecularly with esters,[8] imines,[9] and nitro groups.[9] Aryl ketones give moderate yields of benzofurans (eq 5); aryl substituents in the 2-position of the furan are advantageous. Coupling with imines is analogous to the pinacol coupling, giving 2-aminoethanols (eq 6). The reaction with nitro groups affords cyclic imines and has been used to effect a reasonable synthesis of some diarylpyrrolines (eq 7).

(6)

Benzonitriles are coupled to give 1,2-diarylethanones in moderate yield,[10] while alicyclic dinitriles separated by 3-5 atoms gives pyrazolines in modest yield (eq 8).[11] Aryl aldoximes and ketoximes give 1,2-diamino compounds in low yields.[12]

Alkene Synthesis.

The action of $TiCl_4$/Zn/dihaloalkanes is discussed in ***Titanium(IV) Chloride***. As well as converting 1,2-diols to alkenes (see above), β-hydroxy phenyl sulfides (eq 9),[13,14] β-hydroxy pyridyl sulfides (eq 10),[14] and β-benzoyloxy sulfides (eq 11)[15] undergo reductive elimination to give alkenes. To achieve good yields, either pyridine is used as solvent or an amine is added to the reaction mixture. In the latter case, good yields of *exo*-methylene compounds can be obtained. However, more direct methods, e.g. Wittig or Tebbe, are preferred.

(11)

Phenyl vinyl sulfides may be obtained from β-hydroxy thioacetals[14] or from α-halo-β-hydroxy sulfoxides,[16] while α,α-dichloro sulfoxides give the chloroalkene (eq 12).[16]

(12)

Excellent yields of alkenes are obtained from 1,2-dibromo compounds when treated with zinc and catalytic amounts of $TiCl_4$[17] via a *trans*-stereoselective reductive elimination (eqs 13 and 14).

(13)

(14)

Deoxygenations.

Heteroaromatic amine oxides are reduced to the corresponding nitrogen-containing heteroaromatic system,[18] sulfoxides to sulfides (eq 15),[2] and triphenylarsine oxide to triphenylarsine,[19] all in good to excellent yields. The reduction of sulfoxides proceeds more rapidly and under less extreme conditions than those for ***Titanium(III) Chloride***.

(15)

Difluoromethylaldol Condensations.

Zinc and catalytic quantities of $TiCl_4$ react with chlorodifluoromethyl ketones and ketones or aldehydes to give the aldol products (eq 16).[20] Yields are moderate to good, but poor when the electrophile is an enone, enal, or aromatic carbonyl.

(16)

Simple α-chloro ketones undergo *erythro*-selective aldol reactions,[20] but the yields and selectivities do not reach the levels expected for controlled aldol condensations.

Titanium Tetraisopropoxide[1]

Ti(O-*i*-Pr)$_4$

[546-68-9] · $C_{12}H_{28}O_4Ti$ · Titanium Tetraisopropoxide · (MW 284.28)

(mild Lewis acid used as a catalyst in transesterification reactions, nucleophilic cleavages of 2,3-epoxy alcohols and isomerization reactions; additive in the Sharpless epoxidation reaction and in various reactions involving nucleophilic additions to carbonyl and α,β-unsaturated carbonyl compounds)

Physical Data: mp 18-20 °C; bp 218 °C/10 mmHg; *d* 0.955 g cm^{-3}.

Solubility: sol a wide range of solvents including ethers, organohalides, alcohols, benzene.

Form Supplied in: low-melting solid; widely available.

Handling, Storage, and Precautions: flammable and moisture sensitive; acts as an irritant.

Transesterification and Lactamization Reactions.[2-5]

Ti(O-*i*-Pr)$_4$, as well as other titanium(IV) alkoxides, has been recommended as an exceptionally mild and efficient transesterification catalyst which can be used with many acid-sensitive substrates (eq 1).[2,3] Thus the acetonide as well as C=O, OH, OTBDMS, and lactam functional groups (eq 2) are unaffected by these conditions, although acetates are hydrolyzed to the parent alcohol. The alcohol solvent employed in such processes need not be anhydrous, nor need it be identical with the OR group in the titanate, because exchange of these moieties is generally slow compared to the transesterification reaction.

(1)

(2)

N-Protected esters of dipeptides can be transesterified using Ti(O-*i*-Pr)$_4$ in the presence of 4 Å molecular sieves and this procedure provides a good way of converting methyl esters into their benzyl counterparts. Such reactions (eq 3) proceed without racemization in 70-85% yield.[4] In a related process,[5] β-, γ-, and δ-amino acids undergo lactamization on treatment with Ti(O-*i*-Pr)$_4$ in refluxing 1,2-dichloroethane (eq 4).

R, R^1 = H, Me

n = 1-3

Nucleophilic Cleavage of 2,3-Epoxy Alcohols and Related Compounds.[6-10]

Titanium alkoxides are weak Lewis acids which generally have no effect on simple epoxides. However, reaction of 2,3-epoxy alcohols (available, for example, from the Sharpless-type epoxidation of allylic alcohols) with nucleophiles in the presence of $Ti(O\text{-}i\text{-}Pr)_4$ results in highly regioselective ring-cleavage reactions involving preferential nucleophilic attack at C-3 (eq 5).[6] In the absence of the titanium alkoxide, no reaction is observed under otherwise identical conditions, except in the case of PhSNa.

R = $Me(CH_2)_2$; YH = $CH_2{=}CHCH_2OH$	90%; C-3:C-2 > 100:1
R = $Me(CH_2)_2$; YH = Et_2NH	90%; C-3:C-2 = 20:1
R = $Me(CH_2)_2$; YH = $PhCO_2H$	74%; C-3:C-2 > 100:1
R = $Me(CH_2)_2$; YH = TsOH (with 2,6-lutidine)	64%; C-3:C-2 > 100:1
R = $Me(CH_2)_2$; YH = PhSH	95%; C-3:C-2 = 6.4:1
R = $Me(CH_2)_6$; YH = AcSH	91%; C-3:C-2 > 100:1
R = $Me(CH_2)_6$; $Y^- = NO_3^-$	86%; C-3:C-2 > 100:1

These types of conversion can be extended[7] to 2,3-epoxy carboxylic acids (glycidic acids) and the related amides. The former compounds are readily available through ***Ruthenium(VIII) Oxide***-mediated oxidation of the appropriate 2,3-epoxy alcohols (eq 6).

(6)

The C-3:C-2 selectivity is, in the cases shown above, greater than 100:1, although lower selectivities (e.g. 20:1) are observed with other nucleophiles such as Et_2NH and PhSH. It should be noted that glycidic acids and amides react preferentially with dialkylamines at C-2, but one equivalent or greater of $Ti(O\text{-}i\text{-}Pr)_4$ ensures reaction occurs with high selectivity at C-3. Combining this type of protocol with the Sharpless asymmetric epoxidation reaction has permitted the development of stereoselective syntheses (eqs 7 and 8)[6,7] of all four stereoisomers of the unusual *N*-terminal amino acid of amastatin, a tripeptide competitive inhibitor of aminopeptidases.[8]

(7)

(8)

The reaction of both open-chain and cyclic 2,3-epoxy alcohols with molecular ***Bromine*** or ***Iodine*** in the presence of Ti(O-*i*-Pr)$_4$ at 0 °C leads to the regioselective formation of halo diols (eq 9).[9a] Interestingly, if these reactions are conducted at 25 °C a 1:1 mixture of the C-2 and C-3 cleavage products is obtained, and the same outcome is observed, even at 0 °C, when the acetate derivative of the 2,3-epoxy alcohol is involved as substrate. Dialkylamine hydrochlorides can be used as sources of halide nucleophiles in these types of epoxide ring-cleavage reactions.[9b]

(9)

87% (X = I); C-3:C-2 = 7:1
78% (X = Br); C-3:C-2 = 15:1

2,3-Epithio alcohols have been obtained by reacting 2,3-epoxy alcohols with ***Thiourea*** at room temperature or 0 °C in the presence of Ti(O-*i*-Pr)$_4$ and using THF as solvent (eq 10).[10] The reactions proceed with high regio- and stereoselectivity, *trans*-substituted 2,3-epoxy alcohols giving only *trans*-2,3-epithio alcohols with complete inversion of configuration at both stereogenic centers. However, when *cis*-2,3-epoxy

alcohols are used as starting materials the yields of epithio alcohols were low and thiodiols were also formed. Epithiocinnamyl alcohols could also be prepared from the corresponding epoxycinnamyl alcohols at 0 °C. However, these products were found to decompose to cinnamyl alcohol and sulfur on standing. Without Ti(O-*i*-Pr)$_4$, thiourea was insoluble in THF and the reaction did not proceed. One equivalent of Ti(O-*i*-Pr)$_4$ was required to achieve complete reaction, and THF was the best solvent (no reaction was observed in ether, CH_2Cl_2, or benzene under similar conditions).

(10)

Isomerization Reactions.[11-14]

The reaction of certain 2,3-epoxy alcohols with Ti(O-*i*-Pr)$_4$ can result in isomerization. For example (eq 11), reaction of the illustrated substrate in CH_2Cl_2 results in rearrangement to the isomeric enediol, and this conversion represents a key step in a synthesis of the marine natural product pleraplysillin.[11]

(11)

Under similar conditions, the pendant double bond attached to a 2,3-epoxy alcohol acts as an internal nucleophile attacking at C-3, resulting, after proton loss, in a mixture of cyclized products (eq 12).[12] The cyclopropane-containing products are believed to arise via a retro-homo Prins reaction. Pendant triple bonds can also participate in related cyclization reactions and cyclic allenes result (eq 13).[12] The observation that the *threo* isomer of the substrate shown in eq 12 is stable to Ti(O-*i*-Pr)$_4$ has led to the suggestion that an intramolecular metal alkoxide is the active catalyst in successful cyclization reactions.

Ti(O-*i*-Pr)$_4$ has also played a key role in the synthesis of taxanes (eq 14).[12b,c]

Allylic hydroperoxides, which are readily obtained by reaction of the corresponding alkene with ***Singlet Oxygen***, have been shown to isomerize to the corresponding 2,3-epoxy alcohol when treated with catalytic amounts of Ti(O-*i*-Pr)$_4$ (eq 15).[13] The title reagent is the one of choice when converting di-, tri-, and tetrasubstituted alkenes (both cyclic and acyclic) into the corresponding 2,3-epoxy alcohols by this protocol. The reactions are generally highly stereoselective and deoxygenation of the allylic hydroperoxide (to give the corresponding allylic alcohol) is not normally a process which competes significantly with the isomerization reaction.

This type of chemistry has been extended to the preparation of epoxy diols from chiral allylic alcohols (eq 16).[13,14] The methodology is impressive in that three successive chiral centers are constructed with predictable configuration. Furthermore, the rapid rate of the isomerization process is remarkable, given that α,β-unsaturated diols are generally poor substrates for titanium metal-mediated epoxidations. This rate enhancement is attributed to the tridentate nature of the intermediate hydroperoxides.

Asymmetric Epoxidation Reactions.[15]

While Ti(O-*i*-Pr)$_4$ clearly has the capacity to bring about the nucleophilic ring-cleavage of 2,3-epoxy alcohols (see above), it remains the preferred species for the preparation of the titanium tartrate complex central to the Sharpless asymmetric epoxidation process (see, for example, eq 7). Since *t*-butoxide-mediated ring-opening of 2-substituted 2,3-epoxy alcohols (a subclass of epoxy alcohols particularly sensitive to nucleophilic ring-cleavage) is much slower than by isopropoxide, the use of Ti(O-*t*-Bu)$_4$ is sometimes recommended in place of Ti(O-*i*-Pr)$_4$. However, with the reduced amount of catalyst that is now needed for all asymmetric epoxidations, this precaution appears unnecessary in most instances.

Nucleophilic Additions to Carbonyl Compounds.[16-28]

A wide range of organometallic compounds react with Ti(O-*i*-Pr)$_4$ to produce organotitanium/titanium-ate species which may exhibit reactivities that differ significantly from those of their precursor.[1] Thus Ti(O-*i*-Pr)$_4$ forms -ate complexes with, amongst others, Grignard reagents and the resulting species show useful selectivities in their reaction with carbonyl compounds. For example, the complex with allylmagnesium chloride is highly selective in its reaction with aldehydes in the presence of ketones, or ketones in the presence of esters (eq 17).[16] Interestingly, the corresponding amino titanium-ate complexes react selectively with ketones in the presence of aldehydes.

(17)

Reaction of certain sulfur-substituted allylic anions with Ti(O-*i*-Pr)$_4$ produces a 3-(alkylthio)allyltitanium reagent that condenses, through its α-terminus, with aldehydes to give *anti*-β-hydroxy sulfides in a highly stereo- and regioselective manner (eq 18). These latter compounds can be transformed, stereoselectively, into *trans*-vinyloxiranes or 1,3-dienes.[17]

(18)

The titanium species derived from sequential treatment of α-alkoxy-substituted allylsilanes with ***s-Butyllithium*** then Ti(O-*i*-Pr)$_4$ engages in a Peterson alkenation reaction with aldehydes to give, via electrophilic attack at the α-terminus of the allyl anion, 2-oxygenated 1,3-butadienes which can be hydrolyzed to the corresponding vinyl ketone (eq 19).[18a]

(19)

The titanium-ate complexes of α-methoxy allylic phosphine oxides, generated in situ by reaction of the corresponding lithium anion and Ti(O-*i*-Pr)$_4$, condense with aldehydes exclusively at the α-position to produce homoallylic alcohols in a diastereoselective fashion.[18b] The overall result is the three-carbon homologation of the original aldehyde, and this protocol has been used in a synthesis of (-)-aplysin-20 from nerolidol.[19] The titanium-ate complex produced by reaction of the chiral lithium anion of an (*E*)-crotyl carbamate with Ti(O-*i*-Pr)$_4$ affords γ-condensation products (homoaldols) on reaction with aldehydes.[18c,d] Allyl anions produced by the reductive metalation of allyl phenyl sulfides condense with α,β-unsaturated aldehydes in a 1,2-manner at the more substituted (α) allyl terminus in the presence of Ti(O-*i*-Pr)$_4$.[20] 1,2-Addition of dialkylzincs to α,β-unsaturated aldehydes can be achieved with useful levels of enantiocontrol when the reaction is conducted using a chiral titanium(IV) catalyst in the presence of Ti(O-*i*-Pr)$_4$ (eq 20).[21] Higher ee values are observed when an α-substituent (e.g. bromine) is attached to the substrate aldehyde, but a β-substituent *cis*-related to the carbonyl group has the opposite effect.

(20)

Highly enantioselective trimethylsilylcyanation of various aldehydes can be achieved by using ***Cyanotrimethylsilane*** in the presence of a modified Sharpless catalyst consisting of Ti(O-*i*-Pr)$_4$ and chiral diisopropyl tartrate.[22] Best results are obtained using dichloromethane as solvent and isopropanol as additive and running the reaction at 0 °C. The same type of catalyst system also effects the asymmetric ring-opening of symmetrical cycloalkene oxides with ***Azidotrimethylsilane***. *trans*-2-Azidocycloalkanols are obtained in up to 63% optical yield.[22] The titanium amide complexes derived from the reaction of lithium dialkylamides with Ti(O-*i*-Pr)$_4$ condense with alkyl and aryl aldehydes and the resulting aminal derivatives undergo C-O bond displacement by benzylmagnesium chloride, thereby generating α-substituted β-phenethylamines (eq 21).[23]

(21)

The aldol-type condensation of aldehydes and ketones with ketenimines[24] and ketones[25] can be catalyzed by titanium alkoxides and, in appropriate cases, useful levels of stereocontrol can be achieved (eq 22).

(22)

A variety of useful reducing agents have been generated by combining hydrides with Ti(O-*i*-Pr)$_4$.[26-28] For example, the combination of 5 mol % Ti(O-*i*-Pr)$_4$ with 2.5-3.0 equiv of ***Triethoxysilane*** cleanly hydrosilylates esters to silyl ethers at 40-55 °C, and these latter compounds can be converted into the corresponding primary alcohols via aqueous alkaline hydrolysis (eq 23).[26] The actual reducing agent is presumed to be a titanium hydride species which is produced by a σ-bond metathesis process involving Ti(O-*i*-Pr)$_4$ and the silane. The procedure has considerable merit in that no added solvent is required and the active reagent can be generated and used in air. Halides, epoxides, alcohols, and an alkyne all survive the reduction process. ***Lithium Borohydride*** reduction of 2,3-epoxy alcohols yields 1,2-diols highly regioselectively when used in the presence of Ti(O-*i*-Pr)$_4$,[27] while the combination of the reagent with ***Sodium Cyanoborohydride*** is reported[28] to offer superior results in reductive amination processes with difficult carbonyls and those sensitive to acidic conditions.

(23)

Miscellaneous Applications.[29-31]

The chemoselective oxidation of alcohols and diols using Ti(O-*i*-Pr)$_4$/***t-Butyl Hydroperoxide*** has been reported.[29] The title reagent has also been employed as a catalyst in Diels-Alder reactions[30] and as an additive in the palladium-catalyzed reaction of aryl-substituted allylic alcohols with zinc enolates of β-dicarbonyl compounds (eq 24).[31] The latter reaction is presumed to generate *C*-allylated β-dicarbonyl compounds as the primary products of reaction, but these compounds suffer deacylation in the presence of Ti(O-*i*-Pr)$_4$.

Titanium Tetrakis(diethylamide)[1]

$Ti(NEt_2)_4$

[4419-47-0] · $C_{16}H_{40}N_4Ti$ · Titanium Tetrakis(diethylamide) · (MW 336.48)

(for the in situ protection of aldehydes and ketones,[2] for the formation of enamines from ketones;[3] for conjugate diethylamino addition to α,β-unsaturated ketones and esters;[4] and for diethylamino transfer to carboxylic[5] and phosphonic acid esters[6])

Physical Data: bp 112 °C/0.3 mmHg; *d*204 0.931 g cm^{-3}; ^{13}C NMR (benzene-d_6): δ = 45.5, 15.7 ppm.

Solubility: sol THF, ether, CH_2Cl_2.

Form Supplied in: not commercially available.

Preparative Methods: a number of syntheses of $Ti(NEt_2)_4$ have been described,[7] the following affording a very pure product (eq 1).[8]

It is likely that the parent compound $Ti(NMe_2)_4$ is accessible via the analogous route, although this has not been demonstrated. $Ti(NMe_2)_4$ is best synthesized by reacting $LiNMe_2$, prepared from $HNMe_2$ and *n*-butyllithium, with $TiCl_4$.[7]

Handling, Storage, and Precautions: is moisture sensitive and should be handled and stored under an inert gas atmosphere (e.g. N_2); nonprotic solvents need to be used; syringe techniques are adequate. Use in a fume hood.

In Situ Protection of Aldehydes and Ketones.

Classical reagents such as alkyllithium reagents and Li enolates derived from esters generally do not react chemoselectively with dicarbonyl compounds or other polyfunctional substrates. In many cases, titanation of such reactive reagents using ***Titanium(IV) Chloride***, ***Chlorotitanium Triisopropoxide***, or ***Titanium Tetraisopropoxide*** solves such problems, as in aldehyde-selective addition reactions of keto aldehydes.[1] However, if the *less* reactive site is required to undergo C-C bond formation, a three-step sequence involving protection, reaction, and deprotection is necessary. Since the introduction of protective groups is not always completely regioselective, difficulties arise. In such cases the in situ protection of carbonyl functionalities using $Ti(NR_2)_4$ (R = Me, Et) may solve the problem.[2] Aldehydes readily react with $Ti(NEt_2)_4$ at -78 °C to form amide adducts which are stable in solution (eq 2), whereas ketones require temperatures above -30 °C at which the corresponding adducts begin to fragment. The less bulky reagent $Ti(NMe_2)_4$ forms stable adducts with aldehydes and ketones at low temperatures.[2]

Consequently, complete chemoselective in situ protection of the aldehyde function of keto aldehydes is possible. Addition of a reactive carbon nucleophile such as $CH_2{=}CHCH_2MgCl$, $PhSO_2CH_2Li$, or $CH_2{=}CH(OEt)OLi$ then occurs at the less reactive ketone site. Since deprotection at the aldehyde function occurs quantitatively during aqueous workup, the one-pot procedure constitutes a simple way to enforce ketone selectivity (eq 3).[2]

This protocol for in situ protection has been applied in the regioselective alkenation of keto aldehydes (eq 4).[9]

Site selectivity in diketones is also possible, in such cases the parent compound $Ti(NMe_2)_4$ being the reagent of choice. Here again, the direction of chemoselectivity is reversed with respect to the reaction of organotitanium reagents in the absence of $Ti(NR_2)_4$. In situ protection allows for reactions at the sterically more hindered site, e.g. (eq 5).[2]

The above in situ methodology has limitations in that very reactive carbon nucleophiles need to be employed following the protection step, i.e. rapid reactions below -30 °C need to be carried out at which temperature the protected forms maintain stability. Indeed, refluxing ketones with $Ti(NEt_2)_4$ is a method of enamine formation.[3] A related protocol based on the in situ protection of aldehydes by $TiCl_4/PPh_3$ is also easy to perform, but its synthetic scope remains to be established.[10] Lithium morpholide likewise adds to aldehydes in situ (mainly aromatic aldehydes), but the basic nature of the reagent causes undesired enolization in the case of ketones.[11]

Michael Additions to α,β-Unsaturated Carbonyl Compounds.

Titanium amides such as $Ti(NEt_2)_4$ readily add to α,β-unsaturated esters and ketones in a Michael fashion.[4] The intermediate tris(amino)titanium enolates can be intercepted with aldehydes, the overall process being a tandem conjugate addition-aldol reaction

sequence.[4] α,β-Unsaturated aldehydes were not tested, but an earlier publication reports the reaction of cinnamaldehyde with $Ti(NMe_2)_4$, leading to the corresponding aminal via 1,2-addition.[5]

Dialkylamino Group Transfer to Carboxylic and Phosphonic Acid Esters.

Carboxylic acid esters react with $Ti(NMe_2)_4$ to form the corresponding amides.[5] Similar exchange reactions have been used extensively in phosphorus chemistry, as in the selective diethylamino group transfer to phosphoryl centers (eq 6).[6]

Titanium(III) Chloride-Lithium Aluminum Hydride[1]

$TiCl_3$-$LiAlH_4$

($TiCl_3$)

[7705-07-9] · Cl_3Ti · Titanium(III) Chloride-Lithium Aluminum Hydride · (MW 154.23) ($LiAlH_4$)

[16853-85-3] · AlH_4Li · Titanium(III) Chloride-Lithium Aluminum Hydride · (MW 37.96)

(reagent combination for the production of low-valent titanium which is used for the inter- and intramolecular reductive coupling of carbonyl and dicarbonyl compounds, as well as reductive elimination reactions)

Physical Data: see ***Titanium(III) Chloride*** and ***Lithium Aluminum Hydride***.

Solubility: THF and DME are the favored solvents for reactions involving low-valent titanium.

Form Supplied in: a 4:1 ball-milled mixture of $TiCl_3$ and $LiAlH_4$ is available, which serves as a precursor to the McMurry reagent.

Handling, Storage, and Precautions: most commonly, low-valent titanium species are prepared, under an inert atmosphere (nitrogen or argon), immediately prior to use. Presumably the reagent is pyrophoric, although this property may be due to the residual reducing agent used in the preparation process rather than an inherent property of Ti^0/Ti^I itself. The reagent is moisture sensitive.

Reductive Coupling Reactions.[2-14]

The combination of $TiCl_3$ and $LiAlH_4$ produces the McMurry reagent which has been one of the most popular of the low-valent titanium reagents (see ***Titanium***) employed for reductive coupling of carbonyls to alkenes. Depending on the molar ratio of $TiCl_3$ to $LiAlH_4$ used, either Ti^I or Ti^0 is produced. It has been suggested that the optimum ratio of $TiCl_3$ to $LiAlH_4$ for coupling is 2:1.[3] Crossed intermolecular reductive couplings of two different carbonyl compounds are readily effected by this reagent if one of the components, often acetone, is used in excess (eq 1).[4]

(1)

The McMurry coupling reaction has provided a means for the synthesis of a range of novel hydrocarbons,[1] including strained alkenes,[5] and torsionally distorted systems (eq 2).[6] When the illustrated reaction is carried out in a chiral solvent, the (±)-isomer is produced preferentially.

(2)

Intramolecular couplings of a wide range of α,o-diketones are readily effected by $TiCl_3/LiAlH_4$ and even highly strained cyclopropenes can be prepared (eq 3).[7] However, it is generally found that the ***Titanium(III) Chloride-Zinc/Copper Couple*** reagent is more effective for such intramolecular processes.

(3)

These cyclocoupling processes have been extended to keto esters and keto acids,[8] with the resulting formation of cycloalkanones. Such a conversion has been employed as the key step in the synthesis of a ring-fused cyclononanone (eq 4), a precursor to the natural product isocaryophyllene.[9] Interestingly, accompanying the cyclization process is the (*E*) -> (*Z*) isomerization about the double bond. Such cyclizations presumably proceed through the intermediate enol ether which hydrolyzes to the product cycloalkanone on acidic workup. Such intramolecular keto ester couplings work particularly well for the formation of five- to seven-membered rings, but higher homologs are formed in lower yield. Often, a considerable amount of work is needed to optimize the yields in such reactions. The best results are obtained with a low-valent titanium reagent prepared by the reduction of $TiCl_3$ with $LiAlH_4$ in the presence of ***Triethylamine***. For reasons not fully understood, neither the $TiCl_3$/Zn(Cu) nor the $TiCl_3(DME)_{1.5}$/Zn(Cu) reagent works as well.

(4)

The reagent produced from a 3:1 mixture of $TiCl_3$ and $LiAlH_4$ effects reductive couplings of allylic and benzylic alcohols (eq 5);[10] Ti^{II} alkoxides may be involved.[11] In some cases (e.g. with farnesol), couplings lead to mixtures of regioisomeric products. Reduction of benzyl alcohols affords the corresponding 1,2-diphenylethane.[10] Benzyl halides behave in a similar fashion, while α,α-dihalotoluenes react with the McMurry reagent to give stilbenes (eq 6).[12]

(5)

(6)

Intramolecular variants of such processes are also known. Thus reductive cyclization of certain 1,3-diols affords cyclopropanes (eq 7).[13] In the example given, inversion of configuration is observed at one of the cyclization centers; this has been taken as evidence that an anionic intermediate is involved which cyclizes in the illustrated manner.

(7)

The bis-*O*-methyl ether derivative of the diol shown in eq 7 also cyclizes to give the same product, this time in 60% yield. In a presumably related process (eq 8), the reagent derived from a 4:1 mixture of $TiCl_3$ and $LiAlH_4$ effects the conversion of α,α´-bis(trimethylsiloxy) sulfides into the corresponding alkenes. The reaction probably proceeds via an intermediate episulfide.[14]

PhCH=CHPh (8)

>80% (*E*)

Reductive Elimination Reactions.[12,15-18]

The conversion of β-ionone into vitamin A involves, in the later stages, reaction of the low-valent titanium species produced from a 2:1 mixture of $TiCl_3$ and $LiAlH_4$ with an allylic diol (either the (*E*)- or (*Z*)-isomer) (eq 9). The result is the formation of an (*E*,*E*)-diene.[15]

(9)

Analogous reduction of the primary acetate (as opposed to the primary silyl ether shown) gave a mixture of the (*E*,*E*)- and (*E*,*Z*)-dienes.[15] A similar reduction process has been employed in a synthesis of 13-*cis*-retinoic acid.[16] The McMurry reagent has also been used to prepare

alkenes from the corresponding bromohydrin,[17] epoxide,[18] and *vic*-dibromide.[12] In the latter two cases, at least, the reaction is not stereospecific. For example, reduction of either pure (*Z*)- or pure (*E*)-5-decene epoxide gives a 4:1 mixture of (*E*)- and (*Z*)-5-decene.[18]

Titanium(III) Chloride-Zinc/Copper Couple[1]

$TiCl_3$-Zn(Cu)

($TiCl_3$)

[7705-07-9] · Cl_3Ti · Titanium(III) Chloride-Zinc/Copper Couple · (MW 154.23) (Zn)

[7440-66-6] · Zn · Titanium(III) Chloride-Zinc/Copper Couple · (MW 65.39)

(reagent combination for the production of low-valent titanium which is used for the inter- and intramolecular reductive coupling of carbonyl and dicarbonyl compounds)

Physical Data: see ***Titanium(III) Chloride*** and ***Zinc/Copper Couple***.

Solubility: unknown but presumably low in most organic solvents. THF and DME are the favored solvents for reactions involving this reagent combination.

Handling, Storage, and Precautions: the low-valent titanium species produced by reacting $TiCl_3$ with zinc/copper couple is generally made under an argon atmosphere immediately prior to use. The reagent may be pyrophoric and is certainly moisture sensitive.

Reductive Coupling Reactions.[1-12]

Among the numerous sources of low-valent ***Titanium*** used for the reductive couplings of carbonyl compounds, the Ti^0 reagent produced by reacting $TiCl_3$ with freshly prepared zinc/copper couple[2] is considered the most effective for many intramolecular coupling reactions of dicarbonyls (see, however, ***Titanium(III) Chloride-Lithium Aluminum Hydride***). Up to 22-membered cycloalkenes have been formed by coupling the appropriate open-chain dicarbonyl precursor with this reagent. The reagent has been employed by its originator, McMurry,[2] in the key steps of a number of natural product syntheses. For example, such reductive cyclizations have been used in the preparation of humulene (eq 1),[3] as well as a 45:55 mixture of helminthogermacrene and β-elemene (eq 2).[4] The reagent has also been exploited in the preparation of compactin and mevinolin analogs,[5] flexibilene,[3a,c] some zizaene sesquiterpenes including (±)-isokhusimone,[6] as well as verticillene.[7]

(1)

Under thermally mild conditions (<=25 °C), α,o-dials react with a 1:9 mixture of $TiCl_3$:Zn(Cu) in DME to give 6- to 14-membered cyclic pinacols. *cis*-Pinacols are the major products when 6- to 8-membered rings are produced while *trans*-pinacols predominate in rings of 10 or more members.[8] This type of cyclization has been employed in the synthesis of the 14-membered ring associated with sarcophytol B (eq 3).[8b]

A range of structurally novel hydrocarbons[1] have been prepared using the title reagent, including optically active doubly bridged allenes,[9] betweenanenes,[10] in-out bicycloalkanes,[11] and intracyclic π-systems (eq 4),[12] some of which are capable of forming stable metal complexes.

The intermolecular coupling of two molecules of retinal to yield β-carotene (94%) has been effected with the title reagent and, by virtue of the product's use as a yellow food-coloring agent and a source of vitamin A, this efficient titanium-based synthesis is now licensed for use in commercial production.[13] Aromatic aldehydes and ketones possessing other potentially reducible groups (such as the acyloxy, methoxy carbonyl, and tosyloxy moieties) give Ti^0-induced carbonyl reductive coupling products in high yields when the $TiCl_3$/Zn(Cu) reagent is employed.[14]

McMurry has now developed[15] an optimized procedure for the reductive coupling of dicarbonyls which employs a combination of the solvate

$TiCl_3(DME)_{1.5}$ and a Zn(Cu) couple to form the low-valent titanium reagent.

Titanocenemethylene-Zinc Halide Complex[1]

$Cp_2Ti{=}CH_2.ZnX_2$

(methylenation reagent of unsaturated carbonyl groups[1])

Solubility: sol THF, toluene.

Preparative Methods: the reaction of ***Diiodomethane*** with ***Zinc*** dust in THF at 45 °C produces $CH_2(ZnI)_2$ in ca. 45% yield. Its reaction with ***Dichlorobis(cyclopentadienyl)titanium*** (25 °C, 30-60 min) affords a deep red solution of the titanocenemethylene-zinc halide complex (ca. 45-55% yield).[2]

Handling, Storage, and Precautions: should be handled and stored under an inert atmosphere.

Methylenation of Unsaturated Carbon Centers.

The titanocenemethylene-zinc halide complex reacts rapidly with ketones in good yields (eq 1).[2] The alkenation of an α,β-unsaturated ketone gives the corresponding diene (eq 2).[2] Whereas no clean reaction is observed with acid chlorides, the addition of the titanocenemethylene complex to a nitrile provides, after a workup with D_2O, an α-deuterated ketone (eq 3).[2] The reaction with alkynes is less straightforward and moderate regio- and chemoselectivity is observed (eq 4).[2]

Alternative titanium-based reagents can be used and have found more applications than the titanocenemethylene-zinc halide complex.[1] The Tebbe reagent μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***, although involving the use of pyrophoric ***Trimethylaluminum***, has found broader application in synthesis.[1,3] A related reagent prepared from zinc, a dihalomethane, and ***Titanium(IV) Chloride*** (Takai reagent)[4] proved also to be a useful methylenation reagent of aldehydes and ketones. After a modification, this reagent is also able to perform a methylenation (and alkylidenation) of various carboxylic acid derivatives (eq 5).[5] The preparation modification reported by Lombardo provides a mild, nonbasic method for the methylenation of ketones. The Lombardo reagent is compatible with a wide variety of functional groups. Compared to the original procedure of Takai, the modification of Lombardo involves the preformation of the reagent, which was found to be stable at low temperature (eq 6).[6] Finally, Nysted reported the preparation of the alkenation reagent [$XZnCH_2ZnCH_2ZnX.THF$] which, in the absence of titanium salts, proved to be highly efficient for the methylenation of steroids (eq 7).[7]

p-Toluenesulfinic Acid

[536-57-2] · $C_7H_8O_2S$ · *p*-Toluenesulfinic Acid · (MW 156.22) (Na salt.H_2O)

[824-79-3] · $C_7H_9O_3NaS$ · *p*-Toluenesulfinic Acid · (MW 196.22)

(preparation of alkyl, vinyl, and allyl sulfones; starting material for the preparation of chiral sulfoxides; mild acid catalyst)

Physical Data: mp 85 °C; pK_a 1.66. The sodium salt hydrate has mp >300 °C.[1]

Solubility: sol ethanol, ether; sparingly sol water, hot benzene.

Form Supplied in: commercially available as the sodium salt hydrate; the lithium salt *[16844-27-2]* is also available.

Preparative Methods: isolation of the free acid via acidification of an aqueous solution of the sodium salt has been described;[1b] partial conversion to ***p-Toluenesulfonic Acid*** frequently accompanies drying of the free acid.

Purification: recrystallizes in water in long rhombic needles or plates.

Handling, Storage, and Precautions: should be stored in a cool, dry place away from strong oxidizing agents.

Synthesis of Sulfones.

p-Toluenesulfinic acid is a frequently used reagent for the synthesis of organic sulfones. The sulfone group has played an extensive role in recent synthetic organic chemistry; some of its common applications are described below, following preparation of representative sulfones from the title reagent. Unless otherwise noted, the reactions described use the sodium salt rather than the free acid.

Alkylation of arenesulfinate salts is a very general reaction for the preparation of alkyl sulfones.[2] Reaction conditions utilizing alcoholic or dipolar aprotic solvents are typical, but phase-transfer conditions have been described.[3] Reaction with reactive halides is generally facile (eq 1);[4] triflates have likewise been displaced with ease by *p*-toluenesulfinate.[5]

(1)

The sulfones so obtained are useful in a variety of organic transformations. Alkyl sulfones are readily deprotonated with bases, and the resulting carbanions are good nucleophiles. Sulfones thus function as activating groups which can subsequently be removed under mild conditions.[6] Alkylation of alkyl sulfones by alkyl halides, followed by reductive cleavage with ***Lithium*** metal or ***Sodium Amalgam***, provides a method of coupling alkyl halides which has been useful in the synthesis of 1,4-dienes.[7] Sodium *p*-toluenesulfinate also

undergoes conjugate addition reactions[8] and has been used as a nucleophile in palladium-catalyzed substitution reactions of allylic substrates.[9]

The addition of sulfone-substituted anions to carbonyl compounds yields β-hydroxy sulfones. These are useful intermediates for the synthesis of unsaturated compounds via elimination processes.[10-13] β-Hydroxy sulfones may also be prepared via the regioselective ring opening of epoxides by sodium *p*-toluenesulfinate.[14]

The radical addition of sulfinates to unsaturated compounds via the iodosulfonylation-dehydroiodination[15] reaction sequence constitutes a general method for the preparation of vinyl sulfones; the latter may be rearranged to allylic sulfones by treatment with base.[16] The radical addition may be carried out on α,β-unsaturated carbonyl compounds as well as alkenes.[17] In the case of unsaturated carbonyl compounds the elimination process can be quite stereoselective, (*E*)-alkenes being normally formed. For the addition to nonconjugated alkenes, conditions have been described for the preparation of either (*E*)- or (*Z*)-alkenes.[16]

Cleavage of Vinylsilanes.

p-Toluenesulfinic acid has been used for the protodesilylation of vinylsilanes to provide alkenes.[18] This method is milder than the usual strong acids used for this purpose. The cleavage is not stereospecific.

Synthesis of Chiral Sulfoxides.

Chiral sulfoxides have been used extensively in asymmetric synthesis.[19] An extremely common method for the preparation of these compounds involves the reaction of resolved diastereomeric sulfinate esters with Grignard reagents and organolithium species.[20] Menthol has classically been used to form diastereomeric esters of *p*-toluenesulfinic acid; an improved method using sulfinate esters of *trans*-2-phenylcyclohexanol has recently been reported.[21]

p-Toluenesulfonic Acid

[104-15-4] · $C_7H_8O_3S$ · *p*-Toluenesulfonic Acid · (MW 172.22) (monohydrate)

[6192-52-5] · $C_7H_{10}O_4S$ · *p*-Toluenesulfonic Acid · (MW 190.24) (Na salt)

[657-84-1] · $C_7H_7NaO_3S$ · Sodium *p*-Toluenesulfonate · (MW 194.20)

(acid catalyst frequently used in nonpolar media; effective in carbonyl protection-deprotection; selectively cleaves *N*-Boc, other amine protecting groups; superior for enol ether, acetate preparation; used in esterifications, dehydrations, isomerizations, rearrangements)

Alternate Name: tosic acid.

Physical Data: the anhydrous acid exists as monoclinic leaflets or prisms, mp 106-107 °C; pK_a -6.62 (H_2SO_4).[1] There is also a metastable form, mp 38 °C. The monohydrate is a white crystalline powder, mp 103-106 °C.

Solubility: sol water (67 g/100 mL), ethanol, ethyl ether. The sodium salt is very sol water.

Form Supplied in: widely available as the monohydrate, which is commonly used. Various metal salts are also commercially available.

Analysis of Reagent Purity: by acid-base titrimetry.[46]

Purification: precipitated or crystallized from HCl soln, aq EtOH; the free acid has been crystallized from several organic solvents.[47]

Handling, Storage, and Precautions: highly toxic, oxidizing agent. Extremely irritating to the skin and mucous membranes. Use of gloves and protective clothing is recommended.[2] Use in a fume hood.

Acid Catalyst.

Tosic acid is one of the most widely used organic acid catalysts, particularly in nonpolar solvents. It is utilized frequently in many of the common acid-catalyzed reactions and transformations in organic chemistry, including esterification, formation of acetals, dehydration processes, preparation of enol ethers and acetates, and rearrangement and isomerization processes. A comprehensive literature review of even its recent uses is beyond the scope of this publication; representative examples of each of the above-mentioned classes are presented.

Formation and Cleavage of Acetals.

Tosic acid is perhaps the most common acid catalyst for the protection of ketones as acetals. The reaction is conventionally carried out in refluxing toluene or benzene with removal of water by a Dean-Stark trap (eq 1).[3] Although ***Boron Trifluoride Etherate*** is the customary catalyst for the condensation of ketones with alkyldithiols, tosic acid is a milder reagent and has been used for this purpose (eq 2).[4] *p*-Toluenesulfonic acid may also be used in lieu of $BF_3.Et_2O$ in the tetrahydropyranylation and methoxytetrahydropyranylation of alcohols (3 examples).[5]

(1)

(2)

Treatment of acetals (eqs 3 and 4)[6,7] with aqueous tosic acid effects cleavage to the carbonyl compounds.

(3)

(4)

In a recently described synthesis of (+)-phyllanthocin,[8] spiroacetalization of (**1**) to form key intermediate (**2**) was studied (eq 5). Acid-catalyzed cyclization by tosic acid was found to be superior to ***10-Camphorsulfonic Acid***- or base-catalyzed cyclization using ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.

(5)

Esterification and Lactone Formation.

Tosic acid has been used in lieu of mineral acid in Fischer esterifications of carboxylic acids (eq 6).[9] Hydroxy acids (eq 7)[10,11] and aldehyde carboxylic acids (eq 8)[10] may be cyclized to lactones and enol lactones, respectively, by treatment with tosic acid in organic solvent.

(6)

(7)

(8)

Tosic acid has also been used to catalyze internal translactonization processes (eq 9).[12]

(9)

Dehydration Processes.

Dehydration of ketols to α,β-unsaturated compounds is effectively catalyzed by tosic acid;[13] addition of calcium chloride to the reaction mixture has been noted to give superior results in some instances.[14,15] Other acid-catalyzed processes can occur concomitantly, such as cleavage of silyl ethers.[16] Tosic acid adsorbed on silica gel was found to be an effective catalyst for the dehydration of secondary and tertiary alcohols (16 examples),[17] including a number of steroid alcohols which are resistant to most methods of catalyzed dehydration (eq 10).

(10)

p-Toluenesulfonic acid has been used to catalyze the formation of enamines; water is removed via azeotropic distillation.[18] The dehydration of primary nitro compounds by tosic acid provides access to nitrile oxides, which can subsequently engage in 1,3-dipolar

cycloaddition reactions.[19] Oximes may be dehydrated to nitriles by heating with tosic acid in DMF.[20] Reaction of cyclohexanone oximes with ketene in the presence of tosic acid results in aromatization to aryl amines.[21] This constitutes a milder method for Semmler-Wolff aromatization than those previously reported.

Cationic Rearrangements and Isomerizations.

In a study of Wagner-Meerwein rearrangements of tricyclo[4.3.2.0]undecanones catalyzed by tosic acid,[22] (**3**) was converted to (**4**) in refluxing benzene in 82% yield (eq 11). A similar rearrangement has been utilized in the synthesis of cyclopentanoid sesquiterpenes (eq 12).[23] Similar processes in which the migrating atom is sulfur have been reported;[24] sulfur-containing bicyclo[10.5.0]alkenes and related compounds have been obtained via tosic acid-catalyzed ring expansions of sulfoxides (eq 13).[25]

(3) (4) (11)

(12)

(13)

Treatment of tertiary vinyl alcohols with tosic acid in a mixture of ***Acetic Acid*** and ***Acetic Anhydride*** effects their conversion to allylic acetates (eq 14).[26] Treatment of β-hydroxyalkyl phenyl sulfides with tosic acid in refluxing benzene results in migration of the phenylthio group to generate allylic sulfides.[27]

(14)

Synthesis of Enol Ethers and Acetates.

Tosic acid is, in general, superior to other common catalysts (***Sulfuric Acid***, ***Phosphoric Acid***, potassium acetate) for enolization in the conversion of ketones to their enol acetates using acetic anhydride.[28,29] This methodology has been used extensively in steroid synthesis.[30-33] Isopropenyl acetate may also be used with removal of acetone by slow distillation (eq 15).[34] Enol ethers may similarly be obtained by treatment with tosic acid and alcohol in refluxing benzene or toluene followed by azeotropic removal of water.[35]

(15)

Synthesis of Steroid Acetates.

Tosic acid has been used to good effect in the acetylation of steroid substrates, replacing the commonly used ***Pyridine*** catalyst. Treatment of cholestane-3β,5α,6β-triol with pyridine and acetic anhydride afforded the 3,6-diacetate; heating the triol with tosic acid in acetic anhydride provided the desired triacetate.[36] Acetylation of the 17α-hydroxyl group of progesterone has been accomplished by this method.[37,38]

Addition of Alcohols to Nitriles (Ritter Reaction).

Esters may be prepared by the acid-catalyzed addition of alcohols to nitriles. Tosic acid is the preferred catalyst for this reaction.[39]

Cleavage of Amine Protecting Groups.

t-Butyloxycarbonyl (Boc) groups may be cleaved from protected amines in the presence of *t*-butyl- and *p*-methoxybenzyl esters by the action of tosic acid in a mixture of ethanol and ether (eq 16) (seven examples).[40] *p*-Methoxybenzyloxycarbonyl groups may be removed with tosic acid in acetonitrile.[41]

(16)

Synthesis of Substituted Methylbenzenes.

Tosic acid is lithiated at the 2-position with 2 equiv of ***n-Butyllithium***; the resulting anion may be reacted with various electrophiles. Desulfonylation of the substituted product constitutes a synthesis of *meta*-substituted toluenes.[42]

Synthesis of Sulfones.

Alkyl *p*-tolyl sulfones may be prepared by reaction of the ***p-Toluenesulfonyl Chloride*** with Grignard reagents. *p*-Tolyl aryl sulfones can be synthesized by the condensation of tosic acid with aromatic compounds in ***Polyphosphoric Acid***;[43] alternatively, the sulfonyl chloride may be reacted with aromatic substrates under Friedel-Crafts conditions.[43] Milder conditions using ***Phosphorus(V) Oxide-Methanesulfonic Acid*** have been reported.[44]

Amine Salts.

Amines are frequently converted to their tosylate salts for characterization.[45]

Related Reagents.

Hydrochloric Acid; ***Methanesulfonic Acid***; ***Sulfuric Acid***; ***Trifluoroacetic Acid***; ***Trifluoromethanesulfonic Anhydride***.

p-Toluenesulfonyl Chloride[1]

[98-59-9] · $C_7H_7ClO_2S$ · *p*-Toluenesulfonyl Chloride · (MW 190.66)

(sulfonyl transfer reagent; *O*-sulfonylation of alcohols[2] for conversion to chlorides[3] or intermolecular[4] and intramolecular[5] displacements, vicinal diols for epoxidation,[6] 1,3-diols for oxetane formation,[7] carboxylic acids for esterification[8] or decarboxylation,[9] oximes for Beckmann rearrangements[10] or fragmentations[11] and Neber rearrangements,[12] hydroxamic acids for Lossen rearrangements,[13] nitrones for rearrangements,[14] conversion of *N*-cyclopropylhydroxylamines to β-lactams;[15] *N*-sulfonylation of aliphatic amines[16] for subsequent deamination[17] or displacement,[18] aromatic amines for protection;[19] *C*-sulfonylation of alkenes[20] and silylalkynes;[21] dehydration of ureas,[22] formamides,[23] and amides[24])

Alternate Names: tosyl chloride.

Physical Data: mp 67-69 °C; bp 146 °C/15 mmHg.

Solubility: insol H_2O; freely sol ethanol, benzene, chloroform, ether.

Form Supplied in: white solid, widely available.

Purification: upon prolonged standing the material develops impurities of *p*-toluenesulfonic acid and HCl. Tosyl chloride is purified by dissolving 10 g in a minimum volume of $CHCl_3$ (ca. 25 mL), filtering, and diluting with five volumes (ca. 125 mL) of petroleum ether (bp 30-60 °C) to precipitate impurities (mostly tosic acid, mp 101-104 °C). The solution is filtered, clarified with charcoal, and concentrated to ca. 40 mL by evaporation. Further evaporation to a very small volume gives 7 g of pure white crystals (mp 67.5-68.5 °C).[25]

Tosyl chloride may also be recrystallized from petroleum ether, from benzene, or from toluene/petroleum ether (bp 40-60 °C) in the cold. Tosyl chloride in diethyl ether can be washed with aqueous 10% NaOH until colorless, then dried with Na_2SO_4 and crystallized by cooling in powdered dry ice. It can also be purified by dissolving in benzene, washing with aqueous 5% NaOH, drying with K_2CO_3 or $MgSO_4$, and distilling under reduced pressure.[26]

Handling, Storage, and Precautions: freshly purified tosyl chloride should be used for best results. Tosyl chloride is a moisture-sensitive, corrosive lachrymator.

General Discussion.

The tosylation of alcohols is one of the most prevalent reactions in organic chemistry.[1] Optimized conditions for this reaction include the use of a 1:1.5:2 ratio of alcohol/tosyl chloride/pyridine in chloroform (eq 1).[2a] This procedure avoids formation of unwanted pyridinium salts inherent to reactions where higher relative quantities of pyridine have been employed.[2b]

Good yields (81-88%) for tosylation have also been observed under biphasic conditions where ***Benzyltriethylammonium Chloride*** is employed as a phase-transfer catalyst between benzene and aqueous sodium hydroxide solution.[2c]

It has long been known that it is possible to selectively tosylate primary over secondary alcohols (eq 2).[2d]

It is also possible to regioselectively mono-*O*-tosylate various nonprotected hydroxyl functionalities, as illustrated in Scheme 1.[2e] This method employs a preliminary activation of a glycopyranoside with ***Di-n-butyltin Oxide*** and usually requires the use of a basic catalyst such as ***4-Dimethylaminopyridine*** (DMAP) in conjunction with tosyl chloride. Regioselectivity differs markedly from acylation reactions and is thought to be a function of changes in the kinetics of the reactions with the various tin intermediates which are in equilibrium.

Scheme 1

Regioselective mono- and ditosylation of aldonolactones has also been reported.[2f] A few of these products are shown in Scheme 2. In no instances was the β-hydroxy function tosylated.

Scheme 2

The regioselective tosylation of various cyclodextrins has been reported. The two major products resulting from the tosylation of β-cyclodextrin are heptakis(6-*O*-(*p*-tosyl))-β-cyclodextrin (**1**) and heptakis(6-*O*-(*p*-tosyl))-2-*O*-(*p*-tosyl))-β-cyclodextrin (**2**).[2g,h] Yamamura has also prepared hexakis(6-*O*-(*p*-tosyl))-α-cyclodextrins[2i] as well as polytosylated γ-cyclodextrins.[2j]

(1) 24%

(2) 15%

By proper choice of base it is possible to selectively *O*-tosylate in the presence of a free amine or *N*-tosylate in the presence of a free hydroxyl, with yields in excess of 94% (eq 3). The probable explanation for selective *O*-tosylation in the presence of the stronger base is formation of an adequate amount of phenoxide to allow the anion to act as the nucleophile.[2k]

(3)

Tosyl chloride has been used in the preparation of allylic chlorides from their respective alcohols, leaving in place sensitive groups and with no rearrangement of the allylic substrate (eq 4).[21]

(4)

Studies on reactions of various types of alcohols with the related tosyl chloride/dimethylaminopyridine (TsCl/DMAP) system have led to the following conclusions: allylic, propargylic, and glycosidic hydroxyls quickly react to form the corresponding chlorides, 2,3-epoxy and selected primary alcohols yield chlorides but at a slower rate, and reactions of aliphatic secondary alcohols stop at the tosylate stage. Example reactions are illustrated in eqs 5-10.[3a]

(5)

(6)

Attempted tosylation of 3β-methoxy-21-hydroxy-5α-pregnan-20-one afforded its α-chloro derivative.[3b] This reinforces the rule that as

hybridization α to the alcohol increases in s character, displacement of the intermediate tosylate is facilitated (eq 11).

(11)

The α-chlorination of sulfoxides can also be achieved using tosyl chloride and pyridine, albeit in poor yield (32%), as shown in eq 12.[3c]

(12)

Alcohols treated with tosyl chloride are transformed into their corresponding sulfonate esters without manipulation of existing stereochemistry in the substrate. The *p*-toluenesulfonyloxy moiety subsequently serves as a good leaving group in intermolecular nucleophilic substitution or elimination reactions.[4] Treatment of multifunctional alcohols with tosyl chloride can result in the formation of intermediate *O*-sulfonylated species, which can undergo intramolecular displacement of the tosylate group. For example, treatment of *trans*-2-hydroxycyclohexaneacetamide with tosyl chloride in pyridine is the key step in the conversion of the lactone of *trans*-2-hydroxycyclohexaneacetic acid to its *cis* isomer (eq 13).[5a]

(13)

Alcohols treated with tosyl chloride can also serve as alkylating agents for thioamides to make thiazolines (eq 14).[5b]

(14)

Several useful one-pot procedures employing the reaction of tosyl chloride with vicinal diols have been used to form epoxides. Treatment of variously substituted diols with 1 equiv of tosyl chloride and sodium hydroxide in monoglyme provides access to a variety of 1-alkynyloxiranes (R^1 and/or R^3 being terminal or substituted alkynes) in moderate to good yield (eq 15).[6a]

(15)

Another method entails treatment of the diol in THF with 2.2 equiv of ***Sodium Hydride*** followed by reaction with a slight molar excess of tosyl chloride. This fast reaction, illustrated in eq 16, can be used to prepare enantiopure epoxides in good to excellent yields.[6b]

(16)

Phase-transfer catalysis has also been successfully employed to achieve epoxidation. A variety of cyclic *trans*-substituted diols in dichloromethane were treated with a 50% aqueous solution of sodium hydroxide in the presence of the phase-transfer catalyst benzyltriethylammonium bromide. Consistently good yields were achieved for these as well as glycosidic and acyclic substrates (eq 17).[6c]

(17)

A one-pot conversion of a variety of 1,3-diols to oxetanes has also been reported.[7] The procedure entailed alcohol deprotonation with one equivalent of ***n-Butyllithium*** followed by treatment with tosyl chloride and then a second equivalent of base (eq 18).

(18)

When a solution of a carboxylic acid and an alcohol in pyridine is treated with tosyl chloride, an ester is formed rapidly in excellent yield. This procedure is useful especially in the esterification of tertiary alcohols. The combination of a carboxylic acid and tosyl chloride serves as a convenient method of in situ preparation of symmetrical acid anhydrides for further formation of esters and amides (eq 19). The novelty of this protocol is that the acid can be recycled through the anhydride stage in the presence of the alcohol, thereby resulting in complete conversion to the ester (eq 20).[8a] Reactivity is determined by the strength of the acid: strong acids facilitate the esterifications.[8b]

(19)

Similarly, a two-step procedure employing treatment of a mixture of tosic acid and various amino acids with alcoholic tosyl chloride results in the isolation of the esters of the amino acids as their *p*-toluenesulfonate salts in excellent yield. The tosic acid used in the esterification is added to make the amino acids more soluble and to prevent *N*-tosylation (eq 21).[8c]

A novel formal decarboxylation of the amino acid α-anilino-α,α-diphenylacetic acid has been observed upon treatment with tosyl chloride in pyridine.[9] It has been proposed that a mixed anhydride of *p*-toluenesulfonic acid has undergone an elimination via *N*-deprotonation and synchronous extrusion of carbon monoxide in this reaction. Interestingly, no *N*-tosylation occurs (eq 22).

Spontaneous Beckmann rearrangement has been observed upon *O*-tosylation of oximes. Lactams can therefore be conveniently prepared from cyclic oximes, as shown in eq 23.[10a] The rearrangement has long been known to proceed with retention of configuration of the migrating group.[10b,c] This is complementary to the reaction of oximes with ***Sulfuric Acid*** (eq 24).[10b]

(24)

A Beckmann fragmentation of oximes using tosyl chloride in a basic ethanol-water system has also been observed.[11] Formation of the cyclic product shown in eq 25 was consistent with a base-induced opening of an intermediate lactone followed by rearrangement and incipient extrusion of benzoic acid.

(25)

Oximes which are treated with tosyl chloride can also be used as substrates in the Neber rearrangement to α-amino ketones.[12a] The mixture shown in eq 26 was further subjected to reductive amination to yield 14% of the CNS-active *cis-N,N*-dimethylated α-amino alcohol.[12b]

(26)

2:1:1 inseperable mixture,

Rearrangements of hydroxamic acids using sulfonyl chlorides have been accomplished, albeit without reported yields, the net result being a unique variation of the Lossen rearrangement (eq 27).[13]

(27)

As an alternative to the Beckmann rearrangement, ketonic nitrones can be treated with tosyl chloride in pyridine in the presence of water, as illustrated in eq 28.[14]

(28)

Rearrangement reactions which utilize tosyl chloride seem to progress in a two-step process: the displacement of chlorine from the sulfonyl halide resulting in the formation of an oxygen-sulfur bond, followed by the migration, elimination, or intramolecular displacement of the sulfonylate anion.[8a] When the series of carbinolamines depicted in eq 29 were treated with tosyl chloride, they decomposed into the corresponding electron-deficient nitrogen species, which subsequently triggered ring enlargement to the β-lactams in moderate yields.[15]

(29)

R = various alkyl groups

N-Tosylation is a facile procedure. For inexpensive amines a useful procedure entails treating 2 equiv of the amine with tosyl chloride. This is the first step in the convenient preparation of Diazald (***N-Methyl-N-nitroso-p-toluenesulfonamide***), a ***Diazomethane*** precursor (eq 30).[16a]

(30)

Protection of 3-amino-3-pyrazoline sulfate, a key intermediate in the preparation of 3(5)-aminopyrazole, was achieved in the presence of an excess of sodium bicarbonate in good yields (eq 31).[16b]

(31)

Sodium Carbonate can also be used as the base in the tosylation of amines, as shown in the reaction of anthranilic acid with tosyl chloride. There was no competing nucleophilic attack at sulfur by the resonance-stabilized carboxylate group (eq 32).[16c]

(32)

Primary, benzyl, and unhindered secondary amines can be ditosylated and deaminated in good to excellent yields, using ***Sodium Borohydride*** as the nucleophile, to afford the corresponding alkanes; only highly congested substrates experience competing attack at nitrogen.[17] Similarly, primary aliphatic amines, when ditosylated and treated with iodide ion in DMF at 90-120 °C yielded, as their major products, the corresponding alkyl iodides, with some competition arising from elimination reactions (eqs 33 and 34).[18]

(33)

(34)

Tosyl chloride has been used in the protection of the imidazole residue of N^{α}-acylhistidine peptides[19a,b] and the guanidino residue of arginine peptides.[19c] The resulting nitrogen-protecting group is stable to most conditions but is easily removable in anhydrous hydrogen fluoride at 0 °C.

The tosylation of carbon can be accomplished using electron transfer conditions. Treatment of styrene[20a] and analogs[20b] with ***Copper(II) Chloride*** and tosyl chloride or ***Benzenesulfonyl Chloride*** results in a formal replacement of the vinyl proton by the sulfonyl moiety (eq 35). The intermediacy of a *trans*-β-chloro sulfone has been demonstrated by ^{1}H NMR. Treatment with base induced the elimination of HCl. A variety of other sulfonyl transfer reagents can be employed in the synthesis of isolated β-chloro sulfones, with good results (60-97% yield) for a variety of alkenes (ethylene, 1-butene, 2-butene, 1-octene, acrylonitrile, methyl acrylate, and 1,3-butadiene).[20a]

(35)

Although it was found that tosyl chloride does not react with 3-sulfolene at temperatures below 110 °C, upon further warming to 140 °C addition to the diene afforded 1-chloro-4-tosyl-2-butene in a convenient procedure that did not require the use of a sealed tube or bomb (eq 36).[20c] Cycloheptatriene, 1,4-norbornadiene, and phenylacetylene are a few examples of a variety of compounds which are reactive substrates in this protocol.

