The usual definition of the cross-modulation percentage for measurement purposes is as follows: A 100% modulated noise signal ($m_v = 1$) of amplitude v is received simultaneously with the intelligence signal in the diode-tuned RF circuit. If a 1% modulation of the signal carrier by the noise signal takes place, this amounts to a cross-modulation factor $k = 0.01$. We thus obtain for tuner diodes

$$V = 0.14 \frac{V_R + V_D}{n} \sqrt{\frac{n}{n+1}} \tag{2-98}$$

Figure 2-67 gives the graphs for this equation. In practical operation, FM and VHF/UHF tuners equipped with the tuner diodes BB121 or BB141 exhibit merely the cross-modulation caused by the BJTs or FETs employed. For bipolar transistors, $v \approx 15$–100 mV; for FETs, 100–300 mV.

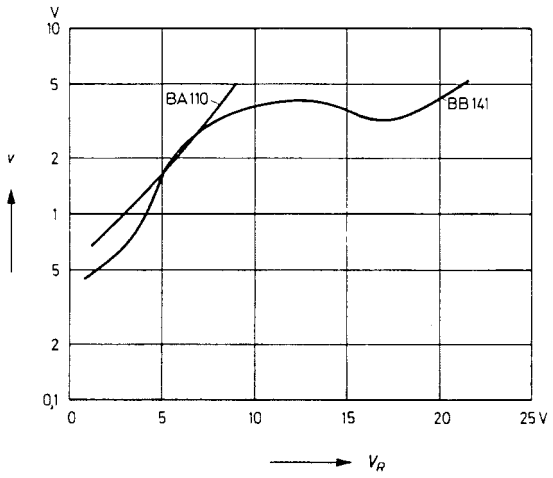

Figure 2-67 Graphical representation of Eq. (2-98).

Static Stability. To ensure trouble-free operation, the static parameters of the tuner diodes, especially the leakage current, must be taken into account. When differentiating the expression for the tuning voltage

$$V_R = V_B - I_R R_B \tag{2-99}$$

we obtain for a known leakage current I_R the tuning voltage variation

$$dV_R = dV_B - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} + dV_B \right) \tag{2-100}$$

This leads to a change in the resonant frequency

$$\frac{df}{f} = \frac{n}{2(V_R + V_D)} \left[dV_D - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} \right) + dV_B \right] \tag{2-101}$$

The resonant frequency is more stable the smaller the exponent n and the higher the tuning voltage V_R. The influence of the temperature dependence of the diffusion voltage V_D and its compensation have already been discussed. If the series bias resistance R_B is not too high, the effect of its variation ($dR_B/R_{B)}$ and the effect of the temperature dependence of the leakage current—doubling for every 10 °C temperature rise—may be neglected.

Generating the Tuning Voltage. The supply voltage V_B in Eq. (2-101) exerts an influence in many respects. The temperature coefficient of the voltage source—usually, for economic reasons, only a Zener diode is provided for stabilization—affects conditions not only with ambient temperature variations, but also when the Zener diode heats up after the set is switched on, or when its operating current varies. Because external temperature compensation of the operating voltage of the Zener diode cannot cover all detrimental effects and, moreover, increases the series bias resistance R_B, as well as any variations the latter may

undergo, the use of a temperature-compensated Zener diode, such as the 1N4065A (nominal Zener voltage, 33 V; temperature coefficient, 0.002 °C/W), is recommended.

Diode Switches. The diode switches described here differ somewhat from the switching diodes used in computer and pulse technology. Whereas in the case of switching diodes the signal itself triggers the switching operation—current does or does not pass through the switching diode depending on the signal level—diode switches allow an alternating current to be switched on or off by means of a direct voltage or a direct current. Figure 2-68 shows an example of the use of diode switches.

Diode Switch Technology. Special manufacturing techniques are needed to attain the low junction capacitance, low differential forward resistance r_F, and the low-inductance structure required for the special applications envisaged. Two conflicting requirements have to be met: On the one hand, a high-resistivity basic material should be used and the diode area should be kept as small as possible to minimize the junction capacitance for a given reverse voltage; on the other hand, the bulk resistance should be kept low. The size of the junction area, therefore, can represent only a compromise between these two requirements. To obtain a low bulk resistance R_B despite the use of high-resistivity silicon around the junction, the diodes are manufactured by the epitaxial process, characterized by a thin high-resistivity layer on a low-resistivity substrate. If the forward current I_F is sufficiently high, then the specific resistance of the epitaxial layer does not affect the bulk resistance, because under these conditions the resistivity of this layer is considerably reduced by being flooded with carriers.

The junction impedance Z_j is somewhat more critical (Figure 2-69). It is composed of the junction capacitance C_S, which does not depend on current, the current-dependent diffusion capacitance

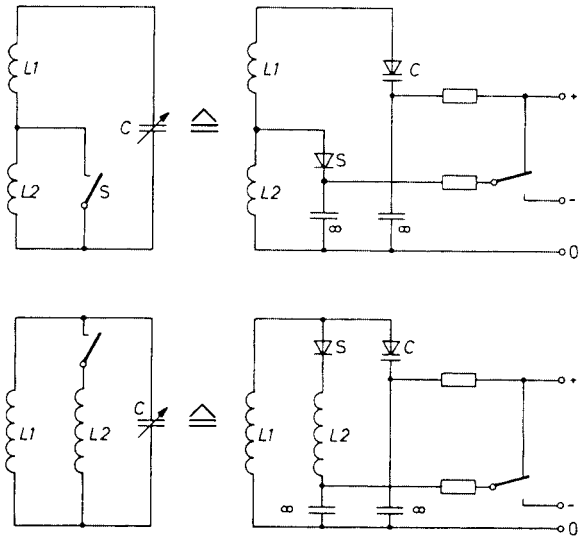

Figure 2-68 Comparison of mechanically and electronically tuned and switched resonant circuits.

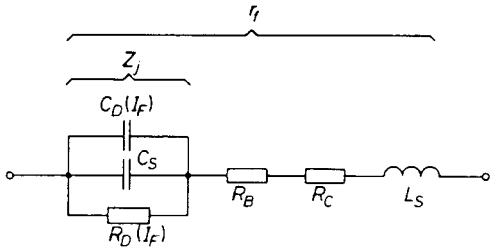

Figure 2-69 Equivalent circuit of diode switches in the frequency range from 1 MHz to 1 GHz.

$$C_D = \frac{\mathfrak{t}_p I_F}{V_T} \tag{2-102}$$

and the diffusion resistance

$$R_D = \frac{V_T}{I_F} \tag{2-103}$$

where $\mathfrak{t}_p$ is the lifetime of the minority charge carriers and

$$V_T = \frac{kT}{q} = 26 \text{ mV} \tag{2-104}$$

is the voltage equivalent of thermal energy. The resistive component of the impedance Z_j is calculated as follows:

$$\text{Re}(Z_j) = \frac{R_D}{1 + \omega^2 R_D^2 (C_S + C_D)^2} \tag{2-105}$$

As can be seen from the following approximations, this resistance becomes rather dependent on current at higher frequencies:

$$\text{For } I_F \to 0 \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega^2 C_S^2 V_T} \tag{2-106}$$

$$\text{For } I_F \to \infty \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega t_p I_F} \tag{2-107}$$

In Figure 2-70 the differential forward resistance is plotted as a function of the forward current. The only parameter by which the differential forward resistance can be reduced for a given current and a given frequency according to Eq. (2-107) is the carrier lifetime. Steps will have to be taken, therefore, to make the carrier lifetime as long as possible.

Because diode switches are designed for applications up to the gigahertz range, a geometry resulting in a low inherent capacitance and inductance had to be used. Furthermore, the device had to be assembled in such a way that virtually no additional contact resistance R_C was introduced. For this reason, a double-plug construction (hard-glass pressure contacts)

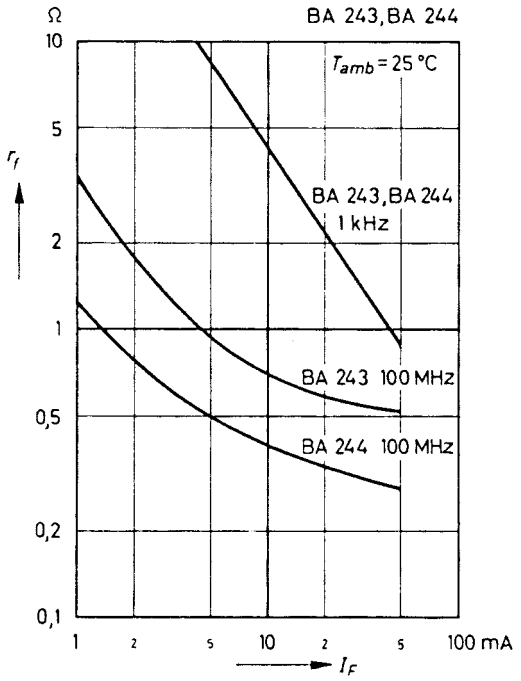

Figure 2-70 Differential forward resistance as a function of forward current.

was chosen to avoid the S- or U-bends customary with other encapsulations. The system is pressure-clamped between two stud-shaped enlargements of the connecting leads, the necessary high pressure being produced as the glass shrinks during cooling. This construction results in an encapsulation of short length (only 4 mm) and low series inductance, the advantages of which can be fully exploited because soldered connections to the leads can be made directly at the glass body.

Diode Switch Data. The silicon planar diode switches BA243 and BA244 are designed for electronic band selection in tuners in the frequency range from 10 to 1000 MHz. The differential forward resistance remains constant and is very low over a wide frequency and current range. The diode capacitance is likewise small and independent of voltage through a wide range. The devices are characterized by low-inductance geometry. The BA243 is intended for the VHF range, and the BA244 for the UHF range. See Table 2-11.

Resonant Circuits Incorporating Diode Switches. Figure 2-71 illustrates the function of the diode switch with reference to a parallel-resonant circuit whose resonant frequency can be switched by short-circuiting part of the circuit inductance. Such a switching procedure may be necessary for a VHF tuner, for example, to switch from band I to band III, because the frequencies of these bands are too far apart.

Capacitor C_K represents the capacitance of the resonant circuit. The symbol ∞ at capacitor C is meant to indicate that the value of this capacitor should be chosen to be much higher than the circuit capacitance. C completes the ac circuit when the inductor L_2 is shorted and

Table 2-11 BA243/244 specifications

Maximum Ratings			
Reverse voltage	V_R	20	V
Forward current at $T_A = 25$ °C	I_F	100	mA
Junction temperature	T_j	150	°C
Storage temperature range	T_s	–55 to +150	°C
Characteristics at $T_A = 25$ °C			
Forward voltage at $I_F = 100$ mA	V_F	<1	V
Leakage current at $V_R = 15$ V	I_R	< 100	nA
Dynamic forward resistance at $f = 50$–1000 MHz, $I_F = 10$ mA			
BA243	r_F	0.7 (< 1)	Ω
BA244	r_F	0.4 (< 0.5)	Ω
Relative variation of dynamic forward resistance with the variation of forward current in the range of $I_F + 2$–40 mA	$\frac{\Delta r_F 100}{r_F \Delta I_F}$	5	%/mA
Capacitance at $V_R = 15$ V, $f = 1$ MHz	C_{tot}	1.3 (< 2)	pF
Relative variation of capacitance with the variation of reverse voltage in the range of $V_R = 7$–20 V, $f = 100$ MHz	$\frac{\Delta C_{tot} 100}{C_{tot} \Delta V_R}$	1	%/V
Series inductance across case	L_S	2.5	nH

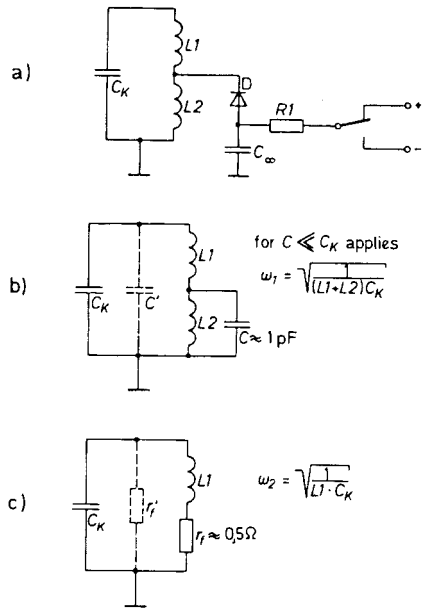

Figure 2-71 (a) Diode switch as bandswitch, shorting a partial inductance; (b) equivalent circuit with blocked diode switch; (c) equivalent circuit with conducting diode switch.

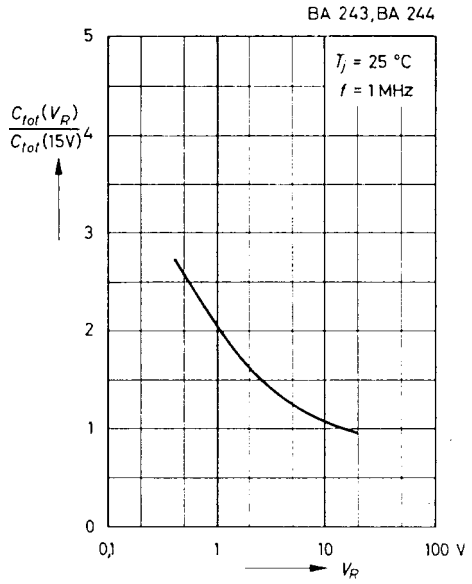

Figure 2-72 Capacitance as a function of the reverse voltage.

enables the switching or reverse voltage to be applied at a point of virtually zero RF potential. The resistor R_1 limits the diode current in the forward direction.

At a reverse voltage of $V_R = 15$ V, for example, the diode switch represents a 1-pF capacitor, as shown in Figure 2-71b. This represents parasitic capacitance C' in the circuit, which reduces the effective capacitance variation of the resonant circuit in the case of capacitive tuning. The capacitance C' is small enough to be negligible in most cases relative to the wiring and winding capacitances. Figure 2-72 shows the relative capacitance of the blocked-diode switches, as a function of the reverse voltage.

At a forward current of, for example, 10 mA, the diode has a differential resistance of approximately 0.5 Ω (see Figure 2-70). The effect of this resistance r_F on the resonant circuit is illustrated in Figure 2-71c. Conversion of a series loss resistance r_F into a parallel loss resistance r'_F is based on the following considerations: The equivalent parallel resistance r'_F affects the tuned circuit in the same way as the series resistance r_F; that is, the Q of the circuit should be the same in both cases. If one assumes that $\omega L >> r_F$, the equivalent of parallel resistance can be expressed as follows:

$$Q = \frac{\omega L_1}{r_F} = \frac{r'_F}{\omega L_1} \tag{2-108}$$

$$r'_f = \frac{(\omega L_1)^2}{r_F} \tag{2-109}$$

An evaluation of this equation shows that a differential resistance $r_F \approx 0.5$ Ω can be tolerated in most applications as regards amplification and selectivity.

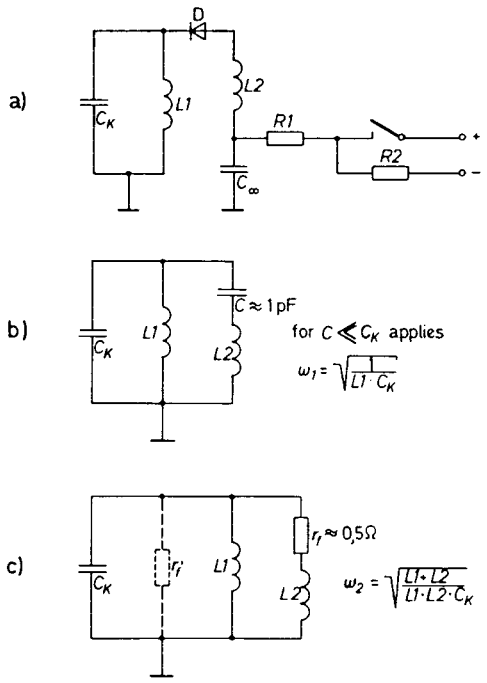

Figure 2-73 (a) Diode switch as a bandswitch, with an inductance in parallel; (b) equivalent circuit with blocked-diode switch; (c) equivalent circuit with conducting diode switch.

Instead of altering the resonant frequency of a tuned circuit by short-circuiting part of its inductance, the same result can be obtained by connecting a second inductance in parallel. The use of the diode switch for this purpose is illustrated in Figure 2-73. This differs from the one shown in Figure 2-71 in that the circuit inductance consists of either L_1 or of L_1 and L_2 in parallel. By applying a permanent negative bias to the diode via a high-value resistor R_2, it is possible to dispense with the use of one switch contact. Figure 2-73b shows the equivalent circuit for the diode under reverse-bias conditions (corresponding to a low resonant frequency), and Figure 2-73c shows the equivalent circuit under forward-bias conditions (corresponding to a higher resonant frequency).

In radio and television receivers, it usually is possible to derive the necessary reverse bias for the diode by rectification of the local oscillator signal, since the power required for blocking the diodes is extremely small. Note that under reverse-bias conditions the inductance L_2 and the capacitance C form a series-tuned acceptor circuit. However, this capacitance being extremely small, any undesirable effects due to its presence can normally be avoided. The same diode switching arrangements described for single-tuned circuits can also be employed in multisection bandpass and broadband filters.

In the following paragraph, a practical example for the use of diode switches will be given, and it will be seen that it is possible, in principle, to replace all of the mechanical RF switch contacts normally employed in receivers by diode switches. In cases where application of the diode dc potentials to a "cold" point in the circuit is not feasible, it may be necessary to apply them via *LC* or *RC* isolating networks.

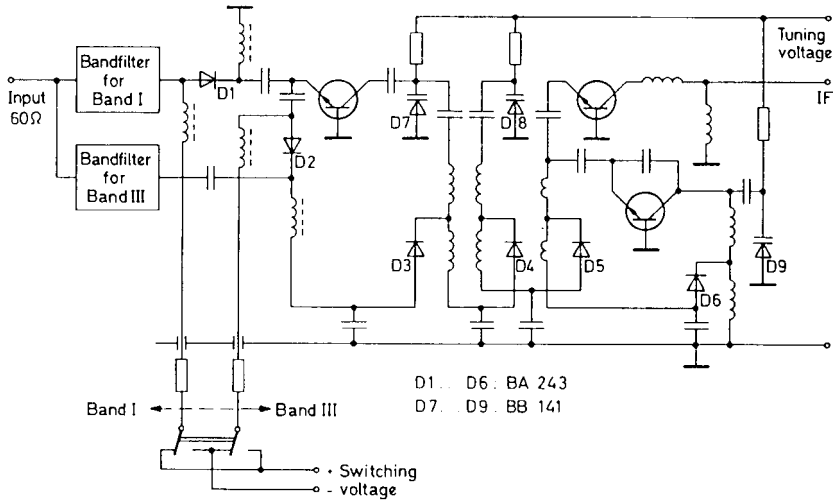

Figure 2-74 Schematic of a VHF television tuner with electronic band selection.

Use of the Diode Switch in a Television Receiver. Figure 2-74 shows the schematic of an electronically tuned and switched band I (48–62 MHz)/band III (175–224 MHz) TV tuner that requires switching of the input filter, bandpass filter, and oscillator circuit. These switching functions are performed by BA243 diode switches. As is customary in most European countries, in this example a broadband input filter between the antenna and the first RF transistor is used rather than a selective front-end circuit. In view of the need to correct noise and power matching over a relatively large frequency range, a switchable filter is employed in most tuners, switching being effected in this case by means of diodes D_1 and D_2.

Diodes D_3–D_6 are used for band-filter switching, for switching the coupling to the mixer transistor, and for switching the oscillator frequency. To minimize the bias-current requirements (each diode requires a bias current of approximately 10 mA), all diodes that are to be activated at the same time are connected in series. This arrangement requires only a few additional RF chokes, which are easily provided because of the high frequencies involved. The direct current required for the diode switches could be obtained by simple rectification, for example, from the heater circuit of the television receiver CRT, and the diode reverse bias could be obtained by rectification of the local oscillator signal, in which case the minute additional power requirement would have to be allowed for in the oscillator design.

A technically sophisticated design for a television tuner takes the form of a combined VHF/UHF unit incorporating electronically switched circuits in which several elements would be common. Such an all-band tuner can be assembled from only three transistors and a combined VHF/UHF band filter in $\lambda/2$ or $\lambda/4$ technology for UHF reception. The VHF circuits are short-circuited when the UHF position is selected.

Multistandard TV receivers require a large number of switch contacts in the tuner, the IF amplifier, the video amplifier, and the time base. The use of diode switches is particularly advantageous in this situation because it renders the physical layout of the equipment virtually independent of the location of the controls and obviates the need for long RF cable runs, which may be prone to interference.

2-2 BIPOLAR TRANSISTORS

2-2-1 Transistor Structure Types

All current RF silicon transistors are of the bipolar *npn* planar epitaxial type. Briefly, the significance of each of these terms is as follows.

Bipolar. In its broadest sense, it is the basic structure shown schematically in Figure 2-75, that is, the familiar three-semiconductor-region structure. *Bipolar* specifically means that the charge carriers of both negative (electron) and positive (hole) polarities are involved in the transistor action. In way of contrast, unipolar types include the junction-gate and insulated-gate field-effect transistors, which are basically one- or two-semiconductor-region structures in which carriers of a single polarity dominate.

npn. This abbreviation is for *negative–positive–negative* and identifies the regions of the structure as to polarity of the dominant or majority carrier in each region. The other polarity type is *pnp*. (See Figure 2-75.)

Silicon. Silicon (Si) is one of two elements from the fourth column of the periodic table that are in widespread use for transistor fabrication [the other is germanium (Ge)]. Other materials used include the compound gallium arsenide (GaAs). Although silicon is in predominant use because it results in the most favorable compromise among high-frequency, high-temperature, high-reliability, and ease-of-use attributes of the usable semiconductor material, silicon–germanium (SiGe) technology is increasingly important because it affords high-frequency performance unachievable with silicon alone.

Planar. The term planar denotes that both emitter–base and base–collector junctions of the transistor intersect the device surface in a common plane (hence, a better term might be *coplanar*). However, the real significance of the so-called planar structure is that the technique of diffusing dopants through an oxide mask, used in fabricating such a structure, results in junctions being formed beneath a protective oxide layer. These protected junctions are less prone to the surface problems sometimes associated with other types of structures, such as the mesa.

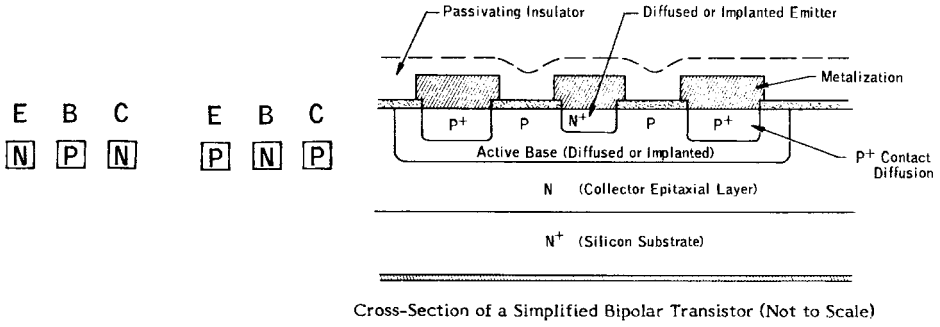

Figure 2-75 Transistor structure schematic.

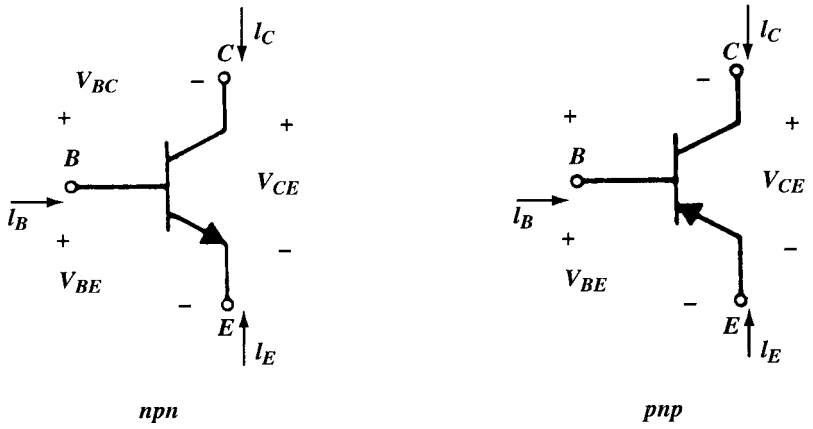

Figure 2-76 Bipolar transistor sign convention.

Epitaxial. This term, as it is commonly used, is actually a shortening of the term *epitaxial-collector*. That is, the collector region of the transistor is formed by the epitaxial technique, rather than by diffusion, which is commonly used to form the base and emitter regions. The epitaxial layer is formed by condensing a single-crystal film of semiconductor material on a wafer or substrate that is usually of the same material. Thus, an epitaxial (collector) transistor is one in which the collector region is formed on a low-resistivity substrate. Subsequently, the base and emitter regions are diffused into the "epi" layer. The epitaxial technique lends itself to precise tailoring of collector-region thickness and resistivity with consequent improved device performance and uniformity.

2-2-2 Large-Signal Behavior of Bipolar Transistors*

In this section, the large-signal or dc behavior of bipolar transistors is considered. Large-signal models are developed for the calculation of total currents and voltages in transistor circuits, and such effects as breakdown-voltage limitations, which are usually not included in models, are also considered. Second-order effects, such as current-gain variation with collector current and Early voltage, can be important in many circuits and are treated in detail.

The sign conventions used for bipolar transistor currents and voltages are shown in Figure 2-76. All bias currents for both *npn* and *pnp* transistors are assumed positive going into the device.

Electrical and Performance Characteristics and Specifications. Electrical characteristics may be described as uniquely defined, measurable electrical transistor properties that are not a function of the measuring circuit or apparatus (except insofar as standard terminations and measurement accuracy are concerned). Performance or operating characteristics are also electrical properties but they are, in general, not unique because their values depend on the measuring circuit (in particular, source and load impedance, which may be arbitrary). As might be expected, the terms are often used somewhat loosely (and sometimes

* Portions of this section, Sections 2-2-3 through 2-2-5, and Sections 2-3-3 through 2-3-6 are based on Paul R. Gray and Robert G. Meyer, *Analysis and Design of Analog Integrated Circuits*, 3rd ed., ©1993 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

interchangeably), especially in cases where only subtle differences are involved. The terms are generally used on transistor datasheets to segregate (for emphasis) under performance or operating characteristics those properties most directly applicable to the primary intended application.

Performance (Operating) Characteristics. Of the numerous performance characteristics that can be specified for high-frequency transistors, perhaps the most fundamental and pertinent characteristics are:

- Power gain and noise figure, for small-signal applications
- Power gain, power output, and efficiency, for large-signal applications

All of these characteristics are, of course, functions of frequency, bias temperature, and so on, and to completely characterize a transistor over its full frequency, bias, and temperature ranges would be prohibitively costly. Consequently, characterization data are given only for restricted ranges of these variables. These data should portray sufficiently the capabilities of a particular device for its intended applications. In the case of maximum ratings, some applications may require additional characterization by the user or through applications assistance from the manufacturer.

POWER GAIN

G_{max}. Of the various definitions for the measurement of power flow in an active two-port device, such as a transistor, two are unique enough to allow specification without recourse to specifying the complete measuring circuit in detail. One of these definitions is termed *maximum available gain* (G_{max}) and is the power gain obtained when the input and output ports are simultaneously conjugately matched to source and load impedances, respectively. Implicit in this definition is the assumption that the two-port is unconditionally stable; that is, that no combination of input/output tuning can result in increasing gain to the point of oscillation.

$|S_{21}|^2$. The other unique power gain is the gain realized when the transistor is inserted between a source and load with identical impedances (in practice, usually $50 + j0\ \Omega$). This particular insertion of transducer gain happens to coincide with the usual definition of the two-port forward scattering parameter, S_{21}. More precisely, it is equal to the magnitude squared of this parameter and is therefore often identified by the symbol $|S_{21}|^2$. For wideband applications, $|S_{21}|^2$ is important because wideband terminations "not too different from 50 Ω" are more easily realized than are wideband transforming networks that provide the matching required for G_{max}.

NOISE FIGURE. A common measure of the noise generated by an active two-port device—noise that sets a lower limit on amplifier sensitivity—is noise factor (F). This is defined as

$$F = \frac{\text{Input signal-to-noise ratio}}{\text{Output signal-to-noise ratio}} \tag{2-110}$$

or more generally as

$$F = \frac{\text{Total output noise power}}{\text{Output power due to source resistance}} \tag{2-111}$$

At high frequencies, spot noise factor or noise factor for a small fractional bandwidth (say, 1%) is used and is usually expressed as *noise figure* (*NF*), in decibels:

$$NF = 10 \log F \tag{2-112}$$

As already discussed, noise figure is a function of source impedance (as well as functions of frequency, bias, etc.) and hence, there is an infinity of noise figures associated with a given device corresponding to the infinity of possible impedances that may be presented to the device input. The only unique one, in the sense that it does not involve arbitrary source impedances, is $NF_{\min}$, the minimum noise figure obtained (at a given bias and frequency) when the input is tuned to optimize this parameter. This is the noise figure value commonly given on datasheets.

In practical amplifiers that involve more than one stage, *overall noise factor* (F_O) is given by

$$F_O = F_1 + \frac{F_2 - 1}{G_1} + \cdots + \frac{F_n - 1}{G_{(n-1)}} \tag{2-113}$$

where n = number of stages
G_n = gain of the nth stage
F_n = noise factor of the nth stage

This expression emphasizes the important fact that for low-noise amplifiers, the first stage must be designed for the lowest noise figure and highest gain possible. [Note that the noise contribution of the second stage is divided (reduced) by the gain of the first stage.] Since the optimum source impedance and bias currents for optimum gain and noise figure do not often coincide, very careful circuit design is required to minimize overall noise figure. For more accuracy, we recommend the noise correlation approach.

POWER OUTPUT. This characteristic is important for both amplifier and oscillator transistors. In both cases, it is extremely circuit sensitive. For amplifiers, maximum useful output is often limited to that power output level at which gain has compressed 1 dB, an indicator of the upper limit of the device's linearity range. For oscillators, it is merely a quantitative measure of RF power for given dc input power.

EFFICIENCY. In the most general sense, this characteristic expresses as a percentage the ratio of RF power output to the total circuit input power, both dc and RF. That expression is efficiency, η, defined as

$$\eta = \frac{P_O}{P_i + P_{\text{dc}}} \times 100 \tag{2-114}$$

where P_O = RF output power
P_i = RF input power
P_{dc} = total dc power input

Since for oscillator transistors there is no RF power input, and for amplifier transistors the maximum input RF power is calculable from the power gain and power output specifications,

the inclusion of P_i in efficiency is redundant. Moreover, since the major portion of the dc power is dissipated by the transistor collector, a more restricted definition of efficiency is pertinent. This parameter, termed *collector efficiency* (η_C), is given by

$$\eta_C = \frac{P_O}{P_{CC}} \times 100 \tag{2-115}$$

where $P_{CC} = V_{CC} \times I_{CC}$
V_{CC} = collector supply voltage
I_{CC} = collector supply current

Electrical Characteristics. Electrical characteristics may be conveniently classified into two main types, dc and ac.

dc CHARACTERISTICS. The importance of dc characteristics of high-frequency transistors lies primarily in biasing and reliability considerations. However, certain dc characteristics are also directly related to high-frequency performance. For example, high-frequency noise figure is affected by dc current gain. The dc characteristics discussed here are those usually found on high-frequency transistor datasheets.

$V_{(BR)CBO}$, I_{CBO}. These two parameters serve to characterize the reverse-biased collector–base *pn* junction and are defined as follows (with the aid of Figure 2-77a). The collector–base breakdown voltage, $V_{(BR)CBO}$, identifies the voltage at which collector current tends to increase without limit, usually due to the high electric field developed across the junction. This voltage sets a limit on the maximum transistor operating voltage and, as mentioned before under maximum ratings, usually is the basis for the collector–base maximum voltage rating. $V_{(BR)CBO}$ should be specified at a value of $I_C = I_{C1}$ in the figure, which is within the avalanche (or high slope) region of the device's reverse characteristic. Typical values of I_{C1} are in the 1–10-μA region for high-frequency transistors.

To further define the quality of the reverse *I–V* characteristic, a specification is usually placed on the collector cutoff current, I_{CBO}, which is measured at some value of collector–base voltage less than $V_{(BR)CBO}$. For a good-quality silicon junction ("sharp" instead of soft; see Figure 2-77a), I_{CBO} is in the nanoampere range.

$V_{(BR)EBO}$, I_{EBO}. These two parameters characterize the reverse-biased emitter–base *pn* junction in an analogous manner to the collector–base junction parameters $V_{(BR)CBO}$ and I_{CBO}, given above, and are shown in Figure 2-77b. No further discussion of these parameters will be given here.

$V_{(BR)CEO}$, I_{CEO}. The collector–emitter breakdown voltage and cutoff current are somewhat more complex in nature than the collector–base and emitter–base parameters. In the latter two, only a single *pn* diode is involved. In the collector–emitter case, two diodes are involved. Moreover, each is influenced by the other through transistor action, since the reverse current of the collector–base diode flows through the emitter–base junction as forward current. Thus, the collector–base reverse current is amplified by the dc current gain of the transistor, resulting in:

- I_{CEO} being greater than I_{CBO} (for a given voltage)
- Typically, the familiar negative-resistance region in the *I–V* characteristic as shown in Figure 2-77c.

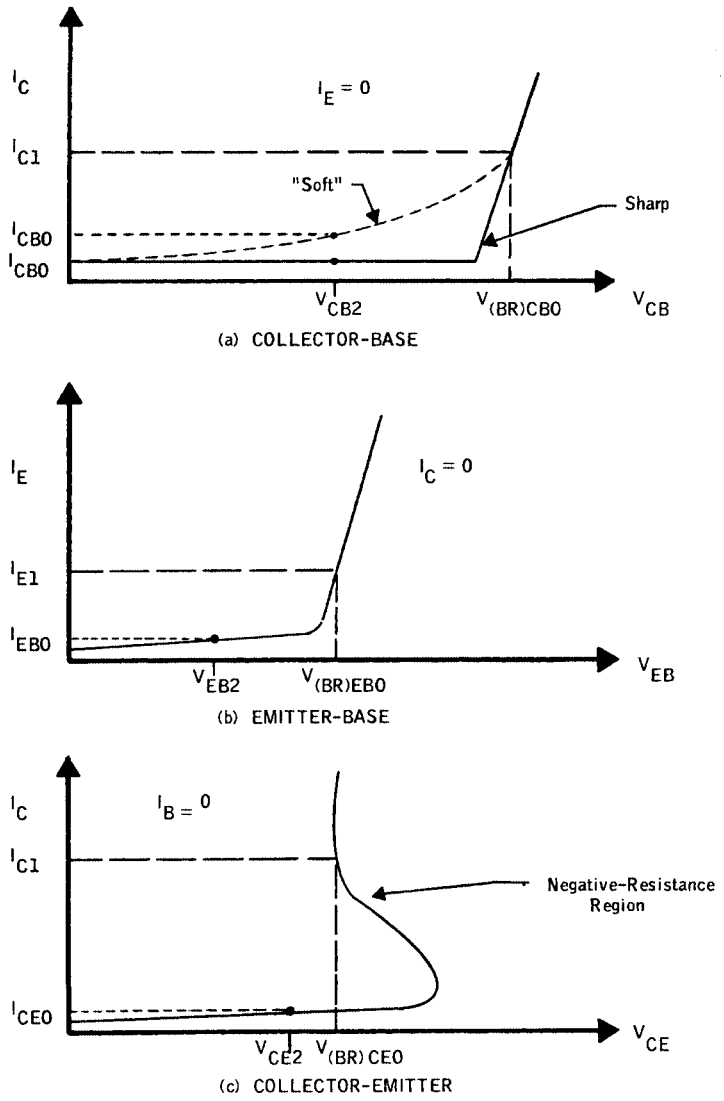

Figure 2-77 Transistor reverse *I–V* characteristics.

Consequently, $V_{(BR)CEO}$ is typically specified at collector currents one to three orders of magnitude higher than in the case of $V_{(BR)CBO}$ and $V_{(BR)EBO}$ to establish the minimum value of this characteristic.

h_{fe}. This parameter is simply the dc common-emitter current gain; that is, the ratio of collector current to base current at some specified collector voltage and current.

ac CHARACTERISTICS. Of the numerous ac characteristics defined for transistors, only relatively few are commonly used in characterizing high-frequency transistors. Some of the more pertinent parameters are briefly covered here.

S Parameters. By far the most useful and conveniently measured set of two-port parameters for transistor high-frequency (roughly 100 MHz and above) characterization is

the *S*-parameter or scattering-matrix set. These parameters completely and uniquely define the small-signal gain and input/output immittance properties of any linear "black box." (By definition, a transistor or any active device is linear under small-signal conditions.) However, these parameters reveal nothing (except possibly indirectly and approximately) about large-signal or noise behavior. Simply interpreted (more general definitions and other interpretations abound in the technical literature), the *S* parameters are merely insertion gains, forward and reverse, and reflection coefficients, input and output, with driven and nondriven ports both terminated in equal impedances, usually $50 + j0\ \Omega$. Such an interpretation tends to make *S* parameters very attractive, once some familiarity is gained, at high (especially microwave) frequencies, since the power flow or gain and reflection-coefficient concepts are more intuitively meaningful than voltage and current conceptual schemes. It should also be mentioned that *S*-parameters can be converted through straightforward matrix transformations to other two-port parameter sets, such as *h*-, *y*-, and *z*-parameters.

Proceeding with more specific definitions, the *S*-parameters are defined analytically by

$$b_1 = S_{11}a_1 + S_{12}a_2 \tag{2-116}$$

$$b_2 = S_{21}a_1 + S_{22}a_2 \tag{2-117}$$

or, in matrix form,

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} \tag{2-118}$$

where, referring to Figure 2-78

a_1 = (incoming power at Port 1)$^{1/2}$
b_1 = (outgoing power at Port 1)$^{1/2}$
a_2 = (incoming power at Port 2)$^{1/2}$
b_2 = (outgoing power at Port 2)$^{1/2}$
E_1, E_2 = electrical stimuli at Port 1, Port 2

From the figure and defining linear equations, for $E_2 = 0$, then $a_2 = 0$, and (skipping through numerous rigorous steps)

$$S_{11} = \frac{b_1}{a_1}$$

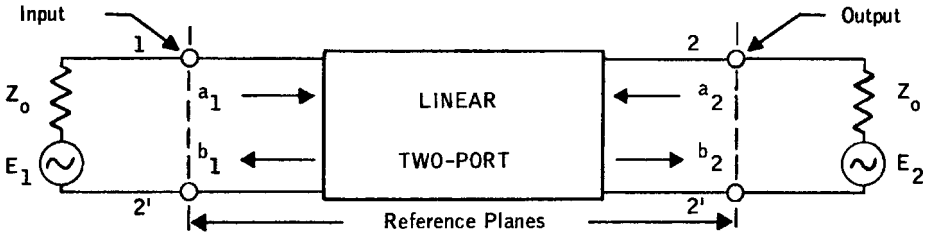

Figure 2-78 Two-port *S*-parameter definition.

$$= \left(\frac{\text{Outgoing input power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \frac{\text{Reflected voltage}}{\text{Incident voltage}}$$

$$= \text{Input reflection coefficient} \tag{2-119}$$

$$S_{21} = \frac{b_2}{a_1}$$

$$= \left(\frac{\text{Outgoing output power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \left(\frac{\text{Output power}}{\text{Available input power}}\right)^{1/2}$$

$$= (\text{Forward transducer gain})^{1/2} \tag{2-120}$$

or, more precisely in the case of S_{21}:

$$\text{Forward transducer gain} = G_{\text{TF}} = |S_{21}|^2 \tag{2-121}$$

$$Z_i = Z_o \tag{2-122}$$

Similarly, at Port 2 for $E_1 = 0$, then $a_1 = 0$, and

$$S_{22} = \frac{b_2}{a_2} = \text{Output reflection coefficient} \tag{2-123}$$

$$S_{12} = \frac{b_1}{a_2} = (\text{Reverse transducer gain})^{1/2} \tag{2-124}$$

$$G_{\text{TR}} = |S_{12}|^2 \tag{2-125}$$

Since many measurement systems display *S*-parameter magnitudes in decibels, the following relationships are particularly useful:

$$|S_{11}|_{\text{dB}} = 10\log|S_{11}|^2$$

$$= 20\log|S_{11}| \tag{2-126}$$

$$|S_{22}|_{\text{dB}} = 20\log|S_{22}| \tag{2-127}$$

$$|S_{12}|_{dB} = 10 \log|S_{12}|^2$$

$$= 20 \log|S_{12}|$$

$$= 10 \log|G_{TR}| = |G_{TR}|_{dB} \tag{2-129}$$

Figure 2-79 shows an example of the use of *S* parameters in transistor stage design.

Transition Frequency. One of the better known, but perhaps least understood, figures of merit for high-frequency transistors is the so-called transition frequency, f_T. Part of the misunderstanding that appears to exist is due to the use of the misleading (but common, for

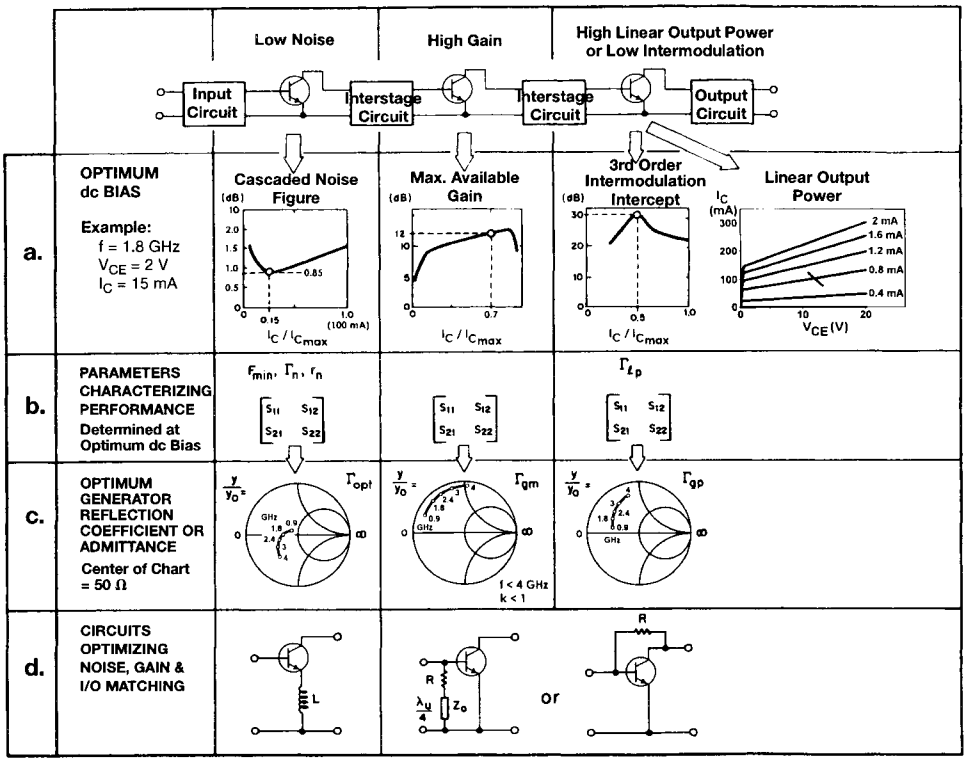

Figure 2-79 Key parameters in applying a BJT in low-noise front-end, high-gain, and linear-power stages. (a) The BJT characteristics that lead to optimum dc bias for a low-noise front end; (b) parameters characterizing device performance; (c) Γ_{opt} for the first stage, and S_{11} and S_{22} for the output stage as simulated by CAD software. The example is based on the Siemens BJTs BFP420 (low-noise stage), BFP450 (high-gain stage), and BFG235 (output stage). Circuits to optimize stage noise, gain, and I/O matching are shown in (d). (Presentation based on Figure 14 in Charles A. Liechti, "Microwave Field-Effect Transistors—1976," *IEEE Trans. Microwave Theory Tech.,* vol. MTT-24, pp. 279–300, June 1976.)

historical reasons) term *short-circuit gain–bandwidth product* for this parameter. By definition, f_T is that characteristic frequency described by the equation

$$f_T = h_{fe} \times f_{\text{meas}} \tag{2-130}$$

where h_{fe} is the magnitude of the small-signal common-emitter short-circuit current gain, and f_{meas} is the frequency of measurement, chosen such that

$$2 \le h_{fe} \le \frac{h_{fe0}}{2} \tag{2-131}$$

where h_{fe0} is the low-frequency value of h_{fe}.

To varying degrees of approximation, depending on the transistor type, f_T is the frequency at which h_{fe} approximates unity. It is not, in general, the frequency at which h_{fe} is precisely equal to unity. To clarify these points further, consider the plot of h_{fe} against frequency sketched in Figure 2-80.

At low frequencies, $f << f_B$, h_{fe} is constant and equal to h_{fe0}.

At f_B, h_{fe} has decreased to 0.707 h_{fe0}; that is, f_B is the 3-dB cutoff frequency for common-emitter short-circuit current gain, h_{fe}.

For frequencies such that

$$2f_B < f < f_T \tag{2-132}$$

h_{fe} varies inversely proportional to frequency. That is, the f_T defining relationship holds:

$$h_{fe} \times f_{\text{meas}} = \text{constant} = f_T \tag{2-133}$$

At frequencies approaching f_T, other parameters, especially package parasitics, can cause $|h_{fe}|$ to depart significantly from this $1/f$ variation. Therefore, the frequency, f_1, at which $|h_{fe}|$ actually equals unity can be somewhat different from f_T.

Applying these frequency-gain characteristics to the common-emitter wideband, low-pass amplifiers gives rise to the terminology of f_T being a "gain–bandwidth product." However,

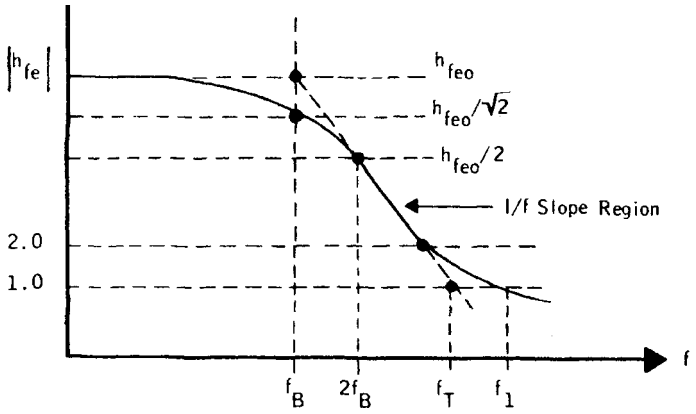

Figure 2-80 $|h_{fe}|$ frequency characteristics.

this is an optimistic approximation at best, since the product of low-frequency circuit gain and the 3-dB cutoff frequency is reduced from f_T by an amount that depends on circuit impedances.

The real significance of f_T lies in the fact that it is a measure of certain internal transistor parameters that do, in fact, affect high-frequency performance: for example, gain (though not in the convenient quantitative manner implied by the term "gain–bandwidth product"). In particular, good high-frequency noise performance requires that f_T be high. Thus, f_T is included on transistor datasheets primarily as a figure of merit, not as a parameter to be used directly in design.

Collector–Base Time Constant, $r_b'C_c$. This is an internal device parameter that relates only indirectly to high-frequency performance. It is primarily a measure of internal feedback within the transistor. It also relates to transistor high-frequency impedance. As the name says (in symbols), it is a measure of transistor base resistance and collector capacitance in combination; however, except for certain low-frequency transistors, it cannot be considered the simple two-element lumped *RC* time constant implied by the terminology. (In high-frequency transistors, base resistance and collector impedance must be considered to be distributed when considered in detail). As a figure of merit, it is included on transistor datasheets to indicate how well base resistance and collector impedance have been minimized. It also allows the estimation of certain gain properties of the transistor (see the $f_{\max}$ parameter, which we'll describe shortly).

Collector–Base Capacitance, C_{cb}. This parameter is simply the total collector–base *pn* junction capacitance measured at a low frequency (typically, 1 MHz), where it can be considered a single lumped element. For high-frequency transistors it is, of course, desirable that C_{cb} be small from bandwidth and stability considerations as well as from gain considerations alone.

Maximum Frequency of Oscillation, $f_{\max}$. This is another figure-of-merit parameter, as opposed to measurable parameters directly usable in the application of transistors. Its importance stems from the following approximate relationships (which will not be derived here):

$$f_{\max} \approx \left(\frac{f_T}{8\pi r_b' C_C} \right)^{1/2} \tag{2-134}$$

$$G_{\max} \approx \left(\frac{f_{\max}}{f_{\text{oper}}} \right)^2 \tag{2-135}$$

These expressions illustrate in a quantitative way the importance and the interrelationship between high f_T and low $r_b'C_C$ insofar as high-frequency gain is concerned. However, since they are approximations and since their derivation involves several assumptions that are not always valid, they must be interpreted with caution. For example, the expression for $G_{\max}$ is obviously not applicable at low frequencies, since as $f \to 0$, $G_{\max} \to \infty$, according to this expression. As a rule of thumb, the $G_{\max}$ expression is a reasonable approximation for frequencies such that

$$5 > \frac{f_{\max}}{f_{\text{oper}}} > 1 \tag{2-136}$$

For accurate analysis of transistor gain and stability, a complete set of two-port parameters must be employed in exact expressions, such as those from which the approximations shown above were derived.

Datasheet Transistor Specifications. The following is a reprint of a Siemens microwave transistor datasheet. This 25-GHz f_T transistor will soon be replaced by a 40-GHz family, based on a silicon–germanium design. Key parameters describing the transistor are:

- The dc parameters, such as maximum current and voltage and dissipation
- Noise figure as a function of generator impedance, bias point, and frequency
- Frequency-dependent behavior, typically expressed in *S* parameters, and also as a function of bias point and frequency
- Large-signal performance to be calculated based on a nonlinear model, such as the Gummel–Poon

The transistor description typically gives details about packaging, as the Gummel–Poon model is intrinsic (without parasitics). Not only does the package determine the parasitics, it also affects the device's ability to transfer heat to its heat sink. The following figures, reproduced with permission from the datasheet for the BFP420 transistor by Siemens (now Infineon Technologies), are a typical representation of the dc-I_C curves, *S* parameters, and noise parameters of a normal, packaged microwave transistor. Besides its dc parameters and capacitance, there are other critical parameters. A BJT's noise figure is a strong function of its dc current gain, and one can determine a 3-dB cutoff frequency referred to as f_T, which shows the gain roll-off as a function of collector current and frequency. Another important measure or figure of merit is $f_{\max}$, the maximum frequency of oscillation:

$$f_{\max} = \sqrt{\frac{|Y_{21}|}{16\pi R_{bb} C_{be} C_{bc}}} \tag{2-137}$$

Figure 2-81 shows a photograph of the die for the BFP420.

Since the intercept point is an important figure of merit, Figure 2-82 shows intercept point as a function of bias point for the BFR93AW BJT. We wish more manufacturers would supply this information.

2-2-3 Large-Signal Transistors in the Forward-Active Region

We saw in the diode case that its description is physics-based and it is, therefore, logical to apply the same modeling for the transistors. The first complete modeling for transistors was described in the Gummel–Poon model, but many engineers use the somewhat more simpler Ebers–Moll model. By combining two diodes, the parasitic elements, and the base separating resistor, we can show the "intrinsic" nonlinear model for the bipolar transistor.

Many equations that have been published contain some approximations, but for exact nonlinear analysis, we have to resort to the somewhat more complex or complete equations as shown in Appendix A for the bipolar model.

Recently, some other models have been proposed by researchers, such as the MEXTRAM models (Philips), but the trouble with these models is that while they may give quite good results for RF applications, it is virtually impossible to obtain parameters for them. So far the only industry-standard model is the Gummel–Poon, and to the authors' knowledge there

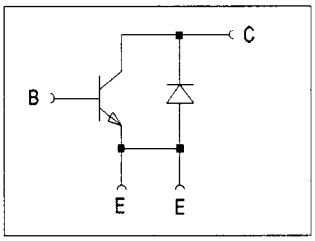
For non-linear simulation:

- Use transistor chip parameters in Berkeley SPICE 2G.6 syntax for all simulators.
- If you need simulation of the reverse characteristics, add the diode with the C'-E'-diode data between collector and emitter.
- Simulation of the package is not necessary for frequencies < 100 MHz.
  For higher frequencies add the wiring of the package equivalent circuit around the non-linear transistor and diode model.

Note:

- This transistor is constructed in a common emitter configuration. This feature causes an additional, reverse biased diode between emitter and collector, which does not effect normal operation.



Transistor Schematic Diagram

The common emitter configuration shows the following advantages:

- Higher gain because of lower emitter inductance.
- Power is dissipated via the grounded emitter leads, because the chip is mounted on the copper emitter leadframe.

Please note, that the broadest lead is the emitter lead.

- The AC-Characteristics are verified by random sampling.

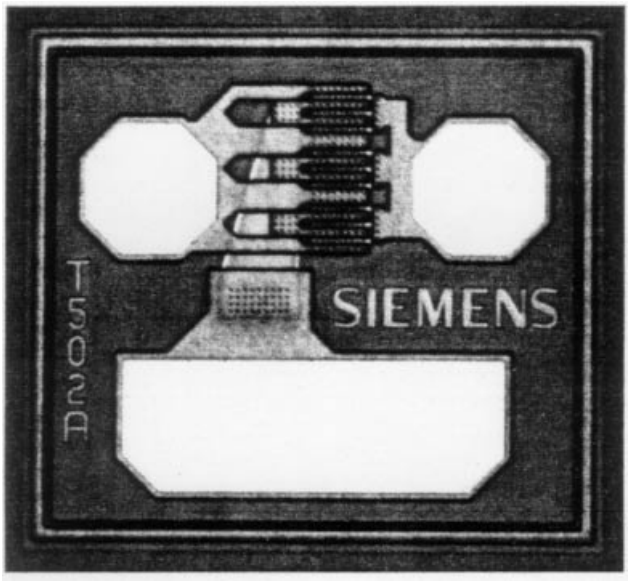


Figure 2-81 Photograph of the BFP420 die (310 × 290 μm). The bonding pad for the base is at the upper right; for the collector at the upper left. The large, lower pad connects to the emitter.

are no accepted or affordable parameter extractor programs available, not even to consider the cost of hardware for such extractions. Hewlett-Packard recently published a system with a hardware cost in the vicinity of $1 million.

A typical *npn* planar bipolar transistor structure is shown in Figure 2-83a, where collector, base, and emitter are labeled *C*, *B*, and *E*, respectively. The impurity doping density in the base and the emitter of such a transistor is not constant but varies with distance from the top surface. However, many of the characteristics of such a device can be predicted by analyzing

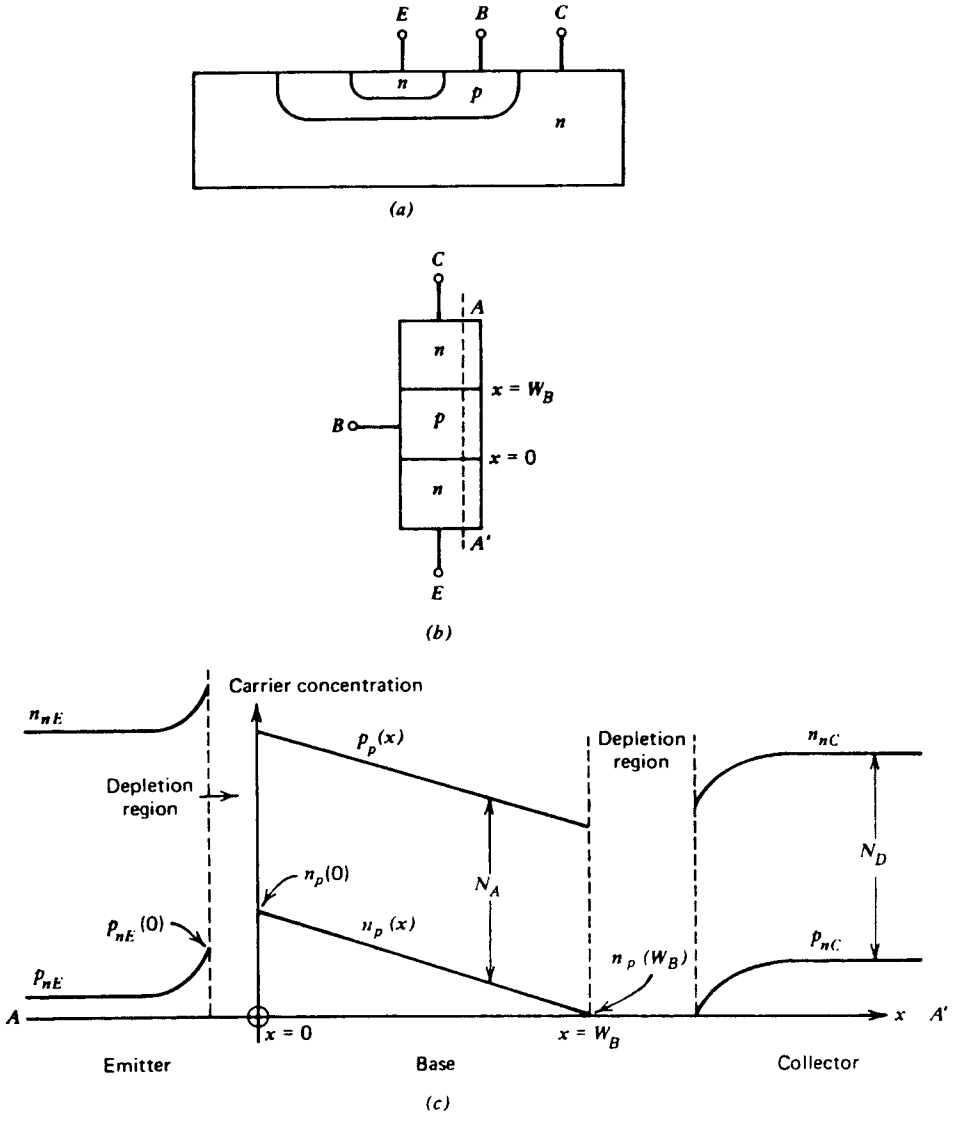

Figure 2-83 (a) Cross section of a typical *npn* planar bipolar transistor structure; (b) idealized transistor structure; (*c*) carrier concentrations along the cross section *AA*′ of the transistor in (b). Uniform doping densities are assumed. (Not to scale)

the idealized transistor structure shown in Figure 2-83b. In this structure, the base and emitter doping densities are assumed constant, and this is sometimes called a "uniform-base" transistor. Where possible in the following analyses, the equations for the uniform-base analysis are expressed in a form that applies also to nonuniform-base transistors.

A cross section AA' is taken through the device of Figure 2-83b and carrier concentrations along this section are plotted in Figure 2-83c. Hole concentrations are denoted by p and electron concentrations by n with subscripts p or n representing p-type or n-type regions. The n-type emitter and collector regions are distinguished by subscripts E and C, respectively. The carrier concentrations shown in Figure 2-83c apply to a device in the *forward-active region*. That is, the base–emitter junction is forward-biased and the base–collector junction is reverse-biased. The minority-carrier concentrations in the base at the edges of the depletion regions can be calculated from a Boltzmann approximation to the Fermi–Dirac distribution function to give [2]

$$n_p(0) = n_{po} \exp \frac{V_{BE}}{V_T} \tag{2-138}$$

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \simeq 0 \tag{2-139}$$

where W_B is the width of the base from the base–emitter junction depletion layer edge of the base–collector depletion layer edge and n_{po} is the equilibrium concentration of electrons in the base. Note that V_{BC} is negative for an *npn* transistor in the forward-active region and thus $n_p(W_B)$ is very small. Low-level injection conditions are assumed in the derivation of Eqs. (2-138) and (2-139). This means that the minority-carrier concentrations are always assumed much smaller than the majority-carrier concentrations.

If *recombination* of holes and electrons in the base is small, it can be shown that the minority-carrier concentration $n_p(x)$ in the base varies *linearly* with distance [3]. Thus, a straight line can be drawn joining the concentrations at $x = 0$ and $x = W_B$ in Figure 2-83c.

For charge neutrality in the base, it is necessary that

$$N_A + n_p(x) = p_p(x) \tag{2-140}$$

and thus

$$p_p(x) - n_p(x) = N_A \tag{2-141}$$

where $p_p(x)$ is the hole concentration in the base and N_A is the base doping density that is assumed constant. Equation (2-141) indicates that the hole and electron concentrations are separated by a constant amount and thus $p_p(x)$ also varies linearly with distance.

Collector current is produced by minority-carrier electrons in the base diffusing in the direction of the concentration gradient and being swept across the collector–base depletion region by the field existing there. The diffusion current density due to electrons in the base is

$$J_n = qD_n \frac{dn_p(x)}{dx} \tag{2-142}$$

where D_n is the diffusion constant for electrons. From Figure 2-83c,

$$J_n = -qD_n \frac{n_p(0)}{W_B} \tag{2-143}$$

If I_C is the collector current and is taken as positive flowing *into* the collector, it follows from Eq. (2-143) that

$$I_C = qA D_n \frac{n_p(0)}{W_B} \tag{2-144}$$

where A is the cross-sectional area of the emitter. Substitution of Eq. (2-138) into Eq. (2-144) gives

$$I_C = \frac{qAD_n n_{po}}{W_B} \exp \frac{V_{BE}}{V_T} \tag{2-145}$$

$$= I_S \exp \frac{V_{BE}}{V_T} \tag{2-146}$$

where

$$I_S = \frac{qA D_n n_{po}}{W_B} \tag{2-147}$$

and I_S is a constant used to describe the transfer characteristic of the transistor in the forward-active region. Equation (2-147) can be expressed in terms of the base doping density by noting that [4]

$$n_{po} = \frac{n_i^2}{N_A} \tag{2-148}$$

and substitution of Eq. (2-148) in Eq. (2-147) gives

$$I_S = \frac{qAD_n n_i^2}{W_B N_A} = \frac{qA\overline{D}_n n_i^2}{Q_B} \tag{2-149}$$

where $Q_B = W_B N_A$ is the number of doping atoms in the base per unit area of the emitter and n_i is the intrinsic carrier concentration in silicon. In this form Eq. (2-149) applies to both uniform- and nonuniform-base transistors and D_n has been replaced by $\overline{D}_n$, which is an average effective value of the electron diffusion constant in the base. This is necessary for nonuniform-base devices because the diffusion constant is a function of impurity concentration. Typical values of I_S as given by Eq. (2-149) are 10^{-14} to 10^{-16} A.

Equation (2-146) gives the collector current as a function of base–emitter voltage. The base current I_B is also an important parameter and, at moderate current levels, consists of two major components. One of these (I_{B1}) represents recombination of holes and electrons in the base and is proportional to the minority-carrier charge Q_e in the base. From Figure 2-83c, the minority-carrier charge in the base is

$$Q_e = \frac{1}{2} n_p(0) W_B q A \tag{2-150}$$

and we have

$$I_{B1} = \frac{Q_e}{\tau_b} = \frac{1}{2} \frac{n_p(0) W_B q A}{\tau_b} \tag{2-151}$$

where τ_b is the minority-carrier lifetime in the base. I_{B1} represents a flow of majority holes from the base lead into the base region. Substitution of Eq. (2-138) into Eq. (2-151) gives

$$I_{B1} = \frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} \exp \frac{V_{BE}}{V_T} \tag{2-152}$$

The second major component of base current (usually the dominant one in the integrated-circuit *npn* devices) is due to injection of holes from the base into the emitter. This current component depends on the gradient of minority-carrier holes into the emitter and is [5]

$$I_{B2} = \frac{q A D_p}{L_p} p_{nE}(0) \tag{2-153}$$

where D_p is the diffusion constant for holes and L_p is the diffusion length (assumed small) for holes in the emitter. $p_{nE}(0)$ is the concentration of holes in the emitter at the edge of the depletion region and is

$$P_{nE}(0) = p_{nEo} \exp \frac{V_{BE}}{V_T} \tag{2-154}$$

If N_D is the donor atom concentration in the emitter (assumed constant) then

$$p_{nEo} \simeq \frac{n_i^2}{N_D} \tag{2-155}$$

The emitter is deliberately doped much more heavily than the base, making N_D large and p_{nEo} small, so that the base-current component, I_{B2}, is minimized.

Substitution of Eqs. (2-154) and (2-155) into Eq. (2-153) gives

$$I_{B2} = \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \exp \frac{V_{BE}}{V_T} \tag{2-156}$$

The total base current, I_B, is the sum of I_{B1} and I_{B2}:

$$I_B = I_{B1} + I_{B2} = \left(\frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} + \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \right) \exp \frac{V_{BE}}{V_T} \tag{2-157}$$

Although this equation was derived assuming uniform base and emitter doping, it gives the correct functional dependence of I_B on device parameters for practical double-diffused

nonuniform-base devices. Second-order components of I_B, which are important at low current levels, are considered later.

Since I_C in Eq. (2-146) and I_B into Eq. (2-147) are both proportional to $\exp(V_{BE}/V_T)$ in this analysis, the base current can be expressed in terms of collector current as

$$I_B = \frac{I_C}{\beta_F} \tag{2-158}$$

where β_F is the forward current gain. An expression for β_F can be calculated by substituting Eqs. (2-145) and (2-157) into Eq. (2-158) to give

$$\beta_F = \frac{qAD_n n_{po}/W_B}{\frac{1}{2}\frac{n_{po}W_B qA}{\tau_b} + \frac{qAD_p n_i^2}{L_p N_D}} = \frac{1}{\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-159}$$

where Eq. (2-148) has been substituted for n_{po}. Equation (2-159) shows that β_F is maximized by minimizing the base width W_B and maximizing the ratio of emitter to base doping densities N_D/N_A. Typical values of β_F for *npn* transistors in integrated circuits are 50–500, whereas lateral *pnp* transistors have values of 10–100. Finally, the emitter current is

$$I_E = -(I_C + I_B) = -\left(I_C + \frac{I_C}{\beta_F}\right) = -\frac{I_C}{\alpha_F} \tag{2-160}$$

where

$$\alpha_F = \frac{\beta_F}{1+\beta_F} \tag{2-161}$$

The value of α_F can be expressed in terms of device parameters by substituting Eq. (2-159) into Eq. (2-161) to obtain

$$\alpha_F = \frac{1}{1+\frac{1}{\beta_F}} = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \simeq \alpha_T \gamma \tag{2-162}$$

where

$$\alpha_T = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n}} \tag{2-163}$$

$$\gamma = \frac{1}{1+\frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-164}$$

The validity of Eq. (2-162) depends on $W_B^2/2\tau_b D_n << 1$ and $(D_p/D_n)(W_B/L_p)(N_A/N_D) << 1$, and this is always true if β_F is large [see Eq. (2-159)]. The term γ in Eq. (2-162) is

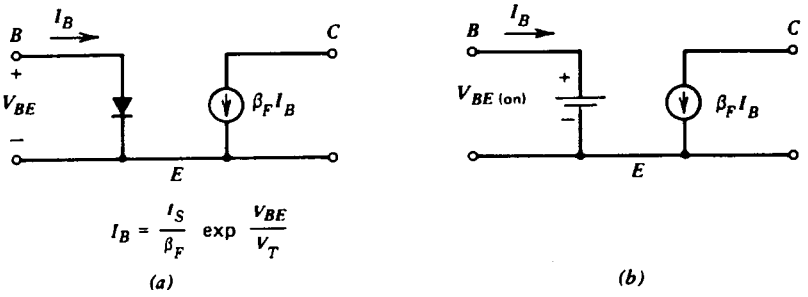

Figure 2-84 Large-signal models of *npn* transistors for use in bias calculations. (a) Circuit incorporating an input diode. (b) Simplified circuit with an input voltage source.

called the *emitter injection efficiency* and is equal to the ratio of the electron current (*npn* transistor) injected into the base from the emitter to the total hole and electron current crossing the base–emitter junction. Ideally $\gamma \to 1$, and this is achieved by making N_D/N_A large and W_B small. In that case very little reverse injection occurs from base to emitter.

The term α_T in Eq. (2-162) is called the *base transport factor* and represents the fraction of carriers injected into the base (from the emitter) that reach the collector. Ideally $\alpha_T \to 1$, and this is achieved by making W_B small. It is evident from the above development that fabrication changes that cause α_T and γ to approach unity also maximize the value of β_F of the transistor.

The results derived above allow formulation of a large-signal model of the transistor suitable for bias-circuit calculations with devices in the forward-active region. One such circuit is shown in Figure 2-84 and consists of a base–emitter diode to model Eq. (2-157) and a controlled collector-current generator to model Eq. (2-158). Note that the collector voltage ideally has no influence on the collector current and the collector node acts as a high-impedance current source. A simpler version of this equivalent circuit, which is often useful, is shown in Figure 2-84b, where the input diode has been replaced by a battery with a value $V_{BE(\text{on})}$, which is usually 0.6–0.7 V. This represents the fact that in the forward-active region the base–emitter voltage varies very little because of the steep slope of the exponential characteristic. In some circuits the temperature coefficient of $V_{BE(\text{on})}$ is important and a typical value for this is –2 mV/°C. The equivalent circuits of Figure 2-84 apply for *npn* transistors. For *pnp* devices the corresponding equivalent circuits are shown in Figure 2-85.

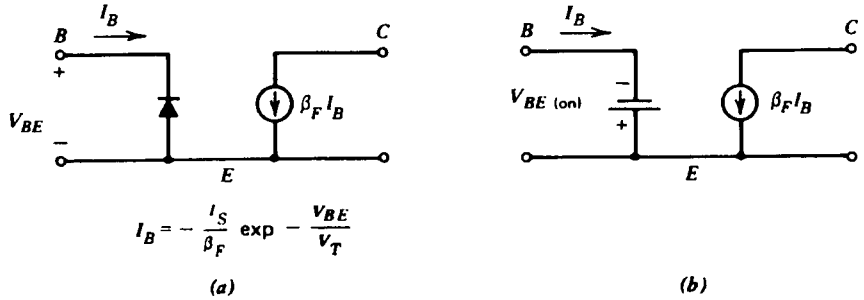

Figure 2-85 Large-signal models of *pnp* transistors corresponding to the circuits of Figure 2-84.

2-2-4 Effects of Collector Voltage on Large-Signal Characteristics in the Forward-Active Region

In the analysis of the previous section, the collector–base junction was assumed reverse-biased and ideally had no effect on the collector currents. This is a useful approximation for first-order calculations, but it is not strictly true in practice. There are occasions where the influence of collector voltage on collector current is important, and this will now be investigated.

The collector voltage has a dramatic effect on the collector current in two regions of device operation. These are the saturation (V_{CE} approaches zero) and breakdown (V_{CE} very large) regions that will be considered later. For values of collector–emitter voltage V_{CE} between these extremes, the collector current increases slowly as V_{CE} increases. The reason for this can be seen from Figure 2-86, which is a sketch of the minority-carrier concentration in the base of the transistor. Consider the effect of changes in V_{CE} on the carrier concentration for constant V_{BE}. Since V_{BE} is constant, the change in V_{CB} equals the change in V_{CE}, and this causes an increase in the collector–base depletion-layer width as shown. The change in the base width of the transistor, ΔW_B, equals the change in depletion-layer width and causes an increase ΔI_C in the collector current.

From Eqs. (2-146) and (2-149) we have

$$I_C = \frac{qA\bar{D}_n n_i^2}{Q_B} \exp \frac{V_{BE}}{V_T} \tag{2-165}$$

Differentiation of Eq. (2-165) yields

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{qA\bar{D}_n n_i^2}{Q_B^2} \left(\exp \frac{V_{BE}}{V_T} \right) \frac{dQ_B}{dV_{CE}} \tag{2-166}$$

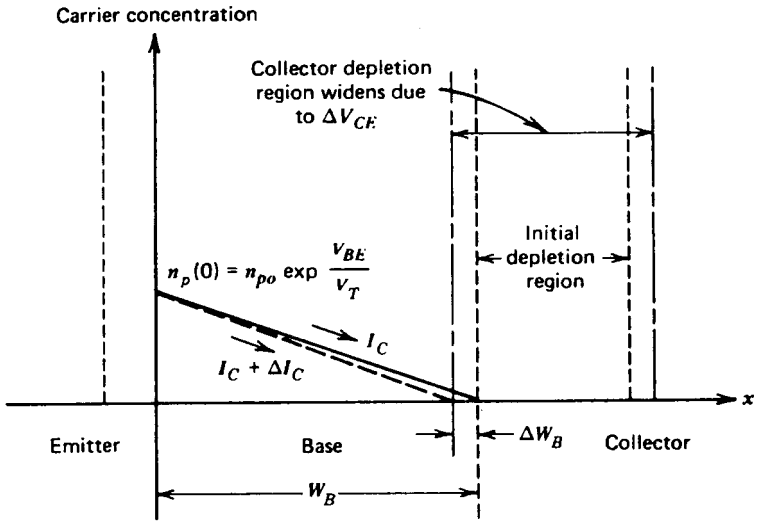

Figure 2-86 Effect of increases in V_{CE} on the collector depletion region and base width of a bipolar transistor.

and substitution of Eq. (2-165) in Eq. (2-166) gives

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{Q_B}\frac{dQ_B}{dV_{CE}} \tag{2-167}$$

For a uniform-base transistor $Q_B = W_B N_A$ and Eq. (2-167) becomes

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{W_B}\frac{dW_B}{dV_{CE}} \tag{2-168}$$

Note that since the base width *decreases* as V_{CE} increases, dW_B/dV_{CE} in Eq. (2-168) is negative and thus $\partial I_C/\partial V_{CE}$ is positive. dW_B/dV_{CE} is a function of the bias value of V_{CE}, but the variation is typically small for a reverse-biased junction and dW_B/dV_{CE} is often assumed constant. The resulting predictions agree adequately with experimental results.

Equation (2-168) shows that $\partial I_C/\partial V_{CE}$ is proportional to the collector-bias current and inversely proportional to the transistor base width. Thus narrow-base transistors show a greater dependence of I_C on V_{CE} in the forward-active region. The dependence of $\partial I_C/\partial V_{CE}$ on I_C results in typical transistor output characteristics as shown in Figure 2-87. In accordance with the assumptions made in the foregoing analysis, these characteristics are shown for constant values of V_{BE}. However, in most integrated-circuit transistors the base current is dependent only on V_{BE} and not on V_{CE}, and thus constant-base-current characteristics can often be used in the following calculation. The reason for this is that the base current is usually dominated by the I_{B2} component of Eq. (2-156), which has no dependence on V_{CE}. Extrapolation of the characteristics of Figure 2-87 back to the V_{CE} axis gives an intercept V_A called the Early voltage, where

$$V_A = \frac{I_C}{\dfrac{\partial I_C}{\partial V_{CE}}} \tag{2-169}$$

Substitution of Eq. (2-168) in Eq. (2-169) gives

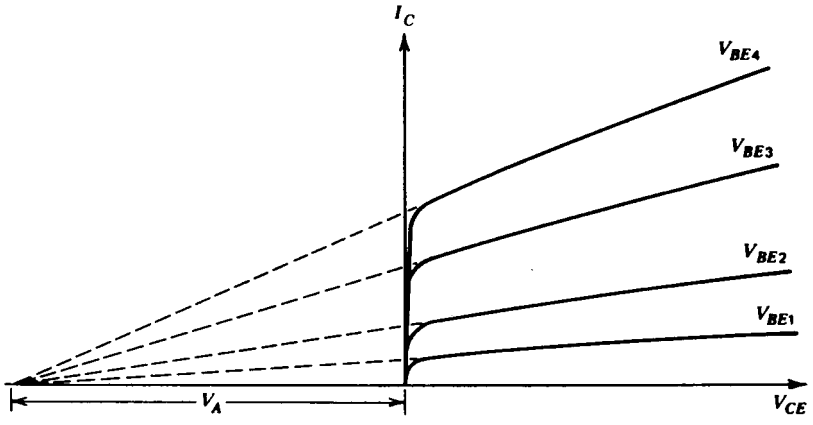

Figure 2-87 Bipolar transistor output characteristics showing the Early voltage, V_A.

$$V_A = -W_B \frac{dV_{CE}}{dW_B} \tag{2-170}$$

which is a constant, independent of I_C. Thus all the characteristics extrapolate to the same point on the V_{CE} axis. The variation of I_C with V_{CE} is called the Early effect and V_A is a common model parameter for circuit-analysis computer programs. Typical values of V_A for integrated-circuit transistors are 15–100 V. The inclusion of Early effect in dc bias calculations is usually limited to computer analysis because of the complexity introduced into the calculation. However, the influence of the Early effect is often dominant in small-signal calculations for high-gain circuits and this point will be considered later.

Finally, the influence of the Early effect on the transistor large-signal characteristics in the forward-active region can be represented approximately by modifying Eq. (2-146) to

$$I_C = I_S \left(1 + \frac{V_{BE}}{V_A}\right) \exp \frac{V_{BE}}{V_T} \tag{2-171}$$

This is a common means of representing the device output characteristics for computer simulation.

2-2-5 Saturation and Inverse Active Regions

Saturation is a region of device operation that is usually avoided in analog circuits because the transistor gain is very low in this region. Saturation is much more commonly encountered in digital circuits, where it provides a well-specified output voltage that represents a logic state. In saturation, both emitter–base and collector–base junctions are forward biased. Consequently, the collector–emitter voltage V_{CE} is quite small and usually in the range 0.05–0.3 V. The carrier concentrations in a saturated *npn* transistor with uniform base doping are shown in Figure 2-88. The minority-carrier concentration in the base of the edge of the depletion region is again given by Eq. (2-139) as

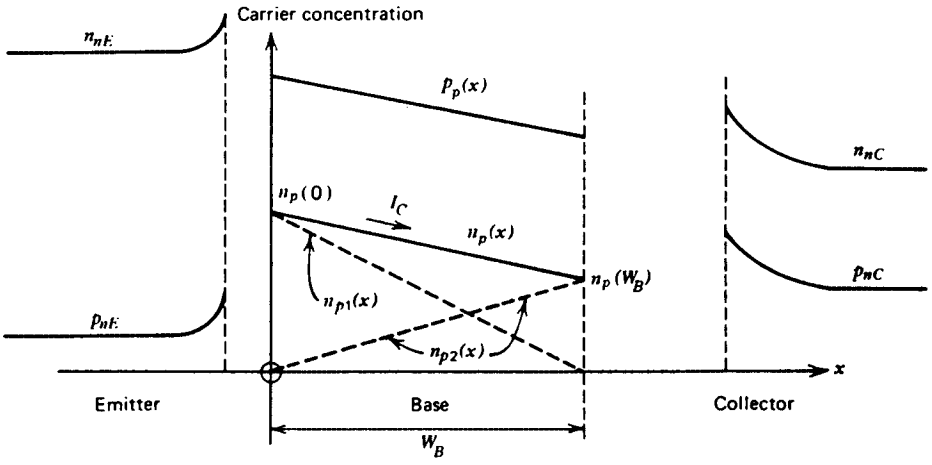

Figure 2-88 Carrier concentrations in a saturated *npn* transistor. (Not to scale)

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \tag{2-172}$$

but since V_{BC} is now positive, the value of $n_p(W_B)$ is no longer negligible. Consequently, changes in V_{CE} with V_{BE} held constant (which cause equal changes in V_{BC}) directly affect $n_p(W_B)$. Since the collector current is proportional to the slope of the minority-carrier concentration in the base [see Eq. (2-142)], it is also proportional to $[n_p(0) - (n_p(W_B)]$ from Figure 2-88. Thus, changes in $n_p(W_B)$ directly affect the collector current, and the collector node of the transistor appears to have a *low impedance*. As V_{CE} is decreased in saturation with V_{BE} held constant, V_{BC} increases as does $n_p(W_B)$ from Eq. (2-172). Thus, from Figure 2-88 the collector current decreases because the slope of the carrier concentration decreases. This gives rise to the saturation region of the $I_C - V_{CE}$ characteristic shown in Figure 2-89. The slope of the $I_C - V_{CE}$ characteristic in this region is largely determined by the resistance in series with the collector lead due to the finite resistivity of the *n*-type collector material. A useful model for the transistor in this region is shown in Figure 2-90

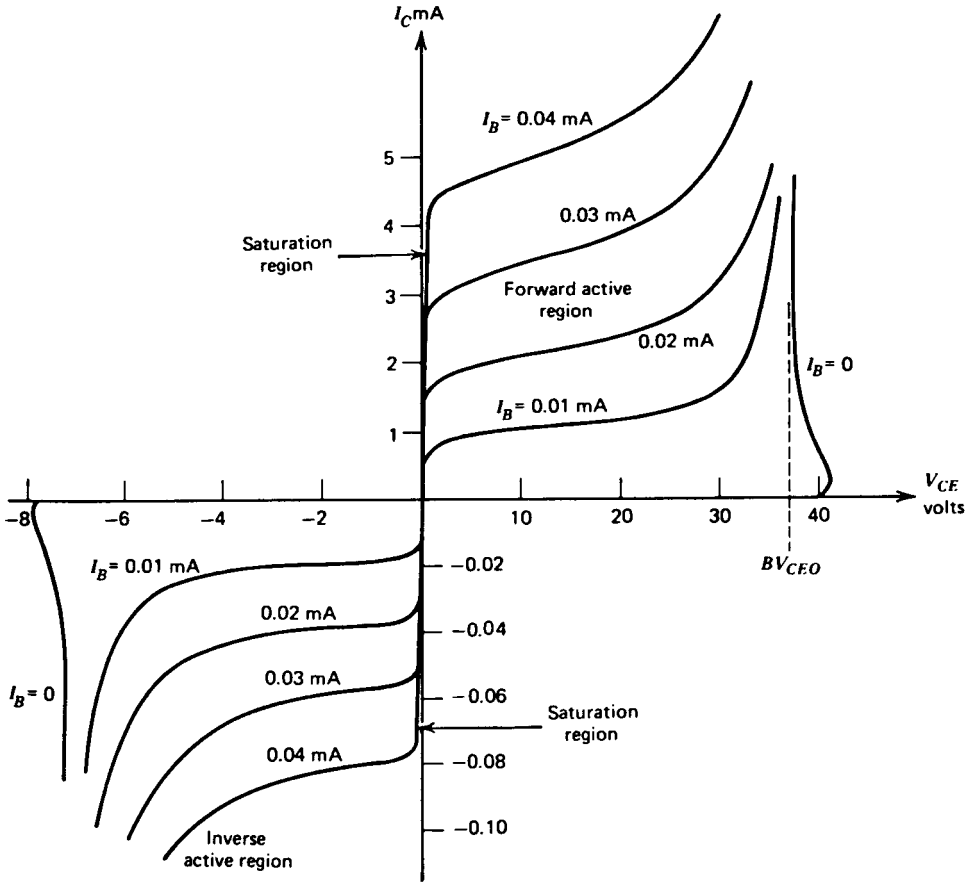

Figure 2-89 Typical $I_C - V_{CE}$ characteristics for an *npn* bipolar transistor. Note the different scales for positive and negative currents and voltages.

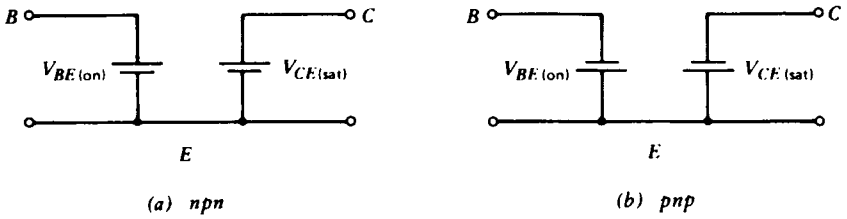

Figure 2-90 Large-signal models for bipolar transistors in the saturation region.

and consists of a fixed voltage source to represent $V_{BE(on)}$, and a fixed voltage source to represent the collector–emitter voltage $V_{CE(sat)}$. A more accurate but more complex model includes a resistor in series with the collector. This resistor can have a value ranging from 20 to 500 Ω, depending on the device structure.

An additional aspect of transistor behavior in the saturation region is apparent from Figure 2-88. For a given collector current, there is now a much larger amount of stored charge in the base than there is in the forward-active region. Thus the base-current contribution represented by Eq. (2-152) will be larger in saturation. In addition, since the collector–base junction is now forward biased, there is a new base-current component due to injection of carriers from the base to the collector. These two effects result in a base current I_B in saturation, which is larger than in the forward-active region for a given collector current I_C. Ratio I_C/I_B in saturation is often referred to as the *forced* β and is always less than β_F. As the forced β is made lower with respect to β_F, the device is said to be more *heavily saturated*.

The minority-carrier concentration in saturation, shown in Figure 2-88, is a straight line joining the two end points, assuming that recombination is small. This can be represented by a linear superposition of the two dotted distributions as shown. The justification for this is that the terminal currents depend *linearly* on the concentrations $n_p(0)$ and $n_p(W_B)$. This picture of device-carrier concentrations can be used to derive some general equations describing transistor behavior. Each of the distributions in Figure 2-88 is considered separately and the two contributions are combined. The *emitter* current that would result from $n_{p1}(x)$ above is given by the classical diode equation

$$I_{EF} = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) \tag{2-173}$$

where I_{ES} is a constant that is often referred to as the "saturation current" of the junction (no connection with the transistor saturation described above). Equation (2-173) predicts that the junction current is given by $I_{EF} \simeq I_{ES}$ with a reverse-bias voltage applied. However, in practice Eq. (2-173) is applicable only in the forward-bias region, since second-order effects dominate under reverse-bias conditions and typically result in a junction current several orders of magnitude larger than I_{ES}. The junction current that flows under reverse-bias conditions is often called the "leakage current" of the junction.

Returning to Figure 2-88, we can describe the *collector* current resulting from $n_{p2}(x)$ alone as

$$I_{CR} = -I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-174}$$

where I_{CS} is a constant. The total collector current I_C is given by I_{CR} plus the fraction of I_{EF} that reaches the collector (allowing for recombination and reverse emitter injection). Thus,

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-175}$$

where α_F has been defined previously by Eq. (2-162). Similarly, the total emitter current is composed of I_{EF} plus the fraction of I_{CR} that reaches the emitter with the transistor acting in an inverted mode. Thus,

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + \alpha_R I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-176}$$

where α_R is the ratio of emitter to collector current with the transistor operating *inverted* (i.e., with the collector–base junction forward biased and emitting carriers into the base and the emitter–base junction reverse biased and collecting carriers). Typical values of α_R are 0.5–0.8. An inverse current gain β_R is also defined,

$$\beta_R = \frac{\alpha_R}{1 - \alpha_R} \tag{2-177}$$

and has typical values 1–5. This is the current gain of the transistor when operated inverted and is much lower than β_F because the device geometry and doping densities are designed to maximize β_F. The inverse-active region of device operation occurs for V_{CE} negative in an *npn* transistor and is shown in Figure 2-89. In order to display these characteristics adequately in the same figure as the forward-active region, the negative voltage and current scales have been expanded. The inverse-active mode of operation is rarely encountered in analog circuits.

Equations (2-175) and (2-176) describe *npn* transistor operation in the saturation region when V_{BE} and V_{BC} are both positive, and also in the forward-active and inverse-active regions. These equations are from the *Ebers–Moll* equations. In the forward-active region, they degenerate into a form similar to that of Eqs. (2-146), (2-158), and (2-160) derived earlier. This can be shown by putting V_{BE} positive and V_{BC} negative in Eqs. (2-175) and (2-176) to obtain

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_{CS} \tag{2-178}$$

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \alpha_R I_{CS} \tag{2-179}$$

Equation (2-178) is similar in form to Eq. (2-146) except that leakage currents that were previously neglected have now been included. This minor difference is significant only at high temperatures or very low operating currents. Comparison of Eq. (2-178) with Eq. (2-146) allows us to identify $I_S = \alpha_F I_{ES}$ and it can be shown [6] in general that

$$\alpha_F I_{ES} = \alpha_R I_{CS} = I_S \tag{2-180}$$

where this expression represents a reciprocity condition. Using Eq. (2-180) in Eqs. (2-175) and (2-176) allows the Ebers–Moll equations to be expressed in the general form

$$I_C = I_S\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \frac{I_S}{\alpha_R}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-181}$$

$$I_E = -\frac{I_S}{\alpha_F}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_S\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-182}$$

This form is often used for computer representation of transistor large-signal behavior.

The effect of leakage currents mentioned above can be further illustrated as follows. In the forward-active region, we have, from Eq. (2-179),

$$I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) = -I_E - \alpha_R I_{CS} \tag{2-183}$$

Substitution of Eq. (2-183) in Eq. (2-178) gives

$$I_C = -\alpha_F I_E + I_{CO} \tag{2-184}$$

where

$$I_{CO} = I_{CS}(1 - \alpha_R\alpha_F) \tag{2-185}$$

and I_{CO} is the collector–base leakage current with the emitter open. Although I_{CO} is given theoretically by Eq. (2-185), in practice, surface leakage effects dominate when the collector–base junction is reverse biased and I_{CO} is typically several orders of magnitude larger than the value given by Eq. (2-185). However, Eq. (2-184) is still valid if the appropriate measured value for I_{CO} is used. Typical values of I_{CO} are 10^{-10} to 10^{-12} A at 25 °C, and the magnitude doubles about every 8 °C. As a consequence, these leakage terms can become very significant at high temperatures. For example, consider the base current I_B. This is

$$I_B = -(I_C + I_E) \tag{2-186}$$

If I_E is calculated from Eq. (2-184) and substituted in Eq. (2-186), the result is

$$I_B = \frac{1 - \alpha_F}{\alpha_F} I_C - \frac{I_{CO}}{\alpha_F} \tag{2-187}$$

But from Eq. (2-161)

$$\beta_f = \frac{\alpha_F}{1 - \alpha_F} \tag{2-188}$$

and use of Eq. (2-188) in Eq. (2-187) gives

$$I_B = \frac{I_C}{\beta_F} - \frac{I_{CO}}{\alpha_F} \tag{2-189}$$

Since the two terms in Eq. (2-189) have opposite signs, the effect of I_{CO} is to *decrease* the magnitude of the external base current at a given value of collector current.

2-2-6 Small-Signal Models of Bipolar Transistors

Figure 2-91 shows the small-signal equivalent BJT model. It consists of an intrinsic model and a package model. Table 2-12 lists its keywords.

In order to better understand the difference between the various technologies, we show Table 2-13, which allows the reader to compare their performances.

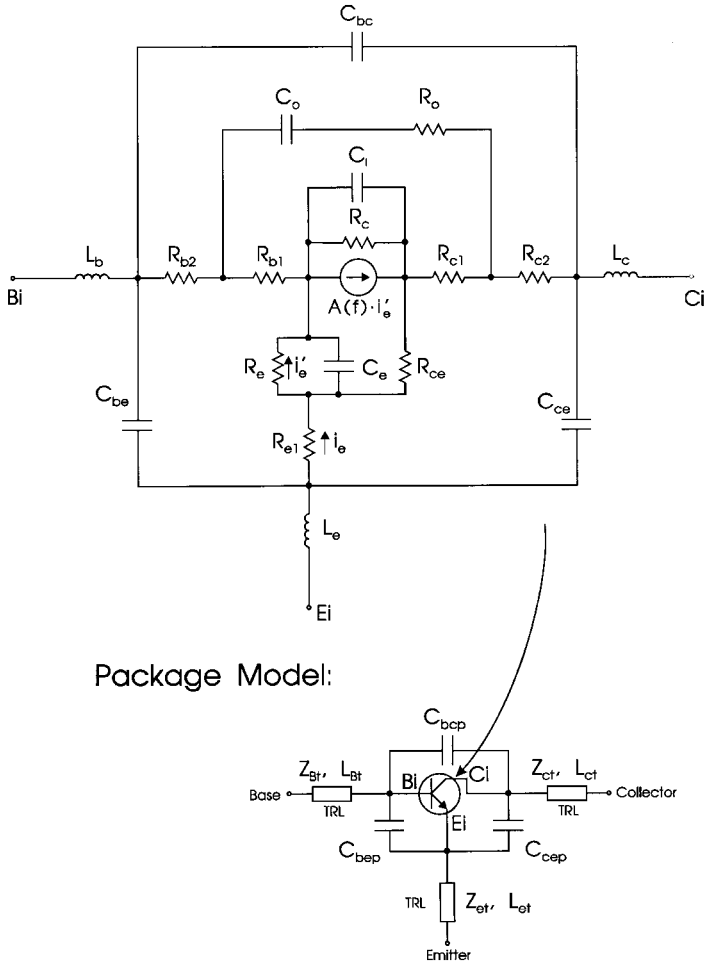

Figure 2-91 Linear BJT model.

Table 2-12 Small-signal equivalent BJT model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
A	Ratio of I_C to I_E at dc		0.0
RE	Emitter resistance	ohm	0.0

LCT	Collector transmission line length at $\varepsilon_r = 1$	meter	0.0
LET	Emitter transmission line length at $\varepsilon_r = 1$	meter	0.0

Notes:

1. $A \equiv \alpha = I_c/I_e$; β = dc current gain = $\alpha(1 - \alpha)$.
2. The bipolar current gain in this model is described by

$$\mathrm{A} = \mathrm{A}(0) = \frac{e^{-j\omega\mathrm{T}}}{1 + j\,(f/F)}$$

where $\omega = 2\,\pi f$ and f is frequency.

3. The current source is controlled by the current through R_e. The current generator has a cutoff frequency with respect to the total emitter current, I_E:

$$\mathrm{F} = g_m/2\pi C_e$$

where $g_m = 1/R_e$. This frequency becomes infinite for the default value for C_e (0.0). The parammeter F specifies the frequency roll-off for the current generator with respect to the current through R_e. Effectively, this frequency parameter may be used to model additional delays in the device.

Table 2-13 Overview of current BJT technologies including BiCMOS

[a] 1.0 µm Design Rule; NF = 3.25 dB, G_A = 12 dB at I_C = 2 mA, freq. = 2 GHz for $16 \times 1 \times 2 \ \mu m^2$; Resistors: 150 Ω/sq. (mono), 300 Ω/sq. (mono), 500 Ω/sq. (poly); Layers of metal, Schottky diodes, linear capacitor (silicided n^+ poly/n^+Si); Gate length = 0.68 µm (*n*-ch)/0.8 µm (*p*-ch), Gate Oxide = 12.5 nm (3 V)/15 nm (5 V), V_{th} = 0.65 V (*n*-ch)/–0.9 V (*p*-ch), Gm (µS/µm) = 204 (*n*-ch)/65 (*p*-ch).

[b] 0.6 µm Design Rule; Gold metallization, ILD: polyimide; Inductors: $Q > 10$ for $L \leq 10$ nH; Capacitors: $Q > 25$ for $C \leq 20$ pF; Schottky diodes (f_c = 100 GHz), Zener diodes, MIS capacitor, thin film resistors, and LPNP, 10 mask process.

[c] Analog devices using this process.

[d] LPNP F_t = 80 MHz; three-layer metallization; Schottky diodes (R_sC_j ~ 4 ps); Implanted resistors: 200 Ω/sq.; Poly resistors: 400/2000 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[e] LPNP F_t = 85 MHz; two-layer metallization; Schottky diodes (R_sC_j ~ 0.8 ps); Implanted resistors: 170/600/1200 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[f] L_n = 0.8 µm, T_{ox} = 18 nm, V_{th} = 0.76 V (nmos), V_{th} = –0.78 V (pmos), 2poly-MIM capacitor: 2.7 fF/µm^2, Schottkys, inductors.

[g] Not known if this process is in production.

[h] 0.8 µm Design Rules; 2.5 fF/µm^2 MIS capacitor; 600 MHz PJFET; 12L; F_t = 4 GHz VPNP; poly resistors 80/400/2000 Ω/sq.

[i] Targeted for 900-MHz GSM radio front-end blocks, a CT2 cordless single-chip radio, and DECT (digital enhanced cordless telephones).

[j] Targeted for multimode 900-MHz GSM, 1.8-GHz PCN and 1.9-GHz PCS based systems. Company is also evaluating integrating SiGe in HSB3.

2-3 FIELD-EFFECT TRANSISTORS

Both diodes and *pnp/npn* transistors work on the injection principle, which means the base–emitter junction generates either free electrons or other carriers, which are being "collected" by the collector connection and the base connection controls it. While this is a fairly complex process, its physics is well understood, and its latest spin-offs, heterojunction BJTs and silicon–germanium transistors, seem to offer a bright future.

In opposition to this, the field-effect transistor (FET) controls the electronic conduction in a solid by an electric field, and this concept actually predates the invention of the bipolar transistor. J. E. Lilienfeld filed for a patent on such a device in 1925 (U.S. Patent No. 1,745,175), and W. Shockley presented a comprehensive theory of the FET in 1952. It took until 1960 before the first commercially available FETs came on the market.

Several types of semiconductor materials have been used for making FETs: silicon, germanium, gallium arsenide, and others have been used. By far the most widely used is silicon, followed now by gallium arsenide.

The FET is a class of electronic semiconductor device in which the conduction of a "channel" between source (*S*) and drain (*D*) terminals is controlled by an electric field impressed on the channel via a gate (*G*) terminal. The conduction channel may utilize *n*-type carriers (electrons) or *p*-type carriers (holes). The electric field that controls the channel conduction may be introduced via a *pn* junction [for a "junction" FET (JFET)], a metal plate separated from the semiconductor channel by an oxide dielectric [for a metal-oxide semiconductor (MOS) FET], or a combination of the two methods. The polarity of the controlling electrical field is a function of the type of carriers in the channel. A FET "family tree" is shown in Figure 2-92.

For today's microwave and RF integrated circuits, the JFET with its high-frequency problems (low cutoff frequency) and large variation in parameters, such as transconductance and pinchoff voltage, has fallen out of favor and is mainly used in discrete circuits such as two-way radios or other RF applications that tolerate these wide variations and temperature dependence. The most-used FET types are MOS for small-signal applications, LDMOS (lateral diffused MOS) for power applications, and GaAs MESFET for lower-power applications (low-voltage applications) as well as high-power applications (recent advertisements by NEC have shown output power up to 100 W). Additional information on the FET family is shown in Figure 2-93.

All members of the FET family are high-impedance-input devices. Figure 2-94 shows the key operating parameters for MOSFETs and MESFETs in low-noise stages, high-gain stages, and linearized power stages. The linearization also improves the matching. This figure is similar to its counterpart in Section 2-2-2.

The following several pages present a typical example of a datasheet* for a JFET (U310) and the chip (NZA) on which it is based, followed by an example of a device with a much higher dynamic range (the CP640 family). The CP640 family and devices similar to them are being replaced by low-power LDMOS, which are not yet well-documented. At least one company, InterFET, is devoted entirely to producing discrete JFETs and JFET-related hybrid and small-scale-integration IC products.

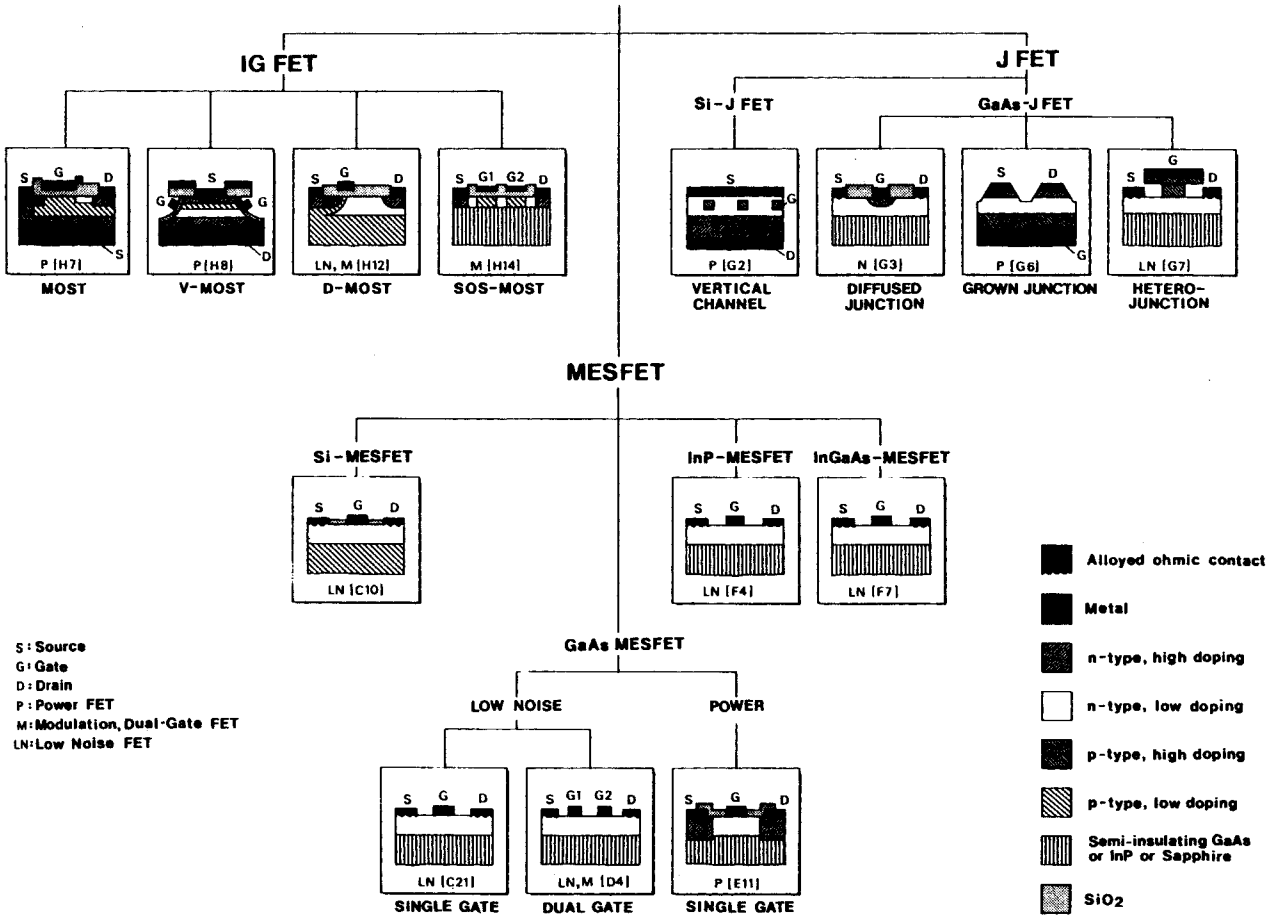

Figure 2-92 "Family tree" of microwave FET types showing cross sections of their structures [7]. Copyright ©1976 IEEE.

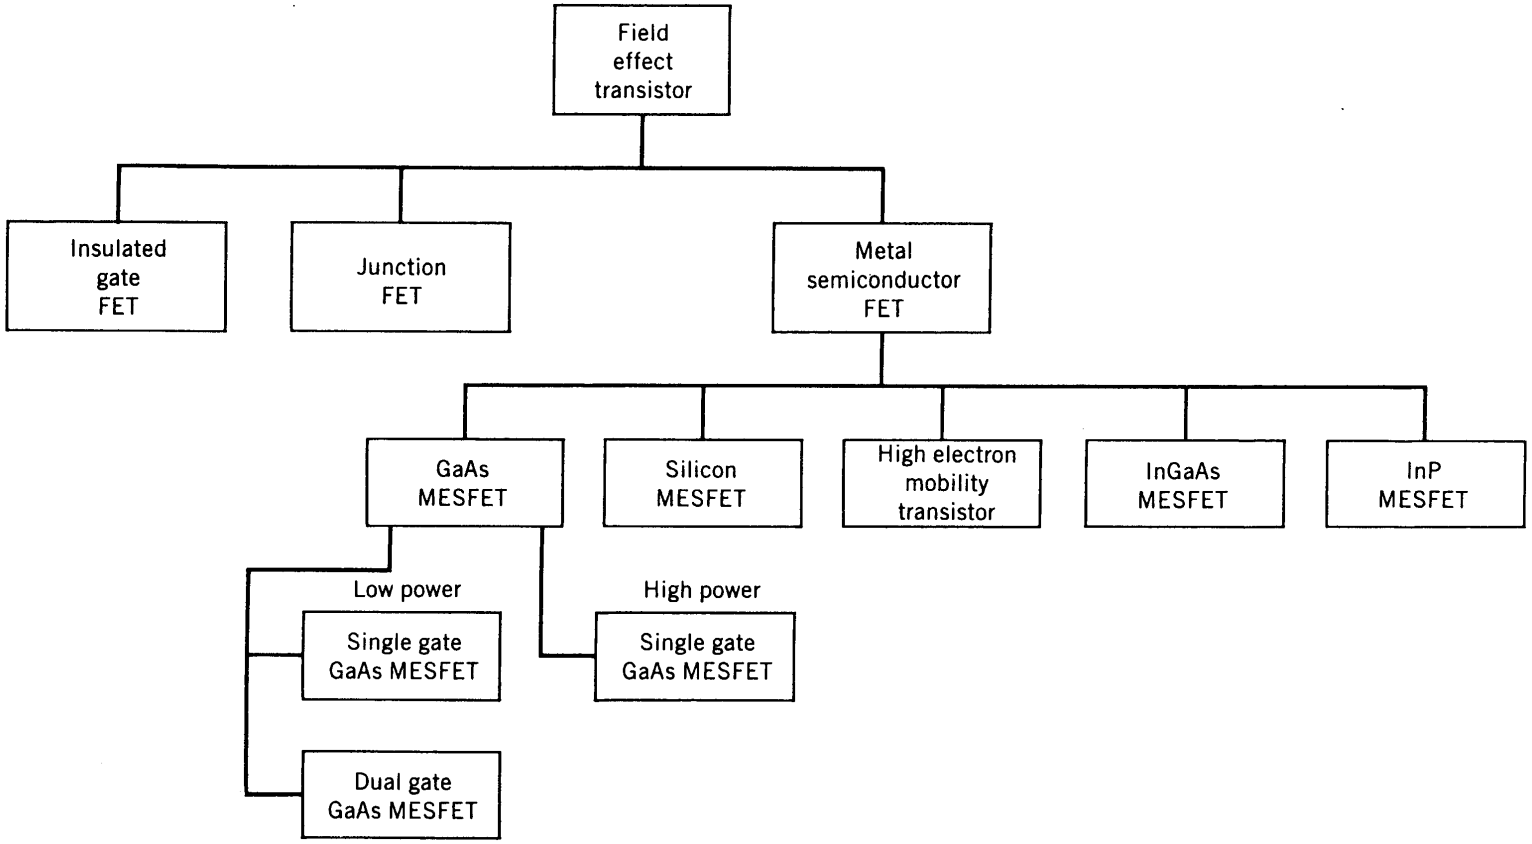

Figure 2-93 Another FET family tree [8].

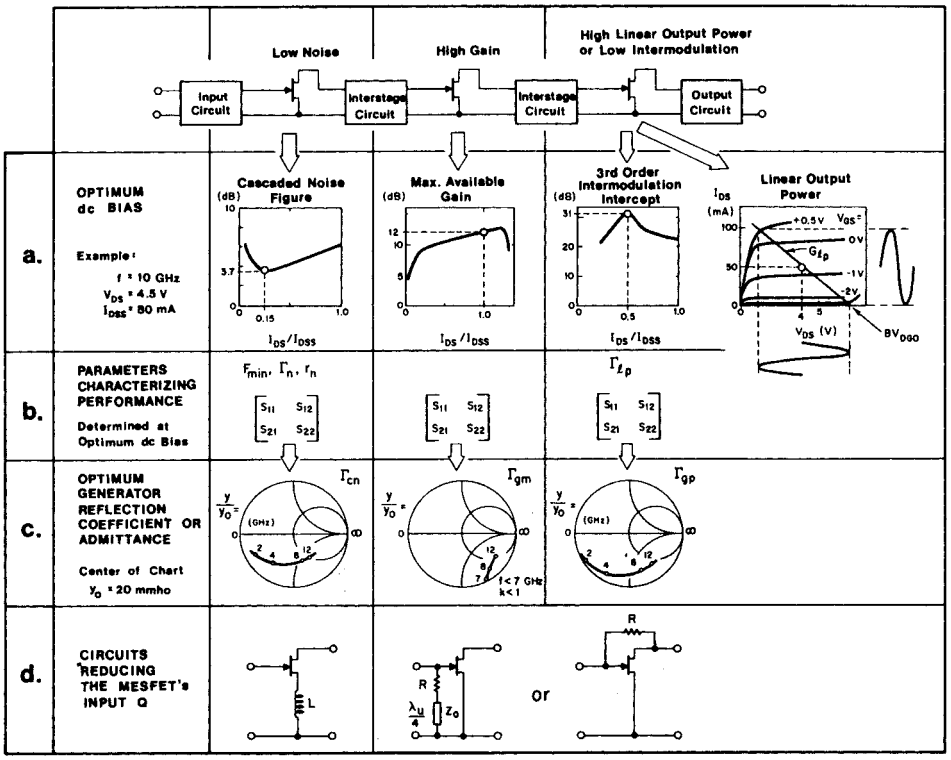

Figure 2-94 Key parameters in operating a MESFET in a low-noise front-end stage, a high-gain intermediate stage, and a linear power stage, showing (a) the device characteristics that lead to optimum dc bias for each service, (b) the parameters that characterize the device performance, (c) the optimum generator reflection coefficient that must be synthesized by each circuit, and (d) circuit arrangements that reduce the transistor's input *Q* or stabilize it at low frequencies. Although this example is based on an HP MESFET with a gate length of 1 μm and a gate width of 500 μm, this principle applies to all members of the FET family [7]. Copyright ©1976 IEEE.

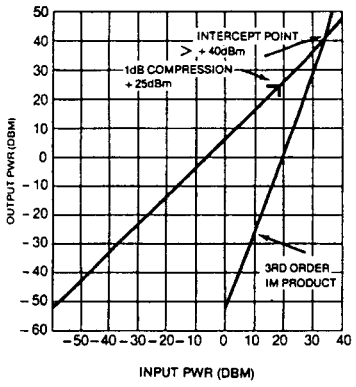
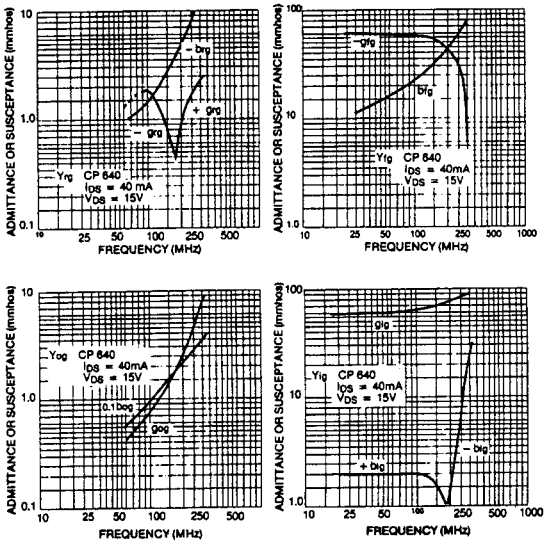
TYPICAL INTERCEPT AND COMPRESSION POINT





2-3-1 Large-Signal Behavior of JFETs

A section view of a junction field-effect transistor (JFET) is shown in Figure 2-95. This structure contains, between the source and the drain contacts, an *n*-type "channel" embedded in a *p*-type silicon substrate. If it is assumed that the *pn* junction forms a barrier to current flow, then it can be seen that channel conduction is a function of the channel width, length, and thickness and of the density and mobility of the carriers. In this structure, current can flow equally well in either direction through the channel; that is, the drain can be positive or negative with respect to the source.

Since we have found that the SPICE models for JFETs are really incomplete and give poor answers, we will only briefly touch here on the JFET's performance. The modified Materka model, one of the best GaAsFET models, turns out to be best suited for JFETs because both transistors act similarly in the dc area. Both have a gate-to-source diode that becomes conductive above 0.7 V at the input and they are also quite similar in other respects. Their equivalent circuits are also quite similar, as parameter extractions for both approaches have shown.

In general, in a three-terminal device, the drain current I_D is a function of two variables: V_{DS} and V_{GS}. This function is best represented by families of characteristic curves, as shown in Figure 2-96. These curves are for the "common source" configuration, with the drain as the output and the gate as the input. They reveal that for this device, if V_{DS} is greater than about 2 V (but less than the drain breakdown), I_D is primarily determined by the gate voltage V_{GS}. Under these conditions it is valid for small signals to characterize the FET by a single transfer characteristic curve, commonly called the "forward transconductance curve," such as the upper curve shown in Figure 2-96b. Some of the relationships between the forward transfer curve and the output characteristic curves of Figure 2-96a will be examined. The value of V_{GS} that reduces I_D to approximately zero is the gate–source cutoff voltage, $V_{GS(\text{off})}$. With reference to the output curve, Figure 2-96a, note that the drain current at $V_{GS} = 0$ tends to become saturated at a drain voltage approximately equal in magnitude to $-V_{GS(\text{off})}$. This drain voltage is often referred to as the pinchoff voltage V_P; however, in this section pinchoff voltage is used interchangeably with gate–source cutoff voltage. V_P will have the same meaning as $V_{GS(\text{off})}$. The symbol I_{DSS} is commonly used to indicate the value of saturated drain current at $V_{GS} = 0$.

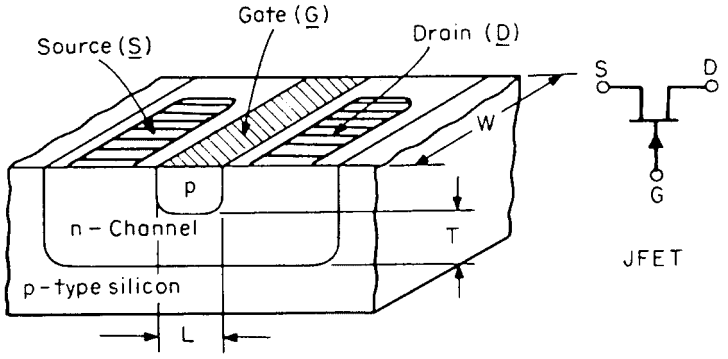


Figure 2-95 Junction field-effect transistor [9].

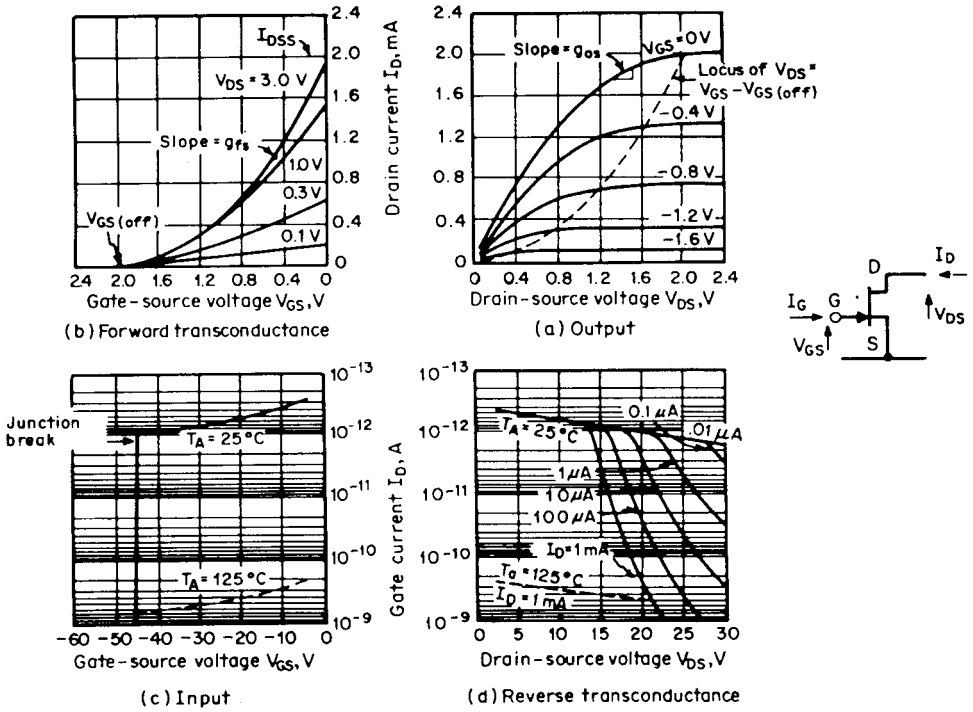

Figure 2-96 Static characteristics of an *n*-channel JFET.

The forward transconductance characteristic of Figure 2-96b can be approximated by a power law relation expressed as

$$I_D = I_{DSS}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^n \tag{2-190}$$

if $V_{DS} \geq -V_{GS(\text{off})}$. By differentiation the small-signal transconductance g_{fs} is given by

$$g_{fs} = \frac{dI_D}{dV_{GS}} = -n\frac{I_{DSS}}{V_{GS(\text{off})}}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^{n-1} \tag{2-191}$$

Some texts indicate a value of $\frac{3}{2}$ for n; however, experimental measurements on a number of n-channel JFET geometries indicate that the exponent n is close to 2, which is the value derived in an approximate treatment by R. D. Middlebrook [10].

A useful relationship between g_{fso}, I_{DSS}, and $V_{GS(\text{off})}$ is derived from the ratio of Eqs. (2-190) and (2-191):

$$\frac{g_{gs}}{I_D} = n(V_{GS} - V_{GS(\text{off})})^{-1} \tag{2-192}$$

At $V_{GS} = 0$, $I_D = I_{DSS}$ and $g_{fs} = g_{fso}$. Using 2 as the value of the constant n leads to

$$g_{fso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-193}$$

For n-channel FETs I_{DSS} is positive and $V_{GS(\text{off})}$ is negative; for p-channel FETs I_{DSS} is negative and $V_{GS(\text{off})}$ is positive; thus g_{fs} is a positive quantity for both p- and n-channel FETs.

Equation (2-190) indicates that for $V_{GS} = V_{GS(\text{off})}$, $I_D = 0$. In a real device this does not happen. Starting from zero, as the gate voltage is made more negative, the drain current decreases until it reaches a very low value equal to the drain-leakage current. At this value, the source current will consist of source–gate leakage. Any further increase in the magnitude of the negative gate voltage will result in an increase in I_D leakage. For the small-signal device illustrated, this minimum I_D is on the order of 2×10^{-13} A.

For some types of applications of the FET, it is helpful to understand the characteristics at very low values of V_{DS}, such as those shown in Figure 2-97. A "very low value" is one that is small compared to the magnitude of $V_{GS} - V_{GS(\text{off})}$. In this region, V_{DS} is small enough to have little effect on channel thickness, so that the I_D/V_{DS} slope is nearly linear. Since the slope is a function of V_{GS}, the FET can be utilized as a voltage-controlled resistor. The conductance slope ($\Delta I_D/V_{DS}$) at $V_{DS} = 0$ is approximately a linear function of $V_{GS} - V_{GS(\text{off})}$.

If g_{ds} at $V_{GS} = 0$ is given the term g_{dso}, then

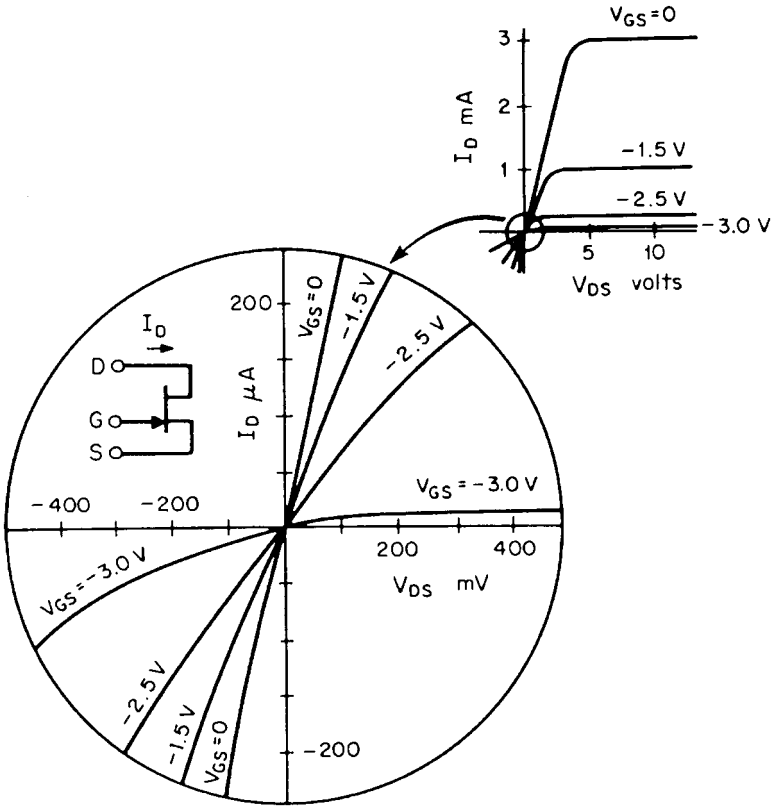

Figure 2-97 Enlargement of n-channel output characteristic around $V_{DS} = 0$.

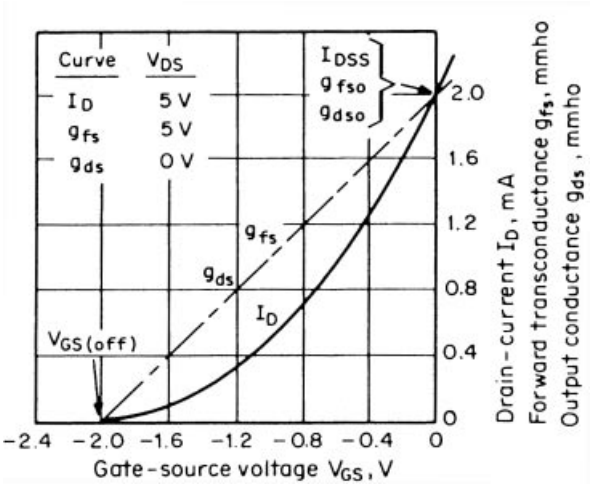

Figure 2-98 JFET I_D, g_{fs}, and g_{ds}.

$$g_{ds} = g_{dso}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right) \tag{2-194}$$

with $V_{DS} = 0$. A plot of this characteristic is shown in Figure 2-98, along with g_{fs} and I_D characteristics.

The relationship between g_{dso}, $V_{GS(\text{off})}$, and I_{DSS} is given by the equation

$$g_{dso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-195}$$

where I_{DSS} and $V_{GS(\text{off})}$ are as indicated in Figure 2-96. It is important to note that Eqs. (2-194) and (2-195) and the g_{ds} curve of Figure 2-98 are valid only for the case where V_{DS} is very small compared to V_P. Drain–source conductance at higher values of V_{DS} will be discussed later. FETs designed to be used as voltage-controlled resistors typically have a high $V_{GS(\text{off})}$ because the $V_{DS}/(V_{GS} - V_{GS(\text{off})})$ ratio should be low to keep distortion low. The actual large-signal JFET model as used in most simulators is shown in Figure 2-99, including a list of its intrinsic keywords (Table 2-14). Again, we had very little luck using this model as published by several SPICE CAD software manufacturers as offered. While we cannot judge on the quality of the parameters that came with the software, it was not possible to closely match even optimized sets of parameters to this large-signal model and obtain acceptable results. However, since the modified Materka model worked very well for this, we recommend that this popular JFET model not be used at frequencies above 10 MHz.

2-3-2 Small-Signal Behavior of JFETs

Figure 2-100 shows the small-signal equivalent transistor model we would recommend. It consists of an empirical FET model and a package model. Table 2-15 lists its keywords. Its advantage is that its built-in noise model is very accurate, even for JFETs and metal semiconductor FETs.

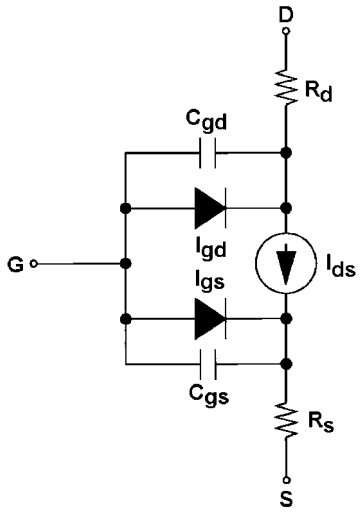

Figure 2-99 The nonlinear JFET model. Table 2-14 lists its intrinsic and extrinsic parameters. In our opinion, this model is limited to frequencies below 10 MHz; above this frequency, the modified Materka model should replace it.

Table 2-14 Large-signal JFET model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
NJF/PJF	Channel-type selection (NJF = *n*-channel, PJF = *p*-channel)		NJF
VT0	Threshold voltage	volt	–2.0
BETA	Transconductance coefficient	ampere/volt^2	1.0E–4
LAMB	Channel-length modulation	/volt	0.0
IS	Gate-junction saturation current	ampere	1.0E–14
PB	Gate-junction potential	volt	1.0
FC	Forward-bias depletion capacitance coefficient		0.5
CGS	Zero-bias gate–source junction capacitance	farad	0.0
CGD	Zero-bias gate–drain junction capacitance	farad	0.0
T	Channel transit-time delay	second	0.0
KF	Flicker noise coefficient		0.0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
SN	Switch to turn device shot noise on (1) or off (0)		1
AREA	Area multiplier		1.0
NOIS	Reference label to a set of noise data		
NAME	Required user-specified name up to 8 characters		
	Extrinsic Model		
RD	Drain ohmic resistance	ohm	0.0
RS	Source ohmic resistance	ohm	0.0

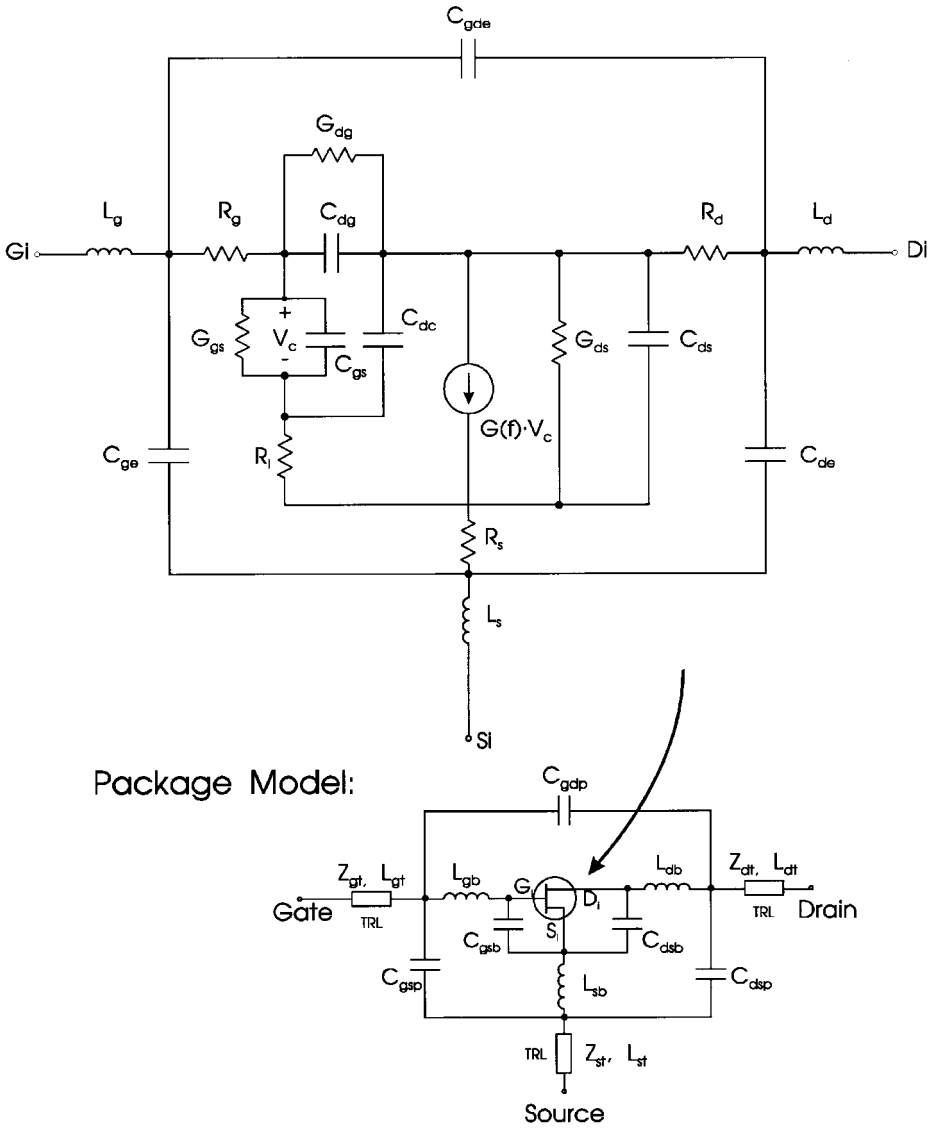

Figure 2-100 Linear FET model.

Electrical noise generated within a JFET is usually represented by equivalent noise sources, $\overline{e}_n$ and $\overline{i}_n$. Both noise voltage $\overline{e}_n$ and noise current $\overline{i}_n$ are frequency dependent and have the characteristics shown in Figure 2-101.

An equivalent noise circuit is shown in Figure 2-102. Above the frequency f_1, $\overline{e}_n$ is approximately given by

$$\overline{e}_n \cong \left(4KTB\,\frac{0.67}{g_{fs}}\right)^{1/2} \tag{2-196}$$

LST	Source transmission line length for $\varepsilon_r = 1$	meter	0.0
FC	Corner frequency of flicker (1/*f*) noise[b]	hertz	10 MHz
FCP	Shape factor of the 1/*f* noise response		1.0
label	User-defined term that refers to temperature coefficient		

[a]The transconductance of this model may be approximately described by $g_m = G\,\frac{e^{-j\omega T}}{1 + j(f/F)}$ where $\omega = 2\pi f$ and f is frequency.
[b]The flicker noise frequency dependence is given by $1/(f/F_c)^{\mathrm{FCP}}$.

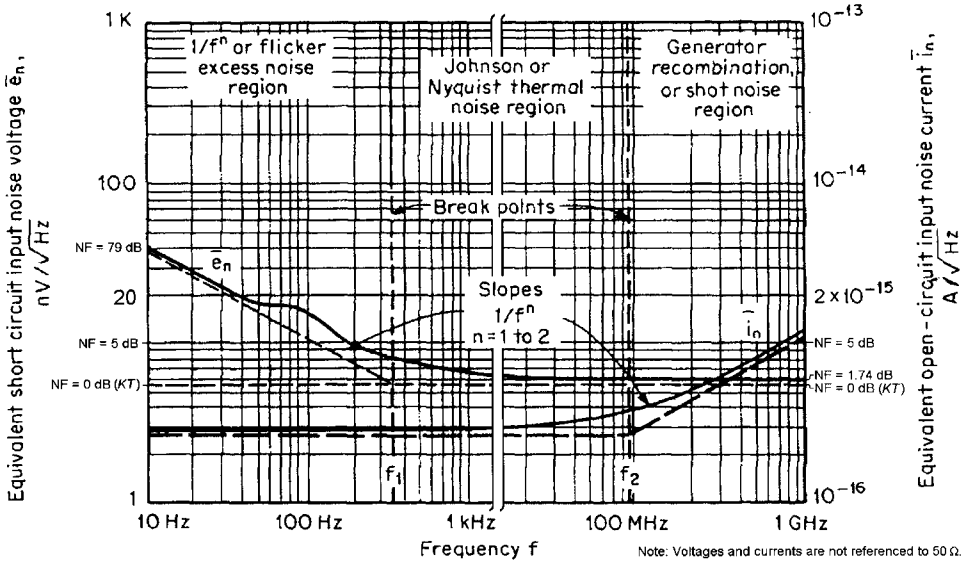

Figure 2-101 JFET noise characteristics.

where $K = 1.374 \times 10^{-23}$ J/K

T = absolute temperature in kelvins (273 K = 0 °C)

B = frequency range in hertz

g_{fs} = transconductance of FET

With the input short-circuited, the noise voltage across the load R_L resulting from the FET is

$$\text{Output noise voltage} = \bar{e}_n A_V \tag{2-197}$$

Below the frequency f_1, $\bar{e}_n$ increases proportional to $1/f^n$ and is expressed as

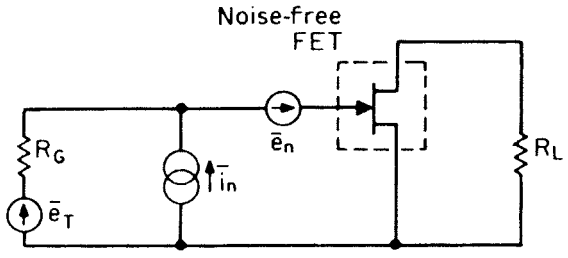

Figure 2-102 Equivalent noise circuit of the FET.

$$\bar{e}_n = \left[4KTB \left(\frac{0.67}{g_{fs}} \right) \left(1 + \frac{f_1}{f^n} \right)^{1/2} \right] \tag{2-198}$$

The low-frequency corner frequency f_1 for JFETs is typically in the 100-Hz to 1-kHz range, and the exponent n is usually between 1 and 2. As indicated by the equations, $\bar{e}_n$ is inversely proportional to the square root of g_{fs}.

The equivalent input noise current $\bar{i}_n$ is caused by the current in the gate-to-channel junction. Its approximate value below f_2 is

$$\bar{i}_n = (2qI_G B)^{1/2} \tag{2-199}$$

where $q = 1.602 \times 10^{-19}$
B = frequency range in hertz
I_G = dc gate current

This expression is fairly accurate when I_G is the result of the active device conductance. Typically, $\bar{i}_n$ will be lower than the calculated value because part of I_G is due to conductance across the device package.

At higher frequencies (above f_2),

$$\bar{i}_n = \left(\frac{4KTB}{R_P} \right)^{1/2} \tag{2-200}$$

where R_P is the real part of gate input impedance. R_P, in terms of Y_{11}, can range from several tens of megohms (at audiofrequencies) to 1 kΩ or less (at VHF/UHF frequencies). The high-frequency corner f_2 is typically in the range of 5–50 kHz and more than 100 MHz for high-frequency devices.

Another form of noise is known as "popcorn" or burst noise, the causes of which have not been completely identified. It shows up as a random short-duration step-function change in drain current, equivalent to an input gate–source voltage change of a few tenths of a microvolt. It is not unlike big bubbles on the surface of boiling water.

As far as the noise is concerned, we can also state that the Materka built-in proprietary noise model is significantly more accurate than the one mentioned above [11–14]. This model is implemented, with minimal documentation of its inner workings because of its proprietary nature, in the linear portion of the circuit simulator in Ansoft's Serenade Design Environment. In many cases, the manufacturer supplies only limited data, so it is most convenient that after SPICE-type parameter extraction is done by using the Scout program, one even gets good noise prediction for JFETs using the modified Materka model.

2-3-3 Large-Signal Behavior of MOSFETs

Metal-oxide-semiconductor field-effect transistors (MOSFETs) are important components in contemporary analog integrated circuits. Whereas initial applications were centered on all-MOS processes, combined bipolar and MOS processes give the designer the best of both worlds. A major advantage of MOS processes for realizing analog functions is that complex, dense digital functions can be realized on the same chip.

Transfer Characteristics of MOS Devices. A cross section of a typical enhancement-mode *n*-channel MOS transistor (NMOS) is shown in Figure 2-103a. Heavily doped *n*-type source and drain regions are fabricated in a *p*-type substrate (often called the body). A thick layer of silicon dioxide is grown over the substrate material and a conductive gate material (metal or polycrystalline silicon) covers this oxide between source and drain. The operation of the device is very similar to that of a JFET in that the gate–source voltage is used to modify the conductance of the region under the gate. This allows the gate voltage to control the current flowing between source and drain, giving gain in analog circuits and switching characteristics in digital circuits.

The enhancement-mode NMOS device of Figure 2-103a shows significant conduction between source and drain only when an *n*-type channel exists under the gate, and this is the origin of the "*n*-channel" designation. The term "enhancement mode" refers to the fact that no conduction occurs for $V_{GS} = 0$, and thus the channel must be "enhanced" to cause conduction. MOS devices can be made equally well by using an *n*-type substrate with a *p*-type conducting channel. Such devices are called enhancement-mode *p*-channel MOS transistors (PMOS). In technologies employing one or the other of these device types, the circuit symbol of Figure 2-103b is commonly used for either one. In complementary MOS technology (CMOS) both device types are present and the circuit symbols of Figure 2-103c will be used to distinguish them. In PMOS and NMOS technologies, the substrate is common to all devices, invariably connected to a dc power supply voltage, and usually not shown on the circuit diagram. In CMOS technology, however, devices of one type or another are fabricated in individual, separate isolation regions, which may or may not be connected to a power supply voltage. If these isolation regions *are* connected to the appropriate power supply, the symbols of Figure 2-103c will be used and the substrate connection will not be shown. If the individual isolation regions are connected elsewhere, however, the devices will be represented by the symbols of Figure 2-103d, where the substrate is labeled *B*. Finally, in NMOS technology an additional device type called a "depletion-mode" device is usually available. This is a conducting channel implanted between the source and drain so that conduction occurs for $V_{GS} = 0$. This device has characteristics that are almost identical to that of a JFET and will be represented by the symbol of Figure 2-103e.

The derivation of the transfer characteristics of the enhancement-mode NMOS device of Figure 2-103a begins by noting that with $V_{GS} = 0$, the source and drain regions are separated by back-to-back *pn* junctions. These junctions are formed between the *n*-type source and drain regions and the *p*-type substrate, resulting in an extremely high resistance (about 10^{12} Ω) between drain and source when the device is off.

Now consider substrate, source, and drain grounded and a positive voltage V_{GS} applied to the gate as shown in Figure 2-104. The gate and substrate then form the plates of a capacitor with the SiO_2 as a dielectric. Positive charge accumulates on the gate and the negative charge in the substrate. Initially, the negative charge in the *p*-type substrate is manifested by creation of a *depletion region* and resulting exclusion of holes under the gate. This is shown in Figure 2-104. The depletion-layer width *X* under the oxide is

$$X = \left(\frac{2\varepsilon\phi}{qN_A} \right)^{1/2} \tag{2-201}$$

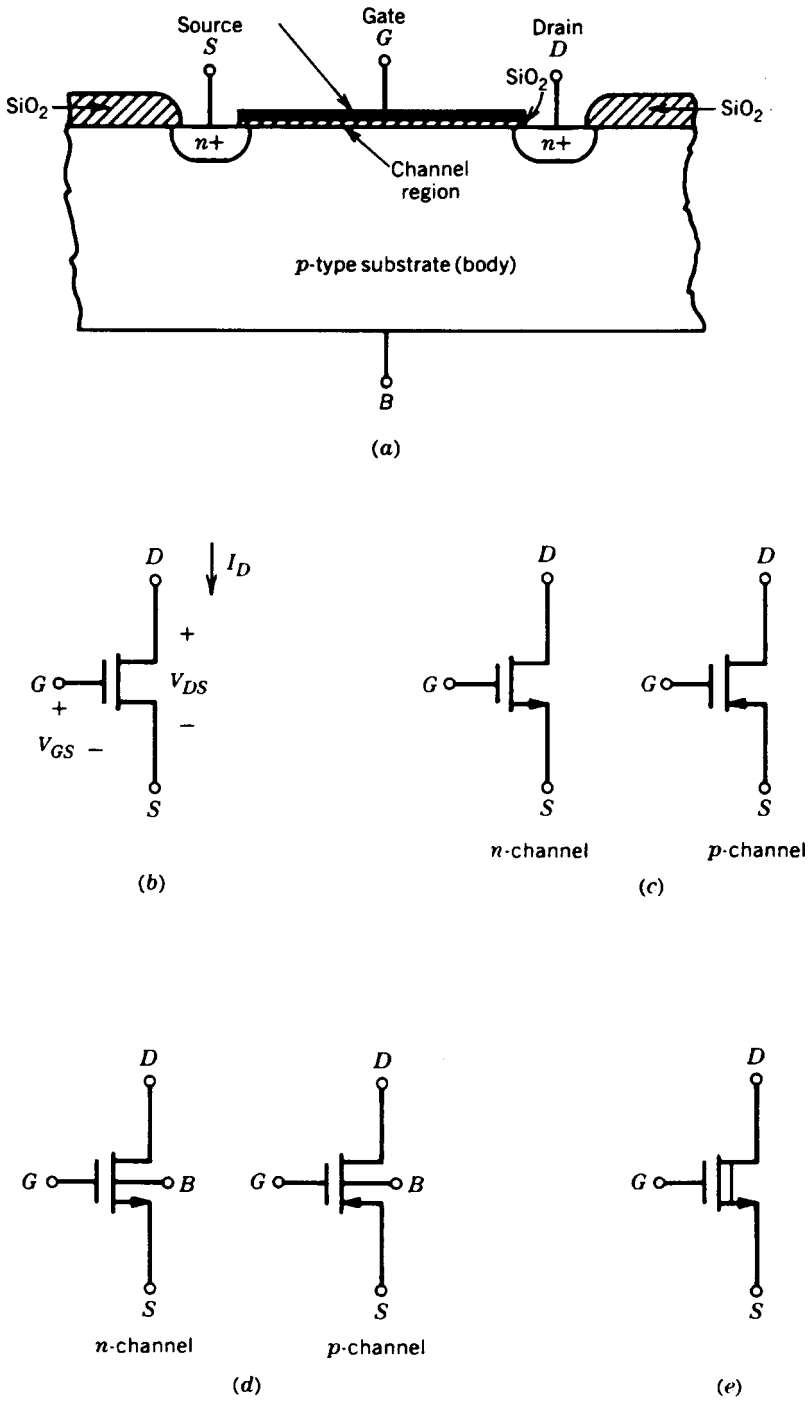

Figure 2-103 (a) Typical enhancement-mode NMOS structure. (b) Enhancement-mode NMOS or PMOS circuit symbol when one device type only is present. (c) NMOS and PMOS symbols used in CMOS circuits. (d) NMOS and PMOS symbols used when the substrate connection is nonstandard. (e) Depletion MOS device symbol.

where ϕ is the potential in the depletion layer at the oxide–silicon interface, N_A atoms/cm^3 is the doping density (assumed constant) of the p-type substrate, and ε is the permittivity of the silicon. The charge per unit area in this depletion region is

$$Q = qN_A X = \sqrt{2qN_A \varepsilon \phi} \tag{2-202}$$

When the potential in the silicon reaches a critical value equal to twice the Fermi level, $\phi_f \simeq 0.3$ V, a phenomenon known as "inversion" occurs [15]. Further increases in gate voltage produce no further changes in the depletion-layer width but instead a thin layer of electronics is induced in the depletion layer directly under the oxide. This produces a continuous n-type region with the source and drain regions and is the conducting channel between source and drain. This channel can then be modulated by increases or decreases in the gate voltage. In the presence of an inversion layer, and with no substrate bias, the depletion region contains a fixed charge

$$Q_{b0} = \sqrt{2qN_A \varepsilon 2\phi_f} \tag{2-203}$$

If a substrate bias voltage V_{SB} (source positive for n-channel devices) is applied between source and substrate, the potential required to produce inversion becomes $(2\phi_f + V_{SB})$ and the charge stored in the depletion region in general is

$$Q_b = \sqrt{2qN_A \varepsilon (2\phi_f + V_{SB})} \tag{2-204}$$

The gate voltage V_{GS}, required to produce an inversion layer, is called the threshold voltage V_t and can now be calculated. This voltage consists of several components. First, a voltage $[2\phi_f + (Q_b/C_{ox})]$ is required to sustain the depletion-layer charge Q_b, where C_{ox} is the gate oxide capacitance per unit area. Second, a work-function difference ϕ_{ms} exists between the

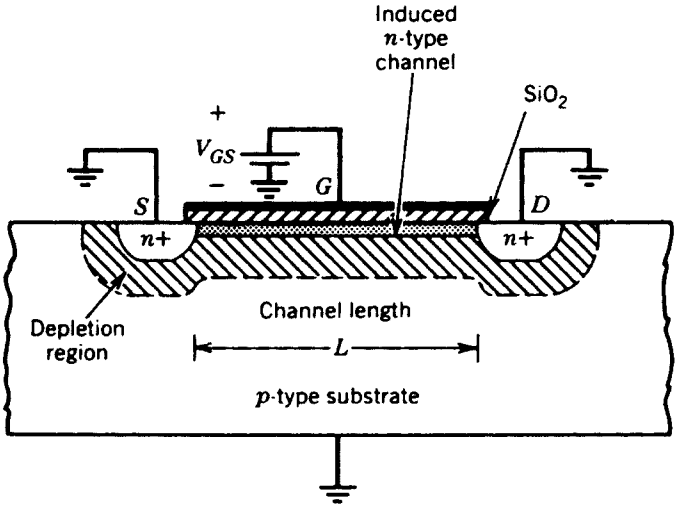

Figure 2-104 Idealized NMOS device cross section with positive V_{GS} applied, showing depletion regions and the induced channel.

gate metal and the silicon. Third, there is always charge density Q_{ss} (positive) in the oxide at the silicon interface. This is caused by crystal discontinuities at the Si–SiO_2 interface and must be compensated by a gate voltage contribution of $-Q_{ss}/C_{ox}$. Thus we have a threshold voltage

$$V_t = \phi_{ms} + 2\phi_f + \frac{Q_b}{C_{ox}} - \frac{Q_{ss}}{C_{ox}}$$

$$= \phi_{ms} + 2\phi_f + \frac{Q_{b0}}{C_{ox}} - \frac{Q_{ss}}{C_{ox}} + \frac{Q_b - Q_{b0}}{C_{ox}} \tag{2-205}$$

$$= V_{t0} + \gamma\left(\sqrt{2\phi_f + V_{SB}} - \sqrt{2\phi_f}\right) \tag{2-206}$$

where Eqs. (2-203) and (2-204) have been used and V_{t0} is the threshold voltage with $V_{SB} = 0$. The parameter γ is defined as

$$\gamma = \frac{1}{C_{ox}}\sqrt{2q\varepsilon N_A} \tag{2-207}$$

and

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{2-208}$$

where ε_{ox} and t_{ox} are the permittivity and thickness of the oxide, respectively. A typical value of γ is 0.5 $V^{1/2}$ and $C_{ox} = 3.5 \times 10^{-4}$ pF/μ^2 for $t_{ox} = 0.1$ μm.

In practice, the value of V_{t0} is usually adjusted in processing by implanting additional impurities into the channel region. Extra *p*-type impurities are implanted in the channel to make $V_{t0} \simeq 0.5$–1.5 V for *n*-channel enhancement devices. By implanting *n*-type impurities in the channel region, a conducting channel can be formed, even for $V_{GS} = 0$. This MOS transistor is called a depletion device, with typical values of V_{t0} in the range –1 to –4 V. If Q_i is the charge density per unit area due to the implant, then the threshold voltage given by Eq. (2-205) is shifted by approximately Q_i/C_{ox}.

The preceding equations can now be used to calculate the large-signal characteristics of an NMOS transistor. For purposes of analysis the source is assumed grounded and bias voltages V_{GS}, V_{DS}, and V_{SB} are applied as shown in Figure 2-105. If V_{GS} is greater than V_t, a conducting channel exists and V_{DS} causes a larger reverse bias from drain to substrate than exists from source to substrate, and thus a wider depletion region exists at the drain. However, for simplicity, we assume that the voltage drop along the channel itself is small so that the depletion layer is constant along the channel.

At a distance *y* along the channel the voltage with respect to the source is $V(y)$ and the gate-to-channel voltage at that point is $V_{GS} - V(y)$. We assume this voltage exceeds the threshold voltage V_t, and thus the induced electron charge per unit area in the channel is

$$Q_I(y) = C_{ox}[V_{GS} - V(y) - V_t] \tag{2-209}$$

The resistance *dR* of a length *dy* of the channel is

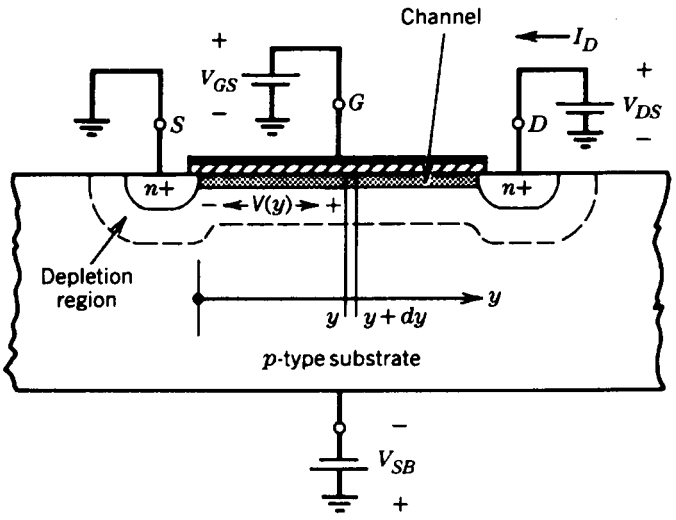

Figure 2-105 NMOS device with bias voltages applied.

$$dR = \frac{dy}{W\mu_n Q_I(y)} \tag{2-210}$$

where W is the width of the device, perpendicular to the plane of Figure 2-105, and μ_n is the average electron mobility of the channel.

The voltage drop dV along the length of the channel dy is

$$dV = I_D\, dR = \frac{I_D}{W\mu_n Q_I(y)}\, dy \tag{2-211}$$

If L is the total channel length, then substitution of Eq. (2-209) into Eq. (2-211) and integration gives

$$\int_0^L I_D\, dy = \int_0^{V_{DS}} W\mu_n C_{\text{ox}}(V_{GS} - V - V_t)\, dV \tag{2-212}$$

This results in

$$I_D = \frac{k'}{2}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-213}$$

where

$$k' = \mu_n C_{\text{ox}} = \frac{\mu_n \varepsilon_{\text{ox}}}{t_{\text{ox}}} \tag{2-214}$$

Equation (2-213) is important and describes the I–V characteristics of an MOS transistor, assuming a continuous induced channel. A typical value of k' for $t_{\text{ox}} = 0.1$ μm is about 20 μA/V^2 for an n-channel device.

