Tungsten(VI) Chloride-*n*-Butyllithium

WCl_6-*n*-BuLi

(WCl_6)

[13283-01-7] · Cl_6W · Tungsten(VI) Chloride-*n*-Butyllithium · (MW 396.61) (*n*-BuLi)

[109-72-8] · C_4H_9Li · Tungsten(VI) Chloride-*n*-Butyllithium · (MW 64.07)

(deoxygenation of epoxides and carbonyl compounds[1])

Physical Data: WCl_6: dark blue crystals; mp 275 °C; bp 347 °C.

Solubility: WCl_6: sol ethanol, ether, benzene, carbon tetrachloride. *n*-BuLi: sol hydrocarbon and ether solvents.

Form Supplied in: reaction of ***Tungsten(VI) Chloride*** and ***n-Butyllithium*** produces a poorly characterized species, thought to be a reduced form of tungsten. The compound obtained by mixing these two reagents is typically used without additional purification. Tungsten(VI) chloride is sold as a solid of high purity, often packaged in ampules. Butyllithium is sold as a solution in hexane, cyclohexane, or pentane.

Purification: both reagents are used without further purification.

Handling, Storage, and Precautions: WCl_6: corrosive and moisture sensitive; stored in ampules. *n*-BuLi: reacts fairly violently with water and air; can be stored indefinitely provided the container is protected from the atmosphere.

Deoxygenation of Epoxides.

The combination of tungsten(VI) chloride and butyllithium leads to a structurally uncharacterized reagent which is very efficient for the deoxygenation of epoxides, affording alkenes.[1] The reagent is stereospecific for the reduction of cyclic epoxides,[1,2] but less stereoselectivity is observed during the preparation of acyclic alkenes from the corresponding epoxides. Reduction of monosubstituted epoxides often leads to substantial amounts of chlorohydrins, which are nonstereospecifically reduced by the reagent at higher temperatures. Tungsten(VI) chloride-butyllithium is the reagent of choice for deoxygenation of highly hindered epoxides. This reagent is effective for reduction of the epoxide functionality in the complex trichothecene derivative in eq 1,[3] and the ryanodol synthesis intermediate in eq 2.[4]

(2)

Deoxygenative Dimerization of Carbonyl Compounds.

Treatment of carbonyl compounds with tungsten(VI) chloride-butyllithium leads to the corresponding symmetrical alkenes resulting from deoxygenation and coupling of the carbonyl compounds.[1] The reaction proceeds most efficiently with aromatic aldehydes (eq 3) and less efficiently with aromatic ketones and aliphatic carbonyl compounds. The scope and limitations of this deoxygenative dimerization reaction have not been as thoroughly investigated as those employing low-valent titanium species.[5]

Tungsten(VI) Chloride-Tetramethylstannane

WCl_6-$SnMe_4$

(WCl_6)

[13283-01-7] · Cl_6W · Tungsten(VI) Chloride-Tetramethylstannane · (MW 396.61) ($SnMe_4$)

[594-27-4] · $C_4H_{12}Sn$ · Tungsten(VI) Chloride-Tetramethylstannane · (MW 178.87)

(alkene metathesis catalyst[1])

Physical Data: WCl_6: dark blue crystals; mp 275 °C; bp 347 °C. $SnMe_4$: bp 74-75 °C.

Solubility: WCl_6: sol ethanol, ether, benzene, carbon tetrachloride. $SnMe_4$: sol all organic solvents.

Form Supplied in: reaction of ***Tungsten(VI) Chloride*** and ***Tetramethylstannane*** produces a poorly characterized species, which is thought to be a metal-carbene complex.[2] The compound obtained by mixing these two reagents is typically used without additional purification. Tungsten(VI) chloride is sold as a solid of high purity, often packaged in ampules. Tetramethylstannane is sold as a neat liquid.

Purification: tetramethylstannane is purified by distillation under nitrogen at atmospheric pressure.

Handling, Storage, and Precautions: WCl_6: corrosive and moisture sensitive; stored in ampules. $SnMe_4$: highly toxic; can be stored for long periods in a refrigerator. The reagent prepared by combination of tungsten(VI) chloride and tetramethylstannane is typically used immediately after mixing the two reagents.

Alkene Metathesis.

The compound generated from tungsten(VI) chloride and tetramethylstannane is a catalyst for the alkene metathesis reaction.[3] Unlike many alkene metathesis catalysts, tungsten(VI) chloride-tetramethylstannane is compatible with ester functionality.[4-7] The most important use of tungsten(VI) chloride-tetramethylstannane is in the ring opening metathesis polymerization (ROMP) of cycloalkenes;[1] however, a few examples have been presented using this reagent for organic synthesis. Self-metathesis of methyl 9-octadecenoate (*cis* or *trans*) with tungsten(VI) chloride-tetramethylstannane leads to a 2:1:1 ratio of methyl 9-octadecenoate (starting material), 9-octadecene, and dimethyl 9-octadecenedioate, respectively (eq 1).[4] This system is presumably at equilibrium. Cometathesis of cyclooctene and alkenic esters by tungsten(VI) chloride-tetramethylstannane leads to dienoic esters (eq 2).[6] Similarly, the chain length of the unsaturated fatty acid ester methyl oleate can be shortened by cometathesis with hexane (eq 3).[7] In general, the cometathesis reactions do not proceed efficiently since all possible metathesis products are produced to some extent.

Tungsten(VI) Fluoride

WF_6

[7783-82-6] · F_6W · Tungsten(VI) Fluoride · (MW 297.85)

(oxidant;[1] Lewis acid[1])

Alternate Name: tungsten hexafluoride.

Physical Data: mp 2.5 °C; bp 17.1 °C.

Solubility: sol nonpolar aprotic organic solvents, basic water.

Form Supplied in: gas.

Handling, Storage, and Precautions: corrosive; moisture sensitive.

Hydrolysis of *N,N*-Dimethylhydrazones and Tosylhydrazones.

Both *N,N*-dimethylhydrazones and tosylhydrazones are oxidatively hydrolyzed under neutral conditions by treatment with tungsten(VI) fluoride in chloroform/water at 0 °C (eq 1).[1] Hydrazones of aromatic aldehydes and of aromatic and aliphatic ketones are readily hydrolyzed under these conditions. In virtually all cases the yield is greater than 80%. Using tungsten(VI) fluoride, the hydrolysis proceeds at lower temperature than with other methods.[2]

Tungsten(VI) Oxide-Chlorosulfuric Acid

WO_3-$ClSO_3H$

(WO_3)

[1314-85-8] · O_3W · Tungsten(VI) Oxide-Chlorosulfuric Acid · (MW 231.85) ($ClSO_3H$)

[7790-94-5] · $ClHO_3S$ · Tungsten(VI) Oxide-Chlorosulfuric Acid · (MW 116.53)

(induces the coupling of α-hydroxy peroxides and epoxides, forming 1,2,4-trioxane derivatives[1])

Alternate Name: tungsten(VI) oxide-chlorosulfonic acid.

Physical Data: WO_3: mp 1473 °C; *d* 7.16 g cm^{-3}; yellow crystals. $ClSO_3H$: bp 151-152 °C/755 mmHg; *d* 1.753 g cm^{-3}.

Solubility: WO_3: sol hot alkali; slightly sol HF. $ClSO_3H$: sol $CHCl_3$, CH_2Cl_2; reactive to many organic functional groups.

Form Supplied in: WO_3: yellow solid. $ClSO_3H$: neat liquid.

Handling, Storage, and Precautions: $ClSO_3H$: reacts violently with water and alcohols; an oxidizer; corrosive.

Synthesis of 1,2,4-Trioxane Derivatives.

Coupling of α-hydroxy peroxides and epoxides in the presence of tungsten(VI) oxide and ***Chlorosulfonic Acid*** catalyst leads to the synthesis of 1,2,4-trioxane derivatives, accompanied by the ketone derived from the hydroperoxide (eq 1).[1] Overall yields of 1,2,4-trioxane derivative are generally in the range of 30-60%. Epoxides tested in this reaction include cyclohexene oxide, styrene oxide, and 1,1-diphenylethylene oxide. The α-hydroxy peroxides are generated from carbonyl compounds and 30% ***Hydrogen Peroxide***, and used without further purification. Examples tested include α-hydroxy hydroperoxides derived from decanal, benzaldehyde, and cyclohexanone. For a listing of other preparations of 1,2,4-trioxane derivatives, see Jefford et al.[2]

L-Tyrosine Hydrazide

[7662-51-3] · $C_8H_{13}N_3O_2$ · L-Tyrosine Hydrazide · (MW 195.24)

(resolution of carboxylic acids and amino acids[1])

Physical Data: crystalline solid; mp 196-198 °C; [α]25D +76° (*c* 4.2, 1N HCl).

Solubility: slightly sol cold methanol or ethanol; readily sol hot methanol or ethanol.

Form Supplied in: the free base (98% purity) is available from several commercial sources. No additional purification before use is required.

Preparative Methods: the synthesis of L-tyrosine hydrazide from L-tyrosine has been described.[2] D-Tyrosine hydrazide has been obtained by resolution of DL-tyrosine hydrazide with Cbz-L-proline.[3]

Handling, Storage, and Precautions: the free base is stable in amber bottles, at room temperature, for indefinite periods of time. No special handling precautions have been described.

Introduction.

L-Tyrosine hydrazide (L-Tyr-$NHNH_2$) (**1**) is useful in the resolution of simple carboxylic acids and amino acid derivatives. It often forms highly crystalline salts with these compounds, which yield diastereomerically pure salts in just one or two recrystallizations. The yields of resolved acids tend to be high, and in many cases both enantiomers can be obtained from the same operation (the more soluble diasteromeric salt that remains in the mother liquors is often quite pure). The tyrosine hydrazide can be recovered without appreciable loss of optical activity.

Resolution of Carboxylic Acids.

A variety of racemic monofunctional carboxylic acids have been resolved with chiral α-amino acid hydrazides, including L-Tyr-$NHNH_2$ and L-leucine hydrazide, which produce mandelic acid analogs with greater than 99% ee.[4] Other examples of resolutions of simple carboxylic acids have appeared in the patent literature (eq 1).[5]

(1)

Resolution of Cyclic Amino Acid Derivatives.

L-Tyr-$NHNH_2$ has been used many times in the resolution of all types of *N*-functionalized amino acids. The high crystallinity of the salts formed has been found to be a great advantage in situations where many other common resolving agents have failed. As indicated above, multiple recrystallizations of the diastereomeric salts formed by L-Tyr-$NHNH_2$ are rarely necessary to obtain amino acids of high optical purity. In most cases, D-α-amino acid derivatives form less soluble salts with L-Tyr-$NHNH_2$ than the corresponding L-α-amino acid derivatives. One of the earliest works in this area was the resolution of (±)-Cbz-proline (eq 2).[3] (±)-Cbz-Alanine and (±)-Cbz-isoleucine (eq 3) have also been resolved.[3] In all cases, the unnatural D-α-amino acids are obtained. This procedure also allows the isolation of D-tyrosine hydrazide by resolution of (±)-Tyr-$NHNH_2$ with Cbz-L-proline.[3] Most other amino acids resolved with L-tyrosine hydrazide also have their amino group protected as the Cbz derivative. For example, both enantiomers of azetidine-2-carboxylic acid are readily available, in high yield and about 100% ee, after one single crystallization of the racemate with L-Tyr-$NHNH_2$ (eq 4).[6] Similarly, both enantiomers of pipecolic acid are obtained by resolution of (±)-*N*-Cbz-pipecolic acid with L-Tyr-$NHNH_2$ (eq 5).[7]

(2)

(3)

Resolution of Acyclic Amino Acid Derivatives.

D-Homoserine is readily available by resolution of (±)-*N*-Cbz-homoserine (eq 6).[8] Both enantiomers of *threo*-2-amino-3,4-dihydroxybutyric acids are available via a similar resolution with L-Tyr-$NHNH_2$.[9] *N*-Cbz-derivatives of amino dicarboxylic acids, such as α-aminosuberic acid, have been resolved with D-Tyr-$NHNH_2$. In this case, the L-amino acid derivatives crystallize preferentially with the resolving agent.[10] Finally, tetrazole analogs of α-amino acids have also been resolved with L-Tyr-$NHNH_2$. For example, racemic tetrazole analogs of *N*-protected alanine, leucine, phenylalanine, and valine are resolved with L-Tyr-$NHNH_2$ to yield, except for the phenylalanine analog, the D-enantiomers (eq 7).[11]

(6)

Uranium(VI) Fluoride[1]

UF_6

[7783-81-5] · F_6U · Uranium(VI) Fluoride · (MW 352.03)

(strong oxidant;[1] fluorinating agent;[2] mild Lewis acid[3])

Physical Data: mp 64.8 °C; sublimes at 56.5 °C; vapor pressure at room temperature 115 mmHg.[4]

Solubility: sol Freon, chloroform, methylene chloride.

Form Supplied in: white crystalline compound. Available in the ^{235}U depleted form as a byproduct of uranium enrichment plants.

Handling, Storage, and Precautions: UF_6, depleted of fissionable ^{235}U, contains less than 0.20% ^{235}U. It is corrosive, moisture sensitive, and mildly radioactive (low level of radiation). Caution should be exercised against these potential hazards. UF_6 is best handled in all copper apparatus. However, Freon solutions of UF_6 are stable and do not attack glass. This reagent should only be handled in a fume hood.

Oxidation.

UF_6 is a strong oxidant. Its oxidizing ability compared with that of other higher fluorides of f- and d-elements in Groups 5 and 6 is in the following sequence: $VF_5 > UF_6 > MoF_6 > WF_6 > MoF_5$.[1] Another study shows that, in acetonitrile, UF_6 is a stronger oxidant than MoF_6, NO^+, and Cu^{2+}.[5] UF_6 reacts with higher alkanes, alkenes, and arenes vigorously to give carbonaceous substances; this is of little synthetic value.[1] However, it has been used to oxidize partially oxidized organic compounds selectively. UF_6 reacts with benzylic alcohols and bromides readily to form aldehydes or ketones in moderate to good yields (eqs 1 and 2).[2] Oxidation of alkyl bromides or iodides is, however, not successful.

(1)

R^1 = H, alkyl, aryl

(2)

Alkyl methyl ethers are oxidatively cleaved to the corresponding carbonyl compounds (eq 3). When alkyl benzyl and alkyl benzhydryl ethers are used in the reaction, the parent alkyl alcohols are obtained together with benzaldehyde and benzophenone, respectively.[2] UF_6 is also effective in cleaving allyl ethers, but the direction of the cleavage is unpredictable. The intermediates of the oxidation can be intercepted by dithiols to form dithioacetals (eq 4). Tertiary amines (*N*,*N*-dimethylamines) react similarly with UF_6 to yield the corresponding carbonyl compounds (eq 5).

(3)

(4)

(5)

Hydrazones and oximes react with UF_6 to regenerate the parent carbonyl functions (eqs 6 and 7).[2] This offers a new alternative for these deprotections.

(6)

(7)

Oxidation of iodine by UF_6 in acetonitrile yields bis(acetonitrile)iodine(I) hexafluorouranate(V).[6a] In the case of bromine, oxidation generates tris(acetonitrile)bromine(I) hexafluorouranate(V) with a possible 1,3,5-triazine like structure (eq 8); this can be further utilized to brominate arenes.[6b]

(8)

Fluorination.

Aliphatic alcohols react with UF_6 in the gas phase to form fluoroalkanes, alkenes, and ethers.[7] For primary alcohols, fluoroalkanes are the major products (eq 9). This is a valuable reaction, since it is difficult to prepare primary fluorides, especially methyl fluoride.

(9)

Both alkyl and aryl aldehydes have been converted to acyl fluorides in moderate yields (eq 10).[2] Adamantanone is oxidatively fluorinated to 2,2-difluoroadamantane in 41% yield (eq 11).[2] On the other hand, UF_6 behaves as a mild Lewis acid towards enolizable ketones, leading to their condensation.[8] UF_6 reacts with carboxylic acids to form acyl fluorides,[1] but in some cases this reaction is accompanied by decarboxylation.[9]

Urea[1]

[57-13-6] · CH_4N_2O · Urea · (MW 60.07)

(nitrogen nucleophile; carbonyl cation equivalent; formation of inclusion complexes is used to purify long, slender compounds)

Physical Data: mp 132.7-132.9 °C; *d* 1.335 g cm^{-3}.

Solubility: sol H_2O (108 g/100 mL at 20 °C), EtOH (5.4 g/100 mL at 20 °C), MeOH (22 g/100 mL at 20 °C).

Form Supplied in: colorless solid.

Purification: reagent graded commercial products are sufficiently pure for most purposes. For further purification, see Perrin and Armarego.[2]

Nitrogen Nucleophile.

The three heteroatoms of urea, i.e. two nitrogens and an oxygen, are moderately nucleophilic. A number of highly regioselective alkylation reactions of urea have been developed. In most cases, the nitrogen atom is alkylated to afford the corresponding ureides or amino compounds. On heating a mixture of a carboxylic acid and urea (**1**) at around 160 °C, the corresponding amide is obtained (eq 1).[3,4] In the presence of ***Triphenyl Phosphite*** and ***Pyridine***, aromatic carboxylic acids react with urea at lower temperatures to give the corresponding arylcarbonylureas in good yields (eq 2).[5]

Urea serves as a nitrogen nucleophile toward tertiary carbocationic species to give *N*-*t*-alkylureas;[6,7] for example, the *t*-butyl cation, generated by treatment of *t*-BuOH with H_2SO_4, is trapped with urea to give *t*-$BuNHCONH_2$, a useful precursor of ***t-Butylamine*** (eqs 3 and 4).[6]

Urea reacts with orthoesters and related compounds to form alkylideneurea derivatives. The reaction with ***N,N-Dimethylformamide Diethyl Acetal*** gives *N*-carbamoyl-*N*′,*N*′-dimethylamidine (eq 5).[8] Active methylene compounds may further participate in the condensation reaction of ***Triethyl Orthoformate*** and urea to form ureidomethylene derivatives (eq 6).[9] Treatment of urea with ***Chlorine*** in the presence of ***Calcium Carbonate*** provides monochlorourea, which may be utilized as a source of ***Hypochlorous Acid*** (eq 7).[10,11]

Under mild conditions, urea undergoes nucleophilic addition to carbon-carbon triple bonds (eq 8)[12] and double bonds (eq 9)[13] activated by

the coordination of Pd^{II} species. Under 1 atm of ***Carbon Monoxide***, intramolecular aminocarbonylation proceeds at 0 °C to room temperature to provide protected β-amino acids (eq 9).[13]

(8)

(9)

Two of the three heteronucleophilic centers of urea react with difunctionalized carbonyl compounds (e.g. dicarbonyl compounds, α-halo- or α-hydroxy carbonyl compounds, and α,β-unsaturated carbonyl compounds) to furnish a wide range of nitrogen heterocycles. The dicarbonyl compounds include ***Glyoxal***, α-diketones (eqs 10 and 11),[14-16] α-keto esters (eq 12),[17] oxalic and malonic esters (eq 13),[18,19] β-diketones (eq 14),[20] and β-keto esters (eq 15).[21] A three component connection reaction of urea, aldehydes, and β-keto esters provides dihydropyrimidines (Biginelli reaction) (eq 16).[22]

(11)

(12)

(13)

$n = 0$ parabanic acid 71.5-76%
$n = 1$ barbituric acid 72-78%

The reaction of urea and carbonyl compounds with α-substituents, such as α-hydroxy ketones[23] and α-halo ketones,[11] may afford either imidazol-2-one derivatives (eq 17) or oxazole derivatives (eq 18).[24] The latter is a rare example of the *N*,*O*-dialkylation of urea.

α,β-Unsaturated ketones and acids react with urea to give dihydropyrimidine derivatives (eq 19)[25] and dihydrouracils (eq 20),[26] respectively. α,β-Unsaturated aldehydes and ketones with β-substituents, such as alkoxy,[27] amino,[28] halogeno,[29] trichloromethyl,[30] etc.,[31] provide substituted pyrimidines (eq 21).

(21)

X = OEt, NMe_2, Cl, CCl_3, etc
R = H, alkyl, aryl

Carbonyl Cation Equivalent.

In the reaction with heteronucleophiles, urea acts as a carbonyl cation or dication equivalent, like phosgene and carbonates, though requiring more drastic conditions. *N*-Substituted or *N*,*N*′-disubstituted ureas can be prepared by transamination of the urea nitrogen atoms with primary amines (eqs 22 and 23).[32] Reaction of urea with *vic*-diamines (eq 24)[33] and 2-aminophenols (eq 25)[34] gives imidazolidin-2-ones and oxazolidin-2-ones, respectively. The reaction with aliphatic 2-amino alcohols, on the other hand, gives imidazolidin-2-ones via substitution by the hydroxyl group for a nitrogen of urea (eq 26).[35,36] The *cis*-1,5-dimethyl-4-phenylimidazolidin-2-ones, obtained by fusing (-)- or (+)-ephedrine hydrochloride and urea, are useful chiral auxiliaries for asymmetric syntheses.[36]

(22)

(23)

(24)

(25)

(26)

Catalyst.

The conversion of ***Tetracyanoethylene*** into dicyanoketene acetals is catalyzed by urea (eq 27).[37]

(27)

Inclusion Compounds (Differentiation of Linear Compounds from Branched Ones).[1,38]

Urea forms inclusion complexes, taking normal alkanes having six or more carbon atoms as guests.[39] In the complexes, hydrogen bonded urea molecules are oriented in a helical lattice, constructing a cylinder-shaped channel. The guest molecule is not bonded to the host but merely trapped in the cylinder. The diameter of the channel is usually about 5.25 Å. Aliphatic hydrocarbons with a single methyl branch, such as 3-methylhexadecane, that form the complex require a channel diameter of about 5.5 Å. This seems the upper limit of thickness. Not only hydrocarbons but many kinds of functionalized alkanes can be included if they are long and slender enough. Compounds that form inclusion complexes include 1-bromohexane, 1- and 2-octanol, 2-heptanone, 1-cyclopentylnonane, and 2-, 3-, and 4- methyltridecane. On the other hand, the following compounds do not form the complex: 3-ethyldodecane, 2-bromooctane, 1-cyclohexyloctane, and 2,4-dimethyldodecane.[40] Thus linear compounds, as in the former group, can be separated from a mixture with small or branched ones such as in the latter. *syn*-9,10-Dihydroxystearic acid has been separated from its *anti* counterpart.[41] The *syn*-diol (mp 95 °C), which is estimated to require a channel diameter of 5.4 Å, readily forms a urea complex. On the other hand, the *anti*-diol (mp 131 °C), which requires a channel diameter of 6 Å, does not form a complex.[38]

Urushibara Nickel[1]

Ni

[7440-02-0] · Ni · Urushibara Nickel · (MW 58.69)

(precipitated metal hydrogenation catalyst; useful principally in reduction of alkynes and alkenes to alkanes,[2] reduction of carbonyls to alcohols,[3] dehydrogenations,[1] and reductive desulfurizations[1])

Preparative Methods: Urushibara catalysts are prepared by acid (U-Ni-A), base (U-Ni-B), or neutral (U-Ni-N) digestion of precipitated nickel. Similar catalysts can be prepared using either iron or cobalt.[1]

Handling, Storage, and Precautions: Urushibara catalysts do not appear to degrade upon short exposure to air.[4] Protection from moisture is required for long-term storage.

Urushibara Catalysts.

The Urushibara catalysts are a family of precipitated metal catalysts that have been compared to the more common ***Raney Nickel*** catalysts. Although the two can catalyze many of the same reactions, Urushibara metals offer several advantages: they are nonpyrophoric, are easily generated, have a long shelf life, and can catalyze highly regio- and stereoselective reductions.

Catalytic Hydrogenation of Alkynes and Alkenes.

Alkenes and alkynes can be reduced to the corresponding alkanes using moderate to high pressures of H_2 and temperatures. In eq 1, the exocyclic alkene is hydrogenated selectively with the use of U-Ni-N. Longer hydrogenation times and use of other Urushibara catalysts result in complete reduction of this substrate. The use of Raney nickel in this example results in nonspecific reduction.[2] Aromatic rings can also be saturated; however, these reactions only proceed at high temperature or under pressure.[1]

(1)

Catalytic Hydrogenation of Carbonyl Compounds.

Ketones and aldehydes can be reduced to their respective alcohols using Urushibara catalysts with hydrogen at atmospheric pressure and room temperature. Eq 2 demonstrates the regio- and stereoselectivity that can be obtained using Urushibara catalysts.[3] Use of Raney nickel results in an equimolar mixture of the two stereoisomers. Hydrogenolysis of the resulting C-O bond can occur with aryl-substituted compounds, giving the corresponding hydrocarbons.[1]

Dehydrogenations.

Urushibara catalysts have been used as dehydrogenation catalysts. Numerous examples exist with steroidal compounds using cyclohexanone as the hydrogen acceptor. In general, dehydrogenations using Urushibara catalysts are comparable to those of Raney nickel.[1]

Reductive Desulfurizations.

Urushibara catalysts, specifically U-Ni-A, have been used in desulfurizations of sulfur-containing compounds such as thiols, sulfides, disulfides, and thioacetals without competing reduction of alkenes. Reductive desulfurizations can be performed using Raney nickel with comparable yields.[1]

Miscellaneous Reductions.

Urushibara catalysts have been employed to reduce oximes, nitriles, hydroxylamines, nitro, and nitroso compounds. These reductions can be very dependent on reaction conditions. Yields of products are generally high and steric biasing can lead to high levels of stereocontrol.[1]

Vanadium(IV) Chloride

VCl_4

[7632-51-1] · Cl_4V · Vanadium(IV) Chloride · (MW 192.74)

(oxidative coupling of phenols)

Alternate Names: vanadium tetrachloride; tetrachlorovanadium; vanadium chloride.

Solubility: sol with decomposition in cold water; sol abs alcohol, ether, chloroform, acetone.

Form Supplied in: commercially available as a bright red liquid.

Handling, Storage, and Precautions: moisture sensitive; spills may be neutralized with water. Toxic and corrosive; use efficient fume hood and wear plastic-covered gloves and apron (attacks neoprene).[1]

Oxidative Coupling of Phenols.

The oxidation of a number of simple phenols and aniline derivatives by vanadium tetrachloride affords dimeric products which are predominantly the result of intermolecular coupling at the *para* position.[2] For example, the addition of ca. 1 equiv of VCl_4 to phenol in dry carbon tetrachloride generates, after isolation, an 8:4:1 mixture of 4,4´-, 2,4´-, and 2,2´-biphenols, respectively (eq 1). Virtually no change in yield is observed when the ratio of phenol to VCl_4 is varied. While the related *p*- and *m*-cresol generate only polymeric products, *o*-cresol does dimerize to 3,3´-dimethyl-4-4´-dihydroxybiphenyl in 26% yield.[2]

Hindered phenols have been coupled with moderate success. For example, dimerization of 3,5-dimethoxyphenol to the corresponding *para-para* adduct 2,2´,6,6´-tetramethoxy-4,4´-dihydroxybiphenyl and its *ortho-para* isomer has been effected in 10.8% overall yield as a 4:1 ratio of the respective regioisomers (eq 2).[1a] The *para-para* coupled dimer is the key intermediate in the total synthesis of the algal metabolite fucophlorethol A. Similarly, 6-*t*-butyl-3-methylphenol undergoes VCl_4-mediated coupling to a mixture of the *para-para* and the *ortho-para* products.[3] The overall yield and regioisomeric ratio are improved by reducing the reaction temperature from 20 °C to 0 °C (eq 3).

Both 1- and 2-naphthols react cleanly to generate 4,4´- and 2,2´-dihydroxybinaphthyl in 40% and 38% yields, respectively.[2] Benzene, toluene, anisole, phenyl acetate and ethyl benzoate are unreactive under standard reaction conditions. Although the attempted coupling of aniline generates little dimerized product, *N*,*N*-dimethylaniline yields *N*,*N*,*N*´,*N*´-tetramethylbenzidine in 52% yield.[2] Generally, VCl_4 complements the use of the less reactive ***Vanadyl Trichloride***

Other Vanadium(IV) Reagents.

When a diethyl ether/pentane solution of vanadium tetrachloride is treated sequentially with 3 equiv of lithium dialkylamide, 1 equiv of MeLi, and 0.8 equiv of an aromatic aldehyde, a one-pot reductive coupling reaction ensues, generating *N*,*N*,*N*´,*N*´-tetraalkyl-1,2-diarylethylenediamines[4] in yields ranging between 14% and 54% (eq 4). The active reagent in this reaction is the in situ generated tris(dialkylamino)methylvanadium(IV). Addition of *N*-methylaniline to a solution of VCl_4 affords an adduct which will effect the cyclization of nerol (**1**) to the corresponding terpinyl halide (**2**) (eq 5).[5] The related TiX_4 complex appears to be the preferred reagent in this type of reaction.

Vanadium(II) Chloride

VCl_2

[10580-52-6] · Cl_2V · Vanadium(II) Chloride · (MW 121.84)

(nitro group to carbonyl conversion; hydrodehalogenation of α-halo ketones; reductions; reductive cleavage of oximes; reductive hydrolysis of 2,4-DNP derivatives)

Alternate Names: vanadium dichloride, vanadium chloride.

Physical Data: mp 910 °C (subl); *d* 3.23 g cm^{-3}.

Solubility: sol with decomposition in hot and cold water; sol alcohols, DMF, THF, ethers.

Form Supplied in: commercially available as a green deliquescent solid.

Vanadium(II) Chloride.

Many reagents based on chromium(II), titanium(II), and titanium(III) ions have found utility in organic synthesis because of their redox potentials (Table 1). Vanadium(II) chloride has found application in modern organic synthesis in part because its redox potential (+0.255 V) is greater than the Sn^{II}-Sn^{III} couple (-0.15 V) although lower than Cr^{II}-Cr^{III} (+0.41 V) or Ti^{II}-Ti^{III} (+0.37 V).[1] A variety of synthetic transformations have been documented.

Conversion of the Nitro Group to the Carbonyl Group.

When an aqueous solution of vanadium chloride is added to a primary or secondary aliphatic nitro compound dissolved in a mixture of water, hydrochloric acid, and DMF, a moderate to good yield (50-70% typically) of the corresponding ketone is isolated (eq 1).[2] The pH-dependent procedure involves initial reduction and subsequent hydrolysis of the resulting carbonyl imine. Several alternative methods are known[3] which will effect the same transformation.

(1)

Hydrodehalogenation of α-Halo Ketones.

When an aqueous solution of vanadium chloride is added to α-halo ketones[1] in THF, a mildly exothermic reaction ensues which yields the halogen-free product after extractive workup (eq 2). Yields are generally quite high, ranging between 80 and 98%.

(2)

Reductions.

This reagent also reduces benzils to benzoins (THF-H_2O, 80-90% yield),[4] quinones to hydroquinones (90-95% yield),[4] and aryl azides to the corresponding amines and N_2 (70-95% yield) (eq 3).[5]

(3)

R = H, 2-Me, 4-Cl, 4-F, 2-CF_3

Reductive Cleavage of Oximes.

Aqueous solutions of VCl_2 have been employed in the mildly exothermic deoximation of oximes to the corresponding carbonyl compounds in 75-90% yield (eq 4).[6]

(4)

87%

Reductive Hydrolysis of 2,4-Dinitrophenylhydrazones.

The regeneration of carbonyl compounds from 2,4-dinitrophenylhydrazones is often problematic owing to the acid stability of the parent molecules. Vanadium chloride promotes the hydrolysis to the respective carbonyl moiety in 67-95% yield via initial reduction of the nitro group.[7]

Other Vanadium(II) Reagents.

Aryl and alkyl halides are reduced by a number of low-valent transition metals.[8] The complex[9] $VCl_2(py)_4$ reduces activated (e.g. Bn-Cl) but not unactivated halo compounds (e.g. vinyl halides). This reagent is selective towards the formation of coupled R-R products to the exclusion of R-H-type products. In contrast, Cr^{II} reduces[10] Bn-Cl to various ratios of bibenzyl and toluene (dependent on the reaction conditions). Bis(cyclopentadienyl)vanadium[11] (Cp_2V) is also effective in these reactions. In an extension of earlier work,[12] 2,2,2-trichloroacetanilide has been selectively reduced to 2,2-dichloroacetanilide using $VCl_2(py)_4$. Other complexes[13] of divalent vanadium having the general formula $V(amine)_4X_2$ are also known. The amine can be either aromatic (e.g. picoline) or aliphatic (e.g. ethylenediamine). The $V(amine)_4X_2$ chemistry remains largely unexplored.

Recently, a bimetallic V^{II} species, $[V_2Cl_3(THF)_6]_2[Zn_2Cl_6]$, prepared in situ from V^{III}, has been introduced[14] to achieve the stereoselective cross coupling of two different alkanals under mild conditions. The intermolecular pinacol cross-coupling reaction has been modified[15] to include chiral aldehydes which yield *syn*-diols in a 91:9 diastereoisomeric ratio (up to 84% ee). Reductive cyclization of δ,ε-enals has also been demonstrated[16] to proceed with excellent stereoselectivity (eq 5), in contrast to what is obtained with other reagents such as Sm^{II}.

Vanadyl Bis(acetylacetonate)[1]

[3153-26-2] · $C_{10}H_{14}O_5V$ · Vanadyl Bis(acetylacetonate) · (MW 265.18)

(precatalyst for oxidation of several functional groups in combination with alkyl hydroperoxides or oxygen;[1] especially useful for the regio- and diastereoselective epoxidation of allylic alcohols,[2] the oxidation of tertiary amines to *N*-oxides,[3] and the oxidation of sulfides to sulfoxides[4] using an alkyl hydroperoxide as the oxidant)

Alternate Name: bis(acetylacetonato)oxovanadium(IV).

Physical Data: mp 256-259 °C; *d* 1.50 g cm^{-3}.

Solubility: insol H_2O; sol EtOH, CH_2Cl_2, $CHCl_3$, C_6H_6.

Form Supplied in: blue-green crystals; widely available.

Handling, Storage, and Precautions: generally used without further purification. Can be handled safely in the open. Should be stored in a cool, dry place in the absence of light. Contact with skin, eyes, and mucous membranes should be avoided. Toxic if swallowed. Generally performs best as an oxidation catalyst when used under anhydrous conditions. Oxidants contaminated with H_2O such as 70% *t*-butyl hydroperoxide (TBHP) are therefore usually dried prior to use with $VO(acac)_2$.

Precursor for Soluble Vanadium(V) Catalysts.

$VO(acac)_2$ is a precatalyst for the oxidation of several functional groups, usually using an alkyl hydroperoxide as the oxidant.[1b] Reaction of $VO(acac)_2$ with an alkyl hydroperoxide quickly oxidizes the vanadium from the +4 to the +5 oxidation state. The resulting organic soluble V^V complexes, whose structure can be represented as $VO(OR)_3$, are usually the actual catalysts in these reactions.[1] $VO(acac)_2$ is a commercially available, stable, crystalline, organic soluble solid and therefore a convenient source of vanadium for oxidation reactions. In contrast, organic soluble V^V compounds, suitable for these reactions, are not as widely available nor as easily handled and therefore not as convenient a source of vanadium as $VO(acac)_2$.[5]

Epoxidation of Allylic Alcohols.

Soluble V^V compounds are the preferred catalysts for nonenantioselective epoxidation of allylic alcohols to epoxy alcohols using alkyl hydroperoxides, especially ***t-Butyl Hydroperoxide***, as oxidants.[2,6] V^V compounds with alkyl hydroperoxides are also capable of epoxidation of nonfunctionalized alkenes[7] to epoxides but at rates ca. 100 times less than for the corresponding allylic alcohols.[6a] This rate differential allows the regioselective monoepoxidation of substrates like geraniol (eq 1).

(1)

Mo^{VI}/TBHP and peracids efficiently epoxidize allylic alcohols as well but, because they also rapidly epoxidize nonfunctionalized alkenes, they tend not to be as regioselective as V^{V}/TBHP.[1] Other d^0 transition metal catalysts, such as W^{VI} and Ti^{IV}, epoxidize allylic alcohols slower and less efficiently than V^{V} and therefore are not as useful for this type of epoxidation reaction.[7] Diastereoselective epoxidation is often observed in V^{V}-catalyzed epoxidations of chiral allylic alcohols, especially cyclic allylic alcohols.[6a,8,9] Diastereoselective epoxidation of homoallylic and bishomoallylic alcohols have also been reported.[6a,10] V^{V}/TBHP often complements the diastereoselectivity of peracids and Mo^{VI}/TBHP observed for the epoxidation of secondary allylic alcohols.[6a,8] For example, epoxidation of 2-cyclooctenol gives either the corresponding *cis*- or *trans*-epoxy alcohol with high diastereoselectivity, depending on whether $VO(acac)_2$/TBHP or ***m-Chloroperbenzoic Acid*** is used (eq 2).[11]

(2)

	% *cis*	% *cis*
$VO(acac)_2$, TBHP	97	3
m-CPBA	0.2	99.8
$MoO_2(acac)_2$	42	58

Hydroxyepoxidation of Alkenes.

$VO(acac)_2$ catalyzes the transformation of allylic hydroperoxides to epoxy alcohols.[12] This process presumably involves intermolecular transfer of oxygen from the hydroperoxide portion of an allylic hydroperoxide to the alkene portion of either a second allylic hydroperoxide or an allylic alcohol derived from hydroperoxide reduction (eq 3).[13]

(3)

$VO(acac)_2$[14] and other forms of vanadium[15] also catalyze the transformation of alkenes to epoxy alcohols using molecular oxygen as the oxidant. This process involves initial oxidation of the alkene to an allylic hydroperoxide either by radical or photolytic processes followed by intermolecular epoxidation to give primarily the epoxy alcohol and usually several byproducts. A convenient photolytic process producing singlet oxygen in the presence of the alkene and a catalytic amount of $VO(acac)_2$ has been developed to promote this transformation in good yield and high diastereoselectivity (eq 4).[14] An obvious requirement of this reaction is that the starting alkene must readily undergo photooxygenation to give the intermediate allylic hydroperoxide. ***Titanium Tetraisopropoxide*** and molybdenyl bis(acetylacetonate) also act as catalysts in this reaction, sometimes with better yields and/or selectivity.[14]

(4)

Oxidation of Amines.

V^V/TBHP efficiently oxidizes tertiary amines to *N*-oxides (eq 5).[16] The reaction is carried out under anhydrous conditions and therefore allows the preparation of anhydrous amine oxides. V^V/TBHP oxidizes aniline to nitrobenzene (eq 6).[17]

(5)

(6)

Oxidation of Sulfides to Sulfoxides.

Similar to the oxidation of tertiary amines to *N*-oxides, V^V/TBHP oxidizes sulfides to sulfoxides in high yield (eq 7).[4,18] The reaction is usually carried out at room temperature in an alcoholic solvent.

(7)

Other Oxidation Reactions.

$VO(acac)_2$ rapidly oxidizes 3,5-di-*t*-butylpyrocatechol at room temperature to the corresponding muconic acid anhydride, 2-pyrone, and *o*-quinone using oxygen as the oxidant (eq 8).[19] This method is more selective for the anhydride than oxygenation with ***Dichlorotris(triphenylphosphine)ruthenium(II)***. V^V/TBHP has also been used in the catalytic oxidation of hydrocarbons.[20] These reactions probably occur by radical mechanisms and are usually not highly selective.

Related Reagents.

Vanadyl Bis(acetylacetonate)-Azobisisobutyronitrile.

Vanadyl Bis(acetylacetonate)-Azobisisobutyronitrile

($VO(acac)_2$)

[3153-26-2] · $C_{10}H_{14}O_5V$ · Vanadyl Bis(acetylacetonate)-Azobisisobutyronitrile · (MW 265.18) (AIBN)

[78-67-1] · $C_8H_{12}N_4$ · Vanadyl Bis(acetylacetonate)-Azobisisobutyronitrile · (MW 164.24)

(catalyst for oxygen-promoted allylic oxidation coupled with hydroxyl-directed epoxidation of C=C double bonds[1])

Physical Data: AIBN: solid, mp 100 °C (dec). $VO(acac)_2$: solid, mp 250 °C (dec).

Solubility: see ***Azobisisobutyronitrile*** and ***Vanadyl Bis(acetylacetonate)***. The combination may be used in 1,2-dichloroethane, 1,1,1-trichloroethane, 1,1,2-trichloroethane, acetonitrile, benzene, 1,4-dioxane, or *n*-hexane.

Form Supplied in: AIBN is sold as a white solid; $VO(acac)_2$ is sold as a green powder.

Handling, Storage, and Precautions: see the individual entries for AIBN and $VO(acac)_2$. AIBN causes convulsions.

Allylic Oxidation/Epoxidation Reactions.

The reagent combination is an effective catalyst for the oxidation of cyclic alkenes, except cyclooctene, to epoxy alcohols using molecular ***Oxygen*** as the oxidant. The conversion proceeds by way of allylic oxidation to give an allylic hydroperoxide, which is reduced by the metal to give an allylic alcohol. Hydroxyl-directed epoxidation of the latter intermediate occurs in situ to give the epoxy alcohol. Cyclohexene is converted to (**1**), together with (**2**), (**3**), and (**4**), the relative amounts of which depend on reaction conditions, primarily solvent (eq 1). Best results are obtained by using cyclohexene (20 mmol), $VO(acac)_2$ (0.01 mmol), AIBN (0.1 mmol), O_2 (1 atm), and 1,1,2-trichloroethane (2.0 mL) at 60 ± 1 °C, which gives 30% yield of a mixture of (**1**) (65%), (**2**) (17%), (**3**) (5%), and (**4**) (13%). While similar conversions can be effected by O_2 in the presence of $CpV(CO)_4$ or V_2O_5, and by $VO(acac)_2$ in the absence of AIBN, the yields and product distribution differ from those obtained by using the title reagent.

1,4-Cyclooctadiene undergoes a transannular epoxidation reaction under the above reaction conditions to give a mixture of (**5**) (43%) and four other products (57% combined yield; the published results are not clear), from which crystalline (**5**) can be obtained in 18% yield by chromatography on Florisil, followed by sublimation of the residue (eq 2).

Vanadyl Trichloride

$VOCl_3$

[7727-18-6] · Cl_3OV · Vanadyl Trichloride · (MW 173.29)

(oxidative decarboxylation; phenolic coupling)

Alternate Names: trichlorooxovanadium; vanadium oxytrichloride.

Physical Data: mp 77 °C; bp 126-127 °C; *d* 1.840 g cm^{-3}.

Solubility: sol ether, dichloromethane, benzene.

Form Supplied in: commercially available as a yellow liquid from a number of vendors.

Preparative Methods: by the action of dry Cl_2 on vanadium(III) oxide or vanadium(V) oxide.[1]

Handling, Storage, and Precautions: decomposes in the presence of moisture into vanadic acid and HCl.

Oxidative Decarboxylation-Deoxygenation.

Stoichiometric amounts of $VOCl_3$ can be utilized in the oxidative decarboxylation-deoxygenation of 3-hydroxycarboxylic acids to tri- and tetrasubstituted alkenes,[2] enabling direct conversion from the products of classical aldol condensations (eq 1). In some cases, byproducts resulting from dehydration, C-C bond cleavage, double-bond migration, and (*E*/*Z*) bond isomerization have been noted, although the latter three problems can be suppressed by the addition of ***1,8-Bis(dimethylamino)naphthalene*** (Proton Sponge). Trichloro(arylimino)vanadium(V), prepared from $VOCl_3$ and the appropriate aryl isocyanate,[2,3] can generate higher yields of alkene, free of byproducts, when used as an alternative reagent.

(1)

Diphenolic Oxidative Coupling.

There are a number of examples of diphenolic oxidative coupling reactions using $VOCl_3$ as the oxidizing agent. Intermolecular coupling of 1- and 2-naphthol generates 4,4´-dihydroxybinaphthyl (eq 2) and 2,2´-dihydroxybinaphthyl in 56% and 65% yield, respectively.[4] Evidence indicates that intermediate vanadium phenoxides are formed in the process. Under identical conditions, *m*-cresol yields a mixture of polymeric products. The more reactive ***Vanadium(IV) Chloride*** can be used to effect the same transformations and to some degree it complements the use of $VOCl_3$.[4]

(2)

When treated with a stoichiometric amount of trichlorooxovanadium, Cbz-protected tyrosine affords the dityrosine derivative in 20% yield (eq 3).[5] A similar reaction with vanadium trifluoride doubles the yield of the desired *ortho-ortho* coupled product and is preferred due to superior functional group compatibility.

(3)

Intramolecular oxidative coupling of phenols, a key step in the biosynthesis of alkaloids and other natural products, can be effected nonenzymatically via this reagent. Although yields are high in simple systems, results are more variable in systems of increased complexity. For example, addition of an ethereal solution of 1,3-bis(hydroxyphenyl)propane to 2.5 equiv of vanadyl trichloride in ether affords the phenolic dienone in 76% yield (eq 4).[6] Initial reaction at -78 °C generates the bis(dichlorovanadate) ester which ultimately undergoes oxidative coupling at higher temperature. One-electron oxidants such as ***Potassium Ferricyanide***, ***Iron(III) Chloride***, ***Manganese Dioxide***, and ***Silver(I) Oxide*** afford low yields of coupled product due to competing polymerization reactions.[7] In a related but more complex example, vanadyl trichloride is utilized in a key coupling step (eq 5) in the total synthesis of (±)-maritidine.[8] Here the bis(hydroxyphenyl) compound is converted to the *para-para* coupled dienone in 24% isolated yield.

(4)

(5)

This reagent has been utilized in the intramolecular oxidative coupling of a number of benzyltetrahydroisoquinolines,[9] as exemplified by the conversion of *cis*-3,*N*-bis(methoxycarbonyl)-*N*-norreticuline to the corresponding isoboldine analog (eq 6).[10] Since four regioisomers are possible, (*para-para*/*para-ortho* morphinanes and *ortho-para*/*ortho-ortho* aporphines), directing the regiochemical outcome can be difficult. It appears that $VOCl_3$ often generates predominantly aporphine products. The effects of steric interactions have been investigated.[11] ***(Diacetoxyiodo)benzene*** and ***Thallium(III) Trifluoroacetate*** have also been utilized to effect the same transformation with less success with regard to yields and regioisomeric ratios.[9a,10]

(6)

Although ***Vanadyl Trifluoride*** is often the reagent of choice,[12] intramolecular coupling of monophenols has been effected in near quantitative yield with $VOCl_3$ in dichloromethane at -78 °C (eq 7).[7,13] On the other hand, oxidative coupling of the nonphenolic substrate (R = Me) leads primarily to the dienone (via alkyl-oxygen cleavage) and a minor component (18%) resulting from coupling and subsequent rearrangement. It has been suggested that, in either case, two successive one-electron oxidations occur with coupling at the cation radical stage.[13] Trialkylamines completely inhibit this reaction. Alternative reagents such as silver bis(trifluoroacetate), thallium tris(trifluoroacetate), and vanadium oxytrifluoride[14] also induce nonphenolic coupling.

Vanadyl Trifluoride

VOF_3

[13709-31-4] · F_3OV · Vanadyl Trifluoride · (MW 123.94)

(phenolic coupling)

Alternate Names: vanadium oxytrifluoride; trifluorooxovanadium.

Physical Data: mp 300 °C.

Solubility: sol TFA, CH_2Cl_2.

Form Supplied in: commercially available as a white solid.

Introduction.

Vanadyl trifluoride has demonstrated utility in intramolecular phenolic coupling reactions, a transformation of pivotal importance in alkaloid biosynthesis. For example, the benzyltetrahydroisoquinoline (**1**) has been converted to the oxoaporphine (**2**) in 59% yield (eq 1).[1] Although alternative reagents such as CrO_3, MnO_2/TFA, and $(CF_3CO_2)_3Tl$[2] have proven less successful in this reaction, $MoOCl_4$/TFA/$CHCl_3$ generates similar yields of oxoaporphine (62%). ***Trifluoroacetic Acid*** is an effective medium for these oxidations, particularly with moisture sensitive oxidants.[1] Reaction temperatures vary between -78 °C and ambient temperature.

(1)

Phenyl Ether Coupling.

Vanadyl trifluoride will promote intramolecular oxidative coupling between nonphenolic aryl ethers, as exemplified in the syntheses of (±)-isostegane,[3] (±)-stegamycin,[4] and the acyl-neospirinedienones.[5] In the total synthesis of (±)-tylophorine (eq 2),[6] for instance, the reaction is complete in 1 h at room temperature in 69% yield.

Asymmetric Synthesis.

Several asymmetric syntheses have employed VOF_3 as an intramolecular coupling agent. Syntheses of (+)-deoxyschizandrin (eq 3),[7] (+)-glaucine, and (+)-homoglaucine[8] have all utilized this reagent in the key oxidative coupling step. In the latter two cases, ruthenium tetrakis(trifluoroacetate) is an equally effective oxidant, and there have been claims that this reagent is superior to vanadyl trifluoride.[9]

Intermolecular oxidative aryl coupling is also promoted by VOF_3, as exemplified by the synthesis of symmetrical biaryl analogs of the biphenomycin antibiotics (eq 4).[10] Moderate yields are obtained and VOF_3 is preferred over other reagents such as ***Vanadyl Trichloride*** because of higher yields and superior functional group compatibility. When these authors[10] attempted an intramolecular version of this transformation, VOF_3 failed to induce the cyclization.

The diaryl chiral oxazolidine (**3**) (eq 5)[11] has been converted to the corresponding spirodienone (**4**) in near quantitative yield by using VOF_3. $VOCl_3$ and ***Phenyliodine(III) Bis(trifluoroacetate)*** have also been utilized to effect this transformation, albeit in lower yields. This example constitutes an efficient simulation of the biosynthetic pathway of alkaloids both in terms of yield and stereochemical outcome.

Biomimetic Oxidative Coupling.

Vanadyl trifluoride has been employed successfully in the biomimetic synthesis of the vancomycin[12] class of glycopeptides. The array of functionality present in the starting material and the degree of asymmetric induction achieved in the cyclization illustrates the utility of this

reagent in complex synthesis. Apparently, the atropdiastereoselection[13] is greatly influenced by the various protective groups on the starting tripeptide (particularly since the Boc group is unstable to these reaction conditions), the substituents on the phenyl ring, and probably the resulting A(1,3) strain, although the mechanistic details of this oxidation are unclear (eq 6). Apparently residual chloride in commercial TFA is sequestered by the Ag^{I} salts, while ***Boron Trifluoride Etherate*** prevents the attack of oxygen nucleophiles on the radical cation and the TFA/TFAA solvent combination[12] traps adventitious water. ***Manganese(III) Acetylacetonate*** is the only other reagent to effect this transformation, although in lower yield. Reagents such as $Tl(TFA)_3$, $FeCl_3$, $VOCl_3$, CoF_3, and the Pt anode failed to induce cyclization.

Vinyl Acetate[1]

[108-05-4] · $C_4H_6O_2$ · Vinyl Acetate · (MW 86.10)

(enzyme-mediated transacetylation of alcohols; *N*- and *O*-transvinylation; acetaldehyde equivalent; cycloaddition reactions with chlorosulfonyl isocyanate to give azetidinones, nitrile oxides to give isoxazoles, nitrones to give isoxazolines, enones to give acetoxycyclobutanes, and arenes to give bi- and tricyclic adducts; source of formaldehyde oxide)

Physical Data: [2] bp 73 °C; mp -92.8 °C; *d* 0.9335 g cm^{-3}.

Solubility: soluble all common organic solvents; somewhat sol water.

Form Supplied in: colorless liquid stabilized with 4 ppm hydroquinone and 300 ppm diphenylamine.

Handling, Storage, and Precautions: extremely flammable with unusual fire and explosion hazards. Readily polymerizes, especially on exposure to light, to give a solid. Removal or loss of the inhibitors results in rapid polymerization, often quite violently. Vinyl acetate is a cancer suspect agent and may cause genetic damage. It is quite irritating to the eyes, skin, and respiratory system.[2a] Use in a fume hood.

Transacetylation.

Vinyl acetate is used extensively in irreversible enzyme-mediated transacetylation of racemic and *meso*-alcohols, usually in organic solvents, to give optically active products with excellent enantiomeric excesses.[3-9] In a typical example, enantioselective transacetylation of the glycal (**1**) with vinyl acetate is performed in dimethoxyethane at room temperature in the presence of the lipase derived from *Pseudomonas cepacia* to give the monoacetate (**2**) and diacetate (**3**), each with an enantiomeric excess of 97% (eq 1).[3] Other examples include the following preparations: the chiral auxiliaries (**5**) and (**6**) derived from racemic *trans*-phenylcyclohexanol (**4**) using an immobilized enzyme (eq 2);[4] the diltiazem intermediate (**8**) (eq 3);[5] the acetate (**11**) derived from the *meso*-diol (**10**) (eq 4);[6] and (**13**) and (**14**), the corresponding racemic alcohol (**12**) of which could not be resolved efficiently by enantioselective epoxidation (eq 5).[7] In addition, regioselective acetylation of primary and secondary alcohols with vinyl acetate in the presence of a lipase proceeds in excellent yields. In general, primary alcohols are acetylated in preference to secondary alcohols,[8a,b] and, with the latter, excellent regioselectivity is obtained depending on the stereochemistry of the alcohol (eq 6).[8c,d] See also ***Acetic Anhydride*** and ***Acetyl Chloride***.

Transvinylation.

N-Vinylation with vinyl acetate is usually carried out in the presence of ***Palladium(II) Chloride***[10] or ***Mercury(II) Acetate*** (eq 7),[11] although a catalyst is apparently not required in the preparation of the alkaloid (**20**) (eq 8).[12] Vinyl esters may be prepared in moderate to good yields by heating the acid with vinyl acetate in the presence of $Hg(OAc)_2$ (eq 9)[13] or $PdCl_2$ (eq 10).[14] Vinyl esters of amino acids, prepared by transesterification with vinyl acetate in ethyl cyanoacetate, have been used as activated esters in peptide synthesis.[15] In an indole synthesis, *O*-vinylation of (**25**) with vinyl acetate in the presence of $PdCl_2$ leads directly, via a hetero-Cope rearrangement, to a regioisomeric mixture of indoles in 83% yield (eq 11).[16] Although not as widely used as ***Ethyl Vinyl Ether***, vinyl acetate has been used to prepare allyl vinyl ethers from allyl alcohols with $Hg(OAc)_2$ as the catalyst.[17]

Acetaldehyde Equivalent.

The reaction of vinyl acetate with a ketone in the presence of ***Cerium(IV) Ammonium Nitrate*** gives an α-(2-acetoxy-2-nitrosylethyl) ketone, which may be solvolyzed to the corresponding acetal (eq 12).[18] A related reaction of vinyl acetate with 2,4-pentanedione leads to 2-methyl-3-acetylfuran in 56% yield (eq 13).[19] Introduction of the ***Acetaldehyde*** unit onto an aromatic ring is possible by a Meerwein reaction between a diazonium salt and vinyl acetate in the presence of ***Copper(II) Chloride*** (eq 14).[20]

(12)

(13)

(14)

Cycloaddition Reactions.

Thermal.

Vinyl acetate reacts rapidly with ***Chlorosulfonyl Isocyanate*** at low temperatures to give, after reduction with $NaHSO_3$, 2-acetoxyazetidinone in 80% yield (eq 15).[21] However, Diels-Alder reactions with vinyl acetate are quite sluggish. With the 2*H*-pyrrole (**35**), the cycloadduct is obtained in 83% yield after 7 days (eq 16),[22] whereas the pyridine (**38**) is produced in 78% yield from the 1,2,4-triazene (**37**) (eq 17).[23] 1,3-Dipolar addition of vinyl acetate with nitrile oxides gives isoxazolines,[24] which may be converted directly to isoxazoles (eq 18);[25] isoxazoles are also obtained by heating potassium nitronates with vinyl acetate.[26] The cycloaddition of vinyl acetate to nitrones yields isoxazolines in a highly regioselective manner,[27] and can be highly stereoselective, as is found with the Cr^0-complexed nitrone (**41**) (eq 19).[28]

Photochemical.

High yields of acetoxycyclobutanes, in which the head-to-tail regioisomer predominates, are obtained from the photoaddition of vinyl acetate to cyclic enones.[29] As illustrated in an approach to the synthesis of taxol, photoaddition of vinyl acetate to the enolic form of the 1,3-dione (**43**) produces the cycloadduct (**44**) in 90% yield as a mixture of diastereomers (eq 20).[30] Similar excellent regioselectivity is realized in the photoaddition of vinyl acetate to the naphthoquinone (**45**), yielding the acetoxycyclobutane (**46**) in an almost quantitative yield (eq 21).[31]

Vinyl acetate also undergoes photoaddition to arenes, producing 1,2- and 1,3-photoadducts.[29,32] Irradiation of benzene at 254 nm in the presence of a large excess of vinyl acetate gives, in low yield, a single 1,2-cycloadduct (**48**) and a regioisomeric mixture of 1,3-cycloadducts (**49**) (eq 22).[33] The latter predominates, except when there is a large difference in electron-donor/acceptor capacity between the aromatic compound and vinyl acetate, as is found with benzonitrile.[34] The photoaddition of ethenes to arenes has been used in the synthesis of several structurally complex natural products,[35] typified by the construction of the propellane system of *rac*-modhephene from the photoaddition of vinyl acetate to indan (eq 23).[36]

Formaldehyde Oxide.

Ozonolysis of vinyl acetate yields formaldehyde oxide, which reacts rapidly with ketones to give lactones (eq 24),[37] and is therefore an alternative to the Baeyer-Villiger oxidation.

9-Vinyl-9-borabicyclo[3.3.1]nonane

[129493-14-7] · $C_{10}H_{17}B$ · 9-Vinyl-9-borabicyclo[3.3.1]nonane · (MW 148.08)

(highly reactive and selective Diels-Alder dienophile[1])

Physical Data: bp 28-30 °C/0.25 mmHg.[1]

Preparative Method: vinylboranes are most conveniently prepared from the reaction of vinylstannanes with bromo- and chloroboranes (eq 1).[1] These preparations may be carried out in situ[2] for Diels-Alder reactions.

Handling, Storage, and Precautions: volatile vinylboranes are extremely pyrophoric; many problems may be avoided using the in situ procedure.[2] Vinyl-9-BBN dimerizes[3] extensively over the course of days at rt, and slowly in a freezer, but some other vinyldialkylboranes are much more stable.[3]

General Discussion.

Vinylboranes are highly reactive, regioselective, and *endo*-stereoselective dienophiles, and exhibit other useful and unusual properties in their Diels-Alder reactions. Vinyl-9-BBN is 200 times more reactive than ***Methyl Acrylate*** with ***1,3-Butadiene*** (eq 2),[1] and reacts with a wide variety of dienes at 25-55 °C. Vinyl-9-BBN is omniphilic because it displays high and surprisingly invariant reactivity with electron-rich, electron-poor, and unactivated dienes.[4]

$k = 3.2 \times 10^{-6}$

The regioselectivity of vinyl-9-BBN reactions is very high (eq 3).[3] However, this selectivity appears mainly due to steric effects; less sterically demanding vinylboranes are much less selective.[3] The large role of steric effects often results in unusual regioselectivities, such as the exclusive formation of the *meta* product from piperylene and the formation of a single regioisomer from vinylcyclohexene (eq 4).[1]

(3)

(4)

Electronic effects can also give rise to unusual regioselectivities with vinylboranes. Although vinyldihaloboranes are more reactive than vinyldialkylboranes,[5] their selectivity is low. However, 2-alkenyl- and *cis*-1-alkenyldibromoboranes are highly regioselective dienophiles and afford the unusual *meta* product (eq 5).[6] A similar *meta* regioselectivity is observed with alkynic boranes.[7] In both cases the unusual selectivity is attributed to a [4 + 3] transition state based on ab initio calculations.[8] Since the corresponding alkenyl-BBN derivatives afford the *para* products, either regioisomer may be obtained by judicious choice of borane.

(5)

As shown in eq 4, the stereoselectivity with vinylboranes is generally >90% *endo*. Examples of lower selectivity have been improved by choice of vinyldialkylborane.[3] An exception to this selectivity has recently been observed in the reaction of 2-propenyl-9-BBN with cyclopentadiene, which affords the *exo* product with high selectivity (eq 6).[6]

(6)

2-Trimethylsilylvinyl-9-BBN is also highly reactive.[9] Acid-catalyzed elimination of the silyl alcohol products readily affords 1,4-cyclohexadienes (eq 7), making 2-trimethylsilylvinyl-9-BBN a highly reactive ***Acetylene*** equivalent for Diels-Alder reactions.

(7)

Related Reagents.

Ethyl Acrylate; ***Methyl Acrylate***; ***Methyl Vinyl Ketone***.

β-Vinyl-α,β-butenolide

(R = H)

[54145-07-2] · $C_6H_6O_2$ · β-Vinyl-α,β-butenolide · (MW 110.12) (R = Me)

[78657-20-2] · $C_7H_8O_2$ · &AAlpha;-Methyl-β-vinyl-α,β-butenolide · (MW 124.15) (R = SPh)

[81470-07-7] · $C_{12}H_{10}O_2S$ · &AAlpha;-Phenylthio-β-vinyl-α,β-butenolide · (MW 218.29)

(lactone annulating reagent with 1,3-dicarbonyl compounds;[1,2] an acceptor in 1,6-conjugate addition reactions with various nucleophiles[3])

Alternate Name: 4-vinyl-2(5*H*)-furanone.

Physical Data: R = H, Me: oil. R = SPh: solid, mp 70 °C.

Solubility: sol CH_2Cl_2 and THF; slightly sol *n*-hexane.

Preparative Method: most conveniently prepared by sulfenylation of β-vinylbutyrolactone,[1,2,4] easily accessible from 2-butene-1,4-diol and ethyl orthoacetate,[5] followed by sulfoxide elimination (eq 1).

Handling, Storage, and Precautions: is relatively unstable, slowly changing into a polymeric white solid, even on refrigeration; however, α-phenylthio-β-vinylbutenolide is much more stable to storage.

Lactone Annulation.

Under basic conditions, 2-methylcyclohexane-1,3-dione adds to β-vinylbutenolide to give a 1,6-conjugate addition product, which then undergoes cyclization under the reaction conditions to yield hydroxybutenolides as a mixture of diastereomers at the C-6 position (eq 2).[1]

Na, THF	47%	11:1
t-BuOK, DME	22%	5:1
KF, DMSO	56%	5:1

When the sodium enolates of β-keto esters react with β-vinylbutenolide in THF or DME, annulated butenolides are produced in moderate yields (eq 3).[2] Racemic frullanolide, a typical allergenic eudesmanolide, has been synthesized from one of these annulated products.[2]

$R^1 = H$, $R^2 = Et$	57%	5:1
$R^1 = R^2 = Me$	51%	2:1
$R^1 = CO_2Me$, $R^2 = Me$	62%	0:1

1,6-Conjugate Addition.

β-Vinylbutenolide reacts with various nucleophiles in 1,6-conjugate addition reactions. For example, treatment of this butenolide with ***Benzeneselenol*** provides the 1,6-conjugate adduct, accompanied by a small amount of the isomeric 1,4-adduct (eq 4).[3]

α-Phenylthio-β-vinylbutenolide.

This reagent is readily accessible from β-vinyl butyrolactone by an eliminative Pummerer rearrangement (eq 1). Annulation of activated carbonyl compounds affords oxygenated perhydrooxobenzofurans (eq 5).[6] The phenylthiobutenolide has been used in the total synthesis of paniculide A, a highly oxygenated bisabolene,[7] and avenaciolide, an antifungal mold metabolite.[8]

(5)

α-Methyl-β-vinylbutenolide.

This reagent is also useful for lactone annulating reactions with 1,3-dicarbonyl compounds under basic conditions.[9,10]

Vinyl Chloroformate

[5130-24-5] · $C_3H_3ClO_2$ · Vinyl Chloroformate · (MW 106.51)

(selective *N*-dealkylation of tertiary amines; amino protection in peptide synthesis; protection of alcohols; polymerization and polymers)

Alternate Names: vinyl chlorocarbonate; VOC-Cl.

Physical Data: bp 68-69 °C; *d* 1.163 g cm^{-3}.

Form Supplied in: colorless liquid, often stabilized with ca. 0.05% BHT; widely available.

Preparative Methods: the high price of VOC-Cl warrants some comments on its synthesis. Two processes have been used commercially. In the first, ethylene glycol is converted to its bis(chloroformate) with phosgene. This fragments to VOC-Cl in 30-40% yield when passed through a hot tube packed with glass helices at 480 °C.[1] More recently, VOC-Cl has been made commercially by a two-step route involving oxymercuration of vinyl acetate (eq 1).[2]

Handling, Storage, and Precautions: is slightly light-sensitive and even more reactive than other chloroformates toward trace moisture. Because the hydrolysis products, HCl and acetaldehyde, interfere in some applications, the reagent is often distilled before use. It is a strong lachrymator and skin vesicant; inhalation is particularly dangerous. Use in a fume hood.

Amino Protection in Peptide Synthesis.[3]

Amino acids are converted to their *N*-VOC derivatives by standard acylation with vinyl chloroformate (VOC-Cl), e.g. by Schnabel's pH-stat process.[4] Like Boc-amino acids, VOC-amino acids often are oils but can be characterized and stored as the crystalline dicyclohexylammonium (DCHA) salts and regenerated by acidification-extraction. The yields of VOC-peptides from the free acids or directly from the salts using ***1,3-Dicyclohexylcarbodiimide***, ***N-Ethyl-5-phenylisoxazolium-3´-sulfonate***, and active esters as the amide coupling agents are similar to those with other amine blocking groups (e.g. Boc-peptides). The crystalline products are stable and can be stored indefinitely (see Table 1).

Table 1 Representative *N*-VOC Amino Acids and Peptides

Amino acid or peptide	Mp (°C)
VOC Gly OH	95 95.5
VOC L-Phe OH	56 58
VOC L-Val OH DCHA	160 161.5
VOC L-Asn OH	157.5 158.5
VOC L-Hyp OH DCHA	179.5 181.5
VOC L-Glu(g-OMe) OH DCHA	155 156
VOC L-Ser(*O*-*t*-Bu) OH	97 97.5
VOC L-Lys(eBoc) OH DCHA	152 154
VOC L-Phe L-Leu OMe	107.5 108.5
VOC L-Glu(g-OMe) Gly OEt	88 89
VOC L-Asn Gly Gly OEt	190.5 192
VOC L-Pro L-Val L-Asn L-Leu *O*-*t*-Bu	216 (dec)
VOC L-Ser(*O*-*t*-Bu) L-Phe L-Leu *O*-Phenacyl	161 163

The high reactivity of the VOC amide C=C bond toward electrophiles is the key to the method used for deprotection.[3] Acid-induced hydrolysis with HCl or HBr in HOAc or by bubbling HCl through an inert solvent containing the peptide, followed by warming the intermediate HCl adduct in EtOH, affords the deblocked peptide salt in excellent yield. These procedures are mild enough to avoid transesterification of side chain esters (eq 2). Unmasking also can be achieved by titration of the vinyl group with Br_2 followed by warming the intermediate adduct with EtOH (eq 3). Under these conditions, Boc-protected secondary functions and *t*-butyl esters remain intact. A third scission with ***Mercury(II) Acetate*** in aqueous HOAc is rarely recommended. Carboxyl unmasking prior to removal of an *N*-VOC group can be performed with ***Zinc-Acetic Acid*** when the carboxyl is masked as a phenacyl ester. However, the VOC group is unstable to conditions required for modification-removal of most other esters (e.g. hydrazinolysis, saponification). The related isopropenyl chloroformate has no value in amine protection but is an excellent reagent of the mixed anhydride class for peptide amide bond formation (eq 4).[5]

$$\text{VOC-L-Glu}(\gamma\text{-OMe})\text{-Gly-OEt} \xrightarrow[\text{2. EtOH, }\Delta]{\text{1. HCl, }CH_2Cl_2} \text{HCl} \cdot \text{H-L-Glu}(\gamma\text{-OMe})\text{-Gly-OEt} \quad (2)$$

95%

N-Dealkylation of Tertiary Amines.

The *N*-dealkylation procedure is illustrated by the selective *N*-deethylation of *N*-ethylpiperidine to obtain piperidine.HCl in 90% yield (eq 5).[6] The VOC-Cl is added to the piperidine in dichloroethane at 0 to -20 °C and the intermediate VOC-piperidine salt is then heated to reflux for a short period to obtain the intermediate carbamate. This can be isolated, but the VOC moiety usually is quantitatively removed in situ by bubbling HCl through a CH_2Cl_2 or 1,2-dichloroethane (DCE) solution and then warming the adduct in MeOH or EtOH, or by titrating the vinyl group with Br_2 and then again warming in the alcohol. Among other dealkylating agents which operate by the same principle, ***Cyanogen Bromide*** (method of von Braun) is not selective in this rigorous test system and the amine catalyzes the self-destruction of ethyl and benzyl chloroformate [ROC(O)Cl -> RCl + CO_2].[7] With phenyl chloroformate, the yield of carbamate under similar conditions is only 34%.

With VOC-Cl, *N*-dealkylation selectivities follow the order: benzyl, allyl, *t*-alkyl >> *s*-alkyl &egt; methyl > *n*-alkyl >> piperidine ring scission.[6,8] Weakly basic tertiary amines like *N*,*N*-dimethylaniline do not react with VOC-Cl even in refluxing DCE. Some examples of *N*-dealkylations accomplished with VOC-Cl include the *N*-demethylation of alkyl amines (eq 6)[9] and other *N*-alkylpiperidines (eq 7).[10,11] Note in eq 7 that the *N*-VOC is removed by base hydrolysis. This dealkylation process also is part of an asymmetric synthesis of α-amino esters (eq 8),[12] as well as the key step of a protocol for resolving tertiary amine enantiomers.[13] Also, VOC-Cl-induced dealkylation permits an improved synthesis of the emergency heroin antidote naloxone from oxymorphone (eq 9).[6,14] Vinyl chloroformate largely has been replaced for *N*-dealkylation by ***1-Chloroethyl Chloroformate***. This latter reagent is cheaper and shows similar dealkylation selectivities and equally facile replacement of the *N*-

alkyl by the carbamate unit.

Protection of Alcohols.

Vinyloxycarbonyl esters (*O*-VOC) of phenols and alcohols are prepared from VOC-Cl by standard methods.[15] Unlike VOC derivatives of amines, *O*-VOC esters are quite stable in acid but are readily hydrolyzed in mild base, conditions under which *N*-VOC is stable (eq 10).[15] This reactivity-selectivity difference can be useful in complex syntheses involving the simultaneous protection of both amine and alcohol functions with a single blocking moiety, while retaining the flexibility to modify either site without deprotecting the other. In related blocking schemes, attempts to free the amine first usually fail because esters are generally easier to hydrolyze than amides in both acid and base. The value of this selectivity in combination with *N*-dealkylation by VOC-Cl is illustrated in a synthesis of nalorphine, the classic narcotic antagonist, from morphine in 77% overall yield (eq 11).[15]

Polymerization and Polymers.

Vinyl chloroformate has been polymerized and copolymerized using standard radical initiators (e.g. peroxydicarbonates, ***Dibenzoyl Peroxide***, and ***Azobisisobutyronitrile***) to yield both high molecular weight poly(vinyl chloroformates) and random copolymers.[16,17] The polymerization is inhibited by traces of acetaldehyde. Treatment of poly(vinyl chloroformate) with amines, alcohols, and phenols affords the corresponding poly(vinyl urethanes) and poly(vinyl carbonates).[16,18] Urethanes and carbonates of VOC-Cl also can be polymerized to similar materials with radical initiators.[16-19] These materials are hard (but not brittle) clear thermoplastics with high decomposition temperatures, excellent chemical resistance, and varying glass transition temperatures.[18] Some products have value as liquid crystals[20] and detergent builders.[21] The divinyl carbonate polymerizes an order of magnitude more easily than the diallyl carbonate to a product of similar properties.[19] Polymers of carbonates of VOC-Cl and dermal drugs (e.g. benzocaine, estradiol, dexamethasone, and hydrocortisone) are recommended as hydrolyzable pro-drugs for topical use.[22]

Pummerer and Other Reactions.

Sulfoxides react with VOC-Cl to give α-chloro sulfides via the Pummerer rearrangement (eq 12). Vinyl chloroformate is more reactive than the conventional reagents, including acetic anhydride, acyl chlorides, and alkyl chloroformates. Additionally, the reaction conditions are neutral and the byproducts are readily removed.