(36)

Radical addition of tosyl chloride to norbornene and aldrin without skeletal rearrangement can be achieved using ***Dibenzoyl Peroxide*** as an

initiator (eq 37).[20a,d] Reaction with 1,4-norbornadiene gives rise to a rearranged addition product.

(37)

Treatment of bis(trimethylsilyl)acetylene with tosyl chloride and a slight excess of anydrous ***Aluminum Chloride*** affords *p*-tolyl (trimethylsilyl)ethynyl sulfone, a precursor to the reactive Michael acceptor ethynyl *p*-tolyl sulfone (eq 38).[21]

(38)

The dehydration of ureas employing tosyl chloride provides access to substituted carbodiimides, as depicted in eq 39. The urea made from treatment of ethyl isocyanate with *N*,*N*-dimethyl-1,3-propanediamine was treated in situ with 1.1 equiv of tosyl chloride and a large excess of ***Triethylamine*** to afford the corresponding carbodiimide in high yield.[22a,b]

(39)

Various ureas upon treatment with tosyl or benzenesulfonyl chloride in the presence of a phase transfer catalyst, benzyltriethylammonium chloride, results in moderate to excellent yields of carbodiimides (eq 40).[22c] The polymeric carbodiimide in eq 41 offers the advantages of cleaner workup and recyclability if used to prepare aldehydes under Moffatt oxidation conditions.[22d]

(40)

Isocyanides can be made from treatment of formamides with tosyl chloride in pyridine, as illustrated in eq 42.[23a,b] Similarly, nitriles can be synthesized in moderate to good yields by dehydration of primary amides using tosyl chloride in pyridine[23a,b] or quinoline (eq 43).[23c]

p-Toluenesulfonyl Cyanide

(R = *p*-tolyl)

[19158-51-1] · $C_8H_7NO_2S$ · *p*-Toluenesulfonyl Cyanide · (MW 181.23) (R = methyl)

[24225-08-9] · $C_2H_3NO_2S$ · Methanesulfonyl Cyanide · (MW 105.13) (R = phenyl)

[24224-99-5] · $C_7H_5NO_2S$ · Benzenesulfonyl Cyanide · (MW 167.20)

(nitrile group as dienophile in [4 + 2] cycloadditions; nitrile group as source of $^+$CN and &bdot;CN)

Alternate Name: tosyl cyanide

Physical Data: R = *p*-tolyl, mp 49-50 °C. R = methyl, bp 68-69 °C/15 mmHg. R = phenyl, bp 73 °C/0.1 mmHg.

Form Supplied in: tosyl cyanide is available as an off-white solid.

Preparative Methods: sulfonyl cyanides are best prepared by the reaction of cyanogen chloride with the sodium salt of a sulfinic acid. Procedures for tosyl cyanide[1] and methanesulfonyl cyanide[2] have been published.

Handling, Storage, and Precautions: tosyl cyanide has been reported to undergo occasionally violent decomposition on drying.[1] Methanesulfonyl cyanide can be stored in a well-stoppered bottle, at or below 0 °C, over a prolonged period without loss of purity and can be distilled without decomposition.[2] Use in a fume hood.

Cycloadditions.

In contrast to the situation with most nitriles, the cyano group of sulfonyl cyanides can function as a dienophile in [4 + 2] cycloadditions under relatively mild conditions. Reaction of cyclopentadiene with either tosyl[1] or methanesulfonyl[3] cyanide leads, after hydrolysis of the intermediate formed, to 2-azabicyclo[2.2.1]hept-5-en-3-one (**1**) (eq 1), a useful intermediate for the preparation of carbanucleosides.

(1)

The reaction of tosyl cyanide with 2-aza-1,3-dienes has been used to prepare pyrimidines (eq 2);[4] ***Trichloroacetonitrile*** showed comparable reactivity in this reaction. The regioselective cycloaddition of tosyl cyanide with 1-alkoxy-1,3-dienes has been used for the preparation of 2-arylsulfonylpyridines.[5]

(2)

Cycloadditions with 1,3-dipoles are also known: tosyl cyanide reacts with diazomethane to give 4-tosyl-1,2,3-triazole (68% yield) and with benzonitrile *N*-oxide to give 3-phenyl-5-tosyl-1,2,4-oxadiazole (78% yield).[6]

Reactions with Nucleophiles.

Tosyl cyanide acts as an electrophilic cyanating agent in reactions with many nucleophiles including phenoxides, Grignard reagents, amines, and thiols.[7] Tosyl cyanide proved to be a much more effective reagent for the cyanations of ketone enolates than either ***Cyanogen Bromide*** or phenyl cyanate, although the yields were low with methyl ketones.[8] Reaction of vinylcuprates with tosyl cyanide provided a stereospecific synthesis of 2-alkenenitriles (yields >90%), although cyanogen chloride could also be used.[9] A convenient synthesis of 2-cyanoimidazoles using either tosyl cyanide or phenyl cyanate has been reported (eq 3).[10]

(3)

A magnesium complex of the cyanobisoxazoline (**2**), prepared in high yield (>70%) using $PhSO_2CN$ (eq 4), was useful as a catalyst for the enantioselective conversion of aldehydes to cyanohydrins using ***Cyanotrimethylsilane***.[11]

(4)

(2)

Both tosyl and methanesulfonyl cyanide react with alcohols in the presence of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** or ***1,4-Diazabicyclo[2.2.2]octane*** at or below rt to give sulfinate esters. A mechanism involving the intermediacy of sulfinyl cyanates was proposed (eq 5).[12]

(5)

Isolable adducts can be obtained from the reaction of sulfonyl cyanides with α-nucleophiles. Reaction of tosyl cyanide with phenylhydrazine gave (**3**), which was reacted further with ***Triethyl Orthoformate*** to the triazole (**4**) (eq 6).[13] Similarly, hydroxylamine reacts with arylsulfonyl cyanides to give isolable arylsulfonyl formamidoximes (63-87%), which were converted to 5-amino-3-arylsulfonyl-1,2,4-oxadiazoles.[14]

Radical Reactions.

The photochemical (UV irradiation)[15] and thermal (***Azobisisobutyronitrile*** catalyzed)[16] addition of sulfonyl cyanides to alkenes has been described (eq 7). The photochemical reaction was reported not to function with alkynes; however, AIBN-catalyzed thermal addition of tosyl cyanide to 1-hexyne gave (**5**) as a mixture of geometrical isomers (eq 8).[16] The AIBN-catalyzed reaction of sulfonyl cyanides with 1,3-dienes gave products of 1,4-addition.[16]

The reaction of sulfonyl cyanides with carbon radicals generated by visible irradiation of (**6**) gave nitriles in good yields (eq 9).[17]

Related Reagents.

Chlorosulfonyl Isocyanate; ***Cyanogen Bromide***; ***Trichloroacetonitrile***.

p-Toluenesulfonylhydrazide[1]

[1576-35-8] · $C_7H_{10}N_2O_2S$ · *p*-Toluenesulfonylhydrazide · (MW 186.26)

(used as a source of diazene;[2] condensed with ketones and aldehydes to form hydrazones that can be converted into reactive intermediates such as diazoalkanes, carbenes, carbenium ions, alkyllithiums, or umpolung synthons;[7] used in 1,3-dipolar cycloaddition reactions to form N-heterocycles; used to make propargyl aldehydes and ketones via the Eschenmoser fragmentation;[44] ketone hydrazones are deoxygenated with mild reagents in a modified Wolff-Kishner reduction[50])

Alternate Name: tosyl hydrazide.

Physical Data: mp 108-110 °C (dec).

Solubility: sol virtually all organic solvents except hydrocarbons; insol water.

Form Supplied in: solid; widely available.

Handling, Storage, and Precautions: is thermally labile at elevated temperatures, but can be stored at or below room temperature. It is a toxic, potentially flammable solid which should be handled with gloves under inert atmosphere.

Alkene Reduction/Allylic Diazene Rearrangement.

p-Toluenesulfonylhydrazide may be thermolyzed in solution to generate diazene (diimide) for alkene reduction.[2] It is the least reactive member of the common arenesulfonylhydrazides, with ***Mesitylenesulfonylhydrazide*** being 24 times more reactive and ***2,4,6-Triisopropylbenzenesulfonylhydrazide*** being 380 times more reactive under base-catalyzed decomposition conditions. The latter has largely supplanted tosyl hydrazide as a source of diazene because of the low-temperature convenience.[3,4]

Sigmatropic rearrangement of allylic and propargylic diazene intermediates is well established and is a reliable means of alkene synthesis.[5] Several options are available to generate these intermediates, such as hydride reduction of tosylhydrazones (refer to eqs 14 and 15), elimination of *p*-toluenesulfinic acid from an allylic hydrazine (eqs 1 and 2), Wolff-Kishner reduction of an α,β-unsaturated ketone, or oxidation of alkylhydrazines.[5]

p-Tolyl sulfones have been prepared in excellent yield by halide displacement with toluenesulfinate ion.[6]

Nucleophilic Addition to Hydrazones.

The bulk of tosyl hydrazide's synthetic utility comes from its condensation products with ketones and aldehydes.[7,8] Synthetically useful addition reactions typically only succeed with nonenolizable ketone hydrazones.[9,10] The treatment of enolizable ketone tosyl hydrazones with alkyllithium nucleophiles invariably results in the formation of a dianion rather than addition to the azomethine bond. In contrast, aldehyde tosylhydrazones do not form dianions but instead undergo addition with both alkyllithiums and cuprate reagents to give reductive alkylation products.[11,12] A versatile extension of this methodology involves either vinyllithium addition to *N*-*t*-butyldimethylsilyl tosylhydrazones or the complementary 1,2-addition of alkyllithium to α,β-unsaturated *N*-*t*-butyldimethylsilyl tosylhydrazones. Reductive addition in either case produces an *N*-TBDMS allylic diazene intermediate which undergoes protodesilylation and subsequent 1,5-sigmatropic rearrangement. (*E*)-Alkenes are prepared with high stereoselectivity due to $A_{1,3}$-strain in the transition state (eqs 1 and 2), and epimerization of adjacent stereocenters is not observed.[5]

Other nucleophiles, such as cyanide ion, similarly add to aldehyde and ketone tosylhydrazones, which constitutes a useful one-carbon homologation.[13] ***Diphenylphosphine Oxide*** or dimethyl phosphite addition followed by decomposition of the intermediate with base or ***Sodium Borohydride*** gives alkyldiphenylphosphine oxides and *s*-alkanephosphonates, respectively.[14]

Formation of tosylhydrazones from α-halo ketones, followed by vinylogous halide elimination using mild base, gives *p*-

toluenesulfonylazoalkenes, which undergo S_N2'-type addition of strong nucleophiles (eq 3).[15] This sequence constitutes a synthetically useful carbonyl umpolung synthon for introducing nucleophiles in the α-position of ketones. Examples of simple alkyllithium and 1,3-diketone enolate nucleophilic addition are also known.[16]

In another example, thermolysis of the tosylhydrazone of an α-hydroxy steroid in ethylene glycol without base resulted in reductive dehydroxylation, presumably through rearrangement of an intermediate epoxydiazene.[17]

Electrophilic Addition to Hydrazone Anions.

α-Deprotonation of tosylhydrazones with 2 equiv of strong base give highly nucleophilic azaenolates that react with a variety of electrophiles.[18] Trisyl hydrazones have also received considerable attention for this transformation[19] (see ***2,4,6-Triisopropylbenzenesulfonylhydrazide***. However, some cyclohexanones, such as 4-*t*-butylcyclohexanone, require tosyl hydrazones for successful alkylation since the corresponding trisyl hydrazones undergo significant Shapiro elimination (see below) even at -78 °C.[18c]

The regioselectivity of deprotonation for unsymmetrical tosylhydrazones often is high, and is dictated by three factors. In many cases the configuration of the C=N double bond plays an important role since the sulfonamide anion induces *syn* deprotonation in ethereal solvents.[20] Thus the ratio of α vs. α´ anions reflects the C=N isomeric ratio, which is typically 85:15 (*E*):(*Z*) or greater in unsymmetrical ketones.[21,22] The *syn*-directing effect is inoperative in TMEDA solvent, allowing excellent regioselectivity of deprotonation, independent of the hydrazone geometrical isomer population.[23] Electron-stabilizing groups in the α-position direct deprotonation, and finally, the acidity of α-hydrogens follows the generalization that methyl > methylene > methine with only a few exceptions.

Bamford-Stevens and Shapiro Reactions.

Tosylhydrazones may be converted into a variety of reactive intermediates depending upon the specific reaction conditions employed. The protic Bamford-Stevens reaction conditions (ethylene glycol; NaOR; heat) give diazoalkane intermediates that, on occasion, can be isolated but more often undergo in situ protonation followed by loss of dinitrogen to give cationic intermediates. These intermediates tend to give the more substituted double bond, but predicting regioselectivity is dubious, and cationic rearrangements are common (eq 4).[24]

Triisopropylbenzenesulfonyl and mesitylenesulfonyl hydrazones are far superior to tosyl hydrazones if isolation of the diazo compound is desired, primarily because much lower temperatures are required to induce the sulfinate elimination.[25]

The aprotic Bamford-Stevens reaction involves deprotonation of the acidic sulfonamide hydrogen in an aprotic solvent (e.g. glyme) to form a salt (Li, Na, and K are common) which is pyrolyzed or photolyzed to generate carbenes (eq 5).[26]

Five- and six-membered ring ketones usually undergo 1,2-hydride migration to preferentially give the more substituted alkene.[27,12,4] Regioselectivity is usually modest but high selectivity is found in some instances, such as the synthesis of furanose glycals,[28] Δ^2 unsaturation in *trans*-A/B steroids, and Δ^3 unsaturation in *cis*-A/B steroids.[29] Nevertheless, examples of competitive cyclopropanation[30] and C-H bond insertion in medium-sized rings[31] abound.

The Shapiro reaction is extremely useful for the regioselective conversion of ketones into alkenes.[1] The anions of tosylhydrazones eliminate *p*-toluenesulfinate and dinitrogen between 0 °C and room temperature over the course of several hours to give the corresponding least-substituted alkene. Acyclic azaenolates have a strong preference for E_{CC} geometry and react equally well to yield (*Z*)-alkenes stereoselectively unless α-branching causes too much allylic strain in the transition state.[1a,3,8,32] This method has been used extensively in the synthesis of natural products such as alkaloids,[33] prostaglandins,[34] and especially terpenes (eq 6).[24a,35]

The intermediate in this reaction is an alkenyllithium, which can be trapped under certain conditions with electrophiles,[21,36] providing general access to allylic alcohols, α,β-unsaturated aldehydes and acids,[37] vinyl halides, vinyl sulfides,[38] and vinylsilanes.[39] Use of trisylhydrazones typically gives superior results because the intermediate alkenyllithium is formed at lower temperature and does not require excess base to circumvent quenching of the intermediate by orthometalation.[40,21] Tandem one-pot electrophilic addition/Shapiro elimination sequences reliably provide alkenes with highly variable substitution patterns (eq 7), including tetrasubstitution.[18c]

Tosylhydrazones of α,β-unsaturated ketones likewise participate in the Shapiro elimination to give 2-lithioalkadiene intermediates which may be protonated to give the corresponding dienes, or be trapped with electrophiles.[41] Regioselectivity cannot be predicted with certainty, but in general an α´-proton is removed (giving the cross-conjugated azaenolate) in preference to a γ-proton, once again analogous to the kinetic deprotonation of α,β-unsaturated ketones.[42] Tosylhydrazones of β-keto esters are deprotonated to give trianions that decompose to give β,γ-unsaturated esters in fair yield.[22,8] Cyclic 1,3-diketone monotosylhydrazones analogously give enones when treated with ***Potassium Carbonate***.[43]

Eschenmoser Fragmentation and Related Eliminations.

Preparation of macrocyclic cycloalkynones by fragmentation of α,β-epoxy ketones is also possible with this reagent (eq 8).[44]

These fragmentation reaction conditions are too harsh to give the corresponding propargylic aldehydes in good yield.[45] More recently, other reagents have proved more efficacious for this transformation (see ***2,4-Dinitrobenzenesulfonylhydrazide*** and ***Mesitylenesulfonylhydrazide***).

Arenesulfonylhydrazones with leaving groups in the α-position proceed through well-documented intermediates or related fragmentation reactions. For instance, treatment of α-bromotosylhydrazones with mild base triggers vinylogous halide elimination to give tosylazoalkenes (eq 9, and also refer to eq 3 and related text). Addition of strong base to these compounds provides 2-lithioalkadienes[46] and is a complementary route to the enone method described above.

In acyclic cases the same intermediates seem to eliminate differently to give alkynes (eq 10).[47] Eq 11 illustrates a Shapiro elimination in which the resultant vinyllithium intermediate fragments by displacing alkoxide to give the unanticipated hydroxyalkyne in high yield.[48] If deprotonation occurs on the α-carbon not occupied by the leaving group, the alkenyllithium intermediate fragments to a hydroxyallene in fair yield (eq 12).[49]

(12)

Reductions of Tosylhydrazones.[50]

Reduction of aldehyde and ketone tosylhydrazones in a Wolff-Kishner-type reaction was first described using ***Lithium Aluminum Hydride*** which was effective in several cases, but proved to be basic enough to produce Shapiro elimination side products.[51,52] More recently, milder reductions such as ***Sodium Borohydride***, ***Sodium Trimethoxyborohydride***, ***Sodium Triacetoxyborohydride***, ***Sodium Cyanoborohydride***, and ***Catecholborane*** have greatly expanded the scope and utility of these reductions well beyond the classic Wolff-Kishner and Clemmenson reductions, to become one of the mildest deoxygenation procedures known.

$NaBH_4$ is an effective tosylhydrazone reducing agent when used in methanolic dioxane ($NaBH(OMe)_3$ is most likely the active reducing species), acetic acid ($NaBH(OAc)_3$ is most likely the active reducing species), and less commonly in isopropanol and DMF (eq 13).[53]

Selective formation of hydrazones (using a stoichiometric amount of tosyl hydrazide) in the presence of relatively hindered or deactivated ketones is easily achieved in high yield and, in the case of eq 13, the ketones are not reduced under the reaction conditions.[54] Reductions occur between room temperature and 70 °C for most tosylhydrazones without epimerization of α-stereocenters.[55] The reaction proceeds by reductive elimination of *p*-toluenesulfinate and extrusion of dinitrogen to form an alkyllithium, which is quenched by solvent. Use of $NaBD_4$ in AcOH or AcOD allows for mono- and dideuterio incorporation.[53c] Catecholborane is an equally effective reducing agent.[56]

(13)

$NaBH_3CN$ has proved particularly serviceable for reducing tosylhydrazones that can be generated in situ, since iminium ions reduce much faster than carbonyl groups with this reagent.[57] The reactions are usually carried out in acidic 1:1 DMF--sulfolane at 100 °C, but even milder conditions have been used,[50b,58] providing products in fair to good yield.[59]

Reduction of α,β-unsaturated tosylhydrazones with the boron reagents gives 1,2-hydride delivery followed by extrusion of toluenesulfinic acid to give an allylic diazene. Note that this process gives a similar intermediate to that obtained by alkyl- and alkenyllithium addition to *N*-TBDMS tosylhydrazones (eqs 1 and 2). Thus, reduction of these systems gives allylic migration of the double bond independent of thermodynamic preference, and is an excellent means of deconjugating double bonds with an intervening methylene (eqs 14 and 15).[60]

(14)

(15)

The $NaBH_4$/MeOH conditions do not give good yields in this process due to predominating Bamford-Stevens-type reactions.[61] $NaBH_4$ and $NaBH_3CN$ work equally well in AcOH but catecholborane is the best reagent for this transformation because 1,4-addition of hydride is minimal. Catecholborane adds axially to bridgehead enones and undergoes 1,5-sigmatropic reduction on the convex face to give *cis*-decalin systems with good selectivity.[62]

Miscellaneous.

Intramolecular 1,3-dipolar cycloadditions of intermediate diazoalkanes derived from tosylhydrazones have been conducted under ***Boron Trifluoride Etherate*** or aprotic Bamford-Stevens reaction conditions to give pyrazolines and related compounds.[63,30a] [4 + 2] Cycloadditions of α,β-unsaturated aldehyde tosylhydrazones gave low yields of dihydropyridines.[64] 1,2-Enone transpositions have been described using vinylsilanes and vinyl sulfides.[65] Tosylhydrazones may also be converted into alkyl hydroperoxides via a two-step procedure.[66]

[*N*-(*p*-Toluenesulfonyl)imino]phenyliodinane

[55962-05-5] · $C_{13}H_{12}INO_2S$ · [*N*-(*p*-Toluenesulfonyl)imino]phenyliodinane · (MW 373.23)

(nitrogen atom source; reacts with heteroatom lone pairs to form ylides; capable of C-H bond insertion or alkene aziridination in the presence of transition metal catalysts)

Physical Data: mp 102-104 °C (dec).[1]

Solubility: v sl sol nonpolar solvents; sol DMSO (decomposes slowly); reacts with THF, MeOH.

Form Supplied in: light yellow solid, commercially available.

Analysis of Reagent Purity: ^{1}H NMR spectra can be obtained in DMSO-d_6, although the reagent slowly reacts with the solvent. Other assays include iodometric analysis[1] and reaction with triphenylphosphine to form the phosphinimine.[2]

Preparative Methods: prepared by the reaction of $PhI(OAc)_2$ with $TsNH_2$ and KOH in MeOH, from which the product precipitates upon addition of water (eq 1).[1] Another preparation employs the reaction of $TsNH_2$ with $PhI(OMe)_2$ in MeOH or in CH_2Cl_2 (eq 2).[2]

$$PhI(OAc)_2 \xrightarrow[\text{MeOH}]{\text{KOH, TsNH}_2} \text{PhI=NTs} \qquad (1)$$

$$\text{PhIO} \xrightarrow[\text{3 mol. sieves}]{\text{MeOH}} \text{PhI(OMe)}_2 \xrightarrow[\text{MeOH or CH}_2\text{Cl}_2]{\text{TsNH}_2} \text{PhI=NTs} \qquad (2)$$

Handling, Storage, and Precautions: store at -20 °C; should be used within 6 months. The reagent can be weighed out in air. No known toxicity. Use in a fume hood.

Nitrogen Atom Transfer to Heteroatoms.

PhI=NTs reacts with heteroatom lone pairs to generate ylides.[1] Reaction with ***Triphenylphosphine*** at 100 °C affords 69% of the phosphinimine (**1**) (eq 3). Likewise, PhI=NTs reacts with ***Thioanisole*** to generate the iminosulfurane (**2**) in 49% yield (eq 4) and with ***Dimethyl Sulfoxide*** to quantitatively produce the sulfoximine (**3**) (eq 5).

Amination of Alkanes and Alkenes.

PhI=NTs can be employed as a nitrogen source in the transition metal-catalyzed amination of alkanes and the allylic amination of alkenes. Manganese porphyrin complexes catalyze the amination of cyclohexane to generate *N*-tosylcyclohexylamine in 15% yield, while adamantane is aminated in 56% yield (eqs 6 and 7).[3] Manganese porphyrins also catalyze the amination of alkenes to generate allylic amine derivatives.[4] In this manner, *N*-tosyl-2-cyclohexeneamine was synthesized in 70% yield based on oxidant (eq 8). The amination of open-chain alkenes is hampered by attenuated reactivity and poor regioselectivity.

A complex generated in situ by the addition of ***Iron(II) Chloride*** to ***Chloramine-T*** effects similar aminations of hydrocarbons.[5] When adamantane is introduced to a solution of this complex, *N*-tosyladamantan-1-amine is isolated in 63% yield (eq 9). Extension of the reaction to other substrates is complicated by the generation of chlorine-containing products.

(9)

The insertion of nitrenes, generated via the photolysis or thermolysis of azides, into C-H bonds is well known, although the yields are generally poor.[6,7] However, when ***Ethyl Azidoformate*** is thermolyzed in the presence of 1-chlorocyclohexene, the allylic insertion product is formed in 49% yield (eq 10).[8] In this case it is not clear if the product is formed through direct insertion or by the ring opening of an aziridine intermediate.

(10)

Aziridination of Alkenes.

Iron- and manganese-porphyrin complexes catalyze the reaction of PhI=NTs with alkenes to form the corresponding *N*-tosylaziridines.[9] Mn(TPP)Cl is generally a better catalyst than the analogous iron complex, affording 80% of the aziridine from the reaction with styrene (eq 11). Good yields are also obtained in the manganese-catalyzed reactions with 1,1- and 1,2-diphenylethylenes.[10] Yields of aziridines derived from aliphatic alkenes remain low and are complicated by the formation of allylic amines.

(11)

TPP = tetraphenylporphyrin

Copper-based complexes have been found to be excellent catalysts for the aziridination of alkenes employing PhI=NTs as the nitrene precursor (eq 12).[11] Both Cu^{I} and Cu^{II} efficiently catalyze the reaction, and the best results are usually obtained with the cationic complexes ***Tetrakis(acetonitrile)copper(I) Perchlorate*** and ***Copper(II) Trifluoromethanesulfonate***. Good yields are obtained with a variety of substrates, including aliphatic alkenes and enolsilanes (eq 13), the latter delivering α-amino ketones upon hydrolysis of the intervening silyloxyaziridine.

(12)

(13)

Other nitrene precursors have been employed in the aziridination of alkenes. Azides have been shown to form aziridines when photolyzed or thermolyzed in the presence of alkenes, though these reactions usually exhibit low yields.[12,13] However, the possibility of a transition metal-catalyzed process remains. In 1968, it was reported that heating ***Benzenesulfonyl Azide*** with cyclohexene in the presence of ***Copper*** powder produces the corresponding aziridine, albeit in low yield (15%).[14] Pd^0 catalyzes the aziridination of allylic ethers with methyl azidoformate.[15]

Asymmetric Aziridination of Alkenes.

The copper-catalyzed aziridination reaction can be rendered enantioselective by the addition of chiral ligands. The first example of an enantioselective aziridination of an alkene employed the bis(oxazoline) ligand (**4**) (R = *t*-Bu) and ***Copper(I) Trifluoromethanesulfonate*** as the metal catalyst (eq 14).[16] This catalyst system affords the aziridine in 97% yield and 61% ee. Other reports have appeared subsequently regarding the extended scope of this reaction.[17-21] Important contributions to this area include the copper/bis(oxazoline)-catalyzed aziridination of aryl acrylate esters (eq 15)[20] and the copper/bis(imine)-catalyzed aziridination of cyclic *cis*-alkenes with the bis(imine) ligand (**5**) (eqs 16 and 17).[19]

(17)

Formation of Isocyanates.

The Pd-catalyzed reaction of PhI=NSO_2Ar in the presence of CO generates the isocyanates $ArSO_2NCO$.[22] Thus ***Bis(benzonitrile)dichloropalladium(II)*** catalyzes the formation of the isocyanate TsNCO (which can be isolated as the urea (**6**) in 60% yield after reaction with 2-chloroaniline) with PhI=NTs (eq 18). This reaction has been reported for several arylsulfonylimino iodinanes. Similar results can be achieved, however, by employing the less expensive chloramine-T and its derivatives as reagents.[23]

p-Toluenesulfonyl Isocyanate[1]

[4083-64-1] · $C_8H_7NO_3S$ · *p*-Toluenesulfonyl Isocyanate · (MW 197.23)

(converts oxiranes to 2-oxazolinones;[2] undergoes many [2 + *x*] cycloadditions; useful for (thio)carbonyl to imine functional group interchange; introduces the Tac protecting group to amino acids[3])

Alternate Name: tosyl isocyanate.

Physical Data: bp 144 °C/10 mmHg; *d* 1.295 g cm^{-3}.

Solubility: sol chlorinated, aromatic, and ethereal solvents; reacts violently with H_2O and basic and protic solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: lachrymator; corrosive; use only in a fume hood. Wear protective gloves and, preferably, a NIOSH-approved respirator. All transfers and reactions should be carried out under anhydrous conditions. Store in a cool dry place, taking care to avoid contamination with protic, basic, or organometallic materials, as these may induce polymerization. See Karol[4a] and Henderson[4b] for toxicity data of isocyanates.

Conversion of Oxiranes to 2-Oxazolinones.

Tosyl isocyanate can be considered either as a heteroatom ring-expanding reagent, or as an NH_3 synthetic equivalent. A prime example might be its Lewis or π-acid catalyzed reaction with epoxides to give *N*-tosylated 2-oxazolinones directly,[2,5] or 1,2-amino alcohols after hydrolysis. An elegant and powerful variation utilizing chiral, nonracemic Pd-phosphine complexes, which exploits the greater reactivity of sulfonylated isocyanates, has also been developed, giving access to optically active cyclic 1,2-amino alcohols (eq 1).[6] In a related sequence, allylic amines are converted to *N*,*N*′-cyclic ureas with I_2 catalysis.[7]

[2 + *x*] Cycloadditions.

Highly reactive tosyl isocyanate readily undergoes a wide variety of [2 + 2] cycloadditions.[8] Much effort has been expended upon the preparation of *N*-tosylated β-lactams. Despite the difficulty of removal of the sulfonyl group without cleaving the β-lactam,[9] novel variations continue to appear (eq 2).[10]

Other [2 + 2] cycloadditions have been reported with hydrazones,[11] and imino ethers.[12] [2 + 3] Cycloadditions that afford pyrrolidinone derivatives from transition metal complexes have recently been reported (eq 3).[13] Higher-order cycloadditions also appear in the literature.[14]

(Thio)carbonyl to Imide Reactions.

Desulfur- and deoxygenations of (thio)lactams, glyoxaldehydes, and phosphine oxides induced by tosyl isocyanate liberate CO_2 or COS. The product *N*-sulfonyl amidines, which give novel stereochemistry in aldol reactions,[15] glyoximines, which may be used directly in aza-Diels-Alder reactions,[16] and phosphinimines[17] are obtained in high yields.

Miscellaneous Reactions.

Reaction (20-80%) with amino acids introduces the *N*-Tac group, which, while stable to cold TFA, dilute base, HBr/acetic acid, and catalytic hydrogenation, may be removed by hot primary alcohols.[3] Tosyl isocyanate is an efficient dehydrating agent for tertiary (especially allylic) alcohols.[18] The *N*-tosyl group is a pharmacophore.[19] Novel ring expansions of medium- and large-ring keto esters triggered by tosyl isocyanate afford macrolactams.[20]

Related Reagents.

Benzenesulfonyl Isocyanate; ***Chlorosulfonyl Isocyanate***.

p-Toluenesulfonyl Azide[1]

[941-55-9] · $C_7H_7N_3O_2S$ · *p*-Toluenesulfonyl Azide · (MW 197.24)

(introduction of azide and diazo groups into organic compounds;[2] serves as a source of nitrene and 1,3-azide dipoles for [3 + 2] cycloadditions;[3] used for the synthesis of *N*-tosylphosphinimines,[4] -sulfimines, and -sulfoximines[5])

Alternate Names: tosyl azide.

Physical Data: mp 21-22 °C; bp 110-115 °C/0.001 mmHg;[6] d^{25} 1.286 g cm^{-3}; *n*25589 1.55010.

Solubility: sol chloroform, diethyl ether, acetone.

Form Supplied in: oily colorless liquid.

Analysis of Reagent Purity: IR (neat) ν = 2130 (strong, N=N=N), 1380 and 1180 (strong, SO_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ = 2.47 (s, CH_3), 7.40 (d, *J* = 8 Hz, *m*-$SO_2C_6H_4$), 7.84 (d, *J* = 8 Hz, *o*-$SO_2C_6H_4$).[7]

Preparative Methods: the simplest synthetic method for tosyl azide is the reaction of ***p-Toluenesulfonyl Chloride*** with ***Sodium Azide***. Tosyl azide prepared in ethanol may contain 7-20% of ethyl *p*-toluenesulfonate;[8] the formation of this byproduct can be avoided by working in aqueous acetone instead of ethanol.[9,10] The ^1H NMR spectrum of tosyl azide prepared (99% yield) according to Curphey exhibits signals for traces of dichloromethane (<1%);[10] the compound is pure by TLC, while HPLC reveals traces (>1.5%) of an impurity. Polymer-bound tosyl chloride can be transformed to polymer-bound tosyl azide.[11] A polymer-bound phase-transfer catalyst may also be employed (94% yield).[12] Further methods for the preparation of tosyl azide are the oxidation of ***p-Toluenesulfonylhydrazide*** by ***Iron(III) Nitrate-K10 Montmorillonite Clay*** (83% yield),[13] by ***Nitrogen Dioxide*** in CCl_4 (95% yield),[14] or by ***Nitrosonium Tetrafluoroborate*** (85% yield). [15]

Handling, Storage, and Precautions: crystallizes to a white solid at -20 °C and can be stored indefinitely at this temperature. Particular care is required for all reactions in which tosyl azide is heated at or above 100 °C. The initial temperature of the explosive decomposition is about 120 °C.[16] Severe explosions during the attempted distillation of tosyl azide have been reported.[6,17] Polymer-bound tosyl azide can be stored indefinitely at room temperature and, in contrast to tosyl azide itself, is not sensitive to mechanical shock. Use in a fume hood.

Synthesis of Azides.

Tosyl azide acts as a transfer reagent to introduce the azide group to anions of C-H acidic compounds such as malonate derivatives (eq 1);[18] aryl azides are obtained from the reactions of aryl Grignard reagents with tosyl azide after cleavage of the primarily formed triazene salt intermediates with sodium pyrophosphate (eq 2);[19] azidothiophenes and -bithiophenes[20] or azidotetrazolium salts[21] can be prepared similarly (using organolithium compounds). The anions of primary amines, generated from the latter by treatment with Grignard reagents[22] or preferably with ***Sodium Hydride*** in THF,[23] also react with tosyl azide to furnish azides (diazo group transfer to primary amines, eq 3). α-Azido sulfones are formed in one step by reactions of aliphatic nitro compounds with ***Potassium Hydride*** in THF and subsequent treatment with tosyl azide (eq 4).[24]

(1)

Synthesis of Diazo Compounds.[2]

The synthesis of diazo compounds from a carbon nucleophile and an arenesulfonyl azide, preferably tosyl azide (eq 5), is known as diazo group transfer.[25] The actual reaction in a somewhat different form has been known for a long time;[26] it was first employed for the synthesis of diazocyclopentadiene from the cyclopentadienide anion and tosyl azide[27] and has since been developed intensively.

X, Y = CO_2R, CHO, COR, $CONR_2$, CN, NO_2, SOR, POR_2, $PO(OR)_2$, Ar

(5)

When X and Y are suitable electron-attracting groups such as CO_2R, COR, NO_2, SO_2R, Ar, etc., the required carbanion can be generated by treatment of the corresponding methylene compound with an appropriate base (NEt_3, pyridine/piperidine, NaOEt, *t*-BuOK). The synthesis of *t*-butyl diazoacetate is an explicit example.[8] The use of a phase-transfer catalyst is sometimes advantageous for the generation of the carbanion.[28] When only one electron-attracting, activating group is present in the substrate, diazo group transfer can be effected by an indirect route in which, for example, a ketone is transformed to an α-formyl ketone which is, in turn, converted by treatment with tosyl azide in the presence of a base to the desired diazo compound by cleavage of *N*-formyltosyl amide (deformylating diazo group transfer, eq 6).[29]

(6)

Tosyl azide is the reagent employed most frequently. However, ***p-Dodecylbenzenesulfonyl Azide***,[16] *p*-carboxybenzenesulfonyl azide,[30] polymer-bound tosyl azide,[11] trifluoromethanesulfonyl azide (triflyl azide),[31] (azidochloromethylene)dimethylammonium chloride,[32] ***2,4,6-Triisopropylbenzenesulfonyl Azide*** (trisyl azide),[33] and others[34] have also been used. 2-Azido-3-ethyl-1,3-benzothiazolium tetrafluoroborate and 2-azido-1-ethylpyridinium tetrafluoroborate[35] have proven to be useful as diazo group transfer reagents since they can also be employed in weakly acidic media with base-sensitive methylene compounds. In addition to the requirement for a less hazardous reagent than tosyl azide, the separation of the inevitably formed amine from the desired diazo compound represents the main stimulant for the continued search for novel diazo group transfer reagents.

Supplementary to the classic diazo group transfer to activated methylene compounds described briefly above, the reactions of tosyl azide with enamines, enol ethers, ynamines, ynethers, activated alkenes and alkynes, cyclopropenes, and methylenephosphoranes may also be included in this reaction type in its widest sense, when the respective reactions give rise to diazo compounds (see the examples in eqs 7 and 8);[36] see also cycloaddition reactions (below) as an alternative.

(7)

(8)

Cycloaddition Reactions.

The 1,3-dipolar cycloadditions of tosyl azide to alkenes primarily furnish the 4,5-dihydrotriazoles which can seldom be isolated.[37] Generally, subsequent reactions such as the [3 + 2] cycloreversion to *N*-tosylimines and diazo compounds (diazo group transfer), the cleavage of nitrogen in *N*-tosylaziridines, or the concomitant 1,2-shift of a substituent in *N*-tosylimines with rearranged molecular skeletons (eq 9) predominate.[38] All processes can occur in parallel; however, there is a pronounced reaction selectivity in dependence on the group X (the electron donating substituent).

(9)

From the plethora of synthetic applications of tosyl azide, its examples of the reactions with nonstrained cycloalkenes leading to *N*-tosylimines (eq 10),[39] with cyclic enamines which give amidines (eq 11),[40] with indoles to furnish 2-tosyliminoindoles (eq 12),[41] and with enol ethers giving rise to imidates in quantitative yield (eq 13)[42] are mentioned as examples. When the alkene carries a further substituent capable of elimination, the cycloadditions give rise to 1,2,3-triazoles directly (eq 14).[43] The *N*-tosyl group can be readily removed by hydrolysis to liberate the corresponding NH compound. Thus in this sense, tosyl azide can be considered as a synthetic equivalent of the difficult to handle hydrogen azide (***Hydrazoic Acid***, HN_3).

(10)

(11)

(12)

(13)

(14)

Miscellaneous.

The reactions of aryl and heteroaryl hydrazides with tosyl azide in the presence of NaOH under phase-transfer conditions give rise to the corresponding aromatic and heteroaromatic compounds (eq 15).[44] After oxidative workup, reactions with trialkylboranes yield alkyl aryl sulfides (eq 16).[45]

N-(*p*-Toluenesulfonyloxy)phthalimide

[56530-39-3] · $C_{15}H_{11}NO_5S$ · *N*-(*p*-Toluenesulfonyloxy)phthalimide · (MW 317.34)

(transformation of aryllithiums and enolates into 3,3-disubstituted quinoline-2,4-diones[1])

Alternate Name: *N*-tosyloxyphthalimide.

Physical Data: mp 161-162 °C.

Solubility: sol ether, THF; slightly sol alcohol.

Preparative Methods: prepared[2] by reaction of *N*-hydroxyphthalimide[3] with diethylamine and ***p-Toluenesulfonyl Chloride*** in dry benzene.

Amination.

For carbanion amination, various *O*-sulfonylhydroxylamines have been used,[4] and Grignard reagents, organolithiums, and enolates have been converted into primary and tertiary amines (eq 1).

$$R_2NOSO_2R^1 + R^2M \longrightarrow R_2NR^2 + MOSO_2R^1 \qquad (1)$$

$$M = Li, MgX; \quad R = Me, Et$$

However, the reactions of aryl carbanions and enolates with *N*-tosyloxyphthalimide gives 3,3-disubstituted quinoline-2,4-diones (eq 2) in moderate to good yields (eqs 3 and 4).[1]

(2)

(3)

(4)

The reaction is carried out as follows. Aryllithium or enolate is prepared by using ***n-Butyllithium*** at -70 °C in THF and a solution of *N*-tosyloxyphthalimide (0.5 equiv) is added with stirring. Stirring is continued until the temperature reaches 15 °C, when the solution is poured into aqueous acid. After extraction with dichloromethane and evaporation, the residue is crystallized.

The proposed mechanism involves the possible intermediate isocyanato ketone, which is attacked by the carbanion to form another carbanion which then undergoes intramolecular attack at the carbonyl group, leading to cyclization to form the dione (eq 5).

O-p-Tolyl Chlorothioformate

[937-63-3] · C_8H_7ClOS · *O-p*-Tolyl Chlorothioformate · (MW 186.67)

(synthesis of alkenes from hindered alcohols;[1] deoxygenation of alcohols[7])

Physical Data: bp 52-53 °C; *d* 1.21 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: commercially available as liquid (97% pure).

Analysis of Reagent Purity: GC.

Handling, Storage, and Precautions: moisture sensitive; keep cold; corrosive; toxic; use in a fume hood.

Synthesis of Alkenes.

Formation of thiocarbonate *O*-esters from sterically hindered alcohols, followed by pyrolysis, provides an alternative to the Chugaev reaction in the synthesis of alkenes. In the examples shown in eqs 1 and 2, pyrolysis of the corresponding xanthates gives lower yields.[1,2]

(1)

(2)

The pyrolysis of thiocarbonate *O*-esters has been utilized in the synthesis of several natural products. In an approach to the synthesis of (-)-acorenone (eq 3), pyrolysis of the xanthate gives consistently low yields.[3] The favored pathway appears to be conversion to the dithiol carbonate. Alternatively, conversion to the thiocarbonate *O*-ester and subsequent pyrolysis gives the desired alkene in 68% yield. This methodology has also been successfully used in a total synthesis of (±)-silphenene (eq 4).[4] Ordinary dehydration conditions lead to retroaldolization, while pyrolysis of the thiocarbonate *O*-ester gives the desired enone in 84% yield. An intermediate in the total synthesis of (-)-hibaene has been prepared by pyrolysis of the respective monothiocarbonate *O*-esters of both epimeric diols (eq 5).[5]

(3)

(4)

(5)

Deoxygenation of Alcohols.

Thiocarbonate esters of alcohols can be deoxygenated using the Barton-McCombie procedure.[6] Several examples of this deoxygenation methodology in the synthesis of deoxyribose nucleosides have been cited (eq 6).[7-9]

(6)

[Heteroaryl(hydroxy)methyl]phosphonates are readily converted to *O*,*O*-thiocarbonates on treatment with *O*-*p*-tolyl chlorothioformate in MeCN/DMAP, while the reaction in pyridine/CH_2Cl_2 affords the isomeric *O*,*S*-thiocarbonates (eq 7).[10] Homolytic cleavage with ***Tri-n-butylstannane***/***Azobisisobutyronitrile*** provides a convenient approach to dialkyl heteroarylmethylphosphonates.

o-Tolyl Isocyanide[1,2]

[10468-64-1] · C_8H_7N · *o*-Tolyl Isocyanide · (MW 117.16)

(synthesis of N-heterocycles and azomethines)

Physical Data: bp 75 °C/16 mmHg; *d* 0.97 g cm^{-3}.

Solubility: sol most organic solvents, e.g. methanol, ethanol, ether, toluene, dichloromethane.

Analysis of Reagent Purity: by gas chromatography.

Preparative Method: see Ugi and Meyr.[3]

Handling, Storage, and Precautions: should be freshly distilled before use. Foul smelling liquid; store and use in a fume hood. Contaminated equipment should be washed with 5% methanolic sulfuric acid.

Introduction.

o-Tolyl isocyanide can be used to synthesize a great variety of compounds.[1,2] The aromatic *o*-methyl group can be lithiated to create a bifunctional isocyanide reagent (eq 1).[4]

(1)

Indole Synthesis.

Reaction of *o*-tolyl isocyanide with ***Lithium Diisopropylamide*** followed by alkylation[5,6] or acylation[7-9] and then cyclization gives 3-substituted indoles (eqs 2-4).

(2)

(3)

(4)

Synthesis of Other Heterocycles.

β,γ-Butenolide imines can be made in reasonable yields by Lewis acid-catalyzed [4 + 1] cycloaddition (eq 5).[10] The azetidine ring system, otherwise very difficult to obtain, results in reasonable yield in a one-step [2 + 2 + 2] cycloaddition using *o*-tolyl isocyanide (eq 6).[11]

(5)

(6)

Azomethines.

Nucleophilic attack of organozinc compounds on the isocyanide carbon leads to the corresponding Schiff bases (eq 7).[12] Similarly, Pd^0 catalysis effects insertion of *o*-tolyl isocyanide into the Si-Si bond of bis-silyl compounds (eq 8).[13]

(7)

(8)

(*R*)-(+)-*p*-Tolylsulfinylacetic Acid

[88981-65-1] · $C_9H_{10}O_3S$ · (*R*)-(+)-*p*-Tolylsulfinylacetic Acid · (MW 198.26)

(optical resolution of amines[1,3,4])

Physical Data: $[\alpha]_D$ = +143.5° (acetone, *c* = 33.0). The absolute configuration of this reagent (and other arylsulfinyl acetic acids) is characterized by two CD Cotton effects which are observed in the presence of the metal cluster $[Mo_2(OAc)_4]$ in DMSO solution above 300 nm.[2]

Preparative Method: prepared by carboxylation of ***(R)-(+)-Methyl p-Tolyl Sulfoxide*** carbanion generated with ***Lithium Diisopropylamide*** (eq 1).[1]

Optical Resolution of Indole Alkaloid Precursors.

This reagent has been used for optical resolutions of tetracyclic alkaloids such as 10,22-dioxokopsane (**1**)[1] and kopsinine (**2**).[3]

The racemic tetracyclic amine (**3**) can be coupled to (*R*)-(+)-*p*-tolylsulfinylacetic acid using the modified carbodiimide reagent ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide Metho-p-toluenesulfonate*** to give the diastereomeric sulfinyl amides (**4**) and (**5**) (eq 2), which are readily separated by HPLC.[1,3]

Similarly, in a total synthesis of strychnine, the optical resolution was carried out by separation of the sulfinyl lactam diastereomers (**7**) and (**8**), which were obtained from the heptacyclic indole alkaloid precursor (**6**); this was first transformed with (*R*)-(+)-*p*-tolylsulfinylacetic acid into the corresponding sulfinyl amide and then converted to the diastereomeric lactams (**7**) and (**8**) by an intramolecular conjugate addition (eq 3).[4]

(*R*)-(+)-α-(*p*-Tolylsulfinyl)-*N,N*-dimethylacetamide

[72298-22-7] · $C_{11}H_{15}NO_2S$ · (*R*)-(+)-α-(*p*-Tolylsulfinyl)-*N,N*-dimethylacetamide · (MW 225.34)

(asymmetric aldol-type condensation[1,2])

Physical Data: $[\alpha]_D$ = +194.7° ($CHCl_3$, *c* = 1).

Preparative Method: prepared[1,2] by reaction of ***Lithio-N,N-dimethylacetamide*** with (*S*)-(-)-menthyl *p*-toluenesulfinate (see ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***) (eq 1).

The Pummerer reaction of optically active (*R*)-(+)-α-(*p*-tolylsulfinyl)-*N,N*-dimethylacetamide with ***Acetic Anhydride*** in the presence of ***1,3-Dicyclohexylcarbodiimide*** is highly stereoselective, affording the corresponding α-acetoxy sulfide in moderate yield but with nearly 70% ee (eq 2).[3,4] The recovered starting sulfoxide is obtained in 63% yield.

Good asymmetric induction is also observed during the aldol-type condensation of the magnesium enolate of (*R*)-(+)-α-(*p*-tolylsulfinyl)-*N,N*-dimethylacetamide with aldehydes (eq 3).[1,2]

A model (**1**), similar to that proposed for aldol-type condensation of α-sulfinyl esters,[5] has been proposed to predict the chirality of the resulting β-hydroxy amides.

(3*R*)-(*p*-Tolylsulfinyl)-*N*-methoxyacetimidic Acid Ethyl Ester

[95614-76-9] · $C_{12}H_{17}NO_3S$ · (3*R*)-(*p*-Tolylsulfinyl)-*N*-methoxyacetimidic Acid Ethyl Ester · (MW 255.37)

(asymmetric aldol-type condensation[1])

Alternate Name: ethyl (*p*-tolylsulfinyl)-*N*-methoxyacetimidate.

Physical Data: $[\alpha]_D$ = +28° (*c* = 1, $CHCl_3$).

Preparative Method: prepared in 89% yield by reacting the lithium enolate of ethyl *N*-methoxyacetimidate with (-)-(*S*)-menthyl *p*-toluenesulfinate (see ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***) (eq 1).[1]

Aldol-Type Condensation.

Aldol-type condensation of the lithium enolate of ethyl (*R*)-(*p*-tolylsulfinyl)-*N*-methoxyacetimidate (prepared with ***n-Butyllithium***) with aldehydes affords, after desulfurization with ***Raney Nickel***, β-hydroxy esters with high enantioselectivity (eq 2).[1]

Anti diastereoselectivity gives the optically active (*S*)-β-hydroxy ester while *syn* diastereoselectivity leads to the (*R*)-β-hydroxy ester, via a chelated six-membered transition state (eq 3). Since the *anti* intermediate is more stable, the (*S*)-β-hydroxy ester predominates under thermodynamic conditions (Table 1, entry 1). Higher diastereoselectivity is achieved by changing the counterion from lithium to a more chelating one such as zinc (Table 1, entry 2). On the other hand, in order to obtain diastereoselection under kinetic control, zirconium enolates (prepared by treating the lithium enolate with ***Dichlorobis(cyclopentadienyl)zirconium***) are used, leading to the (*R*)-β-hydroxy ester (Table 1, entry 3) in high yield.

Table 1 Diastereoselection in the Aldol-Type Reaction

Entry	Aldehyde	Metalation conditions	Condensation conditions	Abs. conf.	ee
1	R = Ph	BuLi, - 78 °C, 15 min	- 78 °C to 0 °C, 4 h	(*S*)	75%

p-Tolylsulfinylmethyllithium[1]

[1519-39-7] · C_8H_9LiOS · *p*-Tolylsulfinylmethyllithium · (MW 160.18)

(asymmetric synthesis; adds diastereoselectively to carbonyl compounds,[1] esters,[1] imines,[1b,f] nitrones,[2] and nitrile oxides[3])

Physical Data: stable in THF even above 0 °C.

Solubility: sol THF.

Form Supplied in: generated in situ from precursors, ***(R)-(+)-Methyl p-Tolyl Sulfoxide***, mp 73-75 °C, $[\alpha]^{20}$ +145° (*c* = 2, acetone), and (*S*)-(-)-methyl *p*-tolyl sulfoxide, mp 75-77 °C, $[\alpha]^{20}$ -147° (*c* = 2, acetone), both of which are commercially available and can also be prepared by a number of methods.[1,4]

Preparative Method: prepared in situ by the reaction of enantiomers of methyl *p*-tolyl sulfoxide with ***Lithium Diethylamide*** or ***Lithium Diisopropylamide*** in THF at 0 to -78 °C.[1]

Handling, Storage, and Precautions: highly sensitive to air and moisture. Its generation and handling must be carried out under an inert atmosphere of nitrogen or argon. Normally, preparation is carried out immediately prior to use.

Introduction.

Most of the synthetic applications are carried out with (*R*)-(+)-*p*-tolylsulfinylmethyllithium. The carbanion undergoes copper-promoted oxidative dimerization to the optically pure 1,2-bis-sulfoxide (eq 1).[5]

Addition to Carbonyl Compounds.

The addition of *p*-tolylsulfinylmethyllithium to carbonyl compounds gives the β-hydroxy-α-*p*-tolylsulfinyl adducts in poor diastereoselectivity; normally, an approximately 1:1 diastereomeric mixture is obtained.[6] The diastereoselection with benzaldehyde is improved to about 80% with the addition of ***Zinc Chloride***.[7] Although proceeding with a poor diastereoselectivity, the reaction can be applied to the asymmetric synthesis of optically active alcohols. The two diastereomeric adducts can be separated by chromatography. Desulfinylation of each diastereomer gives the corresponding optically active alcohol (eq 2).[6] Optically active alcohols can also be prepared from epoxides (eq 3).[6]

(3)

(*R*)-(+)-*trans*-β-Styryl *p*-tolyl sulfoxide, produced by the reaction of the benzaldehyde adduct with excess ***Sodium Hydride*** and ***Iodomethane***, undergoes selective Michael reaction with diethyl sodiomalonate to give the (R_C,R_S) product as the major isomer, which can be obtained in pure form by fractional crystallization. The product can be transformed into optically active (-)-3-phenylbutyric acid (eq 4).[8]

(4)

The dianion of (*R*)-3-(*p*-tolylsulfinyl)propionic acid, prepared from the alkylation product of *p*-tolylsulfinylmethyllithium with lithium bromoacetate, adds to aldehydes to give diastereomeric lactones which can be separated by chromatography; their pyrolyses give optically pure 5-substituted furan-2(5*H*)-ones (eq 5).[9]

(5)

Addition to Esters.

Racemic *p*-tolylsulfinylmethyllithium reacts with (*R*)-(-)-menthyl benzoate in enantiodifferentiating fashion to give the corresponding optically active β-keto sulfoxide together with optically active methyl *p*-tolyl sulfoxide which has the opposite configuration.[10] A similar result is obtained in the reaction of ethyl carboxylates in the presence of (-)-sparteine (eq 6).[11] The optically active β-keto sulfoxides, which are very important chiral synthons for the synthesis of optically active materials, are normally prepared by the reaction of (*R*)-*p*-tolylsulfinylmethyllithium with carboxylic acid esters.[1a] *p*-Tolylsulfinylmethyl phenyl ketone reacts with ***Diethylaluminum Cyanide*** in toluene diastereoselectively to give one diastereomer of the corresponding cyanohydrin which can be transformed into the optically active alcohol (eq 7).[12]

β-Hydroxy sulfoxides of opposite stereochemistry can be prepared in very high diastereomeric excesses (90-95%) by the reduction of β-keto sulfoxides with ***Lithium Aluminum Hydride***, ***Diisobutylaluminum Hydride***, or DIBAL/$ZnCl_2$.[13] The optically pure diastereomers of the β-hydroxy sulfoxides can be transformed into optically active epoxides (eq 8),[14] alcohols (eq 9),[15] and 4-substituted butenolides (eq 10).[16]

Addition to Arenesulfinic Esters.

The reaction of (*R*)-(+)-*p*-tolylsulfinylmethyllithium with (-)-menthyl (*S*)-*p*-toluenesulfinate gives (*S*,*S*)-bis(*p*-tolylsulfinyl)methane. (*S*)-(-)-*p*-Tolylsulfinylmethyllithium reacts similarly with (-)-menthyl (*S*)-*p*-toluenesulfinate, producing (*R*,*S*)-bis(*p*-tolylsulfinyl)methane (eq 11).[4c] In contrast to the poor diastereoselection in the reaction of (*R*)-(+)-*p*-tolylsulfinylmethyllithium with carbonyl compounds, (*S*,*S*)-(+)-bis(*p*-tolylsulfinyl)methyllithium reacts with aromatic aldehydes with high diastereoselectivity. Its reaction with α,β-unsaturated aldehydes yields 4-substituted (*E*,*E*)-(*S*,*S*)-1,1-bis(*p*-tolylsulfinyl)-1,3-butadiene (eq 12).[17]

Addition to Imines.

The addition of (*R*)-(+)-*p*-tolylsulfinylmethyllithium to benzylideneaniline produces (R_SR_S)-(+)-*N*-phenyl-2-amino-2-phenylethyl *p*-tolyl sulfoxide in high diastereoselectivity (eq 13).[18] Acyclic and cyclic imines react similarly. The chair transition state can account for the diastereoselective process. Detailed investigations reveal that diastereoselectivity depends on several factors, i.e. the temperature used for deprotonation of methyl *p*-tolyl sulfoxide (optimum conditions: LDA, THF, 0 °C)[18c] and kinetically and thermodynamically controlled reaction conditions. Equilibrium between the diastereomeric adducts is thought to occur over the timescale of the addition reaction. Diastereoselectivity is better under kinetic control than under the thermodynamic control.[18b] This methodology has been applied to the syntheses of (*R*)-(+)-carnegine and (*R*)-(+)-tetrahydropalmatine (eq 14).[19]

Addition to Nitrones and Nitrile Oxides.

The reaction with 6,7-dimethoxy-3,4-dihydroisoquinoline *N*-oxide in the presence of quinidine is a highly diastereoselective process. The *N*-hydroxytetrahydroisoquinoline adduct can be desulfurized to (*R*)-(+)-salsolidine (eq 18).[2b] The addition of (*R*)-(+)-*p*-tolylsulfinylmethyllithium to arylnitrile oxides gives β-oximino sulfoxides with high optical purity (eq 19).[3]

Related Reagents.

Methyl Phenyl Sulfone; ***Phenylthiomethyllithium***.

(*R*)-(+)-3-(*p*-Tolylsulfinyl)propionic Acid

[90334-31-9] · $C_{10}H_{12}O_3S$ · (*R*)-(+)-3-(*p*-Tolylsulfinyl)propionic Acid · (MW 212.29)

(asymmetric aldol-type condensation[2])

Physical Data: $[\alpha]_D$ = +180° ($CHCl_3$, *c* = 0.7), $[\alpha]_D$ = +188° (MeOH, *c* = 0.7).

Preparative Method: conveniently prepared in 76% yield by addition of a suspension of lithium bromoacetate to a solution of the anion of ***(R)-(+)-Methyl p-Tolyl Sulfoxide*** (eq 1).[1,2]

Aldol-Type Condensation.

Dimetalation of (*R*)-(+)-3-(*p*-tolylsulfinyl)propionic acid with ***Lithium Diisopropylamide*** produces a chiral homoenolate dianion equivalent which reacts with carbonyl compounds to afford β-sulfinyl-γ-hydroxy acids; these spontaneously cyclize to give the corresponding β-sulfinyl γ-lactones (eq 2).[1,2]

Two new chiral carbon atoms are formed in the condensation and four diastereoisomeric β-sulfinyl γ-lactones can therefore in principle be obtained. However, only two diastereoisomers, (3*S*,4*R*,R_S) and (3*R*,4*S*,R_S), are isolated when the carbanion is condensed with pivalic aldehyde, benzaldehyde, or pinacolone (yield 65-70% for aldehydes, ratio 53:47; yield 47% for pinacolone, ratio 81:19). The diastereoselectivity decreases when the two substituents of the carbonyl group are sterically similar. However, single diastereoisomers can easily be separated through chromatography and transformed in high yield into both enantiomers of optically pure saturated (by desulfurization) and α,β-unsaturated γ-lactones (by pyrolytic sulfoxide elimination) (eq 3). The relative and absolute stereochemistry of all the products have been determined by circular dichroism, nuclear Overhauser effects, and X-ray analyses.