As the value of V_{DS} is increased, the induced conducting channel narrows at the drain end and Eq. (2-209) indicates that Q_I at the drain end approaches zero as V_{DS} approaches $(V_{GS} - V_t)$. This results in the same pinchoff phenomenon as occurs in a JFET, and further increases in V_{DS} produce little change in I_D. Equation (2-213) is thus no longer valid if V_{DS} is greater than $(V_{GS} - V_t)$. The value of I_D in this region is obtained by substituting $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-213), giving

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 \tag{2-215}$$

for an MOS transistor in the pinchoff region. As in the case of a JFET, the drain current in the pinchoff region varies slightly as the drain voltage is varied. This is due to the presence of a depletion region between the physical pinchoff point in the channel at the drain end and the drain region itself. If this depletion-layer width is X_d, then the *effective* channel length is given by

$$L_{\text{eff}} = L - X_d \tag{2-216}$$

If L_{eff} is used in place of L in Eq. (2-215), we obtain a more accurate formula for the pinchoff region:

$$I_D = \frac{k'}{2}\frac{W}{L_{\text{eff}}}(V_{GS} - V_t)^2 \tag{2-217}$$

The fact that X_d (and thus L_{eff}) is a function of the drain–source voltage results in a variation of I_D and V_{DS} in the pinchoff region. Using Eqs. (2-216) and (2-217), we obtain

$$\frac{\partial I_D}{\partial V_{DS}} = -\frac{k'}{2}\frac{W}{L_{\text{eff}}^2}(V_{GS} - V_t)^2\frac{dL_{\text{eff}}}{dV_{DS}} \tag{2-218}$$

and thus

$$\frac{\partial I_D}{\partial V_{DS}} = \frac{I_D}{L_{\text{eff}}}\frac{dX_d}{dV_{DS}} \tag{2-219}$$

This equation is analogous to Eq. (2-168) for bipolar transistors. Following a similar procedure, a voltage analogous to the Early voltage can be defined as

$$V_A = \frac{I_D}{\partial I_D/\partial V_{DS}} \tag{2-220}$$

and thus

$$V_A = L_{\text{eff}}\left(\frac{dX_d}{dV_{DS}}\right)^{-1} \tag{2-221}$$

For MOS transistors, the most widely used parameter for the characterization of output resistance is

$$\lambda = \frac{1}{V_A} \tag{2-222}$$

As in the bipolar case, the large-signal properties of the transistor can be approximated by assuming that λ and V_A are constants, independent of bias conditions. Thus we can formulate a better approximation to the I–V characteristics as

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 (1 + \lambda V_{DS}) \tag{2-223}$$

In practical MOS transistors variation of X_d with voltage is complicated by the fact that the field distribution in the drain depletion region is not one dimensional. A vertical component in the field distribution is introduced by the potential difference between the gate and channel and the gate and drain. As a result, the calculation of λ from the device structure is quite different [16], and it is usually necessary to develop effective values of λ from experimental data. The parameter λ is a linear function of effective channel length and is an increasing function of the doping level in the channel. Typical values of λ are in the range 0.05–0.005 V^{-1}. Note that, in the case of a JFET, the pinchoff region for MOS devices is often called the *saturation* region.

A plot of I_D versus V_{DS} for an NMOS transistor is shown in Figure 2-106. Below pinchoff, the device behaves as a nonlinear voltage-controlled resistor, which is often called the *ohmic* or *triode* region. Above pinchoff, the device approximates a voltage-controlled current source. Note that for depletion MOS devices, V_t is negative and I_D is finite, even for $V_{GS} = 0$. For PMOS devices, all polarities of voltage and current are reversed.

The results as previously derived can be used to form a large-signal model of an MOS transistor. The model topology in the pinchoff region is the same as that for the JFET, but using Eq. (2-215) for the controlled-current generator.

MOS Device Voltage Limitations. The voltage limitations of MOS transistors depend on the gate length L. For small values of L (less than about 10 μm), the drain-depletion region

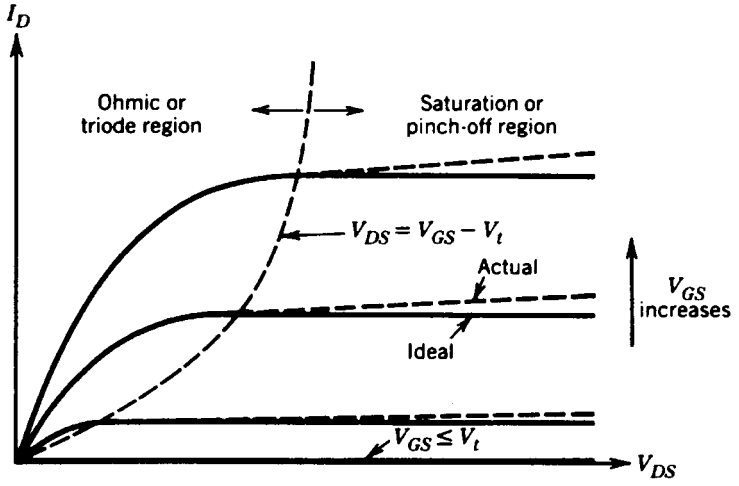

Figure 2-106 NMOS device characteristics.

exerts an appreciable influence on the channel. This causes I_D to rise with increasing V_{DS} in a similar fashion to the bipolar transistor curves of Figure 2-89.

For long channel lengths, the drain-depletion region has little effect on the channel and the I_D-versus-V_{DS} curves follow closely the ideal curves of Figure 2-106. Eventually the drain–substrate *pn*-junction breakdown voltage is exceeded and a sharp breakdown characteristic is obtained, which is similar to the JFET characteristic.

In addition to V_{DS} limitations, MOS devices must also be protected against excessive gate voltages. Typical gate oxides break down with about 25–50 V applied from gate to channel, and this process is destructive to the transistor.

2-3-4 Small-Signal Model of the MOS Transistor in Saturation

The preceding large-signal equations can now be used to derive the small-signal model of the MOS transistor in the saturation or pinchoff region. The important equations are (2-220) and (2-206). Note from Eq. (2-206) that the source–substrate voltage V_{BS} affects V_t, and thus I_D. This is due to the influence of the substrate acting as a second gate and is called *body effect*. As a consequence, I_D is a function of both V_{GS} and V_{BS}, and we require *two* transconductance generators in the small-signal model as shown in Figure 2-107. Variations in the voltage v_{bs} from source to body cause current $g_{mb}v_{bs}$ to flow from drain to source. Note that the body (or substrate) of an NMOS integrated circuit is usually connected to the most negative supply voltage and is thus an ac ground. However, the source connection can have a significant ac voltage impressed on it. Parasitic resistances due to the channel contact regions should be included in series with the source and drain of the model but are usually neglected in hand calculations. These resistances have an inverse dependence on channel width W and have typical values of 50–100 Ω for devices with W of about 1 μm.

The parameters of Figure 2-107 can be determined from Eq. (2-223) by differentiating.

$$g_m = \frac{\partial I_D}{\partial V_{GS}} = k' \frac{W}{L} (V_{GS} - V_t)(1 + \lambda V_{DS}) \tag{2-224}$$

If $\lambda V_{DS} << 1$, this is often approximated as

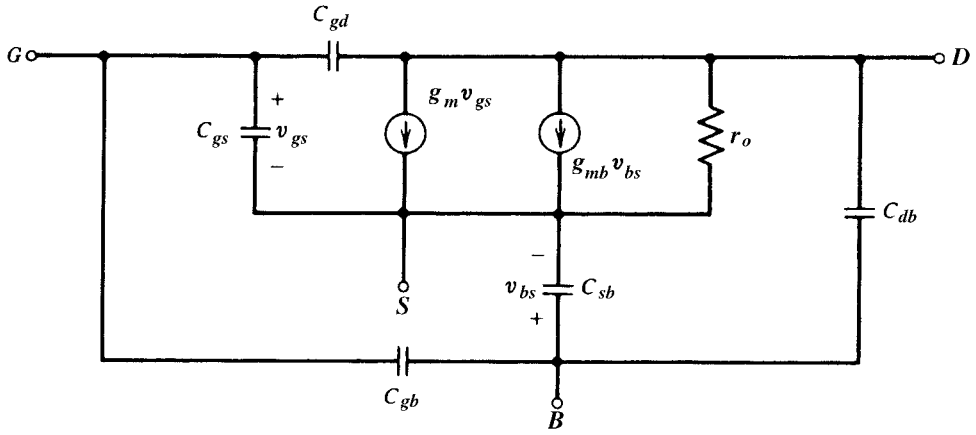

Figure 2-107 Small-signal MOS transistor equivalent circuit.

$$g_m = k' \frac{W}{L} (V_{GS} - V_t) = \sqrt{2k' \frac{W}{L} I_D} \tag{2-225}$$

Like the JFET and unlike the bipolar transistor, the transconductance of the MOSFET depends on both bias current and the *W*/*L* ratio (also on the oxide thickness via *k*′). Similarly,

$$g_{mb} = \frac{\partial I_D}{\partial V_{BS}} = -k' \frac{W}{L} (V_{GS} - V_t) (1 + \lambda V_{DS}) \frac{\partial V_t}{\partial V_{BS}} \tag{2-226}$$

From Eq. (2-206)

$$\frac{\partial V_t}{\partial V_{BS}} = -\frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = -\chi \tag{2-227}$$

where this equation defines a factor χ. This parameter is equal to the rate of change of threshold voltage with body bias voltage. One obtains

$$\chi = \frac{C_{js}}{C_{\text{ox}}} \tag{2-228}$$

where C_{js} is the capacitance per unit area of the depletion region under the channel, assuming a one-sided step junction with a built-in potential $\psi_0 = 2\phi_f$.

Substitution of Eq. (2-227) into Eq. (2-226) gives

$$g_{mb} = \frac{\gamma k' (W/L) (V_{GS} - V_t) (1 + \lambda V_{DS})}{2\sqrt{2\phi_f + V_{SB}}} \tag{2-229}$$

Again, if $\lambda V_{DS} << 1$, we have

$$g_{mb} = \frac{\gamma \sqrt{k' (W/L) I_D}}{\sqrt{2(2\phi_f + V_{SB})}} \tag{2-230}$$

An important quantity is the ratio g_{mb}/g_m, and from Eqs. (2-224) and (2-229) we find

$$\frac{g_{mb}}{g_m} = \frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = \chi \tag{2-231}$$

The factor χ is typically in the range 0.1–0.3.

Finally, the small-signal output resistance can be obtained directly from Eq. (2-218):

$$r_o = \left(\frac{\partial I_D}{\partial V_{DS}} \right)^{-1} = \frac{L_{\text{eff}}}{I_D} \left(\frac{dX_d}{dV_{DS}} \right)^{-1} \tag{2-232}$$

and using Eqs. (2-221) and (2-222), we find

$$r_o = \frac{1}{\lambda I_D} = \frac{V_A}{I_D} \tag{2-233}$$

Small-signal model capacitances are also shown in Figure 2-107. Of these, only the gate–source capacitance C_{gs} is intrinsic to the device operation in the saturation region. Capacitances C_{sb} and C_{db} are parasitic depletion-region capacitances between the substrate and the source and drain regions, respectively. These can be expressed as follows:

$$C_{sb} = \frac{C_{sb0}}{(1 + V_{SB}/\psi_0)^{1/2}} \tag{2-234}$$

$$C_{db} = \frac{C_{db0}}{(1 + V_{DB}/\psi_0)^{1/2}} \tag{2-235}$$

These capacitances are proportional to the gate and source region areas (including sidewalls), and C_{sb} also includes depletion-region capacitance from the induced channel in the body.

Capacitance C_{gb} between gate and substrate models parasitic oxide capacitance between the gate contact material and the substrate outside the active-device area. This is a constant capacitance and models coupling between polysilicon and metal interconnects and the underlying substrate. In fact, parasitic capacitance of this type underlies all polysilicon and metal traces on the chip and should be taken into account when simulating and calculating high-frequency circuit and device performance. Typical values depend on oxide thicknesses and range from about 0.04 to 0.15 fF per square micron of interconnect, with fringing effects becoming important for narrow lines (several microns or less in width).

Capacitances C_{gs} and C_{gd} exist from gate to source and drain, respectively. If C_{ox} is the oxide capacitance per unit area from gate to channel then the total capacitance under the gate is $C_{\text{ox}}WL$. This capacitance is intrinsic to the device operation and models the gate control of the channel conductance. In the ohmic region of device operation, this capacitance is split equally between source and drain so that $C_{gs} = C_{gd} = 1/2C_{\text{ox}}WL$. However, in the saturation region, the channel is very narrow at the drain end and the drain voltage exerts little influence on either the channel or the gate charge. As a consequence, the intrinsic portion of C_{gd} is essentially zero in the saturation region and C_{gd} then consists of a constant parasitic oxide-capacitance contribution due to gate overlap of the drain region. This is on the order of 1–10 fF for small devices.

In order to calculate the corresponding value of C_{gs} in the saturation region, we must calculate the total charge Q_T stored in the channel. This can be obtained by integrating Eq. (2-209) to obtain

$$Q_T = WC_{\text{ox}} \int_0^L [V_{GS} - V(y) - V_t]dy \tag{2-236}$$

Substituting for dy/dV from Eq. (2-211) into Eq. (2-236), we find

$$Q_T = \frac{W^2 C_{\text{ox}}^2 \mu_n}{I_D} \int_0^{V_{GS}-V_t} (V_{GS} - V - V_t)^2 dV \tag{2-237}$$

where the limit $y = L$ corresponds to $V = (V_{GS} - V_t)$ in saturation. Solution of Eq. (2-237) and use of Eqs. (2-214) and (2-215) gives

$$Q_T = \frac{2}{3} WLC_{\text{ox}}(V_{GS} - V_t) \tag{2-238}$$

and thus

$$C_{gs} = \frac{\partial Q_T}{\partial V_{GS}} = \frac{2}{3} WLC_{\text{ox}} \tag{2-239}$$

In addition, there is a contribution to C_{gs} from the constant parasitic oxide capacitance due to gate overlap of the source region.

The f_T of the MOSFET is given by

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs} + C_{gd} + C_{gb}} \tag{2-240}$$

The dependence of MOSFET f_T on device and process parameters can be seen by assuming that the intrinsic device capacitance G_{gs} dominates. Thus from Eq. (2-240) we have

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs}} \tag{2-241}$$

Substituting in Eq. (2-241) for g_m from Eq. (2-225) and C_{gs} from Eq. (2-239) we find for a MOSFET

$$f_T = 1.5 \frac{\mu_n}{2\pi L^2} (V_{GS} - V_t) \tag{2-242}$$

It is interesting to compare this with the intrinsic f_T of a bipolar transistor when parasitic depletion-layer capacitance is neglected. From

$$f_T = \frac{1}{2\pi\tau_F} \tag{2-243}$$

and substituting for τ_f and using the Einstein relationship $D_n/\mu_n = kT/q = V_T$, we find for a bipolar transistor

$$f_T = 2 \frac{\mu_n}{2\pi W_B^2} V_T \tag{2-244}$$

The similarity in form between Eqs. (2-242) and (2-244) is striking. In both cases the intrinsic device f_T increases as the inverse square of the critical device dimension across which carriers are in transit. The voltage V_t = 26 mV is fixed for a bipolar transistor, but MOSFET f_T can be increased by operating at high values of $(V_{GS} - V_t)$. Note that the base width W_B in a bipolar transistor is a vertical dimension determined by diffusions or implants and can typically be made much smaller than the channel length L of a MOSFET, which depends on surface geometry and photolithographic processes. Thus bipolar transistors generally have higher f_T than MOSFETs made with comparable processing. Finally, Eq. (2-242) was derived assuming that the MOSFET square law is valid. However, as discussed in Section 2-3-5, submicron MOSFETs depart significantly from square-law characteristics, and we find that for such devices f_T increases as L^{-1} rather than L^{-2}.

2-3-5 Short-Channel Effects in FETs

The evolution of integrated-circuit processing techniques has led to continuing reductions in both the horizontal and vertical dimensions of the active devices (the minimum allowed dimension of passive devices has also increased). This trend is driven primarily by economics in that more devices and circuits can be processed at one time on a given wafer. A second benefit has been that the frequency capability of the active devices continues to increase, as intrinsic f_T values increase with smaller dimensions while parasitic capacitances decrease.

Vertical dimensions such as the base width of a bipolar transistor in production processes may now be on the order of 0.05 μm or less, whereas horizontal dimensions such as bipolar emitter width or FET gate length may be significantly less than 1 μm. Even at these very small dimensions, the large-signal and small-signal models of bipolar transistors given in previous sections remain valid. However, significant short-channel effects become important in FETs of all types at channel lengths on the order of 1 μm or less and require modifications to the FET models given previously. The primary effect is to modify the classical FET square-law transfer characteristic in the saturation region to make the device more closely approach an ideal linear transfer function. Note, however, that even in processes with submicron capability, many of the FETs in a given analog circuit may be deliberately chosen to be larger than the minimum size and may be well approximated by the square-law model.

The most important short-channel effect in FETs is due to velocity saturation of carriers in the channel [17]. At low electric field values, the linear relation between carrier velocity and field implied by Eqs. (2-210) and (2-211) is valid. At high fields, however, the carrier velocities approach the thermal velocities and subsequently the carrier velocities increase more slowly with increasing field. This is illustrated in Figure 2-108, which shows typical measured electron drift velocity v_d versus tangential electric field strength magnitude $\mathscr{E}$ in an NMOS surface channel. Note that at low field values the velocity is proportional to the field, while at high fields the velocity approaches a constant value called the scattering-limited velocity v_{scl}. A first-order analytical approximation to this curve is

$$v_d = \frac{\mu_n \mathscr{E}}{1 + \mathscr{E}/\mathscr{E}_c} \tag{2-245}$$

where $\mathscr{E} \simeq 1.5 \times 10^6$ V/m and $\mu_n \simeq 0.07$ m^2/V · s is the low-field mobility. Equation (2-245) is also plotted in Figure 2-108. From Eq. (2-245), as $\mathscr{E} \to \infty$ we have $v_{\text{scl}} = \mu_n \mathscr{E}_c$. At the critical field value $\mathscr{E}_c$, the carrier velocity is a factor of 2 less than the low-field formula would predict. In a device with a channel length $L = 1$ μm, we need a voltage drop of only 1.5 V along the channel to have an average field equal to $\mathscr{E}_c$, and this condition is readily achieved in small MOSFETs. Similar results are found for PMOS devices.

As an example of the effects of velocity saturation on FET characteristics, we consider the example of the MOSFET. In the analysis of "Transfer Characteristics of MOS Devices" in Section 2-3-3, we now use the more general expression

$$I_D = WQ_I(y)v_d(y) \tag{2-246}$$

Substituting Eq. (2-245) into Eq. (2-246) and using

$$\mathscr{E} = \frac{dV}{dy} \tag{2-247}$$

for the magnitude of the field, we find that

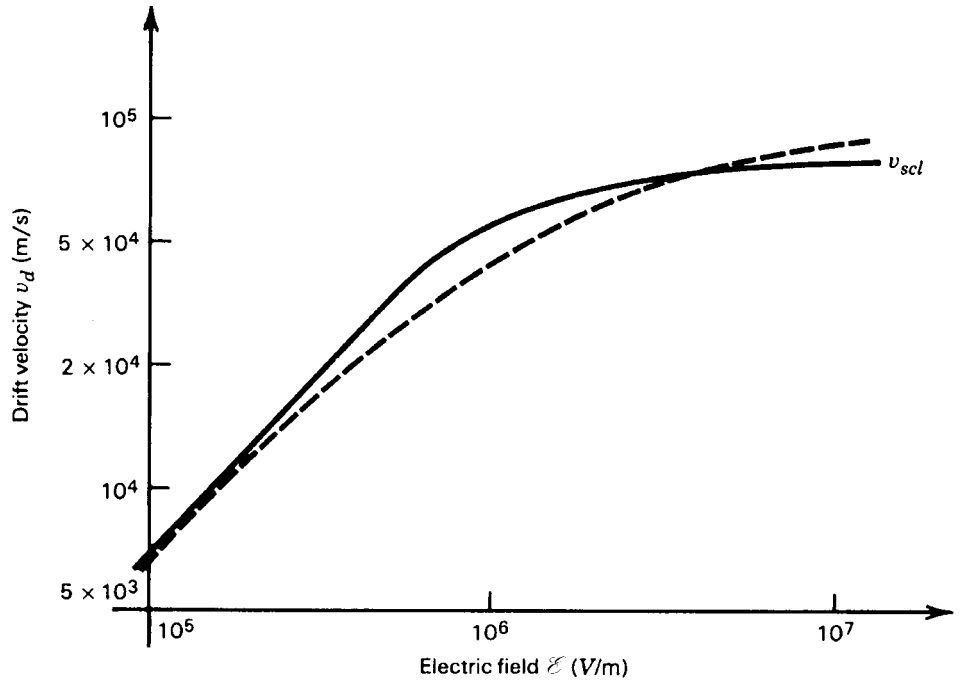

Figure 2-108 Typical measured electron drift velocity v_d versus tangent electric field $\mathscr{E}$ in an MOS surface channel (solid line). Also shown (dotted line) is the analytical approximation of Eq. (2.245) with $\mathscr{E}_c = 1.5 \times 10^6$ V/m and $\mu_n = 0.07$ m^2/V · s.

$$I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right) = WQ_I(y)\mu_n\frac{dV}{dy} \tag{2-248}$$

Note that as $\mathscr{E}_c \to \infty$ and velocity saturation becomes negligible, Eq. (2-248) approaches the original equation (2-211).

Integrating Eq. (2-248) along the channel we obtain

$$\int_0^L I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right)dy = \int_0^{V_{DS}} WQ_I(y)\mu_n dV \tag{2-249}$$

and thus

$$I_D = \frac{\mu_n C_{ox}}{2\left(1 + \dfrac{1}{\mathscr{E}_c}\dfrac{V_{DS}}{L}\right)}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-250}$$

The quantity V_{DS}/L in Eq. (2-250) can be interpreted as the average field in the channel. If this is comparable to $\mathscr{E}_c$, the drain current for a given V_{DS} is less than the simple expression (2-213) would predict.

Equation (2-250) is valid in the triode region. The MOSFET transfer function in saturation can be obtained by using $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-250) to obtain

$$I_D = \frac{k'}{2[1 + \theta(V_{GS} - V_t)]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-251}$$

where $\theta = 1/L\mathscr{E}_c$ and has the dimension volts^{-1}. For $L = 1$ μm, a typical value is $\theta \approx 0.7\ \text{V}^{-1}$. Note that in the presence of velocity saturation effects, the device enters the saturation region for $V_{DS} < (V_{GS} - V_t)$. However, Eq. (2-251) still gives a good estimate of the saturation current.

Thus far, we have only considered the effects of the tangential field due to the V_{DS} along the channel when examining velocity saturation effects. However, there exists a normal field originating from the gate voltage that also inhibits channel carrier mobility. Since the normal field depends on the value of V_{GS}, we find that an empirical modification to θ in Eq. (2-251) can adequately model this effect. In practice, θ is determined by a best fit to measured device characteristics.

Returning to Eq. (2-251) we note that for very short channel lengths, θ becomes large and Eq. (2-251) reduces to

$$I_D \propto (V_{GS} - V_t) \tag{2-252}$$

Thus, the FET characteristics tend toward a *linear* transfer function as the channel length becomes very small (less than 1 μm).

Equation (2-251) has a simple circuit representation. Consider the circuit of Figure 2-109, where an ideal square-law MOSFET has a resistance R_{SX} in series with the source of the FET. Assume

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V'_{GS} - V_t)^2 \tag{2-253}$$

Now

$$V_{GS} = V'_{GS} + I_D R_{SX} \tag{2-254}$$

and substituting Eq. (2-254) into Eq. (2-253) we find that

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V_{GS} - I_D R_{SX} - V_t)^2 \tag{2-255}$$

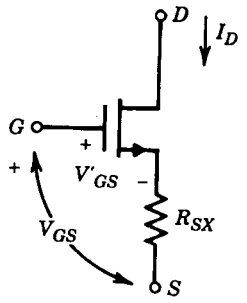

Figure 2-109 Model of velocity saturation of a MOSFET by addition of a series source resistance to an ideal square-law device.

Rearranging Eq. (2-255) we find

$$I_D = \frac{\mu C_{\text{ox}}}{2\left[1 + \mu C_{\text{ox}} \frac{W}{L} R_{SX}(V_{GS} - V_t)\right]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-256}$$

This has exactly the same form as Eq. (2-251) if we identify

$$\theta = \mu C_{\text{ox}} \frac{W}{L} R_{SX} \tag{2-257}$$

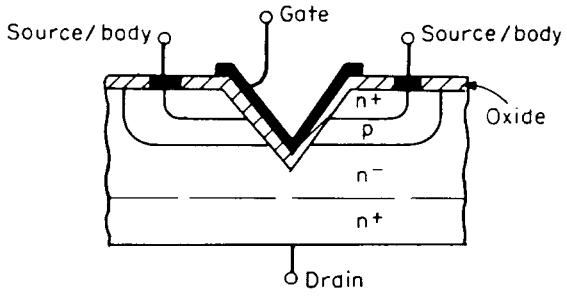
Substituting $\theta = 1/L\mathscr{E}_c$ into Eq. (2-257) we have

$$R_{SX} = \frac{1}{\mathscr{E}_c} \frac{1}{\mu C_{\text{ox}}} \frac{1}{W} \tag{2-258}$$

Thus, the influence of velocity saturation on the large-signal characteristics of a FET can be modeled to first order by a resistor R_{SX} in series with the source of an ideal square-law device. Note that R_{SX} varies inversely with W, as does the intrinsic physical series resistance due to source and drain contact regions. Typically, R_{SX} is larger than the physical series resistance. For $W = 2\ \mu\text{m}$, $\mu C_{\text{ox}} = 40\ \mu\text{A}/V^2$, and $\mathscr{E}_c = 1.5 \times 10^6$ V/m, we find $R_{SX} = 8\ \text{k}\Omega$.

The foregoing analysis has developed a modified large-signal mode for the MOSFET including velocity saturation effects. Small-signal MOSFET modeling for small devices can still be done using the equivalent circuit of Figure 2-107 if the values of g_m and g_{mb} are modified to account for the effects of velocity saturation using Eq. (2-251).

Figure 2-110 shows a cross section of VMOS (vertical MOS) and DMOS (double-diffused MOS) transistors. There is also a TMOS device—a Motorola variant of VMOS—and the



(a) VMOS (vertical channel MOS)

Figure 2-110 Cross section of (a) VMOS and (b) DMOS FETs.

now very popular LDMOS (lateral diffused MOS) power transistor (Figures 2-111 and 2-112). LDMOS FETs operate from a single supply (approximately 8 V and up) and are available for output powers surpassing 100 W at 2 GHz. The feedback capacitance is much lower than VMOS, TMOS, and earlier models, significantly improving circuit stability.

Following is a listing of Motorola high-power LDMOS transistors capable of operation up to 2 GHz:

2-3-6 Small-Signal Models of MOSFETs

Subthreshold Conduction in MOSFETs. The MOSFET analysis of Section 2-3-3 focused on the normal region of operation where this is a well-defined conducting channel under the gate. Changes in the gate voltage are assumed to cause changes in the channel charge only, and not in the depletion region below. However, for gate voltages less than the extrapolated threshold voltage V_t, the applied gate potential affects both the depletion-region charge and the channel charge, which is then very small but not zero. The device can thus conduct finite (but small) current for $V_{GS} < V_t$, so that Eq. (2-215) is not valid in this region. The electrons in the n^+ source region of an NMOS transistor can overcome the potential barrier to the p-type substrate and enter the channel region. This process is very similar to the turn-on of a bipolar transistor, and in fact the MOSFET characteristics in this subthreshold region (also called weak inversion) are very similar to those of a bipolar transistor. Analysis [19] shows that in the subthreshold region of the MOSFET characteristics can be defined by the equation

$$I_D = k_x \frac{W}{L} e^{V_{GS}/nV_T}(1 - e^{-V_{DS}/V_T}) \tag{2-259}$$

where k_x depends on process parameters and $n \simeq 1.5$. The value of n is not equal to unity in this case (as it is for the bipolar transistor) because the applied voltage V_{GS} appears partially at the silicon surface and partially across the depletion layer.

To illustrate this effect, we show measured NMOS characteristics plotted on three different scales in Figure 2-113. In Figure 2-113a we show the transfer characteristic in the forward-active region plotted on linear scales. For this device W = 20 μm and L = 20 μm and short-channel effects are negligible. The same data are plotted in Figure 2-113b as $\sqrt{I_D}$ versus V_{GS}. The resulting straight line shows that the device characteristic is close to an ideal square law. Plots like this are commonly used to obtain V_t by extrapolation (0.7 V in this case) and also k' from the slope of the curve (54 μA/V^2 in this case). Note that near the threshold voltage, the curve deviates from the straight line representing the square law. This is the subthreshold region. The data are plotted a third time in Figure 2-113c on log–linear scales. The straight line obtained for $V_{GS} < V_t$ fits Eq. (2-259) with n = 1.5. At currents below 10^{-12} A, the effect of leakage currents becomes evident.

The major application of subthreshold operation is in very low power applications at relatively low signal frequencies. The limitation to low signal frequencies occurs because the MOSFET f_T becomes very small. Since the device capacitances at very low bias currents

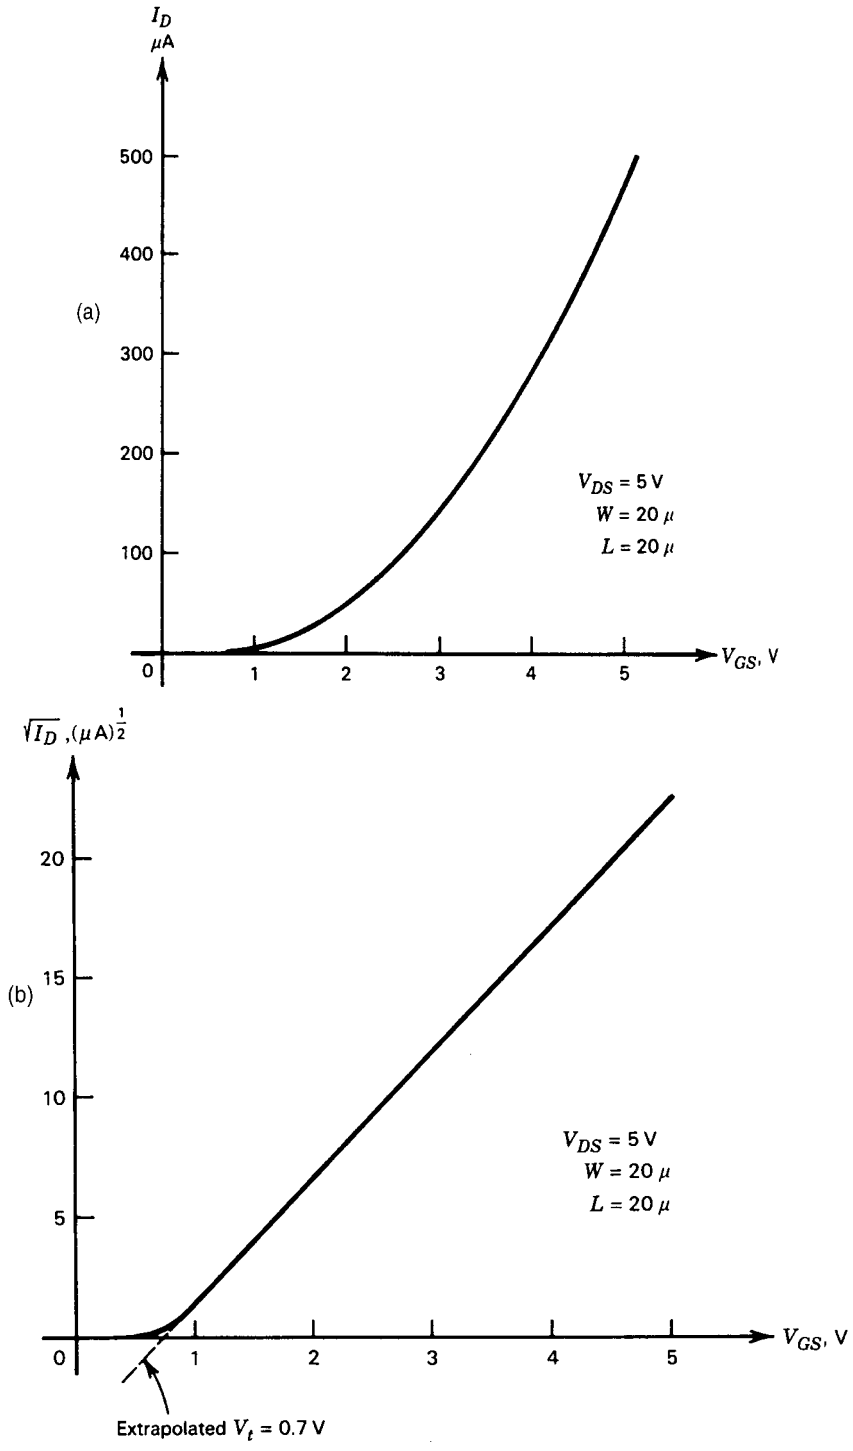

Figure 2-113 (a) Measured NMOS transfer characteristic in the forward-active region. (b) Data from part (a) plotted as $\sqrt{I_D}$ versus V_{GS} showing the square-law characteristic. Figure 2-113. (*Continued*)

are essentially fixed, and the small-signal g_m calculated from Eq. (2-259) becomes proportional to I_D, we see that the value of f_T becomes very small at very low values of I_D.

Substrate Flow in MOSFETs. As the reverse-bias voltages on the device are increased, carriers traversing the depletion regions gain sufficient energy to create new hole–electron pairs in lattice collisions by a process known as *impact ionization.* Eventually, at high enough bias voltages, the process results in large avalanche currents. For collector–base bias voltages well below the breakdown value, a small enhanced current flow may occur across the collector–base junction due to this process with little apparent effect on the device characteristics.

Impact ionization also occurs in MOSFETs but has a significantly different effect on the device characteristics. This is because the channel electrons (for the case of NMOS) create hole–electron pairs in lattice collisions in the drain depletion region, and some of the resulting holes then flow to the substrate, creating a substrate current. (The electrons created

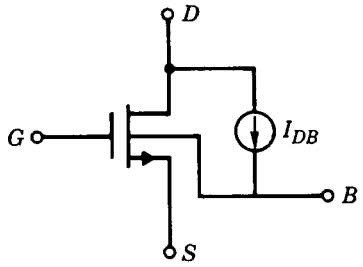

Figure 2-114 Representation of impact ionization in a MOSFET by a drain–substrate current generator.

in the process flow out the drain terminal.) The carriers created by impact ionization are thus not confined within the device as they are in a bipolar transistor. The effect of this phenomenon can be modeled by inclusion of a controlled current generator I_{DB} from drain to substrate, as shown in Figure 2-114 for an NMOS device. The magnitude of this substrate current depends on the voltage across the drain depletion region (which determines the energy of the ionizing channel electrons), and also on the drain current (which is the rate at which channel electrons enter the depletion region). It has been found empirically [20] that the current I_{DB} can be expressed as

$$I_{DB} = K_1(V_{DS} - V_{DS,\text{sat}})I_D e^{-[K_2/(V_{DS}-V_{DS,\text{sat}})]} \tag{2-260}$$

where K_1 and K_2 are process-dependent parameters and $V_{DS,\text{sat}}$ is the value of V_{DS} where the drain characteristics enter the saturation region. Typical values for NMOS devices are $K_1 = 5\ \text{V}^{-1}$ and $K_2 = 30$ V. The effect is generally much less significant in PMOS devices because the holes carrying the charge in the channel are much less efficient in creating hole–electron pairs than are energetic electrons.

The major impact of this phenomenon on circuit performance is that a parasitic resistance from drain to substrate now exists. Since the substrate of an NMOS device in a *p*-substrate process is an ac ground (the common substrate terminal must always be connected to the most negative supply voltage in the circuit), the parasitic resistance shunts the drain to ground and can be a limiting factor in many circuit designs. Differentiating Eq. (2-260) we find for the drain–substrate small-signal conductance

$$g_{db} = \frac{\partial I_{DB}}{\partial V_D}$$

$$= K_2 \frac{I_{DB}}{(V_{DS} - V_{DS,\text{sat}})^2} \tag{2-261}$$

where the gate and source are assumed held at fixed potentials.

In IC applications for RF/UHF circuits, many not-yet-solved problems remain:

1. The flicker corner frequency for MOS devices is somewhere between 100 kHz and 1 MHz.
2. Because of backplane problems in ICs, such as the substrate capacitance, also relative to the source, the performance of an IC-MOS/CMOS is not as good as expected if these effects are not considered.
3. Discrete devices, such as *n*-channel MOS devices, which are also available as dual-gate MOSFETs, can work well up to 1200 MHz. Such performance is not yet shown in silicon-based RFICs.
4. For RF power devices, such as LDMOS and others mentioned, promising results are only shown for discrete devices. There are no equivalent ICs on the market yet.

It will be interesting to see how this technology will work itself upward in frequency. Its main advantage is the BiCMOS process, which allows the mixing of analog and digital circuits nicely. Heterojunction transistors, such as SiGe, are inherently much more linear

and, for the same performance, require less current than MOS technology. On the other hand, we have not seen large-scale production SiGe-based ICs.

In the following five pages, we reproduce the datasheet for the Siemens (now Infineon Technologies) BF999 single-gate MOSFET.* Above 500 MHz, a dual-gate (also referred to as tetrode) MOSFET, such as the BF998, is preferred over a single-gate device. The main reasons for this are:

1. Internally, it is equivalent to two single-gate devices connected in a cascade arrangement, with the output device operating in the grounded-gate configuration, which entirely avoids the Miller effect and therefore remains stable at higher frequencies, operating up to 1.2 GHz.
2. The second gate can be used for AGC. As the Gate 2 voltage changes, the gain varies heavily.
3. By applying a local oscillator signal to Gate 2, this configuration can be used as a mixer.

The major drawbacks of these devices are their wide tolerances and temperature sensitivity. They follow to some degree the CMOS design but seem to have better performance.

The BF995, also called a tetrode, is in reality a dual-gate MOSFET specified to only 300 MHz; however, we are reproducing its datasheet* because the one more applicable for wireless circuits, the BF1005, does not have such a complete set of data.

To demonstrate the capabilities of low-voltage LDMOS transistors, we show the MRF5003 datasheet.† This device is intended for low-voltage applications down to 7.5 V. To the best of our knowledge, this is the lowest-voltage LDMOS transistor on the market. Other members of this family, which produce 5 W (MRF5005) and 15 W (MRF5015), begin to require higher supply voltages. Just to make sure it is not forgotten, the advantage of LDMOS is, besides lower-voltage operation, much-reduced feedback capacitance. LDMOS devices are now available that operate above 1 GHz and produce 60 W. There is now some competition with the recently introduced NEC GaAsFET, which goes up to 100 W in a similar frequency range.

MRF5003

3.0 W, 7.5 V, 512 MHz
N–CHANNEL
BROADBAND
RF POWER FET

The MRF5003 is designed for broadband commercial and industrial applications at frequencies to 520 MHz. The high gain and broadband performance of this device makes it ideal for large–signal, common source amplifier applications in 7.5 Volt and 12.5 Volt mobile, portable, and base station FM equipment.

- Guaranteed Performance at 512 MHz, 7.5 Volts
  Output Power = 3.0 Watts
  Power Gain = 9.5 dB
  Efficiency = 45%
- Characterized with Series Equivalent Large–Signal Impedance Parameters
- S–Parameter Characterization at High Bias Levels
- Excellent Thermal Stability
- All Gold Metal for Ultra Reliability
- Capable of Handling 20:1 VSWR, @ 15.5 Vdc, 512 MHz, 2.0 dB Overdrive
- Suitable for 12.5 Volt Applications
- True Surface Mount Package
- Available in Tape and Reel by Adding R1 Suffix to Part Number.
  R1 Suffix = 500 Units per 16 mm, 7 inch Reel.
- Circuit board photomaster available upon request by contacting
  RF Tactical Marketing in Phoenix, AZ.

DESIGN CONSIDERATIONS

The MRF5003 is a common–source, RF power, N–Channel enhancement mode, Metal–Oxide Semiconductor Field–Effect Transistor (MOSFET). Motorola RF MOSFETs feature a vertical structure with a planar design. Motorola Application Note AN211A, "FETs in Theory and Practice", is suggested reading for those not familiar with the construction and characteristics of FETs.

This surface mount packaged device was designed primarily for VHF and UHF power amplifier applications. Manufacturability is improved by utilizing the tape and reel capability for fully automated pick and placement of parts.

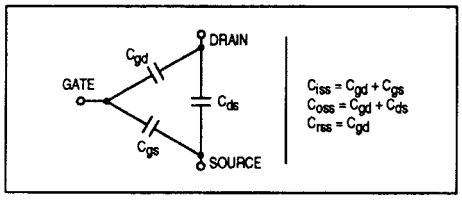
The major advantages of RF power MOSFETs include high gain, simple bias systems, relative immunity from thermal runaway, and the ability to withstand severely mismatched loads without suffering damage.

MOSFET CAPACITANCES

The physical structure of a MOSFET results in capacitors between all three terminals. The metal oxide gate structure determines the capacitors from gate–to–drain (C_{gd}), and gate–to–source (C_{gs}). The PN junction formed during fabrication of the RF MOSFET results in a junction capacitance from drain–to–source (C_{ds}). These capacitances are characterized as input (C_{iss}), output (C_{oss}) and reverse transfer (C_{rss}) capacitances on data sheets. The relationships between the inter–terminal capacitances and those given on data sheets are shown below. The C_{iss} can be specified in two ways:

1. Drain shorted to source and positive voltage at the gate.
2. Positive voltage of the drain in respect to source and zero volts at the gate.

In the latter case, the numbers are lower. However, neither method represents the actual operating conditions in RF applications.



DRAIN CHARACTERISTICS

One critical figure of merit for a FET is its static resistance in the full–on condition. This on–resistance, $R_{DS(on)}$, occurs in the linear region of the output characteristic and is specified at a specific gate–source voltage and drain current. The drain–source voltage under these conditions is termed $V_{DS(on)}$. For MOSFETs, $V_{DS(on)}$ has a positive temperature coefficient at high temperatures because it contributes to the power dissipation within the device.

GATE CHARACTERISTICS

The gate of the RF MOSFET is a polysilicon material, and is electrically isolated from the source by a layer of oxide. The input resistance is very high — on the order of $10^9\ \Omega$ — resulting in a leakage current of a few nanoamperes.

Gate control is achieved by applying a positive voltage to the gate greater than the gate–to–source threshold voltage, $V_{GS(th)}$.

Gate Voltage Rating — Never exceed the gate voltage rating. Exceeding the rated V_{GS} can result in permanent damage to the oxide layer in the gate region.

Gate Termination — The gates of these devices are essentially capacitors. Circuits that leave the gate open–circuited or floating should be avoided. These conditions can result in turn–on of the devices due to voltage build–up on the input capacitor due to leakage currents or pickup.

Gate Protection — These devices do not have an internal monolithic zener diode from gate–to–source. If gate protection is required, an external zener diode is recommended with appropriate RF decoupling.

Using a resistor to keep the gate–to–source impedance low also helps dampen transients and serves another important function. Voltage transients on the drain can be coupled to the gate through the parasitic gate–drain capacitance. If the gate–to–source impedance and the rate of voltage change on the drain are both high, then the signal coupled to the gate may be large enough to exceed the gate–threshold voltage and turn the device on.

DC BIAS

Since the MRF5003 is an enhancement mode FET, drain current flows only when the gate is at a higher potential than the source. See Figure 8 for a typical plot of drain current versus gate voltage. RF power FETs operate optimally with a quiescent drain current (I_{DQ}), whose value is application dependent. The MRF5003 was characterized at I_{DQ} = 50 mA, which is the suggested value of bias current for typical applications. For special applications such as linear amplification, I_{DQ} may have to be selected to optimize the critical parameters.

The gate is a dc open circuit and draws no current. Therefore, the gate bias circuit may generally be just a simple resistive divider network. Some special applications may require a more elaborate bias system.

GAIN CONTROL

Power output of the MRF5003 may be controlled from its rated value down to zero (negative gain) with a low power dc control signal, thus facilitating applications such as manual gain control, ALC/AGC and modulation systems. Figure 16 is an example of output power variation with gate–source bias voltage. This characteristic is very dependent on frequency and load line.

MOUNTING

The specified maximum thermal resistance of 14°C/W assumes a majority of the 0.100″ x 0.200″ source contact on the back side of the package is in good contact with an appropriate heat sink. In the test fixture shown in Figure 1, the device is clamped directly to a copper pedestal. In the demonstration amplifier, the device was mounted on top of the G10 circuit board and heat removal was accomplished through several solder filled plated through holes. As with all RF power devices, the goal of the thermal design should be to minimize the temperature at the back side of the package.

AMPLIFIER DESIGN

Impedance matching networks similar to those used with bipolar transistors are suitable for the MRF5003. For examples see Motorola Application Note AN721, "Impedance Matching Networks Applied to RF Power Transistors." Both small–signal S–parameters and large–signal impedances are provided. While the S–parameters will not produce an exact design solution for high power operation, they do yield a good first approximation. This is an additional advantage of RF power MOSFETs.

Since RF power MOSFETs are triode devices, they are not unilateral. This coupled with the very high gain of the MRF5003 yield a device capable of self oscillation. Stability may be achieved by techniques such as drain loading, input shunt resistive loading, or output to input feedback. Different stabilizing techniques were applied to the test fixture and demonstration amplifiers. The RF test fixture implements a parallel resistor and capacitor in series with the gate while the demonstration amplifier utilizes a 43 Ω shunt resistor from gate to ground. Both circuits have a load line selected for a higher efficiency, lower gain, and more stable operating region.

Two port stability analysis with the MRF5003 S–parameters provides a useful tool for selection of loading or feedback circuitry to assure stable operation. See Motorola Application Note AN215A, "RF Small–Signal Design Using Two–Port Parameters," for a discussion of two port network theory and stability.

2-3-7 GaAs MESFETs

Introduction. More than twenty years ago, for RF applications, the JFET was the dominant FET. As mentioned earlier, its major disadvantage is the fact that the f_T cutoff frequency, defined as

$$f_T = g_m / 2\pi C_{GS} \tag{2-262}$$

limits the operating range of this semiconductor device to 1 GHz at most. Also, the JFET's temperature sensitivity and loose tolerances in transconductance and other RF-related values made it difficult to use. Finally, no RFICs made use of this technology. While at the moment silicon-based MOS technology probably is the most cost-effective and is produced in the largest quantities, it does not rival the metal-semiconductor FET designed on GaAs technology. Figure 2-115 shows the structure of the silicon MOSFET, silicon JFET, and the GaAs MESFET.

Large-Signal Behavior of GaAs MESFETs. The mathematics for the large-signal behavior of the GaAsFET is basically quite similar to that for the JFET; however, the computations for JFET channel current, diode currents, and capacitance are much simpler than for the GaAsFET. Temperature effects are embedded in all the equations for all the transistors mentioned so far. In our opinion, the modified Materka model used by Ansoft and a large number of users is the most complete one; however, the following models are supported by most CAD tools:

- Chalmers (Angelov)
- Curtice–Ettenberg cubic
- Curtice quadratic
- IAF (Berroth)
- ITT PFET and TFET
- Modified Materka–Kacprzak
- Physics-based MESFET
- Raytheon (Statz)
- TriQuint (TOM-1, TOM-2, and TOM-3)
- With some restrictions, metal-insulator-semiconductor FETs (MISFETs), modulation-doped FETs (MODFETs), and high-electron-mobility transistors (HEMTs)

The main advantages of GaAsFET technology derive from the fact that it uses a metal-semiconductor junction with a barrier voltage of 0.8 V, its input capacitance is typically less than 0.2 pF, and the reverse feedback capacitance is less than 0.02 pF, or roughly 10% of the input capacitance. As a result of this, $f_{\max}$ is approximately five times higher than f_T. Table 2-16 shows a comparison of silicon BJT and GaAsFET technologies. While $f_{\max}$ for the bipolar transistor is

$$f_{\max} \simeq \sqrt{\frac{f_t}{8\pi r'_{bb} C_C}} \tag{2-263}$$

the $f_{\max}$ determination for the GaAsFET is given by

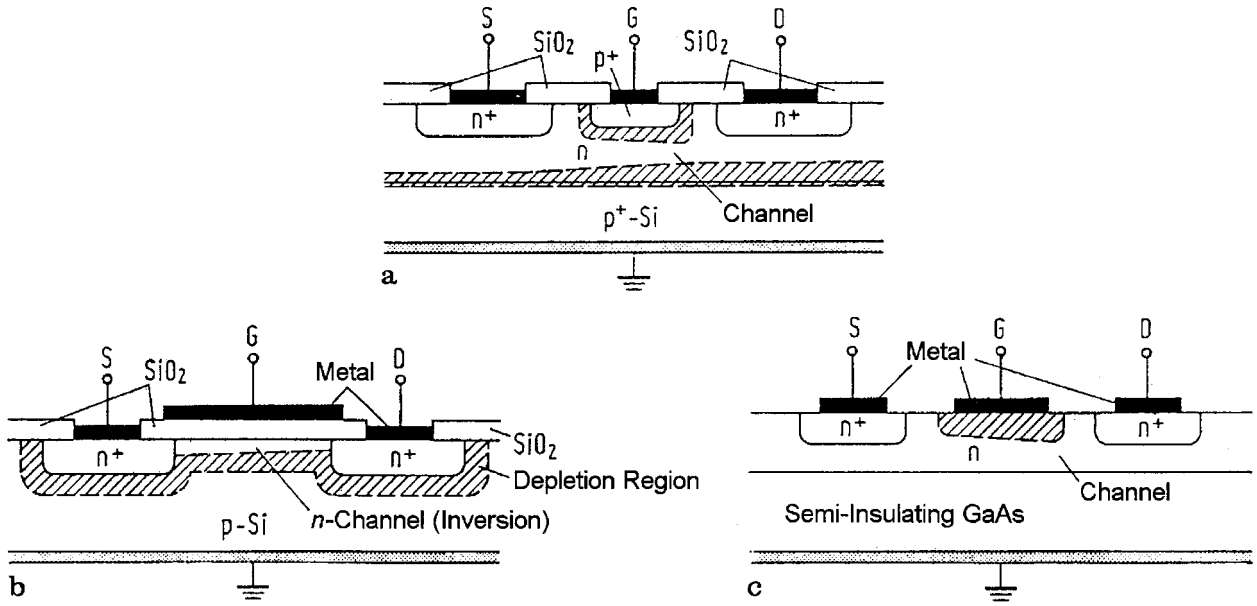

Figure 2-115 This picture is provided to differentiate between the structure of the three technologies. (a) The JFET and (b) the MOSFET are based on silicon; (c) the GaAsFET is based on semi-insulating GaAs. While the MOS transistor has silicon dioxide (SiO_2) as gate insulation, both the JFET and GaAs MESFET have a diode from gate to source, with a barrier voltage of 0.65 V for silicon and 0.8 V for GaAs.

Table 2-16 Comparison of Si BJT, SiGe HBT, and GaAsFET technologies

	Si Bipolar	SiGe HBT	GaAs FET
f_T	25 GHz	100 GHz	22 GHz
$f_{\max}$	40 GHz	200 GHz	110 GHz
Features	Low cost, low 1/*f* noise (5 kHz)	Low 1/*f* noise, very low distortion, high cost, IC only	Highest flexibility, lowest NF_0, well established

$$f_{\max} = \frac{f_T}{2}\sqrt{\frac{R_0}{R_i + R_s + R_g}} \tag{2-264}$$

As a sample calculation,

$$f_{\max}\ \frac{21.9\text{ GHz}}{2}\sqrt{\frac{450}{1 + 1.5 + 2}} = 110\text{ GHz} \tag{2-265}$$

The three major drawbacks of the GaAsFET are:

1. Much higher flicker corner frequency (somewhere between 10 and 100 MHz), probably due to a lack of surface passivation.
2. Much higher output conductance. This tends to load down any circuit connected to the drain. On the other hand, since the transconductance is quite high for even low currents, these devices have very high gains at low frequencies, which can make them quite unstable. In the saturated mode it is not uncommon to find a drain–source resistance of 100–500 Ω, while BJTs and JFETs offer values of several kilohms and higher.
3. Because of the very high flicker corner frequency (from 10 to 100 MHz), MESFETs are really not useful for low-noise mixers and oscillators, and unless there are no devices available in the frequency range above 30 GHz, they should be avoided for these applications.

As to the MESFET's construction and dc properties, Figure 2-116 shows a MESFET's cross section and dc *I*–*V* characteristics.

It was outlined in the beginning that while the GaAsFET is a close relative to the JFET and MOSFET, its actual behavior was found to be described best by a set of analytic equations. The first such model was the one by Curtice in the form of quadratic and cubic models, but it does not have enough derivatives to give enough insight into subtle things such as third- and higher-order intermodulation distortion and accurate harmonic generation. Other researchers have addressed various areas, but we still find that the Materka model has the best approximation, especially using the two-transistor approach outlined later [20, 21]. The large-signal topology for all FETs consists of an intrinsic model with some extrinsic parameters, further complicated by the package, as shown by Figures 2-117 and 2-118. Table 2-17 lists their keywords. The actual intrinsic model and its parameter definition depend on the particular model and since designs using GaAsFET will always be done using CAD tools, we will not go into any details of the equations but will list them. They are not dissimilar from the JFET and MOSFET equations.

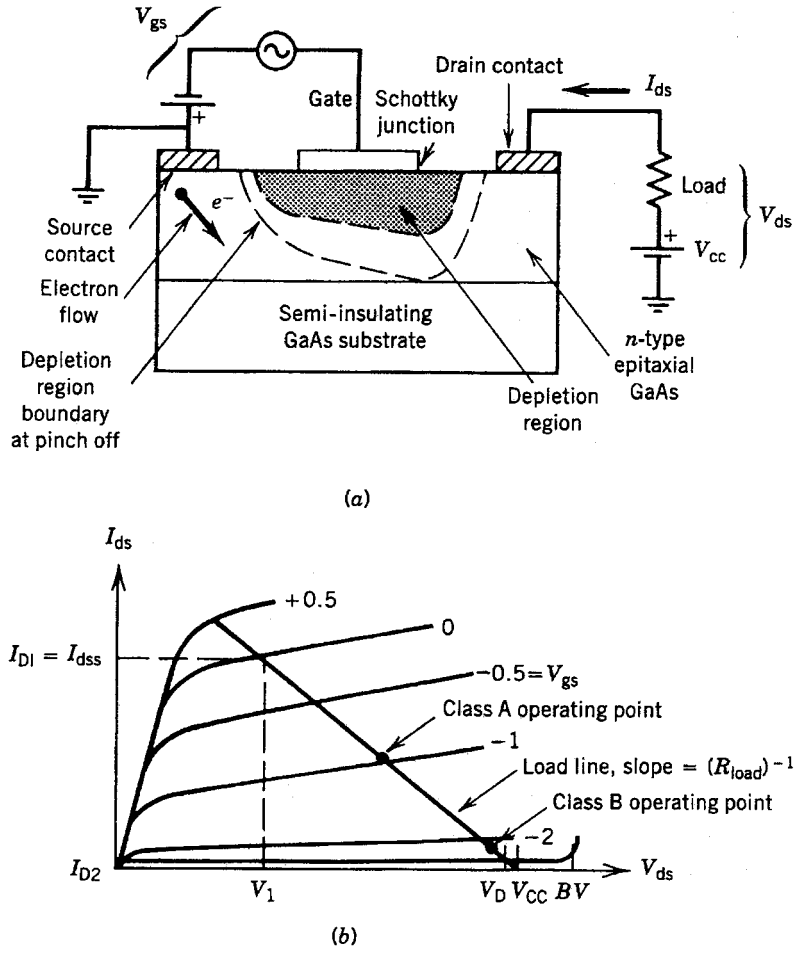

Figure 2-116 (a) Cross section and bias circuit and (b) dc *I–V* curve, including ac load line, for a MESFET.

The Modified Materka-Kacprzak Model Figure 2-119 shows the intrinsic model of the Materka FET. Table 2-18 lists its keywords.

Large-Signal Equations

Device Equations

V_{gsi} = Intrinsic gate–source voltage
V_{dsi} = Intrinsic drain–source voltage
V_1 = Voltage across C_{GS} and R_i
V_{gdi} = Intrinsic gate–drain voltage
$V_T = kT_J/q$ (thermal voltage)
k = Boltzmann's constant
q = Electron charge
T_J = Analysis temperature (kelvins)

Channel Resistance

$$R_i = \begin{cases} \text{R10}(1 - \text{KR}V_{gsi}), & \text{KR}V_{gsi} < 1.0 \\ 0, & \text{KR}V_{gsi} \geq 1.0 \end{cases}$$

Capacitance Model

$$C_{gs} = \text{CGS0}\frac{F1F2}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F3$$

$$C_{gd} = \text{CGS0}\frac{F1F3}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F2$$

where

$$F1 = \frac{1}{2}\left(1 + \frac{V_{\text{eff}} - V_T}{\sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}}\right)$$

$$F2 = \frac{1}{2}\left(1 + \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

Table 2-18 Materka–Kacprzak MESFET model keywords

Keyword	Description	Unit	Default
	Area, Noise, and Name		
AREA	Area multiplier		1.0
KFN	Flicker noise coefficient (Materka model only)[a]		0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
	Channel Current Model		
IDSS	Drain saturation current for $V_{GS} = 0$	ampere	0.1
VP0	Pinchoff voltage for $V_{DS} = 0$	volt	–2.0
GAMA	Voltage slope parameter of pinchoff voltage	/volt	0.0
E	Constant part of power-law parameter		2.0
KE	Dependence of power law on V_{GS}	/volt	0.0
SL	Slope of the $V_{GS} = 0$ drain characteristic in the linear region	ampere/volt	0.15
KG	Drain dependence on V_{GS} in the linear region	/volt	0.0
SS	Slope of the drain characteristic in the saturated region	ampere/volt	0.0
T	Channel transit-time delay	second	0.0
IG0	Diode saturation current	ampere	0
AFAG	Slope factor of forward diode current	/volt	38.696
IB0	Breakdown saturation current	ampere	0
AFAB	Slope factor of breakdown current	/volt	0
VBC	Breakdown voltage	volt	∞
GMAX	Breakdown conductance	ampere/volt	0
K1D	Fitting parameter	/volt	0
K2D	Fitting parameter	volt	0
K3D	Fitting parameter	$volt^2$	0
R10	Intrinsic channel resistance for $V_{GS} = 0$	ohm	0.0
KR	Slope factor of intrinsic channel resistance	/volt	0.0
	Materka Capacitance Model		
C10	Gate–source Schottky barrier capacitance for $V_{GS} = 0$	farad	0.0
K1	Slope parameter of gate–source capacitance	/volt	1.25
MGS	Gate–source grading coefficient		0.5
C1S	Constant parasitic component of gate–source capacitance	farad	0.0
CF0	Gate–drain feedback capacitance for $V_{GD} = 0$	farad	0.0
KF	Slope parameter of gate–drain feedback capacitance	/volt	1.25
MGD	Gate–drain grading coefficient		0.5
FCC	Forward-bias depletion capacitance coefficient		0.8

[a]The flicker noise parameter of the Materka model is KFN so as not to conflict with the KF parameter in the capacitance model.

$$F3 = \frac{1}{2}\left(1 - \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

$$V_{\text{new}} = \begin{cases} A1, & A1 < \text{VMAX} \\ \text{VMAX}, & A1 \geq \text{VMAX} \end{cases}$$

$$A1 = \frac{1}{2}\left(V_{\text{eff}} + V_T + \sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}\right)$$

$$V_{\text{eff}} = \frac{1}{2}\left(V_{gsi} + V_{gdi} + \sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}\right)$$

$$V_T = \text{VP0} + \text{GAMA}\, V_{dsi}$$

$$\delta = 0.2$$

Some of the modifications to the Materka model have been done by Ansoft under various Department of Defense contracts, and by Raytheon and Texas Instruments under similar contracts, with Ansoft being a subcontractor.

The most relevant equation is really the channel current. Its derivatives are largely responsible for the accuracy of the intermodulation distortion, power-added efficiency, and, of course, its dc *I–V* curves.

Enhancement/Depletion FETs To make the designer's life more difficult, it turns out that there are two types of GaAsFETs:

1. *Depletion FETs (DFETs).* Most similar to the JFET; here V_G must be negative to control the device. They are the most commonly produced and are the FET type most referred to in this book.

On one hand:

- They require a negative gate voltage with respect to the source.
- Self-bias allows operation from a single supply voltage.

On the other hand:

- For low-voltage operation, a negative voltage generator may be required.
- Supply voltage must be doubled to accommodate full-swing operation.

2. *Enhancement FETs (EFETs).* Most similar to the MOSFET; here V_G must be positive to bring life to the device. Practically speaking, EFETs are used mostly in integrated circuits; they're typically not available in discrete, packaged form.

On one hand:

- They need only positive supply for biasing.
- They provide higher g_m/mA (for same device width)—5.1 mS versus 3.9 mS at 8 mA.

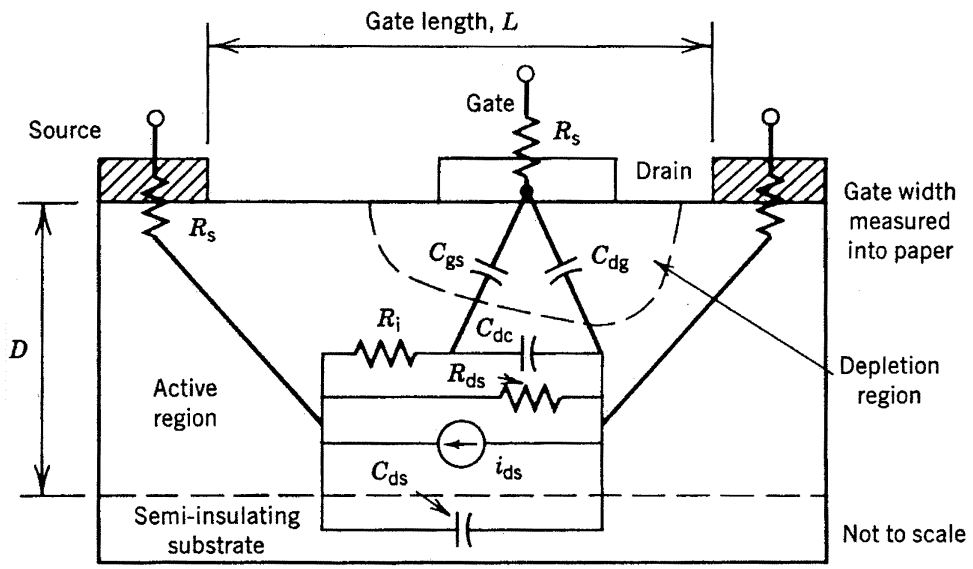

Figure 2-120 Location of lumped-element components for a MESFET.

- They are good for low-power LNAs, giving slightly better NF that DFETs, an NF of 1 dB at 1 GHz, and $I_{dd} < 10$ mA.

On the other hand:

- They have a very limited gate bias range (V_{GS} between 0.15 and 0.7 V).
- The gate conduction degrades NF and input impedance.
- The gate capacitance is higher than that of DFETs.
- The linearity is not as good as that of DFETs.

With today's technologies, all GaAs devices are *n*-channel; we have not seen any *p*-channels yet. More information about biasing will be given in the next chapter.

Figure 2-120 is a lumped-element, two-part equivalent circuit of a MESFET showing the location of lumped-element components.

2-3-8 Small-Signal GaAs MESFET Model

Figure 2-121 shows the applicable linear equivalent circuit for a MESFET and Table 2-19 lists its keywords. As with the MOS transistors, there is a gallium-arsenide dual-gate MOSFET available that is used mostly in special circuits, such as preamplifiers and mixers, whose IF has to be significantly higher than the flicker corner frequency, for example, higher than 200 MHz.

The following two datasheets* show typical GaAsFETs, both low-noise and medium-power. Such devices are, of course, available from a large variety of manufacturers—to name at least two, Siemens and the Nippon Electric Company, which is represented in the United States by California Eastern Laboratories.

ZDT	Drain transmission line impedance	ohm	50
ZST	Source transmission line impedance	ohm	50
LGT	Gate transmission line length for at $\varepsilon_r = 1$	meter	0.0
LDT	Drain transmission line length for at $\varepsilon_r = 1$	meter	0.0
LST	Source transmission line length for at $\varepsilon_r = 1$	meter	0.0
FC	Corner frequency of flicker (1/*f*) noise[b]	hertz	10 MHz
FCP	Shape factor of the 1/*f* noise response	1.0	
label	User-defined term that refers to temperature coefficient		

[a]The transconductance of this model may approximately be described by $g_m = G\dfrac{e^{-j\omega T}}{1 = j(f/F)}$ where $\omega = 2\pi f$ and f is frequency.

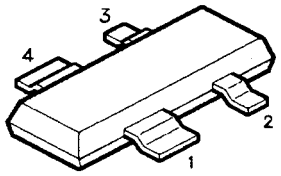
[b]The flicker noise frequency dependence is given by $1/(f/F_c)^{\mathrm{FCP}}$

SIEMENS AlGaAs / InGaAs HEMT CFY 77

Datasheet

Features

* Very low noise
* Very high gain
* For low noise front end amplifiers up to 20 GHz
* For DBS down converters



ESD: Electrostatic discharge sensitive device, observe handling precautions!

2-4 PARAMETER EXTRACTION OF ACTIVE DEVICES

2-4-1 Introduction

We have already seen that all linear models that are used on the market are really derived from large-signal models, and it is our point that the quality of the model depends mostly on the quality of the parameters used to describe the model.

As far as modeling is concerned there are two options. The first option is a physics-based model, which can be applied to items such as diodes and bipolar transistors, including its most advanced versions, such as HBTs, SiGe versions, and other future derivatives. The bipolar transistor is essentially a combination of two diodes whereby the base–emitter junction generates the electrons or holes (depending on how the reader is accustomed to viewing the process) and then transfers those to the collector. The emitter, as its name states, emits the charged particles and the collector collects them, minus some current losses, which are expressed in the current gain of the device. A current gain (β) of 100 means that the collector receives 1% less than the emitter emits.

The second modeling option involves the construction of an analytical mathematic equivalent for the device modeled. Earlier in this chapter, we went through a detailed physics-based derivation about the inner workings of these devices, explaining how, for a given dc bias point, one can simplify them to a small-signal equivalent circuit. This is possible since we assume that the RF current and voltages are less than 1% of the dc equivalent currents and voltages. Reducing a device's complex nonlinear equivalent circuit to a quasistatic linear equivalent circuit allows its manufacturer to generate and publish sets of *S* parameters for it. These parameters are bias, voltage, and temperature dependent. At higher frequencies, parasitics play an enormous role in determining a device's RF performance.

A device operating at signal levels that are more than 1% of its dc equivalent currents and voltages must be evaluated in terms of large-signal performance. Most of the large-signal-equivalent circuits for nonbipolar devices, such as FETs (MOS, silicon JFETs, and members of the GaAsFET family), are analytic approximations that essentially bear no physical insight into the inner workings of the transistors. This fact is particularly painful because to look at high-order intermodulation distortion, one needs to have third and fourth derivatives of mathematically continuous equations. The SPICE approach cannot easily be translated into modern harmonic-balance simulators because such cop-outs as IF THEN ELSE statements in programming provide everything else but a continuous model. In the case of our own work, we used complicated curve-fitting equations to obtain analytic equations and their derivatives to accurately provide a large-signal model that is valid over a wide range of dc and RF.

2-4-2 Typical SPICE Parameters

Since we are about to evaluate bipolar microwave transistors, junction FETs, MOSFETs (model level 3), and GaAsFETs, Tables 2-20, 2-21, 2-22, and 2-23 list typical parameters for the devices we have used. These parameters can be obtained by the Scout program with the appropriate measurements. The BSIM model for MOSFETs, applicable for submicron technology transistors, requires an enormous level of parameter extraction and has not fully been validated for the LDMOS-type transistors currently favored for RF and microwave applications.

Table 2-20 BFR193W BJT

IS = 2.738E – 16	BF = 125	NF = 0.95341
VAF = 24	IKF = 0.26949	ISE = 1.0627E – 14
NE = 1.935	BR = 14.267	NR = 1.4289
VAR = 3.8742	IKR = 0.037925	ISC = 3.7409E – 17
NC = 0.94371	RB = 15	IRB = 0.00091763
RBM = 1.8368	RE1 = 0.76534	RC2 = 0.11938
CJE = 1.1824E – 15	VJE = 0.70276	MJE = 0.48654
TF = 1.8828E – 11	XTF = 0.69477	VTF = 0.8
ITF = 0.00096893	PTF = 0	CJC = 9.3503E – 13
VJC = 1.1828	MJC = 0.30002	XCJC = 0.053563
TR = 1.0037E – 09	VJS = 0.75	MJS = 0
XTB = 0	EG = 1.11	XTI = 3
FCC = 0.72063	LB = 0.57E – 9	LC = 0.00E – 9
LE = 0.43E – 9	CBCP = 0.101E – 12	CCEP = 0.175E – 12
CBEP = 0.061E – 12	VCMX = 10 V	

The meaning and significance of the various parameters is best explored in a book on SPICE or semiconductor physics [22–24].

2-4-3 Noise Modeling

Diode Noise Model. The noise model for the diodes (Figure 2-122 and Table 2-24) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

The noise generators in the diode noise model are the series parasitic resistance, R_S, and the intrinsic junction. Figure 2-122 illustrates the intrinsic junction noise generator. Let Δf be the bandwidth (usually normalized to 1 Hz). The intrinsic noise generator has a mean-square value of

$$\langle i_{Dn}^2 \rangle = 2qI_D\,\Delta f + \mathrm{KF}\,\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\,\Delta f \tag{2-266}$$

Notes on the Diode Noise Model:

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.

[a]The currently implemented model for the junction FET is too primitive for serious RF applications. We have therefore taken the approach (liberty) of using the Materka parameter extraction approach for silicon junction FETs. This has resulted in unparalleled high-quality parameters; in particular, the knee voltage behavior has significantly improved, as well as the overall frequency response.

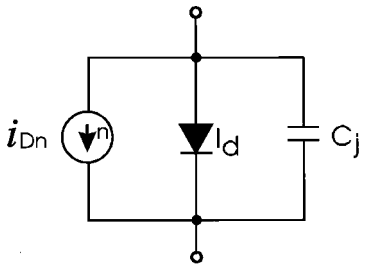

Figure 2-122 Equivalent noise circuit for a diode chip.

Table 2.24 Diode noise model keywords

Keyword	Description	Unit	Default
ID	Required bias current for the data point	Ampere	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner fequency	hertz	

2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.
3. The corner frequency noise model uses the system noise floor to internally compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the diode parameters and *kT*.
4. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

BJT Noise Model. The noise model for the Gummel–Poon BJT model consists of two contributions: shot noise and flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications) (see Table 2-25).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Bias-Independent Flicker Noise Coefficient*. This option involves the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying The Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with the bias point).

Notes on the BJT Noise Model:

Table 2.25 BJT noise model keywords

Keyword	Description	Unit	Default
IB	Required base bias current for the data point	ampere	
VCE	Required collector–emitter voltage for the data point	volt	
VBS	Base–substrate voltage required for LPNP type when four nodes are used	volt	
VCS	Collector–substrate voltage required for NPN or PNP type when four nodes are used	volt	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as bipolar noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model of course considers the actual operating temperature, which must be supplied to the model.

Figure 2-123 shows the BJT noise model. Let Δf be the bandwidth (usually normalized to a 1-Hz bandwidth). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{bn}^2 \rangle = 2qI_B \,\Delta f + \text{KF}\,\frac{I_B^{\text{AF}}}{f^{\text{FCP}}}\,\Delta f \tag{2-267}$$

$$\langle i_{cn}^2 \rangle = 2qI_C \Delta f \tag{2-268}$$

$$\langle i_{R_{bb}}^2 \rangle = \frac{4kT}{R_{bb}}\,\Delta f \tag{2-269}$$

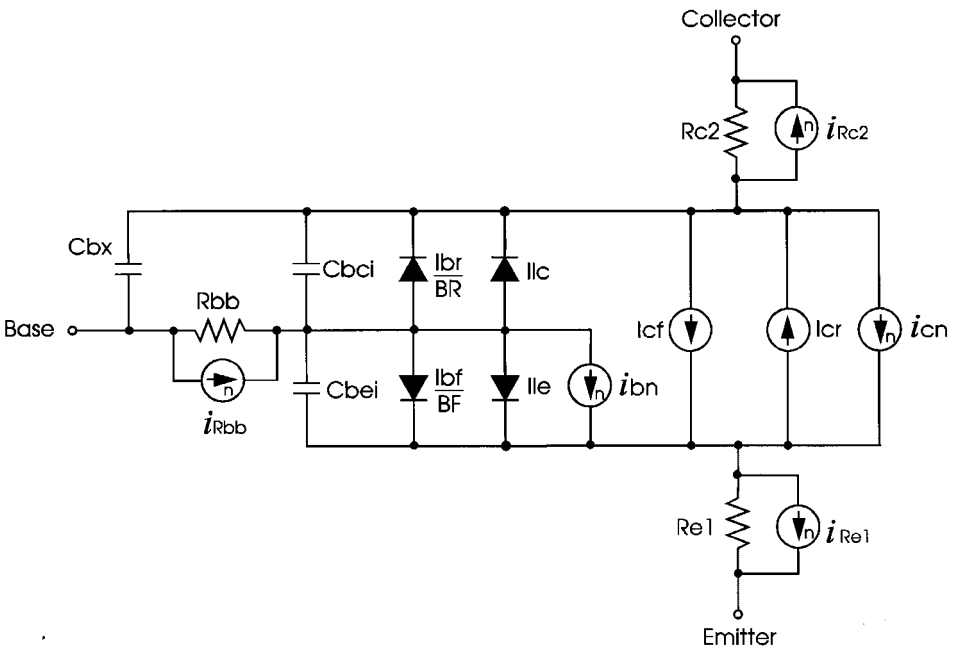

Figure 2-123 BJT noise model (not showing extrinsic parasitics). Current sources with *n* are noise sources.

$$\langle i_{R_{e1}}^2 \rangle = \frac{4kT}{R_{e1}} \Delta f \tag{2-270}$$

$$\langle i_{R_{c2}}^2 \rangle = \frac{4kT}{R_{c2}} \Delta f \tag{2-271}$$

$$I_B = \frac{I_{bf}}{BF} + I_{le} \tag{2-272}$$

$$I_C = I_{cf} - I_{cr} \tag{2-273}$$

JFET and MESFET Noise Models. The noise model for the FETs consists of two contributions: the shot noise and the flicker noise. There are two options to specify noise in the FET model:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (Table 2-26) to determine the flicker noise (this option is usually sufficient for most applications). The shot noise will be automatically computed using the SPICE equation.
2. Using bias-dependent flicker noise coefficients through a reference in the DATA block (specifying KF and AF at multiple bias points) and specifying the four noise parameters [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at multiple bias points.

Option 1: *Specifying the Enhanced SPICE Noise Model.* Option 1 is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model. The drain noise model has the form

$$\langle |I_{dn}|^2 \rangle = 4K_B T \frac{2g_m}{3} \Delta f + \text{KF} \frac{|I_D|^{\text{AF}}}{f^{\text{FCP}}} \Delta f \tag{2-274}$$

Table 2.26 FET noise model keywords

Keyword	Description	Unit	Default
FN	Noise data measurement frequency	hertz	1.0 GHz
VGS	Required gate–source voltage for the data point	volt	
VDS	Required drain–source voltage for the data point	volt	
FMIN	Required minimum noise figure in dB at FN		
MGO	Required magnitude of optimum noise reflection coefficient at FN		
PGO	Required phase of optimum noise reflection coefficient at FN		
RN	Required normalized noise resistance at FN		
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

where the shot noise is derived from g_m and the flicker noise is proportional to KF and the drain channel current, I_D, and inversely proportional to frequency. The AF and FCP parameters tailor the flicker noise dependence on bias and frequency, respectively.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows the specification of the complex bias-dependent nature of the shot noise and flicker noise. At high frequencies, the equivalent noise sources are correlated (the SPICE noise model does not account for this correlation). The complete evaluation of the shot noise sources can be determined from the four noise parameters. Since these are functions of bias, they can be specified over the (V_{GS}, V_{DS}) bias plane.

Additionally, a bias-dependent flicker noise coefficient (i.e., KF and AF vary with current) can be specified.

The MESFET noise model uses the four measured noise data [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at one frequency and multiple arbitrary bias points. The program uses these data and the FET model parameters to de-embed the noise data to an intrinsic noise model. The intrinsic model is accurate at all frequencies and, therefore, can predict the noise performance at all frequencies given data at just one frequency point. Built-in bias-dependent characteristics are used if multi-bias noise data are not provided.

Notes on the FET Noise Model

1. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
2. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Noise in a MESFET is produced by sources intrinsic to the device. The same approach, but with different flicker corner frequencies, is highly applicable to JFETs and MOSFETs. For more detail as to simulation, see the Element library book for the active-device portion of Ansoft's Serenade Design Environment product. The equivalent noisy circuit of an intrinsic FET is represented in Figure 2-124.

The intrinsic FET is internally represented as a noiseless nonlinear two-port with one equivalent noise current connected across the gate–source terminal, and one across the drain–source terminal. The correlations of the gate and drain noise current sources are

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \frac{\omega^2 C_{gs}^2}{g_m} R \tag{2-275}$$

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \, g_m P \tag{2-276}$$

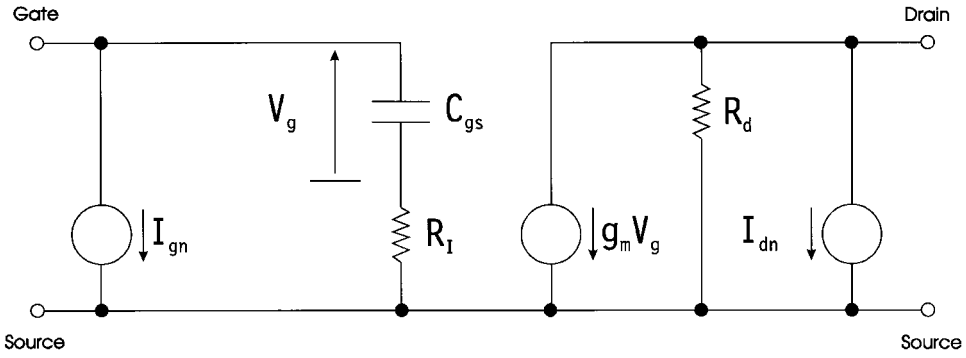

Figure 2-124 Equivalent noise circuit of an intrinsic FET device.

$$\langle I_{gn} I_{dn}^{*} \rangle = 4K_B T\, \Delta f\, j\omega C_{gs} \sqrt{PR}\, C \tag{2-277}$$

The correlation matrix of the noise current sources is

$$C_{dc}(\omega) = \frac{2}{\pi} K_B T\, d\omega \begin{bmatrix} \dfrac{\omega^2 C_{gs}^2}{g_m} R & -j\omega C_{gs}\sqrt{PR}\, C \\ j\omega C_{gs}\sqrt{PR}\, C & g_m P \end{bmatrix} \tag{2-278}$$

The gate and drain noise parameters R and P and the correlation coefficient C are related to the physical noise sources acting in the channel and are functions of the device structure and bias noise parameters. By defining measured noise parameters, $F_{\min}$, R_n, and Γ_{opt}, and using a noise de-embedding procedure, the parameters R, P, and C and the intrinsic noise correlation matrix of a FET device as functions of device bias are determined by the program.

In addition to the noise sources shown above, the flicker (1/f) noise can also be modeled by means of a noise current source connected in parallel with the intrinsic drain port. The flicker noise component in a narrow band, Δf, is expressed in the form

$$\langle |I_f|^2 \rangle = \mathrm{Q}\, \Delta f \frac{|I_D|^{\mathrm{AF}}}{f^{\mathrm{FCP}}} \tag{2-279}$$

where I_D is the instantaneous value of the channel current, and Q, AF, and FCP are empirical parameters. In most practical cases, AF and FCP are directly obtained from measurements (typically, AF = 2 and FCP = 1), while Q is not. In Ansoft's Serenade Design Environment, Q is either provided directly using KF or is computed by providing the flicker corner frequency (FC). FC is the frequency at which the flicker noise equals the shot/diffusion noise. The corner frequency is defined by the equation

$$\mathrm{Q} \frac{|I_D|^{\mathrm{AF}}}{f_{\mathrm{C}}^{\mathrm{FCP}}} = g_m P \tag{2-280}$$

Given the corner frequency FC and the measurement bias point V_{gs} and V_{ds}, the program automatically computes I_D, g_m, and P, and finally Q.

More information on FET noise modeling can be found in the literature [25–31].

MOSFET Noise Model. The MOSFET noise model (Figure 2-125 and Table 2-27) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. It can be turned off by specifying SN = 0. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).

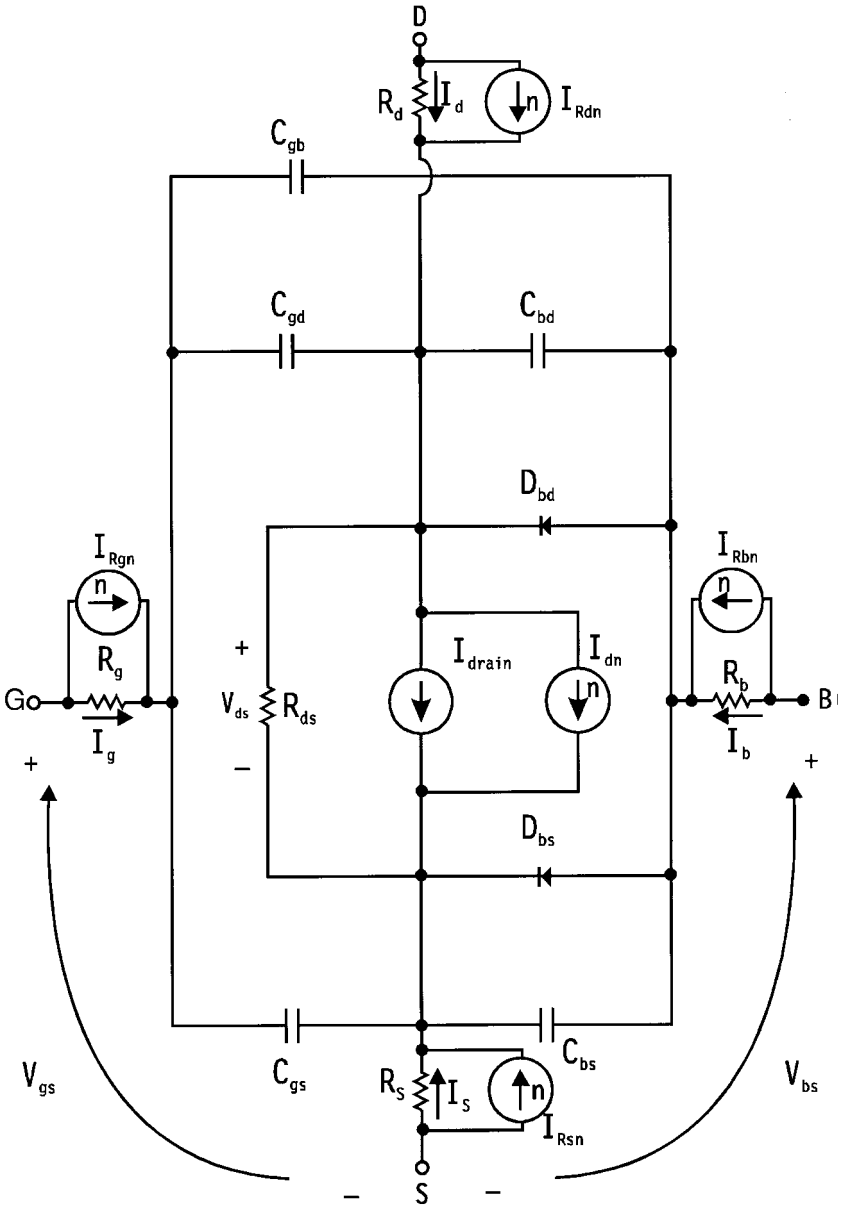

Figure 2-125 Equivalent noise circuit of an intrinsic MOSFET device.

Table 2.27 MOSFET noise model keywords

Keyword	Description	Unit	Default
VGS	Required gate–source bias for the data point	volt	
VDS	Required drain–source for the data point	volt	
VBS	Required drain–bulk for the data point	volt	
KF	Flicker noise coefficient		1.0E–13
AFT	Bias exponent of the flicker noise model		2.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

2. Using bias-dependent flicker noise coefficients through a reference (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Enhanced SPICE Noise Model.* This option is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model (the flicker noise is considered bias dependent).

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with drain current). The MOSFET noise model data are given and referenced by a model parameter.

Notes on the MOSFET Noise Model

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as MOSFET noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Let Δf be the bandwidth (normalized to 1 Hz). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{dn}^2 \rangle = \frac{8kTg_m}{3}\Delta f + \mathrm{KF}\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\Delta f$$

$$\langle i_{Rgn}^2 \rangle = 4\frac{kT}{R_g}\Delta f$$

$$\langle i_{Rdn}^2 \rangle = 4\frac{kT}{R_d}\Delta f$$

$$\langle i_{Rsn}^2 \rangle = 4\frac{kT}{R_s}\Delta f$$

$$\langle i_{Rbn}^2 \rangle = 4\frac{kT}{R_b}\Delta f$$

We include this MOSFET noise model (used for quite awhile) for completeness. At the moment, we do not know which MOSFET noise model the industry will settle on in the future.

Modern CAD tools, such as Ansoft's Serenade product, use these models to generate quite accurate noise data based on a good linear equivalent model. Internally Serenade uses the noise-correlation-matrix method (first introduced by Russer). The same noise-correlation techniques apply to BJTs, all FETs except MOS, and HBTs (such as SiGe devices).

2-4-4 Scalable Device Models

Since diodes and transistors are scalable, here are guidelines for how to scale them:

Microwave Diode

$$I_D = Area \times I_D$$
$$C_j = Area \times C_j$$
$$R_D = R_D/\text{Area}$$

PIN Diode

$$I_D = \text{Area} \times I_D$$
$$C_j = \text{Area} \times C_j$$
$$R_S = R_S/\text{Area}$$
$$R_{\max} = R_{\max}/\text{Area}$$

Bipolar

$$I_{bf} = \text{Area} \times I_{bf} \qquad I_{br} = \text{Area} \times I_{br}$$
$$I_{le} = \text{Area} \times I_{le} \qquad I_{lc} = \text{Area} \times I_{lc}$$
$$I_{cf} = \text{Area} \times I_{cf} \qquad I_{cr} = \text{Area} \times I_{cr}$$
$$C_{bc} = \text{Area} \times C_{bc} \qquad C_{be} = \text{Area} \times C_{be}$$
$$C_{bx} = \text{Area} \times C_{bx} \qquad R_{bb} = R_{bb}/\text{Area}$$
$$\text{RB2} = \text{RB2/Area} \qquad \text{RC2} = \text{RC2/Area}$$
$$\text{RE1} = \text{RE1/Area} \qquad I_{jss} = I_{jss} \times \text{Area}$$
$$C_{jss} = C_{jss} \times \text{Area}$$

Materka FET

$$\begin{aligned}
\text{IGSS} &= \text{IGSS} \times \text{Area} \\
\text{CGS0} &= \text{CGS0} \times \text{Area} \\
\text{CGS1} &= \text{CGS1} \times \text{Area} \\
\text{CDVC} &= \text{CDVC} \times \text{Area} \\
\text{CDVS} &= \text{CDVS} \times \text{Area} \\
R_G &= R_G \times \text{Area}/(\text{Number of fingers} \times 2) \\
R_D &= R_D/\text{Area} \\
R_S &= R_S/\text{Area}
\end{aligned}$$

Generating a Databank for Parameter Extraction. Given the fact that one can measure with an automated system (Rohde & Schwarz, Hewlett-Packard) the bias-dependent *S* parameters of any active device, bipolar and FET, and furthermore, that Hewlett-Packard makes a computer-controllable dc *I–V* curve tracer, we can generate a huge databank that allows us to have corresponding values for both RF and dc operating points. To validate this, one needs to run a large-signal simulator, such as Ansoft's Serenade Design Environment, or its equivalent from other manufacturers, enter the large-signal parameters, and generate a set of *S*-parameters that correspond to the dc values for which we have measurements. The agreement between measured and predicted points for both RF and dc values is a good measure to evaluate the accuracy of the parameter extraction and the simulator's performance. We cannot stress often enough, however, the fact that while most simulator models are quite good, the weakest point of the link is the parameter extraction program.

Currently, the best parameter extraction for bipolar transistors and FETs, excluding the BSIM model, is implemented in the Scout program by Ansoft, based on modified techniques found in the literature. These techniques are based on the fact that present-day nonlinear modeling of microwave devices, especially FETs, is not exactly adequate to describe all effects found within these devices. In the case of FETs, the most troublesome parameter is R_{DS}, which is really more bias dependent than practically all existing models take into consideration. Techniques used in published extraction methods extract nonlinear models independently for each section of a device model, and then assume that the proper response will be generated when all parts are put together. For instance, many extraction techniques independently fit the *I–V* data of the section describing the *I–V* curves and then fit the *C–V* data to the equivalent small-signal models. This results in an approximation to the bias-dependent response of the complete model.

In the technique used in the Scout program, model parameters are extracted simultaneously so the effects between model sections are accounted for and the device is treated as a whole. The most critical area happens to be in the linear region, typically around the pinchoff area, and for very small supply voltages. The Scout techniques use measured data taken at a wide variety of bias ranges and frequencies to define the model response. The possible solution region for the complete model becomes well identified and uniqueness of solution is vastly improved. The Scout program is interactive in nature and displays simultaneously measured versus predicted data. This allows for fine-tuning of the parameters.

Over the years, the industry has adapted a large number of models. Those supported by the Scout parameter extraction program include:

- *npn* Gummel–Poon BJT
- *pnp* Gummel–Poon BJT

- *npn* heterojunction BJT
- *pnp* heterojunction BJT
- General-purpose *n*-channel JFET
- General-purpose *p*-channel JFET
- Chalmers (Angelov) MESFET/HEMT
- Curtice–Ettenberg cubic MESFET/HEMT
- Curtice quadratic MESFET/HEMT
- IAF (Berroth) MESFET/HEMT
- Modified Materka–Kacprzak MESFET/HEMT
- Raytheon (Statz) MESFET/HEMT
- TriQuint (TOM-1 and TOM-2) MESFET/HEMT
- Ansoft physics-based MESFET

The Ansoft physics-based MESFET model is unique and politically sensitive because its users are essentially required to enter all device fabrication parameters to get the appropriate answer, and most, if not all, companies will stay away from handing out such company proprietary recipes. The validation of this model was done using manufacturing data for transistors that were developed under government contract and therefore accessible for the team members. Compact Software/Ansoft over the last ten years has been involved in a large number of government-funded research and development programs, and practically all modern modeling implementations and their validation were done in conjunction with the largest semiconductor manufacturers.

As far as further validation is concerned, besides our looking at the matching of dc *I–V* curves and *S* parameters, important parameters such as 1-dB compression point, power-added efficiency, and harmonic content are important criteria to evaluate the quality of such an undertaking. As far as hardware is concerned, one needs to have a network analyzer, such as the HP8510 or its equivalent. Its selection is determined by the highest cutoff frequency where measurements are necessary. A dc feed capability, up to several amperes, through the measuring ports, and appropriate power supplies are essential, as is a dc *I–V* curve tracer (HP4145). The built-in various optimizers of the program establish the best possible match between the selected parameters and the measured results.

The area of proper modeling has always been fascinating because the active-device model can make or break first-pass success. Figure 2-126 shows the doubler gain comparison of a model supplied by NEC (the device manufacturer, parameter extraction done with Scout, and parameter extraction supplied from the *Microwave Engineering Europe* (*MEE*) magazine in its CAD review of May 1994). It is somewhat unclear where the *MEE* model came from. The actual task given by *MEE* was to simulate a frequency doubler against measured data. This type of simulation required two areas of high precision, one being the model and the other being the electromagnetic modeling of the discontinuities of the circuit—in this case, a stub element. The circuit itself was very simple. The manufacturer-supplied data gave the poorest results (we believe the parameter extraction came from a third party not quite up to speed in this area). The results that came from the Scout parameter extraction and the third one that *MEE* supplied were fairly close, yet the Scout solution, including the electromagnetic simulation part, gave the best answer. More simulators have since appeared on the market, and it would be interesting to revisit this topic. Figure 2-127 shows a physical layout of the doubler circuit.

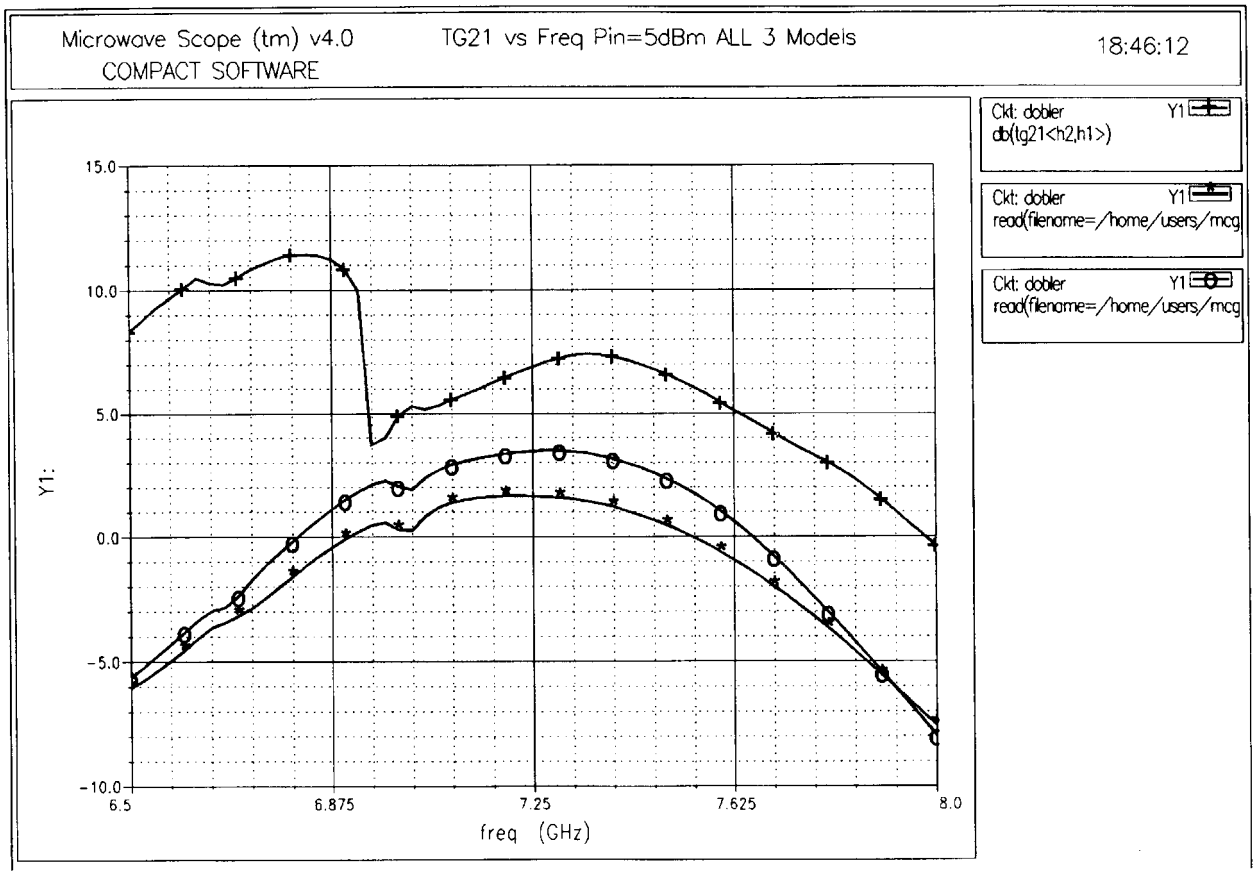

Figure 2-126 Gain comparison of a MESFET doubler based on the three device models used: NEC (+), Ansoft (O), and *Microwave Engineering Europe* (*).

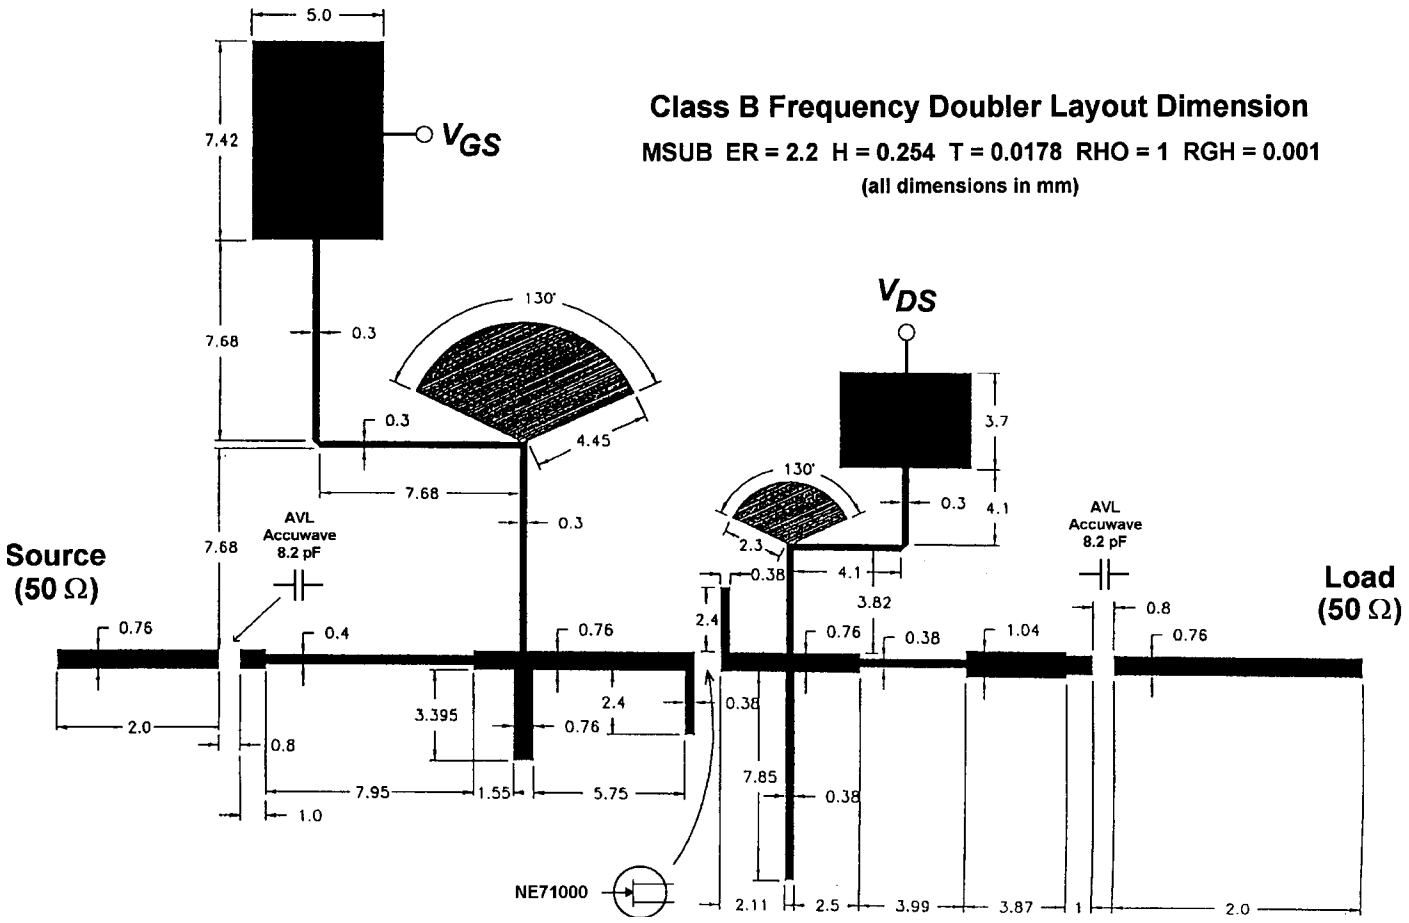

Figure 2-127 Layout of the MESFET doubler.

Test Setup. The measuring equipment required for the actual extraction includes:

- Semiconductor parameter analyzer (HP4145)
- Vector network analyzer (ZVR, HP8510, W360)
- Bias supplies and meters
- Power RF source, power meters, spectrum analyzer, and so on

The required software tools include:

- GPIB controller: Compact NETCOM (network analyzer control program)
- Parameter extraction performed by Scout
- Small-signal and harmonic-balance validation: Serenade nonlinear analysis (Microwave Harmonica) or its equivalent

After we have assembled all these tools, the device extraction process can begin. It will follow the flow as shown in Figure 2-128. Depending on the numbers for the dc/ac measurement, this process can take up to two hours. The Scout program, with its built-in optimizer, can take another two hours. It is therefore reasonable to assume a thorough parameter extraction of a device will take about one day.

Parameter Extraction. As we have outlined, the parameter extraction program Scout, which is optimized for high-frequency and millimeter-wave application, is a Windows-based parameter extraction and optimization program. It requires a network-communication program to acquire dc and *S* parameter measurement data. It supports interactive device fitting and optimization and supports the various models listed earlier. For ease of use, it has an attractive graphical user interface with multiple windows, as can be seen from Figure 2-129. Hewlett-Packard offers more general RF parameter extraction programs, but we did not have access to those. We also expect that some other companies will develop similar tools. An interesting program named HarPE, developed by Professor John Bandler in Canada, may have been withdrawn from the market after his company merger with HP. The program was acclaimed to provide quite good results using measured harmonics. One of the unfortunate deficiencies of most BJT parameter extraction programs known to us is the fact that (as one

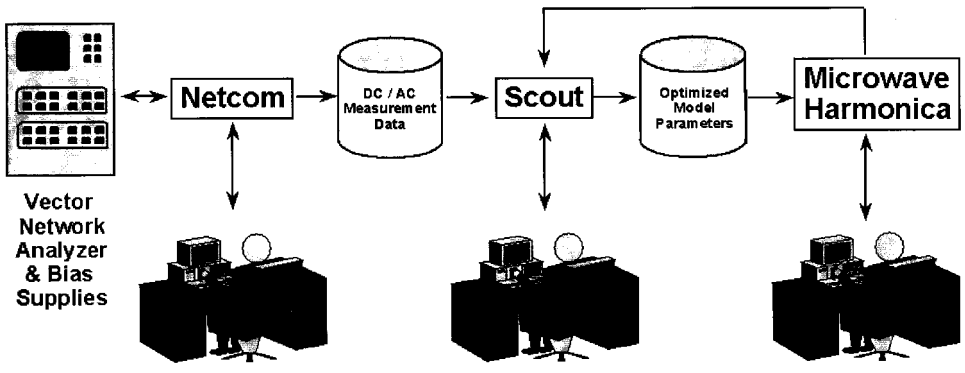

Figure 2-128 Flowchart of the parameter extraction process.

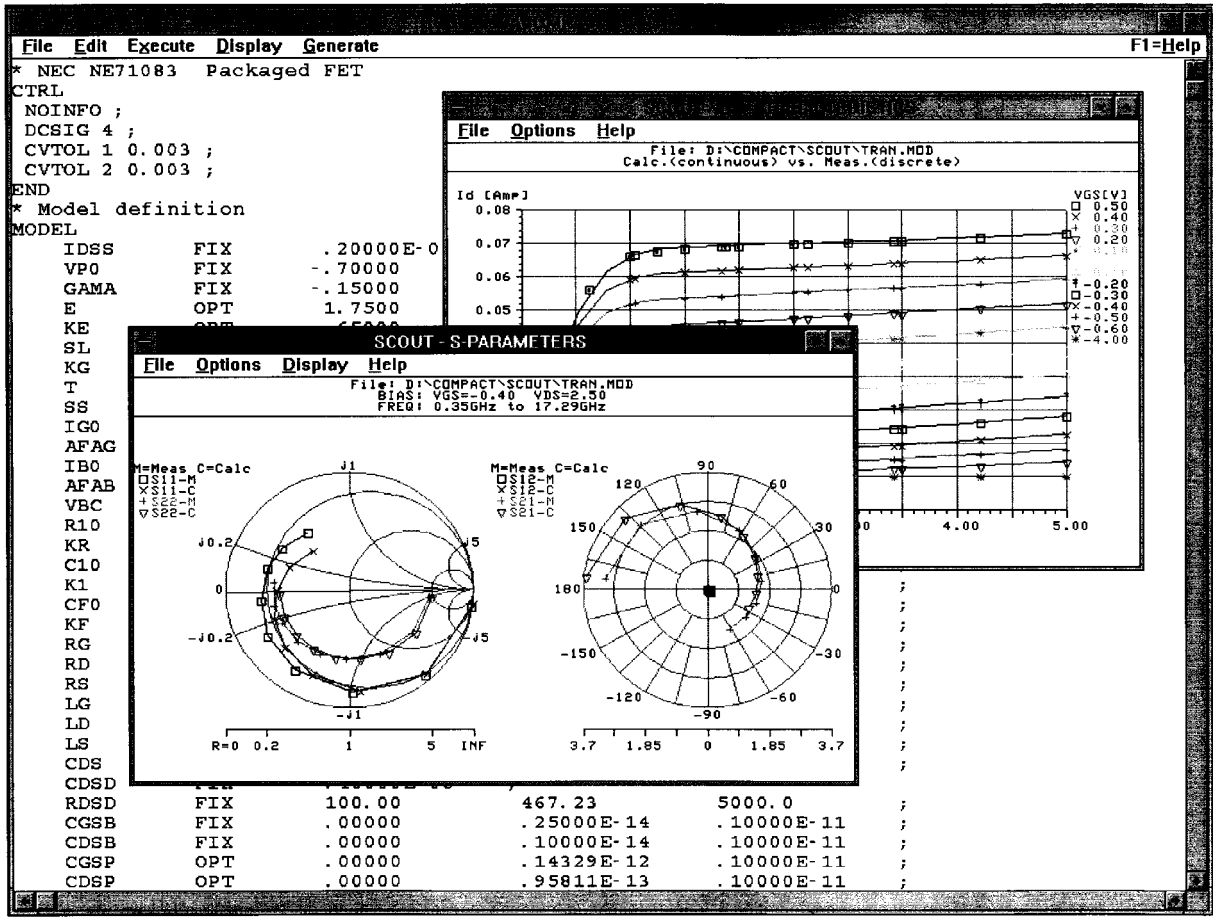

Figure 2-129 The Scout user interface.

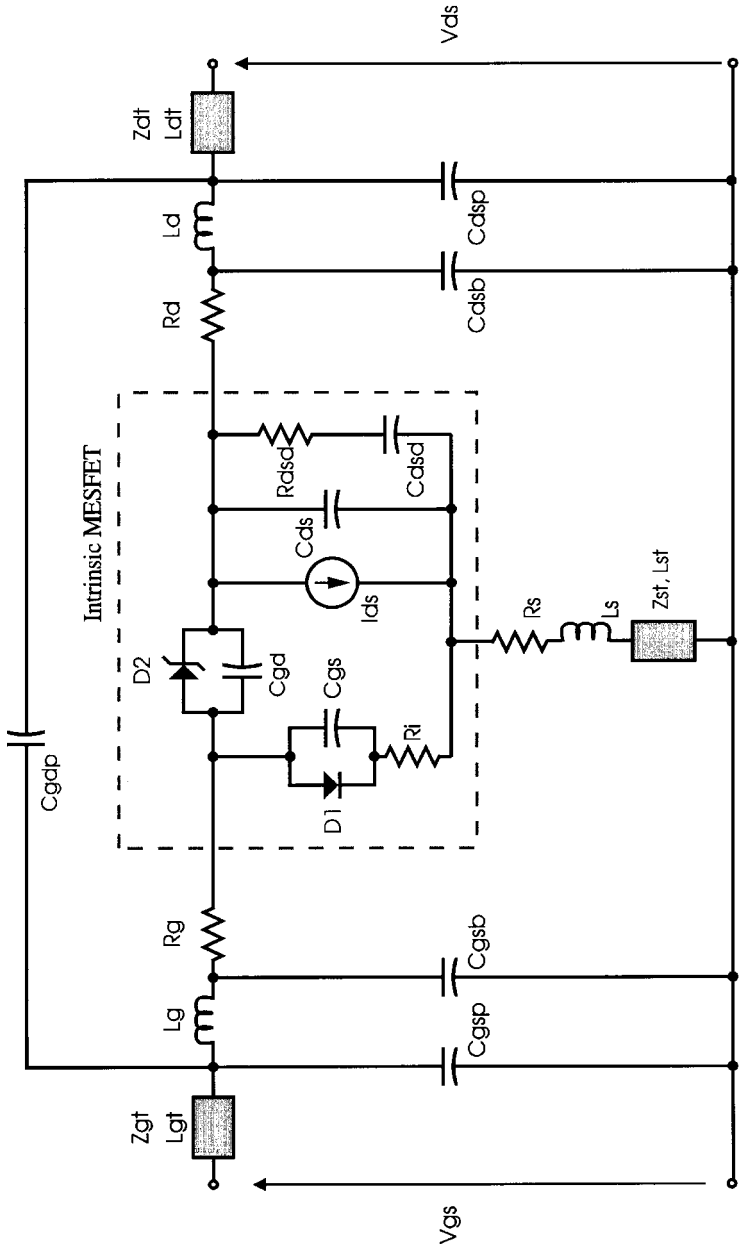

Figure 2-130 Intrinsic model and complete chip/package model.

example) the sensitivity to determine the actual base-spreading resistor for bipolar transistors is poor. The only useful workaround is considering the noise figure of the device, given the fact that the midrange noise factor of any bipolar transistor can be calculated from

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-281)

By solving the equation for R'_{bb}, since we know that R_g, the generator impedance, is 50 Ω, and the emitter diffusion resistance (26 mV/I_C) can be determined from the bias point, we can already eliminate the need to extract R'_{bb} from the HP test equipment. By using HP's program, errors of a factor up to 10 are not uncommon because of the low sensitivity for this parameter. Another headache in the case of the BJT is the determination of the excess phase (PTF) and forward and reverse transit time (TF and TR, respectively). The lack of quality modeling can best be found by examining the measured versus predicted values of S_{22}. Again, practically all the parameter extraction programs we have seen so far suffer from this deficiency.

MESFETs. In the case of a member of the MESFET family, a model as shown in Figure 2-130 is used. It consists of an intrinsic model and a complete chip/package parasitic model. In the case of the MESFET, to obtain first-class results, the following measurements are necessary:

- Dc *I*–*V* measurements
- Dc diode measurements
- Cold-FET and forward-biased-gate *S* parameters
- *S*-parameter measurements over bias
- Harmonic power measurements
- *Z*-Parameter Equations for Figure 2-131

In order to simplify the modeling, it is useful to do cold-FET [Figure 2-131 and Eqs. (2-282), (2-283), and (2-284)] and pinched-FET [Figure 2-132 and Eqs. (2-285), (2-286), and (2-287)] measurements to derive some of the intrinsic or extrinsic values.

$$Z_{11} = R_s + R_g + R_{gs} + \alpha_g R_{ch} + j\omega(L_g + L_s) \tag{2-282}$$

$$Z_{12} = Z_{21} = R_s + \alpha R_{ch} + j\omega L_s \tag{2-283}$$

$$Z_{22} = R_s + R_d + 2\alpha R_{ch} + j\omega(L_s + L_d) \tag{2-284}$$

Capacitance Equations for Figure 2-132

$$C_b = -\frac{\text{Im}(Y_{12})}{\omega} \tag{2-285}$$

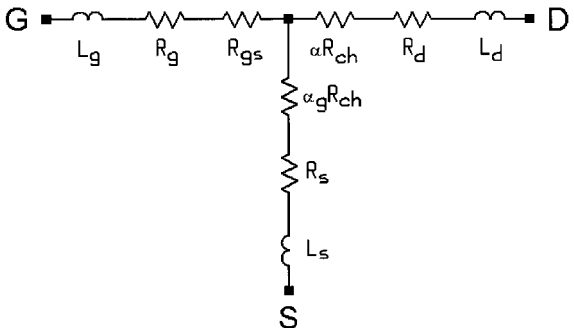

Figure 2-131 Forward-biased gate FET model for cold-FET (V_{DS} = 0, V_{GS} 0) measurements. This approach allows direct extraction of parasitic resistances and inductances.

$$C_{pg} = \frac{\mathrm{Im}(Y_{11})}{\omega} - 2C_b \tag{2-286}$$

$$C_{pd} + C_{ds} = \frac{\mathrm{Im}(Y_{22})}{\omega} - C_b \tag{2-287}$$

For the highest accuracy, the following extraction strategies are recommended:

- Pre-extraction using basic dc and *S* parameters—for example, C_{GS} from S_{11}
- Six extraction steps to determine parameters:
  Basic dc model
  Advanced dc model
  Basic ac model
  Advanced ac model
  Package determination
  Diode characterization
- Large-signal validation
  Power compression and bias shift
  Harmonic power comparison
  Intermodulation characterization

As an example, we are going to use the popular and well-characterized NE71000, which is not a particularly modern device, but has been used for various research projects. Figure

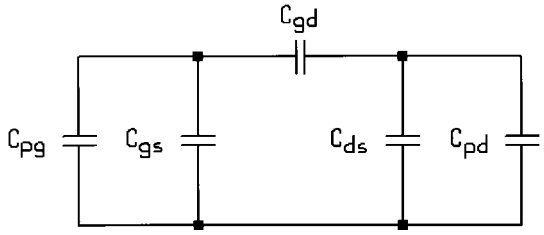

Figure 2-132 Pinched-FET (V_{DS} = 0, V_{GS} *VP*) model. This approach allows direct extraction of parasitic gate and drain capacitances.

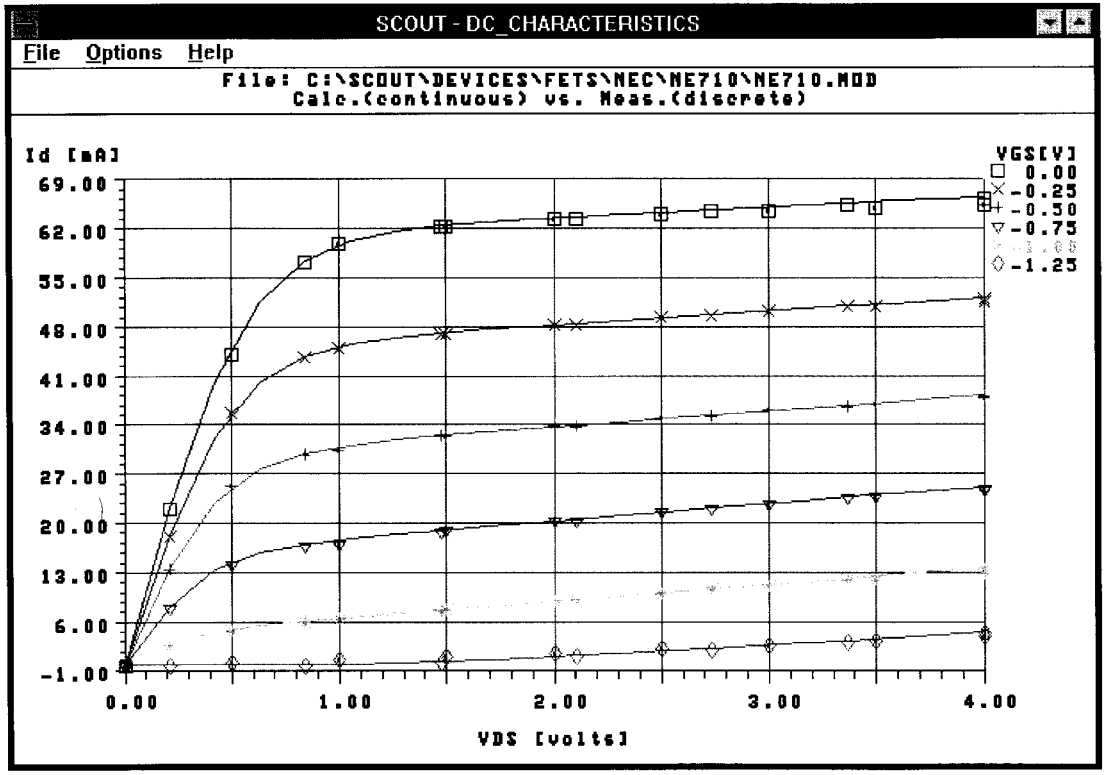

Figure 2-133 Measured NE71000 dc *I–V* curves versus those simulated using the Ansoft Materka model.

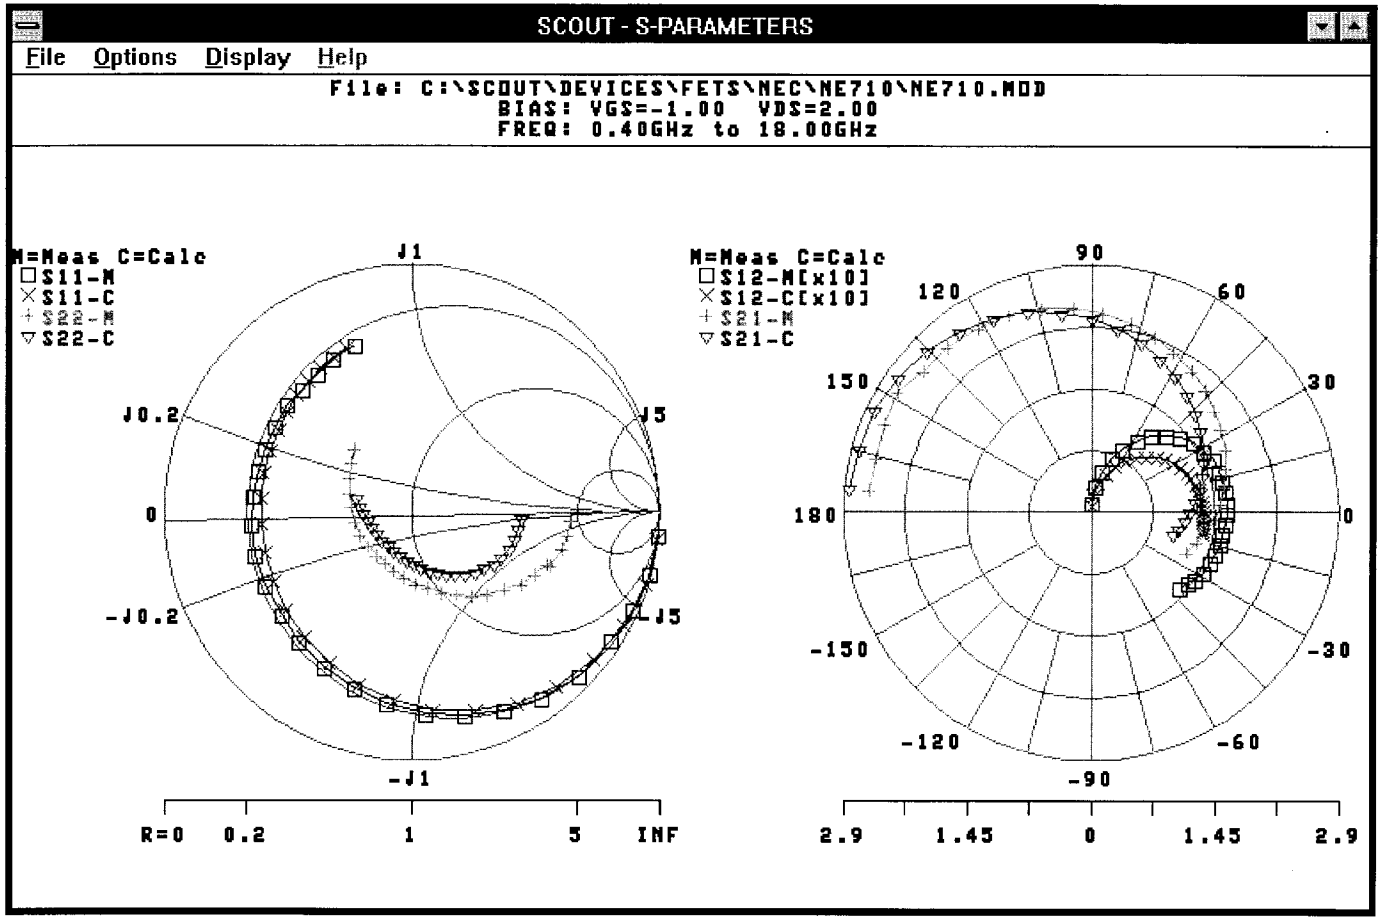

Figure 2-134 Measured versus calculated NE71000 *S* parameters for $V_{GS} = -1.00$ and $V_{DS} = 2.00$.

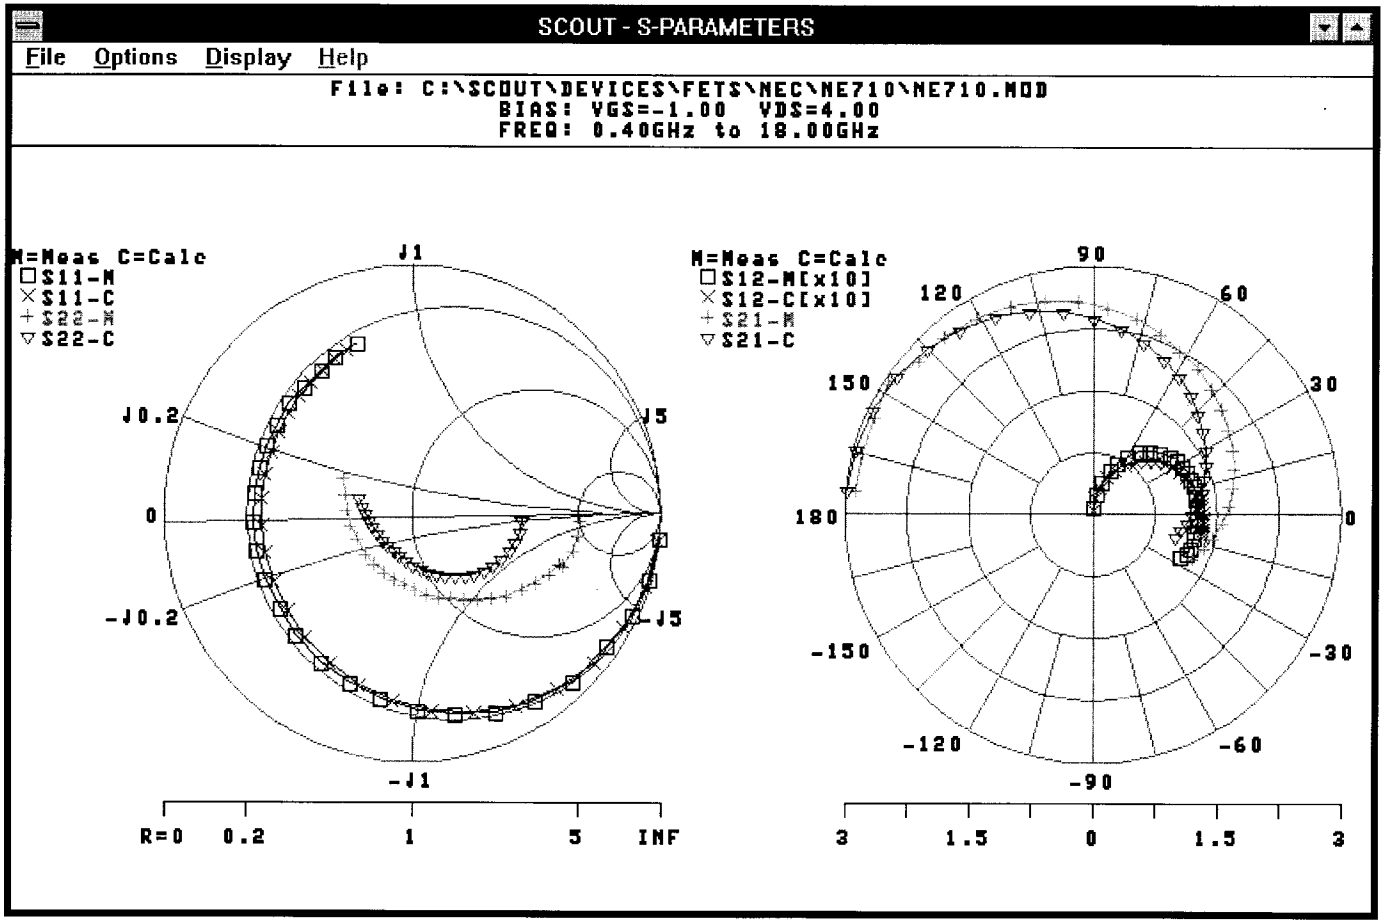

Figure 2-135 Measured versus calculated NE71000 *S* parameters for V_{GS} = –1.00 and V_{DS} = 4.00.

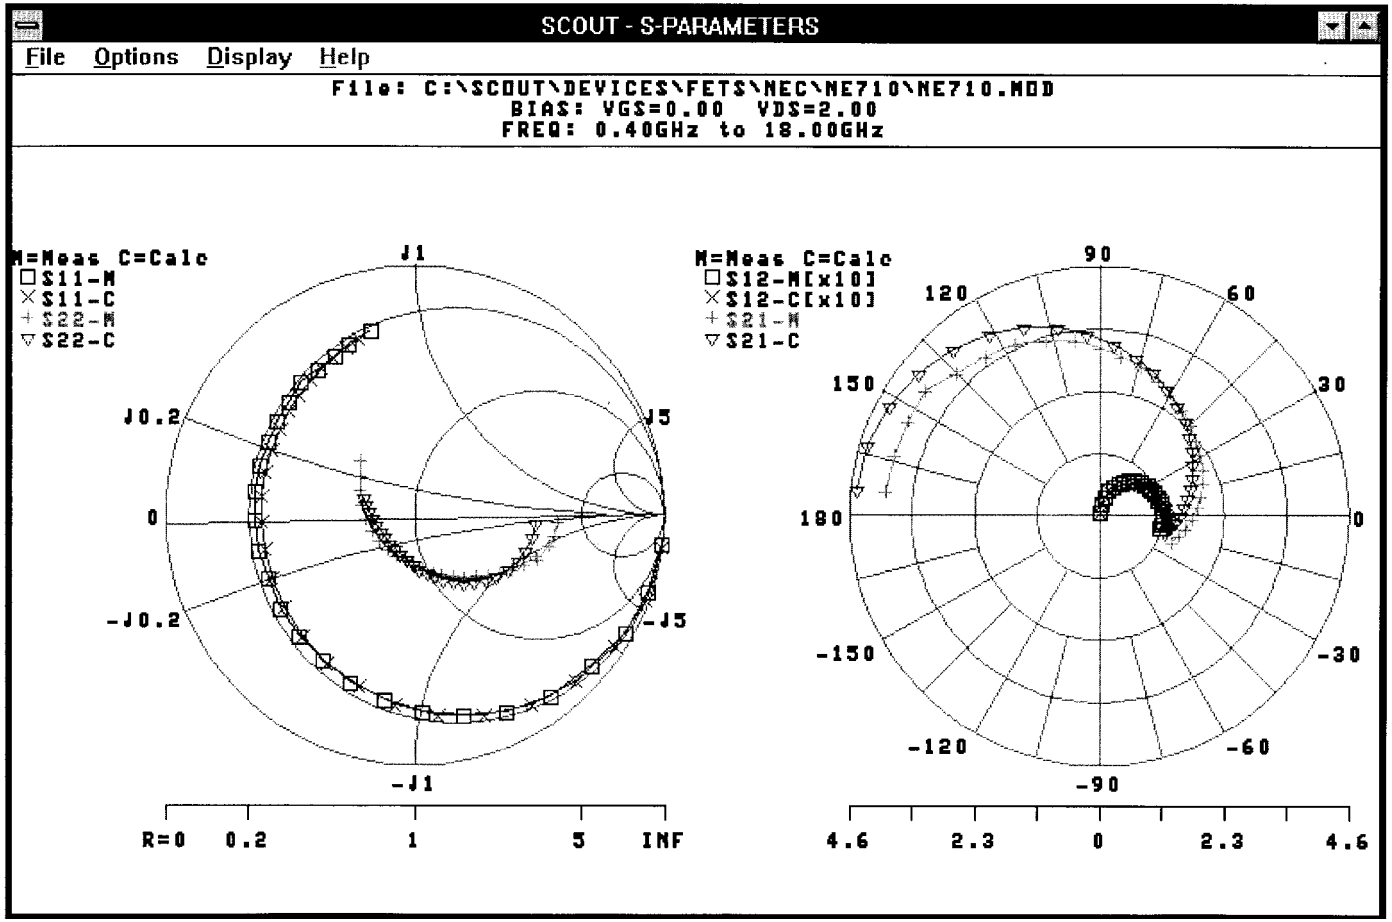

Figure 2-136 Measured versus calculated NE71000 *S* parameters for V_{GS} = 0.00 and V_{DS} = 2.00.

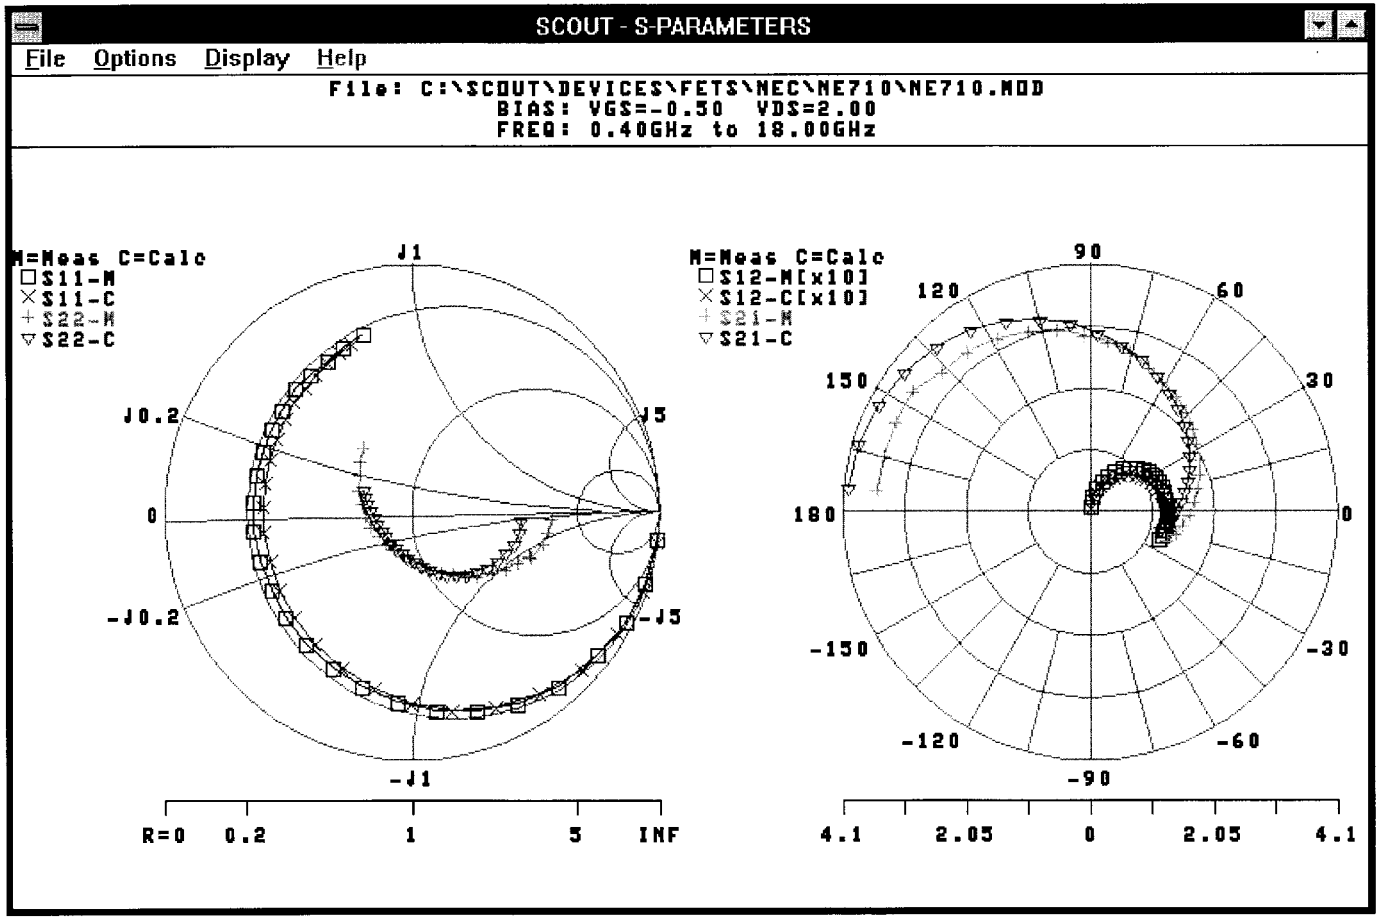

Figure 2-137 Measured versus calculated NE71000 *S* parameters for V_{GS} = –0.50 and V_{DS} = 2.00.

2-133 shows measured versus simulated dc I–V curves for the NE71000. The agreement between measured and predicted dc I–V curves is quite good. In a similar fashion, we obtain the S-parameter fits over bias. They are shown in Figures 2-134 through 2-137.

As mentioned above, 1-dB compression, power saturation, and drain current are functions of the drive. This particular model point is not particularly impressive. We believe this has to do with the original Materka model.

Having brought up the subject of models, Figure 2-138 compares measured data with that obtained with the Angelov, cubic, quadratic, TriQuint, Raytheon, and Materka models. The figure shows that there is no perfect model yet. To put this in perspective, in Figure 2-139 we show the dc I–V error bars for these six models. This graph shows that the least errors for the dc measurement versus modeling are obtained with the Curtice cubic model, followed by the modified Materka model (implemented in Serenade) and TriQuint models. The difference in S parameter matching for RF application is significantly more relevant for the designer.

Things become much more interesting if we compare the S-parameter errors between the Materka shown in Figure 2-140, the Curtice cubic model (Figure 2-141), and the TOM model (Figure 2-142). Improved modeling regarding the R_{DS} is being developed, and we will discuss this at the end of this chapter.

Since the trend is to go to low-voltage power RF operation, several issues must be battled:

- Models are most inaccurate at low V_{DS} and near pinchoff.
- Modeling of low-voltage operation is adversely impacted.
- Thermal effects must be considered, but older models do not account for this.

A Case Study. As a case study, we will consider the Oki KGF1608 power MESFET (0.5 μm × 28 mm). Figures 2-143 and 2-144 show the dc I–V curves and S parameters, respectively. The resolution of the S parameters, based on the scale used, is not particularly impressive.

Figure 2-145 shows the dc I–V curves, with load line, for the KGF1608; the self-heating effect of the transistor can be seen in the droop of the top two curves. Figures 2-146 and 2-147 show drain current and output power versus drive, respectively. The test conditions for these three figures were f = 850 MHz, V_{DS} = 3.4 V, and V_{DS} = 2.025 V.

2-4-5 Conclusions

From all plots of dc and ac error contours, dc I–V curves, and dc error bar charts we can draw the following conclusions.

Dc errors

- *In the Saturation Region*. All the models considered work very well, with a relative error of less than 15%. This means that all models are suitable for typical applications where the device operates in the saturation region.
- *In the Linear Region.* Though the errors in the saturation region are similar for different models, the errors in the linear region are quite different. The Materka, Curtice cubic, and TriQuint models behave better than other models in the linear region. The relative errors of these three models are less than 10%, while other models have more than 60% relative errors at some points.

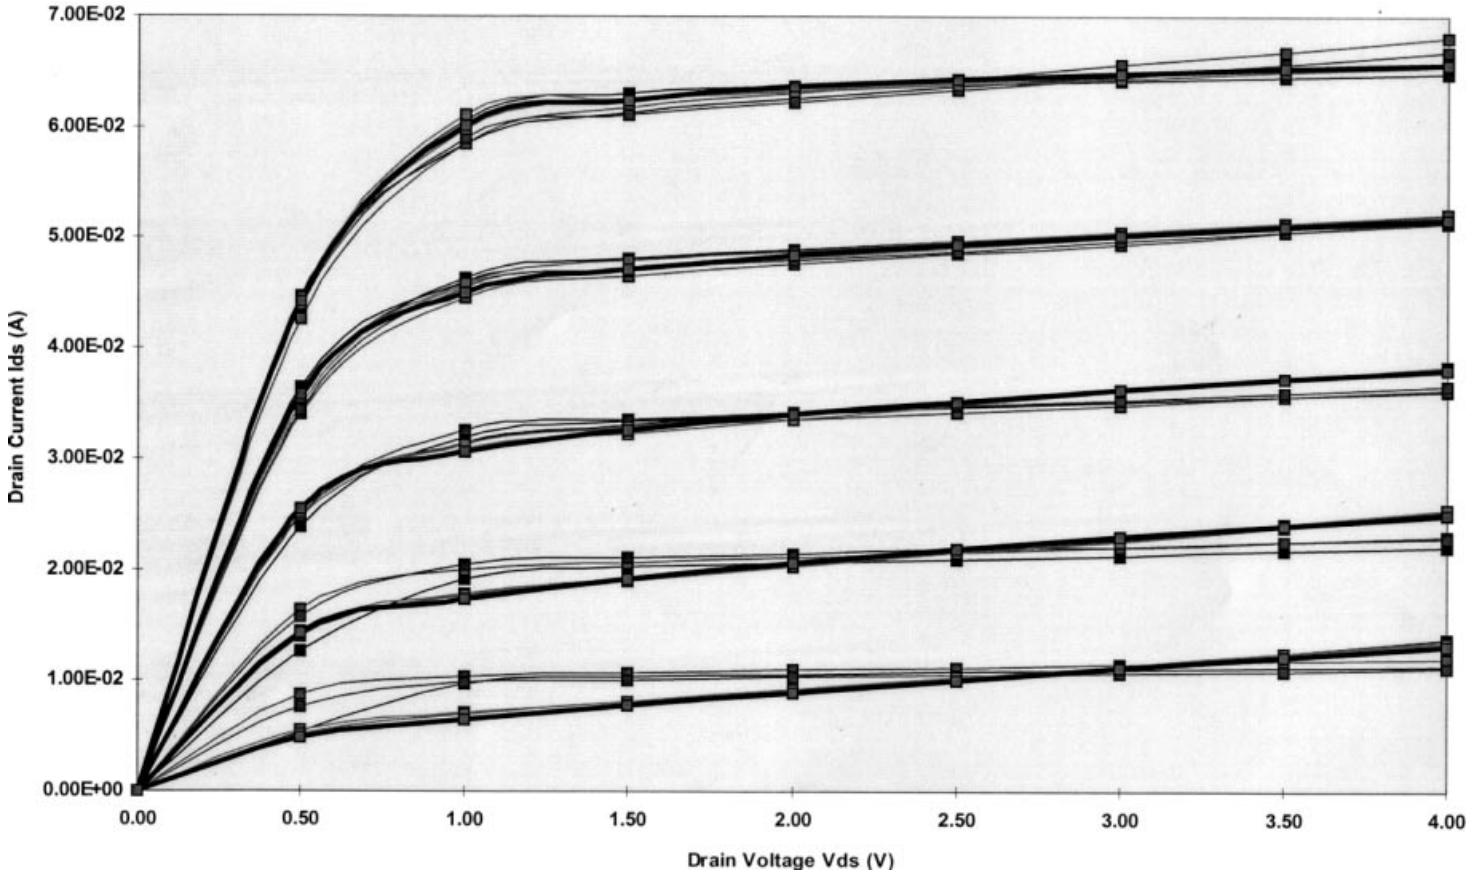

Figure 2-138 Comparison of dc models: Chalmers (Angelov), Curtice cubic, Curtice quadratic, Materka, Raytheon, and TOM (TriQuint).

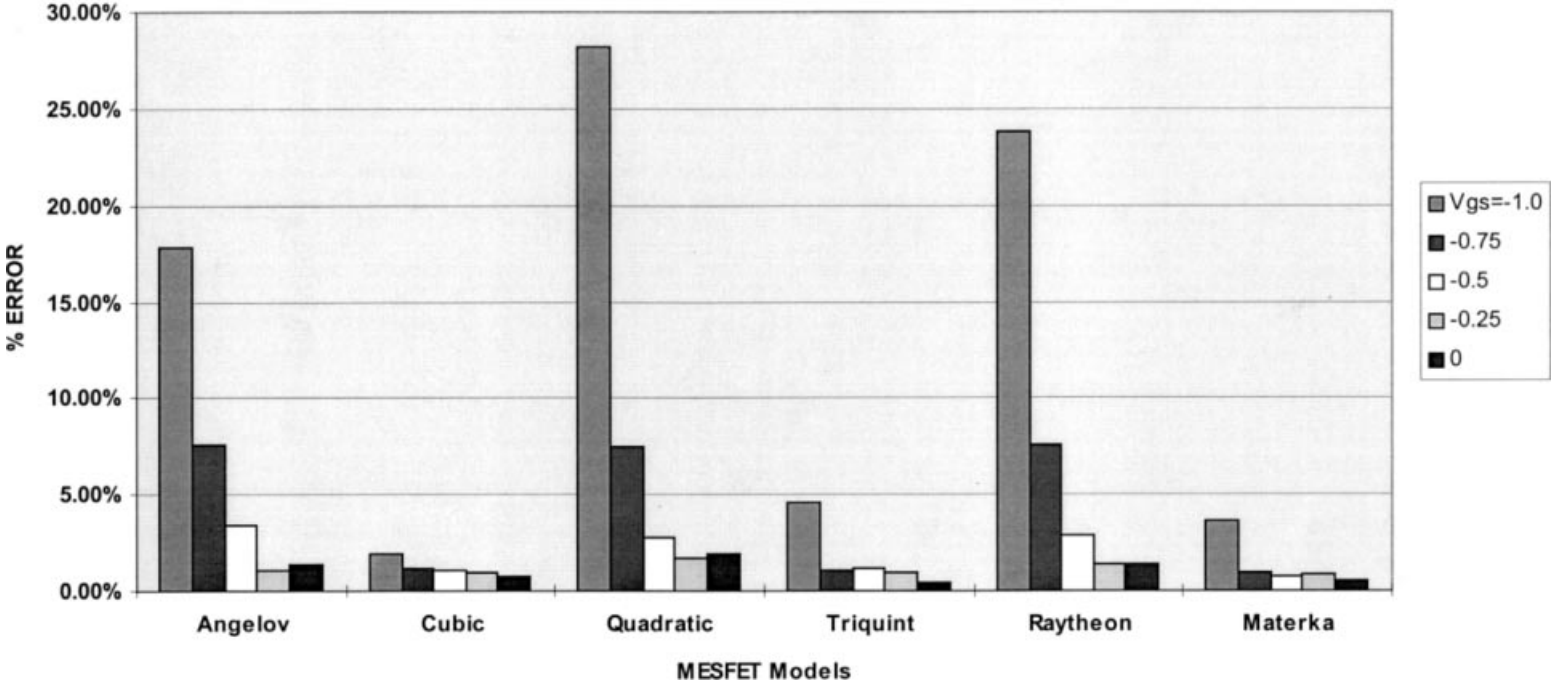

Figure 2-139 Dc *I–V* error bars: Chalmers (Angelov), Curtice cubic, Curtice quadratic, Materka, Raytheon, and TOM.

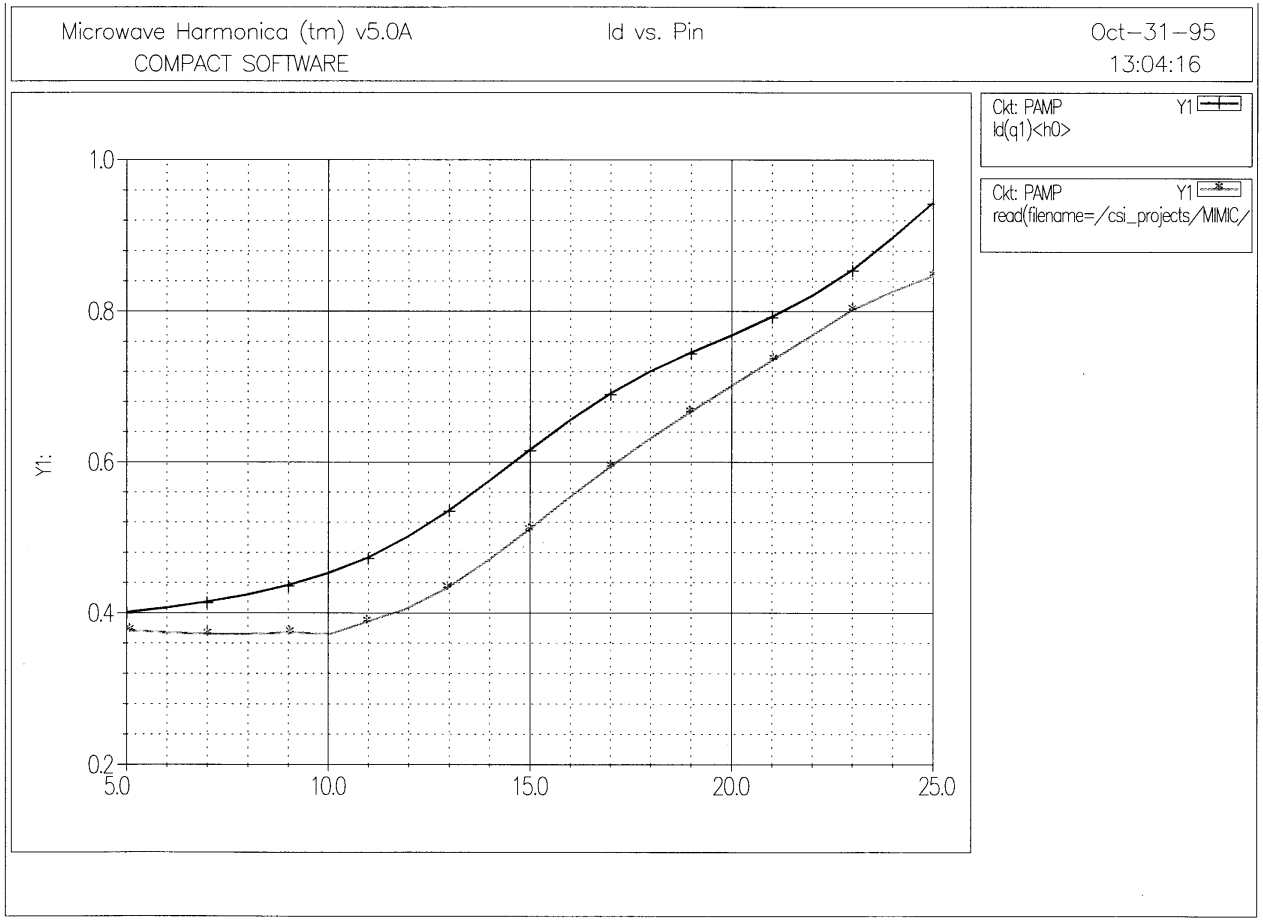

Figure 2-146 Measured versus calculated drain current for the KGF1608 MESFET.

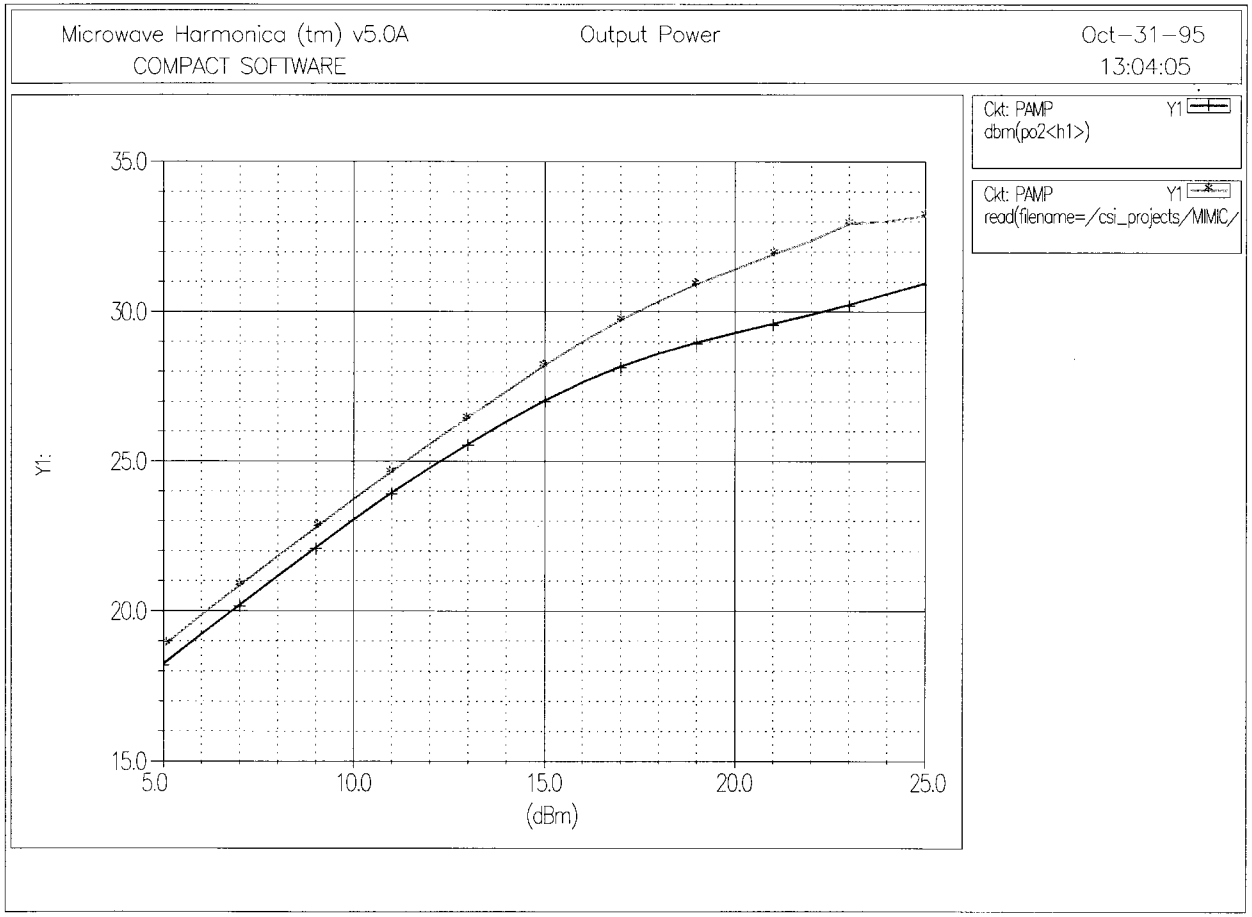

Figure 2-147 Measured versus calculated output power for the KGF1608 MESFET.

ac Errors. From the ac error contour plots we can see that the Chalmers (Angelov) model emerges as the most accurate for ac small-signal operation. The comparison also shows that all models considered are good for ac operations biased in the saturation region with a typical relative error of less than 15%. However, the ac relative errors are much higher in the linear region, particularly for the Curtice quadratic model, which exhibits more than 80% error at some points.

Notes. The above conclusions are based on the matching between the simulated responses of different models and the measured data from a typical NE71000 device; the models may behave differently for a different device. It is not possible to draw any broad-based conclusions as to what model is the best. In order to select the most suitable model for your application, you must consider all the factors, such as bias range, frequency range, and small-signal or large-signal operation, according to your experiences in device modeling.

2-4-6 Device Libraries

All these measurements lead to a nonlinear device library. Figures 2-148 and 2-149 shows a typical datasheet for a device in the library with measured and modeled data. The previous high-power example does not always lead to acceptable results as the models are far from being fully developed. We also show the simulation results using the physics-based model for FETs.