The reaction of penicillin β-sulfoxide with VOC-Cl induces a novel rearrangement which involves cleavage of the C-5-S bond (eq 13).[23] Reaction of imidazoles with VOC-Cl in weakly alkaline solution affords the corresponding imidazol-2-ones, presumably via ring opening to the isocyanate intermediate, followed by ring closure (eq 14).[24]

Vinylcopper[1]

[37616-22-1] · C_2H_3Cu · Vinylcopper · (MW 90.60)

(synthesis of 1,3-dienyl esters;[2] vinyl 1,4-addition to alkynic esters[3] and enones[4])

Alternate Name: ethenylcopper.

Preparative Methods: by the reaction of ***Vinyllithium*** or vinylmagnesium halides and a copper(I) salt.

Handling, Storage, and Precautions: sensitive to air and moisture; dimerization occurs above 0 °C. Use in a fume hood.

General Discussion.

Vinylcopper was initially prepared from ***Vinylmagnesium Chloride-Copper(I) Chloride*** in THF;[5] warming the solution of vinylcopper from -40 to 20 °C results in the formation of 1,3-butadiene. ***Lithium Divinylcuprate*** was reported by House and co-workers in 1969 and shown to undergo 1,4-addition reactions with enones in very good yields.[6] However, in attempts to synthesize 1,3-dienes by the addition of lithium divinylcuprate to alkynic esters, stereochemical mixtures of double bond isomers are obtained. Corey and Chen[2] discovered that vinylcopper, prepared by the addition of 1 equiv of ***Vinyllithium*** to ***Copper(I) Iodide***-diisopropyl sulfide in ether at -78 °C, efficiently adds to alkynic esters to provide the 1,3-diene product with nearly complete stereochemical control (eq 1). Vinylcopper addition to higher homologues of alkynic esters also provides the 1,4-adduct with complete stereocontrol.[3]

(1)

1,6-Addition of vinylcopper to 1,3-dienyl esters is also carried out at -78 to -20 °C. Quenching the reaction mixture with methanol at -20 °C provides the 3,6-heptadiene esters in greater than 95% stereochemical purity (eq 2).[2] The same reaction with lithium divinylcuprate results in a 45:55 mixture of (*E*) and (*Z*) isomers of the 3,4-double bond. Vinylcopper reagents do not readily add to γ-substituted unsaturated esters.[6] For example, no 1,4-addition of vinylcopper is observed with ethyl 4-benzyloxy-2-pentenoate. However, diastereoselective addition to a doubly activated ester does occur in reasonable yield to provide the *anti* diastereomer as the major product (eq 3). Higher yields of the 1,4-addition product are observed for lithium divinylcuprate and the corresponding higher order cyanocuprate, but the diastereoselection does not improve. The reduced reactivity of the neutral vinylcopper species prepared from ***Vinylmagnesium Bromide*** and ***Copper(I) Bromide***-dimethyl sulfide complex in THF, in comparison to that of the corresponding lithium homocuprate reagent, is advantageous in providing the 1,4-addition product in reactions with acetylenedicarboxylates.[7] Cuprate reagents tend to provide low yields of the product due to competing polymerization. Vinylcopper also readily adds to 1-alkynyl sulfoxides to form vinyl sulfoxides in high yields.[8] A useful method for the stereospecific formation of *cis*-β-substituted alkenylcopper reagents is the addition of organocopper reagents to alkynes.[9,10] The substituted vinylcopper reagent obtained in this fashion may react with a second equivalent of the same alkyne or a different alkyne to form a new vinylcopper species, or may react with an alkyl halide in the presence of HMPA.[9a] The vinylcopper reagents prepared from alkynes can also be transformed to vinyl iodides,[9b] or carbonylated[9c] with retention of double-bond stereochemistry.

(2)

(3)

β-Substituted vinylcopper reagents derived from alkynes are also not as reactive as cuprate reagents and do not undergo 1,4-addition to enones readily. The initially formed vinylcopper species can be transformed into the more reactive cuprate by addition of an equivalent of a nontransferable ligand. Epoxides, aldehydes, and unsaturated ketones or esters can then all be used as electrophiles in subsequent reactions.[9d] β-Substituted enones are recalcitrant to 1,4-addition of vinylcopper or lithium divinylcuprate. Successful 1,4-addition of a vinyl group to isophorone is achieved only upon the addition of ***Tri-n-butylphosphine*** (eq 4).[11] Noyori and co-workers devised an efficient three-component coupling route to the prostaglandins which involves the tributylphosphine-promoted conjugate addition of neutral vinylcopper reagents to cyclopentenones.[4] A similar approach to the stereocontrolled synthesis of sterols employs a vinylcopper/tributylphosphine conjugate addition reaction (eq 5).[12] The obvious advantage of the organocopper reagents over the corresponding homocuprate reagents in the synthesis of prostaglandins and sterols is the fact that only 1 equiv of the vinyl group is required. Generation of the higher order cyanocuprate from 2 equiv of vinyllithium and ***Copper(I) Cyanide*** provides the most useful reagent for conjugate addition reactions.[1c]

(4)

(5)

The stereoselective synthesis of dienes has also been accomplished by palladium-catalyzed coupling of neutral vinylcopper derivatives with iodoalkenes.[13] Substitution reactions of allenyl iodides by vinylcopper produces nonconjugated enyne ethers which are not readily accessible by other methods (eq 6).[14] Conjugated enynes have been prepared by trapping the vinylcopper reagent obtained by alkylcopper addition to an alkyne with alkynylphenyliodonium tosylates (eq 7).[15] The alkene geometry is maintained in the alkynylation reaction.

Vinylene Carbonate

[872-36-6] · $C_3H_2O_3$ · Vinylene Carbonate · (MW 86.05)

(reacts as a dienophile[1-4] and a dipolarophile;[5-11] participates in *meta* cycloadditions[12,13] and other radical reactions[14])

Alternate Name: VC; 1,3-dioxol-2-one.

Physical Data: mp 22 °C; bp 165 °C; *d* 1.36 g cm^{-3}.

Solubility: sol Et_2O, benzene.

Form Supplied in: colorless liquid (97%), stabilized with BHT.

Handling, Storage, and Precautions: avoid contact with skin and eyes; do not breathe vapor; cancer-suspect agent. This reagent should only be used in a fume hood.

Introduction.

Since its first synthesis from ethylene carbonate, via a photochemical chlorination-dehydrochlorination sequence (eq 1),[1] vinylene carbonate (**1**) has been widely used in several thermal[15] and photochemical reactions.[16]

(1)

Diels-Alder Reactions.

Though reputedly a poor dienophile, VC, being a symmetrical dioxygenated alkene, has been frequently employed as a 2π participant in Diels-Alder reactions.[2] A [4 + 2] cycloaddition of isobenzofuran and vinylene carbonate takes place under mild conditions and leads to the formation of a highly oxygenated tetrahydronaphthalene (eq 2).[3] A thermal reaction between 2,4-dimethylfuran and VC provides a 7:5 mixture of cycloadducts which have been used in the total synthesis of naturally occurring citreoviral (eq 3).[4]

(2)

1,3-Dipolar Cycloaddition Reactions.

Whereas vinylene carbonate has been reported to be virtually unreactive towards nitrile oxides,[5] its reactivity with other 1,3-dipoles presents appealing syntheses of heterocycles.[6] The reaction of VC with hydroximic acid hydrochlorides, for instance, results in the formation of isoxazolines in modest yields (eq 4).[7]

There are reports that the dipolar cycloaddition reactions of nitrones (both cyclic and open-chain) with VC lead to the formation of mixtures of *endo*- and *exo*-adducts.[8] However, nitrones bearing a chiral center on the carbon substituent of a nitrone undergo *endo* additions with achiral dipolarophiles.[9] This chemistry leads directly to the formation of masked α-hydroxy aldehydes and presents an attractive route for preparing amino sugars from noncarbohydrate precursors. Thus the [3 + 2] reaction of nitrone (**2**) and VC leads to a 1:1 diastereomeric mixture of products (both *endo*) which are readily converted into acylated derivatives of epigentosamines (eq 5).[10] A thermal dipolar reaction of an azomethine ylide with VC leads to the formation of highly functionalized pyrrolidines (eq 6).[11]

Meta Cycloadditions.

Arenes react with VC, under photochemical conditions, to provide *meta* cycloadducts.[12] The photoaddition of VC and anisole provides *meta* adducts in a 65:35 ratio (*endo*/*exo*) and some *ortho* adducts (~30%) are also observed. The reaction with benzonitrile, however, provides a regioisomeric mix of only *endo-meta* adducts.[13]

[917-57-7] · C_2H_3Li · Vinyllithium · (MW 33.99)

(introduction of vinyl groups[2,3])

Physical Data: white solid; no melting point; decomposes upon heating. The ^1H,[4] ^{13}C,[5] and ^7Li NMR[6] and UV-vis[7] spectra of vinyllithium have all been recorded.

Solubility: sol THF, ether; slightly sol pentane, hexane;[8] insol benzene.[9]

Analysis of Reagent Purity: determined by simple acid titration,[8] by reaction with vanadium pentoxide followed by titration with standard permanganate solution,[10] by hydrolysis followed by measurement of ethylene evolution,[11] or by the Gilman procedure.[12]

Preparative Methods: prepared by a variety of methods. Direct metalation of ***Ethylene*** with ***Lithium*** metal in dimethoxymethane yields vinyllithium contaminated with lithium hydride, and other organolithio species, such as butyllithium and 1,4-dilithiobutane.[13] Direct formation from ethylene can also be accomplished using ***Potassium t-Butoxide***, ***n-Butyllithium***, and TMEDA (***N,N,N´,N´-Tetramethylethylenediamine***) in hexane at -40 °C, followed by treatment of the vinylpotassium with ***Lithium Bromide***.[14] The lithium-halogen exchange reaction has been used, starting from vinyl chloride and lithium/sodium dispersions,[10,12] or from vinyl bromide with 2 equiv of ***t-Butyllithium*** in either a Trapp solvent mixture at -120 °C[15,16] or ether at -78 °C.[17] This is the most convenient procedure, but lithium halide is formed during the reaction and is present as a contaminant. Halide-free vinyllithium can be prepared by transmetalation of ***Tetravinylstannane*** with phenyl- or butyllithium,[8] of tetravinyllead with either lithium metal or ***Phenyllithium***,[9] or of divinylmercury with lithium dispersion in pentane.[11]

Purification: ether solutions can be evaporated under an inert atmosphere and the resulting solid washed with anhydrous pentane or hexane.

Handling, Storage, and Precautions: as with most alkyllithium reagents, vinyllithium reacts readily with moisture. Solid vinyllithium should be maintained at -25 °C or below, under an inert atmosphere. The solid suffers a loss in activity with time and should be used immediately upon preparation.[9] Solutions of the reagent in ether or THF, under an inert atmosphere, are stable for up to 1 week at rt.[8] Solid vinyllithium is violently pyrophoric, yielding a brilliant red flash on contact with air.[9]

Vinyl Reagents.

Vinylcuprates are easily assembled from the reaction of vinyllithium and copper species. ***Lithium Divinylcuprate*** (eq 1) has been prepared from vinyllithium using the dimethyl sulfide complex of a copper(I) halide,[18] or from ***Copper(I) Cyanide***.[19] Mixed cuprates are available by the addition of vinyllithium to (2-thienyl)Cu(CN)Li,[20] $(MeCu)_n$,[18] or ***1-Pentynylcopper(I)***.[21] In all the mixed cuprates the vinyl ligand is preferentially transferred.

(1)

Vinylsilanes can be prepared by reaction of a silyl halide with vinyllithium.[22] Alternatively, the reaction of ***Bis(trimethylsilyl) Peroxide*** with vinyllithium yields an 80:20 mixture of ***Vinyltrimethylsilane*** and the trimethylsilyl enol ether (eq 2).[23] Use of the corresponding vinyl Grignard reagent produces exclusively the enol ether.

(2)

Trialkylvinylborates can be prepared by the treatment of trialkylboranes with vinyllithium in ether at 0 °C.[24] Use of a vinyl Grignard reagent to form the vinyl borate leads to lower yields in subsequent reactions. Dimesitylvinylborane is synthesized by lithium-halogen exchange of vinyllithium with fluorodimesitylborane.[25] Dialkyl disulfides[15] or diphenylphosphinodithioates (**1**)[26] react with vinyllithium to produce vinyl alkyl, or aryl, sulfides in good yields (eq 3).

(3)

Ring Formation Reactions.

Vinyllithium reacts with carbonyl compounds, providing a convenient method for the introduction of a double bond for subsequent ring formation. Addition to a vinyl-substituted cyclobutanone, followed by treatment with ***Potassium Hydride***, gives the *cis*- and *trans*-cyclooctenones in 62% yield after Cope rearrangement (eq 4).[2] The vinyllithium addition yields only one diastereomer according to NMR and HPLC analysis. Similar sigmatropic reactions have been used in bicyclic systems. Vinyllithium adds to the carbonyl in bicyclo[3.2.0]heptan-6-ones (eq 5) which, when subsequently treated with potassium hydride, undergo a [1,3]-sigmatropic rearrangement of the 1-vinylcyclobutanols to yield the ring expanded product (**2**).[27] An oxy-Cope rearrangement has been used to construct bicyclo[5.3.1]undecenones after addition of vinyllithium to bicyclo[3.1.1]heptan-6-ones.[28] An intramolecular Diels-Alder reaction has been used to construct Isomer G, a component of thujopsene. The addition of vinyllithium to the acid (**3**) produces the precursor for the Diels-Alder cyclization (eq 6).[29] Further elaboration leads to Isomer G.

(4)

(5)

(6)

Other cyclizations have also utilized vinyl groups introduced by reaction of carbonyl groups with vinyllithium, as in the base-catalyzed cyclization used in the synthesis of aphidicolin,[30] the formation of substituted quinones from dimethyl squarate,[31] and the cyclization using sodium in THF in the synthesis of (±)-patchoulol.[32]

Nucleophilic Additions.

Reaction of vinyllithium with 1-iodooctane in THF gives 1-decene in 92% yield. The use of 1,4-dibromobutane gives 1,7-octadiene in 67% yield.[33] Alkenes are also available from the dimerization of vinyllithium with anhydrous ***Cerium(III) Chloride*** in THF.[34] Aryl or alkyl vinyl ketones are readily formed by treating carboxylic acids with 2 equiv of vinyllithium in DME at 5-10 °C. Propionic acid produces 1-penten-3-one in 92% yield.[3]

Substituted enol silyl ethers are available from vinyllithium addition to silyl ketones (eq 7). Addition of the vinyllithium to the silyl ketone results in a silyloxyallyllithium which can be trapped with various electrophiles to yield the substituted enol silyl ethers.[17] Vinyllithium can also be added to epoxides to give the ring-opened product,[35] added to aldimines in toluene at -42 °C to produce allylamines,[36] and inserted *ortho* to either a 2,6-di-*t*-butyl-4-methoxyphenyl ester substituent[37] or an oxazoline group on a naphthalene ring.[38]

(7)

Electrophile	E	Yield
MeSSMe	MeS	89%
MeI	Me	83%
Pr—≡	H	79%

Related Reagents.

Perfluorinated vinyllithium has been prepared by transmetalation of phenyltris(perfluorovinyl)tin with 3 equiv of phenyllithium in ether at -35 to -40 °C,[39] or by lithium-bromine exchange of perfluorovinyl bromide with 2 equiv of ***t-Butyllithium*** in THF at -110 °C.[16] Vinylsodium is prepared by metalation of ethylene using pentylsodium with sodium isopropoxide.[40] Vinylpotassium is made from vinyl chloride by metal-halogen exchange using a 90% potassium/sodium alloy.[41]

Related Reagents.

1,3-Butadienyl-1-lithium; ***Isopropenyllithium***; ***1-Propenyllithium***; ***Vinylmagnesium Bromide-Methylcopper***.

Vinylmagnesium Bromide[1]

[1826-67-1] · C_2H_3BrMg · Vinylmagnesium Bromide · (MW 131.26)

(introduction of a vinyl unit)

Form Supplied in: widely available in solution in THF (1.0 M).

Preparative Methods: prepared in situ from vinyl bromide and ***Magnesium*** in THF.[3]

Handling, Storage, and Precautions: the solution in THF must be handled with care since it is flammable and may ignite on contact with moisture and air. It should be stored and handled in an inert atmosphere (argon or nitrogen) and measured or transferred by means of a hypodermic syringe or cannula. The solution may deteriorate with time and the concentration of the reagent should be titrated before use.[2]

General Discussion.

Vinylmagnesium bromide reacts with various electrophiles (e.g. aldehydes, ketones, esters, lactones, anhydrides, acid chlorides, carboxylic acids, nitriles, amides, epoxides, allyl halides) (eq 1).[1,3,4]

(1)

Complexation of vinylmagnesium bromide with TDA-1 [$N(CH_2CH_2OCH_2CH_2OMe)_3$] gives a powder which can react as the conventional Grignard reagent in hydrocarbon solvents (toluene, cyclohexane) (eq 2).[5]

(2)

Vinylmagnesium bromide reacts with a silyl ketone to give a tertiary allylic alcohol, which is a useful intermediate for the synthesis of 2-substituted 1,3-dienes (eq 3).[6] A fluorinated 1,3-butadiene bearing a siloxy group is prepared by treatment of a trifluoroacetylsilane with vinylmagnesium bromide (eq 4).[7]

An organocerium reagent, prepared from vinylmagnesium bromide and anhydrous ***Cerium(III) Chloride***, reacts with easily enolizable ketones to afford addition products in good yield (eq 5).[8] Under copper catalysis, vinylmagnesium bromide undergoes conjugate addition to α,β-unsaturated ketones very efficiently (eqs 6 and 7).[9-11]

In the presence of copper(I) salts (2-10%) in THF, vinylmagnesium bromide reacts with alkyl halides (eq 8)[12] and epoxides. In the latter case, pure ***Copper(I) Iodide*** (or ***Copper(I) Bromide***-dimethyl sulfide) is needed for the ring opening of cyclohexene oxide with high stereospecificity (eq 9).[13]

(8)

(9)

Catalyst (10%)	Yield (%)	
CuI (99.999% purity)	70%	100:0
CuI (98% purity)	70%	55:45
$CuBr \cdot Me_2S$	65%	100:0

In the presence of nickel or palladium complexes, vinylmagnesium bromide couples efficiently with aryl halides (eq 10),[14] vinyl halides (eqs 11 and 12),[15,16] and vinyl carbamates (eq 13).[17] The transmetalation of vinylmagnesium bromide occurs easily to give useful vinyl metals (eqs 14 and 15).[18,19]

Vinylmagnesium Bromide-Methylcopper

(CH_2=CHMgBr)

[1826-67-1] · C_2H_3BrMg · Vinylmagnesium Bromide-Methylcopper · (MW 131.26) (MeCu)

[1184-53-8] · CH_3Cu · Vinylmagnesium Bromide-Methylcopper · (MW 78.59)

(vinyl group transfer reagent in 1,4-addition reactions with α,β-unsaturated ketones; can reductively remove a γ-alkoxy group from α,β-unsaturated ketones)

Solubility: sol ether, THF.

Preparative Methods: generated[1,2] in situ from preformed ***Methylcopper***[3] and a commercial 1.0 M solution of ***Vinylmagnesium Bromide*** in THF. A mixture of purified[1,4] copper(I) iodide (*n* mmol) and THF (4*n* mL) is treated with a solution of methyllithium (*n* mmol) in ether at -78 °C. The suspension is warmed to 23 °C, stirred for 15 min, and then cooled to -78 °C and treated with the solution of vinylmagnesium bromide (1*n*-3*n* mmol).

Handling, Storage, and Precautions: must be generated in the absence of moisture and oxygen. It cannot be stored. Use in a fume hood.

Introduction.

The reagent is believed to consist of mixed magnesium homocuprates, $(CH_2{=}CH)_nMeCu(MgBr)_n$ (*n* = 1, 2, or 3), with the formula reflecting mainly the ratio of MeCu to CH_2=CHMgBr rather than the structure of the organocopper(I) ate complexes.[2,5] The magnesium cuprates are a useful alternative to ***Lithium Divinylcuprate***,[3] since the ***Vinyllithium*** required for the generation of $(CH_2{=}CH)_2CuLi$ is no longer available commercially.

Vinyl Group Transfer.

The selective transfer of the vinyl group in the 1,4-addition of higher order magnesium cuprates, derived from MeCu and CH_2=CHMgBr, to an enone is illustrated in eq 1.[2] There is almost no 1,2-addition. Conjugate addition products can be prepared in high yields from sterically hindered ketones (eqs 2 and 3).[1]

(1)

$n = 2$	69%	6.0%
$n = 3$	78%	1.6%

(2)

(3)

Reductive removal of the alkoxy group from a γ-alkoxy enone has been observed with the reagent derived from MeCu and CH_2=CHMgBr.[1] This problem can be overcome by the use of a divinylmagnesium cuprate[6] generated from vinylmagnesium bromide and ***Copper(I) Iodide*** (eq 4).

(4)

Related Reagents.

n-Butylmagnesium Bromide-Methylcopper(I); ***Vinylmagnesium Bromide-Copper(I) Iodide***; ***Vinylmagnesium Chloride-Copper(I) Chloride***.

Vinylmagnesium Chloride-Copper(I) Chloride

(CH_2=CHMgCl)

[3536-96-7] · C_2H_3ClMg · Vinylmagnesium Chloride-Copper(I) Chloride · (MW 86.81) (CuCl)

[7758-89-6] · ClCu · Vinylmagnesium Chloride-Copper(I) Chloride · (MW 99.00)

(mediates conjugate addition in the synthesis of β-vinyl carbonyl compounds[1-3] and 1,6-diketones[4])

Solubility: sol ether, THF.

Preparative Method: generated[2] in situ by stirring vinylmagnesium chloride[5] in THF with varying amounts of anhydrous ***Copper(I) Chloride*** below 0 °C.

Handling, Storage, and Precautions: all reactions must be conducted in the absence of moisture and oxygen. Some reactions have been conducted satisfactorily in THF under reflux conditions.[3] Use in a fume hood.

Conjugate Additions.

The reagent mediates a conjugate 1,4-addition of a vinyl group to α,β-unsaturated carbonyl compounds (eq 1) to give β-vinyl derivatives.[1] With diethyl (*E*)-2-heptenedioates as the substrates, the initial conjugate addition is followed by Dieckmann condensation of the resultant ester enolate (eq 2).[2] Ring opening of γ-lactones by this reagent produces a transient vinyl ketone, which undergoes subsequent conjugate addition with the reagent to also give β-vinyl ketones (eq 3).[3] A similar tandem reaction with esters produces the unsaturated ketones accompanied by 1,6-diketones (eq 4).[4] In a few cases studied, substitution of a carboxylic acid for the ester in this reaction results in the exclusive formation of the diketone. This synthetic approach to 1,6-diketones appears to be limited to the use of fatty acids as the substrates.[4]

Vinyltributylstannane[1]

[7486-35-3] · $C_{14}H_{30}Sn$ · Vinyltributylstannane · (MW 317.15)

(vinyl nucleophile in palladium-mediated cross-coupling reactions;[2] occasionally used as a vinyllithium precursor[3])

Alternate Name: vinyltributyltin.

Physical Data: bp 104-106 °C/3.5 mmHg, 95 °C/1.5 mmHg; *d* 1.085 g cm^{-3}.

Solubility: sol common organic solvents; insol H_2O.

Form Supplied in: neat oil; widely available. Occasionally contaminated with small amounts of Bu_3SnCl.

Analysis of Reagent Purity: the pure compound shows one nonpolar spot by TLC (hexane) and one peak in the GC. ^1H NMR can also be useful.

Preparative Methods: conveniently prepared by the reaction of ***Vinylmagnesium Bromide*** with ***Tri-n-butylchlorostannane***.[4]

Purification: large quantities of material are purified by fractional distillation. Small amounts may be filtered through a plug of silica.

Handling, Storage, and Precautions: is air- and water-stable; requires no special handling or storage. Organostannanes are toxic and should only be used in a well ventilated hood. All glassware should be rinsed in a KOH/EtOH bath during cleaning.

Palladium-Mediated Cross Coupling (the Stille Reaction).

Vinyltributyltin is commonly used as a nucleophile in palladium-mediated cross-coupling reactions with organic electrophiles.[2] The electrophile may be a halide or a pseudohalide which contains an sp or sp^2 carbon at or immediately adjacent to the electrophilic center. Halide reactivity varies in the order: I > Br >> Cl. Either Pd^0 or Pd^{II} catalysts may be used to mediate the reaction, the latter being reduced in situ by excess stannane. Acid chlorides react with vinyltributyltin in the presence of ***Benzylchlorobis(triphenylphosphine)palladium(II)*** in HMPA or chloroform at 65 °C (eq 1).[5] In the latter solvent, yields are lower but the workup is significantly easier. Often the introduction of air into the reaction accelerates cross coupling of acid chlorides. Imidoyl chlorides (eq 2)[6] and vinyl halides also undergo Pd-mediated cross coupling (eqs 3 and 4).[7,8] Coupling of aryl halides typically requires electron poor aromatics or aryl iodides (eq 5).[9]

Hegedus et al. report a case in which an iodide attached to an electron-rich alkene fails to couple under normal conditions.[10] Treatment of the vinyl halide under Heck alkenation conditions in the absence of solvent gives a moderate yield of the desired product (eq 6).[10] Use of weakly donating stabilizing ligands, such as tri(2-furyl)phosphine and triphenylarsine, accelerates transmetalation, allowing coupling under conditions more gentle than those required with normal palladium catalysts [$Pd(PPh_3)_4$, $PdCl_2(PPh_3)_2$, etc.] (eq 7).[11]

(7)

A number of pseudohalides act as electrophiles in palladium-catalyzed cross couplings. Vinyl and aryl triflates couple with a wide variety of organostannanes in the presence of excess of ***Lithium Chloride*** (eq 8).[12-14] Cross coupling with aryl triflates is more difficult that with vinyl triflates, typically requiring either a more nucleophilic catalyst [***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)***, (dppf)$PdCl_2$)] or higher temperatures (dioxane at 98 °C) (eq 9).[15] Use of vinyl[16] or phenyl[17] fluorosulfonates allows lower cost at the expense of lower stability with respect to the analogous triflate (eq 10). Arenesulfonates have also been coupled with vinyltributyltin.[18] However, the generality of this variation is not yet clear.

(8)

(9)

Other electrophiles which undergo cross coupling include hypervalent iodine compounds (eq 11)[19] and aryl diazonium salts (eq 12).[20] Coupling of aryl diazonium salts requires excess vinyltributyltin and 1 equiv of the catalyst to avoid significant byproduct formation.[20] Carbonylative couplings can be achieved if cross coupling is conducted under 1-3 atm of ***Carbon Monoxide*** (eq 13).[14] Vinyltributyltin has also been used in tandem Heck alkenation/Stille couplings, in which the stannane is reacted with an alkyne and an electrophile in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** (eq 14).[21,22]

(13)

(14)

Transmetalation.

Transmetalation from tin offers a facile synthesis of vinyl nucleophiles. Treatment of vinyltributyltin with ***Methyllithium*** affords methyltributyltin and ***Vinyllithium*** (eq 15).[3] Similarly, treatment with higher order cuprates causes quantitative in situ formation of the vinylcuprate (eq 16).[23] Vinyltributyltin will transfer a vinyl group in reactions with both trimethylchlorogermane and tetrachlorogermane.[24] Transmetalation with trimethylchlorogermane requires the presence of a catalytic amount of ***Aluminum Chloride***. Treatment of an excess of vinyltributyltin with ***9-Bromo-9-borabicyclo[3.3.1]nonane*** affords ***9-Vinyl-9-borabicyclo[3.3.1]nonane*** while avoiding the manipulation of air-sensitive compounds.[25] Excess vinyltributyltin is necessary to remove adventitious protic acid, and a greater than usual amount of H_2O_2/NaOH is used during oxidative hydrolysis to allow for reaction with bromotributyltin. Iodosulfonylation of vinyltributyltin followed by elimination of HI (DBU) affords the vinyl sulfone (eq 17),[26] which can subsequently be used in Diels-Alder reactions or can be lithiated.[27]

Vinyltrimethylsilane[1]

[754-05-2] · $C_5H_{12}Si$ · Vinyltrimethylsilane · (MW 100.26)

(ethylene equivalent in electrophilic substitution reactions; precursor to 3-trimethylsilyl-3-buten-2-one, a methyl vinyl ketone surrogate for Robinson annulations; homologation of aldehydes to α,β-unsaturated aldehydes)

Physical Data: bp 55-57 °C; *d*204 0.691 g cm^{-3}; *n*20D 1.391.

Solubility: sol most common organic solvents (THF, Et_2O, benzene, CH_2Cl_2, etc.)

Form Supplied in: commercially available from several suppliers.

Analysis of Reagent Purity: characterized by ^1H, ^{13}C, and ^{29}Si NMR,[2] and IR.[3] ^1H NMR (500 MHz) ($CDCl_3$): δ 0.08 (9H, s), 5.67 (1H, dd, J_{trans} = 20.3 MHz, J_{gem} = 3.8 Hz), 5.93 (1H, dd, J_{cis} = 14.7 Hz, J_{gem} = 3.8 Hz), 6.17 (1H, dd, J_{trans} = 20.3 Hz, J_{cis} = 14.7 Hz) ppm; ^{13}C NMR (125 MHz) ($CDCl_3$): δ -1.62, 130.88, 140.27 ppm; ^{29}Si NMR (19.9 MHz) ($(MeO)_4Si$): δ -71.70 ppm; IR (CCl_4): ν 1594 cm^{-1}.

Preparative Method: prepared in 67-91% yield from ***Vinylmagnesium Bromide*** and ***Chlorotrimethylsilane*** in THF.[4,5]

Purification: fractional distillation at 1 atm using an efficient Vigreux column. Some difficulty in removing trace amounts of THF (bp 67 °C) has been reported.

Handling, Storage, and Precautions: highly flammable; flash point -34 °C; hygroscopic. The reagent should be used in a well ventilated hood. Contact with the eyes and skin should be avoided.

Synthesis of Vinyl Aryl Sulfides.

Vinyltrimethylsilane functions as an ***Ethylene*** equivalent in electrophilic substitution reactions with sulfenyl chlorides (eq 1).[6] Reaction with various arylsulfenyl chlorides provides the stable adducts (**1**) in high yield. Treatment of (**1**) with fluoride ion furnishes vinyl aryl sulfides (**2**) in high yield.

Ar = 2,4-dinitrophenyl, 2-nitrophenyl, phenyl, 4-chlorophenyl, 4-methylphenyl

Synthesis of 3-Triethylsilyl-3-buten-2-one.

Vinyltriethylsilane can be elaborated in five steps to yield ***3-Triethylsilyl-3-buten-2-one*** (**4**) (eq 2), a ***Methyl Vinyl Ketone*** surrogate useful in Robinson annulation reactions (eq 3).[7] The analogous annulation reaction using methyl vinyl ketone gives poor yields.

(2)

(3)

Synthesis of α,β-Unsaturated Primary Amides.

Vinylsilanes react with ***Chlorosulfonyl Isocyanate*** without the aid of Lewis acid catalysts to form β-lactams, e.g. (**5**), which subsequently undergo hydrolysis to the corresponding *trans*-α,β-unsaturated primary amides, e.g. (**6**) (eq 4).[8]

(4)

Synthesis of α,β-Unsaturated Aldehydes.

Vinyltrimethylsilane undergoes [3 + 2] cycloaddition reactions with the aldehyde-derived nitrone (**7**) to provide the corresponding (trimethylsilyl)isoxazolidine adduct (**8**) in 84% yield (eq 5).[9] Treatment of (**8**) with aqueous HF furnishes the α,β-unsaturated aldehyde (**9**) in 95% yield. This methodology is general for the homologation of aldehydes and serves as an alternative to the traditional Wittig-type alkenations.

(7)

(8) (9)

Synthesis of Bicyclopentenones.

The title reagent serves as an ethylene equivalent in aliphatic Friedel-Crafts acylation reactions involving cyclic α,β-unsaturated acid chlorides. For example, the acid chloride (**10**) reacts with vinyltrimethylsilane in the presence of ***Tin(IV) Chloride*** to give the divinyl ketone intermediate (**11**), which then undergoes a Nazarov cyclization, thus producing the bicyclopentenone (**12**) in 46% overall yield (eq 6).[6,10]

(10) (11)

(12)

Synthesis of 1-Chlorocyclopropene.

Vinyltrimethylsilane serves as a useful precursor to 1-chlorocyclopropene (**14**).[13] Reaction of the vinylsilane with

Phenyl(trichloromethyl)mercury[12] in refluxing benzene followed by fluoride-induced elimination of TMSCl from the cyclopropane (**13**) furnishes 1-chlorocyclopropene in good yield, as evidenced in the subsequent Diels-Alder reaction with 1,3-diphenylisobenzylfuran (eq 7). A previous synthesis[13] of 1-chlorocyclopropene gave only 5-10% yield.

Radical Addition Reactions of Vinyltrimethylsilane.

Reaction of the title reagent with ***Benzenesulfonyl Chloride*** under radical addition conditions[14] provides ***(E)-1-Phenylsulfonyl-2-trimethylsilylethylene*** (**15**),[15] an ***Acetylene*** equivalent in Diels-Alder reactions (eq 8). In similar fashion, ***Thiophenol*** adds to vinyltrimethylsilane regioselectively.[16] Oxidation of the thiophenol adduct provides the sulfone (**16**) (eq 9), which serves as a latent exomethylene unit in the enantioselective synthesis of (1*R*)-[(methylenecyclopropyl)acetyl]-CoA (**17**).[17] The sulfone (**16**) is also used in the high yield preparation of allylsilanes, vinyl sulfones, and 2-(benzenesulfonyl)allyl alcohol derivatives.[18]

Reaction of Vinyltrimethylsilane with 2-Azaallylanions.

Reaction of vinyltrimethylsilane with the nonstabilized 2-azaallyl anion (**19**), generated in situ from the (2-azaallyl)stannane (**18**) (eq 10), produces, after quenching with MeI, the pyrrolidine (**20**) as a single diastereomer in 77% yield (eq 11).[21] Some evidence suggests that the cycloaddition is stepwise and that the W-conformation of the anion predominates in the cycloaddition sequence.

Regioselective Hydroesterification of Vinyltrimethylsilane.

Vinyltrimethylsilane undergoes highly regioselective hydroesterification reactions to furnish either ethyl 3-(trimethylsilyl)propionate (**21**) or ethyl 2-(trimethylsilyl)propionate (**22**), depending on the choice of catalyst and reaction conditions (eq 12).[20] Highly regioselective (>96% β-selective) hydroformylations of vinylsilanes containing bulky alkyl and aryl substitutents on silicon have been achieved using ***Carbonylhydridotris(triphenylphosphine)rhodium(I)*** as catalyst.[21]

Catalyst	Yield (21)/(22)	Ratio (21):(22)	$P_{initial}(CO)$
$PdCl_2(PPh_3)_2$ (1-2 mol%)	94%	98:2	60 kg cm^{-2}
$Co(CO)_8$ (2-4 mol%)	74%	1:99	70 kg cm^{-2}

Vinyltriphenylphosphonium Bromide[1]

[5044-52-0] · $C_{20}H_{18}BrP$ · Vinyltriphenylphosphonium Bromide · (MW 369.25)

(phosphonioethylation; two-carbon chain-linking and alkenation; ring formation by Michael-Wittig, Michael-nucleophilic displacement, and Diels-Alder sequences[1])

Physical Data: mp 189-190 °C. The proton,[2] carbon, and phosphorus[3] NMR and the mass spectrum have been reported.[4]

Solubility: sol *t*-butanol.

Form Supplied in: white powder.

Preparative Methods: preparation of vinyltriphenylphosphonium bromide (**1**) has been accomplished by treatment of ethylenebis(triphenylphosphonium) dibromide with borate ion (32%),[5] (2-chloroethyl)triphenylphosphonium bromide with ***Triethylamine*** (72%),[6] (2-bromoethyl)triphenylphosphonium bromide with ***Silver(I) Oxide*** (85%),[7] and (2-phenoxyethyl)triphenylphosphonium bromide with boiling ethyl acetate (92%).[2]

Purification: may be recrystallized from *t*-butanol-ether[6] to give an analytically pure sample having a mp of 189-190°.[2]

Handling, Storage, and Precautions: hygroscopic; irritant; produces sneezing in many individuals. Use in a fume hood.

General Discussion.

Phosphonioethylation has been accomplished by employing a variety of nucleophiles (eq 1). Low concentrations (<=1.5 M) of aqueous ***Sodium Hydroxide*** give only (β-hydroxyethyl)triphenylphosphonium bromide (**2**) (RX = HO), whereas greater concentrations (&egt;2.0 M) of hydroxide give (**2**) (RX = HO) plus products attributable to an initial attack of hydroxide on the P atom.[8] A number of other nucleophiles have been employed to give high yields in the phosphonioethylation reactions; these include alcohols,[2,9] primary and secondary amines,[10,11] nitrosobenzene,[12] thiols,[2,9,13] and methylene groups activated by electrophilic moieties.[14-16]

The Michael-type addition of a nucleophile to (**1**) followed immediately by a Wittig alkenation reaction has sometimes been called the Schweizer reaction (eq 2).[17] The nucleophiles (X) include various carbon, nitrogen, and oxygen species, with one example of a trimethyltin nucleophile.[18,19] Poor yields are reported for reactions of alkyllithiums (13-16%),[20] ***Phenyllithium*** (41%),[20] and diethyl ethylsodiomalonate (14%)[21] with ketones. The reaction of butyl-, vinyl-, and heptynyllithium gives none of the hoped-for product (**3**) with benzaldehyde.[7] However, cuprates give relatively good yields of (**3**). The (*Z*)-isomer predominates;[22] the addition of 5 equiv of ***Hexamethylphosphoric Triamide*** to the reaction enhances formation of the (*Z*)-isomer.[7]

Secondary amines,[21] pyrrole,[23] sulfonamides,[21] and phthalimides,[17] as their salts, react with (**1**) and a variety of aldehydes to give allylamines. The (*Z*)-isomer is formed predominantly unless lithium salts are added.[17] The replacement of (**1**) by vinyltri-*n*-butylphosphonium bromide gives predominantly the (*E*)-isomer.[16] Primary amines have been successfully used only as the dilithio salts.[11] ***Sodium Ethoxide*** and thiophenoxide (see ***Thiophenol***) react with (**1**) and benzaldehyde to yield (**3**).[21]

The Schweizer reaction has been used mainly to prepare carbocyclic and heterocyclic species (eq 3).[24]

The types of ring that have been formed by this Schweizer annulation reaction are illustrated in eqs 4-12 using specific examples. Each equation is preceded by C_nX_m to illustrate the actual elemental components of the ring formed. The types of ring are: cyclopentene (eq 4);[25-27] cyclohexene (eq 5);[25,28-30] pyrrole or dihydropyrrole (eq 6);[31-40] 1,2-dihydroquinoline (eq 7);[41] 2,3-dihydropyridazine (eq 8);[40] dihydrofuran (eq 9);[14,42] 3,4-chromene (eq 10);[43] 2,5-dihydrothiophenes (eq 11);[44-48] and 3,6-dihydro-2*H*-thiopyrans (eq 12).[49]

(12)

A novel extension of the Schweizer annulation reaction is a [2 + 2 + 2] annulation reaction,[50] involving two consecutive Michael-type additions followed by ring closure.[51-53] The reaction has been used successfully employing 1 mol of (**1**) and another Michael acceptor (eq 13) or 2 mol of (**1**) (eq 14).[53]

(13)

(14)

Ring formation employing (**1**) has also been accomplished with reaction sequences involving Michael-type additions followed by a nucleophilic internal substitution reaction (eq 15).[30,54-58]

(15)

[3 + 2] Cycloadditions have yielded pyrroles (eq 16),[59] 2-pyrazolin-3-yltriphenylphosphonium bromides (eq 17),[60] pyrazoles (eq 18),[61] and the adduct from a nitrone, which decomposes spontaneously (eq 19).[62] Diels-Alder, or [4 + 2], cycloadditions have also been explored (eq 20).[63-65]

Vitamin B_{12}[1-3]

[68-19-9] · $C_{63}H_{88}CoN_{14}O_{14}P$ · Vitamin B_{12} · (MW 1355.40)

(radical source via carbon-cobalt bond homolysis; stoichiometric and catalytic radical C-C bond formation; enantioselective catalyst for molecular rearrangements)

Physical Data: odorless and tasteless, hygroscopic, dark red solid; does not have a defined melting point; darkens at 210-220 °C but is not melted at 300 °C.

Solubility: sol H_2O (1 g/80 mL), alcohol; insol acetone, chloroform, ether.

Form Supplied in: powder or crystalline solid; available from biologically oriented chemical suppliers.

Handling, Storage, and Precautions: hygroscopic; absorbs moisture from air. Hydrated crystals are air stable. Aqueous solutions slowly decompose. May be harmful by inhalation, ingestion, or skin absorption and can cause eye and skin irritation. Keep containers tightly closed and store in a cool dry place. Use in a fume hood with safety goggles and chemically resistant gloves and clothing.

Stoichiometric Processes.

In 1964, Schrauzer published the first of many papers on the synthesis and properties of alkyl cobaloximes.[1] This work led to the

development of cobaloximes and related compounds as vitamin B_{12} model compounds, e.g. (**1**)-(**4**), summarized in a review in 1976.[2] By the mid 1970's, many of the fundamental reactions of vitamin B_{12} and model complexes were well established. This work is summarized in several reviews.[3]

$RCo^{III}(dmgH)_2B$
(cobaloxime complex)
(1)

$RCo^{III}\{(DO)(DOH)PN\}X$
('DODOH' or Costa's complex)
(2)

$RCo^{III}(salen)B$
(salen complex)
(3)

$RCo^{III}(salophen)B$
(salophen complex)
(4)

Alkylcobalt complexes provide an easy bridge between two-electron ionic chemistry and one-electron radical chemistry. This has made them popular and useful radical precursors; ionic reactions provide alkylcobalt complexes which then provide alkyl radicals via C-Co bond homolysis. In the mid 1970s and early 1980s, radical chain S_H2' reactions of allylcobaloximes were studied (eq 1).[4] These reactions were not applied to specific synthetic problems.[5]

X = halide, sulfonate ester

(1)

In the late 1980s, and early 1990s, stoichiometric nonchain organocobalt reactions have been developed.[6] Cobalt-based radicals, formed by carbon-cobalt bond homolysis, continue to participate in multistep radical processes to guide reaction pathways into particular directions.[7] The main practical benefits are: (1) radical-alkene additions are possible; (2) polymerization is inhibited; and (3) the alkene is regenerated in the final product by cobalt-mediated β-H elimination. A tandem radical cyclization (eq 2)[8] illustrates the main features. Oxidative addition of the cobalt anion to the alkyl bromide generates the alkyl radical which undergoes cyclization followed by trapping by the Co^{II} radical. This type of reaction was first observed in earlier studies of the mechanism of oxidative addition of Co^{I} to hindered alkyl halides.[9] Photolytic homolysis of the C-Co bond produces the alkyl radical which undergoes cyclization followed by Co^{II}-mediated β-H elimination.

A similar strategy has been applied to the synthesis of kainoids and related compounds (eq 3).[10] Both stoichiometric and catalytic amounts of cobalt reagents have been used in these and other cyclization studies. Several examples of these types of cyclizations have been published,[11] including cyclizations using aryl halides as precursors to aryl radicals.[12]

Alkylcobalt reagents are often prepared from the reaction of anionic Co^{I} complexes with alkyl halides or sulfonate esters. They can also be prepared by conjugate addition of anionic Co^{I} complexes to α,β-unsaturated carbonyl compounds and nitriles, placing the cobalt β to the activating group, or by addition of neutral Co^{III} hydrides to activated alkenes (carbonyl, nitrile, and aryl activating groups), placing the cobalt α to the activating group.[13] Anionic Co^{I} anions open epoxides regioselectively and the resulting cobaloximes show different patterns of reactivity under thermolysis versus photolysis (eq 4).[14] A mechanistic study indicates that cobalt-mediated cyclizations proceed via

radicals,[15] but the reaction mechanism in the reactions in eq 4 has not been studied in detail. Acyl radicals can be generated from readily prepared acyl cobalt complexes.[16] The key step in a formal synthesis of racemic thienamycin is illustrative (eq 5).[17]

(4)

(5)

Intermolecular cross-coupling reactions have been developed.[18] One application to the synthesis of KDO takes advantage of alkene regeneration to allow further synthetic elaboration (eq 6).[19] Similar reactions have been developed for C-C bond constructions at the anomeric center of hexopyranoses,[20] leading to the production of *C*-glycosides, at C-1 of an open-chain pentose, leading to a synthesis of KDO,[21] and at C-3 of ribofuranoses.[22] Nonalkene cross-coupling partners have been used, specifically protonated heteroaromatics[23] and nitroalkyl anions.[24] Nitroalkyl anion cross couplings have been used to prepare *C*-disaccharides (eq 7).[25]

(6)

(7)

Catalytic Processes.

Catalytic processes lead to intramolecular and intermolecular C-C bond constructions which are usually directly analogous to the stoichiometric reactions. This topic was reviewed in 1983.[26] Catalytic processes often lead to reduction rather than alkene regeneration; this is more likely to happen with B_{12} as a catalyst than it is with a cobaloxime. Scheffold pioneered the use of vitamin B_{12} as a catalyst for C-C bond formation,[27] and Tada pioneered the use of model complexes such as cobaloximes.[28] Several of the reactions described in the section on stoichiometric reactions have also been performed catalytically, as mentioned in that section. Commonly used chemical reductants include ***Sodium Borohydride*** and ***Zinc*** metal. Electrochemical reduction has also been used.[29] A novel catalytic system with a Ru^{II} trisbipyridine unit covalently tethered to a B_{12} derivative has been used for photochemically driven catalytic reactions using triethanolamine

as the reductant.[30] A catalytic system using DODOH complexes can lead to reduction products or alkene regeneration depending upon the reaction conditions.[31] These catalytic B_{12} and model complex systems all utilize a Co^{I}-Co^{II}-Co^{III} redox shuttle, shown in eq 8. Several other publications have described catalytic systems such as these,[32] including B_{12}-catalyzed alkene acylations via addition of acyl radicals to activated alkenes[33] and the use of hydrophobic B_{12} derivatives which are designed to provide a binding pocket for enzyme-like catalytic reactions, usually skeletal rearrangement reactions designed to mimic reactions catalyzed by B_{12}-containing enzymes.[34] A catalytic system utilizing a Co^{II}-Co^{III} redox shuttle has been described.[35] A catalytic system for alkene oligomerization has been developed.[36] Cobalt complexes are known to catalyze radical alkene polymerization.[37]

Examples of the use of vitamin B_{12} as a catalyst for enantioselective processes have been reported. The rearrangement of aziridines can proceed catalytically with ee's of up to 95% (eq 9).[38] Analogous rearrangements on achiral epoxides (typically 60% ee)[39] and achiral peroxides (low ee's)[40] have been reported.

Xenon(II) Fluoride[1]

[13709-36-9] · F_2Xe · Xenon(II) Fluoride · (MW 169.29)

(relatively mild fluorine source, capable of electrophilic fluorination of carbon-hydrogen bonds; radical fluorinating agent; fluorodecarboxylation of carboxylic acids)

Physical Data: 129 °C (triple point); *d* 4.32 g cm^{-3}.

Solubility: sol H_2O (25 g/L at 0 °C), with slow decomposition; sol CCl_4, CH_2Cl_2, HF, BrF_3, MeCN.

Form Supplied in: white solid; commercially available.

Preparative Methods: prepared from xenon and fluorine.[2]

Handling, Storage, and Precautions: strong oxidizing agent; hydrolyzes in humid air. Like all other potential sources of elemental fluorine with the ability to fluorinate any substrate, it must be treated with great respect and caution, and should only be used with the proper equipment and precautions for handling reactive fluorinating agents. Contamination by XeF_4 will generate explosive XeO_3 upon hydrolysis.

Fluorodecarboxylation.

Xenon difluoride has the unique ability to convert aliphatic carboxylic acids to fluoroalkanes (fluorodecarboxylation) without fluorinating other portions of the molecule (eq 1).[3-5] This reaction is the fluorine analog of the Hunsdiecker and Kochi reactions. The substrates may contain aryl, aryloxy, and ketonic groups (Table 1).[3] Compounds containing hydroxy groups give complex mixtures. Secondary acids like cyclohexanecarboxylic acid, as well as amino acids, cholic acid, cinnamic acid, *trans*-phenylcyclopropanecarboxylic acid, and benzoic acid resist decarboxylation. Optically active α-trifluoromethyl-α-methoxyphenylacetic acid is fluorodecarboxylated to racemic α-fluoro-α-trifluoromethyl-α-methoxytoluene (**1**).[4] When this reaction is carried out in the presence of $Bu_4N^+\ {}^{18}F^-$, the $^{18}F^-$ is incorporated into (**1**) in 65% radiochemical yield.[4,5] A limitation is illustrated by the reaction of CF_3CO_2H and excess XeF_2 in benzene to give (trifluoromethyl)benzene.[5] A general procedure for fluorodecarboxylation is to combine equimolar amounts of the acid and XeF_2 in CH_2Cl_2 in a polyethylene bottle, slowly bubble HF into the solution, and store overnight at rt. The next day the solution is washed with dilute $NaHCO_3$ and purified. Although ***Bromine Trifluoride*** also promotes fluorodecarboxylation,[6]

o-Xylylene *N,N*-Diethylphosphoramidite

(**1**; R = Et)

[82372-35-8] · $C_{12}H_{18}NO_2P$ · *o*-Xylylene *N,N*-Diethylphosphoramidite · (MW 239.28) (**2**; R = Me)

[69813-53-2] · $C_{10}H_{14}NO_2P$ · *o*-Xylylene *N,N*-Dimethylphosphoramidite · (MW 211.22)

(phosphitylating reagents for alcohols to provide phosphoric monoesters and mixed diesters)

Physical Data: (**1**) bp 95-96 °C/0.1 mmHg; n_D 1.543. (**2**) bp 78-80 °C/0.03 mmHg; n_D 1.555.

Solubility: insol cold H_2O; sol CH_2Cl_2, THF, MeCN.

Form Supplied in: (**1**): crystalline solid; commercially available.

Analysis of Reagent Purity: δ_P (C_6H_6) +143 (**1**), +142 (**2**).

Preparative Methods: a mixture of hexaethyl- or ***Hexamethylphosphorous Triamide*** and ***1,2-Bis(hydroxymethyl)benzene*** is heated until evolution of amine ceases.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: these reagents can be stored for extended periods (>6 months) in the absence of moisture and air. The stability of (**1**) is greater than that of (**2**).

Phosphoric Monoester Synthesis.[1]

The phosphoramidites react smoothly with a variety of sterically hindered alcohols and polyols in the presence of 1*H*-tetrazole to afford the phosphorous triesters, which are oxidized in situ with ***m-Chloroperbenzoic Acid*** to give cyclic phosphoric triesters in high yields (eqs 1-3).[2-4] The triesters are deprotected by hydrogenolysis on ***Palladium on Carbon*** to furnish phosphoric monoesters.

(1)

The reagents are potent alternatives to dibenzyl phosphoramidites. The former reagents can be prepared in one step and are easily purified by distillation, while the acyclic amidites require two steps. See ***Dibenzyl N,N-Diethylphosphoramidite*** and ***Dibenzyl Phosphorochloridate***; dibenzyl phosphorofluoridate and tetrabenzyl pyrophosphate are used for the same purpose.

Phosphoric Diester Synthesis.[5]

o-Xylylene *N*,*N*-diethylphosphoramidite can be used for sequential phosphorylation of two different alcohols to afford the corresponding triester (eq 4), which is converted to the phosphoric mixed diester by deprotection employing hydrogenolysis or disodium disulfide.

Ytterbium(0)

Yb

[7440-64-4] · Yb · Ytterbium(0) · (MW 173.04)

(reducing agent capable of Birch-type reductions of aromatic and alkenic systems;[1-3] promotes the coupling of aldehydes and ketones to generate the corresponding pinacolic product; forms an organoytterbium complex with aromatic substrates which adds nucleophilically to ketones, epoxides, nitriles, and carbon dioxide to generate highly functionalized products[5-7])

Physical Data: mp 824 °C; bp 1427 °C; *d* 6.760 g cm^{-3}; face centered cubic structure at rt.

Form Supplied in: silvery, ductile metal; commercially available as 40 mesh powder, ingot, chip, foil.

Handling, Storage, and Precautions: is somewhat air and moisture sensitive and should be handled under an inert atmosphere.

Dissolving Metal Reductions.

Ytterbium turnings are added piecewise to dry liquid ***Ammonia***, resulting in a deep-blue solution containing the ammoniated electron. Cosolvents such as ether, THF, or *t*-butanol can be added. The blue Yb-NH_3 solution is stable for several hours at -33 °C. Quenching of the solution with water results in replacement of the deep-blue color by a transient green color, characteristic of Yb^{2+}, which changes to a brown suspension with formation of Yb^{3+} species.

Solutions of ytterbium in ammonia[8] have properties similar to those of alkali metal-ammonia solutions[9] and are strongly reducing. This is a consequence of the fact that Yb^0 ($4f^{14}6s^2$), like other lanthanides, is electropositive and dissolves readily in ammonia,[10] an excellent supporting medium for electron transfer.[11] Dissolution of ytterbium in ammonia yields two electron equivalents (eq 1) and results in Yb^{2+} which possesses the closed f shell of xenon. However, Yb^{2+} is readily oxidized in air to Yb^{3+} ($E_{Yb^0 - Yb^{3+}}$ = -2.27 V). The ionic radius of Yb^{2+} is intermediate between that of Li^+ and Na^+. Physical characteristics of ytterbium-ammonia solutions have been described.[12]

$$Yb^0 + nNH_3 \longrightarrow Yb^{2+} + 2\,e^-(NH_3)_n \qquad (1)$$

Solutions of Yb-NH_3 reduce benzenoid[13] and other aromatic rings to 1,4-dihydro aromatics and, as in the reduction with alkali metal-ammonia systems,[14] substituents exert a profound effect on the rate of the reaction and on the structure of the product. Thus benzoic acid is reduced rapidly to the 1,4-dihydro derivative (eq 2), while anisole and *p*-cresyl methyl ether are reduced more slowly to 1-methoxy-1,4-cyclohexadienes (eq 3).

(2)

(3)

Application of this reduction to a derivative of estrone resulted, after hydrolysis of the intermediate enol ether, in dihydrotestosterone (eq 4).[15] In this case, no proton donor was added to the medium.

(4)

Conjugated dienes are cleanly reduced in a 1,4-manner by Yb-NH_3. An application of this reduction in a synthesis of (±)-dehalogenonidifocene resulted in a 9:1 mixture favoring the 1,4-reduction product (eq 5).[16] By contrast, Li-NH_3 gave a 1:1 mixture of 1,4- and 1,2-reduction products and Ca-NH_3 gave a 2:1 ratio of these materials. The greater selectivity of Yb-NH_3 is attributed to the weaker basicity of $Yb(NH_2)_2$ and to the consequent diminished propensity for alkene isomerization of the product.

(5)

Conjugated enones are reduced with Yb-NH_3 and, in the presence of a proton source, afford the saturated ketone together with variable quantities of the alcohol resulting from further reduction (eq 6). If a proton donor is absent, a high yield of pinacol dimer is obtained, as exemplified with cholest-4-en-3-one (eq 6).[17] Pinacol coupling of aromatic ketones has been accomplished with a slurry of Yb power in THF-HMPA which, under appropriate conditions, can also lead to a high yield of cross coupled product.[4] The same reagent effects pinacol-like coupling of diaryl ketones with nitriles to give α-hydroxy ketones, and with epoxides to give 1,3-diols.[6] However, with unsymmetrical epoxides the regioselectivity can be low.[7] It is not clear that this heterogeneous form of the Yb reagent offers significant advantage over the homogeneous Yb-NH_3 system, especially since the metal must be activated (with MeI) before reduction.

(6)

Solutions of Yb-NH_3 reduce alkynes to a *trans*-alkene (eq 7). In certain cases, strained alkenes can be reduced[18] as, for example, in the conversion of norbornadiene to bicyclo[2.2.1]heptene (eq 8).

(7)

(8)

Pinacolic Coupling Reactions.

Ytterbium metal effects the coupling of pinacols (eq 9). Although pinacolic cross-coupling is difficult to achieve, ytterbium metal with diaryl ketones promotes the effective coupling of aldehydes and ketones to afford vicinal diols in good yields (eqs 10 and 11).[4-6] The utility of this protocol is limited, however, in that one of the pinacolic coupling partners must contain aromatic functionality.

(9)

$R^1, R^2 = Ph$ 97%
$R^1 = Ph, R^2 = Me$ 73%

(10)

(11)

Nucleophilic Addition of Organoytterbium Complexes to Other Electrophiles.

Treatment of diaryl ketones with 1-2 equiv of Yb metal promotes the nucleophilic addition to ketones, epoxides, nitriles, and carbon dioxide to form the corresponding crossed pinacol, 1,3-diol, α-hydroxy ketone, and α-hydroxy carboxylic acid, respectively (eqs 12 and 13).[5-7]

(12)

(13)

Reduction of Ketimines.

Ytterbium also provides a method for the reduction of imines (eq 14); however, considerable amounts of coupling products are observed when there are not two aromatic substituents on the substrate.[19]

(14)

$R^1 = R^2 = Ph$	92%
$R^1 = Ph, R^2 = H$	93%

Ketimines are reduced with ytterbium metal and may subsequently be treated with carbon dioxide to generate the ytterbium salt of the α-amino acid, which is converted to the α-amino acid by acidic workup (eq 15).[20] This method too is limited to aromatic functionality on the ketimine substrate.

Ytterbium(II) Chloride[1]

$YbCl_2$

[13874-77-6] · Cl_2Yb · Ytterbium(II) Chloride · (MW 243.94)

(reductive dimerization of unsaturated ketones;[2] hydroperfluoroalkylation of alkenes[3])

Physical Data: mp 720 °C; bp 1930 °C; *d* 5.08 g cm^{-3}; green rhombohedral crystals.

Solubility: sol THF; readily oxidized in H_2O.

Preparative Methods: can be obtained by reduction of the trichloride with various reagents (e.g. Na). In recent papers the trichloride is reduced in situ by ***Zinc***.

Handling, Storage, and Precautions: unstable in water and humid air; oral toxicity of ytterbium trichloride: LD_{50} 6.7 g kg^{-1} in rats.

Cyclodimerization of α,β-Unsaturated Ketones.

Ytterbium dichloride is probably the reactive species formed by reduction of the trichloride with zinc, although it was not characterized as such. This reagent was shown to be more efficient than ***Ytterbium(0)*** metal in promoting the reductive cyclodimerization of α,β-alkenic ketones to cyclopentanols.[2] Thus far, this reaction has only been observed with chalcone (eq 1).

The mechanism postulated involves a single-electron transfer to the conjugated system, followed by addition of the resulting enolate radical to the starting material. The reaction exhibits significant diastereoselectivity. The radical (or the enolate derived from its further reduction) can be trapped by an aldehyde to produce the acyl or hydroxyalkyl compound (eq 2).[4] Starting from 2-propyn-1-ones, a similar process takes place, but the results are more complex. Dimerization occurs following a slightly different mechanism, with a third molecule being trapped to give an hemiacetal (eq 3). In other instances, dimerization predominates to afford either a linear (eq 4) or a cyclobutene product (eq 5).[5]

(2)

Y = COPh + CH(OH)Ph

(3)

(4)

(5)

Hydroperfluoroalkylation of Alkenes.

Addition of a perfluoroalkyl group to several alkenes is easily effected using in situ-generated ytterbium dichloride. Alkenes containing ester (eq 6), ether, alcohol, and phosphonate (eq 7) groups participate in excellent yield via a rapid (5-10 min) and smooth (50-75 °C) reaction.[3]

Ytterbium(II) Iodide

[19357-86-9] · I_2Yb · Ytterbium(II) Iodide · (MW 426.84)

(promotes the reduction of conjugated alkenes, leaving isolated alkenes unaffected;[1a,2] effects the reductive cyclization of halo ketones with good diastereoselectivities[3])

Physical Data: light yellow powder; mp 780 °C; bp 1300 °C; structure determined by X-ray diffraction.

Solubility: sol dilute acid, H_2O.

Preparative Methods: typically prepared in situ via oxidation of ***Ytterbium(0)*** metal with various organic dihalides such as ***1,1-Diiodoethane*** or ***Diiodomethane***;[1a] may also be prepared from reaction of ytterbium metal with excess HgI_2 or from the reaction of excess ytterbium metal with NH_4I and NH_3.[1b -d]

Handling, Storage, and Precautions: should be kept in an inert atmosphere; subject to hydrate formation.[1]

Reduction of Conjugated Alkenes.

Ytterbium diiodide effects the reduction of conjugated alkenes while isolated double bonds remain unchanged under the same reaction conditions.[1a] Cinnamic acid and ethyl cinnamate are cleanly reduced to the saturated carboxylic acid or ester when subjected to YbI_2 in THF/MeOH (eqs 1 and 2).[2] The analogous conjugated ketone and aldehyde, however, suffer competition between C=C and C=O reduction. Isolated ketones appear to be inert under similar reaction conditions.

Reductive Cyclization of Halo Ketones.

Ytterbium(II) iodide has been utilized in the synthesis of five-, six-, and seven-membered rings in good yield from 2-(o-iodoalkyl)cycloalkanones (eqs 3 and 4).[3] In these examples, the ytterbium(II) iodide complex was found to give somewhat higher diastereoselectivities than ***Samarium(II) Iodide***.

Ytterbium(III) Trifluoromethanesulfonate

$Yb(OSO_2CF_3)_3$

[54761-04-5] · $C_3F_9O_9S_3Yb$ · Ytterbium(III) Trifluoromethanesulfonate · (MW 620.28)

(organometallics derived from addition of organolithiums or organomagnesiums to $Yb(OTf)_3$ display enhanced diastereoselectivities in the carbonyl addition to chiral ketones and aldehydes;[2] functions as a Lewis acid in promoting aldol reactions and hydroxymethylation reactions[4])

Alternate Name: ytterbium(III) triflate.

Preparative Methods: prepared by addition of an excess of ytterbium(III) oxide (commercially available, 99.9%) to an aqueous solution of ***Trifluoromethanesulfonic Acid*** (50% v/v) followed by heating at boiling for 0.5-1 h. The mixture is then purified by filtration to remove unreacted ytterbium oxide; residual water is removed under reduced pressure. The resultant hydrate is dried by heating under vacuum (1 mmHg) at 180 to 200 °C for 48 h. The reagent is then used without further purification.[1] The organoytterbium reagent is prepared at -78 °C from $Yb(OTf)_3$ and organolithiums or organomagnesiums.[2]

Handling, Storage, and Precautions: subject to hydrate formation in aqueous media in the presence of amines;[1] however, it survives mild aqueous workup.[4]

Addition to Ketones and Aldehydes.

Organoytterbium triflates display enhanced diastereoselectivity in carbonyl addition to chiral aldehydes and ketones. Because of the imposing steric bulk, organolanthanide reagents are suitable for achieving high diastereofacial selectivity in the addition to chiral aldehydes and ketones. Treatment of 2-methylcyclohexanone with the methylytterbium reagent produces a mixture of diastereomers in a 98:2 ratio, resulting from preferential equatorial attack of the bulky organolanthanide reagent (eq 1).[2]

(1)

Another attractive feature of the ytterbium triflate derived organometallic reagent is the diverse organoytterbiums which may be utilized in the process. Unlike other organometallic reagents possessing similar reactivity, the organoytterbium reagent is not limited to a narrow range of organic ligands which may be incorporated onto the metal center (eq 2). Specifically, high yields and diastereoselectivities may be achieved with both alkyl- and alkenylytterbium reagents. This is in contrast to organotitanium reagents, which may provide incomplete conversion and/or low diastereofacial selectivities in additions to carbonyl substrates.[3] Additionally, tertiary organometallics can be generated and utilized without interference from β-hydride elimination processes, although enolization of the substrates does lower the yield significantly.

(2)

R	Yield (%)	de (%)
Bu	91	98
Ph	73	>98
trans-1-hexenyl	75	93
cis-1-hexenyl	78	95
vinyl	89	95
t-Bu	53	99

Organoytterbium triflates also show enhanced diastereofacial selectivity upon addition to acyclic chiral aldehydes (eq 3).

(3)

Aldol Reactions.

$Yb(OTf)_3$ serves as catalyst in promoting the aldol-type reaction between silyl enol ethers and acetals or aldehydes (eqs 4 and 5).[4]

(4)

(5)

Unlike other Lewis acid catalysts capable of performing similar transformations, water does not interfere with the aldol reaction when ytterbium triflate is employed; hence, troublesome purification and dehydration steps are unnecessary when performing aldol reactions on water-soluble aldehydes. Furthermore, molecules with free hydroxyl and nitrogen functionalities are compatible with the ytterbium triflate promoted aldol reaction because these functionalities do not coordinate to ytterbium triflate. The Lewis acid thus remains active in the presence of such functional groups in contrast to other Lewis acid catalysts. Another important feature which makes ytterbium triflate attractive in these transformations is that the catalyst may be recovered from the aqueous layer after workup because $Yb(OTf)_3$ is not hydrolyzed in the presence of water.

Zinc[1]

Zn

[7440-66-6] · Zn · Zinc · (MW 65.39)

(reducing agent;[2] used for preparation of organozinc reagents,[1,3] Reformatsky reagents,[4] and the Simmons-Smith reagent (cyclopropanation)[5])

Physical Data: mp 419 °C; bp 907 °C; *d* 7.14 g cm^{-3}.

Solubility: insol organic solvents; reacts with aqueous acidic solutions.

Form Supplied in: dust, foil, granular, wire, mossy, rod; widely available at low cost.

Handling, Storage, and Precautions: slowly oxidizes in air; no toxic properties are associated with zinc and zinc organometallics; in several cases the metal requires an activation procedure before use.[6]

Reduction of Carbon-Carbon Multiple Bonds.

Whereas isolated double bonds are rarely reduced by zinc, triple bonds are cleanly converted to alkenes using either ***Zinc/Copper Couple*** or ***Zinc Amalgam***.[7] A regio- as well as stereospecific reduction of a wide range of alkynic derivatives can be performed using zinc powder (eq 1).[8] The reduction of propargylic alcohols proves to be especially efficient (eq 2).[9] Also, the selective *cis* reduction of conjugated dienynes and trienynes proceeds well with Zn(Cu/Ag).[10] The presence of a leaving group at the propargylic position leads to the formation of allenes.[11] The conjugation of a double bond with an electron-withdrawing substituent considerably facilitates the reduction of the double bond.[12] The reduction of α,β-unsaturated ketones produces the corresponding saturated ketones.[13] Nickel catalysis allows the reduction of unsaturated aldehydes, ketones, and esters in an aqueous medium under ultrasonic irradiation (eq 3).[14]

(1)

(2)

(3)

Reduction of Carbonyl Groups.

Zinc reduces ketones to either alcohols or to a methylene unit, depending on the reaction conditions and the nature of the substrate. For example, conjugation is required if reduction to a hydroxy group is desired. The reduction of aryl ketones provides benzylic alcohols (eq 4)[15] and α-diketones can be converted selectively to α-hydroxy ketones (eq 5).[16] The reduction of the carbonyl group of nonconjugated ketones to a methylene unit with zinc and hydrochloric acid in organic solvents such as ether, acetic anhydride, or benzene-ethanol proceeds in satisfactory yields with a wide range of ketones (Clemmensen reaction) (eqs 6-8).[17] The Clemmensen reduction of aromatic α-hydroxy ketones gives conjugated alkenes.[18] Finally, the Clemmensen reduction can also be performed by using zinc and ***Chlorotrimethylsilane*** in an aprotic medium, leading to alkenes (eq 9).[19] This variation has been exploited for the preparation of alkenes (eq 10)[19b] and has been used in new cyclization reactions (eqs 11 and 12).[20] Trimethylsilyl ethers can be regioselectively prepared by the zinc reduction of α-chloro ketones in the presence of TMSCl.[21] Mixed pinacol products have been prepared by using Zn(Cu) as the reducing agent (eq 13).[22]

(11)

(12)

(13)

Reduction of Carbon-Oxygen Bonds.

Carbon-oxygen bonds situated α to an unsaturation are easily reduced with zinc in an acidic medium. In the case of α-hydroxy ketones, ketones are obtained in good yields (eq 14).[23] A wide range of allylic or benzylic ethers, acetates, and alcohols are reduced with zinc (eq 15).[24,25] The reduction of epoxides can lead to either alcohols (eq 16)[26] or alkenes.[26b-e] In the presence of catalytic amounts of Pd^0 and zinc dust, allylic acetates are coupled to give 1,5-dienes (eq 17).[27] Under similar reaction conditions and in the presence of an aldehyde, homoallylic alcohols are obtained in satisfactory yields (eq 18).[27b-d]

(14)

(15)

(16)

(17)

(18)

Reduction of Carbon-Halide Bonds.

Alkyl and alkenyl halides are readily reduced with zinc under various reaction conditions. The reduction produces, as an intermediate, an organic radical which can undergo carbon-carbon bond formation (Barbier reaction)[28] or can be further reduced, usually under acidic conditions. Aliphatic iodides or bromides and benzylic chlorides react readily with ***Zinc-Acetic Acid***, providing the corresponding hydrocarbon.[29] Although aromatic halides are reduced less easily, the tribromothiophene (**1**) is reduced selectively to the bromide (**2**) (eq 19).[29e,g] Various β-chloro enones are cleanly reduced to enones with ***Zinc/Silver Couple*** in methanol at rt (eq 20).[29f] α-Dihalo ketones are reduced smoothly, allowing the preparation of a variety of ketones (eqs 21 and 22).[30] The reductive couplings of α-bromo ketones, tropylium, and 1,3-dithiolylium cations have been observed.[31] In the case of 1,3-dihalides, cyclopropanes are obtained in good yields.[32] If the reduction of the carbon-halide bond is performed in the presence of an electrophile, a radical addition often occurs. Thus phenacyl halides can be coupled with methylenecyclohexanes (eq 23).[33a] Performing the reaction in the presence of an unsaturated ketone provides the 1,4-adducts. Interestingly, the reduction proceeds well in an aqueous medium supporting a radical mechanism, since zinc organometallics react instantaneously with water but only very sluggishly with enones (eq 24).[33b-h] The addition of ***Chloromethyl Methyl Ether*** to 1,2-bis-silyl enol ethers in the presence of zinc leads to ring-enlarged 1,3-cycloalkanediones after acidic treatment.[34] An interesting three-component reaction has been described (eq 25).[34b] A wide range of allylic halides undergo Barbier-type addition to carbonyl groups (eqs 26 and 27).[35,36] The reduction of α,α´-dihalo ketones with a zinc-copper couple in the presence of a diene such as ***Isoprene*** provides cycloaddition products via a zinc oxyallyl cation.[37]

(26)

(27)

Reduction of Carbon-Nitrogen and Carbon-Sulfur Bonds.

Aldimines and oximes are converted to amines, and various heterocycles bearing carbon-nitrogen double bonds are reduced with zinc under acidic conditions.[38] Cyanamides can be cleanly cleaved leading to amines,[39a] and the zinc reduction of acylnitriles provides α-amino ketone derivatives (eq 28).[39b] Aromatic amides can be reduced with zinc dust to aromatic aldehydes.[39c] Activated carbon-sulfur bonds α to a carbonyl group[40a,b] and sulfur ylides[40c,d] can be reduced with zinc.