The condensation of the dilithio derivative of (*R*)-(+)-3-(*p*-tolylsulfinyl)propionic acid with protected glycoaldehydes (*O*-*t*-butyl and *O*-

benzyl) gives 5-alkoxy-4-hydroxy-3-(*p*-tolylsulfinyl)pentanoic acids, which spontaneously cyclize to the corresponding 3-sulfinyl-4-alkoxymethyl butanolides (eq 4).[3] Pure diastereomers can be separated by flash chromatography and are obtained in comparable amounts. The corresponding optically pure butenolides are obtained by pyrolytic elimination of the sulfoxides and then transformed into natural (+)-(*R*)-umbelactone (eq 5).

p-Tolylthiomethyl Isocyanide

[41514-80-1] · C_9H_9NS · *p*-Tolylthiomethyl Isocyanide · (MW 163.26)

(synthesis of imidazoles from cyanides;[1] conversion of aldehydes and ketones to ketene *N*,*S*-acetals[2])

Physical Data: bp 60 °C/0.001 mmHg.

Form Supplied in: ill-smelling colorless liquid, which solidifies at -10 °C; turns yellow on standing.

Analysis of Reagent Purity: IR (neat) 2150 cm^{-1}; ^1H NMR ($CDCl_3$) δ 4.4 (s, CH_2).

Preparative Method: prepared by dehydration of *N*-(*p*-tolylthiomethyl)formamide in 89% yield.[2]

Handling, Storage, and Precautions: should be stored at -20 °C. Use in a fume hood.

Introduction.

p-Tolylthiomethyl isocyanide (**1**) is one of the (hetero) substituted derivatives of methyl isocyanide, and thus belongs to a class of reagents which includes ***p-Tolylsulfonylmethyl Isocyanide*** (TosMIC), ***Diethyl Isocyanomethylphosphonate***, ***Methyl N-(p-Tolylsulfonylmethyl)thiobenzimidate*** (a TosMIC derivative), and ***Ethyl Isocyanoacetate***. TosMIC is a multipurpose synthesis reagent which, for example, forms imidazoles in a base-induced cycloaddition of its C-N-C unit across the C=N bond of imines.[3] *p*-Tolylthiomethyl isocyanide (**1**) has been developed as an alternative for TosMIC on the assumption that the anion of (**1**) is a stronger nucleophile than the anion of TosMIC.[4] Indeed, (**1**) is able to convert cyanides into imidazoles with greater efficiency than TosMIC (eqs 1-3).[1,4] Several analogs of (**1**) have been prepared, among which are (2-naphthylthio)methyl isocyanide (**2**) (mp 76-78 °C) and (*p*-chlorophenylthio)methyl isocyanide (**3**) (mp 76-77 °C).[2] Reagent (**2**) should replace (**1**) in future applications, because: (1) it does not have the characteristic (bad) smell of isocyanides; and (2) being a solid, it is more stable and can be stored for long periods at room temperature.[2]

Synthesis of Imidazoles and Oxazoles.

Imidazoles are formed in one operation by a base-induced cycloaddition of (**1**) to the triple bond of cyanides (eqs 1-3).[1,4] The *p*-tolylthio group remains part of the product, unlike imidazoles prepared from imines and TosMIC where the tosyl group is eliminated.[3] The formation of oxazoles from (**1**) and ***Acetic Anhydride***[5] or ***Methyl Formate***[6] has also been reported.

Synthesis of Ketene *N,S*-Acetals.

The Peterson alkenation of (**2**) with ketones and aldehydes provides 1-(2-naphthylthio)alkenyl isocyanides, which form a new class of ketene *N,S*-acetals (eqs 4 and 5).[2] The trimethylsilyl derivative of (**2**) is formed in situ.

p-Tolyl Vinyl Sulfoxide[1]

[36832-47-0] · $C_9H_{10}OS$ · *p*-Tolyl Vinyl Sulfoxide · (MW 166.26)

(a vinyl sulfoxide,[2] typically used in enantiomerically pure form in conjugate additions,[3] cycloadditions,[4] and Pummerer-type reactions,[5] and to prepare vinyl anions[6])

Physical Data: bp 110 °C/1.0 mmHg; 79-80 °C/0.04 mmHg; (*R*)-(+)-enantiomer: [α]26D +421° (*c* 0.15, EtOH).

Solubility: sol most moderately polar to polar solvents.

Preparative Method: (*R*)-(+)-*p*-tolyl vinyl sulfoxide is usually prepared via Andersen sulfinylation,[7] beginning with (1*R*,2*S*,5*R*,S_S)-(-)-menthyl *p*-toluenesulfinate, which is prepared as follows.[8] A two-neck round-bottom flask, equipped with N_2 inlet and magnetic stirring bar, is purged with N_2 and then charged with 2.75 equiv of ***Thionyl Chloride***. Under a N_2 atmosphere, anhydrous sodium *p*-toluenesulfinate (see ***Sodium Benzenesulfinate***) is added in portions over 1 h, with the addition of dry benzene as needed to facilitate stirring. After stirring for an additional 1.75 h, additional benzene is added and the mixture transferred to a one-neck round-bottom flask. The volatiles are removed by rotary evaporation, with occasional addition of benzene to ensure that all excess $SOCl_2$ has been removed. The flask, containing crude *p*-toluenesulfinyl chloride, is equipped with a magnetic stirring bar and constant pressure addition funnel. Ether is added and the resultant suspension is cooled to 0 °C. 1.0 Equiv of (1*R*,2*S*,5*R*)-(-)-menthol in excess pyridine is added over a few minutes, and the reaction is stirred overnight. The product is isolated by addition of ice, extraction, washing of the ether layer with 20% aq HCl, and drying (Na_2SO_4 + K_2CO_3). Filtration and concentration by rotary evaporation, followed by crystallization from acetone at -20 °C, affords the ester, mp 105-106 °C, $[\alpha]_D^{25}$ -199.4° (*c* 1.5, acetone).

The ester is converted into (*R*)-(+)-*p*-tolyl vinyl sulfoxide in the following manner.[9] A two-neck round-bottom flask equipped with constant pressure addition funnel, N_2 inlet, and magnetic stirring bar is charged with a suspension of 1.3 equiv of (1*R*,2*S*,5*R*,S_S)-(-)-menthyl *p*-toluenesulfinate in dry THF under N_2. Cooling to -78 °C is followed by dropwise addition of 1.0 equiv of ***Vinylmagnesium Bromide*** in THF and slow warming to room temperature. Satd aq NH_4Cl is added; separation is followed by drying ($MgSO_4$) and concentration by rotary evaporation. Distillation under reduced pressure affords the sulfoxide. The corresponding (*S*)-(+)-*p*-tolyl vinyl sulfoxide may be prepared from (1*S*,2*R*,5*S*,R_S)-(+)-menthyl *p*-toluenesulfinate. Alternative preparations via TBAF-mediated desilylation of (*R*)-(+)-*p*-tolyl α-trimethylsilylvinyl sulfone[10] and hydrogenation of (*R*)-(+)-ethynyl *p*-tolyl sulfoxide[2] are possible. Although rarely used, (*RS*)-*p*-tolyl vinyl sulfoxide should be available in a manner analogous to the preparation of (*RS*)-phenyl vinyl sulfoxide, by oxidation of the sulfide.[11]

Handling, Storage, and Precautions: sulfoxides are known to undergo thermal racemization.[12]

Conjugate Additions.

Compared to α,β-unsaturated ketones, vinylic sulfoxides are sluggish substrates for conjugate additions. Nonetheless, excellent chemical yields are obtained with heteroatom nucleophiles, including amines, thiols, and alcohols.[9a,9c,13] Michael additions of active methylene compounds,[13b,14] such as ***Diethyl Malonate*** or ***Ethyl Acetoacetate***,[15] are less satisfactory. Alkylmetal conjugate donor reagents, such as cuprate reagents, are rarely successful;[16] α-metalation of the vinyl moiety usually competes or predominates.[17] It is not uncommon to enhance reactivity by introducing an α-carbonyl substituent[6] using an α-acylation strategy that exploits an intermediate conjugate addition (e.g. eq 1).[18]

Cycloadditions.

Aryl vinyl sulfoxides are useful, moderately reactive, dienophiles in [4 + 2] cycloadditions;[11a] they function, for example, as synthons for ***Acetylene***,[19] ***Ethylene***,[20] vinylsilanes,[21] and ketene.[22] Enantiomerically pure aryl vinyl sulfoxides can be used to induce asymmetry in Diels-Alder reactions.[4,13a,18,23] In an application to 1,3-dipolar cycloaddition, (*R*)-(+)-*p*-tolyl vinyl sulfoxide reacts with the *N*-phenyl nitrone of benzaldehyde to produce a 95:5 mixture of (3*R*,4*R*,*RS*$_S$)-3-phenyl-4-(*p*-tolylsulfinyl)isoxazolidines in 57% yield (eq 2); the asymmetric induction at C-3 exceeds 90%.[23a]

Pummerer-Type Reactions.

An alternative to activating aryl vinyl sulfoxides to nucleophilic addition by α-acylation is to employ an additive Pummerer-type reaction,[24] which is initiated by attack of an electrophile on the sulfoxide oxygen and results in α,β-disubstituted alkyl aryl sulfides. *p*-Tolyl vinyl sulfoxide undergoes vicinal Pummerer diallylation with excess ***Allylmagnesium Bromide*** (eq 3);[23b] similarly, enantiomerically pure aryl vinyl sulfoxides have been used in highly efficient asymmetric syntheses of quaternary carbon centers[25] and γ-butyrolactones.[26] Although aryl vinyl sulfoxides are unreactive under classical Pummerer reaction conditions, an anomalous Pummerer reaction between ***Isopropenyl Acetate*** and phenyl vinyl sulfoxides provides a route to β-keto sulfides.[27]

Other Reactions.

Electrophilic addition of ***Bromine*** to (*R*)-(+)-*p*-tolyl vinyl sulfoxide is chemically efficient, but proceeds with low asymmetric induction.[9c,28] ***Triphenylstannane***, on the other hand, fails to undergo addition.[29] Homopolymerization of (*R*)-(+)-*p*-tolyl vinyl sulfoxide fails when any of a number of radical initiators are used, but copolymerization with styrene in bulk using ***Azobisisobutyronitrile*** as initiator

produces an optically active polymer.[9a] Finally, aryl vinyl sulfoxides can be converted to their corresponding sulfoximides using *N*-aminophthalimide and ***Lead(IV) Acetate***; the configuration of the sulfur center apparently is retained.[13c,30]

p-Tolylsulfonylmethyl Isocyanide[1]

[36635-61-7] · $C_9H_9NO_2S$ · *p*-Tolylsulfonylmethyl Isocyanide · (MW 195.26)

(reductive cyanation of ketones[2a] and aldehydes;[2b] synthesis of azoles (pyrroles, oxazoles, imidazoles, thiazoles, etc.) by delivering a C-N-C fragment to polarized double bonds;[3] connective reagent for coupling of alkyl halides (or carbonyl compounds) by a CO[4a] or a CH_2 bridge;[4b] preparation of (formal) Knoevenagel condensation products from aldehydes and ketones[5])

Alternate Name: tosylmethyl isocyanide; TosMIC.

Physical Data: mp 116-117 °C (dec).

Solubility: sol THF, CH_2Cl_2, $CHCl_3$, DME, AcOEt, benzene; slightly sol Et_2O, EtOH, MeOH.

Form Supplied in: white to near-white, odorless, commercially available solid.

Analysis of Reagent Purity: IR (Nujol) 2150 (N=C), 1320, 1155 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 2.5 (s, CH_3), 4.6 (s, CH_2); ^{13}C NMR ($CDCl_3$) δ 61.1 (CH_2), 165.7 (N=C).

Preparative Method: by dehydration of *N*-(*p*-tolylsulfonylmethyl)formamide.[6]

Handling, Storage, and Precautions: shelf stable.

Introduction.

p-Tolylsulfonylmethyl isocyanide is the best known compound of a series of (hetero-)substituted derivatives of methyl isocyanide, which includes ***Diethyl Isocyanomethylphosphonate***, ***p-Tolylthiomethyl Isocyanide***, ***Methyl N-(p-Tolylsulfonylmethyl)thiobenzimidate*** (a TosMIC derivative), and ***Ethyl Isocyanoacetate***. TosMIC is a multipurpose synthesis reagent, and by far the most versatile and most widely applicable reagent of the above series.

Typical Applications.

One characteristic example of each category of TosMIC applications will be given first (to be followed by further illustrative examples below).

Reductive Cyanations.

Most ketones are converted with TosMIC in one operation into cyanides (introduction of a one-carbon unit) using ***Potassium t-Butoxide*** (1-7 equiv) in nonprotic solvents (e.g. DME, DMSO) (eq 1).[2a] The reductive cyanation of aldehydes is carried out at lower temperatures and needs addition of MeOH in the final stage of the process (eq 2).[2b,7] In eqs 1 and 2, the carbonyl oxygen is removed (unlike the well known addition of HCN); hence the name of this process: reductive cyanation.

(1)

(2)

Synthesis of Azoles.

Reaction of TosMIC with aldehydes in protic solvents, e.g. MeOH at 20 °C, leads to oxazolines (eq 3),[8a] whereas oxazoles are formed in refluxing MeOH by elimination of *p*-toluenesulfinic acid (salt) (eq 4).[5c,8a] Reaction of TosMIC with acid chlorides, anhydrides, or esters leads to oxazoles in which the tosyl group is retained.[8]

(3)

(4)

Imidazoles are obtained analogously from imines,[3b] thiazoles from dithioesters or CS_2,[9] and 1,2,4-triazoles from diazonium salts.[10] More widely applied, however, is the synthesis of pyrroles from TosMIC and Michael acceptors (eq 5).[11] The pyrroles are formed in one operation; dihydropyrrole derivatives (compare eqs 3 and 4) are not usually observed. The pyrrole ring positions 1, 2, and 5 remain intrinsically unsubstituted, which is one of the virtues of this method, since such pyrroles otherwise have to be prepared by temporarily using protective groups at these positions.[11]

(5)

Connective Reagent.

The two methylene hydrogens of TosMIC have been replaced consecutively by base-induced alkylations (eqs 6 and 7).[12] Reactions as in eq 6 are carried out under phase-transfer catalysis (PTC) conditions to prevent twofold alkylation. In the product of eq 7, two alkyl halides (MeI and octyl iodide) are connected by the TosMIC methylene group; hence the name: connective reagent. This application of TosMIC is

complementary to other reagents with activated methylenes, such as ***1,3-Dithiane***[13] and ***Methylthiomethyl p-Tolyl Sulfone***. Acid hydrolysis of the geminal Tos and N=C groups produces ketones (i.e. a CO bridge, eq 7), whereas reduction with ***Lithium*** in liquid ammonia provides a methylene bridge (eq 8).[4b] Monosubstituted TosMIC derivatives, as obtained by eq 6, may replace TosMIC in eqs 3-5 to provide azoles with an additional substituent, e.g. an additional Me at position 2 of the pyrrole ring in eq 5.[3c]

(6)

(7)

(8)

Knoevenagel Condensation Products.

Reactions of TosMIC with aldehydes or ketones have been directed such that formal Knoevenagel condensation products are formed by overall elimination of H_2O (as contrasted to the reductive cyanation in eqs 1 and 2). In fact, this process requires two steps (eqs 9 and 10).[5b,d] Knoevenagel products have also been obtained by applying Peterson alkenation conditions to TosMIC (eq 11).[14]

(9)

(10)

(11)

The isocyano carbon of TosMIC is directly involved in the initial stages of the reductive cyanations, the azole syntheses, and the (formal) Knoevenagel condensations, but not in the application of TosMIC as a connective reagent. In fact, the first three types of reaction are based on a common reaction scheme;[2a,15] different products are obtained by using different reaction conditions. To emphasize this point, eq 12 describes the three different products that have been obtained separately from TosMIC and benzaldehyde.[2b,5d,8a]

Fundamental Aspects of TosMIC Chemistry.

In this section, the interrelation of TosMIC reactions is discussed briefly. TosMIC is prepared in two steps: a Mannich reaction of ***p-Toluenesulfinic Acid*** (TosH), formaldehyde, and formamide gives *N*-(*p*-tolylsulfonylmethyl)formamide (TosMIC precursor), which is dehydrated ($POCl_3/Et_3N$ or *i*-Pr_2NH) to TosMIC.[6] The Mannich reaction is reversible, but after dehydration to TosMIC the reverse reaction (of the TosMIC precursor) is blocked. Both TosMIC and the TosMIC precursor are *N*,*S*-acetals of formaldehyde. The methylene group of TosMIC is highly activated (estimated $pK_a = 14$) by the two electron-withdrawing substituents. Deprotonation of TosMIC has been achieved with an array of bases, ranging from ***Potassium Carbonate*** in MeOH to ***n-Butyllithium*** in THF. Even dilithio-TosMIC has been reported.[8b] Thus TosMIC is a formaldehyde derivative of reversed polarity (umpolung);[13] eqs 6-8 are based on this principle. Acid-catalyzed hydration of dialkylated TosMIC derivatives provides formamides, which upon hydrolysis (reversed Mannich) lead to the product ketones (eqs 7 and 35-38). In other applications of TosMIC, attack of the TosMIC anion on a carbonyl carbon is followed (or accompanied) by ring closure of the carbonyl oxygen to the electrophilic isocyano carbon to form an oxazoline (eq 3). Base-induced ring opening of these oxazolines gives α,β-unsaturated tosylformamides (eq 9), which have been dehydrated subsequently (eqs 10 and 12). Base-induced elimination of TosH from these unsaturated tosyl formamides gives *N*-formylketenimines ($R_2C{=}C{=}NCH{=}O$; not identified), which through nucleophilic removal of the formyl group eventually produce cyanides (eqs 1, 2, and 13-16). Details of these reactions have been described.[2a,15]

Reductive Cyanation.

Few examples have been described of the reaction of TosMIC with aldehydes. Examples are given in eqs 2 and 13.[2b,16] The reaction with ketones, however, is very general (eqs 1 and 14-16).[2a,15,16] Only severely sterically hindered ketones (e.g. di-*t*-butyl ketone) and readily enolizable ketones (e.g. benzyl phenyl ketone) will not undergo the reductive cyanation reaction.[2a]

(16)

Synthesis of Azoles (Pyrroles in Particular).

The reaction of TosMIC, or monosubstituted TosMIC derivatives (see eq 6), with Michael acceptors has been used frequently for the synthesis of 1,2,5-unsubstituted pyrroles and 1,5-unsubstituted pyrroles, respectively (eqs 5 and 21-24; compare eqs 25-29, 31, and 32). Over 50 papers and patents refer to this type of application of TosMIC.[17] Fewer papers deal with the use of TosMIC in the synthesis of other azoles, such as oxazoles from aldehydes (eq 4), imidazoles from imines (eq 17),[3b] thiazoles from dithioesters or CS_2 (eq 18),[9] and 1,2,4-triazoles from diazonium salts (eq 19).[10] Eqs 20 and 21 show that monosubstituted TosMIC molecules react similarly to give azoles with an additional substituent.[3c]

(17)

(18)

(19)

(20)

(21)

The usual electron-withdrawing groups (EWG) in Michael acceptors are operative in the TosMIC based pyrrole synthesis (COR, CO_2R, CN, NO_2; eqs 5, 21-25, 27, and 28). Only for EWG = CHO, will the TosMIC anion react preferentially with the aldehyde group to form oxazoles,[5c,11] as is also the case with aromatic aldehydes (cf. eqs 4 and 20). Several base/solvent systems have been used in the TosMIC pyrrole syntheses; the trend is to use an excess of base (up to 3 equiv) when less reactive Michael acceptors are used, whereas lower temperatures (to -70 °C) are recommended for the more reactive Michael acceptors. TosMIC has been used for the synthesis of antibiotically active pyrroles such as verrucarine E (eq 22)[18a] and 3-cyano-4-(2,3-dichlorophenyl)pyrrole (Fenpiclonil®) (see eq 31). Three

separate reactions have been reported between TosMIC and methyl sorbate (a dienyl Michael acceptor): depending on the conditions of the reaction, one of the two monopyrroles or an oxazole is formed (eq 23).[8b] A bipyrrole has been synthesized from ethyl sorbate using 2 equiv of TosMIC. However, this process requires three steps. After the introduction of the first pyrrole ring, the remaining α,β-double bond needs to be activated (by *N*-sulfonylation of the first-formed pyrrole ring) before the second pyrrole ring can be realized (eq 24).[19a] Recently, a heptapyrrole has been developed along related lines.[19b] Other pyrrole syntheses based on TosMIC will be discussed in the next section.

(24)

Knoevenagel-Type Condensation Products; Synthesis of (Di)Vinylpyrroles, Indoles, 3-Nitropyrroles, 3-Cyanopyrroles, and 3,4-Dialkylpyrroles.

Two different types of reactions are possible with the (formal) Knoevenagel condensation products (eqs 9-12) of TosMIC. They can act as Michael acceptors (eqs 29-32) or as monosubstituted TosMIC derivatives. Eqs 25-28 provide examples of the latter type of reaction. γ-Deprotonation of the condensation product of TosMIC and cyclopentanone (eq 25)[5b] produces an allylic anion, which reacts exclusively via its α-carbon with Michael acceptors to form pyrroles, in much the same way as in eq 21. The difference, clearly, is that in eq 25 a 2-(alk-1-enyl)pyrrole is formed. These 2-vinylpyrroles are efficient precursors for an alternate synthesis of indoles, provided that they bear a second vinyl substituent at position 3. Thermal or photochemical electrocyclic ring closure of the 6π-electron system, followed by dehydrogenation, leads to indoles (eqs 26-28). When the 3-vinyl substituent is part of an aromatic ring, electrocyclization is achieved photochemically (eq 26) but not thermally.[5b] Thermal ring closure is effective with normal 3-vinyl substituents, obtained via dienic and trienic Michael acceptors (eqs 27 and 28, respectively).[5b,20] The main product of eq 28 is formed by an intramolecular Diels-Alder reaction of the initially formed dihydroindole (not shown).[20]

(27)

In yet another synthesis of pyrroles, the Knoevenagel condensation products of TosMIC and aldehydes (eqs 11 and 12) are used as Michael acceptors (eqs 29-32). Eq 29 shows a highly efficient, one-step synthesis of 3-nitropyrroles (difficult to access otherwise),[21b] in which the ***Nitromethane*** carbon links the isocyano- and β-carbons of the Michael acceptor into a pyrrole ring.[21a] The same product of eq 29 has been obtained in the reaction of TosMIC and β-nitrostyrene in only 27% yield.[22] No reaction takes place when the nitromethane in eq 29 is replaced by acetonitrile. 3-Cyanopyrroles, however, are obtained effectively when cyanoacetate is used instead. Eq 31[3a] gives an example in the form of an alternate synthesis of a commercially employed seed-protecting agent, which is produced from TosMIC and ethyl α-cyano-2,3-dichlorocinnamate.[21c] This approach even applies to the synthesis of 3,4-dialkylpyrroles (eq 32),[3a] which obviously cannot be prepared from TosMIC and alkenes (compare eq 5).

(31)

(32)

TosMIC as a Connective Reagent.

The principle of using TosMIC as a connective reagent to form CO or CH_2 bridges has been exploited in several different ways (eqs 6-8 and 33-38). Eq 33 describes the synthesis of muscalure, a pheromone of the common house fly.[4b] The isocyano group is retained at the bridging carbon when electroreduction is applied (eq 34).[23] A practical synthesis of cyclobutanone is based on the use of TosMIC as an intramolecular connective reagent (eq 35),[24a] a method which has been extended to the (first) synthesis of (*R*)- and (*S*)-2-methylcyclobutanone from *rac*-1,3-dibromobutane and a chiral analog of TosMIC, (+)-neomenthylsulfonylmethyl isocyanide.[24b] Eq 36 gives another recent example of the synthesis of cyclic ketones.[24c] Several symmetrical and unsymmetrical acyclic diketones have been prepared by using TosMIC twice (eq 37).[4a] TosMIC has been used extensively in the construction of hydroxyacetyl side chains of corticosteroids and acetyl side chains as in progesterone (eq 38),[5e] starting from 17-oxo steroids.

TosMIC Analogs and Derivatives.

Three labeled TosMIC compounds have been reported: Tos^{14}CH$_2$N=C,[2a] TosCH$_2$N=^{13}C,[18a] and TosCH$_2$^{15}N=C.[18b] Derivatives of TosMIC, of which one or both methylene hydrogens are replaced by alkyl, aryl, silyl, or alkylidene groups, have been included in the above discussion. Furthermore, the *p*-tolyl group of TosMIC has been replaced by various other aryl or alkyl groups,[1a,b] among which are several chiral groups.[24b,25a] The TosMIC sulfur has been made a stereogenic center by replacing one oxygen for a TosN= group.[25b] Also, both oxygens of the sulfonyl group have been formally removed, providing the reagent ***p-Tolylthiomethyl Isocyanide***. Finally, the isocyano carbon of TosMIC has been equipped with two substituents, for example Ph and MeS groups,[26a] two MeO groups,[26a] or a Ph$_3$C-N= group.[26b] All analogs and derivatives of TosMIC show TosMIC-like ch emistry, but they have been applied much less frequently than TosMIC itself.

1,1,1-Triacetoxy-1,1-dihydro-1,2-benziodoxol-3(1*H*)-one[1]

[87413-09-0] · $C_{13}H_{13}IO_8$ · 1,1,1-Triacetoxy-1,1-dihydro-1,2-benziodoxol-3(1*H*)-one · (MW 424.16)

(selective oxidation of primary,[1] secondary,[1] allylic,[2] allenic,[3] propargylic,[4] benzylic,[5] and α-fluorinated alcohols;[6] monoprotected 1,2- and 1,3-diols and amino alcohols;[7-10] α- and β-hydroxy ketones,[11,12] α- and β-hydroxy esters,[13,14] β-hydroxy amides,[15] β-hydroxy sulfones;[16] nucleosides;[17] carbohydrates;[18] compatible with a variety of protecting groups,[19,20] unsaturation,[21,22] basic nitrogen,[23] divalent sulfur[24] and selenium,[25] and halogen[26])

Alternate Names: Dess-Martin periodinane; TAPI.

Physical Data: mp 124-126 °C (dec).

Solubility: appreciably sol CH_2Cl_2, $CHCl_3$, MeCN, THF; effectively insol aromatic and aliphatic hydrocarbons, ether.

Form Supplied in: white free-flowing moisture- and light-sensitive solid; not currently commerically available due to the potential explosion hazard (see below).

Analysis of Reagent Purity: recommended methods include ^{1}H NMR,[1] and standardization by oxidation of benzyl alcohol;[27] however, a typical iodimetric titration used for the standardization of peracids and other oxidants can likely also be employed. NMR data for the reagent: ^{1}H NMR (300 MHz in $CDCl_3$): δ 8.29 (d, *J* = 8.1 Hz, 2H), 8.09 (t, *J* = 8.1 Hz, 1H), 7.91 (t, *J* = 7.4 Hz, 1H), 2.32 (s, 3H), 1.99 (s, 6H); minor impurity peaks are observed at δ 8.39 (d), 8.21 (d), 8.00 (d), 7.27 (s), and 2.08 (s); ^{13}C NMR (75 MHz in $CDCl_3$): δ 175.7, 174.0, 166.1, 142.2, 135.8, 133.8, 131.7, 126.5, 125.9, 20.4, 20.2.

Preparative Method: prepared from commercially available 2-iodobenzoic acid (recrystallized) by oxidation with ***Potassium Bromate*** in aqueous sulfuric acid at 65 °C for 3.6 h to afford the highly insoluble and sensitive (explosion hazard) hydroxyiodinane oxide (**2**) which is washed free of residual $KBrO_3$ by sequential washing with water, ethanol, and then water again; vacuum filtration then affords the oxide as a moist solid (thorough drying is not recommended due to explosion hazard). This moist oxide is directly transformed to the reagent by treatment with excess ***Acetic Anhydride*** and ***Acetic Acid*** at 62 -> 96 °C for ~35 min (or until conversion is complete by analysis of an aliquot of the reaction mixture by NMR) followed by cooling for 12 h at room temperature. The solid reagent is collected by vacuum filtration under an inert atmosphere (glove bag/box or Schlenk techniques should be employed), and dried on the filter bed for 0.5 h; this affords the reagent (**1**) in 68-75% yield over the two steps (eqs 1 and 2).[1,27] A recent modification by Ireland recommends the use of ***p-Toluenesulfonic Acid*** as a catalyst in the conversion of the oxide (**2**) to (**1**).[28]

Difficulties have sometimes attended the preparation of (**1**) for a variety of reasons, including but not limited to: (1) incomplete removal of $KBrO_3$ and possibly Br_2 during preparation of the hydroxyiodinane oxide (**2**); (2) incomplete or lack of removal of traces of ethanol used in washing the oxide intermediate (an obligatory process to avoid a potential explosion hazard); (3) incomplete acetylation of the oxide (**2**), as the presence of the monoacetoxy periodinane oxide has been implicated in the impact sensitivity shown by some but apparently not all samples of the reagent; and (4) partial or complete hydrolysis of the reagent during isolation by excessive exposure to atmospheric moisture (partial hydrolysis affords the aforementioned monoacetoxyiodinane oxide, and complete hydrolysis produces iodoxybenzoic acid, known to be explosive, which may contribute to the impact sensitivity observed).[1]

Purification: the reagent, when prepared properly, is sufficiently pure for use after standardization if desired. No purification method has been described.

Handling, Storage, and Precautions: the reagent is a moisture- and light-sensitive material.[1] While it can be handled briefly in the air, extensive exposure to moisture should be avoided. Transfers of solutions should be conducted using syringe techniques, and transfers of the solid are best done in a glove bag or box to avoid deterioration of the reagent. The pure solid reagent is stable indefinitely at room temperature when precautions are taken to avoid exposure to moisture and light.[1] Storage should be in an amber bottle under an inert atmosphere or other means of protection from atmospheric moisture. Safety evaluations show that the precursor oxide is impact sensitive, and explosively decomposes when heated (>150 °C), with the onset varying with the sample. Handling the material as a moist solid appears to significantly reduce, but not completely remove, this explosion hazard. The pure periodinane has been stated to not exhibit impact sensitivity and to thermally decompose without explosion.[1] An independent evaluation of typical samples prepared as above shows that, although the reagent is less sensitive than the precursor oxide, it has the potential to decompose violently when heated (>200 °C) and shows impact sensitivity, although less than the oxide precursor. Thus, prudence requires that the preparation, handling, and use of this reagent and its precursor be conducted with due care and precaution against potential explosion (use of appropriate explosion shields, etc.), particularly on a substantial scale. Nevertheless, as the following discussion will attest, the reagent has been prepared and utilized widely with only one report of an explosion,[29] so that there is good cause to believe that, with appropriate precautions, the reagent can be prepared and handled safely on a normal laboratory scale.

Introduction.

In the short time since its original description in the literature in 1983, the Dess-Martin periodinane (**1**) has enjoyed remarkably widespread use as a reagent for the oxidation of complex, sensitive, multifunctional alcohols of a startling array of structural types. The periodinane (**1**) is a member of the 12-I-5 group of hypervalent iodine species. A number of related structures, which also function as oxidizing agents for alcohols, have been described.[1] Among the advantages of the periodinane (**1**) over the myriad of other oxidizing agents which are available are: (1) functional groups lacking a hydroxylic function are exchanged into the ligand sphere of (**1**) slowly. Alcohols, particularly primary alcohols, undergo rapid and near-quantitative ligand exchange which is largely insensitive to the steric environment of the OH group. This ligand exchange is the obligatory first step in oxidation, which provides an inherent functional group selectivity in the oxidation reactions of (**1**). (2) The reagent is exceptionally versatile, having probably the broadest scope of any of the oxidizing agents commonly employed to convert alcohols to carbonyl derivatives, and generally provides exceptionally clean reactions and excellent yields. (3) When pyridine or di-*t*-butylpyridine is employed to buffer the reaction mixture and sodium thiosulfate/sodium bicarbonate is employed for workup, the entire oxidation/workup procedure can be conducted under near-neutral conditions compatible with even the most sensitive functionality. (4) The workup procedure is very simple, and the byproducts from the oxidation are readily removed by precipitation or chromatography, even without use of an aqueous workup. (5) The reagent is a shelf-stable solid, possessing adequate stability to moisture to permit ready metering and handling, even on very small scale, as is typically required in synthetic sequences leading to complex multifunctional molecules. The rates of oxidation of allylic and benzylic alcohols are highest, but oxidation of electron deficient carbinols such as α-fluorinated alcohols still occurs in good yields.

Typical Oxidation and Workup Procedures.

The oxidation of alcohols is conducted at temperatures ranging from -20 to 35 °C (with ambient temperature being most common), typically in CH_2Cl_2 and occasionally in $CHCl_3$, acetonitrile, or THF, by admixing the reagent (typically 1-3 equiv per OH group), either as the solid or as a solution in the reaction solvent, with a solution of the alcohol. For very acid-sensitive substrates or products, the reaction mixture is buffered by the prior addition of 3-10 equiv of pyridine or 2,6-di-*t*-butylpyridine. The reaction mixture is then held at the appropriate temperature for as little as 5 min to as long as 120 h (most commonly 0.5-1.5 h) before dilution with ether (precipitation of periodinane byproducts occurs), addition of

either aqueous NaOH solution or, for base-sensitive products, a mixture of aqueous $Na_2S_2O_3$ and $NaHCO_3$, stirring until the phases are homogeneous (~15 min), and isolation of the products by extraction. It is possible to avoid the use of aqueous workup conditions altogether by introduction of the reaction mixture, after dilution with ether, directly onto a chromatographic column for separation of the organic oxidation product(s).

Oxidation of Primary Alcohols to Aldehydes.

Since many oxidants will satisfactorily accomplish this transformation, this discussion will focus on cases where (**1**) has been of particular value. The strength of the periodinane (**1**) is its ability to effect oxidation under neutral conditions, thus avoiding side reactions in sensitive substrates possessing multiple functional groups such as the enediyne (**3**) (eq 3),[30] or a variety of protecting groups, as in the azadirachtin intermediate (**4**) (eq 4).[31] Side reactions, such as β-elimination of oxygen and nitrogen functions, are seen with other oxidants for (**5**) (eq 5),[32,33] as are epimerization of α-stereogenic centers or exchange of label in labeled substrates,[34,35] and conjugation of β,γ-unsaturation.[36]

(3)

(3)

(4)

(4)

(5)

Disubstituted malondialdehydes (**6**) (eq 6) and malonaldehyde esters have been prepared without the intervention of oxidative cleavage.[37,38] Relative reactivity data based on steric environment is sparse; however, a notable case of selectivity for a primary over a hindered secondary alcohol in the preparation of the spiroacetal aldehyde (**7**) (eq 7) has been recorded.[39] Very few failures have been documented, and often no other oxidation reagent proved satisfactory in these cases.[40]

(6)

(6)

(7) R = TBDMS

Oxidation of Secondary Alcohols to Ketones.

In the case of secondary alcohols, (**1**) has also proven valuable in avoiding epimerization of α-stereogenic centers,[41,42] loss of β-acyloxy, β-alkoxy, and protected nitrogen functions during oxidations such as of β-acyloxy ketone (**8**) (eq 8), and undesired conjugation of β,γ-unsaturation as in the case of the alkaloid intermediate (**9**) (eq 9).[43-45] Overoxidation at activated methylene groups, such as benzylic centers or susceptible aromatic systems, is not normally a problem.[46,47]

(9)

(9)

Appropriately protected α-heteroatom-substituted systems are smoothly oxidized without epimerization or isomerization of the β,γ-double bond, as in the ketone (**10**) (eq 10).[48] Oxidation of secondary alcohols in suitably protected nucleosides and carbohydrates has also been documented, even in cases where the substrates are exceedingly acid-sensitive such as the trisaccharide (**11**) (eq 11).[49,50] Even sterically-congested secondary alcohols undergo smooth oxidation, most often in excellent yield as in the case of ketone (**12**) (eq 12).[51-53]

(10)

(10)

(11)

(12)

Secondary α- and β-hydroxy ketones and esters, and β-hydroxy amides and sulfones, are also smoothly oxidized to the corresponding α- and β-diketones, α- and β-keto esters, β-keto amides, and β-keto sulfones, such as the β-keto ester (**13**) (eq 13).[54] Remarkably, even substrates containing divalent sulfur and selenium, as well as bromine, have been smoothly oxidized to the corresponding ketones, such as the β-lactam (**14**) (eq 14).[55,56] Furthermore, substrates containing secondary basic nitrogen centers have been smoothly oxidized without concomitant oxidation at nitrogen, for example ketone (**15**) (eq 15).[57] Even electron-deficient, weakly nucleophilic substrates such as α-trifluoromethyl and α,α-difluoroalkyl alcohols also undergo smooth transformation to the corresponding ketones.[58,59]

(13)

(14)

(15)

In some cases, unprotected 1,2-diols undergo fragmentation to carbonyl compounds in a manner similar to their reactions with related periodates and periodic acid.[1,60] However, an example of the selective oxidation of a complex 2,3-dihydroxypyran to the related α-hydroxy δ-lactone (**16**) in excellent yield has been described (eq 16).[61] Of course, oxidation of remote primary-primary and secondary-secondary diols to the dicarbonyl compounds proceeds uneventually when sufficient periodinane (**1**) is employed, but statistical mixtures usually result from attempts at selective oxidation, except in cases where the hydroxyl groups differ markedly in steric environment.[39,69]

(16)

(16)

Oxidation of Primary and Secondary Allylic, Benzylic, Propargylic, and Allenyl Alcohols.

The oxidation of allylic and benzylic alcohols by the periodinane (**1**) has been demonstrated to be significantly faster (&egt;~5×) than that of the corresponding saturated alcohols in competition experiments.[1] This selectivity is exemplified by the oxidation of the precursor secondary allylic-secondary diol to the ketol (**17**) (eq 17).[62]

(17)

(17)

However, in some instances, oxidative cleavage occurs in preference to simple oxidation (see below). It is in the oxidation of this general class of allylic, benzylic, and related unsaturated and acetylenic alcohols that the periodinane (**1**) has proven consistently superior to other oxidants for complex acid and base-sensitive substrates. As shown below, the range of complex substrates is truly impressive. For example, acid- and oxidation-sensitive benzyl and pyridyl alcohols are smoothly oxidized to the corresponding carbonyl compounds (**18**) and (**19**) (eqs 18 and 19).[63,64] In the latter case, the aldehyde (**19**) is obtainable in acceptable yields only by use of the periodinane (**1**). In the case of 6α-epipretazzetine (**20**) (eq 20), no overoxidation and isomerization to tazzetine is observed.[65] Furthermore, no concomitant oxidation of susceptible aromatic systems or nitrogen is detected.

In the case of allylic alcohols, including α-methylenecycloalkanols and cyclopentenols, the periodinane (**1**) has afforded exceedingly acid-, base-, thermal-, and/or oxidation-sensitive enones, e.g. (**21**) and (**22**), in excellent yields (eqs 21 and 22).[66,67] Most impressively, (*Z*)-allylic alcohols afford the corresponding aldehydes and ketones with minimal or no loss of the geometric integrity of the alkene, as seen in the oxidations affording (**23**) and (**24**) (eqs 23 and 24).[68,69]

(21)

(21)

(22)

(22)

(23)

(23)

(24)

(24)

Allylic and propargylic alcohols possessing α´- or δ-stereogenic centers can be oxidized without compromising the integrity of the stereogenic centers, even in demanding situations such as the cases of the ketone (**25**) (eq 25) and the diynone (**26**) (eq 26).[70,71] Primary and secondary allenic alcohols also afford the corresponding carbonyl derivatives smoothly upon oxidation with (**1**).[72,73] Even allylic benzylic systems afford the corresponding aryl vinyl ketones largely or completely without oxygen transposition, even in the remarkably hindered ketone (**27**) (eq 27).[74,75] Note that the ketone (**27**) has an internal barrier to rotation about the aryl-carbonyl single bond of in excess of 20 kcal mol^{-1}.

(25)

(25) R = TBDMS

(26)

(26)

Examples have also been reported of oxidation of allylic or benzylic alcohols by (**1**) in the presence of divalent sulfur and basic nitrogen without concomitant oxidation at these heteroatoms.[76,77]

Oxidation at Methine and Methylene Groups.

Relatively recently, as a result of the interest in the synthesis of derivatives of the immunosuppressive agent FK-506, which possesses the relatively rare 2,3-dioxo amide unit, it has been recognized that the periodinane (**1**), when employed in excess, is capable of oxidizing α-thioaryl β-keto amides to the related 2,3-dioxo amides, accompanied by the derived enol(s) and the hydrate of the 2-oxo function. This oxidation, whose mechanism has not been established as yet, may proceed via the enol or via the corresponding sulfoxide by way of a Pummerer-type rearrangement.[78] Subsequently, the direct oxidation of β-keto esters and amides by the periodinane (**1**) to 2,3-dioxo esters and amides has been reported.[79]

1,3,5-Triazine[1]

[290-87-9] · $C_3H_3N_3$ · 1,3,5-Triazine · (MW 81.09)

(C_1 electrophile; formylating agent;[2] methylenating and aminomethylenating agent;[3] in combination with cyclic amines, dehydro-Mannich bases[4,5] are formed)

Alternate Name: *s*-triazine.

Physical Data: mp 80-82 °C (very pure: 85-86 °C); bp 114 °C; *d* 1.38 g cm^{-3}.

Solubility: sol alcohol, ether, most organic solvents; 1 g dissolves freely in 10 mL methanol.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: very volatile; hygroscopic and very sensible to solvolysis in water, alcohols, and solvents with OH groups. Distillation over sodium for purification has to be done cautiously to avoid overheating at the end, otherwise triazine-sodium compounds are formed which can lead to explosive decomposition of triazine.[1]

Formylating Agent.

In Gattermann's aldehyde synthesis, ***Hydrogen Cyanide*** can be replaced by 1,3,5-triazine. Under the action of ***Hydrogen Chloride***, the triazine undergoes an electrophilic attack on aromatic compounds. The intermediate aldimine hydrochlorides are hydrolyzed to the aldehydes (eq 1).[2] Nucleophilic arenes such as furans, pyrroles and polyhydroxybenzenes need no catalyst,[2a,b] while phenols and alkylbenzenes require ***Aluminum Chloride***.[2b,c] Formylation of 2-hydroxydeoxybenzoins and cyclocondensation with ***Boron Trifluoride Etherate*** affords isoflavones.[6]

X = O, NH, NMe, NBu; R, R' = H, Me

31-86% (1)

Methynylating Agent.

Although the triazine ring is aromatic, it is nonetheless very susceptible to nucleophilic attack. Two molecules of a primary amine H_2NR can add to each carbon atom, leading to ring cleavage, release of ammonia, and 3 equiv of a disubstituted formamidine, RHN-CH=NR. 1,3,5-Triazine is a synthetic equivalent for ***Formic Acid***, formamide, or trialkyl orthoformates. As the only byproduct is gaseous ammonia, contamination of the main product is avoided; yields are good and the products pure. The starting materials can also be mixed and melted for reaction. Reaction of aliphatic or aromatic diamines with triazine leads to heterocyclic compounds (eq 2); 2-aminophenols and thiophenols may also be used.[7]

Acidic α-methylene compounds such as malonic acid derivatives can also be used. The electron-rich nitrogen atom of the triazine can abstract a proton and the resulting carbanion can add to the triazine carbon. The intermediate aminomethylene compound may recyclize to produce 4,5-disubstituted pyrimidines (eq 3).[8]

1,3,5-Triazine can aminomethylenate aromatic or heterocyclic amines, thus introducing a =CH-NH_2 group. The formamidine may react further (eq 4),[3] e.g. to 4-aminoquinazolines. Other compounds which have CH acidic protons that can be aminomethylenated include derivatives of malonic acid[9] or barbituric acid[10] and cyclopentadiene (gives pentafulvenes).[11] Pyrazolinones can also condense to the bispyrazolinones.[12]

When the auxiliary base required for the aminomethylenation (a cyclic amine) is used as the solvent, a three-component reaction takes place, which can be considered as a Mannich-type condensation. Dehydro-*N*-Mannich bases are obtained from ***Cyanamide***[4a,b] or heterocyclic amines[4c,d] (eq 5). Carbon acidic components yield dehydro-*C*-Mannich bases.[5] 1,3,5-Triazines react regioselectively with dienophiles in cycloaddition reactions.[13a] Pyrimidine annulation occurs with pyrrolidine enamines in an inverse electron demand Diels-Alder reaction.[13b]

1,2,4-Triazine[1]

[290-38-0] · $C_3H_3N_3$ · 1,2,4-Triazine · (MW 81.09)

(electron-deficient heteroaromatic azadiene capable of participation in inverse electron demand Diels-Alder reactions with electron-rich dienophiles[1])

Alternate Names: as-triazine; α-triazine; isotriazine.

Physical Data: mp 16-17.5 °C; bp 158 °C; *n*25D 1.5150.

Solubility: sol $CHCl_3$, THF, dioxane, DMSO.

Form Supplied in: pale yellow oil.

Preparative Methods: [2] a cooled (-75 °C) solution of monomeric ***Glyoxal*** (90.0 mmol) in absolute MeOH (200 mL) is added to a solution of formamidrazone hydrochloride (40 mmol) in absolute MeOH (300 mL) at -50 °C. Et_3N (200 mmol) is added and the resulting reaction mixture is allowed to stand at 25 °C for 24 h. The MeOH is removed in vacuo at 20 °C and the residue extracted with Et_2O (peroxide free, 5×). Vacuum distillation of the residue after evaporation of the Et_2O affords 1,2,4-triazine (bp 25-28 °C/0.5 mmHg). Alternative preparations of 1,2,4-triazine have been detailed.[2]

Handling, Storage, and Precautions: best stored at 0 °C or below. It is stable to acid, less stable to base, and is hygroscopic; should be stored under anhydrous conditions since it reacts slowly with water and protic solvents.

Cycloaddition Reactions.

1,2,4-Triazine (**1**) is the parent agent representative of a class of synthetically accessible, substituted, electron-deficient 1,2,4-triazines capable of diene 4π participation in inverse electron demand Diels-Alder reactions with electron-rich dienophiles.[1] Cycloaddition reactions between 1,2,4-triazine and enamines have been shown to be general and regioselective, and occur with [4 + 2] addition exclusively across C-3/C-6 of the 1,2,4-triazine nucleus with the more nucleophilic carbon of the dienophile attaching to C-3. This cycloaddition reaction is followed by in situ retro-Diels-Alder reaction with loss of N_2 and in situ elimination of pyrrolidine to afford 3,4-disubstituted pyridines (eq 1).[3] A general pyridine annulation based on a catalytic Diels-Alder reaction has been developed (eq 2),[4] and its application in the synthesis of rigid norbornylogous spacers for long-range electron transfer studies has been described (eq 3).[5]
[4 + 2] Cycloaddition reactions of 1,2,4-triazine with *N*,*O*-ketene acetals (eq 4)[6] and ynamines (eq 5)[7] have also been detailed. However, the cycloaddition reaction of (**1**) with ynamines generally proceeds through a C-5/N-2 cycloaddition process with subsequent loss of a nitrile to afford substituted pyrimidines (eq 5).[1,7]

(1)

(2)

(3)

(4)

(5)

Less nucleophilic alkenes, including β-enamino ketones, β-alkoxy enones, trimethylsilyl enol ethers, and tri-*n*-butylstannyl enol ethers, are not sufficiently reactive to participate in a Diels-Alder reaction with the parent 1,2,4-triazine.[3] Complementary addition of electron-withdrawing substituents to the 1,2,4-triazine nucleus increases its rate of participation in inverse electron demand Diels-Alder reactions (eqs 6-9),[8,9] influences the mode of [4 + 2] cycloaddition,[1] and controls the observed regioselectivity (eqs 6, 8, and 9)[8] (see also ***Triethyl 1,2,4-Triazine-3,5,6-tricarboxylate***).

1,2,4-Triazole

[288-88-0] · $C_2H_3N_3$ · 1,2,4-Triazole · (MW 69.08)

(transacylating agent used for ester and amide synthesis, especially in peptide synthesis; cyclization reactions; oligonucleotide synthesis)

Physical Data: mp 120-121 °C; bp 260 °C (dec above 187 °C); fp 140 °C.

Solubility: sol water, alcohol.

Form Supplied in: white powder.

Acylating Reagent.

The great ability of triazole to accept and transfer acyl groups has made it a catalyst for the synthesis of esters and amides. In particular, triazole has been used in peptide synthesis, for the formation of peptide links as well as for the introduction of amino-protecting groups. It acts as a bifunctional catalyst, accelerating the aminolysis of *p*-nitrophenyl esters[1] and *p*-thiocresyl esters.[2] The catalytic effect is both by a general base mechanism (eq 1) and a specific mechanism (eq 2).

(1)

(2)

It has been used to introduce the Boc group onto an amino acid from *t*-butyl carbonates (eq 3), and it allows the coupling of an *N*-protected amino acid with a fully unprotected amino acid (eq 4). Interestingly, racemization is not observed during coupling of amino acids in the presence of 1,2,4-triazole.[1] Nevertheless, its coupling efficiency depends on the reaction medium and in solvents like DMF, which increase the rate of aminolysis, its usefulness is limited. 1,2,4-Triazole is now seldom used in peptide synthesis, whereas other catalytic additives like ***1-Hydroxybenzotriazole*** are widely used as activated esters as well as in conjunction with coupling reagents like ***1,3-Dicyclohexylcarbodiimide***.

Catalysis of Ring Formation.

1,2,4-Triazole can induce the formation of isoxazole rings from conjugated ketones and hydroxylamine (eq 5).[3]

Oligonucleotide Synthesis.

Sulfonyl derivatives of 1,2,4-triazole, e.g. (**1**), are used as efficient coupling reagents in oligonucleotide synthesis by the phosphotriester method.[4] A nitro derivative (**2**) allows esterification of amino acids onto hydroxymethyl polymers.[5]

Tribenzylchlorosilane

$(PhCH_2)_3SiCl$

[18740-59-5] · $C_{21}H_{21}ClSi$ · Tribenzylchlorosilane · (MW 336.96)

(reagent for alcohol protection[5])

Physical Data: mp 141-142 °C;[1,2] a somewhat higher value (143-145 °C) is cited in the Aldrich catalog.

Solubility: sparingly sol cold petroleum ether; moderately sol hot petroleum ether; sol ether.

Form Supplied in: white crystalline solid; commercially available.

Preparative Methods: prepared by reaction of benzylmagnesium chloride with $SiCl_4$ in ether;[3] separation from mono- and dibenzylated chlorosilane byproducts is then accomplished by fractional distillation (boiling range 300-360 °C/100 mmHg). Other preparations involve the chlorination of tribenzylsilane using Cl_2[1] or an acyl chloride.[1,3] No yields are reported for any of the above preparative procedures.

Purification: can be recrystallized from petroleum ether.[2]

Handling, Storage, and Precautions: corrosive; should be handled with caution. It does not fume perceptibly in air,[2] but it is moisture sensitive and is slowly decomposed by water over several hours to give the corresponding silanol.[3]

Protection of Alcohols.

Tribenzylchlorosilane is highly reactive towards nucleophilic displacement of chloride ion,[4] but it has found only limited application as a bulky silyl protecting group for alcohols. The protection of the allylic alcohol (**1**) as the tribenzylsilyl ether (**2**) (eq 1) allowed for high π-facial selectivity in a subsequent epoxidation reaction at the 10,11-double bond.[5] The tribenzylsilyl ether group can be efficiently deprotected to the free alcohol using AcOH/THF/H_2O (3:1:1) at room temperature.[5]

(1)

(2) (1)

Silylation of Azomethine Anions.

The only other synthetically useful reaction reported for tribenzylchlorosilane involves the *C*-silylation of azomethine anions. Deprotonation of the parent imine (***n-Butyllithium***) followed by *C*-trapping of the resulting azomethine anion affords the α´-silylimine in moderate yield (eq 2).[6]

(2)

Related Reagents.

t-Butyldimethylchlorosilane; ***t-Butyldimethylsilyl Trifluoromethanesulfonate***; ***Chlorotriethylsilane***.

Tribromoacetyl Bromide

[10588-31-5] · C_2Br_4O · Tribromoacetyl Bromide · (MW 359.64)

(tribromoacetylating agent for amines and alcohols;[1] precursor for the synthesis of dibromoketene[2])

Physical Data: bp 86 °C/11 mmHg; *d* 2.810 g cm^{-3}.

Solubility: sol ether, benzene, toluene.

Form Supplied in: not commercially available.

Preparative Method: prepared by the action of ***Phosphorus(III) Bromide*** on tribromoacetic acid.[1,2]

Purification: can be purified by vacuum distillation.

Handling, Storage, and Precautions: moderately stable at room temperature; should be freshly distilled prior to use. Light-sensitive; should be used and stored with the rigorous exclusion of light.

Tribromoacetylation of Amines and Alcohols.

Tribromoacetamides have been prepared by the reaction of tribromoacetyl bromide with the requisite amine (eq 1).[1] The tribromoacetamides so produced are light sensitive and must be used immediately. Photoirradiation of these amides promotes homolytic cleavage and can generate the corresponding dibromo primary radical.[3] Alcohols can also be acylated with tribromoacetyl bromide (eq 2).[1] However, unless use of the tribromide is absolutely necessary, commercially available ***Trichloroacetyl Chloride*** is superior and the corresponding trichloroacetylated products can usually be used in subsequent reactions in the same manner as the tribromoacetylated materials.

(1)

(2)

Generation of Dibromoketene.

Tribromoacetyl bromide can be debrominated with ***Zinc*** that has been activated with copper to afford a solution of dibromoketene in ether (eq 3).[2] The dibromoketene generated in this manner readily undergoes [2 + 2] cyclization with ***Cyclopentadiene*** to give the corresponding cyclobutanone (eq 4).[2] Dibromoketene has been used effectively in the synthesis of prostaglandins and other natural products.[4,5] Dibromoketene has also been prepared by the elimination of HCl from dibromoacetyl chloride and by reaction of trimethylsilyl tribromoacetate with ***Triphenylphosphine***.[6,7] In fact, this latter method is superior for the preparation of dibromoketene as a synthetic precursor, as the subsequent cyclization can be performed in a single reaction vessel (eq 5).[7] High yields of the cyclized material are obtained in this manner.

2,2,2-Tribromoethyl Chloroformate

[17182-43-3] · $C_3H_2Br_3ClO_2$ · 2,2,2-Tribromoethyl Chloroformate · (MW 345.20)

(protecting agent for alcohols[1,2] and carboxylic acids[3])

Physical Data: bp 47-50 °C/0.05 mmHg, 103 °C/10 mmHg.

Form Supplied in: no longer commercially available.

Preparative Method: prepared[1] by the reaction of 2,2,2-tribromoethanol with ***Phosgene*** in benzene under pyridine catalysis.

Handling, Storage, and Precautions: although no details are available, the high toxicity and the lachrymatory and corrosive nature of the closely related ***2,2,2-Trichloroethyl Chloroformate*** suggest that 2,2,2-tribromoethyl chloroformate should be handled with caution.

Protection of Alcohols.

2,2,2-Tribromoethyl chloroformate has found application in the protection of primary and secondary alcohols. The attraction of the resulting tribromoethoxycarbonyl protecting group includes its stability to the acidic conditions (e.g. 80% acetic acid at 100 °C for 35 min, or at rt for 6 h) used for the removal of many other *O*-protecting groups (e.g. the trityl group).[1] In addition, it is readily removed via β-elimination using a ***Zinc/Copper Couple***, preferably in acetic acid but also (albeit more slowly) in ethanol or DMF, under conditions where many common protecting groups (e.g. *O*-acetyl, *N*-benzoyl, and *O*-trityl)[1] survive. Deprotection of tribromoethyl carbonates using a Zn/Cu couple in acetic acid (complete in 20 min at rt) proceeds an order of magnitude faster than cleavage of the more widely used trichloroethyl (troc) carbonates (see ***2,2,2-Trichloroethyl Chloroformate***) suggesting that it has potential (as yet untapped) as a complementary protecting group to the troc group. Selective protection of primary over secondary alcohols can be accomplished, albeit in only modest yield, using tribromoethyl chloroformate in the presence of either *N*,*N*-diethylaniline or 2,6-lutidine as base (eq 1).[2]

(1)

Tribromoethyl chloroformate is useful for the protection of primary and secondary hydroxyl groups in nucleosides and their derivatives;[1] reactions are generally complete in 0.5-2.0 h at 0 °C in anhydrous pyridine/DMF and typically proceed in good to excellent yield. Since tribromoethyl chloroformate reacts vigorously with DMF at rt and reacts slowly even at 0 °C, DMF solutions must be prepared at 0 °C and then immediately be added to the nucleoside in pyridine in order to avoid significant chloroformate decomposition. Selective 5´-protection of 2´-deoxynucleosides is possible (eq 2). Attempts to protect 2´,3´-dihydroxynucleosides lead to the formation of a 2´,3´-cyclic carbonate in addition to the desired 2´,3´-bis(tribromoethyl) carbonate (eq 3). Prior *N*-protection of nucleosides containing amino-substituted bases is necessary; nucleosides containing free amino groups give complex mixtures of products.

(2)

(3)

Protection of Carboxylic Acids.

Tribromoethyl chloroformate has been used for the protection of benzoic acid as its tribromoethyl ester.[3] An attractive feature of the

tribromoethyl ester protecting group is its facile cleavage by electrolytic reduction (-0.70 V, 85% yield). In contrast, cleavage of the related trichloroethyl ester requires much higher voltages (-1.65 V) and often results in the formation of small amounts of dichloroethyl ester byproduct (see ***2,2,2-Trichloroethyl Chloroformate***).[3]

Tribromomethyllithium

$LiCBr_3$

[16644-71-6] · CBr_3Li · Tribromomethyllithium · (MW 258.65)

(nucleophilic tribromomethylation[1])

Physical Data: low temperature ^{13}C and ^{6}Li NMR data are available,[2] as are matrix IR data.[3]

Preparative Methods: solutions of the title compound can be obtained by treatment of ***Carbon Tetrabromide*** with ***n-Butyllithium*** or ***Phenyllithium*** in THF/ether/hexane (4:4:1) at -110 °C for ca. 1 hour,[4] by deprotonation of ***Bromoform*** with ***Dichloromethyllithium*** in THF at -100 °C,[5] and by deprotonation of $CHBr_3$ with lithium dimethylamide in THF/HMPA at -105 °C.[6]

Handling, Storage, and Precautions: there is considerable decomposition of the reagent at -100 °C over several hours,[4] increasing in rate with increasing temperature. Comparison of ether and THF as solvents for reagents of this type suggests that the latter both accelerates the formation of α-halo organolithiums at low temperature and increases their thermal stability.[7]

General Considerations.