Physics-Based MESFET Modeling. We mentioned a physics-based model earlier. Figure 2-150 shows the measured versus predicted dc *I–V*, I/O power, and *S* parameters for an Alpha Industries MBE MESFET developed under a government contract. The simulation does not handle the trapped energy, which explains the negative slope on the third trace of the output dc *I–V* curve.

The process for bipolar transistors is quite similar and less tricky than the ones just described. Good examples can be found in the user manual for Compact Scout.

2-4-7 A Novel Approach for Simulation at Low Voltage and Near Pinchoff Voltage

As mentioned earlier, the most critical zone is the area of operating the FET both close to the pinchoff voltage and at low operating voltages. A crucial reason for the inadequate results is the modeling of the drain–source resistance as a function of bias point. This is particularly important in calculating the power-added efficiency. When doing your modeling, there is always a temptation to look at both high currents and operating voltages. Figure 2-151 shows a reasonable agreement between measured and predicted dc *I–V* performance. However, the very moment the transistor is modeled close to the linear region (Figure 2-152), things change drastically and the results from 0 to 6 mA have little resemblance to those from 0 to 50 mA. The modified Materka model (Figures 2-153 and 2-154) gives a significantly better match than the Angelov model.

In order to overcome the modeling inaccuracy for the FETs, Thomas Meier of Siemens AG in Munich has come up with the concept of combining two transistors in parallel, whereby the second one is not really connected for dc (Figure 2-155). Figure 2-156 compares measured and simulated R_{DS} using this new approach.

NE67300

Manufacturer : **NEC**
Model Keyword : **NE - 67300**
Device Type : **Mesfet**
Model Type : **Materka**
Package Type : **Chip**

Electrical Characteristics:
Idss : 40mA
Vp : 1.1V
Gain : 8.5dB @ 18GHz
P1db : N/A
Fmin : N/A

Model Data Range:
Vgs : -1.2V to 0.0V
Vds : 0.0V to 4.0V
Freq: 0.4GHz to 18GHz

Verification :
Type : Power sweep, 50Ω
Vgs : -0.6V Vds : 3.0V Ids : 30mA Freq: 6.0GHz

Comments : The S-parameters that appear in the figure were measured and simulated with wire bonds present. The length of each wire bond is approximately 30 mils. To obtain the S-parameters for the manufacture's data sheets, the wire bond inductances would be removed from the equivalent circuit.

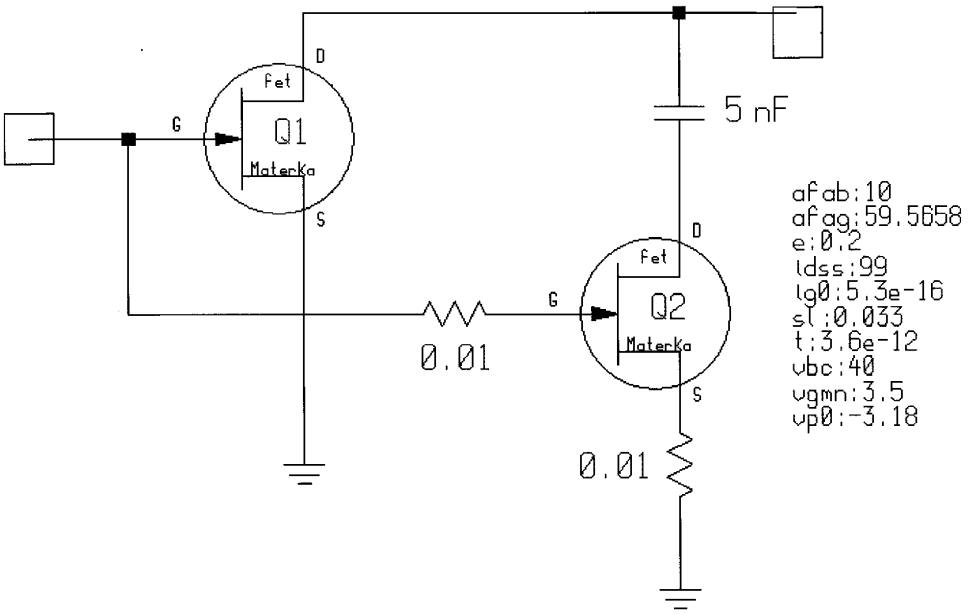

Figure 2-155 By putting two transistors in parallel, with the second one having no dc connection at the drain, one can simulate a dynamic R_{DS} quite well. Regardless of parameter values used for Q1, the parameters listed are necessary to get an accurate R_{DS} result.

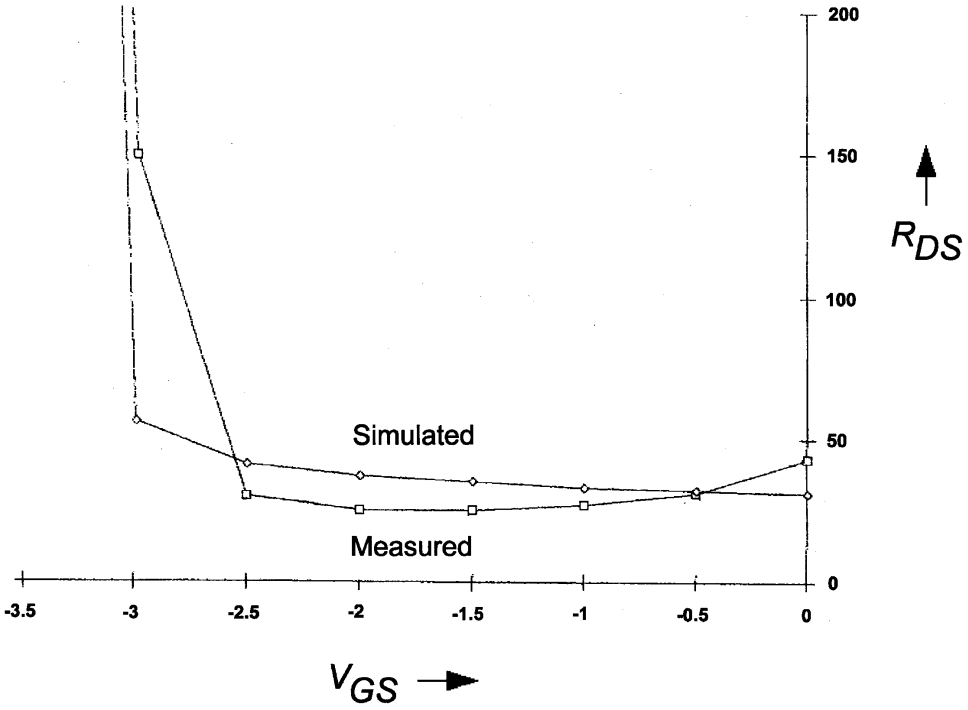

Figure 2-156 Measured versus simulated R_{DS} for the paralleled MESFET approach.

One might ask the question: "Why not fix the existing models?" It turns out that in order to get the best possible convergence and speed, one has to use analytic derivatives for voltage and current; at least the first and second derivatives, if not the third, are required. The programming of such a model becomes so difficult, however, and the calculation of its derivative is so highly likely to have subtle errors, that it turns out that the parallel configuration shown in Figure 2-155 is the best possible compromise for fast computation and accurate results.

A similar approach for bipolar transistors has been discussed by Philips with their MEXTRAM model. However, we have not seen any parameter extraction for this model and also we have not seen any industry acceptance for it. While, in principle, it will cover all derivatives of all members of the BJT family, its topology consists out of three discrete transistors connected and we doubt very much that a reliable parameter extraction program/mathematically continuous model for nonlinear simulation is supplied by the university that developed this jointly with Philips. At the time of writing this book, Philips has not yet provided us with the code for both, and until this happens, we are not in a position to qualify this any further.

2-4-8 Example: Improving the BFR193W Model

We have already mentioned the difficulty encountering the proper base-spreading resistor values and others by using standard parameter extraction programs. Table 2-28 is a copy from the Siemens semiconductor book showing Gummel–Poon Berkeley SPICE syntax parameters for the BFR193W BJT.

The first thing that will happen is that the observant reader will notice that the minimum possible base-spreading resistor, RBM (valid at large current densities), is larger than the actual base-spreading resistor, RB, "claimed to be measured" at 1 Ω (see Table 2-28).

Another headache is caused by the measured noise performance of the same device at an operating point of 10 mA. Using the above-mentioned simplified equation

Table 2.28. BFR193W transistor chip data: SPICE parameters (Gummel–Poon model, Berkeley–SPICE 2G.6 syntax)

All parameters are ready to use, no scaling is necessary. Extracted on behalf of SIEMENS Small Signal Semiconductors by Institut für Mobil-und Satellitenfunktechnik (IMST).

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-288)

we obtain the following results:

1. Inserting 1 Ω (value for RB provided by IMST) and R_B = 15 Ω (measured by the authors), here are the interesting results:

$$F = 1 + \frac{1}{50} + \frac{2.6}{100} = 1.046 \tag{2-289}$$

as noise factor or, as noise figure, F (dB) = 0.2 dB (IMST).

2. Or using the measured 15 Ω, one obtains

$$f = 1 + \frac{15}{50} + \frac{2.6}{100} = 1.326 \tag{2-290}$$

as noise factor or, as noise figure, F (dB) = 1.22.

The Siemens datasheet claims a noise figure of 1.3 dB, and therefore the measured versus calculated data differ by 0.08 dB. Since our noise figure was calculated well below f_T, which is seen from the fact that there are no frequency-dependent terms in the noise figure calculation, it is not unusual that the 900-MHz noise figure is 1.3 dB or slightly higher. This simple example shows how easy it is to provide measurement data that are inconsistent with the laws of physics. It is therefore highly recommended to add the noise figure as an additional parameter in the parameter extraction to reduce the number of variables—specifically, those for which the standard extraction has little sensitivity.

The collector–emitter junction capacitance is another important parameter that frequently gets measured incorrectly. The way around this is to remember the definition

$$f_{\max} = \sqrt{\frac{f_T}{8\pi R'_{bb} C_c}} \tag{2-291}$$

f_T can be measured from the 3-dB point of the emitter current gain (β) and R'_{bb} was just computed above, so the equation can be solved for C_c, as there is a relationship between measured $g_{\max}$ and $f_{\max}$. There are several correlations between the parameters of the equivalent circuit as published in different places, and therefore one can restrict the degree of freedom within the optimization process and obtain much better results. This approach is applicable to all types of transistors, bipolar and FET, and can be used to improve the accuracy of parameters that not only affect a transistor's RF performance but also its noise performance.

AMPLIFIER DESIGN WITH BJTs AND FETs

3-1 PROPERTIES OF AMPLIFIERS

3-1-1 Introduction

The goal of this chapter is to move from the details on the semiconductor devices themselves to our first practical application. One of the more interesting features of amplifiers is that they can easily become what will be covered in Chapter 5: *oscillators*. This is due to the high gain of the devices, unaccounted for parasitic elements, and other design flaws. The amplifiers we need will fall into three categories:

- Low-noise amplifiers
- High-gain amplifiers
- Medium- to high-power amplifiers

See Figure 3-1. The low-noise amplifier always operates in Class A, typically at 15–20% of its maximum useful current. The high-gain amplifier can operate in Class A, as well as Class B (mostly push–pull). The higher dc current for the same device results in a higher noise figure and more gain, and ultimately more output power. Class C operating mode is really reserved for either FM transmissions or constant-carrier modes like CW. Some of the modern digital modulation types are sensitive to phase distortion rather than amplitude changes and because of the resulting output spectrum designers have stayed away from Class C operation.

Some of these amplifiers, such as bipolar versions, can be dc-coupled with very few difficulties; others, like those in the FET families, will cause more headaches. An interesting example, although much too high in frequency for the purpose of this book, is shown in Figures 3-2, 3-3, 3-4, and 3-5. It shows a three-stage amplifier that has noise feedback for the first two stages and resistive feedback for the output stage. These are the three types of amplifiers, regardless of technology, we will be evaluating. The achievement of accurate noise analysis of this circuit, reported in Rohde et al. [1], marked the first time a complete

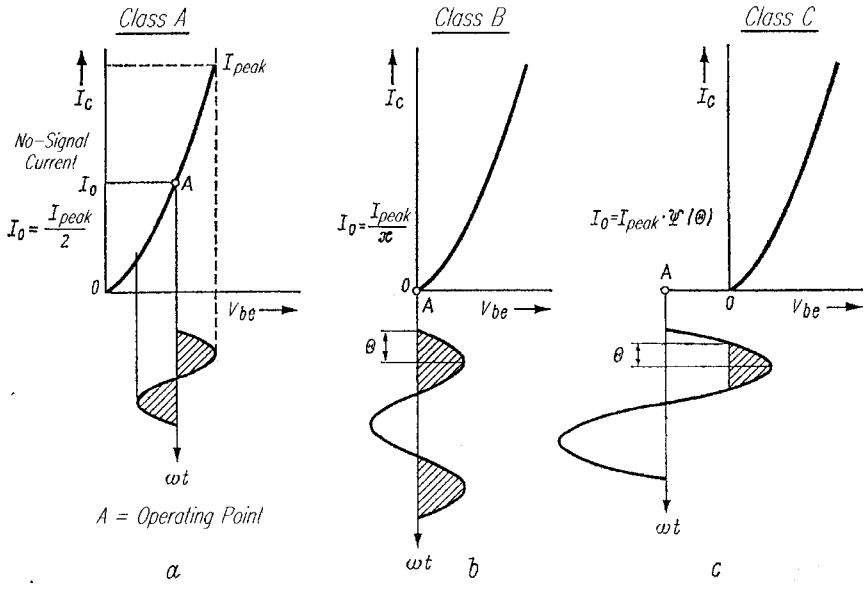

Figure 3-1 Definition of Class A, B, and C operation and resulting bias, including conduction angle (Θ, to be discussed in Section 3-2-2). The transfer characteristic can be either quadratic or exponential. This results in different distortion but does not change the basic operating mode.

linear noise model with essentially no frequency limitation had been developed. Its accuracy depends solely on the accuracy of the element values of the linear equivalent circuit, which can be obtained from measured *S*-parameters by an optimization process. Needless to say, this technique is also applicable at lower frequencies, such as 1.5–3 GHz, and its deviation from measured values has never been worse than 0.2 dB or, relative to the noise figure, 10% expressed in dB.

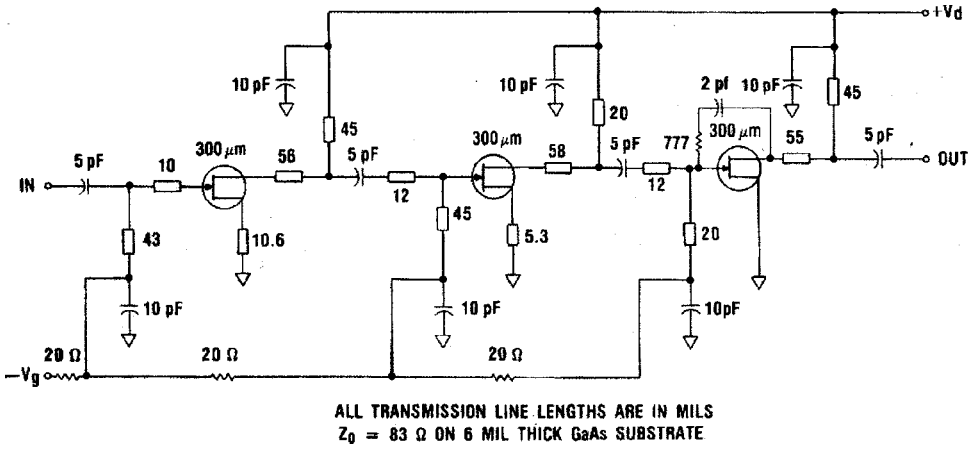

Figure 3-2 Schematic of the X-band GaAs monolithic low-noise amplifier (Texas Instruments EG8021). For reasons of linearity, all three stages operate in Class A.

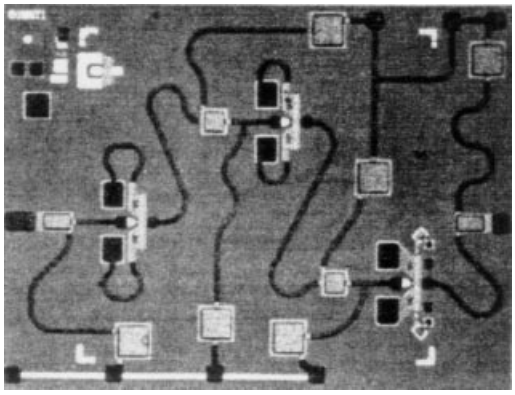

Figure 3-3 Photograph of the EG8021 monolithic amplifier chip. The area pictured is 0.09 inch by 0.12 inch in size.

The results of Figure 3-4 were obtained by using the linear FET model as supplied by Texas Instruments. It becomes somewhat obvious that a match for S_{11} of –60 dB is not likely. We then replaced the linear transistor with the SPICE-type nonlinear model, resulting in the responses shown in Figure 3-5. S_{11} now looks much more realistic in the center of the range, but at the same time exhibits a tendency toward instability at frequencies around 8 GHz. The actual circuit, when measured, did not exhibit this potential instability; on the other hand,

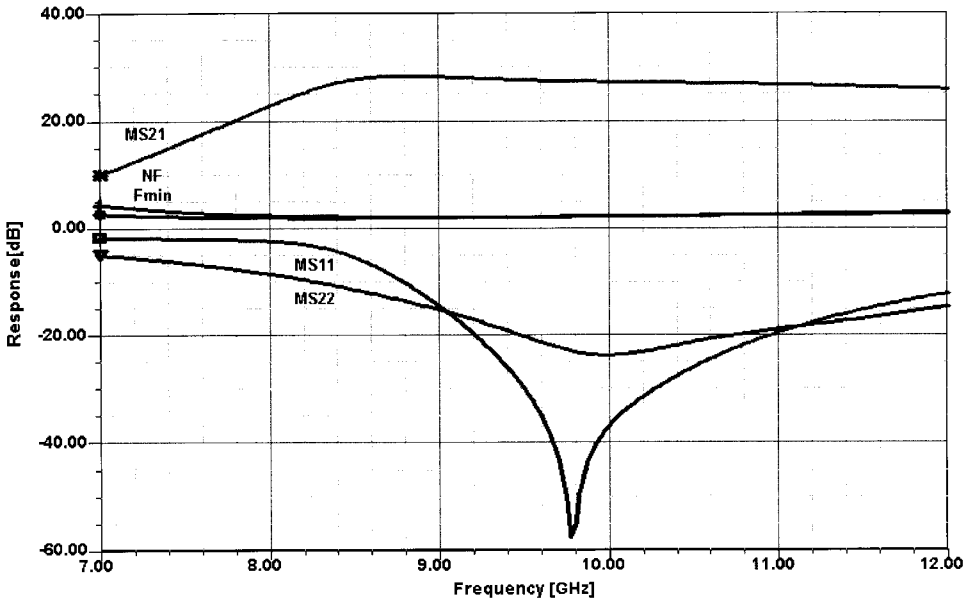

Figure 3-4 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the TI linear FET model. The values at 10 GHz are: F_{min}, 2.20 dB; NF, 2.21 dB; S_{11}, –36.8 dB; S_{21}, 27.2 dB; and S_{22}, –23.7 dB.

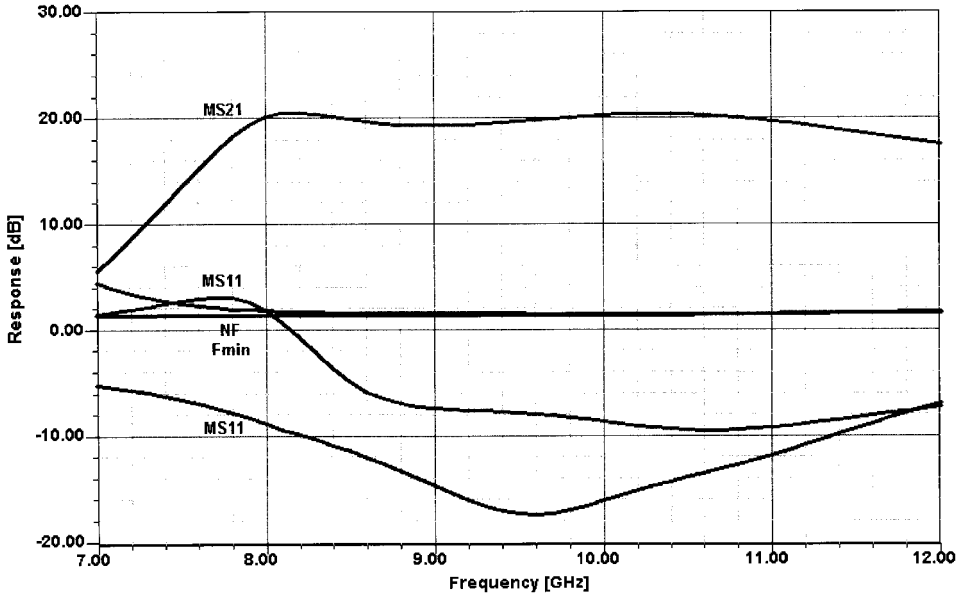

Figure 3-5 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the nonlinear FET model. The values at 10 GHz are: F_{min}, 1.53 dB; NF, 1.65 dB; S_{11}, –8.5 dB; S_{21}, 20.3 dB; and S_{22}, –15.9 dB.

the noise figure and gain agreed quite well. The discrepancies between the results with the linear and nonlinear models emphasize the importance of accurate device modeling.

Figure 3-6 shows a wideband amplifier, specifically a distributed amplifier, that covers 1–20 GHz. Figure 3-7 shows its simulated frequency-dependent gain, matching, and noise performance. The example given here as the upper frequency for wireless systems is rapidly expanding and the technology to accommodate this is already in place. Modern CAD tools can handle such high frequencies accurately, which means one can trust them at the significantly lower wireless frequencies of 500 MHz to 3 GHz. Above 1500 MHz, one really should model using distributed elements. We will come to this later in this chapter.

Input/output and interstage matching will become another challenging task, specifically if one requires sufficient bandwidth. As circuits become more complex and as the operating frequency increases, passive components play an increasingly important role; the use of

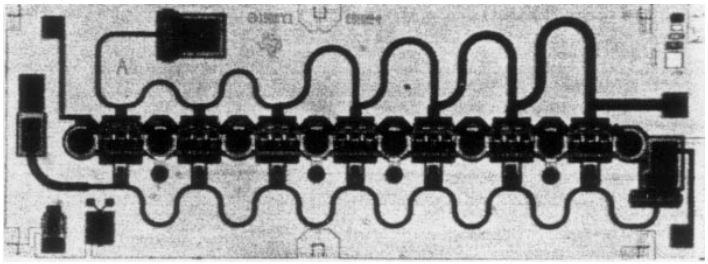

Figure 3-6 Photo of the 1–20-GHz distributed amplifier.

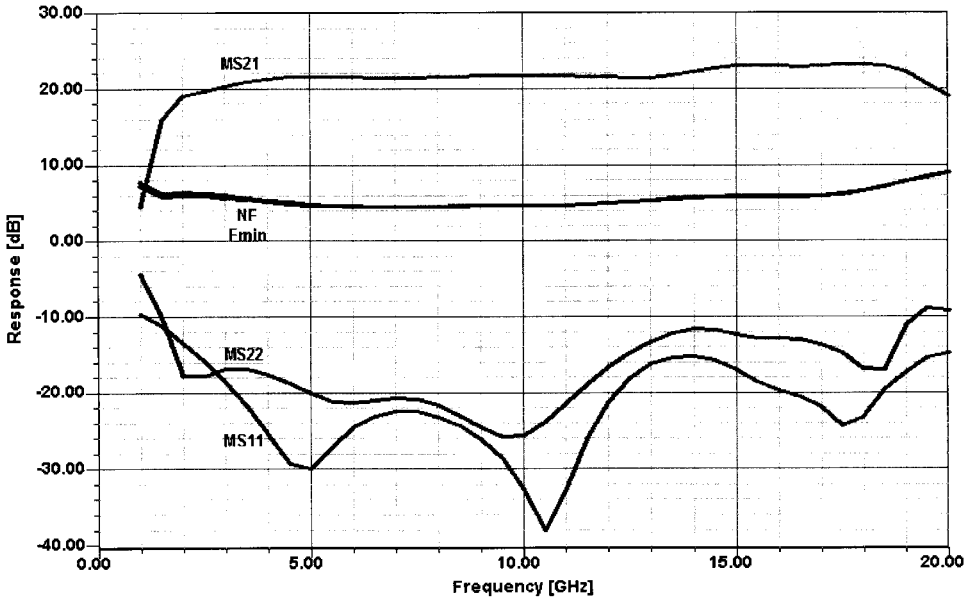

Figure 3-7 Simulated F_{min}, NF, S_{11}, S_{21}, and S_{22} responses. At the center of the range, the following numbers were found: F_{min}, 4.80 dB; NF, 4.80 dB; S_{11}, –32.8 dB; S_{21}, 21.8 dB; and S_{11}, –25.2 dB.

distributed elements is practically a necessity above 1500 MHz. For this reason, we begin this chapter by covering the application of transistors as amplifiers, following this with a discussion of the surrounding external circuitry, such as transmission lines, inductors, capacitors, and resistors. Monolithic ICs on silicon are a totally different ball game, and neither of the authors has sufficient expertise in this area. For this reason, we refer readers who will concentrate on MMIC design to the literature mentioned at the end of this chapter.

The goal of the applications presented here is to address, where possible, high-performance wireless stages that are less subject to constraints of space, power consumption, and cost, than portable/mobile applications. This is consistent with our preface, in which we have clearly stated our goal. The designers of handsets typically cannot consider the full variety of circuits we will present here. These types of stages (low noise, high gain and power) frequently will be used with filtering, and we will give some examples of input filters, including a tracking high-performance design.

A key topic besides the frequently mentioned gain is the whole noise issue. We will give the reader a complete introduction to this important area, followed by a similar introduction to the gain and matching of transistors. *Caution*: The majority of applications published go through the exercise of using *S*-parameters manually to design low-noise and small-signal amplifiers. While we have been tempted to repeat the information found in several textbooks, we feel that today's engineers will have access to CAD tools one way or another. It is highly unlikely that readers will undertake the inefficient process of going through all the design steps manually (a procedure that can take days); hopefully, engineers will resort to a linear/nonlinear CAD tool to do so. Only for the purpose of summarizing the necessary steps will we provide the relevant information regarding gain, stability, and related topics, demonstrating their usefulness or possible misuse with a modern CAD tool—in our case,

the Serenade Design Environment product from Ansoft. At this time, several additional companies beside Ansoft and Hewlett-Packard have emerged, but it is dangerous to list all of them as they come and go.

3-1-2 Gain

In practical terms, when we talk about gain we mean the output power relative to the input power. The industry standard now uses 50 Ω; however, at the point at which we have to match high-impedance devices such as monolithic crystal filters where the impedance jumps, things are not so obvious. The transformation equation that allows us to transform from one impedance to another is

$$m = \sqrt{\frac{R_2}{R_1}} \tag{3-1}$$

This correction factor, m, is required to do the transformation from R_1 (50 Ω) to R_2 (e.g., 1.2 kΩ). It needs to be understood that while the power gain remains the same, the voltage gain requires this correction factor. Since the power gain is expressed as 10 log A, A being the loop gain, 20 log A is the voltage gain, both expressed in dB. The reason for 10 versus 20 is that the power gain is always the voltage squared, which accounts for the 2. As a reminder of these relationships we present the following:

Distinction: Power Ratios–Voltage Ratios

$$n \text{ dB} = 10 \log_{10}(P_2/P_1) \quad \xrightarrow{PP = V^2/Z} \quad n = 10 \log_{10}\left(\frac{V_2^2/Z_2}{V_1^2/Z_1}\right)\text{dB}$$

$$Z_2 = Z_1 \rightarrow n \text{ dB} = 10 \log_{10}(V_2^2/V_1^2) = 10 \log_{10}(V_2/V_1)^2$$

$$\Longrightarrow \boldsymbol{n \text{ dB} = 20 \log_{10}(V_2/V_1) \text{ dB}}$$

The gain is typically defined under the condition of real resistive source and load terminations, which means that all the available power is being supplied to the amplifier, and likewise through proper matching at the output all the available power is fed to the termination. This gain figure is typically measured at a single spot frequency, but since most amplifiers are not totally flat, one needs to specify the gain tolerances or gain flatness. A good number is x dB ± 0.5 dB gain variation. In the case of a narrowband amplifier, the gain typically is shaped like a tuned circuit or like a critically coupled bandpass filter frequency response, while in the case of a real wideband application, the desired gain has some kind of ripple, which is due to the various compensation components in the circuit. An extreme case of a wideband amplifier is a 6–18-GHz single-stage amplifier that uses some very clever matching. This is shown in the following example. Figure 3-8 shows the circuit diagram, and Figure 3-9 shows its frequency-dependent performance.

While this is a cute approach for generating a single-stage amplifier over such a wide bandwidth, in real life it is not acceptable. The reason for this is that neither S_{11} nor S_{22} meets any useful specifications over the entire range. Typically, S_{11}/S_{22} values are only a few dB, while in reality more than 10 dB is required. We have chosen this example to show that gain

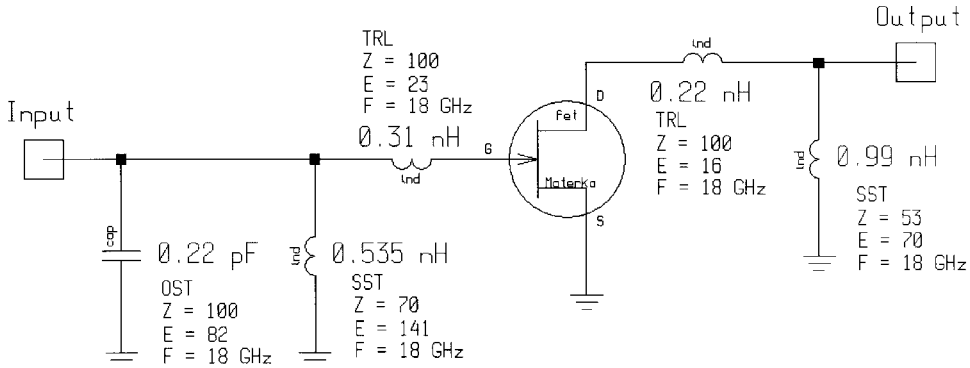

Figure 3-8 A 6–18-GHz FET amplifier.

and matching, depending on the circuit topology, are connected. We get similar results for the noise figure, whereby the best achievable noise figure ($F_{\min}$) and the actual 50-Ω noise figure are only a few dB apart; however, its frequency dependence in a wideband stage is certainly not acceptable.

Another parameter associated with gain is the stability factor K of the circuit. A value of $K > 1$ is mandatory to guarantee stability together with the S_{11} and S_{22} magnitudes being less than 1. Figure 3-10 plots the K stability factor, which for absolute stability must be >1, and maximum stable gain (MSG) as well as $G_{\max}$. It turns out that MSG is a highly artificial

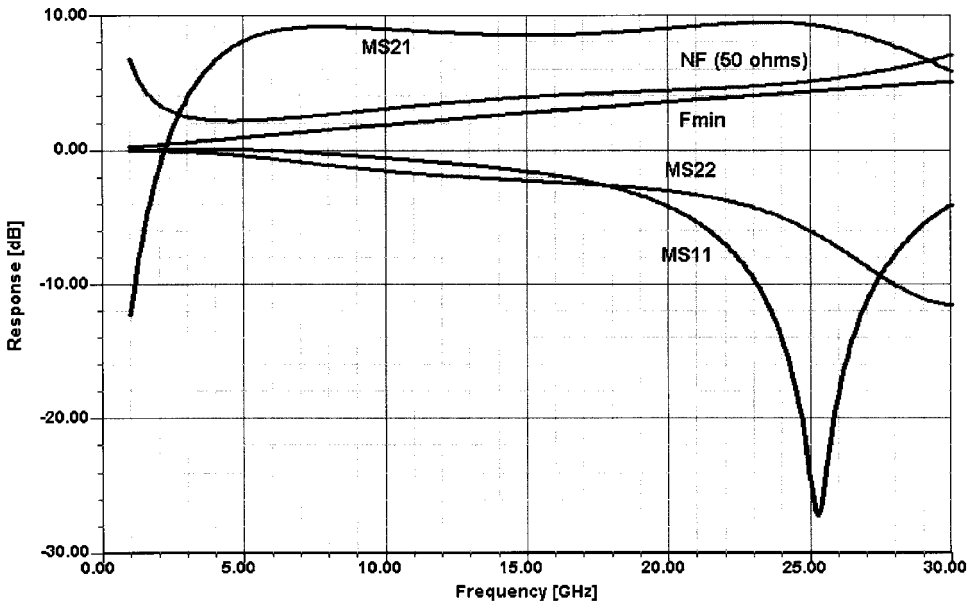

Figure 3-9 Frequency-dependent gain, matching, and noise performance of the amplifier shown in Figure 3-8.

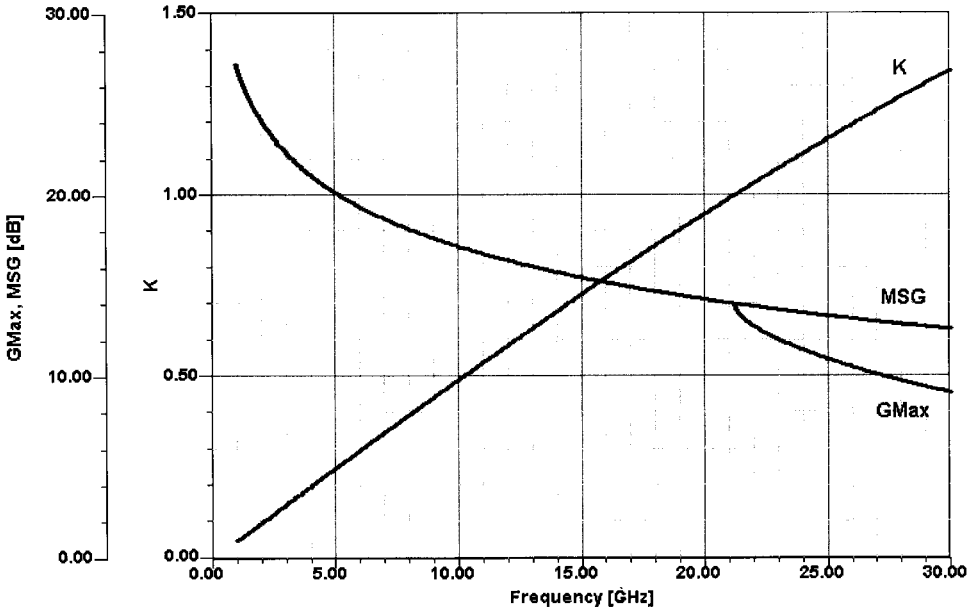

Figure 3-10 G_{max}, maximum stable gain (MSG), and K performance of the amplifier in Figure 3-8.

definition of stability that implies that input and output are terminated with pure resistances and then conjugately matched. There are four ways of achieving this resistive loading, either in the emitter as a shunt resistor between gate/drain or base/collector, or in parallel to the input and output to ground. Needless to say, this is not a real operating mode because it deteriorates both noise and gain. In our case, the entity G_{max} is a function of S_{12} of the circuit, not just the transistor, and depends highly on S_{12}. If we bring the system close to oscillation, then G_{max} will increase at the expense of bandwidth. Unfortunately, some of these microwave definitions of gain (see Table 3-1) have become widely used in industry without always being useful. Evaluating these equations for S_{12} is not legitimate because other quantities like K become infinite, and the entire system of equations falls apart. The power gain with input and output conjugately matched, or the transducer power gain for arbitrary source and load matching, still give more insight into the system.

In the above example, we specifically stated that the input and output VSWR was totally unacceptable, and this was due to a one-stage design. Figure 3-11 shows an amplifier chip built around two transistors with standard feedback techniques applied; Figures 3-12 and 3-13 show its frequency-dependent gain, matching, stability, and noise performance. This amplifier was one of the early examples of GaAsFET wideband amplifiers, but it is interesting because while it has wild (and wide) gain swings, it exhibits a fairly constant input and output impedance or reflection coefficient. A further evaluation of the circuit shows that not only is the circuit unconditionally stable, but that the maximum stable gain has an extremely high value based on essentially minimal S_{12}, the K factor is always significantly higher than 1, and G_{max} follows, to some degree, the actual gain response of the amplifier. (Ultimately, designers gave up on simple *RCL* feedback amplifiers for such a wide bandwidth, replacing them with distributed amplifiers previously called traveling wave amplifiers.) The problem of gain and stability starts at audiofrequency amplifiers, where the

Table 3-1 Nine power gains

Transducer power gain in 50-Ω system	$G_T = \lvert S_{21}\rvert^2$
Transducer power gain for arbitrary Γ_G and Γ_L	$G_T = \dfrac{(1-\lvert\Gamma_G\rvert^2)\,\lvert S_{21}\rvert^2\,(1-\lvert\Gamma_L\rvert^2)}{\lvert(1-S_{11}\Gamma_G)\,(1-S_{22}\Gamma_L)-S_{12}S_{21}\Gamma_G\Gamma_L\rvert^2}$
Unilateral transducer power gain	$G_{\mathrm{TU}} = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)\,(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2\lvert 1-S_{22}\Gamma_L\rvert^2}$
Power gain with input conjugate matched	$G = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{22}\Gamma_L\rvert^2(1-\lvert S'_{11}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{11}\rvert^2}$ (for $\Gamma_L = 0$)
Available power gain with output conjugate matched	$G_A = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2(1-\lvert S'_{22}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{22}\rvert^2}$ (for $\Gamma_G = 0$)
Maximum available power gain[a]	$G_{ma} = \left\lvert\dfrac{S_{21}}{S_{12}}\right\rvert\,(k-\sqrt{k^2-1})$
Maximum unilateral transducer power gain	$G_{\mathrm{TUmax}} = \dfrac{\lvert S_{21}\rvert^2}{(1-\lvert S_{11}\rvert^2)(1-\lvert S_{22}\rvert^2)}$
Maximum stable power gain	$G_{ms} = \dfrac{\lvert S_{21}\rvert}{\lvert S_{12}\rvert}$
Unilateral power gain	$U = \dfrac{1/2\lvert S_{21}/S_{12}-1\rvert^2}{k\lvert S_{21}/S_{12}\rvert-\mathrm{Re}(S_{21}/S_{12})}$

[a]Definition for $G_{\max}$: If $k > 1$, it is called G_{ma}, and if $k < 1$, it is called G_{ms}.

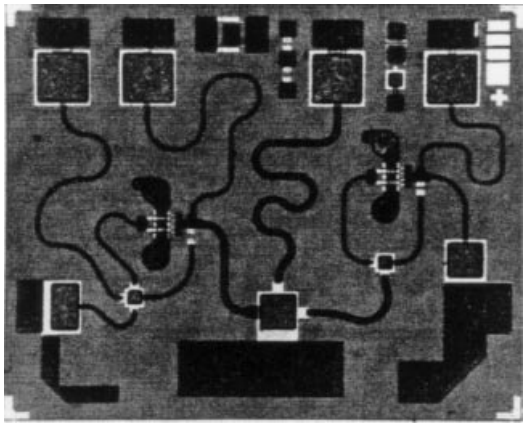

Figure 3-11 A two-stage, wideband feedback amplifier.

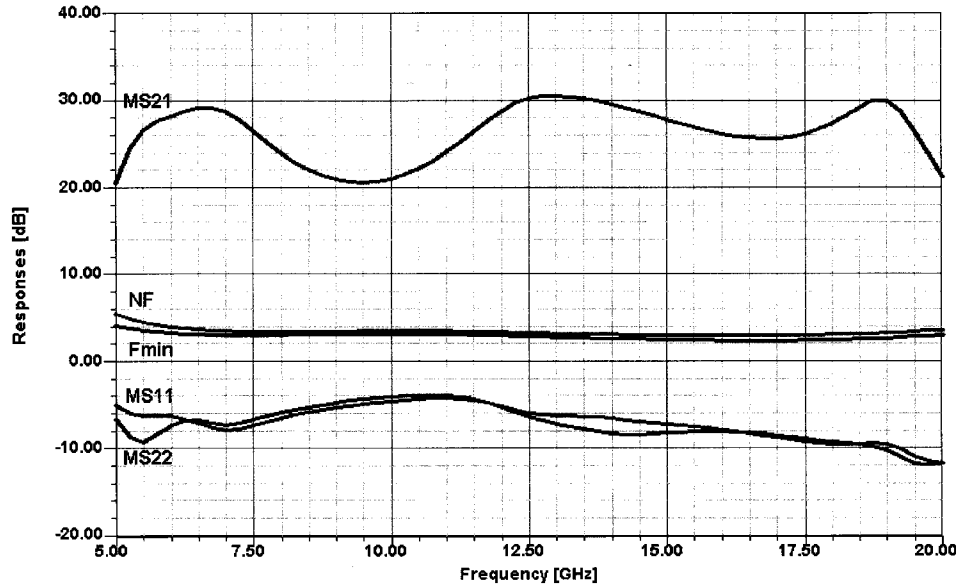

Figure 3-12 Frequency-dependent gain, matching, and noise performance for the amplifier in Figure 3-11.

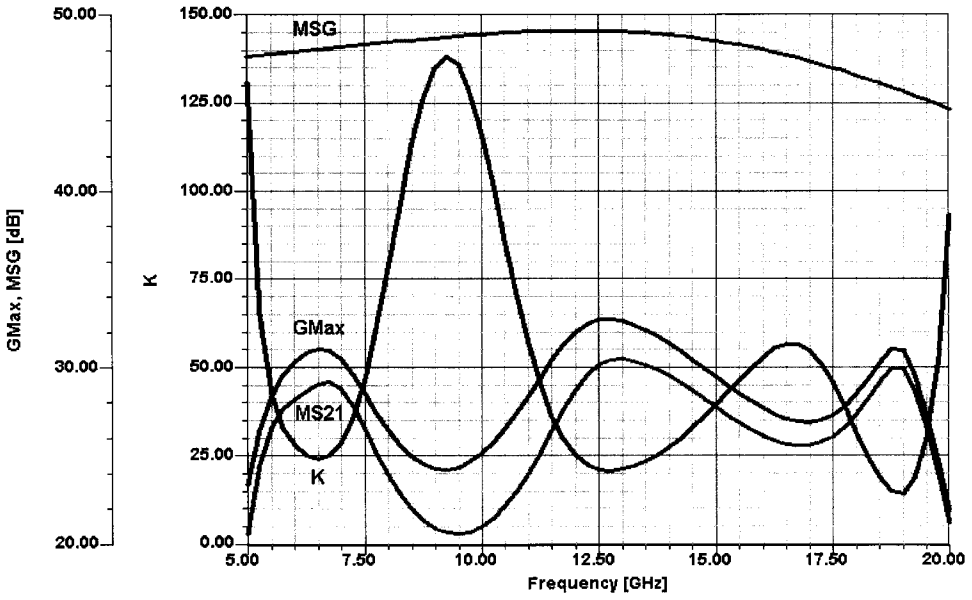

Figure 3-13 Frequency-dependent G_{max}, K, maximum stable gain, and gain performance for the amplifier in Figure 3-11.

motorboating phenomenon has been known for years, and the problem moves up in frequency with more modern technology and is largely dependent not only on the device and the circuit, but also on the layout. The motorboating effect has to do with ground loops and the fact that if the printed circuit traces from the power supply connection to the output power stage present too high a resistance, then at high currents the voltage will drop to a point below useful operation and then, as the volume is lowered, become stable again. In this case the amplitude of the signal through the amplifier controls the stability of the output stage. Needless to say, this most unpleasant effect applies to high-power stages for all output transistors, where we use Class B or C operation, meaning that the dc operating current as a function of output does not remain constant.

In terms of gain, there is also an important gain characteristic called *differential gain* and *differential phase*. These expressions were first used in television circuits, where linearity in both areas is an absolute must. The amplitude of the signal determines the black and white contrast, and the phase determines the color. As an example, transmitting an image of one of our presidents playing golf in California to the New York area is done by many microwave hops. Any multipath reception, such as that caused by reflection from airplanes, may have little effect on the signal amplitude, but the resulting phase shift can transform a green lawn to a red lawn if a total shift of 180° occurs. Given a particular operating point, if the 1-dB compression point of multiple amplifiers in the chain is approached or exceeded, their differential gain, which is defined by the IEEE as "the difference between (a) the ratio of the output of a small high-frequency sine-wave signal at two different levels of a low-frequency signal on which it is superimposed, and (b) unity," may increase. This mode of saturation charges all the capacitances of the amplifier transistors, causing huge phase shifts that result in the known problem of changing colors. The same applies, of course, in test equipment amplifiers, in which such changes cannot be tolerated. A somewhat similar, but not quite the same, problem is spectral regrowth [evaluated in terms of adjacent-channel power ratio (ACPR)], which is also due to nonlinearities. The question of linearity has already been covered in detail in Chapter 1. Needless to say, any overdrive condition also changes an amplifier's input and output SWR.

3-1-3 Noise Figure (NF)*

Introduction. In this section we look at the best way to describe noise in active devices (black boxes). Even when a two-port is linear, the output waveform will differ from the input, because of the failure to transmit all spectral components with equal gain (or attenuation) and delay. By careful design of the two-port, or by limitation of the bandwidth of the input waveform, such distortions can largely be avoided. However, noise generated within the two-port can still change the waveform of the output signal. In a linear passive two-port, noise arises only from the losses in the two-port; thermodynamic considerations indicate that such losses result in the random changes that we call noise. When the two-port contains active devices, such as transistors, there are other noise mechanisms present. A very important consideration in a system is the amount of noise that it adds to the transmitted signal. This is often judged by the ratio of the output signal power to the output noise power

*Section 3-1-3 is reprinted from Chapter 2 of George D. Vendelin, Anthony M. Pavio, and Ulrich L. Rohde, *Microwave Circuit Design Using Linear and Nonlinear Techniques*, copyright 1990 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

(S/N). The ratio of signal plus noise power to noise power [$(S + N)/N$] is generally easier to measure and approaches S/N when the signal is large.

In the evaluation of a two-port it is important to know the amount of noise added to a signal passing through it. An important parameter for expressing this characteristic is the noise factor. The signal energy coming from a generator or antenna is amplified or attenuated in passing from the input to the output of a two-port, as is the noise that accompanies the input signal energy. A system generally includes a cascade of two-port networks that constitute one overall two-port that amplifies the signal to a high-enough power level for its intended use. The *noise factor* of a system is defined as the ratio of signal-to-noise ratios available at input and output:

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}} \geq 1 \tag{3-2}$$

The noise figure (or factor) of a receiver is an easily measured quantity that describes the signal-to-noise ratio reduction of that receiver.

When this ratio of powers is converted to decibels, it is generally referred to as the *noise figure* rather than noise factor. Various conventions are used to distinguish the symbols used for noise factor and noise figure. Here we use F to represent the noise factor and NF to represent the noise figure, although the terms are usually used interchangeably.

For an amplifier with the power gain G, the noise factor can be rearranged as

$$F = \frac{S_i/N_i}{GS_i/G(N_i + N_a)} \tag{3-3}$$

when N_a is the additional noise power added by the amplifier referred to the input. This can be computed to be

$$F = 1 + N_a/N_i \tag{3-4}$$

The noise factor is often replaced by the noise figure (NF), which is defined in decibels as

$$\text{NF} = 10 \log_{10} F \tag{3-5}$$

In applications like satellite receivers, the noise factor becomes such a small number that it is inconvenient to work with. Many people have adopted the use of an equivalent noise temperature for a circuit to remedy this situation. Since the thermal noise power available from a resistor at temperature T_e is

$$N = kT_eB \tag{3-6}$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), T_e is the effective temperature in kelvins, and B is the bandwidth in hertz. The equation above may be used to associate an effective noise temperature with circuits containing more than just thermal noise sources. This allows Eq. (3-4) to be written as

$$F = 1 + \frac{kT_eB}{kT_0B} = 1 + \frac{T_e}{T_0} \tag{3-7}$$

where T_e is the effective noise temperature of the circuit and T_0 is the temperature of the generator resistor in kelvins. The noise temperature T_e now characterizes our circuit noise contribution and can directly be related to the noise factor.

Assuming a reference noise temperature of 290 K (–273 + 290 = 17 °C), let us determine the noise temperature of the system with a noise factor of 2.6 (4.15 dB):

$$T_e = (2.6 - 1)\ (290) = 464 \text{ K}$$

This temperature T_e should not be confused with the environmental operating temperature T_0. It is quite common to operate low-noise amplifiers with T_e below 100 K at an ambient temperature of 290 K.

Signal-to-Noise Ratio. Let us consider the signal-to-noise ratio of power delivered from a generator to a load as shown in Figure 3-14. The signal power delivered to the input is given by

$$S_{\text{in}} = P_{\text{in}} = \frac{E_g^2 \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-8}$$

where E_g is the rms voltage of the input signal supplied to the system, and the noise power supplied to the input is expressed by

$$N_{\text{in}} = \frac{\overline{v_n^2} \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-9}$$

where the noise power at the input is provided by the noise energy of the real part of Z_g. The input impedance Z of the system in the form $Z = R_{\text{in}} + jX_{\text{in}}$ is assumed to be complex.

The Johnson noise of a resistor [here $\text{Re}(Z_g)$], given by the mean-square voltage

$$\overline{v_n^2} = 4kTRB \tag{3-10}$$

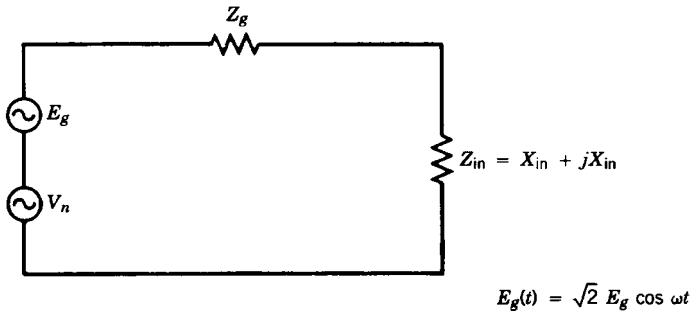

Figure 3-14 Combination of signal and noise voltages supplied to a complex termination.

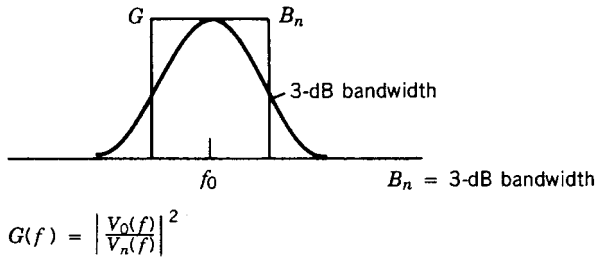
where k (Boltzmann's constant) = 1.38×10^{-23} J/K, T is the absolute temperature of the resistor, and B is the bandwidth, is sufficiently small that the resistive component of impedance does not change. The available signal power from the generator has a lower limit, even if the signal is attenuated by the highest possible attenuation. The generator resistor acts as a Johnson noise generator, its power being

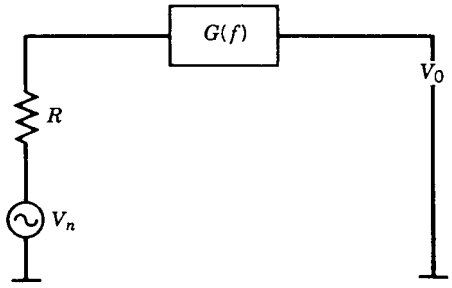
$$P_A = \frac{4kTRB}{4R} = kTB \tag{3-11}$$

where k is Boltzmann's constant, T is the absolute temperature, and B is the bandwidth. This power is the maximum available output power.

For an ambient temperature of 290 K, $kT = 4 \times 10^{-21}$ W/Hz. This expression is also given as kT = –204 dBW/Hz = –174 dBm/Hz = –114 dBm/MHz. We can combine Eqs. (3-8) to (3-10) to obtain

$$\left(\frac{S}{N}\right)_{\text{in}} = \frac{E_g^2}{4kT\text{Re}(Z_g)B} \tag{3-12}$$





$$V_0^2 = \int_0^\infty 4kT_0RG(f)\,dF$$
$$= 4kT_0R \int_0^\infty G(f)\,dF$$
$$B_n = \frac{1}{G} \int_0^\infty G(f)\,dF$$
B_n = noise bandwidth

Figure 3-15 Graphical and mathematical explanations of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

This is the value of *S/N* contributed by the generator, which does not include the noise generated by the load, in this case $\mathrm{Re}(Z_{\mathrm{in}})$, which would need to be included in the measurement of the total *S/N* across the input impedance.

A critical parameter is the noise bandwidth, B_n, which is defined as the equivalent bandwidth, as shown in Figure 3-15. For reasons of group delay correction, most practical filters have round rather than sharp corners. The noise figure measurements shown later can be used to determine the "integrated" bandwidth, which is B_n.

An active system such as a combination of amplifiers and mixers will add noise to the input signals, and the noise factor that describes this is defined as the *S/N* ratio at the input to the *S/N* ratio at the output, which is always greater than unity [2]. In practice, a certain minimum signal-to-noise ratio is required for operation. For example, in a communication system such a minimum is required for intelligible transmission, either voice or data. For high-performance TV reception, to provide a noise-free picture to the eye, a typical requirement is for a 60-dB *S/N*. In the case of a TV system, a large dynamic range is required, as well as a very large bandwidth to reproduce all colors truthfully and all shades from high-intensity white to black. Good systems will have a bandwidth of 8 MHz or more.

Noise Figure Measurements. Some of the noise equations are based on mathematical models and physics. To understand some of these expressions, it is useful to look at a practical system, with amplifiers, that has to be evaluated.

Let us look at Figure 3-16, which consists of a signal generator, the system or device under test (DUT), and a selective receiver with a built-in root-mean-square (rms) voltmeter to determine the signal and noise voltages. It is necessary that the system have enough gain so that the noise voltage supplied by the generator will be indicated [3].

If we assume that our selective receiver is a video noise meter calibrated in rms voltage levels, we can perform two measurements. With an input termination connected to the TV system (typically, 75 Ω for cable TV, 50 Ω for satellite TV), the noise receiver/meter will read a value for proper termination that can easily be calculated. Since one-half of the mean-square noise voltage appears across the input,

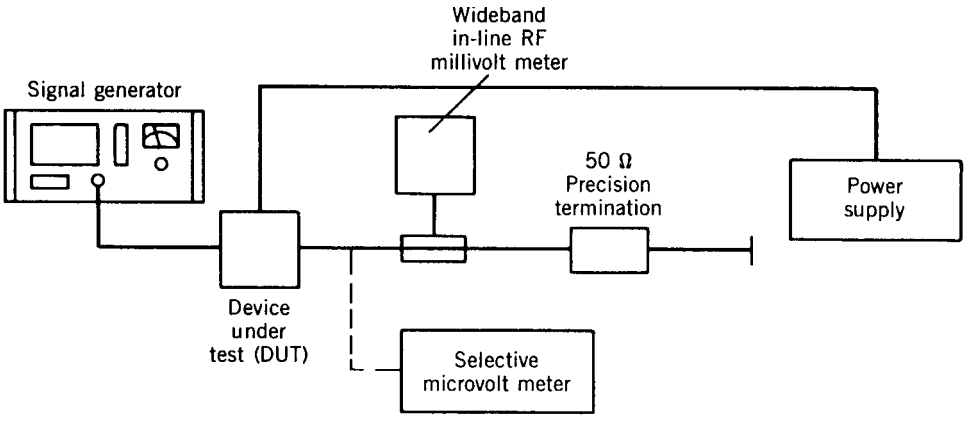


Figure 3-16 Test setup to measure signal-to-noise ratio.

$$v_{\text{in}} = \frac{v_n}{2} = \frac{\sqrt{4kTRB}}{2} \tag{3-13}$$

With $B = 10$ MHz, $T = 290$ K (T is always expressed in absolute temperature; $T_0 = -273$ °C), and $k = 1.38 \times 10^{-23}$ J/K, then for $R = 75\ \Omega$,

$$v_{\text{in}} = \frac{v_n}{2} = 1.73\ \mu\text{V} \tag{3-14}$$

where the rms noise voltage has been referred to the input port. We can verify this with our first measurement.

Now we increase the input voltage of the signal generator to a value that indicates a 60-dB *S/N* ratio at the output port. This should be about

$$E_g = \frac{v_n}{2}\sqrt{F} \times 1000 = 1.73\sqrt{F} \quad \text{mV}$$

where F is the noise factor of the receiver. For a receiver noise factor of 10, we would obtain $E_g = 5.48$ mV (rms value). If the noise energy equivalent to a noise factor of F is assumed, we need $\sqrt{F}$ times more voltage. For a 60-dB ratio, this means that $E_g = 1000 \times (v_n/2) \times \sqrt{F}$.

As they are done here, over a power range of 60 dB, the measurements can be performed over such a wide range only if special equipment is available. In cases where the internal detector of a piece of communication equipment is used, the signal-to-noise ratio measurements are performed over much smaller power ranges.

Let us assume that for the above-mentioned case ($F = 10$) we find a *S/N* ratio of 10 dB at the output for an input signal of 5.47 μV. By rewriting Eq. (3-7) as

$$E_g = \frac{v_n}{2}\sqrt{F} = \sqrt{KTRBF} \tag{3-15}$$

with F being the noise factor, we can solve for F with

$$F = \frac{P_s}{P_n} = \frac{E_g^2/R}{kTB} \tag{3-16}$$

While the input power from the thermal energy of the input termination resistor was $kTB = 4 \times 10^{-4}$ W, the input power required for the 10-dB *S/N* ratio was

$$P_s = \frac{(5.47 \times 10^{-6})^2}{75} = 3.98 \times 10^{-13}\ \text{W} \tag{3-17}$$

The noise factor is defined as the ratio P_s/P_n:

$$F = \frac{3.98 \times 10^{-13}}{4 \times 10^{-14}} = 10 \tag{3-18}$$

which is the proof.

This method is used more frequently at the 3-dB point, or double the input power if the dynamic range of the detector is small or only a linear indicator is available. Because of hum and other pickup, this is not an easy measurement. Using a signal generator is very expensive because in a laboratory or production environment a wide frequency range requires several generators.

Another method is the use of a wideband noise generator. Modern gas discharge diodes or avalanche diodes are available that provide essentially white noise energy over a large frequency range. These microwave diodes typically have an output of 30 dB above kT when switched on and kT when switched off. To provide good matching at microwave frequencies, a 15-dB attenuator is cascaded. This means that the noise power of the source in the ON condition is about 15 dB above kT.

In the early 1960s, low-cost noise figure test equipment was built around vacuum diodes whose operating range was limited to 1200 MHz due to the resonance effects of the structure. Today, automatic noise gain analyzers use calibrated solid-state noise sources up to 26.5 GHz. It appears that the upper frequency limit has to do with matching, and the lower-frequency limit with $1/f$ noise.

Noisy Two-Port Description. Based on the convention by Rothe and Dalke [4], any linear two-port can be in the form shown in Figure 3-17. This general case of a noisy two-port can be redrawn showing noise sources at the input and at the output. Figure 3-17b shows this in admittance form and Figure 3-17c in impedance form. The internal noise sources are assumed to produce very small currents and voltages, and we assume that linear two-port equations are valid. The internal noise contributions have been expressed by using external noise sources:

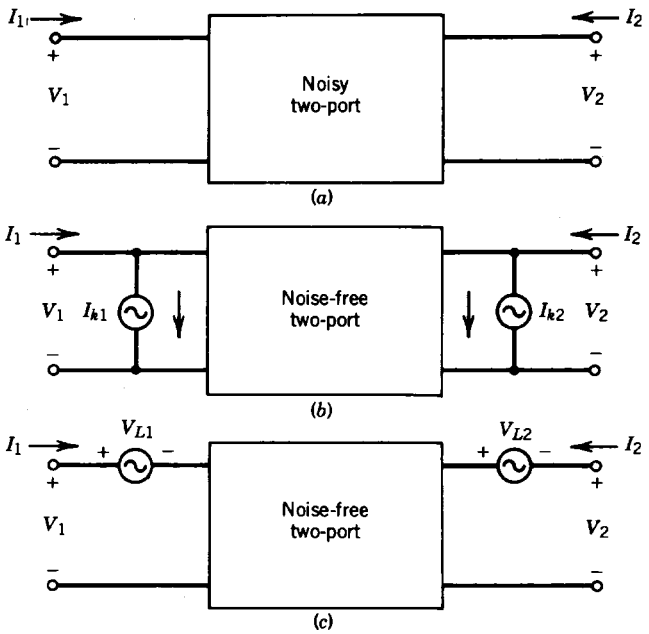

Figure 3-17 Noisy linear two-ports: (a) general form, (b) admittance form, and (c) impedance form.

$$I_1 = y_{11}V_1 + y_{12}V_2 + I_{K1}$$
$$I_2 = y_{21}V_1 + y_{22}V_2 + I_{K2} \tag{3-19}$$

$$V_1 = z_{11}I_1 + z_{12}I_2 + V_{L1}$$
$$V_2 = z_{21}I_1 + z_{22}I_2 + V_{L2} \tag{3-20}$$

where the external noise sources are I_{K1}, I_{K2}, V_{L1}, and V_{L2}.

Since we want to describe our noisy circuit in terms of the noise figure, the *ABCD*-matrix description will be more convenient since it refers both noise sources to the input of the two-port [5]. This representation is given below (note the change in direction of I_2):

$$V_1 = AV_2 + BI_2 + V_A$$
$$I_1 = CV_2 + DI_2 + I_A \tag{3-21}$$

where V_A and I_A are the external noise sources.

It is important to remember that all of these matrix representations are interrelated. For example, the noise sources for the *ABCD*-matrix description can be obtained from the *z*-matrix representation shown in Eq. (3-20). This transformation is

$$V_A = -\frac{I_{K2}}{y_{21}} = V_{L1} - \frac{V_{L2}z_{11}}{z_{21}} \tag{3-22}$$

$$I_A = I_{K1} - \frac{I_{K2}y_{11}}{y_{21}} = -\frac{V_{L2}}{z_{21}} \tag{3-23}$$

The *ABCD* representation is particularly useful because it allows us to define a noise temperature for the two-port referenced to the input. The two-port itself (shown in Figure 3-18) is assumed to be noise-free.

In the past, *z* and *y* parameters have been used, but in microwave applications it has become common to use *S*-parameter definitions. This is shown in Figure 3-19. The previous equations can be rewritten in their new form using *S*-parameters:

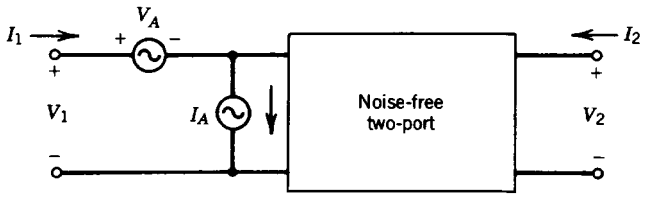

Figure 3-18 Chain-matrix form of linear noisy two-ports.

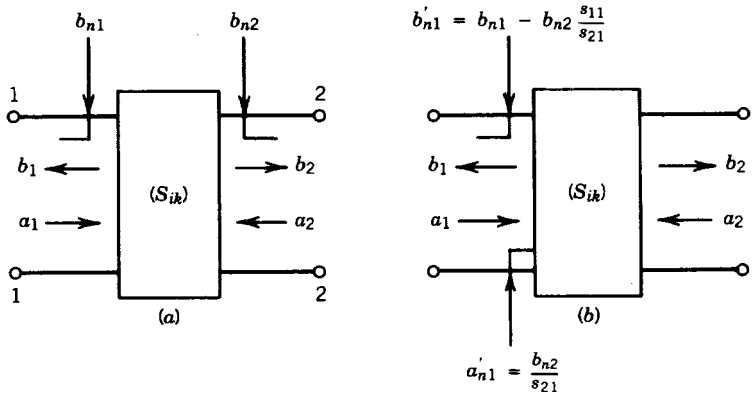

Figure 3-19 *S*-parameter form of linear noisy two-ports.

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \begin{bmatrix} b_{n1} \\ b_{n2} \end{bmatrix} \tag{3-24}$$

There are different physical origins for the various sources of noise. Typically, thermal noise is generated by resistances and loss in the circuit or transistor, whereas shot noise is generated by current flowing through semiconductor junctions and vacuum tubes. Since these many sources of noise are represented by only two noise sources at the device input, the two equivalent noise sources are often a complicated combination of the circuit internal noise sources. Often, some fraction of V_A and I_A is related to the same noise source. This means that V_A and I_A are not independent in general. Before we can use V_A and I_A to calculate the noise figure of the two-port, we must calculate the correlation between the V_A and I_A shown in Figure 3-18.

The noise source V_A represents all the device noise referred to the input when the generator impedance is zero; that is, when the input is short-circuited. The noise source I_A represents all the device noise referred to the input when the generator admittance is zero; that is, the input is open-circuited.

The correlation of these two noise sources considerably complicates analysis. By defining a correlation admittance, we can simplify the mathematics and get some physical intuition for the relationship between noise figure and generator admittance. Since some fraction of I_A will be correlated with V_A, we split I_A into correlated and uncorrelated parts as follows:

$$I_A = I_n + I_u \tag{3-25}$$

I_u is the part of I_A uncorrelated with V_A. Since I_n is correlated with V_A, we can say that I_n is proportional to V_A and the constant of proportionality is the correlation admittance:

$$I_n = Y_{\text{cor}} V_A \tag{3-26}$$

This leads us to

$$I_A = Y_{\text{cor}} V_A + I_u \tag{3-27}$$

The following derivation of noise figure will use the correlation admittance. Y_{cor} is not a physical component located somewhere in the circuit. Y_{cor} is a complex number derived by correlating the random variables I_A and V_A. To calculate Y_{cor}, we multiply each side of Eq. (3-27) by V_A^* and average the result. This gives

$$\overline{V_A^* I_A} = Y_{\text{cor}} \overline{V_A^2} \tag{3-28}$$

where the I_u term averaged to zero since it was uncorrelated with V_A. The correlation admittance is thus given by

$$Y_{\text{cor}} = \frac{\overline{V_A^* I_A}}{V_A^2} \tag{3-29}$$

Often, people use the term "correlation coefficient." This normalized quantity is defined as

$$c = \frac{\overline{V_A^* I_A}}{\sqrt{\overline{V_A^2} I_A^2}} = Y_{\text{cor}} \sqrt{\frac{\overline{V_A^2}}{I_A^2}} \tag{3-30}$$

Note that the dual of this admittance description is the impedance description. Thus, the impedance representation has the same equations as above with Y replaced by Z, I replaced by V, and V replaced by I.

V_A and I_A represent internal noise sources in the form of a voltage source acting in series with the input voltage and a source of current flowing in parallel with the input current. This representation conveniently leads to the four noise parameters needed to describe the noise performance of the two-port. Again using the Nyquist formula, the open-circuit voltage of a resistor at the temperature T is

$$\overline{V_A^2} = 4kTRB \tag{3-31}$$

This voltage is a mean-square fluctuation (or spectral density). It is the method used to calculate the noise identity. We could also define a noise equivalent resistance for a noise voltage as

$$R_n = \frac{\overline{V_A^2}}{4kTB} \tag{3-32}$$

The resistor R_n is not a physical resistor but can be used to simulate different portions of the noise equivalent circuit.

In a similar manner a mean-square current fluctuation can be represented in terms of an equivalent noise conductance G_n, which is defined by

$$G_n = \frac{\overline{I_A^2}}{4kTB} \tag{3-33}$$

and

$$G_u = \frac{\overline{I_u^2}}{4kTB} \tag{3-34}$$

for the case of the uncorrelated noise component. The input generator to the two-port has a similar contribution:

$$G_G = \frac{I_G^2}{4kTB} \tag{3-35}$$

with Y_G being the generator admittance and G_G being the real part. With the definition of F above, we can write

$$F = 1 + \left| \frac{I_A + Y_G V_A}{I_G} \right|^2 \tag{3-36}$$

The use of the voltage V_A and the current I_A has allowed us to combine all the effects of the internal noise sources.

We can use the previously defined [Eq. (3-29)] correlation admittance, $Y_{\text{cor}} = G_{\text{cor}} + jB_{\text{cor}}$, to simplify Eq. (3-36). First, we determine the total noise current:

$$\overline{I_A^2} = 4kT(|Y_{\text{cor}}|^2 R_n + G_u)B \tag{3-37}$$

where R_n and G_u are defined in Eqs. (3-32) and (3-34). The noise factor can now be determined:

$$F = 1 + \frac{G_u}{G_g} + \frac{R_n}{G_g}[(G_G + G_{\text{cor}})^2 + (B_G + B_{\text{cor}})^2] \tag{3-38}$$

$$F = 1 + \frac{R_u}{R_g} + \frac{G_n}{R_g}[(R_G + R_{\text{cor}})^2 + (X_G + X_{\text{cor}})^2] \tag{3-39}$$

The noise factor is a function of various elements, and the optimum impedance for the best noise figure can be determined by minimizing F with respect to generator reactance and resistance. This gives

$$R_{0n} = \sqrt{\frac{R_u}{G_n} + R_{\text{cor}}^2} \tag{3-40}$$

$$X_{0n} = -X_{\text{cor}} \tag{3-41}$$

and

$$F_{\min} = 1 + 2G_n R_{\text{cor}} + 2\sqrt{R_u G_n + (G_n R_{\text{cor}})^2} \tag{3-42}$$

(To distinguish between optimum noise and optimum power, we have introduced the convention 0*n* instead of the more familiar abbreviation *opt*.) At this point we see that the optimum condition for minimum noise figure is not a conjugate power match at the input port. We can explain this by recognizing that the noise source V_A and I_A represent all the

two-port noise, not just the thermal noise of the input port. We should observe that the optimum generator susceptance, $-X_{corr}$, will minimize the noise contribution of the two noise generators.

In rearranging for conversion to S parameters, we write

$$F = F_{\min} + \frac{g_n}{R_G}|Z_G - Z_{0n}|^2 \tag{3-43}$$

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-44}$$

From the definition of the reflection coefficient,

$$\Gamma_G = \frac{Y_0 - Y_G}{Y_0 + Y_G} \tag{3-45}$$

and with

$$g_G = \frac{G_G}{Y_0} \tag{3-46}$$

$$r_n = \frac{R_n}{Z_0} \tag{3-47}$$

the normalized equivalent noise resistance,

$$F = F_{\min} + \frac{4r_n|\Gamma_G - \Gamma_{0n}|^2}{g_G(1 - |\Gamma|^2)|1 + \Gamma_{0n}|^2} \tag{3-48}$$

$$r_n = (F_{50} - F_{\min})\frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-49}$$

$$\Gamma_{0n} = \frac{Z_{0n} - Z_0}{Z_{0n} + Z_0} \tag{3-50}$$

The noise performance of any linear two-port can now be determined if the values of the four noise parameters, $F_{\min}$, r_n (= $R_n/50$), and Γ_{0n} (magnitude and phase), are known.

Figure 3-20 shows the noise factor of a high-frequency transistor as a function of B_g for G_g = constant and as a function of G_g for $B_g = B_{opt}$.

Noise Figure of Cascaded Networks. In a system with many circuits connected in cascade (Figure 3-21), we must consider the contributions of the various circuits. In considering the equivalent noise resistor R_n in series with the input circuit,

$$F = \frac{R_G + R_n}{R_G} \tag{3-51}$$

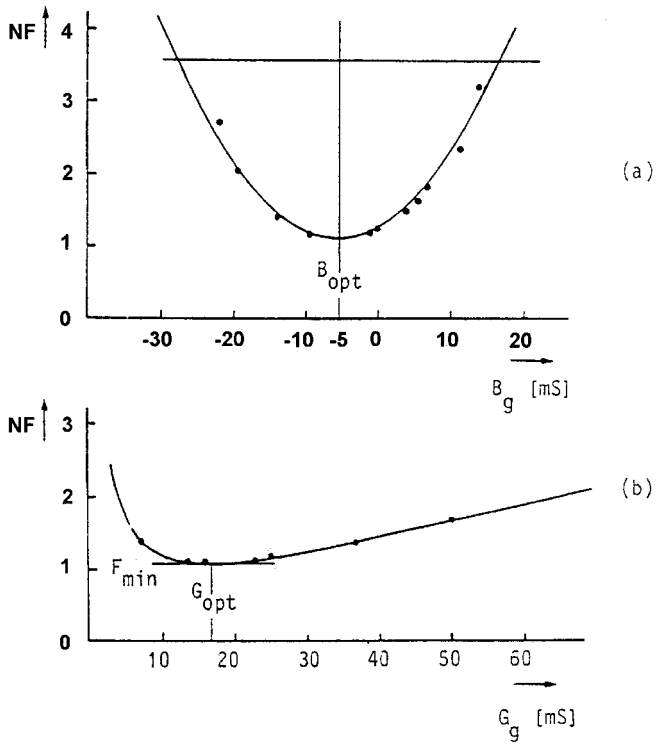

Figure 3-20 Noise factor in high-frequency BJTs for $f = 600$ MHz: (a) as a function of B_g for G_g = constant and (b) as a function of G_g for $B_g = B_{opt}$.

$$F = 1 + \frac{R_n}{R_G} \tag{3-52}$$

The excess noise added by the circuit is R_n/R_G.

In considering two cascaded circuits a and b, by definition the available noise at the output of b is

$$N_{ab} = F_{ab} G_{ab} kTB \tag{3-53}$$

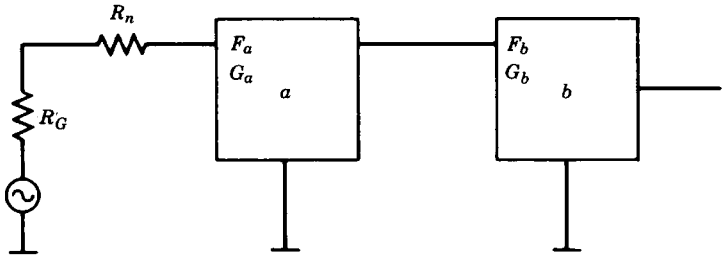

Figure 3-21 Cascaded noisy two-ports with the noise factors F_a and F_b and the gain figures G_a and G_b.

with B the equivalent noise bandwidth in which the noise is measured. The total available gain G is the product of the individual available gains, so

$$N_{ab} = F_{ab} G_a G_b kTB \tag{3-54}$$

The available noise from network a at the output of network b is

$$N_{a/b} = N_a G_b = F_a G_a G_b kTB \tag{3-55}$$

The available noise added by network b (its excess noise) is

$$N_{b/b} = (F_b - 1) G_b kTB \tag{3-56}$$

The total available noise N_{ab} is the sum of the available noise contributed by the two networks:

$$\begin{aligned} N_{ab} &= N_{a/b} + N_{b/b} = F_a G_a G_b kTB + (F_b - 1) G_b kTB \\ &= \left(F_a + \frac{F_b - 1}{G_a} \right) G_a G_b kTB \end{aligned} \tag{3-57}$$

$$F_{ab} = F_a + \frac{F_b - 1}{G_a} \tag{3-58}$$

For any number of circuits, this can be extended to

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \frac{F_4 - 1}{G_1 G_2 G_3} + \cdots \tag{3-59}$$

When considering a long chain of cascaded amplifiers, there will be a minimum noise figure achievable for this chain. This is a figure of merit and was proposed by Haus and Adler [6]. It is calculated by rearranging Eq. (3-59):

$$(F_{\text{tot}})_{\min} = (F_{\min} - 1) + \frac{F_{\min} - 1}{G_A} + \frac{F_{\min} - 1}{G_A^2} + \cdots + 1 \tag{3-60}$$

where $F_{\min}$ is the minimum noise figure for each stage and G_A is the available power gain of the identical stages. Using

$$\frac{1}{1 - X} = 1 + X + X^2 + \cdots \tag{3-61}$$

we find a quantity $(F_{\text{tot}} - 1)$, which is defined as the noise measure M. The minimum noise measure

$$(F_{\text{tot}})_{\min} - 1 = \frac{F_{\min} - 1}{1 - 1/G_A} = M_{\min} \tag{3-62}$$

refers to the noise of an infinite chain of optimally tuned, low-noise stages, so it represents a lower limit on the noise of an amplifier.

The minimum noise measure $M_{\min}$ is an invariant parameter and is not affected by feedback. It is somewhat similar to a gain–bandwidth product, in its use as a system invariant. The minimum noise measure is achieved when the amplifier is tuned for the available power gain and $\Gamma_G = \Gamma_{0n}$, given by Eq. (3-50).

Influence of External Parasitic Elements. Mounting an active two-port such as a transistor usually adds stray capacitance and lead inductance to the device, as shown in Figure 3-22. These external components consisting of transmission lines and parasitic reactances modify the noise parameters and the gain. Some researchers have published the results of these parasitic effects and have made manual computations or used some limited computer programs.

In a paper by Fukui [7], an attempt was made to determine the necessary equations, but the formulas are too involved even for pocket calculators. A more generic study by Iversen [8] is also very involved because of the various matrix manipulations and is more suitable for a computer. Besser's paper [9] in the *IEEE MTT-S* in 1975 and Vendelin's paper [10] in the same issue have shown for the first time some practical results using computers and even optimization methods, using an early version of COMPACT. The intention of these investigations was to find feedback that modifies the device noise and scattering parameters such that a noise match could also provide a low-input VSWR. It can be seen from these discussions that some feedback, besides resulting in some gain reduction, may improve the noise matching at the input for a limited frequency range.

A more recent paper by Suter [11] based on a report by Hartmann and Strutt [12] has given a simple transformation starting from the *S*-parameters and the noise parameters from common-source (or common-emitter) measurements. The noise parameters for the "packaged" device are calculated. This means that the parameters for the "new" device, including

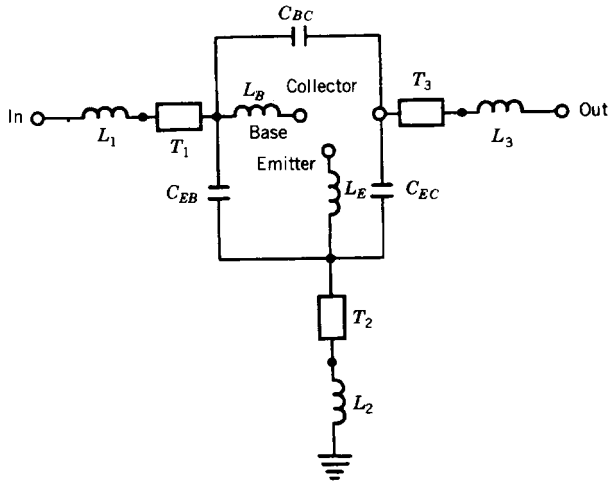

Figure 3-22 Equivalent circuit of the transistor package.

the common-gate (or common-base) case, are calculated. The equations are device dependent. They are valid for any active two-port.

A transformation matrix, n, may be used to combine the noise sources of the various circuit configurations. The transformation matrix parameters are given in Table 3-2 for series feedback, shunt feedback, and the common-gate (base) case, which will be important for oscillator analysis. The transformation matrix gives the new noise parameters as follows:

$$R'_n = R_n|n_{11} + n_{12}Y_{\text{cor}}|^2 + G_n|n_{12}|^2 \tag{3-63}$$

$$G'_n = \frac{G_nR_n}{R'_n}|n_{11}n_{22} - n_{12}n_{21}|^2 \tag{3-64}$$

$$Y'_{\text{cor}} = \frac{R_n}{R'_n}(n_{21} + n_{22}Y_{\text{cor}})(n^*_{11} + n^*_{12}Y^*_{\text{cor}}) + \frac{G_n}{R'_n}n_{22}n^*_{12} \tag{3-65}$$

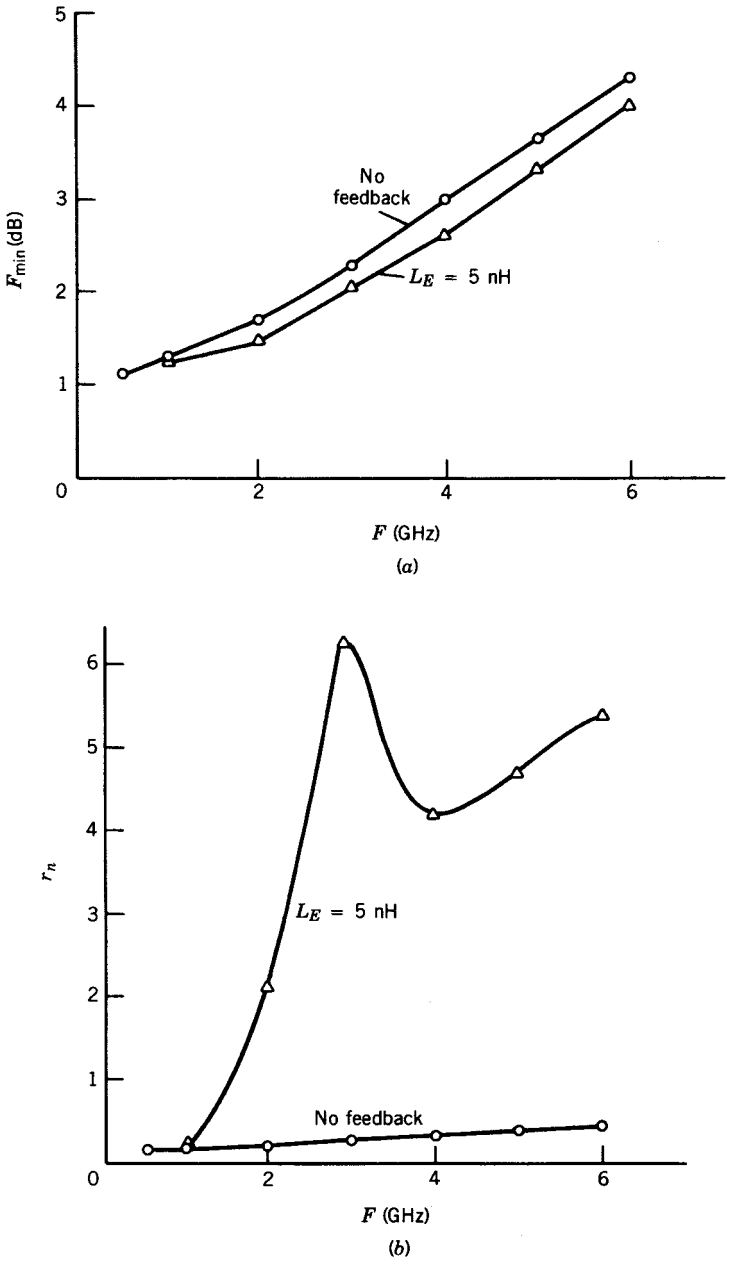

Figure 3-23 Noise parameters versus feedback for the AT-41435 silicon bipolar transistor: (a) F_{min} versus frequency and feedback; (b) r_n versus frequency and feedback; (c) Γ_{0n} versus frequency and feedback.

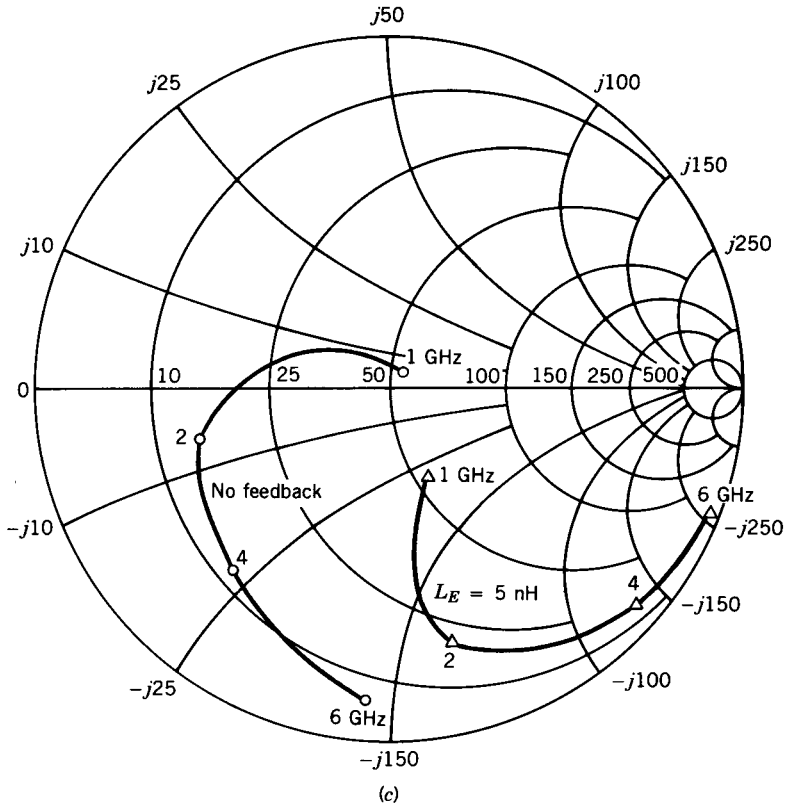

Figure 3-23 (*Continued*)

A final transformation to the more common noise-parameter format given by Eq. (3-44) is still needed [10]:

$$F_{\min} = 1 + 2R_n'(G_{\text{cor}}' + G_{0n}') \tag{3-66}$$

$$R_n = R_n' \tag{3-67}$$

$$G_{0n} = \sqrt{\frac{G_n'}{R_n'} + G_{\text{cor}}'^2} \tag{3-68}$$

$$B_{0n} = -B_{\text{cor}}' \tag{3-69}$$

Figure 3-23 shows the noise figure as a function of external feedback for a low-noise microwave bipolar transistor, the AT-41435.

Bias-Dependent Noise Parameters. Since we have elaborated on the effect of parasitics, it is now useful to point out that noise is also a strong function of bias point and frequency. Figure 3-24 shows the noise figure expressed in dB as a function of different dc currents and frequencies for a BFP420 BJT by Siemens. A change in the collector voltage will also affect the noise parameters, not quite as strongly as shown here, but still significantly. The reason

[b]$Z_S = Z_L = 50\ \Omega$.

for the turning point of the noise figure has to do with the fact that for lower currents the f_T cutoff frequency has not reached its peak yet, and therefore the noise increases. The increase of the noise at higher currents is due to the Schottky noise calculated from the equation

$$P_n = 2Iq \tag{3-70}$$

where P_n is the noise power, I is the saturation, collector, or drain current, and q is the charge of an electron (1.60×10^{-19} coulomb).

Table 3-3 shows the common-emitter noise parameters for the BFP420.

Noise Circles. From the section entitled "Influence of External Parasitic Elements," we see that the noise factor is a strong function of the generator admittance (or impedance) presented to the input terminals of the noisy two-port. Noise tuning is used to change the values of the input admittance to obtain the best noise performance. There is a range of values of input reflection coefficient over which the noise figure is constant. In plotting these points of constant noise figure, we obtain the so-called noise circles, which can be drawn on the Smith chart Γ_G plane [13]. Starting with the noise equation [see Eq. (3-44)] for a 50-Ω generator impedance, we find that

$$F_{50} = F_{\min} + 4r_n \frac{|\Gamma_{0n}|^2}{|1 + \Gamma_{0n}|^2} \tag{3-71}$$

We want to find the position of the reflection coefficient on the Smith chart, as in the case of the gain circles, for which F is constant. First we rearrange Eq. (3-67) to read

$$r_n = (F_{50} - F_{\min}) \frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-72}$$

By introducing

$$N_i = \frac{F_i - F_{\min}}{4r_n} |1 + \Gamma_{0n}|^2 \tag{3-73}$$

we can find an expression for a circle of constant noise figure as introduced by Rothe and Dahlke [4] (see also Fukui [13]). The center for the noise circle is

$$C_i = \frac{|\Gamma_{0n}|}{1 + N_i} \tag{3-74}$$

and the radius is

$$r_i = \frac{\sqrt{N_i^2 + N_i(1 - |\Gamma_{0n}|^2)}}{1 + N_i} \tag{3-75}$$

with the definition of N used previously. However, if we consider only the minimum noise figure for a given device, we will not obtain the minimum noise figure for the multistage amplifier system. This was explained when the noise measure was introduced. (See Figure 3-25.) Therefore, a better way to design the amplifier would be to use circles at constant noise measure instead of circles of constant noise figure. This was recently done by Poole

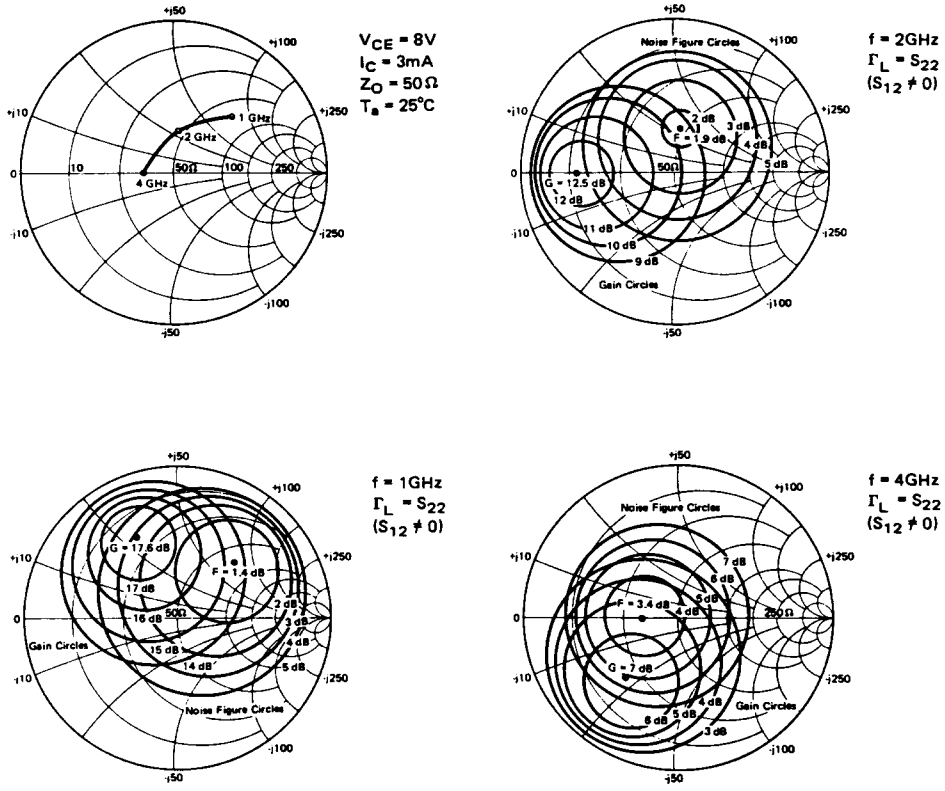

Figure 3-25 Typical noise figure circles and gain circles.

and Paul [14]. They derived the expressions for the noise measure circles as a function of S parameters, noise parameters, and Γ_G, using

$$G_A = \frac{|S_{21}|^2(1 - |\Gamma_G|^2)}{(1 - |S_{22}|^2) + |\Gamma_G|^2 (|S_{11}|^2 - |\Delta|^2) - 2\,\mathrm{Re}(\Gamma_G C_1)} \tag{3-76}$$

where

$$C_1 = S_{11} - S_{22}^* \Delta$$

$$\Delta = S_{11}S_{22} - S_{12}S_{11}$$

In terms of the generator reflection coefficient, the noise measure can be expressed as

$$M = [(F_{\min} - 1)(1 - |\Gamma_G|^2)|S_{21}|^2|1 + \Gamma_{0n}|^2 + 4r_n|S_{21}|^2|\Gamma_G - \Gamma_{0n}|^2]$$

$$\times \left\{|1 + \Gamma_{0n}|^2[|S_{21}|^2(1 - |\Gamma_G|^2) - (1 - |S_{22}|^2) - |\Gamma_G|^2(|S_{11}|^2 - |\Delta|^2) + 2\,\mathrm{Re}(\Gamma_G C_1)]\right\}^{-1} \tag{3-77}$$

Equation (3-77) can be shown to represent circles in the source reflection coefficient plane described by the following:

$$|\Gamma_G|^2 + |\Gamma_m|^2 - \Gamma_G\Gamma_m^* - \Gamma_G^*\Gamma_m = r_m^2 \tag{3-78}$$

The centers and radii of the constant-noise-measure circles are given by

$$C_m = \frac{M|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-79}$$

$$r_m = \frac{\sqrt{M^2M_a + MM_b + M_c}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-80}$$

where

$$P = |S_{21}|^2 + |S_{11}|^2 - |\Delta|^2$$

$$Q = |S_{21}|^2 + |S_{22}|^2 - 1$$

$$W = |1 + \Gamma_{0n}|^2(F_{\min} - 1)$$

$$M_a = |1 + \Gamma_{0n}|^4(PQ + |C_1|^2)$$

$$M_b = |1 + \Gamma_{0n}|^2|S_{21}|^2[8r_n\,\mathrm{Re}(\Gamma_{0n}C_1)$$

$$- (4r_n|\Gamma_{0n}|^2 + W)P - (W - 4r_n)Q]$$

$$M_c = |S_{21}|^4[W - 4r_n(1 - |\Gamma_{0n}|^2)]$$

The value of the minimum noise measure can be found by considering the noise measure circle of zero radius; that is, set r_m equal to zero in Eq. (3-80). This results in

$$M_{\min} = \frac{-M_b \pm \sqrt{M_b^2 - 4M_a M_c}}{2M_a} \tag{3-81}$$

Equation (3-81) yields the same value of $M_{\min}$ as would have been obtained by using the immittance parameter equation given by Fukui [13] and can, therefore, be considered as the reflection coefficient plane analog of Fukui's expression. The elimination of the need for the parameter R_{eg}, however, results in a considerable simplification as compared with the earlier approach [13].

The value of the minimum noise measure is taken as the smallest nonnegative value of $M_{\min}$ given by Eq. (3-81). The source reflection coefficient that results in the minimum noise measure can now be obtained by employing Eq. (3-79):

$$\Gamma_{0m} = \frac{M_{\min}|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M_{\min}|1 + \Gamma_{0n}|^2 P + |S_{21}|^2\,(4r_n - W)} \tag{3-82}$$

The output reflection coefficient of the device, when Γ_{0m} is presented to the input port, is given by

$$S'_{22} = \frac{S_{22} - \Delta\Gamma_{0m}}{1 - S_{11}\Gamma_{0m}} \tag{3-83}$$

Noise Correlation in Linear Two-Ports Using Correlation Matrices. In the introduction to two-port noise theory, it was indicated that noise correlation matrices form a general technique for calculating noise in n-port networks. Haus and Adler [6] have described the theory behind this technique. In 1976, Hillbrand and Russer [15] published equations and transformations that aid in supplying this method to two-port CAD.

This method is useful because it forms a base from which we can rigorously calculate the noise of linear two-ports combined in arbitrary ways. For many representations, the method of combining the noise parameters is as simple as that for combining the circuit element matrices. In addition, noise correlation matrices can be used to calculate the noise in linear frequency conversion circuits. The following is an introduction to this subject.

A linear, noisy two-port can be modeled as a noise-free two-port with two additional noise sources. These noise sources must be chosen so that they add directly to the resulting vector of the representation, as shown in Eqs. (3-84) and (3-85) and Figure 3-17:

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-84}$$

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \tag{3-85}$$

where the i and v vectors indicate noise sources for the y and z representations, respectively. This two-port example can be extended to n-ports in a straightforward, obvious way.

Since the noise vector for any representation is a random variable, it is much more convenient to work with the noise correlation matrix. The correlation matrix gives us deterministic numbers with which to calculate. The correlation matrix is formed by taking the mean value of the outer product of the noise vector. This is equivalent to multiplying the noise vector by its adjoint (complex conjugate transpose) and averaging the result:

$$\langle \bar{i}\ \bar{i}^{+} \rangle = \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] = \begin{bmatrix} \langle i_1 i_1^* \rangle & \langle i_1 i_2^* \rangle \\ \langle i_1^* i_2 \rangle & \langle i_2 i_2^* \rangle \end{bmatrix} + [C_y] \tag{3-86}$$

where the angular brackets denote the average value.

Note that the diagonal terms are the "power" spectrum of each noise source and the off-diagonal terms are complex conjugates of each other and represent the "cross-power" spectra of the noise sources. "Power" is used because these magnitude-squared quantities are proportional to power.

To use these correlation matrices in circuit analysis, we must know how to combine them and how to convert them between various representations. An example using y matrices will illustrate the method for combining two-ports and their correlation matrices. Given two matrices y and y', when we parallel them we have the same port voltages, and the terminal currents add (Figure 3-26):

$$\begin{aligned} I_1 &= y_{11}V_1 + y_{12}V_2 + y'_{11}V_1 + y'_{12}V_2 + i_1 + i'_1 \\ I_2 &= y_{21}V_1 + y_{22}V_2 + y'_{21}V_1 + y'_{22}V_2 + i_2 + i'_2 \end{aligned} \tag{3-87}$$

or

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} + y'_{11} & y_{12} + y'_{12} \\ y_{21} + y'_{21} & y_{22} + y'_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 + i'_1 \\ i_2 + i'_2 \end{bmatrix} \tag{3-88}$$

Here we can see that the noise current vectors add just as the y parameters add. Converting the new noise vector to a correlation matrix yields

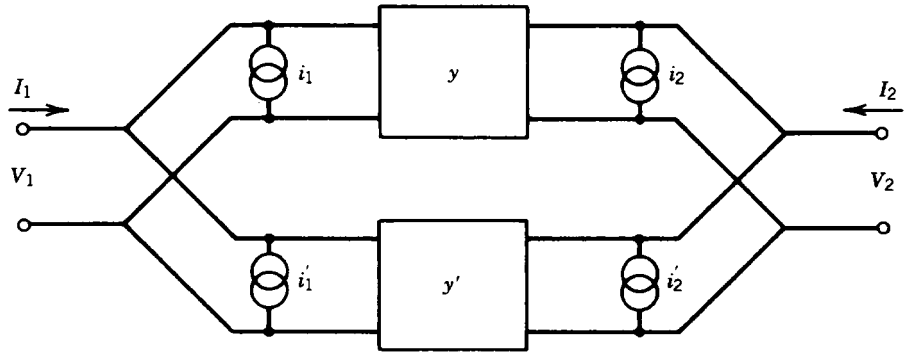

Figure 3-26 Parallel combination of two-ports using y parameters.

$$\langle \bar{i}_{\text{new}} \bar{i}^{+}_{\text{new}} \rangle = \left\langle \begin{bmatrix} i_1 + i_1' \\ i_2 + i_2' \end{bmatrix} [i_1^* + i_1'^* \quad i_2 i_2'^*] \right\rangle \tag{3-89}$$

$$= \begin{bmatrix} \langle i_1 i_1^* \rangle + \langle i_1' i_1'^* \rangle & \langle i_1 i_2^* \rangle + \langle i_1' i_2'^* \rangle \\ \langle i_2 i_1^* \rangle + \langle i_2' i_1'^* \rangle & \langle i_2 i_2^* \rangle + \langle i_2' i_2'^* \rangle \end{bmatrix} \tag{3-90}$$

The noise sources from different two-ports must be uncorrelated, so there are no cross products of different two-ports. By inspection, Eq. (3-90) is just the addition of the correlation matrices for the individual two-ports, so

$$[C_{y\text{new}}] = [C_y] + [C_y'] \tag{3-91}$$

The same holds true for g, h, and z parameters, but $ABCD$ parameters have the more complicated form shown below. If

$$[A_{\text{new}}] = [A][A'] \tag{3-92}$$

then

$$[C_{A\text{new}}] = \{C_A] + [A]\,[C_{A'}]\,[A]^{+} \tag{3-93}$$

The transformation of one representation to another is best illustrated by an example. Let us transform the correlation matrix for a Y representation to a Z representation. Starting with

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = [Y] \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-94}$$

we can move the noise vector to the left side and invert y:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 - i_1 \\ I_2 - i_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Y^{-1}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-95}$$

Table 3-4 π Noise matrix $T_{\alpha\beta}$ transformation

		Original Form (α Form)					
		Y		Z		A	
Resulting Form (β Form)	Y	1	0	y_{11}	y_{12}	$-y_{11}$	1
		0	1	y_{21}	y_{22}	$-y_{21}$	0
	Z	z_{11}	z_{12}	1	0	1	$-z_{11}$
		z_{21}	z_{22}	0	1	0	$-z_{21}$
	A	0	A_{12}	1	$-A_{11}$	1	0
		1	A_{22}	0	$-A_{21}$	0	1

Since $(Y)^{-1} = (Z)$, we have

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Z] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-96}$$

so

$$= [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} = [T_{yz}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-97}$$

where the signs of i_1 and i_2 are superfluous since they will cancel when the correlation matrix is formed. Here the transformation of the Y noise current vector to the Z noise voltage vector is done simply by multiplying by (Z). Other transformations are shown in Table 3-4.

To obtain the noise correlation matrix, we again form the mean of the outer product:

$$\langle vv^+ \rangle = \begin{bmatrix} \langle v_1 v_1^* \rangle & \langle v_1 v_2^* \rangle \\ \rangle v_1^* v_2 \rangle & \langle v_2 v_2^* \rangle \end{bmatrix} = [Z] \left\langle \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] \right\rangle [Z]^+ \tag{3-98}$$

or

$$[C_z] = [Z]\,[C_y]\,[Z]^+ \tag{3-99}$$

where

$$v^+ = [i_1^* \quad i_2^*]\,[Z]^+ \tag{3-100}$$

This is called a congruence transformation. The key to all of these derivations is the construction of a correlation matrix from the noise vector, as shown in Eq. (3-90).

These correlation matrices may easily be derived from the circuit matrices of passive circuits with only thermal noise sources. For example,

$$[C_z] = 2kT\Delta f\,\mathrm{Re}([Z]) \tag{3-101}$$

and

$$[C_y] = 2kT\Delta f\,\mathrm{Re}([Y]) \tag{3-102}$$

The $2kT$ factor comes from the double-sided spectrum of thermal noise. The correlation matrix from the $ABCD$ matrix may be related to the noise figure, as shown by Hillbrand and Russer [15]. We have

$$F = 1 + \frac{\overline{Y}[C_a]\overline{Y}^+}{2kT\,\mathrm{Re}(Y_G)} \tag{3-103}$$

where

$$\overline{Y} = \begin{bmatrix} Y_G \\ 1 \end{bmatrix}$$

Expressing the noise factor in terms of the correlation matrix, we obtain a complete formula:

$$F = 1 + \frac{C_{22}^{A}(f) + 2\,\mathrm{Re}\{Y_g(f)\,C_{12}^{A}(f)\} + |Y_g(f)|^2\,C_{11}^{A}(f)}{2kT_0\,\mathrm{Re}\{Y_g(f)\}} \tag{3-104}$$

Once we transform this in the Y parameter form, we obtain the following equation:

$$F(f) = F_{\min}(f) + \frac{R_n(f)|Y_{\mathrm{opt}}(f) - Y_g(f)|^2}{\mathrm{Re}\{Y_g(f)\}} \tag{3-105}$$

It should be noted that all these values are frequency dependent, as expressed in this equation.

The *ABCD* correlation matrix can be written in terms of the noise figure parameters as (double-sided spectrum)

$$[C_a] = 2kT\begin{bmatrix} R_n & \dfrac{F_0 - 1}{2} - R_n Y_{0n}^{*} \\ \dfrac{F_0 - 1}{2} - R_n Y_{0n} & R_n|Y_{0n}|^2 \end{bmatrix} \tag{3-106}$$

The noise correlation matrix method forms an easy and rigorous technique for handling noise in networks. This technique allows us to calculate the total noise for complicated networks by combining the noise matrices of subcircuits. It should be remembered that although noise correlation matrices apply to n-port networks, noise figure calculations apply only to pairs of ports. The parameters of the C_a matrix can be used to give the noise parameters:

$$Y_{0n} = \sqrt{\frac{C_{ii*}}{C_{uu*}} - \left[\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right)\right]^2} + j\,\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right) \tag{3-107}$$

$$F_0 = 1 + \frac{C_{ui*} + C_{uu*}Y_{0n}^{*}}{kT} \tag{3-108}$$

$$R_u = C_{uu*} \tag{3-109}$$

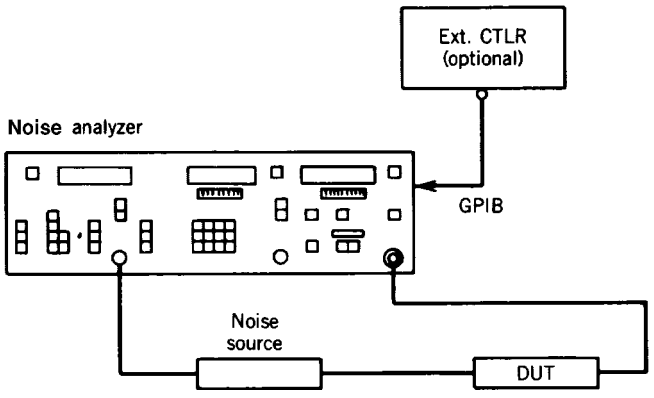

Figure 3-27 Noise figure measurement.

Noise Figure Test Equipment. Figure 3-27 shows the block diagram of a noise test setup. It includes the noise source and the other components. The metering unit has a special detector that is linear and over a certain dynamic range measures linear power. The tunable receiver covers a wide frequency range (e.g., 10–1800 MHz) and controls the noise source. The receiver is a double-conversion superheterodyne configuration with sufficient image rejection to avoid double-sideband noise measurements that would give the wrong results.

These receivers are microprocessor controlled and the measurement is a two-step procedure. The first is a calibration step that measures the noise figure of the receiver system and a reference power level. Then the device under test (DUT) is inserted and the system noise figure and total output power are measured. The noise factor is calculated by

$$F_1 = F_{\text{system}} - \frac{F_2 - 1}{G_1} \tag{3-110}$$

and the gain is given by the change in output power from the reference level [16]. The noise of the system is calculated by measuring the total noise power with the noise source on and off. With the excess noise ratio (ENR) known [16],

$$F_{\text{system}} = \frac{\text{ENR}}{Y - 1} \tag{3-111}$$

The noise bandwidth is usually set by the bandwidth of the receiver, which is assumed to be constant over the linear range. The ENR of the noise source is given by

$$\text{ENR} = \frac{T_{\text{hot}}}{T_{\text{cold}}} - 1 \tag{3-112}$$

where T_{cold} is usually room temperature (290 K). This ENR number is about 15 dB for noise sources with a 15-dB pad and 5 dB for noise sources with a 25-dB pad. Since both gain and noise were stored in the initial calibration, a noise/gain sweep can be performed.

For frequencies above 1800 MHz, we can extend the range with the help of the external signal generators, as shown in Figure 3-28. As shown, a filter ahead of the external mixer reduces the noise energy in the image band. If the DUT has a very broad frequency range

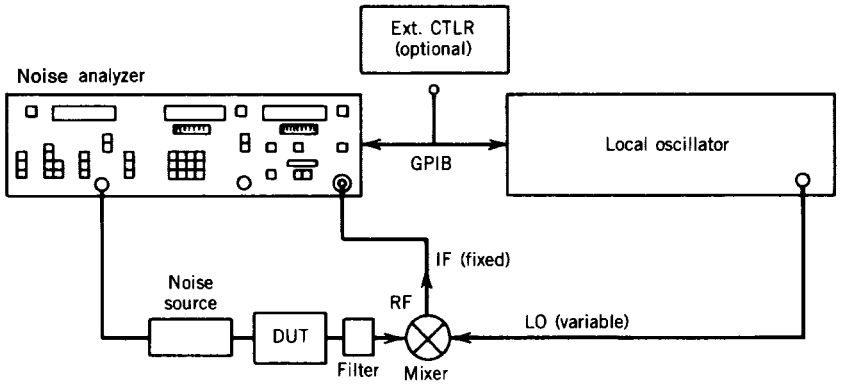

Figure 3-28 Single-sideband (SSB) noise figure measurements using an external mixer.

and has flat gain and noise over that range, a double-sideband (DSB) measurement is possible, with the image-rejection filter removed. However, a single-sideband (SSB) measurement is always more accurate [17].

How To Determine the Noise Parameters. The noise figure of a linear two-port network as a function of source admittance may be represented by

$$F = F_{\min} + \frac{R_n}{G_G}\left[(G_{0n} - G_G)^2 + (B_{0n} - B_G)^2\right] \tag{3-113}$$

where $G_G + jB_G$ = generator admittance presented to the input of the two-port
$G_{0n} + jB_{0n}$ = generator admittance at which optimum noise figure occurs
R_n = empirical constant relating sensitivity of the noise figure to generator admittance, with dimensions of resistance

It may be noted that for an arbitrary noise figure measurement with a known generator admittance, Eq. (3-113) has four unknowns—$F_{\min}$, R_n, G_{0n}, and B_{0n}. By choosing four known values of generator admittance, a set of four linear equations is formed and solutions of the four unknowns can be found [18, 19]. Eq. (3-113) may be transformed to

$$F = F_{\min} + \frac{R_n|Y_{0n}|^2}{G_G} - 2R_nG_{0n} + \frac{R_n|Y_G|^2}{G_G} - 2R_nB_{0n}\frac{B_G}{G_G} \tag{3-114}$$

or

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-115}$$

Let

$$X_1 = F_{\min} - 2R_nG_{0n}$$

$$X_2 = R_n|Y_{0n}|^2$$

$$X_3 = R_n$$

$$X_4 = R_nB_{0n}$$

Then the generalized equation may be written

$$F_i = X_1 + \frac{1}{G_{si}}X_2 + \frac{|Y_{si}|^2}{G_{si}}X_3 - 2\frac{G_{si}}{B_{si}}X_4 \tag{3-116}$$

or, in matrix form,

$$[F] = [A]\,[X] \tag{3-117}$$

and the solution becomes

$$[X] = [A]^{-1}\,[F] \tag{3-118}$$

These parameters completely characterize the noise behavior of the linear two-port network. Direct measurement of these noise parameters by this method would be possible only if the receiver on the output of the two-port were noiseless and insensitive to its input admittance. In actual practice, the receiver itself behaves as a noisy two-port network and can be characterized in the same manner. What is actually being measured is the system noise figure of the two-port and the receiver. Thus, it becomes apparent that to do a complete two-port noise characterization, the gain of the two-port must be measured [20]. In addition, any losses in the input-matching networks must be carefully accounted for, because they add directly to the measured noise figure reading [21].

3-1-4 Linearity

Consistent with the elaborate discussion of linearity questions above, here is a quick refresher on what must be considered in amplifiers.

Dynamic Range, Compression, and IMD. An amplifier's dynamic range is related to the minimum discernible signal and the 1-dB compression point according to the equation

$$DR_n = \frac{(n-1)(IP_{n(\text{in})} - MDS)}{n} \tag{3-119}$$

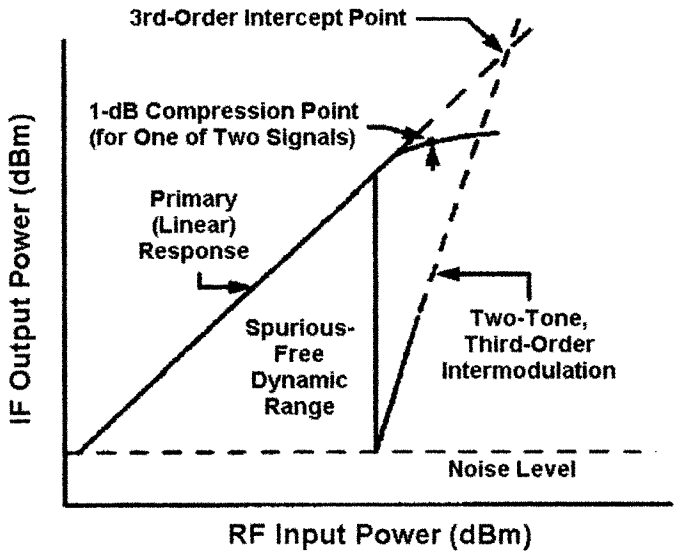

Figure 3-29 Amplifier linearity evaluation, including compression and two-tone IMD dynamic range. $P_{-1\text{dB}}$ for a single-tone cannot be read directly from this graph because the values shown are the result of two equal-power tones.

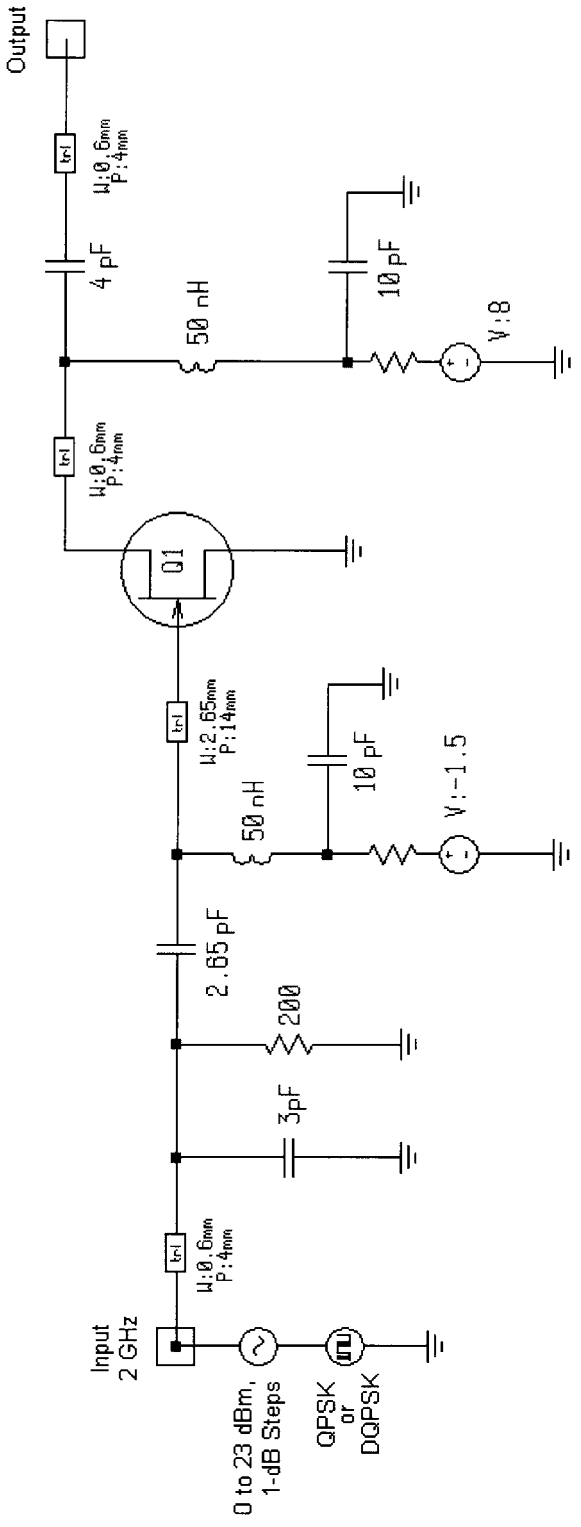

Figure 3-30 The power amplifier schematic.

where DR is the dynamic range in decibels, n is the order, $IP_{(in)}$ is the input intercept power in dBm, and MDS is the minimum detectable signal power in dBm. Once the 1-dB compression point is known, it is a fair assumption that the third-order intercept point, expressed in dBm, is 10 dB above this.

The intermodulation distortion gives the quality of an amplifier to withstand multiple signals without generating large intermodulation products or when using amplitude-modulated signals (cross-modulation). Figure 3-29 provides a quick reminder of IMD issues.

In some amplifiers, we would like to have control over the gain. While the better way to control gain while obtaining high linearity is a PIN-diode attenuator, special AGC circuits have become part of the amplifiers. Figure 3-48 shows a circuit of the SL610, made by Plessey, which has an AGC input provision. The noise figure of the PIN-diode attenuator is essentially equal to its attenuation. The AGC in multistage amplifiers is distributed over several stages and there is a lesser correlation between noise and AGC than in purely passive attenuators.

Special Case of Linearity Requirements for Digital Modulation. For cellular telephone systems we use digital modulation formats, such as QPSK and π/4-DQPSK, that combine phase and amplitude modulation. Amplifiers handling such signals must be carefully characterized and designed if adequate amplitude and phase linearity are to be maintained.

Examples of Power Amplifiers: Looking into the Effects of Distortion. This example presents modulation analysis using QPSK in a 2-GHz power amplifier (Figure 3-30). The simple amplifier was designed using the electronic Smith Tool of Serenade to determine the matching network for a narrowband design. The example demonstrates setup of modulation analysis and available results.

Siemens among others provides integrated amplifiers based on the concept depicted in Figure 3-30, the most popular ones being the CGY96 and CGY94. For the purpose of measurements, these amplifiers were actually put on a breadboard. Figure 3-31 shows the big brother, the CGY96. It is a GaAs MMIC intended as a power amplifier for GSM Class 4 phones with 3.2 W (35 dBm) at 3.5 V at an overall power added efficiency of 50%. Table 3-5 shows its electrical characteristics.

For the purpose of our experiments, we considered the CGY94 because it requires less external peripheral circuits. Table 3-6 shows its electrical characteristics. For those of us interested in seeing part of the internal circuit, Figure 3-32 shows the chip. This two-stage amplifier uses an interesting internal feedback scheme. Its schematic is shown in Figure 3-33.

For the purpose of looking at the waveforms, we will continue with the single-stage amplifier (Figure 3-30) and then compare the measured versus predicted performance of this CGY94-based amplifier.

A modulation source is connected to the RF source at the input port of the amplifier. The RF source specifies the carrier power (or voltage or current) and the modulation source specifies the modulation format and properties of the modulated signal.

A brief review of the modulation source used in this example indicates the following properties:

Property	Value	Description
NB	128	Number of bits
BR	1.2288E6	Bit rate
N	8	Number of samples per bit
BW1	590.E3	One-sided bandwidth of the main channel in the PIB or P1IB calculation
FS1	740.E3	Start baseband frequency of the fist adjacent channel
BW2	590.E3	One-sided bandwidth of the main channel in the P2IB calculation
FS2	1990.E3	Start baseband frequency of the second adjacent channel
BW3	590.E3	One-sided bandwidth of the main channel in the P3IB calculation
FS3	3240.E3	Start baseband frequency of the third adjacent channel
M	4	Order of the signal space; M = 4 is QPSK
DLY	0.0	Fractional bit delay
IASC	1.0	I channel amplitude scale; multiplier for the I waveform to model amplitude imbalance
QASC	1.0	Q channel amplitude scale; multiplier for the Q waveform to model amplitude imbalance
LPF	3	Baseband low-pass filter; 3 = root-raised cosine filter
LPFC	665.E3	–3 dB cutoff frequency of LPF
LPFN	3	Number of resonators if LPF = 1
LPFR	0.35	Roll-off factor if LPF = 3 or LPF = 4
FILE	N/A	File name of user-defined modulated signal file

The modulation source is a QPSK stream with a bit rate of 1.2288 Mbps. A total of 128 bits will be analyzed, and each bit is sampled eight times to construct an accurate analog waveform. The BW and FS parameters are defined here to specify the main (in-band) channel and adjacent channel for ACPR calculations. Imbalance of the I and Q amplitudes and phases can be described by the IASC, QASC, and DLY parameters, if desired. The modulation signal

is often filtered, and several types of filters are available. Here a root-raised cosine filter is used with a cutoff frequency of 665 kHz and a roll-off factor of 0.35.

Analysis. Figure 3-34 shows the compression characteristics of the amplifier as the available RF source power (a sinusoid) is swept. Note that P_{-1dB} is 11.5 dBm referred to the input and 28.5 dBm referred to the output. We will look at modulation characteristics in the linear region of operation at a source power of 0 dBm, and the nonlinear region at a source power of 20 dBm.

Next, we will view the voltage across the transistor to examine its behavior under compression. Figure 3-35 shows the drain–source voltage of the FET as the source power is swept. It is clear from this graph that clipping due to pinchoff and forward-gate conduction

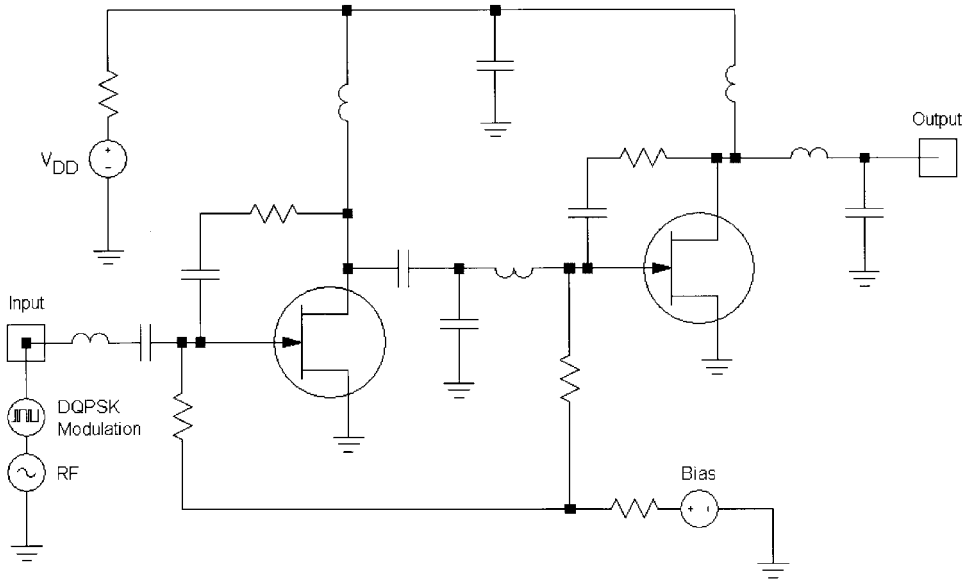

Figure 3-33 Schematic of the CGY94 GaAs MMIC power amplifier.

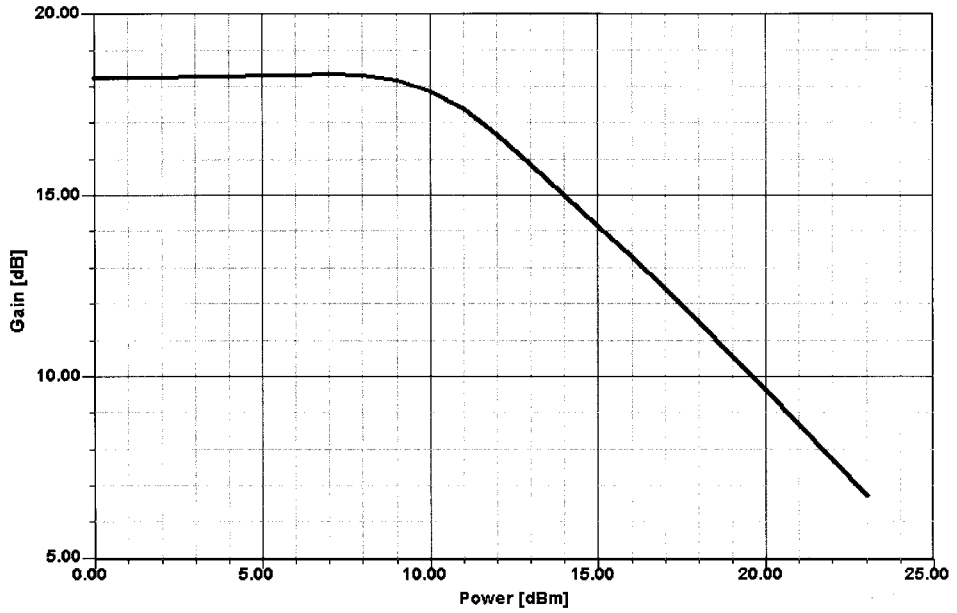

Figure 3-34 Single-tone RF power sweep analysis of the FET amplifier.

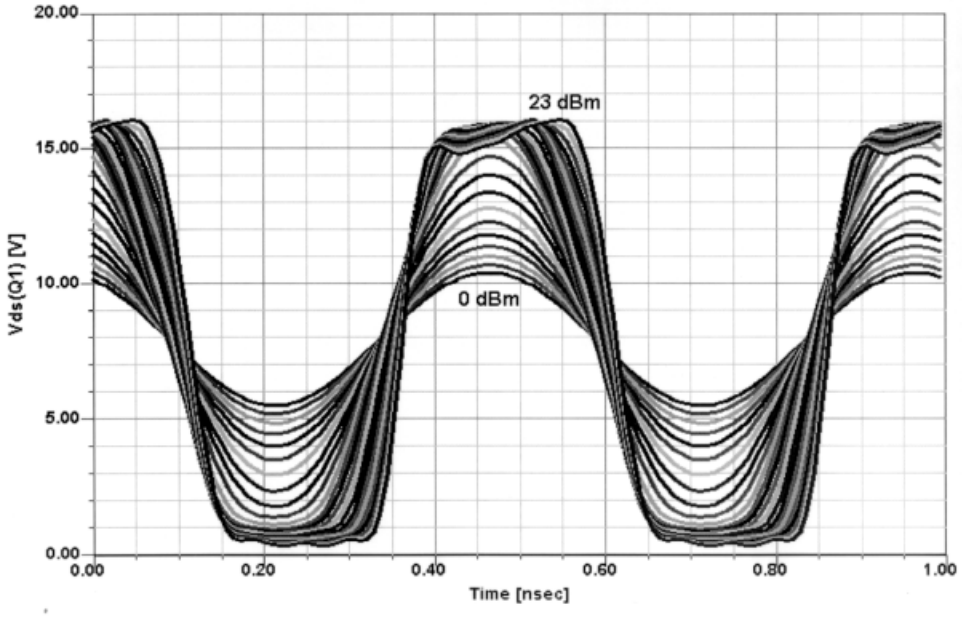

Figure 3-35 V_{DS} of the FET versus RF source power.

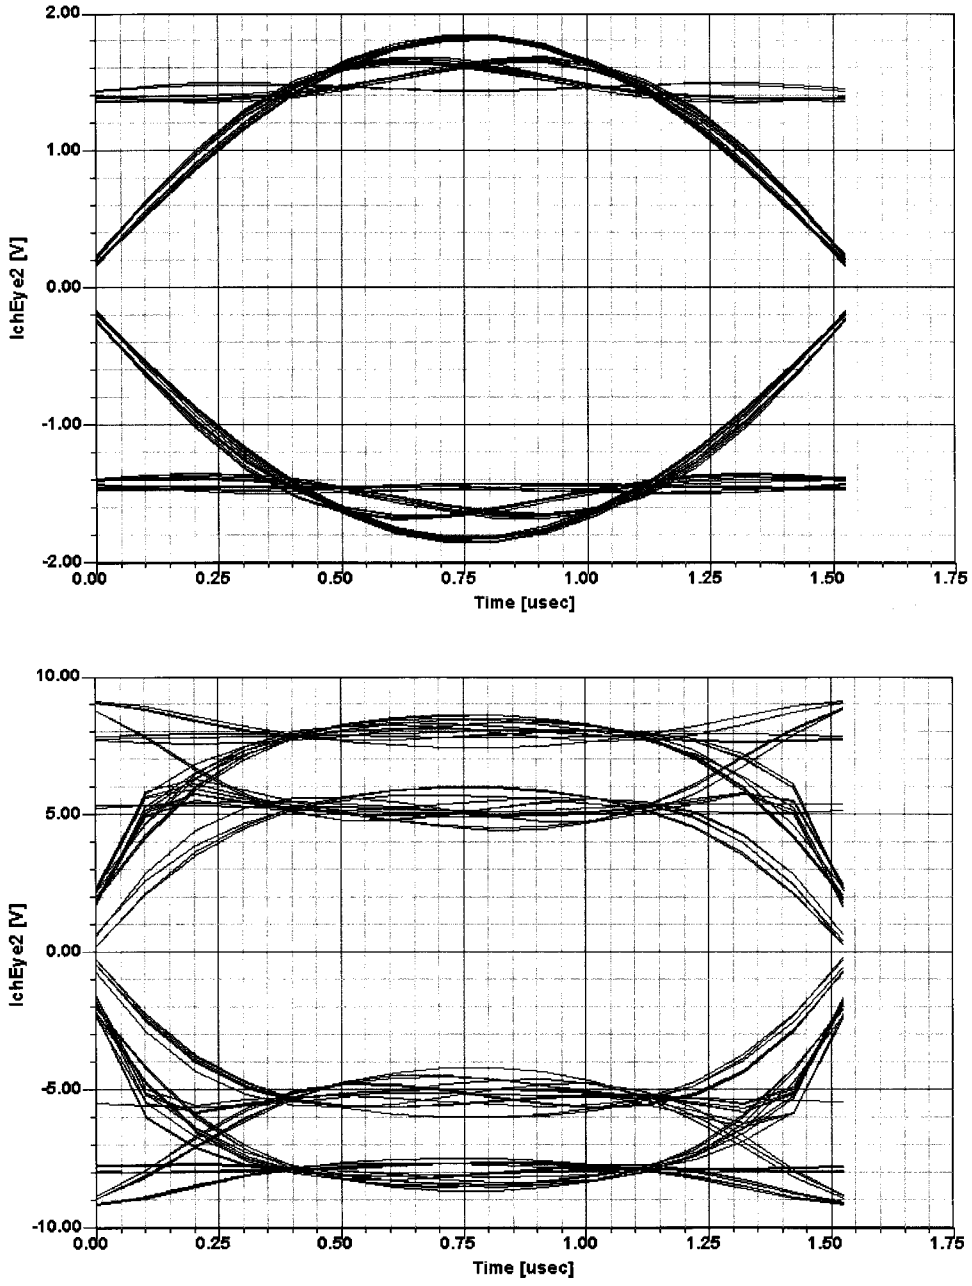

Figure 3-36 Eye diagrams of the I channel for source powers of (a) 0 dBm and (b) 20 dBm.

is limiting the performance of the device. A phase shift of the voltage waveform as power is increased is also apparent. The combination of the power compression and phase shift, or AM to PM conversion, will be used in the modulation analysis to determine the overall distortion of the modulated signal.

The output available from modulation analysis includes:

- I and Q channel waveforms
- Eye and constellation diagrams
- Spectral plots
- ACPR, in-band, and adjacent power

Figure 3-36 shows the eye diagrams for the 128-bit QPSK signal at two RF source powers, 0 and 20 dBm. Operating linearly at 0 dBm input, the amplifier doesn't distort the eye and it remains wide open. Note that in this example the filter bandwidth doesn't produce any intersymbol interference, as evidenced by the open eye. At an input power of 20 dBm, the amplifier compresses the signal, and distortion in the eye is evident.

We can also view the modulation spectrum at these two power levels to investigate the intermodulation distortion and spectral regrowth that takes place. Figure 3-37 shows the spectral plots. The lower trace corresponds to 0 dBm source power and shows almost no regrowth, while the upper trace at 20 dBm source power shows considerable regrowth.

The uncorrupted modulation source can also be shown. This corresponds to the source as a pure voltage without any circuit influence.

Now we evaluate the CGY94 board in a similar fashion. Figure 3-38 shows the waveform used for CAD purposes. Needless to say, such a signal cannot be produced by any signal

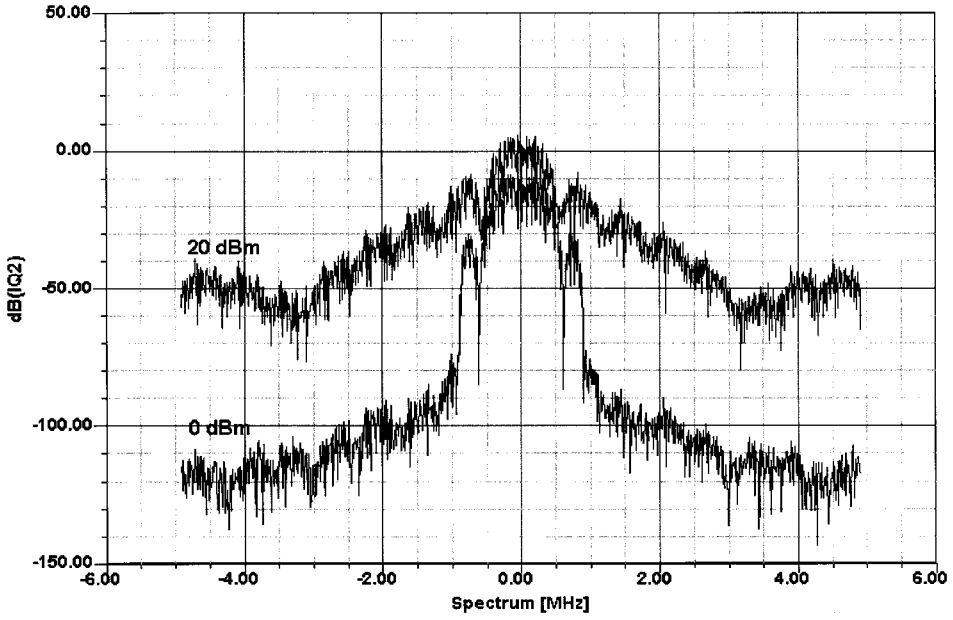

Figure 3-37 Spectrum of the modulation signal at the amplifier output. Source powers are 0 and 20 dBm.

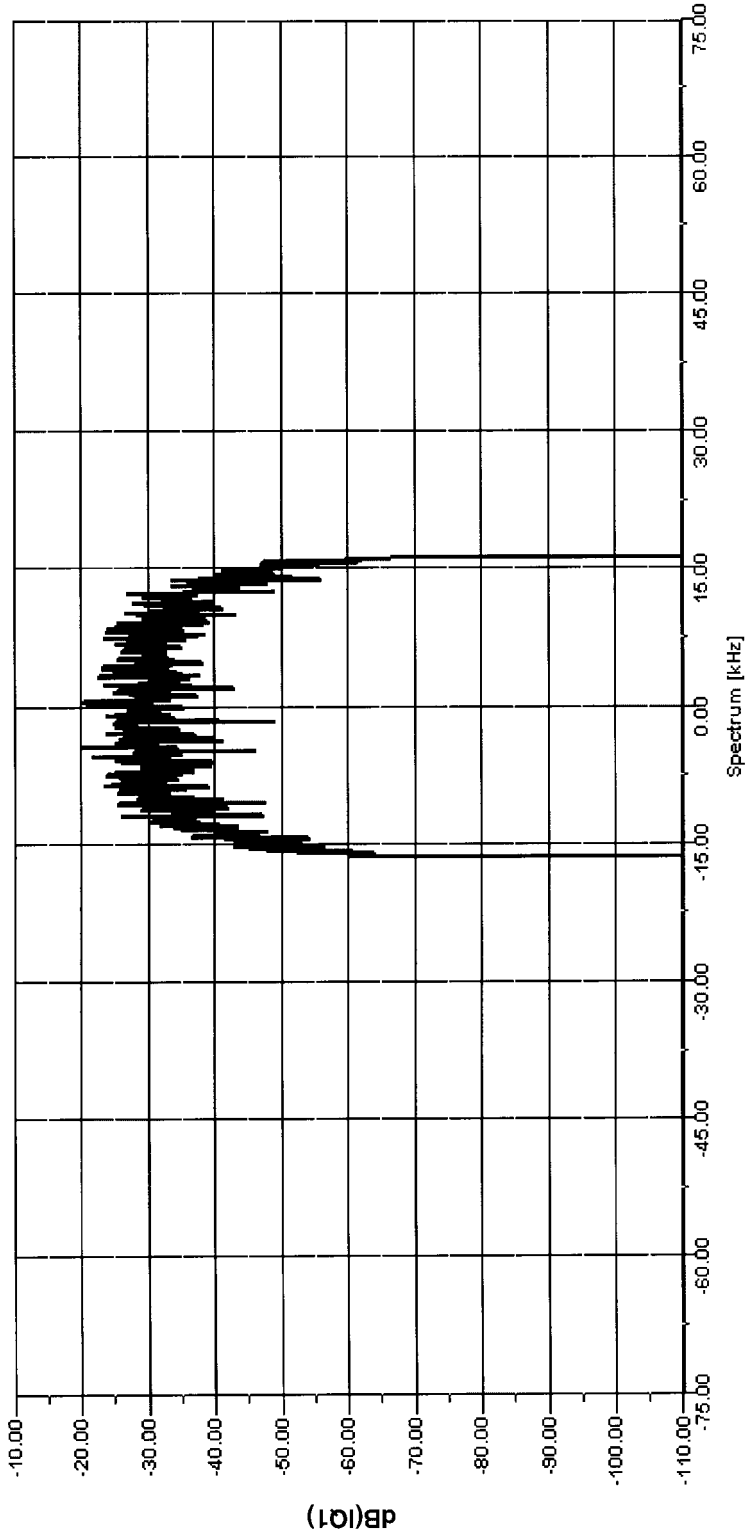

Figure 3-38 Simulated signal used for CAD analysis of the CGY94 amplifier.

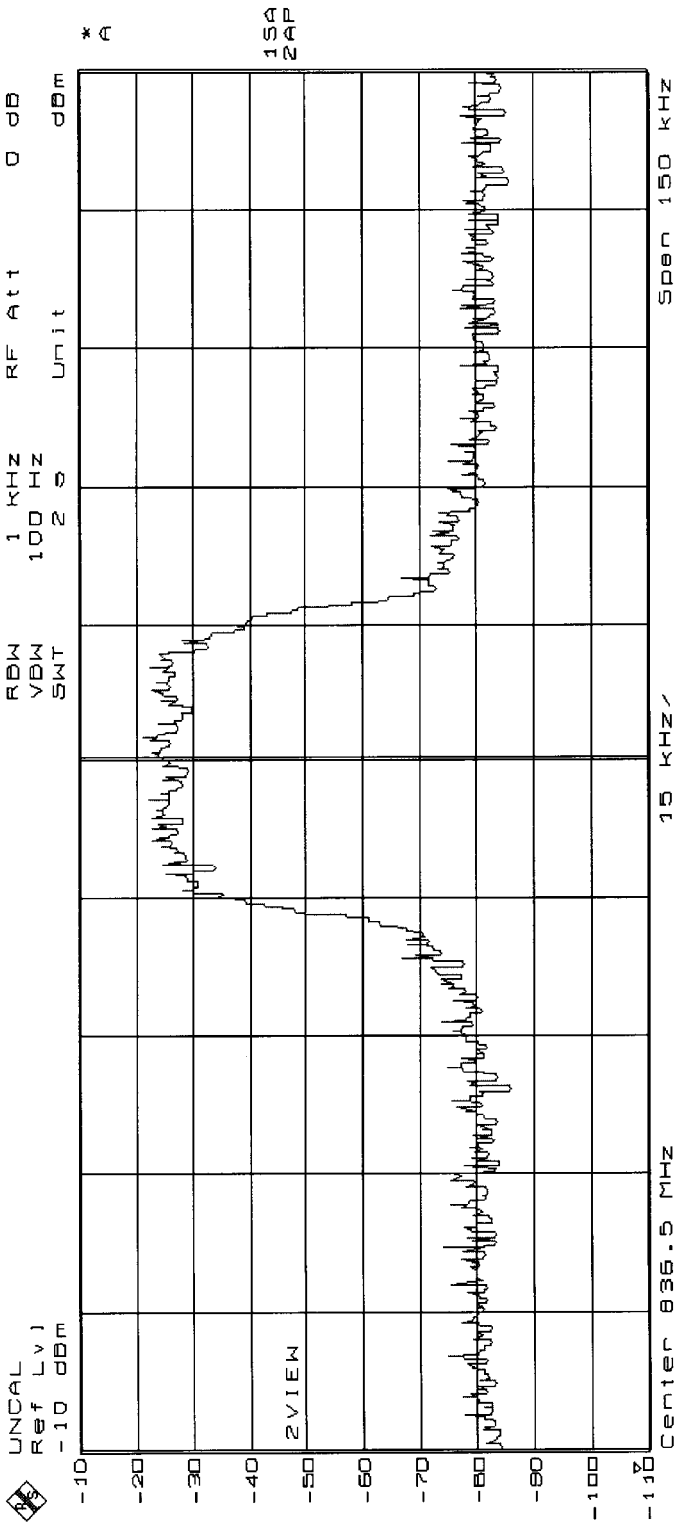

Figure 3-39 Real signal used for testing the actual amplifier.

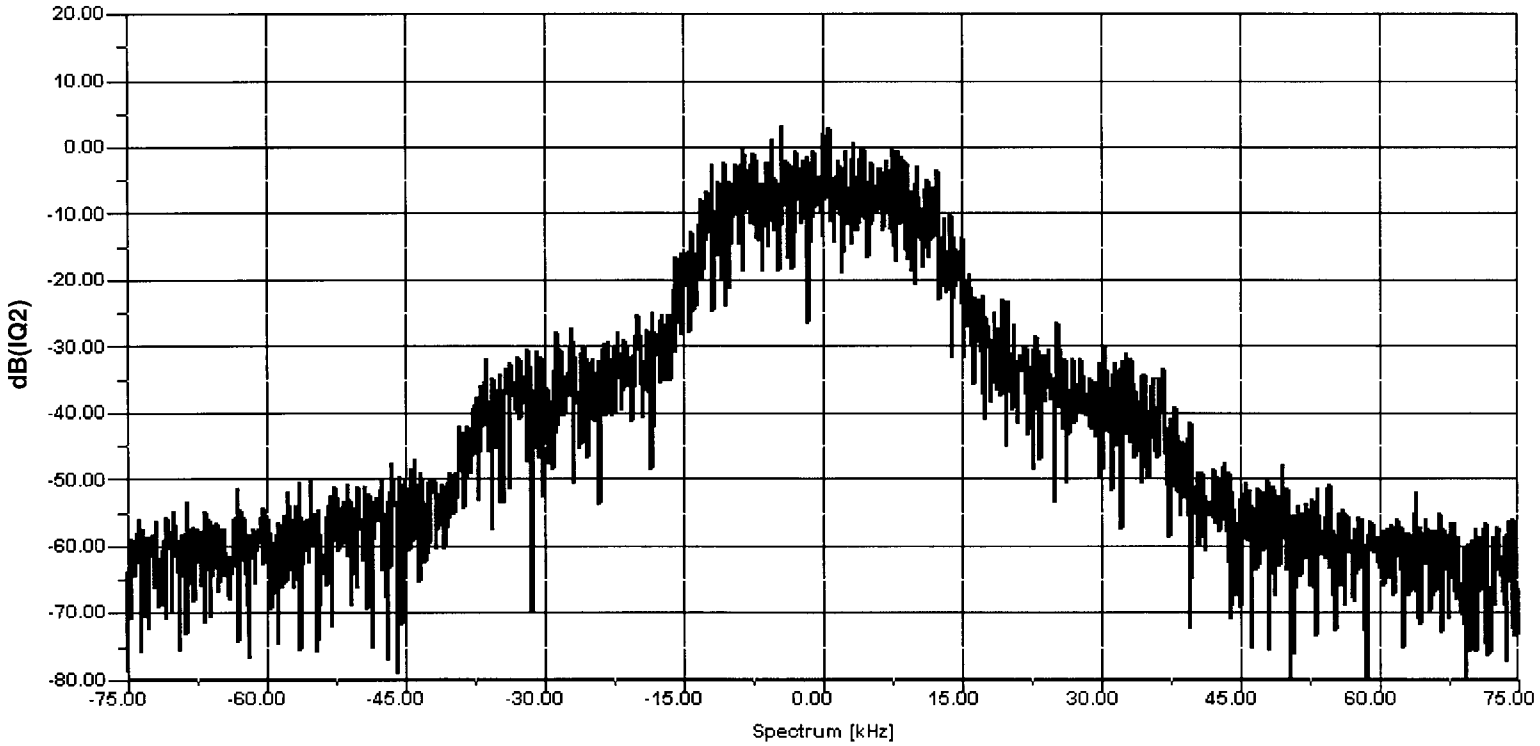

Figure 3-40 Spectral regrowth predicted by the simulation.

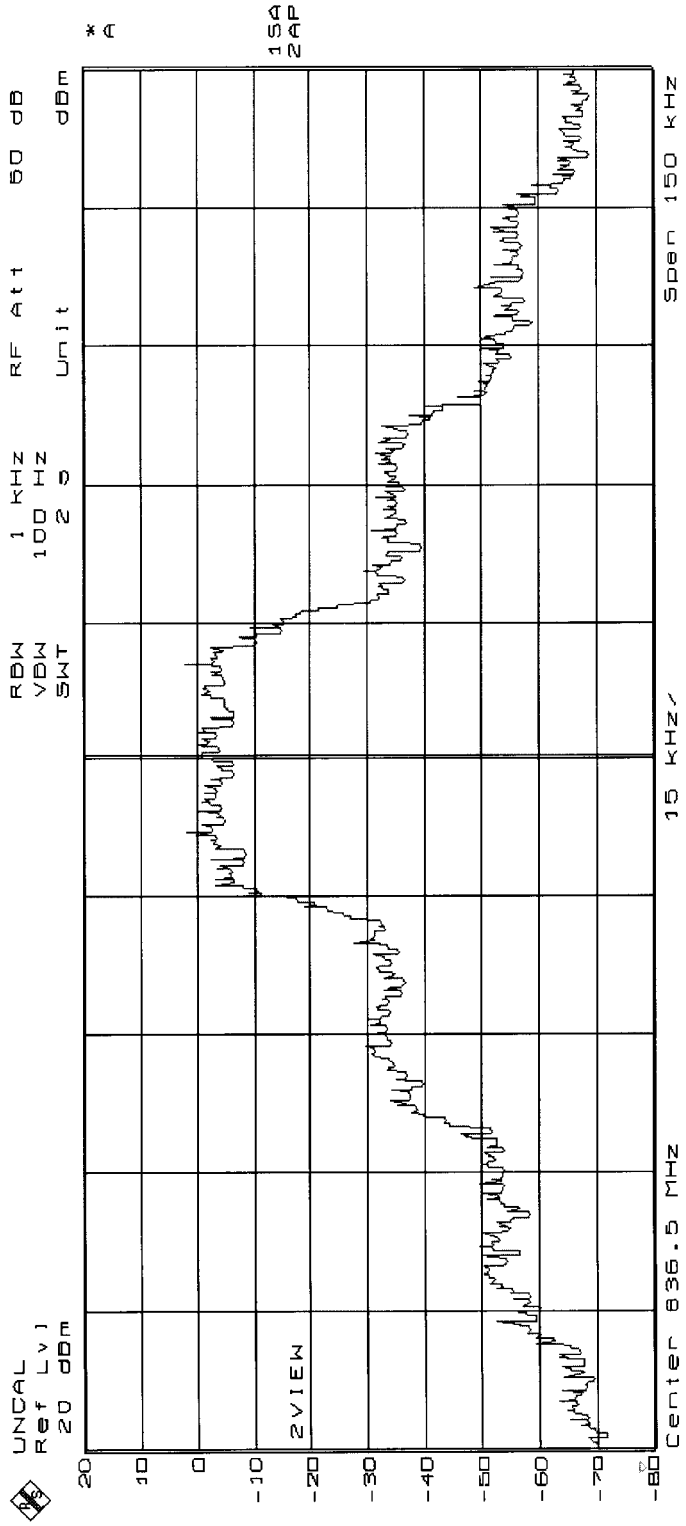

Figure 3-41 Measured spectral regrowth of the CGY94 amplifier.

generator. The one generated by an actual signal generator is shown in Figure 3-39. The wideband noise is around –80 dBm and the input level is about –25 dBm, consistent with the simulation signal. Looking at the output, Figure 3-40 shows the simulated signal with the expected increase in bandwidth. This is due to the nonlinearity of the amplifier and is consistent with Figure 3-37 for the single-stage amplifier. The actual measured output for the CGY94 shown in Figure 3-41 is quite close to its simulated output, indicating that the mathematical approach used for simulating is correct. This is only one example; in reality, many more waveforms can be analyzed and predicted using this method. Figure 3-41 shows essentially three distinct steps, which are sufficiently close to the response shown in the simulation. A dynamic range of 70 dB, while displayed in Figures 3-40 and 3-41, is not really necessary for good-quality transmission, and the discrepancy between the two pictures is in part due to the limited modeling quality of the active device as provided by the company that did the parameter extraction for this transistor.

Another useful view to aid in the understanding of the compression and distortion within the amplifier is to look at the magnitude of the complex waveform. Since the signal is composed of the in-phase and quadrature-phase components it is represented as

$$s(t) = i(t) + j \cdot q(t) \tag{3-120}$$

The time-domain magnitude is written

$$|s(t)| = \sqrt{i(t)^2 + q(t)^2} \tag{3-121}$$

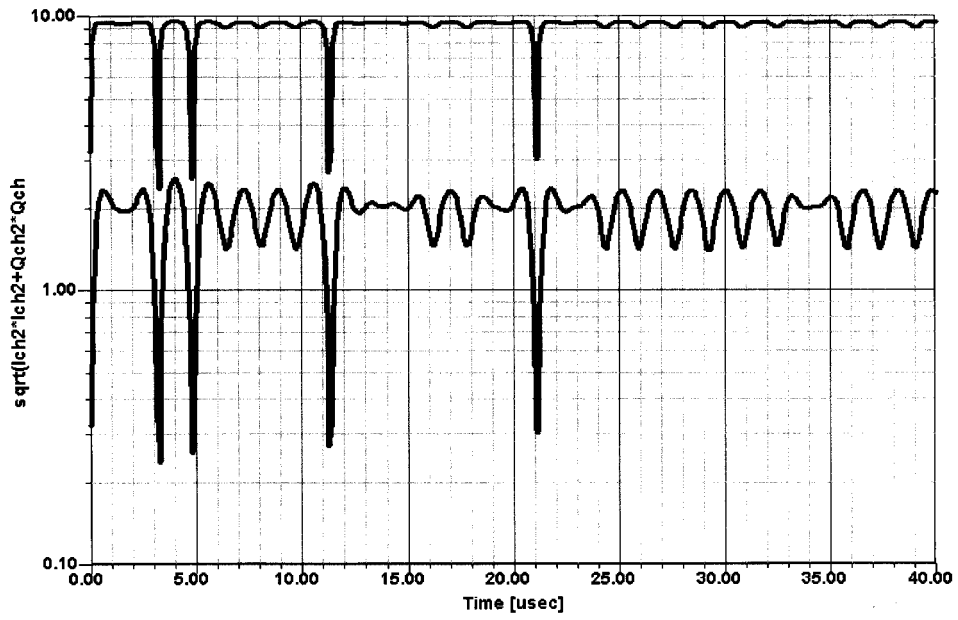

Figure 3-42 Time-domain magnitude of the complex modulation signal at source powers of 0 and 20 dBm.