(28)

Reduction at Heteroatoms.[2]

Nitrogen-oxygen bonds of oximes,[41] nitro,[42] and nitroso[43] groups are readily reduced by zinc in acidic medium. Zinc in acetic acid has often been used for the workup procedure of alkene ozonolysis to afford aldehydes or ketones.[2] Sulfinates and thiols can be obtained selectively by the reduction of aromatic sulfonyl chlorides or disulfides.[44]

Dehalogenation and Related Reactions.[6c,45]

Zinc dust is a very efficient reducing agent for the dehalogenation of 1,2-dihalides or 1-halo-2-alkoxy derivatives, leading to alkenes. The reaction allows an access to highly reactive ketenes,[46] alkenes,[47] or alkynes[48] not readily available by standard methods (eqs 29-31). The reduction of β-alkoxy halides using ***Zinc-Graphite*** proved to be especially interesting when applied to sugar derivatives (eq 32).[6c,45e,49] The dehalogenation using zinc is such a straightforward and chemoselective reaction that several protecting groups have been devised which use this reaction as a deblocking step.[50]

(29)

(30)

(31)

(32)

The Reformatsky Reaction.[4]

The insertion of zinc into α-halo esters produces zinc ester enolates which react readily with aldehydes or ketones, leading to aldol products. Historically, this reaction has been important since it allowed the first quantitative generation of an ester enolate. However, several modern synthetic methods for the stereoselective preparation of aldol products using metal enolates compete favorably with the Reformatsky reaction.[51] The nature of the zinc activation[6] has proved to be important for fast and quantitative zinc insertion. Remarkably, the Zn(Ag) couple on graphite reacts with ethyl bromoacetate at -78 °C within 20 min,[52a] whereas Rieke zinc requires 1 h at 25 °C,[52b] as does zinc generated from the reaction of ***Zinc Chloride*** with ***Lithium*** under ultrasound irradiation[52c] (eq 33).[52a] Interesting synthetic applications have been reported (eqs 34 and 35).[4,52] 4-Bromocrotonate reacts with ketones and Zn(Cu) with solvent-dependent regioselectivity.[52f] See also ***Ethyl Bromozincacetate***.

(33)

(34)

(35)

The Simmons-Smith Reaction.[5,53]

Cut Zn foil readily inserts into ***Diiodomethane*** providing iodomethylzinc iodide,[53] which cyclopropanates a wide range of alkenes in good yields (see ***Ethylzinc Iodide***, ***Iodomethylzinc Iodide***, ***Diethylzinc***, ***Ethyliodomethylzinc***). The in situ generation of iodomethylzinc iodide is often used. The Zn(Ag) couple has proved to be especially active for cyclopropanations (eq 36).[53d]

(36)

Preparation of Organozinc Reagents.[1,3a]

The insertion of zinc into organic halides provides the most general synthesis of organozinc halides. Primary and secondary organic iodides react with zinc dust (2-3 equiv) in THF between 20 °C and 50 °C, leading to organozinc iodides in high yields.[3a,54a-c] Benzylic chlorides and bromides react under even milder conditions, providing the corresponding benzylic zinc halides without the formation of significant amounts of Wurtz coupling products.[54d -f] Two remarkable properties characterize organozinc reagents: (i) their high functional group compatibility, which allows the preparation of polyfunctional organometallic zinc species bearing almost all common functional groups with the exception of nitro, azido, or hydroxy functions (see the reagents **3**,[54b] **4**,[54g,h] **5**,[54i] **6**,[54j] **7**,[54k-o] **8**,[54p] **9**,[54n,o] **10, 11**,[54q] and **12-14**,[54f] and eq 37); and (ii) their ability to undergo transmetallation with other metallic salts, such as copper salts, thus giving polyfunctional copper reagents which react readily with a wide range of electrophiles (enones,[54b,r] aldehydes,[54s] alkynes,[54t-v] nitro alkenes,[54w-y] allylic halides,[54b,z] alkynyl halides,[54g] acid chlorides,[54b,aa] and alkylidenemalonates[54ab]). Similarly, efficient transmetalations with Pd^{II} salts allow the coupling reactions to be performed (eq 38).[55,56] Zinc insertion also proceeds well with various polyfluorinated alkyl iodides[57] and with primary alkyl and benzyl phosphates and mesylates.[58] Alkenyl and aromatic halides undergo the zinc insertion far less readily and require the use of polar solvents[59] or highly activated zinc.[60] The use of a sacrificial zinc electrode offers an interesting alternative.[61] Allylic zinc halides are formed under very mild conditions and, contrary to other classes of organozinc reagents, display a high reactivity toward organic electrophiles (comparable to organomagnesium species).[36e-h,54a,62] A wide range of synthetic applications of zinc reagents for the formation of carbon-carbon bonds has been reported (eqs 39-44).[56,60a,63-66] Diorganomercurials also react with zinc dust, providing diorganozincs.[67,68]

Zinc-Acetic Acid[1]

Zn-AcOH

(Zn)

[7440-66-6] · Zn · Zinc-Acetic Acid · (MW 65.39) (AcOH)

[64-19-7] · $C_2H_4O_2$ · Zinc-Acetic Acid · (MW 60.06)

(reducing agent; causes reductive elimination of vicinal heteroatoms;[2-15] cleaves heteroatom-heteroatom bonds;[16-27] reduces allylic, benzylic, or α-carbonyl-substituted heteroatoms,[28-34] activated carbonyls,[35-37] and alkenes[38-40])

Physical Data: see entries for ***Zinc*** and ***Acetic Acid***.

Form Supplied in: although zinc is available in a variety of forms, the overwhelming majority of zinc-acetic acid reductions use zinc powder.

Purification: acid washing is not uncommon, but not always vital.

Introduction.

Zinc in acetic acid is capable of a wide range of reduction reactions. Although many of these can also be performed by a great number of other reagents, this reagent is of particular value in that good chemoselectivities can often be achieved. Some such instances are noted in the text and equations below; many of the references have also been chosen to demonstrate selective reduction in sensitive, polyfunctional molecules.

Reductive Elimination of Vicinal Heteroatoms.[2-15]

A great variety of combinations of heteroatom substituents has been successfully reductively eliminated by Zn/AcOH (eq 1 and Table 1). Cosolvents such as ether, THF, CH_2Cl_2, *i*-PrOH, or water have all been used. Reaction temperatures vary from case to case, but yields reported are typically good to excellent.

(1)

Table 1 Reductive Eliminations of Vicinal Heterosubstituents (eq 1)

X	Y	Yield (%)
Cl	OR	see next section
Cl	Cl	96[2]
Cl	SO_2R	87[3]
Cl	NO_2	79[4]
Br	OR	88[5]
Br	Br	94[6]
OR	OR	92[7]

A set of protecting groups, based upon Zn/AcOH elimination of the 2,2,2-trichloroethoxy group, has been developed, and is discussed below as a special case. Table 1 records several of the combinations of heteroatoms successfully eliminated under these conditions. Perhaps surprisingly, the relative stereochemistry of the two carbon centers does not have to permit *trans* coplanarity of the heteroatoms.[4,7]

Heterocyclic rings may be cleaved by these reactions. Thus, effective reversal of iodolactonization (eq 2)[8] or of epoxidation (after iodide ring opening) (eq 3)[9] may be achieved.

(2)

(3)

Halogenated oximes (**1**) eliminate to give the nitrile in variable, but often good to excellent, yields (eq 4).[10]

(1)

(4)

2,2,2-Trichloroethoxy-Based Protecting Groups.[11-15]

Valuable protecting groups for alcohols,[11] phenols,[11c] amines,[11c] and carboxylic acids,[12] and an introduction/protection reagent for thiols,[13] all dependent upon the lability of this group to Zn/AcOH reductive elimination, have been developed. They are summarized in Table 2.

Table 2 Protecting Groups Based on OCH_2CCl_3 Elimination

Functionality	Protected form
ROH[11a]	$ROCH_2CCl_3$
ROH[11b]	$ROCH_2OCH_2CCl_3$
ROH[11c,d]	$ROC(O)OCH_2CCl_3$
ROH[11e]	$ROC(O)OCMe_2CCl_3$
ArOH[11c]	$ArOC(O)OCH_2CCl_3$
R_2NH[11c]	$R_2NC(O)OCH_2CCl_3$
RCO_2H[12]	$RC(O)OCH_2CCl_3$
RSH[13]	$RSC(O)OCH_2CCl_3$

The trichloroacetylidene acetal has also been proposed as a potential protection for diols, similarly deprotectable.[14] Also, along similar lines, the 2-iodoethyl carbamate protection for amines, deprotectable by Zn dust alone in MeOH, has been proposed,[15] but has found relatively little use.

Heteroatom-Heteroatom Cleavage.[16-27]

N=N double bonds can be cleaved[16] by Zn/AcOH; less frequently, hydrazines[17] may be obtained from the reduction (eqs 5 and 6).[17] Hydrazones may also be reduced to amines,[18] as used[18b] in a variant of the classical Knorr pyrrole synthesis. Diazo ketone (**2**) has been successfully reduced, despite the apparent potential for adverse side reactions (eq 7).[19]

Aromatic nitro groups[20a] (aliphatic nitro groups can yield oximes,[20b] even though not all such would be stable under all reaction conditions), hydroxylamines,[21] oximes[22] (once again, finding use[22b] in a Knorr pyrrole synthesis), *N*-nitro-[23a] and *N*-nitrosoamines,[23b] aromatic *N*-oxides,[24] and aromatic N-S bonds[25] have all been reduced to amines with Zn/AcOH. These references include ample evidence of the ability of this reagent to perform the desired reaction, while leaving intact, for example, bromides,[22] carbon-bonded sulfur atoms,[20,23b] and isolated C=C double bonds.[21] It will, of course, be understood that the newly liberated amines often undergo spontaneous intramolecular reactions.

Sulfonamides[26] can also be reduced to the thiols.

Zn/AcOH can act as a useful alternative reagent for reductive workup of ozonolysis reactions,[27] which can be considered, at least formally, to involve O-O bond cleavage (see ***Ozone***).

Curiously, the vigor of the conditions reported to have been employed for these disparate reactions does not seem to follow any consistent pattern; reaction conditions, therefore, may need individual determination in many cases.

Carbon-Heteroatom Cleavage.[28-34]

Substitution of N,[28] O,[29] S,[30] or halogen,[31] for example, at an allylic, benzylic, or α-carbonyl-substituted carbon atom renders the heteroatom liable to cleavage with Zn/AcOH. In allylic systems, double bond migration usually occurs. If conjugated to a carbonyl group, migration still occurs, giving the β,γ-product (eq 8),[32a] but these can be easily reconjugated (eq 9).[32b] Homoallylic reduction[33] has also been reported in a constrained system (eq 10).

(8)

(9)

(10)

Cleavage α to a carbonyl group has been exploited in the use of phenacyl protecting groups.[34] The reduction of compounds such as (**3**) (for their formation, via ***Dichloroketene*** see ***Trichloroacetyl Chloride***) retains the strained four-membered ring, and often gives excellent yields (eq 11).[31c]

(11)

Carbonyl Reduction.[35-37]

Quinones are reduced to hydroquinones by Zn/AcOH at reflux.[35a] Incorporation of Ac_2O into the reaction mixture gives the respective diacetate.[35a] Under milder conditions (rt), the intermediate γ-hydroxycyclohexenone may be intercepted in surprisingly high yield (72-90%).[35b]

Diaryl ketones may be reduced to the alcohols,[36a] but a competing dimerization has also been reported[36b] in some unusual cases. Reduction of phthalimide (**4**) proceeds well and, notably, with regiospecificity (eq 12).[37]

(12)

Reduction of Activated Alkenes.[38-40]

Carbonyl (mono-[38a] or di-[38b]) substitution renders a C=C double bond liable to reduction by Zn/AcOH. α,β,γ,δ-Dienones may yield either α,β-[38a] or β,γ-enones[38c] in equally high yields. A recent modification,[39] at lower temperature (rt), and with much shorter reaction times, uses ultrasonication; excellent yields were achieved.

α,β-Unsaturated nitro compounds can also be reduced.[40] Under mild conditions an oxime can be obtained (eq 13)[40a] (cf. ***Sodium Borohydride***, which reduces the C=C double bond); more vigorous reaction leads to the corresponding ketone.[40b]

(13)

Aza-Heterocycle Ring Contraction.

A variety of polyaza six-ring heterocycles undergo contraction with formal excision of N, e.g. eq 14.[41a] Further heteroatoms in the ring are tolerated: 1,2,3-triazines yield pyrazoles[41b] and 1,2,4-triazines yield imidazoles,[41c] with the latter usually requiring reflux temperature. The utility of indole syntheses from cinnolines[41d] by this method should be noted. Adjacency of heteroatoms is not required: conversions of pyrimidine to pyrrole[42a,b] and 1,3,5-triazine to imidazole[42c] have been recorded. The mechanism of these conversions is unclear, but ring dihydro derivatives[41a,42b] are thought to be involved.

(14)

Reduction of Aryl Substituents.

Although, as mentioned above, many potentially labile functionalities are stable to Zn/AcOH, aryl iodides may be dehalogenated.[43] Substitution of Cl or Br at the 2-position of heteroaromatics also renders them liable to reduction, often with superb selectivity (eqs 15 and 16).[44]

Zinc Amalgam[1]

Zn/Hg

(Zn)

[7440-66-6] · Zn · Zinc Amalgam · (MW 65.39) (Hg)

[7439-97-6] · Hg · Zinc Amalgam · (MW 200.59)

(reducing agent in the Clemmensen reduction,[1] principally of aryl ketones to alkanes)

Solubility: insol organic solvents.

Preparative Methods: various forms of zinc (zinc turnings, wool, or powder, or mossy or granulated zinc) have been successfully employed, with preliminary activation of the metal by washing with hot HCl reportedly being of advantage. Amalgam formation is then accomplished by treatment of the zinc metal with an aqueous, possibly very slightly acidic, solution of $HgCl_2$. After an appropriate length of time, the aq solution is decanted, replaced by fresh HCl, and the amalgam is used immediately.[1a]

Handling, Storage, and Precautions: as well as the corrosive nature of the (usually conc) HCl often employed, requiring normal chemical precautions, the mercury-containing wastes must be disposed of with due attention.

Clemmensen Reduction.[1]

The reagent as prepared above has been successfully used to reduce a wide variety of substances. If the substrate is not adequately soluble in the aqueous acidic solution, a miscible organic cosolvent may, on occasion, be usefully added. An immiscible solvent such as toluene, however, is commonly employed, but efficient stirring, and extended reaction times at reflux, are often required.

A more modern variant uses Zn/Hg (or Zn alone[1]) with HCl in anhydrous solvents. Reaction can often proceed much more rapidly, even at the lower temperatures sometimes used - a clear advantage if the substrate is not fully stable to acidic conditions. Phenolic acetate esters, for example, are typically cleaved under the classical reaction conditions.[2]

A great number of ketones, and some aldehydes, have been reduced by this method to the corresponding alkanes (eq 1), often in excellent yields.[1] The reaction can tolerate a wide variety of aryl substituents.

(1)

R^1 usually aryl

Polyfunctional substrates, however, may exhibit some differences of reactivity. Thus, for example, α-, but not β- or longer, keto acids[1a] are reduced to α-hydroxy acids. Acyloins (**1**) may be completely reduced,[3] or reduced only to the ketone[4] or alkene (stilbene).[5] $ArCOCCl_3$ is reduced near-quantitatively to $ArCH_2CH_3$[6] (aromatic Cl[7a] or Br[7b] substitutents are usually retained, but dehalogenation may occur rarely as a side reaction[7c]). The α-thioether linkage of (**2**) is retained,[8a] but the S atom of (**3**) is excised[8b] before reduction of the carbonyls.

(1)

(2)

(3)

Some benzophenones may react as expected,[1a] but dimerization to pinacols has also been recorded in certain cases.[9] Rarely, the alcohol may be formed,[10] possibly intramolecularly trapped.[6b] α,β-Unsaturated ketones may reduce normally (but with competing dimerization)[11a] or cyclize[1,11b] (eq 2).[11b] On occasion, diketones may react by intramolecular pinacol coupling,[12] but further reactions are common.[1b]

(2)

Compounds not suitable for reduction under these acidic Clemmensen conditions may still be reduced by the Wolff-Kishner[13a] reduction (or, better, its Huang-Minlon modification[13b]), which, being performed under basic conditions, serves as a complementary procedure.

Other Reductions.

The dithioesters RCS_2Me may be reduced to the thioethers RCH_2SMe,[14] but with unspectacular yields. Nitro groups may also be reduced to amines.[15] Certain benzylic alcohols[16a] or alcohol derivatives (e.g. a lactone[16b]) are cleaved to the alkane. Allylic alcohols[17a] or acetates[17b] are reduced with migration of the double bond. Sulfonyl chlorides may be reduced to the thiol.[18]

Ring Contractions.

3-Oxopiperidine (**4**) undergoes ring contraction[19a,b] under Clemmensen conditions (eq 3). The corresponding (3-oxo)azepine[19c] and their thia analogs[19d] react similarly, although the latter do so in lower yields.

(4)

(3)

3-Arylindoles[20a] and azaindoles[20b] can be formed by reduction of, for example, (**5**) in AcOH (eq 4) (see also ***Zinc-Acetic Acid*** for similar reactions).

(4)

Reformatsky-Type Reactions.

Zn/Hg has been noted to effect this reaction in a few cases, such as the propargyl bromide hydroxymethylation with ***Formaldehyde*** (eq 5)[21] (note: no allene formed), and γ-addition of a crotyl group (from the bromide) to a ketone.[22]

Zinc Borohydride[1]

$Zn(BH_4)_2$

[17611-70-0] · B_2H_8Zn · Zinc Borohydride · (MW 95.09)

(mild reducing agent for carbonyl groups;[1] can be used in the presence of base-sensitive functional groups; stereoselective reducing agent[2])

Solubility: sol ether, DMF, CH_2Cl_2, toluene, THF.

Preparative Method: commercially available anhydrous ***Zinc Chloride*** (ca. 10 g) in a 200 mL flask was fused three or four times under reduced pressure and then anhydrous ether (ca. 100 mL) was added. The mixture was refluxed for 1-2 h under argon and allowed to stand at 23 °C. The supernatant sat. solution of $ZnCl_2$ (0.69 M) in ether (80 mL; 55 mmol) was added to a stirred suspension of ***Sodium Borohydride*** (4 g; 106 mmol) in anhydrous ether (300 mL). The mixture was stirred for 2 d and stored at rt under argon. The supernatant solution was used for reduction.[3]

Handling, Storage, and Precautions: the solutions are sensitive to moisture and must be flushed with N_2 or argon. However, it is preferable to use freshly prepared reagent.

Mild Reducing Agent.

$Zn(BH_4)_2$ is a mild reducing agent and only aldehydes, ketones, and azomethines[4] are reduced to the corresponding alcohols and amines under normal conditions. Moreover, the ether solutions are almost neutral and thus can be used for the chemoselective reduction of aldehydes and ketones in the presence of nitrile,[5] ester,[5,6] γ-lactone,[7] aliphatic nitro,[8] and base-sensitive functional groups (eqs 1 and 2).[5,9] Selective reduction of saturated ketones and conjugated aldehydes over conjugated enones can also be effected with $Zn(BH_4)_2$ in DME (eq 3).[10]

(1)

(2)

(3)

Although $Zn(BH_4)_2$ is usually unreactive towards carboxylic acids and esters, activated esters (eq 4)[11] and thiol esters (eq 5)[12] undergo reduction, giving alcohols. Even carboxylic acids can be reduced to alcohols with this reagent in the presence of ***Trifluoroacetic Anhydride*** (TFAA) (eq 6)[13] and acid chlorides undergo reduction by the addition of ***N,N,N´,N´-Tetramethylethylenediamine*** (eq 7).[14] Acetals are reductively cleaved to ethers when ***Chlorotrimethylsilane*** is added (eq 8).[15]

(4)

(5)

(6)

(7)

(8)

Reduction of aliphatic carboxylic esters takes place under ultrasonic activation to give alcohols.[16] The reducing ability of this system is enhanced by the addition of a catalytic amount of *N*,*N*-dimethylaniline and thus aromatic esters which are unaffected under the normal conditions undergo reduction (eqs 9 and 10).[16]

(9)

(10)

Unsymmetrical epoxides are reductively cleaved to the less substituted alcohols by the use of silica gel-supported $Zn(BH_4)_2$ (eq 11).[17,18] The same reagent is effective for regioselective 1,2-reduction of conjugated ketones and aldehydes to give allylic alcohols (eq 12).[19] $Zn(BH_4)_2$ supported on cross-linked ***Poly(4-vinylpyridine)*** (XP4) reduces aldehydes in the presence of ketones with high chemoselectivity (eqs 13 and 14).[20] This polymer-supported reagent can be stored at rt without appreciable change in its reactivity.

(11)

cis:*trans* = 90:10

(12)

(13)

(14)

Tertiary and benzylic halides are reductively dehalogenated with $Zn(BH_4)_2$ (eq 15).[21] This process has been applied for the selective reduction of the distant double bond(s) in geranyl farnesyl and geranyl geranyl derivatives.[22]

(15)

Stereoselective Reductions.

syn-α-Methyl-β-hydroxy esters or their equivalents which repeatedly appear in the framework of polyoxomacrolide antibiotics are synthesized stereoselectively by the reduction of the corresponding α-methyl-β-keto esters[23,24] or α-methyl-β-hydroxy ketones[25] with $Zn(BH_4)_2$ in ether. Excellent selectivities are obtained when the carbonyl group is conjugated with phenyl or vinyl groups (eq 16)[23-25] or the esters in α-methyl-β-keto esters are replaced by the amides (eq 17).[26] Ketones having a phosphine oxide group in place of esters or amides produce *syn* products by the $Zn(BH_4)_2$ reduction, while reduction with ***Lithium Triethylborohydride*** gives the *anti* isomer stereoselectively (eq 18).[27] The *syn*-directing reduction is presumed to proceed through a metal-mediated cyclic transition state and thus the use of a complex hydride like $Zn(BH_4)_2$, whose metal possesses a high coordinating ability, is advantageous for producing excellent selectivity.

(16)

syn:*anti* = >99:1

(17)

syn:*anti* = 98:2

(18)

syn:*anti* = 98:<2

Acylation of chiral *N*-propionyloxazolidinones gives chiral α-methyl-β-keto imides, whose $Zn(BH_4)_2$ reduction affords optically active *syn*-α-methyl-β-hydroxy derivatives with virtually complete stereoselectivity (eq 19).[28,29] In the same way, chiral carboxamides (eq 20)[30] and (*R*)-*N*-acylsultams (eq 21)[31] also afford chiral *syn* products with high selectivities.

(19)

(20)

syn:*anti* = 99:1

(21)

syn:*anti* = 99.1:0.9

Selectivity of $Zn(BH_4)_2$ reductions of β-hydroxy[32,33] or *N*-aryl-β-amino[34] ketones lacking α-substituents is generally unsatisfactory. A case where an excellent result is obtained is shown in eq 22.[32] For the stereoselective preparation of *syn*- and *anti*-1,3-diols the use of other reagents is recommended.[35] However, in the reduction of β-keto esters, with chiral ester units, the *syn* selectivity is improved significantly (eq 23).[36] Reduction of the same keto ester with DIBAL-BHT (***Diisobutylaluminum 2,6-Di-t-butyl-4-methylphenoxide***) affords the diastereomer with high selectivity (eq 24).[36]

(22)

syn:*anti* = 91:9

(23)

(24)

$Zn(BH_4)_2$ reduction of α-hydroxy ketones gives *anti* products predominantly over *syn* products. The selectivity is dependent on the substitution pattern of the α-hydroxy ketones. When R^1 is phenyl or R^2 is a sterically demanding group, *anti* selectivity is excellent (eq 25).[37] This is reasonably explained by considering a zinc-chelated five-membered transition state.[1,37] Other highly selective examples of $Zn(BH_4)_2$ reductions[38-42] of α-hydroxy ketones are shown in eqs 26 and 27.[38,41]

(25)

$R^1 = Ph, R^2 = Me$	98:2
$R^1 = Pr, R^2 = i\text{-}Pr$	96:4

(26)

$R = (CH_2)_2OTHP$ *anti*:*syn* = 95:5

(27)

anti:*syn* = 98.5:1.5

In the cases where two functional groups are present on the α- or β-position of the keto group, reduction proceeds through the more stable transition state. When alkoxy and alkylthio functions are present on the α-position of the keto group, $Zn(BH_4)_2$ coordinates preferentially with the former (eq 28).[43] Reduction of a ketone having two alkoxy groups on the α- and β-positions produces the *anti*-2-alkoxy alcohol almost exclusively, showing that a five-membered transition state involving the α-alkoxy group is contributing far more than six-membered one (eq 29).[44] There is also a case where the three-dimensional structure of the ketone governs the selection of the transition state (eq 30).[45]

(28)

anti:*syn* = 99:1

(29)

$R = p\text{-}MeOC_6H_4$ 1,2-*anti*:1,2-*syn* = >99:1

(30)

α-OH:β-OH = 17:1

Optically active α-hydroxy imines are reduced with $Zn(BH_4)_2$ to give *anti*-hydroxy amines (eq 31).[46] α,β-Epoxy ketones produce *anti*-epoxy alcohols with high selectivity, irrespective of the substitution pattern of the epoxide (eq 32).[47,48] The corresponding aziridino ketones and imines are also reduced with $Zn(BH_4)_2$ to the *anti* isomer with high selectivity (eqs 33 and 34).[49]

Zinc Bromide[1]

$ZnBr_2$

[7699-45-8] · Br_2Zn · Zinc Bromide · (MW 225.19)

(used in the preparation of organozinc reagents via transmetalation;[1] a mild Lewis acid useful for promoting addition[2] and substitution reactions[3])

Physical Data: mp 394 °C; bp 697 °C (dec); *d* 4.201 g cm^{-3}.

Solubility: sol Et_2O, H_2O (1 g/25 mL), 90% EtOH (1 g/0.5 mL).

Form Supplied in: granular white powder; principal impurity is H_2O.

Analysis of Reagent Purity: melting point.

Purification: heat to 300 °C under vacuum (2×10^{-2} mmHg) for 1 h, then sublime.

Handling, Storage, and Precautions: very hygroscopic; store under anhydrous conditions. Irritant.

Organozinc Reagents.

The transmetalation of organomagnesium, organolithium, and organocopper reagents by anhydrous $ZnBr_2$ in ethereal solvents offers a convenient method of preparing organozinc bromides and diorganozinc reagents.[1a] Alternatively, anhydrous $ZnBr_2$ may be reduced by potassium metal to result in highly activated Zn^0, which is useful for the preparation of zinc reagents through oxidative addition to organic halides.[4] Alkyl, allylic, and propargylic zinc reagents derived by these methods have shown considerable value in their stereoselective and regioselective addition reactions with aldehydes, ketones, imines, and iminium salts.[1a,5] Zinc enolates used in the Reformatsky reaction may also be prepared through transmetalation using $ZnBr_2$.[1b] Organozinc species are especially useful in palladium- and nickel-catalyzed coupling reactions of sp^2 carbon centers. In this fashion, sp^2-sp^3 (eq 1)[6] and sp^2-sp^2 (eqs 2 and 3)[7,8] carbon-carbon bonds are formed selectively in high yields. The enantioselective cross coupling of secondary Grignard reagents with vinyl bromide is strongly affected by the presence of $ZnBr_2$, which accelerates the reaction and inverts its enantioselectivity (eq 4).[9]

(1)

(2)

(3)

(4)

without $ZnBr_2$ $R^1 = Me, R^2 = H$; >95% (52% ee)
with $ZnBr_2$ $R^1 = H, R^2 = Me$; >95% (49% ee)

Organozinc intermediates formed via transmetalation using $ZnBr_2$ have been used to effect carbozincation of alkenes and alkynes through metallo-ene and metallo-Claisen reactions. Both intermolecular and intramolecular variants of these reactions have been described, often proceeding with high levels of stereoselectivity and affording organometallic products that may be used in subsequent transformations (eqs 5 and 6),[10] including alkenation (eq 6).[10b,c] Bimetallic zinc-zirconium reagents have also been developed that offer a method for the alkenation of carbonyl compounds (eq 7).[11]

Concerted Ring-Forming Reactions.

The mild Lewis acid character of $ZnBr_2$ sometime imparts a catalytic effect on thermally allowed pericyclic reactions. The rate and stereoselectivity of cycloaddition reactions (eq 8),[12] including dipolar cycloadditions (eq 9),[13] are significantly improved by the presence of this zinc salt.

(8)

with $ZnBr_2$, 3 h 80%, 95% *endo*

(9)

single isomer

Some intramolecular ene reactions benefit from $ZnBr_2$ catalysis to afford the cyclic products under milder conditions, in higher yields and selectivities (eqs 10 and 11).[14,15] Generally, the use of $ZnBr_2$ is preferred over ***Zinc Chloride*** or ***Zinc Iodide*** in this type of reaction.[15]

(11)

$(R^1 = CN, R^2 = H):(R^1 = H, R^2 = CN) = 88:12$

Activation of C=X Bonds.

Lewis acid activation of carbonyl compounds by $ZnBr_2$ promotes the addition of allylsilanes and silyl ketene acetals.[16] Addition to imines has also been reported.[17] In general, other Lewis acids have been found to be more useful, though in some instances $ZnBr_2$ has proven to be advantageous (eq 12).[2]

(12)

$ZnBr_2$, THF, 20 °C, 6 h	100:0
CsF, CH_2Cl_2. 20 °C, 14 h	5:95

Activation of C-X Bonds.

Even more important than carbonyl activation, $ZnBr_2$ promotes substitution reactions with suitably active organic halides with a variety of nucleophiles. Alkylation of silyl enol ethers and silyl ketene acetals using benzyl and allyl halides proceeds smoothly (eq 13).[3] Especially useful electrophiles are α-thio halides which afford products that may be desulfurized or oxidatively eliminated to result in α,β-unsaturated ketones, esters, and lactones (eq 14).[18] Other electrophiles that have been used with these alkenic nucleophiles include ***Chloromethyl Methyl Ether***, $HC(OMe)_3$, and ***Acetyl Chloride***.[3,19]

(13)

(14)

Enol ethers and allylic silanes and stannanes will engage cyclic α-seleno sulfoxides,[20] o-acetoxy lactams,[21] and acyl glycosides (eq 15)[22] in the presence of $ZnBr_2$ catalysis. Along these lines, it has been found that $ZnBr_2$ is superior to ***Boron Trifluoride Etherate*** in promoting glycoside bond formation using trichloroimidate-activated glycosides (eq 16).[23] Imidazole carbamates are also effective activating groups for $ZnBr_2$-mediated glycosylation (eq 17).[24]

(15)

(16)

(17)

Cyclic acetals also undergo highly selective, Lewis acid-dependent ring opening substitution with ***Cyanotrimethylsilane*** (eq 18).[25]

Reduction.

Complexation with $ZnBr_2$ has been shown to markedly improve stereoselectivity in the reduction of certain heteroatom-substituted ketones (eqs 19 and 20).[26,27] Furthermore, the *anti* selectivity observed in $BF_3.OEt_2$-mediated intramolecular hydrosilylation of ketones is reversed when $ZnBr_2$ is used instead (eq 21).[28]

Deprotection.

$ZnBr_2$ is a very mild reagent for several deprotection protocols, including the detritylation of nucleotides[29] and deoxynucleotides,[30] *N*-deacylation of *N*,*O*-peracylated nucleotides,[31] and the selective removal of Boc groups from secondary amines in the presence of Boc-protected primary amines.[32] Perhaps the most widespread use of $ZnBr_2$ for deprotection is in the mild removal of MEM ethers to afford free alcohols (eq 22).[33]

Miscellaneous.

An important method for the synthesis of stereodefined trisubstituted double bonds involves the treatment of cyclopropyl bromides with $ZnBr_2$. The (*E*) isomer is obtained almost exclusively by this method (eq 23).[34]

The rearrangement of a variety of terpene oxides has been examined (eq 24).[35] While $ZnBr_2$ is generally a satisfactory catalyst for this purpose, other Lewis acids, including $ZnCl_2$[36] and ***Magnesium Bromide***,[37] are advantageous in some instances.

In the presence of $ZnBr_2$/48% ***Hydrobromic Acid***, suitably functionalized cyclopropanes undergo ring expansion to afford cyclobutane (eq 25)[38] and α-methylene butyrolactone products (eq 26).[39] One-carbon ring expansion has been reported when certain trimethylsilyl dimethyl acetals are exposed to $ZnBr_2$ with warming (eq 27).[40]

Zinc Carbonate

$ZnCO_3$

[3486-35-9] · CO_3Zn · Zinc Carbonate · (MW 125.40)

(mild inorganic base, capable of chelation;[1] catalyst for heterocyclization[2,3] and Claisen rearrangement[4,5])

Physical Data: dec with evolution of CO_2 at 300 °C; *d* 4.42-4.45 g cm^{-3}.

Solubility: insol H_2O, organic solvents.

Form Supplied in: white crystalline powder; commercially available.

Preparative Method: addition of 0.1M Na_2CO_3 to 0.1M $ZnSO_4$ gives a precipitate of zinc carbonate, which is filtered off, and dried in vacuo.[1]

Handling, Storage, and Precautions: reputed to be nontoxic.

Coumarin Ring Synthesis.[1]

The specific chelating properties of zinc (or magnesium) carbonate were required in the formation of coumarin (**2**) from phenol (**1**) (eq 1). The nonchelating sodium or potassium carbonates do not effect this transformation. Although yields are only moderate, (**1**) is exceptionally sensitive to acidic reagents[1], rendering some other procedures for coumarin synthesis under acidic conditions[6] impractical in this case. Moreover, this cyclization step to the aflatoxin system had proved difficult in a previous synthesis.[7]

(1)

Heterocyclization.

Phenolic[2] and enolic[3] alkynes are cyclized to furans or pyrans (eqs 2-4) with, in some cases, very small catalytic quantities of $ZnCO_3$.

(2)

(3)

(4)

Claisen Rearrangements.

Various dienals[4] and dienones[5] can be prepared by Claisen rearrangement of enol sulfoxides (**3**), followed by PhSOH elimination (eq 5). The rearrangement occurs on distillation from small amounts of $ZnCO_3$. These fairly vigorous conditions, however, suggest that alternative catalysts[8] would often be preferred with less robust molecules.

(3)

(5)

R^1-R^5 = alkyl, 58-85%

Zinc Carboxylate Salts.[9]

$ZnCO_3$ reacts with carboxylic acids to form the zinc salts, which can be used to effect solvolysis of tertiary halides (see ***Zinc Oxide***).

Zinc Chloride[1]

[7646-85-7] · Cl_2Zn · Zinc Chloride · (MW 136.29)

(used in the preparation of organozinc reagents via transmetalation;[1] a mild Lewis acid useful for promoting cycloaddition,[2] substitution,[3] and addition reactions,[4] including electrophilic aromatic additions;[5] has found use in selective reductions[6])

Physical Data: mp 293 °C; bp 732 °C; *d* 2.907 g cm^{-3}.

Solubility: sol H_2O (432 g/100 g at 25 °C), EtOH (1 g/1.3 mL), glycerol (1 g/2 mL).

Form Supplied in: white, odorless, very deliquescent granules; principal impurities are H_2O and zinc oxychloride.

Analysis of Reagent Purity: melting point.

Purification: reflux (50 g) in dioxane (400 mL) in the presence of Zn^0 dust, then filter hot and allow to cool to precipitate purified $ZnCl_2$. Also, anhydrous material may be sublimed under a stream of dry HCl, followed by heating to 400 °C in a stream of dry N_2.

Handling, Storage, and Precautions: very hygroscopic; store under anhydrous conditions; moderately irritating to skin and mucous membranes.

Organozinc Reagents.

The transmetalation of organomagnesium, organolithium, and organocopper reagents is an important and versatile method of preparing useful zinc reagents.[1a] Alternatively, $ZnCl_2$ may be employed for direct insertion of Zn^0 into carbon-halogen bonds using Mg^0/ultrasound[7] or prior reduction with K^0.[8] The addition of the resulting allylic and propargylic or allenic zinc reagents to carbonyl compounds, imines, and iminium salts represents an important method of selective carbon-carbon bond formation.[9,11] These reactions are generally guided by chelation and the Zimmerman-Traxler transition state[10] to control the relative stereochemistry about the new carbon-carbon bond (eq 1),[12] as well as with respect to preexisting stereocenters (eq 2).[13] Anions derived from propargylic deprotonation add to carbonyl compounds with a high degree of regiochemical integrity in the presence of $ZnCl_2$, i.e. allenic organozinc intermediates cleanly afford the propargylic product (eq 3).[11b]

Alkylzinc reagents, often in the presence of copper salts, effectively participate in conjugate addition reactions[14] and clean S_N2' reactions (eq 4).[15]

Organozinc reagents are superior species for palladium- and nickel-catalyzed coupling reactions.[16] This offers an exceptional method for the selective formation of sp^2-sp^3 (eq 5),[17] sp^2-sp^2 (eqs 6 and 7),[18,19] and sp^2-sp (eq 8)[20] carbon-carbon bonds. In addition, the palladium-catalyzed coupling reactions of sp and sp^2 halides with vinylalanes (eq 9),[21] vinylcuprates,[22] vinylzirconium (eq 10)[23] and acyliron species[24] often proceed more effectively in the presence of $ZnCl_2$. This effect has been noted in other metal-mediated carbon bond formations,[25] though the role of this $ZnCl_2$ catalysis is not understood at present.

Organozinc reagents have been successfully exploited in asymmetric carbon bond formation.[26] Chiral glyoxylate esters engage organozinc species derived from Grignard reagents in selective addition reactions to afford enantiomerically enriched α-hydroxy acids (eq 11).[27] Enantioselective addition reactions of Grignard reagents have been achieved by sequential addition of $ZnCl_2$ and a chiral catalyst to afford secondary alcohols (eq 12).[28]

Zinc Enolates.

Zinc enolates can be prepared by deprotonation of carbonyl compounds using standard bases, followed by transmetalation with $ZnCl_2$.[1b]

These enolates offer important opportunities for stereoselective aldol condensations, including higher yields and stereochemical selection for *threo* crossed-aldol products (eq 13).[29] Both of these consequences are the result of the reversible formation of a six-membered zinc chelate intermediate (**1**) which favors the *anti* disposition of its substituents. Though their use has been mostly replaced by kinetically controlled aldol methodology, zinc enolates sometimes present advantages in specific cases.[30] For example, chelated zinc enolates derived from α-amino acids have been shown to be of value in the stereoselective synthesis of β-lactams (eq 14).[31] Controlled monoalkylation of unsymmetrical ketones has been accomplished via treatment of zinc enolates with α-chlorothio ethers (eq 15),[32] and mild allylation of β-dicarbonyl compounds may be realized through exposure of the corresponding zinc enolate to an allyl alcohol in the presence of a palladium catalyst (eq 16).[33]

(16)

Homoenolates.

Readily available mixed Me_3Si/alkyl acetals are converted into zinc homoenolates in high yield through exposure to $ZnCl_2$ in Et_2O (eq 17).[34] These mildly reactive species, which tolerate asymmetry α to the carbonyl, are useful for a variety of bond-forming reactions. In the presence of Me_3Si activation they undergo addition to aldehydes and, when admixed with CuBr.DMS (see ***Copper(I) Bromide***), can be allylated or conjugatively introduced to α,β-unsaturated ketones (eq 18).[35] Copper salts are not required for conjugate addition to propargylic esters (eq 19).[36] These zinc species also participate in useful palladium-catalyzed bond-forming processes (eq 20).[37]

(20)

Cycloaddition Reactions.

Catalysis by $ZnCl_2$ is often a powerful influence on cycloaddition reactions.[2] In addition to improving the rate of Diels-Alder reactions, enhanced control over regioselectivity (eq 21)[2c] and stereochemistry (eq 22)[2e] may be observed. An exceedingly important application of $ZnCl_2$ catalysis is found in the reaction of electron-rich dienes with carbonyl compounds.[2a,b] Intensive mechanistic studies on these reactions has uncovered two mechanistic pathways that afford stereochemically contrasting products, depending upon which Lewis acid is employed (eq 23).[38] It was concluded that cycloaddition reactions catalyzed by $ZnCl_2$ proceed via a classical [4 + 2] concerted process, whereas Lewis acids such as ***Boron Trifluoride Etherate*** and ***Titanium(IV) Chloride*** afford products through sequential aldol/cyclization processes. Examples abound wherein advantage has been taken of the predictable Cram-Felkin selectivity of this $ZnCl_2$ catalysis to exploit asymmetric variants of this reaction to synthesize a variety of natural products (eq 24).[39] The selective cycloaddition of electron-rich dienes with imines has also been catalyzed by $ZnCl_2$ (eq 25).[40]

(24)

(25)

Activation of C=X Bonds.

The mild Lewis acid character of $ZnCl_2$ is frequently exploited to promote the addition of various nucleophiles to carbon-heteroatom double bonds.[4] The well-established Knoevenagel condensation and related reactions have been effectively catalyzed by $ZnCl_2$ (eq 26).[41] The addition of enol ethers and ketene acetals to aldehydes and ketones has been noted (eq 27),[42] though $ZnCl_2$ has been used less widely in these aldol-type condensations than other Lewis acids, including $TiCl_4$, ***Magnesium Bromide***, and ***Tin(IV) Chloride***, to name a few.[4] In some instances, excellent levels of stereocontrol have been observed (eq 28).[43] Analogous additions to imines have been noted as well.[4e-g,44] Some conjugate addition reactions may also benefit from $ZnCl_2$ catalysis (eq 29).[45]

(26)

Δ, PhMe, 24 h	50%
1 equiv $ZnCl_2$, CH_2Cl_2, 0 °C, 2 d	98%

The formation of cyanohydrins using ***Cyanotrimethylsilane*** and ***Isoselenocyanatotrimethylsilane*** has been effectively catalyzed by $ZnCl_2$ (eq 30),[46] as has Strecker amino acid synthesis via the treatment of imines with $Me_3SiCN/ZnCl_2$.[47] The combination of carbonyl compounds with ***Acetyl Chloride*** or ***Acetyl Bromide*** may be promoted by $ZnCl_2$ to afford protected vicinal halohydrins (eq 31).[48]

no $ZnCl_2$	78%
with $ZnCl_2$	>95%

(31)

It is noteworthy that the treatment of carbonyl compounds with ***Chlorotrimethylsilane***/$ZnCl_2$ results in a useful synthesis of Me_3Si enol ethers which, in turn, may be useful for other carbon bond-forming processes (eq 32).[49]

(32)

Activation of C-X Bonds.

The activation of C-X single bonds toward nucleophilic substitution is also mediated by the Lewis acidic character of $ZnCl_2$.[3] Benzylic (eq 33),[50] allylic (eq 34),[3d,51] propargylic,[52] and tertiary halides (eq 35)[53] undergo substitution with mild carbon and heteroatom[3e] nucleophiles.

(33)

(34)

(35)

In a similar fashion, acetals (eq 36)[54] and orthoesters (eq 37)[55] may be used as electrophiles in substitution reactions with electron-rich alkenic nucleophiles. The combination of $ZnCl_2$ with co-catalysts has sometimes proven advantageous in these reactions (eq 38).[56]

(36)

(37)

(38)

The regioselective ring opening reactions of epoxides (eq 39),[57,58] oxetanes,[58] and tetrahydrofurans (eq 40)[59] has been promoted by $ZnCl_2$ to afford adducts with suitable nucleophiles.

(39)

(40)

Activation by $ZnCl_2$ of allylic (eq 41)[60] and propargylic chlorides (eq 42),[61] as well as α-chloroenamines (eq 43),[62] in the presence of simple alkenes has been shown to yield four-membered and five-membered cycloadducts.

(41)

(42)

(43)

Chlorination of alcohols by ***Thionyl Chloride***,[63] the preparation of acyl chlorides from lactones and anhydrides,[64] and the bromination and iodination of aromatic rings by ***Benzyltrimethylammonium Tribromide*** and ***Benzyltrimethylammonium Dichloroiodate***, respectively,[65] are all effectively catalyzed by the presence of $ZnCl_2$. In addition, $ZnCl_2$ acts as a source of chloride for the halogenation of primary, secondary, and allylic alcohols using ***Triphenylphosphine-Diethyl Azodicarboxylate***.[66]

Reduction.

The very useful reducing agent ***Zinc Borohydride*** is prepared by exposure of $NaBH_4$ to $ZnCl_2$ in ether solvents.[67] Its use in selective reductions is described elsewhere.[6a] A complex reducing agent resulting from the mixture of NaH/*t*-pentyl-OH/$ZnCl_2$, given the acronym ZnCRA (***Zinc Complex Reducing Agents***), is found to open epoxides in a highly regioselective fashion, favoring hydride delivery at the least hindered position.[68] A related reagent, ZnCRASi, which includes Me_3SiCl in the mixture, selectively reduces ketones in high yield, though the levels of selectivity do not compete with other selective reagents.[69]

The reduction of ketones and aldehydes by silicon and tin hydrides in the presence of $ZnCl_2$ has been documented.[70] In the presence of Pd^0 catalysts and $ZnCl_2$, these hydrides selectively reduce α,β-unsaturated aldehydes and ketones to the corresponding saturated products (eq 44).[71] The presence of $ZnCl_2$ has been shown to modify the reactivity of several common reducing agents. For example, the mixture of ***Sodium Cyanoborohydride*** and $ZnCl_2$ selectively reduces tertiary, allylic, and benzylic halides (eq 45),[72] ***Sodium Borohydride***, in the presence of $ZnCl_2$ and $PhNMe_2$ will reduce aryl esters to primary alcohols,[73] and ***Lithium Aluminum Hydride*** with $ZnCl_2/CuCl_2$ desulfurizes dithianes (eq 46).[74]

(44)

(45)

(46)

Stereoselectivity is also modified by the presence of $ZnCl_2$ (eq 47).[75] Enantioselective reduction of aryl ketones has been observed with ***Diisobutylaluminum Hydride*** (DIBAL) modified by $ZnCl_2$ and chiral diamine ligands (eq 48).[76]

(47)

(48)

Protection/Deprotection.

The acetylation of carbohydrates and other alcohols has been realized using ***Acetic Anhydride***/$ZnCl_2$ (eq 49).[77] It is found that $ZnCl_2$ imparts selectivity to both acetylation[78] and acetonide formation[79] of polyols, which is useful in the synthetic manipulation of carbohydrates. Synthetically useful selective deprotection of acetates (eq 50)[80] and dimethyl acetals (eq 51)[81] has been reported to be mediated by $ZnCl_2$.

(49)

(50)

(51)

Acylation.

Unsaturated esters are obtained through acylation of alkenes by anhydrides using activation by $ZnCl_2$ (eq 52).[82] The mixture of $RCOCl/ZnCl_2$ is effective in the acylation of silyl enol ethers to afford β-dicarbonyl products (eq 53).[83] Friedel-Crafts acylation is catalyzed by $ZnCl_2$, using anhydrides or acyl halides as the electrophiles (eqs 54 and 55).[84,85]

(52)

(53)

(54)

(55)

Aromatic Substitution.

Several important classes of aromatic substitutions are mediated by $ZnCl_2$, including the Hoesch reaction (eq 56)[86] and the Fischer indole synthesis (eq 57).[87] Haloalkylation of aromatic rings using ***Formaldehyde*** or ***Chloromethyl Methyl Ether*** is readily accomplished through the agency of $ZnCl_2$ and warming (eq 58).[88]

(56)

(57)

(58)

Zinc Chloride Etherate in Dichloromethane[1]

$ZnCl_2.OEt_2$

[21512-92-5] · $C_4H_{10}Cl_2OZn$ · Zinc Chloride Etherate · (MW 210.43)

(Lewis acid catalyst solution that is considerably more active than $ZnCl_2$ in either diethyl ether or dichloromethane)

Physical Data: density depends on solvent composition; see Table 1.

Solubility: sol a variety of inert solvents.

Form Supplied in: 2.2 M solution in dichloromethane.

Preparative Methods: ***Zinc Chloride*** (20.0 g, 0.147 mol) is dissolved in dry diethyl ether with initial cooling (exothermic!) and shaking, which takes up to 12 h for the more concentrated solutions. These solutions (which are very viscous when less than 30 mL of ether are used) are diluted with CH_2Cl_2 to obtain the 1.47 M catalyst solutions shown in Table 1.

Table 1 Zinc Chloride Diethyl Ether Complex Solutions in Dichloromethane

Et_2O (ml)	CH_2Cl_2 (ml)	$[Et_2O]/[ZnCl_2]$	d (g cm^{-3})	Rel. activity[a]
17.0	76.3	1.12	1.33	1460
25.0	69.3	1.64	1.30	305
36.5	58.4	2.40	1.23	41
46.0	49.1	3.00	1.18	18
61.0	33.7	4.02	1.09	3
77.0	18.3	5.06	0.994	1

[a] Activity of solutions observed by dissolving 1 mL of these solutions in 15 mL of CH_2Cl_2. For details see Mayr and Striepe.[1]

Handling, Storage, and Precautions: the solutions described in Table 1 can be stored at ambient temperature for several months. Precipitation of $ZnCl_2$ takes place when solutions with a $[Et_2O]/[ZnCl_2]$ ratio <2 are diluted with CH_2Cl_2 at room temperature. Separation can be avoided by cooling the catalyst solution at -70 °C before addition of the extra solvent and the reactants. The reagent is relatively insensitive toward traces of moisture;[1] tentative addition of water causes a similar reduction in the catalytic activity as the same molar amount of ether.[1]

Catalytic Activity of Zinc Chloride Solutions.

Because of its low solubility in inert solvents (e.g. chlorinated hydrocarbons), zinc chloride acts as a weak Lewis acid catalyst for a variety of organic reactions.[2] It is highly soluble in ether and related solvents,[3] but the catalytic activity of such solutions is low because of coordinative saturation of the

catalytic sites. Highly active forms of $ZnCl_2$ can be obtained, however, when small amounts of ether are used to solubilize $ZnCl_2$ in inert solvents, and it has been shown that solutions of $ZnCl_2.Et_2O$ in dichloromethane possess a catalytic activity that is 10^3-10^4 times greater than that of the ether-free reagent. Dichloromethane solutions, in which the molar ratio $[Et_2O]/[ZnCl_2]$ exceeds 5-8, possess a lower catalytic activity than heterogeneous $ZnCl_2/CH_2Cl_2$ systems.

Alkylations and Related Reactions.

Zinc chloride etherate in dichloromethane has most frequently been used to catalyze additions of alkyl,[4] benzyl,[4,5] allyl[6] and propargyl chlorides[7] to alkenes and dienes (eqs 1-3). The major advantage of this catalyst system is that it works well for polymerization-sensitive compounds such as allylic chlorides or conjugated π-systems. The scope of these reactions has been discussed.[4]

(1)

$R^1, R^2, R^3 = H$, alkyl; R^4 = alkyl

(2)

(3)

Carbocationic cycloadditions of allyl[6,8] and propargyl cations[9] with alkenes and dienes have been induced with this reagent (eqs 4 and 5).

Acetylcyclopentadienes have been obtained by $ZnCl_2.OEt_2$-catalyzed reactions of allyl chlorides with 2,4-pentanedione (eq 6).[10]

Alkoxyalkylations of allylsilanes with α-halogeno ethers and acetals have been reported.[11] In addition, $ZnCl_2.OEt_2/CH_2Cl_2$ is useful for *C*-glycosidations, as demonstrated by reaction of the *O*-benzyl protected glucopyranosyl trichloroacetimidate (**1**) with ***Furan*** to give the 2-glucosylfuran (**2**) (eq 7).[12] Similar results have been reported for related heteroarenes.[12]

Zinc chloride etherate in 1,2-dichloroethane has been found to be superior to ***Tin(IV) Chloride*** in *O*-glycosidation reactions. While benzoate (**3**) and the sensitive enynol (**4**) gave the acetal (**5**) in 61% yield in presence of $ZnCl_2.OEt_2$ (eq 8), the corresponding reaction with $SnCl_4$ gave only 23% of the desired acetal.[13]

Dialkoxyalkylations of silyl enol ethers have been achieved with orthoesters in the presence of this catalyst (eqs 9 and 10).[14]

While the reactions of orthoformates with allylsilanes in presence of ***Titanium(IV) Chloride*** (>1 equiv) gave only bisallylic ethers, the corresponding reactions with catalytic amounts of $ZnCl_2.OEt_2/CH_2Cl_2$ gave homoallyl acetals selectively (eq 11).[15]

Acylations.

Acylations of silylated enol ethers and alkenes have also been reported (eq 12).[16]

Diels-Alder Reaction.

The reaction of (**6**) with (**7**) with formation of the dihydropyran (**8**) took place exclusively with $ZnCl_2.OEt_2$ as the catalyst while the thermal reaction of (**6**) with (**7**) predominantly gave an ene product (eq 13).[17]

Ene Reaction.

Catalytic amounts of $ZnCl_2.OEt_2$ in CH_2Cl_2 provide a selective and simple preparative procedure to convert citronellal (**9**) in high yields into the isomers of isopulegol (**10**) (eq 14).[18]

(14)

Ether Cleavage.

Attempted deprotection of 2-(trimethylsilyl)ethyl ether (**11**) with anhydrous ***Tetra-n-butylammonium Fluoride*** under various conditions resulted in complete decomposition. Treatment of (**11**) with zinc chloride etherate, however, afforded racemic terrein (*rac*-**12**) in almost quantitative yield (eq 15).[19]

(15)

Related Reagents.

Titanium(IV) Chloride; ***Zinc Bromide***; ***Zinc Chloride***; ***Zinc Trifluoromethanesulfonate***.

Zinc Complex Reducing Agents[1]

NaH-*t*-C_5H_{11}ONa-ZnX_2

(NaH)

[7646-69-7] · HNa · Zinc Complex Reducing Agents · (MW 24.00) (*t*-C_5H_{11}ONa)

[14593-46-8] · $C_5H_{11}NaO$ · Zinc Complex Reducing Agents · (MW 110.15) ($ZnCl_2$)

[7646-85-7] · Cl_2Zn · Zinc Complex Reducing Agents · (MW 136.29) ($Zn(OAc)_2.2H_2O$)

[5970-45-6] · $C_4H_{10}O_6Zn$ · Zinc Complex Reducing Agents · (MW 219.53)

(zinc-containing complex reducing agents (ZnCRAs); reduces many functional groups[1])

Physical Data: light gray solid of uncertain structure containing Zn^0 species.[2]

Solubility: insol organic solvents.

Preparative Methods: *t*-C_5H_{11}ONa-ZnCRA (*x.y.z*) is conveniently prepared by the reaction of *t*-C_5H_{11}OH (*y* equiv) with a mixture of ***Sodium Hydride*** (*x* + *y* equiv) and ZnX_2 (X = Cl, OAc) (*z* equiv) in THF or DME. Commercial NaH (55-60% in oil) is used after three washings with anhydrous THF or DME under N_2. *t*-C_5H_{11}OH is distilled from sodium. ZnX_2 is dried in vacuo (15 mmHg) for 16 h at 100-110 °C.

Handling, Storage, and Precautions: ZnCRAs are nonpyrophoric but are handled and stored under inert atmosphere (N_2 or, better, Ar). Hydrolysis must be performed by slow addition of cold water or EtOH to destroy the reagent.

Designation.

t-C_5H_{11}ONa-ZnCRA (*x.y.z*) means a reagent obtained from *x*, *y*, and *z* equivalents of NaH, *t*-C_5H_{11}ONa, and ZnX_2 (X = Cl, OAc), respectively.

Reduction of Organic Halides.

t-C_5H_{11}ONa-ZnCRAs are very mild and thus selective reducing agents. They are appreciably less basic than NaH and *t*-C_5H_{11}ONa.

t-C_5H_{11}ONa-ZnCRA (4.2.1) reduces alkyl halides in THF or DME (primary >> secondary >>> tertiary and I > Br >> Cl). Moreover, benzyl halides are easily reduced while vinyl halides are unreactive. Thus selective reductions may be easily performed, as exemplified in eqs 1 and 2.[3]

(1)

(2)

Ketones and nitriles are tolerated during the reduction of reactive halides (eqs 3 and 4).[3]

(3)

(4)

Reduction of Ketones.

t-C_5H_{11}ONa-ZnCRA (4.1.1) alone or, better, in the presence of ***Magnesium Bromide*** (electrophilic assistance), easily reduces saturated ketones under mild conditions and in very good yields.[4,5] Although able to reduce hindered ketones, the reagent is sensitive to steric hindrance, leading to stereoselective reductions (eqs 5 and 6).[5]

(5)

(6)

t-C_5H_{11}ONa-ZnCRA (4.1.1) does not reduce carbon-carbon double bonds and is well suited for the selective reduction of α,β-unsaturated ketones to the corresponding allylic alcohols.[6]

Efficiency and chemoselectivity of *t*-C_5H_{11}ONa-ZnCRA may be considerably improved by addition of ***Chlorotrimethylsilane*** (ZnCRASi).[7] Thus ketones as well as highly enolizable aldehydes are very rapidly reduced in excellent yields (eqs 7 and 8). The stereoselectivity of ZnCRASi broadly resembles one ZnCRA.[5] *t*-C_5H_{11}ONa-ZnCRASi is highly chemoselective in the reduction of the carbonyl groups of ketones and aldehydes in the presence of carbon-carbon double bonds (eqs 9 and 10).

(7)

(8)

(9)

(10)

Finally, excellent chemoselectivity was also found during the reduction of aldehydes and ketones in the presence of halides, acetals, and nitro aromatic derivatives, as illustrated in eqs 11 and 12.[8]

(11)

(12)

ZnCRAs and especially ZnCRASis are more efficient and chemoselective than NiCRAs (see ***Nickel Complex Reducing Agents***) in the reduction of ketones and aldehydes.

Reduction of Epoxides.

t-C_5H_{11}ONa-ZnCRA (4.2.1) reduces epoxides regioselectively at the less substituted carbon atom (eq 13).[9]

(13)

With less reactive epoxides, the constitution of the reagent must be changed and a (8.2.1) ratio of the constituents is necessary.[9] The regioselectivity is not changed under such conditions (eq 14). Interestingly, the regioselectivity of these reductions is opposite to that observed with NiCRAs.

(14)

Reduction of Aromatic Nitro Compounds.

In the presence of $MgBr_2$, t-$C_5H_{11}ONa$-ZnCRA (7.1.1) selectively reduces a number of aromatic nitro compounds to their azoxy derivatives in good to excellent yields (eqs 15 and 16).[10] A few percent of azo derivatives are sometimes also produced. Note that under such conditions NiCRAs lead to the corresponding anilines.

Zinc-Copper(II) Acetate-Silver Nitrate

Zn(Cu/Ag)

(Zn)

[7440-66-6] · Zn · Zinc-Copper(II) Acetate-Silver Nitrate · (MW 65.39) ($AgNO_3$)

[7761-88-8] · $AgNO_3$ · Zinc-Copper(II) Acetate-Silver Nitrate · (MW 169.88) ($Cu(OAc)_2.H_2O$)

[6046-93-1] · $C_4H_8CuO_5$ · Zinc-Copper(II) Acetate-Silver Nitrate · (MW 199.67)

(reagent for selective reduction of activated or conjugated triple bonds to (*Z*)-alkenes;[1,2] compatible with many functional groups)

Physical Data: see ***Zinc***, ***Copper(II) Acetate***, and ***Silver(I) Nitrate***.

Solubility: insol organic solvents and water; reacts with dilute acids and bases.

Preparative Method: argon is passed for ca. 15 min through a well stirred suspension of commercial zinc dust (5.0 g, ca. <60 µm; >230 mesh ASTM) in water (30 mL). $Cu(OAc)_2.H_2O$ (0.5 g) is added and after 15 min $AgNO_3$ (0.5 g) is introduced (exothermic reaction). The mixture is stirred for 30 min, and the activated metal is collected by suction filtration under argon. The dark solid is washed with water (2 × 30 mL), MeOH (2 × 30 mL), acetone (2 × 30 mL), and Et_2O (2 × 30 mL). The Et_2O-moist Zn dust is transferred into 20 mL $MeOH/H_2O$ (1:1, v/v) and is ready for use.

Handling, Storage, and Precautions: the reagent has to be freshly prepared prior to use. The activated metal may be briefly stored covered with solvent (e.g. $MeOH/H_2O$; 1/1, v/v) in the absence of oxygen. The dry reagent is pyrophoric!

Reduction of Triple Bonds.

Zinc metal, previously activated by successive treatment with $Cu(OAc)_2$ (10%) and $AgNO_3$ (10%), reduces conjugated or activated triple bonds stereospecifically to (*Z*)-alkenes.[1,2] Best results are obtained in a polar protic solvent like $MeOH/H_2O$ (1:1, v/v) under neutral conditions. The conditions are exceptionally mild and most reductions can be conducted at 25 °C using an excess of activated metal (ca. 1:10 -> 100). As a consequence, even a thermolabile, acid- and base-sensitive tetraene like the naturally occurring 2*Z*,4*Z*,6*E*,8*Z*-undecatetraene (eq 1) can be prepared without competing isomerization and polymerization. Unlike Lindlar's catalyst (see ***Palladium on Calcium Carbonate (Lead Poisoned)***), Zn(Cu/Ag) does not reduce simple, nonactivated alkynes. However, nonconjugated propargylic alcohols are readily reduced at 25 °C.

The reduction of (*Z*)-enynes is effected at 25 °C, but temperatures of 40-50 °C are necessary for simple (*E*)-enynes. The reduction of highly unsaturated dienediynes (eqs 1 and 2) proceeds at 25 °C independent of the enyne stereochemistry.[1] Overreduced products are usually not observed. Both α- and β-branched enynes react sluggishly at elevated temperatures (40-50 °C; eq 3).[3]

The stereospecific reduction of conjugated enynes to (*Z*)-alkenes is ideally suited for the synthesis of leukotriene B_4 (eq 4)[4,5] and other fatty acid-derived polyenoic metabolites like (5*S*,12*S*)-DiHETE,[6] (12*R*)- or (12*S*)-HETE,[7] and (13*S*)-HODE.[8] Hydrogenolytic fission of allylic alcohols, ethers, and esters does not occur.[9,10] Reactive halides may be incompatible with the reagent. Ketones and esters are tolerated; however, aldehydes are reduced to alcohols. In general, Zn(Cu/Ag) exhibits a somewhat higher reactivity, but similar selectivity, to Rieke zinc metal which can be used for analogous reductions of propargylic alcohols at 65 °C in polar protic solvents.[11] Introduction of deuterium atoms is possible using deuterated solvents ($MeOD/D_2O$) and Zn(Cu/Ag), but complete deuteration is difficult to achieve. A recently disclosed stereoselective synthesis of conjugated (*E*)-trienes from 1.6-dibenzoate-2,4-dienes utilizes Zn(Cu/Ag) for the generation of the dienediol intermediates from readily available diynoic precursors (eq 5).[12] The sequence has been extended to LTB_4.[10]

Zinc-Copper(I) Chloride

Zn-CuCl

(Zn)

[7440-66-6] · Zn · Zinc-Copper(I) Chloride · (MW 65.39) (CuCl)

[7758-89-6] · ClCu · Zinc-Copper(I) Chloride · (MW 99.00)

(forms zinc-copper couple;[1] thence capable of initiating Reformatsky[2] and related reactions, and Simmons-Smith methylenation[3])

Physical Data: see ***Copper(I) Chloride*** and ***Zinc***

Zinc-Copper Couple.[1]

A typical procedure involves mixture of zinc, usually activated,[4] and a catalytic amount of CuCl, often 10 mol %, before introduction of the organic halide appropriate for subsequent reaction. Enhancement of the procedure can be effected by the use of ultrasound,[5] substitution of ***Silver(I) Acetate***[2c,6] for CuCl, or, in certain cases, incorporation of ***Chlorotrimethylsilane***.[7]

Reformatsky Reactions.[2]

The multiply halogenated ester (**1**) reacts with aldehydes in the presence of Zn/CuCl, 4Å molecular sieve (MS), and ***Acetic Anhydride*** to give unsaturated esters (**2**) (eq 1).[2a] The double bonds are predominantly or exclusively in the (*Z*) configuration. Omission of Ac_2O from the reaction leads to lower yields of (**2**) and substantial amounts of β-hydroxycarboxylate. Ketones react poorly in this procedure (20%). Similar reactivity has been demonstrated with the ester $CF_3CCl_2CO_2Me$,[2b] giving α-trifluoromethyl-α,β-unsaturated esters. The α-halo ketones (**3**) react similarly (eq 2),[2c,2d] but only with aldehydes; ketones react only if CuCl is replaced by AgOAc and ***Diethylaluminum Chloride*** is also required.

Reformatsky-Type Reaction of an Allylic Halide.[2e]

The allylic trihalide (**4**) undergoes exactly analogous reactions with both aldehydes and ketones, although the latter react more sluggishly,

and usually in lower yield (eq 3). In some cases, AgOAc is still preferred to CuCl, but the reagents seem more equivalent in this case than in those cited above. Reactivity at the α-position of the allylzinc reagent is noteworthy, since γ-alkylation of carbonyls is more usual.[8]

α,α´-Dibromo Ketone Cycloaddition.[5,7,9]

Zn/CuCl can cause a cycloaddition reaction between an α,α´-dibromo ketone and a suitable diene, as in eq 4, leading to seven-membered rings. A similar reaction, but superior in terms of yield, uses ***Nonacarbonyldiiron***,[10] but this reagent is appreciably more toxic and expensive. The Zn/CuCl reaction is substantially improved by addition of Me_3SiCl[7] or, even better, ultrasonication.[5]

Alkene Acylation.[11]

Acylation of alkenes by acyl chlorides (eq 5) is promoted by zinc activated by any of a number of reagents, the best of which appears to be Zn/CuCl and ***Diiodomethane***. Although this normally gives rise to the so-called Simmons-Smith reagent (see below),[3] no trace of alkene methylenation is observed under these conditions. Other catalysts such as ***Aluminum Chloride***, ***Zinc Iodide***, or ***Zinc Chloride*** may also effect the reaction in certain cases, but with inferior yields.

Simmons-Smith Reaction.[3]

This reaction, as demonstrated originally for cyclohexene (eq 6), is treated at length elsewhere (see ***Zinc/Copper Couple*** and ***Diiodomethane***).

Zinc/Copper Couple[1]

Zn(Cu)

[12019-27-1] · Zn · Zinc/Copper Couple · (MW 65.39)

(an activated form of zinc metal that can be used for cyclopropanation;[1] conjugate addition of alkyl iodides to enones;[2] preparation of dichloroketene;[3] preparation of 2-oxyallyl cations for cycloaddition reactions[4])

Physical Data: see ***Zinc***.

Solubility: insol organic solvents and H_2O.

Form Supplied in: reddish-brown or dark gray powder; often prepared directly before use.

Preparative Methods: although zinc-copper couple is commercially available, freshly prepared reagents are often more active. Of the many preparations described in the literature,[1] LeGoff's is both simple and results in a very active zinc-copper couple.[5] Zinc dust (35 g) was added to a rapidly stirred solution of 2.0 g $Cu(OAc)_2.H_2O$ (see ***Copper(II) Acetate***) in 50 mL of hot acetic acid. After 30 s the couple was allowed to settle, decanted, and washed once with acetic acid and three times with ether. A less reactive couple can be prepared from granular zinc using the same procedure. Modified procedures for preparing zinc-copper couples are given in many of the references.

Handling, Storage, and Precautions: zinc-copper couple deteriorates in moist air and should be stored under nitrogen. Very active zinc-copper couple is oxygen sensitive. It evolves hydrogen on contact with strong aqueous acids.

Introduction.

Zinc-copper couple is an active form of zinc metal, and for many reactions the presence of copper does not appear to exert any special influence beyond activating the surface of the zinc. Many of the reactions of zinc-copper couple could probably be effected using zinc metal activated in situ with ***Chlorotrimethylsilane*** or ***1,2-Dibromoethane***,[6] but the advantage of zinc-copper couple is that it is a storable form of activated zinc that is easily prepared and handled.

Simmons-Smith Cyclopropanation.[1,7]

Zinc-copper couple reduces ***Diiodomethane*** to generate ***Iodomethylzinc Iodide***, which is in equilibrium with bis(iodomethyl)zinc and zinc iodide.[8] This Simmons-Smith reagent is widely used to cyclopropanate alkenes. As shown in eqs 1 and 2, the cyclopropanation is stereospecific, with methylene adding cis to the starting alkene.[7]

(1)

(2)

Hydroxyl groups or sterically accessible ethers will direct the Simmons-Smith reagent to the proximate face of an alkene,[9] and this stereoselectivity has been used extensively in synthesis (eq 3).[10]

(3)

One important application of directed cyclopropanation is the stereoselective introduction of methyl groups in terpene synthesis. In eq 4 the allylic alcohol is again used to direct the cyclopropanation to the desired face of the ketone.[11] Oxidation to the ketone and lithium-ammonia reduction gave the β-methyl ketone. This stepwise approach to β-methyl substitution of an enone complements a ***Lithium Dimethylcuprate*** addition because it can be carried out on β-disubstituted enones and the stereochemistry is reliably predictable based on the alcohol stereochemistry.

(4)

Wenkert developed an alternative to the classic alkylation of ketones by cyclopropanating the derived enol ether, followed by acid catalyzed hydrolysis of the cyclopropyl ether. This sequence was used to introduce the angular methyl group of (-)-valeranone with complete control of stereochemistry (eq 5).[12]

Mash has found that optically pure acetals prepared from chiral diols and cycloalkanones will cyclopropanate with good diastereoselectivity (eq 6), presumably through selective coordination of the Simmons-Smith reagent to the more accessible acetal oxygen. Hydrolysis of the acetals leads to bicyclo[*n*.1.0]alkanones in good to excellent optical purity.

Alkyl Zinc Preparations and Reactions.

Dialkylzinc compounds have been prepared from the corresponding alkyl iodides and zinc-copper couple,[13] but are more commonly prepared using activated zinc or from the appropriate Grignard reagent and ***Zinc Chloride***. Zinc-copper couple is useful for preparing a variety of unusual alkyl zinc compounds such as (iodomethyl)zinc iodide. Apart from cyclopropanations, (iodomethyl)zinc iodide reacts with ***Tri-n-butylchlorostannane*** to give ***RI031M***, an important reagent in the preparation of α-alkoxylithium reagents (eq 7).[14]

Propargyl bromide (see ***Propargyl Chloride***) reacts with zinc-copper couple in the presence of an aromatic aldehyde to produce the alkyne adduct in good yield (eq 8). Presumably the allenylzinc bromide is formed in situ and reacts with 1,3-rearrangement; none of the allene adduct is reported.[15]

Yoshida's group found that zinc-copper couple was very effective in the preparation of zinc homoenolates and bishomoenolates. Reaction of ethyl 4-iodobutyrate with zinc-copper couple in benzene and DMA gave the homoenolate (**1**), which coupled with acyl chlorides, vinyl iodides, or vinyl triflates in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** (eq 9).[16]

Zinc homoenolates prepared in this manner can be transmetalated to titanium homoenolates and coupled with aldehydes (eq 10),[17] or reacted with ***t-Butyldimethylchlorosilane*** to give the cyclopropyl ethers.[18]

Zinc-copper couple leads to higher yield and faster reactions in the Reformatsky reaction than the more commonly used zinc metal (eq

11).[19]

Semmelhack reported an unusual cyclization reaction that probably proceeds through an allylic zinc intermediate (eq 12).[20] Model cyclizations were carried out using allylic bromides, but the actual cyclization was performed on the allylic sulfonium salt. In contrast to the result with zinc-copper couple, cyclization of the sulfonium salt intermediate with ***Bis(1,5-cyclooctadiene)nickel(0)*** gave the other *cis*-fused lactone in 43% overall yield.

Conjugate Additions of Alkyl Iodides to Alkenes.

An intriguing new carbon-carbon bond forming reaction has been developed that promises to be very useful in synthesis. Luche's group found that alkyl iodides will add to alkenes bearing a strong electron-withdrawing group when sonicated with zinc-copper couple in an aqueous solvent.[21] This reaction is notable because the conditions are very mild, it is compatible with many reactive functional groups, and moderately hindered carbon-carbon bonds can be formed in good yield. Luche proposed that the reaction proceeds through a radical intermediate generated in the reduction of the alkyl iodide with zinc-copper couple, but the evidence is not completely clear. When the reaction is conducted in a solvent system with a good deuterium atom donor and a good proton source, the proton is incorporated into the product, whereas when the role of the hydrogen and deuterium are reversed, deuterium is incorporated into the product (eq 13).[2]

A radical intermediate should give the opposite incorporation pattern, but Luche invokes a rapid reduction of the α-keto radical to give the enolate, which would give the observed incorporation. Thus the addition can still proceed through a radical even though the quenching is ionic. The best direct evidence of radical involvement is cyclization of the radical intermediate in eq 14, but the yield is quite low.

Several other features of this reaction are noteworthy: both water and copper are required, and (*S*)-octyl iodide couples well but leads to a racemic product.

The conjugate addition reactions of alkyl iodides work well in complex and highly functionalized molecules. The side chain of a vitamin D analog was prepared using the reaction shown in eq 15.[22] Unlike most transition metal-catalyzed reactions, this procedure did not affect the vinyl triflate.

Surprisingly, the coupling reaction will also work in carbohydrate systems. The alkyl iodide derived from ribose was coupled in good yield

with 2-butenenitrile (eq 16), without undergoing reductive elimination to form an alkene.[23] This new coupling procedure promises to be very useful in synthesis.