Alkyllithiums bearing halogens on the α-carbon are frequently referred to as carbenoids reflecting a major mode of reactivity. Good general reviews of such species are available.[1] At very low temperatures, however, this reagent reacts like a typical alkyllithium. It should be noted that $LiCBr_3$ has been studied much less than the analogous ***Trichloromethyllithium***, perhaps due to the greater thermal stability of the latter. However, the reagents are not analogous in all of their reactions.

Nucleophilic Tribromomethylation/Carbonyl Homologation.

The reagent can be used in the displacement of iodides and bromides to produce terminal tribromoalkanes (**1**) (eq 1).[8] Such compounds serve as intermediates in a homologation process.[9] The tribromoalkane can be metalated to (**2**) and added to an aldehyde to provide an intermediate lithioalkoxide (eq 2). This can be treated with *n*-BuLi to provide the dilithium reagent (**3**), which undergoes Fritsch-Buttenberg-Wiechell rearrangement to either (**4**) or (**5**) depending on the identity of R´. Quenching of the mixture gives rise to (**6**) and/or (**7**) in 50-100% yield. The aldehyde is usually formed as a minor product when benzaldehydes or alkenals are used as substrates. Cyclic ketones undergo ring expansion in the same process as shown in eq 3.

$$R{-}X + LiCBr_3 \xrightarrow[\text{-110 °C}]{\text{THF, HMPA}} \underset{\textbf{(1)}}{R{-}CBr_3} \qquad (1)$$

The adducts of $LiCBr_3$ with cyclohexanone and other ketones have been prepared by Yamamoto in a general synthesis of polyhalomethylcarbinols.[10] Addition of ***Lithium Dicyclohexylamide*** to a solution of cyclohexanone and $CHBr_3$ in THF results in deprotonation of the $CHBr_3$ and carbonyl addition giving the adduct (eq 4).

Dibromomethylenation.

The reagent can also be used to convert aldehydes to 1,1-dibromoalkenes.[11] Addition of $LiCBr_3$ to aldehydes and *O*-alkylation with ***Iodomethane***, ***Chlorotrimethylsilane***, or ***Acetyl Chloride*** gives the alkoxy (or acyloxy) tribromoalkane (**8**) (eq 5). Treatment of (**8**) with slightly more than 1 equiv of *n*-BuLi in THF/ether at -60 °C results in formation of the dibromoalkene (**10**) by loss of ROLi from the presumed intermediate (**9**). Yields are moderate.

Cyclopropanation/C-H Insertion.

Cory has developed a clever in situ procedure for the construction of bridged ring systems incorporating a cyclopropane.[12] Treatment of CBr_4 with ***Methyllithium*** at -75 °C followed by an alkene results in the formation of a dibromocyclopropane via decomposition of $LiCBr_3$ to dibromocarbene. Treatment with a second equivalent of MeLi transmetalates a halogen and promotes carbene formation via α-elimination of LiBr. The carbene can insert into a proximate C-H bond, resulting in a large increase in molecular complexity in a single operation. Thus (**11**) is converted to (**12**) and (**13**) in good yield (eq 6), while the more complex (**14**) is converted to (**15**) in 26% yield (eq 7).

Counterions Other than Li.

The analogous reagents $NaCBr_3$ and $KCBr_3$ have also been prepared by deprotonation of $CHBr_3$ using the requisite metal hexamethyldisilazide.[13] No significant chemical reactivity was reported.

Related Reagents.

Tri-*n*-butylamine

***n*-Bu$_3$N**

[102-82-9] · $C_{12}H_{27}N$ · Tri-*n*-butylamine · (MW 185.40)

(high boiling tertiary amine, used as a base in intramolecular Diels-Alder reactions,[1] metal-catalyzed couplings and reductions, ketene generation, and hydrogenations)

Physical Data: bp 216 °C; mp -70 °C; *d* 0.778 g cm^{-3}.

Solubility: sparingly sol H_2O; very sol alcohols and ethers; sol acetone, benzene.

Form Supplied in: liquid; commercially available.

Handling, Storage, and Precautions: a corrosive and toxic liquid. Bottles of tri-*n*-butylamine should be flushed with nitrogen or argon to prevent exposure to carbon dioxide. The vapors are harmful and care should be taken to avoid absorption through the skin. Use in a fume hood.

Intramolecular Diels-Alder Reactions.

The addition of tri-*n*-butylamine to high-temperature intramolecular Diels-Alder reactions[1] tends to reduce unwanted acid-catalyzed side reactions involving the reaction substrates and/or the Diels-Alder adducts. For example, heating the trienol (**1**) at 185 °C in chlorobenzene containing a catalytic amount of tri-*n*-butylamine leads to the four possible isomeric Diels-Alder products (**2**) in nearly quantitative yield (eq 1).[2] Omitting the tri-*n*-butylamine results in only a 14% yield of the desired adducts. A major byproduct is the tetraene (**3**), the product of an acid-promoted dehydration.

Similarly, heating the mixture of the substituted 1,3-cyclopentadienes (**4**) in tri-*n*-butylamine at 190 °C for 10 h leads to the norbornadiene (**5**) in a distilled yield of 78% (eq 2).[3] In contrast, use of HMPA as solvent at 220 °C generates the double bond isomer (**6**), the product of either an allene/alkyne equilibration of (**4**) prior to the intramolecular Diels-Alder reaction or an acid-catalyzed rearrangement of the Diels-Alder product (**5**). An acid-catalyzed isomerization of (**5**) to (**6**) has been observed using dilute sulfuric acid at room temperature.[3]

(2)

Metal-Catalyzed Reactions.

o-Bromoacetanilides and related substrates undergo palladium-catalyzed carbonylations using palladium catalysts and gaseous CO in tri-*n*-butylamine and water to generate anthranilic acid derivatives (eq 3).[4] The method finds use in the carbonylative cyclization of substituted aminopyridines to prepare pyrido[2,1-*b*]quinazolines (eq 4).[5]

(3)

(4)

Enol trifluoromethanesulfonates (triflates) and aryl triflates undergo efficient Pd-catalyzed couplings with olefinic substrates to afford dienes,[6] carbonylations with CO to afford carboxylic acids,[7] and reductions with trialkylammonium formates to afford alkenes.[8] β-Hydroxy enol triflates undergo a carbonylative cyclization with ***Tetrakis(triphenylphosphine)palladium(0)*** and tri-*n*-butylamine under a CO atmosphere to generate α,β-butenolides in good yields (eq 5).[9] Likewise, treatment of the enol triflate (**7**) with tri-*n*-butylamine, ***Palladium(II) Acetate***, and ***1,1´-Bis(diphenylphosphino)ferrocene*** (dppf) under a CO atmosphere in aqueous DMF leads to the diacid (**8**) in 42% isolated yield (eq 6).[10]

(5)

(7) (6) (8)

Enol triflates, as well as aryl triflates and aryl fluoroalkanesulfonates,[11] are selectively deoxygenated to the corresponding alkenes and arenes using the combination of ***Formic Acid*** and tri-*n*-butylamine in the presence of a catalytic amount of ***Bis(triphenylphosphine)palladium(II) Acetate*** in DMF (eq 7).[8,12] In the case of highly hindered aryl triflates, use of ***1,3-Bis(diphenylphosphino)propane*** (dppp) as a ligand tends to increase the yields of the desired arenes (eq 8).[13]

(7)

(8)

Aryl iodides react with 4-hydroxy-2-alkynoates in the presence of formic acid, tri-*n*-butylamine, and a palladium(II) catalyst in DMF to generate highly substituted α,β-butenolides via a one-pot hydroarylation/cyclization sequence (eq 9).[14] The regioselectivity is controlled

by steric constraints and metal-coordination factors involved during the Pd-C bond forming step. 4-Hydroxy-2-alkynoates undergo a reductive cyclization under similar conditions to afford butenolides in high yields (eq 10). Use of a large excess of formic acid leads to fully saturated lactones.

Heck-type reactions,[15] involving the coupling of aryl halides and substituted alkenes to produce arylated alkene derivatives, can be accomplished using tri-*n*-butylamine as a base and a variety of palladium catalysts. The arylation of conjugated alkenes is catalyzed efficiently using the clay-anchored catalyst montmorillonite-ethylsilyldiphenylphosphinepalladium(II) chloride, in tri-*n*-butylamine at 100 °C to produce the *trans*-alkenic products selectively in excellent yields (eq 11).[16] The cross coupling between aryl iodides and vinyl acetates to generate *trans*-stilbene derivatives is made possible with the use of the clay-anchored catalyst and tri-*n*-butylamine (eq 12).[17]

C-Glycosides are assembled using a palladium-mediated glycal-aglycon coupling sequence.[18] Reaction of furanoid glycals with aryl halides in the presence of a catalytic amount of palladium acetate and tri-*n*-butylamine in DMF at room temperature results in high yields of *C*-furanosyl products, usually with a high degree of regio- and stereocontrol (eq 13).[19] Good regio- and stereocontrol is found with 3-deoxypyranoid glycals under similar reaction conditions.[20]

The reduction of enantiomerically enriched phosphine oxides is accomplished using an excess of ***Trichlorosilane*** to afford phosphines with retention of configuration. However, the use of strong organic amine bases (pK_b < ca. 5), such as ***Triethylamine***, leads to phosphines with inversion of configuration, while the use of weak amine bases (pK_b > ca. 7) results in retention of configuration.[21] Treatment of enantiomerically enriched bisphosphine oxides with trichlorosilane and tri-*n*-butylamine[22] (or triethylamine)[23] in acetonitrile at 70 °C affords enantiopure phosphines in high yields (eq 14).[21] The combination of tri-*n*-butylamine and acetonitrile ensures a homogeneous reaction mixture and prevents incomplete reduction and the production of *meso*-bisphosphines.

The high boiling point of tri-*n*-butylamine makes it an attractive base in reactions requiring high temperatures. For example, intramolecular ketene-alkene [2 + 2] cycloaddition is accomplished by slowly adding the acid chloride (**9**) to an excess of tri-*n*-butylamine in refluxing toluene to afford the tricyclic ketone (**10**) in 71-87% yield (eq 15).[24] The elimination of the anomeric methoxy group is catalyzed by the tri-*n*-butylammonium chloride produced in the reaction.

Thermolysis of ethyl alkynyl ethers in the presence of 10 equiv of tri-*n*-butylamine in refluxing xylenes (137-144 °C) leads to good yields of macrocyclic lactones. The tri-*n*-butylamine facilitates the cyclization step involving the ketene intermediate produced by a retro-ene reaction (eq 16).[25]

Hydrogenations.

The enantioselective hydrodechlorination of L-5,5-dichloro-1-(chlorocarbonyl)proline esters (**11**) to afford L-proline in 78% yield is achieved using a 10% ***Palladium on Carbon*** catalyst and 180 bar of H_2 pressure in tri-*n*-butylamine at 50 °C. The tri-*n*-butylammonium chloride produced in the reaction remains in solution and the catalyst retains its full activity (eq 17).[26] When other tertiary amine bases such as triethylamine are used, the trialkylammonium salt produced tends to precipitate onto the catalyst surface. As a result, the catalyst becomes deactivated and the overall yield is reduced.

Tri-*n*-butylborane

***n*-Bu$_3$B**

[122-56-5] · $C_{12}H_{27}B$ · Tri-*n*-butylborane · (MW 182.20)

(good chelating reagent;[1,2] radical initiator;[3] starting material for the synthesis of Bu_2BOTf[4] and Bu_2BSR[5])

Physical Data: bp 108-110 °C/20 mmHg, 90-91 °C/9 mmHg; *d* 0.747 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid; commercially available.

Purification: distillation from CaH_2.

Handling, Storage, and Precautions: moisture sensitive. Use in a fume hood.

Stereoselective Reduction of β-Hydroxy Ketones.

Highly stereoselective reduction of β-hydroxy ketones is realized via boron chelates.[1] Dibutylboronates of β-hydroxy ketones are formed in situ from β-hydroxy ketones and tributylborane with the catalytic action of air in THF. Treatment of the mixture with ***Sodium Borohydride*** at -78 °C then affords *syn*-1,3-diols stereoselectively (eq 1). The selectivity is better when the reduction is carried out at a lower (-100 °C) temperature. In some instances, triisobutylborane gives a better selectivity than tributylborane, but the reduction proceeds more slowly.

(1)

R	
Ph	98:2
Bu	96:4

For example, this stereoselective reduction is utilized in the synthesis of a β-hydroxy-δ-lactone HMG-CoA reductase inhibitor (eq 2).[6] This procedure is also applicable to the stereoselective reduction of *syn*-α-substituted β-hydroxy ketones.[1] The reduction gives 1,3-diols with *syn,syn* stereochemistry exclusively (eq 3). However, the stereoselectivity of reduction of *anti*-α-substituted β-hydroxy ketones depends on the alkyl substituents, R^1 and R^2 (eq 4).

R^1	R^2	
i-Pr	Me	100:0
Ph	Bu	100:0

R^1	R^2	
i-Pr	Me	27:73
Ph	Bu	87:13

Stereoselective Reaction of Allylic Boronates.[2]

In the presence of an equimolar amount of tributylborane (***Triethylborane*** is also effective), but-2-enyllithium reacts with aldehydes to give

the *anti*-homoallyl alcohols predominantly. For example, in the reaction with benzaldehyde the *anti*-isomer is obtained in 74% yield, along with the *syn*-isomer in 15% yield (eq 5).

Bu_3B-Induced Chlorination of Alkanes.[3]

The chlorination of alkanes with ***Chlorine***, ***t-Butyl Hypochlorite***, or ***N-Chlorosuccinimide*** proceeds at 20 °C in carbon tetrachloride, in the presence of a catalytic amount of tributylborane, even in the dark, giving monochloroalkanes. For the chlorination of 2,3-dimethylbutane, 3-methylpentane, and *n*-heptane, the regioselectivity is dependent on the chlorinating reagents, as shown in eq 6. Trihexylborane and tricyclohexylborane are also effective initiators.

Cl_2	35%	47%
t-BuOCl	80%	9%
NCS	63%	0.6%

Dibutylboryl trifluoromethanesulfonate.

Di-n-butylboryl Trifluoromethanesulfonate, which is useful for cross-aldol reactions of ketones with aldehydes (eq 8), is prepared from equimolar amounts of tributylborane and ***Trifluoromethanesulfonic Acid*** (eq 7).[4]

Alkylthiodibutylboranes.

Alkylthiodibutylboranes are easily prepared from tributylborane and thiols (eq 9).[5] The reaction of these boranes with ketene generates vinyloxyborane intermediates, which react with ketones, aldehydes, or nitriles to afford β-hydroxy or β-imino thioesters (eq 10).[7]

Alkylthiodibutylboranes also react with α,β-unsaturated ketones to generate vinyloxyborane intermediates, which react with aldehydes to afford β-hydroxy ketone derivatives (eq 11).[7]

Tri-*n*-butylfluorostannane

Bu_3SnF

[1983-10-4] · $C_{12}H_{27}FSn$ · Tri-*n*-butylfluorostannane · (MW 309.10)

(selective silyl/stannyl exchange of enol silyl ethers;[1] fluoride source[2])

Alternate Name: fluorotributyltin.

Form Supplied in: white solid; commercially available. *Drying:* this chemical seems not to be hygroscopic. Drying may be done in vacuo (ca. 0.1 mmHg) for 6 h at 100 °C (bath temperature).[1,2]

Handling, Storage, and Precautions: this reagent is toxic (acute oral LD_{50} (rats): 200 mg kg^{-1})[3] and should be handled with care. Use in a fume hood.

Arylation, Alkenylation, and Aldol Reactions of Enol Silyl Ethers via Tin Enolates and/or α-Stannyl Ketones.

This reagent reacts with enol silyl ethers of methyl ketones to generate tin enolates and/or α-stannyl ketones in the presence of a palladium catalyst (eq 1).[1] The palladium may work as a mild Lewis acid to activate the enol silyl ether. The resulting stannyl enolate derivatives can be trapped in situ with aryl or alkenyl bromides in the presence of the palladium catalyst to give α-aryl or α-alkenyl ketones in a regioselective manner, as shown in eqs 2 and 3.[1,4] The reaction with aldehydes affords aldols (eq 4).[5] The latter example demonstrates site selectivity for silyl/stannyl exchange at the less hindered silyl enol ether.

Pd cat = $Pd[(o\text{-}MeC_6H_4)_3P]_2Cl_2$

Selective Desilylation of Bis-silyl Enol Ethers.

As described above, the silyl/stannyl exchange with Bu_3SnF/Pd catalyst is greatly influenced by the steric hindrance around the enol silyl ether moiety. Thus the highly selective desilylation of bis-silyl enol ether derivatives of diketones is also possible, (probably via intermediacy of a tin derivative) (eqs 5 and 6).[6,7] This method for the differentiation of two ketone groups should complement existing methods for selective monosilylation of diketones.

Additive to Facilitate Reactions.

Some other uses of Bu_3SnF (and also Me_3SnF or Ph_3SnF) to promote reactions have been documented and are illustrated in eqs 7 and 8.[2,8,9] In the latter case, it is proposed that Bu_3SnF serves as a mild source of fluoride ion.

R_3SnF	Yield (%)	ee (%)
Bu_3SnF	78	82

Tri-*n*-butylhexadecylphosphonium Bromide[1]

$C_{16}H_{33}{+}PBu_3Br^-$

[14937-45-2] · $C_{28}H_{60}BrP$ · Tri-*n*-butylhexadecylphosphonium Bromide · (MW 507.75)

(phase-transfer catalyst[2,3])

Alternate Name: HDBP.

Physical Data: mp 56-58 °C.

Solubility: insol H_2O.

Form Supplied in: white solid; widely available.

Preparative Method: by heating equimolar amounts of 1-bromohexadecane and ***Tri-n-butylphosphine*** at 65 °C for 3 days (yield 68%).[4,5]

Introduction.

Tributylhexadecylphosphonium bromide is used as a typical phase-transfer catalyst in two-phase reactions carried out without or with a base. HDBP is thermally stable,[6] but is much less stable under basic conditions than corresponding quaternary ammonium salts.[7] Because of its high lipophilicity, HDBP cannot be readily removed from nonpolar solvents. A method of removal of HDBP from the crude products consists in stirring of the reaction mixture with an ion exchange resin (H-form) at room temperature.[8] It appears that HDBP does not offer any advantages over typical phase-transfer catalysts, i.e. tetraalkylammonium salts, being much more expensive; nevertheless, it has been applied in many reactions.

Reductions with Aqueous $NaBH_4$.

Haloalkanes and sulfonate esters are reduced by ***Sodium Borohydride*** to hydrocarbons (eq 1);[9] CO_2R, $CONR_2$, NO_2, and CN groups are not affected. By using $NaBD_4$ in D_2O, deuterio derivatives can be obtained. The reactions can also be catalyzed by tetraoctylammonium chloride. Alkyl-, aryl-, and arylsulfonyl azides are reduced to the corresponding amines or sulfonamides (eq 2).[10] Using this reaction, alkyl bromides can be converted into amines in a one-pot phase-transfer reaction. The halide first reacts with ***Sodium Azide***/H_2O in the presence of HDBP; the aqueous phase is then replaced by an aqueous solution of $NaBH_4$.[10]

Other Reactions.

HDBP has been used in the reduction of disulfides and *N*-tosylsulfilimines to thiols and sulfides, respectively, by aminoiminomethanesulfinic acid (eq 3),[11] and in the debromination of *vic*-dibromoalkanes by ***Sodium Iodide*** and an excess of ***Sodium Thiosulfate***[12] or ***Sodium Sulfide***[13] (eq 4); the latter process is also catalyzed by quaternary ammonium salts.[14]

N-Alkylation of potassium phthalimide with alkyl halides or methanesulfonates has been achieved in a solid-liquid two-phase reaction (eq 5).[15] ***18-Crown-6*** is an equally efficient catalyst.[16] HDBP catalyzes the addition of hydrohalic acids to alkenes (eq 6),[17] and the conversion of water-insoluble *n*-alkanols into alkyl chlorides with aq HCl (eq 7);[18] other catalysts can also be used.[19]

(6)

(7)

The cleavage of dialkyl and aryl alkyl ethers with concd. HBr is accelerated by HDBP.[20] Dialkyl ethers are converted into alkyl bromides (eq 8), whereas alkyl aryl ethers form phenols and alkyl bromides. Other catalysts have also been used.

(8)

The addition of ***Chloramine-T*** to sulfides produces sulfilimines (eq 9);[20] other catalysts have also been used.[21] The selective oxidation of sulfides to sulfoxides by ***Sodium Periodate*** (eq 10)[22] has been achieved using HDBP. HDBP has been used in the conversion of alkyl halides or methanesulfonates into alkyl fluorides with aq ***Potassium Fluoride*** (eq 11).[23] Secondary alkyl halides undergo β-elimination in competition with substitution.

Tri-*n*-butyl(iodoacetoxy)stannane[1]

[73927-91-0] · $C_{14}H_{29}IO_2Sn$ · Tri-*n*-butyl(iodoacetoxy)stannane · (MW 475.04)

(γ-lactone preparation;[2] annulation)

Alternate Names: tributylstannyl iodoacetate; tributyl(iodoacetoxy)tin.

Physical Data: mp 94.4 °C.

Solubility: insol cold H_2O; sol THF, CH_2Cl_2, acetone, alcohol.

Preparative Method: [3] two equiv of iodoacetic acid and one equiv of ***Bis(tri-n-butyltin) Oxide*** are heated to 130 °C for 30 min. The cooled mixture is extracted with hot hexanes. The hexanes are removed in vacuo to afford tributyl(iodoacetoxy)tin. This preparation generates a product sufficiently pure for use in the reactions described below.

Handling, Storage, and Precautions: best results are obtained if the reagent is used within one week of the date of preparation. Use in a fume hood.

General Discussion.

Tributyl(iodoacetoxy)tin is readily prepared by the reaction of bis(tri-*n*-butyltin) oxide and iodoacetic acid.[3] This reaction has general applicability for the preparation of other halo esters and of higher homologs. By using this reagent in the presence of ***Azobisisobutyronitrile***, many alkenes can be converted into γ-lactones in a single step (eq 1). The reaction of tributyl(iodoacetoxy)tin with alkenes proceeds by way of a radical mechanism.[4] As illustrated in eq 2, the mechanism involves a radical chain reaction beginning with homolytic cleavage of the carbon-iodine bond followed by radical addition to the alkene. The reaction of the resulting radical with a molecule of tributyl(iodoacetoxy)tin followed by a rapid cyclization with concurrent loss of tributyliodotin completes the mechanism. Because of the electrophilic nature of the radical, this reaction proceeds well with electron-rich alkenes. Electron-deficient alkenes do not react.

(1)

R = Bu, CH_2TMS, OEt, CH_2OH

This reaction has been used for the preparation of a bicyclic furo[2,3-*b*]furan subunit (eq 3) in the synthesis of clerodane terpenes.[5] The intramolecular variant of this reaction has also been reported.[1] In this case a strained bicyclic lactone is formed in 40% yield (eq 4).

Tri-*n*-butyl(iodomethyl)stannane

[66222-29-5] · $C_{13}H_{29}ISn$ · Tri-*n*-butyl(iodomethyl)stannane · (MW 431.03)

(preparation of (α-heteroalkyl)stannanes for subsequent tin-lithium exchange[1] or [2,3]-Wittig rearrangement;[2] preparation of (tri-*n*-butylstannyl)methyllithium[3])

Alternate Name: tributyl(iodomethyl)tin.

Physical Data: colorless liquid; bp 100-110 °C/0.01 mmHg.

Preparative Methods: prepared by treatment of ***Iodomethylzinc Iodide*** with ***Tri-n-butylchlorostannane***,[4] or by reaction of tri-*n*-butyl(chloromethyl)tin with NaI.[5]

Handling, Storage, and Precautions: potentially toxic; should be handled in a well ventilated hood.

General Discussion.

Tri-*n*-butyl(iodomethyl)tin (**1**) has been used extensively as an electrophile in the preparation of α-heteroalkylstannanes such as tri-*n*-butylstannylmethyl ethers,[2] *N*-acylated α-aminostannanes,[1] and *S*-stannylmethyl phosphinothioates.[6] Tri-*n*-butylstannylmethyl ethers of allylic alcohols undergo tin-lithium exchange and [2,3]-sigmatropic rearrangement upon treatment with ***n-Butyllithium***. For example, the stannylated ether (**2**) provides the homoallylic alcohol (**3**) with nearly exclusively the (*Z*) configuration (eq 1).[2]

(1)

Diastereoselective [2,3]-Wittig rearrangements of this type have been reported.[7] This reaction sequence has been applied to the synthesis of alkene dipeptide isosteres,[8] as well as a number of natural products including (-)-punctatin A (eq 2).[9] The homoallylic (tri-*n*-butylstannyl)methyl ether (**4**) undergoes stereoselective anionic cyclization to the *cis*-2,4-disubstituted tetrahydrofuran (**5**) upon transmetalation with *n*-BuLi (eq 3).[10] Tin-lithium exchange of the oxazolidinone-derived α-aminostannane (**6**) generates nitrogen-substituted organolithium compounds which react with a variety of electrophiles (eq 4).[1]

(4) **(5)**

(6)

Tri-*n*-butyl(iodomethyl)tin is a useful reagent for the preparation of alkenes from sulfides,[11] sulfones,[12] and nitriles.[13] The moderately hindered sulfone (**7**) is converted to the corresponding exocyclic alkene by fluoride-induced desulfonylstannylation of (**8**) (eq 5).[14] Tri-*n*-butyl(iodomethyl)tin has also been used to prepare (tri-*n*-butylstannyl)methyllithium (**9**), which reacts with electrophiles as a methylene double anion equivalent.[15] For example, transmetalation of (**1**) using *n*-BuLi followed by addition of an ester generates the corresponding ketone enolate which may participate in aldol reactions (eq 6).

Tri-*n*-butyl(1-methoxymethoxy-2-butenyl)stannane

[84510-37-2] · $C_{18}H_{38}O_2Sn$ · Tri-*n*-butyl(1-methoxymethoxy-2-butenyl)stannane · (MW 405.27)

(allylation of aldehydes[1])

Alternate Names: α-methoxymethoxycrotylstannane; tributyl(1-methoxymethoxy-2-butenyl)tin.

Physical Data: colorless, odorless oil.

Solubility: sol CH_2Cl_2, THF, ether; insol H_2O.

Form Supplied in: not commercially available.

Preparative Methods: racemic forms can be prepared from ***Crotonaldehyde*** via addition of ***Tri-n-butylstannyllithium***, followed by protection of the resulting hydroxystannane with ***Chloromethyl Methyl Ether*** (MOM-Cl) and ***Diisopropylethylamine*** (eq 1).[1] Tributyl(1-benzyloxymethoxy-2-butenyl)tin can be similarly prepared.

(1)

Optically enriched tributyl(1-methoxymethoxy-2-butenyl)tin can be prepared by asymmetric reduction of the corresponding acyltin, which is obtained by oxidation of the racemic hydroxystannane with ***1,1´-(Azodicarbonyl)dipiperidine*** (ADD) or DIAD (diisopropyl azodicarboxylate), (eq 2).[1,2] The reduction of acylstannanes by (*R*)-BINAL-H produces hydroxystannanes in the (*S*)-configuration in greater than 95% ee. The results of asymmetric induction for acylstannanes are different from those of normal ketones, i.e. the reduction of normal prochiral ketones by (*R*)-BINAL-H usually produces (*R*)-alcohols. This fact was explained by Marshall with the assumption of a pentacoordinated tin complex (**1**).[1] α-Ethoxy analogs can be prepared from diethoxymethyltributyltin via treatment with acetyl chloride, followed by a vinyl Grignard reagent (eq 3).[3]

(1)

Handling, Storage, and Precautions: stable over a period of several months if stored in a refrigerator. However, decomposition occurs slowly if exposed to air at rt. It is recommended that tributyl(1-methoxymethoxy-2-butenyl)tins are freshly prepared before use.

Allylation of Aldehydes.

In the presence of ***Boron Trifluoride Etherate***, tributyl(1-methoxymethoxy-2-butenyl)tin undergoes facile addition to aldehydes via an SE´ mechanism (eqs 4 and 5).[1] The major product is the *syn*-(*E*)-isomer for aliphatic aldehydes. Comparable results can be achieved using tributyl(1-benzyloxymethoxy-2-heptenyl)tin (eq 6).

R	*syn-(E)*	*syn-(Z)*
C_6H_{13}	70	27
(E)-BuCH=CH	80	17
BuC≡C	51	25

In contrast, additions to aromatic aldehydes give products with almost exclusively *syn*-(*Z*) stereochemistry (eq 7).[4] The reactions occur through an SE´ mechanism with respect to the α-alkoxyallylstannanes. The aldehydes, when complexed to $BF_3.Et_2O$, are sufficiently electrophilic to attack the double bond of the allyltributyltin.

X	*syn-(E)*	*anti-(Z)*
H	>95%	<5%
Cl	>95%	<5%
NO_2	>95%	<5%

An important feature of the Lewis acid-catalyzed reaction is that the C-C bond formation occurs stereospecifically *anti* to the Bu_3Sn group of the allylic stannanes. This is consistent with steric and stereoelectronic principles.[5] Possible transition states producing the different results for aliphatic and aromatic aldehydes have been suggested (eqs 8 and 9).[4] Of the two favorable staggered transition states, aliphatic aldehydes slightly prefer the antiperiplanar arrangement in order to avoid gauche interactions between the methyl group and the R^1 group. In contrast, aromatic aldehydes prefer the synclinal arrangement due to their strong *anti* complexation with the Lewis acid.[6] In the antiperiplanar transition state, a *syn*-pentane interaction exists between the methyl group and the BF_3. While the loose complexation of aliphatic aldehydes with BF_3 tolerates this unfavorable interaction, the tight complexation of aromatic aldehydes with BF_3 prefers the synclinal arrangement. The synclinal arrangement allows the inside alkoxy alignment of the methoxymethoxy group. This conformation has been suggested to be favored in electrophilic additions to the allylic system.[7]

Antiperiplanar

Synclinal

In the absence of a Lewis acid, high temperature is required to complete the reaction of an aldehyde with tributyl(1-methoxymethoxy-2-

butenyl)tin.[8] Based on the stereochemistry of the product, a cyclic transition state has been suggested for the thermal reactions (eq 10).

(10)

Intramolecular Allylations via α-Alkoxyallyltributyltins.

Because of the relative stability of α-alkoxyallyltributyltins towards the aldehyde function at room temperature, the intramolecular version of the allylation reactions has been applied to form macrocycles (eq 11).[2,9] These experiments are carried out under highly dilute conditions (ca. 0.001 M). A solution of the substrate (an α-alkoxyallyltributyltin aldehyde) is added dropwise to a solution of $BF_3.Et_2O$ in CH_2Cl_2 over several hours. Usually, the reaction is completed when the addition is finished. Consistent high yields are obtained with the substrate shown in eq 11. Several members of the cembranolide family of natural products have been synthesized using this strategy.[2]

(11)

Isomerization of Tributyl(1-methoxymethoxy-2-butenyl)tins.[11]

Treatment of (*S*)-tributyl(1-methoxymethoxy-2-butenyl)tin with $BF_3.Et_2O$ at -78 °C leads to a facile 1,3-stereospecific isomerization to produce (*S*)-(γ-methoxymethoxyallyl)tin (eq 12). Mechanistic studies of the rearrangement have shown that the 1,3-tin migration is intermolecular.[10,11] The product of the 1,3-isomerization is a useful reagent for the enantioselective synthesis of carbohydrates.[12]

(12)

Double Diastereofacial Differentiation.

Although the π-facial selectivity of the allylation by tributyl(1-methoxymethoxy-2-butenyl)tin is only moderate on aliphatic aldehydes (eqs 4 and 5), much greater selectivity can be achieved by using α-chiral aldehydes. Excellent π-facial selectivity is obtained when matched pairs of α-chiral aldehydes and (1-methoxymethoxy-2-butenyl)stannanes are allowed to react (eq 13).[13] On the other hand, poor selectivity is observed when mismatched pairs are the reacting partners (eq 14).

(13)

(14)

+ Isomeric adducts 48%

Kinetic Resolution.

When a racemic mixture of tributyl(methoxymethoxy-2-butenyl)tin is allowed to react with an optically pure α-chiral aldehyde, a single adduct can be isolated along with the recovery of enantiomerically enriched (γ-methoxymethoxyallyl)tin (eq 15).[13] The (*S*)-enantiomer of the allylstannane reacts much faster than the (*R*)-enantiomer with the α-chiral aldehyde to produce the adduct. The (*R*)-enantiomer rearranges to give the (*R*)-(γ-methoxymethoxyallyl)tin (eq 16).

(15)

(16)

Summary.

The allylation of aldehydes using tributyl(1-methoxymethoxy-2-butenyl)tin leads to adducts with two new stereocenters. These reactions proceed under mild conditions and in high yields. The stereochemistry of the products can be predicted by controlling the reaction conditions and substrate structures. BF_3-catalyzed additions are highly *syn* selective. In contrast to many other allylic metallic reagents, (1-alkoxyallyl)stannanes are stable and isolable intermediates, making the intramolecular version of the allylation reaction practical.

Tri-*n*-butyl[(methoxymethoxy)methyl]stannane

[100045-83-8] · $C_{15}H_{34}O_2Sn$ · Tri-*n*-butyl[(methoxymethoxy)methyl]stannane · (MW 365.20)

(hydroxymethyl anion equivalent[1])

Physical Data: bp 117 °C/0.34 mmHg.

Solubility: sol THF.

Analysis of Reagent Purity: by gas chromatographic analysis on a 0.25 mm × 30 m DB-1701 fused silica capillary column, 12 psi column pressure, 120-250 °C at 10 °C/min, then 250 °C; retention time: 13.1 min. ^{1}H NMR (300 MHz CD-Cl_3): δ 0.8-1.1 (m, 15H), 1.2-1.7 (m, 13H), 4.02 (d, 2 H, *J* = 4.5 Hz).

Preparative Methods: the most convenient preparation involves the two-step procedure outlined in eq 1.[2] The first step involves the addition of ***Tri-n-butylstannyllithium*** to ***Paraformaldehyde*** as described by Still.[2,8] In the second step, methoxymethylation is achieved via acetal exchange with ***Dimethoxymethane***, promoted by ***Boron Trifluoride Etherate*** and ***Molecular Sieves***.[2,6] This procedure provides the desired reagent in higher yields compared to an alternative procedure which uses ***Phosphorus(V) Oxide*** to promote the acetal exchange step.[9] This method is also superior to an alternative approach which involves alkylation of (tributylstannyl)methanol with ***Chloromethyl Methyl Ether***.[10]

Purification: by filtration through alumina followed by distillation.[2]

Handling, Storage, and Precautions: as with all organostannanes, precautions should be taken to avoid all contact with tributyl[(methoxymethoxy)methyl]stannane. The reagent should be handled in a fume hood. The reagent can be stored neat in a freezer under nitrogen for several months.

Addition to Carbonyl Compounds.

Tributyl[(methoxymethoxy)methyl]stannane undergoes tin-lithium exchange with ***n-Butyllithium*** to generate the organolithium intermediate (**1**), a hydroxymethyl anion equivalent. (**1**) adds to ketones to form monoprotected 1,2-diols in very good yield (eq 2), and the acetal protective group can be removed under mild acidic conditions (eq 3).[1] This stannane reagent complements the (isopropoxydimethylsilyl)methyl group as a hydroxymethyl anion equivalent, since the latter group is converted to alcohol using oxidative basic conditions.[3]

The stannane reagent has been added to a variety of carbonyl compounds. Aldehydes[4] and lactones[5] react with (**1**) in a manner analogous to the ketone example above. Other substrates include β-alkoxy enones (eq 4)[6] and α,β-unsaturated carbonyl compounds.[7] In the latter case, the intermediate tertiary alcohol formed by 1,2-addition of (**1**) is converted by oxidation to a 3-substituted α,β-unsaturated enone (eq 5).

In synthetic work, tributyl[(methoxymethoxy)methyl]stannane is preferred over the closely related (ethoxyethylmethyl)tributylstannane developed earlier by Still.[8] Since the MOM ether reagent does not contain a chiral center, the formation of diastereomeric intermediates is avoided.

Related Reagents.

t-Butoxymethyllithium.

Tri-*n*-butyl(methoxy)stannane[1]

***n*-Bu_3SnOMe**

[1067-52-3] · $C_{13}H_{30}OSn$ · Tri-*n*-butyl(methoxy)stannane · (MW 321.14)

(mild methoxide source with strong nucleophilic properties but with reduced basicity, making it less likely to induce elimination reactions; precursor to other alkoxytributylstannanes)

Alternate Names: tributyltin methoxide; methoxytributylstannane.

Physical Data: bp 90 °C/0.1 mmHg; *d* 1.129 g cm^{-3}; ^1H NMR ($CDCl_3$) 3.54 ppm (OMe); ^{119}Sn NMR 83 ppm.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: toxic, as are most organotin reagents; should be manipulated in a fume hood and handled with gloves. Readily hydrolyzable, it must be stored in the absence of moisture and CO_2. Exposure to moist air leads to hexabutyldistannoxane and tributylstannyl carbonate.

Introduction.

This reagent can be used in substitution, oxidation, or addition reactions. It is also employed as a catalyst for urethane, polylactone, polylactide, and polycarbonate synthesis.

Substitution Reactions.

Methoxytributylstannane and related compounds react with acyl chlorides or anhydrides to give esters under very mild conditions (eq 1).[2] This smooth reaction is particularly useful in carbohydrate chemistry.[1d]

$$Bu_3SnOMe + RCOX \xrightarrow{-Bu_3SnX} RCO_2Me \qquad (1)$$

$$X = Cl, OCOR$$

Methoxytributylstannane is also useful for the preparation of peresters, as reactive stannyl peroxide intermediates are quantitatively obtained from the corresponding hydroperoxides.[3] Methoxytriethylstannane can be used under palladium catalysis to give aryl esters from aryl iodides and carbon monoxide (eq 2).[4]

$$ArI + CO + Et_3SnOMe \xrightarrow[-Et_3SnI]{PhPdI(PPh_3)_2} ArCO_2Me \qquad (2)$$

These esterifications have been generalized to organosulfur and organophosphorus chemistry. With sulfenyl chlorides,[5] Bu_3SnOMe gives access to sulfenates in better yields than does ***Sodium Methoxide*** (eq 3). *O*-Alkyl *S*,*S*-diaryl phosphorodithioates are converted to *O*,*O*-dialkyl *S*-aryl phosphorothioates (eq 4)[6] and dinucleoside *S*-aryl phosphorothioates give dinucleoside *O*-methyl phosphates (eq 5).[7]

(3)

(4)

(5)

In the presence of ***Lithium Chloride*** as an activating agent, methoxytributylstannane promotes mild, chemoselective debenzoylations. Thus debenzoylation of 7,13-diacetylbaccatin III (a precursor of taxol) occurs only at C-2 (eq 6). In a highly polar solvent, NMP, none of the four other acyl groups is affected to any appreciable extent.[8] *O*-Deacetylation of sugars is readily accomplished with methoxytributylstannane. Anomeric acetates are more reactive than primary or secondary acetates, thereby enabling selective removal.[9]

(6)

Dioxybis(tributylstannane), prepared from methoxytributylstannane and ***Hydrogen Peroxide***, allows the preparation of primary, secondary, and tertiary dialkyl peroxides from the corresponding triflates in good yields.[10]

The modulation of the nucleophilicity of an alkoxy group by the tin atom is particularly useful in methoxylation reactions,[11] where the absence of base even allows the use of base sensitive halides (eq 7).

$$Bu_3SnOMe + RX \longrightarrow ROMe + Bu_3SnX \qquad (7)$$

Alkyl glycosides can be prepared by using alkoxytributylstannanes. Per-*O*-acetyl-α-D-glucopyranosyl bromide reacts with methoxytributylstannane in the presence of catalytic amounts of ***Tin(IV) Chloride*** to give methyl per-*O*-acetyl-β-D-glycoside (eq 8). Replacement of tin(IV) chloride by 0.5 equiv of triethylammonium bromide completely changes the course of the reaction; epimerization to the more reactive β-anomeric configuration occurs during the reaction, affording an *exo*-orthoester (eq 9).[12]

(8)

(9)

When 2-, 3-, 4-, or 5-halogenated alcohols are used, methoxytributylstannane first reacts with the hydroxyl in an exchange reaction. Then the alkoxide intermediates undergo intramolecular alkoxylation to give oxiranes, oxetanes, tetrahydrofurans, or tetrahydropyrans, respectively (eq 10).[13] The displacement is stereospecific, as *erythro*-3-bromo-2-butanol leads mainly to (*E*)-butene oxide and *threo*-3-bromo-2-butanol to the (*Z*)-isomer (*n* = 1).

(10)

Methoxylation with methoxytributylstannane is not limited to halogenated derivatives. Under palladium catalysis, allyl acetates are transformed into allyl methyl ethers. This chemoselective approach to allyl etherification is often stereoselective and tolerates other electrophilic functional groups such as primary halides. It has been applied to carbohydrate chemistry (eq 11).[14]

(11)

β-Lactams are stereospecifically methoxylated at the 4-position by methoxytributylstannane when a phenylsulfinyl group is used as leaving group (eq 12). Thus 3-substituted or unsubstituted 4-phenylsulfinyl-2-azetidinones lead to the corresponding 4-methoxy-2-azetidinones in the presence of catalytic amounts of ***Trimethylsilyl Trifluoromethanesulfonate*** at rt.[15]

(12)

Enoxytributylstannanes (tin enolates) can be regiospecifically prepared by transesterification of enol acetates derived from aldehydes[16] or ketones[17] with methoxytributylstannane. The formation of new carbon-carbon bonds can be accomplished with primary alkyl halides, allyl halides, or functional halides. This coupling is regiospecific (eqs 13 and 14).

(13)

(14)

Under palladium catalysis, aryl[18], vinyl,[19] or heteroaryl[20] halides, or allyl acetates[21] may be used instead of allyl or alkyl halides (eqs 15 and 16). This reaction is also regiospecific.[22] It allows arylation of chroman-4-ones into isoflavanones.[23] In contrast, a different reaction takes place in acetonitrile, which leads to α-enones. This process has been applied to the synthesis of α,β-unsaturated large-ring ketones from enol esters (eq 17).[24]

(15)

(16)

(17)

Metalation of alkynes by methoxytributylstannane gives alkynyltributylstannanes, which are able to undergo further reactions with acyl chlorides, leading to alkynyl ketones (eq 18).[25] With 1,3-dienes, [4 + 2] cycloadditions give cyclic vinylic organotins which are easily transformed into functional cyclohexadienes (eq 19) through vinyllithium intermediates.[26]

(18)

(19)

Oxidation Reactions.

Alkoxystannanes, conveniently prepared from methoxytributylstannane and alcohols, are oxidized under very mild conditions by bromotrichloromethane,[27] ***1,1-Di-t-butyl Peroxide***,[28] ***Bromine***,[29] ***N-Bromosuccinimide***,[30] or ***Nitronium Tetrafluoroborate*** (eq 20).[31] Secondary alcohols are selectively transformed into ketones, even in the presence of primary alcohols.[32]

(20)

Disulfides are obtained when thiols are treated with methoxytributylstannane and anhydrous ***Iron(III) Chloride***, through an oxidation reaction involving thiostannane intermediates (eq 21). Tertiary, as well as primary, secondary, or aryl thiols may also be employed. Various functionalities, such as hydroxy, amino, amido, or ester groups, remain intact under the reaction conditions.[33]

$$RSH + Bu_3SnOMe \xrightarrow{FeCl_3} 1/2\ RSSR + Bu_3SnCl \qquad (21)$$

Addition Reactions.

Enoxytributylstannanes, prepared from methoxytributylstannane, add to aldehydes[34] to give predominately the *anti*-aldols at low temperature, whereas *syn* selectivity is observed at higher temperature (eq 22).[35]

(22)

Intramolecular opening of oxiranes by tin alkoxides leads to cyclic ethers. After treatment by methoxytributylstannane, substituted 3-epoxybutanols stereospecifically give either oxetanemethanols (eq 23) or 3-oxolanols (eq 24) on heating, depending on the substituents.[36]

(23)

(24)

Nucleophilic additions of methoxytributylstannane to isocyanates or ketenes lead to reactive intermediates giving heterocycles after further condensations. Mixed isocyanurates are obtained when different isocyanates are involved in the reaction (eq 25).[37]

(25)

Alkoxides resulting from the opening of halogenated lactones by methoxytributylstannane add to isocyanates to give 2-oxazolidones (eq 26),[38] or 2-oxazinones,[39] depending on the ring size of the starting lactones. Other heterocumulenes, such as diimides, isocyanates or carbon dioxide, react equally well (eq 27).

A Darzens reaction can be performed under mild, neutral conditions with the stannyl carbamate resulting from the addition of methoxytributylstannane to ethyl isocyanate (eq 28). This adduct selectively generates organotin enolates from α-halo ketones even when enolizable α´-hydrogens are present in the halo ketone.[40]

Methoxytributylstannane adds to silylketenes under very mild conditions (eq 29). Condensation of the adduct with aldehydes in the presence of titanium tetrachloride gives β-hydroxy-α-silyl esters with very high *syn* selectivity. A stereocontrolled elimination in these esters subsequently leads to (*E*)- or (*Z*)-α,β-unsaturated esters, depending on the conditions used.[41]

(29)

Stannyl quinones are formed by the thermal isomerization of 4-stannyloxy-4-alkynylcyclobutenones (eq 30) via a ketene intermediate. Once this intramolecular rearrangement is accomplished, the stannyl group can be substituted under palladium catalysis by various organic halides to give substituted quinones.[42]

(30)

Iminocarbonylation of aryl bromides, involving the palladium-catalyzed condensation of *t*-butyl isocyanide, methoxytributylstannane, and an aryl bromide, leads to imidates (eq 31).[43]

(31)

Catalysis.

Methoxytributylstannane is used as a catalyst for polymerization of lactones,[44] lactides,[45] and 1,3-dioxan-2-one.[46] The reaction is suggested to proceed by a coordinative insertion mechanism involving the cleavage of the acyl-oxygen bond of the monomer, and not by an ionic mechanism.

Related Reagents.

Di-n-butyltin Oxide; ***Sodium Methoxide***.

Tri-*n*-butylphosphine

[998-40-3] · $C_{12}H_{27}P$ · Tri-*n*-butylphosphine · (MW 202.36)

(1,4-addition catalyst; used with disulfides for the thioetherification of alcohols; acylation catalyst; used to prepare active esters)

Physical Data: bp 240 °C; bp 130 °C/20 mmHg; *d* 0.812 g cm^{-3}.

Solubility: sol most organic solvents; slightly sol MeCN, H_2O.

Form Supplied in: widely available, neat; usually requires distillation.

Analysis of Reagent Purity: ^{31}P NMR.[1]

Purification: distillation at reduced pressure. Improperly stored bottles of Bu_3P are invariably contaminated with tributylphosphine oxide and butyl dibutylphosphinate.

Handling, Storage, and Precautions: can be stored at room temperature indefinitely under an inert atmosphere. Oxygen should be rigorously excluded to avoid free radical chain oxidation. Tributylphosphine is pyrophoric and has an unpleasant odor. Toxicity: LD_{50} (rat) 750 mg kg^{-1}.[2]

Introduction.

Of the commonly used tertiary phosphines, tributylphosphine[3] is exceptionally nucleophilic. It is a relatively weak base (pK_a 8.70 in $MeNO_2$, 5.60 in MeOH)[4] and rather stable to atmospheric oxidation, surviving for days in nondegassed solvents under nitrogen. Exposure to O_2 results in radical oxidation, giving mixtures of $Bu_2P(O)OBu$ and Bu_3PO in variable ratios, depending on the solvent.[5]

Thioetherification.

Tributylphosphine reacts with disulfides and alcohols to give the corresponding thioethers and Bu_3PO. This mild procedure was first used to prepare nucleoside thioethers (eq 1).[6] The activation step is similar to that used in the synthesis of peptides with ***Triphenylphosphine/2,2´-Dipyridyl Disulfide***,[7] and is conceptually related to the Mitsunobu activation method. This protocol has been used effectively in the synthesis of complex small molecules.[8] In some synthetic applications, thioetherification is followed by oxidation (***m-Chloroperbenzoic Acid***) and elimination (0 °C) to obtain the alkene.[9]

(1)

The thioetherification of diols occurs with remarkable chemoselectivity: ***Diphenyl Disulfide***/Bu_3P (Hata reagent) can distinguish between primary and secondary neopentyl alcohols.[10] Activation of allylic alcohols by the Hata reagent results in partial allylic transposition, giving ca. 2:1 mixtures of isomers (eq 2).[11] Thiophenylsuccinimides have also been employed in the preparation of phenyl thioethers.[12]

Thio- and selenoetherification is believed to proceed with inversion of configuration at the reacting center. In accord with this presumption, chiral secondary alcohols react with phenyl selenocyanates and Bu_3P, undergoing 93-96% inversion to the phenyl selenoethers.[13] The fidelity of the inversion may be subject to the same electronic factors which affect the Mitsunobu activation of ionization-prone alcohols.[14]

Activated Esters.

Aryl thio- and selenocyanates react with freshly distilled Bu_3P and carboxylic acids to give thiol- and selenolesters,[15] which can be isolated, or reacted in situ with amines (eq 3). The resulting amides are obtained in high yields with the Grieco reagent, although the method fails for the preparation of large ring lactams.[16] Analogously, carboxylic acids react with ***Diphenyl Diselenide***/Bu_3P to give activated selenolesters, which are used in the synthesis of peptides.[17]

Acylation Catalyst.

Tributylphosphine has been used as a nucleophilic acylation catalyst.[18] Acetylation and benzoylation of hindered secondary and tertiary alcohols with ***Acetic Anhydride*** and ***Benzoic Anhydride*** in the presence of 0.1 equiv of Bu_3P occurs in high yield with or without added base. In some applications, catalytic rate accelerations match those of ***4-Dimethylaminopyridine*** (DMAP). The Bu_3P/Ac_2O reagent may prove to be a nonbasic alternative to DMAP and might be utilized in situations where DMAP fails or gives significant side reactions. The use of Bu_3P as a nucleophilic catalyst has been extended to a wide variety of substrates.[19]

1,4-Addition Catalyst.

Tributylphosphine has been most widely used as a 1,4-addition catalyst.[20] Although arylalkylphosphines and triphenylphosphine have been used in this application, Bu_3P is markedly superior due to its pronounced nucleophilicity (eq 4).[21] Amines fail to catalyze the reaction, and because phosphines are less basic (thus unable to deprotonate the nitroalkane), nucleophilic catalysis has been inferred. The yields correlate with phosphine nucleophilicity. The problem of monoalkylation of gramine-derived 3-methyleneindoline species with nitroalkanes has been solved using Bu_3P.[22] The authors observe no reaction in the absence of Bu_3P and speculate that the intermediacy of P^V may account for the selectivity observed. Recently, this method has been applied in the synthesis of (+)-paraherquamide (eq 5).[23] Interestingly, demethoxycarbonylation of the carbamate also occurs.

(4)

Catalyst	Equiv.	Yield (%)	Time (h)
Bu_3P	0.5	82	1.5
Ph_3P	10.0	36	160.0

(5)

The Bu_3P-catalyzed 1,4-addition of alcohols to ynoates has recently been reported.[24] In addition to short reaction times (10 min vs. 8 h with Ph_3P), tributylphosphine gives enhanced (*E*)/(*Z*) ratios (99:1 vs 5:1 with Ph_3P) in the resulting 3-benzyloxy enoates. Tributylphosphine also catalyzes the ring opening of cyclobutenones.[25] Presumably, initial 1,4-addition is followed by electrocyclic ring opening. The crystalline tricyclohexylphosphine has been used to initiate (by 1,4-addition) an Ireland ester enolate Claisen rearrangement,[26] and ***Triphenylphosphine*** (or Bu_3P) isomerizes alkynones to the all-*trans* dienones.[27] Tributylphosphine has been utilized in aqueous systems (pK_a 8.43 in H_2O).[28]

Tributylphosphine can intercept π-allyl palladium complexes to yield allylic phosphonium salts, which have been deprotonated and used in

Wittig alkenation of aldehydes.[29] The use of Bu_3P shows improved (*E*) selectivities over Ph_3P, and does not isomerize the alkene geometry of the allylic starting material. In these examples, the role of tributylphosphine extends well beyond that of ancillary ligand.[30]

Mitsunobu Reaction.[31]

Different selectivities have been obtained using Bu_3P rather than Ph_3P in the Mitsunobu reaction.[32] In one case, Bu_3P gives retention of configuration whereas Ph_3P shows (normal)[31] inversion of alcohol configuration.[33] Although a complete mechanistic picture is as yet unclear, recent studies suggest a more reactive Bu_3P/***Diethyl Azodicarboxylate*** (DEAD) reagent. ^{31}P NMR monitoring of the Bu_3P/DEAD/ROH reaction shows the presence of an alkoxyphosphonium species instead of the derived phosphorane which is observed with Ph_3P.[34] Furthermore, the Bu_3P-derived betaine reacts faster with nucleophiles than the Ph_3P-derived betaine, which has synthetic implications for the order of addition of reagents (e.g. Bu_3P, DEAD, ROH, then $R'CO_2H$).[28] Premature addition of the carboxylic acid component results in symmetrical anhydride formation, which may explain some of the poor yields reported using Bu_3P. A more reactive Mitsunobu reagent, comprised of Bu_3P and ***1,1´-(Azodicarbonyl)dipiperidine***, has been described.[35]

Miscellaneous.

The synthesis of *O*-silyl cyanohydrins by the 1,2-addition of ***Cyanotrimethylsilane*** to aldehydes benefits from tributylphosphine catalysis.[36] In the reaction of TMSCN with hydrocinnamaldehyde, Bu_3P gives the best yield (eq 6). In a hindered intramolecular example of the aza-Wittig reaction, Ph_3P fails to give any product but Bu_3P gives moderate yields of the desired 1,4-benzodiazepin-5-ones.[37]

Tri-*n*-butylstannylacetylene[1]

[994-89-8] · $C_{14}H_{28}Sn$ · Tri-*n*-butylstannylacetylene · (MW 315.13)

(addition of organometallic reagents affords alkenic stannanes; palladium-catalyzed coupling yields enynes; 1,3-dipolarophile)

Physical Data: bp 70 °C/0.2 mmHg; *d* 1.089 g cm^{-3}.

Solubility: sol common hydrocarbon and ethereal solvents.

Form Supplied in: available from several commercial sources.

Preparative Method: prepared by the reaction of ***Lithium Acetylide*** with ***Tri-n-butylchlorostannane***.[2]

Purification: distillation.

Handling, Storage, and Precautions: organostannane reagents are potentially toxic.[3] Therefore their preparation and use must be conducted wearing appropriate protective clothing and in a well ventilated fume hood.

Addition Reactions.

Addition of ***Tri-n-butylstannane*** to tributylstannylacetylene (**1**) affords the synthetically useful reagent *trans*-1,2-bis(tributylstannyl)ethylene.[2] Stannylcupration of (**1**) with the higher order cuprate $(Me_3Sn)_2Cu(CN)Li_2$, followed by protonation of the intermediate vinyl cuprate, yields *trans*-1-(tributylstannyl)-2-(trimethylstannyl)ethylene in excellent yield.[4] Hydrozirconation of (**1**) with ***Chlorobis(cyclopentadienyl)hydridozirconium*** and protonation of the intermediate vinylzirconate proceeds smoothly to afford ***Vinyltributylstannane***.[5] Addition of ***Triethylborane*** to (**1**) stereospecifically affords (*E*)-2-(diethylboryl)-1-(tributylstannyl)-1-butene, through an alkynylborate intermediate.[6]

Cross-Coupling Reactions.

Stille et al. pioneered the palladium-catalyzed cross-coupling reaction of organostannanes with a variety of electrophilic partners. These reactions proceed under mild conditions which are often compatible with typically sensitive functional groups.[1] Tributylstannylacetylene (**1**) couples smoothly with vinyl halides to afford the corresponding enyne in high yield (eq 1).[7a] The alkene geometry of the starting halide is retained in the product.[7] Aryl halides and triflates also couple with (**1**) to afford the corresponding arylacetylenes.[8]

(1)

Cycloaddition Reactions.

Tributylstannylacetylene is an effective 1,3-dipolarophile, reacting with nitrile oxides to afford 5-tributylstannylisoxazoles (eq 2).[9] The synthetic utility of this latent 1,3-dicarbonyl equivalent is demonstrated by its straightforward conversion to chromones,[9a,b] 4(1*H*)-

quinolones, and indoles.[9a] Tributylstannylpyrazoles are prepared by reaction of (**1**) with diazoalkanes.[10]

(2)

Tributylstannylacetylene is an effective dienophilic partner in the inverse electron demand Diels-Alder reaction. Stannyl-substituted pyrazines are prepared in moderate yield by reaction with 1,2,4,5-tetrazines.[11] Stannyl-substituted pyridines are formed in moderate to poor yields by reaction with (6*H*)-1,3-oxazin-6-ones (eq 3).[12] These compounds are best prepared from the corresponding halo-substituted heterocycles.[13]

Tri-*n*-butylstannylcopper

Bu_3SnCu

[82097-93-6] · $C_{12}H_{27}CuSn$ · Tri-*n*-butylstannylcopper · (MW 353.65)

(incorporation of tributyltin via reaction with electrophilic substrates[1-6])

Physical Data: prepared in situ; its THF solution is dark red.

Solubility: sol THF.

Preparative Methods: Bu_3SnCu (**1**) is prepared by reaction of ***Tri-n-butylstannyllithium*** with 1 equiv of ***Copper(I) Iodide*** (eq 1).[1,2,5,8] A closely related reagent, $Bu_3SnCu.Me_2S$ (see ***Trimethylstannylcopper-Dimethyl Sulfide***), is readily obtained by treatment of Bu_3SnLi with an equimolar quantity of $CuBr.Me_2S$ (**2**) (see ***Copper(I) Bromide***) (eq 2).[3,4,9-13]

(1)

(2)

Handling, Storage, and Precautions: should be prepared in dry solvent and used under an inert atmosphere. Organotin compounds are toxic;[7] therefore, reaction workup should be carried out in a fume hood.

Substitution Reactions.

