
(2)

(3)

Those orthoformates obtained from 1,2-diols (eq 4)[3] can undergo cycloelimination upon pyrolysis to afford alkenes in high yield.[17] There are a variety of methods for carrying out this overall process,[18] but the orthoester route is competitive if the alkene is thermally stable.

(4)

Acetals and Enol Ethers.

The conversion of the orthoformate to formate is energetically favored. As a result, the acetalization of ketones by orthoformate is a highly favored process and allows the formation of acetals under exceedingly mild conditions. A wide variety of ketones can be converted into dimethyl acetals by the action of trimethyl orthoformate and ***p-Toluenesulfonic Acid***. The methyl formate thus evolved is distilled away.[4]

The process is general and allows isolation of quite sensitive acetals (eq 5).[19] The technique accommodates protection of α,β-unsaturated carbonyl compounds.[20,21,22] While some form of acid catalysis is usually needed, there is great flexibility in the choice of acid, including Amberlyst 15[23] and, in particular, ***Montmorillonite K10***.[24] Cyclic acetals are also accessible (eq 6).[25]

(5)

(6)

Upon distillation of some acetals,[26] or upon attempted acetalization of highly conjugated species,[26,27] the enol ether can also be observed. The choice of acid often determines whether the acetal or the enol ether is isolated.

Orthoformates are also useful in promoting the formation of other acetals[5] by functioning as dehydrating agents. This function is useful for β-lactone formation as well (eq 7).[28,29]

(7)

Esterification.

In a related process, orthoformates are good esterification agents; they operate on carboxylic acids (eq 8),[7] sulfonic acids,[30] and carboxyboranes,[31] often without the need for acid catalysis.

(8)

Formylation.

The orthoformate carbon is highly reactive in a number of bond-forming reactions. It is capable of reaction under both electrophilic and nucleophilic conditions and serves as a formylation reagent.

Active Methylene Compounds.

Triethyl orthoformate can formylate diethyl malonate under slightly acidic conditions.[8] With less activated compounds it can be induced to undergo a Mannich reaction,[32] and can also formylate a cyclohexanone enolate anion (eq 9).[33]

(9)

This reaction is noteworthy in its propensity for *C*-alkylation and the fact that the protected acetal raises the pK_a of the product relative to the unprotected β-dicarbonyl compound.

Heteroatom Nucleophiles.

The formylation of anilines is well known[34] and provides entry to a large array of functional groups.[35] Of greater interest is the ability of the product to be trapped in a subsequent reaction to afford heterocycles (eq 10).[9,36-38] Orthoformates also react readily with phosphorus nucleophiles.[39]

(10)

Organometallic Reactions.

In addition to the enolate reactions described above, orthoformates can also carry out the formal formylation of Grignard reagents.[10]

Electrophilic Formylation.

It has been shown that the dialkoxycarbenium ion can be readily formed by acid treatment of orthoformates. While the reactive ion can be isolated and used directly,[11] the typical practice is to generate it in situ.

While not as universal as the Gatterman-Koch reaction, the cation works well for the formylation of activated aromatic compounds (eq 11).[40,41] Of greater synthetic utility is the effective formylation of alkynes (eq 12)[42] and alkenes (see below).

(11)

(12)

Reactions of silyl enol ethers with dialkoxycarbenium ions result in α-formyl ketones (eq 13),[43] much like those achieved above through the use of enolate anions. With a dienol silane (eq 14), regioselective γ-formylation is achieved.[44] In extended alkenic systems, cationic cyclization (eq 15) can be realized.[45]

(13)

(14)

R = CH_2=$CHCH_2$

(15)

Solvent for Thallium Trinitrate Oxidations.

While ***Thallium(III) Nitrate*** oxidations of aromatic ketones and chalcones often gives rise to mixtures of products, the use of trimethyl orthoformate as solvent gives substantially cleaner reactions and higher yields (eq 16).[12]

(16)

Related Reagents.

Diethyl Phenyl Orthoformate; ***Dimethoxycarbenium Tetrafluoroborate***; ***Dimethylchloromethyleneammonium Chloride***; ***N,N-Dimethylformamide***; ***N,N-Dimethylformamide Diethyl Acetal***; ***Methyl Formate***.

(powerful alkylating agent for the ethylation of sensitive or weakly nucleophilic functional groups;[1] analogous methylations are achieved using trimethyloxonium salts[2])

Alternate Name: Meerwein's salt.

Physical Data: (**1**) mp 92 °C; 116 °C; (**2**) 142-144 °C; (**3**) 130-133 °C; 135-137 °C; (**4**) 139 °C; (**5**) 141-143 °C; 179-180 °C; (**6**) 262 °C; (**7**) 156-158 °C; 159 °C; (**8**) 239-241 °C (**9**) 120-130 °C with effervescence and resolidifying; 181-183 °C.

Solubility: (**1**)-(**8**) sol liquid sulfur dioxide; (**1**) and (**5**) sol dichloromethane, chloroform, nitromethane; insol diethyl ether; (**2**) and (**6**) sol dichloromethane, arsenic trifluoride; (**3**) and (**7**) sol nitromethane; slightly sol dichloromethane, chloroform, tetrachloromethane, 1,2-dichloroethane; (**9**) sol nitromethane. A scale of solvent nucleophilicity has been based on the solvolysis of (**2**).[3]

Form Supplied in: (**2**), (**3**), (**5**), and (**7**) are commercially available as colorless solids; (**1**) is supplied as a 1 M solution in dichloromethane or as a colorless solid stabilized with diethyl ether.

Preparative Methods: there is an established method for (**1**).[4] (**5**) is reported[2] being contaminated by ethyldimethyloxonium salt. Convenient syntheses of pure (**5**) have been published;[5,6] similar methods yield (**2**) and (**6**).[7] Syntheses of (**3**) and (**7**),[1a,8] (**4**) and (**8**),[8] and (**9**)[9] are available.

Handling, Storage, and Precautions: solvent-free (**1**) is hygroscopic; it is conveniently stored in diethyl ether at -20 °C in a tightly stoppered bottle.[10] Contrary to recommendations,[4] the use of a dry box or an inert atmosphere is not required for most applications of (**1**). A sample of the oxonium salt-ether slurry may be transferred to the tared reaction flask, and after removal of the ether on a rotary evaporator the resulting solid may be used without further purification.[10] When alkylation requires the absence of acid, (**1**) should be handled in a dry box and before use it should be washed with anhydrous diethyl ether and dried by a stream of nitrogen.

Solvent-free (**5**) is less hygroscopic[2] than (**1**) and is stored in a tightly sealed bottle at -20 °C. It may be handled in the air for short periods of time. (**9**) is nonhygroscopic, may be stored at rt, but is more laborious to prepare than (**5**).

Trialkyloxonium salts have irritant and corrosive properties and are toxic due to their alkylating ability. In comparison with other alkylating agents, the dangers are minimized by the fact that oxonium salts are water-soluble, nonvolatile, crystalline solids, which are rapidly solvolyzed in aqueous solution. Nevertheless, skin and eyes should strictly be protected from contact with the solid

agents or their solutions. Use in a fume hood.

General Reactivity.

The high alkylating potential of trialkyloxonium salts has been well known since their discovery.[11] When either methylation or ethylation of weakly nucleophilic functional groups is desired, the use of the more reactive Me_3O^+ is preferred to that of Et_3O^+ salts.[2b] Ranking the common methylating agents in a sequence of decreasing methylating ability, $Me_2Cl^+SbF_6^-$ > $(MeO)_2CH^+BF_4^-$ > $Me_3O^+BF_4^-$ ($SbCl_6^-$, PF_6^-) > $MeOSO_2CF_3$ > $MeOSO_2F$ > $(MeO)_2SO_2$ > MeI,[12,13] demonstrates that Me_3O^+ salts possess high, but not the highest, reactivity (see also ***O-Methyldibenzofuranium Tetrafluoroborate***). Since the low solubility of Me_3O^+ salts may be a problem, sometimes the less reactive (and more toxic) $MeOSO_2F$ (magic methyl)[13] may be the reagent of choice for methylations. Trialkyloxonium SbF_6^-, $SbCl_6^-$, and PF_6^- salts are less sensitive to decomposition due to high anion stability than the corresponding tetrafluoroborates.[1e] Nevertheless, the latter are preferentially used depending on convenience and availability.

Alkylation of Anionic Nucleophiles.

The efficient transfer of alkyl groups from Me_3O^+ or Et_3O^+ salts to anionic nucleophiles has been applied to remove halide ions via alkylation and to replace them by suitable complex anions. Thus *N*-cyano- or *N*-acyl-*N*,*N*,*N*-trialkylammonium tetrafluoroborates have been obtained under anhydrous conditions via reaction of the corresponding halides with $Et_3O^+BF_4^-$ (**1**).[14] Since, besides the desired salts, only volatile alkyl halides and the corresponding ethers are formed, the method is superior to the treatment with ***Silver(I) Tetrafluoroborate***, which requires separation from silver halide precipitates. Using $Me_3O^+BF_4^-$ (**5**) the first stable β-phospha- and β-arsatrimethinecyanines (**10**$^+BF_4^-$)[15,16] have been prepared from the appropriate bromophosphane or -arsane precursors (**10**), the solutions of which show only low equilibrium concentrations of cyanine bromides (**10**$^+Br^-$), (eq 1); there are similar applications to transition metal-halogen complexes.[17]

(1)

Of the numerous alkylations of anionic substrates with trialkyloxonium salts,[1c,e] esterification of carboxylate anions is of special preparative interest. Although oxonium salts are readily hydrolyzed in aqueous solution, water may be a suitable solvent, when a high excess of $Et_3O^+BF_4^-$ (**1**) or $Me_3O^+BF_4^-$ (**5**) is used in the presence of $NaHCO_3$ or ***Diisopropylethylamine***.[18,19] Under these conditions, the in situ generated carboxylate anions of *N*-acylamino acids,[18] dipeptides (eq 2),[18] or labile hemins[19] are smoothly *O*-alkylated. ε-Amino, guanidino, carboxamido, and hydroxyl functions of alcohols or phenols may be present, but remain unaltered. Smooth esterifications of even sterically hindered carboxylic acids with equimolar amounts of (**1**) and (**5**) may conveniently be performed in dichloromethane using diisopropylethylamine as base.[10] Similarly, ethyl (*Z*)-2-methyl-4-oxo-2-butenoate is prepared from the corresponding hydroxybutenolide via *O*-ethylation of a carboxylate anion intermediate (eq 3).[20]

In the absence of a suitable base, no esterification of acetamino acids is achieved using $Me_3O^+BF_4^-$ (**5**), since under these conditions the carboxamide is more reactive than the carboxylic acid. The resulting imino ester salt may readily be converted into the corresponding *N*-ethylamino acid via reduction with $NaBH_4$ (eq 4).[21]

Trialkyloxonium salts, like other strongly electrophilic agents, when treated with ambident anions yield considerable amounts of products derived from alkyl attack at the site of highest electron density.[1d,e,22] Thus, in aprotic polar solvents, enolates of aliphatic ketones give mainly enol ethers via *O*-ethylation with $Et_3O^+BF_4^-$ (**1**),[23] while *C*-alkylation is predominant with the less reactive ethyl iodide (eq 5).[22,23] The ambident anions of imines behave similarly: with (**1**), enamines (via *N*-alkylation) are preferentially formed instead of the usually obtained *C*-alkylation products.[24] A discussion of the factors influencing the competition of *C*- and *heteroatom*-alkylation is available.[22] Exclusive mono- or bis-*O*-alkylations have been reported to occur for the reactions of cyclic β-diketones with equimolar or excess amounts of (**1**) (eq 6).[25]

Being formal analogs of enolates, lithium transition metal acylate complexes are readily *O*-alkylated with $Et_3O^+BF_4^-$ (**1**) or $Me_3O^+BF_4^-$ (**5**) to give alkoxycarbene complexes.[26] The metal acylate complexes are conveniently prepared from commercially available metal carbonyl complexes via addition of a suitable nucleophile (e.g. alkyl-, aryl-, alkynyllithium, or lithium dialkylamide). Nucleophilic addition and subsequent alkylation may be performed in a one-pot reaction (eq 7).[26,27] Alkoxycarbene complexes (especially those of chromium or tungsten) are valuable, versatile building blocks for numerous organic syntheses.[28] The unique benzannulation depicted in eq 8 may serve as a representative example;[28a] the starting material of this reaction is available via addition of ***Phenyllithium*** to ***Hexacarbonylchromium*** and sequential methylation with (**5**).[26]

Ethylations of lithium (or sodium) 1-alkynyltrialkylborates with $Et_3O^+BF_4^-$ (**1**) afford (*Z*)/(*E*)-alkenyldialkylboranes via an addition-rearrangement mechanism.[29,30] The boranes may readily be hydrolyzed to the corresponding (*Z*)/(*E*)-alkenes (eq 9).[29a] Oxidation of the alkenyldialkylborane intermediates provides a valuable route to ketones free of complications associated with the production of (*Z*)/(*E*) mixtures (eq 9).[29a] The highly stereoselective formation of a cyclic (*E*)-alkenylborane is favored, when 3-methoxypropynyltriethylborate is alkylated with (**1**) (eq 10).[30]

Alkylations of Uncharged Nucleophiles.

Usually Me_3O^+ or Et_3O^+ salts are applied to alkylate uncharged molecules.[1] The resulting cationic intermediates, though frequently subject to subsequent reactions with nucleophiles, have been isolated as stable salts in many cases.[1a,c,e] Thus trialkyloxonium salts are obtained from alicyclic (or acyclic dialkyl) ethers (eq 11)[11b] and alkoxycarbenium salts from dialkyl (or vinyl) ketones.[1a] The structures of some of these salts have been determined by using X-ray diffraction, e.g. the 1-ethoxyhomotropylium cation prepared from cyclooctatrienone according to eq 12 has been shown to be best regarded as a linear ethoxyoctatrienyl cation and not as a homoaromatic system.[31] *O*-Alkyllactonium salts may be generated from lactones (eq 13)[32,33] as well as trialkoxycarbenium salts from dialkyl carbonates.[1a,32a] However, most acyclic esters do not react with Me_3O^+ or Et_3O^+ salts.[1a,c,e,33] A discussion on the basis of equilibrium constants and calculations of methyl affinities has been published.[33] Even *O*-alkylation of *N*-methylenecarbamates leading to 1,1-dialkoxy-2-azapropenylium salts can only be achieved if the *N*-alkylation is sterically unfavorable, otherwise iminium salts are preferentially formed (eq 14).[34]

Reactions of Me_3O^+ or Et_3O^+ salts frequently afford isolable salts via elimination of a suitable leaving group from reactive, primary alkylation products, e.g. the alkylation of an alkoxy function generates an unstable trialkyloxonium intermediate, which readily loses a dialkyl ether to yield a stabilized carbocation. The formation of alkoxycarbenium salts from acetals (eq 15)[32a] or that of 1,3-dioxolan-2-ylium salts from 2-alkoxyethyl carboxylates (eq 16)[35] may serve as examples. The latter reaction has also been used to prepare ethylene acetals and hence aldehydes from esters via hydride transfer to 1,3-dioxolan-2-ylium intermediates (eq 17).[36]

Alkylations with Me_3O^+ or Et_3O^+ salts are usually performed to increase the reactivity of numerous functional groups toward nucleophiles. This is achieved by generating heteroatom-stabilized cations (mostly carbenium ions) from hetero-π-systems or by improving the leaving group ability of saturated *n*-bases via alkylation. For preparative applications, *O*- and *S*-alkylations play the most important role.

Activation via *O*-Alkylation.

With $Et_3O^+BF_4^-$, 2,3-disubstituted cyclopropenones afford 1-ethoxycyclopropenylium salts,[37,38] which readily react with nucleophiles;[38] the

synthesis of cyclic acetals or dithioacetals from 2,3-diphenylcyclopropenone may serve as an example (eq 18).[39] *O*-Alkyllactonium salts, generated according to eq 13, are smoothly converted into cyclic orthoesters with sodium alkanolates[32] or into thionolactones via sulfhydrolysis with sodium hydrosulfide (eq 19).[40] Besides these kinetically controlled additions to the carbenium center, many reactions of lactonium salts with nucleophiles have been reported to occur with ring opening.[1a,c,32a] The highly regio- and stereoselective formation of methyl (*E*)-4,8-alkadienoates via the in situ methylation of γ-alkenyl-γ-butyrolactones in the presence of allylsilanes illustrates this mode of reaction (eq 20).[41]

(19)

(20)

The rather intractable carboxamide or lactam groups are transformed into highly reactive, versatile intermediates by *O*-alkylations with Me_3O^+ or Et_3O^+ salts.[1c,e,42] Depending on the structure of the substrates and the workup, the resulting alkoxyaminocarbenium salts[1,42,43] (eq 21)[32a] are obtained or their subsequent transformation products: imino esters[1c,44] (eq 22)[44a], amide acetals[1c,42,43] (eq 23),[43a] or ketene *O*,*N*-acetals[43,45] (eq 24)[43a], which are usually submitted to further conversions.[1a,c,e,42-45]

(21)

(23)

(24)

The important bis-lactim ether method for the enantioselective synthesis of, for example, nonproteinogenic amino acids from the corresponding 2,5-diketopiperazines,[46] is based on the amide *O*-alkylation (eq 25)[46a] as well as the smooth hydrolysis of secondary[1c,21,47] or tertiary[48] carboxamides (eq 26)[48] and lactams.[49]

(25)

(26)

Activation via *S*-Alkylation.

Although several reagents are available for *S*-alkylations of acyclic or cyclic thioethers, Me_3O^+ or Et_3O^+ salts are frequently preferred since they provide sulfonium salts with nonnucleophilic anions.[1c,e,50] Deprotonation of suitable sulfonium derivatives yields sulfonium ylides as intermediates or isolable species,[51] which are of high preparative value. The stereoselective epoxy-annulation of ketosulfonium salts via sulfonium ylides serves as an example[52] (eq 27).[52a] Sulfonium salts are usually generated to provide leaving groups, e.g. for nucleophilic displacements[53] (eq 28)[53a] or for the formation of reactive iron carbene complexes[54] (eq 29).[54a]

(27)

(28)

(29)

The rather impracticable hydrolysis of cyclic thioacetals may smoothly be performed via *S*-alkylation[50] with excess $Me_3O^+BF_4^-$ in the presence of water (eq 30).[55] Similarly, a thioamide is easily hydrolyzed after *S*-alkylation with $Et_3O^+BF_4^-$ (eq 31);[56] analogous activations of thiono functions have been reported.[57]

The example depicted in eq 31 shows the striking chemoselectivity of ethylations with $Et_3O^+BF_4^-$ in favor of a thioamide group, which is exclusively attacked at the sulfur atom.[56] The carboxamide function present, which has a similar reactivity,[47b] in this case is sterically shielded.

Activation via *N*-Alkylation.

Alkylations of amines or imines leading to ammonium[58] or iminium salts[59] usually do not require powerful alkylating agents; nevertheless, Me_3O^+ or Et_3O^+ salts have also been applied.[1,58,59] Thus a dibenzo[*b*,*g*][1,5]thiazocine derivative with $Me_3O^+BF_4^-$ is exclusively methylated at the amino group[60] (eq 32).[60a] However, the corresponding sulfoxide yields the *O*-methylated product, in which significant N-S interaction with the hypervalent sulfur atom has been shown to be present[60b] (eq 33).[60a,b]

(33)

Besides numerous *N*-alkylations of alicyclic or aromatic five- and six-membered N-heterocycles,[1,61] reactions of preparative interest of Me_3O^+ or Et_3O^+ salts have been carried out with nitriles. The resulting nitrilium salts[1c,62] are versatile and reactive intermediates;[63] (see also ***O-Methyldibenzofuranium Tetrafluoroborate***). Their hydrolysis yields secondary carboxamides, and reactions with alcohols or amines result in the formation of imino esters or amidines.[63]

N-Ethylnitrilium salts are conveniently converted into aldehydes by reduction with trialkylsilanes and sequential hydrolysis of the resulting imines (eq 34).[64] The same salts yield secondary amines via imino esters formed in situ, and subsequent reduction with ***Sodium Borohydride*** (eq 35).[65] Since neither the nitrilium salts nor the intermediates have to be isolated, the transformations are performed as one-pot procedures starting from suitable nitriles.[64,65] *N*-Methylnitrilium salts have also been used for the smooth acylation of pyrrole and indole derivatives (eq 36).[66]

Triethyl Phosphite[1]

$(EtO)_3P$

[122-52-1] · $C_6H_{15}O_3P$ · Triethyl Phosphite · (MW 166.18)

(can react with electrophiles to form phosphonates or phosphates; can function as a reducing agent for a variety of functional groups; forms a stable complex with copper(I) iodide)

Physical Data: bp 155-157 °C/760 mmHg; *d* 0.958 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: clear, free flowing liquid in >97% purity.

Handling, Storage, and Precautions: should be stored in a dry place, preferably in a fume hood due to its pungent odor. The reagent is purified[1b] by treating with sodium (to remove water and dialkyl phosphonate), followed by decanting and distillation. The purified material may then be stored over activated molecular sieves.

Transesterification.

Hoffman reported that triethyl phosphite is easily transesterified when heated in the presence of aliphatic alcohols.[2] The uncatalyzed transformation occurs in three distinct steps which proceed at approximately equal rates. Transesterification using trimethanolethane in the presence of triethylamine affords the corresponding crystalline phosphite (eq 1).[3]

(1)

Organophosphonates.

Triethyl phosphite[4] has been used extensively in the synthesis of phosphonates via the Arbuzov reaction.[5,6] This general protocol works well with a variety of electrophiles and is carried out by simply heating the reactants between 100 °C and 150 °C using phosphite as solvent. Phosphonates bearing electron withdrawing groups β to phosphorus represent a valuable class of reagents which have been creatively applied to the stereoselective synthesis of alkenes (eqs 2-6).[6g-k] Acyl phosphonates, prepared from the corresponding acid halides, have been utilized as intermediates in the overall reduction of acids to aldehydes (eq 7),[7] and as intermediates in the preparation of vinylphosphonates (eq 8).[8]

(7)

(8)

A nonclassical Arbuzov approach to α-methoxybenzylphosphonates employs the treatment of acetals of aromatic aldehydes with triethyl phosphite in the presence of ***Boron Trifluoride Etherate*** (eq 9).[9] In contrast, direct arene phosphorylation has been achieved through treatment of aromatic substrates with triethyl phosphite and ***Cerium(IV) Ammonium Nitrate***.[10] In this case the active species is believed to be a phosphite radical cation (eq 10).

(9)

(10)

Vinyl Phosphates.

Perkow[11,12] discovered that α-halo aldehydes and ketones are converted to vinyl phosphates upon treatment with triethyl phosphite (eq 11). These intermediates are easily reduced to alkenes under dissolving metal conditions (eq 12).[13] In cases where the vinyl phosphate is acyclic, treatment with a strong base generally provides good yields of the corresponding alkyne (eq 13).[14]

(11)

(12)

(13)

Deoxygenation.

Triethyl phosphite is capable of deoxygenating a variety of organic substrates. Hydroperoxides, for example, are rapidly converted to alcohols after treatment with one equivalent of the reagent at ambient temperature (eq 14).[15] The reduction of peroxides generated in situ via enolate oxidation is a powerful technique for achieving regio and stereoselective α-hydroxylation (eq 15).[16] In addition to reducing hydroperoxides, triethyl phosphite has been utilized for the deoxygenation of *endo*-peroxides (eq 16),[17] diaroyl peroxides (eq 17)[18] and the reductive coupling of phthalic anhydride (eq 18).[19]

(14)

(15)

(16)

(17)

(18)

Scott reported that terminal epoxides can be reduced using forcing conditions while internal epoxides are generally unaffected, even at temperatures approaching 200 °C.[20] In contrast, Saegusa and co-workers discovered that α-keto acids are easily reduced to α-hydroxy acids under mild conditions in good to excellent yields (eq 19).[21]

(19)

The deoxygenation of nitrogenous functionalities using triethyl phosphite has also received attention.[22] Reductive cyclization of aromatic nitro-containing compounds has provided entry into a variety of heterocycles (eqs 20 and 21).[23] It has been suggested that a highly reactive nitrene

intermediate is involved in the cyclization process.[24] Aryl nitroso compounds subjected to these conditions experience a similar fate, although the reactive intermediate in this case is believed to be polar in nature (eq 22).[25]

(20)

(21)

R = Me, OMe

(22)

Azides are also subject to reduction by triethyl phosphite via a modified Staudinger process (eq 23).[26]

(23)

R^1 = alkyl; $R^1 = R^2 = H$

$R^1 = R^2$ = alkyl; $R^3 = H$

$R^1 = R^2 = R^3$ = alkyl

Desulfurization.

A frequently encountered application of triethyl phosphite is the conversion of cyclic thiocarbonates to the corresponding alkenes (Corey-Winter synthesis).[27] The reaction proceeds stereospecifically via a carbene intermediate and often results in good yields of desired alkene (eqs 24 and 25).[28]

(24)

(25)

The conversion of thiiranes to alkenes proceeds readily, in contrast to epoxide reduction.[29] For example, the episulfides of *cis*- and *trans*-2-butene are reduced smoothly and with high stereospecificity. Thiols[30] and disulfides[31] are reduced efficiently as well. In some cases, reductive desulfurization can be coupled with carbon-carbon bond formation. For example, reaction of di-*n*-butyl disulfide with triethyl phosphite in the presence of carbon monoxide gives a nearly quantitative yield of the corresponding homologated thioester (eq 26).[32]

(26)

In a completely unrelated example, [2,2]paracyclophane was synthesized from the corresponding bis-thioether via photochemical extrusion of sulfur mediated by triethyl phosphite (eq 27).[33] The concept of linking proximal carbon atoms with the extrusion of sulfur was used successfully by Eschenmoser in his synthesis of a vitamin B_{12} intermediate (eq 28),[34] while a modification of Barton's method allowed the synthesis of the highly strained diquadricyclanylidene (eq 29).[35]

(27)

(28)

(29)

A bimolecular coupling mediated by triethyl phosphite was applied to the synthesis of an interesting unsymmetrical tetrathiafulvalene, although yields were low due to competing homo coupling (eq 30).[36]

(30)

Carbonyl Adducts.

Triethyl phosphite reacts with α-diketones to form isolable cyclic phosphate esters. Upon additional heating, the corresponding alkynes are obtained (eq 31).[37]

(31)

Use in Cuprate Chemistry.

When added to solutions of *cis*-divinylcuprates, trimethyl phosphite facilitates the transfer of both vinyl groups via stabilization of the vinylcopper intermediate (eq 32).[38]

Copper(I) Iodide-Triethyl Phosphite is formed in 89% yield by the reaction of triethyl phosphite and ***Copper(I) Iodide*** in refluxing benzene.[39] The salt has been used to form arylcopper intermediates which participate in a modified Ullmann coupling sequence (eq 33).[40]

Related Reagents.

Trimethyl Phosphite.

Triethyl Phosphonoacetate[1]

$(EtO)_2P(O)CH_2CO_2Et$

[867-13-0] · $C_8H_{17}O_5P$ · Triethyl Phosphonoacetate · (MW 224.22)

(treatment with a base gives a phosphoryl-stabilized carbanion that reacts with aldehydes,[1] ketones,[1] nitrones,[2] epoxides,[3] nitroso compounds,[4] ketenes,[5] alkyl halides,[6c] and halogenating agents[6a,b])

Alternate Names: ethyl (diethoxyphosphinyl)acetate; diethyl (ethoxycarbonyl)methylphosphonate.

Physical Data: bp 152-153 °C/20 mmHg; *d* 1.130 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: irritant; store under N_2.

Reactions with Aldehydes and Ketones.

$(EtO)_2P(O)CH_2CO_2Et$ in either DME, THF, DMF, MeCN, dioxane, benzene, or toluene is deprotonated by ***Sodium Hydride***,[7] ***Sodium Amide***,[8] metal alkoxides,[9] and other bases to give a phosphoryl-stabilized carbanion, $[(EtO)_2P(O)\text{-}CHCO_2Et]\ M^+$. Subsequent reaction of the carbanion with an aldehyde or ketone gives an (*E*)-α,β-unsaturated ester as the major product in a Horner-Wadsworth-Emmons (HWE) reaction (eqs 1-4)[1] (see also ***Trimethyl Phosphonoacetate***). The phosphate ester byproduct is water soluble, unlike the Wittig byproduct (Ph_3PO), and is easily removed at the completion of the reaction. Ketones and aliphatic aldehydes often give the (*Z*)-α,β-unsaturated ester in addition to the (*E*)-isomer,[1c,d] the isomer ratio being influenced by the reaction solvent (eq 1).[7a] Some ketones and aldehydes that are unreactive to Wittig alkenation conditions (e.g. 3-keto steriods[9,10] and glucose derivatives[11]) will react with the carbanion of $(EtO)_2P(O)CH_2CO_2Et$. The Peterson alkenation reaction of lithio ethyl trimethylsilylacetate with aldehydes and ketones offers a mild alternative to both the HWE and Wittig approaches to α,β-unsaturated esters.[12] The Peterson reaction often gives the (*Z*)-isomer as the major product.[12b] (*Z*)-Alkenes are also obtained from HWE reactions using bis(2,2,2-trifluoroethyl) phosphonates (see also ***Trimethyl Phosphonoacetate***).[13]

(1)

Milder reaction conditions have been developed to increase yields, accommodate sensitive substrates and minimize undesired side reactions such as double bond migrations, Knoevenagel condensation, Cannizzaro reaction, and Michael addition.[1] HWE reactions of aldehydes and $(EtO)_2P(O)CH_2CO_2Et$ have been carried out in two-phase liquid-liquid conditions (aqueous $NaOH/CH_2Cl_2$) in the presence of a phase transfer catalyst, thus eliminating the need for anhydrous solvents.[14] Superior yields and reduced reaction times were obtained

using aromatic aldehydes and ketones under solid-liquid two-phase conditions (powdered NaOH or KOH/THF) (eq 2).[14b,c]

(2)

Aliphatic and particularly aromatic aldehydes give high yields of (*E*)-α,β-unsaturated esters using $(EtO)_2P(O)CH_2CO_2Et$ and K_2CO_3 (eq 2)[15] or Cs_2CO_3[16] under solid-liquid conditions. K_2CO_3 has also been used in highly concentrated (6-10 molar) aqueous solutions under heterogeneous liquid-liquid conditions in the absence of organic solvent (eq 2).[15a,c] The combination of aqueous K_2CO_3 and $(EtO)_2P(O)CH_2CO_2Et$ has been employed elsewhere, e.g. under these conditions glutaraldehyde and succinaldehyde give 1-ethoxycarbonyl-6-cyclohexenol and 1-ethoxycarbonyl-5-cyclopentenol, respectively,[17] and aqueous formaldehyde gives ethyl α-(hydroxymethyl)acrylate[15a] rather than the normal HWE product. The use of D_2O, rather than water, gives a general preparation of α-deuterated α,β-unsaturated esters[18] (%D > 90).

Furfural reacts with $(EtO)_2P(O)CH_2CO_2Et$ and activated ***Barium Hydroxide*** catalyst at 70 °C in dioxane containing a trace of water to give (*E*)-ethyl 3-(2´-furyl)acrylate in quantitative yield.[19] Reaction times are reduced in comparison with other solid-liquid procedures.[19] No secondary reactions were observed, in contrast to aqueous base catalysis, and the method is applicable to hindered aldehydes.[19] A reduction in both the amount of $Ba(OH)_2$ catalyst required and the reaction time is obtained using sonochemical, rather than thermal activation.[20]

The reaction of an aldehyde with $(EtO)_2P(O)CH_2CO_2Et$ and ***Diisopropylethylamine*** (DIPEA)[21,22] or ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU)[21,23] in a stirred suspension of ***Lithium Chloride*** in dry MeCN gives excellent yields of (*E*)-α,β-unsaturated esters (eq 3).[21] The method is widely used with base-sensitive aldehydes.[21-23] Few reports have appeared using a ketone rather than an aldehyde under these conditions.[21,24] The use of DIPEA, rather than DBU, has been reported to give less epimerization of the aldehyde component (eq 4).[22b] An interesting extension of this reaction proceeds by an in situ oxidation and HWE coupling (eq 5).[22c] The combination of $(EtO)_2P(O)CH_2CO_2Et$, TEA, LiCl and an aldehyde also gives high yields of an α,β-unsaturated ester.[25] The use of $(CF_3CH_2O)_2P(O)CH_2CO_2Et$ has extended the scope of this reaction to include ketones.[25,26] Other catalysts of the HWE reaction include ***Alumina***, and ***Potassium Fluoride-Alumina***.[27] Polymer-bound phosphonates have also received some attention.[28]

(3)

(4)

$(EtO)_2P(O)CH_2CO_2Et$, DIPEA, LiCl, rt	95:5	65%
$(EtO)_2P(O)CH_2CO_2Et$, DBU, LiCl, rt	22:78	85%
$Ph_3PCH_2CO_2Et$, toluene, reflux	58:42	76%

(5)

Diisobutylaluminum Hydride (DIBAL) reduction of saturated esters[29] and lactones[29a] at -78 °C in the presence of the NaH-derived carbanion of $(EtO)_2P(O)CH_2CO_2Et$ gives good yields of the homologous esters with >90% (*E*) stereochemistry and with little or no overreduction of either the starting material or product ester (eq 6).[29a] The reaction of $(EtO)_2P(O)CH_2CO_2Et$ with either glucopyranoses[11b] or hydroxy phthalides in the presence of 1 mol % of tetra-*n*-hexylammonium bromide[30] gives ring-opened alkenes in good yields.

(6)

The addition of an acyl phosphonate [e.g. $(EtO)_2P(O)COPh$] to the NaH-derived phosphoryl carbanion of $(EtO)_2P(O)CH_2CO_2Et$, gives the (*Z*)-alkene as the major product.[31] The analogous Wittig alkenation reaction gives (*E*)-alkenes.[31]

Other Reactions.

Nitrones react with $(EtO)_2P(O)CH_2CO_2Et$ and NaH in DME or alkali metal alkoxides in alcoholic solvents to give aziridines and cyclic enamines (eq 7).[2] Cyclopropanes are prepared by refluxing an epoxide with $(EtO)_2P(O)CH_2CO_2Et$,[3a] or the corresponding sodium phosphoryl carbanion in dioxane or DME[3b] (eq 8).[3c,d]

NaH, DME, reflux	35%	-
t-BuONa, *t*-BuOH, reflux	75%	-
MeONa, MeOH, reflux	6%	36%

7-Pteridinones are prepared by treating the sodium phosphoryl carbanion of $(EtO)_2P(O)CH_2CO_2Et$ with 4,6-diamino-5-nitrosopyrimidines (eq 9).[4] Ketenes react with the NaH-derived carbanion of $(EtO)_2P(O)CH_2CO_2Et$ in DME at 50 °C to give allenes (eq 10).[5,6a] α-Alkylated and arylated phosphonates are prepared by reacting the carbanion of $(EtO)_2P(O)CH_2CO_2Et$ with an allyl[6c] and benzyl[32] halide, respectively. Triethyl phosphonoacetate is also readily halogenated at the α-position.[6a,b]

Triethylsilane[1]

Et_3SiH

[617-86-7] · $C_6H_{16}Si$ · Triethylsilane · (MW 116.31)

(mild reducing agent for many functional groups)

Physical Data: mp -156.9 °C; bp 107.7 °C; *d* 0.7309 g cm^{-3}.

Solubility: insol H_2O; sol hydrocarbons, halocarbons, ethers.

Form Supplied in: colorless liquid; widely available.

Purification: simple distillation, if needed.

Handling, Storage, and Precautions: triethylsilane is physically very similar to comparable hydrocarbons. It is a flammable, but not pyrophoric, liquid. As with all organosilicon hydrides, it is capable of releasing hydrogen gas upon storage, particularly in the presence of acids, bases, or fluoride-releasing salts. Proper precautions should be taken to vent possible hydrogen buildup when opening vessels in which triethylsilane is stored.

Introduction.

Triethylsilane serves as an exemplar for organosilicon hydride behavior as a mild reducing agent. It is frequently chosen as a synthetic reagent because of its availability, convenient physical properties, and economy relative to other organosilicon hydrides which might otherwise be suitable for effecting specific chemical transformations.

Hydrosilylations.

Addition of triethylsilane across multiple bonds occurs under the influence of a large number of metal catalysts.[2] Terminal alkynes undergo hydrosilylations easily with triethylsilane in the presence of platinum,[3] rhodium,[3a,4] ruthenium,[5] osmium,[6] or iridium[4] catalysts. For example, phenylacetylene can form three possible isomeric hydrosilylation products with triethylsilane; the (*Z*)-β-, the (*E*)-β-, and the α-products (eq 1). The (*Z*)-β-isomer is formed exclusively or preferentially with ruthenium[5] and some rhodium[4] catalysts, whereas the (*E*)-β-isomer is the major product formed with platinum[3] or iridium[4] catalysts. In the presence of a catalyst and carbon monoxide, terminal alkynes undergo silylcarbonylation reactions with triethylsilane to give (*Z*)- and (*E*)-β-silylacrylaldehydes.[7] Phenylacetylene gives an 82% yield of a mixture of the (*Z*)- and (*E*)-isomers in a 10:1 ratio when 0.3 mol % of ***Dirhodium(II) Tetrakis(perfluorobutyrate)*** catalyst is used under atmospheric pressure at 0 °C in dichloromethane (eq 2).[7d] Terminal alkenes react with triethylsilane in the presence of this catalyst to form either normal anti-Markovnikov hydrosilylation products or allyl- or vinylsilanes, depending on whether the alkene is added to the silane or vice versa.[8] A mixture of 1-hexene and triethylsilane in the presence of 2 mol % of an iridium catalyst ($[IrCl(CO)_3]_n$) reacts under 50 atm of carbon monoxide to give a 50% yield of a mixture of the (*Z*)- and (*E*)-enol silyl ether isomers in a 1:2 ratio (eq 3).[9] Hydrolysis yields the derived acylsilane quantitatively.[9]

A number of metal complexes catalyze the hydrosilylation of various carbonyl compounds by triethylsilane.[10] Stereoselectivity is observed in the hydrosilylation of ketones[11] as in the reactions of 4-*t*-butylcyclohexanone and triethylsilane catalyzed by ruthenium,[12] chromium,[13] and rhodium[12,14] metal complexes (eq 4). Triethylsilane and ***Chlorotris(triphenylphosphine)rhodium(I)*** catalyst effect the regioselective 1,4-hydrosilylation of α,β-unsaturated ketones and aldehydes.[15,16] Reduction of mesityl oxide in this manner results in a 95% yield of product that consists of 1,4- and 1,2-hydrosilylation isomers in a 99:1 ratio (eq 5). This is an exact complement to the use of phenylsilane, where the ratio of respective isomers is reversed to 1:99.[16]

$(Ph_3P)_3RuCl_2$, AgTFA, PhMe, Δ	5:95
Et_4N^+ $[HCr_2(CO)_{10}]^-$, DME, Δ	10:90
$(Ph_3P)_3RhCl$, PhMe, Δ	11:89
$[Rh(\eta^3\text{-}C_3H_5)\{P(OMe)_3\}_3]$, PhH	29:71

Silane Alcoholysis.

Triethylsilane reacts with alcohols in the presence of metal catalysts to give triethylsilyl ethers.[17] The use of dirhodium(II)

perfluorobutyrate as a catalyst enables regioselective formation of monosilyl ethers from diols (eq 6).[17a]

Formation of Singlet Oxygen.

Triethylsilane reacts with ozone at -78 °C in inert solvents to form triethylsilyl hydrotrioxide, which decomposes at slightly elevated temperatures to produce triethylsilanol and ***Singlet Oxygen***. This is a convenient way to generate this species for use in organic synthesis.[18]

Reduction of Acyl Derivatives to Aldehydes.

Aroyl chlorides and bromides give modest yields of aryl aldehydes when refluxed in diethyl ether with triethylsilane and ***Aluminum Chloride***.[19] Better yields of both alkyl and aryl aldehydes are obtained from mixtures of acyl chlorides or bromides and triethylsilane by using a small amount of 10% ***Palladium on Carbon*** catalyst (eq 7).[20] This same combination of triethylsilane and catalyst can effect the reduction of ethyl thiol esters to aldehydes, even in sensitive polyfunctional compounds (eq 8).[21]

Radical Chain Reductions.

Triethylsilane can replace toxic and difficult to remove organotin reagents for synthetic reductions under radical chain conditions. Although it is not as reactive as ***Tri-n-butylstannane***,[22] careful choice of initiator, solvent, and additives leads to effective reductions of alkyl halides,[23,24] alkyl sulfides,[23] and alcohol derivatives such as *O*-alkyl *S*-methyl dithiocarbonate (xanthate) and thionocarbonate esters.[22,23,25,26] Portionwise addition of 0.6 equiv of ***Dibenzoyl Peroxide*** to a refluxing triethylsilane solution of *O*-cholestan-3β-yl *O*´-(4-fluorophenyl) thionocarbonate gives a 93% yield of cholestane (eq 9).[22] The same method converts bis-xanthates of *vic*-diols into alkenes (eq 10).[22] Addition of a small amount of thiol such as *t*-dodecanethiol to serve as a polarity reversal catalyst[24] with strong radical initiators in nonaromatic solvents also gives good results.[23,25] Treatment of ethyl 4-bromobutanoate with four equiv of triethylsilane, two equiv of dilauroyl peroxide (DLP), and 2 mol % of *t*-dodecanethiol in refluxing cyclohexane for 1 hour yields ethyl butanoate in 97% yield (eq 11).[23]

(10)

(11)

Ionic Hydrogenations and Reductive Substitutions.

The polar nature of the Si-H bond enables triethylsilane to act as a hydride donor to electron-deficient centers. Combined with Brønsted or Lewis acids this forms the basis for many useful synthetic transformations.[27] Use of ***Trifluoromethanesulfonic Acid*** (triflic acid) at low temperatures enables even simple alkenes to be reduced to alkanes in high yields (eq 12).[28] ***Boron Trifluoride*** monohydrate is effective in promoting the reduction of polycyclic aromatic compounds (eq 13).[29] Combined with thiols, it enables sulfides to be prepared directly from aldehydes and ketones (eq 14).[30] Combinations of triethylsilane with either ***Trifluoroacetic Acid***/ammonium fluoride or ***Pyridinium Poly(hydrogen fluoride)*** (PPHF) are effective for the reductions of alkenes, alcohols, and ketones (eq 15).[31] Immobilized strong acids such as iron- or copper-exchanged ***Montmorillonite K10***[32] or the superacid ***Nafion-H***[33] facilitate reductions of aldehydes and ketones[32] or of acetals[33] by increasing the ease of product separation (eq 16). Boron trifluoride and triethylsilane are an effective combination for the reduction of alcohols, aldehydes, ketones (eq 17),[34] and epoxides.[35] ***Boron Trifluoride Etherate*** sometimes may be substituted for the free gas.[36]

(12)

(13)

(14)

(15)

(16)

(17)

Triethylsilane in 3M ethereal ***Lithium Perchlorate*** solution effects the reduction of secondary allylic alcohols and acetates (eq 18).[37] The combination of triethylsilane and ***Titanium(IV) Chloride*** is a particularly effective reagent pair for the selective reduction of acetals.[38] Treatment of (±)-frontalin with this pair gives an 82% yield of tetrahydropyran products with a *cis*:*trans* ratio of 99:1 (eq 19).[38b] This exactly complements the 1:99 product ratio of the same products obtained with ***Diisobutylaluminum Hydride***.[38b]

(18)

(19)

Triethylsilane and trityl salts[39] or ***Trimethylsilyl Trifluoromethanesulfonate***[40] are effective for the reduction of various ketones and acetals, as are combinations of ***Chlorotrimethylsilane*** and indium(III) chloride[41] and ***Tin(II) Bromide*** and ***Acetyl Bromide***.[42] Isophthaldehyde undergoes reductive polycondensation to a polyether when treated with triethylsilane and ***Triphenylmethyl Perchlorate***.[43]

Triethylsilane reduces nitrilium ions to aldimines,[44] diazonium ions to hydrocarbons,[45] and aids in the deprotection of amino acids.[46] With aluminum halides, it reduces alkyl halides to hydrocarbons.[47]

Related Reagents.

Phenylsilane-Cesium Fluoride; ***Tri-n-butylstannane***; ***Tricarbonylchloroiridium-Diethyl(methyl)silane-Carbon Monoxide***; ***Triethylsilane-Trifluoroacetic Acid***.

Triethylsilane-Trifluoroacetic Acid[1]

Et_3SiH-CF_3CO_2H

[617-86-7] · $C_6H_{16}Si$ · Triethylsilane-Trifluoroacetic Acid · (MW 116.31)

[599-00-8] · $C_2HF_3O_2$ · Triethylsilane-Trifluoroacetic Acid · (MW 114.03)

(useful reducing agent combination for ionic hydrogenation of many functional groups[1])

Physical Data: see ***Triethylsilane*** and ***Trifluoroacetic Acid***.

Solubility: Et_3SiH: insol H_2O; sol hydrocarbons, chlorocarbons, ethers. CF_3CO_2H: sol H_2O, chlorocarbons, ethers.

Form Supplied in: both are colorless liquids; widely available in pure form.

Purification: simple distillation, if needed.

Handling, Storage, and Precautions: triethylsilane is a flammable, nonpyrophoric liquid, physically similar to comparable hydrocarbons. Proper precautions should be taken to vent possible hydrogen buildup when opening vessels in which triethylsilane is stored. As with all organosilicon hydrides, it is capable of releasing hydrogen gas upon storage, particularly in the presence of acids, bases, or fluoride-releasing salts. Trifluoroacetic acid is a corrosive, toxic acid that produces serious chemical burns upon contact with skin.

Introduction.

The reagent combination of ***Triethylsilane*** as a hydride donor and ***Trifluoroacetic Acid*** (TFA) as a proton donor constitutes a powerful, yet selective, means for the hydrogenation of many functional groups. Many acetals, alcohols, aldehydes, alkenes, cyclopropanes, hemiacetals, ketones, and thiophenes and some alkynes, dihydropyridines, disulfides, enamines, ethers, furans, imidazolones, imines, indoles, *O*-acyl oximes, sulfides, thiopyrans, *p*-quinones, and α,β-unsaturated ketones are reduced by this reagent system. Functionalities which are generally unaffected by these reductive conditions include most amide, arene, carboxylate, ester, ether, halide, nitrile, nitro, sulfonate, and phenolic and primary aliphatic hydroxy groups.

The reactions are sometimes run without solvent, but most often a solvent such as $MeNO_2$, CCl_4, $CHCl_3$, or, preferably, CH_2Cl_2 is used. Reactions are performed at room temperature or below and are worked up by careful addition of a base such as solid, anhydrous ***Potassium Carbonate*** followed by filtration and distillation to separate the product from the solvent and residual reagents and byproducts.[2] Only a slight stoichiometric excess of the silane is normally used, but often several equivalents of acid are used in order to conduct the reductions at reasonable rates.

Specific Functional Group Reductions.

Alcohols capable of producing carbenium ions spanning a range of stabilities of more than 24 pK_{R^+} units are reduced to hydrocarbons when treated with trifluoroacetic acid in the presence of triethylsilane.[2] Cyclopropylcarbinols may be reduced to cyclopropane hydrocarbons without ring opening.[3] Use of deuteriated silane yields deuterium-labeled hydrocarbons (eq 1).[4] Stereospecific reduction of metal-complexed alcohols can be effected without concomitant reduction of isolated terminal C=C bonds (eq 2).[5]

(1)

(2)

Sequential treatment of amides, lactams, or ureas with aqueous, basic ***Formaldehyde*** followed by triethylsilane and trifluoroacetic acid causes the intermediate methylols to be reduced to the corresponding *N*-methylated products, generally in very high yields (eq 3).[6] Cyclic hemiacetals may be reduced to cyclic ethers with a high degree of stereoselectivity (eq 4).[7]

(3)

(4)

Alkenes that yield carbenium ions no more stable than secondary alkyl cations upon protonation do not normally undergo reduction by the action of triethylsilane and trifluoroacetic acid: thus isolated terminal -CH=CH_2 groups and simple vicinal 1,2-disubstituted alkenes are normally unaffected, while conjugated or more highly substituted alkene functions are reduced to alkanes.[8] Substituted cyclopropanes undergo reductive ring opening,[9] but alkynes are nearly inert to these conditions.[10] Only the isolated trisubstituted C=C bond is reduced when an unsaturated chroman derivative is treated with a 2-nitropropane solution of triethylsilane and trifluoroacetic acid containing ***Lithium Perchlorate*** (eq 5).[11]

(5)

The reagent combination of triethylsilane and trifluoroacetic acid reduces electron-rich or aromatic aldehydes and ketones to a methyl or

methylene group, respectively.[12] Addition of a catalytic amount of $LiClO_4$ or ***Boron Trifluoride Etherate*** to the reaction mixture permits regioselective reduction of the side chain carbonyl group even in polyfunctional enones (eq 6).[13] Many aldehydes and ketones react to give symmetrical ethers in the absence of external alcohols[14] and unsymmetrical ether products when the reductions are run in the presence of added alcohols (eq 7).[15] Reduction of α,β-unsaturated ketones using a ketone:silane:acid ratio; = 1:1:10 gives products with the C=C bond reduced, whereas changing the ratio to 1:3:10 gives products with both the C=C and C=O bonds reduced (eq 8).[16]

(6)

(7)

(8)

Reduction of *O*-benzoyl oximes gives *O*-benzoyl amines (eq 9).[17] Tryptophan is reduced and other indoles undergo stereoselective transformations into *cis*-indolines (eq 10).[18]

(9)

For related discussions, see also the entry on ***Triethylsilane***.

3-Triethylsilyl-3-buten-2-one

[20533-29-3] · $C_{10}H_{20}OSi$ · 3-Triethylsilyl-3-buten-2-one · (MW 184.39)

(methyl vinyl ketone surrogate[1] useful as Michael acceptor in Robinson annulation reactions[2])

Physical Data: bp 83 °C/7 mmHg.

Analysis of Reagent Purity: ^{1}H NMR spectrum ($CDCl_3$): δ 6.58 (d, *J* = 2 Hz, 1H, C*H*), 6.11 (d, *J* = 2 Hz, 1H, C*H*), 2.15 (s, 3H, CH_3), 0.4-1.2 [m, 15H, $Si(CH_2CH_3)_3$]; IR: 1669 cm^{-1}; mass spectrum: *m/e* 184 (M^+).

Preparative Methods: can be prepared by the reaction of 1-bromo-1-triethylsilylethylene with acetaldehyde.[1] This substance was obtained pure only by preparative gas chromatography. The less pure distilled product can be used in annulations.[2]

Handling, Storage, and Precautions: this material showed no tendency to deteriorate when stored under an argon atmosphere at -20 °C.

Annulation.

One of the most useful synthetic applications of the Michael reaction is the Robinson annulation reaction,[3] which is often utilized in the synthesis of steroids and terpenes. In general, the annulation of cyclohexanone with ***Methyl Vinyl Ketone*** (MVK) and its homologs, especially under aprotic, kinetic enolate conditions, produces rather poor yields of the desired products.[4] This is mainly due to polymerization of the very reactive vinyl ketone under basic conditions, but other factors, including the fact that the intermediate Michael adduct and the original ketone have similar pK_a values and reactivities such that competitive reaction of the product with the vinyl ketone can ensue, may also be involved.

In 1973, Stork and Ganem[2] reported that under aprotic conditions, α-silylated vinyl ketones such as 3-triethylsilyl-3-buten-2-one participate in Michael additions with the lithium enolate of cyclohexanone to give, following cyclization of the product with ***Sodium Methoxide*** in methanol, the desired octalone in 80% overall yield (eq 1) (see also ***3-Trimethylsilyl-3-buten-2-one***). The silyl group is easily removed during the aldol cyclization step; removal occurs by nucleophilic attack on silicon, resulting in displacement of the ketone enolate. The corresponding reaction with methyl vinyl ketone itself gave less than 5% of the Michael addition product.[2]

(1)

The annulation of 2-alkylcyclohexanones with methyl vinyl ketone and its homologs has also been examined. While condensation at the less substituted α-carbon can be effected using the corresponding enamines,[5] the basic conditions required for reaction at the more substituted α-carbon generally result in polymerization of the methyl vinyl ketone and low yields. This type of difficulty has been avoided with the use of alkyl halides instead of methyl vinyl ketone, but a number of steps are then required to transform the added alkyl group into the desired 3-ketoalkyl function.[6] Application of the 3-triethylsilyl-3-buten-2-one technology, via reaction with the potassium enolate of 2-methylcyclohexanone in *t*-butanol, produced the desired functionalized octalone in 60% yield following cyclization using a sodium hydroxide-isopropanol solution (eq 2).[2] The steric effect of the large triethylsilyl group may also play a role by preventing further unwanted reactions at the α-carbon of the Michael adduct.

Triethylsilyl Hydrotrioxide

$Et_3SiOOOH$

[101631-06-5] · $C_6H_{16}O_3Si$ · Triethylsilyl Hydrotrioxide · (MW 164.31)

(alkene oxidation, dioxetane formation[1])

Preparative Methods: addition of ***Triethylsilane*** (2 equiv) to a cold (-78 °C), saturated methylene chloride solution of ***Ozone*** (ca. 0.04 M) results in discharge of the color with formation of triethylsilyl hydrotrioxide within 45 s.[2]

Handling, Storage, and Precautions: is prepared in solution immediately before use. In methylene chloride at -78 °C, the half-life of the reagent has been estimated to be a few minutes.[2] Precautions appropriate for reactions which utilize or generate peroxides should be used.

Alkene Oxidation Reactions.

The reaction of triethylsilane with ozone and use of the intermediate triethylsilyl hydrotrioxide in oxidation reactions have been described. Initial oxidation reactions reported included the formation of the 9,10-endoperoxide from 9,10-dimethylanthracene (eq 1), and an allylic hydroperoxide from 2,3-dimethyl-2-butene (eq 2). Researchers also observed a near-IR emission from triethylsilyl hydrotrioxide as it decomposed at -60 °C, consistent with generation of singlet oxygen.[2] Other workers have characterized triethylsilyl hydrotrioxide by NMR spectroscopy and and measured the kinetics of its decomposition in deuterated acetone.[3]

(1)

(2)

Subsequent work examined the use of triethylsilyl hydrotrioxide in alkene oxidations and found it to be effective in oxidative cleavage of unactivated terminal and internal alkenes into carbonyl fragments, and in formation of 1,2-dioxetanes from vinyl aromatics and vinyl ethers.[1,4-6] The results of this research indicated that the reaction proceeds via direct interaction of the alkene and triethylsilyl hydrotrioxide without the intermediacy of singlet oxygen. Allylbenzene reacted with triethylsilyl hydrotrioxide followed by ***Lithium Aluminum Hydride*** reduction to give 2-phenylethanol (eq 3). The same sequence of reactions gave 1-nonanol and 1,9-nonanediol in 64% and 74% yield, respectively, from methyl oleate (eq 4).[1] It has been noted in the cleavage of alkenes by triethylsilyl hydrotrioxide that the presence of an ether or ester function in the molecule results in improved yields, even when the oxygen function is remote from the double bond. Addition of diethyl ether or ethyl acetate does not improve the reactions of unsaturated hydrocarbons.[5]

(3)

In the case of an enol ether derivative (eq 5), reaction with triethylsilyl hydrotrioxide produced an intermediate dioxetane which was cleaved to give 3-phenylpropionaldehyde upon warming. In contrast, reaction of the same enol ether with photochemically generated singlet oxygen proceeded via an ene pathway. After hydrolysis, this gave an α,β-unsaturated aldehyde in 37% yield.[1]

Reaction of triethylsilyl hydrotrioxide with a keto vinyl ether and subsequent rearrangement of the dioxetane intermediate resulted in formation of the 1,2,4-trioxane product in 58% overall yield (eq 6).[5] This model system for the naturally occurring antimalarial artemisin was similarly prepared in 48% yield using singlet oxygen.[7] Both singlet oxygen and triethylsilyl hydrotrioxide have been used in the synthesis of a regiospecifically oxygen-18 labeled model system.[6]

3-Triethylsilyloxy-1,4-pentadiene

[62418-65-9] · $C_{11}H_{22}OSi$ · 3-Triethylsilyloxy-1,4-pentadiene · (MW 198.42)

(a masked vinyl ketone synthon;[7,8] a precursor for either the diene or dienophile in the intramolecular Diels-Alder reaction[2])

Physical Data: bp 140 °C; *n*20D 1.4390.

Solubility: sol pentane, benzene, THF, ether, CH_2Cl_2.

Analysis of Reagent Purity: NMR, GC (4.56 min on 1 mm 5% OV 225 on Chromosorb W at 108 °C) or TLC: R_f = 0.15 (pentane) or 0.6 (benzene).

Form Supplied in: commercially available.

Preparative Methods: by silylation of 3-hydroxy-1,4-pentadiene with ***Chlorotriethylsilane***.[1,2] Other relatives of the title compound are available by silylation with ***Chlorotrimethylsilane***[2] or ***t-Butyldimethylchlorosilane***.[3] 3-Trimethylsilyloxy-1,4-pentadiene is usually prepared and used in situ. Storage of 3-trimethylsilyl-1,4-pentadiene at -30 °C is recommended.[2] The dianion of the parent 3-hydroxy-1,4-pentadiene can also be prepared.[4]

Handling, Storage, and Precautions: use in a fume hood.

General Discussion.

3-Triethylsilyloxy-1,4-pentadiene may be used to prepare the useful 3-triethylsilyloxypentadienyl anion via metalation with ***s-Butyllithium*** (eq 1).[1,2]

(1)

Reaction of the 3-triethylsilyloxypentadienyl anion with electrophiles is usually regioselective for the γ-adduct (eq 2 and Table 1).[2,5,7] This reaction provides a direct route to substituted dienes, as well as to vinyl ketones after hydrolysis. A representative procedure is as follows: a solution of 3-triethylsiloxy-1,4-pentadiene in THF was cooled to -78 °C and a solution of *s*-butyllithium in cyclohexane (1.1 equiv) was added dropwise over 30 min. The electrophile dissolved in THF was then added dropwise to the often yellow pentadienyl anion solution. The reaction mixture was stirred for 15 min and then quenched with saturated NH_4Cl solution and the product extracted with ether.

(2)

Table 1 Regioselective Reactions of 3-Triethylsilyloxy-1,4-pentadiene with Typical Electrophiles

Entry	Electrophile (E^+)	Yield (%)	Ratio γ to α product	Ref.
1	H_2O	87	100:0	2
2	TMSCl	89	100:0	2
3	MeCl	85	100:0	2
4	*i*-PrI	85	23:77	2
5	$PhCH_2Cl$	84	49:51	2
6	CH_2O	84	83:17	2
7		77	96:4	2
8		63	4:1	5
9	$PhSiMe_2Cl$	75	100:0	7

A wide variety of electrophiles may be used and the selectivity is based on kinetics. In some cases the products have been thermally interconverted (cf. entry 8, Table 1).[5,6] Because of polarity differences, the isomeric products usually can be separated by silica gel chromatography.

Elaboration of the alkylation products to give vinyl ketones may be accomplished with ***Potassium Fluoride*** in methanol at -10 to 0 °C or in *i*-PrOH at 25 °C (eq 3). For example, preparation of β-hydroxylethyl vinyl ketone synthons has been accomplished using a $PhMe_2Si$ unit as a masked hydroxyl group (eq 3).[7,8]

(3)

The method has been used to prepare intermediates for intramolecular Diels-Alder reactions (eqs 4 and 5).[2-6] The title reagent may provide ether the diene for the intramolecular Diels-Alder (eq 4)[4] or, after hydrolysis, the dienophile (eq 5).[3]

Triethylsilyl Perchlorate

Et_3SiClO_4

[18244-91-2] · $C_6H_{15}ClO_4Si$ · Triethylsilyl Perchlorate · (MW 214.75)

(potent silylating agent; Lewis acid catalyst)

Physical Data: distillable colorless liquid, bp 45-46 °C/1 mmHg[1] or 43-45 °C/0.5 mmHg.[2]

Solubility: sol most organic solvents; CH_2Cl_2 is most commonly used

Preparative Methods: prepared from ***Chlorotriethylsilane*** using ***Silver(I) Perchlorate***[1] (eq 1) or from ***Triethylsilane*** by treatment with silver perchlorate[3] or ***Triphenylmethyl Perchlorate***[2] (eq 2). Of these methods, the trityl perchlorate procedure may be safer and more cost-effective.

$$Et_3SiCl \xrightarrow{AgClO_4} Et_3SiClO_4 \qquad (1)$$

$$Et_3SiH \xrightarrow[\text{or } AgClO_4]{Ph_3\overset{+}{C}\ \ ClO_4^-} Et_3SiClO_4 \qquad (2)$$

Handling, Storage, and Precautions: reacts rapidly with water and other protic solvents. As for any perchlorate derivative, appropriate precautions should be taken when handling or storing.

General Discussion.

Triethylsilyl perchlorate, a covalent silyl ester of perchloric acid, is a more reactive silylating agent than is chlorotriethylsilane. This is evidenced from the fact that the silyl perchlorate ester is cleaved rapidly and quantitatively by ***Sodium Borohydride***, while the chloride derivative requires the use of ***Lithium Aluminum Hydride*** (eq 3).[4]

$$Et_3SiClO_4 \xrightarrow[\text{dyglyme, rt}\ 100\%]{NaBH_4} Et_3SiH \qquad (3)$$

Wilcox and Babston reported that alkyl esters of aliphatic acids react with Et_3SiClO_4 in the presence of Hünig's base (***Diisopropylethylamine***) or ***2,2,6,6-Tetramethylpiperidine*** to provide (*Z*)-silyl ketene acetals selectively (eq 4).[5] The stereoselectivity of these reactions is dependent on a number of factors, including the nature of the base, the solvent polarity, and workup conditions. This procedure offers higher (*Z*) selectivity than does the usual deprotonation-silylation protocol using ***Lithium Diisopropylamide***/HMPA.

While alkyl esters generally undergo *O*-silylation in reactions with triethylsilyl perchlorate, ethyl diazoacetate was found to give exclusively the *C*-alkylation product (eq 5).[6] This procedure, which presumably involves the intermediacy of a diazonium perchlorate salt, affords higher yields of the α-silyl diazoester relative to other methods.

Triethylsilyl perchlorate has been shown to catalyze the Mukaiyama-Michael reaction of silyl ketene acetals with hindered α-enones, enabling 1,5-keto esters having contiguous quaternary centers to be prepared in high yield (eq 6).[7] Upon treatment of an equimolar mixture of unsubstituted and β,β-dimethyl silyl ketene acetals with the enone and a catalytic quantity of Et_3SiClO_4, only the more highly substituted adduct was obtained. To account for this, a mechanism was postulated in which the Lewis acid mediates the transfer of an electron from the silyl ketene acetal to the enone.

(α-Triethylsilyl)propionaldehyde Cyclohexylimine

[119711-55-6] · $C_{15}H_{31}NSi$ · (α-Triethylsilyl)propionaldehyde Cyclohexylimine · (MW 253.56)

(reagent used for the selective formation of (*E*)-α-methyl-α,β-unsaturated aldehydes[1])

Physical Data: bp 84-86 °C/0.1 mmHg.

Solubility: sol THF, sol ether.

Analysis of Reagent Purity: ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.65 (d, *J* = 6.7, 1H); 2.87 (tt, *J* = 10.6 and 4.1 Hz, 1H); 2.03 (pentet, *J* = 7.0 Hz, 1H); 1.82-1.20 (m, 10H); 1.16 (d, *J* = 7.0 Hz, 3H); 0.96 (t, *J* = 7.8 Hz, 9H); 0.60 (q, *J* = 7.9 Hz, 6H).[1]

Preparative Methods: prepared from propionaldehyde *N*-cyclohexylimine[1,2] by treatment with ***Lithium Diisopropylamide*** in THF at -78 °C for 30 min followed by the addition of ***Chlorotriethylsilane*** and gradually warming to 0 °C over a 3-4 h period.[2,3]

Purification: by fractional distillation.[1]

Handling, Storage, and Precautions: use in a well-ventilated fume hood.

Formation of (*E*)-α-Methyl-α,β-unsaturated Aldehydes.

The anions of α-silyl aldimines have been used to prepare unsaturated aldehydes by means of Peterson alkenation reactions.[4,5] The anions of α-trimethylsilyl- or α-triethylsilylpropionaldehyde *t*-butylimine are easily prepared by treatment of the silyl aldimine with LDA or ***s-Butyllithium*** (eq 1).[4]

Condensation of the α-lithio species with aldehydes and ketones conveniently yields α,β-unsaturated aldehydes following hydrolysis of the intermediate unsaturated imines (eqs 2 and 3).[3,4]

(2)

(3)

While the trimethyl and triethylsilyl aldimines (**1**) and (**2**) showed similar behavior in producing α,β-unsaturated aldehydes, the ability to isolate the triethylsilyl reagent (**2**) without contamination by the *N*-silyl enamine isomer makes it the preferred reagent.[3] Additionally, the replacement of the *t*-butylimine with a cyclohexylimine affords a reagent (**5**) which is easily purified by fractional distillation.[1] The anion of α-triethylsilylpropionaldehyde cyclohexylimine (**5**) is formed by the addition of *s*-BuLi in THF at -78 °C (eq 4).[1] This anion condenses with aldehydes to produce α-methyl-α,β-unsaturated aldehydes in good yield after hydrolysis (eq 4).

(5)

(4)

91%, *(E)*:*(Z)* = 100:1
[*(E)*:*(Z)* = 2:1 with $(CO_2H)_2$ workup]

The ratio of (*E*)- to (*Z*)-alkene products is dependent on the workup conditions. Addition of the α-silylaldimine anion to a carbonyl species gives a mixture of (*E*)- and (*Z*)-α-β-unsaturated imines, which upon hydrolysis with aqueous ***Oxalic Acid*** affords moderately selective formation of (*E*)-α,β-unsaturated aldehydes (eqs 4 and 5). Treatment of the mixture of imines with anhydrous ***Trifluoroacetic Acid*** in THF for a short period of time prior to aqueous hydrolysis serves to isomerize the imines and produce the *trans*-aldehyde with high selectivity (eqs 4 and 5).[1] The anhydrous trifluoroacetic acid workup protocol thus provides a highly selective method for the preparation of (*E*)-α-methyl-α,β-unsaturated aldehydes.[6]

Triethylsilyl Trifluoromethanesulfonate[1]

$Et_3SiOSO_2CF_3$

[79271-56-0] · $C_7H_{15}F_3O_3SSi$ · Triethylsilyl Trifluoromethanesulfonate · (MW 264.38)

(potent silylating agent;[2-4] Lewis acid catalyst)

Physical Data: 85-86 °C/12 mmHg; *d* 1.169 g cm^{-3}.

Solubility: readily sol hydrocarbons, dialkyl ethers, halogenated solvents. CH_2Cl_2 is employed most commonly. Reactions in 1,2-dichloroethane proceed faster than those in CCl_4 or Et_2O. Protic solvents and THF react with trialkylsilyl triflates and are therefore not suitable.

Form Supplied in: neat colorless liquid.

Preparative Methods: can be prepared by reacting ***Chlorotriethylsilane*** with ***Trifluoromethanesulfonic Acid*** followed by distillation.[1]

Handling, Storage, and Precautions: trialkylsilyl triflates are generally corrosive and moisture sensitive. Appropriate precautions should be taken to ensure that the reagent is handled and stored under rigorously anhydrous conditions.

Reactive Silylating Agent.

Triethylsilyl ethers are generally more stable towards hydrolysis than are trimethylsilyl ethers, and consequently the Et_3Si moiety has gained increasing use as a protecting group for alcohols. However, since it is often difficult to silylate sterically hindered hydroxyl groups using Et_3SiCl, ***Triethylsilyl Perchlorate*** and triethylsilyl triflate (Et_3SiOTf) were introduced to overcome this problem. Although both reagents are much more potent than Et_3SiCl, the triflate is considered to be safer than the perchlorate and is more convenient because it is commercially available.

Secondary and tertiary alcohols can be silylated under mild conditions using Et_3SiOTf and ***2,6-Lutidine*** or a trialkylamine as a proton scavenger (eqs 1 and 2).[2-4]

(1)

(2)

Silyl enol ethers can be conveniently prepared by treatment of ketones with Et_3SiOTf and ***Triethylamine*** (eq 3).[1,5] Similarly, esters can be converted to silyl ketene acetals; however, large amounts of the *C*-silylated product may also be isolated (eq 4).[1,6,7] Equilibration of *O*- and *C*-silylated products may occur in the presence of catalytic amounts of Et_3SiOTf.[1]

(3)

(4)

α-Diazo esters react with Et_3SiOTf and Hünig's base (***Diisopropylethylamine***) to give exclusively α-silyl-α-diazo esters, which can be converted to other silylated compounds by loss of dinitrogen (eq 5).[8]

(5)

Nitroalkanes have been shown to give α-siloxy *O*-silyloximes upon reaction with two molar equivalents of the silylating agent (eq 6).[9] The reaction is believed to proceed via a nitrogen-to-carbon 1,3-silyloxy rearrangement.

(6)

Linderman and Ghannam have utilized Et_3SiOTf to trap the alkoxide formed from the addition of stannyl anion to aldehydes (eq 7).[10] Upon treatment with excess ***n-Butyllithium***, these adducts undergo a reverse Brook rearrangement to afford α-hydroxysilanes.

Lewis Acid Catalyst.

Jefford has reported that condensation reactions of 2-trimethylsiloxyfuran with aldehydes can be catalyzed by Et_3SiOTf to give mainly the *threo* addition product (eq 8).[11] Conversely, the *erythro* adduct is favored when fluoride ion is used as the catalyst.

Fraser-Reid has reported that an equimolar mixture of ***N-Iodosuccinimide*** and Et_3SiOTf efficiently promotes the glycosylation of hindered glycoside donors with *n*-pentenyl glycoside acceptors (eq 9).[12]

Related Reagents.

Chlorotriethylsilane; ***Triethylsilyl Perchlorate***; ***Trimethylsilyl Trifluoromethanesulfonate***.

Triethyl 1,2,4-Triazine-3,5,6-tricarboxylate[1]

[74476-38-3] · $C_{12}H_{15}N_3O_6$ · Triethyl 1,2,4-Triazine-3,5,6-tricarboxylate · (MW 297.30)

(electron-deficient heteroaromatic azadiene capable of participation in inverse electron demand Diels-Alder reactions employed for the preparation of substituted pyridines)

Physical Data: bp 168-169 °C/1 mmHg, 173 °C/3 mmHg; *n*26D = 1.4949.

Solubility: sol $CHCl_3$, EtOAc, Et_2O; insol H_2O.

Form Supplied in: viscous, yellow oil.

Preparative Methods: a solution of ethyl oxalamidrazonate (88 mmol) in absolute EtOH (350 mL) is added dropwise to a stirring solution of diethyl dioxosuccinate (114 mmol) in absolute EtOH (86 mL) at 25 °C under N_2. After addition is complete, the stirring is allowed to continue at 25 °C for 16 h before the solution is warmed at reflux for 2 h. The reaction mixture is cooled and the solvent is removed under reduced pressure. Chromatography (SiO_2, 10-40% Et_2O-hexane gradient elution) affords the pure reagent.[2]

Handling, Storage, and Precautions: can be stored at 25 °C but is hygroscopic and reacts with protic solvents; should be stored under anhydrous conditions.

Cycloaddition Reactions.

Triethyl 1,2,4-triazine-3,5,6-tricarboxylate (**1**) is a highly electron-deficient heteroaromatic azadiene capable of participation in inverse electron demand Diels-Alder reactions with a variety of electron-rich dienophiles[1] including enamines (eq 1),[3] ketene-*N*,*O*-acetals (eq 2),[4] alkynes (eq 3),[5] benzynes,[6] benzocyclopropenes (eq 4),[7] and indoles (eq 5).[8] The reaction is regioselective with the cycloaddition occurring across C-3/C-6 of the 1,2,4-triazine nucleus with the more nucleophilic carbon of the electron-rich dienophile preferentially attaching to C-3 of 1,2,4-triazine (eqs 1 and 2).[3,4] A decrease or loss of regioselectivity is observed when the reacting sites in the dienophile become electronically and sterically less distinguishable (eqs 3 and 5).[5-8] The reaction is accompanied by a retro Diels-Alder reaction with loss of N_2 and in situ aromatization, constituting a general approach to the preparation of substituted pyridines (eqs 1-5). The methodology has been successfully applied (eq 6) in the total syntheses of streptonigrin (**2**),[9] and lavendamycin (**3**).[10]

Trifluoroacetic Acid

CF_3CO_2H

[76-05-1] · $C_2HF_3O_2$ · Trifluoroacetic Acid · (MW 114.03)

(solvent; acid catalyst for diverse organic transformations, including solvolysis,[9] rearrangements,[3] reductions,[17] oxidations,[22] and trifluoromethylation[8,16])

Alternate Name: TFA.

Physical Data: [1] freely flowing clear liquid, mp -15.4 °C, bp 72 °C; pK_a 0.23 (25 °C, H_2O); *d* 1.480 g cm^{-3}. Trifluoroacetic acid and water form an azeotrope, bp 105.5 °C, 20.8% water.

Solubility: miscible with water and most organic solvents, but has limited solubility in alkanes (with more than six carbons) and carbon disulfide.

Form Supplied in: neat liquid; commercially available.

Purification: distilled from traces of $(CF_3CO)_2O$ or P_2O_5; $KMnO_4$ has caused *serious explosions*.[33]

Handling, Storage, and Precautions: [2] is a strong organic acid. It is extremely corrosive and especially destructive to tissue of mucous membranes. Inhalation is a major hazard. Use of a NIOSH/MSHA approved respirator is recommended. Use in a fume hood with gloves and protective clothing to avoid contact. TFA is hygroscopic. Listed incompatibilities include oxidizing and reducing agents; however, literature references report the use of both types of reagents with TFA. TFA should never be mixed with basic solvents or acid-sensitive materials. The acute toxicity of TFA is low.

Acid-Catalyzed Rearrangements.

There are many examples of rearrangements catalyzed by TFA, including acid-catalyzed epoxide ring opening (eq 1),[3] biomimetic cyclizations (eq 2),[4] Cope rearrangements (eq 3),[5] and natural product synthesis (eq 4).[6] The cited references are given as examples; a comprehensive listing is beyond the scope of this publication. Often these reactions are initiated through protonation and dehydration to provide a cationic intermediate for cyclization. TFA is a general catalyst for most acid-catalyzed rearrangements. The physical properties of TFA may provide benefits over alternative acids. The volatility of this catalyst will allow product isolation by simple solvent evaporation. Less volatile alternatives, such as ***Sulfuric Acid*** or ***p-Toluenesulfonic Acid***, may require neutralization or an extractive workup. Owing to the low nucleophilicity of trifluoroacetate anion, TFA has been used as a solvent for basic research into solvolysis mechanisms.[7]

(1)

Synthesis of Trifluoromethyl Organic and Organometallic Compounds.

The reaction of TFA with Grignard reagents is general for the formation of trifluoromethyl ketones (eq 5).[8] The reaction is useful only with readily available Grignard reagents, as 1 equiv of organometallic reagent is consumed deprotonating TFA. The best yields are obtained using 2.5-3.0 mol of Grignard reagent per equiv of TFA. Phenyl, alkynyl, and normal alkyl Grignard reagents give superior results. Strongly reducing Grignard reagents, such as ***Isopropylmagnesium Bromide***, tend to produce trifluoromethyl alcohols from reduction of the initially formed ketone.

The condensation of ***Mercury(II) Oxide*** with 2 mol of TFA produces ***Mercury(II) Trifluoroacetate***. Thermal decarboxylation in the presence of carbonate followed by sublimation yields bis(trifluoromethyl)mercury.[9] Treatment of bis(trifluoromethyl)mercury with Cu^0 in NMP or DMA produces a stable trifluoromethylcopper reagent.[10] Addition of an aromatic or benzylic halide leads to displacement and incorporation of the trifluoromethyl group (eq 6). Alternatives for the introduction of a trifluoromethyl group as a nucleophile are limited. The trifluoromethyl derivatives of lithium and magnesium are unknown, probably due to fluoride elimination to produce difluorocarbene.[11] Bis(trifluoromethyl)mercury has been used to synthesize trifluoromethyl organometallic derivatives of germanium,[12] tin,[13] zinc,[14] and cadmium.[15]

(6)

Direct trifluoromethylation of electron-poor aromatic and heterocyclic systems can be accomplished by treatment with TFA and ***Xenon(II) Fluoride***.[16] The initial reaction is thought to produce $Xe(O_2CCF_3)_2$ which undergoes decomposition to yield carbon dioxide, xenon, and trifluoromethyl radicals. Aromatic and heterocyclic compounds can react with the trifluoromethyl radicals, often with a high degree of selectivity. Yields of trifluoromethylated products vary between good to moderate, but the reaction allows entry into structures that would otherwise be difficult to synthesize. The chemistry has been extended to heterocyclic systems, as demonstrated with an intermediate reaction in the production of 5-(trifluoromethyl)-2´-deoxyuridine, a known antiviral compound (eq 7).[16]

(7)

Reductions with Boron and Silicon Hydrides.

Sodium Borohydride,[17] ***Sodium Cyanoborohydride***,[18] ***Borane-Tetrahydrofuran***,[19] and ***Triethylsilane***[20] have been used in conjunction with TFA to reduce a variety of functional groups. These reactions generally proceed by protonation of a functional group followed by delivery of hydride.

Of special note is the reduction of cobalt-complexed secondary α-alkynic alcohols with sodium borohydride and TFA.[21] Oxidative decomposition of the resulting cobalt complex produces secondary alkynes in good to moderate yields. Production of the identical diastereomer from either epimeric alkynic alcohol is consistent with formation of a common intermediate by protonation and dehydration, followed by stereoselective hydride addition (eq 8).

(8)

Baeyer-Villiger Oxidations in TFA.

Trifluoroacetic acid has been reported to catalyze the action of ***m-Chloroperbenzoic Acid*** in the Baeyer-Villiger oxidation of cyclic and acyclic ketones.[22]

Trifluoroperacetic Acid (TFPAA) is remarkably efficient for the oxidation of ketones in the Baeyer-Villiger reaction.[23] This reagent has been prepared from ***Trifluoroacetic Anhydride*** and concentrated ***Hydrogen Peroxide***. Since 90% hydrogen peroxide is no longer available as a commercial reagent, alternatives are needed for classical oxidation procedures. A combination of TFA and sodium percarbonate has been used as a replacement for TFPAA in the Baeyer-Villiger reaction (eq 9).[24] Yields vary between good to excellent. The procedure is not applicable to aliphatic ketones, as TFA esters are produced from transesterification with the solvent.

(9)

Cleavage of Nitrogen- and Oxygen-Protecting Groups.

Trifluoroacetic acid has found many applications in the removal of protecting groups. Examples include solvolysis under aqueous and anhydrous conditions. Groups that have been cleaved with TFA include *N*-Boc,[25] *N*-benzyloxymethyl,[26] benzyl ether,[27] *p*-methoxybenzyl ether,[28] *t*-butyl ether,[29] *t*-butyloxymethyl ether,[30] triphenylmethyl ether,[31] and dimethyl acetals.[32]

Related Reagents.

Acetic Acid; ***Fluorosulfuric Acid***; ***Formic Acid***; ***Hydrochloric Acid***; ***Hydrofluoric Acid***; ***Oxalic Acid***; ***Sulfuric Acid***; ***p-Toluenesulfonic Acid***; ***Trichloroacetic Acid***; ***Triethylsilane-Trifluoroacetic Acid***.

Trifluoroacetic Anhydride[1]

[407-25-0] · $C_4F_6O_3$ · Trifluoroacetic Anhydride · (MW 210.04)

(activating agent; oxidation)

Alternate Name: TFAA.

Physical Data: mp -65 °C; bp 39-40 °C; *d* 1.487 g cm^{-3}.

Solubility: sol C_6H_6, CH_2Cl_2, Et_2O, DMF, THF, MeCN.

Form Supplied in: colorless liquid; commercially available.

Analysis of Reagent Purity: by standard analytical techniques.

Preparative Methods: by distilling ***Trifluoroacetic Acid*** from ***Phosphorus(V) Oxide***.[1]

Handling, Storage, and Precautions: corrosive and moisture sensitive; toxic by inhalation; should be freshly distilled prior to reaction. Use in a fume hood.

Activated Esters.

Mixed anhydrides may be prepared by reaction of carboxylic acids with trifluoroacetic anhydride.[2] The method has been used widely as a means of activating carboxyl groups to nucleophilic attack. The method has also been highly useful in Friedel-Crafts acylation of arenes (eqs 1 and 2).[3,4] Sulfonic acids are also activated to nucleophilic attack; substituted sulfones result. Intramolecular Friedel-Crafts reactions are also facilitated, but only for formation of six-membered rings.[5]

(1)

(2)

Anhydrides of diacids are prepared in (about) 90% yield by reaction with TFAA in ether.[6] The method involves formation of the monotrifluoroacetyl mixed anhydride, which may be converted to the cyclic anhydride by heating under vacuum (eq 3).[7]

(3)

An inversion of alkene geometry is made possible by the reaction of their derived epoxides with lithium halides and TFAA (eq 4);[8] the products of this reaction are the corresponding halohydrin trifluoroacetates, which undergo a *syn* elimination upon reaction with ***Lithium Iodide***.

(4)

Primary alkanols and 2-alkenols are converted into the corresponding halides in high yield by a one-pot, two-step reaction via transformation into intermediate trifluoroacetates, followed by nucleophilic substitution with lithium halides (eq 5).[9]

(5)

Sulfoxides are reduced to sulfides under mild conditions with ***Trifluoroacetic Anhydride-Sodium Iodide*** (eq 6).[10]

(6)

Primary amides are converted under mild conditions to the corresponding nitriles using TFAA in pyridine (eq 7).[11] Similarly, aldoximes are converted to nitriles by TFAA in pyridine (eq 8).[12]

(7)

(8)

TFAA in triethylamine can be used for the dehydration of aldols to enones where other methods are less successful (eq 9).[13] When ***Acetic Anhydride*** is employed instead of TFAA, the reaction proceeds slowly.

(9)

The Pummerer rearrangement of sulfoxides to α-acyloxy sulfides, induced by TFAA, has been used as a means of converting sulfoxides to aldehydes (eq 10).[14]

(10)

e.g. R = C_7H_{15}, $PhCH_2OCH_2$

Methyl aryl sulfides are converted in a mild, one-pot, three-step procedure via Pummerer rearrangement of the corresponding sulfoxides, and without purification of intermediates, to provide arylthiols in excellent yields (eq 11).[15]

(11)

Oxidation.

Trifluoroacetoxydimethylsulfonium trifluoroacetate is prepared in situ from ***Dimethyl Sulfoxide*** and TFAA below -50 °C and reacts rapidly with alcohols in the presence of ***Triethylamine*** to give the corresponding carbonyl compounds (eq 12).[16]

(12)

TFAA/DMSO also efficiently converts vicinal diols to the corresponding α-dicarbonyl compounds or derivatives thereof (eq 13).[17] Unlike the Swern oxidant (***Dimethyl Sulfoxide-Oxalyl Chloride***), this reagent mixture gives good yields for halogenated substrates. The preparation of previously inaccessible compounds (such as σ-homo-*ortho*-benzoquinones) is thus facilitated.

(13)

Undesired electrophilic chlorination as a side-reaction in Swern oxidations is avoided by use of TFAA in place of oxalyl chloride.[18] See also ***Dimethyl Sulfoxide-Trifluoroacetic Anhydride***.

Miscellaneous.

Enamines of α-amino acids react rapidly with TFAA to give pyrrole derivatives (eq 14).[19]

(14)

The reaction of TFAA with triethylamine *N*-oxide leads to formation of the trifluoroacetate salt of *N*,*N*-dimethylformaldimmonium ion. This ion is a superior reagent in the Mannich reaction.[20]

TFAA is used to prepare trifluoroacetamides from amines; these amides may be used in Gabriel-type reactions. The use of TFAA delivers an amide of enhanced acidity and which is easily hydrolyzed in situ, thereby allowing a one-pot alkylation process (eq 15).[21]

(15)

Reaction of TFAA with ammonium nitrate provides an in situ source of trifluoroacetyl nitrate, which has been used for the nitration of enol acetates[22] and as an *N*-nitrating agent.[23]

TFAA efficiently cleaves *N*-tosyl protecting groups from histidine (eq 16).[24]

Trifluoroacetic Anhydride-Sodium Iodide

[407-25-0] · $C_4F_6O_3$ · Trifluoroacetic Anhydride-Sodium Iodide · (MW 210.04)

[7681-82-5] · INa · Trifluoroacetic Anhydride-Sodium Iodide · (MW 149.89)

(deoxygenation; converts alcohols to iodides)

Physical Data: see ***Trifluoroacetic Anhydride*** and ***Sodium Iodide***.

Introduction.

The primary use for the combination of trifluoroacetic anhydride and sodium iodide is deoxgenation. It has also been used for the conversion of alcohols to iodides.

Deoxygenation of Sulfoxides.[1]

Sulfoxides are rapidly deoxgenated to sulfides by the use of trifluoroacetic anhydride with sodium iodide. The reaction proceeds instantaneously under cooling at 0 °C when trifluoroacetic anhydride is added to an acetone solution of the sulfoxide and sodium iodide. Dialkyl, alkyl/aryl, and diaryl sulfoxides are all deoxygenated with yields in excess of 90%, with reaction times less than 10 min (eq 1).

Deoxygenation of Epoxides.[2,3]

Epoxides are deoxygenated with retention of geometry by treatment with trifluoroacetic anhydride (1 equiv) and sodium iodide (4 equiv). Trifluoroacetyl iodide is generated in situ, which reacts with the epoxide in the presence of the excess sodium iodide to give the alkene. The yields are 77-95% after 24 h with a 1:1 mixture of MeCN and THF as solvent (eqs 2 and 3).

(3)

Conversion of Alcohols to Iodides.[4]

Primary and secondary alcohols are converted to the corresponding iodides in a one-pot two-step reaction. An intermediate trifluoroacetate is formed by reaction of the alcohol with trifluoroacetic anhydride and this is transformed into the halide via nucleophilic substitution with sodium iodide. Substituting sodium iodide with ***Lithium Iodide*** gives higher yields (eq 4). The corresponding chlorides and bromides may be synthesized by use of the appropriate sodium/lithium halide.

Trifluoroacetyl Chloride

[354-32-5] · C_2ClF_3O · Trifluoroacetyl Chloride · (MW 132.47)

(useful for the preparation of trifluoro ketones[1,2] and for the elimination of epoxides to alkenes[3])

Physical Data: bp -27 °C; mp -146 °C.

Form Supplied in: nonflammable gas supplied in metal cylinders.

Preparative Methods: can be generated in situ from ***Trifluoroacetic Anhydride*** and ***Lithium Chloride***[3] or ***Trifluoroacetic Acid*** and ***Phosphorus(V) Chloride***.[2]

Handling, Storage, and Precautions: highly toxic material; handle accordingly. Use in a fume hood.

General Considerations.

Trifluoroacetyl chloride has limited use in organic synthesis due to its in situ preparation or use of the gas form. The preparation of common trifluoroacetate derivatives is achieved by the action of trifluoroacetic anhydride with the corresponding alcohol or amine.

Trifluoroacetyl chloride has been used to effect the elimination of epoxides to the corresponding alkene. The intermediate chlorohydrin trifluoroacetate must be treated with iodide to achieve elimination (eq 1).

(1)

In practice, the conversion of an alkene from one geometry to the other can be realized via epoxidation and then treatment with trifluoroacetyl chloride followed by ***Sodium Iodide***.

Trifluoroacetophenone[2] is prepared by the action of trifluoroacetyl chloride on benzene in the presence of ***Aluminum Chloride*** (eq 2).

(2)

Trifluoroacetyl chloride reacts with ***N,O-Dimethylhydroxylamine*** hydrochloride in the presence of ***Triethylamine*** to form *N*-methoxy-*N*-methyltrifluoroacetamide (eq 3).[1,4] This interesting reagent reacts with Grignard reagents to form trifluoro ketones (eq 4).

(3)

(4)

Trifluoroacetyl chloride is used to acylate an ylide which leads to α,α,α-trifluoro-β-keto esters (eq 5).[5]

(5)

Related Reagents.

Trifluoroacetic Anhydride.

Trifluoroacetyl Hypoiodite

[359-47-7] · $C_2F_3IO_2$ · Trifluoroacetyl Hypoiodite · (MW 239.92)

(source of electrophilic iodine, I^+,[1] in electrophilic aromatic substitution reactions[2] and in addition reactions across double bonds;[3] mild oxidant capable of generating alkoxy radicals[4])

Solubility: sol aromatic solvents, halogenated solvents, ether, acetonitrile, trifluoroacetic acid.

Preparative Methods: is formed in situ from the reaction of equimolar amounts of ***Iodine*** and ***Silver(I) Trifluoroacetate*** or ***Mercury(II) Trifluoroacetate*** in a suitable solvent, typically trifluoroacetic acid (eq 1).[1] Trifluoroacetyl hypobromite can be similarly prepared using bromine instead of iodine.

$$I_2 + AgO_2CCF_3 \underset{rt}{\overset{CF_3CO_2H}{\rightleftharpoons}} CF_3CO_2I + AgI\,(s) \qquad (1)$$

If 2 mol of the silver salt are introduced, then the acyl hypohalite complexes with the additional silver salt to form the complex indicated in eq 2. This preparation is used in addition reactions, whereas the equimolar preparation has been applied in electrophilic substitution reactions.

$$I_2 + 2\,AgO_2CCF_3 \underset{rt}{\overset{CF_3CO_2H}{\rightleftharpoons}} (CF_3CO_2)_2AgI + AgI\,(s) \qquad (2)$$

Trifluoroacetyl hypoiodite may also be formed from equimolar amounts of ***Phenyliodine(III) Bis(trifluoroacetate)*** and iodine (eq 3).[5] This preparation is purported to allow for milder and faster iodination.[6]

$$I_2 + PhI(O_2CCF_3)_2 \underset{rt}{\overset{CCl_4}{\rightleftharpoons}} 2\,CF_3CO_2I + PhI \qquad (3)$$

Handling, Storage, and Precautions: is thermally labile and decomposes to trifluoromethyl iodide and carbon dioxide.[2] Concentrated solutions can decompose by as much as 30% per day; negligible decomposition occurs when the concentration of trifluoroacetyl hypoiodite is kept below 20 mM.[1]

Electrophilic Aromatic Substitution.

Because of the inductive effect of the trifluoromethyl group, trifluoroacetyl hypoiodite is unusually reactive as a positive iodine source for electrophilic aromatic substitution reactions. The relative reactivity order of hypohalites compared to other electrophilic halogen sources has been reported to be Br_2 < ICl &AApprox; CH_3CO_2I &LLt; CF_3CO_2I < CH_3CO_2Br &LLt; CF_3CO_2Br.[1] Product yields from reactions of trifluoroacetyl hypoiodite with aromatics range from 50% to 100% and favor *para* substitution (eq 4).[2,6,7]

(4)

Addition to Alkenes.

Acyl hypoiodites, complexed by an additional equivalent of silver salt, e.g. $(CF_3CO_2)_2AgI$, add across double bonds to form *vic*-iodocarboxylates. The *vic*-iodocarboxylates are converted in 60-90% yields to *trans*- or *cis*-diols, respectively, under anhydrous and wet conditions[3] (iodine and thallium(I) carboxylates also form *vic*-iodocarboxylates in 60-90% yield).[8] The *vic*-iodotrifluoroacetate derived from the reaction of trifluoroacetyl hypoiodite with an alkene has been used to effect anti-Markovnikov hydration of unsaturated sugars (eq 5).[9]

(5)

Other Applications.

When the AgI precipitate is quantitatively removed from the reagent preparation, the trifluoroacetyl hypoiodite, thus prepared, reacts with alcohols to produce alkoxy radicals. The radicals decompose upon irradiation to give aldehydes, ketones, and furans or mixtures thereof in 80-90% yields.[4]

Related Reagents.

N-Trifluoroacetylimidazole

[1546-79-8] · $C_5H_3F_3N_2O$ · *N*-Trifluoroacetylimidazole · (MW 164.10)

(dehydration; protection; acylation)

Physical Data: mp 136-137 °C; bp 45-46 °C/14 mmHg.

Solubility: sol most common solvents, e.g. ether, THF.

Analysis of Reagent Purity: commercial material is 98+% pure.

Preparative Methods: ***N,N´-Carbonyldiimidazole*** (20.5 g) is dissolved in 100 ml of dry THF and treated dropwise with 28.8 g of ***Trifluoroacetic Acid*** in 80 mL of dry THF. The resulting solution is cooled for several hours. Removal of the solvent and distillation of the filtrate gives 14.4 g of material. Alternatively, ***Imidazole*** (25.8 g) in 120 mL of dried THF is treated dropwise, with cooling, with 39.9 g of ***Trifluoroacetic Anhydride*** in 50 mL of dried THF. Filtration, removal of solvent, and distillation gives 24.8 g of product.[1]

Purification: by distillation.

Handling, Storage, and Precautions: store under nitrogen, carefully excluding water. Irritant; moisture sensitive; keep cold; flammable.

Formation of Protected Amino Acids.

The protection of various amino acids has been achieved using this reagent with ***p-Nitrophenol*** to form the *p*-nitrophenyl esters;[2] yields are 50-80%. The method seems less satisfactory than currently available techniques, e.g. the ***1,3-Dicyclohexylcarbodiimide*** method, but may be of use in some specific cases where other methods give low yields, e.g. preparation of *p*-nitrophenyl *N*-benzyloxycarbonyl-β-benzyl-L-aspartate. The formation of simple alkyl and aryl esters by this method proceeds better at higher temperatures. At room temperature, a dramatic increase in yield may be achieved by adding a catalytic amount of alkoxide base. However, neither higher temperature nor alkoxide base increases the yield in the amino acid protection sequence mentioned above.

Synthesis of Carboxylic Acid Anhydrides.

When 1 mol of *N*-trifluoroacetylimidazole is treated with *2* mol of carboxylic acid in THF, a mixed anhydride and the pure anhydride are formed in an equilibrium reaction. The sparingly soluble salt of trifluoroacetylimidazole precipitates out of the solution, driving the reaction to completion (Scheme 1). Thus on standing for 5 h the pure anhydride is obtained in high yield, usually in excess of 80%.[3]

Scheme 1

Synthesis of Trifluoroacetyl Amides.

Reaction of trifluoroacetylimidazole with an equimolar amount of amine in THF or ether, evaporation of solvent followed by washing with water gives the corresponding trifluoroacetamide in good yields (80%).[1]

Synthesis of Nitriles from Aldoximes.

N-Trifluoroacetylimidazole converts aldoximes to nitriles[4] under mild and practically neutral conditions. The reaction is carried out by heating the aldoximes with *N*-trifluoroacetylimidazole in ether or THF under reflux for 2-3.5 h. A wide range of aldoximes are dehydrated, e.g. aliphatic, aromatic, and alkenic. The reaction also tolerates halogen and nitro functional groups. The dehydration of aldoximes is generally considered to be a base-promoted bimolecular mechanism.[5]

Synthesis of Acylated Aromatic Hydrocarbons.

N-Trifluoroacetylimidazole is a powerful acetylating agent for alcohols and amines. If the imidazole is used together with a strong Brønsted acid the nitrogen is protonated to form an imidazolium ion, increasing the electrophilicity of the acyl group. Thus it was found that *N*-trifluoroacetylimidazole in conjuction with trifluoroacetic acid could acylate aromatic hydrocarbons to give ketones[6] in good yield (70-90%).

The use of other acyl imidazoles was also investigated, e.g. PhCO, *p*-$NO_2C_6H_4CO$, and *p*-ClC_6H_4CO imidazoles, and the yields for acyl transfer here too are good (80-95%) except for the *p*-nitrophenyl acyl group which was transferred with a yield of only 16%.

Imidazoles of aliphatic carboxylic or aromatic carboxylic acids containing electron-donating groups gave 2-acylfluorenes in especially high yields. A mechanism is given, as well as a discussion of the Hammett plots for the corresponding reactions.

Synthesis of Volatile Derivatives for GLC.

The reagent is used for the preparation of volatile trifluoroacetyl derivatives of amines, alcohols, etc. for GLC purposes which are sensitive to electron-capture detection.[7]

2,2,2-Trifluoroethyl *p*-Toluenesulfonate[1]

[433-06-7] · $C_9H_9F_3O_3S$ · 2,2,2-Trifluoroethyl *p*-Toluenesulfonate · (MW 254.25)

(trifluoroethylation agent for heteroatom nucleophiles; can function as a nucleophile for synthesis of α-keto acids and 2,2-difluorovinyl compounds)

Alternate Name: 2,2,2-trifluoroethyl tosylate

Physical Data: mp 40-41 °C; bp 102-104 °C/0.8 mmHg; *n*25D 1.4635.

Solubility: sol THF, ether, CH_2Cl_2, toluene.

Form Supplied in: white crystalline solid, commercially available.

Purification: recrystallize from hexane-ether.

Preparative Methods: easily prepared by treating 2,2,2-trifluoroethanol with ***p-Toluenesulfonyl Chloride*** in pyridine[1a] or in aqueous acetone containing NaOH.[1b]

Handling, Storage, and Precautions: quite stable; can be handled without any special technique and stored at room temperature; use in a fume hood.

Trifluoroethylation Agent.

Although this reagent is sluggish in substitution reactions compared to its nonfluorinated counterpart,[2] heteroatom nucleophiles react with the reagent to permit introduction of the 2,2,2-trifluoroethyl group. Thiols,[3,4] thiophenols,[3] and phenols[3b] undergo *S*- and *O*-trifluoroethylation via their sodium salts in good yields (eq 1). For the preparation of alkyl trifluoroethyl ethers, there is an alternative route via the alkylation of trifluoroethanol with alkyl halides.[3b,5] Trifluoroethylation of alkali selenolates[6] and tellurolates[7] is also achieved (eq 2), whereas trifluoroethyl iodide is a better choice in the case of tellurium. *N*-Trifluoroethylation is carried out with amines (eq 3)[8a] and pyrroles[8b] under forcing conditions, while the indole nitrogen is not alkylated but undergoes tosylation instead.[8c] In the trifluoroethylation of less reactive nucleophiles, 2,2,2-trifluoroethyl trifluoromethanesulfonate generally gives better results, especially in case of nitrogen[9a] and carbon nucleophiles.[9b]

$$\mathrm{RSNa} \xrightarrow[\text{DMF, rt}]{\mathrm{CF_3CH_2OTs}} \mathrm{RSCH_2CF_3} \qquad (1)$$

$$\mathrm{PhZNa} \xrightarrow[\text{THF-HMPA, }\Delta]{\mathrm{CF_3CH_2OTs}} \mathrm{PhZCH_2CF_3} \qquad (2)$$

Z = Se, 76%; Te, 20%

(3)

Synthesis of α-Keto Acids and 2,2-Difluorovinyl Compounds.

The reagent reacts with 2 equiv of ***Lithium Diisopropylamide***[10] or ***n-Butyllithium***[11a] at -78 °C to generate 2,2-difluoro-1-tosyloxyvinyllithium (**1**). This vinyllithium reagent reacts with carbonyl compounds[5,10] to give 3,3-difluoro-2-tosyloxyallyl alcohols (**2**) which undergo ***Sulfuric Acid***-catalyzed hydration to 2-tosyloxyacrylic acids (**3**). Base-catalyzed hydrolysis of (**3**) then affords the two-carbon homologated α-keto acids (eq 4).[10]

(4)

Vinyllithium (**1**) is also utilized via 2,2-difluorovinylboranes (**4**) (eq 5) to synthesize a wide variety of *gem*-difluorovinyl compounds: 1,1-difluoro-1-alkenes,[11b-e] 1,1-difluoro-1,3-alkadienes,[11f] 1,1-difluoro-1-alken-3-ynes,[11h] 1,1-difluoro-2-iodo-1-alkenes,[11c] β,β-difluoro-α,β-enones,[11a] and 2,2-difluorovinylphosphines,[11g] as well as difluoromethyl ketones[12] (eqs 6-10). In these reactions, the reagent functions as a building block for a difluorovinylidene unit (CF_2=C), to which two different substituents can be successively attached.

(5)

(6)

(7)

(8)

(9)

(10)

In addition, trifluoroethyl ethers, thioethers, and selenoethers prepared as above are available for the introduction of an alkyne moiety, leading to alkynic ethers and thioethers (eq 11)[3b] and thio-[3a] and selenoynamines[6a] (eq 12).

2,2,2-Trifluoroethyl Trifluoroacetate

[407-38-5] · $C_4H_2F_6O_2$ · 2,2,2-Trifluoroethyl Trifluoroacetate · (MW 196.06)

(agent for the efficient trifluoroacetylation of ketone enolates; useful in the preparation of α-diazo ketones)

Alternate Name: TFEA.

Physical Data: bp 55 °C; *d* 1.464 g cm^{-3}.

Solubility: sol most commonly used organic solvents.

Form Supplied in: colorless liquid, widely available.

Purification: distillation from calcium hydride at atmospheric pressure.

Handling, Storage, and Precautions: for most applications the reagent can be adequately dried by simple distillation and can be stored under argon over 4Å molecular sieves. It is a flammable liquid and is reported to be corrosive.

General Considerations.

2,2,2-Trifluoroethyl trifluoroacetate has been employed for the in situ activation of a variety of ketone substrates as α-trifluoroacetyl derivatives.[1] In general, activation via trifluoracetylation is superior to older technology, such as Claisen formylation, since kinetically generated ketone enolates react essentially instantaneously with TFEA at -78 °C in high yield. Formylation of ketone substrates with ethyl formate is usually carried out using either ***Sodium Hydride*** or ***Sodium Ethoxide*** as the base and generally requires 12-48 h at room temperature for complete reaction.[2] TFEA is superior to other trifluoroacetylating agents, such as CF_3CO_2Et and ***Trifluoroacetic Anhydride***, in that the desired *C*-acylated products are rapidly formed in high yields.

Synthesis of α-Diazo Ketones via Detrifluoroacetylative Diazo Transfer.

Danheiser and co-workers have employed this strategy in an improved method for the synthesis of α-diazo ketones.[3] The diazo group transfer reaction requires that a stabilized β-diketone enolate be formed in situ for subsequent reaction with a sulfonyl azide reagent. The efficiency of the diazo group transfer reaction is improved, in some cases dramatically, by substituting the trifluoroacetylation of kinetically generated ketone enolates with TFEA for the classic formylation step. The method is particularly advantageous for diazo transfer reactions involving base-sensitive substrates such as certain α,β-enones and heteroaryl ketones. For example, as shown in eq 1, the yield of 1-diazo-4-phenyl-3-buten-2-one is improved from 17% to 85% when trifluoroacetylation with TFEA is substituted for Claisen formylation with ethyl formate. A variety of α-diazo ketones, which are not synthetically accessible via the classic procedures, can be obtained in excellent yields when the kinetic trifluoroacetylation procedure is employed (e.g. eq 2). This method has also been used by Doyle to achieve diazo group transfer to a base-sensitive *N*-acyloxazolidone derivative (eq 3).[4]

A crucial requirement for the success of the trifluoroacetylation reaction is that TFEA be rapidly added (1-5 s) to a cooled (-78 °C) solution of the ketone enolate (a small amount of white smoke may be noted above the reaction solution). The reaction is allowed to stir for 10 min, and then is quenched by pouring directly into a solution of 5% aq H_2SO_4. If the reagent is added too slowly in a dropwise fashion, varying amounts of starting material are often recovered from the reaction.

Trifluoroiodomethane

CF_3I

[2314-97-8] · CF_3I · Trifluoroiodomethane · (MW 195.91)

(trifluoromethylating reagent)

Alternate Name: trifluoromethyl iodide.

Physical Data: bp -22 °C.[1]

Solubility: sol ether, acetone, alcohol, benzene.

Form Supplied in: gas; commercially available.

Preparative Methods: prepared by the fluorination of CI_4 with IF_5 (eq 1),[2] or by the Hunsdiecker reaction of ***Silver(I) Trifluoroacetate*** with an excess of ***Iodine*** (eq 2),[3] or by the reaction of trifluoroacetyl fluoride with ***Lithium Iodide*** (eq 3).[4] More recently, Chen reported a convenient method for the synthesis of CF_3I by the reaction of XCF_2CO_2Me (X = Br, Cl) with iodine, KF, and CuI (eq 4).[5]

$$CI_4 + IF_5 \xrightarrow[74\%]{} CF_3I \qquad (1)$$

$$CF_3CO_2Ag + I_2 \xrightarrow[90\%]{} CF_3I \qquad (2)$$

$$CF_3C(O)F + LiI \xrightarrow[73\%]{} CF_3I \qquad (3)$$

$$XCF_2CO_2Me + I_2 \xrightarrow[70\%]{KI,\ CuI} CF_3I \qquad (4)$$

$$X = Cl, Br$$

Addition to Alkenes and Alkynes.

Radical addition of CF_3I to alkenes and alkynes is initiated by irradiation,[6] peroxide,[6a] metals,[7] boranes,[8] enzymes,[9] and heating[10] to give the corresponding adducts (eq 5). Enamines react with CF_3I rapidly at room temperature without UV irradiation or initiator to form trifluoromethylated ketones after hydrolysis.[11]

$$CF_3I + H_2C{=}CHR \xrightarrow{\text{initiation}} CF_3CH_2CHIR \qquad (5)$$

Addition to Carbonyl Compounds.

Addition of CF_3I to carbonyl compounds is promoted by metals and metal salts such as ***Zinc***,[12] Zn/MV^{2+} (MV^{2+} = methyl viologen),[13] ***Tin(II) Chloride***,[14] Zn/ultrasound,[15] and ***Magnesium***[16] to form the corresponding trifluoromethylated alcohols (eq 6).

$$CF_3I + RCHO \xrightarrow{\text{metal}} CF_3CH(OH)R \qquad (6)$$

Coupling with Organic Halides.

In the presence of copper metal, CF_3I undergoes coupling with aryl and vinyl iodides to afford the corresponding trifluoromethylated aromatics and alkenes, respectively.[17] Pregenerated CF_3Cu (from the reaction of CF_3I with copper metal in HMPA at 120 °C) reacts with benzyl, allyl, vinyl, acyl, and alkyl bromides to give the corresponding trifluoromethylated products (eq 7).[18]

$$CF_3I + Cu + RX \longrightarrow RCF_3 \qquad (7)$$

$$R = \text{aryl, allyl, vinyl, acyl, alkyl; } X = \text{Br, I}$$

Reaction with Thiolates.

Photoreaction of CF_3I with thiols in liquid NH_3 gives the corresponding trifluoromethyl sulfides (eq 8).[19]

$$CF_3I + RS^- \xrightarrow{h\nu,\ NH_3} CF_3SR \qquad (8)$$

Addition to Aromatic Compounds.

Trifluoromethylation of benzene, thiophene, pyridine, and imidazole has been accomplished via thermolysis or irradiation of CF_3I in the presence of the appropriate aromatic compound (eq 9).[20]

Trifluoromethanesulfonic Acid[1]

CF_3SO_2OH

[1493-13-6] · CHF_3O_3S · Trifluoromethanesulfonic Acid · (MW 150.09)

(one of the strongest organic acids; catalyst for oligomerization/polymerization of alkenes and ethers; precursor for triflic anhydride and several metal triflates; acid catalyst in various reactions)

Alternate Name: triflic acid.

Physical Data: bp 162 °C/760 mmHg, 84 °C/43 mmHg, 54 °C/8 mmHg; *d* 1.696 g cm^{-3}.

Solubility: sol water and in many polar organic solvents such as DMF, sulfolane, DMSO, dimethyl sulfone, acetonitrile; sol alcohols, ketones, ethers, and esters, but these generally are not suitable inert solvents (see below).

Analysis of Reagent Purity: IR;[2] ^{19}F NMR.[3]

Preparative Methods: best prepared by basic hydrolysis of CF_3SO_2F followed by acidification.[2]

Purification: distilled with a small amount of Tf_2O.[4]

Handling, Storage, and Precautions: is a stable, hygroscopic liquid which fumes copiously on exposure to moist air. Transfer under dry nitrogen is recommended. Contact with cork, rubber, and plasticized materials will cause rapid discoloration of the acid and deterioration of the materials. Samples are best stored in sealed glass ampules or glass bottles with Kel-F™ or PTFE plastic screw cap linings. Use in a fume hood.

Reaction with P_2O_5.

Trifluoromethanesulfonic acid (TfOH) reacts with an excess of ***Phosphorus(V) Oxide*** to give ***Trifluoromethanesulfonic Anhydride*** (eq 1),[5] while treatment with a smaller amount of P_2O_5 (TfOH:P_2O_5 = 6:1) and slower distillation leads to trifluoromethyl triflate (eq 2).[6]

$$CF_3SO_3H + P_2O_5\ (\text{excess}) \xrightarrow[-H_2O]{\Delta} (CF_3SO_2)_2O \qquad (1)$$

$$6\ CF_3SO_3H + P_2O_5 \xrightarrow[70\%]{\Delta} 3\ CF_3SO_2OCF_3 + 3\ SO_2 + 2\ H_3PO_4 \qquad (2)$$

The synthetic utility of trifluoromethyl triflate as a trifluoromethanesulfonylating agent is severely limited, because the reagent is rapidly destroyed by a fluoride-ion chain reaction in the presence of other nucleophiles.[7]

Dehydration of a 2:1 mixture of CF_3CO_2H and TfOH with P_2O_5 affords trifluoroacetyl triflate (eq 3),[8] which is a very reactive agent for trifluoroacetylations at O, N, C, or halogen centers (eq 3).[8a]

(3)

Protonation and Related Reactions.

TfOH is one of the strongest monoprotic organic acids known. The acid, and its conjugate base ($CF_3SO_3^-$), have extreme thermal stability, are resistant to oxidation and reduction, and are not a source of fluoride ions, even in the presence of strong nucleophiles. They do not lead to sulfonation as do ***Sulfuric Acid***, ***Fluorosulfuric Acid***, and ***Chlorosulfonic Acid*** in some reactions. TfOH is therefore effectively employed in protonation reactions.

The strong protonating property of TfOH is used to generate allyl cations from suitable precursors in low-temperature ionic Diels-Alder reactions. 3,3-Diethoxypropene and 2-vinyl-1,3-dioxolane add to cyclohexa-1,3-diene in the presence of TfOH to give the corresponding Diels-Alder adducts, the latter in high yield (eq 4).[9]

(4)

An intramolecular Diels-Alder reaction with high stereoselectivity occurs involving allyl cations by protonation of allyl alcohols (eq 5).[10]

(5)

Alkynes and allenes are protonated with TfOH to give vinyl triflates (eqs 6 and 7),[11] which are precursors to vinyl cations.

(6)

(7)

A convenient synthesis of pyrimidines is developed by protonation of alkynes with TfOH in the presence of nitriles (eq 8).[12]

(8)

Triflic acid catalyzes the transformation of α-hydroxy carbonyl compounds to ketones (eq 9).[13]

(9)

Oximes undergo Beckmann rearrangement with TfOH in the presence of Bu_4NReO_4 to give amides in high yield (eq 10).[14]

(10)

TfOH protonates nitroalkenes, even nitroethylene, to give *N*,*N*-dihydroxyiminium carbenium ions, which react with arenes to give arylated oximes. This overall process provides a route to α-aryl methyl ketones from 2-nitropropene (eq 11)[15] and constitutes a versatile synthetic method for the preparation of α-arylated ketones, otherwise difficult to synthesize by the conventional Friedel-Crafts reaction.

(11)

TfOH catalyzes the removal of *N*-*t*-butyl groups from *N*-substituted *N*-*t*-butylcarbamates to give carbamate-protected primary amines (eq 12).[16]

(12)

The methyl group attached to the phenolic oxygen of tyrosine is smoothly cleaved by TfOH in the presence of ***Thioanisole*** (eq 13).[17] This deblocking method was successfully applied to the synthesis of a new potent enkephalin derivative.

1,3,4-Oxadiazoles are prepared in good yields from silylated diacylhydrazines (formed in situ) by acid-catalyzed cyclization using TfOH (eq 14).[18]

TfOH protonates naphthalene at room temperature to give a complex mixture of products.[19] TfOH promotes aldol reaction of silyl enol ethers with aldehydes and acetals, leading to new C-C bond formation (eq 15).[20] TfOH competes well with other reagents employed for the aldol reaction, while ***Methanesulfonic Acid*** does not afford any product.

Cyclization of 3- and 4-arylalkanoic acids to bicyclic ketones is effected by TfOH via the corresponding acid chlorides (eq 16).[21]

Allylic *O*-methylisoureas are cyclized with TfOH containing ***Benzeneselenenyl Trifluoromethanesulfonate*** to 5,6-dihydro-1,3-oxazines (eq 17).[22]

(17)

Tscherniac amidomethylation of aromatics with *N*-hydroxymethylphthalimide in TfOH proceeds smoothly at room temperature to give the corresponding α-amido-methylated products (eq 18).[23]

(18)

TfOH catalyzes the amination[24] and phenylamination[25] of aromatics via the corresponding aminodiazonium ion generated from ***Azidotrimethylsilane*** and ***Phenyl Azide*** respectively (eq 19).

(19)

Electrophilic hydroxylation of aromatics is carried out by protonation of ***Bis(trimethylsilyl) Peroxide*** with TfOH in the presence of the substrate (eq 20).[26]

(20)

Phenol and 2,3,5,6-tetramethylphenol are protonated with TfOH under irradiation to afford rearranged products (eqs 21 and 22).[27]

(21)

(22)

Other Applications.

TfOH is the starting material for the preparation of the electrophilic reagent ***Trimethylsilyl Trifluoromethanesulfonate***. The latter is prepared by reacting TfOH with ***Chlorotrimethylsilane***[28] or more conveniently with Me_4Si (eq 23).[29]

(23)

Functionalized silyl triflates can also be prepared using TfOH (eq 24).[30]

(24)

Reaction of aromatic compounds with ***Bis(pyridine)iodonium(I) Tetrafluoroborate*** in the presence of TfOH is an effective method to form the monoiodo compounds regioselectively (eq 25).[31]

(25)

Ionic hydrogenation of alkenes with trialkylsilanes is possible in the presence of the strong acid TfOH, even at -75 °C (eq 26).[32]

(26)

Hydroxycarbonyl compounds can be selectively reduced to carbonyl compounds by means of TfOH in the presence of trialkylboranes (eq 27).[33]

(27)

The triphenylmethyl cation is nitrated with ***Nitronium Tetrafluoroborate*** in the presence of TfOH (eq 28).[34]

(28)

Sterically hindered azidophenyltriazines decompose in TfOH at 0 °C to give isomeric triflates (eq 29).[35]

(29)

Benzoyl triflate prepared from TfOH and ***Benzoyl Chloride*** is a mild and effective benzoylating agent for sterically hindered alcohols[36] and acylative ring expansion reactions.[37] The applications of TfOH in Koch-Haaf carboxylation,[38] Fries rearrangement,[39] and sequential chain extension in carbohydrates[40] are also documented. Recent applications of TfOH in cyclization reactions have been published.[41-43]

Trifluoromethanesulfonic Anhydride[1]

$(CF_3SO_2)_2O$

[358-23-6] · $C_2F_6O_5S_2$ · Trifluoromethanesulfonic Anhydride · (MW 282.16)

(preparation of triflates;[1] mild dehydrating reagent; promoter for coupling reactions in carbohydrates[2])

Alternate Name: triflic anhydride.

Physical Data: bp 81-83 °C/745 mmHg; *d* 1.677 g cm^{-3}; *n*20D 1.3210.

Solubility: sol dichloromethane; insol hydrocarbons.

Form Supplied in: colorless liquid in ampules. Once opened it should be immediately used.

Analysis of Reagent Purity: IR, NMR.

Preparative Methods: by distillation of ***Trifluoromethanesulfonic Acid*** with an excess of ***Phosphorus(V) Oxide***.[1]

Purification: by redistillation with a small amount of P_2O_5. It is advisable to freshly distill the reagent from a small quantity of P_2O_5 before use.

Handling, Storage, and Precautions: the pure reagent is a colorless liquid that does not fume in air and is stable for a long period. It is not soluble in water and hydrolyzes only very slowly to triflic acid over several days at room temperature. Preferably stored under N_2 in a stoppered flask.

Reaction with Alcohols and Phenols.

The reaction of alcohols and phenols with triflic anhydride (Tf_2O) at ~0 °C in the presence of a base (usually ***Pyridine***) in an inert solvent (usually dichloromethane) for 2-24 h affords the corresponding reactive trifluoromethanesulfonate esters (triflates).[1] When triflic anhydride and pyridine are combined, the pyridinium salt forms immediately and normally precipitates out from the reaction mixture. Nevertheless, the salt is an effective esterifying agent, reacting with the added alcohol to give triflates in high yields (eq 1).[3]

Pyridine can become involved in nucleophilic substitution when very reactive triflates are being synthesized.[2,3] One approach to minimize this disadvantage is to replace it with sterically hindered bases, such as 2,6-di-*t*-butyl-4-methylpyridine,[3,4] 2,4,6-trisubstituted pyrimidines,[5] or nonnucleophilic aliphatic amines (usually *N*,*N*-diisobutyl-2,4-dimethyl-3-pentylamine). No salt formation appears to take place under these conditions. The triflic anhydride seems to be the direct triflating agent and the base only neutralizes the triflic acid formed. Numerous alkyl triflates have been prepared in the literature[1b] by the above method. Some recent examples of triflates prepared from alcohols are illustrated in eqs 2 and 3.[6,7] As an exception, 2,6-dinitrobenzyl alcohol does not react with Tf_2O although similar sulfonyl esters could be prepared.[8]

(2)

(3)

Alkyl triflates have come to be recognized as useful intermediates for the functionalization of organic substrates by nucleophilic substitution, e.g. in carbohydrate chemistry.[9] Triflate is the best leaving group known[1b] next to the nonaflate and hence a large number of triflates, obtained in good yields by reaction of the corresponding alcohols (or alkoxides) with Tf_2O, have been used to generate unstable or destabilized carbocations under solvolytic conditions.[1b] Some new typical examples are shown in (**1**)-(**4**).[10-13]

(1)

(2)

(3)

(4)

Alkyl triflates are known to be powerful reagents for the alkylation of aromatic compounds.[1b,14] However, the reaction of alkyl triflates with heterocycles affords *N*-alkylation products.[15]

In an improved modification of the Ritter reaction, primary and secondary alcohols react with Tf_2O in CH_2Cl_2 in the presence of a 2:1 excess of nitriles to give the corresponding amides in good yields (eq 4).[16]

Aryl triflates are prepared from phenols at 0 °C using pyridine as solvent.[1b] Sometimes it is useful to conduct the reaction in CH_2Cl_2 at -77 °C, as in the preparation of 3,5-di-*t*-butyl-4-hydroxyphenyl triflate (eq 5).[17] Aryl triflates are synthetically transformed into several products of interest and applications in organic chemistry, by cross-coupling reactions with organometallics (eqs 5 and 6).[18]

Reaction of Tf_2O with Amines.

The reaction of 1 equiv of Tf_2O in CH_2Cl_2 and Et_3N with amines (or their salts) affords trifluoromethanesulfonamides (triflamides) in good yields.[19,20] If 2 equiv of Tf_2O are used, triflimides are formed. The triflamides are soluble in alkali and readily alkylated to triflimides (eq 7).[19,20]

Triflamides can be deprotected reductively (***Sodium-Ammonia***) to yield the corresponding amines.[21] This protocol has been employed in the facile two-step synthesis of aza macrocycles starting from trifluoromethanesulfonyl derivatives of linear tetramines (eq 8).[22]

Several triflamides (**5**-**8**)[23] and *O*-triflylammonium salts[24] have been used for the formation of vinyl triflates from regiospecifically generated metalloenolates or for preparing triflates from alcohols.

(5)

(6)

(7)

(8)

Reaction of Tf_2O with Carbonyl Compounds.

The reaction of Tf_2O with carbonyl compounds consists of the electrophilic attack of the anhydride on the carboxylic oxygen, resulting in the formation of triflyloxycarbenium ions as intermediates (eq 9). According to the nature of the carbonyl compound, the triflyloxycarbenium cations can eliminate a proton giving a vinyl triflate, undergo a rearrangement, or be trapped by the gegenion yielding *gem*-bistriflates (eq 9).

(9)

In the case of acyclic and monocyclic ketones, the reaction with Tf_2O affords vinyl triflates in good yields. Several methods exist to realize this reaction.[1b,25] For example, the reaction is carried out at room temperature in CH_2Cl_2 (or pentane) in the presence of 2,4-di-*t*-butyl-4-methylpyridine (DTBMP) (eq 10).[4]

(10)

Other bases such as pyridine,[1b] lutidine,[1b] Et_3N,[1b] polymer-bound 2,6-di-*t*-butyl-4-methylpyridine,[26] and 2,4,6-trialkyl-substituted pyrimidines[27] were also used. The commercially available *N*,*N*-diisobutyl-2,4-dimethyl-3-pentylamine is a very convenient base to prepare the vinyl triflates.[28] In the case of nonfunctionalized ketones, anhydrous Na_2CO_3 has been proved to be very successful.[1b,25]

The reaction of ketones with Tf_2O is governed by Markovnikov's rule and results in the formation of the more substituted triflate as the major product. When the reaction of ketones[27] and α-halo ketones[29] with Tf_2O is carried out in the presence of a nitrile, the intermediate trifloxy cation (eq 9) can be trapped, forming pyrimidines in good yields (eq 11).

X = Cl, Br, I

$R^1 = R^2$ = alkyl, aryl

The reaction of Tf_2O with strained bicyclic ketones such as 2-norbornanone and nopinone takes place with Wagner-Meerwein rearrangement of the corresponding triflyloxy cations, forming bridgehead triflates in good yields (eq 12).[30] These triflates are key compounds in the preparation of other bridgehead derivatives by substitution[31] and of substituted cyclopentanes by fragmentation.[32]

(12)

In the reaction of Tf_2O with norcaranones and spiro[2.5]octan-4-one, the cyclopropane ring undergoes fragmentation to give vinyl triflates (eqs 13 and 14).[33]

(13)

(14)

However, a cyclopropane ring is formed in the reaction of 5-methylnorborn-5-en-2-one with Tf_2O under the same conditions (eq 15).[34]

(15)

When the ketone can accomplish neither the stereoelectronic conditions for the elimination of TfOH nor for a rearrangement, the reaction of ketones with Tf_2O results in the formation of a *gem*-bistriflate (eqs 16 and 17).[35]

(16)

(17)

Sensitive ketones such as 3-pentyn-2-one also afford the corresponding vinyl triflate on treatment with Tf_2O in the presence of a base (eq 18).[36]

(18)

Substituted cyclopropenones and tropones react with Tf_2O with the formation of the corresponding dication ether salts (eq 19).[37]

(19)

Treatment of trifluoroacetyl ylides with Tf_2O results in the formation of *gem*-bistriflates (eq 20).[38]

(20)

Reaction of Tf_2O with Aldehydes.

The reaction of aliphatic aldehydes with Tf_2O in the presence of 2,6-di-*t*-butyl-4-methylpyridine (DTBMP) in refluxing CH_2Cl_2 or $ClCH_2CH_2Cl$ for 2 h affords the corresponding vinyl triflates as a mixture of (*Z*)- and (*E*)-isomers.[4,39] When the reaction is carried out at 0 °C, *gem*-bistriflates are formed as products (eq 21).[40] The *gem*-bistriflates result due to the trapping of the intermediate triflyloxycarbenium ion by the triflate anion. Primary vinyl triflates have been used extensively in the generation of alkylidene carbenes,[41] and *gem*-bistriflates are interesting precursors for *gem*-dihaloalkanes[42,43] and (*E*)-iodoalkenes.[44]

(21)

Reaction with Dicarbonyl Compounds.

1,3-Diketones can be reacted with an equimolar amount of Tf_2O or in excess to furnish the corresponding vinyl triflates or dienyl triflates (eq 22).[45] These triflates are transferred into monoketones, monoalcohols, alkanes, and unsaturated ketones by means of various reducing reagents.[45]

(22)

The reaction of 3-methylcyclopentane-1,2-dione with Tf_2O/Et_3N affords the vinyl triflate in 53% yield (eq 23).[46] The reaction takes place probably through the enol form. The product was coupled with alkenylzinc compounds in the presence of a palladium catalyst.[46]

The reaction of β-keto esters[47] with Tf_2O in the presence of a base results in the formation of 2-carboxyvinyl triflates (eq 24). These substrates undergo nucleophilic substitution of the TfO- group (eq 24)[47] and also coupling reactions.[48]

Reaction with Carboxylic Acids and Esters.

The reaction of carboxylic acids and esters with Tf_2O takes place according to the scheme shown in eq 25.[49]

The trifluoromethanesulfonic carboxylic anhydrides are highly effective acylation agents, which react without catalysts even with deactivated aromatics to yield aryl ketones (eq 26).[50]

Alkyl arylacetates react with Tf_2O to give a cation which in the presence of a nitrile affords isoquinoline derivatives via cyclization of the intermediate nitrilium cation (eq 27).[50]

Reaction of Tf_2O with Amides.