(16)

Reductive Coupling of Carbonyl Compounds.

Carbonyl compounds can be reductively dimerized to diols or alkenes. A pinacol cross-coupling reaction between α,β-unsaturated ketones and acetone has been reported. When carvone is sonicated with zinc dust and ***Copper(II) Chloride*** in acetone/water, the cross-coupling product is isolated in 92% yield (eq 17).[24] Acetone itself does not dimerize under the reaction conditions, and β,β-disubstituted enones fail to react, presumably due to a higher reduction potential.

(17)

The McMurry coupling uses low valent titanium to reductively dimerize carbonyl compounds to alkenes.[25] The reagent is usually prepared from ***Titanium(III) Chloride*** and an added reducing agent like ***Potassium***, ***Lithium***, or ***Lithium Aluminum Hydride***. One of the best reagents is prepared from $TiCl_3(DME)_{1.5}$ and zinc-copper couple (eq 18).[26] The same dimerization gives only 12% yield with $TiCl_3/LiAlH_4$.

(18)

Preparation of Dichloroketene.

Dichloroketene can be prepared by reducing ***Trichloroacetyl Chloride*** with zinc-copper couple.[3] Dichloroketene undergoes facile [2 + 2] cycloadditions with alkenes[27] and alkynes[28] to give cyclobutanones and cyclobutenones.[29] Recently the use of a chiral auxiliary has been reported to control the facial selectivity of dichloroketene additions (eq 19).[30] Ring expansion with ***Diazomethane*** gave the dichlorocyclopentanone, and subsequent reduction removed the chiral auxiliary and gave the optically enriched cyclopentenone.

Dichloroketene will react with vinyl sulfoxides to give γ-lactones with efficient stereochemical transfer from the sulfoxide stereogenic center (eq 20).[31] Optically pure vinyl sulfoxides give lactones with high enantiomeric excesses. The chlorine atoms can be removed by reduction with zinc-copper couple or ***Aluminum Amalgam*** to give the lactone.

(20)

Reduction of α-halo acyl chlorides normally gives ketenes, but Hoffmann has reported an unusual reductive trimerization of 1-bromocyclopropanecarbonyl chloride that does not proceed through the corresponding ketene.[32] Reduction with zinc-copper couple in MeCN gave the unusual trimer in 20% yield (eq 21), whereas the corresponding ketene is known to dimerize. Hoffmann suggests that a Reformatsky-type intermediate may react with a second molecule of acyl chloride rather than eliminating to generate the ketene.

(21)

Preparation of 2-Oxyallyl Cations.

Zinc-copper couple reduces α,α´-dibromo ketones to zinc oxyallyl cations, and these allyl cations will undergo [3 + 4] cycloadditions with dienes (eq 22).[33]

(22)

The original procedure used zinc-copper couple directly, but more recently sonicating the reactions has been reported to improve the yields significantly: the coupling in eq 23 gives 60% yield without sonication and 91% yield with sonication.[4]

(23)

These reactions can be carried out using ***Nonacarbonyldiiron*** as the reducing agent in comparable yield, but the iron reagent is quite toxic and does not offer any advantage in simple cases.[34]

Reduction of α,α´-dibromo ketones under slightly different conditions, using *N*-methylformamide as the solvent without diene or sonication, leads to 1,4-diketones (eq 24).[35] Unsymmetrically substituted ketones give statistical mixtures of products.

(24)

Reduction of 1,2- and 1,3-Dihalides and Halo Ethers.

Zinc-Acetic Acid is commonly used to reduce 1,2-dihalides to alkenes. Several modifications of this procedure use zinc-copper couple as the reducing agent.[36] Bromooxiranes prepared from allyl alcohols are reduced with zinc-copper couple and sonication to give the 1,3-transposed allylic alcohol (eq 25).[37] The oxirane ring strain facilitates the alkene formation; notice that the tetrahydrofuran in eq 16 does not form an alkene.

(25)

The 2,2,2-trichloroethyl group is used as a protecting group for many functional groups such as carboxylic acids and carbamic acids (amines), and is usually removed by reduction with zinc metal. In some cases it is advantageous to remove these protecting groups with zinc-copper couple.[38]

Under forcing conditions, oxiranes can be reduced to the corresponding alkene. Reaction of eupachloroxin with zinc-copper couple in refluxing ethanol for 3 d gave eupachlorin without reducing the many other functional groups in the molecule (eq 26).[39] The reduction is stereoselective: *cis*-oxiranes give *cis*-alkenes and *trans*-oxiranes give *trans*-alkenes.

Reduction of 1,3-dibromides with zinc-copper couple gives cyclopropanes (eq 27).[40] Cyclopropanes are also formed when 2-bromoethyloxiranes are reduced using zinc-copper couple with sonication.[41]

Reduction of C-C Multiple Bonds.

Alkenes with powerful electron-withdrawing groups like esters, ketones, or nitriles are reduced with zinc-copper couple in refluxing methanol (eq 28).[42] Isolated alkenes are not reduced.

Unactivated alkynes are reduced to (*Z*)-alkenes under the same conditions.[43] Terminal alkynes are reduced to vinyl groups without the over-reduction that can sometimes accompany Birch-type reductions. This reduction was recently applied to the synthesis of leukotriene B_4 (eq

29).[44]

Reduction of Other Functional Groups.

Zinc metal has been used to reduce many functional groups and zinc-copper couple would be effective in most of these reactions. Zinc-copper couple reduces alkyl halide to the corresponding hydrocarbon, and in the presence of D_2O this leads to an expedient synthesis of specifically deuterated materials (eq 30).[45]

Aromatic nitro compounds are reduced to the protected hydroxylamines, *N*-acetoxy-*N*-acetylarylamines, with zinc-copper couple in the presence of acetic acid and acetic anhydride. In contrast, zinc metal reduces 4-nitrostilbene to azoxystilbene.[46] Oximes can be reduced to amines with zinc-copper couple, and this procedure is reported to be much more effective than an ***Aluminum Amalgam*** reduction (eq 31).[47]

Related Reagents.

Chloroiodomethane-Zinc/Copper Couple; ***Dibromomethane-Zinc/Copper Couple***; ***Potassium Iodide-Zinc/Copper Couple***; ***Titanium(III) Chloride-Zinc/Copper Couple***.

Zinc Cyanide[1]

$Zn(CN)_2$

[557-21-1] · C_2N_2Zn · Zinc Cyanide · (MW 117.43)

(mild Lewis acid used as an alternative to HCN in Gattermann formylation reactions, in the synthesis of α-cyanoenamines, and in the cyanosilylation of carbonyl compounds)

Physical Data: mp 800 °C (dec).

Solubility: practically insol water, alcohols; sol aq solutions of alkali cyanides.

Form Supplied in: white crystalline powder, with alkali metal chlorides as possible impurities. *Drying:* one of the cyanides most stable to heat, it volatilizes only to a small extent on strong heating.[2]

Preparative Methods: can be made by the action of cyanogen on the metal at 300 °C, by dissolving ***Zinc Oxide*** in ***Hydrogen Cyanide***, or by a metathetical reaction (see below).

Handling, Storage, and Precautions: as required by national poisons rules; extremely toxic by ingestion, inhalation, and skin contact. Irritating to the eyes. All work must be carried out in an efficient fume hood.

Gattermann Reactions.

In the classical Gattermann aldehyde synthesis, hydrogen cyanide and ***Hydrogen Chloride*** are used together with a Lewis acid such as ***Aluminum Chloride*** or ***Zinc Chloride***. In the Adams modification,[3] zinc cyanide is used together with hydrogen chloride as a more convenient reagent system, effectively generating hydrogen cyanide and zinc chloride. Any phenol that can be formylated using the classical Gattermann reaction conditions can be converted equally well into a hydroxy aldehyde by the Adams method. Pure zinc cyanide is said to be ineffective but may be activated by the addition of potassium chloride.[4]

Although the mechanism of the Gattermann reaction has not been investigated in detail, it is known that an initial nitrogen-containing product is hydrolyzed to the aldehyde (eq 1). It has been suggested that the electrophile may be a protonated dimer of HCN.[5] In some cases the hydrocyanic acidium ion may be involved; in others, a Lewis acid complex could be formed between hydrogen cyanide and, for example, zinc chloride or aluminum chloride. In this connection, a very high acidity is required for reaction to occur with benzene; evidence has been presented in favor of a diprotonated HCN in that case.[6] In reactions involving the system $Zn(CN)_2$-HCl-$AlCl_3$, a relative rate for the formylation of toluene versus benzene (K_T/K_B) of 128 was obtained.[7]

$$\mathrm{ArH} + \mathrm{Zn(CN)_2} \xrightarrow{\mathrm{HCl}} \mathrm{ArCH{=}\overset{+}{N}H_2\ Cl^-} \xrightarrow{\mathrm{H_2O}} \mathrm{ArCHO} \qquad (1)$$

Early examples showed that both α- and β-naphthol could be formylated in good yields, in the absence of a Lewis acid other than the zinc chloride, as indicated (eq 2).[3a] Anisole (eq 3) and resorcinol dimethyl ether are converted in good yields into the expected aldehydes in the presence of added aluminum chloride.[3b] Another improvement in the experimental procedures involves the use of tetrachloroethane as the solvent; this method has been used in the formylation of hindered systems such as 1,3,5-triisopropylbenzene.[8] A detailed and checked method for the preparation of mesitaldehyde is available.[9] The first stage in the synthesis of a number of fungal metabolites involves the formylation of orcinol at the 4-position.[10] Another recent example is shown in eq 4,[11] and others are known.[12] As with Friedel-Crafts alkylation and acylation reactions of alkylarenes, it is not unusual to observe rearrangement of the substrate in the presence of aluminum chloride. Thus, although 2,3-dimethylnaphthalene was formylated to give the expected product at 55 °C, at temperatures in excess of 65 °C 1-formyl-2,4-dimethylnaphthalene was formed in good yield (eq 5).[13]

(2)

(3)

(4)

(5)

Electron-rich heterocycles are formylated particularly easily; the product shown in eq 6 was obtained in a quantitative yield.[14]

(6)

The reaction of a suitably activated phenylacetonitrile can lead to the formation of isoquinoline derivatives. The method can be regarded as a modification of the Gattermann reactions of 3,5-dihydroxybenzyl ketones, which lead to the corresponding 3-alkyl-6,8-dihydroxyisoquinolines. The cyclization of the intermediate imine was assumed to occur during the workup.[15] In the reaction of 3,5-dimethoxyphenylacetonitrile using zinc cyanide and either ***Hydrogen Bromide*** or hydrogen chloride (eq 7), ^{15}N-labeling showed that the nitrogen in the product came from the zinc cyanide.[16] It is noteworthy that two activating substituents are required; an attempted reaction was unsuccessful using 3,4-dimethoxyphenylacetonitrile. β-Oxoaldimines are formed when ketones such as deoxybenzoin are reacted under Gattermann conditions.[17] Hydrolysis of the products leads to β-keto aldehydes and so, with a suitable phenol, a one-step synthesis of an isoflavone can be accomplished.[18] This method is exemplified in the synthesis of pseudobaptigenin (eq 8).[19]

(7)

(8)

Cyanoenamine Formation.

A number of methods are available for the conversion of α-chloroenamines into α-cyanoenamines. The α-chloroenamines, which can function as keteniminium chlorides, are able to undergo nucleophilic substitution with cyanide ion. Substrates such as 1,2-dichloro-*N*,*N*-dimethylpropenylamine (eq 9) require a Lewis acid catalyst, and zinc cyanide in chloroform was found to be satisfactory.[20]

(9)

Cyanosilylation of Carbonyl Compounds.

A development from an in situ procedure, in which ***Chlorotrimethylsilane*** and a cyanide are used to replace ***Cyanotrimethylsilane***,[21] uses zinc cyanide to obtain cyanohydrin trimethylsilyl ethers (eq 10)[22] in good yields.[23] Other silylated cyanohydrins have been prepared by a development of the in situ method.[24] For example, 1-benzenesulfonyl-2-formylpyrrole was converted into its cyanohydrin *t*-butyldimethylsilyl ether, and piperonal into the *t*-butyldiphenylsilyl and triisopropylsilyl analogs in very high yields by using ***Potassium Cyanide***, ***Zinc Iodide***, and the appropriate chlorosilane.

Zinc-1,2-Dibromoethane[1]

Zn-$BrCH_2CH_2Br$

(Zn)

[7440-66-6] · Zn · Zinc-1,2-Dibromoethane · (MW 65.39) ($BrCH_2CH_2Br$)

[106-93-4] · $C_2H_4Br_2$ · Zinc-1,2-Dibromoethane · (MW 187.86)

(combination reagent used for the regio- and *cis*-stereospecific reduction of alkynes)

Physical Data: zinc: mp 419.5 °C; *d* 7.140 g cm^{-3}; 1,2-dibromoethane: mp 9-10 °C; bp 131-132 °C; *d* 2.18 g cm^{-3}.

Solubility: 1,2-dibromoethane: sol alcohol, ether, acetone, benzene.

Form Supplied in: zinc: dust, foil, granular, mossy, pieces, powder, shot, splatter, sticks, wire; 1,2-dibromoethane: clear oil.

Preparative Method: the reducing agent is prepared by refluxing Zn and 1,2-dibromoethane in ethanol until evolution of ethylene has subsided.

Purification: the reducing agent is not purified prior to use.

Handling, Storage, and Precautions: for specific information, consult ***Zinc*** and ***1,2-Dibromoethane***.

General Discussion.

1,2-Dibromoethane-activated zinc serves as a versatile, mild reducing agent for alkynes. The products are exclusively (*Z*)-alkenes with yields ranging from 70-90%.[1] In substrates containing two differentiated alkyne linkages the reagent exhibits selectivity. Conjugated triple bonds are reduced preferentially over nonconjugated bonds. Terminal alkynes are reduced over internal alkynes (eq 1). However, if the terminal alkyne has an appending silyl group, the internal bond is reduced (eq 2).

(1)

(2)

Hetero-substituted diynes yield products with the triple bond nearest the heteroatom being reduced. Sulfur does not poison the

reaction: 2-thienylacetylene was converted to 2-vinylthiophene (80%). Other heteroatoms (OR, NR_2) are also stable under these conditions.

The activity of this reagent can be improved, at the expense of selectivity, by adding ***Copper(I) Bromide*/*Lithium Bromide*** to the zinc/1,2-dibromoethane mixture prior to the addition of the substrate.[2] Under these conditions, monoalkynes containing a heteroatom (OR, NR_2) are reduced to (*Z*)-alkenes. Sulfides are not reduced under these conditions.

Zinc-Dimethylformamide[1]

Zn-Me_2NCHO

(Zn)

[7440-66-6] · Zn · Zinc-Dimethylformamide · (MW 65.39) (DMF)

[68-12-2] · C_3H_7NO · Zinc-Dimethylformamide · (MW 73.11)

(reducing agent for halides,[3] azides,[10] and aldehydes[11])

Physical Data: zinc: mp 419.5 °C; *d* 7.140 g cm^{-3}; DMF: bp 153 °C; *d* 0.944 g cm^{-3}.

Solubility: sol DMF, THF, Et_2O, toluene, alcohol.

Preparative Methods: see text.

Handling, Storage, and Precautions: see ***Zinc*** and ***N,N-Dimethylformamide***.

Reduction of Halides.

The first use of a mixture of zinc and DMF as a dehalogenating reagent was employed by Alder and Fremery in 1961.[1] In a study of formation of *ortho* biradicals, they employed Zn/DMF to reduce α,α´-dibromoxylene (eq 1) which generated unstable 5,6-dimethylene-1,3-cyclohexadiene. This diene undergoes a Diels-Alder reaction with dienophiles like ***Acrylonitrile***, ***Acrolein***, and ***Ethyl Acrylate*** in high yield. A similar reaction has also been employed in the dimethylenecyclooctatriene system.[2]

(1)

A systematic study of Zn/DMF as a dehalogenating reagent was investigated by Mehta and Kapoor.[3] It was found that ordinary zinc powder reacts with a variety of alkyl halides in DMF to furnish the corresponding organozinc compounds. Aqueous decomposition of these solutions gave the expected hydrocarbons in good yield. The procedure is a satisfactory alternative for dehalogenation when the commonly employed hydride complexes[4] or metal amines[5] cannot be used. For example, 8,15-dibromolongibornan-9-one was reduced to longibornan-9-one in 82% yield using Zn/DMF (eq 2).

(2)

In a subsequent study, reaction of dibromocyclopropane with Zn/DMF gave monobromocyclopropane (eq 3), allene (eq 4), or a mixture of

products (eq 5), depending on the ring system of the substrate.[6] Thus no generalization could be made. The yields of some of the products formed from *gem*-dibromocyclopropanes were comparable to those obtained by other methods.

(3)

(4)

(5)

Reduction of Azides.

Carbohydrate azides are valuable intermediates for the synthesis of amino sugars. This transformation is commonly brought about by catalytic reduction[7] or by treatment with ***Lithium Aluminum Hydride***[8] or ***Sodium Borohydride***.[9] Ohrui and Emoto discovered that Zn/aq DMF is an excellent reagent to reduce an azide group to the corresponding amine group (eq 6).[10] This reaction was complete in 45 min whereas the corresponding sodium borohydride reduction required 20-30 h.

Reduction of Aldehydes to Alcohols.

A mixture of Zn and ***Antimony(III) Chloride*** in aqueous DMF reduces aldehydes to the corresponding alcohols in excellent yield.[11] A variety of aliphatic (eq 7), aromatic (eq 8), and α,β-unsaturated (eq 9) aldehydes were reduced to alcohols under relatively mild conditions.

Zinc-Graphite[1]

Zn-Gr

[7440-66-6] · Zn · Zinc-Graphite · (MW 65.39)

(very highly activated form of zinc, able to convert halides into organozinc species under mild conditions;[2,3] eliminates α-oxy halides to alkenes[4])

Solubility: insol in all common solvents; compatible with THF and other ethereal solvents.

Preparative Methods: ***Potassium-Graphite*** is prepared by reaction between ***Potassium*** metal and degassed graphite at 150 °C. When cool the potassium graphite is suspended in THF. ***Zinc Chloride*** is added and a very vigorous reaction ensues before the THF is heated to reflux to ensure complete reaction. Zinc/silver-graphite is prepared by the addition of 10 mol % ***Silver(I) Acetate*** to the zinc chloride mixture. These preparations have only been reported on a 15 mmol scale; because molten potassium is used and the reduction of zinc chloride is highly exothermic, great caution should be exercised in any scale-up.[3,5]

Handling, Storage, and Precautions: the reagent consists of highly active metal particles; it should be handled under argon and used immediately after preparation.

Introduction.

The reagent prepared by reduction of zinc chloride with potassium graphite does not consist of intercalated zinc; instead, very fine particles of zinc are deposited upon the graphite, which serves as an inert carrier.[1a] A comparison of the conditions required to condense ethyl bromoacetate with cyclohexanone was used to demonstrate that more active zinc is formed by this method than by other activation methods. The superiority of zinc/silver-graphite over simple zinc-graphite is also apparent (Table 1).[5]

Table 1 Comparison of Zinc Reagents

Zinc reagent	Temp. (°C)	Yield (%)
Zinc dust	80	56
Zn Cu couple	66	82
Rieke zinc	25	95
$ZnCl_2$/Li naphthalenide	25	95 98
Zinc graphite	0	75
Zinc/silver graphite	- 78	92

The advantages of using zinc-graphite are that the workup of the reaction is simple, substrates formerly considered as poor may be converted to zinc reagents in good yield and, because low temperatures are used, stereocontrol may be better. Graphite may be removed from the reaction mixtures after quenching by simple filtration, in contrast to the soluble reagents like naphthalene used in Rieke and similar methods, which are usually removed by chromatography.

Organozinc Reagents.

Zinc-graphite and zinc/silver-graphite have been used to generate organozinc reagents from α-chloro[2,3] and α-bromo[2,3] esters and lactones, γ-bromo crotonates,[3,5] allylic bromides,[3,6] and 2-bromomethyl-2-propenoates.[3,7]

One class of substrate where the high reactivity of zinc/silver-graphite has been used to effect a previously difficult transformation is α,α-dihaloacetates. Use of zinc/silver-graphite allows the synthesis of α-halo-β-hydroxy esters in excellent yield.[8] If ***Potassium Carbonate*** is added during workup, then glycidic esters may be isolated directly (eq 1).[8]

Examples of the improved stereoselectivity achievable by the use of zinc/silver-graphite have been found in the reactions of 2-bromomethyl-2-propenoates with chiral ketones (eq 2).[5,7]

Zn dust 50 °C, 1 h	41	35	24
Zn/Ag-Gr -78 °C, 10 min	0	96	0

Eliminations.

The use of zinc/silver-graphite for the synthesis of glycals and eliminative ring opening of sugar derivatives has been reviewed.[1a] The advantages of using zinc/silver-graphite are that yields are high and, because low temperatures are used, most protecting groups are compatible.

The conversion of glycosyl bromides to glycals is typical of these reactions (eq 3). This reaction can not be carried out using Rieke zinc. In the presence of azido groups, either in the substrate or in another compound in the flask, the mechanism changes and reduction occurs (eq 3). This type of elimination has found application in a novel unmasking reaction used by Ireland in an approach to FK506 synthesis.[9]

Related Reagents.

Zinc Iodide[1]

ZnI_2

[10139-47-6] · I_2Zn · Zinc Iodide · (MW 319.19)

(used in the preparation of organozinc reagents via transmetalation;[1] a mild Lewis acid useful for promoting addition[2] and substitution reactions[3])

Physical Data: mp 446 °C; bp 625 °C (dec); *d* 4.740 g cm^{-3}.

Solubility: sol H_2O (1 g/0.3 mL), glycerol (1 g/2 mL); freely sol EtOH, Et_2O.

Form Supplied in: white, odorless, granular solid; principal impurities are H_2O and iodine.

Analysis of Reagent Purity: mp.

Purification: heat to 300 °C under vacuum for 1 h, then sublime.

Handling, Storage, and Precautions: very hygroscopic and light sensitive; store under anhydrous conditions in the absence of light.

Organozinc Reagents.

Organozinc reagents may be prepared through transmetalation of organolithium, organomagnesium, and organocopper species with ZnI_2, although ***Zinc Chloride*** and ***Zinc Bromide*** are used far more frequently.[1a] It is more usually the case that organozinc iodides are prepared by zinc insertion into alkyl iodides using ***Zinc/Copper Couple***.[1a] These zinc reagents possess reactivity analogous to the other organozinc halides, finding particular use in palladium-catalyzed coupling reactions (eq 1).[4] An alternative method for the preparation of the Simmons-Smith reagent (***Iodomethylzinc Iodide***) involving the treatment of ***Diazomethane*** with ZnI_2 has been reported (eq 2).[5]

(1)

$$CH_2N_2 + ZnI_2 \longrightarrow ICH_2ZnI + N_2 \qquad (2)$$

Cycloaddition Reactions.

The catalytic effect of ZnI_2 on the Diels-Alder reaction has been noted (eq 3),[6] but its use in such cycloaddition reactions is rare compared with $ZnCl_2$ and $ZnBr_2$.

(3)

Activation of C=X Bonds.

Catalysis of aldol condensation reactions using silyl ketene acetals and ZnI_2 has been the subject of several studies.[7] It is observed that ZnI_2 favors the activation of functionalized carbonyl compounds via β-chelates to impart useful stereoselectivity (eq 4).[7a] In analogous fashion, diastereoselective additions to imines and nitrones have been reported which offer useful access to β-lactams (eq 5).[8] α,β-Unsaturated esters are subject to conjugate addition reactions by silyl ketene acetals, also through the agency of ZnI_2 activation (eq 6).[9]

(4)

(5)

(6)

An important role for ZnI_2 has been found in the catalysis of R_3SiCN addition to ketones and aldehydes to afford silyl protected cyanohydrins.[10] This is a very general reaction that is effective even with very hindered carbonyl compounds (eq 7).[11] Diastereoselective

cyanohydrin formation has been reported when these reaction conditions are applied to asymmetric carbonyl substrates (eq 8).[2a]

(7)

(8)

Activation of C-X Bonds.

The Lewis acidity of ZnI_2 may be exploited to activate various carbon-heteroatom bonds to nucleophilic substitution. Treatment of epoxides and oxetanes with ***Cyanotrimethylsilane***/ZnI_2 results in selective C-N bond formation with ring opening (eq 9).[12] Similarly, C-S and C-Se bonds may be formed by treating cyclic ethers with ZnI_2 and $RSSiMe_3$ and $RSeSiMe_3$, respectively (eq 10).[13]

(9)

(10)

Treatment of 4-acetoxy- and 4-sulfoxyazetidin-2-ones with ZnI_2 results in the formation of the corresponding imine or iminium species which subsequently suffers silyl-mediated addition. These reactions result in the formation of *trans* substitution (eqs 11 and 12).[14,15]

(11)

(12)

$(R^1 = Me, R^2 = H):(R^1 = H, R^2 = Me) = 3:1$

Substitution reactions of orthoesters[3b] and acetals,[3c] including anomeric bond formation in carbohydrates (eq 13),[16] have been catalyzed by ZnI_2.

(13)

Reduction.

Allyl and aryl ketones, aldehydes, and alcohols are reduced to the corresponding hydrocarbon by ***Sodium Cyanoborohydride***/ZnI_2 (eq 14).[17] This is a reasonably reactive reducing mixture which will also attack nitro and ester groups.

(14)

Deprotection.

Methyl and benzyl ethers may be cleaved by the combination of ***(Phenylthio)trimethylsilane***/ZnI_2 (eq 15).[18] Similar cleavage of alkyl and benzyl ethers takes place using ***Acetic Anhydride***/ZnI_2 to afford the corresponding acetate (eq 16).[19]

Zinc/Nickel Couple[1]

Zn/Ni

[7440-66-6] · Zn · Zinc/Nickel Couple · (MW 65.39)

(reducing reagent for a variety of organic functional groups;[2] coupling agent for alkenyl and aryl halides;[3] induces addition of organic halides to alkenes;[4] reagent for Simmons-Smith cyclopropanation[5])

Physical Data: dark gray powder, of variable composition.

Preparative Methods: the zinc/nickel couple is usually prepared from zinc dust and ***Nickel(II) Chloride*** or ***Nickel(II) Bromide*** (dry or hydrate). Zinc dust (10 g) suspended in water (3 mL) and 4.04 g of $NiCl_2.6H_2O$ were added to 10 mL of water at 60 °C. After disappearance of Ni^{II} coloration, the solid is filtered, washed, and dried under reduced pressure. The couple is frequently prepared immediately before use. It can be prepared in the presence of the organic substrates in alcohols or DMF, etc., and in the presence of ***Triphenylphosphine***, ***Potassium Iodide***, or ***Pyridine***. Sonication at room temperature improves both the preparation and the reaction step.

Handling, Storage, and Precautions: the Zn/Ni couple seems to have good stability in air.

Hydrogenation Reagent.

Many organic functionalities can be reduced by the zinc/nickel couple in water or aqueous organic solvents.[1,6] It has been reported that nitriles are reduced to primary amines with almost no secondary amine (eq 1),[2] but this result has not been confirmed. Nitro groups are reduced to amines in high yields (eq 2).

Halides, alkenes, saturated aldehydes, and ketones react readily with the Zn/Ni couple.[1,2] Water is essential as the source of hydrogen. Hydrogenation of alkenes proceeds rapidly, but that of carbonyl groups more slowly. Although original reaction conditions involved heating, improved yields were obtained by sonication (eq 3).[7,8] Adjusting the pH (eq 4) and the nickel to zinc ratio (eq 5) change the selectivity. Use of D_2O instead of water as the hydrogen source yields 1,2-dideuterated alkanes.[9]

(4)

(5)

Coupling of Alkenyl and Aryl Halides.

Alkenyl halides couple to provide dienes in the presence of Zn, $NiCl_2$, and ***Potassium Iodide*** (eqs 6 and 7). The KI helps the formation of the Zn/Ni couple and exchanges the substrate halogen atom for iodine.[3] Reaction with Ni^0 occurs in the next step, followed by the coupling itself. Chlorides do not react. Generally, one alkenic unit retains its configuration, but the second one is frequently isomerized (eq 7).

(6)

(7)

Aryl and heteroaryl halides undergo the Ullmann coupling in high yields under mild conditions.[10] The method was used in cyclophane synthesis (eq 8).[11] Aryl trifluoromethanesulfonates are equally successfully coupled under sonication (eq 9).[12]

(8)

(9)

Additions of Alkyl, Alkenyl, or Aryl Groups to Alkenes.

The Zn/Ni couple is an example of the new class of reagents that permit organometallic-like reactions under nonanhydrous conditions (see also ***Zinc/Copper Couple***). With styrene, a Heck-type addition-elimination sequence is observed (eq 10).[4] A Reformatsky-like reaction occurs between ethyl difluoroiodoacetate and nonactivated alkenes (eq 11).[13] Conjugate additions take place with activated alkenes (eq 12), even when alkenyl or aryl halides are used which are inert with the Zn/Cu couple.[14]

(10)

(11)

Cyclopropanation.

Electron-deficient alkenes undergo the Simmons-Smith cyclopropanation in the presence of NaI and ***Dibromomethane*** (eq 13). With fumarate and maleate esters, the reaction proves to be nonstereoselective, in contrast to the zinc/cobalt couple.[5]

Zinc Oxide

ZnO

[1314-13-2] · OZn · Zinc Oxide · (MW 81.39)

(mild base; forms salts which effect tertiary alkyl halide solvolysis;[1] acid scavenger;[2] catalyst of aldol,[3] Wittig,[4] Knoevenagel,[4] and other reactions)

Physical Data: mp 1975 °C; *d* 5.47 g cm^{-3}.

Solubility: insol H_2O, alcohol; sol acids, alkalis.

Form Supplied in: the commercial material is often obtained as a coarse white or grayish powder. This has a much lower water content and surface area[4] than that produced by drying $Zn(OH)_2$, and for some reactions is much less suitable.

Preparative Methods: by drying $Zn(OH)_2$,[4] precipitated from $Zn(NO_3)_2$ by addition of NaOH.

Handling, Storage, and Precautions: reputedly nontoxic as powder, but ZnO fume is harmful by inhalation. Should be stored sealed, as it will absorb CO_2 from air.

Tertiary Alkyl Halide Solvolysis.[1]

ZnO (or ***Zinc Carbonate***) reacts with carboxylic acids to form zinc salts. These salts, either preformed or formed in situ, react with tertiary (but not reliably with primary, secondary, or α-carbonyl-substituted) halides to give the corresponding esters (eq 1). Five equiv of the acid as solvent (in situ generation) or aprotic solvents are suitable. Similarly, in aqueous (e.g. 80% aq acetone), alcoholic, or phenolic solvents, ZnO causes formation of the alcohol or appropriate ether (eq 2). The former reaction is particularly useful for formation of *t*-butyl esters (yields 91-95%), as a protection for carboxylic acids.

$$Zn(OCOR)_2 + t\text{-}R^1\text{-}Hal \longrightarrow t\text{-}R^1OCOR \qquad (1)$$

$$t\text{-}R^1\text{-}Hal \xrightarrow[ROH]{ZnO} t\text{-}R^1OR \qquad (2)$$

Acid Scavenger.[2]

The presence of small quantities of ZnO (and/or ***Potassium Carbonate***) is reported to improve yields greatly in particularly acid-sensitive *o*-quinodimethane reactions. Such activity could find more general use.

Basic/Amphoteric Catalyst.

ZnO gave a good yield in an intramolecular aldol reaction (eq 3),[3] slightly superior to the use of other inorganic catalysts (TiO_2, ThO_2, ***Alumina***) (yields 73-75%).

(3)

ZnO (or ***Magnesium Oxide***) is also able to catalyze Wittig, Wittig-Horner, and Knoevenagel reactions.[4] Commercial ZnO may be rendered more efficient by addition of a limited amount of water or polar organic solvent. In a reaction where the Wittig-Horner and Knoevenagel pathways may compete (eq 4), the proportions of products (**1**) and (**2**) are greatly influenced by these small amounts of added solvents, or by addition of small amounts of other metal salts. Thus ***Hexamethylphosphoric Triamide*** favours formation of (**2**), but ***Mercury(II) Chloride*** or ***Cadmium Chloride*** (among others) favor (**1**). These results were rationalized in terms of properties of both basic and acidic sites on the catalyst surface, as also noted[5] as an explanation of the catalytic utility of ZnO in several industrial scale processes.

(4)

Two-carbon homologation of ketones is made possible via ZnO-catalyzed rearrangement of alkynic acetates (**3**) (eq 5).[6] The allenic acetate (**4**) is then easily hydrolyzed to the α,β-unsaturated aldehyde.[6b]

Zinc/Silver Couple

Zn/Ag

[7440-66-6] · Zn · Zinc/Silver Couple · (MW 65.39)

(dehalogenation; preparation of organozinc compounds for carbon-carbon bond formation; cyclopropanations)

Physical Data: Zn: mp 419.5 °C; *d* 7.140 g cm^{-3}.

Solubility: insol most solvents. The reactions are typically run as suspensions with THF as solvent for preparation of organozinc reagents and MeOH utilized for most of the reductions. Et_2O, DMSO, and DMA have also been used as solvents.

Preparative Methods: ***Zinc*** powder (100 g) is added all at once to a refluxing solution of ***Silver(I) Acetate*** (100 mg) in 200 mL of acetic acid. The mixture is stirred for 30 s and quickly cooled. The zinc/silver couple is isolated by decantation and washed with anhydrous ether (6 × 100 mL), dried under vacuum, and stored at room temperature.[1] An alternative method uses zinc dust that has been prewashed with 10% HCl and uses a slightly higher Ag to Zn ratio.[2]

Handling, Storage, and Precautions: Zn is a moisture-sensitive, flammable solid. The Zn/Ag couple appears to be stable for months at room temperature if stored under an inert atmosphere.

Reductions.

The Zn/Ag couple is a very effective reducing agent for carbon-halogen bonds. It has been used to dehalogenate β-chloro-α,β-unsaturated ketones in good yield (eqs 1 and 2).[2,3]

(1)

X = Cl, Br

(2)

Aldehydes and ketones can be protected as their 5,5-dibromo-1,3-dioxane derivatives by reaction with 2,2-dibromo-1,3-propanediol. This carbonyl protecting group introduces no new chirality and is stable to a number of reagents that would normally react with the carbonyl. These derivatives can be deprotected under neutral conditions using Zn/Ag couple (eq 3).[4]

(3)

The debromination of 1,2-dibromides to form the corresponding alkene can be accomplished with Zn/Ag couple, as shown for the preparation of the Dewar benzene derivative (eq 4).[5]

(4)

The final steps in the synthesis of one of the tricothecenes required the alkene and hydroxymethyl group to be simultaneously protected as the intramolecular bromo ether. The unraveling of the bromo ether was accomplished using Zn/Ag couple (eq 5).[6]

(5)

Zn/Ag couple has been utilized to debrominate selectively the bromohydrin penicillinate (eq 6). This produces a mixture of diastereomers in the ratio indicated.[7]

Reduction of the α-bromoacylphosphate produces the intermediate ketene which undergoes cycloaddition to produce the cyclobutanedione (eq 7). Attempts to prepare the acid chloride to use in place of the phosphate failed.[8]

Carbon-Carbon Bond Formation.

Zn/Ag couple is an effective alternative to the commonly employed ***Zinc/Copper Couple*** couple in the Simmons-Smith reaction. It is reportedly superior for cyclopropanations of α,β-unsaturated carbonyl compounds, conjugated alkenes, and alkenes derived from ketones (enol derivatives) because of increased reactivity, better yields, and short reaction times (eqs 8 and 9).[9]

(8)

(9)

The use of the Zn/Ag couple has been suggested for the large scale [4 + 3] cycloaddition of α,α,α´,α´-tetrabromoacetone and furan. The yield is lower than the iron carbonyl promoted reaction but has advantages in terms of economics and operational simplicity (eq 10).[10]

(10)

The synthesis of β,γ-unsaturated ketones from nitriles and allylic bromides has been improved by employing the Zn/Ag couple. The method is simple and provides the ketones in good to excellent yield. The use of crotyl or isopropenyl bromides results in the formation of the products from γ-attack (eq 11). The reactions can be run in ether, benzene, or THF. The use of THF tends to suppress Wurtz couplings.[1]

(11)

(Trimethylsilylmethyl)difluorochloropropene regioselectively couples with carbonyl compounds to afford 2,2-difluoro-3-[(trimethylsilyl)methyl]-3-butenols in good yield (eq 12).[11]

(12)

In a synthesis of steganone, the diketo dibromide was intramolecularly cyclized utilizing Zn/Ag couple (eq 13).[12]

(13)

Zn/Ag couple is an effective reagent for use in the Reformatsky reaction. If bromocrotonates are employed, there is the possibility of either α- or γ-attack. In the case of the crotonates, unlike the allylic halides, the product is dependent on the choice of solvent. When ether is used, the products arise from α-attack, while products derived from γ-attack are formed if THF is used (eq 14).[13]

An intramolecular version of the Blaise reaction was employed in the synthesis of corynantheine alkaloids. This variant of the Blaise reaction utilized Zn/Ag couple and ultrasonic irradiation (eq 15). The use of other forms of activated Zn or the omission of ultrasound resulted in poor or nonexistent yields of products.[14]

The use of ultrasound also resulted in an increase in yield for a Zn/Ag mediated coupling of the allylic bromide of the dihydrothiophene *S,S*-dioxide (eq 16).[15]

Zinc *p*-Toluenesulfonate

[13438-45-4] · $C_{14}H_{14}O_6S_2Zn$ · Zinc *p*-Toluenesulfonate · (MW 407.81) (.6H_2O)

[60553-56-2] (.*x*H_2O; hydrate)

[123334-05-4]

(agent for tosylation[1] under mild Mitsunobu conditions, usually with inversion)

Alternate Name: zinc tosylate.

Solubility: insol H_2O, benzene.

Form Supplied in: white solid; the hydrate is commercially available.

Preparative Method: anhydrous material[1] is prepared when the precipitate formed from mixture of ***p-Toluenesulfonic Acid*** and ***Zinc Chloride*** in water is filtered off and dried in vacuo at rt for 1 h. Purification is not usually required.

Handling, Storage, and Precautions: no unusual precautions are noted, but storage in a well stoppered container is advisable.

Tosylate Formation with Inversion of Configuration.

Alkyl tosylates can be formed directly from secondary alcohol functionality with retention of carbon stereochemistry by treatment with ***p-Toluenesulfonyl Chloride*** and ***Pyridine***. However, conversion of an alcohol to the corresponding tosylate of opposite stereochemistry typically requires a minimum of three steps. For example, inversion of the stereocenter with benzoic acid under Mitsunobu reaction conditions, hydrolysis of the resulting ester, and finally conventional tosylation of the alcohol, provides an attractive route for this transformation.[2] A similar route, the inversion of a secondary alcohol directly with *p*-TsOH, ***Diethyl Azodicarboxylate*** (DEAD), and ***Triphenylphosphine***, does not produce the desired tosylate product.[1]

Modification of this procedure, through the use of bis(*p*-toluenesulfonato)zinc ((*p*-TsO)$_2$Zn) with Mitsunobu conditions, allows this transformation to proceed in a single step.[1] Although somewhat slower than the analogous inversion with benzoic acid, treatment of secondary alcohols with (*p*-TsO)$_2$Zn, DEAD, and Ph_3P gives the desired tosylate product in high yield. This reaction is effective for tosylate formation from either acyclic or cyclic secondary alcohols with clean inversion of stereochemistry (eq 1). As expected, this reaction is very sensitive to the steric hindrance at the reacting sp^3 center; moderately hindered alcohols, e.g. (**1**), require longer reaction times and greater quantities of DEAD and Ph_3P to undergo the transformation in high yield (eq 2). Similarly, the use of *p*-TsOLi is effective for this transformation, but yields are slightly lower than those obtained with (*p*-TsO)$_2$Zn.

Tosylation with Retention of Stereochemistry.[1]

Although dihydrocholesterol (**2**) undergoes clean tosylation with inversion in 88% yield using the procedure described above, cholesterol (**3a**) itself gives an 85% yield of the 3β-tosylate (**3b**).

It was suggested that this anomaly could be explained by the intermediacy of a cyclopropylmethyl/homoallylic species, trapped by addition of tosylate ion. Indeed, the more vigorous Mitsunobu reaction[2] of (**3a**) with benzoic acid leads to a mixture of four products, confirming involvement of this type of homoallylic rearrangement.

Although anomalous, it is conceivable that this Mitsunobu procedure could be of use in effecting tosylation with retention in less common systems in which neighboring group effects, for example, override the normal stereochemical outcome.

Zinc Trifluoromethanesulfonate

$(CF_3SO_3)_2Zn$

[54010-75-2] · $C_2F_6O_6S_2Zn$ · Zinc Trifluoromethanesulfonate · (MW 363.55)

(mild Lewis acid; catalyst for a variety of reactions)

Alternate Name: zinc triflate.

Physical Data: mp >300 °C.

Solubility: insol CH_2Cl_2; slightly sol MeOH; sol MeCN, H_2O.

Form Supplied in: white powder; commercially available.

Preparative Method: may be prepared from addition[1] of ***Trifluoromethanesulfonic Acid*** to ***Zinc Carbonate*** in MeOH, filtration, and drying in vacuo.

Handling, Storage, and Precautions: moderately hygroscopic; store well sealed.

Introduction.

The mild Lewis acidic properties of this metal trifluoromethanesulfonate, similar in many ways to magnesium triflate[1] but with some distinct differences from other metal triflates[2] (notably ***Copper(II) Trifluoromethanesulfonate***[2c]), have been exploited in several delicate synthetic operations. It will undoubtedly find more uses in the future. Some specific examples follow.

Thioacetalization.[1]

The thioacetalization of (**1**) with ethane-1,2-dithiol proved to be impossible by a variety of more traditional methods,[3] but could be effected by zinc triflate without β-elimination of the lactone oxygen (eq 1).

Magnesium triflate can similarly be used to effect the reaction, but on occasion may require a more extended reaction time. In the case of Δ^4-cholesten-3-one, however, magnesium triflate (but not the zinc reagent) causes some double bond isomerization. α,β-Unsaturated ketones may also react by conjugate addition of the thiol in addition to acetalization.

Glycosylation.[4]

Zinc triflate is one of a number of Lewis acids which can catalyze glycosylation reactions (eq 2). The choice of catalyst is highly dependent upon substrate and leaving group OX, and on occasion zinc triflate can be more suitable than, for example, ***Boron Trifluoride Etherate*** or ***Trimethylsilyl Trifluoromethanesulfonate***. Stereochemical control at the anomeric center, however, is also variable, and far from complete.

(2)

A catalytic amount (0.1 mol %) of $Zn(OTf)_2$ gives low stereoselectivity in reaction of cholesterol with 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl chloride.[4b] Other zinc salts, notably zinc *p*-(*t*-butyl)benzoate,[4b] give a much more selective β-glycosylation product.

Onium Ion Formation.[5]

$Zn(OTf)_2$ permits replacement of the MeO group of (**2**) with a carbon substituent (eq 3), presumably via onium ion intermediates.[5a] Reaction with ***Titanium(IV) Chloride*** in CH_2Cl_2, however, resulted in cleavage of the alternative (endocyclic) acetal bond, possibly owing to coordination[5a] to both O and N atoms. *O*-Addition to such onium ions may also be effected with zinc triflate.[5b]

(3)

Alkylation of Electron-Rich Aromatics.

Aziridines (**3**) react with indoles (X = electron-releasing group) to give tryptophan derivatives only in the presence of $Zn(OTf)_2$ (eq 4).[6a] Although yields are fairly poor (19-60%), optical purity is excellent (>95%). Addition of other carbon nucleophiles (organocuprates[7]) to (**3**) can also lead to mixtures of products, in which α-amino acid derivatives may predominate.

(4)

Intramolecular alkylation of electron-rich aromatics (eq 5)[6b] can be an effective procedure, giving rise to benzofurans, benzothiophenes, indoles, or naphthalene derivatives. TMS triflate is also effective.

Zinc-Zinc Chloride

Zn-$ZnCl_2$

(Zn)

[7440-66-6] · Zn · Zinc-Zinc Chloride · (MW 65.39) ($ZnCl_2$)

[7646-85-7] · Cl_2Zn · Zinc-Zinc Chloride · (MW 136.29)

(mild reducing agent; causes reductive elimination of vicinal heteroatoms;[1-3] reduces activated carbonyls[4] and alkenes;[5] reductively opens some strained rings[6])

Physical Data: see ***Zinc*** and ***Zinc Chloride***.

Form Supplied in: $ZnCl_2$ is available both as solid and in ether solution. The latter has not been used in most of the following examples, but is very likely to be suitable in many cases. Various grades of Zn or $ZnCl_2$ can find use. Utilization under moist conditions (as well as anhydrous) has been noted.

Reductive Vicinal Eliminations.[1-3]

Zinc powder in the presence of catalytic amounts of $ZnCl_2$ causes reductive elimination of vicinal halogens (except fluorine, which is inert to these conditions), thereby yielding alkenes[1] or alkynes.[2] These reactions, performed in alcoholic solvents, are essentially similar to those effected by ***Zinc-Acetic Acid***. Similar treatment of bromo ether (**1**) also results in alkene formation (eq 1).[3]

(1)

(1)

Reduction.[4,5]

The keto group of α-ketoamides,[4] and a single carbonyl of α-diketones,[4] are reduced efficiently to the alcohol by Zn/$ZnCl_2$ in EtOH. This reaction, of course, can be carried out by a host of other reagents. Quinones[4] are also reduced to hydroquinones, in a reaction claimed to be superior to the procedure using ***Chromium(II) Chloride***.[7] The presence of $ZnCl_2$, however, is not crucial to this reaction; it can be omitted, or replaced by a variety of other metal salts.[4] Activated alkenes may also be reduced, as shown in eqs 2[5a] and 3[5b].

(2)

(3)

Reductive Ring Opening.[6]

Strained (three- or four-membered) carbocyclic ring systems (**2**) may be reductively opened by $Zn/ZnCl_2$ in protic solvents, if substituted by carbonyl groups (eq 4). For four-membered rings, two carbonyl substituents (i.e. $R^2 = COR^3$) are required;[6a] a similar reaction can also be effected by Zn/AcOH.[8] Three-membered rings react much more readily;[6a] the greater strain in this case permits cleavage of (**2**) (R^2 = aryl) by a very much extended reaction time,[6c] and even with Zn/AcOH.[6c]

(4)

Reductive Coupling.[9]

Aryl aldehydes, on exposure to $Zn/ZnCl_2$, usually react to give a mixture of the respective benzyl alcohol and the dimerized α-glycol (**3**) (R = H), the latter being favored by absence of solvent during the reaction. In aq THF, solvent composition affects the isomeric composition of the glycols. Acetophenones and diaryl ketones yield the glycols in excellent yields. This reagent is insensitive to oxygen, and reacts efficiently at room temperature, giving appreciable advantage over other favored reagents such as ***Aluminum***, ***Titanium(IV) Chloride***, or ***RZ021-***.[9]

(3)
R = H, Me, Ar

Zirconium(IV) Chloride

$ZrCl_4$

[10026-11-6] · Cl_4Zr · Zirconium(IV) Chloride · (MW 233.02)

(Lewis acid)

Physical Data: subl. 331 °C, mp 437 °C/25 atm; *d* 2.803 g cm^{-3}.

Solubility: sol alcohol, ether.

Form Supplied in: white solid; widely available.

Purification: crystallize repeatedly from conc hydrochloric acid.

Handling, Storage, and Precautions: extremely hygroscopic; decomposed by water to $ZrOCl_2$ and HCl. Reagent causes burns, and is harmful if inhaled or swallowed or if it comes in contact with skin. It is stable at high temperatures under N_2, H_2, or O_2. Use in a fume hood.

Precursor for Other Zirconium Reagents.

$ZrCl_4$ is used as starting material for other zirconium derivatives. Its Lewis acid character is involved in most of its reactions. As a Lewis acid its catalytic power is comparable with that of ***Titanium(IV) Chloride*** in Friedel-Crafts reactions.[1]

Diels-Alder Reactions.

$ZrCl_4$ has been employed as one of the Lewis acid catalysts in the addition of the acrylate of (*S*)-ethyl lactate with cyclopentadiene,[2] and further in asymmetric Diels-Alder cycloaddition reactions with chiral α,β-unsaturated *N*-acyloxazolidinones.[3]

[2 + 2] Adduct Formation.

$ZrCl_4$ is a good catalyst for the [2 + 2] adduct formation between ethyl propiolate and TMS enol ethers (eq 1).[4]

(1)

Carbonyl Addition Reactions.

Like $TiCl_4$ and other Lewis acids, $ZrCl_4$ is a good catalyst in aldol coupling reactions. $ZrCl_4$ is not superior, however, to other Lewis acids in a stereochemical study of the reactions of allylstannanes and a methyl homolog with aldehydes.[5] Corresponding intramolecular cyclization reactions are fast, selective, and insensitive to the nature of the Lewis acid (87-99% *syn*).[6] Stereoisomeric ratios and yields were relatively insensitive to the nature of the Lewis acid catalyst in adduct formation between ***Allyltrimethylsilane*** and methyl β-

formylcarboxylate (eq 2).[7]

In the aldol reaction between menthyl pyruvate and 1-naphthol, the de of the menthyl 2-(1-hydroxy-2-naphthyl)propionate adduct was 74%, the yield 92%.[8] The adduct of 1-naphthol and ethyl pyruvate using the chiral dibornacyclopentadienyl ligated zirconium chloride (**1**) had an ee >84% (eq 3).[9]

Hydroalumination Reactions.

$ZrCl_4$ will promote the addition of ***Lithium Aluminum Hydride*** to alkenes under mild conditions to yield hydroaluminated intermediates for further transformations (eq 4).[10] The reaction has been extended to allylic alcohols. Deoxygenation accompanied the use of titanium analogs.[11]

(4)

Esters and Amides.

Mild esterification conditions utilizing $ZrCl_4$ and ***Silver(I) Trifluoromethanesulfonate*** will effect reaction between silyl carboxylates and silyl ethers.[12] Chemoselective amination of the ester function in α-chlorocarboxylic methyl esters can also be effected (eq 5). $ZrCl_4$ and ***Aluminum Chloride*** are good Lewis acids for this transformation, which proceeds without significant epimerization of enantiomerically enriched chloropropionate.[13]

(5)

The affinity for oxygenated functions can be used to effect ring-opening reactions of cyclic ethers, leading to 6-hydroxy-2,4-cycloheptadien-1-ones.[14]

Zirconium(III) Chloride

$ZrCl_3$

[10241-03-9] · Cl_3Zr · Zirconium(III) Chloride · (MW 197.57)

(complex formation, potential reducing agent)

Physical Data: mp above 400 °C (disproportionation to Zr and $ZrCl_4$); *d* 3.0 g cm^{-3}.

Solubility: reacts with protic solvents with formation of H_2 gas; sol benzene, toluene, CS_2.

Form Supplied in: blue-black solid; changes to brown upon air exposure; not widely available. Synthesized from Zr and $ZrCl_4$.[1]

Purification: none, except new synthesis.

Handling, Storage, and Precautions: extremely hygroscopic; decomposed by moist air. Dissolving in H_2O destroys the compound with $ZrOCl_2$, H_2, and HCl formation. Heating in air forms $ZrCl_4$ needles and ZrO_2. Disproportionates to Zr and $ZrCl_4$ above 400 °C. Reagent causes burns, and is harmful if inhaled or swallowed. Use in a fume hood.

General Discussion.

Zirconium trichloride can be prepared from finely divided zirconium metal and ***Zirconium(IV) Chloride*** at elevated temperature (500 °C or more).[1,2]

The chemistry of tervalent zirconium halides is relatively unexplored. So far, the main interest has been directed towards complex formation with mono- and bidentate nitrogen donor ligands, e.g. acetonitrile, pyridine, lutidines, bipyridine, and phenanthroline.[2-4]

There appear to be no reports in the literature on the use of zirconium trichloride nor its complexes in directed organic reactions. This stands in contrast to the wide use of ***Titanium(III) Chloride*** in reductive coupling reactions of oxo compounds to vicinal diols and alkenes and reduction of functional groups.

Zirconium Tetraisopropoxide

$Zr(O\text{-}i\text{-}Pr)_4$

[2171-98-4] · $C_{12}H_{28}O_4Zr$ · Zirconium Tetraisopropoxide · (MW 327.62) (.*i*-PrOH)

[50939-84-9] · $C_{15}H_{36}O_5Zr$ · Zirconium Tetraisopropoxide-Isopropanol · (MW 387.73)

(hydrogenation catalyst; Meerwein-Ponndorf-Verley reduction; Oppenauer oxidation; ester synthesis; diketopiperazine synthesis)

Physical Data: $Zr(O\text{-}i\text{-}Pr)_4$: bp 160 °C/0.1 mmHg; $Zr(O\text{-}i\text{-}Pr)_4$.*i*-PrOH: mp 138-141 °C.[1]

Solubility: $Zr(O\text{-}i\text{-}Pr)_4$ readily sol organic solvents; $Zr(O\text{-}i\text{-}Pr)_4$.*i*-PrOH sparingly sol isopropanol.

Form Supplied in: $Zr(O\text{-}i\text{-}Pr)_4$.*i*-PrOH: white solid.

Purification: $Zr(O\text{-}i\text{-}Pr)_4$.*i*-PrOH: crystallization from isopropanol followed by drying at rt/0.5 mmHg. $Zr(O\text{-}i\text{-}Pr)_4$: heating of $Zr(O\text{-}i\text{-}Pr)_4$.*i*-PrOH at 90-120 °C/1 mmHg to remove isopropanol followed by distillation.[1]

Handling, Storage, and Precautions: moisture sensitive; irritating to eyes, respiratory system, and skin. Use in a fume hood.

Preparation of $ClZr(O\text{-}i\text{-}Pr)_3$.

$Zr(O\text{-}i\text{-}Pr)_4$ is a good substrate for the preparation of $ClZr(O\text{-}i\text{-}Pr)_3$ (eq 1),[2-4] which is a useful reagent for further conversion to other organozirconium reagents ($RZr(O\text{-}i\text{-}Pr)_3$) by organolithium or Grignard derivatives as described for the titanium analogs (see ***Titanium Tetraisopropoxide***).[5]

$$3\ Zr(O\text{-}i\text{-}Pr)_4 + ZrCl_4 \longrightarrow 4\ ClZr(O\text{-}i\text{-}Pr)_3 \qquad (1)$$

Meerwein-Ponndorf-Verley Reduction and Oppenauer Oxidation.

The zirconate reagent in the Meerwein-Ponndorf-Verley reduction is known to show high functional group selectivity due to both steric and electronic effects. Thus aldehydes are reduced in preference to ketones, and selective reduction of the carbonyl group occurs in α,β-unsaturated carbonyl compounds.[2,6] The sensitivity to electronic effects was demonstrated in a study of the reduction of benzaldehydes: the efficiency and rate of the aldehyde conversion to the benzyl alcohol was dependent on the electron-withdrawing properties of the *p*-substituent.[2,6] In the dihydro formation of 5-halo-2-pyrimidinones, regioselective formation of the 3,4-dihydro isomer predominates whereas the 3,6-dihydro isomer is formed with ***Lithium Tri-t-butoxyaluminum Hydride***.[7]

In the reverse reaction, the Oppenauer oxidation, studies on the oxidation of secondary alcohols with ***Chloral*** as the hydride acceptor again demonstrate the sensitive nature of $Zr(O\text{-}i\text{-}Pr)_4$ to electronic and steric effects (eqs 2 and 3).[2]

(2)

(3)

$Zr(O\text{-}i\text{-}Pr)_4$ is not a good catalyst for the oxidation of allylic alcohols to α,β-unsaturated aldehydes, in contrast to $Cp_2Zr(O\text{-}i\text{-}Pr)_2$ and ***Bis(η^5-cyclopentadienyl)dihydridozirconium***.[8]

Michael-Aldol Reaction.

In an intramolecular Michael-aldol reaction, the *n*-propoxide $Zr(O\text{-}n\text{-}Pr)_4$ was far superior to the isopropoxide $Zr(O\text{-}i\text{-}Pr)_4$.[9]

Ester Synthesis.

Isopropoxide groups in $Zr(O\text{-}i\text{-}Pr)_4$ are readily exchanged by other alkoxy groups,[1] and by aryloxy and iminoxy (oxime) groups.[10] In salicylaldehyde the initial ester exchange at room temperature is succeeded by a Meerwein-Ponndorf-Verley reduction of the formyl group on heating the zirconium phenoxide in benzene.[11]

Zirconates, like titanates,[2] should be useful reagents for esterification or reesterification, especially when either or both of the ester components are acid or base sensitive. In carbonylation reactions with aryl, vinyl, or alkyl bromides and rhodium or palladium catalysis, good yields of the corresponding esters are formed in the presence of zirconates or titanates.[12] In another esterification and catalysis process, ketenes react with aldehydes and ketones in the presence of titanium or zirconium alkoxides to form essentially β-hydroxy esters.[13] $Zr(O\text{-}i\text{-}Pr)_4$, although giving 83% yield in the above reaction, was not in any way superior but only complementary to $Zr(O\text{-}n\text{-}Bu)_4$, $Zr(O\text{-}n\text{-}Pr)_4$, $Zr(OEt)_4$, $Ti(O\text{-}t\text{-}Bu)_4$, $Ti(O\text{-}n\text{-}Bu)_4$, $Ti(O\text{-}n\text{-}Pr)_4$, and $Ti(OEt)_4$.

Diketopiperazine Synthesis.

Zirconates are water absorbents. Thus $Zr(O\text{-}i\text{-}Pr)_4$ effects dimerization of amino acids (glycine, alanine) to the corresponding diketopiperazines (eq 4).[14] The reaction proceeds in a similar fashion if the corresponding titanium reagent is employed.

$$[RCHCONH]_2 + 2\,Zr(OR')_2O + 4\,R'OH \qquad (4)$$

$$R = H,\ Me;\ R' = i\text{-}Pr,\ Bu$$

2-Chloro-1,3-dimethylimidazolidium Hexafluorophosphate

[101385-69-7] · $C_5H_{10}N_2Cl{\cdot}PF_6$ · (278.57)

(reagent used for the coupling and esterification of sterically hindered amino acids[1])

Physical Data: mp 227-229 °C.

Solubility: soluble in DMF; partially soluble in H_2O, MeOH, EtOAc, CH_2Cl_2, and $CHCl_3$.

Form Supplied in: colorless solid; available from Aldrich, Fluka, and Watanabe Chemical Industries.

Analysis of Reagent Purity: IR (KBr), 1650, 1555, 1420, 1345, 1310, 840 cm^{-1}. ^1H NMR (270 MHz, DMSO-d_6) δ 3.07 (s, 6H), 3.64 (s, 4H).

Handling, Storage, and Precautions: can be stored refrigerated for at least 5 years without loss of reactivity. 2-Chloro-1,3-dimethylimidazolidium hexafluorophosphate (CIP) is an irritant and should be used in a fumehood, when possible.

Scope

2-Chloro-1,3-dimethylimidazolidium hexafluorophosphate (CIP), in the presence of an additive, is best suited for the coupling of sterically hindered α,α-dialkylamino acids, *N*-methylamino acids, and peptide fragments. The coupling reaction proceeds under slightly basic conditions, with diisopropylethylamine generally being used as an organic base. A catalytic amount of the additive is sufficient for the coupling reaction to proceed, and a suitable additive can be selected for each reaction type. 1-Hydroxy-7-azabenzotriazole (HOAt, **1**)[2] or *N*-dimethylaminopyridine (DMAP, **2**)[3] is generally best suited for use as an additive. An optically active α-amino acid can be activated by CIP to yield the coupling product with negligible racemization.

Coupling of α,α-Dialkylamino Acid

The efficient coupling of an α,α-dialkylamino acid is particularly difficult when the carboxyl and amino components are both α,α-dialkylamino acids.[4] In the presence of 0.25 equiv of HOAt as an additive, CIP mediates the solution-phase coupling of an α,α-dimethylamino acid (Aib, α-aminoisobutyric acid) to yield Z-Aib-Aib-OMe, in 82% yield (1).[5] The reaction proceeds at 25 °C in less than 60 min. The same dipeptide ester was prepared using PyBrop,[6] a typical coupling reagent in peptide synthesis, under the same conditions in 17% yield. The amount of D-Val in the Z-Val-Aib-OMe, which was prepared by the CIP/HOAt procedure, was less than 0.5%. In the CIP-mediated Aib coupling, a Z or Fmoc group as an amino protecting group gave much better results than a Boc protecting group, probably due to the facile formation of the *N*-carboxy anhydride during the activation of the Boc amino acid.[7]

The CIP-mediated coupling of Aib proceeds through the oxazolone,[8] followed by its transformation to a highly active HOAt ester. The active intermediate ester reacts quickly with an amino component to give the condensation product and HOAt. The liberated HOAt functions as a catalyst for the coupling. The coupling procedure was successfully applied to an efficient synthesis of Alamethicin F30, a linear peptide consisting of 19 α-amino acids including eight Aib residues and a C-terminal α,α-aminoalcohol, phenylalaninol (Pheol). The stepwise coupling of Aib residues using CIP/HOAt proceeded nearly quantitatively in CH_2Cl_2 or DMF at 25 °C within 60 min to yield the necessary fragments without any difficulty.[9]

More complex and hindered α,α-dialkylamino acids can also be coupled with CIP/HOAt. CIP-mediated activation was applied for the difficult coupling of three adjacent α-methylcysteine residues. The coupling reaction proceeded at 25 °C in a 60% yield (2).[10]

The procedure was the key step in the convergent syntheses of the polythiazoline alkaloids, mirabazole B (**3**),[11] mirabazole C (**4**),[10] and thiangazole(**5**).[12]

Coupling of *N*-methylamino Acid

An *N*-methylamino acid is incorporated with difficulty using conventional peptide coupling reagents because of its steric hindrance and marked tendency to racemize.[13] CIP/HOAt was found to mediate the solution-phase coupling of the *N*-methylamino acid at 25 °C in CH_2Cl_2 in quantitative yield. The most hindered coupling between two *N*-methylated residues proceeds within 3 h, to give a 97% yield of the product with no detectable racemization: the corresponding D-isomer was produced in less than 0.5% yield (3).[14]

In the coupling of Z-MeVal-OH with MeAla-NHNH-Boc in solution phase, an efficient conventional reagent, BOP-Cl,[15] resulted in an 87% yield after an 18 h reaction time providing <0.5% isomerization, whereas the 1,3-dicyclohexylcarbodiimide (DCC)/DMAP procedure resulted in a 72% yield after a 24 h reaction, with 37% isomerization.[16]

The CIP-mediated activation procedure can be applied to the coupling of *N*-methylamino acids on solid support.[14,17] Quantitative-to-moderate coupling yields were obtained by a single coupling reaction (1-3 h) at 25 °C with practically no racemization. The coupling between two *N*-methylated amino acids proceeded on solid support in 53% yield after a 3 h single coupling reaction (4). The content of the D-isomer was less than 2%. As a reaction solvent, the use of DMF resulted in better yields than CH_2Cl_2.

Solid phase coupling using CIP/HOAt was successfully applied to a convergent synthesis of Dolastatin 15, a cytostatic depsipeptide isolated from a marine mollusk. A tetrapeptide fragment was obtained by cleavage of **6**, which was prepared by the successive CIP-mediated coupling of *N*-methylamino acids on a 2-chlorotrityl polystyrene resin. The overall yield based on starting resin was 50%.[14]

Fragment Coupling

The reaction efficiency of fragment coupling is generally low, compared with the coupling of a single amino acid. A greater fragment size results in a lower coupling efficiency. Fragment coupling is also prone to racemization via the oxazolone, which is formed during the activation of the C-terminus, i.e. during the activation of the *N*-acylamino acid.[18] These difficulties can be avoided by taking advantage of the high reactivity of a coupling reagent combined with a judicious choice of coupling position.

CIP/HOAt was employed for the coupling of an *N*-terminal 11-residue fragment with a Gly residue at its C-terminus, and a C-terminal nine-residue fragment to yield protected Alamethicin F-30. The coupling reaction proceeded at 25 °C within 60 min to yield 66% of the homogeneous product after purification.[19] The same coupling procedure was used in the final coupling reaction in the synthesis of Dolastatin 15 (**7**). The coupling reaction at the Pro residue proceeded at 25 °C within 2 h to yield Dolastatin 15 in 89% yield.[14]

CIP/HOAt can also be applied to the coupling of fragments with an optically active α-amino acid at the C-terminus. In the synthesis of Trichovirin I4A (**8**) using CIP/HOAt, coupling efficiency and the rate of racemization were found to be greatly dependent on the coupling site. Fragment coupling between the Ala and Val residues proceeded within 60 min at 25 °C in 81% yield with no detectable racemization, whereas fragment coupling between the more hindered Val and Aib residues resulted in a lower yield (69%) of the epimerized product.[19]

Macrocyclization

Head-to-tail cyclization represents a type of intramolecular fragment coupling and an efficient coupling reagent required for this transformation. A low reaction rate, as the result of an improper choice of the coupling reagent or the coupling site, facilitates extensive side reactions such as dimerization, oligomerization, and racemization.

CIP/HOAt was employed for the intramolecular cyclization to yield the key intermediate **9** in the synthesis of MEN11420, a glycosylated bicyclic peptide which has potent tachykinin antagonistic activity. CIP-mediated cyclization at the site between Dap(Boc) and Phe proceeded in DMF within 15 min to yield the cyclized monomeric product containing 6% of the D-Phe isomer. In contrast, cyclization at the more hindered site between the glycosylated-Asn and Leu proceeded in the presence of an excess amount of CIP (9 equiv) within 15 min to yield the monomeric product contaminated with 33% of the D-Leu isomer.[20]

Esterification

CIP can be used for the esterification of a carboxylic acid to a hindered alcohol, such as a hindered secondary alcohol and a resin-bound alcohol. The CIP-mediated esterification of an Fmoc amino acid to a 4-alkoxybenzylalcohol resin was conducted at 25 °C within 60 min using 3 equiv of the Fmoc amino acid and 6 equiv of CIP in pyridine/CH_2Cl_2 (1:1). The reaction proceeded faster, with the same or lower level of racemization than the anchoring reaction using DIPCDI or PyBrop. For example, Fmoc-Lys(Boc)-OH was anchored to the alcohol resin in 74% yield accompanied by an 0.8% formation of the corresponding D-isomer, whereas a 57% yield using DIPCDI and a 33% yield using PyBrop was obtained.[21]

The esterification of Boc-Pro-OH with a secondary alcohol was achieved, after a 10 h reaction at 25 °C, using CIP in the presence of an additive (5).[14] The additive, DMAP, gave better results than HOAt, giving the desired product in 92% yield.

(5)

CIP can also be used for the introduction of a sterically hindered 2-azidomethylbenzoyl (AZMB) group into the 3´-hydroxy function of nucleosides (6). The esterification reaction proceeded within 2 h at 25 °C to yield the desired product in 66% isolated yield.[22] An excess amount of CIP (2.5 equiv) was necessary for a smooth reaction because of the steric hindrance involved.

(6)

Related Reagents.

3-(Diethoxyphosphoryloxy)-1,2,3-benzotriazin-4(3H)-one (DEPBT);[23] ethyl 1-hydroxy-1H-1,2,3-triazole-4-carboxylate (HOCt);[24] 5-(1H-benzotriazol-1-yloxy)-3,4-dihydro-1-methyl 2H-pyrrolium hexachloroantimonate (BDMP);[25] 2-bromo-3-ethyl-4-methyl thiazolium tetrafluoroborate (BEMT).[26]

Bis(tricyclohexylphosphine)(4-polystyrylmethylidene)ruthenium Dichloride

[223415-64-3]P · $[Cl_2(PCy_3)_2Ru{=}CHC_6H_4CHCH_2)]_m(C_6H_5CHCH_2)_n$loading ca. 0.1 mmol g^{-1}

(polymer ‘boomerang’ supported alkene metathesis complex that catalyses ring-closing metathesis of dienes, minimizes ruthenium contamination of the ring-closed adduct without chromatography, and can be recycled and re-used by simple filtration)

Alternate Name: vinyl polystyrene polymer-supported Grubbs' catalyst, ‘Boomerang’ catalyst.

Solubility: insoluble in all solvents; swells in CH_2Cl_2, toluene and THF; does not swell in MeOH.

Form Supplied in: commercially available from NovaBiochem as a lilac powder.

Preparative Methods: Bis(tricyclohexylphosphine)(4-polystyrylmethylidene)ruthenium dichloride (PS-Grubbs' catalyst) is commercially available from NovaBiochem.[1] It can also be conveniently prepared by shaking Grubbs' catalyst $[Cl_2(PCy_3)_2Ru{=}CHPh]$[2] with vinylpolystyrene[3] (1-2% cross-linked with divinylbenzene) in dichloromethane solution for 1-2 h, followed by filtration (1).

Handling, Storage, and Precautions: when dry may be stored in a sealed vessel for a period of months.

Ring-Closing Metathesis

PS-Grubbs' catalyst is used for ring-closing metathesis, minimizes the ruthenium contamination of the ring-closed adduct without extensive chromatography, and can be recycled and re-used by simple filtration.[4] Specifically, it has been applied for the preparation of five-membered carbocycles (2),[4] dihydropyrans (3),[4] bicyclic β-lactams (4)[4] and sulfonamides (5).[5]

(2)

(3)

(4)

(5)

The advantage of the PS-Grubbs' catalyst over the traditional Grubbs' catalyst is that ruthenium contamination of the product is minimized and its use is simplified. Typically, the PS-Grubbs' catalyst is suspended in dichloromethane, the diene added and the mixture shaken for 40 min, followed by filtration. The product is obtained by simple evaporation of the washings, with minimal ruthenium contamination. The recovered catalyst can be re-used but is less active. The lifetime and activity of a given batch of PS-Grubbs' catalyst can be extended to allow three recycles by the simple addition of hex-1-ene or 3,3-dimethylbut-1-ene (9 mol%) to the mixture.[4] These volatile alkenes are removed with the dichloromethane solvent in the evaporation stage to obtain the product.

The mechanism by which the PS-Grubbs' catalyst operates has been dubbed a ‘boomerang’ process. Initial metathesis with a given diene releases the catalyst from the solid support into solution. Homogeneous alkylidene [$Cl_2(PCy_3)_2Ru{=}CHR$] catalysed metathesis ensues and the system therefore displays very similar activities to the homogeneous Grubbs' catalyst [$Cl_2(PCy_3)_2Ru{=}CHPh$]. It is therefore expected that for any ring-closing metathesis that Grubbs' catalyst [$Cl_2(PCy_3)_2Ru{=}CHPh$] can catalyse, PS-supported Grubbs' catalyst will be equally effective. After metathesis is complete, the resin recaptures the catalyst at a vacant vinyl site.

Recent improvements in the catalyst design to allow extended catalyst recycling and re-use (up to five times) have been achieved by the incorporation of an imidazol-2-ylidene ligand *in lieu* of one the PCy_3 ligands (6).[6] In this system oct-1-ene (10 mol %) and PPh_3 (5 mol %) were used as additives to extend catalyst lifetime in re-cycle mode. Other ‘boomerang’ catalysts for ring-closing metathesis have been reported by Jafarpour & Nolan,[7] Yao,[8] Garber et al.[9] and Dowden.[10]

Poly(*exo-N*-hydroxy-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboximide)

[259796-15-1]F · $(C_8H_7NO_4)_n$ · (181.15)

(polymeric acyl transfer reagent for activated carboxylic acids, chloroformates and isocyanates in amine acylation and related reactions)

Alternate Name: ROMPGEL-*N*-hydroxysuccinimide.

Solubility: soluble in DMF, DMSO; insoluble in H_2O, most organic solvents.

Form Supplied in: gray granular solid.

Analysis of Reagent Purity: the purity of the precursor polymer is verified by ^{1}H NMR. IR confirms complete desilylation of the product.

Preparative Methods: see text.[1]

Purification: stirring in methanolic ammonia in THF overnight followed by filtration, sequential washing with H_2O, THF, CH_2Cl_2 and diethyl ether and drying at 40 °C and 20 mmHg.

Handling, Storage, and Precautions: stable to air, light and heat.