Bu_3SnCu (**1**) reacts with methyl 3-chloro- and 3-iodoacrylates to produce the corresponding 3-tributylstannylacrylates. These reactions, which presumably proceed via a conjugate addition-elimination mechanism, occur under mild conditions and, importantly, are stereospecific (eqs 3 and 4).[1] In similar fashion, treatment of ethyl (*Z*)-3-(*p*-tolylsulfonyloxy)acrylate with (**1**) provides, stereoselectively, ethyl (*Z*)-3-tributylstannylacrylate (eq 5).[1]

(3)

X = Cl, 58%; I, 62%

(4)

X = Cl, 62%; I, 47%

(5)

In a related process, reagent (**1**) reacts with (*E*)-2-chloro-1-(phenylsulfonyl)ethylene to provide the corresponding tributylstannane (eq 6),[2] a useful intermediate for the synthesis of 1-tributylstannyl-1-alken-3-ols.[2]

(6)

Tributylstannylcopper replaces the 4-iodo group of the functionalized pyrimidines (**3**) and (**4**) (eq 7).[5] The stannylated products (**5**) and (**6**) are valuable for the preparation of substituted pyrimidine derivatives.[5]

Reactions with Alkynic Substrates.

Reagent (**2**) is very useful for effecting the highly stereocontrolled conversion of α,β-alkynic esters into alkyl (*E*)-3-tributylstannyl-2-alkenoates.[3,9,11-13] Examples are given in eqs 8 and 9.[11,12] The (*E*)-3-tributylstannyl-2-alkenoates are valuable synthetic intermediates that have been employed as precursors to radical cyclization substrates,[9,11,12] to configurationally defined alkenyllithium reagents,[3,13] and in natural product synthesis.[3,9,13] For instance, compounds (**7**) (eq 8) and (**8**) (eq 9) have been transformed into the intermediates (**9**) and (**10**), respectively. Radical-mediated cyclization of (**9**) provides primarily the highly functionalized heterocycle (**11**) (eq 10),[11] while treatment of (**10**) with bis(cyclopentadienyl)titanium(III) chloride gives the ester alcohol (**12**) with high stereoselectivity (eq 11).[12] Additionally, (**13**), derived by reaction of ethyl 2-pentynoate with (**2**),[3] is readily converted into (**14**). The latter substance is a convenient precursor to (*Z*)-3-lithio-2-pentene (**15**), which played an important role in a total synthesis of the unusual natural product triophamine (**16**).[3]

Reagent (**2**) can also be employed to achieve the stereoselective *cis*-addition of the elements of Bu_3Sn-H across the triple bond of propargylic alcohols. Examples are given in eqs 12 and 13.[4,6,10] Substance (**17**) has been used in the synthesis of novel compounds structurally related to the enediyne antibiotic dynemycin A.[6] The diol stannane (**18**) has served as an excellent precursor for the preparation of 3-lithiofuran[4] and 2-tributylstannyl-1,3-butadiene.[14] Diels-Alder reactions of the latter material have been investigated.[10,14]

N-[(Tri-*n*-butylstannyl)methyl]benzaldimine

[116360-40-8] · $C_{20}H_{35}NSn$ · *N*-[(Tri-*n*-butylstannyl)methyl]benzaldimine · (MW 408.27)

(synthesis of 2-phenylpyrrolidines by [3 + 2] cycloaddition of the derived 2-azaallyl anion with alkenes;[1,2] related compounds allow synthesis of other 2-substituted, 2,2-disubstituted, 2,5-disubstituted, or 2,2,5-trisubstituted pyrrolidines or pyrrolines[1-3])

Physical Data: bp 145-155 °C/0.1 mmHg (Kugelrohr air bath).

Solubility: freely sol common organic solvents.

Form Supplied in: clear, colorless oil; not available commercially.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: prepared by Staudinger reaction between benzaldehyde, ***Triphenylphosphine***, and (azidomethyl)tributylstannane [prepared from (iodomethyl)tributylstannane and ***Sodium Azide***].[2] A more convenient procedure for the preparation of similar stannanes by condensation of an aldehyde or ketone with (aminomethyl)tributylstannane has been developed.[3] Related 2-azaallylstannanes such as 1-alkyl-, 1,1-dialkyl-, 1,3-dialkyl-, and 1,1,3-trialkyl-2-azaallylstannanes may also be prepared, particularly using the latter method.

Handling, Storage, and Precautions: since tetraalkylstannanes in general are considered toxic,[4] handling in a fume hood is recommended. The reagent is stable in a freezer for extended periods, but is easily hydrolyzed by aqueous acids, and is partially hydrolyzed by silica gel chromatography.

Synthesis of 2-Phenylpyrrolidines.

Treatment of *N*-[(tributylstannyl)methyl]benzaldimine with ***n-Butyllithium*** in the presence of stilbene produces 2,3,4-triphenylpyrrolidine in good yield (eq 1).[1,2] The reaction proceeds by transmetalation to produce a 2-azaallyl anion, which undergoes a [$_\pi4_s$ + $_\pi2_s$] cycloaddition with stilbene, generating an *N*-lithiopyrrolidine. Quenching the reaction with water or other electrophiles allows the introduction of a variety of *N*-substitutents. The anionophile must be present during the transmetalation, since the 2-azaallyl anions have a limited lifetime under these conditions. The best anionophiles are those that are relatively stable to butyllithium at low temperature, and are relatively reactive due to the presence of substituents which may stabilize negative charge build up. Successful examples include stilbene, styrene, α-methylstyrene, diphenylacetylene, phenyl vinyl sulfide, phenyl vinyl selenide, and various vinylsilanes.[1,2] More electron-deficient anionophiles such as acrylates are unsuccessful. Examples are shown in eq 2.[2]

Related Pyrrolidine Syntheses using 2-Azaallyl Anion Cycloadditions.

In addition to the synthesis of 2-arylpyrrolidines as shown above, the 2-azaallyl anion method is useful for the preparation of a variety of 2-alkylpyrrolidines.[1,2] Similar restrictions regarding the anionophile apply. For example, vinyl selenides are excellent reaction partners (eq 3).[2] The phenylseleno group may be reductively or oxidatively removed, producing simple pyrrolidines or pyrrolines (eq 4).[2] Intramolecular examples are also known (eq 5).[1,2] More recently, 2-azallyl anions bearing two or three alkyl groups have been generated and used in cycloadditions, leading to 2,2-disubstituted, 2,5-disubstituted, and 2,2,5-trisubstituted pyrrolidines.[3] Example are shown in eqs 6 and 7. Note that 1,3-dialkyl-2-azaallyl anions produce pyrrolidines with a 2,5-*cis*-relationship, presumably due to the preferential formation of the W form of the anion (eq 7).

(3)

(4)

(5)

(6)

(7)

Related Methods for Pyrrolidine Synthesis.

Kaufmann has studied the formation and cycloaddition of 2-azaallyl anions derived from the deprotonation of imines such as *N*-benzylidenebenzylamine with amide bases.[5] Only anions bearing two or more aryl groups may be used, unless the cycloaddition is intramolecular, where one aryl group on the anion is necessary.[6] The generation of aryl-substituted 2-azaallyl anions by the desilylation of

N-(trimethysilyl)methanimines has been reported.[7,8] A variety of 2-azaallyl anions bearing strong electron-withdrawing groups have been generated and used in cycloaddition reactions.[9] The lower reactivity of these anions necessitates the use of more reactive anionophiles such as acrylates. Azomethine ylides are closely related to 2-azaallyl anions, and have also been used to synthesize pyrrolidines by dipolar cycloadditions with alkenes.[10] A review which compares the two methods has appeared.[11]

(*E*)-3-Tri-*n*-butylstannyl-2-propenyl 2-Tetrahydropyranyl Ether[1]

[55723-10-9] · $C_{20}H_{40}O_2Sn$ · (*E*)-3-Tri-*n*-butylstannyl-2-propenyl 2-Tetrahydropyranyl Ether · (MW 431.31)

(efficiently transmetalated by alkyllithium reagents;[2] palladium-catalyzed coupling affords substituted allylic alcohols)

Physical Data: bp 140-142 °C/0.1 mmHg;[2] ^{1}H NMR data have been reported.[4]

Solubility: sol THF, DMF.

Preparative Method: hydrostannation of propargyl tetrahydropyranyl ether affords the (*Z*)-isomer *[87830-21-5]*, which isomerizes at temperatures above 80 °C.[2,3]

Purification: can be purified by distillation.[2,3]

Handling, Storage, and Precautions: organostannane reagents are potentially toxic. Therefore their preparation and use must be conducted wearing appropriate protective clothing and in a well-ventilated hood. The reagent should be stored under an inert atmosphere and protected from light.

Transmetalation.

Alkyllithium reagents efficiently transmetalate (*E*)-3-tributylstannyl-2-propenyl 2-tetrahydropyranyl ether (**1**) to afford (*E*)-3-lithiopropenyl 2-tetrahydropyranyl ether, which exhibits reactivity typical of vinyllithium reagents.[2]

Cross-Coupling Reactions.

Stille et al. pioneered the palladium-catalyzed cross-coupling reaction of organostannanes with a variety of electrophilic partners. These reactions proceed under mild conditions, which are often compatible with typically sensitive functional groups.[1] Palladium-catalyzed couplings of (**1**) with vinyl halides (eq 1)[5] and heteroaryl halides (eq 2)[6] have been reported. Coupling of (**1**) (7:1 *E*/*Z* ratio) with aromatic triflates affords a 3:1 mixture of alkenic products (eq 3).[7a] Isomerically pure allylic alcohols can be obtained directly from the palladium-catalyzed coupling of (*E*)- and (*Z*)-1-(tributylstannyl)-1-propen-3-ol with aromatic triflates.[7a]

(1)

Aromatic triflates[7b] and allylic halides[8] couple with (**1**) in the presence of carbon monoxide to afford the corresponding α,β-unsaturated ketones (eq 4).[7b]

Coupling of (**1**) (1:1 *E*/*Z* ratio) with sulfonyl chlorides affords the corresponding isomerically pure (*E*)-allylic sulfone in good yield (eq 5).[9] Presumably, a mixture of allylic sulfones is formed initially which subsequently isomerizes under the reaction conditions to provide the thermodynamically more stable (*E*)-isomer. Similar isomerizations are observed in the palladium-catalyzed coupling of acid chlorides with (*Z*)-vinylstannanes.[10]

(*E*)-1-Tri-*n*-butylstannyl-2-trimethylsilylethylene[1,2]

[58207-97-9] · $C_{17}H_{38}SiSn$ · (*E*)-1-Tri-*n*-butylstannyl-2-trimethylsilylethylene · (MW 389.35)

(used in the Pd^0-catalyzed cross coupling of vinyl and aryl halides or triflates;[1,2] a source of β-trimethylsilylvinyllithium[3])

Physical Data: bp 96-102 °C/0.5 mmHg.

Analysis of Reagent Purity: IR 1538 cm^{-1} (C=C); ^1H NMR ($CDCl_3$, CH_2Cl_2) δ 0.12 (9H, s), 0.95 (9H, t, *J* = 7 Hz), 1.41 (18H, m), 6.65 and 7.08 (2H, AB pattern, *J* = 23 Hz).

Solubility: sol ethers, DMF, hydrocarbon, aromatic solvents.

Preparative Method: bis(tri-*n*-butylstannyl)ethylene is treated successively with molar equivalents of ***n-Butyllithium*** and ***Chlorotrimethylsilane*** to give (*E*)-1-tri-*n*-butylstannyl-2-trimethylsilylethylene.[5]

Handling, Storage, and Precautions: most tin compounds are toxic and are readily absorbed through the skin.[4] Their preparation and use should be carried out at all times in a well-ventilated fume hood.

Pd^0-Catalyzed Cross Couplings.

In general, (*E*)-1-tri-*n*-butylstannyl-2-trimethylsilylethylene undergoes the same types of Pd^0-catalyzed cross-coupling reactions as other substituted vinylstannanes. It readily couples with vinyl halides in the presence of catalytic amounts of Pd^0, giving 1,3-dienes in high yields (eq 1).[6] Vinyl and aryl triflates can undergo the cross-coupling reactions with the organostannane reagent, yielding 1,3-dienes provided ***Lithium Chloride*** is also present (eq 2).[7,8]

(1)

(2)

When the coupling reactions of vinyl and aryl triflates are carried out in the presence of ***Carbon Monoxide*** and LiCl, good yields of the cross-coupled ketones are obtained (eqs 3 and 4).[9] This is a particularly attractive route to divinyl ketones which are important substrates in the Nazarov cyclization.

(3)

(4)

The reagent also couples predominantly 1,4 to acyclic vinyl epoxides to give allylic alcohols. The regioselectivity is controlled by the substitution pattern of the vinyloxirane. The 1,4 versus 1,2 selectivity could be further enhanced by the addition of water (10 equiv based on the vinyl epoxide) (eq 5).[10,11]

(5)

For additional discussion about palladium-catalyzed coupling reactions, see also those entries dealing with organopalladium catalysis (e.g. ***Tetrakis(triphenylphosphine)palladium(0)***, ***Tris(dibenzylideneacetone)dipalladium***, and ***(E)-1-Trimethylsilyl-2-trimethylstannylethylene***.

Transmetalation Reactions.

Transmetalation of trimethylsilyl-2-trimethylstannylethylene at low temperature with BuLi affords *trans*-β-trimethylsilyllithium in high yield, as evidenced by derivatization of 2-methyldimedone isobutyl ether (eq 6).[3,12-14]

Tri-*n*-butylstibine[1]

***n*-Bu_3Sb**

[2155-73-9] · $C_{12}H_{27}Sb$ · Tri-*n*-butylstibine · (MW 293.14)

(agent for making carbon-carbon bonds between α-halogeno carboxylic derivatives[2] (or α-halo ketones)[3] and carbonyl compounds in neutral conditions; can promote the cyclopropanation reaction between electron-deficient alkenes with dibromomalonate and its analogs;[4] formation of quaternary stibonium salt)

Physical Data: bp 131 °C/12 mmHg; *d* 1.197 g cm^{-3}.

Solubility: insol H_2O, ethanol; sol ether, petroleum ether, THF etc.

Preparative Method: prepared from ***Antimony(III) Chloride*** and 3 equiv of *n*-butylmagnesium bromide in absolute ether.[5]

Handling, Storage, and Precautions: pyrophoric; store and handle under nitrogen. Use in a fume hood.

General Discussion.

Phenyl-substituted stibonium salts are difficult to form by reaction of triphenylstibine with halides. Ylides with strong α electron-withdrawing groups in the alkylidene moiety can be prepared by reaction with diazo compounds, but they are unreactive to carbonyl compounds.[6] In contrast, trialkylstibines react readily with halides, especially with α-halo carboxylic derivatives, to form quaternary stibonium salts which react with carbonyl compounds to form alkenation products (eq 1).[1]

$$Bu_3Sb + XCHRE + R^1R^2CO \xrightarrow{60\text{-}130\ ^\circ C} R^1R^2C{=}CRE + Bu_3SbX(OH) \quad (1)$$

$$R = H, Me, Et;\ R^1, R^2 = alkyl, H;\ X = Cl, Br, BPh_4$$
$$E = CO_2Et, CONEt_2, COMe, CN$$

When R = H, R^1 = alkyl, R^2 = H, and E = CO_2Et (or $CONEt_2$, COMe), the products are highly stereoselective; when R = H, R^1 = alkyl, R^2 = H, and E = CN, the (*E*):(*Z*) ratio of products is ca. 3:2.[2]

β-Hydroxy ketones can be synthesized in excellent yield by the reaction of α-bromo ketones with various aldehydes mediated by Bu_3Sb in the presence of a catalytic amount of ***Iodine*** (2-4%).[7]

The reaction of ***Diethyl Dibromomalonate*** and its analogs with electron-deficient alkenes mediated by Bu_3Sb takes places easily under mild conditions and gives cyclopropane derivatives in high yields (eqs 2 and 3).[4]

(2)

E = CHO, CN, COMe, CO_2Et; X = CO_2R, CN, Ph; R = Me, Et

(3)

A Barbier-type reaction by means of Bu_3Sb has been reported (eq 4).[8] The *erythro*/*threo* ratio is approximately 2:1 to 3:1.

(4)

Since Sb has a greater tendency to form pentaalkyl derivatives than do P and As, treatment of quaternary stibonium with a strong nucleophilic base R´M affords pentaorganyl stiboranes (λ^5-stibanes).[9] These react with aldehydes to give secondary alcohols (eq 5).[10] In the presence of ***Aluminum Chloride***, pentaorganylstiboranes react with ketones to give tertiary alcohols.[11]

(5)

E = Ph, CH=CH$_2$, CH=CHCO$_2$Et, CN; X = Br, I, BPh$_4$; R^2 = Bu, *t*-Bu, Ph; M = Li, MgBr

The reaction of Bu_3Sb with propargyl bromide (see ***Propargyl Chloride***), bromo-2-butyne, and trimethylsilylpropargyl bromide gave allenic and alkynic stibonium salts. The pentaorganylstiboranes formed by reaction with BuM react with aldehydes to give alkynic or allenic alcohols as major products (eqs 6-8).[12]

(6)

(7)

(8)

With less nucleophilic bases such as ***Lithium Diisopropylamide*** or ***Potassium t-Butoxide***, the quaternary stibonium salts give stibonium ylides. These react with carbonyl compounds to give alkenes (eq 9).[13]

(9)

A novel alkenation of diazo compounds with carbonyl compounds mediated by Bu_3Sb and a catalytic amount of copper(I) halide has been reported (eq 10).[14] Stibonium ylides have been suggested as possible intermediates in these reactions.[15]

Tri-*n*-butyltin Azide[1]

***n*-Bu$_3$SnN$_3$**

[17846-68-3] · $C_{12}H_{27}N_3Sn$ · Tri-*n*-butyltin Azide · (MW 332.13)

(nucleophilic azide equivalent; useful for the preparation of tetrazoles and triazoles via 1,3-dipolar cycloaddition reactions;[2] cleaves oxiranes to give 1,2-azido alcohols;[3] reacts with anhydrides and acid chlorides to give isocyanates[4])

Alternate Name: azidotributylstannane.

Physical Data: bp 118-120 °C/0.18 mmHg.[4,5]

Solubility: sol most nonprotic organic solvents (i.e. toluene, hexane, acetonitrile, THF, etc.).

Preparative Method: prepared in 91% yield by the reaction of ***Tri-n-butylchlorostannane*** with aqueous ***Sodium Azide*** at 0 °C.[4,5]

Purification: distillation.[4,5]

Handling, Storage, and Precautions: organotin derivatives are known to be toxic.[6] Avoid inhalation and contact with skin. Organotin azides are claimed to be thermally very stable.[2a] However, extreme caution should be exercised when heating an azide solution due to the possibility of explosion. Use in a fume hood.

Preparation of Tetrazoles.

The reaction of tributyltin azide with nitriles serves as one of the most convenient and versatile methods for the preparation of tetrazoles.[2a] The reaction proceeds via a 1,3-dipolar cycloaddition to give directly a 5-tributyltin-substituted tetrazole (eq 1). The Sn-N bond is readily cleaved by treatment with ***Hydrochloric Acid*** to give the free tetrazole and Bu$_3$SnCl. In general, reactions are carried out under inert atmosphere either neat or in solvents such as acetonitrile, 1,2-dimethoxyethane, THF, benzene, toluene, and xylene. Reaction temperature and duration are largely dependent on steric and electronic factors associated with the nitrile substrate.[2a]

Tributyltin azide has been used in the synthesis of many complex molecules of pharmaceutical interest where a tetrazole is desired as a carboxylic acid bioisostere. Examples that illustrate the use of this reagent include application to the synthesis of an HMG-CoA reductase inhibitor (eq 2),[7] NMDA antagonist (eq 3),[8] leukotriene receptor antagonist (eq 4),[9] and a peptide inhibitor of vitamin K dependent carboxylation (eq 5).[10]

(3)

(4)

Phe-Leu-Abu(tetrazole)-Glu-Val (5)

Additionally, tributyltin azide has been used in the preparation of a key biphenyltetrazole intermediate employed in the synthesis of angiotensin II receptor antagonists (eq 6).[11,12] It was found that treatment of the tin adduct with ***Sodium Hydroxide*** followed by trityl chloride led directly to the highly crystalline trityl-protected tetrazole.[12] This modification facilitates isolation of the tetrazole that is generally made difficult by the presence of organic soluble tin residues.

(6)

In a similar manner to that described for nitriles, tributyltin azide reacts with isothiocyanates to yield thiotetrazoles upon acidic workup (eq 7).[2d,e] A comparison of tributyltin azide with other methods for tetrazole synthesis has been published.[12]

(7)

Preparation of 1,2,3-Triazoles.

Tributyltin azide reacts with mono- and disubstituted alkynes via a 1,3-dipolar cycloaddition reaction to yield tributyltin-substituted 1,2,3-triazoles (eqs 8 and 9).[2b,c] As with tetrazoles, the Sn-N bond is readily cleaved by treatment with HCl to give the triazole N-H derivative.

(8)

(9)

Preparation of Isocyanates, Carbamates, and Ureas.

Tributyltin azide reacts with acid chlorides under mild conditions to give isocyanates.[4] In a one-pot procedure, the isocyanate can be treated with an amine or alcohol to yield a urea (eq 10) or carbamate (eq 11), respectively. Anhydrides can be used in place of acid chlorides. This method serves as an alternative to using ***Azidotrimethylsilane***.[13]

(10)

(11)

Preparation of 1,2-Azido Alcohols.

In contrast to trimethylsilyl azide, tributyltin azide is very reactive toward nucleophilic ring cleavage of oxiranes leading to 1,2-azido alcohols.[3] Reactions are typically carried out neat at 60 °C. The rate of reaction is highly dependent on the structure of the oxirane. Simple, nonsterically hindered oxiranes react rapidly (eq 12), while those with neighboring alkoxy groups (eq 13) or ester functions (eq 14) require longer reaction times. This difference in reactivity is attributed to modulation of the Lewis acidity of the tin species by the neighboring oxygen functionality.

(12)

(13)

One limitation of this method is the difficulty of removing organotin residues from the reaction products. This has partially been addressed by studying a catalytic system using 10 mol % tributyltin azide and trimethylsilyl azide.[3a] Additionally, the use of dibutyltin diazide in place of tributyltin azide in nucleophilic cleavage of oxiranes has been reported to circumvent some of the problems associated with product isolation, as well as displaying enhanced reactivity.[3b]

Tri-*n*-butylchlorostannane

***n*-Bu_3SnCl**

[1461-22-9] · $C_{12}H_{27}ClSn$ · Tri-*n*-butylchlorostannane · (MW 325.55)

(precursor of other organotributyltin reagents;[1] allylic tributyltins for the diastereoselective synthesis of homoallyl alcohols;[2] tributyltin enolates for alkylation[3] and regioselective C-C bond formation[4])

Alternate Name: tributyltin chloride.

Physical Data: bp 171-173 °C/25 mmHg; *n*20D 1.400; *d* 1.200 g cm^{-3}; fp >110 °C.

Form Supplied in: colorless liquid; widely available.

Solubility: sol ether, THF, hexane, CH_2Cl_2, MeOH.

Handling, Storage, and Precautions: in general, tributyltin compounds are highly toxic. The LD_{50} value for oral administration of Bu_3SnCl to rats is 122-349 µg g^{-1}. This reagent is absorbed through the skin to induce temporary skin burns. It must be handled with gloves in a well-ventilated hood. The reagent is air-stable, but slowly decomposes in presence of moisture.

Precursor to other Tributyltin Reagents.

Since the chlorine atom can be readily replaced by a variety of nucleophiles, tributyltin chloride is widely used for the preparation of other synthetically useful organotin compounds[1] such as ***Tri-n-butylstannane***,[5] ***Tri-n-butyl(methoxy)stannane***,[6] diethylaminotributyltin,[7] ***Cyanotributylstannane***,[8] ***Tri-n-butyltin Azide***,[9] ***Hexabutyldistannane***,[10] and ***Bis(tri-n-butyltin) Oxide*** (eq 1).[11]

(1)

Tri-n-butylstannyllithium is readily prepared by the treatment of tributyltin chloride with ***Lithium*** metal[12] and is a valuable reagent for the preparation of organotin compounds.[1a] The stannyllithium is also prepared from *n*-Bu_3SnH and ***Lithium Diisopropylamide***, or from $Bu_3SnSnBu_3$ and ***n-Butyllithium***. Among these preparative methods, the procedure using *n*-Bu_3SnH provides the highest yield of *n*-Bu_3SnLi.[10a] The reaction of the stannyllithium reagent with aldehydes followed by alcohol protection affords α-alkoxystannanes, which are

treated with *n*-butyllithium to yield α-alkoxyllithium derivatives (eq 2).[14] ***Tri-n-butylstannylcopper*** (or cuprate) reagents are prepared from the stannyllithium and copper salts.[15] These reagents are employed for the preparation of β-stannyl-α,β-unsaturated carbonyl compounds (eq 3).[16]

Allyl-, Alkenyl-, and Alkynyltin Reagents.

Simple allyltins are prepared by the reaction of Grignard reagents with tributyltin chloride.[17] γ-Alkoxyallyltins are obtained by trapping the allyl anions generated from allyl ethers.[2a] In this case, tributyltin chloride attacks the γ-position of the allyl anions to produce the (*Z*)-allyltins, owing to the strong coordination ability of the oxygen atom toward the lithium atom. γ-Methoxyallyltin reacts with aldehydes in the presence of Lewis acids to give *syn*-1,2-diol derivatives with high diastereoselectivity (eq 4).[2] An intramolecular allylic tin-aldehyde condensation has been applied to the synthesis of medium-ring cyclic ethers (eq 5).[18]

(5)

Tributyltin chloride reacts with alkenylcopper reagents, generated by the reaction of alkylcoppers and terminal alkynes, to give (*Z*)-alkenyltin derivatives (eq 6).[19] In contrast, the reaction of the alkenylaluminum obtained by hydroalumination affords the (*E*)-isomer (eq 7).[20] Dienyltin derivatives are prepared via the hydrozirconation of 1-en-3-yne.[21] Terminal alkynes react with *n*-$Bu_3SnAlEt_2$, prepared in situ from *n*-Bu_3SnLi and ***Diethylaluminum Chloride***, in the presence of Cu^I or Pd^0 catalysts, to give 1,2-dimetallo-1-alkenes with high regio- and stereoselectivity. These intermediates can be selectively functionalized at the vinyl-aluminum bond to provide alkenyltins (eq 8).[13]

(6)

(7)

(8)

Alkynyltins are easily made by the reaction of lithium or sodium acetylides with tributyltin chloride.[22] These compounds undergo coupling with vinyl iodides in the presence of a palladium catalyst to give conjugated enynes (eq 9).

Tin Enolates.

Tin enolates prepared by transmetalation of lithium enolates with tributyltin chloride undergo rapid aldol condensations with aldehydes (eq 10).[23] This approach has been used to enhance the yield of the alkylation of the enolate generated by the conjugate addition of lithium enolate to cyclopentenone (eq 11).[3] A complicated mixture is obtained in the absence of the tin reagent.

The reaction of lithium dienolates with tributyltin chloride gives γ-stannylated α,β-unsaturated esters, which are stable enough to be isolated by distillation (eq 12).[4] The aldol-type condensation of the tin-masked dienolates proceeds at the α-position of the dienolates with high regio- and stereoselectivity in the presence of Lewis acid.[4a,b] On the other hand, the palladium-catalyzed coupling reaction with organic halides takes place at the position directly bonded to tin.[4a,c]

Related Reagents.

Tributyltin chloride is used more frequently than ***Chlorotrimethylstannane***, perhaps owing to its lower toxicity. The latter reagent is useful in reactions which require a sterically compact trialkylstannyl substituent. See also ***Chlorotriphenylstannane***.

Tri-*n*-butylstannane[1]

***n*-Bu_3SnH**

[688-73-3] · $C_{12}H_{28}Sn$ · Tri-*n*-butylstannane · (MW 291.11)

(source of Bu_3Sn&bdot; radical which produces carbon radicals by (a) abstraction of X from C-X derivatives[1,2] and (b) addition to alkenes, alkynes,[3,4] and carbonyl compounds; hydrogen donor (with concomitant generation of the chain carrier, Bu_3Sn&bdot;) for radicals;[2] hydrostannylation of alkenes, alkynes,[5,6] and carbonyl compounds;[7] desulfurative stannylation of propargylic or allylic sulfides;[8] catalyst for S_H2' reactions of allylic stannanes;[9] radical ring expansion;[10,11] selective reduction of acid chlorides to aldehydes;[12] oxygenation[13] and carbonylation[14] of radicals; source of tributyltin anion[15])

Alternate Name: tributyltin hydride; TBTH.

Physical Data: bp 80 °C/0.4 mmHg; *d* 1.082 g cm^{-3}.

Solubility: freely sol organic solvents.

Form Supplied in: clear colorless liquid; 97% pure.

Analysis of Reagent Purity: major impurity is oxidation product $(Bu_3Sn)_2O$; purity ascertained by gas volumetric methods using dichloroacetic acid or by IR spectroscopy.[1e]

Handling, Storage, and Precautions: irritant. Even though this reagent appears to be relatively innocuous,[1a] tin compounds in general are toxic[16] and should be handled with care in a fume hood. It should be kept in brown bottles away from light and air. Some pressure may develop upon long term storage. Workup procedures for the isolation of tin-free organic products from reactions involving TBTH have been published.[1e,77b]

Introduction.

Tributyltin hydride is the most commonly used source of Bu_3Sn&bdot; which initiates a variety of radical chain reactions.[1,2] Bu_3Sn&bdot; may be generated either thermally or photochemically. ***Azobisisobutyronitrile*** (AIBN) is the most commonly used radical initiator. Three important classes of reactions have been recognized for R_3Sn&bdot;: (a) atom or group abstraction, (b) addition to multiple bonds, and (c) homolytic substitution reactions. The primary products of (a) and (b) are themselves radicals and they undergo a variety of useful transformations such as atom abstraction reactions, rearrangements, fragmentation reactions, and intra- and intermolecular additions to carbon-carbon and other multiple bonds. Tributyltin hydride acts as a hydrogen atom source to trap the radical products, with concomitant generation of the radical chain carrier Bu_3Sn&bdot;. These primary steps are illustrated for prototypical radical reactions in eqs 1-6.

$$RX + Bu_3Sn\bullet \longrightarrow R\bullet + Bu_3SnX \qquad (1)$$

$$R\bullet \longrightarrow \left[\begin{array}{c}\text{rearrangement}\\ \text{fragmentation}\\ \text{addition to C=X}\end{array}\right] \longrightarrow R'\bullet \qquad (2)$$

$$R\bullet + Bu_3SnH \longrightarrow RH + Bu_3Sn\bullet \qquad (3)$$

$$R'\bullet + Bu_3SnH \longrightarrow R'H + Bu_3Sn\bullet \qquad (4)$$

The lifetimes of the radicals R&bdot; and R´&bdot;, are determined by the chain transfer steps 3 and 4 and side reactions of steps 5 and 6. For the efficient formation of preparatively useful radical intermediates R and R´&bdot;, the kinetics of each step must cooperate. For example, only reactions that are faster than the chain transfer step 3 can be executed in step 2. It should be understood that the overall rates of the chain transfer steps can be controlled to some extent by the concentration of the Bu_3SnH reagent. Likewise, the rates of step 2 can be altered by electronic and steric characteristics of R&bdot; and of any reaction partners involved. Fortunately kinetics, thermodynamics,[17] and substituent effects for the individual steps have been studied in some detail and it is possible to design useful synthetic strategies.[18]

Reactions Initiated by Bu_3Sn Radical.

C-X Homolysis followed by H abstraction.

Dehalogenation.

Chemoselective replacement of halogens (except fluorine) with hydrogen is one of the major uses of TBTH in synthesis.[1h] The examples below show the versatility of the method and the range of substrates that can be used in this reaction. Replacement of bridgehead halogen (eq 7)[19] and selective removal of one of the halogens from a geminal dihalocyclopropane (eq 8)[20] are particularly noteworthy. TBTH can be generated catalytically for the dehalogenation reaction (eq 9).[21]

Applications in the β-lactam[22] and carbohydrate (eqs 10 and 11)[23,24] areas illustrate the compatibility of the radical intermediates with a wide range of functional groups and reaction conditions. It should be noted that unlike reactions involving polar intermediates, hydroxyl and amino groups need not be protected under conditions where radicals are generated. Bu_3SnT is the reagent of choice for the regiochemical introduction of tritium into the steroid molecule (eq 12).[25] Debromination with TBTH was a crucial step in a model study directed towards the synthesis of a highly labile thromboxane A_2 analog (eq 13).[26]

(12)

(13)

Deoxygenation.

Deoxygenation of secondary alcohols is best carried out by treatment of the corresponding thiocarbonyl derivatives with TBTH (eq 14).[27,28] Many common functional groups such as amine, alcohol, amido, carbonyl, epoxide, and tosylate are stable to the reaction conditions.

(14)

Typical thiocarbonyl derivatives are xanthates (eq 15),[29] thiocarbonyl imidazolides (R´ = imidazolyl in eq 14), and phenoxythionocarbonate (eq 16).[30] Thioimidazolides, which are prepared under essentially neutral conditions from alcohols and ***1,1´-Thiocarbonyldiimidazole***, are best suited for acid- or base-sensitive substrates (eq 17).[31] Pentafluoro- or trichlorophenyl thionocarbonate is used for the deoxygenation of a primary alcohol under similar conditions.[32] A new procedure for the deoxygenation of tertiary alcohols[33] has also been reported.

(15)

(16)

$Z = CO_2Et$

(17)

Decarboxylation.

Photolysis or thermolysis of acyl derivatives of *N*-hydroxy-2-thiopyridone in the presence of TBTH (or, better, *t*-butyl thiol) gives the norhydrocarbon derived from the acyl moiety (eq 18). This method is applicable to a wide variety of aliphatic carboxylic acids (eq 19).[34]

Homolysis of C-N Bonds.

Isocyanides,[35] isothiocyanates, and nitro compounds[36] undergo homolysis of the C-N bond upon treatment with TBTH. Primary amino groups are converted into isocyanides via dehydration of the corresponding formamides. A highly selective reaction of 6β-isocyano-β-lactam (eq 20)[37] proceeds in 63% yield; as expected, the convex α-face of the bicyclic skeleton is more accessible to the hydride reagent.[38]

Homolysis of C-S, C-Se, and C-Te Bonds.

TBTH, in the presence of AIBN, reduces primary and secondary thiols,[39] sulfides with at least one radical stabilizing group (for example, α-carbonyl, α-thio, benzyl, *t*-Bu), and thiones to the corresponding hydrocarbons.[40] Se-[41] and Te-C[42] bonds are also cleaved by tin hydrides. Since the Ph-S or Ph-Se bond is almost never cleaved, thiophenyl and selenophenyl derivatives are among the most widely used radical precursors for C-C bond forming reactions (see below). Selenophenyl esters provide aldehydes (80 °C or *hν*, rt) or the norhydrocarbon (164 °C), depending on the reaction conditions.[41]

Radical Rearrangements.

An alternative to the classical Wharton reaction uses the thioimidazolide intermediate for the radical generation and subsequent epoxide opening (eq 21).[43]

Ring opening of the cyclopropylmethyl radical is one of the most studied radical reactions, though synthetic applications in this area involving TBTH are limited.[44,45] A recent example is shown in eq 22.[46] Opening of *N*-acylaziridines by TBTH has also been described.[47]

1,2-Migrations to a radical center are rare and take place only at low TBTH concentrations.[48] The example shown in eq 23[49] is particularly noteworthy since it provides a ready access to 2-deoxy sugar derivatives.

An interesting protocol for the ring expansion of ketones relies on the ability of carbonyl groups to act as acceptors for radicals. The subsequent fragmentation of the resultant oxy radicals is controlled by strategically placed stabilizing groups (eq 24)[10,11] or leaving groups.[50]

(24)

Intramolecular Additions to Unsaturated Centers.

The hex-5-enyl radical cyclization is one of the most useful radical reactions and this subject has been extensively reviewed.[2,51,57] The examples shown (eqs 25-29)[52-56] illustrate the range of tolerance to various functional groups and the choice of radical precursors possible for this versatile reaction. The stereochemistry of hex-5-enyl radical cyclization has been the subject of a recent review.[57]

(25)

(26)

(27)

(28)

(29)

Appropriately placed haloalkyl side chains, which are readily prepared from allylic or propargylic alcohols, can be used for the stereocontrolled introduction of the hydroxymethyl group (eq 30)[58,60] or lactone annulation.[59] The silacyclopentane in eq 30 produces a 1,3-diol upon Tamao oxidation with ***Hydrogen Peroxide*** and ***Potassium Fluoride***[60] or it can be completely desilylated by treatment with ***Potassium t-Butoxide*** in DMSO.[61]

(30)

Several examples of the use of vinyl[2d,3,63,64] and allyl (eq 31)[65] radicals in synthesis have been described. Curran has described the use of a catalytic amount of TBTH for atom transfer reactions.[66]

(31)

Exo-hept-6-enyl radical cyclization is about 30 times slower than the corresponding hex-5-enyl cyclization. Nonetheless, by increasing the rate of cyclization (for example, in eq 32[59] with an electron-withdrawing group on the alkene), synthetically useful reactions to make six-membered rings can be accomplished.[67-69]

(32)

Acyl radicals generated from selenoesters undergo facile cyclization or intermolecular addition to electron-deficient alkenes faster than H-atom abstraction to give five- and six-membered ketones.[69]

TBTH is useful for the formation of macrolides via radical cyclization from iodoacrylates, if the concentration of both the reagent and substrate are kept low (eq 33). This method is not applicable for medium sized rings, but proceeds well for compounds with 11 or more atoms in the ring. *Endo* cyclization mode is favored when n = 16 or higher.[70]

(33)

$n = 8$, 27%; 12, 67%

Intermolecular Additions.

With reactive acceptors in high concentrations, intermolecular addition of radicals proceed with considerable ease and several synthetically useful reactions have been discovered (eqs 34 and 35).[71,72] The example of the *C*-glycoside synthesis (eq 35) is particularly noteworthy; only the α-glycoside is obtained. Stereochemical control in these reactions has been the subject of a recent review.[73] A recent example illustrates the power of this method for rapid assembly of prostaglandin analogs (eq 36).[74]

(34)

(35)

Radicals generated at the end of an intramolecular cyclization can be trapped if the acceptors are sufficiently reactive (eq 37).[62] Such radicals have also been trapped by ***t-Butyl Isocyanide*** to provide the corresponding nitrile.[75] One-carbon elongation can also be achieved by addition of an electrophilic radical to an enamine (eq 38).[76] Clever use of available kinetic and thermodynamic data can lead to the development of new annulation reactions, as shown in eq 39.[77]

Fragmentation and Homolytic Substitution Reactions.

Allyltributyltin derivatives,[78,79] which have found wide applicability, may be synthesized by intermolecular S_H2 reaction of an appropriately substituted allylic compound (eq 40).[8,80] Intramolecular[9,81] S_H2' reactions have been used for cyclizations.

Tributyltin hydride has ben used in catalytic amounts to effect carbocyclic ring expansions of β-stannyl ketones.[50] As shown in eq 41, the fragmentation reaction can be coupled to a radical cyclization reaction to produce ring expanded products from relatively simple substrates.

Hydrostannylation of Alkenes, Alkynes, and Carbonyl Compounds.

Hydrostannylation of alkynes and alkenes is a well known reaction[1,6] which may be carried out under either thermal (eqs 42 and 43)[21,4] or sonochemical[82] initiation conditions. The intermediate radical formed upon the addition of R_3Sn&bdot; to alkynes and alkenes can be trapped by an appropriately placed double bond to give carbocyclic compounds.[63,64,83] TBTH adds to the strained single bond of [1.1.1]propellane (eq 44).[84]

Addition of TBTH to carbonyl compounds requires catalysis by Pd^0 and a promoter Lewis acid (eq 45),[7] or a proton source.[85] Mechanistic studies suggest that TBTH is a hydride donor. Even though the radical additions to simple ketones are slow, α,β-enones readily generate *O*-stannyl ketyls which participate in hex-5-enyl radical cyclization reactions.[86]

Applications in Organometallic Methodology.

Highly selective reduction of acid chlorides (eq 46)[87] and vinyl triflates[6] may be achieved by the use of Bu_3SnH under Pd catalysis. TBTH/Pd^0 is also an effective system for the reduction of allylic substrates under mild conditions. This reaction is remarkably tolerant of other common functional groups like hydroxy, epoxide, aldehyde, nitrile, and lactone. Radical scavengers improve the yield of the reaction.[88] Pd^0 catalyzes carbonylation of aliphatic, vinyl, and aromatic halides under ***Carbon Monoxide*** in the presence of TBTH.[6] A synthesis of alkyl hydroperoxide uses the homolytic cleavage of an Hg-C bond by tin hydride.[89] Tributyltin hydride has been used to generate a low-valent niobium reagent which is useful for coupling of imines and aldehydes (eq 47).[90]

$$\mathrm{RCOCl} + \mathrm{Bu_3SnH} \xrightarrow[\text{TBTH, } C_6H_6,\ \sim 80\%]{1\ \text{mol\%}\ Pd(Ph_3P)_4} \mathrm{RCHO} \qquad (46)$$

$$\mathrm{NbCl_5} + 2\ \mathrm{Bu_3SnH} \xrightarrow[-\mathrm{Bu_3SnCl}]{\text{DME, -78 °C}} \mathrm{NbCl_3(DME)} + \mathrm{H_2} \quad (47)$$

92%

Carbonylation and Oxygenation of Radicals.

TBTH mediates the oxygenation (eq 48)[13] and carbonylation (eq 49)[14] of radicals.

$$C_8H_{17}Br + \mathrm{TBTH} \xrightarrow[\text{AIBN, 80 °C}]{\text{CO (80 atm)}, C_6H_6} C_8H_{17}CHO \qquad (49)$$

61%

TBTH as a Source of Bu_3Sn Anion.

Tributyltin hydride is the best source of tributyltin Grignard or the corresponding lithium reagent, both of which have been used extensively in synthesis.[91] Eqs 50 and 51 are illustrative.[15,92,93]

$$i\text{-PrMgCl} + \mathrm{TBTH} \xrightarrow[\text{reflux, 2 h}]{\text{ether}} \mathrm{Bu_3SnMgCl} \xrightarrow{CH_2O} \mathrm{Bu_3SnCH_2OH} \qquad (50)$$

56%

Tri-*n*-butylstannyllithium

***n*-Bu$_3$SnLi**

[4226-01-1] · $C_{12}H_{27}LiSn$ · Tri-*n*-butylstannyllithium · (MW 297.04)

(reagent for the synthesis of α-alkoxystannanes,[1] β-stannyl ketones,[1] allenylstannanes,[2] allylstannanes,[3] acylstannanes,[4] and vinylstannanes[5])

Alternate Name: tributyltinlithium.

Preparative Methods: by the reaction of ***Hexabutyldistannane*** and ***n-Butyllithium***, or by the deprotonation of ***Tri-n-butylstannane***.

Handling, Storage, and Precautions: should be used soon after preparation; however, storage of a THF solution for short periods of time (<12 h) at 0 °C is possible. For some applications the purity of the starting material used for generation of the tributyltinlithium reagent is critical. Tributyltin hydride should be distilled prior to deprotonation. Sensitive to air and moisture. Volatile tetraalkylstannanes are toxic and should be handled in a well-ventilated fume hood. Contact with the eyes and skin should be avoided.

General Discussion.

Tributyltinlithium can be prepared from hexabutylditin by reaction with butyllithium[6] or with ***Lithium*** metal,[7] or from ***Tri-n-butylchlorostannane*** and lithium metal.[7b] A more convenient method which eliminates the need to separate the tetraalkyltin byproducts involves the deprotonation of tributyltin hydride by ***Lithium Diisopropylamide***.[1] One of the most extensive uses of tributyltinlithium is in the synthesis of α-alkoxystannanes. Condensation of tributyltinlithium and aldehydes or ketones leads to unstable α-hydroxystannanes which can be protected by a variety of α-chloro ethers (eq 1).[1,8]

(1)

In reactions with α-substituted aldehydes, the addition of tributyltinlithium resulted in the same selectivity as unhindered Grignard reagents, while β-oxygenated aldehydes gave a higher degree of stereocontrol due to a cyclic chelate mechanism. The α-alkoxystannane can be transmetalated by reaction with butyllithium to provide an α-alkoxy organolithium reagent (eq 2).[6] The relative order of stabilities of α-alkoxyorganolithio reagents obtained from transmetalation of the corresponding α-alkoxystannanes has been defined.[8b] The lithio reagent appears to be stable at low temperatures and can be employed in a variety of subsequent reactions, including alkylation, addition to carbonyls, and transmetalation to organocuprate derivatives.[9] A synthesis of dendrolasin was accomplished using the α-alkoxystannane methodology,[1] offering several advantages over alternative approaches which involved a nonregioselective allyl anion addition (eq 3).

(2)

(3)

Conjugate addition of α-alkoxyorganocuprates to cyclic enones followed by an intramolecular Mukaiyama aldol reaction provided a ring annulated tetrahydrofuran (eq 4).[10] The overall procedure is equivalent to regiocontrolled cycloaddition of an unstabilized carbonyl ylide. α-Alkoxyorganostannanes are also precursors for the stereoselective synthesis of enol ethers by a retro Diels-Alder reaction[11] or by transmetalation induced β-elimination.[12]

(4)

Addition of tributyltinlithium to 4-*t*-butylcyclohexanone was shown to be a reversible process.[8] Under thermodynamic conditions, axial addition of the tin anion predominated (93:7), while under kinetic conditions (addition at -100 °C) the equatorial stannane predominated (25:75). Both the axial and equatorial stannane underwent transmetalation and alkylation with retention of configuration. The tin anion addition/transmetalation/alkylation sequence provided access to axially substituted cyclohexanols, in contrast to the equatorially substituted products obtained by simple organometallic addition reactions (eq 5).

(5)

α-Alkoxyallylstannanes are also obtained by the direct addition of tributyltinlithium to unsaturated aldehydes.[3] The α-alkoxyallylstannanes undergo Lewis acid-catalyzed rearrangement to provide γ-alkoxyallylstannanes.[13] Lewis acid-catalyzed alkylation of ketene silyl acetals with acetal-protected α-alkoxystannanes followed by transmetalation and ring closure of the derived amide resulted in a novel synthesis of furanones (eq 6).[14]

Enantiopure α-alkoxystannanes obtained by the asymmetric reduction of acylstannanes[15] have been employed in the synthesis of optically pure α-alkoxy carboxylic acids,[16] as well as transformed into the corresponding α-alkoxyorganocuprate reagents via the intermediate α-alkoxy lithio species.[17] Transmetalation of enantiopure α-alkoxyorganostannanes and the subsequent alkylation reaction was shown to occur with complete retention of configuration.[18] Access to enantiopure α-alkoxyallylstannanes has also been realized by the asymmetric reduction of unsaturated acylstannanes.[19] An alternative route to enantiopure α-alkoxyorganostannanes involves the direct displacement of α-chloroboronate esters.[20] Mitsunobu inversion of enantiopure α-alkoxyorganostannanes with ***Phthalimide*** provides a route to optically active α-aminoalkyl stannanes.[21] An alternative route to nonracemic (α-aminoalkyl)tributylstannanes has been realized by the direct displacement of sulfones (eq 7).[22]

The (α-aminoalkyl)organolithio anions can also be obtained by transmetalation using butyllithium; however, the α-amino lithio species are not as configurationally stable as the α-alkoxy lithio derivatives. Racemic α-aminostannanes are available by the reaction of tributyltinlithium and iminium ions.[23]

Tributyltinlithium also undergoes direct displacement or nucleophilic addition reactions with a variety of other electrophiles. The synthesis of allenylstannanes is accomplished by tributyltinlithium addition to propargylic halides.[2] The direct synthesis of acylstannanes can be accomplished by the reaction of tributyltinlithium and ethyl esters in the presence of ***Boron Trifluoride Etherate***.[4] Addition of tributyltinlithium to thionolactones results in a functionalized stannane that may be transmetalated and alkylated with allyl halides.[24] Addition of tributyltinlithium to epoxides followed by stereospecific elimination of the derived β-acetoxystannane provides a method for the stereospecific transformation of epoxides to alkenes with retention of stereochemistry.[25] A different elimination process results in the conversion of β-stannylvinyl sulfones to γ-hydroxyvinylstannanes.[26] 1,4-Addition of tributyltinlithium to the unsaturated sulfone provides an intermediate enolate which is trapped by reaction with an aldehyde. The alkoxide formed then undergoes an elimination reaction in which the alkoxide assists in the 1,2-elimination of the stannyl and sulfone groups (eq 8).

Tributyltinlithium does not always undergo clean displacement or addition reactions. In a synthesis of 1-methoxy-1,3-dienes, tributyltinlithium promotes metal-halogen exchange rather than displacement of an allyl chloride (eq 9).[27] A similar competing metal halogen exchange process was observed in the stannylation of chlorosilanes.[28]

1,4-Addition of tributyltinlithium to enones occurs readily in THF or THF/NH_3. In contrast, ethereal tributyltinlithium adds only in a 1,2-fashion to cyclohexenone.[6] The β-trialkylstannyl ketone can be further transformed by alkyllithium addition to the carbonyl followed by oxidation with excess ***Dipyridine Chromium(VI) Oxide***, resulting in an overall enone transposition. Tributyltinlithium will even add to β,β-disubstituted unsaturated esters (eq 10).[6,29] This relatively unusual reactivity is attributed to the long length of the Sn-C bond (2.2 Å).

Although the β-stannyl carbonyl moiety is a reactive functional group, many synthetic reactions can be accomplished on the molecule without loss of the tin.[29] The 1,4-addition product obtained from cycloalkenones can also undergo transmetalation and alkylation if the ketone is first protected as an enol ether (eq 11).[30]

(11)

A similar sequence has been carried out on the morpholine enamine of β-tributylstannylcyclohexanone.[31] 1,4-Addition of tributyltinlithium to 2-phenylselenocyclopentenone with in situ alkylation of the enolate results in a 2-alkyl-2-phenylseleno-3-tributylstannylcyclopentanone. Destannyl-selenylation can be readily accomplished using a variety of Lewis acids or fluoride sources, ultimately to provide a 2-substituted cyclopentenone derivative.[32] The synthesis of a prostaglandin precursor was achieved using this methodology (eq 12).

(12)

1,4-Addition products obtained from tributyltinlithium addition to cycloalkenones are also useful precursors for a variety of rearrangement and fragmentation reactions. Lewis acid-catalyzed rearrangement of the alcohol derived from reduction or alkyllithium addition to the carbonyl results in the formation of cyclopropanes.[33] If the ketone is not reduced prior to the addition of a Lewis acid, the cyclopropanol intermediate undergoes fragmentation in situ to provide either the destannylated ketone or the ring contracted product.[34] The cyclopropanol product could be isolated only when the tributyltin bearing carbon was a primary carbon, or when the carbonyl was an aldehyde. The direction of cleavage was consistent with protonation at the less substituted carbon of the cyclopropanol. Treatment of the β-tributylstannyl ketones obtained by 1,4-addition with ***m-Chloroperbenzoic Acid*** resulted in a tin-directed Baeyer-Villager reaction, ultimately providing the alkene ester fragmentation product (eq 13).[35]

(13)

Migration of the β-tributylalkyl substituent occurred preferentially over *t*-butyl or naphthyl groups; therefore the reaction resulted in a complete reversal of the normal migratory aptitude realized in the Baeyer-Villager reaction. The directing effects of the tin group were also extended to the Beckmann fragmentation of the derived β-tributylstannyl oximes (eq 14).[35]

(14)

Oxidative fragmentation of β-tributylstannyl cycloalkanols with iodosobenzene results in the generation of ring-opened keto alkenes.[36] The fragmentation reaction is stereoelectronically controlled and requires an antiperiplanar arrangement of breaking bonds. β-Tributylstannylcyclohexanol derivatives which cannot adopt the correct orientation do not fragment, but rather undergo reaction at a butyl group on tin.[36c] A similar oxidative fragmentation can also be achieved on a cyclic hemiacetal, resulting in formation of a macrocyclic lactone (eq 15).[37]

(15)

Oxidative fragmentation can also be induced using ***Lead(IV) Acetate***. An intramolecular dipolar cycloaddition reaction has been accomplished by in situ generation of a nitrile oxide and an alkene by the fragmentation reaction (eq 16).[38]

(16)

A one pot four-component annulation procedure has also been developed which is initiated by tributyltinlithium 1,4-addition to an enone.[39] The first intermediate enolate then acts as the nucleophile for a Michael addition reaction to a second enone, followed by a subsequent Michael reaction to an enoate. This sequence results in a cyclic hemiacetal containing a β-tributylstannyl moiety. Lead tetraacetate oxidative fragmentation then results in the generation of a macrocyclic lactone (eq 17).

(17)

87%

Transmetalation of tributyltinlithium to a variety of other organometallic reagents has also been accomplished. Organotincuprate reagents undergo 1,4-addition to enones,[40] addition to alkynes,[41] enynes,[42] and addition-elimination reactions to provide β-tributylstannyl unsaturated esters[5] and amides.[43] Tributyltin boron and aluminum reagents have also been prepared.[44]

Tri-*n*-butyltin Trifluoromethanesulfonate[1]

***n*-$Bu_3SnOSO_2CF_3$**

[68725-14-4] · $C_{13}H_{27}F_3O_3SSn$ · Tri-*n*-butyltin Trifluoromethanesulfonate · (MW 439.18)

(powerful stannylating reagent;[1] readily stannylates vinylcuprates and vinylaluminum compounds;[1-3] catalyzes hydrostannation of aldehydes and ketones by tin hydrides[4])

Physical Data: mp 41-43 °C; bp 155-167 °C/0.08 mmHg.

Solubility: freely sol polar and nonpolar organic solvents.

Preparative Methods: by analogy to the preparation of trialkyltin carboxylates,[5] tribuyltin trifluoromethanesulfonate is prepared from ***Bis(tri-n-butyltin) Oxide*** and either ***Trifluoromethanesulfonic Acid*** (with subsequent removal of water) or ***Trifluoromethanesulfonic Anhydride***,[2] as in eq 1.

$$(CF_3SO_2)O + (Bu_3Sn)_2O \xrightarrow[93\%]{} 2\ Bu_3SnOSO_2CF_3 \qquad (1)$$

The following procedure is quite convenient: freshly distilled trifluoromethanesulfonic anhydride[6] is caused to react with an equal molar amount of tributyltin oxide cooled at 20 °C under nitrogen. When the exothermic reaction completely subsides, the flask is set up for a short-path distillation and the resulting red oil is distilled at about 0.1 mmHg. The distillate is collected without cooling to prevent crystallization of the product in the condenser. Alternatively, this reagent can be prepared in situ by the action of trifluoromethanesulfonic acid on ***Tri-n-butylstannane*** in benzene or dichloroethane.[4]

Handling, Storage, and Precautions: this reagent is deliquescent. Therefore it is best handled as a solution in benzene, ether, or hexane, stored at room temperature under nitrogen. Solutions can be dried with 4Å molecular sieves. As with certain other trialkyltin electrophiles, tributyltin trifluoromethanesulfonate is foul smelling. The toxicity of this class of compounds has been described.[7] Use in a fume hood.

Transmetalation Reactions.

The powerful electrophilic property of this reagent makes it particularly attractive for the conversion of vinylcuprates and vinylalanes into vinylstannanes. For example, the reaction of vinyl heterocuprates[8] with this reagent occurs readily to give the corresponding (*Z*)-vinylstannane, even at -78 °C (eq 2). Stannylation of vinylalanes[9] occurs readily to give the corresponding vinylstannane (eq 3). Complementary methods are available for the preparation of both (*Z*)-[2] and (*E*)-vinylstannanes.[1,3] The configuration of the vinylstannane is controlled at the vinylaluminum stage: treatment of ***Propargyl Alcohol*** with ***Lithium Aluminum Hydride*** followed by tributyltin trifluoromethanesulfonate affords the (*Z*)-allyl alcohol, whereas if the addition of $LiAlH_4$ is followed by NaOMe and then the reagent, the (*E*)-allyl alcohol results (eq 4).[1]

(3)

(4)

The (*E*)-vinylstannane also results when the alkyne is treated sequentially with ***Diisobutylaluminum Hydride***, ***Methyllithium***, and then the title reagent.[3] For example, treatment of 1-octyne with DIBAL in hexane followed by MeLi and then the reagent afforded (*E*)-1-tributylstannyl-1-octene in good yield (eq 5).

(5)

The title reagent is also suitable for the preparation of allylstannanes from allyllithium reagents,[10] and vinylstannanes from vinyllithium reagents.[11]

Hydrostannation Catalyst.

This triflate is a catalyst in the hydrostannation of aldehydes and ketones by tributyltin hydride.[4] Treatment of aldehydes and ketones with one equiv of Bu_3SnH in benzene or dichloroethane in the presence of 20% of the reagent afforded the corresponding primary or secondary alcohol in high yield. Using this system, aldehydes are preferentially reduced in the presence of methyl ketones (ca. 99:1). In addition, the reagent can be employed as a cocatalyst with $PdCl_2(PPh_3)_2$ in the 1,4-reduction of enone systems (eq 6).

(6)

Stereospecific Arylation of Arylsulfanyl Lactones.

The title reagent catalyzes the rapid and stereospecific cyclization of certain chiral arylsulfanyl lactones to the corresponding optically pure γ-butyrolactones (eq 7).[12]

(7)

Related Reagents.

Tri-n-butylchlorostannane.

Thomas M. Eckrich

Tri-*n*-butyl(trimethylsilylmethyl)stannane

[77425-85-5] · $C_{16}H_{38}SiSn$ · Tri-*n*-butyl(trimethylsilylmethyl)stannane · (MW 377.34)

(precursor to trimethylsilylmethyllithium; methylenation of aldehydes and ketones)

Alternate Name: tributyl(trimethylsilylmethyl)tin.

Physical Data: bp (distillation) 146 °C/2.5 mmHg.

Preparative Methods: is conveniently prepared by the action of ***Tri-n-butylstannyllithium*** on ***(Chloromethyl)trimethylsilane*** in THF/hexane at 0 °C.[1] Alternatively, ***Trimethylsilylmethylmagnesium Chloride*** can be treated with ***Tri-n-butylchlorostannane*** in refluxing ether.[2] Excellent yields (>90%) may be realized by either method.

Handling, Storage, and Precautions: organotin compounds should be considered toxic and should be handled with appropriate care. Use in a fume hood.

Precursor for Trimethylsilylmethyllithium.

Trimethylsilylmethyllithium is a useful reagent for methylenation of aldehydes and ketones (Peterson alkenation),[3] for preparation of α-silyl ketones from carboxylic acids, esters, and acid chlorides,[4] and for further elaboration to synthetically useful organometallic reagents.[5-7] The utility of this versatile organolithium reagent is enhanced by its ready availability from a stable precursor. Peterson reported that tributyl(trimethylsilylmethyl)tin did not undergo transmetalation with ***n-Butyllithium*** in hexane at 25 °C and that addition of ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) resulted in minor improvement. Seitz and Zapata[1] observed a solvent dependency in the transmetalation reaction and were able to define conditions for rapid and complete conversion of tributyl(trimethylsilylmethyl)tin to trimethyl(silylmethyl)lithium (eq 1).