The reaction of a 2-oxo-1,2-dihydroquinoline with Tf_2O in the presence of pyridine affords the corresponding 2-quinoline triflate (eq 28).[51]

The reaction of tertiary amides with Tf_2O gives a mixture of *O*-sulfonylated (major) and *N*-sulfonylated (minor) products. In the presence

of collidine and an alkene, [2 + 2] cycloadducts are formed which hydrolyze to give cyclobutanones (eq 29).[52]

Treatment of DMF with Tf_2O results in the formation of an imminium triflate, which formylates less active aromatics. It is a convenient variation of the Vilsmeier-Haack reaction (eq 30).[53]

The reaction of *N*-methylpyridone and substituted urea systems with Tf_2O gives heteroatom-stabilized dicarbonium salts (eqs 31 and 32).[37,54]

Secondary amides can be converted to tetrazoles with Tf_2O in the presence of ***Sodium Azide*** (eq 33).[55]

(33)

R^1 = alkyl, Ph; R^2 = alkyl, $(CH_2)_2OAc$, $(CH_2)_2OTBDMS$

Other Applications.

Activated arenes can be converted to aryl triflones by Friedel-Crafts reaction with Tf_2O using ***Aluminum Chloride*** as catalyst (eq 34).[56]

(34)

The reaction of Tf_2O with Ph_3PO in CH_2Cl_2 at 0 °C affords triphenylphosphine ditriflate, which can be used as an oxygen activator, and then to a diphosphonium salt (eq 35).[57]

(35)

The less stable dimethyl sulfide ditriflate, obtained from Tf_2O and DMSO, has been used to oxidize alcohols (eq 36).[58]

(36)

Tetrahydropyran is not a suitable solvent in reactions involving Tf_2O because it is cleaved, affording 1,5-bistrifloxypentane (eq 37).[59]

(37)

Diols react with Tf_2O to yield the corresponding ditriflates; however, the reaction of 1,1,2,2-tetraphenyl-1,2-ethanediol with Tf_2O takes

place with rearrangement (eq 38).[59]

(38)

Vinylene 1,2-bistriflates are formed by the reaction of azobenzils with Tf_2O (eq 39).[60]

(39)

The reaction of enolates, prepared from silyl enol ethers and ***Methyllithium***, with Tf_2O affords vinyl triflates (eq 40).[61]

(40)

The combination of equimolecular quantities of ***Iodosylbenzene*** and Tf_2O generates $PhI(OTf)_2$, a compound also formed by treatment of Zefiro's reagent with Tf_2O. As shown in eq 41, this compound can be used to prepare *para*-disubstituted benzene derivatives in good yields.[62]

(41)

Tf_2O is a suitable promoter for the stereoselective glucosidation of glycosyl acceptors using sulfoxides as donors.[63]

The reaction of Tf_2O with a catalytic amount of ***Antimony(V) Fluoride*** at 25 °C produces trifluoromethyl triflate in 94% yield (eq 42).[64]

$$(CF_3SO_2)_2O \xrightarrow[80\%]{SbF_5} CF_3OSO_2CF_3 \qquad (42)$$

Useful application of Tf_2O as dehydrating reagent is accounted by the synthesis of isocyanides from formamides and vinylformamides (eq 43).[65]

(43)

Reaction of enaminones with Tf_2O in a 1:1 molar ratio affords 3-trifloxypropeniminium triflates by *O*-sulfonylation. From a cyclic enaminone, by using a 2:1 molar ratio, the corresponding bis(3-amino-2-propenylio) bistriflate is obtained (eq 44).[66]

Trifluoromethanesulfonyl Chloride[1]

[421-83-0] · $CClF_3O_2S$ · Trifluoromethanesulfonyl Chloride · (MW 168.53)

(trifluoromethylsulfonation agent;[1] chlorinating agent;[2] metal-catalyzed chlorotrifluoromethylation of alkenes[3])

Alternate Name: triflyl chloride.

Physical Data: bp 29-32 °C, *d* 1.583 g cm^{-3}.

Solubility: sol CH_2Cl_2, THF, dioxane.

Form Supplied in: colorless liquid, 99 +%.

Analysis of Reagent Purity: IR: 1424, 1306, 1237, 1115, 771, 611, 565, 532, 404 cm^{-1}.[4]

Preparative Methods: dried ***Zinc Trifluoromethanesulfonate*** is heated with PCl_5.2ZnCl at 260 °C. Fractional distillation of the volatile products gives TfCl (94% yield).[5]

Handling, Storage, and Precautions: moisture sensitive; store under N_2 in the cold. This toxic reagent is corrosive and is a lachrymator. It should only be handled in a fume hood.

Triflate and Triflamide Formation.

Triflyl chloride (TfCl) reacts as an electrophile with oxygen and nitrogen nucleophiles to produce triflate or triflamide derivatives. The trifluoromethanesulfonate group is a highly electron-withdrawing moiety and is a useful leaving group in organic synthesis for nucleophilic displacement, solvolysis, and metal-catalyzed coupling reactions.[1] The sulfonation reaction works well with amines[6] and alcohols, and is especially suitable for phenols.[7] An amine base such as ***Triethylamine*** or ***Diisopropylethylamine*** is usually added as an acid scavenger and to activate the substrates; however, the reactivity of the starting materials can be increased with prior anion formation by a stronger base.[8] Less reactive substrates may be sulfonated using ***Trifluoromethanesulfonic Anhydride*** or other derivatives of triflic acid such as those formulated from imidazole[9] or amides.[10] These are the reagents of choice for the formation of enol triflates from carbonyl compounds having α-hydrogens.[1] Mixed sulfonic anhydrides can be formed by reaction of the silver salt of an alkylsulfonic acid with triflyl chloride.[11]

An enol has been activated toward intramolecular nucleophilic addition with TfCl (eq 1).[12] A pyridine heterocycle reacts in a similar way.[13] In these reactions the triflinate anion ($CF_3SO_2^-$) functions as the leaving group. This sulfinate anion has also been studied as a nucleophile and potassium trifluoromethanesulfinate may be prepared by the reduction of TfCl with ***Potassium Iodide***.[14]

Chlorination of Activated Methylenes.

Triflyl chloride acts as a mild chlorinating reagent with certain carbon acids and nucleophiles.[15] Carbon acids in the pK_a range between diethyl malonate and methyl dichloroacetate react with TfCl in the presence of an amine base such as Et_3N or ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** to replace one or two acidic hydrogens with chlorine. The reaction is highly selective with the rate of chlorination being at least 10^5 greater than the rate of sulfonation. Yields are generally excellent and the reagent is often much more efficient than other chlorinating agents such as ***N-Chlorosuccinimide***. This transformation has been utilized for the synthesis of 2,2-disubstituted tetrahydrofurans, pyrans, and pyrrolidines (eq 2).[16]

When triflyl chloride and ***Sodium Azide*** are added to carbon acids, a similar reaction is observed and the corresponding azides are obtained in 50-60% yields.[17] The reactive species in this transformation is thought to be $F_3CSO_2N_2$. Similar reactivity has been seen with TfCl and ***Silver(I) Nitrate***. The intermediate $F_3CSO_2NO_2$ reacts with activated methylenes and ***Potassium t-Butoxide*** to give nitro derivatives in fair yields.[18]

Metal-Catalyzed Chlorotrifluoromethylation of Alkenes.

Dichlorotris(triphenylphosphine)ruthenium(II) catalyzes the reaction between triflyl chloride and alkenes to give vicinally chloro/trifluoromethyl-substituted alkanes with the extrusion of sulfur dioxide.[19] The reaction works well for alkenes bearing either electron-withdrawing or electron-donating substituents (eq 3). Terminal alkenes give the best yields but the reaction works with internal double bonds as well. Temperatures &egt;120 °C are required for complete extrusion of sulfur dioxide. Treatment of the products with aqueous ***Potassium Hydroxide*** causes the elimination of HCl to give vinyltrifluoromethane derivatives. The same ruthenium catalyst promotes the reaction between triflyl chloride and arenes to give trifluoromethylated aromatic compounds.[20] Trifluoromethyl iodide, an alternative reagent for the introduction of the trifluoromethane group, is less convenient to work with since it is a gas at rt.[3]

Trifluoromethanesulfonylmethyl Methyl Sulfone

[93916-15-5] · $C_3H_5F_3O_4S_2$ · Trifluoromethanesulfonylmethyl Methyl Sulfone · (MW 226.22)

(equivalent of alkene polyanion[1])

Alternate Name: mesyl triflone.

Physical Data: mp 115-116 °C.

Solubility: insol cold H_2O; sol HCO_3^-, common organic solvents.

Preparative Methods: by triflation of ***Dimethyl Sulfone*** in base (EtMgBr/THF) with trifyl fluoride (CF_3SO_2F)[1] or by analogous sulfonylation of methyl triflone ($CH_3SO_2CF_3$)[2] with ***Methanesulfonic Anhydride***.

Purification: recrystallized from H_2O, dried over P_2O_5 in vacuo.

Handling, Storage, and Precautions: stable solid, no known toxicity.

General Discussion.

The reagent acts as an alkene polyanion equivalent ($^{2-}C{=}C^{2-}$) owing to successive alkylations of its di- or trianion followed by base-catalyzed cheletropic extrusion of SO_2 to form the product alkene (eq 1).[1]

(1)

The successive alkylations, or reactions with other electrophiles, proceed with regiochemical control owing to the very different acidities of the two kinds of C-H bonds at α and α´. The most acidic proton (p*K* 4.3 in H_2O) is at α, and the dianion (2 mol ***n-Butyllithium***/THF at -78 °C) is also fully formed at the α-carbon. Alkylation of this dianion can yield either one or two alkylations at α, the former returning the stable anion of the α-monosubstituted reagent as product; the monoanion at α is very sluggish to alkylation. Successive alkylations, with added base (BuLi) and alkylating agent, proceed cleanly in the order R^1, R^2, R^3, R^4. With stoichiometric control of added base and carbon electrophile, as many as three substitutions may be carried out in one pot without isolation. Only when the α-carbon is fully substituted does treatment with base (*t*-BuO^- was the most effective[1]) afford the Ramberg-Bäcklund extrusion[3] of SO_2; otherwise, the presence of the

stable α-anion precludes it. Although the regiochemistry of substitution is well controlled, the alkene stereochemistry of the product (eq 1) is not controllable.

The final substitution (R^4) requires very active alkylating agents and elevated temperatures unless it is a cyclization. α-Alkylations which provide carbonyl activation, as with α-halo carbonyls, give rise to elimination of triflinate directly (eq 2).[1]

Acylation at α´ is facile (on α,α´-dianions) and requires an extra equivalent of base for the acidic α-acyl sulfone products. Aldehydes and ketones react similarly at α´ to afford β-hydroxy sulfones. Spontaneous cyclization occurred (eq 3) when the allylic alcohol from acrolein was oxidized to the unsaturated ketone (eq 3) and treatment with base completed the conversion to 3-methylcyclopentenone. However, mesylation of the β-hydroxy sulfone gave the four- instead of six-membered cyclization in eq 3 by direct rather than allylic displacement. Other cyclizations are shown in eq 4, the epoxide yielding only the six-membered ring, the dibromo derivative both five- and six-membered rings.

Reaction of the stable α-monoanion with ***Formaldehyde*** quantitatively eliminates triflate ion to create α-methylene sulfones (eq 5).[4] Higher aldehydes did not react with the α-anion, but bromination is facile even at low temperature.

(5)

X-ray structures of several disulfones and their anions have been discussed,[5] and some related ones used in synthesis. The dimesyl analog ($MeSO_2CH_2SO_2Me$) also exhibits its dianion at α and is quite parallel in reactivity toward alkylation.[6] As expected, the α-monoanion is more reactive and more basic (p*K* = 12.5). When fully substituted at α the deprotonation of phenylsulfonyl methyl sulfones at α´ also initiates the Ramberg-Bäcklund rearrangement with loss of phenylsulfinate ion.[7] When no α´-CH is available for deprotonation, treatment with base serves to eliminate triflinate, as in eq 6, and is also used to create cyclic vinyl sulfones when the α-dialkylation is done with α,o-dihalides.[8]

(6)

In summary, the mesyl triflone reagent is useful for preparing 1,1-disubstituted alkenes (eq 1) ($R^2 = R^3 = H$) or cyclopentenones such as dihydrojasmone.[9] However, cyclohexenones were not formed[1] and, while more substituted acyclic alkenes are readily obtained, they arise as *cis-trans* mixtures.

N-Trifluoromethanesulfonyl-*N´*-phenacylhydrazine

(R = Ph)

[41804-90-4] · $C_8H_7F_3N_2O_3S$ · *N*-Trifluoromethanesulfonyl-*N´*-phenacylhydrazine · (MW 268.24) (R = *t*-BuO)

[56572-25-9] · $C_6H_{11}F_3N_2O_4S$ · *N*-Trifluoromethanesulfonyl-*N´*-*t*-butoxycarbonylhydrazine · (MW 264.26)

(conversion of alkyl halides to hydrazones of aldehydes and ketones)[1]

Alternate Name: N-triflyl-*N´*-phenacylhydrazine.

Physical Data: R = Ph, mp 156-158 °C. R = *t*-BuO, mp 92-94 °C.

Solubility: insol H_2O; sol common organic solvents.

Preparative Methods: triflation of the commercial acylhydrazines with ***Trifluoromethanesulfonic Anhydride*** and ***Triethylamine*** in CH_2Cl_2.

Handling, Storage, and Precautions: both are stable solids with no known toxicity, but the *t*-butyl derivative may decompose on long standing at rt and decomposes on mild heating.

General Discussion.

Designed to afford protected derivatives of sensitive aldehydes or ketones directly from the corresponding alkyl halides, these reagents fulfill this function as shown in eq 1. Owing to the various mild methods available for deprotecting hydrazones,[2] they serve as useful protection derivatives. Triflamide anions are excellent nucleophiles for displacement reactions of primary and activated secondary halides (or sulfonates) in MeCN, and the added base (***Potassium Carbonate***) eliminates triflinate ion to form the hydrazones. The *N´*-acyl group is necessary to activate the elimination, which does not occur in its absence. In the case of the *t*-butoxy derivative, the unsubstituted hydrazone may be recovered with acid as with other *t*-BOC amine derivatives. This also makes possible the synthesis of unsymmetrical azines, $R_2C{=}N{-}N{=}CR'_2$.

N-[4-(Trifluoromethyl)benzyl]cinchoninium Bromide[1]

[95088-20-3] · $C_{27}H_{28}BrF_3N_2O$ · *N*-[4-(Trifluoromethyl)benzyl]cinchoninium Bromide · (MW 533.47)

(chiral phase-transfer catalyst for asymmetric alkylations,[2a] amino acid synthesis,[7] hydroxylations,[6] Michael additions,[3] and Robinson annulations[2b])

Physical Data: mp 245 °C (dec).

Solubility: <10^{-5} M in toluene; 20 mM in toluene as dimer.[2a]

Form Supplied in: crystalline salt; commercially available. Can contain anywhere from 0 to 25 mol % of the dihydro analog, usually 15 mol %.

Handling, Storage, and Precautions: do not breath dust; avoid contact with skin and eyes.

Asymmetric Alkylation.[1,2]

N-[4-(Trifluoromethyl)benzyl]cinchoninium bromide (**1**) has been used as chiral phase-transfer catalyst[1,2] in the alkylation of indanones (eq 1).[2a] For the alkylation of α-aryl-substituted carbonyl compounds the diastereomeric *N*-[4-(trifluoromethyl)benzyl]cinchonidinium bromide (**2**) was used to obtain the opposite stereochemistry (eqs 2 and 3).[5] The asymmetric alkylation of oxindoles was used as the key step in an asymmetric synthesis of (-)-physostigmine (eq 4).[4]

(1)

(2)

(3)

(4)

In all cases it was reported that the trifluoromethyl group enhances the interaction in the prochiral ion pair, resulting in higher ee. The exception appears to be the asymmetric synthesis of α-amino acids via alkylation of the benzophenone Schiff base of glycine alkyl esters with allyl bromide, which produced a 56% ee with the trifluoromethyl-substituted catalyst compared to 66% with the unsubstituted catalysts *N*-benzylcinchoninium chloride (**3**) or *N*-benzylcinchonidinium chloride (**4**) (eq 5).[7]

The unsubstituted catalyst (**3**) was also used in an asymmetric Gabriel synthesis of α-amino acids via solid-liquid chiral phase-transfer alkylation of potassium phthalimide with 2-bromocarboxylates.[10]

In general, nonpolar solvents and less reactive alkyl halides (Cl > Br > I) give higher ee values. Aqueous 50% NaOH is the preferred base, as it acts as a dehydrating agent and keeps the organic solvent dry, thus promoting a tight ion pair. During the reaction the catalyst is extracted into the organic layer as a dimer of ammonium bromide and its zwitterionic oxide,[2a] but it reacts as a monomer resulting in an order of 0.5 for the catalyst in the alkylation reaction. The catalyst degrades during the reaction via Hofmann elimination to tertiary amines, which are readily removed by acid extractions during the workup.[2a] Therefore the catalyst usually cannot be recovered. An economical alternative catalyst is *N*-(3,4-dichlorobenzyl)cinchoninium chloride, which may give equivalent results.[2a,3,4a,9] Reduction in catalyst concentration and reaction times may be achieved by addition of a very small amount of a PEG cocatalyst (PEG 400 or PEG *p*-isooctylphenyl ether).[2e,9] The ee will depend on the interaction of the catalyst with the substrate in the ion pair and in certain cases an electron-donating substituent on the benzyl group may provide optimal interaction, as was found for an asymmetric Michael reaction using *N*-methyl-*N*-benzyl ephedrinium bromide as the phase-transfer catalyst.[8]

Asymmetric Michael Addition.

A chiral catalytic addition of methyl vinyl ketone to 2-propylindanone in 93% yield and 80% ee (*S* enantiomer) has been reported (eq 6).[3]

The (*R*) enantiomer was prepared with 40% ee using the cinchonidine catalyst (**2**). When the vinyl group of the catalyst was hydrogenated to the ethyl group (*N*-[4-(trifluoromethyl)benzyl]dihydrocinchonidinium bromide, **5**), the ee improved to 52%. Equally good results were obtained using the basic catalyst dimer[2a] in a homogeneous system which allowed the use of Michael acceptors not compatible with hydroxide bases.

Asymmetric Hydroxylation.

The catalyst has been used for asymmetric α-hydroxylations of indanones and α-tetralones using the standard conditions in combination with oxygen and ***Triethyl Phosphite*** (eq 7).[6] Substituents on the aromatic ring of the substrates will influence the π-π interaction in the ion pair and affect the ee. Similarly, (*E*)-2-ethylidene-1-tetralone was oxidized to the α-hydroxy ketone (eq 8).

(7)

(8)

Asymmetric Robinson Annulation.

2-Propyl-1-indanone undergoes Robinson annulation with the catalyst and methyl vinyl ketone (eq 6).[3] Higher ee values were achieved using 1,3-dichloro-2-butene (Wichterle Reagent) as an MVK surrogate for the Michael addition and overall Robinson annulation (eq 9).[2b,d,e]

(9)

Using (**2**) as catalyst provided the (*R*) enantiomer in 99% yield, 78% ee. The key introduction of asymmetry during the synthesis of (+)-podocarp-8(14)-en-13-one was the phase-transfer-catalyzed Robinson annulation of 6-methoxy-1-methyl-2-tetralone with ethyl vinyl ketone. The authors carried out a comparative study of the *N*-(4-trifluoromethyl)benzyl derivatives of cinchonine, cinchonidine, dihydrocinchonine, and dihydrocinchonidine and found that (**5**) produced the highest ee of the desired (*S*) enantiomer at -45 °C using toluene and 60% aq KOH (eq 10).[5]

Trifluoromethylcopper(I)[1]

[77152-08-0] · $CCuF_3$ · Trifluoromethylcopper(I) · (MW 132.56)

(trifluoromethylation of aryl, heteroaryl, and allyl halides,[2] propargyl tosylates,[3] and iodonucleosides[4])

Physical Data: obtained only in solution; stabilized by HMPA.[20]

Preparative Methods: by reaction of copper metal and trifluoromethyl halides, or difluorocarbene precursors for in situ reactions; or preformed by metathesis of trifluoromethyl organometallic reagents, with subsequent reaction with electrophiles (see below).

Handling, Storage, and Precautions: sensitive to air and moisture; undergoes chain-extension reactions to form pentafluorocopper in the absence of electrophiles; several precursors of trifluoromethylcopper are toxic; HMPA is carcinogenic. Use in a fume hood.

General Considerations.

Trifluoromethylcopper was initially prepared by Kobayashi and co-workers by the reaction of ***Trifluoroiodomethane*** and ***Copper*** metal in the presence of aryl, allyl, or heteroaryl iodides.[2] Since these initial studies, many reports of the preparation and reaction of trifluoromethylcopper have appeared.[1a,b] Trifluoromethyl-substituted nucleosides have been obtained by reaction of iodonucleosides with CF_3Cu (eq 1).[4]

(1)

Trifluoromethyl-substituted allenes have been prepared from primary, secondary, or tertiary propargyl tosylates (eq 2).[3] Reaction of CF_3Cu with 5-iodo-1,3-dioxin-4-ones provides the corresponding trifluoromethyl derivatives which serve as precursors for α-CF_3-β-keto esters (eq 3).[5] Trifluoromethylation reactions are generally carried out using aryl iodides as the substrate. Aryl bromides or chlorides often result in lower yields and lead to the production of larger amounts of perfluoroethyl byproducts.[6] Improved yields of trifluoromethylated aromatics from aryl chlorides have been realized for *ortho*-substituted substrates, and by adding charcoal to the reaction mixture.[7]

(2)

Methods for the preparation of the reagent can be grouped into two general categories: in situ generation from CF_3X and copper metal, by decomposition of metal trifluoroacetates in the presence of ***Copper(I) Iodide***, or from a variety of difluorocarbene precursors in the presence of a fluoride source; and preformation by metathesis reactions. In situ generation is readily accomplished with CF_3I; however, the iodide is expensive and the reaction must be carried out at high temperatures in an autoclave.[2] CF_3Br may also be used, but the yields of trifluoromethylated products are generally not as high as those obtained in reactions using the iodide precursor.[8] CF_3I/Cu in situ generation and reaction of $CuCF_3$ is best accomplished in pyridine or HMPA. ***Trifluoromethanesulfonyl Chloride*** and copper metal also provide in situ generation of CF_3Cu for reaction with aryl iodides.[9] Generation of CF_3Cu from decomposition of metal trifluoroacetates in the presence of copper iodide and an aryl iodide provides the aryl trifluoromethyl derivative in good yield.[10] Sodium trifluoroacetate/copper iodide reactions may be effectively carried out in NMP, HMPA, or DMF. The presence of other functional groups such as nitro, chloro, and methoxy on the aryl iodide do not interfere with the reaction (eqs 4 and 5); however, free hydroxy (phenol) or aryl amino groups are not tolerated.[11]

The reaction appears to be a nucleophilic aromatic substitution reaction, as evidenced by the positive ρ value obtained from a Hammett plot of *para*-substituted iodobenzene derivatives.[11] CF_3Cu may also be generated by the reaction of *N*-nitrosotrifluoromethane sulfonamide (TNS-TF) and copper metal.[12] A drawback to this approach is the formation of CF_3NO as well as the instability of TNS-TF. Trifluoromethyltriethylsilane has also been employed as a precursor for in situ generation of CF_3Cu.[13] Aryl and vinyl iodides, as well as allyl and benzyl bromides, undergo trifluoromethylation when admixed with Et_3SiCF_3/CuI (eq 6). No trifluoromethylation is observed in reactions of Et_3SiCF_3 without the addition of copper iodide.

Possibly the most common method for the generation of CF_3Cu involves in situ formation from difluorocarbene precursors. The reagent may be directly prepared by the reaction of CF_2Br_2 with zinc, cadmium,[14] or copper[1a] metal in DMF (Scheme 1).

Scheme 1

The mechanism involves generation of difluorocarbene via radical anion formation with subsequent reaction of CF_2**:** and DMF. The fluoride produced then combines with CF_2**:** to generate CF_3^-, which reacts with the in situ formed copper halide to provide CF_3Cu. Without in situ trapping by an electrophile, CF_3Cu will undergo rapid chain extension to C_2F_5Cu. The chain extension reaction can be suppressed by adding excess fluoride anion to the reaction mixture; however, this procedure frequently results in decreased yields of the desired trifluoromethylated product. Fluorosulfonyldifluoromethyl iodide undergoes a single electron transfer (SET) process with copper metal to ultimately provide CF_3Cu via a difluorocarbene intermediate.[15] Methyl fluorosulfonyldifluoroacetate also provides CF_3Cu upon reaction with CuI by means of a difluorocarbene intermediate;[16] the reaction involves initial loss of methyl iodide followed by fragmentation of the copper salt to CO_2, SO_2, Cu^I, difluorocarbene, and fluoride. An advantage of this method is that no perfluoroethyl byproducts are observed in reactions with aryl iodides. A similar process from a less expensive source of difluorocarbene, methyl chlorodifluoroacetate, requires excess ***Potassium Fluoride*** for the generation of CF_3^- anion.[17] Generation of CF_3Cu by the latter method also eliminates the need to prepare FO_2SCF_2COF, the precursor for both fluorosulfonyl intermediates, from tetrafluoroethylene and sulfur trioxide.

Metathesis reactions of trifluoromethyl organometallic compounds to CF_3Cu provide a means to pregenerate the reagent and allow for trifluoromethylation at much lower temperatures than the methods discussed above. The use of preformed CF_3Cu, rather than in situ methods, has also allowed for the multiple trifluoromethylation of thermally unstable polyiodoheteroaryl species (eq 7).[1a]

Trifluoromethylmercury, -zinc, and -cadmium species can all undergo metathesis to CF_3Cu. Trifluoromethylmercury has not been generally employed, presumably due to potential toxicity problems.[18] Metathesis of trifluoromethylzinc is prohibitively slow and therefore not synthetically useful; however, metathesis of trifluoromethylcadmium with CuBr in DMF at -50 °C allows for clean formation of the copper reagent.[19] Warming the mixture leads to the formation of two additional trifluoromethylcopper species, observed by ^{19}F NMR, with

the gradual loss of CF_3Cu. Storage at rt produces C_2F_5Cu, with complete consumption of the CF_3Cu after 11 h. The conversion of CF_3 to C_2F_5Cu can be accelerated by heating the mixture to 70 °C. The CF_3Cu reagent may be stabilized by adding HMPA, allowing trifluoromethylation reactions to be carried out in good yield at elevated temperatures.

S-(Trifluoromethyl)dibenzothiophenium Triflate[1]

[129946-88-9] · $C_{14}H_8F_6O_3S_2$ · *S*-(Trifluoromethyl)dibenzothiophenium Triflate · (MW 402.36)

(trifluoromethylating agent for many nucleophilic substrates)

Physical Data: mp 155 °C.

Solubility: sol MeCN, DMF, DMSO; slightly sol THF, CH_2Cl_2; insol Et_2O.

Form Supplied in: white crystals; commercially available.

Analysis of Reagent Purity: ^1H and ^{19}F NMR, IR.

Purification: recrystallization from CH_3CN/Et_2O at rt.

Handling, Storage, and Precautions: nonhygroscopic and thermally stable crystals; should be stored in a dry atmosphere protected from light.

Trifluoromethylation.[1,2]

S-(Trifluoromethyl)dibenzothiophenium triflate (**1**) is an electrophilic trifluoromethylating agent. Other related useful trifluoromethylating agents are *S*-(trifluoromethyl)-3,7-dinitrodibenzothiophenium triflate (**2**) and *Se*-(trifluoromethyl)dibenzoselenophenium triflate (**3**). The trifluoromethylating power order of these compounds varies as (**3**) < (**1**) < (**2**). The strongest reagent (**2**) smoothly fluorinates less reactive nucleophiles, while the mildest reagent (**3**) satisfactorily reacts with the more reactive nucleophiles. The title reagent (**1**) trifluoromethylates nucleophiles of intermediate reactivity. Thus (**1**) can trifluoromethylate metal salts of active methylene compounds (eq 1), acetylides (eq 2), enamines, enol silyl ethers (eq 3), reactive aromatics, heteroaromatics (eq 4), arenethiolates, and iodide anions in good yields. Enolate anions are trifluoromethylated in high yields by (**1**) in the presence of an equivalent amount of 2-phenylbenzo-1,3-dioxa-2-borole (eq 5).[3]

(1)

(2)

(3)

(4)

(5)

While (**1**) cannot trifluoromethylate triphenylphosphine, the more powerful reagent (**2**) provides access to (trifluoromethyl)triphenylphosphonium triflate in 78% yield. While (**1**) reacts with an alkanethiolate to give a trifluoromethyl alkyl sulfide in 47% yield along with 30% of a dialkyl disulfide as a byproduct, (**3**) produces a trifluoromethyl alkyl sulfide in 87% yield. The powerful trifluoromethylating agent (**2**) readily reacts with activated aromatics and heteroaromatics to yield trifluoromethylated compounds in good yields. Triflates (**1**)-(**3**) are all commercially available. The corresponding perfluoroalkyl analogs, *S*-(perfluoroethyl)-, -(perfluorobutyl)-, and -(perfluorooctyl)dibenzothiophenium triflates, are also available. Similar perfluoroalkylations are expected.[1] Since (**3**) is much more reactive than (**1**), the stability decreases, and (**3**) should be stored in a refrigerator.

Trifluoromethyl Hypofluorite[1]

CF_3OF

[373-91-1] · CF_4O · Trifluoromethyl Hypofluorite · (MW 104.01)

(electrophilic fluorinating agent[1b] for the preparation of α-fluoro carbonyl compounds,[10] 2-fluoroaldoses,[13] fluoro dienones,[17] aryl fluorides,[17] 5-fluoropyrimidines (and nucleosides),[22] *N*-fluoroamides,[18] and *N*,*N*-difluoroamines;[27] regioselective replacement of tertiary hydrogen by fluorine[28])

Alternate Name: fluoroxytrifluoromethane

Physical Data: mp <-215 °C; bp -97 °C; *d* 1.9 g cm^{-3} (at -97 °C).

Solubility: slightly sol $CFCl_3$, CF_3CO_2H, CF_3CH_2OH; slightly sol (reacts slowly) $MeCO_2H$, MeCN, $MeNO_2$ (solubility in all solvents increases at low temperature).

Form Supplied in: not presently commercially available; has been available as a compressed gas.

Analysis of Reagent Purity: hypofluorite can be estimated by iodometric titration ($CF_3OF + 2KI + H_2O$ -> $I_2 + CO_2 + 2KF + 2HF$). Comparison of the oxidizing capacity with gas volume and/or acid produced during reduction is a reasonable measure of reagent purity. Reaction with stilbene[2] has been used to assay identity and purity of hypofluorites.[3e]

Preparative Methods: continuous flow fluorination of CO by ***Fluorine*** over supported ***Silver***[3a] or ***Cesium Fluoride***[3b,c] catalyst (latter preferred). Static fluorination of COF_2 by F_2 over CsF.[3d] The aggressive nature of both F_2 and CF_3OF, the extremely exothermic nature of the reactions ($\Delta H_{formation}$ CF_3OF = -775 kJ mol^{-1}), and the variable quality of the catalyst render these preparations rather hazardous. Commercial production (ca. 300 g scale) was plagued by explosions of the liquified product obtained in the first procedures and by rupture of safety discs (200 atm) in the batch process.[4] Fluorination of COF_2 over CsF in an open continuous flow reactor to produce the reagent as needed (without condensation or other accumulation of large amounts of the product) should be considered. A reasonable small-scale alternative may be use of the mixed C_1 and C_2 hypofluorites obtained by the fluorination of CF_3CO_2Na[3e] (a variety of hypofluorites appear to attach a fluorine atom to most substrates in essentially the same way).[5]

Purification: the reagent as prepared often contains COF_2, which may be removed by passing the gas through water.

Handling, Storage, and Precautions: although thermally stable and reported to survive storage for a year in passivated metal cylinders,[3c] CF_3OF is an extremely aggressive oxidant (H_2O is oxidized slowly at neutral pH, quite rapidly at higher pH; unpassivated metal tubing can ignite and burn; explosions have resulted when using PVC tubing). It is recommended that apparatus coming in contact with the reagent be made of glass, passivated metal, or fluorocarbon (e.g. Teflon, Kel-F). Solutions of CF_3OF in $CFCl_3$ are reported to be quite stable;[3e] solutions in most other solvents should be considered metastable and potentially explosive; solutions in oxidizable solvents, particularly ethers, may react spontaneously and explosively. Slow addition of the reagent to the substrate (to minimize accumulation of reagent) is recommended. Reactions should be carried out on a small scale and precautions suited to potentially explosive reactions taken. CF_3OF is highly toxic ($L(ct)_{50}$ ~172 ppm, similar to that of OF_2 and perfluoroisobutene).[4] Daily exposure to 0.1 ppm for 2 h is reported to cause bone damage in rats.[6] Laboratory workers anticipating use of CF_3OF should first familiarize themselves with handling[3c,13a,18] and safety precautions.[3a,c,d,e,22b]

Preparation of α-Fluoro Carbonyl Compounds.

Electrophilic addition of CF_3OF is well illustrated by the fluorination of the vinyl acetate (**1**) to give adducts (**2**) and (**3**) and α-fluoro ketone (**4**) (eq 1).[7]

Formation of F_2 adducts such as (**2**) (presumably through decomposition of CF_3O^- into COF_2 and F^-) is characteristic of electrophilic reactions of CF_3OF[1b] (inclusion of a mild, insoluble, inorganic base, for example CaO, MgO, or $NaHCO_3$, protects sensitive substrates). Similar chemistry has been used to prepare 6- and 9-fluorinated steroids.[8,9]

Silyl enol ethers from aldehydes, ketones, esters, and amides react with CF_3OF to provide α-fluoro carbonyl compounds in good yield (eq 2). R can vary widely; note the regioselectivity implicit in formation of (**5**) and (**6**).[10] (A similar fluorination of less complex substrates with F_2 has been reported.[11] Compare also the fluorination of enolate anions with *N*-fluoro-*N*-methyltoluenesulfonamide.) Fluorination of enamides, e.g. (**7**) -> (**8**), provides intermediates for branched chain fluoro sugars (eq 3).[12]

(**5**) 71%

(**6**) 80%

Acetyl D-glucal (**9**) fluorinates smoothly to give the 2-fluoro glucose (**11**) and mannose (**10**) analogs (eq 4).[13a]

Each of the adducts (X = F or X = OCF_3) can be hydrolyzed to the corresponding pyranose in good yield; this reaction has been used for the synthesis of fluorinated pentoses,[13b] hexoses,[13c] and disaccharides.[13d] The fluorination of acetyl glucal by F_2 (little stereoselectivity[14]) and with ***Acetyl Hypofluorite***[15] (gluco:manno ca. 20:1) has been reported. 8-Fluoroerythronolides A and B have been prepared by a similar fluorination (90%) of an internal enol ether.[16]

Direct Fluorination of Aromatic Rings.

CF_3OF substitutes F for H *ortho* or *para* to good electron-releasing groups in benzene (and condensed benzene) derivatives.[3c,17] While intrinsic *ortho*:*para* selectivity is not great (ca. 3:1 with anisole and from 2.5:1 to 9:1 in some *N*-acylanilides[3c]), the preparation of (**12**)-(**15**) by the direct fluorination of the corresponding hydrocarbon illustrates the utility of the method.[3c,17a,c,d]

(14) 60%

(15) 65%

AcOF has been also used for direct fluorination, but it is a good deal less reactive.

Hydroxy substituted aromatics with *o*- or *p*-alkyl or fluorine substituents tend to undergo *ipso* fluorination to give α- or γ-fluorocyclohexadienones; thus (**16**)[18] and (**17**)[17a] were prepared by fluorination of the corresponding phenols, while (**18**)[17a,b] was obtained from fluorination of either the acetate or the methyl ether. Enforced *ipso* fluorination of pentafluorophenol is the key step in a convenient synthesis of perfluorocyclopentadiene.[19]

(16)

(17)

(18) 65%

CF_3OF tends to give addition products (rather than substitution) with deactivated aromatics, the K region of polycyclics[20] and heterocyclics (such as *N*-acylindole and benzofuran).[21]

5-Fluoropyrimidines (and Nucleosides).

CF_3OF in polar solvents converts pyrimidines into addition products, e.g. (**19**) -> (**20**) (eq 5) (X = OH, OMe, or other nucleophile derived from the solvent).[22] If R^3 = H (otherwise the adducts are stable), heating[22a] or treatment with ***Triethylamine***[22b] causes elimination of HX leading to a 5-fluoro pyrimidine, (**20**) -> (**21**). The latter procedure is favored as it permits the direct preparation of analogs of cytosine (Y = NH)[22b] as well as those with X = O and allows for the direct fluorination of nucleosides[22b] (R^1 = ribosyl, deoxyribosyl, etc.).

A variety of 5-F pyrimidines (and nucleosides) of biological interest have been so prepared.[22c] Radiolabeled 5-F compounds are conveniently prepared through direct fluorination of the readily available 5-H compounds.[23] Barbituric acid analogs (R^2 = OH) are also converted into 5-F compounds.[22a] (Pyrimidines have been fluorinated by F_2,[24] and 5-fluorouracil (**21**) (X = O, R^1 = R^2 = H) is prepared commercially on a quite large scale with F_2).[25]

N-Fluoro Amides and *N,N*-Difluoramines.

CF_3OF reacts with amides, first producing an N-F amide which may be further fluorinated (and cleaved) in a second step to give a difluoramino compound and an acyl derivative (X = F or OCF_3) (eq 6).[18]

Although the rapidity of the second step impairs the synthesis of N-F carboxamides, fluorination at low conversion leads to acceptable yields (50-70%) of rather complex products[26] (i.e. **22**). N-F sulfonamides (**23**) are formed in good yield,[18] as are N-F phosphoramides, e.g. (**24**).[26]

As amide nitrogen reacts with CF_3OF rather more slowly than activated aromatic rings,[18] this method is limited to the preparation of *N,N*-difluoramines bearing more robust substituents. This limitation is circumvented by fluorination of imino ethers (readily prepared by

alkylation of amides) (eq 7), e.g. preparation of (**24**) and (**25**) from the corresponding imino ethers having R^1 = Ph.[18]

(25) 85%

(26) 52%

Schiff bases react with CF_3OF,[27] and if the reaction is carried out in the presence of an alcohol[27b] the final cleavage is highly regioselective, affording RNF_2 (eq 8); in the absence of alcohol the alternative cleavage giving $ArCF_2NF_2$ intrudes.

Use of Ar = Ph leads to easy purification of compounds such as (**27**), while use of Ar = *p*-NaO_2C-C_6H_4 leads to easy recovery of the neutral compounds, e.g. (**28**).

(27) 64%

(28) 71%

Direct Replacement of sp^3 H by F.

CF_3OF reacts slowly with saturated hydrocarbons in the presence of a radical chain inhibitor (O_2, $PhNO_2$, etc., the absence of which leads to nonselective radical fluorination) to selectively replace tertiary hydrogen atoms with F.[28] This remarkable electrophilic reaction is quite regioselective (virtually restricted to tertiary H and extremely sensitive to remote electron-withdrawing groups); note (**29**)-(**31**), each obtained by fluorination of the corresponding hydrocarbon. The same regioselectivity and comparable (or superior) yield can be obtained with F_2.[28]

(29) >40%

(30) 90%

(31) >40%

Miscellaneous Reactions.

Fluorination of diazo compounds;[29a] fluorodemetalation of organometallics;[29b] photoinitiated radical replacement of H by F;[29c] photoinitiated radical addition to alkenes.[29d]

Trifluoromethylthiocopper(I)

CF_3SCu

[3872-23-9] · $CCuF_3S$ · Trifluoromethylthiocopper(I) · (MW 164.63)

(source of nucleophilic CF_3S for preparation of aryl and vinyl sulfides)

Physical Data: mp 113-115 °C (1:1 DMF adduct).

Solubility: sol ether.

Form Supplied in: copper-colored solid; commercially available.

Preparative Methods: can be prepared by two different procedures (eq 1). Heating of finely divided ***Copper*** powder with bis(trifluoromethylthio)mercury neat at 80-100 °C until the appearance of an orange color persists, and then heating for 30 min at 150 °C, gives the desired product upon cooling, ether extraction, and evaporation.[1,2] Stirring of copper powder and bis(trifluoromethyl) disulfide in DMF for 1 h gives trifluoromethylthiocopper as its 1:1 DMF adduct.[3,4] Additionally, this reagent has been prepared by metal exchange of trifluoromethylthiosilver with ***Copper(I) Bromide***.[5]

Handling, Storage, and Precautions: stable for several months when stored over phosphorus pentoxide at ambient temperature. Use in a fume hood.

Sulfide Formation.

Trifluoromethylthiocopper has been employed in reactions with bromodibenzocycloheptenones to synthesize precursors to tricyclic antipsychotic agents (eq 2).[6] Conveniently, the copper reagent is formed from its mercury salt and copper (see eq 1) in the presence of the aryl bromide, and then reacted in situ to give the aryl sulfide in high yield. These aryl sulfides have also been prepared by heating a diaryl disulfide with trifluoromethylthiocopper in acetonitrile (eq 3). 1,2-Dithioalkenes, made with trifluoromethylthiocopper, have served as precursors to 1,2-bis(trifluoromethylthio)alkynes. The alkynes are prepared in three steps from 1,2-dibromoethene in good yield (eq 4).[7]

Trifluoromethyltrimethylsilane

Me_3SiCF_3

[81290-20-2] · $C_4H_9F_3Si$ · Trifluoromethyltrimethylsilane · (MW 142.22)

(nucleophilic trifluoromethylating agent;[1,2] difluorocarbene precursor[1])

Physical Data: bp 54-55 °C; d^{20} 0.963 g cm^{-3}.

Solubility: sol THF, ether, CH_2Cl_2.

Form Supplied in: colorless liquid; commercially available.

Preparative Methods: is prepared[2,6] based on the original procedure of Ruppert,[7] by the reaction of ***Chlorotrimethylsilane*** with the complex of trifluoromethyl bromide and hexaethylphosphorous triamide in benzonitrile (eq 1). Other less convenient procedures for its preparation are also reported.[8,9]

$$\text{TMSCl} + CF_3Br \xrightarrow[\text{benzonitrile}]{(Et_2N)_3P} \text{TMSCF}_3 \quad (1)$$

75%

Handling, Storage, and Precautions: is an acid-, base-, and moisture-sensitive compound and should be stored under anhydrous conditions in a refrigerator. Use in a fume hood.

Introduction.

$TMSCF_3$ is a valuable reagent for trifluoromethylation of electrophilic substrates under nucleophilic catalysis or initiation.[1,2] Homologous trifluoromethyltrialkylsilanes have also been used for the same purpose.[3-5]

$TMSCF_3$ reacts as a trifluoromethide equivalent with a wide variety of electrophilic substrates such as carbonyls, sulfonyl fluorides, sulfoxides, deactivated aromatics, sulfur dioxide, and alkenes, etc.

Reactions with Carbonyl Compounds.

$TMSCF_3$ reacts with aldehydes in the presence of a catalytic amount of ***Tetra-n-butylammonium Fluoride*** (TBAF) in THF to form the corresponding trifluoromethylated carbinols in good to excellent yields following aqueous hydrolysis of the silyl ethers (eq 2).[2,3,6,10] The reaction also works very well for ketones under the same conditions, with the exception of extremely hindered ones such as 1,7,7-trimethylbicyclo[2.2.1]heptan-2-one, di-1-adamantyl ketone, and fenchone. The reaction has been characterized as a fluoride-induced autocatalytic reaction.[3,10] Other initiators such as ***Tris(dimethylamino)sulfonium Difluorotrimethylsilicate*** (TASF), ***Potassium Fluoride***, $Ph_3SnF_2^-$, and RO^- can also be used for these reactions. For the reactions of $TMSCF_3$ and perfluorinated ketones and pentafluorobenzaldehyde, excess of KF is needed.[16,17]

(2)

$TMSCF_3$ has been used in the preparation of polycyclic aromatic carcinogens, the key step being the addition of $TMSCF_3$ to the carbonyl group (eq 3).[11]

(3)

A series of tripeptides containing the trifluoromethyl group has been prepared as potent inhibitors of human leukocyte elastase (HLE) by using $TMSCF_3$.[12] $TMSCF_3$ has also been used to prepare trifluoromethyl analogs of L-fucose and 6-deoxy-D-ribose.[13] Gassman et al. have prepared 1-trifluoromethylindene starting from 1-indanone.[14]

1,2-Diketones such as benzil give only the monoadduct. On the other hand, the highly enolizable cyclohexane-1,3-dione did not give the addition product with $TMSCF_3$.[15]

A series of α,β-conjugated enones and ynones react with $TMSCF_3$ to give predominant 1,2-addition products (eq 4).[3,15]

(4)

Simple unactivated esters do not react with $TMSCF_3$.[3] However, activated esters such as trifluoroacetic acid esters do react.[3] Cyclic esters, i.e. lactones, react with $TMSCF_3$ to give the corresponding adducts.[3] An efficient and simple synthesis of trifluoropyruvic acid monohydrate has been developed starting from di-*t*-butyl oxalate.[18]

Direct trifluoromethylation of α-keto esters give Mosher's acid derivatives (eq 5).[19]

(5)

Acyl halides such as benzoyl chloride react with $TMSCF_3$ to give a mixture of the trifluoroacetophenone and hexafluorocumyl alcohol in the presence of equimolar TBAF.[3] Cyclic anhydrides react readily with $TMSCF_3$; however, a stochiometric amount of TBAF is required. Acyclic anhydrides react less cleanly.[3]

Simple amides, such as benzamide and acetamide, do not react with $TMSCF_3$ even with molar quantities of TBAF.[3] However, an

activated amide carbonyl such as in *N*-trifluoroacetylpiperidine reacts to give an adduct which upon subsequent hydrolysis gives hexafluoroacetone trihydrate.[15] Imidazolidinetriones react with $TMSCF_3$ to give 5-trifluoromethyl-5-hydroxyimidazolidine-2,4-diones upon aqueous acid workup.[20] Imides such as *N*-methylsuccinimide react smoothly to afford the hemiaminal adducts (eq 6).[15]

(6)

Sulfur Derivatives.

Kirchmer and Patel have reported[17] the preparation of trifluoromethylsulfinyl fluorides, sulfonyl fluorides, sulfoxides, and sulfuranes using $TMSCF_3$ in the presence of a catalytic amount of KF.

$TMSCF_3$ reacts with ***Dimethyl Sulfoxide*** in the presence of catalytic amount of TBAF to give Me_2CF_3SOTMS.[17] Arylsulfonyl fluorides react with $TMSCF_3$ to give the corresponding trifluoromethyl sulfones.[1,21]

Sulfur Dioxide reacts with $TMSCF_3$ in the presence of TMSONa to give the sodium trifluoromethyl sulfinate. The sulfinate has been further oxidized to trifluoromethanesulfonic acid in 30% overall yield.[1]

Nitroso Group.

Nitrosobenzene reacts with $TMSCF_3$ to afford the *O*-silylated trifluoromethylated hydroxylamine quantitatively.[1]

Aromatic Compounds.

Nucleophilic trifluoromethylation of aromatic compounds containing nitro, fluoro, and trifluoromethyl groups as substituents using $TMSCF_3$ has been investigated.[22,15] Yagupolskii et al. have reported that $TMSCF_3$-TASF (1:1) reacts with 1,2,4,5-tetrakis(trifluoromethyl)benzene at -30 °C to give the stable carbanion salt (eq 7).[23]

(7)

Phosphorus Compounds.

Treatment of $(BuO)_2P(O)F$ with $TMSCF_3$ and a catalytic amount of KF gave $(BuO)_2P(O)CF_3$ in 93% isolated yield.[1]

Generation of Difluorocarbene.

Treatment of $TMSCF_3$ with an anhydrous fluoride source such as TASF in THF results in the generation of singlet difluorocarbene. In the presence of an acceptor such as tetramethylethylene, the corresponding adduct can be isolated.[1]

Related Reagents.

Trifluoromethylcopper(I).

Trifluoroperacetic Acid[1]

[359-48-8] · $C_2HF_3O_3$ · Trifluoroperacetic Acid · (MW 130.03)

(electrophilic reagent capable of reacting with many functional groups; delivers oxygen to alkenes, arenes, and amines;[1] useful reagent for Baeyer-Villiger oxidation of ketones[27,44])

Alternate Names: TFPAA; peroxytrifluoroacetic acid.

Solubility: sol CH_2Cl_2, dichloroethane, ether, sulfolane, acetonitrile.

Form Supplied in: not available commercially.

Analysis of Reagent Purity: assay using iodometry.[2]

Preparative Methods: the preparation and handling of TFPAA should be carried out behind a safety shield. A mixture of ***Trifluoroacetic Anhydride*** (46.2 g; 0.22 mole) and CH_2Cl_2 (50 mL) is cooled with stirring in an ice bath. 90% H_2O_2 (caution: for hazards see ***Hydrogen Peroxide***) (5.40 mL, 0.20 mol) is added in 1 mL portions over a period of 10 min. When the mixture has become homogeneous, it is allowed to warm to rt and then again cooled to 0 °C.[3] TFPAA prepared from 30% aqueous H_2O_2 and ***Trifluoroacetic Acid*** has been used for some reactions.[4-6] Hydrogen peroxide of high concentration (70%) is not widely available due to hazards involved in handling, storage, and transportation. The commercially available ***Hydrogen Peroxide-Urea*** (UHP) system, which is safe to handle, has been introduced recently as a substitute for anhydrous H_2O_2 in the preparation of TFPAA.[2,7,8]

Purification: in the preparation of TFPAA, a slight excess of trifluoroacetic anhydride is used to ensure that no water is present in the reagent. The reaction between H_2O_2 and trifluoroacetic anhydride is very fast; the reagent is ready for use after the reactants have been mixed and the solution has become homogeneous. No special purification steps are employed. Suitable buffers (Na_2CO_3, Na_2HPO_4) are used to neutralize the highly reactive and strongly acidic trifluoroacetic acid which is present along with TFPAA in the reagent.

Handling, Storage, and Precautions: the reagent can be stored at -20 °C for several weeks[9] and exhibits no loss in active oxygen content after 24 h in refluxing CH_2Cl_2.[40] However, since it can be prepared in a short time, the usual practice is to prepare the reagent when needed. Note that solutions of TFPAA in CH_2Cl_2 can lose activity by evaporation of the volatile peracid.[41] Since peroxy acids are potentially explosive, care is required while carrying out the reactions and also during workup of the reaction mixture. Solvent removal from excess H_2O_2-CF_3CO_2H experiments can result in explosions; the peroxide must be destroyed by addition of MnO_2 (until a potassium iodide test is negative) before solvent removal.[10a] For a further discussion of safety, see Luxon.[10b] This reagent should only be handled in a fume hood.

General Considerations.

Trifluoroperacetic acid oxidizes simple alkenes, alkenes carrying a variety of functional groups (such as ethers, alcohols, esters, ketones, and amides), aromatic compounds, alkanes,[11] amines and N-heterocycles. Ketones undergo oxygen insertion reactions (Baeyer-Villiger oxidation).

Epoxidations of Alkenes.

Due to the presence of the strongly electron withdrawing CF_3 group, TFPAA is the most powerful organic peroxy acid and as such is more reactive than performic[21] or 3,5-dinitroperbenzoic acids.[41] It reacts readily even with electron-poor alkenes to furnish the corresponding

epoxides (see ***m-Chloroperbenzoic Acid***).

Trifluoroacetic acid is a strong acid which opens epoxides readily.[12,44] Since TFPAA is a much weaker acid than trifluoroacetic acid (pK_a 3.7 vs. 0.3), the latter reagent can be selectively neutralized with Na_2CO_3 or Na_2HPO_4, leading to the isolation of epoxides in high yields. When the substrate is highly reactive, Na_2CO_3 is used as buffer; when the substrate reacts sluggishly, Na_2HPO_4 is used as buffer.[12] The TFPAA reagent is rapidly decomposed by Na_2CO_3.

Since monosubstituted alkenes are not electron rich, they react sluggishly with the standard organic peroxy acids. By contrast, the monosubstituted alkene 1-pentene (**1**) is epoxidized efficiently by TFPAA (eq 1).[12] TFPAA prepared from 0.3 mol of 90% H_2O_2 and 0.36 mol of trifluoroacetic anhydride in CH_2Cl_2 is added during 30 min to a stirred mixture of (**1**) (0.2 mol), Na_2CO_3 (0.9 mol), and CH_2Cl_2 (200 mL). Since the alkene is volatile the reaction flask is fitted with an efficient ice water-cooled condenser. The reaction mixture boils during the addition of the peracid. After all the reagent has been added, the reaction mixture is heated under reflux for 30 min, cooled, and the insoluble salts are removed by centrifugation. The salt is thoroughly washed with CH_2Cl_2. Fractional distillation of the combined CH_2Cl_2 extracts furnishes the epoxide (**2**) in 81% yield.

(1)

The alkene (**3**), which is resistant to epoxidation by *m*-CPBA or ***Peracetic Acid***, has been epoxidized with TFPAA to furnish in 83% yield a mixture of esters (**4**) and (**5**) (eq 2).[13] Esters (**4**) and (**5**) undergo facile deacylation when chromatographed on silica gel to furnish alcohols (**6**) and (**7**).

(2)

Epoxidation of allyldiphenylphosphine oxide (**8**) with TFPAA furnishes in quantitative yield the corresponding epoxide, 2-(diphenylphosphinoylmethyl)oxirane; *m*-CPBA epoxidation of (**8**) furnishes the epoxide in only 56% yield.[14] Epoxide (**9**) is obtained in 80% yield through regio- and stereoselective epoxidation of the corresponding alkene with TFPAA in CH_2Cl_2 in the presence of Na_2HPO_4 buffer.[15]

(8)

(9) R =

(Z)

The tertiary amine of (**10**) is expected to react more readily than the disubstituted double bond on treatment with an organic peracid. Selective epoxidation of the double bond in (**10**) was achieved by initially treating it with CF_3CO_2H. This led to salt formation due to protonation of the amine. Epoxidation of the salt with TFPAA and subsequent workup furnished the epoxide (**11**) (eq 3).[16]

(3)

(10) **(11)**

Alkenes have been epoxidized efficiently employing TFPAA prepared by the UHP method (eq 4).[2]

(4)

α,β-Unsaturated esters and α,β-unsaturated ketones are resistant to epoxidation by organic peracids since the double bonds are not electron rich; however, these compounds can be epoxidized by TFPAA. 1-Acetylcyclohexene[17] and methyl methacrylate[12] furnish the corresponding epoxides in 50% and 84% yields, respectively, when treated with TFPAA/Na_2HPO_4 in CH_2Cl_2 (reflux for about 0.5 h). The α,β-unsaturated ester (**12**) has been epoxidized stereoselectively by TFPAA (eq 5).[18] With *m*-CPBA, this epoxidation requires a higher reaction temperature which results in the formation of a complex mixture.

With organic peracids, allyl alcohols form hydrogen bonds involving the hydrogen of the alcohol, as in (**13**).[19] Ganem has suggested that, with TFPAA, allylic ethers form hydrogen bonds involving the hydrogen of the peracid (**14**).

Epoxidation of (**15**) having an allylic ether substituent axially oriented is *syn* selective (*syn:anti* epoxidation = 12.4:1) (eq 6);[19] this selectivity is due to the formation of the hydrogen bond of the type shown in (**14**). The stereoselectivity in the epoxidation of (**15**) is solvent dependent. When (**15**) is epoxidized in THF (which disrupts hydrogen bonding) the ratio of *syn*:*anti* epoxides obtained is 1:12. The epoxidation of the allyl alcohol (**16**) with TFPAA is highly *syn* selective (*syn*:*anti* epoxidation = 100:1); the *syn* selectivity in the epoxidation of (**16**) with *m*-CPBA is much less (*syn*:*anti* epoxidation = 5.2:1).

The diol (**17**) is epoxidized stereoselectively to furnish (**18**) (eq 7).[20]

Oxidation of Alkenes to Diols and Ketones.

Alkenes react readily with a CF_3CO_3H/CF_3CO_2H mixture to furnish hydroxy trifluoroacetates, e.g. (**19**) -> (**20**) (eq 8).[21] In this reaction, high molecular weight byproducts are formed due to the condensation of hydroxy trifluoroacetates with the epoxides formed from alkenes. The formation of the byproduct can be avoided by adding triethylammonium trifluoroacetate. After the formation of the glycol ester is complete, the solvent is evaporated under reduced pressure and the crude ester is subjected to methanolysis to furnish the vicinal diol (**21**). α,β-Unsaturated esters are also hydroxylated by this procedure.

The allyl alcohol (**22**) reacted readily with TFPAA to furnish the 1,3-dioxolane (**23**) (eq 9).[8] This reaction could not be carried out with *m*-CPBA even in refluxing ethylene dichloride. The homoallyl alcohol (**22**) (R^1 = H, R^2 = OH) was reacted with TFPAA prepared from commercially available urea-hydrogen peroxide; the major product formed was the dioxolane (**23**) (R^1 = H, R^2 = OH).

(±)-Allosamizoline (**25**) has been synthesized from the (dimethylamino)oxazoline (**24**).[22] 5.4 M TFPAA in CF_3CO_2H is added carefully to (**24**) at 0 °C. The reaction mixture is evaporated in vacuum and the resulting mixture of epoxides is solvolyzed by heating with 10% aqueous CF_3CO_2H at 40 °C. Hydrogenolysis (Pd/C, H_2, MeOH) of the solvolysis product furnishes pure (±)-(**25**) (overall yield 67%) and the epoxide (**26**) (yield 16%).

Epoxidation of sterically congested alkenes occurs with TFPAA under basic conditions (eq 10).[45]

Treatment of tetrasubstituted alkenes with TFPAA/BF_3 furnishes ketones via rearrangement. 1,2-Dimethylcyclohexene has been transformed to the ketone (**27**) (eq 11);[23] the reagents TFPAA and 47% ***Boron Trifluoride Etherate*** are added simultaneously.

(11)

Arene Oxidation.

Arenes are exhaustively oxidized to aliphatic carboxylic acids. Heteroaromatic systems, such as pyridine, quinoline, and dibenzothiophene, are quantitatively oxidized to their *N*-oxides and sulfone rather than undergo ring oxidation. The heteroatom oxidation deactivates the ring towards electrophilic attack by TFPAA.[6] Benzene undergoes direct catalytic oxidation to phenyl trifluoroacetate using a TFPAA/Co^{III} reagent.[24]

With BF_3.

The combination TFPAA/***Boron Trifluoride*** is a potent electrophilic oxidant for π-systems.[46] As a source of positive hydroxyl, it is used to convert aromatics into cyclohexadienones (eq 12)[26a] and phenols,[25] and alkenes into ketones (eq 13).[26b] See also eq 11 above.

(12)

(13)

R^1	R^2	R^3	Yield
Me	Me	Me	75%
Me	Me	H	53%
Et	Me	H	70%
Me	Cl	Me	77%

Baeyer-Villiger Oxidation.

On treatment with organic peroxy acids, ketones undergo oxygen insertion reactions to furnish esters (see ***m-Chloroperbenzoic Acid***).[44] This reaction, known as the Baeyer-Villiger rearrangement, has several applications and has been reviewed recently.[27] When carrying out this oxidation with TFPAA, Na_2HPO_4 buffer is added to prevent the reaction between trifluoroacetic acid and the Baeyer-Villiger product. The ketone (**28**) reacts with TFPAA to furnish brassinolide tetracetate (**29**) (eq 14).[28] The migration of C-7 rather than C-5 carbon in this oxidation is due to the effect of the acetate groups at C-2 and C-3. A systematic study of the Baeyer-Villiger reaction of 5α-cholestan-6-ones

having substituents at C-1, C-2, and C-3 has been carried out.[29]

(14)

The oxidations of the ketone (**30**) and α-tetralone (**31**) have been reported (eqs 15 and 16).[30,2] Epimerization of α-substituents is generally not observed when ketones are oxidized with buffered TFPAA.[42]

(15)

(16)

Complete stereospecificity and high regioselectivity (25:1) is observed in the oxidation of an *erythro* ketone (eq 17). Oxidation of the *threo* ketone is also stereospecific but gives a 5:3 mixture of ester regioisomers.[47]

(17)

Heteroatom Oxidations.

Aromatic primary amines carrying electron-withdrawing groups are oxidized efficiently by TFPAA to the corresponding nitro compounds (eq 18).[21,31] The amine dissolved in CH_2Cl_2 is added to the peracid. The above oxidation cannot be carried out with aromatic amines such as *p*-anisidine, which are unusually sensitive to electrophilic attack; for these sensitive amines, peracetic acid is the preferred oxidant.

(18)

Oxidation of 2,3,4,5,6-pentachloroaniline with TFPAA in $CHCl_3$-water at rt furnishes, in 78% yield, 2,3,4,5,6-pentachloronitrosobenzene.[32] The electron-deficient heterocycle (**32**) furnishes the *N*-oxide (**33**) on oxidation with TFPAA prepared from urea-hydrogen peroxide (eq 19).[7] Electron-deficient pyridines are oxidized to the corresponding *N*-oxides with TFPAA; perbenzoic and peracetic acid are not effective for this transformation.[43]

(19)

Oxidation of the isoxazoline (**34**) furnishes the hydroxy ester (**35**) (eq 20) via an initial oxaziridine intermediate.[33]

(20)

Nitro compounds have many applications in organic chemistry.[34] Strained polynitro polycyclic compounds are of interest as a new class of energetic materials.[35] Since oximes are readily available, their oxidation to nitro compounds has been studied. Oxidation of the oxime (**36**) furnishes a mixture of nitro compounds; the major component is the *cis* isomer (eq 21).[36] During the oxidation of oximes, ketones are obtained as byproducts. Hindered oximes such as camphor oxime are not oxidized by TFPAA.

(21)

Oximes yield primary, secondary, and alicyclic nitroalkanes (72%),[48] and α-chloro ketoximes give α-nitroalkenes (31-66%).[49]

Oxidation of the oxime (**37**) furnishes a mixture of *endo,endo* and *exo,exo* isomers (eq 22).[35b] Oximes have been converted to nitro compounds using a multistep method.[35a] ***Sodium Perborate*** in glacial acetic acid oxidizes oximes to nitro compounds.[37]

(22)

α-Unsubstituted α,β-epoxy ketoximes are oxidized to γ-hydroxy-α-nitroalkenes (eq 23).[38] Aldoximes are oxidized to nitroalkanes (60-80%) with the reagent prepared from urea-H_2O_2 and trifluoroacetic anhydride. Ketoximes fail to react with this reagent system.[50]

(23)

Nitroso compounds are oxidized to the corresponding nitro compounds (eq 24)[39] or to nitramines.[40,51] 30% H_2O_2 is added to a solution of the nitrosopyrimidine (**38**) in CF_3CO_3H during 1.5 h. After workup the nitro compound (**39**) is obtained in high yield; in this reaction, oxidative hydrolytic desulfurization is observed.

(24)

Miscellaneous Reactions.

Aromatic azines are oxidized to their azine monoxides with TFPAA.[52] Organosulfides can be oxidized by TFPAA to either sulfoxides or sulfones under mild conditions in high yield.[5,53]

Triisobutylaluminum[1]

***i*-Bu$_3$Al**

[100-99-2] · $C_{12}H_{27}Al$ · Triisobutylaluminum · (MW 198.37)

(reducing agent with unique stereochemical preferences;[2] used in combination with CH_2I_2 as a selective cyclopropanation agent[16])

Physical Data: mp 0 °C; bp 46 °C/1 mmHg; *d* 0.781 g cm^{-3} (25 °C).

Solubility: freely miscible with saturated and aromatic hydrocarbons; reacts violently with H_2O and protic solvents.

Form Supplied in: as a neat liquid in a stainless container or as solutions in hexane, heptane, or toluene.

Analysis of Reagent Purity: brochures from manufacturers describe an apparatus and method for assay.

Handling, Storage, and Precautions: the reagent is indefinitely stable under an inert atmosphere. The neat liquid or the dense solutions are highly pyrophoric. Solutions more dilute than a certain concentration are not pyrophoric and are safer to handle. The nonpyrophoric limits are 20 wt % in isopentane, 22 wt % in hexane, and 25 wt % in heptane, respectively. Use of halogenated hydrocarbon as a solvent should be avoided because of possible explosive reactions sometimes observed for mixtures of CCl_4 and organoaluminums.

Carbonyl Reduction.

i-Bu$_3$Al acts primarily as a reducing agent rather than an alkylating agent toward carbonyl compounds.[2] Although the reactivity is modest and enolization sometimes competes, some unique stereochemical features are noted in the reduction of cyclic[3a] and acyclic ketones.[3b] Enones undergo mainly 1,2-reduction, whereas 1,4-reduction occurs in the presence of a Ni catalyst (eq 1).[4]

Alkylation.

Alkylation of allyl acetates[5] or glycal derivatives[6] proceeds regioselectively (eqs 2 and 3). The 1,4-addition to nitroalkenes gives, after hydrolysis, α-alkylated ketones.[7a] Application to the synthesis of alkylated dihydro-2(3*H*)-furanones[7b] (eq 4) and 1,4-diketones has been reported.[7c]

(2)

(3)

(4)

Cross couplings of *i*-Bu_3Al with carboxylic acid chlorides or thioesters can be achieved under Pd- or Cu-catalyzed conditions (eq 5).[8] A Ni catalyst is effective for coupling with alkynyl bromides (eq 6).[9] Reactions with propargyl acetates are effectively catalyzed by ***Iron(III) Chloride*** to give substituted allenes (eq 7).[10]

(5)

(6)

(7)

Rearrangements.

The [3,3]-sigmatropic rearrangement of allyl vinyl ethers is promoted by *i*-Bu_3Al, which also reduces intermediate aldehydes to give primary alcohols (eq 8).[11] Synthesis of a seven-membered ring via ring enlargement has been reported (eq 9).[11c] When ***Trimethylaluminum*** or ***Triethylaluminum*** are used, alkylated products are obtained. Reductive ring contraction reactions are effected by *i*-Bu_3Al to deliver cyclobutyl- or cyclopropylmethanols (eqs 10 and 11).[12]

(8)

(9)

(10)

(11)

Alkylative Beckmann rearrangement of oxime sulfonates is achieved by trialkylaluminums to give, after in situ reduction with ***Diisobutylaluminum Hydride***, the rearranged amines (eq 12).[13] Related alkylative Beckmann fragmentations have also been reported (eq 13).[14]

(12)

(13)

Regioselective ring cleavage of chiral acetals is effected by *i*-Bu_3Al (eq 14).[15a] Related reactions involving kinetic resolution have also been reported.[15b]

(14)

Cyclopropanation.

The reagent combination of CH_2I_2 and *i*-Bu_3Al (or other organoaluminums) leads to cyclopropanation of alkenes (eq 15).[16] The regioselectivity of this reagent is markedly different from the Simmons-Smith reaction.

2,4,6-Triisopropylbenzenesulfonyl Azide[1]

[36982-84-0] · $C_{15}H_{23}N_3O_2S$ · 2,4,6-Triisopropylbenzenesulfonyl Azide · (MW 309.48)

(agent for diazo[2] and azide[3] transfer to enolates)

Alternate Name: trisyl azide.

Physical Data: mp 41-43 °C.

Solubility: freely sol most organic solvents.

Preparative Methods: readily prepared by treatment of the commercially available triisopropylbenzenesulfonyl chloride (trisyl chloride) with sodium azide.[4]

General Considerations.

The reactions of arylsulfonyl azides with enolates have been reported to give a range of products, depending on the fragmentation of the initial adduct.[3,5] This may differ according to the nature of the enolate, the particular sulfonyl azide, and the quenching procedure. Net diazo transfer is usually observed for stabilized enolates, while azide transfer is more common with more reactive enolates.

Diazo Transfer to Ketones.

Triisopropylbenzenesulfonyl azide has been used for the direct transfer of the diazo group to ketone enolates under phase transfer conditions to furnish α-diazo ketones (eqs 1-4).[2,6-8]

(2)

(3)

(4)

The method may be used as a more direct alternative to the stepwise procedure of hydroxymethylenation, followed by treatment with ***p-Toluenesulfonyl Azide*** and ***Triethylamine***,[9] but its greatest value lies with the reactions of sterically hindered substrates (eqs 5-9),[2,10-12] for which the two-stage process is ineffective. The utility of the trisyl azide in these conversions stems from the steric hindrance afforded by the *ortho* isopropyl groups; simpler arylsulfonyl azides are degraded too rapidly under these conditions to be useful. The method appears to be less effective with cyclopentanones (eq 9)[13] and several failures have been reported with such substrates.[14]

Azide Transfer to Enolates.

Kinetically controlled azide transfer to the lithium enolates of azetidinones was originally demonstrated with tosyl azide using ***Chlorotrimethylsilane*** as a quenching reagent,[15] but was found not to be general for other enolates. One of the problems is competing diazo transfer. In a systematic study of azide transfer to imide enolates,[5] it was found that azide transfer is more strongly favored by more electropositive counterions (K > Na >> Li), and by more electron-rich arylsulfonyl azides (trisyl > tosyl > *p*-nitrobenzenesulfonyl). The steric requirements of the trisyl group undoubtedly play a role also. Triazenes are implicated as intermediates and it is the treatment of these compounds which determines the product distribution rather than the initial step. Triazene (**1**) was sufficiently stable to be isolated as a mixture of tautomers and it was found that decomposition to azide (**2**) could be effected with potassium acetate, but not lithium acetate. Thus the counterion effect noted above is expressed in triazene decomposition, rather than the initial addition of the enolate to the azide.

(1)

(2)

The most general protocol (eq 10) has therefore been based on ***Potassium Hexamethyldisilazide*** (KHMDS) as the base, addition of trisyl azide at -78 °C and then acetic acid at the same temperature.[5] Excellent levels of diastereoselectivity are observed with most substrates and

the method has been used widely in the enantioselective synthesis of α-amino acids from chiral imides.[16] Chemoselective azidation of an imide enolate in the presence of an ester function has been demonstrated (eq 11).[17] The product distribution is nevertheless finely balanced, as discovered with the respective dimethyl and dibenzyl ethers of the 3,5-substituted phenylacetyl imide (**3**) (eq 12).[18]

(10)

R = CH_2Ph ds = 97% (91% yield)
R = Me ds = 97% (74% yield)
R = Ph ds = 91% (82% yield)
R = *t*-Bu ds = 99% (90% yield)

(11)

97% ds

The azide transfer methodology may also be applied to a variety of esters[19] and is compatible with a number of other functional groups (eqs 13-15).[20,21] It may also be used with phosphonates (eq 16),[22] and if the counterion to the anion is lithium, as in the earlier imide study, it is possible to isolate the simple adduct retaining the sulfonyltriazine moiety (eq 17). Reaction with an *N*-hydroxy β-lactam afforded the deoxy-α-azido lactam via the *O*-sulfonate.[23]

(14)

(15)

(16)

R^1, R^2 = Me; >95% ds (52-68% yield)
R^1 = Me, R^2 = H; 57% ds (52-70% yield)

$R^1, R^2 = Me$; >95% ds (70-93% yield)
$R^1 = Me, R^2 = H$; 92% ds (75% yield)

Related Reagents.

p-Toluenesulfonyl Azide and ***Methanesulfonyl Azide*** have been used widely for diazo transfer to stabilized enolates.[9] The latter reagent simplifies isolation of the desired product,[24] but is potentially explosive and must be handled with care. Relative to other aryl analogs, the electron-deficient *p*-nitrobenzenesulfonyl analog favors diazo transfer to imide enolates.[5]

2,4,6-Triisopropylbenzenesulfonylhydrazide[1]

[39085-59-1] · $C_{15}H_{26}N_2O_2S$ · 2,4,6-Triisopropylbenzenesulfonylhydrazide · (MW 298.50)

(used as a diazene equivalent;[3] condensed with ketones and aldehydes to form hydrazones that can be converted into reactive intermediates such as diazoalkanes, carbenes,[13] carbenium ions, alkyllithiums,[9] or umpolung synthons)

Alternate Name: trisyl hydrazide; TPSH.

Physical Data: mp 121-122 °C (dec).

Solubility: sol virtually all ethereal, halogenated, protic, and aprotic solvents; insol water and hydrocarbon solvents.

Analysis of Reagent Purity: NMR, IR, TLC.

Preparative Methods: may be prepared in 96% yield by treating commercially available 2,4,6-triisopropylbenzenesulfonyl chloride[2] with hydrazine hydrate in THF,[3,4] being careful to keep the reaction and workup temperatures below or around 0 °C. The solid can be dried in vacuo over P_2O_5 for 24 h.

Handling, Storage, and Precautions: decomposes rapidly in solution at rt to diazene, particularly under basic or neutral conditions; acid retards this degradation significantly. It is stable in solid form at -20 °C for months and may be freed from acidic impurities as described in the literature.[3] 2,4,6-Triisopropylbenzenesulfonylhydrazide is a toxic, potentially flammable solid which should be handled with gloves under an inert atmosphere.

Alkene Reduction.

2,4,6-Triisopropylbenzenesulfonyl hydrazide (TPSH) undergoes solvent-dependent thermal degradation into diazene (diimide) between 35 and 65 °C, resulting in the in situ reduction of alkenes and other double bonds in good to excellent yields.[3-6] TPSH remains one of the best sources of diazene, and addition of amine bases increases the rate of both diazene formation and hydrogenation. It is the most reactive of the common arenesulfonylhydrazides, being 380 and 24 times more reactive than ***p-Toluenesulfonylhydrazide*** and ***Mesitylenesulfonylhydrazide***, respectively, under base-catalyzed conditions.[3]

Formation of Hydrazones.

Much of the rich chemistry exhibited by TPSH comes from its condensation products with ketones and aldehydes. Such trisyl hydrazones are typically prepared in excellent yield by mixing equimolar amounts of reagents in methanol or ethanol at room temperature with a catalytic amount of acid such as HCl and storing the reaction in the cold.[7] The product precipitates and is filtered off. Very hindered ketones such as camphor and diisopropyl ketone require stoichiometric amounts of acid and extraordinarily hindered ketones may not condense at all.[1,8]

Electrophilic Additions to Hydrazone Anions.

Trisylhydrazones can be quantitatively deprotonated with 2 equiv of ***n-Butyllithium*** to give dianions which are highly nucleophilic and participate in alkylation, aldol, halogenation, and epoxide-opening reactions at low temperature.[9] Regioselectivity of deprotonation is dictated

by three factors. First, and most important, is the geometry of the hydrazone C=N double bond, since the second equivalent of base is directed *syn* to the sulfonamide nitrogen anion in ethereal solvents.[10] Thus the mixture of azaenolates is determined by the ratio of isomeric hydrazones. TMEDA solvent negates the *syn*-directing effect and has been used extensively to deprotonate the less substituted α-carbon independent of hydrazone geometry.[11] Second, anion-stabilizing substituents in the α-position direct deprotonation. Third, is a general rule that methyl > methylene > methine in acidity. The preferred proton abstracted is illustrated with arrows in eq 1.[9d,12]

(1)

Bamford-Stevens and Shapiro Reactions.

Thermal decomposition of the monoanions of arenesulfonylhydrazones in aprotic solvents such as glyme (the aprotic Bamford-Stevens reaction[13]) is a method of choice for forming diazo compounds and carbenes. Trisylhydrazones are well suited to this end and have been shown to be the superior reagent for diazoalkane formation in several instances (eq 2).[14]

(2)

Trisylhydrazones were originally investigated as an alternative to the shortcomings of tosylhydrazones in the Shapiro reaction.[12a] The former have the advantage that their anions decompose at lower temperatures and the bulky isopropyl substituents preclude *ortho* metalation, enabling the use of stoichiometric amounts of base. Acyclic azaenolates have a strong preference for $(E)_{CC}$ geometry[10] and undergo the Shapiro elimination to stereoselectively produce alkenes of (*Z*) geometry (eqs 3 and 4). The stereochemical fidelity of the azaenolate is compromised significantly, however, if there is hydrocarbon branching at the α´-center due to allylic strain.[1]

(3)

(4)

The resulting vinyllithium intermediates may be trapped with a proton or some of the representative electrophiles shown in eqs 3-6.[11,15]

(5)

(6)

Additional electrophiles include CO_2, DMF, formaldehyde, ethyl chloroformate, ketones, D_2O, halophosphines, halides, and propargylic tosylates.[9d,11,12a,16]

The Shapiro elimination also provides access to a diverse array of one-pot electrophile-substituted double bonds (eqs 7 and 8).[9]

(7)

(8)

Several investigators have attenuated the potent nucleophilicity of vinyllithium intermediates by transmetalation or trapping. Vinylstannanes,[17] chromium-carbene complexes,[18] and particularly vinylsilanes[19,20] have been prepared. Alkenyllithiums react faithfully to give 1,2-addition products with α,β-unsaturated ketones, and mixed cuprate reagents have also been prepared with some success by trapping vinyllithiums with phenylthiocopper for 1,4-addition (eq 9).[21,22]

(9)

Intercepting the vinyllithium with a trialkylboron Lewis acid (eq 10) forms an ate complex that can then undergo iodine-promoted alkyl migration and elimination to give excellent yields of hindered trisubstituted alkenes.[23,24] This transformation constitutes a formal S_N2 displacement of a secondary halide and appears generally applicable to cyclic and acyclic ketones.

(10)

Intramolecular vinyllithium trapping has been used as an alternative to radical cyclization. Five- to seven-membered ring alkylidene cycloalkanes are formed via S_N2 displacement of a hydrocarbon-tethered leaving group by an alkenyllithium intermediate in 30-72% yield.[25] Another more general alternative is an analogous alkenyllithium condensation with a tether containing an unactivated terminal alkene (eqs 11 and 12).[26,27]

(11)

(12)

The resulting alkyllithium produced after cyclization has also been successfully trapped with several electrophiles in fair to excellent yield. This annulation stereoselectively gives the *syn* isomer in 10:1 to >50:1 but is limited to five-membered ring formation and has not been applied to highly functionalized carbocycles.

Condensation of trisylhydrazones with α,β-unsaturated ketones yields hydrazones that are selectively deprotonated α rather than γ to form 2-lithioalkadienes or quenched to form dienes (eqs 13 and 14).[28] 2-Halo ketone hydrazones give the same intermediate after treatment with strong base.[29]

(13)

(14)

Miscellaneous.

Ketones may be homologated by one carbon in moderate yield by forming the trisylhydrazone and reacting it with cyanide ion in boiling methanol.[30] 1,2-Carbonyl transpositions are possible in good to excellent yield by sulfenylation of a trisylhydrazone dianion, Shapiro elimination, and hydrolysis of the thioenol ether.[31] Vinylsilanes have been used to the same end.[32] Hydrazones of amides (amidrazones) have been prepared indirectly by treatment of a trisyl carbazate with ***Phosphorus(V) Chloride*** and then ***Morpholine***. These compounds act as acyl anion equivalents and may also undergo the Shapiro elimination to form a lithio enamine which can be attacked by two electrophiles.[33] Finally,

trisylhydrazones of α-keto amides may be indirectly synthesized from isocyanides; when treated with alkyllithium base, they undergo the Shapiro reaction to give allenylates. These intermediates react with electrophiles to give α-substituted-α,β-unsaturated amides in good to excellent yield.[34]

Triisopropyl Borate

B(O-*i*-Pr)$_3$

[5419-55-6] · $C_9H_{21}BO_3$ · Triisopropyl Borate · (MW 188.11)

(used for the preparation of boronic acids and esters;[1a] also used as Lewis acid catalyst or additive in many reactions)

Physical Data: bp 139-141 °C; *n*20D 1.3764; *d* 0.815 g cm^{-3}.

Solubility: very sol ether, ethanol, isopropanol, benzene; dec in H_2O.[2]

Form Supplied in: colorless liquid, about 98% pure.

Purification: by distillation.

Handling, Storage, and Precautions: moisture sensitive; must be stored under nitrogen in a cool dry place; irritating to the skin and to the eyes.[3]

Synthesis of Borinic and Boronic Acids and Esters.

B(O-*i*-Pr)$_3$ is a useful reagent for the preparation of isopropyl borinates (eq 1)[1b] or diisopropyl boronates (eq 2)[1a,1c-i] by reaction with 2 or 1 equiv of the appropriate organolithium or Grignard reagent, followed by addition of just 1 equiv of HCl. B(O-*i*-Pr)$_3$ is superior to B(OMe)$_3$ for these reactions.

Borinic esters are useful intermediates for the preparation of tertiary alcohols, ketones, α-haloborinic esters, lithium dialkylborohydrides, and new types of dialkylboranes.[1b] Boronic esters can be easily converted into the corresponding boronic acids by aqueous hydrolysis,[1c] with or without the presence of an acid (see also ***Trimethyl Borate***). An improved procedure for the preparation of both borinic and boronic isopropyl esters involves the pyrolysis of the intermediate ate complexes.[1e] Many boronic esters and acids can be prepared by the procedure summarized in eqs 1 and 2; some examples include allyl (substituted or not),[1f,g] 1-alkynyl,[1h] and 1-alkenyl[1j] boronic esters. Usually B(O-*i*-Pr)$_3$ gives better yields in boronic acids synthesis (especially for methylboronic acid) than B(OMe)$_3$ or other trialkyl borates.[1a,1d,1g]

Reaction of triisopropyl borate with ***Chloromethyllithium***,[1a] ***Bromomethyllithium***,[4a] or α-haloallyllithium[4b] represents an efficient entry into α-haloboronates, which can in turn undergo various substitution reactions.

Use of Boronic Esters and Acids.

One of the main uses of diisopropoxyboranes is their conversion into other boronates, passing through the corresponding boronic acids.

These new boronates are usually cyclic and can be chiral either on the diol residue[1f,g] used for the esterification, on the R-B moiety,[1a] or both.[1i] Allyl and substituted allyl boronates have been used in stereoselective C-C bond formation, by reaction with aldehydes (for a series of examples see ***Trimethyl Borate***).[1a,f,g,5] They can also react with C=N electrophiles, such as aldoximes, imines, and sulfenimides,[5] although more slowly than with aldehydes.

The reaction of $BrCH_2Li$ with simple boronates (achiral or chiral) inserts a CH_2 group into the carbon-boron bond, affording homologated boronates.[4a] Reaction with Cl_2CHLi inserts the CHCl group.[1a] The resulting α-haloboronic esters are useful starting materials for various substitution reactions. The same applies for α-haloallylboronates.[4b]

Diisopropyl boronates[1a] and boronic acids have been employed as nucleophilic partners in palladium-catalyzed cross-coupling reactions. However, only few have been prepared from $B(O\text{-}i\text{-}Pr)_3$ (usually boronic acids are prepared using $B(OMe)_3$ and ***Catecholborane*** as boron reagents), including some arylboronic acids used in the synthesis of 5-arylnicotinates.[6] (1-Alkynyl)diisopropoxyboranes can be used in ***Boron Trifluoride Etherate***-catalyzed conjugate addition to α,β-unsaturated ketones to provide 3-alkynyl ketones.[1h] Finally, a regiospecific synthesis of 2-fluoro-3-*O*-methylestrone (**2**) was realized by electrophilic displacement of boronic acid (**1**) with ***Cesium Fluoroxysulfate*** (CFS) (eq 3);[7] boronic acid formation was regiospecific in position 2 when the metalation [1. *n*-BuLi; 2. $B(O\text{-}i\text{-}Pr)_3$] was performed on the η^6-arenetricarbonylchromium(0) complex, derived from estrone.

Miscellaneous.

$B(O\text{-}i\text{-}Pr)_3$ has been used to prepare a boron reagent from lithium (trimethylsilyl)acetonitrile, which was employed for the stereoselective alkenation of aldehydes to give α,β-unsaturated nitriles. Compared to Li, Ti, and Mg reagents, this boron reagent gives the best results in regard to chemical yields and (*Z*/*E*) ratios.[8] $B(O\text{-}i\text{-}Pr)_3$, together with other trialkyl borates, has been used to transform unactivated bromides (R^1 = alkyl, vinyl, aromatic) into the corresponding homologated ester, via a carbonylation reaction catalyzed by 1,5-hexadienerhodium(I) chloride dimer and ***Tetrakis(triphenylphosphine)palladium(0)***;[9a] the same reaction can also be performed on benzyl chlorides in the presence of iodide ion and the above mentioned Rh^I catalyst (eq 4).[9b]

$$3\ R^1CH_2X + B(OR^2)_3 + 3\ CO \xrightarrow{\text{cat.}} 3\ R^1CH_2CO_2R^2 + BX_3 \quad (4)$$

Finally, the reaction of $B(O\text{-}i\text{-}Pr)_3$ with KH[10] gives ***Potassium Triisopropoxyborohydride***, a mild reducing agent for carbonyl compounds, disulfides, and haloboranes.

Triisopropyl Phosphite[1]

(i-PrO)$_3$P

[116-17-6] · $C_9H_{21}O_3P$ · Triisopropyl Phosphite · (MW 208.27)

(corresponding phosphonate esters afford high (*E*) selectivity in Wadsworth-Emmons alkenations[4,5])

Physical Data: bp 63-64 °C/11 mmHg; n_D 1.411; *d* 0.844 g cm^{-3}; fp 67 °C.

Solubility: sol organic solvents.

Form Supplied in: clear liquid; widely available.

Purification: by distillation at reduced pressure to avoid decomposition by Michaelis-Arbuzov reaction.

Handling, Storage, and Precautions: moisture sensitive, toxic (RTECS# TH2800000). Stable at rt for extended periods of time. Use in a fume hood.

Phosphonate/Phosphate Formation.

The reactions of the triisopropyl ester of P(OH)$_3$ are only marginally different from those of the triethyl or trimethyl esters. It may be used advantageously in situations which require a higher reaction temperature or a more sterically congested center (e.g. to prevent dealkylation of phosphonate esters). It can be used as a source of phosphonates (Michaelis-Arbuzov reaction)[1] for Wadsworth-Emmons alkenation reactions.[2] Control of the stereochemistry of the α,β-unsaturated ester may be possible by proper choice of the phosphonate ester. In contrast to the high (*Z*) selectivity observed[3] using the bis(trifluoroethyl) phosphonate, diisopropyl phosphonates[4,5] afford high (*E*) selectivity in some cases (eq 1).[5] This has been attributed to the increased bulk of the phosphorus ester, but other reports[6] dispute this and attribute the improved stereoselectivity to other factors.

(1)

Reaction with α-halo ketones affords enol phosphates (Perkow reaction),[7] which can be converted to alkenes (eq 2).[6]

Like all phosphites, triisopropyl phosphite can be used as a reagent for removal of O,[8] S,[9] Hal,[10] etc. from organic substrates (e.g. epoxides, episulfides, thiadiazolines). Like most reactions of trivalent phosphorus derivatives (phosphites or phosphines) with organic substrates, these reactions begin by formation of an alkoxyphosphonium salt or a derivative. Subsequent decomposition of the addition products leads to various products, depending on the functional groups involved. The use of triisopropyl phosphite as a ligand for transition metals is common. The much larger cone angle of triisopropyl phosphite[11] relative to the ethyl and methyl esters can be advantageous. Phosphites are less basic and less nucleophilic than phosphines (trialkyl or triaryl).

Reduction of Carbonyl Groups.

Triisopropyl phosphite has been used as a simple alternative to the Clemmensen or Wolff-Kischner reductions.[12] Refluxing the aldehyde or ketone with excess phosphite affords the deoxygenated reduced product in good yield under essentially neutral conditions (eq 3). A mechanism similar to the Meerwein-Pondorf-Verley reduction was proposed.

(3)

Related Reagents.

Triethyl Phosphite; ***Triethyl Phosphonoacetate***; ***Trimethyl Phosphite***; ***Trimethyl Phosphonoacetate***.

Triisopropylsilyl Chloride

***i*-Pr$_3$SiCl**

[131154-24-0] · $C_9H_{21}ClSi$ · Triisopropylsilyl Chloride · (MW 192.84)

(hydroxy protecting group;[1,2] formation of triisopropylsilyl ynol ethers;[3] *N*-protection of pyrroles;[4,5] prevents chelation with Grignard reagents[6])

Alternate Names: TIPSCl; chlorotriisopropylsilane.

Physical Data: bp 198 °C/739 mmHg; *d* 0.901 g cm^{-3}.

Solubility: sol THF, DMF, CH_2Cl_2.

Form Supplied in: clear, colorless liquid; commercially available (99% purity).

Analysis of Reagent Purity: bp; NMR.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: moisture sensitive; therefore should be stored under an inert atmosphere; corrosive; use in a fume hood.

Hydroxy Protecting Group.

Several hindered triorganosilyl protecting groups have been developed to mask the hydroxy functionality. Although the *t*-butyldiphenylsilyl (TBDPS) and *t*-butyldimethylsilyl (TBDMS) groups are the most widely used, the triisopropylsilyl group (TIPS) has several properties which make it particularly attractive for use in a multi-step synthesis.[1,2]

Introduction of the TIPS group is most frequently accomplished using TIPSCl and ***Imidazole*** in DMF,[1] although several other methods exist, including using TIPSCl and ***4-Dimethylaminopyridine*** in CH_2Cl_2. It is possible to silylate hydroxy groups selectively in different steric environments. For example, primary alcohols can be silylated in the presence of secondary alcohols (eq 1)[7] and less hindered secondary alcohols can be protected in the presence of more hindered ones (eq 2).[8]

(1)

A comparison of the stability of different trialkylsilyl groups has shown that TIPS ethers are more stable than TBDMS ethers but less stable than TBDPS ethers toward acid hydrolysis.[2] The rate difference is large enough that a TBDMS group can be removed in the presence of a TIPS group (eq 3).[7] Under basic hydrolysis, TIPS ethers are more stable than TBDMS or TBDPS ethers.[2] The cleavage of TIPS ethers can also be accomplished by using ***Tetra-n-butylammonium Fluoride*** (TBAF) in THF at rt.[1] This is most convenient if only one silyl protecting group is present or if all of those present can be removed in one synthetic step.

An additional feature of TIPS ethers is that they are volatile enough to make them amenable to GC and MS analysis. In fact, MS fragmentation patterns have been used to discern the structures of isomeric nucleosides.[9]

Formation of Silyl Ynol Ethers.

Esters can also be transformed into triisopropylsilyl ynol ethers.[3] The ester is first converted to the ynolate anion, followed by treatment with TIPSCl to furnish the TIPS ynol ether (eq 4). This method has even proven successful with lactones as starting materials (eq 5).

N-Protection of Pyrroles.

Pyrroles typically undergo electrophilic substitution at the α-(2)-position, but when protected as *N*-triisopropylsilylpyrroles, substitution

occurs exclusively at the β-(3)-position (eq 6).[4] It has been shown that 3-bromo-1-(triisopropylsilyl)pyrrole undergoes rapid halogen-metal exchange with ***n-Butyllithium*** to generate the 3-lithiopyrrole, which can be trapped by electrophiles to provide the silylated 3-substituted pyrrole (eq 7).[5] As expected, the silyl group can be removed with TBAF to furnish the 3-substituted pyrrole. It should also be mentioned that the *N*-TIPS group also enhances the stability of some pyrroles. For example, 3-bromopyrrole is very unstable, but the *N*-silylated derivative is stable for an indefinite period of time.[5]

(6)

(7)

Prevention of Chelation in Grignard Reactions.

The bulky TIPS protecting group has proven extremely effective in preventing competing chelation of α- and β-oxygen functionalities during Grignard reactions (eq 8).[6] It was determined that this effect is steric and not electronic since TMS and TBDMS ethers did not affect selectivity.

(8)

Related Reagents.

t-Butyldimethylchlorosilane; ***t-Butyldiphenylchlorosilane***.

Triisopropylsilyl Trifluoromethanesulfonate[1]

$(i\text{-Pr})_3SiOSO_2CF_3$

[80522-42-5] · $C_{10}H_{21}F_3O_3SSi$ · Triisopropylsilyl Trifluoromethanesulfonate · (MW 306.46)

(highly reactive silylating agent and Lewis acid capable of converting primary and secondary alcohols[1] to the corresponding triisopropylsilyl ethers and converting ketones[1] and lactones[2] into their enol silyl ethers; protection of terminal alkynes;[3] promoting conjugate addition of alkynylzinc compounds to α,β-enones;[4] preparation of (triisopropylsilyl)diazomethane[5])

Alternate Name: TIPS triflate.

Physical Data: colorless oil; bp 83-87 °C/1.7 mmHg; *d* 1.173 g cm^{-3}.

Solubility: sol most organic solvents, such as pentane, CH_2Cl_2, etc.

Form Supplied in: liquid; widely available.

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$) δ 1.6-1.05 (m).

Preparative Methods: to 38.2 g (0.242 mol) of triisopropylsilane at 0 °C under argon is added 23.8 mL (0.266 mol) of ***Trifluoromethanesulfonic Acid*** dropwise. The solution is stirred at 22 °C for 16 h, at which time no further hydrogen gas evolves (removed through a bubbler). The resulting product is distilled through a 30-cm vacuum jacketed Vigreux column under reduced pressure: 71.7 g (97% yield) of TIPS triflate; bp 83-87 °C/1.7 mmHg.[1a]

Handling, Storage, and Precautions: store under argon at 0 °C; unpleasant odor; reacts rapidly with water and other protic solvents.

Silylation of Alcohols.[1]

Primary and secondary alcohols are silylated by TIPS triflate in excellent yields. Treatment of 1-phenylethanol with 1.3 equiv of TIPS triflate and 2.5 equiv of ***2,6-Lutidine*** in CH_2Cl_2 at 0 °C for 2 h provides a 98% yield of α-(triisopropylsilyloxy)ethylbenzene (eq 1).[1a]

$$\mathrm{ROH} \xrightarrow[\mathrm{CH_2Cl_2}]{(i\text{-Pr})_3\mathrm{SiOTf},\ 2,6\text{-lutidine}} \mathrm{ROSi}(i\text{-Pr})_3 \qquad (1)$$

Formations of Enol Silyl Ethers.[1,2]

Aldehydes, ketones, and lactones are readily converted into the corresponding enol TIPS ethers. Reactions of cycloalkanones with 1.1 equiv of TIPS triflate and 1.5 equiv of ***Triethylamine*** in benzene at 23 °C for 1 h gives >98% yields of the corresponding enol silyl ethers (eq 2).[1a]

(2)

Silylation of 2-morpholinones with 1.2 equiv of TIPS triflate and 1.5 equiv of triethylamine in $CDCl_3$ for 2 min provides silyl ketene acetals, which upon standing at rt undergo Claisen rearrangement to afford pipecolic esters (eq 3).[2]

(3)

Alkynyltriisopropylsilanes.[3]

The acidic alkynic H can be protected with TIPS triflate. Silylation of 1-lithiopropyne with 1 equiv of TIPS triflate in ether at -40 to 0 °C gives an 87% yield of 1-TIPS-propyne (eq 4).[3a] 1,3-Bis(triisopropylsilyl)propyne, derived from treatment of 1-TIPS-propyne with ***n-Butyllithium*** in THF at -20 °C for 15 min followed by TIPS triflate at -78 to -40 °C (eq 5), is lithiated with *n*-BuLi in THF at -20 °C for 15 min and then allowed to react with aldehydes (eq 6). The *cis*-enynes are isolated in high yields.[3a] TIPS-propargylmagnesium bromide together with ***Copper(I) Iodide*** has been used in the displacement of the mesylate derivative of farnesol.[3b]

(4)

R = Cy, 71%
R = C_6H_{13}, 57%
R = *t*-Bu, 79%

Conjugate Addition of Alkynylzinc Bromides.[4]

Alkynylzinc bromides undergo conjugate addition with α,β-unsaturated ketones in the presence of ***t-Butyldimethylsilyl Trifluoromethanesulfonate*** or TIPS triflate (***Trimethylsilyl Trifluoromethanesulfonate*** is also effective) in ether-THF at -40 °C to give the corresponding 1,4-adducts (54-96% yields). A representative example is illustrated in eq 7.

(7)

(Triisopropylsilyl)diazomethane.[5]

Silylation of ***Diazomethane*** with TIPS triflate and ***Diisopropylethylamine*** in ether at -20 °C to 25 °C gives a 45% yield of (triisopropylsilyl)diazomethane (eq 8).[5] This silylated diazomethane is used to prepare stable silyl-substituted nitrilimines.[5]

(8)

Related Reagents.

Triisopropylsilyl Chloride.

Trimethylacetyl Chloride

[3282-30-2] · C_5H_9ClO · Trimethylacetyl Chloride · (MW 120.59)

(ether cleavage;[1] synthesis of ketones from carboxylic acids;[2] peptide synthesis;[3] selective protection of polyols[4])

Alternate Names: pivaloyl chloride; 2,2-dimethylpropanoyl chloride.

Physical Data: bp 105-106 °C; *d* 0.979 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: flammable; can cause severe burns and is irritating to the eyes and respiratory system; toxic by contact with the skin, by inhalation, and if swallowed. It should be used in a fume hood. During use, avoid sources of ignition and any contact. Avoid exposure to moisture.[5]

Ether Cleavage.

Ethers can be cleaved by the action of trimethylacetyl chloride (*t*-BuCOCl) and ***Sodium Iodide*** to give the corresponding trimethylacetate and alkyl iodide.[1] The reaction is regioselective, the cleavage occurring at the less substituted α-carbon-oxygen bond.[1,6] Other acyl chlorides can be used, but the reaction is more regioselective with trimethylacetyl chloride.[1] The reaction is particularly useful for cleaving methyl ethers (eq 1).[1]

(1)

Ketone Synthesis.

Carboxylic acids can be converted to ketones by first forming the mixed anhydride with trimethylacetyl chloride and then treating it with a Grignard reagent (eq 2).[2] In addition to trimethylacetyl chloride, *ortho*-substituted benzoyl chlorides such as *o*-anisoyl chloride can be used to form the mixed anhydride. Yields were found to be slightly higher than when trimethylacetyl chloride was used.[2]

(2)

The carboxylic acid (**1**) has been converted to the ketone (**2**) via the mixed anhydride with trimethylacetyl chloride (eq 3).[7]

A γ-keto aldehyde synthesis has been developed using similar methodology. The ethoxy lactam (**3**) was converted to its *N*-trimethylacetyl derivative (**4**), which was then treated with a Grignard reagent. Acid workup gave the γ-keto aldehyde (**5**) (eq 4).[8]

Peptide Synthesis.

Trimethylacetyl chloride has been used to synthesize peptidic bonds by the mixed anhydride method (eq 5).

A comparison of a range of carboxylic acid chlorides showed trimethylacetyl chloride to be one of the most effective for peptide synthesis, though slightly inferior to diethylacetyl chloride.[3] The extent of racemization that occurred using various acyl chlorides has been studied and trimethylacetyl chloride was shown to give only a very small amount of racemization.[9] Trimethylacetyl chloride has been used in the synthesis of adrenocorticotrophic hormone.[10,11]

Selective Protection of Polyols.

The protection (as the trimethylacetate) of a primary alcohol in the presence of two secondary alcohols has been achieved in high yield using 1 equiv of trimethylacetyl chloride (eq 6).[4]

(6)

The selective protection of a less hindered primary alcohol in the presence of another more hindered one has also been achieved (eq 7).[12]

(7)

Sucrose has been selectively protected using trimethylacetyl chloride. By varying the conditions a variety of penta-, hexa-, and heptatrimethylacetates was obtained.[13]

Trimethylaluminum[1]

Me_3Al

[75-24-1] · C_3H_9Al · Trimethylaluminum · (MW 72.10)

(Lewis acid with methylation ability;[2-8] can effect useful C-C bond forming reactions including carboalumination,[14] methylenation,[15,16] and cyclopropanation;[17] can serve as a precursor to various sophisticated Lewis acids[27] or chiral catalysts[28,29])

Physical Data: mp 15 °C; bp 127 °C; *d* 0.743 g cm^{-3} (30 °C).

Solubility: freely miscible with saturated and aromatic hydrocarbons; reacts violently with H_2O and protic solvents.

Form Supplied in: clear colorless liquid; widely available as a neat liquid in a stainless container or 1-2 M solution in hydrocarbon solvents (hexane, heptane, toluene).

Analysis of Reagent Purity: brochures from manufacturers describe an apparatus and method for assay.

Handling, Storage, and Precautions: indefinitely stable under an inert atmosphere. Neat trimethylaluminum or concentrated solutions are highly pyrophoric. Solutions that are more dilute are not pyrophoric and are safer to handle. The nonpyrophoric limits are 11 wt % in hexane and 14 wt % in heptane. Halogenated hydrocarbons should be avoided because of possible explosive reactions sometimes observed for mixtures of CCl_4 and organoaluminums.

Methylation.

The Lewis acidity of Me_3Al has been used to activate electronegative atoms, such as oxygens, halogens, and other functional groups. It also methylates the resulting electrophilic species. Bridgehead methylation of bicyclo[2.2.2]octyl bromide (eq 1)[2a] and regioselective methylation of terpene derivatives[3a] are early examples that show these features. More recent examples include methylation of bromododecahedrane[2b] and unusual aromatic substitutions of *N*-hydroxyaniline derivatives (eq 2).[3b] Substitution reactions of glycosyl fluorides,[4] benzyl or glycal acetates,[5a,b] and sulfonyl groups[6] at activated positions can be effected with Me_3Al (eqs 3-6).

(1)

(2)

(3)

(4)

(5)

(6)

Boron Trifluoride Etherate alters the reactivity of γ- or δ-lactols toward Me_3Al (eq 7).[7] Me_3Al traps isocyanates generated from certain sigmatropic rearrangements (eq 8).[8]

In connection with the asymmetric Sharpless epoxidation, the regioselective cleavage of 2,3-epoxy alcohols and their derivatives has been well studied. In contrast to organocuprates, which provide 1,3-diols via C-2 attack, trialkylaluminiums give 1,2-diols via C-3 attack (eq 9).[9a,b] It should be noted that substrates with a phenyl group at C-3 undergo the methylation largely in retentive manner.[9c,d] ***n-Butyllithium*** catalyzes the regioselective β-addition to α- and β-alkoxy epoxides (eq 10).[10a,b] This regioselectivity also holds for epoxy acids (eq 11).[9d] A mixed reagent, Me_3Al and water (5:3), effects the regioselective and stereospecific methylation of γ,δ-epoxy acrylates (eq 12).[10c,d]

(9)

(10)

(11)

(12)

Asymmetric reactions via regioselective ring cleavage of chiral unsaturated acetals have been reported. The regioselectivity is sensitive to the solvent employed (eq 13).[11a,b] Recent developments have been described by Ishihara et al.[11c,d]

Cross couplings of organoaluminums with vinyl halides,[13b] enol phosphates,[12a] carboxylic acid chlorides, and thioesters[12b,c] are achieved by employing Pd or Cu catalysts (eqs 14 and 15). Unsaturated *N*-acylsulfoximines[13a] or *C*-alkylated purine nucleosides are thus prepared (eq 16).[13b]

Other useful C-C bond formations using Me_3Al include the carboalumination of 1-alkynes. The procedure with ***Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)zirconium*** (eq 17) has broad applicability,[14a-c] and has been used in many natural product syntheses (eq 18).[14d] Direct manipulation of the alkenylalanes provides a stereoselective route to trisubstituted alkenes (eq 19).[14e,f]

(17)

(18)

(19)

The Tebbe reagent (see μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***) is conveniently generated in situ by the reaction of ***Dichlorobis(cyclopentadienyl)titanium*** and Me_3Al, which, in contrast to the Wittig reaction, methylenates ester carbonyls to provide enol ethers (eq 20).[15] See also ***Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)titanium***. A triad reagent, ***Diiodomethane-Zinc***-Me_3Al, effects chemoselective methylenation of aldehydes (eq 21),[16] while the combination of CH_2I_2 and Me_3Al (or other organoaluminums) leads to cyclopropanation of alkenes (eq 22).[17] The regiochemical course of the latter reaction is markedly different from the Simmons-Smith reaction. Regioselective addition of polyhalomethanes to alkenes is induced by Me_3Al (eq 23).[18]

(20)

(21)

(22)

(23)

Carbon-heteroatom bond formation is often facilitated by the co-addition of Me_3Al. Aminolysis of esters is achieved by the action of amines or their hydrochlorides in the presence of Me_3Al (eq 24),[19a-c] the latter procedure being particularly useful when volatile amines are concerned (see ***Dimethylaluminum Amide***). The technique is also applicable to the synthesis of acid hydrazides.[19d] Selenoformamides are available from the corresponding formamides by reaction with $(Me_2Al)_2Se$, generated in situ from $(Bu_3Sn)_2Se$ (eq 25).[20] The corresponding tellurium chemistry works also. Me_3Al-LiSPh offers a tandem Michael-aldol approach to the oxahydrindene subunit of avermectins (eq 26).[21a]

(24)

(25)

(26)

The steric course of reduction of cyclic imines is impressively reversed by a mixed reagent, ***Lithium Aluminum Hydride***-Me_3Al (eq 27).[21b]

DIBAL, CH_2Cl_2	>99:<1
$LiAlH_4$-Me_3Al, THF	5:95

Rearrangements.

Allyl vinyl ethers undergo [3,3]-sigmatropic rearrangements in the presence of Me_3Al, which also captures the resulting aldehyde (eq 28).[22] In contrast, use of ***Triisobutylaluminum*** results in a primary alcohol.

Me_3Al effects sequential Beckmann rearrangement-methylation of oxime sulfonates. The rearranged imines can be stereoselectively reduced with ***Diisobutylaluminum Hydride*** to give amines (eq 29, cf. eq 27).[23a-c] Related alkylative ring enlargement[24] or alkylative Beckmann fragmentation[23d] reactions are also known (eqs 30 and 31).

β-Hydroxy methanesulfonates or *N*-nitrosulfoximines have been activated by Me_3Al to induce asymmetric pinacol-type rearrangement (eq 32)[25] or carbocyclization reactions (eq 33).[26]

(32)

(33)

Lewis Acid.

Me_3Al serves as the precursor to various sophisticated Lewis acids with different acidities, such as $MeAl(OTf)_2$[26] and $MeAl(OC_6F_5)_2$,[11c,d] or other acids with unique spatial environments (eq 34).[27] Chiral Lewis acids, such as (**1**)[28] and (**2**),[29] serve as catalyst for asymmetric Diels-Alder reactions. The catalyst generated from (**3**) and Me_3Al has been used for asymmetric cyanohydrin synthesis.[30]

Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)titanium

(Me_3Al)

[75-24-1] · C_3H_9Al · Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)titanium · (MW 72.10) (Cl_2TiCp_2)

[1271-19-8] · $C_{10}H_{10}Cl_2Ti$ · Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)titanium · (MW 248.98)

(carbometallation of alkynes and 1-metalloalkynes; conversion of monosubstituted alkenes to 1,1-disubstituted alkenes; preparation of the Tebbe reagent)

Physical Data: Me_3Al: bp 125 °C; *d* 0.752 g cm^{-3}. Cl_2TiCp_2: mp 287-289 °C; *d* 1.600 g cm^{-3}.

Form Supplied in: Me_3Al: liquid available neat or as solution in hexanes or toluene. Cl_2TiCp_2: bright-red crystals. Both are commercially available.

Preparative Methods: this reagent is obtained by mixing the two components.

Handling, Storage, and Precautions: Me_3Al is a very pyrophoric compound. It must be handled under an inert atmosphere.

Controlled Carbometallation of Alkynes.

The reaction of diphenylacetylene with a 1:1 mixture of ***Trimethylaluminum*** and ***Dichlorobis(cyclopentadienyl)titanium***, in 1,2-dichloroethane at 22 °C, produces, after 12 h, an alkenylmetal species, which after hydrolysis or iodinolysis gives (*Z*)-1,2-diphenylpropene or (*E*)-1-iodo-1,2-diphenylpropene, in 84 and 75% yields, respectively (eq 1).[1] Both products are >97-98% stereoisomerically pure. The current scope of this reaction is, however, much more limited than the corresponding methylmetallation with the ***Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)zirconium*** system.[2] Thus the reaction of 5-decyne produces 6-methyl-4,5-decadiene in 92% yield, rather than the expected 5-methyl-5-decene.[1] Presumably the carbometallated product undergoes dehydrometallation (eq 2). Terminal alkynes also react with Me_3Al-Cl_2TiCp_2, but the yields of carbometallated products are low.[1] Nevertheless, at least in some cases the Me_3Al-Cl_2TiCp_2 system is superior to the Me_3Al-Cl_2ZrCp_2 system. For example, the reaction of diphenylacetylene shown in eq 1 is not only faster but also higher yielding than the corresponding reaction with Me_3Al-Cl_2ZrCp_2.[1]

Carbometallation of 1-Metalloalkynes.

The reaction of 1-metalloalkynes, such as 1-octynylzinc chloride, 1-octynyldicyclohexylborane, and 1-octynyldimethylalane, with Me_3Al-Cl_2TiCp_2 proceeds smoothly and gives, after hydrolysis, 2-methyl-1-octene in 75, 81, and 84% yield, respectively (eq 3).[1] The reaction is >97-98% regioselective, and the intermediacy of 1,1-dimetalloalkenes is indicated by the formation of >95% pure 1,1-dideuterio-2-methyl-1-octene upon deuterolysis of (**1a**) and (**1c**). In the case of 1-octynyltrimethylsilane, the reaction produces an 80% yield of a 70:30 mixture of the desired methylmetallation product (**2a**) and an allene that can be derived from its regioisomer (**2b**) via dehydrometallation (eq 4).[1] When 1-pentynyldimethylalane is reacted with Me_3Al-Cl_2TiCp_2 (1:1) in CH_2Cl_2 at 23 °C, a 1,1-dimetalloalkene species (**3**) is formed in 90-100% yield. The reaction must involve addition of a Me-Ti bond to the alkyne, as the same compound can also be obtained by the reaction of the alkynylalane with preformed $Cl(Me)TiCp_2$.[3] Although (**3**) is formed as a single isomer, which is probably the (*E*) isomer, it undergoes a slow stereoisomerization to give a 60:40 mixture of (*E*) and (*Z*) isomers. The reaction of (**3**) with cyclohexanone or benzaldehyde gives the corresponding allenes in 83% and 67% yields, respectively (eq 5).[3]

$R^1, R^2 = (CH_2)_5$, 83%

$R^1 = Ph, R^2 = H$, 67%

Reaction with Monosubstituted Alkenes.

Monosubstituted alkenes react with 1-2 equiv of a 1:1 mixture of Me_3Al and Cl_2TiCp_2 to give 2-methyl-1-alkenes in moderate to excellent yields (eq 6).[4] The reaction tolerates the presence of ester, hydroxy, and halogens such as Br, provided that these groups are not directly attached to the sp^2 carbon center. A speculative but reasonable mechanism of the reaction involves alkylation of Cl_2TiCp_2 with Me_3Al, addition of the Ti-Me bond to an alkene, and β-dehydrotitanation.

(6)

Preparation of the Tebbe Reagent.

The reaction of Me_3Al with Cl_2TiCp_2 mixed in a 2:1 ratio in toluene at rt for 2-3 d gives a titanium-aluminum reagent (**4**), commonly called the Tebbe reagent (see μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***), as reddish orange crystals in 80-90% yields (eq 7).[5] This complex may be isolated, stored at low temperatures, and used all under an inert atmosphere. Alternatively, it may be generated in situ and used in the same reaction vessel without purification.[6] The formation of (**4**) from 2 equiv of Me_3Al and Cl_2TiCp_2 is believed to involve the following sequence of reactions. The reaction of Me_3Al with Cl_2TiCp_2 gives $Me(Cl)TiCp_2$ and Me_2AlCl. Another molecule of Me_3Al reacts with $Me(Cl)TiCp_2$ to induce an α-hydrogen abstraction reaction assisted by Me_3Al complexed with $Me(Cl)TiCp_2$, which leads to the formation of (**4**) along with $ClAlMe_2$ and methane (eq 8).[7]

The Tebbe reagent reacts with a variety of compounds containing π-bonds, such as alkenes, alkynes, aldehydes, ketones, esters, and amides, as summarized in Scheme 1.[8]

Scheme 1

The reactive species in these reactions is believed to be $Cp_2Ti{=}CH_2$, which can be generated by the interaction of (**4**) with a Lewis base, such as ***4-Dimethylaminopyridine*** or THF. Alternatively, 1,1-bis(η^5-cyclopentadienyl)-3,3-dimethyltitanacyclobutane (**5**), obtainable by the reaction of (**4**) with isobutylene (eq 9),[9] and even Cp_2TiMe_2[10] can serve as sources of $Cp_2Ti{=}CH_2$.

The reaction of diphenylacetylene with (**4**) to give (**6**) (eq 10)[11] is noteworthy in view of the fact that the reaction of the same alkyne with freshly mixed Me_3Al-Cl_2TiCp_2 gives the methylmetallation product (eq 1).

The methylenation of aldehydes and ketones with (**4**) appears to be markedly superior to the Wittig reaction in cases where the carbonyl group is hindered.[12] The most noteworthy feature of the methylenation with (**4**) is that esters and amides, which are normally inert to the Wittig reagents, can be methylenated with (**4**).[13]

Use of Me_3Al-Cl_2TiCp_2 in the Ziegler-Natta Polymerization.

Polymerization of alkenes with Me_3Al-Cl_2TiCp_2 must have been attempted. However, the literature is virtually devoid of reports on such reactions. On the other hand, various other reagent systems consisting of methylaluminum and titanocene derivatives, such as Me_2AlCl-Cl_2TiCp_2, Me_3Al-Me_2TiCp_2-H_2O, and $(MeAlO)_n$-Me_2TiCp_2, have been employed in polymerizing ethylene and other alkenes.[14]

Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)zirconium

(Me_3Al)

[75-24-1] · C_3H_9Al · Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)zirconium · (MW 72.10) (Cl_2ZrCp_2)

[1291-32-2] · $C_{10}H_{10}Cl_2Zr$ · Trimethylaluminum-Dichlorobis(η^5-cyclopentadienyl)zirconium · (MW 292.32)

(regioselective and stereoselective methylalumination of alkynes; regioselective carbometallation of metallated alkynes)

Physical Data: Me_3Al: bp 125 °C; *d* 0.752 g cm^{-3}. Cl_2ZrCp_2: mp 245 °C.

Form Supplied in: Me_3Al: liquid, available neat or as solution in hexanes or toluene. Cl_2ZrCp_2: colorless crystals. Both are commercially available.

Preparative Method: obtained simply by mixing the two components.

Handling, Storage, and Precautions: Me_3Al is extremely pyrophoric and must be used and stored under an inert atmosphere of N_2 or Ar. Cp_2ZrCl_2 may be handled in air, but it appears advisable to avoid extensive exposure to air, moisture, and light. Use in a fume hood.

NMR Behavior.

The ^1H NMR spectrum of a mixture of ***Trimethylaluminum*** and ***Dichlorobis(cyclopentadienyl)zirconium*** (2:1 ratio) in 1,2-dichloroethane at 30 °C, the usual conditions under which its reactions are carried out, exhibits two broad signals (half width = 4 Hz) at δ -0.31 and 6.40 ppm. When this mixture is quenched with THF (2 equiv), the high-field Me signal splits into three, at δ 0.25, -0.75, and -0.95, while the downfield Cp signal splits into two, at δ 6.45 and 6.22. Analysis of these signals indicates that the THF-quenched mixture consists of Cl_2ZrCp_2, $Cl(Me)ZrCp_2$, $Me_3Al.THF$, and $Me_2AlCl.THF$.[1-3] Thus, under the reaction conditions, Me_3Al and Cl_2ZrCp_2 undergo Me-Cl exchange, which is rapid on the NMR timescale, to form $Cl(Me)ZrCp_2$ (eq 1).

Controlled Methylalumination of Alkynes.

Controlled carbometallation of alkynes provides a very selective and efficient route to trisubstituted alkenes, many of which are important building blocks of a wide variety of natural products, especially those of terpenoid origin.[4] Alkynes react with organoalanes to give carbometallation products. However, with terminal alkynes, metallation of the terminal carbon atom is the major pathway, and the regioselectivity of the carbometallation product, obtained in generally poor yields, is low.[5,6] With internal alkynes the reaction requires higher temperatures, at which the product of initial carbometallation competes with the trialkylalane for the alkyne.[6,7] The use of transition metal complexes in conjunction with the organoalane reagent leads to a dramatic improvement of the chemo- and regioselectivity of the carboalumination reaction. Negishi and co-workers have reported that alkynes react with an organometallic reagent obtained by mixing Me_3Al and Cl_2ZrCp_2 to give alkenyl metals in high yields.[1] The reaction is not complicated by the known hydrogen abstraction of terminal alkynes with organozirconium[8] or organoaluminum[5,6] compounds. Studies by NMR spectroscopy have indicated that the product of carbometallation is largely an organoalane. Therefore the reaction is catalytic with respect to zirconium. Indeed, the reaction of 1 equiv of phenylacetylene with 2 equiv of Me_3Al in the presence of 0.1 equiv of Cl_2ZrCp_2 for 12 h at 25 °C produces, after hydrolysis, α-methylstyrene in high yield.[1] The stereoselectivity of the reaction is excellent (>98 % *cis* addition) (eq 2), as is the regioselectivity in the cases of terminal alkynes (eqs 2 and 3).[1] A recent modification of the reaction conditions by using a stoichiometric amount of H_2O leads to a remarkable acceleration of the reaction.[9] Internal alkynes can also be stereoselectively methylaluminated in high yields (eq 4).[1]

The Zr-catalyzed methylalumination can accommodate various heterofunctional groups such as OH, OTBDMS, SPh, I, and TMS.[10] Of particular synthetic utility are those alkynes containing heterofunctional groups in the propargylic or homopropargylic position. Interestingly,

and in marked contrast with some other known carbometallation reactions of propargyl and homopropargyl derivatives,[11] this reaction is very highly stereoselective (>98%) and regioselective (92-100%, except for the case of homopropargyl phenyl sulfide with which the reaction is 83% regioselective), the regioselectivity being essentially the same as that observed with simple terminal alkynes (eq 5). The yields of methylalumination products are generally in the 50-90% range. Table 1 illustrates the scope of this methylalumination reaction.

(5)

Z = OH, OTBDMS, SPh, I, TMS, etc.; n = 1 or 2

Table 1 Carboalumination of Terminal Alkynes Catalyzed by Zirconocene Dichloride

Alkyne	Major product	
	Yield (%)	Regioselectivity[a] (%)
$HC^{o}CC_6H_{13}$	³ 98	³ 95[1]
$HC^{o}CPh$	³ 98	³ 95[1]
$HC^{o}CCH{=}CH_2$	³ 86	³ 95[12]
$HC^{o}CC(Me){=}CH_2$	70	³ 95[13a]
$HC^{o}C(CH_2)_2CH{=}CMe_2$	72	³ 95[13a]
$HC^{o}CCH_2OH$	41	94[10a]
$HC^{o}CCH(OH)C_5H_{11}$	60	>98[10a]
$HC^{o}CCH_2SPh$	78	>98[10a]
$HC^{o}CCH_2SiMe_3$	63	³ 95[10b]
$HC^{o}C(CH_2)_2OH$	87	94[10a]
$HC^{o}C(CH_2)_2I$	74	>98[10a]
$HC^{o}C(CH_2)_2SPh$	78	83[10a]

[a] The major regioisomer is (*E*)-$R^1(Me)C{=}CHAlR^2_2$, and the stereoisomeric purity in each case is ³ 98%.

From the viewpoint of synthetic applications, alkenylalanes are very useful reagents. They react with a wide variety of electrophiles, and the C-Al bond can be readily converted into C-X (X = H, D, halogen, Hg, B, Zr, Cu, C, etc.) with essentially complete retention of stereochemistry via protonolysis,[6] deuterolysis,[6] halogenolysis,[13] transmetallation,[14] reactions with various carbon electrophiles such as $ClCO_2Et$, CO_2, $(CH_2O)_n$, $ClCH_2OMe$,[15] and epoxides[16] (preferably after ate complexation), and Pd- or Ni-catalyzed cross-coupling reactions.[12,17] Applications include syntheses of allylic or homoallylic alcohols,[15,16] conjugated dienes or enynes,[14c] 1,4-dienes,[12] and 1,5-dienes or enynes.[18] This methodology has been applied to the synthesis of various natural products such as geraniol,[15] farnesol,[18] monocyclofarnesol,[19] α-farnesene,[12] dendrolasin,[20] mokupalide,[20] vitamin A,[21] brassinolide,[22] milbemycin,[23] verrucarin,[24] udoteatrial,[25] and zoapatanol.[26]

The methylalumination of alkynes with Me_3Al-Cl_2ZrCp_2 appears to involve direct addition of a Me-Al bond, rather than a Me-Zr bond, to alkynes via a four-centered process which is facilitated by a $ZrCp_2$ species, as depicted in eq 6.[2] However, the reaction of 1-pentynyldimethylalane with either this reagent system or preformed $Cl(Me)ZrCp_2$ must involve direct addition of the Me-Zr bond, as depicted

in eq 7.[27]

Methylalumination of 1-Metalloalkynes.

The methylmetallation reaction of 1-alkynes that are terminally metallated with $AlMe_2$ or $SiMe_3$ with Me_3Al-Cl_2ZrCp_2 is a highly regioselective process, leading to the formation of 1,1-dimetalloalkenes (eqs 7 and 8).[27,28] Whereas the reaction of alkynylsilanes gives the methylaluminated products (the reaction can proceed with a catalytic amount of Cl_2ZrCp_2),[28] that of alkynyldimethylalanes is a methylzirconation reaction which can also be achieved by using preformed $Cl(Me)ZrCp_2$.[27] It is noteworthy that the methylalumination of 1,4-bis(trimethylsilyl)-1,3-butadiyne gives exclusively the product of *trans* addition.[28]

1,1-Dimetalloalkenes are of potential interest for the development of selective routes to tri- and tetrasubstituted alkenes through differentiation of the two metal groups. Some promising results have been obtained along this line. Thus, for example, treatment of (**1**) with ***Acetyl Chloride*** in the presence of ***Aluminum Chloride*** gives a 92:8 mixture of (*Z*)- and (*E*)-4-methyl-3-hepten-2-one in 61% yield.[27]

However, the most extensive synthetic application of these 1,1-dimetalloalkenes to date is the synthesis of cycloalkenylmetals. Treatment of 1-(trimethylsilyl)-4-bromo-1-butyne with Me_3Al (2 equiv) in the presence of Cl_2ZrCp_2 (1 equiv) in $(CH_2Cl)_2$ at 25 °C gives a cyclobutene (**2**) in 92% yield after 6 h, rather than the expected methylmetallation product (eq 9).[29]

The reaction evidently involves the intermediacy of the methylalumination product shown in eq 9. A π-type cyclization involving the intermediacy of a cyclopropylcarbinyl species must be operating,[29] since (1) alkylation of alkenylalanes with alkyl halides does not occur under comparable conditions, (2) the Zr-catalyzed methylalumination is known to give exclusively or predominantly *cis* addition products which are wrong isomers for a σ-type cyclization, and (3) the reaction is regioselective but nonregiospecific (eq 10).[30] These results are consistent with the mechanism shown in eq 11.

The reaction is not limited to the formation of four-membered rings. The methylalumination reaction of 1-(trimethylsilyl)-6-bromo-1-hexyne gives 1-(trimethylsilyl)-1-cyclohexene as the major product.[31] On the other hand, the corresponding reaction of 1-(trimethylsilyl)-5-bromo-1-pentyne gives only the noncyclized methylalumination product.[31]

Synthetically more attractive is the reaction of o-halo-1-alkynylalanes (**3**) with Me_3Al-Cl_2ZrCp_2, which gives the corresponding cycloalkenylmetals (**4**), readily convertible to a wide variety of cyclobutenyl derivatives (eq 12).[30] The same method can be applied to the synthesis of cyclopentenyl or cyclohexenyl analogs of (**4**), such as (**5**) and (**6**), in good yields.[32]

Ziegler-Natta Polymerization of Alkenes.

Some reagent systems consisting of methylaluminum and zirconocene derivatives have been used as homogeneous Ziegler-Natta polymerization catalysts. Satisfactory activity levels have been attained through the use of an additional component. For example, the use of Al_2O_3, $MgCl_2$, or SiO_2-supported Cl_2ZrCp_2 with Me_3Al promotes the polymerization of propene with a fairly good activity.[33] The most satisfactory Cl_2ZrCp_2-based system known to date makes use of methylaluminoxanes which are obtained by controlled hydrolysis of Me_3Al.[34]

Trimethylamine

[75-50-3] · C_3H_9N · Trimethylamine · (MW 59.13)

(low boiling tertiary amine used as base in dehydrochlorinations, nucleophilic substitutions, 1,4-additions, and aldol-type condensations)

Physical Data: bp 2.9 °C; mp -117 °C; *d* 0.656 g cm^{-3}.

Solubility: sol alcohols, H_2O, ethers, benzene, toluene, xylene, ethylbenzene, $CHCl_3$.

Form Supplied in: anhydrous trimethylamine is supplied as liquefied gas in steel cylinders; 23-25% aqueous solutions are available.

Handling, Storage, and Precautions: corrosive; toxic; lachrymator. The vapors are harmful and care should be taken to avoid absorption through the skin. Use in a fume hood.

Dehydrochlorinations: Ketene Generation.

The use of trimethylamine as the base in generating ketenes from 2-arylpropionic acid chlorides allows for selective asymmetric esterifications with a variety of chiral non-racemic α-hydroxy esters.[1] Treatment of the acid chloride of racemic ibuprofen with a large excess of trimethylamine in heptane at rt generates the unisolated ketene, which is further reacted with ethyl (*S*)-lactate at -78 °C to afford, in high diastereo- and enantioselectivity, the corresponding (*S*,*S*)-2-arylpropionate (eq 1). The more sterically demanding tertiary amines, such as ***Triethylamine*** or ***Diisopropylethylamine***, lead to much lower diastereoselectivities.

Nucleophilic Substitutions.