Peptide Bond Formation

This polymeric reagent bears the same functionality and follows the same reactivity as N-**hydroxysuccinimide** (HOSu), namely as an acyl transfer reagent. The reagent can be prepared by ring-opening metathesis polymerization (ROMP) of the TBS-protected ether (**1**) using **benzylidenebis(tricyclohexylphosphine)dichlororuthenium**[2] (Grubbs' catalyst) (**2**), followed by removal of the silyl group, optimally with **triethylamine trihydrofluoride**,[3] precipitating the granular polymer (1).[1]

(1)

Once formed, the hydroxy functionality can be derivatized to give activated esters, either by using an acid chloride and **triethylamine** as base (2), or with a carboxylic acid and using **1,3-dicyclohexylcarbodiimide** (DCC) as the coupling reagent (3). The polymer is purified by washing away the solution-based reagents with excess solvent. The polymer can also be converted to an activated carbonate (chloroformate and **triethylamine** as base, 4), or to an activated carbamate by reaction with an isocyanate (5).

Acid chloride, NEt_3	R = Alkyl, Ar	(2)
Carboxylic acid, DCC	R = Alkyl, Ar	(3)
Chloroformate, NEt_3	R = OAlkyl	(4)
Isocyanate	R = NHAlkyl	(5)

The stable esters (**4**) can be reacted with a range of nucleophiles, with acyl transfer. Traditional usage of HOSu involves at least an aqueous wash to remove the polar succinimide and, more often, further chromatographic purification of the product. Reaction of an amine nucleophile with 1.3 equiv of a ROMPGEL-*N*-hydroxysuccinimide-supported ester is sufficient to give essentially quantitative conversion to the product. Here, since both the remaining unreacted activated ester and the *N*-hydroxysuccinimide by-product are bound in the polymer matrix, both can be removed by a single filtration. Evaporation of the solvent gives essentially pure product in excellent isolated yields. Amines can be effectively acylated in this way (6). Polystyrene-supported *ortho*-nitrophenol[4] and polystyrene-supported *N*-hydroxybenzotriazole[5] are other examples of polymer-supported acyl transfer reagents.

Amine hydrochloride salts can also be acylated directly, employing **triethylamine** as an HCl shuttle and the strong base polystyrene-supported triazabicyclo[3.3.0]decane[6] (P-TBD) as the HCl sink (7). Amino acid esters are acylated with minimal (<1%) racemization.

ROMPGEL-*N*-hydroxysuccinimide can also be used to form carbamates (8) and ureas (9).

95%
>95% purity

(8)

92%
>95% purity

(9)

For bulk acylation purposes (where the same acyl group is to be transferred to a range of nucleophiles), it is more convenient to acylate the monomer (**5**) and to polymerize this derivative directly. Low molecular weight monomers may lead to liquid ROM-polymers, so between 5-30 mol % **norbornadienene** (NBD) can be added, forming cross-links[7] between neighboring linear chains and giving the required insoluble polymer gel (**4**)[1,8] (10).

R = Alkyl, Ar, OAlkyl, NHAlkyl

Hydroxylamine (released from the hydrochloride salt in situ by adding solid potassium hydroxide) is cleanly acylated and with a single filtration and evaporation gives hydroxamic acids (11). Replacing hydroxylamine with N,O-**dimethylhydroxylamine** gives the corresponding Weinreb amides.[9]

Amidoximes can also be acylated, initially on oxygen. If the reaction is carried out in the presence of P-TBD, dehydrative cyclization occurs to give the corresponding 1,2,4-oxadiazoles in good-to-excellent yield and essentially pure, after a single filtration and evaporation (12).[8]

In general, ROMPGEL-supported esters react only with amine nucleophiles. For electron-poor acyl groups, however, some *O*-acylation can be observed (13).[1]

Finally, the polymer can be recycled after use by washing with methanolic **ammonia** to remove any remaining acyl group. Re-acylation and subsequent reaction give the new product in >95% purity with no sign of the remnant acyl group being incorporated (14).[1]

Related Reagents.

N-hydroxysuccinimide; N-hydroxybenzotriazole; polystyrene-supported N-hydroxybenzotriazole.

(*S*,*S*)-1,2-Bis(2,5-diethylphospholano)benzene

[136779-28-7] · $C_{22}H_{36}P_2$ · (362.47)

(ligand for asymmetric catalysis; rhodium(I) complexes are efficient catalysts in highly enantioselective hydrogenation of various unsaturated substrates [enol acylates,[1,2] (*N*-acylamino)acrylates,[1,3,4] and *N*-acylhydrazones[5]])

Alternate Name: (*S*,*S*)-ethyl-DuPHOS

Physical Data: bp 138-145 °C/0.04 mmHg; $[\alpha]_D$ +265 (*c* 1, hexane).

Solubility: soluble in most organic solvents.

Form Supplied in: colorless oil; commercially available.

Analysis of Reagent Purity: optical rotation; NMR spectroscopy.

Preparative Methods: the preparation of (*S*,*S*)-ethyl-DuPHOS is based on (3*R*,6*R*)-octane-3,6-diol as an enantiomerically pure starting compound.[1,3] The latter is synthesized by a three-step procedure[6,7] starting from methyl 3-oxopentanoate, which is transformed to methyl (*R*)-3-hydroxypentanoate (99% ee) by enantioselective hydrogenation with a Ru-(*R*)-BINAP catalyst,[8] followed by hydrolysis to the hydroxy acid. The subsequent electrochemical Kolbe coupling reaction leads to (3*R*,6*R*)-octane-3,6-diol in a protocol that can be scaled up to multigram quantities (1).[3,6]

The chiral octanediol in turn is converted into the corresponding cyclic sulfate by reaction with **thionyl chloride** and subsequent oxidation with **sodium periodate** and a catalytic amount of **ruthenium(III) chloride** (0.1 mol%) (2).[3] In the final step, 1,2-diphosphinobenzene[9] is lithiated by treatment with n-**butyllithium** (*n*-BuLi; 2 equiv, 1.6 mol% in hexane) followed by the addition of the (3*R*,6*R*)-octane-3,6-diol cyclic sulfate (2 equiv) and a further addition of 2.2 equiv of *n*-BuLi. (*S*,*S*)-Ethyl-DuPHOS is obtained

in a yield of over 70% [78% yield was described for the (*R*,*R*)-enantiomer by an analogous method[3]].[1] In addition to (*S*,*S*)-ethyl-DuPHOS, a variety of related bisphospholanes either linked by an ethylene bridge, or bearing other 2,5-alkyl substituents, or with opposite configuration have been prepared by this methodology.[1,3]

Handling, Storage, and Precautions: the reagent is sensitive to air and should be handled and stored under argon or nitrogen.

Catalyst Precursors

Rhodium Complexes

Cationic rhodium(I) complexes such as {Rh[(*S*,*S*)-ethyl-DuPHOS](cod)}$^+$X$^-$ (X=OTf, PF_6, BF_4, SbF_6) are usually employed as precatalysts for enantioselective hydrogenation[1-4] or hydrosilylation[10] reactions. The precatalysts can be prepared from the chiral ligand and [Rh(cod)$_2$]$^+$X$^-$-complexes by a standard method.[3,11] The corresponding {Rh[(*S*,*S*)-ethyl-DuPHOS](nbd)} complex can be accessed equally well by the method of Schrock and Osborne[11] or by exchange of cod in the relevant rhodium complex by norbornadiene (nbd).[12]

Enantioselective Hydrogenations

C=C Double Bond

The most commonly used reactions that employ {Rh[(*S*,*S*)-Et-DuPHOS](cod)}$^+$X$^-$ complexes involve the enantioselective hydrogenation of α-(*N*-acyl)enamide carboxylates. α-Amino acids are obtained in quantitative yield with high optical purity (95-99% ee) (3).[1,3,4]

(3)

In this reaction, the (*S*,*S*)-ethyl-DuPHOS-catalyst produces the *S*-configurated α-amino acid derivatives when the substrate has one substituent in the β-position (R^2=H). The catalyst tolerates a range of substituents R^1 in the unsaturated substrate. The reaction conditions are mild (25 °C, MeOH, low hydrogen pressure) and the reaction proceeds rapidly (turnover frequencies 5000 h^{-1}). High substrate-to-catalyst ratios can be employed (up to 50 000). In general, high enatiomeric excesses are observed, independent of the geometry of the enamide (*E*- or *Z*-isomer) used. This feature is advantageous because frequently the unsaturated α-enamide carboxylic acids derivatives are synthesized as a mixture of both stereoisomers. Due to the high stereodiscriminating ability of the catalyst, separation prior to hydrogenation is not required. Access to a great number of natural, unnatural and nonproteogenic amino acids is possible in this manner (Table 1).

Table 2 Enantioselective hydrogenation of dehydroamino alcohols and dehydro-α-amino aldoximes with {Rh[(*S*,*S*)-ethyl-DuPHOS](cod)} OTf (MeOH or THF, 25 °C, 0.2 MPa H_2, 12 h, S/C = 1000:1)

R^1	R^2	% ee amino alcohol	% ee amino aldoxime
Me	H	95	94
Ph	H	93	90
Cy	H	96	99
2-MeOPh	H	93	88
Bn	H	>99	98
2-Naphthyl	Ac	98	81
2-Furanyl	Ac	98	–
2-Thienyl	Ac	96	–

The highly enantioselective hydrogenation of the corresponding dehydroamino acids (R^3=H) and the synthesis of *N*-Cbz-protected α-amino acids (R^4=OBn) are likewise possible.[3,16] Enantioselectivities of >99% can be achieved after 20-40 hours. Amino acid esters can be used directly for the synthesis of peptides. Deprotection of the amino groups can be carried out under mild conditions, thus avoiding racemization reactions.

Evidence has been given that the use of the Rh(P_2)(nbd) precatalyst is favored over the application of the corresponding cod-precatalyst. Börner and Heller[17] found that hydrogenation of the cod of the precatalyst takes place in parallel to the enantioselective hydrogenation of methyl (*Z*)-*N*-acetylaminocinnamate.[17,18] About 50% of the Rh-precatalyst remained unchanged after complete hydrogenation of the prochiral substrate. Therefore, precious ligand and Rh complex are wasted. This can be avoided by the application of {Rh[(*S*,*S*)-ethyl-DuPHOS](nbd)}$^+X^-$ as precatalyst. The hydrogenation of nbd proceeds much faster than that of cyclooctadiene. As an alternative, prehydrogenation of the cod-precatalyst in MeOH is possible for generating the catalytically active species.

Excellent enantio- and regioselectivities were also observed when *N*-acetylamino acrylates bearing additional functional groups, e.g. alkenes, were applied as substrates (4).[3,4]

regioselectivity: > 98 %
enantioselectivity: > 99 %

In these hydrogenations, less than 2% of the γ,δ-double bond was reduced. This feature indicates the ethyl-DuPHOS ligand to be superior in comparison to related DuPHOS/BPE-ligands or other chelating diphosphines. Other functional groups that are generally sensitive to reduction such as carbonyl groups, nitro groups, and halides also survive under the mild conditions applied to hydrogenation of the double bond adjacent to the acylamino group.

Diastereoselective hydrogenation of a bis(dehydroamino acid) derivative, recognized to be important for the syntheses of isotyrosine, in the presence of {Rh[(*S*,*S*)-ethyl-DuPHOS](cod)}$^{+}$OTf^{-} as catalyst yielded excellent results (5).[19]

(5)

a **c:** $R^1 = R^3 =$ Cbz, Boc, Ac, $R^2 = R^4 =$ Me

d: $R^1 =$ Cbz, $R^2 =$ TMSE, $R^3 =$ Boc, $R^4 =$ Me

The possibility of preparing an isotyrosine derivative with four orthogonal protecting groups gives access to a highly versatile building block for several biologically active natural compounds. Enantioselectivities in excess of 98% ee for the *S,S*-enantiomer and diastereoselectivities above 84% have been observed. In general, the yields exceeded 90%.

The formation of stereogenic C-N bonds by hydrogenation of the enamine structure is not only limited to amino acids. Likewise, chiral 1,2-aminoalcohols or 1,2-diamines can be produced by the enantioselective hydrogenation of dehydro-β-amino alcohols (or their esters) and of dehydro-α-amino aldoximes, respectively (6 and 7, Table 2).[20] Esters and aldoximes thus obtained can be converted into the corresponding alcohols or diamines by standard methods. By this means, simple amines with one aryl group attached to the double bond can also be hydrogenated with high enantioselectivity.[21]

Table 2 Enantioselective hydrogenation of dehydroamino alcohols and dehydro-α-amino aldoximes with {Rh[(*S,S*)-ethyl-DuPHOS](cod)}$^+$OTf$^-$ (MeOH or THF, 25 °C, 0.2 MPa H_2, 12 h, S/C = 1000:1)

(6)

(7)

Enol acetates and corresponding derivatives constitute another class of unsaturated compounds that can advantageously be hydrogenated with high enantiomeric excess. This reaction is related to the enantioselective reduction of ketones. Acylated enol carboxylates (as an equivalent of α-keto carboxylic acid) can likewise be successfully reduced with rhodium(I) catalysts based on (*S*,*S*)-ethyl-DuPHOS (8).[2] Subsequent deprotection of the hydroxyl group or reduction of the carboxylic acid derivatives so obtained deliver chiral α-hydroxy carboxylates and 1,2-diols, respectively.

(8)

Burk et al.[2] showed that the Rh-(*S*,*S*)-ethyl-DuPHOS complex is able to reduce acylated α-hydroxy carboxylates with high enantiomeric excess independently of the *E*:*Z* ratio of the alkene substrate (Table 3). However, the reaction failed when substrates branched in β-position were tested.

Table 3 Enantioselective hydrogenation of various enol esters with {Rh[(*S*,*S*)-ethyl-DuPHOS](cod)} OTf complex (MeOH, 25 °C, 0.4–0.6 MPa H_2, 48 h, S/C = 500:1)

Ph	Et	Bz	10	98.0
α-Naphthyl	Et	Bz	3	93.2

[a] *S*-configurated products were obtained.

Finally, several examples of the enantioselective hydrogenation of unsaturated substrates without any heteroatom attached to the olefinic double bond are noteworthy. Of particular relevance to the production of pharmaceutics, agrochemicals, flavors and aroma stuffs is the formation of the chiral 2-substituted succinates based on relevant itaconic acid derivatives. Burk et al.[22] demonstrated that a rhodium(I) catalyst derived from (*S*,*S*)-ethyl-DuPHOS is able to hydrogenate aryl- or alkyl-substituted itaconic acid derivatives with excellent enantioselectivity (9, Table 4).

Table 4 Enantioselective hydrogenation of itaconic acid derivatives with {Rh[(*S*,*S*)-ethyl-DuPHOS](cod)}$^+$ BF_4 (MeOH, 25 °C, 0.56 MPa H_2)

R	S/C	Time (h)	% ee[a]
Et	1000	1	99
i-Pr	3000	2	99
n-Bu	1500	2	97
CH_2CH_2Ph	2000	2	99
Cyclohexyl	1500	3	98
Ph	3000	12	97
1-Naphthyl	3000	12	98

[a] *R*-configuration was obtained.

(9)

Prior separation of the *E*:*Z* mixtures of the itaconic acid substrates (usually representing mixtures of 2:1 to more than 10:1) and also by-products of the synthesis do not affect the results.

A catalyst based on ethyl-DuPHOS also showed its high potential in the enantioselective hydrogenation of a sodium glutarate as the pivotal intermediate in the multi-step synthesis of candoxatril (10).[23]

(10)

By application of the relevant Rh-(*S*,*S*)-ethyl-DuPHOS catalyst, no isomerization of the starting material to the enol ether occurred by migration of the double bond. This side reaction operates in the presence of the corresponding ruthenium catalysts. When (*S*,*S*)-ethyl-DuPHOS was applied as ligand the *R*-enantiomer was formed instead of the desired *S*-enantiomer, necessary for the synthesis of candoxatril.

Another example of the synthesis of a compound with pharmaceutical relevance is the chemical transformation of *rac*-warfarin into enantiomerically pure (*R*)- or (*S*)-warfarin.[24] In the first step, *rac*-warfarin is oxidized to the corresponding α,β-unsaturated ketone. The latter can be easily hydrogenated to the desired enantiomer by application of the appropriate DuPHOS-catalyst (11). Prior transformation of dehydrowarfarin into the sodium salt or its methyl ether improved the yield and suppressed side reactions. Simultaneously, the enantioselectivity of the hydrogenation product was enhanced. The (*S*,*S*)-ethyl-DuPHOS-complex leads to *R*-configured warfarin.

(11)

C=N Double Bond

The enantioselective reduction of a C=N double bond is an interesting alternative for the production of chiral amines by hydrogenation of enamides. Required imines or oximes can be prepared by reaction of ketones with amines or hydroxylamines. However, to date, trials to reduce these substrates with ethyl-DuPHOS catalysts gave no satisfying results. Therefore, transformation of ketones or α-keto acids into acylhydrazones and subsequent enantioselective hydrogenation has proven advantageous (12, Table 5).[25,26]

Table 5 Enantioselective hydrogenation of benzoylhydrazones with $\{Rh[(S,S)\text{-ethyl-DuPHOS}](cod)\}^{+}OTf^{-}$ catalyst (*i*-PrOH, 0.4 MPa H_2, S/C = 500:1)[a]

R^1	R^2	Temperature (°C)	Time (h)	% ee
Ph	Me	−10	24	95
p-MeO-Ph	Me	0	12	88
p-EtO_2C-Ph	Me	0	12	96
Ph	Bn	−10	24	84
CO_2Me	Et	0	36	91
CO_2Me	Pr	0	36	90
CO_2Me	Ph	0	36	91
i-Pr	Me	−10	36	73
Et	Me	−10	36	43

[a] The reactions were preferentially carried out by employment of (*R*,*R*)-ethyl-DuPHOS giving rise to the *S*-configurated product. However, as Burk et al.[26] pointed out, the antipodal (*S*,*S*)-configurated ligand gave same yields and enantiomeric excess, but products with *R*-configuration.

(12)

Chiral hydrazines can be transformed to α-amino acids and amines by cleavage of the N-N bond. Conversion to α-hydrazino acids by hydrolysis of the esters or into hydrazines by deacylation is likewise possible.[26]

(*S*,*S*)-Ethyl-DuPHOS has been employed mainly for enantioselective hydrogenation. Several types of reaction can be run very successfully. In other enantioselective reactions, this ligand has been used only rarely, one example being the enantioselective allylation of benzaldehyde by application of the corresponding silver(I) catalyst. However, in this example, the reaction failed.[27]

It is likely that several results obtained with the homologous ligands of R-DuPHOS (R=Me, Pr) or their opposite enantiomers can be related also to (*S*,*S*)-ethyl-DuPHOS. Recently, Burk has published a review about the application of phospholane ligands in asymmetric catalysis, which gives a good survey of the use of DuPHOS- and BPE-ligands.[28]

Related Reagents.

Di-(-)-(1*R*,2*S*)-2-phenyl-1-cyclohexyl Diazenedicarboxylate

[206359-91-3] · $C_{26}H_{30}N_2O_4$ · (434.53)

(reagent used as a chiral azo-enophile in asymmetric azo-ene reactions)

Alternate Name: (1*R*-{1α[*E*(1*R**,2*S**)],2β})-Bis(2-phenylcyclohexyl) diazenedicarboxylate.

Physical Data: $[\alpha]_D$ -56.9 (*c* 0.65, $CHCl_3$).

Solubility: soluble in CH_2Cl_2, diethyl ether, and most organic solvents.

Form Supplied in: yellow oil.

Analysis of Reagent Purity: ^{1}H NMR, IR, TLC, elemental analysis.

Preparative Methods: The title reagent is prepared[1] by reaction of (1*R*, 2*S*)-2-phenyl-1-cyclohexanol with excess phosgene in the presence of quinoline to afford a chloroformate which is treated directly with hydrazine monohydrate (0.5 equiv) to afford di-(-)-(1*R*, 2*S*)-2-phenyl-1-cyclohexyl diazanedicarboxylate. Oxidation of the diazanedicarboxylate to the diazenedicarboxylate is then readily effected using *N*-bromosuccinimide and pyridine (1).

Purification: flash chromatography using hexane-ethyl acetate (9:1) as eluent.

Handling, Storage, and Precautions: store in closed vessels under an inert atmosphere in the refrigerator. Protect from light.

Azo-ene reactions

The ene reaction[1] provides a powerful method for C-C bond formation with concomitant activation of an allylic C-H bond. A variety of functionalized carbon skeletons can be constructed due to the range of enophiles which can be used. For example, carbonyl compounds give homoallylic alcohols[2] and imino derivatives of aldehydes afford homoallylic amines.[3] The azo-ene reaction offers a method for effecting allylic amination by treatment of an alkene with an azo-diester to afford a diacyl hydrazine which upon N-N cleavage furnishes a carbamate. Subsequent hydrolysis of the carbamate provides an allylic amine. Use of chiral diazenedicarboxylates provides a method for effecting stereoselective electrophilic amination.

Lewis acid-mediated ene reaction of di-(-)-(1*R*,2*S*)-2-phenyl-1-cyclohexyl diazenedicarboxylate with cyclohexene using tin(IV) chloride in dichloromethane at -60 °C for 5 min afforded the azo-ene adduct in 80% yield after purification by flash chromatography (2).[4] The ^{1}H NMR spectrum of the azo-ene adduct recorded at 380 K in deuterated toluene established the presence of only one diastereomer. Further analysis of the ene adduct by HPLC on a Whatman Partisil 5 normal phase silica column using hexane-ethyl acetate (9:1) as eluent confirmed the presence of only one diastereomer.

(2)

80% >97:3

Use of cyclopentene, *trans*-hex-3-ene and *trans*-oct-4-ene afforded the ene adducts in good yield with a diastereomeric excess of 86:14 in each case. The diastereoselectivity observed using di-(-)-(1*R*,2*S*)-2-phenyl-1-cyclohexyl diazenedicarboxylate as a chiral azo-enophile offered a significant improvement over the use of di-(-)-menthyl azodicarboxylate where the level of asymmetric induction achieved in Lewis acid-mediated ene reactions with simple alkenes was not impressive.[5] Moreover, it proved difficult to cleave the N-N bond in the menthyl ester azo-ene adducts whereas sodium/liquid ammonia was used to smoothly cleave the N-N bond in the diacylhydrazine adducts formed using di-(-)-(1*R*,2*S*)-2-phenyl-1-cyclohexyl diazenedicarboxylate as azo-enophile.

The absolute stereochemistry at the newly formed stereogenic carbon of the major diastereomer of the ene adduct can be predicted by analysis of the transition model for the ene reaction (3). The (1*R*,2*S*)-2-phenyl-1-cyclohexyl chiral auxiliary adopts a chair conformation with equatorial placement of the bulky phenyl group. Complexation of the carbonyl group to the Lewis acid affords the more stable *s-trans* conformation about the C-N sigma bond. In this conformation, the phenyl group shields the N_β-*re*-face. Therefore the cyclic alkene preferentially attacks from the less hindered N_β-*si*-face. Ene reaction proceeds through a six-membered cyclic transition state affording the (1´*R*)-diastereomer of the ene adduct.

(3)

Related Reagents.

The synthesis of chiral diazenedicarboxylates as potential chiral electrophilic aminating agents has received little attention. A series of chiral bornyl, isobornyl and menthyl diazenedicarboxylates has been reported[6] and their reaction with achiral enolates of esters and *N*,*N*-dimethyl amides afforded α-hydrazino acid derivatives with little or no selectivity. Incorporation of a chiral azodicarboxamide unit into a chiral bridging binaphthyl moiety afforded α-hydrazino acid derivatives with high stereoselectivity in reactions with achiral oxazolidinone anions.[7]

(+/-)-Boc-α-phosphonoglycine Trimethyl Ester

[89524-98-1] · $C_{10}H_{20}NO_7P$ · (294.24)

[synthon for α,β-dehydroamino acids (DAA) and amino acids]

Alternate Name: methyl 2-(*t*-butoxycarbonylamino)-2-(dimethoxyphosphinyl)acetate.

Physical Data: white solid, mp 47-48 °C.

Solubility: alcohol and most organic solvents.

Form Supplied in: Form Supplied in: available in six steps from crude glyoxylic acid.[1] The first four steps[2] can be carried out on a kilogram scale. Deprotection of the *N*-benzyloxycarbonyl-2-(dimethoxylphosphinyl)glycine methyl ester and reaction with Boc_2O affords the title compound (1).

Purification: recrystallization from diethyl ether/pentane (1:1) at 0 °C.

Handling, Storage, and Precautions: reagent should be used in a fume hood.

Reaction with Aldehydes

The main use of phosphoglycinate is to synthesize α,β-dehydroamino acids (DAA) by condensation with an aldehyde in a Wittig-Horner-type olefination (2).[3]

In order to obtain high yields and to limit the amounts of by-products, the choice of base is critical. The use of *t*-BuOK, NaH, lithium diisopropylamide, or potassium hexamethyldisilazide affords yields ranging from 70 to 95%,[4] along with small amounts of side-products, which are often difficult to separate from the DAA. This is of paramount importance if the next step is a metal-catalyzed hydrogenation, since the impurities can poison the catalyst. Also, in most cases, the diastereoselectivity of double bond formation is fairly low. Nevertheless, the use of DBU or NEt_3 in CH_2Cl_2 is often superior to alkali bases, resulting in nearly quantitative yields and high diastereoselectivities (3). Addition of LiCl is not necessary and may be detrimental in terms of yields.

Base	*E*/*Z*	Yield (%)
t-BuOK	27:73	94
DBU	5:95	100

Also, the use of TMG [4-6] as base in THF at -70 °C to +20 °C is reported to give rise to even better *Z*-diastereoselectivity, yield, and product purity. All types of aldehyde can react, except 2-alkenals, which suffer decomposition in the basic reaction medium. Complex or sterically hindered aldehydes react well. The olefination is applicable to the synthesis of non-conjugated 2-amino-2,*n*-alkadienoic esters which can be selectively hydrogenated to give (,(- and (,(-dehydroamino acid derivatives. Also, the reaction conditions (neutral or alkaline) are compatible with aldehydes that contain acid-sensitive groups.[7] Aldehydes can also be coupled to di- or tripeptides containing a phosphoglycinate unit (4).

(4)

If the reaction is applied to the synthesis of histidine or tryptophane derivatives, the nitrogen atom in the heterocyclic moiety must be protected. No racemization was observed during the olefination of the above dipeptide.

The stereocontrol of double bond geometry depends heavily on the base used during the olefination. In most cases, *Z*-geometry prevails. The *E*-isomer can be converted to the *Z*-isomer by means of HCl/Et_2O,[8] NEt_3/charcoal in $MeOH/CHCl_3$, thiophenol/AIBN/benzene at 80 °C,[9] illumination[10] or DBU/charcoal in $MeOH/CHCl_3$ at 20 °C (5).[3]

(5)

The protecting group associated with **1** can be easily changed. *N*-*t*-butoxycarbonyl- can be replaced by *N*-Benzyloxycarbonyl-, *N*-acetyl-, *N*-chloroacetyl-, and *N*-formyl, in the fifth step of 1 without any problem and the methyl ester can be replaced by $-CH_2CH_2TMS$ (TMSE). Any type of combination can be realized. Orthogonally protected phosphoglycinates have been prepared (6).[11]

(6)

98:2 diasteriomeric ratio

Different protecting groups on **1** can affect the yield of the olefination (7),[6] as well as the *E*/*Z* ratio. Methyl esters are preferred over ethyl esters

due to their ease of hydrolysis.

(7)

Reaction with Ketones

Ketones react with **1**, or its analogs, in the presence of TMG as base. Good *Z*-selectivity is observed. Recourse to DBU is synthetically useless since a large excess of ketone is required for the olefination to proceed.[3]

Related Reagents.

(+)-*N*-Fluoro-2,10-(3,3-dichlorocamphorsultam)[1]

[151556-58-0] · $C_{10}H_{14}Cl_2FNO_2S$ · (302.19)

(neutral, aprotic, electrophilic fluorinating agent for the asymmetric α-fluorination of enolates[1])

Physical Data: mp 161-162 °C, $[\alpha]^{20}_D$ +16.4 (*c* 1.3, $CHCl_3$).

Solubility: soluble in THF, CH_2Cl_2, $CHCl_3$; insoluble in hexane, pentane, H_2O.

Form Supplied in: white solid.

Preparative Methods: the title reagent **1** can be prepared by fluorination of the corresponding (+)-2,10-(3,3-dichlorocamphorsultam)[2] using 10% F_2/N_2 in dry chloroform in the presence of sodium fluoride.[3,4]

Purification: purified by silica gel chromatography using a mixture of CH_2Cl_2/*n*-pentane (70:30) as eluent.

Handling, Storage, and Precautions: can be stored in a bottle in the refrigerator for months without noticeable decomposition.

Fluorination of Ketone Enolates

(+)-*N*-Fluoro-2,10-(3,3-dichlorocamphorsultam) (**1**) reacts with ketone enolates to give α-fluoro ketones. For example, reaction of the sodium enolate of propiophenone **2** gives α-fluoropropiophenone **3** in 41% isolated yield (1). No enantioselectivity, however, is observed due to racemization of the product under the reaction conditions.[4] When a tertiary substituted ketone such as α-methyltetralone (**4**) is employed, the desired α-fluorinated product (*S*)-(-)-**5** is obtained in 76% ee and 53% isolated yield (2).[4] In this reaction, (+)-**1** was found to be more reactive, affording higher yields and better enantioselectivities than its parent (-)-*N*-fluoro-2,10-camphorsultam; i.e., 35% ee, <5% yield.[5]

(1)

(2)

Fluorination of Ester Enolates

(+)-*N*-Fluoro-2,10-(3,3-dichlorocamphorsultam) (**1**) also reacts with the enolates generated from esters. For example, treatment of methyl 2-phenylpropionate **6** with NaHMDS in THF followed by addition of (+)-**1** affords the corresponding α-fluoro ester **7** in 54% yield and 33% ee (3). The absolute configuration was not determined. The enantioselectivity observed with (+)-**1** is better than (-)-*N*-fluoro-2,10-camphorsultam; i.e., < 10% ee (30% yield).[5]

(3)

Fluorination of β-Ketoester Enolates

(+)-*N*-Fluoro-2,10-(3,3-dichlorocamphorsultam) (**1**) is reactive towards the enolates generated from β-ketoesters. Thus, treatment of the sodium enolate of **8** with (+)-**1** afforded the desired product **9** in 95% isolated yield and 46% ee with undetermined stereochemistry (4). Reduced yields and enantioselectivities were noted under similar conditions for (-)-*N*-fluoro-2,10-camphorsultam (28% yield, 25% ee).[4]

(4)

Related Reagents.

(+)-N-fluoro-2,10-camphorsultam;[4,5] (-)-N-fluoro-2,10-(3,3-dimethoxycamphorsultam);[4] (3S)-(−)-N-fluoro-3-cyclohexyl-3-methyl-2,3-dihydrobenzo[1,2-d]isothiazole 1,1-dioxide;[6] N-fluoro-o-benzenesulfonimide;[7] N-fluorobenzenesulfonimide.[8]

[122833-58-3] · $C_8H_{18}N_2O_4S_2$ · (270.36)

(catalyst for organozinc-mediated additions to aldehydes,[1] catalyst for Simmons-Smith type cyclopropanation of allylic alcohols[2])

Physical Data: mp 157 °C; $[\alpha]_D^{20}$ -20.1 (*c* 3.07, pyridine).

Solubility: soluble in most organic solvents except hydrocarbons.

Form Supplied in: white solid.

Preparative Methods: The enantiopure sulfonamide **1a** is prepared via sulfonylation of (*R*,*R*)-1,2-diaminocyclohexane **2** in the presence of an excess of triethylamine (1).[3] Use of excess amine base is essential for obtaining a high yield of the bis-sulfonamide. Synthesis of related bis-sulfonamides is easily accomplished by substituting the desired sulfonyl chloride in the former procedure.

Recrystallization of the bis-sulfonamide **1a** from hexane/ethyl acetate and drying over P_2O_5 allows for isolation of the analytically pure reagent. Methanesulfonyl chloride and (*R*,*R*)-1,2-diaminocyclohexane **2** are commercially available from a number of sources. However it should be noted that racemic 1,2-diaminocyclohexane **2** can be resolved via formation of the tartrate salt.[4] Typically, the diamine can be obtained in >99:1 enantiomeric ratio (er) after two crystallizations from water. Determination of the enantiopurity of the diamine is accomplished via formation of the bis-3-toluyl amide and analysis via chiral stationary phase HPLC (Chiralcel AD; hexane/*i*-PrOH; 95:5, 1.0 mL min^{-1}).

Handling, Storage, and Precautions: The sulfonamide is a shelf-stable, non-hygroscopic compound which does not require special precautions for storage or handling.

Introduction

The 1,2-bis-(methanesulfonamido)-cyclohexane **1a** is an important member of a larger class of C_2-symmetric bis-sulfonamide ligands which have had a powerful impact on the field of organozinc chemistry.[1,2] The success of these ligands is, in part, due to the straightforward installation of a variety of sulfonamide groups, providing access to a wide array of sterically and electronically diverse ligands.

Additions to Aldehydes

Alkylation of aromatic and aliphatic aldehydes with a combination of titanium tetraisopropoxide, $Ti(O\text{-}i\text{-}Pr)_4$, and diethylzinc, $ZnEt_2$, in the presence of a catalytic amount of the bis-sulfonamide **1a** leads to formation of (*S*)-1-phenyl-1-propanol **4** with high enantioselectivity (2, 1).[5] Use of the (*R*,*R*)-1,2-(trifluoromethanesulfonamido)-cyclohexane **1b** [CAS 122833-60-7] allows for an equally selective reaction, but at exceptionally low catalyst loadings. In the case of aromatic aldehydes, these reactions are fairly rapid, requiring at most 2 hours to reach full conversion.

Table 1 Alkylation of benzaldehyde in the presence of sulfonamide catalysts **1a–b**

R	Cat. loading (%)	Temp. (°C)	Yield (%)	**4** (er)
Me (**1a**)	4	23	90	95:5
Me (**1a**)	4	0	97	83:17
CF_3 (**1b**)	4	0	99	99:1
CF_3 (**1b**)	0.05	−20	97	99:1

er, enantiomeric ratio.

Through the use of the bis-sulfonamide **1b**, the scope of the reaction has been expanded to include a larger number of aldehydes and organozinc reagents (Table 2). High yields and selectivities are obtained in the alkylations of conjugated aldehydes (**5**) as well as simple aliphatic aldehydes (**7**,**9**). The broad scope of this reaction with respect to the electrophile contrasts the slightly limited scope of the reaction when

considering the structure of the nucleophile. The use of small alkylzinc reagents, such as dimethylzinc, leads to a depressed selectivity (entry 4). However, the use of larger alkylzinc reagents still provides the exceptional selectivity observed in the case of diethylzinc (entries 5 and 6).

Table 2 Substrate scope in the alkylation of aldehydes with sulfonamide **1b**

Entry	R^1	R^2	Loading (%)	Temp. (°C)	Yield (%)	Product	er
1	PhCH=CH (**5**)	CH_3CH_2	2	−50	85	**6**	>99:1

3	n-C_5H_{11} (**9**)	CH_3CH_2	4	−20	87	**10**	>99:1
4	Ph (**3**)	CH_3	4	0	99	**11**	86:14
5	Ph (**3**)	n-C_4H_9	2	−20	98	**12**	99:1
6	Ph (**3**)	n-C_5H_{11}	2	−50	99	**13**	>99:1

er, enantiomeric ratio.

(3)

The scope of the reactive partners has been fully explored and expanded to include a diversity of functionalized organozinc reagents. Preparation of the functionalized organozinc reagent proceeds via hydroboration and boron-zinc exchange of a simple terminal alkene. The resulting organozinc reagent can then be used in an identical manner to that shown above. In the presence of <10 mol % of catalyst **1b**, high yields and selectivities can be obtained (4).[6] One drawback of this method is that 50% of the starting alkene must be sacrificed. However, recent reports have revealed that use of a mixed organozinc species, which is accessible by disproportionation of two symmetric organozinc reagents, obviates this wasteful complication (5).[7]

Comparable selectivity can be obtained in the alkylation of benzaldehyde **3** with diethylzinc using the titanium TADDOL complex **20** (>99:1 er) or 3-*exo*-(dimethylamino)isoborneol, **21** (>99:1 er), although both methods employ higher catalyst loadings.[8,9] While benzaldehyde is illustrative, the substrate scope is equally broad in the case of these two catalysts.

Cyclopropanation of Allylic Alcohols

Simmons-Smith type cyclopropanation of the allylic alcohol **22** in the presence of a catalytic amount of the bis-sulfonamide **1a** leads to formation of the corresponding cyclopropane **23** in high yield and selectivity (6, Table 3).[10] The reaction is rapid (<1 h) and can be performed at low temperature (either 0 °C or -20 °C). Substrate scope encompasses both di- and tri-substituted allylic alcohols (**24** and **26**). However, substitution at the 2 position, as in **28**, leads to a drastic decrease in selectivity. The presence of additional oxygenated functionality (**30**) in the proximity of the alkene also lessens selectivity.[11] The method is limited to the cyclopropanation of allylic alcohols. Other alkene-containing substrates, such as allylic ethers, homo-allylic alcohols and allylic carbamates, do not react with high selectivity.

er, enatiomeric ratio.

The optimal procedure calls for a three-flask protocol which segregates the individual reactive components. Pre-formation of the zinc alkoxide, zinc sulfonamide complex and the cyclopropanation reagent, $Zn(CH_2I)_2$, by combination of diethylzinc with the allylic alcohol, bis-sulfonamide and diiodomethane, respectively, is essential for high selectivity and reproducibility. While the individual reaction components are soluble in halogenated solvents such as dichloromethane, the zinc sulfonamide complex is a highly insoluble species which is prone to aggregation. Because of the nature of the zinc carbenoid, a heterogenous reaction is always observed. None of the related bis-sulfonamide catalysts shown in Table 4 are able to dissolve the precipitate. Still, a survey of catalyst structure reveals that large variations in sulfonamide structure can be tolerated without compromising selectivity (entries 1 and 2).[10,12] Bulky sulfonamide groups, however, clearly interfere with the selective cyclopropanation process (entries 3 and 4).

Table 4 Selectivity of various sulfonamides in the cyclopropanation of **22**

Entry	R	Compound	**23** (cr)
1	*n*-Bu	**1c**	92:8
2	4-$NO_2C_6H_4$	**1d**	89:11
3	*i*-Pr	**1e**	86:14
4	2,4,6-MeC_6H_2	**1f**	62:38

This method is comparable to similar, catalytic Simmons-Smith-type methods employing the titanium TADDOL catalyst **20** (95:5 er) or the C_1-symmetric bis-sulfonamide catalyst **32** (93:7 er) for the cyclopropanation of the allylic alcohol **22** (6).[13,14] However, due to the preliminary nature of these earlier investigations, substrate scope and generality have not been extensively documented. All of the aforementioned methods are limited by their dependence on the allylic alcohol functionality. Only one method for Simmons-Smith-type cyclopropanation of other substrate classes has been developed. Use of a stoichiometric, chiral dioxaborolane [CAS 161344-85-0] additive allows for selective cyclopropanation of allylic ethers, homo-allylic alcohols and allylic carbamates.[15]

(catalyst for asymmetric aldol additions of trichlorosilyl enolates to aldehydes,[1] catalyst for asymmetric allylations and crotylations of allylic trichlorosilanes to aldehydes,[2] catalyst for asymmetric ring opening of epoxides using silicon tetrachloride[3])

Physical Data: mp 110 °C; $[\alpha]_D^{22}$ +18.2 (*c*=1.3, $CHCl_3$).

Solubility: soluble in most organic solvents except hydrocarbons.

Form Supplied in: white needles.

Preparative Methods: The enantiopure phosphoramide (*S*,*S*)-**1a** is prepared from treatment of (*S*,*S*)-*N*,*N*´-dimethyl-1,2-diphenyl-1,2-ethanediamine (**5**) with piperidinylphosphoric dichloride (**6**) and triethylamine (1).[4] Synthesis of related phosphoramides is easily accomplished by substituting the desired diamine backbone in the former procedure. Recrystallization of phosphoramide (*S*,*S*)-**1a** from hexane followed by drying over P_2O_5 allows for isolation of analytically pure material. Enantiopure 1,2-diphenyl-1,2-ethanediamine (**5**) can be prepared from benzil and cyclohexanone according to the method of Pikul & Corey.[5] Bis-formylation of the diamine with acetic formic anhydride followed by $LiAlH_4$ reduction affords *N*,*N*´-dimethyldiamine **5**. Alternatively, enantiopure **5** can be prepared directly from benzaldehyde and methylamine according to the method of Alexakis et al.[6] Piperidinylphosphoric dichloride (**6**) is prepared from piperidine, triethylamine and phosphorous oxychloride according to the modified procedure of Peyronel et al.[7]

Handling, Storage, and Precautions: The phosphoramide is a stable, hygroscopic compound which is best stored in a dessicator or dry-box. Avoid prolonged exposure to air or moisture.

Introduction

[4*S*-(4α,5β)]-1-(1,3-Dimethyl-2-oxido-4,5-diph-enyl-1,3,2-diazaphospholidine-2-yl)piperidine (**1a**) and its derivatives are an important class of phosphoramides which have seen much success as Lewis-basic catalysts for aldol additions,[8] allylations,[9] crotylations, and epoxide openings.[10] The three nitrogen subunits of the phosphoramide provide the opportunity for a large number of structurally diverse analogs, allowing a wide spectrum of properties and shapes to be customized.[11]

Ester enolate aldol additions to aldehydes

Among the first examples of aldol additions employing chiral Lewis bases as catalysts were the additions of trichlorosilyl ketene acetals to aldehydes.[12] Silyl ketene acetal **7** could be generated by metathesis of methyl tributylstannylacetate with $SiCl_4$. Treatment of **7** with benzaldehyde and 10 mol % of a phosphoramide in CH_2Cl_2 at -78 °C afforded aldol products in good to high yields with moderate enantioselectivities for all phosphoramides employed. Reaction of **7** with pivalaldehyde provided aldol products in similar yields and with slightly improved enantioselectivities. The increase in stereoselection is presumably attributed to a less competent background reaction inherent with additions to more sterically encumbered aldehydes (2, Table 1).

(2)

Ketone enolate aldol additions to aldehydes

Addition of methyl ketone trichlorosilyl enolate **9** to benzaldehyde in the presence of catalytic amounts of phosphoramide (*S*,*S*)-**1** affords aldol products in excellent yields.[13] The level of enantioselectivity was found to be dependent upon the amount of (*S*,*S*)-**1a** used, with higher loadings providing better selectivities. A typical procedure involves equilibration of a solution of trichlorosilyl enolate and (*S*,*S*)-**1a** in CH_2Cl_2 at -78 °C followed by addition of aldehyde. Reactions are quenched upon completion by quickly pouring the cold reaction mixture into a rapidly stirring aqueous $NaHCO_3$ solution placed in an ice bath. Alternatively, completed reactions may be quenched using a cold 1:1 mixture of a saturated aqueous KF solution and an aqueous 1 M KH_2PO_4 solution. In either case, rapid stirring of the cold quench mixture prevents acid-catalyzed β-elimination of the aldol products to give undesired α,β-unsaturated ketones (3, Table 2).

The generality of methyl ketone enolate additions to benzaldehyde was demonstrated by varying the spectator portion of the nucleophile.[13] In all cases, high yields were achieved using as little as 5 mol % (*S*,*S*)-**1a**. The enantioselectivity of the process, however, was sensitive to the enolate structure with larger groups, such as *t*-butyl and phenyl (4, Table 3, entries 5 and 6), providing lower enantioselectivities. The success of a functionalized enolate (4, Table 3, entry 7) demonstrated the tolerance for oxygenated substituents in the phosphoramide-catalyzed aldol addition, whereby no deleterious effect was observed on either the yield or enantioselectivity as compared with unfunctionalized enolates.

The phosphoramide-catalyzed aldol addition was less sensitive to variations on the electrophile. Using 2-hexanone trichlorosilyl enolate **13** as an example aldol additions to various aldehydes affords aldol products in good to high yields and with excellent enantioselectivities, using as little as 5 mol % catalyst.[13] Additions to branched aliphatic aldehydes, such as cyclohexanone and pivalaldehyde (5, Table 4, entries 5 and 6), were sluggish when using 5 mol % catalyst. However, increasing the catalyst loading to 10 mol % provides good yields of the aldol products after 6 h with excellent enantioselectivities.

er, enantiomeric ratio.

Recently, the synthetic utility of phosphoramide-catalyzed aldol additions of trichlorosilyl enolates to aldehydes has been enhanced by the ability to generate the delicate trichlorosilyl enolates in situ.[13] Treatment of the corresponding TMS enol ether with $Hg(OAc)_2$ followed by addition of a solution phosphoramide and aldehyde afford aldol products in high yields over two steps without affecting stereoselectivities. This is exemplified by the addition of chiral α-oxygenated trichlorosilyl enolates to benzaldehyde. Using the (*S*)-lactate-derived methyl ketone enol ether **15**, addition to benzaldehyde afforded aldol products in high diastereoselectivity for the matched-sense using (*R*,*R*)-**1a**.[13,14] Although the reaction was compatible with various oxygen functionalities, the stereoselectivity was highly dependent upon the nature of the protecting group, with the OTBS group superior to both the benzyloxy or pivaloyl protecting groups (6, Table 5).

(6)

To further exemplify the dependence of the stereochemical course of chiral enolate additions catalyzed by phosphoramides, a detailed survey of additions to aldehydes using chiral β-hydroxyenolate **17** and 10 mol % of **1a** was performed.[15] Unlike additions of **15**, diastereoselectivities of the resultant aldol products using **17** could be switched depending upon the configuration of the phosphoramide employed (7, Table 6).

Table 6 Addition of TMS enol ether **17** to aldehydes catalyzed by **1a**

(7)

The phosphoramide-catalyzed aldol addition of substituted enolates to aldehydes provides the opportunity to generate disubstituted aldol products with high stereoselectivity. The (*S*,*S*)-**1a**-catalyzed addition of cyclohexanone trichlorosilyl enolate **19** to aldehydes has been well studied and demonstrates good substrate generality.[16] The aldol reactions of this *E*-enolate are rapid when 10 mol % of (*S*,*S*)-**1a** is used. Reactions are typically complete within 2 h affording *anti*-aldol products in high yields with excellent diastereo- and enantioselectivities. Although the typical procedure using methyl ketone enolates can be followed, higher diastereoselectivities may be achieved by slow addition of a solution of aldehyde to the mixture of enolate and catalyst in CH_2Cl_2 at -78 °C over several minutes.[17] Remarkably, a dramatic switch in diastereoselectivity is observed when phosphoramide **1b** (10 mol %) is employed as a catalyst (8, Table 7, entry 2). Although the level of enantioselectivity was modest, the change in diastereoselectivity demonstrates that small structural changes in the phosphoramide can have profound effects on the stereochemical course of the reaction. This is further exemplified through a systematic substitution of the internal

(phospholidino) nitrogens (8, Table 7, entries 1 and 8), the external nitrogen (8, Table 7, entries 1 and 3-7),[18,19] as well as changes to the electronic demand of the aryl substituent (8, Table 7, entries 1 and 9-11).[20]

er, enantiomeric ratio.

In contrast to the *E*-enolates derived from cyclic ketones, addition of propiophenone trichlorosilyl enolate (*Z*)-**21** to aldehydes requires longer reaction times and higher loadings of catalyst.[16] Although the yields of the aldol products remain high, both the diastereo- and enantioselectivities are attenuated as compared to their *E* counterparts (9, Table 8).

Allylic additions to aldehydes

Although phosphoramide **1** is capable of promoting the addition of allyltrichlorosilane to aldehydes, the enantioselectivities were modest at best compared with the cyclohexyldiamine analogs **3**.[21] Preliminary results showed the allylations to be high yielding but giving only moderate enantioselectivities when using one equivalent of phosphoramide as a promoter. As observed in the stereoselective aldol additions with phosphoramides, subtle changes to the nitrogen substituents also dramatically affect the stereochemical course of allylations using allylic trichlorosilanes (10, Table 9, entries 7-9).[22] Under optimized conditions, as few as 0.25 equivalents of phosphoramide may be used with little erosion in yield or stereoselectivity (10, Table 9, entries 3-5).

er, enantiomeric ratio; NA, not available.

The phosphoramide-catalyzed allylic additions to aldehydes have also been extended to include stereoselective crotylations. When using geometrically defined 2-butenyltrichlorosilanes, additions to benzaldehyde afford homoallylic alcohols in good yields and excellent diastereoselectivity (11).[21a] Enantioselectivities, however, remain comparable to the results for allylic additions. Interestingly, the crotylation results suggest that addition proceeds through a cyclic transition structure.[23]

Epoxide openings using $SiCl_4$

The binaphthyldiamine-derived phosphoramide (*R*)-**4** is an effective catalyst for the opening of various epoxides with $SiCl_4$ to afford chlorohydrins in high yields.[24] The rate and stereoselectivity for the ring opening of *meso*-epoxides are extremely dependent upon the structure of the epoxide. In the examples shown for epoxycycloalkanes, only cyclohexene oxide [10 mol % (*R*)-**4**] affords a chlorohydrin in high yield and good enantioselectivity (12, Table 10, entry 2). In contrast, cyclopentene oxide and cyclooctene oxide give essentially racemic chlorohydrin (12, Table 10, entries 1 and 3) with cyclooctene oxide requiring more than 5 days for complete reaction. In comparison to the cyclic epoxides, the acyclic substrates afford chlorohydrins with increased enantioselectivities (12, Table 10, entries 4 and 5). In a typical procedure, a solution of epoxide in CH_2Cl_2 is added to a mixture of $SiCl_4$ and phosphoramide at -78 °C in CH_2Cl_2. To avoid opening of epoxides by adventitious HCl,[25] it is essential to maintain $SiCl_4$ acid free.[26]

Table 10 Stereoselective ring opening of *meso*-epoxides catalyzed by (*R*)-**4**

Entry	Epoxide (R)	Time (h)	er	Yield (%)
1	$-(CH_2)_3-$	0.3	1.16:1	87
2	$-(CH_2)_4-$	0.3	3.13:1	90

(-)-*endo*-Bornyltriazolinedione

[73462-83-6] · $C_{12}H_{17}N_3O_2$ · (235.29)

(reagent used in cycloaddition reactions[1] as a dienophile of high reactivity for the trapping of unstable intermediates,[2,3] and 1,3-dienes,[4] the preparation of optically active axially symmetric molecules,[5] and the resolution of hydrocarbons and chiral dienes[6,7])

Alternate Name: 4-(1,7,7-trimethylbicyclo[2.2.1]hept-2-yl)-[1,2,4]triazole-3,5-dione.

Physical Data: mp 152-154 °C; sublimation point 75-85 °C at 0.1 Torr; $[\alpha]^{20}_{D}$ -77 (*c* 5.7, CH_2Cl_2)

Form Supplied in: red solid prepared from optically pure *d*-camphor oxime[8] in a five-step sequence (1): reduction with sodium in *n*-amyl alcohol followed by fractional recrystallization of the resulting hydrochloride salts of bornylamines[9,10] gives the *endo*-isomer in enantiomerically pure form; treatment with phosgene and direct condensation of the isocyanate with (ethoxycarbonyl)hydrazine gives a compound which cyclizes upon treatment with base; subsequent nitrogen dioxide oxidation furnishes (-)-*endo*-bornyltriazolinedione as a red crystalline solid.[11-13]

Form Supplied in:

Handling, Storage, and Precautions: stable for prolonged periods when stored cold in the absence of light; easy to handle; solid.

The main interest in (-)-*endo*-bornyltriazolinedione resides with its high dienophilic character in cycloaddition processes to yield separable mixtures of diastereoisomeric urazoles. The non-destructive resolution of cyclooctatetraenes, which allows direct access to optically pure derivatives, is a typical illustration and has been amply demonstrated.[14-19] Typically, (-)-*endo*-bornyltriazolinedione is heated with racemic 1,2,3-trimethylcyclooctatetraene in ethyl acetate to afford a mixture of diastereoisomeric adducts, which can be separated by fractional recrystallization from ethyl acetate and hexane. HPLC is an alternative separation technique leading to both enantiomerically pure antipodes. The chiral auxiliary is subsequently removed by basic hydrolysis-manganese dioxide oxidation to afford the optically pure cyclooctatetraenes (2).

(2)

This method of resolution of polyolefins has been extensively studied for cyclooctatetraene systems where excellent enantiomeric excesses are normally observed. Lanthanide-induced shifting can be used to determine the diastereoisomeric composition of the urazoles.[14] Alternate means

for the resolution of polyenes based on kinetic resolution using (+)-tetra-2-pinanylborane have been described,[20,21] but this reagent consumes valuable substrate. Chiral platinum complexes[22] can also be used but at prohibitive cost on a large scale and with poor regioselectivity when several coordination sites are present.

The utilization of an optically active triazolinedione for asymmetric transfer has also led to the preparation of enantiomerically pure polycyclic hydrocarbons. The method provides a straightforward means for introducing optical activity into chiral propellanes that possess a conjugated diene unit. Racemic propellane[5] reacts with (-)-*endo*-bornyltriazolinedione in ethyl acetate at -78 °C to give, after HPLC separation, the two optically pure urazoles. Subsequent reduction with lithium aluminum hydride affords the two propellanes in enantiomerically pure form (3).

From a purely synthetic viewpoint, triazolinedione adducts have served as substrates for gaining access to numerous target molecules such as prismane,[23] semibullvalene,[24] bridged semibullvalenes,[25] elassovalene,[26] caged compounds,[27] and azoalkanes. Indeed, the title reagent can be used not only as a chiral source, but also as an azo donor. In the synthesis of 4,5-diazatwis-4-ene,[28] for example, (-)-*endo*-bornyltriazolinedione was a pivotal reactant that allowed incorporation of the azo unit in addition to providing a means for resolution. The first step involved cycloaddition to cyclooctatetraene dibromide with formation of a separable mixture of diastereoisomers. Eventual removal of the chiral moiety in a modified hydrolysis-oxidation sequence yielded the desired azo compound (4).

The high crystallinity of the urazole obtained by cycloaddition has also made (-)-*endo*-bornyltriazolinedione a useful reagent for obtaining crystalline derivatives. Diels-Alder cycloaddition of (-)-*endo*-bornyltriazolinedione to a diene of unknown configuration resulted in the formation of a single cycloadduct[4] whose structure was confirmed by X-ray diffraction analysis of the urazole (5).

(5)

X-ray structure

Applications of (-)-*endo*-bornyltriazolinedione to asymmetric synthesis in cycloaddition reactions have shown low levels of induction. In the examples studied, (-)-*endo*-bornyltriazolinedione reacted almost instantaneously with various dienes even at low temperature (<96 °C) resulting in low asymmetric induction (<10%).[29] The high reactivity of triazolinedione in [4+2] π-cycloadditions due to its high dienophilicity minimized differentiation between the transition states and has to date impeded its use in asymmetric synthesis.

Related Reagents.

4-phenyl-1,2,4-triazoline-3,5-dione; (-)-(α)-(methylbenzyl) triazolinedione; (dehydroabiethyl)triazolinedione; (+)-tetra-2-pinanylborane; chiral platinum complexes.

(*R*)-*B*-Methyl-4,5,5-triphenyl-1,3,2-oxazaborolidine

[155268-88-5] · $C_{21}H_{20}BNO$ · (313.21)

(catalyst used for the borane-mediated stereoselective reduction of ketones)

Solubility: soluble in most organic solvents, e.g. THF, diethyl ether, $CHCl_3$, toluene.

Analysis of Reagent Purity: ^1H NMR (C_6D_6).

Preparative Methods: (*R*)-1,1,2-Triphenyl-2-aminoethanol, the precursor of the oxazaborolidine, is prepared in 60-73% yield by portionwise addition of solid methyl (*R*)-phenylglycinate hydrochloride to an excess of **phenylmagnesium bromide** (3 M in diethyl ether) at 0 °C. The amino alcohol (>99% ee, after recrystallization from ethanol) is treated with trimethylboroxine in refluxing toluene in a flask provided with a Dean-Stark trap and under argon. Removal of all the volatiles under vacuum gives (*R*)-*B*-methyl-4,5,5-triphenyl-1,3,2-oxazaborolidine [(*R*)-**1**]as a colorless oil, which is then diluted with toluene up to a known concentration.[1]For reductions, a sample of that solution is transferred via cannula to another flask and the solvent is removed under vacuum and replaced by THF under argon. (*S*)-*B*-Methyl-4,5,5-triphenyl-1,3,2-oxazaborolidine [(*S*)-**1**] can be obtained from methyl (*S*)-phenylglycinate hydrochloride in a similar way. Both enantiomers of methyl phenylglycinate hydrochloride are commercially available at moderate prices.

Purification: Occasionally in the ^1H NMR spectrum of the oxazaborolidine (C_6D_6), besides the expected signal at δ 5.38 ppm, a singlet at δ 4.93 ppm can be observed which is due to hydrolyzed, ring-cleaved material. The product may be purified by further treatment with a small amount of trimethylboroxine in refluxing toluene.

Handling, Storage, and Precautions: This oxazaborolidine is sensitive to water and to oxygen. However, its toluene solution can be stored at room temperature under argon for months with negligible loss of its catalytic activity. Care should be exercised to avoid contact of this compound with eyes and skin, and it should be manipulated in a well-ventilated fume hood.

Enantioselective Ketone Reduction

After the pioneering work of Itsuno et al.,[2] Corey's group isolated the 1,3,2-oxazaborolidine derived from chiral **α,α-diphenyl-2-pyrrolidinemethanol** (**2**) and applied it (and also other related *B*-alkyl compounds) to the stereoselective reduction of ketones with **borane-**

tetrahydrofuran, **borane-dimethyl sulfide** (BMS) or **catecholborane.**It was named the CBS method (after Corey, Bakshi, and Shibata).[3] Since then, the CBS method has become a standard and has been extensively used, specially for aromatic and α,β-unsaturated ketones, not only in academic laboratories but also in industrial processes.[4]

Among the diverse 1,2-amino alcohols described as precursors of oxazaborolidines,[5] the use of both enantiomers of highly enantioenriched 1,1,2-triphenyl-2-aminoethanol, which lead to oxazaborolidines (*R*)-**1** and (*S*)-**1**, is especially attractive as they arise from inexpensive (*R*)- or (*S*)-phenylglycine, respectively. Oxazaborolidines (*R*)-**1** and (*S*)-**1**are efficient catalysts in the borane-mediated stereoselective reduction of some types of prochiral ketones.

Typically, reductions are performed by slow addition (~15-30 min) of the ketone (1.0 mmol) to a solution of BMS (1.0 mmol) and 0.1-1.0 mmol of **1** (~1 M in THF) under argon at 0 °C (1). Yields are excellent in general after stirring for a further few minutes. The slow addition of ketone appears to enhance the stereoselectivity and in many cases causes the ee noted with 0.1 mmol of **1** to be similar or only slightly lower than that in the stoichiometric case.

(1)

Alcohols **3**-**8**, obtained by the reduction of the corresponding ketones with equimolar amounts of BMS and (*R*)-**1**, are obtained with high ees (ee values given are obtained using 0.1 equiv of (*R*)-**1**). Enantioselectivity is excellent (often similar or only slightly lower than those reported in the CBS reduction) for aromatic and hindered methyl ketones,[1a,6] (e.g. **3**-**5**) and is also good for linear and α-monobranched enones[7] (e.g. **7** and **8**), but lower for linear methyl ketones like 2-octanone (**6**). In should be noted that in the reduction of unsaturated ketones, the time of addition is critical (the optimum being around 15-20 min) in order to avoid concomitant olefin hydroboration. In sharp contrast to the CBS process, the use of **catecholborane** (instead of BMS) or alternative solvents proved to be detrimental.

As far as the stereochemical course of the reaction is concerned, the configuration of the emergent stereocenter may be explained in terms of the mechanism proposed by Corey et al. for similar oxazaborolidine mediated reactions.[4] Thus, the transition state operates such that the bigger group (R_L) is located remotely from the methyl group on the boron atom (2).

(2)

Accordingly, the experience gained with oxazaborolidine **1** suggests an order of 'empirical' size of R groups.[8] Obviously, better enantioselectivities in the reduction of the ketone carbonyl group are achieved when the substituents R_L and R_S are dissimilar.

The reduction of α-phenylthio enones constitutes a recent application of these findings to the preparation of chiral α-hydroxy thioesters (3).[9]

(3)

Reduction of Acetylenic Ketones

The enantioselective reduction of α,β-acetylenic ketones (R-CO-C&tbond;C-R´, R´ = H or TMS) with BMS and **1**affords the corresponding propargylic alcoholsin good to excellent yields and >90% ee (see eq 4 as and example).[1b] In some cases, the reductions of more sterically crowded hexacarbonyldicobalt complexes (e.g.**9**) derived from the acetylenic ketones also lead, after decomplexation with Cerium (IV) Ammonium Nitrate (CAN), to the same alcohols. However, the use of an oxazaborolidine with an α-face more available for complexation, such as those derived from commercially available (1*S*,2*R*)-2-amino-1,2-diphenylethanol, is required (5).[10] Remarkably, the temporary transformation of the acetylenic moiety into its $Co_2(CO)_6$ complex, not only reverses the stereoselectivity in the reduction step, but also enhances it.

(4)

In addition, the highly enantioenriched propargylic alcohols obtained in such a way are versatile building blocks. Theyhave been applied to the syntheses of the alkyl side chains of zaragozic acids A and C,[11]several metabolites isolated from marine sponges,[12] and the octalactin A ring.[13]

On the other hand, the BMS/(*R*)- or (*S*)-**1** mixture is capable of displaying high asymmetric induction in the reduction of acetylenic ketones, thereby overriding the normally small diastereofacial selectivity of a chiral α-substituted 1-trialkylsilyl-1-alkyn-3-one (e.g. **10**) in a predictable and controlled manner (reagent control) (6). Remarkably, the stereoselectivity noted in such reductions has shown strong dependence upon the steric requirement of the C(1) substituent. Thus, an increasing stereoselectivity has been noted in the reduction of ketones **10**as R changes from Me to Et to *i*-Pr. An explanation for such an unexpected remote effect has been suggested based on abinitio calculations.[14]

Further work according to this double asymmetric strategy has led to the establishment of a stereodivergent route to β-hydroxy γ-substituted carboxylic acids and α-hydroxy β-substituted carboxylic acids (including *N*-Boc-statine and *N*-Boc-norstatine).[15]

Reduction of 1,4-Diketones

Synthetic access to C_2-symmetric 1,4-diols, useful building blocks for the preparation of chiral 2,5-disubstituted pyrrolidines and phospholanes, involves reduction of the parent 2-alkane-1,4-diones, or, even better, reduction of the related (*E*)-alk-2-ene-1,4-diones (**11**) (7) or 2-alkyne-1,4-diones (**12**) (8), followed by catalytic hydrogenation.[16]

(7)

(8)

Generally, reduction of diketones **12** (or in some cases their hexacarbonyldicobalt complexes) yields better stereoselectivities than the related ethylenic diketones **11**, especially when R is a sterically demanding group. In addition, the propargylic diols obtained can be easily transformed not only into the saturated 1,4-diols, but also into (*Z*)- or (*E*)-alk-2-ene-1,4-diols. The C_2-symmetric allylic 1,4-diols have been very recently used as building blocks in a formal synthesis of (-)-methylenolactocin and (-)-phaseolinic acid.[17]Related to this, it should be noted that reduction of the unstable (*Z*)-alk-2-ene-1,4-diones (**13**) is an unsuitable route to (*Z*)-alk-2-ene-1,4-diols since a considerable amount of 1,4-reduction (9) is also observed.[17,18]

S-(1-Oxido-2-pyridinyl)-1,1,3,3-tetramethylthiouronium Hexafluorophosphate (HOTT)

[212333-72-7] · $C_{10}H_{16}N_3OSPF_6$ · (371.28)

(reagent used to convert carboxylic acids into Barton esters and for peptide coupling/amidation)

Physical Data: mp 115-116°C.

Solubility: acetonitrile, CH_2Cl_2, THF (moderate solubility).

Form Supplied in: white solid.

Purification: recrystallized from CH_2Cl_2.

Handling, Storage, and Precautions: it is advised to protect the solid from prolonged exposure to light since 2-mercaptopyridine *N*-oxide and related compounds can be light-sensitive.

Preparative Methods: the title reagent can be prepared by slowly adding Et_3N to a dry CH_2Cl_2 solution of 2-mercaptopyridine-*N*-oxide and tetramethylchloroformamidinium hexafluorophosphate.[1] After removal of CH_2Cl_2 from the reaction mixture, the resulting solid mass is pulverized, washed with $CHCl_3$, and then filtered to give a white solid of sufficient purity to be used in subsequent reactions.[2]

Barton Esterification: Reductive Decarboxylation

O-Acyl thiohydroxamates or Barton esters are useful precursors of carbon-centered radicals via thermolysis or photolysis.[3] Several different methods are available for converting carboxylic acids into Barton esters (eq 1).[4] These reactions generally proceed via the attack of a 2-mercaptopyridine-*N*-oxide salt on an activated carboxylic acid that has either been preformed (acid chloride, mixed anhydride) or generated in situ (with 1,3-dicyclohexylcarbodiimide or tri-*n*-butylphosphine +2,2´-dithiodipyridine-1,1´-dioxide). However, HOTT has the distinct advantages of (1) being easy to prepare and handle without the need for any special precautions, (2) facilitates efficient Barton esterification of carboxylic acids, and (3) simplifies subsequent work-up and purifications by avoiding the need to remove by-products like 1,3-dicyclohexylurea.

(1)

The HOTT reagent has been shown to significantly improve the yields of reductive decarboxylations of 2,3:4,6-di-*O*-isopropylidene-2-keto-L-gulonic acid (eq 2) and peracetylated *N*-acetylneuraminic acid (eq 3).[2] In both cases, the yield of reduced product nearly doubled when HOTT was used to esterify these hindered carboxylic acids.

78% yield
(42% via acid chloride) (2)

(3)

50% yield
(27% via carbodiimide)

Barton Esterification: Oxidative Decarboxylation

HOTT-mediated Barton esterification was coupled to oxidative decarboxylation in a synthesis of the sesquiterpene (+)-culmorin (eq 4).[5] Use of the HOTT reagent was clearly superior with this hindered substrate when compared with the acid chloride method.

Barton Esterification: Radical Addition

One of the best examples illustrating the benefits of HOTT for this transformation is shown in eq 5. The Barton esterification of this very hindered acid was followed by IR spectroscopy by monitoring the disappearance of the carbonyl stretch of the acid (1740 cm^{-1}) and the appearance of the carbonyl stretch of the Barton ester (1810 cm^{-1}). Barton esterification using HOTT was complete within 20 min, whereas over 4 h was required when using the combination of DCC and 2-mercaptopyridine-*N*-oxide.

73% yield
(47% via carbodiimide)

HOTT was used to effect Barton esterification in a novel approach to 1, 3, 5,…(2*n*+1) polyols based on iterative stereocontrolled homologation of chiral hydroxyalkyl radicals (eq 6).[6]

(6)

General notes: As with most Barton esterifications, the reaction should be performed in the dark and under anhydrous conditions.

Peptide Coupling

The HOTT reagent, as well as the corresponding tetrafluoroborate salt (TOTT), have also been reported to be inexpensive alternatives to uronium- and phosphonium-based peptide coupling reagents (eq 7).[7] Yields were generally on the same order as those observed with standard peptide coupling reagents. An advantage of these reagents -at least in some instances -may be a reduced propensity of the *N*-protected amino acid component to racemize during the coupling reaction.

(7)

Synthesis of Primary Amides

Carboxylic acids can be converted to their primary amides using HOTT (or TOTT) as the coupling agent (eq 8 and 9).[8] The reaction conditions are very mild and do not adversely affect other functionality prone to nucleophilic attack by ammonia. A simple extractive work-up is sufficient to obtain the primary amides in pure form.

Chloro[(1,2,5,6*H*)-1,5-cyclooctadiene] (*H*5-2,4-Cyclopentadiene-1-yl) Ruthenium

[97913-63-8] · $C_{13}H_{17}RuCl$ · (310)

(catalyzes the coupling reaction between alkenes and alkynes to yield Alder ene-type products)

Physical Data: air- and light-sensitive golden orange solid, mp 230-235°C.

Solubility: soluble in water and various organic solvents including alcohols, DMF and acetone.

Form Supplied in: readily synthesized in high yield.[1]

Cycloadditions

Chloro[(1,2,5,6*H*)-1,5-cyclooctadiene] (*H*5-2,4-cyclopentadiene-1-yl) ruthenium [CpRu(COD)Cl] catalyzes the cycloaddition of cyclooctadiene with a variety of alkynes to give the corresponding cycloadducts (eq 1).[2] Terminal alkynes also undergo this ruthenium-catalyzed cycloaddition process. The reaction is highly chemoselective. However, the presence of aromatic groups on the alkyne moiety greatly diminish the yield of the cycloadduct. Interestingly, hexa-1,5-diene and octa-2,6-diene do not undergo cycloaddition under similar conditions.

(1)

Sterically bulky alkynes undergo such cycloadditions, but at a much slower rate. This has been exploited in the cycloaddition of a diyne which cycloadds exclusively to the less sterically congested alkyne (eq 2).[2]

(2)

Alkene-Alkyne Coupling Reactions

The most important synthetic application of CpRu(COD)Cl is that it catalyzes the addition of terminal alkenes to terminal alkynes. Reacting oct-1-ene and oct-1-yne at elevated temperature in the presence of 5 mol% of CpRu(COD)Cl gave a 5:1 ratio of the branched and linear 1,4-diene (eq 3).[3] Other simple unfunctionalized alkenes/alkynes yielded the branched isomer as the major product. In a comparative study with other ruthenium complexes, CpRu(COD)Cl was found to be the most effective in such transformations.[4] Unlike arene ruthenium complexes, the use of CpRu(COD)Cl does not employ a promotor or phosphines to increase the effectiveness of the catalyst.

(3)

Remote functionality on the alkene tether (alcohols, esters, enoates and ketones) and on the alkyne tether (ester and silyl ethers) did not affect the process in terms of yield or selectivity.[3,4] Interestingly, a normally reactive enoate does not interfere with the coupling (eq 4).

Internal alkynes also undergo coupling with terminal alkenes (eq 5). Only one regioisomer is possible.[3,4]

The ruthenium-catalyzed Alder ene-type reaction has been applied to the formal synthesis of alternaric acid.[5] In model studies it was found that relatively acidic substrates, such as carboxylic acids, inhibit the reaction. Esters, however, underwent clean conversion (eq 6).

(6)

$R^1 = H$ trace

$R^1 = Me$ 49%

$R^2 = t\text{-}Bu$

In the key ruthenium-catalyzed coupling step, high regioselectivity was obtained with the free diol (protection reduced regioselectivity) and the Fmoc-protected ester (eq 7). The ratio of products was 8.9:1 in favor of the branched isomer.

(7)

CpRu(COD)Cl catalyzes the coupling of γ-amido-α,β-alkynoate esters with monosubstituted alkenes (eq 8).[6] Carbon-carbon bond formation occurs at the α-carbon of the alkynoate (4.2:1 ratio of α/β-regioisomers). Interestingly the usually more reactive conjugated diene was a spectator in the reaction. No Diels-Alder-type products were observed. The reaction is tolerant of a range of functionality on the alkene moiety, including esters and propargyl alcohols. The integrity of stereogenic centers on the alkyne moiety was maintained throughout the reactions.

Propargyl Substituents

Substitution at the propargylic position of the alkyne moiety has a profound effect on the regioselectivity of the addition. A cyclohexane substituent at that center reduces selectivity.[3,4] Remarkably oxygen substituents reversed selectivity in favor of the linear product.[3,4] Placing an acetal at the propargylic position increased the linear to branched selectivity to 6:1 (eq 9). The acetal hydrolyzes under the reaction conditions.

In optimization studies, using aqueous DMF as the solvent gave the highest yields and regioselectivity for the reaction of methyl 10-undecenoate and but-2-yn-1-ol (eq 10).[4] A methanol/Bu_4NCl system was found to give comparable yields to aqueous DMF but the regioselectivity of the reaction was diminished.

The combination of having oxygen substituents and branching at the propargylic center results in the highest regioselectivity (up to 9.9:1 in favor of the linear isomer).