Methylenation of Carbonyl Compounds.

Tributyl(trimethylsilylmethyl)tin was the reagent of choice in Peterson alkenation of a complex and sterically encumbered decalone derivative (eq 2).[8] ***Methylenetriphenylphosphorane*** (the Wittig reagent) is often less effective in the case of hindered ketones.

Tricarbonyl(η^6-chlorobenzene)chromium

[12082-03-0] · $C_9H_5ClCrO_3$ · Tricarbonyl(η^6-chlorobenzene)chromium · (MW 248.59)

(phenyl cation equivalent[1])

Alternate Name: (chlorobenzene)chromium tricarbonyl

Physical Data: mp 102-103 °C.

Solubility: sol THF, ether, benzene.

Form Supplied in: yellow crystals; not commercially available.

Preparative Method: prepared from the reaction of chlorobenzene with ***Hexacarbonylchromium*** in refluxing dioxane.[2]

Purification: recrystallized from ether/petroleum ether. Can also be purified by column chromatography on silica gel.

Handling, Storage, and Precautions: slightly air sensitive. Use in a fume hood.

Nucleophilic Substitution.

Treatment of tricarbonyl(chlorobenzene)chromium (**1**) with various nucleophiles at 25 °C effects nucleophilic substitution of chlorine.[1,3] Nucleophiles derived from carbon acids having a pK_a > ~20 lead to the arylated products in high yield (eq 1).
Tricarbonyl(fluorobenzene)chromium is recommended for phenylation of less reactive nucleophiles. Nucleophilic addition produces the pentadienylchromium complex (**2**), which converts to the substituted arene complex (**3**). Oxidative removal of the metal with ***Iodine*** produces the free arene (**4**). Kinetically, nucleophiles attack the *ortho* and *meta* positions, and thus nucleophilic addition at low temperature followed by oxidation leads to chlorobenzene derivatives (**5**) and (**6**) (eq 2), in addition to (**4**).[4]

Orthometalation.

Treatment of the title reagent with ***n-Butyllithium*** produces the lithiated arene complex (**7**), which is stable at low temperature. Treatment of complex (**7**) with electrophiles produces the *ortho*-substituted chlorobenzene derivatives (e.g. **8**) (eq 3).[5] At temperatures higher that -78 °C, complex (**7**) undergoes decomposition through a benzyne mechanism.[6]

Related Reagents.

(η^6-Benzene)tricarbonylchromium; ***Dibenzenechromium***; ***Hexacarbonylchromium***.

Tricarbonyl(cyclobutadiene)iron[1]

[12078-17-0] · $C_7H_4FeO_3$ · Tricarbonyl(cyclobutadiene)iron · (MW 191.96)

(stable, storeable source of cyclobutadiene)

Physical Data: pale yellow solid, mp 26 °C; bp 68-70 °C/3.0 mmHg; X-ray diffraction.[2]

Solubility: sol polar solvents; sparingly sol in pentane.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: NMR, elemental analysis.

Preparative Methods: may be prepared in good overall yields by the reaction of 3,4-dihalocyclobutene or 1,2,3,4-tetrahalocyclobutane with ***Nonacarbonyldiiron***,[3] or by the photolysis of photo-α-pyrone with ***Pentacarbonyliron*** (eq 1).[4] The reaction of *cis*-3,4-carbonyldioxycyclobutene with $Fe_2(CO)_9$ or ***Disodium Tetracarbonylferrate(-II)*** generates the title reagent (**1**), and while this reaction is stereospecific it is not known if it occurs with inversion or retention of configuration.[5] Thermal reaction of $Fe(CO)_5$ with Ni, Pd, or Pt cyclobutadiene complexes results in π-ligand exchange to give the iron cyclobutadiene complexes in high yield.[6] A variety of simple substituted (cyclobutadiene)$Fe(CO)_3$ complexes may be prepared by these methods. More recently, methodology for the regiospecific preparation of 1,2- or 1,3-differentially disubstituted (cyclobutadiene)$Fe(CO)_3$ complexes from squaric esters has been reported.[7] 1,2-Disubstituted (cyclobutadiene)$Fe(CO)_3$ complexes with two different substituents are chiral, and the two enantiomers may be separated by standard resolution techniques.[8] The optically active cyclobutadiene complexes are stable to racemization at 120 °C for 48 h.

Purification: recrystallization from pentane.

Handling, Storage, and Precautions: may be stored under an inert atmosphere for extended periods.

Reactions of (Cyclobutadiene)$Fe(CO)_3$.

The organic chemistry of (**1**) is much like that of ***Ferrocene***. Acylation, formylation, chloromethylation, aminomethylation, mercuration, sulfonation, and deuteration of (**1**) can be effected by electrophilic substitution (eq 2).[9] Friedel-Crafts alkylation of (**1**) to give simple monoalkyl derivatives is not possible. Acylation of monoalkyl-substituted (cyclobutadiene)$Fe(CO)_3$ complexes generates 1,3-disubstituted (major) and 1,2-disubstituted (minor) derivatives.

(2)

(1)

El = COMe, CHO, CH_2Cl (**3**), CH_2NMe_2, HgCl (**2**), SO_3H, D

In comparison to ferrocene, direct lithiation of (**1**) by treatment with methyl- or butyllithium is not possible.[1] However, treatment of the chloromercury derivative (**2**) with ***Methyllithium*** or ***Phenyllithium*** at -78 °C effects transmetalation (eq 3). (Lithiocyclobutadiene)$Fe(CO)_3$ can serve as a nucleophile toward triphenylmethyl chloride, ***Chlorotrimethylsilane***, and ketones.[10]

(3)

(2)

Functionalized sidechains attached to (cyclobutadiene)$Fe(CO)_3$ undergo a variety of standard organic transformations without disturbing the organometallic portion of the molecule.[8,9a,11] Solvolysis of (chloromethylcyclobutadiene)$Fe(CO)_3$ (**3**) in 5% aqueous acetone proceeds at a rate 10^8 times faster than that of ***Benzyl Chloride*** (eq 4).[10,12] The rapid rate of this S_N1 solvolysis is attributed to the stability of the α-carbocation. Chemistry of this type has been used to generate the (cyclobutadiene)$Fe(CO)_3$ analog of phenylalanine (**4**) (eq 5).[13]

(3)

(4)

(5)

(4)

Liberation of the Ligand.

The cyclobutadiene ligand may be liberated by oxidation of the complex with ***Cerium(IV) Ammonium Nitrate*** or ***Lead(IV) Acetate***. In the absence of other reactants the cyclobutadiene ligand undergoes dimerization to afford a mixture of *syn*- and *anti*-tricyclo[4.2.0.$0^{2,5}$]octa-3,7-diene (eq 6).[14]

(6)

(1)

In the presence of alkenes, alkynes, or dienes, the liberated cyclobutadiene can act as either a diene or dienophile in Diels-Alder cycloadditions.[15-22] The cyclobutadiene thus generated appears to be a singlet diene. Cycloaddition occurs in a stereospecific fashion with respect to the geometry of the alkene component and with *endo* selectivity. Compound (**1**) has been used as a source of cyclobutadiene for the synthesis of a wide variety of theoretically interesting molecules, including cubane,[16] homocubanone,[17] caged keto sulfides,[18] tricyclo[4.1.0.0^{2,5}]heptanes,[19] tricyclo[4.1.0.0^{2,5}]hept-3-ene,[20] bicyclo[4.2.0]octa-2,4,6-trienes,[21] Dewar benzenes,[22] and Dewar furan.[23] Oxidation of optically active disubstituted (cyclobutadiene)Fe(CO)$_3$ complexes in the presence of a symmetrical alkene generates racemic products (eq 7).[8] Thus the chemical oxidation appears to generate free cyclobutadiene. Additional evidence for the presence of the free ligand was provided by the three-phase test. Transfer of the ligand from a polymer-bound (cyclobutadiene)iron complex by oxidation in the presence of a separately polymer-bound dienophile can only be accounted for by the generation of the free ligand, since there is negligable contact between the functionalized sites of the two different polymeric supports.[24] In contrast, oxidation of the optically enriched complex (**5**) containing a dangling dienophile produced the achiral phthalan and the optically active tricyclic ketone (**6**) (eq 8).[25] The product (**6**) is proposed to arise via initial coordination of the dienophile to the oxidized complex, followed by alkene insertion, carbonyl migration, and reductive elimination.

(7)

(8)

Photolysis of substituted (cyclobutadiene)Fe(CO)$_3$ complexes in the presence of alkynes affords substituted benzenes as a mixture of regioisomers (eq 9).[26] The distribution of products is not statistical, which suggests that the free cyclobutadiene ligand is not involved. It is proposed that the reaction occurs via initial loss of carbon monoxide and coordination of the alkyne. Insertion of the alkyne generates a bridged species which reductively eliminates to a Dewar benzene. Secondary photolysis of the Dewar benzene gives the aromatic product.

(9)

The photochemical reduction of (benzoylcyclobutadiene)Fe(CO)$_3$ in acetic acid gives 2-cyclobutenyl phenyl ketone as the product (eq 10).[27]

Tricarbonyl(cyclohexadienyl)iron Tetrafluoroborate[1]

[33678-01-2] · $C_9H_7BF_4FeO_3$ · Tricarbonyl(cyclohexadienyl)iron Tetrafluoroborate · (MW 305.82)

(mild electrophile capable of reacting with a wide range of nucleophiles under mild conditions[1,2])

Physical Data: mp 193 °C (dec).

Solubility: readily sol H_2O, DMSO, DMF, $MeNO_2$; difficult in nonpolar solvents.

Form Supplied in: yellow solid; widely available.

Preparative Methods: readily obtained from tricarbonylcyclohexadieneiron by hydride abstraction with trityl fluoroborate in methylene chloride followed by precipitation of the salt with ether. Salts of this type are invariably yellow microcrystalline involatile solids.

Handling, Storage, and Precautions: this solid is stable to air and moisture.

Introduction.

As might be expected from its cationic nature, the dienyl-$Fe(CO)_3$ complex reacts with nucleophiles to give neutral diene complexes.[1a] The cation possesses sufficient stability towards water to be recrystallized from it and yet, on the other hand, conveniently reacts with nucleophiles stronger than water to afford addition products with attack occurring at carbon to give 5-substituted 1,3-cyclohexadiene-$Fe(CO)_3$ derivatives. The reaction is usually very clean and is regiospecific (terminal C atom) and stereospecific (opposite Fe).[1c]

C-X Bond Formation.

Reaction of the cation with anions RO^- (R = H, Me, CMe_3, $SiMe_3$) gives the corresponding complexes as well as dimeric products in yields depending on RO^- and the reaction conditions.[2c,3] The (5-*exo*-halogenocyclohexa-1,3-diene)$Fe(CO)_3$ can be prepared from reaction of the cation with ***Potassium Fluoride***, KBr, or KCl in the presence of ***18-Crown-6***.[4] In contrast, iodide ion ultimately gives the product from addition at iron and displacement of carbon monoxide.[5]

Addition of a wide variety of anilines and pyridines to the cation forms novel *C*- or *N*-alkylation products, depending on the substituents and conditions (eq 1).[6] Electron-withdrawing substituents (4-NO_2) on the arene favor *N*-alkylation whereas electron-donating substituents (3-OMe, 3-NR_2) favor *C*-alkylation.

(1)

The *N*-alkylation products may undergo dissociation to the cation upon treatment with acid.[7] Amides[1a,8] form adducts with the cation when the reaction is carried out at higher temperature. Thiourea forms the *S*-linked adducts.[6c,9] Attack of nucleophiles such as nitrosoarenes,[10a] nitrosoalkanes,[10b] phosphorus,[11] ***Acetonitrile***,[12] and thiocyanate[13] also give the corresponding 1,3-diene 5-*exo*-substituted products.

Nucleophilic addition of phosphite and phosphines to the cation has led to a variety of novel phosphorus adducts (eq 2).[14] Reaction of an electron-rich transition metal π-complex could readily give stereo- and regioselective C-C bond formation (eq 3).[15]

(2)

(3)

Addition of metal carbonyl anions [such as $Re(CO)_5^-$, $Mn(CO)_5^-$, $(\eta^5\text{-}(C_5H_5W(CO)_3)^-$] to the cation gives heterobimetallic η^1:η^4-hydrocarbon-bridged complexes, and addition of organometallic nucleophiles [$M(CO)_4^{2-}$ (M = Os, Ru)] leads to the heterotrimetallic η^1:η^4-hydrocarbon-bridged complexes.[16] Hydride reduction of the cation favors simultaneous attack at the ring carbon atom and $Fe(CO)_3$ group.[17] The cation is reduced efficiently by ***Sodium Borohydride***[18] and ***Tri-n-butylstannane***.[14b] Dissolving metal reductions lead to dimerization.[14b]

Alkylating Agent.

Although it is impossible to achieve direct alkylation in good yield with Grignard or alkyllithium reagents,[19] alkylation of the cation can be achieved using organoboron, -zinc, -cadmium, and -copper reagents,[1c,20] enolates,[18,21] allylstannane,[22] enamines,[23] and electron-rich π-systems.[24]

The cation reacts with a wide variety of aromatic compounds.[1a,23,25] Activated arenes, $ArMMe_3$ (M = Si or Sn, Ar = 2-furyl, 2-thienyl, substituted benzene), are more reactive towards the cation than Ar-H compounds.[25] Dimethylaluminum acetylides react with the cation to give the corresponding alkynyl substituted complexes in high yield without competing reduction products (eq 4).[26] Trialkylalkynylborates also react in a stereo- and regiospecific manner to yield novel complexes.[27] Tetraphenylborate serves as a biphenyl anion synthon (eq 5).[28] The reaction of 2-halogenocycloheptadienone enolate with the cation gives 2-substituted tropone (eq 6).[29]

(4)

(5)

(6)

Aryl Cation Equivalent.

Complexes resulting from nucleophilic addition to the cation can usually be subjected to oxidative reaction conditions which will remove the metal and oxidize the resultant cyclohexadiene to a substituted aromatic compound.[1c] The regio- and stereoselective reactions of the cation with arylamines (eq 7) show excellent potential for application in organic synthesis. A procedure of consecutive iron-induced C-C and C-N bond formation has been developed. The synthesis of various highly substituted dihydrocarbazole and aromatic carbazole derivatives[6c,30] involves electrophilic aromatic substitution of an arylamine, followed by oxidative cyclization to the carbazole derivatives.[30]

Tricarbonylchloroiridium-Diethyl(methyl)silane-Carbon Monoxide

$[Ir(CO)_3Cl]_n$-$HSiEt_2Me$-CO

($[Ir(CO)_3Cl]_n$)

[32594-40-4] · C_3ClIrO_3 · Tricarbonylchloroiridium-Diethyl(methyl)silane-Carbon Monoxide · (MW 311.70) ($HSiEt_2Me$)

[760-32-7] · $C_5H_{14}Si$ · Tricarbonylchloroiridium-Diethyl(methyl)silane-Carbon Monoxide · (MW 102.28) (CO)

[630-08-0] · CO · Tricarbonylchloroiridium-Diethyl(methyl)silane-Carbon Monoxide · (MW 28.01)

(carbonylation of alkenes[1])

Physical Data: $[Ir(CO)_3Cl]_n$: mp 235 °C (dec).

Solubility: $[Ir(CO)_3Cl]_n$: insol common organic solvents.

Form Supplied in: brown solid ($[Ir(CO)_3Cl]_n$); clear liquid ($HSiEt_2Me$); gas (CO).

Purification: $[Ir(CO)_3Cl]_n$: sublimes readily at 150 °C in a stream of CO.

Handling, Storage, and Precautions: $[Ir(CO)_3Cl]_n$: air stable. Use in a fume hood.

Reactions with Alkenes.

The reaction of alkenes with $HSiEt_2Me$ and ***Carbon Monoxide*** (50 atm) in the presence of $[Ir(CO)_3Cl]_n$ at 140 °C gives 1-silyl-1-silyloxyalkenes (eq 1).[1] The reaction is applicable to a wide variety of terminal alkenes bearing a functional group such as silyl, alkoxy, acetal, cyano, and epoxy. The products obtained can be easily hydrolyzed to acylsilanes. ***Triethylsilane*** and ***Dimethyl(phenyl)silane*** can be also used in place of $HSiEt_2Me$. $Ir_4(CO)_{12}$ also exhibited catalytic activity.

Related Reagents.

Carbon Monoxide; ***Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide***; ***Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide***.

Tricarbonyl(4-methoxy-1-methylcyclohexadienyl)iron Hexafluorophosphate[1]

[51508-58-8] · $C_{11}H_{11}F_6FeO_4P$ · Tricarbonyl(4-methoxy-1-methylcyclohexadienyl)iron Hexafluorophosphate · (MW 408.04)

(regiospecifically reacts with a wide range of nucleophiles;[2] serves as a cyclohexenone γ-cation equivalent[1])

Solubility: easily sol MeCN, $MeNO_2$; difficult in nonpolar solvents; partially sol H_2O.

Form Supplied in: yellow powder.

Preparative Methods: easily prepared from 4-methylanisole by Birch reduction, followed by complexation with ***Pentacarbonyliron*** and hydride abstraction.

Handling, Storage, and Precautions: is stable to air and moisture. Potent alkylating agent. Toxicity unknown.

Introduction.

Despite the stability of this iron-bound carbocation, it is highly reactive toward nucleophiles. The cation regiospecifically reacts with a wide range of nucleophiles, including cyanide, malonate, β-diketone enolates, and silyl ketene acetals, to give synthetically useful products. The presence of the iron results in addition almost exclusively at the methyl terminus of the dienyl system (the less electron-rich terminus) on the face of the ligand opposite to the metal to give the substituted diene complexes.[2] Nucleophiles react at C-1 or C-5, but do not attack at C-2, C-3, or C-4.[3]

C-X Bond Formation.

Morpholine and hydroxide ion add at the methylated terminus C-1 of the diene system,[4] in preference to the electronically deactivated terminus C-5 (eq 1), while treatment with ***Sodium Borohydride*** gives addition of H^- at both termini (eq 2).[4] A possible explanation is partial attack on carbonyl to give a formyl complex with transfer of hydride directly to the carbon system.[5]

2:3

C-C Bond Formation.

A wide range of carbon nucleophiles react with the cation under mild conditions to give the corresponding C-C bonded product. Nitrile adducts can be obtained with ***Sodium Cyanide***[6] or with ***Cyanotrimethylsilane*** (eq 3).[7,8] The product obtained from reaction of analogs of the complex with sodium malonate can be used for the synthesis of spirocyclic compounds.[9a,10] Reaction of the Reformatsky reagent $BrZnCH_2CO_2Me$ leads to a mixture of alkylation products and triene.[2]

Alkylation with sodium or potassium enolates has potential in organic synthesis.[1,11,12] The reaction intermediates with enolates of keto esters derived from cyclopentanones, cyclohexanones,[13] and tetralones have been used for the synthesis of C-nor-D-homosteroids,[1b,12] D-homosteroids,[12] 12,13-epoxy-14-methoxytrichothecene,[11a] quassinoids,[14] and 6-keto steroids.[13,15] The cation reacts with the potassium enolate of methyl 2-oxocyclopentanecarboxylate to give a quantitative yield of the two diastereoisomers (eq 4) (one of these has been transformed to trichothecane), thus leading to the controlled formation of two contiguous quaternary centers.[11]

Simple lithium enolates of ketones and esters have proven too basic, causing deprotonation of the cation to give a triene complex instead of the desired addition products. Reaction of the cation with silylketene acetals gives high yields of the desired products (eq 5). Most of the reactions occurred with very high regioselectivity.[16]

A number of tin enolates react cleanly with the cation in cases where the use of lithium enolate or silyl enol ethers is problematic. This new C-C bond forming reaction allows diastereoselective construction of proximate quaternary centers and provides a key step in a short synthesis of (±)-trichodiene (eq 6),[18] (±)-trichodermol,[19] 3,14-dihydroxytrichothecenes,[20] and (±)-12,13-epoxytrichothec-9-ene.[18]

Cyclohexenone γ-Cation Equivalents.

Decomplexation and hydrolysis of the enol ether generates the 4-substituted cyclohexenone, making the starting complex the synthetic equivalent of a cyclohexenone γ-cation.[1] Illustrative of this are syntheses of polycyclic natural compounds, especially terpenes and steroids (eq 7).[1c,16,21,22]

(7)

Chiral Form of the Cation.

Induction[23] of asymmetry during the complexation of 1-methoxy-4-methylcyclohexadiene and reaction[24] of the resulting complex with triphenylmethyl tetrafluoroborate provides a convenient route to partially resolved cation. The complete resolution of the cation by selective crystallization of enantiomers has been achieved.[25]

Reaction of racemic cation with a chiral carbanion occurs enantioselectively.[26,27] The chiral intermediates are converted into optically active natural steroids.[26a]

Tricarbonyl(naphthalene)chromium

[12110-37-1] · $C_{13}H_8CrO_3$ · Tricarbonyl(naphthalene)chromium · (MW 264.21)

(catalyst for the hydrogenation of alkynes,[2] 1,3-dienes,[3] dienol acetates,[4] and for the isomerization of conjugated dienes,[5] silyloxymethyl-[6] and aminomethylbutadiene[7])

Physical Data: mp 150-160 °C.

Solubility: sol THF, acetone.

Form Supplied in: a red moisture-sensitive crystalline solid.

Preparative Method: prepared in 75-83% yield by treating naphthalene with ***Hexacarbonylchromium*** in dry decalin.[1]

Purification: recrystallized under nitrogen from petroleum ether.

Handling, Storage, and Precautions: should be handled under a nitrogen or argon atmosphere, and a glove box would be ideal. The solid should be stored at low temperature, in the dark, under nitrogen.

Hydrogenation Catalyst.

The title reagent (**1**) is an arene chromium complex which catalyzes the stereoselective hydrogenation of alkynes to the (*Z*)-alkene (in degassed THF) (eq 1).[2]

(1)

The title reagent has been reported to catalyze the 1,4-hydrogenation of a carbocyclic 1,3-diene, resulting in the stereospecific formation of an exocyclic (*Z*)-alkene in 95% yield (eq 2).[3]

(2)

The resulting exocylic carbocyclic alkene was used in the synthesis of carbacyclin. Use of (**1**) (20 mol %) in the 1,4-hydrogenation of a dienol acetate in the presence of hydrogen (eq 3) resulted in the stereospecific synthesis of a trisubstituted exocyclic (*Z*)-allylic acetate (87% yield).[4] This intermediate was used in the synthesis of anthracycline analogs.

(3)

The use of (**1**) as a hydrogenation catalyst requires the use of polar coordinating solvents (THF or acetone) and degassing of the reaction mixture. Hydrogen or an inert gas is introduced into the reaction flask, depending on the substrate.

Isomerization of Conjugated Dienes.

The title reagent will catalyze the rt isomerization of conjugated dienes, with complete control of the stereochemistry of the resulting alkene in the absence of any molecular hydrogen.[4] The mechanism involves a stereo- and regiocontrolled 1,5-hydrogen shift of the (*Z*)-conjugated diene. Under very mild conditions the stereospecific isomerization of the diene occurs to give an exocylic (*Z*)-diene. Aromatization by means of mild oxidation results in the formation an aryl excocyclic (*Z*)-alkene (eq 4).[5]

Extension of this methodology to silyloxymethyl- (eq 5)[6] and aminomethylbutadiene derivatives (eq 6)[7] resulted in the stereocontrolled synthesis of (*Z*)-silyl dienol ethers and (*Z*)-dienamines. Yields are good to excellent (57-97%) and the resulting heteroatom-substituted butadienes have been successfully shown to undergo inter- and intramolecular Diels-Alder reactions.[6,7]

Tricarbonyl(pentadienyl)iron Tetrafluoroborate

$(C_5H_7)Fe(CO)_3^+BF_4^-$

[12079-72-0] · $C_8H_7BF_4FeO_3$ · Tricarbonyl(pentadienyl)iron Tetrafluoroborate · (MW 293.81)

(organometallic electrophile towards a variety of carbon and heteroatom nucleophiles)

Physical Data: yellow solid, mp 163-165 °C (dec) (PF_6^- salt).

Solubility: sol polar solvents (e.g. $MeNO_2$, Me_2CO); slightly sol $CHCl_3$, CH_2Cl_2; reacts with water, alcohols.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: NMR, elemental analysis.

Preparative Methods: was first prepared by the protonation of tricarbonyl(η^4-pentadienol)iron with ***Tetrafluoroboric Acid*** in the presence of ***Acetic Anhydride*** (eq 1).[1]

Hexafluorophosphoric acid or perchloric acid may also be used to generate the corresponding PF_6^- and ClO_4^- salts. A wide variety of substituted pentadienyl cations, which may be of greater synthetic interest, have been prepared by protonation of substituted dienol and dienyl ether complexes.[2-17] Bis[(dienyl)$Fe(CO)_3$] dications have been prepared by protonation of bis-dienol complexes.[18] Protonation of tricarbonyl(1,3,5-hexatriene)iron generates the tricarbonyl(1-methylpentadienyl)iron cation.[19] Hydride abstraction from (*cis*-pentadiene)$Fe(CO)_3$ (but not the *trans* isomer) with ***Triphenylcarbenium Tetrafluoroborate*** gives the title cation (eq 2).[1] This methodology has been used to prepare a few substituted cations.[20-22]

Purification: by reprecipitation from $MeNO_2$/ether.

Handling, Storage, and Precautions: the solid may be stored under inert atmosphere for extended periods. Perchlorate salts of the cation are explosive.

Reaction with Metal Hydrides.

Reaction of the (pentadienyl)$Fe(CO)_3^+$ cation with ***Sodium Cyanoborohydride*** gives (*cis*-pentadiene)$Fe(CO)_3$ (eq 2),[8] while reduction of

the cation with ***Sodium Borohydride*** or ***Lithium Triethylborohydride*** gives mixtures of (*cis*- and (*trans*-pentadiene)$Fe(CO)_3$.[1,8] In general, reaction of substituted (pentadienyl)$Fe(CO)_3^+$ cations with metal hydrides gives mixtures of 1,3-diene complexes, resulting from nucleophilic addition at either the C-1 or C-5 terminus (eq 3);[2,8,13,15,16,22] however, reaction of (1,5-diphenylpentadienyl)$Fe(CO)_3^+$ with $NaBH_3CN$ gives nearly equal proportions of products resulting from attack at the terminal (C-1) and internal (C-2) positions (eq 4).[5]

Reaction with Heteroatom Nucleophiles.

Reaction of (pentadienyl)$Fe(CO)_3^+$ cation with water results in formation of (*trans*-pentadienol)$Fe(CO)_3$ (eq 1).[1] In general, reaction of substituted (pentadienyl)$Fe(CO)_3^+$ cations with water or alcohols results in the formation of *trans*-dienol or *trans*-dienyl ether complexes, presumably via nucleophilic attack on the transoid form of the pentadienyl ligand (eq 5).[2,4,7,10,13-17] An exception is the (1-methoxycarbonylpentadienyl)$Fe(CO)_3^+$ cation, which reacts with water to give (5-methoxycarbonyl-(2*Z*,4*E*)-pentadien-1-ol)$Fe(CO)_3$ (eq 6).[11]

The reaction of (pentadienyl)$Fe(CO)_3^+$ cations with substituted anilines and with benzylamines gives the corresponding dienylamine and bis(dienyl)amine complexes. More basic amine nucleophiles give (*Z*)-dienylamine complexes, while less basic amines give (*E*)-dienyl complexes.[23,24] The reaction of (pentadienyl)$Fe(CO)_3^+$ cations with ***Triphenylphosphine*** gives (*Z*,*E*)-dienylphosphonium salts.[9,13,15-17,24] Upon deprotonation, the ylides isomerize to the corresponding (*E*,*E*)-dienylphosphorane complexes, which can be used in Wittig condensations with aldehydes.[25] Nucleophilic attack by halide ions occurs at iron.[26]

Reaction with Metals.

The reaction of (pentadienyl)$Fe(CO)_3^+$ cations with ***Zinc*** results in reductive dimerization of the ligand to afford a bis-complexed (η^8-1,3,7,9-decatetraene) (eq 7).[2,18,21] The reaction of (pentadienyl)$Fe(CO)_3^+$ with $CpMo(CO)_3^-$ is believed to proceed via rapid, reversible formation of a (*Z*)-diene bimetallic complex at low temperature (-78 °C). Upon warming to rt, only an (*E*)-diene complex is isolated (eq 8).[27] This bimetallic complex eventually decomposes on standing to give the bis-complexed (η^8-1,3,7,9-decatetraene).

(7)

(8)

$MoL_n = MoCp(CO)_3$

Reaction with Carbon Nucleophiles.

The parent (pentadienyl)$Fe(CO)_3^+$ cation reacts with organocadmium reagents[28] and with functionalized organocuprates[29] to afford the corresponding substituted (*Z*)-diene complex (eq 9). Likewise, substituted (pentadienyl)$Fe(CO)_3^+$ cations react with organocuprates by attack at the less hindered terminus.[13,15,30,31] In contrast, reaction of (pentadienyl)$Fe(CO)_3^+$ cations with organolithium reagents or alkynylcerates results in attack at both C-1 and at C-2.[32] In general, attack by malonate anion on (pentadienyl)$Fe(CO)_3^+$ cations gives (*Z*)-diene complexes (eq 10).[10,13-15,20,31,33] For substituted pentadienyl cations the regioselectivity is variable and depends on the substituents present on the pentadienyl ligand. Attack at a substituted pentadienyl terminus occurs in a stereospecific fashion, presumably by approach of the nucleophile on the face of the ligand opposite to iron. A few examples of pentenediyl complexes, formed by nucleophilic attack of malonate at C-2, have been reported.[14,31,33] With weak carbon nucleophiles, such as electron-rich aromatics,[6] and ***Allyltrimethylsilane***,[13,17,34] the acyclic (pentadienyl)$Fe(CO)_3^+$ cation reacts via its less stable transoid isomer (eq 11).

(9)

R = Ph, Bn, allyl, $(CH_2)_nFG$
M = Cd, Cu(CN)ZnI

Applications to Natural Product Synthesis.

(Pentadienyl)Fe$(CO)_3^+$ cations react as organometallic electrophiles in the the formation of (diene)iron complexes. In order for these cations to be useful in organic synthesis there must exist methods for excising the metal. The diene ligand may be liberated by oxidation of iron.[1] Photochemical reduction of (diene)Fe$(CO)_3$ complexes in AcOH leads to the corresponding alkene,[35] and nucleophilic attack on neutral (diene)Fe$(CO)_3$ complexes has been reported.[36] Substituted (pentadienyl)Fe$(CO)_3^+$ cations have been used in the synthesis of Δ^3-lepelin,[13] AF toxin IIa,[37] 5-HETE methyl ester,[30c] and lasiol.[31]

Trichloramine

NCl_3

[10025-85-1] · Cl_3N · Trichloramine · (MW 120.36)

(reactive *N*-haloamine for the amination of aromatics,[1] tertiary chlorides,[2] and tertiary hydrocarbons;[3] also for chlorination of alkenes[4] and organoboranes[5])

Alternate Name: nitrogen trichloride.

Physical Data: mp <-40 °C; bp <71 °C; explodes at ca. 95 °C; *d* 1.653 g cm^{-3}.

Solubility: insol cold H_2O; sol toluene, methylene chloride, *o*-dichlorobenzene; decomposes in hot H_2O.

Preparative Methods: not commercially available; prepared from calcium hypochlorite, ammonium chloride, and hydrochloric acid in methylene chloride-water, followed by separation of the organic phase, drying, and storage in solution at 0-5 °C or below.[6,7]

Analysis of Reagent Purity: determination of positive chlorine can be carried out iodometrically.[6,7]

Handling, Storage, and Precautions: toxic and may explode, especially on heating or when concentrated. Dilute, cold solutions of NCl_3 in various organic solvents are stable for several days.[6] Store under inert atmosphere. Use only behind a safety shield in an efficient fume hood.

Amination of Aromatics.

The reaction of benzene and derivatives with NCl_3 and ***Aluminum Chloride*** in organic solvents can be a useful preparation for *meta*-substituted amines. However, yields are only moderate, and mixtures of isomers are often obtained. Arenes include mono-[7-9] and dialkylbenzenes,[9,10] halobenzenes,[11] biphenyl, and naphthalene.[1] With trichloroamine/$AlCl_3$, the conversions of toluene to *m*-toluidine (eq 1) and of 1,3-dimethylbenzene to 3,5-dimethylaniline (eq 2) in moderate yields have been observed.

(1)

(2)

An addition-elimination mechanism involving a chloroarenium intermediate has been proposed for the amination reactions (eq 3).[10]

(3)

Amination of halobenzenes and halotoluenes with trichloramine/$AlCl_3$ proceeds by two competing processes in moderate yields.[11] For example, fluorobenzene gives predominantly *m*-fluoroaniline and *p*-chloroaniline (eq 4). It has been proposed that the former is produced by a substitution (addition-elimination) mechanism, while the latter is formed by a pathway involving nucleophilic displacement of halide in a chloroarenium cation by a nitrogen containing nucleophile (eq 5).

X = F	19%	1%	13%
X = Cl	33%	1%	-

Amination of biphenyl gives 3-aminobiphenyl (eq 6) and amination of naphthalene gives a mixture of 1- and 2-amino derivatives in low yields.[1]

(6)

Amination of Alkanes.

The trichloramine/$AlCl_3$ system has also been used for the amination of monocyclic[12,13] bicyclic,[13,14] and tricyclic[3,15] alkanes. C_5-C_8 cycloalkanes and their mono- and dimethyl derivatives are aminated in good yields.[13] Methylcyclohexane[12,16] and methylcyclopentane[13] are converted to 1-amino-1-methylcycloalkanes on treatment with trichloramine/$AlCl_3$ (eq 7). Treatment of decalin and hydrindane with the trichloroamine/$AlCl_3$ system affords *cis*-9-aminodecalin (eq 8) and *cis*-8-aminohydrindane, respectively, in good yields.[13]

(7)

(8)

The trichloroamine/$AlCl_3$ amination route provides a simple one-step method of obtaining aminoadamantanes in high yield (eq 9).[3,15] Diamantane[17] can also be efficiently aminated in this fashion. When hydrocarbons which do not contain a tertiary hydrogen are subjected to reaction with NCl_3/$AlCl_3$, cationic rearrangements and fragmentations are observed.[18]

(9)

Amination of Alkyl-Substituted Aromatics.

Various monoalkyl substituted arenes have been aminated on the alkyl side chain to form *t*-benzylamines in the system trichloroamine/$AlCl_3$/*t*-butyl bromide (an efficient additive).[19-21] *p*-Alkyl and *p*-haloisopropylbenzenes give the corresponding aminated products in high yields (eq 10).

(10)

Tertiary Amines from Chlorides.

When simple tertiary alkyl chlorides are exposed to NCl_3 and $AlCl_3$ in methylene chloride at -10 °C, varying yields of the corresponding amines can be obtained. *t*-Pentyl chloride under these conditions provides *t*-pentylamine in 82% yield (eq 11), while *t*-octylamine is obtained in 35% yield from the corresponding chloride.[2]

$$MeCH_2CMe_2Cl \xrightarrow[\substack{CH_2Cl_2,\ -10\ °C \\ 82\%}]{NCl_3,\ AlCl_3} MeCH_2CMe_2NH_2 \qquad (11)$$

Primary and secondary halides give isomeric amines resulting from skeletal rearrangement, as well as aziridines (eqs 12-14). Mechanistic details of this reaction have been reported.[22]

(12)

(13)

(14)

Vicinal Dichlorides from Alkenes.

The reaction of NCl_3 with a variety of mono- and disubstituted alkenes, both cyclic and acyclic, affords the corresponding 1,2-dichlorides in high yield. For example, cyclopentene with NCl_3 at 0 °C gives *trans*-1,2-dichlorocyclopentane in 89% yield (eq 15).[4]

(15)

These transformations tend to be high yielding and the products formed are generally simple to purify. In comparison with other reagents commonly used for chlorination of alkenes (***Sulfuryl Chloride***, ***Chlorine***, ***Phosphorus(V) Chloride***),[4,23] NCl_3 usually gives fewer byproducts such as allylic chlorides. However, this method fails in the case of trisubstituted alkenes, as well as for styrene.

Conversion of Organoboranes to Alkyl Chlorides.

Trialkylboranes can be oxidized to the corresponding alkyl chlorides with NCl_3 in methylene chloride at 0 °C.[5,24] Yields range from 66-94% overall from the alkene (eq 16).

(16)

Other reagents (PCl_5, SO_2Cl_2, ***N,N-Dichlorourethane***) known to chlorinate organoboranes are usually considerably less efficient.

Other Reactions.

Fluorocyclohexane is obtained in 45% yield from cyclohexene in the presence of NCl_3 and ***Boron Trifluoride***.[25]

Trichloroacetic Acid

[76-03-9] · $C_2HCl_3O_2$ · Trichloroacetic Acid · (MW 163.38)

(strong acid catalyst used in diazotization reactions and porphyrin syntheses; dichlorocarbene precursor)

Alternate Name: TCA.

Physical Data: mp 57-58 °C; bp 196-197 °C; *d* 1.629 g cm^{-3}.

Solubility: sol alcohol, ether, water.

Form Supplied in: white crystals, widely available.

Handling, Storage, and Precautions: very caustic; should only be handled in a fume hood. Rubber gloves should be worn when handling this reagent. Extremely destructive to mucous membranes and tissues of upper respiratory tract, eyes, skin. Keep away from strong bases.

Diazotization of Amines.[1]

Trichloroacetic acid is used as a catalyst in the diazotization of amines by nitrites (eq 1). In this reaction, strong mineral acids (***Hydrochloric Acid***, ***Sulfuric Acid***) give unsatisfactory results, as does ***Acetic Acid***. Other catalysts used for this reaction are perfluorobutyric acid and ***Trifluoroacetic Acid***.

(1)

Synthesis of Porphyrins.[2]

The use of TCA as a catalyst allows the use of aldehydes with acid labile groups, such as acetals, in the synthesis of porphyrins (eq 2). This method is a convenient alternative to other methods available, which may not be as tolerant of other functionalities in the aldehydes.

Condensation of Silanols and Alkoxysilanes.[3]

Along with various other acids and bases, TCA catalyzes the condensation of silanols with alkoxysilanes (eq 3). This catalysis is believed to be bifunctional, with the acidic proton of TCA coordinating to the oxygen of the alkoxy silane, while the carbonyl oxygen coordinates to the proton of the silanol.

$$Me(Me_2SiO)_3Me_2SiOH + MeSi(OMe)_3 \xrightarrow[45\%]{TCA,\ rt} Me(Me_2SiO)_3Me_2SiOSi(OMe)_2Me \quad (3)$$

Addition of Chloro-Substituted Carbons into Organic Molecules.

In the presence of strong base, TCA, as well as its esters and salts, reacts with alkenes to give 1,1-dichlorocyclopropanes (eq 4).[4] The reaction of base with TCA eliminates CO_2, leaving a trichloromethyl anion. This anion loses chloride ion to give dichlorocarbene, which subsequently reacts with the alkene to give the substituted cyclopropane. Dihalocarbenes from other sources undergo analogous reactions. The 1,1-dichlorocyclopropanes formed are subject to rearrangement, as shown by the reaction of norbornene with ***Ethyl Trichloroacetate*** (eq 5).[5]

(5)

TCA can be used to effect the Michael addition of trichloromethyl anion into alkenes and aromatic systems with strong electron-withdrawing groups attached, rather than forming 1,1-dichlorocyclopropanes (eqs 6-8).[6] TCA can also react with carbonyls to give 1-(trichloromethyl)-substituted alcohols (eq 9).[7]

(6)

(7)

(8)

(9)

Enamines react with TCA to give trichloromethyl derivatives, which are somewhat unstable (eq 10).[8] These rearrange to give α-chloroamides, via aziridinium salts. The trichloromethyl derivatives are generated by addition of the trichloromethyl anion to a carbocation formed by protonation of the enamine. Imines undergo a similar reaction.[9]

(10)

Primary aryl amines react via a dichlorocarbene formed from the decomposition of ***Sodium Trichloroacetate*** to yield isocyanates (eq 11).[10]

(11)

Interconversion of Optically Active Alcohols.

2-Alkoxybenzothiazolium salts of optically active alcohols, formed in situ by the reaction of 2-fluorobenzothiazolium with the appropriate alcohol, react with TCA to give the corresponding esters of trichloroacetate, which then undergo saponification to give back the optically active alcohols with inverted configuration (eq 12).[11]

Trichloroacetic Anhydride

[4124-31-6] · $C_4Cl_6O_3$ · Trichloroacetic Anhydride · (MW 308.74)

(reagent for formation of trichloroacetic esters and amides; formation of trichloromethyl heterocycles;[3] acylation of electron-rich alkenes[5])

Alternate Name: TCAA.

Physical Data: mp -5 °C; bp 139-141 °C/60 mmHg; *d* 1.690 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: clear liquid, widely available.

Purification: distill in vacuo.

Handling, Storage, and Precautions: should be kept under inert gas; very reactive with water; corrosive.

General Reactivity.

The reactivity of trichloroacetic anhydride roughly parallels that of ***Trifluoroacetic Anhydride***. For the formation of trichloroacetic esters and amides, ***Trichloroacetyl Chloride***[1] and hexachloroacetone[2] are generally preferred to react with alcohol and amines, respectively.

Trichloromethyl Heterocycles.

A common use of TCAA has been its condensation with acylhydrazines, oximinoamides, or imidate esters to provide the corresponding five-membered trichloromethyl heterocycles (eq 1).[3] The trichloromethyl group can then be displaced; for example, a 1,2,4-oxadiazole can be reacted with an appropriate nucleophile to provide the 5-amino compound (eq 2). A unique cyclization is the formation of a tetracyclic trichloromethyl amide diacetal (eq 3).[4]

(1)

(2)

(3)

Formation of 2-Trichloroacyl Vinyl Sulfides.

Reaction of TCAA with trithioorthoacetates produces acylated vinyl sulfides in high yields (eq 4).[5] Later results indicated that the reaction proceeds through a ketene dithioacetal[6] and that the reaction may be extended to vinylketene dithioacetals (eqs 5 and 6)[7] and other functional groups.[8]

(4)

(5)

(6)

Schiff Bases and Enamines.

Morimoto and Sekiya discovered that reactions of TCAA with Schiff bases and enamines provided an interesting array of heterocycles and chlorinated products (eqs 7-9).[9]

Trichloroacetonitrile

Cl_3CCN

[545-06-2] · C_2Cl_3N · Trichloroacetonitrile · (MW 144.38)

(makes trichloroacetimidates from alcohols; trichloroacetimidates are used to introduce nitrogen into molecules via rearrangements[1c] and cyclizations; trichloroacetimidates are useful alkylating agents[1d,e])

Physical Data: mp -42 °C; bp 83-84 °C; *d* 1.440 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: neat colorless liquid.

Analysis of Reagent Purity: ^1H NMR, ^{13}C NMR.

Handling, Storage, and Precautions: toxic lachrymator; use only in a fume hood. Reagent can be absorbed through the skin. Always wear gloves when handling this reagent.

Preparation of Trichloroacetimidates.

The imidates derived from the addition of alcohols to trichloroacetonitrile have become important and versatile intermediates in synthetic chemistry.[1] Consequently the principal synthetic use of trichloroacetonitrile has been in the formation of these useful trichloroacetimidate intermediates. The imidates are most often prepared by simple addition of a sodium or potassium alkoxide to the electron-deficient trichloroacetonitrile (eq 1).[1c,d,2] In certain cases, slight modifications of the above procedure are utilized.[2d,3] The product imidates are isolable and, despite their propensity to rearrange,[2b,e,4] can in some instances be purified by distillation[2a,d,e] or chromatography. Typically the addition reaction is sufficiently clean to use the imidates without further purification.[2f]

Rearrangement of Trichloroacetimidates.

The thermal rearrangement of imidates has been known for many years.[2b,4] In 1974, Overman[2c] described a useful conversion of allylic alcohols to allylic amines utilizing a [3,3]-sigmatropic rearrangement of allylic trichloroacetimidates (eq 2).[1c,2e] In addition to simple thermolysis it was found that the rearrangement could be catalyzed at room temperature with either Hg^{II} or Pd^{II} salts.[1c,5] As with many sigmatropic rearrangements, the reaction is stereoselective and produces double bonds of defined stereochemistry while efficiently transferring chirality.[1c,5,6]

(2)

A comparison of reaction conditions[5b,c,d] has shown that palladium catalysis is particularly effective in achieving complete chiral transfer (eq 3).[5b] Propargylic imidates also rearrange when heated in refluxing xylene.[1c,7] The initially formed allene undergoes a series of tautomerizations so that amino 1,3-dienes are the ultimate products (eq 4).[1c] These dienes have found use in the Diels-Alder reaction.[1c]

(3)

(4)

Electrophilic Cyclization of Trichloroacetimidates.

Trichloroacetimidates derived from allylic[8a,c-f] and homoallylic[8b,c] alcohols undergo electrocyclic ring closure when treated with a source of I^+ (eq 5).[8c] Cyclization can also be triggered via the Lewis acid-mediated opening of epoxides.[9] In at least one case the imidate proved more reactive than related reactions using carbamates.[9c] These are useful methods for the stereoselective introduction of nitrogen into cyclic and acyclic systems.

Alkylation using Trichloroacetimidates.

Under mildly acidic conditions, alkyl trichloroacetimidates act as reasonable alkylating agents[2f,10] toward heteroatom nucleophiles, most notably alcohols (eq 6). Alkyl groups which have been transferred include benzyl,[2f,10a,b,d] allyl,[2f] propargyl,[10e] and *t*-butyl.[10c] This methodology has been used to protect alcohols. The use of glycosyl trichloroacetimidates has found widespread use in the synthesis of oligosaccharides and glycoconjugates (eq 7).[1d,e,11] This is a particularly powerful method for controlling stereochemistry at the anomeric position.

$$R = ArCH_2,\ CH_2{=}CHCH_2,\ MeC{\equiv}CCH_2,\ t\text{-}Bu$$

Trichloroacetyl Chloride

[76-02-8] · C_2Cl_4O · Trichloroacetyl Chloride · (MW 181.82)

(acylation of amines to give trichloroacetamides;[1] undergoes Friedel-Crafts type acylations as an alkyl choroformate equivalent;[2] convenient precursor of dichloroketene;[3] acylates enol ethers;[4] reacts with organozinc reagents to generate trichloromethyl ketones[5])

Physical Data: mp -146 °C; bp 114-116 °C; *d* 1.629 g cm^{-3}

Solubility: sol ether, THF, dichloromethane, benzene, toluene.

Form Supplied in: colorless oil.

Analysis of Reagent Purity: commercial reagent is 99% pure.

Preparative Method: can be generated by action of ***Phosphorus Oxychloride*** on ***Trichloroacetic Acid***.

Purification: distillation with the rigorous exclusion of moisture.

Handling, Storage, and Precautions: reagent is highly toxic and should be handled with gloves.

Formation of Trichloroacetamides.

Amines can be readily converted into the corresponding trichloroacetamides with trichloroacetyl chloride and ***Triethylamine*** (eq 1).[6] Dehydration of amides can be performed in a similar fashion, which allows mild access to the corresponding nitriles (eq 2).[7] Allylic trichloroacetamides can also be used to generate aminochlorohydrins (eq 3).[8]

(1)

(2)

Friedel-Crafts Acylations.

Trichloroacetyl chloride undergoes facile addition to heterocycles in a Friedel-Crafts fashion (eq 4).[9] Given the ability of these products to undergo haloform-type reactions, this allows access to aryl acids, esters, and amides (eq 5).[10,11]

Preparation of Dichloroketene.

Dehalogenation of trichloroacetyl chloride with activated ***Zinc*** yields a solution of dichloroketene (eq 6).[3]

Acylation of Enol Ethers.

Trichloroacetyl chloride adds to enol ethers and thioenol ethers in a regiospecific fashion, and these adducts undergo elimination to generate α,β-unsaturated ketones (eq 7).[12,13]

(7)

Generation of Trichloromethyl Ketones.

Addition of trichloroacetyl chloride to an organozinc reagent proceeds without catalyst to give trichloromethyl ketones (eq 8).[5] These can be reduced enantioselectively and therefore serve as a source of asymmetric α-hydroxy and α-amino acids[14]

(8)

Related Reagents.

Dichloroketene; ***Tribromoacetyl Bromide***.

Trichloroacetyl Isocyanate[1]

[3019-71-4] · $C_3Cl_3NO_2$ · Trichloroacetyl Isocyanate · (MW 188.39)

(derivatization of alcohols to the trichloroacetyl[2] and unsubstituted[3] carbamates (urethanes); reacts also with phenols, amines, and thiols;[2] [4 + 2] cycloadditions with strained[4] and electron-rich[5] alkenes)

Physical Data: bp 80-85 °C/20 mmHg; *d* 1.581 g cm^{-3}.

Solubility: sol CH_2Cl_2, ether, THF; reacts with H_2O and protic solvents.

Form Supplied in: colorless oil; widely available.

Handling, Storage, and Precautions: should be stored in the absence of moisture and be handled in a fume hood; lachrymator.

Carbamates.

The strong electrophilic properties of this reagent allow ready reaction to occur with alcohols and phenols (*O*-acylation) to form trichloroacetyl carbamates (urethanes),[2,3] with amines to give trichloroacetyl ureas,[2d] and with thiols to give trichloroacetyl thiocarbamates.[2b] These in situ derivatizations are useful for the expeditious classification of alcohols as well as amines and thiols by NMR spectroscopy.[2] However, *C*-acylation sometimes takes place if a pyrrole or furan nucleus is present in the molecule.[6] Selective removal of the trichloroacetyl group is readily achieved by mild hydrolysis under neutral to weakly basic conditions (aq ***Potassium Carbonate***[3a,b,d] or aq $NaHCO_3$[3f] in MeOH or EtOH; ***Ammonia*** in MeOH;[3g] ***Alumina***;[3e] SiO_2 in MeOH[3c]) to give unsubstituted carbamates (eq 1).[3d,7] This procedure has been often used for the synthesis of carbamates in the field of antibiotics.[3c,f,g] This method is complementary to the use of ***Chlorosulfonyl Isocyanate*** to prepare unsubstituted carbamates from alcohols.[7] Carbamates are useful for stereoselective alkene functionalization. Iodonium ion mediates cyclization of allylic and homoallylic carbamates to give cyclic carbonates.[3b] Base-catalyzed intramolecular conjugate addition to activated alkenes afforded oxazolidinones and perhydrooxazinones (eq 1).[7]

(1)

Trichloroacetyl isocyanate is an effective dehydrating reagent in the preparation of 1,2-benzisoxazoles from salicylaldoximes (eq 2).[8]

Cycloaddition with Alkenes.

This isocyanate reacts preferably as a 4π component with strained (eq 3)[4b] and electron-rich alkenes (eq 4)[5b] to give [4 + 2] cycloaddition products, in contrast to the [2 + 2] reactions of sulfonyl isocyanates.[4,5] Various other heterocycles have been synthesized similarly via cycloadditions[5,10] and also via *O*-[8] and *N*-acylation.[9]

Oxidation of 4-phenylurazole to triazolinedione is more effectively achieved by use of a DMSO-CCl_3CONCO combination compared with other Pfitzner-Moffatt-type systems.[11]

Related Reagents.

Chloroacetyl Isocyanate; ***Chlorosulfonyl Isocyanate***.

2,4,6-Trichlorobenzoyl Chloride[1]

[4136-95-2] · $C_7H_2Cl_4O$ · 2,4,6-Trichlorobenzoyl Chloride · (MW 243.89)

(strong acylating agent; used with DMAP in the formation of esters,[1] thioesters,[2] amides,[3] and, particularly, small- and medium-ring lactones[1,4])

Physical Data: bp 107-108 °C/6 mmHg; *d* 1.561 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: liquid; commercially available.

Purification: redistill under reduced pressure.[5]

Preparative Methods: first prepared by Yamaguchi from 2,4,6-trichloroaniline,[7] but Seebach has reported a simpler synthesis from 1,3,5-trichlorobenzene (**1**) (eq 1).[8]

Handling, Storage, and Precautions: irritant and moisture sensitive. Incompatible with strong bases (see Aldrich safety index for ***Benzoyl Chloride***).[6]

Carboxylic Acid Derivatives.

2,4,6-Trichlorobenzoyl chloride was designed to react rapidly with carboxylic acids to form mixed anhydrides (**2**),[9] which would then quickly react with alcohols, amines, and thiols to give esters (**3**), amides (**4**), and thioesters (**5**) in high yields (eq 2).

The trichloro-substituted phenyl ring serves two purposes: to prevent any side reaction occurring, due to attack of the alcohol at the carbonyl adjacent to the aromatic ring, and to make the carboxylate anion (**6**) a good leaving group, enhancing the rate of reaction.

Lactone Formation.

Although many methods exist for lactonizing α,o-hydroxy acids,[10] 2,4,6-trichlorobenzoyl chloride remains one of the most powerful and has been widely used in the synthesis of naturally occurring macrolides.[11] Yamaguchi first showed how 9-, 12-, and 13-membered lactones could be synthesized using high dilution techniques (Table 1)[1] and went on to demonstrate the potential of his reagents by using them to synthesize methynolide and (±)-brefeldin A (**7**) (eq 3), 12- and 13-membered lactones, respectively.[7,12]

Table 1 Synthesis of Lactones[1]

Ring size of lactone formed	DMAP (equiv)	Time of addition (h)	Yield of monomer (%)	Yield of dimer (%)
9	3	8	36	23
10[13]	6	20	33	0
12	6	5	48	20
13	6	1.5	67	10

(3)

(7)

Other groups have also used the Yamaguchi lactonization procedure to synthesize natural products, most notably Seebach in the synthesis of (+)-myscovirescine M_2, a 27-membered lactone, in which the seco acid was converted to the lactone in 83% yield.[14] Symmetrical diolides (**8**) have been prepared from unprotected seco acids in fair yields (eq 4)[15] when other lactonization procedures failed.[9] Unsymmetrical diolides require protected seco acids.[16]

(4)

(8)

More recently, treatment of 3-hydroxybutanoic acid (**9**) under the Yamaguchi lactonization conditions of high dilution gave, in equal proportions, macropentolides, macrohexolides, and macroheptolides in good yields (eq 5).[17]

(5)

The Shanzer lactonization method produces a lower overall yield of macrolides, but an increased ratio of the higher homologs.[18]

Effect on Stereochemistry.

The Yamaguchi esterification is also often used in preference to other methods because of its lack of racemization of stereogenic centers. Kunz used it to esterify an *N*-Boc protected aspartate (**10**)[19] when other methods have been known to racemize the chiral center (eq 6).[20]

(6)

The Yamaguchi lactonization also leaves intact any stereochemistry at the carbon bearing the hydroxyl group. This is in contrast to the Mitsunobu lactonization, which inverts that stereochemistry (eq 7).[21]

Furthermore, when no base is present during esterification, double bonds are also little affected, as Greene showed when converting a variety of alcohols to angelate esters (**12**) in quantitative yield; standard esterification procedures gave a mixture of angelate and tiglate esters (eq 8).[22]

Limitations of the Yamaguchi Lactonization Conditions.

The tendency of the Yamaguchi lactonization conditions to form diolides from some seco acids, as shown by Seebach,[15] can also pose a problem. Steglich has shown that some α,o-hydroxy acids (**13**) tend to dimerize under the Yamaguchi lactonization conditions. However, by using a modified Mitsunobu lactonization, the monolide was obtained in 59% yield (eq 9). All other lactonization procedures also gave varying amounts of diolide, including the standard Mitsunobu lactonization procedure.[23]

[66270-36-8] · $C_5H_6Cl_4O_2$ · 2,2,2-Trichloro-*t*-butoxycarbonyl Chloride · (MW 239.91)

(easily removable acid- and base-stable protecting group for nitrogen, including amino acids[1] and nucleosides;[2] protecting group for alcohols[3,4])

Alternate Name: TCBOC-Cl.

Physical Data: mp 30-32 °C; bp 77-81 °C/12 mmHg.

Form Supplied in: colorless solid; commercially available.

Preparative Method: from trichloro-*t*-butanol with ***Phosgene***[1] or triphosgene (***Bis(trichloromethyl) Carbonate***) (eq 1).[5]

Handling, Storage, and Precautions: moisture sensitive.

General Discussion.

As a protecting group for amines, the TCBOC group is stable to acid and base conditions normally used to remove Boc groups (e.g. TFA) or to hydrolyze methyl esters (NaOH-methanol).[1] The TCBOC group is attached under standard Schotten-Baumann conditions (eq 2). In addition to the reductive conditions[6] originally described for removal of the TCBOC group (eq 3), sodium-2-thiophenetellurolate[7] and zinc-acetylacetone[8] (neutral conditions) also deprotect in high yield. Nucleosides,[2,8] indoles,[7,9] indolines,[7,10] and anilines[7] have been *N*-protected with the TCBOC group.

(3)

R = Val-Ala-Phe-O-*t*-Bu; CoPc = lithium cobalt(I) phthalocyanine

The TCBOC group is useful as an alcohol protecting group (eq 4). Horner-Emmons reagent (**3**) is stable below 0 °C and can be used to prepare α-keto esters (eq 5).[3] As an alcohol protecting group the TCBOC group is not stable to aqueous base,[4] in contrast to its use as an amine protecting group.

Trichloro(cyclopentadienyl)titanium[1]

[1270-98-0] · $C_5H_5Cl_3Ti$ · Trichloro(cyclopentadienyl)titanium · (MW 219.33)

(preparation of various cyclopentadienyltitanium(IV) complexes,[1] e.g. enantioselective templates by exchanging two of the chloride ligands with chiral alkoxides;[2] replacement of the third chloride by allyl groups[3] or by ester enolates[4] affords reagents for stereoselective allyltitanation of aldehydes[2b,3] and for aldol reactions,[4] respectively; combination with metal hydrides or with *n*-BuLi results in low-valent species, reagents for various reductions;[5] catalysts for alkene polymerizations are obtained by activation with organoaluminum compounds, methylaluminoxane, or aluminosilicates;[6] Ti-imido complexes derived from primary amines undergo intramolecular cyclizations with triple bonds;[7] the Lewis acidity is used to cleave epoxides and acetals;[8] methyl or ethyl derivatives can be used for the chemoselective alkyltitanation of aldehydes in the presence of ketones[9])

Physical Data: mp 208-211 °C (benzene); crystal structure.[10]

Solubility: sol aromatic hydrocarbons (toluene, dichlorobenzene, xylene), CH_2Cl_2, $CHCl_3$, Et_2O, THF, similar aprotic solvents.

Form Supplied in: yellow-orange powder or crystals.