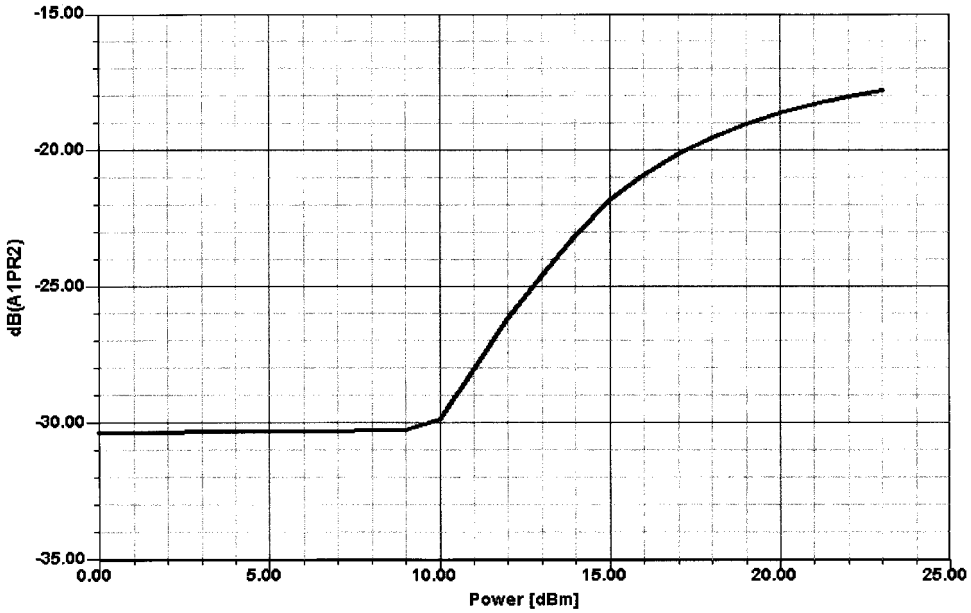

Figure 3-43 Adjacent-channel power ratio as function of RF source power.

Figure 3-42 shows the magnitude at source powers of 0 and 20 dBm. The *X* axis has been rescaled to 40 μs for improved viewing. Note the significant compression of the 20-dBm waveform at the higher signal levels. It is clear from this view that the signal is severely distorted.

We can also compute the adjacent-channel power ratio (ACPR) against the RF power sweep. ACPR is the ratio of the adjacent-channel power to the in-band channel power. The bandwidth (BW) and adjacent-channel start frequency (FS) are used for this calculation. For accurate ACPR calculation, a large number of bits are needed. This example uses 128 bits so the computation time is short, but 512 or more bits should be used for a more accurate computation.

Figure 3-43 shows the ACPR as a function of RF source power. The ACPR is nearly constant (and nonzero due to the gradual skirt of the baseband filter and inherent spillover to the adjacent channel) up to the P_{-1dB} compression point . As the intermodulation products spill into the adjacent channel and spectral regrowth occurs, the ACPR degrades.

π/4-DQPSK Circuit Analysis. Next, we will examine the same amplifier using a π/4-DQPSK modulation source. The task is identical to the previous one except for the source and the number of bits. The number of bits for this project has been increased from 128 to 256. Figure 3-44 shows the eye diagrams from this modulation format, at source powers of 0 and 20 dBm. The distortion and related intersymbol interference are clearly evident.

The constellation plot at 0 dBm is shown in Figure 3-45.

It may be interesting to take a look at the different waveforms currently in use. Figure 3-46 shows a spectrum analyzer picture of the most popular ones.

For reasons of time-division management, the European standard, GSM, which is now offered by Omnipoint at the 1.8-GHz band in the United States, uses gating to reduce the actual bandwidth of the spectrum. Figure 3-47 compares the GSM signal with and without gating.

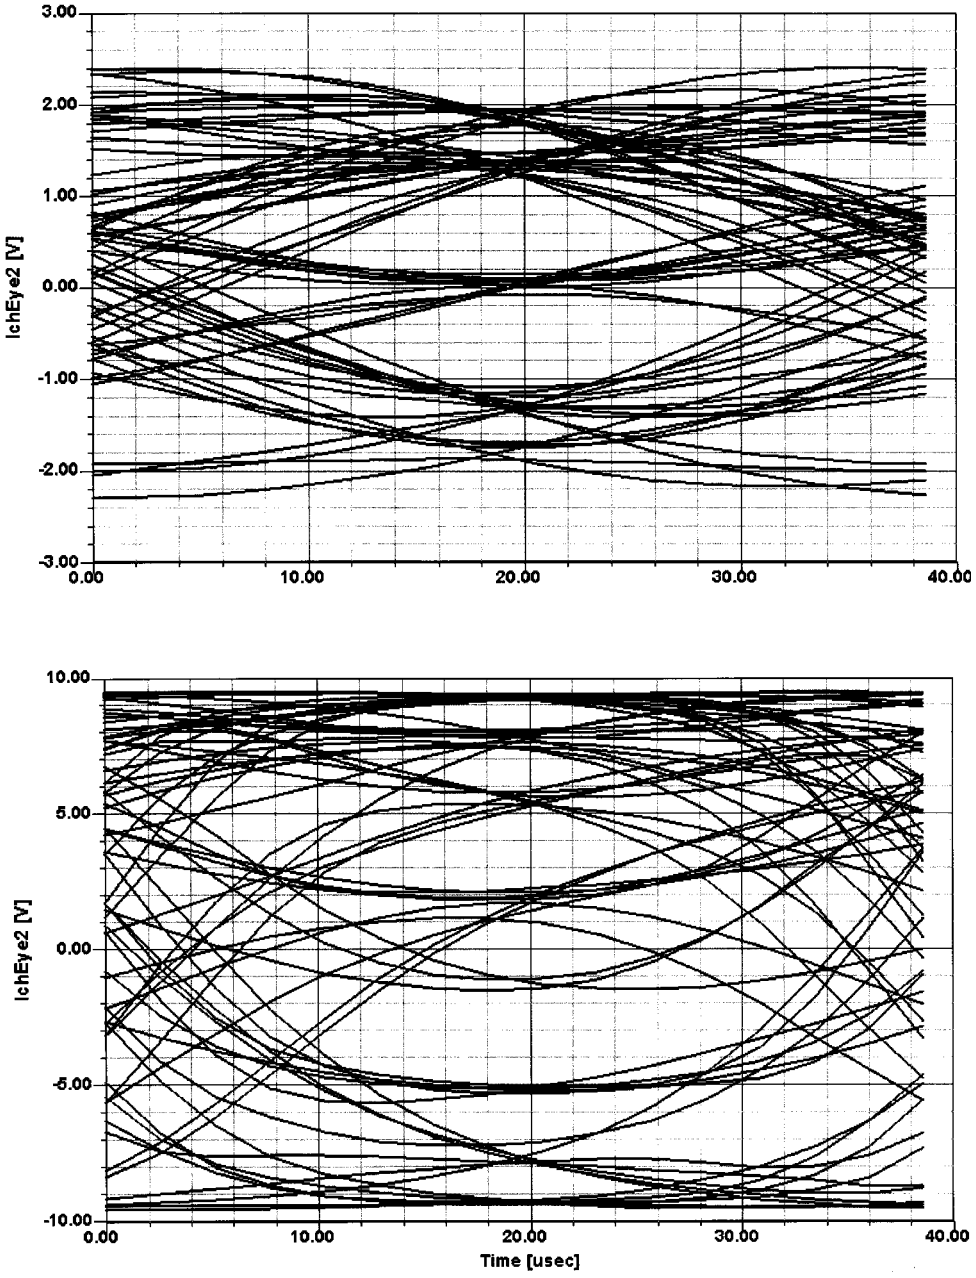

Figure 3-44 Eye diagrams for $\pi/4$-DQPSK at source powers of (a) 0 dBm and (b) 20 dBm. The distortion and related intersymbol interference are clearly visible.

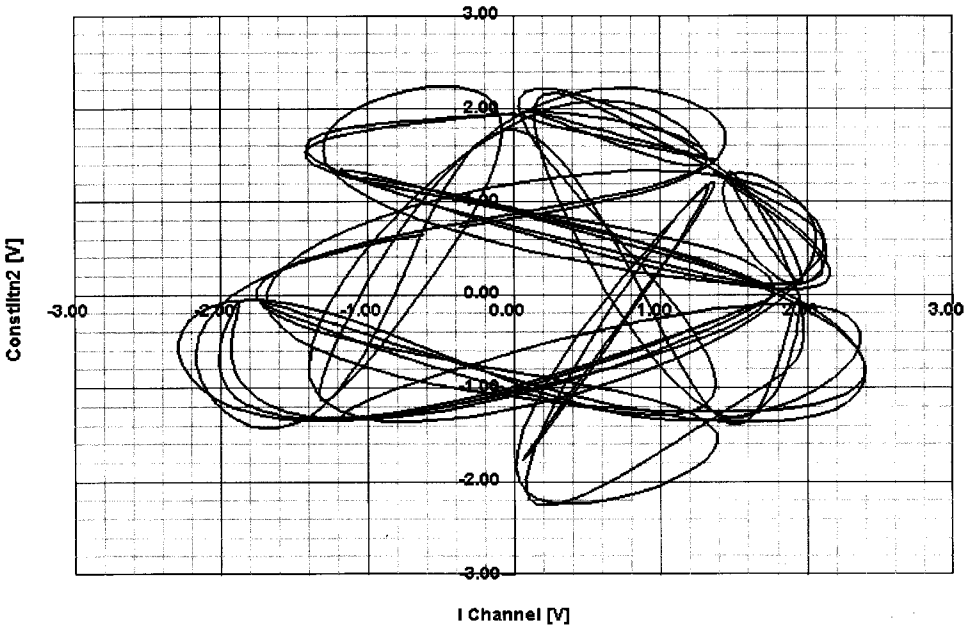

Figure 3-45 Constellation diagram for π/4-DQPSK at Port 2 and 0-dBm source power.

3-1-5 AGC

Many wireless systems consist of an up conversion or down conversion using an intermediate frequency, typically 10% or less of the receiving frequency (the FM broadcast IF has been set at 10.7 MHz for the same reason).

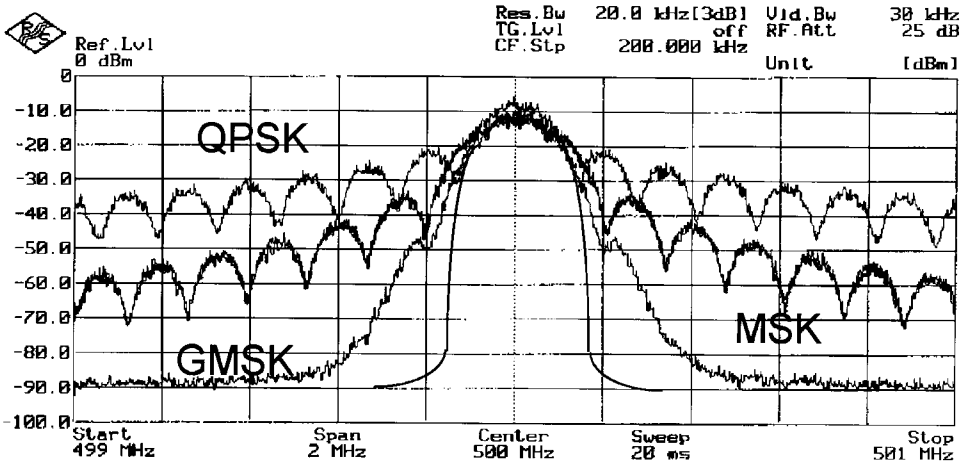

Figure 3-46 Spectrogram showing the characteristics of MSK, GMSK, and QPSK.

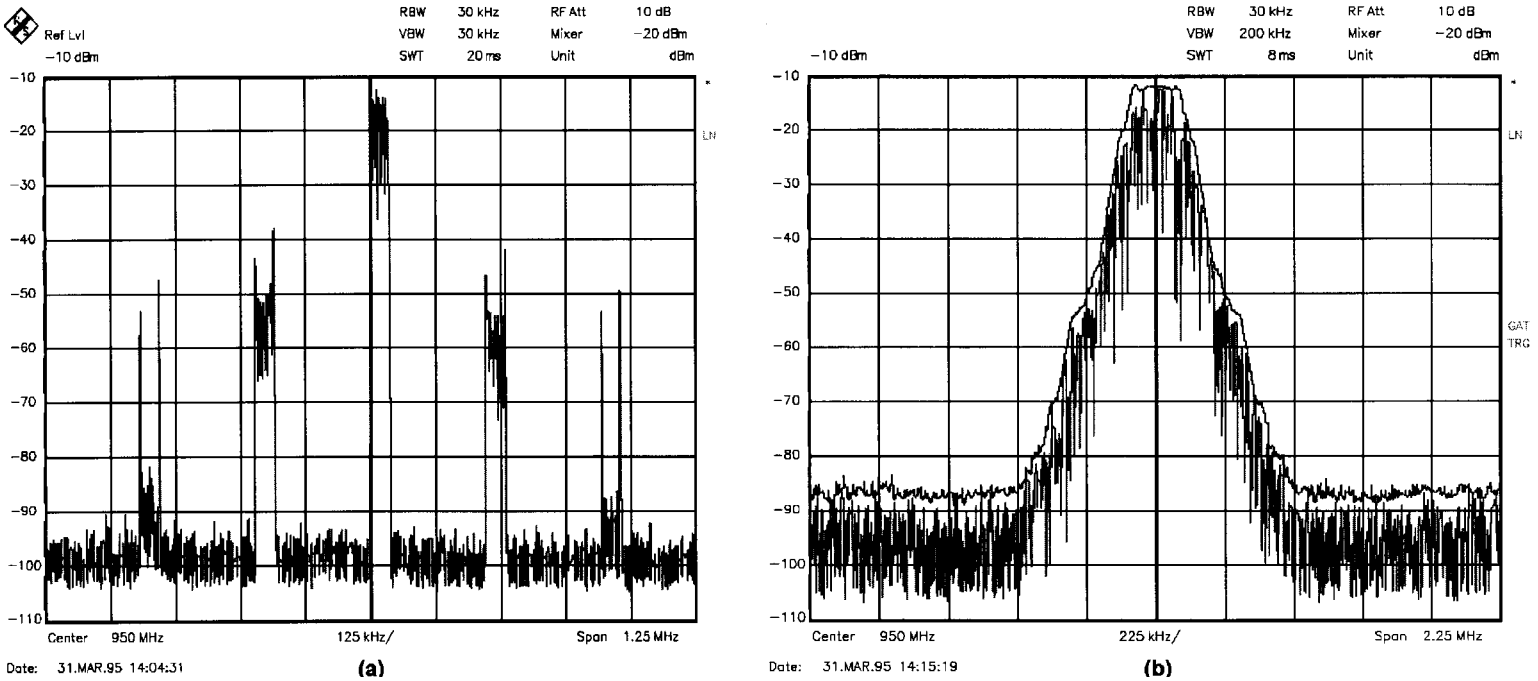

Figure 3-47 Pulsed GSM signal (a) without gating and (b) with gating.

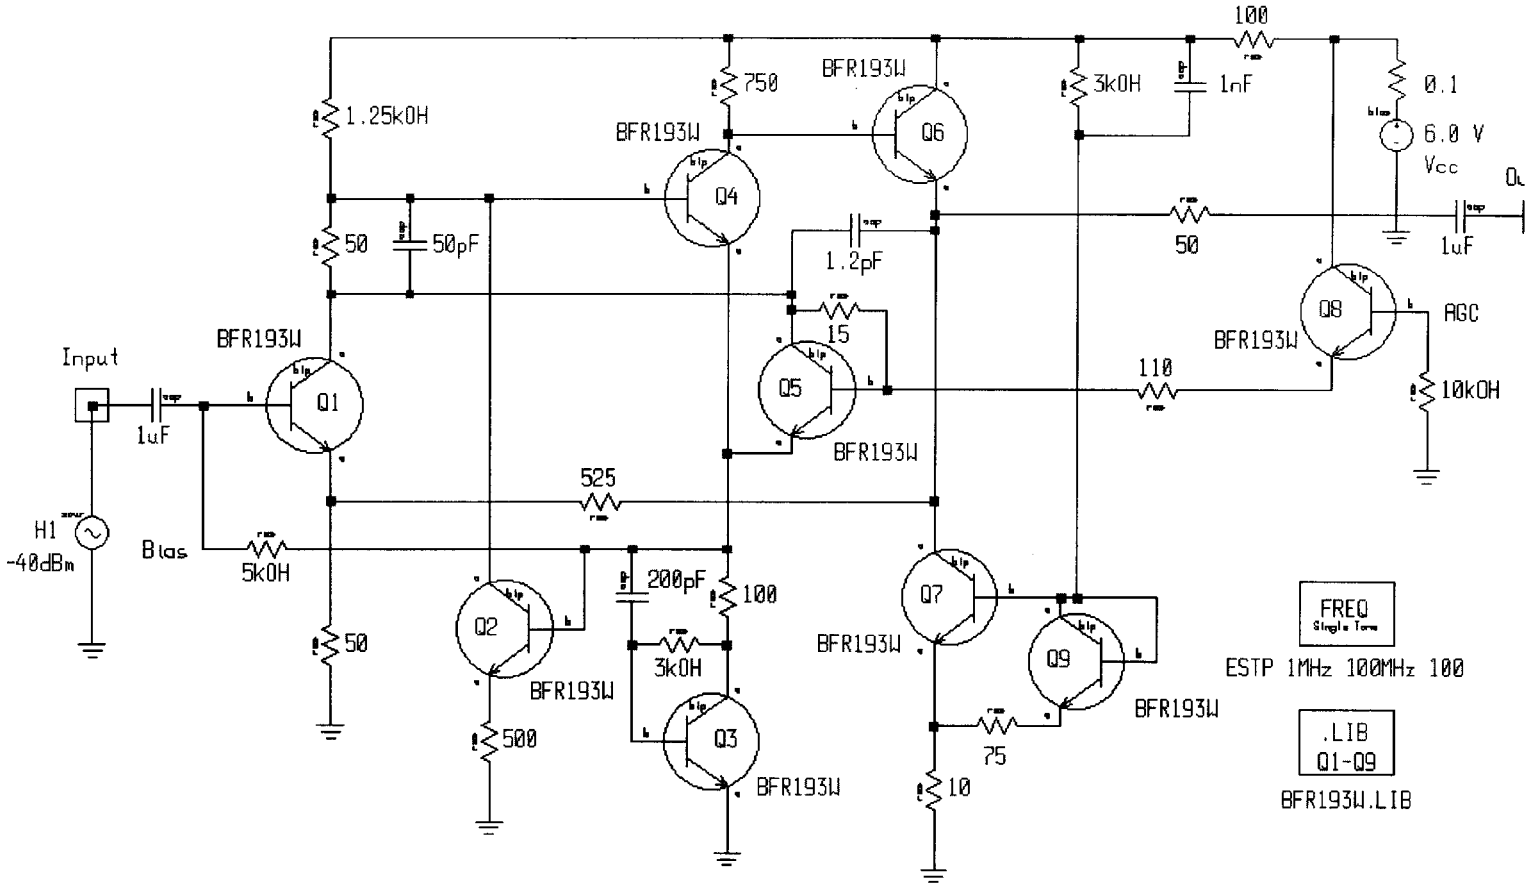

Figure 3-48 Schematic of the Plessey SL610 wideband amplifier with AGC. The 75-Ω resistor in the emitter of Q9 had to be added to obtain the appropriate dc current.

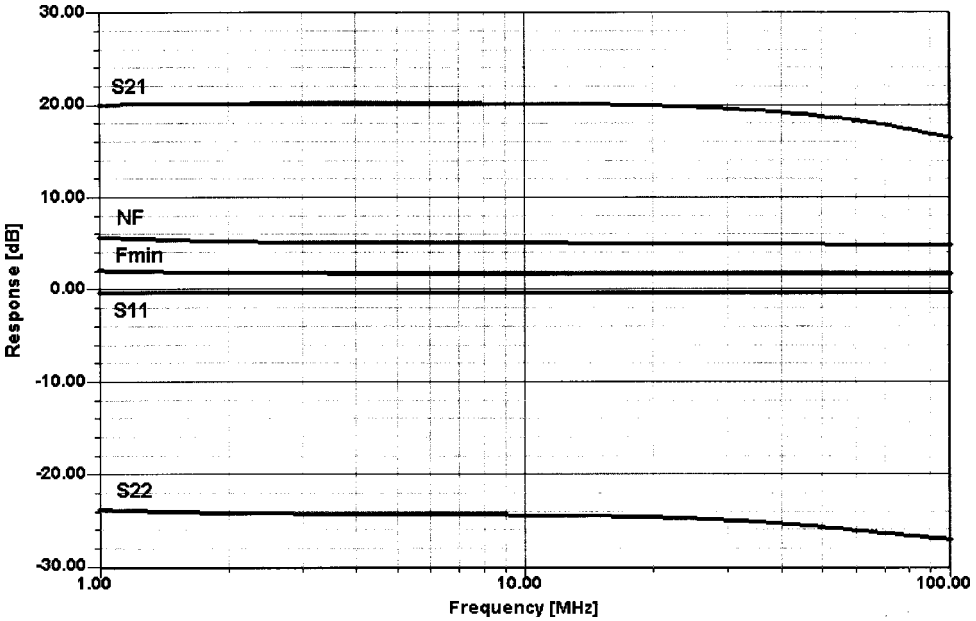

Figure 3-49 Simulated frequency response of the Plessey SL610 wideband amplifier IC with AGC = 0 V.

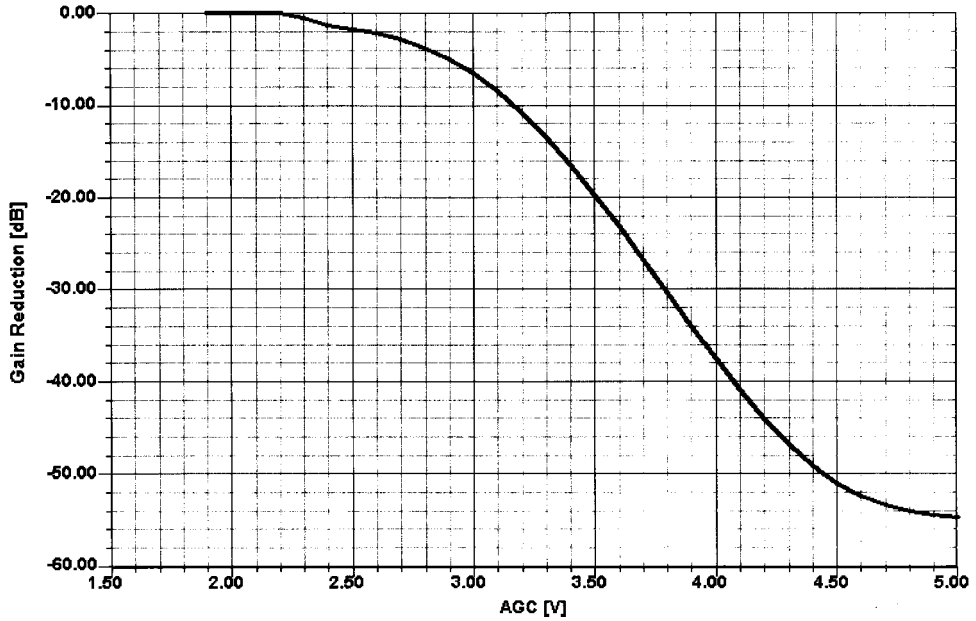

Figure 3-50 Simulated gain reduction versus AGC of the Plessey SL610 wideband amplifier IC.

Table 3-7 CGY121A features

- Variable gain amplifier (MMIC amplifier) for mobile communication
- Typical gain control range over 50 dB
- Positive control voltage
- 50-Ω input and output matched
- Low power consumption
- Operating voltage range: 2.7–6 V
- Frequency range 800 MHz to 2.5 GHz

We therefore will show two amplifiers with AGC and available data. The first one is a wideband amplifier type SL610, which has been manufactured by Plessey; its current fate is unknown. However, since we put the circuit into the simulator it provides significant insight into the operation of such AGC stages. Figure 3-48 shows the actual schematic of the SL610 entered in Ansoft's Serenade Design Environment for simulation.

The AGC action is derived from Q8 through Q5, which, together with Q4, forms a differential amplifier. Each consecutive stage (Q1, Q4, Q6) has increasing current, totaling about 20 mA; the last transistor takes about 13 mA. Based on the feedback surrounding the transistors, the actual transistor characteristics are less important. We have shown this by putting much higher f_T devices into the circuit than were available for the original design (20 years ago). The circuit is still interesting today because of its good large-signal-handling capability.

Table 3-8 CGY121A electrical characteristics at 900 MHz and 1.8 GHz

Characteristics	Symbol	Minimum	Typical	Maximum	Unit
(T_A 25 °C, f = 900 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)

Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm
(T_A 25 °C, f = 1800 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	15.5	17.5	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	10	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	8.5	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm

Figure 3-49 shows the amplifier's frequency response which is extremely close to the measured data. The good simulation also can be seen from comparing the published AGC curve with the one we found in the simulation. The bias of the first transistor remains essentially constant, resulting in a noise figure more independent of the AGC than the PIN-diode attenuator, and also stabilizes the input impedance as a function of AGC. Figure 3-50 shows the SL610's predicted AGC response.

The same requirement is applicable for the wireless frequency range. Tables 3-7 and 3-8 and Figures 3-51 through 3-54 present specifications for the recently introduced CGY121A GaAs MMIC by Infineon Technologies AG, formerly the Semiconductor Group part of Siemens AG.

3-1-6 Bias and Power Voltage and Current (Power Consumption)

Biasing of transistors operating in Class A or B follows some standard rules. The only deviation from this tends to be when the operating voltage is very low, below 3 V, because then the luxury of using voltage drops for good dc stability as a function of temperature disappears. (We will discuss low-voltage design in detail in Section 3-2-6.) In our simple example (Figure 3-55), we are operating from a 12-V power supply, and the first rule of thumb is to make sure that the voltage between the emitter and ground is at least 0.7 V. This is necessary to compensate the base–emitter junction threshold voltage, which decreases by about 2 mV/°C as the temperature increases. A larger voltage drop in the emitter–ground connection greatly reduces the influence. In this amplifier the emitter–ground path consists of an emitter unbypassed resistor of 10 Ω in series with a bypassed 501-Ω resistor, resulting in an overall voltage drop of 2.6. We could reduce the supply voltage by about 1.9 V at the collector side and still maintain a safety margin of 0.7 V at the emitter–ground connection. The current 2.6 V, so to speak, is overkill.

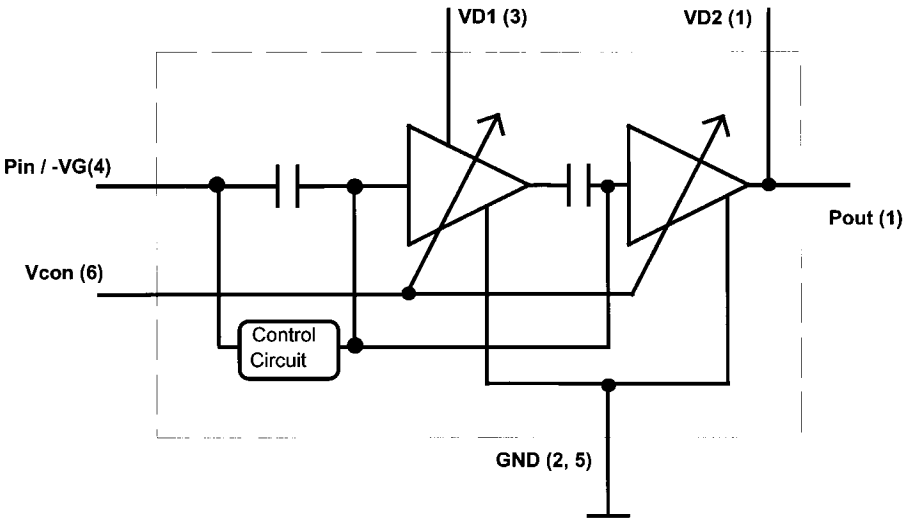

Figure 3-51 Functional block diagram of the gain-controllable CGY121A GaAs MMIC. Gain control is achieved by applying 0–3 V dc to the Vcon pin.

R3	6.8 Ω

Figure 3-52 CGY121A 900-MHz application circuit and parts list.

On the collector side, for an *RC* type of amplifier, it is not a bad idea to set the collector voltage at about half the supply, which allows the RF swing to be half the supply voltage. In this case, we have violated the rule because of our 2.6-V drop. Assuming we had chosen a 0.7-V drop, then the collector–emitter voltage would be 6.3 V available for the swing. The choice of 5 mA for the transistor has come from a combination of good linearity and low noise figure. While the 10-Ω unbypassed resistor will grade the noise figure somewhat, it reduces the emitter-current-dependent distortion. The base–emitter diffusion resistance equals 26 mV/5 mA, or roughly 5 Ω. The 10-Ω resistor is twofold larger and therefore adds to the linearity and to the noise.

To determine the base bias resistor it is a good assumption that the current going through the two resistors (in our case, 8.2 and 3.3 kΩ) is about 10% (or a slightly higher fraction) of

Figure 3-53 CGY121A 1.9-GHz application circuit and parts list.

the collector current. Since the dc current gain of the transistor is typically between 50 and 100, it is sufficient if the current through the resistive network is between 5 and 10 times higher than the dc bias current taken off the network. This type of bias scheme is only valid for Class A to AB_1. Later, we will see that for monolithic circuits, additional transistors will be used to generate the required voltage drops. Lately, combinations of *npn* and *pnp* transistors have become popular to avoid using any resistance in the emitter for dc biasing purposes. Figure 3-56 shows such a circuit. This, of course, invites thermal runaway. To minimize the circuitry, there are bias ICs, such as the Siemens BCR400R, now available. Figures 3-57 and 3-58 show its application in biasing BJTs and FETs, respectively; it can also be used to control PIN-diode bias current for TR antenna switching, as shown in Figure 3-59.

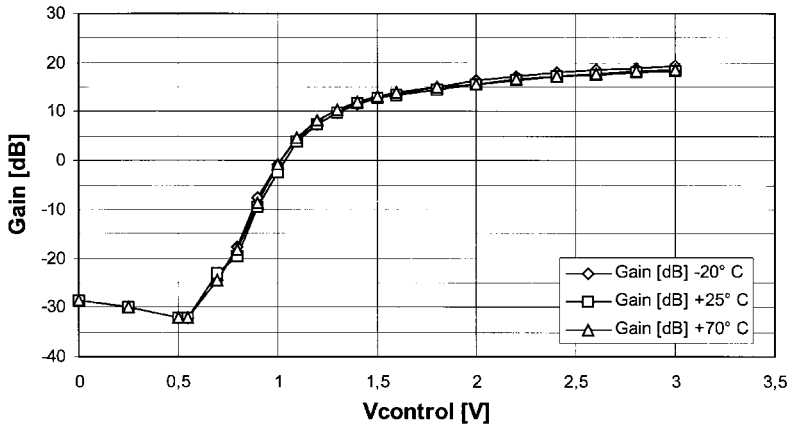

Figure 3-54 CGY121A gain versus $V_{control}$ at 1.9 GHz.

To validate this, we have used the Serenade 8.0 CAD tool, which has a built-in bias- and temperature-dependent noise model for BJTs and FETs. The SPICE-type dc analysis determines the actual currents, which were mentioned above. By maintaining the same bias and just bypassing both emitter resistors at the same time, the set of curves shown in Figure 3-60 will be obtained. As an exercise, we recommend the user to determine the optimum generator impedance for F_{min} with a 10-Ω resistor. Again, both the emitter current and collector voltage affect the noise figure, the intermodulation, and f_T. If a transistor is used

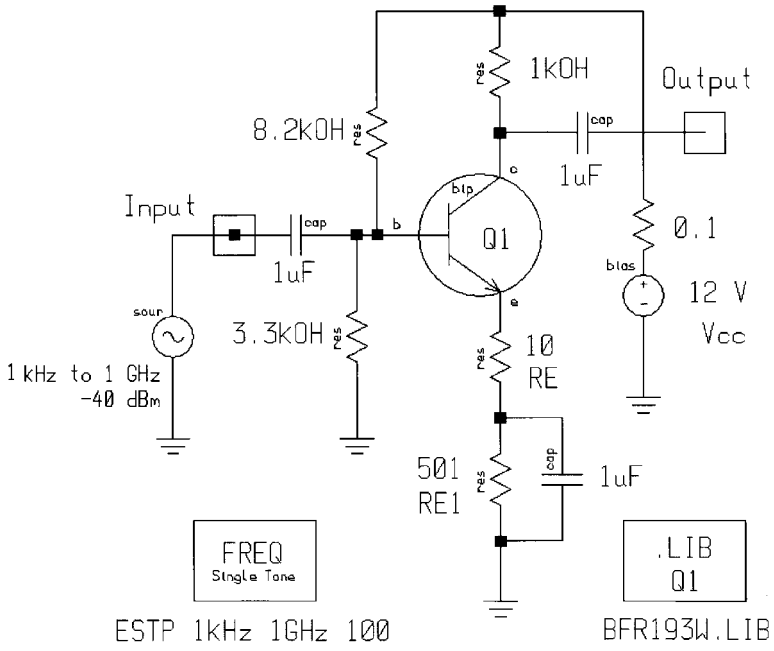

Figure 3-55 BJT amplifier example.

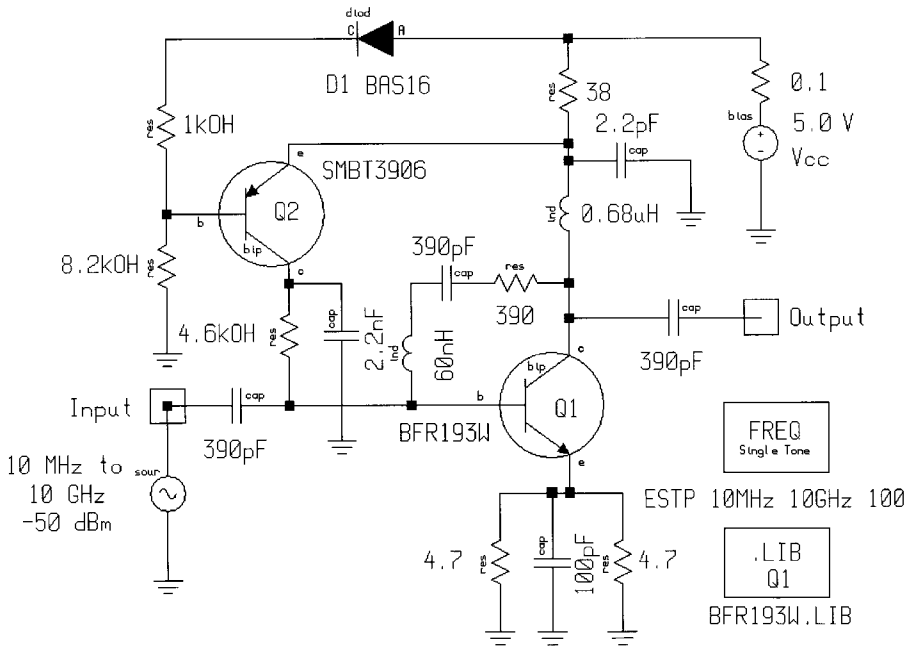

Figure 3-56 Wideband amplifier with active biasing. The 4.7-Ω resistors in the BFR193W emitter compensate the circuit's gain at low frequencies.

that is intended to be operated at significantly higher currents, then f_T will suffer while the other two parameters are less affected.

The dc input power translates into thermal dissipation, and Figure 3-60 is a plot of the noise figure as a function of temperature with and without emitter feedback. The heavy dc stabilization prevents a significant effect on the other parameters. The actual dc shift is from 5.0 to 5.2 mA for a temperature change of 70 K.

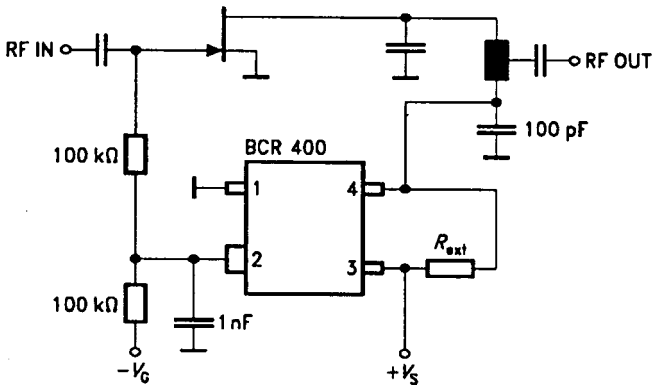

Figure 3-57 The Siemens BCR400 bias controller applied to a GaAsFET.

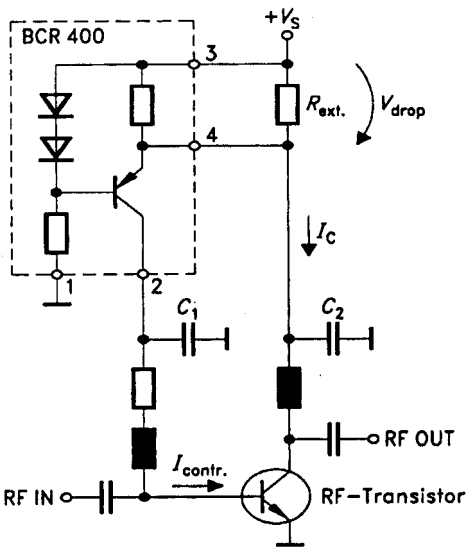

Figure 3-58 The Siemens BCR400 bias controller applied to a BJT.

As far as FETs are concerned, the enhancement types, typically PMOS, can use a similar type of bias, while the NMOS types complicate the designer's life as they require a negative gate voltage. For low-noise operation, these devices are operated somewhat close to the pinchoff voltage. Putting a source resistor in place causes mostly headaches simply because the gain is so high that the transistors are always ready to find a frequency at which they love to oscillate. The transistor will look for every possible parasitic to turn the amplifier into an oscillator.

3-2 AMPLIFIER GAIN, STABILITY, AND MATCHING

Most semiconductor manufacturers describe their devices these days by providing either their *S* parameters (small-signal) or SPICE-type parameters (large-signal). One of our headaches in writing this book has been that many of the published models don't translate

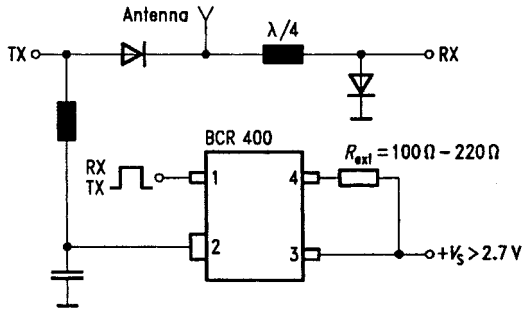

Figure 3-59 The Siemens BCR400 bias controller applied to TR switching.

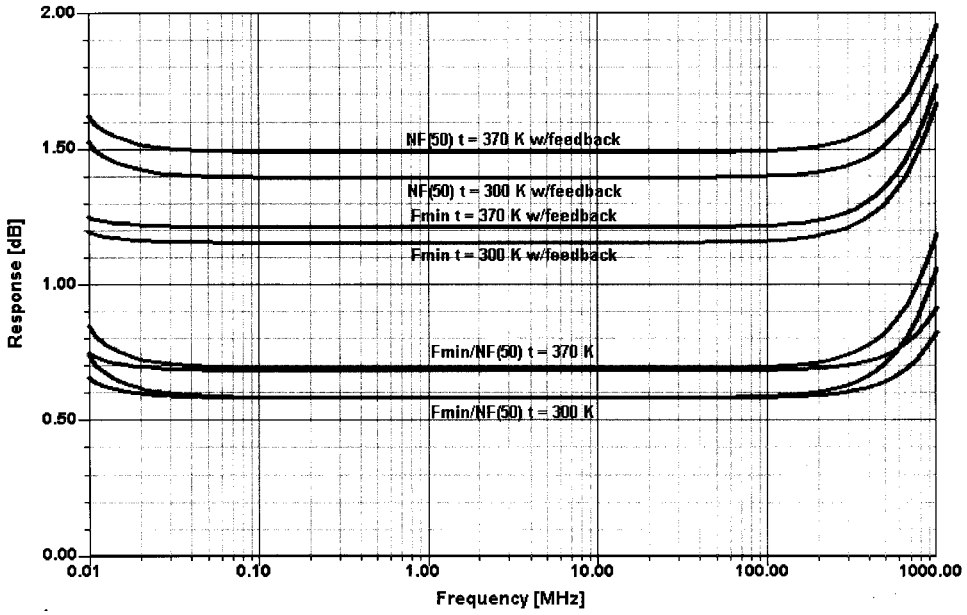

Figure 3-60 F_{min} and NF for the amplifier in Figure 3-55, with and without emitter feedback, at 300 and 370 K.

from large signal to small signal without giving unexpected or false results. Despite the availability of tools to do it right, many companies still can only provide data that are practically inadequate, and unfortunately the CAD manufacturers then get the blame for results for which they are not really responsible.

Tables 3-9 and 3-10 show typical data for a bipolar transistor (the BFP420 by Siemens). The next section presents a summary of the derivation and use of *S* parameters as published by Hewlett-Packard and others.

3-2-1 Scattering Parameter Relationships

Scattering (*S*) parameters characterize a network in terms of incident and reflected waves (Figures 3-61 and 3-62).

$$b_1 = s_{11}a_1 + s_{12}a_2 \tag{3-122}$$

$$b_2 = s_{21}a_1 + s_{22}a_2 \tag{3-123}$$

Notice that

$$s_{11} = \frac{b_1}{a_1} = \frac{V_1/I_1 - Z_0}{V_1/I_1 + Z_0} = \frac{Z_1 - Z_0}{Z_1 + Z_0} \tag{3-124}$$

and

Table 3-9 BFP420 common-emitter *S* parameters[a]

[a]Input matched for minimum noise figure, output for maximum gain.
[b]$Z_S = Z_L = 50\ \Omega$.

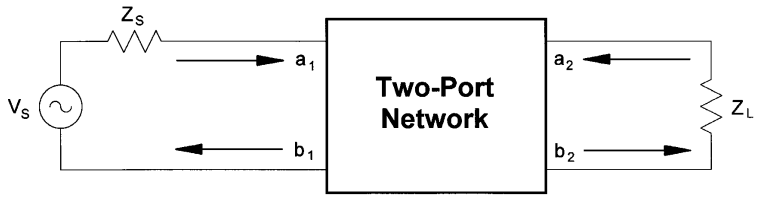

Figure 3-61 *S* parameters characterize a network (a two-port is shown) in terms of incident waves (a_1, a_2) and reflected waves (b_1, b_2). Figure 3-62 shows the flow graph for this network.

$$Z_1 = Z_0 \frac{(1 + s_{11})}{(1 - s_{11})} \tag{3-125}$$

where $Z_1 = V_1/I_1$ is the input impedance at Port 1.

This relationship between reflection coefficient and impedance is the basis of the Smith Chart transmission-line calculator. Consequently, the reflection coefficients S_{11} and S_{22} can be plotted on Smith charts, converted directly to impedance, and easily manipulated to determine matching networks for optimizing a circuit design.

The above equations show one of the important advantages of *S* parameters: They are simply gains and reflection coefficients, both familiar quantities to engineers. By comparison, some of the *Y* parameters described earlier in the article are not so familiar. For example, the *Y* parameter corresponding to insertion gain S_{21} is the "forward transadmittance," Y_{21}. Clearly, insertion gain gives by far the greater insight into the operation of the network.

S parameters are simply related to power gain and mismatch loss, quantities that are often of more interest than the corresponding voltage functions:

$$|s_{11}|^2 = \frac{\text{Power reflected from the network input}}{\text{Power incident on the network input}} \tag{3-126}$$

$$|s_{21}|^2 = \frac{\text{Power delivered to a } Z_0 \text{ load}}{\text{Power available from } Z_0 \text{ source}} \tag{3-127}$$

$$|s_{12}|^2 = \text{Reverse transducer power gain with } Z_0 \text{ load and source.} \tag{3-128}$$

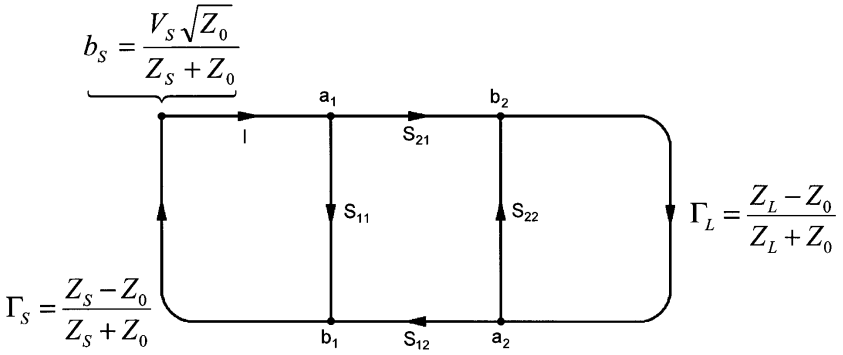

Figure 3-62 Flow graph for the network shown in Figure 3-61.

$$|s_{22}|^2 = \frac{\text{Power reflected from the network output}}{\text{Power incident on the network output}} \tag{3-129}$$

From this we obtain:
Input reflection coefficient with arbitrary Z_L:

$$s'_{11} = s_{11} + \frac{s_{12}s_{21}\Gamma_L}{1 - s_{22}\Gamma_L} \tag{3-130}$$

Output reflection coefficient with arbitrary Z_S:

$$s'_{22} = s_{22} + \frac{s_{12}s_{21}\Gamma_S}{1 - s_{11}\Gamma_S} \tag{3-131}$$

Voltage gain with arbitrary Z_L and Z_S:

$$A_V = \frac{V_2}{V_1} = \frac{s_{21}(1 + \Gamma_L)}{(1 - s_{22}\Gamma_L)(1 + s'_{11})} \tag{3-132}$$

$$\text{Power gain} = \frac{\text{Power delivered to load}}{\text{Power input to network}}:$$

$$G = \frac{|s_{21}|^2 (1 - |\Gamma_L|^2)}{(1 - |s_{11}|^2) + |\Gamma_L|^2 (|s_{22}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_L N)} \tag{3-133}$$

$$\text{Available power gain} = \frac{\text{Power available from network}}{\text{Power available from source}}:$$

$$G_A = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)}{(1 - |s_{22}|^2) + |\Gamma_S|^2 (|s_{11}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_S M)} \tag{3-134}$$

$$\text{Transducer power gain} = \frac{\text{Power delivered to load}}{\text{Power available from source}}:$$

$$G_T = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|(1 - s_{11}\Gamma_S)(1 - s_{22}\Gamma_L) - s_{12}s_{21}\Gamma_L\Gamma_S|^2} \tag{3-135}$$

Unilateral transducer power gain ($S_{12} = 0$):

$$G_{Tu} = \frac{|s_{21}|^2(1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|1 - s_{11}\Gamma_S|^2|1 - s_{22}\Gamma_L|^2}$$

$$= G_0 G_1 G_2 \tag{3-136}$$

$$G_0 = |s_{21}|^2 \tag{3-137}$$

$$G_1 = \frac{1 - |\Gamma_S|^2}{|1 - s_{11}\Gamma_S|^2} \tag{3-138}$$

$$G_2 = \frac{1 - |\Gamma_L|^2}{|1 - s_{22}\Gamma_L|^2} \tag{3-139}$$

Maximum unilateral transducer power gain when $|S_{11}| < 1$ and $|S_{22}| < 1$:

$$G_u = \frac{|s_{21}|^2}{|(1 - |s_{11}|^2)(1 - |s_{22}|)^2|}$$

$$= G_0\, G_{1\max}\, G_{2\max} \tag{3-140}$$

$$G_{i\max} = \frac{1}{1 - |s_{ii}|^2} \quad i = 1, 2 \tag{3-141}$$

Constant-gain circles (unilateral case: $S_{12} = 0$):

- Center of constant-gain circle is on line between center of Smith Chart and point representing S_{ii}^*
- Distance of center of circle from center of Smith Chart:

$$r_i = \frac{g_i |s_{ii}|}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-142}$$

- Radius of circle:

$$\rho_i = \frac{\sqrt{1 - g_i}(1 - |s_{ii}|^2)}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-143}$$

where $i = 1, 2$ and

$$g_i = \frac{G_i}{G_{i\max}} = G_i(1 - |s_{ii}|^2) \tag{3-144}$$

Unilateral figure of merit:

$$u = \frac{|s_{11}s_{22}s_{12}s_{21}|}{|(1 - |s_{11}|^2)(1 - |s_{22}|^2)|} \tag{3-145}$$

Error limits of unilateral gain calculation:

$$\frac{1}{(1 + u^2)} < \frac{G_T}{G_{Tu}} < \frac{1}{(1 - u^2)} \tag{3-146}$$

Conditions for absolute stability. No passive source or load will cause a network to oscillate if a, b, and c are all satisfied:

$$\text{a.}\quad |s_{11}| < 1, |s_{22}| < 1 \tag{3-147}$$

$$\text{b.} \quad \left| \frac{|s_{12}s_{21}| - |M^*|}{|s_{11}|^2 - |D|^2} \right| > 1 \tag{3-148}$$

$$\text{c.} \quad \left| \frac{|s_{12}s_{21}| - |N^*|}{|s_{22}|^2 - |D|^2} \right| > 1 \tag{3-149}$$

where

$$D = s_{11}s_{22} - s_{12}s_{21} \tag{3-150}$$

$$M = s_{11} - Ds_{22}^* \tag{3-151}$$

$$N = s_{22} - Ds_{11}^* \tag{3-152}$$

Condition that a two-port network can be simultaneously matched with a positive real source and load:

$$K > 1 \tag{3-153}$$

$$K = \frac{1 + |D|^2 - |s_{11}|^2 - |s_{22}|^2}{2|s_{12}s_{21}|} \tag{3-154}$$

Source and load for simultaneous match

$$\Gamma_{mS} = M^* \left[\frac{B_1 \pm \sqrt{B_1^2 - 4|M|^2}}{2|M|^2} \right] \tag{3-155}$$

$$\Gamma_{mL} = N^* \left[\frac{B_2 \pm \sqrt{B_2^2 - 4|N|^2}}{2|N|^2} \right] \tag{3-156}$$

where

$$B_1 = 1 + |s_{11}|^2 - |s_{22}|^2 - |D|^2 \tag{3-157}$$

$$B_2 = 1 + |s_{22}|^2 - |s_{11}|^2 - |D|^2 \tag{3-158}$$

Maximum available power gain. If $K > 1$,

$$G_{A\max} = \left| \frac{s_{21}}{s_{12}} (K \pm \sqrt{K^2 - 1}) \right| \tag{3-159}$$

In conclusion, *a two-port network (active or passive) is unconditionally stable* when

$$K > 1$$

$$|S_{12}S_{21}| < 1 - |S_{11}|^2$$

and

$$|S_{12}S_{21}| < 1 - |S_{22}|^2$$

3-2-2 Low-Noise Amplifiers

A low-noise amplifier combines a low noise figure, reasonable gain, and stability without oscillation over its entire useful frequency range. These amplifiers are typically operated in Class A, which is characterized by a bias point more or less at the center of maximum current and voltage capability of the device used, and by RF current and voltages that are sufficiently small relative to the bias point that the bias point does not shift. This means that an amplifier operating at, say, 3 V and 1 mA for low-noise, high-gain operation will not be Class A if the RF current is larger than 0.1% of the current or the voltage swing is more than 0.1% of the current swing. These amplifiers can be designed using standard linear *S* parameters, which are (hopefully) available from the device manufacturer for the bias point of interest. If suitable *S* parameters are not available, we must resort to a CAD tool that allows us to determine a device's bias point as a function of its bias network and to generate small-signal *S* parameters for the device. With suitable *S* parameters in hand, and assuming the amplifier will be frequency selective, we then connect tuned circuits to the input and output to provide matching.

In designing amplifiers, the "power gain" of a circuit is mentioned frequently. This is actually deceptive because power gain is somewhat associated with dc power dissipation, and in considering it, we are on the verge of discussing large-signal performance. Therefore it would be better to define the power gain as a function of operating mode, such as "Class A power gain." We have also outlined that there is a difference between noise matching and gain matching. If we can be allowed to step back into the vacuum-tube era for a moment, the reader should be reminded that the difference between power gain and noise matching had to do with the grid-plate feedback capacitance which, via the Miller effect, showed up in parallel with the input. This actually detunes the input slightly off-center relative to the best gain. The reason for this is that as the feedback increases, Y_{12} or S_{12} starts playing a role, and the frequently assumed unilateral case no longer exists. The difference between noise matching and gain matching increases as a function of frequency. It can be brought closer together if appropriate reactive feedback is used. The two choices are: (1) increase the emitter or source inductance or (2) slightly increase the base-to-collector/gate-to-drain capacitance. Needless to say, the penalty for this is potential instability, and a sweep must be done from a few megahertz to several gigahertz to make sure the stage doesn't "take off."

The most efficiency this circuit provides is 50%; even this is a theoretical limit if one tries to keep distortion under control.

While the equation $P_{\text{OUT}} = (V_{\text{bat}} - V_{\text{sat}})^2/2R_L$ is valid, it really applies only to power amplifiers in the sense that for Class A, high-gain operation R_L can be made significantly higher as the absolute power output is not the important item. While the supply voltage V_{bat} is always known, the saturation voltage V_{sat} has to be obtained by the load line dc analysis. Note: The RF saturation voltage is always higher than the dc one. When looking at Figure 3-63, it becomes obvious that the conducting angle is 180°, which implies that the entire sine wave at the input is reproduced as an essentially undistorted sine wave at the output.

We can now calculate the components of the distorted current in separating them into the dc component, the fundamental frequency, and its first and second harmonics:

$$\text{Fundamental} \quad i_{c1} = i_{\text{peak}} \cdot f_1(\Theta) \tag{3-160}$$

$$\text{Second harmonic} \quad i_{c2} = i_{\text{peak}} \cdot f_2(\Theta) \tag{3-161}$$

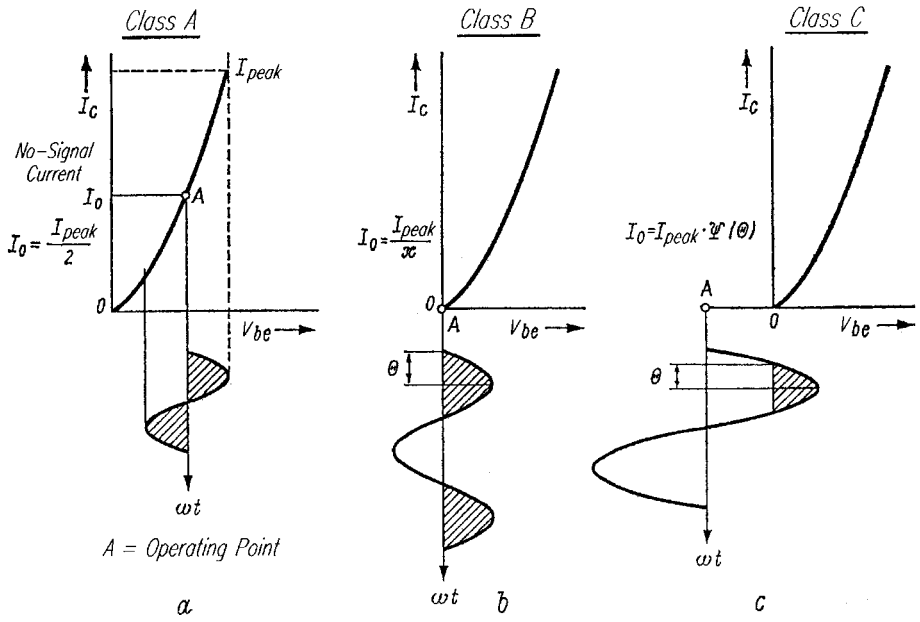

Figure 3-63 Definitions of Class A, B, and C operation, including conduction angle (Θ). Figure 3-64 shows the determination of Θ.

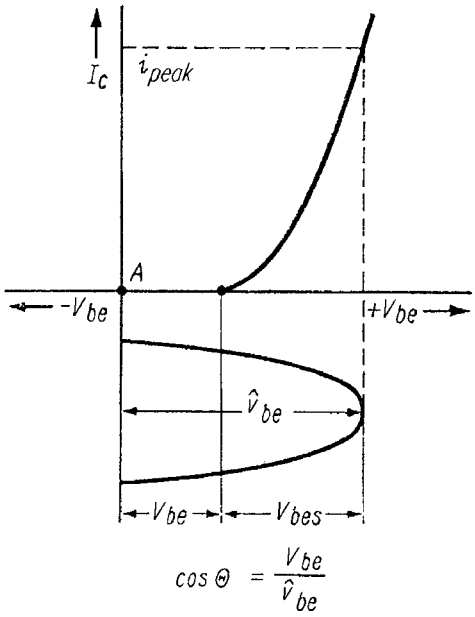

Figure 3-64 Determination of the conduction angle Θ from the base threshold voltage V_{be} and the base RF voltage $\hat{v}_{be}$.

$$\text{Third harmonic} \quad i_{c3} = i_{\text{peak}} \cdot f_3(\Theta) \tag{3-162}$$

For the collector dc current we obtain

$$I_c = i_{\text{peak}} \cdot \Psi(\Theta) \tag{3-163}$$

The frequency-dependent currents are a function of the conduction angle Θ. Figure 3-65 shows these transfer characteristics as a function of the conduction angle for a square-law dynamic transfer function; for higher-order transfer functions, the values don't change much. Tables for this can be found in various sources, including Clark and Hess [47]. Since the transistors exhibit a mixture of an exponential and a linear transfer characteristic (due to the unwanted parasitic emitter/source and collector/drain resistances when building the device), the plot in figure 3-65 is sufficiently valid for practical purposes. This function plot allows us to determine the amplitude of the current at various frequencies once the conducting angle has been set. For example, for Θ = 70°, the maximum collector current is $i_{\text{peak}} = I_c/0.253$, meaning that the peak current of the transistor is approximately four times larger than the dc value one would measure. Once the peak collector current is known, the fundamental and harmonic currents can be calculated:

$$i_{c1} = \frac{I_c}{0.253} f_1(\Theta)$$

$$i_{c1} = \frac{I_c}{0.253} 0.436$$

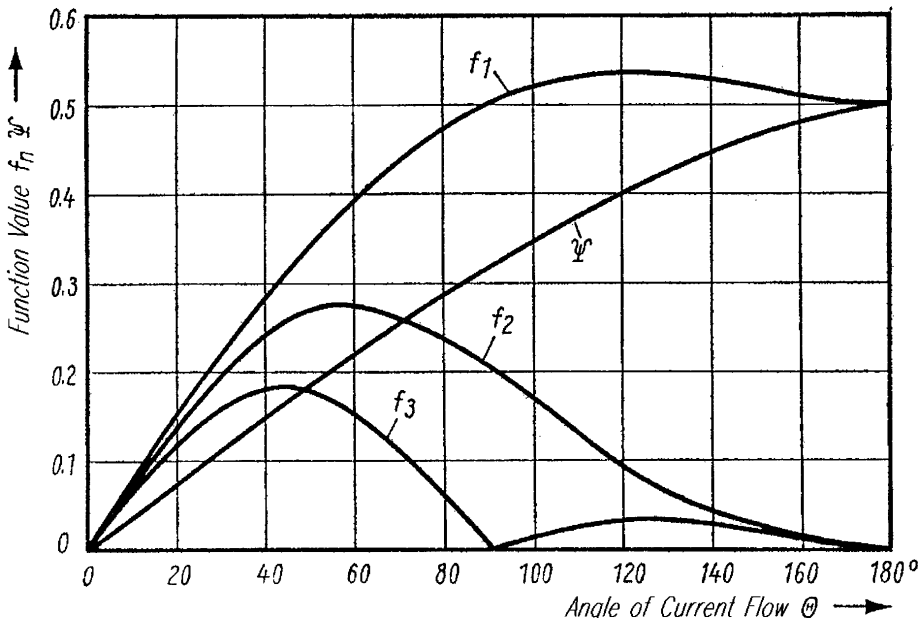

Figure 3-65 Function values for the fundamental, second harmonic, third harmonic, and dc components (f_1, f_2, f_3, and Ψ, respectively) versus device conduction angle.

In order to obtain i_{c2} and i_{c3} one needs to do the same calculations as above with the appropriate functions for f_2 and f_3.

It becomes obvious that the distorted collector current generates a lot of harmonics, which definitely requires sufficient low-pass filtering at the output, even for Class A operation. We already stated that for Class A operation the conduction angle is 180° while it is 90° for Class B operation. The conduction angle for Class C operation can be solved from the ratio of the knee voltage V_{be} and the peak value of the ac voltage at the base. We find

$$\cos \Theta = \frac{V_{be}}{\hat{V}_{be}} \tag{3-164}$$

where $\Theta = 90°$ and $V_{be} = 0$. Given the voltage V_{bes}, which determines the peak collector current (up to i_c peak), we can calculate the effective RF voltage at the base as

$$\hat{v}_{be} = \frac{v_{bes}}{1 - \cos \Theta} \tag{3-165}$$

Therefore, the peak value of v_b becomes v_{bes} for $\Theta = 90°$.

The necessary base voltage V_{be} for maximum current is obtained by the transistor model. Then one finds the threshold voltage at which the transistor becomes conductive and by using Eqs. (3-164) and (3-165) it can be checked whether this results in the appropriate conducting angle. An example for this will be shown in the high-power stage section.

Design Guidelines. The design of a one-stage amplifier consists of finding

- An input lossless matching network M_1
- An input lossless matching network M_2

so that the maximum or desired transistor gain is achieved over the operating bandwidth of the amplifier. Usually, the common-emitter or common-source configuration is chosen for highest gain per stage. If the stability factor K is greater than unity, these two networks can be found to give the maximum available gain $G_{\max}$. If the stability factor is less than or equal to unity, the amplifier could be terminated in a matching structure that causes oscillation; that is, $G_{\max}$ is infinite. This should be avoided by locating the regions of instability in the Γ_G and Γ_L planes. The input and output terminations (Γ_G and Γ_L) must be designed to avoid the instability regions. Usually, these unstable regions are near the conjugate match for S_{11} and S_{22}. Thus, a stable amplifier will require some input and/or output mismatch if K is less than or equal to unity.

There are at least two alternative approaches for potentially unstable amplifiers:

1. Add resistive matching elements to make $K \geq 1$ and $G_{\max} \approx G_{ms}$.
2. Add feedback to make $K \geq 1$ and $G_{\max \approx Gms}$.

For narrowband amplifiers, it is usually recommended that one accept a transistor with $K < 1$, design the amplifier for a gain approaching G_{ms}, and ensure that the Γ_G and Γ_L terminations provide stability at all frequencies, both inside and outside the amplifier passband.

The design of an amplifier would usually have the following specifications:

Gain and gain flatness
Bandwidth and center frequency ($f_2 - f_1, f_0$)
Noise figure
Linear output power
Input reflection coefficient ($VSWR_{in}$)
Output reflection coefficient ($VSWR_{out}$)
Bias voltage and current

For small-signal amplifiers, the small-signal S parameters are sufficient to complete the design. After selecting an appropriate transistor based on these specifications, a one-stage amplifier design should be considered if sufficient gain can be achieved; otherwise, a two-stage amplifier should be designed.

The circuit topology should be chosen to allow dc bias for the transistor. Usually, RF short-circuited stubs are placed near the transistor to allow dc biasing. If the topology does not allow dc bias, a broadband bias choke or high-resistance bias circuit that does not affect the amplifier performance must be used.

The following steps can be tabulated for the design of a one-stage amplifier (see Figure 3.66):

1. Select a transistor based on a datasheet description of the S parameters, noise figure, and linear output power.
2. Calculate K and G_{max} or G_{ms} versus frequency.
3. For $K > 1$, select the topologies that match the input and output (and allow dc biasing) at the upper band edge f_2. Ideally, this will give G_{max} and $S'_{11} = S'_{22} = 0$. Usually, $S_{12} = 0$ is assumed for the initial design. Next, the topology may be varied to flatten gain versus frequency at the expense of S'_{11} and S'_{22}.
4. For $K < 1$, plot the regions of instability on the Γ_G and Γ_L planes and select topologies that partially match the input and output at the upper band edge and avoid the unstable regions. The gain will approach G_{ms} as an upper limit. Next, the topology may be varied to flatten gain versus frequency.
5. After finding initial M_1 and M_2, plot the amplifier S parameters versus frequency; make adjustments in topology until the specifications for gain, input reflection coefficient, and output reflection are satisfied. Also plot Γ_G and Γ_L versus frequency to verify amplifier stability.
6. Design the dc bias circuit. Lay out the elements of the complete amplifier and check realizability.

As a beginning point in an amplifier design, the circuit topologies may be designed with the assumption that S_{12} is zero. Later, an exact design procedure will be described that includes the topologies with terminations in the stable region.

Design Examples. Throughout this book we always address the issue that we have to separate the battery-operated handheld applications and the more stationary designs like those for base stations. In the case of the handheld or low-voltage applications, the dynamic range requirements are significantly less than the front-end of a base station requires.

NE68133 Matched Amplifier. We will first consider the design of a low-voltage, low-current, low-noise amplifier based on the NEC BJT NE68133. This device was chosen

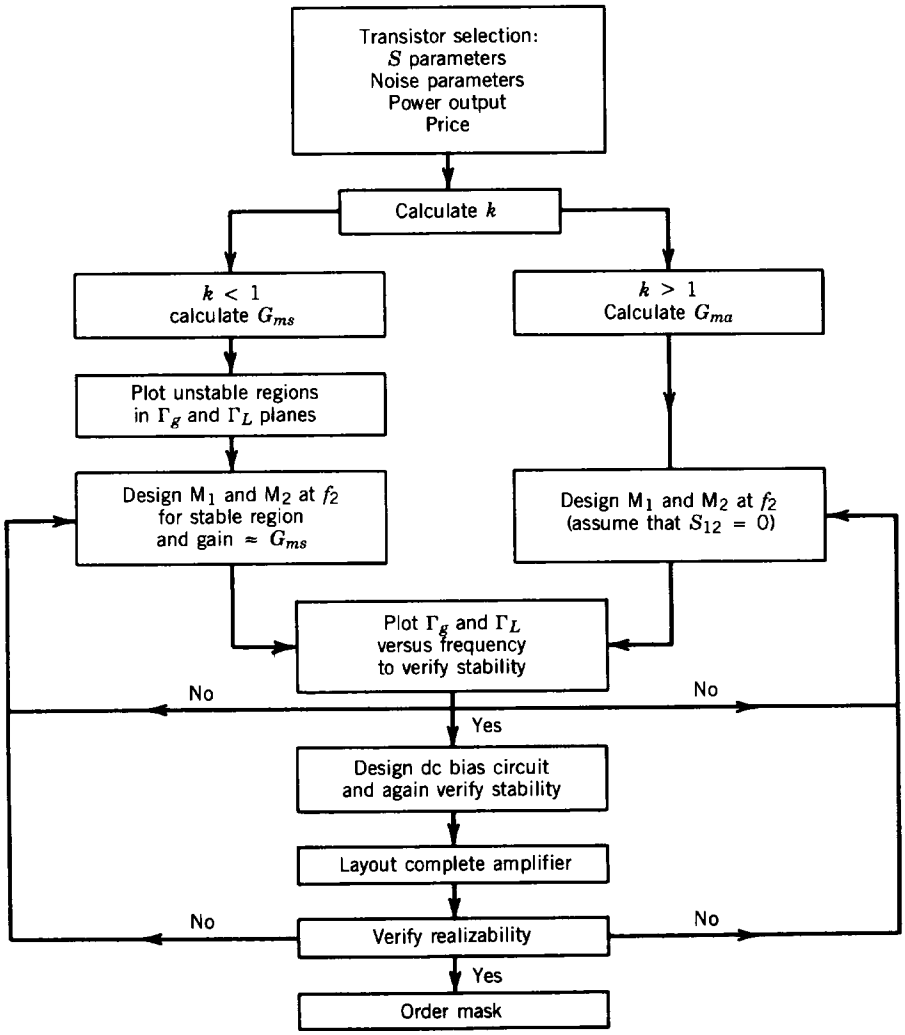

Figure 3-66 Simplified amplifier design procedure.

because it is unconditionally stable, has a minimum noise figure of about 1.2 dB at 7 mA, has 15.5 dB gain, and has an f_T of 8 GHz. While it is possible to start the design based on the published S and noise parameters, we will choose also to involve the nonlinear model, as this allows us more freedom in selecting the bias point including the collector voltage. The actual topology of the amplifier is shown in Figure 3-67.

Determining appropriate values for the input and output matching networks is essential to finalizing the design. The next several figures illustrate matching-network syntheses undertaken with the interactive Smith Tool in Ansoft's Serenade Design Environment. We evaluate the point of tangency as well as stability circles in the source and load planes, indicating that our impedance match will result in a stable amplifier.

In Figure 3-68, the center circle (with 1.1 marker) refers to the noise circle for which the noise figure of 1.1 dB can be obtained. The left circle (with the 14.3 marker) corresponds to

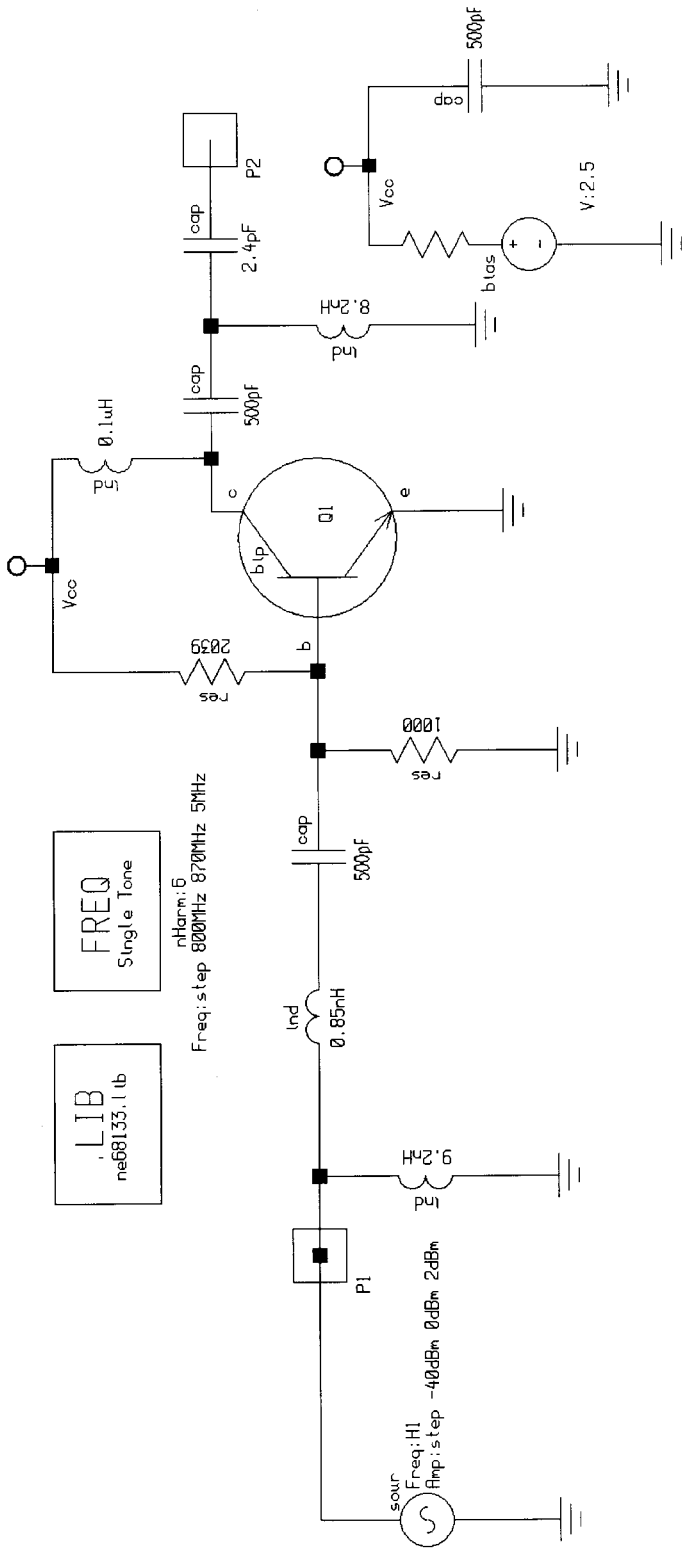

Figure 3-67 The NE68133 low-noise amplifier.

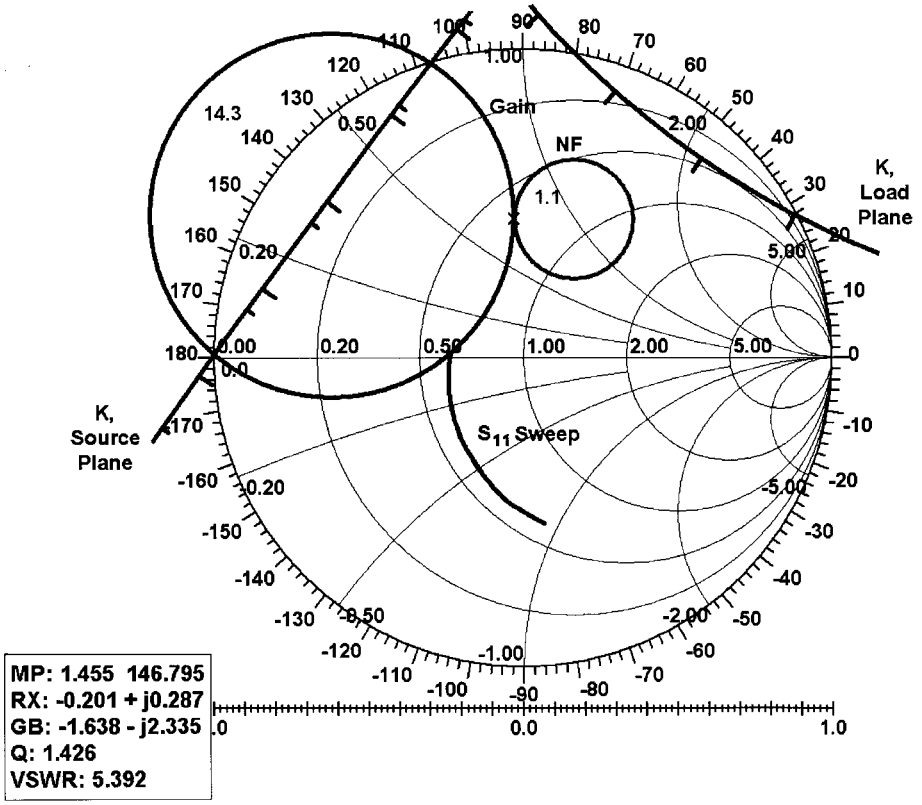

Figure 3-68 Display from the interactive Smith Tool, showing circles for gain, noise figure, and source- and load-plane stability, as well as a sweep of S_{11} versus frequency. In synthesizing an input matching circuit, we choose a single working frequency and work from the chart's origin to the point of tangency between the gain and noise figure circles. See Figure 3-69.

source-plane terminations that correspond to 14.3 dB of available gain. In order to get the required noise figure *and* gain, the input termination must be at the point of tangency of both circles. The arc touching the X axis close to 0.50 is the amplifier's S_{11} response from 800 to 875 MHz. The shallow arc that nearly bisects the 14.3-dB gain circle is actually a portion of the source-plane stability circle; the arc at the top right is a portion of the load-plane stability circle. Because we will be terminating the amplifier input with a value inside the source-plane stability circle, and terminating the amplifier output with a value outside the load-plane stability circle, the amplifier will be unconditionally stable at the frequency at which the match is obtained.

The next task is to obtain the values for the network circuit that matches the input for the 1.1-dB noise figure. A noise matching will not result in the best possible S_{11} matching (Figure 3-69). This translates into an inductor of 9.2 nH to ground and a series inductor of 0.85 nH based on the large-signal model of the NE68133 at the chosen bias point.

After we have determined our input matching network, it is time to find the output matching (Figure 3-70). First, find the termination point on the output plane that corresponds to 14.3-dB gain and 1.1-dB NF at the input plane. The output gain circle goes through the

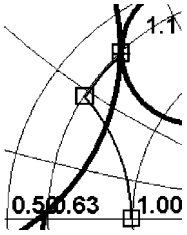

Figure 3-69 Input matching-network extraction, assuming lossless matching components and no parasitic effects.

1.1-dB NF circle at two points, and for reasons of easy matching we selected the lower point. The next step is to find the conjugate reflection coefficient $\Gamma_L = S_{22}^*$. This is the lower square marker in Figure 3-70. The remaining task is to find the matching network that brings this value to 50 Ω. By doing so, we first obtain a shunt inductance $L_{\text{shunt}} = 8.2$ nH and a series capacitor $C_{\text{series}} = 2.4$ pF. Again, these are the values applicable to the large-signal equivalent circuit.

The careful reader will have noticed that we have been avoiding the issue of small-signal exact matching using the manufacturer-supplied parameters. If this is done, the narrow band response shown in Figure 3-71 will be obtained. Therefore, we must optimize the circuit for a better frequency response to obtain the one shown in Figure 3-72.

After this optimization, we were well able to meet the specification of a center band gain of 14 dB and a corresponding NF of 1.1 dB. To show the flatness of the gain, Figure 3-73 shows a gain variation in the range of 0.25 dB.

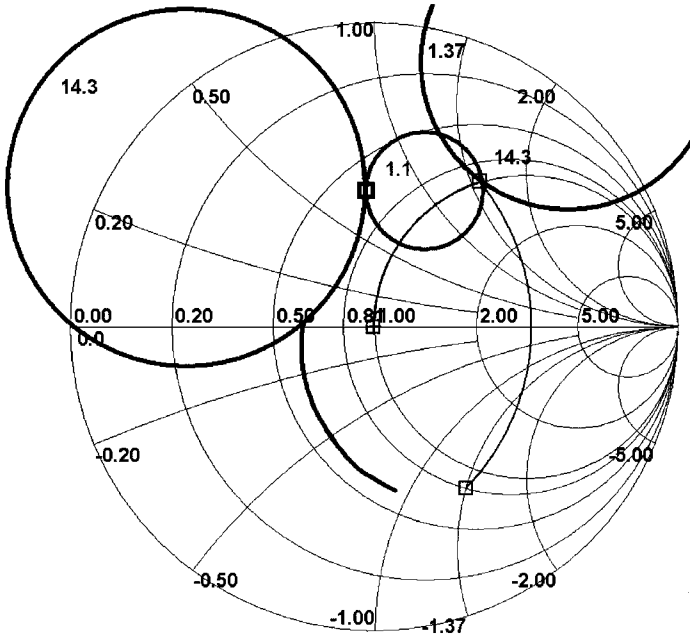

Figure 3-70 Output matching-network extraction.

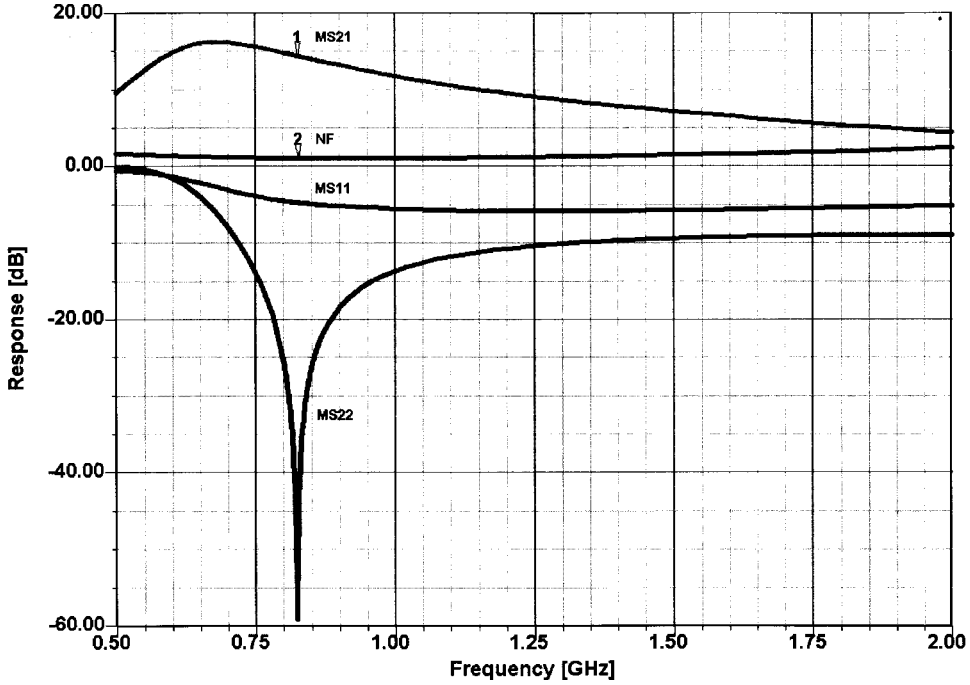

Figure 3-71 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-67.

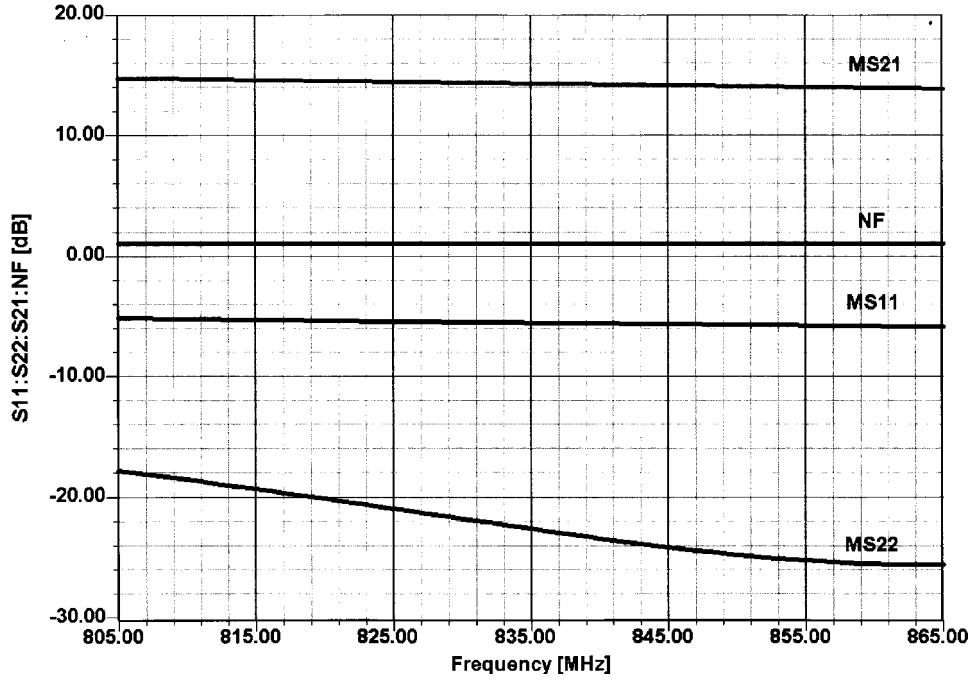

Figure 3-72 Optimized performance of input/output reflection, gain, and noise figure.

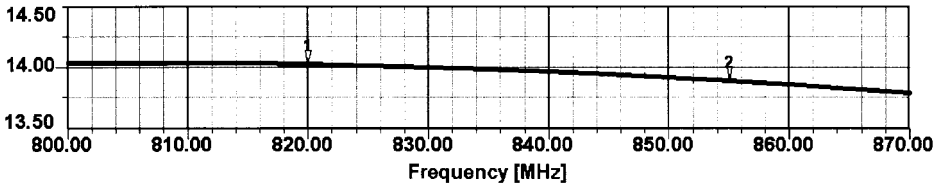

Figure 3-73 High-resolution display of gain as a function of frequency.

The next step is to look into the large-signal performance. The first order of business is to determine the third-order intercept point, which is based on a two-tone analysis. Given the fact that we run the device at low voltage and at a just-reasonable current, the actual intercept point of +13.5 dBm is quite a good number. Figure 3-74 shows the fundamental and third-order outputs. The crossover point between the two, as shown in Chapter 1, is defined as the third-order intercept point. If we had chosen the third harmonic output rather than the fundamental, we would have shown the fifth-order intercept point. The second-order IMD product ($f_1 \pm f_2$) typically can be minimized by input selectivity.

How an amplifier's linearity affects its ability to preserve the characteristics of digital signals is a major concern in wireless design. Figures 3-75 and 3-76 show constellation diagrams with the amplifier handling a PSK signal at drive levels of –40 dBm and +10 dBm, respectively. As expected, we see significant distortion at the higher drive levels due to circuit nonlinearities.

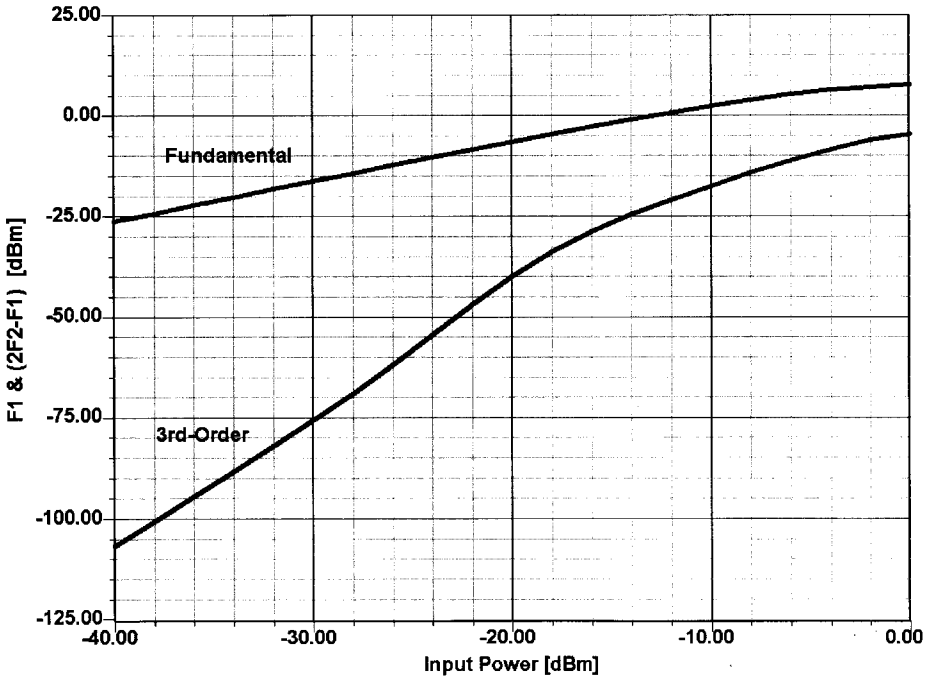

Figure 3-74 Simulated fundamental and third-order IMD outputs of the NE68133 amplifier.

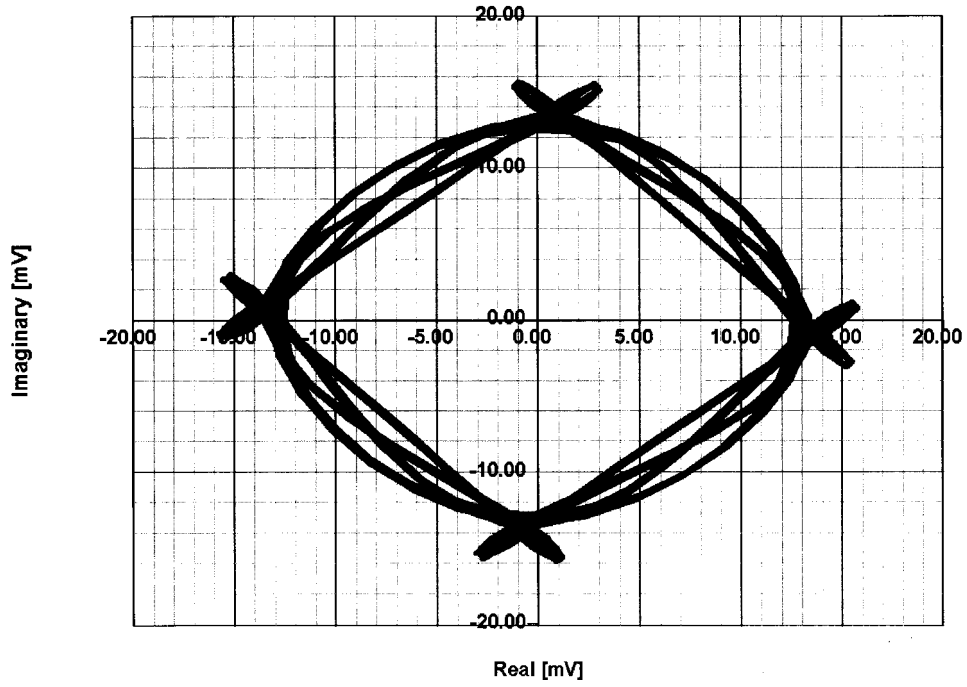

Figure 3-75 Output constellation at –40-dBm input.

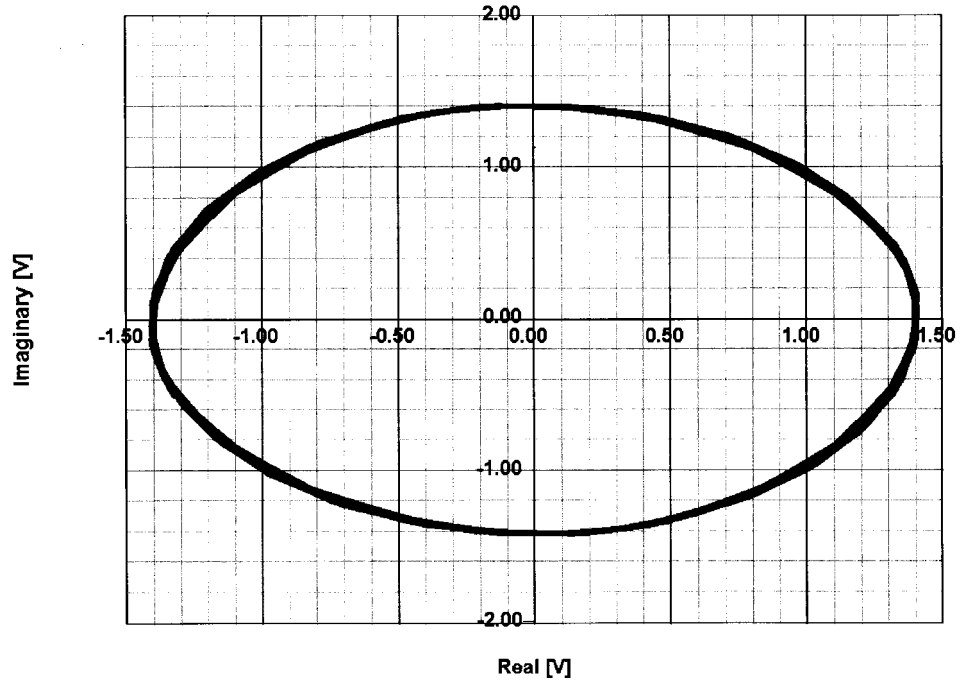

Figure 3-76 Output constellation at 10-dBm input.

BFP420 Matched Amplifier. The NE68133 has an attractive f_T of 8 GHz, but if more gain is needed, one may play with the concept of using a much "hotter" device, such as the BFP420. Recall that the NEC device was unconditionally stable, and our first worry is how the Siemens BFP420 will behave.

A study of Figure 3-77 shows that indeed the NEC device had to be stable all over and therefore was a good basis for a risk-free design. Things change dramatically with the BFP420, for which the K factor is essentially less than 1 up to a corner frequency of 2.75 GHz, where the transistor becomes unconditionally stable. Around 1.75 GHz, the K factor for the NEC transistor barely touches 1. We explained earlier that $G_{\max}$ deviating from the maximum stable gain is a more realistic number, since the conditions for maximum stable gain involve feedback and conjugate matching.

To improve the stability of the BFP420, we will now set out to use the same topology as the previous amplifier but with a resistive feedback between base and collector (Figure 3-78). A good value for this is always somewhere around 200–500 Ω. It must be remembered that this voltage feedback also stabilizes the input and output impedance and reduces the Miller effect because of the feedback being resistive and more dominant.

While the first example covered a fairly narrow frequency band, we are now attempting to cover a much wider frequency range; specifically, from 1.5 to 3 GHz reasonable gain and noise. This, by definition, requires a much higher gain-bandwidth product, and the simple matching network at the input and output provides a nonoptimal input and output matching (Figure 3-79). The feedback introduces some additional noise. This application shows the limits of single-stage UHF/SHF amplifiers with feedback.

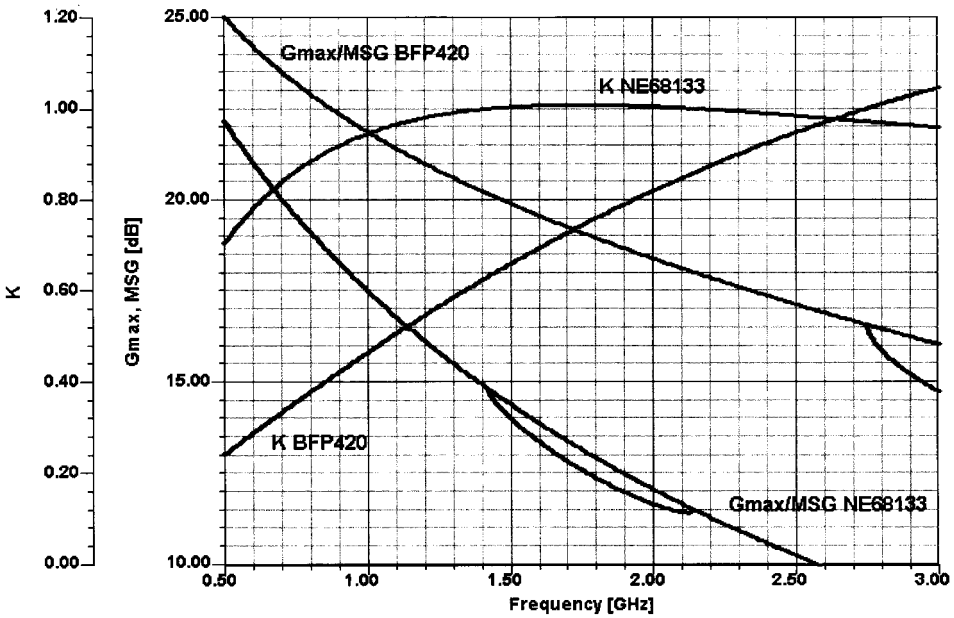

Figure 3-77 Comparison of K, $G_{\max}$, and maximum stable gain (MSG) for the NE68133 and BPF420 BJTs.

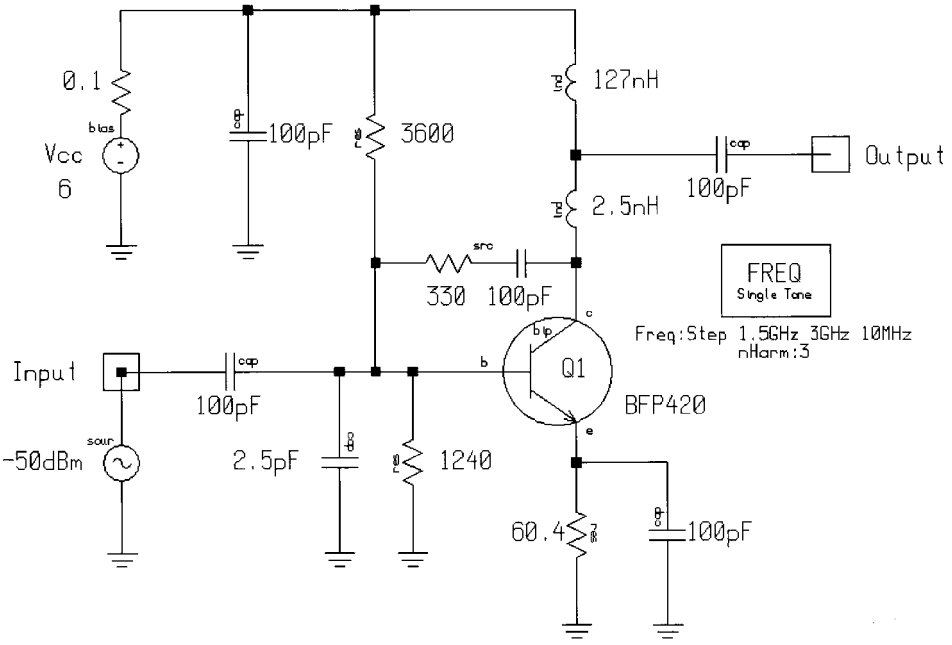

Figure 3-78 BFP420 amplifier with resistive voltage feedback from collector to base.

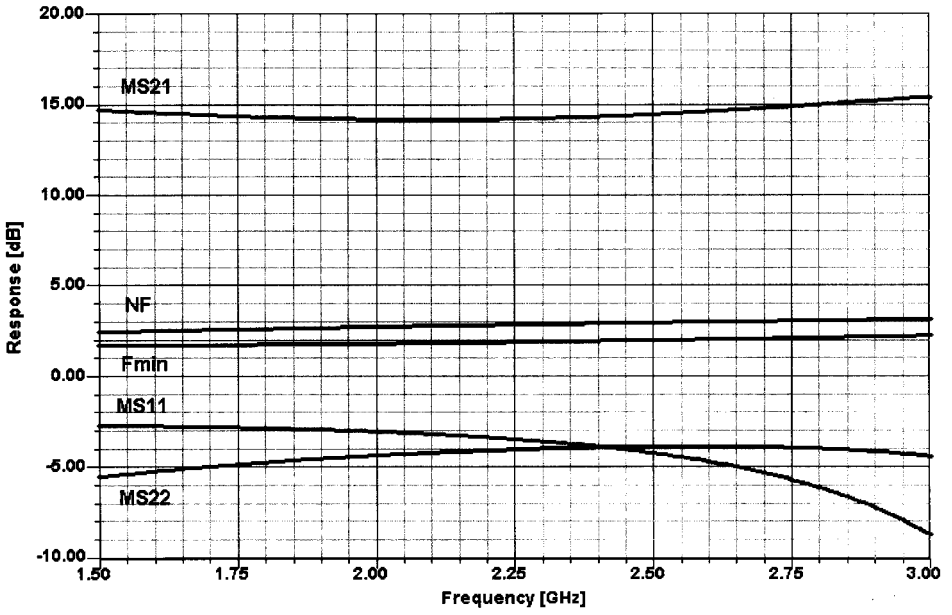

Figure 3-79 Frequency-dependent gain, matching, and noise performance of the BFP420 feedback amplifier.

Narrowband BFP420 Amplifier. Our next attempt will be to design a narrowband input stage that combines very high selectivity with good noise figure. This can only be achieved by using two tuned single-stage resonators with capacitive/magnetic coupling. The following amplifier is tailored to have a center frequency of 900 MHz. The transistor will operate at 12 V/10 mA to have a sufficient dynamic range. The input selectivity is achieved by the use of two top-coupled tuned circuits, followed by a BFP420 (Figure 3-80). The first order of business is to determine the input tuned circuit. The tuning capacitance for the two tuned circuits is arbitrarily set to a manageable 2 pF (small values have too much tolerances and larger values will require smaller inductances, resulting in lower Q). The reactance of the first tuned circuit is

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi \times 9\text{E}8 \times 2\text{E}{-}12} = 88.42\ \Omega$$

The necessary inductance for resonance will be

$$\omega L = 88.42$$

or

$$L = 88.42/\omega = 88.42/(2\pi \times 9\text{E}8) = 15.64\ \text{nH}$$

We will make both tuned circuits identical, but with different loaded Qs. By multiplying 88.42 times the loaded Q (20 for the input resonator and 50 for the output resonator), the resulting parallel-resonant resistance is $88.42 \times 20 = 1768\ \Omega$ at 900 MHz (for the input resonator) and $88.42 \times 50 = 4421\ \Omega$ (for the output resonator). These values are achieved by loading the input with the 50-Ω source and by loading the output with the input of the transistor. Therefore, the input transformation ratio $m_1 = 1768.4/50 = 35.37$. At the output, the equivalent number $m_2 = 4421/50 = 88.42$. For the purpose of simulation, and because it is extremely difficult to find the physical location of the appropriate tap on an air-wound coil for the necessary impedance, we do this "on paper" by incorporating an ideal transformer. We are also going to show later the actual transmission-line-based filter and its modeling. This filter will have a higher insertion loss based on the PC-board material used.

Using our nonlinear simulator, in small-signal ac mode, we obtain the frequency response and noise figure shown in Figure 3-81. In actually building this circuit, there is another problem besides these transformers—the top-coupling capacitor. We have used a grounded-T configuration to obtain a practically realizable value of 36 pF, whose lead inductance will not influence the circuit. (The actual coupling capacitance value for top coupling without the T configuration would have 0.1 pF. We would like to see this value repeatably realized.)

If the actual noise would be calculated relative to the output tuned circuit, the equivalent noise resistor R_n of 5 Ω would now be multiplied by m_2, resulting in 442 Ω. Fortunately, the Serenade simulator has a highly accurate BJT noise model that is both bias and temperature dependent, so the simulator will give us the answer directly.

We have not put any matching circuit at the output and leave this task to the reader. In practice, the slight tilt in the MS_{21} curve in Figure 3-81 would be tuned out. Also note that the minimum noise figure ($F_{\min}$) and the actual 50-Ω noise figure (NF) agree somewhat off center. This has to do with the Miller effect, which results in the well-known difference between noise matching and input-gain matching. By varying the coupling capacitor to move from the overcoupled response, which gives a low noise figure, to a critically coupled

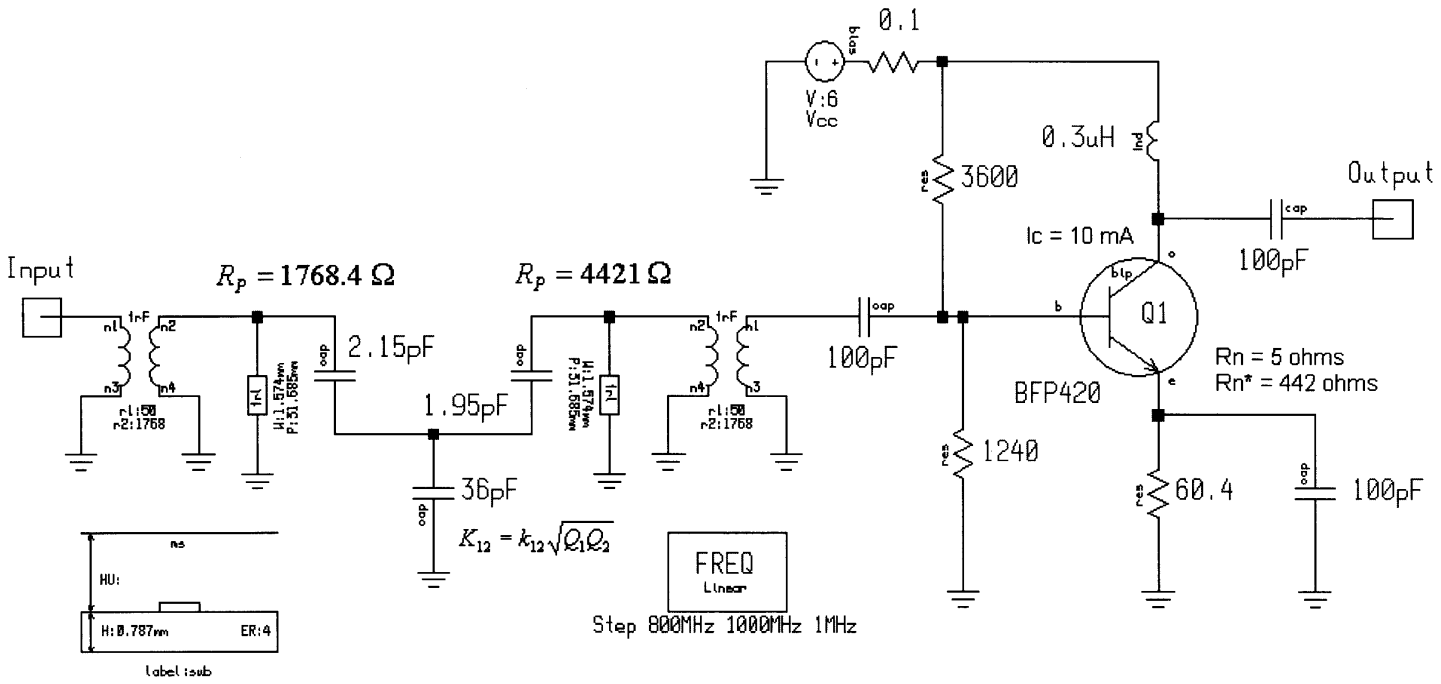

Figure 3-80 BFP420 amplifier with narrowband input filtering. Ideal transformers are used to match the filter's input and output to the input port and the BFP420 base, respectively.

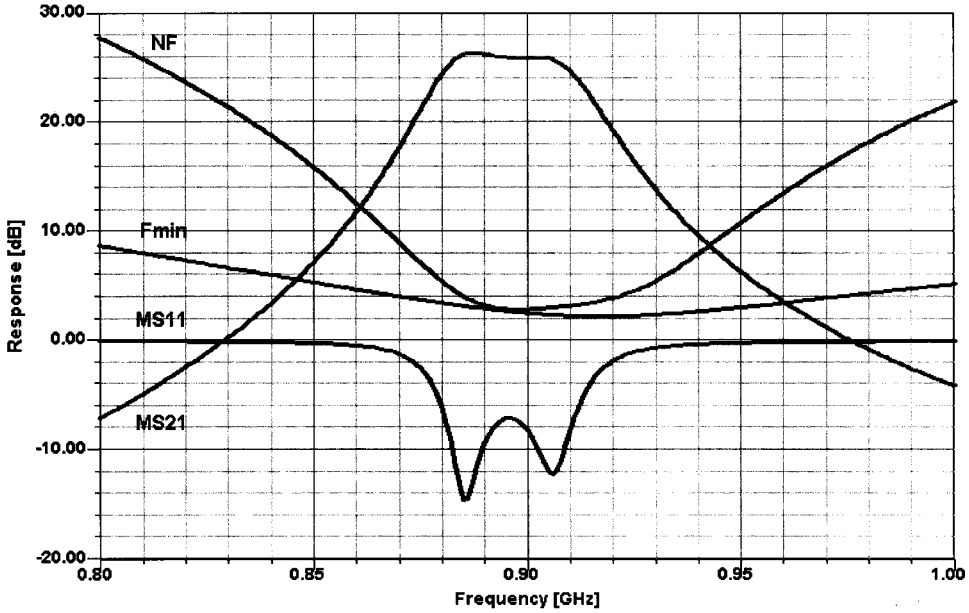

Figure 3-81 Frequency-dependent gain, matching, and noise performance of the narrowband BFP420 amplifier.

response ($K = 1$), we get significantly better selectivity and narrow bandwidth (at the obvious expense of the noise figure) as shown in Figure 3-82.

Since we somewhat compromised by not providing the reader with an actual input and output coupling that can be built, and furthermore, because the inductance in question (15.26 nH) is hard to realize with a high Q, we now show the printed circuit approach for the input filter. By using a Teflon-based material for the PC board, the losses would be less; however, the radiation would be more because ε would go down to 2.1 from the value we used (4). It is also convenient to introduce this filter to show that at higher frequencies, where lumped elements are really no longer available, one has to switch to distributed elements. A list of the commonly used distributed elements will be shown later; the transmission line and T junction are probably the most frequently used elements, followed by spiral and rectangular inductors, and bends.

The actual implementation of the input filter on a printed circuit board requires distributed elements (Figure 3-83). In practice, one has two parallel coupled lines with a tap somewhere toward the ground connection and, for modeling accuracy, we have to introduce a T junction with the appropriate impedance of 50 Ω for the input and a different impedance (if necessary) for the output. The coupling mechanism now is magnetic coupling, since no one can physically change the distance between the transmission lines by tuning some mechanical elements, one has to get it right the first time. This can only be achieved with a high-precision simulator. The reason why these simulators are so expensive is the investment of research time and personnel to produce valid models over a huge frequency and impedance range. Since we are now curious about the frequency response, we have plotted in Figure 3-84 the frequency response, which shows a higher (expected) insertion loss. The PC-board material is partially responsible for this.

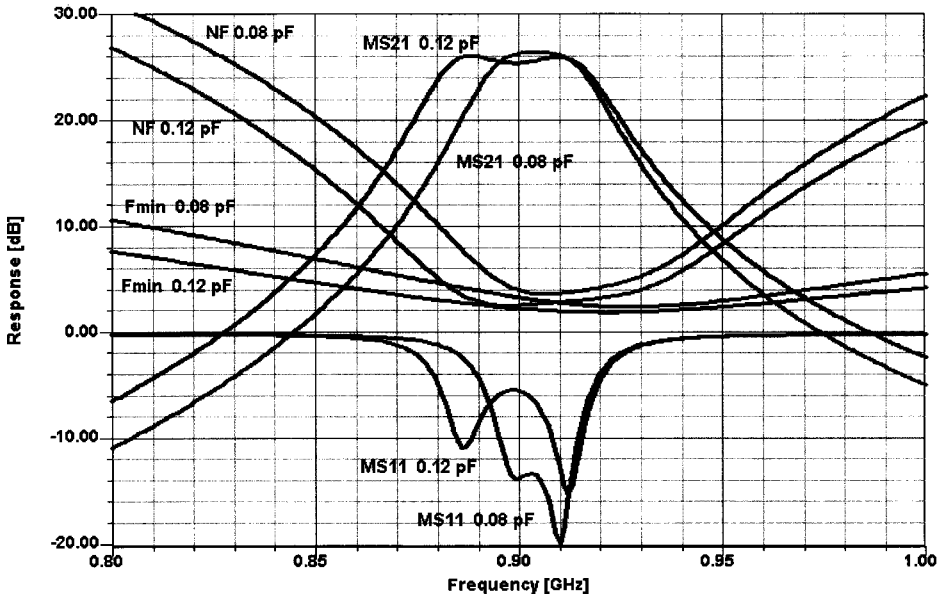

Figure 3-82 Comparison of filter responses with critical coupling (0.08-pF response) and overcoupling (0.12-pF response).

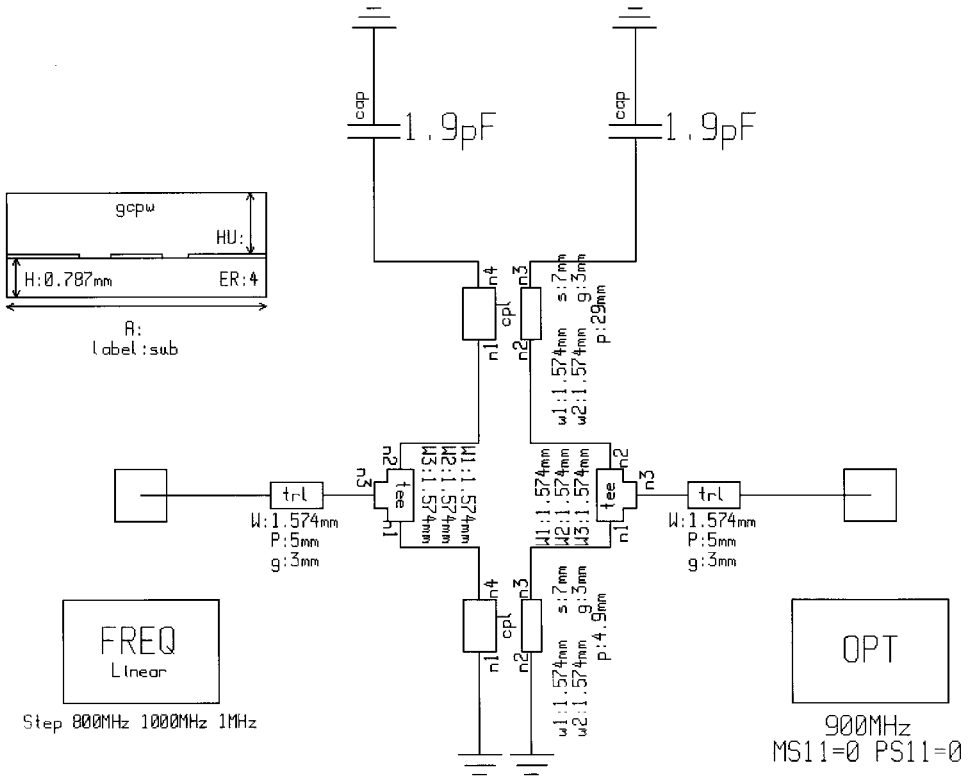

Figure 3-83 Input filter using distributed-element resonators and matching.

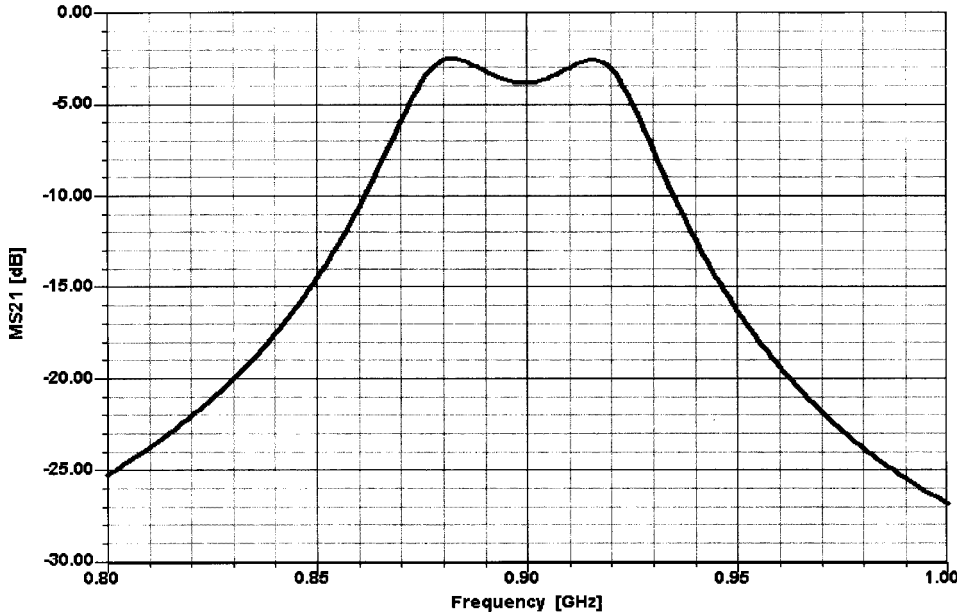

Figure 3-84 Gain versus frequency response for the distributed-element filter.

At the end of this chapter we will have a chance to discuss passive elements as needed for microwave frequencies, and one should consider frequencies above 1500 MHz as microwave frequencies.

GaAsFET Feedback Amplifier. The implementations we have shown so far have been based on bipolar transistors. Figure 3-85 shows a single-stage feedback amplifier using a GaAsFET. The feedback is based around an *LRC* network and some attempts at matching at the input and output are made. Figure 3-86 shows its frequency-dependent gain, matching, and noise performance.

3-2-3 High-Gain Amplifiers

In most cases, high-gain amplifiers receive an already amplified signal, which means we are less concerned about the signal-to-noise ratio but remain concerned about distortion. To reduce distortion, we have two options: (1) increase the dc current in the active device, which always improves the current-related distortion; and (2) add some voltage feedback, which reduces the voltage distortion. In simple terms again, only current feedback can reduce the current-related distortion of a square-law or exponential transfer characteristic and only voltage feedback can reduce the effect of overdrive as a function of the load, but only to some degree. Its main purpose remains to reduce the input impedance to useful values, specifically for FETs, since current feedback increases the input and output impedances. Some ultrasensitive circuits still require Class A operation, but now at higher current levels; these are typically CATV applications, and there are several transistors available that can be operated at 5–15 V but at 60 mA or higher. Because of the higher power consumption, this excludes handheld cordless or cellular telephones. The same circuit as used before (Figure 3-85) for

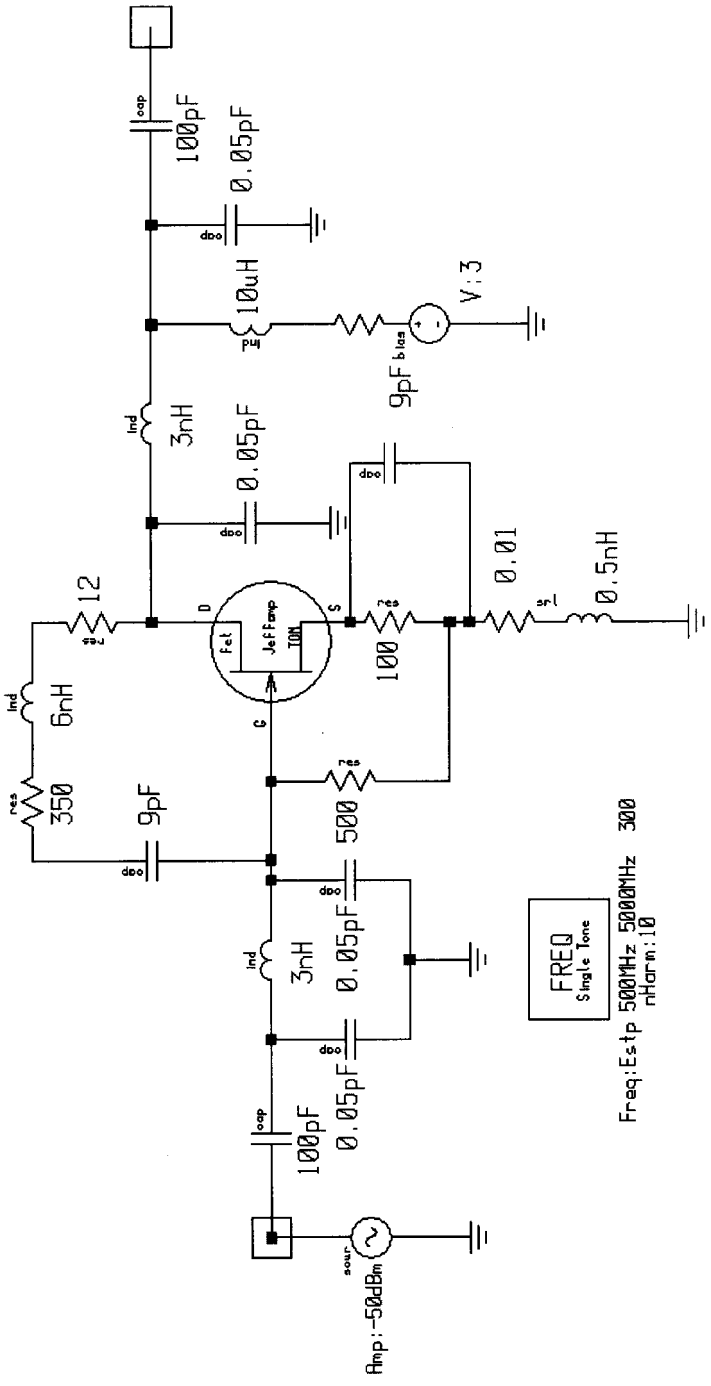

Figure 3-85 GaAsFET feedback amplifier.

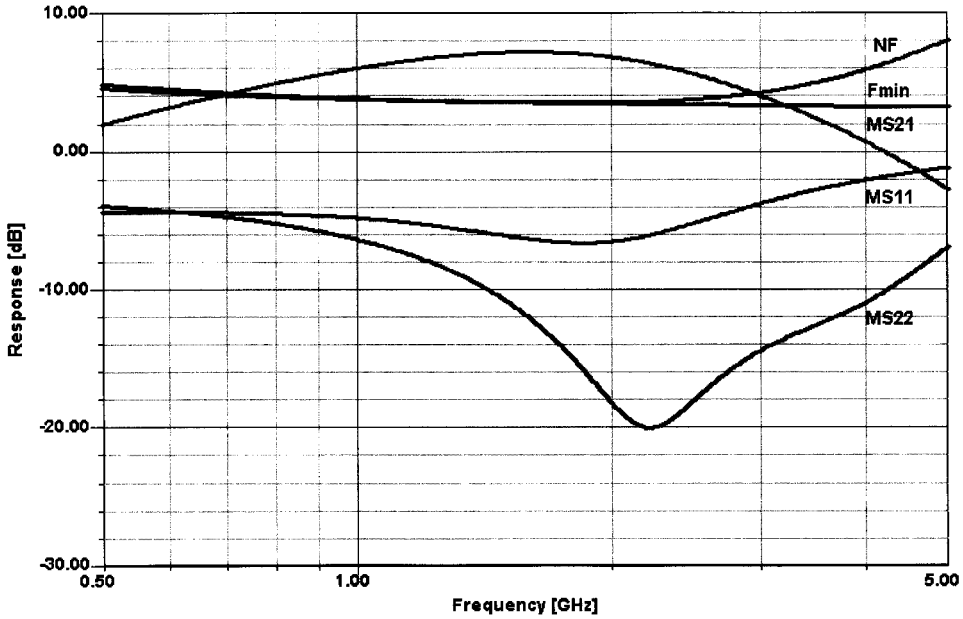

Figure 3-86 Frequency-dependent gain, matching, and noise responses for the GaAsFET amplifier.

Class A operation now can be operated at a higher current, which automatically increases the gain and the noise figure and reduces distortion. This is based on the fact that the transconductance (g_m) increases at higher currents. The second transistor in the TI circuit achieves this by being in reality a larger device, which could be modeled by several transistors, like the first stage, in parallel. This automatically increases the dc current by the scaling factor. The same is even more true for the output stage. Likewise, bipolar transistors can also be scaled. A visual inspection of some transistors in their packages will reveal that they are really not just one transistor, but several operating in parallel, each with its own ballast resistors (for bipolar transistors) or other means (for FETs).

Using tuned circuits rather than wideband matching, it is possible to go to Class AB or B operation. Class AB is really a hybrid between A and B, and Class B is probably better known. Figure 3-63 shows the Class B operating point. Most Class B stages are operated in push–pull because, together with the tuned circuit, one-half of the cycle is supplied by the other transistor. The definition of Class B operation is a conducting angle of 90° (see Figure 3-63). At this point it should be noted that some older texts define the conducting angle as being twice the value we have defined in this chapter.

Without going into further details, the highest efficiency in Class B operation is 78.5%. Based on the fact that modern wireless applications generally use a hybrid of amplitude and angle modulation, pure Class C operation finds little application today because of the severe nonlinear distortion it introduces. A Class B stage has less "power gain" than a Class A stage but provides much more output power. We have already mentioned the problem associated with characterizing a Class A stage in terms of power gain. That's the only time Kirchhoff's equations are valid, meaning that the sums of all currents and voltages have to be zero. Because Kirchhoff's equations do not consider nonlinearities and harmonic contributions,

the very moment we move into considering medium- and higher-power amplifiers, the nonlinearities will dominate and the performance of the stage is best analyzed with a high-quality circuit simulator with the appropriate dynamic range and good modeling capability. Without question, this applies to Class C operation also. As pointed out previously, the high-gain amplifier is optimized for gain rather than noise figure and typically requires more collector or drain current. This can easily be seen by rebiasing the FET amplifier as shown above to a significantly higher value of 33 mA. This is accomplished by changing the source resistor down to 3 Ω. As a result of this, we obtain the gain, matching, and noise figure responses shown in Figure 3-87.

It may be a surprise to the reader that the actual noise figure now is less than that shown in Figure 3-86. This device is now operating at 33 mA; the reason for this has to do with the fact that if the transconductance is too low, the noise figure also increases, and the NF curve for the FET has a similar-looking current-dependent minimum—a curve that is frequently not supplied by the manufacturer. This amplifier, now operating at 33 mA, should have quite good large-signal capabilities; we will examine this shortly.

Another interesting piece of information is the display of the dc I–V curves with the "load line." Since we have reactances in the circuit, we do not see a line but rather an ellipse, indicating the storage of energy. (The actual load line would be a line through the two foci of the ellipse.) This curve allows us to see immediately that at this operating point the transistor is neither going into current saturation nor becoming voltage limiting. The input power can be increased further until such a condition exists. Figure 3-88 shows the dc I–V curve for the amplifier shown in Figure 3-85.

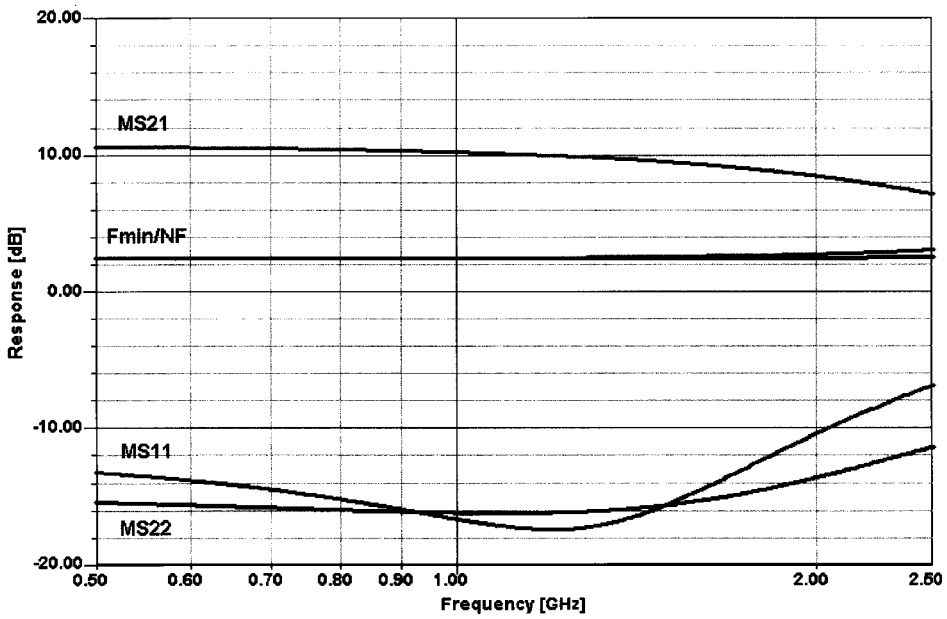

Figure 3-87 Frequency-dependent gain, matching, and noise performance for the GaAsFET amplifier of Figure 3-85 rebiased for a drain current of 33 mA.

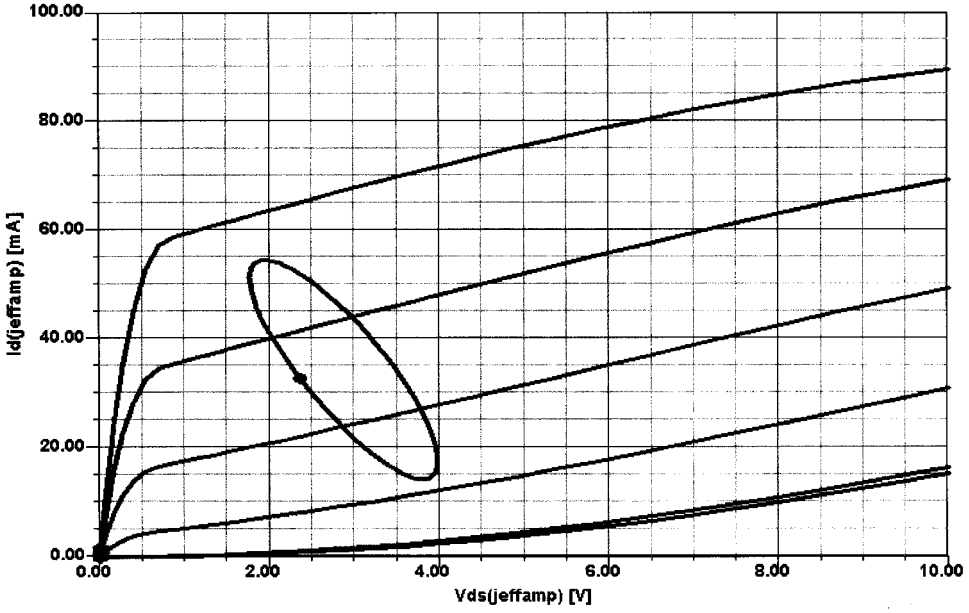

Figure 3-88 The dc *I–V* curves for the GaAsFET operating at I_D = 33 mA, including the ac load line. The load line is an ellipse rather than a straight line for the reason described in the text.

Besides looking for the adjacent-channel power ratio (ACPR), the other traditionally important points are third-order intercept point and the equivalent of a multitone simulation, as used for CATV application but relevant to the multisignal environment of wireless applications. Figure 3-89 shows the determination of the amplifier's third-order intercept point. It is most important for the reader to understand that very low values for input and output level have to be used to determine the crossover point. If this advice is not followed, totally erroneous numbers can occur.

Since an antenna supplies a large number of signals (this is true of handheld radios as well as base-station sites), a three-tone standard has been adopted as a good approximation of multisignal operation. This standard is in accordance with the German DIN 45004E,3.3 three-tone measurement. The requirement is that the intermodulation distortion products at the output are better than 60 dB suppressed relative to the largest of the three tones. One tone is used as the reference, and the other two tones are 6 dB less. This measurement has been derived from television, whereby the video transmitter, based on the vestigial sideband power, is 6 dB above the two sidebands produced by the FM sound transmitter using a modulation index of 5. The result of a three-tone test can be seen in Figure 3-90. This amplifier clearly meets the DIN specification for linearity at input levels up to –9/–15 dBm at the input.

Bipolar transistors are also quite popular for this purpose. Figure 3-91 shows a single-stage amplifier with an intrinsic transistor and all the other "hidden" intrinsics, normally not visible, added. The three diodes belong to those intrinsic elements, which are needed for accurate microwave modeling but which are not provided by the standard nonlinear models. The reader will see that we went into great detail to model all the necessary parts. This feedback amplifier, whose frequency response is shown in Figure 3-92, has been quite

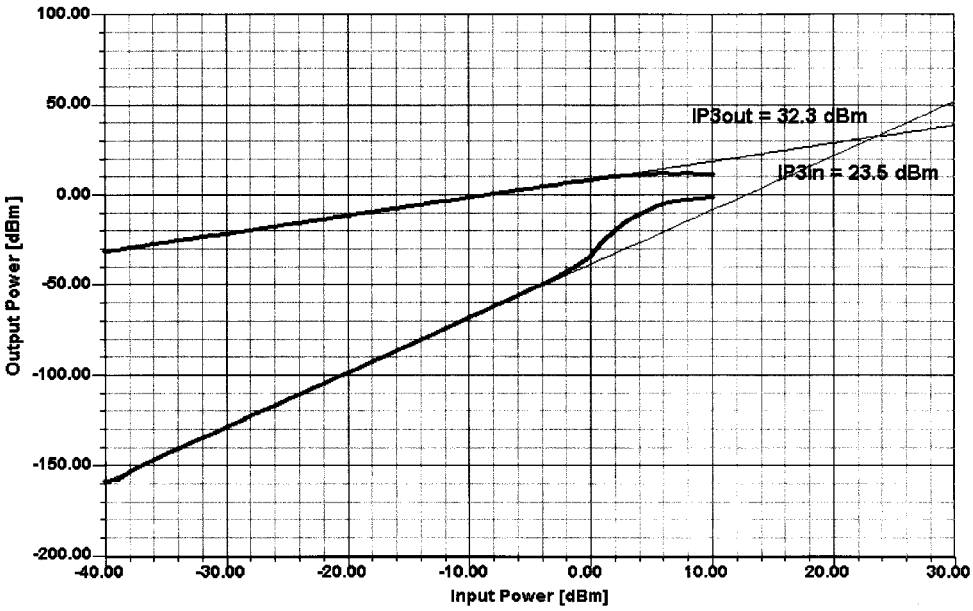

Figure 3-89 Determination of the third-order intercept point based on a two-tone measurement using tones spaced at 5% of the operating frequency (1.8 GHz).

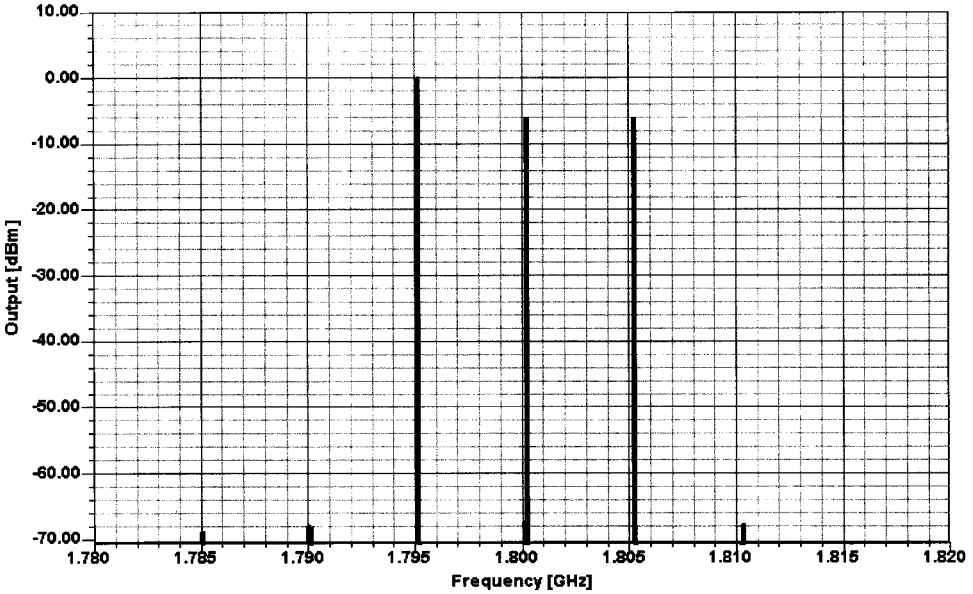

Figure 3-90 Simulated three-tone analysis of the GaAsFET amplifier with $I_D = 33$ mA.

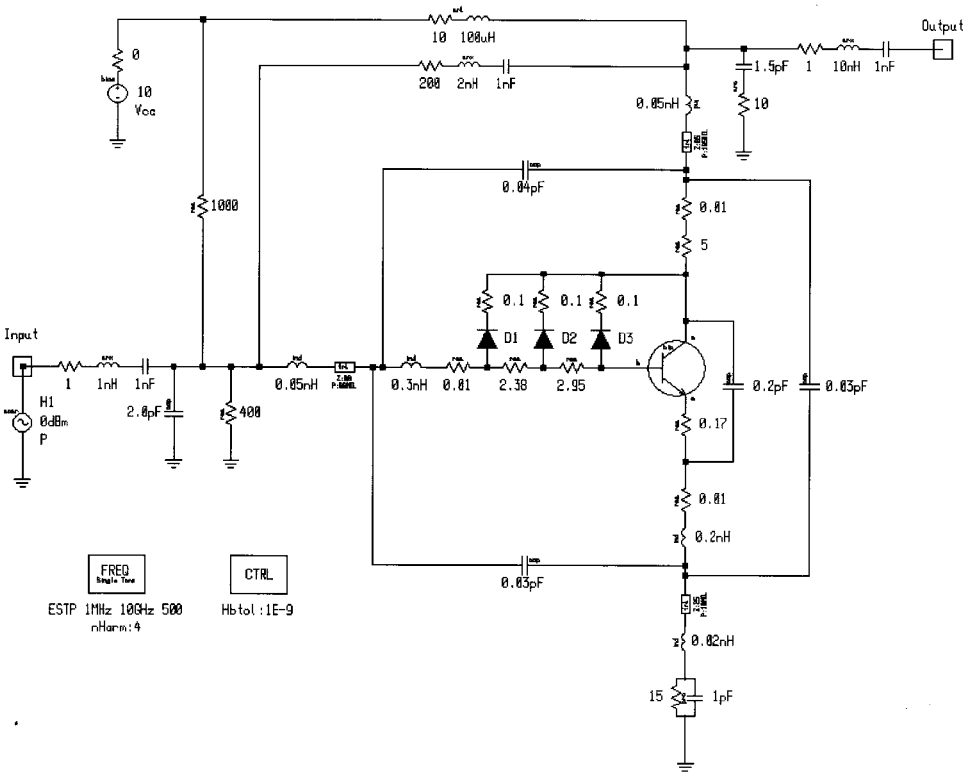

Figure 3-91 A high-linearity single-transistor amplifier modeled in great detail.

difficult to design, but there are monolithic circuits available where the higher gain–bandwidth product is being used to advantage.

Figure 3-92 shows the predicted frequency-dependent gain, matching, and noise figure at a bias point of 108 mA at 10 V. Using the same DIN three-tone test procedure, Figure 3-93 shows the expected good result.

Since this test requires two equal signals and one larger signal, we need to expect one IMD product larger than the rest. We have set our window for a dynamic range of 70 dB, and yes, in the lower left corner, we can see the product between the first two signals, while the other products are below the –50 dB level.

As a little task, Figure 3-94 shows a simple amplifier, based on a modern Siemens transistor, which is a feedback amplifier with fewer modeling details surrounding the transistor. Its associated frequency-dependent performance is shown in Figure 3-95. Interested readers are invited to improve its performance by using their skills and intuition.

Permitting higher currents and actually combining two transistors leads to our first MMIC. The following simulation is based on the MGA64135. Needless to say, there are some compensation networks inside the MMIC and distributed elements that affect the frequency response. However, with this arrangement, it is possible to obtain an appreciable gain at our wireless frequencies. The noise figure, based on the feedback, however, it not too impressive. This is a problem that occurs with most feedback amplifiers, which try to minimize the distortion and yet would like to keep the noise figure down. Figure 3-96 shows the schematic

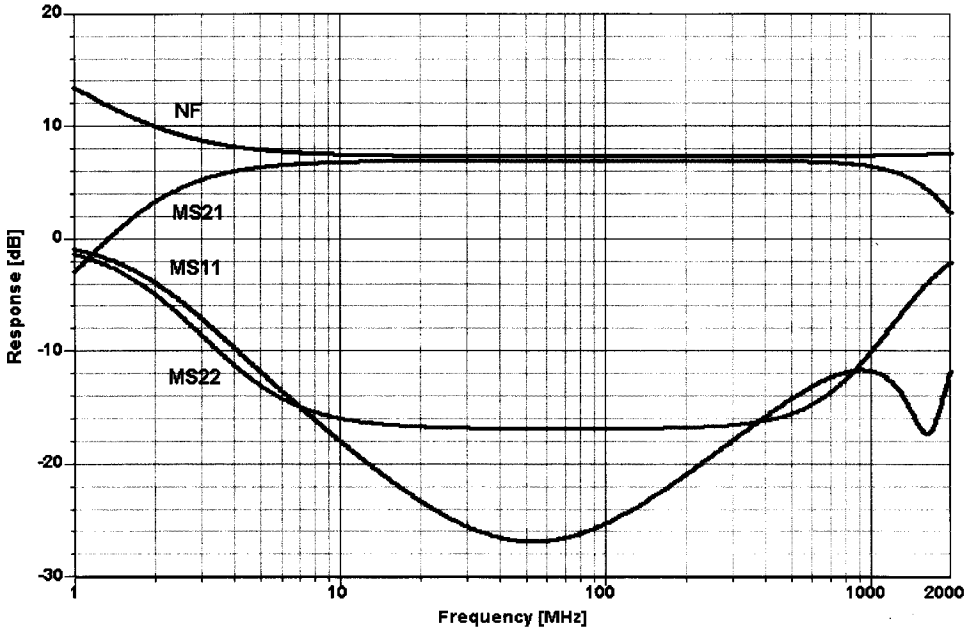

Figure 3-92 Simulated frequency-dependent gain, matching, and noise figure performance of the circuit in Figure 3-91.

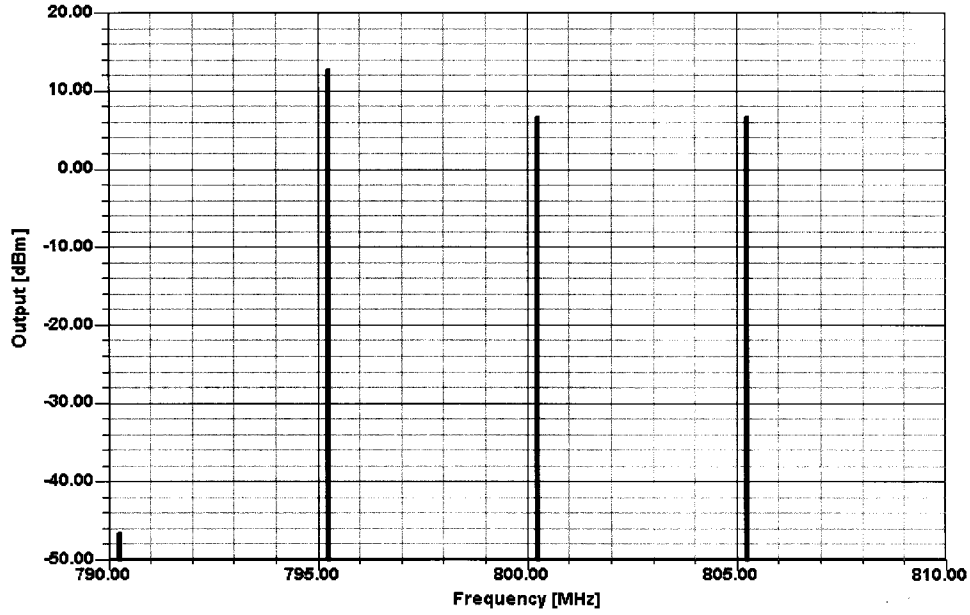

Figure 3-93 Simulated three-tone output spectrum of the amplifier in Figure 3-91.

of the GaAs MMIC; Figure 3-97 shows its frequency-dependent gain, matching, and noise performance; Figure 3-98 shows its two-tone response, which is used to obtain the intercept point ($IP_{3,in}$ = 8.5 dBm, $IP_{3,out}$ = 22 dBm); and, finally, Figure 3-99 shows the three-tone test results at an input RF level of –21/–27 dBm. While the gain–bandwidth product is considerably larger than the single-stage amplifier we examined before, the intercept point and three-tone performance do not reach the same values. As a general rule, the dynamic

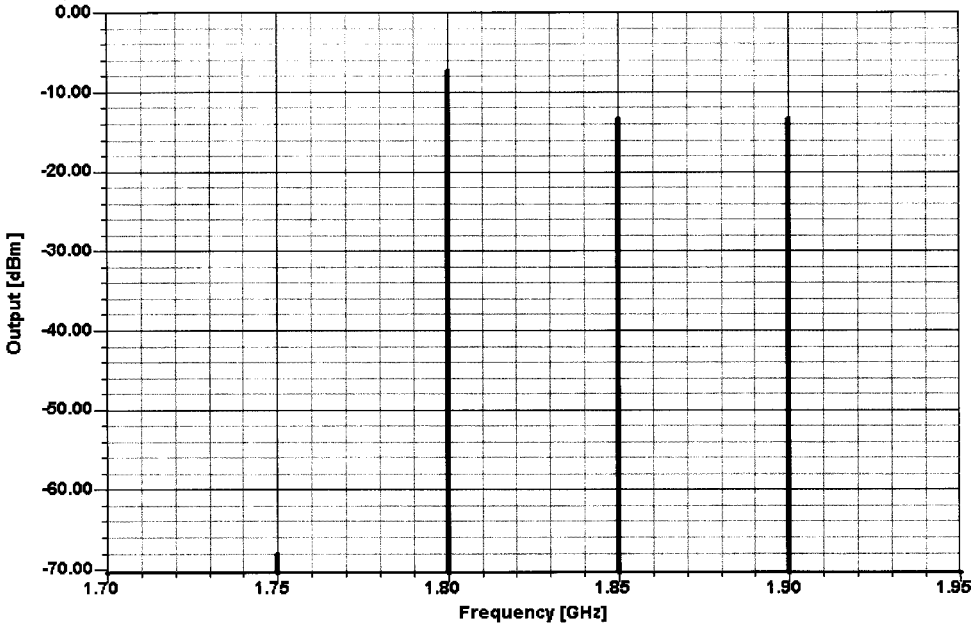

Figure 3-99 Simulated three-tone test of the MGA64135 MMIC. The test tones were 1.80 GHz (–21 dBm), 1.85 GHz (–27 dBm), and 1.90 GHz (–27 dBm). The 1.75-GHz IMD product is down 60.5 dB relative to the 1.80-GHz signal.

range is directly proportional to the power dissipated in the devices: specifically, the current. As explained earlier several times, the first-order nonlinearity comes from the voltage-to-current transfer characteristic, such as the transconductance itself, and can only be improved by a combination of resistive feedback in the emitter/source and by high currents. At these dc levels, the base–emitter (gate–source) junction gets linearized because the differential values are getting smaller compared to the parasitic loss resistances, including external dc/RF feedback. Once again, the voltage feedback reduces the voltage clipping but is initially more responsible for the input and output matching.

3-2-4 Low-Voltage Open-Collector Design [22–25]*

Why R_C Acts Like a Source Resistor. An open-collector output allows a designer the flexibility to choose the value of the R_C resistor. Choice of this resistor value not only sets the dc bias point of the device but also defines the source impedance value. Figure 3-100 shows the ac model of the transistor. Converting the output structure by applying a Norton and Thevenin transformation, one can conclude that R_C becomes the source resistance. Thus, by choosing R_C to be equal to the load, maximum power transfer will then occur.

Figure 3-101 shows an active transistor with collector and base resistors. From basic transistor theory, Eq. A in Figure 3-101 is generated and has the same form as the general equation for a straight line ($y = mx + b$).

Figure 3-101 Basic transistor analysis.

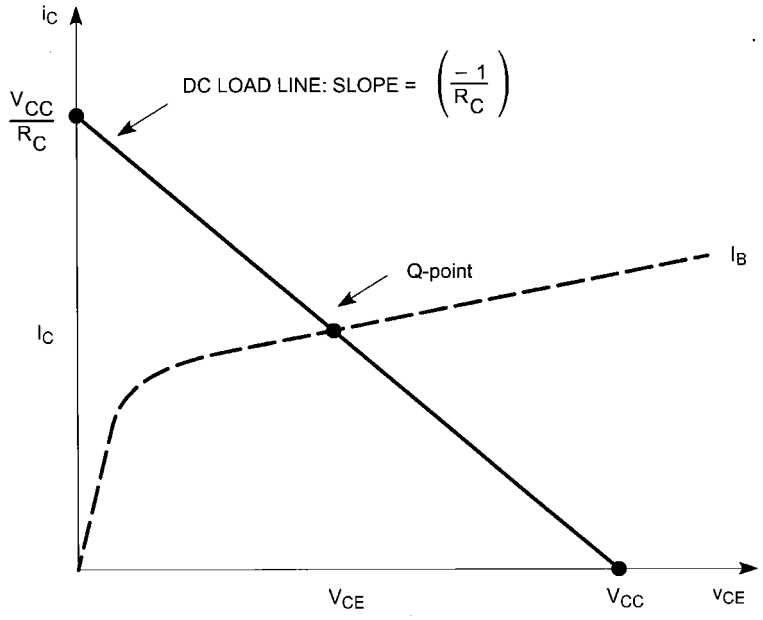

Figure 3-102 Load line and Q-point graph.

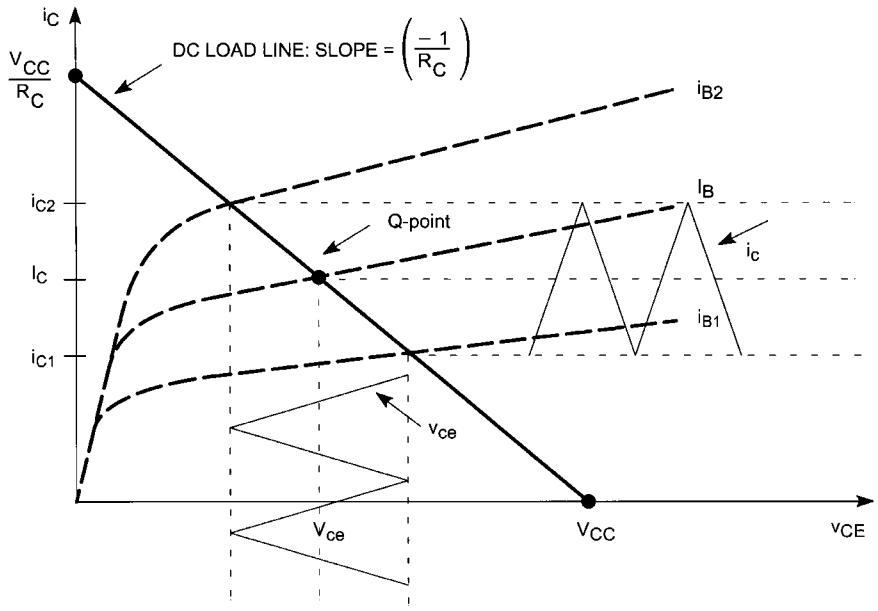

Figure 3-103 Graphical analysis for the circuitry in Figure 3-101.

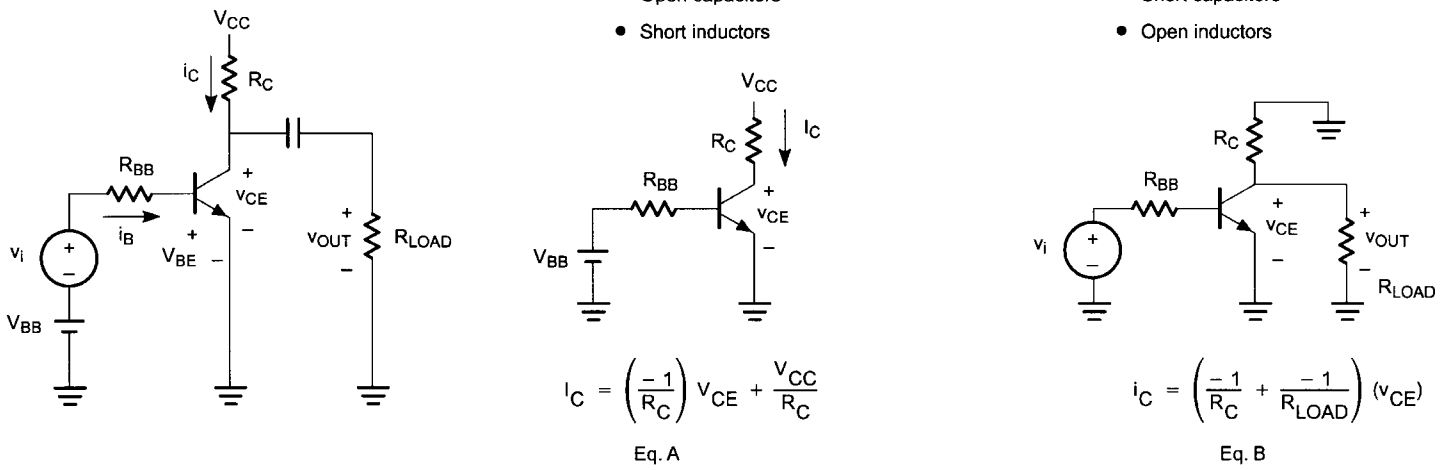

Figure 3-104 Basic transistor analysis with R_{LOAD}.

The slope of the dc load line is generated by the value of the collector resistor ($m = (1/R_C)$ and is shown in Figure 3-102. For a given small-signal base current, the collector current is shown by the dotted curve. The intersection of the dotted curve and the dc load line is called the *quiescent point* (Q-point) and dc bias determinant. The location of the Q-point is important because it determines whether the transistor is operated in the cutoff, active, or saturation region(s). In most cases, the Q-point should be in the active region because this is where the transistor acts like an amplifier.