2-Amino-6-chloropurines react with trimethylamine and β-hydroxypropionitrile in the presence of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) to generate the corresponding guanines in high yields.[2] The mechanism of the overall hydrolysis consists of a series of nucleophilic displacements involving the intermediacy of the 6-trimethylammonium salt and 6-(2-cyanoethoxy) derivatives. Base-induced β-elimination of acrylonitrile from the cyanoethoxy intermediate completes the reaction sequence and leads to guanines in good overall yields (eq 2). Similarly, treatment of *O*-6-sulfonated guanosines with trimethylamine and alcohols leads to the *O*-alkylated guanosine derivatives in good yield (eq 3).[3] In related chemistry, treatment of triacetyl-2-chloroadenosine with trimethylamine in MeCN at an elevated temperature leads

to the 2-(*N*,*N*-dimethylamino)adenosine derivative in a near quantitative yield (eq 4). The reaction mechanism involves a chloride ion induced dealkylation of the trimethylammonium salt intermediate.[4]

(4)

Trimethylammonium salt intermediates prepared from chloropyrimidines and chloroquinazolines react efficiently with ***Tetraethylammonium Cyanide*** to produce the heterocyclic nitriles in excellent yields.[5] Trimethylamine in ether (or toluene) reacts with 3-chloro-2-cyclopentenone to produce the trimethylammonium salt derivative in 90% yield. Subsequent treatment with an aqueous solution of ***Potassium Cyanide*** generates the 3-cyanocyclopentenone derivative in 79% yield (eq 5).[6]

(5)

Treatment of cyclic phosphotriesters with an amine, for example anhydrous trimethylamine, and a slight excess of ***Trimethylsilyl Trifluoromethanesulfonate*** at 0 °C effects nucleophilic ring opening to afford phosphate diesters in good yields (eq 6).[7]

(6)

1,4-Additions.

Trimethylamine (25% aqueous solution) adds in a 1,4-fashion to alkyl propiolates with accompanying hydrolysis of the ester group to generate the (*E*)-(carboxyvinyl)trimethylammonium betaine as the sole isomer (eq 7).[8] In contrast, addition of trimethylammonium tetrafluoroborate to methyl propiolate in refluxing MeOH results in a 57:43 ratio of (*E*)- and (*Z*)-β-trimethylammonium acrylate esters (eq 8).[9] Remarkable stereochemical control is encountered with other alkynes containing electron-withdrawing groups. Trimethylammonium tetrafluoroborate adds selectively to 3-butyn-2-one to generate the (*E*)-isomer exclusively, while propiolonitrile, under identical reaction conditions, affords only the (*Z*)-isomer (eq 9).[9]

Aldol-Type Condensations.

α-Ketoaldehyde hemiacetals combine with nitroalkanes in the presence of methanolic trimethylamine to produce α-diketones in high yields. This variation of the Henry nitro-aldol reaction involves the addition of the nitroalkane to the aldehyde followed by base-induced β-elimination of nitrite (eq 10).[10]

Conversions of Hydrazones to Vinyl Halides.

Treatment of hydrazones with iodine in the presence of a tertiary amine leads to vinyl iodides in good yields.[11] In reactions where isomeric vinyl iodides may be produced, the steric nature of the tertiary amine seems to exert a minor influence on the regiochemical outcome (eq 11).[12]

Trimethylamine *N*-Oxide

Me_3NO

[62637-93-8] · C_3H_9NO · Trimethylamine *N*-Oxide · (MW 75.13)

(reagent for conversion of alkyl halides and sulfonates to aldehydes and ketones; precursor for azomethine ylide useful for synthesis of *N*-methylpyrrolidines; reagent for decomplexation of tricarbonyldieneiron complexes)

Alternate Name: TMANO.

Physical Data: mp 213-214 °C (dec).[1] Various melting points have been reported, ranging from 208 °C[2] to 225-227 °C. The dihydrate, $Me_3NO.2H_2O$, is a white solid, mp 96 °C.

Solubility: sol H_2O, EtOH; insol Et_2O benzene, and other hydrocarbon solvents; sparingly sol hot $CHCl_3$.

Form Supplied in: the dihydrate is commercially available as a white solid.

Preparative Methods: aqueous ***Trimethylamine*** (100 mL, 33%) is mixed with a pure 3% aqueous solution of ***Hydrogen Peroxide*** (600 mL) and is set aside at rt for 24 h. The solution is evaporated to dryness, and the product is recrystallized from EtOH-Et_2O to give the dihydrate as needles, mp 96 °C.[3,4] Several procedures are available for preparing the anhydrous reagent. The dihydrate is heated at 105 °C and 15 mmHg for several hours, after which it is sublimed at 180-200 °C and 15 mmHg. A more convenient procedure is to remove water by azeotropic distillation with benzene or toluene (Dean-Stark trap), or by co-distillation from a suspension of the reagent in DMF, followed by solvent removal in vacuo.

Handling, Storage, and Precautions: no reported hazards for this reagent. The anhydrous material is hygroscopic and should be prepared and used fresh or stored at rt in a vacuum desiccator over P_2O_5. Trimethylamine *N*-oxide is an oxidizer and should be stored away from reducing agents.

Preparation of Aldehydes and Ketones.

Alkyl bromides, iodides, and tosylates react with Me_3NO in $CHCl_3$ to give reasonable yields of aldehydes and ketones (eqs 1-3).[5]

$$RCH_2X \xrightarrow[50\text{-}60\ ^\circ C]{Me_3NO,\ CHCl_3} RCHO \qquad (1)$$

$R = C_5H_{11}$, X = I, 31%; $R = C_5H_{11}$, X = Br, 48%
$R = C_7H_{15}$, X = I, 50%; $R = C_7H_{15}$, X = OTs, 55%

(2)

(3)

Oxidation of Organoboranes.

Trimethylamine *N*-oxide is a useful alternative to alkaline ***Hydrogen Peroxide*** for the conversion of intermediates from the hydroboration of alkenes and alkynes to alcohols, especially in those cases where the product is sensitive to either high pH or H_2O_2. For example, cyclopropanols are reported to be unstable to alkaline H_2O_2, making hydroboration of cyclopropenes problematic. Oxidation of the intermediate boranes with Me_3NO in hot toluene, followed by methanolysis of the derived tricyclopropylborate, gives cyclopropanols in good overall yield (eq 4).[6]

(4)

Later studies by Kabalka and Hedgecock[7] have shown that commercially available Me_3NO dihydrate is an effective reagent for organoborane oxidation, and tolerates a wide variety of functional groups. Owing to the fact that the amine oxide is not appreciably soluble in organic solvents such as THF, toluene, and $CHCl_3$, it is recommended that the oxidation is carried out with vigorous stirring.[8] Rates of oxidation are sensitive to the nature of the alkyl group (secondary cycloalkyl > secondary alkyl > *n*-alkyl > β-branched primary alkyl), and the second and third alkyl groups are removed more slowly. Choice of solvent does not appear to affect the rate of oxidation; the recommended reaction conditions are diglyme at reflux. Two simple examples are given in eqs 5 and 6.

(5)

(6)

A useful example of the application of Me_3NO for borane oxidation is found in the formal total synthesis of (±)-perhydrohistrionicotoxin by

Carruthers and Cumming (eq 7).[9] Oxidation of the borane intermediate from the azaspirocycle by using alkaline hydrogen peroxide proved extremely difficult and gave a low yield of the desired alcohol (34% as a mixture of stereoisomers), this being attributed to the formation of a stable aminoborane.[10] Carruthers overcame this problem by using Me_3NO in refluxing diglyme, to give a mixture of stereoisomers that could be separated by chromatography of their acetate derivatives. The alcohol shown in eq 7 is a known intermediate in a synthesis of perhydrohistrionicotoxin.[11]

(7)

55%, + stereoisomer 5%

Trimethylamine *N*-oxide is also useful for oxidation of vinylborane intermediates formed during the hydroboration of alkynes.[12] The use of hydrogen peroxide in such reactions leads to overoxidation (eq 8), and this is avoided by using Me_3NO in refluxing THF in a one-pot procedure to generate acylsilanes from silylalkynes (Scheme 1).

$R^1CH_2CO_2H$ (8)

R = Bu, 86%; C_6H_{13}, 91%; Cy, 83%; *i*-Pr, 75%; $Cl(CH_2)_3$, 85%; $MeCH_2CH(OTMS)CH_2$, 76%; TMS, 75%

Scheme 1

Extension of this chemistry to the oxidation of organoaluminum derivatives has been described by Kabalka and Newton,[13] which is an extension of a reaction first reported by Köster.[14] It should be noted, however, that vinylalanes are not oxidized by this procedure; $R^1CH{=}CHAlR^2_2$ gives only the products of oxidation of the Al-R^2 bonds, with no aldehydes being detected. Examples of the procedure are shown in eq 9.

Azomethine Ylides from Me_3NO: Synthesis of *N*-Methylpyrrolidines.

Treatment of anhydrous Me_3NO with ***Lithium Diisopropylamide*** (LDA) gives an azomethine ylide which reacts in situ with alkenes in a dipolar cycloaddition to give *N*-methylpyrrolidines (eq 10).[15] Previous methods for generating azomethine ylides required electron-withdrawing or conjugatively stabilizing substituents.[16] Reaction of the azomethine ylide with dihydronaphthalenes has been described,[17] but the poor solubility of Me_3NO in THF was a problem for ylide generation, and it was found that a four-fold excess of the reagent was necessary to ensure complete consumption of all the alkene (eq 11).

Decomplexation of Diene-$Fe(CO)_3$ Complexes.

Me_3NO has been used extensively in organometallic chemistry as a reagent for the selective removal of carbonyl ligands. An extension of this reactivity leads to applications in the decomplexation of diene-iron tricarbonyl complexes, which are being used increasingly as intermediates for organic synthesis. The first report of Me_3NO being used for this type of ligand disengagement was by Shvo and Hazum,[18]

summarized in eqs 12-15. The last two examples are particularly noteworthy, since the complexes are quite sensitive to the acidic conditions that are generated when transition metal oxidants such as ***Iron(III) Chloride*** or ***Cerium(IV) Ammonium Nitrate*** are used for decomplexation. Until the development of this method the removal of $Fe(CO)_3$ from diene complexes was considered a major obstacle to their synthetic application. The reaction conditions vary according to the diene, and must be determined empirically.

(12)

(13)

(14)

(15)

Evidence that the mechanism of the reaction involves two amine oxide molecules per diene-$Fe(CO)_3$ comes from the isolation of an intermediate that has a carbonyl ligand replaced by Me_2NH (eq 16).[19a] A plausible mechanistic explanation is shown in Scheme 2, though this is somewhat different from the mechanism proposed for reaction of Me_3NO with $Fe(CO)_5$.[19b]

(16)

Scheme 2

A large number of examples of the use of Me_3NO for decomplexation can now be found in the synthetic literature. A comparison with iron(III) chloride is revealed by the decomplexation shown in eq 17.[20] While the methyl-substituted complex (X = Me) could be demetalated using $FeCl_3$ or Me_3NO, the use of $FeCl_3$ is problematic when X = OR, SPh, or NHR, owing to the propensity of these complexes to undergo acid-promoted scission of the C-X bond to regenerate the dienyl-$Fe(CO)_3$ cation. Me_3NO is non-acidic and does not suffer this limitation.

(17)

X = OMe, 42%; OPh, 39%; SPh, 33%; NMe_2, 52%; NH-*t*-Bu, 72%; Me, 48%

Similar compatibility with heteroatom substituents is observed during the synthesis of (-)-gabaculine reported by Birch et al.,[21] who also found that *N*,*N*-dimethylacetamide is an excellent solvent for decomplexation (Scheme 3), by Pearson and Ham[10] in their formal synthesis of perhydrohistrionicotoxin (eq 18), and by Pearson and Srinivasan in some approaches to cycloheptadiene triols (eqs 19 and 20).[22] The other useful aspect of Me_3NO for these decomplexations is that vinyl ether groups are not hydrolyzed to ketones under the reaction conditions.

Scheme 3

Owing to the fact that the decomplexation reaction proceeds via nucleophilic attack on a carbonyl ligand, Me_3NO is not very useful for converting diene-$Fe(CO)_2PR_3$ complexes to dienes, since the poorer π-acceptor capacity of the phosphine ligand places more electron density at the carbonyls. For this reason, it has been found better to use ***Dipyridine Chromium(VI) Oxide*** in CH_2Cl_2 for decomplexation of the phosphine-substituted derivatives (eq 21).[23]

(21)

Shvo and Hazum have also reported the use of Me_3NO as promoter during the conversion of dienes to diene-$Fe(CO)_3$ complexes.[24] Reaction of $Fe(CO)_5$ with Me_3NO at controlled temperature leads to the formation of a coordinatively unsaturated $Fe(CO)_4$ derivative by a mechanism related to that shown in Scheme 2. In the presence of a diene, rapid coordination of alkene occurs, followed by a second CO loss and alkene coordination to give the diene complex (eqs 22 and 23). It should be noted that the normal conditions for $Fe(CO)_5$ -> diene-$Fe(CO)_3$ conversion are refluxing in di-*n*-butyl ether (ca. 140 °C).

(22)

(23)

This observation, coupled with the fact that diene-$Fe(CO)_2PR_3$ complexes are quite resistant to Me_3NO, leads to a mild method for the conversion of diene-$Fe(CO)_3$ to diene-$Fe(CO)_2PR_3$ complexes (eqs 24-26).[22,25,26] The examples in eq 24 (R^1 or R^2 = OMe) are especially interesting because other methods for ligand exchange (thermal or photochemical) with these electron-rich diene complexes either fail completely or give very low yields.

(24)

$R^1 = R^2 = H$, 64%
$R^1 = H$, $R^2 = OMe$, 48%
$R^1 = OMe$, $R^2 = H$, 54%

Trimethylaminoacetohydrazide Chloride[1]

[123-46-6] · $C_5H_{14}ClN_3O$ · Trimethylaminoacetohydrazide Chloride · (MW 167.67)

(separation of aldehydes and ketones from impurities;[2] dehydration of aldols to enones[4])

Alternate Name: Girard T reagent.

Physical Data: mp 188-192 °C (dec).

Solubility: very sol H_2O; sol MeOH, cold EtOH; very sol acetic acid.

Form Supplied in: white solid; widely available.

Purification: recrystallization from EtOH.

Handling, Storage, and Precautions: very hygroscopic; develops a strong odor upon standing in air; store under inert gas.

Trimethylaminoacetohydrazide chloride has been used primarily to separate lipophilic ketones and aldehydes from various impurities via their water-soluble hydrazones (eqs 1 and 2). Several procedures for its use are published.[2]

(1)

(2)

With the advent of column and flash chromatography techniques, this procedure has not been widely utilized in the organic literature for some time. It was commonly employed to separate ketonic steroids from nonketonic components in extraction-isolation protocols.[1] Recently, the reagent supported on silica gel has been used to isolate ketones and aldehydes.[3]

Dehydration of 3-keto-5β-hydroxy steroids to Δ^4-3-keto steroids can be effected by refluxing with the reagent in acetic acid (eq 3).[4]

(3)

Related Reagents.

Semicarbazide.

2,4,6-Trimethylbenzoic Acid

[480-63-7] · $C_{10}H_{12}O_2$ · 2,4,6-Trimethylbenzoic Acid · (MW 164.22)

(mild, hindered Brønsted acid; protecting group for carbohydrates)

Alternate Names: mesitoic acid; mesitylenecarboxylic acid.

Physical Data: needles (prisms from pet ether); mp 154-155 °C; pK_a 4.43 (25 °C); pK_{a1} 3.45 (25 °C).[1]

Solubility: sol alcohol, ether, acetone, $CHCl_3$; slightly sol H_2O.

Form Supplied in: crystalline solid.

Preparative Method: many are described, including the addition of CO_2 to the Grignard reagent derived from bromomesitylene.[10]

Purification: crystallized from H_2O, pet ether, or CCl_4.[11]

Handling, Storage, and Precautions: gloves should be worn while handling; may cause irritation.

Catalysis of Sigmatropic Rearrangements.

Mesitoic acid has been used on numerous occasions for orthoester Claisen rearrangements and related processes, where its character as a mild, not readily esterified, Brønsted acid is of virtue. The examples cited (eqs 1-3)[2-4] are typical; see also Trudell and Cook.[5]

(1)

(2)

(3)

Reductive Carbonylation.

In the presence of mesitoic acid and 1,10-phenanthroline, palladium metal on alumina support is an effective catalyst for the reductive carbonylation of nitrobenzenes to generate isocyanates, ArNCO;[6] the additional presence of alcohols results in the formation of urethanes.[7]

Synthesis of Sugar Derivatives.

In a recent synthesis of 6-deoxy-6-fluorolactosides, the mesitoyl moiety was utilized as a protecting group (eq 4). Esterification of the free hydroxy groups of disaccharide (**1**) was accomplished using the mixed anhydride of mesitoic acid and ***Trifluoroacetic Acid***. Use of mesitoyl groups in (**2**) allowed for the selective hydrolysis of the butyrate ester. Following incorporation of a fluorine into the molecule, the mesitoyl groups were removed reductively with AlH_3 without affecting the C-F bond.[8]

Mesitoyl groups have also been used for the selective protection of 1,4:3,6-dianhydro-D-glucitol.[9]

Related Reagents.

Acetic Acid; ***Hydrochloric Acid***; ***Methanesulfonic Acid***; ***Oxalic Acid***; ***p-Toluenesulfonic Acid***.

Trimethyl Borate

$B(OMe)_3$

[121-43-7] · $C_3H_9BO_3$ · Trimethyl Borate · (MW 103.93)

(used for the preparation of boronic acids and esters;[1a] also used as Lewis acid catalyst or additive in various reactions)

Physical Data: mp -34 °C; bp 68-69 °C; *n*20D 1.3568; *d* 0.915 g cm^{-3}.

Solubility: sol in every proportion in Et_2O and MeOH; very sol EtOH; sol benzene; dec in H_2O.[2]

Form Supplied in: colorless liquid, with purity &egt;99%; azeotrope with methanol (bp 53-58 °C); MeOH is usually present as an impurity.

Preparative Methods: an improved preparation has been recently reported.[3]

Purification: if necessary, the small quantities of MeOH can be removed by adding anhydrous lithium chloride to the bottle of commercial reagent; the mixture is allowed to stand with occasional stirring. The upper layer is then decanted and distilled.[4]

Handling, Storage, and Precautions: is moisture sensitive; must be stored under nitrogen in a cool dry place. It is extremely flammable and forms explosive mixtures in air. Container explosion may occur under fire conditions. $B(OMe)_3$ is irritating to the skin and, as a vapor, to the eyes, mucous membranes, and upper respiratory tract.[5]

Synthesis of Boronic Acids and Esters.

Trimethyl borate is an inexpensive starting material for the preparation of dimethyl boronates, precursors of boronic acids. The classical synthesis involves the reaction with Grignard or alkyllithium reagents (eq 1); treatment with an aqueous acid, followed by extraction with an organic solvent, permits the direct isolation of the boronic acids (eq 2).[1] Various conditions have been used to hydrolyze boronic esters: ***Acetic Acid***,[4a] ***Hydrochloric Acid***,[4b,6] ***Sulfuric Acid***,[7] aqueous ammonium chloride.[8] In some cases, a direct exchange of the OMe group with another alcoholic residue can be effected.[9]

$$RM \xrightarrow{B(OMe)_3} [RB(OMe)_3^-M^+] \longrightarrow RB(OMe)_2 \qquad (1)$$

$$RB(OMe)_2 \xrightarrow{H_3O^+} RB(OH)_2 \qquad (2)$$

$$M = MgCl, MgBr, Li$$

A wide variety of boronic esters or acids can be prepared by this methodology: alkyl- and arylboronic acids are available from both Grignard and lithium reagents,[1,10] allylboronic acid and esters from ***Allylmagnesium Bromide***,[6] γ-substituted allylboronic acids and esters from organolithium reagents,[8] and allenylboronic esters as the only product starting from propargyl Grignard reagents.[11] Vinylboronic esters can be obtained in a stereospecific manner from the corresponding Grignard reagents.[1a,7] The organometallic reagent which reacts with trimethyl borate can also contain an heteroatom, such as sulfur[12a] or silicon,[12b] α to the carbon-metal bond. Finally, lithium derivatives of pyrrole[13a] and furan[13b] can be transformed into the corresponding boronic esters.

For boronic acid synthesis, other electrophilic boron reagents, e.g. ***Fluorodimethoxyborane Diethyl Etherate*** or ***Triisopropyl Borate***, can be used. In the case of substituted allylboronic acids and esters, these two reagents have been employed preferentially.[14]

Use of Boronic Acids and Esters.

Boronic acids and esters are versatile intermediates which have found many applications in organic synthesis, especially in the field of stereocontrolled C-C bond formation.

Dimethyl alkyl- or arylboronates react with H_2O_2 to give the corresponding alcohols or phenols. Coupled with the above described condensation of $B(OMe)_3$ with Grignard or lithium reagents, this reaction allows the overall hydroxylation of organometallic compounds. Applications include the synthesis of phenols[4b] from aryl bromides and of 4-hydroxyisoxazolines[4c] from isoxazolines via the 4-lithio derivative.

Reaction of dimethyl vinylboronates with bromine furnishes the corresponding vinyl bromides with inversion of configuration, allowing the transformation of a (*Z*)- or (*E*)-vinyl bromide into the corresponding (*E*) or (*Z*) diastereoisomer.[1a]

Boronic acids (with R^1 = allyl, substituted allyl, allenyl, and vinyl; R^2 = H; eq 3), obtained from trimethyl borate, can be easily transformed into acyclic boronates, cyclic boronates, or 1,3,2-oxazaborolidines by reaction with the appropriate aliphatic alcohol,[1a,6] a chiral (e.g. phenylbornanediol, diisopropyl tartrate, pinanediol) or achiral diol (pinacol, ethylene glycol)[1a,6] or a chiral or an achiral 2-amino alcohol.[6] This procedure allows the preparation of very pure reagents, in which the single organic group is totally differentiated from a chemical point of view from the alkoxy ligands; in this way the carbon-boron linkage can be utilized very efficiently. Chiral allylboronates can be used for enantio- and diastereoselective C-C bond forming reactions[1,14] with aldehydes (eq 3); the chirality can be present either α to the boron atom (when R^4 &neq; H) or in the chiral auxiliary R^1; also the aldehyde can be achiral or chiral. Finally, if the reaction is carried out between a chiral allylboronic ester and a stereochemically matched chiral aldehyde, greater stereoselectivity can be obtained in taking advantage of double stereodifferentiation effects.

(3)

Allylboronates also react with C=N electrophiles such as aldoximes, imines, and sulfenimides,[14] although the reactions are considerably slower than those with aldehydes.

Boronic acids or esters are also suitable reagents for cross-coupling reactions, used for the formation of a C-C single bond (eq 4); this method is especially useful for the preparation of unsymmetrically substituted biaryls. One or both components can also be heterocycles. Organoboronic acids and esters used for this kind of reaction have R^1 = phenyl,[15a] various aryl,[10,15a] 2-[15a] and 3-furyl,[13b] 2-thienyl,[15a] *N*-Boc-pyrrolidin-2-yl;[13a] R^2 is usually hydrogen except for R^1 = 3-furyl, where the dimethyl boronate is used directly.[13b] R^3 is usually an aromatic or heteroaromatic moiety, but alkenyl or allyl derivatives have also been used. X is a halogen (bromine or iodine)[10,13b] or a triflate.[13b] This coupling reaction has also been used for a new synthesis of hemispherands.[15b]

(4)

A stereocontrolled synthesis of terminal (*E*)- and (*Z*)-dienes can be performed by reacting pinacol (*E*)-1-trimethylsilyl-1-propene-3-boronate with aldehydes; the intermediate β-trimethylsilyl alcohols can then be transformed into both (*E*)- and (*Z*)-dienes.[8] Vinylboronates are also prepared from the reaction of the anion of a trimethylsilyl methaneboronic ester (derived from trimethyl borate) and various aldehydes or ketones.[12b]

Anions prepared from cyclic bis(phenylthio)methaneboronic esters, derived from the corresponding dimethyl boronates, can be used to prepare ketene dithioacetals through homologation of carbonyl compounds (eq 5).[12a]

(5)

More recently, an arylboronic acid has been used as an intermediate for the preparation of 2-borono-1,3-xylyl crown ethers.[16]

Boronic esters can be reduced by ***Lithium Aluminum Hydride*** to the corresponding lithium alkylborohydrides, which are easily converted into monoorganylboranes,[17a] such as tripylborane, a compound similar to thexylborane, but considerably more stable.[17b]

Use of Trimethyl Borate as Catalyst or Additive.

Trimethyl borate has been used, like other boron compounds, as a catalyst for the reduction of esters to alcohols by ***Lithium Borohydride***.[18a] Trimethyl borate also promotes a rapid ionic reaction of methyl hypobromite with alkenes and dienes.[18b] Finally, trimethyl borate, as with other boronic acids and various boranes, has been used to catalyze anti-Markovnikov hydration of alkenes in the presence of dichloroaluminum hydride under dry air.[18c]

Trimethyl borate has been successfully used to improve the yields in the Reformatsky reaction.[19] This is due to the mildly acidic properties of the boron reagent which neutralizes the zinc alkoxides, so that base-catalyzed side reactions of starting materials are prevented.

Reactions of aldehydes with 1,3-bis(trimethylsilyl)propenyl anion are poorly stereoselective. However, when this condensation was carried out in the presence of $B(OMe)_3$, only *anti* compound (**1**) was obtained (eq 6); (**1**) can in turn be stereospecifically transformed into either (1*E*,3*E*)- or (1*E*,3*Z*)-1-trimethylsilylbuta-1,3-dienes.[20]

(6)

(1)

Miscellaneous.

Trimethyl borate has been used as an electrophilic reagent to trap the product of the regio- and stereoselective ***Dichlorobis(cyclopentadienyl)zirconium***-catalyzed ethylmagnesation of allylic[21a] and homoallylic[21b] alcohols (eqs 7 and 8).

(7)

(8)

$B(OMe)_3$, in the presence of ***Borane-Dimethyl Sulfide***, has been used to promote the chemoselective reduction of a carboxylic acid to an alcohol in the presence of an ester.[22]

Trimethyl borate was used also to prepare other borates or tetraalkoxy boron ate compounds. For example, functionalized borate (**2**), obtained by in situ treatment of juglone with $B(OMe)_3$ and a tartaric acid derived chiral diol, has been used as dienophile in an asymmetric Diels-Alder reaction (eq 9).[23]

(9)

Finally, in the synthesis of aplasmomycin, a boron-containing antibiotic, the boron ate unit was introduced as the last step by the reaction of deboro aplasmomycin with $B(OMe)_3$.[24]

Related Reagents.

2,2,6-Trimethyl-4*H*-1,3-dioxin-4-one[1]

[5394-63-8] · $C_7H_{10}O_3$ · 2,2,6-Trimethyl-4*H*-1,3-dioxin-4-one · (MW 142.17)

(acetylketene equivalent, used for acetoacetylation and cycloaddition reactions; can be functionalized to provide substituted acylketenes; diketene equivalent)

Alternate Name: diketene-acetone adduct.

Physical Data: mp 12-13 °C; bp 65-67 °C/0.2 mmHg; *d* 1.088 g cm^{-3}.

Solubility: miscible with most organic solvents.

Form Supplied in: neat liquid; 95% (major impurity acetone).

Analysis of Reagent Purity: GC (keep injector port 200-225 °C); NMR.

Preparative Methods: the diketene-acetone adduct (**1**) is one of a series of 1,3-dioxin-4-ones which can be prepared by the reaction of diketene with an aldehyde or ketone in the presence of an acidic catalyst[2] or a quaternary ammonium salt (eq 1).[3] An alternate preparatory method is the reaction of a β-keto acid with acetone.[4]

Purification: high-vacuum distillation at temperatures below 80 °C.

Handling, Storage, and Precautions: generally nonhazardous; anticipate release of acetone upon heating over 80 °C; will also produce CO_2 if heated in presence of water; extremely good solvent: will dissolve some plastic tubing. Use in a fume hood.

Chemical Transformations: Acetylketene Generation.

Dioxinone (**1**) generates acetylketene (**2**) and acetone upon heating at temperatures around 120 °C,[5] via a retro Diels-Alder reaction. The acetylketene thus produced reacts in situ with nucleophiles, including alcohols, amines, and thiols, to provide acetoacetic acid derivatives, e.g. (**3**) (eq 2).[6] The diketene-acetone adduct is thus a convenient, safe, and nonlachrymatory alternative to diketene. In practice, dioxinone (**1**) is often added to a solution of the nucleophile in xylene at 110 °C and the acetone is removed by evaporation or distillation; no catalyst is required. Most of these acetoacetylation reactions are complete within 20 min at 120 °C if the acetone is removed efficiently, although polymeric nucleophiles may require higher reaction temperatures or longer times. Changing the substituents at C-2 will alter the temperature at which the acetylketene is liberated (see below). Irradiation at 254 nm will also provide acetylketene from (**1**).[7] Nucleophilic ring opening

can also be effected with base (***Potassium Carbonate***, MeOH).[8]

(2)

Virtually every synthetic transformation which utilizes dioxinone (**1**) ultimately involves the generation of an acylketene or a β-keto ester, often following elaboration of the dioxinone nucleus.

Preparation of Heterocycles.

Dioxinone (**1**), as an acetylketene equivalent, reacts with a wide variety of functional groups in a manner analogous to diketene[9] to provide heterocycles. For example, heating dioxinone (**1**) in the presence of electron-rich alkenes, such as enamines or enol ethers, will provide the corresponding pyrone derivative (**4**) via a [4 + 2] cycloaddition reaction, as illustrated in the preparation of 2,6-dideoxy sugar (**5**) (eq 3).[10,11]

(3)

DeMayo Reactions.

The [2 + 2] photocycloaddition of alkenes to dioxinone (**1**) (eq 4), followed by reduction and then cyclization of the resultant retro-aldol product, affords cyclohexenones (**6**).[12]

(4)

Synthesis of Modified Dioxinones.

Many dioxinones are modified prior to acylketene generation, either at C-5 or on the C-6 methyl group, to enhance the synthetic utility.[1] Thus dioxinone (**1**) can be halogenated[13] at C-5 or on the 6-methyl group[14] prior to further synthetic elaboration (eqs 5 and 6). The latter bromomethyl dioxinone (**7**) is readily converted into a Wittig[15] or Horner-Emmons reagent.[14]

(5)

(6)

An alternate approach to modification of dioxinone (**1**) on the C-6 methyl group is via deprotonation (eq 7),[16] sometimes accompanied by silyl enol ether formation (eq 8).

(7)

(8)

The resulting elaborated dioxinones have been used to effect ring closure of large rings via intramolecular ketene trappings,[16] methoxide-mediated ring openings to the β-keto esters,[16c,17] and in intramolecular photocycloaddition reactions (eq 9),[18] thereby demonstrating the synthetic utility and versatility of the diketene-acetone adduct (**1**). Both (*R*)- and (*S*)-2-*t*-butyl dioxinones are enantiopure acetoacetate derivatives that are useful for asymmetric synthesis.

(9)

Related Reagents.

Trimethylene Oxide

[503-30-0] · C_3H_6O · Trimethylene Oxide · (MW 58.09)

(three-carbon homologation)

Alternate Name: oxetane.

Physical Data: bp 50 °C; *d* 0.893 g cm^{-3}.

Solubility: sol H_2O and most common organic solvents.

Form Supplied in: commercially available in 97% purity.

Preparative Methods: from 3-chloropropyl acetate and ***Potassium Hydroxide***;[1] from ***1,3-Propanediol*** and ***Diethyl Azodicarboxylate/Triphenylphosphine***.[2]

Purification: by distillation.

Reaction with Carbon Nucleophiles.

Trimethylene oxide readily undergoes ring opening with a variety of carbon nucleophiles to give the three-carbon homologated alcohol. Substituted oxetanes undergo analogous reactions. Grignard reagents and alkyllithiums react cleanly, although reduced yields are obtained with secondary Grignard reagents (eq 1).[3] Alkyl cuprates,[4] alkenyllithium,[5] alkenylaluminum,[6] alkynyllithium,[7] and allyllithium[8] reagents have been used to open oxetane. Reaction with ester and amide enolates provides access to 5-hydroxy esters and amides (eq 2)[9] and ketone imine salts react with oxetane (eq 3) as well.[10] ***Boron Trifluoride Etherate*** is frequently used to assist the ring opening. Oxetane reacts with allylsilanes and ***Titanium(IV) Chloride*** to give the ring-opened products (eq 4).[11]

(1)

(2)

(3)

(4)

Reaction with Heteroatom Nucleophiles.

Trimethylene oxide undergoes ring opening with a wide variety of heteroatom nucleophiles. Reaction with ***Cyanotrimethylsilane*** gives, after hydrolysis of the isocyanide, 3-aminopropanol (eq 5).[12,13] 3-Hydroxydimethylsulfonium salts are obtained on reaction with ***Trifluoromethanesulfonic Acid*** and ***Dimethyl Sulfide***.[14] Phosphonium salts are obtained on reaction with ***Triphenylphosphine*** and ***Trifluoroacetic Acid*** or triflic acid (eq 6).[15] Reaction with phosphine anions gives the 3-hydroxypropylphosphines.[16] Trimethylene oxide is readily opened by selenium nucleophiles, such as phenylselenide anion, which gives 3-hydroxypropyl phenyl selenide.[17]

(5)

(6)

Reductive Opening of Oxetane.

Reduction with ***Lithium 4,4´-Di-t-butylbiphenylide*** (LDDB) gives the 3-lithioalkoxide, which reacts with a wide variety of electrophiles (eq 7).[18] A similar opening occurs with the ***Potassium/18-Crown-6*** complex.[19]

Trimethylironlithium

Me_3FeLi

[26220-97-3] · C_3H_9FeLi · Trimethylironlithium · (MW 107.91)

(alternative to ***Lithium Dimethylcuprate***[1] for constructing new carbon-carbon bonds by its reaction with alkenones,[5] alkyl halides,[2] vinyl halides, and allyl halides)

Alternate Name: lithium trimethylferrate.

Preparative Method: prepared in situ by reaction of FeI_2 and MeLi in ether.

Handling, Storage, and Precautions: decomposes in solution at 0 °C after several hours.

Carbon-Carbon Bond Formation.

Methylation of Organohalides.

Alkylation of alkyl halides using organocopper reagents has been widely studied.[1] Other organometallic reagents have also been studied for their efficacy in carbon-carbon bond formation, including trimethylironlithium.[2]

The reagent appears to work most effectively with vinyl, phenyl, and primary alkyl halides. However, it is generally ineffective with secondary and tertiary alkyl halides, under the conditions examined (Table 1). The reaction between trimethylironlithium and organohalides is considerably faster than similar reagents prepared from manganese or cobalt. The reaction of tri-*n*-butylironlithium with organohalides failed.

Table 1 Methylation of Organohalides with Trimethylironlithium in Ether[2]

Halide	Temp. (°C)	Time (h)	Product	Yield (%)
1-Iododecane	- 78	3	*n*-Undecane	2
Iodocyclohexane	- 20	1	Methylcyclo-hexane	10
3-Bromocyclohexane	- 20	1	3-Methylcyclo-hexene	50
Iodobenzene	- 78	3	Toluene	50
trans-1-Iodo-1-nonene	- 78	1	*trans*-2-Decene	90
trans-1-Bromo-2-phenylethylene	- 78	1.5	*trans*-1-Phenyl-propene	83
1-Bromocyclohexene	- 78, 0	3, 12	1-Methylcyclo-	75

1-Bromocyclohexene	- 78, 0	3, 12	1-Methylcyclo-hexene	75
7,7-Dibromonorcarane	- 78, 0	4, 12	7,7-Dimethyl-norcarane	65

In general, trialkylironlithium appears to be inferior to organocuprates in effecting carbon-carbon bond formation. However, it has been found to be superior to organocuprates and other methylating reagents in special cases.[3] For instance, the methylation of allyl bromide (**1**) gave the corresponding alkene (**2**) in excellent yield, without an allylic transposition[4] that was found to occur with lithium dimethylcuprate (eq 1).

(1)

Methylation of Cycloalkenones.[5]

The methylation of cyclohexenone (**3**) with trimethylironlithium gave the conjugate addition product, 3-methylcyclohexanone (**4**), in 26% yield, and cyclohexenol (**5**), in 28% yield (eq 2). Greater regioselectivity to produce cyclohexanone (**4**) is achieved with organocuprates and organomanganese reagents.

(2)

Miscellaneous Reactions.

The reaction of trimethylironlithium with epoxyvinyl sulfone (**6**) gave predominantly ketone (**7**) and reduction product (**8**) rather than the anticipated 1,2- and 1,4-addition products (eq 3).[6]

Trimethyl(3-methyl-2-butenyl)stannane

[17314-40-8] · $C_8H_{18}Sn$ · Trimethyl(3-methyl-2-butenyl)stannane · (MW 232.97)

(γ-regioselective prenylation of aldehydes and ketones; α-regioselective prenylation of quinones; palladium-catalyzed regioselective coupling with electrophiles)

Alternate Name: prenyl trimethylstannane.

Physical Data: bp 56-57 °C/15 mmHg.

Solubility: sol most organic solvents.

Preparative Methods: by the reaction of ***Trimethylstannyllithium*** with 3-methyl-2-butenyl bromide.[1] Alternatively, it is prepared from 3-methyl-2-butenylmagnesium bromide and ***Chlorotrimethylstannane***.[2]

Handling, Storage, and Precautions: is air- and moisture-stable. However, it should be kept under N_2 in a refrigerator for prolonged storage.

Prenylation of Aldehydes and Ketones.

Prenyltrimethylstannane reacts with aldehydes and ketones in the presence of ***Boron Trifluoride Etherate*** at low temperatures to give the corresponding homoallyl alcohols in high yield (eq 1).[3] The $BF_3.OEt_2$-mediated reaction of the prenyltin reagent with acenaphthenequinone affords the γ-adduct exclusively (eq 2), whereas the photochemical reaction in MeCN produces a 68:32 mixture of the α- and γ-adducts in 87% yield.[4] An α-regioselective prenylation occurs in the photochemical reaction of benzil with the prenyltin reagent (eq 3).[4]

(1)

(2)

Prenylation of Quinones.

Lewis acid (BF_3) mediated allylation of α,β-unsaturated ketones with allylstannanes affords only 1,4-addition products.[3] However, the $BF_3.OEt_2$-mediated reaction of *o*-quinones, such as 9,10-phenanthrenequinone and acenaphthenequinone, with allylstannanes gives exclusively 1,2-addition products (quinols) (eq 2). Similarly, *p*-quinones, such as 2,6-dimethoxybenzoquinone and 2-methoxy-1,4-naphthoquinone, afford only 1,2-adducts (quinols).[1] On the other hand, the allylation of simple benzoquinone with allyltrialkylstannane produces allylhydroquinone (1,4-adduct) in high yield, which is converted to allylbenzoquinone upon oxidation with ***Silver(I) Oxide*** or ***Iron(III) Chloride***.[1] The reaction of benzoquinone with 3-methyl-2-butenyltributylstannane gives the α-1,4 adduct (eq 4).[1] Similarly, α-1,4-addition products are obtained from 2,3-dimethyl-, 2,5-dimethyl-, 2,6-dimethyl, and trimethylbenzoquinone, 2-methyl-1,4-naphthoquinone, and 2,3-dimethoxy-5-methylbenzoquinone. 2-Acetyl-1,4-naphthoquinone, in which the C-3 position is sterically crowded, gives a 70:30 mixture of γ-1,4 and α-1,4 adducts in 80% yield upon treatment with the title reagent.[5]

Substitution with Allylic Substrates and Vinyl Epoxides.

The allylic-allylic coupling of trimethyl(3-methyl-2-butenyl)stannane with allylic acetates promoted by bis(diethylaluminum) sulfate affords, in general, a mixture of the γ-α´ and γ-γ´ products (eq 5).[2] It should be noted that the coupling takes place at the γ-position of the tin reagent. The coupling with allylic ethers and halides results in lower yields. The coupling between allylic stannanes and allylic halides takes place at rt in CH_2Cl_2 at high pressures (~10 kbar) to give head-to-tail coupling products (γ-α´ adducts), with allylic rearrangement of the tin reagents, in high yields.[6] The $BF_3.OEt_2$-mediated reaction of the tin reagent with vinyl epoxides normally gives 1,2-addition products, with 1,3-allylic rearrangement of the allylstannane, in high yields (eq 6).[7]

Palladium-Catalyzed Coupling.

The palladium-catalyzed coupling reaction of organotin reagents with organic electrophiles, such as acid halides, allylic halides, aromatic and benzylic halides, vinyl iodides and triflates, and α-halo esters, takes place under mild conditions in high yields.[8] A wide variety of organic halides and organotin compounds can be coupled either directly or in the presence of carbon monoxide (to yield a ketone R^1COR^2). Moreover, a wide variety of functional groups (e.g. CO_2R, CN, OH, and even CHO) are tolerated on either reaction partner. In addition, the coupling of allylic components (i.e. allylstannane or allyl halide) is regioselective and occurs stereospecifically with inversion of configuration at sp^3 carbon centers bound to tin and/or halogen. Usually retention of configuration of the double bond is observed, regardless of which reactant contains the double bond. The palladium-catalyzed direct coupling of prenyltributyltin with allyl bromide occurs with preferential allylic rearrangement of the tin reagent (eq 7).[9] However, no allylic rearrangement takes place in coupling reactions of the prenyl bromide partner (eq 8). In contrast to direct coupling, carbonylative coupling occurs without allylic rearrangement of the allylic tins and allylic halides, and CO insertion takes place exclusively at the least hindered site (eq 9).[10]

2,4,4-Trimethyl-2-oxazoline

[1772-43-6] · $C_6H_{11}NO$ · 2,4,4-Trimethyl-2-oxazoline · (MW 113.18)

(a masked ethyl acetate equivalent; generation of the anion with *n*-BuLi followed by treatment with electrophiles affords homologated acetic acids and esters, β-hydroxy esters, β-keto esters, α,β-unsaturated esters, and γ-butyrolactones[1])

Alternate Name: 4,5-dihydro-2,4,4-trimethyloxazole.

Physical Data: bp 112-113 °C.

Form Supplied in: commercially available.

Preparative Method: can be prepared by the thermal condensation (98-110 °C) of acetic acid and 2-amino-2-methyl-1-propanol in 73% yield (eq 1).[2]

Handling, Storage, and Precautions: no special precautions are warranted.

Preparation of Analogs.

Other 2-substituted oxazolines can be prepared in a similar fashion to the preparation of the title reagent, from the appropriate carboxylic acid. Substituted oxazolines can be formed under milder conditions by cyclocondensations with the corresponding orthoesters (DMF, 110 °C) or imino ether hydrochlorides (MeOH, 0 °C).[3] 2-Alkyl- and 2-aryl-4,4-dimethyl-2-oxazolines may also be prepared by rearrangement of *N*-acyl-2,2-dimethylaziridines.[2b]

α-Alkylations.

Lithiation of the C-2 methyl group of the title compound occurs with ***n-Butyllithium***. Treatment of the resulting anion with electrophiles forms substituted oxazolines (eq 2). One of the remaining methylene protons from the same position can be abstracted in a similar fashion and the resulting anion alkylated again. Subsequently, the mono- or dialkylated oxazoline can be easily transformed to the corresponding carboxylic acid or ethyl ester. Thus the title compound functions as an acetic acid synthon. Some illustrative examples of this methodology are listed in Table 1.[3,5-8] This protocol has been used to synthesize radiolabelled amino acids.[4]

(2)

Table 1 Homologated Acetic Acids, Produced According to Eq 2

RX	Product	Yield (%)
		80[3,5]
		95[3,5]
		94[3]
		37[6]
(-)-*(S)*-Menthyl *p*-toluenesulfinate		83[7]
		70[8]

The initial 2-alkylated 4,4-dimethyl-2-oxazoline can also be prepared directly from homologs of acetic acid. α-Branching substituents can then be introduced by alkylation of the 2-alkyloxazoline. Thus *n*-butyric acid is converted to the desired oxazoline by condensation with 2-amino-2-methyl-1-propanol in 88% yield (eq 3).[3] The standard protocol of metalation, electrophile addition, and oxazoline hydrolysis affords the 2-substituted butyric acid in 61% yield (eq 3).[3] Since hydrolysis of the *N*-methylated heterocycle can be carried out under basic conditions, acid-labile groups such as the 1,3-dioxolane can be incorporated into the carboxylic acid product.

The stability of the anion of 2,4,4-trimethyl-2-oxazoline allows efficient alkylation with epoxides to form, after oxazoline hydrolysis, the corresponding γ-butyrolactone or γ-hydroxy acids (Table 2).[9,10]

Table 2 Lactones, Produced According to Eq 2

Epoxide	Product	Yield (%)
		85[9]
		70[9]
		65[9]
		–[10]

Aldol Condensations.

The lithiated title reagent also adds cleanly to aldehydes and ketones. Acidic hydrolysis of the oxazoline gives a mixture of the α,β- and β,γ-unsaturated acids or esters (eqs 4 and 5).[3,5,11] When the hydrolysis is performed with lower concentrations of acid, it is possible to isolate the β-hydroxy ester (eq 4).[5]

The lithiated oxazoline can also be used as an enol acetate equivalent in the aldol reaction.[12] The chiral sulfoxide (entry 5, Table 1), prepared from 2,4,4-trimethyl-2-oxazoline, has been used in the aldol reaction as an enol acetate equivalent, albeit with moderate enantiomeric enrichment (ee <= 53%).[7]

Acylation Reactions.

In addition, the lithium anion of 2,4,4-trimethyl-2-oxazoline undergoes *C*- and *N*-acylation with acid chlorides.[13] Further alkylation leads to a stable enol, which is a masked β-keto acid or ester (eq 6). These oxazoline enols are also accessible from the reaction of 2-alkylated 4,4-dimethyl-2-oxazolines with acid anhydrides in the presence of $AlCl_3/Et_3N/MeCN$ followed by treatment with KOH/MeOH.[14]

Addition of the lithio anion to nitriles forms the corresponding enamino oxazolines (eq 7).[15,16]

1,3-Dipolar Cycloadditions of Oxazoline *N*-oxides.

The *N*-oxide of 2,4,4-trimethyl-2-oxazoline has been utilized in [3 + 2] cycloadditions (eq 8).[17]

Asymmetric [3 + 2] cycloadditions have been accomplished by utilizing the *N*-oxides of chiral oxazolines.[18]

Carboxyl Protection.

2-Alkyl-2-oxazolines can also serve as protected forms of esters and carboxylic acids[19] because they are resistant to attack by Grignard reagents[5] and ***Lithium Aluminum Hydride***.[20] The oxazolines can be converted to ethyl esters (3 M HCl, EtOH) or carboxylic acids (MeI, 25 °C; 1 M NaOH, 25 °C).[19]

Related Reagents.

5,6-Dihydro-2,4,4,6-tetramethyl-1,3(4H)-oxazine; ***Dilithioacetate***; ***Ethyl Lithioacetate***; ***2-(o-Methoxyphenyl)-4,4-dimethyl-2-oxazoline***; ***Methoxy(phenylthio)trimethylsilylmethane***; ***2-Methylbenzothiazole***; ***2-Methyl-2-thiazoline***; ***N,4,4-Trimethyl-2-oxazolinium Iodide***.

N,4,4-Trimethyl-2-oxazolinium Iodide

[30093-97-1] · $C_6H_{12}INO$ · *N*,4,4-Trimethyl-2-oxazolinium Iodide · (MW 241.09)

(a formylation and deuteroformylation reagent for aryl, benzyl, vinyl, and alkynyl Grignard reagents[1,2])

Physical Data: mp 215 °C (dec).

Preparative Method: by alkylation of commercially available 4,4-dimethyl-2-oxazoline with ***Iodomethane*** (eq 1). Filtration and purification affords the 2-oxazolinium salt in 80% yield.[1]

Handling, Storage, and Precautions: slightly hygroscopic; store under an inert atmosphere; use in a fume hood.

Synthetic Utility.

N,4,4-Trimethyl-2-oxazolinium iodide is used as a formylating reagent. Aryl, vinyl, benzyl, and alkynyl Grignard reagents react with the title compound in the presence of HMPA to form the corresponding oxazolidine adducts (eq 2, Table 1).[1] Hydrolysis of the oxazolidine with ***Oxalic Acid*** releases the free aldehyde. However, aliphatic Grignard reagents do not successfully enter into this protocol.[1,2]

Table 1 Aldehyde Formation

Trimethyloxonium Tetrafluoroborate[1]

[420-37-1] · $C_3H_9BF_4O$ · Trimethyloxonium Tetrafluoroborate · (MW 147.93)

(methylating agent;[1] activates C-X multiple bonds;[2] esterifies polyfunctional carboxylic acids;[3] catalyst for polymerization of cyclic sulfides and ethers; Beckmann rearrangement of oximes[4])

Physical Data: mp 179.6-180.0 °C (sealed tube, with dec).

Solubility: sol nitrobenzene, nitromethane, $CHCl_3$, acetone (hot), SO_2 (liq); slightly sol CH_2Cl_2; insol common organic solvents.

Form Supplied in: white crystalline solid; commercially available; is contaminated by ethyldimethyloxonium tetrafluoroborate.

Analysis of Reagent Purity: ^{1}H NMR (CD_2Cl_2/SO_2) δ 4.68 (s, CH_3); ^{13}C NMR (CD_2Cl_2/SO_2) δ 78.8 (CH_3).

Purification: highly pure oxonium salt is obtained from dimethoxycarbenium tetrafluoroborate and dimethyl ether.[5] The resulting solid is vacuum dried at 50 °C/1 mmHg for 30 min.

Handling, Storage, and Precautions: when prepared according to Curphey,[6] the oxonium salt is stable, nonhygroscopic, and may be readily handled in the air for short periods of time. The dry oxonium salt should be stored under argon at -15 °C or as a suspension in CH_2Cl_2 at -20 °C for prolonged periods. Batches stored in this manner for over a year have been successfully used for alkylations. Highly pure samples[5] showed no change in spectral data after this time. Reactions of the reagent should be performed under an argon or a nitrogen atmosphere; dry solvents are also necessary. Because of its caustic nature and potent properties as an alkylating agent, direct contact with the skin must be avoided.

Functional Group Methylations.

The powerful alkylating property of trimethyloxonium tetrafluoroborate allows methylation of sensitive or weakly nucleophilic functional groups. Smooth alkylation of a variety of anions or uncharged molecules has been reported. Examples include carboxylic acids,[7] ketones,[2,8] lactones,[4,9] nitriles,[4,10] *O*-acetals,[4] *S*-acetals,[11] sulfoxides,[12] sulfides,[13] thioamides,[14] thiophenes,[13g] and sulfonium ylides.[14] As should be expected for strongly electrophilic agents,[1c] the hard oxonium salt yields considerable amounts of products derived from methylation at the site of the highest electron density (HSAB principle) when it reacts with ambident nucleophiles. *O*-Methylation of sulfoxides,[15] *N*-methylation of sulfoximides,[16] sulfinyl amines,[17] sulfodiimides, and nitriles[10] and *S*-methylation of thioamides[14b] have been observed. The very reactive cationic intermediates (e.g. carboxonium, carbosulfonium, or nitrilium ions) as primary products in those reactions are versatile intermediates for synthetic transformations. Ketones can be converted into α-acetoxy ketones via *N*-methylation of the oxime acetates (eq 1)[18] and thioamides to amides (eq 2).[14a,b]

The reactions of thioacetals with $Me_3O^+BF_4^-$ constitute a high-yielding method for deprotection of thioacetals to give ketones (eq 3).[11a,19]

The reagent has been employed as a quaternizing agent for a variety of N-heterocycles.[20] Regioselective *N*-methylation has been observed (eq 4).[20c] Thiazoles are exclusively *N*-methylated,[20a,b] whereas tetrazoles yield regioisomeric products.[20d,h] The dication of squaric acid bis(amidine) is prepared by regioselective *N*-methylation (eq 5).[21]

(4)

(5)

1,3-Benzothiazolines react preferentially at nitrogen,[22] whereas heterocycles containing dipolar carbonyl groups usually yield products resulting from *O*-methylation.[2,23] Furthermore, $Me_3O^+BF_4^-$ is the reagent of choice for the synthesis of higher alkylated products which are otherwise not obtainable. Examples are the preparation of vinylidene disulfonium salts (eq 6),[13c] dionium salts of *N*,*S*-[13b] and *S*,*S*-acetals,[11a-c,24] or 1,4-dithianium ditetrafluoroborates (eq 7),[19] and a heterocyclophane-type tetrasulfonium salt (eq 8). The latter introduces a hydrophobic cavity into the aqueous phase, thus serving as an inclusion catalyst.[25]

mixture of two stereoisomers

Trialkyloxonium salts such as $Me_3O^+BF_4^-$ are excellent reagents for the generation of cyclopropenylium cations by *O*-methylation of suitable cyclopropenones (eq 9).[26]

(9)

The reaction of trialkyloxonium salts with carboxylic acids is a mild, general esterification procedure that does not require the use of more hazardous reagents such as ***Hexamethylphosphoric Triamide-Thionyl Chloride***, ***Iodomethane***, ***Dimethyl Sulfate***, ***3-Methyl-1-p-tolyltriazene***, or ***Diazomethane***. The reaction proceeds smoothly with sterically hindered acids, as well as with acids containing various functional groups such as amides or nitriles (eq 10).[3,7]

(10)

One of the major advantages of the use of oxonium salts is that alkylations can be effected under reaction conditions that are generally much milder than those necessary with conventional alkyl halides and sulfonates. $Me_3O^+BF_4^-$ has been used as a suspension in CH_2Cl_2 or dichloroethane, or as a solution in nitromethane or liquid SO_2. Alkylations in water[27] and trifluoroacetic acid[28] have been described, and direct fusion has been used in cases where other conditions failed.[29] An S_N2 mechanism must be assumed in the reaction of the reagent with nucleophiles. The rates of the complete hydrolysis decrease in the sequence $Me_3O^+ >> Et_3O^+ > Pr_3O^+ > c\text{-}C_5H_{10}{+}OEt$.[30] Comparative studies on the alkylating ability of common methylating agents[31] show that Me_3O^+ ions are more reactive than the trifluoromethanesulfonate ester (factor 5 to 12), following the order $Me_3O^+ > MeOSO_2CF_3 > MeOSO_2F > MeOClO_3$. In terms of availability, stability, and freedom from hazards, however, oxonium salts often appear the reagents of choice (including comparisons with other powerful alkylating agents such as dialkoxycarbenium ions,[32] dialkylhalonium ions,[33] and haloalkanes in the presence of silver salts[34]). While the carcinogenic properties of other potent alkylating agents are well documented,[35] any such dangers associated with trialkyloxonium salts are presumably minimized by the fact that these compounds are water-soluble, nonvolatile, crystalline solids which are rapidly solvolyzed in aqueous solution.[1b,36] Although ***Triethyloxonium Tetrafluoroborate*** is the cheaper and much more used oxonium salt in synthetic chemistry, $Me_3O^+BF_4^-$ effects alkylations which the triethyl analog does not.[11,37]

Use in Transition Metal Chemistry.

$Me_3O^+BF_4^-$ has been successfully used in the generation of transition metal carbene complexes by direct methylation of lithium acylcarbonylmetalates (eq 11).[38] Oxidative addition processes by which metal-carbon σ-bonds are formed have also been observed.[39] $Me_3O^+BF_4^-$ also serves as a halide acceptor in the reaction with square planar platinum(II) complexes.[40]

(11)

Catalytic Properties.

$Me_3O^+BF_4^-$ has been used as a catalyst for the polymerization of cyclic sulfides and in the polymerization of THF to macrocyclic ethers.[4] A valuable modern application is the catalytic Beckmann rearrangement of oximes in homogeneous liquid phase,[41] the active species being a formamidinium salt.

Other Reactions.

The reaction of γ-alkenyl-γ-butyrolactones with allylsilanes in the presence of $Me_3O^+BF_4^-$ as the lactone-activating agent is reported to proceed with high regio- and stereoselectivity to afford methyl (*E*)-4,8-alkadienoates in high yields (eq 12).[42]

(12)

$Me_3O^+BF_4^-$ has also been used as a methylating agent of the lithium enolate of a β-keto sulfoxide, leading to a mixture of isomeric dienol ethers, which are of potential interest as substrates for asymmetric Diels-Alder cycloadditions (eq 13).[43]

(13)

Trimethyl Phosphate

[512-56-1] · $C_3H_9O_4P$ · Trimethyl Phosphate · (MW 140.09)

(esterification of carboxylic acids;[1] *N,N*-dimethylation of anilines;[2] *N*-methylation of nitrogen heterocycles[3])

Physical Data: bp 197 °C; *d* 1.197 g cm^{-3}.

Solubility: sol H_2O (1 g mL^{-1}), ethanol, ether.

Form Supplied in: liquid; widely available.

Purification: distillation at ambient or reduced pressure.

Handling, Storage, and Precautions: stable for extended periods of storage. It is a cancer suspect agent and possible mutagen and should be handled with due caution.

Esterification of Carboxylic Acids.

Trimethyl phosphate is an effective reagent for the preparation of methyl esters of hindered carboxylic acids (eq 1)[1a] and serves as an alternative to toxic ***Dimethyl Sulfate***.[4] It can also effect the *O*-methylation of unprotected amino acids,[1b] although some *N,O*-dimethylated product is observed.

(1)

N,N-Dialkylation of Anilines.

Trimethyl phosphate reacts with anilines to give *N*,*N*-dimethylated products (eq 2).[2a,b] A wide variety of substitution is tolerated, although substituents which significantly decrease the basicity of nitrogen, such as *p*-nitro, are not. All three methyl groups of the reagent molecule are utilized in these alkylations.

N-Alkylation of Nitrogen Heterocycles.

The title reagent has been used to *N*-methylate a wide variety of nitrogen heterocycles, including imidazoles,[3a] benzimidazoles (eq 3),[3a] pyrazoles,[3a] 1,2,4-triazoles,[3a] benzotriazoles,[3a] quinolines,[3b] purines,[3c,d] pyrimidines,[3e,f] and phenothiazines.[3g]

Ring Opening of Isoxazolidines.

Trimethyl phosphate reacts with *N*-alkylisoxazolidines to form, depending on the substitution pattern of the isoxazolidine, α,β-enones[5a] (eq 4) or tertiary allylic alcohols.[5b]

Methylation of α-Lithio Sulfoxides.

Trimethyl phosphate reacts with α-lithio sulfoxides to form the corresponding α-methyl sulfoxides.[6] The coordinating ability of the reagent with the lithium counterion can lead to a reversal of product stereochemistry compared with similar alkylations with ***Iodomethane***.[6a,b]

Use as a Solvent.

Trimethyl phosphate is an excellent dipolar aprotic solvent for a variety of synthetic transformations. In aromatic halogenation reactions[7] and the halogenative cleavage of cyclic acetals,[8] trimethyl phosphate acts as an acid scavenger, very rapidly reacting with liberated hydrogen halide to form methyl halide. Trimethyl phosphate also has an accelerating effect on the diphosgene-mediated conversion of carboxamides to nitriles,[9] and on the phosphoryl chloride-mediated direct phosphorylation of unprotected nucleosides to 5´-nucleotides.[10]

Trimethyl Phosphite[1]

$(MeO)_3P$

[121-45-9] · $C_3H_9O_3P$ · Trimethyl Phosphite · (MW 124.09)

(reducing agent for various functional groups; can function as a potent thiophile for sulfur extrusion; forms a stable complex with copper(I) iodide and methylcopper)

Physical Data: bp 111-112 °C/760 mmHg; *d* 1.052 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: clear, free flowing liquid; commercially available in >99% purity.

Purification: treatment with sodium (to remove water and dialkyl phosphonate), followed by decanting and distillation.[2]

Handling, Storage, and Precautions: store in a dry place, preferably in a fume hood due to its pungent odor; purified material should be stored over activated molecular sieves.

Use in the Arbuzov and Perkow Reactions.

Although used less frequently than ***Triethyl Phosphite***, trimethyl phosphite has seen significant application in the synthesis of organophosphonates (eq 1)[3] and phosphates (eq 2)[4] via Arbuzov and Perkow reactions, respectively. For example, an interesting α-diazophosphonate reagent developed by Seyferth has been applied to the one-step conversion of aldehydes to terminal alkynes (eq 3).[5] Since the potentially hazardous diazophosphonate is purified by distillation, use of the relatively volatile dimethyl derivative is warranted.

(1)

(2)

Carbonyl Adducts.

Trimethyl phosphite reacts readily with 1,4- and 1,2-benzoquinones to give methyl esters of hydroquinone monophosphates (eq 4)[6] and cyclic oxyphosphoranes (eq 5),[6] respectively. Ramirez and co-workers reported that trimethyl phosphite promotes the dimerization of methyl pyruvate to give, after basic hydrolysis, a mixture of diastereomeric tartrates (eq 6).[7]

Deoxygenation.

The reductive decomposition of ozonides can be conveniently accomplished using trimethyl phosphite (eq 7).[8] The innocuous byproduct, trimethyl phosphate, is easily removed from the crude reaction mixture either by extraction or evaporation.

The reagent has been equally efficacious in the conversion of nitrile oxides to nitriles (eq 8).[9] Additionally, Seebach and co-workers have reported the synthesis of a cyclic ε-tetrazine via reduction of the corresponding *N*-oxide (eq 9).[10]

(8)

(9)

Desulfurization.

Trimethyl phosphite (in addition to triethyl phosphite) has been applied successfully to the Corey-Winter alkene synthesis.[11] The key step of the sequence involves phosphite-mediated decomposition of a thiocarbonate derivative which proceeds stereospecifically and often results in good yields of desired alkene (eqs 10 and 11).[12] Alkynes have also been synthesized using this method, albeit in lower overall yields (eq 12).[13]

(10)

(11)

(12)

Treatment of 1,3-dithiacyclohexane-2-thione[14] with trimethyl phosphite affords the corresponding ylide quantitatively. The phosphorane has been applied the one-carbon homologation of aldehydes to carboxylic acids (eq 13).[15]

(13)

In addition, trimethyl phosphite has been used to capture intermediates formed during [2,3]-sigmatropic rearrangement of allylic sulfoxides (eq 14)[16] and in the conversion of penicillin derivatives to azetidinones (eq 15).[17]

(14)

(15)

Dehalogenation.

Dershowitz[18] has reported that vicinal dibromides are smoothly converted to alkenes by heating in the presence of trimethyl phosphite. The reagent was successfully applied to systems where other reagents, such as ***Sodium Iodide*** or ***Zinc*** dust proved unsatisfactory (eq 16). The dehydrohalogenation of a steroidal allylic bromide has also been reported (eq 17).[19]

(16)

(17)

Copper Complexes.

Copper(I) Iodide-Trimethyl Phosphite is formed in 84% yield by the reaction of trimethyl phosphite and ***Copper(I) Iodide*** in refluxing benzene.[20] The salt has been used as a catalyst in the decomposition of diethyl diazomalonate to give ethers (eq 18)[21] and cyclopropanes (eq 19).[20] Furanones have been prepared using related methodology (eq 20).[22]

(18)

(19)

(20)

Trimethyl phosphite-methylcopper is a relatively stable complex of ***Methylcopper***. The reagent adds readily, in a conjugate sense, to

cyclohexenones, with a strong preference for axial attack (eq 21).[23]

(21)

Esterification.

Trimethyl phosphite has been used in the conversion of a sensitive indolecarboxylic acid to the corresponding methyl ester under neutral conditions (eq 22).[24]

Trimethyl Phosphonoacetate[1]

[5927-18-4] · $C_5H_{11}O_5P$ · Trimethyl Phosphonoacetate · (MW 182.13)

(with a base gives a phosphoryl-stabilized carbanion that reacts with aldehydes,[1] ketones,[1a-c] ketenes,[2] pyrylium salts,[3] triflates,[4a] alkyl halides,[4b] alcohols,[5] amines,[5] azides,[6] and CS_2[7])

Alternate Name: dimethyl (methoxycarbonyl)methylphosphonate.

Physical Data: bp 118 °C/0.85 mmHg; *d* 1.125 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: store under N_2.

Reactions with Aldehydes and Ketones.

n-Butyllithium,[1d,8] ***Sodium Amide***,[9] ***Sodium Hydride***,[1d,10b] ***Potassium Hydride***,[1d] ***Potassium t-Butoxide***,[8,10] ***Sodium Methoxide***,[11] KOMe,[12] ***Potassium Hexamethyldisilazide*** (KHMDS),[13] and other bases deprotonate $(MeO)_2P(O)CH_2CO_2Me$ in solvents such as THF, DME, MeCN, DMF, DMSO, MeOH, benzene, toluene, and dioxane to give a phosphoryl-stabilized carbanion, $[(MeO)_2P(O)\text{-}CHCO_2Me]X^+$. The anion reacts with aldehydes and ketones to give an (*E*)-α,β-unsaturated ester as the major product (eq 1)[14] in a Horner-Wadsworth-Emmons (HWE) reaction (see also ***Triethyl Phosphonoacetate***). Hemiacetals (eq 2)[15] also react with $[(MeO)_2P(O)\text{-}CHCO_2Me]X^+$ to give an α,β-unsaturated ester. In some instances, $(MeO)_2P(O)CH_2CO_2Me$ and the aldehyde undergo a Knoevenagel condens ation (eq 3).[16]

The aldehyde reactivity in HWE reactions with $(MeO)_2P(O)CH_2CO_2Me$ is seemingly unaffected by complexation (eq 4)[2,17a] or conjugation (eqs 4 and 5).[17] Cyclohexanones with a C-2 equatorial alkyl group are unreactive to $[(MeO)_2P(O)\text{-}CHCO_2Me]X^+$ under normal conditions.[18] Reaction occurs if the substituent can readily attain a conformation or configurational (epimerization) conversion to an axial position. Compounds containing 2 equivalent carbonyl groups undergo a double HWE reaction.[19]

Other basic conditions for the HWE reaction with $(MeO)_2P(O)CH_2CO_2Me$ have been developed to accommodate base-sensitive aldehydes and to minimize undesired side reactions.[11c,16] ***Potassium Carbonate*** has been used in heterogeneous liquid-liquid conditions in the absence of organic solvents (eq 5).[17b,20,21] ***Sodium Hydroxide*** has also been used in liquid-liquid conditions[20] in the presence of a phase-transfer catalyst and both NaOH[20] and K_2CO_3[20] have been used in solid-liquid two-phase conditions. Other bases used include ***Cesium Carbonate***,[15c,20] ***Barium Hydroxide***,[20] ***Lithium Hydroxide***,[22] and a combination of ***Lithium Chloride*** and either ***Diisopropylethylamine*** (DIPEA) (eq 6),[20,23] ***1,8-Diazabicyclo[5.4.0]undec-7-ene***,[20] or ***Triethylamine***.[20] HWE reactions have also been carried out in the presence of crown ethers[13b] and the treatment of polymer-bound phosphonates at rt with aldehydes and ketones gives alkenes in high yields and with high (*E*) stereoselectivity.[24]

(6)

The (*E*/*Z*) ratio of unsaturated esters formed in the reaction of $[(MeO)_2P(O)\text{-}CHCO_2Me]X^+$ with aldehydes is dependent on the metal cation (X^+), reaction temperature, solvent, and the degree of α-substitution of the aldehyde.[1d] None of the effects alone is very large, but the combination of effects allows for a degree of control on the stereoselectivity of the reaction. (*E*) Selectivity is promoted with α-trisubstituted aldehydes, Li^+, rt, and nonchelating solvents such as benzene and DME. Formation of (*Z*)-unsaturated esters is promoted with α-mono and disubstituted aldehydes, and Na^+ or K^+ at -78 °C in THF. The (*E*/*Z*) stereochemistry in HWE reactions of trialkyl phosphonates is also influenced by the nature of the phosphonate carboxylic ester substituent.[1c]

A comparison of the alkenation of ketones and aldehydes using $(MeO)_2P(O)CH_2CO_2Me$ under HWE conditions and Ph_3PCHCO_2Me under Wittig conditions suggests that the former gives superior (*E*) stereoselectivity and occurs under milder reaction conditions (e.g. eq 5).[17b,25] α,β-Unsaturated esters are prepared from aromatic, saturated, and unsaturated aliphatic aldehydes with high (*Z*) stereoselectivity under Still-modified HWE conditions, using bis(trifluoroethyl) phosphonoesters $(CF_3CH_2O)_2P(O)CHRCO_2Me$ (R = H, Me) and/or strongly dissociated base systems like $KN(TMS)_2$/18-crown-6.[13a,25c,26] A predominance of (*Z*)-alkene has also been reported using $(MeO)_2P(O)CH_2CO_2Me$ under these conditions (eq 7).[13b,26a]

(7)

The reduction of a saturated ester or lactone with ***Diisobutylaluminum Hydride*** at -78 °C in the presence of $[(MeO)_2P(O)\text{-}CHCO_2Me]Na^+$ gives a good yield (60-80%) of the homologous ester with little or no overreduction of the starting material or product ester (eq 8).[20,27]

(8)

Reactions with Ketenes.

The anion of trimethyl phosphonoacetate, derived from reaction with ***Sodium Hydride***, reacts with tricarbonyl(vinylketene)iron(0) complexes to give (*E*)- and (*Z*)-tricarbonyl(vinylallene)iron(0) complexes in the ratio of 7:3 (eq 9).[2] Oxidation of the vinylallene complexes with ***Iron(III) Chloride*** leads to the release of the organic ligands as 5-alkyl-5-styrylfuran-2(5*H*)-ones (eq 9).[2]

(9)

Other Reactions.

$[(MeO)_2P(O)\text{-}CHCO_2Me]Na^+$ reacts with pyrylium salts (eq 10).[3] α-Substituted phosphonates are prepared by alkylating $[(MeO)_2P(O)\text{-}CHCO_2Me]Na^+$ with either an alkyl triflate (eq 11)[4a] or iodide[4b] (see also ***Triethyl Phosphonoacetate***). Differentially substituted phosphonoacetates and phosphonoacetamides are prepared by reacting $(MeO)_2P(O)CH_2CO_2Me$ with ***4-Dimethylaminopyridine*** and an alcohol or amine, respectively.[5] The reaction of $[(MeO)_2P(O)\text{-}CHCO_2Me]Na^+$ with an azide gives an α-diazo phosphonate.[6] Reaction with CS_2 gives an 1,1-alkenedithiolate (eq 12) that can be alkylated, oxidized, protonated, and phosgenated.[7] Trialkyl phosphonates react with epoxides,[20] but only under forcing conditions.[28]

Trimethyl 2-Phosphonoacrylate

(**1**; R^1 = Me, R^2 = Me)

[55168-74-6] · $C_6H_{11}O_5P$ · Trimethyl 2-Phosphonoacrylate · (MW 194.14) (**2**; R^1 = Et, R^2 = Et)

[20345-61-3] · $C_9H_{17}O_5P$ · Triethyl 2-Phosphonoacrylate · (MW 236.23) (**3**; R^1 = Me, R^2 = Et)

[993-88-4] · $C_8H_{15}O_5P$ · Diethyl Methyl 2-Phosphonoacrylate · (MW 222.20)

(reactive, bifunctional Michael acceptor for tandem conjugate addition-alkenation and annulation reactions; useful enophile for ene reactions and dienophile for Diels-Alder reactions)

Physical Data: (**1**) bp 90-92 °C/0.1 mmHg. (**2**) bp 98.5-99.5 °C/0.13 mmHg. (**3**) bp 95-98 °C/0.15 mmHg.

Solubility: sol Et_2O, THF, EtOH, and most polar organic solvents.

Form Supplied in: (**1**) is commercially available; (**2**) and (**3**) must be synthesized.[2,3]

Analysis of Reagent Purity: IR and NMR spectroscopy and GC.

Preparative Method: (**1**) is prepared by heating ***Trimethyl Phosphonoacetate*** at reflux with a mixture of ***Paraformaldehyde***, MeOH, and ***Piperidine*** (previously heated at reflux).

Handling, Storage, and Precautions: commercial (**1**) is supplied with 0.5% 2,6-di-*t*-butyl-*p*-cresol as a stabilizer.

Conjugate Addition-Alkenation.

3-Substituted 2-phosphonomethylacrylates[1] can be prepared using phosphorus nucleophiles which undergo Michael addition to trimethyl 2-phosphonoacrylate. The resulting carbanion undergoes Horner-Emmons-type alkenation with aldehydes (eq 1). A similar sequence can be utilized to prepare functionalized dienes,[1] trienes, and their analogs (eq 2).

A variety of carbanion nucleophiles add to vinyl phosphonates to produce stabilized phosphonate anions capable of undergoing reactions with aldehydes and ketones to give unsaturated esters (eq 3).[2]

Annulation.

Oxygen and nitrogen nucleophiles add to phosphonoacrylates and lead to the formation of heterocyclic compounds (eq 4). Michael addition of *N*-lithio-4-vinylazetidin-2-one to vinyl phosphonate gives an addition product which can be converted to Δ^1-carbapenems[4] via ozonolysis and intramolecular Horner-Wittig reaction (eq 5). An imine-enamine annulation was used in the synthesis of the indoloquinolizidine alkaloid (±)-deplancheine.[4] Similarly, synthesis of six-membered carbocyclic compounds can be achieved by 2:1

condensation reactions of the phosphonoacrylate with cyclopentanone enolates (eq 6). Phosphonoacrylate annulation was also used in the construction of a [3.3.0]pyrazolidinone[4] from the monocyclic pyrazolidinone.

(4)

(5)

(6)

Sulfur Nucleophiles.

Michael addition of mercaptoacetaldehyde to phosphonoacrylate gives methyl 2,5-dihydrothiophene-3-carboxylate, which thermally decomposes to methyl 1,3-butadiene-2-carboxylate (eq 7). Similarly, sulfur nucleophiles[5] such as phenylthiolate and isopropylthiolate have been utilized in the synthesis of β-acetoxy- and β-hydroxy-α-methylene-γ-butyrolactones (eq 8),[5] confertin,[5] and arteannuin B.[5]

(7)

Ene and Diene Reactions.

Trimethyl 2-phosphonoacrylate undergoes facile ene reactions[6] with a variety of alkenes, using ***Ethylaluminum Dichloride*** as a Lewis acid catalyst (eq 9). It also undergoes [4 + 2] cycloadditions with isoprene (eq 10) and 6,6-diphenylfulvene.[6] Irradiation of acyl-*N*-hydroxy-2-thiopyridones in the presence of trimethyl 2-phosphonoacrylate affords derivatives of phosphonic analogs of nucleotides.[7]

Related Reagents.

Diethyl Phosphonite; ***Ethyl Acrylate***; ***Methyl 2-Methylthioacrylate***; ***Methyl 2-Trimethylsilylacrylate***; ***Triethyl Phosphite***; ***Triethyl Phosphonoacetate***; ***Vinyltriphenylphosphonium Bromide***.

2,4,6-Trimethylpyrylium Tetrafluoroborate[1,2]

(**1**; $X^- = BF_4^-$)

[773-01-3] · $C_8H_{11}BF_4O$ · 2,4,6-Trimethylpyrylium Tetrafluoroborate · (MW 210.00) (**2**; $X^- = ClO_4^-$)

[940-93-2] · $C_8H_{11}ClO_5$ · 2,4,6-Trimethylpyrylium Perchlorate · (MW 222.64) (**3**; $X^- = CF_3OSO_2^-$)

[40927-60-4] · $C_9H_{11}F_3O_4S$ · 2,4,6-Trimethylpyrylium Triflate · (MW 272.27) (**4**; $X^- = HO_2CCH_2SO_3^-$)

[80731-12-0] · $C_{10}H_{14}O_6S$ · 2,4,6-Trimethylpyrylium Sulfoacetate · (MW 262.31)

(synthon reacting with various nucleophiles)

Physical Data: (**1**) mp 244 °C (dec). (**2**) mp 244 °C (dec). (**3**) mp 119-120 °C. (**4**) mp 115-116 °C.

Solubility: (**1**) sol H_2O, AcOH, CF_3CO_2H. (**2**) sol CF_3CO_2H. (**3**) sol H_2O, $CHCl_3$, MeOH, EtOH, $(ClCH_2)_2$. (**4**) sol H_2O, MeOH, EtOH, AcOH; insol Et_2O, Me_2CO.

Form Supplied in: white solids.

Preparative Methods: 2,4,6-trimethylpyrylium salts were the first pyrylium salts devoid of hydroxy or alkoxy substituents to be obtained, by Baeyer and Piccard in 1911.[3] Until then, protonated or alkylated γ-pyrones were the only known pyrylium salts. At that time, pyrones were puzzling nitrogen-free bases; the discussion about which of their two oxygen atoms was attacked lasted a long time and eventually led to the clarification of the concepts of aromaticity and aromatic sextet. Pertinent references may be found in reviews.[1]

A low-yield synthesis[3] was based on the reaction of 2,6-dimethyl-4-pyrone with methylmagnesium iodide, followed by treatment with acid (perchloric acid was then favored).

The preferred syntheses of 2,4,6-trimethylpyrylium perchlorate (**2**) are based either on the diacetylation of ***Isobutene*** (eq 1),[4] or on the acetylation of mesityl oxide (eq 2),[5] using ***Acetic Anhydride*** and 60-70% perchloric acid. In the former synthesis, instead of the gaseous isobutene, one uses *t*-butanol which is dehydrated in situ.[6]

In both methods, isomesityl oxide is the actual reaction intermediate. The reaction mechanism is shown in eq 3.

Since organic perchlorates may explode on impact when dry, other anions have lately been preferred, namely tetrafluoroborate or trifluoromethanesulfonate (triflate), obtained from *t*-butanol with Ac_2O and the corresponding acid, analogously to eq 1. When using 48% fluoroboric acid, the yield of fluoroborate (**1**) is 50%,[7] and when using anhydrous triflic acid, the yield of triflate (**3**) is 42%.[8]

2,4,6-Trimethylpyrylium sulfoacetate (**4**) can be prepared inexpensively on a large scale (in kg amounts) according to published procedures[9] starting either from isobutene or from *t*-butanol (eq 4). Excess acetic anhydride is no longer required for reacting with the water from $HClO_4$ or HBF_4 solutions. The sulfoacetate (**4**) crystallizes from the reaction mixture on addition of acetone, in which it is insoluble. It has a high solubility in water.

Purification: recrystallize from: (**1**), EtOH, MeOH; (**2**), H_2O, AcOH; (**3**), dioxane-AcOH (7:1) or $CHCl_3$-CCl_4 (2:1); (**4**), MeOH-Me_2CO.

Handling, Storage, and Precautions: all salts may be stored indefinitely. Reports on possible mutagenic activity make it desirable to avoid direct contact with skin. The perchlorate (**2**) is explosive; therefore it should be prepared only in the required amount for further use. The dry perchlorate should be handled with great care, and never be heated, crushed, rubbed, or pushed through a narrow opening. It may be kept in a cork-stoppered flask when moistened with water or dry THF. Use in a fume hood.

Reactions.

Like other pyrylium salts, the title products (**1**)-(**4**) react readily with many nucleophiles, yielding adducts initially (usually 2*H*-pyrans, but exceptionally 4*H*-pyrans with hydrides or Grignard reagents). The 2*H*-pyrans are valence isomeric with open-chain 2,4-pentadien-1-ones, which then may recyclize to a variety of products, mainly aromatic or heteroaromatic. The result is the incorporation of the pyrylium five-carbon chain with its substituents into new acyclic, carbocyclic, or heterocyclic systems, triggered by the initial reaction with the nucleophile.[2] In the following, (**2**) or (**3**) may always replace (**1**), and the same is true for (**4**), but in this case one must take into account the CO_2H group of the anion which may sometimes interfere with the nucleophile.

In some cases, the recyclization involves one of the α-methyl groups in (**1**). Thus 3,5-dimethylphenol (**5**) is formed by boiling (**1**) with aqueous alkali hydroxides (eq 5), and similar reactions occur with other pyrylium salts having α-methyl or α-methylene groups.[5a,10] With secondary amines, (**1**) affords *N*,*N*-dialkyl-3,5-dimethylaniline derivatives similarly (**6**).[11]

Reactions With Oxygen Nucleophiles.

Hydrogen Peroxide converts (**1**) into 2-acetyl-3,5-dimethylfuran.[12] The yield is increased appreciably if the reaction is carried out in a phosphate buffer; enol esters have been identified as byproducts.[13]

Reactions With Nitrogen Nucleophiles.

Ammonia and primary amines (RNH_2) react with (**1**), yielding *sym*-collidine and *N*-substituted collidinium salts, respectively. In the latter reaction, depending on the R group, an aniline derivative (secondary amine) analogous to the tertiary amine (**6**) may be obtained as a byproduct, but in some cases this may become the main product.[14] Amino acids and terminal amino groups in polypeptides give rise to pyridinium salts on reacting with (**1**); this reaction may have biochemical significance.[15]

The *N*-substituted pyridinium salts prepared from isopropylamine (**7a**) or from amino alcohols or their esters (**7b-7d**) present ^1H and ^{13}C NMR chemical shift nonequivalence of their α-methyl peaks; the intramolecular rotation barriers ΔG^+ are 13-15 kcal mol^{-1} for (**7a**) and (**7b**), 17 kcal mol^{-1} for (**7c**), and 19 kcal mol^{-1} for (**7d**). Such values are among the highest for sp^2-sp^3 single bonds.[16]

(7a) $R^1 = R^2 = Me$
(7b) $R^1 = Ph,\ R^2 = CH_2OH$
(7c) $R^1 = Me,\ R^2 = CH_2OH$
(7d) $R^1 = Et,\ R^2 = CH_2OH$

(8)

X-ray crystallography showed that the dihedral angle of *N*-phenyl-2,4,6-trimethylpyridinium perchlorate is 85°.[17] The *N*-aryl ring current therefore strongly shields the six α-methyl protons and deshields slightly the three γ-methyl protons relative to *N*-alkyl-2,4,6-trimethylpyridinium. The chemical shift difference between the two α/γ methyl peaks in (**8**), when the sizes of *N*-aryl or -hetaryl groups are similar, measures the relative ring current in these groups.[18]

Hydroxylamine affords 2,4,6-trimethylpyridine *N*-oxide with (**1**).[6a,19] An indolizine (**10**) synthesis is based on the reaction between (**1**) and aminoacetaldehyde acetals (**9**) (R = Me or Et) (eq 6).[20]

Reactions With Carbon Nucleophiles.

With sodium cyclopentadienide, (**1**) yields 4,6,8-trimethylazulene.[21] Alkali cyanides react with (**1**), yielding (*Z*)-5-cyano-2,4-dien-1-ones; these are converted to (*E*)-isomers by cold mineral acids.[22] Benzylmagnesium chloride attacks (**1**) in the γ-position, yielding a 4*H*-pyran which, on treatment with strong acids, undergoes ring opening and recyclizes to 1,3-dimethylnaphthalene, splitting off acetone (eq 7).[23] Since the 2,4,6-trimethylpyrylium cation may be synthesized from acetone and acetylacetone in the presence of strong acids,[24] it was logical to devise a synthesis of naphthalene derivatives from 1,3-diketones and benzylmagnesium chloride.[25]

Nitronate anions (e.g. ***Nitromethane*** with 2 equiv of ***Potassium t-Butoxide***) convert (**1**) into aromatic nitro derivatives (i.e. 2,4,6-trimethylnitrobenzene).[26] With acetylacetone or ***Ethyl Acetoacetate***, (**1**) affords 2,4,6-trimethylacetophenone, whereas with ***Ethyl Cyanoacetate*** it forms mesitonitrile;[27] such reactions exemplify the versatility of pyrylium synthons.[2]

Isotopic Exchange of Methyl Hydrogens.

Brief heating of (**1**) in D_2O, namely for 10 min at 80 °C (the less-soluble perchlorate (**2**) works even better because it crystallizes at the end of the isotopic exchange), leads mainly to γ-methyl deuteration. On further refluxing in D_2O for 1 h, all nine methyl hydrogens are deuterated. If this fully deuterated salt is heated in H_2O for 20 min, only the γ-methyl is de-deuterated (eq 8). Thus, specifically methyl-deuterated 2,4,6-trimethylpyrylium salts (i.e. only in γ, only in α, or in both α and γ) may be obtained and converted afterwards, without loss of isotopic labels, into pyridines, azulenes, benzene derivatives, etc.[28] Secondary isotope effects of deuterium in specifically labeled 2,4,6-trimethylpyridine were thus investigated, proving that lanthanide shift reagents feel only the smaller size of CD_3 vs. CH_3, pK_a differences are due only to the higher donor ability of CD_3 groups, and quaternization by CH_3I or CD_3I is affected comparably by both steric and electronic differences between CH_3 and CD_3 groups.[29]

Trimethylselenonium Hydroxide

Me_3SeOH

[44124-85-8] · $C_3H_{10}OSe$ · Trimethylselenonium Hydroxide · (MW 141.09)

(methylating agent for relatively nonnucleophilic heteroatoms[1])

Solubility: sol H_2O, MeOH.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: solution concentration can be determined by titration with 0.1 N hydrochloric acid.

Preparative Method: a solution in methanol-water can be generated by addition of ***Silver(I) Oxide*** (1 equiv) to a solution of trimethylselenonium iodide (1.3 equiv).[1] Typical concentrations of ~0.7 N are obtained.

Handling, Storage, and Precautions: the solution is stable at temperatures below 10 °C, undergoing ~5% decomposition after 1 month. The solution is alkaline, and therefore would not be compatible with acidic solvents. Since one of the byproducts of the reaction is dimethyl selenide, reactions should be carried out in a fume hood.

Methylation Reactions.

Trimethylselenonium hydroxide is a mild methylating agent, reacting with carboxylic acids, thiols, phenols, and other weakly basic heteroatoms.[1] The reactions are typically performed by adding the substrate (1.0 equiv) to a solution of the electrophile (1.1 equiv) in methanol-water and concentrating the mixture on a rotary evaporator.[1] The reaction flask is then equipped with a distillation head and heated with stirring. In the case of solid nucleophiles, DMF is added prior to heating the reaction mixture.[1] The dimethyl selenide (bp 56-57 °C) produced in the reaction is collected in the distillation, and could be reused by regeneration of trimethylselenonium iodide with ***Iodomethane***.[2] The pure methylated products could then be purified by direct distillation or recrystallization of the crude residue.

The reactions with carboxylic acids (eq 1), phenols (eq 2), and thiols (eq 3) are complete within 15 min and progress in quantitative yield.[1] Ring amines in aromatic heterocycles are also smoothly converted to the methylated derivatives as well (eq 4).[1] Alcohols and both aliphatic and aromatic amines do not react under these conditions. Selective methylations can thus be readily performed (eq 5).[1] Multiple methylations can be effected in a single pot, as in the synthesis of caffeine (eq 6).[1] Trimethylselenonium hydroxide and triethylselenonium hydroxide can also be used to quantitatively alkylate fatty acids on a GC (eq 7).[3]

(1)

(2)

(3)

(4)

(5)

(6)

(7)

Trimethylselenonium hydroxide is the most reactive of the onium hydroxides, which generally follow the reactivity order of Me_3SeOH > Me_3SOH > Me_3SO_2H > $PhMe_3NOH$ (see also ***Trimethylsulfonium Hydroxide***).[1] Trimethylselenonium hydroxide has several advantages over more conventional methylating agents. Purification is

facilitated as compared with MeI or ***Dimethyl Sulfate*** because no inorganic salts are generated. Due to the carcinogenicity of ***Diazomethane***, as well as its *N*-nitroso precursors, trimethylselenonium hydroxide should be considered as a safer alternative. Finally, since the dimethyl selenide can be recovered and reused, the relatively high cost of this starting material is less of a deterrent.

N-Trimethylsilylacetamide

[13475-12-6] · $C_5H_{13}NOSi$ · *N*-Trimethylsilylacetamide · (MW 131.28)

(silylating agent of alcohols[2] and carboxylic acids;[4] acetamide dianion equivalent;[7] aminating agent)

Alternate Name: MSA.

Physical Data: mp 46-49 °C; bp 84 °C/18 mmHg; fp 57 °C.

Form Supplied in: moist white crystals.

Handling, Storage, and Precautions: handle and store under nitrogen; combustible and easily hydrolyzed.

Silylating Reagent.

N-Trimethylsilylacetamide has poor silylation potential[1] and although not as frequently used as ***N,O-Bis(trimethylsilyl)acetamide*** (BSA) as a silylating agent, this reagent has found a number of uses. *N*-Trimethylsilylacetamide has been used to silylate alcohols,[2] the hydroxy groups of sugars,[3] carboxylic acids,[4] amino groups,[5] and the oxygen of phosphate esters (eqs 1 and 2).[6]

(1)

Acetamide Dianion Equivalent.

The dianion of *N*-trimethylsilylacetamide can be used as a soluble alternate to the insoluble acetamide dianion. The dianion can be alkylated or acylated at carbon (eqs 3-5).[7]

In an unusual reaction, *N*-trimethylsilylacetamide in the presence of ***Trifluoromethanesulfonic Anhydride*** can be used to *N*-glycosylate the anomeric positions of sugars (eq 6).[8]

(6)

Related Reagents.

N,N´-Bis(trimethylsilyl)urea.

Trimethylsilylacetic Acid[1]

[2345-38-2] · $C_5H_{12}O_2Si$ · Trimethylsilylacetic Acid · (MW 132.26)

(preparation of α,β-unsaturated carboxylic acids and α-trimethylsilylbutyrolactones[2])

Physical Data: mp 40 °C.

Solubility: sol ethereal solvents.

Preparative Methods: obtained from the reaction of ***Trimethylsilylmethylmagnesium Chloride*** with ***Carbon Dioxide***;[3] can also be prepared by reaction of ***Acetic Acid*** with 2 equiv of ***Lithium Diisopropylamide***, followed by ***Chlorotrimethylsilane*** and hydrolysis.[4]

Handling, Storage, and Precautions: prone to isomerization and should not be stored for extensive periods.

Anionic Reactions.

In a manner similar to α-silyl esters, trimethylsilylacetic acid (**1**) can be used to prepare α,β-unsaturated carboxylic acids from carbonyl compounds by a Peterson alkenation reaction (eq 1).[1] However, the dianion of acid (**1**) is required.[2] The yields are generally inferior to analogous reactions with α-silyl esters.[5]

(1)

The dianion of acid (**1**) also reacts with alkyl halides to afford substituted α-trimethylsilylcarboxylic acids.[2] With epoxides, the dianion provides γ-hydroxy acids that cyclize to α-silylbutyrolactones (eq 2).[2] The resultant α-silyl lactones (**2**) are precursors to a wide variety of functionalized derivatives. The direct conversion of a butyrolactone to its α-silyl analog is complicated by the competition of the *O*-silylation pathway.

(2)

Derivatives.

Trimethylsilylacetyl thiolesters, which have been used as precursors to β-lactams, are prepared by reaction of the appropriate thiol

with the acid chloride derivative of (**1**).[6] Acid (**1**) has also been used as a precursor to 1-diazo-3-trimethylsilylacetone, which provides cyclopropyl trimethylsilylmethyl ketones upon reaction with alkenes, through reaction of the acid chloride or a mixed anhydride derivatives of the acid (**1**) with ***Diazomethane***.[4]

Silylacetic acids undergo a thermal rearrangement to afford the silyl ester (eq 3). The same migration of the silyl group is observed at lower temperatures when base catalysis is employed.[7]

(3)

Related Reagents.

t-Butyl α-Lithiobis(trimethylsilyl)acetate; ***t-Butyl Trimethylsilylacetate***; ***Dilithioacetate***; ***Ethyl Lithio(trimethylsilyl)acetate***; ***Ethyl Trimethylsilylacetate***.

Trimethylsilylacetone[1]

[5908-40-7] · $C_6H_{14}OSi$ · Trimethylsilylacetone · (MW 130.29)

(reacts with Grignard or organolithium reagents to provide, after elimination, 2-substituted 2-propenes;[2] in combination with fluoride ion, gives chemistry of the corresponding enolate ion;[3] can direct electrophilic substitution to either side of the carbonyl group[3b,4])

Physical Data: clear liquid; bp 74 °C/96 mmHg; *d* 0.8274 g cm^{-3} (26 °C), *n*26D 1.4188.

Preparative Methods: the best procedure for the preparation of trimethylsilylacetone is the reaction of ***Trimethylsilylmethylmagnesium Chloride*** or bromide with ***Acetic Anhydride***.[5] Other useful preparative methods for α-trimethylsilyl ketones involve the reaction of trimethylsilylmethylmagnesium chloride with acid chlorides,[6] or with aldehydes followed by oxidation of the resulting β-hydroxysilane to the ketone.[2e] When the trialkylsilyl group is very large, particularly the triisopropylsilyl group, a rearrangement from the silyl enol ether to the α-silyl ketone is possible.[7]

Handling, Storage, and Precautions: α-trimethylsilyl ketones thermally rearrange to the more stable silyl enol ethers at temperatures above approximately 100 °C and normally within 1 h at 140 °C or above; they hydrolyze to the parent ketone upon treatment with acid or base and are difficult to purify by chromatography due to desilylation; use in a fume hood.

Preparation of 2-substituted α-Alkenes.

The reaction of trimethylsilylacetone with Grignard and organolithium reagents has been employed in the synthesis of 2-substituted propenes via the formation of a β-hydroxysilane, which is then subjected to a Peterson elimination (eq 1).[2] It was also used to prepare β,γ-unsaturated esters, nitriles, and amides (eq 2).[2b]

(1)

(2)

Y = CO_2-*t*-Bu, CN, $CONMe_2$

The reaction of acid chlorides with 2 equiv of a trimethylsilylmethyl organometallic reagent, where the metal can be chloromagnesium, lithium, or, best, dichlorocerium, proved to be an excellent direct synthesis of allylsilanes via the intermediacy of an α-trimethylsilyl ketone (eq 3).[2d] By reaction of α-trimethylsilyl ketones with ***Vinylmagnesium Bromide***, one can prepare 2-substituted 1,3-butadienes (eq 4).[2c,2f]

Reaction with Electrophiles.

The electrophilic substitution of α-silyl ketones gives the same products as those derived from the corresponding silyl enol ether. Thus reaction with ***Bromine*** or ***Thionyl Chloride*** gives the α-bromo (or chloro) ketone, with the halogen replacing the trimethylsilyl group (eq 5).[4a,b]

The Lewis acid-catalyzed reaction with aldehydes results in aldol condensation to give the β-hydroxy ketone with substitution on the side of the trimethylsilyl group as would be the case with the silyl enol ether. One potential advantage of this reaction is the ability to control the regioselectivity through the synthesis of the α-silyl ketone (eq 6).[3b]

Electrophilic reaction with acetals is also possible, as shown with the optically active acetal (eq 7), which gives very high diastereoselectivity.[8] This has been employed in an approach to aklavinone[9] and *cis*-2-substituted 6-methylpiperidines.[4e]

<3% of other diastereomer

Reaction with Fluoride Ion.

The reaction of α-trimethylsilyl ketones with fluoride ion results in attack of the fluoride ion on the trimethylsilyl group and formation of the corresponding enolate ion. This represents an in situ method for regioselective generation of the enolate ion in the presence of the electrophile (eqs 8 and 9). This can be especially advantageous when the more substituted enolate ion is desired.[3]

Reaction with Strong Bases.

Trimethylsilylmethyl ketones that do not carry another α-substituent can be regioselectively deprotonated on the side bearing the trimethylsilyl group (eq 10). This can lead to α,β-unsaturated ketones when the resulting enolate reacts with aldehydes (eq 11).[10]

(11)

The enolate chemistry of α-substituted α-trimethylsilyl ketones can be directed to either side of the ketone. Thus deprotonation with LDA occurs away from the trimethylsilyl side for steric reasons (eq 12), whereas Lewis acid-catalyzed reactions occur on the trimethylsilyl side of the molecule (eq 13).[10]

Trimethylsilylacetonitrile

[18293-53-3] · $C_5H_{11}NSi$ · Trimethylsilylacetonitrile · (MW 113.26)

(α-carbanion is a useful alternative to $LiCH_2CN$ for nucleophilic cyanomethylation; (*Z*)-selective Peterson alkenation)

Physical Data: bp 84-85 °C/54 mmHg,[1] 66 °C/35 mmHg,[2] 65-70 °C/20 mmHg;[3] *d* 0.827 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: liquid; commercially available.

Preparative Methods: from ***Chlorotrimethylsilane***, ***Zinc***, and XCH_2CN, (X = Cl, 61% yield; X = Br, 81% yield).[3]

Handling, Storage, and Precautions: is an organic cyanide and should be handled with due care in a fume hood.

Metalation.

Exposure to ***Lithium Diisopropylamide*** or ***n-Butyllithium*** in ether[3] or THF at -78 °C generates lithiotrimethylsilylacetonitrile [*70980-14-2*], which is stable at -78 to -20 °C.[3-5]

Peterson Alkenation (Cyanomethylenation).

The anion, typically lithiotrimethylsilylacetonitrile, undergoes Peterson alkenations with aldehydes to furnish α,β-unsaturated nitriles, principally as the (*Z*) isomer (eq 1),[6-9] in contrast to the Horner-Emmons-Wittig condensation, which gives predominantly the (*E*) isomer.[9] Use of the boronate-stabilized anion of trimethylsilylacetonitrile, especially in the presence of HMPA, increases the (*Z*) selectivity (eq 1) but no effect is observed in the case of benzaldehyde.[6,7] Acyclic α-chlorocarbonyl compounds[8] exhibit poor (*E*/*Z*) stereoselectivity. Other trialkylsilylacetonitriles (e.g. Ph_3SiCH_2CN, *t*-$BuMe_2SiCH_2CN$)[6,7] exhibit similar (*E*/*Z*) stereoselectivity, but higher homologs of trimethylsilylacetonitrile (e.g. $Me_2PhSiCH(Me)CN$, $Me_2PhSiCH(Et)CN$) give 1:1 (*E*/*Z*) mixtures.[10]

(1)

M = Li, 82%, (*Z*):(*E*) = 7:1
M = B(O-*i*-Pr)$_2$, 90%, (*Z*):(*E*) = 12:1

Michael Addition.

The reaction of α,β-unsaturated aldehydes[3,6] and ketones[11,12] with trimethylsilylacetonitrile proceeds with 1,2- and 1,4-regioselectivity, respectively. A synthesis of (+)-sesbanimide[11,13] highlights the utility of trimethylsilylacetonitrile in a Michael addition to an α,β-unsaturated ester: lithiotrimethylacetonitrile gives exclusively the 1,4-addition product, whereas ***Lithioacetonitrile*** gives mainly the 1,2-addition product. Desilylation of the former adduct results in the product of overall 1,4-addition of lithioacetonitrile.

Reactions with Other Electrophiles.

The anion of trimethylsilylacetonitrile reacts with allylic, propargylic, and benzylic bromides,[14] with some alkyl bromides and iodides,[5,14] with epoxides to afford γ-(trimethylsilyloxy)nitriles,[3] and with Me_3GeCl,[15] Me_3SiCl,[16] and $(Me_3SiO)_2$[17] to afford the expected α-substitution products. Trimethylsilylacetonitrile also reacts with (*n*-Bu)$_3$SnOMe[18] to afford (*n*-Bu)$_3$SnCH$_2$CN.

Cyanomethylation.

Trimethylsilylacetonitrile is a useful synthetic equivalent for the anion of acetonitrile in condensation reactions with carbonyl compounds[19-21] and glycosyl fluorides,[22] leading to β-(trimethylsilyloxy)nitriles (eq 2)[21] and cyanomethyl glycosides, respectively. However, the addition of trimethylsilylacetonitrile to hindered ketones using cyanide catalysis fails;[20b] enolizable ketones may form silyl enol ethers;[19,20b] and the β-(trimethylsilyloxy)nitriles derived from cyclic ketones undergo spontaneous elimination to give α,β-unsaturated nitriles.[19]

Trimethylsilylacetylene

[1066-54-2] · $C_5H_{10}Si$ · Trimethylsilylacetylene · (MW 98.24)

(ethynylation by palladium(0)-catalyzed coupling/condensation with aryl and vinyl halides[1] and triflates,[2] or by nucleophilic attack of the corresponding acetylide on electrophilic centers;[3,4] reacts with alkyl iodides,[5] tin hydrides,[6] and dichloroketene[7] in a regioselective and stereoselective manner)

Alternate Names: trimethylsilylethyne; TMSA.

Physical Data: bp 53 °C; *d* 0.695 g cm^{-3}.

Solubility: sol all organic solvents.

Form Supplied in: colorless transparent liquid; supplied in ampules.

Handling, Storage, and Precautions: once transferred from the ampule to a sample bottle, it can be stored for long periods without loss of purity and material if stored cold. It is a flammable liquid classified as an irritant. Use in a fume hood.

Ethynylations.

All ethynylation processes involve two steps: (a) coupling of the trimethylsilylethynyl group to the substrate either by a palladium(0)-catalyzed reaction or by nucleophilic attack of the derived acetylide on an electrophilic center; and (b) replacement of the trimethylsilyl group with a proton. Although ***2-Methylbut-3-yn-2-ol*** can be used for ethynylation and is a much cheaper reagent than TMSA, the advantage of TMSA is in the mild conditions needed for removal of the trimethylsilyl group. Deprotection of the 2-methyl-2-hydroxybutynyl group requires heating in toluene at >70 °C with NaH[8] or NaOH,[9] whereas replacement of the trimethylsilyl group occurs at room temperature and can be effected with dilute aqueous methanol solutions of NaOH or KOH,[10] with LiOH in aqueous THF,[11] or with mild bases such as K_2CO_3[12] or Na_2CO_3[13] in MeOH and KF in aqueous DMF.[14] The yields usually range from good to high.

Palladium(0)-Catalyzed Coupling Reactions.

Treatment of the title reagent with vinyl (eq 1)[1b] and aryl (eq 2)[1c] halides and triflates (eqs 3 and 4)[2c,d] and an appropriate Pd catalyst affords vinylalkynes in good yield. For halides, the order of reactivity is I > Br >> Cl.[15] Vinyl chlorides undergo this reaction, and one-step diethynylation of dichloroethylenes can be achieved in good yield (eq 5).[16] Aromatic chlorides, however, undergo ethynylation with terminal alkynes only if there is a strong electron-withdrawing group, such as nitro, on the ring.[15]

(1)

(2)

(3)

(4)

(5)

Heteroaromatic and heterocyclic vinyl halides and triflates can also be effectively ethynylated using TMSA (eqs 6 and 7).[17] The product heterocycles can be elaborated into polycyclic compounds (eq 8).[18]

(7)

(8)

Aromatic compounds with nitro groups *ortho* to the alkyne have been converted into indoles (eq 9).[19] Alkynic ketones have been prepared from either the corresponding acyl halides[20] or by carbonylative ethynylation[21] of vinyl halides and triflates with TMSA.

(9)

Generally, the palladium(0)-catalyzed reaction requires a base to deprotonate the terminal alkyne. Often, the solvent for the reaction is an amine which also serves as base. Alternatively, the amine can be used in slightly more than a stoichiometric amount in nonbasic solvents such as THF,[2c] benzene,[16b] or DMF.[1b,22] Sodium alkoxides[22] and acetate[2a] have also been used as bases. Various Pd^{II} and Pd^{0} complexes

are effective for the coupling reaction. In one case, Pd^0-catalyzed coupling of TMSA with a vinyl halide gives appreciable amounts (40-45%) of a fulvene instead of the expected enyne when the reaction is conducted using $(MeCN)_2PdCl_2$ in the absence of CuI (eq 10).[23] With appropriate choice of reaction conditions, however, it is possible to reduce or totally eliminate this fulvene formation (eq 10).

(10)

Reaction of Trimethylsilylacetylides with Electrophiles.

Lithium (Trimethylsilyl)acetylide is easily generated from TMSA and ***n-Butyllithium***[4c,3b] or ***Methyllithium***[24] at low temperatures. The corresponding Grignard reagent can be prepared from TMSA and ***Ethylmagnesium Bromide***. The zinc chloride derivative can be generated by transmetalation of the lithium acetylide.[4a] A cerate derivative has also been described.[25] All of these acetylides add to the carbonyl group of ketones[26] and aldehydes[3,24] to generate alcohols. The tertiary sulfide shown in eq 11 reacts smoothly with zinc acetylides without elimination, a complication that occurs with the more basic Li and Mg acetylides.[4a]

(11)

Radical-Initiated and Transition Metal-Catalyzed Additions.

Some radical and transition metal-catalyzed additions to TMSA are unique when compared with additions to other terminals alkynes, because they show remarkable regioselectivity and/or stereoselectivity. The regioselectivity of a metal-catalyzed addition may be complementary to that of a radical-initiated process (eq 12). For example, rhodium[27] and molybdenum[28] complex-catalyzed additions of trialkyltin or triaryltin hydrides to TMSA give mainly the 1,1-disubstituted ethylenes, whereas radical hydrostannylation through sonication[29] or ***Triethylborane***[6] initiation gives the 1,2-adducts with the (*E*)-isomers predominating. Other terminal alkynes undergo radical or metal-catalyzed hydrostannylation with either poorer or reverse selectivity.

(12)

(*E*)-1,2- (*Z*)-1,2- 1,1-

Et_3B-initiated radical addition of various alkyl iodides to TMSA occurs with high regioselectivity, giving (*Z*)-1-iodo-1-trimethylsilyl-2-alkylethylenes stereospecifically (eq 13).[5]

(13)

(*E*) (*Z*)

R^1 = TMS, R = *i*-Pr, 79% 0:100

R^1 = Ph, R = *i*-Pr, 81% 21:79

Cycloaddition Reactions.

Unlike [2 + 2] additions involving other alkynes, TMSA adds to dichloroketene[7,30] and keteniminium salts[31] in a highly regioselective manner to give cyclobutanones (eqs 14 and 15). The regiochemistry in this cycloaddition is opposite to that predicted from the electronic effects of the trimethylsilyl group and has been explained using MO considerations.[30] The cycloaddition of TMSA to Fischer carbene complexes to provide naphthoquinones has also been reported (eq 16).[32]

(Trimethylsilyl)allene[1]

[14657-22-8] · $C_6H_{12}Si$ · (Trimethylsilyl)allene · (MW 112.27)

(propargylic anion equivalent;[2-4] substrate for ene reaction[5])

Alternate Name: trimethyl-1,2-propadienylsilane.

Physical Data: bp 90-93 °C.

Solubility: sol CH_2Cl_2, benzene, most organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: IR (tf) 2955, 2900, 1935, 1250, 1210, 1055, 840, 800, 750, and 690 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ 0.15 (s, 9H), 4.27 (d, 2H, *J* = 7.7), 4.88 (dd, 1H, *J* = 6.6, 7.7).[4b]

Preparative Methods: two methods have been reported for the preparation of (trimethylsilyl)allene [(TMS)allene] (**1**). Reductive deoxygenation of the tosylhydrazone derivative affords the title compound in 51% yield.[4b] The tosylhydrazone is readily prepared from the corresponding aldehyde, which in turn is accessed by formylation of (trimethylsilyl)ethynylmagnesium bromide with DMF (eq 1).[6] (TMS)allene has also been prepared by flash vacuum pyrolysis of methyl (trimethylsilyl)propargyl ether, which is obtained from silylation of methyl propargyl ether (eq 2).[7]

Purification: distillation at atmospheric pressure.[4b]

Handling, Storage, and Precautions: stable indefinitely when stored under nitrogen in the refrigerator.

Propargylic Anion Equivalent.

(TMS)allene reacts with electrophiles at the C-3 position in an S_E2' process analogous to electrophilic substitution reactions of allyl- and propargylsilanes.[8] For example, upon treatment with trimethylsilyl chlorosulfonate or ***Sulfur Trioxide-1,4-Dioxane***, (TMS)allene yields silyl esters of sulfonic acids (eq 3).[2] (TMS)allene undergoes conjugate addition with α,β-unsaturated acyl cyanides to yield δ,ε-acetylenic acyl cyanides.[3]

Particularly important is the reaction of (TMS)allene with aldehydes and ketones, which provides a convenient route to secondary and tertiary homopropargylic alcohols, respectively. Treatment of (**1**) (1.1-1.5 equiv) with a mixture of carbonyl compound and 1.1-1.5 equiv of ***Titanium(IV) Chloride*** in methylene chloride produces mixtures of homopropargylic alcohols and (trimethylsilyl)vinyl chlorides. Exposure of the crude reaction product to 2.5 equiv of ***Potassium Fluoride*** in DMSO[9] then furnishes the desired homopropargylic alcohols (eq 4).[4]

Carbonyl compound	% Yield
$PhCH_2CH_2CHO$	84
$PhCH_2COMe$	72
Cyclohexanone	89

Several alternative reagents function as propargylic anion equivalents.[10] Homopropargylic alcohols can be prepared by the addition of allenylboronate esters to aldehydes (though not to ketones).[11] Brown has recently reported that 9-allenyl-9-BBN reacts with aldehydes and ketones to produce homopropargylic alcohols in good yields.[12] ***Allenyllithium*** unfortunately combines with carbonyl compounds to afford mixtures of allenic and acetylenic alcohols.[13] Allenylmagnesium bromide reacts with carbonyl compounds to furnish homopropargylic alcohols in poor yields; in some cases, mixtures of allenic and alkynic products are obtained.[12] Diallenyltin dibromide, which is generated by reaction of propargyl bromide with tin metal in the presence of aluminum, reacts with both aldehydes and ketones to afford homopropargylic alcohols in good yield.[14] Alternatively, triisopropylsilyl derivatives of these alkynes can be prepared by the reaction of the lithium derivative of 1-(triisopropylsilyl)propyne with ketones and aldehydes by using the procedure described by Corey and Rucker.[15] Trimethylsilyl analogs of these alkynes have been prepared using the Reformatsky reagent derived from trimethylsilylpropargyl bromide: zinc-mediated condensation of trimethylsilylpropargyl bromide with aldehydes and ketones delivers homopropargylic alcohols (eq 5).[16]

(5)

Synthesis of Silylacetylenes via Ene Reaction.

(TMS)allene undergoes ene reactions with ***4-Phenyl-1,2,4-triazoline-3,5-dione*** and other reactive enophiles to give silylacetylenes.[5]

Related Reagents.

Allenyllithium; ***1-Methyl-1-(trimethylsilyl)allene***; ***Allyltrimethylsilane***; ***Propargylmagnesium Bromide***; ***3-Trimethylsilyl-1-propyne***.

Trimethylsilylallyllithium[1]

[67965-38-2] · $C_6H_{13}LiSi$ · Trimethylsilylallyllithium · (MW 120.22)

(addition to ketones and aldehydes;[2] synthesis of dienes with defined stereochemistry;[3] reaction with alkyl halides,[4] epoxides,[5] and other electrophiles[6])

Alternate Name: [1-(trimethylsilyl)-2-propenyl]lithium.

Physical Data: ^{1}H and ^{13}C NMR solution studies of the TMEDA complex in THF[7a] and the X-ray structure of the TMEDA complex of a closely related reagent have been reported.[7b]

Solubility: sol THF, ether.

Preparative Method: prepared in situ, under an inert atmosphere, by reaction of ***Allyltrimethylsilane*** with ***n-Butyllithium*** or with ***s-Butyllithium***.[1,7a]

Handling, Storage, and Precautions: solutions are inflammable. Preclude contact of the solutions with air and moisture.

Addition to Ketones and Aldehydes.[2]

Trimethylsilylallyllithium (**1**) adds to most aldehydes and ketones to give γ-(*E*)-vinylsilanes (eq 1) and only very small amounts of α-condensation products or Peterson elimination products.[2] The stereoselectivity has been investigated by NMR studies carried out in solution, which show that (**1**) exists exclusively in the *exo* conformation.[7]

(1)

However, other types of silylallyllithium compounds with internal complexing capabilities are suspected to exist in the *endo* conformation under certain conditions. For example, (dialkylaminomethyl)dimethylsilylallyllithiums give the usual γ-(*E*)-vinylsilane products with reasonable selectivity when they react with aldehydes and ketones in toluene. However, if a small amount of 1,2-dimethoxyethane is added to the reagent, the stereoselectivity of the reaction is reversed, giving the γ-(*Z*)-vinylsilane as the major product (eq 2).[8]

DME at -90 °C	7:1	72%
-78 °C	1:10	82%

These γ-condensation products are useful in organic synthesis. For example, the vinylsilane portion of the molecule can be used as an internal nucleophile in cyclization reactions, as demonstrated in the synthesis of substituted aromatic compounds (eq 3).[9] They can also be used as lactone precursors (eq 4), as demonstrated in the synthesis of the steroidal 17-spiro-γ-lactone (**2**).[2]

(2)

The reactivity of the double bond in these hydroxyvinylsilane products is affected by the trimethylsilyl group. The reaction of (**3**) with ***N-Bromosuccinimide*** leads to the formation of a β-bromooxetane at 0 °C or of a diene product at 40 °C (eq 5). The expected formation of the tetrahydrofuran product has not been observed.[2]

(5)

Synthesis of Dienes with Defined Stereochemistry.[3]

The normal γ-regioselectivity in the reaction of (**1**) with ketones and aldehydes can be modified by the use of other metal counter-ions. Thus α-substitution products can be obtained selectively if ***Magnesium Bromide*** or other Lewis acids are added to the reaction media (eq 6). The resulting alcohols are also diastereomerically enhanced. These observations are explained by the formation of a six-membered ring transition state (**4**) where the metal ion M^+ coordinates with the carbonyl oxygen. Other reagents used to control the regio- and stereoselectivity of the reactions of (**1**) with aldehydes are shown in eq 7.[2c,3c-g] The alcohols are useful for the stereospecific formation of dienes by the Peterson alkenation reaction (eq 6).[3a] The same logical approach has been used to obtain (*E*)- or (*Z*)-4-aryl (or alkyl)-(*E*)-1-(trimethylsilyl)-1,3-butadienes from the deprotonation of 1,3-bis(trimethylsilyl)propene, an α-trimethylsilylated equivalent of (**1**), and reaction with benzaldehyde (eq 8).[3b]

*The ratios were inferred from the stereochemistry of the dienes obtained after Peterson eliminations of the α-condensation products

(8)

Reaction with Alkyl Halides, Epoxides, and Other Electrophiles.[4-6]

Trimethylsilylallyllithium reacts with alkyl halides at low temperature, giving mixtures of α- and γ-(*E*) products in ratios that vary with the electrophile and the reaction conditions (eq 9).[4] In these reactions the γ-(*E*)-alkylation product generally predominates. For example, when trimethylsilylallyllithium is formed by deprotonation of allyltrimethylsilane with *n*-butyllithium in the presence of potassium *t*-butoxide in THF, the (*E*)-vinylsilane alkylation product is obtained in better then 85% yield (eq 10). This has been exploited in the synthesis of (*Z*)-9-tricosene epoxide, the sex pheromone of the gypsy moth.[4a]

(9)

(10)

This γ-regioselectivity can be further improved by the use of bulky substituents attached to the silicon atom.[4a,b] In recent years, attempts have been made at developing reagents closely related to trimethylsilylallyllithium that will permit α-alkylation in high regio- and diastereoselectivity. In some instances, significant changes in regioselection can be achieved once the silicon is substituted with alkoxy or aminomethyl groups.[4c,4e] In particular, the use of chiral, lithium-chelating, amino groups attached to silicon as shown in eq 11, has been successfully applied to the regio- and diastereoselective alkylation of allylsilanes.[4c,e] This same approach gives even better results in the synthesis of chiral propargylic alcohols (eq 12).[4d]

(11)

α:γ = 85:15
one diastereomer

(12)

α:γ >98:2 >99% ee

Trimethylsilylallyllithium reacts with epoxides (at -40 °C in THF for 2 h) to give alcohols in good yields. Highest α-selectivity is obtained with smaller monosubstituted epoxides; larger trisubstituted epoxides give γ-products. In unsymmetrical epoxides, attack is on the less hindered side[5a] with the notable exception of trimethylsilyl-substituted ones, where the attack occurs predominantly on the carbon bearing the trimethylsilyl group. This approach has been used to synthesize 1-silyl-substituted 1,4-dienes (eq 13).[5b] Trimethylsilylallyllithium also reacts with many other electrophiles including imines,[6a] carbon dioxide,[6b] substituted naphthalene,[6c] selenocyanogen,[6d] and dimethylformamide.[2a]

(13)

$R^1 = R^2 = R^3 = H$	10:1
$R^1 = R^2 = Me$, $R^3 = H$	1:2
$R^1, R^2 = -(CH_2)_4-$, $R^3 = Me$	1:10

Related Reagents.

The literature contains numerous examples of reagents having different substitutions on the silicon moiety. The introduction of bulky and/or aromatic groups on the silicon atom, for example in (**5**) (R = Ph, *p*-tolyl, vinyl, *t*-Bu),[6b] (**6**),[6b] and (**7**) (R = OMe, Ph, Et, *i*-Pr),[2a,4a,6b,10] has been used to modify the reactivity of the allylic anion. The influence exerted by these groups is mediated through their steric and/or electronic interactions with the allylic anion and with its counter ion. It is not surprising then that the presence of chelating amino or ether

functions on the silicon atom, for example in (**5**) [R = NEt_2, $N(i\text{-}Pr)_2$, $NH(CH_2CH_2NMe_2)$, pyrrolidino, CH_2(methoxymethylpyrrolidine), $CH_2N(CH_2CH_2OMe)_2$], also modifies the reactivity of the allyllithium attached to it.[4c,11] The silylallyllithium reagents are normally obtained by deprotonation of the corresponding allylsilanes. However, γ-deprotonation of vinylsilanes can also be used for the same purposes, as is the case when either (**8**) or (**9**) are used to give the corresponding silylallyllithium reagent.[12] Other reagents (**10**)-(**17**) having heteroatom substituents on the allyl group have also been used.[3b,7b,13-19]

2-Trimethylsilyl-1,3-benzothiazole

[32137-73-8] · $C_{10}H_{13}NSSi$ · 2-Trimethylsilyl-1,3-benzothiazole · (MW 207.40)

(silyl heterocycle that reacts with a variety of electrophiles)

Physical Data: bp 139 °C/15 mmHg; *n*25D = 1.57.

Solubility: sol all organic solvents.

Analysis of Reagent Purity: NMR.

Purification: vacuum distillation.

Handling, Storage, and Precautions: can be stored indefinitely in the refrigerator in the absence of moisture.

Reaction with Carbon Electrophiles.

The ability of this reagent to transfer the benzothiazol-2-yl unit to carbon electrophiles, is demonstrated by reactions with aldehydes, acyl halides, and chloroformates that give trimethylsilyl carbinols, ketones, and esters (eq 1).[1]

The reaction with benzaldehyde is performed under a dry nitrogen atmosphere at 160 °C for 40 h; acyl halides and ***Ethyl Chloroformate*** react under milder reaction conditions. The reaction of 2 equiv of 2-trimethylsilyl-1,3-benzothiazole and ***Phosgene***[2] occurs at 0 °C and provides a bis-heteroaryl ketone; ***Oxalyl Chloride***[2] is converted to the (benzothiazol-2-yl)-substituted diketone. In these reactions the use of the corresponding stannylated derivative leads in several cases to complex product mixtures. The reactivity toward electrophiles is increased in the presence of a catalytic amount of fluoride ion.[3] The easy F^--catalyzed desilylation, promoted by ***Cesium Fluoride*** or SiO_2-supported ***Tetra-n-butylammonium Fluoride***, allows reaction with a wider range of electrophiles such as saturated lactones (eq 2). δ-Valero- and ε-caprolactone react smoothly under F^- catalysis, affording the corresponding keto alcohols from acyl-oxygen bond cleavage. Ring size effects are also seen; reaction of β-propiolactone fails because of ring opening and polymerization, whereas γ-butyrolactone gives only modest conversion yields (15%). With cyclohexen-2-one as an electrophile, conjugated addition of the benzothiazol-2-yl carbanion occurs, with formation of the Michael adduct.

Stereoselective Additions.

The addition of 2-trimethylsilyl-1,3-benzothiazole to α-asymmetric aldehydes proceeds[4] under mild conditions in good chemical yield and with significant stereoselectivity. In particular, the reaction with D-glyceraldehyde gives the *anti*-isomer with 80% diastereomeric purity (eq 3). The diastereoselectivity appears to vary depending on the azole nucleophile. Reaction of 2-lithiobenzothiazole with the same aldehyde (Et_2O, -78 °C) shows a complete lack of stereoselectivity. Unmasking the formyl group, using suitable procedures from the literature,[5a,b] allows 2-trimethylsilyl-1,3-benzothiazole to be used as a formyl anion equivalent in the diastereoselective synthesis of α-

hydroxy carbonyl derivatives.

Synthesis of Heterocyclic-Substituted Tertiary Phosphines.

Electrophilic cleavage of the C-Si bond of 2-trimethylsilyl-1,3-benzothiazole by ***Phosphorus(III) Chloride***, $PhPCl_2$, and Ph_2PCl, affords the tris-, bis-, and mono(benzothiazol-2-yl)phosphines in good yields (eq 4). The procedure involves the electrophilic cleavage of the C-Si bond and formation of a C-P bond.[6] The reactions are conducted neat and the phosphorus derivatives appear quite air-stable even at room temperature. Attempts to prepare tris(benzothiazol-2-yl)phosphines by reaction of the corresponding heteroaryl organolithium reagent and PCl_3 were unsuccessful.

(*E*)-1-Trimethylsilyl-1,3-butadiene[1]

[71504-26-2] · $C_7H_{14}Si$ · (*E*)-1-Trimethylsilyl-1,3-butadiene · (MW 126.30)

(diene for Diels-Alder reactions,[2,3] creating allylsilanes that can be converted to a variety of functionalized cyclohexenes with a shift of the double bond from its original position in the cycloaddition;[3] synthesis of a chiral allylborane;[4] synthesis of allylsilanes[5,6] and trienes[7])

Physical Data: bp 110-115 °C, 70-74 °C/210 mmHg.

Solubility: freely sol all organic solvents.

Analysis of Reagent Purity: NMR: δ ($CDCl_3$) 6.6-4.9 (5H, m), 0.02 (9H, s).[3] UV: λ_{max} (EtOH) 231 nm (ε 22 000).[2]

Preparative Methods: prepared geometrically pure by Wittig[2] or Peterson[3] reactions on (*E*)-3-trimethylsilylpropenal,[8] by pyrolysis of silylated 3-sulfolenes,[9] and by coupling (*E*)-2-trimethylsilylvinyl bromide with ***Lithium Divinylcuprate***.[10] It can also be prepared geometrically impure, but largely (*E*), from ***Allyltrimethylsilane*** by a vinylogous Ramberg-Bäcklund reaction,[11] and from ***1,3-Butadienyl-1-magnesium Chloride*** and ***Chlorotrimethylsilane***.[4]

Handling, Storage, and Precautions: reasonably stable in the absence of air and radical initiators. It should be kept in a stoppered flask or sealed ampule in the presence of hydroquinone. Its toxicity is unknown, but the presence of a trimethylsilyl group is generally benign.

Diels-Alder Reactions.

(*E*)-1-Trimethylsilyl-1,3-butadiene undergoes Diels-Alder reactions with the usual dienophiles, with unimpaired *endo* stereoselectivity, but at a somewhat slower rate than 1,3-butadiene itself (eq 1).[2,3] The regioselectivity with unsymmetrical dienophiles is poor (eq 2).[2,3] The adducts are allylsilanes, which react with electrophiles in the usual way (eqs 3 and 4) to give cyclohexenes with a double bond shifted from the original position.[3]

(1)

(2)

(3)

(4)

Because of the low level of regiocontrol imparted by the silyl group, other substituents on 1-silylated dienes can impart better regiocontrol (eq 5).[3]

(5)

Trimethylsilylallylboranes.

The diene is used as a starting material for the synthesis of the chiral allylborane (**1**) or its enantiomer (eq 6).[4]

(6)

Allylsilanes.

Reduction of the diene with ***Lithium*** and *t*-butanol in liquid ammonia gives ***Crotyltrimethylsilane***,[5] and reaction with Grignard reagents gives longer chain (*E*)-allylsilanes (eq 7).[6]

(7)

Triene Synthesis.

Like other vinylsilanes, 1-trimethylsilyl-1,3-butadiene can be used in a Hiyama coupling reaction with vinyl iodides (eq 8).[7]

3-Trimethylsilyl-3-buten-2-one

[43209-86-5] · $C_7H_{14}OSi$ · 3-Trimethylsilyl-3-buten-2-one · (MW 142.30)

(methyl vinyl ketone homolog[1] useful as a Michael acceptor in annulation reactions,[2,3] γ,δ-unsaturated ketone formation,[4] and Peterson condensations;[5] precursor to a stabilized Diels-Alder diene[6])

Physical Data: bp 72 °C/50 mmHg.

Analysis of Reagent Purity: ^{1}H NMR (CCl_4): δ 6.53 (d, *J* = 2 Hz, 1H, C*H*), 6.18 (d, *J* = 2 Hz, 1H, C*H*), 2.23 (s, 3H, CH_3), 0.14 [s, 9H, Si(CH_3)$_3$]. Analysis by gas chromatography on a 1.85m 3% silicon gum rubber (SE-30) column at 25 °C gives a single peak.

Preparative Methods: prepared by the reaction of ***(1-Bromovinyl)trimethylsilane*** with ***Acetaldehyde***.[1] An alternative synthesis from ***Acrolein*** has been published.[7]

Handling, Storage, and Precautions: shows no tendency to deteriorate when stored under an argon atmosphere at -20 °C.

Annulation.

3-Trimethylsilyl-3-buten-2-one has been employed as a ***Methyl Vinyl Ketone*** homolog in an improved method for the annulation of ketones.[2] Based on work by Stork and Ganem,[3] who employed ***3-Triethylsilyl-3-buten-2-one*** as a Michael acceptor in the Robinson annulation reaction, Suzuki and co-workers[8] prepared a functionalized bicyclic ketone via a silyl enol ether as shown in eq 1. In general, the annulation of 2-alkylcycloketones with methyl vinyl ketone and its homologs produces rather poor yields of the desired cyclized products.