Analysis of Reagent Purity: ^1H NMR δ ($CDCl_3$): 7.06 ppm (impurity, partial hydrolysis: 6.92 ppm); ^{13}C NMR: 123.4 ppm (impurity: 122.2 ppm).

Preparative Methods: the title reagent $CpTiCl_3$ (**1**) is most conveniently prepared by ligand redistribution between ***Dichlorobis(cyclopentadienyl)titanium*** and ***Titanium(IV) Chloride***,[1,11] or by reaction of 1-trimethylsilyl-2,4-cyclopentadiene with $TiCl_4$.[12] Another method involves chlorination of Cp_2TiCl_2 with ***Sulfuryl Chloride***/***Thionyl Chloride***[13] or titanation of cyclopentadienyl-Tl.[14]

Purification: by recrystallization in the presence of HCl(g)[1,11] followed by sublimation in high vacuum.[10]

Handling, Storage, and Precautions: the crystalline solid must be protected from moisture and prolonged exposure to UV light should be prevented. Reactions should be carried out in dry equipment with absolute solvents in an inert atmosphere (Ar, N_2).

Preparation of Chiral Cyclopentadienyldialkoxytitanium Chlorides.

Cyclopentadienyltitanium complexes can be prepared from $CpTiCl_3$ (**1**) by exchanging one, two, or all three of the chloride ligands.[1] Reaction with alcohols (ROH) results in spontaneous substitution of one chloride with evolution of HCl, affording monoalkoxides (**2**). For the second substitution to the dialkoxides (**3**) the HCl has to be withdrawn from the equilibrium (**2**) &ibond; (**3**) by neutralization with a tertiary amine, e.g. ***Triethylamine***.[3] Preferred solvents for these ligand exchanges are Et_2O and hydrocarbons. In the case of diols leading to favorable cyclic Ti complexes, e.g. (*R*,*R*)-(**4**), the second substitution can also be effected by heating in toluene under a slow stream of Ar or N_2 (eq 1).[2b]

The use of two identical chiral alcohols or a C_2-symmetrical chiral diol leads to chiral Ti complexes without a stereogenic metal center. ***Chloro(cyclopentadienyl)bis[3-O-(1,2:5,6-di-O-isopropylidene-α-D-glucofuranosyl)]titanium*** (**5**)[2a,3] and ***Chloro(η^5-cyclopentadienyl)[(4R,trans)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-O^{α},O$^{α´}$]titanium*** ((*R*,*R*)-**4**)[2b] have been successfully used for the enantio- and diastereoselective additions of nucleophiles to achiral and chiral aldehydes.[2c,d] The cyclic complex (*R*,*R*)-(**4**) and its enantiomer are especially suited for the transfer of allyl and terminally monosubstituted allyl groups, affording homoallyl alcohols of excellent optical purity. The branched *anti*-isomers are obtained in the case of substituted nucleophiles.[2b] While the titanate (**5**) with ligands derived from D-glucose can be used for allyltitanations as well,[3] its optimal use is for highly stereoselective aldol reactions of acetate,[4a] propionate,[4b] and glycine ester enolates.[4c] In this case the enantiomer is not readily available.

Reductions.

Reducing agents can be obtained by the combinations $CpTiCl_3$/***Lithium Aluminum Hydride***,[5a,b,e,f] $CpTiCl_3$/***Sodium Borohydride***,[5d] $CpTiCl_3$/***n-Butyllithium***,[5c,6a] and $CpTiCl_3$/***Sodium Naphthalenide***.[5g] The four-stage conversion of $CpTiCl_3$ (**1**) and $LiAlH_4$ has been studied by calorimetric titration; the titanium is thereby reduced to Ti^{III}.[5a] $CpTiCl_3/LiAlH_4$ has been used for inter- and intramolecular pinacol couplings (eq 2),[5b] deoxygenations of endoxides (eq 3),[5e] and reduction of acetals.[5f]

(3)

Reaction of $CpTiCl_3$ (**1**) with BuLi gives a Ti^{II} species, which catalyzes the hydrogenation of simple alkenes.[5c,6a] This catalyst can be immobilized on alumina.[5c] The combination $CpTiCl_3/NaBH_4$ allows the selective reduction of aromatic iodides in the presence of chlorides and bromides.[5d] The reducing power of ***Alumina***-supported (**1**) and Na naphthalenide is sufficient for nitrogen fixation, i.e. the conversion of N_2 to NH_3.[5g] Similar reagents can be obtained from $TiCl_4$, ***Titanium(III) Chloride***, Cp_2TiCl_2, aluminum chlorides, or by using ***Potassium Hydride***, ***Magnesium***, and ***Magnesium Amalgam*** as reducing components.

Alkene Polymerization.

While $CpTiCl_3$ (**1**) is inactive, efficient catalysts for alkene polymerizations are obtained in combination with methylaluminoxane (MAO).[6c,d,e,g] The reaction between (**1**) and MAO has been studied by EPR.[6c] Instead of MAO, ***Diethylaluminum Chloride***[6a] and aluminosilicates[6b,f] have also been used for activation. The prominent features of these catalysts are the stereoregular syndiotactic polymerization of styrene[6c,e] and the *cis*-1,4-polymerization of certain 1,3-dienes.[6e,g] In contrast, a regioirregular polymer is obtained from propene.[6f] Stereoregular Ziegler-Natta-type polymerization catalysts, especially for polypropylene, can also be obtained from *ansa*-bridged titanocenes or zirconocenes with planar chirality.[15]

Lewis Acid Catalysis and Other Applications.

Reaction of $CpTiCl_3$ (**1**) with primary amines gives highly reactive Ti-imido complexes which undergo rapid but reversible cyclodimerization. These imides undergo facile intramolecular [2 + 2] cycloadditions with triple bonds, affording highly strained titanacycles (**6**), which, under catalytic conditions (0.2 equiv. **1**) are further transformed to 1-pyrrolines or 1-piperines,[7a] e.g. (**7**), an elaborated intermediate for the alkaloid monomorine (eq 4).[7b] With stoichiometric amounts of (**1**) the intermediate (**6**) can be trapped by hydrolysis, *C*-acylation with nitriles, or *N*-acylation with acid chlorides (eq 5).[7a]

(4)

(6) $n = 1, 2$

(5)

Further applications of $CpTiCl_3$ (**1**) include regioselective opening of propylene oxide[8a] and, in combination with ***Sodium Iodide***, the cleavage of cyclohexanone acetals[8b] $CpTiCl_2Me$ can be prepared from (**1**) with Me_2Zn, ***Trimethylaluminum***, ***Methyllithium***, or MeMgCl. In competition experiments it transfers its methyl group to aldehyde and ketone carbonyls (much like ***Methyltitanium Triisopropoxide***), with high preference for aldehydes. However, an advantage over $(i\text{-PrO})_3TiMe$ is its thermal stability, also exhibited by the ethyl analog.[9]

Trichloro(cyclopentadienyl)zirconium[1]

[34767-44-7] · $C_5H_5Cl_3Zr$ · Trichloro(cyclopentadienyl)zirconium · (MW 262.67)

(catalyst for alkene polymerization[2-4])

Physical Data: mp 237-238 °C (dec).

Solubility: insol most noncoordinating solvents; however, it becomes sol in benzene or chloroform in the presence of two equiv of donor agents such as ether, THF, triethylamine, or pyridine.

Form Supplied in: cream solid; readily available as a powder or as the 1,2-dimethoxyethane adduct, $CpZrCl_3$.DME.[4]

Preparative Methods: photoinduced chlorination of ***Dichlorobis(cyclopentadienyl)zirconium***.[1]

Purification: can be purified by vacuum sublimation.

Handling, Storage, and Precautions: solid material is moisture sensitive.

Catalyst for Alkene Polymerization.[2-4]

Trichloro(cyclopentadienyl)zirconium, along with methylaluminoxane (MAO) as co-catalyst, has been mainly used as a catalyst of alkene polymerizations in Ziegler-Natta type processes. Thus 1,5-hexadiene[2] (eq 1) and ethylene[3,4] undergo cyclopolymerization in the presence of $CpZrCl_3$/MAO.

(1)

Precursor for the Synthesis of Other Organometallic Intermediates.

Other Zr-containing organometallic complexes can be synthesized from $CpZrCl_3$. Thus optically active (**1**) was prepared according to eq 2.[5]

Similarly, an allyl-zirconium complex (**2**) was obtained as shown in eq 3.[6]

Related Reagents.

Trichloro(cyclopentadienyl)titanium.

Trichloro(1,2-dimethoxyethane)niobium

$NbCl_3(DME)$

[110615-13-9] · $C_4H_{10}Cl_3NbO_2$ · Trichloro(1,2-dimethoxyethane)niobium · (MW 289.40)

(synthesis of 1,2-amino alcohols,[2] pyrroles,[3] 1,2-diols,[5] *cis*-alkenes, and naphthols[7])

Physical Data: mp 230 °C (dec).

Solubility: sol THF.

Preparative Methods: can be prepared according to the literature procedure,[1] or purchased from commercial sources. The best results are obtained with freshly prepared material.

Handling, Storage, and Precautions: all reactions and manipulations should be performed under nitrogen, either in a dry box or using standard Schlenk techniques. $NbCl_3(DME)$ is stable at room temperature when stored under an inert atmosphere.

Synthesis of 1,2-Amino Alcohols.[2]

Addition of an imine to $NbCl_3(DME)$ results in formation of a metallaaziridine, which is functionally the equivalent of a C,N dianion (eq 1). Subsequent addition of aldehydes or ketones to this intermediate, followed by hydrolysis, gives 1,2-amino alcohols. The yield of this reaction ranges from 33-97%, with *syn*-amino alcohols being obtained as the major diastereomer (Table 1). A wide variety of aldehydes are tolerated; however, nonenolizable imines generally give superior results.

Table 1 Synthesis of 1,2-Amino Alcohols

Ph	Allyl	*i*-Pr	H	60	3:1
$PhCH_2CH_2$	Allyl	Et	Et	34	-

[a] ds represents *syn*:*anti* ratio.

Synthesis of Pyrroles.[3]

Pyrroles may be directly obtained from the reaction of α,β-unsaturated imines with $NbCl_3$(DME), followed by addition of either a primary ester or ***N,N-Dimethylformamide*** (Table 2). The niobium intermediate behaves like a homoenolate equivalent, condensing with the ester or formamide at the β-position. Following carbon-carbon bond formation, cyclization and dehydration occur to give the pyrrole. Aldehydes and ketones react with α,β-unsaturated imines and $NbCl_3$(DME) to give 2-aminotetrahydrofurans, which hydrolyze to lactols when chromatographed on silica gel.[4]

Table 2 Synthesis of Pyrroles

R^1	R^2	R^3	Y	Yield (%)

Me	Ph	H	NMe_2	58
Me	Ph	PhCH=CH	OMe	63
Me	Ph	CF_3	OMe	60
$-(CH_2)_3-$		H	NMe_2	47

Synthesis of 1,2-Diols.

Aldehydes can be converted to 1,2-diols in the presence of $NbCl_3$(DME), as shown for the coupling of benzaldehyde to (±)-stilbenediol in 78% yield (eq 2).[5] This reaction must be conducted at -10 °C in order to avoid acetalization of the product or reduction of the 1,2-diol to an alkene. Mixtures of products were obtained when unsymmetrical cross couplings of aldehydes were attempted.[6]

(2)

Synthesis of *cis*-Alkenes and Naphthols.[7]

$NbCl_3$(DME) reacts with internal alkynes to form alkyne complexes, which can be hydrolyzed with aqueous hydroxide to give *cis*-alkenes exclusively (eq 3). In contrast, reaction of $NbCl_3$(DME) with terminal alkynes yields cyclotrimerization products.

(3)

Niobium alkyne complexes are functionally equivalent to 1,2-dianions of *cis*-alkenes, and further reaction of these intermediates with benzene-1,2-dicarbaldehyde yields 2,3-disubstituted 1-naphthols (Table 3). The regioselectivity of these reactions appears to be influenced predominantly by steric factors. Alkynes substituted with *t*-Bu, TMS, or TBDMS groups, for example, give naphthols with the bulky group at the 3-position.

Table 3 Synthesis of 2,3-Disubstituted 1-Naphthols

2,2,2-Trichloroethanol

[115-20-8] · $C_2H_3Cl_3O$ · 2,2,2-Trichloroethanol · (MW 149.40)

(formation of 2,2,2-trichloroethyl esters and amides;[2] protection of phosphoryl groups in nucleotide synthesis[5])

Physical Data: mp 17 °C; bp 150 °C; *d* 1.557 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: clear liquid, widely available.

Handling, Storage, and Precautions: poisonous liquid when absorbed by intravenous or intraperitoneal routes. Do not mix with strong alkali solutions.[1]

2,2,2-Trichloroethyl Esters.

The 2,2,2-trichloroethyl moiety is a useful protecting group for acids since it is both formed and cleaved under very mild conditions (eq 1).[2] Woodward exploited the facile removal of this group in his classic synthesis of cephalasporin C (eq 2).[3]

(1)

(2)

2,2,2-Trichloroethyl Acetals.

These acetals are most conveniently formed by exchange with dialkyl acetals. They are cleaved under conditions similar to the above esters (eq 3).[4]

(3)

Nucleotide Synthesis.

In various instances the trichloroethyl group has been utilized in nucleotide chemistry for the protection of phosphoryl groups (eqs 4-6). In this seminal example the mononucleotide of thymidine-3´-*O*-acetate was formed.[5a] Selectively formed phosphotriesters have been converted to diesters under similarly mild conditions.[5] See also ***2,2,2-Trichloroethyl Phosphorodichloridate*** for related chemistry.

2,2,2-Trichloroethyl *trans*-1,3-Butadiene-1-carbamate[1]

[77627-82-8] · $C_7H_8Cl_3NO_2$ · 2,2,2-Trichloroethyl *trans*-1,3-Butadiene-1-carbamate · (MW 244.51)

(a diene which provides regio- and stereoselective control in Diels-Alder reactions[1])

Physical Data: mp 70-71 °C; IR (KBr): cm^{-1} 3350, 1710, 1660, 1540, 710; ^1H NMR ($CDCl_3$): δ 7.0-5.3 (m), 5.2-4.8 (m), 4.68 (s); ^{13}C NMR: δ 150.7, 132.8, 124.9, 113.3, 112.7, 93.8, 73.5.[2]

Preparative Method: the synthesis of *trans*-1,3-butadienecarbamates utilizes a modified Curtius rearragement.[3,4] In the synthesis of 2,2,2-trichloroethyl *trans*-1,3-butadiene-1-carbamate, ***Malonic Acid*** and ***Acrolein*** were condensed in pyridine to obtain *trans*-2,4-pentadienoic acid in 44-51% yield (eq 1).[5] This compound, which may be stored in a freezer for several months,[4] was treated with ***Ethyl Chloroformate*** and the resulting mixed anhydride transformed into the azide derivative. Due to the explosive nature, the azide was not isolated but immediately added to a refluxing solution of ***2,2,2-Trichloroethanol*** in toluene. Purification by silica gel column chromatography (hexane-ethyl acetate = 9:1) then afforded the title compound.[4]

Diels-Alder Reactions.

2,2,2-Trichloroethyl *trans*-1,3-butadiene-1-carbamate, like the related *N*,*N*-dialkyl- and *N*-acyl-*N*-alkyl-1,3-dienes,[6-11] are masked dienamines for Diels-Alder reactions. The advantage of this reagent, however, is that it is thermally more stable than the *N*,*N*-dialkyl-1,3-dienes and, hence, capable of giving higher yields even with poor dienophiles.[1a,12] In addition, the carbamate protecting group is removed under relatively mild conditions (activated ***Zinc-Acetic Acid***, rt, 24 h), providing higher yields of the amine product (eq 2).[2] Like other 1,3-diene-1-carbamates,[13-15] the title compound also gives excellent regio- (*ortho*) and stereo- (*endo*) selectivity in Diels-Alder reactions.[2,12,16] Its reaction with ethyl

atropate, which gives exclusively a product possessing the acylamino and aryl groups in a *cis* orientation,[12] has been exploited in an elegant, stereospecific synthesis of (±)-tilidine (eq 2).[2] Noteworthy is the stereochemical outcome of this Diels-Alder reaction, which was opposite to that provided by the related *N*,*N*-dialkyl-1-amino-1,3-dienes.[1b,17]

Related Reagents.

Benzyl 1,3-Butadiene-1-carbamate.

2,2,2-Trichloroethyl Chloroformate

[17341-93-4] · $C_3H_2Cl_4O_2$ · 2,2,2-Trichloroethyl Chloroformate · (MW 211.85)

(protecting agent for many functional groups;[1-5] agent for the net carboxylation of organometallic reagents;[18] achieves the *N*-demethylation and *N*-debenzylation of tertiary amines;[19,20] activates N-heteroaromatic rings toward reaction with organostannanes[25-28])

Alternate Names: troc-Cl; Troc-Cl; TrOC-Cl; Teoc-Cl; TCEC-Cl.

Physical Data: colorless liquid, bp 171-172 °C/760 mmHg, 75-76 °C/60 mmHg; d^{25} 1.539 g cm^{-3}; *n*20D 1.4700.

Preparative Methods: widely available commercially. It can be readily prepared by passing ***Phosgene*** into a solution of ***2,2,2-Trichloroethanol*** in benzene/diethylaniline[1a] or benzene/ether/pyridine.[1b] An alternate two-step approach (93% yield) has been described that employs ***S-Ethyl Chlorothioformate*** instead of phosgene.[2]

Handling, Storage, and Precautions: highly toxic, lachrymatory, and corrosive; it should be handled with caution in a fume hood.

Functional Group Protection.

Alcohols,[1,3] phenols,[1,4] and thiols[5] are readily protected as their trichloroethyl (troc) carbonates/thiocarbonates using 2,2,2-trichloroethyl chlorofomate and ***Pyridine*** or pyridine/***4-Dimethylaminopyridine***. Chemoselective protection of the less crowded of two alcohols is possible (eq 1).[6] Electron-deficient alcohols[7] and thiols[8] (but not phenols)[9] are readily protected. Alkyl- and arylamines are protected as their *N*-troc-carbamate derivatives using troc-Cl/pyridine (eq 2)[1,10] or under Schotten-Baumann conditions.[1] α-Amino acids are typically *N*-troc-protected under Schotten-Baumann conditions (eq 3);[11] however, refluxing a suspension of the α-amino acid in EtOAc containing troc-Cl is reported to be more convenient and high yielding.[12] It should be noted that other reagents are more commonly employed for *N*-α-amino acid protection (see ***Benzyl Chloroformate***, ***t-Butyl Azidoformate***).

Protection of the usually recalcitrant aryl α-keto acids as their trichloroethyl esters can be achieved using troc-Cl under basic conditions (eq 4).[13] However, the efficiency of such reactions with other carboxylic acids is typically much below those using other chloroformates.[2,14] Both *O*- and *N*-troc-protecting groups are stable under a wide variety of reaction conditions;[1,15] deprotection is usually effected using ***Zinc-Acetic Acid***/rt,[1] or under milder conditions using Zn/MeOH/reflux[1] or Zn/THF-H_2O/pH 4.2/25 °C.[16] Troc-protected alcohols are cleaved ten times more slowly than the corresponding tribromoethyl carbonates (see ***2,2,2-Tribromoethyl Chloroformate***). Troc thiocarbonates can be deprotected to either the thiol or disulfide by electrolysis.[17] 2,2,2-Tribromoethyl esters are cleaved at significantly lower voltages than are needed for electrolytic cleavage of the corresponding trichloroethyl esters.

(4)

Carboxylation of Organometallic Reagents.

Troc-Cl has proved useful in the trichloroethoxycarbonylation of alkynyllithium[18] species, although analogous methoxycarbonylation reactions are much more common (see ***Methyl Chloroformate***.) The facile reductive cleavage of the resulting trichloroethyl ester to the corresponding carboxylic acid (see above) makes this an attractive overall *C*-carboxylation protocol.

N-Dealkylation of Tertiary Amines.

Tertiary amines can be readily *N*-demethylated using troc-Cl.[19,20] The common practice of adding mild base appears unnecessary and may actually promote unwanted side reactions.[20] Facile cleavage of the resulting *N*-troc carbamate to the free secondary amine is typically performed using Zn/HOAc,[19] although milder conditions have also proved useful.[16,21] This *N*-demethylation protocol is cleaner and more selective than the classical von Braun reaction (see ***Cyanogen Bromide***), avoids the strongly basic conditions required for the cleavage of carbamates derived from other chloroformates, and is compatible with a variety of sensitive functionalities.[19] The *N*-debenzylation of tertiary benzylamines using troc-Cl appears always to be favored over other *N*-dealkylation pathways (eq 5)[22] and is an attractive alternative to hydrogenolytic *N*-debenzylation. Selective *N*-deallylation is also often preferred over loss of a simple alkyl group,[22b] although steric encumbrance can reverse this trend.[23] The troc-Cl-mediated *N*-dealkylative removal of primary alkyl groups can be unreliable[24] and ***Vinyl Chloroformate*** should be considered for such conversions. In reactions of troc-Cl with tertiary cyclohexylamines bearing only simple *N*-alkyl substituents, deamination to the cyclohexene can compete effectively with *N*-dealkylative removal of a methyl or primary alkyl group.[22b]

(5)

Activation of N-Heteroaromatic Rings Toward Reaction with Organostannanes.

Troc-Cl strongly activates pyridine toward regioselective 1,4-addition of prenyl[25] and benzylstannanes (eq 6),[26] while regioselective 1,2-addition is observed with ***Allyltributylstannane*** (eq 7).[27]

(6)

(7)

Quinoline and isoquinoline ring systems undergo selective 1,2-addition reactions with allenylstannanes.[28] Significantly higher yields are obtained when using troc-Cl rather than methyl chloroformate, due to better activation of the aromatic ring toward nucleophilic attack conferred by the strongly electron-withdrawing *N*-troc group.

Trichloroethylene

[79-01-6] · C_2HCl_3 · Trichloroethylene · (MW 131.38)

(starting material for the preparation of dichloroacetylene;[1-4] reagent for the preparation of alkynic ethers;[12] reagent for ethynylation and vinylation)

Alternate Name: trichloroethene.

Physical Data: bp 86.9 °C; *d* 1.464 g cm^{-3}.

Solubility: practically insol water; miscible with ether, alcohol, chloroform. *Drying:* can be dried by distillation from phosphorus pentoxide.

Handling, Storage, and Precautions: is slowly decomposed (with formation of HCl) by light in the presence of moisture. Avoid prolonged exposure to excessive heat. Moderate exposures to humans can cause symptoms similar to alcohol inebriation. Higher concentrations can have a narcotic effect. Deaths occurring after heavy exposure have been attributed to ventricular fibrillation. Found to induce hepatocellular carcinomas in mice. Dichloroacetylene (see below) is known to be toxic and, in its pure form, explosive. Use in a fume hood.

Preparation of Dichloroacetylene.

A dichloroacetylene-ether complex is readily prepared from trichloroethylene with ***Lithium Hexamethyldisilazide*** in hexanes at -78 °C[1] or with ***Potassium Hydride*** and catalytic methanol in THF at room temperature.[2] Alternatively, the dichloroacetylene-ether complex can be obtained from a mixture of trichloroethylene and diethyl ether in an aqueous solution of ***Sodium Hydroxide*** in the presence of either a phase transfer catalyst[3] or a catalytic amount of ***Dimethyl Sulfoxide***.[4]

Dichloroacetylene reacts with tertiary ketone or ester enolates to give chloroethynyl adducts in 64-90% yields.[5] The chloroethynyl group can be converted to the ethynyl derivative using ***Copper*** powder in HOAc/THF, or can be directly reduced (H_2/Lindlar catalyst) to the vinyl derivative (eq 1).[5] This method is limited to tertiary enolates.

Additional enolate addition/elimination reactions with chloroacetylenes that yield alkynyl derivatives have been reported for ***1-Chloro-2-phenylacetylene***[5] and 1-chloro-2-phenylthioacetylene.[5] Similar alkynylations have been reported for tertiary β-dicarbonyl enolates using alkynyllead triacetates[6] or alkynyliodonium tetrafluoroborates.[7] Direct vinylations have been reported using alkenyllead triacetates,[8] vinyl halides and nickel catalysis,[9] or enol ether iron complexes.[10]

Dichloroacetylene reacts with alkylthiolates under mild conditions to yield bis(alkylthio)acetylenes (eq 2).[11]

Preparation of Alkynic Ethers.

Secondary alcohols, on treatment in THF with 2 equiv of potassium hydride and trichloroethylene, followed by ***n-Butyllithium*** and a primary iodide (or water), are converted in 66-87% yield to alkynic ethers (eq 3).[12] The potassium alkoxides react with trichloroethylene first to generate and then to add to dichloroacetylene. The resulting dichloro enol ethers on treatment with *n*-butyllithium are converted to the corresponding acetylides, which are then either alkylated or protonated.

Reaction with Other Nucleophiles.

Trichloroethylene reacts with the enolate of 2,6-dimethylcyclohexenone (***Lithium Diisopropylamide***, HMPA, in THF, -78 °C) to yield the dichlorovinyl adduct (**1**) in 60% yield.[5,13] While the dichlorovinyl adduct may serve as a masked ethynyl group,[13] the reagent of choice is the independently generated dichloroacetylene described above. Under more vigorous conditions (***Sodium Hydride***, HMPA, refluxing THF) the tertiary enolate of diethyl ethylmalonate reacts to give dichlorovinyl adduct (**2**) in 64% yield.[5] These reactions have been demonstrated to proceed through the in situ generation of dichloroacetylene.[14] Comparable reactions have been reported for

CClF=CHCl,[5] CF_2=CHF,[15,16] CF_2=CH_2,[16] and ***Chlorotrifluoroethylene***.[16]

(1)

(2)

Trichloroethylene reacts with ***Sodium Amide*** and excess dimethylamine to yield bis(dimethylamino)acetylene (eq 4).[17] With lithium dialkylamides in ether as the base in the presence of excess dialkylamines, the intermediate 1,2-dichloro dialkyl enamines or chloro ketene aminals can be isolated (eq 5).[18] Trichloroethylene also reacts with secondary aliphatic amines in the presence of an aqueous solution of NaOH and a catalytic quantity of ***Benzyltriethylammonium Chloride*** to give glycinamides (eq 6).[19]

(4)

(5)

(6)

Trichloroethylene will undergo palladium-catalyzed coupling with arylmagnesium halides to yield (*Z*)-1,2-dichloroethylenes (eq 7).[20] Under alternate conditions with alkylmagnesium halides, 1,1-dichloroalkenes are obtained (eq 8).[21]

2,2,2-Trichloroethyl Phosphorodichloridate

[18868-46-7] · $C_2H_2Cl_5O_2P$ · 2,2,2-Trichloroethyl Phosphorodichloridate · (MW 266.26)

(preparation of phospholipids via phosphotriester intermediates)

Physical Data: mp 28-30 °C.

Form Supplied in: white solid; commercially available.

Preparative Method: a solution of ***2,2,2-Trichloroethanol*** (1 equiv), ***Triethylamine*** (1 equiv) in THF is added to a solution of ***Phosphorus Oxychloride*** (1 equiv) at -70 °C.[1]

Preparation of Phospholipids.

2,2,2-Trichloroethyl phosphorodichloridate (**1**) is a convenient source of phosphate for the synthesis of oligonucleotides. The reaction of (**1**) with amines provides phosphoramidochloridates, which are reacted with glycerols to provide phosphotriesters. The amine and trichloroethanol protecting groups can be efficiently and selectively cleaved, providing phospholipids.

An example of this strategy is the reaction of (**1**) with aniline to provide the phosphoramidochloridate (**2**).[2] Reaction of phosphoramidochloridate (**2**) with 1,2-distearoylglycerol (**3**) afforded phosphotriester (**4**) (eq 1). Both protecting groups were selectively removed in subsequent steps.[3]

Trichloroiodosilane

Cl_3SiI

[13465-85-5] · Cl_3ISi · Trichloroiodosilane · (MW 261.34)

(selective ether-cleaving reagent;[1] also cleaves acetals;[1,2] mediates reaction of aromatic aldehydes with nitriles to yield secondary amides;[3] aromatic aldehydes and acrylonitrile give iminoaldehydes[4])

Physical Data: bp 114.5 °C/760 mmHg; mp <-60 °C.

Preparative Methods: prepared through halogen exchange by heating $SiCl_4$ and ***Sodium Iodide*** in methylene chloride-acetonitrile or toluene-acetonitrile.[1] It also has been prepared by the reaction of $SiCl_4$ and ***Hydrogen Iodide***,[5] by heating $SiHCl_3$ with ***Iodine***,[5] and by heating silicon with ICl.[6]

Handling, Storage, and Precautions: Cl_3SiI is a moisture-sensitive material; it could be conveniently used in situ. Use in a fume hood.

Ether Cleavage.

An important application of Cl_3SiI is in regiospecific and selective cleavage of alkyl-alkyl and alkyl-aryl ethers. Primary-secondary alkyl ethers are cleaved to yield primary alkyl iodide and secondary alcohol on workup. This cleavage pattern is opposite to that of boron halides like ***9-Bromo-9-borabicyclo[3.3.1]nonane***[7] and ***Boron Tribromide***,[8] which yield secondary bromide and primary alcohol (eq 1). Compared to ***Iodotrimethylsilane***, Cl_3SiI shows a greater degree of regiospecificity and slightly faster rate of reaction.[1]

(1)

Selective cleavage of diethers is possible with this reagent (eq 2).

Miscellaneous Transformations.

Aromatic aldehydes and nitriles like ***Acetonitrile*** or benzonitrile are converted by Cl_3SiI to secondary amides, through a redox reaction (eq 3). When ***Acrylonitrile*** is used instead, the product is an imino aldehyde (eq 4).

Trichloroisocyanuric Acid[1]

[87-90-1] · $C_3Cl_3N_3O_3$ · Trichloroisocyanuric Acid · (MW 232.41)

(powerful chlorinating agent for sulfides,[3,4] amides and imides,[5] aromatic compounds,[6] ketones,[7] and ethers;[8] oxidizing agent for secondary alcohols,[9] ethers,[10] alkenes,[11] and oximes[12])

Alternate Names: TCICA; 1,3,5-trichloro-1,3,5-triazine-2,4,6(1*H*,3*H*,5*H*)-trione; trichloro-*s*-triazinetrione; isocyanuric chloride.

Physical Data: mp 249-251 °C.

Solubility: 0.2% in H_2O; very sol acetonitrile; sol acetone, acetic acid, ethyl acetate; sl sol benzene, chloroform, methylene chloride.

Form Supplied in: white granular solid; widely available for swimming pool use; purity 97-99%; available chlorine 88-91% as measured by iodometric titration.[2]

Analysis of Reagent Purity: mp or iodometric titration.

Purification: can be recrystallized from 1,2-dichloroethane or benzene.

Handling, Storage, and Precautions: moisture sensitive, but may be stored under nitrogen at rt for over a year. The dust is extremely destructive to mucous membranes and upper respiratory tract, eyes, and skin. This reagent has been reported to explode after a delay period when in contact with alcohols, amines, or dialkyl sulfoxides, or when contaminated with organic compounds. As with other strong oxidizing agents, it should be added to a solvent.

Chlorination Reactions.

Trichloroisocyanuric acid is an inexpensive, convenient, and effective chlorinating and oxidizing agent. It is more reactive than other *N*-chloro compounds and can often be used in place of chlorine. The cyanuric acid formed as a byproduct is easily removed by filtration.

Allyl phenyl sulfides are converted to 1-(phenylthio)-3-chloro-1-alkenes, which are acrolein synthons (eq 1).[3] Alkyl phenyl sulfides are dichlorinated to 1,1-dichloroalkyl phenyl sulfides.[4] In acetonitrile at rt, amides and imides are chlorinated at nitrogen.[5] Aromatic compounds are chlorinated on the ring or benzylic position.[6] Ketones are converted to α-chloro ketones[7] (see also ***Chlorine***, ***N-Chlorosuccinimide***, and ***Sulfuryl Chloride***). Dry cyclic ethers give 2,3-dichloro cyclic ethers.[8]

(1)

Oxidation Reactions.

Secondary alcohols are rapidly oxidized to ketones in acetone containing pyridine[9] (see also ***N-Bromosuccinimide***, ***N-Chlorosuccinimide***, ***Potassium Dichromate***, ***Potassium Permanganate***, ***Pyridinium Chlorochromate***, ***Sodium Dichromate***, and ***Sodium Hypochlorite***). Esters are formed by oxidation of ethers in the presence of water.[10] Alkenes react to form chlorohydrins in acetone containing acetic acid and water.[11] Oximes are converted to *gem*-chloronitro compounds (eq 2).[12]

(2)

Other Applications.

N,N´-Disubstituted carbodiimides are produced on treatment of *N,N´*-disubstituted thioureas with trichloroisocyanuric acid in the presence of pyridine or aqueous NaOH.[13] Dithioacetals are converted to ketones by the action of trichloroisocyanuric acid and ***Silver(I) Nitrate*** in aqueous acetonitrile.[14]

Trichloromethyl Chloroformate[1]

[503-38-8] · $C_2Cl_4O_2$ · Trichloromethyl Chloroformate · (MW 197.82)

(convenient substitute for phosgene; an effective reagent for the synthesis of isocyanates,[2] carbamoyl chlorides,[3] carboxylic acid chlorides,[4] *N*-carboxy-α-amino acid anhydrides,[5] chloroformates,[6] carbonates,[7] isocyanides,[8] nitriles,[9] and various heterocyclic compounds)

Alternate Names: diphosgene; TCF

Physical Data: bp 128 °C, 53-55 °C/53 mmHg; *d* 1.65 g cm^{-3}.

Solubility: sol most organic solvents, but insol water.

Form Supplied in: commercially available as a colorless liquid.

Analysis of Reagent Purity: IR (neat) 1815, 1054, 968, 912, 814, and 764 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ 143.9 and 108.4.

Preparative Method: most conveniently prepared by photochlorination of methyl chloroformate.[10]

Purification: distillation at reduced pressure is recommended to avoid possible decomposition to phosgene which occurs at elevated temperatures.[10]

Handling, Storage, and Precautions: although the vapor pressure is low, care should be taken to handle this toxic compound, as in the case of phosgene.[11] It readily decomposes to phosgene in some cases, particularly rapidly on contact with activated charcoal or iron(III) oxide. It is best to store the reagent in a refrigerator to avoid spontaneous decomposition. The reagent should be used in a fume hood.

Carbonylation of Amines to Form Isocyanates.

Both aromatic and aliphatic primary amines (as the free amines or hydrochlorides) give the corresponding isocyanates on treatment with TCF. As in the case of other reactions of TCF, inert solvents such as THF, dioxane, dichloromethane, 1,2-dichloroethane, benzene, and toluene are commonly used. Phenyl isocyanate, for example, is prepared from aniline and 0.5 molar amount of TCF in dioxane (eq 1).[2] In a similar manner, diisocyanates are readily derived from diamines.

(1)

Various kinds of isocyanates are prepared from esters of α-amino acids by heating with TCF in toluene in the presence of activated charcoal, which promotes the decomposition of TCF to phosgene. Use of amine hydrochlorides may be effective to avoid the formation of 1,3-disubstituted ureas.[12]

Secondary amines give carbamoyl chlorides, as exemplified by the formation of bis(2-chloroethyl)carbamoyl chloride.[3] Monochloroformylation takes place with a urea (eq 2).[13] TCF is also useful for synthesizing various kinds of heterocycles including cyclic ureas,[14] pyrazolooxadiazines,[15] and oxadiazolinones[16] from amine derivatives.

(2)

Synthesis of Acid Chlorides.

Carboxylic acids are easily converted into acid chlorides by the action of TCF. Benzoic acid gives benzoyl chloride when heated with TCF.[4] Treatment of amino acids with TCF results in the formation of isocyanato acid chlorides. 3-Aminopropanoic acid, for example, gives 3-isocyanatopropanoyl chloride (eq 3).[2,10] 2-Isocyanatobenzoyl chloride is prepared similarly from anthranilic acid in 85% yield in the presence of ***Phosphorus(V) Chloride***,[2] although anthranilic acid and the pyridine analogs are cyclized to anhydrides by TCF quantitatively in the absence of PCl_5 (eq 4).[2,17]

(3)

(4)

Synthesis of *N*-Carboxy-α-amino Acid Anhydrides (NCAs) from α-Amino Acids.

Various α-amino acids afford NCAs on treatment with TCF in an appropriate solvent such as THF, and addition of activated charcoal has been suggested to improve the synthesis (eq 5).[5] The reactions, however, proceed smoothly in some cases in the absence of activated charcoal, as evidenced by the quantitative formation of NCAs. Starting from L-glutamic acid, a seven-membered γ-NCA is produced instead of the ordinary five-membered NCAs.[18]

(5)

Synthesis of Chloroformates and Carbonates from Alcohols.

Chloroformates are readily prepared from aromatic or aliphatic alcohols and TCF in high yields.[19] *N*-Hydroxyphthalimide is also converted into the chloroformate quantitatively.[6]

Depending on the reaction conditions (particularly in aqueous alkali solution), however, symmetric carbonates are obtained.[7] When bisphenols in aqueous alkali are treated with TCF in 1,2-dichloroethane in the presence of a phase-transfer catalyst, polycarbonates can be synthesized.[20]

Both 1,2- and 1,3-diols favorably cyclize with TCF to form carbonates. For instance, methyl α-L-rhamnoside gives a five-membered cyclic carbonate almost quantitatively with TCF in pyridine (eq 6).[21] Similarly, 1,3-diols form six-membered cyclic carbonates.[22]

(6)

When 2-aminoethanol and 3-aminopropanol are treated with TCF in dioxane, isocyanato chloroformates are synthesized. In the reaction with 2-aminoethanol at 55 °C, however, a cyclic carbamate, 2-oxazolidinone, is also obtained as a minor product.[2] Amino alcohols, prepared by reducing α-amino acids, are converted into oxazolidinones efficiently at -15 °C (eq 7).[23] 2-Aminobenzyl alcohol gives rise to a six-membered cyclic carbamate in a similar way.[24]

(7)

Dehydration of Formamides and Amides to Isocyanides and Nitriles.

Dehydration of *N*-alkyl- or *N*-arylformamides with TCF or phosgene is an effective way to synthesize isocyanides (eq 8), and the yields are generally higher with TCF than with phosgene, as shown in Table 1.[8]

(8)

Table 1 Synthesis of Isocyanides (RNC) from Formamides (RNHCHO)

R	Yield (%) with TCF	Yield (%) with phosgene
t-Bu	97	82
Cy	98	88
Bn	95	82
4-$MeOC_6H_4$	95	64

Aromatic diisocyanides can be synthesized in a similar manner.[25] In the preparation of unstable diisocyanides such as *o*-diisocyanobenzene, however, the reaction should be carried out at low temperatures, and the yield is improved to 92% by starting at -78 °C from 26% at rt.[26]

Both aromatic and aliphatic amides are dehydrated with TCF in ***Trimethyl Phosphate*** to give nitriles in high yields (eq 9).[9] This preparative procedure is superior to the conventional transformation carried out with ***p-Toluenesulfonyl Chloride*** in pyridine.

$$RCONH_2 \xrightarrow[\text{0-60 °C, 97\%}]{\text{TCF, } (MeO)_3PO} RCN \qquad (9)$$

Miscellaneous Reactions.

In the Swern oxidation using the combination ***Dimethyl Sulfoxide-Oxalyl Chloride***, the latter may be replaced by TCF to facilitate the reaction. Various aldehydes and ketones are thus synthesized from primary and secondary alcohols in moderate to high yields.[27]

Direct introduction of a chloroformyl group is possible by heating acid chlorides with TCF at 225 °C. 2-Methylpropanoyl chloride, for example, affords dimethylmalonyl chloride in 70% yield. Cyclohexanecarbonyl chloride gives 1,1-cyclohexanedicarboxylic acid in 81% yield by treating with TCF followed by hydrolysis.[28] Some alcohols, including benzyl and *t*-butyl alcohols, are transformed into the corresponding chlorides by chlorination with TCF.[2,29]

Trichloromethylisocyanide Dichloride[1]

$Cl_3C\text{-}N{=}CCl_2$

[29164-55-4] · C_2Cl_5N · Trichloromethylisocyanide Dichloride · (MW 215.28)

(strong chlorinating agent; used as a reagent in forming heterocycles and dehydrating amides[1,2])

Physical Data: bp 59-60 °C/12 mmHg; *d* 1.698 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: liquid; must be synthesized.

Preparative Methods: synthesized by chlorinating triethylamine hydrochloride (in low yields)[5] and, in better yields, with *N,N*-dimethylcarbamoyl chloride (**1**) at 250 °C (eq 1).[5,6]

Purification: redistil under reduced pressure.[3]

Handling, Storage, and Precautions: corrosive; moisture and air sensitive. Store under an inert atmosphere (see Aldrich safety index for phosphorus pentachloride[4]).

Chlorination of Functional Groups.

Trichloromethylisocyanide dichloride has been extensively used for the chlorination of functional groups.[1] Alcohols, carboxylic and sulfonic acids, aldehydes, and phosphorus pentasulphide are converted to alkyl chlorides (**2**), acid and sulfonic chlorides (**3**,**4**), alkyl dichlorides (**5**), and phosphorus thiochloride (**6**),[7] respectively (eqs 2-6).

Synthesis of Heterocycles.

Various heterocycles have been synthesized using trichloromethylisocyanide dichloride, normally involving a double nucleophilic attack from various substrates such as nitriles,[8] hydrazines,[9] and aromatic amines[10] (eqs 7-10).

X = NR; O, 90%

Heterocycles have also been formed by activating a carboxylic acid or amide towards cyclization with an amide by using trichloromethylisocyanide dichloride (eq 11).[1]

(11)

Dehydration of Amides.

Trichloromethylisocyanide dichloride has also been used to dehydrate amides in good yields (eq 12).[1]

Trichloromethyllithium

Li-CCl_3

[2146-66-9] · CCl_3Li · Trichloromethyllithium · (MW 125.30)

(dichlorocyclopropanation and for nucleophilic trichloromethylation)

Physical Data: low-temperature ^{13}C and ^{6}Li NMR data are available,[1] as are matrix IR data.[2]

Preparative Methods: solutions of the title compound can be obtained by treatment of ***Chloroform*** with ***n-Butyllithium*** in THF/ether/pentane (4:1:1) or ether/pentane (1:1) at -110 °C for 20 min.[3] Alternatively, CCl_4 or $BrCCl_3$ may be treated with ***Methyllithium*** or *n*-BuLi in THF/ether/petroleum ether mixtures at -110 °C.[4] The TMEDA complex with $LiCCl_3$ can be prepared by reaction of either $CHCl_3$ or $BrCCl_3$ with the *n*-BuLi.TMEDA complex in isopentane at -108 °C.[5] Deprotonation of $CHCl_3$ with lithium dimethylamide in THF/HMPA at -105 °C does not proceed cleanly.[6]

Handling, Storage, and Precautions: generally stable from -110 °C to about -80 °C, depending on the solvent. There is evidence that carbenoids of this nature show greater thermal stability in THF than in ether.[7] At -70 °C, solutions turn from clear to dark brown with a dark brown-black precipitate. Isolation of the decomposition products reveals what appear to be carbene-derived compounds.[3b] In contrast, the TMEDA complex is stable above -80 °C and decomposes to a brown-black solid material at -60 °C. When the reagent is generated in the presence of LiBr, a rapid exchange to give Li-$CBrCl_2$ occurs.[4b] The reagent is probably best generated from lithium halide-free solutions of alkyllithiums.

General Considerations.

Alkyllithiums bearing halogens on the α-carbon are frequently referred to as carbenoids, reflecting a major mode of reactivity. Good general reviews of such species are available.[8] At very low temperatures, however, the reagent reacts like a typical alkyllithium. The accumulated data suggest that there may be more than one isomeric form of $LiCCl_3$. In solution a C-Li structure is present, as shown by the observation of Li-C *J* coupling in the ^{13}C NMR spectrum.[3a] A calculational study suggests that the reagent may also exist as the rather unusual triply bridged species (**1**).[9] It should be noted that Li-CCl_3 has been studied much more intently than the analogous Li-CBr_3, perhaps due to the greater thermal stability of the former. However, the reagents are not analogous in all of their reactions.

(1)

Cyclopropanations.

Formal loss of LiCl from Li-CCl_3 would provide dichlorocarbene and, indeed, when alkenes are added to solutions of Li-CCl_3 at around -70 °C, rapid reaction occurs resulting in dichlorocyclopropanes.[3c,4b,10,11] Alkene geometry is maintained in these reactions. The situation appears to involve conversion to **:**CCl_2 and subsequent cyclopropanation.[12] The TMEDA.$LiCCl_3$ complex is more stable in the presence of alkenes and gives dichlorocyclopropanes only slowly at -78 °C, requiring extended periods of time (eq 1).[13]

Similarly, reaction of Li-CCl_3 with alkynes provides the dichlorocyclopropenes (**3**), which can be hydrolyzed to cyclopropenones (**4**) in overall yields of about 20% (eq 2).[14]

Nucleophilic Trichloromethylation.

Li-CCl_3 reacts as a nucleophile within its temperature limitations. Electrophiles which require reaction temperatures higher than about -70 °C will not react well with the reagent. Yamamoto has partially solved the problem by generating the lithium reagent via deprotonation of $CHCl_3$ with amide base in the presence of carbonyl compounds, resulting in trichlorocarbinols (eq 3).[15] While this appears to be a general reaction between haloalkyllithiums and aldehydes and ketones, reactions of Li-CCl_3 have only been reported with cyclohexanone and cyclopentanone. However, using CCl_4/*n*-BuLi generating conditions, Blumbergs reported the addition of Li-CCl_3 to phenyl cyclobutyl ketone and phenyl isopropyl ketone to provide adducts (**5**) and (**6**) in 44% and 54% yields, respectively.[16] There is a single report of the nonselective addition of Li-CCl_3 to 2-cyclopenten-1-one in low yield.[17]

(5) R = cyclobutyl, 44%
(6) R = isopropyl, 54%

Transformations of Trichloromethylcarbinol Adducts.

Trichloromethylcarbinols serve as intermediates in the production of 1,1-dichloroalkenes and alkynes via a β-elimination process, as well as in a homologation process via an α-elimination to produce α-chloro ketones.[18] A trichloromethylcarbinol adduct (**7**) from an aldehyde or ketone can be converted to a methyl or a trimethylsilyl ether (**8**) via *O*-alkylation. This can be treated with *n*-BuLi to provide the lithium reagent (**9**) which undergoes Fritsch-Buttenberg-Wiechell rearrangement to (**11**) or it may undergo loss of RO-Li to give (**10**), depending on the identity of R^1, R^2, and R^3 (eq 4). The reactivity observed appears to be linked to the sizes of the three R groups. Large alkyl groups favor the rearrangement process leading to chloro ketones. When R^1 = H and R^2 is not too large, dichloroalkenes and alkynes result.

Counterions Other than Li.

The analogous reagents $NaCCl_3$ and $KCCl_3$ have also been prepared by deprotonation of $CHCl_3$ using the requisite metal hexamethyldisilazide.[19] No significant chemical reactivity was reported.

Related Reagents.

Dibromomethyllithium; ***Dichloromethyllithium***; ***Tribromomethyllithium***.

Trichloroperoxyacetamidic Acid

[84694-15-1] · $C_2H_2Cl_3NO_2$ · Trichloroperoxyacetamidic Acid · (MW 178.40)

(oxygen atom transfer reagent that is useful for the epoxidation of alkenes at a neutral pH[8])

Physical Data: not isolated; prepared in situ.

Solubility: sol standard organic solvents such as CH_2Cl_2.

Preparative Methods: ***Trichloroacetonitrile*** (8.5 g, 0.049 mol) and 5-methyl-5-hepten-2-one (3.72 g, 0.029 mol) in 40 mL of methylene chloride were added dropwise to a stirring solution of 5.0 mL of 30% ***Hydrogen Peroxide*** (0.44 mol). The H_2O_2 solution was adjusted to pH 6.8 by the addition of 2.25 g of K_2HPO_4 prior to addition. The biphasic mixture was magnetically stirred at room temperature while the depletion of alkene was monitored by GLC (6 ft column, 10% UCW on Chromosorb W, 130 °C). After 3 h, 25 mL of pentane was added, and the precipitated trichloroacetamide was removed by filtration through a fritted disk and washed with pentane. More complete removal of the trichloroacetamide may be achieved by chilling the reaction mixture prior to filtration. The filtrates were washed with water (20 mL), cold 3% Na_2SO_3 solution (25 mL), and brine (25 mL), and then dried ($MgSO_4$). The solvents were removed by aspiration, and the yellow residue was fractionally distilled to afford 3.35 g (80%) of epoxide, bp 42-42.5 °C/20 mmHg).

Handling, Storage, and Precautions: this reagent is generated in situ and is not stable to storage.

Alkene Epoxidation.

Epoxides are typically prepared from alkenes on a laboratory scale by the action of organic peroxides and metal catalysts or by oxidation with a peroxy acid.[1,2] The more commonly used commercially available oxidants for the epoxidation of simple alkenes include ***Peracetic Acid***, ***m-Chloroperbenzoic Acid*** (*m*-CPBA), and ***Monoperoxyphthalic Acid***, magnesium salt hexahydrate (MMPP). ***Trifluoroperacetic Acid*** is one of the most reactive peroxy acids, but it suffers the disadvantage of having to be prepared in situ by the action of trifluoroacetic anhydride and 90% hydrogen peroxide.[3] The resulting solution is highly acidic and can have a deleterious effect upon the yield of epoxide.

Although hydrogen peroxide is not sufficiently electrophilic to directly epoxidize a nonconjugated carbon-carbon double bond, its reactivity may be enhanced by placing the OOH moiety in conjugation with a multiple bond, as exemplified by a peroxy acid (**1**).[4]

(1)

(2)

One of the earliest and most useful adaptations of this concept was accomplished by Payne.[5] He successfully activated the O-O bond by the in situ formation of a peroxyimidic acid (**2**) resulting from the base-catalyzed addition of H_2O_2 to a nitrile. Both aceto- and benzonitrile were employed as coreactants in the epoxidation of a variety of alkenes in methanol solvent. More recently, Rebek[6] and co-workers have developed a number of reactive oxidizing reagents resembling (**1**) and (**2**) and related activated hydroperoxides.

The mechanism of alkene epoxidation involves a bimolecular nucleophilic attack of the alkene (HOMO) on the antibonding σ* orbital of the O-O bond.[7] Consequently, heterolytic cleavage of the peroxide bond is facilitated by electron-withdrawing groups on the multiple

bond. A trichloromethyl substituent increases the reactivity of a peroxy acid and a peroxyimidic acid.[8] Reaction of 30% aqueous H_2O_2 with the electron-deficient nitrile trichloroacetonitrile affords a highly efficient oxygen transfer reagent that can compete with *m*-CPBA on both a cost and reactivity basis (eq 1).

(1)

The rate of epoxidation is faster with more highly substituted and strained alkenes. Trichloroperoxyimidic acid (**3**) is sufficiently reactive to effect epoxidation of the terminal alkene 1-nonene (71%). This reagent will also epoxidize the deactivated double bond of α,β-unsaturated ketones in a highly chemoselective manner without affording products derived from a Baeyer-Villiger oxidation (eq 2).

(2)

Another unique feature of the reagent is its ability to epoxidize 1-cyclopenteneacetonitrile without disturbing the nitrile functional group. The oxygen transfer reaction is stereospecific, as evidenced by the formation of only the (*Z*)-epoxide from (*Z*)-stilbene, and the (*E*)-epoxides from (*E*)-cinnamyl alcohol, (*E*)-stilbene, and (*E*)-cyclooctene. The procedure is readily adaptable to the large-scale syntheses of epoxides. For example, 50 g (0.45 mol) of *cis*-cyclooctene on treatment with 1.5 equiv of CCl_3CN and 3 equiv of H_2O_2 (pH 6.8) afforded 48.0 (84%) of *cis*-cyclooctene oxide. On a 2 molar scale the yield of epoxide was 76%.

One potential disadvantage of this procedure from an operational perspective is the fact that it operates in a very narrow pH range. An increase in pH favors the formation of (**3**), but a competing reaction with the anion of H_2O_2 reduces the concentration of active oxygen (eq 3). The formation of dioxygen is pH dependent. Maintaining the optimal pH is best achieved by the use of a pH meter. The mechanism for the addition of H_2O_2 to a nitrile has been studied by Wiberg[9a] in the pH range 7-8 and by McIsaac and his co-workers[9b] at a pH of 9.75. The rate limiting step for oxygen atom transfer is the nucleophilic attack of (**3**) on the carbon-carbon double bond.[9c]

Trichlorosilane[1]

Cl_3SiH

[10025-78-2] · Cl_3HSi · Trichlorosilane · (MW 135.45)

(reducing agent; hydrosilating agent; precursor of trichlorosilane radical)

Physical Data: mp -126.5 °C; bp 31-32 °C; *d* 1.342 g cm^{-3}.

Solubility: sol benzene, carbon disulfide, chloroform, carbon tetrachloride; dec by water.

Form Supplied in: high quality colorless liquid.

Purification: can be purified by treatment with quinoline to remove hydrogen chloride followed by distillation, first at atmospheric pressure and then under vacuum.

Handling, Storage, and Precautions: this reagent is highly flammable and corrosive; should be stored in the absence of moisture and handled in a fume hood.

Functional Group Reductions.

Trichlorosilane has often been used together with tertiary amines (usually ***Tripropylamine*** or ***Tri-n-butylamine***) to reduce the carbonyl groups of aromatic aldehydes, ketones, acids, amides, acid chlorides, and anhydrides to give the corresponding benzylic trichlorosilanes (eq 1);[1] this is referred to as reductive silylation. The mechanism of this reaction remains unclear; however, studies indicated the possible formation of the trichlorosilyl anion by the action of tertiary amines on trichlorosilane (eq 2).[2] The adduct (**1**) was proposed based on the known propensity of tetracoordinated silicon to form five or six-coordinate complexes.[3] This method provided a new way to form silicon-carbon bonds and, more importantly, the benzylic trichlorosilane products can be cleaved by base treatment to give toluenes. This transformation can be carried out without isolation of the intermediate organosilane (eq 3).[4]

(1)

$$Cl_3SiH + R_3N \rightleftharpoons \underset{\textbf{(1)}}{[R_3N\text{-}SiHCl_3]} \rightleftharpoons R_3NH^+ + {}^-SiCl_3 \qquad (2)$$

Aromatic esters are unaffected during this reduction; consequently it is possible to effect selective reduction of half-esters (eq 4).[5]

In contrast to the above results, reduction of aldehydes and ketones with premixed trichlorosilane and lithium derivatives of phenols or 1,2-diols gives the corresponding alcohols; pentacoordinate hydridosilicates (such as **2**) are believed to function as the reducing agent (eqs 5 and 6).[6]

It has also been found that the trichlorosilyl radical is generated in the presence of radical initiators (hν, ***1,1-Di-t-butyl Peroxide***). This radical readily reacts with aliphatic carboxylates (eq 7)[7] and acetals[8] to give dialkyl ethers, and with alkyl halides[9] and acid chlorides[10] to give alkanes. The reaction is believed to proceed by a radical chain mechanism.

Trichlorosilane also reduces enamines (eq 8)[11] and imines[12] to the corresponding amines; one-step hydroamidation of a Schiff base gives the acetamide (eq 9).[13]

(8)

(9)

Reduction of carbamates and isocyanates with trichlorosilane give isocyanides.[13] This provides a relatively simple method for synthesis of vinyl isocyanides from alkenes (eq 10).[14] Due to the mild conditions of the reductions, it has been applied in the resolution of alcohols. Along this line, diastereomeric carbamates obtained by treating racemic alcohols with optically pure isocyanates are separated and reduced to give the desired (*R*)- and/or (*S*)-alcohols (eq 11).[15] This method has been extensively used, such as in the enantioselective syntheses of (+)-sterpurene,[16] NRDC 182,[17] ascofuranone, and ascofuranol.[18]

(10)

(11)

Hydrosilation.

The additions of trichlorosilane to alkenes and alkynes usually are highly stereoselective[19] and can be effected under a wide variety of conditions. For example, the additions can be brought about thermally,[20] or by using metal complexes (eq 12).[21] In the presence of chiral catalysts, additions proceed enantioselectively.[22] It has been demonstrated that the trichlorosilyl group is a synthetic equivalent for the OH, Cl, and Br groups.[23]

(12)

The addition can also be carried out under radical conditions.[24] The trichlorosilyl radical is more electrophilic than trialkylsilyl radicals, and adds faster to both alkenes and carbonyl groups (eqs 13 and 14).[25]

(13)

(14)

Reaction with Halides.

Organic halides undergo a variety of transformations in the presence of trichlorosilane, depending upon the reaction conditions. One of the most important applications is the formation of allylsilanes (eqs 15 and 16).[26]

(15)

(16)

Reaction with Sulfur and Phosphine Compounds.

Trichlorosilane is also used for the reduction of phosphine oxides to phosphines (eq 17).[27] Sulfenyl, sulfinyl, and sulfonyl chlorides are reduced to symmetrical disulfides.[28]

Triethoxydiiodophosphorane

$(EtO)_3PI_2$

[59547-92-1] · $C_6H_{15}I_2O_3P$ · Triethoxydiiodophosphorane · (MW 419.98)

(Arbuzov-type intermediate; can be used as a dehydrating or condensing agent[1])

Physical Data: not isolated; prepared in situ.

Solubility: prepared and used in ether, dichloromethane, or acetonitrile.

Preparative Methods: was first prepared[1] as an unstable intermediate during the reaction between ***Phosphorus(III) Iodide*** and ***Triethyl Phosphite***. It was reported as being unstable at room temperature, decomposing to give ethyl iodide and diethyl phosphoriodate.[1] This same report also indicated that the reaction between triethyl phosphite and iodine at -5 °C gave the same two products. A subsequent report[2] described similar reactions with similar results. In 1979, it was reported[3] that the reaction between methyl phosphite and iodine at 0 °C in ether, dichloromethane, or acetonitrile gave a 1:1 adduct with a single ^{31}P NMR absorption which was assigned the triethoxydiiodophosphorane structure. This solution was stable over several days at room temperature.

Handling, Storage, and Precautions: in solution the phosphorane has a half-life of several days.

As Intermediates in the Arbuzov Reaction.[3]

Phosphoranes such as (**2**) are considered to be intermediates in the Arbuzov reaction (eq 1).

(2)

Only in exceptional cases can they be isolated, but they can be observed by ^{31}P NMR.[4] The relative stability of triethoxydiiodophosphorane allows it to be used as a dehydrating or condensing agent.[3]

Dehydrating Agent.