Figure 3-103 shows the ac collector–emitter voltage (V_{CE}) output swing with respect to an ac collector current (I_C). Collector current is determined by the ac voltage presented to the input transistor's base (v_i) because it affects the base current (i_b), which then affects i_c. This is how v_i is amplified and seen at the output. Recall that this is with no external load (R_{LOAD}) present at the collector. Since no load is present, the slope of the ac load line is identical to that of the dc load line as seen in Eqs. A and B of Figure 3-101 ($m = -1/R_C$).

Open Collector with R_{LOAD}. A filter with some known input impedance is a typical load for the output of the transistor. For simplicity, we will assume a resistive load (R_{LOAD}) and neglect any reactance. Since a resistive load is used (see Figure 3-104), the ac output swing is measured at V_{OUT} or V_{CE}.

A dc blocking capacitor is used between the R_{LOAD} and the V_{CE} output to assure that the Q-point is not influenced by R_{LOAD}. It is also necessary to avoid passing dc to the load in applications where the load is a SAW filter. However, R_{LOAD} will affect the ac load line, which is seen in Eq. B in Figure 3-104. Note that the V_{CE} voltage swing is reduced; thus, the V_{OUT} signal is reduced (see Figure 3-105).

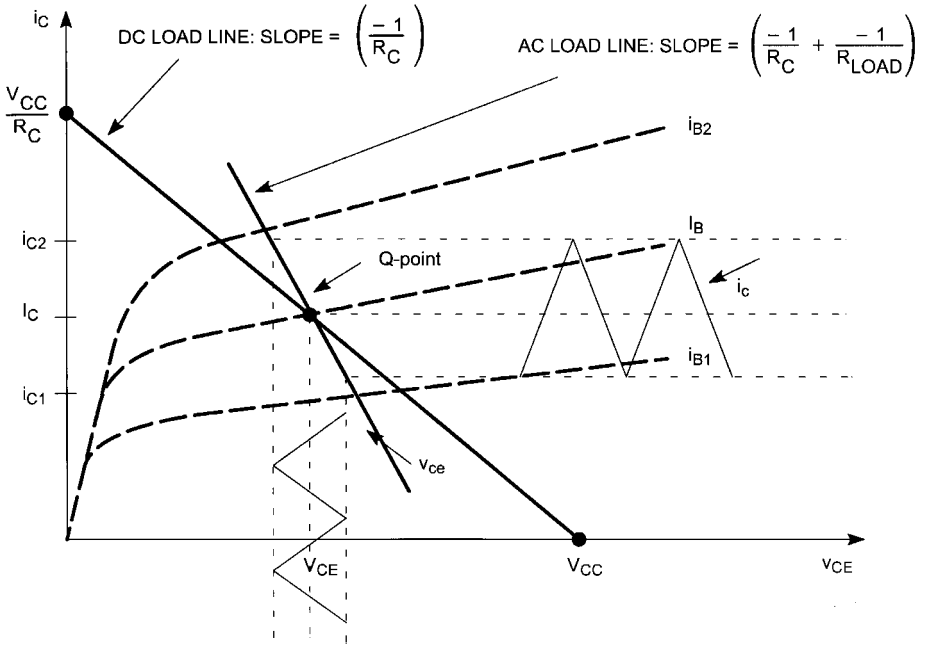

Figure 3-105 Graphical analysis for the circuitry in Figure 3-104. The ac load line intersects the Q point, and the slope is steeper than the dc load line due to R_{LOAD}, which makes V_{CE} smaller.

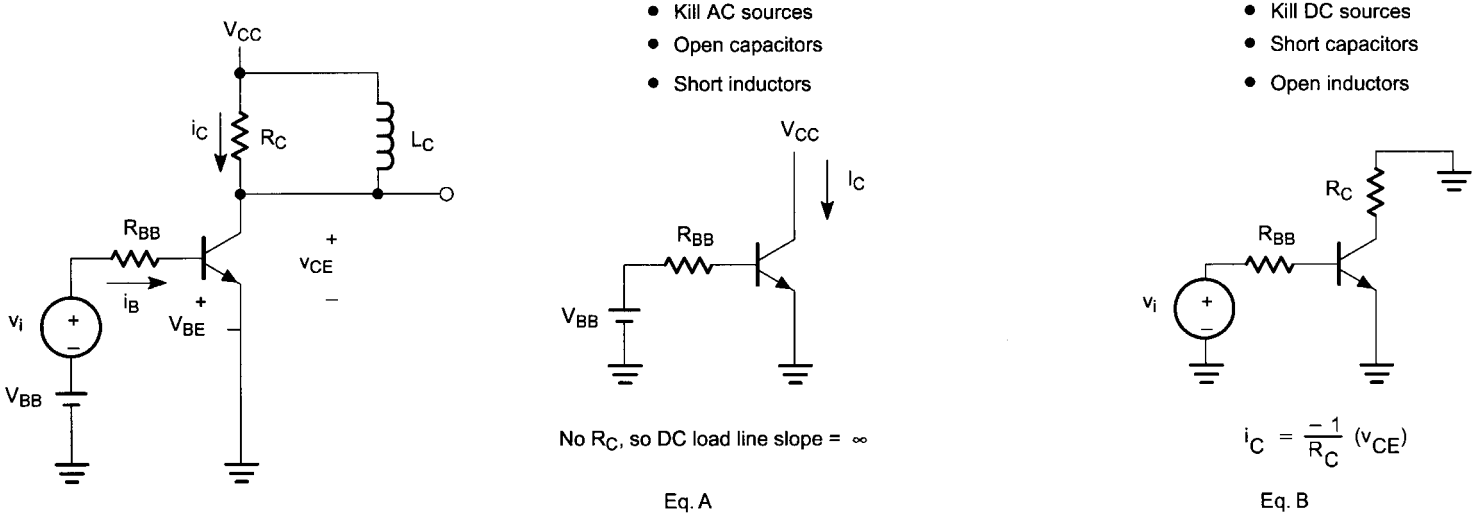

Figure 3-106 Basic transistor analysis with inductor added to collector.

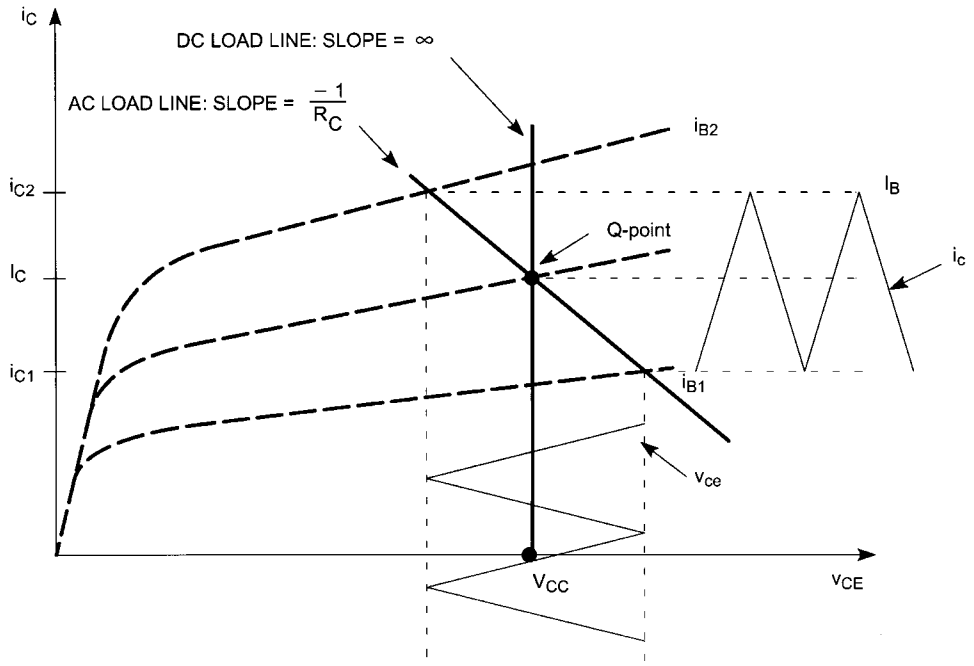

Figure 3-107 Graphical analysis for the circuitry in Figure 3-106.

Since the values of R_C and R_{LOAD} affect the ac load line slope, the value chosen is important. The higher the impedance of R_{LOAD} and R_C, the greater the ac output swing will be at the output, which means more conversion gain in a mixer. This is due to the slope getting flatter, thus allowing for more output swing.

Open Collector with Inductor (L_C). Adding an inductor in parallel with R_C can increase the ac output signal V_{CE}. Figure 3-106 shows the dc and ac analyses of this circuit configuration. In Eq. A in Figure 3-106, there is no R_C influence because the inductor acts like a short in the dc condition. This means the slope of the dc load is infinite and causes the Q-point to be centered around $V_{CC,}$ thus moving it to the right of the curve. The ac load line slope is set only by R_C because no load is present. Note that it has the same ac load line slope as the first condition in Eq. B of Figure 3-101.

Referring to Figure 3-107, one might notice that the base current (ac and dc) curves spread open as V_{CE} increases. This is caused by a noninfinite Early voltage (see Figure 3-108), which causes the collector current to be dependent on V_{CE}. Taking advantage of this nonideal condition, the peak-to-peak ac output swing V_{CE} can thereby be increased by moving the dc Q-point to the right due to the wider spreading between the curves corresponding to different base currents. Figure 3-109 combines Figures 3-103 and 3-107 to show the different ac output signals with different Q-points.

Looking at the ac output level, one might ask how the V_{CE} peak voltage can exceed the supply voltage V_{CC}. Recall that the inductor is an energy-storing device ($v = L\ di/dt$). Therefore, total instantaneous voltage is V_{CC} plus the voltage contribution of the inductor.

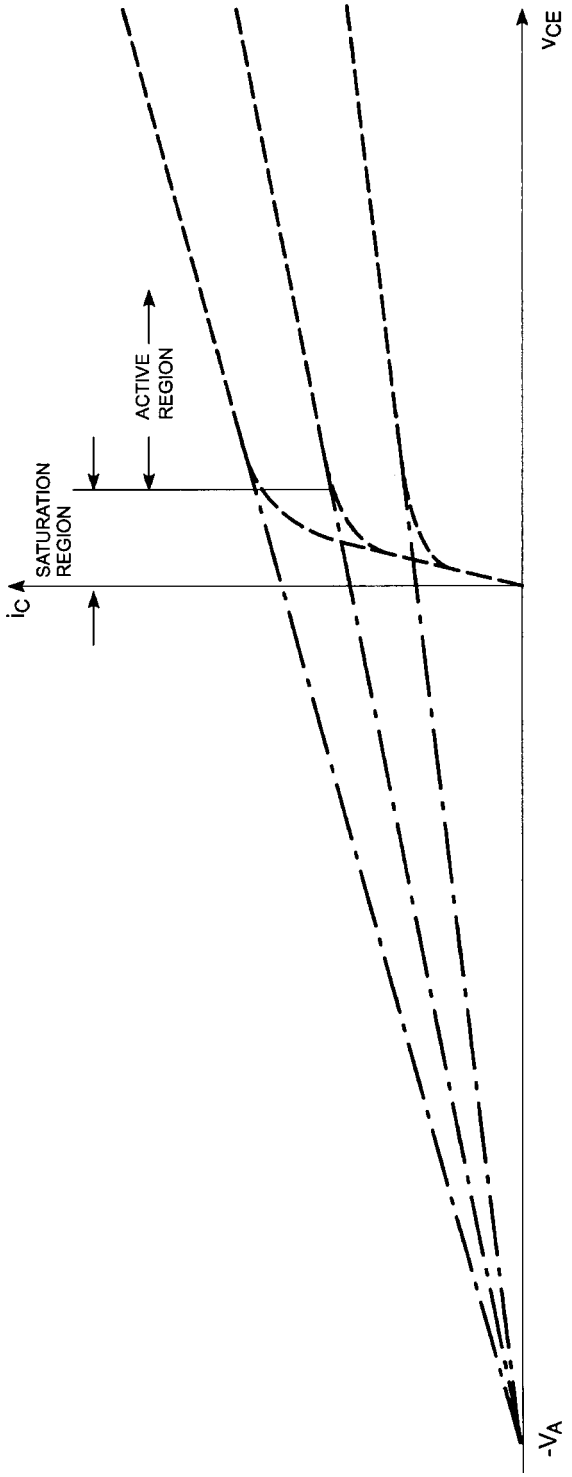

Figure 3-108 Graphical representation of Early voltage effect.

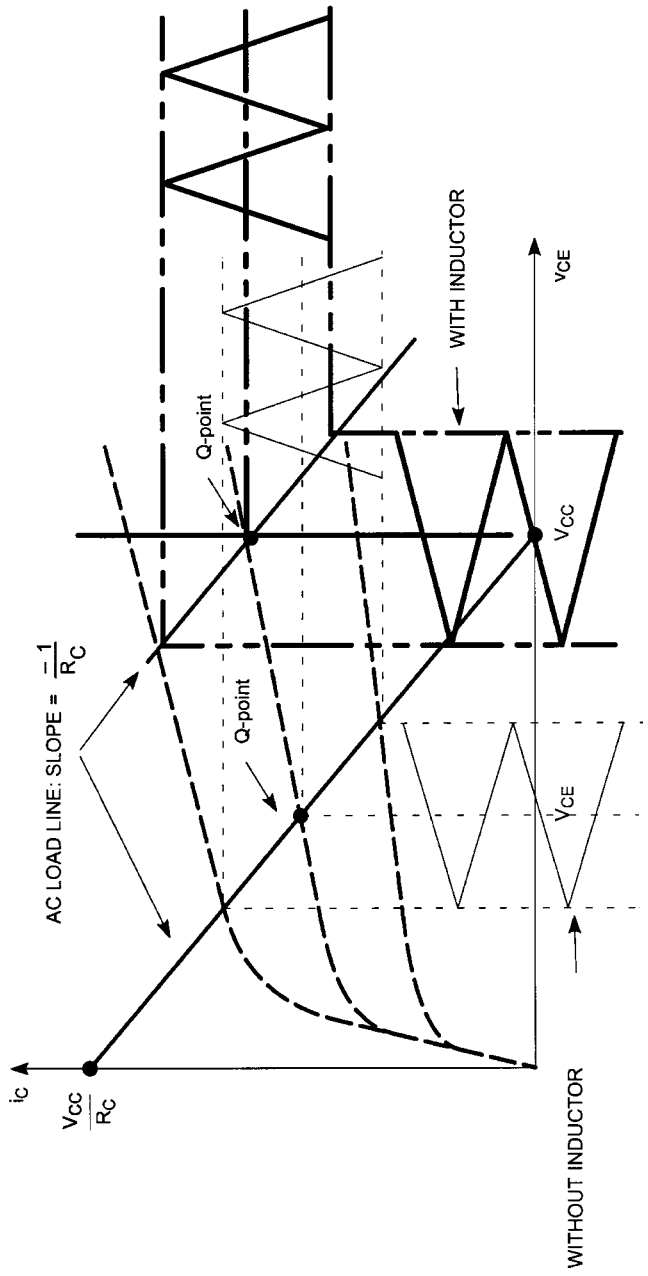

Figure 3-109 Comparison of open-collector circuit with inductor versus without inductor.

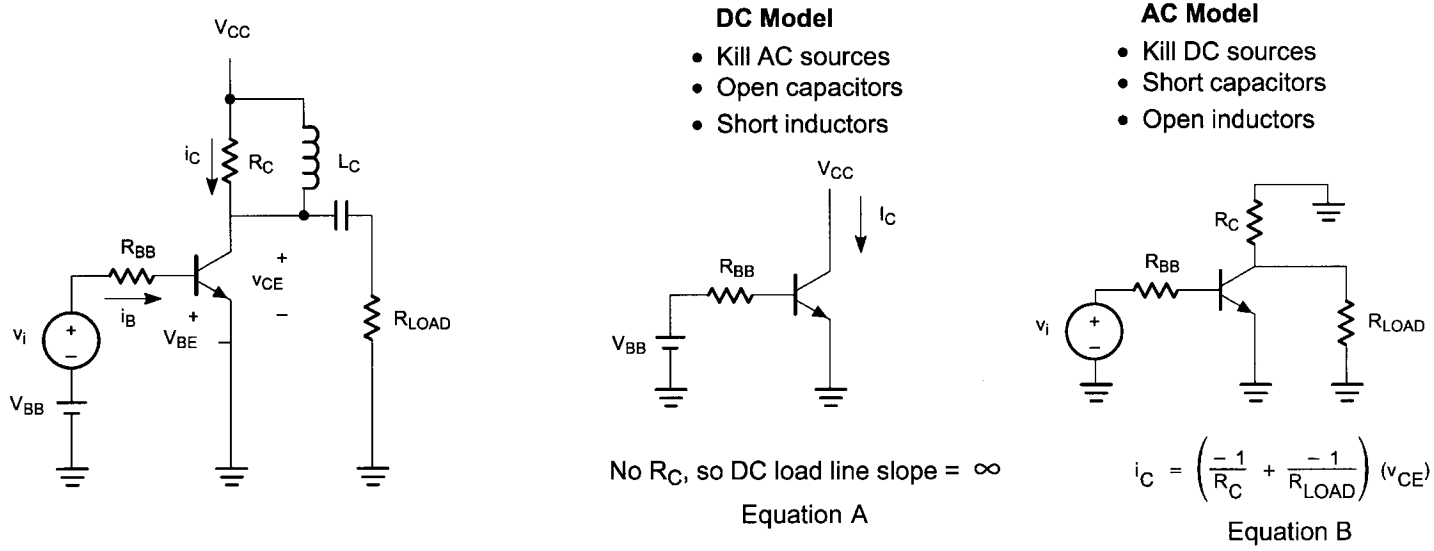

Figure 3-110 Basic transistor analysis with inductor and R_{LOAD}.

Open Collector with Inductor (L_C) and R_{LOAD}. Figure 3-110 shows the dc and ac analyses with the inductor and load resistor. Again, from the dc analysis, the inductor causes R_C to be nonexistent so the dc load line is vertical. In the ac analysis, the ac load line slope is influenced by both R_C and R_{LOAD} (see Eq. B in Figure 3-110). The ac load line slope is the same as the example of the open collector without the inductor. Figure 3-111 shows the response for the open collector with L_C and R_{LOAD}. Figure 3-112 combines Figures 3-105 and 3-111 showing the increase in ac output swing.

In conclusion, for the load line, R_C plays a role in setting up the bias-determined Q-point as well as the ac source impedance. However, when an inductor is placed in parallel with R_C, a different Q-point is set and the ac source impedance is altered. Moving the Q-point takes advantage of the transistor's nonideal i_c dependence on V_{CE} to get more signal output without having to change the base current. Since R_C is in parallel with R_{LOAD} in the ac condition, it influences the ac load line slope.

Flexible Matching Circuit [25]. A useful variation of the open-collector matching concepts previously outlined provided the capability of delivering equal power to two unequal resistive loads. This allows the power delivered to the load to be measured indirectly at another test point in the circuit where the impedance can be defined arbitrarily. If this impedance is defined to be 50 Ω, a spectrum analyzer can easily be placed directly into the circuit. This is an excellent troubleshooting technique and a valuable option to have available in high production environments.

Figure 3-113 shows the schematic for this flexible matching circuit. In this circuit, C_B functions only as a dc blocking capacitor and presents a negligible impedance at the frequency of interest. Recall from the previous open-collector matching discussions that,

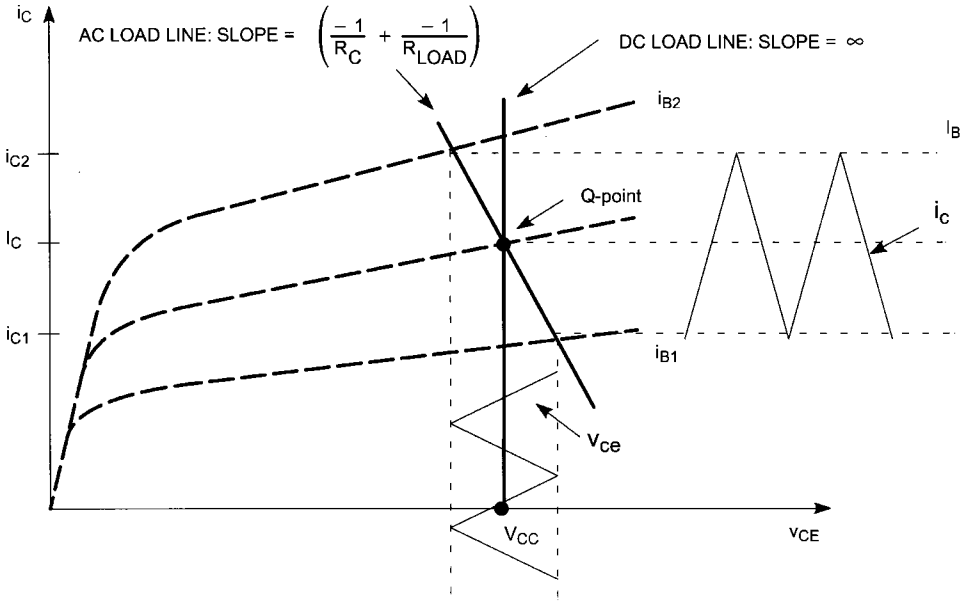

Figure 3-111 Graphical analysis for the circuitry in Figure 3-110.

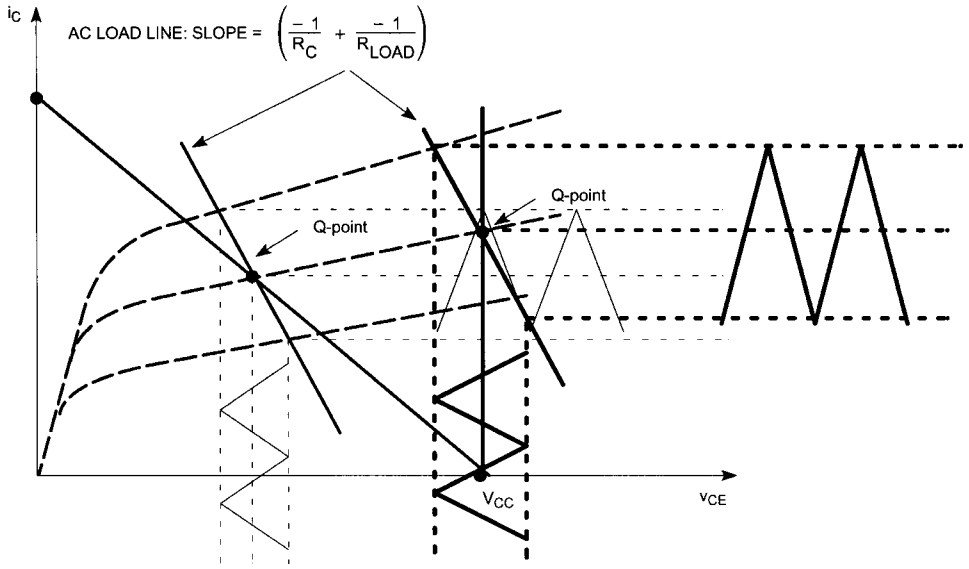

Figure 3-112 Comparison of open-collector R_{LOAD} circuit with inductor versus without inductor.

when R_C is placed in parallel with an inductor, it has no effect on the Q-point but does influence the slope of the ac load line as

$$\text{Slope} = \frac{-1}{R_C} + \frac{-1}{R_{\text{LOAD}}} \tag{3-166}$$

The capacitor C_S not only functions as a dc blocking capacitor but is also chosen such that the impedance presented by the combination of L, R_C, and C_S is equal to R_{LOAD} for optimum power transfer. The analysis is done in the following manner. First, note that inductor L is connected to V_{CC}, which is an affective ac ground. So L can be redrawn to ground. Next, R_C and C_S are converted to their parallel equivalent values as shown in Figure 3-114.

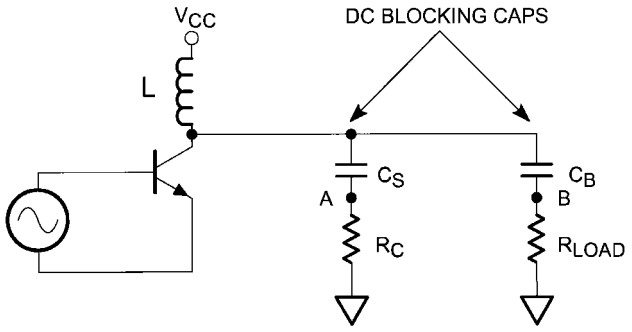

Figure 3-113 Flexible matching circuit.

Figure 3-114 Converting from series to parallel configuration.

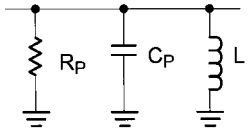

Figure 3-115 Converting from series to parallel configuration. Goal: Find L_C and C_p such that R_p looks like the R_{LOAD} value at the resonant frequency.

The resulting parallel *LCR* circuit is shown in Figure 3-115. At resonance, the parallel L–C_P combination will be an effective open circuit leaving only R_P. R_P is then simply chosen to be equal to R_{LOAD}.

Starting with the most simple transistor configuration and using *RC* types of dc-coupled amplifier circuits, we next present an overview of possible configurations for this application.

3-3 SINGLE-STAGE FEEDBACK AMPLIFIERS

This amplifier (Figure 3-116) is a standard minimal configuration amplifier with reduction of current distortion because of the emitter feedback. The voltage gain is

$$\text{VG} = \frac{R_L}{(26\text{mV})/I_C + R_e} \tag{3-167}$$

where R_L is the total load seen at the collector.

The feedback amplifier in Figure 3-117 uses voltage feedback to "correct" the input and output impedance to be close to 50 Ω but does not improve the current distortion. The voltage gain of this circuit is

$$\text{VG} = \frac{R_F}{R_g} \tag{3-168}$$

$$R_{\text{IN}} = R_{\text{OUT}}$$

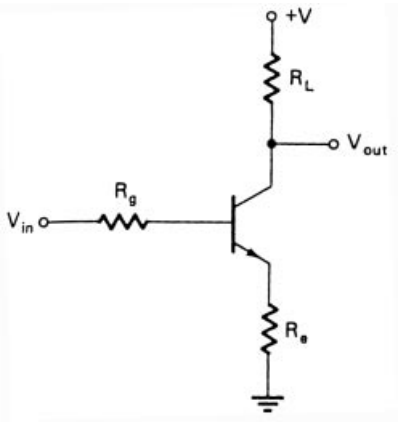

Figure 3-116 Single-stage amplifier with current feedback (provided by R_e).

$$= R_F R_D \quad \text{with} \quad R_D = \frac{26\text{mV}}{I_C} \tag{3-169}$$

Example. For $I_C = 10$ mA $\rightarrow R_D = 2.6\ \Omega$ and assuming $R_F = 200\ \Omega$, the input resistance $R_{\text{IN}} = 22.63\ \Omega$. The gain is calculated by getting the inverse of $R_D = g_m = 0.39$ A/V. Once this is multiplied with the output impedance of 22.63 Ω, the resulting gain becomes 10 log (8.6) or 9.3 dB. The gain can be increased by either using a larger collector current or a larger feedback resistor. It should be reminded that this circuit does not improve the distortion caused by the base–emitter junction.

To reduce the current distortion as well, we use the circuit shown in Figure 3-118, which contains both types of feedback. In reality, the collector–base resistor is frequently split into an unbypassed section responsible for the feedback and a larger resistor responsible for the appropriate biasing. The example circuit in Figure 3-119 shows this.

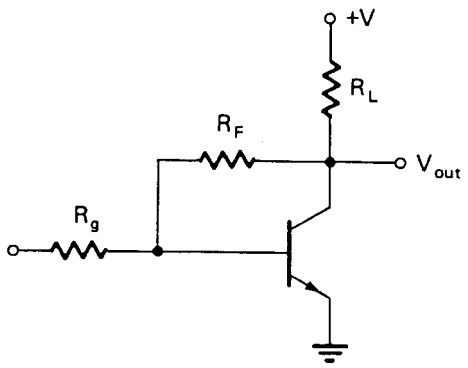

Figure 3-117 Single-stage amplifier with voltage feedback (provided by R_F).

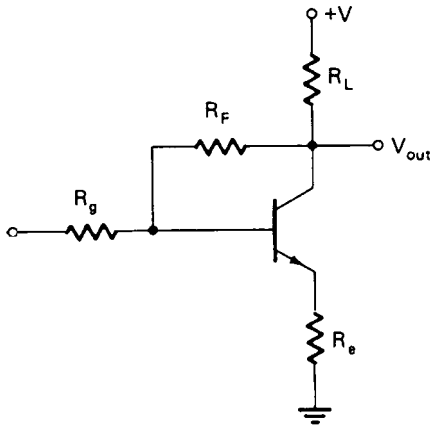

Figure 3-118 Single-stage amplifier with voltage and current feedback.

By using two of the fairly recent BFP420 transistors in parallel, and balancing the transistors by using the appropriate emitter resistors (which in total will result in 10 Ω) plus the bypassed value, we obtain the frequency-dependent gain, matching, and noise responses shown in Figure 3-120. To determine the appropriate feedback resistor R_F, we recommend the formula

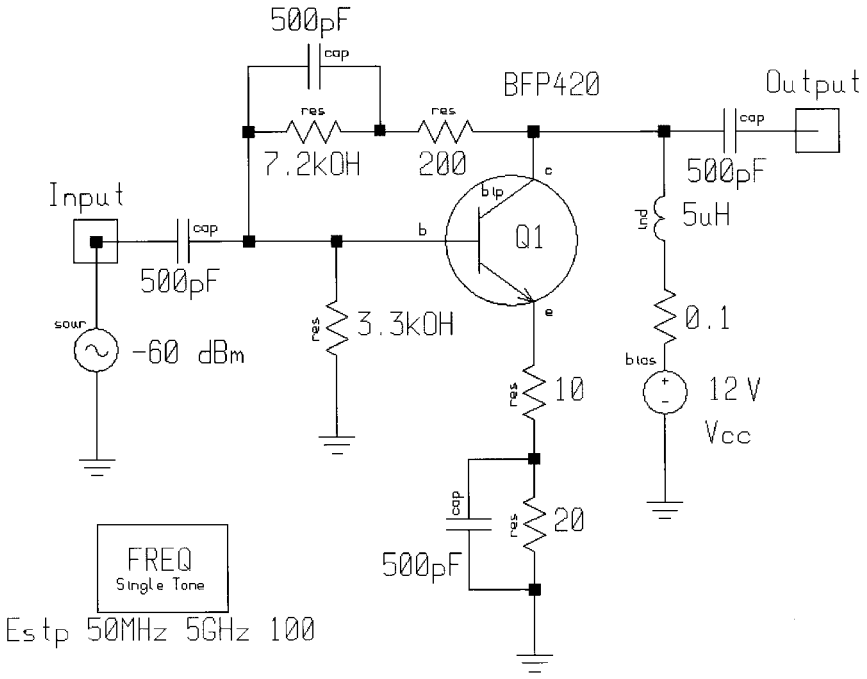

Figure 3-119 Practical amplifier circuit showing voltage and current feedback, and illustrating how reactances (in this case, 500-pF bypass capacitors) and multiple resistors can be used to provide different ac and dc resistances for the paths from collector to base and emitter to ground.

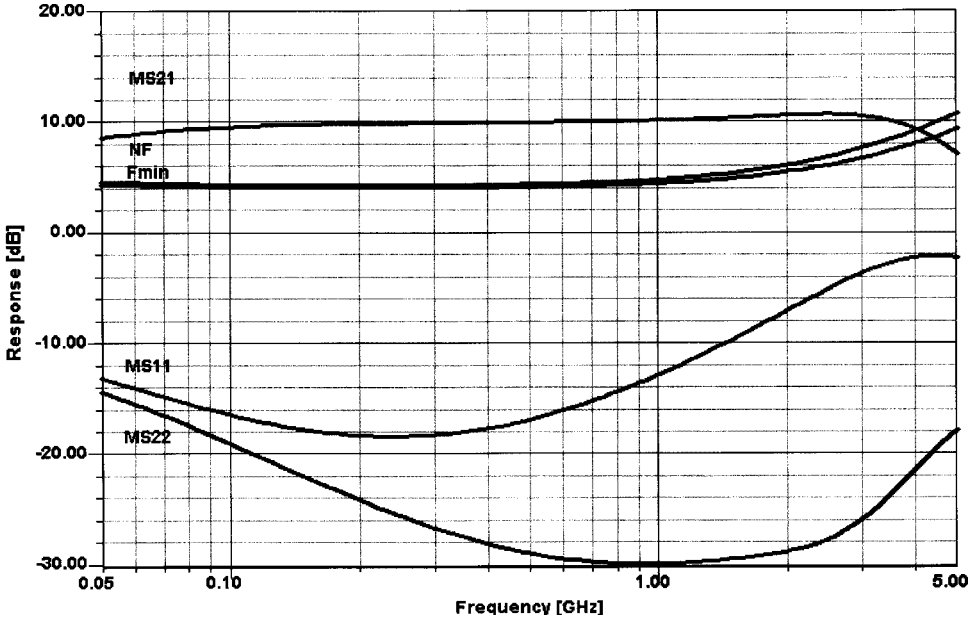

Figure 3-120 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-119.

$$R_F = \frac{(Z_{\text{in}}\, Z_{\text{out}})}{R_E} \tag{3-170}$$

This equation requires some additional comments. The combined shunt and series feedback only work as long as a sufficient transconductance is provided. In other words, there must be enough open-loop gain that will be reduced to obtain more bandwidth. A necessary condition for this approach, which really comes from the frequency range of less than 30 MHz, is that

$$Z_{\text{in}} = \frac{26\ \text{mV}}{I_C}\,\beta >> R_F \tag{3-171}$$

This requires a minimum transconductance of

$$g_m = \frac{1 + S_{21}}{Z_{\text{in}}} \tag{3-172}$$

where S_{21} must be a negative number that reflects the 180° phase shift. Of course, life becomes interesting when S_{21} goes through 1, but it (hopefully) never becomes negative and larger than 1 at the same time.

Example. The BFP420 has been used here frequently. A 10-dB gain would require an S_{21} of 3.16 ($\sqrt{10}$); therefore, we need to inspect the datasheet, which shows that the magnitude

of S_{21} is 3.16 around 4.5 GHz, yet the phase shift has changed from 180° to around 20°. In order to design an amplifier, we now set

$$R_F = Z_{\text{in}}(1 + |S_{21}|) \tag{3-173}$$

which is valid until S_{21} becomes too small. For a given 10 dB or 3.16 for S_{21}, the resulting RF is 4.16×50, or 208 Ω. The transconductance under these conditions becomes

$$g_m = \frac{1 + |S_{21}|}{Z_0} \tag{3-174}$$

where $Z_0 = 50$ Ω (the desired input impedance). g_m now becomes 83.2 mS. We now test the input and find

$$\frac{\beta}{g_m} = Z_{\text{in}} = \frac{50}{0.0832} = 600\ \Omega \tag{3-175}$$

Therefore, the emitter feedback resistor is not necessary to meet the previously mentioned condition whereby the input impedance needs to be higher than RF. Assuming the transconductance now is 0.00832, or 10% of the previous value, the input impedance would be 60 Ω, no longer meeting the prescribed requirement. Therefore, we need an unbypassed emitter resistor that fulfills the equation

$$R_E = \frac{Z_0^2}{R_F} - \frac{1}{g_{m_{\text{dc}}}} \tag{3-176}$$

where

$$g_{m_{\text{dc}}} = \frac{1 - S_{21_{\text{max}}}}{Z_0} \tag{3-177}$$

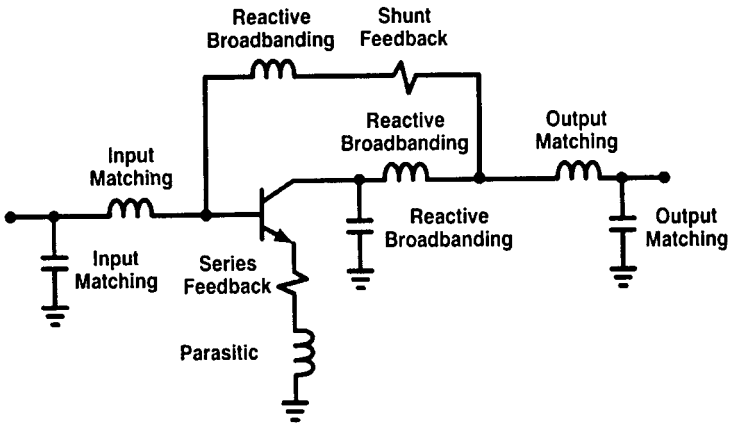

Figure 3-121 Elements of a feedback amplifier.

Again, the reader should be cautioned that in the common-emitter circuit, there is a 180° phase shift, and therefore $S_{21_{\max}}$ is a negative quantity, resulting in reality in

$$g_{m_{\text{dc}}} = \frac{1 + S_{21_{\max}}}{Z_0}$$

In our case,

$$g_{m_{\text{dc}}} = \frac{-S_{21}}{2Z_0} = \frac{38}{2 \times 50} = \frac{38}{100} = 0.38$$

so

$$R_E = \frac{50^2}{208} - \frac{1}{0.38} = 12 - 2.6 = 9.4\ \Omega \tag{3-178}$$

In practice, the designer would use a 10-Ω resistor.

Since the gain of the transistor continues to fall as a function of frequency, one can compensate to a degree for the cutoff frequency by putting an inductance in series that follows the equation

$$L_F = \frac{R_F}{2\pi f_{3\text{dB}}} \tag{3-179}$$

Assuming $f_{3\text{dB}}$ = 2 GHz, the resulting series inductance L_F = 16.6 nH. Basically, the same applies to circuits where the second transistor is used as an emitter follower to feed the signal back from the collector to the base of the first transistor.

In summary (see Figure 3-121):

- Resistive negative feedback at lower frequencies reduces open-loop gain and simultaneously matches input and output.
- Reactive elements set the gain and matching at high frequencies. Feedback is reduced at high frequencies.
- Emitter bypass capacitors are not used, as they would destroy the impedance match.

This is equally valid for FETs.

The next level of complexity can be reached by using two transistors with dc feedback.

3-3-1 Lossless or Noiseless Feedback

All the amplifiers shown above are based on a combination of resistive and reactive feedback. The very moment resistive feedback is used, the noise figure increases, as does the intercept point. As long as the intercept point increases overproportionally compared to the noise figure, this is an acceptable method. However, there are many cases in which an extremely low noise figure and a higher than normally achievable intercept point are required. To avoid this degradation of performance, Norton of Anzac developed a negative feedback structure based on the capabilities of the ferrite transformer. This patented technique (U.S. Patent Nos. 3,624,536 and 3,891,934, since expired), known as *lossless feedback*, provides lower noise figure and higher linear output than can be achieved using resistive feedback with the same transistor. Transformer feedback is used in which the transformer in the feedback network acts as a directional coupler. The coupling ratio between the input and output of the coupler

determines the magnitude of the feedback, and hence the gain. Across the frequency band over which the transformer operates as intended, the feedback is negative due to the in-phase coupling and the inversion of the active device.

This technique was used in amplifiers ranging from 5 to 500 MHz, 20 to 1000 MHz, and 300 to 1800 MHz. The difficulty associated with this type of amplifier is the fact that it is based on transformers that use twisted pairs of wires as transmission lines. In some implementations used at higher frequencies, actual directional couplers were used at the expense of bandwidth; in these circuits, the coupling was determined by the spacing of the coupler lines rather than transformer turns ratio. These microstrip couplers have much narrower bandwidths than transformers and are fairly large.

Another headache with the lossless feedback design is the fact that many of these transistor configurations are used in either grounded-base or grounded-emitter with transistors that have f_T values of 25 GHz and higher. Such devices are very hot, and achieving freedom from oscillation over a wide frequency range is a continuing problem, even for the circuits we have shown so far. A similar clever technique has been implemented in the termination-insensitive mixer, which we will examine in Chapter 4.

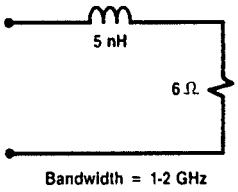
3-3-2 Broadband Matching

The circuitry above has enabled us to extend the frequency range of the amplifier and avoid the normal sharp cutoff. According to Fano [26], there is a limit to the bandwidth of matching. The concept is that impedance plus bandwidth determines the ability to match, since there is a Q of the circuit and there is a Q of the device. The following equations are valid:

$$|\rho_{\text{Bode}}| = e^{-(\pi Q_T / Q_{BP})} \tag{3-180}$$

$$Q_T = \frac{\sqrt{f_1 f_2}}{f_2 - f_1} \tag{3-181}$$

$$Q_{BP} = \frac{\text{Im}(Z)}{\text{Re}(Z)} = \frac{X_s}{R_s} \tag{3-182}$$



$$Q_{BP} = \frac{2\pi\sqrt{(2\text{ GHz})(1\text{ GHz})(5\text{ nH})}}{6\,\Omega} = 7.40$$

$$Q_T = \frac{\sqrt{(2\text{ GHz})(1\text{ GHz})}}{(2\text{ GHz} - 1\text{ GHz})} = 1.414$$

$$|\rho_{\text{Bode}}| = e^{-\left(\frac{\pi(1.414)}{7.40}\right)} = .549$$

$$\text{VSWR}_{\text{Bode}} = \frac{1 + .549}{1 - .549} = 3.43 : 1$$

Figure 3-122 Broadband matching example showing the Bode limit.

Figure 3-122 shows an example. This combination results in a VSWR of 3.43, which for practical purposes is already too high. The workaround is special circuitry (such as exponentially staggered impedance jumps in the matching network like 50 Ω > 20 Ω > 7 Ω > 3 Ω). This means we first transform the 50-Ω source of load impedance down to 3 Ω, and then look for a matching network that matches the transistor output/input, which is within a few ohms of 3 Ω. A detailed discussion of such matching can be found in the "Numerical Design" portion of Section 3-12-2 under the title "Broadband Matching Using Bandpass-Filter Networks—High-Q Case."

3-4 TWO-STAGE AMPLIFIERS

There are two popular configurations that have been used mostly for low-frequency applications. The first one (Figure 3-123, implemented in the circuit shown in Figure 3-124) shows a nice high-frequency performance assuming the emitter and collector currents are essentially the same. As for distortion products, this circuit behaves equivalently to the shunt impedance example from Figures 3-118 and 3-119, with the additional gain of the second transistor. Its frequency matching and noise performance are also shown, in Figure 3-125.

The next two-stage circuit (Figure 3-126, implemented in Figure 3-127) uses the collector current of the second stage as the feedback to the first. Proper biasing of this circuit is quite difficult and interactive. Figure 3-128 shows the frequency-dependent gain, matching, and noise figure. We believe that this circuit can be optimized further, but we leave such investigations to the reader.

A *cascode* amplifier is a special form of two-stage circuit. Although a cascaded pair acts like a single transistor, its merits are in its reduced feedback and resulting higher gain–bandwidth product. Figure 3-129 shows a simple cascode application that assumes the presence

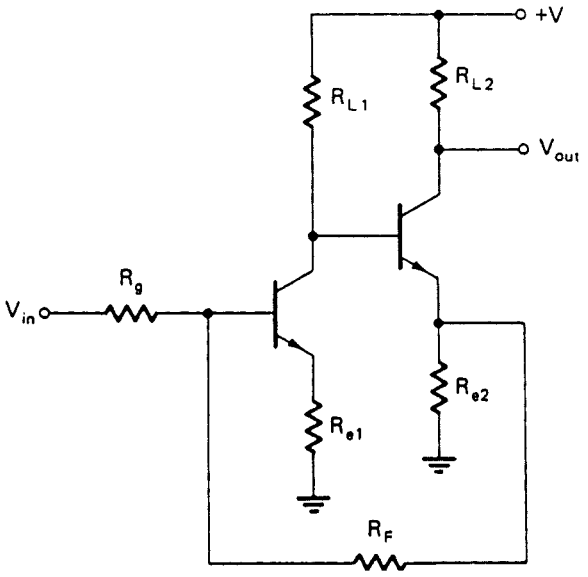


Figure 3-123 Two-stage amplifier with voltage feedback.

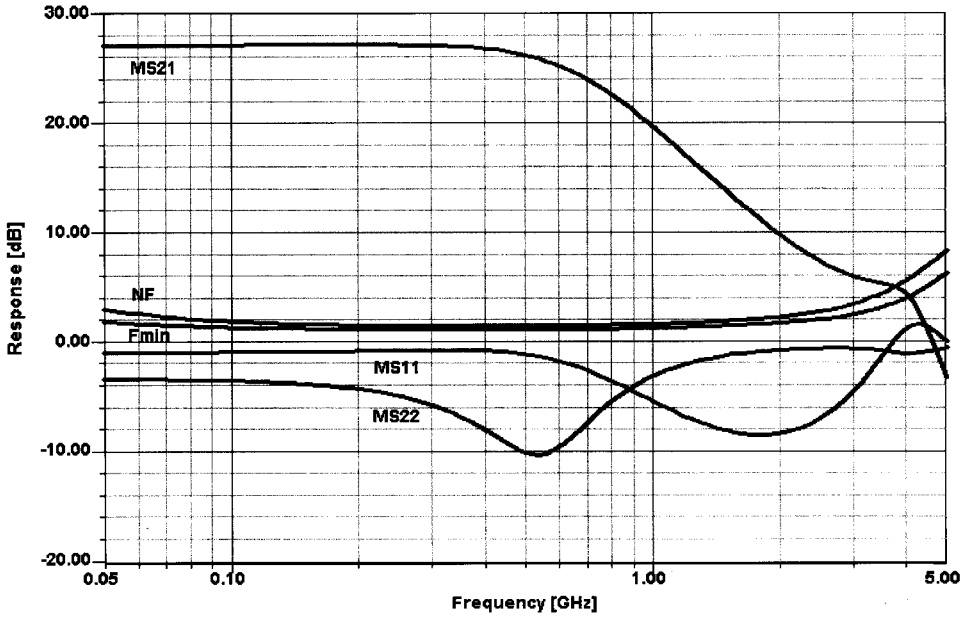

Figure 3-128 Gain, matching, and noise performance of the amplifier in Figure 3-127.

of an output transformer that absorbs the output capacitance. Figure 3-130 shows this circuit's frequency-dependent gain, matching, and noise performance.

It has been obvious to us that most published wireless application circuits are evaluated on a no-input-selectivity basis; that is, their reported performance does not take into account the filtering that is usually present in practical implementations. Evaluated in this way, a low-noise design may achieve a noise figure of less than 2 dB—1.2 dB or so is typical—but this is misleading because filters and connectors introduce insertion loss, resulting in a higher noise figure.

The cascode is a nice preamplifier combination. It combines (depending on the transistor) a low noise figure with essentially no feedback. Since the output of a grounded-base transistor provides a high-impedance source, this configuration is ideal to work into the SAW filters frequently used in wireless applications at the operating frequency. Special transistor pairs are available for use in cascode; as can be seen from this example, not every transistor combination is ideal. This one gives a higher noise figure than wanted and at frequencies above 2 GHz it tends to show possible instabilities. Both Siemens and Motorola are now offering transistors appropriate for these cascodes. Mostly, one would resort to transistors of less-exotic cutoff frequencies to guarantee stability. Typically, grounded-base/gate transistors tend to become oscillators, specifically because this configuration, like the emitter follower, allows a higher operating frequency while maintaining the same gain–bandwidth product; the actual gain for the last two circuit configurations is less. A grounded-base/gate stage has a high voltage gain and the emitter/source follower has power gain at low impedance levels. We invite our readers to experiment with the capacitor from the base of Q1 to ground in Figure 3-129 to get an interesting education about these transistors and their willingness to oscillate.

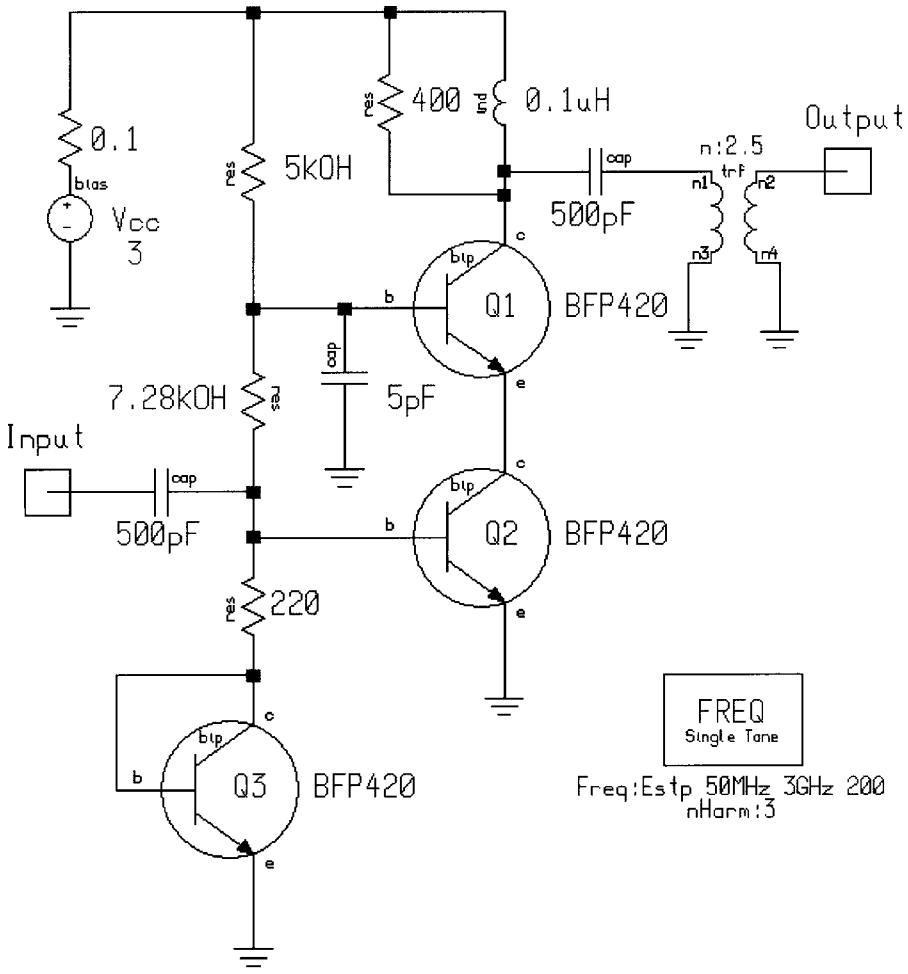

Figure 3-129 Schematic of the cascode amplifier.

The MC13144 is an example of a commercially available VHF to 2-GHz low-noise amplifier with programmable bias. As can be seen from Table 3-11, it is ideal for the 900-MHz range and its programmable gain/bias makes it very attractive. This design (Figure 3-131) is based on the cascode mentioned above and, because of high integration, uses many transistors for bias and level shifting.

The 900-MHz application circuit in Figure 3-132 shows the required external components for a successful design. Input and output are made tunable. The 5.6- and 39-nH inductances can be made from small air-wound coils. The output ceramic filter provides the necessary selectivity ahead of the mixer. With such a highly selective device in the input, the noise figure would deteriorate too much. The antenna is rarely in the vicinity of sufficiently strong transmitters to require such strong input filtering.

There are two more interesting applications for two-stage amplifiers: The one implemented in the Hewlett-Packard MSA-0735 MMIC has become a quite common one, and its usefulness up to higher frequencies depends mostly on the cutoff frequency of the transistors,

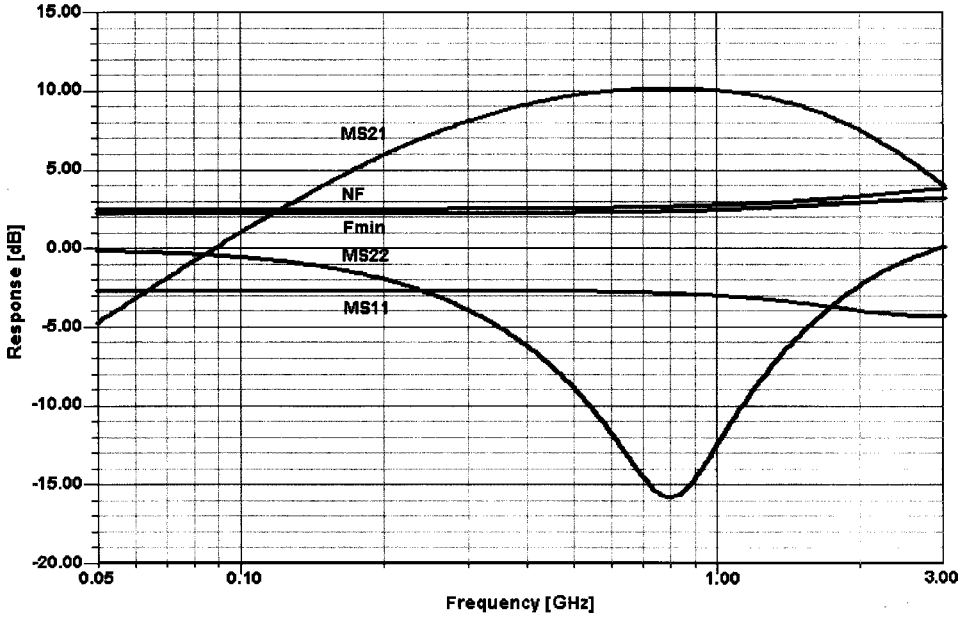

Figure 3-130 Frequency-dependent gain, matching, and noise performance of the cascode amplifier.

their parasitics, and the phase shift of the gain. The typical configuration is shown in Figure 3-133, and its frequency-dependent gain, match, and noise figure in Figure 3-134. There is an increase of S_{22} at higher frequencies; this indicates unwanted phase shift in the circuit. Some manufacturers hide the compensation circuits to overcome such peaking; most of the schematics shown by the manufacturers are really intended only to show operating principles, with proprietary details omitted.

Thanks to the properties of GaAs transistors, we can extend the frequency range significantly. The amplifier we are about to look at goes back several years and is described in great detail in Goyal [27]. Essentially what we have, seen in Figure 3-135, is an FET version of Figure 3-127. The main goal of this circuit was to have an all-monolithic circuit, avoiding all ac coupling and accomplishing all matching and interaction with dc coupling. The transistor Q1 is the main gain stage, which has the transistor Q2 as an active load. The output impedance of Q2 is $1/g_m$—typically in the area of 50–200 Ω, depending on the biasing,

Table 3-11 MC13144 features

Gain at 900 MHz, 17 dB
Noise figure at 900 MHz, 1.4 dB
P_{-1dB}, −7.0 dBm
$IP_{3,in}$, −5.0 dBm
Low operating supply voltage (1.8–6.0 Vdc)
Programmable bias with Enable 1 and Enable 2. [Enable 1 and Enable 2 programmed high for optimal noise figure and gain associated with NF. Enable can be overridden for external bias programming (up to 15 mA.)]

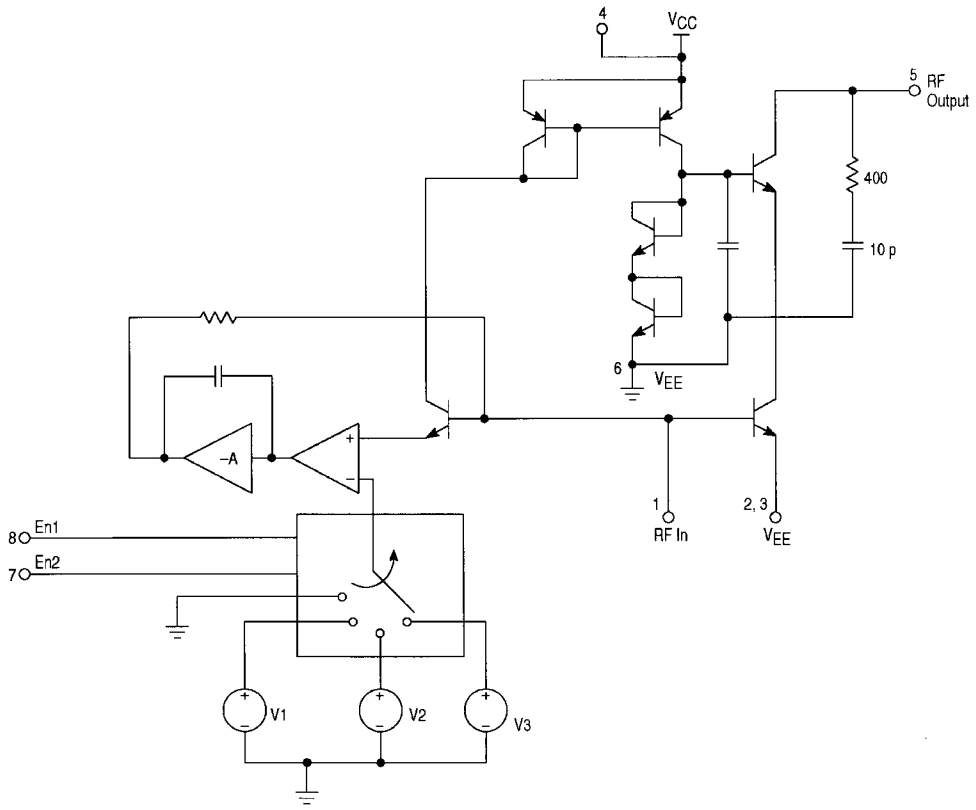

Figure 3-131 Schematic of the Motorola MC13144 cascode LNA.

which affects the transconductance. Transistor Q3 has the same function as an emitter/source follower; again, its dc bias determines its transconductance and therefore its output impedance. (Given this, a device that has a transconductance of 20 mS, or close to it, would establish a very good output match to 50 Ω.) The drains of Q1 and Q5 are at approximately 3.5 V. The diodes at the source of Q3 are level shifters that must shift the dc voltage at the gate of Q5 and at the drain of Q4 to approximately −1.5 V relative to ground—the necessary bias condition for Q1 and Q5. The standard shunt feedback circuit would show resistive feedback between the drain of Q1 (gate of Q2) and the gate of Q1; in the previous examples, we calculated the magic value of this part to be about 200 Ω. Adding in parallel to Q1 the transistor Q5 allows the designer to use a feedback scheme that isolates the feedback loop from the input. Dc-wise, the two transistors are tied together via a 10-kΩ resistor, which can be included in the actual packaged device. Insufficient information was published to allow us to duplicate the design, considering all the intricacies involved (we somewhat object to the fact that even in the *IEEE MTT-S Transactions*, so little information is given about the actual implementation of this design—using space constraints as an excuse—that its educational value is usually minimal); it shows a new principle without revealing the design steps necessary to obtain a practical circuit. Several variations of this type of circuit are available; the literature is full of discussions about them. The magnitude of the feedback is set by the ratio of the width of Q5 to that of Q1. Typical values for the Q5/Q1 ratio range

from 0.15 to 0.30. In simulation, sizing the devices can best be accomplished by using the scaling factor for the FET model.

One of our questions was: "What would the perfect input termination for Q1 be?" By using an ideal transformer and playing with its turns ratio (needless to say, we did this with CAD), we determined experimentally that, relative to the gate, 200 Ω and a series inductor of 5–8 nH—the sort of details that designers often avoid telling their audiences—gave the ideal frequency response. Overall, we believe that the inventor of this circuit can be quite proud of the overall performance. The FETs we chose were taken from the Texas Instruments nonlinear foundry library; however, any similar device from another company would have worked equally well. The feedback loop used in this IC is an example of an approach frequently referred to as *active feedback*. The performance of this amplifier can be evaluated from Figure 3-136, which shows the frequency-dependent gain, matching, and noise figures (even including F_{min}).

3-5 AMPLIFIERS WITH THREE OR MORE STAGES

Most three-stage amplifiers are obtained by adding another buffer or power-gain stage to the previously described principal designs. As an example, we decided to evaluate the recent NEC UPC2749 IC, a silicon MMIC intended for application as a low-noise 1900-MHz amplifier operating at 3 V. Table 3-12 briefly summarizes its electrical specifications.

Table 3-12 NEC UPC2749 electrical characteristics

(T_A = 25 °C, $Z_L = Z_S$ = 50 Ω, V_{CC} = 3.0 V)			
	Part Number Package Outline		UPC2749T TO6
Symbols	Parameters and Conditions	Units	Typical
I_{CC}	Circuit current (no signal)	mA	6
G_S	Small-signal gain, f = 900 MHz dB	14.5	
	f = 1900 MHz	dB	16
f_{corner}	–3-dB Gain corner frequency	GHz	2.9
P_{1dB}	1 dB Compressed output power at 1900 MHz	dBm	–12.5
P_{SAT}	Saturated output power, f = 1900 MHz	dBm	–6
NF	Noise figure, f = 900 MHz	dB	3.2
	f = 1900 MHz	dB	4.0
RL_{IN}	Input return loss, f = 1900 MHz	dB	10
RL_{OUT}	Output return loss, f = 1900 MHz	dB	12.5
ISOL	Isolation, f = 1900 MHz	dB	30
OIP_3	SSB output third-order intercept, f_1 = 500 MHz, f_2 = 510 MHz	dBm	–3
	f_1 = 1000 MHz, f_2 = 1010 MHz	dBm	–3
	f_1 = 1900 MHz, f_2 = 1902 MHz	dBm	–3.5
	f_1 = 2000 MHz, f_2 = 2010 MHz	dBm	–4
$R_{TH(J-A)}$	Thermal resistance (junction to ambient)		
	Free air	°C/W	
	Mounted on a 50 × 50 × 1.6 mm epoxy glass PWB	°C/W	

In modeling the UPC2749's three transistors, we chose to use our favorite, the BFP420, which is not without its headaches at the higher frequencies. Figure 3-137 shows the circuit diagram, which closely resembles the one published by NEC; again, the only hard facts we had were the IC's basic circuit topology, gain, and dc current. Given those numbers, we staggered the current in the three devices by setting them at 0.64 mA for the first stage, 1.85 mA for the second stage, and 3 mA for the third stage. It should be noted that the two output transistors are not unlike the approach used for the Hewlett-Packard MSA-0735 (Figure 3-133). Taking (hopefully) all the right assumptions, we end up with a design that closely resembles the manufacturer's specifications for both power consumption, gain, and noise. This can be verified by looking at the results plotted in Figure 3-138.

The final example is a more complex derivative of the Philips NE/SA5204A amplifier, which was intended for standard 6-V operation and has a fairly "normal" circuit arrangement. This can be seen from Figure 3-139. A much more elaborate cousin of this is the low-voltage NEC UPC2710 amplifier. According to its specifications, it operates at 5 V but has significantly more gain than the NE/SA5204. Table 3-13 shows its electrical specifications and Figure 3-140 shows its measured gain as published by the manufacturer.

The actual interior of the circuit is shown in Figure 3-141. It consists of the standard preamplifier and then a Darlington configuration with the collectors tied together. The middle section of the circuit acts as a power supply responsible for the bias relative to the emitter of the first transistor influencing the rest of the circuit as well. Since NEC mentioned that they use their NESAT III process (f_T of 20 GHz at V_{ce} = 3) in producing the UPC2710T and we

R_{TH}	Thermal resistance (junction to ambient)	°C/W	

obtained some information regarding it, we decided to use our standard BFP420 (f_T of 25 GHz; see the datasheet in Chapter 2) for the purpose of simulation.

In our effort to simulate this circuit, we chose a combination of values that pretty much complies with the manufacturer's published specifications, but S_{22} is not close, as shown in Figure 3-142. We stopped at this point and invite our readers with CAD capabilities to provide the final touch in meeting all the published specifications for the circuit. We are particularly

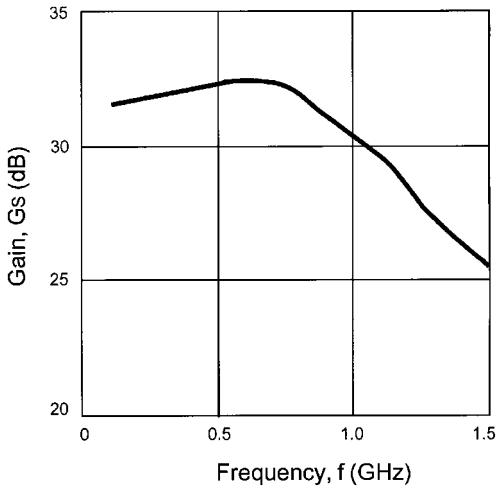

Figure 3-140 Manufacturer-supplied gain versus frequency for the NEC UPC2710T MMIC.

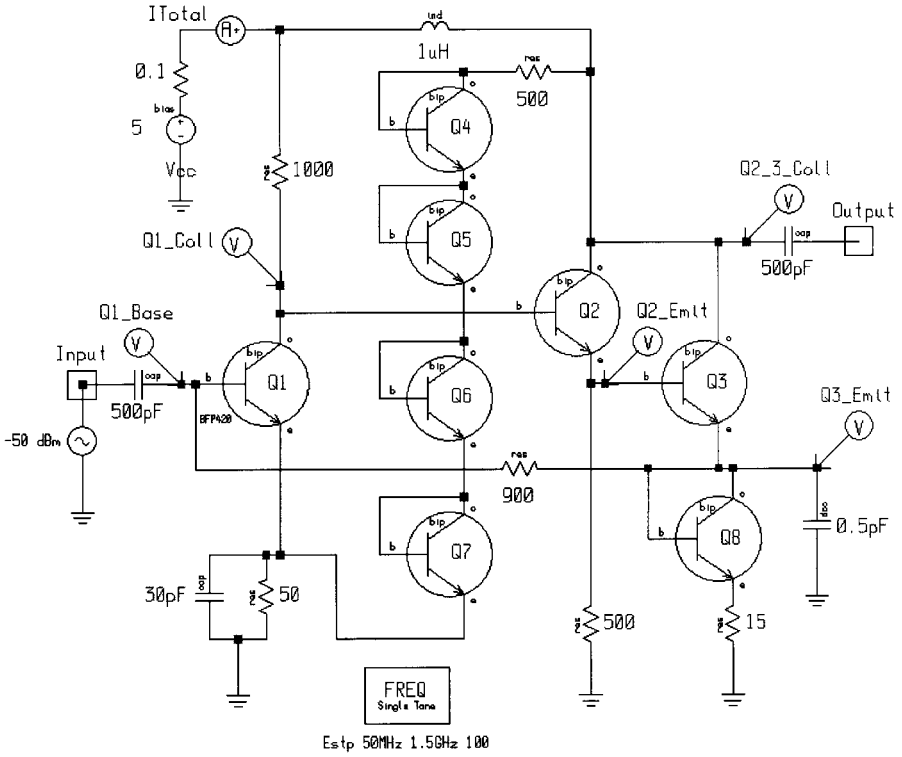

Figure 3-141 Schematic of the UPC2710T silicon MMIC entered for simulation.

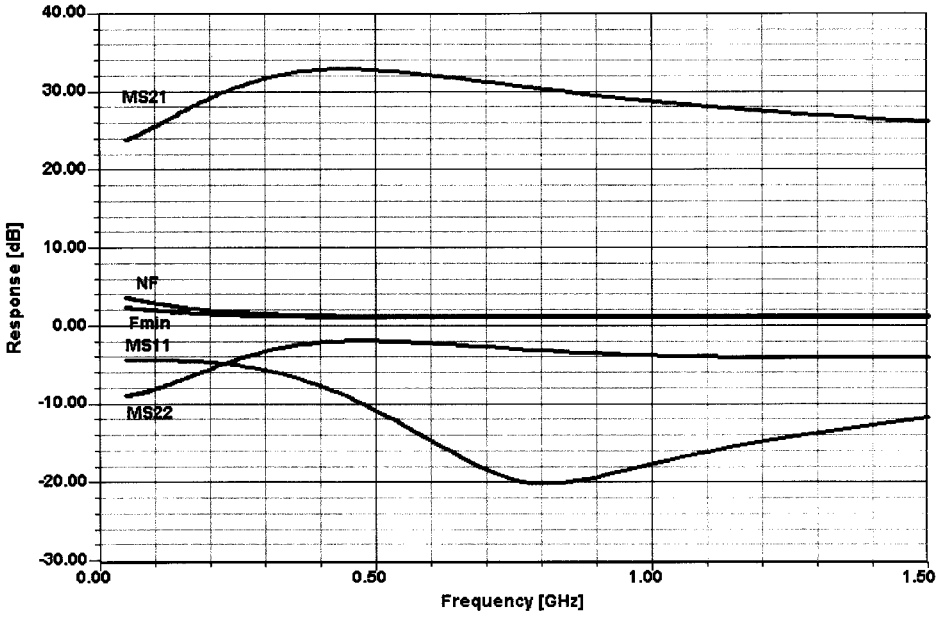

Figure 3-142 Simulated gain, match, and noise performance of the UPC2710T.

recommending such an effort because it shows very nicely the interaction of all the circuit elements in a fairly drastic way. Because of this, we admire the IC design even more, since the manufacturer has to sell a pretty consistent amplifier as a function of different production runs.

3-5-1 Stability of Multistage Amplifiers

Stability, needless to say, is a big issue, and the delay of the various stages adds to the phase shift, resulting in possible instabilities. The fact that S_{11} and/or S_{22} can become larger than 0 (in dB) means there is the potential of oscillating, depending on the reactances available. If a cable of inappropriate length is added, hell will break loose. Figure 3-143 shows the dangerous peaking of our simulation of the Philips NE5204A, in which the internal compensation was intentionally not assumed correctly. We will all agree that the high-end performance of this amplifier can generate high anxiety. As the production process of the aging device becomes more modern—meaning that transistors with much higher f_T will be the basis for the production—it will become quite difficult to maintain a previously achieved stability. This, by the way, applies also to discrete transistors, which for reasons of economics and multiple manufacturers will be improved over time. Such evolution results in generally smaller base-spreading resistances and capacitances, and other parameter changes, which, overall, cause headaches in manufacturing. We will leave the topic of three-stage amplifiers on this note.

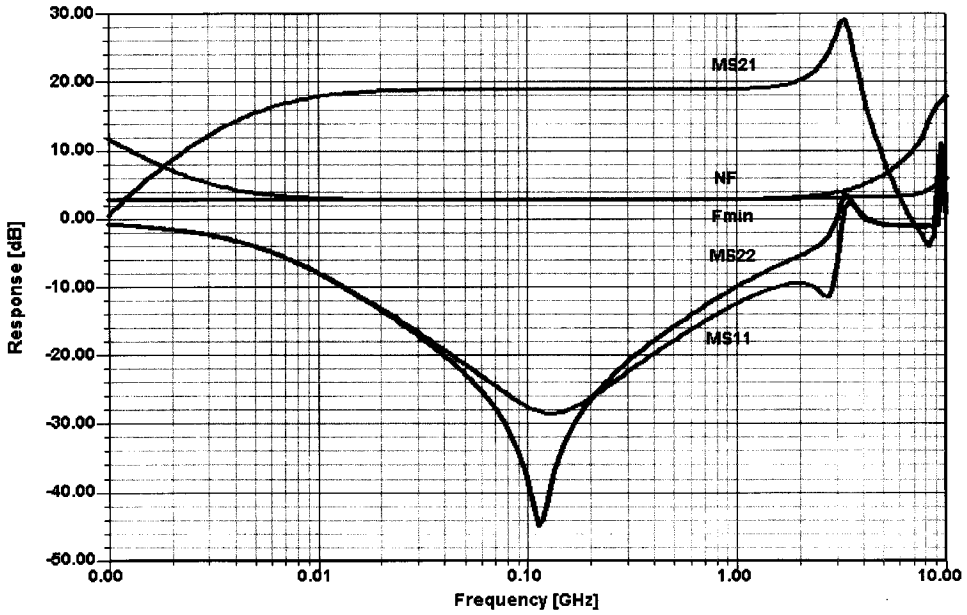

Figure 3-143 Simulated gain, match, and noise performance of the NE5204A IC.

3-6 A NOVEL APPROACH TO VOLTAGE-CONTROLLED TUNED FILTERS INCLUDING CAD VALIDATION [28]

Modern receivers control input stages as well as the oscillator band and frequency by electrical rather than mechanical means. Tuning is accomplished by voltage-sensitive capacitors (varactor diodes), and band switching by diodes with low forward conductance. Since the wireless band (essentially 400 MHz to 2.4 GHz) is so full of strong signals, the use of a tracking filter is desired as a solution to improve the performance and prevent second-order IMD products or other undesired overload effects. The dc control voltage needed for the filter can easily be derived from the VCO control voltage. There may be a small dc offset, depending on the IF used.

3-6-1 Diode Performance

The capacitance versus voltage curves of a varactor diode depend on the variation of the impurity density with the distance from the junction. When the distribution is constant, there is an "abrupt junction" and capacitance follows the law

$$C = \frac{K}{(V_d + V)^{1/2}} \tag{3-183}$$

where V_d is the contact potential of the diode and V is applied voltage.

Such a junction is well approximated by an alloyed junction diode. Other impurity distribution profiles give rise to other variations, and the above equation is usually modified to

$$C = \frac{K}{(V_d + V)^n} \tag{3-184}$$

where n depends on the diffusion profile and $C_0 = K/V_d^n$.

A so-called graded junction, having a linear decrease in impurity density with the distance from the junction, has a value of n. This is approximated in a diffused junction.

In all cases these are theoretical equations, and limitations on the control of the impurity pattern can result in a curve that does not have such a simple expression. In this case, the coefficient n is thought of as varying with voltage. If the impurity density increases away from the junction, a value of n higher than 0.5 can be obtained. Such junctions are called hyperabrupt. A typical n value for a hyperabrupt junction is about 0.75. Such capacitors are used primarily to achieve a large tuning range for a given voltage change. Figure 3-144 shows the capacitance–voltage variation for the abrupt and graded junctions as well as for a particular hyperabrupt-junction diode. Varactor diodes are available from a number of manufacturers, such as Motorola, Siemens, and Philips. Maximum values range from a few to several hundred picofarads, and useful capacitance ratios range from about 5 to 15.

Figure 3-145 shows three typical circuits that are used with varactor tuning diodes. In all cases, the voltage is applied through a large resistor R_e or, better, an RF choke in series with a small resistor. The resistance is shunted across the lower diode and may be converted to a shunt load resistor across the inductance to estimate Q. The diode also has losses that may result in lowering the circuit Q at high capacitance, when the frequency is sufficiently high. This must be considered in the circuit design.

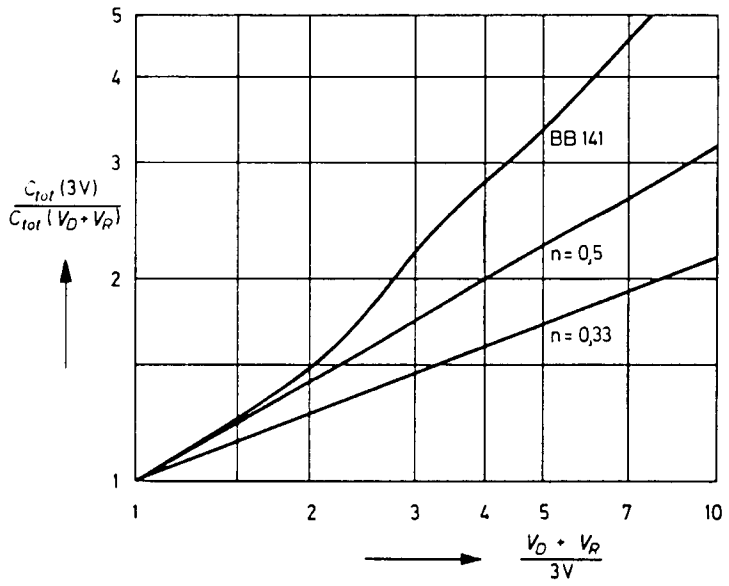

Figure 3-144 Voltage-dependent change of capacitance of different types of diodes. The BB141 is a hyperabrupt-junction diode with $n = 0.75$.

The frequency-dependent performance is not determined solely by applying the dc tuning voltage to Eq. (3-184). If the RF voltage is sufficient to drive the diode into conduction on peaks, an average current will flow in the circuits of Figure 3-145, which will increase the bias voltage. The current is impulsive, giving rise to various harmonics of the circuit. Even in the absence of conduction, Eq. (3-184) deals only with the small-signal capacitance. When the RF voltage varies over a relatively large range, the capacitance changes. In this case, Eq. (3-184) must be changed to

$$\frac{dQ}{dV} = \frac{K}{(V + V_d)^n} \tag{3-185}$$

Here Q is the charge on the capacitor. When this relation is substituted in the circuit differential equation, it produces a nonlinear differential equation, dependent on the parameter n. Thus, the varactor my generate direct current and harmonics of the fundamental frequency. Unless the diodes are driven into conduction at some point in the cycle, the direct current must remain zero.

The current of Figure 3-145c can be shown to eliminate the even harmonics, and it permits a substantially larger RF voltage without conduction than either circuit in Figure 3-145a or 3-145b. When $n = 0.5$, only the second harmonic is generated by the capacitor, and this can be eliminated by the back-to-back connection of the diode pair. Integrating Eq. (3-185), we find

$$Q + Q_A = \frac{K}{1 - n}(V + V_d)^{1-n}$$

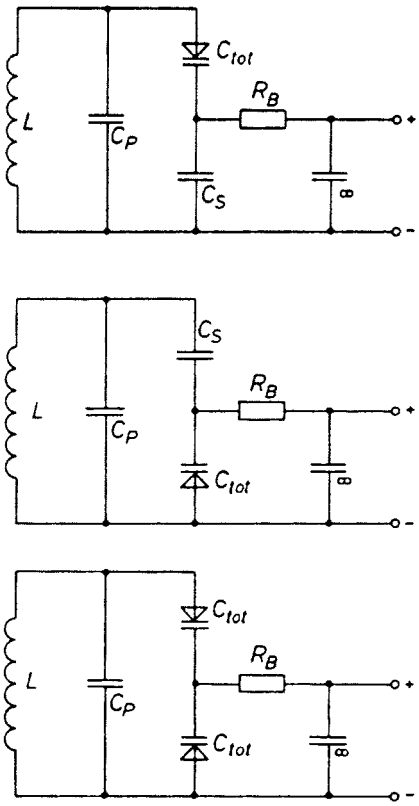

Figure 3-145 Various configurations to apply tuning diodes in a tuned circuit. The bottom version shows the lowest distortion.

$$= \frac{C_v}{1-n}(V + V_d) \tag{3-186}$$

C_v is the value of Eq. (3-184) for applied voltage V, and Q_A is a constant of integration. By letting $V = V_1 + v$ and $Q = Q_1 + q$, where the lowercase letters represent the varying RF and the uppercase letters indicate the values of bias when RF is absent, it follows that

$$q + Q_1 + Q_A = \frac{K}{1-n}[v + (V_1 + V_d)]^{1-n} \tag{3-187}$$

$$1 + \frac{v}{V'} = \left(1 + \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-188}$$

where $V' = V_1 + V_d$ and $Q' = Q_1 + Q_A$. For the back-to-back connection of identical diodes, $K_{11} = K_{12} = K_1$, $V_1' = V_2' = V'$, $Q_1' = Q_2' = Q'$, $q = q_1 = -q_2$, and $v = v_1 - v_2$. Here the new subscripts 1 and 2 refer to the top and bottom diodes, respectively; v is the RF voltage across

the pair in series, and q is the charge transferred through the pair in series. This notation results in

$$\frac{v}{V'} \equiv \frac{v_1 - v_2}{V'} = \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} - \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-189}$$

For all n, this eliminates the even powers of q, and hence the even harmonics. This can be shown by expanding Eq. (3-189) in a series expansion and performing term by term combination of the equal powers of q. In the particular case $n = \frac{1}{2}$, $v/V' = 4q/Q'$, and the circuit becomes linear.

The equations hold as long as the absolute value of v_1/V' is less than unity, so that there is no conduction. At the point of conduction, the total value of v/V' may be calculated by noting that when $v_1/V' = 1$, $q/Q' = -1$, so $q_2/Q' = 1$, $v_2/V = 3$, and $v/V = -4$. The single-diode circuits conduct at $v/V' = -1$, so the peak RF voltage should not exceed this. The back-to-back configuration can provide a fourfold increase in RF voltage handling over the single diode. For all values of n, the back-to-back configuration allows an increase in the peak-to-peak voltage without conduction. For some hyperabrupt values of n, such that $1/(1 - n)$ is an integer, many of the higher-order odd harmonics are eliminated, although only $n = \frac{1}{2}$ provides elimination of the third harmonic. For example, $n = \frac{2}{3}$ results in $1/(1 - n) = 3$. The fifth harmonic and higher odd harmonics are eliminated, and the peak-to-peak RF without conduction is increased eightfold; for $n = \frac{3}{4}$ the harmonics 7 and above are eliminated, and the RF peak is increased 16 times. It must be noted in these cases that the RF peak at the fundamental may not increase so much, since the RF voltage includes the harmonic voltages.

Since the equations are only approximate, not all harmonics are eliminated, and the RF voltage at conduction, for the back-to-back circuit, may be different from that predicted. For example, abrupt-junction diodes tend to have n of about 0.46–0.48 rather than exactly 0.5. Hyperabrupt junctions tend to have substantial changes in n with voltage. The diode illustrated in Figure 3-144 shows a variation from about 0.6 at low bias to about 0.9 at higher voltages, with wiggles from 0.67 to 1.1 in the midrange. The value of V_d for varactor diodes tends to be in the vicinity of 0.7 V.

3-6-2 A VHF Example

The application of tuning diodes in double-tuned circuits in TV tuners has been common practice for many years. Figure 3-146 shows the circuit diagram. The input impedance of 50 Ω gets transformed up to 10 kΩ. The tuned circuits consist of the 0.3-μH inductor and two sets of antiparallel diodes. By dividing the RF current in the tuned circuit and using several diodes instead of just one pair, intermodulation distortion is reduced.

The coupling between the two tuned circuits is tuned via the 6-nH inductor that is common to both circuits. This type of inductance is usually printed on the circuit board. The diode parameters used for this application were equivalent to the Siemens BB515 diode. The frequency response of this circuit is shown in Figure 3-147.

The coupling is less than critical. This results in an insertion loss of about 2 dB and relatively steep passband sides. Once the circuit's large-signal performance (Figure 3-148) is seen, a third-order intercept point of about –2 dBm is not so unexpected. The reason for this poor performance is the high impedance (high L/C ratio), which provides a large RF voltage swing across the diodes. A better approach appears to be using even more diodes and at the same time changing the impedance ratio (L/C ratio).

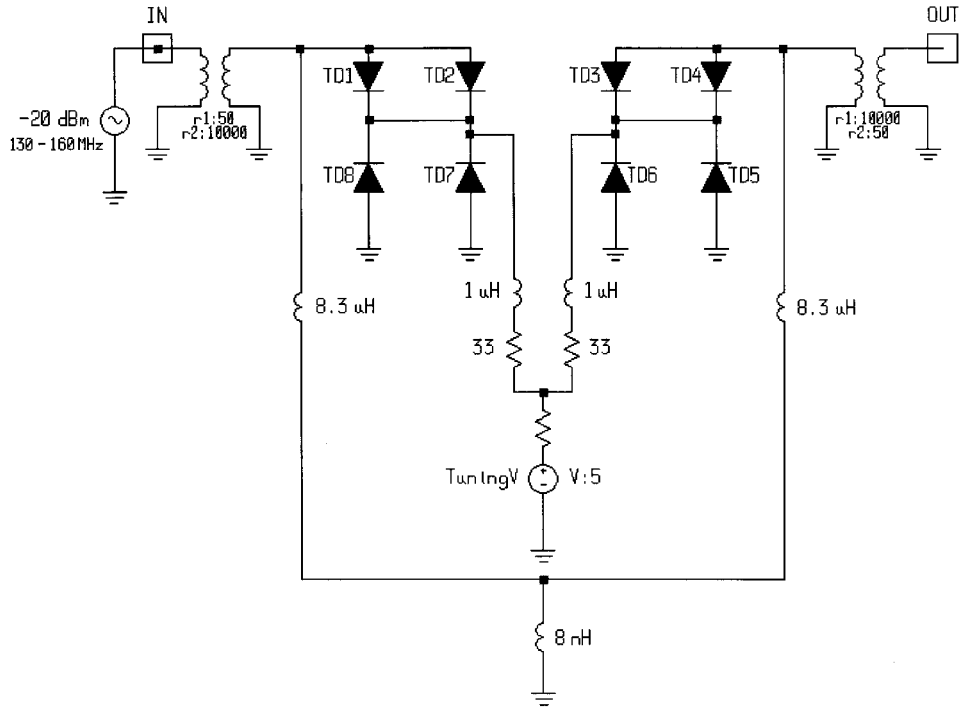

Figure 3-146 Double-tuned filter at 161 MHz using hyperabrupt-junction tuning diodes. By using several parallel diodes, the IMD performance improves.

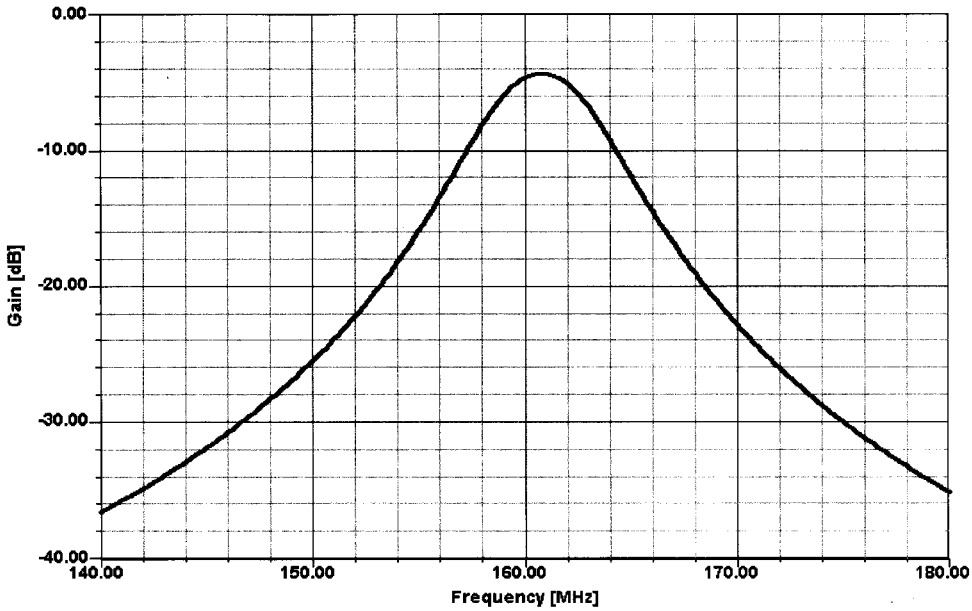

Figure 3-147 Frequency response of the tuned filter shown in Figure 3-146. The circuit is undercoupled (less than transitional coupling); $Q \times k < 1$.

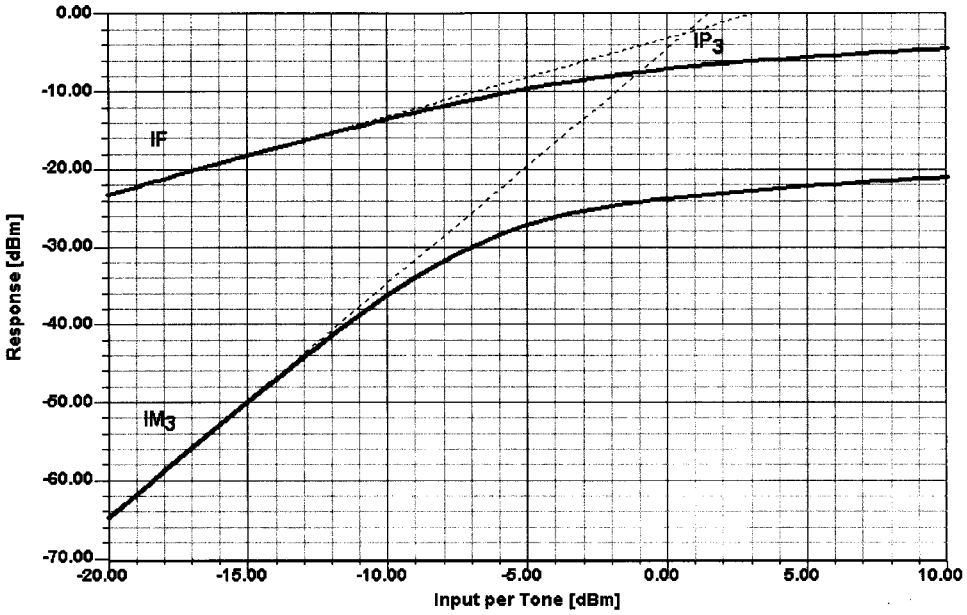

Figure 3-148 Prediction of intercept point of the double-tuned circuit shown in Figure 3-146. Note the compression of both the input signal and the IMD product.

3-6-3 An HF/VHF Voltage-Controlled Filter

The above example used a step-up procedure typically done by a tap at the input and output inductance. This method allows an impedance transformation; however, if one desires to change it into a series-tuned arrangement, it has to be done with a transformer. The large-signal conditions in the frequency range from 10 to 30 MHz on a medium- to large-sized antenna are equivalent to, if not worse than, the conditions for VHF operation. The only exception would be line of sight into the transmitter such as a tower in the middle of the city. Examples of such hostile conditions would be any large city, such as Munich, New York, Miami, Chicago, and San Francisco, where the authors had significant experience with intermodulation distortion problems.

By translating the circuit into a low-impedance-drive arrangement, building it symmetrically, and reducing the tuning range somewhat by capacitors and many series diode pairs, the filter's large-signal performance was significantly improved. The tuning diodes had about 125 pF at 1 Vdc per unit. Initial tests trying to use a high-capacitance diode, such as the BB112, resulted in much higher IMD products. The B112 has a 1-V capacitance of 470 pF down to about 20 pF at 8 V. Standard diodes show about 30 pF at 1 V, while the diodes used in the experiment had a 125-pF capacitance at 1 V. These experimental diodes were made available from a well-known manufacturer for this evaluation. Figure 3-149 shows the circuit diagram.

A step-down transformer drives the tuned circuit with a source impedance of 12.5 Ω. The circuit is symmetrical. There are two 0.8-μH inductors and 2×5 diodes in the loop. The output of the circuit is transformed back up to 50 Ω. The tuning voltage is supplied via a heavily filtered arrangement. This circuit has actually been implemented in Rohde & Schwarz field strength meter equipment. They guarantee an intercept point of about +20 dBm. The selectivity of these circuits is quite reasonable and mostly intended to reduce

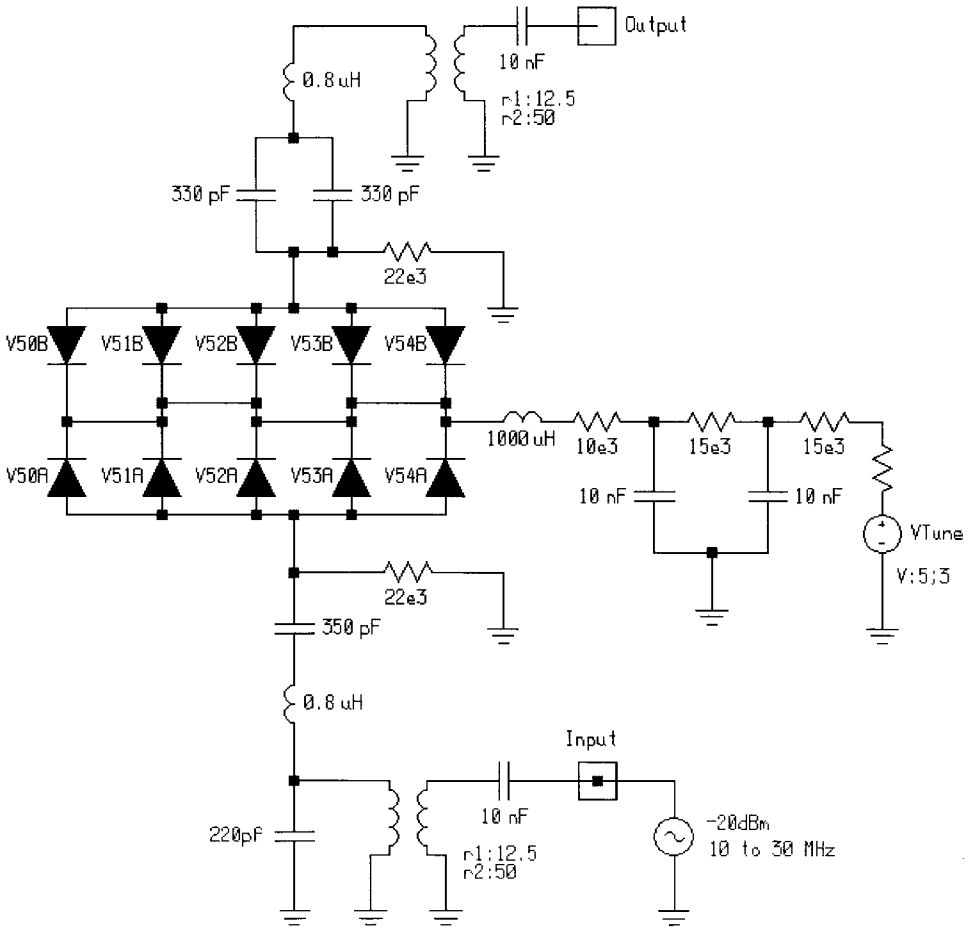

Figure 3-149 High dynamic range of a 10–20-MHz filter.

second-order intermodulation distortion products by about 10 dB, at the same time having a high third-order intercept point. Figure 3-150 shows the selectivity curves at two different tuning voltages.

The most interesting number, however, is the third-order intercept point (already determined as about 20 dBm), which still had to be simulated. This sometimes sounds like a contradiction: Once the measured values are available and are acceptable, why would one want—or, rather, need—to do a simulation besides the necessity to develop a high-input intercept filter? It was desirable to validate the nonlinear models and prove that the above-mentioned equations will hold true. This type of simulation is now more difficult because the number of nonlinear elements went from four to ten, and some numerical problems, such as convergence difficulties, can be expected, and the effect of harmonic frequency cancellation (compensation) can also be seen. By using diode combinations that result in $1(1 - n)$, n being an integer number, these IMD products can drastically be reduced. This implies that each of the five diode pairs has a selected value for n to meet this condition. Later, a final attempt will be made to improve the first VHF filter with the proper diode combinations.

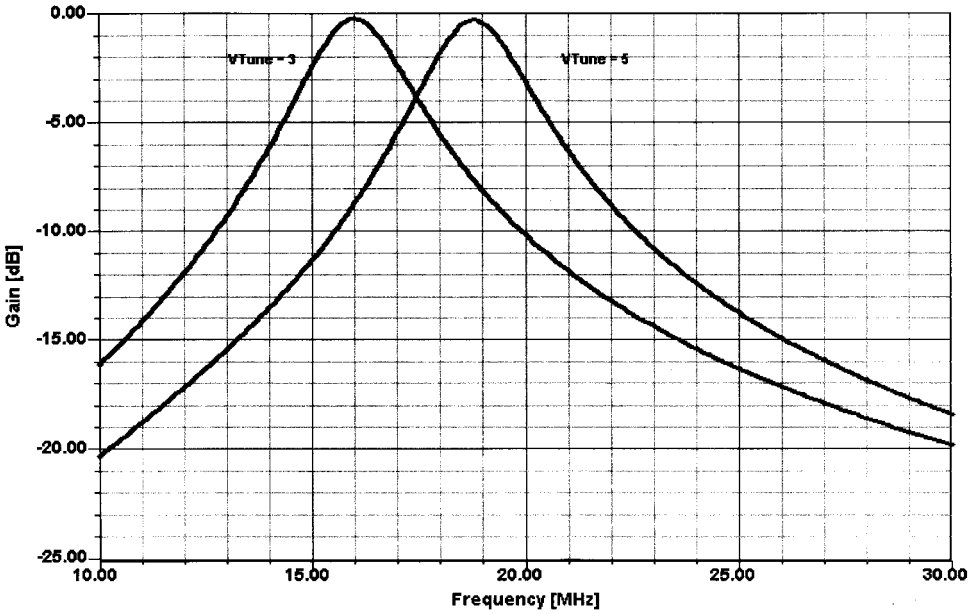

Figure 3-150 Frequency response of the filter shown in Figure 3-149. Filters of this type are intended to reduce second-order IMD by providing about 20-dB suppression at half the center frequency.

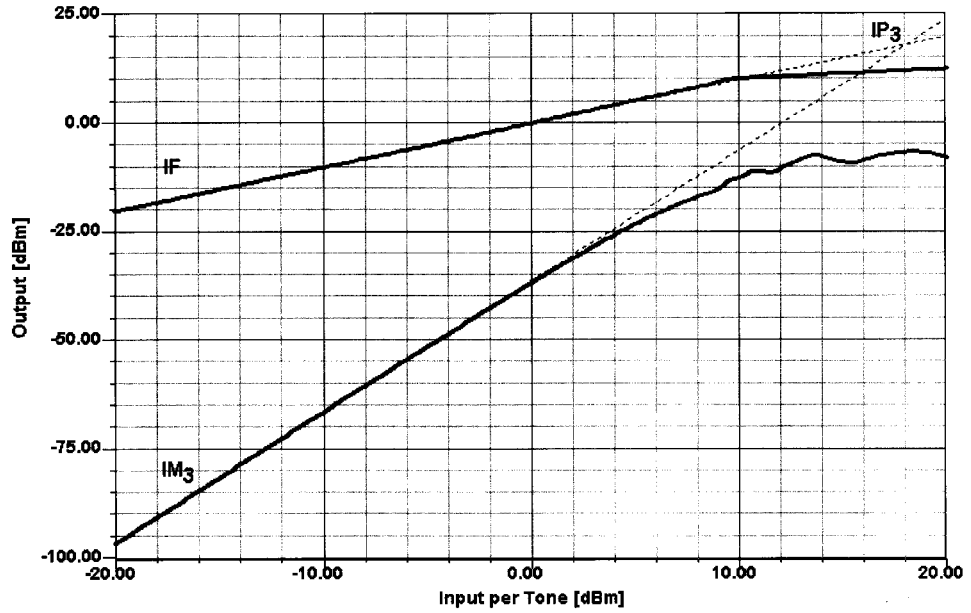

Figure 3-151 Prediction of third-order intercept point of the filter shown in Figure 3-149. The reason for the curves on the IMD plot lies in the interaction between the ten nonlinear devices.

Figure 3-151 shows the calculation of third-order intercept point for the arrangement shown in Figure 3-149. This number has now increased to +18 dBm. The difference between selection and measurement is approximately 2 dB. The reason for this more pessimistic value compared to the measured value probably has to do with slight variations of the exponent of the diodes' voltage-dependent capacitance. Therefore, the authors consider both the circuit performance and the simulation accuracy to be extremely good. This type of circuit, as mentioned earlier, has wide application in oscillator circuits. Danzeisen of Rohde & Schwarz was probably the first to have used this type of circuit by paralleling many diodes for improved performance.

3-6-4 Improving the VHF Filter

By selecting the appropriate diode combinations and circuit modifications as shown in Figure 3-152, a significant IMD improvement of the circuit shown in Figure 3-146 is obtained. A special shunt arrangement of several diodes with different exponents has been developed, which allows its value to be "adjusted." This circuit, for which a patent has been applied, showed an improvement from –2 dBm to 32 dBm. The same high operating Q was maintained. Figure 3-153 shows the frequency response after the modification. Note that a coupling slightly greater than critical ($Q \times k = 1.1$) has been selected.

3-6-5 Conclusion

After explaining some of the nonlinearities in mathematical terms, we have given some examples of voltage-tuned circuits and discussed their large-signal performance. This section has also shown that modern CAD tools can accurately predict the performance of such circuits.

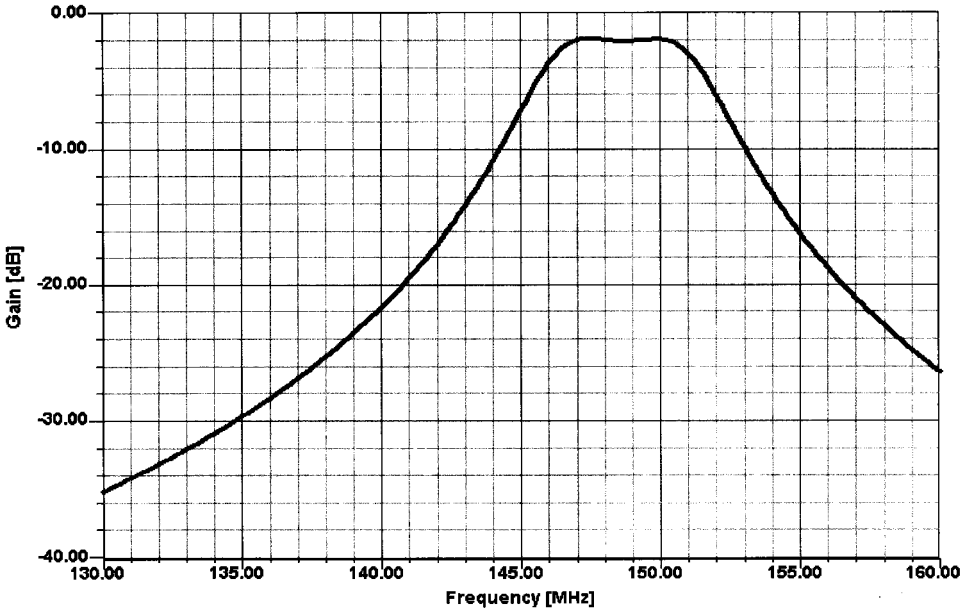

Figure 3-152 The frequency response of the improved circuit derived from Figure 3-146.

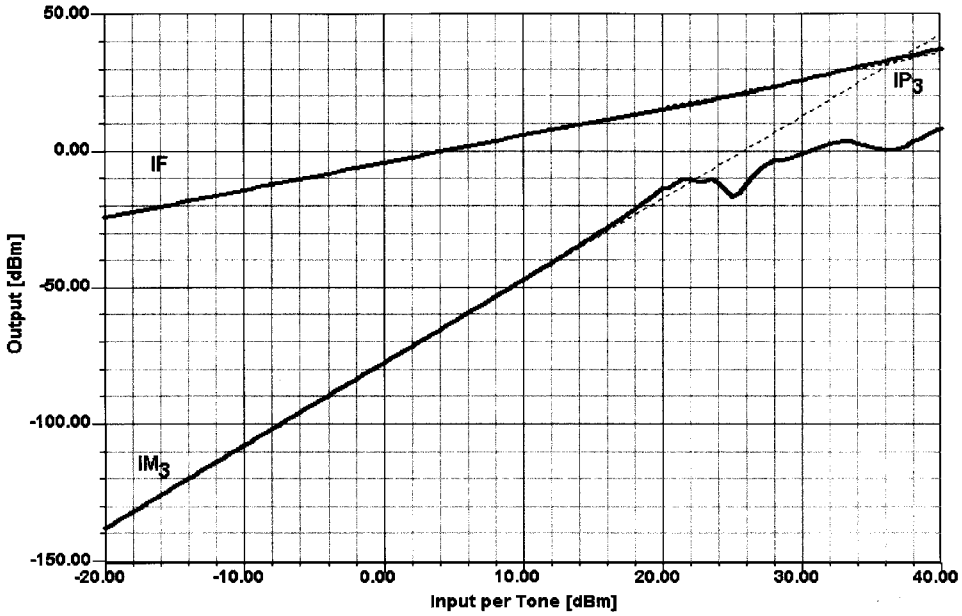

Figure 3-153 Predicted IMD performance of the improved version of the circuit shown in Figure 3-146. This type of improvement is significant for all applications. A patent is in the process of being obtained for this; therefore, the circuit cannot be disclosed at present.

3-7 DIFFERENTIAL AMPLIFIERS

The differential amplifier (Figure 3-154) goes back many years and also was the first step from TTL to ECL. The differential amplifier consists of an emitter follower (Q1) and a grounded-base stage (Q2). The constant-current generator (Q3) between ground and the emitters of Q1 and Q2 determines the current for these stages; the dc operating currents of Q1 and Q1 are the same. Most modern integrated circuits use this differential amplifier in one way or another.

If the circuit is operated about its point of symmetry, the dc component of the current through either Q1 or Q2 remains half of the emitter constant current through Q3 for all symmetrical driving signals. In addition, for input signals that are aperiodic, no even harmonics are generated. This assumes that the stage is driven symmetrically at both inputs. In our case, the differential amplifier has its second stage grounded, meaning that there is a base-to-ground capacitor, and the stage is asymmetrically fed. As the input voltage is increased, the differential stage becomes a limiter, which limits the current between plus and minus I_S, with I_S being the source current. The resulting output will become a square wave. This stage can also be used as a line receiver, translating a sine wave to an output logic suitable for driving emitter-coupled logic (ECL) stages.

One can assume that the differential amplifier has a transconductance of

$$g_m = \frac{\alpha g_{\text{in}}}{2} \tag{3-190}$$

where α is the ratio of collector to emitter current. Within the limits of the output being a sine wave, this stage has very low distortion. The output current now is determined by

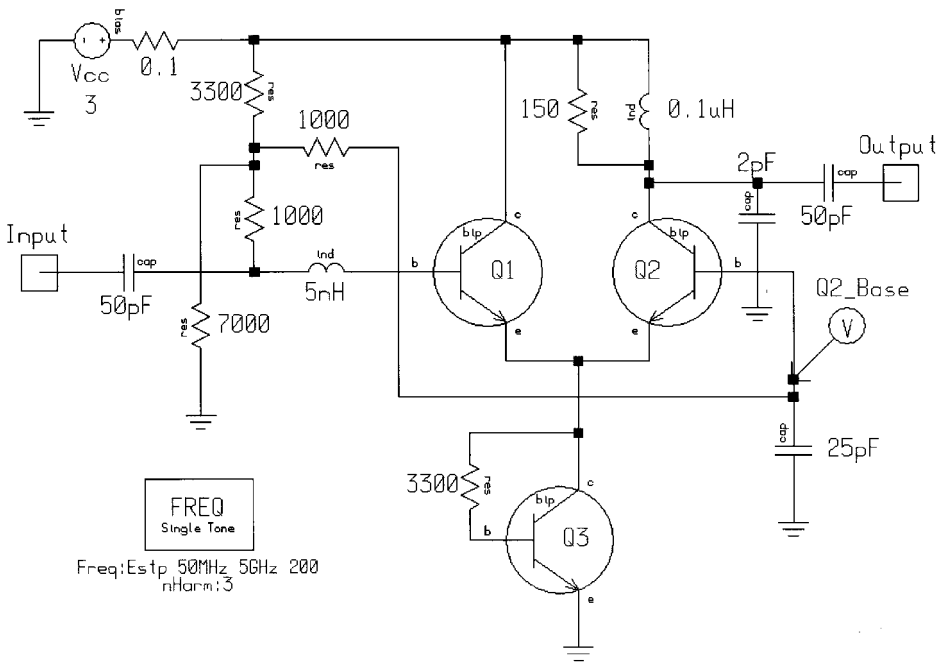

Figure 3-154 The differential amplifier schematic. The transistors are Siemens BFP420s. Figure 3-155 shows the circuit's frequency-dependent gain, matching, and noise performance.

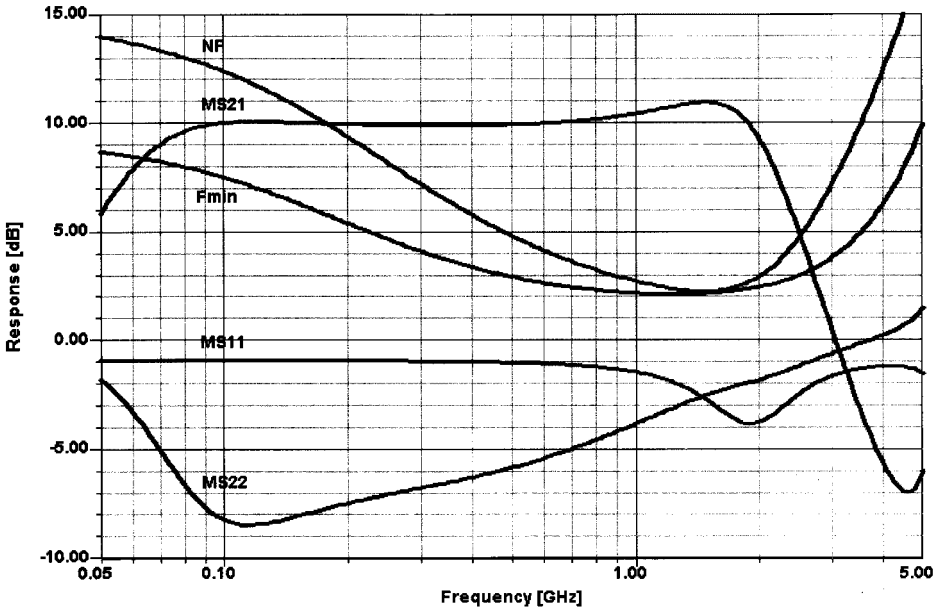

Figure 3-155 Frequency-dependent gain, matching, and noise performance of the differential amplifier.

$$i = \frac{I_{\text{in}}}{2} \tanh\left(\frac{x}{2} \cos \omega t\right) \tag{3-191}$$

where ωt is the input frequency and I_{in} is the current forced by Q3. The reason why the transconductance has to be divided by 2 comes from the fact that the current is split into two equal components for Q1 and Q2. Multiplying the new transconductance with the output load gives the voltage gain of this amplifier; its power gain can be obtained by multiplying this with $\sqrt{\text{output resistance} \div \text{load resistance}}$.

Having done the linear analysis and having learned that because of the hyperbolic tangent functions this amplifier can also be used as a line receiver, and converting sinusoidal waves to square waves, it may be useful to take a closer look at these issues. If we take a CAD oscilloscope, we see the resulting output waveform being a nonequal duty cycle output voltage, which results in high harmonic content. The amount of harmonic content can be controlled by the drive power and by the actual bias. Figure 3-156 shows the resulting output waveform.

If we now switch to a CAD spectrum analyzer, we can evaluate the harmonic content (Figure 3-157). Figure 3-158 shows the output transistor's dc I–V curves and ac load line under these conditions. Based on the previously defined conducting angle of the differential amplifier, one can optimize for harmonic content. Therefore, it is logical at this point to look at frequency multipliers, as they are sometimes needed. Finally, we are curious to see the so-called load line of the output transistor, which is, based on the interaction of all the stages, not looking the same way as the expected one, which we know from previous amplifier examples. Part of the reason for this is that for a certain voltage range, the collector voltage is in the negative region, and all kinds of saturation effects result in this surprising waveform. By reducing the input power, one would obtain a more "expected" load line. We invite readers with CAD capabilities to play with this example, as it gives a lot of insight into the operation of ECL stages.

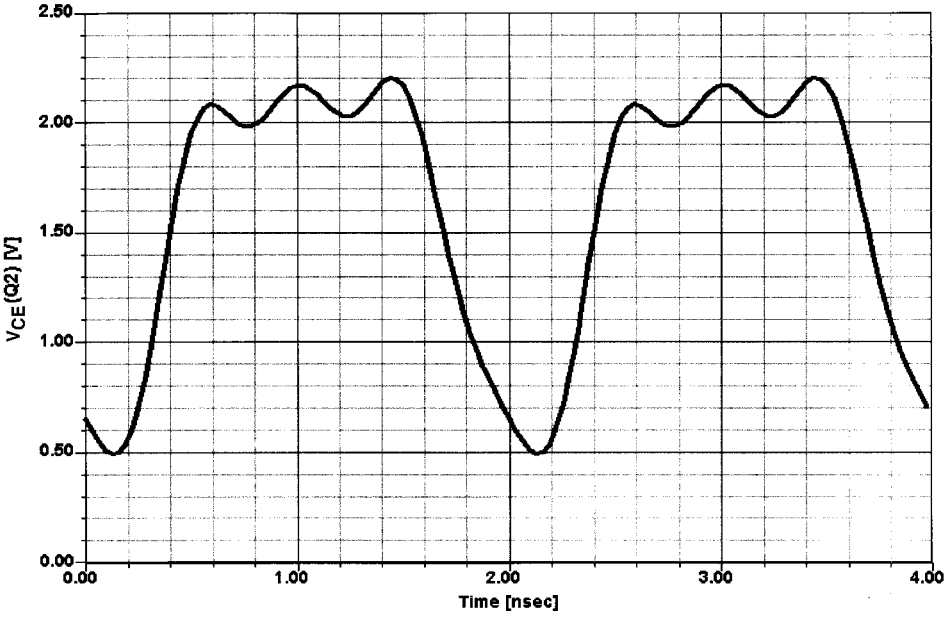

Figure 3-156 V_{CE} versus time for output transistor Q2 with a drive of 10 dBm.

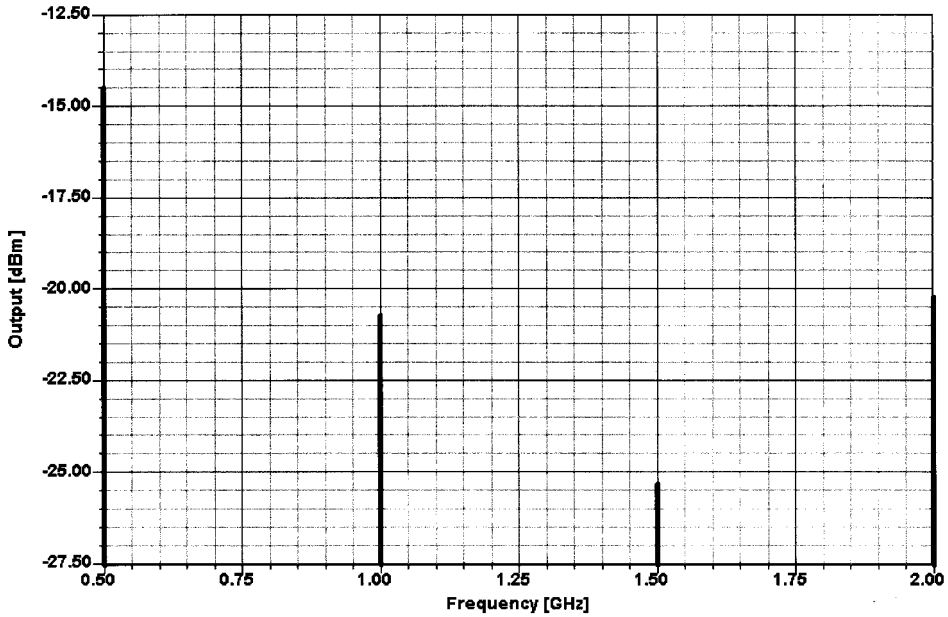

Figure 3-157 Output spectrum of the differential amplifier with a drive of 10 dBm. The biasing is not optimal for frequency multiplication.

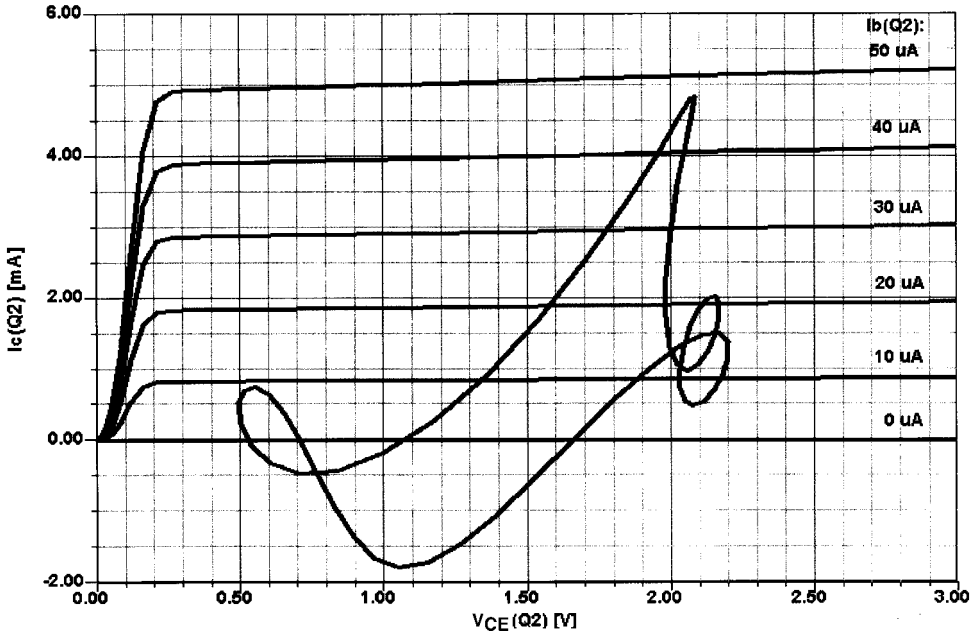

Figure 3-158 The dc *I–V* curves and ac load line for output transistor Q2 with a drive of 10 dBm.

3-8 FREQUENCY DOUBLERS

Having seen that the harmonic content invites us to bias a stage from Class A into Class B or C if our goal is a harmonically rich current, we will now evaluate a single stage that will be biased close to cutoff and driven by a relatively low frequency (500 MHz). To obtain the best results, we will use a parallel notch filter in the output, followed by a high-pass matching circuit to "catch" the desired harmonic. The input frequency is heavily suppressed by the notch filter. Based on its finite Q, there is a limited range over which this frequency can be varied with constant subharmonic attenuation. Figure 3-159 will be our test circuit.

This circuit consists of a bias transistor, Q2. This method has been discussed before and solves the temperature-dependent bias emitter thermal runaway problems through "temperature compensation." The purists among our readers may point out that the currents drawn by Q1 and Q2 are not quite identical (which would give 100% cancellation), but the approach shown is sufficient to do its job. Also, we have chosen a Class AB operation point, which is defined by Q1's 1-mA dc standing current. The conducting angle has not been optimized for the second harmonic—a task that the interested reader can do by using the conducting angle relationship shown at the beginning of this chapter. To give readers with access to nonlinear CAD some homework, we have not set this at the optimum point.

The second transistor, here called Q1 (because of its importance at RF), has a matching network at the input. This is recommended for optimum energy transfer. The matching condition can be validated by examining Figure 3-160. If we look at the higher frequency response, the input shows a possible trend of oscillation (negative loss); this could actually be eliminated by using a low-pass filter at the input instead of the high-pass filter used now. Findings of this type always make us nervous, and we hope that the nonlinear models are sufficiently accurate at higher frequencies to predict such behavior correctly. In the case of the FET doubler mentioned in Chapter 2, we found that the device modeling done by Compact (now Ansoft) gave the best results, the university answers were fairly close, and the device manufacturer data were worst. We have since become highly skeptical about device modeling unless we can validate it ourselves. Synergy Microwave has a complete set of test equipment in the laboratory, including network and spectrum analyzers with special software created by Rohde & Schwarz that can be used in addition to the Scout program to do in-house validation. This was achieved by the use of nonlinear optimization at a drive level of 0 dBm. One could say that this is similar to using a load-pull approach at the input, and then resorting to the large-signal S parameters obtained. Another note of caution: Capacitors at these low values tend to have a very large percentage error; for instance, a 1-pF capacitor, if not selected carefully, can vary between 0.7 and 1.3 pF—a 50% error. Needless to say, this is not acceptable for useful production.

The output consists of a high-pass filter and a notch filter with the purpose of reducing the subharmonic significantly. We have again done this on purpose, leaving room for the reader to come up with a more inventive output circuit like a Cauer-type (same as elliptical) low-pass filter with discrete notches at higher harmonics of the input frequency, such as 1.5 GHz, 2 GHz, and so on. In addition, we have shown three ways how to implement the inductance for the notch filter. This is equally applicable for other inductors in this value range. As frequency increases, this becomes more interesting but one needs to remember that many materials like silicon and gallium arsenide are extremely lossy. The same inductor approach has been used in Figure 5-61 of Chapter 5. For silicon, even the manufacturer becomes an issue. Figure 3-161 shows a top view of a "rectangular" inductor that actually approaches the spiral inductor; its implementation can be seen in Figure 3-162. Modeling this was a

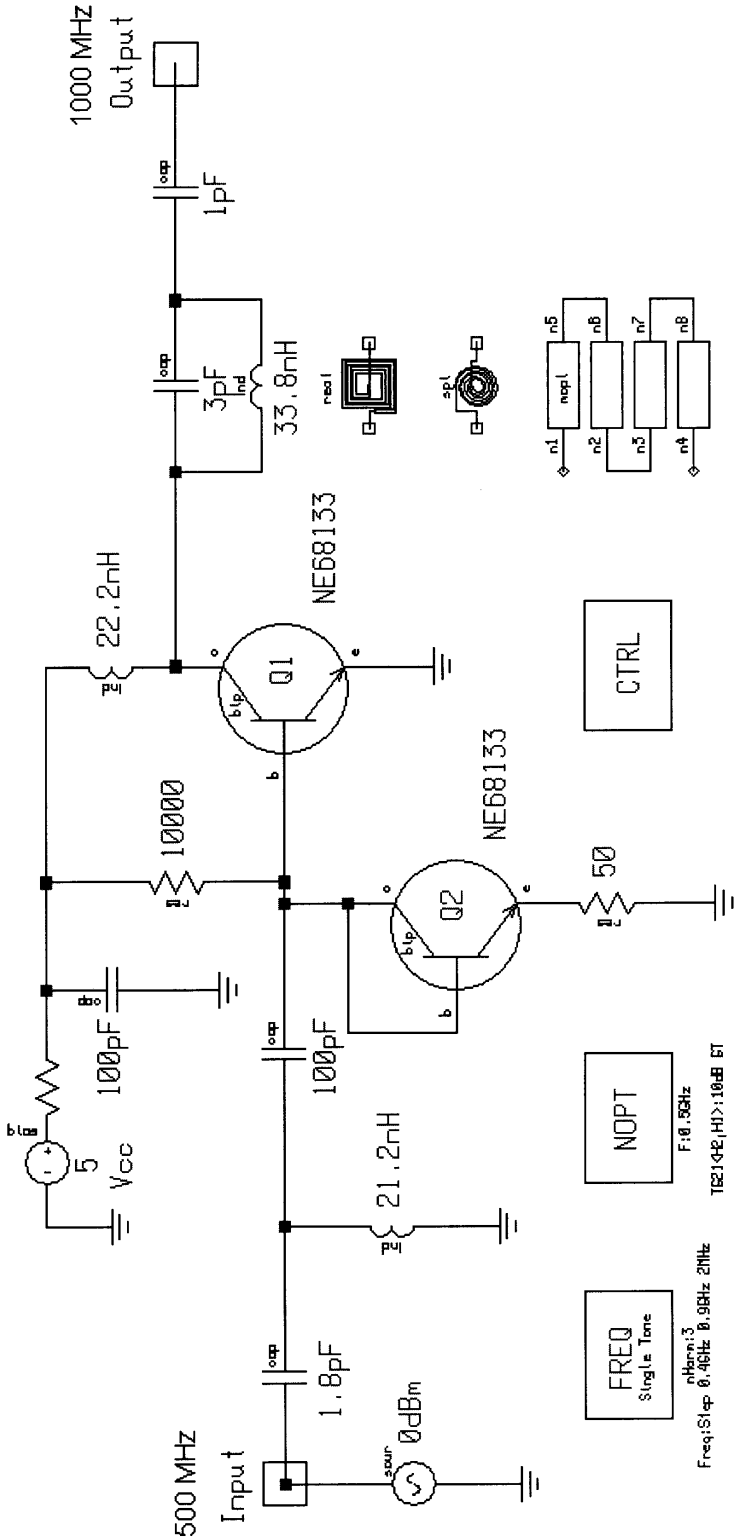

Figure 3-159 BJT frequency doubler schematic. A parallel-tuned trap in Q1's collector attenuates fundamental feedthrough.

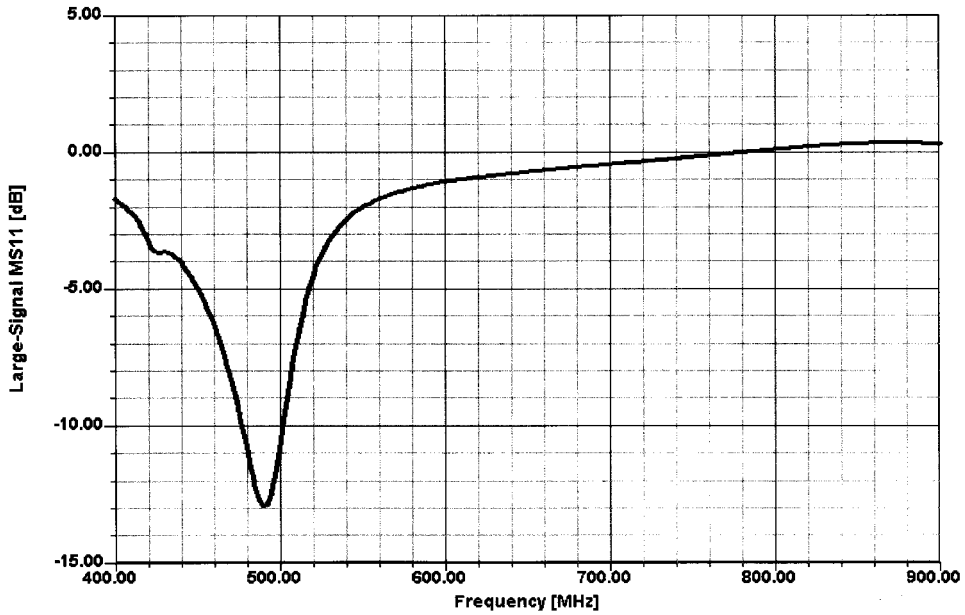

Figure 3-160 Large-signal MS_{11} for the BJT doubler. Note the positive region above 800 MHz.

nightmare, and during our Compact days, we actually had to modify the electromagnetic simulator to accommodate this and get results where measurements and simulation agreed. Figure 3-163 shows the measured and simulated Q as a function of frequency of a silicon-based inductor. In the case of other materials, such as PC board or GaAs, the models in the CAD tools are sufficient to predict the losses of the inductors. Following this initial exercise, Motorola then developed an improved silicon spiral inductor; its frequency-dependent Q is shown in Figure 3-164. Note that this Q was measured and not simulated.

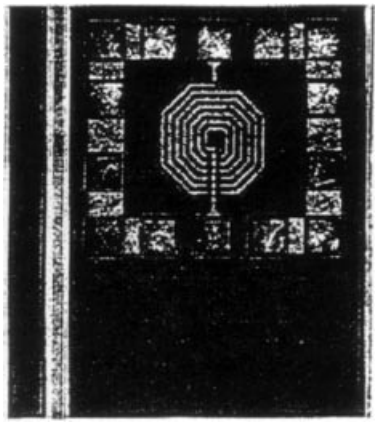

Figure 3-161 A 6.5-turn spiral inductor in silicon.

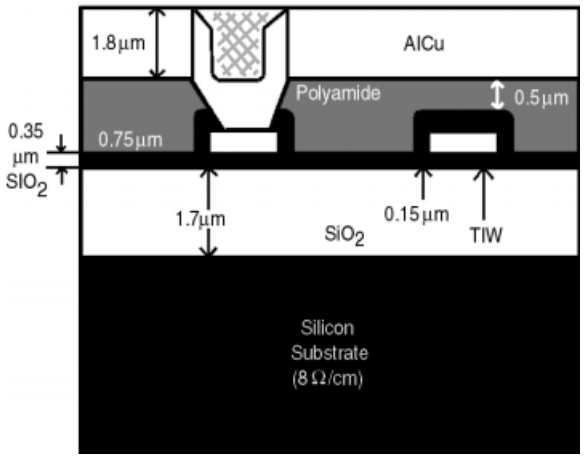

Figure 3-162 Cross section of the silicon inductor.

One of the reasons why we use a transistor multiplier is that we expect gain (because of the square-law characteristic, an FET would have been better tailored for a doubler); therefore, we have "measured" the gain of this circuit while driving it with 0 dBm. Another important factor is that, because of the way the CAD tool displays it, the gain is referenced to the 500-MHz input. Mentioning this is important; otherwise, the reader may look for the 1-GHz gain, which does not exist. Figure 3-165 shows the doubler gain.

By now we are curious to see the doubler in action, and by reviewing Figure 3-166 we can see the output spectrum. The output spectrum validates the statement that the output circuit, while doing a marvelous job of removing the 500-MHz input frequency, does not cure the problem of unwanted multiples of the input frequency. Again, a Cauer low-pass filter, while introducing some possible additional loss, should be considered for this circuit to have a bandpass response. On the other hand, many oscillators have very little harmonic suppression, and the same type of postfiltering needs to be considered. There are two-transistor solutions available also, such as push–push for frequency doubling (push–pull would

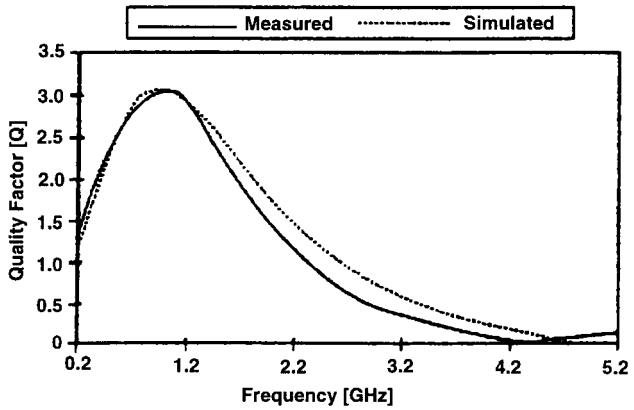

Figure 3-163 Measured and simulated *Q* versus frequency for the simulated inductor.

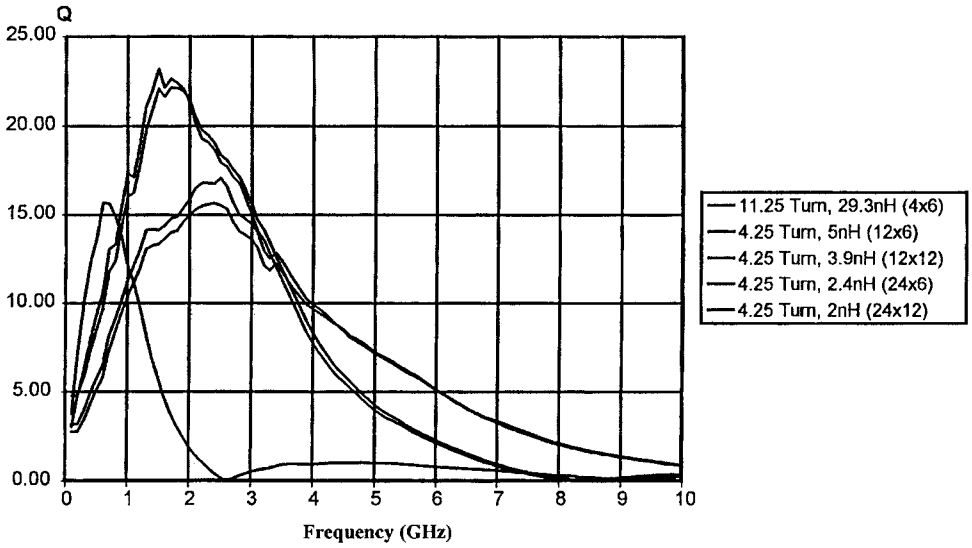

Figure 3-164 *Q* versus frequency for Motorola improved inductor.

eliminate the desired second harmonic quite well). Actually, two diodes could also have been used for doubling, but since this requires transformers and a postamplifier, we have shown the preferred application. The only advantage of the diode application is that it is wideband, while this BJT circuit, as we have just learned, must be made narrowband for reasons of spectral purity.

Finally, we are curious to see the actual operating state of this amplifier, and this can be done by analyzing the load line (Figure 3-167). This is as complicated as the analysis for the differential amplifier. Because of the stored energy in the various tuned circuits, the load line looks quite impressive and would probably be difficult to predict without a nonlinear CAD tool.

3-9 MULTISTAGE AMPLIFIERS WITH AUTOMATIC GAIN CONTROL (AGC)

Having discussed the basic differential amplifier, we will now evaluate the performance of the MC1350/1490 video amplifier chip from Motorola. Most of the circuitry in the chip is self-explanatory. Figure 3-168 shows its inner circuit, and Figure 3-169 show a recommended application. By grounding one side of the input, we effectively get the same performance as the differential amplifier just discussed, with one difference being that the input is now fed to the constant-current generator. To minimize the distortion at the two lower transistors, they are decoupled by a 66-Ω resistor. Figure 3-170 shows the frequency-dependent gain, matching, and noise figure. Since this particular device has been specifically designed for AGC purposes, we also show in Figure 3-171 its gain reduction versus applied AGC voltage.

3-10 BIASING

A lot has been written about biasing, and since the purpose of this book is not to focus too much on dc, the following examples including RF consequences have been selected and considered sufficient. Early application reports by Motorola and others have provided a wealth of data. As a side effect of the introduction of the wireless era, we find that the engineers are so pressed for time that the number of complete application reports has approached zero. This is one of the reasons why we have tried to minimize the mathematical basis of this book (some is still needed), while still providing practical assistance. Figure 3-172 shows a textbook type of approach for RF.

In order to decouple the transistor from the biasing, we use RF chokes and dc decoupling (bypass) capacitors. This is the technique used in previous examples, so one might ask, "What's new?" As frequency increases, these inductors are either not manufacturable or have such a low Q that their use becomes questionable. This is the point where one may introduce the so-called distributed elements.

Figure 3-173 shows the very same circuit but resorting to distributed rather than lumped elements. The newly introduced elements (part of any good, up-to-date CAD tool; see element library for how to use their physical element descriptions) are described next.

- *Transmission Line.* Any printed connection between two points on a circuit board is a transmission line (Figure 3-174). Its characteristic electrical impedance is a function of the square root of the dielectric constant (ε_r), the width, metallization, thickness and height above substrate of the line, and the loss tangent of the substrate. Since lines frequently have to be laid out in the form of curved connections or have a bend in their direction, we have to add elements capable of describing the high-frequency conse-

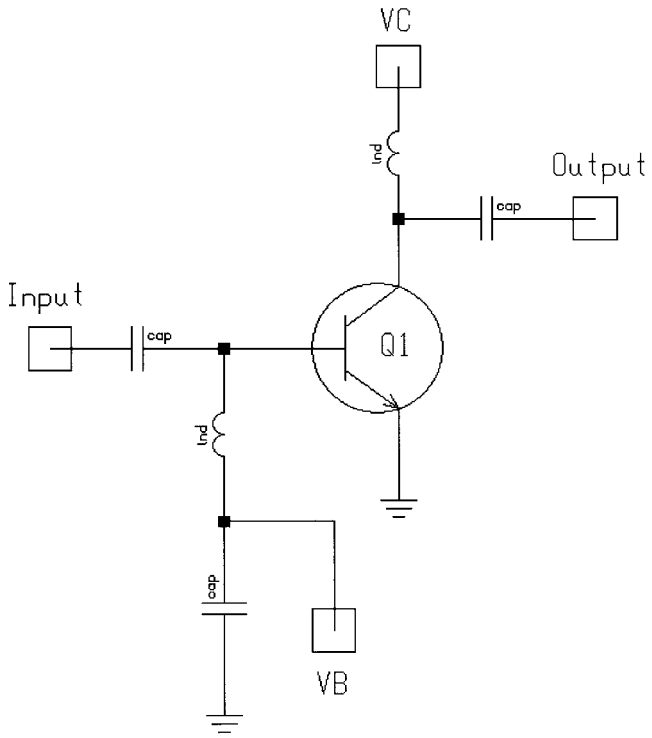

Figure 3-172 Simple BJT RF amplifier with lumped elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

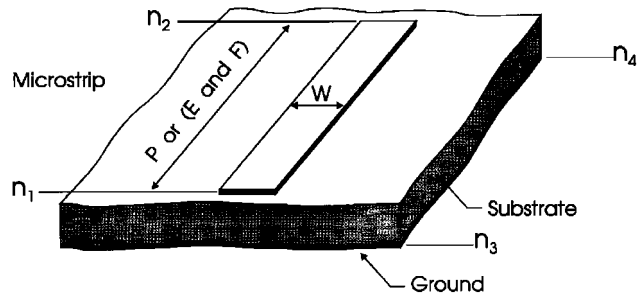

Figure 3-174 Transmission line in microstrip.

quences of such connections. Figures 3-175 and 3-176 show mitered and radial bend elements that perform this function.

- T *Junction, Cross, and* Y *Junction.* By the time a point like a collector or base, or its FET equivalent, spreads out into connections with other elements, we need additional modeling capability to describe ⊤ connections, crossings, and Y junctions. Figures 3-177, 3-178, and 3-179 show the way in which these connections must be modeled.

If the need exists, the standard inductances must be replaced with a transmission line whose length is λ/8 at the operating frequency. At higher frequencies, these transmission lines, however, then go into λ/4 resonant mode and later become capacitive. This type of design makes it fairly narrowband. A way around this is the use of printed inductors, as shown in Figures 3-180 and 3-181.

These inductors have a self-resonant frequency similar to the transmission line mentioned above, but the safety margin is significantly higher.

Talking about printed inductors, a logical extension of this is the printed transmission-line-based transformer, as shown in Figure 3-182. One can consider this as two interlaced rectangular inductors and, based on the substrate material, they are useful over a wide frequency range. Besides being used as a transformer, they can also be used to transit from

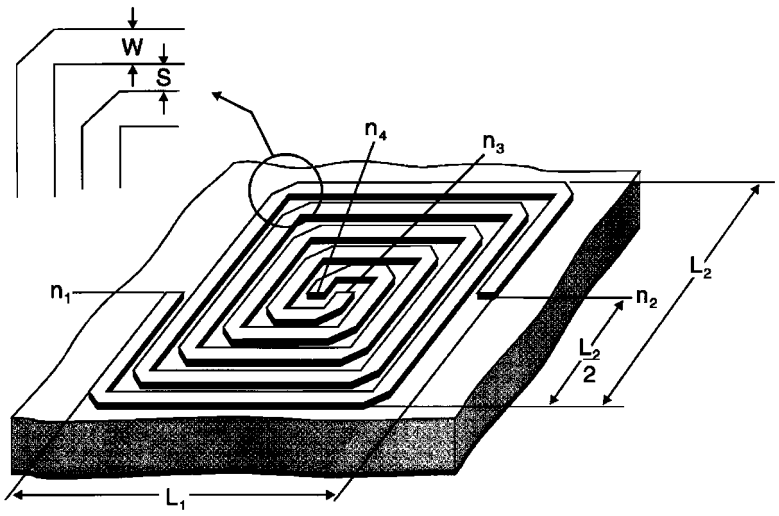

Figure 3-182 Transformer in microstrip.

unbalanced to balanced transmission provided that the difference in length from a connection point of view does not cause any problems (this is a layout issue).

A popular form of combining stages is the so-called Lange coupler (Figure 3-183) invented by the German Julius Lange. It is one of the major contributions in wideband applications.

Useful application of the Lange coupler probably starts at 4 GHz. It consists of parallel transmission lines with the appropriate connections as shown. Lange couplers are typically built with four, six, and eight fingers. The Ansoft Serenade product has a Lange coupler synthesis program that can be used to gain more insight into this coupler's application. We assume that other modern software has similar capabilities.

Where meander-type inductors are necessary, a neat way to implement and simulate them is to use the multiple coupled lines element (Figure 3-184) of the Serenade product, which both quickly and accurately calculates the behavior of the meander, including self-resonances and losses. We made use of this arrangement in our previous examples.

- *Interdigital Capacitors.* The issue of tolerances of small capacitors already has been brought up. The interdigital capacitor can be made on printed circuit board material as

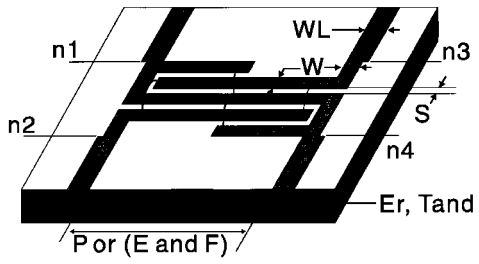

Figure 3-183 Four-strip Lange coupler.

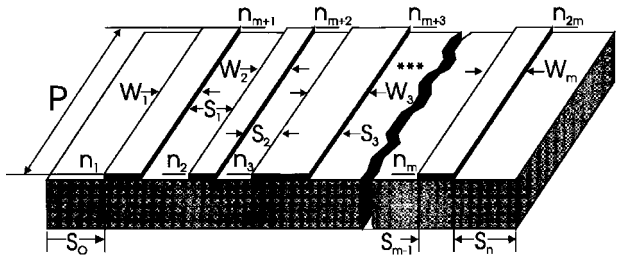

Figure 3-184 Multiple coupled lines element in microstrip.

well as gallium arsenide, and if its dimensions are continuous with the transmission-line width it does not cause any abrupt changes in impedance. This type of capacitor permits one to obtain very small values. An alternative to this is the use of transmission lines with a length of $\frac{3}{8}\lambda$. We learned earlier that a transmission line is inductive at frequencies below its fundamental resonance, is resistive at below resonance, and becomes capacitive above resonance. Again, bandwidth is also an issue. An interdigital capacitor consists of a number of parallel fingers as shown in Figure 3-185, and its capacitance can be varied by adjusting the number of fingers and their spacing. The advantage of the interdigital capacitor compared to discrete components is its low variation in value.

- *Radial Stubs.* The radial stub (Figure 3-186) is not much different from a $\lambda/4$ resonator, but its bandwidth is much greater than a simple transmission line. This is another way to ground the "cold" side of a transmission line or part of a circuit that needs to be grounded for RF. Of course, the interdigital capacitor comes in a version that is a combination of a capacitor and a via hole.
- *Via Holes.* The "cold" end of the transmission line, being considered either an inductor or a capacitor, needs to be connected to a sufficiently large copper backplane. One very efficient way to do this, especially if there is not enough copper left on the top of the board, is the use of via holes (Figure 3-187). One could theoretically generate

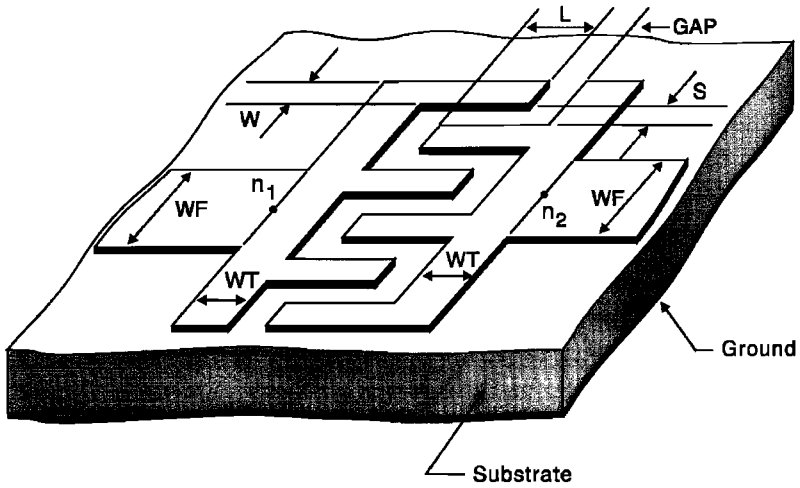

Figure 3-185 Interdigital capacitor.

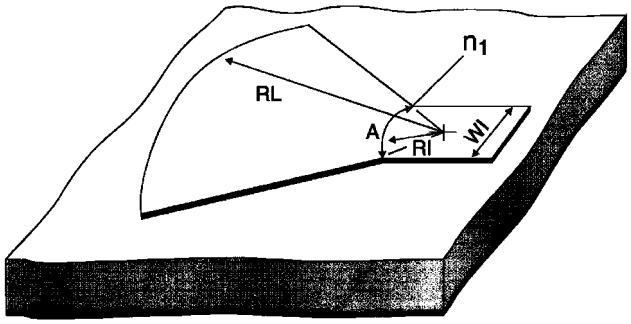

Figure 3-186 Radial stub.

a via hole with a rivet, but most manufacturing processes don't allow this; the normal solution is to use plated-through holes left open. In PC boards, via holes are typically cylindrical; on substrates like GaAs, they may be conical.

- *Correction Elements.* Although the behavior of an actual circuit proceeds regardless of our ability to measure and describe it, we do not enjoy this luxury in simulating circuit behavior in software. In a simulator, effects that are insufficiently described will be inaccurately simulated. For instance, segments of high-impedance transmission line (e.g., 120 Ω) are frequently used for dc feeds and RF chokes. In predicting the effect of a transition from 120-Ω line to 50-Ω line, a simulator must be alerted to the discontinuity so it can do the necessary mathematical corrections to account for the impedance jump. To do this, a specific circuit element, the STEP (Figure 3-188), must be inserted between the 120-Ω and 50-Ω line elements in the simulation circuit file. In addition to substrate data, we characterize a STEP by providing the widths of its input and output lines. The element itself has no physical length.

A similar correction is necessary if a transmission line is used as a resonator or just "left open" at one end. Such a transmission line tends to radiate and, because of its high-impedance properties, it reacts differently as far as its electrical length is concerned. A zero-length one-port element, the OPEN (Figure 3-189), must be added to such a line for mathematically correct calculation.

We end this excursion into distributed elements here. Interested readers may want to obtain a CD containing the element library of their favorite CAD tools that combine capabilities in the microwave area with a full set of distributed circuit elements. It is most important to keep

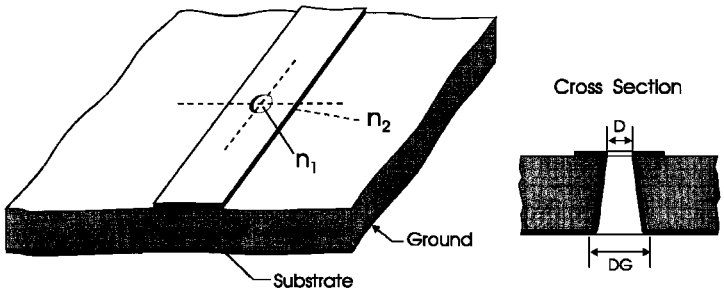

Figure 3-187 Via hole.

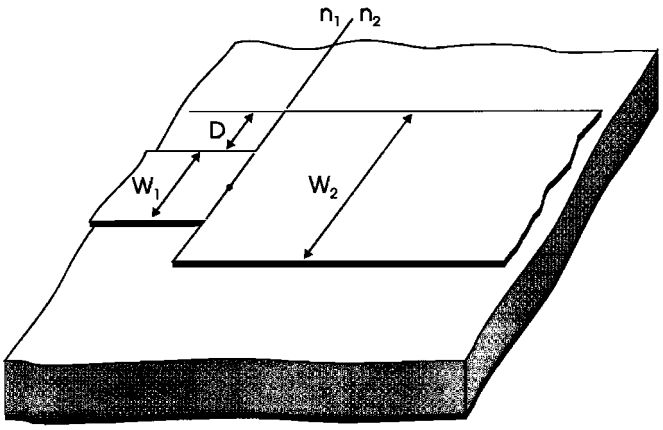

Figure 3-188 The STEP element tells the simulator to calculate the effects of joining transmission lines of differing characteristics.

in mind that, as frequency increases, we rapidly move into the area where we must consider all these distributed elements to achieve accurate simulations—even if doing so makes simulation a painful and time-consuming effort.

Finally, anyone who adventures into this area *must* obtain a foundry manual from the company that will build the integrated circuit or hybrid under design. There are basically two foundries, one applicable for MOS technology and one for GaAs. In the case of the bipolar transistor, the foundry service is not yet well-established. While we were able to interest one German company and one U.S. company in generating a custom bipolar IC within the activities of this book, the only "open" foundry we know of for bipolar (actually HBT) technology is the one operated by TRW. As of 1999, this seems to be the leading company for BJT-related products, and many currently available ICs have been developed with this foundry service.

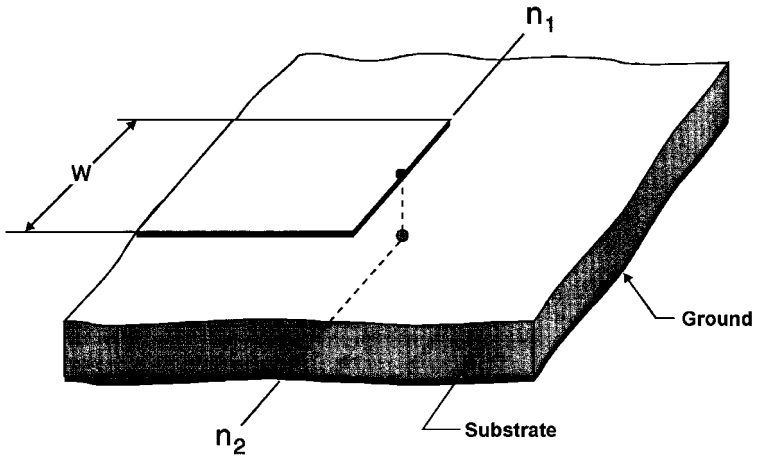

Figure 3-189 The OPEN element tells the simulator to calculate the effects of leaving the end of a transmission line unconnected.

We mention the issue of foundries here again because each foundry has its own proprietary approach to modeling discontinuities. The availability of a foundry service somewhat eases the requirement that a designer be fully up to speed on the nuances of discontinuities, because a foundry's designer service will help customers account for all relevant parasitics or discontinuities in their designs. In addition, there are tables of *S* parameters for standard cells of either capacitors, resistors, or inductors. The designer may then be forced to adjust the circuit so that it will work with a particular inductance value or value of another component within the resolution of the table that describes these elements. Information on the active parts, such as diodes and transistors, was given in Chapter 2.

3-10-1 RF Biasing

Applying the knowledge we have just acquired about distributed elements, Figure 3-190 shows a somewhat exaggerated case of using the various elements. While it is consistent with the simple RF case with which we started, modeling of this type is certainly necessary at higher frequencies. Many but not all of the elements we have just described are used, but we have not solved the question of the actual dc biasing.