(1)

The conjugate addition of enolate anions to activated 3-trimethylsilyl-3-buten-2-one helped solve another long-standing problem in organic synthesis by permitting the annulation reaction to be carried out in aprotic solvents under conditions where enolate equilibration is avoided. The annulation of thermodynamically unstable lithium enolates with MVK, where equilibration to the more stable enolate occurs prior to Michael addition, often yields a mixture of structural isomers.[9] For example, Boeckman successfully employed 3-trimethylsilyl-3-buten-2-one in a Robinson annulation sequence (eq 2). Thus treatment of cyclohexenone with ***Lithium Dimethylcuprate*** in diethyl ether and then with 3-trimethylsilyl-3-buten-2-one gives the desired Michael adduct, which is converted into the functionalized octalone in 52% overall yield.[10]

(2)

Boeckman originally postulated that the enolate copper bond played a part in the success of this sequence. In 1974, however, Boeckman[11] and Stork and Singh[12] reported simultaneously that lithium enolates can be used under aprotic conditions for regiospecific annulation with 3-trimethylsilyl-3-buten-2-one (eq 3).

(3)

The most general annulation procedure is to first generate an enolate by lithium-ammonia reduction of an enone in the presence of *t*-butanol; the enolate is then trapped as the trimethylsilyl enol ether, which can be examined spectroscopically to establish homogeneity. The enolate is then regenerated with ***Methyllithium*** in dry glyme or diethyl ether at -78 °C prior to the addition of the α-silylated vinyl ketone. In this case, only traces of the linear tricyclic ketone are formed. The trimethylsilyl group helps stabilize the intermediate carbanion formed by conjugate addition, relative to that of the starting ketone, thus facilitating the forward reaction and at the same time discouraging equilibration of the enolate of the starting ketone.

Michael Condensation.

In 1988, Hagiwara and co-workers extended this annulation technology to include the two-fold Michael reaction of kinetic enolates derived from 1-acetylcyclohexenes (eq 4).[13] The kinetic enolates of 1-acetylcyclohexenes are generated from the corresponding trimethylsilyl enol ethers by treatment with MeLi in THF prior to the addition of 3-trimethylsilyl-3-buten-2-one. This one-pot annulation produces the desired decalone as a single isomer in 39% yield.

(4)

1-Alkenyldialkoxyboranes also react with 3-trimethylsilyl-3-buten-2-one in the presence of ***Boron Trifluoride Etherate*** through a facile 1,4-addition to give γ,δ-unsaturated ketones in good yields with high regio- and stereoselectivity (eq 5). Without BF_3 etherate this reaction does not occur and other Lewis acids, such as $AlCl_3$, $TiCl_4$, $SnCl_4$, and $ZnCl_2$, are less effective.[4]

(5)

Michael-Peterson Condensation.

3-Trimethylsilyl-3-buten-2-one also undergoes smooth Michael addition with Grignard reagents (R = Me, *n*-Pr, *i*-Pr, *t*-Bu, Ph), generating magnesium enolates which are then trapped with benzaldehyde to give (*E*)- and (*Z*)-enone isomers after Peterson condensation (eq 6).[5] For example, treatment of the α-silyl vinyl ketone with methylmagnesium iodide followed by reaction with benzaldehyde yields a 7:1 mixture of (*E*)- and (*Z*)-isomers of 3-ethyl-4-phenyl-3-buten-2-one in 45% yield. (*E*)-Alkenes become the major products under thermodynamic control when the condensation with benzaldehyde is carried out at room temperature in diethyl ether. (*Z*)-Isomers are favored as kinetically controlled products at -78 °C in THF.

(6)

Diene Adduct.

3-Trimethylsilyl-3-buten-2-one undergoes a Shapiro reaction to give the 2,3-bis(trimethylsilyl)buta-1,3-diene in 32% yield (eq 7). This compound undergoes Diels-Alder reactions with a number of dienophiles (e.g. maleic anhydride, benzoquinone) in benzene at 60 °C to give silylated cycloaddition adducts.[6]

9-[1-(Trimethylsilyl)-2(*E*)-butenyl]-9-borabicyclo[3.3.1]nonane

[100701-75-5] · $C_{15}H_{29}BSi$ · 9-[1-(Trimethylsilyl)-2(*E*)-butenyl]-9-borabicyclo[3.3.1]nonane · (MW 248.34)

(*anti*-(*Z*)-selective allylation reagent for aldehydes and pyruvates;[2] stereoselective synthesis of (*Z*)-2-butenylsilane[1])

Alternate Name: 9-trimethylsilylcrotyl-9-borabicyclo[3.3.1]nonane.

Physical Data: bp 85-87 °C/0.03 mmHg.

Solubility: sol most organic solvents.

Preparative Methods: prepared as described by Yatagai et al.[1]

Handling, Storage, and Precautions: the neat liquid must be handled and stored in the absence of air. May be kept as CH_2Cl_2 or THF solutions under a N_2 atmosphere. Use in a fume hood.

Anti-(*Z*)-Selective Crotylation of Aldehydes.

The reaction of α-trimethylsilyl-substituted crotyl-9-BBN with aldehydes in the presence of ***Pyridine*** affords *anti*-homoallyl alcohols having (*Z*) double bond geometry (eq 1).[2] The use of 1 or 2 equiv of pyridine is essential to obtain high stereoselectivity. Without pyridine, a complex mixture of products, coupled both at the α- and γ-position of the crotyl reagent, are obtained. Perhaps pyridine coordinates the boron atom to form the corresponding ate complex, which prevents allylic rearrangement of the crotylboron. The reaction with aldehydes proceeds through a six-membered chair transition state in which the trimethylsilyl group adopts an axial position, giving (*Z*) geometry of the double bond in the homoallyl alcohol products. The *anti*-(*Z*)-alkenylsilanes thus obtained are useful for the further elaboration of complex molecules. For example, epoxidation with ***m-Chloroperbenzoic Acid*** proceeds with high diastereoselectivity to give the corresponding epoxides in good yield (eq 2).

(1)

R = Ph, Bu, PhCH=CH

(2)

The reaction of methyl pyruvate with α-silyl-substituted crotyl-9-BBN gives the *anti*-(*Z*)-adduct as a single diastereoisomer in 60% yield along with the α-adduct (35%) (eq 3).[3] ***n-Butyllithium*** is used instead of pyridine for converting the crotylboron reagent to the corresponding ate complex. The *anti*-(*Z*)-adduct can be converted into *cis*-crobarbatic acid methyl ester via the procedure[4] of Magnus (eq 4). The reaction of simple crotyl-9-BBN with pyruvates produces the *anti*-isomers either predominantly or exclusively. The *anti* diastereoselectivity can be improved by increasing the steric bulk of the ester groups; *anti*/*syn* = 73:27 in the case of the methyl ester, whereas the ratio becomes 100:0 in the case of the 2,6-di-*t*-butyl-4-methylphenyl ester. However, as mentioned above, the α-silyl-substituted crotyl-9-BBN produces a 100:0 selectivity even in the case of the methyl ester.

(3)

(4)

α-Trimethylstannylallyl-9-BBN, prepared by a procedure similar to the synthesis of α-trimethylsilylallyl-9-BBN, also exhibits *anti*-(*Z*) diastereoselectivity in reactions with aldehydes and pyruvates, as observed in the case of the silyl reagent.

Synthesis of (*Z*)-2-Alkenylsilanes.

Protonolysis of 2-alkenyl-1-trimethylsilyl-9-BBN affords (*Z*)-2-alkenylsilanes with high stereoselectivity (eq 5).[1] Similarly, protonolysis of 2-alkenyl-1-trimethylstannyl-9-BBN gives (*Z*)-2-alkenylstannanes.

Trimethylsilyl-*t*-butylamine

(R = Me)

[5577-67-3] · $C_7H_{19}NSi$ · Trimethylsilyl-*t*-butylamine · (MW 145.36) (R = Et)

[17940-20-4] · $C_{10}H_{25}NSi$ · *t*-Butyldimethylsilyl-*t*-butylamine · (MW 187.45) (R_3Si = $MePh_2Si$)

[91308-43-9] · $C_{17}H_{23}NSi$ · Methyldiphenylsilyl-*t*-butylamine · (MW 269.50) (R_3Si = *t*-$BuMe_2Si$)

[93066-37-6] · $C_{10}H_{25}NSi$ · Triethylsilyl-*t*-butylamine · (MW 187.45)

(precursor of a strong, hindered base for the regioselective deprotonation of unsymmetrical ketones;[1] the derived lithium amide reacts with chloromethyl ethers to give alkoxymethylamines, which can be converted to substituted *t*-butylamines[2])

Physical Data: R = Me: bp 119 °C; *n*20D 1.4076; d^{20} 0.574 g cm^{-3};[3] pK_a 33.1 (cf. 35 for dialkylamines).[4] R = Et: bp 101 °C. R_3Si = $MePh_2Si$: bp 109 °C/0.4 mmHg. R_3Si = *t*-$BuMe_2Si$: bp 84 °C/27 mmHg.

Solubility: sol most organic solvents; reacts with protic solvents. The derived lithium trialkylsilyl-*t*-butylamides have solubilities similar to, or greater than, those of lithium diisopropylamide, with THF or THF/hexane being excellent solvents.

Form Supplied in: not commercially available; best prepared immediately prior to use.

Preparative Methods: these lithium reagents are prepared by the reaction of the parent amines with ***n-Butyllithium*** in THF/hexane. The parent amines are prepared by the reaction of lithium *t*-butylamide and the corresponding chlorosilanes (eq 1). Trimethylsilyl-*t*-butylamine can be prepared by the reaction of ***t-Butylamine*** and ***Chlorotrimethylsilane*** (eq 2).[2,3]

Purification: best purified by distillation.

Handling, Storage, and Precautions: aminosilanes react readily with protic solvents, especially water, and must be maintained in a dry environment. They are thermally stable. Use in a fume hood.

Deprotonation of Unsymmetrical Ketones.

The lithium amides of hindered amines have been employed with great success in the deprotonation of aldehydes, ketones, esters, lactones, amides, and lactams.[5] In the search for greater regio- and stereoselectivity, more hindered systems have been sought.[6] The trialkylsilyl-*t*-butylamines are readily prepared and their lithium reagents are strong bases with high regioselectivity in the deprotonation of unsymmetrical ketones. The results of a study of the deprotonation of six representative unsymmetrical ketones as outlined in eq 3 are given in Table 1.

Table 1 Regiospecificity of Deprotonation of Unsymmetrical Ketones According to eq 3[a]

2-Methylcyclohexanone	98:2	>99:1	97:3	>99:1	>99:1
Trimethylsilylacetone	81:19	98:2	97:3	>99:1	>99:1

[a] (**3a**) lithium trimethylsilyl-*t*-butylamide; (**3b**) lithium triethylsilyl-*t*-butylamide; (**3c**) lithium *t*-butyldimethylsilyl-*t*-butylamide; (**3d**) lithium methyldiphenylsilyl-*t*-butylamide.

As can be seen from the data presented in Table 1, the lithium trialkylsilyl-*t*-butylamides are excellent hindered bases for the stereospecific deprotonation of unsymmetrical ketones. Of particular interest is the increased ability of these bases to provide the kinetic enolate of phenylacetone, where the thermodynamic enolate benefits from the presence of the phenyl group. Also of interest is the effect of the trimethylsilyl group in ***Trimethylsilylacetone***, where the selectivity is very high with the silylated amides as opposed to that of LDA. This effect of the trimethylsilyl group in the ketone is presumably due to the fact that the steric effect of the silyl group and its longer bond in the silyl amides better matches that of the longer C-Si bond in trimethylsilylacetone.

Preparation of Substituted *t*-Butylamines.

The reaction of lithium trimethylsilyl-*t*-butylamide with chloromethyl ethers gives alkoxymethylamines (eq 4). Organomagnesium, -aluminum, or -zinc reagents react to give nucleophilic displacement of the alkoxy group, providing substituted amines (eqs 5 and 6), which after desilylation can give substituted *t*-butylamines.[2]

Trimethylsilylcopper[1]

Me_3SiCu

[91899-54-6] · C_3H_9CuSi · Trimethylsilylcopper · (MW 136.76)

(nucleophilic silylmetal reagent useful for the regioselective preparation of allyltrimethylsilanes from allylic halides,[2-4] allylic sulfonates,[4] and allylic phosphates[5])

Preparative Method: prepared in situ by adding 1 equiv of ***Copper(I) Iodide*** dissolved in dimethyl sulfide (2.5 M solution) to a vigorously stirred solution of 1 equiv of ***Trimethylsilyllithium***[6] (prepared from hexamethyldisilane and methyllithium-lithium bromide complex) in HMPA at 0-5 °C under argon.[2] The reagent is used immediately in silylation reactions.

Handling, Storage, and Precautions: prepared and used under dry air-free conditions (argon atmosphere, dry solvents, etc.). Since reactions with this reagent employ HMPA (a carcinogen) as solvent, suitable precautions should be taken. Use in a fume hood.

Silylcopper Reagents.[1]

Trimethylsilylcopper (TMSCu) is one of the many silylcopper reagents which were developed in the 1980s and used in the synthesis of allylsilanes from various allylic substrates. Other well-studied silylcopper reagents include $(Me_3Si)_2CuLi$,[7] $(Me_3Si)Cu(CN)Li$,[8] $(PhMe_2Si)_2CuLi$,[7,9-11] and $(PhMe_2Si)_2Cu(CN)Li_2$.[12-14] In all cases, these reagents are prepared in situ from 1 equiv of a silyllithium reagent (Me_3SiLi or $PhMe_2SiLi$) by reaction with 0.5-1.0 equiv of copper(I) iodide or copper(I) cyanide.

Synthesis of Allylsilanes.

TMSCu reacts with a variety of allylic substrates to form allylsilanes stereoselectively and in good to excellent yields. Thus the reagent reacts readily with primary allylic halides,[2-4] sulfonates from secondary and tertiary alcohols,[4] and primary and secondary allylic phosphates[5] to yield a variety of allylsilanes. Representative examples of these reactions are shown in eqs 1-3. This methodology seems particularly attractive for the synthesis of 3-trimethylsilyl-1-alkenes which are presently unavailable by other methods. For example, (*E*)-8-*t*-butyldiphenylsilyloxy-2,6-dimethyl-3-trimethylsilyl-1,6-octadiene, a key intermediate in Corey's synthesis of tricyclohexaprenol, has been prepared from a primary allylic chloride using this methodology (eq 4).[15] Moreover, this method has been used in the preparation of 2,3-bis(trimethylsilyl)alk-1-enes (eq 5)[4] and ***(2-Bromoallyl)trimethylsilane*** (eq 6),[2] a useful intermediate in organic synthesis.[8]

(2)

(3)

(4)

(5)

(6)

The reactions of TMSCu are in marked contrast to the reactions of ***Trimethylsilyllithium*** with similar substrates.[3,4] Whereas treatment of a 1-chloro-2-alkene with TMSCu affords a 3-trimethylsilyl-1-alkene, reaction of TMSLi with these same starting materials yields terminal (*E*)-allylsilanes where the stereochemistry of the double bond is retained in the product (eq 7). Thus a single allylic halide yields either of two regioisomers by proper choice of reaction conditions. With allylic phosphates, TMSCu affords as major product the allylsilane resulting from attack by what is formally an S_N2'-like reaction. With TMSLi, however, the major product is always the isomeric allylsilane having a more substituted internal double bond (eq 8).

TMSCu 87% 98:2
TMSLi 78% 0:100

TMSCu 92% 25:75
TMSLi 69% 100:0

Other silylcuprate reagents have also been used to prepare allylsilanes from allylic halides,[10] acetates,[11,13] and urethanes.[13c,14,16] Moreover, other silylmetal reagents have been used in similar preparations of allylsilanes. For example, silylaluminum reagents have been used to prepare allylsilanes from allylic acetates[17] and allylic phosphates,[18] and silylmanganese reagents react with allylic sulfides and allylic ethers.[19] One advantage that the present methodology has over many other methods is that it utilizes a *trimethyl*silylmetal reagent to afford an allyl*trimethyl*silane. The silyl byproducts obtained in the preparation and reaction of these allylsilanes are volatile and easily separable from the desired product. Many of the other existing methods yield allylsilanes where one or more of the alkyl groups on the silicon is replaced by phenyl.

Related Reagents.

Lithium Cyano(dimethylphenylsilyl)cuprate; ***Trimethylsilyllithium***.

Trimethylsilyldiazomethane[1]

[18107-18-1] · $C_4H_{10}N_2Si$ · Trimethylsilyldiazomethane · (MW 114.25)

(one-carbon homologation reagent; stable, safe substitute for diazomethane; [C-N-N] 1,3-dipole for the preparation of azoles[1])

Physical Data: bp 96 °C/775 mmHg; *n*25D 1.4362.[2]

Solubility: sol most organic solvents; insol H_2O.

Form Supplied in: commercially available as 2 M and 10 w/w% solutions in hexane, and 10 w/w% solution in CH_2Cl_2.

Analysis of Reagent Purity: concentration in hexane is determined by ^1H NMR.[3]

Preparative Method: prepared by the diazo-transfer reaction of ***Trimethylsilylmethylmagnesium Chloride*** with ***Diphenyl Phosphorazidate*** (DPPA) (eq 1).[3]

Handling, Storage, and Precautions: should be protected from light.

One-Carbon Homologation.

Along with its lithium salt, which is easily prepared by lithiation of trimethylsilyldiazomethane ($TMSCHN_2$) with ***n-Butyllithium***, $TMSCHN_2$ behaves in a similar way to ***Diazomethane*** as a one-carbon homologation reagent. $TMSCHN_2$ is acylated with aromatic acid chlorides in the presence of ***Triethylamine*** to give α-trimethylsilyl diazo ketones. In the acylation with aliphatic acid chlorides, the use of 2 equiv of $TMSCHN_2$ without triethylamine is recommended. The crude diazo ketones undergo thermal Wolff rearrangement to give the homologated carboxylic acid derivatives (eqs 2 and 3).[4]

Various ketones react with $TMSCHN_2$ in the presence of ***Boron Trifluoride Etherate*** to give the chain or ring homologated ketones (eqs 4-6).[5] The bulky trimethylsilyl group of $TMSCHN_2$ allows for regioselective methylene insertion (eq 5). Homologation of aliphatic and alicyclic aldehydes with $TMSCHN_2$ in the presence of ***Magnesium Bromide*** smoothly gives methyl ketones after acidic hydrolysis of the initially formed β-keto silanes (eq 7).[6]

$$PhCOCH_2Ph \xrightarrow[\substack{CH_2Cl_2,\ -15\ °C,\ 1\ h \\ 74\%}]{TMSCHN_2,\ BF_3 \cdot Et_2O} PhCOCH_2CH_2Ph \qquad (4)$$

(5)

(6)

$$t\text{-}BuCHO \xrightarrow[\substack{2.\ 10\%\ aq\ HCl \\ 89\%}]{1.\ TMSCHN_2,\ MgBr_2} t\text{-}BuCOMe \qquad (7)$$

O-Methylation of carboxylic acids, phenols, enols, and alcohols can be accomplished with $TMSCHN_2$ under different reaction conditions. $TMSCHN_2$ instantaneously reacts with carboxylic acids in benzene in the presence of methanol at room temperature to give methyl esters in nearly quantitative yields (eq 8).[7] This method is useful for quantitative gas chromatographic analysis of fatty acids. Similarly, *O*-methylation of phenols and enols with $TMSCHN_2$ can be accomplished, but requires the use of ***Diisopropylethylamine*** (eqs 9 and 10).[8] Although methanol is recommended in these *O*-methylation reactions, methanol is not the methylating agent. Various alcohols also undergo *O*-methylation with $TMSCHN_2$ in the presence of 42% aq. ***Tetrafluoroboric Acid***, smoothly giving methyl ethers (eq 11).[9]

(8)

(9)

(10)

(11)

Alkylation of the lithium salt of $TMSCHN_2$ ($TMSC(Li)N_2$) gives α-trimethylsilyl diazoalkanes which are useful for the preparation of vinylsilanes and acylsilanes. Decomposition of α-trimethylsilyl diazoalkanes in the presence of a catalytic amount of ***Copper(I) Chloride*** gives mainly (*E*)-vinylsilanes (eq 12),[10] while replacement of CuCl with rhodium(II) pivalate affords (*Z*)-vinylsilanes as the major products (eq 12).[11] Oxidation of α-trimethylsilyl diazoalkanes with ***m-Chloroperbenzoic Acid*** in a two-phase system of benzene and phosphate buffer (pH 7.6) affords acylsilanes (α-keto silanes) (eq 12).[12]

(12)

(*E*)-β-Trimethylsilylstyrenes are formed by reaction of alkanesulfonyl chlorides with $TMSCHN_2$ in the presence of triethylamine (eq 13).[13] $TMSC(Li)N_2$ reacts with carbonyl compounds to give α-diazo-β-hydroxy silanes which readily decompose to give α,β-epoxy silanes (eq 14).[14] However, benzophenone gives diphenylacetylene under similar reaction conditions (eq 15).[15]

(13)

Silylcyclopropanes are formed by reaction of alkenes with $TMSCHN_2$ in the presence of either ***Palladium(II) Chloride*** or CuCl depending upon the substrate (eqs 16 and 17).[16] Silylcyclopropanones are also formed by reaction with trialkylsilyl and germyl ketenes (eq 18).[17]

[C-N-N] Azole Synthon.

$TMSCHN_2$, mainly as its lithium salt, $TMSC(Li)N_2$, behaves like a 1,3-dipole for the preparation of [C-N-N] azoles. The reaction mode is similar to that of diazomethane but not in the same fashion. $TMSC(Li)N_2$ (2 equiv) reacts with carboxylic esters to give 2-substituted 5-trimethylsilyltetrazoles (eq 19).[18] Treatment of thiono and dithio esters with $TMSC(Li)N_2$ followed by direct workup with aqueous methanol gives 5-substituted 1,2,3-thiadiazoles (eq 20).[19] While reaction of di-*t*-butyl thioketone with $TMSCHN_2$ produces the episulfide with evolution of nitrogen (eq 21),[20] its reaction with $TMSC(Li)N_2$ leads to removal of one *t*-butyl group to give the 1,2,3-thiadiazole (eq 21).[20]

(19)

(20)

X = OMe or SMe X = OMe, 79%; SMe, 84%

(21)

$TMSCHN_2$ reacts with activated nitriles only, such as cyanogen halides, to give 1,2,3-triazoles.[21] In contrast with this, $TMSC(Li)N_2$ smoothly reacts with various nitriles including aromatic, heteroaromatic, and aliphatic nitriles, giving 4-substituted 5-trimethylsilyl-1,2,3-triazoles (eq 22).[22] However, reaction of α,β-unsaturated nitriles with $TMSC(Li)N_2$ in Et_2O affords 3(or 5)-trimethylsilylpyrazoles, in which the nitrile group acts as a leaving group (eq 23).[23] Although α,β-unsaturated nitriles bearing bulky substituents at the α- and/or β-positions of the nitrile group undergo reaction with $TMSC(Li)N_2$ to give pyrazoles, significant amounts of 1,2,3-triazoles are also formed. Changing the reaction solvent from Et_2O to THF allows for predominant formation of pyrazoles (eq 24).[23] Complete exclusion of the formation of 1,2,3-triazoles can be achieved when the nitrile group is replaced by a phenylsulfonyl species.[24] Thus reaction of α,β-unsaturated sulfones with $TMSC(Li)N_2$ affords pyrazoles in excellent yields (eq 25). The geometry of the double bond of α,β-unsaturated sulfones is not critical in the reaction. When both a cyano and a sulfonyl group are present as a leaving group, elimination of the sulfonyl group occurs preferentially (eq 26).[24] The trimethylsilyl group attached to the heteroaromatic products is easily removed with 10% aq. KOH in EtOH or HCl-KF.

(22)

(23)

(24)

(25)

(26)

Various 1,2,3-triazoles can be prepared by reaction of TMSC(Li)N_2 with various heterocumulenes. Reaction of isocyanates with TMSC(Li)N_2 gives 5-hydroxy-1,2,3-triazoles (eq 27).[25] It has been clearly demonstrated that the reaction proceeds by a stepwise process and not by a concerted 1,3-dipolar cycloaddition mechanism. Isothiocyanates also react with TMSC(Li)N_2 in THF to give lithium 1,2,3-triazole-5-thiolates which are treated in situ with alkyl halides to furnish 1-substituted 4-trimethylsilyl-5-alkylthio-1,2,3-triazoles in excellent yields (eq 28).[26] However, changing the reaction solvent from THF to Et_2O causes a dramatic solvent effect. Thus treatment of isothiocyanates with TMSC(Li)N_2 in Et_2O affords 2-amino-1,3,4-thiadiazoles in good yields (eq 28).[27] Reaction of ketenimines with TMSC(Li)N_2 smoothly proceeds to give 1,5-disubstituted 4-trimethylsilyl-1,2,3-triazoles in high yields (eq 29).[28] Ketenimines bearing an electron-withdrawing group at one position of the carbon-carbon double bond react with TMSC(Li)N_2 to give 4-aminopyrazoles as the major products (eq 30).[29]

(27)

(28)

(29)

(30)

Pyrazoles are formed by reaction of $TMSCHN_2$ or $TMSC(Li)N_2$ with some alkynes (eqs 31 and 32)[24,30] and quinones (eq 33).[31] Some miscellaneous examples of the reactivity of $TMSCHN_2$ or its lithium salt are shown in eqs 34-36.[20,31,32]

Trimethylsilyldiethylamine[1]

Me_3SiNEt_2

[996-50-9] · $C_7H_{19}NSi$ · Trimethylsilyldiethylamine · (MW 145.36)

(selective electrophilic trimethylsilyl source;[2] nucleophilic source of the diethylamino group[3])

Physical Data: bp 127-129 °C; *d* 0.767 g cm^{-3}; *n*20D 1.4110.

Solubility: sol pentane, hexane, acetonitrile, ether, THF, acetone.

Form Supplied in: liquid; commercially available.

Analysis of Reagent Purity: NMR, GC.

Preparative Methods: prepared by reaction of diethylamine with ***Chlorotrimethylsilane***,[4] ***Hexamethyldisilazane***,[5] or ***Cyanotrimethylsilane***.[6]

Purification: distillation.

Handling, Storage, and Precautions: stable indefinitely when maintained in a dry environment; destroyed by water.

Trimethylsilyl Group Transfer.

The major use of this reagent has been in the protection of functional groups (particularly hydroxyl) as the trimethylsilyl derivatives. This is illustrated in work on brefeldin A (eq 1)[7] and in the synthesis of prostaglandin E_2 methyl ester (eq 2), where selective protection of two hydroxyl groups occurred.[2] In addition, axial alcohols are converted into trimethylsilyl ethers much faster than equatorial alcohols.[8] Another multifunctional molecule which has been protected is the alcohol produced by cleaving the enone shown in eq 3.[9]

(2)

(3)

Unsaturated γ-butyrolactones are converted into 2-silyloxyfurans,[10] while the corresponding *N*-methyllactams give trimethylsilyloxypyrroles.[11] Amines can be converted into trimethylsilyl derivatives, as in the case of putrescine which forms the *N*,*N*´-bis(trimethylsilyl) compound in 95% yield.[12] Carboxylic acids can be silylated, as in the case of amino acid hydrochloride salts in DMF.[13] The hydroxyl group of acid-sensitive compounds, such as that in eq 4, can be protected so that conversion to the phosphoryl chloride moiety gives trimethylsilyl chloride instead of HCl as a byproduct, thus enabling the other groups to survive.[14]

(4)

Diethylamino Group Transfer.

The diethylamino group can be transferred to electrophilic compounds. ***Oxalyl Chloride*** is converted into the monoamide with 1 equiv of $TMSNEt_2$ at -23 °C and the bisamide with excess silylamine at room temperature;[2] ***Benzeneselenenyl Chloride*** gives the selenenamide.[15] Unsaturated lactones give β-diethylamino lactones with $TMSNEt_2$ and a trace of diethylamine.[10] Conjugated enones give β-amino enol silyl ethers (eq 5),[16] while 1-triphenylsilylpropynone gives simple conjugate addition of diethylamine.[17]

2-Trimethylsilyl-1,3-dithiane

[13411-42-2] · $C_7H_{16}S_2Si$ · 2-Trimethylsilyl-1,3-dithiane · (MW 192.46)

(precursor of dithioketene acetals[1] which are good substrates for both cationic[2] and anionic[3] cyclization processes; the anion reacts with unsaturated ketones and aldehydes to give vinyl dithioketene acetals that can be used as dienes[4] or for the preparation of substituted α,β-unsaturated alkyl ketones;[5] alkylation of the anion provides a general synthesis of acylsilanes[6,7])

Physical Data: bp 54-55 °C/0.17 mmHg.

Solubility: insol H_2O; sol organic solvents.

Form Supplied in: commercially available.

Preparative Method: prepared by alkylation of ***2-Lithio-1,3-dithiane*** with ***Chlorotrimethylsilane*** (eq 1).[1]

Handling, Storage, and Precautions: use in a fume hood.

2-Lithio-2-trimethylsilyl-1,3-dithiane.

This reagent (**1**) is generated from the title compound by treatment with ***n-Butyllithium*** at -78 °C (eq 2)[1] and is the species utilized in many of the following transformations.

Thioketene Acetals.

Anion (**1**) reacts with aldehydes and ketones to provide the corresponding thioketene acetals;[1] aryl and unsaturated aldehydes and ketones are good substrates for this reaction (eqs 3 and 4). Enolizable alkyl ketones also react to provide thioketene acetals (eq 5). Alternative methods for the preparation of these cyclic thioketene acetals involve the use of phosphonate derivatives,[8] mixed zinc-titanium organometallic reagents,[9] and *N*,*N*-dimethyl thioamides.[10] The phosphonate reagents are more nucleophilic than (**1**) and are superior when competitive deprotonation is a problem.

(3)

(4)

(5)

A variation of this method has also been developed for cases in which reactions with (**1**) give poor results (eq 6). Thus the carbonyl compound is treated with ***2-Lithio-1,3-dithiane*** followed by TMSCl to generate the silyl ether. Subsequent addition of a second equivalent of *n*-butyllithium effects alkenation, affording the thioketene acetal in good yield.[11]

(6)

Cationic and Anionic Cyclizations.

The thioketene acetals derived from the reaction of anion (**1**) have found several applications in cyclization methodology. The thioketene acetals can be used as either electrophiles (eq 7)[2] or nucleophiles (eq 8)[3] in a cyclization process which depends on the experimental conditions.

(7)

(8)

Substituted trimethylsilyldithianes can be converted into nucleophiles via fluoride ion desilylation and used in anionic cyclization strategies.[12] This anion not only undergoes condensations with carbonyls (eq 9), but it is also an effective Michael donor (eq 10).

(9)

$n = 1$, 60-76%
$n = 2$, 57-61%

(10)

Unsaturated Dithioketene Acetals.

The reaction of anion (**1**) with various α,β-unsaturated aldehydes and ketones occurs in a 1,2-fashion and provides vinyl thioketene acetals that are acceptable dienes for Diels-Alder reactions (eq 11);[4] dienes of this type are difficult to access using other protocols. This method is also convenient for the introduction of a protected carbonyl group.

(11)

60%

Treatment of acrolein and cyclohexenone with 2-lithio-2-trimethylsilyl-1,3-dithiane provides the corresponding unsaturated dithioketene acetals (eq 12).[5a] Subsequent exposure to *n*-butyllithium followed by MeI produces protected forms of α,β-unsaturated ketones in almost quantitative yield; anion addition occurs distal to the dithiane and alkylation takes place at the dithiane stabilized anion (eqs 13 and 14).[5b] Another interesting application is the use of suitably substituted 2-aryl-2-trimethylsilyl-1,3-dithianes as precursors for *o*-quinodimethanes (eq 15).[13]

(12)

(13)

(14)

(15)

Acylsilanes.[14]

The reaction of anion (**1**) with alkyl halides generates a functionalized dithiane which, when hydrolyzed under mild conditions, provides the corresponding acylsilane (eq 16).[2] More highly substituted acylsilanes have been accessed by initial formation of the dithiane from the aldehyde, followed by deprotonation and silylation with TMSCl (eq 17). Acylsilanes have been used as sterically hindered aldehyde equivalents for regiocontrol in addition reactions (eq 18)[15] and also as precursors for silyl-substituted vinyl triflates (eq 19).[16]

(16)

(17)

(18)

(19)

There are several alternative methods for the formation of acylsilanes; these include the reaction of silyl cuprates with acid halides,[17] palladium-assisted coupling of acyl halides with ***Hexamethyldisilane***,[18] the reaction of thiopyridyl esters with ***Tris(trimethylsilyl)aluminum*** in the presence of Cu^{I} salts,[19] and the hydroboration of trimethylsilyl-substituted alkynes.[20] While all of

these procedures are complementary, the method involving the title compound provides an easy, inexpensive route to acylsilanes.

β-Trimethylsilylethanesulfonyl Chloride

[97203-62-8] · $C_5H_{13}ClO_2SSi$ · β-Trimethylsilylethanesulfonyl Chloride · (MW 200.79)

(protection of primary and secondary amines as their sulfonamides, which are cleaved by fluoride ion[1])

Alternate Name: SESCl.

Physical Data: bp 60 °C/0.1 mmHg; yellow oil.

Solubility: sol most common organic solvents.

Preparative Methods: can be most conveniently synthesized from commercially available ***Vinyltrimethylsilane*** (**1**) (eq 1).[1] Radical addition of sodium bisulfite to the vinyl group catalyzed by *t*-butyl perbenzoate yields the sulfonate salt (**2**) which can be directly converted to SESCl (**3**) with ***Phosphorus(V) Chloride***. The chloride (**3**) can then be purified by distillation. The intermediate sulfonate salt (**2**) is commercially available. The chloride (**3**) can also be prepared in 62% yield from the salt (**2**) using ***Sulfuryl Chloride*** and ***Triphenylphosphine*** (eq 2).[2] A less convenient procedure to synthesize SESCl (**3**) using β-trimethylsilylethylmagnesium chloride (**4**) and sulfuryl chloride has also been developed (eq 3).[1]

Handling, Storage, and Precautions: stable liquid that can be stored at room temperature for weeks. Prone to hydrolysis.

Protection of Amines.

Sulfonamides are among the most stable of amine protecting groups and it is this stability that detracts from their utility, since harsh reaction conditions are often needed for their removal. The advantage of using the β-trimethylsilylethanesulfonyl (SES) protecting group is that the sulfonamide (**5**) can be easily cleaved to regenerate the parent amine (eq 4)[1] in good yields with either ***Cesium Fluoride*** (2-3 equiv) in DMF at

95 °C for 9-40 h, or ***Tetra-n-butylammonium Fluoride*** trihydrate (3 equiv) in refluxing MeCN. The main disadvantage of the latter procedure is an occasional difficulty in separating tetrabutylammonium salts from some amines.

$$TMSF + H_2C{=}CH_2 + SO_2 + RR'NH \quad (4)$$

The sulfonamides can be prepared from a wide variety of primary and secondary amines using sulfonyl chloride (**3**) in DMF containing ***Triethylamine***. For aromatic and heterocyclic amines, ***Sodium Hydride*** is the preferred base. The sulfonamides are generally quite stable and are untouched by refluxing TFA, 6 M HCl in refluxing THF, 1 M TBAF in refluxing THF, $LiBF_4$ in refluxing MeCN, $BF_3.OEt_2$, and 40% HF in ethanol. Table 1 lists a few examples of various amines and their protection as SES sulfonamides and cleavage with CsF in DMF at 95 °C.[1]

Table 1 Synthesis and Cleavage of SES Sulfonamides with CsF, DMF, 95 °C

Amine	% Yield sulfonamide	% Yield of cleavage (time)
	92	82 (29 h)
	92	86 (16 h)
	83	93 (40 h)
	93	91 (9 h)
	88	89 (24 h)

SESCl in Synthesis.[3]

The SES group has been used successfully in the synthesis of glycosides (eq 5).[4] Reaction of (**6**) with SES-sulfonamide and ***Iodonium Di-sym-collidine Perchlorate*** provides the iodo sulfonamide (**7**) in 82% yield. Treatment of (**7**) with (benzyloxy)tributylstannane in the presence of ***Silver(I) Trifluoromethanesulfonate*** provides the β-benzyl glycoside (**8**). Fluoride treatment of (**8**) removes both the silyl ether and the SES

group, giving the amino alcohol (**9**).

The smooth removal of the SES protecting group from pyrrole and pyrrole-containing peptides demonstrates the synthetic potential of this protecting group in heterocyclic chemistry (eq 6).[5] The SES group of (**10**) is removed with TBAF.$3H_2O$ in DMF at room temperature to yield (**11**). Other protecting groups (i.e. mesylate, triflate) cannot be removed without destruction of the substrates.

The *N*-SES group can be incorporated by treating an aldehyde with *N*-sulfinyl-β-trimethylsilylethanesulfonamide (SESNSO) (**13**), which can be made by treating the sulfonamide (**12**) with ***Thionyl Chloride*** and a catalytic amount of *N,N*-dichloro-*p*-toluenesulfonamide (eq 7) (see also ***N***-

Sulfinyl-p-toluenesulfonamide).[6] The *N*-sulfonyl imine can be used in situ in a number of reactions. For example, the *N*-sulfonyl imine from aldehyde (**14**) reacts with 2,3-dimethylbutadiene (eq 8)[7] to give the Diels-Alder adduct (**15**). Treatment of (**15**) with fluoride ion affords the bicyclic lactam (**16**). Also, the *N*-sulfonyl imine derived from isobutyraldehyde and (**13**) reacts with ***Vinylmagnesium Bromide*** to provide the allylic SES-sulfonamide (**17**) in 65% yield (eq 9).[8]

In a total synthesis of the antitumor antibiotic (-)-bactobolin (**18**), the choice of protecting group on the nitrogen was crucial (eq 10).[6] Unlike other protecting groups, the SES group is compatible with a wide variety of transformations and reagents, and is easily removed at the end of the synthesis.

2-(Trimethylsilyl)ethanol

[2916-68-9] · $C_5H_{14}OSi$ · 2-(Trimethylsilyl)ethanol · (MW 118.28)

(protecting reagent for carboxyl, phosphoryl, hydroxyl, and amino groups)

Physical Data: bp 50-52 °C/10 mmHg, 71-73 °C/35 mmHg; *d* 0.825 g cm^{-3}.

Form Supplied in: colorless liquid; 99% purity; widely available.

Preparative Methods: three methods of preparation have been reported: (a) from the treatment of ethyl bromoacetate with ***Zinc*** followed by the reaction with ***Chlorotrimethylsilane***[1] and subsequent reduction of the resultant ***Ethyl Trimethylsilylacetate*** with ***Lithium Aluminum Hydride***[2,3] or ***Borane-Tetrahydrofuran***[4] (eq 1); (b) from the hydroboration/oxidation[5,6] or oxymercuration/demercuration[7] of ***Vinyltrimethylsilane*** (eq 2); and (c) most conveniently, by the reaction of the Grignard reagent formed from ***(Chloromethyl)trimethylsilane*** with ***Paraformaldehyde*** (eq 3).[8]

Handling, Storage, and Precautions: corrosive; irritant.

A variety of methods are available for the protection of carboxylic acids as 2-(trimethylsilyl)ethyl esters.[9] 2-(Trimethylsilyl)ethyl esters are stable to conditions used in peptide synthesis. Deprotection of the ester is readily accomplished by treatment with ***Tetra-n-butylammonium Fluoride*** (TBAF).[9] Hemisuccinates have been prepared indirectly under nonacidic conditions by monoprotection of succinic anhydride as 2-

(trimethylsilyl)ethyl esters followed by esterification (eq 4) and then selective deprotection of the resultant diester (eq 5).[10]

Transesterification of methyl esters to 2-(trimethylsilyl)ethyl esters under mild and neutral conditions takes place in the presence of ***Titanium Tetraisopropoxide*** (eqs 6-8).[11] Deprotection of the 2-(trimethylsilyl)ethyl ester in the presence of an *O*-TBDMS protected secondary hydroxyl group has been achieved (eq 9).[11b] An alternative method for the transesterification uses ***1,8-Diazabicyclo[5.4.0]undec-7-ene/Lithium Bromide*** and 2-(trimethylsilyl)ethanol.[12]

Protection of hydroxyl groups as 2-(trimethylsilyl)ethyl ethers[13a] and 2-(trimethylsilyl)ethyl carbonates[13b] (eq 10) has been utilized as illustrated below. The 2-(trimethylsilyl)ethyl carbonate group can be cleaved under mild conditions using TBAF in dry THF (eq 11).[13b]

Methods for the protection of pyranosides and furanosides as 2-(trimethylsilyl)ethyl glycosides (eq 12) and deprotection using dry ***Lithium Tetrafluoroborate*** in MeCN have been developed (eq 13).[14]

(12)

G = OH, halogen; $n = 0, 1$

(13)

2-(Trimethylsilyl)ethanol has been used as a protecting group in phosphate monoester synthesis and involves the use of 2-(trimethylsilyl)ethyl dichlorophosphite (eq 14).[15] Bis[2-(trimethylsilyl)ethyl] *N*,*N*-diisopropylphosphoramidite has been prepared from dichloro(diisopropylamino)phosphine and 2-(trimethylsilyl)ethanol and used as a phosphitylating agent in the synthesis of phosphotyrosine containing peptides (eq 15).[16]

(14)

2-(Trimethylsilyl)ethoxycarbonyl (Teoc) groups have been used to protect amine functionalities (eq 16).[17] Using a mixture of tetra-*n*-butylammonium chloride and KF.2H_2O deprotects the Teoc group.[18] *N*-Debenzylation and concurrent protection as *N*-Teoc results when tertiary *N*-benzylamines are treated with ***2-(Trimethylsilyl)ethyl Chloroformate***.[19]

A new method for the synthesis of imidazolones involves the replacement of the C-2 nitro group of *N*-protected dinitroimidazoles by nucleophilic addition of the sodium salt of 2-(trimethylsilyl)ethanol (eq 17).[20]

(17)

Reaction of 2-(trimethylsilyl)ethyl benzenesulfenate with halides in the presence of TBAF yields phenyl sulfoxides (eq 18).[21] 2-(Trimethylsilyl)ethyl benzenesulfenate is prepared by the reaction of ***Benzenesulfenyl Chloride*** and the lithium salt of 2-(trimethylsilyl)ethanol.

2-(Trimethylsilyl)ethoxymethyl Chloride[1]

[76513-69-4] · $C_6H_{15}ClOSi$ · 2-(Trimethylsilyl)ethoxymethyl Chloride · (MW 166.75)

(protection of alcohols,[1,2] secondary aryl amines,[3] and imidazole, indole, and pyrrole nitrogens;[4-6] electrophilic formaldehyde equivalent;[7] acyl anion equivalent[8])

Alternate Name: SEM-Cl.

Physical Data: bp 57-59 °C/8 mmHg; *d* 0.942 g cm^{-3}.

Solubility: sol most organic solvents (pentane, CH_2Cl_2, Et_2O, THF, DMF, DMPU, HMPA).

Form Supplied in: liquid; commercially available 90-95% pure; HCl is typical impurity.

Analysis of Reagent Purity: GC.

Preparative Methods: several syntheses have been reported.[2,9-12]

Handling, Storage, and Precautions: water sensitive; corrosive; should be stored in a glass container under an inert atmosphere; a lachrymator; flammable (fp 46 °C).

Reagent for the Protection of Alcohols.

Lipshutz and co-workers introduced the use of SEM-Cl for the protection of primary, secondary, and tertiary alcohols (eq 1).[2] SEM-Cl is now widely employed in organic synthesis for the protection of hydroxyl functionalities (eqs 2 and 3).[13,14]

(1)

(2)

(3)

The resulting SEM ethers are stable under a variety of conditions. Most SEM ethers are cleaved with a fluoride anion source (eqs 4 and 5),[2,15-17] although this fragmentation is generally much less facile than fluoride-induced cleavage of silyloxy bonds. Therefore the selective deprotection of other silyl ethers in the presence of SEM ethers is possible (eq 6).[15] Vigorous conditions with anhydrous fluoride ion are required for the cleavage of some tertiary SEM ethers (eq 7).[18,19]

(4)

(5)

(6)

R = H (7)

The stability of SEM ethers has necessitated the development of a variety of other deprotection methods. SEM protective groups are stable to the acidic conditions used to hydrolyze THP, TBDMS, and MOM ethers (AcOH, H_2O, THF, 45 °C),[2] but can be removed under strongly acidic conditions with ***Trifluoroacetic Acid***.[20] SEM, MTM, and MOM ethers are selectively cleaved in the presence of MEM, TBDMS, and

benzyl ethers with ***Magnesium Bromide*** (eq 8).[21] SEM, MOM, and MEM phenolic protective groups are removed with ***Diphosphorus Tetraiodide*** (eq 9).[22]

(8)

(9)

SEM-Cl has also proven useful in carbohydrate synthesis where the resulting SEM ethers can be cleaved under less acidic conditions than those required for the cleavage of MOM and MEM ethers (eq 10).[23]

(10)

Reagent for the Protection of Acids.

Carboxylic acids can be protected as SEM esters (eq 11).[24,25] Cleavage of the SEM esters occurs with refluxing methanol[24] or magnesium bromide (eq 12).[25,26]

(11)

(12)

Reagent for the Protection of Secondary Amines.

SEM-Cl can be used to protect secondary aromatic amines (eq 13),[3] and is an ideal reagent for the protection of imidazoles, indoles, and pyrroles (eqs 14-16).[4-6,27] Many functional groups are compatible with the introduction and cleavage of SEM amines, and the SEM substituent is unusually stable to further functionalization of the molecule.[4-6,27] Recently, a one-pot method for protection and alkylation of imidazoles employing ***n-Butyllithium*** and SEM-Cl has been developed (eq 17).[28-30]

(13)

(14)

(15)

(16)

(17)

One-Carbon Homologations.

SEM-Cl has functioned as an alternative to the use of ***Formaldehyde*** (eq 18).[7] The enolate of the lactone (**1**) undergoes *C*-alkylation with SEM-Cl, and the resulting SEM substituent can be subsequently treated with trifluoroacetic acid to afford the alcohol (**2**).

(18)

SEM-Cl has been transformed to a formaldehyde carbanion equivalent.[8] SEM-Cl is converted to the ylide upon treatment with ***Triphenylphosphine*** and ***Sodium Hydride***. This ylide reacts with a variety of aldehydes and ketones affording enol ethers (eq 19).[8] Hydrolysis with 5% aqueous HF gives the corresponding aldehyde.

2-(Trimethylsilyl)ethoxycarbonylimidazole

[81616-20-8] · $C_9H_{16}N_2O_2Si$ · 2-(Trimethylsilyl)ethoxycarbonylimidazole · (MW 212.36)

(introduction of the trimethylsilylethoxycarbonyl protecting group[1])

Physical Data: mp 29-30.5 °C;[1] bp 99-100 °C/1 mmHg.[3]

Solubility: insol H_2O; sol benzene, ether, THF, chloroform.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: NMR.[1]

Preparative Method: from ***2-(Trimethylsilyl)ethanol*** and ***N,N´-Carbonyldiimidazole***.[1]

Purification: silica gel chromatography.[1]

Handling, Storage, and Precautions: stable crystalline solid; possibly moisture sensitive.

Protecting Group Formation.

2-(Trimethylsilyl)ethoxycarbonylimidazole (**1**) is a useful reagent for the introduction of the 2-trimethylsilylethoxycarbonyl (Teoc) alcohol protecting group. For example, (**1**) has been used to protect the secondary hydroxyl group of verrucarol (**2**) as the Teoc derivative (eq 1).[1] Note that the apparently low yield (54%) of this reaction is due to the presence of a second reactive hydroxyl group in (**2**). The yield based on consumed (**2**) is a more respectable 81%. Although other examples of the use of (**1**) have not yet been reported, the reagent appears to have significant potential for the protection of alcohols and amines.

Alternative reagents for the introduction of the Teoc group include ***2-(Trimethylsilyl)ethyl Chloroformate*** (**3**; X = Cl),[2] trimethylsilylethyl azidoformate (**3**; X = N_3),[2] trimethylsilylethyl methoxyvinyl carbonate (**4**),[3] trimethylsilylethyl 4-nitrophenyl carbonate (**5**),[4] and the aminoxy carbonates (**6**).[7] Of these, only the 4-nitrophenyl carbonate (**5**) is commercially available. The carbonate (**5**) has been used to block NH groups in amino acids[4,5] and indoles.[6]

(3)

(4)

(5)

(6)

Although (**1**) is not commercially available, it is a stable, crystalline solid which is readily prepared in excellent yield by condensation of commercially available 2-trimethylsilylethanol and carbonyldiimidazole (eq 2).[1] This procedure avoids the use of potentially dangerous phosgene gas which is required for the preparation of the other reagents. Alternatively, (**1**) may be prepared in a somewhat less convenient manner from (**4**).[3] The stability, easy preparation, and reactivity of (**1**) combine to make it an excellent reagent for the introduction of the Teoc protecting group.

2-(Trimethylsilyl)ethyl Chloroformate

[20160-60-5] · $C_6H_{13}ClO_2Si$ · 2-(Trimethylsilyl)ethyl Chloroformate · (MW 180.73)

(introduction of the trimethylsilylethoxycarbonyl (Teoc) protecting group for amines[1-3] or alcohols;[4,5] activation of tertiary amines for dealkylation[6] or ring opening;[7-10] starting material for alternative reagents for introduction of the trimethylsilylethoxycarbonyl protecting group[11])

Physical Data: bp 34 °C/1 mmHg;[6] bp 42-43 °C/4 mmHg;[12] *d* 0.9944 g cm^{-3}.[1]

Solubility: insol H_2O; sol benzene, ether, THF, chloroform.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: NMR.

Preparative Method: prepared from ***2-(Trimethylsilyl)ethanol*** and ***Phosgene***.[6,11,12]

Purification: distillation.

Handling, Storage, and Precautions: moisture sensitive; stable for three months under nitrogen at 0 °C;[6] probably toxic; handle in a fume hood.

Protection of Amines.[1]

2-(Trimethylsilyl)ethyl chloroformate (**1**) is a useful reagent for the introduction of the trimethylsilylethoxycarbonyl (Teoc) protecting group for amines.[1-3] For example, *p*-chloroaniline reacts with (**1**) to form the expected trimethylsilylethyl carbamate (eq 1).[1] The Teoc protecting group is stable to hydrogenation (H_2, ***Palladium on Carbon***) and mild acid or base. It can be removed with fluoride ion or with a strong acid (e.g. ***Trifluoroacetic Acid***). It is possible to selectively cleave a *t*-butyldimethylsilyl (TBDMS) ether in the presence of a trimethylsilylethyl carbamate (eq 2).[3] For a discussion of alternative reagents for the introduction of the Teoc group, see ***2-(Trimethylsilyl)ethoxycarbonylimidazole***.

(1)

(2)

Protection of Alcohols.[4]

2-(Trimethylsilyl)ethyl chloroformate (**1**) is also useful for the introduction of the trimethylsilylethoxycarbonyl (Teoc) protecting group for alcohols.[4,5] The Teoc protecting group is stable to mild acid but it is base sensitive. It can be cleaved with fluoride ion or with ***Zinc Chloride*** or ***Zinc Bromide*** (eq 3).[4]

(3)

Dealkylation or Ring Opening of Tertiary Amines.[6-10]

Under certain conditions, 2-(trimethylsilyl)ethyl chloroformate (**1**) is reactive enough to acylate a tertiary amine. The resulting quaternary ammonium species is a sufficiently good leaving group for one of the carbon-nitrogen bonds to be cleaved by reaction with a suitable nucleophile. This process has been used to debenzylate tertiary amines (eq 4).[6] Subsequent removal of the Teoc group (see above) to afford the free amine results in a net debenzylation of the tertiary amine. Demethylation of tertiary amines is also possible but yields are generally lower.[6] Alternatively, for cyclic tertiary amines, acylation of the nitrogen followed by reaction with a nucleophile can result in a ring-opening reaction (eq 5).[7] In a strained ring system (e.g. an aziridine), acylation of the nitrogen followed by reaction with a nucleophile can result in ring opening even for secondary amines (eq 6).[8]

(4)

Synthesis of Alternative Teoc Reagents.[11]

The chloroformate (**1**) has been used as a starting material for the preparation of alternative reagents for the introduction of the Teoc group (eq 7).[11] For a discussion of additional alternative reagents for the introduction of the Teoc group, see ***2-(Trimethylsilyl)ethoxycarbonylimidazole***.

(Trimethylsilyl)ethynylcopper(I)[1]

[53210-13-2] · C_5H_9CuSi · (Trimethylsilyl)ethynylcopper(I) · (MW 160.78)

(coupling agent for introduction of the (trimethylsilyl)ethynyl group;[2] preparation of mixed cuprates[3])

Alternate Name: copper(I) trimethylsilylacetylide.

Physical Data: orange-red unstable solid.

Solubility: sol THF, THF-HMPA mixtures; insol ether.

Preparative Methods: by treatment of ***Trimethylsilylacetylene*** with ***Copper(I) t-Butoxide***,[2] by addition of $CuBr.SMe_2$ (see ***Copper(I) Bromide***) to a THF solution of ***Lithium (Trimethylsilyl)acetylide***,[4] or by treatment of trimethylsilylacetylene with ***Triethyl Phosphite*** and ***Copper(I) Chloride***.[5]

Handling, Storage, and Precautions: best generated in situ and used immediately.[2] THF solutions are unstable above -20 °C.[2] The solid is unstable, and all such copper(I) acetylides are potentially explosive. Use in a fume hood.

Coupling Agent.

Copper trimethylsilylacetylide is a versatile coupling agent for introduction of the trimethylsilylethynyl group to activated molecules. Due to the instability of the reagent, the Castro coupling reaction cannot be attempted, but additions to acyl chlorides,[2] activated amines,[6] and terminal (methoxy)iodoallenes have been reported.[7] This last reaction proceeds via an S_N2' mechanism, and a similar addition has been observed with α-acetoxy alkynes (eq 1) giving allenic alkynes in high yield.[8] Coupling between copper TMS-acetylide and 1,2-dichloroalkenes has also been demonstrated.[9,10] Coupling of the copper acetylide (generated in situ) to give the biologically important enediyne framework can be achieved using palladium catalysis (eq 2).[10]

(1)

R = Br, 33%; OAc, 98%; OSOMe, 98%

(2)

Mixed Organocuprates.

The trimethylsilylethynyl group acts as a nontransferable dummy ligand (see also ***1-Pentynylcopper(I)-Hexamethylphosphorous Triamide***, ***1-Hexynylcopper(I)***, ***(3-Methoxy-3-methyl-1-butynyl)copper(I)***) when copper trimethylsilylacetylide is converted to a mixed alkyl or vinyl cuprate.[3,11,12] In one report, utilization of a mixed cuprate derived from a terminally lithiated allene allows chemoselective conjugate delivery of the allenic moiety to an α,β-unsaturated system (eq 3), which gives a functionalized and versatile enone system on hydrolysis.[3] The effects of ***Chlorotrimethylsilane*** on such conjugate additions have been studied.[11] On using a mixed cuprate derived from combination with ***n-Butyllithium*** in the presence of TMSCl, smooth and efficient 1,4-butylation ensues (eq 4).[11] The stoichiometry of the TMSCl employed has a marked effect on the reaction profile. Mixed magnesioorganocuprates have also been employed in conjugate addition reactions.[12] The highest yields of the corresponding 1,4-addition products are recovered using a stoichiometry of 3:1 Grignard reagent-copper TMS-acetylide.[12]

Copper Homoenolates.

Magnesium homoenolates, typically generated by addition of ***Vinylmagnesium Bromide*** to an acyltrimethylsilane, undergo conjugate addition to enones (eq 5) in the presence of copper trimethylsilylacetylide, giving easy access to 1,6-diketones.[4,13] The reaction presumably proceeds via a mixed copper homoenolate, with the trimethylsilylethynyl group acting as a nontransferable ligand.

Related Reagents.

3-Trimethylsilyl-2-propynylcopper(I).

N-(Trimethylsilyl)imidazole[1]

[18156-74-6] · $C_6H_{12}N_2Si$ · *N*-(Trimethylsilyl)imidazole · (MW 140.29)

(silylating agent for alcohols and 1,3-dicarbonyl compounds;[2] reaction with esters to give imidazolides; preparation of *O*-trimethylsilyl monothioacetals; aromatization of the A-ring of steroids)

Physical Data: bp 93-94 °C/14 mmHg; fp 5 °C; *d* 0.956 g cm^{-3}.

Form Supplied in: liquid.

Handling, Storage, and Precautions: flammable. Harmful by inhalation, in contact with skin, and if swallowed. Possible carcinogen. Use in a fume hood. When using, wear protective gear and clothing. Handle and store under N_2. Store in a cool dry place.

General Discussion.

N-(Trimethylsilyl)imidazole is a powerful silylating agent for alcohols (eq 1).[2] 1,3-Dicarbonyl compounds, although usually existing mostly in the enol form, are not efficiently silylated by standard methods. *N*-(Trimethylsilyl)imidazole has proved to be an ideal reagent for this transformation (eq 2).[3]

(1)

(2)

N-(Trimethylsilyl)imidazole reacts with phenyl and 2,2,2-trifluoroethyl esters under base catalysis to give acylimidazolides (eq 3).[4] These imidazolides show reactivity similar to acyl chlorides and therefore are useful in synthesis.[5]

(3)

N-(Trimethylsilyl)imidazole is used in the preparation of *O*-trimethylsilyl monothioacetals directly from corresponding carbonyl compounds and thiols (eq 4).[6] The basicity of the medium due to the imidazole generated during the reaction effectively prevents dithioacetalation.

(4)

Aromatization of the A-ring of steroid systems has been achieved by the use of *N*-(trimethylsilyl)imidazole (eq 5).[7]

Trimethylsilylketene[1]

[4071-85-6] · $C_5H_{10}OSi$ · Trimethylsilylketene · (MW 114.24)

(reactive acylating agent for amines and alcohols;[2] building block for synthesis of coumarins;[3] synthesis of α-silyl ketones via the addition of organocerium reagents;[4] treatment with stabilized ylides forms trimethylsilyl-substituted allenes;[2a] cycloaddition with aldehydes affords β-lactones;[5] forms small rings with diazomethane;[6] treatment with *n*-BuLi forms a ketene enolate[7])

Physical Data: [2a,7] bp 81-82 °C; *d* 0.80 g cm^{-3}.

Solubility: sol CH_2Cl_2, $CHCl_3$, CCl_4, THF, diethyl ether, and most standard organic solvents; reacts with alcoholic and amine solvents.

Form Supplied in: colorless oil; not commercially available.

Analysis of Reagent Purity: [8] IR (CCl_4) 2130 cm^{-1}; ^1H NMR (60 MHz, CCl_4) δ 1.65 (s, 1 H), 0.12 (s, 9 H) ppm; ^{13}C NMR (50.3 MHz, $CDCl_3$) δ 179.4, 0.5, -0.2 ppm.

Preparative Methods: most often prepared (eq 1) by pyrolysis of ***Ethoxy(trimethylsilyl)acetylene*** at 120 °C (100 mmol scale, 65% yield).[2a] Recently, pyrolysis of *t*-butoxy(trimethylsilyl)acetylene has been shown to be a convenient alternative for the preparation of trimethylsilylketene (**1**). Thermal decomposition of *t*-butoxy(trimethylsilyl)acetylene causes elimination of 2-methylpropene slowly at temperatures as low as 50 °C and instantaneously at 100-110 °C (30 mmol scale, 63% yield).[8] The main advantage of this method is that it is possible to generate trimethylsilylketene in the presence of nucleophiles, leading to in situ trimethylsilylacetylation (eq 2). Increased shielding of the triple bond prevents problems such as polymerization and nucleophilic attack that occur when the ketene is generated in situ from (trimethylsilyl)ethoxyacetylene. Trimethylsilylketene can also be prepared (eq 3) via the dehydration of commercially available ***Trimethylsilylacetic Acid*** with ***1,3-Dicyclohexylcarbodiimide*** (DCC) in the presence of a catalytic amount of ***Triethylamine*** (100 mmol scale, 63%).[9] Other typical methods used for ketene generation such as dehydrohalogenation of the acyl chloride[10] and pyrolysis of the anhydride[10b,11] have been applied to the preparation of (**1**); however, both methods afford low yields.

(3)

Purification: purified by distillation at 82 °C/760 mmHg.

Handling, Storage, and Precautions: unusually stable for an aldoketene with respect to dimerization and decomposition. Samples stored neat under nitrogen at room temperature show no noticeable decomposition after several months.

Trimethylsilylacetylation of Alcohols and Amines.

Trimethylsilylketene (**1**) has been used as a potent acylating agent for amines and alcohols (eq 4).[2a] It reacts almost instantaneously with hindered amines to form α-silyl amides in quantitative yield. Reaction with alcohols such as *t*-butanol is much slower (CCl_4, 48 h, rt, 80% yield). However, ***Boron Trifluoride Etherate*** strongly catalyzes α-silylacetate formation. Hindered tertiary alcohols that cannot be acylated by standard reagents such as benzoyl chloride, acetyl chloride, and acetic anhydride (even in the presence of DMAP) can be acylated by (**1**). Desilylation can be effected using ***Potassium Fluoride*** in methanol to produce the acetate directly (eq 5).[12] When the addition of alcohols to (**1**) is catalyzed by zinc halides, a high degree of functionality can be tolerated in the substrate, including carbonyl, acetal, thioacetyl, epoxy, and alkenic groups.[2b] In contrast, $BF_3.Et_2O$ catalysis results in partial product desilylation with alcohols containing carbonyl groups and also causes cleavage of acetal groups. Other reactions used to prepare α-silyl acetates including the Reformatsky reaction,[13] *C*-silylation of esters,[14] and silyl migration from acylsilanes[15] are incompatible with many active functional groups. Functionalized α-silyl acetates serve as useful precursors to butenolides (eq 6).[2b]

(4)

(5)

Synthesis of Coumarins via Cyclization-Elimination.

Reaction of (**1**) with *o*-acylphenols affords coumarins in high yields in a one-pot reaction (eq 7).[3] The reaction is applicable to a variety of functionalized aromatic systems. Coumarins form more readily in somewhat higher yield using this procedure as compared to a similar method involving the use of a cumulated phosphorus ylide reagent, ***Ketenylidenetriphenylphosphorane***.[16] Workup and product isolation is easier in view of the triphenylphosphine oxide byproduct formed in the ylide reaction. Other methods used to convert *o*-acylphenols to coumarins include approaches based on Knovenagel[17] and Pechmann[18] reactions. The method described above involves milder conditions and often provides coumarins in higher yields.

One-pot Formation of α-Silyl Ketones.

α-Silyl ketones can be prepared in a one-pot synthesis by the addition of organocerium reagents to (**1**) followed by subsequent quenching with aqueous ammonium chloride or alkyl halides (eq 8).[4] The organocerium reagents can be easily prepared from ***Cerium(III) Chloride*** and an alkyl- or aryllithium. Organolithium reagents are not suitable for this reaction because proton abstraction is preferred resulting only in complicated reaction mixtures of products.[7] A variety of other methods have been reported for the synthesis of α-silyl ketones, including methods based on 1,3-O to C silyl migration from lithiated silyl enol ethers,[19] other types of migration from silicon-containing compounds,[20] isomerization of silicon-containing allyl alcohols,[21] and Si-H insertion reactions of diazo ketones,[22] as well as classical preparations involving carboxylic acid derivatives[23] and the oxidation of β-hydroxy silanes.[21,23] However, most of these methods require multistep procedures and are less convenient.

Preparation of Trimethylsilyl-Substituted Allenes.

Treatment of (**1**) with a stabilized phosphorus ylide, ***(Ethoxycarbonylmethylene)triphenylphosphorane***, affords the silyl substituted allenic ester in 85% yield (eq 9).[2a] These alkenation reactions only occur with stabilized phosphorus ylides; unstabilized ylides reportedly form complex mixtures with trimethylsilylketene.

(9)

Preparation of β-Lactones.

Reaction of (**1**) with saturated aldehydes in the presence of $BF_3.Et_2O$ results in mixtures of both *cis*- and *trans*-2-oxetanones (eq 10). Ketones are reported not to undergo cycloadditions with (**1**).[5c,d] Cycloadditions have been described with both saturated and α,β-unsaturated aldehydes. Distillation is reported to promote a 1,3-shift of the organosilyl group accompanied by ring opening to yield the trimethylsilyl dienoate ester.[5a]

(10)

Recently, a method for the stereoselective preparation of the *cis*-substituted β-lactones using catalytic ***Methylaluminum Bis(4-bromo-2,6-di-t-butylphenoxide)*** has been described (eq 11).[5e] This method is reported to work well for alkyl, aryl, and unsaturated aldehydes. Stoichiometric amounts of catalyst lead to desilylation followed by ring opening to afford (*Z*)-alkenoic acids.

(11)

Reaction with Diazomethane to Form Silylated Cyclopropanes and Cyclobutanones.

The reaction of (**1**) and ***Diazomethane*** results in a mixture of products. Treatment of equimolar amounts of (**1**) with diazomethane at -130 °C leads to (trimethylsilyl)cyclopropanone in moderate yield (eq 12).[6] The product obtained can then react with a second equivalent of diazomethane upon warming to -78 °C, resulting in ring expansion to a mixture of 2- and 3-(trimethylsilyl)cyclobutanones. Alternatively, these isomeric products may be obtained directly with 2 equiv of diazomethane. Treatment of the isomeric (trimethylsilyl)cyclobutanone mixture with methanol makes it possible to obtain pure 3-substituted isomer in 84% yield.[24] This 3-(trimethylsilyl)cyclobutanone derivative can also be formed by a more elaborate route via the regioselective [2 + 2] addition of ***Dichloroketene*** to ***Trimethylsilylacetylene*** followed by hydrogenation and reductive removal of the two chlorine atoms.[25] ***Trimethylsilyldiazomethane*** has also been reported to react with (**1**) to form bis-silyl substituted cyclopropanones.[26]

(12)

Formation of the Ketene Enolate.

Addition of (**1**) to a solution of ***n-Butyllithium*** at -100 °C presumably forms the ketene enolate. Quenching with ***Chlorotrimethylsilane*** then affords the bis-silylketene in high yield (eq 13).[7] Attempts to trap the enolate with other electrophiles have been unsuccessful. Other methods[27] affording bis(trimethylsilyl)ketene have been reported including a very similar method involving deprotonation of (**1**) with ***Triethylamine*** and quenching with ***Trimethylsilyl Trifluoromethanesulfonate***.[28] However, the yield for this reaction is much lower (48%). Other reactions report bis(trimethylsilyl)ketene as a byproduct.[29]

Trimethylsilyllithium

Me_3SiLi

[18000-27-6] · C_3H_9LiSi · Trimethylsilyllithium · (MW 80.15)

(synthesis of β-silyl ketones;[1] homologation of sterically hindered ketones;[2] inversion of alkene stereochemistry[3])

Preparative Method: by the reaction of ***Hexamethyldisilane*** and ***Methyllithium*** in HMPA.

Handling, Storage, and Precautions: should be used immediately after preparation. The red HMPA solution of trimethylsilyllithium is sensitive to air and moisture. HMPA is carcinogenic and should be used only in a well-ventilated hood. Contact with eyes and skin should be avoided.

General Discussion.

Triorganosilyl alkali metal species in which at least one substituent on silicon is an aryl group were prepared by cleavage of the corresponding hexaorganodisilanes by alkali metals in the 1950s; however, the hexaalkyldisilanes are inert to metal cleavage.[4] The generation of trimethylsilyl alkali metal species has more recently been accomplished by the reaction of hexamethyldisilane and potassium methoxide,[3] sodium methoxide,[5] or methyllithium[1] in HMPA. ***Trimethylsilylpotassium*** (TMSK) and trimethylsilylsodium have also been obtained by the reaction of hexamethyldisilane and KH or NaH in HMPA.[6] The most useful method for the generation of trimethylsilyllithium (TMSLi) is the procedure reported by Still.[1] A deep red solution of TMSLi is obtained upon reaction of hexamethyldisilane with methyllithium in HMPA at 0 °C in 15 min (eq 1); however, further reaction leading to a disilane anion is possible (eq 2).[7] The solid state structure of TMSLi has been determined by single crystal X-ray analysis as a hexameric species.[8]

$$\text{TMS-TMS} \xrightarrow[\text{HMPA, 0 °C}]{\text{MeLi}} \text{TMSLi} + Me_4Si \qquad (1)$$

$$\text{TMS-TMS} + \text{TMSLi} \longrightarrow \text{TMS-SiMe}_2\text{Li} + Me_4Si \qquad (2)$$

TMSLi adds to cyclohexenone in THF-HMPA to give exclusively the 1,4-addition product (eq 3).[1] The intermediate enolate may be stereoselectively alkylated at carbon with alkyl halides, or *O*-silylated with ***Chlorotrimethylsilane*** to provide the enol ether. Nucleophilic 1,4-addition to cyclohexenones is quite stereoselective. Reaction of 5-methylcyclohex-2-enone with TMSLi occurs predominantly by axial attack, resulting in a 92:8 ratio of axial to equatorial products.[9] TMSLi also undergoes diastereoselective nucleophilic addition to 1-naphthyloxazolines (eq 4);[10] however, the addition of the silyl nucleophile is not as selective as the addition of simple alkyllithium reagents. The diminished diastereoselection is presumably due to the presence of HMPA required in the generation of TMSLi.

(3)

(4)

R = Bu, E = $MeCO_2Cl$ 94:6
R = TMS, E^+ = MeI 40:60

The β-silyl ketones obtained by 1,4-addition of TMSLi have been employed in the synthesis of alkenic acids by means of a silicon directed Baeyer-Villager oxidation (eq 5).[11] Peracid oxidation of the β-silyl ketone results in formation of the unstable seven-membered ring lactone which undergoes acid-catalyzed ring opening with concomitant stereoselective 1,2-migration of the trimethylsilyl group to provide the stable six-membered ring lactone. Saponification followed by stereoselective alkene generation, either via *anti*-elimination using ***Boron Trifluoride Etherate*** or *syn*-elimination using ***Potassium Hydride***, leads to the *trans*- or *cis*-alkene, respectively. The directed Baeyer-Villager approach has been applied to the stereoselective synthesis of *exo*- and *endo*-brevicomin.[12] The regioselectivity of the β-silyl-directed oxidation is not completely controlled. Quaternary carbons migrate preferentially over a less substituted β-silyl alkyl group.

TMSLi also undergoes direct nucleophilic 1,2-addition to saturated ketones and aldehydes. A novel route for the homologation of sterically hindered ketones which involves the addition of TMSLi to the α-trimethylsilyloxy aldehyde derived from the cyanohydrin of a ketone has been developed.[2] The initial alkoxide undergoes an intramolecular oxygen-to-oxygen silyl migration, leading to a β-hydroxy silane (eq 6). Treatment of the β-hydroxy silane with excess base induces alkene formation by a Peterson alkenation reaction. Hydrolysis of the silyl enol ether product then provides the homologated aldehyde. Reduction of the aldehyde to the hydroxymethyl group provides a key intermediate in the synthesis of aphidicolin (eq 6),[2] stemodin, and stemodinone.[13]

(6)

Stereoselective nucleophilic addition of TMSLi to 2-methylcyclohexanone provides an intermediate for the study of the stereochemistry of the aliphatic Brook rearrangement (eq 7).[14] The reverse Brook rearrangement has provided a method for the synthesis of a variety of (α-hydroxyalkyl)trialkylsilanes which does not require the difficult preparation of trialkylsilyl anions.[15] The method involves nucleophilic addition of readily available ***Tri-n-butylstannyllithium*** to a carbonyl, *O*-silylation, and subsequent O-to-C migration of the silyl group induced by Sn-Li transmetalation (eq 8). The yields of (α-hydroxyalkyl)trimethylsilanes obtained by this procedure are frequently greater than the yields obtained by the direct addition of TMSLi. Direct addition of TMSLi[16] or TMSK[3] to epoxides has also been reported. Due to the stereospecific nature of the Peterson alkenation reaction, the epoxidation and TMSK deoxygenation of an alkene can result in stereospecific inversion of the double bond stereochemistry (eq 9). The epoxidation-deoxygenation sequence has been employed as a method to protect an alkene during catalytic hydrogenation.[16] Allylsilanes may be prepared by the S_N2 displacement of allyl chlorides.[17] The reaction appears to be a direct nucleophilic displacement and does not involve electron transfer processes. TMSLi can also undergo transmetalation to a variety of other organometallic species such as ***Trimethylsilylcopper***. Vinylsilanes can be obtained by the reaction of an alkyne with TMSLi in the presence of Mn^{II} and methylmagnesium chloride.[18] TMSLi has not been used as extensively as the more readily accessible dimethylphenylsilyllithium for generation of other silyl organometallic reagents.[4,19]

Related Reagents.

Dimethyl(phenyl)silane; ***Hexamethyldisilane***; ***Trimethylsilylpotassium***.

Trimethylsilyl Methanenitronate[1]

($R^1 = R^2 = H$, R_3Si = TMS)

[51146-35-1] · $C_4H_{11}NO_2Si$ · Trimethylsilyl Methanenitronate · (MW 133.25) ($R^1 = C_5H_{11}$, $R^2 = H$, R_3Si = TBDMS)

[75157-17-4] · $C_{12}H_{27}NO_2Si$ · *t*-Butyldimethylsilyl 1-Hexanenitronate · (MW 245.49) ($R^1R^2 = (CH_2)_5$, R_3Si = TBDMS)

[75157-19-6] · $C_{12}H_{25}NO_2Si$ · *t*-Butyldimethylsilyl Cyclohexanenitronate · (MW 243.47)

(react with alkenes in a 1,3-dipolar cycloaddition reaction;[1c,3-5] undergo Bu_4NF-mediated diastereoselective carbonyl addition to aldehydes;[6-12] react with alkyllithium reagents to give oximes;[13] oxidative coupling leads to 1,2-dinitro alkanes;[14,15] cross coupling with silyl enol ethers or enamines gives β-nitro carbonyl derivatives;[15] conversion of thiocarbonyl to carbonyl groups;[1c,16] can be converted into carbonyl compounds (cf. Nef reaction)[17])

Alternate Name: [(trimethylsilyl)-*aci*-nitro]methane.

Physical Data: $R^1 = C_5H_{11}$, $R^2 = H$, R_3Si = TBDMS: bp 80-90 °C/0.02 mmHg. $R^1R^2 = (CH_2)_5$, R_3Si = TBDMS: bp 150 °C/0.01 mmHg. A more complete list of silyl nitronates is given by Torssell.[1c]

Solubility: sol pentane and in all nonprotic common organic solvents.

Preparative Methods: a large number of silylation conditions can be applied to primary or secondary nitroalkanes,[1,2] including: R_3SiCl/Et_3N (or Ag^+ or Li_2S), R_3SiOTf, LDA/R_3SiCl, R_3SiCl/DBU,[17a] silylated amides, etc. The first reports were published by Ioffe, Tartakovskii, and their colleagues in the early 1970s.[1] The silyl nitronates are isolated by nonaqueous workup and purified by bulb-to-bulb distillation, with the TBDMS derivatives being much more thermally stable than the TMS derivatives.[2] From crystal structure analyses and NMR studies it is concluded that the silyl group migrates rapidly from one nitronate oxygen to the other and that the more stable configuration of silyl nitronates derived from primary nitroalkanes is (*E*).[2,8]

Handling, Storage, and Precautions: although there are indications that some trimethylsilyl nitronates are thermally unstable,[1c] there have been no reports of violent decompositions. Silyl nitronates are, of course, extremely sensitive to moisture, and they are more resistant to base than to acid. All silyl nitronates should be kept under an inert atmosphere and stored in a freezer.

Reactions of Silyl Nitronates with C-C Bond Formation.

Silyl nitronates are synthetically equivalent to nitrile oxides in [3 + 2] cycloadditions. The [3 + 2] adducts shown in eq 1 lose trialkylsilanol very readily, with formation of Δ^2-isoxazolines.[1c,3-5] Silyl nitronates are somewhat less reactive than nitrile oxides, which is not a disadvantage in intramolecular cycloadditions.[3] The reaction is also applicable to the CF_3-substituted silyl nitronate ($R^1 = CF_3$, $R^2 = H$).[18] Depending upon the method of reduction, either the amino alcohol (**1**) or its epimer (**2**) can be obtained with a diastereoselectivity of ca. 4:1. When the silyl nitronate is derived from a secondary nitroalkane, no silanol elimination can occur; the corresponding isoxazolidines undergo a rearrangement to nitroso silyl ethers such as (**3**).[1d,19] The isoxazolidines derived from primary nitroalkanes are not only precursors to amino alcohols but also to β-hydroxy ketones. Thus the nitrile oxide/silyl nitronate [3 + 2] cycloaddition route constitutes an alternative access to aldols.[1c,20,21] This method becomes especially attractive when rendered enantioselective. Addition of a silyl nitronate from a primary nitroalkane to a chiral acrylamide (such as ***10,2-Camphorsultam***,[4] ***trans-2,5-Dimethylpyrrolidine***,[22] or Kemp-Rebek acid derivatives[5]), silanol elimination, and reductive removal of the auxiliary gives 3-substituted Δ^2-isoxazoline-5-methanols in either enantiomeric form (eq 2).

(1)

R^2 = alkyl, vinyl, phenyl, COR, $CONR_2$, CO_2R

(1) (2) (3)

(2)

The second most important synthetic application of silyl nitronates in C-C bond-forming reactions is their fluoride-mediated addition to aldehydes.[6-12] Silyl nitronates from secondary nitroalkanes lead to free nitro aldols such as (**4**),[8] while those from primary nitro alkanes give silylated products. In contrast to the classical Henry reaction, the silyl variant is highly diastereoselective with aldehydes, furnishing *erythro-O*-silylated nitro aldols (e.g. **5**).[9] It is important that the reaction temperature does not rise above 0 °C, otherwise *threo*/*erythro* equilibration takes place. The same *erythro*-nitro aldol derivatives are available by diastereoselective protonation of silyloxy nitronates (eq 3) (usually the dr is >20:1), while the nonsilylated *threo*-epimers (R^3 = H, dr = 7:3-20:1) are formed by kinetic protonation of lithioxy lithio nitronates in THF/DMPU (eq 4).[9] Other recent modifications of the nitroaldol addition using titanium nitronates[23] or $ClSiR_3$ in situ[24] are less selective. It should also be mentioned that there are recent reports[25] about the enantioselective addition of nitromethane to aldehydes in the presence of rare earth binaphthol complexes.

(4)

Reactions of Silyl Nitronates with Strong Base.[13]

With 2 equiv of an alkyllithium, the nitronates from primary nitroalkanes give oximes with the newly introduced alkyl group attached to the oxime carbon (eq 5). The analogous reaction of silyl nitronates from secondary nitroalkanes produces oximes in which chain extension has occurred in the α-position (eq 6). These reactions take place when alkyllithium is added to 0.1 molar silyl nitronate in THF at dry-ice temperature, with subsequent warming to room temperature before aqueous workup. Probably a nitrile oxide is the intermediate in the first case and a nitroso alkene in the second case. Finally, oxidative cross couplings of silyl nitronates with silyl enol ethers, ketene acetals, or enamines produce β-nitro carbonyl compounds (eq 7) or, by HNO_2 elimination, α,β-unsaturated ketones and esters.[15]

(5)

(6)

(7)

Functionalization Reactions of Silyl Nitronates.

Silyl nitronates can be used for a number of transformations in which the carbon skeleton is not changed. Thus they are intermediates en route from nitroalkanes to ketones (the transform[26] of the Nef reaction). Peroxy acid treatment converts silyl nitronates, which would not survive the classical conditions of the Nef reaction, to ketones[17a] (eq 8). Aldehydes can be obtained analogously, using stannyl nitronates.[17b]

(8)

Silyl nitronates can also be further silylated to the interesting *N*,*N*-bis(silyloxy)enamines (eq 9).[27] In contrast to the *N*,*N*-bis(lithioxy)enamines, the double bond in the bis(silyloxy)enamines appears to have electrophilic rather than nucleophilic reactivity. With primary and secondary amines, α-amino oximes are produced (eq 9)[27] in a kind of S_N' substitution, followed by hydrolytic desilylation. In this manner, the bis(silyloxy)enamine is reacting as a nitroso alkene.

(9)

Conversion of Thioketones to Ketones.[16]

Thioketones generated by a Norrish-type photofragmentation of a sulfenyl acetophenone are trapped in situ by [3 + 2] dipolar cycloaddition with a silyl nitronate (eq 10). Fluoride treatment of the resulting heterocycle produces the ketone.[16b] This transformation is compatible with a variety of functional groups and has been used as part of a synthetic manipulation in which an α-acyl cyclic thioether is converted stereoselectively, with ring enlargement, to a ketolactone (methynolide synthesis).[16a]

(10)

Silyl Nitronate Reactivity Pattern.

As illustrated by the examples described above, silyl nitronates provide a^1 and d^1 acyl and aminoalkyl synthons (**6** and **7**), as well as a^2 α-carbonyl and aminoalkyl synthetic building blocks (**8** and **9**).[1e,28]

(Trimethylsilyl)methanesulfonyl Chloride-Cesium Fluoride

($Me_3SiCH_2SO_2Cl$)

[18143-34-5] · $C_4H_{11}ClO_2SSi$ · (Trimethylsilyl)methanesulfonyl Chloride-Cesium Fluoride · (MW 186.76) (CsF)

[13400-13-0] · CsF · (Trimethylsilyl)methanesulfonyl Chloride-Cesium Fluoride · (MW 151.91)

(source of free sulfene in solution;[1] source of silylated sulfene[8])

Physical Data: $Me_3SiCH_2SO_2Cl$ is a colorless liquid, bp 50-52 °C/0.6 mmHg, 57 °C/1 mmHg; mp 18 °C, *n*20D 1.4700,[3] 1.4680.[7a] See also ***Cesium Fluoride***.

Solubility: acetonitrile is the preferred solvent due to solubility of CsF and absence of hydrogen bonding; $Me_3SiCH_2SO_2Cl$ is soluble in most organic solvents.

Preparative Methods: $Me_3SiCH_2SO_2Cl$ is: (1) formed in 58% isolated yield via reaction of ***(Chloromethyl)trimethylsilane*** with ***Thiourea*** in ethanol followed by concentration and chlorination in water, extraction, and distillation;[2] (2) formed in 63% isolated yield by ***Peracetic Acid*** oxidation of (trimethylsilyl)methanethiol followed by treatment with ***Phosphorus(V) Chloride***;[2] (3) formed in 84% yield through reaction of Me_3SiCH_2Cl with ***Magnesium*** followed by sequential reaction of the Grignard reagent with ***Sulfur Dioxide*** followed by ***Chlorine***;[3] and (4) formed in 53% yield through reaction of tetramethylsilane with ***Sulfuryl Chloride***.[7a]

Handling, Storage, and Precautions: like most sulfonyl chlorides, the title compound hydrolyzes slowly to produce HCl and therefore should be kept dry. The byproduct of hydrolysis is hexamethyldisiloxane. Hydrolysis is very rapid with 5% NaOH solution.[7a]

Formation of Sulfene Adducts.

A widely used procedure for the generation of sulfene involves the treatment of ***Methanesulfonyl Chloride*** with ***Triethylamine***. While adducts of sulfene, generated by this route, can usually be isolated in satisfactory yield, the amine or its acid salt may isomerize or decompose base- or acid-sensitive reaction partners. Furthermore, the interpretation of reaction mechanisms can sometimes be complicated by the presence of the amine. Thus the amine may form a complex with sulfene prior to its reaction with other substrates. In the presence of a fluoride ion source such as CsF, $Me_3SiCH_2SO_2Cl$ undergoes fluorodesilylation to give sulfene which can be trapped with ***Cyclopentadiene*** giving the Diels-Alder adduct 2-thiabicyclo[2.2.1]hept-5-ene 2,2-dioxide in 69% yield (eq 1). The same reaction fails when mesyl chloride-triethylamine is used as a sulfene source. Additional examples of sulfene adducts, including a number of thietane *S*,*S*-dioxides, formed from $Me_3SiCH_2SO_2Cl$ are given in Table 1.[1,2,5,8] This procedure can also be used with homologs of $Me_3SiCH_2SO_2Cl$ such as $Me_3SiCHRSO_2Cl$, $(Me_3SiCH_2SO_2)_2O$, $(Me_3SiCHRSO_2)_2O$, $Me_3SiCH_2S(O)Cl$,[4] and 1-(trimethylsilyl)cyclopropanesulfonyl chloride.[5,6] If $Me_3SiCH_2SO_2Cl$ is treated with triethylamine in the presence of the electron-rich alkene ***Ketene Diethyl Acetal***, then the silylated sulfene trimethylsilylthioformaldehyde *S*,*S*-dioxide ($Me_3SiCH{=}SO_2$) is trapped.[8] The mechanism of hydrolysis of $Me_3SiCH_2SO_2Cl$ in the presence of KF has been studied.[3]

1-Trimethylsilyl-1-methoxyallene[1]

(X = H)

[77129-88-5] · $C_7H_{14}OSi$ · 1-Trimethylsilyl-1-methoxyallene · (MW 142.30) (X = Li)

[82200-98-4] · $C_7H_{13}LiOSi$ · 3-Lithio-1-trimethylsilyl-1-methoxyallene · (MW 148.23)

(precursor to acylsilanes, 2-trimethylsilylfurans, and dihydrofurans)

Physical Data: bp 40-43 °C/28 mmHg.[2]

Solubility: sol THF, ether.

Preparative Method: from methoxyallene by deprotonation with ***n-Butyllithium*** and quenching the allenyl anion with ***Chlorotrimethylsilane***.[3]

Handling, Storage, and Precautions: best stored at -20 °C or below, over anhydrous K_2CO_3. Hydrolysis, desilylation, or polymerization take place in the presence of acid.

α,β-Unsaturated Acylsilanes.

Deprotonation at C-3 of 1-trimethylsilyl-1-methoxyallene (**1**) takes place with *n*-BuLi in THF. Trapping the lithioallene with an alkyl halide, followed by hydrolysis of the methyl enol ether with ***Trifluoroacetic Acid***, leads to the (*E*)-acylsilane (eq 1).[3] Fluorodesilylation with ***Tetra-n-butylammonium Fluoride*** prior to the hydrolysis step produces the corresponding α,β-unsaturated aldehyde.

(1)

Furan and Dihydrofuran Synthesis.

Trapping the 3-lithio derivative of (**1**) with decanal leads to the allenic alcohol (eq 2). Aqueous acid under carefully controlled conditions produces 2-trimethylsilyl-5-nonylfuran.[2] The addition product of the 3-lithio derivative of (**1**) with cyclopentanone undergoes acid-catalyzed conversion to the butenolide (**2**) (eq 3). This unusual transformation apparently takes place through formal loss of Me_3Si^- from a cyclic intermediate.[2]

Deprotonation of (**1**) with ***Lithium Diethylamide*** takes a different course (eq 4). The initially formed allenyl anion isomerizes to the acetylide, which is trapped with ketones or aldehydes to produce propargyl alcohols (**3**).[4] The isomerization is postulated to take place through proton transfer steps mediated by diisopropylamine. This is consistent with the observation that no such isomerization takes place with alkyllithium reagents. The propargyl alcohols (**3**) are converted to methoxydihydrofurans (**4**) with catalytic ***Potassium Hydride*** in DMSO.[4]

R^1	R^2	(3)	(4)
-$(CH_2)_5$-		89%	71%
-$(CH_2)_6$-		86%	77%
C_8H_{17}	H	83%	56%

Related Silanes.

1-Trimethylsilyl-1-(ethoxyethoxy)allene (**5**) undergoes efficient reaction with electrophiles to produce substituted unsaturated acylsilanes (eq 5).[5] The reaction products can be converted to diverse 2-silyloxy-1,3-butadienes. Exposure of (**5**) to ***Boron Trifluoride Etherate*** leads to rearrangement in which an oxonium ion is intercepted at C-2 of the allene (eq 5).[6] This rearrangement proceeds via an intermolecular pathway. Acylstannanes can also be prepared through this method.

(5)

E^+	E	Yield
H_2SO_4	H	65%
PhSeCl	PhSe	73%
SO_2Cl_2	Cl	65%

Epoxidation of *t*-butyldimethylsilyl-1-(ethoxyethoxy)allene (**6**) with ***m-Chloroperbenzoic Acid*** leads to an α-keto acylsilane,[6] presumably through an allene oxide intermediate (eq 6). Deprotonation of (**6**) at C-3 and trapping of the anion with ***Selenium***, followed by ***Iodomethane***, produces an allenyl selenide. The reaction of this material with peracid follows a different course, leading to an acetylenic acylsilane, presumably via [2,3]-sigmatropic rearrangement of an allenyl selenide (eq 6).[7]

Trimethylsilylmethyl Azide[1]

[87576-94-1] · $C_4H_{11}N_3Si$ · Trimethylsilylmethyl Azide · (MW 129.27)

(amination of organometallic compounds; preparation of heterocyclic compounds; precursor of azomethine ylide)

Physical Data: bp 43 °C/43 mmHg; IR ν_{max} 2100 cm^{-1}; ^1H NMR ($CDCl_3$) δ = 0.12 (s, 9H), 2.75 (s, 2H); MS *m/z* 129, 73.

Solubility: sol organic solvents; insol water.

Form Supplied in: colorless liquid.

Preparative Method: obtained in high yield by reaction of ***Sodium Azide*** and ***(Chloromethyl)trimethylsilane*** in DMF[1a] or HMPA[1b] at 80 °C.

Handling, Storage, and Precautions: useful, safe substitute for methyl azide, bp 20 °C, which is explosive. Trimethylsilylmethyl azide is stable to temperatures of at least 120 °C and can be stored in a refrigerator for more than 6 months.

Amination.

Trimethylsilylmethyl azide reacts with aryl Grignard reagents at room temperature to give aniline derivatives in 70-95% yield (eq 1).[1a] An intermediate of the reaction is probably a triazene, which is hydrolyzed by neutral water to yield an amine. Amination of Grignard reagent with other azides (sulfonyl azide and thiomethyl azide) is known, but relatively drastic conditions are required to decompose the intermediate.[2] The azide also reacts with aryllithium compounds to afford amines (eq 2), but yields are generally lower.[1a,3]

(1)

(2)

Azomethine Ylide Precursor.

The azide is readily converted into a precursor of azomethine ylides (eq 3).[4,5] Reactions of the ylides with carbon-carbon multiple bonds and carbonyl group are used in a synthesis of pyrroline and oxazole derivatives (eq 4).[6-8]

Silylmethyl-Substituted Heterocumulenes.

(Trimethylsilylmethyl)iminotriphenylphosphorane is obtained from a one-pot reaction of the azide and ***Triphenylphosphine*** (eq 3). The reactions of the phosphorane with ***Carbon Dioxide*** or ***Carbon Disulfide*** (eq 5) give trimethylsilylmethyl isocyanate or trimethylsilylmethyl isothiocyanate in 68 and 94% yields, respectively.[4]

[3 + 2] Cycloaddition.

The azide reacts with alkynes (eq 6),[1b] phosphaalkynes (eq 7),[9] and isothiocyanates (eq 8)[10] to give [3 + 2] cycloaddition products, which can be used as synthons for the preparation of a large variety of other heterocycles.

Miscellaneous.

The azide is used for the preparation of other heterocyclic compounds. Typical examples are the formations of disilaaziridine (eq 9)[11] and *s*-triazine (eq 10)[12] derivatives.

2-Trimethylsilylmethyl-1,3-butadiene[1]

[70901-64-3] · $C_8H_{16}Si$ · 2-Trimethylsilylmethyl-1,3-butadiene · (MW 140.33)

(isoprenylation reagent;[1] Diels-Alder diene[1])

Physical Data: bp 69-70 °C/80 mmHg.

Analysis of Reagent Purity: ^{1}H NMR.

Purification: by distillation.

Solubility: sol common organic solvents.

Preparative Methods: prepared most conveniently by the coupling reaction of the Grignard reagent prepared from ***(Chloromethyl)trimethylsilane*** with 2-chloro-1,3-butadiene (chloroprene) in the presence of a catalytic amount of $Ni[Ph_2P(CH_2)_3PPh_2]Cl_2$ (91% yield) (eq 1).[2] Alternatively, it can be prepared by the reaction of the same Grignard reagent with allenylmethyl phosphate in 57-73% yield (eq 2).[3] Direct metalation of ***Isoprene*** followed by the reaction with ***Chlorotrimethylsilane*** gives 2-trimethylsilylmethyl-1,3-butadiene in low yield.[4] Thermal isomerization of 1-trimethylsilylmethylcyclobutene to 2-trimethylsilylmethyl-1,3-butadiene has also been reported.[5]

Handling, Storage, and Precautions: can be stored in a glass bottle under nitrogen.

Isoprenylation.

Like other allylic silanes, 2-trimethylsilylmethyl-1,3-butadiene reacts with various electrophilic species such as acetals, acid chlorides, and carbonyl compounds with the aid of a Lewis acid to give the corresponding isoprenylated compounds (eqs 3-6).

(4)

(5)

(6)

The direct reaction of 2-trimethylsilylmethyl-1,3-butadiene with isovaleraldehyde gives (±)-ipsenol (2-methyl-6-methylene-7-octen-4-ol) in rather low yield (30%) (eq 5). However, ipsenol is obtained in 62% overall yield by the reaction of 2-trimethylsilylmethyl-1,3-butadiene with isovaleryl chloride, followed by reduction with ***Diisobutylaluminum Hydride*** (eq 7). Similarly, (±)-ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) is obtained by reduction of myrcenone, prepared by the reaction of 2-trimethylsilylmethyl-1,3-butadiene with 3,3-dimethylacryloyl chloride, in 75% overall yield (eq 8).

(7)

The methyl ether of ipsenol can be prepared by the reaction of 2-trimethylsilylmethyl-1,3-butadiene and isovaleraldehyde dimethyl acetal with ***Iodotrimethylsilane*** catalysis (90%) (eq 9)[6] and from methyl 1-chloro-3-methylbutyl ether (72%).[7] Isoprenylation of carbonyl compounds with 2-trimethylsilylmethyl-1,3-butadiene initiated by a catalytic amount of ***Tetra-n-butylammonium Fluoride*** (TBAF) (eq 10) is the most convenient route to ipsenol and ipsdienol.[8] Reactions with γ-vinylbutyrolactone[9] and *N*-alkylmethyleneiminium salt[10] are also reported.

Diels-Alder Reactions.

2-Trimethylsilylmethyl-1,2-butadiene and ***2-Trimethylstannylmethyl-1,3-butadiene*** undergo facile cycloaddition with dienophiles (eq 11). The reactions of 2-trimethylsilylmethyl- and 2-trimethylstannylmethyl-1,3-butadiene with unsymmetrical dienophiles give the so-called *para* product predominantly, and the selectivity is much higher in the reactions with 2-trimethylsilylmethyl- and 2-trimethylstannylmethyl-1,3-butadiene compared to reactions with isoprene. The *para*/*meta* ratios in the reactions with ***Methyl Acrylate*** (eq 12) are: 70/30 (X = H), 84/16 (X = $SiMe_3$), and 91/9 (X = $SnMe_3$).[11]

(12)

2-Trimethylsilylmethyl-1,3-butadiene undergoes highly regioselective ***Aluminum Chloride***-catalyzed Diels-Alder reactions with dienophiles such as ***Acrolein*** and ***Methyl Vinyl Ketone*** in which the *para* isomers are obtained almost exclusively (eqs 13 and 14). The adducts are converted readily to a variety of naturally occurring mono- and sesquiterpenes (eq 15).[12]

(13)

Formation of π-Allylic Complex Followed by Acyldemetalation.

2-Trimethylsilylmethyl-1,3-butadiene forms a titanium(III) complex by the reaction with ***Dichlorobis(cyclopentadienyl)titanium*** and *n*-PrMgBr. The complex reacts with carboxylic acid chlorides RCOCl (R = alkyl, alkenyl) to give β,γ-unsaturated ketones (eq 16).[13]

(16)

The regioselectivity of nucleophilic additions to the $Co(CO)_3BF_4$ complex has also been examined.[14] Ziegler-Natta polymerization of 2-trimethylsilylmethyl-1,3-butadiene catalyzed by ***Triethylaluminum*** and ***Titanium(IV) Chloride*** gives predominantly *cis*-1,4-polymer. However, anionic polymerization yields a polymer whose microstructure is composed of *cis*-1,4-, *trans*-1,4-, and 3,4-units.[15]

Related Reagents.

Allyltrimethylsilane; ***2-Trimethylstannylmethyl-1,3-butadiene***.

Trimethylsilylmethylcopper[1]

[48003-18-5] · $C_4H_{11}CuSi$ · Trimethylsilylmethylcopper · (MW 150.79)

(organocopper reagent which undergoes smooth S_N2' and addition reactions)

Physical Data: exists in tetrameric form;[2] tetrakis[trimethylsilylmethylcopper(I)] consists of discrete, centrosymmetric, tetrameric units containing a square plane of copper atoms (Cu-Cu 2.42 Å), with the methylene carbons lying in the same plane and bridging the edges.

Solubility: sol THF.

Preparative Method: prepared under an inert atmosphere of argon by addition of ***Trimethylsilylmethylmagnesium Chloride*** (prepared starting from (trimethylsilyl)methyl chloride) to a solution of $LiCuBr_2$ in THF at -65 °C and then stirring for 15 min.

Handling, Storage, and Precautions: air- and moisture-sensitive reagent prepared in situ. Use in a fume hood.

Substitution Reactions.

Trimethylsilylmethylcopper is a suitable reagent to convert α-acetylenic oxiranes, α-allenic oxiranes and α-allenic methanesulfinates, as well as disulfonates, into the corresponding 1,3-substitution products in good yield (80-90%) (eq 1). These reactions proceed with good regiospecificity. The advantage of trimethylsilylmethylcopper over R_2CuM is that RCu generally gives cleaner reaction products, especially when propargylic compounds are the substrates. Trimethylsilylmethylcopper is more effective than R_2CuM in reactions with sulfinates because R_2CuM attacks the sulfinate functionality itself.[3] This conversion consists of two successive 1,3-substitution reactions (eq 2).

(1)

(2)

Addition Reactions.

Trimethylsilylmethylcopper adds smoothly to a variety of activated carbon-carbon triple bonds (eq 3). The adducts are formed predominantly in a stereoselective or even stereospecific *cis*-addition in good yields (70-95%).

Trimethylsilylmethylenedimethylsulfurane

[28872-77-7] · $C_6H_{16}SSi$ · Trimethylsilylmethylenedimethylsulfurane · (MW 148.38)

(vinyl sulfide preparation; preparation of silylcyclopropyl ketones from α,β-unsaturated ketones)

Physical Data: bp 46 °C/7 mmHg.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: from trimethylsilylmethyldimethylsulfonium iodide by treatment with ***n-Butyllithium*** in Et_2O,[1] ***s-Butyllithium*** in THF,[2] or ***Potassium t-Butoxide*** in DMSO.[3]

Purification: distillation at reduced pressure or fractional condensation in a -45 °C trap.

Handling, Storage, and Precautions: undergoes thermal decomposition; best prepared in situ with *s*-BuLi.

General Discussion.

The addition of this ylide to α,β-unsaturated ketones affords silylcyclopropyl ketones in moderate yields (36-65%) (eq 1).[2] The choice of conditions is very important as silylcyclopropanation is observed only with the reagent prepared in situ from trimethylsilylmethyldimethylsulfonium iodide and *s*-BuLi in THF.

(1)

Treatment of aryl or saturated ketones with trimethylsilylmethylenedimethylsulfurane affords vinyl sulfides (eq 2).[2] The use of *t*-BuOK in DMSO leads to desilylation of the vinylsulfonium intermediate, giving a mixture of products depending upon the substrate used.[3] The most predominant product results from elimination of trimethylsilanol followed by a 2,3-sigmatropic rearrangement of the allyl substituted sulfurane intermediate (eq 3).

Trimethylsilylmethyllithium[1]

[1822-00-0] · $C_4H_{11}LiSi$ · Trimethylsilylmethyllithium · (MW 94.18)

(methylenation of carbonyl compounds;[1b] reacts with carboxylic acid derivatives to provide α-silyl ketones;[1d,2] synthesis of allylsilanes[1k,3])

Physical Data: mp 112 °C.

Solubility: sol ethereal solvents; reacts with protic solvents.

Preparative Methods: obtained by reaction of ***(Chloromethyl)trimethylsilane*** with ***Lithium*** metal in an inert solvent.[4] It is also available by displacement of a heteroatom group based on sulfur,[5] silicon,[6] or tin.[7]

Handling, Storage, and Precautions: reacts with protic solvents. It should be prepared and handled in inert solvents under an atmosphere of dry nitrogen or argon.

Peterson Alkenation.

Trimethylsilylmethyllithium (**1**) provides an alternative to a Wittig approach for the preparation of methylene compounds from carbonyl precursors.[1b,c,7] In some cases the use of (**1**) is superior to the Wittig approach.[8] Condensation of (**1**) with a carbonyl compound results in the formation of a β-hydroxysilane. Elimination to the alkene can be accomplished by use of acidic or basic conditions (eq 1).[1a,b,9] ***Acetyl Chloride*** or ***Thionyl Chloride*** can also be used to accomplish this elimination.[10] A wide variety of aldehydes and ketones have been used as substrates in this reaction.[1b] The use of ***Cerium(III) Chloride*** has been advocated with reagent (**1**) to favor nucleophilic addition with enolizable carbonyl compounds. The use of the lithium agent (**1**) gives superior yields compared to the use of ***Trimethylsilylmethylmagnesium Chloride*** with cerium.[11]

The carbonyl compound can also contain additional functionality.[1b,12] Thus, treatment of an α,β-epoxy ketone with excess lithium reagent (**1**) provides the allyl alcohol (**2**) (eq 2).[13] The use of an α-phenyl selenoaldehyde as electrophile allows either an allyl selenide or a β-silyl aldehyde to be obtained, depending upon the reaction conditions used with the hydroxysilane (eq 3).[14] With α,β-unsaturated ketones, the lithium reagent (**1**) adds in the 1,2-sense; the Grignard analog can provide 1,4-addition.[15] The cuprate derived from (**1**) undergoes the expected reactions for this class of compounds, such as 1,4-addition.[16]

Reaction with Carboxylic Acid Derivatives.

Reaction of (**1**) with carboxylic acid derivatives provides β-silyl ketones (**3**) (eq 4). The reaction yield is very dependent upon the presence of α-hydrogens in the substrate; lower yields are obtained when deprotonation can occur at this center.[2] The reaction occurs with esters, lactones, acid chlorides, and the parent carboxylic acids.[7,17] The resultant β-silyl ketones can be desilylated by simple hydrolysis,[2] or used as a substrate in a Peterson alkenation approach to enones.[1b] The use of a cerium reagent with the acid chloride has been advocated for the preparation of allylsilanes.[18]

Other Electrophiles.

A mixed higher order cuprate derived from (**1**) allows for the stereoselective preparation of allylsilanes through an epoxide ring opening (eq 5); use of a lower order cuprate results in low yields and mixtures of products.[3]

The organolithium reagent (**1**) also reacts with a wide variety of other electrophiles, including silyl chlorides to provide bis(silyl)methane derivatives,[4a,19] and nitriles to provide β-silyl amines after in situ reduction of the intermediate imine derivative.[20] α-Silyl epoxides are opened to provide the substituted vinylsilane.[21] Reaction of (**1**) with arenesulfonyl fluorides provides α-silyl sulfones,[16c] key intermediates for the preparation of vinyl sulfones.[5b,c,22] Reaction of the lithium reagent (**1**) with ***Aluminum Chloride*** followed by a vinyl triflate results in formation of an allylsilane (eq 6).[23] With ***Carbon Monoxide*** as an electrophile with (**1**), a rapid entry to acylsilanes, or silyl enol ethers by subsequent reaction with ***Chlorotrimethylsilane***, can be realized.[24] The alkyllithium (**1**) is the precursor to a wide variety of organometallic compounds that contain the trimethylsilylmethyl ligand.[25]

Analogs.

The displacement of a heteroatom to introduce the lithium allows for a wide range of substituted analogs of the reagent (**1**) to be prepared.[1b,5,26] The presence of an aromatic group on the same carbon atom as the silyl moiety allows for direct deprotonation by butyllithium to form the lithium reagent.[27] Higher alkyl analogs of (**1**) are also available by the addition of an alkyllithium to a vinylsilane.[1a,10,27,28] All of these higher homologs react with carbonyl compounds and other electrophiles, as expected.[1b,d]

Related Reagents.

Bis(trimethylsilyl)methane; ***(Diisopropoxymethylsilyl)methylmagnesium Chloride***; ***Trimethylsilylmethylmagnesium Chloride***; ***(Trimethylstannylmethyl)lithium***.

Trimethylsilylmethylmagnesium Chloride[1]

[13170-43-9] · $C_4H_{11}ClMgSi$ · Trimethylsilylmethylmagnesium Chloride · (MW 147.00)

(methylenation of carbonyl compounds;[1b,2] provides a variety of methods to prepare allylsilanes[1k])

Solubility: sol ethereal solvents; reacts with protic solvents.

Preparative Method: from ***(Chloromethyl)trimethylsilane*** and ***Magnesium*** in an ethereal solvent.[3,4]

Handling, Storage, and Precautions: this Grignard reagent reacts with protic solvents.

Peterson Alkenation.

Trimethylsilylmethylmagnesium chloride (**1**) reacts with carbonyl compounds to give β-hydroxysilanes (**2**).[2,4,5] These silanes can then be eliminated to provide an alkene under acidic or basic conditions, such as with ***Sodium Hydride*** or ***Potassium Hydride*** (eq 1).[1a,1b,5,6] The elimination can also be accomplished by ***Acetyl Chloride*** or ***Thionyl Chloride***.[7] For the introduction of *exo*-methylene groups, reagent (**1**) has been found to be superior to a Wittig approach;[8] the silicon reagent reacts rapidly and the byproduct is simple to remove.[1b]

(1)

This methodology has found application in the carbohydrate field for homologation of a saccharide,[9] as other functional groups can be tolerated.[1b,10] The resultant alkene can be functionalized in a wide variety of ways.[11] The use of ***Paraformaldehyde*** as electrophile provides a simple method to ***2-(Trimethylsilyl)ethanol***.[12]

Many of the uses of the Grignard reagent (**1**) are complementary to those of ***Trimethylsilylmethyllithium***, although the cerium reagent derived from the lithium analog provides higher yields with enolizable aldehydes and ketones.[13]

With α,β-unsaturated carbonyl compounds the Grignard reagent reacts in a 1,2-manner,[14] although 1,4-addition can be observed in certain cases.[15] The resultant β-hydroxysilane from a 1,2-addition can be isomerized to the β-ketosilane with a rhodium catalyst.[16] In the presence of copper(I), the Grignard reagent (**1**) reacts in a 1,4-manner with α,β-unsaturated carbonyl compounds.[15,17]

The use of substituted carbonyl compounds allows for the formation of functionalized alkenes; for example, α,β-epoxy ketones afford the monoepoxide of a diene.[18] The successive treatment of α-chlorocarbonyl compounds with (**1**) and ***Lithium*** powder provides a regioselective entry to allylsilanes (eq 2).[19]

(2)

Reagent (**1**) does also react with imines that, in turn, can be generated in situ.[20]

Reaction with Carboxylic Acid Derivatives.

In addition to carbonyl compounds, reagent (**1**) also reacts with carboxylic acid derivatives.[4] Thus lactones provide hydroxy allylsilanes (**3**) (eq 3).[21]

(3)

(3)

Reaction of excess (**1**) with esters provides the tertiary alcohol in an analogous manner,[1d] and subsequent elimination provides the allylsilane.[22] The addition of the second equivalent of (**1**), however, is dependent on the steric requirements of the intermediate β-silyl ketone.[23] The addition of ***Chlorotrimethylsilane*** to the reaction mixture has been advocated as higher yields of the resultant allylsilane are obtained.[24] The use of ***Cerium(III) Chloride*** with Grignard reagent (**1**) promotes nucleophilic attack on esters, and the allylsilanes can be obtained in high yield (eq 4).[25] The yields seem to be higher than for the analogous reaction between an acid chloride and the cerium reagent prepared from trimethylsilylmethyllithium.[26] 1,2-Addition is observed with α,β-unsaturated esters.[25] Other functional groups, such as acetals, thioacetals, halogens, hydroxy, acetates, and sulfides, can be incorporated at the α-position of the ester group without detrimental effects.[27]

(4)

Reaction with diketene in the presence of a nickel catalyst gives 3-(trimethylsilylmethyl)but-3-enoic acid (**4**) (eq 5).[28]

(5)

(4)

The Grignard reagent (**1**) does react with acid chlorides to provide ketones after hydrolytic workup.[2] The use of a copper(I) catalyst allows isolation of β-silyl ketones (eq 6).[29]

(6)

β-Silyl ketones are hydrolytically unstable and can be converted to the desilylated ketone by simple acid or base treatment,[30] or used in a Peterson alkenation reaction to provide enones.[1b,29a] They are also precursors to silyl enol ethers by rearrangement.[29c,31] Reaction of the β-silyl ketone with a vinyl Grignard reagent provides a rapid entry to 2-substituted 1,3-dienes by a Peterson protocol.[32]

Reaction of (**1**) with ***Carbon Dioxide*** provides ***Trimethylsilylacetic Acid***,[33] while treatment of (**1**) with ***Ethyl Chloroformate*** gives ***Ethyl Trimethylsilylacetate***.[34] The use of ethyl oxalyl chloride as substrate for (**1**) provides a simple preparation of ethyl 2-(trimethylsilylmethyl)propenoate.[35] Condensation of (**1**) with benzonitrile resulted in isolation of acetophenone (64%) and desoxybenzoin (45%).[4]

Reaction with Alkyl Halides.

The Grignard reagent (**1**) can be alkylated by allyl halides to afford the homoallylsilane.[4,36] The use of a nickel(II) catalyst facilitates coupling of the Grignard reagent (**1**) to vinyl halides[37] and aryl halides, triflates and *O*-carbamates[38] and provides a useful method for the preparation of allyl- and benzylsilanes (eq 7). Palladium catalysis is also effective to couple (**1**) with vinyl halides.[37b,39]

(7)

Reaction with Sulfur Compounds.

In a similar coupling reaction to those of alkyl halides, (**1**) reacts in the presence of a nickel catalyst with allylic dithioacetals to yield 1-(trimethylsilyl)butadienes (eq 8).[40]

(8)

Dithioacetals derived from alkyl aryl ketones react with the Grignard reagent (**1**) in the presence of a nickel catalyst.[41,42] The use of an orthothioester as substrate in place of a thioacetal provides 1,3-bis(trimethylsilyl)propenes as a mixture of the (*E*)- and (*Z*)-isomers.[43] With α-oxoketene dithioacetals (**5**), the Grignard reagent (**1**) reacts, in the presence of ***Copper(I) Iodide***, to provide 1-trimethylsilyloxy-3-thiadienes (eq 9).[44]

(9)

Reaction with Other Electrophiles.

Reaction occurs between (**1**) and epoxides to yield γ-hydroxysilanes.[45] Michael addition is observed with nitroalkenes; the silyl group can then promote a Nef reaction to afford β-silyl ketones (eq 10).[46]

(10)

With aromatic nitro compounds, nucleophilic addition of (**1**) occurs on the aromatic nucleus (eq 11).[47]

(11)

A nickel catalyst allows reaction between (**1**) and an enol phosphate,[48] silyl enol ether,[49] or substituted dihydrofurans[50] and dihydropyrans[51] to afford allylsilanes. Additional functionality can be tolerated in the substrate.[52]

Coupling of (**1**) with propargylic tosylates, mesylates, or acetates in the presence of copper(I) leads to α-trimethylsilylallenes,[53] while the use of a propargyl alcohol substrate leads to the substituted allylsilane (eq 12).[54]

(12)

With alkynes, copper-catalyzed addition of the Grignard reagent (**1**) provides the allylsilane.[55] The intermediate vinylcopper reagent can also be trapped with electrophiles.[56]

The reagent (**1**) also reacts with wide variety of electrophiles, including carbon dioxide,[33] cyanogen,[57] silyl chlorides,[3,58] metal halides,[59] and ***Phosphorus(III) Chloride***.[59a] With methyl phenyl sulfinate, reaction of (**1**) leads to the formation of (phenylthio)(trimethylsiloxy)methane, a protected form of formaldehyde, by a sila-Pummerer rearrangement.[60]

The Grignard reagent (**1**) is the precursor of numerous organometallic compounds that contain the trimethylsilylmethyl ligand.[61]

Related Reagents.

(Diisopropoxymethylsilyl)methylmagnesium Chloride; ***Trimethylsilylmethylpotassium***; ***(Trimethylstannylmethyl)lithium***.

2-Trimethylsilylmethyl-2-propen-1-ol[1]

[81302-80-9] · $C_7H_{16}OSi$ · 2-Trimethylsilylmethyl-2-propen-1-ol · (MW 144.32)

(derivatives function as trimethylenemethane (TMM) precursors and undergo cyclopentannulation reactions; methylenecyclopentanes; 2-acetoxymethyl-3-trimethylsilylpropene;[2] [3 + 2] annulation;[3] three-carbon condensative expansion;[4] cyclocontraction-spiroannulation[5])

Alternate Names: 2-(hydroxymethyl)-3-trimethylsilylpropene; 2-(hydroxymethyl)-2-propenyltrimethylsilane; (hydroxymethyl)allyl trimethylsilane; 2-(trimethylsilylmethyl)allyl alcohol.

Physical Data: bp 54-56 °C/2 mmHg; *n*20D 1.454; *d* 0.861 g cm^{-3}; fp 71 °C.

Solubility: insol water; sol all organic liquids.

Form Supplied in: liquid, 90% pure; remainder of the mixture (approx. 10%) is 3-trimethylsilyl-2-methyl-2-propen-1-ol or 3-trimethylsilylmethyl-2-propen-1-ol.

Preparative Method: prepared in four steps from methallyl alcohol. The synthesis begins with the metalation with ***n-Butyllithium*** (2 equiv) producing the dianion which is bis-silylated by trapping with ***Chlorotrimethylsilane*** to generate the allylsilane. The TMS ether is subsequently removed by hydrolysis (eq 1). The primary allylic alcohol serves as a precursor to more functionalized reagents.

Useful derivatives of the alcohol are the primary allylic chloride, mesylate, and acetate. These are easily prepared in a short number of steps as shown (eq 2) or by functionalization of the primary allylic alcohol.

Purification: by distillation under reduced pressure.

Handling, Storage, and Precautions: flammable liquid; irritant; store at 0-4 °C.

Introduction.

The title allylsilane reagent has been employed as a conjunctive reagent which is considered to be a synthetic equivalent of a zwitterionic, bifunctional compound possessing a nucleophilic allylic anion synthon and an electrophilic cation synthon in the same molecule (**1**).

(1)

[3 + 2] Annulations.

The primary allylic halide ***2-Chloromethyl-3-trimethylsilyl-1-propene*** or the mesylate derived from the corresponding alcohol behaves as a bifunctional reagent possessing both nucleophilic and electrophilic reaction centers. For example, they have been shown to participate in [3 + 2] carbon annulations for the construction of methylenecyclopentanes. The reaction proceeds through a Lewis acid-promoted conjugate addition (Sakurai reaction) followed by an internal alkylation of the derived ketone enolate (eq 3).

(3)

n	X	Yield (%)	Yield (%)
2	H	80	60
1	H	8	-
2	SPh	80	79
1	SPh	63	73

In a related study, the annulation is combined with a ring expansion reaction. The reaction utilizes a β-keto sulfone as the two-carbon component along with an allylic mesylate as the bifunctional reagent. The alkylation/cyclization process is outlined in eq 4. The subsequent ring expansion appears to be a general process except for cases involving fused six- and seven-membered ring systems (eq 5).

(4)

n	Alkylation yield (%)	Cyclization yield (%)
1	81	94
2	71	79
3	80	79

(5)

Methylenecyclopentane Annulation.

The acylated derivative 2-acetyloxymethyl-3-trimethylsilylpropene is known to be an effective three-carbon component in cyclopentane annulations. It has been demonstrated that 2-acetoxymethylallyltrimethylsilane adds to a variety of electron-deficient alkenes in the presence of a catalytic amount of ***Tetrakis(triphenylphosphine)palladium(0)*** and ***1,2-Bis(diphenylphosphino)ethane*** to produce methylenecyclopentanes (eqs 6-8).

(6)

(7)

cis:*trans* = 1.3:1

(8)

Cyclocontraction-Spiroannulation.

The mesylate derivative of 2-hydroxymethyl-3-trimethylsilylpropene participates in an interesting annulation reaction involving a β-keto sulfone as the two-carbon component (eq 9).

The reaction is thought to involve a pinacol-type rearrangement in which the phenylsulfonyl group serves as a leaving group in the presence of a Lewis acid (eq 10).

Related Reagents.

3-Acetoxy-2-trimethylsilylmethyl-1-propene; ***3-Iodo-2-trimethylsilylmethyl-1-propene***.

Trimethylsilylmethylpotassium[1]

(**1**; M = K)

[53127-82-5] · $C_4H_{11}KSi$ · Trimethylsilylmethylpotassium · (MW 126.34) (**2**; M = Na)

[53127-81-4] · $C_4H_{11}NaSi$ · Trimethylsilylmethylsodium · (MW 110.23)

(can act as a strong base with benzylic and allylic compounds[2])

Preparative Methods: trimethylsilylmethylpotassium (**1**) and -sodium (**2**) are prepared by reaction of ***Bis(trimethylsilyl)mercury*** with the appropriate metal as a suspension in cyclohexane.[2,3] Trimethylsilylmethylsodium can also be prepared by reaction of ***Bis(trimethylsilyl)methane*** with ***Sodium Methoxide*** in HMPA.[4]

Handling, Storage, and Precautions: both of these organometallic reagents should be prepared just prior to use and not stored for extended periods. All reactions with these reagents should be performed under an inert atmosphere.

Base Reactions.

Both metal reagents (**1**) and (**2**) act as bases. The tricyclic ether (**3**) is readily deprotonated by the hindered base (**1**), but pentylsodium or butylpotassium proved superior in other cases.[2] However, reagent (**1**) provides an alternative to the ***n-Butyllithium-Potassium t-Butoxide*** system (eq 1).[1]

(1)

Both reagents (**1**) and (**2**) react with benzylic compounds to afford benzyl anions. The reaction can accommodate alkyl or silyl groups on the benzylic position or as substituents on the aromatic ring (eq 2).[2,3]

(2)

The use of trimethylsilylmethylpotassium (**1**) as a base also allows deprotonation of allylic positions. The allyl carbanions produced by the action of substrate with (**1**) react with ***Ethylene Oxide*** to afford the 4-en-1-ol product; unsymmetrical allylic anions can result in a mixture of products, although reaction is favored at the least substituted center (eq 3).[5]

The potassium reagent (**1**) will deprotonate simple alkenes to give allylic anions.[2] Subsequent reaction with a chloroborane results in the allylic borane, which, in turn, can be converted to an allyl alcohol (eq 4).[6]

Pentadienyl-type organometallic reagents are available by reaction of (**1**) with homoconjugated and conjugated dienes, without significant polymerization. The regioselectivity of the metalation is dependent on the structure of the substrate, U-shaped delocalized systems usually being preferred.[7] However, the factors affecting the regioselectivity are subtle, as illustrated by reaction at the 14-position of 7-dehydrocholesterol (**4**) (eq 5).[8]

Peterson Alkenation.

Trimethylsilylmethylsodium (**2**) is prepared in situ by the action of sodium methoxide on bis(trimethylsilyl)methane (**5**),[4] and reacts with nonenolizable carbonyl compounds to provide alkenes by a Peterson alkenation reaction (eq 6). Alternative procedures are available that circumvent the use of HMPA, and allow reaction with enolizable carbonyl compounds.[9]

Trimethylsilylmethyl Trifluoromethanesulfonate[1]

[64035-64-9] · $C_5H_{11}F_3O_3SSi$ · Trimethylsilylmethyl Trifluoromethanesulfonate · (MW 236.32)

(preparation of azomethine ylides, sulfonium ylides, ammonium ylides, and phosphonium ylides from imines, amines, sulfides, or phosphines via alkylation[1,2,3a] and fluoride-induced desilylation[1,2,3b])

Alternate Name: trimethylsilylmethyl triflate.

Physical Data: bp 156-158 °C,[2] 49-51 °C/9 mmHg.[4a]

Solubility: miscible with common organic solvents (ethers, halocarbons, hydrocarbons).

Form Supplied in: colorless oil.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$, ppm): δ 0.19 (9 H, s) 4.27 (3 H, s).

Preparative Methods: Me_3SiCH_2OH + ***Trifluoromethanesulfonic Anhydride/Pyridine*** in CH_2Cl_2 (68%);[2,4a] Me_3SiCH_2OMe + ***Trimethylsilyl Trifluoromethanesulfonate*** (93%);[4b] ***Diazomethane*** + $Me_3SiOSO_2CF_3$ (81%).[4c]

Purification: distillation.

Handling, Storage, and Precautions: can be stored indefinitely in the refrigerator under anhydrous conditions.

Azomethine Ylides from Imines.

An imine is alkylated with the title reagent ($TMSCH_2OTf$) to give a salt such as (**1**) which is not isolated, but is treated with ***Cesium Fluoride*** to generate the reactive azomethine ylide (**2**). In the presence of ***Dimethyl Acetylenedicarboxylate*** as the dipolarophile, (**2**) is trapped by [2 + 3] cycloaddition to afford a pyrroline (eq 1). Azomethine ylides (**3**)-(**8**)[2,5] can be generated and trapped in the same way with external dipolarophiles, while (**9**)[5h] undergoes the analogous internal [2 + 3] cycloaddition process.[5] Other desilylation approaches to azomethine ylides have been developed since the initial report in 1979,[1] and the topic has been reviewed.[2,6]

(9)

2,3-Sigmatropic Rearrangement.

The desilylation approach permits regiospecific methylide generation from sulfides or amines. If the ylide also contains an allylic group as a heteroatom substituent, then 2,3-sigmatropic rearrangement (eq 2) occurs smoothly. This process has been demonstrated for the ammonium ylide (**10**),[2] and the sulfonium ylides (**11**)[2] and (**12**).[7] Rearrangement by 2,3-shift can also involve an aromatic double bond in ylide (**13**), as shown in eq 3.[8] In this case, two nonaromatic intermediates can be detected, but chromatography affords the aromatized product 2,3-dimethyl(methylthiomethyl)benzene. Similar intermediates have been reported in the rearrangement of *N*-benzylammonium methylides generated by the desilylation method.[9]

(13)

Miscellaneous Applications.

Alkene formation is possible via sulfide alkylation with $TMSCH_2OTf$, followed by ylide generation with CsF.[2] The process involves a five-center elimination (eq 4). The same procedure leads to the ammonium ylide (**14**), and spontaneous fragmentation occurs at room temperature to give (*E*)-cyclododecene (70%).[2] Sulfonium methylide generation and trapping by intramolecular attack at a C=O bond is also known, resulting in the formation of epoxides or fragmentation products.[10] Treatment of ***Triphenylphosphine*** with $TMSCH_2OTf$ followed by desilylation with CsF in the presence of benzophenone results in the in situ generation and Wittig trapping of the phosphonium ylide $Ph_3P{=}CH_2$.[2] Finally, $TMSCH_2OTf$ can also be used for the *C*-alkylation of α-lithio vinylcarbamates.[11]

Trimethylsilyl Nonaflate

[68734-62-3] · $C_7H_9F_9O_3SSi$ · Trimethylsilyl Nonaflate · (MW 372.32)

(Lewis acid capable of generating enol silyl ethers from ketones;[1] selective Friedel-Crafts catalyst for nucleoside formation from silylated heterocycles and peracylated sugars;[2] catalyzes *cis*/*trans* equilibration of substituted cyclopropanes;[3] used in the formation of mixed iodonium sulfonates[4])

Physical Data: bp 70-72 °C/12 mmHg.[5]

Solubility: sol most organic solvents.

Preparative Methods: can be conveniently generated in situ by the addition of ***Chlorotrimethylsilane*** to a suspension of potassium nonaflate.[1] Other methods of preparation exist;[5,6] however, the aforementioned method appears to be the most efficient.

Handling, Storage, and Precautions: should be used as prepared.

General Discussion.

It has been shown that enolizable ketones can be efficiently converted to their corresponding enol silyl ethers by the reaction of trimethylsilyl nonaflate and ***Triethylamine*** at the temperature of refluxing cyclohexane (eqs 1 and 2).[1]

(1)

$n = 1$, 72%; $n = 2$, 82%

(2)

Trimethylsilyl nonaflate as well as ***Trimethylsilyl Trifluoromethanesulfonate*** and ***Trimethylsilyl Perchlorate*** have been shown to be selective and efficient Friedel-Crafts catalysts for the formation of nucleosides from silylated heterocycles and peracylated sugars. They are also useful catalysts for the rearrangement of persilylated protected nucleosides.[2] The aforementioned catalysts are more advantageous to the typically employed ***Tin(IV) Chloride*** owing to their reduced Lewis acidity.

Trimethylsilyl nonaflate is also an effective Lewis acid catalyst for the low-temperature *cis*/*trans* equilibration of methyl 2-trimethylsiloxycyclopropanecarboxylates via heterolytic cleavage of a carbon-carbon bond (eq 3).[3]

Mixed iodonium sulfonates of the type $PhI(CN)OSO_2C_4F_9$ can be generated in a one-pot procedure by the reaction of PhIO and trimethylsilyl nonaflate followed by the addition of ***Cyanotrimethylsilane***.[4]

Related Reagents.