Internal propargyl alcohols react with terminal alkenes to yield Baylis-Hillman-type products.[7] Baylis-Hillman reactions are usually quite limited to electrophilic partners that do not interfere with the nucleophile. Yields were good and the isomeric ratio high in favor of the branched isomer in many examples. Hydroxy- and cyano- groups on the propargyl alcohol moiety gave particularly high regioselectivities, yielding almost exclusively the branched product. The addition of indium triflate as a co-catalyst was found to improve regioselectivity towards the branched isomer. Alkyl substituents at the propargylic center had no significant effect on the outcome of the reaction. Remote functionality on the alkyne moiety (R^1) was found to have a large effect on regioselectivity (eq 11). Placement of a hydroxyl group two or three carbons away from the alkyne (R^1=-OH or -CH_2OH) led to only one regioisomer, the branched product. Placing cyano- or cyano/hydroxyl groups in a similar manner [R^1=-CN or -$CH(CN)CH_2OH$] yields only the branched isomer.

(11)

ratio 10:1

65 %

Silyl-alkynes are effective in controlling the regioselectivity of the coupling reaction with terminal alkenes.[8] Although terminal alkynes couplings proceed with high chemoselectivity, the reactions have previously produced mixtures of isomers. For example, propargyl alcohols react with oct-1-ene to yield a single product (eq 12). In comparison the same alkyne, without the silyl substituent, yields a 1:1.3 mixture of the branched and linear regioisomers. However, a more reactive ruthenium catalyst (with the absence of chloride ligands) has been shown to be more effective in such transformations.[8]

(12)

52%

Allylic Alcohols

CpRu(COD)Cl promotes the coupling of internal and terminal alkynes with allylic alcohols to yield linear and branched γ,δ-unsaturated ketones (eq 13 and 14).[9]

ratio 2.3:1

60%

50%

In contrast to other ruthenium coupling reactions, both aliphatic and aromatic acetylenes are efficient partners. Aromatic alkynes frequently inhibit such reactions, a consequence of the ease in forming arene complexes. Aqueous DMF as the solvent gave the best rates of reaction and regioselectivity. Alkynes conjugated to esters gave similar yields and regioselectivity in comparison with terminal alkynes (eq 15).[9]

ratio 2.4:1

76 %

An application of this methodology has been achieved for the introduction of a steroid side chain (eq 16).[9] Reacting the alkyne with an allylic alcohol yielded the linear product in moderate yield.

43%

The reaction of propargyl alcohol derivatives with allylic alcohols was found to give the highest regioselectivity in favor of the linear products in 50-60% isolated yields (eq 17).[9]

Butenolide Formation

CpRu(COD)Cl coupling reactions of an alkene to an alkyne have been utilized in the synthesis of butenolides. Methyl 10-undecenoate reacted with 4-hydroxybutynoate and 5 mol% of CpRu(COD)Cl to yield a 2.9:1 ratio of the butenolide and hydroxy ester (eq 18).[10,11] Butenolide formation proceeds via attack at the α-carbon of the acrylate followed by elimination of ethanol. Introducing alkyl substituents at the propargylic position increased regioselectivity towards the butenolide (eq 18; ratios given are for butenolide/ester).

Studies have shown that the remote functionality in the terminal alkene has some effect on regioselectivity.[10] With an alcohol functionality on the alkene the corresponding butenolide was the only regioisomer obtained in 71% yield (eq 19).

Of particular interest is that the ruthenium-catalyzed coupling of an alkene to an alkyne yields the corresponding butenolide with stereochemical information at the propargylic position intact (eq 20).[10]

Pentenolides have been synthesized in much the same way (eq 21).[11]

This methodology has been successfully applied to an efficient synthesis of ancepsenolide.[10,11] The key step involves the double addition of the alkyne to a diene with 10 mol% of CpRu(COD)Cl (eq 22).

This type of coupling has been applied to the synthesis of the hydroxybutenolide terminus of the acetegenins.

Noteworthy is that, in general, electron-deficient alkynes produce predominantly the β-alkylated product in Lewis acid-assisted and thermal Alder ene-type reactions (path a; eq 23). In contrast the ruthenium-catalyzed Alder ene-type reaction yields predominantly α-alkylation (path b; eq 23). In addition, the reaction is more general than standard Alder ene-type reactions. Alder ene reactions are rarely used synthetic transformations due to the lack of generality and extreme conditions (temperatures in excess of 400°C have been used) associated with the reaction.

Allene-Alkene Coupling

Allenes have been utilized in replace of the alkyne component in the ruthenium-catalyzed coupling with terminal alkenes to yield 1,3-dienes (eq 24).[13] In such reactions, a dummy alkyne was added to activate the ruthenium catalyst. The reaction gave excellent chemoselectivity with a range of allene partners. Only the *E*-isomers of the dienes were obtained.

Three-Component Coupling Reactions

The ruthenium-catalyzed Alder ene-type reaction has been adapted to synthesize *E*-vinyl chlorides by the inclusion of chloride ions in the reaction mixture (eq 25).[14]

(25)

Once again excellent chemoselectivity is observed; phthalididimide, keto-, hydroxy- and ester groups are all tolerated. *E*/*Z* selectivities were generally high. Internal alkynes undergo a similar reaction to yield tetrasubstituted alkenes (eq 26). It should be noted that *cis*-vinyl chlorides are precursors to α-hydroxyesters upon dihydroxylation of the alkene.

(26)

Such three component coupling reactions have been extended to the synthesis of 1,5-diketones using water as the additive (eq 27).[15] Indium salts were found to substantially increase the yield of the reaction. Chemoselectivity was high. Unfortunately the reaction conditions are quite harsh requiring the use of sealed tubes at 100°C.

(27)

Cycloisomerization

CpRu(COD)Cl catalyzes the cycloisomerization-oxidation of homopropargyl alcohols to yield γ-butyrolactones (eq 28).[16] In this particular use of CpRu(COD)Cl, two phosphine ligands replaces the COD ligand in the first instance which is then the active catalyst in the system. The reaction is highly chemoselective and a number of examples have been performed. *N*-Hydroxysuccinimide was used as the oxidant - more conventional oxidants failed under the reaction conditions.

(28)

This methodology has been applied to the total synthesis of the acetogenin (-)-miricatacin (eq 29).[16] Stereochemical integrity was maintained throughout the reaction.

1-Benzoyl-2(*S*)-*tert*-butyl-3-methylperhydropyrimidin-4-one

[139119-52-1] · $C_{16}H_{22}N_2O_2$ · (274.36)

(reagent used for the enantioselective synthesis of β-amino acids; in particular, α- and α,α-substituted β-amino acids.)

Physical Data: mp 99-100°C; $[\alpha]_D^{29}$ +51.2 (*c* 1, $CHCl_3$).

Solubility: soluble in THF and most organic solvents.

Preparative Methods: [1,2,3] Step 1:

According to the procedure described by Lakner et al.,[1] with benzoyl chloride instead of methyl chloroformate, 13.2 g (0.2 mol) of KOH and 300 mL of water are placed in a 1 L round-bottomed flask before the addition of 30.0 g (0.2 mol) of L-(*S*)-asparagine with vigorous stirring. The resulting mixture is cooled to 0°C and treated with 25.0 mL (19.8 g, 0.23 mol) of pivalaldehyde. Stirring is continued for 1 h at 0°C and for 5 h at ambient temperature. The reaction mixture is cooled to 0°C before the addition of 16.8 g (0.2 mol) of $NaHCO_3$ and 23.2 mL (28.1 g, 0.2 mol) of benzoyl chloride, and stirring is continued for 2 h at ambient temperature prior to quenching with 73 mL of 10% aqueous HCl. The desired product, which precipitates from solution, is filtered, washed with cold water, and dried under vacuum to afford 54.0 g (88%) of 1-benzoyl-2(*S*)-*tert*-butyl-6(*S*)-carboxy-perhydropyrimidin-4-one [(2*S*,6*S*)-**1**], mp 202-203°C; $[\alpha]_D^{29}$ -107.0 (*c* 1, EtOH). Step 2:

In a 3 L round-bottomed flask provided with a magnetic stirrer, 28.0 g (92 mmol) of (2*S*,6*S*)-**1** is dissolved in 900 mL of dry THF, 700 mL of toluene, and 11.2 mL (11.0 g, 138.4 mmol) of pyridine. The resulting solution is treated with 3.7 g (18.4 mmol) of copper diacetate monohydrate, and the resulting suspension is stirred at ambient temperature for 2 h. The reaction flask is then submerged in an ice-water bath before the addition of 61.6 g (138.8 mmol) of lead tetraacetate. The cooling bath is removed and the reaction mixture is heated to 80-90°C for 12 h. The precipitate is removed by filtration and washed several times with EtOAc until the extracts come out free of product (TLC). The organic extracts are combined with the original filtrate, dried over anhydrous Na_2SO_4, and concentrated. The crude product is purified by flash chromatography (eluent hexane-EtOAc, 80:20 r 50:50) to give 16.0 g (73%) of 1-benzoyl-2(*S*)-*tert*-butyl-2,3-dihydro-4(*H*)-pyrimidin-4-one [(*S*(-**2**], mp 209-210°C; $[\alpha]_D^{29}$ +556.4 (*c* 1, $CHCl_3$). Step 3:

N-Methylation of (*S*)-**2** is best accomplished following the procedure of Juaristi et al.[3] In a 50 mL round-bottomed flask provided with magnetic stirrer is placed 3.0 g (11.6 mmol) of (*S*)-**2** and 15 mL of acetonitrile. The resulting solution is treated with 1.1 mL (11.6 mmol) of dimethyl sulfate (slow addition) and 0.5 g (11.6 mmol) of NaOH (slow addition). The reaction mixture is stirred for 3 h at 45-50°C (mineral oil bath) and the acetonitrile is removed at reduced pressure. The residue is suspended in 50 mL of water and extracted with three 50 mL portions of EtOAc. The combined organic extracts are dried over anhydrous Na_2SO_4 and concentrated to give the crude product that is purified by flash chromatography (hexane-EtOAc, 80:20 r 50:50) to afford 2.7 g (84%) of 1-benzoyl-2(*S*)-*tert*-butyl-3-methyl-2,3-dihydro-4(*H*)-pyrimidin-4-one, mp 141-142°C; $[\alpha]_D^{29}$ +560.2 (*c* 1, $CHCl_3$). Step 4:

According to the procedure of Juaristi et al.,[2] heterocycle (*S*)-**3** (5.0 g, 18.4 mmol), 40 mL of EtOAc, 0.5 g of 10% Pd(C), and 0.4 mL of acetic acid is placed in a hydrogenation flask. The reaction mixture is pressurized to 75 atm of hydrogen, heated to 45°C, and stirred for 24 h. The catalyst is removed by filtration over Celite, the filtrate is washed with aqueous 10% $NaHCO_3$, dried over anhydrous Na_2SO_4, filtered, and evaporated at reduced pressure to give 4.5 g (90%) of 1-benzoyl-2(*S*)-*tert*-butyl-3-methylperhydropyrimidin-4-one [(*S*(-**4**], mp 99-100°C; $[\alpha]_D^{29}$ +51.2 (*c* 1, $CHCl_3$). The overall yield in the preparation of (*S*)-**4** from (*S*)-asparagine (four steps) is 49%.

Preparation of enantiopure α-substituted β-amino acids[2,4]

In preliminary studies, racemic 2-*tert*-butyl-perhydropyrimidinone, *rac*-**4**, was alkylated with high diastereoselectivity via its corresponding enolate (eq 5).[5] The high stereoselectivity encountered in the reaction of *rac*-**4**-Li with various electrophiles was ascribed to steric hindrance generated by the axial disposition of the *tert*-butyl group at C(2),[5,6] which directs approach to the electrophile from the enolate face opposite to this group.

$$RX = CH_3I,\ PhCH_2Br,\ n\text{-}BuI,\ n\text{-}C_6H_{13}I,\ CH_2{=}CHCH_2Cl$$

These observations paved the road for the development of a new method for the asymmetric synthesis of α-substituted β-amino acids. Thus, an efficient protocol for the preparation of enantiopure pyrimidinone (*S*)-**4** was developed (vide supra, eq 1-4).

Enolate (*S*)-**4**-Li was generated upon treatment of the heterocycle with lithium diisopropylamide (LDA) in THF solution and under a nitrogen atmosphere. The electrophile was then added at -78°C to afford the *trans*-alkylated products with high diastereoselectivity and in good yields (eq 6, Table 1).

Table 1 Diastereoselectivity of enolate (*S*)-**4**-Li alkylation

Product	RX	ds (%)	mp (°C)	$[\alpha]_D^{20}$	Yield (%)
5	MeI	>96	121–2	+39.5	77
6	*n*-BuI	95	80–1	+26.7	75
7	*n*-$C_6H_{13}I$	96	70–1	+31.2	80
8	$PhCH_2Br$	>96	173–4	−64.0	80

(6)

(*S*)-**4** (2*S*,5*R*)-**5-8**

The final step of the overall conversion of (*S*)-asparagine to 2-alkyl-3-aminopropanoic acid, the hydrolysis of heterocycles **5-8**, was achieved by heating with 6 N HCl in a sealed tube at 90-100°C. The free amino acids **9-12** were purified by chromatography on an ion-exchange column (eq 7, Table 2).

Table 2 Hydrolysis of products **5–8**

R	mp (°C)	$[\alpha]_D^{20}$	Yield (%)
Me	185–6	11.8	80
n-Bu	170–1	+5.3	80
n-C_6H_{13}	219–20	+6.6	80
$PhCH_2$	225–6	+11.3	85

(7)

(2*S*,5*R*)-**5 8** (*R*)-**9 12**

Epimerization of adducts 5-8, and hydrolysis to give the enantiomeric α-alkylated β-aminopropionic acids

In principle, α-substituted β-amino acids of opposite configuration, (*S*)-**9-12**, can be obtained when enantiomeric pyrimidinone (*R*)-**4** [from (*R*)-asparagine] is used as the starting material, following the reaction sequence described above. Nevertheless, a practical alternative consisted in the epimerization of *trans*-adducts **5-8** to afford the *cis*-diastereoisomers **13-16** (eq 8). Hydrolysis of *cis*-**13-16** provided the desired (*S*)-α-substituted β-amino acids, (*S*)-**17-20** (eq 9).[2]

(2*S*,5*R*)-**5** **8** (2*S*,5*S*)-**13** **16**

(2*S*,5*S*)-**13** **16** (*S*)-**17** **20**

Clearly, protonation (aqueous NH_4Cl) of the enolates generated from **5**-**8** takes place on the face opposite to the *tert*-butyl group, and this reaction is also highly stereoselective.

Preparation of enantiopure α,α-disubstituted β-amino acids[7,8]

(2*S*,5*R*)-**5**-**8** were alkylated via their corresponding enolates to provide suitable precursors of enantiopure α,α-dialkylated β-amino acids. Thus, enolates (2*S*)-**5**-**8**-Li were generated upon treatment of the appropriate heterocycle with LDA in THF solution and under nitrogen atmosphere. The electrophile (methyl iodide, ethyl iodide, *n*-butyl bromide, *n*-hexyl iodide, or benzyl bromide) in solvent *N,N´*-dimethylpropyleneurea (DMPU) was then added at -78°C to afford the dialkylated products with high diastereoselectivity and in excellent yields (Table 3). The use of DMPU as cosolvent was necessary to effect the dialkylation in high yield (eq 10).[9]

Table 3 Diastereoselectivity of enolate (2*S*)-**5**–**8**-Li alkylations

R^1	R^2	ds (%)	mp (°C)	$[\alpha]_D^{20}$	Yield (%)
Me	*n*-Bu	>97	184–5	+30.3	81

(10)

21 **26**

Hydrolysis of geminal disubstituted perhydropyrimidinones **21**-**26** necessitated drastic conditions: 8 N HCl at 100-140°C in a sealed tube. While these harsh conditions may not be tolerated by sensitive amino acids,[10] they proved harmless to the α,α-disubstituted β-amino acids **27**-**32**. Nevertheless, milder conditions could be employed when *p*-dioxane was used as cosolvent, since improved solubility of the substrate in the aqueous medium resulted in much faster hydrolysis (eq 11).

(11)

21 **26** **27** **32**

Related Reagents.

Owing to the high price of pivalaldehyde, we have substituted this aldehyde with isobutyraldehyde in the synthesis of imino ester (2*S*,6*S*)-**33**, which proved to be a convenient substrate for the enantioselective synthesis of α-substituted aspartic acids (eq 12).[11,12]

(12)

(2*S*,6*S*)-**33** (2*S*,6*S*)-**34-37**

Hydrolysis of the alkylated products (2*S*,6*S*)-**34-37** and isolation of the desired amino acids was facilitated by the presence of the labile imino group.[13] Indeed, hydrolysis was achieved by heating with 17% HCl in a sealed tube at 95°C. The free amino acids **38-41** were purified by chromatography on an ion-exchange column (eq 13).[8,11]

(2*S*,6*S*)-**34 37** (*S*)-**38 41**

R= Me, Et, *n*-Bu, CH_2Ph (13)

On the other hand, Beaulieu et al.[14] have reported the synthesis of unusually functionalized optically active β-substituted β-amino acids via the highly diastereoselective ((95:5) transformation of enantiopure *N*-(*o*-iodobenzoyl)-2-*tert*-butylperhydropyrimidinone [(*S*)-**42**] (eq 14).

(*S*)-**42**

(14)

(*S*)-**43**

In this context, dihydropyrimidinone (*R*)-**44** has been exploited by Chu et al.[15] and Konopelski et al.[16] in the enantioselective synthesis of β-alkyl β-amino acids. Furthermore, *N*-phenethylperhydropyrimidinone (*S*)-**45**,[17,18] as well as the 6-substituted analogs **46**-**48** (configuration not indicated)[19-22] are useful substrates for the asymmetric synthesis of α,β-disubstituted β-amino acids.

Polymer-Supported Bis(acyloxy)iodate(I)

[68574-12-9]F

(a new electrophilic polymer-supported reagent which efficiently promotes iodo acetoxylations of alkenes as well as iodination of terminal alkynes[1])

Physical Data: Loading 2.1 mmol g^{-1} (based on the amount of iodide attached to the commercial resin, assuming that all iodide ions are transformed into the active species); polymer matrix: copoly(styrene-DVB), 20-50 mesh.

Solubility: insoluble in most organic and aqueous solvents.

Form Supplied in: macroscopic, light yellow resin beads; readily available by following the procedure provided below.

Preparative Methods: a suspension of polymer-bound iodide (available from Fluka; 1 equiv, 2.9 mmol g^{-1} resin) and $PhI(OAc)_2$ (1.8 equiv) in dry dichloromethane (3 mL $mmol^{-1}$ iodide) under nitrogen is shaken at 300 rpm for 6 h at room temperature. The brownish suspension was protected from light. Filtration and washing of the resin with dichloromethane (3×, 25 mL g^{-1} resin) and drying in vacuo affords the light yellow title polymer. The weight increase serves as an indicator for efficient ligand transfer onto polymer-bound iodide and gives most reproducible results (about 90% conversion with respect to theoretical iodide). Recycling: a suspension of the used polymer (18 g) in concentrated HI (25 mL, 67%) is stirred vigorously for 10 min. After addition of another 10 mL of distilled water, the suspension is stirred for an additional 30 min. Filtration and washing of the resin with $water_{(dest)}$ (500 mL), absolute methanol, (400 mL) and absolute dichloromethane (300 mL) affords the dark brown supported iodide resin which can be used again after treatment with $PhI(OAc)_2$ without substantial loss of activity.

Handling, Storage, and Precautions: The bis(acyloxy)iodate(I) resin can be prepared on a 100 g scale. It is the most labile resin (thermally and photochemically) among resin-bound haloates, including the bis(azido)iodate(I) resin and the bis(acyloxy)iodate(I) resin described so far. It can be stored below -15°C and protected from light for at least 1 week, but preferentially should be used shortly after its preparation. Because of its sensitivity to air and moisture, the resin should be stored under nitrogen. A strong smell of acetic acid indicates the decomposition of the active species. This resin is not yet fully tested and should be used only with the usual precautions.

Background

The development and use of polymer-supported reagents has seen a dramatic increase over the past 5 years, although the basic principles of this technique have been known for at least 30 years.[2] The advantage of this hybrid solid-solution-phase technique lies in the simple work-up and isolation of the reaction products, even if these reagents are used in excess in order to drive the reaction to completion. Haloate(I) complex **1** is a new electrophilic member of this class of reagents with diverse chemical properties[1,3-6] as is briefly depicted below.

1,2-Iodoacetoxylations of alkenes[1,3-5]

General Procedure

A mixture of alkene or alkyne (1 equiv) and resin (3-4 equiv) is shaken at 300 rpm under protection from light in dry dichloromethane (1.5 mL $mmol^{-1}$) at room temperature. Completion of the reaction is monitored by TLC. Filtration terminates the reaction. The resin is washed with dichloromethane (3×40 mL g^{-1} resin), and the combined organic washings and filtrate are concentrated under reduced pressure. In some cases, further purification by column chromatography is necessary.

Following this general procedure (see also reference 1), in most cases, 1,2-functionalization of alkenes affords single iodoacetoxylation products **2-5**.

The addition proceeds with *trans* selectivity, as demonstrated for cyclohexene- and indene-transformation products **6** and **7**. The transformation of alkoxyallenes into the corresponding vinyliodides **8** and **9** demonstrates that inductive effects of the double bond substituents determine the chemoselectivity of the process.

Halogenated substrates react very sluggishly at room temperature; at 80°C complete consumption of alkenes is achieved. Under these conditions 4-bromostyrene gives the desired 1,2-addition product **10** in moderate yield, while 3-chloro-1-phenylprop-1-ene yields iodoacetoxylation product **11** in low yield. In contrast, allyl chloride undergoes nucleophilic substitution to furnish allyl acetate **12** as the major product.

Importantly, hydroxy groups are tolerated under the reaction conditions but can be converted to derivatives. Allyl alcohol **13** affords acetate **15** in excellent yield, indicating that the expected addition to give **14** is followed by an acyl migration to the terminal alcohol group (eq 1). In contrast, the corresponding homoallyl alcohol gives an intermediate cation which is trapped in an intramolecular mode by the hydroxy group to furnish tetrahydofuran **16**.

Likewise, partially, and even fully, unprotected glycals can, in the presence of reagent **1**, undergo a 1,2-functionalization as summarized for glycosyl acetates **22**, **24** and **17**. In addition, the iodoacetoxylation of protected carbohydrate-derived glycals is carried out in different solvents (see ref 3) with excellent yields of the corresponding 2-deoxy-2-iodo-glycosyl acetates (**18**-**21**, **23**). In most cases, filtration of the resin and removal of the solvent in vacuo affords the reaction products with high purity.

TES = triethylsilyl; TBS = tributylsilyl

20; $R^1 = R^2 = Bn$; $\alpha : \beta = 1.5 : 1$; (3 equiv **1**, 92%)

21; $R^1 = R^2 = TBS$; $\alpha : \beta = 1.2 : 1$; (3 equiv **1**, 98%)

22; $R^1 = H$, $R^2 = TBS$; $\alpha : \beta = 2.5 : 1$; (4 equiv **1**, 83%)

23; R = TBS; $\alpha : \beta = 1 : 1$; (4 equiv **1**, 97%)

24; R = H; $\alpha : \beta = 1 : 9$; (4 equiv **1**, 88%)

Furthermore, the title reagent **1** promotes transformation of vinyl and allyl silanes and, instead of the expected desilylation, the 1,2-addition products **25-29** are formed as major products (see ref 5).

All transformations are achieved using an excess of the immobilized reagent **1**. This may be rationalized by assuming that only the most accessible haloate(I) anions are involved in the cohalogenation process. If acylated, hypohalites are the active species after release from the polymer, their degradation prior to the reaction with alkenes may also contribute to the need for a formal excess of reagent.

When comparing this polymer-supported technique with the solution variant[7-9] using tetraethylammonium iodide and (diacetoxyiodo)benzene for the in situ preparation of $Et_4NI(OAc)_2$ (see refs 7 and 8) and subsequent iodoacetoxylation, the isolated yields for the acetates that are derived from the solution variant are reduced due to their lability during the recommended reductive aqueous work-up.

Iodination of alkynes[1]

A second set of experiments using terminal alkynes for the transformation with the title reagent **1** affords alkynyl iodides **30**-**33**, presumably generated by electrophilic attack of the iodonium ion and formation of an intermediate vinyl cation followed by deprotonation. Remarkably, the nitrile functionality in **32** is tolerated.

The formation of the unusual cyclization product **34**, generated from the corresponding acyclic terminal alkyne, may be rationalized by electrophilic attack of a second equivalent of the iodonium ion onto the triple bond in the corresponding intermediate iodoalkyne and subsequent cyclization.

It is noteworthy that, unlike classical reagents for the acetoxyiodination of alkenes, the use of the title reagent **1** does not require glacial acetic acid or heavy metals. More specific features and advantages of this reagent are: (1) the polymer is readily available, (2) the preparation is short and straightforward, (3) the work-up of the reaction products is simple filtration and concentration, (4) the reaction mixture is free of iodobenzene, which is the common by-product when hypervalent reagents like the starting diacetoxyiodobenzene are employed, (5) the reagent is storable to some extent, (6) the reagent is generated and can be applied in different organic solvents, and (7) the reagent is recyclable.

Polymer-Supported Bis(acyloxy)bromate(I)

[256385-96-3]F

(a new polymer-supported oxidant described which performs the oxidation of primary and secondary alcohols into their corresponding carbonyl compounds[1])

Physical Data: 2.4 mmol g^{-1} (based on the amount of bromide attached to the commercial resin, assuming that all bromide ions are transformed into the active species; polymer matrix: copoly(styrene-DVB), 20-50 mesh.

Solubility: insoluble in organic solvents and aqueous solutions.

Form Supplied in: macroscopic, brown resin beads; available by following the procedure provided below.

Preparative Methods: a suspension of untreated polymer-bound bromide (e.g. available from Fluka; 1 equiv, 3.2 mmol g^{-1} resin) and $PhI(OAc)_2$ (1.8 equiv) in dry dichloromethane (3 mL $mmol^{-1}$ bromide) is shaken under nitrogen at 300 rpm for 8 h at room temperature. The brownish suspension is protected from light. Filtration and washing of the resin with dichloromethane (3×, 20 mL g^{-1} resin) and drying in vacuo affords the brown title polymer. The weight increase serves as an indicator for efficient ligand transfer onto polymer-bound bromide and gives the most reproducible results (about 85-90% conversion with respect to theoretical bromide). Recycling: a suspension of the used polymer (5 g) in NaOH (2×20 mL, 1 M) is stirred vigorously for 10 min. After washing with distilled water (2×25 mL), the wet resin is treated with HBr (2×25 mL, 2 N). Filtration and washing of the resin with $water_{(dest)}$, (40 ml) absolute methanol (30 mL) and absolute dichloromethane (30 mL) affords the light yellow supported bromide resin, which can be used again after treatment with $PhI(OAc)_2$ without substantial loss of activity.

Handling, Storage, and Precautions: The immobilized bis(acyloxy)bromate(I) complex can be prepared on a 100 g scale. Protected from light, it can be stored below -15°C for weeks without loss of activity. Because of its sensitivity to air and moisture, it should be stored under argon. A strong smell of acetic acid indicates the decomposition of the active species. This resin is not yet fully tested and should only be used with the usual precautions.

Background

Since the beginning of modern synthetic organic chemistry, the goal of chemists has been to produce single compounds in as pure form as possible. In this context, the development and applications of polymer-supported reagents has seen a dramatic increase in interest lately.[2] The advantage of this hybrid solid-solution-phase technique lies in the simple work-up and isolation of the reaction products, even if these reagents are used in excess in order to drive the reaction to completion.

Haloate(I) complex **1**[1] is a new member of this class of reagents with diverse chemical properties.[3-5]

Oxidation of Alcohols[1]

General Procedure

A mixture of alcohol (1 equiv), resin **1** (3-6 equiv) and catalytic amounts of 2,2,6,6-tetramethyl-l-piperinyloxyl (2 mol%) are shaken at 300 rpm in dry dichloromethane (1.5 mL $mmol^{-1}$) at room temperature. Completion of the reaction is monitored by TLC. Filtration terminates the reaction. The resin is washed with dichloromethane (3×40 mL g^{-1} resin), and the combined organic washings and filtrate are concentrated under reduced pressure. Generally, no further purification by column chromatography is necessary.

Under these conditions primary alcohols are oxidized into aldehydes **2-8** and, importantly, secondary alcohols are converted into ketones **9-15** in excellent yields (yields in parentheses refer to determination by GC).

14
(3 equiv **1**, 44 (85)%)

15
(3 equiv **1**, 94%)

Considering that a polymer-bound reagent is employed, the reactions proceed rather rapidly (see ref 1). In addition, no over-oxidation to the corresponding carboxylic acids is observed.

Following the general procedure, the products isolated after filtration and evaporation of the solvent are very pure and can be used directly in the next step. In this context, this new oxidation method is well suited for applications in natural product total synthesis because the integrity of a chiral center in the α-position is often a problem during the oxidation process and especially during work-up of the generated carbonyl compound. In fact, the transformation of a chiral alcohol into aldehyde **7** is achieved without any detectable racemization (>95% ee), while the Swern and, to a lesser extent, the Dess-Martin oxidation led to the partly racemized aldehyde **7**, either during the reaction or work-up by flash column chromatography.

In comparison with other polymer-supported oxidants, for example, Ley's immobilized perruthenate which is very efficient for oxidizing primary and secondary benzylic alcohols but cannot be employed for secondary alcohols, the title reagent **1** is a powerful tool for the oxidation of all kinds of alcohols. Olefinic double bonds, however, are not tolerated under these conditions.

1,2-Bromoacetoxylation of Alkenes[3]

General Procedure

A mixture of alkene (1 equiv) and resin **1** (3-7 equiv) is shaken at 300 rpm under light protection in dry dichloromethane (1.5 mL $mmol^{-1}$) at room temperature. Completion of the reaction is monitored by TLC. Filtration terminates the reaction. The resin is washed with dichloromethane (3×20 mL g^{-1} resin), and the combined organic washings and filtrate are concentrated under reduced pressure. In some cases, purification by column chromatography is necessary.

Similar to the analogous polymer-supported reagents for efficient iodoacetoxylation (see refs 6-8) and iodoazidation[9] of alkenes, the title reagent **1** is used to promote the corresponding 1,2-bromoacetoxylations. Following the general procedure, the addition often proceeds with *trans* selectivity, as demonstrated for cyclohexene and indene transformation products **16** and **17**. Reaction of alkoxyallene with resin **1** leads to vinylbromide **18**, clearly demonstrating that the relative electron density of the double bond determines the chemoselectivity of the process.

16 (5 equiv **1**, 63%) **17** (5 equiv **1**, 67%) **18** (4 equiv **1**, 60%)

In contrast to iodoacetoxylation[6-8] and iodoazidation,[9] however, this process often lacks good regio- and stereoselectivity. Two examples are depicted below (eq 1 and 2).

19 **20**, 43% **21**, 26% two diastereomers

(1)

22, 8% two diastereomers

23 **24**, 12% **25**, 12% **26**, 30%

(2)

In contrast, the bromoacetoxylation of protected carbohydrate-derived glycals furnishes the corresponding 2-bromo-2-deoxy-glycosyl

acetates **27** and **28** in excellent yields.[7] In most cases, filtration of the resin and removal of the solvent in vacuo affords the reaction products in high purity.

Furthermore, reaction of vinyl silane **29** with the title reagent **1** also affords the 1,2-addition product **30** in good yield (eq 3).[8] Remarkably, desilylation or formation of products derived from desilylation was not observed.

Potassium Tris(1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,11,11,12,12,13,13,14,14,15,15,16,16,17,17,17-triacontafluoro-8,10-heptadecanedionato) Ruthenate

[195870-97-4] · $C_{51}H_3F_{90}O_6RuK$ · (2558.57)

(reagent used for epoxidation of alkenes)

Physical Data: mp 162-163°C.

Solubility: soluble in perfluorooctyl bromide and other perfluorinated solvents, MeOH and THF; slightly soluble in diethyl ether.

Form Supplied in: violet crystals, not commercially available; major impurity: perfluorohexane.

Preparative Methods: the complex is prepared from the corresponding diketone **1** and $RuCl_3$ in the presence of base (eq 1).[1]

A ruthenium(III) chloride solution in water/EtOH is refluxed for 4 h, thereafter an ethereal solution of the perfluorinated diketone **1** is added, followed by potassium bicarbonate. The mixture is then left to reflux for 1 h. Extraction with perfluorohexane and further recrystallization from acetone/chloroform gives the product in a 62% yield. The above diketone **1** is obtained by condensation[2,3] of the corresponding perfluorinated methyl ester and perfluorinated methylketone in the presence of NaOMe in diethyl ether.

Handling, Storage, and Precautions: the compound can be stored at room temperature and in the presence of moisture for several months. It decomposes at temperatures >60°C. Data on toxicity are not known yet; it is suggested that use the same precautions as for the other salts of Ru(II) be used.

Epoxidation

The potassium tris(1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,11,11,12,12,13,13,14,14,15,15,16,16,17,17,17 triacontafluoro-8,10-heptadecanedionato) ruthenate complex has been used in fluorous biphasic system catalysis (FBS) for the epoxidation of disubstituted alkenes (eq 2).[1]

(2)

85% recovered yield (1st run);
catalyst recyclable for up to 10 runs
(85% conversion after the 10th run)

The FBS[4,5] is based on the property of perfluorinated solvents to be immiscible with most organic solvents at room temperature, and completely miscible with them at temperatures >50-60°C. In this way, a catalyst containing perfluorinated 'ponytails' is selectively soluble in a perfluorinated phase, but it reacts with the substrate in a homogeneous catalytic system when the temperature is increased. After cooling down, the reaction system separates into two phases again: the catalyst is recovered only in the perfluorinated one and can be easily recycled, while the products are in the organic solvent. Another advantage of the FBS is the high solubility of several gases[6] in the perfluorinated medium; consequently, it is suitable for 'green' oxidations[7-9] with molecular oxygen.

This ruthenium compound produces a violet solution in perfluorooctyl bromide, but in the presence of aldehydes and O_2 it quickly becomes brown; probably due to the formation of Ru(III) or oligomeric species with mixed valences. However, the brown solution shows the same activity as the violet one and can be recycled several times. It is important to carry out the reaction at the lowest temperature possible (not more than 60°C) in order to avoid the decomposition of the complex.

The compound is suitable for selective epoxidations of disubstituted alkenes in the presence of molecular oxygen and isopropylaldehyde,[1,10,11] with yields around 71-85% and reaction times between 8 and 16 h; functional groups such as esters or carboxylic acids are very well tolerated, and terminal double bonds are not reactive at all under these conditions. After the reaction, the

perfluorinated phase containing the ruthenium complex can be recycled up to ten times with negligible loss of activity[1] (from 100% conversion in the first run to 85% at the 10th run). Because of the recyclability of the catalyst, the work-up of the organic phase containing the product is quite simple and clean.

Related Reagents.

‘fluorous tin hydride’.

Bis(η^5-2,4-cyclopentadienyl)bis(trimethylphosphine)titanium

[95936-00-8] · $C_{16}H_{28}P_2Ti$ · (330.21)

(used as a source of 'Cp_2Ti')

Physical Data: mp (105°C decomposes); black needles.

Solubility: soluble in most organic solvents.

Preparative Methods: bis(η^5-2,4-cyclopentadienyl)bis(trimethylphosphine)titanium is prepared by the reduction of Cp_2TiCl_2 by magnesium in the presence of trimethylphosphine.[1] It may also be generated in situ from Cp_2TiCl_2, butyllithium and trimethylphosphine.

Handling, Storage, and Precautions: $Cp_2Ti(PMe_3)_2$ is pyrophoric and must be handled and stored in an argon filled glove-box.

Reductive Cyclization

One of the most important features of bis(η^5-2,4-cyclopentadienyl)bis(trimethylphosphine)titanium [$Cp_2Ti(PMe_3)_2$] is the ease of dissociation of both of the PMe_3 ligands to yield a complex with two open coordination sites. Treatment of enynes with a catalytic amount of $Cp_2Ti(PMe_3)_2$ in the presence of trialkylsilyl cyanides, followed by hydrolysis produces bicyclic cyclopentenones (eq 1).[2] Although a variety of metal complexes promote cyclopentenone formation, most require a stoichiometric amount of metal complex.

(1)

$Cp_2Ti(PMe_3)_2$ also catalyzes the reductive cyclization of 1,6-enones[3] and 1,6-enals[4] to cyclopentanols. These reactions proceed with good diastereoselectivity to produce predominately the *syn* diastereomer (eq 2).

(2)

Imines also form the titanocycles, but do not cleave to form cyclopentylamines. When a stoichiometric amount of $Cp_2Ti(PMe_3)_2$ is used in the presence of enones, followed by CO, the CO inserts into the resulting metallacycle and, after thermal reductive elimination, produces γ-butyrolactones (eq 3).[5]

(3)

A catalytic version of this reaction which uses trialkylsilylcyanides as the CO equivalent, is also an effective method for generating lactones. However, generation of 'Cp_2Ti' is carried out in situ using 2 equiv of ethylmagnesium bromide or butyllithium.[6]

Dichloro[1,2-ethanediylbis(1,2,3,3*a*,7*a*-η)-4,5,6,7-tetrahydro-1*H*-indene-1-ylidene] titanium

[] · $C_{20}H_{24}Cl_2Ti$ · (383.18)

(used as a source of 'Cp$_2$TiH')

Alternate Name: [(EBTHI)TiCl$_2$][1]

Physical Data: red solid; mp 256-261°C.

Solubility: THF, diethyl ether, dichloromethane.

Form Supplied in: (EBTHI)TiCl$_2$ is commercially available in the racemic form but can be resolved by using (*R*)-2,2´-binaphth-1,1´-diol and *p*-aminobenzoic acid.[2]

Handling, Storage, and Precautions: No special handling is required.

Synthesis of Homoallylic Alcohols

The complex (*S*,*S*)-dichloro[1,2-ethanediylbis(1,2,3,3*a*,7*a*-η)-4,5,6,7-tetrahydro-1*H*-indene-1-ylidene]titanium [(*S*,*S*)-EBTHITiCl$_2$] is a precatalyst for the formation of chiral allyl and crotyl titanium species. Activation of the catalyst with *n*-propylmagnesium bromide and allyl- or crotylmagnesium bromide followed by treatment with an aldehyde produces homoallylic alcohols in moderate enantioselectivity (eq 1).[3] Unfortunately, in the case of the crotyl species, high des are restricted to pivaldehyde and benzaldehyde.

Reduction

In general, the reduction of dialkyl ketones proceeds with poor selectivity. Treatment of (*S*,*S*)-EBTHITiCl$_2$ with PhMeSiH$_2$ produces the active catalyst for the reduction of a variety of dialkyl ketones.[4] The yields of the reactions are good and the ee's are low to moderate, however the results are similar to other dialkyl ketone reductions in the literature (eq 2).[5]

(2)

Reduction of esters using *rac*-EBTHITiCl$_2$ to the corresponding alcohols proceeds without opening of an epoxide.[6] Imines are reduced with (*R*,*R*)-EBTHITiCl$_2$, although the corresponding (*R*,*R*,*R*)-binaphth-1,1´-diol complex is more common. This reaction proceeds with good-to-excellent yields and high enantioselectivities.[7]

Cycloisomerization

Cycloisomerization of 1,6-dienes with *rac*-EBTHITiCl$_2$ is easily accomplished. Treatment of the diene with EBTHITiCl$_2$ and *n*-butylmagnesium bromide produces cyclohexenes, whereas the use of Cp$_2$TiCl$_2$ and *n*-butylmagnesium bromide yields cyclopentenes (eq 3).[8]

Dicarbonyl(acetylacetonato) Rhodium(I)

[14874-82-9] · $C_7H_7O_4Rh$ · (258.04)

(catalyst (precatalyst) for various carbonylation reactions, silylcarbocyclizations, conjugate additions to enones, carbamoylstannation, and reduction of aromatic nitro compounds)

Physical Data: mp 155°C[1]; IR (CCl_4) 2990, 2911, 1553, 1513, 1429, 1374, 1276, 1193, 1126, 1019, 933, 782 cm^{-1}; ^1H NMR (CCl_4) δ 5.52 (1H), 2.11 (6H).

Solubility: soluble in acetone, benzene, chlorinated solvents; sparingly soluble in MeOH, ether, aliphatic hydrocarbons.

Form Supplied in: dark green crystalline solid; commercially available.

Analysis of Reagent Purity: NMR, IR, mp.

Preparative Methods: prepared from tetracarbonyl-μ-dichlorodirhodium(I).[1]

Purification: vacuum sublimation at ca. 90°C.[1]

Handling, Storage, and Precautions: stable in air; best stored in a dry atmosphere.

Hydroformylation

Dicarbonyl(acetylacetonato) rhodium(I) [$Rh(acac)(CO)_2$] is a common precatalyst for the hydroformylation of alkenes.[2] In combination with ligands, alkenes are hydroformylated to aldehydes under mild conditions (eq 1). Chemo-, regio-, and stereoselectivity depend upon the nature of the substrate and upon the ligands employed.

(1)

Silylformylation

The $Rh(acac)(CO)_2$-catalyzed intermolecular silylformylation of terminal alkynes with **dimethyl(phenyl)silane** and **carbon monoxide** affords (*Z*)-1-silyl-2-formylalk-1-enes with complete regio- and stereoselectivity (eq 2).[3]

Triethylsilane and *tert*-butyldimethylsilane also participate in intermolecular silylformylation.[4] The regioselectivity is completely reversed in the intramolecular silylformylation of alkynes (eq 3).[5] Internal and terminal alkynes are silyformylated with complete regio- and stereoselectivity, with exclusive formation of products arising from *exo*-cyclization.

The intramolecular silylformylation of alkenes affords β-silyl aldehydes with exclusive formation of aldehydes arising from *exo*-cyclization (eq 4).[6] When the phenyl groups on silicon are replaced with allyl groups, tandem silyformylation-allylsilylation occurs to afford, after oxidation of the carbon-silicon bond, 1,3,5-*syn*-triols (eq 5).[7]

(5)

92:8; 59%

Carbocyclizations

Rh(acac)$(CO)_2$ catalyzes the intramolecular silylcarbocyclization of triynes,[8] enynes,[9] and ynals.[10] The silylcarbotricylization of enediynes affords bis-cyclopentyl products (eq 6).[11] This cascade carbometallation sequence proceeds stereospecifically, and complements traditional Heck chemistry.

(6)

55%

The carbonylative carbotricyclization of enediynes is catalyzed by Rh(acac)$(CO)_2$ to afford fused 5-7-5 tricyclic products (eq 7).[12] In a reaction that complements the Pauson-Khand reaction, Rh(acac)$(CO)_2$ catalyzes the carbonylative bicyclization of 1,6-diynes to afford

bicyclo[3.3.0]octenones.[13]

(7)

Conjugate Additions

The conjugate addition of aryl- and alkenylboronic acids to enones is catalyzed by $Rh(acac)(CO)_2$ (eq 8).[14]

(8)

The asymmetric conjugate addition of α-cyano phosphonates[15] and α-cyano Weinreb amides[16] to enones and enals is catalyzed by $Rh(acac)(CO)_2$ in the presence of chiral ligands (eq 9).

(9)

94%
ee = 89%

Other Transformations

Carbamoylstannation of terminal alkynes is catalyzed by Rh(acac)$(CO)_2$ to afford 3-trimethylstannyl-2-enamides (eq 10).[17]

(10)

78%

In the presence of phosphine[18] and amine[19] ligands, Rh(acac)$(CO)_2$ catalyzes the reduction of aromatic nitro compounds to anilines with CO/H_2O. Rh(acac)$(CO)_2$ catalyzes the addition of aryl- and alkenylboronic acids to aldehydes,[20] and catalyzes the formylation of organomercurial chlorides (eq 11).[21]

(*R*,*R*)-1,2-Bis(aminocarbonylphenyl-2´-diphenylphosphino)cyclohexane

[138517-61-0] · $C_{44}H_{40}N_2O_2P_2$ · (690.76)

(chiral phosphine ligand used in asymmetric Pd^0-catalyzed allylic substitution reactions)[1]

Physical Data: mp 134-136°C.[2]

Solubility: soluble in chlorinated solvents, ethers, alcohols, toluene and most organic solvents. Partially soluble in acetonitrile.

Form Supplied in: white to off-white crystalline solid. Major impurity is the corresponding monophosphine oxide (<1%).

Analysis of Reagent Purity: NMR and IR details are available.[3,4] Optical rotation $[\alpha]_D^{25}$ +46.7 (*c* 2.4, CH_2Cl_2).[3] $[\alpha]_D^{25}$ +88 (*c* 7.0, CH_2Cl_2);[2] crystalline material. Chiral HPLC: Chiracel OD-R, UV 210 nm, 0.8 mL min^{-1}, 100% MeOH. Retention time (*R*,*R*)=6.3 min, retention time (*S*,*S*)=9.4 min. Achiral HPLC: Hypersil BDS C8, UV 254 nm, 1.0 mL min^{-1}, 85% MeOH, 15% H_2O. Retention time ligand=9.5 min, retention time monophosphine oxide=5.2 min, retention time bisphosphine oxide=3.6 min.

Preparative Methods: commercially available. The ligand can be prepared by the coupling of (1*R*,2*R*)-(-)-1,2-diaminocyclohexane [20439-47-8] with 2-(diphenylphosphino)benzoic acid [17261-28-8],[5] using reagents such as DCC.[3] An alternative procedure has been developed whereby (1*R*,2*R*)-(+)-1,2-diaminocyclohexane L-tartrate salt [39961-95-0][6] is coupled to a mixed anhydride of 2-(diphenylphosphino)benzoic acid and diphenylchlorophosphate.[2] The procedure is reproduced below 2-(Diphenylphosphino)benzoic acid (20 g, 65.3 mmol, 2 equiv) is suspended in dichloromethane (150 mL) and cooled in an ice-water bath to 0°C (internal temperature). Triethylamine (10.1 mL, 71.8 mmol, 2.2 equiv) is added dropwise and a clear solution is obtained. This process is exothermic and a rise in temperature to 5°C is observed. The solution is re-cooled to 0°C and diphenylchlorophosphate (13.4 mL, 64.7 mmol, 1.98 equiv) is added slowly, maintaining the internal temperature between 0-5°C. The yellow solution is stirred for 1 h at 0°C. (1*R*,2*R*)-(+)-1,2-Diaminocyclohexane-L-tartrate salt (8.63 g, 32.65 mmol, 1 equiv) is suspended in water (50 mL, 5.8 vol) and potassium carbonate (15 g, 107.8 mmol, 3.3 equiv) is added. This process is exothermic and a clear solution is obtained after approximately 10 min. After 30 min, the clear aqueous solution of diamine is added to the mixed anhydride solution at 0°C, and the resulting yellow two-phase mixture is stirred for 2 h at 0°C, then allowed to warm to room temperature. After 14 h, the mixture is poured into a separating funnel and 200 mL of dichloromethane and 100 mL of water are added. The organic phase is separated, washed with 2 N HCl (100 mL) and saturated aqueous $NaHCO_3$ solution (100 mL), then dried over magnesium sulfate. The dried organic phase is filtered through a silica pad and the pad is washed with dichloromethane (50 mL). The combined filtrates are evaporated to dryness under reduced pressure, producing a yellow foam (22.3 g, 99% crude). The foam is crystallized from boiling acetonitrile (390 mL, 17.5 vol) to afford a white crystalline solid. The solid is dried under vacuum to provide the phosphine ligand (15 g, 67%).

Purification: column chromatography on silica gel, eluting with 15-30% ethyl acetate/hexanes.[3,4] Recrystallization from hot

acetonitrile.[2,7]

Handling, Storage, and Precautions: store under nitrogen at room temperature. Oxidation to phosphine oxides may occur upon prolonged exposure to air. No known toxicology data.

Chiral Diphosphine Ligands

In 1992, Professor Barry Trost introduced a family of chiral diphosphine ligands for palladium(0)-catalyzed asymmetric allylic substitution reactions. The first ligands were based on 2-(diphenylphosphino)benzoic acid with a variety of chiral backbones.[3] The most useful of these backbones are *trans*-1,2-diaminocyclohexane, *trans*-1,2-diphenylethanediamine, and *trans*-11,12-diamino-9,10-dihydro-9,10-ethanoanthracene. The ligand based on the diaminocyclohexane backbone has proved to be the most generically useful ligand, with the most reported applications. Throughout this text the term 'ligand' refers to (*R*,*R*)-1,2-bis(aminocarbonylphenyl-2´-diphenylphosphino)cyclohexane.

Catalyst Preparation

Two palladium sources are generally used to form the active precatalysts (**1**) and (**2**) in situ, the allylpalladium chloride dimer [12012095-2] and the tris(dibenzylideneacetone)dipalladium(0)-chloroform adduct [52522-40-4]. For the palladium dibenzylideneacetone complex (**1**), NMR data to support the proposition that the bis-phosphine acts as a bidentate ligand has been reported.[8] A triflate salt of the π-allyl palladium complex has been isolated and is stable in the solid state. However, no crystals suitable for X-ray analysis were obtained.[7] An X-ray crystal structure of the ligand and a bis-palladium complex has been reported.[7] The palladium complexes are generated just before use under an inert atmosphere; exposure to air affords a catalytically inactive tetra-coordinated palladium(II) species.[8]

1

Reactions with Carbon Nucleophiles

A wide range of carbon nucleophiles have been used in asymmetric allylic alkylation reactions (AAA). The first reported reactions involved the use of the sodium salt of malonates as the nucleophile. Five-, six-, and seven-membered ring allylic acetates and carbonates (in general, the carbonates are more reactive substrates) are ionized by the catalyst, prepared from the ligand and a palladium source, to provide a single palladium(0) intermediate (eq 1). Reaction of the intermediate with the sodium malonate in the presence of tetra-*n*-hexylammonium bromide gives the malonate product in high yield (*n*=1, 81%) and enantiomeric excess (*n*=1, 98%).[9] The use of microwave radiation has been reported to accelerate the rate of this reaction with carbon, oxygen and nitrogen nucleophiles.[10]

In addition to cyclic allylic substrates, malonate nucleophiles have been used in reactions with both symmetrical[11] and unsymmetrical[12] acyclic systems, and with geminal dicarboxylates.[13] Malonates and Meldrum's acid have also been used as nucleophiles in the desymmetrization of *meso* diesters.[14]

Azlactones have been used as nucleophiles to provide access to a variety of α-alkylated amino acid derivatives. This has been demonstrated with 3-acetoxycyclohexene and with geminal dicarboxylates (eq 2).[15] The enantiomeric and diastereoisomeric excess of the products increase with more bulky R groups.

(2)

This method has also been applied to unsymmetrical acyclic allyl esters.[16] The reaction of an azlactone with a geminal diacetate substrate gave access to an advanced intermediate for the synthesis of sphingofungin F.[17]

This methodology has been used to provide efficient protocols for the asymmetric allylic alkylation of β-keto esters,[18] ketone enolates,[19] barbituric acid derivatives,[20] and nitroalkanes.[21]

Several natural products and analogs have been accessed using asymmetric desymmetrization of substrates with carbon nucleophiles. The palladium-catalyzed reaction of a dibenzoate with a sulfonylsuccinimide gave an advanced intermediate in the synthesis of L-showdomycin (eq 3).[22]

(3)

The alkylation of a dibenzoate with (phenylsulfonyl)nitromethane gave an intermediate for the synthesis of (+)-valienamine.[23]

The reaction of azlactones or a Meldrum's acid derivative with 2-phenylbut-3-ene-2-yl acetate, in the presence of the racemic ligand and a palladium source has provided a new method for controlling alkene geometry. By varying the reaction conditions excellent selectivities for either *E* or *Z* geometry could be obtained.[24]

Reactions with Nitrogen Nucleophiles

The palladium(0)-catalyzed asymmetric desymmetrization of *cis*-3,5-dibenzoyloxy-1-cyclopentene, with 6-chloropurine and 2-amino-6-chloropurine as nucleophiles, has been utilized in the synthesis of (-)-carbovir[25] and (-)-neplanocin.[26] In these examples, the diphenylethanediamine[3] and the anthracenyldiamine[3] based ligands were found to be superior to the standard ligand.

Phthalimide has been used as a nucleophile with cyclic (as depicted for carbon nucleophiles in eq 1)[9] and acyclic allylic carbonates.[27] In addition, phthalimide has been used for the amination of 3,4-epoxybut-1-ene and, in this case, the 1,2-bis(aminocarbonyl-1'-naphthyl-2´-diphenylphosphino)cyclohexane ligand was found to provide the catalyst of choice.[28]

Azide has been used as a nucleophile in the desymmetrization of a dicarbonate derivative (eq 4).[29] In this example, a key intermediate in the synthesis of (+)-pancratistatin was produced.

(4)

Basic hydrolysis of the allylic azide affords the rearranged 1,2-isomer, which was an intermediate in the synthesis of (+)-conduramine E.[30] Following a similar strategy, but starting with *cis*-3,6-dibenzoyloxycyclohex-1-ene, a total synthesis of the non-opioid analgesic (-)-epibatidine was developed.[31]

Trost has reported enhanced enantioselectivity in the desymmetrization of *meso*-biscarbamates in the presence of triethylamine.[32] Under these conditions, high yields (>80%) and enantiomeric excesses (93-99% ee) are obtained. This methodology has been applied to the synthesis of (-)-swainsonine.[33]

α-Amino esters have been used as nucleophiles in the reaction with acyclic allylic esters and isoprene monoepoxide, providing access to diastereoselective *N*-alkylated α-amino esters.[34] By employing the feature ligand, asymmetric palladium(0)-catalyzed cyclization of 2-(tosylamino)phenol with (*Z*)-1,4-bis[(methoxycarbonyl)oxy]but-2-ene provides 2-vinylbenzomorpholine in 79% ee.[35] A number of alternative diphosphine ligands were studied and found to be inferior.

The asymmetric synthesis of indolizidine alkaloids is described utilizing a palladium-catalyzed amination process. Ionization of an allylic carbonate provides a symmetrical π-allyl palladium complex, subsequent reaction with a protected homoallylamine gave the product in 93% yield and >99.5% ee (eq 5).[36]

The product of the allylic amination process is set up for a ring-closing-ring-opening metathesis process, and subsequent elaboration to alkaloid derivatives.

Reactions with Oxygen Nucleophiles

The first report of the reaction of oxygen nucleophiles was for the deracemization of cyclic allylic ethers, for example, the palladium(0)-catalyzed reaction of 2-cyclohexenyl-1-methyl carbonate with sodium pivalate afforded the pivalate ester in 94% yield and 92% ee.[37] This reaction was extended to other cyclic allylic carbonates.

Racemic conduritol B acetates and carbonates provide very versatile substrates for asymmetric allylic substitution reactions. Reaction of conduritol B tetraacetate with sodium pivalate in the presence of a palladium catalyst, generated from the ligand and allylpalladium chloride dimer, resulted in a kinetic resolution to give the monosubstituted product in 44% yield (>99% ee) and the recovered tetraacetate in 50% yield (83% ee) (eq 6). This method provided a key intermediate for the synthesis of (+)-cyclophellitol.[38]

(6)

50%, 83% ee 44%, >99% ee

Later work has shown that a dynamic kinetic asymmetric transformation could be obtained if the acetates were converted into carbonate groups. With the tetra(2,2,2-trichloroethyl) carbonate derivative, reactions with carbon and nitrogen nucleophiles gave exclusively the monosubstituted products in high yield (61-95%) and excellent enantiomeric excesses (95-99%).[39] However, carboxylate nucleophiles afforded the disubstituted products in high yield and enantiomeric excess (eq 7).[39] This allowed an efficient synthesis of D-myo-inositol-1,4,5-trisphosphate to be devised.

R = Me

R = CH_2CCl_3

(7)

The reaction of isoprene monoxide with a range of alcohol pronucleophiles in the presence of the ligand (3 mol%), $Pd_2dba_3.CHCl_3$ (1 mol%) and triethylboron (1 mol%) gave the glycol monoethers in excellent yield and enantiomeric excess.[40] The use of *p*-methoxybenzyl alcohol and 3-nonyl-3,4-epoxybut-1-ene afforded an intermediate that was converted into (-)-malyngolide (eq 8).[41]

Extending this methodology to 3,4-epoxybut-1-ene was not successful with the featured ligand and the more sterically encumbered 1,2-bis(aminocarbonyl-1´-naphthyl-2´-diphenylphosphino)cyclohexane ligand was required.[40] The use of inorganic carbonates for the asymmetric synthesis of vinylglycidols has also been reported.[42] Reaction of isoprene monoxide with sodium bicarbonate, or sodium carbonate in the presence of the ligand, $Pd_2dba_3.CHCl_3$ and triethylboron afforded the diol in 91% yield and 97% ee. In the absence of triethylboron a cyclic carbonate was formed. Again, the 2-naphthyl ligand was required to provide optimum selectivity with 3,4-epoxybut-1-ene.[42]

The palladium(0)-catalyzed asymmetric *O*-allylation of phenols has been described using five-, six- and seven-membered ring allylic carbonates and acyclic allylic carbonates (eq 9).[43] The products from these reactions were subjected to a Claisen rearrangement to provide *C*-alkylated phenols. A study of various ligands for the reaction of phenol with 2-cyclohexenyl-1-methyl carbonate clearly showed that the Trost ligand is superior.[44]

This methodology has been expanded to geranyl methyl carbonate for the synthesis of the vitamin E nucleus, and to tiglyl methyl carbonate for the synthesis of (-)-calanolide A and B.[45] In the latter example, the anthracenyldiamine[3]-based ligand was required for optimum selectivity. The synthesis of (-)-aflatoxin B lactone utilizes a dynamic kinetic asymmetric transformation, whereby a suitably functionalized

phenol reacts with a racemic 5-acyloxy-2-(5*H*)-furanone to provide a single product in 89% yield.[46] One final example of phenol as a nucleophile is for the deracemization of Baylis-Hillman adducts.[47]

Cyclic 1,2-diketones, such as 3-methylcyclopentane-1,2-dione, act as oxygen nucleophiles in palladium(0)-catalyzed reactions with a range of cyclic and acyclic allylic esters.[48] The products of these reactions were subjected to a lanthanide-catalyzed Claisen rearrangement to access the *C*-alkylated products.

Reactions with Sulfur Nucleophiles

The use of sulfur nucleophiles in palladium-catalyzed allylic substitution reactions is less well documented than that of carbon, nitrogen and oxygen nucleophiles. The asymmetric synthesis of allylic sulfones utilizing a catalytic phase transfer system has been used to produce (3*S*)-(phenylsulfonyl)cyclohex-1-ene on a 45 g scale (eq 10).[49] In many cases, it has been reported that allylic carbonates are more reactive than allylic acetates in asymmetric allylic substitution reactions.[49,50]

(10)

A range of cyclic allylic carbonates was found to be useful in this process and a myriad of useful functionalized building blocks were accessed via dihydroxylation and epoxidation reactions.[49] The reaction of lithium *tert*-butylsulfinate with acyclic allylic acetates in the presence of the ligand, $Pd_2(dba)_3.CHCl_3$ and tetrahexylammonium bromide under phase-transfer conditions (CH_2Cl_2/H_2O) led to a kinetic resolution whereby the starting material was isolated in 96% ee and the *tert*-butyl sulfone in 95% ee.[50] With cyclic allylic carbonates, a single *tert*-butyl sulfone is obtained in 76-92% yield and 89-93% ee.[50] However, stopping the reaction at 54% conversion gave the sulfone (49% yield, 98% ee) and the carbonate (34% yield, 99% ee), this kinetic resolution protocol was later extended to thiols with cyclic and acyclic allylic carbonates.[51] In general, the synthesis of allylic sulfides requires higher catalyst loading and was found to be unsuccessful for *tert*-butyl thiol and thiophenol.[52] However, cyclic and acyclic allylic *S*-*p*-chlorophenyl, *S*-2-pyridyl and *S*-2-pyrimidyl sulfides could be obtained in high yield and enantiomeric excess, in the presence of the ligand and $Pd_2(dba)_3.CHCl_3$ in organic solvent.[52]

A more efficient method to access single enantiomer thiols and sulfides has been developed using a palladium(0)-catalyzed rearrangement of *O*-allylic thiocarbamates (eq 11).[53]

(11)

This reaction was carried out on cyclic and acyclic allylic carbonates. The *S*-allylic thiocarbamate products were hydrolyzed to the corresponding thiol or reacted with 2-chloropyrimidine in the presence of potassium hydroxide to provide the sulfide without any loss in stereochemical purity for either example.[53]

α-Acetoxysulfones can be regarded as acid-stable, but base-labile, chiral aldehyde equivalents. These can be accessed through the palladium(0)-catalyzed reaction of geminal esters with sodium benzenesulfinate under phase-transfer conditions (eq 12).[54]

(12)

Osmium tetroxide-catalyzed dihydroxylation of the chiral α-acetoxysulfones and acetonide formation affords versatile chemical intermediates. Reduction with DIBAL-H provides primary alcohols, and addition of Grignard reagents provides secondary alcohols with excellent stereochemical control of the newly formed chiral center.[54]

Polymer-Supported Schwesinger Base

[98015-45-3]

(polymer-bound strong base for acylation and alkylation reactions)

Alternate Name: P-BEMP, PS-BEMP (BEMP=2-*tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine).

Physical Data: loading 2.3 mmol g^{-1} on polymer (batch dependent).

Solubility: the reagent, immobilized on 1-2% cross-linked polystyrene divinylbenzene co-polymer, is insoluble in all common organic and aqueous solvents.

Form Supplied in: brown powder, commercially available.

Analysis of Reagent Purity: the loading of the reagent is best determined by elemental analysis. The functional activity can be determined by the degree of chemical transformation from use of stoichiometric quantities of reagents.

Handling, Storage, and Precautions: harmful if inhaled or ingested; irritant. Stable at room temperature.

Phosphazene bases have been shown to be useful alternatives to ionic bases for a number of chemical transformations.[1] Of these, 2-*tert*-butylimino-2-diethylamino-1,3-dimethyl-perhydro-1,3,2-diazaphosphorine (BEMP) has a basicity (pK_B=27.5) comparable to 5 M aqueous potassium hydroxide/Bu_4N/acetonitrile and potassium carbonate/18-crown-6/acetonitrile.[2] The commercially available[3] polymer-supported equivalent, PS-BEMP,[2] retains the basicity of the solution phase reagent and has been exploited in the alkylation and acylation of weakly nucleophilic NH-containing compounds.

Alkylation of Heterocycles

In an early paper, Xu and co-workers[4] studied the *N*-alkylation of a number of weakly acidic NH-containing aromatic heterocycles. Indoles, pyrazoles, and phthalazinones were alkylated with α-bromo ketones or esters in the presence of PS-BEMP in acetonitrile at room temperature. Simple filtration and evaporation, after removal of excess alkylating agent with aminomethyl polystyrene, gave the required products in high chemical yield (93-98%) and high purity (93-99%). The use of more weakly basic resins resulted in no alkylation and this enabled the authors to develop a one-pot procedure for the selective dialkylation of a pyrazole (eq 1).

(1)

Similar procedures using PS-BEMP for the alkylation of purines[5] and pyrroles[6] and for S_NAr reactions towards fluoroquinolone antibacterial agents[7] have been reported.

Alkylation of Sulfonamides

The principle of orchestrated multi-step synthesis using polymer-supported reagents[8] has been applied to the preparation of a series of hydroxamic acids as potential matrix metalloproteinase inhibitors.[9] Alkylation of the weakly acidic sulfonamide NH with benzylic halides, a key step in the synthesis, was achieved utilizing PS-BEMP in dichloromethane. Scavenging of the excess alkylating agent with aminomethyl polystyrene followed by filtration and evaporation gave the required products in high yield and purity (eq 2).

Alkylation and Acylation of Weakly Nucleophilic Species

In an analogous way to the alkylation of heterocycles, PS-BEMP has been utilized for the derivatization of weakly nucleophilic heterocyclic amines and hydrazones. Having investigated a range of polymer-bound acyl transfer reagents, Kim and Le found PS-BEMP in THF to be a superior reagent for the acylation of amino-pyridines, -pyrazoles, -thiazoles, -benzothiazoles, and -quinolines with acid chlorides.[10] Amides were produced in high purity but only in moderate yield using this chemistry. The alkylation of hydrazone **1**, a key intermediate towards the polymer-supported synthesis of sildenafil,[11] was achieved in excellent yield with the excess, unreacted α-bromoester being sequestered with aminomethyl polystyrene or polymer-supported trisamine (eq 3).

Application of PS-BEMP to Ring Forming Reactions

In a later stage of the same polymer-supported synthesis of sildenafil,[11] PS-BEMP was employed to effect the rapid deprotonation and concomitant cyclization of substituted hydrazone **2** to a tetrasubstituted pyrazole (eq 4).

Using an orchestrated sequence of polymer-supported reagents, Ley and co-workers demonstrated the ten-step synthesis of (±)-epibatidine.[12] The key step in the formation of the epibatine framework, a transannular cyclization, was mediated by PS-BEMP (eq 5). The authors found that the supported phospazene base allowed the reaction to proceed in higher yield and more rapidly than under the thermal conditions reported in a previous synthesis. Additionally, no by-products arising from intermolecular alkylation were observed. The only impurity, approximately 10% of the unreacted starting material, could be sequestered using aminomethyl polystyrene.

PS-BEMP has also been utilized in the synthesis of the bis(indole) marine alkaloid, rhopaladin D.[13] The key step, formation of the central imidazolinone ring, was effected by an aza-Wittig reaction of phosphorane **3** with indolyl-3-glyoxylyl chloride in the presence of PS-BEMP. Intramolecular cyclization of the resulting imidoyl chloride gave the required rhopaladin ring system (eq 6).

Borohydride Exchange Resin

(chemoselective nucleophilic hydride reducing reagent for aldehydes and ketones, and many other functional groups in the presence of metal salt catalysts)

Physical Data: loading 2-3 mmol g^{-1} of boron on the polymer (batch dependent).

Solubility: cross-linked polystyrene divinylbenzene co-polymers are insoluble in all common solvents.

Form Supplied in: white microporous or macroreticular solid, available from several large international suppliers.

Analysis of Reagent Purity: the loading is usually obtained from elemental analysis.

Purification: polymer washed using water, then methanol. Drying may be completed in vacuo between 25°C and 60°C.

Handling, Storage, and Precautions: harmful if inhaled or ingested. Decomposition occurs under acidic conditions to form toxic diborane gas and flammable/explosive hydrogen gas. All reactions should be carried out under a well ventilated fumehood. Long-term storage should be in a refrigerator under nitrogen.

Borohydride Exchange Resin (BER)

For many years, insoluble cross-linked polystyrene resins with quaternary ammonium termini have been used as supports for anionic reagents in organic synthesis.[1-14] Polymer bound borohydride was first reported by two independent groups in 1961,[15,16] with the first published reports of borohydride supported on ion-exchange polymer **1** appearing over a decade later.[6,17]

Borohydride exchange resin is available from several commercial suppliers.[18] It can also be prepared by the chemical modification of cross-linked polystyrene-based quaternary ammonium ion exchange polymers. The chloride forms of Amberlyst A-26, Amberlite IRA-400 or Amberlite IRA-900[19] are suspended in an aqueous solution of sodium borohydride for 1 h. The resin is then filtered and washed with distilled water and then methanol before drying under vacuum for several hours (eq 1).[17] After use, the polymeric reagent can easily be regenerated by washing with aqueous hydrochloric acid and water before refunctionalizing as above.

An important modification of reactions with borohydride exchange resin is its use in conjunction with catalytic metal salts which enhance its reducing power.[14]

Supported zinc[20,21] (**2**) and zirconium[22] (**3**) borohydrides have also been prepared on cross-linked poly(4-vinylpyridine). The unsupported forms of these reagents are unstable and require careful storage and use. However, the polymeric versions offer not only greater ease of handling, but can also be stored for several months at room temperature. Furthermore, these poly(4-vinylpyridine)-supported reagents have loadings which are approximately three times higher (~10 mmol g^{-1}) than the equivalent polystyrene-based polymers.

Reduction of Aldehydes and Ketones

Borohydride exchange resin readily reduces aldehydes and a variety of ketones to their respective alcohols without affecting esters (except aryl acetates)[23] or amides (eq 2). Reactions can be performed in either methanol or ethanol, but rates of reaction are much higher in methanol. Aldehydes are more reactive towards borohydride exchange resin than ketones and a high level of chemoselectivity has also been observed within these groups.[24]

(2)

R^1= alkyl, aryl

R^2= H, alkyl

Enhanced rates of reaction and chemoselectivity have been seen using BER (borohydride exchange resin) with **lithium chloride** or **lithium nitrate** to reduce carbonyl groups in the presence of other reducible functionalities such as alkenes, amides, halides, nitriles, and nitro groups.[25] Improved rates of reduction also occur when BER is used in conjunction with **$Ni(OAc)_2$** or **$CuSO_4$**. Additionally, nickel catalysis has also been seen to further reduce aromatic aldehydes[26, 27] to methyl arenes (eq 3).

(3)

When BER reacts with α,β-unsaturated aldehydes and ketones, selective formation of the α,β-unsaturated alcohols occurs with no reduction of the double bond (eq 4).[19,28,29] This is in contrast to sodium borohydride, where conjugate reduction is found to be a substantial competing process.

(4)

R^1= aryl

R^2= H, alkyl, aryl

For a comparison, **Amberlyst A-26**, **Amberlyst IRA-400**, and **sodium borohydride** on alumina were all tested. The A-26 was more reactive than IRA-400, but both showed similar selectivity. The alumina-supported material reacted fastest but showed reduced selectivity. The importance of the choice of supporting material is also highlighted in an alternative report, where the support used was Seralite-SRA-400. Here a complete reversal of selectivity was reported in which unsaturated ketones are reduced to saturated ketones and α,β-unsaturated aldehydes are reduced to saturated alcohols.[30] Also, if BER is used in conjunction with copper sulfate, most α,β-unsaturated ketones and aldehydes are reduced to the corresponding saturated alcohols.[31]

Poly(4-vinylpyridine)-supported zirconium borohydride is another reliable reagent for reduction of aldehydes or ketones and is reported to leave conjugated double bonds intact.[22] Zinc borohydride on poly-eta-(pyrazine)[32] can be used as an alternative. However, for absolute selectivity for aldehydes over ketones, zinc borohydride on poly(4-vinylpyridine)[20] can be applied.

Reduction of Nitro Compounds

Uncatalyzed BER reacts with nitroalkenes which are reduced to the respective nitroalkanes.[33] However, it is unable to reduce aliphatic or aromatic nitro groups unless it is employed in conjunction with a transition metal catalyst such as $Ni(OAc)_2$,[27] $NiCl_2.6H_2O$,[34] $PdCl_2$,[35,36] CuCl,[35] $Cu(OAc)_2.4H_2O$[35] $CuSO_4$,[37] or Ni_2B.[37] These systems give successful reduction of both aliphatic and aromatic nitro groups to the corresponding amines in excellent yields (eq 5).

(5)

R^1= alkyl, aryl

Reduction of Azides

For the general reduction of aliphatic and aromatic azides, catalytic nickel acetate[38] or copper sulfate[37] are usually employed, although poly(4-vinylpyridine)-supported $Zr(BH_4)_2$ has also been reported to facilitate these reactions (eq 6).[22]

(6)

R^1= alkyl, aryl

R^2, R^3= H, alkyl, aryl

Borohydride exchange resin itself only reduces aryl azides and sulfonyl azides to the corresponding aryl amines and sulfonamides respectively.[39] Aryl azides with electron-withdrawing substituents are readily reduced at room temperature, whereas unactivated phenylic and benzylic azides require reflux for long periods. Aliphatic azides do not react under these conditions (eq 7).

(7)

Reduction of Imines

BER is useful in the reductive amination of aldehydes and ketones in acidified methanol or ethanol.[40-43] Secondary or tertiary amines are produced in high yield from the reaction between aldehydes and primary or secondary amines (eq 8). Ketones react well when coupled with less hindered aliphatic amines, but low yields are obtained with aromatic amines.