3-10-2 dc Biasing

The following discussion is the recommended procedure for biasing a transistor. We will start with the collector current (in our example, Figure 3-191, 10 mA). To separate RF and dc, we have a combination of a load resistor (R_L) and an inductance (L_C). Information about this operation was given already in Section 3-2-6. The emitter resistor should have a voltage

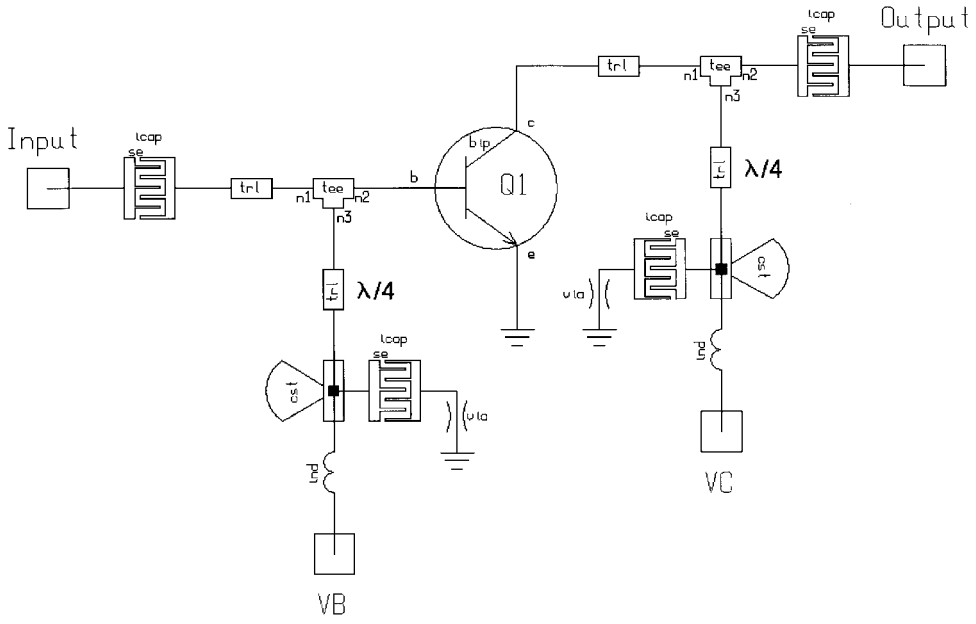

Figure 3-190 Simple BJT RF amplifier with distributed elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

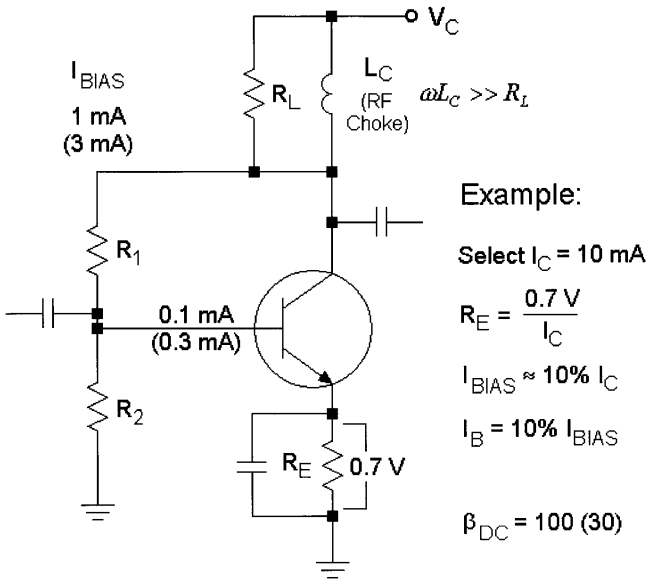

Figure 3-191 A dc biasing example.

drop of about 0.7 V, and therefore the emitter resistor is $0.7/I_C$. The next assumption is that the transistor has a dc current gain of 100, and therefore we decide to have the bias resistor chain (R_1 and R_2) draw 10% of I_C, or 1 mA. Assuming a collector voltage of 5 V, the value of $R_1 + R_2$ has to be 5 kΩ to result in the required 1 mA. Because the base current now is 10% of the divider current, the base will draw 0.1 mA. The voltage across R_2 has to be the voltage drop across R_E (0.7 V) + V_{BE}, which is also 0.7 V, or 1.4 V. Given the 1 mA, R_2 = 1.4/1E–3 = 1.4 kΩ. R_1 therefore is 5 kΩ – 1.4 kΩ = 3.6 kΩ. This concludes the calculation.

In the case of a dc beta of only 30, we need to raise I_{BIAS} from 1 mA to 3 mA since the base current now will be 0.3 mA. This changes the resistor values. $R_1 + R_2$ = 5 V/3 mA = (rounded) 1.6 kΩ. Following the same approach, we need 1.4/3E–3 = (rounded) 470 Ω. This makes R_1 = 1600 Ω – 470 Ω = (rounded) 1100 Ω. These roundings were necessary because resistors can only be bought in certain resistance steps.

However, for low battery voltages, the 0.7 V between the emitter and ground cannot be wasted. Therefore, a dc stabilization circuit, to which we have already referred, will be considered next. Figure 3-192 shows a combination of an RF transistor, Q1, and a dc stabilization transistor, Q2. The most important thing about this circuit is the fact that the difference between the supply voltage and the collector of Q1 is 0.3 V, which is approximately half of the voltage we had to "waste" across R_E in the above-mentioned circuit. Plus, the voltage drop is now in the collector, and given the fact that we feed Q1's collector through the inductor of a quasi-tuned circuit rather than through only a resistor, we get a much higher voltage swing. The base–collector diode temperature dependency of Q2 is compensated for with the silicon diode feeding the base. It is also fascinating to see that, because of the low currents, both the voltage drop of the diode and V_{BE} of Q2 are about the same, and yet Q1, operating at a reasonable current, shows the expected 0.7–0.8 V V_{BE}. We have supplied all the necessary dc voltages to give the reader an incentive to calculate the mechanism of this stabilization. The key equation to this is to determine the current in the voltage divider feeding

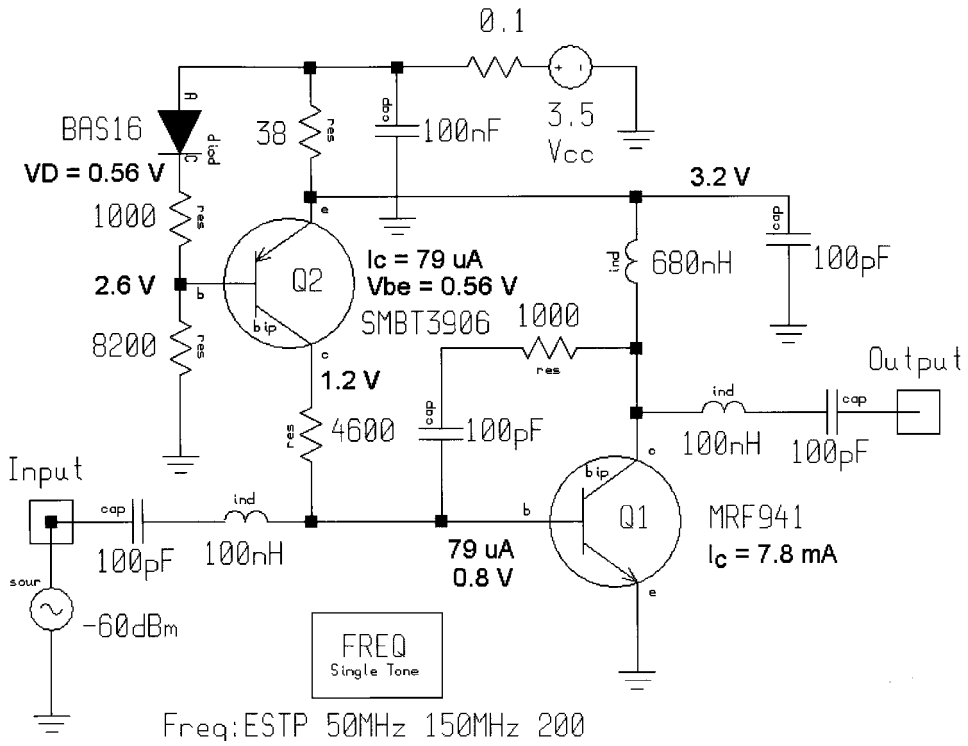

Figure 3-192 An RF amplifier with active biasing. (After the low-noise amplifier circuit in [29].)

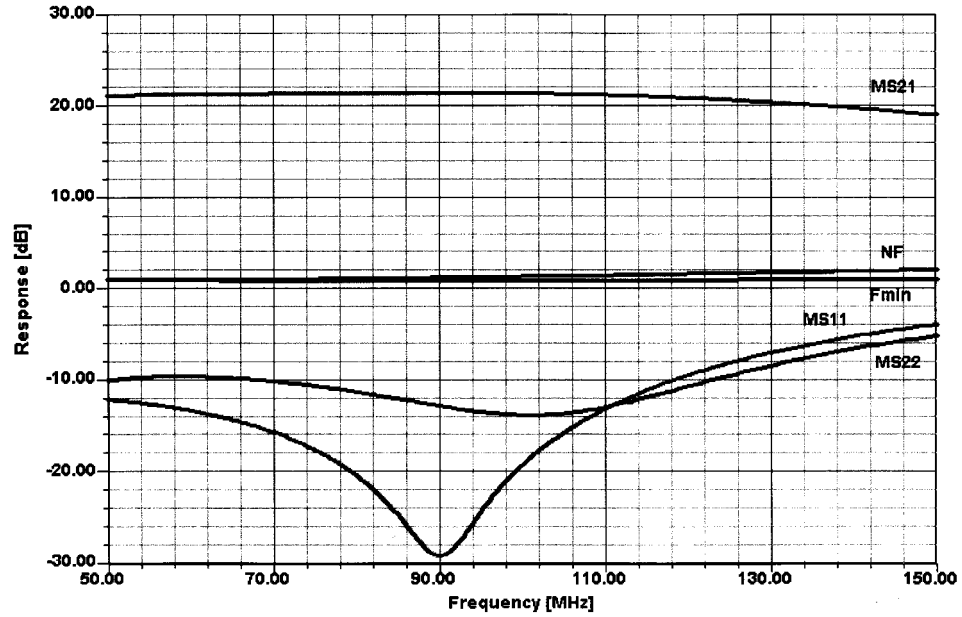

Figure 3-193 Frequency-dependent gain, matching, and noise responses for the amplifier in Figure 3-192.

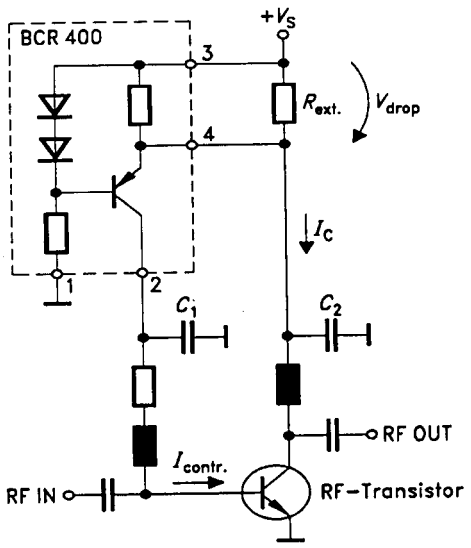

Figure 3-194 The Siemens BCR400 active bias controller can be applied to FETs as well as BJTs.

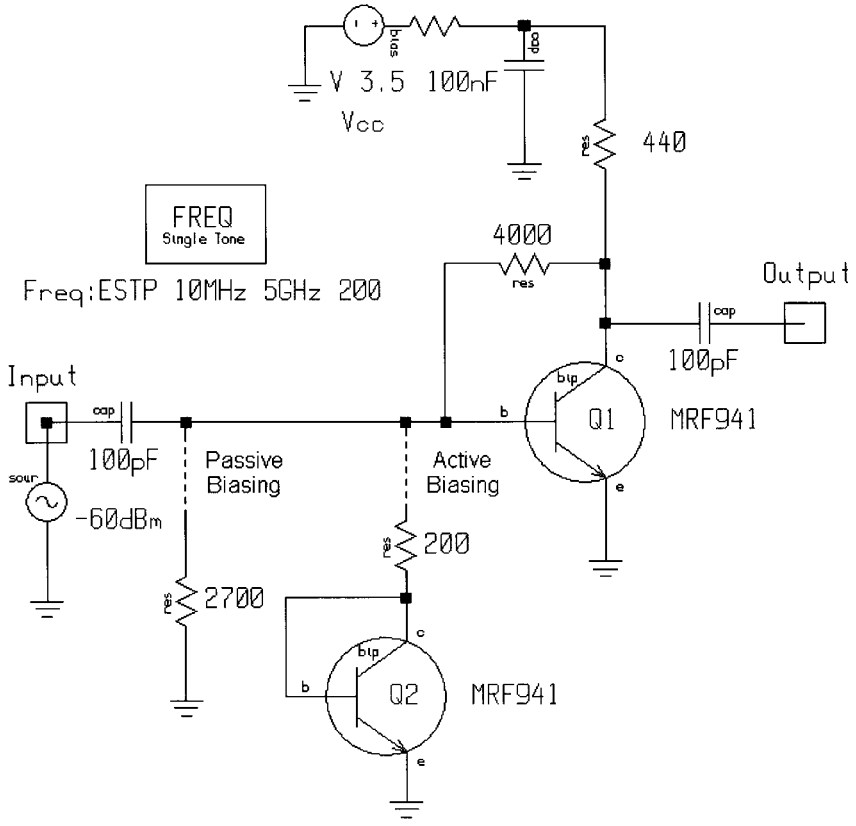

Figure 3-195 Amplifier stage (I_C = 3 mA) showing active and passive bias alternatives.

Q2, and proceeding from there. On the other hand, having a nice CAD tool that provides insight into the dc voltages and allows the addition of dc voltage probes makes life much easier. To prove that this circuit actually works, Figure 3-193 shows its frequency-dependent gain, matching, and noise figure performance. It is based on a Motorola application, which had excessive voltage drop for Q1 and which we have improved to be suitable for low-voltage operation [29].

Integrated active bias solutions are also available. Figure 3-194 shows the Siemens BCR400 active bias controller applied to a BJT; it can also be applied to FETs and TR switching diodes, as we saw in Figures 3-57 and 3-59, respectively.

3-10-3 dc Biasing of IC-Type Amplifiers

In integrated circuits, we do not have the unlimited flexibility described earlier. This results frequently in constant-current sources or transistors being used as diodes for biasing purposes. Our first suspicion is that this is going to cause a lot of noise in the IC; Figure 3-195 shows a test example.

As suspected, choosing the same bias point of 3 mA, the noise figure using active bias is quite a bit higher than the passive one, as shown in Figure 3-196.

3-11 PUSH–PULL/PARALLEL AMPLIFIERS

Since it is practically impossible to obtain $S_{11} = S_{22} = 0$, using a combiner at the input and output reduces the problem. Figure 3-197 shows the 3-dB hybrid approach. It has a practical

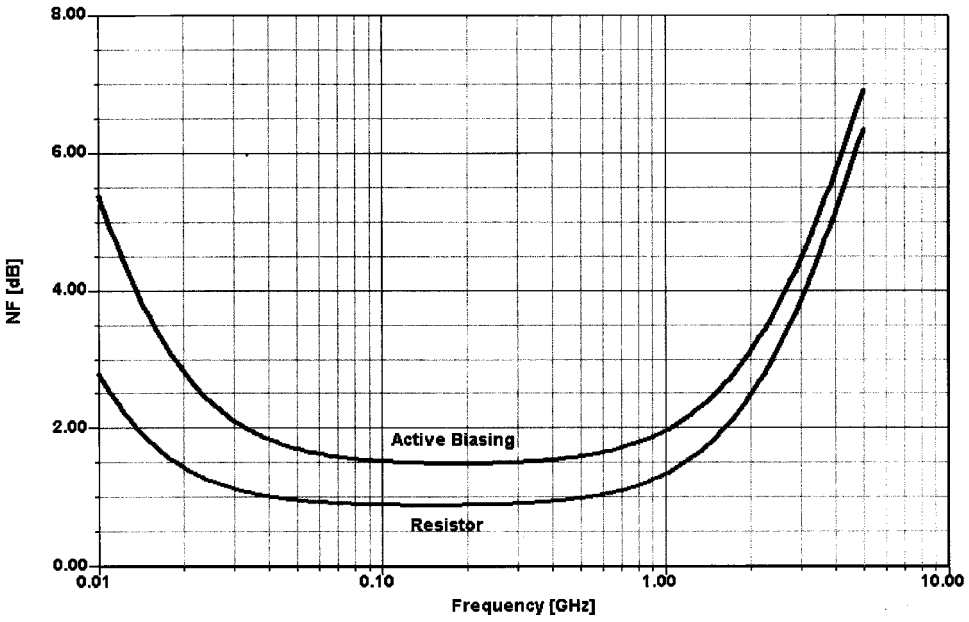

Figure 3-196 Frequency-dependent noise figure of the amplifier circuit shown in Figure 3-195. The active biasing curve is considerably noisier.

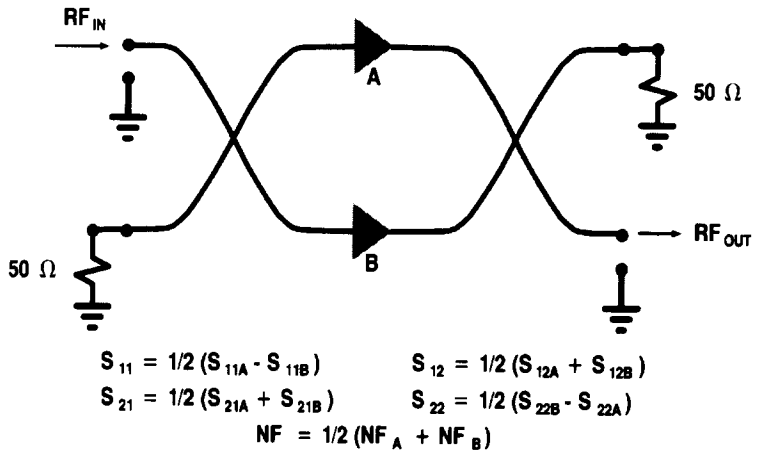

Figure 3-197 Combining power with 3-dB hybrid couplers.

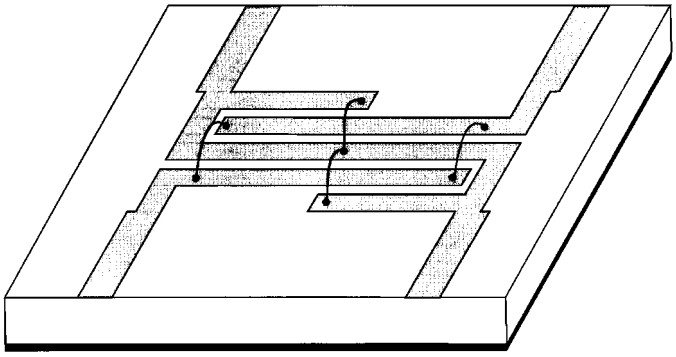

Figure 3-198 Four-strip version of the Lange coupler, a broadband 90° hybrid.

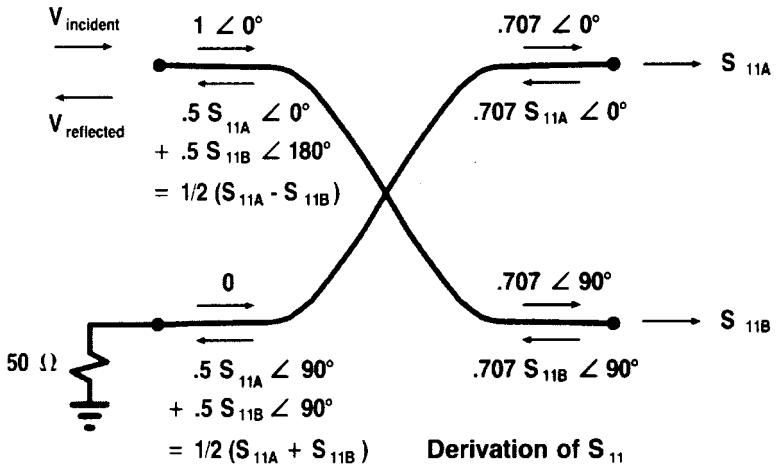

Figure 3-199 3-dB hybrids. This analysis method may be applied to any coupler.

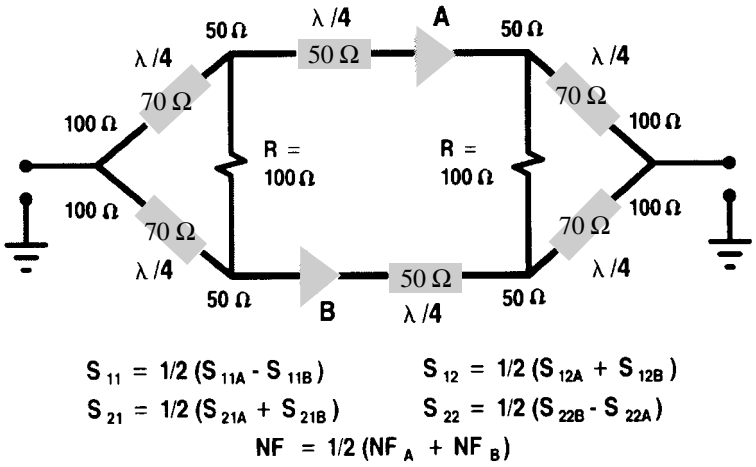

Figure 3-200 Wilkinson divider/combiners.

bandwidth limit of about 4:1; its advantage is that it is compact and ideal for cascading. If one stage opens, P_{OUT} and gain drop only 6 dB; however, it does not protect against load mismatch. A recommended distributed form is the Lange coupler (Figure 3-198). To analyze this approach, Figure 3-199 shows the resulting impedances and necessary phase shifts. If a Wilkinson coupler [30] is used instead of the 3-dB hybrid, the bandwidth is reduced. The Wilkinson coupler is larger in size than the 3-dB hybrid but more easily realized, leading to lower cost. Figure 3-200 shows the actual impedances necessary for matching, with A1 and A2 being the actual amplifiers combined.

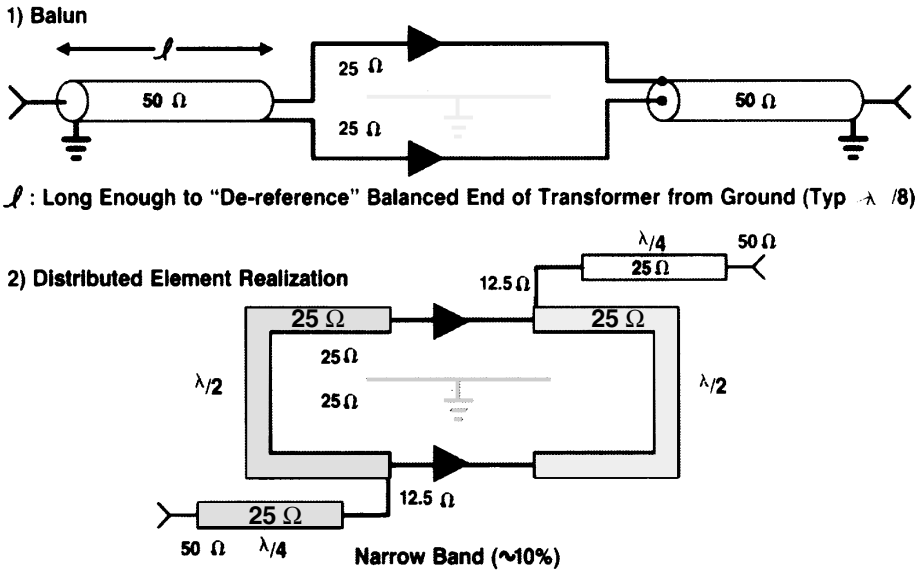

Figure 3-201 Push–pull amplifiers.

The solution for push–pull amplifiers resorts to a balun with the following results obtained: Bandwidths of greater than one decade are achievable; the balun structure gives 4:1 impedance advantage; there is no isolation; $S_{11} \neq 0$, $S_{22} \neq 0$; and cancellation of even-order products is provided.

Since most amplifiers have 50-Ω rather than 25-Ω impedances, Figure 3-201 shows a circuit that matches 25 Ω to 50 Ω on both sides. Since the standard amplifier operates at 50 Ω rather than 25 Ω, an additional network may be necessary to transform the impedance up to 50 Ω again. A similar problem occurs at the amplifier output.

3-12 POWER AMPLIFIERS

Power amplifiers are devices that are tasked to transform as much dc power into RF/microwave power as possible. Depending on the technology, devices are available that can produce at least 100 W up to 2 GHz. Since the transconductance of FETs at conducting angles of less than 180° becomes very small, the actual power gain sharply decreases compared to Class A operation while the power-added efficiency is optimized to values of 55% (Class B) or so. The dissipation of these devices is, of course, quite high, while in Class B operation this is even more of an issue. Power devices in Class C are dying to have big heat sinks to survive. One of the nice things about FETs is a much reduced thermal runaway effect compared to their bipolar brothers.

Power amplifier classes are defined in terms of the device conduction angle and/or the type of device operation:

Class A	"Linear" operation; 180° conduction angle
Class AB	"Linear" operation; conduction angle between 90° and 180°
Class B	"Linear" operation; 90° conduction angle
Class C	Fixed drive; less than 90° conduction angle
Class D	Switched operation, conduction range may vary with time from 0° to 180° or may be fixed.

There are also Classes E and F, which are currently under evaluation and showing some promising results.

Figure 3-202 shows Class C operation. The output of the amplifier is a current pulse train, which frequently leads to misunderstanding as to the calculation of its load. Given the fact that the amplifier is a current generator, it is silly to assume one has to do a conjugate matching looking backward into the amplifier. This is the condition for Class A operation. Unfortunately, this is still not understood by some engineers, but we hope we can clear this up today. The theoretical efficiency is 89.7% at a conducting angle of less than 180°; in practice, efficiencies more than 85% are not obtainable. (All of these efficiencies are those of the device itself; losses in matching networks are not taken into account in these efficiency values.) Considering optimal gain and optimal output power, the conducting angle actually settles somewhere between 100° and 140°. Again, the power gain in Class C operation is less than in Class A and Class B operation.

3-12-1 Example 1: 7-W Class C BJT Amplifier for 1.6 GHz

The following demonstrates how to design a 1.6-GHz, 7-W amplifier operating in Class C. We need to point out again that all modulation forms that contain the information in both

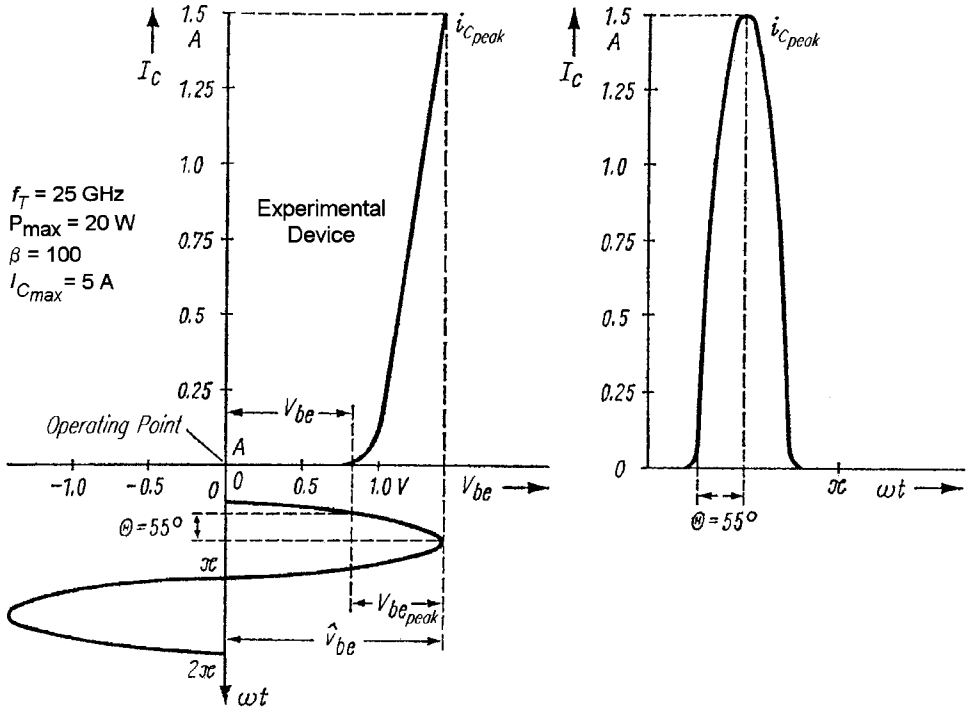

Figure 3-202 Output current as a function of drive voltage, taking into consideration the knee voltage of the base–emitter *pn* junction. The output is a series of current pulses with a duty cycle determined by the conduction angle.

amplitude and phase require more linearity than Class C affords. Needless to say, this affects the efficiency; therefore, at a later point we will also show a Class AB power amplifier. This is a tutorial, so we will present a UHF example and walk the reader through all the problems involved in the design. The selection of the transistor is done by first looking at the f_T, which in our case should be at least 4–5 GHz. The first order of business is to define the point of operation for the output amplifier. To do this, we need to determine the maximum voltage and current values supplied by the manufacturer. We have chosen a device that operates at 28 V and can sustain a peak collector current of 1.5 A. Figure 3-202 lets us determine the conducting angle Θ from the I_C/V_{BE} plane. This figure shows on the left side the I_C/V_{BE} plane and the necessary voltage to drive the amplifier.

Initially, we assume that the base–emitter junction is operated without any bias ($V_{BE} = 0$). The dc I–V curve shows that the collector current starts at about 650 mV. The amplifier itself, therefore, is already in Class C operation. For full output power, the drive voltage $V_{BE,\text{peak}}$ has to be 1.14 V. Therefore, the conducting angle can be determined by

$$\cos \Theta = \frac{V_{BE}}{\hat{\boldsymbol{v}}_{BE}} = \frac{0.65}{1.14} = 0.57$$

$$\cos 0.57 = 55^\circ$$

V_{BE} is the dc voltage at which the transistor starts conducting. From Figure 3-65 and Eqs. (3-160), (3-161), and (3-162), the fundamental current i_{c1} can be determined from

$$i_{c1} = i_{\text{peak}} \cdot f_1(\Theta)$$

or

$$i_{c1} = 1.5 \text{ A} \times 0.36 = 0.54 \text{ A}$$

The average collector dc current can be determined from

$$i_{c2} = i_{\text{peak}} \cdot f_2(\Theta)$$

or

$$i_{c2} = 1.5 \text{ A} \times 0.21 = 0.315 \text{ A}$$

The collector saturation voltage $V_{CE(\text{sat})}$, unfortunately, is around 2–3 V; for the purpose of the calculation, we assume that the saturation voltage is 3 V, and, therefore, we can assume that the maximum collector ac voltage $\hat{v}_{CE} \approx (V_B - 3) = 25$.

The appropriate collector load has to be

$$R_C = \frac{\hat{v}_{CE}}{i_{C1}} = \frac{25}{0.54} = 46.3 \ \Omega$$

The maximum output power is

$$P_{\text{out}} = \frac{(V_{CE} - V_{CE(\text{sat})})^2}{2R_C} = \frac{625}{92.6} = 6.75 \text{ W}$$

The only way to increase the power would be to have a smaller collector load at a higher current. In this family of Motorola transistors, there was no 10-W transistor; that's why we have chosen a 20-W experimental device, which for this purpose is overkill. The theoretical efficiency of the amplifier is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{6.75 \text{ W}}{0.315 \times 28} = 85\%$$

If the saturation voltage would be less, our efficiency would automatically increase, since for the given load, the actual output power would increase (6.75 W $\rightarrow$ 7.5 W). Assuming that this stage would operate at 1900 MHz with a gain of roughly 22 dB, the required drive would be significantly less than the output power, or roughly 40 mW. For the purpose of the following calculations, we will assume that the drive power is 0.7 W. The total dissipation of the device now adds up to be

$$P_T = P_{\text{in(dc)}} - P_{\text{out}} + P_{\text{drive}}$$

$$P_T = (28 \times 0.315) - 6.75 + 0.7 = 2.77$$

Power-added efficiency is derived from this. Knowing the power dissipation, one can calculate a thermal resistance R_{therm} of the heat sink and the transistor:

$$R_{\text{therm}} = \frac{T_J - T_A}{P_T}$$

Where T_J is the device junction temperature and T_A is the ambient temperature. For a maximum ambient temperature of 60 °C and a maximum junction temperature of 150 °C, the thermal resistance is

$$R_{\text{therm}} = \frac{120 - 60}{2.77} = 21.7\ ^\circ\text{C/W}$$

R_{therm} is the sum of thermal resistance of the transistor and its package, and the thermal resistance between the transistor package and the heat sink, and the thermal resistance between the heat sink and the ambient air. Therefore,

$$R_{\text{therm}} = R_{\text{th(case)}} + R_{\text{th(case/heat sink)}} + R_{\text{th(heat sink)}}$$

The required thermal resistance of the heat sink is calculated from

$$R_{\text{th(heat sink)}} = 21.7 - 10 - 1.4 = 15.6\ ^\circ\text{C/W}$$

Assuming an aluminum heat sink (a 2-mm-thick plate), the required heat-sink surface area A (cm^2) is

$$A = \frac{1}{\alpha R_{\text{th(heat sink)}}}; \quad \alpha \approx 1.5\ \frac{\text{mW}}{^\circ\text{Ccm}^2}$$

Therefore, the required area is

$$A = \frac{1}{1.5 \times 0.0156} = 42.7\ \text{cm}^2$$

The next task is to match both the input and output to the (most likely) 50-Ω source and termination. The following section will guide us through the procedure. The input impedance Z_{11} (after some lengthy search) was found to be $1 + j10\ \Omega$. This means that the input consists of the base-spreading resistance (approximately 1 Ω) and an input capacitance, which because of phase shift now turns out to be inductive. Since the popular method for input matching these days is a pi configuration, we are going to use a simple pi filter both for input and output matching. There are several equations in the literature that give the values for the two capacitors and inductors; most of them result in an incorrect resonance frequency. Since we have access to software tools, we decided to take three approximate values and use the optimizer to give us the appropriate matching. The only remaining variable in such an approach is the bandwidth. If we specify $S_{21} = 1$ and $S_{11} = 0$ (100% energy transfer and perfect return loss), we will realize that this is possible at only one frequency. We therefore need to identify a frequency band or bandwidth over which an acceptable match is needed. As the bandwidth increases, the match for such a simple circuit will get poorer; there are not enough elements available to do better. In this case, we took the center frequency ±100 MHz.

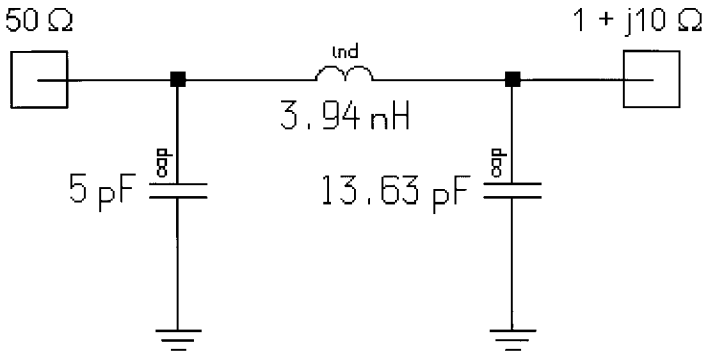

Figure 3-203 Input matching network for the amplifier used in this tutorial.

Figures 3-203 and 3-204 show the actual circuit with the element values and the resulting input match. Likewise, we did the same thing at the output, but the actual resulting dynamic output capacitance is not known *a priori*. For low frequencies, the integral equation gives a value of $2C_{CE}$; however, practical tests in frequencies above 500 MHz show that the actual increase is only 1.3 times the dc output capacitance. Therefore, we decided to design the filter with no output capacitance assumed, and the input capacitance of about 5 pF must be reduced for proper reactive matching. Mathematically, this could result in a negative number, specifically if the resulting output capacitance exceeds the 5-pF value. To compensate for this, one needs to use an RF choke that tunes out the resulting dynamic output capacitance and then one can revert to the original 5 pF as calculated.

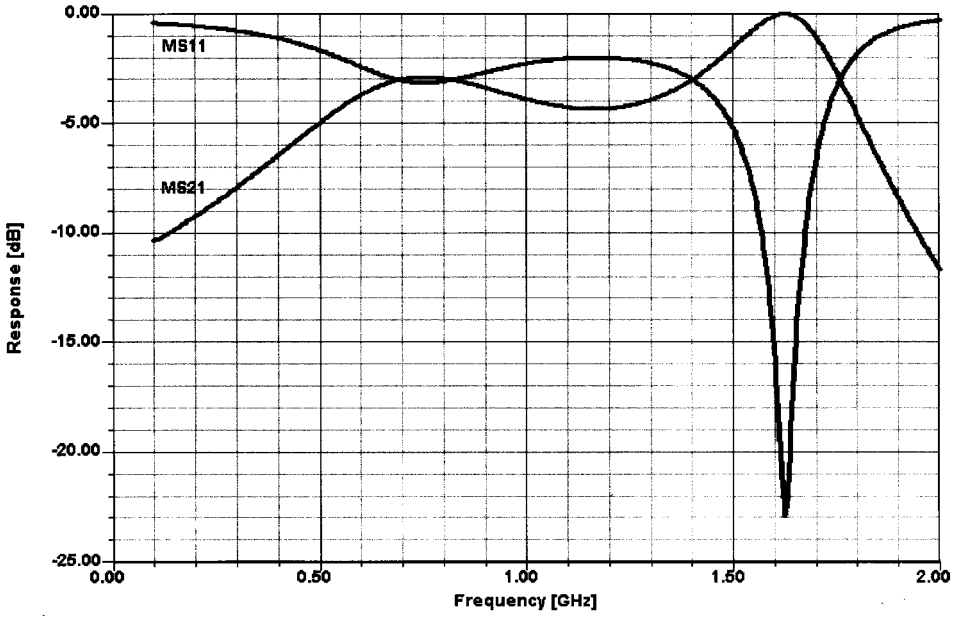

Figure 3-204 Frequency response of the input matching network.

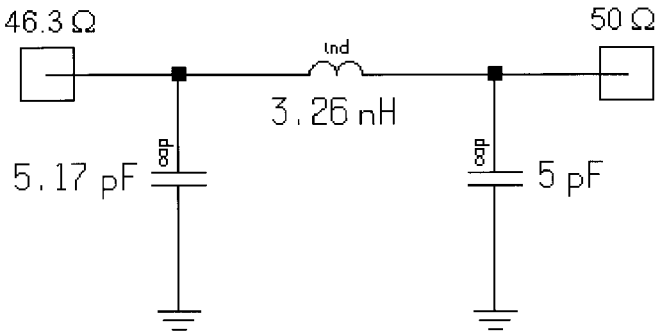

Figure 3-205 Output matching network for the amplifier.

The selection of the actual component is another issue, because these capacitors need to handle several amperes of RF current. It is not always easy to find capacitors with the appropriate value that can handle the current. The inductors can be printed. The paragraph following this section therefore will deal with the issue of how to translate the lumped values into distributed values, which will make the current handling much easier (we hope).

For this, we did the same optimizing approach by using a 50-Ω source and a 46.3-Ω load. Figures 3-205 and 3-206 show the circuit with the appropriate values and its simulated frequency-dependent responses.

The next step is to connect the input and output matching network to an "actual" transistor. This is a point where difficulties arise, since very few, if any, companies provide SPICE-type

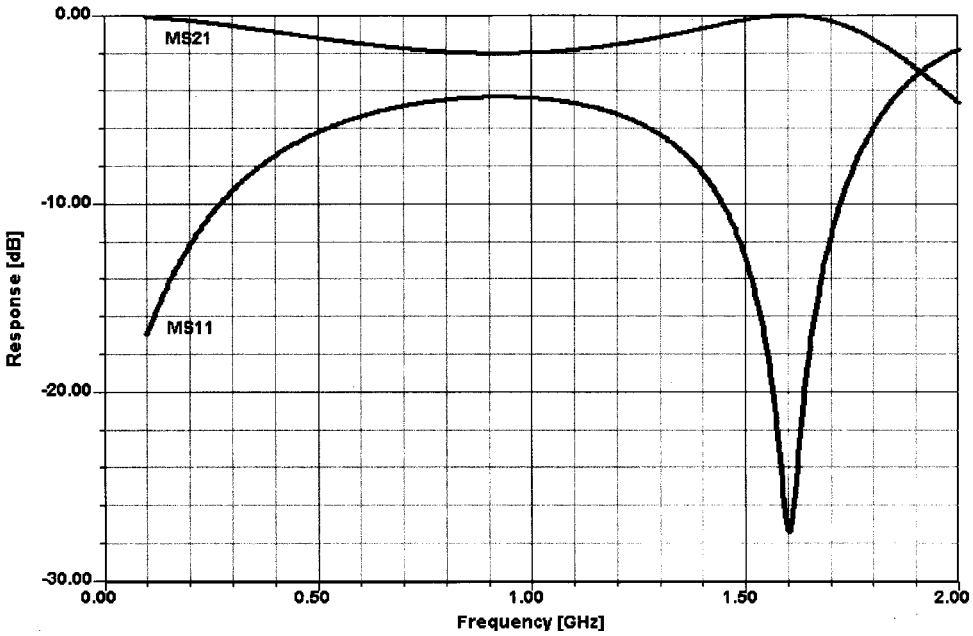

Figure 3-206 Frequency response of the output matching network.

parameters for transistors operating at currents of more than 200 mA. Figures 3-207 and 3-208 show the overall schematic and frequency response of the actual amplifier with all filters connected. Figure 3-209 details the amplifier's peak gain response. If more bandwidth is needed, the matching circuit must be increased in complexity, as will be shown in the following section.

Now is a good time to look at the final results of our simulation, which is based on the various assumptions as outlined above. Figure 3-210 shows the dc *I–V* curves with a straight load line and no reactances. This was accomplished by using a wideband transformer instead of an output matching circuit. Figure 3-211, however, shows the "load line" that results when the transformer is replaced with a real matching network. Based on the harmonics content and its improper termination, one can see how the output load line opens and shows ringing in the low-current area. If we expect to see the saturation voltage, we will be disappointed because the saturation voltage is frequency dependent (increases with frequency) and this figure gives an erroneous impression. Hence, we show dc *I–V* curves. To display the conduction angle, which we showed previously, we examine the output current as a function of time at a drive level of +16.5 dBm (Figure 3-212). During the negative half, the transistor is not conducting as predicted, so this validates our assumptions. Next, we are interested in determining the power gain. Therefore, we look at the output spectrum for a drive level of +16.5 dBm (Figure 3-213). It shows an output level of 38.6 dBm. If we subtract the drive level (16.5 dBm) from this, we see that the power gain is 22.1 dB at this drive level. Since we are used to thinking in watts, Figure 3-214 shows the absolute output power and the harmonics prior to filtering. Figure 3-215 shows the output spectrum after replacing the transformer with a simple pi output network.

During the conduction period, there will be a voltage across the transistor 180° out of phase, as shown in Figure 3-216. Finally, to highlight the nonlinearity of a Class C amplifier, Figure 3-217 shows the amplifier's output power versus drive, and Figure 3-218 shows the amplifier's gain versus drive. When the transistor turns on is clearly evident.

A particular difficulty arises in the case of FETs, where the charge energy makes for a difference between dc and pulsed measurements. Figure 3-219 shows this. Some of the more modern transistors, such as SiGe types, may need some pulsing also; as can be seen in Figure 3-219, even depending on the pulsing, one may get different dc *I–V* curves. This area is still under investigation, and even the "experts" do not agree on all aspects of this. In real life, it turns out that a lot of experimentation is the answer. Anyone who thinks that a pure CAD approach will give the right design answers immediately will encounter many surprises! This is not a fault of the CAD tools—assuming that they are properly engineered—but rather the availability of appropriately "tweaked" models for high-power applications, and the willingness of device suppliers to standardize on certain models and support them.

Because of the difficulties involved in cooling transistors under test and simulating RF pulse and CW conditions, depending on the application, manufacturers have so far stayed away from investing money in this area. The designer must therefore resort to application notes published by device manufacturers. Because even slight layer changes can have a large impact on the frequency response of a given device, application-note-based designs can run into difficulty if a device's fabrication has significantly evolved since the publication of its application notes.

Given the multitude of models outlined in Chapter 2, the CAD user is sometimes left hanging as to which is the best model to use. The latest indications are that the MEXTRAM (*m*ost *e*xquisite *t*ransistor *m*odel), developed by the University of Delft, Holland, with Philips of Holland, shows the most promising result, specifically in the area of IMD products. While

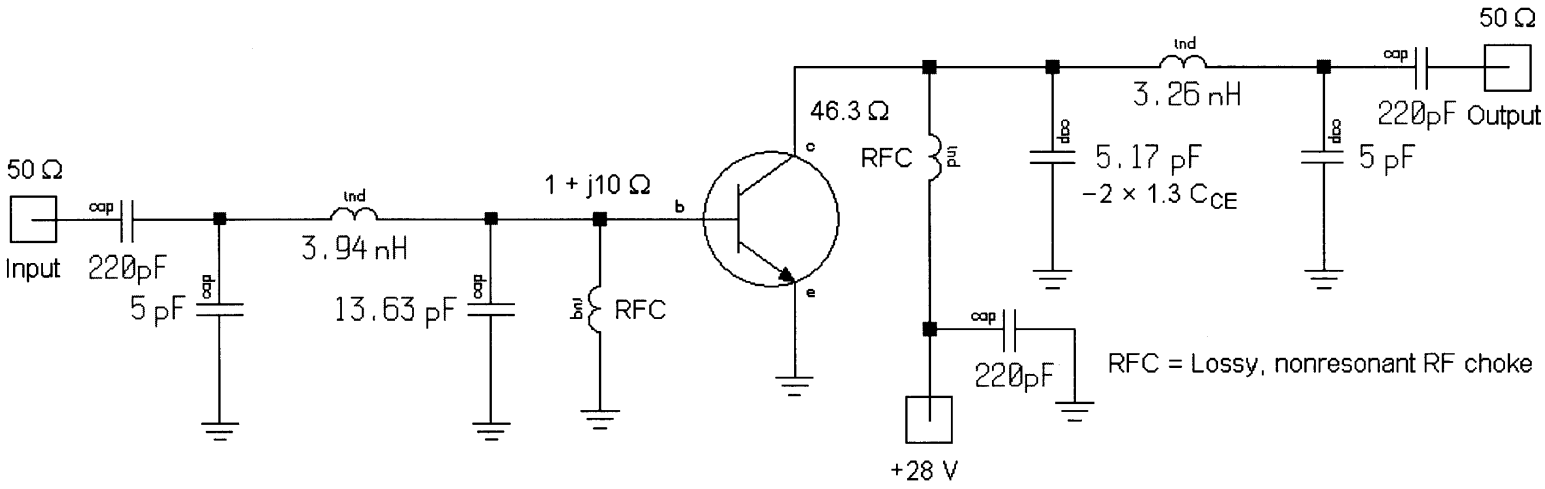

Figure 3-207 Actual schematic of our experimental 1.6-GHz amplifier. The RF chokes have enough RF losses not to be resonant and yet don't load the circuit. This is frequently accomplished with either ferrite beads or resistors in parallel with the chokes.

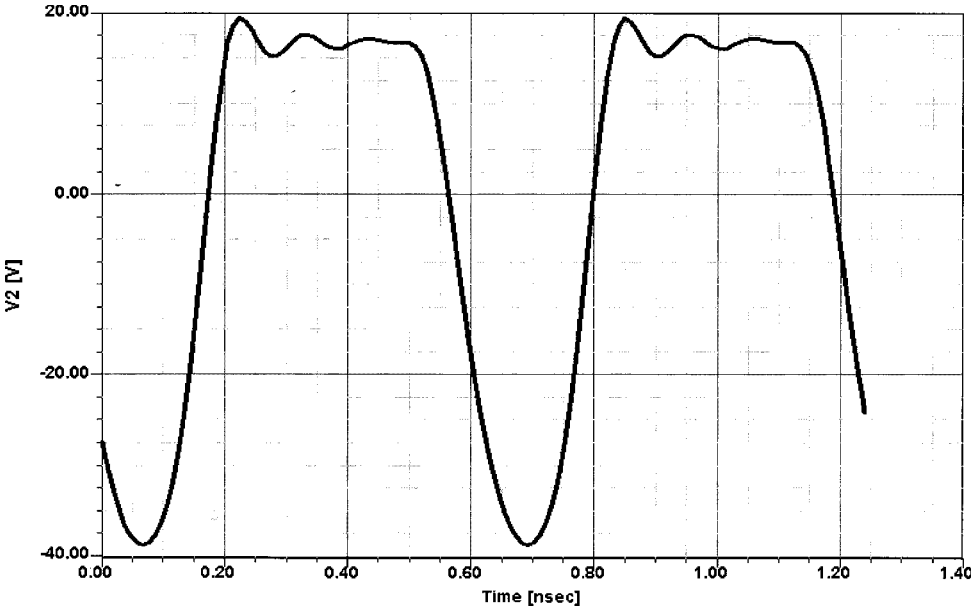

Figure 3-216 Output voltage at the collector. The voltage is asymmetrical compared to 0; this is important in the selection of a device capable of handling these voltages.

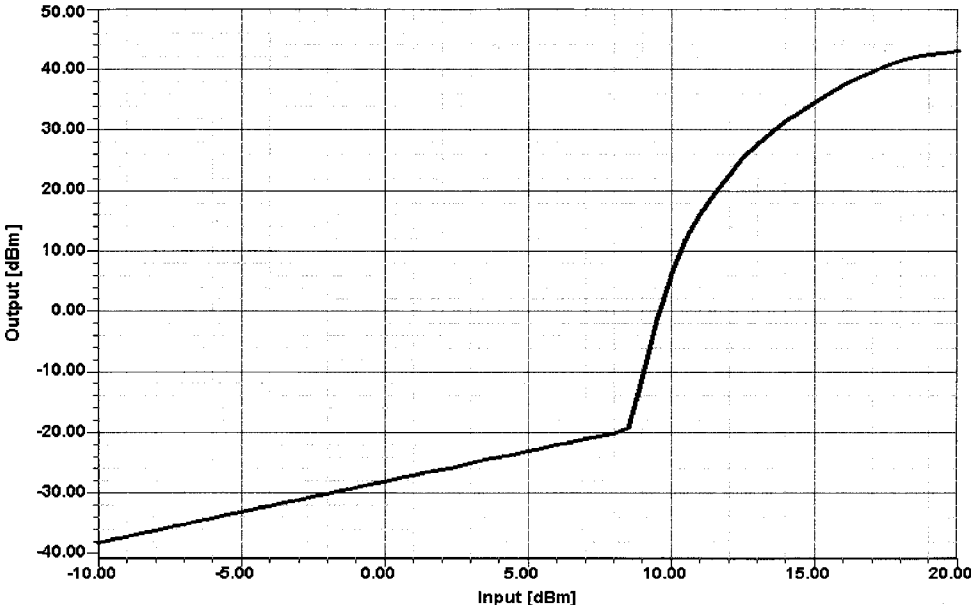

Figure 3-217 Output power versus input power for the Class C amplifier. Until the transistor turns on (at a drive level of about 8.5 dBm), only fedthrough power appears at the output.

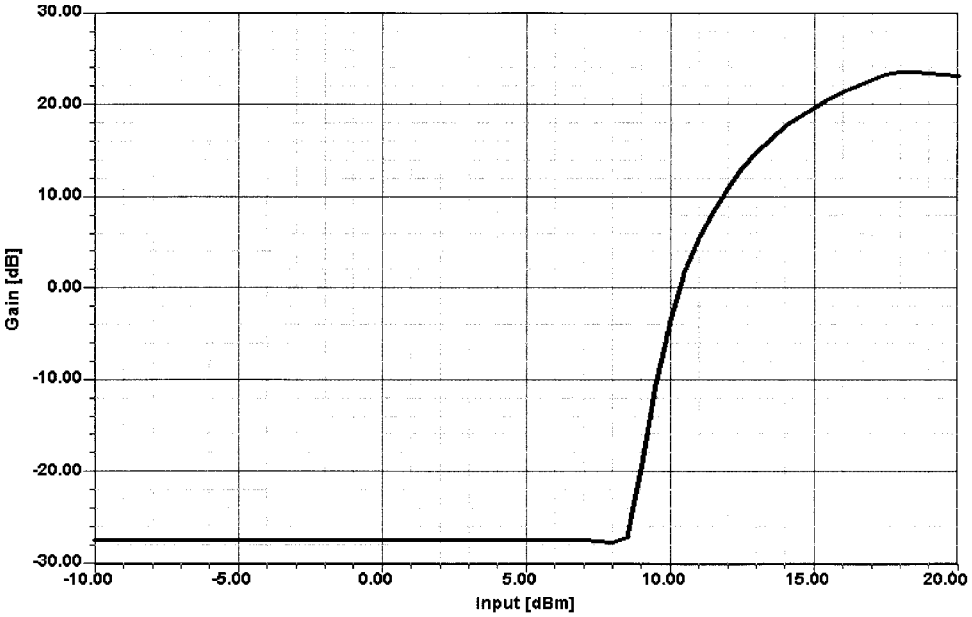

Figure 3-218 Amplifier gain as a function of drive. It is evident that one needs to cross the 0.65-V point for the transistor to become conductive and show gain. The initial amplification as a function of drive shows a very steep curve that then levels off and drops as the amplifier moves into saturation.

other later models have up to seven internal nodes, MEXTRAM fortunately uses only five. (The MEXTRAM model actually consists of three transistors, which makes modeling fun.) Power-added efficiency simulation is not available, since the MEXTRAM model was developed for small-signal applications, meaning circuits that operate at less than 100 mW of RF output power.

As if the absence of trustworthy high-power device models is not challenge enough, in developing this 1.6-GHz Class C amplifier example, we ran into another complication: Using a CAD optimizer to simultaneously match the circuit's input and output networks failed because of the device's input-impedance variation with drive. Every matching adjustment that improved the drive to the device resulted in an input-impedance change that reduced the drive to the device! In the end, the optimizer couldn't keep up. In actually building such a circuit, one would make the matching-network values adjustable on the initial breadboard and then, with the necessary input drive level applied, iteratively adjust the input and output matching for the desired output level. It appears that the CAD program could not handle such a degree of nonlinearity.

We then went to the approach of using large-signal *S* parameters at a drive level slightly less than 16 dBm, but this detuned the input filter, resulting in a poorer input match than the one initially predicted. Likewise, the output matching, which in a power stage must result in maximum output power rather than a conjugate match, was less impressive. The large-signal *S* parameters at the output for a power amplifier are somewhat dubious because Class C operation generates so many harmonics that the output termination will reflect a lot of energy and, depending on the output filter topology, different results can be expected. We firmly believe that there will be further mathematical improvement in the CAD tools, and we very much invite

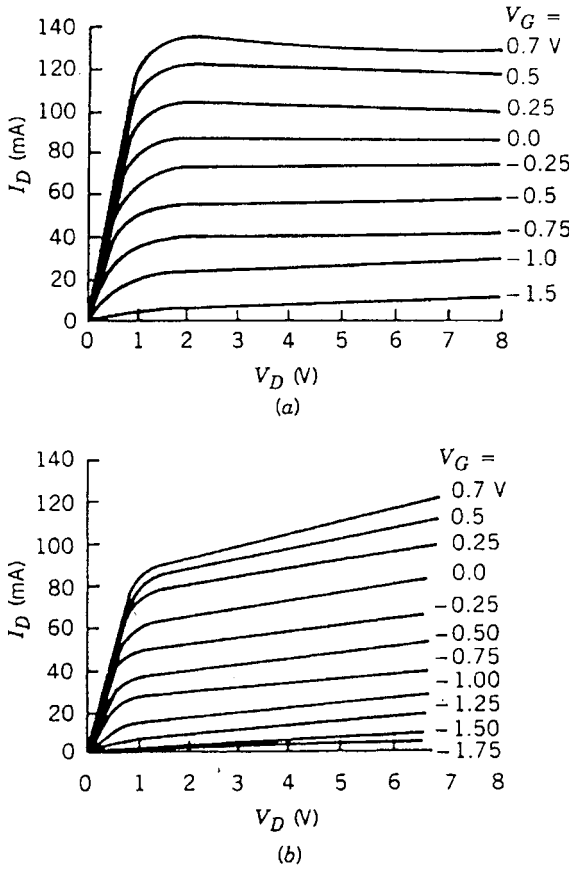

Figure 3-219 Comparison of FET drain current characteristics obtained from (a) pulsed *I–V* and (b) rectified sine-wave evaluation. The rectified sine-wave curves can be considered equivalent to curves obtained at dc.

our readers to use such a nonlinear example to test their tools, provided that a high-power model becomes available in this power range.

It has been rumored that the load-pull technique, rather than the application of large-signal *S* parameters, is a vehicle to solve such matching problems. However, the load-pull technique is really applied only to the fundamental frequency and does not deal with the issue of harmonics of the output current. More details about the load-pull technique and its capabilities are found in Appendix B.

Actual measurements of amplifiers of this type show that our simulated efficiency and drive level come quite close to reality, but at a frequency somewhat offset from that chosen for the design. As an example, the input and output filters tuned at 1.4 GHz instead of 1.6 GHz using the large-signal *S* parameters. Again, an iterative process, similar to manually trimming a prototype, will give a similar result. This is consistent with our earlier statement that most final designs are really hand-tweaked, and that CAD can only bring us close, but not all the way, to a good solution. For passive problems, the CAD does a significantly better job; the nonlinear cases are the ones that still cause headaches.

3-12-2 Impedance Matching Networks Applied to RF Power Transistors*

Introduction. Some graphical and numerical methods of impedance matching will be reviewed here. The examples given refer to high-frequency power amplifiers.

Although matching networks normally take the form of filters and therefore are also useful to provide frequency discrimination, this aspect will be considered only as a corollary of the matching circuit.

Matching is necessary for the best possible energy transfer from stage to stage. In RF power transistors, the input impedance is of low value, decreasing as the power increases or as the chip size becomes larger. This impedance must be matched either to a generator—of generally 50-Ω internal impedance—or to a preceding stage. Impedance matching has to be made between two complex impedances, which makes the design still more difficult, especially if matching must be accomplished over a wide frequency band.

Device Parameters

Input Impedance. The general shape of the input impedance of RF power transistors is as shown in Figure 3-220. It is a large-signal parameter, expressed here by the parallel combination of a resistance R_p and a reactance X_p [31].

The equivalent circuit shown in Figure 3-221 accounts for the behavior illustrated in Figure 3-220. With the presently used stripline or flange packaging, most of the power devices for VHF low band will have their R_p and X_p values below the series resonant point f_s. The input impedance will be essentially capacitive.

Most of the VHF high-band transistors will have the series-resonant frequency within their operating range; that is, they will be purely resistive at one single frequency f_s, which the parallel-resonant frequency f_p will be outside.

Parameters for 1- or 2-GHz transistors will be beyond f_s and approach f_p. They show a high value of R_p and X_p with inductive character.

A parameter that is very often used to judge on the broadband capabilities of a device is the input Q or Q_{IN}, defined simply as the ratio R_p/X_p. Practically, Q_{IN} ranges around 1 or less for VHF devices and around 5 or more for microwave transistors.

Q_{IN} is an important parameter to consider for broadband matching. Matching networks normally are low-pass or pseudo-low-pass filters. If Q_{IN} is high, it can be necessary to use bandpass filter-type matching networks and to allow insertion losses. But broadband matching is still possible. This will be discussed later.

Output Impedance. The output impedance of RF power transistors, as given by all manufacturers' datasheets, generally consists of only a capacitance C_{OUT}. The internal resistance of the transistor is supposed to be much higher than the load and is normally neglected. In the case of a relatively low internal resistance, the efficiency of the device would decrease by the factor

$$1 + R_L/R_T \tag{3-192}$$

*Based on Motorola application note AN-721 ("Impedance Matching Networks Applied to RF Power Transistors"). Copyright of Motorola; used by permission.

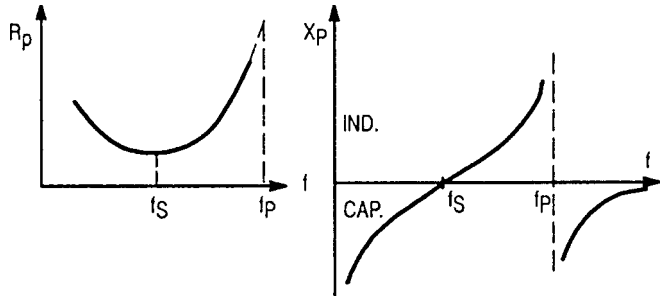

Figure 3-220 Input impedance of RF power transistors as a function of frequency.

where R_L is the load resistance, seen at the collector–emitter terminals, and R_T is the internal transistor resistance equal to

$$\frac{1}{\omega_T (C_{TC} + C_{DC})} \tag{3-193}$$

defined as a single parameter, where ω_T is the transit angular frequency and C_{TC} and C_{DC} are the transition and diffusion capacitances, respectively, at the collector junction.

The output capacitance, C_{OUT}, which is a large-signal parameter, is related to the small-signal parameter C_{CB}, the collector–base transition capacitance.

Since a junction capacitance varies with the applied voltage, C_{OUT} differs from C_{CB} in that it has to be averaged over the total voltage swing. For an abrupt junction and assuming certain simplifications, $C_{\text{OUT}} = 2C_{CB}$.

Figure 3-222 shows the variation of C_{OUT} with frequency. C_{OUT} decreases partly due to the presence of the collector lead inductance, but mainly because of the fact that the base–emitter diode does not shut off anymore when the operating frequency approaches the transit frequency, f_T.

Output Load. In the absence of a more precise indication, the output load R_L is taken as

$$R_L = \frac{[V_{CC} - V_{CE(\text{sat})}]^2}{2P_{\text{OUT}}} \tag{3-194}$$

with $V_{CE(\text{sat})}$ equal to 2 or 3 V, increasing with frequency.

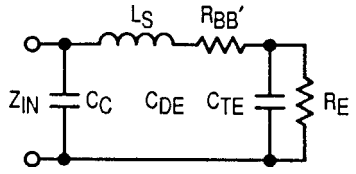

Figure 3-221 Equivalent circuit for the input impedance. R_E is the emitter diffusion resistance; C_{DE} and C_{TE} are the diffusion and transition capacitances, respectively, of the emitter junction; $R_{BB'}$ is the base-spreading resistance; C_C is the package capacitance; and L_S is the base lead inductance.

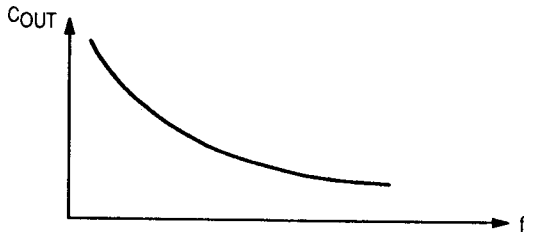

Figure 3-222 Output capacitance C_{OUT} as a function of frequency.

The above equation just expresses a well-known relation, but it also shows that the load, in first approximation, is not related to the device, except for $V_{CE(sat)}$. The load value is primarily dictated by the required output power and the peak voltage; it is not matched to the output impedance of the device.

At high frequencies this approximation becomes less exact, and for microwave devices the load that must be presented to the device is indicated on the datasheet.

Strictly speaking, impedance matching is accomplished only at the input. Interstage and load matching are more impedance transformations of the device input impedance and of the load into a value R_L (sometimes with additional reactive component) that depends essentially on the power demanded and the supply voltage.

Matching Networks. In the following, matching networks will be described by the order of complexity. These are ladder-type reactance networks. The different reactance values will be calculated and determined graphically. Increasing the number of reactances broadens the bandwidth. However, matching networks consisting of more than four reactances are rare. Above four reactances, the improvement is small.

Numerical Design

TWO-RESISTANCE NETWORKS. Resistance terminations will first be considered. Figure 3-223 shows the reactive L section and the terminations to be matched.

Matching or exact transformation from R_2 into R_1 occurs at a single frequency f_0. At f_0, X_1 and X_2 are equal to

$$X_1 = \pm R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = R_1 \frac{1}{\sqrt{n-1}} \tag{3-195}$$

$$X_2 = \mp \sqrt{R_2(R_1 - R_{2)}} = R_1 \frac{\sqrt{n-1}}{1} \tag{3-196}$$

At f_0, $X_1X_2 = R_1R_2$. X_1 and X_2 must be of opposite sign. The shunt reactance is in parallel with the larger resistance.

The frequency response of the L section is shown in Figure 3-224, where the normalized current is plotted as a function of the normalized frequency.

If X_1 is capacitive and consequently X_2 is inductive, then

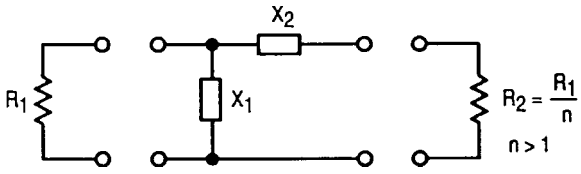

Figure 3-223 Two-reactance matching network.

$$X_1 = -\frac{f_0}{f} R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = -\frac{f_0}{f} R_1 \frac{1}{\sqrt{n-1}} \tag{3-197}$$

and

$$X_2 = \frac{f}{f_0} \sqrt{R_2(R_1 - R_2)} = \frac{f}{f_0} R_1 \frac{\sqrt{n-1}}{1} \tag{3-198}$$

The normalized current absolute value is equal to

$$\left|\frac{I_2}{I_0}\right| = \frac{2\sqrt{n}}{\sqrt{(n-1)^2 \cdot (f/f_0)^4 - 2\,(f/f_0)^2 + (n+1)^2}} \tag{3-199}$$

where $I_0 = \sqrt{n}E/2R_1$ and is plotted in Figure 3-224 [32].

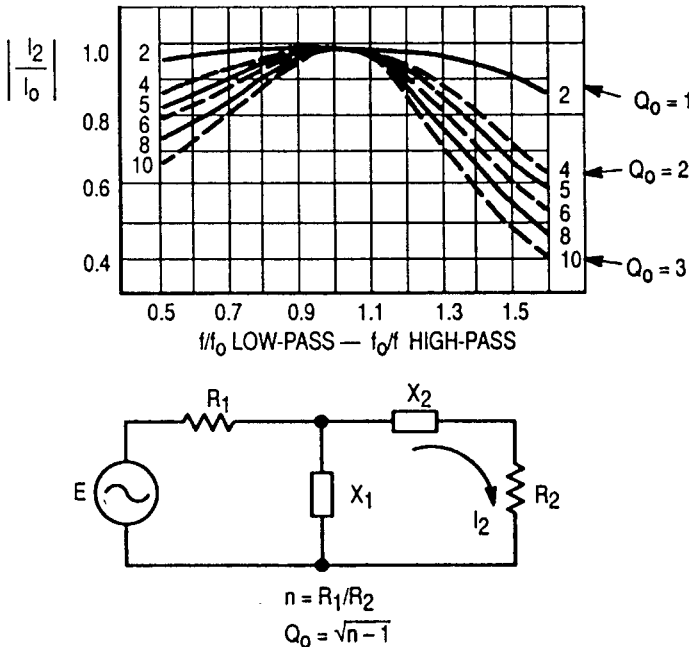

Figure 3-224 Normalized frequency response for the L section in low-pass or high-pass form.

If X_1 is inductive and consequently X_2 is capacitive, the only change required is a replacement of f by f_0 and vice versa. The L section has low-pass form in the first case and high-pass form in the second case.

The Q of the circuit at f_0 is equal to

$$Q_0 = \frac{X_2}{R_2} = \frac{R_1}{X_1} = \sqrt{n-1} \tag{3-200}$$

For a given transformation ratio n, there is only one possible value of Q. On the other hand, there are two symmetrical solutions for the network that can be either a low-pass filter or a high-pass filter.

The frequency f_0 does not need to be the center frequency, $(f_1 + f_2) / 2$, of the desired band limited by f_1 and f_2. In fact, as can be seen from the low-pass configuration of Figure 3-224, it may be interesting to shift f_0 toward the high-band edge frequency f_2 to obtain a larger bandwidth w, where

$$w = \frac{2(f_1 + f_2)}{f_2 - f_1} \tag{3-201}$$

This will, however, be at the expense of poor harmonic rejection.

Example. For a transformation ratio of $n = 4$, we can determine the following values from the above relations:

Bandwidth w	0.1	0.3
Maximum insertion losses	0.025	0.2
X_1/R_1	1.730	1.712

If the terminations R_1 and R_2 have a reactive component X, the latter may be taken as part of the external resistance as shown in Figure 3-225. This compensation is applicable as long as

$$Q_{int} = \frac{X_{\text{int}}}{R_2} \quad \text{or} \quad \frac{R_1}{X_{\text{int}}} < n - 1 \tag{3-202}$$

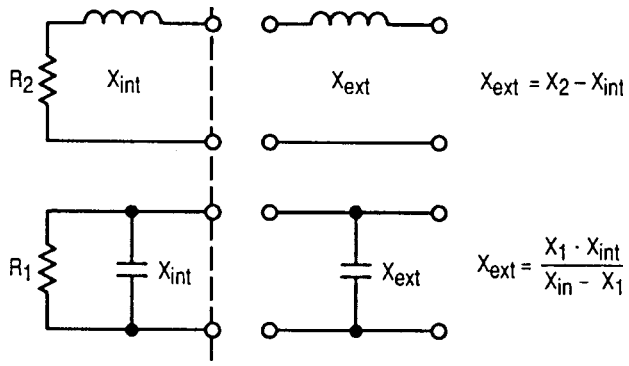

Figure 3-225 Termination reactance compensation.

Tables giving reactance values can be found in Matthaei et al. [33, 34].

USE OF TRANSMISSION LINES AND INDUCTORS. In the preceding section, the inductance was expected to be realized by a lumped element. A transmission line can be used instead (Figure 3-226).

As can be seen from the computed selectivity curves (Figure 3-227) for the two configurations, transmission lines result in a larger bandwidth. The gain is important for a transmission line having a length $L = \lambda/4$ ($\Theta = 90°$) and a characteristic impedance $Z_0 = \sqrt{R_1 R_2}$. It is not significant for lines short with respect to $\lambda/4$. One will notice that there is an infinity of solutions, one for each value of C, when using transmission lines.

THREE-REACTANCE MATCHING NETWORKS. The networks that will be investigated are shown in Figure 3-228. They are made of three reactances alternately connected in series and shunt.

A three-reactance configuration allows the designer to make the quality factor (Q) of the circuit and the transformation ratio $n = R_2/R_1$ independent of each other and consequently to choose the selectivity between certain limits.

For narrowband designs, one can use the following formulas (see [35], where tables are given):

Network (a)

$$X_{C1} = R_1/Q \quad Q \text{ must be selected first} \tag{3-203}$$

$$X_{C2} = R_2 \sqrt{\frac{R_1 R_2}{(Q^2 + 1) - R_1/R_2}} \tag{3-204}$$

$$X_L = \frac{QR_1 + (R_1 R_2/X_{C2})}{Q^2 + 1} \tag{3-205}$$

Network (b)

$$X_{L1} = R_1 Q \quad Q \text{ must be selected first} \tag{3-206}$$

$$X_{L2} = R_2 B \tag{3-207}$$

$$A = R_1(1 + Q^2) \tag{3-208}$$

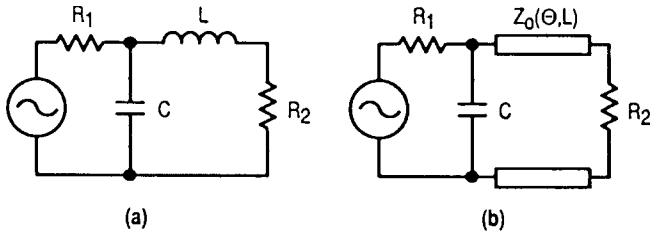

Figure 3-226 Use of a transmission line in the L section.

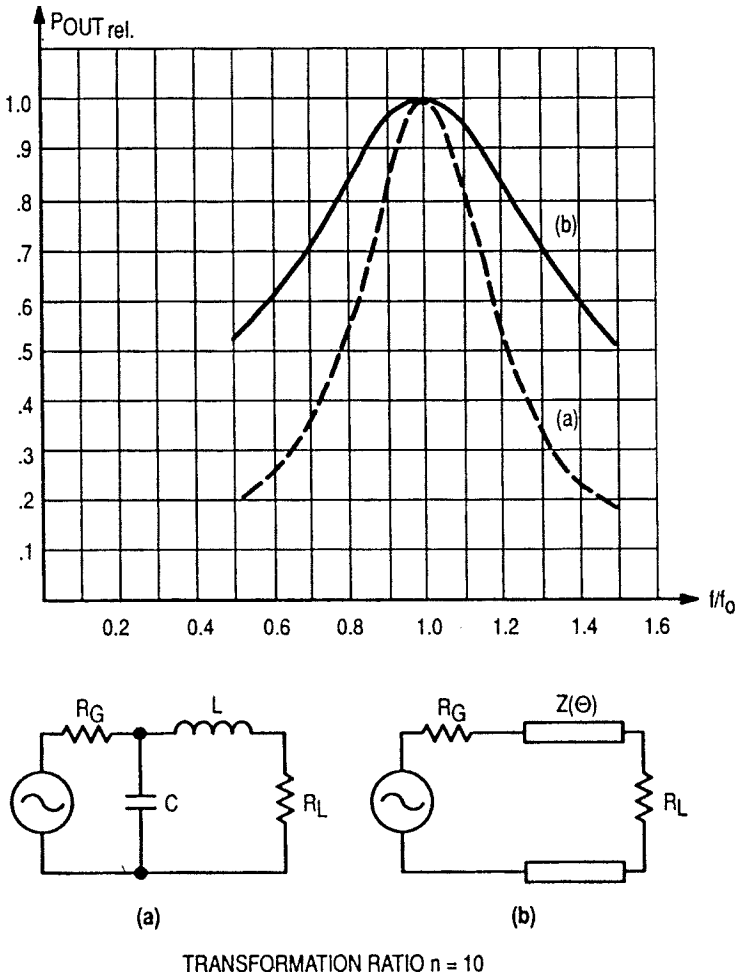

Figure 3-227 Bandwidth of the L section for $n = 10$ (a) with lumped constants and (b) with transmission line (λ/4).

$$X_{C1} = \frac{A}{Q + B} \tag{3-209}$$

$$B = \sqrt{\frac{A}{R_2} - 1} \tag{3-210}$$

Network (c)

$$X_{L1} = QR_1 \quad Q \text{ must be selected first} \tag{3-211}$$

$$X_{C2} = AR_2 \tag{3-212}$$

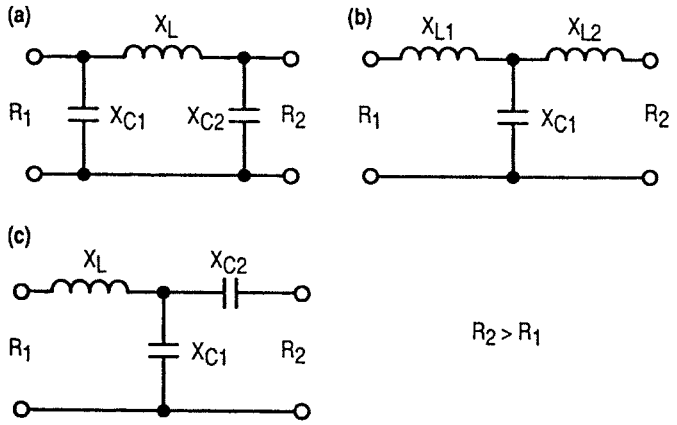

Figure 3-228 Three-reactance matching networks.

$$A = \sqrt{\frac{R_1(1+Q^2)}{R_2} - 1} \tag{3-213}$$

$$X_{C1} = \frac{B}{Q - A} \tag{3-214}$$

$$B = R_1(1+Q^2) \tag{3-215}$$

The network that yields the most-practical component values should be selected for a given application.

The three-reactance networks can be thought of as being formed of an L section (two reactances) and of a compensation reactance. The L section essentially performs the impedance transformation, while the additional reactance compensates for the reactive part of the transformed impedance over a certain frequency band.

Figure 3-229 shows a representation in the Z plane of the circuit of Figure 3-228a split into two parts: $R_1 - C_1 - L_1$ and $C_2 - R_2$. Exact transformation from R_1 into R_2 occurs at the points of intersection M and N. Impedances are then conjugate, or $Z' = R' + jX'$ and $Z'' = R'' + jX''$ with $R' = R''$ and $X' = -X''$.

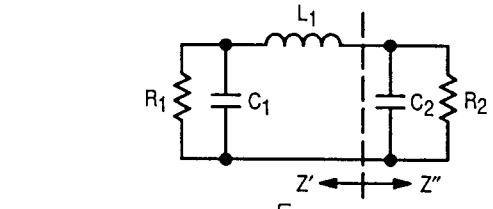
The only possible solution is obtained when X' and $-X''$ are tangential to each other. For the dashed curve, representing another value of L_1 or C_1, a wider frequency band could be expected at the expense of some ripple inside the band. However, this can only be reached with four reactances, as will be shown below.

With a three-reactance configuration, there are not enough degrees of freedom to permit $X' = -X''$ and simultaneously obtain the same variation of frequency on both curves from point M' to point N'. Exact transformation can, therefore, be obtained at only one frequency.

The values of the three reactances can be calculated by making

$$X' = -X'', \quad R' = R'', \quad \text{and} \frac{dX'}{dR'} = -\frac{dX''}{dR''} \tag{3-216}$$

The general solution of these equations leads to complicated calculations. Therefore, computed tables should be used.



$$Z' = \frac{R_1}{1 + \omega^2 R_1^2 C_1^2} + j\omega \left[L1 - \frac{R_1^2 C_1}{1 + \omega^2 R_1^2 C_1^2} \right] = R' + jX'$$

$$Z'' = \frac{R_2}{1 + \omega^2 C_2^2 R_2^2} - \frac{j\omega^2 C_2 R_2^2}{1 + \omega^2 C_2^2 R_2^2} = R'' + jX''$$

$$|x'| = \left(\frac{L_1}{C_1 R_1^2} - \frac{R'}{R_1} \right) \sqrt{\frac{R_1}{R'} - 1}$$

$$|x''| = \sqrt{R' R_2 - R'^2}$$

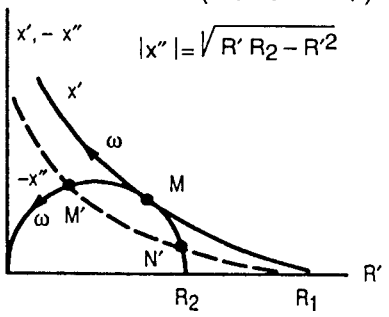


Figure 3-229 *Z*-plane representation of the circuit of Figure 3-228a.

One will note from Figure 3-229 that the compensation reactance contributes somewhat to the impedance transformation; that is, R' varies when going from M to R_2.

The circuit of Figure 3-228b is dual with respect to the first one and gives exactly the same results in a *Y*-plane representation. The circuit of Figure 3-228c is somewhat different since only one intersection M exists, as shown in Figure 3-230. Narrower frequency bands must be expected from this configuration. The widest band is obtained for $C_1 = \infty$.

Again, if one of the terminations has a reactive component, the latter can be taken as a part of the matching network, provided that it is not too large (see Figure 3-227).

FOUR-REACTANCE NETWORKS. Four-reactance networks are used essentially for broadband matching. The networks that will be considered in the following consist of two two-reactance sections in cascade. Some networks have pseudo-low-pass filter character; others, bandpass filter character. In principle, the former show narrower bandwidth since they extend the impedance transformation to very low frequencies unnecessarily, while the latter ensure good matching over a wide frequency band around the center frequency only (see Figure 3-233).

The two-reactance sections used in the networks in Figure 3-231 have either transformation properties or compensation properties. Impedance transformation is obtained with one series reactance and one shunt reactance. Compensation is made with both reactances in series or in shunt. If two cascaded transformation networks are used, transformation is accomplished partly by each one.

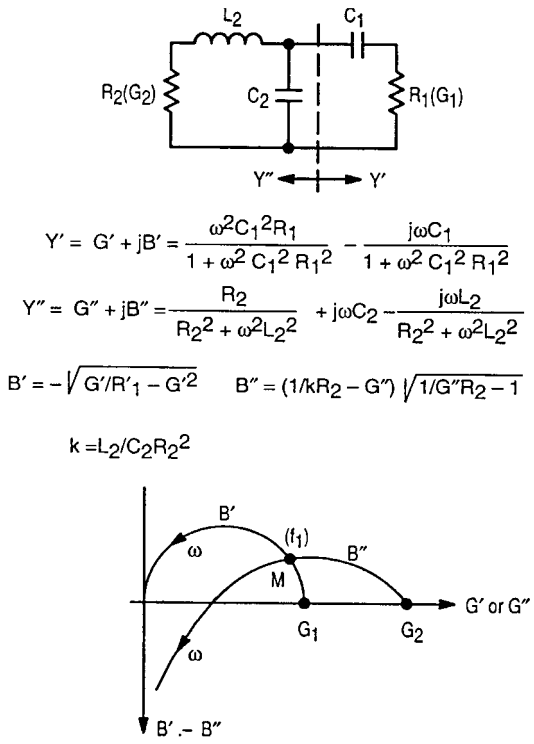

Figure 3-230 *Y*-plane representation of the circuit of Figure 3-228c.

With four-reactance networks there are two frequencies, f_1 and f_2, at which the transformation from R_1 into R_2 is exact. These frequencies may also coincide. For the network in Figure 3-231b, for instance, at point M, R_1 or R_2 is transformed into $\sqrt{R_1R_2}$ when both frequencies fall together. At all points (M), Z_1 and Z_2 are conjugate if the transformation is exact.

In the case of Figure 3-231b, the reactances are easily calculated for equal frequencies:

$$X_1 = \frac{R_1}{\sqrt{(n-1)^{1/2}}} \tag{3-217}$$

$$X_2 = R_1\sqrt{\frac{n^{1/2}-1}{n}} \tag{3-218}$$

$$X_1X_4 = R_1R_2 = X_2X_3 \tag{3-219}$$

$$X_3 = \frac{R_1}{\sqrt{n(n^{1/2}-1)}} \tag{3-220}$$

$$X_4 = \frac{R_1}{n}\sqrt{n^{1/2}-1} \tag{3-221}$$

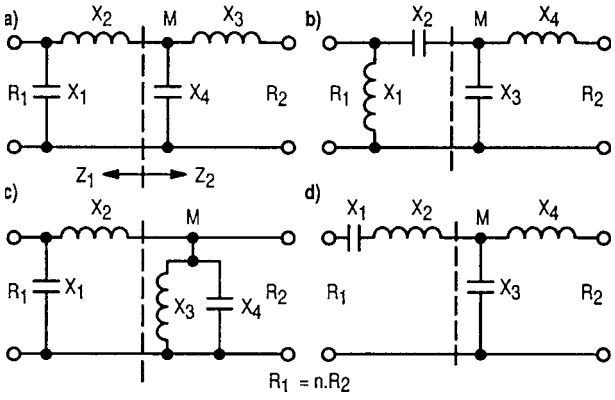

Figure 3-231 Four-reactance networks.

For the network in Figure 3-231a, normally at point M, Z_1 and Z_2 are complex. This pseudo-low-pass filter has been computed elsewhere [33]. Many tables can be found in the literature for networks of four and more reactances having Chebyshev character or maximally flat response [33, 34, 36].

Figure 3-232 shows the transformation path from R_1 to R_2 for networks (a) and (b) in Figure 3-231 on a Smith Chart.

Case (a) of Figure 3-232 has been calculated using tables in Matthaei [34]. Case (b) has been obtained from the relationship given above for $X_1, \ldots, X_4$. Both apply for a transformation ratio equal to 10 and for $R_1 = 1$. There is no simple relationship for $X_1', \ldots, X_4'$ of network (b) if f_1 is made different from f_2 for larger bandwidth. Figure 3-233 shows the respective bandwidths of networks (a) and (b) for the circuits shown in Figure 3-232.

If the terminations include a reactive component, the computed values for X_1 or X_4 may be adjusted to compensate for this.

For configuration (a), it can be seen from Figure 3-232 that, in the considered case, the Q values are equal to 1.6. For configuration (b), Q_1', which is equal to Q_2', is fixed for each transformation ratio

n	2	4	8	10	16
$Q'_1 = Q'_2$	0.65	1	1.35	1.46	1.73

$$Q' = \sqrt{n^{1/2} - 1} \qquad (3\text{-}222)$$

The maximum value of reactance that the terminations may have for use in this configuration can be determined from the above values of Q'.

If R_1 is the load resistance of a transistor, the internal transistor resistance may not be equal to R_1. In this case, the selectivity curve will be different from the curves given in Figure 3-233. Figure 3-234 shows the selectivity for networks (a) and (b) when the source resistance R_1 is infinite. From Figure 3-234 it can be seen that network (a) is more sensitive to changes in R_1 than network (b).

As mentioned earlier, the four-reactance network can also be thought of as two cascaded two-reactance sections: one used for transformation, the other for compensation. Figure 3-235 shows commonly used compensation networks, together with the associated L section.

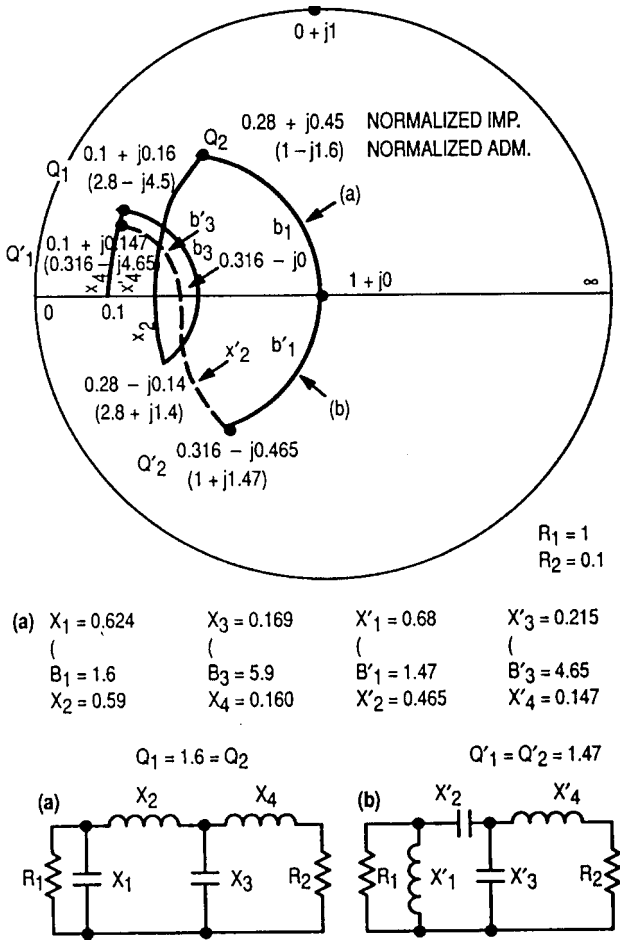

Figure 3-232 Transformation paths for networks (a) and (b).

The circuit of Figure 3-235a can be compared to the three-reactance network shown in Figure 3-228c. The difference is that capacitor C_2 of that circuit has been replaced by an *LC* circuit. The resulting improvement can be seen by comparing Figure 3-236 with Figure 3-230.

By adding one reactance, exact impedance transformation is achieved at two frequencies. It is now possible to choose component values such that the point of intersection M' occurs at the same frequency f_1 on both curves and simultaneously that N' occurs at the same frequency f_2 on both curves. Among the infinite number of possible intersections, only one allows the achievement of this.

When M' and N' coincide in M, the new $dX'/df = dX''/df$ condition can be added to the condition $X' = -X''$ (for three-reactance networks) and similarly $R' = R''$ and $dR'/df = dR''/df$.

Again, a general solution of the above equations leads to still more complicated calculations than in the case of three-reactance networks. Therefore, tables are preferable [33, 34, 36].

The circuit of Figure 3-235b is the dual of the circuit of Figure 3-233a and does not need to be treated separately. It gives exactly the same results in the *Z* plane. Figure 3-235c shows a higher-order compensation requiring six reactive elements.

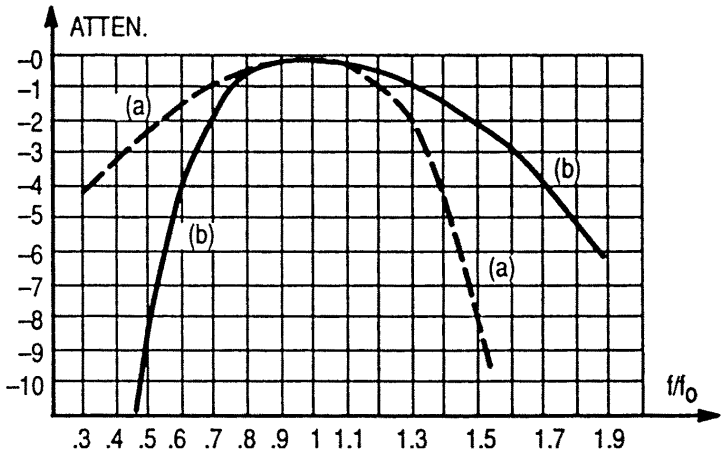

Figure 3-233 Selectivity curves for networks (a) and (b) of Figure 3-232.

The above-discussed matching networks employing compensation circuits result in narrower bandwidths than the former solutions (see p. 573) using two transformation sections. A matching arrangement with higher-order compensation, such as in Figure 3-235c, is not recommended. Better use can be made of the large number of reactive elements by using them all for transformation.

When the above configurations are realized using short portions of transmission lines, the equations or the usual tables no longer apply. The calculations must be carried out on a computer because of their complexity. However, a graphical method can be used (see the next section) that will consist essentially in tracing a transformation path on the Z–Y chart using the computed lumped element values and replacing it by the closest path obtained with distributed constants. The bandwidth change is not significant as long as short portions of lines are used.

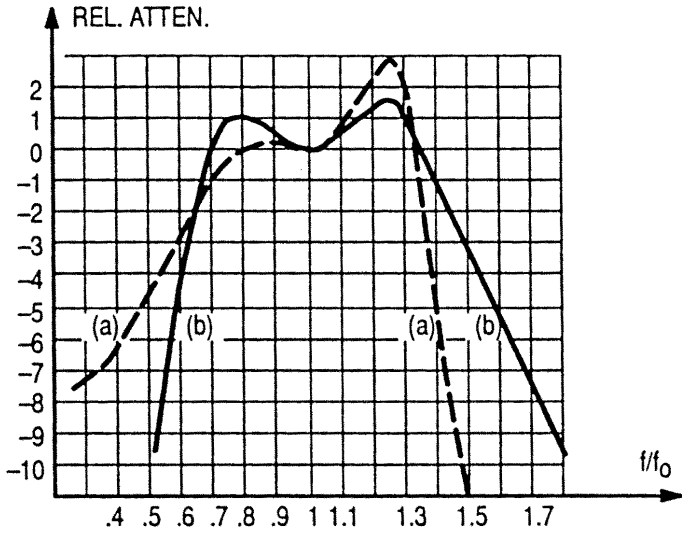

Figure 3-234 Selectivity curves for networks (a) and (b) of Figure 3-232 with infinite R_1.

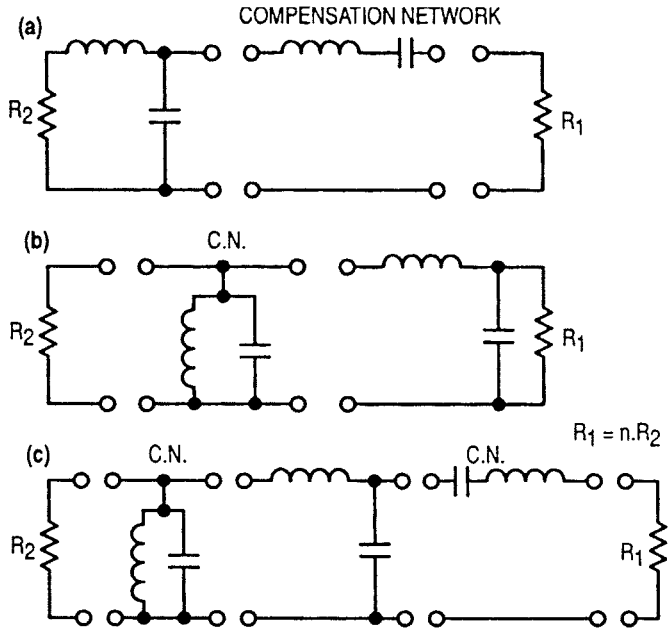

Figure 3-235 Compensation networks used with an L section.

MATCHING NETWORKS USING QUARTER-WAVE TRANSFORMERS. At sufficiently high frequencies, where λ/4-long lines of practical size can be realized, broadband transformations can easily be accomplished by the use of one or more λ/4 sections. Figure 3-237 summarizes the main relations for (a) one-section and (b) two-section transformations. A compensation network can be realized using a λ/2-long transmission line. Figures 3-238 and 3-239 show the selectivity curves for different transformation ratios and section numbers.

EXPONENTIAL LINES. Exponential lines have largely frequency-independent transformation properties. The characteristic impedance of such lines varies exponentially with their length l:

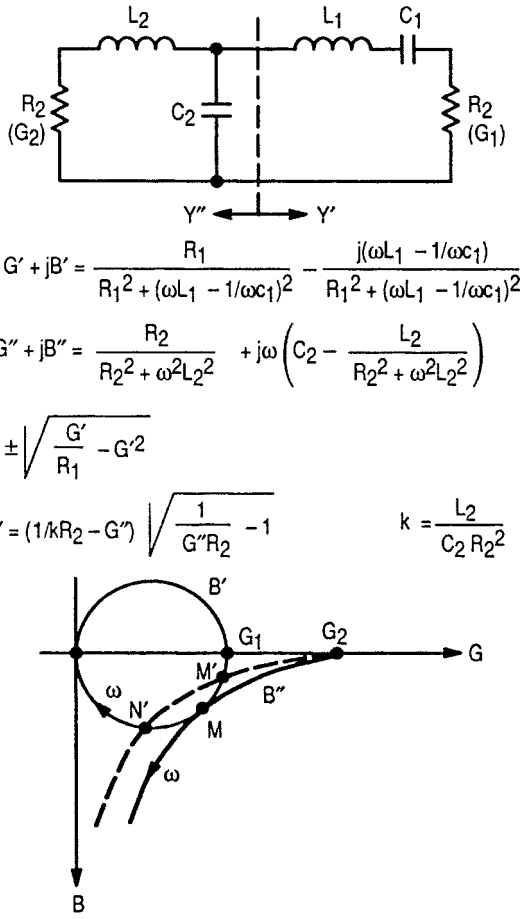
$$Z = Z_0 e^{kl} \tag{3-223}$$

where k is a constant, but these properties are preserved only if k is small.

BROADBAND MATCHING USING BANDPASS FILTER NETWORKS—HIGHQ CASE. The above circuits are applicable to devices having low input or output Q, if broadband matching is required. Generally, if the impedances to be matched can be represented, for instance, by a resistor R in series with an inductor L (sometimes a capacitor C) within the band of interest and if L is sufficiently low, the latter can be incorporated into the first inductor in the matching network. This is also valid if the representation consists of a shunt combination of a resistor and a reactance.

Practically, this is feasible for Q values around 1 or 2. For higher Q values or for input impedances consisting of a series or parallel resonant circuit (see Figure 3-221), as it appears to be for large bandwidths, a different treatment must be followed.

Let us first recall that, as shown by Bode [37] and Fano [38], limitations exist on the impedance matching of a complex load. In the example of Figure 3-240, the load to be matched consists of a capacitor C and a resistor R in shunt.



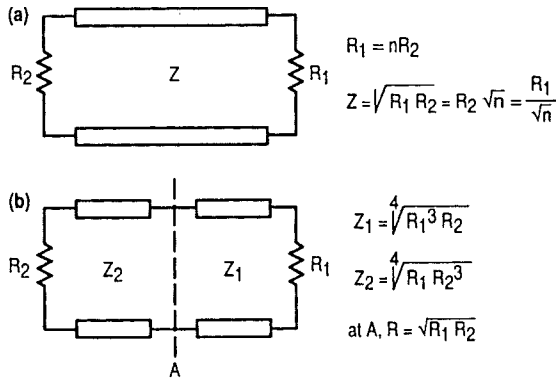
$$Y' = G' + jB' = \frac{R_1}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2} - \frac{j(\omega L_1 - 1/\omega c_1)}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2}$$

$$Y'' = G'' + jB'' = \frac{R_2}{R_2^2 + \omega^2 L_2^2} + j\omega\left(C_2 - \frac{L_2}{R_2^2 + \omega^2 L_2^2}\right)$$

$$B' = \pm\sqrt{\frac{G'}{R_1} - G'^2}$$

$$B'' = (1/kR_2 - G'')\sqrt{\frac{1}{G''R_2} - 1} \qquad k = \frac{L_2}{C_2 R_2^2}$$

Figure 3-236 *Y*-plane representation of the circuit of Figure 3-235a.



$$R_1 = nR_2$$

$$Z = \sqrt{R_1 R_2} = R_2\sqrt{n} = \frac{R_1}{\sqrt{n}}$$

$$Z_1 = \sqrt[4]{R_1^3 R_2}$$

$$Z_2 = \sqrt[4]{R_1 R_2^3}$$

$$\text{at A, } R = \sqrt{R_1 R_2}$$

Figure 3-237 Transformation networks using λ/4-long transmission lines.

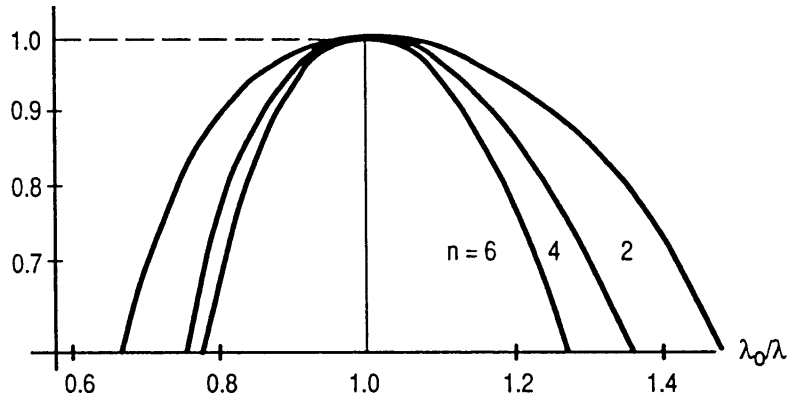


Figure 3-238 Selectivity curves for two λ/4-section networks at different transformation ratios.

The reflection coefficient between the transformed load and generator is equal to

$$\Gamma = \frac{Z_{\text{IN}} - R_G}{Z_{\text{IN}} + R_G} \tag{3-224}$$

When $\Gamma = 0$, there is perfect matching; when $\Gamma = 1$, there is total reflection. The ratio of reflected to incident power is

$$\frac{P_r}{P_i} = |\Gamma|^2 \tag{3-225}$$

The fundamental limitation on the matching takes the form

$$\int_{\omega=0}^{\infty} \ln\left(\frac{1}{|\Gamma|}\right) d\omega \le \frac{\pi}{RC} \qquad \text{Bode equation} \tag{3-226}$$

and is represented in Figure 3-241.

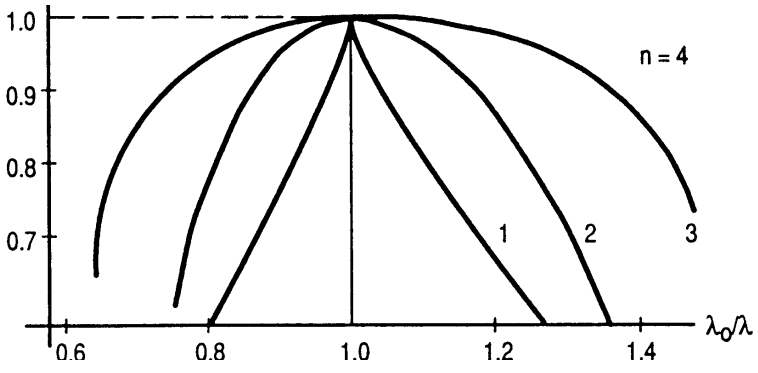

Figure 3-239 Selectivity curves for one, two, and three λ/4 sections.

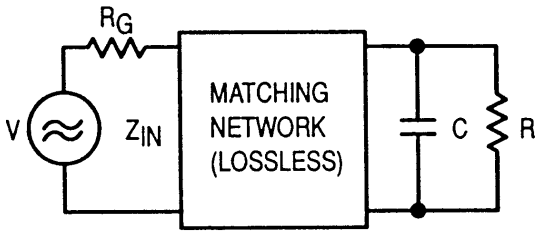

Figure 3-240 General matching conditions.

The meaning of the Bode equation is that the area S under the curve cannot be greater than π/RC and, therefore, if matching is required over a certain bandwidth, this can only be done at the expense of less power transfer within the band. Thus, power transfer and bandwidth appear as interchangeable quantities.

It is evident that the best utilization of the area S is obtained when $|\Gamma|$ is kept constant over the desired band ω_c and made equal to 1 over the rest of the spectrum. Then

$$|\Gamma| = e^{-\pi/\omega_c RC} \tag{3-227}$$

within the band and no power transfer happens outside. A network fulfilling this requirement cannot be obtained in practice because an infinite number of reactive elements would be necessary.

If the attenuation is plotted versus frequency for practical cases, one may expect to have curves like the ones shown in Figure 3-242 for a low-pass filter having Chebyshev character.

For a given complex load, an extension of the bandwidth from ω_1 to ω_2 is possible only with a simultaneous increase of the attenuation a. This is especially noticeable for Q values exceeding 1 or 2 (see Figure 3-243). Thus, devices having relatively high input Q values are usable for broadband operation, provided the consequent higher attenuation or reflection introduced is acceptable.

For average insertion losses or attenuation a (neglecting the ripple), the attenuation decreases if the number n of the network element increases. But above $n = 4$, the improvement is small. For a given attenuation a and bandwidth, the larger the n the smaller the ripple; for a given attenuation, the larger the n the larger the bandwidth.

Computations show that for $Q < 1$ and $n \leq 3$, the attenuation is below 0.1 dB (approximately). The impedance transformation ratio is not free here. The network is a

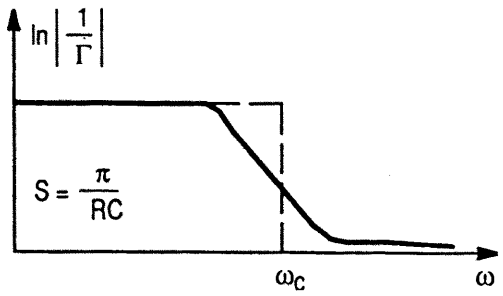

Figure 3-241 Representation of the Bode equation.

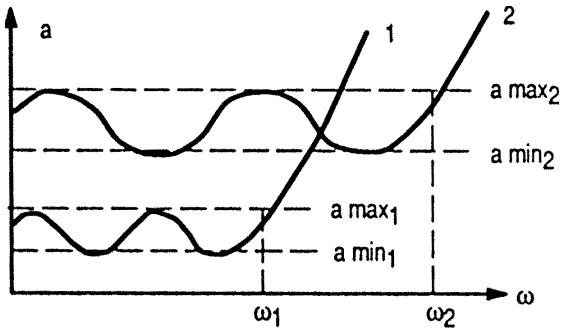

Figure 3-242 Attenuation versus angular frequency for different bandwidths with the same load.

true low-pass filter. For a given load, the optimum generator impedance will result from the computation.

Before impedance transformation is introduced, a conversion of the low-pass prototype into a bandpass filter network must be made. Figure 3-244 summarizes the main relations for this conversion. r is the conversion factor. For the bandpass filter, $Q_{\text{IN max}}$, or the maximum possible input Q of the device to be matched, has been increased by the factor r (from Figure 3-244, $Q'_{\text{IN max}} = rQ_{\text{IN max}}$).

Impedance inverters will be used for impedance transformation. These networks are suitable for insertion into a bandpass filter without affecting the transmission characteristics.

Figure 3-245 shows four impedance inverters. Note that one of the reactances is negative and must be combined in the bandpass network with a reactance of at least equal positive value. Insertion of the inverter can be made at any convenient place [32, 39].

When using the bandpass filter for matching the input impedance of a transistor, reactances $L'_1C'_1$ should be made to resonate at ω_0 by addition of a convenient series reactance.

As stated earlier, the series combination of R_0, L'_1 and C'_1 normally constitutes the equivalent input network of a transistor when considered over a large bandwidth. This is a good approximation up to about 500 MHz.

In practice, the normal procedure for using a bandpass filter matching network will be the following:

1. For a given bandwidth center frequency and input impedance of a device to be matched—for example, 50 Ω—first determine Q'_{IN} from the datasheet as

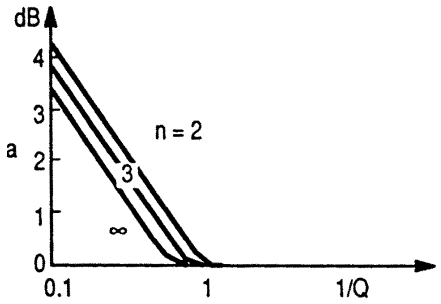

Figure 3-243 Insertion losses as a function of 1/*Q*.

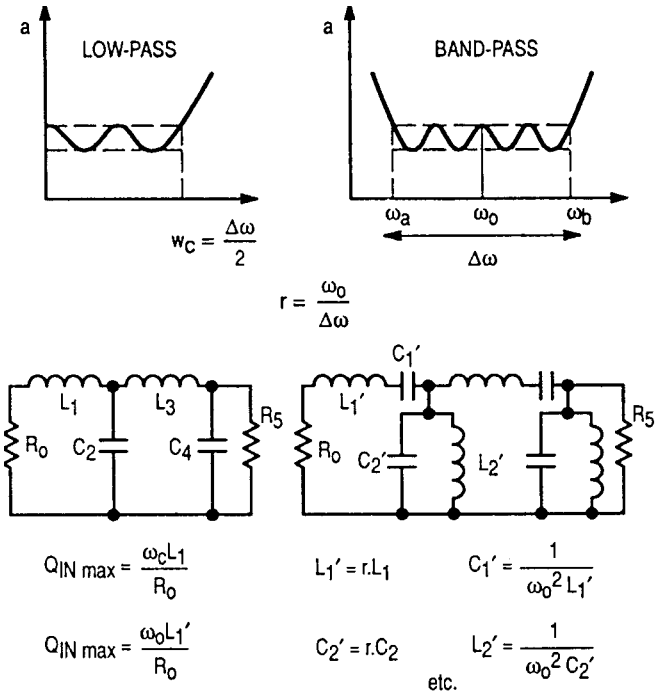

Figure 3-244 Conversion from low-pass filter into bandpass filter.

$$\frac{\omega_0 L_1'}{R_0} \tag{3-228}$$

after having eventually added a series reactor for centering.

2. Convert the equivalent circuit $R_0 L_1' C_1'$ into a low-pass prototype $R_0 L_1$ and calculate Q_{IN} using the formulas of Figure 3-244.
3. Determine the other reactance values from tables [33] for the desired bandwidth.
4. Convert the element values found by Step 3 into series- or parallel-resonant circuit parameters.
5. Insert the impedance inverter in any convenient place.

In the above discussions, the gain roll-off has not been taken into account. This is of normal use for moderate bandwidths (e.g., 30%). However, several methods can be employed to obtain a constant gain within the band despite the intrinsic gain decrease of a transistor with frequency. Tables have been computed elsewhere [40] for matching networks approximating 6 dB/octave attenuation versus frequency.

Another method consists of using the above-mentioned network and then adding a compensation circuit, as shown in Figure 3-246.

Resonance ω_b is placed at the high edge of the frequency band. Choosing Q correctly, roll-off can be made 6 dB/octave. The response of the circuit of Figure 3-246 is expressed by

$$\frac{1}{1 + Q^2(\omega/\omega_b - \omega_b/\omega)^2} \tag{3-229}$$

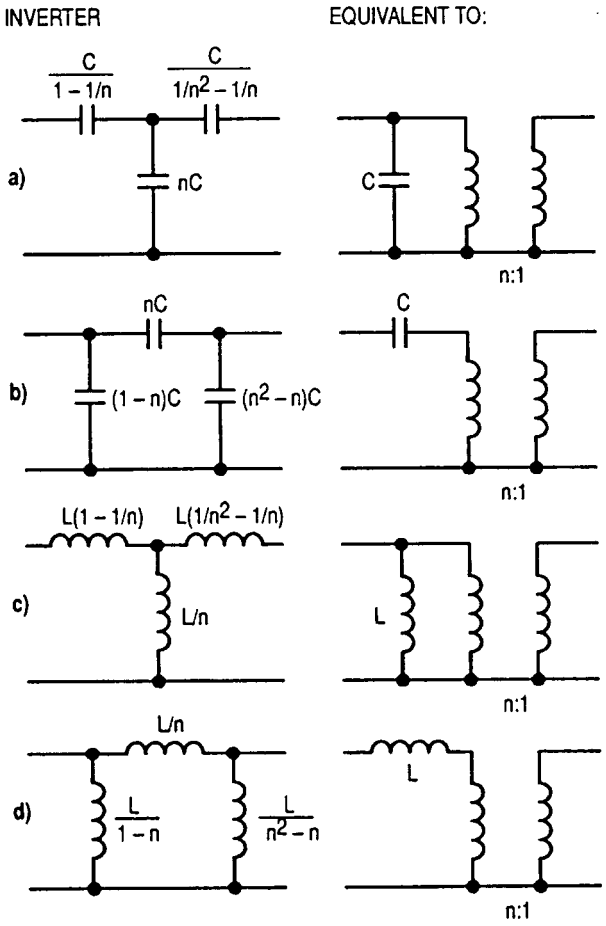

Figure 3-245 Impedance inverters.

where $\omega < \omega_b$. This must be equal to ω/ω_b for 6 dB/octave attenuation.

At the other band edge a, exact compensation can be obtained if

$$Q = \frac{(\omega_b/\omega_a)^2 - 1}{\omega_a/\omega_b - (\omega_b/\omega_a)^2} \tag{3-230}$$

There are several methods available for synthesis of matching networks. They should not be confused with filters because they can be either high-pass, low-pass, or bandpass, and their main purpose is to match one complex impedance to another. In many cases, one of the terminations happens to be 50 Ω and real, but this is just a "lucky" case of the general approach. An excellent paper on this [41] refers to the "real frequency" technique. Another equally important publication is the one by Cuthbert [42], since followed by his book [43]. Two more good references are Vendelin et al. [44] and Potter [45].

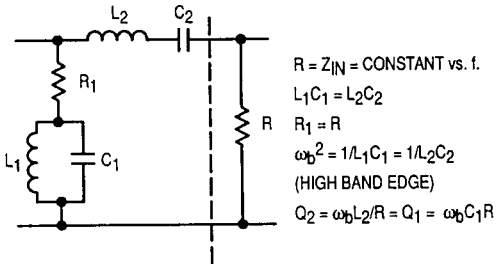

Figure 3-246 Roll-off compensation network.

3-12-3 Example 2: Low-Noise Amplifier Using Distributed Elements

In our previous examples, the amplifiers were built around lumped elements. Since a transmission line length of less than $\lambda/4$ is an inductor and $\frac{3}{4}\lambda$ is a capacitor, the whole amplifier can be built around microstrip technology.

If anyone wonders why we are going to show a low-noise amplifier in the middle of the power section, the reason is that we will select a low-power Siemens transistor, which, being operated in Class A, has an intercept point of +30 dBm and can easily achieve a noise figure of less than 2 dB. Such an amplifier is attractive when feeding an input stage from an antenna that sees many signals and curtails the bandwidth with an input filter of good selectivity that needs a good output termination, which in many cases works against the achievement of a good noise figure because when designing for best noise figure the input impedance of the transistor stage is far from 50 Ω.

First, we will start with the textbook approach and use the Smith diagram to obtain the best noise figure of which the device is capable. Figure 3-247 shows the actual approach to input and output matching.

We start our design by querying the Smith Tool about the minimum noise figure and the gain that comes with it. We mark the point of the lowest noise figure (labeled Γ_{opt}). The small

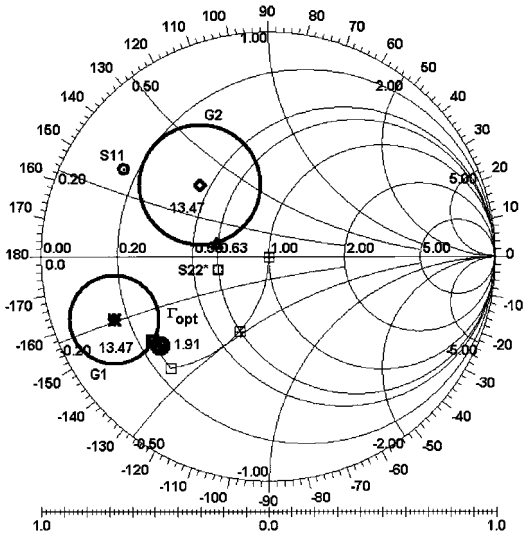

Figure 3-247 Input and output matches for 13.47 dB of gain and NF = 1.91 dB as displayed by the interactive Smith Tool.

noise circle yields the location for Γ_{opt} and tells us the minimum noise figure is going to be 1.91 dB. (By the way, this assumes no further losses, even in soldering the transistor to the PC board.) Then we construct the input gain circle (G1), which touches Γ_{opt} and turns out to represent 13.47 dB of available gain.

The next step is to find a matching network between Γ_{opt} and the 50-Ω source impedance. Immediately there is a conflict: If we look at S_{11}, which is the input reflection coefficient shown in the Smith diagram, it is on the other side of the complex plane and sufficiently far away, indicating that there is going to be quite a difference between noise matching and power-gain matching. We have two options for matching the input: Either we start from the origin and move toward the position of Γ_{opt}, or we start with Γ_{opt} and go to 50 Ω. Depending on the direction in which we do this, the result can be different topologies, such as a high-pass or low-pass filter. The high-pass filter is obtained by starting with Γ_{opt}; the low-pass topology is obtained by starting at the 50-Ω point. The Smith Tool then provides us with the corresponding values of capacitors and inductors after the transformation has been accomplished.

The final step is to do the same type of matching at the output. We start with S_{22}, and either select S_{22}^* (the complex conjugate for highest gain) or S_{22load}. As a rule, the second one is always a lower impedance (in terms of the real part) than the conjugate match. This graphic procedure is somewhat trial and error. As to the topology, a high-pass match should be preferred at the input and a low-pass match at the output. The reason for this is that the high-pass filter will tend to protect the stage from the enormous number of signals present below 1 GHz; using a low-pass filter at the output suppresses unwanted harmonics that the amplifier may generate. Figure 3-248 shows one of the approaches we like best simply because it gives a good input termination and we were trying for a simultaneous match for best noise figure and power gain.

The way we were able to achieve this was to take advantage of the existing feedback in the transistor and select a less-than-optimal output termination but gaining at the input. Taking advantage of the Miller effect, we rotate the phase angle of the feedback with the load to move the optimum noise and gain matching points closer. The danger in this is that the circuit is now highly sensitive to both input and output termination. The output *must* see 50 Ω to maintain this good input match, but since the second transistor stage can now be optimized for best input match, a two-stage combination can be configured to meet this

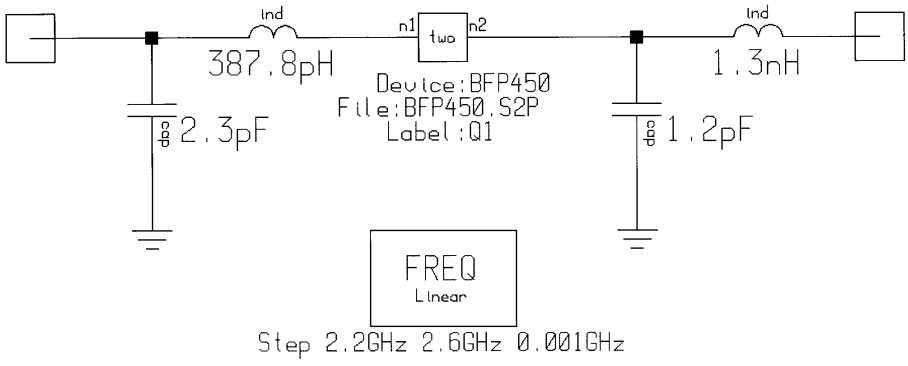

Figure 3-248 A 2.4-GHz amplifier using a BFP450 transistor and lumped-element input and output matching.

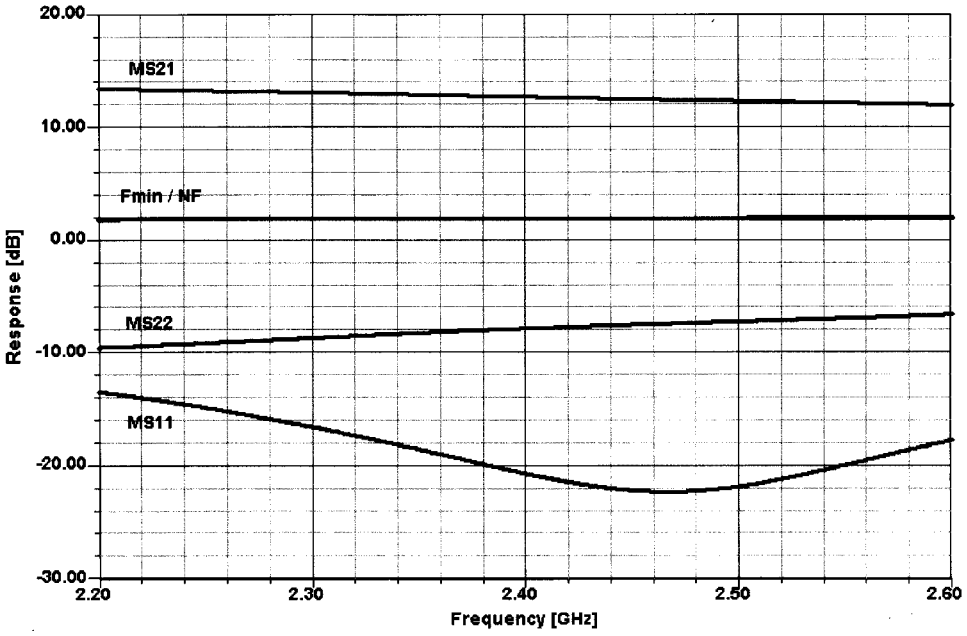

Figure 3-249 Frequency-dependent gain, matching, and noise characteristics of the matched high-dynamic-range BFP450 2.4-GHz amplifier.

requirement. Also, let us not forget that the device is running at 50 mA and as far as bipolar transistors are concerned, this is probably the best amplifier combination we have seen for getting the highest dynamic range and lowest noise figure. The resulting gain, matching, and noise figure characteristics are shown in Figure 3-249.

Now we turn to using distributed elements and at the same time use a shunt feedback at the output; to be specific, we will load it with 150 Ω. The reason for this is to be able to obtain a good compromise at the input that will depend less on the output and at the same

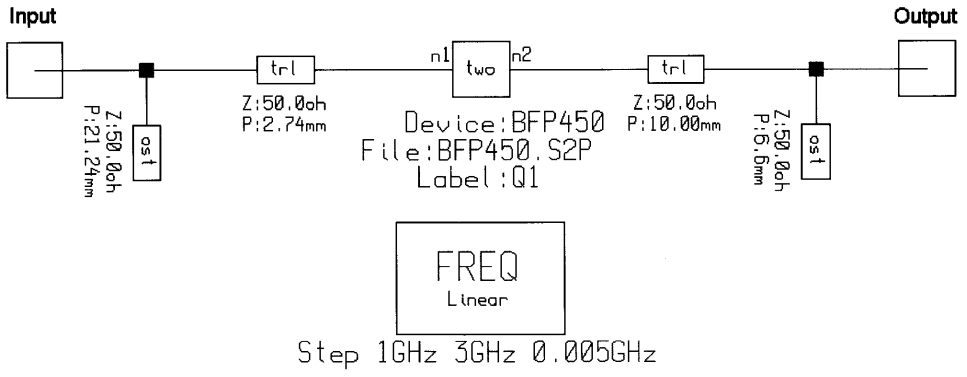

Figure 3-250 Distributed-element input and output matching for the 2.4-GHz BFP450 amplifier.

time improve the S_{22} matching at the output. The procedure for doing the matching with a transmission line offers only certain degrees of freedom, while doing the matching with lumped elements allows the choice of series or parallel inductors or capacitors. In the case of a transmission line, we have open stubs, shorted stubs, and transmission lines. This may result in somewhat more complex matching schemes. On the positive side, they can easily be trimmed, are reproducible, and certainly cost less than exotic capacitors, which need to have small tolerances and to be able to handle high RF currents.

The resulting input and output matching is shown in Figure 3-250, and its frequency response in Figure 3-251. We were able to maintain a good input and output match with an insignificant deterioration of the noise figure.

Since this is a high-dynamic-range amplifier, we also show its predicted two-tone response in Figure 3-252. The manufacturer specifies an $IP_{3,in}$ of 29 dB for a bias point of $V_{CE} = 3$ V and $I_C = 50$ mA with $Z_S = Z_{S,opt}$ and $Z_L = Z_{L,opt}$ at 1.8 GHz. Significantly, however, the manufacturer-supplied nonlinear BFP450 library we used exhibits considerably different characteristics at $V_{CE} = 4$ V and $I_C = 50$ mA than those reflected in the corresponding S parameters supplied by the same manufacturer. In our circuit, the S parameters resulted in about 13.5 dB of gain (based on a compromise between matching for optimum noise and maximum gain) versus about 9.5 dB of gain for the nonlinear library (match optimized for maximum gain). The difference between the 2.4-GHz F_{min} values returned for the two modeling approaches is similarly striking: 1.90 dB for the bare S parameter set and 7.76 dB for the bare nonlinear library biased to $V_{CE} = 4$ V and $I_C = 50$ mA. Clearly, the nonlinear modeling of the BFP450 needs work!

Having fully evaluated the amplifier at 2.4 GHz as a working example, we note that this frequency is used by radio amateurs for some applications. We will therefore supply

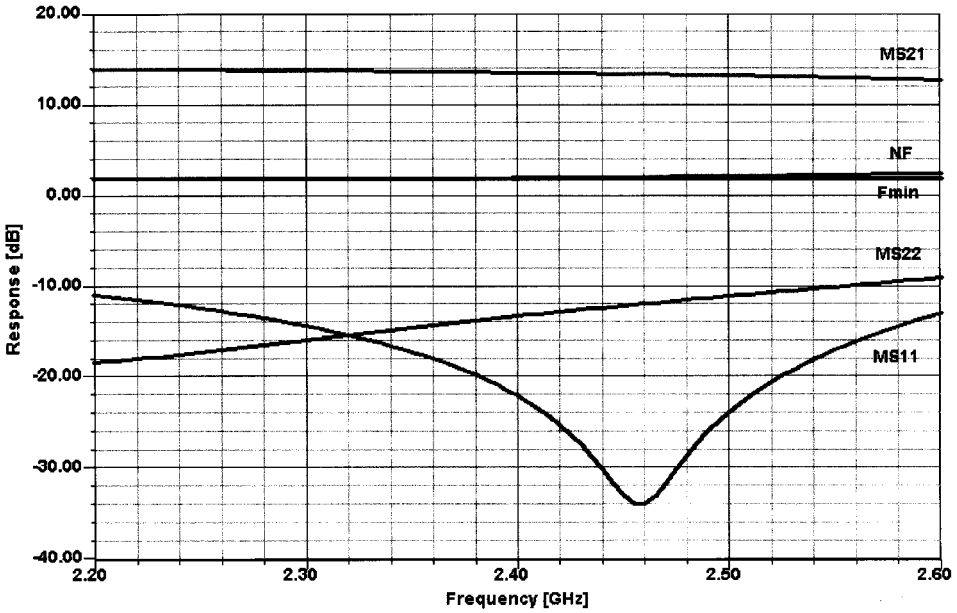

Figure 3-251 Predicted frequency-dependent gain, matching, and noise performance for the BFP450 amplifier with distributed-element matching.

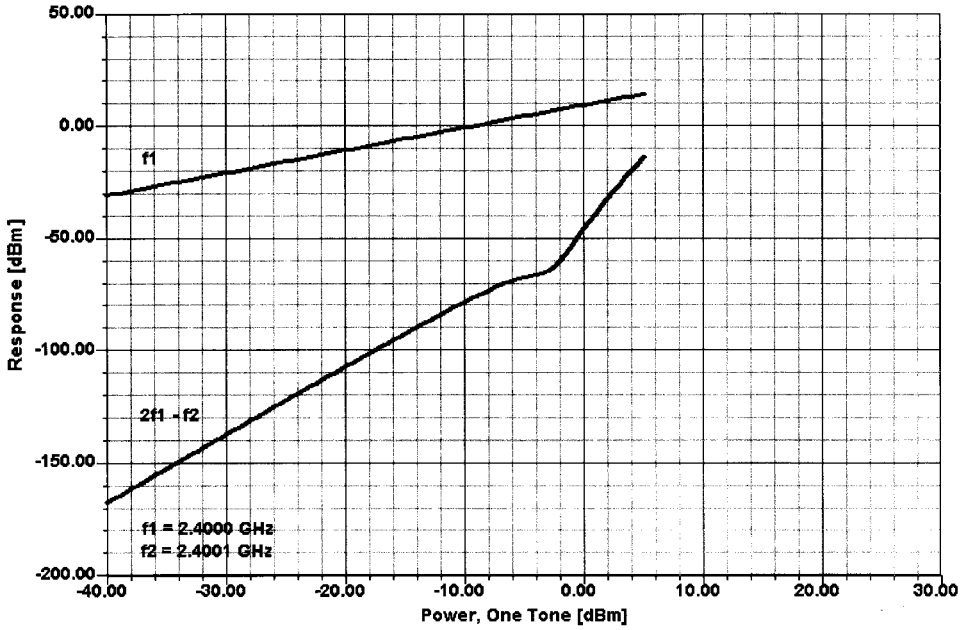

Figure 3-252 Predicted two-tone response of the BFP450 amplifier with the circuit adjusted for maximum gain (9.5 dB): $IP_{3,in} \approx 28.5$ dBm and $IP_{3,out} \approx 38$ dBm. That this version's gain is significantly lower than that of the *S*-parameter-based equivalent illustrates the need for better accuracy in parameter extraction.

examples for 432 and 1296 MHz, popular spot frequencies in the amateur 70- and 23-cm bands, respectively. Figures 3-253 and 3-254 show the 432-MHz version's schematic and frequency-dependent responses. Figures 3-255 and 3-256 show the schematic and frequency-dependent responses for the 1296-MHz version.

Using a bipolar transistor that operates at much less current, the noise figure can be improved at the expense of the dynamic range/intercept point. It is possible to reduce the noise figure by about 1 dB or so, but the reduction in intercept point will be much more dramatic. Another choice is the use of GaAsFETs for this application, but their matching in comparable circuits has been described as a nightmare simply because the devices have too much gain and very high input impedances (essentially 0.2 pF in series with 3 Ω) combined with reasonable output impedances in the vicinity of 240 Ω. Here is a wide field in which engineers can experiment and examine price/performance and performance/real estate issues. GaAsFETs also tend to require more than 30–40 mA to be alive, and even the low operating voltage of 4–5 V makes the device consume a lot of dc power.

3-12-4 Example 3: 1-W Amplifier Using the CLY15

The following is an application showing a fairly wideband amplifier with +30 dBm (1 W) output. We need to point out that in accordance with the various digital modulation modes used with this amplifier, this is not continuous operation, but a much less than 1:1 duty cycle operation. The device would probably not survive operating at full output under CW conditions. This is subject to a discussion with the manufacturer, Siemens, who has not

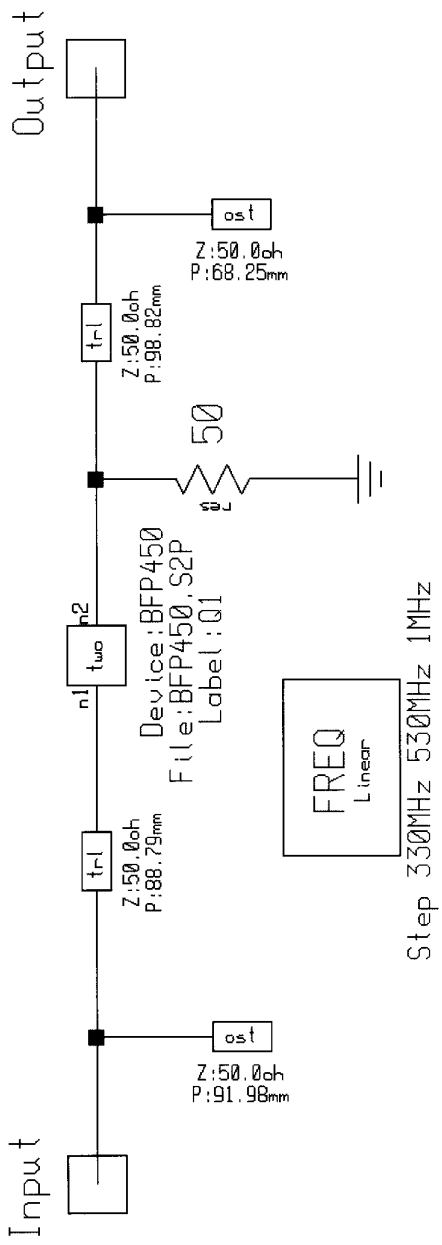

Figure 3-253 Schematic of BPF450 amplifier for 432 MHz. Because f_T = 25 GHz for the BFP450, at this lower frequency we must shunt the device output with a 50-Ω resistor to maintain stability.

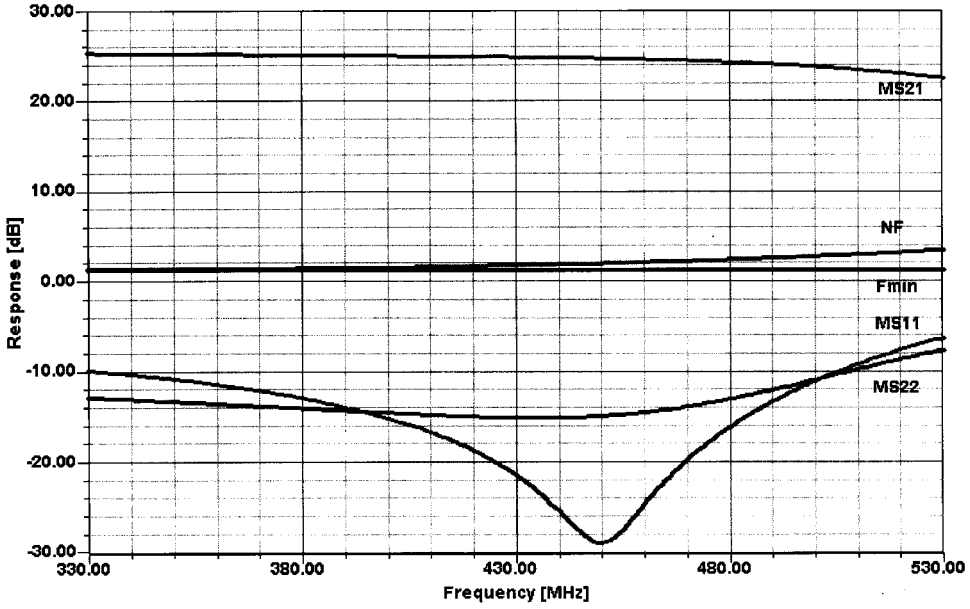

Figure 3-254 Frequency-dependent gain, matching, and noise performance for the BPF450 amplifier at 432 MHz. As with the circuit in Figure 3-253, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

released sufficient data for us to make a judgment as to the CLY15's continuous power capability. Since there is no useful large-signal model available at the time of this writing, we will design this Class A amplifier using large dc bias *S* parameters. In the actual design there will be some cut-and-try, but we find that in this type of application this is still the best way of handling the design.

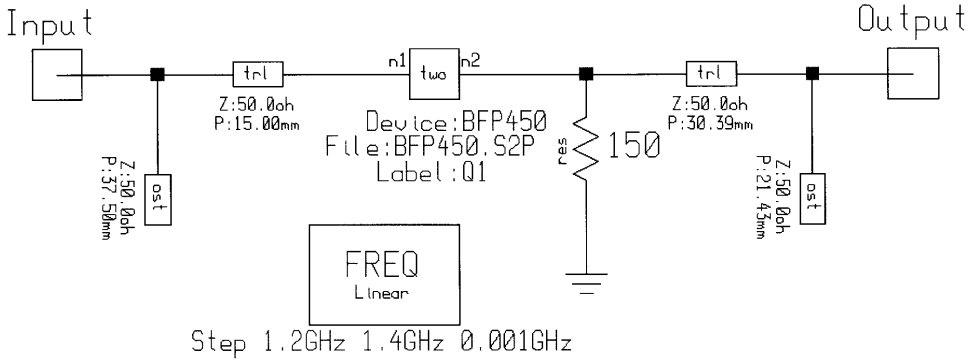

Figure 3-255 Schematic of the BPF450 amplifier for 1296 MHz. A loading resistor is still necessary to ensure stability, but because the transistor exhibits less gain at this frequency than at 432 MHz, we can increase the loading resistor to 150 Ω.

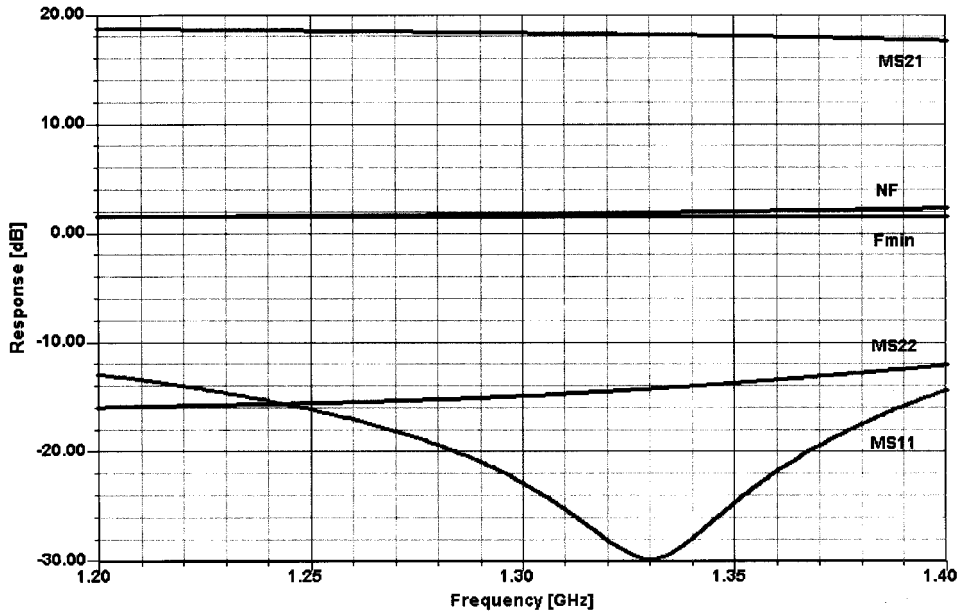

Figure 3-256 Frequency-dependent gain, matching, and noise responses of the BFP450 amplifier at 1296 MHz. As with the two previous versions, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

The CLY15 (gate width 16 mm) is the largest of a series of Siemens GaAsFETs; it was already mentioned in Chapter 2, where its datasheet is reproduced. Its device family also includes the CLY2 (gate width 2 mm), CLY5 (4 mm), and CLY10 (8 mm). It is possible that bigger devices will be offered in the future. One of the most critical parameters will be the saturation voltage; from the datasheet of the CLY15, we can see that at 1.5 A the saturation voltage is approximately 1 V. This drop of 1 V includes losses that result from other parasitic elements; the dc *I–V* curve (Figure 3-257a) indicates a saturation voltage of 0.75. Since we aim for 1-W output power, the resistive portion of the load will be $(5 - 1)^2 / (1 \times 2) = 8\ \Omega$. This assumes a supply voltage of 5 V.

The next step is to design the input and output matching network. Previewing the *S* parameters, it will be noticed that they are essentially inductive, which means that the input match, using lumped elements, will result in a combination of capacitors at both the input and the output. Figures 3-258 and 3-259 show the ways in which the input and output matches were done on the Smith diagram resulting in lumped matching elements. Inspecting the lumped input matching, we find the following. We start with S_{11}, which is in the lower part of the Smith diagram, and determine its conjugate match, S_{11}^*. We already pointed out that this device is inductive, which means that matching it from the conjugate point will require two capacitors. The first one is a series capacitor, as identified in the Smith diagram, and followed by a shunt capacitor to transform the impedance to 50 Ω. A close inspection of the Smith diagram shows that the resulting point is not quite on S_{11}; it is an iterative process to exactly find the crossover point, yet the input match of better than 20 dB is more than acceptable.

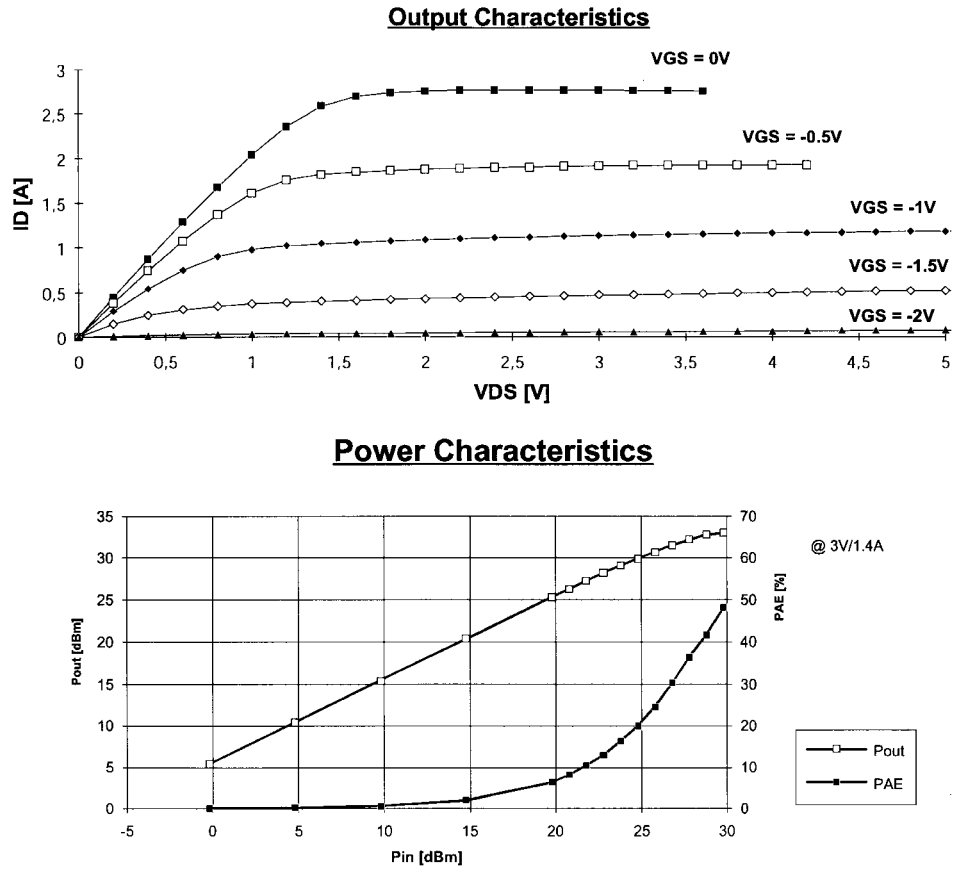

Figure 3-257 Output and power characteristics for the CLY15 medium-power GaAsFET.

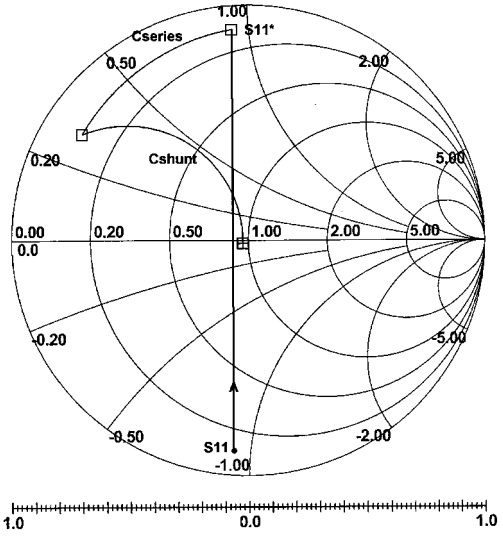

Figure 3-258 Input match for S_{11}^{*} using lumped elements.

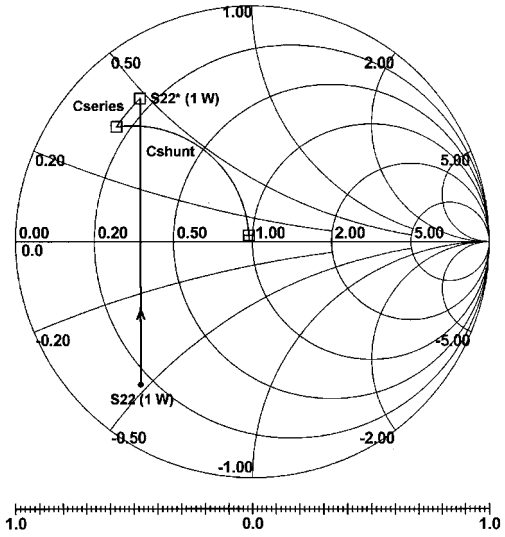

Figure 3-259 Output match for S_{22}^* (1 W) using ideal lumped elements.

As far as the output is concerned, we use the same technique by moving from S_{22} to S_{22}^*. S_{22} has been determined from the required output power; as we showed above, the real portion is 8 Ω. Using the lumped elements, the matching technique is identical; we first need to use a series capacitor and then a shunt capacitor for the transformation. The arc for the series capacitor this time is much longer, resulting in a series capacitance of 11.2 pF instead of the 2.1-pF capacitance used at the input. The actual schematic is shown Figure 3-260. The drawback of lumped elements is that it is not practical to buy components that can handle the heavy RF currents that flow in the input and output networks. Taking the values obtained

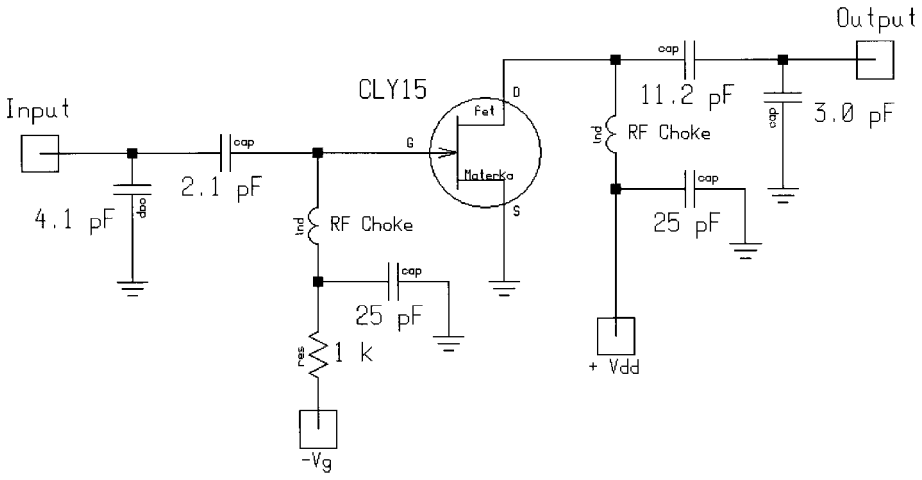

Figure 3-260 The complete amplifier using the CLY15 medium-power GaAsFET, with lumped-element input and output matching.

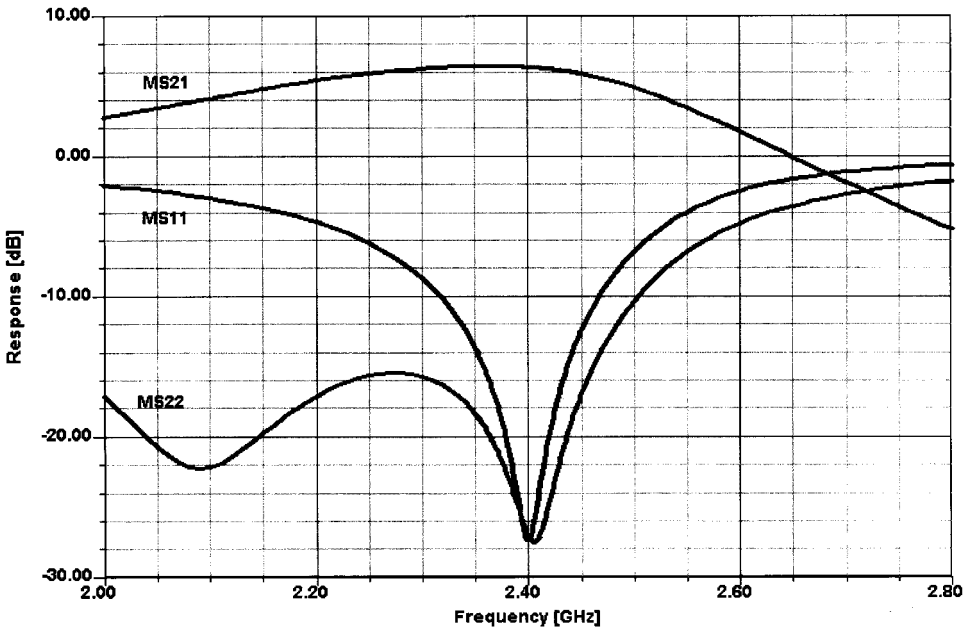

Figure 3-261 Frequency-dependent gain and matching responses of the CLY15 amplifier using ideal lumped elements.

from the lumped input and output matching approach, Figure 3-261 shows the resulting frequency response.

The next step is to provide the same matching condition using distributed elements, which of course have the advantage that they can be printed on the PC board. Instead of using ideal elements, we used a loss tangent of 2E–3, or a Q of 500. The manufacturer of the R4000 material (Rogers) provided this specification. Now we start with the same approach by moving from S_{11} to S_{11}^*. From there, we use an open stub with a transmission-line impedance of 50 Ω, followed by a transmission line to the point in the left lower corner, and, finally, a shorted transmission-line stub allows the 50-Ω matching. For this amplifier, we are not looking for noise matching but for input and output power matching. Figure 3-262 shows this match on the Smith Chart.

At the output, the procedure is again similar: We move from the S_{11} for 1 W to a conjugate value, then use an open stub that acts like a capacitor until we cross the real axis; finally, a λ/4 transmission line is used to match from approximately 75 Ω to 50 Ω. Figure 3-263 shows this match on the Smith Chart. This concludes the distributed matching design for the CLY15 amplifier.

Finally, the complete circuit using distributed elements is shown in Figure 3-264. From a dc point of view, we took advantage of the incoming shorted stub by using a transmission line of the appropriate length and a bypass capacitor to ground. This allows us to feed the gate with the required negative voltage without interfering with the frequency response of the amplifier. When evaluating the total frequency response (Figure 3-265), we noticed that this circuit seems to have a higher Q than the lumped equivalent. Again, to obtain a wider bandwidth more transformation stages will be needed. We leave this task to the interested reader.

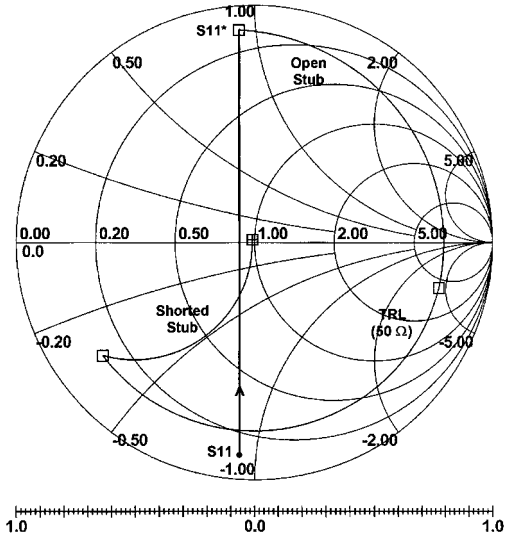

Figure 3-262 Input match for S_{11}^* (1 W) using distributed elements.

The 1-dB bandwidth of the amplifier using distributed, lossy elements is 120 MHz. If a wider bandwidth is required, matching networks with more elements are required. Because of the gain–bandwidth product, the peak gain for such a wider-bandwidth arrangement will be less than this narrowband example.

Having used a lumped to distributed transformation, we next present a power amplifier that uses coaxial lines, baluns, and other transformation steps capable of handling the increased power requirement.

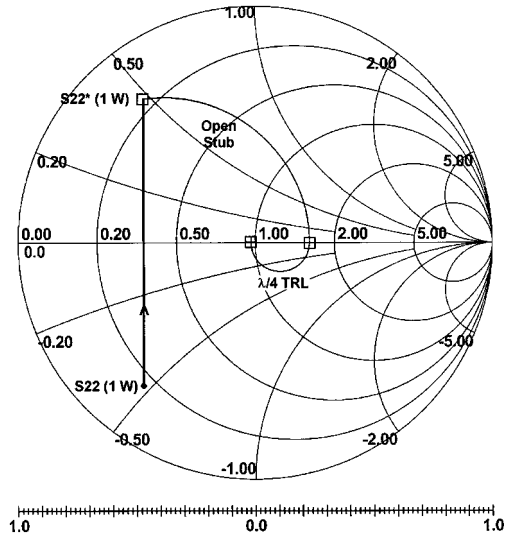

Figure 3-263 Output match for S_{22}^* (1 W) using distributed elements.

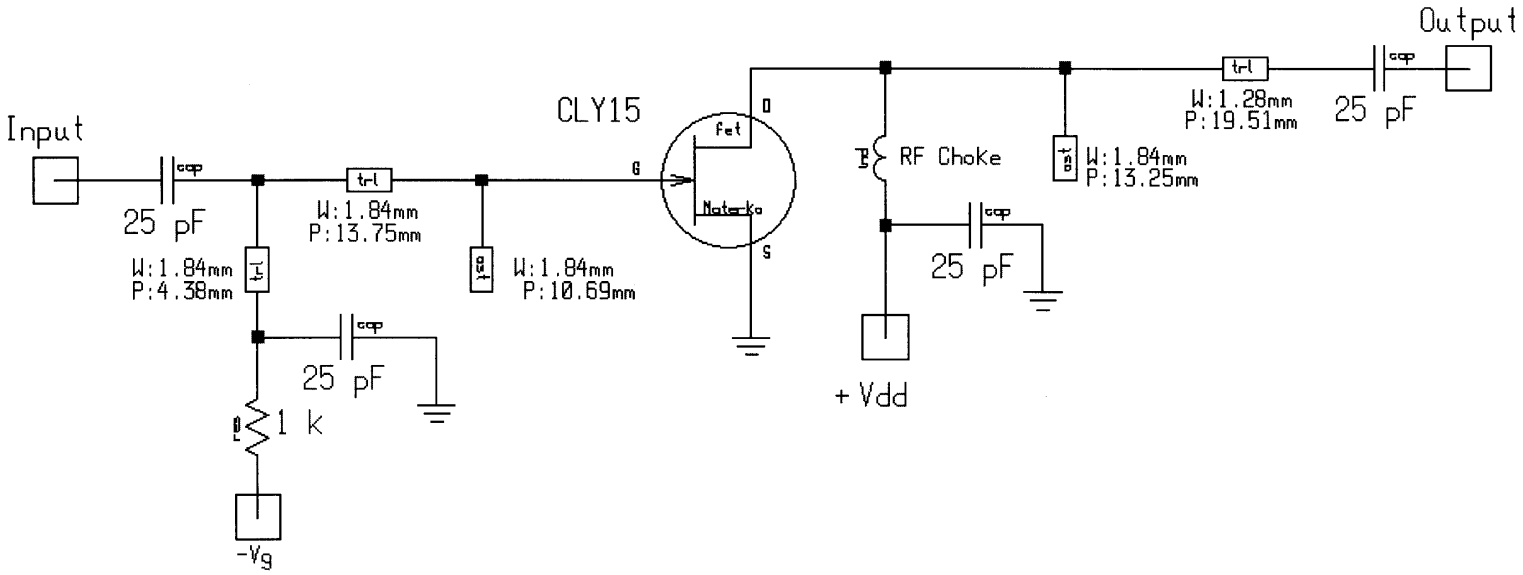

Figure 3-264 The complete amplifier using the CLY15 medium-power GaAsFET, with distributed-element input and output matching.