Iodotrimethylsilane.

1-Trimethylsilyloxy-1,3-butadiene

[6651-43-0] · $C_7H_{14}OSi$ · 1-Trimethylsilyloxy-1,3-butadiene · (MW 142.30)

(easily prepared[1] reactive diene for Diels-Alder reactions and other cycloadditions;[2-21] reactive silyl enol ether for aldol and Michael reactions,[22-28] and electrophilic additions[29-32])

Physical Data: bp 131 °C, bp 49.5 °C/25 mmHg; *d* 0.811 g cm^{-3}.

Solubility: sol most standard organic solvents.

Form Supplied in: liquid commercially available (98% purity) as an approximately 85:15 mixture of (*E*)- and (*Z*)-isomers.

Preparative Methods: can be prepared easily.[1]

Handling, Storage, and Precautions: is a flammable liquid and is moisture sensitive.

Diels-Alder Reactions and Other Cycloadditions.

Although commercially available, 1-trimethylsilyloxy-1,3-butadiene (**1**) can be easily prepared by silylation of ***Crotonaldehyde***.[1] It has often been used as a reactive diene in Diels-Alder reactions. For example, reaction with ***Dimethyl Acetylenedicarboxylate*** (**2**) affords the cyclohexadiene diester (**3**) in 68% yield. This initial Diels-Alder adduct can be converted into two different aromatic products by the proper choice of conditions: namely, thermal elimination affords the phthalate (**4**), while oxidation produces the phenol (**5**), both in good yield (eq 1).[2] Reaction with ***Methyl 3-Nitroacrylate*** (**6**) followed by hydrolysis of the initial adduct (**7**) and elimination of the β-nitro group leads to the cyclohexadienol (**8**) (eq 2).[3] Many other Diels-Alder reactions of this type have been carried out using (**1**), as shown in Table 1.[4] In general, the *endo* adduct is favored, especially at lower temperatures.

Table 1 Diels-Alder Reactions of 1-Trimethylsilyl-1,3-butadiene (**1**)

Dienophile	Conditions	Yield	Ratio (**10**):(**11**)
Z = CHO, R = H	50 °C, 48 h	88%	11:1[4a]
Z = CHO, R = H	130 °C, 7 h	53%	86:14[4b]
Z = CHO, R = Me	150 °C, 7 h	69%	65:35[4b]
Z = CHO, R = CO_2Me	40 °C, 48 h	>90%	83:17[4c]
Z = R = COPh	80 °C, 5 h	93%	no stereochem. given[4d]
Z = NO_2, R = TMS	100 °C, 37 h	83%	100:0[4e]
Z = NO_2, R = OCOPh	25 °C	90%	6:1[4f]

Cyclic enones, lactones, and lactams have also been used often as dienophiles in Diels-Alder reactions with (**1**), again giving mainly the *endo* adduct,[5] e.g. (**12**) reacted with (**1**) to give (**13**) as the major product in 74% yield (eq 3).[5a] As mentioned earlier, the initial adducts are often oxidized (either directly or after hydrolysis of the silyl ether) with Jones reagent to the corresponding enone,[6] e.g. (**14**) to give (**15**) (eq 4).[6a] This corresponds to the annulation of a cyclohexenone unit onto an existing enone or unsaturated lactone unit and has been used often in synthesis, e.g. in the preparation of aureolic acid derivatives such as (**17**) from (**16**) and (**1**) (eq 5).[6c]

(3)

(**13**)

(4)

(5)

There are some exceptions to the preference for *endo* stereochemistry, especially with unsaturated sulfones.[7] A curious and useful reversal of the stereochemical preference has been reported, namely Diels-Alder cycloaddition of the pyrazolecarboxylate (**18**) with (**1**) followed by photochemical elimination of nitrogen gave mainly the *endo* adduct (**19n**) (eq 6), whereas cycloaddition of (**1**) with the cyclopropenecarboxylate (**20**) gave nearly exclusively the *exo* adduct (**19x**) (eq 7).[8]

Stereocontrol with acyclic dienophiles can also be high,[9] e.g. (**21**) giving only (**22**) (eq 8),[9a] although the relative stereochemistry of the adjacent allylic center can cause nearly stereorandom addition as well.[9a] The versatility of the initial adducts has been evidenced most clearly in the synthesis of anthraquinones and their derivatives. The adducts of (**1**) with various quinones and substituted quinones have been transformed into simple aromatics,[10] phenols,[11] e.g. (**23**) gave (**24**) (eq 9),[11a] cyclohexenones,[12] e.g. (**25**) gave (**26**) (eq 10),[12a] and allylic alcohols,[13] all in excellent yields.

(9)

(10)

The reaction can be carried out with excellent enantiocontrol (generally 80% or better) using juglone (**27**) and a catalyst prepared from ***Trimethyl Borate*** and a tartaramide to give (**28**) (eq 11).[13a] Finally, with metal complexes of tropene and tropone systems, one can obtain either normal [4 + 2] cycloadditions[14a] or novel [6 + 4] cycloadditions, e.g. (**29**) giving (**30**) (eq 12).[14b,c] Other [4 + 2] cycloadditions have also been reported, using as dienophiles aldehydes[15] to give pyran derivatives such as (**31**), vinyl chlorides,[16] singlet oxygen,[17] nitrosoalkanes[18] to give compounds such as (**32**), and phosphaalkenes (eq 13).[19] Several [2 + 2] cyclizations are known, namely carbene and ketene additions to (**1**), all of which occur at the unsubstituted double bond.[20] One clever use of (**1**) in synthesis is the tandem [2 + 2]-Cope process which converts (**33**) into (**34**) (eq 14).[20d] Finally, a nickel(0)-catalyzed [4 + 4] cyclization of (**1**) gives the *trans*-3,4-bis(silyloxy)-1,5-cyclooctadiene (**35**) in excellent yield (eq 15).[21]

(11)

(12)

Aldol Condensations.

The nucleophilicity of the γ-carbon atom in 1-trimethylsilyloxy-1,3-butadiene (**1**) allows Lewis acid-catalyzed aldol condensations to be carried out, with (**1**) acting as the equivalent of the enolate of crotonaldehyde.[22-26] The products usually have the (*E*) stereochemistry about the newly formed double bond. Orthoesters are good electrophiles;[22,1d] when orthoformate is used as the electrophile, the (*E*)-monoacetal of glutacondialdehyde (**36**) is formed in good yield.[22e] This was then used in a very short synthesis of the antiviral agent AZT (**37**) (eq 16).[22e] 1,3-Dithienium salts and 2-alkoxydithiolanes have also been used to produce the dithioacetals corresponding to (**36**).[23] Simple acetals and α-chloro ethers can be used as the electrophiles with (**1**) to generate initially δ-alkoxy-α,β-unsaturated aldehydes and then the doubly unsaturated aldehydes after treatment with base.[24,1c] A clever approach to the synthesis of indole from pyrrole involves the condensation of (**1**) with the endoperoxides derived from *N*-alkoxycarbonylpyrrole as shown in eq 17.[25a] An approach to the piperidine alkaloids uses similar chemistry.[25b,c]

(16)

(17)

Finally, a conceptually similar reaction involves the addition of (**1**) to an acyl imminium salt to give an intermediate (**38**) (eq 18) which was then used in an intramolecular Diels-Alder approach to the heteroyohimboid alkaloids.[26] A Michael adduct is formed when (**1**) is allowed to react with 2,2-bis(phenylsulfonyl)styrene, probably as the result of a Diels-Alder reaction in which the adduct reverses to a zwitterion and internally deprotonates.[27] Also the lithium enolate derived from (**1**) has been added in a Michael fashion to α,β-unsaturated ketones to give, after silylation, the same adducts as the direct Diels-Alder reaction but at much lower temperatures.[28]

(18)

Electrophilic Additions.

Finally, various electrophiles (other than the carbon species in aldol and other condensations) have been added to (**1**) in good yield, namely: ***Benzenesulfenyl Chloride***,[29] ***Bromine*** or ***N-Bromosuccinimide***,[30] and ***t-Butyl Hypochlorite***.[31] There are also several reports of the reaction of (**1**) with various transition metal electrophiles which generate either a silyloxydiene bound to the metal[32] or a crotonaldehyde unit bound to the metal.[33]

2-Trimethylsilyloxy-1,3-butadiene

[38053-91-7] · $C_7H_{14}OSi$ · 2-Trimethylsilyloxy-1,3-butadiene · (MW 142.30)

(easily prepared[1] reactive diene for Diels-Alder reactions[2-40] and other cycloadditions;[41-44] reactive silyl enol ether for aldol, Michael reactions, and electrophilic additions[45-46])

Physical Data: bp 50-55 °C/50 mmHg; *d* 0.811 g cm^{-3}.

Solubility: sol most standard organic solvents.

Form Supplied in: liquid available commercially.

Preparative Methods: can be prepared easily from methyl vinyl ketone.[1]

Handling, Storage, and Precautions: is a flammable liquid and is moisture sensitive.

Diels-Alder Reactions.

Although commercially available, 2-trimethylsilyloxy-1,3-butadiene (**1**) can be easily prepared by silylation of ***Methyl Vinyl Ketone***.[1] It has been often used as a reactive diene in Diels-Alder reactions. In nearly all cases with a strongly activated dienophile, the trimethylsilyloxy group ends up 1,4 to the activating group in the adduct. Several representative examples are shown in Table 1.[1-14] The initial Diels-Alder adduct is a silyl enol ether and as such can be converted into several different products by simple silyl enol ether chemistry, e.g. the adduct (**3**) from the reaction of (**1**) with ***Dimethyl Fumarate*** (**2**) (eq 1) can be hydrolyzed to the cyclohexanone (**4**) in either acid or base, converted into the α-bromo or α-hydroxy ketone (**5**) or (**6**) on treatment with ***Bromine*** or ***N-Bromosuccinimide*** and ***m-Chloroperbenzoic Acid***, respectively, and finally via a Mukaiyama-type aldol (PhCHO/***Titanium(IV) Chloride***) to the enone (**7**).[1b,2]

Table 1 Diels-Alder Reactions of 2-Trimethylsilyl-1,3-butadiene **(1)**

Z	R^1	R^2	R^3	Conditions	Yield (%)	Ratio	Ref.

[a] Yield of cyclohexanone after hydrolysis. [b] Product is 93% pure.

Alkynic dienophiles also work well, e.g. ethyl propiolate and (**1**) produce the expected cyclohexadiene ester in 77% yield.[15] In addition to simple dienophiles, a number of allenic dienophiles have also been utilized, as shown in Table 2.[16-19] Cyclic dienophiles, enones, lactams, etc., are often reacted with (**1**) to give fused bicyclic systems, but generally the yields are only in the 25-45% range,[20-24] e.g. reaction of (**1**) with (**13**) gives (**14**) in 27% yield (eq 2).[20b]

Table 2 Allenic Dienophiles in Diels-Alder Reactions with **(1)**

(1) **(11)** **(12)**

Z	R	Conditions	Yield (%)	Ref.
CO_2TMS	CO_2TMS	PhH, 82 °C, 20 h	80	16
CO_2Et	CO_2Et	PhH, 82 °C, 14 h	97	17
SO_2Ph	H	160 °C, 3 h	79	18
CO_2TMS	$CH_2OTBDMS$	PhMe, 110 °C, 24 h	62	19

(2)

More reactive dienophiles, e.g. β-nitroenones,[21] enediones,[22] 1,2-disulfonylethylene,[23] etc., give higher yields, as do Lewis acids,[24] e.g. ***Zinc Bromide*** (eq 3),[24a] and the use of high pressure.[25] Stereofacial differentiation of (**1**) with cyclic enones,[26] lactones,[27] and lactams[28] is generally excellent, e.g. (**1**) reacts with (**17a,b**) to give (**18a,b**) with high selectivity in good yield (eq 4).[26] Reaction of (**1**) with quinones has often been used[29] in syntheses of anthraquinones and their derivatives, e.g. to prepare the A ring of the anthracyclines.[29b-g] Double Michael reactions[30] have been used quite often instead of Diels-Alder reactions to provide the same products, often in higher yields. The preparation of the azabicyclic ketone (**20**) is an interesting example of a tandem Diels-Alder reaction-aldol-type condensation (eq 5).[31] An example of an aldol reaction followed by a Diels-Alder is also known.[32]

(3)

(17b) R = C(Me)=CH_2, R^1 = Me

(4)

(18a) 66% 100:0
(18b) 73% 95:5

(1) **(19)**

(5)

(20)

Finally, there is one example of (**1**) acting as the dienophile, namely in the Diels-Alder reaction with α-nitrosostyrene, where 6-vinyl-6-silyloxy-4,5-dihydrooxazine is formed in 65% yield.[33]

Heterodienophiles.

Many heterodienophiles have been reacted with (**1**).[34-37] Mesoxalate, glyoxalate, and hexafluoroacetone all give the 4-pyranone silyl ether derivatives in fair yield.[34] The corresponding thiomesoxalate affords the 3-thiopyranone-4,4-diester in good yield,[35a,b] as does an α-oxosulfine,[35c] while alkyl thioformates yield the 4-thiopyranones.[35d] By far the largest group of heterodienophiles used are imine derivatives.[36-37] Activated imines, e.g. diacyl imines,[36] afford the 4-piperidones, while aryl-fused dihydropyridines, e.g. (**21**), furnish fused 4-piperidones, e.g. (**22**), in good yield when reacted with (**1**) in the presence of a Lewis acid (eq 6).[37]

(21) (22) (6)

Finally, several imines give products of an aldol-type condensation rather than Diels-Alder reaction when reacted with (**1**) in the presence of Lewis acids.[38] Phosphaalkenes react with (**1**) to give ultimately the aromatic phosphinine[39] and dimethyl azodicarboxylate affords the expected [4 + 2] adduct in 83% yield.[40]

[2 + 2] and Other Cycloadditions, Carbene Additions.

Several [2 + 2] cyclizations of (**1**) with various alkenes are known.[41] Quite often these vinyl cyclobutyl silyl ethers can be thermally rearranged to the normal Diels-Alder product,[16,19,41] e.g. (**23**) giving (**25**) via (**24**) (eq 7).[41a] These [2 + 2] adducts can also be transformed via palladium catalysis into α-methylenecyclopentanones[41d,e] in good yield, e.g. (**26**) gives (**28**) via (**27**) (eq 8).[41d] Metal complexes of ***1,3,5-Cycloheptatriene*** react with (**1**) to give a novel [6 + 4] cycloaddition, e.g. (**29**) giving (**30**) (eq 9).[42]

(23) (24) (25) (7)

Even [3 + 2] cycloadditions occur when cyclopropyl ketones are treated with (**1**) under photolytic or Lewis acid conditions to produce cyclopentane systems.[43] Cyclopropanations of (**1**) are well known, in all cases adding to the more electron-rich silyloxy alkene.[1a,44] The vinylcyclopropanol silyl ethers can be converted into a number of different products, e.g. cyclopentanones, 2-methylcyclobutanones, vinyl ketones, and β-alkoxy ketones (eq 10). One clever use of (**1**) in synthesis is the tandem [2 + 2]-Cope process which converts (**34**) into (**35**) (eq 11).[44i]

(11)

Aldol Condensations and Electrophilic Additions.

2-Trimethylsilyloxybutadiene (**1**) can act as the enolate of methyl vinyl ketone (MVK) towards reactive carbon atoms in an aldol- like process to give the products of overall addition of MVK to reactive centers.[45] Various strong electrophiles have been added to (**1**), e.g. bromine, NBS, *m*-CPBA, alkylating agents, and acylating agents, usually reacting at the carbon of the silyl enol ether to give α-bromo, α-silyloxy, or α-alkyl ketones in good yields.[46] With acylating agents, however, the *O*-acylated products are obtained.[46e]

Related Reagents.

1-Acetoxy-1,3-butadiene; ***2-Methoxy-1,3-butadiene***; ***1-Methoxy-3-trimethylsilyloxy-1,3-butadiene***; ***1-Trimethylsilyloxy-1,3-butadiene***.

2-Trimethylsilyloxyfuran[1]

[61550-02-5] · $C_7H_{12}O_2Si$ · 2-Trimethylsilyloxyfuran · (MW 156.28)

(provides 5-substituted 2(5*H*)-furanones by alkylation,[2] aldolization,[3] and conjugate addition;[4] transforms quinones into furo[3,2-*b*]benzofurans;[5] useful for the four-carbon elongation of sugars[6])

Alternate Name: TMSOF.

Physical Data: bp 44-46 °C/17 mmHg; *d* 0.93 g cm^{-3}.

Solubility: sol most organic solvents, e.g. CH_2Cl_2, Et_2O, benzene, THF, MeCN.

Form Supplied in: colorless liquid; commercially available (98% pure) but expensive.

Preparative Method: accessible by silylation of 2(5*H*)-furanone,[1c,5b] which is obtained at very low cost by oxidation of furfural (see also α,β-***Butenolide***).

Handling, Storage, and Precautions: flammable liquid; sensitive to moisture. To avoid hydrolysis, it should be kept under Ar at -18 °C or below. For best results, reactions should be performed under strictly anhydrous conditions in aprotic solvents. Use in a fume hood.

Synthetic Applications.

In recent years, 2-trimethylsilyloxyfuran has emerged as a keystone for the rapid assembly of a wide variety of 5-substituted 2(5*H*)-furanones. This is readily achieved by reaction with an electrophile and desilylation. Electrophilic attack usually occurs exclusively at C-5;[3-10] products arising by C-3 attack are observed only rarely.[2c,11] Consequently, this electron-rich furan is viewed as a stable, readily accessible synthon for the γ-anion of 2(5*H*)-furanone (**1**).

(1)

Carbon-Heteroatom Bond Formation.

Bromination of 2-trimethylsilyloxyfurans affords the corresponding 5-bromo-2(5*H*)-furanones in quantitative yields (eq 1).[1a] Similarly, reaction with ***Lead(II) Acetate*** provides 5-acetoxy-2(5*H*)-furanones (eq 2).[8] Oxidation can also be effected by using ***Iodosylbenzene*** in conjunction with a nucleophile, such as ***p-Toluenesulfonic Acid***, and ***Boron Trifluoride Etherate*** (eq 3).[9] Replacement of TsOH by ***Azidotrimethylsilane*** in eq 3 provides 5-azido-2(5*H*)-furanone.[9]

Alkylation.

Upon activation with ***Silver(I) Trifluoroacetate***, primary alkyl iodides and allylic bromides are readily transformed into 5-alkyl- and 5-allyl-2(5*H*)-furanones, respectively (eq 4).[2] Significantly, typical S_N1-unreactive halides such as ethyl iodoacetate work equally well.[2b] This method has served as a basis for short syntheses of several natural products,[13] including eldanolide[2a] and the Whisky lactones.[2c]

Alternatively, 5-allyl-2(5*H*)-furanones can be obtained from TMSOF and allylic acetates using ***Lithium Perchlorate*** in ether.[13] 5-Propargyl-2(5*H*)-furanones are prepared by coupling with hexacarbonyldicobalt complexes of propargylium cations (eq 5).[10] Reaction of the intermediate complex with ***Cerium(IV) Ammonium Nitrate*** removes the cobalt. Fluoroalkylation is achieved by using bis(fluoroalkanoyl) peroxides in 1,1,2-trichloro-1,2,2-trifluoroethane (Freon 113) (eq 6).[14] This process is believed to involve combination of a fluoroalkyl radical with the furan-derived radical cation.

Aldol-Type Reactions.

The facile condensation of 2-trialkylsilyloxyfurans with carbonyl compounds[3] and their derivatives[7a] has spawned many synthetic applications.[15-19] Aldol products derived from aldehydes, ketones, or acetals can be readily transformed into 4-ylidenebutenolides.[3a] Dehydration of 5-(1´-hydroxyalkyl)-2(5*H*)-furanones is achieved by using ***Acetic Anhydride*** and 4-pyrrolidinopyridine (PPY) in ***Triethylamine*** (eq 7).[3a]

The diastereoselectivity of the reaction of TMSOF with aldehydes can be controlled by the choice of catalyst. Lewis acids such as ***Triethylsilyl Trifluoromethanesulfonate*** (TESOTf), $BF_3.OEt_2$, and ***Tin(IV) Chloride*** favor *syn* selectivity, while the use of fluoride ion confers *anti* selectivity (eq 8).[3b] In both situations, open transition states are involved.[3b] Impressive diastereofacial preference is encountered in the aldol reaction of TMSOF with chiral aldehydes (eq 9).[6a] This chemistry is particularly useful for the four-carbon elongation of sugars.[6]

(8)

BnCHO, TESOTf, -78 °C, 92% 82:18
BnCHO, Bu_4NF, -78 °C, 73% 19:81

(9)

≥95:5

Ketones,[16] orthoamides,[17] and *N*-acyl-*N*,*O*-acetals[18] also undergo diastereoselective condensation with TMSOF in the presence of Lewis acids. Thus 1-benzyloxycarbonyl-2-ethoxypyrrolidine leads preferentially to the *syn* product (eq 10).[19]

(10)

syn:*anti* = 5:1

Conjugate Addition.

In comparison to aldol condensation, the conjugate addition of 2-trialkylsilyloxyfurans to enones has received only scant attention.[8,20] Yet some interesting applications have already surfaced. Especially noteworthy is the high level of stereochemical discrimination in the few recorded cases.[21] For example, full diastereoselectivity is observed in the fluoride ion-induced addition of TMSOF to a chalcone (eq 11).[4]

(11)

Activated quinones undergo uncatalyzed reaction with TMSOF to produce furo[3,2-*b*]benzofurans (eq 12).[22] Furofuran annulation is explicable by initial conjugate addition of the furan, subsequent aromatization, and eventual intramolecular conjugate addition of the resulting hydroxy group onto the butenolide.[5] This protocol is of relevance to the synthesis of pyranonaphthoquinone antibiotics.[23]

(12)

Diels-Alder Reaction.

In view of the propensity of furans to undergo [4 + 2] cycloadditions,[24] 2-trialkylsilyloxyfurans are potentially useful for the rapid construction of various phenol derivatives.[25] Although TMSOF performs poorly in Diels-Alder reactions, some of its more substituted analogs are highly effective.[26] An illustration is provided by the short synthesis of a naturally occurring hydroxyphthalide (**2**) via cycloaddition of 3,5-dimethyl-2-(trimethylsilyloxy)furan with ***Maleic Anhydride*** (eq 13).[26] Unlike TMSOF, the more stable 2-pivaloyloxyfuran is strongly recommended for similar transformations.[27]

Related Reagents.

Several other 2-trialkylsilyloxyfurans have served as building blocks for the synthesis of natural products[28a,b] and analogs.[28c] The commercially available (4-methoxy-2-(trimethylsilyloxy)furan (**3**) is especially useful for preparing 5-substituted methyl tetronates.[29] 5-Ethylthio-2-(trimethylsilyloxy)furan (**4**)[21a] has been employed for the synthesis of mitomycins.[21] The easily prepared 2-(*t*-butyldimethylsilyloxy)-3-methylfuran (**5**)[12a] is the reagent of choice for constructing furanosesquiterpenes[12] and spirocyclic alkaloids of the *Ergot* family.[30]

(3) (4) (5)

Other related reagents are γ-***Butyrolactone***, ***Dihydro-5-(hydroxymethyl)-2(3H)-furanone***, ***2,5-Dihydro-2,5-dimethoxyfuran***, ***Furan***, ***5-Lithio-2,3-dihydrofuran***, and β-***Vinyl***-α,β-***butenolide***.

(*Z*)-2-(Trimethylsilyloxy)vinyllithium

[78108-48-2] · $C_5H_{11}LiOSi$ · (*Z*)-2-(Trimethylsilyloxy)vinyllithium · (MW 122.19)

(vinylogation of aldehydes and ketones under mild conditions; preparation of β-methoxy aldehydes and β-silyl silyl enol ethers)

Solubility: sol Et_2O, THF.

Preparative Methods: bromine-lithium exchange starting from ***(Z)-2-Bromo-1-(trimethylsilyloxy)ethylene*** in dry Et_2O (0.15 M) and ***t-Butyllithium*** at -70 °C under inert atmosphere.[1] One equivalent of *t*-BuLi is sufficient if (*Z*)-(trimethylsilyloxy)vinyllithium is condensed with reactive electrophilic reagents which are added 10-20 min after the end of the addition of *t*-BuLi.[1,2] In other cases, two equivalents of *t*-BuLi are needed, the second equivalent is used to destroy *t*-BuBr formed during the exchange[3] and the electrophilic reagents are added after the end of addition of *t*-BuLi.

Handling, Storage, and Precautions: when prepared with 2 equiv of *t*-BuLi the reagent is stable in Et_2O over 20 h at -70 °C;1 from -60 °C it begins to decompose with formation of ***Acetylene***.[4]

General Discussion.

(*Z*)-(Trimethylsilyloxy)vinyllithium (**1**) has essentially been used for a one-pot vinylogation of carbonyl compounds. Condensation of (**1**) with aldehydes and ketones (**2**) occurs readily at low temperature (-70 °C); then treatment of the reaction mixture with an acidic solution in mild conditions (1 N ***Hydrochloric Acid***, 0 °C to rt) produces the α,β-unsaturated aldehydes (**3**), without double bond migration. The (*E*) isomers are obtained alone (from aldehydic compounds) or very predominantly (from ketonic compounds). The intermediate adducts, γ-hydroxy enol ethers (**4**), can be isolated by slightly basic mild hydrolysis (eq 1).[1]

(1)

As condensation with α,β-unsaturated compounds occurs exclusively in a 1,2-fashion,[1,2] this reagent has been used in terpene synthesis. A synthesis of retinal (**3b**) in three steps from β-ionone (**2a**) (via β-ionylideneacetaldehyde and C_{18} ketone) was reported using reagent (**1**) for the first and third steps (eq 2).[5]

(2)

For the step (**2a**) -> (**3a**), reagent (**1**) competes favorably with other classical vinylogation reagents: ***Formylmethylenetriphenylphosphorane*** (0%);[6] lithium cyclohexylvinylamide (2 steps, 34%);[7] lithio salt of ***5,6-Dihydro-2,4,4,6-tetramethyl-1,3(4H)-oxazine*** (3 steps, 54%);[8] lithium *t*-butyl-2-trimethylsilylvinylamide (1 step, 88%)[9] (see Duhamel et al.[2] for other comparative studies).

Thus (*Z*)-(trimethylsilyloxy)vinyllithium (**1**) is an excellent reagent for the preparation of building blocks such as (**4**), (**5a**), and (**5b**) (eq 3), which are useful for short convergent syntheses of terpenoid compounds (eqs 4 and 5).[10]

Condensation of acetylacetaldehyde dimethyl acetal with reagent (**1**) leads to the δ-aldolacetal (**3c**) in 90% yield, which has been transformed by classical methods into bromoacetal (**4**) and bromo enol ethers (**5a,5b**) (eq 3).[10]

(3)

For the first time a one-step synthesis of retinal (**3b**) from β-ionone (**2a**) was reported, using reagents (**5a**) and (**5b**) (eq 4),[10] whereas two-step syntheses of dehydrocitral from acetone (60%), *pseudo*-retinal from *pseudo*-ionone (61%), and retinal from β-ionone (55%) were

described using reagent (**4**).[10]

A short synthesis of phytol (**6**) from 6-methyl-5-hepten-2-one was described using reagents (**1**) and (**4**). Condensation of 6-methyl-5-hepten-2-one with (**4**) yielded the hydroxy acetal (**7**), which was converted in one pot into *pseudo*-phytone (**8**). Catalytic hydrogenation of (**8**) gave phytone, which was transformed into phytol (**6**) after condensation with (**1**) followed by reduction (eq 5).[11]

The adduct of (**1**) with carbonyl compounds can be trapped by methyl fluorosulfonate, leading to γ-methoxy enol ethers (**9**) precursors of β-

methoxy aldehydes (**10**) (eq 6).[12]

Depending on the experimental conditions, reaction of (**1**) with ***t-Butyldimethylsilyl Trifluoromethanesulfonate*** leads either to the expected β-trimethysilyl enol ether (**11**), or to its isomer (**12**) formed by a 1,3-migration of the trimethylsilyl group from the oxygen atom to the carbon atom (**1** -> **13**). Reaction with ***t-Butyldimethylchlorosilane*** always gives (**12**).[13] Trimethylsilyl enol ether (**11**) is easily hydrolyzed to 2-(*t*-butyldimethylsilyl)acetaldehyde (**14**) (eq 7).[14]

The study of the ^{1}H NMR spectra of (**1**) in Et_2O-d_{10} at -70 °C is in agreement with the proposed structure; the isomeric enolate (**13**) is not normally detected (eq 7), but in THF at -70 °C it slowly forms.[4]

5-Trimethylsilyl-1,3-pentadiene

[72952-73-9] · $C_8H_{16}Si$ · 5-Trimethylsilyl-1,3-pentadiene · (MW 140.33)

(useful pentadienylation reagent;[1] an allyl silane;[7] a precursor for 1-trimethylsilyldienes and intramolecular Diels-Alder substrates[2])

Alternate Name: 2,4-pentadienyltrimethylsilane.

Physical Data: bp 41 °C/36 mmHg or 105 °C/760 mmHg; *n*20D 1.4570.

Solubility: sol hexane, benzene, CH_2Cl_2, ether, THF.

Analysis of Reagent Purity: by NMR, GC (8.4 min on 3 mm × 3 M 5% Apiezon L on Chromosorb W at 80 °C) or TLC: 5% $AgNO_3$/silica gel (4:1 hexane/benzene).

Preparative Method: may be prepared in 85% yield by the reaction of ***Pentadienyllithium*** with ***Chlorotrimethylsilane*** in THF at room temperature.[1-3] Generally the product is ~95% (*E*) isomer as judged by IR (strong band at 1000 cm^{-1}) or NMR (*trans* coupling constant of 15.2 Hz for proton at C-3, 5.92 ppm).

Handling, Storage, and Precautions: stable liquid; the toxicological properties of this reagent are unknown. It should be handled in a well ventilated hood.

General Discussion.

2,4-Pentadienyltrimethylsilane is used as a stable (storable) nucleophilic substitute for pentadienyllithium. This compound reacts with Lewis acid (***Boron Trifluoride Etherate***, ***Iodotrimethylsilane***, ***Titanium(IV) Chloride***) activated electrophiles in the same manner as allylsilanes (eq 1). Generally only ε-substitution is observed (cf. Table 1).[1,4,5,7]

(1)

Table 1 Reaction of $H_2C{=}CHCH{=}CHCH_2MMe_3$ with Typical Electrophiles

Entry	Electrophile (E^+)	M	Lewis acid	Product	Yield (%)	Ref
1		Si	$TiCl_4$	ε-adduct	64	1
2	$PhCH(OMe)_2$	Si	$BF_3 \cdot OEt_2$	ε-adduct	85	4, 5
3	PhCHO	Si	$BF_3 \cdot OEt_2$	ε-adduct	16	5
4	*t*-BuCOCl	Si	$BF_3 \cdot OEt_2$	34% ε-adduct, 25% γ-adduct	-	5
5		Si	$BF_3 \cdot OEt_2$		40	1, 7
6		Sn	$BF_3 \cdot OEt_2$		70	7
7		Si	$BF_3 \cdot OEt_2$		91	7
8		Sn	$BF_3 \cdot OEt_2$		85[a]	7

[a] After reoxidation to the quinone.

Other electrophiles which have been used include acetals,[4] acid chlorides,[5] and heteroatom-based electrophiles. A useful varient of the title compound is the more reactive 2,4-pentadienyltrimethylstannane (Table 1, entries 6 and 8).[6,7] Lewis acid-catalyzed conjugate addition reactions have been observed with the tin analog,[7,8] but are not observed with 2,4-pentadienyltrimethylsilane due to a competing Diels-Alder reaction (Table 1, entries 5 and 7).

In a typical reaction of 2,4-pentadienyltrimethylsilane with electrophiles, a carbonyl compound was dissolved in CH_2Cl_2 and cooled to -40 °C and 0.3 equiv $TiCl_4$ (or $BF_3.OEt_2$) was added. After 5 min, 0.66 equiv 2,4-pentadienyltrimethylsilane was added and the mixture warmed to 5-25 °C over a 5 min to 2 h period (depending on the reactivity of the electrophile). After quenching with $NaHCO_3$ the product was extracted with ether.

2,4-Pentadienyltrimethylsilane may also be deprotonated adjacent to silicon with ***Lithium Diisopropylamide***, forming the 1-(Me_3Si)-pentadienyl anion.[2] This anion reacts with many electrophiles to give ε-substituted dienes (eq 2) which are ideal candidates for protodesilyation or intramolecular Diels-Alder reactions.

(2)

The reaction of the 1-(Me_3Si)-pentadienyl anion with cyclohexanone gives a 59/41 mixture of γ- and ε-regioisomers.

Trimethylsilyl Perchlorate[1]

[18204-79-0] · $C_3H_9ClO_4Si$ · Trimethylsilyl Perchlorate · (MW 172.66)

(nucleoside synthesis;[1] selective cleavage of *t*-Boc group;[2] disiloxane[3] formation and general silylation characteristics[4,5])

Alternate Name: TMSP.

Physical Data: bp 35-38 °C/14 mmHg.

Preparative Method: prepared by a silver salt-trimethylsilane anion exchange (eq 1).[6] Not commercially available.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: explosive; fumes when exposed to air. Use in fume hood.

Catalytic Synthesis of Nucleosides from Silylated Heterocycles and 1-*O*-Acyl or 1-*O*-Alkyl Sugars.[1]

Trimethylsilyl perchlorate, prepared in situ, acts as a strong Lewis acid suitable as a Friedel-Crafts catalyst in the reaction of silylated heterocycles, like uracil (**1**), with 1-*O*-acyl or 1-*O*-alkyl sugars such as 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose (**2**). This Friedel-Crafts reaction produces the nucleoside 4-*O*-silylated ribosyl benzoate (**3**) (eq 2).

Since trimethylsilyl perchlorate is produced by the reaction, it can be used catalytically. Workup of these Friedel-Crafts reactions is effected by $NaHCO_3/CH_2Cl_2$. The use of this reagent as the catalyst is an improvement over the past nucleoside synthesis which employed ***Tin(IV) Chloride***, where isolation and purification were complicated by the formation of emulsions and colloids. This rate of nucleoside formation is also greatly enhanced by an increase in temperature. Trimethylsilyl perchlorate can be effectively substituted with ***Trimethylsilyl Trifluoromethanesulfonate***. Yields ranged from 60-90%.

Selective Acidic Cleavage of the *t*-Butoxycarbonyl Group.[2]

Trimethylsilyl perchlorate enables selective cleavage of *t*-Boc groups in the presence of the benzyloxycarbonyl (*Z*) group and *t*-butyl esters. This difficult selective cleavage is executable at rt over a 5 min period in benzene, CH_2Cl_2, or benzene/acetonitrile with 1.0 equiv of trimethylsilyl perchlorate as the promoter. Yields are quantitative (Table 1).

Table 1 Cleavage of *t*-Boc Groups Using TMSP

Peptide	Solvent	Product	Yield (%)
(1) Boc Ala Phe OMe	C_6H_6	H Ala Phe OMe·$HClO_4$	87
(2) Boc Val Leu OMe	C_6H_6	H Val Leu OMe·$HClO_4$	~100
(3) Z Lys (Boc)Arg (NO_2)OMe	C_6H_6/MeCN (1:1)	Z Lys Arg(NO_2) OMe·$HClO_4$	~100
(4) Boc Gly Ile Val Glu(O-*t*-Bu) OBn	C_6H_6/MeCN (1:1)	H Gly Ile Val Glu(O-*t*-Bu) OBn·$HClO_4$	~100

Disiloxane Formation[3] and Silylations.

$(Me_3Si)_3CSiMe_2OH$, a sterically hindered silanol, gives the disiloxane $(Me_3Si)_3CSiMe_2OSiMe_3$ in 87% yield, when treated with 4.5 equiv of trimethylsilyl perchlorate in benzene at room temperature for 10 min (eq 3). The same result may be effected with ***Iodotrimethylsilane***, ***N,O-Bis(trimethylsilyl)acetamide***, or ***Methyllithium*** followed by ***Chlorotrimethylsilane***.

$$(TMS)_3CSiMe_2OH + 4.5\ \text{equiv}\ TMSOClO_3 \xrightarrow[87\%]{\text{rt, 10 min}} (TMS)_3CSiMe_2OTMS + HClO_4 \qquad (3)$$

The above disiloxane formation is an example of a silylation. The active nucleophilic species and kinetics of different silylations have been studied. The ideal silylation mixture should consist of a polar solvent to stabilize salts, a highly electrophilic silane, such as trimethylsilyl perchlorate, trimethylsilyl iodide, or trimethylsilyl trifluoromethanesulfonate, a strong nucleophile, such as ***N-Methylimidazole***, ***4-Dimethylaminopyridine***, or ***Hexamethylphosphoric Triamide*** and a proton acceptor like ***Triethylamine***.[4] It has also been shown that trimethylsilyl perchlorate forms bis(trimethylsilyl)imidazolium salts which are postulated to be active intermediates in other silylation reactions.[5]

Trimethylsilyl Polyphosphate

(can activate functional groups containing an oxygen atom; cyclodehydration agent for synthesis of heterocycles)

Alternate Names: polyphosphoric acid trimethylsilyl ester; PPSE.

Solubility: sol dichloromethane, chloroform, 1,2-dichloroethane, benzene, toluene, xylene, 1,2-dichlorobenzene.

Form Supplied in: colorless or pale yellow, viscous liquid; commercially available.

Preparative Methods: prepared by heating a mixture of ***Phosphorus(V) Oxide*** and ***Hexamethyldisiloxane*** (2-3.5 moles per mole P_4O_{10}) in a solvent such as dichloromethane or without solvent (eq 1).[1,2]

PPSE consists mainly of three tetraphosphoric acid trimethylsilyl esters together with a small amount of tetrakis(trimethylsilyl) pyrophosphate.[3]

Handling, Storage, and Precautions: PPSE is hygroscopic, and should be stored strictly in the absence of moisture.

Transformations of Functional Groups Containing an Oxygen Atom.

PPSE is capable of activating functional groups containing an oxygen atom by interaction with a phosphorus atom or a trimethylsilyl moiety. These reactivities of PPSE in conjunction with its aprotic nature and high solubility in organic solvents render this reagent useful in transformations of some functional groups. Thus amides are smoothly dehydrated by PPSE at reflux in chloroform to give nitriles (eq 2).[4] Ketoximes are readily subjected to the Beckmann rearrangement to yield amides.[1] Acetophenone oximes possessing OH, NH_2, or SH groups at *ortho* positions are converted to 2-methylbenzoxazole, 2-methylbenzimidazole, and 2-methylbenzothiazole, respectively, via the Beckmann rearrangement and cyclization (eq 3).[3] On the other hand, aldoximes are dehydrated by PPSE to afford nitriles.[5] It is noted that aromatic nitriles are conveniently prepared from aromatic aldehydes by refluxing with ***Hydroxylamine*** hydrochloride and PPSE (eq 4).[4]

(3)

(4)

Primary and secondary alcohols are converted to the corresponding alkyl iodides by treatment with the ***Sodium Iodide***-PPSE reagent system (eq 5).[6] The reaction of optically active secondary alcohols results in the formation of virtually racemized alkyl iodides. Carboxylic acids are activated by PPSE, undergoing condensation with two equivalents of amines to afford amidines in high yields (eq 6).[7]

(5)

(6)

Reagent for Cyclodehydration.

PPSE can be used as a condensation agent for the preparation of such heterocycles as 1,3-dioxane derivatives (eq 7),[2] 9*H*-selenoxanthen-9-ones and related sulfur and oxygen congeners (eq 8),[8] 1,3-oxazin-6-ones,[9] 2*H*-1,2,4-benzothiadiazine derivatives,[10] and benzoxazoles (see also ***Polyphosphoric Acid*** (PPA) and ***Polyphosphate Ester*** (PPE)).[11,12]

Trimethylsilylpotassium

Me_3SiK

[56859-17-7] · C_3H_9KSi · Trimethylsilylpotassium · (MW 112.31)

(highly reactive nucleophile and one-electron transfer reagent;[1-3] deoxygenates substituted epoxides with inversion of stereochemistry[4,5])

Solubility: sol DME, THF, HMPA, hexane.

Analysis of Reagent Purity: ^{13}C NMR (HMPA) δ 4.2.[6]

Preparative Methods: prepared quantitatively by the cleavage of the silicon-silicon bond of ***Hexamethyldisilane*** with ***Potassium Hydride*** or potassium alkoxides (KOMe or ***Potassium t-Butoxide***) (eqs 1 and 2).[1,2,7-9] It can also be conveniently prepared by deprotonation of Me_3SiH with KH (eq 3).[2,3] These procedures circumvent the need to handle volatile organomercury compounds that previous routes required.[10]

Handling, Storage, and Precautions: solutions of Me_3SiK are air and moisture sensitive and must be handled under inert atmospheres. The toxicity of Me_3SiK is not currently known; however, the preparations employing ***Hexamethylphosphoric Triamide*** and ***18-Crown-6*** necessitate handling these solutions in a fume hood using chemically resistant gloves.

Nucleophilic and Electron Transfer Reactions.

Me_3SiK is a highly reactive nucleophile and one-electron transfer reagent. It readily couples with halides and enones via S_N2 and 1,4-additions (eqs 4 and 5). When 1-bromohex-5-ene and benzophenone are treated with Me_3SiK, electron transfer induced cyclization and dimerization occur (eqs 6 and 7). The course of these reactions can be substantially influenced by the nature of the solvent, resulting in enhancement of either nucleophilic substitution or electron transfer.[1-3]

(5)

(6)

(7)

Aryl halides can be converted in one step to aryl trimethylsilanes in good yields with Me_3SiK (eq 8).[11] These are particularly useful intermediates for directing electrophilic substitutions on carbon.[12]

(8)

Deoxygenation of Epoxides with Inversion.

Me_3SiK stereospecifically deoxygenates substituted epoxides with inversion of stereochemistry. Reactions of *cis*- and *trans*-epoxides with $Me_3SiSiMe_3$ and KOMe give the *trans*- and *cis*-alkenes, respectively (eqs 9 and 10).[4,5]

3-Trimethylsilyl-2-propen-1-yl Acetate

(**1**; R^1 = H, R^2 = (*E*)-$SiMe_3$)

[86422-21-1] · $C_8H_{16}O_2Si$ · 3-Trimethylsilyl-2-propen-1-yl Acetate · (MW 172.33) (**2**; R^1 = H, R^2 = (*Z*)-$SiMe_3$)

[86422-22-2] (*E* + *Z*)

[80401-14-5] (**3**; R^1 = $SiMe_3$, R^2 = H)

[80401-11-2]

(preparation of vinylsilanes via the corresponding allylmetal complexes;[1] oxygenated allylsilane reagents for nucleophilic addition and substitution reactions[2])

Preparative Methods: (i) from 3-trimethylsilyl-2-propyn-1-ol by reduction (***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Red-Al), 70%)[3] and acetylation (***Acetyl Chloride***, ***Pyridine***, 78%);[4] (ii) from 3-trimethylsilyl-2-propyn-1-ol by reduction (P-2 ***Raney Nickel***, H_2, 86%)[5] and acetylation; (iii) from allyloxytrimethylsilane by a metalation-rearrangement sequence (***t-Butyllithium***, 90%)[2a,6] and acetylation (***Acetic Anhydride***, ***Triethylamine***, 76%).[2a]

Handling, Storage, and Precautions: use in a fume hood.

Preparation of Vinylsilanes.

Both (*E*)- and (*Z*)-3-trimethylsilyl-2-propen-1-yl acetates (**1** and **2**), together with their allylic isomer (**3**) (1-trimethylsilyl-2-propen-1-yl acetate) are useful reagents for the formation of vinylsilanes by way of transition metal-catalyzed allylic alkylations. Reaction of the π-allylpalladium intermediate generated from (**1**)-(**3**) with several types of nucleophiles has been studied.[4,7] In general, these alkylations exhibit high regioselectivity, with reaction occurring at the position γ to silicon. ***Diethyl Malonate*** sodium enolate reacts with either (**2**) or (**3**) in the presence of Pd^0 to give alkylated products in good yields and favoring the (*Z*)-vinylsilane isomer (eq 1).[1] Cyclohexanone enamine participates in the alkylation reaction, giving the (*E*)-vinylsilane as the sole product (eq 2).[1] Although lithium enolates are problematic, addition of tri-*n*-butyltin trifluoroacetate allows product formation in good yield (eq 3).[8]

(1)

Reagent	Yield (%)	(*E*):(*Z*)
(2)	72	22:78
(3)	65	27:73

(2)

(3)

Other metals besides palladium are also effective.[9] Reaction of the cationic allyltetracarbonyliron complex derived from (**1**) or (**2**) with silyl enol ethers, *O*-silyl ketene acetals, or allylstannanes, followed by oxidative decomplexation, gives the vinylsilane products.[10] The process was shown to occur with near complete retention of stereochemistry (cf. eqs 4 and 5).[10]

(4)

(5)

Nucleophilic Addition and Substitution Reactions.

Allylsilane (**3**) has been shown to undergo conjugate addition to enones in the presence of ***Tetra-n-butylammonium Fluoride*** (eq 6).[2a] The reaction demonstrates high regioselectivity, as no products arising from 1,2-addition to the enone or attack at the γ-position of the allylsilane were isolated. Stereoselective *C*-glycosidation can be effected by reaction of allylsilane (**3**) with D-mannopyranoside derivatives in the presence of ***Boron Trifluoride Etherate*** (eq 7).[2b] The α-*C*-glycoside arises from axial addition to the pyranoside oxonium ion.

Related Reagents.

Allyltrimethylsilane; ***3-Bromo-1-trimethylsilyl-1-propene***; ***1-Pyrrolidino-1-cyclohexene***; ***Tetrakis(triphenylphosphine)palladium(0)***; ***Trimethylsilylallyllithium***.

2-(3-Trimethylsilyl-1-propenyl)magnesium Bromide-Copper(I) Iodide[1]

[103559-91-7] · $C_6H_{13}BrMgSi$ · 2-(3-Trimethylsilyl-1-propenyl)magnesium Bromide-Copper(I) Iodide · (MW 217.49)

[7681-65-4] · CuI · 2-(3-Trimethylsilyl-1-propenyl)magnesium Bromide-Copper(I) Iodide · (MW 190.45)

(used in methylenecyclopentane annulation via conjugate addition to enones;[2b] can serve as hydroxymethylvinyl anion equivalent[3])

Preparative Methods: copper(I) iodide-catalyzed reactions of 2-(3-trimethylsilyl-1-propenyl)magnesium bromide (**1**) have been carried out in ether or THF by combining (**1**) with a catalytic amount of ***Copper(I) Iodide*** at -30 to 0 °C. Two different preparations of (**1**) have been reported.[2a,3]

Handling, Storage, and Precautions: use in a fume hood.

Methylenecyclopentane Annulation.

Trost and Coppola[2b] applied the copper(I) iodide-catalyzed addition of (**1**) to enones; the conjugate adducts were converted to the corresponding methylenecyclopentanes in good yield (eqs 1-3). Attempts to generate stoichiometric cuprates were complicated by oxidative dimerization.

(2)

(3)

1-Hydroxymethylvinyl Anion Equivalent.

Copper(I) iodide-catalyzed addition of (**1**) to epoxides affords allylsilanes (**2**) (eq 4).[3] Oxidation of (**2**) to the corresponding allylic alcohols (**3**) constitutes formal addition of a hydroxymethylvinyl anion to an epoxide (eq 5). Alcohols (**3**) were converted to the corresponding α-methylene-γ-lactones (**4**) upon further oxidation (eq 6).

(4)

(5)

(6)

3-Trimethylsilyl-1-propyne

[13361-64-3] · $C_6H_{12}Si$ · 3-Trimethylsilyl-1-propyne · (MW 112.27)

(propargylation agent; allenylation agent; can give addition reactions on the triple bond)

Alternate Name: propargyltrimethylsilane.

Physical Data: bp 91-93 °C/760 mmHg; 40 °C/140 mmHg; *d* 0.753 g cm^{-3}; *n*20D 1.4140. IR (cm^{-1}, neat): 3320 s, 2120 m (C&tbond;CH); 1250 s, 845 s, 755 w (Si-C). ^1H NMR: (CCl_4, δ ppm): 0.11 (s, 9H, $SiMe_3$); 1.41 (d, *J* 2.5 Hz, 2H, CH_2); 1.66 (t, *J* 2.5 Hz, 1H, CH).[1-4]

Solubility: sol ether, THF, CH_2Cl_2.

Form Supplied in: colorless liquid, commercially available.

Analysis of Reagent Purity: IR and NMR.

Preparative Methods: the main method of preparation is shown in eq 1.[1-3] The title reagent can be obtained by other methods,[4] but in poor yields.

(1)

Purification: by distillation.

Handling, Storage, and Precautions: usually stored in a refrigerator. The reagent should be handled in a well-ventilated hood.

Reactivity.

3-Trimethylsilyl-1-propyne is the simplest of the propargylic silanes, which are convenient reagents in organic synthesis.[5,6]

Propargylation Reactions.

3-Trimethylsilyl-1-propyne is metalated easily by using an organomagnesium or a lithium compound, leading to the corresponding alkynic organometallic reagent which can react with many electrophiles.

Alkylation Reactions.[7-9]

These reactions may be obtained with various halides, a number of them having other functionalities (eqs 2 and 3).

Reactions with Epoxides.[10,11]

These reactions allow preparation of β-alkynic alcohols (eq 4); the use of ***n-Butyllithium***, followed by ***Diethylaluminum Chloride***, may increase the yield.

Reactions with Aldehydes and Ketones.[12-16]

These are exemplified by eqs 5 and 6. Under the conditions of eq 6, the major product results from further reaction between the initial alcoholate and the excess ***Formaldehyde***. Secondary and tertiary alcohols are also obtained easily (eq 7). The yields are best when *n*-BuLi is used as the base and when HMPA is used as a cosolvent in the reaction with the ketone.

Reactions with Chloroformates.[17]

These are exemplified by eq 8.

Reactions with Polyoxymethylene and Amines[13] (Mannich Reaction).

These are exemplified by eq 9.

Allenylation Reactions.

The propargyltrimethylsilanes undergo Lewis acid-catalyzed reactions with electrophiles, with regiospecific rearrangement, to give substituted allenes eq (10)[18-21]. The catalysts usually employed are ***Aluminum Chloride***, ***Boron Trifluoride Etherate***, and ***Titanium(IV) Chloride***.

Substitution Reactions.

Few examples have been described. Generally, the reaction occurs with regiospecific rearrangement. Substitution of halides[18] is shown in eq 11, and of OH, $OSiMe_3$, and OCOR groups[19,20] in eq 12.

Ortho-propynyliodoarenes are obtained by reductive iodono-Claisen rearrangement of allenyliodinanes (eq 13).[21] When both *ortho* positions and the *para* position of aryliodinanes are occupied, *ipso*-propynylarenes are formed (eq 14).

(14)

Reactions with Acetals[22,23] and Hemiacetals.[24-26]

These are exemplified by eqs 15 and 16. The synthesis of *C*-glycosides bearing an allenyl group has been accomplished[25,26] by use of 3-trimethylsilyl-1-propyne.

(15)

(16)

Reactions with Aldehydes and Ketones.[22,27-29]

These reactions generally lead to α-allenyl alcohols (eq 17). With titanium(IV) chloride as catalyst, the major product is a chloroprenic derivative formed from the α-allenyl *O*-silylated alcohol (eq 18).[22] The yields are good with aliphatic aldehydes bearing a primary or a secondary group and with activated ketones; they are poorer with aliphatic ketones (23-25%). With two equivalents of an aldehyde, the formation of a heterocyclic compound may be observed (eq 19).[28] By using ***Tetra-n-butylammonium Fluoride*** as catalyst, α-allenyl alcohols are easily obtained[29] with aliphatic and aromatic aldehydes (eq 20).

(17)

Reactions with in situ Generated Iminium and α-Acyl Iminium Ions.[30-32]

These reactions allow the preparation of α-allenyl amines and amides (eqs 21 and 22). The photoinduced addition reaction leads to a mixture of two products (eq 23).[32]

Reactions with Acid Chlorides.[33]

These reactions lead to α-allenyl ketones (eq 24).

Reactions with Conjugated Heteroatomic Systems.[3a,34]

3-Trimethylsilyl-1-propyne seems unable to undergo 1,4-addition to monofunctional conjugated carbonyl derivatives such as R´CH=CH-CO-R´´, R´CH=CH-CO_2R´´, or R´CH=CH-CN, but readily undergoes 1,4-addition reactions with alkylidenemalonates and analogs (eq 25)[3a] and with conjugated acyl cyanides (eq 26).[34] Similar results are obtained with alkylideneacetylacetates and -cyanoacetates (45-65%).[3a]

Reactions of the Triple Bond.

Preparation of Complexes with Transition Metals.[5b,35]

3-Trimethylsilyl-1-propyne reacts with ***Octacarbonyldicobalt*** to give the complex shown in eq 27.[35] This complex can react with alkenes to lead to 2-trimethylsilylmethylcyclopentenones (28-30%).

Preparation of a Bis-silylated Conjugated Enyne.[36]

This is shown in eq 28.

Related Reagents.

(Trimethylsilyl)allene.

3-Trimethylsilyl-2-propynylcopper(I)[1]

[55630-32-5] · $C_6H_{11}CuSi$ · 3-Trimethylsilyl-2-propynylcopper(I) · (MW 174.81)

(agent for the introduction of the trimethylsilylpropynyl group via 1,6-conjugate additions[2] and vinyl substitutions;[3] preparation of lithium bis(trimethylsilylpropynyl)cuprate[4])

Alternate Name: trimethylsilylpropargylcopper

Physical Data: brown heterogenous solution in ether.

Solubility: sol pyridine, THF; slightly sol ether.

Analysis of Reagent Purity: addition of aqueous ammonium chloride gives >95% conversion to 1-trimethylsilylpropyne.[2]

Preparative Method: a solution of ***1-Lithio-3-trimethylsilyl-1-propyne*** containing ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) in ether[2] or THF is added to a slurry of ***Copper(I) Iodide*** in ether at -78 °C, then warmed to -10 °C and used immediately.[3]

Handling, Storage, and Precautions: dry copper(I) acetylides are potentially explosive. Use in a fume hood.

Coupling Reactions.

Trimethylsilylpropynylcopper adds to conjugated esters in a 1,6-manner if facilitated, giving mixtures of products dependent on the nature of the system.[2] Addition to an unsubstituted (*E*)-dienoic ester gave an 8:2 mixture of allene:propynyl-substituted adducts (eq 1).

Best conversion yields (80%) are obtained by using 3.5 equiv of the copper reagent; use of 1.2 equiv results in a lower yield (42%) but an unaltered ratio.[2] If a δ-substituted dienoic ester is employed, the ratio reverses (eq 2), showing marked sensitivity to steric effects in this region;[2] for best conversion to products (70%), 3.5 equiv of copper reagent are employed.[2]

Finally, if a β,γ-disubstituted dienoic ester is used, selectivity reverses in favor of the allenic adduct (eq 3), pointing to the δ-carbon as the single most important dictator of steric control in this reaction (in this sequence, only 1.2 equiv of cuprate were employed, accounting for the low (35%) overall conversion to products). Results obtained using *t*-butyldimethylsilylpropynylcopper paralleled those indicated above. As expected, however, the ratios of products showed sensitivity towards this more sterically bulky coupling agent, with a 95:5 ratio of allene:alkyne products in the addition to the unsubstituted dienoate (eq 1) and a 97:3 ratio of alkyne:allene in the addition to the δ-substituted system (eq 2).[2] Vinyl substitution has been reported, using an iodohexene and 2 equiv of trimethylsilylpropynylcopper; the corresponding adduct was obtained in 80% yield (eq 4).[3] Using 1 equiv of copper acetylide, however, the yield drops to 63%. A mechanism has been proposed to account for this coupling, and is assumed to involve a four-centered transition state assembly.[3]

Lithioorganocuprates.

Lithium bis(trimethylsilylpropynyl)copper, prepared by addition of lithium trimethylsilylpropyne to copper(I) iodide, has been used as a nucleophilic source of the trimethylsilylpropynyl group (eq 5).[4] Chemoselective 1,2-addition resulted in a 90% isolated yield of the desired

secondary alkynyl alcohol (eq 5); use of the corresponding lithium or bromomagnesium acetylides resulted in substantial recovery of allenic products.[4]

Related Reagents.

1-Hexynylcopper(I); ***1-Pentynylcopper(I)***; ***(Trimethylsilyl)ethynylcopper(I)***.

2-(Trimethylsilyl)thiazole[1]

[79265-30-8] · $C_6H_{11}NSSi$ · 2-(Trimethylsilyl)thiazole · (MW 157.34)

(useful formyl anion equivalent;[1] effective one-carbon homologating reagent of alkoxy aldehydes, amino aldehydes, and dialdoses[2])

Physical Data: bp 51-53 °C/10 mmHg; *d* 0.992 g cm^{-3}; n_D 1.4980.

Solubility: insol H_2O; very sol CH_2Cl_2, diethyl ether, THF.

Form Supplied in: liquid; widely available.

Analysis of Reagent Purity: ^1H and ^{13}C NMR.

Purification: distillation under reduced pressure.

Preparative Method: although 2-(trimethylsilyl)thiazole (**1**) is commercially available, it can be easily prepared on a multigram scale from 2-bromothiazole, ***n-Butyllithium***, and ***Chlorotrimethylsilane*** as shown in eq 1.[3]

Handling, Storage, and Precautions: is stable upon storage under an inert atmosphere in a refrigerator. Nevertheless, it should be freshly distilled for best results. Irritating to the eyes, respiratory system, and skin. Wear suitable protective clothing, gloves and eye/face protection. Use in a fume hood.

General Discussion.

2-(Trimethylsilyl)thiazole (**1**) reacts with various C-electrophiles such as azolium halides (eq 2),[4] ketenes (eq 3),[5,6] acyl chlorides (eq 4),[6,7] ketones, and aldehydes (eq 5)[6-8] under mild conditions to give the corresponding 2-substituted thiazoles in very good isolated yields. No catalysts are required in these carbodesilylation reactions.

(3)

(4)

(5)

R = H, CF_3

The general mechanism via an *N*-thiazolium-2-ylide, earlier proposed for all these reactions,[6,7] has found substantial support in the identification of spirodioxolane intermediates in the reaction of (**1**) with aldehydes.[9]

The reaction of (**1**) with chiral alkoxy aldehydes led to the discovery of a new methodology for the one-carbon chain elongation of these compounds.[2a,b] The methodology proved to be capable of iteration and therefore suitable for the stereoselective synthesis of polyalkoxy aldehydes (carbohydrate-like materials).

The homologation of D-glyceraldehyde acetonide (**2**) serves to illustrate the method.[3] This consists of two sequential operations: first, addition of 2-(trimethylsilyl)thiazole (**1**) to the aldehyde (**2**) followed by in situ desilylation and protection as the *O*-benzyl derivative (**3**) (eq 6); secondly, aldehyde release in the resultant adduct[10] by a three-step sequence involving methylation of the thiazole ring to the *N*-methylthiazolium salt; reduction to thiazolidine; hydrolysis to α-benzyloxy aldehyde (**4**) (eq 7).

(6)

(2)

(3)

ds [3] 95%

Hence, (**1**) serves as a synthetic equivalent for the formyl anion synthon which adds to the aldehyde in a stereoselective manner, creating a new chiral hydroxymethylene center. The repetition of the first and second operational sequences above over six consecutive cycles with high levels of diastereoselectivity and chemical yields in each cycle provided a series of protected D-aldoses[2c] having up to nine carbons in the chain (eq 8).

The utility of this approach to long-chain sugars (thiazole route to carbohydrates) is illustrated by the conversion of protected L-threose (**5**) and dialdogalactopyranose (**6**) into higher homologs (eqs 9 and 10).[2c,d] The extension of this methodology to other dialdoses has been reported.[11]

(9)

(10)

This technique, in combination with an inversion of configuration of the carbon adjacent to the thiazole ring, has been employed[2e] for the chain extension of D-glyceraldehyde acetonide (**2**) into all possible tetrose and pentose homologs (eq 11).

(11)

The 2-(trimethylsilyl)thiazole-based one-carbon extension strategy was also used for the construction of amino tetroses as well as amino pentoses[12] using α-amino aldehydes as chiral educts. An interesting finding was that the reactions of (**1**) with the *N*-diprotected α-amino aldehydes were *anti* selective (eq 12), whereas those with the *N*-monoprotected α-amino aldehydes were *syn* selective (eq 13).

(12)

(13)

These opposite diastereoselectivities were explained by assuming a Felkin-Anh-Houk model (*anti* addition) and a proton-bridged Cram cyclic model (*syn* addition) for the case of differentially protected α-amino aldehydes (**7**) and (**8**). The resulting 1,2-amino alcohols proved to be convenient precursors to L-amino sugars and sphingosines.[12]

This strategy has been also employed for the synthesis of a dipeptide mimic,[13] as illustrated in eq 14.

(14)

In summary, 2-(trimethylsilyl)thiazole (**1**) appears to be a useful formyl anion equivalent.[14] The advantages over other precursors to the formyl anion (see ***Benzothiazole***) can be found in the stability of the thiazole ring to a wide range of reaction conditions and its ready conversion into the formyl group under mild and neutral conditions. Few of the many formyl anion equivalents[14] have been demonstrated to be capable of producing labile α-alkoxy aldehydes without racemization.

Related Reagents.

(4aR)-(4aα,7α,8aβ)-Hexahydro-4,4,7-trimethyl-4H-1,3-benzoxathiin; ***2-Lithio-1,3-dithiane***; ***1,1,3,3-Tetramethylbutyl Isocyanide***.

Trimethylsilyl Trifluoromethanesulfonate[1]

[88248-68-4; 27607-77-8] · $C_4H_9F_3O_3SSi$ · Trimethylsilyl Trifluoromethanesulfonate · (MW 222.29)

Alternate Name: TMSOTf.

Physical Data: bp 45-47 °C/17 mmHg, 39-40 °C/12mmHg; *d* 1.225 g cm^{-3}.

Solubility: sol aliphatic and aromatic hydrocarbons, haloalkanes, ethers.

Form Supplied in: colorless liquid; commercially available.

Preparative Methods: may be prepared by a variety of methods.[2]

Handling, Storage, and Precautions: flammable; corrosive; very hygroscopic.

Silylation.

TMSOTf is widely used in the conversion of carbonyl compounds to their enol ethers. The conversion is some 10^9 faster with TMSOTf/***Triethylamine*** than with ***Chlorotrimethylsilane*** (eqs 1-3).[3-5]

(1)

(2)

(3)

Dicarbonyl compounds are converted to the corresponding bis-enol ethers; this method is an improvement over the previous two-step method (eq 4).[6]

(4)

In general, TMSOTf has a tendency to *C*-silylation which is seen most clearly in the reaction of esters, where *C*-silylation dominates over *O*-silylation. The exact ratio of products obtained depends on the ester structure[7] (eq 5).[8] Nitriles undergo *C*-silylation; primary nitriles may undergo *C*,*C*-disilylation.[9]

(5)

TMS enol ethers may be prepared by rearrangement of α-ketosilanes in the presence of catalytic TMSOTf (eq 6).[10,11]

(6)

Enhanced regioselectivity is obtained when trimethylsilyl enol ethers are prepared by treatment of α-trimethylsilyl ketones with catalytic TMSOTf (eq 7).[12]

(7)

The reaction of imines with TMSOTf in the presence of Et_3N gives *N*-silylenamines.[13]

Ethers do not react, but epoxides are cleaved to give silyl ethers of allylic alcohols in the presence of TMSOTf and ***1,8-Diazabicyclo[5.4.0]undec-7-ene***; The regiochemistry of the reaction is dependent on the structure of the epoxide (eq 8).[14]

(8)

Indoles and pyrroles undergo efficient *C*-silylation with TMSOTf (eq 9).[15]

(9)

t-Butyl esters are dealkylatively silylated to give TMS esters by TMSOTf; benzyl esters are inert under the same conditions.[16]

Imines formed from unsaturated amines and α-carbonyl esters undergo ene reactions in the presence of TMSOTf to form cyclic amino acids.[17]

Carbonyl Activation.

1,3-Dioxolanation of conjugated enals is facilitated by TMSOTf in the presence of 1,2-bis(trimethylsilyloxy)ethane. In particular, highly selective protection of sterically differentiated ketones is possible (eq 10).[18] Selective protection of ketones in the presence of enals is also facilitated (eq 11).[19]

(10)

(11)

The similar reaction of 2-alkyl-1,3-disilyloxypropanes with chiral ketones is highly selective and has been used to prepare spiroacetal starting materials for an asymmetric synthesis of α-tocopherol subunits (eq 12).[20]

(12)

The preparation of spiro-fused dioxolanes (useful as chiral glycolic enolate equivalents) also employs TMSOTf (eq 13).[21]

(13)

TMSOTf mediates a stereoselective aldol-type condensation of silyl enol ethers and acetals (or orthoesters). The nonbasic reaction conditions are extremely mild. TMSOTf catalyzes many aldol-type reactions; in particular, the reaction of relatively nonnucleophilic enol derivatives with carbonyl compounds is facile in the presence of the silyl triflate. The activation of acetals was first reported by Noyori and has since been widely employed (eq 14).[22,23]

(14)

In an extension to this work, TMSOTf catalyzes the first step of a [3 + 2] annulation sequence which allows facile synthesis of fused cyclopentanes possessing bridgehead hydroxy groups (eq 15).[24]

(15)

The use of TMSOTf in aldol reactions of silyl enol ethers and ketene acetals with aldehydes is ubiquitous. Many refinements of the basic reaction have appeared. An example is shown in eq 16.[25]

(16)

The use of TMSOTf in the reaction of silyl ketene acetals with imines offers an improvement over other methods (such as Ti^{IV}- or Zn^{II}-mediated processes) in that truly catalytic amounts of activator may be used (eq 17);[26] this reaction may be used as the crucial step in a general synthesis of 3-(1´-hydroxyethyl)-2-azetidinones (eq 18).[27]

(17)

(18)

Stereoselective cyclization of α,β-unsaturated enamide esters is induced by TMSOTf and has been used as a route to quinolizidines and indolizidines (eq 19).[28]

(19)

The formation of nitrones by reaction of aldehydes and ketones with ***N-Methyl-N,O-bis(trimethylsilyl)hydroxylamine*** is accelerated when TMSOTf is used as a catalyst; the acceleration is particularly pronounced when the carbonyl group is under a strong electronic influence (eq 20).[29]

(20)

β-Stannylcyclohexanones undergo a stereoselective ring contraction when treated with TMSOTf at low temperature. When other Lewis acids were employed, a mixture of ring-contracted and protiodestannylated products was obtained (eq 21).[30]

(21)

The often difficult conjugate addition of alkynyl organometallic reagents to enones is greatly facilitated by TMSOTf. In particular, alkynyl zinc reagents (normally unreactive with α,β-unsaturated carbonyl compounds) add in good yield (eq 22).[31] The proportion of 1,4-addition depends on the substitution pattern of the substrate.

(22)

The 1,4-addition of phosphines to enones in the presence of TMSOTf gives β-phosphonium silyl enol ethers, which may be deprotonated and alkylated in situ (eq 23).[32]

(23)

Miscellaneous.

Methyl glucopyranosides and glycopyranosyl chlorides undergo allylation with allylsilanes under TMSOTf catalysis to give predominantly α-allylated carbohydrate analogs (eq 24).[33]

(24)

Glycosidation is a reaction of massive importance and widespread employment. TMSOTf activates many selective glycosidation reactions (eq 25).[34]

(25)

TMSOTf activation for coupling of 1-*O*-acylated glycosyl donors has been employed in a synthesis of avermectin disaccharides (eq 26).[35]

Similar activation is efficient in couplings with trichloroimidates[36] and *O*-silylated sugars.[37,38]

2-Substituted Δ^3-piperidines may be prepared by the reaction of 4-hydroxy-1,2,3,4-tetrahydropyridines with a variety of carbon and heteronucleophiles in the presence of TMSOTf (eqs 27 and 28).[39]

Iodolactamization is facilitated by the sequential reaction of unsaturated amides with TMSOTf and ***Iodine*** (eq 29).[40]

By use of a silicon-directed Beckmann fragmentation, cyclic (*E*)-β-trimethylsilylketoxime acetates are cleaved in high yield in the presence of catalytic TMSOTf to give the corresponding unsaturated nitriles. Regio- and stereocontrol are complete (eq 30).[41]

(30)

A general route to enol ethers is provided by the reaction of acetals with TMSOTf in the presence of a hindered base (eq 31).[42] The method is efficient for dioxolanes and noncyclic acetals.

(31)

α-Halo sulfoxides are converted to α-halovinyl sulfides by reaction with excess TMSOTf (eq 32),[43] while α-cyano- and α-alkoxycarbonyl sulfoxides undergo a similar reaction (eq 33).[44] TMSOTf is reported as much superior to ***Iodotrimethylsilane*** in these reactions.

(32)

3-Trimethylsilyl-3-trimethylsilyloxy-1-propene[1]

[66662-17-7] · $C_9H_{22}OSi_2$ · 3-Trimethylsilyl-3-trimethylsilyloxy-1-propene · (MW 202.49)

(homoenolate anion[2] and homoenolate dianion[3] equivalents; synthesis of acylsilanes)

Physical Data: bp 62 °C/35 mmHg; *n*20D 1.4228.

Preparative Methods: allyl trimethylsilyl ether is lithiated with ***s-Butyllithium*** in THF-HMPA to give a rapidly equilibrating mixture of a carbanion and a silylallyloxy anion (eq 1). Silylation of the mixture with ***Chlorotrimethylsilane*** affords 3-trimethylsilyl-3-trimethylsilyloxy-1-propene (**1**) exclusively. Several other derivatives with bulky substituent(s) on the silyloxy group were also prepared.[2]

Handling, Storage, and Precautions: use in a fume hood.

Homoenolate Anion Equivalent.

The reaction of (**1**) with acid chlorides in the presence of ***Titanium(IV) Chloride*** affords the corresponding γ-keto aldehydes after hydrolysis (eq 2).[2] *O*-Acylation to form the 1-silyl allyl ester (17-30%) competes with the S_E' alkylation of the double bond. Bulkier silyloxy derivatives give γ-keto aldehydes in higher yield.

$R^1 = R^2 = Me$	20%	30%
$R^1 = R^2 = Et$	43%	17%
$R^1 = Me$, $R^2 = t$-Bu	45%	-

Homoenolate Dianion Equivalent.

The intermediate in the reaction is believed to be an enol silane and/or enol titanate which gives the expected product with carbon electrophiles such as acetals (eq 3).[3]

Synthesis of Acylsilanes.

The title reagent (**1**) and other related derivatives undergo sequential isomerization to α-silylalkenyl ethers upon treatment with ***Palladium on Carbon*** which subsequently give acylsilanes by hydrolysis (eq 4).[4]

Related Reagents.

Allyltrimethylsilane; ***1-Ethoxy-1-(trimethylsilyloxy)cyclopropane***; ***1-Methoxyallyllithium***; ***Trimethylsilylallyllithium***.

(*E*)-1-Trimethylsilyl-2-trimethylstannylethylene[1,2]

[58207-97-9] · $C_8H_{20}SiSn$ · (*E*)-1-Trimethylsilyl-2-trimethylstannylethylene · (MW 263.08)

(reagent for Pd^0-catalyzed cross-coupling reactions with aryl and vinyl halides or triflates;[1,2] source of β-trimethylsilylvinyllithium[3])

Physical Data: bp 22 °C/0.04 mmHg; n_D 1.4723.

Solubility: sol ether, DMF, hydrocarbon, aromatic solvents.

Analysis of Reagent Purity: ^{1}H NMR (CCl_4/CH_2Cl_2) δ 0.12 (s, 9H, Me_3Si), 0.17 (s, 9H, Me_3Sn), 6.30-7.20 (AB pattern, J_{AB} = 22 Hz, 2H, vinyl).

Preparative Method: trans-1,2-bis(tri-*n*-butylstannyl)ethylene is treated successively with ***n-Butyllithium***, ***Chlorotrimethylsilane***, *n*-BuLi, and ***Chlorotrimethylstannane*** to give (*E*)-trimethylsilyl-2-trimethylstannylethylene in good yield.[3]

Handling, Storage, and Precautions: organotin reagents are extremely toxic and readily absorb through the skin.[4] The reagent should be handled at all times in an efficient fume hood, wearing the appropriate personal safety equipment (i.e. gloves, safety eyewear).

Palladium-Catalyzed Coupling Reactions.

Vinyl and aromatic halides undergo palladium-catalyzed cross-coupling reactions with trimethylsilyl-2-trimethylstannylethylene to give substituted 1,3-dienes and styrenes, respectively (eqs 1 and 2).[5,6] Vinyl triflates also undergo cross-coupling reactions to give 1,3-dienes, provided that ***Lithium Chloride*** is added to the reaction (eq 3).[7,8]

(3)

The reactions employ mild conditions, are regioselective and stereospecific, and give high yields of products. In addition, tedious protection-deprotection steps are not necessary because the reactions tolerate a wide variety of functional groups.[5,6]

When the coupling of vinyl triflates is carried out in the presence of ***Carbon Monoxide*** and lithium chloride, carbon monoxide insertion occurs, yielding unsymmetrical divinyl ketones (eqs 4 and 5).[9,10] This is a particularly useful procedure for the formation of intermediates for the Nazarov cyclization reaction.[11]

(4)

(5)

For additional discussion about palladium-catalyzed coupling reactions, see also those entries dealing with organopalladium complexes (e.g. ***Tetrakis(triphenylphosphine)palladium(0)***, ***Tris(dibenzylideneacetone)dipalladium***, and/or ***(E)-1-Tri-n-butylstannyl-2-trimethylsilylethylene***).

Transmetalation Reactions.

Transmetalation of trimethylsilyl-2-trimethylstannylethylene at low temperature with *n*-BuLi affords ***(E)-2-(Trimethylsilyl)vinyllithium*** in high yield (eq 6).[3]

(Trimethylsilyl)vinylketene

[75232-81-4] · $C_7H_{12}OSi$ · (Trimethylsilyl)vinylketene · (MW 140.28)

(reactive diene for [4 + 2] cycloadditions[1])

Alternate Name: 2-(trimethylsilyl)-1,3-butadien-1-one.

Physical Data: bp 49.0-50.5 °C/1.6 mmHg.

Solubility: sol CH_2Cl_2, $CHCl_3$, CCl_4, toluene, benzene, hexane, most organic solvents.

Form Supplied in: yellow-green liquid; not commercially available.

Analysis of Reagent Purity: IR ($CDCl_3$) 2085, 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.25 (s, 9 H), 4.82 (dd, *J* = 1, 10 Hz, 1 H), 4.88 (dd, *J* = 1, 17 Hz, 1 H), 5.92 (dd, *J* = 10, 17 Hz, 1 H) ppm; ^{13}C NMR ($CDCl_3$) δ -1.0 (q), 22.3 (s), 111.6 (t), 125.1 (d), 183.7 (s) ppm.

Preparative Methods: conveniently prepared as outlined in eq 1. Treatment of 1-(trimethylsilyl)propyne (**2**)[2] with 1.1 equiv of ***Diisobutylaluminum Hydride*** (25 °C, 21 h) and 1.1 equiv of ***Methyllithium*** (0 °C, 0.5 h) in ether-hexane,[2] followed by reaction of the resulting vinylalanate with anhydrous ***Carbon Dioxide***,[3] yields (*Z*)-2-(trimethylsilyl)-2-butenoic acid (**3**) in 68% yield. Exposure of the potassium salt of this acid (**4**) to 1.1 equiv of ***Oxalyl Chloride*** in pentane containing a catalytic amount of ***N,N-Dimethylformamide*** (0-25 °C, 1.5 h) then produced a mixture of the acid chloride (**5**) and its geometric isomer, which was dehydrohalogenated without further purification. A solution of (**5**) in pentane was added dropwise over 1-2 h to a solution of 0.9 equiv of ***Triethylamine*** in pentane at 25 °C, and the resulting mixture was heated at reflux for 15-24 h and then filtered with the aid of pentane. Solvent was evaporated at -50 °C (0.5 mmHg), and the residue was distilled at 25 °C (1 mmHg) and then again at 5 mmHg into a receiver cooled at -78 °C. In this manner a yellow-green liquid of (trimethylsilyl)vinylketene (**1**) was obtained in 39-50% overall yield (from **3**).

Handling, Storage, and Precautions: purified vinylketenes can be stored under nitrogen in solution at 0 °C without appreciable decomposition for 1-2 weeks.

Reactive Enophile in [4 + 2] Cycloadditions.

Vinylketenes are not effective as dienes in Diels-Alder reactions because they undergo only [2 + 2] cycloaddition with alkenes, as predicted by frontier molecular orbital theory. However, silylketenes exhibit dramatically different properties from those found for most

ketenes.[4] (Trimethylsilyl)vinylketene (**1**) is a relatively stable isolable compound which does not enter into typical [2 + 2] cycloadditions with electron-rich alkenes. Instead, (**1**) participates in Diels-Alder reactions with a variety of alkenic and alkynic dienophiles. The directing effect of the carbonyl group dominates in controlling the regiochemical course of cycloadditions using this diene. For example, reaction of (**1**) with ***Methyl Propiolate*** produced methyl 3-(trimethylsilyl)salicylate with the expected regiochemical orientation. Protodesilylation of this adduct with ***Trifluoroacetic Acid*** in chloroform (25 °C, 24 h) afforded methyl salicylate in 78% yield (eq 2).

Diels-Alder addition of (**1**) to alkenic dienophiles furnishes cyclohexenone derivatives (eqs 3 and 4). Addition of (**1**) to naphthoquinone afforded a mixture of several cycloadducts which could be oxidized to a single anthraquinone (eq 5).

The reactivity of (trimethylsilyl)vinylketene compares favorably to previously reported vinylketene equivalents. Both vinylketene acetals[5] and thioacetals[6] have been reported to undergo [4 + 2] cycloadditions in good yield. However, due to the limited reactivity of hindered (*Z*)-dienes, only highly electrophilic dienophiles react. Specially activated vinylketene thioacetal substrates have been made with an electron-donating group at the 3-position of the diene to promote reaction with weaker dienophiles. Unfortunately, due to their strong nucleophilic character, these dienes were found to participate in a stepwise Michael-type process. Concerted [4 + 2] cycloadditions were only seen with a few dienophiles.[6c] Vinylketenimines are shown to be isolable by distillation, are stable at room temperature, and undergo [4 + 2] cycloadditions in moderate to good yield. Again, reaction only occurs with electron-deficient dienophiles.[7]

A general route to substituted (silyl)vinylketenes has been developed and several substituted ketenes have been prepared. The synthesis of 1-(1-cyclohexenyl)-2-triisopropylsilylketene is representative of this general approach (eq 6).[10]

Thus detrifluoroacetylative diazo transfer[8] furnished the diazo ketone in 80% yield, which was converted to the silyl diazo ketone in 75% yield by the method of Maas.[9] The key photolysis step was effected by irradiating a degassed 0.1 M solution of the silyl diazo ketone in hexane in a Vycor tube using a low-pressure mercury lamp (300 nm) for 2 h. Concentration and chromatographic purification furnished the desired (silyl)vinylketene in 73% yield.[10]

1-(Trimethylsilyl)vinyllithium

[51666-94-5] · $C_5H_{11}LiSi$ · 1-(Trimethylsilyl)vinyllithium · (MW 106.19)

(adds 1,2 to ketones and aldehydes;[1] 1,4-additions to enones via the cuprates;[2] diene synthesis;[3] formation of vinylsilanes[4])

Alternate Names: 1-lithio-1-(trimethylsilyl)ethylene; α-(trimethylsilyl)vinyllithium.

Solubility: sol THF, ether.

Preparative Method: prepared in situ under an inert atmosphere by lithium-halogen exchange of ***(1-Bromovinyl)trimethylsilane*** with ***t-Butyllithium***.

Handling, Storage, and Precautions: solutions are inflammable; it is critical to preclude contact with air and moisture.

Addition to Ketones and Aldehydes.[1]

α-(Trimethylsilyl)vinyllithium (**1**) adds to ketones and aldehydes. The adducts do not undergo the expected Peterson elimination reaction when treated with ***Sodium Hydride*** or ***Potassium Hydride***, but the corresponding allene can still be obtained if the alcohol is converted to the chloride followed by fluoride-catalyzed β-elimination (eq 1).[5a,b] Other uses have also been made of the allyl chlorides made in this manner: they react with cuprates,[5c] or they can be oxidized to the epoxides to serve as precursors to allene oxides.[5d-l]

(1)

Under certain conditions (KH in HMPA), products from the homo-Brook rearrangement are observed (eq 2).[6] This is therefore a good method of desilylation of β-hydroxyvinylsilanes to the corresponding vinyl alcohols. Other conditions for desilylation were found to give better yields (eq 3).[7] Since α-(trimethylsilyl)vinyllithium was found to add to chiral aldehydes with better diastereoselectivity than ***Vinyllithium***, the overall sequence is an improvement for chelation controlled 1,2-asymmetric induction.[7a] In the sequence of eq 3, diastereoselectivity varied as the protecting group R´ was changed; it was 20:1 for R´-benzyl. This illustrates the usefulness of α-

(trimethylsilyl)vinyllithium in stereoselective polyol synthesis.[7]

(2)

(3)

The alcohol adducts from α-(trimethylsilyl)vinyllithium and aldehydes have found many uses in organic synthesis. The ketones obtained by oxidation (eq 4) are especially good Michael acceptors and have been used in a modified Robinson annulation reaction for the construction of cyclohexenones.[8] Cyclopropanation leads to cyclopropylsilane adducts, which can be converted into a variety of cyclopentenes (eq 5).[9] Halogenation followed by stannylation gives synthons (eq 6) useful for making substituted vinylsilanes through radical reactions.[10]

(4)

(5)

Rearrangements of alcohols bearing an epoxide functionality give ketones that can be stereoselectively reduced. The new stereocenter formed is of opposite configuration when the trimethylsilyl group R is present on the vinyl moiety (eq 7).[11b,c] Thus α-(trimethylsilyl)vinyllithium can be viewed as a large vinyl anion equivalent (e.g. eq 3) which complements vinylmagnesium and lithium chemistry.[11] These reactions were elegantly used in the total syntheses of avenaciolide, isoavenaciolide,[11b,c] and (+)- and (-)-eldanolide.[11f]

1,4-Additions to Enones via the Cuprates.[2]

α-(Trimethylsilyl)vinyllithium undergoes Michael addition to enones, in good yields, in the presence of copper salts (eq 8).[2] The vinyl group can be oxidized to the epoxide, which is then converted to the acyl group.[2,12] The overall transformation is the addition of an acyl anion equivalent. α-(Trimethylsilyl)vinyllithium compares favorably with other acyl anion equivalents, particularly with the vinyl ether analogs which do not add well to hindered enones.[13]

Diene Synthesis.[3]

α-(Trimethylsilyl)vinyllithium dimerizes in the presence of ***Copper(I) Iodide***. This reaction was first observed as a side product during the formation of organocuprates,[3a] then developed for the synthesis of 2,3-bis(trimethylsilyl)buta-1,3-diene (eq 9).[3b]

(9)

Reactions with Other Electrophiles.[4]

α-(Trimethylsilyl)vinyllithium reacts with ethylene oxide to give an intermediate which has been used to set up an impressive eight-membered ring cyclization for the synthesis of (-)-laurenyne (eq 10).[4a] Here, vinyltrimethylsilane was preferred over the simple vinyl moiety because of its greater reactivity.

(10)

The reaction of this anion with carbon monoxide leads to the formation of an interesting cyclopropyl product (eq 11).[4c] Other electrophiles, for example selenium cyanide,[4d] ***Iodine***,[4f] chlorosilanes,[4g] and imines,[4h] react with α-(trimethylsilyl)vinyllithium to give the corresponding adducts.

(11)

Related Reagents.

Other types of 1-lithio-1-vinylsilanes have been made, mainly through the lithium-halogen exchange reaction described before. For example, one or all of the methyl groups on silicon can be substituted by phenyls. The compounds (**2**)[4c] and (**3**)[14] have properties similar to α-(trimethylsilyl)vinyllithium.

(2)

(3)

Monosubstitution in the 2-position on the vinyl moiety has been extensively exemplified in the literature. The stereochemistry of the double bond implies two possible types of reagents. For example, the 2-(*Z*)-monosubstituted (**4**,[15] **5**[11d]) and the 2-(*E*)-monosubstituted (**6**,[16a] **7**[16b]) 1-lithiovinylsilanes have been treated with carbonyl and alkyl electrophiles.

(4) R = C_6H_{13}
(5) R = $PhCH_2OCH_2$

(6) R = *i*-Pr
(7) R = Ph

The stereochemistry of the 1-lithiovinylsilanes is easily lost, as exemplified in eq 12 where (**9**), prepared by a transmetalation reaction, subsequently equilibrates to a mixture containing (**9**) and (**10**).[15,16b]

(8) **(9)** **(10)** (12)

One other related reagent includes the species (**11**),[17] obtained from silylcupration of the corresponding lithium acetylide. This is yet another way to obtain 1-lithiovinylsilanes substituted in the β-position.

(*E*)-2-(Trimethylsilyl)vinyllithium

[55339-31-6] · $C_5H_{11}LiSi$ · (*E*)-2-(Trimethylsilyl)vinyllithium · (MW 106.19)

(for introduction of the β-(trimethylsilyl)vinyl moiety; the resulting alkenylsilanes undergo useful electrophilic substitutions of the TMS group[1])

Form Supplied in: not available commercially; prepared in situ in either THF or diethyl ether.

Preparative Methods: attempts to produce synthetically useful quantities of (*E*)-2-(trimethylsilyl)vinyllithium (**1**) by reaction of ***Lithium*** metal with ***(2-Bromovinyl)trimethylsilane*** (**2**) failed because of concomitant metalation-elimination processes involving (**1**) and (**2**).[2] However, the transmetalation process between (**2**) and excess ***t-Butyllithium*** has been effectively used to provide (**1**) (eq 1).[3] An alternative route to (**1**) employs the transmetalation of a 1-(trimethylsilyl)-2-stannylethylene with organolithium reagents (eqs 2 and 3).[4,5]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar, N_2) to exclude oxygen and moisture.

Substitution Reactions.

Alkylating agents containing primary alkyl or methyl groups react with (**1**) in synthetically useful yields (eqs 4 and 5).[4,5] Reaction of (**1**) with ***1,2-Dibromoethane*** affords (**2**),[4] while the use of metal or metalloidal halides generally results in high yields of coupling products (eqs 6-9).[4-7]

(5)

(6)

(7)

(8)

(9)

An important subset of the reaction with metal halides is the conversion of (**1**) into more discriminating reagents. Thus the reaction of (**1**) with ***Copper(I) Iodide*** forms a diorganocuprate (**3**) which adds in a 1,4-fashion to conjugated enones (eqs 10 and 11).[3a,b,8] In this same vein, (**2**) was transformed into an alkenylzinc reagent which displayed selectivity between adjacent aldehyde and ester functionalities (eq 12).[9]

(10)

(11)

(12)

Addition Reactions.

The behavior of (**1**) with carbonyl-containing compounds is completely straightforward, with aldehydes (eqs 13 and 14),[10,11] ketones (eqs 15 and 16),[12,13] and ***Carbon Dioxide*** (eq 17)[4] leading cleanly to expected products. Sato and co-workers have observed (**1**) to display considerable chemoselectivity in favor of an aldehyde functionality when presented with an ester as the alternative (eq 18).[13]

(13)

(14)

(15)

(16)

1-(Trimethylsilyl)vinylmagnesium Bromide-Copper(I) Iodide[1]

[49750-22-3] · $C_5H_{11}BrMgSi$ · 1-(Trimethylsilyl)vinylmagnesium Bromide-Copper(I) Iodide · (MW 203.46)

[7681-65-4] · CuI · 1-(Trimethylsilyl)vinylmagnesium Bromide-Copper(I) Iodide · (MW 190.45)

(reacts with epoxides to give homoallylic alcohols useful for the synthesis of α-methylenebutyrolactones;[2] can function as a synthon for epoxides;[3,4] adds to D-glyceraldehyde acetonide to give epoxy alcohols and D-threose derivatives[3,4])

Preparative Methods: prepared in situ under anhydrous conditions by reacting 1-(trimethylsilyl)vinylmagnesium bromide (**1**) with ***Copper(I) Iodide*** (**2**) in various molar ratios.

Handling, Storage, and Precautions: use in a fume hood.

α-Methylenebutyrolactone Synthesis.

Epoxides react with (**1**) in the presence of catalytic amounts of (**2**) to give homoallylic alcohols (**3**) (eq 1) which were used in a synthesis of α-methylene lactones (**4**) (eq 2).[2] In the absence of (**2**) the reaction fails to give the desired homoallylic alcohols (**3**).

(1)

Addition to D-Glyceraldehyde Acetonide: Preparation of Epoxy Alcohols and D-Threose Derivatives.

2,3-*O*-isopropylideneglyceraldehyde (**5**) reacts with (**1**) in the presence of excess (**2**) to give the *syn* addition product (**6**) with high diastereoselectivity (>98:2 *syn*:*anti*, eq 3).[3,4] Sharpless epoxidation of (**6**) followed by protodesilylation gave epoxy alcohol (**7**) (eq 4).[3] Alternatively, (**6**) can be converted to the D-threose derivative (**8**) by a sequence of three steps: protodesilylation, protection, and ozonolysis.[4] Replacement of ***Copper(I) Cyanide*** and ***Methyllithium*** for CuI in this reaction gives predominantly the *anti* addition product in 87% yield.

(4)

Related Reagents.

2-(3-Trimethylsilyl-1-propenyl)magnesium Bromide-Copper(I) Iodide; ***Vinylmagnesium Bromide***; ***Vinylmagnesium Bromide-Copper(I) Iodide***.

Trimethylstannylcopper-Dimethyl Sulfide

$Me_3SnCu.Me_2S$

[89041-25-8] · $C_5H_{15}CuSSn$ · Trimethylstannylcopper-Dimethyl Sulfide · (MW 289.53)

(transfer of trimethyltin to electrophilic substrates, including β-iodo α,β-unsaturated ketones,[1] α,β-alkynic carboxylic acid derivatives,[2-5] and terminal alkynes[6])

Physical Data: prepared in situ; its THF solution is deep red.

Solubility: sol THF.

Preparative Method: $Me_3SnCu.Me_2S$ (**2**) is readily prepared[1] by addition of solid $CuBr.Me_2S$[8] (see ***Copper(I) Bromide***) to a solution of ***Trimethylstannyllithium*** (**1**)[7b,9] in THF (eq 1). The actual structure of the stannylcopper(I) reagent is not known. Formula (**2**) is employed for convenience and on the basis of analogy with alkylcopper(I) reagents.

Handling, Storage, and Precautions: the reagent is sensitive to air and must be prepared in dry THF and used under an inert atmosphere. Since organotin compounds exhibit toxicity,[7a] reaction workup should be carried out only in a well-ventilated fume hood.

Reaction with α,β-Unsaturated Carbonyl Systems.

Reagent (**2**) is appreciably less reactive than the parent Me_3SnLi (**1**). Although (**1**) efficiently effects conjugate addition of the Me_3Sn function to α,β-unsaturated ketones and esters,[1,9] (**2**) reacts with these substrates sluggishly or not at all.[1] On the other hand, (**2**) is an excellent agent for the transformation of β-iodo α,β-unsaturated ketones[10] into the corresponding β-trimethylstannyl enones (eq 2).[1] The latter substances are potentially useful intermediates for organic synthesis.[11]

(2)

Reaction with α,β-Alkynic Carboxylic Acid Derivatives.

An important use of reagent (**2**) results in the regioselective *cis* addition of the elements of Me_3Sn-H across the triple bond of α,β-alkynic esters[2,5] and *N,N*-dimethylamides[4] (eqs 3 and 4). Attempts to trap the intermediates derived from the ester substrates with electrophiles other than protons have not been successful.[3-5,12] On the other hand, the corresponding intermediates obtained from the amide substrates can be trapped with reactive alkylating agents (eq 4).[4] The synthetic utility of alkyl (*E*)-3-trimethylstannyl-2-alkenoates (cf. **3**) has been demonstrated in a variety of contexts.[13]

Interestingly, treatment of α,β-alkynic esters with reagent (**2**) under suitable conditions provides alkyl (*E*)-2,3-bis(trimethylstannyl)-2-alkenoates (eq 5).[3] The latter compounds, which may also be prepared by Pd^0-catalyzed addition of ***Hexamethyldistannane*** to α,β-alkynic esters,[14a,c] are useful substrates for the stereocontrolled preparation of tetrasubstituted alkenes.[14b]

Reaction with 1-Alkynes.

Under appropriate conditions, $Me_3SnCu.Me_2S$ (**2**) reacts with 1-alkynes to provide, regioselectively, 2-trimethylstannyl-1-alkenes[6,15-22] (eq 6).[15] This process can be carried out successfully in the presence of a variety of functional groups. Functionalized 2-trimethylstannyl-1-alkenes are useful intermediates for organic synthesis[16-19,23] (see also ***4-Chloro-2-trimethylstannyl-1-butene***).

Related Reagents.

Bis(methylthio)(trimethylstannyl)methane; ***Lithium Phenylthio(trimethylstannyl)cuprate***; ***Tri-n-butylstannylcopper***; ***Tri-n-butylstannyllithium***; ***2-Trimethylstannylmethyl-1,3-butadiene***.

2-Trimethylstannylmethyl-1,3-butadiene[1]

[71092-51-8] · $C_8H_{16}Sn$ · 2-Trimethylstannylmethyl-1,3-butadiene · (MW 230.95)

(isoprenylation reagent;[1] Diels-Alder diene[1])

Physical Data: bp 77-78 °C/40 mmHg.

Analysis of Reagent Purity: ^{1}H NMR δ 0.07 (9H, s), 1.89 (2H, d, *J* = 1.0 Hz), 4.65-5.20 (4H, m), 6.33 (1H, dd, *J* = 10.0, *J* = 17.4 Hz); λ_{max} (hexane) 239.5 (ε 10 000).

Solubility: sol common organic solvents but avoid hydroxylic solvents.

Purification: by distillation.

Preparative Methods: by the reaction of the Grignard reagent prepared from chloromethyltrimethylstannane and chloroprene in the presence of a catalytic amount of dichlorobis(diphenylphosphino)propanenickel(II) in 75% yield,[2] analogous to the procedure employed for the preparation of ***2-Trimethylsilylmethyl-1,3-butadiene***.[3] The reaction of ***Trimethylstannyllithium***[4] with α-bromoisoprene[5] also gives 2-trimethylstannylmethyl-1,3-butadiene in 70% yield.[6]

Handling, Storage, and Precautions: can be stored in a glass bottle under nitrogen. Organotin derivatives are known to be toxic. Therefore the reagents should be handled in a well-ventilated hood and contact with the skin and eyes should be avoided.

Diels-Alder Reaction.

2-Trimethylstannylmethyl-1,3-butadiene undergoes Diels-Alder reactions with a variety of dienophiles in high yield (eqs 1 and 2). With unsymmetrical dienophiles, the para products are obtained with higher selectivity than the reaction of the silicon analog (see ***2-Trimethylsilylmethyl-1,3-butadiene***).[2]

Allylation Reaction.

2-Trimethylstannylmethyl-1,3-butadiene enters the usual allylation reactions with carbonyl compounds in the presence of ***Boron Trifluoride Etherate*** (eq 3).[7]

Cross-Coupling Reaction.

Zinc Chloride-catalyzed reaction with ***Allyl Bromide*** results in the formation of allyl coupling products (eq 4).

(Trimethylstannylmethyl)lithium[1]

[76373-10-9] · $C_4H_{11}LiSn$ · (Trimethylstannylmethyl)lithium · (MW 184.80)

(methylenation reagent for several electrophiles;[1] methylene double anion equivalent connecting two different electrophiles with methylene bridge[1])

Solubility: sol ethers (THF, diethyl ether, DME).

Preparative Methods: treatment of bis(trimethylstannyl)methane with *n*-butyllithium or ***Methyllithium*** in dry THF.[2] Bis(trimethylstannyl)methane can be obtained by the reaction of dichloromethane with 2 equiv of trimethylstannylsodium in liq NH_3 (89%)[3] or by the reaction of ***Diiodomethane*** with ***Tin(II) Bromide*** followed by the treatment with methylmagnesium iodide.[4]

Purification: the precursor bis(trimethylstannyl)methane should be distilled under reduced pressure before use (88-92 °C/15 mmHg).

Handling, Storage, and Precautions: since organotin reagents are toxic, all experiments should be performed in a good fume hood and with gloves.

Methylenation Reagent for Carbonyl Compounds.

The title reagent (**1**) or the analogous (tributylstannylmethyl)lithium react with ketones (**2**), affording β-stannyl alcohols (**3**) which undergo Peterson-type eliminations upon acid treatment or heating to methylene compounds (**4**) (eq 1).[5]

In contrast to the Wittig or Peterson reaction, which sometimes fails with enolizable ketones (5-20%),[6] the present reaction gives the desired alkenes in good yields (64-96%).[5] Remarkably, the reaction with *cis*-1-decalone in the presence of ***Hexamethylphosphoric Triamide*** proceeds with no epimerization, giving the *cis-exo* methylene compound in 91% yield, while the Wittig reaction affords the product as a mixture of *cis* and *trans* isomers in 32% yield.

Methylenation Reagent for Miscellaneous Electrophiles.

Reagent (**1**) reacts with the oxiranes (**5**) to form γ-stannyl alcohols (**6**) in the presence of 2 equiv HMPA. The alcohols (**6**) are easily converted into cyclopropanes (**7**) with Lewis acids (eq 2).[5]

The reaction pattern of (**1**) with carbonyl groups is influenced by the presence of leaving groups at the α-position. Acyclic α,β-epoxy ketones (**8a**) produce cyclopropanols (**10**) as a single product, while cyclic ketones (**8b**) produce mixtures of (**10**) and (**12**).[7] Presumably nonselective attack of (**1**) produces the diastereomers of (**9**), which cyclize either to (**10**) or (**11**) under stereoelectronic control; β-elimination of (**11**) would produce (**12**). Cyclopropanols (**10a**) and (**10b**) can be converted into β,γ-unsaturated ketones (**13**) and (**14**), respectively, upon Lewis acid treatment. Acyclic enone (**13**) (R = Me) can be obtained in one pot in about 80% yield from the epoxy ketones (**8a**) by successive treatments with reagent (**1**) and ***Hydrogen Chloride*** (eq 3).

(8a) acyclic
(8b) cyclic

(3)

(11) (12)

(13)

(14)

Reaction with Esters: Reagent for Connecting Two Different Kinds of Electrophiles with a Methylene Bridge.

Reagent (**1**) reacts with esters (**15**) to produce enolates (**17**), which are trapped by protons or aldehydes to afford methyl ketones or aldols, respectively (eq 4).

Enolates (**17**) react with methyl formate to afford β-keto aldehydes (**20**) in enol form. As an application, D-mycaroside (**22**) has been synthesized (eq 5).[8]

An analog of reagent (**1**), (trimethylstannyl)methylmagnesium iodide, has been used for methylenation of thioacetals (**23**) in the presence of a Ni^{II} catalyst (eq 6).[9]

Related Reagents.

Trimethylsulfonium Hydroxide

[172387-03-5] · $C_3H_{10}OS$ · Trimethylsulfonium Hydroxide · (MW 94.20)

(quantitative pyrolytic *O*-alkylation of fatty acids during gas chromatographic analysis)

Preparative Methods: by treating ***Trimethylsulfonium Iodide*** with ***Silver(I) Oxide*** in methanol;[2] by electrochemical method;[3] and in aqueous solution, by treating trimethylsulfonium iodide with ***Tetra-n-butylammonium Hydroxide*** using an extraction procedure.[1] The reagent has been reported to be stable in cool methanol for at least six months.[4]

General Discussion.

Trimethylsulfonium hydroxide is primarily referred to in the literature as a reagent for derivatizing fatty acids during gas chromatographic analysis through pyrolytic alkylation (eq 1).[5]

$$RCO_2H + Me_3S^+ OH^- \xrightarrow[-H_2O]{} RCO_2^- Me_3S^+ \xrightarrow[-Me_2S]{} RCO_2Me \quad (1)$$

The transformation takes place in the injection port, alleviating the need for more time consuming methods. Alternative methods include basic hydrolysis followed by acid-catalyzed re-esterification,[6] transesterification with sodium methoxide,[7] pyrolytic alkylation using a trialkylselenonium hydroxide,[4] and pyrolytic alkylation using a quaternary ammonium hydroxide.[8] Each of these methods has limitations. Hydrolysis and re-esterification require a significant amount of laboratory time. The transesterification using sodium methoxide fails to derivatize any free acids present in the initial mixture. Selenium reagents have handling problems due to their toxicity. Amine byproducts from a quaternary ammonium hydroxide have sufficiently long retention times to complicate a chromatogram.

Yamauchi has used trimethylsulfonium hydroxide to 2´-*O*-methylate pyrimidine ribonucleosides selectively.[9] A variety of metal ion catalysts for this methylation procedure were evaluated on a semipreparative scale.

The use of trimethylsulfonium hydroxide as a pyrolytic *O*-alkylating agent avoids many of the problems associated with other methods. The reagent is conveniently prepared from readily available starting materials and is relatively stable in solution.

Trimethylsulfonium Iodide

$Me_3S^+X^-$

(X = I)

[2181-42-2] · C_3H_9IS · Trimethylsulfonium Iodide · (MW 204.09) (X = Br)

[3084-53-5] · C_3H_9BrS · Trimethylsulfonium Bromide · (MW 157.09)

(precursor of dimethylsulfonium methylide[1])

Physical Data: Me_3SI, mp 211-212.5 °C (dec); Me_3SBr, mp 201-202 °C (dec, sealed tube), 172 °C (dec).

Solubility: sol H_2O, alcohol, THF, DMSO.

Form Supplied in: Me_3SI, white crystals; Me_3SBr, white deliquescent crystals.

Preparative Methods: Me_3SI is prepared in almost quantitative yield by mixing equimolar amounts of ***Dimethyl Sulfide*** and ***Iodomethane*** at room temperature. After standing overnight, the resulting solid white cake is crushed and recrystallized from absolute ethanol to give pure trimethylsulfonium iodide.[1b,2]

To prepare Me_3SBr, a mixture of Me_2S and an excess amount (more than 3.0 equiv) of ***Bromomethane*** is heated at 100 °C for 4 h in a sealed tube. During workup the contents of the tube give out a strong irritating odor. The resulting white crystals are washed with ethyl acetate and recrystallized from a small amount of water to give white, deliquescent crystals of trimethylsulfonium bromide.[2a]

Handling, Storage, and Precautions: irritant.

Formation of Dimethylsulfonium Methylide.

Treatment of trimethylsulfonium iodide (or bromide) with strong bases such as the methylsulfinyl carbanion[1b,3] (***Potassium t-Butoxide*** in ***Dimethyl Sulfoxide***, ***Sodium Hydride*** in DMSO-THF, ***Sodium Ethoxide*** in DMSO) or ***n-Butyllithium*** in THF gave a solution of ***Dimethylsulfonium Methylide***. This heat-labile reagent generated in situ is an exceedingly selective methylene-transfer reagent which is of great use for converting carbonyl compounds into epoxides (even in the case of α,β-unsaturated carbonyl compounds).[4] This ylide also converts imines to aziridines.

Trimethylsulfoxonium Iodide[1]

$Me_3SO^+X^-$

(X = I)

[1774-47-6] · C_3H_9IOS · Trimethylsulfoxonium Iodide · (MW 220.09) (X = Cl)

[5034-06-0] · C_3H_9ClOS · Trimethylsulfoxonium Chloride · (MW 128.64)

(precursor of dimethylsulfoxonium methylide,[1] which transfers a methylene group to ketones and aldehydes to form epoxides and to α,β-unsaturated carbonyl compounds to produce cyclopropyl derivatives;[1-3] a methylation reagent;[4] can function as a catalyst[5])

Physical Data: trimethylsulfoxonium iodide: mp 170 °C (dec), yellow crystalline powder; trimethylsulfoxonium chloride: 227 °C (subl), white powder. The vibrational spectra of both iodide and chloride salts, as well as NMR studies of molecular motion of both salts, have been investigated.[6-8] pK_a = 18.2 for sulfoxonium ion in DMSO.

Solubility: trimethylsulfoxonium iodide: 3.85 g/100 g H_2O (20 °C).[9] Trimethylsulfoxonium chloride has greater solubility in THF than trimethylsulfoxonium iodide.[10] Both sulfoxonium salts sol H_2O, DMSO, *t*-butanol.

Form Supplied in: both iodide and chloride salts are widely available in powder form.

Analysis of Reagent Purity: the purity of trimethylsulfoxonium iodide and trimethylsulfoxonium chloride can be determined by an $AgNO_3$ titration method. A miscible organic solvent, such as acetone, ethanol, or propanol, is usually adopted to carry out the titration process.[11] For precise data, the $AgNO_3$(aq) solution should be protected from light and stored in a dark glass bottle.

Purification: trimethylsulfoxonium iodide and trimethylsulfoxonium chloride are precursors of dimethylsulfoxonium methylide. Except when used under phase transfer conditions, the sulfur ylide is usually prepared by deprotonation of trimethylsulfoxonium iodide or trimethylsulfoxonium chloride with moisture-sensitive strong bases such as ***Sodium Hydride***, ***n-Butyllithium***, etc. Therefore drying the salts prior to use is crucial. Trimethylsulfoxonium iodide can be purified by recrystallization from H_2O and dried in a desiccator over P_2O_5 before use.[2,9]

Preparative Methods: trimethylsulfoxonium iodide is commonly prepared by reaction of ***Dimethyl Sulfoxide*** with ~2.5 equiv of ***Iodomethane***.[12] After refluxing for 24 h at 80 °C, the reaction mixture is cooled and the crude solid product filtered and washed with acetone to give the trimethylsulfoxonium iodide. Iodomethane has to be handled in a fume hood because of its high volatility and toxicity.[12-14] Excess MeI is used to ensure the completion

of the reaction.

Trimethylsulfoxonium chloride can be obtained by the treatment of trimethylsulfoxonium iodide with benzyltributylammonium chloride in a mixed solvent system (CH_2Cl_2/H_2O).[10] The end point is reached when two clear phases are obtained. The aqueous phase is then washed with CH_2Cl_2. After evaporation of H_2O, solid trimethylsulfoxonium chloride is obtained. Direct oxidation of trimethylsulfonium chloride with ***Sodium Hypochlorite*** in the presence of catalytic amount of ***Ruthenium(VIII) Oxide*** in H_2O at room temperature also provides trimethylsulfoxonium chloride.[15] Alternatively, trimethylsulfoxonium chloride can be synthesized by treating a hot aqueous solution of trimethylsulfoxonium iodide with AgCl. After removal of iodide salt, the aqueous filtrate is evaporated to dryness to give trimethylsulfoxonium chloride.[6]

Handling, Storage, and Precautions: both the iodide and chloride salts are hygroscopic and have to be stored in a cool, dry place. They are incompatible with strong oxidizing agents and strong base. The iodide salt is sensitive to light and needs to be protected from light as much as possible.

Preparation of Dimethylsulfoxonium Methylide.

Trimethylsulfoxonium iodide and trimethylsulfoxonium chloride are primarily utilized in the preparation of ***Dimethylsulfoxonium Methylide***, an extremely useful organic synthesis reagent.

Methylation.

Trimethylsulfoxonium iodide can be converted to ***Trimethylsulfonium Hydroxide*** in a mixture of MeOH and water in the presence of ***Silver(I) Oxide*** at room temperature. After filtration, the reaction mixture is concentrated and used directly as a methylation reagent. Uracil, thymine, and cytosine were reported to be converted to their corresponding *N*-methylated products in excellent yield using this reagent. In the same manner, uridine, thymidine, and inosine were smoothly methylated to produce corresponding *N*-methylated nucleosides.[16] Quaternization of tertiary amines is usually accomplished with MeI. Direct treatment of trimethylsulfoxonium iodide with aqueous perchloric acid also provided trimethylsulfoxonium perchlorate, which readily quaternized tertiary amines to their corresponding perchlorate salts in one step.[17]

Other Usages.

Trimethylsulfoxonium iodide is used as a catalyst in the conversion of oxathiolane to oxathiin in toluene under acidic conditions.[5] It is also used in the promotion of the reaction between ***Phosphorus(V) Sulfide*** and an alcohol to form the desired dialkyl phosphorodithioic acid.[18]

Trimethylstannane[1]

Me_3SnH

[1631-73-8] · $C_3H_{10}Sn$ · Trimethylstannane · (MW 164.84)

(hydrostannation of alkenes and alkynes;[2] radical hydrogen source;[3] Me_3SnLi precursor[4])

Alternate Name: trimethyltin hydride.

Physical Data: bp 59-60 °C; *d* 1.477 g cm^{-3}.

Solubility: sol common organic solvents; slightly sol H_2O; insol NH_3.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: best analyzed by ^1H NMR (C_6D_6).

Preparative Method: synthesized by the reaction of ***Lithium Aluminum Hydride*** with ***Chlorotrimethylstannane*** in ethereal solvents.[5] Highest yields are obtained by using high boiling solvents such as bis(2-ethoxyethyl) ether.[6]

Purification: fractional distillation from $LiAlH_4$.

Handling, Storage, and Precautions: unstable to oxidative and photolytic processes; best used immediately upon synthesis. Neat compound can be stored up to a month in a 0 to -20 °C refrigerator, under an inert atmosphere (N_2 or Ar), protected from light. Organostannanes are toxic and should only be used in a well-ventilated hood. All glassware should be rinsed in a KOH/EtOH bath during cleaning.

Hydrostannation.

One of the primary uses of Me_3SnH is for the hydrostannation of π-bonds. Addition of tin hydride can proceed via either a radical or an ionic pathway, depending on the reaction conditions and the substituents adjacent to the π-bond. Hydrostannation can also be mediated by a Pd^0 catalyst. Hydrostannation of terminal alkynes can form three products (eq 1).[2] The major product of the ionic pathway is the α-stannane, formed by addition of the trimethyltin moiety at the most substituted position.[7] Radical hydrostannation typically affords a mixture of the *cis*-β- and *trans*-β-products, with the latter predominating.[7] The palladium-mediated reaction can form any of the above products. The stereochemistry of the product can vary with the substituents on the alkyne. A striking example of this is the palladium-mediated hydrostannation of alkynic esters versus alkynic ketones.[8] The ester gives predominantly *syn* (kinetic) addition, while the ketone gives predominantly *anti* (thermodynamic) addition. Allenes can be hydrostannated under either radical or palladium-catalyzed conditions, but typically lead to a regio- and stereochemical mixture of products.[9]

1,1-Distannyl-1-alkenes, formed by thermal radical hydrostannation of 1-stannyl-1-alkynes (eq 2), can be used to generate α-stannylvinyl anions upon treatment with ***Methyllithium***.[10] The anion can then be treated with electrophiles to form stereochemical mixtures of alkylated products (eq 3). The corresponding bis(tributylstannyl)alkene selectively affords the (*E*)-product. Addition of 2 equiv of methyllithium and electrophile forms the dialkylated product (eqs 4 and 5). Butyllithium cannot be used in this reaction due to alkyl exchange equilibria between tin and lithium.

Hydrostannation of alkenes affords alkyltins. For example, (*E*)-2,3-disubstituted propenoates can be irradiated with a mercury lamp for 4.5 h in the presence of trimethyltin hydride to give the β-stannane (eq 6).[11] In this case, use of thermal free radical conditions (AIBN, 70 °C) causes reduced yields (~25%).[11]

Trimethylstannyllithium.

Treatment of trimethyltin hydride with LDA affords ***Trimethylstannyllithium***, which can be used in nucleophilic reactions.[12] While less convenient than the Me_6Sn_2/MeLi generation of Me_3SnLi, this approach is also less expensive and affords fewer tin byproducts. Nucleophilic attack of trimethylstannyllithium on geminal dibromoalkenes gives the distannyl product in good yield.[13] Use of the analogous dichloro alkene gives only Me_6Sn_2 and an alkyne. Treatment of Me_3SnLi with ***t-Butyldimethylchlorosilane*** affords the silylstannane (eq 7), which can be added across an alkyne in the presence of Pd^0 (eq 8).[4]

(7)

(8)

Reaction of trimethyltin hydride with a cuprate in THF at -78 °C forms the stannylcuprate, which will undergo conjugate additions.[14] Trimethylstannyllithium will also undergo conjugate addition with enones (eq 9).[15,16] After protection of the carbonyl group as an enamine, the trimethylstannyl group can be transmetalated to the alkyllithium with MeLi. Bu_3SnH can also be used for this reaction.

(9)

Radical Reductions.

Alkyl halides are reduced with trimethyltin hydride in the presence of radical initiators, such as ***1,1´-Azobis-1-cyclohexanenitrile*** (ACHN).[3] Tributyltin hydride will also work in this reaction.

Related Reagents.

Hexamethyldistannane; ***Tri-n-butylstannane***; ***Triphenylstannane***.

Trimethylstannyllithium

Me_3SnLi

[17946-71-3] · C_3H_9LiSn · Trimethylstannyllithium · (MW 170.77)

(synthesis of allylstannanes,[1] vinylstannanes,[2] acylstannanes,[3] α-hydroxyalkylstannanes,[4] and β-stannyl ketones[5])

Alternate Name: trimethyltinlithium.

Preparative Methods: prepared by the reaction of ***Hexamethyldistannane*** and ***Methyllithium***, ***Chlorotrimethylstannane*** and ***Lithium*** metal, or by deprotonation of ***Trimethylstannane***.

Handling, Storage, and Precautions: should be used immediately after preparation. For some applications the purity of the starting material is critical. Trimethylstannane should be distilled immediately prior to deprotonation. Sensitive to air and moisture. Volatile organostannanes are toxic and should be used always in a well ventilated fume hood. Contact with eyes and skin should be avoided.

General Discussion.

Trimethyltinlithium is prepared by the reaction of trimethyltin chloride and lithium[6] or by the deprotonation of trimethylstannane using ***Lithium Diisopropylamide***.[5,7] In each case the generation of the reagent is a complicated reaction process, leading to several other reactive species in addition to trimethyltinlithium itself (eq 1).[8]

$$\begin{aligned} Me_3SnCl + Li^0 &\longrightarrow Me_3SnLi \rightleftharpoons [Me_2Sn:] + MeLi \\ [Me_2Sn:] + Me_3SnLi &\longrightarrow Me_5Sn_2Li \end{aligned} \qquad (1)$$

The reaction of trimethyltinlithium with alkyl halides has been the subject of intensive mechanistic study. There are three potential reaction mechanisms for the displacement of an alkyl halide with trimethyltinlithium: direct S_N2 displacement, initial electron transfer leading to the formation of radical intermediates, or initial metal-halogen exchange leading to a carbanion intermediate.[9] Several additives have been explored as a means to delineate radical versus carbanionic pathways: however, the influence of additives such as dicyclohexylphosphine or *t*-butylamine on the mechanism of the reaction has been called into question.[9] Evidence for radical pathways has been obtained by several studies using internal radical traps such as 6-bromohexene,[10] 6-bromoheptene (eq 2),[11] and cyclopropylmethyl bromide.[12] Several studies have used stereochemical probes to determine the possible mechanisms for trimethyltinlithium displacement of alkyl halides.[13] Displacement of a nonracemic secondary alkyl bromide or tosylate also results in a nonstereoselective reaction for the alkyl bromide (~40% inversion) and a stereoselective (100% inversion) process for the tosylate.[14] 4-Methyl- or 4-*t*-butylcyclohexyl bromide and tosylate have been examined as substrates for trimethyltinlithium reactions.[15] In each of these studies the cyclohexyl bromides undergo substitution with loss of stereochemistry, implying a radical process (eq 3). The corresponding tosylates are displaced with complete inversion of stereochemistry by an S_N2 process (eq 4). Radical chain processes are also implicated in the reaction of trimethyltinlithium and 1-bromo-4-iodobicyclo[2.2.2]octane.[16] In a related study using 1,4-dihalobicyclo[2.2.1]heptanes, trimethyltinlithium substitution by an $S_{RN}1$-type mechanism has been postulated; however, a polar mechanism involving formation of a carbanion effectively competes with the chain process.[17]

Trimethyltinlithium can be used for the synthesis of allylstannanes by the displacement of allyl halides,[1] and in the synthesis of 1-trimethylstannyl-2,4-dienes by reaction with 5-tetrahydropyranoxy-1,3-dienes (eq 5).[18] Direct displacement of vinyl halides can also be realized, providing access to 1,1-distannyl-1-alkenes.[2] Acylstannanes are obtained by the reaction of trimethyltinlithium and ethyl esters or thiophenyl esters in the presence of ***Boron Trifluoride Etherate***.[3] Direct displacement of α-chloro boronates can be accomplished leading to α-trimethylstannyl boronate esters with inversion of configuration.[19] The trimethylstannyl-substituted boronate thus obtained can undergo transmetalation with an additional equivalent of trimethyltinlithium to provide the α-lithio boronate ester. Silylation of the alkoxide intermediate obtained by addition of trimethyltinlithium to carbonyl compounds provides α-silyloxystannanes which are useful precursors for the synthesis of (α-alkoxyalkyl)trialkylsilanes.[4] (α-Alkoxyalkyl)stannanes and (α-alkoxy)trialkylsilanes can be employed in the stereoselective synthesis of acyclic ethers by means of a directed Mukaiyama aldol reaction.[20]

Trimethyltinlithium undergoes conjugate addition reactions with enones in THF or THF/NH_3.[5,21] This approach has been used in the synthesis of several potential chiral Lewis acids derived from conjugate addition of trimethyltinlithium to verbenone, carvone, and pinene. Subsequent regioselective cleavage of one of the methyl groups from the trimethyltin moiety is possible using ***Tin(IV) Chloride*** or ***Mercury(II) Chloride*** (eq 6).[21]

Oxidative cleavage of the trimethyltin moiety to give an alcohol has been accomplished with retention of configuration.[22] Initial 1,4-

addition of trimethyltinlithium to cyclohexenone, followed by alkylation of the enolate intermediate and reduction of the ketone, provides a β-hydroxy trimethylstannyl-substituted cyclohexane ring. Subsequent reaction with ***Bromine*** and ***m-Chloroperbenzoic Acid*** results in cleavage of the trimethyltin moiety to give the cyclohexane diol (eq 7).

The 1,4-addition product obtained by the reaction of trimethyltinlithium and cyclohexenone has also provided a substrate for the study of the γ-effect of tin in solvolysis reactions.[23] Providing that the Sn-C-C-C-X bonds adopt a planar W orientation, the tin substituent serves to enhance solvolysis through an extended hyperconjugation effect. Oxidative fragmentation of β-hydroxy trimethylstannyl-substituted cyclohexanes by ***Lead(II) Acetate*** has also been employed in the stereospecific synthesis of (*E*)- and (*Z*)-keto alkenes (eq 8).[24] 1,4-Addition of trimethyltinlithium to cyclohexenone, followed by reduction of the ketone and oxidative fragmentation, has resulted in the synthesis of *exo*- and *endo*-brevicomin. Treatment of β-trimethylstannylcyclohexanones with Lewis acids results in the destannylated cyclohexanone or in a ring-contracted cyclopentanone through the intermediacy of a cyclopropanol (eq 9).[25] If the ketone is first transformed into an epoxide, Lewis acid treatment results in the synthesis of cyclopropane products (eq 10).[26,27] The Lewis acid-catalyzed reaction proceeds through an ionic intermediate since there is no stereochemical restriction on the reaction. Cyclopropane formation can also be induced by protic acid treatment; however, a concerted 1,3-elimination reaction occurs which places a stereoelectronic restriction on the reaction. Only stannyl epoxides which can adopt a planar W configuration of the Sn-C-C-C-OH bonds can undergo 1,3-elimination. Other conformationally restricted isomers undergo a 1,2-shift.[27] Trimethyltinlithium can undergo transmetalation to a variety of copper species which have been extensively studied by NMR.[28]

Related Reagents.

Tri-n-butylstannyllithium.

Trimethyl(trifluoromethyl)stannane[1]

Me_3SnCF_3

[754-25-6] · $C_4H_9F_3Sn$ · Trimethyl(trifluoromethyl)stannane · (MW 232.84)

(a low-temperature difluorocarbene source[1])

Alternate Name: (trifluoromethyl)trimethyltin.

Physical Data: mp -57 to -53.2 °C;[2] bp 100-101 °C;[3] ^{1}H NMR (90 MHz) δ 0.42; ^{19}F NMR (84.6 MHz) δ -28;[4,5] IR (KBr) (cm^{-1}) 3080, 3010, 2940, 1330, 1220, 1210, 1205, 1160, 1075, 810, 785, 730, 541, 520.[2,3]

Solubility: sol benzene, carbon tetrachloride, DME, petroleum ether, pyridine, methylene chloride.

Preparative Methods: prepared in 81% yield by reaction of ***Hexamethyldistannane*** with ***Trifluoroiodomethane*** in a sealed tube at 80 °C for 20 h (eq 1).[3] Without compromising the yield, this reaction may also be performed at rt by irradiating for 6 h with a 250 W UV lamp.[6,7] Reaction of Me_3SnX (X = $OCOCF_3$ or Br) with an alkylating agent, such as $(CF_3)_2Cd$, may also be used to synthesize trimethyl(trifluoromethyl)tin in high yields.[8-10]

$$Me_3SnSnMe_3 + CF_3I \xrightarrow[h\nu,\ rt,\ 6\ h]{80\ °C,\ 20\ h\ \text{or}} Me_3SnCF_3 + Me_3SnI \quad (1)$$

Handling, Storage, and Precautions: prolonged contact or heating with water causes decomposition to produce fluoroform. Temperatures above 150 °C cause decomposition to trimethyltin fluoride.[3]

Thermal Generation of Difluorocarbenes.

Heating trimethyl(trifluoromethyl)tin in a sealed tube at 150 °C for 15 h is believed to produce difluorocarbene as evidenced by the formation of *gem*-difluorocyclopropanes in the presence of alkenes (eq 2).[3] Additionally, difluorocarbene insertion into an acid fluoride bond also occurs under these conditions.[11]

Nucleophile-Initiated Generation of Difluorocarbenes.

The addition of ***Sodium Iodide*** to trimethyl(trifluoromethyl)tin allows the generation of difluorocarbene at significantly lower temperatures (eq 3),[12,13] thereby making reactions with thermally unstable alkenes accessible. The reaction is believed to occur via a pentacoordinated trimethyl(trifluoromethyl)tin iodide intermediate. The trifluoromethyl anion, which is unstable even at -100 °C, then decomposes to produce the difluorocarbene.

Fluoride[14] and chloride[15] anions are also effective as nucleophiles and generate difluorocarbene in good yields. The ***Tris(dimethylamino)sulfonium Difluorotrimethylsilicate*** (TASF) catalyzed conversion of sulfonyl fluorides to aryl trifluoromethyl sulfones is an illustration of the use of the former anion (eq 4).[14] Interestingly, the corresponding silicon reagent, ***Trifluoromethyltrimethylsilane***, is as effective as the tin reagent in these reactions.[14]

Lewis Acid-Initiated Generation of Difluorocarbenes.

Reaction of trimethyl(trifluoromethyl)tin with Lewis acids such as BX_3 (X = F, Cl) appears to produce difluorocarbene, as indicated by its insertion into the boron-halogen bond.[16,17] This too presumably occurs via the aforementioned decomposition of the trifluoromethyl anion.

Triphenylacetonitrile *N*-Oxide

[13412-55-0] · $C_{20}H_{15}NO$ · Triphenylacetonitrile *N*-Oxide · (MW 285.36)

(1,3-dipolar reagent[1])

Physical Data: mp 152-153 °C.[2]

Solubility: sol benzene, dioxane.

Form Supplied in: colorless solid; not commercially available.

Analysis of Reagent Purity: IR 2280, 1320 cm^{-1}; the corresponding isocyanate, the primary decomposition product, has a strong band at 2250 cm^{-1}.

Preparative Methods: usually prepared[2,3] by treatment of silver fulminate with triphenylmethyl chloride. The compound is reported[4] to be readily available from triphenylacetaldehyde oxime by treatment with bromine in an $NaOH/H_2O/CCl_4$ mixture at 0 °C, but no experimental details are provided.

Purification: recrystallization from a minimum amount of benzene.

Handling, Storage, and Precautions: if the reagent is being prepared from silver fulminate, extreme caution should be exercised due to the shock sensitivity. Unlike other nitrile oxides, which are usually generated in situ, triphenylacetonitrile oxide is a fairly stable solid. Upon heating it rearranges to triphenylmethyl isocyanate. Introducing a 3- or 4-trifluoromethyl group dramatically increases the proclivity towards rearrangement.[2]

1,3-Dipolar Cycloaddition.

Like other nitrile oxides (see ***Acetonitrile N-Oxide***) this reagent is useful for 1,3-dipolar cycloaddition reactions. Alkenes give 3-triphenylmethyl-Δ^2-isoxazolines containing a labile Ph_3C group which may be used to trigger other events. For example, photolysis of 3-triphenylmethyl-Δ^2-isoxazolines fragments the heterocycle, presumably by homolysis of the Ph_3C-C bond (eq 1).[4] The triphenylmethyl group of 3-triphenylmethyl-Δ^2-isoxazolines is also the key to a novel preparation of cyclic ethers (eq 2).[5] The regiochemistry of dipolar cycloadditions of nitrile oxides containing bulky substituents has been studied.[6]

Related Reagents.