(8)

R^1= alkyl, aryl

R^2= H, alkyl, aryl

R^3, R^4= alkyl, benzyl

Although secondary and tertiary amines are prepared in good yield using these methods, yields of primary amines are moderate to poor. However, reductive amination of aldehydes and ketones with hydrazine has been found to be a good alternative (eq 9). The intermediate hydrazones undergo N-N cleavage with BER-$Ni(OAc)_2$ in refluxing methanol to afford the resultant primary amines in good yield.[44]

(9)

An alternative reducing reagent for reductive amination is supported cyanoborohydride **4**, which is commercially available or can be prepared in a similar manner to BER using sodium cyanoborohydride and the chloride form of the polymer.[45]

Reductions of Alkyl and Aryl Halides and Tosylates

Borohydride exchange resin alone is able to react with only certain halides.[46] However, in the presence of $Ni(OAc)_2$ most aliphatic or aromatic halides and tosylates are successfully reduced (eq 10).[47, 48]

(10)

Borohydride exchange resin used in conjunction with $CuSO_4$ and BER-nickel boride (Ni_2B) has been successfully employed in the reduction of bromides and iodides or benzylic chlorides.[37]

A BER-Ni_2B system prepared in situ from BER-$Ni(OAc)_2$ in methanol has been used for a novel C-C bond formation via radical addition or radical cyclization of alkyl halides with electron deficient alkenes of α,β-unsaturated esters, ketones and nitriles.[49,50]

Reduction of Alkenes

Although most double bonds are unreactive to BER, an exception to this is conjugated nitroalkenes which can be efficiently reduced to saturated nitroalkanes (eq 11).[33]

(11)

R^1, R^3= H, alkyl

R^2= H, alkyl, aryl

The reductions of α,β-unsaturated amides, esters, and nitriles using BER require a catalyst. When BER-$CuSO_4$ is used, the saturated species are formed with no concurrent reduction of the amide, ester, or nitrile functionalities (eq 12).[51]

(12)

R^1, R^2, R^3= H, alkyl

When catalyzed by cobalt, nickel, or copper, BER has been shown to reduce a wide variety of isolated double bonds (eq 13).[52,53] Mono- and di-substituted alkenes are successfully reduced. Less hindered alkenes and those attached to electron-withdrawing substituents show enhanced rates, whereas hindered and trisubstituted olefins are not reduced.

(13)

R^1= H, alkyl, aryl

R^2, R^3= H, alkyl

Nickel Boride (Ni_2B) also catalyses the selective borohydride exchange resin-mediated hydrogenation of mono- and di-substituted olefins. Monosubstituted alkenes are quantitatively hydrogenated in 1 h at 0°C in the presence of di-substituted alkenes and trisubstituted α,β-unsaturated acid derivatives. Disubstituted double bonds are hydrogenated at reflux in 1 h without affecting trisubstituted olefins, benzenes, or heteroaromatics.[54]

Reduction of Alkynes

It was reported that $Pd(OAc)_2$-doped BER in the presence of cesium iodide promotes hydrogenation of alkynes to give *cis*-alkenes (eq 14).[55] This method was excellent for the semihydrogenation of terminal and internal alkynes.

(14)

R^1= alkyl

R^2= H, alkyl

Reduction of Oximes

Oximes are resistant to reduction by BER, but aromatic oximes can be transformed to primary benzylamines using BER-$Ni(OAc)_2$ (eq 15).[56] Aryl aldoximines with electron-withdrawing substituents such as nitro and chloro are readily reduced, but simultaneous reduction of the nitro and chloro groups also occurs. Reduction of aryl aldoximes with electron-donating substituents is slow, but they can be successfully reduced using higher temperatures and longer reaction times.

(15)

Reduction of Acid Chlorides and Epoxides

BER successfully reduces acid chlorides to alcohols.[34,57] Poly(4-vinylpyridine)-supported $Zr(BH_4)_4$ converts acid chlorides to aldehydes and epoxides to the more substituted alcohols (eq 16).[22] $AlCl_2(BH_4)$ supported on poly(4-vinylpyridine) has also been used to open epoxides in a similar manner.[58]

(16)

Reduction of Nitriles

Generally, nitriles are inert to BER and copper-catalyzed BER although benzonitriles can be converted to benzylamines using BER-$Ni(OAc)_2$ (eq 17).[27]

(17)

Deoxygenation of Amine *N*-Oxides

Under copper catalysis, BER quantitatively deoxygenates both tertiary amine *N*-oxides and heteroatomic *N*-oxides. For example, BER-$CuSO_4$ is able to cleanly reduce pyridine-*N*-oxide to pyridine in 99% yield in refluxing methanol (eq 18).[37,59]

(18)

Reduction of Nitrosoamines

Nitrosoamines have been used for the introduction of alkyl groups at the α-position. BER-$CuSO_4$ has been successfully utilized in the reduction of nitroso compounds to give the corresponding secondary amines (eq 19).[60]

(19)

R^1, R^2= alkyl, aryl

Reduction of Mixed Anhydrides

BER-Ni$(OAc)_2$ converts mixed anhydrides of aromatic carboxylic acids to alcohols (eq 20).[61]

(20)

Reduction of Aryl Diazonium Fluoroborates

Borohydride exchange resin will reduce substituted aryl diazonium fluoroborates to the corresponding phenylhydrazines under mild conditions (eq 21).[62]

(21)

X = F, Cl, Br, NO_2

Formation of Phenyl Sulfides

Borohydride exchange resin readily reduces phenyl disulfides in methanol under neutral conditions. The resultant mixtures, on reaction with alkyl halides or epoxides, provide convenient and selective reagents for the preparation of phenyl sulfides (eq 22). Filtration of the resin leaves a solution of products which is essentially free from both sulfur- and boron-containing side products.[63]

R^1= alkyl, allyl, aryl

X= Cl, Br, I, OTs

(22)

R^1= alkyl, aryl

R^2= H, alkyl

Formation of Thiols

After thioacetate formation by the reaction of a variety of halides with a polymer-supported thioacetate, a palladium-catalyzed methanolysis protocol yields thiols selectively in high yield in a one-pot reaction (eq 23).[64] This method, involving palladium deposited on BER, requires 3 equiv of BER to prevent the formation of disulfide by-products.

(23)

R^1= alkyl, aryl

X= Cl, Br, I, OTs

Reduction of Selenium

Selenium may be reduced by BER to give an immobilized selenide that reacts with alkyl halides or tosylates to form dialkyl selenides in high yields. No release of toxic or malodorous by-products occurs, as these are scavenged from the reaction by the polymer (eq 24).[65]

(24)

Related Reagents.

sodium borohydride, nickel boride, sodium cyanoborohydride.

Polymer-Supported Carbonate

Physical Data: loading 3.5 mmol g^{-1}.

Solubility: the reagent is insoluble in all common aqueous and organic solvents.

Form Supplied in: white and brown beads, commercially available, containing 20% water. Commercial supplier: Fluka.

Purification: the polymer should be washed in dichloromethane and dried in vacuo prior to use.

Handling, Storage, and Precautions: powdered resin is harmful if inhaled or ingested. Stable at room temperature.

Polymer-supported carbonate (PS-carbonate), first described in 1981,[1] is a weakly basic reagent with several applications for organic synthesis, notably for the neutralization of acidic solutions, as a source of nucleophilic carbonate, and for mediating various functional group interconversions and deprotections.

The earliest application of carbonate resin was for the conversion of primary alkyl halides to alcohols under mild conditions in excellent yields (eq 1), although secondary halides gave some elimination products under the same conditions.[1] The order of reactivity was determined as $I^- Br^- Cl^-$.

(1)

This reagent has also been applied to the formation of triols from α-iodo carbonates.[2] The reaction proceeds via an epoxide intermediate which is only hydrolysed in the presence of a proximal hydroxyl group (eq 2). This reaction elegantly overcomes the usual problematic aqueous work-up encountered due to the high solubility of the triol products in water.

More recently, the synthesis of several heterocyclic systems has been achieved using PS-carbonate. Oxazoles were formed cleanly from α-iodotrichloroacetamides in high yield (eq 3),[3] and oxazolidin-2-ones were synthesized stereoselectively from β-iodo α-hydroxyammonium salts (eq 4).[4] The latter reaction involves insertion of carbon dioxide and proceeds via an α-epoxycarbamate intermediate.

(4)

The formation of oxazolidin-2-ones has also been elegantly accomplished in one pot from enantiopure allylic amine salts using iodine adsorbed onto PS-carbonate as a supported source of both iodine for the iodolactonization and carbon dioxide for the carbamate formation (eq 5).[5] Selectivity for the *E* product increased upon benzyl protection of the ammonium salt.

(5)

PS-carbonate has recently been used in several multi-step organic syntheses in conjunction with other polymeric reagents. Ley et al. reported the synthesis of (±)-oxomaritidine and some elaborated analogs,[6] in which carbonate resin was used in the final step to remove a trifluoroacetate protecting group and mediate an intramolecular 1,4-addition to cleanly furnish the target molecule (eq 6).

The same group has also reported the use of this reagent in the formation of a cyclic hemiacetal from α-bromoketones and catechol.[7] Aminomethylpolystyrene was added to remove any remaining α-bromoketone to give the desired product in high purity as a mixture of open and closed chain forms (eq 7).

(7)

Yield 90 98%

A further application of this reagent is the neutralization of ammonium salts. Treatment of several salts with PS-carbonate in refluxing methanol yielded the free amines in clean fashion (eq 8).[3] This principle has been applied to the purification of a range of bicyclo[2.2.2]octane derivatives following an intermolecular cycloaddition step.[8] Polymer-supported thiol and diisopropylethylamine (DIPEA) were used to remove unreacted cyclohexenone and the resultant ammonium salts were neutralized with the carbonate resin to afford the desired product after simple filtration and evaporation (eq 9).

X = Cl or AcO

Polymer-Supported Perruthenate

(reagent used for the oxidation of primary alcohols)

Physical Data: loading 1 mmol g^{-1} on polymer (batch dependent).

Solubility: cross-linked polystyrene divinylbenzene co-polymer is insoluble in all common aqueous and organic solvents.

Form Supplied in: black powder; commercially available.

Analysis of Reagent Purity: the loading is best determined by the degree of chemical transformation from use of a stoichiometric amount of the reagent. The loading can also be estimated by elemental analysis.

Purification: the polymer is washed successively using water, acetone and dichloromethane, and subsequently dried in vacuo.

Handling, Storage, and Precautions: harmful if inhaled or ingested. Stable at room temperature and may be stored for longer periods of time if kept refrigerated in the dark.

Polymer-supported perruthenate (PSP) is a mild and effective oxidant used mainly for the conversion of primary alcohols to aldehydes. This polymer-supported oxidant can be used either in stoichiometric amounts or as a catalyst in combination with a co-oxidant.[1] The reagent is prepared by adding Amberlyst A-26 anion exchange resin (which contains quaternary ammonium groups) to an aqueous solution of potassium perruthenate and sonicating the mixture until the solution turns clear. Alternatively, an aqueous solution of potassium perruthenate can be slowly eluted through a chromatographic column packed with Amberlyst A-26 (prewashed with water, dichloromethane, acetone, and toluene). The resulting black polymer beads are washed successively with water, acetone, and dichloromethane, and dried under vacuum at room temperature. Catalytic oxidations of primary alcohols containing a variety of functional groups can be carried out at room temperature in dichloromethane using *N*-methyl morpholine *N*-oxide as the co-oxidant in the presence of 4Å molecular sieves (eq 1).[2]

(1)

Clean oxidations can be carried out using stoichiometric amounts of PSP without the need for additives that result in product contamination. Alternatively, clean catalytic oxidations can be carried out by using molecular oxygen as the co-oxidant. These reactions are normally carried out in toluene (presaturated with oxygen) at 85°C under an atmosphere of oxygen (eq 2).[3] After the reaction is complete, PSP can be recovered by a simple filtration and the reduced reagent can be regenerated by external treatment with *N*-methyl morpholine *N*-oxide.

(2)

Secondary hydroxyl amines can be oxidized to the corresponding nitrones using PSP. Performing the operation in the presence of an electron-poor dipolarophile results in the formation of isoxazolidines through sequential oxidation and [2+3] cycloaddition (eq 3).[4]

Polymer-Supported Ammonium Periodate

(an oxidizing reagent commonly used for the cleavage of 1,2-diols and the oxidation of sulfides to sulfoxides or sulfones)

Alternate Name: polymer-supported ammonium metaperiodate, polymer-supported quaternary ammonium periodate, polymer-supported quaternary ammonium metaperiodate.

Form Supplied in: commercially available as (polystyrylmethyl)trimethylammonium metaperiodate [polymer matrix is copoly(styrenedivinylbenzene) 20-50 mesh].

Purification: the polymer is washed with an appropriate solvent and dried in vacuo.

Handling, Storage, and Precautions: keep cool and dry, store under argon. Prolonged storage at <-18°C.

Introduction

Sodium and potassium periodates are frequently used to oxidize a variety of functional groups. However, due to the poor solubility of these salts, reactions are generally performed in protic media. In contrast, polymer-supported ammonium periodates can be used in a variety of solvents, including aprotic solvents, with the additional practical advantage that work-up is a simple filtration.

Oxidative Cleavage of 1,2-Diols

Harrison et al. demonstrated that polymer-supported ammonium periodate prepared from Amberlite IRA 904 or Amberlyst A26 cleaved 1,2-diols in high yield in a variety of solvents.[1] For the cleavage of cyclohexane-1,2-diol in dichloromethane (eq 1), it was observed that trace amounts of water accelerated the reaction, possibly by creating a favorable microenvironment in the resin.

(1)

The synthesis of a series of trihydroxy nucleosides, using polymer-supported ammonium periodate prepared from Amberlyst A27 (chloride form), represents the first example of the concomitant use of two antagonistic reagents (eq 2).[3]

Base	Yield
Adenine	70%
Cytosine	79%
Guanine	40%
Uracil	73%

(2)

A solution of the diol was pumped through a column containing a mixture of the periodate and borohydride resins, which brought about the cleavage and in situ reduction of the unstable dialdehyde as soon as it formed.

A mixture of the polymer-supported ammonium periodate and borohydride reagents has also been used for the reduction of other diols to primary alcohols (eq 3).[3]

(3)

Oxidation of Alcohols to Carbonyls

The oxidation of benzylic alcohols to carbonyl compounds has been achieved with clay (K10-montmorillonite)-supported tetrabutylammonium periodate (TBAPI) (eq 4).[4] A series of primary and secondary alcohols were oxidized to the corresponding aldehydes or ketones with reasonable yields.

(4)

Interestingly, the addition of Lewis acid catalysts is not required, unlike solution-phase tetrabutylammonium periodate which alone is incapable of achieving these oxidations in aprotic solvents.

Oxidation of Quinols

A number of quinols (eq 5) and catechols (eq 6) have been oxidized using supported periodate, prepared from Amberlite IRA 904 (chloride

form), to give quinones in good yield.[1]

(5)

(6)

Oxidation of Sulfides to Sulfoxides

Polymer-supported ammonium periodate has been used for the oxidation of sulfides to sulfoxides, for example, the oxidation of methylpenicillin V was efficiently achieved in 89% using a periodate reagent prepared from Amberlyst A26 (eq 7).[1]

(7)

Similarly, a variety of aromatic and aliphatic sulfides were oxidized by periodate supported on strong anion exchange resin Amberlite IRA-400.[5]

Clay (K10-montmorillonite)-supported tetrabutylammonium periodate is a mild reagent for the facile oxidation of sulfides to sulfoxides in water.[4] The oxidation is faster and more efficient than its periodate or tetrabutyl ammonium periodate/aluminum trichloride solution-phase counterparts.

Miscellaneous Reactions

The versatility of the polymer-supported periodate has been demonstrated by the oxidation of α-haloketones to acids (eq 8) and the oxidative decarboxylation of arylacetic acids and α-hydroxy acids to carbonyl compounds (eq 9 and 10).[6] The reactions were performed in ethanol using the periodate form of IRA-400.

(8)

(9)

(10)

Salunkhe et al. have used a polymer-supported periodate generated from Amberlyst A26 to oxidize hydrazides to 1,2-diacyl hydrazines (eq 11).[7] It was found that the resin could be used repeatedly, as it was regenerated to its initial activity by treatment with dilute hydrochloric acid.

(11)

In addition, triphenylphosphine, hydrazobenzene, and benzohydroxamic acid are oxidized to triphenyl phosphine oxide, azobenzene, and nitrosocarbonylbenzene, respectively, using a supported ammonium periodate prepared from Amberlyst A26.[1]

Related Reagents.

tetrabutylammonium periodate has been immobilized on montmorillonite clay; sodium periodate has also been immobilized on a variety of mineral supports, such as alumina, clay, and silica.[8]

Polymer-Supported Thiophenol

Physical Data: loading 1.0-1.5 mmol g^{-1} (based on benzyl bromide uptake).

Solubility: 1% cross-linked polystyrene backbone is insoluble in all common aqueous and organic solvents.

Form Supplied in: yellow powder; bead size 75-150 µm, 100-200 mesh (95% within). Commercially available; retailer: Argonaut Technologies.[1]

Purification: the polymer is washed in dichloromethane and dried in vacuo.

Handling, Storage, and Precautions: harmful if inhaled or ingested. Stable at room temperature.

Applications

Polymer-supported thiophenol (PS-thiophenol) has two principal applications in synthetic chemistry; it functions either as a scavenging agent or as a traceless solid-phase linker.[2] This functionalized polymer is commonly used as a phase transfer scavenger for a wide range of electrophiles including alkyl halides. It is easy to remove by filtration, thus enabling the preparation of products of high purity without the need for additional purification or isolation procedures. As with all scavenging procedures, 2 or 3 equiv of resin should be used to ensure complete removal of the surplus electrophile. The scavenging ability or nucleophilicity of PS-thiophenol has been found experimentally to be superior to the corresponding benzyl thiol attached to a polystyrene backbone.[1] Optimal scavenging results require either the formation of the potassium thiolate salt (formed using potassium trimethylsilylonate) (eq 1)[1] or the addition of diisopropylethylamine and mesoporous carbonate (eq 2).[1]

PS-thiophenol has been utilized in combinatorial library synthesis as an effective and clean method to remove excess electrophilic substrate[3] or alkylating reagent (eq 3).[4]

(3)

Another useful application of the resin involves amine deprotection reactions. PS-thiophenol/base can be used to remove the Fmoc protecting group and simultaneously capture the contaminating component (eq 4).[5]

(4)

The reagent can also be used to attach suitable substrates, i.e. molecules susceptible to nucleophilic attack, onto the solid phase and thus facilitate a trivial purification procedure (eq 5).[6]

(5)

While attached to the resin, the isolated moiety can undergo further chemical manipulation with the PS-thiophenol acting as a linker moiety.[7] Cleavage is achieved by the addition of an amine (primary or secondary), causing nucleophilic displacement from the resin, which

also results in additional modification of the molecule (eq 6). The functionalized polymer acts as a traceless linker without the need for oxidation to the sulfone or sulfoxide.

(1*R*,5*R*)-2*H*-1,5-Benzodithiepin-3(4*H*)-one 1,5-Dioxide

[183595-53-1] · $C_9H_8O_3S_2$ · (228.29)

(chiral auxiliary for asymmetric desymmetrization of cyclic *meso*-1,2-diols)

Alternate Name: 2*H*-1,5-benzodithiepin-3(4*H*)-one, 1,5-dioxide, (1*R*-*trans*)-; (1*R*,5*R*)-1,5-benzodithiepan-3-one 1,5-dioxide.

Physical Data: colorless prisms, mp 195.0-196.0°C (decomposes) (from hexane/EtOAc), $[\alpha]_D^{25}$-100.3 (*c* 0.29, $CHCl_3$).

Solubility: soluble in MeOH, acetone, EtOAc, THF, CH_2Cl_2, and $CHCl_3$.

Form Supplied in: colorless powder; not commercially available.

Analysis of Reagent Purity: ^1H and ^{13}C NMR; elemental analysis.

Preparative Methods: the title reagent can be prepared from commercially available (1,2-benzenedithiol[1] and 1,3-dichloroacetone. After condensation of these reagents in the presence of DMAP, the resulting 1,5-benzodithepan-3-one is enantioselectively oxidized to the (*R*)-monosulfoxide by modified Sharpless oxidation [cumene hydroperoxide, Ti(O-*i*-Pr)$_4$] in the presence of (+)-diethyl tartrate as a chiral ligand.[2,3] Subsequent dry ozonation[4] of the (*R*)-monosulfoxide affords (1*R*,5*R*)-bis-sulfoxide **1**, having >98% optical purity. Alternative use of (-)-diethyl tartrate in the modified Sharpless oxidation makes possible convenient access to enantiomeric (1*S*,5*S*)-**1**.[5,6]

Purification: purification is performed by column chromatography. Since unpurified (1*R*,5*R*)-bis-sulfoxide **1** is only slightly soluble in the eluent, the following procedure is convenient. The crude material is dissolved in EtOAc and mixed with silica gel (ca. 5 g silica gel per 1 g of crude reagent). After solvent evaporation, the silica gel residue containing **1** is added to the top of the column and eluted with hexane-EtOAc (2:1).

Handling, Storage, and Precautions: the reagent can be stored for at least 1 month at room temperature without loss of its chemical and optical purities.

Introduction

(1*R*,5*R*)-2*H*-1,5-Benzodithiepin-3(4*H*)-one 1,5-dioxide (C_2-symmetric bis-sulfoxide **1**) has been used as a chiral auxiliary for asymmetric desymmetrization of cyclic *meso*-1,2-diols via diastereoselective acetal cleavage reaction. The procedure consists of three steps (eq 1), that is, acetalization (step 1), acetal cleavage reaction followed by benzylation (step 2), and hydrolysis of the vinyl ether (step 3). Due to the C_2-symmetry of **1**, the chiral auxiliary gives only one product in step 1. In addition, no regio- or geometric isomers of the enol ether are formed in step 2. This reagent can be recovered by acid-promoted hydrolysis and reused.

Acetal Formation Involving C_2-Symmetric bis-Sulfoxide and *meso*-1,2-Diols (Step 1)

Acetalization of *meso*-1,2-diols with this reagent should be conducted with TMSOTf and 2,6-lutidine in dichloromethane below 4°C.[7] Higher temperatures and prolonged reaction times cause undesirable racemization and decomposition of the reagent. When the reactivity of *meso*-1,2-diols with the chiral auxiliary is low, acetalization using the mono-TMS ether of *meso*-diols and TMSOTf is recommended.[8]

Diastereoselective Acetal Fission Followed by Benzylation (Step 2)

Upon treatment with KHMDS and 18-crown-6 in THF at -78°C, the acetal from the (*R*,*R*)-bis-sulfoxide is rapidly converted into the alkoxide having the (1*S*,2*R*) configuration. The counter cation of the base is very important for high selectivity. Diastereoselectivity was seen to increase in the order LiHMDS (8% de) <NaHMDS (90% de) <KHMDS (>96% de).

Hydrolysis of the Vinyl Ether and Reagent Recovery (Step 3)

The resulting vinyl ether can be hydrolyzed with 10% HCl in acetone at room temperature. The chiral auxiliary is recovered without loss of optical purity and is reusable.

Desymmetrization of Functionalized *meso*-1,2-diols

Using this methodology, various cyclic *meso*-1,2-diols can be desymmetrized with very high (>96% ee) and predictable selectivity. The enantiomers are obtained through use of an appropriate chiral auxiliary. Bis-sulfoxide **1** has been applied to the desymmetrization of a poly-oxygenated *meso*-diol containing five stereogenic centers (eq 2).

(2)

Allosamizoline

However, the same chiral auxiliary is not suited to the desymmetrization of acyclic *meso*-diols since the acetalization step is sluggish. Nonetheless, an acyclic *meso*-diol such as erythritol can be desymmetrized by prior protection of the terminal primary hydroxyl groups as an *o*-xylyl ether (eq 3).

(3)

Aspicilin

Desymmetrization by means of this methodology was successfully applied to a synthesis of key intermediates for mosin B,[9] aspicilin,[10] *gala*-quercitol,[11] and allosamizoline.[8]

(*R*,*R*)-1,2-Diamino-1,2-di-*tert*-butylethane

[171357-23-6] · $C_{10}H_{24}N_2$ · (172.31)

(vicinal diamine as a source of chirality; precursor for the synthesis of bidentate ligands)

Physical Data: bp 240°C; $[\alpha]_D^{25}$-15 (*c* 0.145, CH_2Cl_2).

Solubility: most organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Purification: shake with powdered K_2CO_3 in diethyl ether, filter, concentrate, and distill under reduced pressure.

Analysis of Reagent Purity: ^{1}H and ^{13}C NMR.

Handling, Storage, and Precautions: store under argon or nitrogen atmosphere; may be corrosive, like other vicinal diamines.

Preparative Methods: although syntheses of enantiomerically pure diamines have been developed mainly through resolution of racemic diamines, few methods have been reported for the diastereoselective synthesis of vicinal diamines. In particular, the addition of Grignard or zinc reagents to the carbon-nitrogen double bonds of chiral 1,2-bisimines[1] derived from glyoxal and (*S*)- or (*R*)-phenethylamine, followed by removal of the phenethyl group, has been shown to be an attractive alternative method. Following a similar procedure, 1,2-diamino-1,2-di-*tert*-butylethane **3** can be synthesized in an optically pure form in three steps, as the *R*,*R*- or *S*,*S*-enantiomer, starting, respectively, from glyoxal and (*S*)- or (*R*)-phenethylamine.[2] Indeed, addition of the chiral (*S*,*S*)-1,2-bis-imine **1** to a suspension of *tert*-butylmagnesium chloride in hexane at 50°C leads cleanly and in good yield to a single diastereomer of the (*R*,*R*)-diamine (**2**) (eq 1).

Deprotection of the chiral auxiliary groups is performed using ammonium formate, acetic acid, and palladium hydroxide in refluxing ethanol (eq 2). This sequence gives, after purification by distillation, the free optically pure (*R*,*R*)-diamine **3**.[3]

The *N*,*N*´-dimethyl derivative **4** is obtained in three steps by formation of the corresponding imidazolidine with acetone, alkylation with iodomethane, and hydrolysis (eq 3).

The *N*-tosyl derivative **5**, a possible precursor for the synthesis of ruthenium hydrogen transfer catalysts of type **6**,[4] is obtained in good yield by slow addition of TsCl in dichloromethane at 0°C (eq 4).

Utility

Many asymmetric syntheses have been developed using vicinal diamines as the source of chirality. The major interest lies in their use as precursors for the synthesis of a broad family of bidentate ligands.[5] Many reactions have also been described using the *N*-alkyl derivatives of these diamines as chiral auxiliaries and protecting groups of aldehydes.[6] Most of these applications generally use the framework of 1,2-diphenyl-1,2-diaminoethane (**7**) or 1,2-diaminocyclohexane (**8**), whose preparations have been fully described.[7]

However, 1,2-diamino-1,2-di-*tert*-butylethane (**3**) holds particular interest because of its increased steric bulk and the absence of benzylic protons. Its recent ready availability should render it as attractive as the frequently used vicinal diamines **7** and **8**. To our knowledge, only one application of this diamine has been previously described in the literature (eq 5),[3b] where the regio- and enantioselective epoxidation of conjugated aliphatic dienes were studied using the chiral manganese salen complex (**9**).

Potassium (Diphenylphosphino)-1,3-pentadien-1-yl-5-ylidene Borate

[178327-14-5] · $C_{17}H_{15}BPK$ · (300.18)

(triphenylphosphine analog[1])

Physical Data: white crystalline solid.

Solubility: not available.

Preparative Methods: 1-diphenylphosphinoboratabenzene is prepared by adding a 0.5 M solution of potassium diphenylphosphide in THF to borabenzene-trimethylphosphine at 20°C.[2,3]

Purification: recrystallized from THF at (-35°C).

Handling, Storage, and Precautions: air sensitive; all reactions are run in oven dried glassware under either an atmosphere of argon using Schlenk techniques or under an atmosphere of nitrogen inside a dry box.

Zirconium Complex

1-Diphenylphosphinoboratabenzene (DPB) σ bonds (η^1) to metal centers,[4,5] while the rest of the class of boratabenzenes,[6] such as 1-methylboratabenzene,[7] 1-phenylboratabenzene,[8] and 1-dimethylaminoboratabenzene,[9] act as surrogates of the cyclopentadiene anion by π-bonding (η^6) to the metal center.[10,11] One exception is a magnesium complex, magnesium (1-dimethylaminoboratabenzene)$_2$, where one ligand participates in η^6 bonding while the second η^1 bonds.[12] The electronic nature of the zirconecene catalyst can be tuned using DPB as a negatively charged analog of triphenylphosphine.[13] The X-ray crystal structures of K-DPB·(18-crown-6) and K-1-diphenylaminoboratabenzene·(18-crown-6) provide evidence that the 1-diphenylaminoboratabenzene N-B bond has significant π-bonding, while DPB shows little π-bonding with the boron atom.[5] Potassium 1-diphenylphosphinoboratabenzene is added to Cp_2ZrHCl (eq 1) to obtain the zirconecene complex in 49% yield.[4]

$Cp_2ZrH(DPB)(PMe_3)$ (1)

Iron Complex

Diphenylphosphide is a unique phosphorus(III) ligand because it has a set of electrons available which increases the electron density on a metal center.[4,13g] The isoelectronic iron complexes $[CpFe(CO)_2(PPh_3)]^{+}$[14] and $CpFe(CO)_2(PPh_2)$[15] allow for a variation of the electronic density on the metal center. DPB adds to $CpFe(CO)_2I$ which provides an iron complex where the electron density on the iron atom is greater than the PPh_3 complex and less than the PPh_2 (eq 2).[4]

$CpFe(DPB)(CO)_2$ (2)

DPB is the only boratabenzene known to η^1 bond with iron metal. 1- Dimethylaminoboratabenzene bonds η^6 and it has recently found utility in iron complexes.[16]

Rhodium Complex

Recently, rhodium metal has been found to be extremely useful in organic synthesis. DPB was used to prepare the rhodium complex $Rh(PMe_3)_3(DPB)$ (eq 3).[4,17]

$Rh(PMe_3)_3(DPB)$ (3)

Related Reagents.

triphenylphosphine, trimethylphosphine, trimethylphosphite.

(4*R*,5*R*)-4,5-Dicyclohexyl-2-ethyl-1,3,2-dioxaborolane[1]

[152428-72-3] · $C_{16}H_{29}BO_2$ · (264.21)

(representative starting material for asymmetric synthesis via α-halo boronic esters[1,2])

Alternate Name: ethylboronic acid, (*R*,*R*)-1,2-dicyclohexyl-1,2-ethanediol ester; (*R*,*R*)-DICHED ethylboronate.

Physical Data: bp 85-87°C (100-200 Pa); ^{1}H NMR δ 0.78 (q, BCH_2), 0.96 (t, CH_3), 0.90-1.28 Hz and 1.50-1.77 (m, cyclohexyl), 3.82 (m, OCH).[1]

Preparative Methods: transesterification of B(O-*i*-Pr)$_3$ with (*R*,*R*)-1,2-dicyclohexyl-1,2-ethanediol[2] yields (4*R*,5*R*)-4,5-dicyclohexyl-2-isopropoxy-1,3,2-dioxaborolane, which reacts with ethylmagnesium chloride in THF at -78°C.[1]

Another simple route to (*R*,*R*)-1,2-dicyclohexyl-1,2-ethanediol [(*R*,*R*)-DICHED] ethylboronate (**3**) involves transesterification of dibutyl ethylboronate (**1**) with (*R*,*R*)-DICHED (**2**) (eq 1).[1]

The original preparation of **2** by hydrogenation of 1,2-diphenyl-1,2-ethanediol (**4**) over a rhodium on alumina catalyst[2] has been substantially improved by in situ conversion of **4** to its methoxyborate ester (**5**) (eq 2), which allows the use of an active catalyst prepared in situ from rhodium chloride with ~2% reductive cleavage of the benzylic hydroxyl groups, a major side reaction if the free diol is hydrogenated.[3]

The hydrogenation is necessary because **4** is not a satisfactory chiral director.[2,3] The large-scale preparation of **4** or its (*S*,*S*)-enantiomer from *trans*-stilbene is easily accomplished via Sharpless dihydroxylation.[4] However, commercial samples of potassium osmate are sometimes less soluble than the batch used by Wang and Sharpless. The oxidation is fully reliable if the osmium compound is dissolved in water and added slowly to the reaction mixture.[3]

Ethylboronic esters such as **1** are readily accessible via the classical reaction of the ethyl Grignard reagent with a trialkoxyborane[5] or the recent hydroboration of ethylene with boron trichloride and triethylsilane.[6] However, an efficient and practical alternative is the direct ethylation of (*R*,*R*)-DICHED isopropoxyborate (**6**), prepared in situ from **2** and triisopropyl borate, with ethylmagnesium chloride (eq 3).[1] It is important to prepare **6** that is free from hydroxylic contaminants and to ethylate it with a full equivalent of Grignard reagent in order to avoid the formation of by-product difficult to separate by distillation, most likely the B-O-B linked dimeric anhydride of DICHED borate.

A close analog of **3**, (*R*,*R*)-DICHED methylboronate (**8**), has been made from commercially available trimethylboroxine and 1,2-diphenyl-1,2-ethanediol via the corresponding boronic ester (**7**) by hydrogenation over rhodium on alumina, prepared in situ from rhodium chloride (eq 4).[3] This hydrogenation resulted in no detectable benzylic cleavage. In any attempt to adapt this approach to compounds of higher molecular weight, it should be taken into account that diphenylethanediol esters such as **7** can decompose, probably via pinacol rearrangement, if overheated during distillation.

(4)

Handling, Storage, and Precautions: (*R*,*R*)-DICHED ethylboronate (**1**) and similar boronic esters are generally stable during transfer and weighing in air, and do not hydrolyze. Their susceptibility to autoxidation appears comparable to that of common aldehydes, and storage in rigorously sealed containers is advised. No special hazards are known.

Applications

The major use of DICHED ethylboronate (**3**) and similar compounds is as starting material for highly stereoselective asymmetric synthesis. Actual isomer ratios obtained with **3** have never been measured accurately, but the closely related 1,2-diisopropyl-1,2-ethanediol propylboronate has been shown to furnish stereoselection >1000:1 after homologation with $LiCHCl_2$ and substitution with methylmagnesium bromide.[7] This very high ratio is the result of a sequential double diastereoselection. The wide range of synthetic applications possible with this homologation and substitution chemistry has been reviewed.[8]

The homologation process is illustrated by the conversion of the DICHED ethylboronate (**3**) to the corresponding 1-chloropropylboronate (**10**) via a borate complex (**9**) (eq 5). The structure of the borate complex and geometry of the metal cation catalysis of the rearrangement are supported by theoretical calculations.[9] If zinc chloride is not added, the lithium ion from $LiCHCl_2$ presumably functions in the same way, but reactions are slower and stereoselection is not as high.

(5)

Displacement of chloride from **10** by nucleophiles follows an analogous pathway, illustrated here by the reaction of lithium benzyl oxide with **10** to produce cation-coordinated borate **11**, which rearranges to **12** (eq 6). Regardless of the mechanistic details, it is significant that the steric relationship of the alkyl substituent in intermediate **11** is similar to that of the chlorine atom that is not displaced in **9**.

The 1-(benzyloxy)propyl boronic ester **12** was then used as an intermediate in the first synthesis of pure stegobinone, the pheromone of two anobiid beetle pests, the drugstore beetle and the furniture beetle. This pheromone is inactivated by small amounts of an epimer, and high stereopurity is therefore critical. Homologation of **12** with $LiCHCl_2$ and the usual zinc chloride catalyst followed by methylation yielded boronic ester **13**, which with $LiCHCl_2/ZnCl_2$ yielded chloro boronic ester **14** (eq 7).

Intermediate **14** served as a source of both halves of stegobinone. Oxidation of **14** with hydrogen peroxide yielded aldehyde **15** (eq 8) in 50-55% based on **3**, diastereomeric purity >99%.[1]

Methylation of **14** yielded boronic ester **16**, which was converted to ketone **17** in several steps (eq 9).[1]

Ketonic boronic ester **17** was converted to a boron enolate **18** with 9-BBN triflate and used in an aldol condensation with aldehyde **15** to produce the complete carbon skeleton of stegobinone (**19**) (eq 10). The steps not illustrated are standard organic transformations.

Stegobinone (**19**) epimerizes very easily at the enolizable asymmetric center, and the epimer is repellent to the insects. If the preparation does not supply very pure stegobinone initially, purification by standard methods is difficult. The boronic ester method is fairly lengthy but provides isomerically pure **19**. A synthetic equivalent of intermediate aldehyde **15** might alternatively be made via aldol chemistry, though not necessarily more efficiently. The boronic ester route described here is especially useful for the highly stereocontrolled synthesis of the paired methyl substituents in intermediate **17**.

(Triethylamine)(pentacarbonyl)molybdenum

[33846-95-6] · $C_{11}H_{15}MoNO_5$ · (337.18)

(catalyst for cycloisomerizations of terminal alkynyl alcohols, and other mechanistically related transformations of terminal alkynes[1])

Physical Data: for $(Et_3N)Mo(CO)_5$: λ_{max} 393 nm; IR ν (trans CO stretch) 1915 cm^{-1}; for $(Me_3N)Mo(CO)_5$: mp 70°C[2], mp 80°C;[3] IR ν 2072, 1941, 1921 cm^{-1}.

Preparative Methods: $(Me_3N)Mo(CO)_5$ has been prepared by reaction of commercially available $Mo(CO)_6$ with trimethylamine *N*-oxide in dichloromethane, and purified by recrystallization from a pentane solution.[2] $(Et_3N)Mo(CO)_5$ is best prepared in situ by 350 nm irradiation of $Mo(CO)_6$ in an inert solvent such as cyclohexane or diethyl ether, in the presence of triethylamine.[4,5]

Handling, Storage, and Precautions: $(Et_3N)Mo(CO)_5$ is generated from $Mo(CO)_6$, which is a toxic solid compound. As the photochemical procedure for generating $(Et_3N)Mo(CO)_5$ also produces carbon monoxide, and decomposition of $(Et_3N)Mo(CO)_5$ may be reasonably expected to evolve carbon monoxide, all transformations of $(Et_3N)Mo(CO)_5$ and the $Mo(CO)_6$ precursor should be conducted in an efficient fume hood. $Mo(CO)_6$ is reported to be incompatible with strong oxidizing agents,[6] and diethyl ether solutions of $Mo(CO)_6$ may explode during storage.[7]

Cycloisomerizations of 4-Hydroxyalk-1-ynes to Dihydrofurans

$(Et_3N)Mo(CO)_5$ and $(Me_3N)Mo(CO)_5$ react with homopropargylic alcohols (4-hydroxyalk-1-ynes) to provide cycloisomeric dihydrofurans.[8] Yields are somewhat lower with $(Me_3N)Mo(CO)_5$ prepared from $Mo(CO)_6$ and trimethylamine *N*-oxide, so the photochemically generated $(Et_3N)Mo(CO)_5$ catalyst is currently preferred. This alkynol cycloisomerization transformation is compatible with aromatic rings, silyl ethers, and carboxylic esters and amides.[9] The stereochemical integrity of chiral secondary alcohol substrates is maintained under the reaction conditions. Dihydrofuran products from alkynol cycloisomerization have been converted into several biologically important nucleosides, including cordycepin (**5**), the anti-AIDS compound stavudine (**6**),[10] and puromycin aminonucleoside (**9**) (eq 1-3).[9]

(3)

$(Et_3N)Mo(CO)_5$ is not a general catalyst for cycloisomerization of 5-hydroxyalk-1-ynes, although the cyclic carbamate-containing alkynyl alcohol **10** provided a modest yield of the highly substituted dihydropyran **11** (eq 4).[11] Tungsten carbonyl-catalyzed methods have subsequently been developed for high-yield cycloisomerizations of substituted 5-hydroxyalk-1-ynes to the corresponding dihydropyrans.[12] The enyne ester **12** undergoes cyclization with stoichiometric $(Et_3N)Mo(CO)_5$ to provide the molybdenum oxacarbene complex **13** (eq 5).[13]

(4)

(5)

12 **13**

Cyclizations of 4-Hydroxyalk-1-ynes in the Presence of Electrophiles

$(Et_3N)Mo(CO)_5$-catalyzed cyclizations of 4-hydroxyalk-1-ynes in the presence of tributyltin triflate provide 1-(tributylstannyl)dihydrofurans in good yield, resulting from reaction of an organomolybdenum catalytic intermediate with tributyltin triflate (eq 6).[14] This transformation was utilized in a synthesis of the natural product manoalide (eq 7).[15]

(6)

14 **15**

R = R' = H
R = Ph, R' = H
R = H, R' = Me

16

(7)

17

In contrast, alkynyl alcohol cyclizations in the presence of aldehydes are accompanied by carbon-carbon bond formation at C-2 of the

cyclization product, and enolizable aldehydes including acetaldehyde afford the conjugated diene **18** (eq 8).

(8)

Cycloisomerization Syntheses of Furans.

Reactions of epoxyalkynes including **19** with $(Et_3N)Mo(CO)_5$ produce the corresponding furan **20** (eq 9). However, the substrate **21** affords furan **22** via a mechanism of alkynol cyclization coupled with opening of the epoxide leaving group (eq 10).[16] The cyclic hemiacetal substrate **23** also provides furan **24**, an intermediate in the total synthesis of salinomycin (eq 11).[17]

(9)

(10)

(11)

Cyclizations of Terminal Alkynes Tethered to Other Nucleophiles.

$(Et_3N)Mo(CO)_5$-promoted azacycloisomerizations of alkynes tethered to nitrogen nucleophiles have been explored. Although primary alkylamines are incompatible with the $(Et_3N)Mo(CO)_5$ catalyst and *N*-acetamide or *N*-sulfonamide substrates are unreactive, the *tert*-butylcarbamate derivative of 1-aminobut-3-yne **25** undergoes cycloisomerization to the corresponding cyclic enecarbamate **26** (eq 12). Similarly, *ortho*-aminophenylacetylene **27** undergoes cycloisomerization to indole **28** (eq 13).[18]

(12)

(13)

Stabilized enolates obtained from deprotonation of 1,3-diketones, β-ketoesters, or substituted malonate esters **29** undergo cyclization with stoichiometric $(Et_3N)Mo(CO)_5$ to provide substituted cyclopentenes **30** (eq 14).[19]

(1*R*,2*S*)-1-Lithio-1-phenylsulfonyl-2-{[(*tert*-butyldiphenyl)silyl]oxymethyl}Oxirane

[181208-42-4] · $C_{25}H_{27}LiO_4SSi$ · (458.08)

(oxiranyllithium; oxiranyl anion; nucleophilic epoxide; acyl anion equivalent; epoxy sulfone)

Solubility: soluble in THF, diethyl ether.

Preparative Methods: prepared by lithiation of (1*R*,2*S*)-1-phenylsulfonyl-2-{[(*tert*-butyldiphenyl)silyl]oxymethyl}oxirane (**1**, $[\alpha]_D$ +55.9 °, *c* 1.0, $CHCl_3$) (1.0 equiv) in THF (0.15 M solution) with *n*-BuLi (1 equiv, 1.6 M solution in hexane) in the presence of DMPU or hexamethylphosphoramide (HMPA) (3.0 equiv) at -100°C under argon. Deprotonation is completed within a few minutes (eq 1).[1]

Handling, Storage, and Precautions: the oxiranyllithium is very unstable, even at -100°C under argon, and should be reacted with electrophiles immediately. The reagent is also conformationally unstable and slowly isomerizes to the *trans*-isomer when addition of an electrophile is delayed (about 5% isomerization after 20 min at -100°C). Elevated temperatures (>-78°C) cause rapid decomposition.[1,2]

Introduction

Although epoxides are widely recognized as extremely versatile synthetic intermediates in view of their electrophilic nature, the reaction of an epoxide as a nucleophile, i.e. an oxiranyl anion, is less common. Recently, cumulative studies on the chemistry of oxiranyl anions have appeared and some aspects of the anions have been discussed.[3,4]

Preparation of (1*R*,2*S*)-1-Phenylsulfonyl-2-{[(*tert*-butyldiphenyl)silyl]oxymethyl}oxirane and Related Compounds

Epoxidation of (*Z*)-vinyl sulfone, which is available from the Peterson olefination of (*S*)-*O*-pentylideneglyceraldehyde[5] and phenyl trimethylsilylmethyl sulfone[6] in three steps (40% overall yield), with *t*-BuOOH/*t*-BuOK in THF gives epoxy sulfone (eq 2). Deprotection of the ketal group and recrystallization affords an optically pure epoxy diol, which is then treated with sodium periodate followed by sodium borohydride to give an alcohol. Protection of the resulting alcohol as its silyl ether yields (1*R*,2*S*)-1-phenylsulfonyl-2-{[(*tert*-butyldiphenyl)silyl]oxymethyl}oxirane (**1**).[7] Its enantiomer is available in the same manner starting from (*R*)-isopropylideneglyceraldehyde.[8]

(2)

Racemic epoxy sulfone derivatives are easily prepared from allyl ethers by reaction with sodium *p*-toluenesulfinate in the presence of iodine followed by treatment with triethylamine, separation of *E*- and *Z*-isomers, and epoxidation with *t*-BuOOH and *n*-BuLi in THF (eq 3).[2]

(3)

Reaction of Sulfonyl-Stabilized Oxiranyllithiums

Reaction of sulfonyl-stabilized oxiranyllithiums with primary alkyl halides gives acceptable yields of products.[1] More reactive alkyl triflates give generally better yields but, due to the instability of oxiranyllithiums, yields are often not reproducible when electrophiles are added to a solution of the preformed oxiranyllithiums. It is recommended that the alkylation reaction be carried out by an in situ trapping method.[2] Treatment of a solution of epoxy sulfone (1.0 equiv) and triflate (1.5 equiv) in THF-DMPU (or HMPA) at -100°C under argon with *n*-BuLi (1.0 equiv) followed by stirring for 30 min affords the coupled product in high yield (eq 4).[9] The product can be converted to a tetrahydropyranone derivative by exposure to *p*-toluenesulfonic acid. The strong electron-withdrawing ability of the sulfonyl group works against the adjacent C-O bond-breaking in an acid-catalyzed epoxide ring-opening process and, consequently, favors the 6-*endo* mode pathway which yields the tetrahydropyranone after elimination of phenylsulfinic acid. Reaction with a halogenated metal Lewis acid yields a halo ketone instead of a cyclization product (eq 4).[10] These reactions demonstrate that the oxiranyllithium reagent serves as a functionalized acyl anion equivalent and a three-carbon building block.

(4)

Reiterative application of this protocol has allowed the stereocontrolled construction of polytetrahydropyrans[9,10] and polycyclic ethers containing six- and seven-membered rings (eq 5).[7]

(5)

Reaction of the oxiranyllithium with aldehydes is also carried out by an in situ trapping method at very low temperatures in order to avoid decomposition of the reagent. Its applicability to a complex situation has been demonstrated in a synthesis of hemibrevetoxin B (eq 6).[11,12] It is noteworthy that deprotonation of **1** by *n*-BuLi is much faster than butyl addition to the aldehyde.

(6)

While alkylation of sulfonyl-stabilized oxiranyllithiums with primary alkyl triflates proceeds in high yield, the reaction towards epoxides is relatively slow (~2 h) and the decomposition of oxiranyllithium is marked, such that it decreases the yield, especially in the case of a *Z*-isomer (eq 7 and 8).[2] Addition of boron trifluoride diethyl etherate promotes this epoxide-epoxide coupling reaction. One of the diastereoisomers of eq 8 has been elaborated via 5-*endo* cyclization into a marine tetrahydrofuran isolated from a brown alga.[13]

Related Reagents.

Optically active trisubstituted sulfonyl-stabilized oxiranyllithiums can be generated by deprotonation of the corresponding epoxy sulfones[14] (eq 9). Due to the diminished reactivity of the reagents by steric hindrance, the reaction with triflates requires HMPA to obtain a high yield of product (eq 10).[12]

Diisopropyl Squarate

· $C_{10}H_{14}O_4$ · (198.22)

(reagent used as a highly oxygenated four-carbon building block in a wide variety of annulation reactions)

Physical Data: mp 43-44°C.

Solubility: soluble in alcohol, diethyl ether, and most organic solvents.

Form Supplied in: white crystalline solid readily prepared from squaric acid.

Purification: the compound is usually pure enough for subsequent use as obtained from the syntheses outlined below.

Preparative Methods: diisopropyl squarate (87%) is readily prepared by azeotropic removal of water from a solution of squaric acid in 1:1 benzene-2-propanol.[1,2] The same compound (81%), as well as examples of other dialkyl squarates that can not be prepared by the above route, are available from a general method involving refluxing a solution of squaric acid in the appropriate alcohol (solvent) in the presence of the corresponding orthoformate (eq 1).

Handling, Storage, and Precautions: the solid can be stored under normal laboratory conditions for an extended period of time without apparent decomposition. However, as a precaution, storage in the refrigerator is recommended. One should be careful when preparing and handling dialkyl squarates since many members are powerful skin irritants and sensitizers.[3]

Synthesis of Substituted Cyclobutenones and Cyclobutenediones

Diisopropyl squarate and related esters are valuable synthetic intermediates for the construction of a variety of 4-substituted 3-alkoxycyclobutenediones. Monoalkylated cyclobutenones were prepared directly in one pot by treating a dialkyl squarate with the appropriate lithium reagent followed by quenching the reaction mixture with HCl or trifluoroacetic anhydride (TFAA) (eq 2).[2,4]

(2)

R = H, Me, C_6H_5, ≡—C_4H_9

A modification of the above procedure leads to a general synthesis of substituted cyclobutenedione monoketals.[5] An illustrative example is the synthesis of 2-phenyl-3,4,4-trimethoxycyclobutenone (85%) upon treatment of dimethyl squarate with phenyllithium followed by quenching with methanol and TFAA. Subsequent treatment of this product with methyllithium followed by TFAA gave 2-phenyl-3-methyl-4,4-dimethoxycyclobutenone in 94% yield (eq 3). By changing the order of substituent introduction, the regioisomer was obtained in good yield. These reaction sequences provide access to a variety of isomeric cyclobutenedione monoacetals in a regiodefined fashion. A related method leading to monoacetalization has also appeared.[6]

(3)

3-Tributylstannyl-4-isopropoxycyclobutenedione is readily prepared in 65% yield from diisopropyl squarate upon treatment with 1,1,1-trimethyl-2,2,2-tri-*n*-butyldistannane in the presence of a catalytic amount of cyanide ion.[7] Stille cross-coupling reactions with alkyl iodides then provide a complementary route to 3-alkyl-4-isopropoxycyclobutenediones. This work was extended to include the synthesis of 3-acylcyclobutenediones, a rare class of compounds in which the cyclobutenediones bear an electron-withdrawing group (eq 4).[8] The starting material is 3-(piperidinyl)-4-tri-*n*-butylstannylcyclobutenedione, prepared from 3-tri-*n*-butylstannyl-4-isopropoxycyclobutenedione upon treatment with piperidine.

(4)

R=C_6H_5, *p*-(MeO)C_6H_4, Et, *o*-(MEM)C_6H_4

Numerous examples of 4-allylcyclobutenones are available from the corresponding 4-hydroxy or 4-alkoxy analogs upon treatment with allylsilanes in the presence of Lewis acids. The example outlined in eq 5 provides evidence for a carbocationic intermediate in such

transformations. Specifically, both regioisomeric starting cyclobutenones give nearly quantitative yields of a single adduct.[9] This and related examples lead to the general conclusion that allylation of unsymmetrically substituted 4-hydroxycyclobutenones takes place predominately at that site best able to stabilize cationic charge density. A number of heterocyclic, carbocyclic, and acyclic 4-allylcyclobutenones are available from readily available cyclobutenedione monoketals, a transformation that has recently been reviewed.[10] The example provided in eq 6 is illustrative.

94 99%

Synthesis of 4-Methylidenecyclobutenones

A variety of cyclobutenediones and cyclobutenones have been shown to react with dimethyl titanocene to provide the corresponding methylidene product.[11] For example, 3-phenyl-4-isopropoxycyclobutenedione reacts at the ketonic carbonyl group to give 4-methylidene-3-phenyl-2-isopropoxycyclobutenone in 75% yield (eq 7). The reaction also takes place with dialkoxy squarates. For example, diisopropyl squarate gives 4-methylidene-2,3-diisopropoxycyclobutenone in 80% yield.

(7)

In a related study, dialkyl squarates were shown to undergo olefination under Wittig or Horner-Emmons reaction conditions.[12] For example, eq 8 outlines Wittig olefination of diisopropyl squarate to give the alkylidene product in 88% yield in an *E*/*Z* ratio of 1:1. Horner-Emmons conditions using a phosphonate gave the same product (91%) but in an *E*/*Z* ratio of 1:19. It is noteworthy that simple acid hydrolysis of the product gives squarylacetic acid esters, potentially valuable active methylene compounds.

(8)

Synthesis of Bicyclo[3.2.0]heptenones

4-Allylcyclobutenones, available as described above or from direct allylation of cyclobutenediones upon treatment with allyllithium reagents, are valuable reagents for the synthesis of highly substituted bicyclo[3.2.0]heptenones. For example, thermolysis of dialkoxy squarate-derived 4-allyl-2-ethenyl-3-methyl-4-trimethylsiloxycyclobutenone (refluxing toluene) provides the corresponding bicycloheptenone in nearly quantitative yield (eq 9).[13] This general and efficient transformation is envisaged to proceed via electrocyclic ring opening of the starting cyclobutenone to give a vinylketene intermediate that is disposed to undergo intramolecular 2+2 cycloaddition to the proximal allyl double bond.

(9)

Synthesis of Quinones and Related Compounds

A particularly important transformation of dialkyl squarates is their conversion to cyclobutenones bearing a site of unsaturation at position 4. Such compounds undergo ring expansion to the corresponding aromatic compounds, thus constituting a valuable annulation method. Numerous examples of this method were reviewed in 1995.[14] Selected examples are provided in eq 10-13.[15-19] It is noted that the π-unsaturation at position 4 can be found in aryl, alkenyl, or acyl groups. The annulation method is general and accommodates multiple substitution patterns. An important example illustrating these points is its use as a key step in the synthesis of porphyrin-quinones as outlined in eq 13.

(11)

(12)

(13)

The above reactions are envisaged to involve 4π electrocyclic ring opening of the cyclobutenone followed by 6π electrocyclic ring closure of the resulting dienylketene.

Interesting variations of the above reactions are outlined in eq 14 and 15. The former depicts a general transformation of a 4-allenylcyclobutenone to a quinone methide intermediate that is trapped in an intramolecular Diels-Alder cycloaddition.[20] This appears to be a general reaction and represents one of the few known routes to these reactive intermediates under neutral (thermal) conditions. The latter provides an example of a general reaction of 4-alkynylcyclobutenones. These undergo electrocyclic ring opening to the corresponding dienynylketene followed by ring closure to a diradical intermediate which suffers H-atom transfer to give the quinone directly.[14,21,22]

(14)

(15)

A diversity of compounds is available by this annulation methodology. Other ring systems stemming from this method include angucyclines,[23] benzophenanthridines,[24] piperidinoquinones,[25] benzofurans,[26] pyranoquinones,[27] naphthols,[28] naphthalenes,[29,30] indolizines,[31] naphthoquinones,[32] dihydroquinolines,[33] 2-pyridinones,[34] xanthones,[35,36] and highly oxygenated angularly fused polycyclic aromatic compounds.[37]

A particularly interesting example is outlined in eq 16.[29] Here the diisopropyl squarate-derived alkynylcyclobutenone provides the ring-opened allene upon treatment with butyllithium. Subsequently, the allene undergoes electrocyclic ring closure (toluene, 110°C) to give the substituted naphthalene.

(16)

Cascade Rearrangements Leading to Polycyclic Compounds

A series of papers have appeared which outline a remarkable cascade rearrangement induced by the addition of 2 equiv of an alkenyl or alkynyl lithium reagent to squarate esters. These remarkable reactions result in the stereo- and regio-controlled conversion of achiral reagents to complex polycyclic products possessing several sterogenic centers.[38] A relatively simple example is outlined in eq 17, which shows the conversion of diisopropyl squarate to an α,β-bis(alkoxyl)-γ-hydroxycyclopentenone, a common structural array found in the products arising from most of the cascade rearrangements. The reader is referred to an excellent review of this topic for a detailed analysis of the mechanism as well as an overview of the synthetic scope of this remarkable reaction.[38] Selected examples revealing the exceptional complexity of structural features available in simple laboratory operations are provided in eq 18 and 19.

(17)

(18)

(19)

Synthesis of Polyquinanes from Dialkyl Squarate-derived Bicyclo[3.2.0]heptenones

A method complementary to the above squarate cascade starts with dialkyl squarate-derived bicyclo[3.2.0]heptenones.[39-42] Illustrative examples are outlined in eq 20-23. These reactions proceed via an initial oxy-Cope ring expansion upon treatment of the starting bicycloheptenone with an alkenyllithium reagent. The resulting bicyclo[6.2.0]undecenes are generally not isolated but subjected directly to work-up conditions that hydrolyze the trimethylsilyl enol ether and thus induce an intramolecular transannular ring closure to the corresponding polyquinanes.

Tricarbonyl[(2,3,4,5,6,7-η)-thiepin-1,1-dioxide]chromium(0)[1]

[1452247-44-5] · $C_9H_6CrO_5S$ · (278.201)

(reagent used for promotion of [6+2], [6+4], [6+2+2], and [6+2+2+2] higher-order cycloaddition reactions)

Physical Data: red solid; mp 173-174°C.

Solubility: THF, ethyl acetate, CH_2Cl_2, $CHCl_3$, and 1,2-dichloroethane.

Form Supplied in: prepared from thiepin-1,1-dioxide and trisacetonitriletricarbonylchromium.

Purification: flash column chromatography on silica gel using hexanes/ethyl acetate.

Handling, Storage, and Precautions: the compound can be handled in air and is generally stable for several months when stored in the freezer.

Preparative Methods: as shown below, thiepin chromium complex **1** is readily prepared via standard methods[1] from thiepin-1,1-dioxide[2] **2** and trisacetonitriletricarbonylchromium(0)[3] **3**. The reaction proceeds in 12 h at room temperature to give an 86% yield of the desired chromium complex 1 (eq 1).[4]

[6+2] Higher-Order Cycloaddition Reactions.

Chromium complex **1** undergoes a variety of higher-order cycloaddition reactions.[5] Thus, a reaction between complex **1** and disubstituted alkyne partners in the presence of UV light (uranium filter) produces [6π+2π] cycloadducts in good yields (eq 3, Table 1). Cyclooctyne (entry 5, Table 1) notably provides an 80% yield of the cycloadduct.[6]

Table 1

Entry	R	R'	Yield
1	Ph	TMS	78%
2	n-Pr	TMS	65%
3	n-Bu	TMS	65%
4	Ph	Et	42%
5	$(CH_2)_6$		80%

Surprisingly, unlike the tricarbonylcycloheptatriene chromium(0), complex **1** does not react with alkenes to give [6π+2π] cycloadducts.[7]

[6+2+2] Higher-Order Cycloaddition Reactions.

Rigby and coworkers have advanced the field of multicomponent cycloaddition reactions using thiepin chromium complex **1** and terminal alkynes.[8] The reaction proceeds via a process that can be viewed formally as two consecutive [6π+2π] cycloaddition events to give tetracycle **5** (eq 3). The cycloaddition events occur in the coordination sphere of the chromium, thus the reaction sets the six new stereogenic centers in tetracycle **5** stereospecifically, and only one diastereomer is observed.[9]

(3)

Examples of the [6+2+2] reaction are included in Table 2.[8a] The reaction requires either photochemical (entries 1-3) or thermal (entry 4) conditions to provide tetracycles**5**.

Table 2

Entry	R	Conditions[a]	Yield
1		A	32
2	t-Bu	A	70

3	TMS	B	35
4	TMS	C	

[a] Reaction conditions: (A) hv, U-glass filter, 1,2-dichloroethane, 1 h. (B) hv, pyrex glass filter, 1,2-dichloroethane, 1 h. (C) 160 °C, sealed tube Bu_2O, 12 h.

Furthermore, the 2 components can be tethered together so the new product will have one additional ring. Thus, diyne **6** is slowly added over 2 h to a solution of complex **1** in a photochemical reactor to provide a 57% yield of pentacycle **8**. Likewise, slow addition of diyne **7** gives pentacycle **9** in a diminished yield, presumably due to competitive polymerization (eq 5).[10]

(5)

8 X = CH_2 57%
9 X = $(CH_2)_2$ 32%

[6+2+2+2] Higher-Order Cycloaddition Reactions.

Recently, Rigby and coworkers observed another product during their studies on the three component cycloaddition reactions using tethered alkynes. Thus, a photochemically promoted reaction between thiepin chromium complex **1** and excess octa-1,7-diyne **10** gave pentacycle **12** in 45% yield. Likewise, nonadiene **11** provided pentacycle **13** in 38% yield (eq 6).[11]

1 **10** X = $(CH_2)_2$

11 X = $(CH_2)_3$

(6)

12 X = $(CH_2)_2$ 45%

13 X = $(CH_2)_3$ 38%

The mechanism leading to pentacycles **12** and **13** has not been established; however, the reaction may proceed via two sequential [6π+2π] cycloaddition reactions followed by a what appears to be a [3+2] cycloaddition. If the final step involves a [3+2] cycloaddition reaction, then these examples would represent the first examples of a chromium-mediated [3+2] cycloaddition reaction.[11]

[6+4] Higher-Order Cycloaddition Reactions.

By far, the most extensively investigated reaction of chromium complex **1** is the [6+4] cycloaddition reaction.[4,7a,12] The reaction between complex **1** and several dienes was examined, and it was determined that electron-rich 4 partners provided much higher yields than those of electron deficient partners. Thus, diene **14** reacts with chromium complex **1** under photochemical conditions to give an excellent yield of cycloadduct **15**, whereas, diene **16** gives a 38% yield of the corresponding cycloadduct **17** (eq 7).[12b]

(7)

1 **14** R = OAc **15** R = OAc 78%

16 R = CO_2Me **17** R = CO_2Me 38%

Other more complex dienes have also been examined in this reaction and are listed below (eq 8-11).[7,13]

(8)

1 **18** **19**

1 **20**

(9)

21

(10)

1 **22** **23**

(11)

1 **24** **25**

The [6π+4π] cycloaddition reaction can also be promoted thermally. For example, a *tert*-butylmethylether solution of chromium complex **1** and diene **14** was heated to reflux (110°C) for 48 h. Upon isolation via column chromatography on silica gel, compound **15** was again obtained but with a diminished yield (47%) (eq 12).[12b]

Sulfur Dioxide Extrusion and Applications Toward Total Synthesis.

The sulfur-containing products, which result from the higher-order cycloaddition reactions described above, have been submitted to various conditions to extrude the elements of sulfur dioxide. For example, photolysis (quartz filter) of cycloadduct **15** for 15 min promotes a cheletropic extrusion of sulfur dioxide to give a 54% yield of cyclodecatetraene **26** (eq 13).[4]

(13)

A very different sulfur dioxide extrusion protocol has been applied to the total synthesis of (+)-estradiol (**30**) by Rigby and coworkers.[13] In the event, the trimethylsilyl-substituted chromium thiepin complex **27** participated in a [6π+4π] cycloaddition reaction to provide a 70% yield of the structurally complex dihydrothepin **28**. Subsequent sulfur dioxide extrusion via a Ramberg-Bäcklund-type ring contraction gave tetracycle **29**. The total synthesis of (+)-estradiol (**30**) was completed using a four-step sequence of standard reactions (eq 14).[13]

2,5-Dihydro-2,2-dimethyl-5,5-bis(propylthio)-1,3,4-oxadiazole

[222625-77-6] · $C_{10}H_{20}N_2OS_2$ · (248.41)

(reagent used as bis(propylthio)carbene precursor)

Physical Data: solid at -78°C, thermolysis occurs at 0°C and above.

Solubility: hexanes, cyclohexane, dichloromethane, benzene, toluene, xylene.

Form Supplied in: colorless oil as synthesized.

Purification: column chromatography at 0°C using hexanes-ethyl acetate (20:1); product elutes first; collect fractions in an ice bath; remove solvent in vacuo at 0°C; dry under high vacuum at 0°C for 1 h.

Handling, Storage, and Precautions: to prevent premature thermolysis, reagent should be stored in a sealed flask in a cooler with dry ice at -78°C. Since the reagent is thermally labile and thermolysis is exothermic, avoid exposure to heat to prevent rapid evolution of nitrogen gas leading to a possible explosion. Thermolysis will occur at 0°C and above. Use of an explosion shield and slow addition to refluxing solvents are recommended.

[1+4] Cycloaddition with Vinyl Isocyanates

Upon thermolysis in refluxing benzene, 2,5-dihydro-2,2-dimethyl-5,5-bis(propylthio)-1,3,4-oxadiazole yields the bis(propylthio)carbene precursor, which reacts as a 1,1-dipole equivalent in [1+4] cycloaddition reactions with various vinyl isocyanate substrates leading to highly functionalized adducts such as hydroindolones (eq 1).[1-3] Reductive desulfurization with Raney nickel yields the enamide or the fully reduced system (eq 2).[1] Cyclohexyl isocyanide also behaves as a 1,1-dipole equivalent in [1+4] cycloadditions with vinyl isocyanates, however the adducts are less functionalized.[4,5]

(2)

Dimethoxy carbene has been shown to behave as a carbonyl 1,1-dipole equivalent in [1+4] cycloadditions with vinyl isocyanates also yielding functionalized adducts.[6] However, the oxadiazole precursor requires higher thermolysis temperatures and hydrolysis of the acetals in the resultant adducts can be difficult for acid-sensitive systems.

[4+1+1] Cycloaddition with Vinyl Isocyanate

When a large excess of 2,5-dihydro-2,2-dimethyl-5,5-bis(propylthio)-1,3,4-oxadiazole carbene precursor is added rapidly in refluxing benzene to a vinyl isocyanate, two equivalents of carbene add to the substrate prior to ring closure, leading to a six-membered adduct (eq 3).[1,2] However, no carbene insertion into the amide N-H bond occurs. This phenomenon is not observed with the dimethoxy carbene.[2]

(3)

Addition of Bis(propylthio)carbenes to Aryl Isocyanates

Addition of 2,5-dihydro-2,2-dimethyl-5,5-bis(propylthio)-1,3,4-oxadiazole in refluxing benzene and an aryl isocyanate releases the bis(propylthio)carbene in situ which then adds easily to the aryl isocyanate to yield a substituted isatin with the ketone functionality protected as a thioacetal (eq 4).[7] Ring closure also occurred when the 2,5-dihydro-2,2-dimethyl-5,5-bis(propylthio)-1,3,4-oxadiazole carbene precursor was added to 1-naphthyl isocyanate in refluxing acetonitrile (eq 5).[7] Formation of thioacetal protected isatin products are unique to the bis(propylthio)carbene as other nucleophilic carbenes added to aryl isocyanates afforded only modest yields of hydantoin products.[8]

(4)

(5)

Dimerization

Upon thermolysis of 2,5-dihydro-2,2-dimethyl-5,5-bis(propylthio)-1,3,4-oxadiazole in refluxing benzene and in the absence of any electrophile, the resultant bis(propylthio)carbene will dimerize (eq 6).[1] Since the reaction is highly exothermic, care must be taken in the execution of this reaction. Use of an explosion shield and slow addition of the carbene precursor are recommended.

(6)

Related Reagents.

dimethoxy carbene, cyclohexyl isocyanide.

Cyanuric Fluoride

[675-14-9] · $C_3F_3N_3$ · (135.05)

(reagent used for conversion of carboxylic acids to acid fluorides; deoxygenation of alkyl sulfoxides; and activation of alkenyl boronic acids for 1,4-addition reactions)

Alternate Name: 2,4,6-trifluoro-1,3,5-triazine, cyanuryl fluoride.

Physical Data: mp -38°C; bp 72-74°C; d 1.574 g mL^{-1}.

Form Supplied in: colorless liquid.

Purification: the commercial reagent is generally used as received.

Handling, Storage, and Precautions: highly toxic; very toxic by inhalation, in contact with skin, and if swallowed. Causes burns. Readily absorbed through the skin. Lachrymator. In case of accident or if you feel ill, seek medical advice immediately (show the label when possible). In case of contact with eyes, rinse immediately with plenty of water and seek medical advice. Do not breath vapor. Wear suitable protective clothing, gloves, and face/eye protection. Refrigerate. Moisture sensitive; keep container tightly closed. Disposal: dissolve or mix with a combustible solvent and incinerate.

Acid Fluoride Synthesis

Cyanuric fluoride first appeared as a reagent for the mild and direct conversion of carboxylic acids into acid fluorides. This method represented a significant advancement for the preparation of acid fluorides.[1] Previously reported methods include treatment of acid chlorides with potassium fluoride,[2] potassium hydrogen fluoride,[3] or potassium fluorosulfinate.[4] Acid fluorides were also prepared from carboxylic acids using sulfur tetrafluoride,[5] diethyl(2-chloro-1,1,2-trifluoroethyl)amine,[6] thionyl fluoride,[7] benzoyl fluoride,[8] and selenium tetrafluoride.[9] These methods are less direct and are often incompatible with other functional groups in the substrate.

In a typical procedure,[1] a solution of 0.4 equiv of cyanuric fluoride in acetonitrile is added to a mixture of 1.0 equiv each of a carboxylic acid and pyridine in acetonitrile at room temperature. After being stirred for 1 h, the reaction is subjected to a standard aqueous work-up which then provides the desired acid fluoride in generally high yields for a variety of carboxylic acid starting materials (eq 1). Each mole equivalent of cyanuric fluoride reacts to give three moles of acyl fluoride.

Acid	Yield (%)
Acetic acid	70
Propiolic acid	85
Cyclopentylcarboxylic acid	54
Cyclohexylcarboxylic acid	95
Cinnamic acid	95
Benzoic acid	97

The ability to prepare acid fluorides under these mild conditions opened up a number of synthetic applications. Perhaps the most significant application to date is the increased use of acid fluorides as activated intermediates in peptide bond formation.[10,11] The use of Fmoc amino acid chlorides as activated N-protected peptide building blocks has been limited by the propensity of *t*-butyl ester- or ether-protected side chains (e.g. serine, threonine, glutamate, aspartate) to cyclize onto the acid chloride with the loss of *t*-butyl chloride. Carpino et al. have shown that the corresponding amino acid fluorides are not subject to this same side reaction.[10] The general reactivity pattern for acid fluorides compared with acid chlorides is that they are less sensitive to uncharged oxygen nucleophiles such as water or methanol but display similar reactivity to charged or nitrogen nucleophiles. The Fmoc amino acid fluorides were prepared from the corresponding Fmoc amino acids under similar conditions to those described above and were isolated as white crystalline solids. A number of the exemplified amino acids contained protected acid and amide side chains (eq 2 and 3).

(2)

(3)

Acid fluorides have the additional advantage that they are more reactive in peptide coupling reactions of hindered amino acid derivatives. This is due at least in part to the small size of the fluoride leaving group.[12] Hindered acid fluorides like Fmoc-Aib-F can be prepared in the usual way with cyanuric fluoride.

Reduction of Acids to Alcohols

The mild conditions required for the conversion of carboxylic acids to acid fluorides has resulted in a method for the reduction of carboxylic acids to alcohols by way of the acid fluorides.[13] A variety of carboxylic acids were converted to acid fluorides under standard conditions. A quick aqueous work-up was followed by $NaBH_4$ reduction (eq 4). This mild reaction sequence has the distinct advantage over $NaBH_4$-I_2 in that it is compatible with N-protected amino acids. The resulting alcohols are obtained in generally high yields with no observable loss in enantiomeric purity.

R	Yield (%)
Ph	95
Bn	94
$-(CH_2)_8Me$	92
Cbz-Phe	81
Fmoc-Leu	90

Other Uses

A recent use for cyanuric fluoride is the activation of alkenyl boronic acids for the 1,4 addition of α,β-unsaturated ketones.[14,15] Hara et al. have shown that alkenyl boronic acids when treated with cyanuric fluoride undergo 1,4 addition to unsaturated ketones.[14] Presumably, this reaction takes place via the alkenyl fluoro alkoxy borane intermediate followed by coordination of the carbonyl oxygen to the boron and intramolecular carbon-carbon bond formation (eq 5). Selective 1,4 additions to α,β,α´,β´-unsaturated ketones could be achieved by introducing substituents on one of the double bonds (eq 6).[15]

Cyanuric fluoride has also been used as a reagent for the selective deoxygenation of sulfoxides (eq 7 and 8).[16] Stirring the sulfoxide with cyanuric fluoride in dioxane followed by aqueous work-up gave good yields of the corresponding sulfides.