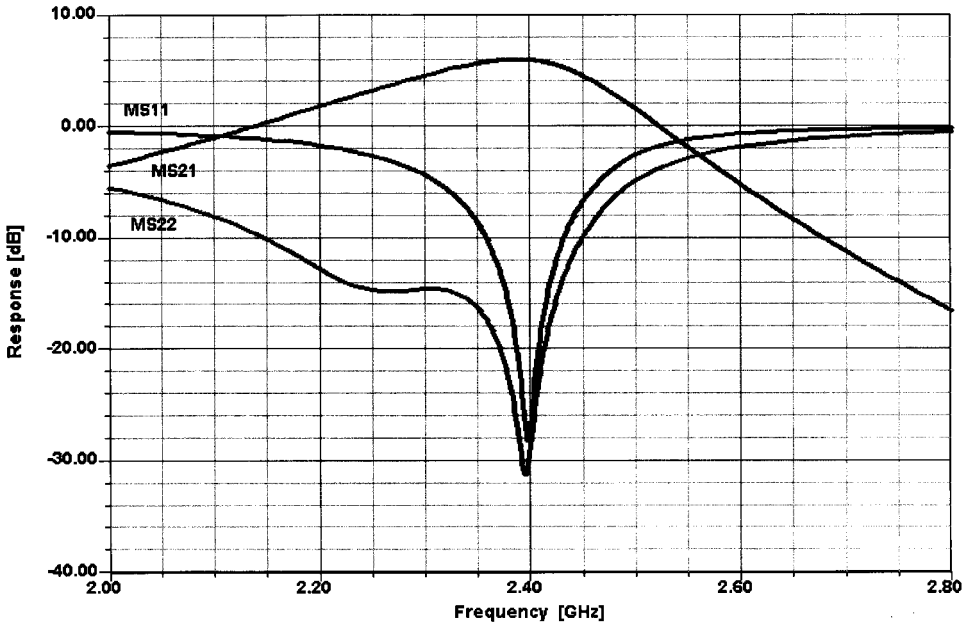

Figure 3-265 Frequency-dependent gain and matching using distributed, lossy elements.

3-12-5 Example 4: 90-W Push–Pull BJT Amplifier at 430 MHz

The last complete application we want to examine is a 90-W output, push–pull amplifier using two TRW transistors (that are no longer made—an all-too-frequent occurrence after a design is complete, resulting in a scramble for replacements). Figure 3-266 shows the circuit diagram of this UHF transistor amplifier, and Figure 3-267 shows its mechanical design. The amplifier requires 28 Vdc and will draw approximately 6 A, requiring 15 W of drive at 438 MHz. This amplifier operates in Class AB, which means it is not limited to amplifying FM and other angle-modulated signals, and can accommodate even single-sideband (SSB) operation.

The drive power coming from the source connected to the input N connector (15 W) is fed through a short piece of coaxial cable to the PC board sitting on top of the heat sink. To change from single ended to push–pull, a 50-Ω coaxial cable is coiled to provide sufficient electrical length to act as a balun that provides two symmetrical paths through the amplifier. The RC section of 10 Ω in parallel with a 220-pF capacitor stabilizes the amplifier at lower frequencies, while at higher frequencies the 10-Ω resistor has no contribution. There are two independent 4:1 transformers, one for each section; they are built using 25-Ω coaxial cable with a set of two binocular ferrite cores to force the transformation. The dc supply is also fed to the transistors at this point. The stabilization circuit consists of a temperature monitor using the *pn* junction of a transistor, side-mounted on the heat sink, and a combination of operational amplifiers and adjustments. This guarantees proper, temperature-independent biasing. The 4:1 input baluns result in 12.5 Ω impedance, or 3.125 Ω per transistor. Since the input impedance at this drive level is somewhere in the vicinity of $[(1 \ldots 2) + j(3 \ldots 5)]$ Ω; the final matching is accomplished by an *RC* section in which the inductance is actually printed

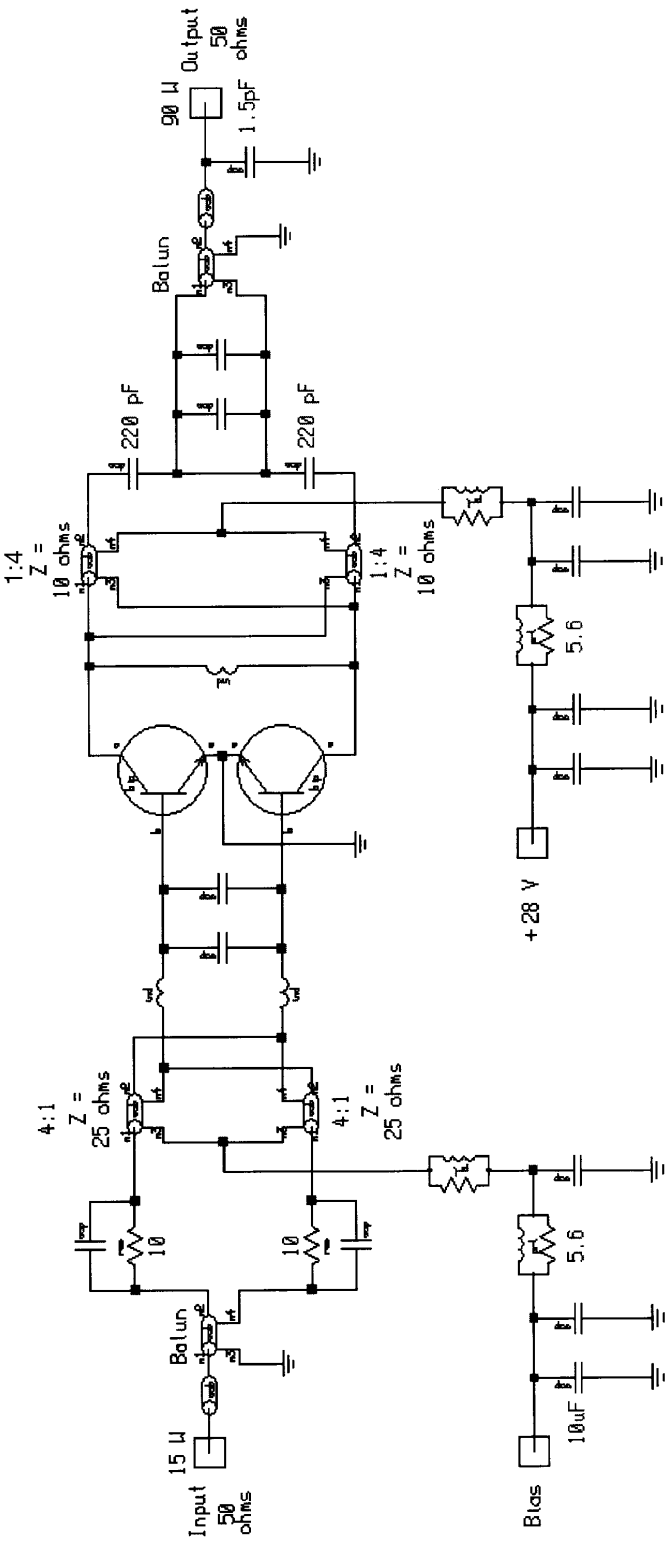

Figure 3-266 Circuit diagram of the 90-W, push–pull, 438-MHz linear amplifier.

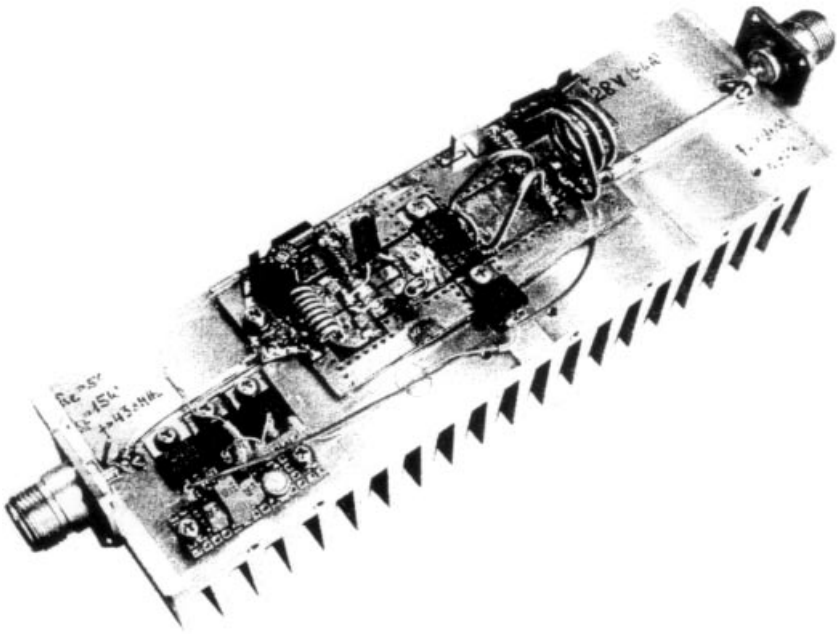

Figure 3-267 Mechanical assembly of the 90-W amplifier shown in Figure 3-266.

and the shunt capacitor across is soldered from base to base as close to the transistor bodies as possible. A ceramic-dielectric variable capacitor in parallel with this allows fine tuning.

The output consists of an inductor from collector to collector that tunes out the capacitive reactance and makes the transistor output impedance real. We then follow the same pattern by taking a 1:4 transformer, but this time built using 10-Ω rigid line instead of 25-Ω rigid line. Together with the output capacitance, prior to the output balun, this is a medium-bandwidth matching arrangement that transforms up to 50 Ω. The collector impedance per collector had to be $(28 - 2)^2/2 \times 90$, resulting in roughly 3.8 Ω—not that different from the input match at the balun point. This way, the matching networks at the input and output can be identical. At the output of the matching network, another coiled 50-Ω coaxial cable serves as balun; because it must operate at the 90-W level, larger-diameter line was used than in the input balun. Finally, another section of rigid line is used to connect the output balun on the PC board to the output N connector. The output capacitor again helps in the transformation.

Both the base and collector voltage supplies are heavily filtered using ferrite-bead-based RF chokes and heavy wire inductors wound on low-impedance resistors. A fairly large number of these amplifiers were actually built and are still in use.

3-12-6 Quasiparallel Transistors for Improved Linearity

Some applications require really low intermodulation distortion. One of the authors (Rohde), during his tenure at RCA Government Systems Division, and his team developed a parallel-device topology that is somewhat similar to the conventional parallel approach but shows vastly increased linearity. In creating higher-power devices, manufacturers parallel several transistors in one package, connecting them in a clever way so the overall drive, dissipation, and output power are equally divided between all the devices. Special nickel–chromium

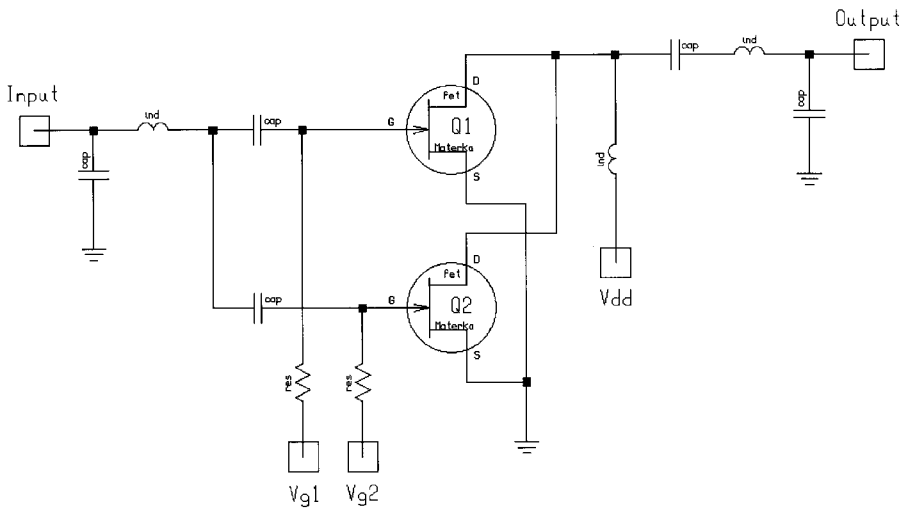

Figure 3-268 The quasiparallel amplifier topology looks like a standard parallel amplifier. Biasing the devices to different operating points nets an improvement in IMD performance.

ballasting resistors in the many fingers of the emitter connections of the multiple internal devices equalize any differences among the transistors while increasing the saturation voltage by only a small amount. In our high-linearity design, we used two transistors in parallel, one being biased somewhere between Class A and B, and the second one somewhere between Class B and C (Figure 3-268). The exact bias voltages and operating points had to be found through experiment. In practice, Q1, the "initially on" transistor, is driven to a point close to that at which its IMD products would increase. Q2 is biased such that at this same drive level it adds to the output power.

We frequently referred to this configuration as "turbocharged." The IMD products at full output power were down 40–45 dB, compared to 26–30 dB for a single transistor. While such an arrangement shows superior IMD performance, because of the somewhat abrupt kick-in of the second transistor, the transconductance response is semismooth, a characteristic that might make alert readers think that IMD will occur at this point. On the other hand, the transconductance for Q1, in effect, saturates or stays constant, so when the transconductance responses of both transistors are overlaid, the result is a smooth response overall.

This technique has been validated up to 100 W and up to at least 50 MHz. Its drawbacks include the need for two transistors with their associated costs, additional real estate, and higher input and output capacitances. Nonetheless, considering that MOS transistors capable of operation to 1 GHz were unavailable when this technique was developed, we believe that it should be revisited.

The Class D and higher operating modes require a large number of additional components and will make the efficiency higher (selective in frequency), but not necessarily reduce the IMD products. A further point of consideration is that it is incorrect to assume that reducing the input level to a given Class A will necessarily reduce its IMD products. As with tubes, the closer one gets to the knee, even in Class A operation, the worse the IMD. (This phenomenon was particularly troublesome in systems using 1-kW amplifiers up to 150 MHz;

underdrive with the intent of getting better IMD performance produced just the opposite result.) If a wide power range is considered, we recommend using a bias scheme that includes sufficient intelligence to find the best operating point.

Another hot amplifier issue is that of IMD as a function of load impedance. If an amplifier is used at output power considerably below its design value, its load impedance will be too low and, depending on the circuit configuration, the result may be additional IMD.

3-12-7 Distribution Amplifiers

It is not uncommon that a signal from a particular source like an antenna has to be distributed to several places. A condominium is a typical situation in which energy from a main signal source must be split for distribution to a larger number of users—there must be enough voltage or power to produce a noise-free picture. An amplifer capable of doing this is a *distribution* amplifier, not to be confused with a *distributed* (or traveling-wave) amplifier, such as that shown earlier in this chapter in Figure 3-6. An interesting means of achieving this is to use multiple Wilkinson couplers following an amplifier. Figure 3-269 shows an arrangement that makes heavy use of multiple power dividers to provide multiple outputs. Theoretically, the reverse is also possible: If we want to collect energy from a number of sources and combine them, as on a cable, we can use Wilkinson couplers at the *input* of a gain block. Note, however, that depending on the level and number of the combined signals, this may put enormous strain on the linearity of the amplifier. What we want to avoid is a lot of distortion, which, in the case of television, will show up as color confetti in the noise and signal.

3-12-8 Stability Analysis of a Power Amplifier

One of the hidden pitfalls in narrowband circuit design is that a circuit may be unstable outside the frequency range of interest. Circuits containing structures built from distributed elements, which exhibit multiple resonances, can be particularly susceptible to such instabilities. In this example, we analyze the stability of a simple FET power amplifier designed using small-signal concepts and the interactive Smith Tool utility in Ansoft's Serenade

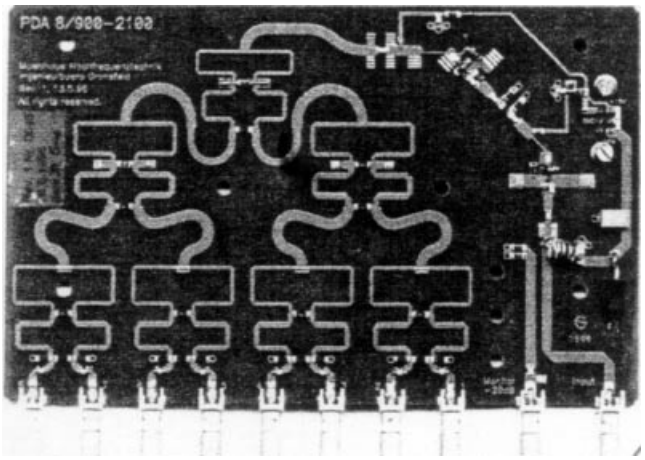

Figure 3-269 Distribution amplifier showing the use of multiple Wilkinson power dividers.

Design Environment. The evaluation shows how K-factor analysis alone is not sufficient to check for stability of a design.

Small-Signal ac Analysis. We begin by taking the Figure 3-270 amplifier, which was designed for about 16 dB of gain at 2.2 GHz. Due to the very low, capacitive input impedance of the FET and the proximity of the source-plane gain circles and stability circles to the edge of the Smith Chart, the matching network attempts to transform 50 Ω to an impedance of approximately $(2.5 + j15)$ Ω. The impedance lies close to the stability circles at 2 GHz but remains in a stable region. The bias point selected (–3.5 V) is chosen for Class AB operation. Higher linear gain can be achieved by reducing the gate voltage to –2.0 V; at this bias point, the amplifier gain will increase to about 19 dB.

First, we will do a small-signal ac analysis and examine the S parameters and K and B_1 factors [see Eqs. (3-154) and (3-157), respectively] from 1 GHz to 6 GHz—well beyond the bandwidth of the design. Figure 3-271 shows the circuit's frequency-dependent gain and matching characteristics.

If we examine B_1 and the stability factor K, we see that the amplifier is not unconditionally stable in the 2.2-GHz passband as shown in Figure 3-272. K dips slightly below 1, although B_1 remains above zero. In practice, a slight change in design would be required to bring K above 1 and remove this potential instability. However, for our example, this is of no consequence, as we shall see below.

Nyquist Stability Analysis. Now we will utilize a Nyquist stability analysis to check the stability of the amplifier. To fully realize the advantages of a Nyquist stability analysis, we must sweep frequency over a very wide range. We want to be able to pick up instabilities at *any* frequency, not just near the design frequency. In this example we sweep from 1 kHz to 20 GHz. A start frequency of 1 kHz is chosen so we can determine the starting point of the Nyquist plot and we ensure that any low-frequency resonances are picked up. The stop frequency is chosen past the f_{max} of the transistor (where we know it cannot oscillate).

The analysis results are shown in polar plot form in Figure 3-273 and in magnitude–angle form in Figure 3-274. The polar graph shows the real and imaginary parts of the system determinant as frequency is swept. The magnitude–angle graph shows the magnitude and cumulative angle (no cut at ±180°) of the system determinant as frequency is swept. The key to interpreting these graphs lies in the following statement drawn from the Nyquist criterion:

The circuit will be unstable if the Nyquist plot encircles the origin in a clockwise direction.

The term "unstable" refers to the existence of natural frequencies lying in the right-half of the complex frequency plane (RHP). These natural frequencies on the RHP will cause oscillations. To encircle the origin in a clockwise direction means that the Nyquist plot will travel in a clockwise path, cross the negative real axis, and continue to completely surround the origin. If the path appears to encircle the origin but then "unravels" itself in a counter-clockwise direction, the origin is not actually encircled. Figure 3-273 shows that the origin is not encircled and therefore this circuit is stable.

The magnitude–angle plot can assist in determining if a clockwise encirclement has actually been made with the help of the following:

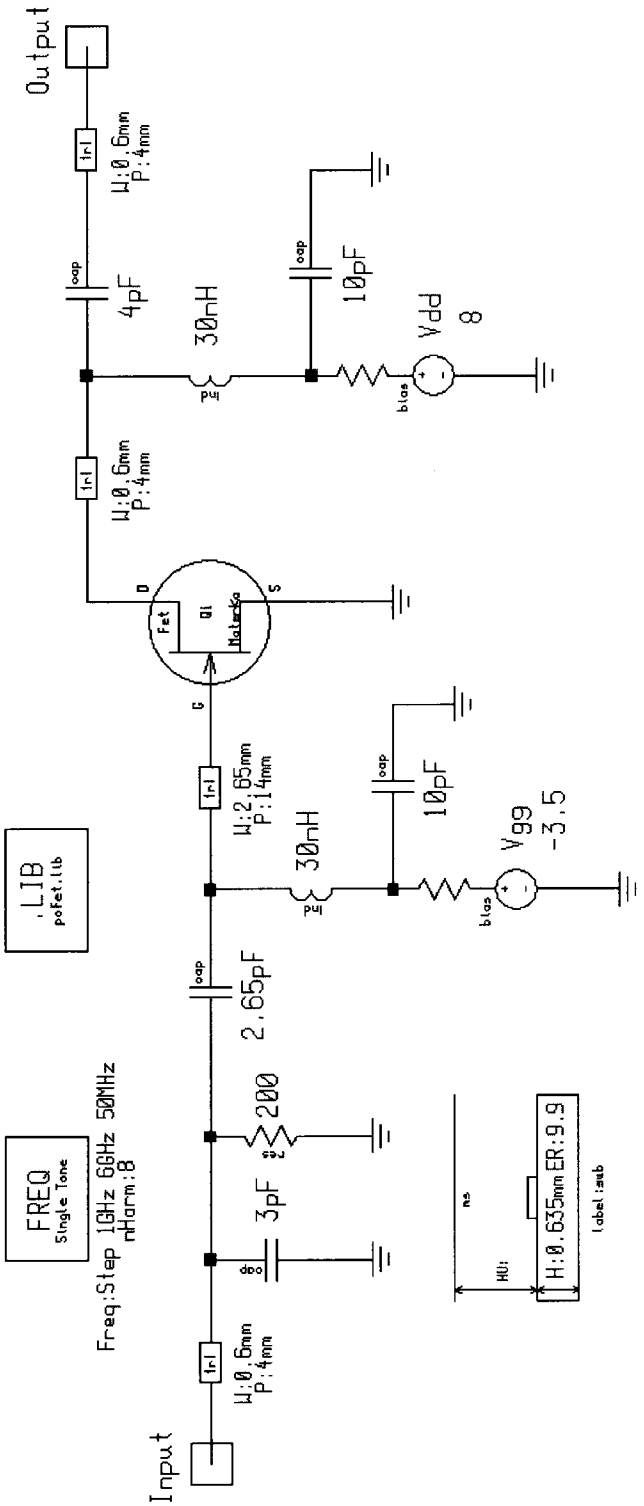

Figure 3-270 A 2.2-GHz amplifier design for stability analysis.

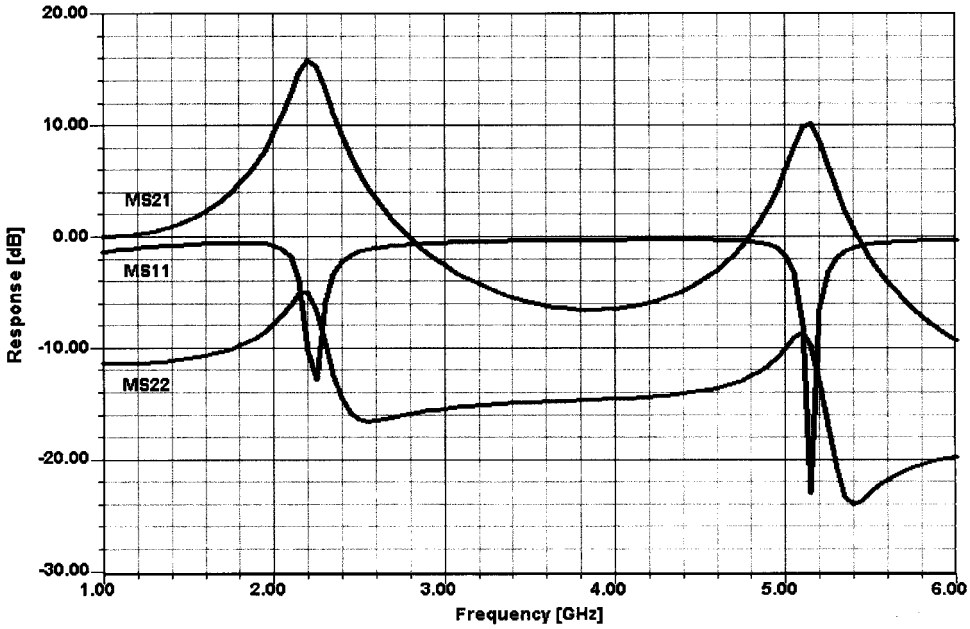

Figure 3-271 Frequency-dependent gain and matching characteristics of the amplifier. Although the circuit is designed for 2.2-GHz operation, the periodic responses of its distributed-element-based input and output matching networks result in a second gain peak near 5.1 GHz. As we shall see, however, instabilities may result at frequencies that cannot be intuited from this graph.

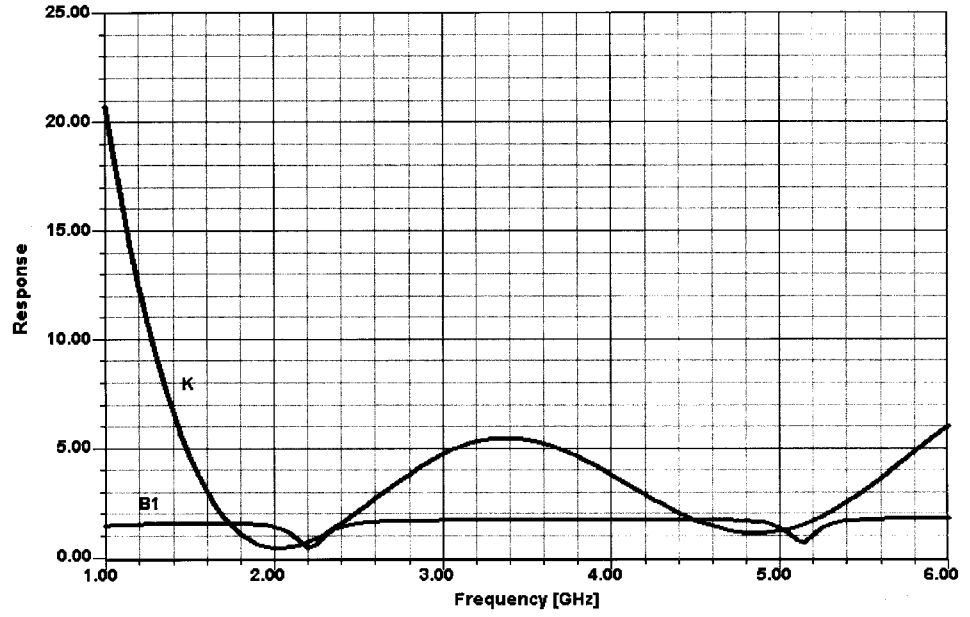

Figure 3-272 K and B_1 for the 2.2-GHz amplifier.

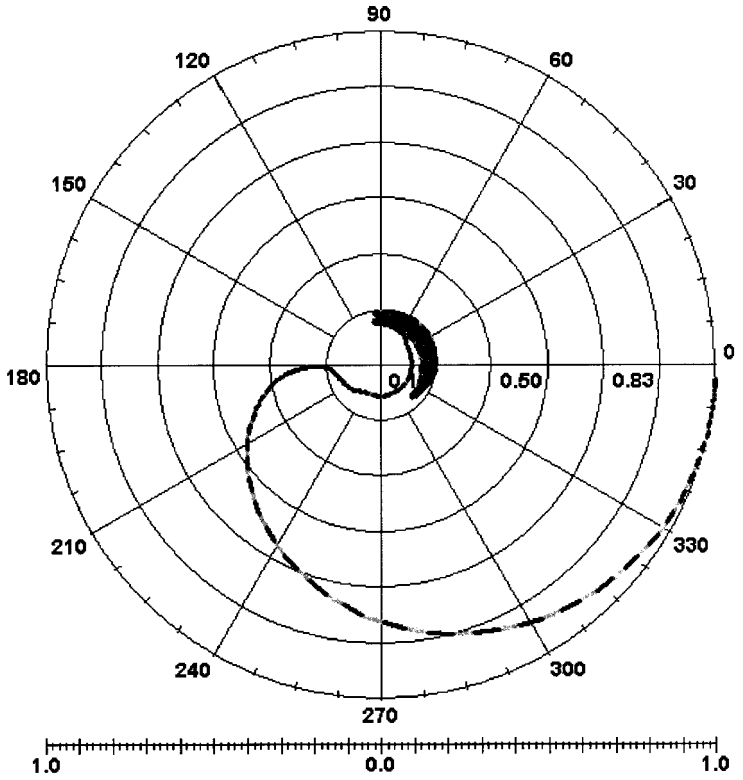

Figure 3-273 Polar Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

- To travel in a clockwise direction on a polar chart means to decrease phase angle. On a magnitude–angle plot, the phase will become more negative as frequency is increased (although it may not be monotonic).
- If the path crosses the negative real axis on the polar chart, it will cross –180° on the magnitude–angle plot.
- Encirclement will occur if the phase angle continues to decrease to, say, –360°. If "unraveling" occurs, the phase angle will not stay below –360°. Figure 3-274 clearly shows that the phase angle decreases to about –180° but does not decrease any more. Rather, the angle returns to a positive value and oscillates between about –40° and +100°. Therefore an encirclement did not occur, and the circuit is stable.

An Unstable Case. Let us now change the gate bias to –2 V—a value that increases the amplifier gain enough to cause instability. Figures 3-275 and 3-276 show the results. From Figure 3-275 we can see that the origin is encircled in a clockwise direction. Figure 3-276 confirms this since the phase angle goes through –180° and continues without unraveling.

Approximate Frequency of Oscillation. The frequency where the Nyquist plot crosses –180° is often the approximate frequency of the unstable right-half-plane zeros and provides an estimate of the potential oscillation. For this example, there is a sharp crossing at 200 MHz that is characteristic of a circuit resonance. Note that the frequency is not related

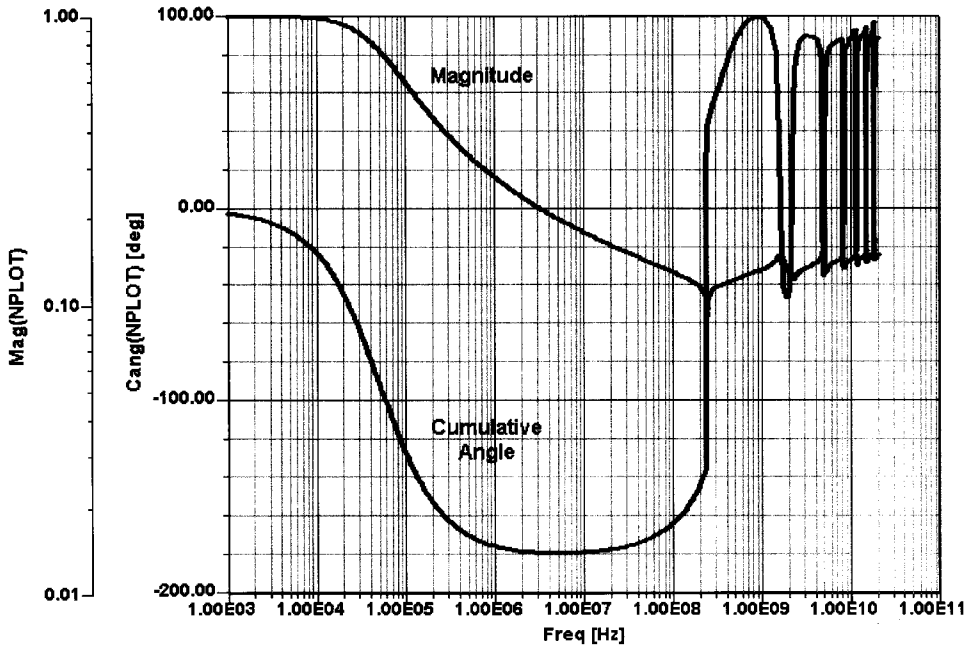

Figure 3-274 Magnitude and cumulative angle Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

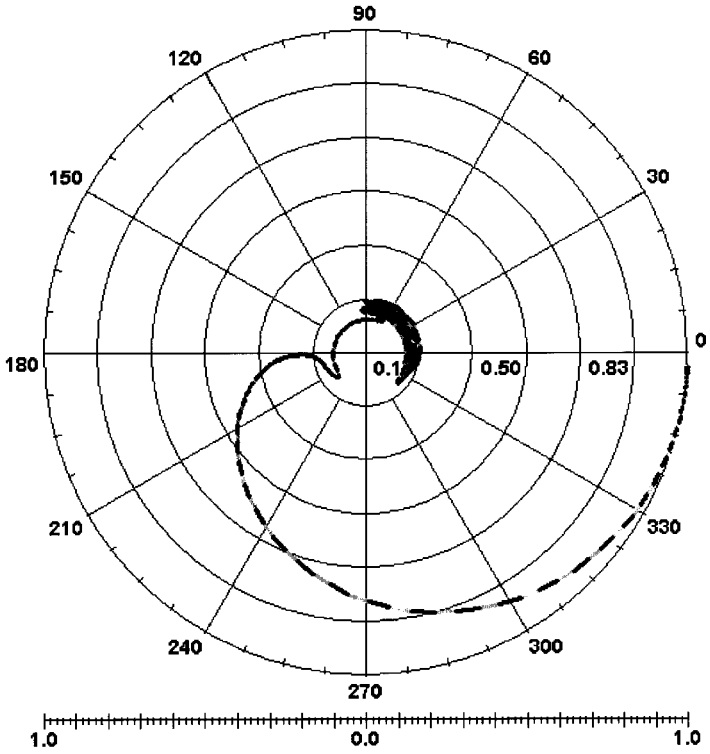

Figure 3-275 Polar Nyquist plot of the unstable amplifier.

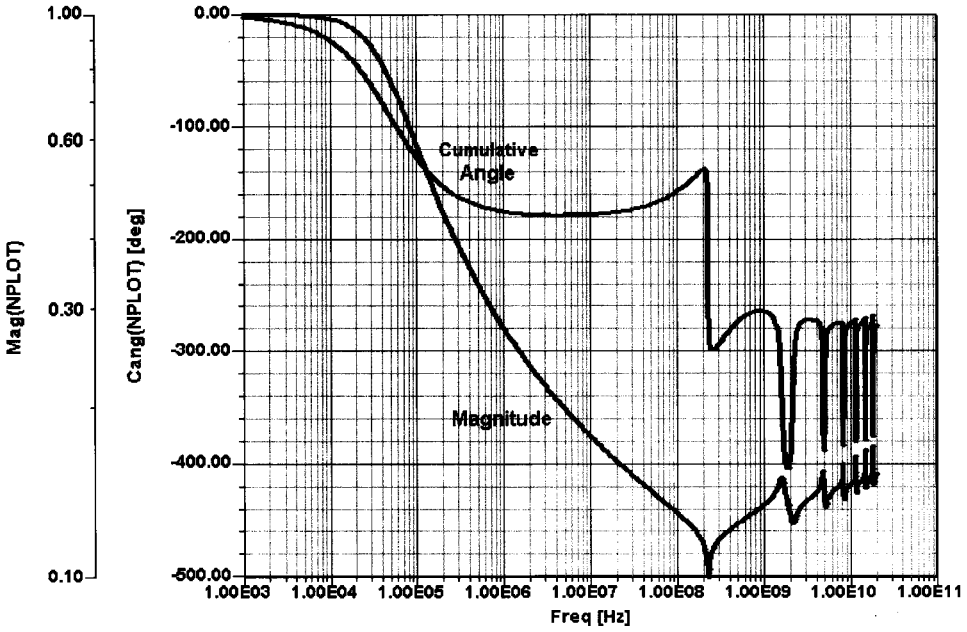

Figure 3-276 Magnitude–cumulative angle Nyquist plot of the unstable amplifier.

to a resonant frequency in a rigorous mathematical fashion, but it has been our experience that this frequency approximates the resonant frequency. To confirm the circuit's readiness for oscillation in the vicinity of this frequency, we evaluate it with Serenade's Oscillator Design Aid from 10 MHz to 1 GHz. The Design Aid finds an initial resonant frequency near 230.6 MHz—not too far from the –180° crossing frequency of 200 MHz of the Nyquist plot. Figure 3-277 shows this point.

Oscillator analysis finds a final oscillation frequency of 228.48 MHz. Figure 3-278 shows the resulting output spectrum at Port 2. At this point we decided to do a quick jump into Chapter 5 and take advantage of the CAD capability to predict the resulting phase noise, which is shown in Figure 3-279. As we compare this with other measured results, the approximately 228-MHz oscillator has a poor phase noise since the same phase noise is achievable at 1 GHz and higher. We remind the reader that this is an unwanted effect, but all of us who have built amplifiers will have experienced either low-frequency oscillations (motorboating) or very-high-frequency oscillation, sometimes caused by the components in the immediate vicinity of the transistor itself and found somewhere above 3 GHz. This case is really a demonstration case; a closer look reveals that the transconductance required for this condition is unrealistically high; but nonetheless it is a good example to demonstrate the stability issue.

Where Does Oscillation Begin? An interesting question to solve now is, "What gate bias voltage is needed for oscillation to begin?" Ansoft's Serenade Design Environment includes oscillator synchronous stability analysis, which uses a modification of the harmonic-balance technique to determine critical points, such as the voltage needed to "turn on" an oscillator. Mathematically, this is called a *Hopf bifurcation* because the behavior of

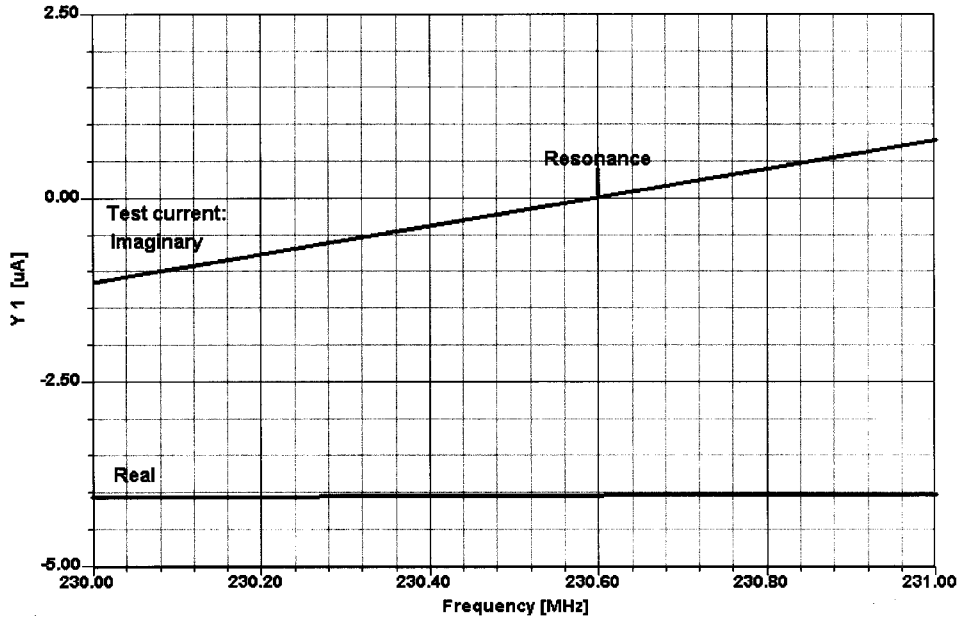

Figure 3-277 Graph from Serenade Oscillator Design Aid analysis of the amplifier. A resonant frequency is indicated where the imaginary part of the test current equals zero and the real part is negative.

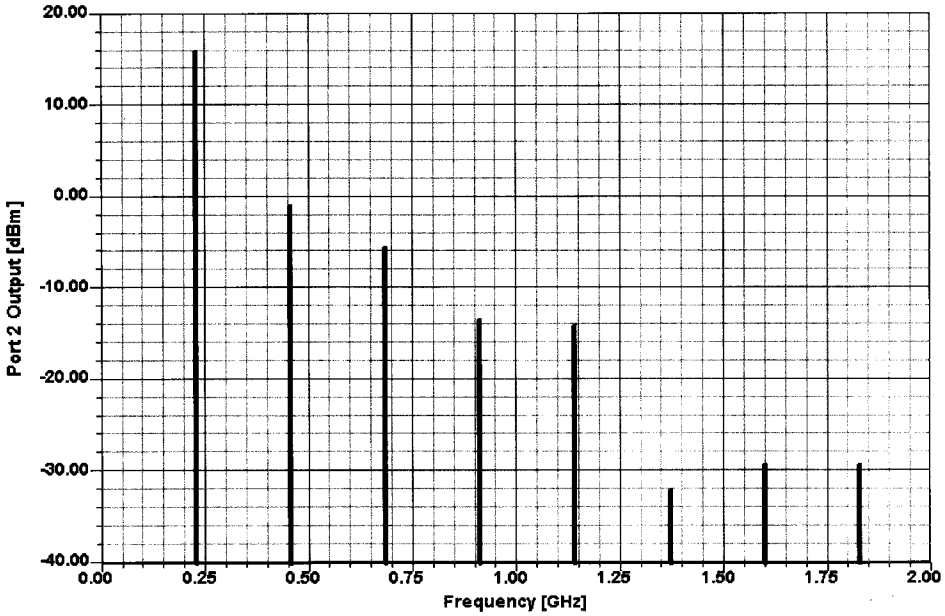

Figure 3-278 Predicted output spectrum of the unintended oscillator.

the circuit changes dramatically from a dc steady state to an oscillatory response. Figure 3-280 shows this effect by plotting output power versus gate bias. The turning point at –3.2 V (22 mW) is clearly visible, as is the bifurcation at –3.1 V (0 mW output).

Figure 3-280 can be interpreted as follows:

1. If the bias voltage is increased from, say, –4.0 V, the circuit will begin to oscillate at the bifurcation voltage and the output power will jump to 26 mW.
2. If the circuit is oscillating and the voltage is decreased from –2.0 V, the circuit will cease oscillating at the turning voltage of –3.2 V.
3. The branch between the turning point and the bifurcation point is unstable and cannot be realized in practice. This forms a hysteresis loop around points (–3.1 V, 0 mW), (–3.1 V, 26 mW), (–3.2 V, 22 mW), and (–3.2 V, 0 mW).

This amplifier stability analysis section is based on the stability analysis examples provided by Ansoft for the Serenade Design Environment.

An interesting example that combines both CAD and the feed-forward amplifier technique can be found in the Serenade Design Environment system simulator examples manual. This technique has been under evaluation for the last two years, but our feeling is that not enough measured data at frequencies above 500 MHz with reliable performance information have yet been made available in the literature. Along these lines, work done at Ansoft under a U.S. Air Force contract has provided very good insight into high-efficiency amplifiers at microwave frequencies [46].

3-13 POWER AMPLIFIER DATASHEETS AND MANUFACTURER-RECOMMENDED APPLICATIONS

Having discussed the various aspects of BJTs and FETs, we have decided to use MOS examples from Ericsson and Motorola, and a bipolar example from Motorola, as good examples to show the technology required to build high-power transistor amplifiers in this frequency range. In the following pages, we reproduce, with permission, datasheets for Ericsson's PTF 10009 FET and Motorola's MRF186 FET, followed by Motorola's MRF899 BJT.

ERICSSON

PTF 10009
85 Watts, 1.0 GHz
LDMOS Field Effect Transistor

Description

The 10009 is a common source N-channel enhancement-mode lateral MOSFET intended for large signal amplifier applications to 1.0 GHz. It is rated at 85 watts minimum output power. Nitride surface passivation and gold metallization are used to ensure excellent device lifetime and reliability. 100% lot traceability is standard.

- Performance at 960 MHz, 28 Volts
  - Output Power = 85 Watts
  - Power Gain = 13.0 dB Typ
  - Efficiency = 50% Typ
- Gold Metallized
- Silicon Nitride Passivated
- Excellent Thermal Stability

The RF MOSFET Line
RF Power Field-Effect Transistor
N–Channel Enhancement–Mode Lateral MOSFET

MRF186

120 W, 1.0 GHz
28 VOLTS
LATERAL N–CHANNEL
BROADBAND
RF POWER MOSFET

Designed for broadband commercial and industrial applications at frequencies from 800 MHz to 1.0 GHz. The high gain and broadband performance of this device makes it ideal for large–signal, common source amplifier applications in 28 volt base station equipment.

- Guaranteed Performance @ 960 MHz, 28 Volts
  Output Power — 120 Watts (PEP)
  Power Gain — 11 dB
  Efficiency — 30%
  Intermodulation Distortion — –28 dBc
- Excellent Thermal Stability
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 28 Vdc, 960 MHz, 120 Watts CW

The RF Line
NPN Silicon RF Power Transistor

MRF899

150 W, 900 MHz
RF POWER
TRANSISTOR
NPN SILICON

Designed for 26 Volt UHF large–signal, common emitter, Class AB linear amplifier applications in industrial and commercial FM/AM equipment operating in the range 800–960 MHz.

- Specified 26 Volt, 900 MHz Characteristics
  Output Power = 150 Watts (PEP)
  Minimum Gain = 8.0 dB @ 900 MHz, Class AB
  Minimum Efficiency = 35% @ 900 MHz, 150 Watts (PEP)
  Maximum Intermodulation Distortion –28 dBc @ 150 Watts (PEP)
- Characterized with Series Equivalent Large–Signal Parameters from 800 to 960 MHz
- Silicon Nitride Passivated
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 26 Vdc, and Rated Output Power
- Gold Metallized, Emitter Ballasted for Long Life and Resistance to Metal Migration
- Circuit board photomaster available upon request by contacting RF Tactical Marketing in Phoenix, AZ.

AMPLIFIER DESIGN WITH BJTs AND FETs

3-1 PROPERTIES OF AMPLIFIERS

3-1-1 Introduction

The goal of this chapter is to move from the details on the semiconductor devices themselves to our first practical application. One of the more interesting features of amplifiers is that they can easily become what will be covered in Chapter 5: *oscillators*. This is due to the high gain of the devices, unaccounted for parasitic elements, and other design flaws. The amplifiers we need will fall into three categories:

- Low-noise amplifiers
- High-gain amplifiers
- Medium- to high-power amplifiers

See Figure 3-1. The low-noise amplifier always operates in Class A, typically at 15–20% of its maximum useful current. The high-gain amplifier can operate in Class A, as well as Class B (mostly push–pull). The higher dc current for the same device results in a higher noise figure and more gain, and ultimately more output power. Class C operating mode is really reserved for either FM transmissions or constant-carrier modes like CW. Some of the modern digital modulation types are sensitive to phase distortion rather than amplitude changes and because of the resulting output spectrum designers have stayed away from Class C operation.

Some of these amplifiers, such as bipolar versions, can be dc-coupled with very few difficulties; others, like those in the FET families, will cause more headaches. An interesting example, although much too high in frequency for the purpose of this book, is shown in Figures 3-2, 3-3, 3-4, and 3-5. It shows a three-stage amplifier that has noise feedback for the first two stages and resistive feedback for the output stage. These are the three types of amplifiers, regardless of technology, we will be evaluating. The achievement of accurate noise analysis of this circuit, reported in Rohde et al. [1], marked the first time a complete

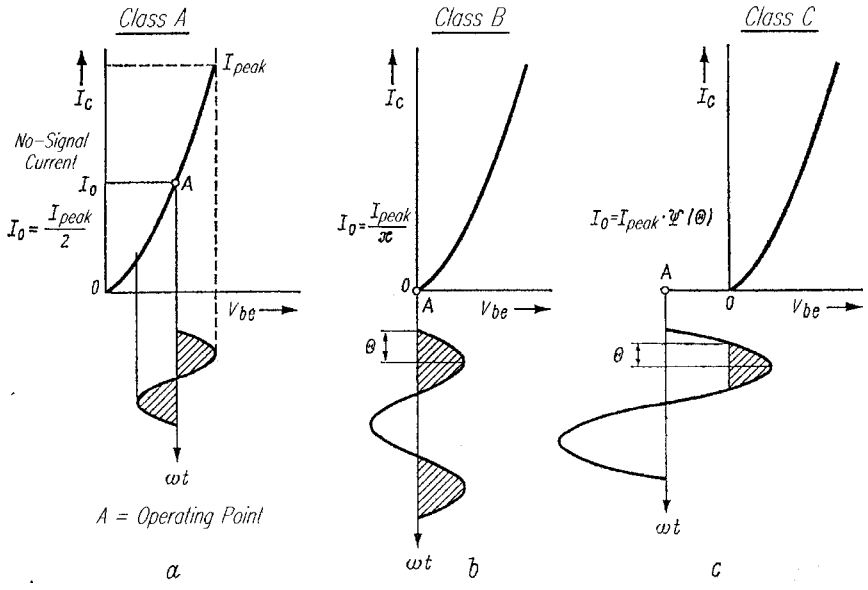

Figure 3-1 Definition of Class A, B, and C operation and resulting bias, including conduction angle (Θ, to be discussed in Section 3-2-2). The transfer characteristic can be either quadratic or exponential. This results in different distortion but does not change the basic operating mode.

linear noise model with essentially no frequency limitation had been developed. Its accuracy depends solely on the accuracy of the element values of the linear equivalent circuit, which can be obtained from measured *S*-parameters by an optimization process. Needless to say, this technique is also applicable at lower frequencies, such as 1.5–3 GHz, and its deviation from measured values has never been worse than 0.2 dB or, relative to the noise figure, 10% expressed in dB.

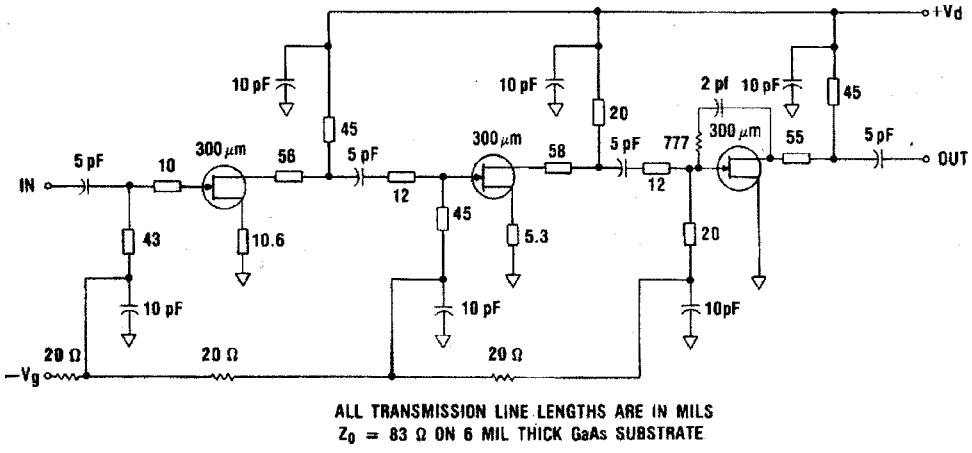

Figure 3-2 Schematic of the X-band GaAs monolithic low-noise amplifier (Texas Instruments EG8021). For reasons of linearity, all three stages operate in Class A.

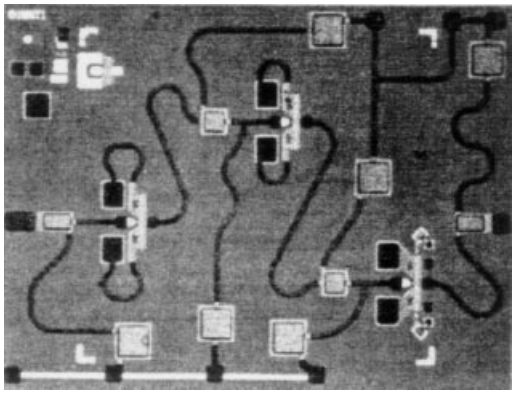

Figure 3-3 Photograph of the EG8021 monolithic amplifier chip. The area pictured is 0.09 inch by 0.12 inch in size.

The results of Figure 3-4 were obtained by using the linear FET model as supplied by Texas Instruments. It becomes somewhat obvious that a match for S_{11} of –60 dB is not likely. We then replaced the linear transistor with the SPICE-type nonlinear model, resulting in the responses shown in Figure 3-5. S_{11} now looks much more realistic in the center of the range, but at the same time exhibits a tendency toward instability at frequencies around 8 GHz. The actual circuit, when measured, did not exhibit this potential instability; on the other hand,

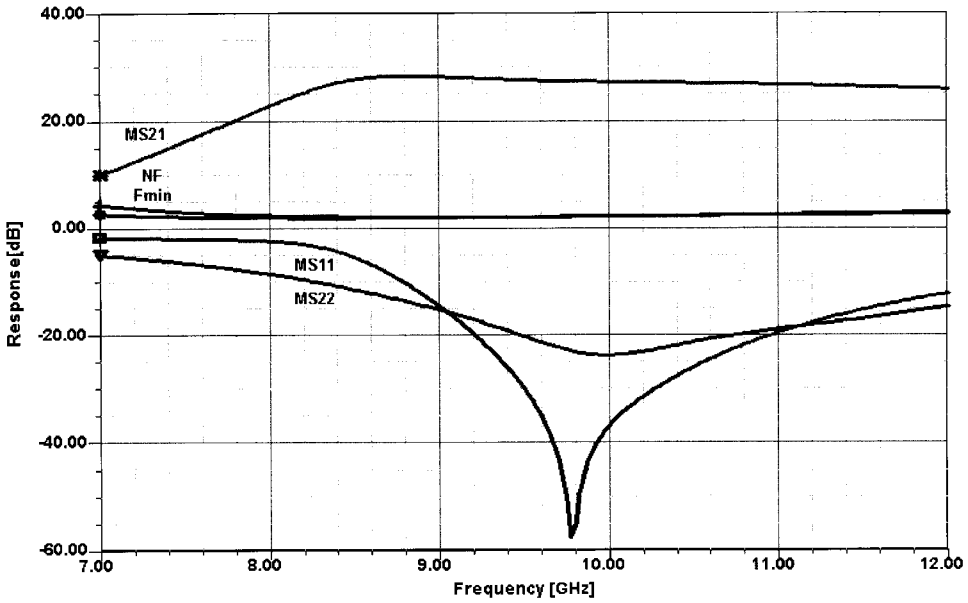

Figure 3-4 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the TI linear FET model. The values at 10 GHz are: F_{min}, 2.20 dB; NF, 2.21 dB; S_{11}, –36.8 dB; S_{21}, 27.2 dB; and S_{22}, –23.7 dB.

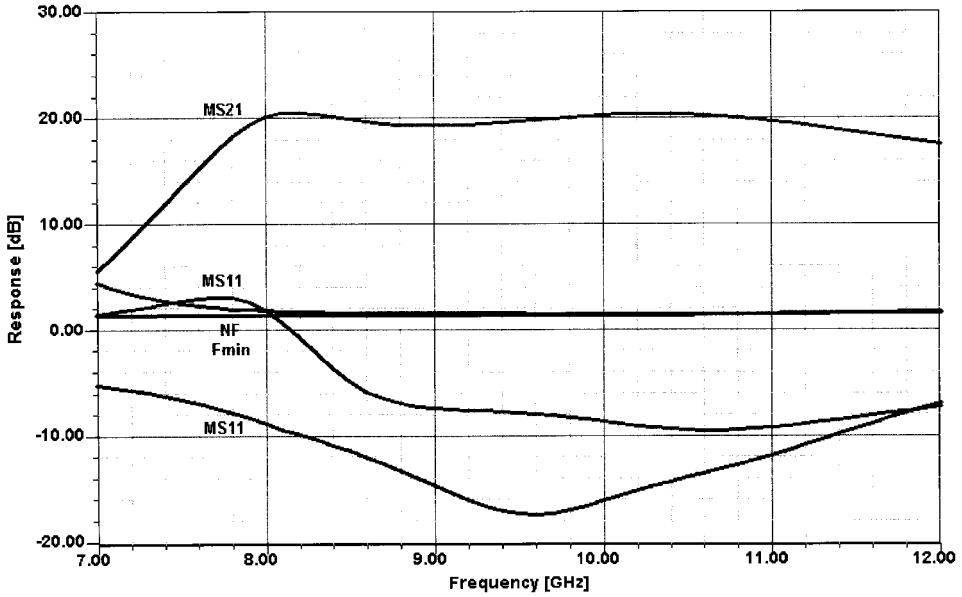

Figure 3-5 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the nonlinear FET model. The values at 10 GHz are: F_{min}, 1.53 dB; NF, 1.65 dB; S_{11}, –8.5 dB; S_{21}, 20.3 dB; and S_{22}, –15.9 dB.

the noise figure and gain agreed quite well. The discrepancies between the results with the linear and nonlinear models emphasize the importance of accurate device modeling.

Figure 3-6 shows a wideband amplifier, specifically a distributed amplifier, that covers 1–20 GHz. Figure 3-7 shows its simulated frequency-dependent gain, matching, and noise performance. The example given here as the upper frequency for wireless systems is rapidly expanding and the technology to accommodate this is already in place. Modern CAD tools can handle such high frequencies accurately, which means one can trust them at the significantly lower wireless frequencies of 500 MHz to 3 GHz. Above 1500 MHz, one really should model using distributed elements. We will come to this later in this chapter.

Input/output and interstage matching will become another challenging task, specifically if one requires sufficient bandwidth. As circuits become more complex and as the operating frequency increases, passive components play an increasingly important role; the use of

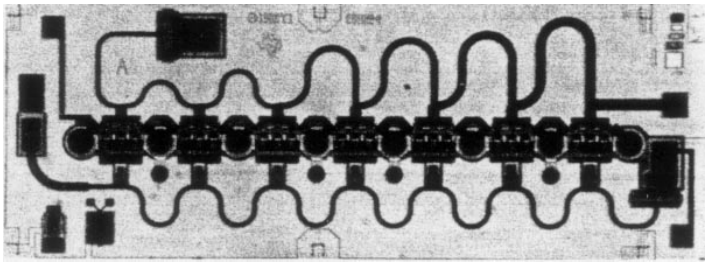

Figure 3-6 Photo of the 1–20-GHz distributed amplifier.

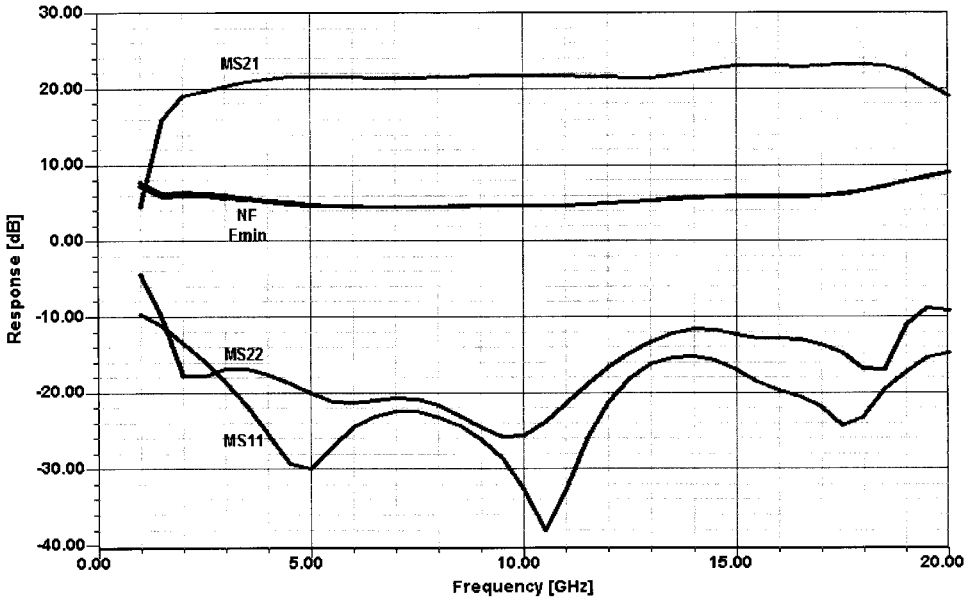

Figure 3-7 Simulated F_{min}, NF, S_{11}, S_{21}, and S_{22} responses. At the center of the range, the following numbers were found: F_{min}, 4.80 dB; NF, 4.80 dB; S_{11}, –32.8 dB; S_{21}, 21.8 dB; and S_{11}, –25.2 dB.

distributed elements is practically a necessity above 1500 MHz. For this reason, we begin this chapter by covering the application of transistors as amplifiers, following this with a discussion of the surrounding external circuitry, such as transmission lines, inductors, capacitors, and resistors. Monolithic ICs on silicon are a totally different ball game, and neither of the authors has sufficient expertise in this area. For this reason, we refer readers who will concentrate on MMIC design to the literature mentioned at the end of this chapter.

The goal of the applications presented here is to address, where possible, high-performance wireless stages that are less subject to constraints of space, power consumption, and cost, than portable/mobile applications. This is consistent with our preface, in which we have clearly stated our goal. The designers of handsets typically cannot consider the full variety of circuits we will present here. These types of stages (low noise, high gain and power) frequently will be used with filtering, and we will give some examples of input filters, including a tracking high-performance design.

A key topic besides the frequently mentioned gain is the whole noise issue. We will give the reader a complete introduction to this important area, followed by a similar introduction to the gain and matching of transistors. *Caution*: The majority of applications published go through the exercise of using *S*-parameters manually to design low-noise and small-signal amplifiers. While we have been tempted to repeat the information found in several textbooks, we feel that today's engineers will have access to CAD tools one way or another. It is highly unlikely that readers will undertake the inefficient process of going through all the design steps manually (a procedure that can take days); hopefully, engineers will resort to a linear/nonlinear CAD tool to do so. Only for the purpose of summarizing the necessary steps will we provide the relevant information regarding gain, stability, and related topics, demonstrating their usefulness or possible misuse with a modern CAD tool—in our case,

the Serenade Design Environment product from Ansoft. At this time, several additional companies beside Ansoft and Hewlett-Packard have emerged, but it is dangerous to list all of them as they come and go.

3-1-2 Gain

In practical terms, when we talk about gain we mean the output power relative to the input power. The industry standard now uses 50 Ω; however, at the point at which we have to match high-impedance devices such as monolithic crystal filters where the impedance jumps, things are not so obvious. The transformation equation that allows us to transform from one impedance to another is

$$m = \sqrt{\frac{R_2}{R_1}} \tag{3-1}$$

This correction factor, m, is required to do the transformation from R_1 (50 Ω) to R_2 (e.g., 1.2 kΩ). It needs to be understood that while the power gain remains the same, the voltage gain requires this correction factor. Since the power gain is expressed as 10 log A, A being the loop gain, 20 log A is the voltage gain, both expressed in dB. The reason for 10 versus 20 is that the power gain is always the voltage squared, which accounts for the 2. As a reminder of these relationships we present the following:

Distinction: Power Ratios–Voltage Ratios

$$n \text{ dB} = 10 \log_{10}(P_2/P_1) \quad \xrightarrow{PP = V^2/Z} \quad n = 10 \log_{10}\left(\frac{V_2^2/Z_2}{V_1^2/Z_1}\right)\text{dB}$$

$$Z_2 = Z_1 \rightarrow n \text{ dB} = 10 \log_{10}(V_2^2/V_1^2) = 10 \log_{10}(V_2/V_1)^2$$

$$\Longrightarrow \boldsymbol{n \text{ dB} = 20 \log_{10}(V_2/V_1) \text{ dB}}$$

The gain is typically defined under the condition of real resistive source and load terminations, which means that all the available power is being supplied to the amplifier, and likewise through proper matching at the output all the available power is fed to the termination. This gain figure is typically measured at a single spot frequency, but since most amplifiers are not totally flat, one needs to specify the gain tolerances or gain flatness. A good number is x dB ± 0.5 dB gain variation. In the case of a narrowband amplifier, the gain typically is shaped like a tuned circuit or like a critically coupled bandpass filter frequency response, while in the case of a real wideband application, the desired gain has some kind of ripple, which is due to the various compensation components in the circuit. An extreme case of a wideband amplifier is a 6–18-GHz single-stage amplifier that uses some very clever matching. This is shown in the following example. Figure 3-8 shows the circuit diagram, and Figure 3-9 shows its frequency-dependent performance.

While this is a cute approach for generating a single-stage amplifier over such a wide bandwidth, in real life it is not acceptable. The reason for this is that neither S_{11} nor S_{22} meets any useful specifications over the entire range. Typically, S_{11}/S_{22} values are only a few dB, while in reality more than 10 dB is required. We have chosen this example to show that gain

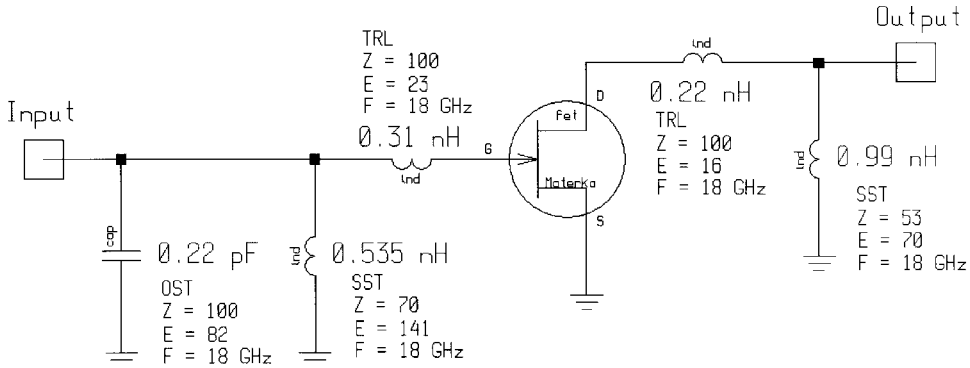

Figure 3-8 A 6–18-GHz FET amplifier.

and matching, depending on the circuit topology, are connected. We get similar results for the noise figure, whereby the best achievable noise figure ($F_{\min}$) and the actual 50-Ω noise figure are only a few dB apart; however, its frequency dependence in a wideband stage is certainly not acceptable.

Another parameter associated with gain is the stability factor K of the circuit. A value of $K > 1$ is mandatory to guarantee stability together with the S_{11} and S_{22} magnitudes being less than 1. Figure 3-10 plots the K stability factor, which for absolute stability must be >1, and maximum stable gain (MSG) as well as $G_{\max}$. It turns out that MSG is a highly artificial

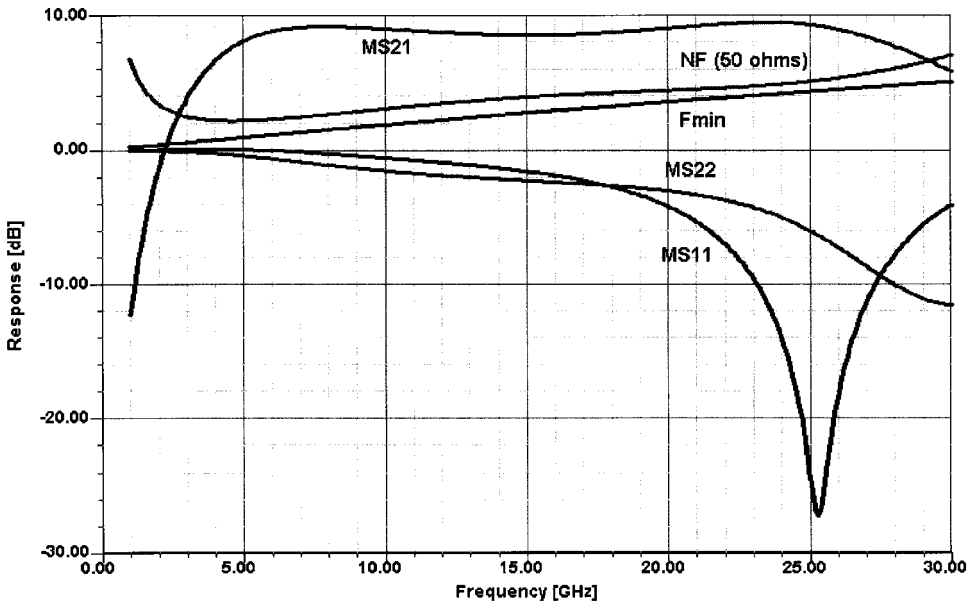

Figure 3-9 Frequency-dependent gain, matching, and noise performance of the amplifier shown in Figure 3-8.

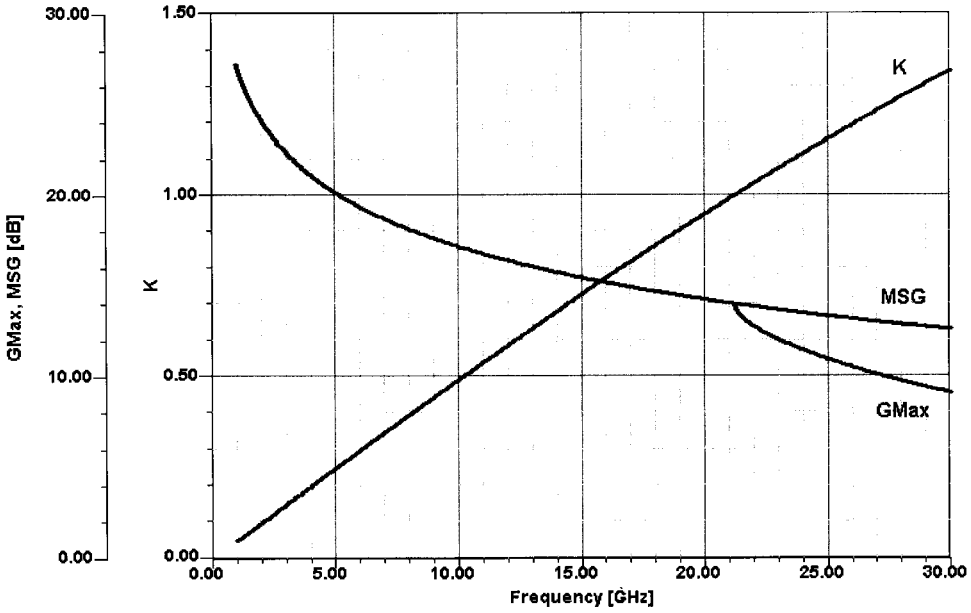

Figure 3-10 G_{max}, maximum stable gain (MSG), and K performance of the amplifier in Figure 3-8.

definition of stability that implies that input and output are terminated with pure resistances and then conjugately matched. There are four ways of achieving this resistive loading, either in the emitter as a shunt resistor between gate/drain or base/collector, or in parallel to the input and output to ground. Needless to say, this is not a real operating mode because it deteriorates both noise and gain. In our case, the entity G_{max} is a function of S_{12} of the circuit, not just the transistor, and depends highly on S_{12}. If we bring the system close to oscillation, then G_{max} will increase at the expense of bandwidth. Unfortunately, some of these microwave definitions of gain (see Table 3-1) have become widely used in industry without always being useful. Evaluating these equations for S_{12} is not legitimate because other quantities like K become infinite, and the entire system of equations falls apart. The power gain with input and output conjugately matched, or the transducer power gain for arbitrary source and load matching, still give more insight into the system.

In the above example, we specifically stated that the input and output VSWR was totally unacceptable, and this was due to a one-stage design. Figure 3-11 shows an amplifier chip built around two transistors with standard feedback techniques applied; Figures 3-12 and 3-13 show its frequency-dependent gain, matching, stability, and noise performance. This amplifier was one of the early examples of GaAsFET wideband amplifiers, but it is interesting because while it has wild (and wide) gain swings, it exhibits a fairly constant input and output impedance or reflection coefficient. A further evaluation of the circuit shows that not only is the circuit unconditionally stable, but that the maximum stable gain has an extremely high value based on essentially minimal S_{12}, the K factor is always significantly higher than 1, and G_{max} follows, to some degree, the actual gain response of the amplifier. (Ultimately, designers gave up on simple *RCL* feedback amplifiers for such a wide bandwidth, replacing them with distributed amplifiers previously called traveling wave amplifiers.) The problem of gain and stability starts at audiofrequency amplifiers, where the

Table 3-1 Nine power gains

Transducer power gain in 50-Ω system	$G_T = \lvert S_{21}\rvert^2$
Transducer power gain for arbitrary Γ_G and Γ_L	$G_T = \dfrac{(1-\lvert\Gamma_G\rvert^2)\,\lvert S_{21}\rvert^2\,(1-\lvert\Gamma_L\rvert^2)}{\lvert(1-S_{11}\Gamma_G)\,(1-S_{22}\Gamma_L)-S_{12}S_{21}\Gamma_G\Gamma_L\rvert^2}$
Unilateral transducer power gain	$G_{\mathrm{TU}} = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)\,(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2\lvert 1-S_{22}\Gamma_L\rvert^2}$
Power gain with input conjugate matched	$G = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{22}\Gamma_L\rvert^2(1-\lvert S'_{11}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{11}\rvert^2}$ (for $\Gamma_L = 0$)
Available power gain with output conjugate matched	$G_A = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2(1-\lvert S'_{22}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{22}\rvert^2}$ (for $\Gamma_G = 0$)
Maximum available power gain[a]	$G_{ma} = \left\lvert\dfrac{S_{21}}{S_{12}}\right\rvert\,(k-\sqrt{k^2-1})$
Maximum unilateral transducer power gain	$G_{\mathrm{TUmax}} = \dfrac{\lvert S_{21}\rvert^2}{(1-\lvert S_{11}\rvert^2)(1-\lvert S_{22}\rvert^2)}$
Maximum stable power gain	$G_{ms} = \dfrac{\lvert S_{21}\rvert}{\lvert S_{12}\rvert}$
Unilateral power gain	$U = \dfrac{1/2\lvert S_{21}/S_{12}-1\rvert^2}{k\lvert S_{21}/S_{12}\rvert-\mathrm{Re}(S_{21}/S_{12})}$

[a]Definition for $G_{\max}$: If $k > 1$, it is called G_{ma}, and if $k < 1$, it is called G_{ms}.

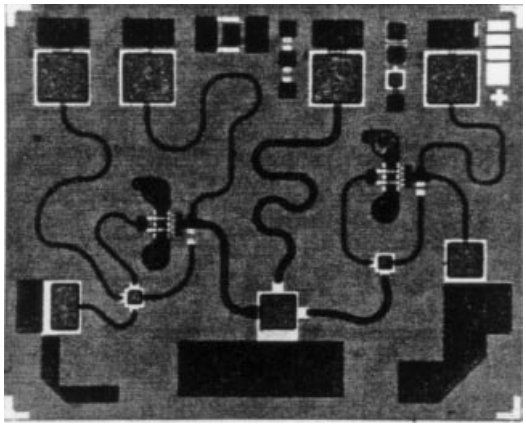

Figure 3-11 A two-stage, wideband feedback amplifier.

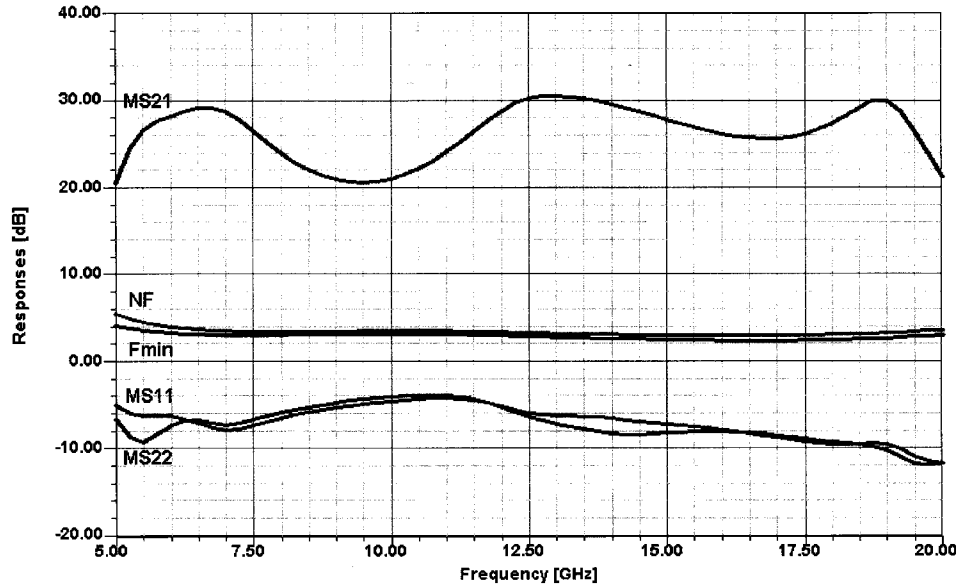

Figure 3-12 Frequency-dependent gain, matching, and noise performance for the amplifier in Figure 3-11.

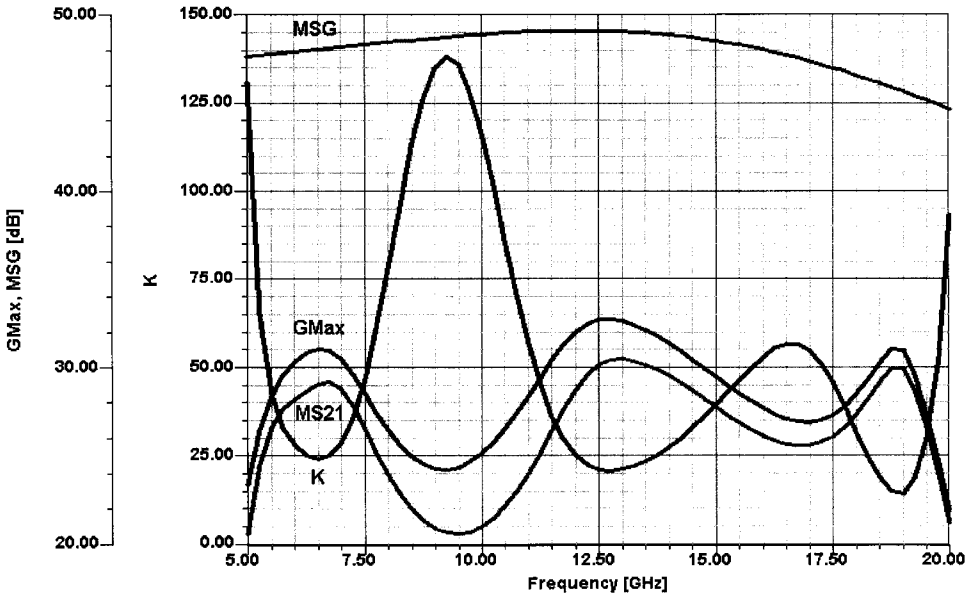

Figure 3-13 Frequency-dependent G_{max}, K, maximum stable gain, and gain performance for the amplifier in Figure 3-11.

motorboating phenomenon has been known for years, and the problem moves up in frequency with more modern technology and is largely dependent not only on the device and the circuit, but also on the layout. The motorboating effect has to do with ground loops and the fact that if the printed circuit traces from the power supply connection to the output power stage present too high a resistance, then at high currents the voltage will drop to a point below useful operation and then, as the volume is lowered, become stable again. In this case the amplitude of the signal through the amplifier controls the stability of the output stage. Needless to say, this most unpleasant effect applies to high-power stages for all output transistors, where we use Class B or C operation, meaning that the dc operating current as a function of output does not remain constant.

In terms of gain, there is also an important gain characteristic called *differential gain* and *differential phase*. These expressions were first used in television circuits, where linearity in both areas is an absolute must. The amplitude of the signal determines the black and white contrast, and the phase determines the color. As an example, transmitting an image of one of our presidents playing golf in California to the New York area is done by many microwave hops. Any multipath reception, such as that caused by reflection from airplanes, may have little effect on the signal amplitude, but the resulting phase shift can transform a green lawn to a red lawn if a total shift of 180° occurs. Given a particular operating point, if the 1-dB compression point of multiple amplifiers in the chain is approached or exceeded, their differential gain, which is defined by the IEEE as "the difference between (a) the ratio of the output of a small high-frequency sine-wave signal at two different levels of a low-frequency signal on which it is superimposed, and (b) unity," may increase. This mode of saturation charges all the capacitances of the amplifier transistors, causing huge phase shifts that result in the known problem of changing colors. The same applies, of course, in test equipment amplifiers, in which such changes cannot be tolerated. A somewhat similar, but not quite the same, problem is spectral regrowth [evaluated in terms of adjacent-channel power ratio (ACPR)], which is also due to nonlinearities. The question of linearity has already been covered in detail in Chapter 1. Needless to say, any overdrive condition also changes an amplifier's input and output SWR.

3-1-3 Noise Figure (NF)*

Introduction. In this section we look at the best way to describe noise in active devices (black boxes). Even when a two-port is linear, the output waveform will differ from the input, because of the failure to transmit all spectral components with equal gain (or attenuation) and delay. By careful design of the two-port, or by limitation of the bandwidth of the input waveform, such distortions can largely be avoided. However, noise generated within the two-port can still change the waveform of the output signal. In a linear passive two-port, noise arises only from the losses in the two-port; thermodynamic considerations indicate that such losses result in the random changes that we call noise. When the two-port contains active devices, such as transistors, there are other noise mechanisms present. A very important consideration in a system is the amount of noise that it adds to the transmitted signal. This is often judged by the ratio of the output signal power to the output noise power

*Section 3-1-3 is reprinted from Chapter 2 of George D. Vendelin, Anthony M. Pavio, and Ulrich L. Rohde, *Microwave Circuit Design Using Linear and Nonlinear Techniques*, copyright 1990 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

(S/N). The ratio of signal plus noise power to noise power [$(S + N)/N$] is generally easier to measure and approaches S/N when the signal is large.

In the evaluation of a two-port it is important to know the amount of noise added to a signal passing through it. An important parameter for expressing this characteristic is the noise factor. The signal energy coming from a generator or antenna is amplified or attenuated in passing from the input to the output of a two-port, as is the noise that accompanies the input signal energy. A system generally includes a cascade of two-port networks that constitute one overall two-port that amplifies the signal to a high-enough power level for its intended use. The *noise factor* of a system is defined as the ratio of signal-to-noise ratios available at input and output:

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}} \geq 1 \tag{3-2}$$

The noise figure (or factor) of a receiver is an easily measured quantity that describes the signal-to-noise ratio reduction of that receiver.

When this ratio of powers is converted to decibels, it is generally referred to as the *noise figure* rather than noise factor. Various conventions are used to distinguish the symbols used for noise factor and noise figure. Here we use F to represent the noise factor and NF to represent the noise figure, although the terms are usually used interchangeably.

For an amplifier with the power gain G, the noise factor can be rearranged as

$$F = \frac{S_i/N_i}{GS_i/G(N_i + N_a)} \tag{3-3}$$

when N_a is the additional noise power added by the amplifier referred to the input. This can be computed to be

$$F = 1 + N_a/N_i \tag{3-4}$$

The noise factor is often replaced by the noise figure (NF), which is defined in decibels as

$$\text{NF} = 10 \log_{10} F \tag{3-5}$$

In applications like satellite receivers, the noise factor becomes such a small number that it is inconvenient to work with. Many people have adopted the use of an equivalent noise temperature for a circuit to remedy this situation. Since the thermal noise power available from a resistor at temperature T_e is

$$N = kT_eB \tag{3-6}$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), T_e is the effective temperature in kelvins, and B is the bandwidth in hertz. The equation above may be used to associate an effective noise temperature with circuits containing more than just thermal noise sources. This allows Eq. (3-4) to be written as

$$F = 1 + \frac{kT_eB}{kT_0B} = 1 + \frac{T_e}{T_0} \tag{3-7}$$

where T_e is the effective noise temperature of the circuit and T_0 is the temperature of the generator resistor in kelvins. The noise temperature T_e now characterizes our circuit noise contribution and can directly be related to the noise factor.

Assuming a reference noise temperature of 290 K (–273 + 290 = 17 °C), let us determine the noise temperature of the system with a noise factor of 2.6 (4.15 dB):

$$T_e = (2.6 - 1)\ (290) = 464 \text{ K}$$

This temperature T_e should not be confused with the environmental operating temperature T_0. It is quite common to operate low-noise amplifiers with T_e below 100 K at an ambient temperature of 290 K.

Signal-to-Noise Ratio. Let us consider the signal-to-noise ratio of power delivered from a generator to a load as shown in Figure 3-14. The signal power delivered to the input is given by

$$S_{\text{in}} = P_{\text{in}} = \frac{E_g^2 \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-8}$$

where E_g is the rms voltage of the input signal supplied to the system, and the noise power supplied to the input is expressed by

$$N_{\text{in}} = \frac{\overline{v_n^2} \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-9}$$

where the noise power at the input is provided by the noise energy of the real part of Z_g. The input impedance Z of the system in the form $Z = R_{\text{in}} + jX_{\text{in}}$ is assumed to be complex.

The Johnson noise of a resistor [here $\text{Re}(Z_g)$], given by the mean-square voltage

$$\overline{v_n^2} = 4kTRB \tag{3-10}$$

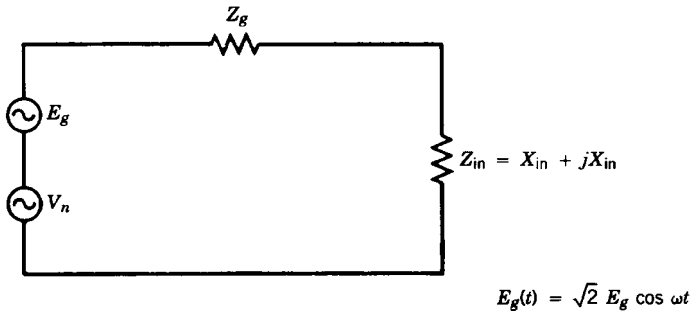

Figure 3-14 Combination of signal and noise voltages supplied to a complex termination.

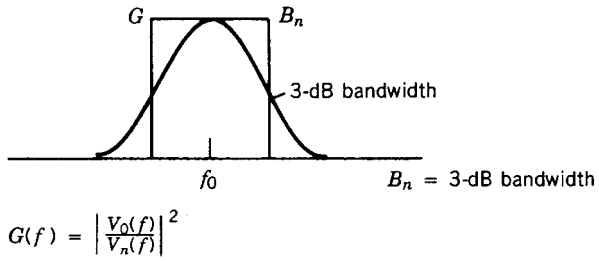
where k (Boltzmann's constant) = 1.38×10^{-23} J/K, T is the absolute temperature of the resistor, and B is the bandwidth, is sufficiently small that the resistive component of impedance does not change. The available signal power from the generator has a lower limit, even if the signal is attenuated by the highest possible attenuation. The generator resistor acts as a Johnson noise generator, its power being

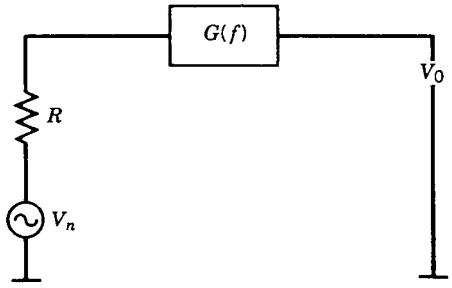
$$P_A = \frac{4kTRB}{4R} = kTB \tag{3-11}$$

where k is Boltzmann's constant, T is the absolute temperature, and B is the bandwidth. This power is the maximum available output power.

For an ambient temperature of 290 K, $kT = 4 \times 10^{-21}$ W/Hz. This expression is also given as kT = –204 dBW/Hz = –174 dBm/Hz = –114 dBm/MHz. We can combine Eqs. (3-8) to (3-10) to obtain

$$\left(\frac{S}{N}\right)_{\text{in}} = \frac{E_g^2}{4kT\text{Re}(Z_g)B} \tag{3-12}$$





$$V_0^2 = \int_0^\infty 4kT_0RG(f)\,dF$$
$$= 4kT_0R \int_0^\infty G(f)\,dF$$
$$B_n = \frac{1}{G} \int_0^\infty G(f)\,dF$$
B_n = noise bandwidth

Figure 3-15 Graphical and mathematical explanations of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

This is the value of *S/N* contributed by the generator, which does not include the noise generated by the load, in this case $\mathrm{Re}(Z_{\mathrm{in}})$, which would need to be included in the measurement of the total *S/N* across the input impedance.

A critical parameter is the noise bandwidth, B_n, which is defined as the equivalent bandwidth, as shown in Figure 3-15. For reasons of group delay correction, most practical filters have round rather than sharp corners. The noise figure measurements shown later can be used to determine the "integrated" bandwidth, which is B_n.

An active system such as a combination of amplifiers and mixers will add noise to the input signals, and the noise factor that describes this is defined as the *S/N* ratio at the input to the *S/N* ratio at the output, which is always greater than unity [2]. In practice, a certain minimum signal-to-noise ratio is required for operation. For example, in a communication system such a minimum is required for intelligible transmission, either voice or data. For high-performance TV reception, to provide a noise-free picture to the eye, a typical requirement is for a 60-dB *S/N*. In the case of a TV system, a large dynamic range is required, as well as a very large bandwidth to reproduce all colors truthfully and all shades from high-intensity white to black. Good systems will have a bandwidth of 8 MHz or more.

Noise Figure Measurements. Some of the noise equations are based on mathematical models and physics. To understand some of these expressions, it is useful to look at a practical system, with amplifiers, that has to be evaluated.

Let us look at Figure 3-16, which consists of a signal generator, the system or device under test (DUT), and a selective receiver with a built-in root-mean-square (rms) voltmeter to determine the signal and noise voltages. It is necessary that the system have enough gain so that the noise voltage supplied by the generator will be indicated [3].

If we assume that our selective receiver is a video noise meter calibrated in rms voltage levels, we can perform two measurements. With an input termination connected to the TV system (typically, 75 Ω for cable TV, 50 Ω for satellite TV), the noise receiver/meter will read a value for proper termination that can easily be calculated. Since one-half of the mean-square noise voltage appears across the input,

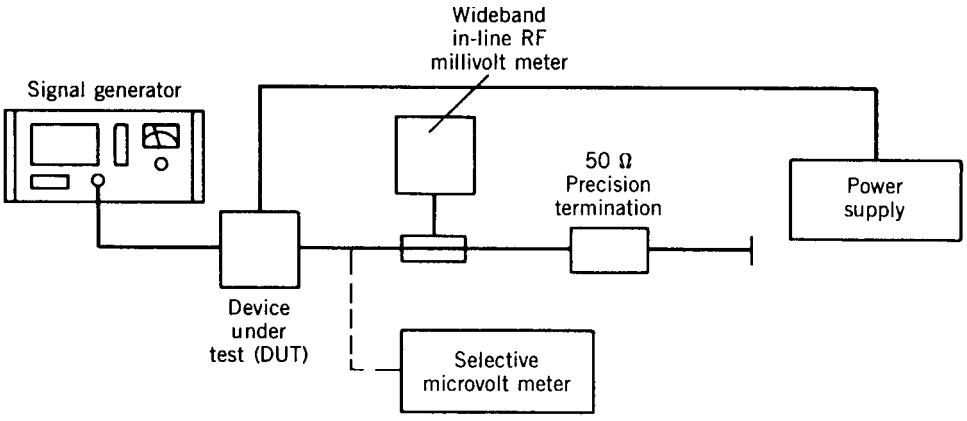


Figure 3-16 Test setup to measure signal-to-noise ratio.

$$v_{\text{in}} = \frac{v_n}{2} = \frac{\sqrt{4kTRB}}{2} \tag{3-13}$$

With $B = 10$ MHz, $T = 290$ K (T is always expressed in absolute temperature; $T_0 = -273$ °C), and $k = 1.38 \times 10^{-23}$ J/K, then for $R = 75\ \Omega$,

$$v_{\text{in}} = \frac{v_n}{2} = 1.73\ \mu\text{V} \tag{3-14}$$

where the rms noise voltage has been referred to the input port. We can verify this with our first measurement.

Now we increase the input voltage of the signal generator to a value that indicates a 60-dB *S/N* ratio at the output port. This should be about

$$E_g = \frac{v_n}{2}\sqrt{F} \times 1000 = 1.73\sqrt{F} \quad \text{mV}$$

where F is the noise factor of the receiver. For a receiver noise factor of 10, we would obtain $E_g = 5.48$ mV (rms value). If the noise energy equivalent to a noise factor of F is assumed, we need $\sqrt{F}$ times more voltage. For a 60-dB ratio, this means that $E_g = 1000 \times (v_n/2) \times \sqrt{F}$.

As they are done here, over a power range of 60 dB, the measurements can be performed over such a wide range only if special equipment is available. In cases where the internal detector of a piece of communication equipment is used, the signal-to-noise ratio measurements are performed over much smaller power ranges.

Let us assume that for the above-mentioned case ($F = 10$) we find a *S/N* ratio of 10 dB at the output for an input signal of 5.47 μV. By rewriting Eq. (3-7) as

$$E_g = \frac{v_n}{2}\sqrt{F} = \sqrt{KTRBF} \tag{3-15}$$

with F being the noise factor, we can solve for F with

$$F = \frac{P_s}{P_n} = \frac{E_g^2/R}{kTB} \tag{3-16}$$

While the input power from the thermal energy of the input termination resistor was $kTB = 4 \times 10^{-4}$ W, the input power required for the 10-dB *S/N* ratio was

$$P_s = \frac{(5.47 \times 10^{-6})^2}{75} = 3.98 \times 10^{-13}\ \text{W} \tag{3-17}$$

The noise factor is defined as the ratio P_s/P_n:

$$F = \frac{3.98 \times 10^{-13}}{4 \times 10^{-14}} = 10 \tag{3-18}$$

which is the proof.

This method is used more frequently at the 3-dB point, or double the input power if the dynamic range of the detector is small or only a linear indicator is available. Because of hum and other pickup, this is not an easy measurement. Using a signal generator is very expensive because in a laboratory or production environment a wide frequency range requires several generators.

Another method is the use of a wideband noise generator. Modern gas discharge diodes or avalanche diodes are available that provide essentially white noise energy over a large frequency range. These microwave diodes typically have an output of 30 dB above kT when switched on and kT when switched off. To provide good matching at microwave frequencies, a 15-dB attenuator is cascaded. This means that the noise power of the source in the ON condition is about 15 dB above kT.

In the early 1960s, low-cost noise figure test equipment was built around vacuum diodes whose operating range was limited to 1200 MHz due to the resonance effects of the structure. Today, automatic noise gain analyzers use calibrated solid-state noise sources up to 26.5 GHz. It appears that the upper frequency limit has to do with matching, and the lower-frequency limit with $1/f$ noise.

Noisy Two-Port Description. Based on the convention by Rothe and Dalke [4], any linear two-port can be in the form shown in Figure 3-17. This general case of a noisy two-port can be redrawn showing noise sources at the input and at the output. Figure 3-17b shows this in admittance form and Figure 3-17c in impedance form. The internal noise sources are assumed to produce very small currents and voltages, and we assume that linear two-port equations are valid. The internal noise contributions have been expressed by using external noise sources:

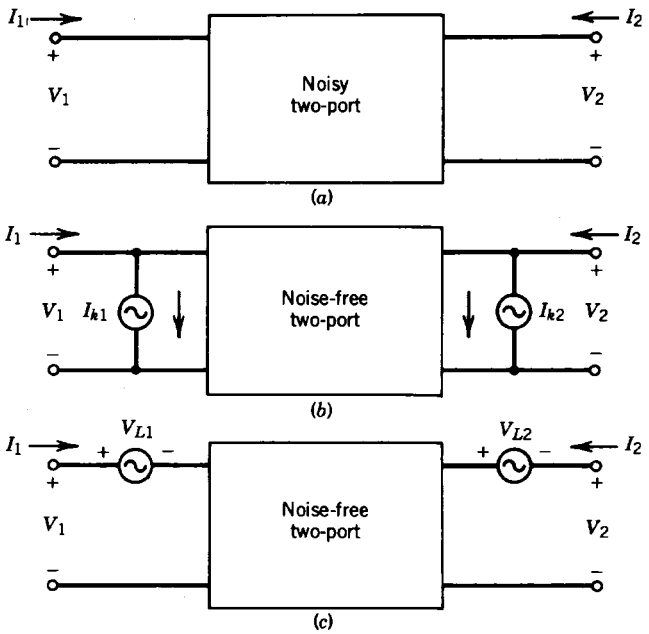

Figure 3-17 Noisy linear two-ports: (a) general form, (b) admittance form, and (c) impedance form.

$$I_1 = y_{11}V_1 + y_{12}V_2 + I_{K1}$$
$$I_2 = y_{21}V_1 + y_{22}V_2 + I_{K2} \tag{3-19}$$

$$V_1 = z_{11}I_1 + z_{12}I_2 + V_{L1}$$
$$V_2 = z_{21}I_1 + z_{22}I_2 + V_{L2} \tag{3-20}$$

where the external noise sources are I_{K1}, I_{K2}, V_{L1}, and V_{L2}.

Since we want to describe our noisy circuit in terms of the noise figure, the *ABCD*-matrix description will be more convenient since it refers both noise sources to the input of the two-port [5]. This representation is given below (note the change in direction of I_2):

$$V_1 = AV_2 + BI_2 + V_A$$
$$I_1 = CV_2 + DI_2 + I_A \tag{3-21}$$

where V_A and I_A are the external noise sources.

It is important to remember that all of these matrix representations are interrelated. For example, the noise sources for the *ABCD*-matrix description can be obtained from the *z*-matrix representation shown in Eq. (3-20). This transformation is

$$V_A = -\frac{I_{K2}}{y_{21}} = V_{L1} - \frac{V_{L2}z_{11}}{z_{21}} \tag{3-22}$$

$$I_A = I_{K1} - \frac{I_{K2}y_{11}}{y_{21}} = -\frac{V_{L2}}{z_{21}} \tag{3-23}$$

The *ABCD* representation is particularly useful because it allows us to define a noise temperature for the two-port referenced to the input. The two-port itself (shown in Figure 3-18) is assumed to be noise-free.

In the past, *z* and *y* parameters have been used, but in microwave applications it has become common to use *S*-parameter definitions. This is shown in Figure 3-19. The previous equations can be rewritten in their new form using *S*-parameters:

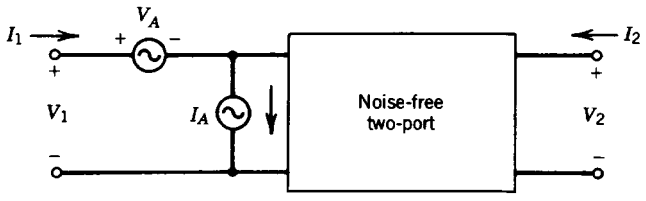

Figure 3-18 Chain-matrix form of linear noisy two-ports.

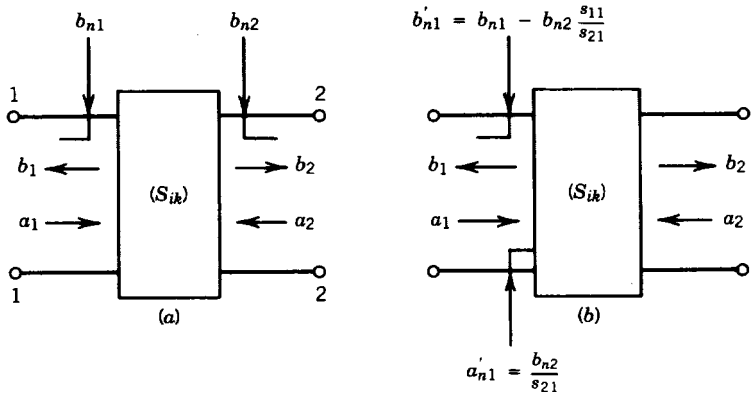

Figure 3-19 *S*-parameter form of linear noisy two-ports.

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \begin{bmatrix} b_{n1} \\ b_{n2} \end{bmatrix} \tag{3-24}$$

There are different physical origins for the various sources of noise. Typically, thermal noise is generated by resistances and loss in the circuit or transistor, whereas shot noise is generated by current flowing through semiconductor junctions and vacuum tubes. Since these many sources of noise are represented by only two noise sources at the device input, the two equivalent noise sources are often a complicated combination of the circuit internal noise sources. Often, some fraction of V_A and I_A is related to the same noise source. This means that V_A and I_A are not independent in general. Before we can use V_A and I_A to calculate the noise figure of the two-port, we must calculate the correlation between the V_A and I_A shown in Figure 3-18.

The noise source V_A represents all the device noise referred to the input when the generator impedance is zero; that is, when the input is short-circuited. The noise source I_A represents all the device noise referred to the input when the generator admittance is zero; that is, the input is open-circuited.

The correlation of these two noise sources considerably complicates analysis. By defining a correlation admittance, we can simplify the mathematics and get some physical intuition for the relationship between noise figure and generator admittance. Since some fraction of I_A will be correlated with V_A, we split I_A into correlated and uncorrelated parts as follows:

$$I_A = I_n + I_u \tag{3-25}$$

I_u is the part of I_A uncorrelated with V_A. Since I_n is correlated with V_A, we can say that I_n is proportional to V_A and the constant of proportionality is the correlation admittance:

$$I_n = Y_{\text{cor}} V_A \tag{3-26}$$

This leads us to

$$I_A = Y_{\text{cor}} V_A + I_u \tag{3-27}$$

The following derivation of noise figure will use the correlation admittance. Y_{cor} is not a physical component located somewhere in the circuit. Y_{cor} is a complex number derived by correlating the random variables I_A and V_A. To calculate Y_{cor}, we multiply each side of Eq. (3-27) by V_A^* and average the result. This gives

$$\overline{V_A^* I_A} = Y_{\text{cor}} \overline{V_A^2} \tag{3-28}$$

where the I_u term averaged to zero since it was uncorrelated with V_A. The correlation admittance is thus given by

$$Y_{\text{cor}} = \frac{\overline{V_A^* I_A}}{V_A^2} \tag{3-29}$$

Often, people use the term "correlation coefficient." This normalized quantity is defined as

$$c = \frac{\overline{V_A^* I_A}}{\sqrt{\overline{V_A^2} I_A^2}} = Y_{\text{cor}} \sqrt{\frac{\overline{V_A^2}}{I_A^2}} \tag{3-30}$$

Note that the dual of this admittance description is the impedance description. Thus, the impedance representation has the same equations as above with Y replaced by Z, I replaced by V, and V replaced by I.

V_A and I_A represent internal noise sources in the form of a voltage source acting in series with the input voltage and a source of current flowing in parallel with the input current. This representation conveniently leads to the four noise parameters needed to describe the noise performance of the two-port. Again using the Nyquist formula, the open-circuit voltage of a resistor at the temperature T is

$$\overline{V_A^2} = 4kTRB \tag{3-31}$$

This voltage is a mean-square fluctuation (or spectral density). It is the method used to calculate the noise identity. We could also define a noise equivalent resistance for a noise voltage as

$$R_n = \frac{\overline{V_A^2}}{4kTB} \tag{3-32}$$

The resistor R_n is not a physical resistor but can be used to simulate different portions of the noise equivalent circuit.

In a similar manner a mean-square current fluctuation can be represented in terms of an equivalent noise conductance G_n, which is defined by

$$G_n = \frac{\overline{I_A^2}}{4kTB} \tag{3-33}$$

and

$$G_u = \frac{\overline{I_u^2}}{4kTB} \tag{3-34}$$

for the case of the uncorrelated noise component. The input generator to the two-port has a similar contribution:

$$G_G = \frac{I_G^2}{4kTB} \tag{3-35}$$

with Y_G being the generator admittance and G_G being the real part. With the definition of F above, we can write

$$F = 1 + \left| \frac{I_A + Y_G V_A}{I_G} \right|^2 \tag{3-36}$$

The use of the voltage V_A and the current I_A has allowed us to combine all the effects of the internal noise sources.

We can use the previously defined [Eq. (3-29)] correlation admittance, $Y_{\text{cor}} = G_{\text{cor}} + jB_{\text{cor}}$, to simplify Eq. (3-36). First, we determine the total noise current:

$$\overline{I_A^2} = 4kT(|Y_{\text{cor}}|^2 R_n + G_u)B \tag{3-37}$$

where R_n and G_u are defined in Eqs. (3-32) and (3-34). The noise factor can now be determined:

$$F = 1 + \frac{G_u}{G_g} + \frac{R_n}{G_g}[(G_G + G_{\text{cor}})^2 + (B_G + B_{\text{cor}})^2] \tag{3-38}$$

$$F = 1 + \frac{R_u}{R_g} + \frac{G_n}{R_g}[(R_G + R_{\text{cor}})^2 + (X_G + X_{\text{cor}})^2] \tag{3-39}$$

The noise factor is a function of various elements, and the optimum impedance for the best noise figure can be determined by minimizing F with respect to generator reactance and resistance. This gives

$$R_{0n} = \sqrt{\frac{R_u}{G_n} + R_{\text{cor}}^2} \tag{3-40}$$

$$X_{0n} = -X_{\text{cor}} \tag{3-41}$$

and

$$F_{\min} = 1 + 2G_n R_{\text{cor}} + 2\sqrt{R_u G_n + (G_n R_{\text{cor}})^2} \tag{3-42}$$

(To distinguish between optimum noise and optimum power, we have introduced the convention 0*n* instead of the more familiar abbreviation *opt*.) At this point we see that the optimum condition for minimum noise figure is not a conjugate power match at the input port. We can explain this by recognizing that the noise source V_A and I_A represent all the

two-port noise, not just the thermal noise of the input port. We should observe that the optimum generator susceptance, $-X_{corr}$, will minimize the noise contribution of the two noise generators.

In rearranging for conversion to S parameters, we write

$$F = F_{\min} + \frac{g_n}{R_G}|Z_G - Z_{0n}|^2 \tag{3-43}$$

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-44}$$

From the definition of the reflection coefficient,

$$\Gamma_G = \frac{Y_0 - Y_G}{Y_0 + Y_G} \tag{3-45}$$

and with

$$g_G = \frac{G_G}{Y_0} \tag{3-46}$$

$$r_n = \frac{R_n}{Z_0} \tag{3-47}$$

the normalized equivalent noise resistance,

$$F = F_{\min} + \frac{4r_n|\Gamma_G - \Gamma_{0n}|^2}{g_G(1 - |\Gamma|^2)|1 + \Gamma_{0n}|^2} \tag{3-48}$$

$$r_n = (F_{50} - F_{\min})\frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-49}$$

$$\Gamma_{0n} = \frac{Z_{0n} - Z_0}{Z_{0n} + Z_0} \tag{3-50}$$

The noise performance of any linear two-port can now be determined if the values of the four noise parameters, $F_{\min}$, r_n (= $R_n/50$), and Γ_{0n} (magnitude and phase), are known.

Figure 3-20 shows the noise factor of a high-frequency transistor as a function of B_g for G_g = constant and as a function of G_g for $B_g = B_{opt}$.

Noise Figure of Cascaded Networks. In a system with many circuits connected in cascade (Figure 3-21), we must consider the contributions of the various circuits. In considering the equivalent noise resistor R_n in series with the input circuit,

$$F = \frac{R_G + R_n}{R_G} \tag{3-51}$$

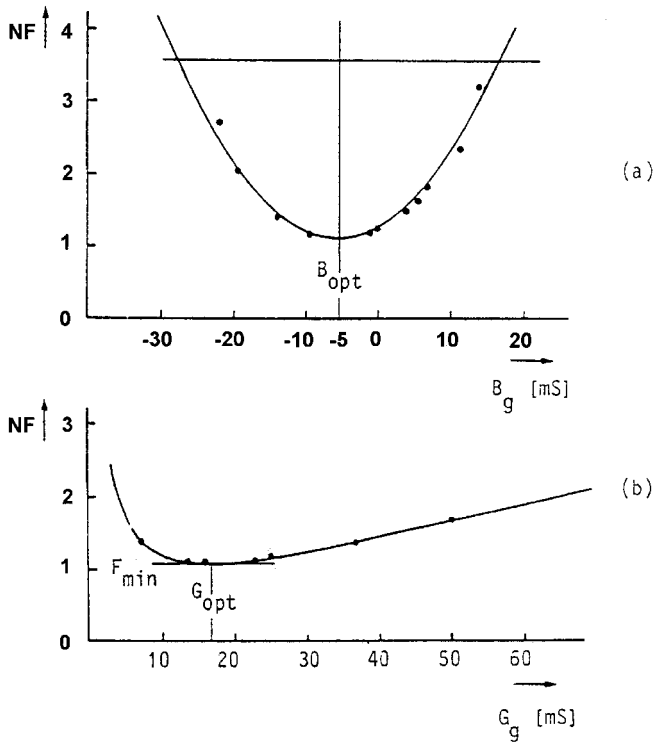

Figure 3-20 Noise factor in high-frequency BJTs for $f = 600$ MHz: (a) as a function of B_g for G_g = constant and (b) as a function of G_g for $B_g = B_{opt}$.

$$F = 1 + \frac{R_n}{R_G} \tag{3-52}$$

The excess noise added by the circuit is R_n/R_G.

In considering two cascaded circuits a and b, by definition the available noise at the output of b is

$$N_{ab} = F_{ab} G_{ab} kTB \tag{3-53}$$

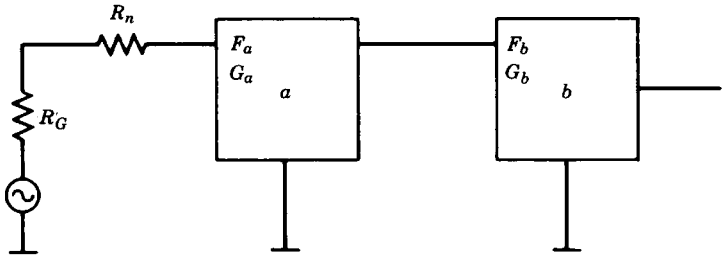

Figure 3-21 Cascaded noisy two-ports with the noise factors F_a and F_b and the gain figures G_a and G_b.

with B the equivalent noise bandwidth in which the noise is measured. The total available gain G is the product of the individual available gains, so

$$N_{ab} = F_{ab} G_a G_b kTB \tag{3-54}$$

The available noise from network a at the output of network b is

$$N_{a/b} = N_a G_b = F_a G_a G_b kTB \tag{3-55}$$

The available noise added by network b (its excess noise) is

$$N_{b/b} = (F_b - 1) G_b kTB \tag{3-56}$$

The total available noise N_{ab} is the sum of the available noise contributed by the two networks:

$$\begin{aligned} N_{ab} &= N_{a/b} + N_{b/b} = F_a G_a G_b kTB + (F_b - 1) G_b kTB \\ &= \left(F_a + \frac{F_b - 1}{G_a} \right) G_a G_b kTB \end{aligned} \tag{3-57}$$

$$F_{ab} = F_a + \frac{F_b - 1}{G_a} \tag{3-58}$$

For any number of circuits, this can be extended to

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \frac{F_4 - 1}{G_1 G_2 G_3} + \cdots \tag{3-59}$$

When considering a long chain of cascaded amplifiers, there will be a minimum noise figure achievable for this chain. This is a figure of merit and was proposed by Haus and Adler [6]. It is calculated by rearranging Eq. (3-59):

$$(F_{\text{tot}})_{\min} = (F_{\min} - 1) + \frac{F_{\min} - 1}{G_A} + \frac{F_{\min} - 1}{G_A^2} + \cdots + 1 \tag{3-60}$$

where $F_{\min}$ is the minimum noise figure for each stage and G_A is the available power gain of the identical stages. Using

$$\frac{1}{1 - X} = 1 + X + X^2 + \cdots \tag{3-61}$$

we find a quantity $(F_{\text{tot}} - 1)$, which is defined as the noise measure M. The minimum noise measure

$$(F_{\text{tot}})_{\min} - 1 = \frac{F_{\min} - 1}{1 - 1/G_A} = M_{\min} \tag{3-62}$$

refers to the noise of an infinite chain of optimally tuned, low-noise stages, so it represents a lower limit on the noise of an amplifier.

The minimum noise measure $M_{\min}$ is an invariant parameter and is not affected by feedback. It is somewhat similar to a gain–bandwidth product, in its use as a system invariant. The minimum noise measure is achieved when the amplifier is tuned for the available power gain and $\Gamma_G = \Gamma_{0n}$, given by Eq. (3-50).

Influence of External Parasitic Elements. Mounting an active two-port such as a transistor usually adds stray capacitance and lead inductance to the device, as shown in Figure 3-22. These external components consisting of transmission lines and parasitic reactances modify the noise parameters and the gain. Some researchers have published the results of these parasitic effects and have made manual computations or used some limited computer programs.

In a paper by Fukui [7], an attempt was made to determine the necessary equations, but the formulas are too involved even for pocket calculators. A more generic study by Iversen [8] is also very involved because of the various matrix manipulations and is more suitable for a computer. Besser's paper [9] in the *IEEE MTT-S* in 1975 and Vendelin's paper [10] in the same issue have shown for the first time some practical results using computers and even optimization methods, using an early version of COMPACT. The intention of these investigations was to find feedback that modifies the device noise and scattering parameters such that a noise match could also provide a low-input VSWR. It can be seen from these discussions that some feedback, besides resulting in some gain reduction, may improve the noise matching at the input for a limited frequency range.

A more recent paper by Suter [11] based on a report by Hartmann and Strutt [12] has given a simple transformation starting from the *S*-parameters and the noise parameters from common-source (or common-emitter) measurements. The noise parameters for the "packaged" device are calculated. This means that the parameters for the "new" device, including

where

$$S'_{11} = S'_{22} = \frac{Z_P}{2 + Z_P}$$

(*continued*)

Table 3-2 (*Continued*)

$$S'_{12} = S'_{21} = \frac{2}{2 + Z_P}$$

$$P = (1 - S'_{11})(1 + S'_{22}) + S'_{12}S'_{21}$$

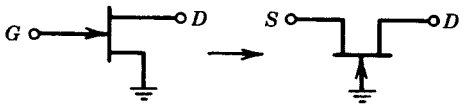
$$Q = (1 - S_{11})(1 + S_{22}) + S_{12}S_{21}$$

$$C_2 = (1 + S_{11})(1 + S_{22}) - S_{12}S_{21}$$

$$C'_2 = (1 + S'_{11})(1 + S'_{22}) - S'_{12}S'_{21}$$

$$[S]_{\text{DEVICE}} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}$$

Common Gate



$$[n] = \begin{bmatrix} n_{11} = \dfrac{2S_{21}}{-2S_{21} + C_4} & n_{12} = 0\ \Omega \\ n_{21} = \dfrac{1}{Z_0}\dfrac{C_3C_4 - 4S_{12}S_{21}}{V(-2S_{21} + C_4)}S & n_{22} = -1 \end{bmatrix}$$

where

$$V = (1 + S_{11})(1 + S_{22}) - S_{12}S_{21}$$

$$C_3 = (1 - S_{11})(1 + S_{22}) + S_{12}S_{21}$$

$$C_4 = (1 + S_{11})(1 - S_{22}) + S_{12}S_{21}$$

$$[S]_{\text{DEVICE}} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} = \text{common-source } S \text{ parameters}$$

the common-gate (or common-base) case, are calculated. The equations are device dependent. They are valid for any active two-port.

A transformation matrix, n, may be used to combine the noise sources of the various circuit configurations. The transformation matrix parameters are given in Table 3-2 for series feedback, shunt feedback, and the common-gate (base) case, which will be important for oscillator analysis. The transformation matrix gives the new noise parameters as follows:

$$R'_n = R_n|n_{11} + n_{12}Y_{\text{cor}}|^2 + G_n|n_{12}|^2 \tag{3-63}$$

$$G'_n = \frac{G_nR_n}{R'_n}|n_{11}n_{22} - n_{12}n_{21}|^2 \tag{3-64}$$

$$Y'_{\text{cor}} = \frac{R_n}{R'_n}(n_{21} + n_{22}Y_{\text{cor}})(n^*_{11} + n^*_{12}Y^*_{\text{cor}}) + \frac{G_n}{R'_n}n_{22}n^*_{12} \tag{3-65}$$

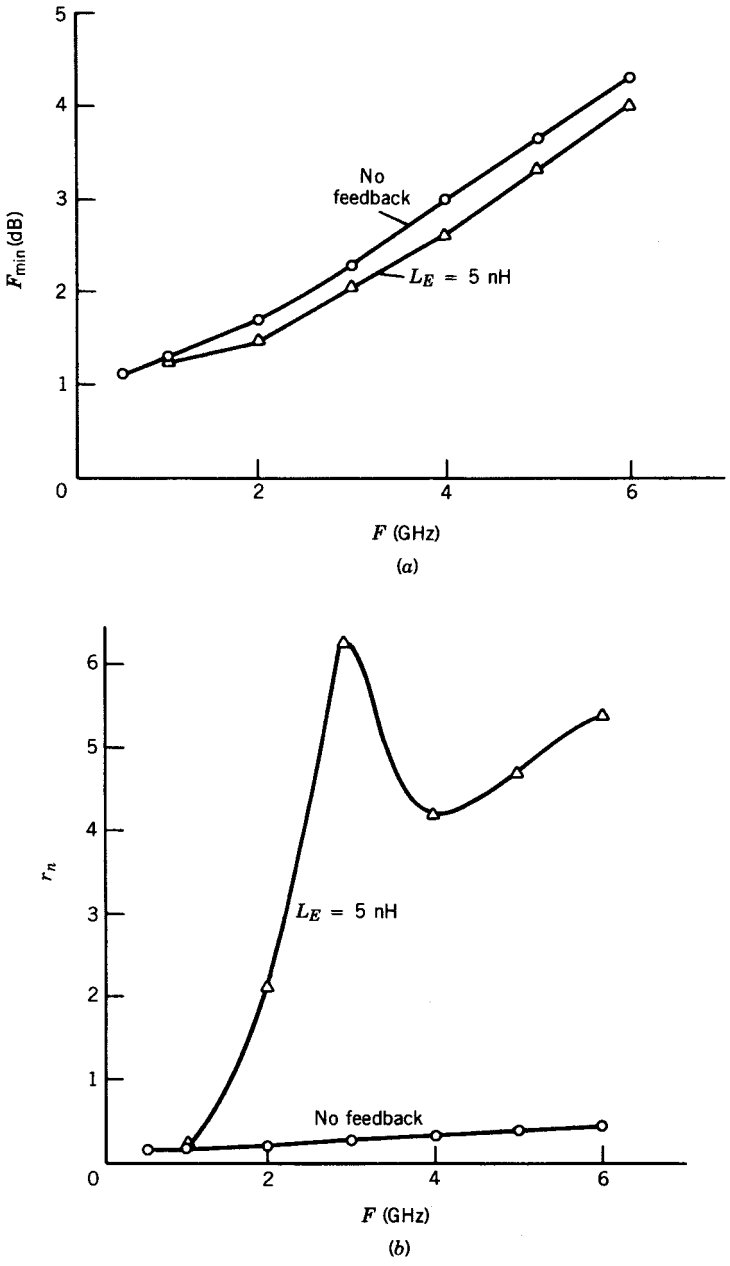


Figure 3-23 Noise parameters versus feedback for the AT-41435 silicon bipolar transistor: (a) F_{min} versus frequency and feedback; (b) r_n versus frequency and feedback; (c) Γ_{0n} versus frequency and feedback.

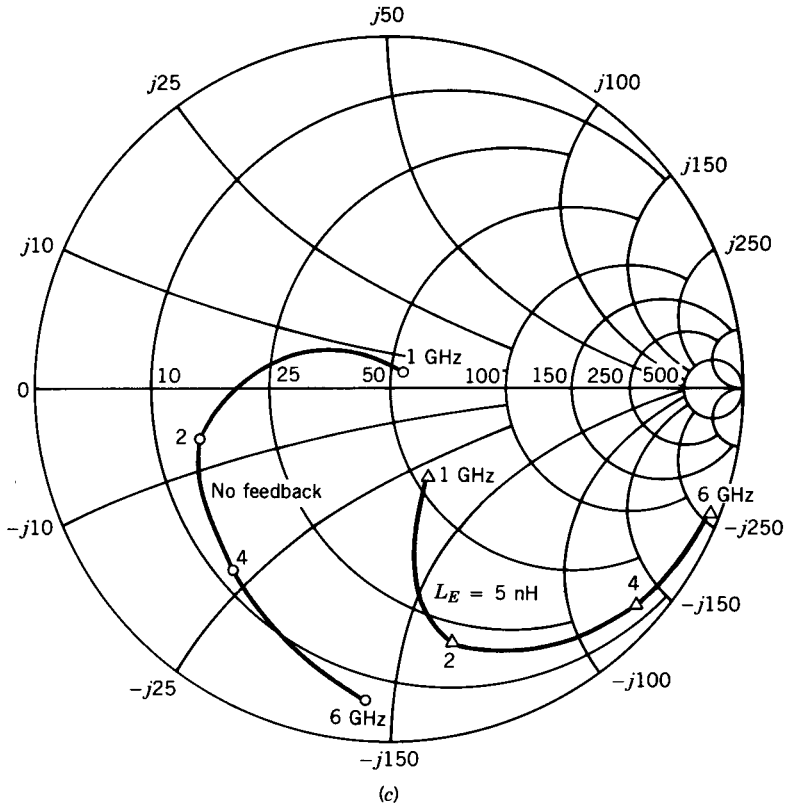

Figure 3-23 (*Continued*)

A final transformation to the more common noise-parameter format given by Eq. (3-44) is still needed [10]:

$$F_{\min} = 1 + 2R_n'(G_{\text{cor}}' + G_{0n}') \tag{3-66}$$

$$R_n = R_n' \tag{3-67}$$

$$G_{0n} = \sqrt{\frac{G_n'}{R_n'} + G_{\text{cor}}'^2} \tag{3-68}$$

$$B_{0n} = -B_{\text{cor}}' \tag{3-69}$$

Figure 3-23 shows the noise figure as a function of external feedback for a low-noise microwave bipolar transistor, the AT-41435.

Bias-Dependent Noise Parameters. Since we have elaborated on the effect of parasitics, it is now useful to point out that noise is also a strong function of bias point and frequency. Figure 3-24 shows the noise figure expressed in dB as a function of different dc currents and frequencies for a BFP420 BJT by Siemens. A change in the collector voltage will also affect the noise parameters, not quite as strongly as shown here, but still significantly. The reason

[b]$Z_S = Z_L = 50\ \Omega$.

for the turning point of the noise figure has to do with the fact that for lower currents the f_T cutoff frequency has not reached its peak yet, and therefore the noise increases. The increase of the noise at higher currents is due to the Schottky noise calculated from the equation

$$P_n = 2Iq \tag{3-70}$$

where P_n is the noise power, I is the saturation, collector, or drain current, and q is the charge of an electron (1.60×10^{-19} coulomb).

Table 3-3 shows the common-emitter noise parameters for the BFP420.

Noise Circles. From the section entitled "Influence of External Parasitic Elements," we see that the noise factor is a strong function of the generator admittance (or impedance) presented to the input terminals of the noisy two-port. Noise tuning is used to change the values of the input admittance to obtain the best noise performance. There is a range of values of input reflection coefficient over which the noise figure is constant. In plotting these points of constant noise figure, we obtain the so-called noise circles, which can be drawn on the Smith chart Γ_G plane [13]. Starting with the noise equation [see Eq. (3-44)] for a 50-Ω generator impedance, we find that

$$F_{50} = F_{\min} + 4r_n \frac{|\Gamma_{0n}|^2}{|1 + \Gamma_{0n}|^2} \tag{3-71}$$

We want to find the position of the reflection coefficient on the Smith chart, as in the case of the gain circles, for which F is constant. First we rearrange Eq. (3-67) to read

$$r_n = (F_{50} - F_{\min}) \frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-72}$$

By introducing

$$N_i = \frac{F_i - F_{\min}}{4r_n} |1 + \Gamma_{0n}|^2 \tag{3-73}$$

we can find an expression for a circle of constant noise figure as introduced by Rothe and Dahlke [4] (see also Fukui [13]). The center for the noise circle is

$$C_i = \frac{|\Gamma_{0n}|}{1 + N_i} \tag{3-74}$$

and the radius is

$$r_i = \frac{\sqrt{N_i^2 + N_i(1 - |\Gamma_{0n}|^2)}}{1 + N_i} \tag{3-75}$$

with the definition of N used previously. However, if we consider only the minimum noise figure for a given device, we will not obtain the minimum noise figure for the multistage amplifier system. This was explained when the noise measure was introduced. (See Figure 3-25.) Therefore, a better way to design the amplifier would be to use circles at constant noise measure instead of circles of constant noise figure. This was recently done by Poole

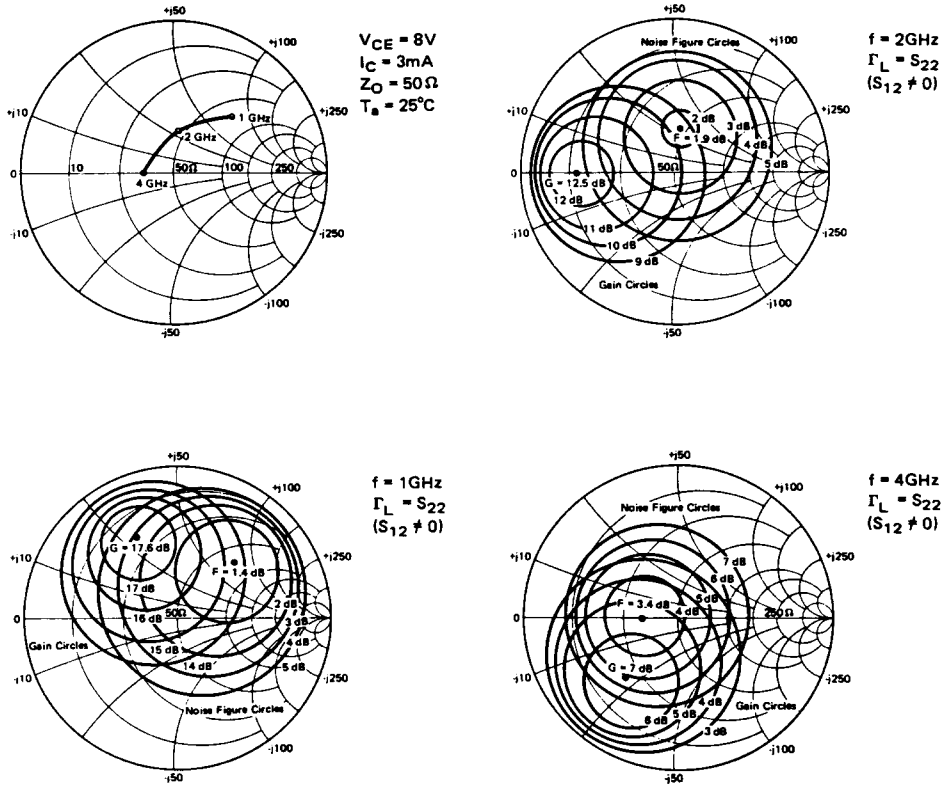

Figure 3-25 Typical noise figure circles and gain circles.

and Paul [14]. They derived the expressions for the noise measure circles as a function of S parameters, noise parameters, and Γ_G, using

$$G_A = \frac{|S_{21}|^2(1 - |\Gamma_G|^2)}{(1 - |S_{22}|^2) + |\Gamma_G|^2 (|S_{11}|^2 - |\Delta|^2) - 2\,\mathrm{Re}(\Gamma_G C_1)} \tag{3-76}$$

where

$$C_1 = S_{11} - S_{22}^* \Delta$$

$$\Delta = S_{11}S_{22} - S_{12}S_{11}$$

In terms of the generator reflection coefficient, the noise measure can be expressed as

$$M = [(F_{\min} - 1)(1 - |\Gamma_G|^2)|S_{21}|^2|1 + \Gamma_{0n}|^2 + 4r_n|S_{21}|^2|\Gamma_G - \Gamma_{0n}|^2]$$

$$\times \left\{|1 + \Gamma_{0n}|^2[|S_{21}|^2(1 - |\Gamma_G|^2) - (1 - |S_{22}|^2) - |\Gamma_G|^2(|S_{11}|^2 - |\Delta|^2) + 2\,\mathrm{Re}(\Gamma_G C_1)]\right\}^{-1} \tag{3-77}$$

Equation (3-77) can be shown to represent circles in the source reflection coefficient plane described by the following:

$$|\Gamma_G|^2 + |\Gamma_m|^2 - \Gamma_G\Gamma_m^* - \Gamma_G^*\Gamma_m = r_m^2 \tag{3-78}$$

The centers and radii of the constant-noise-measure circles are given by

$$C_m = \frac{M|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-79}$$

$$r_m = \frac{\sqrt{M^2M_a + MM_b + M_c}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-80}$$

where

$$P = |S_{21}|^2 + |S_{11}|^2 - |\Delta|^2$$

$$Q = |S_{21}|^2 + |S_{22}|^2 - 1$$

$$W = |1 + \Gamma_{0n}|^2(F_{\min} - 1)$$

$$M_a = |1 + \Gamma_{0n}|^4(PQ + |C_1|^2)$$

$$M_b = |1 + \Gamma_{0n}|^2|S_{21}|^2[8r_n\,\mathrm{Re}(\Gamma_{0n}C_1)$$

$$- (4r_n|\Gamma_{0n}|^2 + W)P - (W - 4r_n)Q]$$

$$M_c = |S_{21}|^4[W - 4r_n(1 - |\Gamma_{0n}|^2)]$$

The value of the minimum noise measure can be found by considering the noise measure circle of zero radius; that is, set r_m equal to zero in Eq. (3-80). This results in

$$M_{\min} = \frac{-M_b \pm \sqrt{M_b^2 - 4M_a M_c}}{2M_a} \tag{3-81}$$

Equation (3-81) yields the same value of $M_{\min}$ as would have been obtained by using the immittance parameter equation given by Fukui [13] and can, therefore, be considered as the reflection coefficient plane analog of Fukui's expression. The elimination of the need for the parameter R_{eg}, however, results in a considerable simplification as compared with the earlier approach [13].

The value of the minimum noise measure is taken as the smallest nonnegative value of $M_{\min}$ given by Eq. (3-81). The source reflection coefficient that results in the minimum noise measure can now be obtained by employing Eq. (3-79):

$$\Gamma_{0m} = \frac{M_{\min}|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M_{\min}|1 + \Gamma_{0n}|^2 P + |S_{21}|^2\,(4r_n - W)} \tag{3-82}$$

The output reflection coefficient of the device, when Γ_{0m} is presented to the input port, is given by

$$S'_{22} = \frac{S_{22} - \Delta\Gamma_{0m}}{1 - S_{11}\Gamma_{0m}} \tag{3-83}$$

Noise Correlation in Linear Two-Ports Using Correlation Matrices. In the introduction to two-port noise theory, it was indicated that noise correlation matrices form a general technique for calculating noise in n-port networks. Haus and Adler [6] have described the theory behind this technique. In 1976, Hillbrand and Russer [15] published equations and transformations that aid in supplying this method to two-port CAD.

This method is useful because it forms a base from which we can rigorously calculate the noise of linear two-ports combined in arbitrary ways. For many representations, the method of combining the noise parameters is as simple as that for combining the circuit element matrices. In addition, noise correlation matrices can be used to calculate the noise in linear frequency conversion circuits. The following is an introduction to this subject.

A linear, noisy two-port can be modeled as a noise-free two-port with two additional noise sources. These noise sources must be chosen so that they add directly to the resulting vector of the representation, as shown in Eqs. (3-84) and (3-85) and Figure 3-17:

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-84}$$

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \tag{3-85}$$

where the i and v vectors indicate noise sources for the y and z representations, respectively. This two-port example can be extended to n-ports in a straightforward, obvious way.

Since the noise vector for any representation is a random variable, it is much more convenient to work with the noise correlation matrix. The correlation matrix gives us deterministic numbers with which to calculate. The correlation matrix is formed by taking the mean value of the outer product of the noise vector. This is equivalent to multiplying the noise vector by its adjoint (complex conjugate transpose) and averaging the result:

$$\langle \bar{i}\ \bar{i}^{+} \rangle = \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] = \begin{bmatrix} \langle i_1 i_1^* \rangle & \langle i_1 i_2^* \rangle \\ \langle i_1^* i_2 \rangle & \langle i_2 i_2^* \rangle \end{bmatrix} + [C_y] \tag{3-86}$$

where the angular brackets denote the average value.

Note that the diagonal terms are the "power" spectrum of each noise source and the off-diagonal terms are complex conjugates of each other and represent the "cross-power" spectra of the noise sources. "Power" is used because these magnitude-squared quantities are proportional to power.

To use these correlation matrices in circuit analysis, we must know how to combine them and how to convert them between various representations. An example using y matrices will illustrate the method for combining two-ports and their correlation matrices. Given two matrices y and y', when we parallel them we have the same port voltages, and the terminal currents add (Figure 3-26):

$$\begin{aligned} I_1 &= y_{11}V_1 + y_{12}V_2 + y'_{11}V_1 + y'_{12}V_2 + i_1 + i'_1 \\ I_2 &= y_{21}V_1 + y_{22}V_2 + y'_{21}V_1 + y'_{22}V_2 + i_2 + i'_2 \end{aligned} \tag{3-87}$$

or

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} + y'_{11} & y_{12} + y'_{12} \\ y_{21} + y'_{21} & y_{22} + y'_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 + i'_1 \\ i_2 + i'_2 \end{bmatrix} \tag{3-88}$$

Here we can see that the noise current vectors add just as the y parameters add. Converting the new noise vector to a correlation matrix yields

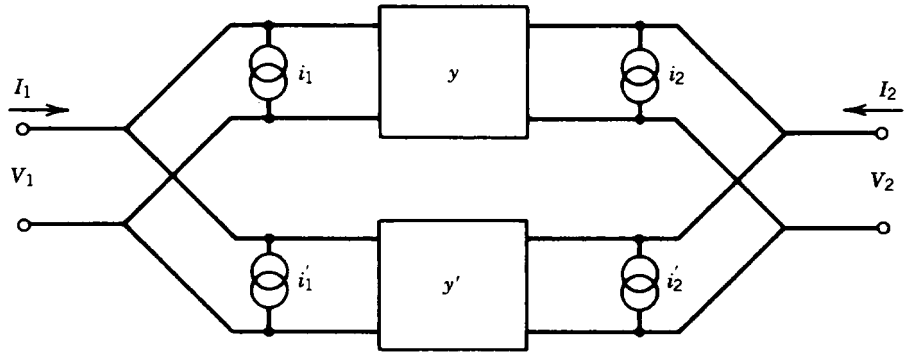

Figure 3-26 Parallel combination of two-ports using y parameters.

$$\langle \bar{i}_{\text{new}} \bar{i}^{+}_{\text{new}} \rangle = \left\langle \begin{bmatrix} i_1 + i_1' \\ i_2 + i_2' \end{bmatrix} [i_1^* + i_1'^* \quad i_2 i_2'^*] \right\rangle \tag{3-89}$$

$$= \begin{bmatrix} \langle i_1 i_1^* \rangle + \langle i_1' i_1'^* \rangle & \langle i_1 i_2^* \rangle + \langle i_1' i_2'^* \rangle \\ \langle i_2 i_1^* \rangle + \langle i_2' i_1'^* \rangle & \langle i_2 i_2^* \rangle + \langle i_2' i_2'^* \rangle \end{bmatrix} \tag{3-90}$$

The noise sources from different two-ports must be uncorrelated, so there are no cross products of different two-ports. By inspection, Eq. (3-90) is just the addition of the correlation matrices for the individual two-ports, so

$$[C_{y\text{new}}] = [C_y] + [C_y'] \tag{3-91}$$

The same holds true for g, h, and z parameters, but $ABCD$ parameters have the more complicated form shown below. If

$$[A_{\text{new}}] = [A][A'] \tag{3-92}$$

then

$$[C_{A\text{new}}] = \{C_A] + [A]\,[C_{A'}]\,[A]^{+} \tag{3-93}$$

The transformation of one representation to another is best illustrated by an example. Let us transform the correlation matrix for a Y representation to a Z representation. Starting with

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = [Y] \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-94}$$

we can move the noise vector to the left side and invert y:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 - i_1 \\ I_2 - i_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Y^{-1}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-95}$$

Table 3-4 π Noise matrix $T_{\alpha\beta}$ transformation

		Original Form (α Form)					
		Y		Z		A	
Resulting Form (β Form)	Y	1	0	y_{11}	y_{12}	$-y_{11}$	1
		0	1	y_{21}	y_{22}	$-y_{21}$	0
	Z	z_{11}	z_{12}	1	0	1	$-z_{11}$
		z_{21}	z_{22}	0	1	0	$-z_{21}$
	A	0	A_{12}	1	$-A_{11}$	1	0
		1	A_{22}	0	$-A_{21}$	0	1

Since $(Y)^{-1} = (Z)$, we have

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Z] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-96}$$

so

$$= [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} = [T_{yz}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-97}$$

where the signs of i_1 and i_2 are superfluous since they will cancel when the correlation matrix is formed. Here the transformation of the Y noise current vector to the Z noise voltage vector is done simply by multiplying by (Z). Other transformations are shown in Table 3-4.

To obtain the noise correlation matrix, we again form the mean of the outer product:

$$\langle vv^+ \rangle = \begin{bmatrix} \langle v_1 v_1^* \rangle & \langle v_1 v_2^* \rangle \\ \rangle v_1^* v_2 \rangle & \langle v_2 v_2^* \rangle \end{bmatrix} = [Z] \left\langle \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] \right\rangle [Z]^+ \tag{3-98}$$

or

$$[C_z] = [Z]\,[C_y]\,[Z]^+ \tag{3-99}$$

where

$$v^+ = [i_1^* \quad i_2^*]\,[Z]^+ \tag{3-100}$$

This is called a congruence transformation. The key to all of these derivations is the construction of a correlation matrix from the noise vector, as shown in Eq. (3-90).

These correlation matrices may easily be derived from the circuit matrices of passive circuits with only thermal noise sources. For example,

$$[C_z] = 2kT\Delta f\,\mathrm{Re}([Z]) \tag{3-101}$$

and

$$[C_y] = 2kT\Delta f\,\mathrm{Re}([Y]) \tag{3-102}$$

The $2kT$ factor comes from the double-sided spectrum of thermal noise. The correlation matrix from the $ABCD$ matrix may be related to the noise figure, as shown by Hillbrand and Russer [15]. We have

$$F = 1 + \frac{\overline{Y}[C_a]\overline{Y}^+}{2kT\,\mathrm{Re}(Y_G)} \tag{3-103}$$

where

$$\overline{Y} = \begin{bmatrix} Y_G \\ 1 \end{bmatrix}$$

Expressing the noise factor in terms of the correlation matrix, we obtain a complete formula:

$$F = 1 + \frac{C_{22}^{A}(f) + 2\,\mathrm{Re}\{Y_g(f)\,C_{12}^{A}(f)\} + |Y_g(f)|^2\,C_{11}^{A}(f)}{2kT_0\,\mathrm{Re}\{Y_g(f)\}} \tag{3-104}$$

Once we transform this in the Y parameter form, we obtain the following equation:

$$F(f) = F_{\min}(f) + \frac{R_n(f)|Y_{\mathrm{opt}}(f) - Y_g(f)|^2}{\mathrm{Re}\{Y_g(f)\}} \tag{3-105}$$

It should be noted that all these values are frequency dependent, as expressed in this equation.

The *ABCD* correlation matrix can be written in terms of the noise figure parameters as (double-sided spectrum)

$$[C_a] = 2kT\begin{bmatrix} R_n & \dfrac{F_0 - 1}{2} - R_n Y_{0n}^{*} \\ \dfrac{F_0 - 1}{2} - R_n Y_{0n} & R_n|Y_{0n}|^2 \end{bmatrix} \tag{3-106}$$

The noise correlation matrix method forms an easy and rigorous technique for handling noise in networks. This technique allows us to calculate the total noise for complicated networks by combining the noise matrices of subcircuits. It should be remembered that although noise correlation matrices apply to n-port networks, noise figure calculations apply only to pairs of ports. The parameters of the C_a matrix can be used to give the noise parameters:

$$Y_{0n} = \sqrt{\frac{C_{ii*}}{C_{uu*}} - \left[\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right)\right]^2} + j\,\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right) \tag{3-107}$$

$$F_0 = 1 + \frac{C_{ui*} + C_{uu*}Y_{0n}^{*}}{kT} \tag{3-108}$$

$$R_u = C_{uu*} \tag{3-109}$$

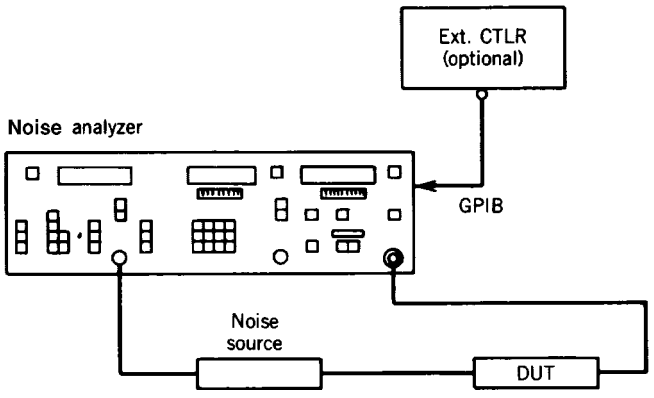

Figure 3-27 Noise figure measurement.

Noise Figure Test Equipment. Figure 3-27 shows the block diagram of a noise test setup. It includes the noise source and the other components. The metering unit has a special detector that is linear and over a certain dynamic range measures linear power. The tunable receiver covers a wide frequency range (e.g., 10–1800 MHz) and controls the noise source. The receiver is a double-conversion superheterodyne configuration with sufficient image rejection to avoid double-sideband noise measurements that would give the wrong results.

These receivers are microprocessor controlled and the measurement is a two-step procedure. The first is a calibration step that measures the noise figure of the receiver system and a reference power level. Then the device under test (DUT) is inserted and the system noise figure and total output power are measured. The noise factor is calculated by

$$F_1 = F_{\text{system}} - \frac{F_2 - 1}{G_1} \tag{3-110}$$

and the gain is given by the change in output power from the reference level [16]. The noise of the system is calculated by measuring the total noise power with the noise source on and off. With the excess noise ratio (ENR) known [16],

$$F_{\text{system}} = \frac{\text{ENR}}{Y - 1} \tag{3-111}$$

The noise bandwidth is usually set by the bandwidth of the receiver, which is assumed to be constant over the linear range. The ENR of the noise source is given by

$$\text{ENR} = \frac{T_{\text{hot}}}{T_{\text{cold}}} - 1 \tag{3-112}$$

where T_{cold} is usually room temperature (290 K). This ENR number is about 15 dB for noise sources with a 15-dB pad and 5 dB for noise sources with a 25-dB pad. Since both gain and noise were stored in the initial calibration, a noise/gain sweep can be performed.

For frequencies above 1800 MHz, we can extend the range with the help of the external signal generators, as shown in Figure 3-28. As shown, a filter ahead of the external mixer reduces the noise energy in the image band. If the DUT has a very broad frequency range

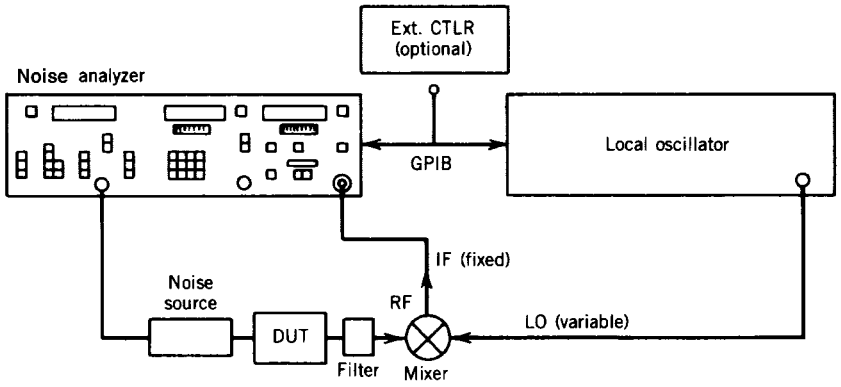

Figure 3-28 Single-sideband (SSB) noise figure measurements using an external mixer.

and has flat gain and noise over that range, a double-sideband (DSB) measurement is possible, with the image-rejection filter removed. However, a single-sideband (SSB) measurement is always more accurate [17].

How To Determine the Noise Parameters. The noise figure of a linear two-port network as a function of source admittance may be represented by

$$F = F_{\min} + \frac{R_n}{G_G}\left[(G_{0n} - G_G)^2 + (B_{0n} - B_G)^2\right] \tag{3-113}$$

where $G_G + jB_G$ = generator admittance presented to the input of the two-port
$G_{0n} + jB_{0n}$ = generator admittance at which optimum noise figure occurs
R_n = empirical constant relating sensitivity of the noise figure to generator admittance, with dimensions of resistance

It may be noted that for an arbitrary noise figure measurement with a known generator admittance, Eq. (3-113) has four unknowns—$F_{\min}$, R_n, G_{0n}, and B_{0n}. By choosing four known values of generator admittance, a set of four linear equations is formed and solutions of the four unknowns can be found [18, 19]. Eq. (3-113) may be transformed to

$$F = F_{\min} + \frac{R_n|Y_{0n}|^2}{G_G} - 2R_nG_{0n} + \frac{R_n|Y_G|^2}{G_G} - 2R_nB_{0n}\frac{B_G}{G_G} \tag{3-114}$$

or

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-115}$$

Let

$$X_1 = F_{\min} - 2R_nG_{0n}$$

$$X_2 = R_n|Y_{0n}|^2$$

$$X_3 = R_n$$

$$X_4 = R_nB_{0n}$$

Then the generalized equation may be written

$$F_i = X_1 + \frac{1}{G_{si}}X_2 + \frac{|Y_{si}|^2}{G_{si}}X_3 - 2\frac{G_{si}}{B_{si}}X_4 \tag{3-116}$$

or, in matrix form,

$$[F] = [A]\,[X] \tag{3-117}$$

and the solution becomes

$$[X] = [A]^{-1}\,[F] \tag{3-118}$$

These parameters completely characterize the noise behavior of the linear two-port network. Direct measurement of these noise parameters by this method would be possible only if the receiver on the output of the two-port were noiseless and insensitive to its input admittance. In actual practice, the receiver itself behaves as a noisy two-port network and can be characterized in the same manner. What is actually being measured is the system noise figure of the two-port and the receiver. Thus, it becomes apparent that to do a complete two-port noise characterization, the gain of the two-port must be measured [20]. In addition, any losses in the input-matching networks must be carefully accounted for, because they add directly to the measured noise figure reading [21].

3-1-4 Linearity

Consistent with the elaborate discussion of linearity questions above, here is a quick refresher on what must be considered in amplifiers.

Dynamic Range, Compression, and IMD. An amplifier's dynamic range is related to the minimum discernible signal and the 1-dB compression point according to the equation

$$DR_n = \frac{(n-1)(IP_{n(\text{in})} - MDS)}{n} \tag{3-119}$$

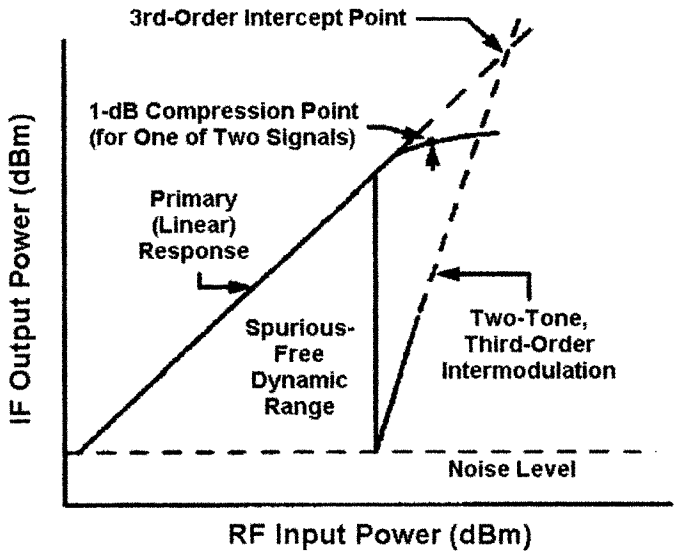

Figure 3-29 Amplifier linearity evaluation, including compression and two-tone IMD dynamic range. $P_{-1\text{dB}}$ for a single-tone cannot be read directly from this graph because the values shown are the result of two equal-power tones.

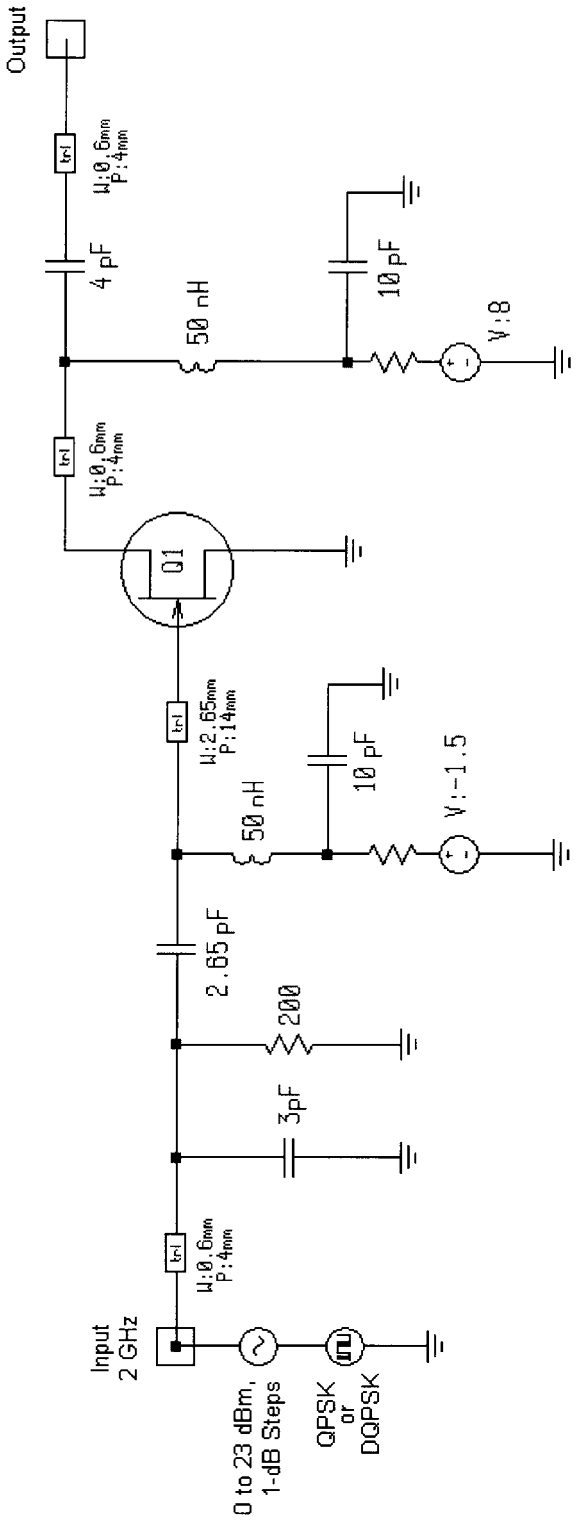

Figure 3-30 The power amplifier schematic.

where DR is the dynamic range in decibels, n is the order, $IP_{(in)}$ is the input intercept power in dBm, and MDS is the minimum detectable signal power in dBm. Once the 1-dB compression point is known, it is a fair assumption that the third-order intercept point, expressed in dBm, is 10 dB above this.