Acetonitrile N-Oxide; ***1-Pyrroline 1-Oxide***.

Triphenylarsine[1]

[603-32-7] · $C_{18}H_{15}As$ · Triphenylarsine · (MW 306.25)

(nucleophilic agent for the synthesis of arsonium salts, which undergo epoxidation or alkenation reactions; can be used as a ligand)

Physical Data: plates (EtOH), mp 60.5 °C; bp 360 °C, 232-234 °C/14 mmHg.

Solubility: insol H_2O, ethanol; sol ether, THF, acetonitrile, etc.

Form Supplied in: commercially available.

Preparative Method: prepared from arsenic trichloride, chlorobenzene, and powdered sodium in benzene under reflux.[2]

Handling, Storage, and Precautions: use in a fume hood.

Introduction.

Arsonium ylides are more reactive than the corresponding phosphonium ylides since the covalent canonical form (ylene form) makes a smaller contribution to the overall structure of arsonium ylides (eq 1) than to that of phosphonium ylides.[1] This has been supported by X-ray crystallography.[3]

$$Ph_3As{=}CR^1R^2 \longleftrightarrow Ph_3\overset{+}{A}s\text{-}\bar{C}R^1R^2 \qquad (1)$$

Arsonium Salts.

Reaction of triphenylarsine with halo compounds forms arsonium salts which are converted to ylides on treatment with base. These perform alkenation reactions under PTC conditions.[4] A general procedure for the synthesis of unsaturated aldehydes, ketones, esters, and amides directly via arsonium salts in the presence of a weak base (solid ***Potassium Carbonate***) under PTC conditions at rt has been devised (eq 2).[5] All the arsonium salts are stable and can be stored for a long time. The Ph_3AsO byproduct can be easily reconverted to Ph_3As by reduction.[6]

$$R(CH{=}CH)_mCHO + Ph_3\overset{+}{A}s(CH{=}CH)_nXBr^- \xrightarrow[\text{trace } H_2O,\ rt\ \ -Ph_3AsO]{K_2CO_3\ (s),\ \text{solvent}} R(CH{=}CH)_{m+n+1}X \qquad (2)$$

$$m = 0,\ 1,\ 2;\ n = 0,\ 1$$
$$X = CHO,\ COMe,\ CO_2R,\ CONR^1R^2$$

Formylmethyltriphenylarsonium bromide (**1**) (eq 3) reacts with aldehydes to give (*E*)-α,β-enals exclusively (eq 4).[7,8]

(3)

(4)

Formylallyltriphenylarsonium bromide (**3**) reacts with aldehydes to give mixtures comprising mostly (2*E*,4*E*)- with some (2*E*,4*Z*)-dienals. The latter can be isomerized to the former by treating with a catalytic amount of ***Iodine*** in daylight (eq 5).[9]

(5)

2-(Oxoamido)triphenylarsonium bromides (**5**)[10] react with saturated and unsaturated aldehydes at rt in the presence of K_2CO_3(s) to afford (2*E*)-unsaturated amides (**6**) or (2*E*,4*E*)-dienamides in excellent yields. No (*Z*) stereoisomer is detected (eq 6).[10] A vinylog (**7**)[11] reacts with aromatic aldehydes to give exclusively the (2*E*,4*E*)-products in 80-98% yield (eq 7); with aliphatic aldehydes, (2*E*,4*E*/2*E*,4*Z*) products are formed in a ratio of 85/15. The (2*E*,4*Z*) product can be isomerized to the (2*E*,4*E*) product.[11] The reactions of aldehydes with arsonium salts are listed in Table 1.

Triphenylarsonium salts have been used to synthesize a variety of natural products under very mild conditions: (*EZ*)-,diene sex pheromones,[12] pellitorine,[10b] trichonine,[13] *Achillea* amide,[10b] *Otanthus maritima* amide,[10a] (+)-yingzhaosu A,[14] LTA_4 methyl ester,[15] 19-hydroxy-LTB_4,[16] and lipoxins A_4 and B_4[17] have all been successfully synthesized.

Since tributylarsine is more reactive towards halides than triphenylarsine, Wittig-type alkenation of carbonyl compounds can be performed catalytically. Thus the reaction of various aldehydes with ***Methyl Bromoacetate*** (or ***Bromoacetone***) in the presence of ***Triphenyl Phosphite*** and Bu_3As (0.2 equiv) provides α,β-unsaturated esters (or α,β-unsaturated ketones) in 60-87% yields and with (*E*)/(*Z*) ratios of 97:3-99:1 (eq 8).[18]

$$RCHO + BrCH_2CO_2Me + (PhO)_3P + K_2CO_3 \xrightarrow[\text{THF-MeCN, rt}]{\text{cat. } Bu_3As} RCH{=}CHCO_2Me + (PhO)_3PO \qquad (8)$$

An efficient one-pot synthesis of α-iodo- α,β-unsaturated esters, ketones, and nitriles via arsonium salts has been reported (eq 9).[19] A one-pot synthesis of *trans*-fluorovinylic epoxides has also been achieved (eq 10).[20]

(10)

Silylated enynyl carboxylic esters can be synthesized with high stereoselectivity by the reaction of trimethylsilyl-2-propynylidenetriphenylarsorane, prepared in situ from the corresponding arsonium salt with ***n-Butyllithium***, and $BrCH_2CO_2R$ (eq 11).[21] Triphenylarsoranylideneketene reacts with 2-benzoylpyrrole in methylene chloride to give 1-phenylpyrrolizin-3-one in 85% yield (eq 12).[22]

(11)

(12)

Methylenetriphenylarsorane ($Ph_3As{=}CH_2$), which is thermally unstable both in the solid state and in solution, has been isolated and characterized by analytical and spectroscopic methods.[23] Triphenylarsonium ethylide ($Ph_3As{=}CHCH_3$), prepared from triphenylethylarsonium tetrafluoroborate with ***Potassium Hexamethyldisilazide*** in THF/HMPT at -40 °C, reacts with aliphatic aldehydes to give *trans*-epoxides with high selectivity (eq 13). Stereoselection is lower with aromatic aldehydes (83% (*E*) for benzaldehyde). The reagent also reacts with ketones to form trisubstituted epoxides.[24]

(13)

The synthesis and reactivity of (3,3-diisopropoxypropyl)triphenylarsonium ylide have been reported. This reagent can be considered as a β-formylvinyl anion equivalent (eq 14), as shown by the conversion of aldehydes to 4-hydroxy-2(*E*)-enals under very mild conditions (eq 15).[25] This route has been successfully applied to the total synthesis of (±)-hepoxilin A_3.[26]

(14)

(15)

Homologation of aldehydes using (phenylthiomethylene)triphenylarsorane has been reported. Reaction with aldehydes gives exclusively α-phenylthio epoxides in THF and enol phenol thioethers in THF/HMPA. The former adducts are readily transformed to α-thiophenoxy carbonyl compounds and the latter to one-carbon homologated aldehydes (eq 16).[27]

Large rate enhancement in Stille cross-coupling reactions is observed with triphenylarsine (a factor of 70 over the triphenyl phosphine-based catalyst) (eq 17).[28]

Related Reagents.

Dibutyl Telluride; ***Tri-n-butylstibine***; ***Triphenylphosphine***.

Triphenylbismuthine[1]

[603-33-8] · $C_{18}H_{15}Bi$ · Triphenylbismuthine · (MW 440.31)

(catalyst for glycol cleavage;[5] phenylating agent for alcohols[7] and amines;[8] source of phenyl radicals under photolytic conditions[4])

Alternate Name: triphenylbismuth.

Physical Data: mp 77.6 °C.[2]

Solubility: CH_2Cl_2, $CHCl_3$, CCl_4, benzene, toluene, ether, THF, ethyl acetate; insol H_2O, alcohols; decomposed in acidic solvents.

Preparative Method: conveniently prepared by reaction of ***Phenylmagnesium Bromide*** with $BiCl_3$ in ether.[3]

Handling, Storage, and Precautions: must be stored in dark bottles in the absence of moisture or acidic vapors. Use in a fume hood.

α-Glycol Cleavage.[5]

Triphenylbismuthine acts as a catalyst in the oxidative cleavage of α-glycols by ***N-Bromosuccinimide*** or ***N-Bromoacetamide*** in the presence of ***Potassium Carbonate*** to give the corresponding aldehydes and/or ketones. The oxidation is best performed by dropwise addition of an acetonitrile solution of NBS (4 equiv) to the mixture of the glycol, Ph_3Bi (0.01-0.1 equiv), and K_2CO_3 (4 equiv) in acetonitrile-water (99:1) in the dark at room temperature (eq 1). Yields are similar or better than those obtained with ***Lead(IV) Acetate***, periodic acid and its salts, or the stoichiometric ***Triphenylbismuth Carbonate*** reagent. In contrast with these reagents, which cleave only *cis*-decalin-9,10-diol, the catalytic system cleaves both the *cis*- and the *trans*-decalin-9,10-diol isomers at nearly the same rate.

Copper-Catalyzed Phenylations.

Although there is no reaction between Ph_3Bi and ***Copper(II) Acetate***, triphenylbismuthine can transfer a phenyl group to alcohols, phenols, or amines when a stoichiometric amount of copper diacylate is used.

Alcohols and phenols.[6,7]

When primary or secondary alcohols are treated with Ph_3Bi in the presence of copper diacetate (Ph_3Bi:$Cu(OAc)_2$ = 1:2) without solvent in sealed ampules, the *O*-phenyl ethers are formed in 43-91% yields (based on the bismuth reagent) at a very slow rate (several days at rt) (eq 2). No reaction with phenol has been described under these conditions. However, when a CH_2Cl_2 solution of 3,5-di-*t*-butylphenol is treated with a mixture of Ph_3Bi (1.2 equiv), $Cu(OAc)_2$ (2 equiv), and Et_3N (4 equiv), the corresponding *O*-phenyl ether is obtained in 44% yield after 10 h at rt. These *O*-phenylation reactions, particularly of phenols, are better performed with the more general copper-catalyzed ***Triphenylbismuth Diacetate*** system.

$$\mathrm{ROH} + \mathrm{Ph_3Bi} + \mathrm{Cu(OAc)_2} \xrightarrow{\text{neat}} \mathrm{R\text{-}O\text{-}Ph} \qquad (2)$$

Amines.[7]

Amines react smoothly at rt with Ph_3Bi (1.2 equiv) and $Cu(OAc)_2$ (0.5 equiv) to give high yields of *N*-mono- or *N*,*N*-diphenylated amines. Generally, monophenylated compounds are obtained with primary amines (eq 3) in variable yields, depending upon the basicity and steric hindrance of the substrate (6% for *p*-nitroaniline, 25% for mesitylamine, but 82% for *p*-methoxyaniline). With *n*-butylamine, the monophenyl (60%) and diphenyl (38%) derivatives are obtained. This reaction is less efficient than the related copper-catalyzed triphenylbismuth diacetate system. However, since Ph_3Bi is commercially available, this reaction is of interest for the monophenylation of anilines and a variety of aliphatic and heterocyclic amines.

$$\mathrm{RNH_2} + \mathrm{Ph_3Bi} + \mathrm{Cu(OAc)_2} \xrightarrow[\text{rt}]{\mathrm{CH_2Cl_2}} \mathrm{RNH\text{-}Ph} \qquad (3)$$

Palladium-Catalyzed Phenylation.[8]

Triarylbismuthines Ar_3Bi (Ar = Ph, *p*-MeC_6H_4, *p*-$MeOC_6H_4$) react with $Pd(OAc)_2$ (1 equiv) and ***Triethylamine*** (2 equiv) in HMPA to afford quantitatively the corresponding biaryl after heating for 10 min at 65 °C. When the reaction is performed in presence of acyl chlorides at 65 °C for 5 h in HMPA, phenyl ketones are obtained in 89-96% yields (eq 4). In the absence of the catalyst, phenyl ketones are also formed but in low yields.[9]

$$\mathrm{RCOCl} + \mathrm{Ph_3Bi} + \mathrm{Pd(OAc)_2} + \mathrm{Et_3N} \xrightarrow[\text{65 °C}]{\text{HMPA}} \mathrm{RCO\text{-}Ph} \qquad (4)$$

Other Uses.

Triphenylbismuthine can also function as a catalyst or cocatalyst in the polymerization of hydrocarbons,[1c] and as a source of phenyl radicals under photolytic conditions.[4]

Triphenylbismuth Carbonate[1]

Ph_3BiCO_3

[47252-14-2] · $C_{19}H_{15}BiO_3$ · Triphenylbismuth Carbonate · (MW 500.32)

(oxidation of alcohols; glycol cleavage;[4], *C*-phenylation of phenols,[3] carbonyl compounds,[7] and nitrogen derivatives[7])

Physical Data: mp 164 °C.[2]

Solubility: insoluble most organic solvents; reacts with carboxylic and sulfonic acids to give the corresponding diesters.

Preparative Method: prepared by reaction of ***Triphenylbismuth Dichloride*** with ***Potassium Carbonate*** in acetone-water.[3]

Handling, Storage, and Precautions: stable white powder; can be stored in the refrigerator for months. Use in a fume hood.

Oxidation of Alcohols.[4]

Ph_3BiCO_3 is a very effective heterogeneous oxidant for primary, secondary, allylic, and benzylic alcohols, which are converted into the corresponding carbonyl derivatives under neutral conditions. Thiols are oxidized to disulfides, but the thiocarbonyl group in xanthates, *N*,*N*-dialkyl thionocarbamates, and di-*t*-butyl thioketone remain unaffected. Aniline, dimethylaniline, pyrrolidine, indole, and 3-pyrrolidinocholesta-3,5-diene are not oxidized. Hydrazo compounds are oxidized to azo compounds and hydrazones to diazo compounds.

Glycol Cleavage.

Very high yields of carbonyl derivatives are obtained upon oxidation of 1,2-glycols with Ph_3BiCO_3.[4] As an example, the monobactam polyol in eq 1 is cleaved by Ph_3BiCO_3 to the disulfide in 85% yield.[5]

Phenylation.

Phenols.[3,6]

The nature of the product of the reaction of Ph_3BiCO_3 with phenols is very dependent upon the nature of the phenolic substrate. Thus, whereas β-naphthol reacts in the presence of TMG to give α-phenyl-β-naphthol (76%) (eq 2), 2,6-dimethylphenol gives 2,2´,6,6´-

tetramethyldiphenoquinone (92%) (eq 3), and phloroglucinol is converted to a perphenyl enedione and a small amount of 2,4,6-triphenylphloroglucinol (eq 4).

(2)

(3)

(4)

24% 40%

Carbonyl Compounds.[6,7]

The arylation of ketones by Ar_3BiCO_3 (Ar = Ph, 4-$MeOC_6H_4$, 4-MeC_6H_4, 4-$NO_2C_6H_4$) under basic conditions leads to *C*-arylation of the carbons α to the carbonyl. When a THF solution of a ketone is treated with an excess of Ph_3BiCO_3 (2-8 equiv) in the presence of KH as base, the α,α´-perphenylated products are obtained in 60-93% yield (eq 5).

(5)

Enolic compounds, such as 1,3-dicarbonyl compounds, react with Ph_3BiCO_3 under neutral conditions to give the corresponding α-mono- or diphenyl derivatives. One major exception is dimedone, which affords a bismuthonium ylide instead of the 2,2-diphenylated compound. β-Keto sulfones also react easily with Ph_3BiCO_3 to afford the α-phenyl-β-keto sulfones;[8] this reaction can be used for a very efficient synthesis of isoflavanone and isoflavone derivatives. α-Arylglycine derivatives are obtained by the reaction of arylidene imines of glycine ethyl esters with Ar_3BiCO_3 under reflux in DMF (eq 6).[9] When the arylidene group is derived from *p*-chlorobenzaldehyde, a moderate yield of the diphenylated product is obtained, but selective monophenylation is realized with the benzophenone imine. This arylation procedure has also been extended to the synthesis of α-substituted α-phenylglycines.[10]

(6)

Nitrogen Derivatives.

Ph_3BiCO_3 generally does not react with amines, but with *N*-phenylhydroxylamine it gives *N*,*N*-diphenylhydroxylamine.[11] Amides are reported to be *N*-phenylated in high yield.[12] Thus *N*,*N*-diphenylacetamide (90%) is obtained from the reaction of the sodium salt of acetamide with Ph_3BiCO_3; *N*-phenyl-*N*-methylbenzamide (90%) is obtained similarly from *N*-methylbenzamide. However, these results could not be repeated, although amides have been *N*-phenylated by ***Triphenylbismuth Dichloride*** in the presence of BTMG.[13] 2-Nitropropane reacts with Ph_3BiCO_3 under basic conditions (KH in THF) to afford α-nitrocumene in 80% yield.[7]

Triarylbismuth carbonates are highly efficient and selective reagents for the arylation of phenolic and enolic substrates. A useful though not so widely applicable class of reagents, which are complementary to the organobismuth reagents for the arylation of phenols and enols, are the aryllead triacetates.

Triphenylbismuth Diacetate[1]

$Ph_3Bi(OAc)_2$

[7239-60-3] · $C_{22}H_{21}BiO_4$ · Triphenylbismuth Diacetate · (MW 558.41)

(oxidation of alcohols and glycols;[3] *O*- and *N*-phenylation[9,14,16])

Physical Data: mp 187-189 °C.[2]

Solubility: sol CH_2Cl_2, $CHCl_3$; insol ether, MeOH.

Preparative Methods: prepared by treatment of ***Triphenylbismuth Carbonate*** with ***Acetic Acid*** in CH_2Cl_2,[3] or by ***Lead(IV) Acetate*** oxidation of ***Triphenylbismuthine***.[2a] The best yield (60%) is obtained by treatment of Ph_3Bi with $Pb(OAc)_4$ in AcOH for 2 h at rt, followed by addition of water, filtration, and recrystallization (CH_2Cl_2-ether).

Handling, Storage, and Precautions: stable white solid; can be stored under inert gas in the refrigerator for some months. Use in a fume hood.

Oxidation of Alcohols and 1,2-Glycols.

Under basic conditions (either ***Potassium Carbonate*** or an organic base such as ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** or ***1,1,3,3-Tetramethylguanidine***), this reagent oxidizes alcohols to the corresponding carbonyl compounds.[3,4] In a fashion similar to Ph_3BiCO_3, $Ph_3Bi(OAc)_2$ reacts with vicinal glycols in the presence of K_2CO_3[3] or with the stannylene derivatives of vicinal glycols[5] under neutral conditions to afford the two corresponding carbonyl fragments in high yield.

Phenylation of Alcohols.

In the absence of base, $Ph_3Bi(OAc)_2$[6,7] and the related reagent $Ph_4BiOCOCF_3$[8] (prepared by reaction of Ph_5Bi with 1 equiv of CF_3CO_2H, mp 120-132 °C, $C_{26}H_{20}BiF_3O_2$, MW 630.44, *[83566-43-2]*) react with primary and secondary alcohols to afford mostly the corresponding *O*-phenyl ethers with various amounts of oxidation products. In the presence of a copper catalyst, 62-97% of the *O*-phenyl ethers can be obtained with simple alcohols and $Ph_3Bi(OAc)_2$ (eq 1). As copper catalyst, ***Copper(II) Chloride***, ***Copper(I) Chloride***, ***Copper(II) Acetate***, or metallic ***Copper*** can be used.[9]

$$\mathrm{ROH} + \mathrm{Ph_3Bi(OAc)_2} \xrightarrow{\mathrm{CuX_n}} \mathrm{R\text{-}O\text{-}Ph} \qquad (1)$$

Miscellaneous Phenylation Reactions.

In a very simple procedure, α-, β-, γ-, or δ-diols can be efficiently monophenylated by simple reflux of the diol and $Ph_3Bi(OAc)_2$ (1 equiv) in CH_2Cl_2 until disappearance of the diol (eq 2).[10] For secondary-tertiary diols, the secondary *O*-phenyl ethers are obtained, and for axial-equatorial diols, the axial ethers are obtained. With an excess of $Ph_3Bi(OAc)_2$, the bis-ether can be obtained.[9] Addition of a small amount of $Cu(OAc)_2$ (0.1 equiv or less) increases the reaction rate significantly, and the reaction can then be performed in a variety of solvents (eq 3).[9] Moreover, addition of chiral pyridine oxazolines leads to a moderate optical induction in the case of the *meso-cis*-1,2-cyclohexanediol.[11]

Whereas thiols are oxidized with Ph_3BiCO_3 or Ph_3BiCl_2 and base or $Ph_4BiOCOCF_3$ and base, they gave the corresponding phenyl thioether when treated with $Ph_4BiOCOCF_3$ under neutral or acidic conditions.[12] However, in the case of hydroxythiols, the copper-catalyzed reaction with $Ph_3Bi(OAc)_2$ leads to mixtures of mono- and di-*O*-phenylated disulfides.[9]

Phenols react with $Ph_4BiOCOCF_3$ (under neutral conditions or with acid catalysis) in benzene under reflux to afford moderate to good yields of the *O*-phenyl ethers.[13] Faster rates and better yields can be obtained through copper catalysis. However, $Ph_3Bi(OAc)_2$ under copper metal catalysis in CH_2Cl_2 at rt effects a more efficient and selective *O*-phenylation of electron-poor as well as electron-rich phenols (eq 4). Except for highly hindered phenols, such as 2,6-di-*t*-butylphenol, yields are generally high.[14]

Enols are subject to mono-*O*-phenylation with $Ph_4BiOCOCF_3$ under neutral or, preferably, acidic conditions.[12] Copper catalysis leads to some improvement. Enols can also give the *O*-phenyl ethers by reaction with $Ph_3Bi(OAc)_2$ or the analogous reagent $Ph_3Bi(OCOCF_3)_2$ (prepared by action of CF_3CO_2H on Ph_3BiCO_3, mp 133 °C, $C_{22}H_{15}BiF_6O_4$, MW 666.35, *[83566-43-2]*) under copper metal catalysis. Yields are moderate to good.[14]

Phenylation of Amines.

Under metallic copper catalysis, $Ph_3Bi(OAc)_2$ and $Ph_3Bi(OCOCF_3)_2$ react with aliphatic, heterocyclic, or aromatic amines in CH_2Cl_2 at rt to give the mono-*N*-phenyl derivatives in high yields (eq 5).[15,16] A number of α-amino acid esters are also selectively mono-*N*-phenylated under these conditions.[17] A wide range of variously substituted anilines have been mono- or di-*N*-phenylated with these reagents (eq 6). The most conveniently prepared reagent [$Ph_3Bi(OAc)_2$] is less reactive than $Ph_3Bi(OCOCF_3)_2$. Thus after 45 min, mesitylamine gives 40% of *N*-phenylmesitylamine with the former reagent, but 95% with the latter. Similarly, 4-nitroaniline gives 22% and 98%, respectively. Indoles are *N*- or *C*-3 phenylated only with $Ph_3Bi(OCOCF_3)_2$ under copper catalysis.[18]

$$ArNH_2 + Ph_3Bi(OAc)_2 \xrightarrow[rt]{\substack{Cu\ cat. \\ CH_2Cl_2}} ArNH\text{-}Ph \qquad (6)$$

The system $Ph_3Bi(OAc)_2$ + copper catalysis provides a broader spectrum of reactivity than the similar aryllead triacetates under copper catalysis, which do not effect phenol *O*-arylation but which do react with anilines to give high yields of unsymmetrical diarylamines.[19]

Triphenylbismuth Dichloride[1]

Ph_3BiCl_2

(Ph_3BiCl_2)

[594-30-9] · $C_{18}H_{15}BiCl_2$ · Triphenylbismuth Dichloride · (MW 511.21) (Ph_5Bi)

[3049-07-8] · $C_{30}H_{25}Bi$ · Pentaphenylbismuth · (MW 594.53) ($Ph_4BiOCOCF_3$)

[83566-43-2] · $C_{26}H_{20}BiF_3O_2$ · Tetraphenylbismuth Trifluoroacetate · (MW 630.44) (Ph_4BiOTs)

[83566-44-3] · $C_{31}H_{27}BiO_3S$ · Tetraphenylbismuth Tosylate · (MW 688.63)

(phenylation of phenols,[6] ketones and enols,[5] and nitro compounds[8])

Physical Data: mp 159-160 °C.[2]

Solubility: sol CH_2Cl_2, $CHCl_3$, benzene, toluene; insol ether, THF, MeOH.

Preparative Methods: easily prepared[2] by oxidation of ***Triphenylbismuthine*** either by bubbling ***Chlorine*** gas into an ethereal solution of Ph_3Bi at 0 °C, or by addition of 1 equiv of ***Sulfuryl Chloride*** to a solution of Ph_3Bi in CH_2Cl_2 at -78 °C. The action of ***Phenyllithium*** on Ph_3BiCl_2 leads to pentaphenylbismuth (mp 77-78 °C).[2] Addition of 1 equiv of a carboxylic or sulfonic acid to Ph_5Bi affords compounds of the type Ph_4BiX.[3] ($Ph_4BiOCOCF_3$: mp 120-132 °C; Ph_4BiOTs: mp 155-162 °C).

Handling, Storage, and Precautions: stable white solid; can be stored in the refrigerator in the absence of moisture. Pentaphenylbismuth is a poorly stable violet powder which can be stored under inert gas in the refrigerator for some days. $Ph_4BiOCOCF_3$ and Ph_4BiOTs are white powders which can be stored in the refrigerator under inert gas for some weeks. These reagents should be used in a fume hood.

Oxidation of Alcohols.[4]

Treatment of primary or secondary alcohols with (a) Ph_3BiCl_2 or Ph_4BiX in the presence of a strong base (e.g. ***1,1,3,3-Tetramethylguanidine***, BTMG (*t*-butyltetramethylguanidine), or ***1,8-Diazabicyclo[5.4.0]undec-7-ene***) or with (b) Ph_5Bi under neutral conditions leads to oxidation to the corresponding carbonyl compounds under mild conditions in moderate to high yields (eq 1). Because of the similar reactivity patterns of these reagents, the system Ph_3BiCl_2 + base is the reagent of choice, due to its facile preparation and stability. An excess of reagent must be avoided, as possible side reactions such as α-*C*-phenylation can occur (see below).[5] The reaction of salts of tertiary alcohols, e.g. *t*-BuOLi, with Ph_3BiCl_2 results in the formation of the *O*-phenyl ethers e.g. *t*-BuOPh.[4c] In the presence of a base such as BTMG, Ph_3BiCl_2 cleaves glycols efficiently in the same way as Ph_3BiCO_3.

(1)

Phenylation of Phenols.[6]

The reaction of phenols with organobismuth(V) reagents leads to a variety of products (eq 2). Phenols bearing electron-donating substituents react with Ph_3BiX_2 or Ph_4BiX in the presence of a strong base (BTMG, TMG, NaH, or KH) or with Ph_5Bi under neutral conditions to give mostly or only the *o*-mono- or *o,o´*-di-*C*-phenylated derivatives. With 2,6-disubstituted phenols, either 6-phenyl-6-methylcyclohexa-2,4-dienone or 4-phenyl-2,6-di-*t*-butylphenol are obtained, in contrast to the reaction with Ph_3BiCO_3 which gives diphenoquinones. Unactivated phenols or phenols bearing *meta* electron-withdrawing substituents afford mixtures of *O*- and *ortho*-*C*-

phenylphenols. Phenols bearing *para* electron-withdrawing substituents give exclusively *O*-phenyl ethers after thermal decomposition of the aryloxybismuth intermediate. As these *O*-phenyl ethers can be obtained under milder conditions (neutral, rt) with ***Triphenylbismuth Diacetate*** under $Cu(OAc)_2$ catalysis, the present system does not compete efficiently.

Phenylation of Ketones and Enolic Compounds.[5]

In the presence of a strong base, ketones react with Ph_3BiCl_2 or Ph_4BiX to afford mostly or only the perphenylated derivatives. For example, cyclohexanone affords 2,2,6,6-tetraphenylcyclohexanone in 80% yield with Ph_4BiOTs + KH.[7] Ph_5Bi does not react with nonenolizable ketones, but with enolizable ketones the reaction does take place. Thus 2-phenylethanol is oxidized by Ph_5Bi and the aldehyde further reacts to afford, eventually, triphenylacetaldehyde in 69% yield.[5] Enolizable compounds such as β-dicarbonyl derivatives react with Ph_5Bi under neutral conditions, or with Ph_3BiCl_2 and Ph_4BiX (both in the presence of a strong base), to afford generally the α-perphenylated derivatives. For example, this reaction occurs with acetylacetone, ethyl acetoacetate, ethyl cyclohexanone-2-carboxylate (eq 3), ethyl cyclopentanone-2-carboxylate, diethyl malonate, and dimedone.[5,8]

Ph_5Bi	57%
Ph_3BiCl_2, BTMG	75%
$Ph_4BiOCOCF_3$, BTMG	91%

With acetylacetone, Ph_3BiCl_2 and base leads to 3,3-diphenylacetylacetone (74%), whereas $Ph_4BiOCOCF_3$ in benzene under reflux in the absence of base gives a moderate yield of the 3-monophenyl derivative (34%). In the case of dimedone and Meldrum's acid, the reaction of their sodium salts with Ph_3BiCl_2 leads only to the stable crystalline bismuthonium ylides.[9] In an application in natural products chemistry, high yields of 3-phenyl-4-hydroxycoumarins have been obtained from the reaction of 4-hydroxycoumarins with Ph_5Bi at -23 °C.[10] With caprolactam-type malonic derivatives, completely different results are observed, depending on the reagent used. Thus 3-cyano-ε-caprolactam reacts only with Ph_5Bi to give 74% of 3-cyano-3-phenyl-ε-caprolactam; 3-ethoxycarbonyl-ε-caprolactam does not react with Ph_5Bi and gives only the *N*-phenylcaprolactam derivative through reaction with Ph_3BiCl_2 and base.[11]

Phenylation of Nitro Compounds.

In the presence of BTMG, 2-nitropropane reacts with Ph_3BiCl_2 or Ph_4BiOTs to produce α-nitrocumene (86 or 77% respectively).[8] The reaction using Ph_3BiCl_2 and TMG has been applied to the synthesis of α-methyl-α-phenylglycine via arylation of α-nitropropionic acid esters.[12]

Triphenylcarbenium Tetrafluoroborate

$Ph_3C^+ BF_4^-$

[341-02-6] · $C_{19}H_{15}BF_4$ · Triphenylcarbenium Tetrafluoroborate · (MW 330.15)

(easily prepared[1] hydride abstractor used for conversion of dihydroaromatics to aromatics,[2-4] and the preparation of aromatic and benzylic cations;[5-8] oxidative hydrolysis of ketals[9] and thioketals;[10] conversion of acetonides to α-hydroxy ketones;[9] oxidation of acetals[11] and thioacetals;[12] selective oxidation of alcohols and ethers to ketones;[9,13-15] oxidation of silyl enol ethers to enones;[16] hydrolysis of TBS and MTM ethers;[17] oxidation of amines and amides to iminium salts;[18-20] oxidation of organometallics to give alkenes;[21-23] sensitizer for photooxidation using molecular oxygen;[24] Lewis acid catalyst for various reactions;[25] polymerization catalyst;[26] other reactions[27-30])

Alternate Name: trityl fluoroborate.

Physical Data: mp ~200 °C (dec).

Solubility: sol most standard organic solvents; reacts with some nucleophilic solvents.

Form Supplied in: yellow solid; commercially available.

Preparative Methods: the most convenient procedure involves the reaction of Ph_3CCl with ***Silver(I) Tetrafluoroborate*** in ethanol.[1b] The most economical route employs the reaction of Ph_3CCl with the anhydrous ***Tetrafluoroboric Acid***-Et_2O complex.[1c]

Purification: recrystallization of commercial samples from a minimal amount of dry MeCN provides material of improved purity, but the recovery is poor.[1a]

Handling, Storage, and Precautions: moisture-sensitive and corrosive. Recrystallized reagent can be stored at rt for several months in a desiccator without significant decomposition. This compound is much less light-sensitive than other trityl salts such as the perchlorate.[1a]

Preparation of Aromatic Compounds via Dehydrogenation.

Dihydroaromatic compounds are easily converted into the corresponding aromatic compound by treatment with triphenylcarbenium tetrafluoroborate followed by base.[2] Certain α,α-disubstituted dihydroaromatics are converted to the 1,4-dialkylaromatic compounds with rearrangement (eq 1).[3] Nonbenzenoid aromatic systems, e.g. benzazulene[4a] or dibenzosesquifulvalene,[4b] are readily prepared from their dihydro counterparts. Aromatic cations are also easily prepared by hydride abstraction, for example, tropylium ion (e.g. in the synthesis of heptalene (eq 2)),[5] cyclopropenyl cation,[6] and others, including heterocyclic systems.[7] Some benzylic cations, especially ferrocenyl cations,[8] can also be formed by either hydride abstraction or trityl addition.

(1)

(2)

Oxidation by Hydride Abstraction.

In the early 1970s, Barton developed a method for the oxidative hydrolysis of ketals to ketones, e.g. in the tetracycline series (eq 3).[9] The same conditions can also be used to hydrolyze thioketals.[10] Acetonides of 1,2-diols are oxidized to the α-hydroxy ketones in good yield by this reagent (eq 4).[9] The hydrogen of acetals is easily abstracted (eq 5), providing a method for the conversion of benzylidene units in sugars to the hydroxy benzoates.[11] The hydrogen of dithioacetals is also abstracted to give the salts.[12] Since benzylic hydrogens are readily abstracted, this is also a method for deprotection of benzyl ethers.[9,13] Trimethylsilyl, *t*-butyl, and trityl ethers of simple alcohols are oxidized to the corresponding ketones and aldehydes in good yield. Primary-secondary diols are selectively oxidized at the secondary center to give hydroxy ketones by this method (eq 6).[14] 2,2-Disubstituted 1,4-diols are oxidized only at the 4-position to give the corresponding lactones.[15] Trimethylsilyl enol ethers are oxidized to α,β-unsaturated ketones, thereby providing a method for ketone to enone conversion (eq 7).[16] *t*-Butyldimethylsilyl (TBDMS) ethers are not oxidized but rather hydrolyzed to the alcohols, as are methylthiomethyl (MTM) ethers.[17] Benzylic amines and amides can be oxidized to the iminium salts,[18] allylic amines and enamines afford eniminium salts,[19] and orthoamides give triaminocarbocations.[20]

(3)

(4)

(5)

(6)

(7)

Generation of Alkenes from Organometallics.

Various β-metalloalkanes can be oxidized by trityl fluoroborate to the corresponding alkenes.[21-23] The highest yields are obtained for the β-iron derivatives (eq 8), which are easily prepared from the corresponding halides or tosylates.[21] Grignard reagents and organolithiums also undergo this reaction (eq 9),[22] as do Group 14 organometallics (silanes, stannanes, etc.).[23]

(8)

(9)

Sensitizer of Photooxygenation.

Barton showed that oxygen, in the presence of trityl fluoroborate and ordinary light, adds to cisoid dienes at -78 °C in very high yields.[24] For example, the peroxide of ergosterol acetate is formed in quantitative yields under these conditions (eq 10),[24a,b] which have been used also for photocycloreversions of cyclobutanes.[24c]

(10)

Lewis Acid Catalysis.

Trityl fluoroborate is a good Lewis acid for various transformations,[25] e.g. the Mukaiyama-type aldol reaction using a dithioacetal and silyl enol ether (eq 11).[25a] It has also been used as the catalyst for the formation of glycosides from alcohols and sugar dimethylthiophosphinates (eq 12)[25b] and for the formation of disaccharides from a protected α-cyanoacetal of glucose and a 6-*O*-trityl hexose.[25c] Michael additions of various silyl nucleophiles to conjugated dithiolenium cations also proceed well (eq 13).[25d,e] Finally, the [4 + 2] cycloaddition of cyclic dienes and oxygenated allyl cations has been effected with trityl fluoroborate.[25f]

Polymerization Catalyst.

Several types of polymerization[26] have been promoted by trityl fluoroborate, including reactions of orthocarbonates[26a] and orthoesters,[26b-d] vinyl ethers,[26e-g] epoxides,[26h,i] and lactones.[26j,k]

Other Reactions.

Trityl fluoroborate has been used often to prepare cationic organometallic complexes, as in the conversion of dienyl complexes of iron, ruthenium, and osmium into their cationic derivatives.[27] It alkylates pyridines on the nitrogen atom in a preparation of dihydropyridines[28a] and acts as a tritylating agent.[28b] It has also been used in attempts to form silyl cations and silyl fluorides from silanes.[29] Finally, it has been reported to be a useful desiccant.[30]

1,1,2-Triphenyl-1,2-ethanediol[1,2]

[95061-46-4] · $C_{20}H_{18}O_2$ · 1,1,2-Triphenyl-1,2-ethanediol · (MW 290.38)

(derived chiral monoesters undergo stereoselective aldol additions; formation of *O*-silyl orthoesters and cyclic phosphonates)

Physical Data: mp 126 °C. (*R*): [α]25D +214° (*c* = 1, ethanol), +220° (*c* = 1, 95% ethanol); (*S*): [α]25D -217° (*c* = 1, ethanol).

Solubility: sol dichloromethane, chloroform, THF, ethanol; insol hexane.

Form Supplied in: white solid; the (*R*)-form is commercially available.

Preparative Methods: (*R*)-1,1,2-triphenylethane-1,2-diol [(*R*)-(**1**)] is easily available from commercial (*R*)-***Mandelic Acid***, which is first esterified to give methyl mandelate and then treated with ***Phenylmagnesium Bromide*** (3.5 equiv). In an analogous way, (*S*)-(**1**) is accessible from (*S*)-mandelic acid, which is also commercially available (eq 1).[2]

anti-Selective and Diastereofacially Selective Aldol Additions.

2-Trimethylsilyloxy-1,2,2-triphenylethyl propionate, which is prepared from (*R*)-(**1**) by esterification with propionyl chloride and subsequent silylation of the tertiary hydroxy group, reacts in a highly stereoselective manner upon deprotonation, transmetalation with ***Dichlorobis(cyclopentadienyl)zirconium***, and addition to 2-methylpropanal. The diastereoselectivity is 96:4, which is the ratio of the major product to the sum of all other diastereomers. Subsequent reduction with ***Lithium Aluminum Hydride*** affords (2*S*,3*R*)-2,4-dimethyl-1,3-pentanediol in 95% ee (eq 2).[3] *anti*-Selective aldol additions which deliver chiral nonracemic products have been a longstanding problem of asymmetric synthesis.[4] Doubly deprotonated 2-hydroxy-1,2,2-triphenylethyl propionate has been applied in a total synthesis of dolastatin.[5]

When 1,1,2-triphenylethane-1,2-diol-derived esters are submitted to a monodeprotonation and subsequently treated with ***Chlorotrimethylsilane***, the formation of 2-trimethylsilyloxy-1,3-dioxolanes results. The orthoester moiety thus obtained serves as a protecting group for carboxylic acids (eq 3); it is stable towards alkyllithium reagents and can be cleaved under nonacidic conditions by alkaline hydrolysis.[6]

Methanephosphonyl dichloride reacts with (*R*)-(**1**) to give 2-methyl-4,4,5-triphenyl-2-oxo-1,3,2-dioxaphospholane (eq 4); the (R_P,R_C) diastereomer forms predominantly (9:1).[7]

A series of enantiomerically pure 1,1-diaryl-2-phenylethane-1,2-diols is available from methyl mandelate by addition of the corresponding substituted arylmagnesium bromides or aryllithium reagents.[2b,8]

Related Reagents.

Triphenylmethyl Hexafluorophosphate

[437-17-2] · $C_{19}H_{15}F_6P$ · Triphenylmethyl Hexafluorophosphate · (MW 388.31)

(catalyst for Michael additions,[1] aldol reactions,[2] photooxygenation;[3] reagent for hydride abstraction[4] and alkoxy abstraction[5])

Alternate Names: trityl hexafluorophosphate; triphenylcarbenium hexafluorophosphate.

Physical Data: mp 145 °C (dec.)[6]

Form Supplied in: brown powder; widely available.

Handling, Storage, and Precautions: trityl hexafluorophosphate should be stored in the dark as exposure to light darkens the compound. It is rapidly hydrolyzed by exposure to moist air.[7,8]

Michael Reactions.

Silyl enol ethers and α,β-unsaturated ketones react in the presence of trityl hexafluorophosphate (2-3 mol %) to give predominantly the *anti* Michael addition products (eq 1).[1] Steroeselectivity is similar to that found when ***Triphenylmethyl Perchlorate*** is used as the catalyst.[1]

(1)

Aldol Reactions.

Trityl hexafluorophosphate catalyzes the reaction of silyl enol ethers with aldehydes to give aldol products (eq 2).[2] Yields are similar to those obtained with trityl perchlorate as catalyst, being slightly higher or lower depending on the substrate.[2]

(2)

Photooxygenation.

Ergosteryl acetate can be converted photochemically to the corresponding peroxide by oxygen in the presence of trityl hexafluorophosphate (eq 3).[3] Other trityl salts can also be used.[3]

Hydride Abstraction.

Trityl hexafluorophosphate has been used with great success to abstract hydride ions from transition metal-complexed alkenic systems. For instance, with iron as the transition metal, the complex (**1**) gives the cyclobutatropylium iron complex (**2**) (eq 4).[9]

The regiochemistry of hydride abstraction by trityl hexafluorophosphate from a cycloheptadienyl iron complex can be controlled. The complex (**3**) undergoes hydride abstraction to give the iron cycloheptadienyl cation complex (**4**) (eq 5).[10,11]

The ability of trityl hexafluorophosphate to abstract hydride from variously substituted cyclohexadiene iron complexes has been reported. The two complexes (**5**) and (**6**) undergo smooth hydride abstraction, whereas the complexes (**7**) and (**8**) are resistant to hydride abstraction with trityl hexafluorophosphate (Scheme 1).[4]

Scheme 1

Other transition metal alkene complexes are known to undergo hydride abstraction with trityl hexafluorophosphate. The π-allyl molybdenum complex (**9**) gives the cycloheptadiene complex (**10**) upon treatment with trityl hexafluorophosphate (eq 6).[12,13]

(6)

Hydride abstraction also occurs from the benzyl rhenium complex (**11**) when it is treated with trityl hexafluorophosphate; the rhenium carbene complex (**12**) results (eq 7).[14]

(7)

Alkoxy Abstraction.

Upon treatment with trityl hexafluorophosphate the alkoxy substituted π-allyl molybdenum complex (**13**) is ionized by ethoxy abstraction to give the complex (**14**). Fluoroboric acid failed to achieve the same ionization cleanly (eq 8).[5]

(8)

Alkoxy abstraction has also been observed with the two cyclopentadienyliron dicarbonyl complexes (**15**) and (**16**), which both give vinyl ether cyclopentadienyliron dicarbonyl complexes (**17**) and (**18**) upon treatment with trityl hexafluorophosphate (eqs 9 and 10).[15]

Triphenylmethyl Hydroperoxide[1]

Ph_3COOH

[4198-93-0] · $C_{19}H_{16}O_2$ · Triphenylmethyl Hydroperoxide · (MW 276.35)

(oxidant useful for enantioselective metal-catalyzed epoxidation of allylic alcohols[2] and enantioselective oxidation of sulfides to sulfoxides[3])

Alternate Names: trityl hydroperoxide, THP.

Physical Data: mp 87.5-88.5 °C; *d* 1.27 g cm^{-3}.

Solubility: insol H_2O; sol most organic solvents.

Form Supplied in: commercially available as white, crystalline solid, 95+%.

Analysis of Reagent Purity: iodometric titration[7] (see ***t-Butyl Hydroperoxide***).

Preparative Methods: has been prepared in several ways.[4] The following method involves the acid-catalyzed reaction of triphenylmethanol with 30% ***Hydrogen Peroxide*** in acetic acid.[5] Triphenylmethanol (5.2 g, 20 mmol) is dissolved in 60 mL of glacial acetic acid, and ether (20 mL) is added to prevent solidification of the acetic acid at ice bath temperatures. Concentrated H_2SO_4 (4 drops, 0.08 mL) and 10 mL of 30% H_2O_2 are added to this solution. The solution is stirred at 0 °C for 3.5 h and then neutralized with aqueous NaOH. Care must be taken to keep the solution cold during the neutralization. The mixture is then extracted twice with ether, and the ether extracts are combined, washed sequentially with 5% $NaHCO_3$ and water, and then dried over anhydrous $MgSO_4$. The ether is removed in vacuo and the hydroperoxide is recrystallized from pentane. The yield of white solid is 5 g (91%), mp 84-86 °C. This compound consistently shows an assay purity of 99% by iodometric titration.

Purification: purified by recrystallization from ether, petroleum ether, pentane, pentane-ether, or $CHCl_3$-pentane.[6]

Handling, Storage, and Precautions: an unusually stable hydroperoxide which is relatively resistant (but still susceptible) to induced explosive decomposition. Like most alkyl hydroperoxides, it should be stored cold (ca. 0 °C) in the absence of light in a container such as a polyethylene bottle that is unlikely to shatter if there is pressure buildup. Exposing the pure hydroperoxide or concentrated solutions to heat, acid, reducing materials, or transition metal salts should be avoided. Upon completion of reactions, steps should be taken to safely destroy any remaining reagent. This can usually be done safely by exposing the reaction mixture to a mild reducing agent such as aqueous sodium sulfite, dimethyl sulfide, or triphenylphosphine. The reagent should always be handled in a fume hood.

Enantioselective Epoxidation of Allylic Alcohols.

THP can be used in place of *t*-butyl hydroperoxide (TBHP) as the oxidant in the Sharpless asymmetric epoxidation of allylic alcohols to give scalemic epoxy alcohols.[2] Usually, THP has been used for mechanistic studies and not for synthetic advantage. In one case, however, use of THP with a nontartrate ligand resulted in a reversal of enantioselectivity (eq 1).[8] With tartrate ligands, enantioselectivity is not reversed going from TBHP to THP.

(1)

Enantioselective Oxidation of Sulfides to Sulfoxides.

THP has also been used in the titanium-tartrate catalyzed asymmetric oxidation of prostereogenic sulfides to give scalemic sulfoxides.[3] Unlike ***Cumyl Hydroperoxide*** (which gives improved results over TBHP), THP gives poor asymmetric induction (eq 2).[9]

(2)

Hydroperoxide	Yield (%)	ee (%)
TBHP	90	89
CHP	93	96
THP	90	16

Triphenylmethyl Isocyanide[1]

Ph_3C-NC

[1600-49-3] · $C_{20}H_{15}N$ · Triphenylmethyl Isocyanide · (MW 269.36)

(cyanide transfer via metal-isonitrile exchange reaction[2])

Alternate Names: trityl isocyanide; isocyanotriphenylmethane.

Physical Data: mp 130-133 °C (benzene).[3]

Solubility: insol water, cold methanol, hexane; sol common organic solvents.

Form Supplied in: white solid.

Analysis of Reagent Purity: IR ν = 2130 cm^{-1}; NMR.

Preparative Method: easily prepared in 94% yield from *N*-triphenylmethylformamide by dehydration with ***Dimethylchloromethyleneammonium Chloride*** (Vilsmeier reagent).[4]

Purification: recrystallization from benzene.

Handling, Storage, and Precautions: can be stored indefinitely at room temperature; quickly adds water in the presence of acids; easily undergoes isocyanide-nitrile rearrangement (60-80 °C in acetonitrile).[5] Since some isocyanides are known to be toxic, appropriate precautions are recommended.[6]

Reactions with Organometallic Reagents.

Addition of organolithium reagents to triphenylmethyl isocyanide leads to the formation of unstable α-metalloaldimines which readily undergo elimination reaction to give nitriles and triphenylmethyllithium (eq 1).[7] However, only when ***t-Butyllithium*** is used can the nitrile (tertiary) be isolated in high yield (88%). In all other cases, subsequent reaction of the nitrile with the organolithium reagent (used therefore in excess) gives rise to symmetrical ketones upon acid hydrolysis (eq 2). Sequential addition of *t*-BuLi and another organolithium reagent produces unsymmetrical (*t*-alkyl-alkyl) ketones in good yields (eq 3). The intermediate ketimine can also be isolated when 2 equiv of *t*-BuLi are used and the reaction mixture is hydrolyzed with water (eq 4).

$$Ph_3C\text{-}NC + t\text{-}BuLi \xrightarrow[88\%]{\text{THF, -78 °C}} t\text{-}Bu\text{-}NC + Ph_3CLi \qquad (1)$$

(2)

(3)

(4)

Secondary Grignard reagents react readily with triphenylmethyl isocyanide to give secondary nitriles in 70-95% yield. Tertiary and aromatic organomagnesium compounds fail to give synthetically useful reactions. Reaction of primary Grignard reagents gives neither nitriles nor ketones as main products. When *n*-butylmagnesium bromide is treated with triphenylmethyl isocyanide, 5-amino-4-cyano-4-nonene is isolated in 50-60% yield (eq 5). Reaction of triphenylmethyl isocyanide with organometallic reagents can be stopped at the nitrile stage when organocopper (dialkylcuprate) reagents are used, but low yields mitigate its use as a synthetic tool.[7]

(5)

Synthesis of Masked Acyl Cyanides.

Triphenylmethyl isocyanide reacts readily with ***2-Lithio-1,3-dithiane*** to give the expected nitrile in 83% yield (eq 6).[8] The product can subsequently be alkylated with a variety of alkylating reagents in high yields.

Triphenylmethyllithium

Ph_3CLi

[733-90-4] · $C_{19}H_{15}Li$ · Triphenylmethyllithium · (MW 250.28)

(sterically hindered strong base; can function as a nucleophile)

Form Supplied in: red solution in THF, DME, and toluene; diethyl ether solution is colorless.

Analysis of Reagent Purity: the concentration of colored solutions can be determined by titration with a standard solution of 2-butanol to a colorless endpoint.[2]

Preparative Methods: solutions in ether solvents (containing some hexane) are most conveniently prepared by adding commercial solutions of ***n-Butyllithium*** in hexane to a solution of triphenylmethane in the ether, usually with ice-water cooling.[1] Crystals of the diethyl ether complex may be obtained as red needles by removal of the solvent.[3] Preparative methods up to 1959 have been reviewed.[4]

Handling, Storage, and Precautions: the red color of the reagent is rapidly discharged on exposure to air or water. Solutions in THF and diethyl ether are stable indefinitely,[3] but solutions in DME slowly lose titer at room temperature and form Ph_3CH, LiOMe, and CH_2=CHOMe.[2]

Reaction as a Base.

Triphenylmethyllithium is a strong base (the pK_a of Ph_3CH is 31.5) and rapidly converts a number of carbonyl compounds into the corresponding lithium enolates. The reagent played an important role in pioneering studies of enolate chemistry, but the more recently developed lithium dialkylamides possess significant advantages including greater base strength and faster rates of proton removal. A considerable advantage is the easier separation of dialkylamine, compared to Ph_3CH, from reaction mixtures. It has been observed that triphenylmethyllithium is now rarely used, in favor of the amide bases.[5] Nevertheless, triphenylmethyllithium has several unique characteristics which may make it the base of choice for some applications. The bright red color of triphenylmethyllithium together with the colorless nature of Ph_3CH allows a simple check for the completion of proton transfer as well as a rough estimation of the rate. For some applications, this advantage can be gained for other bases by addition of small quantities of Ph_3CH as an indicator.[6] Triphenylmethane is a relatively inert material compared to secondary amines and this fact may be advantageous for transformations subsequent to proton transfer. Quenching lithium amide-generated enolate solutions with D_2O often results in less than quantitative incorporation of deuterium because of the readily exchangeable protons of secondary amines. Of eight bases examined, triphenylmethyllithium gave the highest incorporation of deuterium in compound (**1**), an intermediate in the synthesis of the antibiotic Fludalanine (eq 1).[7]

Triphenylmethyllithium can react with conjugated enones by single electron transfer,[2] and this can provide an alternate mechanism for the formation of conjugated enolates (eq 2).[8] This may account for the occasional reports of superior yields,[9] or different regiochemistry,[10] obtained for proton removal with triphenylmethyllithium in such systems.

Reaction as a Nucleophile.

Triphenylmethyllithium can function as a surprisingly efficient nucleophile, especially in cases where proton transfer is not possible. Addition reactions with nonenolizable aldehydes and ketones,[4] and conjugate addition with enones, have been reported.[2,8] The reaction with organic halides and tosylates, in some cases at least, proceeds with inversion.[11,12]

Triphenylmethyl Perchlorate

[3058-33-1] · $C_{19}H_{15}ClO_4$ · Triphenylmethyl Perchlorate · (MW 342.79)

(catalyst for Michael additions,[1] aldol reactions,[2] and glycosidation[3])

Alternate Names: trityl perchlorate; triphenylcarbenium perchlorate.

Physical Data: mp 143 °C.[4]

Preparative Methods: perchloric acid is added to triphenylmethanol in acetic anhydride. The trityl perchlorate is separated, washed with ether, and dried.[5]

Purification: recrystallize from dry acetonitrile as yellow prisms.[4]

Handling, Storage, and Precautions: trityl perchlorate should be stored in the dark as exposure to light darkens the compound.[4] It is rapidly hydrolyzed by exposure to moist air.[4] All perchlorates present a potential explosion hazard.

Michael Reactions.

Silyl enol ethers react with α,β-unsaturated ketones in the presence of catalytic amounts of trityl perchlorate (2-3 mol %[1]) to give 1,5-dicarbonyl compounds.[6] No 1,2 addition products were obtained. It is possible to isolate the intermediate silyl enol ethers, which is not the case if ***Titanium(IV) Chloride*** is used as catalyst (eq 1).[6] *Anti* Michael adducts are obtained preferentially with selectivities of up to >95:5 (eq 2).[1] Silyl enol ethers of thioesters also react to give 5-keto thiol esters.[7] Allylsilanes have been reacted with α,β-unsaturated ketones to give δ,ε-unsaturated ketones (eq 3).[8] 1,4-Benzoquinones react with silyl enol ethers to give benzofurans.[9] Trityl perchlorate was found to be a more effective catalyst for Michael addition reactions than other trityl salts.[6]

Aldol Reactions.

In the presence of a catalytic amount of trityl perchlorate (1-5 mol %), silyl enol ethers react with acetals to give β-alkoxy ketones (eq 4).[10] Orthoformates react in a similar way.[10] Aldehydes react with silyl enol ethers to give β-silyloxy ketones (eq 5).[2] The reaction can be made *threo* selective, with selectivities of up to 82:18 reported.[11] Alkyl enol ethers and acetals react in the presence of trityl perchlorate to give β-alkoxy ketones.[12] A tandem Michael-aldol reaction has been reported which gives γ-acyl-δ-hydroxy ketones (eq 6).[13]

Glycosidation.

Perbenzylated 1-*O*-bromoacetyl-β-D-glucose reacts with alcohols in the presence of trityl perchlorate to give α-glucosides.[14] α-Ribosides can be prepared in a similar manner.[14] Other nucleophiles (silyl enol ethers, allylsilanes, and ***Cyanotrimethylsilane***) react with benzylated 1-*O*-acetyl ribose to give α-*C*-ribofuranosides (eq 7).[3]

Triphenylphosphine

[603-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine · (MW 262.30)

(deoxygenation of ozonides, peroxides, epoxides, and *N*-oxides; reduction of azides; reduction of organosulfur compounds; dehalogenations)

Physical Data: mp 79-81 °C; bp 377 °C; *d* (solid) 1.18 g cm^{-3}; *n*20D 1.59.

Solubility: insol H_2O; sol alcohol, benzene, chloroform; v sol ether.

Form Supplied in: white crystalline solid, widely available; polymer supported, ca. 3 mmol P per gram of resin is also available.

Purification: crystallize from hexane, methanol, or 95% ethanol; dry at 65 °C/<1 mmHg over $CaSO_4$ or P_2O_5.[1]

Handling, Storage, and Precautions: classified as an irritant upon acute exposure and a neurological hazard upon chronic exposure.[2] It is incompatible with strong oxidizing agents. Arylphosphines are less reactive toward molecular oxygen than benzyl- or alkylphosphines, but air oxidation of triphenylphosphine nonetheless occurs to an appreciable extent, particularly in solution, to give triphenylphosphine oxide.[3] Triphenylphosphine has low fire and explosion hazards, but, when heated to decomposition, it emits highly toxic fumes of phosphine and PO_x.[4] Use in a fume hood.

Introduction.

Triphenylphosphine is a fairly general reducing agent as the following examples indicate. The chemistry in which triphenylphosphine participates is, in most cases, driven by the formation of triphenylphosphine oxide, a thermodynamically favored reaction. The enthalpies of formation of triphenylphosphine and triphenylphosphine oxide are $\Delta_f H°_m$ = (207.02 ± 3.52) kJ mol^{-1} and $\Delta_f H°_m$ = -(116.41 ± 3.42) kJ mol^{-1}, respectively.[5] Triphenylphosphine oxide, however, is a highly crystalline nonvolatile material which often requires chromatography to effect its removal from desired reaction products. While less relevant to its chemistry, it is noteworthy that triphenylphosphine is a considerably weaker base than trialkylphosphines; its pK_a is 2.73 compared to, for instance, tributylphosphine with a pK_a of 8.43.[6]

Deoxygenations.

Triphenylphosphine has found widespread use in the reduction of compounds containing the hydroperoxide or endoperoxide functionality to form, depending upon the substrate, alcohols, carbonyl compounds, or epoxides. The primary driving force behind this class of reactions is the formation of the strong P=O bond at the expense of the relatively weak (45-50 kcal mol^{-1}) O-O bond.[7] For example, triphenylphosphine constitutes a mild, selective method for the reductive decomposition of ozonides to ketones and aldehydes. Compared to triphenylphosphine, ***Dimethyl Sulfide*** has enjoyed more popularity for this purpose,[8] probably because of its comparable mildness and the relative ease in removing the byproduct dimethyl sulfoxide compared to triphenylphosphine oxide. Nevertheless, the convenience of handling of triphenylphosphine and its lack of unpleasant odor render it an attractive alternative, as its use in the following examples illustrates (eqs 1 and 2).[9,10]

Treatment of hydroperoxides with triphenylphosphine affords the corresponding alcohols in high yields under mild conditions and with retention of configuration at the carbon bearing the peroxide (eqs 3 and 4).[11,12] The reaction of endoperoxides, on the other hand, affords epoxides with inversion of configuration at one of the two carbon atoms (eq 5).[13] Vinylogous endoperoxides react with triphenylphosphine to afford the allylic epoxides (eq 6).[14] These examples should not imply that reaction of endoperoxides with triphenylphosphine is necessarily facile, since certain endoperoxides have been shown to be inert to PPh_3.[15] Nevertheless, the transformation of the α-methylene-β-peroxy lactone to afford the β-lactone (eq 7)[16] illustrates the wide scope of the peroxide deoxygenation capability of triphenylphosphine.

(4)

(5)

(6)

(7)

The deoxygenation of epoxides affords the corresponding alkenes and results in an inversion in the stereochemistry of substitutents attached to the double bond.[17] While the reaction has been known since the mid 1950s,[18] it has not found widespread use. Triphenylphosphine has found utility as a reducing agent of *N*-oxides. While several alternative reagents and conditions are available, these often require fairly strong reducing conditions which are incompatible with a wide range of functionality.[19] In fact, triphenylphosphine-mediated reductions of *N*-oxides require much more vigorous conditions than do the corresponding reductions of peroxides. For example, reduction of trimethylamine oxide with trialkylphosphines requires refluxing in glacial acetic acid,[20] and the reduction of pyridine *N*-oxide derivatives is best carried out at temperatures above 200 °C in the absence of solvent.[21] However, it has been found that aromatic amine oxides are reduced in high yield with triphenylphosphine at room temperature with irradiation (eq 8).[22] While not general, under special conditions triphenylphosphine is also capable of reducing aromatic nitroso[23] and nitro groups (eq 9).[24]

(8)

(9)

Reduction of Azides (Staudinger Reaction).

In 1919, Staudinger and Meyer[25] reported that the addition of triphenylphosphine to organic azides produced iminophosphoranes. This reaction proceeds by attack on nitrogen by phosphorus to produce an unstable phosphazide which extrudes dinitrogen to give the iminophosphorane (eq 10). This is known as the Staudinger reaction.[26]

(10)

The iminophosphorane is a useful functional group for synthesis and can be isolated, although it is usually generated and used in situ. Iminophosphoranes can be hydrolyzed to amines. This forms the basis for the conversion of azides to amines using triphenylphosphine in the presence of water (eqs 11-13).[27] This mild and chemoselective reduction is an attractive alternative to other known methods (***Lithium Aluminum Hydride***, ***Diborane***, catalytic hydrogenation) that effect this transformation.[28] The reduction shown in eq 14 attests to the chemoselectivity of triphenylphosphine for this transformation. This reaction is sensitive to steric effects, but even tertiary azides can be reduced. Reduction of azides at a chiral center produce amines with the same configuration.

(11)

(12)

(13)

(14)

Reactions of Iminophosphoranes.

Iminophosphoranes are reactive nucleophilic ylides; electrophiles react with the nitrogen.[29] Aldehydes and ketones are particularly favored reaction partners with iminophosphoranes, producing imines and triphenylphosphine oxide.[30,31] This reaction is analogous to the Wittig reaction and is known as the aza-Wittig reaction. Again, the driving force for this reaction is the formation of triphenylphosphine oxide (eq 15). Two intramolecular examples are shown in eqs 16 and 17.[32,33]

Two other examples of reactions proceeding through the intermediacy of an iminophosphorane are shown in eqs 18 and 19.[34,35] Both reactions result in aziridine formation, and the driving force is the production of triphenylphosphine oxide.

(19)

Reduction of an azide with triphenylphosphine in the presence of phthalic anhydride results in the formation of a phthalimide, a common protecting group for an amine (eq 20).[36] This reaction is facilitated by the addition of 0.1 equiv of tetrabutylammonium cyanide. If the reduction is performed in the presence of a carboxylic acid, an amide is formed (eq 21).[37] This reaction works with either aromatic or aliphatic (primary, secondary) azides and either aromatic or aliphatic carboxylic acids.

(20)

(21)

Reduction of Organosulfur Compounds.

Triphenylphosphine converts episulfides to alkenes[38] smoothly at room temperature (eq 22). In contrast to the reaction of triphenylphosphine with epoxides, the reduction is stereospecifically *syn*.[39] This *syn* elimination can also be promoted with alkyllithiums,[40] lithium aluminum hydride,[41] and excess ***Iodomethane***,[40] and by exposure to carbenes.[42] This sulfur extrusion reaction plays a crucial role in Barton's method of alkene formation from carbonyl compounds.[43] This process (eq 23) is particularly effective for the formation of tetrasubstituted and highly hindered alkenes, where a paucity of methods exist for effective formation of these compounds. For example, cyclohexanone is easily converted to the azosulfide (**1**) in two steps, which, upon heating to 100 °C in the presence of triphenylphosphine, gives bicyclohexylidene via the episulfide (**2**) in good overall yield.

(22)

(23)

Aryl disulfides can also be reduced to aryl thiols with triphenylphosphine in aqueous dioxane (eq 24).[44] The resulting aryl thiols are easily removed from the triphenylphosphine oxide byproduct by extraction with aqueous base. The rate of reaction is faster for arenes with electron-withdrawing groups and is susceptible to catalysis by either acid or base. This reaction can also be accomplished with $LiAlH_4$, ***Sodium Borohydride***, and ***Zinc*** and dilute acid,[45] or by heating with alkali.[46]

(24)

In addition, arenesulfonic acids, their sodium salts, and alkyl arenesulfonates can be reduced to the corresponding aryl thiols by triphenylphosphine and a catalytic amount of ***Iodine*** (eq 25).[47] Since no reaction occurs in the absence of iodine or triphenylphosphine, the initial reduction is presumably mediated by iodotriphenylphosphonium iodide. The reaction can be greatly accelerated by the addition of a tertiary amine such as ***Tri-n-butylamine***. Use of bromine in place of iodine results in a considerably lower yield of thiol.

(25)

Triphenylphosphine has also been used to convert α-aryl-α-chloro sulfides to stilbenes.[48] The reaction (eq 26) requires addition of PPh_3 to the α-chloro sulfide prior to base addition; reversing the order of addition leads to negligible stilbene formation. The mechanism is not clear, but studies have shown that the phosphonium salt is not an intermediate in the process.

(26)

Eschenmoser[49] has used triphenylphosphine in an alkylation-sulfide contraction sequence useful in preparing secondary vinylogous amides and enolizable β-dicarbonyl compounds (eq 27). Although the precise mechanism is not known, an episulfide intermediate has been postulated. Addition of 0.1-0.2 equiv of a base such as ***Potassium t-Butoxide*** is necessary in some cases to promote enolization of the starting material.

(27)

Dehalogenation.

Triphenylphosphine has been used to reduce bromine or iodine atoms in the *ortho* or *para* positions of phenols (eq 28).[50] The procedure consists of heating the phenol and 1 equiv of triphenylphosphine in benzene at 100-150 °C for 1-5 h followed by alkaline hydrolysis. The corresponding aryl chlorides do not undergo this reaction. In the case of 2,4-dibromophenol, the *ortho* bromine atom is reduced preferentially.

(28)

Secondary and tertiary α-bromo ketones react with triphenylphosphine in refluxing benzene-methanol to afford the debrominated ketone in 60-70% yields (eq 29).[51] No quaternary phosphonium salts resulting from nucleophilic displacement of bromide are observed. The intermediacy of enol phosphonium salts has been proposed. Under conditions similar to those employed for bromo ketones, 2-chlorohexanone is dechlorinated to only a slight extent and direct quaternization is not detected.

(29)

Triphenylphosphine debrominates ethyl methacrylate dibromide and methyl acrylate dibromide to the unsaturated esters (eq 30).[52] Dehydrobromination or displacement of bromide is not observed. Triphenylphosphine also debrominates α-bromodiphenylacetyl bromide at room temperature to generate ***Diphenylketene*** (eq 31).[53] The mildness of this method avoids problems of other approaches such as the use of unstable intermediates such as phenylbenzoyldiazomethane and polymerization of the ketene.

(30)

(31)

Finally, triphenylphosphine has been utilized in the preparation of alkyl-substituted thiirene dioxides via a 1,3-elimination of bromine from bis(α,α-dibromoalkyl) sulfones (eq 32).[54] The tetrabromo sulfones are synthesized from ***Dimethyl Sulfone*** in two steps.[55]

(32)

Miscellaneous.

Trost[56] has reported that triphenylphosphine catalyzes the isomerization of ynones, ynoates, and ynamides to their corresponding diene-carbonyl compounds (eq 33). Conjugation of the alkyne with an electron-withdrawing group is necessary for the reaction to occur, and the reactivity order with respect to the electron-withdrawing group is ketone > ester > amide. Esters and amides require the addition of a weak protic acid such as ***Acetic Acid*** to facilitate the isomerization. Several examples of selectivity with polyfunctional alkynes have been reported (eq 34). The mildness and selectivity of this method over transition metal-catalyzed alkene redox reactions[57] allows for greater functional group compatibility.

(33)

(34)

Treatment of arylbromonitromethanes with an equimolar amount of triphenylphosphine in an inert solvent such as benzene leads to formation of ***Benzonitrile Oxide***,[58] which can be isolated as diphenylfuroxan; use of methyl acrylate as the solvent leads to isoxazolines via a [3 + 2] cycloaddition of the benzonitrile oxide generated in the reaction with ***Methyl Acrylate*** (eq 35). However, reaction of 2 equiv of triphenylphosphine with alkyl-1-bromo-1-nitromethanes leads to formation of the corresponding nitriles,[59] presumably via reduction of an intermediate nitrile oxides by the second equivalent of triphenylphosphine (eq 36). The putative alkyl nitrile oxide intermediate cannot be isolated or trapped by conducting the reaction in a solvent such as stilbene.

(35)

(36)

Triphenylphosphine in refluxing acetonitrile has also been used in the dequaternization of pyridinium salts (eq 37).[60] Placement of an electron-withdrawing group on the pyridine ring facilitates the dequaternization reaction.

(37)

R = alkyl; Y = CN, COMe, Et

Triphenylphosphine has found wide application as a coreagent with a variety of other compounds including diethyl azodicarboxylate and carbon tetrachloride. These reagent combinations are covered in subsequent articles.

Related Reagents.

Molybdenum(V) Chloride-Triphenylphosphine; ***Triphenylphosphine-N-Bromosuccinimide***; ***Triphenylphosphine-Carbon Tetrabromide***; ***Triphenylphosphine-Carbon Tetrabromide-Lithium Azide***; ***Triphenylphosphine-Carbon Tetrachloride***; ***Triphenylphosphine-Diethyl Azodicarboxylate***; ***Triphenylphosphine-Hexachloroacetone***; ***Triphenylphosphine-Iodine***; ***Triphenylphosphine-Iodoform-Imidazole***; ***Triphenylphosphine-2,4,5-Triiodoimidazole***.

[603-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine-*N*-Bromosuccinimide · (MW 262.30) (NBS)

[128-08-5] · $C_4H_4BrNO_2$ · Triphenylphosphine-*N*-Bromosuccinimide · (MW 177.99) (NCS)

[128-09-6] · $C_4H_4ClNO_2$ · Triphenylphosphine-*N*-Chlorosuccinimide · (MW 133.54) (NIS)

[516-12-1] · $C_4H_4INO_2$ · Triphenylphosphine-*N*-Iodosuccinimide · (MW 224.99)

(conversion of primary alcohols to alkyl halides)

Physical Data: See ***Triphenylphosphine***, ***N-Bromosuccinimide***, ***N-Chlorosuccinimide***, and ***N-Iodosuccinimide***.

Preparative Methods: the mixed reagent is prepared in situ as needed by combining triphenylphosphine, the alcohol, and *N*-halosuccinimide in a suitable solvent (usually DMF) and heating.

Handling, Storage, and Precautions: precautions in handling should be made as described for the individual reagents. This mixed reagent is not appropriate for storage. Recrystallization of the triphenylphosphine and *N*-halosuccinimide is necessary to achieve the most efficient halogenation reaction. In addition, the use of anhydrous solvent is important for the success of the reaction.

Introduction.

The combination of triphenylphosphine and *N*-halosuccinimide was applied by Hanessian[2] to the preparation of primary halides from carbohydrate precursors. This method is related to a number of other methods for hydroxyl substitution via oxyphosphonium salts as described in a comprehensive review.[1]

Conversion of Alcohols to Alkyl Halides.

The typical procedure[2] as applied to the preparation of methyl 5-deoxy-5-iodo-2,3-*O*-isopropylidene-β-D-ribofuranose (eq 1) involves the addition of 2 equiv of *N*-iodosuccinimide followed by 2 equiv of triphenylphosphine to a cooled solution of the alcohol in anhydrous DMF and heating the mixture to 50 °C for 20 min. Methyl alcohol is added to destroy excess reagent, followed by *n*-butanol to aid in the removal of DMF under reduced pressure. After concentration, the product is purified from the byproducts (succinimide and triphenylphosphine oxide) by addition of ether and aqueous extraction followed by column chromatography. Isolated yields of 70-85% are regularly obtained using this procedure for the preparation of chlorides, bromides, and iodides. In addition, the reaction conditions allow the preparation of primary halides in the presence of many functional groups used in carbohydrate chemistry, including the ester, amide, lactone, benzylidene acetal, and acetonide groups (eq 2). In fact, moderate yields (49-82%) of a number of primary halides are obtained using this procedure on sugars containing one or more free secondary hydroxyl groups (eq 3).[2-4]

(1)

(2)

(3)

Other examples of the use of this method include the preparation of tetrahydrofurfuryl bromide,[5] 3α-cholestanyl bromide (using THF as solvent, 85% yield),[6] and intermediates toward the syntheses of alkaloids (eqs 4 and 5).[7] The reaction of the reagent with DMF alone generates the formamidinium salt which can ultimately result in the isolation of the formate ester derivative of the alcohol substrate (eq 6).[1,8] It is therefore important that the *N*-halosuccinimide is added last for the preparation of alkyl halides. Other solvents used for this reaction include CH_2Cl_2 (which can facilitate the workup of the reaction products) and HMPA.[9]

(4)

(5)

(6)

The standard procedure has often been found to be unsatisfactory for substrates which are prone to acid-catalyzed rearrangements (including migration of acetonide protecting groups) and cleavage and is also not suitable for substrates containing labile protecting groups such as THP ethers.[10,11] In some cases this problem has been circumvented by the addition of various bases such as $BaCO_3$ (eq 7),[12] ***Pyridine***, and ***Imidazole***. A recent study has achieved the preparation of 3-bromo-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose by addition of 2 equiv of *N*-halosuccinimide to a refluxing solution of the secondary alcohol and 2 equiv each of PPh_3 and imidazole in toluene or chlorobenzene (eq 8). Previous applications of PPh_3 and *N*-halosuccinimide alone afforded only the primary halide products resulting from acetonide migration. The use of pyridine and imidazole have also been found to play an essential role in the conversion of carbohydrates to halides using the reagents ***Triphenylphosphine-Iodine*** and ***Triphenylphosphine-Carbon Tetrachloride***, respectively.[13]

Triphenylphosphine-Carbon Tetrabromide[1]

Ph_3P-CBr_4

(Ph_3P)

[603-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine-Carbon Tetrabromide · (MW 262.30) (CBr_4)

[558-13-4] · CBr_4 · Triphenylphosphine-Carbon Tetrabromide · (MW 331.61)

(reagent combination for the conversion of alcohols to bromides, aldehydes and ketones to dibromoalkenes, and terminal alkynes to 1-bromoalkynes; carboxyl activation)

Physical Data: Ph_3P: mp 79-81 °C; bp 377 °C; *d* 1.0749 g cm^{-3}. CBr_4: mp 90-91 °C; bp 190 °C; *d* 3.273 g cm^{-3}.

Solubility: sol MeCN, CH_2Cl_2, pyridine, DMF.

Preparative Method: the reactive species is generated in situ by reaction of Ph_3P with CBr_4.

Handling, Storage, and Precautions: Ph_3P is an irritant; CBr_4 is toxic and a cancer suspect agent. All solvents used must be carefully dried because the intermediates are all susceptible to hydrolysis. This reagent should be used in a fume hood.

Conversion of Alcohols to Alkyl Bromides.

The reaction of alcohols with ***Triphenylphosphine*** and ***Carbon Tetrabromide*** results in the formation of alkyl bromides. The conditions are sufficiently mild to allow for the efficient conversion of alcohols into the corresponding bromides. The uridine derivative (eq 1) is transformed into its bromide with Ph_3P and CBr_4.[2]

(1)

The geometry about the double bond of an allylic alcohol is usually not compromised (eq 2).[3] Allylic rearrangement is also not commonly observed. Although ketones are known to react with this reagent combination, the reaction of an allylic alcohol has been selectively achieved in the presence of a ketone (eq 3).[4]

(2)

(3)

Regioselective bromination of primary alcohols in the presence of secondary alcohols is possible. These reactions are usually performed in pyridine as solvent. The reaction of the methyl glucopyranoside (eq 4) results in the selective formation of the primary bromide in 98% yield.[5] An investigation of this reaction with a chiral deuterated neopentyl alcohol yielded a partially racemized bromide.[6]

(4)

Silyl ether protected alcohols (eq 5) have been converted directly into the corresponding bromides with Ph_3P and CBr_4. The reaction works best if 1.5 equiv of acetone are added.[7] Tetrahydropyranyl ether protected alcohols have also been directly transformed into the bromides using this reagent combination. The reaction has been reported to proceed with inversion of configuration (eq 6).[8] If unsaturation is appropriately placed within a tetrahydropyranyl (eq 7) or a methoxymethyl (eq 8) protected alcohol, cyclization occurs to afford tetrahydropyrans.[9] The conversion of an alcohol to the bromide without complications with a methoxymethyl protected alcohol in the molecule is possible (eq 9).[10]

(5)

(6)

(7)

(8)

(9)

Amides from Carboxylic Acids.

N-Methoxy-*N*-methyl amides can be prepared from carboxylic acids and the amine hydrochlorides. In the case of an α-phenyl carboxylic acid (eq 10), the amide is formed in 71% yield and no racemization is detected.[11]

(10)

Dibromoalkenes from Aldehydes and Ketones.

Benzaldehyde is transformed into the dibromoalkene in 84% yield when treated with Ph_3P and CBr_4 (eq 11).[12] An alternative procedure for the conversion of an aldehyde to the dibromoalkene uses ***Zinc*** dust in place of an excess of the phosphine. This allows the amount of Ph_3P and CBr_4 to be reduced to 2 equiv each as opposed to 4 equiv. This procedure gives comparable results to the original procedure. The dibromoalkenes can be reacted with ***n-Butyllithium*** to form the intermediate lithium acetylide. The acetylides can then be reacted with electrophiles such as H_2O (eq 12) and CO_2 (eq 13). This offers a convenient method for the formyl to ethynyl conversion.[13]

(11)

(12)

62% overall

(13)

~78% overall

Ketones are converted to dibromomethylene derivatives. These intermediates can be transformed to isopropylidene compounds by reaction with ***Lithium Dimethylcuprate*** and ***Iodomethane*** (eq 14).[14] No racemization was reported for the chain extension of the aldehyde derived from (*S*)-ethyl lactate under the reaction conditions (eq 15).[15]

(14)

~80% overall

(15)

~70% from *(S)*-ethyl lactate

β-Bromo Enones from 1,3-Diketones.

The reaction of Ph_3P and CBr_4 with a 1,3-diketone efficiently converts it to the β-bromo enone (eq 16).[16]

(16)

1-Bromoalkynes from Terminal Alkynes.

Terminal alkynes on reaction with Ph_3P and CBr_4 afford 1-bromoalkynes in high yield (eq 17).[17]

Triphenylphosphine-Carbon Tetrabromide-Lithium Azide

Ph_3P-CBr_4-LiN_3

(PPh_3)

[603-53-0] · $C_{18}H_{15}P$ · Triphenylphosphine-Carbon Tetrabromide-Lithium Azide · (MW 262.30) (CBr_4)

[558-13-4] · CBr_4 · Triphenylphosphine-Carbon Tetrabromide-Lithium Azide · (MW 331.61) (LiN_3)

[19597-69-4] · LiN_3 · Triphenylphosphine-Carbon Tetrabromide-Lithium Azide · (MW 48.97)

(reagent combination for the conversion of alcohols to azides)

Physical Data: Ph_3P: mp 79-81 °C; bp 377 °C; *d* 1.0749 g cm^{-3}. CBr_4: mp 90-91 °C; bp 190 °C; *d* 3.273 g cm^{-3}. LiN_3: mp 115-298 °C (dec).

Solubility: sol DMF.

Preparative Method: reactive intermediates are generated in situ by reaction of Ph_3P, CBr_4, and LiN_3.

Handling, Storage, and Precautions: Ph_3P is an irritant; CCl_4 is toxic and a cancer suspect agent; use in a fume hood. All solvents used must be carefully dried because the intermediates are all susceptible to hydrolysis. All azides are potentially explosive; workup with halogenated solvents is not recommended.

5´-Azido Nucleosides.

Introducing the azido group selectively to the 5´-position of various nucleosides can be accomplished with a combination of ***Triphenylphosphine***, ***Carbon Tetrabromide***, and lithium azide. This works well for uridine (eq 1) and thymidine. The yields are somewhat lower for *N*4-benzoylcytidine (eq 2) and *N*6-benzoyladenosine. The method is unsuccessful at introducing the azido group into the 5´-position of *N*2-benzoylguanosine.[1]

Triphenylphosphine-Carbon Tetrachloride[1]

Ph_3P-CCl_4

(Ph_3P)

[605-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine-Carbon Tetrachloride · (MW 262.30) (CCl_4)

[56-23-5] · CCl_4 · Triphenylphosphine-Carbon Tetrachloride · (MW 153.81)

(reagent combination for the conversion of a number of functional groups into their corresponding chlorides and for dehydrations)

Physical Data: Ph_3P: mp 79-81 °C; bp 377 °C; *d* 1.0749 g cm^{-3}. CCl_4: mp -23 °C; bp 77 °C; *d* 1.594 g cm^{-3}.

Solubility: sol CCl_4, MeCN, CH_2Cl_2, 1,2-dichloroethane.

Preparative Method: reactive intermediates are generated in situ by reaction of Ph_3P and CCl_4.

Handling, Storage, and Precautions: Ph_3P is an irritant; CCl_4 is toxic and a cancer suspect agent; use in a fume hood. Solvents must be carefully dried because the intermediates are all susceptible to hydrolysis.

Combination of Triphenylphosphine and Carbon Tetrachloride.

This reagent combination is capable of performing a range of chlorinations and dehydrations. The reactions are typically run using the so-called two-component or three-component systems. Carbon tetrachloride can function as both the reagent and solvent. However, the rates of the reactions are highly solvent-dependent, with MeCN providing the fastest rates.[1]

Conversion of Alcohols to Alkyl Chlorides.

The reaction of alcohols with ***Triphenylphosphine*** and carbon tetrachloride results in the formation of alkyl chlorides.[2] The mild, neutral conditions allow for the efficient conversion of even sensitive alcohols into the corresponding chlorides (eqs 1 and 2).[3,4] The reaction typically proceeds with inversion of configuration.[5] In eq 3, it is interesting to note that the reaction not only proceeds with inversion of configuration but also no acyloxy migration is observed.[6]

The conversion of an allylic alcohol to an allylic chloride occurs with no or minimal allylic rearrangement (eqs 4 and 5).[7] For the synthesis of low boiling allylic alcohols, it is advantageous to substitute hexachloroacetone (HCA) for CCl_4 (eq 6). The stereochemical integrity of the double bond also remains intact under these conditions.[8]

If the conversion of the alcohol to the chloride is attempted in refluxing MeCN, dehydration to form the alkene occurs (eqs 7 and 8).[9] Occasionally the separation of the product from the triphenylphosphine oxide produced in the reaction can be problematic. This can be overcome by using a polymer-supported phosphine.[10] Simple filtration and evaporation of the solvent are all that is required under these conditions. Not only is the workup facilitated, but the rate of the reaction is also increased by employing the supported reagent.[10c]

Conversion of Acids to Acid Chlorides.

The reaction of carboxylic acids with triphenylphosphine-CCl_4 reportedly produces acid chlorides in good yield under mild conditions (eq 9).[11] These conditions will allow acid sensitive functional groups to survive. Phosphoric mono- and diesters are successfully converted into the phosphoric monoester dichlorides and diester chlorides, respectively. The reaction of the diethyl ester does not produce the acid chloride. Instead, the anhydride is formed. Phosphinic acid chlorides can also be prepared from the corresponding phosphinic acid under these conditions (eq 10).[12]

(10)

Epoxides to *cis*-1,2-Dichloroalkanes.

Epoxides are converted into *cis*-1,2-dichlorides by the action of triphenylphosphine in refluxing CCl_4.[13] Cyclohexene oxide forms *cis*-1,2-dichlorocyclohexane (eq 11) contaminated by a trace of the *trans*-isomer. Cyclopentene oxide gives only the *cis*-isomer.

(11)

Dehydrations.

Diols may be cyclodehydrated to the corresponding cyclic ethers. The reaction is most effective for 1,4-diols (eq 12). Dehydration of 1,3- and 1,5-diols is not as successful, except in the case of the configurationally constrained 1,5-diol shown in eq 13.[14] The reaction of *trans*-1,2-cyclohexanediol with the reagent affords *trans*-2-chlorocyclohexanol with none of the *cis*-isomer or the *trans*-dichloride being detected. If the reaction is performed in the presence of K_2CO_3 as an HCl scavenger, the epoxide is formed (eq 14).[14] The yields are not as good with substituted acyclic diols.[15]

(12)

(13)

(14)

Dehydration of *N*-substituted β-amino alcohols with triphenylphosphine-CCl_4 and ***Triethylamine*** produces aziridines in good yield (eq 15).[16] This reaction has been successfully employed in the preparation of stable arene imines (eq 16).[17] Azetidines can be obtained from the corresponding 3-aminoalkanols (eq 17).[18] Additionally, reaction of 2-(3-hydroxypropyl)piperidine under these conditions yields octahydroindolizine (eq 18).

(15)

(16)

(17)

(18)

Substituted hydroxamic acids successfully cyclize to form β-lactams as long as Et_3N is present (eq 19). In the absence of the base, complex mixtures are formed.[19] Unsubstituted amides can be converted into nitriles via dehydration (eq 20).[20] This is the reagent of choice for the transformation of the amide to the nitrile in eq 21.[21]

(19)

(20)

(21)

Nitriles can also be obtained from aldoximes using this reagent (eq 22).[22] Ketoximes produce imidoyl chlorides via a Beckmann rearrangement under these conditions (eq 23).[23] Imidoyl chlorides are also available by the reaction of monosubstituted amides with Ph_3P-CCl_4 in acetonitrile (eq 24).[24]

(22)

(23)

(24)

N,*N*,*N*´-Trisubstituted ureas afford chloroformamidine derivatives (eq 25),[25] while *N*,*N*´-disubstituted ureas and thioureas produce carbodiimides (eq 26).[26] When carbamoyl chlorides are treated with the reagent in MeCN, they are converted into isocyanates (eq 27).[27] Dehydration of *N*-substituted formamides provides access to isocyanides (eq 28).[28]

Amide Formation.

The synthesis of an amide can be accomplished by initial reaction of an acid with Ph_3P-CCl_4 and then reaction of the intermediate with 2 equiv of the appropriate amine. A tertiary amine, such as ***Diisopropylethylamine***, can be employed as the HCl scavenger in cases where one would not want to waste any of a potentially valuable amine.[29] This method has been used in the construction of an amide in the synthesis of the skeleton of the lycorine alkaloids (eq 29).[30]

The method is effective for peptide coupling in that the yields are typically good; however, the reaction is often accompanied by racemization of the product.[31] The racemization problem can be suppressed, but this involves a change in the phosphine employed[32] or

slightly modified reaction conditions. These modified conditions have been used successfully in the construction of a hexapeptide without racemization (eq 30).[33]

If amino alcohols, amino thiols, or diamines are used, the intermediate amides cyclodehydrate under the reaction conditions to form Δ^2-oxazolines (eq 31), Δ^2-oxazines, Δ^2-thiazolines, or Δ^2-imidazolines.[33] The reaction requires the use of 3 equiv of the Ph_3P-CCl_4 reagent. The reaction is reported to fail if a commercial sample of the polymer-supported phosphine is used instead of triphenylphosphine.

1,1-Dichloroalkenes and Vinyl Chlorides.

The reaction of aldehydes produces a mixture of the 1,1-dichloroalkene and the dichloromethylene derivatives. These are the result of reaction of the in situ generated ***Dichloromethylenetriphenylphosphorane*** and ***Triphenylphosphine Dichloride***, respectively. Benzaldehyde (eq 32) produces a 1:1 mixture of the dichloroalkene and benzal chloride in 72% yield.[34]

Ketones can also be used in this transformation, but sometimes enolizable ketones lead to the formation of the vinyl chloride derived from the enol. This is usually more of a problem for six-membered ring ketones than for five-membered ring ketones. Cyclopentanone yields predominantly the 1,1-dichloroalkene (eq 33), while cyclohexanone provides mainly the vinyl chloride (eq 34).[35]

Triphenylphosphine Dibromide[1]

[1034-39-5] · $C_{15}H_{18}Br_2P$ · Triphenylphosphine Dibromide · (MW 389.10)

(bromination of alcohols,[3,4] phenols,[22] and enols;[3] cleavage of ethers[23,32,33] and acetals[25] to alkyl bromides; cyclization of amino alcohols[34,35] to cyclic amines; conversion of carboxylic acid derivatives into acyl bromides;[36,37] bromination[39] or dehydration[38] of carboxamide groups)

Alternate Names: bromotriphenylphosphonium bromide; dibromotriphenylphosphorane.

Physical Data: adduct:[2] colorless crystalline solid; mp 235 °C (dec). Ph_3P: mp 80.5 °C; bp 377 °C (in inert gas); *d*254 1.194 g cm^{-3}; *n*80D 1.6358. Br_2: mp -7.2 °C; bp 59.5 °C; *d*254 3.12 g cm^{-3}.

Solubility: adduct: sol CH_2Cl_2, MeCN, PhCN, DMF; less sol PhH, PhCl. Ph_3P: sol ether, PhH, $CHCl_3$, AcOH; less sol alcohol; pract. insol. H_2O. Br_2: sol H_2O (3.58 g/100 mL); very sol. alcohol, ether, $CHCl_3$, CCl_4, CS_2.

Form Supplied in: adduct: hygroscopic solid; commercially available; purity 95-96%. Both parent compounds, Ph_3P and Br_2, are widely available. Ph_3P: odorless platelets or prisms; purity ~99%; typical impurity Ph_3PO ~1%. Br_2: dark reddish liquid, volatile, with suffocating odor; vaporizes rapidly at rt; purity >99.5%.

Analysis of Reagent Purity: adduct: ^{31}P NMR (CH_2Cl_2) +49 ppm (ionic form);[2] Raman (solid phase) 239 cm^{-1} (P-Br). Typical impurities, Ph_3P and Ph_3PO: ^{31}P NMR (various solvents) -5 to -8 ppm and +25 to +29 ppm, respectively.

Preparative Methods: several preparations are described,[2,23b,32b] but in most cases the hygroscopic reagent is prepared just before use by addition of ***Bromine*** to ***Triphenylphosphine*** in a dry solvent with cooling.

Handling, Storage, and Precautions: adduct: corrosive; very hygroscopic; moisture sensitive; incompatible with strong oxidizing agents and strong bases; may decompose on exposure to moist air or water; do not get in eyes, on skin, or on clothing; keep containers tightly closed and store in a cool dry place; these reagents should be handled in a fume hood.

Introduction.

The Ph_3PBr_2 adduct was first used in synthesis in 1959[3] for the preparation of alkyl and acyl bromides from alcohols and carboxylic acids, and for the dehydration of amides and oximes to nitriles. Since then it has been widely employed as a versatile reagent for a number of synthetic reactions.

Conversion of Alcohols into Alkyl Bromides.

It has been established that Ph_3PX_2 reagents present considerable advantages over phosphorus halides (i.e. PX_3, PX_5) for which only two replaceable groups would be necessary and desirable.[4a] The mechanism[4b] of the reaction of Ph_3PBr_2 with an alcohol involves initial rapid formation of an alkyloxyphosphonium bromide,[4,5,7a] which then collapses slowly to the phosphine oxide and an alkyl bromide (eq 1). S_N2 substitution and high yields are generally observed with primary and secondary alcohols.[3,4a] This reagent shows little tendency to induce either carbonium ion rearrangement in the carbon skeleton or elimination reactions; this is illustrated by the preparation of neopentyl bromide from neopentyl alcohol (eq 2)[4a] and in the steroid field,[6] in which cholesterol and 3β-cholestanol give respectively 3β-bromocholest-5-ene and 3α-bromocholestane in yields of about 80%. Inversion of configuration is found in the S_N2 reactions of (+)-*endo*-norbornanol (eq 3)[7a,8] and 7-norbornanol. However, a similar reaction with (-)-*endo*-norbornanol leads mainly to racemic bromide via a nonclassical norbornyl cation intermediate.[7b] Likewise, little rearrangement is observed in the bromination of 3-methyl-2-butanol (eq 4).[9] Greater amounts of rearranged product are formed in the same reaction with Ph_3PCNBr (3%), ***Bromine-Triphenyl Phosphite*** (55.6%), or ***Triphenylphosphine-Carbon Tetrabromide*** (6-10%).

Ph_3PBr_2 can be used with sensitive substrates which incorporate cyclopropyl rings (e.g. cyclopropyl carbinol[11,12]) or unsaturation[10,13] (e.g. cinnamyl alcohol and alkynediols) with little if any side reactions. Cyclopropyl carbinols are transformed into bromides in good yield without ring opening or ring expansion, with the formation of only trace amounts of homoallylic bromides; no bromocyclobutane derivatives are detected (eq 5). Ph_3PBr_2 also proves superior to ***Phosphorus(III) Bromide*** for the bromination of alkynediols to dibromoalkynes (eq 6).[13]

R = H, Me, Et, Pr, Bu, *i*-Pr, *t*-Bu

Ph_3PBr_2 provides comparable yields to Ph_3P/CBr_4 in the bromination of diethyl 1-hydroxyalkylphosphonates.[14] A number of other primary,[15] secondary,[11-14] and even tertiary alcohols are brominated with Ph_3PBr_2, but with preponderant elimination[4a,6,16] in the latter case. A polymer-supported Ph_3PBr_2 reagent[17] has been successfully applied to alcohol bromination in refluxing $CHCl_3$; product isolation is facilited by the ready separation of supported from the nonsupported species. However, note that a polymer-supported Ph_3P/CBr_4 reagent leads to better bromination results than the Ph_3PBr_2 system in a number of cases.

Similar mono- and dibrominations have also been achieved in the carbohydrate field (eq 7).[18] Configurational inversion at chiral centers is

observed throughout. Ph_3PBr_2/***Imidazole*** (ImH) or Ph_3P/2,4,5-tribromoimidazole/ImH combinations in refluxing PhMe or in PhMe-pyridine mixtures are preferred in some cases. In the nucleoside field,[19] double activation is achieved with Ph_3PBr_2 in pyridine, leading both to bromination of the 5´-position of the sugar moiety and to substitution on the C-6 position of the adenine part (eq 8).[19b]

(7)

(8)

A variety of solvents such as CCl_4, PhH, triglyme, $CHCl_3$, PhMe, pyridine, NMP, MeCN, DMF, and mixtures of these have been employed in these bromination reactions, depending on substrate solubility. Both *O*- and *C*-formylations are encountered in some cases when DMF is the solvent. Ph_3PBr_2 and both Ph_3PX_2 analogs (X = Cl, I) can react with DMF according to the sequence in eq 9.[20] The intermediate alkoxyimonium bromide (**3**) affords either the expected bromide by heating, or the formyl ester by hydrolytic workup with secondary[20] or tertiary[16] alcohols (e.g. eq 10). Vilsmeier-type formylation reactions on nucleophilic carbon atoms can also take place, as developed early[38a] and then encountered later as a side reaction in the steroid field.[21] Such *O*-formylation of secondary alcohols is interestingly used in the differentiation of diols, leading to a new synthesis of bromo formates (eq 10).[20b] Under mild conditions, primary alcohols still afford bromides whereas secondary ones are converted almost exclusively to the corresponding formate esters.

(9)

Synthesis of Aryl Bromides from Phenols.

Already developed in the pioneering work,[4a] the preparation of aryl bromides from phenols with Ph_3PBr_2 was later extended to a number of substrates (eq 11).[22]

(11)

$X, Y = C, N; R^2 = H; R^3 = H, Cl, NO_2, MeO;$

Alkyl Bromides from Ethers and Acetals.

Ph_3PBr_2 cleaves dialkyl ethers to give the two alkyl bromides under essentially neutral conditions.[23] This reaction offers obvious advantages as it avoids both the strongly acidic and basic media which are usually employed for ether cleavage. Brominations are generally conducted at reflux in high boiling solvents such as PhCl, PhCN, DMF, or NMP. Primary and secondary alkyl groups provide good yields of bromides without rearrangement in PhCl or PhCN, at 60 to 120 °C,[23a,b] as illustrated in eq 12.[23c] Phenyl alkyl ethers initially afford aryloxyphosphonium bromides which collapse to bromobenzene only by heating at higher temperature (>230 °C as seen before). Alkyl *t*-butyl ethers are cleaved more easily in DMF[23b] or in MeCN,[24] usually between 60 and 110 °C; the *t*-butyl group is converted into isobutene in this process. In a related reaction, endoxides are transformed into arenes[28] by Ph_3PBr_2 treatment in PhCl. Aromatization takes place via HBr elimination from the initially formed dibromide.

(12)

Direct conversion of tetrahydropyranyl (THP)[25] and tetrahydrofuranyl ethers[26] (THF) to bromides can be achieved by Ph_3PBr_2 treatment under milder conditions (eq 13).[25a] THP and THF ethers afford good yields of acyclic, saturated, and unsaturated,[25c] primary, secondary,

and even tertiary alkyl bromides; under the same conditions, cyclohexyl THF ethers provide mainly cyclohexene derivatives. In view of the fact that the preceding reaction of THP ethers can be stopped (at low temperature) at the stage of either the alkoxyphosphonium (see eq 1) or the pentacovalent $ROPPh_3Br$ intermediate, hydrolysis of the reaction mixture at -50 °C, leads to the corresponding alcohols in good yield (74-97%) (eq 14).[29] The method is efficient for the deprotection of secondary and tertiary THP ethers, as well as for acyclic acetal ether, dialkyl acetals, and *O*-glucosides. Acetal functions can be removed with retention of stereochemistry, as illustrated in the conversion of (-)-menthol THP ether into (-)-menthol with full recovery of the optical activity. This procedure is not applicable to primary THP ethers, where the corresponding bromides are formed under these conditions.

(13)

(14)

Reaction of hindered trialkylsilyl ethers with Ph_3PBr_2 in CH_2Cl_2 at rt affords primary and secondary alkyl bromides in excellent yield (70-94%); the reaction is valuable in the β-lactam field.[27a] The reaction rate is increased by addition of a catalytic amount of ***Zinc Bromide***. Silylated enol ethers, such as trimethylsilyl(1-phenylvinyloxy)silane, provide vinyl bromides such as α-bromostyrene with Ph_3PBr_2 in refluxing CCl_4.[27b]

α-Alkynyl Ketones and β-Bromo-α-Vinyl Ketones from β-Diketones.

The previously described bromination of alcohols can be applied to the enol form of β-diketones. The first attempts in this field were conducted with the Ph_3PBr_2/***Triethylamine*** system on dibenzoylmethane, leading to phenylethynyl phenyl ketone.[30a] Elimination at the oxyphosphonium stage or HBr elimination from the initially generated vinyl bromide is probably involved in this reaction. Analogously, reaction of unsymmetrical β-diketones[30b] with excess Ph_3PBr_2/Et_3N proceeds with the formation of 3:1 mixtures of α,β-ynones in good overall yield (eq 15). Ethynyltriphenylphosphonium bromides are similarly obtained[30c] starting from (benzoylmethylene)- and (carbamoylmethylene)triphenylphosphoranes.

(15)

Similar treatment of unconjugated β-diketones[31] in PhH or MeCN as solvent leads to β-bromo-α,β-unsaturated ketones with superior results relative to the same transformation with PBr_3 as the brominating agent (eq 16).[31c] The reaction of acyclic 2,4-pentanedione with Ph_3PBr_2/Et_3N in PhH-MeCN[31c] or in CH_2Cl_2,[31d] but in the absence of Et_3N, appears not to be totally stereoselective, since a mixture of the geometrically isomeric bromo enones is produced, with 88% (*E*/*Z* ~ 87/13) and 85% (*E*/*Z* ~ 93/7) yields, respectively.

(16)

R^1 = H, Me, allyl, 2-cyanoethyl

n = 0, 1; R^2 = H, Me; R^3 = H, Me

Epoxide Opening to Vicinal Dibromides or Bromohydrins.

Epoxide ring opening with Ph_3PBr_2[32a] takes place in MeCN or PhH at 20-50 °C, affording vicinal dibromides (32-74%); *cis-trans* isomer mixtures are obtained in the case of cycloalkene epoxides. This reaction involves initial cleavage of the epoxide C-O bond at the most substituted epoxide carbon; bromoalkoxyphosphonium salts are thus formed, and these undergo subsequent substitution to give dibromides and Ph_3PO. In further studies,[32b] reaction of *cis*-epoxides in PhH produced *erythro*-dibromides exclusively (eq 17); *trans*-epoxides exhibit less specificity, leading to a mixture of *threo*- and *erythro*-dibromides. Use of a more polar solvent such as CH_2Cl_2 or MeCN, instead of PhH, with *cis*-epoxides provides *erythro-threo* mixtures (60-40 to 50-50). By reacting epoxides first with HCl and then with Ph_3PBr_2, it is possible to obtain vicinal bromochlorides stereospecifically that are also products of two S_N2 displacements.

(17)

R^1 = nonyl; R^2 = Bu

The reaction can also be carried out so as to give bromohydrins. In the steroid field[33a] with conformationally rigid epoxides, oxirane cleavage appears to be quite stereoselective and leads only to the bromohydrin resulting from the usual *anti* opening of the ring in high yield (90-97%). Less hindered and rigid substrates afford regioisomeric mixtures of cyclic *trans*-bromohydrins. Equivalent results[33b] are obtained, in the steroid series, by use of polymeric Ph_3PBr_2 for the transformation of epoxides to bromohydrins under mild nonacidic conditions; oxirane ring opening remains regio- and stereoselective.

Cyclization of β- and γ-Amino Alcohols to Aziridines and Azetidines.

β-Amino alcohols undergo cyclization upon Ph_3PBr_2/Et_3N treatment,[34] providing the corresponding aziridines along with substituted piperazines as dimeric byproducts (eq 18). Walden inversion is observed in the ring closure of both *threo*- and *erythro*-ephedrine and this supports the postulated 1,2-*trans*-elimination. Application of this procedure to the synthesis of 1-monosubstituted aziridines is unsuccessful, giving only the piperazine byproduct. *N*-Aryl γ-amino alcohols are cyclized to azetidines by Ph_3PBr_2/Et_3N in MeCN (eq 19).[35a] Under these conditions, some starting material is recovered unchanged along with mixed tetrahydroquinolines as side products and the expected *N*-arylazetidine. Comparable results are obtained (45-65%)[35b] with some other *N*-protecting groups.

R^1 = Bu, *t*-Bu, cyclohexyl, benzyl; R^2 = Me, Ph

(19)

R^1 = Me, Ph; R^2 = H, Me; R^3 = H, Me, Ph

Acyl Bromides from Carboxylic Acids, Anhydrides, and Esters.

Carboxylic acid bromides are prepared by reaction of Ph_3PBr_2 with various carboxylic acids and anhydrides in boiling PhCl.[36a] Milder conditions and better yields were later obtained in a comparative study[36b] by using CH_2Cl_2 at rt (eq 20). Further improvements are observed through the use of the corresponding trimethylsilyl esters; acyl bromides are thus obtained under mild and neutral conditions, allowing reactions with sensitive acid substrates without side reactions (eq 20). This transformation is also applicable to generate the acyl bromides of more hindered trialkylsilyl esters such as the TBDMS, TIPS, and TBDPS carboxylates; in CH_2Cl_2, the reaction rate increases in the presence of a catalytic amount of $ZnBr_2$.[27a]

$$RCO_2Z \xrightarrow{Ph_3PBr_2} RCOBr \qquad (20)$$

Z = H; PhCl, reflux	50-80%
Z = H; CH_2Cl_2, rt	64-90%
Z = TMS; CH_2Cl_2, rt	70-90%

R = Ph, 2-ClC_6H_4, 4-ClC_6H_4, Et, $PhCH_2CH_2$, PhCH=CH, $PhCH(CO_2Z)$, MeCH=CH

Direct reaction of less reactive alkyl esters and lactones[37] with Ph_3PBr_2 affords both acyl and alkyl bromides. This reaction is achieved at MeCN reflux[37a-c] for α-halogenated esters such as CF_3CO_2R, but only at higher temperatures and with longer reaction times for unhalogenated ones. The reaction of an ester with Ph_3PBr_2 presumably forms an oxonium salt, which then undergoes cleavage through reaction with bromide ion. Prolonged heating (80-110 °C) of lactones with Ph_3PBr_2 gives the expected acyl alkyl dibromides, but in low yield (<=50%) due to a concomitant degradation.[37d]

Dehydration of Ureas and Amides to Carbodiimides, Nitriles, Isocyanides, and Ketenimines.

Dehydration of *N,N´*-disubstituted ureas by heating with Ph_3PBr_2/Et_3N in PhH or PhCl at 70-80 °C affords carbodiimides[38a] in good yields. Subsequent improvements[38d] involving milder conditions provides access to certain unstable derivatives from *N,N´*-disubstituted ureas; this procedure compares favorably with previous ones and with another related approach using the ***Triphenylphosphine-Carbon Tetrachloride*** reagent system (eq 21). Reaction of *N,N´*-dialkylidene ureas with Ph_3PBr_2 in PhH leads to α-haloalkyl carbodiimides.[38e]

By the same Ph_3PBr_2/Et_3N procedure carried out in refluxing PhH, disubstituted cyanamides such as Me_2NCN are obtained from the *N*,*N*-disubstituted urea Me_2NCONH_2 (67%); similarly, isocyanides result from monosubstituted formamides (56-73%),[38a,40b] and nitriles from primary amides and oximes (58-68%).[3] Via the same route, ketenimines ($R^1R^2C{=}C{=}NR^3$) are prepared[38a,40b] in CH_2Cl_2 at reflux by dehydration of secondary amides having a C-H bond adjacent to the carbonyl function (45-93%). Application of this procedure to sulfimides gives highly reactive ketenimines, which are used for further reactions without isolation; [2 + 2] cycloaddition of such species with Schiff bases provides, in good yield, *N*-(tosyl)azetidin-2-imines related to β-lactam derivatives (eq 22).[38b] The diphosphorylated ketenimine $[(EtO)_2(O)P]_2C{=}C{=}NPh$ is obtained analogously in 87% yield with Ph_3PBr_2/Et_3N from the α,α-diphosphorylated acetanilide.[38c]

Imidoyl Bromides from Secondary Amides.

In the case of the secondary diarylamide benzanilide, reaction with Ph_3PBr_2/Et_3N in refluxing PhH provides *N*-phenylbenzimidoyl bromide in 65% yield, whereas a 70% yield is attained with the Ph_3P/CBr_4 reagent system.[39] The closely related *N*-methylbenzamide affords a dimeric compound[40b] with Ph_3PBr_2 in boiling CH_2Cl_2 by intermolecular *N*-imidoylation (see below for a similar intramolecular process) between generated imidoyl bromide or oxyphosphonium species and the starting carboxamide. Cyclodehydration of secondary carboxylic diamides with Ph_3PBr_2/Et_3N affords intramolecular *O*-imidoylation products with a benzoxadiazepine structure.[40] Without Et_3N, intramolecular *N*-imidoylation products with an o-imino lactam structure are obtained; *O*-imidoylated products rearrange to *N*-analogs under acidic conditions.

Iminophosphoranes from Amines, Hydrazines, and Related Derivatives.

Compounds containing a P=N bond, such as iminophosphoranes, are widely used as synthetic intermediates, especially in the heterocyclic field. Aromatic primary amines are generally transformed into iminotriphenylphosphoranes, and aliphatic amines into aminophosphonium bromides with Ph_3PBr_2/Et_3N in PhH, PhCl, CCl_4, or CH_2Cl_2 as solvent;[41a,b] more basic conditions are usually required to convert an alkylaminophosphonium salt into the corresponding iminophosphorane.[41b] As protected primary amines, these phosphinimines (iminophosphoranes) can then be subjected to monoalkylation, the Ph_3P protecting group being cleaved in a subsequent step to provide secondary amines (eq 23).[41a-c]

Some aliphatic and aromatic phosphinimines (prepared as above) undergo a Wittig-like condensation with CO_2 or CS_2, giving rise to isocyanates and isothiocyanates, respectively (eq 23).[41d] Dehydration reactions promoted by Ph_3PBr_2/Et_3N are used for intramolecular cyclizations involving an imide carbonyl group and an aromatic amine;[42] an aza-Wittig reaction of a phosphinimide intermediate is assumed to occur. Iminophosphoranes derived from hydrazines[43a] and acylhydrazines[43b,c] are also used as intermediates in heterocyclic synthesis. Reactions of metalated amines RNHMgX with Ph_3PBr_2 in PhH-ether can also provide aminophosphonium salts $Ph_3{+}PNHR\ Br^-$ in fair to good yields (33-74%).[43d]

Other Applications.

Reaction of Ph_3PBr_2 with benzoins in MeCN at rt provides diaryl α-diketones in excellent yields (75-98%).[44] Ph_3PBr_2 is used as a precursor in the synthesis of dialkoxytriphenylphosphoranes such as $(CF_3CH_2O)_2PPh_3$[45] and $(t\text{-}BuCH_2O)_2PPh_3$,[46] which are used as alkylating or acylating and cyclodehydration agents, respectively. Direct synthesis of β-lactams by [2 + 2] cycloaddition between carboxylic acids and imides, thus avoiding the use of acid halides, is achieved with Ph_3PBr_2 (40-55%).[47] Ph_3PBr_2, as a dehydrating agent, effects esterification reactions with tertiary alcohols,[48a] such as *t*-BuOH in PhH-HMPA, and with aromatic or aryl allylic acids and primary or secondary aliphatic alcohols in petroleum ether (27-85%).[48b]

Preparation of ***Bromotrimethylsilane*** in quantitative yield occurs by deoxygenation of $(Me_3Si)_2O$ with Ph_3PBr_2 (in 1,2-dichlorobenzene at reflux) in the presence of a catalytic amount of Zn; a one-pot preparation of pseudohalogenosilanes, in excellent yield (80-95%), can follow by subsequent addition of the appropriate salt XM in DMF (X = N_3, NCO, CN; M = K, Na,).[49] Treatment of Ph_3PBr_2 with ***Iodotrimethylsilane*** in CH_2Cl_2 at 0 °C yields Ph_3PI_2 (86%).[50] Reaction of Ph_3PBr_2/Et_3N with $EtO_2CCH_2CH{=}CHCO_2Et$ in PhH leads to the corresponding alkylidenephosphonium ylide in 80% yield.[51] Beckmann rearrangement of cycloalkanone oximes into lactams (74-81% yields) is effected by Ph_3PBr_2 in dry PhH at 50-60 °C.[52] The Ph_3PBr_2-Et_3N reagent system compares favorably with a number of other related phosphorus reagents for the rearrangement of *N*-allylamides into nitriles under mild conditions via 3-aza-Claisen reaction.[53]

Triphenylphosphine Dichloride[1]

Ph_3PCl_2

[2526-64-9] · $C_{18}H_{15}Cl_2P$ · Triphenylphosphine Dichloride · (MW 333.20)

(conversion of alcohols,[6-10] phenols,[13] and enols[15] into alkyl chlorides; synthesis of *vic*-dichlorides[16] or chlorohydrins[17] from epoxides; conversion of carboxylic acids[11] and derivatives[20] into acyl chlorides; chlorination[23,24] or dehydration[11] of the CONH group; production of iminophosphoranes from amines and related compounds[27-29])

Alternate Names: dichlorotriphenylphosphorane; triphenyldichlorophosphorane; chlorotriphenylphosphonium chloride.

Physical Data: adduct:[2] white crystalline solid; mp 85-100 °C;[4] fp 20 °C. Ph_3P: mp 80.5 °C; bp 377 °C (in inert gas); *d*254 1.194 g mL^{-3}; *n*80D 1.6358. Cl_2: mp -101 °C; bp -34.6 °C; d^0 3.214 g L^{-1}.

Solubility: adduct: slightly sol ether, THF, PhMe; sol CCl_4, CH_2Cl_2, DMF, MeCN, pyridine; insol petroleum ether. Ph_3P: sol ether, PhH, $CHCl_3$, AcOH; less sol alcohol; pract insol H_2O. Cl_2: sol CCl_4, alcohol.

Form Supplied in: very hygroscopic solid; commercially available; purity ~80%; the remainder is 1,2-dichloroethane. The precursors Ph_3P and Cl_2 are both widely available. Ph_3P: odorless platelets or prisms; purity ~99%; typical impurity is Ph_3PO ~1%. Cl_2: greenish-yellow gas, with suffocating odor; purity &egt;99.3%; typical impurities are Br_2, C_2Cl_6, C_6Cl_6, and H_2O.

Analysis of Reagent Purity: adduct:[2,3] ^{31}P NMR (various solvents and solid state) +47 to +66 (ionic form), -6.5 to +8 (covalent form); Raman (solid state) ν(P-Cl) 593 cm^{-1} (ionic form), 274 cm^{-1} (covalent form). Typical impurities, Ph_3P and Ph_3PO: ^{31}P NMR (various solvents) -5 to -9 and +25 to +42, respectively.

Preparative Methods: various preparations have been described;[5] the adduct is usually prepared just before use by addition of a stoichiometric amount of ***Chlorine*** to ***Triphenylphosphine*** in a dry solvent.[2]

Handling, Storage, and Precautions: adduct: exceedingly sensitive to moisture; incompatible with strong oxidizing agents and strong bases; may decompose on exposure to moist air or water; do not get in eyes, on skin, or on clothing; keep containers closed and store in a cool dry place; these reagents should be handled in a fume hood.

Alkyl Chlorides from Alcohols and Ethers.

The reaction of Ph_3PCl_2 with alcohols provides an excellent synthetic method for the preparation of alkyl chlorides.[6] Mechanistic studies[6c] suggest the rapid initial formation of an alkyloxyphosphonium intermediate which then undergoes slow conversion into Ph_3PO and alkyl chloride (eq 1).[6b,c] It is assumed that chlorination takes place by an S_N2 reaction in most cases; thus, inversion of configuration is observed in the transformation of (-)-menthol to (+)-neomenthyl chloride (eq 2).[6a] As illustrated in eq 1, primary,[6b,7] secondary,[6] and even tertiary[6b] alcohols are chlorinated with Ph_3PCl_2, although reactions of tertiary alcohols are often accompanied by elimination (10%).

$$\mathrm{ROH} \xrightarrow[\text{fast}]{Ph_3PCl_2} \mathrm{R\overset{+}{O}PPh_3\ Cl^-} \xrightarrow[\text{slow}]{S_N2} \underset{90\text{-}99\%}{\mathrm{OPPh_3} + \mathrm{RCl}} \qquad (1)$$

R = Bu, neopentyl, Cy, *t*-Bu; DMF, reflux

(2)

Ph_3PCl_2, generated in situ from Ph_3P and ***Hexachloroacetone*** (HCA) has proven to be a very efficient reagent for the regio- and stereoselective chlorination of allylic alcohols (eq 3),[8] and for the regioselective conversion of sterically hindered cyclopropylcarbinyl alcohols into cyclopropylcarbinyl chlorides (eq 4).[9] Chlorination of allylic alcohols occurs in less than 20 min, with total preservation of the double bond geometry and with >99% inversion of configuration for optically active alcohols. Primary and secondary alcohols give predominantly the unrearranged chlorides, while tertiary alcohols provide mostly rearranged products, with elimination to dienes becoming an important side reaction with more highly substituted systems. Similarly, cyclopropylcarbinyl alcohols yield the corresponding chlorides with no trace of homoallylic chlorides or cyclobutane derivatives.

(4)

R = H, Me, Et, Pr, Bu, *i*-Pr, *t*-Bu

In the carbohydrate field, primary and secondary alcohols are chlorinated in excellent yield (80-95%) with the Ph_3PCl_2/ImH (***Imidazole***) reagent system in PhMe, MeCN, or a MeCN/pyridine mixture at rt to reflux temperature.[10] Polymer-supported Ph_3PCl_2,[11] prepared by the $Ph_3PO/COCl_2$ (***Phosgene***) procedure,[5b] has been used to transform $PhCH_2OH$ to $PhCH_2Cl$ (88%) in MeCN as a solvent; the simple workup consists of filtration of polymeric phosphine oxide and solvent removal. Several examples have been reported of the direct conversion of ethers into chlorides, as in eq 5.[7] Enol ethers such as acetophenone trimethylsilyl ether give α-chlorostyrene (30%) by Ph_3PCl_2 treatment at CCl_4 reflux.[12]

(5)

Aryl Chlorides from Phenols and Arenes.

Heating phenols with Ph_3PCl_2 at 120-140 °C leads to the corresponding aryl chlorides in good yield (eq 6).[13] A related chlorination reaction employs the Ph_3PCl_2/BSPO (***Bis(trimethylsilyl) Peroxide***) reagent system as the electrophilic chlorine source. With this reagent, in MeCN at rt, aromatic hydrocarbons bearing electron-donating substituents, such as 2,4,6-tri-*t*-butylbenzene and mesitylene, afford 1-monochloroarenes, while anisole gives a mixture of 2- and 4-chloro derivatives, in moderate to good yields (44-86%).[14a] Similar aromatic *para* chlorination has also been observed by heating anisole with Ph_3+PCl PCl_5^-, albeit in low yield (33%).[14b]

(6)

$R^1 = H, NO_2, Me; R^2 = H; R^3 = H, Me, NO_2, Ph$
$R^1 + R^2, R^2 + R^3 = Ph$

Vinyl Chlorides, Alkynyl Ketones, and β-Chloro-α-vinyl Ketones from Ketones and β-Diketones.

1-Chlorocyclohexene (45%) and α,α-dichlorotoluene (59%) are produced by the reaction of cyclohexanone and benzaldehyde with Ph_3PCl_2/***Triethylamine*** and Ph_3PCl_2 alone, respectively, in refluxing PhH.[6a] In MeCN as solvent, polymer-supported Ph_3PCl_2 converts acetophenone into α-chlorostyrene (75%).[11] In a similar fashion, unsymmetrical fluorinated β-diketones give 3:1 mixtures of α,β-ynones (eq 7) in good overall yields (slightly lower than those obtained with ***Triphenylphosphine Dibromide***).[15a] β-Chloro-α,β-unsaturated ketones are prepared in high yield from cyclic β-diketones (eq 8).[15b,c]

(8)

$R^1, R^2, R^3 = H, Me; n = 0, 1$

Epoxide Cleavage to Vicinal Dichlorides and Chlorohydrins.

Early reports of work in this area described the ring opening of ethylene oxide with Ph_3PCl_2 in CCl_4 at rt, leading to 1,2-dichloroethane.[16a] Subsequently,[16b,c] excellent yields were reported in the reaction of Ph_3PCl_2 with aliphatic epoxides to produce the corresponding vicinal dichlorides. The ring opening takes place stereospecifically with both *cis* and *trans* epoxides in PhH or CH_2Cl_2 at reflux, in each case providing the dichloride derived from S_N2 displacement on each C-O bond (eq 9).[16c] Alkoxyphosphonium chloride intermediates have even been isolated and characterized in a study involving ethylene oxide derivatives.[16d]

(9)

The reaction of epoxides with Ph_3PCl_2 in anhydrous CH_2Cl_2 at rt[17a] results in chlorohydrins in generally high yields (90-96%). With conformationally rigid epoxides the oxirane ring cleavage appears to be quite stereoselective, leading only to the products resulting from the usual *anti* opening of the ring. Less hindered and rigid cyclic substrates provide regioisomeric mixtures of cyclic *trans*-chlorohydrins. The reaction of the polymer-supported Ph_3PCl_2 reagent proceeds in a similar fashion with even higher yields and easier workup; simple filtration and evaporation provides the product (eq 10).[17b]

(10)

Acid Chlorides from Acids and Esters.

Mono- and dicarboxylic acids give acyl chlorides on reaction with Ph_3PCl_2[6a] or polymer-supported Ph_3PCl_2[11] in PhH, CH_2Cl_2, or MeCN (eq 11).[11] On similar Ph_3PCl_2 treatment in PhH at -10 °C to rt, sulfamic acid (H_2NSO_3H) is transformed into $Ph_3P{=}NSO_2Cl$ in 95% yield.[18] Analogously, Ph_3PCl_2, generated in situ from Ph_3P and $(EtO)_2P(=O)SCl$, reacts with Et_3N and $(EtO)_2P(O)SH$ at -78 °C to provide the corresponding acid chloride $(EtO)_2P(S)Cl$.[19]

(11)

$$R = PhCH_2,\ 4\text{-}MeC_6H_4\ (n = 1);\ 1,4\text{-}C_6H_4,\ 1,3\text{-}C_6H_4\ (n = 2)$$

Direct cleavage of esters or lactones[20] to both acid and alkyl chlorides is achieved with Ph_3PCl_2; halogenated esters (RCO_2Me; R = CF_3, CCl_3, CH_2Cl) are readily cleaved in refluxing MeCN, while esters of nonhalogenated acids and lactones (eq 12) require higher temperatures or/and the use of additives such as ***Boron Trifluoride***. Cleavage is considerably retarded by steric hindrance in the alkoxy fragment. A mechanism involving initial nucleophilic cleavage of the O-alkyl bond with Cl^- is proposed for halogenated esters, whereas an initial electrophilic attack by Ph_3+PCl on the carbonyl oxygen is assumed for the cleavage of nonhalogenated esters.

(12)

Similar transformations of esters to acid chlorides have also been achieved in the phosphonate diester field[21] and in the conversion of trialkyl phosphites into dialkyl chlorophosphites.[22] Ph_3PCl_2 acts as a mild reagent for the replacement of a single ester linkage by a chloride in phosphonate diesters (eq 13).

Chlorination and Dehydration of Substituted Carboxamide Groups.

Secondary amides and *N*,*N*,*N*´-trisubstituted ureas possessing an N-H bond are converted to imidoyl chlorides[11,23] and chloroformamidines,[5a,24] respectively, by reaction with Ph_3PCl_2 (eqs 14 and 15). Unsupported or polymer-supported reagent has been used, with or without Et_3N, in a variety of solvents. Under very similar conditions, with Ph_3PCl_2 in CH_2Cl_2 at reflux, the primary amide $PhCONH_2$ is dehydrated to the nitrile PhCN (78%),[11] while aryl-substituted arylhydroxamic acids are dehydrated to the corresponding aryl isocyanates.[25] In the latter case, dehydration occurs via Lossen-type rearrangement of a phosphorane intermediate. In a related reaction, chlorination-dehydrochlorination of *N*-acylated hydrazines with the Ph_3PCl_2/Et_3N system is a smooth one-pot procedure to generate nitrilimines.[26] Thus, by such treatment, PhCONHNHPh affords [PhC&tbond;+N--N-Ph] in situ; this reacts with alkenic or alkynic dipolarophiles to give pyrazolines and pyrazoles.

Iminophosphoranes from Amines, Hydrazines, and Related Derivatives.

Iminophosphoranes (or phosphinimines) are commonly used as intermediates, especially in heterocyclic synthesis. Phosphinimines can be obtained via phosphorylation of primary amines with Ph_3PCl_2 alone,[27] or in the presence of Et_3N,[28] if necessary, to ensure the last dehydrochlorination step. In the heterocyclic β-enamino ester field, iminophosphoranes are submitted to vinylogous alkylation[28a] or cycloaddition (eq 16)[28a,b] with ring enlargement. The $=PPh_3$ moiety, which serves as a temporary amino protecting group, is then cleaved hydrolytically. Reaction of phosphinimines with aryl isocyanates affords carbodiimides,[28c] whereas iminophosphoranes of acyl hydrazines undergo dimerization to tetrazines.[28d] Other phosphinimines and phosphonium salts have been prepared from phosphorylation of amino derivatives, such as hydrazines,[29a] urethanes,[29b] and *N*-silylated imines,[29c] with Ph_3PCl_2.

Other Applications.

Ph_3PCl_2 is a good condensation reagent for the synthesis of ketones (48-90%) from carboxylic acids and Grignard reagents. The versatility of the method is illustrated by the chemoselective reaction of carboxylic acids possessing such functional groups as halogen, cyano, and carbonyl (eq 17).[30]

Beckmann rearrangement of benzophenone oxime to PhC(Cl)=NPh (82%) is promoted by Ph_3PCl_2/Et_3N in CH_2Cl_2 at rt.[31a] Cyclopentanone and cyclohexanone oxime are converted to δ-valero- and ε-caprolactam (76 and 86%) with Ph_3PCl_2 in PhH at 50-60 °C.[31b] The action of heat (120-130 °C) on a mixture of Ph_3PCl_2 with the highly fluorinated propanol $(CF_3)_2C(OH)CH_2SO_2CF_3$ leads to elimination of the CF_3SO_2 group and formation of the vinylic chloride $(CF_3)_2C{=}CHCl$.[32] Ph_3PCl_2 reacts with $Pb(SCN)_2$ to form $Ph_3{+}P{-}N{=}C{=}S\ SCN^-$, another reagent of the pseudohalophosphonium type, which is used for converting hydroxy groups into thiocyanate and isothiocyanate functions.[33] Ylides such as triphenylphosphonio(vinylsulfonylphenylsulfonylmethanide), $CH_2{=}CHSO_2{-}C{-}{-}(+PPh_3)SO_2Ph$, can be prepared by reaction of Ph_3PCl_2 with the very activated methylene derivative $CH_2{=}CHSO_2CH_2SO_2Ph$.[34] Heating Ph_3PCl_2 with $(Me_3Si)_2S$ at 60-70 °C leads to the formation of Ph_3PS (85%) after distillation of the Me_3SiCl byproduct.[35] Ph_3PCl_2 is reduced to Ph_3P with formation of alkyl or aryl chlorides by reaction with organometallic reagents (Mg, Li).[36]

2. The Ph_3PCl_2 adduct can be prepared by different routes; the most common involves the reaction of Ph_3P and Cl_2, both being generally used in solution, in order to ensure a correct 1/1 stoichiometry. As illustrated by physical studies,3 the resultant product is often a mixture of several compounds depending on starting materials (Ph_3P, Ph_3PO, Cl_2, $COCl_2$, CCl_3CCl_3, CCl_3COCCl_3), on their stoichiometries, and on the polarity of the solvent used for the preparation. ^{31}P NMR studies under various conditions, and solid state Raman measurements, lead to different values for ionic P^{IV} and molecular P^{V} species or to average values corresponding to equilibrated mixtures of the both structures according to the polarity of the solvent.

Triphenylphosphine-Diethyl Azodicarboxylate[1]

(Ph_3P)

[603-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine-Diethyl Azodicarboxylate · (MW 262.30) (DEAD)

[1972-28-7] · $C_6H_{10}N_2O_4$ · Triphenylphosphine-Diethyl Azodicarboxylate · (MW 174.18)

(reagent in the Mitsunobu reaction, which is a versatile, mild dehydration reaction, widely used for the synthesis of esters and ethers, for the formation of C-N, C-S, and C-halogen bonds, and for inverting the configuration of a stereogenic carbon containing an OH group[1])

Physical Data: see ***Triphenylphosphine*** and ***Diethyl Azodicarboxylate***.