Finally, cyanuric fluoride has been used in solid-phase synthesis as a method for activating a carboxylic acid functionality on solid support for loading a nucleophile onto a resin.[17,18] For example, in 1998 Böhm et al. demonstrated carboxypolystyrene activation as the acyl fluoride followed by resin loading with a primary amine linker (eq 9).[17] In 1999, Sams et al. employed a similar method to activate substituted benzoic acids loaded onto Wang resin with *N*-methylmorpholine (NMM) in dichloromethane. The resulting acyl fluorides were coupled with derivatives of *N*-hydroxyamidine in the presence of *N*-methylmorpholine (eq 10).[18]

(*R*,*R*)-2-Butyl-4,5-bis(dimethylaminocarbonyl)-1,3-dioxaborolane[1]

[161344-85-0] · $C_{12}H_{23}BN_2O_4$ · (270.13)

(enantioselective cyclopropanation[1])

Solubility: soluble in CH_2Cl_2, $ClCH_2CH_2Cl$, toluene, benzene and most organic solvents.

Form Supplied in: colorless oil, not commercially available.

Analysis of Reagent Purity: NMR (^1H, ^{11}B).

Preparative Methods: the reagent is easily prepared from commercially available butylboronic acid (or its more stable diethanolamine complex) and (*R*,*R*)-(+)-*N*,*N*,*N*´,*N*´-tetramethyltartaric acid diamide.[2] The other enantiomer is also readily available from (*S*,*S*)-(+)-*N*,*N*,*N*´,*N*´-tetramethyltartaric acid diamide.

Purification: not easily purified since the reagent hydrolyzes slowly in the presence of moisture and oxidizes slowly in the presence of oxygen. The formation of crystals over time is an indication of decomposition.

Handling, Storage, and Precautions: the reagent is stable indefinitely when stored under an inert atmosphere.

Enantioselective Cyclopropanation of Allylic Alcohols

(*R*,*R*)-2-Butyl-4,5-bis(dimethylaminocarbonyl)-1,3-dioxaborolane (**1**) is one of the most effective chiral additives for the enantioselective cyclopropanation of allylic alcohols.[3] The synthesis of a wide range of substituted cyclopropylmethanols proceeds with excellent enantiocontrol (85-93% ee) when a solution of the alcohol and the dioxaborolane ligand is added to bis(iodomethyl)zinc. The use of the DME complex of bis(iodomethyl)zinc is preferable on large scale (eq 1).[4]

The reaction can also be used in bidirectional chain synthesis to generate bis(cyclopropyl) derivatives simultaneously (eq 2 and 3).[5] This reaction was used as the key step for elaboration of the polycyclopropane natural products FR-900848 and U-106305.

Extremely high diastereoselectivities are also observed when the antipode of the starting material is used, providing efficient access to the other diastereomer (eq 4).

The reaction has also been extended to the enantioselective cyclopropanation of 3-tributylstannylprop-2-en-1-ol,[5a] to 3-iodo-[3a] and 3-chloroprop-2-en-1-ol.[6] The first two are useful precursors in palladium-catalyzed cross-coupling reactions[7] while the last was used in the total synthesis of callipeltoside A.

The enantioselective cyclopropanation reaction is quite general and practical. For example, the cyclopropanation reaction has been used to synthesize 3-methylcyclopropylmethanol, a precursor to curacin A.[8] Tri- and tetrasubstituted allylic alcohols are also converted into their corresponding cyclopropanes with high enantiocontrol (eq 5).

$R^1 = H, R^2 = Et$ >98% (89% ee)
$R^1 = Me, R^2 = Me$ 85% (88% ee) (5)

Polyenes can also be cyclopropanated at the allylic alcohol position with high chemo- and enantioselectivities due to the strong directing ability of the chiral ligand. This reaction has been used to generate key precursors of bicyclohumulenone (eq 6)[9] and noranthoplone (eq 7).[3a]

(6)

(7)

Unprecedented high *anti*-selectivities are obtained when *E*-substituted chiral allylic alcohols are treated with bis(iodomethyl)zinc and the dioxaborolane ligand (eq 8).[10] In contrast, the *syn*-isomer is obtained if the substrate is treated with the zinc reagent in the absence of the chiral ligand.[11] The method complements that involving the direct reduction of cyclopropylketones with $LiAlH_4$ or DIBAL-H.[12]

Enantioselective Synthesis of 1,2,3-trisubstituted Cyclopropanes

The chiral dioxaborolane ligand can also be used to generate 1,2,3-substituted cyclopropyl units when the appropriate 1,1-diiodoalkane is used in the preparation of the zinc reagent (eq 9).[13] The reaction affords 1,2,3-trisubstituted cyclopropanes with excellent enantio- and diastereocontrol, including those obtained from functionalized zinc reagents (eq 10).

(10)

Use as a Chiral Auxiliary: Synthesis of Cyclopropylboronic Acids

The chiral dioxaborolane unit can also be used as an effective chiral auxiliary in the synthesis of enantiomerically enriched cyclopropylboronic acids. For example, 1-alkenylboronic esters bearing the tetramethyltartramide group undergo diastereoselective cyclopropanations to afford the cyclopropylboronic acid (eq 11).[14] These products can be used for *in situ* Suzuki coupling reactions[15] or can be oxidized to produce 2-substituted cyclopropanols.

6-Chloro-2,4-dimethoxy-s-triazine

[3140-73-6] · $C_5H_6ClN_3O_2$ · (175.58)

(peptide coupling reagent; used to prepare active esters which can be used for the preparation of amides and esters;[1] used in the reduction of carboxylic acids to aldehydes or alcohols[2])

Alternate Name: CDMT, 2-chloro-4,6-dimethoxy-1,3,5-triazine.

Physical Data: mp 71-74°C; bp 125-128°C/66.661 Pa.

Solubility: soluble in most organic solvents.

Form Supplied in: white solid; commercially available.

Preparative Methods: commercially available; prepared from cyanuric chloride and MeOH.[3] An improved procedure for a large-scale preparation has been reported.[4]

Purification: commercial reagent is generally used as received.

Handling, Storage, and Precautions: irritant; sternutator. Avoid inhalation. Should be handled with gloves in a fume hood. Relatively stable but should be stored under anhydrous conditions.

Amide Formation

6-Chloro-2,4-dimethoxy-s-triazine (CDMT) is utilized primarily as a coupling reagent in the condensation of amines and carboxylic acids for the preparation of peptides and other amides. Treatment of CDMT with a tertiary amine, preferably *N*-methylmorpholine (NMM), and a carboxylic acid yields an intermediate 6-acyloxy-2,4-dimethoxy-s-triazine (**1**) which serves as the acylating agent.[1,5] A typical example is shown in eq 1. The procedure involves adding *N*-methylmorpholine (1.02 equiv) to a solution of the corresponding carboxylic acid (1.02 equiv) and CDMT (1.0 equiv) at -5°C to 0°C in CH_2Cl_2, CH_3CN, THF, or DMF. The mixture is stirred for 1-4 h until formation of **1** is complete. The corresponding amine (1.0 equiv) and NMM (1.0 equiv) are then added, the mixture is allowed to warm to room temperature and stirred until the reaction is complete. Yields typically range from 75-98%. One major advantage offered by CDMT over other peptide coupling reagents, such as the carbodiimide reagents (see **1,3-dicyclohexylcarbodiimide**),[6] is the ease of purification. Since the triazine ring is weakly basic, a dilute acid wash will remove any by-products as well as any excess reagent from the reaction mixture. Furthermore, protected functional groups, as well as the unprotected hydroxyl group in serine, do not interfere with the coupling reactions, and racemization is not commonly observed. It is also worth noting that CDMT is inexpensive and has been used on kilogram scale.[7]

Studies directed toward a better understanding of the mechanism of activation of carboxylic acids by CDMT revealed that the reaction proceeds through quarternary triazinylammonium salts such as 4-(4,6-dimethoxy-1,3,5-triazin-2-yl)-4-methyl-morpholinium chloride (DMTMM) (**2**)[8,9] prior to formation of acyloxytriazines shown in eq 1. In fact, DMTMM, synthesized quantitatively by treatment of CDMT with NMM in THF (eq 2), is a white solid and is stable for a month at ambient temperature. It can be used directly in condensation reactions of amines and carboxylic acids,[10,11] thus providing a useful, “one-step” variant of CDMT. The example in eq 2 illustrates the complexity of amines and carboxylic acids that can be coupled using DMTMM or CDMT.[11,12] It should be noted that the stability of DMTMM varies in different solvents. For instance, DMTMM completely demethylates in CH_2Cl_2 in 3 h. Therefore, lower yields of amides are observed when CH_2Cl_2 is used as solvent for the condensation reactions. DMTMM is, however, very stable in THF and alcoholic solvents. Amides can be obtained from the condensation of carboxylic acids and amines with DMTMM in THF with yields similar to those observed in the CDMT-NMM system. A typical procedure involves adding DMTMM (1.1 equiv) to a mixture of the corresponding acid

(1.0 equiv) and amine (1.1 equiv) in THF and stirring at room temperature for 3-24 h. Furthermore, it is not necessary to dry the THF or perform the reaction under a N_2 atmosphere.

(2)

Ester Formation

Alcohols react much more slowly than amines with the 6-acyloxy-2,4-dimethoxy-s-triazine intermediates similar to **1**. Using typical CDMT-NMM conditions, ethyl benzoate was prepared by condensation of benzoic acid and ethanol in 65% yield, but the reaction time was 10 days.[1] It was later determined that ester formation proceeds much faster and in higher yields when the intermediate acyloxytriazine is isolated.[13] It was also determined that the rate of esterification can be increased by catalysis with 5 mol% $MgBr_2$ (eq 3). A typical procedure involves preparing the acyloxytriazine with CDMT, NMM and the corresponding carboxylic acid as described in the previous section. After work-up, the corresponding alcohol (10 equiv) and $MgBr_2$ (0.05 equiv) are then added to the crude, intermediate acyloxytriazine (1.0 equiv), and the mixture is stirred until the reaction is complete. Primary, secondary, and tertiary alcohols can be acylated under these conditions with yields between 44-92%. The reaction conditions are mild, but reaction times are somewhat long (typically 2-4 days), and the alcohol must be used in excess.

(3)

Carboxylic acids can also be esterified using DMTMM and the corresponding alcohols.[10,11] A typical procedure involves adding NMM (0.1-1.2 equiv) to a mixture of the carboxylic acid (1.0 equiv) and DMTMM (1.1-2.0 equiv) in the corresponding alcohol (solvent). Reaction times range from 4-21 h. The yields are quite good, but in most cases, the alcohol must be used in large excess.

Reduction of Carboxylic Acids

Active esters prepared from CDMT (e.g. 6-acyloxy-2,4-dimethoxy-s-triazines) can be reduced directly to aldehydes by treatment of hydrogen (1 atm) at room temperature in the presence of 10 mol% Pd/C (eq 4).[2] A typical procedure involves adding a carboxylic acid (1.0 equiv) to a mixture of DMTMM, prepared from CDMT (1.0 equiv) and NMM (1.02 equiv), in DME. The active ester is filtered, added to a mixture of Pd/C (10 mol%) in ethanol and stirred under a hydrogen atmosphere until the reaction is complete. Yields range from 75-84% when aliphatic carboxylic acids are used, but yields of aldehydes drop dramatically with aromatic carboxylic acids as substrates. The main product in these cases is the corresponding alcohol. Even with aliphatic carboxylic acids, the reactions have to be monitored carefully to avoid further reduction to the corresponding alcohols. In fact, if the hydrogen pressure is increased to 3-5 atm, alcohols can obtained in high yields.

Other Uses

CDMT can be used as a source of 2,4-dimethoxy-s-triazine for the preparation of 6-substituted-2,4-dimethoxy-s-triazine derivatives. In these cases, substitution or coupling reactions occur at the carbon bearing the chlorine. Some examples include modified Sonogashira Pd-mediated couplings to form 6-alkynyl-2,4-dimethoxy-s-triazine derivatives,[14] glycosolations of thioglycosides,[15] nickel(0)-catalyzed cross-coupling reactions with arylboronic acids[16] and addition of amines to form 6-amino-2,4-dimethoxy-s-triazine derivatives.[17]

Related Reagents.

cyanuric chloride, benzotriazol-1-yloxytris(dimethylamino)phosphinium hexafluoro-phosphate (BOP), O-benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium hexafluoro-phosphate (HBTU), bis(2-oxo-3-oxazolidinyl)phosphinic chloride (BOP), 1,3-dicyclohexylcarbodiimide (DCC), and 1-ethyl-3-(3´-dimethylaminopropyl)carbodiimide hydrochloride (EDCI).

Tetrakis{1-[(4-dodecylphenyl)sulfonyl]-(2*S*)-prolinate} Dirhodium

[179162-32-4] · $C_{90}H_{140}N_4O_{16}Rh_2S_4$ · (1866)

(chiral catalyst for asymmetric reactions of diazo compounds, especially aryldiazoacetates and vinyldiazoacetates[1])

Physical Data: mp 195-200°C $[\alpha]^{22}_D$ -165 ° (*c* = 1, $CHCl_3$); ^1H NMR (200 MHz, $CDCl_3$) δ 7.74 (d, 8 H, *J* = 9.2 Hz), 7.53 (d, 8 H, *J* = 9.2 Hz), 4.32 (m, 4 H), 3.25 (m, 4 H), 3.05 (m, 4 H), 2.07 (m, 4 H), 1.85 (m, 4 H), 1.57 (m, 8 H), 1.25 (bs, 36 H), 0.85 (m, 10 H).

Solubility: very soluble in most organic solvents including hydrocarbons.

Form Supplied in: green solid; available from Aldrich Chemical Co. The linear alkylbenzene side chains consist of a mixture of 1% C_{10}, 40% C_{11}, 28% C_{12} and 31% C_{13}.

Preparative Methods: from dirhodium tetraacetate by ligand exchange with *N*-[1-(dodecylphenyl)sulfonyl]-(2*S*)-prolinate.[2]

Purification: further purification is generally not necessary. May be dried by heating under vacuum at 100°C. May be purified by column chromatography on silica with ether/petroleum ether as solvent. If contaminated with the free ligand, can be purified by dissolving in diethyl ether and extracting the organic layer with aqueous sodium bicarbonate, followed by drying the organic layer over $MgSO_4$, then filtering and evaporation of the solvent.

Handling, Storage, and Precautions: the catalyst is moisture, air, and thermally stable. It may be stored at room temperature for extended periods of time without any apparent decomposition. The toxicity of the title reagent, Rh_2(*S*-DOSP)$_4$, is unknown. Strong nucleophiles such as nitriles, phosphines, amines, pyridines, and sulfides will tend to coordinate to the axial site of the catalyst. This may cause partial poisoning of the catalyst or catalyst decomposition, depending on the coordinating ligand. Reactions carried out under non-anhydrous conditions tend to result in lower enantioselectivity.[3]

Introduction

The title reagent Rh_2(*S*-DOSP)$_4$ and its *R*-enantiomer have been shown to be exceptional chiral catalysts for transformations of carbenes derived from aryldiazoacetates and vinyldiazoacetates. The related *p-tert*-butylphenyl prolinate derivative Rh_2(TBSP)$_4$ is also commercially available. All of these catalysts display higher levels of asymmetric induction in reactions that are carried out in hydrocarbon solvents and Rh_2(DOSP)$_4$ is generally favored over Rh_2(TBSP)$_4$ because it is soluble in hydrocarbon solvents even at -78°C. All of these catalysts are considered to be conformationally flexible but preferentially adopt a D_2-symmetric arrangement in solution.[1,2] This is a critical component for their effectiveness as chiral catalysts. Conformationally rigid analogs of Rh_2(*S*-DOSP)$_4$ have been reported[4] and these are also promising chiral catalysts.

Asymmetric Cyclopropanations

Rh_2(*S*-DOSP)$_4$ has been shown to be an exceptional chiral catalyst for asymmetric cyclopropanations of vinyldiazoacetates,[2,5] aryldiazoacetates,[6] and alkynyldiazoacetates.[7] Enantioselectivities of greater than 90% ee are very common with this catalyst. The decomposition of a vinyldiazoacetate by Rh_2(*S*-DOSP)$_4$ in the presence of styrene generates a vinylcyclopropane in 98% de and 98% ee (eq 1). This product has been applied to the asymmetric synthesis of (+)-sertraline[8] and the cyclopropane analogs of phenylalanine.[2]

(1)

(69% yield, 98% ee, 98% de)

A special feature of Rh_2(*S*-DOSP)$_4$ is that it is designed for asymmetric transformations of donor/acceptor substituted carbenoids, unlike most of the chiral catalysts for diazo decomposition which are optimized for the cyclopropanation chemistry of unsubstituted diazoacetates.[9] Indeed, the rhodium prolinates rarely induce good asymmetric induction in the reactions of other classes of carbenoids.[2,10] The highest levels of enantioselectivity are obtained when the reactions are carried out in hydrocarbon solvents, and Rh_2(*S*-DOSP)$_4$ is ideally suited because it is soluble in hydrocarbon solvents even at -78°C.[2] Typically, 1 mol% of catalyst is used and the reactions are virtually instantaneous at room temperature, while at -78°C, the reaction times are 12-48 h. Several comparison studies with various other chiral rhodium and copper catalysts have been reported in recent years,[6b,c,11] but so far none have outperformed Rh_2(*S*-DOSP)$_4$ on a regular basis. Cyclopropanations with Rh_2(*S*-TBSP)$_4$ carried out under non-anhydrous reaction conditions result in considerable lowering of the enantioselectivity.[3] Using trioctylphosphine oxide as an additive can minimize this effect.[3] Asymmetric cyclopropanations have also been carried out with Rh_2(*S*-TBSP)$_4$ in supercritical fluids.[3]

Rh_2(*S*-DOSP)$_4$ catalyzed decomposition of vinyldiazoacetates in the presence of vinyl ethers leads to donor/acceptor substituted vinylcyclopropanes.[12] On treatment with diethylaluminum chloride these vinylcyclopropanes undergo a stereoselective rearrangement to cyclopentanes. An illustrative example is shown in eq 2, whereby the tricyclic system is formed in 86% ee.[12] The extent of retention of the asymmetric induction during the vinylcyclopropane rearrangement is very dependent on the cyclopropane substitution pattern.

(2)

53% yield, 88% ee

79% yield, 86% ee

Rhodium(II) carboxylate-catalyzed decomposition of vinyldiazoacetates in the presence of dienes is a very effective stereoselective method for the construction of highly functionalized cycloheptadienes.[13] The [3+4] cycloaddition proceeds via a divinylcyclopropane, which undergoes a Cope rearrangement in a stereodefined manner, leading to cycloheptadienes with stereocontrol at up to three stereogenic centers. When these reactions are catalyzed by Rh_2(*S*-DOSP)$_4$ highly enantioselective reactions are obtained.[14] The reactions with phenylbutadiene and cyclopentadiene illustrate the synthetic potential of this chemistry (eq 3 and 4).[14] Asymmetric [3+4] cycloadditions are also possible between vinylcarbenoids and furans[15] or *N*-BOC-pyrroles[16] leading to the synthesis of 8-oxabicyclo[3.2.1]octadienes or tropanes.

(3)

87% yield, 98% ee

(4)

Reasonably high asymmetric induction can be obtained in intramolecular cyclopropanations.[17] Rh_2(*S*-DOSP)$_4$-catalyzed decomposition of a *Z*,*E*-diene generated a tricyclic system in 93% ee with full control of relative stereochemistry (eq 5). As this reaction initially forms a *trans*-divinylcyclopropane, heating to 140°C is required to induce equilibration to the *cis*-divinylcyclopropane followed by the Cope rearrangement. In general, the intramolecular cyclopropanations are not as highly enantioselective as the intermolecular cyclopropanations, and with certain substrates, other chiral catalysts can result in higher enantioselectivity than Rh_2(*S*-DOSP)$_4$.[18]

(5)

Aryldiazoacetates are capable of being used in solid-phase synthesis.[19] The traditional diazoacetates do not react effectively with substrates on solid support because the carbenoid intermediates are highly reactive and prone to dimerization.[20] The carbenoids derived from aryldiazoacetates are considerably more chemoselective,[21] and when Rh_2(*S*-DOSP)$_4$ is used as catalyst, effective asymmeric cyclopropanation of an alkene on a solid support is possible (eq 6).[19] This protocol can be used to achieve asymmetric cyclopropanation of elaborate alkenes because the alkene is used as the limiting reagent.

83% yield, 91% ee, 85:15 *E*/*Z*

[3+2] Cycloaddition

The Rh_2(*S*-DOSP)$_4$ catalyzed reaction of certain vinyldiazoacetates with styryl ethers results in a very unusual transformation.[22] As illustrated in eq 7, instead of the normal cyclopropanation, a [3+2] cycloaddition product is formed. Remarkably, this product is formed as the all *cis* diastereomer in 98% ee. Selective cuprate additions to these [3+2] cycloaddition products can generate, stereoselectively, cyclopentanes with five contiguous stereocenters.

79% yield, 98% ee

Asymmetric C-H Insertion

A major advantage with the use of aryldiazoacetates is that effective intermolecular C-H insertions can be achieved.[23] Rh_2(*S*-DOSP)$_4$-catalyzed decomposition of methyl phenyldiazoacetate in the presence of cyclohexane results in the formation of the C-H insertion product in 95% ee (eq 8).[24] The reaction has been extended to a range of alkanes and the selectivity of competing insertions between secondary and tertiary C-H sites depends on a delicate balance between steric and electronic effects.[24]

(8)

80% yield, 95% ee

Highly efficient C-H insertion into allylic C-H positions is possible as illustrated in the example with 1,4-cyclohexadiene shown in eq 9.[25] Similar highly enantioselective C-H insertions are possible with cycloheptatriene,[26] while the reaction with cyclohexene proceeded with moderate enantioselectivity but poor diastereoselectivity.[27]

(9)

84% yield, 94% ee

The intermolecular C-H insertion is a very general method for C-H functionalization and represents a surrogate to many classic synthetic transformations. The allylic C-H insertion of trisubstituted vinyl silyl ethers shown in eq 10 represents the equivalent of an asymmetric Michael addition.[28] Remarkably, the C-H insertion product in this case is formed with very high diastereoselectivity. In general, high diastereoselectivity is observed for C-H insertions at methylene sites in which there is considerable size differential between the two substituents.[23]

(10)

65% yield, 84% ee, >90% de

Another spectacular example of a highly diastereoselective intermolecular C-H insertions is the reaction between aryldiazoacetates and

tetralkoxysilanes, which generate silyl-protected β-hydroxy esters,[29] products that would be typically prepared by an aldol reaction. The utility of this reaction is illustrated in the example with tetraethoxysilane, in which the C-H insertion product is formed in 95% ee and >90% de (eq 11). Highly diastereoselective C-H insertions are also possible with allyl silyl ethers.[30]

C-H insertions adjacent to nitrogen results in the formation of products that would be typically formed by a Mannich reaction. *N*-BOC-pyrrolidine is another substrate that undergoes highly diastereoselective C-H insertions, as illustrated in eq 12.[31] The related reaction with *N*-BOC-piperidine[31,32] is also a very important transformation because it represents a very direct synthesis of ritalin.

The chemoselectivity of the C-H insertion is sufficiently great that these reactions can display very impressive levels of kinetic resolution.[33] An illustrative example is the C-H insertion with the racemic 2-substituted pyrrolidine derivative shown in eq 13.[33] The C-H insertion product is formed in 98% ee with excellent control of stereochemistry at three stereogenic centers. By appropriate control of reaction conditions, a double C-H insertion on *N*-BOC-pyrrolidine is possible, generating a 2,5-disubstituted pyrrolidine with excellent control of stereochemistry at four stereogenic centers.[31]

(2 equiv)

(13)

85% yield, 98% ee, >94% de

Highly asymmetric intramolecular C-H insertions are also possible in Rh_2(*S*-DOSP)$_4$-catalyzed reactions, as illustrated in eq 14.[34] The level of asymmetric induction is very dependent on the substitution pattern at the C-H insertion site, with the highest level of C-H insertion obtained for reactions at tertiary C-H sites.[34,35]

(14)

98% yield, 94% ee

Combined C-H Insertion Cope Rearrangement

The reaction of vinyldiazoacetates at allylic C-H sites does not result in the predominant formation of the products of a simple C-H insertion.[25] Instead, combined C-H insertion/Cope rearrangement products with very high enantioselectivity are formed, as illustrated in the example shown in eq 15.[25] This process has been applied to a very short asymmetric synthesis of (+)-sertraline.

(15)

Si-H Insertions

Vinyldiazoacetates and aryldiazoacetates are capable of undergoing effective asymmetric Si-H insertions when the reaction is catalyzed by Rh_2(*S*-DOSP)$_4$. An illustrative example is shown in the reaction of a vinyldiazoacetate that results in the formation of an allylsilane in 95% ee (eq 16).[36]

In summary, the Rh_2(*S*-DOSP)$_4$-catalyzed reactions of aryldiazoacetates and vinyldiazoacetates offer a wide range of applications in organic synthesis. The carbenoids derived from these diazo systems are highly chemoselective and the reactions catalyzed by Rh_2(*S*-DOSP)$_4$ are often highly enantioselective.

(*S*,*S*)-1,2-Bis(*tert*-butylmethylphosphino)ethane[1]

[20300-53-7] · $C_{12}H_{28}P_2$ · (234.30)

(a chiral ligand for transition metal-catalyzed asymmetric reactions)

Alternate Name: BisP*.

Physical Data: mp 23.5-25.5 °C.

Solubility: soluble in most organic solvents.

Form Supplied in: borane complex of **1** is commercially available as colorless crystals.

Preparative Methods: phosphorus trichloride is allowed to react sequentially with alkylmagnesium chloride, methylmagnesium bromide, and BH_3-THF complex in THF to give alkyldimethylphosphine-borane (eq 1).[1] The phosphine-borane so obtained is enantioselectively deprotonated by *s*-BuLi in the presence of (-)-sparteine in Et_2O at -78 °C to -50 °C, followed by oxidative coupling using $CuCl_2$ to give a BisP*-borane complex. Recrystallization from toluene affords enantiomerically pure product. The boranato group is removed by the reaction with trifluoromethanesulfonic acid in toluene, followed by treatment with aqueous KOH.

Purification: filtered through Al_2O_3 with Et_2O elution under N_2 or Ar atmosphere.

Handling, Storage, and Precautions: stench. Undergoes oxidation to the phosphine oxide on standing in air. Usually prepared before use by deboranation of the air stable phosphine-borane.

Rhodium-Catalyzed Asymmetric Hydrogenation of Olefins

A rhodium complex of BisP* (**1**) is a highly effective catalyst for asymmetric hydrogenation of some olefinic compounds.[1] BisP*-rhodium complex **2** is prepared from **1** and $[Rh(nbd)_2]BF_4$ in THF (eq 2). The hydrogenation of α-(acylamino)-acrylic derivatives are carried out at room temperature and an initial H_2 pressure of 2 or 6 atm in the presence of the catalyst (0.2 mol%). The reactions proceed rapidly and are complete within 0.2-2 h to afford α-amino acid derivatives with enantioselectivity of up to 99.9% (eq 3). This methodology can also be applicable to β-unsubstituted and β,β-disubstituted α-(acylamino)acrylates. The excellent enantioselectivities are again observed in hydrogenation of itaconic acids,[2] enamides,[3] and dehydro-β-amino acids[4] (eq 4-6).

(2)

(3)

(4)

(5)

(6)

Ruthenium-Catalyzed Asymmetric Hydrogenation of β-Keto Esters

A ruthenium complex of **1** catalyzes enantioselective hydrogenation of β-keto esters.[5] The **1**-Ru complex is prepared by reacting **1** with (COD)Ru(2-methylallyl)$_2$, followed by treatment with methanolic HBr in acetone.[6] The hydrogenations are carried out at 50-70 °C and an initial H_2 pressure of 6 atm in the presence of the **1**-RuBr$_2$ complex (0.13-1.4 mol %). Various types of β-keto esters and related substrates are hydrogenated to afford β-hydroxy esters in high yield and with excellent enantioselectivity (eq 7). In the case of α-keto esters, slightly lower enantioselectivity is observed, and γ-keto esters are not subjected to hydrogenation under the conditions.

1,1,3,3-Bis(tetramethylene)chlorouronium Hexafluorophosphate

[207915-96-6; 135540-11-3] · $C_9H_{16}ClF_6N_2P$ · (332)

(peptide synthesis coupling reagent)

Alternate Name: PyClU,[1] BTCFH.[2]

Physical Data: mp 151-153 °C,[1] 146-148 °C.[3]

Solubility: soluble in CH_2Cl_2, $CHCl_3$, DMF, DMSO, NMP, acetone.

Form Supplied in: colorless crystals.

Analysis of Reagent Purity: ^{1}H-NMR; elemental analysis.

Preparative Methods: addition of $POCl_3$[1] or a 20% solution of phosgene in toluene[3,4] to the corresponding urea and then addition of KPF_6/H_2O.

Purification: recrystallization (acetone/Et_2O).

Handling, Storage, and Precautions: the toxicological properties of this reagent have not been investigated and no special instructions for storage and handling are mentioned in the literature.

Reagent for Peptide Synthesis

This reagent, which was designed for coupling *N*-methylated amino acids (eq 1), gives results comparable to those obtained with **PyBroP**.[1] Compared with the hydroxybenzotriazol-based activator **HBTU**, which produces the moderately activated benzotriazolyl esters from carboxylic acids, PyClU gives high yields and low racemization.[1,5] However, significant epimerization is observed during segment condensation.[6]

(1)

In addition, the homologous tetrafluoroborate salt TPyClU proved to be efficient for monoester formation from *N*-protected α-amino phosphonic acid (eq 2).[7]

(2)

R = *i*-PrOH (83%), PhCH2OH (86%), *t*-BuOH (65%)

Preparation of Coupling Reagents for Peptide Synthesis

Several related uronium coupling reagents have been prepared from PyClU:

Bromotripyrrolidinophosphonium Hexafluorophosphate[1]

[132705-51-2] · $C_{12}H_{24}BrF_6N_3P_2$ · (466)

(reagent for carboxylic acid activation, particularly used for peptide synthesis; reagent for formamidine synthesis)

Alternate Name: PyBroP.

Physical Data: mp 138-139 °C.

Solubility: soluble in CH_2Cl_2, $CHCl_3$, DMF, DMSO, NMP, acetone.

Form Supplied in: colorless crystals.

Analysis of Reagent Purity: ^{31}P NMR, HPLC.

Preparative Methods: addition of Br_2 to tripyrrolidinophosphine[2] or addition of tripyrrolidinophosphine oxide to an acetonitrile solution of phosphoryl tribromide,[1,2] then addition to a KPF_6 solution in water.

Purification: recrystallization from CH_2Cl_2/Et_2O; CH_2Cl_2/hexane; acetone/Et_2O; EtOAc.

Handling, Storage, and Precautions: the toxicological properties of this reagent have not been investigated and no special instructions for storage and handling are mentioned in the literature.

Introduction

Treatment of a carboxylic acid with bromotripyrrolidinophosphonium hexafluorophosphate (PyBroP) in the presence of base produces the unstable acylphosphonium intermediate. Such species directly react with a nucleophile or decompose into a different activated form (e.g. carboxylic anhydride).[1] The reagent was first designed for coupling in peptide synthesis but is also widely used for the synthesis of amides or esters, and for macrocyclization. This reagent gives results that are comparable to those obtained with BroP [bromotris(dimethylamino)phosphonium hexafluorophosphate][3] with the advantage of not producing the carcinogen **HMPA** as a side product of the coupling reaction.[4] By-products have been observed from slowly reacting activated carboxylates: (i) the formation of pyrrolidide derivatives due to the presence of small amounts of pyrrolidine in the commercial phosphonium salt (avoided by recrystallization of the reagent),[5] and (ii) a side reaction in DMF but favorable for the preparation of formamidines.[6]

Reagent for Peptide Synthesis

PyBroP was efficiently used in both liquid and solid phase peptide synthesis, but it can lead to epimerization when used for segment condensation.[7] Compared with hydroxybenzotriazol-based activators like BOP, PyBOP, HBTU or DCC/HOBT, which produce the moderately activated benzotriazolyl esters from carboxylic acids, PyBroP is highly recommended for coupling *N*-methylated amino acids,[1,8-14] as illustrated by the difficult coupling of NMeVal (eq 1),[1,8] and other *N*-alkylated amino acids[15-17] as well as α-disubstituted amino acids (e.g. α-MeSer,[18] Aib[19] or α-MeCys (eq 2).[20] Coupling of *N*-alkylated amino acids can be improved by addition of HOAt.[21] The addition of a catalytic amount of **DMAP** or **4-pyrrolidinopyridine** is recommended to improve both the rate and the yield of the coupling reaction for non-epimerizable substrates.[10,13,18-20] PyBroP activation of Boc-amino acids can, however, give moderate yields due to the formation of the *N*-carboxyanhydride (NCA).[1,22]

(1)

(2)

Synthesis of Amides

PyBroP has been employed in the synthesis of unsubstituted amides,[23] *N*-monosubstituted amides (eq 3),[24] and disubstituted amides, even from conformationally constrained derivatives (eq 4)[25] and anilines.[19,26,27] It has also been used for activation of conjugated carboxylic acids (eq 5).[28]

(5)

PyBroP also gives good results for the synthesis of macrocyclic lactams (eq 6),[29] including cyclic peptides at high dilution[13] with addition of HOAt[30] or on solid phase.[31]

(6)

Synthesis of Carboxylic Esters

Ester linkage from carboxylic acid activation with PyBroP was reported for primary and secondary alcohols. This reagent gives impressive results for depsipeptide synthesis (eq 7).[32] PyBroP has been used to attach nucleosides to a hydroxylated solid support.[33]

(7)

In addition, this activation was selected over carbodiimide-derived reagents for the preparation of polymer-bound activated esters derived from **1-hydroxybenzotriazole** (eq 8)[34,35] and for the preparation of the storable *p*-nitrophenyl esters in solution.[36]

(8)

R=

PyBroP gives improved yields for the cyclization step in the synthesis of the macrocyclic dynemicin A, when compared with the Yamaguchi macrolactonization protocol (eq 9).[37]

(9)

Synthesis of Amidines

Formamidinium formation has been reported as a side reaction of PyBroP with DMF in solid-phase peptide synthesis. This reaction proved to be suitable for the synthesis of formamidines from aliphatic or aromatic amines and DMF (eq 10).[6]

(10)

R-NH_2 = aniline (56%), benzyl amine (77%), benzene-1,3-diamine (53%), pyridine-2,6-diamine (48%)

Preparation of Coupling Reagents for Peptide Synthesis

Several phosphonium-related coupling reagents for peptide synthesis have been prepared from PyBroP (eq 11): PyBOP,[2] PyAOP,[38] and CF_3PyBOP.[39]

A = C; B = H: PyBOP(90%)
A = N; B = H: PyAOP (76%)
A = C; B = CF_3: CF_3PyBOP (69%)

Chlorotripyrrolidinophosphonium Hexafluorophosphate

[133894-48-1] · $C_{12}H_{24}ClF_6N_3P_2$ · (421)

(reagent for carboxylic acid activation, coupling agent in peptide synthesis)

Alternate Name: PyCloP.

Physical Data: mp 150-151 °C.[1]

Solubility: soluble in CH_2Cl_2, $CHCl_3$, DMF, DMSO, NMP, acetone.

Form Supplied in: colorless crystals.

Analysis of Reagent Purity: ^{31}P NMR, HPLC.

Preparative Methods: addition of chlorine to a diethyl ether solution of tripyrrolidinophosphine, then addition of KPF_6 in water.[2] Addition of tripyrrolidinophosphine oxide to a DCM solution of phosphoryl trichloride, then addition of KPF_6 in water.[1-3]

Purification: recrystallization (CH_2Cl_2/Et_2O).

Handling, Storage, and Precautions: the toxicological properties of this reagent have not been investigated and no special instructions for storage and handling are mentioned in the literature.

Introduction

Treatment of a carboxylic acid with PyCloP in the presence of base produces the unstable acylphosphonium intermediate. This species directly reacts with a nucleophile or decomposes into a different activated form (e.g. carboxylic anhydride). This reagent gives results that are comparable to those obtained with **PyBroP** (bromotripyrrolidinophosphonium hexafluorophosphate).[1]

Reagent for Peptide Synthesis

Compared with hydroxybenzotriazol-based activators like BOP, PyBOP, HBTU, or DCC/HOBT, which produce moderately activated benzotriazolyl esters from carboxylic acids, PyCloP is highly recommended for coupling *N*-methylated amino acids, as illustrated by the difficult coupling of NMeVal (eq 1),[1,4] and used in the total synthesis of natural peptoids.[5-7] PyCloP activation of Boc-amino acids can, however, give moderate yields due to the formation of *N*-carboxyanhydride (NCA).[1,8]

(1)

Activation of a Monothiocarboxylic Acid

Using different phosphorus reagents for activation of a monothiocarboxylic acid, the observed oxygen/sulfur selectivities correlate with the hardness/softness of the reaction center. Compared with the soft leaving bromine atom in PyBroP (S selective) or the hard oxygen atom in PyBOP (O selective), the PyCloP is borderline in O/S (25:47) selectivity (eq 2).[3]

(2)

Preparation of Coupling Reagents for Peptide Synthesis

PyBOP, a related phosphonium coupling reagent for peptide synthesis, has been prepared from PyCloP,[2] and several analogs of PyBOP have also been prepared as reagents for thioacylation of monothiocarboxylic acid [3] (eq 3).

(3)

Y = H, PyBOP (75%)
NO_2, PyNOP (68%)
CF_3, PyFOP (92%)

PyDOP (94%)

PyPOP (92%)

Related Reagents.

Pentafluorophenyl diphenylphosphinate (FDPP)

[138687-69-1] · $C_{18}H_{10}F_5PO_2$ · (384.25)

(reagent used as carboxyl activating group and coupling agent in a wide variety of amide bond formations)

Solubility: soluble in most organic solvents.

Form Supplied in: white powder and chunks.

Handling, Storage, and Precautions: decomposition occurs upon prolonged exposure to moisture in air. Storage in a cool dry place extends the life of the reagent. The toxicological properties have not been thoroughly investigated; however, hazardous combustion products may include, but are not limited to, carbon monoxide, carbon dioxide, hydrogen fluoride, and phosphorus oxides. FDPP is incompatible with strong oxidizing agents.

Physical Data: mp 47-50 °C

Purification: silica gel chromatography (short column to minimize decomposition) eluting with 20% ethyl acetate in petroleum ether followed by drying under reduced pressure for 2 days over phosphorus pentoxide.

Preparative Methods: FDPP can be conveniently prepared by mixing equimolar amounts of diphenylphosphinic chloride, pentafluorophenol, and imidazole in anhydrous CH_2Cl_2 at room temperature (eq 1).[1] There are slight procedural variations in the literature as to order of addition and reaction duration.[2,3] It has been found that using an excess of the diphenylphosphinic chloride (1.5-2 equiv) to drive the reaction to completion simplifies the purification, as the residual hydrolyzed reagent adheres tightly to the silica gel column and is, therefore, easier to separate than residual pentafluorophenol.[4]

Coupling to Generate Linear Molecules

When Chen and Xu reported the new reagent, FDPP, in 1991,[1] the use of diphenylphosphinic mixed anhydrides in peptide chemistry was known,[5,6] as was the use of pentafluorophenyl esters.[7-11] However, the need to preactivate amino acids or to prepare active esters was unattractive. FDPP can be used directly as a coupling reagent without preactivation.[1] Chen and Xu demonstrated the utility of the reagent by preparing several small oligopeptides in solution and by preparing Leu-enkephalin via solid-phase synthesis.[1] Their solution-phase protocol called for equimolar amounts of the carboxyl and amine hydrochloride components, 3 equiv of Hünig's base, and 1.2 equiv of FDPP in DMF at room temperature for 1.5 h. The yields of isolated products were all greater than 80%. Using HPLC[12] (for the coupling product of Z-Gly-Phe-OH and Val-OMe·HCl) and the Young test[13] (for the coupling product of Bz-Leu-OH and Gly-OEt·HCl), they observed almost no racemization with FDPP; whereas, pentafluorophenyl diphenylphosphate (FDP)[14,15], 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), benzotriazol-1-yl-oxytris(dimethylamino)phosphonium hexafluorophosphate/1-hydroxybenzatriazole (BOP/HOBt), and dicyclohexylcarbodiimide (DCC) all showed significant levels of racemization. In the solid phase protocol, they employed the chloromethyl resin and carried out the reactions with 3 equiv of Boc-amino acid, FDPP, and 9 equiv of Hünig's base. This method provided extremely high yields and proved superior to the DCC method because no insoluble by-product was generated.

The use of FDPP in the formation of a variety of dipeptides has been studied in comparison to BOP, HBTU, and isobutyl chloroformate (IBCF).[3] Product yields, HPLC diastereomeric yields,[12] and optical rotations were measured for each example. In general, FDPP did give high yields and good optical purity. When Fmoc was used as the nitrogen protecting group, significantly lower yields and lower optical purity resulted. FDPP gave excellent yields for the formation of proline methyl ester dipeptides, outperforming HBTU, BOP, and IBCF; however, these reagents provided better optical purity than FDPP. Overall, BOP was the most successful coupling reagent for the dipeptides studied.

The search for an economical synthesis of the β-hydroxyproline fragment found in the cyclopeptide alkaloids nummularine F and mauritine was the impetus for another comparative study of carboxyl activating reagents (eq 2).[16] Relatively expensive isopropenyl chloroformate (IPCF) was used previously for this reaction. It was shown that the more affordable FDPP and BOP-Cl both possessed reactivity comparable to IPCF. In addition, the reactivity of FDPP in this reaction was shown to be greater than that of BOP, pentafluorophenol/DCC, phosgene, diphenylphosphinic chloride, DCC, *N*,*N*-carbodiimidazole, 2,4,6-trichlorobenzoyl chloride, pentafluorophenyl trifluoroacetate, and oxalyl chloride.

(2)

In the cryptophycin synthesis, FDPP was employed for the coupling shown in eq 3.[2] The amine component was used as its TFA salt, and when DCC/HOBt or BOP-Cl was used, the desired product was contaminated with the trifluoroacetamide to varying degrees. The problem could be circumvented by exchanging the counterion for tosylate, but this replacement incurred significantly longer reaction times. FDPP gave a comparable yield of product uncontaminated by the trifluoroacetamide.

(3)

FDPP has also been employed in the coupling of *N*-protected amino acids to substituted γ-thiapyrone amines (eq 4).[17] When α-amino acids were used, the yields varied from 48-61% over a range of substitution patterns. The authors observed no signs of racemization in the ^{1}H and ^{13}C NMR spectra. Using Fmoc-protected β-amino acids, yields ranged from 39-46% for different substitution patterns, and longer reaction times (7-9 h) were required. Peptoid carboxyl components gave even lower yields at the same extended reaction time. It is unclear whether the low yields, with β-amino acids and peptoids, are due to the nature of these molecules or to the Fmoc protecting group, which is known to give lower coupling yields when used with FDPP.[3]

(4)

One way of immobilizing stationary phases onto silica gel involves amide bond formation; wherein the coupling partners are stationary phases derivatized with a free carboxylic acid and silica gel derivatized with an amino group. Low yields and racemization of chiral stationary phases often prove problematic, so Yang and co-workers investigated a variety of conditions and coupling reagents for this reaction.[18] While model reactions in solution phase gave generally high yields, the extent of racemization encountered with FDPP was greater than that found when using diisopropylcarbodiimide/1-hydroxy-7-azabenzotriazole (DIC/HOAt), DIC/HOBt, diphenylphosphoryl azide (DPPA), 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ), *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*´,*N*´-tetramethyluronium hexafluorophosphate (HATU), and benzotriazolyloxy-tris[pyrrolidino]-phosphonium hexafluorophosphate (PyBop). However, for aminopropylsilica gel couplings (eq 5), yields were generally much lower, and the extent of racemization was much greater with all reagents except EEDQ. In this particular coupling, FDPP performed similarly to DIC/HOAt, DIC/HOBt, DPPA, HATU, and PyBop.

The use of FDPP has also been investigated for the thioacylation of iminoacid residues with monothioacids (eq 6).[19] FDPP gave a good yield of coupled product (81%) but a very low ratio of thio to oxo product. It was found that, for this reaction, coupling reagents with a leaving group bearing a delocalized charge, such as PfpO$^-$, had inherently lower selectivity for thioamide formation. Polar solvents also lowered the selectivity, and FDPP couplings are usually performed in DMF.

FDPP has also shown utility in the coupling of *N*-protected amino acid residues to linear diamino substrates bearing a free secondary hydroxyl group. The desired hydroxy amides were obtained in good yields for testing as HIV-1 protease inhibitors.[20]

Macrocyclization

While it is not always the reagent of choice, FDPP often provides excellent yields in macrocyclizations over a wide variety of substrates. In Deng and co-workers' 1994 synthesis of the macrocyclic pentapeptide cyclotheonamide B, FDPP was used to accomplish the macrolactamization in >80 % yield (eq 7).[21]

Mtr = 2,3,6-trimethyl-4-methoxy benzenesulfonyl

(7)

Pentafluorophenyl diphenylphosphinate (FDPP)

In their 1996 approach to the same molecule,[22] the WSCI/HOBt-mediated macrolactamization, which had been performed in 42% yield on an analog that had a vinylogous D-tyrosine in place of the vinylogous L-tyrosine, yielded only 16% for the desired substrate. DPPA and diethyl phosphorocyanidate (DEPC) gave only 8% and 12%, respectively, even after an extended reaction time of 3.5 days. The pentafluorophenyl ester also gave only 8% cyclized product. However, cyclization with FDPP gave 43% yield in only 4.5 h, and optimization increased the yield to 57% (eq 8).

(8)

Deng and co-workers had similar success using FDPP for the macrolactamization en route to alterobactin A, a siderophore from an open ocean bacterium.[23,24] In this case, FDPP in the presence of NMM in DMF provided a 53% yield of cyclized product despite the relative steric congestion about the amino terminus (eq 9).

Mtr = 2,3,6-trimethyl-4-methoxy benzenesulfonyl

(9)

During the synthesis of new didemnin B analogs for investigation of the structure activity relationship of these cyclodepsipeptides,[25] improvements were made to the original[26] macrocycle synthesis. Among these modifications was the use of FDPP for the cyclization step. Previously, the best yields (42%) had been attained with DPPA after 72 h at 0 °C.[26] The product of dimerization was always a major contaminant

despite the use of very dilute conditions. The use of FDPP at room temperature for 3-4 h accomplished the cyclization in 68% yield (eq 10).[3,25]

R = Si(*i*-Pr)$_3$

(10)

R = Si(*i*-Pr)$_3$

In a 1995 synthesis of the cryptophycins, FDPP was used for the macrolactamization reactions, giving a 62% yield of cryptophycin D (eq 11).[2,27,28]

Cryptophycin D (11)

The same yield was achieved for a similar cyclization to give a product that proved not to be identical with cryptophycin C, leading to a revision of the structure of this natural product. The following year, a chemoenzymatic approach to the molecule was published by a different group in an effort to make the synthesis amenable to gram-scale preparation.[29] A more hindered site of cyclization was chosen, and FDPP cyclized in >70% yield in each case examined. A representative example is shown in eq 12.

Cryptophycin C (12)

In the synthesis of astin G,[30] FDPP was useful for the coupling of the dipeptide and tripeptide fragments to form the linear precursor, giving the same yield (80%) as BOP. However, cyclization to form the 16-membered ring was unsuccessful with both FDPP and DPPA. HBTU proved to be the best reagent for this difficult cyclization, which proceeded in only 16% yield (eq 13).

Cyclooligomerization

A less common use for FDPP is the cyclooligomerization reaction. Bertram et al. found that cyclic peptides containing thiazole moieties could be efficiently constructed in one step from the monomeric unit (eq 14).[31] They found that FDPP gave consistently high yields of cyclic products. The optimum procedure employed 3 equiv of Hünig's base and 1.5 equiv of FDPP added to a suspension of the monomer at a concentration of about 50 mM in acetonitrile. The reaction duration was approximately 18 h at room temperature. The yields were consistently >80% under these conditions, and the major products were the cyclic trimer and tetramer, in a ratio of 5:2.

Couplings on Microarrays

In a recent adaptation of DNA microarray technology, Korbel et al. have used chiral fluorescent probes to measure the ee of tens of thousands of samples on reaction microarrays.[32] Their protocol employed an FDPP-mediated coupling of an equimolar mixture of two pseudoenantiomeric fluorescent reporters to the immobilized amino acid samples. During the coupling, the ee information of the sample becomes coded as a ratio of the fluorescent probes that is observable upon measurement of fluorescent emission at the appropriate excitation wavelength for each fluorophore.

Polymer-Supported Hydroxide[1]

(the reagent is used as a base, a source of nucleophilic hydroxide, or a scavenger in a wide array of reactions[1])

Alternate Name: quaternary ammonium hydroxide anion exchange resin, Amberlite IRA-400 (OH^- form), Amberlite IRA 420 (OH^- form), Amberlite IRA 410 (OH^- form), Amberlite IRN-150, Amberlite IRA 900 (OH^- form), Amberlite IRA 904 (OH^- form), Amberlite IRA 910 (OH^- form), Amberlite A5836, Amberlyst A26 (OH^- form), Ambersep 900, Dowex-1 (OH^- form), Dowex-3 (OH^- form), Dowex 1-X4 (OH^- form), Dowex 1-I 9880, Dowex 1-I0131, Dowex 550 A (OH^- form), Amberjet 4400.

Form Supplied in: available on a variety of polystyrene-divinylbenzene cross-linked supports of both macroreticular and gel-type ion exchange resins. The reagent can be obtained with a range of basicities (pH) broadly characterized as weakly basic to strongly basic resins. The standard commercial form comes as large spherical beads (up to 4 mm in diameter) usually supplied with a water content of 30-60% by mass.

Purification: elute and wash with suitable solvents prior to use and dry under vacuum if required.

Handling, Storage, and Precautions: irritant; wear suitable protective clothing. Deactivates upon prolonged exposure to air by absorption of carbon dioxide. Decomposition of the tetraalkyl moiety can occur with strong acids/bases, oxidants and high temperatures.

General

Polymer-supported hydroxide has properties fully comparable to its solution phase counterparts. Some practical advantages of the polymer-supported hydroxide over the solution-phase bases is that no neutralization or separation steps are required other than simple filtration and evaporation of solvent leading to essentially pure products. The spent resin can also be easily regenerated and recycled by a simple base activation and washing sequence.[3] The resin also shows a good tolerance of most polar and nonpolar organic solvents although some protic and highly acid solvents can ion exchange with the hydroxide resin (e.g. alcohols, which can form the alkoxides on support).

Hydrolysis

Polymer-supported hydroxide serves as a nucleophile in various hydrolysis reactions. Hydrolysis of esters to the constituent acids and alcohols can be carried out under aqueous or methanolic conditions at ambient temperature.[4,5] Amides can also be formed from the corresponding nitriles[6] and cyclic iodo carbonates are smoothly converted into epoxy alcohols with retention of stereochemistry (eq 1).[7]

(1)

Elimination Reactions

Dehydrochlorination can be carried out efficiently using a strongly basic polymer supported hydroxide column and this method has been used to form indolium hydroxide (eq 2).[8] When an excess of base such as ammonia or triethylamine was used instead of the ion-exchange resin, a significant amount of undesired demethylation of the indolium salt was observed, forming 1-methylindole.

(2)

Condensation Reactions

The hydroxide anion-exchange resins have also been shown to be excellent catalysts in cyanohydrin formation,[9] aldol,[10] nitroaldol,[11-14] Knoevenagel, Claisen,[15] Dieckmann,[16] Cannizzaro,[11] and Michael condensations.[17-20] Amberlite IRA-420 (OH^-) has been employed as a strong polymer-supported base to effect the Henry reaction between various aldehydes and nitroalkanes (eq 3).[11-14] This reaction has also been utilized in a clean five-step synthesis of an array of 1,2,3,4-tetra-substituted pyrroles where all subsequent steps used polymer-supported reagents.[11] It should be noted that a large excess of the nitro compound (usually used neat) is needed for clean reactions and to prevent the Cannizzaro reaction on electron-poor aldehydes. The corresponding Henry reactions involving ketones proceed more slowly and with lower yields.[13]

(3)

The same Amberlite IRA-420 resin under modified conditions has been used to effect a Cannizzaro reaction of electron-poor benzaldehydes.[11] In combination with a solid-supported oxidant to reoxidize the benzylic alcohols to the aldehydes, this method was used to generate quantities of benzoic acids.

Amberlite IRA-904 has been used in the dynamic resolution of cyanohydrins formed and racemized in situ by the basic anion exchange resin (eq 4).[9] The lipase used in the resolution was stable to the basic resin and enantiomeric excesses of up to 91% were achieved.

(4)

Aldol reactions have also been carried out using polymer-supported hydroxide for the synthesis of a variety of heterocyclic ketols and their dehydration products with improved yields over the conventional solution phase preparation.[10] The catalyzed reaction of a range of pyridinecarboxaldehydes and substituted acetophenones in ethanol furnished the corresponding aldol or α,β-unsaturated ketones, the propensity for dehydration was shown to be a direct function of the strength of the polymer base used.

In a similar way the polymer-supported hydroxide resin Ambersep 900 (OH^-) was used in the formation of a library of oxazoles via deprotonation of *p*-tolylsulfonylmethyl isocyanide (TosMIC) and subsequent addition to aromatic aldehydes.[21] A base-induced elimination of sulfinic acid which is sequestered by the basic resin leaves after filtering a clean solution of the oxazole product (eq 5).

In library generation, purification by removal of impurities can be a tedious process, Beemashakar et al. have shown the advantage of using the hydroxide resin as both a reagent and purification aid in the combinatorial synthesis of 2,4-pyrrolidinediones.[22] In this synthesis, the hydroxide resin acts both as a base for the Dieckmann reaction and as product-sequestering agents in a 'catch-and-release' purification; the product remains tightly bound to the resin, enabling impurities to be removed by simple filtration and subsequent acidification releases the product into solution (eq 6).

Alkylation Reactions

In the presence of a hydroxide resin, phenols can be converted to the corresponding ethers and acids to ester using alkyl halides or dialkyl sulfates; in this case any unreacted phenol or acid becomes bound to the basic resin aiding purification.[23-27] This protocol serves as a very facile method for carrying out *O*-alkylation of phenoxides with various alkyl halides. In these reactions, primary halides give higher yields than secondary, and bromides consistently give improved yields over chlorides.[25,26]

Shimo and Wakamatsu[3] and Gelbard[27] have reported the alkylation of various active methylene group-containing compounds like ethyl malonate, cyanoacetic esters and cyanoacetamides with various alkyl halides in the presence of Amberlite IRA-400 and IRA-900 (OH^-).[28]

Another interesting example is the intramolecular alkylation leading to ring closure and formation of β- and γ-lactams as demonstrated by Chatterjee et al. (eq 7).[29]

(7)

In a related process, Domann et al. have recently employed the polymeric resin Amberlyst A26 in the formation of epoxysilanes from vinyl silanes in a one-pot process (eq 8).[30] Starting from the vinylsilanes, the **polymer-bound haloate(I) reagent** generated the 1,2-cohalogenated product which under basic conditions was transformed to the corresponding epoxysilane in good yield and high purity.

(8)

Horner-Wittig Reactions

Amberlyst A26 (OH^- form) has found use in the activation of stabilized phosphonates bearing α-nitrile or ester functionality for the olefination of carbonyl compounds (eq 9).[31] The reactions described gave good yields, although the *E*/*Z* ratio was not as high as would be expected under normal solution-phase conditions. It was however noted that the process was independent of the solvent used, with the resin providing a microenvironment making the reaction independent of the external medium (i.e. a greater range of solvents could be employed).

(9)

X= CN, CO_2R

Scavenging

The hydroxide resins have also been employed as purification aids, for example, in the preparation of a library of azo-dyes which were subjected to a 'catch-and-release' work-up which involved shaking the colored solution with Dowex(OH).[32] This procedure captured only the product leaving a colorless solution after filtration. The isolated resin was subsequently washed with acetic acid to release pure product. Amberlite IRA-420 has also been used as a scavenger to remove unreacted 2-aminothiophenol.[33] The polymer-supported hydroxide has also been employed extensively for the removal of acids and phenols and in a more conventional role for liberating the free base from protonated salts.

Related Reagents.

Quaternary tetraalkylammonium hydroxide has also been grafted onto other supports such as silica and MCM-41.[2]

Cyclohexyl Chloroformate

[13248-54-9] · $C_7H_{11}ClO_2$ · (162.62)

(cyclohexyloxycarbonyl (Hoc); amine and indole protecting group for peptide synthesis)

Alternate Name: carbonochloridic acid cyclohexyl ester; cyclohexyloxycarbonyl chloride; chloroformic acid cyclohexyl ester.

Analysis of Reagent Purity: ^{1}H NMR.

Form Supplied in: colorless liquid; not commercially available.

Solubility: soluble in most organic solvents.

Handling, Storage, and Precautions: decomposes to CO_2 and cyclohexyl chloride on prolonged storage. Store in a refrigerator. Bottles may develop pressure and should be cooled before opening. Use in a fume hood. Irritating to skin, eyes, mucous membranes.

Physical Data: bp 38-44 °C 2 mmHg;[1] n^{20}_D 1.4587.[1]

Preparative Methods: a 1 L round-bottomed flask equipped with a delivery tube extending to the bottom of the flask, a pressure-equalizing addition funnel and a cold-finger condenser cooled with dry ice-acetone were placed in an ice bath. The exit tube of the condenser was connected to a $CaCl_2$ drying tube and suitable trap for phosgene and HCl. Phosgene was introduced into the flask until 109 g (1.1 mol) has been condensed. The reaction flask is stirred while 100 g (1 mol) of cyclohexyl alcohol was added through the dropping funnel at a rate to keep the mixture in gentle reflux for 1 h. The flask was allowed to stand at room temperature with stirring for 2 h. The solution was then concentrated under reduced pressure at room temperature to remove HCl and the excess phosgene. The residue may be used without further purification.

Note: Phosgene is a highly toxic gas; use in a fume hood.

Introduction

The cyclohexyloxycarbonyl (Hoc) group was originally developed by McKay and Albertson as acid labile N^{α}-amino protection used for peptide synthesis.[2] The reagent used for the introduction of the Hoc group, cyclohexyl chlorofomate, is easily prepared from inexpensive starting materials, cyclohexyl alcohol, and phosgene (eq 1).

(1)

In elongating peptide chains properly, there must be a highly compatibility between the protecting groups for N^{α}-amino function and amino acid side-chain functional groups. The N^{α}-Hoc group is readily cleaved by strong acids such as hydrogen bromide (HBr) in acetic acid[2] or liquid hydrogen fluoride (HF),[3] although most side-chain protecting groups are also removed under these conditions. When compared with other N^{α}-amino protecting groups commonly used for *t*-butyloxycarbonyl or benzyloxycarbonyl (Z)-mediated peptide synthesis, however, the Boc and the Z groups can be selectively removed by much milder conditions such that the side-chain protecting groups remain intact. Therefore, the Hoc group has not gained the practical application for N^{α}-amino protection since it offers no advantage over the Boc and Z groups. However, recently the use of Hoc group has been used as the N^{in}-protecting group for the synthesis of tryptophan (Trp)-containing peptides[4] and also as another orthogonal amino-protecting group in Boc chemistry.[5]

Hoc Group as a Base-Resistant N^{in}-Protecting Group for Trp

The Hoc group, which is compatible with Boc-mediated peptide synthesis, was introduced to the indole moiety of Trp to avoid indole oxidation and alkylation during repetitive acid treatment such as with trifluoroacetic acid (TFA).[4,6] The Hoc group was introduced by acylation of Boc-Trp-OPac (Pac = phenacyl) or Boc-Trp-OBzl using cyclohexyl chloroformate in dichloromethane in the presence of pulverized NaOH and a catalytic amount of tetra-*n*-butyl ammonium hydrogensulfate (TBAHS) at room temperature for 1 h. Removal of the Pac or Bzl ester by using zinc dust in acetic acid or catalytic hydrogenation gave the Trp derivative (eq 2).

In contrast with the widely employed formyl protecting group for Trp,[7] the Hoc group is readily cleaved by HF without resorting to the use of thiols and is also far more stable under conditions using basic nucleophiles (e.g. morpholine and piperidine)[4] (Table 1).

Table 1 Stability of the side-chain protecting groups for Trp in acid and base. Determined by HPLC after treatment of Boc-Trp(X) under acidic (500 eq) or basic (100 eq) conditions (rt, 18 h)

	Loss of protecting group X (%)	
X–	Hoc	For
TFA	0	0
10% DIEA/DMF	0	28
10% piperidine/DMF	0	100
20% morpholine/DMF	0	100

When synthesizing Trp-containing peptides by the Boc-mediated peptide synthesis, therefore, the N^{in}-Hoc group is applicable not only to the standard solid-phase peptide synthesis but also to the preparation of protected peptide segments on base labile linkers such as an *N*-[9-(hydroxymethyl)-2-fluorenyl]succinamic acid (HMFS) linker.[8] The HMFS linker is designed to release fully protected segments with a free α-carboxyl group by treatment with 20% morpholine in DMF. The Hoc group on Trp is completely stable under basic conditions for detachment of the segments from the HMFS resin. The protected segments thus obtained are used for the subsequent segment condensation reaction performed using either solution or solid phase method. Employing this procedure based on performing segment assembly on the solid support and segment condensation in solution, the synthesis of muscarinic toxin 1 (a 66-residue peptide)[9] and green fluorescent protein (a 238-residue protein)[10] was reported. With accumulation of experiments employing the N^{in}-Hoc group, however, it became apparent that modification of Trp associated with use of this group produces two *trans*-isomers of 2-[2´-(*p*-cresol)]-2,3-dihydrotryptophan (**1**) during the HF reaction in the presence of *p*-cresol as a scavenger.[11]

This side reaction for Trp proved to be inherent to the carbamate-type N^{in}-protecting groups (e.g. Hoc, Z and 2,4-dimethylpent-3-yloxycarbonyl[12]). The use of thiols such as butane-1,4-dithiol during the HF reaction was found to almost completely avoid this side reaction, although the Hoc group could be removed by HF without any thiol.

Hoc Group as Another Orthogonal Amino-Protecting Group in Boc Chemistry

In Boc-mediated peptide synthesis, the Boc group is used as N^{α} protection in combination with benzyl (Bzl)/cyclohexyl (Hex)-based side-chain protecting groups. Thus, the orthogonality of protecting scheme consists in the difference in reaction rate when acidolysis is used to remove different classes of protecting groups: generally TFA and HF are employed for removal of the Boc and the side-chain protecting groups, respectively. Regarding removal of the side-chain protecting groups, Bzl-based groups can be cleaved by 1M trimethylsilyl trifluoromethanesulphonate (TMSOTf)-thioanisole/TFA mixture[13] to which Hex-based groups are stable. Therefore, free amino and/or carboxyl groups protected by Bzl-based groups are available prior to cleaving Hex-based protecting groups. By taking advantage of the difference in their removability under acidic conditions, a possibility for the assembly of cyclic lactam peptides was demonstrated.[5]

Related Reagents.

2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile (BOC-ON), t-butylchloroformate (Boc-Cl), benzyl chloroformate.

O-(*N*-Succinimidyl)-1,1,3,3-tetramethyluronium Tetrafluoroborate (TSTU)

[105832-38-0] · $C_9H_{16}BF_4N_3O_3$ · (301.051)

(reagent for carboxamide formation from a carboxylic acid and a primary amine; peptide coupling reagent)

Physical Data: mp 198-201 °C.

Solubility: soluble in DMF, CH_2Cl_2, $CHCl_3$, CH_3CN (0.1 g mL^{-1}), DMF/1,4-dioxane/water (2:2:1).

Form Supplied in: colorless powder. Commercially available from Advanced ChemTech (Louisville, KY, USA), Aldrich (Milwaukee, WI, USA), and Fluka Chemical (Milwaukee, WI, USA).

Handling, Storage, and Precautions: irritant (eye, skin, respiratory tract). Avoid breathing dust, vapor, moisture, or gas. Avoid contact with skin, eyes and clothing. Moisture-sensitive. For long-term storage, keep under nitrogen atmosphere and refrigerate.

Carboxamide Formation

O-(*N*-Succinimidyl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TSTU) reacts with carboxylic acids in the presence of ≥2 equiv base to give succinimidyl active esters,[1,2] which are capable of reacting with primary amines to afford carboxamides (eq 1). The coupling reactions between carboxylic acids and primary amines with TSTU can also be performed in situ. The reaction proceeds rapidly and efficiently with only a slight excess of TSTU. The coupling reaction can be carried out even in the presence of water, such as in DMF/1,4-dioxane/water mixtures.[3] This feature allows hydrophilic amines to be derivatized with hydrophobic carboxylic acids, as demonstrated in the coupling of bathophenanthroline-ruthenium(III) complexes and 5´-amino-5´-deoxy oligonucleotides.[1]

The amino group of an amino alcohol can be selectively acylated by using TSTU without *O*-protection (eq 2).

(2)

81%

TSTU can be employed as a coupling reagent in peptide synthesis, like analogous reagents (see Related Reagents). An amino acid, of which the α-amino group is protected with a urethane-type protecting group, e.g. Boc, Cbz, or Fmoc, can be coupled without a significant level of enantiomerization or epimerization. The segment condensation with these reagents, however, causes significant levels of epimerization of the carboxy-terminal amino acid residue of the acyl component except the cases where the carboxy-terminal residue is Gly or Pro.

Peptides having a *C*-terminal *N*-methylamino acid residue are highly prone to epimerization in the segment condensation. Simultaneous use of *N*-hydroxysuccinimide and $CuCl_2$ with TSTU eliminates the epimerization of the *N*-methylamino acid residue (eq 3), whereas analogous coupling reagents, (benzotriazol-1-yl)oxytris(dimethylamino)phosphonium hexafluorophosphate (BOP) and *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), give significant levels of epimerization, even in the presence of $CuCl_2$.[4]

3,3´-PolyBINOL[1]

· $(C_{38}H_{40}O_4)_n$ · ([560.72]$_n$)

(used as an easily recyclable ligand for asymmetric Lewis acid catalysis)

Solubility: soluble in chloroform, methylene chloride, THF, and toluene. Insoluble in alcohols, H_2O, and hexane.

Form Supplied in: yellow solid.

Preparative Methods: [1,2] prepared from the Suzuki coupling of the phenylenediboronic acid[1] with the optically pure binaphthyl monomer (*R*)- or (*S*)-[2], made from optically pure 1,1´-bi-2-naphthol (BINOL), followed by acid hydrolysis. By using either $Pd(OAc)_2$ or $Pd(PPh_3)_4$ as the catalyst, 3,3´-polyBINOL was obtained with a molecular weight in the range of MW = 6700 to 24 300 (polydispersity index = 1.5-2.5) as determined by gel permeation chromatography relative to polystyrene standard. It was purified by repeated precipitation with methanol from a methylene chloride solution.

Handling, Storage, and Precautions: for long-term storage, keep in closed bottle in the absence of light.

Asymmetric Alkylzinc Addition to Aldehydes[1,2]

3,3´-PolyBINOL was used to catalyze the reaction of dialkylzincs with aldehydes to generate chiral secondary alcohols with good enantioselectivity. The reactions were normally carried out at 0 °C in toluene solution with 5 mol% (based on the repeating unit) of 3,3´-polyBINOL and 1-2 equiv of diethylzinc. The reactions of benzaldehyde and *para*-substituted benzaldehydes proceeded with up to 94% ee. The reactions of aliphatic aldehydes gave up to 83% ee. The polymer was recovered by precipitation with methanol and the recovered polymer showed the same catalytic properties as the original one. These reactions were also found to be independent of the molecular weight and molecular weight distribution of the polymer. The catalyst made of (*R*)-BINOL units gave (*R*)-alcohol products, and the (*S*)-BINOL derivative gave (*S*)-alcohols.

Asymmetric 1,3-Dipolar Cycloaddition of Nitrones to Vinyl Ethers[3]

(*R*)-3,3´-PolyBINOL in combination with $AlMe_3$ was used to catalyze the 1,3-dipolar cycloaddition of nitrones to vinyl ethers with excellent stereocontrol. The reactions were carried out at room temperature in methylene chloride in the presence of 20 mol% of (*R*)-3,3´-polyBINOL + $AlMe_3$. After precipitation and centrifugation to remove the polymer catalyst following completion of the reactions, the isoxazolidine products were essentially both chemically and enantiomerically pure. The *exo*/*endo* product ratio was generally >98:2 and the ee was 93-99%. The recovered polymer showed very similar catalytic properties as the original polymer.

R^1 = Ph, p-tolyl R^2 = Et, Bn, ^{t}Bu

Asymmetric Epoxidation of α,β-Unsaturated Ketones[4]

The zinc complex of (*R*)-3,3´-polyBINOL catalyzed the asymmetric epoxidation of α,β-unsaturated ketones. The reaction was typically conducted by first mixing 0.2 equiv of (*R*)-3,3´-polyBINOL with 0.36 equiv of diethylzinc in diethyl ether at room temperature. Then an α,β-unsaturated ketone and *t*-BuOOH (1.2 equiv) were added. The reaction mixture was then stirred at room temperature for a few hours, after which time it was quenched with 1N HCl and extracted with ethyl acetate. The polymer was recovered by precipitation with methanol from the ethyl acetate solution. The α,β-epoxyketone products were obtained with up to 97% yield and 81% ee. The diastereoselectivity was generally >99%.

Asymmetric Reduction of Ketones[5]

(*S*)-3,3´-PolyBINOL in combination with diethylzinc catalyzed the asymmetric reduction of acetophenone with catecholborane. A 5.5 mol% of the polymer were mixed with 10 mol% of diethylzinc at room temperature, and the mixture was then combined with acetophenone. Subsequently, catecholborane (1.5 equiv) was added at -30 °C. The reaction mixture was stirred at this temperature for 48 h, and quenched with 1N HCl. The polymer was recovered by precipitation with methanol. The product (*R*)-1-phenylethanol was obtained with 62% ee and 90% yield.

(*R*,*R*)-Bis(*tert*-butylmethylphosphino)methane[1]

[224618-29-5] · $C_{11}H_{26}P_2$ · (220.27)

(a chiral ligand for transition metal-catalyzed asymmetric reactions)

Alternate Name: MiniPHOS.

Physical Data: colorless oil.

Solubility: soluble most organic solvents.

Preparative Methods: phosphorus trichloride is allowed to react sequentially with alkylmagnesium chloride, methylmagnesium bromide, and BH_3-THF complex in THF to give alkyldimethylphosphine-borane. The phosphine-borane so obtained is enantioselectively deprotonated by *s*-BuLi in the presence of (-)-sparteine in Et_2O at -78 to -50°C, followed by treatment with alkyldichlorophosphine, methylmagnesium bromide, and BH_3-THF complex to give a MiniPHOS-borane complex as a diastereomixture. After removal of the *meso*-isomer by silica gel chromatography, the enantiomerically pure product is obtained by recrystallization from methanol or ethanol. The boranato group is removed by reaction with trifluoromethanesulfonic acid in toluene, followed by treatment with aqueous KOH to give the desired diphosphine **1** (eq 1).

Purification: filtered through Al_2O_3 with Et_2O elution under N_2 or Ar atmosphere.

Handling, Storage, and Precautions: stench. Undergoes oxidation to the phosphine oxide on standing in air. Usually prepared before use by deboranation of the air stable phosphine-borane.

Rhodium-Catalyzed Asymmetric Hydrogenation of Olefins.

MiniPHOS (**1**) can be used in rhodium-catalyzed asymmetric hydrogenation of olefinic compounds.[1] The complexation with rhodium is carried out by treatment of **1** with $[Rh(nbd)_2]BF_4$in THF (eq 2). The hydrogenation of α-(acylamino)acrylic derivatives proceeds at room temperature and an initial H_2 pressure of 1 or 6 atm in the presence of the 0.2 mol% MiniPHOS-Rh complex **2**. The reactions are complete within 24-48 h to afford almost enantiomerically pure α-amino acids (eq 3). Itaconic acids,[2] enamides,[3] and dehydro-β-amino acids[4] can also be hydrogenated with excellent enantioselectivity (eq 4-6).

Rhodium-Catalyzed Asymmetric Hydrosilylation of Ketones

Complex **2** is a good catalyst for catalytic asymmetric hydrosilylation of ketones (eq 7).[1] The reactions are carried out by using 1-naphthylphenylsilane at -40°C in THF in the presence of **2** (1 mol%) for 3-4 days. Several types of ketones are hydrosilylated to afford optically active alcohols after acidic work-up.