Benzamide and benzaldoxime have been dehydrated to benzonitrile (eqs 2 and 3) by addition of the amide or oxime to an iodine solution in dichloromethane or acetonitrile at 0 °C followed by 1 equiv of ***Triethyl Phosphite*** and 2 equiv of ***Triethylamine***.[3] Stirring for 2 hours at room temperature leads to dehydration. Ease of workup is aided by the water soluble nature of the byproducts.

(2)

(3)

Condensing Agent.

A solution of triethoxydiiodophosphorane allows the preparation of amides from amines and acids (eq 4).[3]

(4)

In the absence of the amine, a slower Arbuzov reaction takes place to give a mixed anhydride via the phosphonium salt (eq 5).[3]

(5)

This reagent has also been used as a condensing agent in the synthesis of a dipeptide from *N*-benzoyl-L-leucine and ethyl glycinate in high yield. The dipeptide obtained was entirely racemic. Addition of ***1-Hydroxybenzotriazole*** to the reaction gave the dipeptide in 83% yield and 39% ee.

Triethoxysilane

$HSi(OEt)_3$

[998-30-1] · $C_6H_{16}O_3Si$ · Triethoxysilane · (MW 164.31)

(useful reagent for the hydrosilylation of carbon-carbon multiple bonds; reducing agent for carbonyl groups)

Physical Data: bp 134-135 °C; *d* 0.89 g cm^{-3}.

Solubility: sol diethyl ether, THF, alkanes, aromatic and chlorinated solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: is moisture sensitive and should be handled in a well-ventilated hood. Contact with the eyes and skin should be avoided.

Hydrosilylation of Carbon-Carbon Multiple Bonds.

$HSi(OEt)_3$ is an efficient reagent for the hydrosilylation of alkenes, alkynes, and conjugated dienes (eq 1).[1] The reaction is promoted by a variety of transition metal catalysts, including platinum, ruthenium, and rhodium. Chloroplatinic acid hexahydrate, $H_2PtCl_6.6H_2O$ (see ***Hydrogen Hexachloroplatinate(IV)***), is by far the most widely used catalyst and has been shown to be very efficient, particularly in the hydrosilylation of alkenic substrates.[2]

The reaction is especially valuable for the introduction of functionalized groups at silicon,[3] as this cannot be achieved by simple organometallic procedures (eq 1).[4] Furthermore, the reaction may be quite regioselective and stereoselective, as in the case of the hydrosilylation of ocimene (eq 2).[5]

Reduction of Functional Groups Catalyzed by Fluoride or Alkoxide

Salts.[6]

A general and powerful reduction method of carbonyl compounds consists of using $HSi(OEt)_3$ activated by ***Potassium Fluoride*** or ***Cesium Fluoride***.[7] The reaction can proceed without solvent (eq 3)[7a] and is accelerated by polar solvents, e.g. DMSO or DMF.[8] The reduction of aldehydes and ketones is rapid at room temperature; also, esters are smoothly converted to alcohols (eq 4).[7b]

(3)

(4)

The reaction is highly chemoselective: aldehydes and ketones possessing functional groups, such as carbon-carbon double bonds, or bromo, nitro, amide, and ester groups, are reduced selectively to the corresponding alcohols (eqs 5 and 6).[7a,9]

(5)

(6)

Alternatively, solutions of $HSi(OEt)_3$ with lithium ethoxide or pinacolate may be used to convert aldehydes and ketones to alcohols.[10] Enantioselective reduction of prochiral ketones is achieved by use of a mixture of $HSi(OEt)_3$ and the dilithium salt of a chiral diol or amino alcohol.[11]

The reaction between carbonyl compounds and $HSi(OEt)_3$ is efficiently catalyzed by inorganic solid bases such as hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, at temperatures ranging from 25 to 90 °C.[12] Enones afford the corresponding 1,2-addition products.

$HSi(OEt)_3$ is easily converted into a more reactive form, namely a pentacoordinate hydridosilicate (eq 7).[13a]

$K[HSi(OEt)_4]$ reduces aldehydes, ketones, and esters in the absence of added catalyst.[13] Treatment of nonenolizable amides yields the corresponding aldehydes. Reaction with 1 equiv of isocyanate in diethyl ether or THF leads quantitatively to the potassium imidate, which can be quenched in situ (eq 8).[13b] Furthermore, use of an excess of aryl isocyanate yields to the corresponding isocyanurate.[13b]

Titanium-Catalyzed Reduction of Esters to Alcohols.

$HSi(OEt)_3$ is used stoichiometrically in conjunction with a titanium-based catalytic system, conveniently prepared by the reaction of 2 equiv of ***n-Butyllithium*** with ***Dichlorobis(cyclopentadienyl)titanium*** (eq 9).[14a]

The combination of a catalytic amount of ***Titanium Tetraisopropoxide***, an inexpensive and air-stable liquid, and $HSi(OEt)_3$ also generates an effective and mild system for the conversion of esters into primary alcohols.[14b]

Selective reduction of a great variety of esters has been achieved with these methods. The procedures represent safer and convenient alternatives to those employing reducing agents such as ***Diisobutylaluminum Hydride*** and ***Lithium Aluminum Hydride***.

Related Reagents.

(2-Dimethylaminomethylphenyl)phenylsilane; ***Diphenylsilane-Cesium Fluoride***; ***Phenylsilane-Cesium Fluoride***; ***Triethylsilane***;

Triphenylsilane.

Triethylaluminum[1]

[97-93-8] · $C_6H_{15}Al$ · Triethylaluminum · (MW 114.19)

(Lewis acid and source of nucleophilic ethyl groups;[2-5] couples with alkenyl halides in the presence of a transition metal catalyst;[8-11] selective hydrocyanation agent in combination with HCN[12])

Physical Data: mp -58 °C; bp 62 °C/0.8 mmHg; *d* 0.835 g cm^{-3} (25 °C).

Solubility: freely miscible with saturated and aromatic hydrocarbons; reacts violently with H_2O and protic solvents.

Form Supplied in: as a neat liquid in a stainless container or as a solution in hydrocarbon solvents (hexane, heptane, toluene).

Analysis of Reagent Purity: brochures from manufacturers, describe an apparatus and method for assay.

Handling, Storage, and Precautions: indefinitely stable under an inert atmosphere. The neat liquid or dense solutions are highly pyrophoric. Solutions more dilute than a certain concentration are not pyrophoric and are safer to handle. The nonpyrophoric limits are 13 wt % in isopentane, 12 wt % in hexane, and 12 wt % in heptane, respectively. Use of halogenated hydrocarbons as solvents should be avoided because of possible explosive reactions sometimes observed for mixtures of CCl_4 and organoaluminums.

Ethylation.

Et_3Al, like other organoaluminums, can act as a Lewis acid to activate Lewis basic functionalities and also as a captor of electrophilic species by ethylation, as illustrated in eq 1.[2] Substitution reactions of glycosyl fluorides (eq 2)[3] and bromides[4] can be effected with Et_3Al. γ-Lactols react with Et_3Al in the presence of ***Boron Trifluoride Etherate*** to deliver 2,5-disubstituted tetrahydrofurans stereoselectively (eq 3).[5]

(3)

trans:*cis* = 13:1

Conjugate addition of Et_3Al to 2-nitrofurans provides, after hydrolysis, dihydro-2(3*H*)-furanones (eq 4).[6] Regioselective addition of Et_3Al to unsymmetrical 1,1´-azodicarbonyl compounds has been reported.[7]

(4)

Cross coupling of Et_3Al with aryl phosphates[8] or alkynyl bromides[9] proceeds with a Ni catalyst to provide alkylated arenes or alkynes (eqs 5 and 6). While Pd or Cu complexes are used as the catalyst for the coupling of Et_3Al with carboxylic acid chlorides or thioesters (eq 7),[10] ***Iron(III) Chloride*** is used for reactions of propargyl acetates to give substituted allenes (eq 8).[11]

(5)

(6)

(7)

(8)

Lewis Acid.

Et_3Al-***Hydrogen Cyanide*** and ***Diethylaluminum Cyanide*** are two optional reagents for conjugate hydrocyanation of α,β-unsaturated ketones.[12,13] The results from these two reagents often differ. Due to a rather slow reaction rate between Et_3Al and HCN, the former reagent contains a proton source (HCN) which can quench aluminum enolate intermediates. An impressive example is shown in eq 9. Preformed Et_2AlCN gives *cis*-isomer, whereas HCN-Et_3Al leads to *trans*-isomer.[14] A variant involves trapping of the enolates as TMS ethers by use of ***Cyanotrimethylsilane***-Et_3Al (eq 10).[14]

The HCN-Et_3Al system has been used to cleave oxiranes in steroids[15a] or carbohydrates (eq 11) to give β-cyano alcohols.[15b]

The ate complex, formed on metalation of allyl *i*-propyl ether with ***s-Butyllithium*** followed by addition of Et_3Al, reacts with carbonyl compounds at the α-position in *syn*-selective manner (eq 12).[16]

Rearrangements.

Allyl vinyl ethers undergo [3,3]-sigmatropic rearrangements promoted by Et_3Al, which also effects subsequent ethylation of the resulting aldehydes (eq 13). Use of ***Triisobutylaluminum*** leads to primary alcohols by β-hydride reduction.[17]

Alkylative Beckmann rearrangements of oxime sulfonates are promoted by trialkylaluminums. The rearrangements give the imines, which are reduced with ***Diisobutylaluminum Hydride*** to the corresponding amines (eq 14).[18] Related alkylative Beckmann fragmentations have also been reported.[19]

(14)

Et_3Al promotes stereospecific pinacol-type rearrangements of chiral β-methanesulfonyloxy alcohols. Aryl[20a] or alkenyl groups[20b] cleanly take part in the 1,2-migration to provide a range of α-chiral ketones (eq 15). The 1,2-migration of alkyl groups is effected by the more Lewis acidic ***Diethylaluminum Chloride***.[20c] The reagent combination of DIBAL and Et_3Al effects the reductive 1,2-rearrangement of α-mesyloxy ketones (eq 16).[20d,e]

(15)

(16)

Cyclopropanation.

The reagent combination of ***Diiodomethane*** and Et_3Al (or other organoaluminums) leads to cyclopropanation of alkenes (eq 17).[21]

(17)

Related Reagents.

Titanium(IV) Chloride-Triethylaluminum.

Triethylamine

[121-44-8] · $C_6H_{15}N$ · Triethylamine · (MW 101.22)

(tertiary amine base used in oxidation, dehydrohalogenation, and substitution reactions)

Alternate Name: TEA.

Physical Data: bp 88.8 °C; mp -115 °C; *d* 0.726 g cm^{-3}.

Solubility: sol most organic solvents.

Purification: dried over $CaSO_4$, $LiAlH_4$, 4&AAring; sieves, CaH_2, KOH, or K_2CO_3, then distilled from BaO, sodium, P_2O_5 or CaH_2.[1]

Handling, Storage, and Precautions: is a corrosive and flammable liquid. Bottles of triethylamine should be flushed with nitrogen or argon to prevent exposure to carbon dioxide. The vapors are harmful and care should be taken to avoid absorption through the skin. Use in a fume hood.

Introduction.

The most widely used organic amine base in synthetic organic chemistry is probably triethylamine. Its popularity stems from availability and low cost, along with ease of removal by distillation due to a mid-range boiling point (88.8 °C). Also, the hydrochloride and hydrobromide salts are somewhat insoluble in organic solvents, such as diethyl ether, and may be removed by simple filtration. Triethylamine finds wide use in oxidations, reductions, eliminations, substitutions, and addition reactions. There follows a brief compilation of the uses of triethylamine.

Oxidations.

The addition of triethylamine and ***Acetic Anhydride*** during the workup of the ozonolysis of cycloalkenes allows for the selective differentiation of the oxidized termini.[2] Ozonolysis of cycloalkenes in MeOH buffered with $NaHCO_3$ generates the intermediate α-methoxy hydroperoxide aldehyde which dehydrates upon exposure to acetic anhydride and triethylamine to produce aldehyde esters (eq 1). Intermediate peroxy acetals are produced with the addition of ***p-Toluenesulfonic Acid*** to the ozonolysis reaction and similarly dehydrate with triethylamine and acetic anhydride to afford acetal esters. Omitting the acetic anhydride and triethylamine leads to acetal aldehydes under reduction conditions (eq 2).

(1)

(2)

In the Swern oxidation[3] of alcohols to ketones and aldehydes, employing ***Dimethyl Sulfoxide-Oxalyl Chloride***, triethylamine is usually the amine base utilized in the basification step of the reaction. Mechanistically, the basification step includes deprotonation of the methyl group of the alkoxysulfonium salt intermediate to form an ylide which then yields the carbonyl compound via an intramolecular proton transfer (eq 3).[3b] A similar mechanism is encountered with ***N-Chlorosuccinimide-Dimethyl Sulfide*** and TEA.[4]

The steric nature of the amine affects the overall performance of the oxidations. In comparative studies involving oxidations with ***Dimethyl Sulfoxide-Trifluoroacetic Anhydride***[5] and ***Dimethyl Sulfoxide-Methanesulfonic Anhydride***[6] the sterically hindered ***Diisopropylethylamine*** was found to be superior to TEA (eq 4).[3b]

Base	Yield (%)
Et_3N	68
DIPEA	94

The treatment of vicinal diols with an excess of DMSO/trifluoroacetic anhydride followed by basification with TEA results in complete oxidation to α-diketones in good yields (eq 5).[7]

Eliminations.

Dehydrohalogenation of alkyl halides to generate alkenes is normally carried out using alcoholic ***Potassium Hydroxide***; however triethylamine has some utility.[8] For example, bridgehead enones are produced efficiently by treatment of β-bromo ketones with 2 equiv of TEA at 0 °C. The highly reactive enones are not isolated (due to their instability) but can be subsequently trapped with a variety of dienes in a Diels-Alder reaction (eq 6).[9]

(6)

Triethylamine accomplishes the dehydrobromination of α,α´-dibromo sulfones using TEA in CH_2Cl_2 to afford α,β-unsaturated bromomethyl sulfones in good yields. Further treatment of the sulfones with ***Potassium t-Butoxide*** induces a Ramberg-Bäcklund-like reaction and leads to 1,3-dienes in moderate to good yields (eq 7).[10]

(7)

Chloroalkylidene malonates are converted via a decarboxylation-elimination reaction to alkynic esters by treatment with triethylamine at 90 °C (eq 8).[11] Likewise, triethylamine is the preferred base for the conversion of *erythro*-2,3-dibromobutanoic acid to *cis*-1-bromopropene (eq 9). Pyridine, Na_2CO_3, or $NaHCO_3$ in DMF lead to poor yields of the bromopropene.[12]

(8)

(9)

Exposure of 2,3-dibromo-3,3-difluoropropionyl chloride to ca. 1 equiv of triethylamine in CH_2Cl_2 at 0 °C induces dehydrobromination and leads to 2-bromo-3,3-difluoroacryloyl chloride in 63% yield (eq 10).[13] Under these reaction conditions, the ketene product of dehydrochlorination is not observed.

(10)

Dehydrohalogenation of acid chlorides with a tertiary amine is the typical method for the preparation of ketenes,[14] most likely involving an acylammonium intermediate.[15] Other methods are available which involve carboxyl group-activating agents and tertiary amine bases. TEA-generated ketenes find wide application in organic synthesis, in particular in the synthesis of β-lactams[16] using stereo- and enantioselective ketene-imine cycloaddition methodology. For example, the diastereoselective Staudinger [2 + 2] ketene-imine cycloaddition reaction[17] between chiral nonracemic oxazolidinone-*N*-acetyl chlorides and imines[18] generates β-lactams in high yields and with good stereocontrol (eq 11).[19]

(11)

The dehydration of primary nitroalkanes and the dehydrochlorination of chloroximes allows for the preparation of highly reactive nitrile oxides (eq 12). The nitrile oxides, which are not isolated, undergo facile [3 + 2] cycloaddition reactions[20] with a variety of trapping agents. Subjecting nitroalkanes to 2 equiv of ***Phenyl Isocyanate*** and a catalytic amount of triethylamine[21] effects dehydration to form nitrile oxides (eq 13).[22] Alternatively, treatment of oximes with aqueous ***Sodium Hypochlorite*** and triethylamine in CH_2Cl_2 efficiently produces the nitrile oxides (eq 14).[23]

(12)

(13)

(14)

Substitutions.

Triethylamine finds use as a proton scavenger in palladium-catalyzed coupling reactions involving aryl, alkenyl, allyl, and alkyl derivatives.[24] The palladium-catalyzed coupling of vinyl halides with alkenes (Heck reaction) is an invaluable method for forming carbon-carbon bonds.[25] The elements of an intramolecular Heck reaction and the coupling of allylic alcohols with vinyl halides to afford aldehydes or ketones have been combined to generate moderate to excellent yields of cyclized products (eq 15).[26]

(15)

In an asymmetric variation of the Heck reaction, triethylamine is used in combination with (*R*)-***2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl*** ((*R*)-BINAP) for preparing enantiomerically enriched 2-aryl-2,3-dihydrofurans from aryl triflates.[27] Though TEA resulted in the highest degree of diastereoselectivity, the base ***1,8-Bis(dimethylamino)naphthalene*** (proton sponge) was found to be superior in regards to enantiomeric purity (eq 16).[28,29]

Base	% ee (yield)	% ee (yield)
DIPEA	82 (92)	60 (8)
Et_3N	75 (98)	9 (2)
proton sponge	96 (71)	17 (29)

Triethylamine also finds use in the enolboronation of various carbonyl compounds using dialkylboron halides.[30] These boron enolates are valuable in the stereocontrolled aldol reaction. Proper choice of boron reagent, reaction solvent, reaction temperature, and tertiary amine base influences the enolate geometry of ketones[31] and esters.[32] The use of the sterically demanding dialkylboron halides, such as dicyclohexylboron chloride (Chx_2BCl), with triethylamine favors formation of the (*E*)-enol borinates, while dialkylboron triflates or dialkylboron halides, such as *B*-chloro-9-BBN, with diisopropylethylamine in ether at -78 °C favor the (*Z*)-enol borinates (eq 17).[31a,b] For similar complementary methodologies for generating both the (*E*)- and (*Z*)-boron enolates of esters, see ***Diisopropylethylamine***.

The asymmetric aldol addition involving *N*-acyloxazolidinones and aldehydes can be carried out with high stereoselectivity utilizing ***Tin(II) Trifluoromethanesulfonate*** and triethylamine. Treatment of *N*-(isothiocyanoacetyl)-2-oxazolidinones and aldehydes with tin(II) triflate and TEA at -78 °C in THF leads to high yields of aldol products with high diastereoselectivity (eq 18).[33]

The regioselective synthesis of silyl enol ethers involves the trapping of the enolate anion of ketones and esters under kinetic or thermodynamic conditions.[34] Treatment of the unsymmetrical ketone 2-methylcyclohexanone with TEA and ***Chlorotrimethylsilane*** in DMF affords a 22:78 mixture of the kinetic and thermodynamic trimethylsilyl enol ethers. Using ***Lithium Diisopropylamide*** in DME under kinetic control leads to a >99:1 mixture of the kinetic and thermodynamic silyl enol ethers in 74% yield (eq 19).[35] Likewise, treatment of acetone with chlorotrimethylsilane, TEA, and anhydrous ***Sodium Iodide*** in acetonitrile leads to acetone trimethylsilyl enol ether in good yield.[36]

The mixture of TEA and ***Zinc Chloride*** is effective for converting α,β-unsaturated ketones and aldehydes into the corresponding silyl enol ethers. The Danishefsky-Kitahara diene is prepared in 68% yield by treatment of 4-methoxy-3-buten-2-one with an excess of TEA and TMSCl in the presence of a catalytic amount of anhydrous $ZnCl_2$ in benzene (eq 20).[37] Under similar reaction conditions, crotonaldehyde and 3-methylcrotonaldehyde are also converted into their corresponding enol ethers. 3-Methylcrotonaldehyde leads to an 80/20 mixture of (*E*/*Z*) dienes, while crotonaldehyde yields the (*E*)-silyl enol ether exclusively (eq 21).[38]

(21)

R = H; *E*:*Z* = 100:0 (62%)
R = Me; *E*:*Z* = 80:20 (74%)

Triethylamine in combination with ***Triethylsilyl Perchlorate*** is somewhat selective in the generation of the (*Z*)-silylketene acetal of isopropyl propionate (eq 22)[39] (see ***2,2,6,6-Tetramethylpiperidine*** for a comparison of other bases). Triethylamine and ***t-Butyldimethylsilyl Trifluoromethanesulfonate*** (TBDMSOTf) are quite effective in preparing silyl enol ethers from sterically hindered ketones and lactones (eq 23).[40]

(22)

(*E*):(*Z*) = 37:63

(23)

Triethylamine is the base of choice in neutralizing the acids liberated in preparing (1) diazo ketones from acid chlorides and ***Diazomethane***, (2) mixed anhydrides from carboxylic acids and alkyl haloformates, and (3) esters from carboxylic acids and alkyl halides, such as phenacyl bromide.[41]

Triethylamine is particularly useful as a proton scavenger in the field of protective group chemistry.[42] For just a few examples: alcohols have been protected as substituted methyl ethers with such alkylating agents as ***Chloromethyl Methyl Sulfide***[43] and ***t-Butyl Chloromethyl Ether***[44] using TEA as a base. Primary alcohols can be selectively silylated in the presence of secondary and tertiary alcohols using ***t-Butyldiphenylchlorosilane*** with TEA and a catalytic amount of ***4-Dimethylaminopyridine*** (eq 24).[45] The selective benzoylation of diols can be achieved using 1-(benzoyloxy)benzotriazole (BOBT) and TEA in CH_2Cl_2 at room temperature (eq 25).[46] Diols, in particular 1,2- and 1,3-diols, react with ***Di-t-butyldichlorosilane*** in the presence of TEA and a variety of silyl transfer agents to afford the di-*t*-butylsilylene derivatives in good yields (eq 26).[47]

(24)

(25)

(26)

Carbamates are cleaved easily to alcohols upon exposure to ***Trichlorosilane*** and TEA[48] and carboxylic acids are conveniently esterified using equimolar amounts of alkyl chloroformates with triethylamine and a catalytic amount of ***4-Dimethylaminopyridine***.[49] TEA is an effective base for the alkylation (protection) of carboxylic acids with ***Chloroacetonitrile*** to produce cyanomethyl esters.[50] Primary amines with pK_a values of 10-11 react with 1,1,4,4-tetramethyl-1,4-dichlorodisilethylene in the presence of TEA at rt to afford the disilylazacyclopentane derivatives in high yields (eq 27).[51] Amines with lower pK_a values require ***n-Butyllithium*** as the base or can be protected via a ***Zinc Iodide***-catalyzed trans-silylation with 1,1,4,4-tetramethyl-1,4-bis(*N*,*N*-dimethylamino)disilethylene (eq 28).[52]

(27)

Triethylamine and other tertiary amines find utility in the derivatization of amino acids as well as coupling reactions to prepare peptides.[53] The basicity and steric nature of the tertiary amine utilized during the coupling reaction influences the degree of racemization.[54]

Related Reagents.

Palladium-Triethylamine-Formic Acid.

(regiospecific and diastereoselective allylation of aldehydes;[2] cross-coupling reaction with organic halides and triflates catalyzed by a palladium complex[3])

Physical Data: (**1**) mp 120 °C (dec); (**2**) mp 94 °C (dec); (**3**) (*E*:*Z* = 90:10), mp 124 °C (dec).

Analysis of Reagent Purity: tetramethylsilane was used as an internal standard for ^1H, ^{13}C, and ^{29}Si NMR: (**1**) ^1H NMR ($CDCl_3$) δ 1.25 (t, *J* = 7 Hz, 9H), 1.69 (d, *J* = 8 Hz, 2H), 3.17 (q, *J* = 7 Hz, 6H), 4.50-4.76 (m, 2H), 5.52-5.91 (m, 1H), 6.67 (m, 8H), 7.69 (bs, 1H); ^{13}C NMR ($CDCl_3$) δ 8.72 (q), 24.60 (t), 46.43 (t), 110.69 (d), 111.56 (t), 118.77 (d), 136.91 (d), 149.48 (s); ^{29}Si NMR ($CDCl_3$) δ -78.40. (**4**) ^1H NMR ($CDCl_3$) δ 1.24 (t, *J* = 7 Hz, 9H), 3.17 (q, *J* = 7 Hz, 6H), 5.59-6.24 (m, 3H), 6.67 (m, 8H), 7.48 (bs, 1H); ^{13}C NMR ($CDCl_3$) δ 8.75 (q), 28.88 (t), 110.77 (d), 118.84 (d), 132.96 (t), 137.78 (d), 149.40 (s); ^{29}Si NMR ($CDCl_3$) δ -87.45.

Handling, Storage, and Precautions: these reagents should be stored under an inert atmosphere in a dry box.

Allylation of Aldehydes.

Triethylammonium bis(catecholato)allylsiliconates (**1**-**3**) are readily prepared from allyltrimethoxysilanes, two equivalents of ***Catechol***, and

Triethylamine.[4] Synthetic routes to other pentacoordinate allylsiliconates have been described.[5,6] Allylsiliconate (**1**) reacts with aliphatic and aromatic aldehydes without Lewis acid[7] or fluoride ion[8] catalysts to give the corresponding homoallyl alcohols in good yield (eq 1). However, these reagents are not effective for the allylation of ketones. The aldehyde allylation occurs even in the presence of the nitro and cyano groups. The reaction of α,β-unsaturated aldehydes proceeds exclusively by 1,2-addition.

R = Ph, *p*-NCC_6H_4, *p*-$O_2NC_6H_4$, $C_6H_4CH{=}CH$, Pr, etc.

The allylation of aldehydes is completely regiospecific and carbon-carbon bond formation occurs at the γ-position of the allyl group of prenyl- (**2**) and crotylsiliconate (**3**). In addition, high *anti* diastereoselectivity is observed in the reaction of (**3**) (Table 1).

Table 1 Allylation of Aldehydes with Prenyl- or Crotylsiliconate

Allylsiliconate	R	Yield (%)	*syn*:*anti*
(2) R^1, R^2 = Me	Ph	72	-
(2) R^1, R^2 = Me	*p*-NCC_6H_4	68	-
(3) R^1 = H, R^2 = Me (*E*:*Z* = 90:10)	Ph	88	10:90
(3) R^1 = H, R^2 = Me (*E*:*Z* = 90:10)	*p*-NCC_6H_4	96	10:90

Allylsiliconates can be generated in situ from trimethoxyallylsilane in the presence of aldehydes (eq 2). Enantioselective allylation of an aldehyde by optically active allyltriethoxysilanes, catechol, and triethylamine reveals that the reaction mechanism involves a cyclic transition state (eq 3), in sharp contrast to the results for the tetracoordinate allylsilane in which the acyclic S_E' pathway has been demonstrated.[9]

Cross-Coupling Reactions.

Triethylammonium bis(catecholato)vinylsiliconate (**4**), derived from vinyltrimethoxysilane, undergoes palladium-catalyzed cross-coupling reactions with aryl halides or triflates (eq 4). ***Tetrakis(triphenylphosphine)palladium(0)***, ***Bis(benzonitrile)dichloropalladium(II)***, and ***Bis(allyl)di-μ-chlorodipalladium*** are effective catalysts for this reaction, but ***Triethyl Phosphite*** or ***Lithium Chloride*** additives are required. The reaction with (*E*)-1-halo-1-alkenes proceeds with retention of stereochemistry to provide 1,3-dienes (eq 5).

(*E*)-1-Hexenylsiliconate (**5**) can be used for the reaction with aryl halides and triflates, although the products are not 1,2-disubstituted ethylenes, normal coupling products, but 1,1-disubstituted ethylenes (eq 6).[10]

Triethylborane

Et_3B

[97-94-9] · $C_6H_{15}B$ · Triethylborane · (MW 98.02)

(precursor of triethylborohydride reducing agents;[1] enoxytriethylborates and -diethylboranes for aldol[19,22] and alkylation[17] reactions; regio- and stereoselective reactions of allyltriethylborates;[26,27] alkylating reagents;[1b] stereocontrol of carbanion reactions;[39,41] radical initiator[44])

Physical Data: mp -93 °C; bp 95 °C; *d* 0.677 g cm^{-3}.

Solubility: sol ethanol, acetone, THF, ether, hexane, benzene, $CHCl_3$.

Form Supplied in: colorless liquid; widely available. Since it is highly flammable, triethylborane diluted with hexane or THF (1.0 M solution) is also available.

Handling, Storage, and Precautions: neat triethylborane ignites instantaneously upon contact with air. The reagent should be handled with a syringe under Ar or N_2 atmosphere. It is stable toward moisture and water, and reputed to be toxic. Use in a fume hood.

Reducing Reagents.

Lithium Triethylborohydride, known as Super-Hydride, is prepared in THF by the reaction of lithium hydride with triethylborane (eq 1).[1] Alkali metal trialkylborohydrides are exceptionally powerful nucleophilic reducing agents capable of cleaving cyclic ethers,[2] reducing hindered halides,[3] *p*-toluenesulfonate esters of hindered and cyclic alcohols,[4] epoxides,[5] and activated alkenes[6] rapidly and quantitatively to the desired products. The advantage of $LiEt_3BH$ is especially evident in the reduction of labile bicyclic epoxides (eq 2). Thus benzonorbornadiene oxide, which invariably gives rearranged products with conventional reducing agents, undergoes facile reduction with $LiEt_3BH$ yielding 93% of *exo*-benzonorborneol in >99.9% isomeric purity. The reactivity of the trialkylborohydrides and the stereochemical course of their reactions are strongly influenced by the steric bulk of the alkyl group on boron.[7] The lithium hydride route (eq 1) provides a convenient entry only to the relatively unhindered lithium trialkylborohydrides. However, ***Potassium Hydride*** reacts rapidly and quantitatively with the hindered trialkylboranes, such as tri-*s*-butylborane, yielding the corresponding sterically hindered trialkylborohydride ***Potassium Tri-s-butylborohydride***.[8] A general synthesis of lithium trialkylborohydrides has been developed using lithium trimethoxyaluminohydride (eq 3).[9]

$$R_3B + LiAl(OMe)_3H \xrightarrow[\substack{0.25\ h \\ 100\%}]{THF,\ 25\ °C} LiR_3BH + Al(OMe)_3\downarrow \quad (3)$$

R = Et, Bu, *s*-Bu, *i*-Bu

The combination of ***Lithium Tri-t-butoxyaluminum Hydride*** and triethylborane induces a rapid, essentially quantitative, reductive ring opening of THF to produce 1-butanol upon hydrolysis (eq 4).[10] Cyclohexene oxide and 1-methylcyclohexene oxide are instantaneously and quantitatively cleaved to their corresponding carbinols. Oxetane is readily cleaved to give 1-propanol in 98% yield. The reductive cleavage of both tetrahydropyran and oxepan is very sluggish and incomplete.

$$+ LiAl(O\text{-}t\text{-}Bu)_3H \xrightarrow[\substack{exothermic\ (\sim 45\ °C) \\ 5\ min}]{Et_3B,\ THF} \xrightarrow[100\%]{H_2O} BuOH \quad (4)$$

Triethyl- or triisopropylborane/***Trifluoromethanesulfonic Acid*** (triflic acid) is a convenient reagent for the selective reduction of hydroxy substituted carboxylic acids, ketones, and aldehydes to yield the corresponding carbonyl compounds (eq 5).[11] Not only tertiary hydroxy but also primary, secondary, and benzylic hydroxy groups are reduced in good to high yields. In general, the triisopropylborane/triflic acid system gives better results than triethylborane/triflic acid.

$$+ Et_3B + MeSO_3H \xrightarrow[\substack{-30\ °C,\ 35\ min,\ then \\ rt,\ 6\ h \\ 71\%}]{ClF_2CCCl_2F} \quad (5)$$

Preparation of R_2BOR' is generally carried out by treating alcohols R´OH with trialkylboranes R_3B in the presence of activating reagents like pivalic acid[13] or air.[14] However, Et_2BOMe can be prepared simply by mixing Et_3B with MeOH in THF at room temperature.[12] Using the Et_2BOMe thus generated as a chelating agent, *syn*-1,3-diols are prepared in >98% stereochemical purity by reducing β-hydroxy ketones with ***Sodium Borohydride***.[12]

Enoxytriethylborates and Enoxydiethylboranes.

Potassium enolates of ketones react with an unhindered trialkylborane such as triethylborane to form a potassium enoxytriethylborate, which undergoes selective α-monoalkylation with alkyl halides in high yields (eq 6).[15] In the absence of Et_3B, the potassium enolate itself gives a mixture of 43% mono- and 31% diallylated cyclohexanone along with 28% of recovered cyclohexanone. Monomethylation, -benzylation, and -propargylation of acetophenone also proceed in high yield in the presence of Et_3B. Lithium enolates, such as those obtained from acetophenone and cyclohexanone, do not form the corresponding enoxytriethylborates. Use of ***Potassium Hexamethyldisilazide*** as a base at -78 °C generates the less stable enolate (**1**) with high regioselectivity, while use of potassium hydride at 25 °C generates the most stable enolate (**2**) with &egt;90% regioselectivity (eq 7).[16] The alkylations of these enolates proceed without complication in the presence of Et_3B (eq 7). Comparable regioselectivities are observed in the alkylations of 2-heptanone.

(6)

(7)

Allylation of potassium enoxyborates can be catalyzed by ***Tetrakis(triphenylphosphine)palladium(0)***.[17] Zinc enolates, readily obtained by treating lithium enolates with dry ***Zinc Chloride***, also undergo the Pd-catalyzed allylation with high regio- and stereoselectivities. Overall retention is observed with respect to the allylic cation center (eq 8).[17] In the presence of $Pd(PPh_3)_4$ catalyst and 2 equiv of BEt_3, lithium enolates of cyclopentanone and cyclohexanone derivatives react with (*E*)- or (*Z*)-allylic acetate (**3**) to provide (*E*)- or (*Z*)-allylation products with high stereospecificity (eq 9).[18] Both the Pd catalyst and BEt_3 are essential for the stereospecific allylation.

(8)

(9)

(*E*)-**(3)**	77%	(*E*):(*Z*) = 98:2
(*Z*)-**(3)**	73%	(*Z*):(*E*) = >97:3

The aldol reaction of preformed lithium enolates with aldehydes in the presence of trialkylboranes, such as BEt_3 and $B(n\text{-}Bu)_3$, leads to product mixtures rich in the more stable *anti*-aldol (eq 10).[19] Use of 3 equiv of BEt_3 gives high *anti* selectivity, while the stereoselectivity is low when 1 equiv of BEt_3 is used (eq 10). When lithium enolates are generated from silyl enol ethers and ***n-Butyllithium*** in THF, use of 1 equiv of BEt_3 is enough to produce high *anti* selectivity. The condensation of the lithio dianion of ethyl 3-hydroxybutyrate with *N*-anisyl cinnamylideneimine in the presence of Et_3B produces excellent 1´,3-*syn*/3,4-*cis* stereoselectivity (eq 11), whereas 1´,3-*syn*/3,4-*trans* selectivity is obtained in the presence of *t*-BuMgCl.[20] Aldol condensation of acetaldehyde and benzaldehyde with the lithium enolate of ethyl *N*,*N*-dimethylglycine in the presence of 1 equiv of Et_3B results in the formation of the corresponding *syn* 3-hydroxy-2-amino acid esters with excellent stereocontrol (>95% de).[21] The stereochemical outcome of these reactions is rationalized via the selective formation of the (*Z*)-enolate of ethyl *N*,*N*-dimethylglycine in the presence of triethylborane.

1 equiv BEt_3, *anti*:*syn* = 1:1
3 equiv BEt_3, *anti*:*syn* = 97:3

(11)

There are several methods for generation of enoxyboranes (boron enolates).[22] Ketenes react with dialkylthioalkylboranes, $R_2BS(t\text{-Bu})$, to yield alkenyloxyboranes formally derived from thioesters.[22a] A variety of ketones and carboxylic acid derivatives are converted to boron enolates upon treatment with dialkylboryl triflates in the presence of a tertiary amine, and the subsequent aldol condensation of these boron enolates has been studied[22b,c] Trialkylboranes readily react with diazoacetaldehyde to give alkenyloxyboranes.[22d] Trialkylboranes spontaneously transfer an alkyl group to the β-position of β-unsubstituted α,β-unsaturated aldehydes and ketones to give alkenyloxyboranes, which are produced regio- but not stereospecifically.[22e] In the presence of 1-10 mol % of diethylboryl pivalate, Et_3B and ketones $RCOCH_2R'$ react at 85-110 °C to give diethyl(vinyloxy)boranes, $Et_2BOCR{=}CHR'$, in 70-90% yield.[22f] Reaction of α-bromo ketones with ***Triphenylsilane*** in the presence of Et_3B provides boron enolates which react with carbonyl compounds to give β-hydroxy ketones in good yields (eq 12).[23] The Et_3B-induced Reformatsky type reaction of α-iodo ketones with aldehydes or ketones proceeds without Ph_3SnH.[23,24] α-Bromocyclopentanone and -cyclohexanone provide *anti*-adducts with high diastereoselectivity (78-100%), whereas the reaction of 7-bromo-6-dodecanone with benzaldehyde gives a 65:35 mixture of the *syn*- and *anti*-adduct. It is proposed that vinyloxy(diethyl)boranes are involved as intermediates.

(12)

Allylborates.

2-Butenyllithium reacts with aldehydes to afford the *anti*- and *syn*-β-methylhomoallyl alcohols in nearly equal amounts. However, if trialkylboranes such as Et_3B are present, the *anti*-product predominates (eq 13).[25] The corresponding allylic borate complexes are presumably involved as intermediates. Lithium allylic boronates, prepared by the addition of trialkylboranes (Et_3B, ***Tri-n-butylborane***, or *n*-Bu-9-BBN) to an ether solution of allylic lithium compounds, regioselectively react with allylic halides to produce head-to-tail 1,5-dienes (eq 14).[26] Regio- and stereocontrol via boron ate complexes is applicable to not only simple allylic but also heteroatom substituted allylic anions.[27] The allyloxy carbanions (**4**) generally react with alkyl halides at the α-position, but react with carbonyl compounds at the γ-position. The Et_3B (or ***Triethylaluminum***) ate complexes of (**4**) react with a ldehydes, ketones, and reactive halides at the α-position. The (alkylthio)allyl carbanion (**5**) reacts with alkyl halides at the γ-position, but with carbonyl compounds at the α-position. The Et_3B (or Et_3Al) ate complexes of (**5**) react with aldehydes, ketones, and allylic halides at the α-position. In general, the aluminum ate complex gives higher regioselectivity than the boron ate complex. The regioselectivity of Me_3Si- or pyrrolidine (*N*-atom)-substituted allylic anions is also controlled by the addition of Et_3B (or Et_3Al).[27] Either branched or linear homoallyl alcohols may be prepared by the reaction of (phenylselenyl)allyl carbanion with aldehydes and triethylborane under appropriate reaction conditions (eq 15).[28] The ethyl group of Et_3B in the initially formed ate complex $PhSeCH(\text{-}BEt_3)CH{=}CH_2\ Li^+$ undergoes a facile migration from boron to the α-carbon to give (**6**), which reacts with benzaldehyde to give the linear adduct. The prolonged reaction period at higher temperatures induces the allylic

rearrangement of (**6**) to (**7**), resulting in the formation of the branched adduct.

(5)

Alkylating Reagents.

Monoalkylation of ketones is accomplished by reaction of trialkylboranes with α-bromo ketones under the influence of ***Potassium t-Butoxide*** in THF.[29] For example, α-bromocyclohexanone reacts with Et_3B to give α-ethylcyclohexanone (eq 16).[29] The reaction involves formation of the anion of the α-bromo ketone, formation of the boron ate complex, and rearrangement of Et from boron to the α-carbon. The use of potassium 2,6-di-*t*-butylphenoxide as a base, instead of *t*-BuOK, provides better results.[30] α-Bromoacetone, chloroacetonitrile, ethyl bromoacetate, and ethyl dibromoacetate are alkylated using this hindered base and R_3B.[30] The reaction of Et_3B with ethyl 4-bromocrotonate in the presence of one equiv of the new base affords ethyl 3-hexenoate (79% *trans*).[31] Monoalkylation of dichloroacetonitrile with Et_3B is achieved in 89% yield, and the dialkylation is carried out by using 2 equiv of base and 2 equiv of Et_3B (97% yield).[32]

Trialkylcarbinols are prepared by the reaction of trialkylboranes with carbon monoxide in diglyme followed by oxidation with ***Hydrogen Peroxide*** (eq 17).[1b] Alternatively, trialkylcarbinols are obtained by the reaction of trialkylboranes with ***Chlorodifluoromethane*** (or ***Dichloromethyl Methyl Ether***) under the influence of lithium triethylmethoxide,[1b,33] or by the cyanidation reaction of trialkylboranes with ***Sodium Cyanide-Trifluoroacetic Anhydride*** followed by oxidation.[1b,34] Bromination of triethylborane under irradiation in the presence of water followed by oxidation gives 3-methyl-3-pentanol in 88% yield (eq 18).[35] In order to effect successful α-bromination-migration, slow addition of bromine is important to avoid polybromination. The use of ***N-Bromosuccinimide*** in the presence of water increases the yield in eq 18 to 97%.[36] The bromination-migration reaction is applicable to simple trialkylboranes and dialkylborinic acids. The cross-coupling reaction of *B*-alkyl-9-borabicyclo[3.3.1]nonanes (*B*-R-9-BBN) with 1-halo-1-alkenes or haloarenes (R´X) in the presence of a catalytic amount of ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)*** and bases, such as NaOH and K_2CO_3, gives the corresponding

alkenes or arenes (R-R´).[37] The use of catalytic amounts of $Cl_2Pd[PPh_3]_2$ in combination with ***Bis(acetylacetonato)zinc(II)*** effects carbonylative coupling of trialkylboranes with aryl iodides to give unsymmetrical ketones in 60-80% yields (eq 19).[38]

Alkynes are easily synthesized by the reaction of iodine with alkyne ate complexes, readily formed in situ from R_3B and lithium acetylides (eq 20).[1b] Treatment of the alkyne ate complexes with mild electrophiles E^+ results in β-attack on the triple bond and a migration of the organic group R from boron to carbon (eq 20).[1b] The protonation reaction with HX yields a mixture of *cis*- and *trans* alkenes, and mixtures of alkene isomers are also obtained in reactions involving MeI, MeOTs, allyl bromide, and oxirane. However, a single stereoisomer results from the reactions with other electrophiles.

Stereochemical Control Element.

Triethylborane acts as a stereo- and regiocontrol element in certain carbanionic reactions; several examples have been demonstrated in eqs 10, 11, and 13-15. Triethylborane-mediated epimerization of a 1α-methylcarbapenem intermediate proceeds with high stereoselectivity to give the 1β-methyl diastereomer (eq 21).[39] The 1β-methyl derivative is also obtained via alkylation of an 2-azetidinon-4-ylacetic acid derivative by using LDA-Et_3Al-MeI.[39] The deuteration of α-lithiobenzyl methyl sulfoxide in the presence of Et_3Al occurs with inversion, while the reaction in the absence of the additive occurs with retention; the use of Et_3B gives a mixture of the retention and inversion product.[40] The reagent RCu.BEt_3, prepared in situ from RCu and BEt_3 in ether at -70 °C, adds to α,β-alkynic carbonyl compounds with high stereospecificity, which cannot be achieved with conventional reagents such as R_2CuLi (eq 22).[41]

(21)

(22)

Lewis Acids and Radical Reactions.

Methylenecyclopropanes react with 2-cyclopentenone in the presence of a Ni^0 catalyst (such as ***Bis(1,5-cyclooctadiene)nickel(0)***), ***Triphenylphosphine***, and triethylborane to afford 6-methylenebicyclo[3.3.0]octan-2-ones (eq 23).[42] Treatment of tantalum-alkyne complexes with dimethylhydrazones and ***Trimethylaluminum*** in a DME, benzene, and THF solvent system at 45 °C gives (*E*)-allylic hydrazines stereoselectively, although the use of Et_3B results in formation of the product in very low yield.[43]

(23)

$R = C_5H_{11}$ *trans*:*cis* = 85:15

Trialkylboranes do not undergo facile addition reactions to carbonyl groups. However, rapid conjugate addition reactions occur with α,β-unsaturated carbonyl compounds, such as ***Acrolein*** and ***Methyl Vinyl Ketone*** (eq 24).[1b] The reaction proceeds through a radical mechanism. Trialkylboranes also participate in facile radical chain reactions with disulfides (e.g. ***Diphenyl Disulfide***), producing the corresponding thioethers (RSPh).[1b] Triphenylgermane adds easily to alkynes (RC&tbond;CH) in the presence of Et_3B to give (*E*)- or (*Z*)-alkenyltriphenylgermanes ($RCH{=}CHGePh_3$) in good yields.[44] The (*Z*)-isomers predominate at -78 °C, whereas the hydrogermylation at 60 °C favors the (*E*)-isomer. Similarly, Et_3B is as efficient as ***Azobisisobutyronitrile*** for initiation of the hydrostannylation of alkynes, resulting in vinyltins.[45] The reaction is sluggish in the absence of oxygen. Triethylborane can also initiate radical cyclization of unsaturated alkynes to vinylstannanes (eq 25).[45] The 1,4-reduction of α,β-unsaturated ketones and aldehydes with ***Triphenylstannane*** or ***Tri-n-butylstannane*** proceeds in the presence of Et_3B to give the corresponding saturated ketones and aldehydes in good yields, whereas the same reaction of α,β-unsaturated esters with Ph_3SnH affords the tin hydride conjugate adduct.[46] Thiols[47a] and perfluoroalkyl iodides[47b] undergo similar addition reactions to alkynes in the presence of catalytic amounts of Et_3B. Treatment of 1-allyloxy-1-phenyl-2-bromo-1-silacyclopentanes with Bu_3SnH in the presence of catalytic amounts of Et_3B provides the cyclization products, which can be converted to 1,4,6-triol derivatives (eq 26).[48] Alkoxymethyl radicals (2-oxahex-5-enyl or 2-oxahept-6-enyl radicals), generated conveniently from phenylseleno precursors upon treatment with AIBN or Et_3B, cyclize to afford substituted tetrahydrofurans and tetrahydropyrans.[49]

(masked malonate ester equivalent;[2,3] regiospecific radical addition to terminal alkenes;[4] Mn^{III}-induced substitution on electron-rich aromatics[5,6])

Physical Data: (**1**) bp 111-112 °C/4 mmHg; mp 45-46 °C; (**2**) bp 138-139 °C/12 mmHg; (**3**) bp 140-142 °C/12 mmHg; (**4**) bp 135-137 °C/12 mmHg; mp 27-29 °C; *d* 1.100 g cm^{-3}.

Preparative Methods: methanetricarboxylate esters are generally prepared from appropriate malonate esters via formation of a metal salt and addition of an alkyl chloroformate (eq 1). Sodiomalonates work well for most esters (e.g. $R^1 = R^2 = Me$);[7] however, magnesiomalonates generally provide better results for ethyl esters.[8] Acylation of malonate esters has also been accomplished using ***Magnesium Oxide*** as the base,[9] which is advantageous for the preparation of symmetric methanetricarboxylate esters ($R^1 = R^2$) because strictly anhydrous conditions are not required.

Trialkyl methanetricarboxylates are easily alkylated;[1] facile dealkoxycarbonylation of these triesters has prompted their use as masked malonate esters.[1,2,3] Conjugate addition (eq 2) of triethyl methanetricarboxylate occurs with a variety of Michael acceptors under phase-transfer conditions, providing a convenient two-carbon chain elongation.[10]

Z = CHO, CO_2Et, CN, COMe, SOPh, SO_2Ph

Trialkyl methanetricarboxylate radicals readily add to terminal alkenes, giving predominately the 1:1 adducts (50-75%).[1,4] Unlike the radical additions of malonate or acetate esters to alkenes, the addition of methanetricarboxylate esters is regiospecific and limited exclusively to α-alkenes.[4] Saponification of the 1:1 adduct, followed by decarboxylation, is a convenient route to *n*-alkylcarboxylic acids and is a two-carbon homologation of the starting alkene. Methanetricarboxylate esters also readily undergo manganese(III)-induced addition to electron-rich aromatic systems;[5] this reactivity is attributed to the very electrophilic nature of the triester radical. This reaction was exploited to give the shortest, most efficient, reported synthesis of the analgesic ketorolac:[6,11] three steps and 64% overall yield from 2-benzoylpyrrole (eq 3).

These triesters react with a variety of amines to give a broad range of products.[1] Condensation of the triethyl ester with pyrazoles provided facile access to cross-conjugated mesomeric betaines without the use of chlorocarbonylketenes (eq 4).[12]

Pyrolysis of *o*-carboranes in the presence of trialkyl methanetricarboxylates produces 9-alkyl-*o*-carboranes in moderate yields, and represents one of the few reliable preparations of these molecules.[13]

Triethyl Orthoacetate[1]

(**1**; R = Et)

[78-39-7] · $C_8H_{18}O_3$ · Triethyl Orthoacetate · (MW 162.26) (**2**; R = Me)

[1445-45-0] · $C_5H_{12}O_3$ · Trimethyl Orthoacetate · (MW 120.17)

(diethyl acetal of ethyl acetate; provides γ,δ-unsaturated ethyl esters from α,β-unsaturated alcohols through the Claisen rearrangement; converts diols to epoxides of the same relative stereochemistry; gives 2-methyl-1,3-heteroatom ring systems)

Physical Data: (**1**) bp 144-146 °C; *d* = 0.8847 g cm^{-3}; (**2**) bp 107-109 °C; *d* = 0.9438 g cm^{-3}.

Orthoester Exchange with Alcohols and Water.

Orthoesters (1,1,1-trialkoxyalkanes, ester acetals) are acid labile, base stable, masked forms of carboxylic acid esters. Mild acid-catalyzed hydrolysis of an orthoester produces an ester and an alcohol, in this instance, ethyl acetate and ethanol. Thus ethyl orthoacetate, and orthoesters in general, can serve to drive the equilibrium in Fischer esterifications of carboxylic acids with ethanol by forming low-boiling ethyl acetate and ethanol from the water generated during the esterification.

Higher molecular weight orthoacetates (orthoesters) of nonallylic alcohols are prepared by acid-catalyzed exchange, with removal of the lower boiling alcohol to shift the equilibrium. When this reaction is conducted with a 1,2-diol such as L(+)-diethyl tartrate in the presence of excess ethyl orthoacetate, two of the ethoxy groups are exchanged to form a 2-ethoxy-2-methyl-1,3-dioxolane (eq 1).

(1)

Interconversion of Orthoesters and Haloesters.

This exchange is an important element in a reaction sequence designed to convert a diol to the corresponding epoxide without loss of stereochemistry. Thus the dioxolane of D(-)-2,3-butanediol, which is formed from methyl orthoacetate, is cleaved with trityl chloride to produce the β-acetoxy chloride, which, upon treatment with KOH, affords D(+)-2,3-epoxybutane (eq 2). The cleavage procedure, which is also effective with 2-ethoxy-2-methyl-1,3-dioxanes (eq 3), occurs through an S_N2 mechanism.[2] Because the formation of methyl trityl ether can complicate isolation, ***Chlorotrimethylsilane***, which gives volatile byproducts, is an effective replacement for trityl chloride in the cleavage of dioxolanes.[3] ***Phosphorus(V) Chloride*** has been found to be effective in the cleavage of a dioxolane derived from ethyl orthoformate (eq 4).[4] These reactions proceed through the formation of a cyclic dioxolenium (eqs 2 and 4) or dioxenium (eq 3) ion, an intermediate that can be accessed in the reverse direction to produce an orthoester. This procedure is typified by the transformation of the tetra-*O*-acetyl glucosyl bromide of eq 5.[5] The remaining ethoxy group of the cyclic orthoester can be exchanged intramolecularly by removing ethanol from the equilibrium even if an unfavorable conformation is required (eq 6).[6]

(2)

(3)

(4)

(5)

(6)

Orthoester Claisen Rearrangement.

The principal use of triethyl and trimethyl orthoacetate and their more substituted analogs[7] is in the orthoester Claisen rearrangement.[1c] The reagent, which is often used as a solvent, is heated in the presence of an allylic alcohol and a weak acid catalyst with removal of ethanol (or methanol) (eq 7).

(7)

The reaction was first applied in the synthesis of the triterpene squalene (**1**), using a symmetrical bis-allylic alcohol (eq 8).[8] The trisubstituted (*E*)-alkene is formed in >98% purity in excellent yield. The ester group of the product is converted into a secondary isopropenyl carbinol and it is then subjected to a second orthoacetate rearrangement.

(1)

(8)

The (*E*)-alkene selectivity is typical of the rearrangement of secondary allylic carbinols. Enantiomerically pure allylic alcohols (**2**) and (**3**), both of which are accessible from a common source, undergo rearrangement to give the same enantiomerically pure ester (**4**) (eq 9).[9] The results of eqs 8 and 9 demonstrate that propionic acid is capable of forming the dioxenium carbocation from the orthoacetate without isomerizing or racemizing the allylic alcohol and that the rearrangement is suprafacial.

(2) *(S)-(E)*

(3) *(R)-(Z)*

(4) *(S)-(E)*

(9)

The ***Propionic Acid*** catalyst is often consumed in the form of the propionate ester of the allylic alcohol, thereby stopping the rearrangement process (eq 10).

$$EtCO_2H + MeC(OR)_3 \longrightarrow EtCO_2C(Me)(OR)_2 + ROH$$

$$EtCO_2C(Me)(OR)_2 + R'OH \xrightarrow{H^+} EtCO_2R' + MeCO_2R + ROH \qquad (10)$$

Esterification can occur in reactions that are slow because of constraints imposed by the transition state. The second step of eq 10 is repressed by using a hindered carboxylic acid, thereby making the rearrangement competitive with esterification. Thus ***Pivalic Acid*** (5 mol %) as a catalyst leads to a 74% yield of ester (**6**); propionic acid affords lower yields and appreciable quantities of the propionate ester of alcohol (**5**) (eq 11).[10a] Alternatively, 2,4-dinitrophenol can be employed as a catalyst (eq 12).[10b] Rearrangement of allylic alcohol (**7**) at 100 °C is slow because of the low boiling point of methyl orthoacetate (bp 107-9 °C). When propionic acid is employed as the catalyst, the methyl ester is obtained in 50% yield along with esterified allylic alcohol. On occasion, the intermediate ketene acetal can undergo elimination to produce dienes if the rate of rearrangement is slow (eq 13).[11]

(5) **(6)**

(11)

(7) (12)

(13)

Carbon-Carbon Bond Formation.

Orthoacetates undergo carbon-carbon bond formation with carbon nucleophiles in the presence of acid catalysts to provide acetals (eqs 14 and 15),[12a,b] enol ethers (eq 16),[13] and azulenes (eq 17).[14] The azulene formation is believed to be an [8 + 2] electrocyclic reaction wherein the ketene acetal from ethyl orthoacetate is functioning as the two-carbon component.

(14)

(15)

(16)

(17)

Exchange with Heteroatoms.

Alkenes are converted into epoxides by 90% ***Hydrogen Peroxide*** in the presence of ethyl orthoacetate. Trisubstituted and 1,2-disubstituted alkenes give yields in excess of 80%. The peroxide is thought to exchange with an ethoxy group to give the diethyl acetal of a peroxy acid as the reactive intermediate.[15] Orthoacetates exchange with one equivalent of a primary amine to give an acetimidate. A second equivalent produces an acetamidine (eq 18).[16]

(18)

Formation of Heterocycles.

Intramolecular versions of eq 18 lead to heterocyclic systems through the intermediate acetimidate. By this method, imidazoles (eq 19),[17] oxazoles,[18] benzotriazepinones (eq 20),[19] quinazolinones,[20] dihydroimidazolium,[21] and tetrahydropyrimidinium[21] salts are prepared. In eq 19, the C-2 carbon and the C-2 methyl group of the product are derived from the acetic acid portion of methyl orthoacetate; the *N*-methyl group comes from the methoxy group of the orthoacetate by alkylation of the dioxenium ion. The oxazoline *N*-oxide (eq 21) is a reactive species that can participate in [3 + 2] cycloadditions.[22]

(19)

(8)

(20)

(21)

Reaction of Acetimidate Intermediates with Carbon Nucleophiles.

Compounds with active methylene groups react with acetimidate-like intermediates to form carbon-carbon bonds in addition to heterocyclic rings. The reaction can be conducted in both the inter-[23] (eq 22) and intramolecular sense (eq 23).[24]

(22)

Triethyl Orthoformate[1]

(**1**; R = Et)

[122-51-0] · $C_7H_{16}O_3$ · Triethyl Orthoformate · (MW 148.23) (**2**; R = Me)

[149-73-5] · $C_4H_{10}O_3$ · Trimethyl Orthoformate · (MW 106.14)

(precursor for higher analogs by reaction with alcohols,[1c] including cyclic orthoesters from polyols;[2] for deoxygenation of 1,2-diols, affording alkenes;[3] acetalization of carbonyl compounds;[4] a dehydrating agent[5] for enol ether formation;[6] esterification of acids;[7] formylation of active methylene compounds,[8] heteroatom nucleophiles[9] and organometallic reagents;[10] formylation of electron-rich species; dialkoxycarbenium ion precursor;[11] solvent for thallium trinitrate reactions[12])

Alternate Name: triethoxymethane.

Physical Data: (**1**) bp 146 °C; *d* = 0.891 g cm^{-3}; (**2**) bp 102 °C; *d* = 0.970 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: clear liquid; widely available.

Purification: distillation.

Handling, Storage, and Precautions: highly moisture sensitive; flammable; irritant with high volatility. Use in a fume hood.

Introduction.

The orthoformates are a remarkably useful group of reagents. They are shelf-stable, yet highly reactive. As alkylating agents, they readily transfer the associated alkyl group, a large variety of which are easily available. As formylation reagents, they are reactive under both acidic and basic conditions. The choice of ester is often arbitrary in this context.

Transesterification.

Higher Orthoformates.

While there are many ways to obtain esters of orthoformic acid,[1c] an easy method takes advantage of the rapid equilibrium among orthoesters (eq 1). By starting with the lowest analog, trimethyl orthoformate, essentially complete conversion to the higher esters is possible by carrying out the reaction at such a temperature as to distill away the evolving methanol. It is important that reactions be carried out under anhydrous conditions to avoid formation of the formate through hydrolysis.

$$HC(OR)_3 + 3\,R'OH \rightleftharpoons HC(OR')_3 + 3\,ROH \qquad (1)$$

Cyclic Orthoformates.[2]

When the above strategy is applied to polyols, cyclic orthoformates can be isolated. Most common are the cyclization of 1,3-diols (eq

2)[2,13] and 1,2-diols,[14] as well as the formation of caged structures from the use of polyols (eq 3).[15,16]