Handling, Storage, and Precautions: all reagents and solvents must be anhydrous. In general, the Mitsunobu betaine (**1**) is generated in situ from the phosphine and the azodicarboxylate; however, in some cases it is essential to preform the betaine. The betaine is an unstable, colorless, crystalline solid, rapidly hydrolyzed on contact with moisture. It can be crystallized from dry THF or $CHCl_3$/hexane.

(1)

The Mitsunobu Reaction.

A mixture of triphenylphosphine (TPP) and diethyl azodicarboxylate (DEAD) is generally used; however, diisopropyl azodicarboxylate (DIAD) is cheaper and works just as well. The overall reaction enables the replacement of the hydroxyl group of an alcohol by a nucleophile X (eq 1).

(1)

The phosphine accepts the oxygen (to give triphenylphosphine oxide) while the azodicarboxylate accepts the two hydrogens (to give the corresponding hydrazine derivative). The reaction occurs under mild (0-25 °C), essentially neutral conditions, can be carried out in the presence of a wide range of functional groups, and usually gives good yields (60-90%). In general, the reaction proceeds well with primary and secondary alcohols, and inversion of configuration is observed.[1] Retention of configuration may result from neighboring group participation,[2] or a change in mechanism if the alcohol is very hindered.[3a] Racemization may result if the C-O bond is prone to S_N1 cleavage.[4] Examples of H-X in the reaction (eq 1) include carboxylic acids, thioacids, phenols, thiols, imides, sulfonamides, hydrazoic acid, heterocyclic compounds, hydrogen halides, phosphate diesters, phosphinic acids, and certain active methylene compounds. The pK_a of H-X should generally be less than 13. LiX or ZnX_2 sometimes give better results than HX.[1c] THF is the most commonly used solvent, but other solvents such as dichloromethane, chloroform, benzene, toluene, ethyl acetate, DMF, and HMPA can also be used. The reaction is faster in nonpolar solvents; for example, formation of ethyl benzoate is about 30 times faster in $CHCl_3$ than in MeCN.[5a] A problem commonly encountered with the Mitsunobu reaction is the separation of the product from triphenylphosphine oxide. This can be overcome by the use of a phosphine containing a basic group such as diphenyl(2-pyridyl)phosphine[6] or (4-dimethylaminophenyl)diphenylphosphine,[7] where an aqueous acid wash removes the corresponding phosphine oxide,

or by using a polymer-bound phosphine.[8] Similarly, dimethyl azodicarboxylate (the corresponding hydrazine is water soluble)[9] and a polymer-supported azodicarboxylate[10] can be used to facilitate product isolation. The reaction is best explained by assuming successive formation of the betaine (**1**), the protonated *N*-phosphonium salt (**2**), and the alkoxyphosphonium salt (**3**), which collapses in S_N2 fashion (eq 2).

Without acidic components, *N*-alkylhydrazinedicarboxylates (**4**) can be formed.[5b,11] NMR studies of the reaction of alcohols with DEAD and TPP in the absence of acidic components have revealed that the key intermediate is the pentavalent dialkoxyphosphorane (**5**).[1c,5] In the presence of an acidic component, phosphorane intermediates are present in equilibrium with the oxyphosphonium salt (**3**).[3]

The combination of DEAD and TPP has been utilized most often as the condensation reaction system, but dimethyl, diisopropyl, and di-*t*-butyl azodicarboxylates (**6**) can also be used instead of DEAD; the azodicarboxamide (**7**) has been used as well.[1,12] Triphenylphosphine can be substituted by a variety of trivalent phosphorus compounds, including substituted triarylphosphines and trialkylphosphines.[1c]

Order of Addition of the Reagents.

The order of addition can be crucial. The most commonly used procedure is to dissolve the alcohol (ROH), the acid (HX), and triphenylphosphine in THF, cool to 0 °C, add the DEAD (or DIAD) slowly with stirring, and then stir at room temperature for several hours. If this procedure fails to give the desired product, the betaine (TPP-DEAD adduct) should be preformed (addition of DEAD to TPP in THF at 0 °C) before addition of a mixture of the ROH and the HX,[13] or addition of ROH followed by slow addition of HX or HX and a buffering salt (strong acids),[14,15] or addition of HX followed by ROH (weak acids).[16] The advantage of preforming the betaine is that X^- is not generated in the presence of a powerful oxidant (the azodicarboxylate). Preformation of the betaine should minimize radical-induced side-reactions (radicals are produced when TPP and DEAD are mixed[17]).

Ester Formation.

A variety of alcohols react at room temperature with carboxylic acids in the presence of DEAD and TPP to produce the corresponding esters.[1] When polyols are used, the reaction generally takes place at the less hindered hydroxyl group, as exemplified in the reaction of 1,3-butanediol (eq 3).[18,19] When 1,2-propanediol or styrene glycol is used, however, the more sterically encumbered C-2 benzoate is predominantly obtained with complete inversion of the stereochemistry.[19] This result has been explained by the formation of a dioxaphospholane (**8**) as the key intermediate (eq 4).[3b,19,20a] With acyclic 1,4-diols such as isomaltitol,[20b] five-membered cyclic ether formation takes place in preference to esterification.

(8)

Thymidine (**9**) reacts with aromatic carboxylic acids to give 5´-*O*-aroylthymidines (**10**) (eq 5). The yield of esters increases with the acidity of the carboxylic acid, indicating the importance of the protonated *N*-phosphonium salt (**2**).[21,22]

The reaction of chiral secondary carbinols with carboxylic acids, DEAD, and TPP gives the corresponding esters with inverted configuration. Removal of the carboxyl group affords the enantiomer of the parent alcohol (eqs 6-9).[23-27] For the purpose of inverting the stereochemistry of a secondary carbinol center, 3,5-dinitrobenzoic acid,[28] *p*-nitrobenzoic acid,[22b] and chloroacetic acid[29] have been recommended, because of increased yield and ease of purification and removal of the carboxyl group from the resulting esters.

(9)

With some exceptions, a primary hydroxyl group is generally more reactive than a secondary one.[22a,30] Steric congestion and electronic effects sometimes retard the reaction and/or result in the formation of a complex mixture.[31]

The solvent also plays an important role in the success of the reaction. In general, reaction in benzene or toluene gives higher yields of inverted products.[1,22b,32] Although pyridine is not suitable in the preparation of nucleotides,[33a] pyridine can be used for the synthesis of sucrose epoxide,[33b] and a mixture of dioxane-pyridine (9:1) can be utilized in the preparation of sugar carboxylates.[22a] Mixed solvent systems may be necessary when the acid and alcohol components have widely differing solubilities. Thus a mixture of HMPA and dichloromethane works well in the synthesis of lipophilic carbohydrate esters such as cord factor.[33c]

Allylic and benzylic cyanohydrins react with carboxylic acids, DEAD, and TPP to give inverted esters with 92-99% ee, while extensive racemization takes place with benzaldehyde cyanohydrins containing strongly electron-donating substituents (eq 10). Saturated aliphatic cyanohydrins afford esters in which the original configuration is retained.[34]

(10)

Propargylic alcohols react with carboxylic acids, DEAD, and TPP to give the corresponding inverted esters without formation of allenic alcohols.[35] Similarly, in allylic alcohols where no bias exists against the normal S_N2 process, clean regiospecific inversion is invariably observed

or implied.[1,36] In specific cases where the S_N2 pathway is hindered for some reason, such as eclipsing of substituents, allylic rearrangement can occur (eqs 11-13).[1,37] When compound (**11**) reacts with benzoic acid, DEAD, and TPP, (**13**) and (**14a,b**) (**a**/**b** = 4:1) are obtained in a ratio of 1:1. Similar treatment of (**11**) in the presence of $PdCl_2$ (0.1 equiv) results in the nearly exclusive production of (**14a,b**) (73%; **a**/**b** = 10:1) via (**12**).[37d]

(13)

Reaction with Thiocarboxylic Acids, Phosphoric Acids, Sulfonic Acids, and their Derivatives.[1]

Thiocarboxylic acids,[38,13] dithiocarboxylic acids,[39] and dimethyldithiocarbamic acid zinc salt,[40] as well as various phosphorus oxyacids[41] and phosphorus thioacids,[42] can also be utilized. α,o-Mercapto alcohols form cyclic thioethers whereas thiols react with both DEAD and TPP-DEAD to form disulfides.[43a] 2-Mercaptoazoles also react with alcohols in the presence of DEAD and TPP.[43b] Although arenesulfonic acids do not enter into the reaction, a combination of DEAD-TPP with methyl *p*-toluenesulfonate as a nucleophile carrier gives the corresponding alkyl sulfonates (eq 14).[44] Alternatively, ***Zinc p-Toluenesulfonate*** reacts with a variety of secondary alcohols to produce the desired tosylates with clean inversion and in good yields, with some exceptions (eq 15).[45]

(14)

(15)

Reaction with Hydroxy Acids.

A study of reactions of *threo*-3-hydroxycarboxylic acids (**15**) with DEAD and TPP revealed that both hydroxyl group activation (HGA) and carboxyl group activation processes (CGA) are involved. With small R^1 and R^2, the zwitterion (**16**) is more stable than (**17**), so that HGA is exclusively observed, resulting in the formation of alkenes. On the other hand, the CGA process via (**17**) is progressively preferred as the size of R^1 and R^2 increases (eq 16).[46a,b] When the reaction is carried out in acetonitrile, CGA predominates.[46c]

Hydroxy acids HO-$(CH_2)_n$-CO_2H with *n* &egt; 3 react with DEAD and TPP to afford the corresponding lactones.[1] This procedure can be utilized in the preparation of macrolide antibiotics and related compounds. Macrolactonization by the use of DEAD-TPP depends on the reaction conditions and the structure of the seco acids. Thus dropwise addition of the hydroxy acid (**18**) over a period of 10 h to a mixture of DEAD (7.7 equiv) and TPP (7.5 equiv) affords the lactone (**19**) in 59% yield as well as the unwanted dilactide (**20**) in a yield of <1%. On the other hand, the reaction of (**18**) with DEAD (5.0 equiv) and TPP (5.0 equiv) at 25 °C for 18 h gives (**19**) and (**20**) in 2% and 40% yields, respectively (eq 17).[47]

The reaction of the seco acid (**21**) of colletodiol with DEAD and TPP gives the lactone (**22**) in 45% yield after recrystallization (eq 18),[48a] while

the seco acid (**23**), which has a closely related structure to (**21**), affords the corresponding lactone (**24**) in only 4% yield (eq 19).[48b,49]

Reaction with Phenols and Other Oxygen Nucleophiles.

When alcohols react with phenols, DEAD, and TPP, the corresponding aryl alkyl ethers are produced. A tertiary amine may facilitate the reaction.[50a] In general, the reaction proceeds with clean inversion of chiral secondary carbinol centers (eq 2; AH = a phenol).[50b] Depending on the structure of the substrate, allylic rearrangement[51,52] and neighboring group participation can be observed.[2,53] Phenols having a hydroxyalkyl chain in a suitable position for cyclization afford the corresponding cyclic aryl ether.[54] Silanols react with phenols and with alcohols in the presence of DEAD and TPP to afford the corresponding silyl ethers.[55] Oximes[56] and *N*-hydroxy imides[57] can also be utilized as acidic components.

Reaction with Di- and Polyols.

Although intermolecular dehydration between two molecules of alcohols to afford acyclic ethers usually does not occur with the DEAD-TPP system, intramolecular cyclization of diols to produce three to seven-membered ethers is a common and high yielding reaction. Contrary to an early report,[58a] 1,3-propanediol does not form oxetane.[5b] Oxetanes can be formed, however, using the trimethyl phosphite modification of the Mitsunobu reaction.[1c] The reaction of (*S*)-1,2-propanediol and (*R*)-1,4-pentanediol with DEAD and TPP affords the corresponding cyclic ethers with 80-87% retention of stereochemistry at the chiral carbon, while (*S*)-phenyl-1,2-ethanediol affords racemic styrene oxide. In contrast to the reaction of the same 1,2-diols with benzoic acid (eq 4), oxyphosphonium salts (**25a**) and (**25b**) have been postulated as key intermediates in the present reaction (eq 20).[58b,e]

The reaction of cyclic *trans*-1,2-diols with DEAD and TPP generally gives the corresponding oxiranes via phosphoranes.[1,33b,59] Cyclic *cis*-1,2-diols also react with DEAD/TPP to afford primarily phosphoranes (**26**) which decompose into final product(s) such as oxiranes (with retention of configuration) (eq 21)[60] and dehydrated alcohols and/or ketones (eq 22).[61]

Carbon-Nitrogen Bond Formation.

Phthalimide reacts with alcohols, DEAD, and TPP to give the corresponding *N*-alkylphthalimides with inversion of configuration (eq 2; HA = phthalimide).[1] Nitrophthalimide is more reactive than phthalimide.[22a] If the reaction site is hindered and an S_N1 process favored, some stereochemical scrambling is observed. For example, the reaction of (**27**) with phthalimide in the presence of DEAD and TPP results in complete epimerization, giving (**28a**) and (**28b**) in a ratio of 1:1 (eq 23).[62] Neighboring group participation is also possible in some cases.[63]

Alcohols having an acidic hydrogen atom adjacent to the hydroxyl group may undergo dehydration rather than substitution.[1] Thus the reaction of diethyl maleate (**29**) with phthalimide, DEAD, and TPP gives diethyl fumarate without any detectable formation of the substituted product.[64a] With ***Hydrazoic Acid***, however, (**29**) gives the expected azido succinate (**30**) in 74% yield (eq 24).[44a] Dehydration is regioselective in some cases.[64b,c]

(24)

Since azides are very useful in organic synthesis (especially for the introduction of primary amino groups and the construction of heterocyclic systems), the direct conversion of alcohols into azides has been extensively studied (eq 2; HA = HN_3).[1,65] ***Diphenyl Phosphorazidate***[66] and the zinc azide/bis-pyridine complex[67] can be used instead of HN_3. Treatment of alcohols with hydrazoic acid, DIAD, and excess TPP in THF, followed by addition of water or aqueous acid, affords amines in moderate to good yields (eq 25).[68]

(25)

Acyclic amides and imides with pK_a < 13 can be expected to function as acidic components in the present reaction system. Thus the reaction of *N*-benzyloxycarbonylbenzamide with ethyl (*S*)-(-)-lactate gives the inverted *N*-alkylated product (**31a**) and the *O*-alkylated product (**31b**) in 19% and 48% yields, respectively (eq 26).[69] This result suggests that the alkoxyphosphonium salt (**3**) is a hard alkylating reagent.

In the alkylation of imidodicarbonates and tosylcarbamates, the yield of alkylated product increases as the acidity of the NH acids increases. Thus imidodicarbonates and tosylcarbamates with pK_a < 13 give the corresponding *N*-alkylated products in 83-93% yields, while lower yields are obtained with less acidic substrates.[70a] The combination of ***1,1´-(Azodicarbonyl)dipiperidine*** (ADDP) with ***Tri-n-butylphosphine*** appears to be superior to that of DEAD with TPP in the alkylation of amides.[12] In the presence of DEAD and TPP, dibenzyl imidodicarbonate does not react with alcohols, but it does react with α-hydroxy stannanes to give the corresponding *N*-alkylated products (eq 27).[71]

The *O*-acylhydroxamate (**32a**) (pK_a 6-7) reacts with benzyl alcohol, DEAD, and TPP to give *N*- and *O*-alkylated products, while the less acidic *O*-alkylhydroxamate (**32b**) (pK_a 9-10) gives only the *N*-alkyl product (eq 28).[72a]

Intramolecular dehydration of 3-hydroxy carboxamides affords the corresponding β-lactams. Side reactions include elimination and formation of aziridines and oxazolidines (eq 29).[72,73] The efficiency of β-lactam formation is dependent on substrate substituents (including protecting groups

for the side-chain amino group) as well as on the choice of azodicarboxylate and P^{III} compound.[1c,74-76] For example, the dipeptide (**33**) reacts with DEAD and TPP to give a 2:1 mixture of the β-lactams (**34a**) and (**34b**). Control of the labile C-5 stereocenter can be achieved by use of ***Triethyl Phosphite*** instead of TPP; (**34a**) and (**34b**) are obtained in a >50:1 ratio (eq 30).[75] 3-Hydroxy *O*-alkylhydroxamates can also be converted into the corresponding β-lactams (eq 31).[1c,77]

(29)

(33)

(30)

(34a) **(34b)**

DEAD-TPP	2:1
DEAD-$(EtO)_3P$	50:1

(31)

Purines and pyrimidines react with various alcohols in the presence of DEAD and TPP (eq 32).[78] The alcohol (**35**) gives a carbocyclic nucleoside (**36**) in 65% yield along with a small amount (9%) of the 7-substituted purine derivative (eq 33).[79-81]

(32)

X = Y = H	70%	9%	21%
X = H, Y = Cl	67%	23%	9%
X = Y = Cl	69%	26%	-

(33)

Reaction with Amino Alcohols and Related Compounds.

Both secondary and tertiary carbamates bearing a vicinal hydroxyl group react with carboxylic acids in the presence of DEAD and TPP to afford the corresponding esters with inversion of configuration (eq 34).[82] Reaction of *N*-*t*-butoxycarbonylserine with methanol, DEAD, and TPP gives the corresponding methyl ester in >98% yield (eq 35).[83] Without methanol, *N*-benzyloxycarbonyl- or *N*-*t*-butoxycarbonylserine reacts with the preformed adduct of DEAD and TPP to afford the β-lactone (eq 35).[84] The *N*-protected serine methyl ester (**37a**) and threonine methyl ester (**37b**) react with DEAD and TPP to give the dehydrated products (**38a**) and (**38b**) (eq 36).[85]

(34)

(35)

(36)

(37a) R = H
(37b) R = Me

(38a) R = H, 63%
(38b) R = Me, 55%

In the absence of an acidic component, β-(*N*-carbonylamino) alcohols afford aziridines or oxazolines, depending on the structure of the substrate. Contrary to the case of (**37**), the *N*-benzyloxycarbonylamino alcohol (**39**), with no acidic hydrogen present at the position adjacent to the hydroxyl group, affords the aziridine (**40**) in 85% yield (eq 37),[86,87] while the *N*-acylamino alcohols (**41**) give the oxazolines (**42**) in 31-68% yields (eq 38).[88]

(37)

(39) **(40)**

(38)

(41) **(42)**

Protection of the amino group by an electron-withdrawing group is not necessarily required for the cyclization. Amino alcohols of general structure HO-$(C)_n$-NHR react with DEAD and TPP to form the corresponding cyclic amines. Thus 2-aminoethanols give aziridines in 18-90% yields.[89] The reaction of the tetrafluoroborate salt of 3-(benzylamino)-1-propanol with DEAD and TPP gives the corresponding azetidine in 50% yield (eq 39).[90] Five- and six-membered cyclic amines are also prepared by the reaction of amino alcohols with DEAD and TPP (eqs 40 and 41).[91] Although azepines are not formed from straight-chain amino alcohols, compound (**43**) gives the azepines (**45a**) and (**45b**) by S_N2' substitution of the intermediate phosphorane (**44**) (eq 42).[92]

(43)

(44)

(42)

(45a) 85% **(45b)** 3%

O-Glycosidation with Phenols.

Monosaccharides possessing a free anomeric hydroxyl group react with phenol, DEAD, and trivalent phosphorus compounds to give phenyl glycosides. The yield is higher with trialkylphosphines (Bu_3P, Pr_3P).[93] Coupling of phenols and 2-α-(phenylthio)- or 2-α-(phenylseleno)-α-D-pyranoses by the use of DEAD and TPP gives aryl 2-deoxy-β-D-glycosides in 70-85% yields with high stereoselectivity (inversion of anomeric center) (eq 43).[94] Intramolecular phenolic glycosidation is also possible.[95]

selectivity = 87:13 to 95:5

$R^1 = H, R^2 = BnO$ or $R^1 = BnO, R^2 = H$
X = PhS or PhSe; ArOH = 2-naphthol, phenol, or 2-cresol

O-Glycosidation with Carboxylic Acids.

Reaction of carbohydrates having a free anomeric hydroxyl group with carboxylic acids gives the corresponding glycosyl esters (eq 44).[96] Intramolecular glycosidation of (**46**) can be accomplished by the use of the preformed Bu_3P-DEAD betaine at low temperature (eq 45).[97]

Glycosidation with Nitrogen Nucleophiles and *N*-Hydroxy Compounds.

Reaction of an anomeric hydroxyl group with nitrogen nucleophiles and with *N*-hydroxy heterocycles affords the corresponding glycosides.[1,98,99] The α-lactol (**48**) (α:β = ca. 8:1) reacts with *N*-hydroxyphthalimide, DIAD, and TPP to give the β-glycoside (**49**) (eq 46).[100]

Carbon-Carbon Bond Formation.

Direct coupling of an alcohol with a carbon acid by the use of DEAD/TPP has been limited to only a few examples because of the lack of carbon acids with pK_a < 13. If enolizable carbonyl compounds are used, alkylation generally takes place on oxygen.[69a,101] Thus the reaction of 1,3-cyclohexanedione with isopropanol, DEAD, and TPP affords exclusively the *O*-alkylated product (eq 47).[101a] Cyanoacetate reacts at the carbon

atom, while diethyl malonate is unreactive.[101a] However, the reaction of diethyl malonate with alcohols in the presence of ADDP and Bu_3P affords *C*-alkylated products in 3-56% yields (eq 48).[12] Ethyl nitroacetate and nitromalonate oxidize the alcohol via an *aci*-nitro ester (eq 49).[102] *o*-Nitroarylacetonitriles of general formula (**50**) undergo alkylation on carbon (eq 50).[16,103]

(47)

$$CH_2(CO_2Et)_2 + ROH \xrightarrow[\text{benzene, rt, 24 h; 3-56\%}]{\text{ADDP, } Bu_3P} RCH(CO_2Et)_2 \quad (48)$$

(49)

(50)

(50)

X = CH or N

γ-Nitro alcohols react with DEAD and TPP to afford α-nitrocyclopropanes in good to excellent yields (eq 51).[104a] On the other hand, nitro alcohols bearing electron-withdrawing or unsaturated substituents at the α-carbon experience exclusive intra- and intermolecular *O*-alkylation and furnish good to excellent yields of alkyl nitronates (eq 52). In contrast, 1-phenylsulfonyl-1-nitro-3-propanol affords the corresponding cyclopropane.[104b] Bis-sulfones readily undergo alkylation by alcohols.[104c] Novel intramolecular S_N2 and S_N2' type arylation occurs with certain aromatic and allylic alcohols (eqs 53 and 54).[105]

(51)

(52)

(53)

(54)

Miscellaneous Reactions.

Dialkyl phosphonates react with alcohols in the presence of DIAD and TPP to give trialkyl phosphites (eq 55).[5a] TPP-DIAD reacts with KHF_2 or HF-pyridine to form difluorotriphenylphosphorane (eq 56).[106]

Triphenylphosphine-Hexachloroacetone

(Ph_3P)

[603-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine-Hexachloroacetone · (MW 262.30) (HCA)

[116-16-5] · C_3Cl_6O · Triphenylphosphine-Hexachloroacetone · (MW 264.73)

(conversion of alcohols, particularly allylic alcohols, into chlorides with high regio- and stereoselectivity)

Physical Data: Ph_3P: see ***Triphenylphosphine***. Hexachloroacetone: mp -3 °C; bp 202 °C, 66 °C/6 mmHg; *d* 1.74 g cm^{-3}.

Solubility: hexachloroacetone: slightly sol H_2O; sol acetone, benzene, chloroform, ether.

Form Supplied in: hexachloroacetone: liquid, widely available.

Handling, Storage, and Precautions: hexachloroacetone: toxic, irritant.

General Discussion.

The conversion of allylic alcohols into chlorides (eq 1) presents difficulties not encountered with saturated compounds. A successful synthesis will be: (a) regiospecific (exclusive formation of either the α- or γ-substituted product); (b) stereoselective or stereospecific (preservation of the β,γ-double bond geometry when unrearranged product is formed; complete inversion or retention of configuration in the unrearranged product when the α-carbon is stereogenic); and (c) gentle (the conditions of the reaction, isolation, and workup should cause neither allylic rearrangement nor decomposition of the product).

There is, at present, no single method that meets all of these criteria for every type of allylic alcohol. Conventional reagents like $SOCl_2$ and PCl_3 have been used, but with mixed results.[1] Some recently developed and frequently used methods are: (a) $MeSO_2Cl$/LiCl/DMF/collidine;[2a] (b) RLi/HMPA, then TsCl, then LiCl/HMPA;[2b] and (c) *N*-chlorosuccinimide/Me_2S/CH_2Cl_2.[2c] All of these are successful with primary substrates, but less so with secondary and tertiary allylic alcohols.[1a,3] The combination ***Triphenylphosphine-Carbon Tetrachloride*** has had notable success, not only for transforming saturated alcohols into chlorides, but also for a variety of condensation reactions.[4] Mechanistic studies[5] have revealed that chloride formation succeeds even for alkyl groups that are prone to rearrange and that it proceeds with inversion of configuration at the alcohol center. The relative mildness of this system prompted Snyder[6] to test it with allylic alcohols (eqs 2 and 3); crotyl alcohol (as an unspecified mixture of (*E*)- and (*Z*)-isomers) reacts without rearrangement, whereas 3-buten-2-ol proceeds regioselectively to an 89:11 mixture of products. One of the drawbacks to this procedure is that low molecular weight allylic chlorides have boiling points very close to those of carbon tetrachloride and its reaction product chloroform, thus making the isolation of product(s) difficult. It was principally for this reason that it was decided to replace CCl_4 with a higher boiling source of Cl^+; hexachloroacetone (HCA) was chosen, not only for its high boiling point, but also because the anionic intermediate after Cl^+ removal would benefit from resonance stabilization.[7]

(2)

(3)

In fact, not only does the triphenylphosphine-hexachloroacetone system work admirably for a wide variety of allylic alcohols, but the conditions of the reaction and isolation are especially mild. Typically, a slight excess of solid Ph_3P is added to an ice-cold solution of the allylic alcohol in hexachloroacetone solvent (although the order of mixing of the reagents appears to be unimportant); after about 10-15 minutes the solution is warmed to room temperature and the product flash-distilled (at about 1-3 mmHg), yielding the allylic chloride(s) in nearly quantitative yield, uncontaminated by Ph_3P, HCA, or their reaction products. If desired, the reaction can be run with a stoichiometric quantity of hexachloroacetone in sulfolane; indeed, it is found that two chlorines (but not more) per HCA molecule can be used in this reaction. Saturated alcohols (1- and 2-butanol, neopentyl alcohol) give excellent yields of unrearranged chloride. The results shown in eqs 4-6[7b] are typical of the behavior of a total of sixteen allylic alcohols. Primary alcohols give essentially 100% unrearranged chloride with total preservation of double bond stereochemistry. Secondary alcohols tend toward ca. 90/10 mixtures of unrearranged/rearranged product. When the α-carbon is stereogenic, the reaction proceeds with complete inversion of configuration. The method fails only for tertiary alcohols, which give significant amounts of rearranged chloride and elimination product.

(4)

(5)

(6)

The system Ph_3P/HCA has also found use with cyclopropylcarbinyl alcohols.[8a] HCA can be replaced by hexabromoacetone in order to make allylic bromides.[8b] HCA, by itself, reacts with enamines,[8c] alcohols in DMF,[8d] tertiary amines,[8e] and miscellaneous nucleophiles.[8f]

Triphenylphosphine Hydrobromide

$Ph_3P.HBr$

[6399-81-1] · $C_{18}H_{16}BrP$ · Triphenylphosphine Hydrobromide · (MW 343.21)

(mild source of anhydrous HBr;[1] catalyst for formation of THP ethers from tertiary alcohols;[2] preparation of phosphonium salts[3,4])

Alternate Name: triphenylphosphonium bromide.

Physical Data: mp 196 °C (dec).

Solubility: sol CH_2Cl_2, $CHCl_3$; slightly sol THF, benzene; insol ether.

Form Supplied in: commercially available white powder.

Analysis of Reagent Purity: acidometric titration.

Preparative Methods: addition of anhydrous ***Hydrogen Bromide*** to an ethereal solution of ***Triphenylphosphine***;[2] addition of Ph_3P to 48% aqueous HBr followed by $CHCl_3$ extraction and drying.[1]

Purification: recrystallization from CH_2Cl_2/Et_2O, or by washing with warm EtOAc to remove excess Ph_3P.

Handling, Storage, and Precautions: corrosive and hygroscopic; keep dry.

Source of Anhydrous HBr.

Triphenylphosphine hydrobromide (**1**) is a convenient, crystalline source of anhydrous HBr for a wide variety of applications, including as a gas.[1] This reagent has found an important use in the glycosidation of glycals[5,6] without interference from allylic (Ferrier) rearrangement (eq 1). There is a distinct preference for the α-anomer, even when the incoming nucleophile is not sterically demanding. Other commonly used acid sources (***Hydrogen Chloride***, ***Hydrogen Fluoride***, Amberlyst H-15 resin, ***p-Toluenesulfonic Acid***) and Lewis acids (***Boron Trifluoride Etherate***) catalyze allylic rearrangement.

(1)

60% yield, α:β = >95:5

$MeCO_2H$ 71% yield, α:β = 92:8

MeOH 87% yield, α:β = 70:30

Catalyst for Formation of THP Ethers.

Tetrahydropyranylation, particularly of tertiary alcohols, can be catalyzed by (**1**) (eq 2).[7] Depending on the substrate, these reactions are complete in about 20 h, and the conditions are quite mild when compared with those needed with catalysts such as ***Pyridinium p-Toluenesulfonate***. Other acid catalysts such as TsOH can lead to elimination or polymerization of sensitive tertiary alcohols.

(2)

Preparation of Phosphorus Ylides.

Treatment of alkyl chlorides with (**1**) results in the formation of phosphonium salts. Rather than a direct displacement of chloride by phosphorus, this reaction proceeds by initial conversion of RCl to RBr, followed by formation of the phosphonium salt.[8] A wide variety of primary alcohols can be converted directly to the phosphonium bromides in high yield by treatment with (**1**).[3] Both aliphatic and allylic alcohols react with (**1**) in sealed tubes at 160 °C within 2 h (eq 3). Secondary (and presumably tertiary) alcohols suffer dehydration under these conditions. Allylic alcohols (such as the carotenoid precursor (**2**))[9] do not undergo allylic transposition (eq 4), although there have been cases where reactive alkenes have produced phosphonium salts upon heating with (**1**).[10]

(3)

Under similar conditions (heating in a sealed tube for 4 h at 180 °C), lactones react to form the free acid phosphonium salt in excellent yield (eq 5).[3] Reactive alkenes such as enol ethers,[4] indene, and α,β-unsaturated carbonyl compounds[11] also undergo addition of (**1**) when other nucleophiles are not present. This reaction has been used to prepare a novel three-carbon Wittig reagent bearing a protected aldehyde function.[11]

(conversion of alcohols,[6,7] thiols,[11c] and enols[9] into iodides; reduction of various sulfur derivatives to sulfides or thiols;[11c] reduction of epoxides,[13] iodohydrins,[16] and vicinal diols[17a] to alkenes; production of iodohydrins from epoxides;[14] esterification of carboxylic acids;[18] acetalizations of carbonyl groups[19])

Alternate Names: triphenylphosphine diiodide; iodotriphenylphosphonium iodide; diiodotriphenylphosphorane.

Physical Data: adduct:[2,4] bright yellow solid (from ether). Ph_3P: mp 80.5 °C; bp 377 °C (in inert gas); *d*254 1.194 g cm^{-3}; *d*804 (liq) 1.075 g cm^{-3}; *n*80D 1.6358. I_2: mp 113.6 °C; bp 184.3 °C; *d* 4.93 g cm^{-3}.

Solubility: Ph_3P: sol ether, PhH, $CHCl_3$, AcOH; less sol alcohol; practically insol H_2O. I_2: sol ether (25.2 g/100 mL), PhH (14.1 g/100 mL), alcohol (21.4 g/100 mL), MeOH (23 g/100 mL), $CHCl_3$, CCl_4; less sol H_2O (0.03 g/100 mL).

Form Supplied in: the adduct is not commercially available. Ph_3P: odorless monoclinic platelets or prisms; purity ~99%; typical impurity: Ph_3PO ~1%. I_2: bluish-black scales or plates with metallic luster; characteristic odor; sharp, acrid taste and violet corrosive vapor; purity &egt;99.8%

Analysis of Reagent Purity: adduct.[2] Ph_3P and Ph_3PO: ^{31}P NMR (PhMe/MeCN, MeCN, pyridine; CCl_4) -5 to -8 and +29 to +25.

Preparative Method: for synthetic purposes the reagent is generally prepared in situ just before use, by addition of ***Iodine*** to ***Triphenylphosphine*** (or vice versa) in different solvents.

Handling, Storage, and Precautions: Ph_3P: irritant; harmful; do not get in eyes, on skin, or on clothing; avoid contact and inhalation; use with adequate ventilation; keep containers tightly closed and store in a cool dry place; incompatible with strong oxidizing agents. I_2: harmful; corrosive; severe lachrymator; do no get in eyes, on skin, or on clothing; avoid prolonged or repeated exposure; keep containers tightly closed in a cool dry place; incompatible with Mg, Zn, Al, Sb, and NH_3; reacts violently with acetaldehyde. These reagents should be handled in a fume hood.

Alkyl Iodides from Alcohols and Thiols.

The $Ph_3P.I_2$ adduct contains two replaceable iodo groups which can be substituted by nucleophiles. Its reaction with alcohols involves the rapid and irreversible formation of an alkoxyphosphonium iodide that decomposes by a slow S_N2 reaction, leading to an alkyl iodide (eq 1).

$$Ph_3\overset{+}{P}I\ I^- + ROH \xrightarrow{fast} Ph_3\overset{+}{P}OR\ I^- + HI \xrightarrow{slow} RI + Ph_3PO \quad (1)$$

Primary and secondary alcohols are converted into alkyl iodides[5-8] by use of the $Ph_3P.I_2$ reagent. The iodination of β-cholestanol in boiling PhH gives α-iodocholestane with inversion of configuration, albeit in low yield (25%); use of the more polar solvent DMF, at 75 °C, leads to complete epimerization to the thermodynamically more stable β-iodide.[6] Retention of configuration, observed in the nucleoside field,

occurs via double inversion; initial formation of the cyclic O^2,3´-anhydro derivative (**2**) is followed by ring opening by iodide ion (eq 2).[5a,b]

$Ph_3P.I_2$ provides better yield[5c] than the related reagent ***Methyltriphenoxyphosphonium Iodide*** (MTPI) in the iodination of the primary alcohol (**4**) (eq 3), whereas MTPI is more efficient in the preceding conversion of the secondary alcohol (**1**) into the iodide (**3**) (70%).[5a]

Although MeCN, $(PhO)_3PO$,[5d] and DMF are often recommended as solvents for these reactions, the latter can react with the Ph_3PX_2 reagent to produce halomethylene-*N*,*N*-dimethyliminium halide (**6**).[8] In the case of $Ph_3P.I_2$, this iminium iodide then reacts in turn with the alcohol to form an alkoxymethylene-*N*,*N*-dimethyliminium iodide (**7**), which gives mixtures of both iodide and formate after heating and hydrolytic workup; the same result could be obtained by assuming reaction of DMF with the alkoxyphosphonium iodide (**8**) (eq 4). Consequently, reactions of secondary alcohols with $Ph_3P.I_2$ in DMF can lead to formylation to the ester together with iodination.[8]

Addition of ***Imidazole*** to the $Ph_3P.I_2$ reagent leads to better yields. Alternatively, the 2,4,5-triodo derivative of imidazole and Ph_3P alone can be used. In the carbohydrate field especially,[7] higher yields are obtained in the conversion of primary (70-97%) and secondary (60-87%) alcohols, with inversion of configuration for the latter. At lower temperatures, primary hydroxyl groups may be selectively replaced by iodo groups.[7b,d] Besides the initially preferred refluxing PhMe,[7a,b] mixed solvents such as PhMe-MeCN (2:1) have been used,[7c,d] allowing certain transformations which are difficult to achieve with PhMe alone as solvent.

Alkanesulfonic acids, sulfinic acids, disulfides, thiosulfonic *S*-esters, and sulfonates are readily reduced to the corresponding thiols by treatment with a mixture of Ph_3P and a catalytic amount of I_2 (see below). Upon treatment with a mixture of Ph_3P and an excess of I_2, however, all these aliphatic sulfur compounds are eventually transformed to the corresponding alkyl iodides (67-100%) (eq 5).[11b,c]

(5)

Vinyl Iodides from Enols.

Treatment of cyclic β-diketones with $Ph_3P.I_2$, in MeCN at reflux in the presence of NEt_3, affords β-iodo-α,β-unsaturated ketones in good yields (eq 6).[9] Unsymmetrical 1,3-cyclohexanediones give isomeric mixtures of 3-iodo-α,β-unsaturated ketones accompanied by deconjugated iodo enones. In MeCN-HMPA this reagent stereoselectively and regioselectively transforms α-hydroxymethylenecyclohexanone and -pentanone into (*E*)-2-iodomethylenecyclohexanone (94%) and -pentanone (73%).[9b] Other reagents useful for similar syntheses of alkyl iodides include ***Methyltriphenoxyphosphonium Iodide***,[1,5a,c] Ph_3P/CI_4,[1,5b] and Ph_3P/*N*-iodosuccinimide.[5b]

(6)

$R^1 = H, Me, allyl, (CH_2)_2CH{=}CH_2;\ R^2 = H, Me;\ R^3 = H, Me;$
$n = 0, 1$

Reduction of Sulfur Derivatives to Sulfides or Thiols.

Aryl and alkyl sulfoxides are readily deoxygenated to sulfides with the $Ph_3P/I_2/NaI$ reagent system in refluxing MeCN (eq 7).[10a] Use of the more reactive $(Me_2N)_3P$ instead of Ph_3P[10b] provides a good alternative to the previous reagent; it requires no heating and leads to an easily removed (unlike Ph_3PO) water-soluble HMPA byproduct.

(7)

$R^1, R^2 = Pr, Bu, PhCH_2, Ph, 4\text{-}MeC_6H_4, \text{-}(CH_2)_4\text{-}$

Arylsulfonic acids, their sodium salts, halides, esters and thioesters, and arylsulfinic acids and their salts are also readily reduced to the corresponding aromatic thiols in good yields with Ph_3P (3-5 mol equiv) in the presence of I_2 (0.5-1 mol equiv) (eq 8).[11a,c]

(8)

$Ar = Ph, 4\text{-}MeC_6H_4, 4\text{-}ClC_6H_4, 1\text{-naphthyl}, 2\text{-naphthyl},$
$2,4\text{-diMeC}_6H_3, 4\text{-}C_{12}H_{25}C_6H_4$
$Y^1 = H, Na, R, Ar^1; R = Et, CH_2\text{-}t\text{-}Bu, C_5H_{11}; Ar^1 = Ph$
$Y^2 = H, Na, Cl, SPh$

Reduction of Allylic Alcohols.

The reduction of allylic alcohols to the corresponding hydrocarbons by $Ph_3P.I_2$ is another valuable reduction achieved by this reagent.[12] This transformation takes place through the corresponding iodide, which is further reduced to the hydrocarbon by the HI resulting from the preceding step. Several allylic alcohols have been reduced in this fashion in moderate yields to the corresponding unsaturated hydrocarbons (24-95%).

Reduction of Epoxides and Iodohydrins to Alkenes.

Attempts to prepare vicinal diiodides from reaction of vicinal iodohydrins with the $Ph_3P.I_2$ reagent lead not to the expected products, but instead directly to the corresponding alkenes.[13] The reaction proceeds in high yields and is a stereospecific *trans* elimination (>98%). As iodohydrins may be obtained by *anti* opening of epoxides with HI, this reaction serves as the basis for a convenient method for the deoxygenation of epoxides to alkenes with retention of configuration. The transformation is typically achieved employing 1.1 equiv each of $Ph_3P.I_2$ and $Ph_3P.HI$ (eq 9). Despite the fact that only 1 equiv of Ph_3P is consumed and that HI and I_2 act only as catalysts, the first attempts to reduce the stoichiometry in reagents were unsuccessful; this problem was later solved[16] by using other reaction conditions (see below).

Iodohydrins from Epoxides.

Contrasting results[14,15] have been reported in the steroid field in the transformation of identically trisubstituted epoxides with $Ph_3P.I_2$. Although the experimental conditions were apparently the same in both cases ($Ph_3P.I_2$, 1.1 equiv, CH_2Cl_2, rt), the reaction products are halohydrins in the first case,[14a,b] and alkenes in the second one.[15] As mentioned elsewhere,[13,16] iodohydrins are readily transformed into alkenes by several routes (e.g. with HI or I_2 and H_2O as catalyst, in the presence of Ph_3P); the presence of traces of water in the solvent or further transformation during workup or the purification steps (in the second case[15]) would account for such discrepancies. The former preparation[14a,b] of iodohydrins under anhydrous conditions was later confirmed[14c] by the use of a polymer-supported phosphine-I_2 adduct. The method requires only a filtration and evaporation for product isolation, avoiding the often tedious Ph_3PO removal. Oxirane-ring opening remains regio- and stereoselective, the yields being somewhat higher than with Ph_3P, most probably due to the simplified workup procedure (eq 10).

Further work[16] with $Ph_3P.I_2$ in moist MeCN clearly demonstrates the importance of both reagent stoichiometry and the presence of water in determining the reaction pathway. The active species is in fact HI, generated in situ from $Ph_3P.I_2$ in moist MeCN. Use of 0.5 equiv of $Ph_3P.I_2$ in moist MeCN provides iodohydrins (75-85%) from epoxides; alkenes are obtained from both iodohydrins (70-90%) and epoxides (70-95%) using respectively 0.6:0.1-0.6:1 and 1.1:0.6:1 molar ratios of Ph_3P, I_2, and substrate, at 80 °C (eq 11).

Alkenes from Vicinal Diols.

The combination of Ph_3P, I_2, and imidazole[17a] in refluxing toluene (or better, in the mixed solvent PhMe-MeCN[17c]) at 50 °C effects the conversion of vicinal diols into alkenes. Hexopyranosidic diols are transformed to alkenes in fair to good yields (eq 12). A further significant improvement over the original system can be achieved by using the combination of Ph_3P alone with 2,4,5-triiodoimidazole and imidazole (ImH).[17b]

(12)

Esterification of Carboxylic Acids.

The adduct of polystyryl(diphenyl)phosphine with iodine,[14c] previously used to convert epoxides into iodohydrins, is a convenient condensing agent for the esterification of carboxylic acids[18] under very mild conditions. The reaction is assumed to proceed via the acyl iodide. The iodine adduct proves to be the most convenient among the three halogen adducts since the chloride complex provides somewhat sluggish ester formation and the use of the bromine analog is inadvisable with unsaturated material due to the occurrence of some bromination of the double bond. The reaction has been applied to a number of acids using MeOH and also cumbersome, difficult to esterify alcohols such as 5α-cholestan-3-ol (eq 13). The high yield and easy isolation of the ester (by a simple filtration and evaporation process) are among the attractive features of this preparation.

(13)

RCO_2H = acetic, benzoic, octanoic, palmitic, stearic, linoleic, 4-$MeC_6H_4CO(CH_2)_2CO_2H$, 4-$MeOC_6H_4CO(CH_2)_2CO_2H$

Acetalization of Carbonyl Compounds.

Carbonyl compounds are smoothly and rapidly acetalized by treatment with alcohols or thiols in anhydrous MeCN in the presence of the polystyryl(diphenyl)phosphine-iodine adduct as a dehydrating agent.[19] Open-chain and cyclic acetals, including 1,3-dioxolanes, 1,3-oxathiolanes, and 1,3-dithiolanes, of miscellaneous aldehydes and ketones have been successfully prepared in this way with high yields (eq 14). The isolation of the product is easily performed by simple filtration of the polymer-linked Ph_3PO which is formed during the reaction.

(14)

Other Applications.

In combination with imidazole as described previously, $Ph_3P.I_2$ allows the one-pot synthesis of alkyl nitrates from alcohols.[20] Treatment of alcohols with the Ph_3P-I_2-ImH reagent system, followed by in situ reaction of the generated iodides with the $AgNO_3$ in ether/MeCN mixture, leads to the formation of alkyl nitrates. The $Ph_3P.I_2$ reagent has also been used to promote the Beckmann rearrangement;[21] the reaction of cycloalkanone oxime with iodine in the presence of Ph_3P provides lactams in one step. In the presence of Et_3N, the $Ph_3P.I_2$ adduct, acting as a dehydrating agent, effects the 3-aza-Claisen rearrangement of α-heteroatom substituted *N*-allyl amides into the corresponding nitriles under very mild conditions.[22] Other phosphine-halogen adducts are studied for this purpose in the same work.

1. Castro, B. R. *OR* **1983**, *29*, 1.
2. There are only three recent references (including 3b,c) in the chemical literature. The adduct must be prepared under an inert atmosphere, in strictly anaerobic and anhydrous conditions using standard Schlenk techniques.3 Physical studies3 show that the balance between four-coordinate covalent and ionic forms, and the five-coordinate covalent form, in solution is solvent dependent; solid material prepared in ether exhibits a four-coordinate covalent form of charge-transfer complex type, while solid samples from $PhNO_2$ display a four-coordinate ionic form. Raman (nujol) 160 (I-I) (solid form from ether: Ph_3P-I-I); ^{31}P NMR (1,2-$ClCH_2CH_2Cl$, MeCN, or $CHCl_3$): +45 to +49 (ionic form); ^{31}P NMR (solid form NMR, PhMe/MeCN or pyridine) -18 to -21 (covalent form). Other physical studies on the related Ph_3P-dihalide adducts also conclude that the extent of ionic behavior is a function of the solvent polarity.

[75-47-8] · CHI_3 · Triphenylphosphine-Iodoform-Imidazole · (MW 393.72) (imidazole)

[288-32-4] · $C_3H_4N_2$ · Triphenylphosphine-Iodoform-Imidazole · (MW 68.09)

(deoxygenation of vicinal diols and epoxides to form alkenes;[1] particularly useful in the synthesis of unsaturated sugars)

Physical Data: see ***Triphenylphosphine***, ***Iodoform***, and ***Imidazole***.

Preparative Method: Bessodes et al.[1] reported that treatment of *cis*- or *trans*-1,2-diols with 4 equiv of triphenylphosphine, 2 equiv of iodoform and 2 equiv of imidazole in refluxing toluene (typically for 1 h) effects elimination of the vicinal diols to form the corresponding alkene.

General Discussion.

Methods for the conversion of vicinal diols to alkenes have found utility in organic synthesis, particularly in the synthesis of unsaturated or dideoxy sugars, and a number of alternative methods have been developed.[2] The use of a mixture of triphenylphosphine, iodoform, and imidazole to accomplish the reductive elimination of vicinal diols was introduced by Bessodes et al.[1] For example, the *cis*- and *trans*-1,2-diols in eq 1 are converted to the corresponding unsaturated sugars in moderate to good yields, the better yields being obtained from the *trans*-isomers. The methodology was introduced as an alternative to the methods of Garegg and Samuelsson which employ a mixture of triphenylphosphine-***Iodine***-imidazole[3] or a mixture of ***Triphenylphosphine-2,4,5-Triiodoimidazole***.[4]

(a) $R^1, R^4 = H$; $R^2, R^3 = OH$; 80%
(b) $R^2, R^3 = H$; $R^1, R^4 = OH$; 65%
(c) $R^2, R^4 = H$; $R^1, R^3 = OH$, 45%

Nagarajan and Rao[5] used the triphenylphosphine-iodoform-imidazole reagent for the reductive elimination of a xylose-derived benzoate in 85% yield (eq 2). The procedure was used by Wee[6] for the reductive elimination of a methyl glucoside derivative bearing both benzoyl and *t*-butyldiphenylsilyl protecting groups. The dehydro-sugar is formed in 94% yield (eq 2). In this latter case the corresponding dimesylate derivative is reported[7] to desilylate under an alternative set of reductive elimination conditions, the Tipson-Cohen method (NaI, Zn, DMF).[8] Reported attempts to apply the method to furanoside substrates were unsatisfactory.[9,10]

(2)

(a) $R^1 = H$, $R^2 = CH_2Ph$, 85%
(b) $R^1 = CH_2OTBDPS$, $R^2 = Me$, 94%

The methodology may have some application in nucleoside synthesis. Chu and co-workers[11] found that treatment of a dimethylpseudouridine derivative affords the dideoxycytidine analog in modest yield (40%) (eq 3). In this case the authors found that ***Tri-n-butylstannane*** reduction of the corresponding dimethyl xanthate is superior, proceeding in an overall 76% yield for the two steps. Halmos and co-workers[12] used the procedure in the preparation of certain keto nucleosides with greater success. Deoxygenation affords the theophylline derivative in 70% yield (eq 4). The authors found this method to be superior to deoxygenation via the thionocarbonate or the 1-dimethylamino(methylene) acetal.

(3)

$R^1 = TBDMSO$

(4)

$R^1 = CH_2O(CH_2)_6OCOPh$

Lichtenthaler and co-workers[13] found that the triphenylphosphine-iodoform-imidazole reagent system is also effective in the deoxygenation of an epoxide. The epoxide derived from fructose is converted to the 3,4-unsaturated dihydropyran in 84% yield (eq 5), although unlike the reported conversions of diol substrates, reaction of the epoxide required two days in refluxing toluene.

Triphenylphosphine Selenide

$Ph_3P{=}Se$

[3878-44-2] · $C_{18}H_{15}PSe$ · Triphenylphosphine Selenide · (MW 341.26)

(conversion of epoxides into alkenes[1])

Physical Data: mp 187-188 °C.[2]

Solubility: very sol dichloromethane; moderately sol on heating in acetonitrile, benzene, 1-butanol, ethanol, methanol; insol ether, water.[2]

Form Supplied in: white solid; commercially available.

Preparative Methods: prepared from ***Triphenylphosphine*** and either ***Potassium Selenocyanate***[2] or elemental ***Selenium***.[3,4]

Purification: recrystallization from ethanol.[2]

Handling, Storage, and Precautions: toxic;[2] use in a fume hood.

Conversion of Epoxides into Alkenes.[1]

Addition of ***Trifluoroacetic Acid*** to a dichloromethane solution of an epoxide and an excess of triphenylphosphine selenide results in deoxygenation of the epoxide to the corresponding alkene. The reaction is stereospecific (eqs 1-3). Other phosphine selenides can also be used.[5]

(1)

(2)

(3)

Conversion of Phosphorus Ylides into Alkenes.[6]

Several nonstabilized ylides, $Ph_3P{=}CHR$, give near thermodynamic mixtures of (*Z*)- and (*E*)-alkenes when treated with a catalytic amount of triphenylphosphine selenide in hot (90 °C) toluene (eq 4).

(4)

$(Z):(E) = 17:83$

Reduction of Selenoxides.[7,8]

Simple selenoxides (e.g. dibenzyl selenoxide), that do not undergo elimination, are reduced slowly (24 h to 13 days) at rt to the corresponding selenides by the action of triphenylphosphine selenide in chloroform (eq 5).

$$(PhCH_2)_2Se{=}O \xrightarrow[\text{rt, >24 h}]{Ph_3P{=}Se,\ CHCl_3} (PhCH_2)_2Se \qquad (5)$$

Formation of Ureas and Carbamates.

Aromatic nitro compounds can be converted into ureas[9] or carbamates[10,11] in processes mediated by elemental selenium (eq 6); elemental selenium is derived in situ from triphenylphosphine selenide, which serves as a carrier for selenium.

$$ArNO_2 + CO + ROH \xrightarrow[\text{25 bar, 160 °C, 30 min}]{Ph_3P{=}Se,\ H_2O_2} ArNHCO_2R \qquad (6)$$

Related Reagents.

Triphenylphosphine Sulfide.

Triphenylphosphine Sulfide

$Ph_3P{=}S$

[3878-45-3] · $C_{18}H_{15}PS$ · Triphenylphosphine Sulfide · (MW 294.37)

(conversion of epoxides into thiiranes[1])

Physical Data: mp 161 °C.[2]

Solubility: insol hexane, water, ether; sol acetone, benzene, carbon disulfide, chloroform, ethanol.[2-5]

Form Supplied in: white solid; commercially available.

Preparative Methods: prepared by a number of methods; most easily prepared from ***Triphenylphosphine*** and ***Sulfur***,[4] or from benzene, sulfur, and ***Phosphorus(III) Chloride*** in the presence of ***Aluminum Chloride***.[5]

Purification: recrystallization from ethanol[2,4] or aqueous acetone.[3,5]

Conversion of Epoxides into Thiiranes.[1]

Addition of ***Trifluoroacetic Acid*** (1 equiv) to a benzene solution of an epoxide and triphenylphosphine sulfide (1 equiv or an excess) serves to convert the epoxide into the corresponding episulfide (eq 1). The reaction is stereospecific, and can also be done using tributylphosphine sulfide (eq 2).[1]

(1)

(2)

Conversion of Phenols into Dihydric Phenols.[6]

Phenols can be converted into mixtures of dihydric phenols using ***Hydrogen Peroxide***, in the presence of a ketone, and a catalytic amount of triphenylphosphine sulfide (eq 3).

Triphenylphosphine-2,4,5-Triiodoimidazole

(Ph_3P)

[603-35-0] · $C_{18}H_{15}P$ · Triphenylphosphine-2,4,5-Triiodoimidazole · (MW 262.30) (2,4,5-triiodoimidazole)

[1746-25-4] · $C_3HI_3N_2$ · Triphenylphosphine-2,4,5-Triiodoimidazole · (MW 445.76)

(deoxygenation of vicinal diols[1] and epoxides to form alkenes; conversion of alcohols to iodides)

Physical Data: see ***Triphenylphosphine***; 2,4,5-triiodoimidazole, mp 190-192 °C.

Preparative Methods: the reagent reported by Garegg and Samuelsson[1,2] is prepared in situ by the combination of a 1:2 ratio of ***Triphenylphosphine*** and 2,4,5-triiodoimidazole in toluene or, preferably, toluene/acetonitrile.[3] 2,4,5-Triiodoimidazole is prepared via the treatment of ***Imidazole*** with ***Iodine*** and ***Sodium Hydroxide*** in a two-phase reaction in water/petroleum ether and recrystallized from methanol.[3]

General Discussion.

Triphenylphosphine-2,4,5-triiodoimidazole-imidazole was introduced as a alternative to the combination of triphenylphosphine-iodine-imidazole[4-8] for the deoxygenation of vicinal diols. Subsequently, the mixture ***Triphenylphosphine-Iodoform-Imidazole***[9] and, more recently, ***Chlorodiphenylphosphine***-iodine-imidazole[10] were introduced as other alternative phosphine-derived reagents for diol reductive elimination. Methods for the conversion of vicinal diols to alkenes have found significant utility in organic synthesis and a number of nonphosphine-based methods have also been developed.[11] Treatment of methyl 2,6-dibenzyl-α-D-glucopyranoside with triphenylphosphine-2,4,5-triiodoimidazole in a 2:1 excess over the substrate affords the unsaturated sugar in a reported 95% yield (eq 1).[1] This conversion was recently used in the preparation of hexose nucleoside analogs.[12]

(1)

Samuelsson[1] and others[13] report that the reagent works best in the case of *trans*-diequatorial or *trans*-diaxial diols; however, Ozaki and co-workers[14] used the reagent effectively on a mixture of *cis*- and *trans*-diols. Treatment of a 2:3 *cis*:*trans* mixture of diols affords the alkene (73% yield) (eq 2), which can subsequently be used in the synthesis of optically active inositol derivatives.

(2)

Kibayashi[15] found the reagent useful in a synthesis of indolizidine 195B (gephyrotoxin 195B). Deoxygenation of the *trans*-diol affords the unsaturated nitrogen heterocycle in 79% yield (eq 3). Small amounts of the corresponding epoxide are isolated, suggesting that the deoxygenation proceeds via initial formation of the epoxide. Kibayashi modified the Samuelsson procedure with the addition of ***Zinc*** powder, a modification that had earlier been employed for the phosphine-iodine based deoxygenation of epoxides.[4] Kibayashi suggests that the deoxygenation is stereospecific, although to date only the reactions of cyclic diols have been reported.

(3)

$R^1 = CH_2{=}CH(CH_2)_3\text{-}$, $R^2 = Bu$

It is reported that the deoxygenation of a furanoside leads to formation of a furan,[16] but Yoda employed Kibayashi's modified procedure to prepare optically active butenolides in 59-78% yield (eq 4).[17]

(4)

$R^1 = Bu, C_8H_{17}, C_{13}H_{27}$

The triphenylphosphine-2,4,5-triiodoimidazole-imidazole mixture has also found use as an alternative to the more frequently used triphenylphosphine-iodine-imidazole[2] mixture for the conversion of alcohols to iodides. For example, the iodide in eq 5 is prepared in 69% yield and used in the total synthesis of the antibiotic A23187.[18] Furthermore, the conversion proceeds with clean inversion of configuration and the conditions are sufficiently mild to tolerate the presence of a benzyloxymethyl protecting group (eq 6).[19,20]

(5)

(6)

The reagent has found use in the conversion of hydroxy groups to iodides in carbohydrate substrates. For example, treatment of the protected furanose in eq 7 affords the corresponding iodide with clean inversion of configuration (78% yield).[2,21] In some cases, secondary hydroxyl groups need not be protected. For example, treatment of benzyl 2-acetamido-2-deoxy-α-D-glucopyranoside with 4 equiv of triphenylphosphine and 2 equiv of 2,4,5-triiodoimidazole in toluene-acetonitrile (2:1) affords the corresponding 6-iodo derivative in 70% yield (eq 8).[3] Toluene-acetonitrile solvent is reported to be superior to toluene alone, and other solvent systems may be applicable.[22] Other selective substitutions in carbohydrates substrates are often possible.[3,23]

(7)

(8)

The corresponding triphenylphosphine-2,4,5-tribromoimidazole reagent behaves similarly.[3,20,24]

Triphenyl Phosphite[1]

$(PhO)_3P$

[101-02-0] · $C_{18}H_{15}O_3P$ · Triphenyl Phosphite · (MW 310.30)

(mildly nucleophilic phosphite for converting alcohols to alkyl halides;[3] coupling agent in peptide and related syntheses,[1b,12] as its ozone adduct, a low-temperature source of singlet oxygen[1b])

Physical Data: mp 22-25 °C; bp 360 °C, 180-189 °C/1 mmHg; *n*25D 1.5890; δ ^{31}P 125-129.

Solubility: insol H_2O (hydrolyzes to $(PhO)_2P(O)H$); miscible most organic solvents; alcoholic solvents may transesterify.

Form Supplied in: colorless liquid, 97% pure, widely available, showing only one peak in ^{31}P NMR. The balance is largely phenol.

Purification: an ethereal solution is washed with aqueous alkali, dried, and distilled.

Handling, Storage, and Precautions: fairly safe to handle, but it is a skin sensitizer and will usually contain phenol.

General Discussion.

The ester converts alcohols to alkyl halides in the presence of a hydrogen halide, a halogen, or another alkyl halide (eqs 1 and 2), the two last being mild and convenient procedures.[2,3] Good yields are obtained, even with neopentyl halides, and the reaction proceeds with inversion at carbon.[4] The intermediate phosphonium salts may be prepared independently but are very susceptible to hydrolysis and are conveniently generated and used as required. Methyltriphenoxyphosphonium iodide has also found use in the deoxygenation of epoxides[5] (with retention of stereochemistry) and the dehydration of secondary alcohols.[6] Phenyl esters of carboxylic acids can be made from the salts and a carboxylate ion[7] or from the free acid and the neutral ester[8] (eqs 3 and 4). Phosphorus[9] and sulfur[10] acids may be esterified similarly.

$$(PhO)_3P + X_2 + ROH \longrightarrow RX + (PhO)_2P(O)X + PhOH \quad (1)$$

$$R^1OH + (PhO)_3P + RCH_2X \longrightarrow R^1X + RCH_2P(O)(OPh)_2 \quad (2)$$

$$X = Cl, Br, I;\ R = \text{primary or secondary alkyl};\ R^1 = Ph, H$$

$$(PhO)_3\overset{+}{P}Me + RCO_2^- \longrightarrow (PhO)_2P(O)Me + RCO_2Ph \quad (3)$$

$$(PhO)_3P + RCO_2H \longrightarrow (PhO)_2P(=O)H + RCO_2Ph \quad (4)$$

The adduct of $(PhO)_3P$ and ***Ozone***,[1b] apparently a cyclic phosphorane (δ ^{31}P -63), is stable below -35 °C and on warming liberates oxygen. It functions in many ways as a convenient low-temperature source of singlet oxygen (eq 5),[11] though there are some significant differences and it functions similarly at temperatures as low as -70 °C where the adduct is quite stable.

In the presence of bases, particularly ***Imidazole***, $(PhO)_3P$ acts either alone[12] or with ***2,2´-Dipyridyl Disulfide***[13] as a coupling agent for peptide synthesis (eq 6) with very little if any racemization. With ***2,2´-Dipyridyl Diselenide***, it has found use in the preparation of nucleoside phosphoranilidates[14] and oligonucleotides.[15] The ester has been occasionally used as a mild deoxygenation agent (eq 5), and in the cyclization of 2-acylaminobenzoic acids to the corresponding 4*H*-3,1-benzoxazin-4-ones.[16] It is a convenient reagent for purifying ***Thionyl Chloride***.[17]

Related Reagents.

Bromine-Triphenyl Phosphite.

Triphenyl Phosphite Ozonide[1]

$(PhO)_3PO_3$

[29833-83-8] · $C_{18}H_{15}O_6P$ · Triphenyl Phosphite Ozonide · (MW 358.30)

(source of singlet oxygen;[2] avoids complicating effects of radiation on reactants and products sometimes associated with photochemical generation of singlet oxygen; can also transfer dioxygen in a bimolecular process[3] not involving singlet oxygen)

Physical Data: reagent is labile and is prepared and used in situ.

Solubility: sol dichloromethane, carbon tetrachloride, benzene, acetonitrile, trichlorofluoromethane, toluene, chlorobenzene, methanol, isopropyl alcohol, acetone, diethyl ether, and pyridine.

Form Supplied in: reagent is prepared as needed.

Analysis of Reagent Purity: ^{31}P NMR.

Preparative Methods: a solution of triphenyl phosphite in CH_2Cl_2 is added to O_3-saturated (blue color) CH_2Cl_2 at -78 °C. Ozone is added periodically in order to maintain the blue color. The alternative procedure of adding ozone to a solution of the triphenyl phosphite in CH_2Cl_2 leads to lower yields of the ozonide since the phosphite reacts with the ozonide. When the ozonide is to be used as a source of singlet oxygen the solution is allowed to warm to about -25 °C in the presence of the substrate. Direct transfer of dioxygen in a bimolecular process occurs at -70 °C.[2,4,5]

Handling, Storage, and Precautions: decomposes with O_2 evolution at temperatures above about -25 °C. While solid triphenyl phosphite ozonide has occasionally been isolated[1b,6-8] this procedure is not recommended since the solid has been observed[1b,7,8] to detonate, with flashes of red light, upon warming.

Use as Singlet Oxygen Source.

In 1959, Knowles and Thompson[4] showed that ***Ozone*** forms a 1:1 adduct with ***Triphenyl Phosphite*** at low temperatures and that this adduct decomposes, with gas evolution, as the reaction solution is allowed to warm up. Corey[9] suggested that the oxygen evolved might be singlet oxygen. Experiments to investigate this possibility were initiated by Murray and co-workers in 1967. In collaboration with Wasserman and Yager[6] they were able to show that the gas evolved from solid triphenyl phosphite ozonide gave the characteristic ESR signal of singlet oxygen. Chemical evidence for the involvement of singlet oxygen was obtained by demonstrating that typical singlet oxygen products were obtained[2] from a variety of substrates when exposed to decomposing triphenyl phosphite ozonide (**1**). Thus 1,3-cyclohexadiene was converted to the endoperoxide in 67% yield (eq 1). The ene reaction was observed when 2,3-dimethyl-2-butene was converted to 2,3-dimethyl-3-hydroperoxy-1-butene in 53% yield by (**1**) (eq 2). Another example of a 1,4-cycloaddition reaction was observed in the transformation of tetraphenylcyclopentadienone to *cis*-dibenzoylstilbene in 38.2% yield. Likewise, α-terpinene was converted to ascaridole in 60% yield. Finally, in this earlier work, 9,10-diphenylanthracene was converted in 77% yield to its endoperoxide.

(1)

(2)

Similar work by Bartlett and Mendenhall[10] showed that (**1**) converts[9,10] dimethylanthracene (49%) and rubrene (87%) to their respective endoperoxides. When the singlet oxygen acceptor 1,3-diphenylisobenzofuran was oxidized[10] by (**1**), a 16% yield of the singlet oxygen product *o*-dibenzoylbenzene was obtained accompanied by an oxygen-1,3-diphenylisobenzofuran copolymer (eq 3).

The third major reaction type ascribed to singlet oxygen has also been achieved using (**1**) as the singlet oxygen source. In this case, 2,2´-adamantylideneadamantane was converted to the dioxetane (eq 4).[11]

Dioxetane intermediates also seem to be involved in the conversion of 1-(2´-methoxyvinyl)pyrene and 1,1-diphenyl-2-methoxyethylene to their cleavage products.[12] Dioxetane-type intermediates have also been invoked[13] in the reaction between (**1**) and several ketenes. The reaction of the tetrathioethylene (**2**) with (**1**) is also believed[14] to proceed through the dioxetane. The products are the disulfide (**3**) and the dithiooxalate (**4**) (eq 5).

Additional evidence that (**1**) is a source of singlet oxygen was obtained by using substrates in which known singlet oxygen reactions proceed to give a characteristic product distribution. The reaction of (**1**) with 2-methyl-2-butene gives[15] two hydroperoxides with the distribution shown (eq 6). The observed ratio is not significantly different from that obtained when other sources of singlet oxygen are used. Singlet oxygen product ratios were also obtained[15,16] by two groups when the substrate is 1,2-dimethylcyclohexene. Kopecky et al.[17] showed that reaction of isopropylidenecyclohexane with (**1**) gives two hydroperoxide products in a ratio which is closer to that given in a reaction believed to involve singlet oxygen and quite different from that obtained in a base-catalyzed displacement reaction of the appropriate β-halohydroperoxide.

Triphenyl phosphite ozonide has been used[18] in an unusual synthesis of the *trans*-triepoxide of benzene from oxepin (eq 7). A somewhat different type of singlet oxygen reaction is observed[19] when 2,6-di-*t*-butylphenol is treated with (**1**). In this case the product *p*-benzoquinone and diphenoquinone (eq 8) are believed to be formed from radicals arising from an initial H-atom abstraction reaction of singlet oxygen with the phenol.

(7)

(8)

Treatment of Wittig reagents with (**1**) gives the expected aldehyde.[20] In an unusual application of this procedure, a trimethylsilyl-substituted Wittig reagent is oxidized to a trimethylsilyl ketone. A bis(trimethylsilyl) Wittig reagent gives the corresponding ketone when oxidized by (**1**) (eq 9). This ketone can be used to introduce carbonyl groups. Disulfides are converted[21] to mixtures of thiosulfinates and thiosulfonates by reaction with (**1**) (eq 10). The reaction initially favors formation of the thiosulfinate, but on standing the reaction mixture changes to give more of the thiosulfonate. This reaction was later extended to the biologically important disulfide lipoic acid,[22] where oxidation of methyl α-lipoate with (**1**) gave all four possible thiosulfinate isomers.

(9)

(10)

The oxidation of diazo compounds by singlet oxygen has provided an alternative route to carbonyl oxides and ozonides. This reaction can be carried out using (**1**) as a singlet oxygen source (eq 11).[23] A carbonyl oxide, produced in this manner, has been used[24] to epoxidize alkenes in low yield. However, the conditions of these reactions are such that some contribution of a direct reaction (see below) of (**1**) with the diazo compound cannot be ruled out.

(11)

Oxidation of acetone azine by (**1**) gives acetone.[25] The reaction is believed to proceed via an electron transfer process. Triphenyl phosphite ozonide has also been used[26] to convert several cyclopropenethiones to their oxygen analogs. The insertion of dioxygen into a silicon-silicon σ-bond has been accomplished using several sources of singlet oxygen, including (**1**) (eq 12).[27a] This reaction was subsequently extended to oxadisilirane substrates, which give disilaozonides when treated with singlet oxygen.[27b]

(12)

The thermal generation of singlet oxygen from (**1**) can be accelerated by the presence of methanol and pyridine.[28] A study of the mechanism of this effect indicates that it results from a successive displacement of phenoxy by methoxy groups in (**1**). The new phosphite ozonides then decompose at increased rates.

The Murray[1a] and Mendenhall[1b] articles contain some description of the chemistry of other phosphite ozonides. In general, this chemistry parallels that of (**1**) described here.

Use in Direct Bimolecular Transfer of Dioxygen.

In a number of cases the reaction of (**1**) with typical singlet oxygen substrates has been shown to proceed in a direct bimolecular manner without the release of singlet oxygen. In these cases, (**1**) is used below its decomposition temperature (usually -60 to -70 °C). Perhaps the most compelling evidence for this separate oxidation process comes from the reaction of (**1**) with *cis*- and *trans*-diethoxyethylene. This reaction gives[3] the same distribution of dioxetanes from each of the stereoisomeric substrates (eq 13). The singlet oxygen reaction is known to give the dioxetanes in a stereospecific reaction with retention. Tetramethylethylene was shown to give the characteristic singlet oxygen ene reaction product when stored with (**1**) at temperatures well below the temperature at which singlet oxygen is released.[3a,16] Relative rates of the reaction of (**1**) with typical singlet oxygen acceptors have been found to differ from those measured for singlet oxygen itself.[1b] When reacted with (**1**) at low temperature, dihydropyran gives[16] two products in a ratio which differs greatly from that given in photosensitized oxidations (eq 14). Also, tricyclopropylethylene under similar low-temperature conditions gave products[29] derived from an intermediate dioxetane, as opposed to the ene reaction products obtained when singlet oxygen is the oxidant.

(13)

(14)

Germacrene reacts directly with (**1**) to give[30] (after reduction) an alcohol (eq 15) which is not formed in the singlet oxygen reaction. The latter reaction proceeds through two other modes of the ene reaction. Silyl enol ethers of α,β-unsaturated ketones are oxidized at low temperature by (**1**)[31] to give alcohols with stereoselectivity different from that observed with ***m-Chloroperbenzoic Acid***. An example is shown in eq 16. Several thioacetals have been oxidized by (**1**)[32] to mixtures of sulfoxides and disulfoxides under conditions where the bimolecular reaction is likely. A pyrimidine derivative has been oxidized by (**1**) to the corresponding endoperoxide.[33] The yields obtained were lower that those given by photosensitized oxidation.

(15)

(16)

Further evidence for the bimolecular reaction is available.[16] An attempt has been made to present separately the two basic reaction modes of (**1**). However, some of the reactions presented in the section on the use of (**1**) as a singlet oxygen source were carried out under conditions such that the direct reaction may also have played a role.

Related Reagents.

Oxygen; ***Ozone-Silica Gel***; ***Singlet Oxygen***.

Triphenylphosphonium Anhydride Trifluoromethanesulfonate

[72450-51-2] · $C_{38}H_{30}F_6O_7P_2S_2$ · Triphenylphosphonium Anhydride Trifluoromethanesulfonate · (MW 838.76)

(oxophilic reagent for net removal of water in various reactions[1,2])

Physical Data: highly hygroscopic, white crystalline solid.[3]

Solubility: slightly sol chlorocarbon solvents; insol Et_2O; reacts with THF.

Preparative Methods: triphenylphosphine oxide in CH_2Cl_2 is treated with ***Trifluoromethanesulfonic Anhydride*** in CH_2Cl_2 at 0 °C. A precipitate of the reagent forms in <15 min.

Handling, Storage, and Precautions: prepared directly before use.

Introduction.

The reagent is a potent oxophile, forming triphenylphosphonium ethers (Ph_3+P-O-R) with OH groups and ***Triethylamine*** (or preformed oxide anions). These activated ethers may be either displaced or eliminated by nucleophiles or bases, respectively, with triphenylphosphine oxide as the leaving group. The hydroxyl substrate is added to a slurry of the reagent and rapid formation of the ether is indicated by solution of the reagent. Subsequent reactions are usually fast, although higher temperatures are available using ethylene dichloride as solvent. Passage of the reaction mixture through a short silica column usually readily entraps the phosphine oxide. The reagent is generally unreactive to carbonyl groups or ethers (except epoxides, below) and is quite selective for attack at oxygen over nitrogen nucleophiles.

Carboxylic Acids.[2]

Usually, dehydration of acids to anhydrides is quickly achieved by adding a solution of the acid and TEA to the reagent slurry (2:2:1 = acid:TEA:reagent). When the α-CH of the acid is modestly acidic, however, dehydration proceeds to the ketene, as in a simple preparation of diphenylketene from diphenylacetic acid. In either case the net result is an overall dehydration of the substrate(s).

Ester formation with primary alcohols is similarly facile, requiring 15 min at room temperature with the mixed acid and alcohol, and is equally effective in acylating phenols. Since the phenol may be activated first with the reagent, its ready *O*-acylation implies a rapid equilibration of the activated species, as in eq 1. With *t*-butyl alcohol, however, the yield is only 42%, implying a large extent of elimination.

The same equilibration appears in amide formation on adding mixed acid and primary or secondary amine to the reagent. While Ph_3+P-NHR may form, it exchanges to activate the acid and then yields the amide.[2] The preference for Ph_3+P-O-R over Ph_3+P-NR_2 in the exchange may arise from the presence of two electron pairs on oxygen to back donate into the phosphorus d-orbitals, instead of only one on nitrogen. In a similar vein, amides and amines yield amidines on treatment with the reagent (eq 2; POP = reagent), although the reaction requires some 8 h at room temperature. The reagent has been used in the same fashion to convert sulfonic acid salts to their esters and amides in the synthesis of thymidine dimer analogs with sulfonic linkages.[4]

The two operations may occur successively with diamines, as in the double dehydration of benzoic acids with phenylene diamines to form benzimidazoles (eq 3; Z = NH). The conversion is complete in less than an hour at rt and appears much superior to traditional methods with higher temperatures and competing diamide formation. Similarly, benzoxazoles are conveniently formed from *o*-aminophenols and benzothiazoles from *o*-aminothiophenols (eq 3; Z = O and S, respectively)[2]. A six-membered perimidine was formed from 1,8-diaminonaphthalene and benzoic acid.

Internal cyclization of phenylalkanoic acids occurs with the reagent without bases present; the expelled triflic acid acts as a strong acid for activation, as in eq 4, to afford indanones, tetralones, and benzosuberones.[2] A case of acid-catalyzed Claisen condensation was also encountered with phenylacetic acid (eq 5).

Other Substitutions.

With the exception of ketene formation, all the reactions above are substitutions at carboxylic carbons. With simple alcohols, activation has the advantage of affording the phosphonium ether without any nucleophile present except the inactive triflate; hence other nucleophiles of choice may be added for displacement. With primary and acyclic secondary alcohols, reduction with ***Sodium Borohydride*** (as a slurry in CH_2Cl_2) occurs at rt in a few hours to give the corresponding alkane.[5] Although Mitsunobu conditions presumably generate the same phosphonium ethers, borohydride reduction did not occur. On activation of cyclohexanols with the reagent, however, borohydride only generates $Ph_3P.BH_3$ and the alcohol is unchanged, apparently owing to steric hindrance. Although azide ion displaces the activated alcohols, halide ions are too unreactive.[6]

The internal displacement of the phosphonium ether is seen in the reaction of diols or amino alcohols with the reagent to form cyclic ethers or amines, respectively (eq 6), with three-, five-, or six-membered rings (the 1,3-diols for four-membered rings fragment to alkene and aldehyde).[7] The amino alcohols again imply the facile *N*/*O* exchange of the phosphonium group.

Eliminations.

Without nucleophiles present, elimination occurs instead, as with diphenylacetic acid to ketene above. Unsubstituted amides and aldoximes give nitriles at rt in minutes.[8] Tertiary alcohols eliminate with ease and phosphonium ethers of secondary alcohols eliminate with K_2CO_3 or

TEA on warming in CH_2Cl_2. Regiochemistry is not yet clear but there is an implication of favored *cis* elimination, for menthol gives both Δ^2- and Δ^3-menthenes[8] (*cis* required for the former) while only *cis* elimination occurred in two tropinol isomers[9] and a decalin case.[10]

Two other eliminations, however, have new synthetic value. Ketones activated by β-carbonyl or aryl groups are easily enolized and the reagent then serves to dehydrate the ketone to an alkyne in good yield (eq 7).[11] Dehydration of simple ketones to alkynes has not yet been perfected.

Although epoxides are easily formed from 1,2-diols with one mole of reagent, the epoxide can react further with another mole, dehydrating to the dienes.[12] This appears to provide a very convenient path for converting alkenes to dienes by successive epoxidation and dehydration, as in the case of limonene (eq 8).

Variations.

The groups on phosphorus need not be phenyl; the related tributyl derivatives have been similarly used[13] to make 1,2-*cis*-furanoside ethers[14] and also as electrophilic catalysts for aldol and Michael reactions of silyl enol ethers.[15] To avoid the chromatographic separation of the product triphenylphosphine oxide, a basic variant of the reagent was created in the same way from $Ph_2PO\text{-}N(CH_2CH_2)_2NMe$, which is then returned from the reaction as its salt and easily extracted into water.[2]

The triphenylphosphonium ethers are also regarded as intermediates in the Mitsunobu reaction, prepared from $Ph_3P + (RO_2C\text{-}N{=})_2$ to activate an alcohol for substitution (see ***Triphenylphosphine-Diethyl Azodicarboxylate***).[16] They were earlier prepared electrochemically from Ph_3P + ROH and used for alkylation of imidazole and thiophenol[17] and carboxylic acids,[18] or applied to amides and ureas for dehydration to nitriles and carbodiimides, respectively, with bases.[19] The acyloxytriphenylphosphonium ions were similarly prepared from $Ph_3P + RCO_2H$ and converted to esters and amides as above, although in lower yields.[20]

2,4,6-Triphenylpyrylium Tetrafluoroborate[1]

[448-61-3] · $C_{23}H_{17}BF_4O$ · 2,4,6-Triphenylpyrylium Tetrafluoroborate · (MW 396.21)

(converts primary amines into pyridinium salts which on reaction with nucleophiles NuH afford R-Nu)

Physical Data: mp 255-257 °C.

Solubility: insol H_2O, EtOH, Et_2O; sol CF_3CO_2H.

Form Supplied in: yellow solid.

Purification: recryst. from AcOH or $(ClCH_2)_2$.

Handling, Storage, and Precautions: may be stored indefinitely. Reports on possible mutagenic activity make it desirable to avoid direct contact with skin. Other 2,4,6-triphenylpyrylium salts are the commercially available sulfoacetate, and the hydrogen sulfate whose synthesis[2] is analogous to that of (**1**) as described by eq 1 below.

Syntheses.

2,4,6-Triphenylpyrylium salts may be obtained by a variety of methods.[3] The strong green fluorescence of 1,3,5-triphenylpentane-1,5-dione (benzylidenediacetophenone) in H_2SO_4 was observed as early as 1896, but the cause was discovered later (H_2SO_4 acts as a dehydrogenating and dehydrating agent, yielding the fluorescent triphenylpyrylium cation). Michael condensation of chalcone (**2**) with acetophenone yields the above 1,5-dione, and this reacts with various hydride acceptors furnishing 2,4,6-triphenylpyrylium salts in excellent yields: with ***Iron(III) Chloride*** in Ac_2O the tetrachloroferrate is obtained;[4] with ***Tetrafluoroboric Acid*** or $HClO_4$ in Ac_2O the fluoroborate (eq 1) and the perchlorate, are obtained respectively.[5] The same two salts may also be obtained using the corresponding triphenylmethyl salts as hydride acceptors,[6] which yield triphenylmethane by hydride transfer.

A procedure which is included in *Organic Syntheses* is based on the above reaction,[7] but the hydride acceptor is chalcone itself in acid medium ($HClO_4$ or HBF_4): its conjugate acid affords 1,3-diphenylpropan-1-one (**3**) by hydride transfer.[8] From two moles of chalcone (**2**), one mole of acetophenone, and one mole of an ethereal solution of tetrafluoroboric acid in 1,2-dichloroethane the yield of 2,4,6-triphenylpyrylium tetrafluoroborate (**1**) was 55-60%.[7]

This optimal synthetic procedure is a two-component synthesis. Other two-component syntheses of (**1**) or salts with other anions include: the replacement of acetophenone in the above reaction by its equivalent synthon, phenylacetylene (***Boron Trifluoride Etherate*** appears to be the best anion-forming reagent, leading[9] to an 80% yield of **1**); the reaction of phenylacetylene and 3-chloro-1,5-diphenylpentanedione in the presence of ***Tin(IV) Chloride***;[10] the benzoylation of dypnone (**4**) with benzoyl fluoride in the presence of boron trifluoride etherate (eq 2); the condensation of dypnone with benzaldehyde in acetic anhydride in the presence of $FeCl_3$; and the condensation of dibenzoylmethane with acetophenone in acetic anhydride with sulfuric acid, when 80% yields are attained.

Finally, three-component syntheses have to be mentioned because they use simpler starting materials in one-step procedures: (i) condensation of two moles of acetophenone with one mole of benzaldehyde in the presence of boron trifluoride or boron trifluoride etherate;[12] the chloroferrate is produced by the same condensation in the presence of acetic anhydride and $FeCl_3$;[4] (ii) as indicated earlier, phenylacetylene may replace acetophenone,[9] and the hydride acceptor is chalcone which is formed in the condensation; (iii) a hydride acceptor becomes unnecessary when two moles of acetophenone are reacted with benzotrichloride in the presence of perchloric acid;[13] instead of benzoylating dypnone, one may react two moles of acetophenone with ***Benzoic Anhydride*** in the presence of $FeCl_3$; (iv) alternatively, one may react two moles of phenylacetylene with ***Benzoyl Chloride*** in the presence of $SnCl_4$; (v) dibenzoylation of α-methylstyrene with benzoyl chloride and ***Aluminum Chloride*** affords triphenylpyrylium tetrachloroaluminate, which can be converted into other salts.[14]

Reactions.

Weak bases (e.g. sodium acetate in aqueous ethanol) convert (**1**) or its salts with other anions into the stable crystalline triphenylpyrylium pseudobase (**5**) (1,3,5-triphenyl-2-pentene-1,5-dione) (see eq 3).

It has been reported[4,15] that substituted pyrylium salts reacted readily with ammonia or primary amines, yielding pyridines and *N*-substituted pyridinium salts, respectively. It has been observed[16] that 2,4,6-triphenylpyrylium salts react with ammonia at room temperature to yield an ether-soluble crystalline adduct which dehydrates at the melting point, resolidifying to 2,4,6-triphenylpyridine.

N-Alkyl-2,4,6-triphenylpyridinium salts may be obtained either from primary amines and 2,4,6-triphenylpyrylium salts, or by quaternization of 2,4,6-triphenylpyridine with alkyl halides. Only the former reaction is relevant to the present context.

Nucleophilic Displacement of NH_2 Groups from Primary Amines via *N*-substituted 2,4,6-Triphenylpyridinium Tetrafluoroborates.

Primary aromatic amines can be diazotized and subsequently converted into a variety of aromatic derivatives by nucleophiles which displace the diazonium group. For aliphatic primary amines, such a displacement may be achieved using pyrylium salts as the key reagents.

In 1926, Ziegler and Fries showed[17a] that 1-methyl-2,4,6-triphenylpyridinium chloride thermolyzed to 2,4,6-triphenylpyridine and presumably methyl chloride. In 1969, Susan and Balaban[17b] reported that 1-methyl-2,4,6-triphenylpyridinium iodide or chloride decomposed on melting, affording 2,4,6-triphenylpyridine and the corresponding methyl halides, which were isolated and identified; it was also observed that *N*-benzyl-2,4,6-triphenylpyridinium salts were easily solvolyzed on recrystallization from ethanol, yielding 2,4,6-triphenylpyridine. These early observations led to the development, by Katritzky and co-workers, of a synthetic method for converting primary amino groups into other functional groups by means of triphenylpyrylium and related cations.

The conversion of a primary amino group into a leaving group is achieved by reaction with 2,4,6-triphenylpyrylium tetrafluoroborate (**1**), which leads to an *N*-substituted 2,4,6-triphenylpyridinium tetrafluoroborate (**6**). The mechanism of this reaction has been studied using *n*-$BuNH_2$ in conjunction with UV and ^{13}C NMR spectroscopic methods;[18] it was concluded that when there is sufficient amine present for each mole of pyrylium salt (either &egt;2 moles of primary amine, or one mole of tertiary amine, such as triethylamine, and &egt;1 mole of RNH_2), the pyrylium salt is converted entirely to a vinylogous amide (**7**), which is then cyclodehydrated to the pyridinium cation (**6**) (eq 3). The protonations and deprotonations are assisted by the reaction solvent, which may be water or a lower alcohol (such as MeOH, EtOH, *i*-PrOH, *t*-BuOH), or dichloromethane with a small amount of acetic acid. With lower amine-to-pyrylium ratios than those mentioned above, a 1,5-diketone (**5**) (pyrylium pseudobase) is also formed from traces of water present or originating in the cyclodehydration. The rate-determining step is the cyclodehydration, which is accelerated when acetic acid is present.

As a result of these mechanistic studies, conditions were found for rapidly obtaining good yields of pyridinium salts (**6**) at room temperature in mildly acidic or basic media from primary amines whose NH_2 group is bound to an aromatic, a primary aliphatic, or a secondary aliphatic carbon atom.

The displacement of 2,4,6-triphenylpyridine from 1-R-2,4,6-triphenylpyridinium salts (**6**) can be achieved with a variety of nucleophiles NuH, yielding RNu compounds as shown in Table 1.

Table 1 Functionalities Obtained from Primary Amines via Pyridinium Salts

Group in the Periodic Table				
1	14	15	16	17
R H^{19}	R $CH(CO_2Et)_2$[20]	R $N(COR)_2$[22]	R OAr[23]	R F[30]
	R $CH(CN)CO_2Et$	R NR_2[23]	R $OCOR$[24]	
	R $CHPhCO_2Et$	R N_3[22]	R ONO_2[25]	R Cl[31]
	R $CHRNO_2$[20,21]	R $NRSO_2Ar$[22]		
			R SO_2Ar[26]	R Br[32]
		R $\overset{+}{P}Ph_3$[23]	R SAr[23]	
			R $SC(S)OR$[27]	R I[33]
			R $SC(S)SR$[28]	
			R SCN[29]	
			R $SeCN$	

Replacement of NH_2 by Hydrogen.

Pyridinium salts (**6**) add H^- from sodium borohydride, yielding 1,2-dihydro derivatives. When R is alkyl, benzyl, arylmethyl, or heteroarylmethyl, these 1,2-dihydropyridines split off 2,4,6-triphenylpyridine on heating at around 200 °C and afford RH compounds in &egt;75% yields. Other R groups yield complex mixtures of products, but pyridinium salts formed from RNH_2 and 2,3,5,6-tetraphenylpyrylium salts react with ***Sodium Borohydride***, yielding 1,4-dihydropyridines which on pyrolysis at 180-200 °C afford RH in good yields.

Replacement of NH_2 by Carbon Nucleophiles.

When R in (**6**) is benzyl, nucleophilic attack by sodium derivatives of ***Ethyl Cyanoacetate***, ethyl phenylacetate or ***Diethyl Malonate*** in refluxing dioxane or 1,2-dimethoxyethane affords the corresponding monobenzylated esters in &egt;70% yields. With other R groups, more sterically hindered pyridinium salts have to be used, such as (**8**) (eq 4). However, (**6**) with any type of R group reacts smoothly with nitronate anions, and affords *C*-alkylated nitro compounds in good yields (unlike other agents which are *O*-alkylating).

(4)

(8)

Replacement of NH_2 by Nitrogen or Phosphorus Nucleophiles.

Pyridinium salts (**6**) alkylate potassium phthalimide or sodium derivatives of succinimide, *N*-ethylbenzenesulfonamide or *N*-phenylbenzenesulfonamide; on hydrolysis of the resulting benzenesulfonamides, secondary amines RNHR´ are obtained. Tertiary amines $PhCH_2NR'_2$ can be obtained from (**6**) with piperidine or morpholine without any interference from quaternary salts; similar selectivity is obtained when the phenyl group in $PhCH_2$ is replaced by an α-, β-, or γ-pyridyl group. Quaternary salts may be obtained, however, by transferring the R group of (**6**) to pyridine or 2- or 4-picoline (&egt;70% yields). At 130 °C in DMF (**6**) reacts with ***Sodium Azide***, forming alkyl or benzyl azides in high yields. Triphenylphosphine reacts with (**6**) to yield phosphonium salts when R is benzyl or 2- or 4-picolyl.

Replacement of NH_2 by Oxygen, Sulfur, or Selenium Nucleophiles.

On heating at ca. 200 °C a powdered mixture of (**6**) with the sodium salt of a carboxylic acid (R´ = Me, Ph, Pr) in the presence of 2,4,6-triphenylpyridine, esters $R'CO_2R$ are obtained in >60% yields. Pyridinium salts whose relief of steric strain is higher, e.g. when using (**8**) instead of (**6**), require lower temperatures, e.g. 100 °C with R´ = Me. From such esters, alcohols may be obtained by hydrolysis. Starting from RNH_2 and 2,4,6-triphenylpyrylium trifluoroacetate, crystalline triphenylpyridinium trifluoroacetates are obtained; on gentle pyrolysis around 160 °C, these salts yield 2,4,6-triphenylpyridine and $ROCOCF_3$ esters, which are easily hydrolyzable to alcohols ROH. Such conversions of Alk-NH_2 into Alk-OH proceed much more cleanly and efficiently than via diazotization.

Two pathways exist for obtaining aldehydes RCHO from RCH_2NH_2 via reaction with (**1**): oxidation of the pyridinium salt (**6**) (R = $ArCH_2$) by ***Potassium Dichromate*** in the presence of Bu_4N^+ BF_4^- in refluxing 1,2-dichloroethane; and pyrolysis of (**6**) with sodium 1-oxido-4,6-diphenyl-2-pyridone. Yields are moderate.

Nitrate esters, $RONO_2$, can be obtained in good yields by pyrolyzing under vacuum 2,4,6-triphenylpyridinium nitrates prepared from RNH_2 and 2,4,6-triphenylpyrylium nitrate.

Phenoxides (sodium phenoxide or α-naphthoxide) react in refluxing dioxane with (**6**) (R = benzyl, 3- or 4-picolyl) in the presence of Bu_4N^+ BF_4^-, affording the corresponding alkyl aryl ethers.

The pyridinium salts formed from 2,4,6-triphenylpyrylium thiocyanate and primary amines afford thiocyanates RSCN on heating with triphenylpyridine; isothiocyanates RNCS are byproducts formed in low yield. An analogous reaction allows the preparation of selenocyanates Alk-SeCN. When using a pyridinium salt with high steric requirements such as (**8**), even aryl thiocyanates may be thus obtained from $ArNH_2$.

Dithiocarbonates are formed in good yield from (**6**) (R = Alk) and potassium ethyl xanthate in refluxing benzene; the more reactive salts (**6**) (R = $PhCH_2$) react similarly both in ethanol and in benzene. Thiols result by hydrolyzing the thiouronium salts formed from (**6**) and thiourea in refluxing chlorobenzene. When (**6**) (R = 4-picolyl) was refluxed in ethanol with sodium *p*-toluenesulfinate, the corresponding sulfone was formed in high yield.

Replacement of NH_2 by Halide Anions.

Primary amines RNH_2 react with 2,4,6-triphenylpyrylium fluoride in refluxing benzene-ethanol so that the resulting water is continuously removed as azeotrope. On heating the pyridinium fluorides so obtained (after careful drying) above their melting points, i.e. at 80-120 °C, the corresponding fluorides RF are formed in high yields. A reaction analogous to the Schiemann procedure, namely pyrolysis of (**6**) with KF and triphenylpyridine, results in low yields of RF contaminated with RH.

To obtain chlorides, (**6**) can be heated at 200-240 °C in a KCl-NaCl-$ZnCl_2$ eutectic, when the RCl distills out in average yields around 50%. Alternatively, one can start from 2,4,6-triphenylpyrylium chloride and RNH_2, removing water by azeotropic distillation and heating the resultant pyridinium chloride at 100-130 °C.

Starting from RNH_2 and 2,4,6-triphenylpyrylium bromide or iodide, one readily obtains the corresponding crystalline halides, which on pyrolysis afford RBr and RI, respectively. For bromides, triphenylpyridine as flux increases the yield and reduces fusion and decomposition temperatures. In the case of iodides, even $ArNH_2$ groups may afford ArI, but in this case the Sandmeyer reaction is equally effective.

In addition to the nucleophilic deaminating substitutions described above, mediated by (**1**), other reactions of (**6**) are possible with particular *N*-substituents R. Thus with R = $PhCH_2CH_2$, elimination yielding styrene occurs on pyrolysis.[34] The N^+,N^- pyridinium betaine (**6**) with R = $ArCON^-$ affords isocyanates RNCO on heating, as an alternative to the Curtius rearrangement.[35] The analogous betaine formed from (**1**) and H_2N-N=CR-NHR´ splits off triphenylpyridine on heating and rearranges to unsymmetrical carbodiimides.[36]

A synthesis of nitriles RCN from aldehydes RCHO is based on converting the aldehyde into its phenylhydrazone. Subsequent reaction with (**1**) in refluxing formamide yields triphenylpyridine and the nitrile. Alternatively, 1-amino-4,6-diphenyl-2-pyridone is reacted with the aldehyde, leading to an aldimine whose pyrolysis affords the nitrile in high yield along with 4,6-diphenyl-2-pyridone.[37]

Conversion into Other (Hetero)aromatic Systems.

In addition to the use of 2,4,6-triphenylpyrylium salts for mediating the nucleophilic displacement of amino groups, they are versatile intermediates for obtaining other interesting compounds such as 2,4,6-triphenylnitrobenzene,[38] 2,4,6-triphenylphenol and -phenoxyl,[39] -phosphabenzenes,[40] and -thiopyrylium salts.[41]

Whereas (**1**) reacts with hydrazine to form a diazepine derivative (**9**), the pseudobase (**5**) is converted by hydrazine into a monohydrazone (**10**) which cyclizes to a pyrazoline derivative (**11**) (eq 5).[42] Both the pyrylium salt and the pseudobase react with monosubstituted hydrazines (R = Ph, Me, SO_2Ar, CO_2H) in ethanol, affording monohydrazones which cyclize to pyrazoline derivatives (**11**). Strong acids split off acetophenone from these pyrazolines and afford pyrazoles (**12**) under aromatization. However, if the monohydrazone (**10**) is refluxed in acetic acid, it undergoes a different cyclization, leading to a pyridinium salt (**13**); the corresponding N^+,N^- pyridinium betaine (**14**) may be a source of nitrenes RN. Similar reactions occur when (**1**) or the pseudobase (**5**) are treated with hydroxylamine in ethanol: a crystalline isoxazoline results, and on treatment with mineral acids an analogous C-C bond splitting occurs leading to 3,5-diphenylisoxazole and PhAc. If the reaction with hydroxylamine is carried out in acetic acid, 2,4,6-triphenylpyridinium *N*-oxide results.[42,43]

Summary of Reactions.

The primary amino group in alkyl or aralkyl amines is a very poor leaving group. By reaction with (**1**) (or other pyrylium salts with higher steric requirements), better leaving groups are obtained. Only ditosylates $RNTs_2$ are comparable, but their versatility is far smaller.

The relative reactivities increase in the order: (**6**) < (**8**) < RN_2^+, and within each of these three classes in the order: R = aryl < alkyl < benzyl. The mechanisms of substitutions or fragmentations differ and may be radical, S_N1, or S_N2.

Advantages of deaminations proceeding via pyridinium salts are the preparation of alkyl and benzyl fluorides, the *C*-alkylation of nitronate anions, the lack of rearrangement in reactions involving neopentyl derivatives,[44] and the accessibility of natural amino compounds. Some of the reactions mediated by (**6**) result in cyclizations, e.g. formation of epoxides; *N*-vinylpyridinium salts, which cannot be obtained by quaternization, may also be prepared.[45]

Optical and Electrochemical Properties.

A recent review,[46] dedicated to (**1**) as a photoinduced electron-transfer (PET) agent, outlines its advantages over cyanoaromatic photosensitizers: enhancement of radical-ion formation and reduction of back-electron transfer (both due to the absence of net charge separation associated with the electron-transfer step); efficiency as a photosensitizer in both the singlet and triplet excited states, and the possibility to favor one of these states by appropriate choice of concentration and temperature; the unique ability to study photooxygenations of organic radical cations with molecular oxygen

without interference from singlet oxygen or superoxide radical anions (both of which are formed when other photosensitizers are used). Of the PET reactions sensitized by (**1**), the above review cites: $[2_\pi; + 2_\pi]$ or $[4_\pi + 2_\pi]$ cycloadditions or cross-cycloadditions; (*Z*/*E*) isomerizations; sigmatropic rearrangements; oxygenation of alkenes yielding 1,2-dioxetanes (derived from the monomeric or dimeric alkene), epoxides, or ring-opened oxidized products; fragmentations of C-C, C-O, C-S, or C-N bonds (in the last case, dinitrogen is often extruded from azo derivatives).

The ability of pyrylium salts, including (**1**), to act as laser solutes has been reviewed.[47] The electrochemistry of pyrylium salts, including (**1**), has also recently been reviewed.[48]

Related Reagents.

2,4,6-Trimethylpyrylium Tetrafluoroborate.

Alexandru T. Balaban

Triphenylsilane

Ph_3SiH

[789-25-3] · $C_{18}H_{16}Si$ · Triphenylsilane · (MW 260.43)

(reducing agent for esters, xanthates, and polychloroalkanes; protecting group for alcohols)

Physical Data: mp 47 °C; bp 152 °C/2 mmHg.

Solubility: sol most organic solvents.

Form Supplied in: white solid; commercially available.

Handling, Storage, and Precautions: this reagent is stable in air. Because the toxicogical properties are unknown, it should be handled in a well-ventilated fume hood. Contact with the eyes and skin should be avoided.

Deoxygenations.

Ph_3SiH is a useful reducing reagent under radical conditions. Esters are reduced to hydrocarbons at 140 °C by Ph_3SiH in the presence of a radical generator, ***1,1-Di-t-butyl Peroxide*** (DTBP) (eq 1).[1]

The best results are obtained with acetate esters compared with other esters, such as isobutyrate, pivalate, or benzoate. Acetates derived from primary, secondary, and tertiary alcohols are all reduced in high yield. Other silanes such as tripropylsilane and diphenylmethylsilane are not as effective, and other radical generators such as AIBN and dibenzoyl peroxide are not suitable for the deoxygenations.

This reaction can be applied to deoxygenation of carbohydrates. Thus both *O*-acetylfuranoses and -pyranoses can be converted to the corresponding deoxy sugars (eqs 2 and 3).[2]

(3)

Xanthates (eq 4)[3] and perhaloalkanes[4] are also reduced by Ph_3SiH.

(4)

Ph_3SiH in combination with ***Trifluoroacetic Acid*** has been used for ionic deoxygenation of tertiary alcohols (eq 5).[5]

(5)

Protecting Group.

Triphenylsilane is used in certain cases for the preparation of triphenylsilyl ethers, which serve as alcohol protecting groups.[6] The triphenylsilyl group is considerably more stable (about 400 times) than the TMS group toward acidic hydrolysis.[7]

Related Reagents.

1,4-Bis(diphenylhydrosilyl)benzene; ***Triethylsilane-Trifluoroacetic Acid***.

(Triphenylstannylmethyl)lithium[1]

[64331-89-1] · $C_{19}H_{17}LiSn$ · (Triphenylstannylmethyl)lithium · (MW 371.01)

(methylenation reagent for several carbonyl compounds[1])

Solubility: sol several kinds of ethers; protonated in protic solvents.

Preparative Methods: iodine-lithium exchange of triphenylstannylmethyl iodide in dry ether with ***n-Butyllithium*** (98%).[1] Triphenylstannylmethyl iodide can be obtained by the reaction of ***Chlorotriphenylstannane*** with Simmons-Smith reagent (***Iodomethylzinc Iodide***) in 66% yield.[2]

Purification: recrystallization of the precursor triphenylstannylmethyl iodide from hexane (white crystalline plates, mp 86-87 °C)

Handling, Storage, and Precautions: the precursor can be stored in a desiccator. Since organotin compounds are toxic, the experiment should be performed in a good fume hood and with gloves.

Methylenation Reagent for Carbonyl Compounds.

Like ***(Trimethylstannylmethyl)lithium***, this reagent (**1**) is an effective methylenation reagent. The reagent reacts with ketones or aldehydes (**2**) to afford β-stannyl alcohols (**3**), which undergo Peterson-type elimination under acidic conditions ($HClO_4$/MeOH, 20 °C or SiO_2/THF, 20 °C, 56-68%, based on **3**)[3] or heating (110-175 °C) to produce methylene compounds (**4**). Overall yields are improved if the alcohols (**3**) are not isolated (eq 1 and Table 1).[4]

Table 1 Reaction of Reagent (**1**) with Carbonyl Compounds followed by Thermolysis

Carbonyl compound (**2**)	b-Hydroxy-stannane (**3**)	Thermo-lysis (°C)	Reaction time (min)	Alkene (**4**)	Overall yield[a] (%)
PhCHO	65	140	15	Styrene	55 (87)
		110	300		62
Ph_2CO	0				
Cyclo-	37	170	45	Methylene-	35
hexanone		132	120	cyclohexane	35 (86)
MeCOPh	41	75	45	a-Methyl-	29
		110	90	styrene	29
Butanal	31	170	60	1-Pentene	31
		132	120		31 (75)
Heptanal	26	132	180	1-Octene	18

[a] Based on carbonyl compound. Values enclosed in parentheses are overall yields without isolation of (**3**).

The analogous (tributylstannylmethyl)lithium can be generated by the same procedure (98-100%), and this reagent also methylenates esters.[5] Note that the preparation of (triphenylstannylmethyl)lithium (**1**) by iodine-lithium exchange should be performed in ether. In THF, the yield of the desired lithium reagent is decreased, producing iodomethyllithium as byproduct (eq 2).[6]

(2)

Coupling Reaction with Allyl Bromide.

Although the reagent (**1**) does not react with ***Allyl Bromide***, a copper derivative (**5**) obtained from (**1**) and ***Copper(I) Chloride*** couples with allyl bromide to afford homoallylstannane (**6**) in 57% yield.[6] This reaction is thought to proceed through the tandem oxidative addition-reductive elimination mechanism (eq 3).

However, an unsuccessful coupling reaction of the cyanocuprate reagent (**8**), prepared from (tributylstannylmethyl)lithium and ***Copper(I) Cyanide***, with alkenyloxirane (**7**) has been reported, although the ordinary alkylcuprates react with (**7**) smoothly. The major reaction of (**8**) is the oxidative coupling of the cuprate to afford 1,2-bis(tributylstannyl)ethane (**9**) (eq 4).[7]

Related Reagents.

Triphenylgermylmethyllithium[8] and triphenylplumbylmethyllithium[3] have also been prepared. See also ***Trimethylsilylmethyllithium*** and ***(Diisopropoxymethylsilyl)methylmagnesium Chloride***.

3-Triphenylstannyl-1-propyne

[4104-89-6] · $C_{21}H_{18}Sn$ · 3-Triphenylstannyl-1-propyne · (MW 389.10)

(addition of a propargyl or an allenyl group to aldehydes; reacts with alkyl halides to give a terminal allenyl or propargyl group; preparation of allenyl iodides and allenyl(aryl)iodinanes; isomerizes to triphenylstannylpropadiene in the presence of Lewis acids or electron donor solvents)

Alternate Name: triphenyl-2-propynylstannane; triphenylpropargylstannane.

Physical Data: mp 81-84 °C.

Solubility: typical reaction solvents include benzene and dichloromethane.

Analysis of Reagent Purity: reagent purity may be analyzed by ^{1}H NMR.[1] The most common impurity is the isomeric allene which may be detected by IR and ^{1}H NMR.

Preparative Methods: prepared from ***Propargylmagnesium Bromide*** and Ph_3SnX (X = Cl or I) in ether (70-75%).[1a,d] Also prepared by treatment of propargyl bromide with Ph_3SnLi (30%).[1b]

Handling, Storage, and Precautions: organostannane reagents are highly toxic and readily absorbed through the skin. Proper safety equipment (i.e. fume hood, gloves, protective eyewear) should be utilized at all times when handling the reagent.[2] Irradiation of 3-triphenylstannyl-1-propyne in C_6D_6 for 19 h resulted in isomerization to the allene. No isomerization was observed after heating in the dark at 70 °C for 7 h.[3] Deliberate isomerization to the allene has also been accomplished by heating the propargylstannane in electron donor solvents or in the presence of Lewis acids.[6]

Addition to Aldehydes.

The addition of 3-triphenylstannyl-1-propyne to aldehydes has been reported to give mixtures of allenyl and propargyl products.[4] Exclusive formation of the homopropargyl alcohol (β-acetylenic alcohol) may be obtained in an enantioselective manner by using the chiral bromoborane prepared from 1,2-diphenyl-1,2-diaminoethane (stilbenediamine).[5] Treatment of triphenylpropargylstannane with the chiral bromoborane gave the allenylborane, which reacted with a variety of aldehydes to form homopropargyl alcohols with excellent enantioselectivity (eq 1).

Exclusive formation of α-hydroxy allenes (α-allenic alcohols) was accomplished by using an allenylstannane, tributylstannylpropadiene, which was prepared by isomerization of the corresponding propargylstannane.[5] Isomerization of 3-triphenylstannyl-1-propyne to its allenyl derivative, triphenylstannylpropadiene, is also readily accomplished in the presence of Lewis acids or electron donor solvents.[6]

See also ***3-Iodo-1-trimethylsilylpropyne*** for the preparation of trimethylsilyl substituted α-allenic and β-acetylenic alcohols.

Reaction with Alkyl Halides.

Baldwin et al. report the formation of terminal allenes from the reaction of 3-triphenylstannyl-1-propyne with alkyl bromides and iodides in the presence of ***Azobisisobutyronitrile*** in refluxing benzene (eq 2).[7] In a related study, Hamon et al. report the formation of terminal alkynes with high diastereoselectivity from the reaction of the propargylstannane with the 8-phenylmethyl ester of *N*-Boc-2-bromoglycine (eq 3).[8] Both reactions are believed to involve radical intermediates; however, nucleophilic addition of the propargylstannane to an intermediate iminium species has also been proposed for the latter reaction (eq 3).

Preparation of Allenyl Iodides and Allenyl(aryl)iodinanes.

Allenyl iodides have been prepared by ***Iodine*** treatment of 3-triphenylstannyl-1-propyne (eq 4).[9] Other carbon-tin bond cleavage reactions using ***Thiocyanogen*** $(SCN)_2$ and ***Sulfur Dioxide*** are also known, giving the allenyl sulfide and the sulfur dioxide insertion product, respectively.[10,11]

(4)

Hypervalent allenyl(aryl)iodinanes have been prepared by reaction of the propargylstannane with aryliodinanes (eq 5).[12] The product then undergoes a reductive iodonio-Claisen rearrangement to yield *o*-propargyliodoarenes.

Triphenyl Thioborate

$(PhS)_3B$

[1041-16-3] · $C_{18}H_{15}BS_3$ · Triphenyl Thioborate · (MW 338.35)

(conversion of esters and α,β-unsaturated esters into phenylthio esters,[1] and for formation of 1,3-bis(phenylthio)alkenes from aldehydes and ketones[2])

Alternate Names: phenyl thioborate; tris(phenylthio)borane.

Physical Data: pale yellow solid; mp 140-143 °C;[3] bp 196 °C/0.1 mmHg.[3]

Solubility: sol benzene, ether, acetone.[4]

Preparative Methods: can be made from ***Boron Triiodide*** and ***Diphenyl Disulfide***;[5] from ***Thiophenol*** and ***Boron Trichloride***;[6] from (phenylthio)borane trimer and thiophenol;[7] or from ***Boron Trisulfide*** and thiophenol.[2,8]

Purification: recrystallize from benzene[7] or distill in vacuo.[3]

Handling, Storage, and Precautions: sensitive to moisture and should be stored in a desiccator. Can be weighed out quickly in air, if humidity is low, but best handled in a dry box.[2]

Conversion of Esters and α,β-Unsaturated Esters into Phenylthio Esters.[1]

Esters are converted into phenylthio esters by heating with phenyl thioborate in refluxing xylene (140 °C) (eq 1), but the same transformation can be done at room temperature with phenyl thioaluminate. With the aluminum reagent, α,β-unsaturated esters give products contaminated with the β-(phenylthio) ester, but the boron reagent does not suffer from this disadvantage (eq 2).

(1)

(2)

Formation of 1,3-Bis(phenylthio)alkenes from Aldehydes and Ketones.[2]

α,β-Unsaturated aldehydes and ketones form 1,3-bis(phenylthio)alkenes on treatment with phenyl thioborate (eq 3). The (phenylthio)alkenes are β-acyl vinyl anion equivalents (eq 4).

Triphenylstannane[1]

Ph_3SnH

[892-20-6] · $C_{18}H_{16}Sn$ · Triphenylstannane · (MW 351.05)

(generation of carbon radicals from selenides,[2] halides,[3] sulfides,[4] and alkynes;[5] radical deoxygenation;[6] reduction of α,β-unsaturated aldehydes and ketones;[7] hydrostannylation of alkynes[5,8] and alkenes;[9] reversible addition of stannyl radicals to double bonds;[10] formation of metal triphenylstannates;[11] reduction of aldehydes and ketones;[12] desulfonation of β-keto phenyl sulfones;[13] hole-transfer-promoted hydrogenation[14])

Alternate Names: triphenyltin hydride; triphenylstannyl hydride.

Physical Data: white needles, mp 26-28 °C;[15,16] bp 156-158 °C/0.15 mmHg;[15] d^{25} 1.3771 g cm^{-3}.[17]

Solubility: sol many common organic solvents; usually used in benzene or toluene.

Form Supplied in: commercially available as a colorless liquid that solidifies in a refrigerator.

Analysis of Reagent Purity: titration of the derived triphenyltin chloride has been used.[18,19] Reactions of Ph_3SnH can be followed by monitoring the 1840 cm^{-1} IR absorption.[1h]

Preparative Methods: reduction of ***Chlorotriphenylstannane*** with ***Lithium Aluminum Hydride*** in ether,[12,16,20] or with ***Sodium Borohydride*** in glyme;[15] reduction of bis(triphenyltin) oxide with polymethylhydrosiloxane;[21] reduction of triphenyltin methoxide with diborane;[22] protonation of Ph_3SnLi.[17,23] The reagent has also been generated in situ from Ph_3SnCl and ***Sodium Cyanoborohydride*** in *t*-butyl alcohol.[24]

Handling, Storage, and Precautions: Ph_3SnH can be stored for several months, and is easily repurified by Kugelrohr distillation (oil-pump vacuum) before use.[25] Organotin hydrides decompose slowly at rt and are best stored at 0 °C or below.

Decomposition is catalyzed by air, silicone grease, metallic surfaces, amines and, in the case of triphenyltin hydride, by light.[1h,15,16] Manipulations of the compound are usually best done in an inert atmosphere and using thoroughly clean apparatus (KOH-MeOH is better than chromic acid for cleaning in this case[26]). Methods have been reported for removing tin species from reactions involving stannanes, but these appear to have been described explicitly only for ***Tri-n-butylstannane***.[6,27-30] Provided that skin contact and inhalation are avoided, Ph_3SnH does not present an unusual hazard.[15]

General.

Many processes with Ph_3SnH can be done also with Bu_3SnH, and vice versa; however, direct comparison of the two reagents has rarely been reported.

Formation of Carbon Radicals from Phenyl Selenides.

Many phenyl selenides have been converted into carbon radicals that have then undergone intramolecular cyclization (eq 1),[31] radical ring opening (eq 2),[32] or reduction (eq 3).[2] Tellurides (eq 4) and telluride dichlorides are also reduced to the corresponding hydrocarbon.[2,33]

Radical Deoxygenation.

Ph_3SnH has occasionally been used for Barton deoxygenation.[6,34] In the example of eq 5, better results are obtained with Bu_3SnH than with Ph_3SnH.[6] Alcohols and carbonyl compounds (ketones or aldehydes) have been deoxygenated by conversion into the corresponding phenyl selenides or selenoacetals, respectively, followed by treatment with Ph_3SnH (eq 6).[2]

(5)

(6)

Formation of Carbon Radicals from Halides.

The triphenylstannyl radical, generated thermally[3,35-37] or electrochemically,[38] can be used for dehalogenation, the radical intermediate being captured by hydrogen transfer (eqs 7-9)[9,35,36] or by an intramolecular process (eqs 10-13).[38-41] In the last example (eq 13), Ph_3SnH gave better results than Bu_3SnH.[41]

(7)

(8)

(9)

(10)

(11)

(12)

(13)

Desulfurization and Disulfide Cleavage.

Ph_3SnH has occasionally been used for desulfurization,[4,42] the process being facilitated in the example shown in eq 14 by the presence of an α-heteroatom.[4] Disulfides can also be cleaved (initially to thiyl radicals).[38,43]

(14)

Cyclization of Acetylenic Alkenes.[5,24,44]

Acetylenic alkenes undergo cyclization on treatment with Ph_3SnH under radical conditions (eqs 15 and 16).[5,24] In the example of eq 15, and in related processes, lower yields were obtained with Bu_3SnH.[24]

(15)

(16)

Reduction of α,β-Unsaturated Aldehydes and Ketones.[7,45 -52]

Double and (apparently) triple bonds conjugated with the carbonyl group in α,β-unsaturated aldehydes and ketones are reduced by Ph_3SnH in a radical process (eqs 17 and 18).[7]

(17)

(18)

Hydrostannylation of Alkynes and Alkenes.

Allenes (eq 19)[53,54] and alkynes (eqs 20 and 21)[8,55] are hydrostannylated in the presence of a palladium catalyst. Use of Ph_3SnH rather than Bu_3SnH gives a higher proportion of the (*Z*)-isomer in (eq 19).[54]

(19)

(Z):*(E)* = 91:9

(20)

(21)

Alkynes[5,56-58] (eq 22)[5] and alkenes[9,59,60] (eqs 23 and 24)[9,59] are also hydrostannylated under radical conditions.

(22)

(23)

(24)

In contrast to α,β-unsaturated aldehydes and ketones (which are usually[46] reduced to the saturated carbonyl compounds), α,β-unsaturated esters[61] are generally[62,63] hydrostannylated[7,57,63-65] under mild radical conditions (eq 25). In the example of eq 25, Bu_3SnH reacted sluggishly and the process was incomplete.[7] The hydrostannylation can be highly stereoselective (eq 26).[66]

(25)

(26)

Reversible Addition of Triphenylstannyl Radicals to Double Bonds.

The process summarized in eq 27 was slightly more stereoselective with Ph_3SnH than with Bu_3SnH, but the proportion of the enone was higher.[10] Ring expansion of the type shown in eq 28 sometimes proceeded more efficiently with Ph_3SnH than with Bu_3SnH.[67]

(27)

(28)

Preparation of Metal Triphenylstannates.

Ph_3SnK is easily prepared from Ph_3SnH and ***Potassium Hydride***,[68] Ph_3SnNa from the stannane and ***Sodium Hydride***,[69] Ph_3SnLi from the stannane and ***Lithium Diisopropylamide***,[11] and $(Ph_3Sn)_2Zn.TMEDA$ from the stannane and ***Diethylzinc*** in the presence of ***N,N,N´,N´-Tetramethylethylenediamine***.[70]

Reduction of Ketones and Aldehydes to Alcohols.[12,71-74]

Reduction of ketones and aldehydes with Ph_3SnH has been reported (eq 29).[12,71,72]

(29)

When a ketone is treated with an acid chloride in the presence of Ph_3SnH, reductive acylation of the ketone occurs (eq 30).[75]

(30)

Desulfonylation of β-Keto Phenyl Sulfones.[13]

Although Bu_3SnH is usually used for desulfonylation of β-keto phenyl sulfones, Ph_3SnH gave a better yield in the case shown in eq 31.

(31)

Hole-Transfer-Promoted Hydrogenation.

Ph_3SnH can be used as a source of hydrogen to saturate double bonds in a process mediated by triarylamminium ions (eq 32).[14]

Tripotassium Nonachloroditungstate(III)

[23403-17-0] · $Cl_9K_3W_2$ · Tripotassium Nonachloroditungstate(III) · (MW 804.05)

(reduces sulfoxides to sulfides[1])

Alternate Name: potassium tri-μ-chlorohexachloroditungstate(III).

Solubility: sol methanol, water, aqueous HCl.

Form Supplied in: green crystals; not commercially available.

Preparative Methods: prepared in a three-step procedure from tungsten trioxide trihydrate.[2] First, tungsten trioxide trihydrate is treated with aqueous potassium carbonate, followed by hydrogen chloride gas, followed by reduction with tin metal.

Purification: recrystallized from aqueous HCl.

Reduction of Sulfoxides to Sulfides.

Sulfoxides are reduced to sulfides by treatment with the title reagent in refluxing methanol (eq 1).[1] The reaction is very specific for the reduction of sulfoxides and not sulfones or sulfimines. Other functional groups not reduced by this reagent include organic halides, phosphine oxides, epoxides, ketones, esters, nitriles, and aromatic nitro compounds. In one report, a vinylic sulfoxide amino acid was efficiently reduced (eq 2).[3] The major disadvantage of this reagent is that it is not commercially available. For a listing of other methods to effect this transformation, see Madesclaire.[4]

Tripropylamine

[102-69-2] · $C_9H_{21}N$ · Tripropylamine · (MW 143.31)

(in combination with trichlorosilane, for silylations, reductive silylations, and reductions;[1] used as base in preparation of activated esters with 2-chloro-*N*-methylpyridinium iodide;[2] used as base in preparation of β-lactams from activated esters and imines[3])

Physical Data: mp -93.5 °C; bp 155-158 °C; *d* 0.753 g cm^{-3}.

Solubility: sol alcohol, ether.

Form Supplied in: liquid, widely available.

Handling, Storage, and Precautions: handle with care; wear gloves and avoid breathing vapors. Use in a fume hood.

Reductive Silylations; Reductions.

Tripropylamine in combination with ***Trichlorosilane*** is an excellent reagent for reductive silylations and reductions in organic synthesis.[1] Benzylic halides are readily converted into benzylic silanes (eq 1),[4] while aromatic ketones,[5] aldehydes,[5] acid chlorides,[6] and aromatic acids[7] undergo reductive silylations with the tripropylamine-trichlorosilane combination. Aromatic ketones and aromatic aldehydes are converted to benzylic silanes which upon base hydrolysis are converted to the fully reduced compounds (eq 2).[1] The reductive silylation and hydrolysis sequence can be carried out in one pot without isolation of the intermediate benzylsilane. Aromatic carboxylic acid groups are efficiently converted into methyl groups using the reductive silylation-hydrolysis protocol.[8] The tripropylamine-trichlorosilane combination is used to reduce an aromatic carboxylic acid group selectively in the presence of an ester group (eq 3).[9] The initially formed benzylic silane esters can be isolated if desired.

(1)

(2)

(3)

Activated Esters.

The reaction of a carboxylic acid with Mukaiyama's reagent ***2-Chloro-1-methylpyridinium Iodide*** and a tertiary amine is a convenient method for preparing activated esters. In Mukaiyama's original work,[10] ***Triethylamine***, ***Tri-n-butylamine***, and ***2,6-Lutidine*** were shown to give good results; tripropylamine was not examined. Tripropylamine has now been used with Mukaiyama's reagent and acrylic acid to efficiently prepare sulfonamidoisobornyl acrylates, nonracemic chiral intermediates for asymmetric Diels-Alder reactions (eq 4).[2] The reaction of activated esters and imines provides an important stereoselective synthesis of β-lactams via the Staudinger reaction. The use of Mukaiyama's reagent with tripropylamine (3 equiv) gives higher yields and greater stereoselectivity when compared with triethylamine or tributylamine (eq 5).[3]

(4)

(5)

cis:*trans* = 15:1

Heterocyclic Synthesis.

The reaction of quinazoline-2,4-dione or 2,4-dichloroquinazoline with a mixture of ***Phosphorus Oxychloride***, tripropylamine, and a cyclic tertiary amine (*N*-methylpiperidine, for example) gives an excellent yield of the 4-chloro-2-substituted quinazoline.[11] The yield was

substantially reduced without the use of tripropylamine. Interestingly, the regiochemistry is opposite to that observed for the reaction of 2,4-dichloroquinazoline with primary and secondary amines, where a 4-substituted-2-chloroquinazoline is obtained.

Tris(acetonitrile)tricarbonylchromium

[16800-46-7] · $C_9H_9CrN_3O_3$ · Tris(acetonitrile)tricarbonylchromium · (MW 259.21)

(preparation of arene-chromium complexes[1])

Physical Data: mp 135 °C (dec).

Solubility: sol THF, acetonitrile.

Form Supplied in: not commercially available.

Preparative Methods: by refluxing ***Hexacarbonylchromium*** in ***Acetonitrile*** in an inert atmosphere. Removal of solvent under an inert atmosphere yields tris(acetonitrile)tricarbonylchromium.[2]

Purification: the crude solid obtained in the above preparation is typically used without further purification.

Handling, Storage, and Precautions: air and thermally sensitive; pyrophoric. Use in a fume hood.

Preparation of Arene-Chromium Complexes.

Treatment of aromatic compounds with tris(acetonitrile)tricarbonylchromium in THF at 65 °C leads to the corresponding (arene)tricarbonylchromium complexes (eq 1),[1] which are very useful reagents for the arylation of nucleophiles.[3] Arene-chromium complexes can be produced at lower temperatures using tris(acetonitrile)tricarbonylchromium than in the conventional procedure using hexacarbonylchromium.[4]

(1)

Alkene Isomerization.

Tris(acetonitrile)tricarbonylchromium catalyzes the isomerization of 1-phenylindene to 3-phenylindene (eq 2).[5] The scope and limitations of this reaction have not been tested.

(2)

Allylic Oxidation.

Treatment of alkenes with ***t-Butyl Hydroperoxide*** in the presence of catalytic amounts of tris(acetonitrile)tricarbonylchromium (generated in situ) affords the corresponding ketone in high yield (eq 3).[6] The position of the alkene is unchanged during the oxidation.

(3)

Related Reagents.

Hexacarbonylchromium; ***(η^6-Benzene)tricarbonylchromium***.

Tris(acetonitrile)tricarbonylmolybdenum

[15038-48-9] · $C_9H_9MoN_3O_3$ · Tris(acetonitrile)tricarbonylmolybdenum · (MW 303.15)

(reductively cleaves the N-O bond of isoxazolines[1])

Physical Data: mp 140 °C (dec).

Solubility: sol acetonitrile and THF.

Form Supplied in: yellow crystals; not commercially available.

Preparative Methods: by refluxing ***Hexacarbonylmolybdenum*** in ***Acetonitrile*** in an inert atmosphere. Removal of solvent under an inert atmosphere yields tris(acetonitrile)tricarbonylmolybdenum.[2]

Purification: the crude solid obtained in the above preparation is typically used without further purification.

Handling, Storage, and Precautions: air and thermally sensitive; pyrophoric; molybdenum(0) is reputed to be of low toxicity. Use in a fume hood.

Reductive Cleavage of the N-O Bond of Isoxazolines.

Treatment of isoxazolines with tris(acetonitrile)tricarbonylmolybdenum followed by silica gel leads to 3-hydroxy ketones (eq 1).[1] The conversion occurs under much milder conditions than when hexacarbonylmolybdenum is employed. The reaction is most efficient with spiro-fused cyclopropyl derivatives, where dehydration is disfavored. In other systems, mixtures of 3-hydroxy ketones and α,β-unsaturated ketones are obtained.

(1)

Reductive Aldol Coupling of α-Chloro Ketones.

Treatment of 2-chloroacetophenone with tris(acetonitrile)tricarbonylmolybdenum, followed by cyclopentadienyllithium, affords a mixture of the aldol product (**1**) and the secondary aldol product (**2**) (eq 2).[3] No demetallation studies have been reported for the resulting molybdenum complex. Only the yield after recrystallization was reported, suggesting that the efficiency of this reaction may be higher than indicated.

Tris(acetonitrile)tricarbonyltungsten

[16800-47-8] · $C_9H_9N_3O_3W$ · Tris(acetonitrile)tricarbonyltungsten · (MW 391.06)

(catalyst for nucleophilic substitution of allylic acetates[1])

Physical Data: mp 135 °C (dec).

Solubility: sol acetonitrile, nitromethane.

Form Supplied in: not commercially available.

Preparative Methods: by refluxing ***Hexacarbonyltungsten*** in ***Acetonitrile*** in an inert atmosphere. Removal of solvent under an inert atmosphere yields tris(acetonitrile)tricarbonyltungsten.[2] Solutions of the reagent can be prepared by photolysis of hexacarbonyltungsten in acetonitrile.

Purification: can be purified by recrystallization from acetone-hexane.[3] The crude solid or solution obtained in the above preparations is typically used without further purification.

Handling, Storage, and Precautions: air and thermally sensitive; pyrophoric. Use in a fume hood.

Allylic Alkylation.

Treatment of allylic acetates or carbonates with various carbon nucleophiles in the presence of tris(acetonitrile)tricarbonyltungsten and bipyridyl leads to the allylic alkylation product (eqs 1 and 2).[1] Suitable nucleophiles include those derived from carbon acids having a pK_a < ~18. The reaction proceeds with retention of configuration (eq 1) and preferentially produces the allylic regioisomer, where nucleophilic attack occurs at the carbon best able to stabilize a positive charge. This is in contrast to palladium-catalyzed allylic alkylation, where the nucleophilic attack generally occurs preferentially at the less-substituted carbon of the allylic system.[4]

Tris(acetylacetonato)cobalt-Diethylaluminum Chloride-NORPHOS

($Co(acac)_3$)

[21679-46-9] · $C_{15}H_{21}CoO_6$ · Tris(acetylacetonato)cobalt-Diethylaluminum Chloride-NORPHOS · (MW 356.29) (Et_2AlCl)

[96-10-6] · $C_4H_{10}AlCl$ · Tris(acetylacetonato)cobalt-Diethylaluminum Chloride-NORPHOS · (MW 120.57) ((+)-NORPHOS)

[71042-54-1] · $C_{31}H_{28}P_2$ · Tris(acetylacetonato)cobalt-Diethylaluminum Chloride-NORPHOS · (MW 462.53)

(catalyst for the formation of optically active deltacyclene derivatives by homo Diels-Alder reaction of norbornadiene with substituted acetylenes[1,2])

Physical Data: see ***Diethylaluminum Chloride*** and ***(+)-trans-(2S,3S)-Bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene*** (NORPHOS).

Solubility: sol THF, benzene, toluene.

Preparative Methods: synthesized in situ from the three components, using a 1.5 excess of the chelate phosphine; the components are commercially available or can be easily prepared.

Handling, Storage, and Precautions: the in situ catalyst should be used in an atmosphere of dry nitrogen or argon, in a fume hood. The catalyst components can be stored indefinitely. They are air stable except Et_2AlCl, which should be kept under exclusion of air.

The Homo Diels-Alder Reaction of Norbornadiene with Acetylenes.

[2 + 2 + 2] Cycloadditions of dienes such as norbornadiene with the double bonds in 1,4-position are called homo Diels-Alder reactions. Using an in situ catalyst (consisting of $Co(acac)_3$-Et_2AlCl-bis(diphenylphosphino)ethane) the products obtained with monosubstituted acetylenes, such as phenyl, *i*-propyl-, *n*-butyl-, *t*-butyl-, and trimethylsilylacetylene, are 4-substituted deltacyclenes.[1,2] In the formation of the polycyclic deltacyclene skeleton, six new stereo centers are generated in one step. Thus enantiocontrol by using optically active phosphine ligands as cocatalysts allows the synthesis of optically active cycloadducts,[3-5] as shown for the reaction of norbornadiene with phenylacetylene to give 4-phenyldeltacyclene (eq 1).

Preparation of the in situ Catalyst and Catalytic Reaction.

(This is a typical procedure for norbornadiene and phenylacetylene or 1-hexyne). Tris(acetylacetonato)cobalt (7.1 mg, 2.0×10^{-2} mmol) and (+)-NORPHOS (13.8 mg, 3.0×10^{-2} mmol) are dissolved in 1 ml of THF under dry nitrogen, using standard Schlenk techniques. Norbornadiene (1.0 mL, 10.0 mmol) and 10 mmol of phenylacetylene or 1-hexyne are added. The reaction is started by addition of 5 mL of a 1M solution of diethylaluminum chloride in hexane. The reaction mixture is kept at 35 °C for 4 h. Then 5 mL of isopropanol are added and the volatile components are removed in vacuum. The oily residue is distilled at 80 °C in high vacuum in a Kugelrohr apparatus. Chemical yield >99%; enantiomeric excess 98.4-99.6% for (+)-4-phenyldeltacyclene and 97.6-98.0% for (+)-4-*n*-butyldeltacyclene.

Product Analysis.

The distilled product is dissolved in 2 mL of dry methylene chloride and an internal standard is added (naphthalene for 4-phenyldeltacyclene, biphenyl for 4-*n*-butyldeltacyclene). The chemical yield and the enantiomeric excess of the product can be determined by GLC using a 40 m column of perpentylated β-cyclodextrin. 4-Phenyldeltacyclene: column temperature 104 °C, retention time (-)-isomer 124.7 min, (+)-isomer 128.2 min; 4-*n*-butyldeltacyclene: column temperature 65 °C, retention time (-)-isomer 78.3 min, (+)-isomer 80.8 min.

Variation of the Optically Active Phosphine Ligand (Cocatalyst) and the Solvent.[5]

In the synthesis of 4-phenyldeltacyclene, (+)-NORPHOS as the optically active ligand and THF as the solvent gave the best results, as indicated in the typical procedure. Used in benzene, the NORPHOS-containing catalyst also gives extremely high enantioselectivities but low chemical yields. With PROPHOS as the ligand, quantitative conversion in THF is only achieved after long reaction times. The enantiomeric excess in this case was ca. 80%. CHIRAPHOS and BDPP as cocatalysts result in slow conversions of the starting materials, BDPP giving high optical yields. In the case of DIOP in benzene, only low chemical and optical yields are obtained. In THF, DIOP-containing catalysts are inactive, as are BINAP-containing catalysts in benzene/THF.

For 4-*n*-butyldeltacyclene, no other cocatalyst gives the quantitative yield and 98-99% enantiomeric excess observed in the NORPHOS-containing system. The PROPHOS system gives 80% enantiomeric excess.

Variation of the Procatalyst (Metal Component) and the Acetylenic Substrate.

The in situ catalysts $Co(acac)_3$-Et_2AlCl-phosphine have proven to be well-suited for the synthesis of 4-aryl- and 4-alkyl-substituted deltacyclenes. The catalysts tolerate remote oxygen functionalities in the acetylenic substrate.[4] However, they could not be used with functionalized acetylenes such as propargylic acid derivatives.

Recently, new procatalysts have been reported. They contain different cobalt sources and reducing agents. The procatalyst CoI_2-Zn has proven valuable in the preparative homo Diels-Alder reaction.[6] It has been shown that monodentate and bidentate ligands of the aminophosphine and phosphite type, e.g. ValNOP and ProliNOP, give high optical yields in the synthesis of 4-

phenyldeltacyclene and 4-*n*-butyldeltacyclene.[7] With these new procatalysts, an extension of the homo Diels-Alder reaction to functionalized acetylenes is possible. High chemical and optical yields are obtained in the reaction of norbornadiene with substrates such as propargylic and homopropargylic ethers and esters.[8]

Tris(acetylacetonato)indium[1]

[14405-45-9] · $C_{15}H_{21}InO_6$ · Tris(acetylacetonato)indium · (MW 412.18)

(mild Lewis acid used as a cocatalyst to effect carbonyl additions[2])

Physical Data: mp 186 °C; ^{1}H NMR ($CDCl_3$) δ 2.02 (C*H*$_3$), 5.41 (C*H*); *d* 1.41 g cm^{-3}.

Solubility: readily sol toluene; moderately sol ethanol; almost insol water.

Form Supplied in: white crystalline solid; readily available. *Drying:* the freshly prepared indium compound can be recrystallized from cold acetone as colorless crystals and sublimed at 260-280 °C.

Handling, Storage, and Precautions: the dry solid can be stored in air. In(acac)$_3$ has a reputed toxicity of LD$_{50}$: 79 mg kg^{-1} with TSCA HMIS: 2-1-0-X.

1,2 vs. 1,4 Cycloadditions.

While organoindium compounds have found recent synthetic applications for a number of organic transformations including allylations,[3] cyclopropanations,[4] Reformatsky,[5] and cross-coupling reactions,[6] catalysis using indium precursors has been relatively unexplored. A recent study has shown that $InCl_3$ can be employed as a cocatalyst along with ***Chlorotrimethylsilane*** for the conversion of *O*-trimethylsilyl monothioacetals to sulfides.[7] In a similar manner, In(acac)$_3$ has been used to control the chemoselectivity in the palladium-catalyzed cycloaddition of carbonyl compounds.[2] As expected, addition of trimethylenemethane to enones in the presence of a palladium catalyst affords the 1,4-adduct exclusively.[8] However, as little as 10 mol % of In(acac)$_3$ can be utilized as a cocatalyst to alter the reaction course from conjugate to 1,2-addition (eq 1). Increasing reaction temperatures by going from refluxing THF to dioxane increases the ratio of 1,2- vs. 1,4-addition products.

Exocyclic enone derivatives, which are particularily prone to conjugate addition, can be diverted from this pathway to give exclusive

formation of the corresponding 1,2-addition products by using an In^{III} cocatalyst (eq 2). Reactions with carbohydrates bearing several Lewis basic sites also proceed with good 1,2-selectivity and diastereoselectivity in the presence of $In(acac)_3$. Steric hindrance may inhibit 1,2-addition, however, as in the case of galactopyranose (eq 3) which gives predominant formation of the 1,4-adduct (1,2 vs. 1,4 = 1:4.2).

(2)

(3)

Finally, addition of trimethylenemethane to keto aldehydes affords the corresponding methylenetetrahydrofuran with enhanced diastereoselectivity (>19:1) when compared to reactions employing tin as a cocatalyst (eq 4).[9] This overall switch in chemoselectivity using indium complexes promises to be useful for a number of nucleophilic reactions.

Tris(acetylacetonato)iron(III)

[14024-18-1] · $C_{15}H_{21}FeO_6$ · Tris(acetylacetonato)iron(III) · (MW 353.21)

(organotransition metal catalyst used in the cross coupling of acid halides or vinyl bromides with Grignard reagents, the stereoselective epoxidation of steroidal alkenes, and the reductive decyanation of alkyl nitriles)

Alternate Names: ferric acetylacetonate; ferric triacetylacetonate; iron acetylacetonate.

Physical Data: mp 182-185 °C (191 °C by differential thermal analysis[1]).

Solubility: sol alcohols, chlorinated solvents.

Form Supplied in: deep red powder.

Analysis of Reagent Purity: CH analysis (calc 57.51% C, 5.96% H).[1]

Purification: recrystallization from ethanol[2] or methanol/H_2O.[1]

Handling, Storage, and Precautions: severe eye irritant and possible teratogen. Poor thermal stability in molten state.[1]

Preparation of Ketones from Acyl Chlorides and Grignard Reagents.[3]

The inclusion of a catalytic amount of $Fe(acac)_3$ in the coupling reaction of acid chlorides and Grignard reagents gives the desired ketones without the significant formation of carbinols which accompanies the reaction in its absence (eq 1).[4] The use of other organometallic reagents[5] in place of Grignard reagents has also effected the formation of ketones without the accompanying formation of secondary and/or tertiary alcohols; however, these reagents lack the generality and convenience shown with the $Fe(acac)_3$ catalyzed reaction (Table 1). The reaction was also extended to aromatic acid chlorides and thiophenyl acid chlorides, which were coupled with long-chain di-Grignard reagents to produce symmetrical 1,*n*-diketones (*n* &egt; 8) and long-chain dicarboxylic thiol esters in moderate to good yield.[6]

(1)

Preparation of Alkenes: Cross Coupling of Vinyl Bromides,[7] Vinyl Sulfones,[8] and Vinyl Sulfoximines[9] with Grignard Reagents.

Fe^{III} complexes containing β-diketonate ligands, such as $Fe(acac)_3$, are useful catalysts for the cross coupling of vinyl bromides with Grignard reagents (eq 2).[7] The coupling reactions with vinyl bromides proceed with primary, secondary, and tertiary Grignard reagents. It is proposed that $Fe(acac)_3$ is initially reduced by the Grignard reagent to form an active Fe^{I} or Fe^{0} catalyst,[10] which has been shown to undergo an irreversible deactivation during the course of the cross-coupling reaction. A similar reagent, ***Tris(dibenzoylmethide)iron(III)***, has been shown to be more resistant to this deactivation and is the preferred iron catalyst for this reaction.[7]

(2)

The cross coupling of Grignard reagents with vinyl sulfones in the presence of $Fe(acac)_3$ or ***Nickel(II) Acetylacetonate*** proceeds with some stereoselectivity; however, the reaction is complicated by reduction byproducts.[8] The stereoselective construction of exocyclic alkenes from the cross-coupling reaction of alkenylsulfoximines, prepared stereoselectively from the corresponding ketone, with Grignard reagents in the presence of stoichiometric amounts of $Fe(acac)_3$ and $NiCl_2$(dppp) has also been reported (eq 3).[9] This serves as a useful alternative to standard Wittig-type alkenations for the construction of exocyclic alkenes.[11]

R = TBDMS R' = Ph, 74%; (*E*):(*Z*) = 4:1
R' = *m*-$C_6H_4CH_2OSiR_3$, 75%; (*E*):(*Z*) = 3:1
R' = $(CH_2)_4OSiR_3$, 34%; (*E*):(*Z*) = 7:1

Epoxidation of Steroidal Alkenes.[12]

$Fe(acac)_3$ is used to catalyze the stereoselective β-epoxidation of cholesterol derivatives (allylic alcohols) with excess ***Hydrogen Peroxide*** in acetonitrile under mild conditions (eq 4). This shows opposite stereoselectivity to epoxidation reactions using conventional organic peracids, where shielding by the angular methyl groups prevents epoxidation on the β-face. This method offers similar stereoselectivity to halohydrin methodology,[13] but the reaction is effected in a single step. The observed stereoselectivity is independent of R, unlike other methodologies.

R = H, Ac

Preparation of *N*-Acylpiperidines: Ene Carbocyclization of Trienes.

The in situ generation of a (bipy)Fe^0L_n catalyst by the reaction of $Fe(acac)_3$ and ***Triethylaluminum*** is used to prepare cyclopentyl, cyclohexyl, and tetrahydropyranyl rings, as well as *N*-acylpiperidines by the formal [4 + 4] ene carbocyclization of trienes, triene ethers, and azatrienes (eq 5).[14]

X = CH_2, O, PhC(O)N

Miscellaneous Reactions.

Hydrocarbons are produced in good to excellent yield from alkyl nitriles upon treatment with $Fe(acac)_3$ and ***Sodium*** sand in benzene.[15] The best results for this reductive decyanation were obtained with saturated alkyl nitriles. Nontransition metal promoted cleavage of primary nitriles in liquid ammonia gives inferior results.[16] The Michael addition of ethyl acetoacetates to cyclic enones was catalyzed by $Fe(acac)_3$ and an electrophilic cocatalyst.[17] Other $M(acac)_n$ compounds were also examined.

Tris(4-bromophenyl)aminium Hexachloroantimonate[1]

[24964-91-8] · $C_{18}H_{12}Br_3Cl_6NSb$ · Tris(4-bromophenyl)aminium Hexachloroantimonate · (MW 816.46)

(a stable radical cation[2] and one-electron oxidant[2])

Physical Data: mp 142 °C.[2]

Solubility: sol acetonitrile, dichloromethane.

Form Supplied in: dark blue crystalline solid.

Purification: one method is as follows: a solution of the title reagent (**1**) in dichloromethane (1 part) is poured into diethyl ether (3 parts) to precipitate the salt; the resulting blue needles are collected and dried under vacuum.[2]

Handling, Storage, and Precautions: is an irritant and is moisture sensitive.

Protective Group Removal.

p-Methoxybenzyl protected alcohols can be deprotected with (**1**) to give the alcohol in excellent yield in moist acetonitrile. Benzyl ethers are not affected by this reagent but can be removed with the analogous tris(2,4-dibromophenyl)aminium hexachloroantimonate.[3,4] The conversion of thioacetals to the corresponding aldehyde or ketone is effected by (**1**) in acetonitrile containing aqueous sodium bicarbonate.[5]

Glycosidation.

Alkyl, aryl, or xanthate glycosides undergo glycosidation reactions with primary or secondary alcohols of *O*-glycosides to give β-*O*-linked disaccharides. This reaction is only observed when acetonitrile is used as solvent (eq 1).[6]

Diels-Alder and Cyclization Catalyst.

As a Diels-Alder catalyst, (**1**) has been shown to increase the rate of this reaction and give improved selectivities.[7] For example, the uncatalyzed Diels-Alder reaction of cyclohexadiene with tetramethylbutadiene proceeds in low yield at 200 °C. With a catalytic amount of (**1**) present the reaction proceeds at -25 °C with improved selectivity (eq 2).

Also, (**1**) has been found to be a good catalyst for single electron acceptors and shown to provide a highly selective route for cycloadditions of neutral or electron-rich acceptors to conjugated dienes (eq 3).[7,8]

Under anhydrous conditions the cyclization of vinylbiphenyls gives the corresponding fluorene (eq 4), but if a trace of water is added the expected electrocyclization product is formed in excellent yield.[9]

$R^1 = H$, $R^2 = Ph$ or $R^1 = R^2 = (CH_2)_n$; $n = 3$ or 4

Rearrangement of Vinylcyclopropanes.

These reactions are readily effected in acetonitrile to give cyclopentanes under mild conditions (eqs 5 and 6).[10]

(6)

Oxidation Reactions.

Epoxides are oxidatively rearranged to ketones or esters in dichloromethane by what is thought to be a radical-type mechanism. For example, tetraphenylethylene oxide is rearranged to 2,2,2-triphenylacetophenone,[11] and the adamantyl derived epoxide in eq 7 is rearranged in quantitative yields to either the corresponding ketone or ester, depending upon the reaction temperature.[11]

(7)

A similar reaction is observed with the epoxide of β-ionone, where a cyclohexane ring can be contracted to a cyclopentane (eq 8).[11]

(8)

β-Ionone also undergoes allylic oxidation to give the allylic alcohol with (**1**).[12] Ketones are oxidized by (**1**) to the α-hydroxy ketone and, at higher temperatures, the α-diketone.[13] When methanol is added to the solvent (acetonitrile), the α-methoxy ketone is formed.[14]

In conjunction with ***Selenium(IV) Oxide***, (**1**) epoxidizes alkenes and enol ethers;[15] in oxygen saturated solutions of dichloromethane, (**1**) can be used to make dioxetanes[16] from alkenes or enol ethers. The oxidation of 2-nitrophenylsulfenamide protected amines or amino acids to the corresponding sulfenimine is readily brought about by (**1**) in the presence of a base such as ***2,6-Lutidine*** (eq 9).[17] Other methods for this conversion have included electrochemical oxidation.

(9)

Other Reactions.

A stable adduct of (**1**) is formed in the presence of 2,3-diazabicyclo[2.2.2]oct-2-ene.[18] α,α-Dimesitylenol ethers undergo oxidative rearrangement to the monomesitylbenzofuran with (**1**),[19] and vinylferrocene undergoes dimerization upon treatment with (**1**).[20]

Tris(cyclopentadienyl)lanthanum-Sodium Hydride[1]

(Cp_3La)

[1272-23-7] · $C_{15}H_{15}La$ · Tris(cyclopentadienyl)lanthanum-Sodium Hydride · (MW 334.21) (NaH)

[7646-69-7] · HNa · Tris(cyclopentadienyl)lanthanum-Sodium Hydride · (MW 24.00)

(reducing agent for alkenes, organohalogen compounds, and organoheteroatom oxides; catalyst for hydrogenation and isomerization of alkenes)

Physical Data: Cp_3La: mp 395 °C (slight dec.). NaH: mp 800 °C (dec.).

Solubility: Cp_3La: sol THF; reacts with H_2O and protic solvents. NaH: slightly sol THF.

Form Supplied in: Cp_3La: white crystalline solid. NaH used as 80% dispersion in mineral oil.

Preparative Methods: because Cp_3La is sensitive to air and moisture, the preparative procedure and all subsequent operations on the compound must be carried out with Schlenk techniques under purified argon. The following procedure has proven efficacious: to a suspension of anhydrous ***Lanthanum(III) Chloride*** in THF was added 4-5 equiv of sodium cyclopentadienide in THF; the mixture was refluxed with stirring for 4 h; the solvent was removed under reduced pressure, and the dry residue was transferred to a sublimation apparatus; on heating at 250-260 °C/10^{-3}-10^{-4} mmHg, Cp_3La sublimed as a white crystalline solid. Alternatively, the residue can be recrystallized from THF to afford $Cp_3La(THF)$ as colorless crystals.

Handling, Storage, and Precautions: tris(cyclopentadienyl)lanthanum and ***Sodium Hydride*** must be used as prepared or purified, and sealed in glass ampules with argon or nitrogen for storage.

Reduction of Alkenes.

Tris(cyclopentadienyl)lanthanum and its analogs, combined with ***Sodium Hydride***, are effective reducing agents for C=C bonds,[2,3] aryl halides, vinyl halides[4,5] and certain organoheteroatom oxides.[6] Reduction of 1-hexene with Cp_3Ln/NaH (Ln = rare earth metal) in THF at 45 °C gives hexane (after hydrolysis). The reducing activity depends strongly upon the ionic radius of the trivalent ion. Generally, the activity decreases in the order: early rare

earths > mid rare earths > heavy rare earths. The reduction rate of internal C=C bonds is much slower than that of terminal ones. As a consequence, the Cp_3Ln/NaH system can be used to reduce terminal C=C bonds regioselectively (eq 1).

(1)

Reduction of Organohalogen Compounds.

Aryl and vinyl halides are stoichiometrically or catalytically reduced by Cp_3La/NaH systems and analogs in THF to afford the corresponding aromatics and alkenes, respectively, in excellent yields (eq 2).[4,5] The reductive activity of the light rare earth reagents is higher than that of heavy ones. The order of ease of reductive dehalogenation of aryl halides by the Cp_3La/NaH system is in agreement with that of the usual reductive dehalogenation of organic halides, i.e. I > Br > Cl > F. As a result, chemoselective reduction of *p*-bromochlorobenzene and *p*-chloroiodobenzene to chlorobenzene can be achieved. However, surprisingly, the reactivity pattern of alkyl halides with the Cp_3La/NaH system and analogs is quite different from that of aryl and vinyl halides. Treatment of alkyl halides with Cp_3La/NaH followed by hydrolysis does not generate the corresponding alkanes, but rather produces alkylated cyclopentadienes (eq 3).[5]

$$RX \xrightarrow[65\ ^\circ C]{Cp_3La,\ NaH,\ THF} RH \qquad (2)$$

R = aryl, vinyl; X = F, Cl, Br, I

(3)

R = alkyl; X = Cl, Br, I

Other Reductions.

Some organoheteroatom oxides such as triphenylarsine oxide, diphenyl sulfoxide and pyridine *N*-oxide are smoothly deoxygenated by the Cp_3La/NaH system and analogs in THF in good yields. The suitable molar ratio of reactants is 2:8:1 (Cp_3La/NaH/oxide). Although triphenylphosphine oxide is essentially inert to Cp_3Sm/NaH, the combination of Cp_3Sm and ***Lithium Aluminum Hydride*** facilitates its reduction to phosphine.[6]

Isomerization and Hydrogenation of Alkenes.

The Cp_3La/NaH system and analogs can catalyze isomerization of 1-alkenes to *cis*- and *trans*-2-alkenes in almost quantitative yields (eq 4).[2,7] The catalytic activity seems to be related to the ionic radius of the rare earth metal. In contrast to their reducing activity, the isomerization activity of late rare earth reagents is better than that of early ones.

It is worth noting that these systems can also catalyze the isomerization of sulfur-containing alkenes such as $PhSCH_2CH{=}CH_2$,[8] while most transition metal catalysts would be deactivated by sulfur compounds. These systems are also effective for the catalytic hydrogenation of alkenes. 1-Hexene was completely converted into hexane under 4 atm pressure of hydrogen in the course of 2 days.[2]

Tris(dibenzoylmethide)iron(III)

[14405-49-3] · $C_{45}H_{33}FeO_6$ · Tris(dibenzoylmethide)iron(III) · (MW 725.63)

(Fe^{III} complex containing β-diketonate ligands serves as catalyst precursor for the cross coupling of Grignard reagents with vinyl bromide[1] and for the intramolecular alkylation of ketones to give bicyclic alcohols[2])

Alternate Name: tris(dibenzoylmethanato)iron.

Physical Data: mp 240 °C (dec).

Solubility: insol hexane; sol benzene; slightly sol alcohol.

Form Supplied in: red powder.

Analysis of Reagent Purity: visible spectrum 408, 500 (sh) nm.

Preparative Methods: ***Iron(III) Chloride*** and excess dibenzoylmethane in ethanol give a red solid; add 50% aq. ammonia; filter the red solid, wash with water, and dry.

Purification: precipitate from hot benzene by addition of hot hexanes.

Handling, Storage, and Precautions: store tightly sealed in a cool, dry place.

Preparation of Alkenes.

Cross Coupling of Vinyl Bromides with Grignard Reagents.[1,3]

Tris(dibenzoylmethide)iron(III), $Fe(dbm)_3$, is an effective catalyst in the stereospecific cross coupling of vinyl bromides with primary, secondary, and tertiary Grignard reagents (eq 1 and Table 1). Improved yields were observed when dimethoxyethane replaced THF as the solvent and lower reaction temperatures were employed.[1b] The cross coupling of vinyl sulfones with Grignard reagents was also successfully accomplished in the presence of $Fe(dbm)_3$.[1c,d]

(1)

Table 1 Cross Coupling of Vinyl Bromides with Grignard Reagents (eq 1)

R	R¢	Conditions	Yield (%)
Et	Me	THF, 25 °C	58[1a]
Ph	Ph	THF, 25 °C	32[1a]
Et	Ph	THF, 25 °C	59[1a]
i-Pr	Me	THF, 25 °C	60[1a]
Cy	Me	THF, 25 °C	54[1a]
t-Bu	Me	THF, 25 °C	27[1a]
Ph	Ph	DME, - 20 °C to rt	90[1b]
Me	SPh	THF, - 78 °C to rt	75[1c]
H	SPh	THF, - 78 °C to rt	60[1c]

The superior performance compared to other Fe^{III} catalysts has been attributed to its resistance to deactivation.[1a] It is superior to other organometallic catalysts, particularly Ni, because it is used at lower concentrations and temperatures and isomerization of the Grignard reagent does not occur.[3] In general, Fe^{III} catalysts are proposed to be readily reduced to Fe^{I} or Fe^{0} species, which serve as the active catalyst in the cross coupling reactions.[3]

Preparation of Bicycloalkanols.

Intramolecular Barbier-type reactions[2] using magnesium have typically failed when used to construct six-membered cycloalkanols.[6] $Fe(dbm)_3$ used in combination with lanthanide reducing reagents, namely ***Samarium(II) Iodide***, has been shown to overcome this shortcoming. The reaction was shown to be quite stereoselective when $n = 1$ ($m = 1$ or 2), but gives poor stereoselectivity when $n > 1$ (eq 2 and Table 2).

(2)

Table 2 Preparation of Bicycloalkanols using Lanthanide Reagents and Catalytic $Fe(dbm)_3$ (eq 2)[2a]

n	*m*	% GC yield (isolated)	*cis*:*trans* ratio (GC)
1	1	90 (60)	>99.5:<0.5
2	1	100 (75)	1.3:1
3	1	85 (77)	2:1
1	2	67	18:1
2	2	96 (75)	1:1.5

Indeed, numerous other organometallic reagents have been utilized to construct the desired bicycloalkanols (*m* = 0-2), including Pd,[7] Ni,[8] and other alkali metals.[9] The Barbier-type reaction with SmI_2 has also proved to be quite general for the efficient, simple construction of a variety of complex, bicyclic ring systems including bridgehead, bicyclic alcohols (eqs 3-5).[2b]

Tris(dibenzylideneacetone)dipalladium-Chloroform

$$(PhCH{=}CHCOCH{=}CHPh)_3Pd_2 \cdot CHCl_3$$

[52522-40-4] · $C_{52}H_{43}Cl_3O_3Pd_2$ · Tris(dibenzylideneacetone)dipalladium · (MW 1035.14)

(air-stable Pd^0 complex used directly as homogeneous Pd^0 catalyst with or without ligand)

Physical Data: mp 122-124 °C (dec),[1] 131-135 °C.[2]

Solubility: insol H_2O; sol chloroform, benzene.

Form Supplied in: deep purple needle-like crystals; commercially available.

Preparative Methods: the reaction of $Na_2[Pd_2Cl_6]$ (from ***Palladium(II) Chloride*** and NaCl) and dibenzylideneacetone (dba) gives ***Bis(dibenzylideneacetone)palladium(0)***, $[Pd(dba)_2]$, which is formulated more correctly as $[Pd_2(dba)_3]dba$.[1,3] Recrystallization from chloroform displaces the uncoordinating dba with chloroform to give the title reagent as deep purple needles.[1]

Sources of Palladium(0).

Many reactions are catalyzed by Pd^0 catalysts.[4] The Pd^0 catalysts are prepared in two ways. One common method for generation of Pd^0 species involves in situ reduction of Pd^{II} salts, most conveniently ***Palladium(II) Acetate***. An alternative involves the use of air-stable, commercially available $Pd_2(dba)_3$ as a Pd^0 catalyst with or without added phosphine. The dba ligand is displaced by the addition of phosphine ligands (eq 1). Some reactions catalyzed with and without added phosphine ligands are described below.

$$Pd_2(dba)_3 + 4\,Ph_3P \longrightarrow 2\,Pd(PPh_3)_2 + 3\,dba \qquad (1)$$

Ene Reactions.

An intramolecular palladium-ene reaction that proceeds smoothly using $Pd_2(dba)_3$ in the presence of ***Triphenylphosphine*** is shown in eq 2.[5]

(2)

Allylation Reactions.

Silyl enol ethers react with allylic carbonates using $Pd_2(dba)_3$ and dppe (***1,2-Bis(diphenylphosphino)ethane***), yielding the allylated ketones under neutral conditions (eq 3).[6]

(3)

Heck Cyclizations.

Sometimes good or different results are obtained when the title reagent is used without added phosphine ligands. Dibenzylideneacetone itself is a good ligand which effects the catalytic activity of the Pd^0 differently than phosphines. The following Pd^0-catalyzed intramolecular cyclization catalyzed by $Pd_2(dba)_3$ without added phosphine ligand is more selective than in the presence of the ligand (eq 4). The cyclization under the ligandless conditions affords (**1**) and (**2**) in ratios as high as 9:1. In addition, the cyclization conducted without phosphine ligands in the presence of Ag salts occurs with virtually complete selectivity to give (**2**).[7]

(4)

$Pd_2(dba)_3$, Et_3N, toluene, 110 °C	89:11	80%
$Pd_2(dba)_3$, Ag_3PO_4, THF, 66 °C	3:97	77%
$Pd(Ph_3P)_4$, Et_3N, MeCN, 82 °C	60:40	66%

Coupling of Enol Triflates with Organotin Reagents.

Coupling of an enol triflate with (*Z*)-1-propenyltri-*n*-butyltin proceeds smoothly using $Pd_2(dba)_3$ as a catalyst in the absence of a phosphine ligand (eq 5).[8]

Comparison of the Catalytic Activity of $Pd_2(dba)_3$ in the Presence and Absence of a Ligand.

$Pd_2(dba)_3$ is a good catalyst, but it is not always as good as other Pd^0 catalysts. When Pd^0-catalyzed reactions of congested molecules are carried out, use of $Pd_2(dba)_3$ is not recommended. For example, in the elimination reaction of a steroidal α-allylic carbonate, the ligand-free catalyst prepared from $Pd(OAc)_2/Bu_3P$ (1:1) gives the homoannular conjugated diene regioselectively.[9] No regioselectivity is observed with the $Pd_2(dba)_3/Bu_3P$ catalyst (eq 6). Also, $Pd_2(dba)_3/Bu_3P$ is less active than $Pd(OAc)_2/Bu_3P$ in a provitamin D synthesis proceeding by the same elimination reaction of the cyclic allylic carbonates.[10]

Tris(dimethylamino)sulfonium Difluorotrimethylsilicate[1]

$(R_2N)_3S^+Me_3SiF_2^-$

(R = Me)

[59218-87-0] · $C_9H_{27}F_2N_3SSi$ · Tris(dimethylamino)sulfonium Difluorotrimethylsilicate · (MW 275.55) (R = Et)

[59201-86-4] · $C_{15}H_{39}F_2N_3SSi$ · Tris(diethylamino)sulfonium Difluorotrimethylsilicate · (MW 359.73)

(anhydrous fluoride ion source; synthesis of C-F compounds by nucleophilic displacement of sulfonates;[3] promoter for electrophilic reactions of silyl enolates of ketones and esters;[4-6] source of sulfonium cation capable of stabilizing or imparting high nucleophilic reactivity to other anions;[4,6,8a,10a] activator of vinylsilanes in Pd-catalyzed cross-coupling reactions;[7] also used for generation[8] and reactions[10] of α- and β-halo carbanions; hydrosilylation[11] and cyanomethylation[14] of ketones)

Alternate Name: TASF.

Physical Data: R = Me, mp 98-101 °C; R = Et, mp 90-95 °C.

Solubility: R = Me, sol MeCN, pyridine, benzonitrile; partially sol THF. R = Et, sol THF, MeCN. Both react slowly with MeCN.

Form Supplied in: R = Me, white crystalline solid, ~90% pure; major impurity is tris(dimethylamino)sulfonium bifluoride [$(Me_2N)_3S^+ HF_2^-$].

Analysis of Reagent Purity: mp; ^{19}F NMR δ (at 200 MHz, $CFCl_3$ standard) $TASMe_3SiF_2$ (CD_3CN) δ -60.3; $TASHF_2$ -145.8 (d, J_{HF} = 120 Hz).

Preparative Methods: the methyl derivative is prepared by the reaction of dimethylaminotrimethylsilane and ***Sulfur Tetrafluoride*** at -70 °C to rt in ether; the precipitated solid is filtered off.[1a] The ethyl derivative is best prepared by the reaction of ***N,N-Diethylaminosulfur Trifluoride*** (DAST) and diethylaminotrimethylsilane.[1b,11b]

Handling, Storage, and Precautions: because of the extreme hygroscopic nature of this compound, it is best handled in a dry box or a polyethylene glove bag filled with high purity nitrogen. Use in a fume hood.

Introduction.

The acronym TASF has been used to refer to both $(Me_2N)_3S^+F_2Me_3Si^-$ and $(Et_2N)_3S^+F_2Me_3Si^-$. To eliminate confusion, the sulfonium salt containing dimethylamino groups is referred to as TASF(Me), and the sulfonium salt containing diethylamino groups is referred to as TASF(Et). Reactions of both reagents are similar. Since both of these salts can be prepared in a rigorously anhydrous state, they have an advantage over quaternary ammonium fluorides which usually contain some water. TASF(Me) has a slight advantage over TASF(Et) in that it is highly crystalline and easier to prepare in a high state of purity, whereas TASF(Et) has an advantage over TASF(Me) in that it has greater solubility in organic solvents. The tris(dialkylamino)sulfonium cation is often referred to by the acronym TAS.

TASF is a source of organic soluble fluoride ion[2] with a bulky noncoordinating counter ion (eq 1).[9]

$$TAS^+ Me_3SiF_2^- \rightleftharpoons Me_3SiF + TAS^+ + F^- \qquad (1)$$

Fluoride Ion Source in Nucleophilic Displacements.

TASF(Me) can be used to prepare fluorides from halides[1b] and sulfonates[3] under relatively mild conditions (eq 2).

Generation of Enolates and Enolate Surrogates from Enol Silanes.

Enol silanes react with TASF(Et) to give highly reactive naked enolates which have been characterized by NMR and electrochemical measurements.[4] These enolates, generated in situ, can be regioselectively alkylated without complications from polyalkylation or rearrangements of the alkylating agent (eq 3).

In the presence of excess ***Fluorotrimethylsilane***, TASF(Et) catalyzes aldol reactions of silyl enol ethers and aldehydes.[4] The stereochemical course of the reaction (*syn* selectivity, independent of the enol geometry, (*Z*)- or (*E*)-(**1**), eq 4), has been interpreted as arising from an extended transition state in which steric and charge repulsions are minimized.

Very potent carbon nucleophiles formally equivalent to ester enolates are generated by the interaction of TASF(Me) with unhindered trialkylsilyl ketene acetals. In contrast to lithium enolates, these TAS enolates add 1,4 (nonstereoselectively) to α,β-unsaturated ketones. These adducts can be alkylated in situ to form two new C-C bonds in one pot, or they can be hydrolyzed to give 1,5-dicarbonyl compounds (eq 5).[5a]

Conjugated esters undergo sequential additions to form polymers (group transfer polymerization).[5b] The molecular weight and the end group functionality of the polymer can be controlled by this method. Mechanistic studies indicate an associative intramolecular silicon transfer process via (**2**), with concomitant C-C bond formation during the polymer growth (eq 6).

Silyl enol ethers and ketene silyl acetals add to aromatic nitro compounds in the presence of TASF(Me) to give intermediate dihydro aromatic nitronates which can be oxidized with ***Bromine*** or ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** to give α-nitroaryl carbonyl compounds;[6a] the latter are precursors for indoles and oxindoles.[6b] The reaction is widely applicable to alkyl-, halo-, and alkoxy-substituted

aromatic nitro compounds, including heterocyclic and polynuclear derivatives (eq 7).

(7)

Cross-Coupling Reactions.

TASF(Et) activates vinyl-, alkynyl-, and allylsilanes in the Pd-mediated cross-coupling with vinyl and aryl iodides and bromides.[7] As illustrated in eqs 8-10, the reaction is stereospecific and chemoselective. This cross-coupling protocol is remarkably tolerant towards a variety of other functional groups such as carbonyl, amino, hydroxy, and nitro. Vinylsilanes can be synthesized from ***Hexamethyldisilane*** and vinyl iodides in the presence of TASF(Et) (eq 10) via cleavage of a Si-Si bond.[7a] Aryl iodides can also be synthesized by this method. TASF is superior to ***Tetra-n-butylammonium Fluoride*** for these reactions. In the absence of a vinylsilane reagent, one of the methyl groups from the difluorotrimethylsilicate is substituted for the halide (eq 11).[7d]

(8)

(9)

(10)

(11)

Generation and Reactions of Unusual Carbanions.

Both α- and β-halo carbanions are generally labile species and their generation and reactions require extremely low temperatures. TASF(Me) has been used to prepare several stable and isolable perfluorinated carbanions (eq 12)[8a] or alkoxides.[8b] As compared to the corresponding metal salts, the TAS^+ counterion has little coordination to the fluorines of the anion,[9] and this presumably slows the decomposition of the TAS salts to carbenoids or alkenes. Addition of α- and β-halo carbanions to carbonyl compounds may be achieved by the in situ generation of these species by the reaction of TASF(Et) with the corresponding silylated derivatives (eq 13).[10]

(12)

(13)

Other Applications.

TASF(Et) catalyzes the addition of ***Dimethyl(phenyl)silane*** to α-alkoxy, -acyl or -amido ketones to give the corresponding *anti* aldols (eq 14).[11] This complements the acid-catalyzed reduction which gives the *syn* isomer.

Dimethyl(phenyl)silane will reduce aldehydes and ketones to hydroxyl compounds under very mild conditions in the presence of a catalytic amount of TASF(Et).[11c]

Aryl or vinyl anions can be generated by the reaction of the corresponding vinyl iodide with Bu_3Sn anion, which in turn is produced from TASF(Et) and $Bu_3SnSiMe_3$. With an appropriately placed carbonyl group, an intramolecular cyclization ensues (eq 15).[12]

A useful variation of the Peterson alkenation relies on the generation of α-silyl carbanions from geminal disilyl compounds containing an additional stabilizing group (CO_2R, SPh, SO_2Ph, OMe, CN, Ph) at the α-carbon.[13] A related reaction is the cyanomethylation of ketones and aldehydes with ***Trimethylsilylacetonitrile*** in the presence of TASF(Me).[14] TASF(Me) was found to be the best fluoride ion source for the synthesis of aryl trifluoromethyl sulfones from the corresponding sulfonyl fluorides and ***Trifluoromethyltrimethylsilane*** or Me_3SnCF_3 (eq 16).[15]

The carbanions formed by scission of a C-Si bond with TASF can also be oxygenated. Benzylic trimethylsilyl groups can be converted to hydroxyl groups in 20-95% yield by reaction with TASF(Me) in the presence of oxygen and ***Trimethyl Phosphite*** (eq 17).[16] No other source of fluoride ion was found that could replace TASF.

Tris(dimethylamino)borane[1]

$B(NMe_2)_3$

[4375-83-1] · $C_6H_{18}BN_3$ · Tris(dimethylamino)borane · (MW 143.08)

(macrolactamization reagent;[4] selective monoalkylation of tetraaza macrocycles;[5] amide and enamine formation[7])

Physical Data: mp -10 °C; bp 147-148 °C; *d* 0.817 g cm^{-3}.

Solubility: sol most aprotic organic solvents; reacts readily with water and alcohols.

Form Supplied in: colorless liquid, commercially available.

Handling, Storage, and Precautions: air and moisture sensitive. Handle and store under nitrogen, use in a fume hood.

Tris(dimethylamino)borane undergoes facile transamination reactions with primary and secondary amines to give higher homologs of tris(alkylamino)boranes.[2] Reaction with triamines, such as 3,3´-diaminodipropylamine, affords unique heterocyclic aminoboranes (eq 1).[3]

(1)

An elegant application of this reaction has been found in the synthesis of macrocyclic spermidine alkaloids. The key step in the synthesis involves a $B(NMe_2)_3$-mediated macrolactamization reaction of triamino ester (**1**) (eq 2). The reaction is carried out with $B(NMe_2)_3$ in refluxing xylene and directly affords the macrolactam (**3**) in high yield.[4] The reaction is believed to proceed via the intermediate (**2**), which allows for a boron-templated cyclization. The scope of this macrolactamization reaction is limited to triamino ester precursors. Attempted cyclization of the corresponding o-monoamino esters failed to give any lactam.

A related application of $B(NMe_2)_3$ has been utilized in the synthesis of monoalkylated derivatives of tetraaza macrocycles.[5] Reaction of $B(NMe_2)_3$ with a tetraaza macrocycle affords a polycyclic aminoborane[6] which incorporates three out of the four nitrogen atoms, thus allowing for selective monoalkylation of the single unprotected nitrogen (eq 3).

Amidation Reactions with $B(NMe_2)_3$ and Higher Homologs.

Tris(dialkylamino)boranes react readily with carboxylic acids to give amides.[7] This reaction, however, has not been widely used in recent years. The reaction is typically carried out in benzene, in the absence of any catalyst, and one molar equivalent of the boron reagent is required for complete reaction.[8] Similarly, reaction with 1,3-diketones gives enamino ketones (eq 4).[7] When the 1,3-diketone is unsymmetrical, then the least-hindered ketone is attacked selectively. Reaction with ketones to give enamines is rather slow; however, in the presence of an acid catalyst, high yields are possible.[7]

Tris(dimethylamino)methane[1]

$(Me_2N)_3CH$

[5762-56-1] · $C_7H_{19}N_3$ · Tris(dimethylamino)methane · (MW 145.29)

(reactive aminomethylenating reagent (formylating reagent) for CH_2- and NH_2-acidic compounds; can serve as a source for bis(dimethylamino)carbene)

Alternate Names: TDAM; *N,N,N´,N´,N´´,N´´*-hexamethylmethanetriamine.

Physical Data: bp 42-43 °C/12 mmHg; *n*20D = 1.4360.

Solubility: miscible with nonpolar aprotic, water-free solvents; reacts with protic solvents such as water, alcohols, and even aprotic, weak CH-acidic solvents such as acetone and acetonitrile on heating.

Form Supplied in: colorless to light yellow liquid; strong amine smell.

Analysis of Reagent Purity: ^{1}H NMR spectrum of a neat sample.

Preparative Methods: can be prepared by reaction of lithium dimethylamide with either *N,N,N´,N´*-tetramethylformamidinium salts[2] or bis(dimethylamino)acetonitrile (eqs 1 and 2).[3] The lithium dimethylamide solution can be prepared from lithium, dimethylamine, and naphthalene in dry THF.[4] Lithium dimethylamide can be replaced by sodium dimethylamide,[2] which is accessible in situ from ***Sodium Hydride***, dimethylamine, and catalytic amounts (~20%) of ***Trimethyl Borate***.[5]

In the reaction of tetramethylformamidinium chloride with triphenylphosphonium ylides, TDAM is formed as a byproduct.[6] TDAM is also obtained as a byproduct in the synthesis of alkanethiobis(dimethylamino)methanes from sodium alkanethiolates and *N,N,N´,N´*-tetramethylformamidinium methylsulfate or from aminal esters and alkanethiols by disproportionation of the primary products.[7] ***Triethyl Orthoformate*** reacts with lithium dimethylamide (prepared in situ from lithium and dimethylamine) in HMPA to give TDAM.[8] In an equilibrium reaction, DMF acetals react with dimethylamine to give TDAM.[9] This reaction can be used on a preparative scale, if the dimethylamine is introduced at about 100 °C in the presence of 2,4,6-trimethylphenol as catalyst.[10] The transamination of bis(dimethylamino)alkoxymethanes with excess dimethylamine affords TDAM.[11] TDAM is produced in good yields in the reaction of tetrakis(dimethylamino)titanium with ***N,N-Dimethylformamide*** in ether (eq 3).[12]

Good yields of TDAM can be obtained by reduction of *N,N,N´,N´,N´´,N´´*-hexamethylguanidinium chloride with a mixture of sodium hydride and ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (75%)[13] or by a mixture of sodium hydride and trimethyl borate (eq 4).[5]

Handling, Storage, and Precautions: should be handled and used with strict exclusion of atmospheric moisture. The product should be stored in a tightly sealed container under a dry nitrogen or argon atmosphere in a refrigerator or freezer. Use in a fume hood.

General Considerations.

Conductivity measurements[4] demonstrate that tris(dimethylamino)methane dissociates into dimethylamide anions and *N,N,N´,N´*-tetramethylformamidinium cations (eq 5). This equilibrium enables an understanding of the important reactions of TDAM. Thus XH_2-acidic compounds are deprotonated by the reagent; if the anions thus formed are small and relatively unstabilized, they combine with formamidinium ions to give adducts which eliminate dimethylamine to form a dimethylaminomethylene group. This mechanism has been confirmed by ^{1}H NMR investigations.[14] If the first step involves large, well-stabilized anions, the reaction stops at the stage of ion pairs.

Reactions.

Even weak CH-acidic compounds such as ketones,[15-22] nitriles and dinitriles,[21,23] lactones,[24-29] 2- or 4-nitro-1-alkylbenzenes,[21,30,31] fluorene and xanthene,[14] 4-methylpyridine,[21] lactams,[15] *N*-substituted α-amino esters,[32] and methylenediphosphonates[33] react according to this scheme. The condensation products contain a masked aldehyde function and are frequently used as difunctional intermediates. Two applications are photooxidation to α-dicarbonyl compounds[15,25,28] and condensation with suitable difunctional compounds to form heterocyclic rings, including pyrimidines,[16-18,26] pyrazoles,[17,19] isoxazoles,[20] 1,4-dihydropyridines,[32] and indoles.[30,31] Eqs 6-11 show some examples.

(11)

If elevated temperatures are required for reactions, it should be noted that tris(dimethylamino)methane decomposes to tetrakis(dimethylamino)ethylene at 150-190 °C (eq 12).[34]

(12)

Tertiary XH-acidic compounds, such as phenylacetylene[35] and α-diazo carbonal compounds[36] undergo bis(dimethylamino)methylation with this reagent, whereas α,α-disubstituted aldehydes are converted to enamines (eqs 13-15).[37]

(14)

$R = CO_2R^1$, CONMePh, COMe, $PO(OR^1)_2$

(15)

Reaction with ***Pentacarbonyliron*** affords a carbamoyltetracarbonyliron anion complex (eq 16).[38,39]

(16)

Tris(dimethylamino)methane can also serve as a strong base in deprotonation of organic compounds.[40,41] The anions thus formed can be used in further reactions (e.g. eq 17).[41]

(17)

In the rhodium-catalyzed reaction of TDAM with CO and a silyl hydride, a substituted 1,2-diamino-3-silyloxypropane derivative is formed (eq 18).[42]

(18)

Prolonged heating of selenium and TDAM affords *N,N,N´,N´*-tetramethylselenourea;[43] bis(dimethylamino)carbene (or an equivalent species) may be an intermediate in this reaction (eq 19).

(19)

Related Reagents.

t-Butoxybis(dimethylamino)methane; ***N,N-Dimethylformamide***; ***N,N-Dimethylformamide Diethyl Acetal***; ***Tris(formylamino)methane***.

Tris(dimethylamino)phosphine-Carbon Tetrachloride[1]

$(Me_2N)_3P$-CCl_4

($(Me_2N)_3P$)

[1608-26-0] · $C_6H_{18}N_3P$ · Tris(dimethylamino)phosphine-Carbon Tetrachloride · (MW 163.24) (CCl_4)

[56-23-5] · CCl_4 · Tris(dimethylamino)phosphine-Carbon Tetrachloride · (MW 153.81)

(reagent combination for the conversion of hydroxyl groups to the corresponding chlorides; hydroxyl group activation; dehydrations)

Alternate Name: hexamethylphosphorous triamide-carbon tetrachloride.

Physical Data: $(Me_2N)_3P$: bp 55-58 °C/15 mmHg; *d* 0.898 g cm^{-3}. CCl_4: mp -23 °C; bp 77 °C; *d* 1.594 g cm^{-3}.

Solubility: sol CCl_4, MeCN, CH_2Cl_2, THF.

Preparative Methods: reactive species is generated in situ by reaction of $(Me_2N)_3P$ and CCl_4.

Handling, Storage, and Precautions: $(Me_2N)_3P$ is an irritant and is flammable. It is best kept under a nitrogen atmosphere. CCl_4 is toxic and a cancer suspect agent. All solvents used must be carefully dried because the intermediates are all susceptible to hydrolysis. The hexamethylphosphoramide produced as a byproduct is a cancer suspect agent. This reagent should be handled in a fume hood.

General Considerations.

The use of ***Hexamethylphosphorous Triamide*** in place of ***Triphenylphosphine*** in the phosphine-carbon tetrachloride reaction has a number of advantages. The separation of the triphenylphosphine oxide from the product can sometimes be problematic. The byproduct of the hexamethylphosphorous triamide reaction, ***Hexamethylphosphoric Triamide***, is water soluble which allows for simple separation from the desired product. The aminophosphine is more nucleophilic, resulting in milder reaction conditions. Also, the alkoxyphosphonium intermediates can sometimes be isolated.[1]

Activation of Hydroxyl Groups.

The combination of hexamethylphosphorous triamide and CCl_4 with an alcohol is a very effective method for the activation of the hydroxyl group for displacement by a variety of nucleophiles. In the absence of any external nucleophiles, the chloride ion formed in the reaction will react with the intermediate alkoxyphosphonium ion to produce the alkyl chloride (eq 1).[2]

(1)

Other nucleophiles are capable of effectively competing with chloride ion for the alkoxyphosphonium ion. If ***Sodium Azide***, ***Potassium Iodide***, or ***Potassium Cyanide*** is added to the reaction mixture, the corresponding azide, iodide, or nitrile will be formed in good yield (eq 2).[3]

(2)

$X^- = N_3^-$, 75%; I^-, 80%; CN^-, 75%

Sometimes it is advantageous to replace the chloride counterion with less nucleophilic counterions such as BF_4^-,[4] ClO_4^-,[5] or PF_6^-.[6] This technique sometimes allows the alkoxyphosphonium salts to be isolated as stable crystalline solids (eq 3).[5] Weaker nucleophiles, such as amines (eq 4), can then be used to displace the alkoxyphosphonium ion.[5]

(3)

(4)

Deoxygenations.

The removal of oxygen functionality can be achieved via activation of hydroxyl groups with this reagent. The reduction of the alkoxyphosphonium ion by ***Lithium Triethylborohydride*** provides a route to deoxy sugars (eq 5).[7]

(5)

The preparation of glycals from lactols can be achieved by initial activation of the anomeric hydroxyl and subsequent Li/NH_3 reduction (eq 6).[8]

(6)

Anomeric Hydroxyl Activation.

Anomeric hydroxyl group activation can be utilized to prepare a number of glycosyl derivatives. Activation followed by reaction with ***Mesityloxytris(dimethylamino)phosphonium Azide*** affords glycosyl azides (eq 7).[9]

For the preparation of disaccharides, the intermediate alkoxyphosphonium ions are reacted with ***Silver(I) p-Toluenesulfonate*** prior to the addition of the second sugar (eq 8).[10]

Dehydrations.

The reaction of 1,2-diols with this reagent combination can lead to the formation of epoxides (eq 9) or spirophosphoranes (eq 10). The course of the reaction is dependent on the stereochemistry of the starting diol. The reaction of *meso*-hydrobenzoin affords the epoxide while the *threo* stereoisomer provides the spirophosphorane. The *trans*-diol of cyclohexane was unaffected.[11]

The selective monofunctionalization of a 1,3-diol is possible. Following activation, the monoalkoxyphosphonium ion can be displaced with

various nucleophiles such as iodide or azide (eq 11).[12] Alternatively, if the alkoxyphosphonium ion was reacted with base, the oxetane was formed (eq 12).[13]

(11)

(12)

Dichloroalkenes.

Aldehydes and the intermediate trichloromethylcarbinols can be converted to dichloroalkenes.[14] Even certain γ-lactones will undergo this transformation. Treatment of the γ-lactone (eq 13) with hexamethylphosphorous triamide produced the dichloroalkene in 79% yield. The use of Ph_3P was ineffective for this transformation. Attempts to use CBr_4 in place of CCl_4 resulted in the formation of complex mixtures.[14]

Tris(2,2-dimethylpropyl)(2,2-dimethylpropylidene)tantalum

$Me_3CCH{=}Ta(CH_2CMe_3)_3$

[54294-45-0] · $C_{20}H_{43}Ta$ · Tris(2,2-dimethylpropyl)(2,2-dimethylpropylidene)tantalum · (MW 464.58)

(converts a carbonyl group into a neopentylidene group[1])

Physical Data: mp 71 °C.

Solubility: sol diethyl ether, hydrocarbon solvents.

Form Supplied in: not commercially available.

Preparative Methods: prepared in a two-step procedure from tantalum pentachloride.[2] First, tris(2,2-dimethylpropyl)tantalum dichloride is prepared from the reaction of tantalum pentachloride and 3 equiv of 2,2-dimethylpropyllithium. Treatment of tris(2,2-dimethylpropyl)tantalum dichloride with 2 equiv of 2,2-dimethylpropyllithium affords tris(2,2-dimethylpropyl)(2,2-dimethylpropylidene)tantalum.

Purification: recrystallized from pentane at -30 °C.

Handling, Storage, and Precautions: air and moisture sensitive.

Carbonyl Alkenation.

Treatment of carbonyl compounds with the title reagent (**1**) affords the carbonyl alkenation product.[1] In the reaction of ketones and aldehydes with (**1**), the reagent functions as a Wittig substitute (eq 1). Unlike the Wittig reaction, the carbonyl alkenation reaction also proceeds for esters (eq 2) and amides (eq 3), affording enol ethers and enamines, respectively. Reaction with carbon dioxide affords the symmetrical allene (eq 4). Only the neopentylidene unit can be transferred using the tantalum chemistry; however, the work by Schrock[1] has led to the discovery of similar reagents (Schrock carbene complexes) capable of transferring a variety of organic groups.[3]

(1)

(2)

(3)

(4)

Enolate Formation.

Treatment of acid chlorides with (**1**) provides the tantalum enolate rather than the vinylic chloride (eq 5).[2] A similar reaction pathway is observed with phenyl esters. In this case, a similar type of product would be predicted from the analogous Wittig reaction.

Tris(ethylthio)borane[1]

$(EtS)_3B$

[998-26-5] · $C_6H_{15}BS_3$ · Tris(ethylthio)borane · (MW 194.23)

(used as an ethanethiol donor)

Physical Data: bp 78-81.5 °C/1.3 mmHg; *d* 1.0191 g cm^{-3}.

Preparative Methods: by reaction of bis(ethylthio)lead with boron trichloride[1,2] or sulfurated borohydride with ethanethiol.[3]

Handling, Storage, and Precautions: store and use in the absence of moisture.

General Discussion.

Like other thioboranes, tris(ethylthio)borane is a reactive intermediate for the synthesis of organic sulfur compounds, relying on the extreme lability of the B-S bond. The major application of tris(ethylthio)borane is as an alternative to ***Ethanethiol***; it is readily available and more easily handled than ethanethiol.

Tris(ethylthio)borane converts both aromatic and aliphatic carboxylic acids to the corresponding ethyl thioesters (eq 1).[2,4]

(1)

It has been shown that ketones and aldehydes are transformed to thioacetals by reaction with tris(ethylthio)borane. In contrast to the usual procedure for the formation of thioacetals, this reaction proceeds smoothly in neutral medium at ambient temperature (eq 2). The driving force is believed to be the formation of the strong B-O bond.[5]

(2)

Epoxides are cleaved in the presence of tris(ethylthio)borane, with attack generally occurring at the less substituted carbon (eq 3). This procedure has been shown to be superior for these transformations.[6]

(3)

Other reactions of tris(ethylthio)borane include those with benzenesulfonic acid esters to afford asymmetric disulfides (eq 4),[7] and with isocyanates to give *N*-ethylthiocarbonylureas (eq 5).[8]

Tris(formylamino)methane[1]

[4774-33-8] · $C_4H_7N_3O_3$ · Tris(formylamino)methane · (MW 145.14)

(a source for formamide; for *N*-formylformamidine (H_2N-CH=N-CHO); for the *N*-formylformimidoyl group (H-C=NH-CHO) as a building block in heterocyclic synthesis)

Alternate Names: TRIFO; *N,N´N´´*-methylidynetrisformamide; triformamidomethane.

Physical Data: mp 162-164 °C (dec).

Solubility: sol formamide; sol aprotic dipolar solvents such as DMF or DMA on heating.

Form Supplied in: white crystals; commercially available.

Analysis of Reagent Purity: melting point.

Preparative Methods: ***Triethyl Orthoformate*** reacts with formamide under catalysis of mineral acids to give TRIFO (eq 1).[2,3] The reaction of excess formamide with inorganic and organic acyl chlorides such as PCl_3, $POCl_3$, $SOCl_2$, acetyl chloride, benzoyl chloride, and ethyl chloroformate proceeds via iminium salts to afford TRIFO.[2,4,5] Analogously, alkylating reagents such as dialkyl sulfates, alkyl sulfonates or triethyloxonium tetrafluoroborate transform formamide to TRIFO. Alkoxymethyleneiminium salts and formamidinium salts are intermediates in these reactions.[2] Pure salts of this type are also converted to the reagent by formamide.[2] Reaction of ***Dimethyl Sulfate*** with formamide is the easiest way to prepare TRIFO.[2]

Handling, Storage, and Precautions: store at rt in closed bottles. Use in a fume hood.

Reactions.

Strong CH_2-acidic compounds such as dimethyl malonate and methyl cyanoacetate are transformed to *N*-formylaminomethylenated compounds when heated with TRIFO.[6] Heterocyclic amines are converted by TRIFO to the corresponding *N*-formylamines,[7,8] whereas primary aromatic amines react with TRIFO to give *N,N´*-diarylformamidines.[9]

Of more importance are the applications of TRIFO as a building block in heterocyclic synthesis. In the synthesis of oxazoles from TRIFO and α-halo and α-hydroxy ketones, TRIFO contributes a formamide molecule for the ring closure.[5] However, in the synthesis of 1,2,4-triazoles from hydrazines[1a,10] or amidrazones,[11] 2-alkylamino-1,3,5-triazine from *N*-alkylguanidines,[5,12-15] and pyrimido[4,5-*d*]pyrimidines from 6-aminouracils,[7,16] as well as pyrazolo[3,4-*d*]pyrimidines from 3-amino-5-pyrazolones,[17] the reagent donates (=CH-N=CH-) fragments (eqs 2-7).

(2)

(3)

(4)

(5)

(6)

(7)

In a pyrimidine synthesis of broad scope (eqs 8-13), TRIFO acts as a donor of formylformamidine which can cyclize α-CH_2-containing ketones,[5,6,18-24] 1,3-cyclohexanediones,[20] 1,2-, 1,3-, and 1,4-dihydroxynaphthalenes,[25] tetrahydrocarbazolones,[26-30]

arylacetonitriles,[31-35] and arylacetamides,[32,33] as well as malonates, cyanoacetates,[6,36,37] and aminoacetonitriles.[31,38]

(8)

$R^1, R^2 = \text{alkyl, aryl}$

$R^1\text{-}R^2 = (CH_2)_n \ (n = 3, 4)$

(9)

(10)

(11)

(12)

$Y = CO_2R, CN, CONH_2$

(13)

The thermolysis of TRIFO affords *s*-triazine in good yield (eq 14).[4,5,12,39] *N*-Formylformamidine is thought to be an intermediate. Some methyl heterocycles (2-methylpyridine, 2-methylquinoline, 2-methylpyrazine, and 2-methylbenzothiazole) react with TRIFO on heating in DMF to give heteroarylpyrimidines with low yields (eq 15).[40]

(14)

(15)

A few examples are known in which TRIFO acts as a C_1 building block in heterocyclic synthesis, e.g. *o*-phenylenediamine reacts with TRIFO to give benzimidazole (eq 16).[1a] By the same reaction, 4-amino-5-carbamoylpyrimidines can be cyclized to give pyrimido[4,5-*d*]pyrimid-4(3*H*)-ones (eq 17).[41,42] On heating urea or *S*-methylisothiourea sulfate with TRIFO, condensation of the urea derivative occurs first producing biuret and *S*,*S*′-dimethyldithioisobiuret which undergo cyclization with another TRIFO molecule to give *s*-triazines (eqs 18 and 19).[9,12,13]

(16)

(17)

(18)

(19)

Vinylogous formamide acetals can be obtained very simply by heating TRIFO with *N*,*N*-dialkylformamide acetals in the presence of the corresponding alcohols (eq 20).[43]

Tris(methylthio)methane[1]

$(MeS)_3CH$

[5418-86-10] · $C_4H_{10}S_3$ · Tris(methylthio)methane · (MW 154.35)

(precursor to tris(methylthio)methyllithium,[2] useful for the preparation of carboxylic acids,[2] esters,[3] ketene thioacetals,[4] α-hydroxy esters,[5] β-alkoxy carbonyl lactones[6] and for ring expansion of cyclic ketones to cyclic 1,2-keto thioacetals[7])

Physical Data: mp 17-18 °C;[8] bp 102 °C/15 mm;[8] *d* 1.16 g cm^{-3}; ^1H NMR (CCl_4) δ 4.63 (s, 1H), 2.16 (s, 9H).[2b]

Form Supplied in: liquid; widely available.

Handling, Storage, and Precautions: stench; irritant; use in a fume hood.

Metalation.

Tris(methylthio)methane undergoes rapid deprotonation with ***n-Butyllithium*** in THF at -78 °C (eq 1) to provide tris(methylthio)methyllithium (**1**),[2] a useful carboxylate anion equivalent. However, subsequent reactions of (**1**) with electrophiles must proceed at temperatures well below -20 °C since the anion decomposes at this temperature via a carbenoid pathway to provide tetrakis(methylthio)ethylene (eq 1).[2]

Alkylation Reactions.[2-4]

Only primary halides are suitable substrates for alkylation reactions with carbanion (**1**). Thus reaction with ethyl bromide takes place at -78 °C to afford 1,1,1-tris(methylthio)propane in 70% yield,[4a] whereas the analogous alkylation reaction using isopropyl iodide is unsatisfactory (22% yield).[2a] An alkylation reaction of carbanion (**1**) with a 1,4-cyclic sulfate has been recently examined for the purpose of preparing shikimate substrate analogs (eq 2). The alkyl sulfate and orthothioester functionalities of the resulting alkylation product were hydrolyzed to afford a deoxycarbohydrate upon concomitant lactonization (eq 2).

(2)

1,2-Addition Reactions with Carbonyl Compounds.

Tris(methylthio)methyllithium participates in 1,2-addition reactions with a variety of carbonyl compounds including aldehydes,[2a,5a,i] ketones,[2a,5b,c] lactones,[5d,e,f] chloroformates,[2a] and carbon disulfide.[5g] A particularly illustrative example was reported in the preparation of a BCE ring model system directed toward the total synthesis of bruceantin (eq 3).[5b] Thus stereoselective addition of (**1**) proceeded smoothly provided the reaction mixture was quenched with saturated ammonium chloride at -60 °C. The resulting alcohol tosylate (eq 3) was efficiently converted to the tetrahydrofuran ring and the orthothioester was transformed to the methyl ester functionality to afford the bruceantin BCE ring system (eq 3).

(3)

1,4-Addition Reactions to α,β-Unsaturated Carbonyl Compounds.

Conjugate addition reactions of (**1**) to butenolides,[6a,b] cyclopentenone,[6c] and nitroalkenes[6d] have been reported which are in contrast to the 1,2-addition observed for the reaction of the enone in eq 3, 2-(trimethylsilylmethyl)propenal,[5i] and cyclohexenone[5h] (which gives an equal mixture of 1,2- and 1,4-addition products).[5h,9] As expected, the enolates that result from the conjugate addition can be trapped.[6a,c] For example, conjugate addition of (**1**) to the butenolide shown in eq 4 followed by addition of gaseous formaldehyde gave a product which was easily converted to the antibiotic protolichesterinic acid.[6a]

(4)

The product of a formal conjugate addition reaction to an aryl methyl ketone was obtained when the arenetricarbonylchromium complex shown in eq 5 was treated with (**1**). This gave an anionic benzocyclohexadienyl intermediate which upon methylation at the metal center underwent CO insertion and acyl transfer to afford a mixture of regioisomers, after decomplexation using triphenylphosphine.[6f]

(5)

Ring Expansion of Strained Ketones.

The alcohols derived from 1,2-addition of (**1**) to cyclopentanones,[7a,b] cyclobutanones,[7a,b,d] or cyclopropyl ketones[7c] undergo Cu^{I}- or acid-promoted regioselective rearrangement to afford ring-expanded 1,2-keto thioacetal products resulting from migration of the more substituted carbon. For example, the alcohol shown in eq 6 rearranged to afford a single 1,2-keto thioacetal, which was subjected to a four-step reaction sequence in order to prepare the sesquiterpene clovene.[7d]

Tris(phenylseleno)borane[1]

$B(SePh)_3$

[29680-62-4] · $C_{18}H_{15}BSe_3$ · Tris(phenylseleno)borane · (MW 479.02)

(an efficient carrier of benzeneselenolate anion equivalent in selenoacetalization reactions,[2-5] in the conversion of *O,O*-acetals into mixed *O,Se*-acetals,[3] in the opening of epoxides,[6] or in the transformation of α,β-unsaturated ketones into 1,1- and/or 1,3-bis(seleno)-2-alkenes;[7] a valuable source of phenylselenyl radicals capable of inducing hydroselenation of alkynes and cyclization of enynes;[8] used for the deoxygenation of sulfoxides[9] and of 1,2-disubstituted epoxides[6])

Physical Data: white needles, mp 152-153 °C.[1]

Solubility: sol carbon disulfide, dichloromethane, chloroform, toluene.

Preparative Methods: in a modified procedure[4] of the original,[1] ***Boron Tribromide*** (14.32 g, 57.1 mM) and dry ***Carbon Disulfide*** (100 mL) are placed in a flask cooled in an ice bath under nitrogen. ***Benzeneselenol*** (26.95 g, 171.6 mM) in 50 mL carbon disulfide is added to the well-cooled solution from the addition funnel over a period of 4 h. The reaction mixture is warmed to room temperature and stirred overnight. The nitrogen flow is stopped, and the solvent is evaporated. The residual yellow solid is suspended in 100 mL of dry pentane, and the stirred mixture refluxed under a slight static pressure of nitrogen. After cooling to rt, the yellow supernatant is removed by syringe. This washing is repeated with two more 100 mL portions of pentane. The resulting white solid is dried under vacuum, weighed (20.48 g, 74%) and stored protected from moisture.

The analogs tris(*p*-tolylseleno)borane and tris(*p*-bromophenylseleno)borane have been similarly prepared.[10] Alternatively, $B(SePh)_3$ can be synthesized[1] from BBr_3 and PhSeNa. Analogous derivatives such as $Al(SePh)_3$,[11] Al(Se-1-naphthyl)$_3$,[11] $Ti(SePh)_4$,[11] $Zr(SePh)_2$,[11] $Cr(SePh)_3$,[11] $Nb(SePh)_3$,[11] $Ta(SePh)_3$,[11] $W(SePh)_4$,[11] $Ni(SePh)_2$,[11] and $Co(SePh)_2$,[11] as well as $Me_3SiSePh$,[12,13] $Me_3GeSePh$,[12b] and $Me_3SnSePh$,[14] have been prepared.

Handling, Storage, and Precautions: stable to heat, air oxygen, and light, but sensitive to humidity which decomposes them into selenols and boric acid. Therefore they must be stored under nitrogen or argon, and all reactions conducted under anhydrous conditions. Use in a fume hood.

General Discussion.

Phenylselenoacetals can be prepared either from carbonyl compounds[2-5,15] or from the corresponding *O,O*-acetals[3] by reaction with tris(phenylseleno)borane in the presence of catalytic amounts of proton acids (eqs 1 and 2).

(1)

(2)

When the amount of $B(SePh)_3$ is reduced and the acid catalyst is omitted, the transacetalization reaction stops half-way, and gives mixed *O*,*Se*-acetals in excellent yield (eq 3).[3]

(3)

The opening of 1,2-disubstituted epoxides gives mainly β-hydroxy selenides after short reaction times (1-3 h), but gives 1,2-disubstituted alkenes after longer reaction times (24-54 h) (eq 4).[6] Trisubstituted epoxides lead to allylic alcohols.[6]

(4)

(Z): $R^1 = C_5H_{11}$; $R^2 = Me$ R = Ph, 0.8 h	77%	0%
(E): $R^1 = C_8H_{17}$; $R^2 = C_7H_{14}CO_2Me$ R = Me, 54 h	0%	71% *(E)*

Selenoacetalization of α,β-unsaturated carbonyl compounds[7] is more complicated for two reasons: 1,4-addition of the phenylselenolate species can compete with 1,2-attack; the well-known 1,3-rearrangement of allyl selenides[16,17] also affects the corresponding selenoacetals.[18] Thus the nature and composition of the products strongly depends on the substitution pattern of the starting α,β-unsaturated carbonyl derivative[7] (eqs 5 and 6).

(5)

Hydroselenation of terminal alkynes proceeds best when an electron-attracting group is present on the C&tbond;C triple bond, and when oxygen is not excluded from the medium; (*Z*)-vinyl selenides are formed with high regio- and stereoselectivity (eq 7).[8]

In spite of these features, a phenylselenyl radical-based mechanism is proposed mainly because the cyclization of enynes possessing a terminal C&tbond;C triple bond (eq 8) presents all the characteristics of such a mechanism.[8] Tris(phenylseleno)borane is also an efficient reagent for the deoxygenation of sulfoxides into sulfides.[8]

All of these reactions[19] can be effected with tris(methylseleno)borane,[20] $B(SeMe)_3$, to give products bearing the MeSe moiety.[4,7,8,13] It is surprising that the usefulness of the aluminum analogs has not been explored, except for the dimethyl derivative $Me_2AlSeMe$ which proved to be an excellent reagent for the conversion of esters into selenolesters.[21]

It is worth noting the close analogy between selenoboranes and thioboranes, both in their syntheses[22] and in their reactivity.[22b,c,23]

Related Reagents.

Dimethylaluminum Methylselenolate; ***9-Phenylseleno-9-borabicyclo[3.3.1]nonane***; ***Tris(ethylthio)borane***; ***Triphenyl Thioborate***.

Tris(phenylthio)methane

$(PhS)_3CH$

[4832-52-4] · $C_{19}H_{16}S_3$ · Tris(phenylthio)methane · (MW 340.56)

(precursor to tris(phenylthio)methyllithium, used for nucleophilic carboxylation;[1] electrophilic formylating agent for aromatic compounds[2] and diazo esters[3])

Physical Data: mp 40-41 °C.

Solubility: freely sol most organic solvents; usually used in THF, methylene chloride, or ether.

Form Supplied in: off-white to pale yellow solid, typically 97-99% pure; commercially available.

Analysis of Reagent Purity: the NMR spectrum will establish the absence of ethyl formate, the usual precursor to the reagent. Residual thiophenol can be removed by washing an ethereal solution of the reagent with 1 N NaOH followed by standing under high vacuum.

Handling, Storage, and Precautions: is stable indefinitely if stored at ambient temperatures in tightly sealed containers to exclude moisture, which promotes hydrolysis to thiophenol and formic acid. The presence of residual thiophenol mandates that the reagent be handled in a fume hood to avoid inhalation of dust and that skin contact be avoided.

Nucleophilic Carboxylation.

The reagent, in THF or ether solution, is quantitatively converted to its lithiated derivative with 1 equiv of ***n-Butyllithium*** at -78 °C. It has also been converted to its sodium and potassium salts with the corresponding alkali metal amides.[4] The lithiated species is a useful nucleophilic carboxylating reagent for a variety of organic electrophiles. This chemistry is discussed in the article ***Tris(phenylthio)methyllithium***.

Electrophilic Formylation.

Apart from its role as precursor to tris(phenylthio)methyllithium, the utility of the reagent in organic synthesis has been very limited. Its use as an aromatic electrophilic formylating agent stems from the ability of certain Lewis acids to generate the bis(phenylthionium) cation (**1**) (eq 1).[1] In the case of intermolecular aromatic formylation, ***Dimethyl(methylthio)sulfonium Tetrafluoroborate*** (DMSTF)[5] is most effective in promoting the reaction. Yields of aldehydes are in the range 35-85%. The best yields are obtained with polycyclic aromatics such as α- or β-naphthol, although more-functionalized substrates still give acceptable results (eq 2). The hydrolysis of the thioacetal by excess DMSTF completes the sequence.

(1)

(1)

(2)

The scope of the substitution is limited to oxygen-activated aromatics. With these substrates there is a pronounced preference for formylation at the *para* position if it is available. If the *para* position is blocked, *ortho* formylation occurs with yields approximately equal to *para* formylation. Unactivated or weakly activated aromatics such as benzene or alkylbenzenes do not react with the reagent. Nitrogen-activated aromatics effectively compete with the reagent for the Lewis acid and are thus unable to react.

An extension of this chemistry has been developed for the preparation of cyclic oxygenated α-keto aromatics such as the methoxy-α-tetralone (**2**).[6] When applied in the intramolecular sense, the scope of the reaction broadens somewhat to include some alkyl-substituted substrates (for six-membered annulation). Annulation of five- or seven-membered rings onto the aromatic nucleus still requires oxygen activation. Although DMSTF was effective in promoting closure in some cases, ***Silver(I) Trifluoromethanesulfonate*** in methylene chloride proved to be a more generally effective catalyst for this reaction (eq 3).

(3)

In the case of diazo esters, ***Boron Trifluoride Etherate*** was shown to promote formylation (eq 4).[3]

Tris(phenylthio)methyllithium[1]

$(PhS)_3CLi$

[14572-78-2] · $C_{19}H_{15}LiS_3$ · Tris(phenylthio)methyllithium · (MW 346.49)

(nucleophilic carboxylating agent for certain carbonyl compounds[2] and alkyl halides;[3] homologating agent for trialkylboranes;[4] carbene precursor[5])

Physical Data: not isolable; decomp above 20 °C to bis(phenylthio)carbene and lithium phenylthiolate.

Solubility: up to 2 M in THF.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: titrate with D_2O or MeI.

Preparative Methods: generally prepared from ***n-Butyllithium*** and ***Tris(phenylthio)methane*** and used immediately; can also be generated from tetra(phenylthio)methane by Li-PhS exchange[2c] or from diphenyl trithiocarbonate and PhLi.[2c]

Purification: not generally practical; may contain products derived from ethyl formate used in preparation of tris(phenylthio)methane.

Handling, Storage, and Precautions: although not acutely pyrophoric, the reagent is readily hydrolyzed and should be handled under a dry, inert atmosphere. The reagent is corrosive to biological tissue. Storage, even in the cold, is not recommended because of instability. The reagent, its precursors, and reaction mixtures derived from its use, should be handled in a fume hood because of the smell of thiophenol.

Nucleophilic Carboxylation/Carbene Precursor.

Following early reports[6] of the deprotonation of trialkyl trithioorthoformates with alkali amides and their subsequent trapping with reactive electrophiles, the generation and trapping of this reagent were independently reported by Brandsma[3] and Seebach.[2a] More detailed studies of the properties of the reagent were later reported by Seebach.[7]

The reagent is quantitatively generated at -78 °C in THF by addition of 1 equiv of *n*-butyllithium to the precursor tris(phenylthio)methane. Upon raising the temperature to near ambient, the establishment of an equilibrium between the reagent and the transiently stable bis(phenylthio)carbene $(PhS)_2C$**:** was demonstrated by isolation from the reaction of products arising from its formation. These included the dimer tetraphenylthioethylene, as well as sulfur-substituted cyclopropanes obtained when ketene acetals and dithioketene acetals were added. Synthetically useful yields of cyclopropane products were obtained only when dithioketene acetals were used.[8]

These studies indicate the importance of generating and using the reagent shortly thereafter, if nucleophilic carboxylation is desired. Because the reagent is relatively bulky and has phenylthio groups as substituents, it is less reactive than the corresponding tris(methylthio) reagent (see ***Tris(methylthio)methane***). Its utility as a nucleophilic carboxylating agent is therefore more limited. Primary alkyl bromides and iodides (eq 1), allyl halides, CO_2 (eq 2), alkyl and aryl disulfides, silyl chlorides,[2a,3] and reactive ketones[9] efficiently interact with the reagent to afford the corresponding adducts. Aldehydes, saturated or unsaturated, react with the reagent to give 1,2-adducts (eq 3),[2a,5] although some variations in this behavior have been reported.[10,11] Ordinary ketones are enolized and recovered. Reactive epoxides and secondary halides give poor yields of alkylation products, apparently because the reagent adds too slowly to these electrophiles and functions as a base. However, unhindered α,β-unsaturated ketones add the reagent in the conjugate sense, affording γ-keto trithioorthotriesters in good to excellent yields (eq 4).[12] In the case of carbon electrophiles, these adducts are hydrolyzed to carboxylic acids with ***Mercury(II) Chloride***, ***Mercury(II) Oxide***, combinations of the two,[13] or $Ag(O_2CCF_3)_2$[11] in aqueous acetone, DMF, or dioxane at &egt;25 °C. Yields of carboxylation products are sometimes improved if the adducts are subjected to alcoholysis, affording the ester,[12,13a] or to partial hydrolysis, affording the thioester.[14] Conventional hydrolysis can then be employed if the carboxylic acid is desired (eq 5).[15]

(1)

(2)

(3)

(4)

(5)

The reagent reacts with lactones such as δ-valerolactone, with various results having been reported (eq 6).[16]

(6)

Recently, a nucleophilic carboxylation using this reagent to prepare the glyoxylate synthon tris(phenylthio)acetaldehyde, was reported (eq 7).[11]

Conjugate addition of the reagent to cyclic unsaturated ketones has the feature of generating regiochemically homogenous enolates which can be trapped in situ with appropriate electrophiles (eq 8).[17]

A useful property of the adducts of the reagent is their continued ability to undergo further lithiation or generate carbenes. These reactive intermediates can, if generated in the appropriate location, induce further transformations typical of carbanions or carbenes such as ring expansions,[9] hydrogen shifts,[5] and conjugate additions (eqs 9-11).[18] Although the reagent is of very limited utility in cyclopropane synthesis when used intermolecularly, intramolecular trapping of the carbenoid center by a nucleophilic alkene is an excellent route to sulfur-substituted cyclopropane-containing bicyclic ketones (eq 12).[19]

Homologation of Trialkylboranes.

When treated with relatively unhindered trialkylboranes, the reagent serves as a homologating agent, affording either ketones or tertiary alcohols. The best substrates for the reaction are boranes containing primary alkyl or cycloalkyl groups. The products are obtained after standard oxidation with basic ***Hydrogen Peroxide***, and their nature depends on the presence or absence of mercury(II) chloride. In the absence of Hg^{2+}, ketones are obtained, whereas in its presence, tertiary alcohols are the products. Primary alkyl groups migrate preferentially. The stoichiometry of the reaction is illustrated in eq 13.[4]

Conrad Santini

Tris(*o*-tolyl)[(2-(trimethylsilyl)ethylidene]phosphorane[1]

[104697-92-9] · $C_{26}H_{33}PSi$ · Tris(*o*-tolyl)[(2-(trimethylsilyl)ethylidene]phosphorane · (MW 404.65)

(*cis*-selective Wittig reaction for synthesis of allylsilanes;[1] with modification of substituents on phosphorus and silicon atoms, β-silylphosphorus ylides give allylic alcohols diastereoselectively[2])

Preparative Methods: prepared in situ from tris(*o*-tolyl)[2-(trimethylsilyl)ethyl]phosphonium iodide and ***n-Butyllithium*** in THF.[1] Tris(*o*-tolyl)phosphorus methylide (prepared in situ from methyltris(*o*-tolyl)phosphonium bromide and *n*-BuLi in THF) and ***(Iodomethyl)trimethylsilane*** were heated under reflux in THF for 5 h. The mixture was poured into H_2O and the phosphonium salt was extracted with CH_2Cl_2. Evaporation of the organic solvent gave an oily residue which was crystallized from THF-Et_2O (mp 111-113 °C). To a stirred suspension of the phosphonium salt in THF (6 mL g^{-1}) was added 1 equiv of *n*-BuLi under a nitrogen atmosphere at 0 °C and the mixture was stirred for 30 min at rt, resulting in a clear yellow ylide solution.

Handling, Storage, and Precautions: unstable to air and moisture. Should be handled under a dry nitrogen atmosphere.

Wittig Reaction with (*Z*) Selectivity.

Phosphorus ylides having silyl groups at the β-position react with aldehydes by two pathways: a Wittig reaction and a vinylation reaction that affords allylic alcohols via migration of the silyl group and elimination of phosphine. [2-(Trimethylsilyl)ethylidene]triphenylphosphorane has been used for synthesis of allylsilanes from aldehydes.[3] The reaction, however, shows low (*Z*/*E*) selectivity. In addition, allylic alcohol is formed as byproduct.[3b,4] With modification of the substituents on the phosphorus atom from phenyl to the bulkier *o*-tolyl group, the title reagent reacts with aliphatic saturated aldehydes to give allylsilanes with high (*Z*) selectivity and without formation of allylic alcohols (eq 1).[1]

(1)

Diastereoselective Alkenylation of Aldehydes.

In the dichotomous reactivity of β-silylphosphorus ylides, electron-donating groups on the phosphorus atom and electron-withdrawing groups on silicon effect the selective formation of allylic alcohols over allylsilanes.[2] Tris(4-methoxyphenyl)[(2-(methyldiphenylsilyl)ethylidene]phosphorane [*110598-64-6*] reacts diastereoselectively with chiral aldehydes to afford allylic alcohols with suppression of the Wittig reaction. With 2-phenylpropanal the *erythro* (*syn*) product predominates[2] and with α-benzyloxy aldehydes (eq 2)[5] and α,β-epoxy aldehydes[6] the ylide gives *erythro* (*anti*) product selectively via the Felkin-Anh model. With α-*N*-Boc-amino aldehydes, [2-(trimethylsilyl)ethylidene]triphenylphosphorane gives the *threo* (*syn*) product preferentially through Cram's chelation

transition state.[7]

Diastereoselective isopropenylation[2] and (*E*) propenylation (eq 3)[8] are also possible using β-silylphosphorus ylides substituted with methyl groups at the α- and β-positions, respectively. The latter ylide was prepared in situ by addition of methyldiphenylsilyllithium to the propenylphosphonium salt.[8]

Enantioselective vinylation of aldehydes (up to 92% ee) was reported by using a β-silylphosphorus ylide carrying a chiral ferrocenyl group on the phosphorus atom.[9]

Tris(trimethylsilyl)aluminum[1]

$(Me_3Si)_3Al$

[65343-66-0] · $C_9H_{27}AlSi_3$ · Tris(trimethylsilyl)aluminum · (MW 246.61) (.OEt_2)

[75441-10-0] · $C_{13}H_{37}AlOSi_3$ · Tris(trimethylsilyl)aluminum Diethyl Etherate · (MW 320.75)

(nucleophilic silylation;[2,3] silylalumination of terminal alkynes;[4] preparation of allyl-, aryl-, and alkenylsilanes[5,6])

Physical Data: mp 60 °C (dec).

Solubility: sol ethers, pentane, benzene; reacts violently with protic solvents.

Form Supplied in: white needles; not commercially available.

Preparative Methods: to ***Aluminum*** powder and granular aluminum in ether is added ***Mercury(0)*** and ***Chlorotrimethylsilane*** followed by ***Lithium*** wire. After the reaction is complete, the solution is filtered and ether is removed. The solid residue is stirred with pentane, which effects removal of insoluble $Li(Me_3Si)_4Al$. Partial concentration and cooling of the pentane solution gives $(Me_3Si)_3Al.OEt_2$ as white needles.[1b,2c]

Handling, Storage, and Precautions: ignites spontaneously in air. The reagent can be conveniently handled as a stock solution in pentane, which can be stored under an inert atmosphere in a freezer. The molarity can be determined by titration.[2c,6]

Carbonyl Additions.

The reagent is a useful nucleophilic trimethylsilyl transfer agent.[2a] Enones and enals undergo 1,2-addition in ether at room temperature, while 1,4-addition occurs at -78 °C (eq 1).[2b] Ester carbonyls, which are amenable to attack only in boiling ether in the presence of ***Aluminum Chloride***, give α,α-bis(trimethylsilyl)alkanols.[2a]

(1)

Functionalized acylsilanes are accessible by the reaction of $(Me_3Si)_3Al.OEt_2$ with (*S*)-2-pyridyl esters in the presence of stoichiometric ***Copper(I) Cyanide*** (eq 2).[3]

(2)

Silylalumination of Alkynes.

Silylalumination of 1-alkynes provides a convenient entry to vinylsilane derivatives in a regio- and stereoselective manner (eq 3).[4]

(3)

Transition Metal Promoted Coupling Reactions.

In the presence of a Ni catalyst, the reagent undergoes cross-coupling reactions with aryl bromides (eq 4).[5] Alkenyl iodides are stereospecifically converted to alkenylsilanes in the presence of a Pd catalyst (eq 5).

(4)

(5)

Allylic acetates are converted to allylsilanes in the presence of Pd^0 complexes or ***Hexacarbonylmolybdenum***. The regioselectivity depends on the catalyst. The Mo^0 catalyst leads to products with the silyl group attached to the less-hindered end of the allyl group. The regioselectivity of the Pd^0-catalyzed reaction depends on the solvent and, in particular, on the ligands. The two catalysts also differ with respect to stereochemistry (eq 6).[6]

Tris(trimethylsilyl)ketenimine[1]

$(Me_3Si)_2C{=}C{=}N\text{-}SiMe_3$

[7351-44-2] · $C_{11}H_{27}NSi_3$ · Tris(trimethylsilyl)ketenimine · (MW 257.66)

(reactions with aldehydes; selective synthesis of (*Z*)-2-alkenenitriles and (*E*)-2-(1-hydroxyalkyl)-2-alkenenitriles)

Physical Data: bp 94-96 °C/19 mmHg.

Solubility: sol ether, THF; modestly sol aprotic solvents; reacts with H_2O and protic solvents.

Form Supplied in: colorless oil.

Analysis of Reagent Purity: IR νfilmmax 2050, 1410, 1260, 840 cm^{-1}. ^1H NMR (CCl_4) δ 0.09 (s, 18 H), 0.19 (s, 9 H).

Preparative Methods: to a solution of ***Trimethylsilylacetonitrile***[2] (3.01 g, 26.6 mmol) in dry diethyl ether (40 mL) is added ***n-Butyllithium*** (10 % w/v in hexane, 38 mL, 59.3 mmol) at -60 °C and stirring is continued for 0.5 h. ***Chlorotrimethylsilane*** (7.48 g, 68.9 mmol) is slowly added and the mixture is allowed to warm to room temperature. The mixture is concentrated and distilled at bp 94-96 °C/19 mmHg to give tris(trimethylsilyl)ketenimine (5.67 g, 83%).

Purification: distill under reduced pressure.

Handling, Storage, and Precautions: bottles of tris(trimethylsilyl)ketenimine should be kept tightly sealed to preclude contact with moisture.

General Discussion.

Tris(trimethylsilyl)ketenimine (**1**) reacts with aldehydes in the presence of ***Boron Trifluoride Etherate*** at room temperature in benzene[3] or dichloromethane to give a 1:1 adduct.[4] Upon heating, the adduct is converted quantitatively into (*E*)-2-trimethylsilyl-2-alkenenitriles (**2**) (eq 1).

(1)

Compound (**2**) is desilylated in an alkaline medium to give pure (*Z*)-2-alkenenitriles (**3**) (eq 2).[3] Several examples are summarized in Table 1.

(2)

Table 1 Yields of (*E*)-2-Trimethylsilyl-2-alkenenitrile (**2**) and (*Z*)-Alkenenitriles (**3**)

Tris(trimethylsilyl)methane[1]

$(Me_3Si)_3CH$

[1068-69-5] · $C_{10}H_{28}Si_3$ · Tris(trimethylsilyl)methane · (MW 232.65)

(precursor of $(Me_3Si)_3CLi$, useful to introduce bulky tris(trimethylsilyl)methyl (trisyl) group; Peterson alkenation reagent)

Physical Data: bp 219 °C, 93-95 °C/13.5 mmHg; *d* 0.836 g cm^{-3}; *n*20D 1.4657.

Solubility: sol common organic solvents.

Analysis of Reagent Purity: ^1H NMR.

Purification: by distillation.

Preparative Methods: the reaction of ***Chlorotrimethylsilane***, ***Lithium*** metal, and ***Chloroform*** in THF gives tris(trimethylsilyl)methane.[2]

Handling, Storage, and Precautions: can be stored in a glass bottle.

Synthesis of Tris(trimethylsilyl)methyl Bromide.[3]

Tris(trimethylsilyl)methyl bromide (trisyl bromide) can be prepared in 75% yield by photochemical bromination of neat tris(trimethylsilyl)methane at 180-190 °C in less than 5 h (eq 1).

$$(TMS)_3CH + Br_2 \xrightarrow[75\%]{\substack{h\nu \\ 180\text{-}190\ ^\circ C}} (TMS)_3CBr + HBr \qquad (1)$$

Trisyl bromide is very reactive toward lithium, magnesium, and phenyllithium to give the corresponding organometallic reagents. These reagents are useful in the Peterson alkenation reaction.

Metalation.

Tris(trimethylsilyl)methyllithium can be prepared by metalation of tris(trimethylsilyl)methane by ***Methyllithium*** in a mixture of diethyl ether and THF (eq 2).[4] An improved procedure is described as follows. To a solution of tris(trimethylsilyl)methane in THF is added a solution of MeLi (10% excess) in diethyl ether with stirring under nitrogen. The diethyl ether is distilled off and the residual solution is boiled under reflux under nitrogen. After 2 h, about 95% of tris(trimethylsilyl)methane is converted to tris(trimethylsilyl)methyllithium. Tris(trimethylsilyl)methyllithium is important for the introduction of $(Me_3Si)_3C$ (trisyl) groups, and for use in Peterson alkenations (eq 3).

$$(TMS)_3CH + MeLi \xrightarrow{Et_2O\text{-}THF} (TMS)_3CLi \qquad (2)$$

$$(TMS)_3CLi + CH_2O \xrightarrow[70\%]{} (TMS)_2C{=}CH_2 \qquad (3)$$

Formation of Bis(trimethylsilyl)methyllithium.

The carbon-silicon bond of tris(trimethylsilyl)methane can be cleaved by lithium methoxide in HMPA to form bis(trimethylsilyl)methyllithium, which subsequently reacts with carbonyl compounds to form alkenes (eq 4).[5]

Similar cleavage of the Si-C bond occurs with fluoride ion. The in situ reaction with carbonyl compounds gives the corresponding alkenes. Thus the reaction of tris(trimethylsilyl)methane with nonenolizable carbonyl compounds in the presence of ***Tris(dimethylamino)sulfonium Difluorotrimethylsilicate*** (TASF) gives the corresponding alkenes in excellent yield (eq 5).[6]

Related Reagents.

Bis(trimethylsilyl)methane.

Tris(trimethylsilyloxy)ethylene

[69097-20-7] · $C_{11}H_{28}O_3Si_3$ · Tris(trimethylsilyloxy)ethylene · (MW 292.66)

(conversion of carboxylic acid chlorides to terminal α-hydroxy ketones;[1,2] conversion of aldehydes and ketones to 2,3-dihydroxyalkanoic acids[3,4])

Physical Data: bp 54-56 °C/0.1 mmHg; *d* 0.886 g cm^{-3}.[5]

Solubility: sol all organic solvents; insol in H_2O (reacts).

Form Supplied in: colorless free-flowing liquid; available commercially.

Preparative Methods: from the bis(trimethylsilyl) derivative of glycolic acid by either forming the enolate with ***Lithium Hexamethyldisilazide*** at -78 °C in THF and trapping with ***Chlorotrimethylsilane***,[1,2] or by the reaction with ***Trimethylsilyl Trifluoromethanesulfonate*** and ***Triethylamine*** at rt (eq 1).[6]

Handling, Storage, and Precautions: is readily hydrolyzed in protic solvents. It should be stored in a sealed container protected from the atmosphere. Since the reaction of the reagent with carboxylic acid chlorides and aldehydes under Lewis acid catalysis in the absence of solvent is highly exothermic, large-scale preparations may require regulation of the reaction temperature either by external cooling or by controlled addition of the reactants.

Carboxylic Acid Chlorides to Terminal α-Hydroxy Ketones.[1,2]

The reaction of 2 equiv of tris(trimethylsilyloxy)ethylene with octanoyl chloride in the absence of solvent either by heating to 90 °C for 2 h or by using a catalytic amount of ***Tin(IV) Chloride*** and allowing the reaction to freely exotherm results in the formation of (**1**), TMSCl, and bis(trimethylsilyl)-glycolic acid (eq 2). Treatment of the reaction mixture with dilute acid in THF or dioxane results in an immediate exothermic hydrolysis (presumably to β-keto acid **2**) and decarboxylation to furnish the hydroxymethyl ketone (**3**). Since the rate of the reaction of the reagent with the liberated HCl (to furnish TMSCl, and bis(trimethylsilyl)glycolic acid) is as least as fast as with the acid chloride, 2 equiv of reagent must be used to achieve complete conversion to the hydroxymethyl ketone. Both aliphatic and aromatic acid chlorides have been used successfully. Very hindered acid chlorides (e.g. 1-adamantanecarbonyl chloride) failed to react. This methodology has been applied in the total synthesis of Ajugarin-IV[7] and in the preparation of some prostaglandin analogs where the terminal hydroxymethyl ketone functional group serves as a biosteric replacement for a carboxylate group.[8]

Aldehydes and Ketones to 2,3-Dihydroxyalkanoic Acids.

The reaction of tris(trimethylsiloxy)ethylene with *n*-hexanal in the absence of solvent using $SnCl_4$ as the catalyst is exothermic and furnishes the adduct (**4**). Direct hydrolysis of the reaction mixture with aqueous acetic acid in THF gives 2,3-dihydroxyoctanoic acid (**5**) as a mixture of diasteromers (eq 3).[3] Similar reactions have also been accomplished under trimethylsilyl trifluoromethanesulfonate or ***Cesium Fluoride*** catalysis.[4] Aliphatic, α,β-unsaturated, and aromatic aldehydes have been used successfully.[3,4] Aliphatic and aromatic ketones have also been used successfully under trimethylsilyl trifluoromethanesulfonate catalysis conditions.[4] This methodology usually results in poor stereoselectivity; both the *erythro* and *threo* isomers are obtained in comparable amounts.

Reaction with Ketenes.

The reaction of tris(trimethylsilyloxy)ethylene with ketene generated from acetyl chloride and triethylamine furnishes the adduct (**6**) in good yield (eq 4); this compound was an intermediate in the synthesis of a series of anthragallols.[9] Similar products result from the reaction of the reagent with halogen-[10,11] and trimethylsilyl-substituted ketenes.[12]

Electrophilic Addition of Acetals and Orthoesters.

With catalysis by trimethylsilyl trifluoromethanesulfonate, acetals and orthoesters undergo electrophilic addition to tris(trimethylsilyloxy)ethylene (eq 5).[4]

Electrophilic Addition of *t*-Alkyl and Benzyl Groups.

Compounds capable of forming a stabilized carbenium ion undergo Lewis acid-catalyzed addition to tris(trimethylsilyloxy)ethylene; these included *t*-alkyl halides[13] and benzyl acetates[14] (eq 6).

Related Reagents.

1,2-Diethoxy-1,2-bis(trimethylsilyloxy)ethylene; ***Ketene Bis(trimethylsilyl) Acetal***; ***1-Methoxy-1-(trimethylsilyloxy)propene***; ***1-Methoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene***; ***Methylketene Bis(trimethylsilyl) Acetal***; ***Methylketene Dimethyl Acetal***; ***Tetramethoxyethylene***.

Tris(trimethylsilyl) Phosphite[1]

$P(OSiMe_3)_3$

[1795-31-9] · $C_9H_{27}O_3PSi_3$ · Tris(trimethylsilyl) Phosphite · (MW 298.60)

(preparation of bis(trimethylsilyl) phosphonate esters by the Arbuzov reaction with halogen-containing compounds or by the Abramov reaction with carbonyl compounds, followed by facile hydrolysis to the corresponding phosphonic acids, $RP(O)(OH)_2$)

Physical Data: bp 84 °C/5 mmHg,[2] 86.5 °C/18 mmHg,[3] 83-84 °C/16 mmHg,[4] 90-92 °C/16 mmHg,[4] 78-81 °C/8 mmHg; *d* 0.893 g cm^{-3}.

Form Supplied in: liquid; commercially available.

Preparative Methods: by silylation of anhydrous phosphorous acid (dried by repeated azeotropic evaporation of a solution in THF with dry benzene) with excess ***Chlorotrimethylsilane*** and excess ***Triethylamine*** in dimethoxyethane,[2] toluene,[3] or Et_2O-THF,[5] followed by evaporation of the solvent and vacuum distillation of the residue. The residue, which contains a mixture of tris(trimethylsilyl) phosphite and bis(trimethylsilyl) phosphonate [$HP(O)(OTMS)_2$], can also be heated with sodium (140 °C, 13-22 h), followed by vacuum distillation to obtain pure tris(trimethylsilyl) phosphite.[4]

Purification: vacuum distill before use.

Handling, Storage, and Precautions: extremely hygroscopic; use in a fume hood.

Arbuzov Reagent with Aliphatic Halides.

The reagent, $P(OTMS)_3$, reacts with alkyl halides such as *n*-butyl bromide[5] to give bis(trimethylsilyl) esters of phosphonic acids. 2,3-Diacyloxyiodopropanes (**1**) (*n* = 0, X = I) react with an excess of $P(OTMS)_3$; after removal of the excess $P(OTMS)_3$ and trimethylsilyl iodide under high vacuum (<1 mmHg) at 80-90 °C, bis(trimethylsilyl) 2,3-diacylphosphonates (**2**) are obtained, which are easily hydrolyzed to the corresponding phosphonic acids (**3**) (eq 1).[2,6,7] 3,4-Dipalmitoyloxy-1-bromobutane (**1**) (*n* = 1, X = Br) is converted into 3,4-dipalmitoyloxybutanephosphonic acid by the same process.[8] The advantage of $P(OTMS)_3$ compared with trialkyl phosphites in the preparation of phosphonic acids is the extreme ease with which the bis(trimethylsilyl) ester groups of (**2**) undergo neutral aqueous hydrolysis. The mild hydrolysis conditions[9] allow otherwise labile groups such as carboxylate esters to remain unaffected during desilylation.

$n = 0$; X = I, $R^{1,2}$ = octanoyl (71%), myristoyl (79%), palmitoyl (43%), stearoyl (87-89%)
$n = 1$; X = Br; $R^{1,2}$ = hexadecyl (75%), R^1 = hexadecyl, R^2 = benzyl (70%)

Ether-linked phosphonolipids are available by the Arbuzov reaction of 2,3-dialkoxyiodopropanes,[7,10,11] 3,4-dialkoxy-1-bromobutanes,[7] and other long-chain alkyl bromides[12] with $P(OTMS)_3$, followed by facile desilylation (eq 1).

Formation of Alkyloxycarbonyl-, Aryloxycarbonyl-, and Acylphosphonates.

Alkyloxy- and aryloxycarbonylphosphonate bis(trimethylsilyl) derivatives, $ROCOP(O)(OTMS)_2$, are prepared from the Arbuzov reaction of alkyl or aryl chloroformates with $P(OTMS)_3$.[13,14] Pivaloyl chloride reacts with $P(OTMS)_3$ to give an acylphosphonate derivative.[15]

Formation of Thiophosphonates.

Thiophosphonic acids (**4**) are prepared from the Arbuzov reaction of thiosuccinimides and thiophthalimides containing various *S*-alkyl and *S*-aryl groups with $P(OTMS)_3$ (eq 2).[16]

R = Bn, 77%; $C_{18}H_{37}$, 64-83%; $CH_2CH(OCOR)CH_2OCOR$, 46%

Arbuzov Reaction with Halomethyl-Containing Compounds.

A variety of chloromethyl- or bromomethyl-containing compounds react with $P(OTMS)_3$ to give the Arbuzov products, $RCH_2COCH_2P(O)(OTMS)_2$[17,18] or $RCH_2P(O)(OTMS)_2$.[19]

Other Arbuzov Reactions.

Aryl halides react with $P(OTMS)_3$ in the presence of catalytic nickel chloride, forming arylphosphonates after hydrolysis of the silyl esters.[20] 1β-Glycosyl triflates react with $P(OTMS)_3$, giving α-D-glucopyranosyl-1-phosphonic acid after hydrolysis.[21]

Addition to Carbonyl Compounds.

$P(OTMS)_3$ adds to alkyl-substituted α-halocarbonyl compounds to form 1:1 adducts, which on hydrolysis yield α-hydroxyphosphonic acids (**5**) (eq 3).[4,22] In contrast, trialkyl phosphites react with bromoacetone to give β-oxophosphonates. $P(OTMS)_3$ also adds to methyl ketones.[23]

O-Silylated salicaldehyde reacts with $P(OTMS)_3$, giving a dihydroxy derivative of benzylphosphinic acid after hydrolysis.[24]

Isocyanates and isothiocyanates react with $P(OTMS)_3$ to give carbamoyl- and thiocarbamoylphosphonates, $RNHC(X)P(O)(OH)_2$ where X = O or S, after treatment with aniline in methanol.[25]

Other Addition Reactions.

Addition of excess $P(OTMS)_3$ to *N*-glycosyl-*C*-aryl nitrones at low temperature in the presence of catalytic $HClO_4$ or zinc triflate gives *N*-hydroxy-α-aminophosphonic acids.[26] Addition to aldimines yields *N*-substituted phosphonates, $(HO)_2P(O)CH(R)NH_2$.[27] *N*-(Phosphonomethyl)glycine derivatives can be made by a modified Abramov reaction of imines or imine precursors with $P(OTMS)_3$.[18a,28] Conjugate additions also take place;[1] for example, addition to acrylonitrile gives $(TMSO)_2P(O)CH_2CH(TMS)CN$ in 52% yield.[29]

Related Reagents.

Trimethyl Phosphite.

Tris(trimethylsilyl)silane[1]

$(Me_3Si)_3SiH$

[1873-77-4] · $C_9H_{28}Si_4$ · Tris(trimethylsilyl)silane · (MW 248.73)

(mediator of radical reactions;[1,2] nontoxic substitute for tri-*n*-butylstannane in radical reactions; slower hydrogen donor than tri-*n*-butylstannane[3])

Physical Data: bp 82-84 °C/12 mmHg; *d* 0.806 g cm^{-3}; *n*20D 1.489.

Solubility: sol pentane, ether, toluene, THF; modestly sol acetone, acetonitrile; insol H_2O; decomposes rapidly in methanol and other alcohols.

Form Supplied in: colorless liquid; commercially available.

Preparative Methods: easy to synthesize.[4]

Handling, Storage, and Precautions: is slightly sensitive to oxygen and should be stored under nitrogen.[5] It showed no toxicity in several biological test systems.[6]

Functional Group Reductions.

Tris(trimethylsilyl)silane is an effective radical reducing agent for organic halides, selenides, xanthates, isocyanides,[2] and acid chlorides (Table 1).[7] The reactions are carried out at 75-90 °C in toluene in the presence of a radical initiator, i.e. ***Azobisisobutyronitrile***. Chromatographic workup affords the products. The silicon-containing byproducts are easily separated. The silane can also be used catalytically when ***Sodium Borohydride*** is employed as the coreductand.[8] If a halide (bromide or iodide) is treated under photochemical initiation conditions with an excess of sodium borohydride and a small amount of tris(trimethylsilyl)silane or its corresponding halide, the silane is continously regenerated from the silyl halide.

Table 1 Reduction of Several Organic Compounds by Tris(trimethylsilyl)silane[2,7]

RX	Yield RH (%)	RX	Yield RH (%)
	82		86
	90		95
	97		99
	95		92

Iodides and bromides are reduced by tris(trimethylsilyl)silane to the corresponding hydrocarbons in high yield after a short reaction time (0.5

h). From tertiary to secondary and primary chlorides the reduction becomes increasingly difficult. A longer reaction time and periodic addition of initiator is required. Photochemical initiation can be used and is quite efficient.[9] Tris(trimethylsilyl)silane is superior to ***Tri-n-butylstannane*** in replacing an isocyanide group by hydrogen. The reaction with tin hydride requires high temperatures (boiling xylene for primary isocyanides) and periodic addition of initiator. Using the silane, primary, secondary, and tertiary isocyanides are reduced at 80 °C in high yields. The reduction of selenides by tris(trimethylsilyl)silane proceeds with high yields; however, the corresponding reaction of sulfides is inefficient.

Acyl chlorides are converted by tris(trimethylsilyl)silane to the corresponding hydrocarbons. Tertiary and secondary acid chlorides react at 80 °C, while the reduction of primary derivatives requires higher temperatures.[7] The radical deoxygenation of hydroxyl groups is carried out by conversion of the alcohol to a thionocarbonate, which can be reduced by tris(trimethylsilyl)silane (eq 1). This very mild method is especially useful in natural product synthesis. It has been utilized for the deoxygenation of lanosterol (eq 2)[6] and the dideoxygenation of 1,6-anhydro-D-glucose (eq 3).[10]

(1)

(2)

(3)

Radical deoxygenation of the *cis*-unsaturated fatty acid derivative with tris(trimethylsilyl)silane gives methyl triacont-21-*trans*-enoate together with the saturated compound (eq 4). If the reaction is carried out with tri-*n*-butyltin hydride, the configuration remains unchanged.[11]

Hydrosilylation of Double Bonds.

Tris(trimethylsilyl)silane is capable of radical hydrosilylation of dialkyl ketones,[12] alkenes,[12,13] and alkynes.[13] Hydrosilylation of alkenes yields the anti-Markovnikov products with high regio- and good diastereoselectivity (eq 5). By using a chiral alkene, complete stereocontrol can be achieved (eq 6).[14] The silyl group can be converted to a hydroxyl group by Tamao oxidation.[13]

Monosubstituted alkynes give alkenes in high yield and stereoselectivity. The formation of (*E*)- or (*Z*)-alkenes depends on the steric demand of the substituents (eq 7). 1,2-Disubstituted phenylalkynes are attacked exclusively β to the phenylated alkyne carbon atom.[13] The silyl moiety can be replaced by a bromine atom with overall retention of configuration (eq 8).[13]

(8)

The hydrosilylation of ketones is in general slower than the corresponding reaction of alkenes and alkynes. In the case of sterically hindered ketones, a catalytic amount of a thiol is necessary to carry out the reaction.[15] The resulting silyl ethers can be easily desilylated by standard procedures. With 4-*t*-butylcyclohexanone the *trans* isomer is formed as the main product (eq 9). The hydrosilylation of a ketone bearing a chiral center in the adjacent position yields mainly the Felkin-Anh product (eq 10).[15]

(9)

(10)

Intramolecular Reactions.

Tris(trimethylsilyl)silane is an effective mediator of radical cyclizations.[16] In addition to halides and selenides, secondary isocyanides can be used as precursors for intramolecular C-C bond formation,[17] which is impossible using the tin hydride (eq 11). Selective cleavage of the carbon-sulfur bond of a 1,3-dithiolane, 1,3-dithiane,[18] 1,3-oxathiolane, or 1,3-thiazolidine[19] derivative is an efficient process to generate carbon-centered radicals, which can undergo cyclization (eq 12).

(11)

(12)

2-Benzylseleno-1-(2-iodophenyl)ethanol reacts smoothly with tris(trimethylsilyl)silane to give benzo[*b*]selenophene (eq 13).[20] A similar homolytic substitution reaction at the silicon atom yields a sila bicycle.[21]

(13)

The silane is superior to the tin reagent in the radical rearrangement of glycosyl halides to 2-deoxy sugars (eq 14).[16] Aromatization of the A-ring of 9,10-secosteroids can be achieved by a mild, radical-induced fragmentation reaction of 3-oxo-1,4-diene steroids (eq 15).[22]

(14)

(15)

Intermolecular Reactions.

Radical carbon-carbon bond formation can be carried out with tris(trimethylsilyl)silane.[16] Again, it is possible to use isocyanides as precursors (eqs 16 and 17).[17]

(16)

(17)

Nonradical Reactions.

Tris(trimethylsilyl)silane reacts with carbenium ions to form a silicenium ion.[23] In this case, tris(trimethylsilyl)silane is only slightly more reactive than trimethylsilane. The reaction of the silane with methyl diazoacetate in the presence of copper catalyst gives the α-silyl ester (eq 18).[24]

Tris[trinitratocerium(IV)] Paraperiodate[1a,b]

$[(NO_3)_3Ce]_3H_2IO_6$

[94316-41-3] · $Ce_3H_2IN_9O_{33}$ · Tris[trinitratocerium(IV)] Paraperiodate · (MW 1203.37)

(mild oxidizing reagent for oxidation of several functional groups;[2] efficient catalyst for dimerization of thiols and selenols[3] and ring opening of epoxides[4])

Alternate Name: TTCPP.

Solubility: insol cold H_2O, THF, EtOH, acetone.

Form Supplied in: yellow solid, easily prepared.

Preparative Methods: a cold solution of potassium periodate (0.01 mol) in H_2O (100 mL) is added dropwise to a solution of ***Cerium(IV) Ammonium Nitrate*** (0.03 mol) in H_2O (30 mL) cooled in ice-bath. The precipitate is filtered and washed with H_2O and acetone, and dried (70%).

Handling, Storage, and Precautions: very air stable and can be stored for months without losing its activity; periodate and cerium are both reputed to have low toxicity.

Introduction.

TTCPP is a convenient reagent for the oxidation of several different functional groups in protic and aprotic solvents under heterogeneous conditions. Separation of the oxidant and isolation of the product are achieved simply by filtration, evaporation, and chromatographic purification. Cerium(IV) reagents usually suffer from disadvantages,[1,5,6] but many of these drawbacks are not observed when using TTCPP.[2]

Oxidations.

Benzylic hydroxyl groups are oxidized to carbonyl compounds in high yields (eq 1) with this reagent.[2]

(1)

α-Hydroxy ketones are oxidized to diketones and decarboxylation occurs with α-hydroxy carboxylic acids to produce aldehydes (eqs 2 and 3).[2]

(2)

(3)

Oxidative cleavage of C-C bonds occurs in the reaction of arylethylene glycols (eq 4); TTCPP is also effective for the high-yield oxidation of phosphines (eq 5).[2]

(4)

(5)

The reagent has also been employed for the oxidation of thiols to disulfides (eq 6).

(6)

Electron-Transfer Reactions.

Catalytic amounts of TTCPP in THF dimerize both thiols and selenols efficiently at room temperature (eq 7).[3]

(7)

Epoxides in different types of alcohols are cleaved by catalytic amounts of TTCPP to afford β-alkoxy alcohols (eq 8).[4]

(8)

Catalytic amounts of TTCPP in acetic acid promote acetolysis of epoxides followed by abstraction of the α-hydrogen adjacent to a carbonyl group to produce β-hydroxyaryl succinates in good yields (eq 9).[4]

(9)

In comparison with the oxidative ability of TTCPP, ***Cerium(IV) Ammonium Nitrate*** (CAN) is relatively inactive in benzene. A comparison between TTCPP, CAN,[16,7,-10] and zinc bismuthate (ZB)[11] is shown in Table 1.

Table 1 Comparative Oxidative Abilities

Substrate	Product	TTCPP (%)	CAN (%)	ZB (%)
Benzyl alcohol	Benzaldehyde	90 95	94	80
Furoin	Furil	100	5	95
Cyclohexanethiol	Dicyclohexyl disulfide	100		99
Benzilic acid	Benzophenone	100		95
Styrene oxide	2-Methoxy-2-phenylethanol	80	90	
Epichlorohydrin	1-Chloro-3-methoxy-2-propanol	75	79

Tris(triphenylphosphine)nickel(0)[1]

$Ni(PPh_3)_3$

[25136-46-3] · $C_{54}H_{45}NiP_3$ · Tris(triphenylphosphine)nickel(0) · (MW 845.59)

(a source of nickel(0) useful for the coupling of aryl, alkenyl, and allyl halides;[2] oligomerization of strained alkenes;[3] oligomerization of allenes[4])

Physical Data: mp 124-126 °C (N_2).

Solubility: sol toluene, benzene, DMF, DMA, Et_2O, THF, HMPA.

Analysis of Reagent Purity: ^{1}H NMR δ 7.37 (*o*-H), 6.96 (*m*- and *p*-H).[5]

Preparative Methods: the standard preparation involves the reduction of ***Nickel(II) Chloride*** with ***Zinc*** dust in the presence of ***Triphenylphosphine***. Anhydrous $NiCl_2$ (2.6 g) was refluxed with 21 g of PPh_3 in 300 mL of acetonitrile for 1 h. After cooling to rt, 2.0 g of zinc dust was added and the mixture was stirred under nitrogen overnight. After removal of solvent, the resulting red solid was dissolved in the minimum volume of hot toluene (60 °C), removed from insoluble impurities by hot filtration, precipitated by the addition of hexane, and dried under vacuum to give a reddish-brown powder.[5] This precipitation has also been carried out in situ from the same starting materials and is currently the favored procedure.[2] Several other methods of preparation have been described.[6]

Handling, Storage, and Precautions: highly oxygen sensitive; special inert-atmosphere techniques must be used.[7] Should be stored at 0 °C.

Coupling of Aryl, Alkenyl, and Allyl Halides.

Tris(triphenylphosphine)nickel(0) reacts with organic halides by oxidative addition of nickel(0) into carbon-halogen bonds to form intermediate nickel(II) complexes.[8] These organometallic intermediates, which are usually not isolated, react with a variety of nucleophiles, leading to replacement of the original halide with the nucleophile and regeneration of a catalytic nickel(0) species. In the case of aryl halides, the arylnickel intermediates can be reacted with cyanide salts to give nitriles,[9] with acetylides to give alkynes,[10] with halide salts to give halogen exchange,[11] with phosphines to give phosphonium salts,[12] and with sodium borohydride to give overall hydrogenation.[13] Aryl amines, ethers, and carboxylic acids have also been formed catalytically through these types of reactions.[14] Aryl bromides and iodides both work well as substrates, and many functional groups are tolerated. However, *ortho* substituents tend to slow the reactions down and give lower yields. A wide array of cross-coupling reactions with Grignard and other organometallic reagents have also been performed, but using $Ni(PPh_3)_4$ as the catalyst.

Homocoupling of aryl halides requires stoichiometric amounts of nickel(0), but can be made catalytic in nickel by the addition of excess zinc, magnesium, or manganese as a reducing agent.[15] Aryl chlorides are reactive for this transformation and the yields of biphenyls from *para*-substituted aryl chlorides are better than in the corresponding stoichiometric reactions (eq 1).[16] Nitro groups destroy the catalytic acivity of the nickel complexes,[17] and *ortho* substituents strongly inhibit the reaction. The presence of acidic functionalities leads to reduction of the arene. A macrocyclic bicycle, bis[18]annulene, was synthesized by this method.[18] This coupling reaction has also been carried out intramolecularly to produce a macrocyclic pentaphenylene in 65% yield.[19]

(1)

R = H, 99%; CHO, 94%; COPh, 100%; CN, 98%

In the case of alkenyl halides, oxidative addition of the nickel(0) catalyst occurs with retention of configuration of the double bond.[20] This reaction has been used for the homocoupling of vinyl bromides,[21] and to make dienoic acids by the insertion of 3-butenoic acids.[22] Allylic halides may be homocoupled as well.[2]

The coordinatively unsaturated $Ni(PPh_3)_3$ catalyst is also formed in solution from $Ni(PPh_3)_4$ by ligand dissociation and is probably the reactive species in oxidative addition reactions of $Ni(PPh_3)_4$ (see ***Tetrakis(triphenylphosphine)nickel(0)*** and ***Bis(1,5-cyclooctadiene)nickel(0)***).[23]

Oligomerization of Strained Alkenes.

3,3-Disubstituted cyclopropenes dimerize with catalytic $Ni(PPh_3)_3$ via a [2 + 2] cycloaddition pathway to form cyclobutanes.[24] Methylenecyclopropane reacts to give mixtures of cyclic and acyclic dimers and trimers (see ***Bis(1,5-cyclooctadiene)nickel(0)***).[25]

Oligomerization of Allenes.

Substituted allenes react with $Ni(PPh_3)_3$ to form dimers and trimers.[26] When carbon monoxide is added, CO insertion leads exclusively to cyclic products.[4] Reaction with a diallene, 2,7-dimethyl-2,3,5,6-octatetraene, quantitatively produced a 10-membered ring trimer (see also ***Bis(triphenylphosphine)nickel(0)***).[27]

Tris(triphenylsilyl) Vanadate

$(Ph_3SiO)_3V{=}O$

[5590-56-7] · $C_{54}H_{45}O_4Si_3V$ · Tris(triphenylsilyl) Vanadate · (MW 893.20)

(catalyst for the 1,3-isomerization of propargylic[1] and allylic alcohols[2])

Alternate Name: oxotris(triphenylsilanolato)vanadium

Physical Data: mp 225-227 °C.

Solubility: sol xylene, benzene, mineral oil.

Form Supplied in: not commercially available.

Preparative Methods: from vanadium pentoxide and triphenylsilanol.[1]

Purification: recrystallize from xylene, benzene, or mesitylene and wash with hexane.

Handling, Storage, and Precautions: hydrolyzes in moist air.

Isomerization of Propargylic Alcohols to α,β-Unsaturated Carbonyl Compounds.

Propargylic alcohols are converted into α,β-unsaturated aldehydes or ketones by treatment with the title reagent (**1**) in mineral oil at 150 °C (eq 1).[1,3] Yields in this reaction are typically greater than 85%. The reaction proceeds via a mechanism involving a [3,3]-sigmatropic rearrangement and thus the reaction proceeds with complete allylic inversion after protonolysis of the oxyallene intermediate.

Isomerization of Allylic Alcohols.

Treatment of allylic alcohols with (**1**) in mineral oil at 150 °C effects clean allylic inversion (eq 2).[2] Since this is an equilibrium process, the reaction is probably limited to cases where the starting allylic alcohol is considerably less stable than its allylic rearrangement product. As in the above case with propargylic alcohols, the reaction proceeds via a [3,3]-sigmatropic rearrangement. In some cases, minor amounts of alcohol oxidation products were also observed. Yields for this process are typically greater than 80%.

Tropylium Tetrafluoroborate[1]

[27081-10-3] · $C_7H_7BF_4$ · Tropylium Tetrafluoroborate · (MW 177.95)

(useful precursor to azulenes,[2,3] cycloheptatrienes,[4-15] heptafulvenes,[4,9,16] 8-azafulvenes,[17] and tropones[18,19])

Alternate Names: tropylium fluoroborate, cycloheptatrienocarbonium fluoroborate.

Physical Data: mp >200 °C (dec).

Solubility: sol polar organic solvents (e.g. MeCN, DMF), and H_2O; reacts with DMSO.[19]

Form Supplied in: white powder; commercially available.

Analysis of Reagent Purity: elemental analysis; λ_{max} 218 nm; (log ε 4.70), 274 nm; (log ε 3.61).[20]

Preparative Methods: most conveniently prepared by the reaction of cycloheptatriene with PCl_3, followed by treatment with ethanolic HBF_4 at 0 °C (0.24 mol scale, 80-89% yield).[20] The reagent is obtained in 98-100% purity.

Purification: can be recrystallized from a large volume of ethyl acetate or ethyl acetate-acetonitrile; however, considerable material is lost and the purity of the reagent is not significantly improved.[20]

Handling, Storage, and Precautions: this material is a nonhygroscopic, stable source of the tropylium ion, making it a superior choice to either the halide (hygroscopic) or perchlorate (potentially explosive) salts. The reagent is a corrosive solid.

Synthesis of Azulenes.

Tropylium tetrafluoroborate ($TpBF_4$) (2 equiv) reacts with a variety of allenylsilanes to generate 2-silylazulenes in fair to excellent yield (eq 1).[2] This [3 + 2] annulation strategy allows for the synthesis of azulenes with complete regiochemical control over substituents on the newly formed five-membered ring. It is necessary to employ a nonnucleophilic acid scavenger to remove HBF_4 generated in the reaction in order to obtain good yields of azulenes; poly(4-vinylpyridine) or methyltrimethoxysilane functions best in this capacity. An analogous reaction with propargylsilanes also gives rise to 2-silylazulenes.[3] The 2-silylazulene products can be readily protodesilyated to yield 1,3-disubstituted azulenes in excellent yield. Certain substituted tropylium tetrafluoroborates will also undergo this reaction to generate azulenes. However, substituents are limited to groups bearing no α-hydrogens (to prevent heptafulvene formation,[21] e.g. *t*-butyl or phenyl).

Synthesis of Substituted Cycloheptatrienes.

Tropylium salts react with a wide array of carbon- and heteroatom-based nucleophiles to provide 7-substituted cycloheptatrienes (7-CHTs). $TpBF_4$ is best suited for this reaction since it is nonhygroscopic and indefinitely stable.[20] For example, $TpBF_4$ reacts with a variety of active methylene compounds such as diethyl acetonedicarboxylate,[4] acetylacetone (eq 2),[5] and malonic acid derivatives[6] to give 7-CHTs. Alkyl-, alkenyl-, and akynyllithium reagents, as well as alkenylzinc and -aluminum derivatives, combine smoothly with $TpBF_4$ to provide access to a host of 7-CHTs.[7] α-Cycloheptatrienyl ketones are also easily prepared from $TpBF_4$ by reaction with enolizable ketones[8] or morpholinoenamines[9] in the presence of an acid catalyst. Other nucleophiles which react with $TpBF_4$ in this manner include isocyanides,[10,11] inorganic cyanides,[11] allylsilanes,[12] stabilized phosphonium ylides,[13] propargylic alcohols,[14] and allylic amines.[15]

Synthesis of Heptafulvenes and 8-Azaheptafulvenes.

In a two-step procedure, $TpBF_4$ can be used to synthesize a variety of heptafulvene derivatives.[4,9,16] As previously discussed, $TpBF_4$ reacts with nucleophiles to give cycloheptatrienes. These CHTs can then be used to produce heptafulvenes. For example, treatment of $TpBF_4$ with 1,3-cyclopentanedione generates a 7-CHT. Reaction of this species with ***Phosphorus(V) Chloride*** yields a new tropylium cation, which when treated with base affords a heptafulvene derivative (eq 3).[16a] 8-Azaheptafulvenes can also be produced from $TpBF_4$ by reaction with a variety of aniline derivatives (eq 4).[17]

(4)

Synthesis of Tropone.

$TpBF_4$ is a convenient starting material for the synthesis of tropone in multigram quantities. This may be accomplished by treating tropyl ether (formed by the reaction of $TpBF_4$ with aq NaOH) with acid-treated silica gel (eq 5).[18] A more direct route involves heating $TpBF_4$ in DMSO; this route provides tropone in 58% yield.[19]

Tungsten(VI) Chloride

WCl_6

[13283-01-7] · Cl_6W · Tungsten(VI) Chloride · (MW 396.61)

(alkene polymerization catalyst;[1] Lewis acid[2])

Physical Data: dark blue crystals; mp 275 °C; bp 347 °C.

Solubility: sol ethanol, ether, benzene, carbon tetrachloride.

Form Supplied in: sold as a solid of high purity, often packaged in ampules.

Purification: used without further purification.

Handling, Storage, and Precautions: corrosive and moisture sensitive; stored in ampules.

Decomposition of Diazo Compounds.

Diazo compounds are converted to the corresponding carbenoid species by treatment with tungsten hexachloride.[2] Tungsten hexachloride is superior to copper catalysts and common Lewis acids in effecting the [3 + 2] cycloaddition reaction between α-carbonyl carbenes and nitriles, forming isoxazoles (eq 1).

(1)

Conversion of β-Hydroxy Carboxylic Acids to Alkenes.

Treatment of β-hydroxy carboxylic acids with tungsten(VI) chloride and base leads to the β-lactones, which afford alkenes after thermal carbon dioxide expulsion (eq 2).[3] The reaction occurs in one pot and is highly stereospecific. More examples have been examined using tungsten oxychloride.

Related Reagents.

Tungsten(VI) Chloride-n-Butyllithium; ***Tungsten(VI) Chloride-Tetramethylstannane***.