The intermodulation distortion gives the quality of an amplifier to withstand multiple signals without generating large intermodulation products or when using amplitude-modulated signals (cross-modulation). Figure 3-29 provides a quick reminder of IMD issues.

In some amplifiers, we would like to have control over the gain. While the better way to control gain while obtaining high linearity is a PIN-diode attenuator, special AGC circuits have become part of the amplifiers. Figure 3-48 shows a circuit of the SL610, made by Plessey, which has an AGC input provision. The noise figure of the PIN-diode attenuator is essentially equal to its attenuation. The AGC in multistage amplifiers is distributed over several stages and there is a lesser correlation between noise and AGC than in purely passive attenuators.

Special Case of Linearity Requirements for Digital Modulation. For cellular telephone systems we use digital modulation formats, such as QPSK and π/4-DQPSK, that combine phase and amplitude modulation. Amplifiers handling such signals must be carefully characterized and designed if adequate amplitude and phase linearity are to be maintained.

Examples of Power Amplifiers: Looking into the Effects of Distortion. This example presents modulation analysis using QPSK in a 2-GHz power amplifier (Figure 3-30). The simple amplifier was designed using the electronic Smith Tool of Serenade to determine the matching network for a narrowband design. The example demonstrates setup of modulation analysis and available results.

Siemens among others provides integrated amplifiers based on the concept depicted in Figure 3-30, the most popular ones being the CGY96 and CGY94. For the purpose of measurements, these amplifiers were actually put on a breadboard. Figure 3-31 shows the big brother, the CGY96. It is a GaAs MMIC intended as a power amplifier for GSM Class 4 phones with 3.2 W (35 dBm) at 3.5 V at an overall power added efficiency of 50%. Table 3-5 shows its electrical characteristics.

For the purpose of our experiments, we considered the CGY94 because it requires less external peripheral circuits. Table 3-6 shows its electrical characteristics. For those of us interested in seeing part of the internal circuit, Figure 3-32 shows the chip. This two-stage amplifier uses an interesting internal feedback scheme. Its schematic is shown in Figure 3-33.

For the purpose of looking at the waveforms, we will continue with the single-stage amplifier (Figure 3-30) and then compare the measured versus predicted performance of this CGY94-based amplifier.

A modulation source is connected to the RF source at the input port of the amplifier. The RF source specifies the carrier power (or voltage or current) and the modulation source specifies the modulation format and properties of the modulated signal.

A brief review of the modulation source used in this example indicates the following properties:

Property	Value	Description
NB	128	Number of bits
BR	1.2288E6	Bit rate
N	8	Number of samples per bit
BW1	590.E3	One-sided bandwidth of the main channel in the PIB or P1IB calculation
FS1	740.E3	Start baseband frequency of the fist adjacent channel
BW2	590.E3	One-sided bandwidth of the main channel in the P2IB calculation
FS2	1990.E3	Start baseband frequency of the second adjacent channel
BW3	590.E3	One-sided bandwidth of the main channel in the P3IB calculation
FS3	3240.E3	Start baseband frequency of the third adjacent channel
M	4	Order of the signal space; M = 4 is QPSK
DLY	0.0	Fractional bit delay
IASC	1.0	I channel amplitude scale; multiplier for the I waveform to model amplitude imbalance
QASC	1.0	Q channel amplitude scale; multiplier for the Q waveform to model amplitude imbalance
LPF	3	Baseband low-pass filter; 3 = root-raised cosine filter
LPFC	665.E3	–3 dB cutoff frequency of LPF
LPFN	3	Number of resonators if LPF = 1
LPFR	0.35	Roll-off factor if LPF = 3 or LPF = 4
FILE	N/A	File name of user-defined modulated signal file

The modulation source is a QPSK stream with a bit rate of 1.2288 Mbps. A total of 128 bits will be analyzed, and each bit is sampled eight times to construct an accurate analog waveform. The BW and FS parameters are defined here to specify the main (in-band) channel and adjacent channel for ACPR calculations. Imbalance of the I and Q amplitudes and phases can be described by the IASC, QASC, and DLY parameters, if desired. The modulation signal

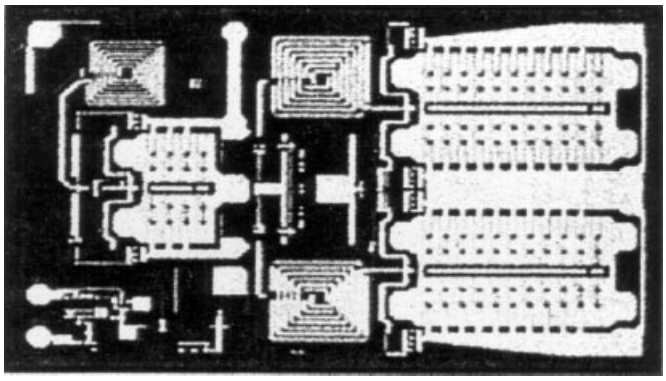

Figure 3-32 The CGY94 amplifier chip.

is often filtered, and several types of filters are available. Here a root-raised cosine filter is used with a cutoff frequency of 665 kHz and a roll-off factor of 0.35.

Analysis. Figure 3-34 shows the compression characteristics of the amplifier as the available RF source power (a sinusoid) is swept. Note that P_{-1dB} is 11.5 dBm referred to the input and 28.5 dBm referred to the output. We will look at modulation characteristics in the linear region of operation at a source power of 0 dBm, and the nonlinear region at a source power of 20 dBm.

Next, we will view the voltage across the transistor to examine its behavior under compression. Figure 3-35 shows the drain–source voltage of the FET as the source power is swept. It is clear from this graph that clipping due to pinchoff and forward-gate conduction

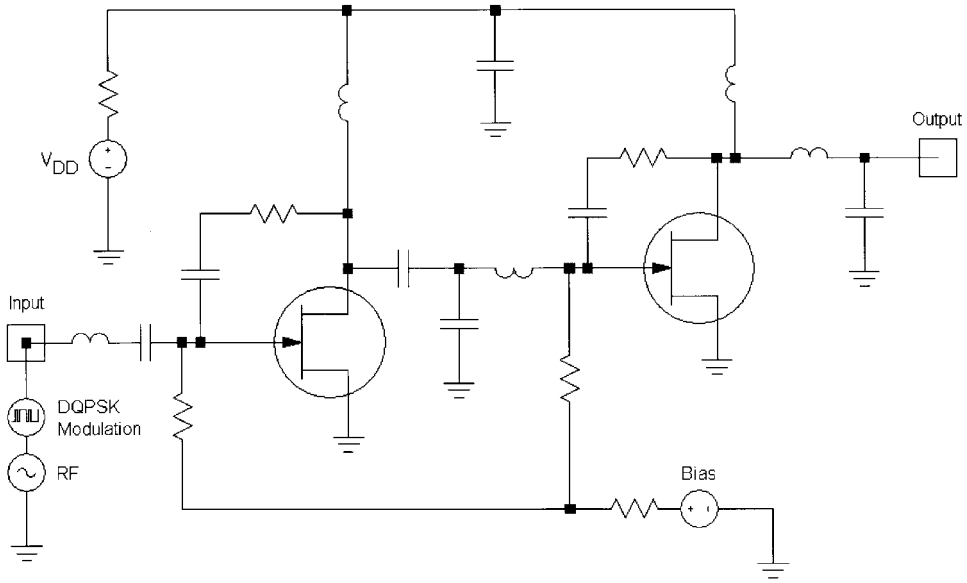

Figure 3-33 Schematic of the CGY94 GaAs MMIC power amplifier.

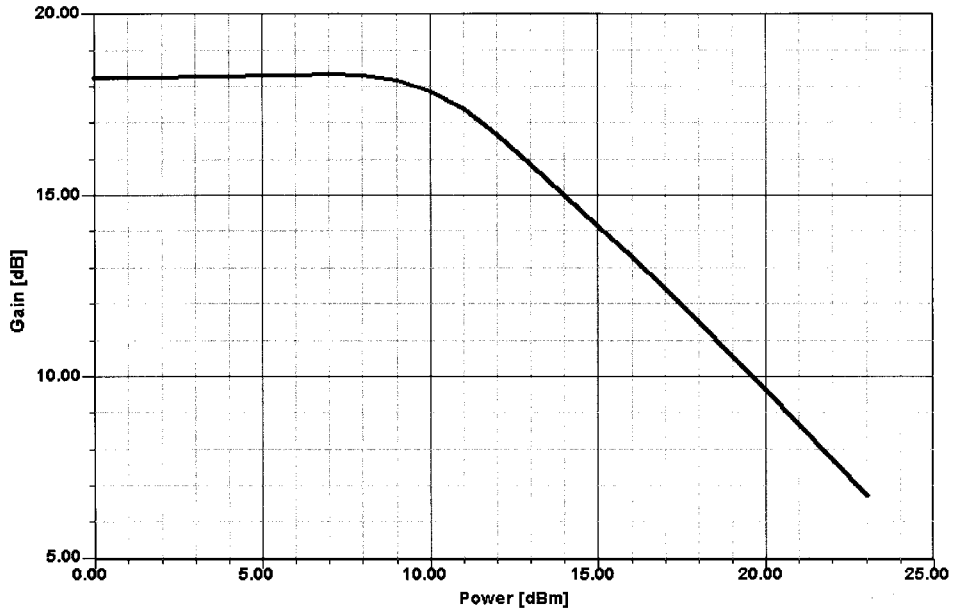

Figure 3-34 Single-tone RF power sweep analysis of the FET amplifier.

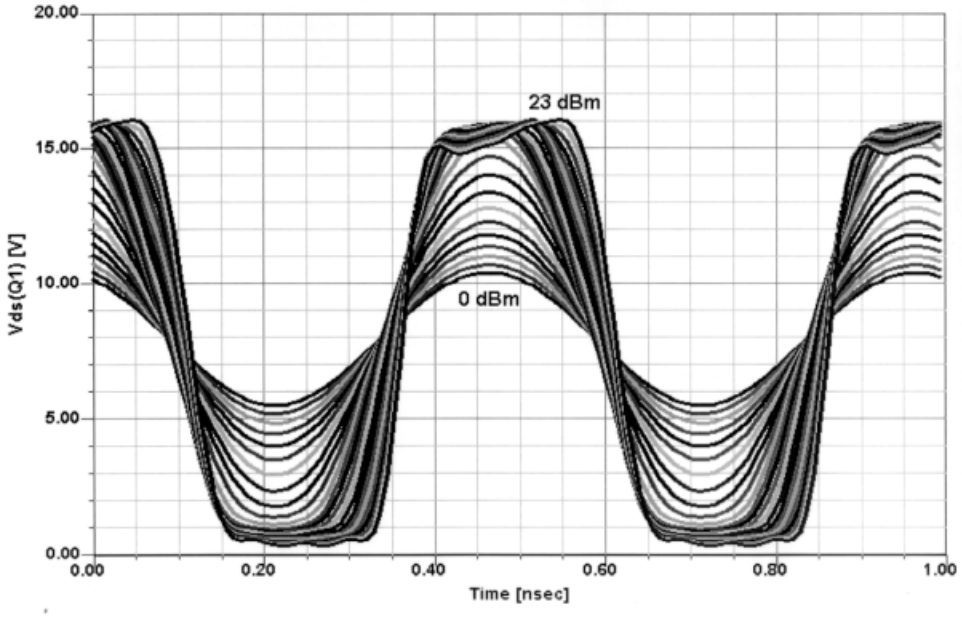

Figure 3-35 V_{DS} of the FET versus RF source power.

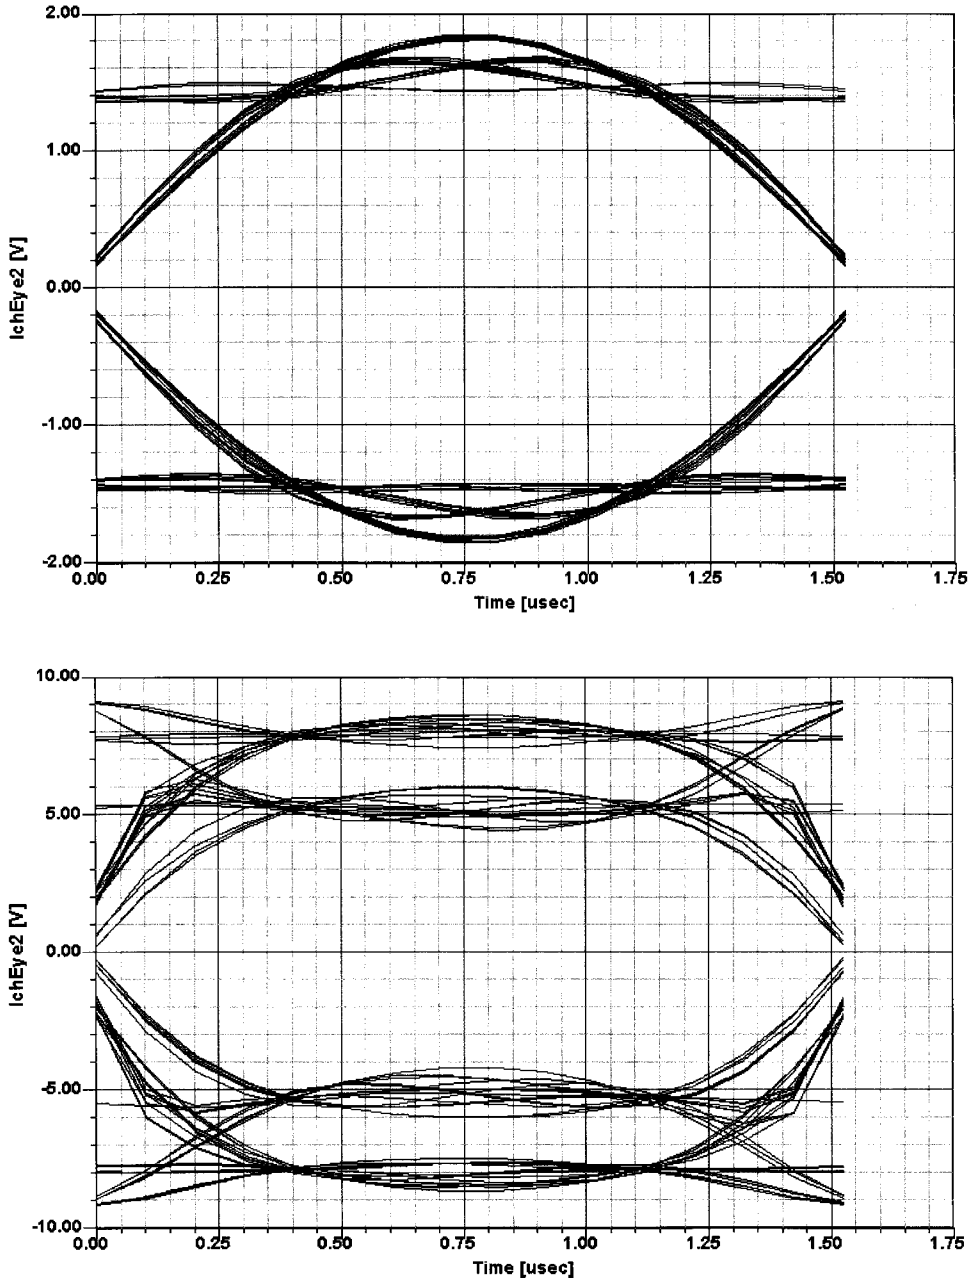

Figure 3-36 Eye diagrams of the I channel for source powers of (a) 0 dBm and (b) 20 dBm.

is limiting the performance of the device. A phase shift of the voltage waveform as power is increased is also apparent. The combination of the power compression and phase shift, or AM to PM conversion, will be used in the modulation analysis to determine the overall distortion of the modulated signal.

The output available from modulation analysis includes:

- I and Q channel waveforms
- Eye and constellation diagrams
- Spectral plots
- ACPR, in-band, and adjacent power

Figure 3-36 shows the eye diagrams for the 128-bit QPSK signal at two RF source powers, 0 and 20 dBm. Operating linearly at 0 dBm input, the amplifier doesn't distort the eye and it remains wide open. Note that in this example the filter bandwidth doesn't produce any intersymbol interference, as evidenced by the open eye. At an input power of 20 dBm, the amplifier compresses the signal, and distortion in the eye is evident.

We can also view the modulation spectrum at these two power levels to investigate the intermodulation distortion and spectral regrowth that takes place. Figure 3-37 shows the spectral plots. The lower trace corresponds to 0 dBm source power and shows almost no regrowth, while the upper trace at 20 dBm source power shows considerable regrowth.

The uncorrupted modulation source can also be shown. This corresponds to the source as a pure voltage without any circuit influence.

Now we evaluate the CGY94 board in a similar fashion. Figure 3-38 shows the waveform used for CAD purposes. Needless to say, such a signal cannot be produced by any signal

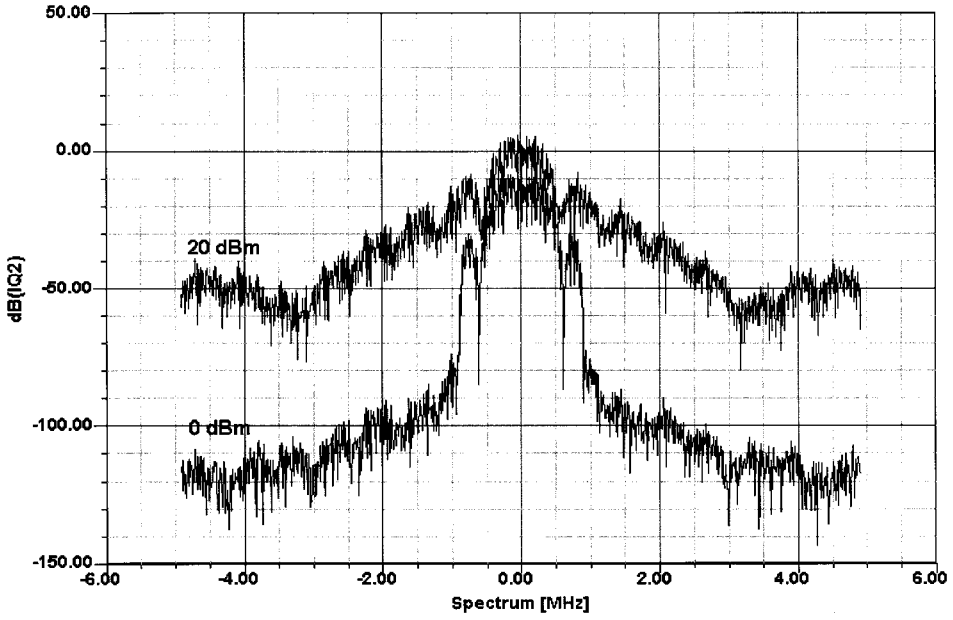

Figure 3-37 Spectrum of the modulation signal at the amplifier output. Source powers are 0 and 20 dBm.

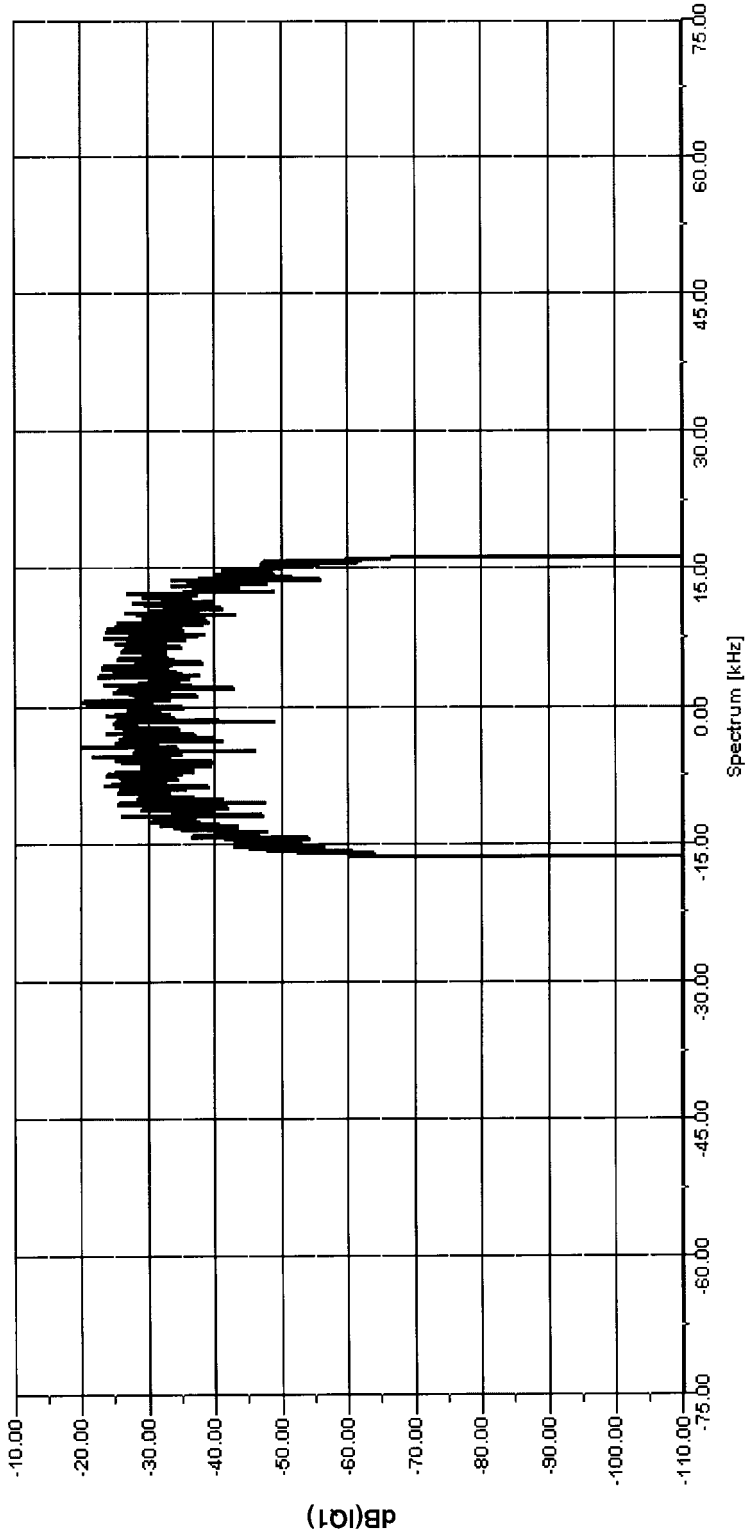

Figure 3-38 Simulated signal used for CAD analysis of the CGY94 amplifier.

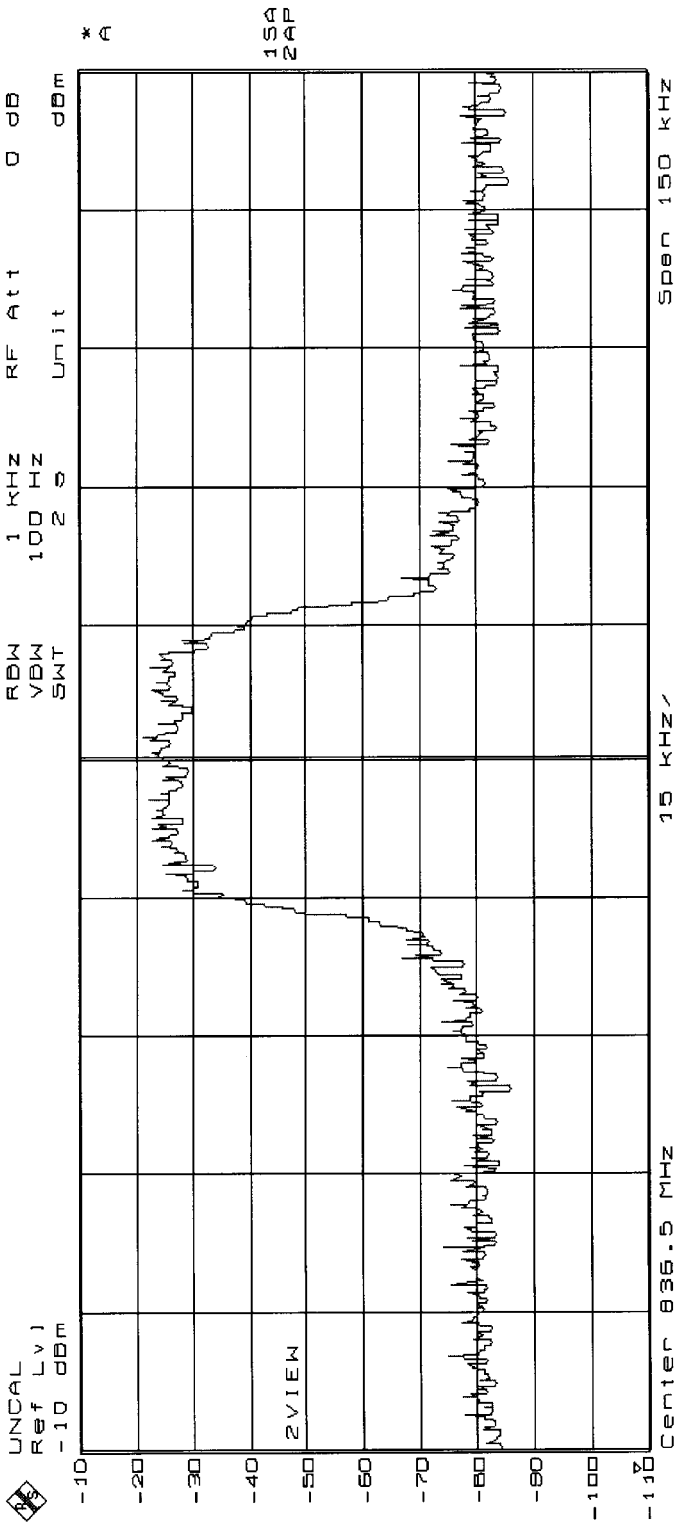

Figure 3-39 Real signal used for testing the actual amplifier.

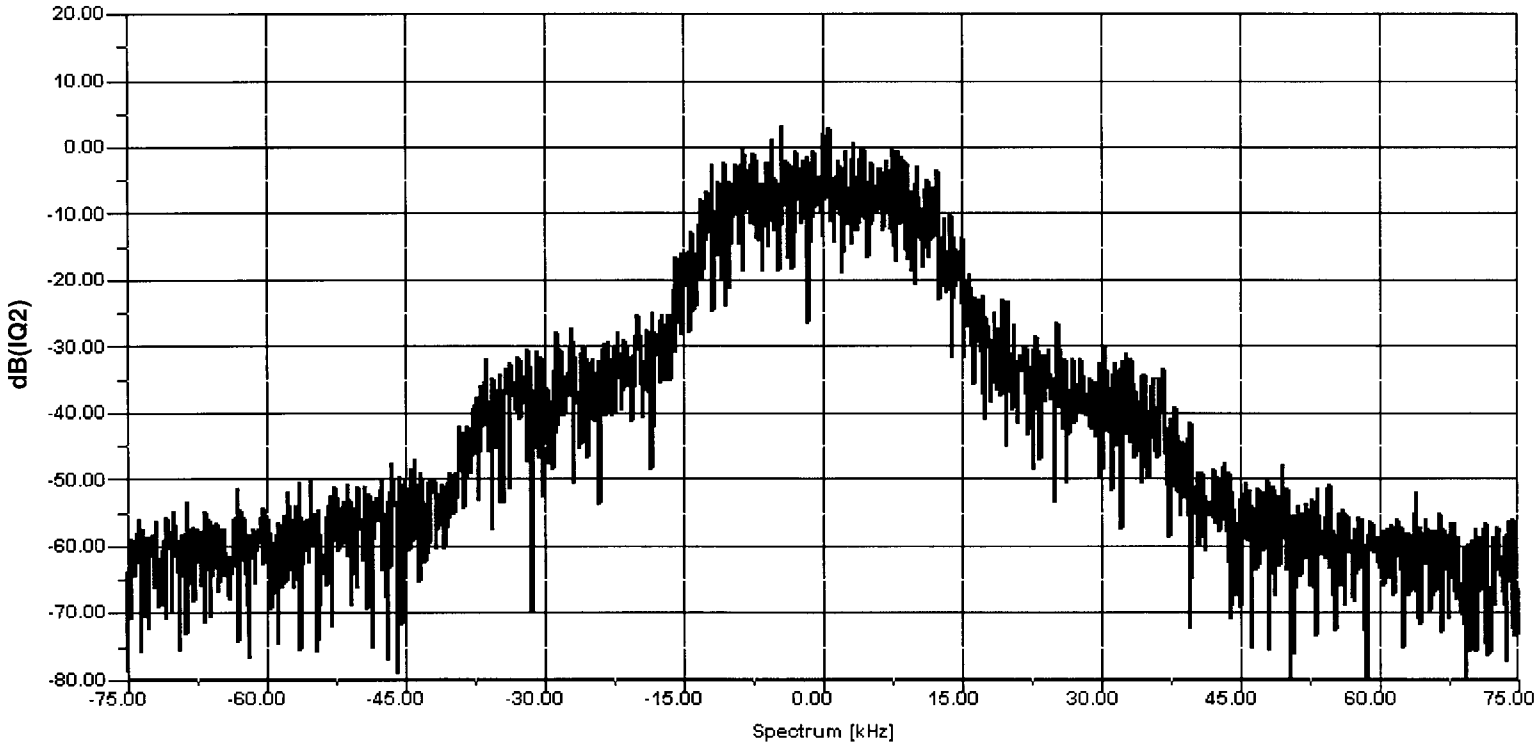

Figure 3-40 Spectral regrowth predicted by the simulation.

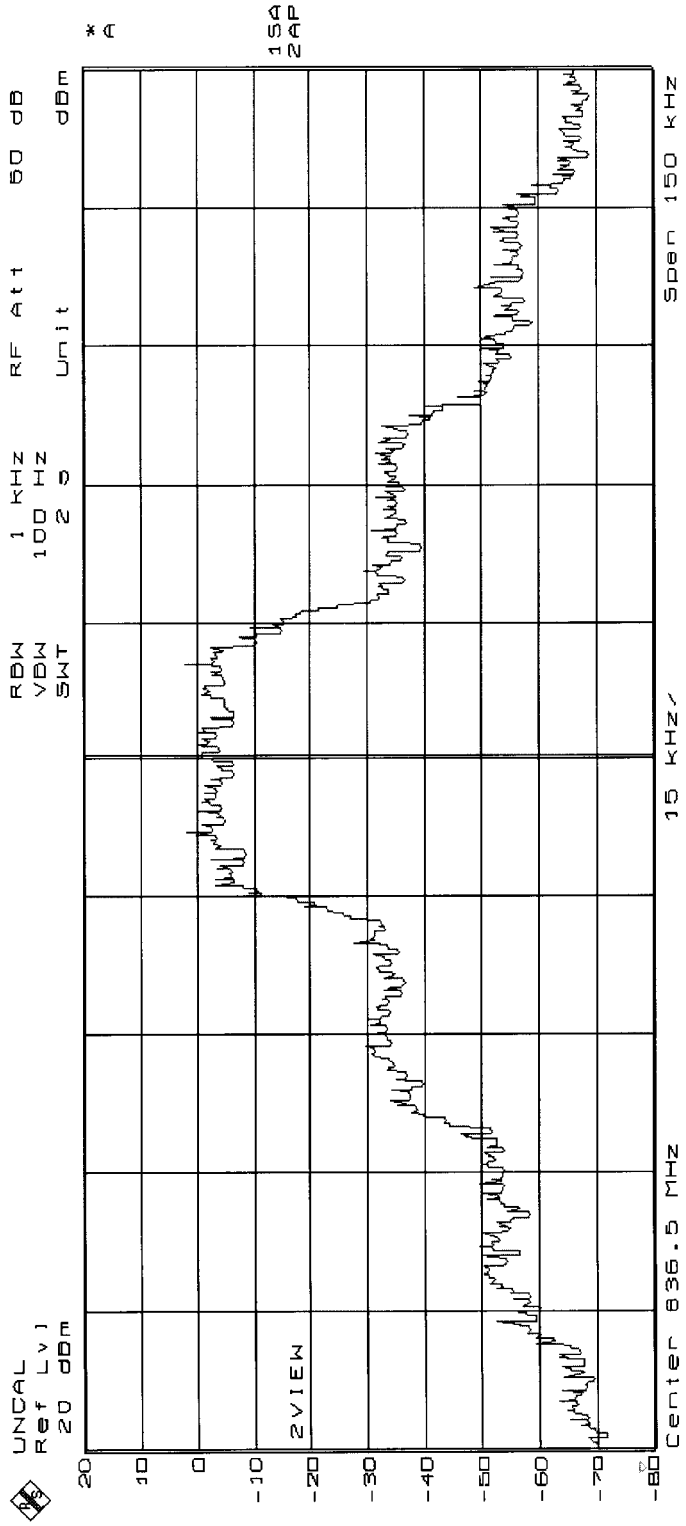

Figure 3-41 Measured spectral regrowth of the CGY94 amplifier.

generator. The one generated by an actual signal generator is shown in Figure 3-39. The wideband noise is around –80 dBm and the input level is about –25 dBm, consistent with the simulation signal. Looking at the output, Figure 3-40 shows the simulated signal with the expected increase in bandwidth. This is due to the nonlinearity of the amplifier and is consistent with Figure 3-37 for the single-stage amplifier. The actual measured output for the CGY94 shown in Figure 3-41 is quite close to its simulated output, indicating that the mathematical approach used for simulating is correct. This is only one example; in reality, many more waveforms can be analyzed and predicted using this method. Figure 3-41 shows essentially three distinct steps, which are sufficiently close to the response shown in the simulation. A dynamic range of 70 dB, while displayed in Figures 3-40 and 3-41, is not really necessary for good-quality transmission, and the discrepancy between the two pictures is in part due to the limited modeling quality of the active device as provided by the company that did the parameter extraction for this transistor.

Another useful view to aid in the understanding of the compression and distortion within the amplifier is to look at the magnitude of the complex waveform. Since the signal is composed of the in-phase and quadrature-phase components it is represented as

$$s(t) = i(t) + j \cdot q(t) \tag{3-120}$$

The time-domain magnitude is written

$$|s(t)| = \sqrt{i(t)^2 + q(t)^2} \tag{3-121}$$

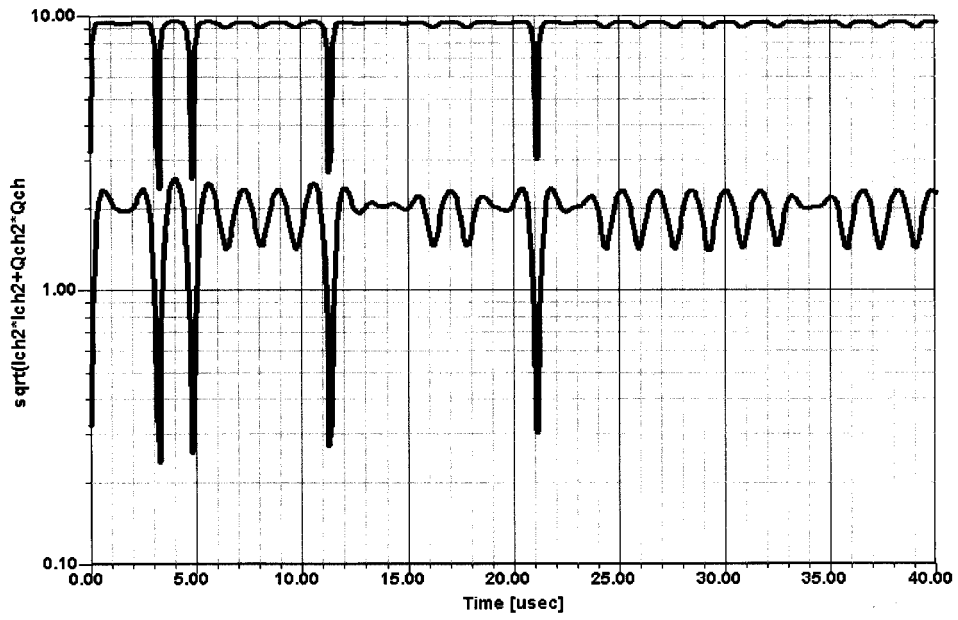

Figure 3-42 Time-domain magnitude of the complex modulation signal at source powers of 0 and 20 dBm.

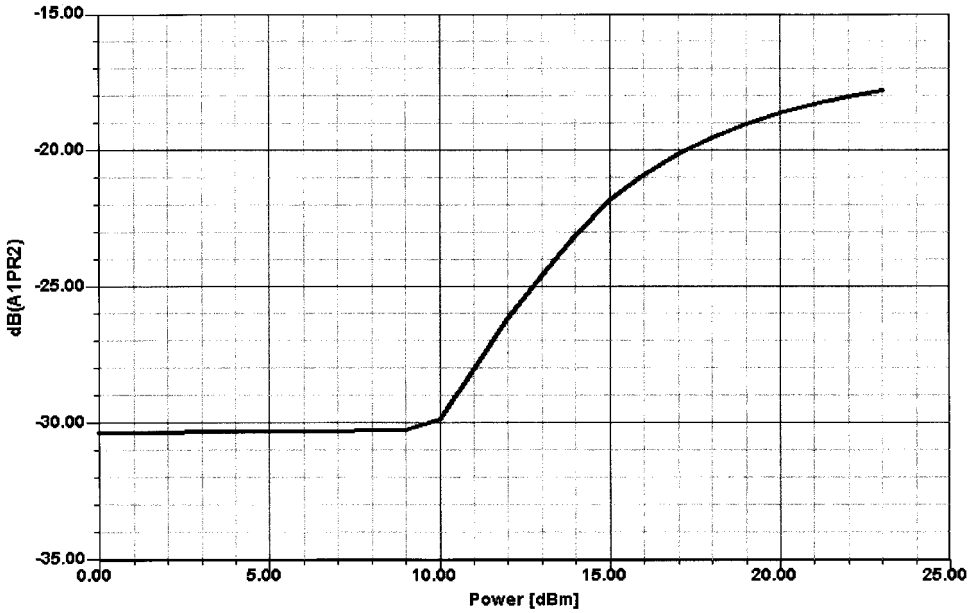

Figure 3-43 Adjacent-channel power ratio as function of RF source power.

Figure 3-42 shows the magnitude at source powers of 0 and 20 dBm. The *X* axis has been rescaled to 40 μs for improved viewing. Note the significant compression of the 20-dBm waveform at the higher signal levels. It is clear from this view that the signal is severely distorted.

We can also compute the adjacent-channel power ratio (ACPR) against the RF power sweep. ACPR is the ratio of the adjacent-channel power to the in-band channel power. The bandwidth (BW) and adjacent-channel start frequency (FS) are used for this calculation. For accurate ACPR calculation, a large number of bits are needed. This example uses 128 bits so the computation time is short, but 512 or more bits should be used for a more accurate computation.

Figure 3-43 shows the ACPR as a function of RF source power. The ACPR is nearly constant (and nonzero due to the gradual skirt of the baseband filter and inherent spillover to the adjacent channel) up to the P_{-1dB} compression point . As the intermodulation products spill into the adjacent channel and spectral regrowth occurs, the ACPR degrades.

π/4-DQPSK Circuit Analysis. Next, we will examine the same amplifier using a π/4-DQPSK modulation source. The task is identical to the previous one except for the source and the number of bits. The number of bits for this project has been increased from 128 to 256. Figure 3-44 shows the eye diagrams from this modulation format, at source powers of 0 and 20 dBm. The distortion and related intersymbol interference are clearly evident.

The constellation plot at 0 dBm is shown in Figure 3-45.

It may be interesting to take a look at the different waveforms currently in use. Figure 3-46 shows a spectrum analyzer picture of the most popular ones.

For reasons of time-division management, the European standard, GSM, which is now offered by Omnipoint at the 1.8-GHz band in the United States, uses gating to reduce the actual bandwidth of the spectrum. Figure 3-47 compares the GSM signal with and without gating.

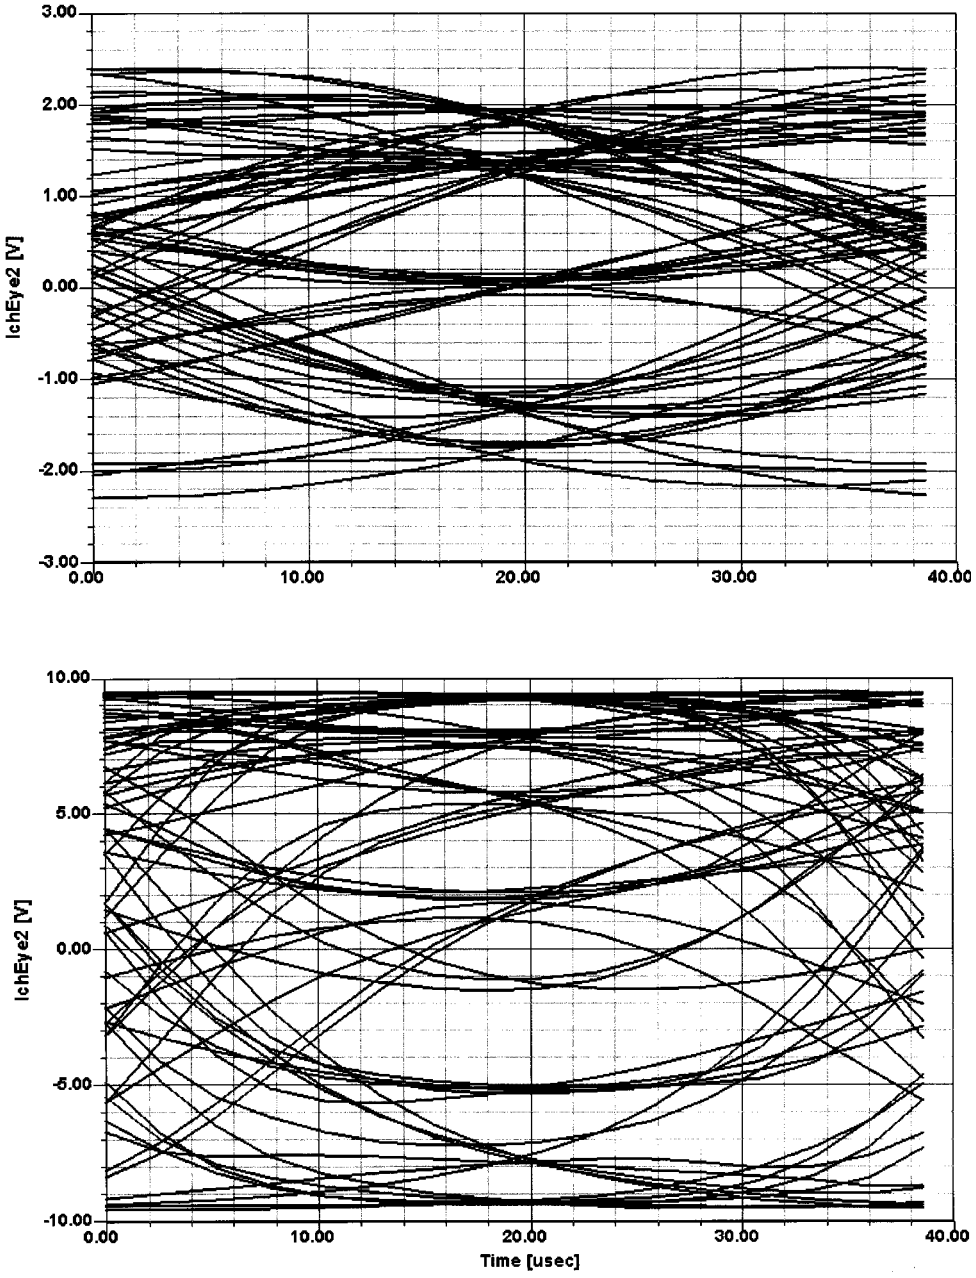

Figure 3-44 Eye diagrams for $\pi/4$-DQPSK at source powers of (a) 0 dBm and (b) 20 dBm. The distortion and related intersymbol interference are clearly visible.

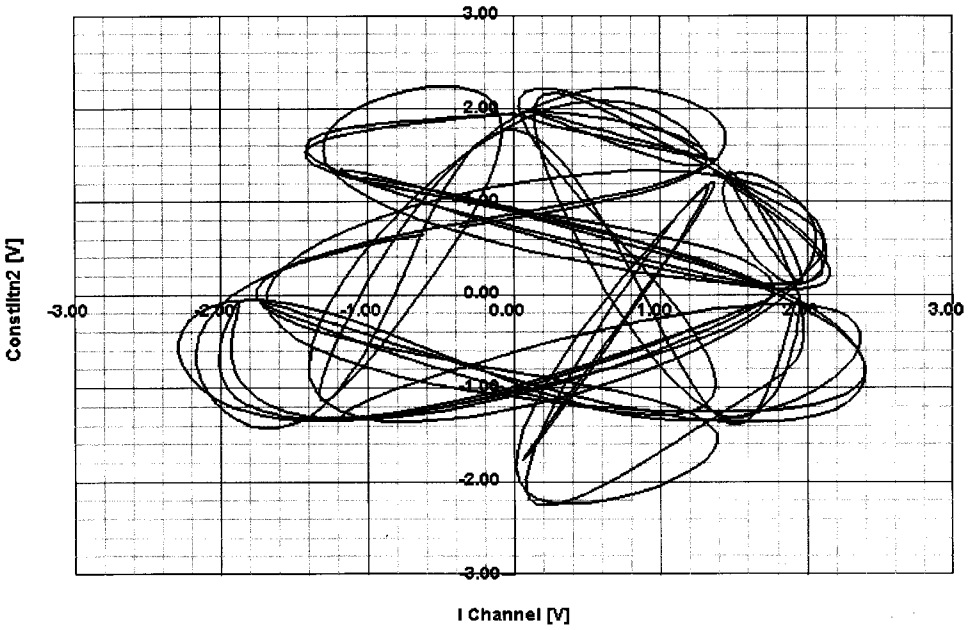

Figure 3-45 Constellation diagram for π/4-DQPSK at Port 2 and 0-dBm source power.

3-1-5 AGC

Many wireless systems consist of an up conversion or down conversion using an intermediate frequency, typically 10% or less of the receiving frequency (the FM broadcast IF has been set at 10.7 MHz for the same reason).

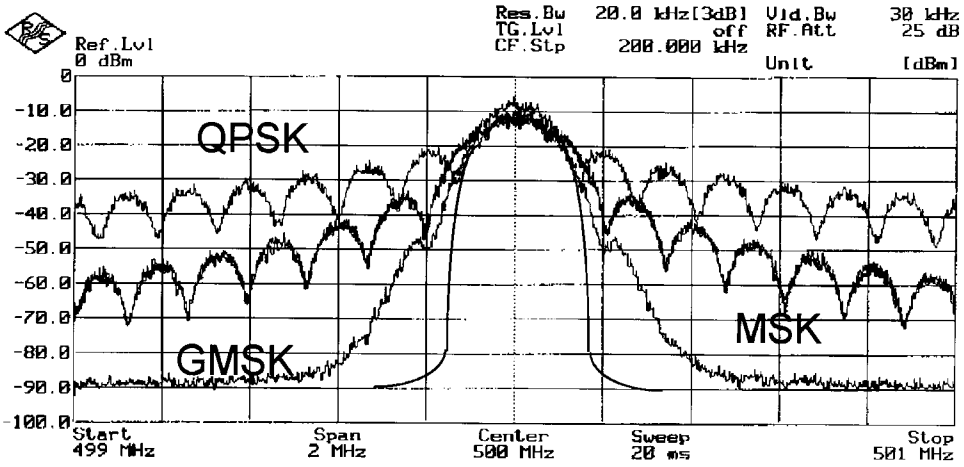

Figure 3-46 Spectrogram showing the characteristics of MSK, GMSK, and QPSK.

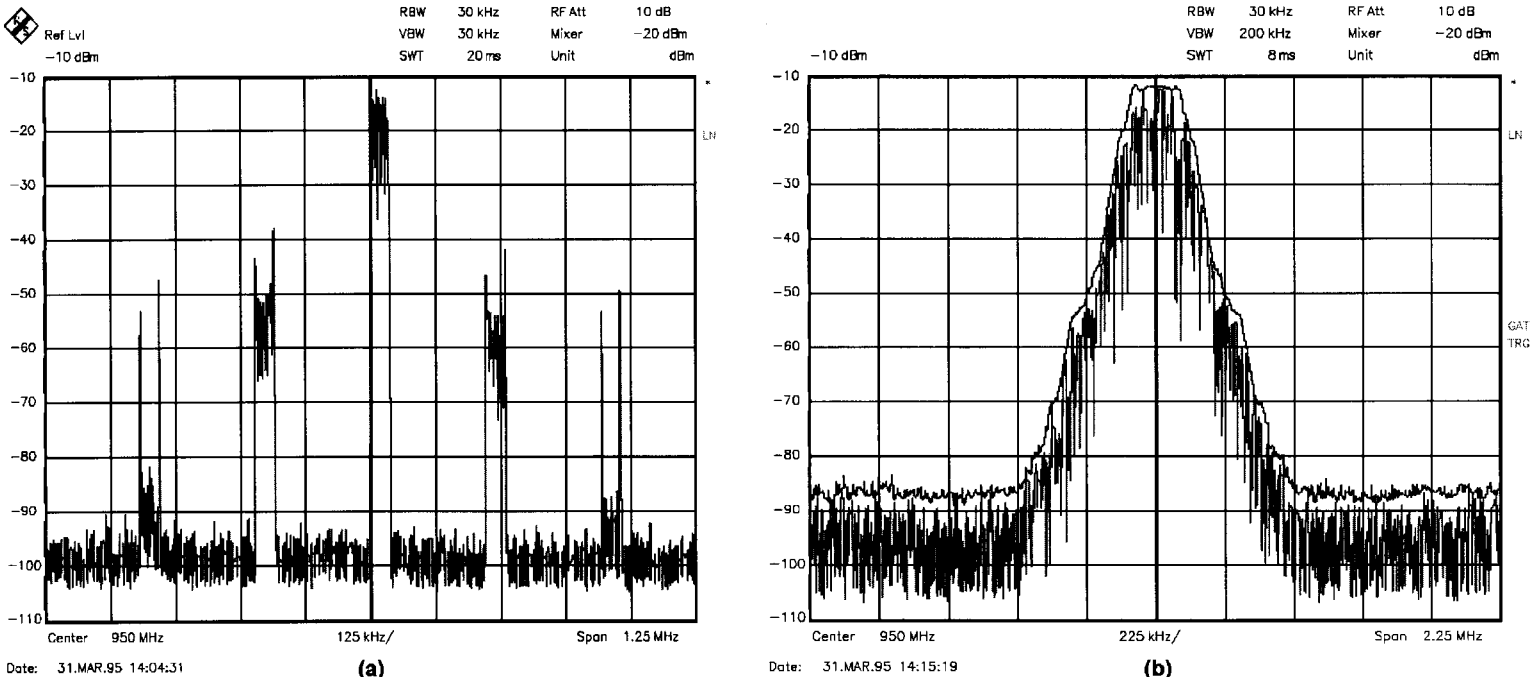

Figure 3-47 Pulsed GSM signal (a) without gating and (b) with gating.

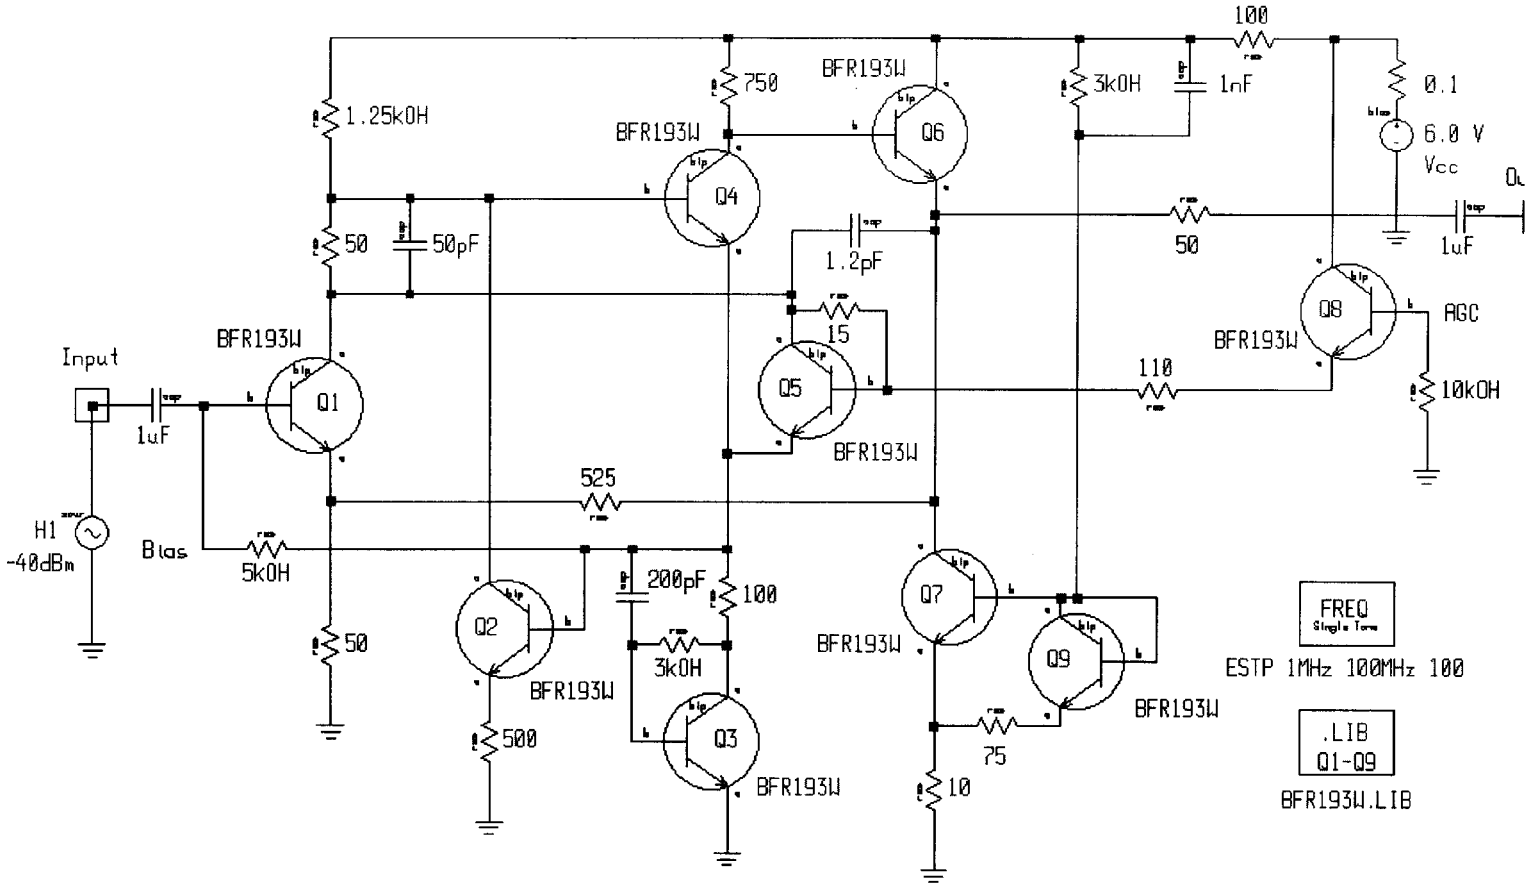

Figure 3-48 Schematic of the Plessey SL610 wideband amplifier with AGC. The 75-Ω resistor in the emitter of Q9 had to be added to obtain the appropriate dc current.

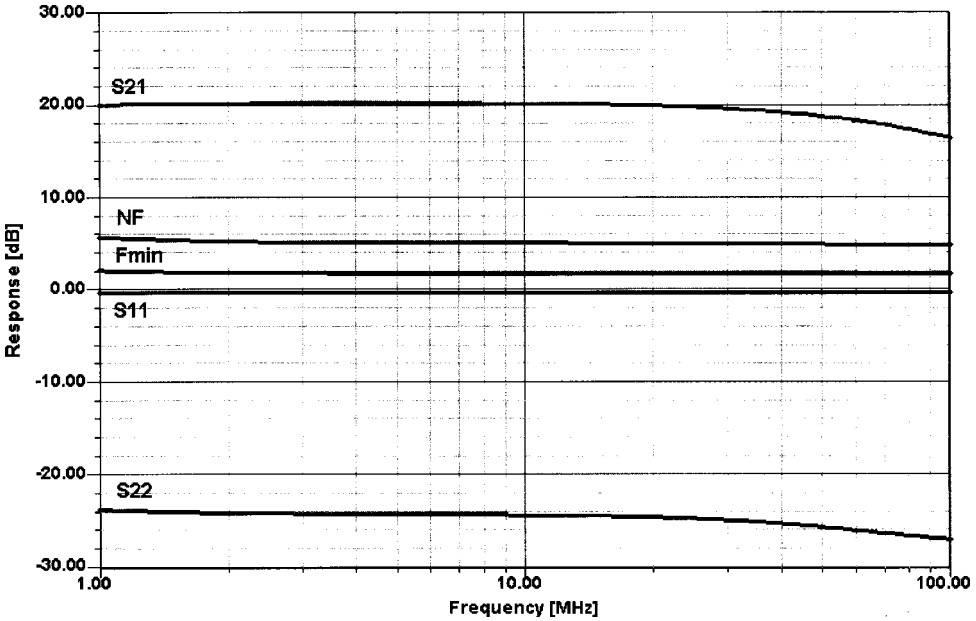

Figure 3-49 Simulated frequency response of the Plessey SL610 wideband amplifier IC with AGC = 0 V.

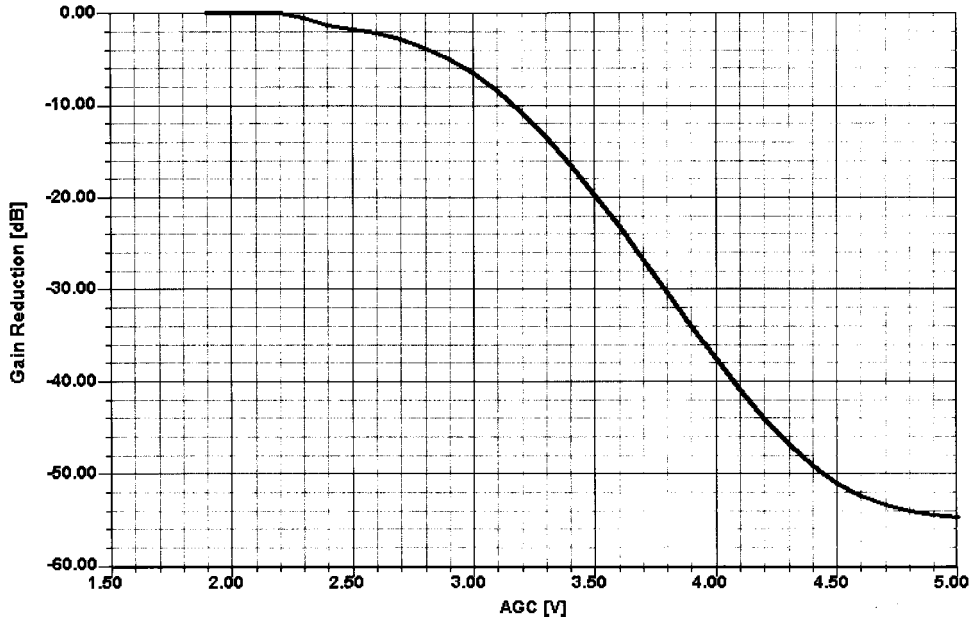

Figure 3-50 Simulated gain reduction versus AGC of the Plessey SL610 wideband amplifier IC.

Table 3-7 CGY121A features

- Variable gain amplifier (MMIC amplifier) for mobile communication
- Typical gain control range over 50 dB
- Positive control voltage
- 50-Ω input and output matched
- Low power consumption
- Operating voltage range: 2.7–6 V
- Frequency range 800 MHz to 2.5 GHz

We therefore will show two amplifiers with AGC and available data. The first one is a wideband amplifier type SL610, which has been manufactured by Plessey; its current fate is unknown. However, since we put the circuit into the simulator it provides significant insight into the operation of such AGC stages. Figure 3-48 shows the actual schematic of the SL610 entered in Ansoft's Serenade Design Environment for simulation.

The AGC action is derived from Q8 through Q5, which, together with Q4, forms a differential amplifier. Each consecutive stage (Q1, Q4, Q6) has increasing current, totaling about 20 mA; the last transistor takes about 13 mA. Based on the feedback surrounding the transistors, the actual transistor characteristics are less important. We have shown this by putting much higher f_T devices into the circuit than were available for the original design (20 years ago). The circuit is still interesting today because of its good large-signal-handling capability.

Table 3-8 CGY121A electrical characteristics at 900 MHz and 1.8 GHz

Characteristics	Symbol	Minimum	Typical	Maximum	Unit
(T_A 25 °C, f = 900 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	17	19	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	11	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	10	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm
(T_A 25 °C, f = 1800 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	15.5	17.5	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	10	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	8.5	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm

Figure 3-49 shows the amplifier's frequency response which is extremely close to the measured data. The good simulation also can be seen from comparing the published AGC curve with the one we found in the simulation. The bias of the first transistor remains essentially constant, resulting in a noise figure more independent of the AGC than the PIN-diode attenuator, and also stabilizes the input impedance as a function of AGC. Figure 3-50 shows the SL610's predicted AGC response.

The same requirement is applicable for the wireless frequency range. Tables 3-7 and 3-8 and Figures 3-51 through 3-54 present specifications for the recently introduced CGY121A GaAs MMIC by Infineon Technologies AG, formerly the Semiconductor Group part of Siemens AG.

3-1-6 Bias and Power Voltage and Current (Power Consumption)

Biasing of transistors operating in Class A or B follows some standard rules. The only deviation from this tends to be when the operating voltage is very low, below 3 V, because then the luxury of using voltage drops for good dc stability as a function of temperature disappears. (We will discuss low-voltage design in detail in Section 3-2-6.) In our simple example (Figure 3-55), we are operating from a 12-V power supply, and the first rule of thumb is to make sure that the voltage between the emitter and ground is at least 0.7 V. This is necessary to compensate the base–emitter junction threshold voltage, which decreases by about 2 mV/°C as the temperature increases. A larger voltage drop in the emitter–ground connection greatly reduces the influence. In this amplifier the emitter–ground path consists of an emitter unbypassed resistor of 10 Ω in series with a bypassed 501-Ω resistor, resulting in an overall voltage drop of 2.6. We could reduce the supply voltage by about 1.9 V at the collector side and still maintain a safety margin of 0.7 V at the emitter–ground connection. The current 2.6 V, so to speak, is overkill.

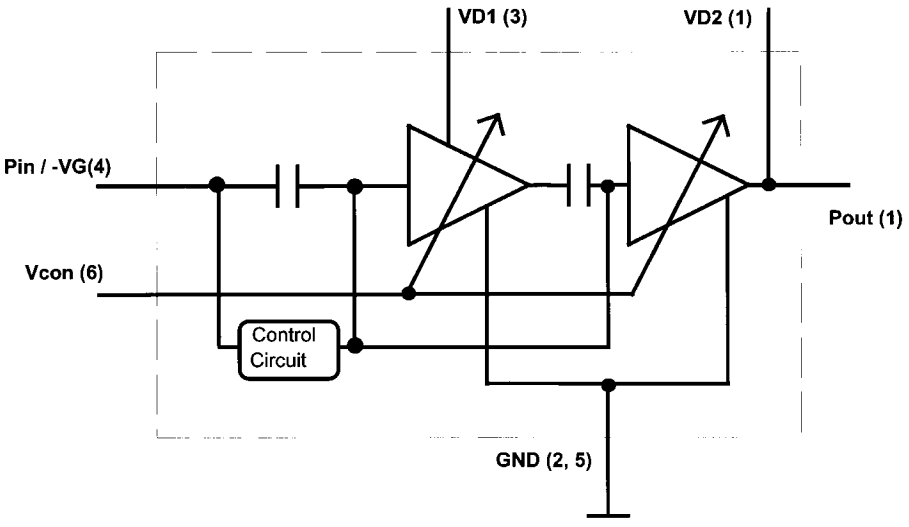

Figure 3-51 Functional block diagram of the gain-controllable CGY121A GaAs MMIC. Gain control is achieved by applying 0–3 V dc to the Vcon pin.

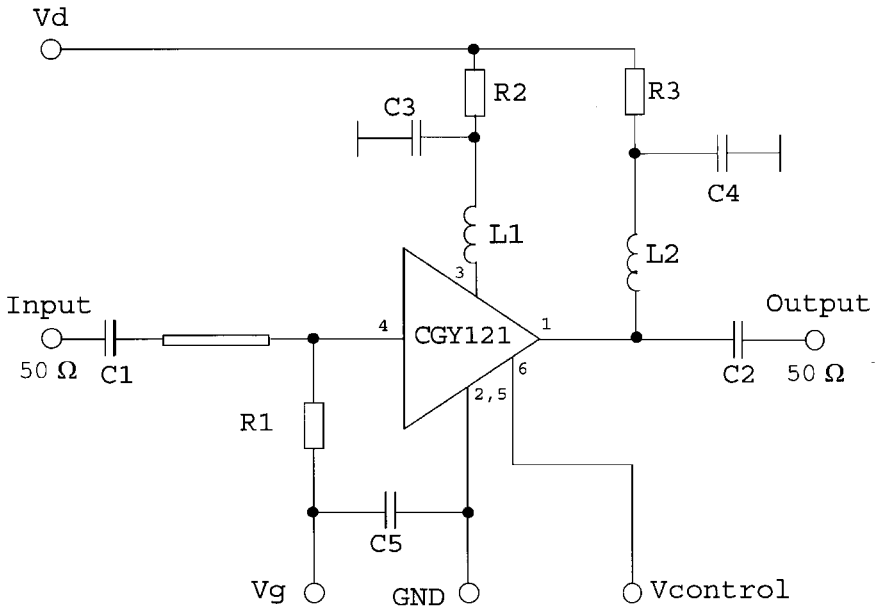


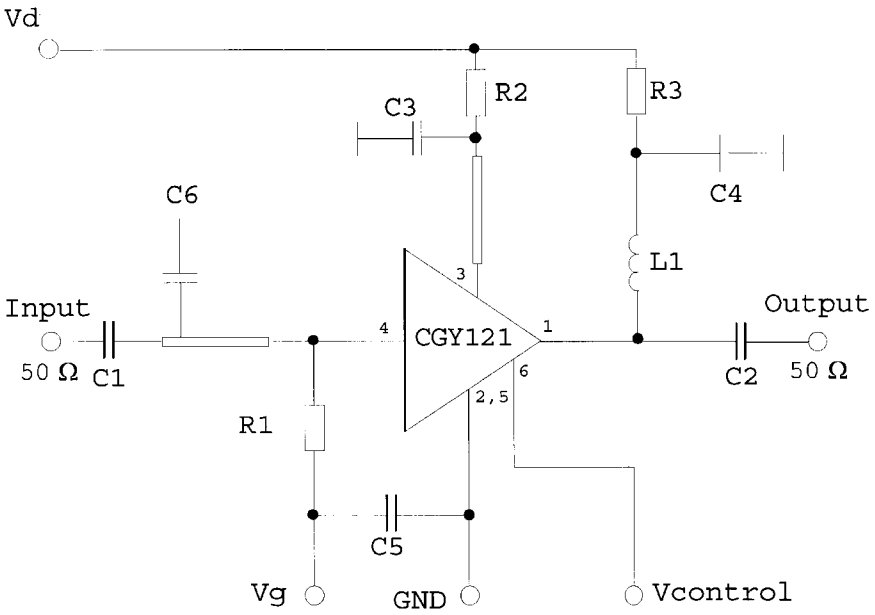
Parts List

Frequency	900 MHz
C1, C2 (Siemens Size 0603)	22 pF
C3, C4 (Siemens Size 0603)	100 nF
C5 (Siemens Size 0603)	47 nF
L1 (Coilcraft 0805CS-150XKBC)	15 nH
L2 (Coilcraft 0805CS-270XMBC)	27 nH
R1 (Siemens B 54102-A1271-J60)	270 Ω
R2 (Siemens B 54102-A1120-J60)	12 Ω
R3	6.8 Ω

Figure 3-52 CGY121A 900-MHz application circuit and parts list.

On the collector side, for an *RC* type of amplifier, it is not a bad idea to set the collector voltage at about half the supply, which allows the RF swing to be half the supply voltage. In this case, we have violated the rule because of our 2.6-V drop. Assuming we had chosen a 0.7-V drop, then the collector–emitter voltage would be 6.3 V available for the swing. The choice of 5 mA for the transistor has come from a combination of good linearity and low noise figure. While the 10-Ω unbypassed resistor will grade the noise figure somewhat, it reduces the emitter-current-dependent distortion. The base–emitter diffusion resistance equals 26 mV/5 mA, or roughly 5 Ω. The 10-Ω resistor is twofold larger and therefore adds to the linearity and to the noise.

To determine the base bias resistor it is a good assumption that the current going through the two resistors (in our case, 8.2 and 3.3 kΩ) is about 10% (or a slightly higher fraction) of



Parts List

Frequency	1.9 GHz
C1, C2 (Siemens size 0603)	12 pF
C3, C4 (Siemens size 0603)	100 nF

C6 (Siemens size 0603)	1.2 pF
L1 (Coilcraft 0805CS-150XKBC)	15 nH
R1 (Siemens B 54102-A1271-J60)	270 Ω
R2 (Siemens B 54102-A1120-J60)	12 Ω
R3	2.7 Ω

Figure 3-53 CGY121A 1.9-GHz application circuit and parts list.

the collector current. Since the dc current gain of the transistor is typically between 50 and 100, it is sufficient if the current through the resistive network is between 5 and 10 times higher than the dc bias current taken off the network. This type of bias scheme is only valid for Class A to AB_1. Later, we will see that for monolithic circuits, additional transistors will be used to generate the required voltage drops. Lately, combinations of *npn* and *pnp* transistors have become popular to avoid using any resistance in the emitter for dc biasing purposes. Figure 3-56 shows such a circuit. This, of course, invites thermal runaway. To minimize the circuitry, there are bias ICs, such as the Siemens BCR400R, now available. Figures 3-57 and 3-58 show its application in biasing BJTs and FETs, respectively; it can also be used to control PIN-diode bias current for TR antenna switching, as shown in Figure 3-59.

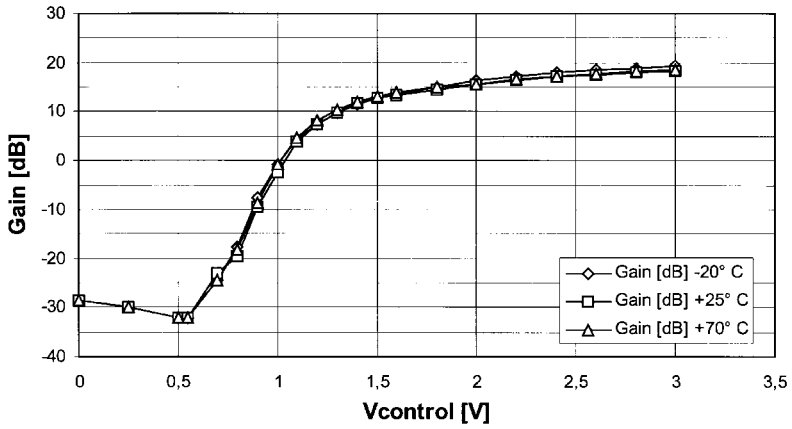

Figure 3-54 CGY121A gain versus $V_{control}$ at 1.9 GHz.

To validate this, we have used the Serenade 8.0 CAD tool, which has a built-in bias- and temperature-dependent noise model for BJTs and FETs. The SPICE-type dc analysis determines the actual currents, which were mentioned above. By maintaining the same bias and just bypassing both emitter resistors at the same time, the set of curves shown in Figure 3-60 will be obtained. As an exercise, we recommend the user to determine the optimum generator impedance for F_{min} with a 10-Ω resistor. Again, both the emitter current and collector voltage affect the noise figure, the intermodulation, and f_T. If a transistor is used

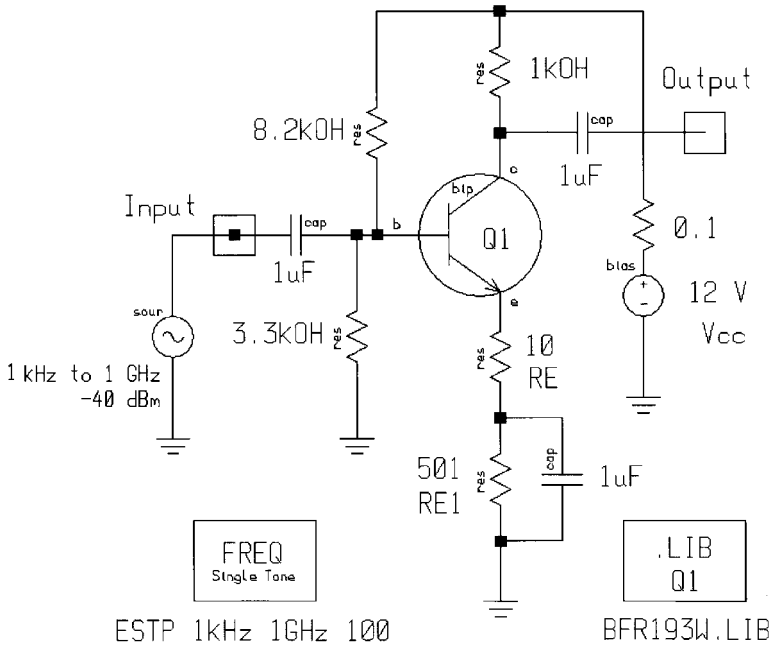

Figure 3-55 BJT amplifier example.

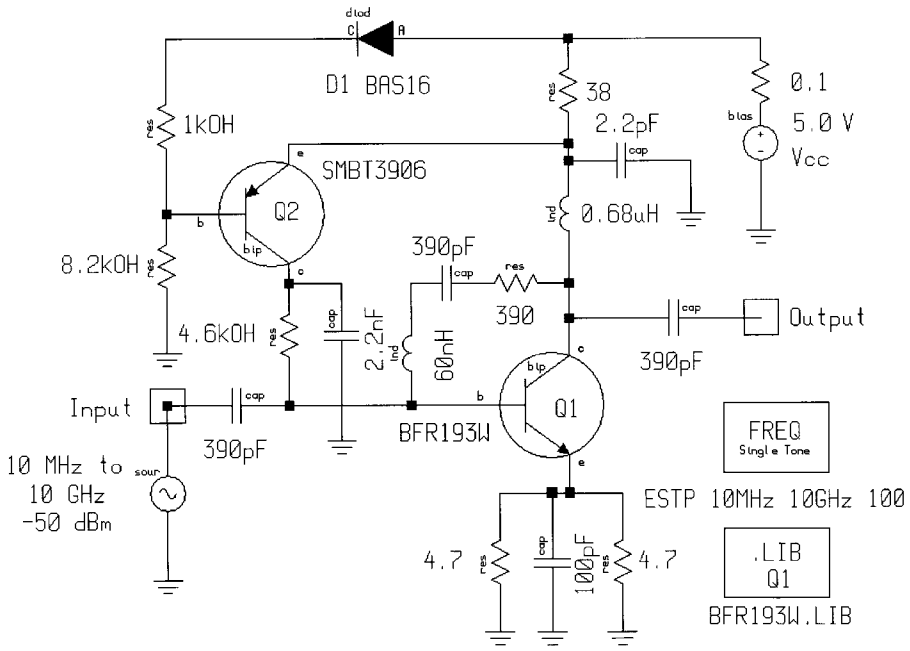

Figure 3-56 Wideband amplifier with active biasing. The 4.7-Ω resistors in the BFR193W emitter compensate the circuit's gain at low frequencies.

that is intended to be operated at significantly higher currents, then f_T will suffer while the other two parameters are less affected.

The dc input power translates into thermal dissipation, and Figure 3-60 is a plot of the noise figure as a function of temperature with and without emitter feedback. The heavy dc stabilization prevents a significant effect on the other parameters. The actual dc shift is from 5.0 to 5.2 mA for a temperature change of 70 K.

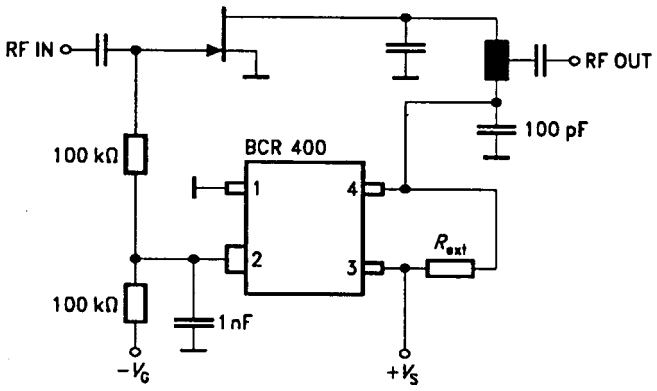

Figure 3-57 The Siemens BCR400 bias controller applied to a GaAsFET.

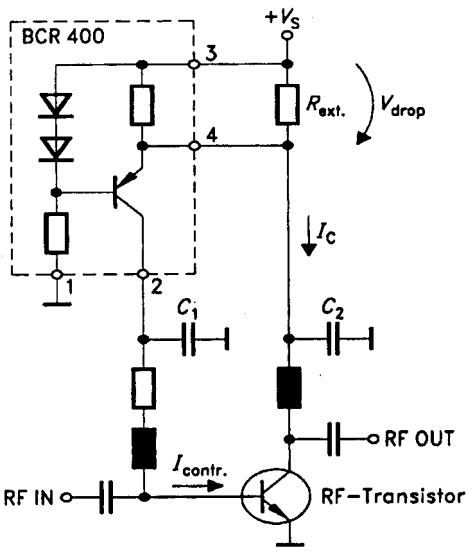

Figure 3-58 The Siemens BCR400 bias controller applied to a BJT.

As far as FETs are concerned, the enhancement types, typically PMOS, can use a similar type of bias, while the NMOS types complicate the designer's life as they require a negative gate voltage. For low-noise operation, these devices are operated somewhat close to the pinchoff voltage. Putting a source resistor in place causes mostly headaches simply because the gain is so high that the transistors are always ready to find a frequency at which they love to oscillate. The transistor will look for every possible parasitic to turn the amplifier into an oscillator.

3-2 AMPLIFIER GAIN, STABILITY, AND MATCHING

Most semiconductor manufacturers describe their devices these days by providing either their *S* parameters (small-signal) or SPICE-type parameters (large-signal). One of our headaches in writing this book has been that many of the published models don't translate

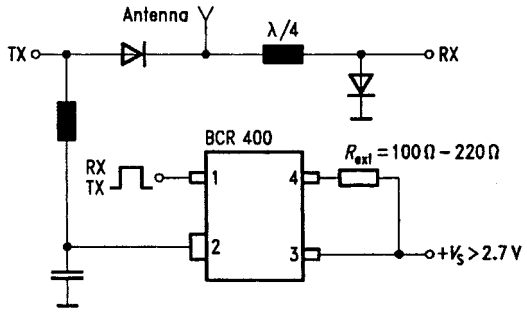

Figure 3-59 The Siemens BCR400 bias controller applied to TR switching.

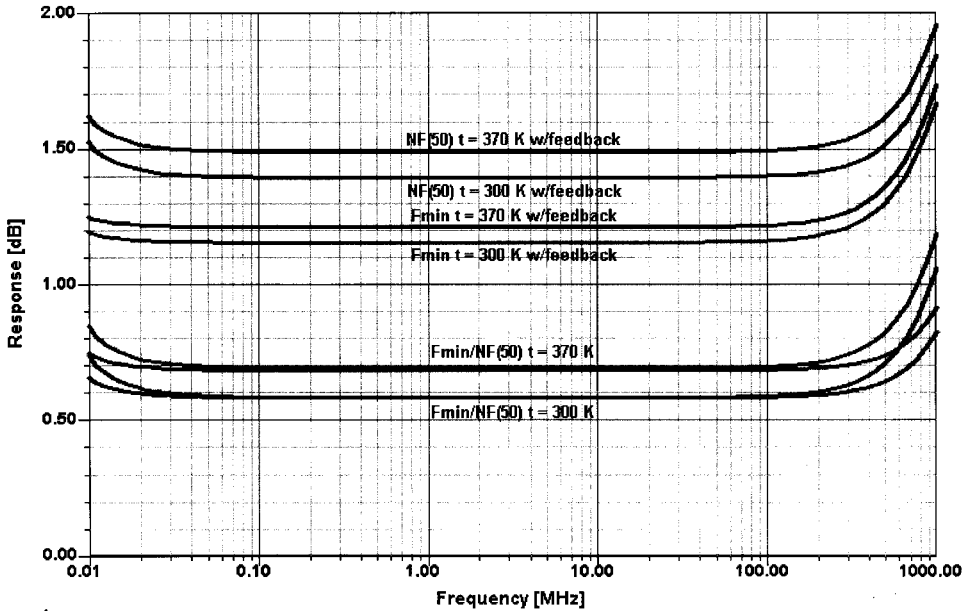

Figure 3-60 F_{min} and NF for the amplifier in Figure 3-55, with and without emitter feedback, at 300 and 370 K.

from large signal to small signal without giving unexpected or false results. Despite the availability of tools to do it right, many companies still can only provide data that are practically inadequate, and unfortunately the CAD manufacturers then get the blame for results for which they are not really responsible.

Tables 3-9 and 3-10 show typical data for a bipolar transistor (the BFP420 by Siemens). The next section presents a summary of the derivation and use of *S* parameters as published by Hewlett-Packard and others.

3-2-1 Scattering Parameter Relationships

Scattering (*S*) parameters characterize a network in terms of incident and reflected waves (Figures 3-61 and 3-62).

$$b_1 = s_{11}a_1 + s_{12}a_2 \tag{3-122}$$

$$b_2 = s_{21}a_1 + s_{22}a_2 \tag{3-123}$$

Notice that

$$s_{11} = \frac{b_1}{a_1} = \frac{V_1/I_1 - Z_0}{V_1/I_1 + Z_0} = \frac{Z_1 - Z_0}{Z_1 + Z_0} \tag{3-124}$$

and

[a]Input matched for minimum noise figure, output for maximum gain.
[b]$Z_S = Z_L = 50\ \Omega$.

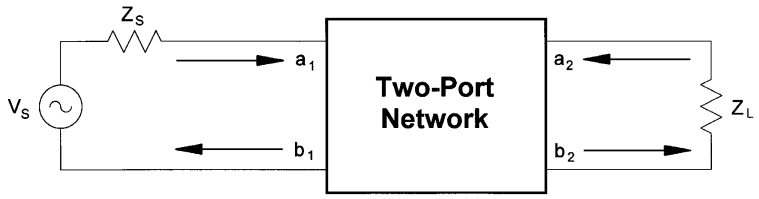

Figure 3-61 *S* parameters characterize a network (a two-port is shown) in terms of incident waves (a_1, a_2) and reflected waves (b_1, b_2). Figure 3-62 shows the flow graph for this network.

$$Z_1 = Z_0 \frac{(1 + s_{11})}{(1 - s_{11})} \tag{3-125}$$

where $Z_1 = V_1/I_1$ is the input impedance at Port 1.

This relationship between reflection coefficient and impedance is the basis of the Smith Chart transmission-line calculator. Consequently, the reflection coefficients S_{11} and S_{22} can be plotted on Smith charts, converted directly to impedance, and easily manipulated to determine matching networks for optimizing a circuit design.

The above equations show one of the important advantages of *S* parameters: They are simply gains and reflection coefficients, both familiar quantities to engineers. By comparison, some of the *Y* parameters described earlier in the article are not so familiar. For example, the *Y* parameter corresponding to insertion gain S_{21} is the "forward transadmittance," Y_{21}. Clearly, insertion gain gives by far the greater insight into the operation of the network.

S parameters are simply related to power gain and mismatch loss, quantities that are often of more interest than the corresponding voltage functions:

$$|s_{11}|^2 = \frac{\text{Power reflected from the network input}}{\text{Power incident on the network input}} \tag{3-126}$$

$$|s_{21}|^2 = \frac{\text{Power delivered to a } Z_0 \text{ load}}{\text{Power available from } Z_0 \text{ source}} \tag{3-127}$$

$$|s_{12}|^2 = \text{Reverse transducer power gain with } Z_0 \text{ load and source.} \tag{3-128}$$

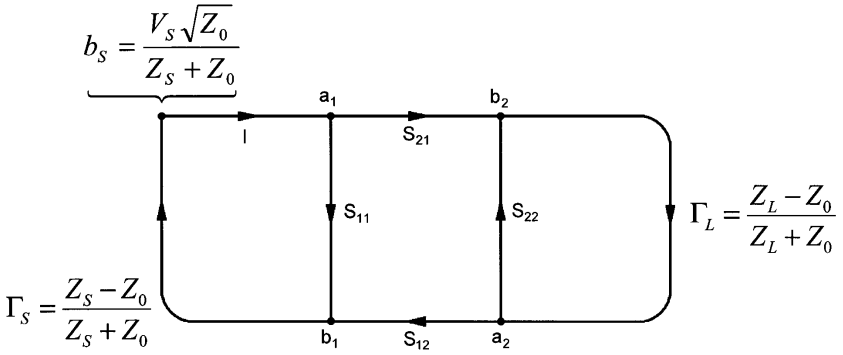

Figure 3-62 Flow graph for the network shown in Figure 3-61.

$$|s_{22}|^2 = \frac{\text{Power reflected from the network output}}{\text{Power incident on the network output}} \tag{3-129}$$

From this we obtain:
Input reflection coefficient with arbitrary Z_L:

$$s'_{11} = s_{11} + \frac{s_{12}s_{21}\Gamma_L}{1 - s_{22}\Gamma_L} \tag{3-130}$$

Output reflection coefficient with arbitrary Z_S:

$$s'_{22} = s_{22} + \frac{s_{12}s_{21}\Gamma_S}{1 - s_{11}\Gamma_S} \tag{3-131}$$

Voltage gain with arbitrary Z_L and Z_S:

$$A_V = \frac{V_2}{V_1} = \frac{s_{21}(1 + \Gamma_L)}{(1 - s_{22}\Gamma_L)(1 + s'_{11})} \tag{3-132}$$

$$\text{Power gain} = \frac{\text{Power delivered to load}}{\text{Power input to network}}:$$

$$G = \frac{|s_{21}|^2 (1 - |\Gamma_L|^2)}{(1 - |s_{11}|^2) + |\Gamma_L|^2 (|s_{22}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_L N)} \tag{3-133}$$

$$\text{Available power gain} = \frac{\text{Power available from network}}{\text{Power available from source}}:$$

$$G_A = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)}{(1 - |s_{22}|^2) + |\Gamma_S|^2 (|s_{11}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_S M)} \tag{3-134}$$

$$\text{Transducer power gain} = \frac{\text{Power delivered to load}}{\text{Power available from source}}:$$

$$G_T = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|(1 - s_{11}\Gamma_S)(1 - s_{22}\Gamma_L) - s_{12}s_{21}\Gamma_L\Gamma_S|^2} \tag{3-135}$$

Unilateral transducer power gain ($S_{12} = 0$):

$$G_{Tu} = \frac{|s_{21}|^2(1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|1 - s_{11}\Gamma_S|^2|1 - s_{22}\Gamma_L|^2}$$

$$= G_0 G_1 G_2 \tag{3-136}$$

$$G_0 = |s_{21}|^2 \tag{3-137}$$

$$G_1 = \frac{1 - |\Gamma_S|^2}{|1 - s_{11}\Gamma_S|^2} \tag{3-138}$$

$$G_2 = \frac{1 - |\Gamma_L|^2}{|1 - s_{22}\Gamma_L|^2} \tag{3-139}$$

Maximum unilateral transducer power gain when $|S_{11}| < 1$ and $|S_{22}| < 1$:

$$G_u = \frac{|s_{21}|^2}{|(1 - |s_{11}|^2)(1 - |s_{22}|)^2|}$$

$$= G_0\, G_{1\max}\, G_{2\max} \tag{3-140}$$

$$G_{i\max} = \frac{1}{1 - |s_{ii}|^2} \quad i = 1, 2 \tag{3-141}$$

Constant-gain circles (unilateral case: $S_{12} = 0$):

- Center of constant-gain circle is on line between center of Smith Chart and point representing S_{ii}^*
- Distance of center of circle from center of Smith Chart:

$$r_i = \frac{g_i |s_{ii}|}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-142}$$

- Radius of circle:

$$\rho_i = \frac{\sqrt{1 - g_i}(1 - |s_{ii}|^2)}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-143}$$

where $i = 1, 2$ and

$$g_i = \frac{G_i}{G_{i\max}} = G_i(1 - |s_{ii}|^2) \tag{3-144}$$

Unilateral figure of merit:

$$u = \frac{|s_{11}s_{22}s_{12}s_{21}|}{|(1 - |s_{11}|^2)(1 - |s_{22}|^2)|} \tag{3-145}$$

Error limits of unilateral gain calculation:

$$\frac{1}{(1 + u^2)} < \frac{G_T}{G_{Tu}} < \frac{1}{(1 - u^2)} \tag{3-146}$$

Conditions for absolute stability. No passive source or load will cause a network to oscillate if a, b, and c are all satisfied:

$$\text{a.}\quad |s_{11}| < 1, |s_{22}| < 1 \tag{3-147}$$

$$\text{b.} \quad \left| \frac{|s_{12}s_{21}| - |M^*|}{|s_{11}|^2 - |D|^2} \right| > 1 \tag{3-148}$$

$$\text{c.} \quad \left| \frac{|s_{12}s_{21}| - |N^*|}{|s_{22}|^2 - |D|^2} \right| > 1 \tag{3-149}$$

where

$$D = s_{11}s_{22} - s_{12}s_{21} \tag{3-150}$$

$$M = s_{11} - Ds_{22}^* \tag{3-151}$$

$$N = s_{22} - Ds_{11}^* \tag{3-152}$$

Condition that a two-port network can be simultaneously matched with a positive real source and load:

$$K > 1 \tag{3-153}$$

$$K = \frac{1 + |D|^2 - |s_{11}|^2 - |s_{22}|^2}{2|s_{12}s_{21}|} \tag{3-154}$$

Source and load for simultaneous match

$$\Gamma_{mS} = M^* \left[\frac{B_1 \pm \sqrt{B_1^2 - 4|M|^2}}{2|M|^2} \right] \tag{3-155}$$

$$\Gamma_{mL} = N^* \left[\frac{B_2 \pm \sqrt{B_2^2 - 4|N|^2}}{2|N|^2} \right] \tag{3-156}$$

where

$$B_1 = 1 + |s_{11}|^2 - |s_{22}|^2 - |D|^2 \tag{3-157}$$

$$B_2 = 1 + |s_{22}|^2 - |s_{11}|^2 - |D|^2 \tag{3-158}$$

Maximum available power gain. If $K > 1$,

$$G_{A\max} = \left| \frac{s_{21}}{s_{12}} (K \pm \sqrt{K^2 - 1}) \right| \tag{3-159}$$

In conclusion, *a two-port network (active or passive) is unconditionally stable* when

$$K > 1$$

$$|S_{12}S_{21}| < 1 - |S_{11}|^2$$

and

$$|S_{12}S_{21}| < 1 - |S_{22}|^2$$

3-2-2 Low-Noise Amplifiers

A low-noise amplifier combines a low noise figure, reasonable gain, and stability without oscillation over its entire useful frequency range. These amplifiers are typically operated in Class A, which is characterized by a bias point more or less at the center of maximum current and voltage capability of the device used, and by RF current and voltages that are sufficiently small relative to the bias point that the bias point does not shift. This means that an amplifier operating at, say, 3 V and 1 mA for low-noise, high-gain operation will not be Class A if the RF current is larger than 0.1% of the current or the voltage swing is more than 0.1% of the current swing. These amplifiers can be designed using standard linear *S* parameters, which are (hopefully) available from the device manufacturer for the bias point of interest. If suitable *S* parameters are not available, we must resort to a CAD tool that allows us to determine a device's bias point as a function of its bias network and to generate small-signal *S* parameters for the device. With suitable *S* parameters in hand, and assuming the amplifier will be frequency selective, we then connect tuned circuits to the input and output to provide matching.

In designing amplifiers, the "power gain" of a circuit is mentioned frequently. This is actually deceptive because power gain is somewhat associated with dc power dissipation, and in considering it, we are on the verge of discussing large-signal performance. Therefore it would be better to define the power gain as a function of operating mode, such as "Class A power gain." We have also outlined that there is a difference between noise matching and gain matching. If we can be allowed to step back into the vacuum-tube era for a moment, the reader should be reminded that the difference between power gain and noise matching had to do with the grid-plate feedback capacitance which, via the Miller effect, showed up in parallel with the input. This actually detunes the input slightly off-center relative to the best gain. The reason for this is that as the feedback increases, Y_{12} or S_{12} starts playing a role, and the frequently assumed unilateral case no longer exists. The difference between noise matching and gain matching increases as a function of frequency. It can be brought closer together if appropriate reactive feedback is used. The two choices are: (1) increase the emitter or source inductance or (2) slightly increase the base-to-collector/gate-to-drain capacitance. Needless to say, the penalty for this is potential instability, and a sweep must be done from a few megahertz to several gigahertz to make sure the stage doesn't "take off."

The most efficiency this circuit provides is 50%; even this is a theoretical limit if one tries to keep distortion under control.

While the equation $P_{\text{OUT}} = (V_{\text{bat}} - V_{\text{sat}})^2/2R_L$ is valid, it really applies only to power amplifiers in the sense that for Class A, high-gain operation R_L can be made significantly higher as the absolute power output is not the important item. While the supply voltage V_{bat} is always known, the saturation voltage V_{sat} has to be obtained by the load line dc analysis. Note: The RF saturation voltage is always higher than the dc one. When looking at Figure 3-63, it becomes obvious that the conducting angle is 180°, which implies that the entire sine wave at the input is reproduced as an essentially undistorted sine wave at the output.

We can now calculate the components of the distorted current in separating them into the dc component, the fundamental frequency, and its first and second harmonics:

$$\text{Fundamental} \quad i_{c1} = i_{\text{peak}} \cdot f_1(\Theta) \tag{3-160}$$

$$\text{Second harmonic} \quad i_{c2} = i_{\text{peak}} \cdot f_2(\Theta) \tag{3-161}$$

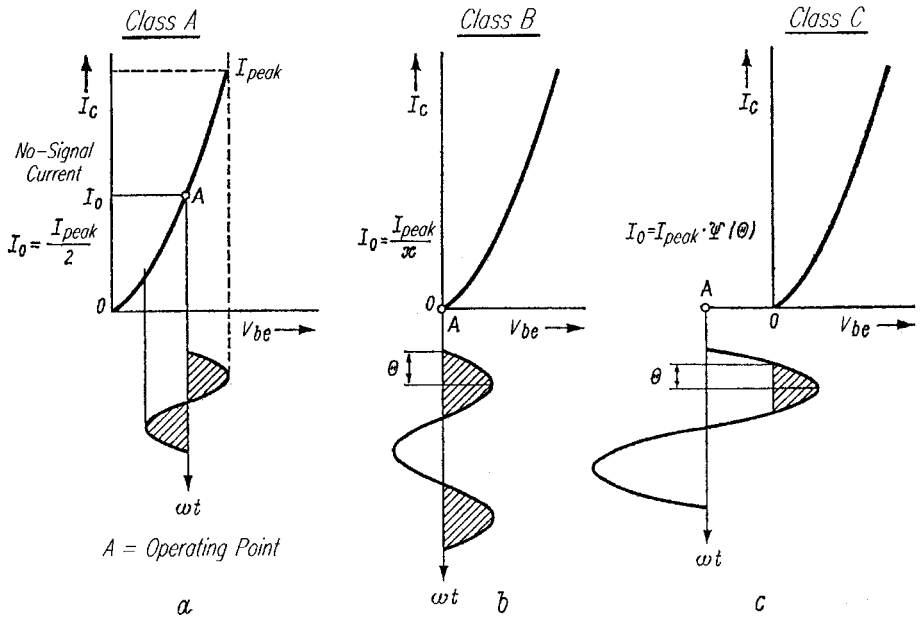

Figure 3-63 Definitions of Class A, B, and C operation, including conduction angle (Θ). Figure 3-64 shows the determination of Θ.

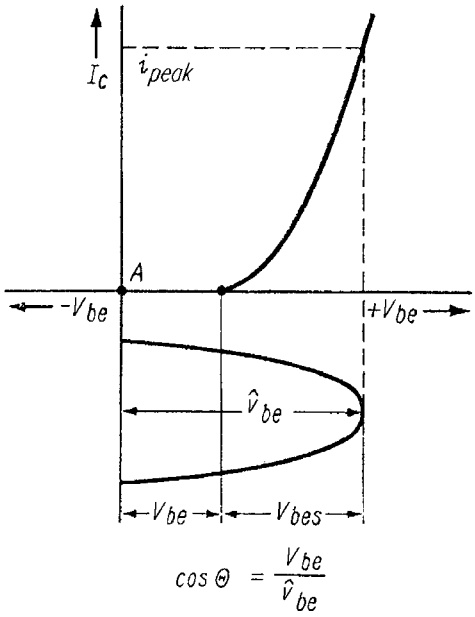

Figure 3-64 Determination of the conduction angle Θ from the base threshold voltage V_{be} and the base RF voltage $\hat{v}_{be}$.

$$\text{Third harmonic} \quad i_{c3} = i_{\text{peak}} \cdot f_3(\Theta) \tag{3-162}$$

For the collector dc current we obtain

$$I_c = i_{\text{peak}} \cdot \Psi(\Theta) \tag{3-163}$$

The frequency-dependent currents are a function of the conduction angle Θ. Figure 3-65 shows these transfer characteristics as a function of the conduction angle for a square-law dynamic transfer function; for higher-order transfer functions, the values don't change much. Tables for this can be found in various sources, including Clark and Hess [47]. Since the transistors exhibit a mixture of an exponential and a linear transfer characteristic (due to the unwanted parasitic emitter/source and collector/drain resistances when building the device), the plot in figure 3-65 is sufficiently valid for practical purposes. This function plot allows us to determine the amplitude of the current at various frequencies once the conducting angle has been set. For example, for Θ = 70°, the maximum collector current is $i_{\text{peak}} = I_c/0.253$, meaning that the peak current of the transistor is approximately four times larger than the dc value one would measure. Once the peak collector current is known, the fundamental and harmonic currents can be calculated:

$$i_{c1} = \frac{I_c}{0.253} f_1(\Theta)$$

$$i_{c1} = \frac{I_c}{0.253} 0.436$$

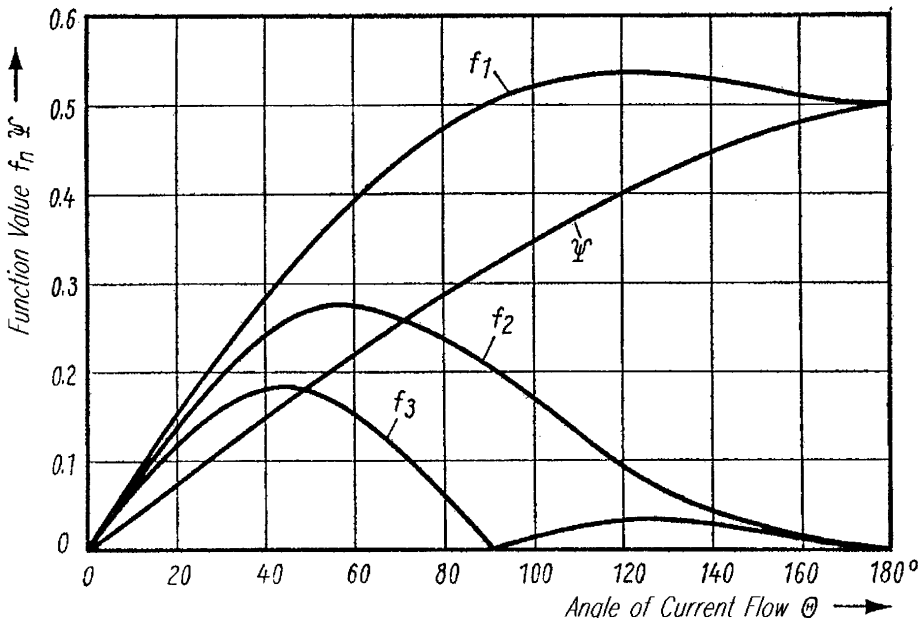

Figure 3-65 Function values for the fundamental, second harmonic, third harmonic, and dc components (f_1, f_2, f_3, and Ψ, respectively) versus device conduction angle.

In order to obtain i_{c2} and i_{c3} one needs to do the same calculations as above with the appropriate functions for f_2 and f_3.

It becomes obvious that the distorted collector current generates a lot of harmonics, which definitely requires sufficient low-pass filtering at the output, even for Class A operation. We already stated that for Class A operation the conduction angle is 180° while it is 90° for Class B operation. The conduction angle for Class C operation can be solved from the ratio of the knee voltage V_{be} and the peak value of the ac voltage at the base. We find

$$\cos \Theta = \frac{V_{be}}{\hat{V}_{be}} \tag{3-164}$$

where $\Theta = 90°$ and $V_{be} = 0$. Given the voltage V_{bes}, which determines the peak collector current (up to i_c peak), we can calculate the effective RF voltage at the base as

$$\hat{v}_{be} = \frac{v_{bes}}{1 - \cos \Theta} \tag{3-165}$$

Therefore, the peak value of v_b becomes v_{bes} for $\Theta = 90°$.

The necessary base voltage V_{be} for maximum current is obtained by the transistor model. Then one finds the threshold voltage at which the transistor becomes conductive and by using Eqs. (3-164) and (3-165) it can be checked whether this results in the appropriate conducting angle. An example for this will be shown in the high-power stage section.

Design Guidelines. The design of a one-stage amplifier consists of finding

- An input lossless matching network M_1
- An input lossless matching network M_2

so that the maximum or desired transistor gain is achieved over the operating bandwidth of the amplifier. Usually, the common-emitter or common-source configuration is chosen for highest gain per stage. If the stability factor K is greater than unity, these two networks can be found to give the maximum available gain $G_{\max}$. If the stability factor is less than or equal to unity, the amplifier could be terminated in a matching structure that causes oscillation; that is, $G_{\max}$ is infinite. This should be avoided by locating the regions of instability in the Γ_G and Γ_L planes. The input and output terminations (Γ_G and Γ_L) must be designed to avoid the instability regions. Usually, these unstable regions are near the conjugate match for S_{11} and S_{22}. Thus, a stable amplifier will require some input and/or output mismatch if K is less than or equal to unity.

There are at least two alternative approaches for potentially unstable amplifiers:

1. Add resistive matching elements to make $K \geq 1$ and $G_{\max} \approx G_{ms}$.
2. Add feedback to make $K \geq 1$ and $G_{\max \approx Gms}$.

For narrowband amplifiers, it is usually recommended that one accept a transistor with $K < 1$, design the amplifier for a gain approaching G_{ms}, and ensure that the Γ_G and Γ_L terminations provide stability at all frequencies, both inside and outside the amplifier passband.

The design of an amplifier would usually have the following specifications:

Gain and gain flatness
Bandwidth and center frequency ($f_2 - f_1, f_0$)
Noise figure
Linear output power
Input reflection coefficient ($VSWR_{in}$)
Output reflection coefficient ($VSWR_{out}$)
Bias voltage and current

For small-signal amplifiers, the small-signal S parameters are sufficient to complete the design. After selecting an appropriate transistor based on these specifications, a one-stage amplifier design should be considered if sufficient gain can be achieved; otherwise, a two-stage amplifier should be designed.

The circuit topology should be chosen to allow dc bias for the transistor. Usually, RF short-circuited stubs are placed near the transistor to allow dc biasing. If the topology does not allow dc bias, a broadband bias choke or high-resistance bias circuit that does not affect the amplifier performance must be used.

The following steps can be tabulated for the design of a one-stage amplifier (see Figure 3.66):

1. Select a transistor based on a datasheet description of the S parameters, noise figure, and linear output power.
2. Calculate K and G_{max} or G_{ms} versus frequency.
3. For $K > 1$, select the topologies that match the input and output (and allow dc biasing) at the upper band edge f_2. Ideally, this will give G_{max} and $S'_{11} = S'_{22} = 0$. Usually, $S_{12} = 0$ is assumed for the initial design. Next, the topology may be varied to flatten gain versus frequency at the expense of S'_{11} and S'_{22}.
4. For $K < 1$, plot the regions of instability on the Γ_G and Γ_L planes and select topologies that partially match the input and output at the upper band edge and avoid the unstable regions. The gain will approach G_{ms} as an upper limit. Next, the topology may be varied to flatten gain versus frequency.
5. After finding initial M_1 and M_2, plot the amplifier S parameters versus frequency; make adjustments in topology until the specifications for gain, input reflection coefficient, and output reflection are satisfied. Also plot Γ_G and Γ_L versus frequency to verify amplifier stability.
6. Design the dc bias circuit. Lay out the elements of the complete amplifier and check realizability.

As a beginning point in an amplifier design, the circuit topologies may be designed with the assumption that S_{12} is zero. Later, an exact design procedure will be described that includes the topologies with terminations in the stable region.

Design Examples. Throughout this book we always address the issue that we have to separate the battery-operated handheld applications and the more stationary designs like those for base stations. In the case of the handheld or low-voltage applications, the dynamic range requirements are significantly less than the front-end of a base station requires.

NE68133 Matched Amplifier. We will first consider the design of a low-voltage, low-current, low-noise amplifier based on the NEC BJT NE68133. This device was chosen

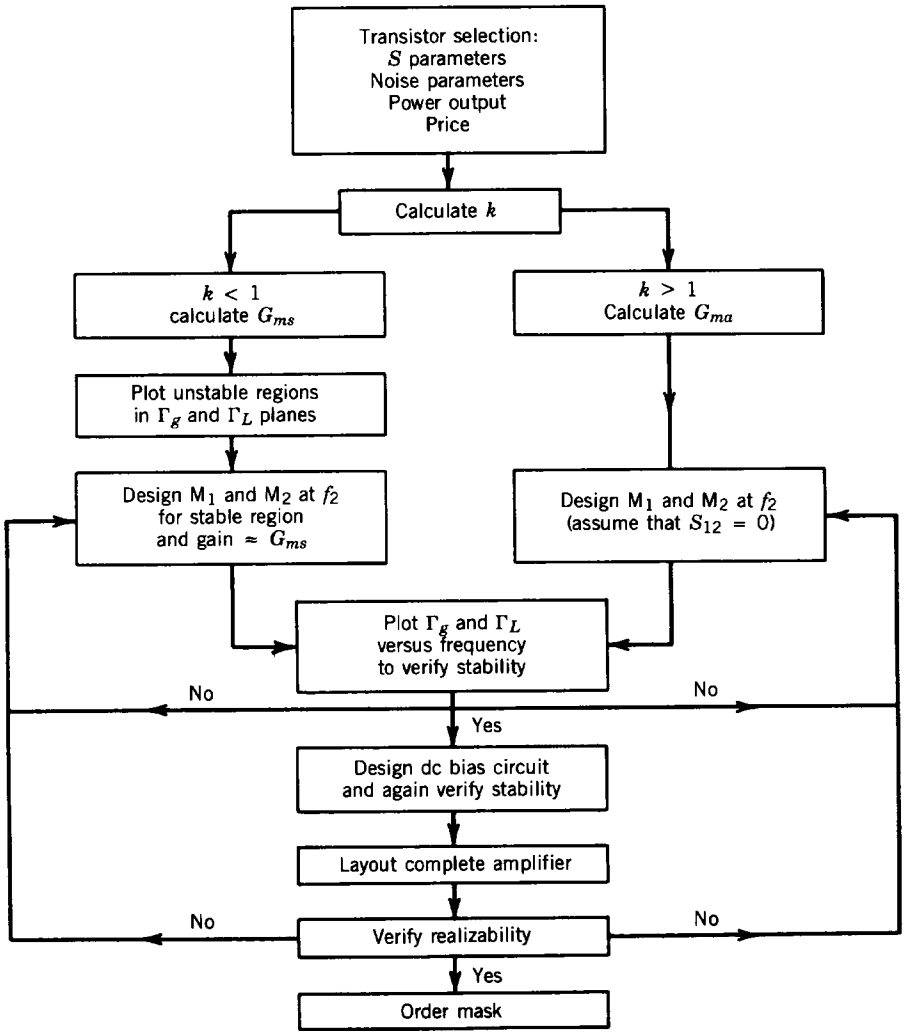

Figure 3-66 Simplified amplifier design procedure.

because it is unconditionally stable, has a minimum noise figure of about 1.2 dB at 7 mA, has 15.5 dB gain, and has an f_T of 8 GHz. While it is possible to start the design based on the published S and noise parameters, we will choose also to involve the nonlinear model, as this allows us more freedom in selecting the bias point including the collector voltage. The actual topology of the amplifier is shown in Figure 3-67.

Determining appropriate values for the input and output matching networks is essential to finalizing the design. The next several figures illustrate matching-network syntheses undertaken with the interactive Smith Tool in Ansoft's Serenade Design Environment. We evaluate the point of tangency as well as stability circles in the source and load planes, indicating that our impedance match will result in a stable amplifier.

In Figure 3-68, the center circle (with 1.1 marker) refers to the noise circle for which the noise figure of 1.1 dB can be obtained. The left circle (with the 14.3 marker) corresponds to

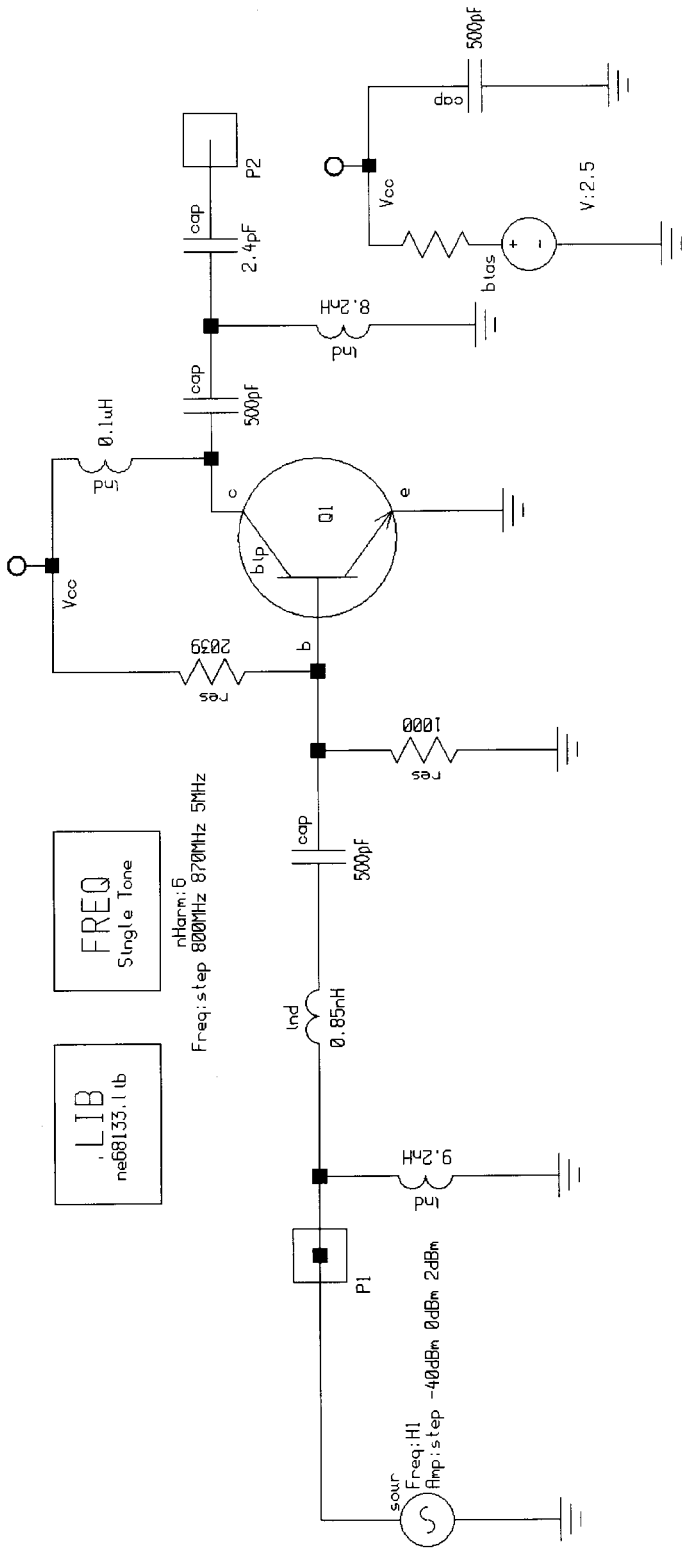

Figure 3-67 The NE68133 low-noise amplifier.

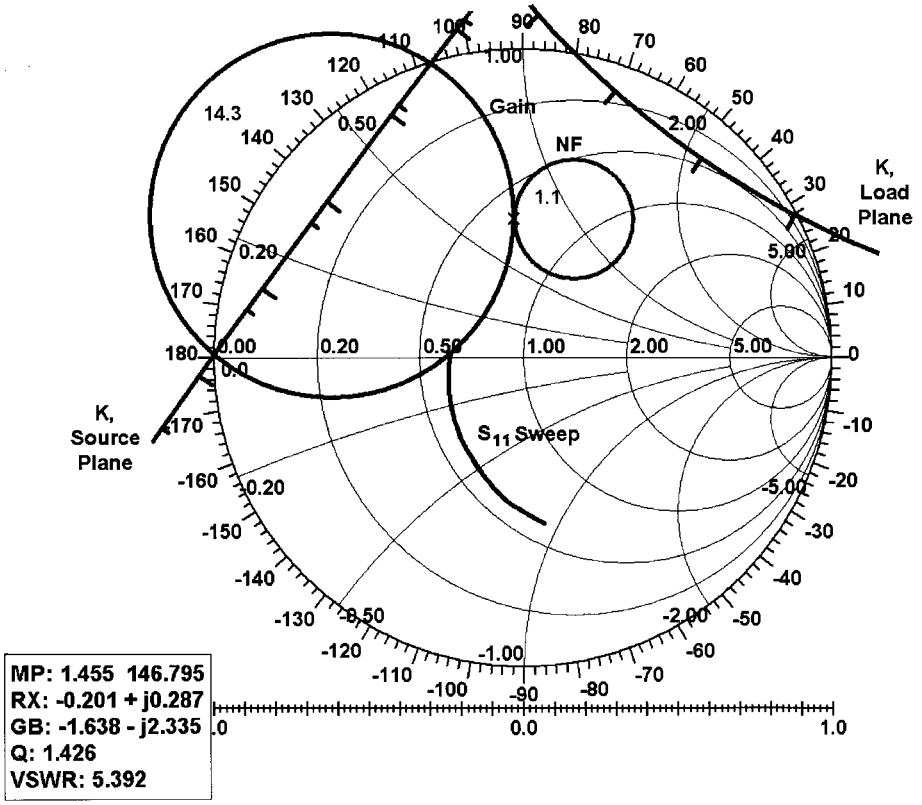

Figure 3-68 Display from the interactive Smith Tool, showing circles for gain, noise figure, and source- and load-plane stability, as well as a sweep of S_{11} versus frequency. In synthesizing an input matching circuit, we choose a single working frequency and work from the chart's origin to the point of tangency between the gain and noise figure circles. See Figure 3-69.

source-plane terminations that correspond to 14.3 dB of available gain. In order to get the required noise figure *and* gain, the input termination must be at the point of tangency of both circles. The arc touching the X axis close to 0.50 is the amplifier's S_{11} response from 800 to 875 MHz. The shallow arc that nearly bisects the 14.3-dB gain circle is actually a portion of the source-plane stability circle; the arc at the top right is a portion of the load-plane stability circle. Because we will be terminating the amplifier input with a value inside the source-plane stability circle, and terminating the amplifier output with a value outside the load-plane stability circle, the amplifier will be unconditionally stable at the frequency at which the match is obtained.

The next task is to obtain the values for the network circuit that matches the input for the 1.1-dB noise figure. A noise matching will not result in the best possible S_{11} matching (Figure 3-69). This translates into an inductor of 9.2 nH to ground and a series inductor of 0.85 nH based on the large-signal model of the NE68133 at the chosen bias point.

After we have determined our input matching network, it is time to find the output matching (Figure 3-70). First, find the termination point on the output plane that corresponds to 14.3-dB gain and 1.1-dB NF at the input plane. The output gain circle goes through the

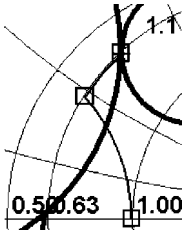

Figure 3-69 Input matching-network extraction, assuming lossless matching components and no parasitic effects.

1.1-dB NF circle at two points, and for reasons of easy matching we selected the lower point. The next step is to find the conjugate reflection coefficient $\Gamma_L = S_{22}^*$. This is the lower square marker in Figure 3-70. The remaining task is to find the matching network that brings this value to 50 Ω. By doing so, we first obtain a shunt inductance $L_{\text{shunt}} = 8.2$ nH and a series capacitor $C_{\text{series}} = 2.4$ pF. Again, these are the values applicable to the large-signal equivalent circuit.

The careful reader will have noticed that we have been avoiding the issue of small-signal exact matching using the manufacturer-supplied parameters. If this is done, the narrow band response shown in Figure 3-71 will be obtained. Therefore, we must optimize the circuit for a better frequency response to obtain the one shown in Figure 3-72.

After this optimization, we were well able to meet the specification of a center band gain of 14 dB and a corresponding NF of 1.1 dB. To show the flatness of the gain, Figure 3-73 shows a gain variation in the range of 0.25 dB.

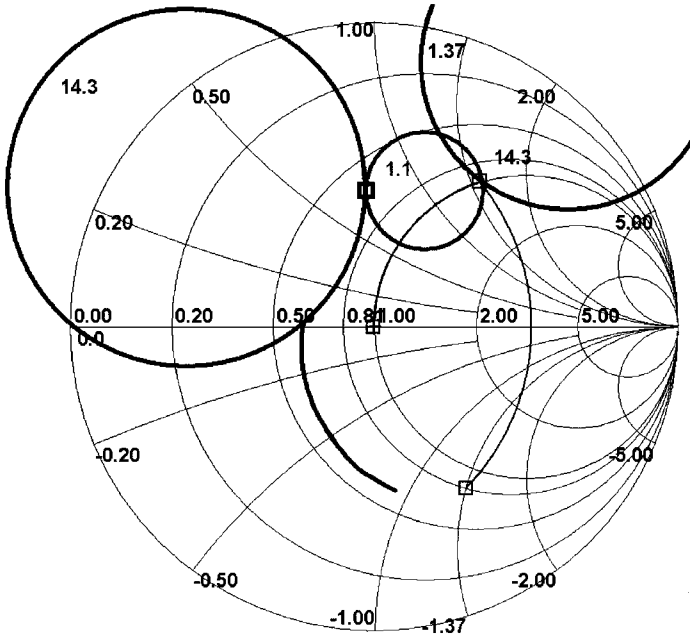

Figure 3-70 Output matching-network extraction.

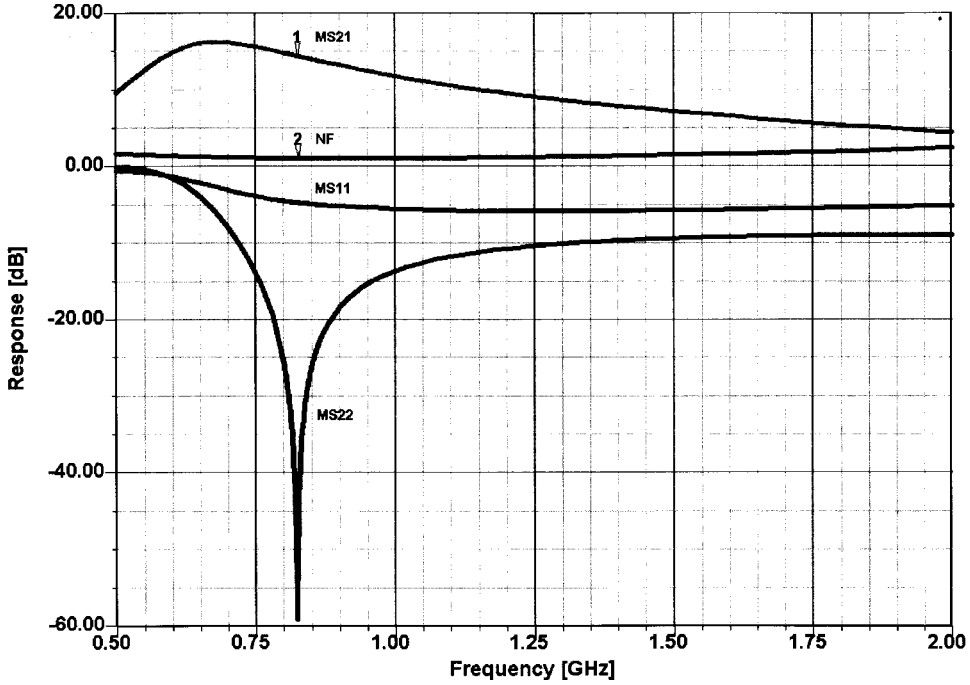

Figure 3-71 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-67.

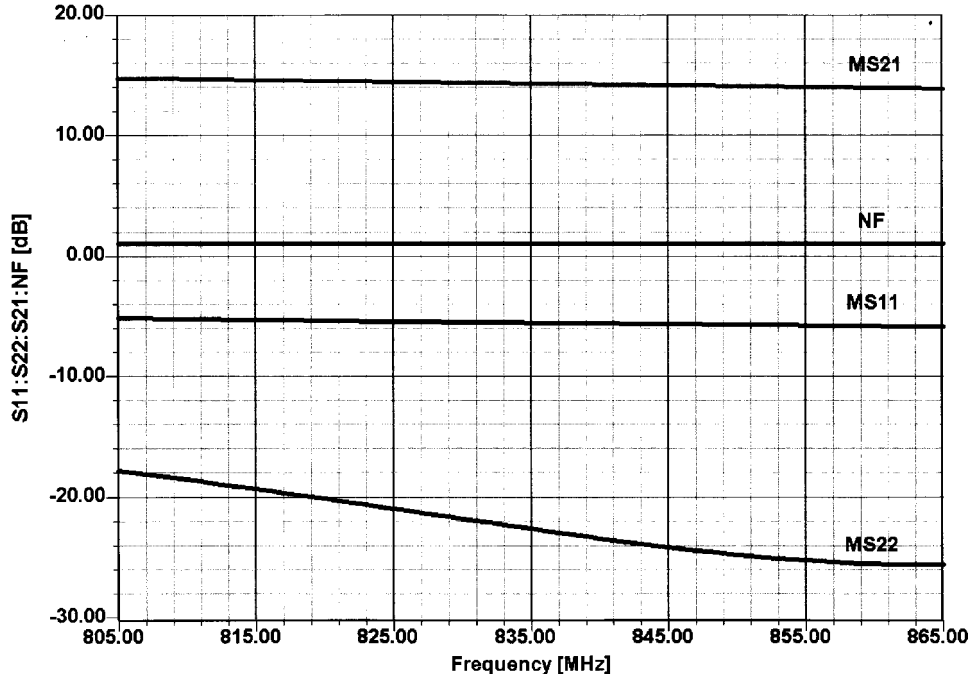

Figure 3-72 Optimized performance of input/output reflection, gain, and noise figure.

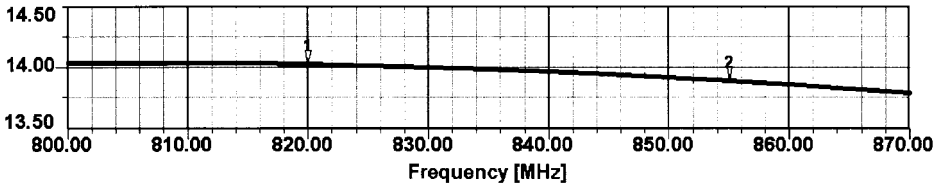

Figure 3-73 High-resolution display of gain as a function of frequency.

The next step is to look into the large-signal performance. The first order of business is to determine the third-order intercept point, which is based on a two-tone analysis. Given the fact that we run the device at low voltage and at a just-reasonable current, the actual intercept point of +13.5 dBm is quite a good number. Figure 3-74 shows the fundamental and third-order outputs. The crossover point between the two, as shown in Chapter 1, is defined as the third-order intercept point. If we had chosen the third harmonic output rather than the fundamental, we would have shown the fifth-order intercept point. The second-order IMD product ($f_1 \pm f_2$) typically can be minimized by input selectivity.

How an amplifier's linearity affects its ability to preserve the characteristics of digital signals is a major concern in wireless design. Figures 3-75 and 3-76 show constellation diagrams with the amplifier handling a PSK signal at drive levels of –40 dBm and +10 dBm, respectively. As expected, we see significant distortion at the higher drive levels due to circuit nonlinearities.

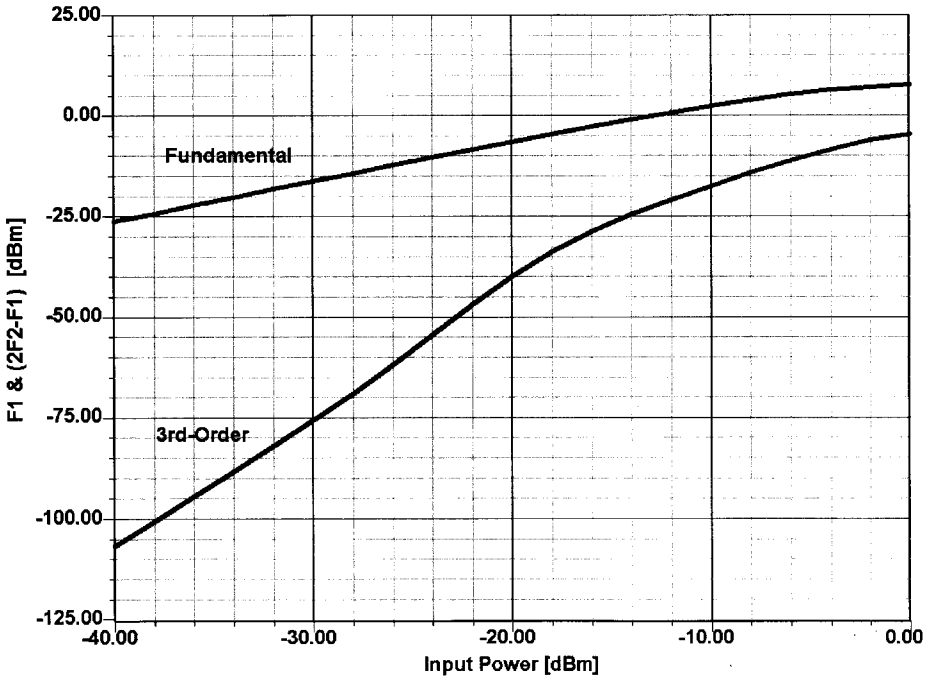

Figure 3-74 Simulated fundamental and third-order IMD outputs of the NE68133 amplifier.

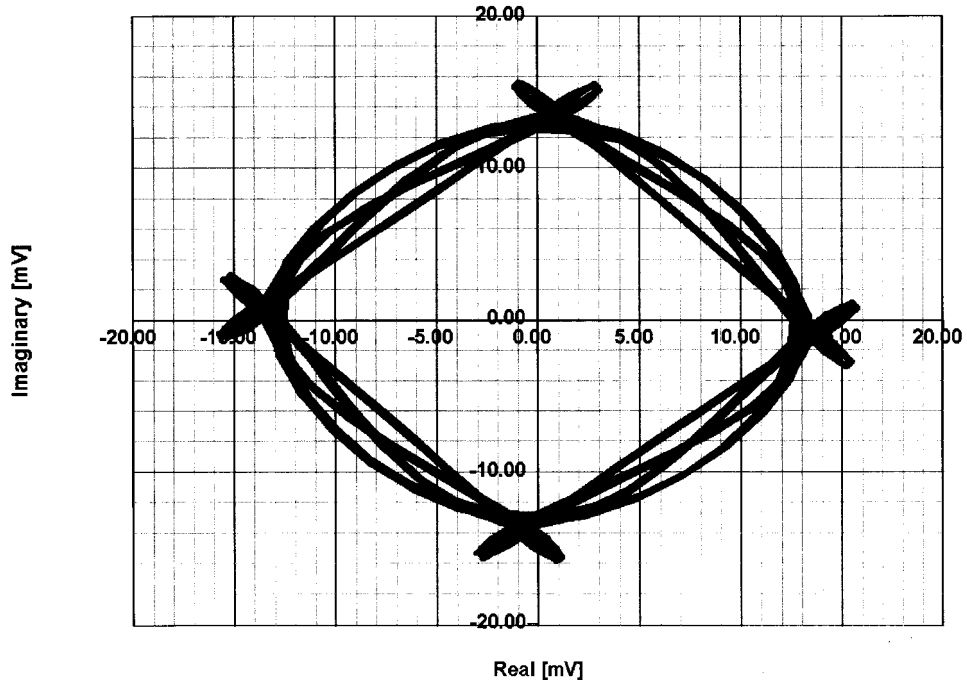

Figure 3-75 Output constellation at –40-dBm input.

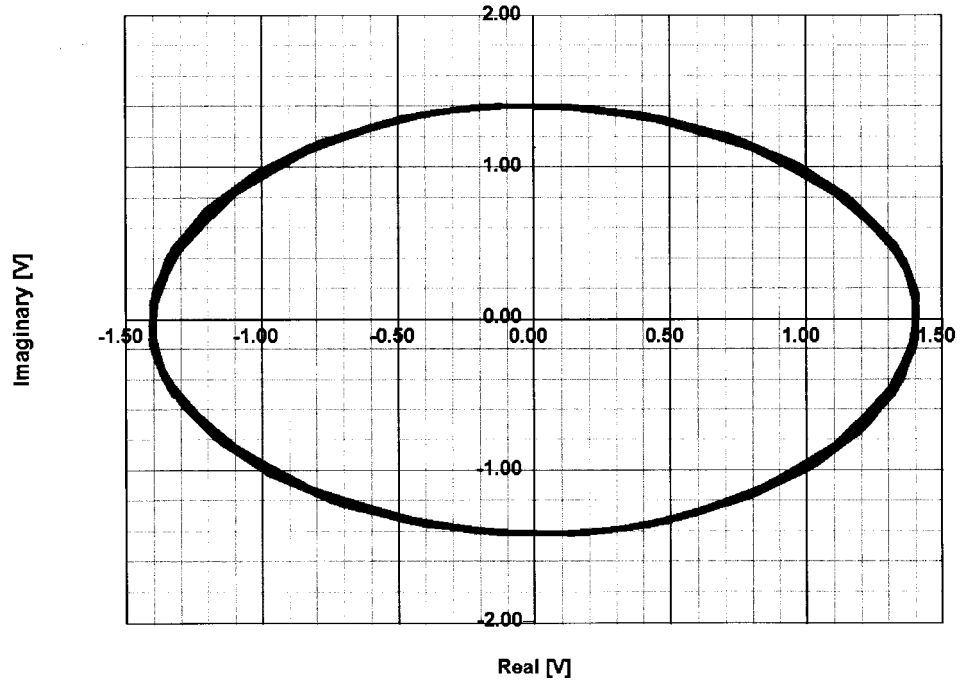

Figure 3-76 Output constellation at 10-dBm input.

BFP420 Matched Amplifier. The NE68133 has an attractive f_T of 8 GHz, but if more gain is needed, one may play with the concept of using a much "hotter" device, such as the BFP420. Recall that the NEC device was unconditionally stable, and our first worry is how the Siemens BFP420 will behave.

A study of Figure 3-77 shows that indeed the NEC device had to be stable all over and therefore was a good basis for a risk-free design. Things change dramatically with the BFP420, for which the K factor is essentially less than 1 up to a corner frequency of 2.75 GHz, where the transistor becomes unconditionally stable. Around 1.75 GHz, the K factor for the NEC transistor barely touches 1. We explained earlier that $G_{\max}$ deviating from the maximum stable gain is a more realistic number, since the conditions for maximum stable gain involve feedback and conjugate matching.

To improve the stability of the BFP420, we will now set out to use the same topology as the previous amplifier but with a resistive feedback between base and collector (Figure 3-78). A good value for this is always somewhere around 200–500 Ω. It must be remembered that this voltage feedback also stabilizes the input and output impedance and reduces the Miller effect because of the feedback being resistive and more dominant.

While the first example covered a fairly narrow frequency band, we are now attempting to cover a much wider frequency range; specifically, from 1.5 to 3 GHz reasonable gain and noise. This, by definition, requires a much higher gain-bandwidth product, and the simple matching network at the input and output provides a nonoptimal input and output matching (Figure 3-79). The feedback introduces some additional noise. This application shows the limits of single-stage UHF/SHF amplifiers with feedback.

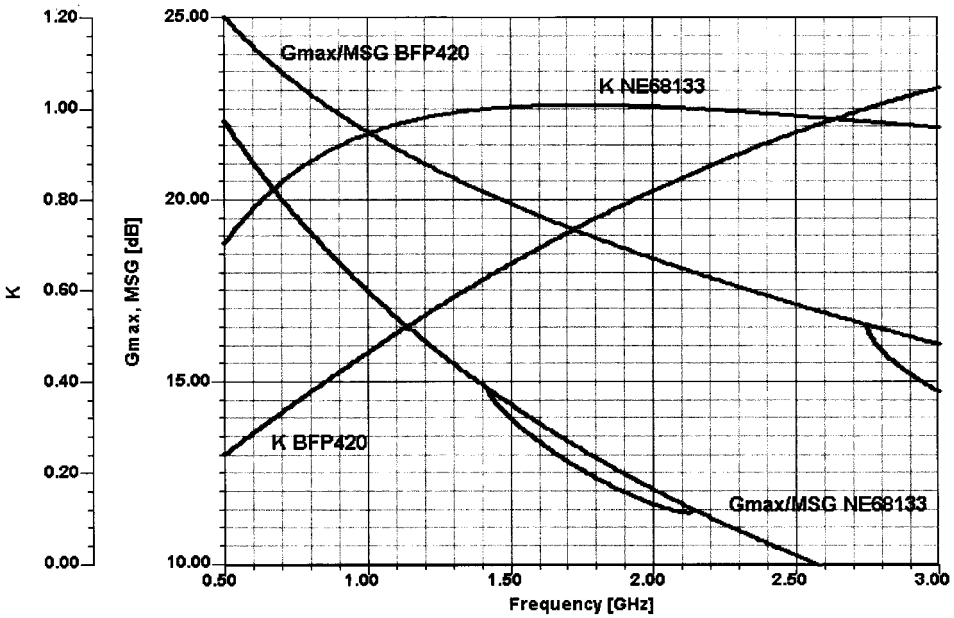

Figure 3-77 Comparison of K, $G_{\max}$, and maximum stable gain (MSG) for the NE68133 and BPF420 BJTs.

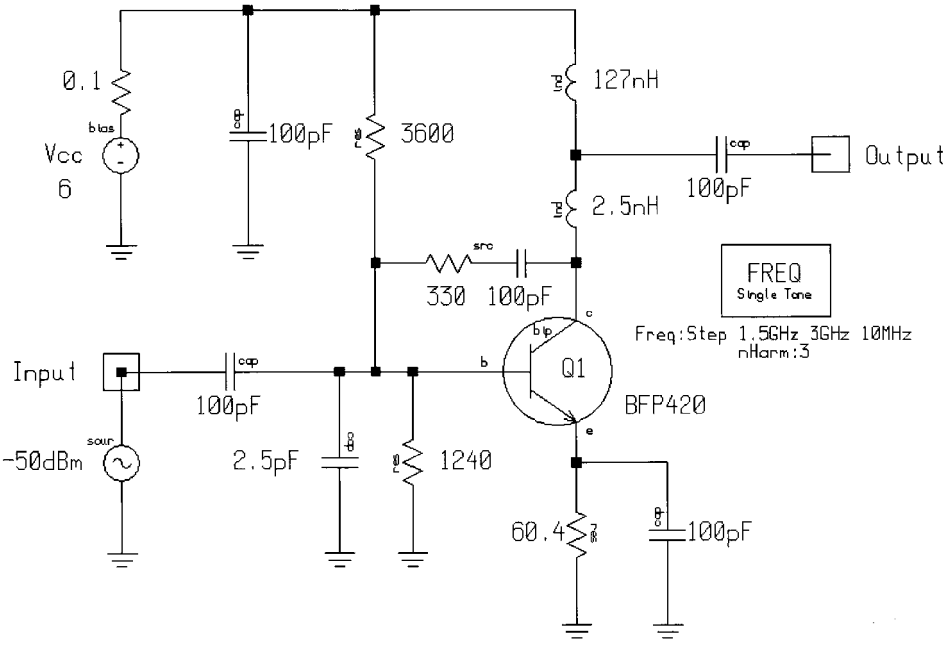

Figure 3-78 BFP420 amplifier with resistive voltage feedback from collector to base.

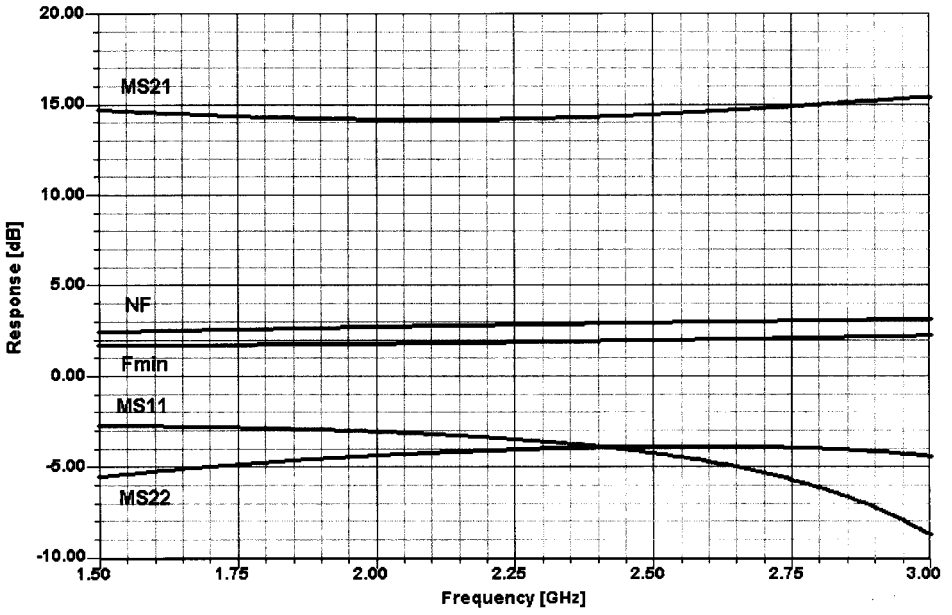

Figure 3-79 Frequency-dependent gain, matching, and noise performance of the BFP420 feedback amplifier.

Narrowband BFP420 Amplifier. Our next attempt will be to design a narrowband input stage that combines very high selectivity with good noise figure. This can only be achieved by using two tuned single-stage resonators with capacitive/magnetic coupling. The following amplifier is tailored to have a center frequency of 900 MHz. The transistor will operate at 12 V/10 mA to have a sufficient dynamic range. The input selectivity is achieved by the use of two top-coupled tuned circuits, followed by a BFP420 (Figure 3-80). The first order of business is to determine the input tuned circuit. The tuning capacitance for the two tuned circuits is arbitrarily set to a manageable 2 pF (small values have too much tolerances and larger values will require smaller inductances, resulting in lower Q). The reactance of the first tuned circuit is

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi \times 9\text{E}8 \times 2\text{E}{-}12} = 88.42\ \Omega$$

The necessary inductance for resonance will be

$$\omega L = 88.42$$

or

$$L = 88.42/\omega = 88.42/(2\pi \times 9\text{E}8) = 15.64\ \text{nH}$$

We will make both tuned circuits identical, but with different loaded Qs. By multiplying 88.42 times the loaded Q (20 for the input resonator and 50 for the output resonator), the resulting parallel-resonant resistance is $88.42 \times 20 = 1768\ \Omega$ at 900 MHz (for the input resonator) and $88.42 \times 50 = 4421\ \Omega$ (for the output resonator). These values are achieved by loading the input with the 50-Ω source and by loading the output with the input of the transistor. Therefore, the input transformation ratio $m_1 = 1768.4/50 = 35.37$. At the output, the equivalent number $m_2 = 4421/50 = 88.42$. For the purpose of simulation, and because it is extremely difficult to find the physical location of the appropriate tap on an air-wound coil for the necessary impedance, we do this "on paper" by incorporating an ideal transformer. We are also going to show later the actual transmission-line-based filter and its modeling. This filter will have a higher insertion loss based on the PC-board material used.

Using our nonlinear simulator, in small-signal ac mode, we obtain the frequency response and noise figure shown in Figure 3-81. In actually building this circuit, there is another problem besides these transformers—the top-coupling capacitor. We have used a grounded-T configuration to obtain a practically realizable value of 36 pF, whose lead inductance will not influence the circuit. (The actual coupling capacitance value for top coupling without the T configuration would have 0.1 pF. We would like to see this value repeatably realized.)

If the actual noise would be calculated relative to the output tuned circuit, the equivalent noise resistor R_n of 5 Ω would now be multiplied by m_2, resulting in 442 Ω. Fortunately, the Serenade simulator has a highly accurate BJT noise model that is both bias and temperature dependent, so the simulator will give us the answer directly.

We have not put any matching circuit at the output and leave this task to the reader. In practice, the slight tilt in the MS_{21} curve in Figure 3-81 would be tuned out. Also note that the minimum noise figure ($F_{\min}$) and the actual 50-Ω noise figure (NF) agree somewhat off center. This has to do with the Miller effect, which results in the well-known difference between noise matching and input-gain matching. By varying the coupling capacitor to move from the overcoupled response, which gives a low noise figure, to a critically coupled

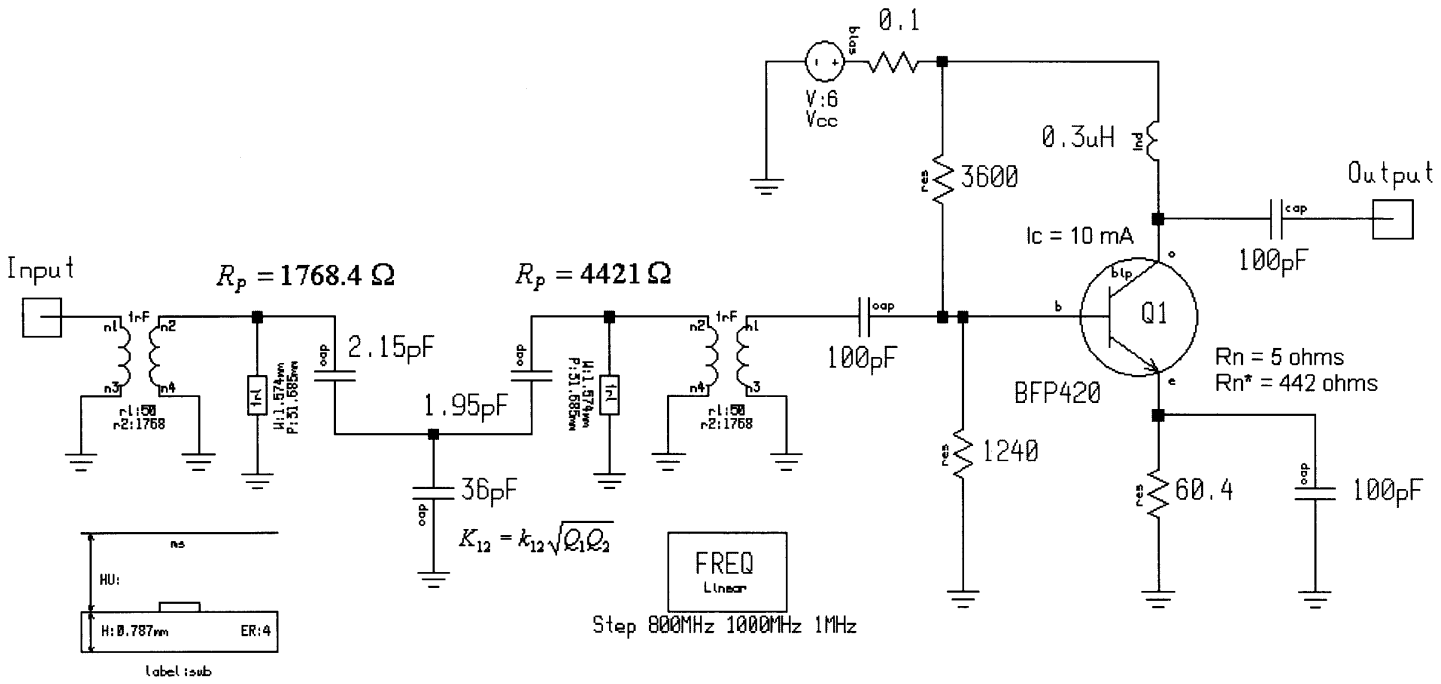

Figure 3-80 BFP420 amplifier with narrowband input filtering. Ideal transformers are used to match the filter's input and output to the input port and the BFP420 base, respectively.

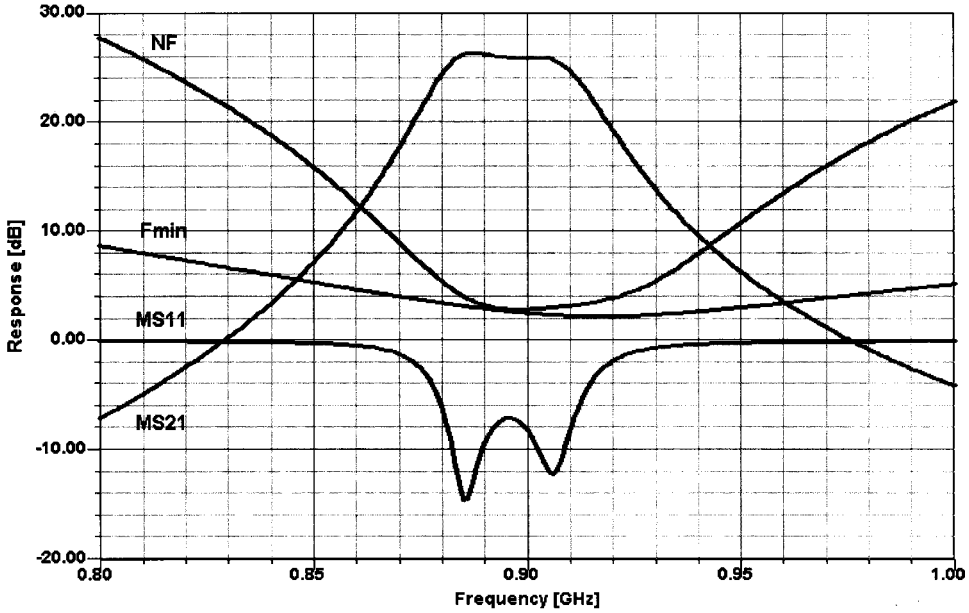

Figure 3-81 Frequency-dependent gain, matching, and noise performance of the narrowband BFP420 amplifier.

response ($K = 1$), we get significantly better selectivity and narrow bandwidth (at the obvious expense of the noise figure) as shown in Figure 3-82.

Since we somewhat compromised by not providing the reader with an actual input and output coupling that can be built, and furthermore, because the inductance in question (15.26 nH) is hard to realize with a high Q, we now show the printed circuit approach for the input filter. By using a Teflon-based material for the PC board, the losses would be less; however, the radiation would be more because ε would go down to 2.1 from the value we used (4). It is also convenient to introduce this filter to show that at higher frequencies, where lumped elements are really no longer available, one has to switch to distributed elements. A list of the commonly used distributed elements will be shown later; the transmission line and T junction are probably the most frequently used elements, followed by spiral and rectangular inductors, and bends.

The actual implementation of the input filter on a printed circuit board requires distributed elements (Figure 3-83). In practice, one has two parallel coupled lines with a tap somewhere toward the ground connection and, for modeling accuracy, we have to introduce a T junction with the appropriate impedance of 50 Ω for the input and a different impedance (if necessary) for the output. The coupling mechanism now is magnetic coupling, since no one can physically change the distance between the transmission lines by tuning some mechanical elements, one has to get it right the first time. This can only be achieved with a high-precision simulator. The reason why these simulators are so expensive is the investment of research time and personnel to produce valid models over a huge frequency and impedance range. Since we are now curious about the frequency response, we have plotted in Figure 3-84 the frequency response, which shows a higher (expected) insertion loss. The PC-board material is partially responsible for this.

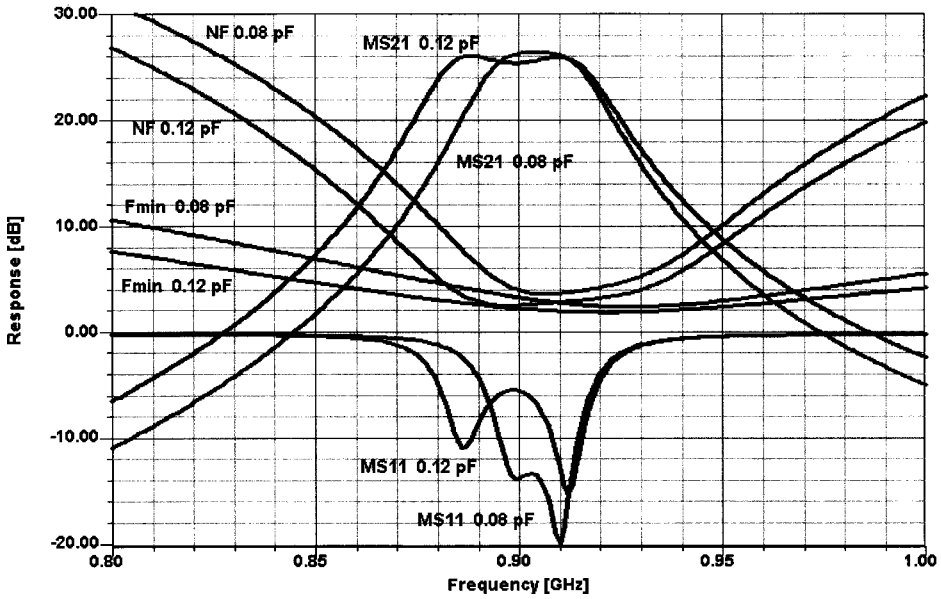

Figure 3-82 Comparison of filter responses with critical coupling (0.08-pF response) and overcoupling (0.12-pF response).

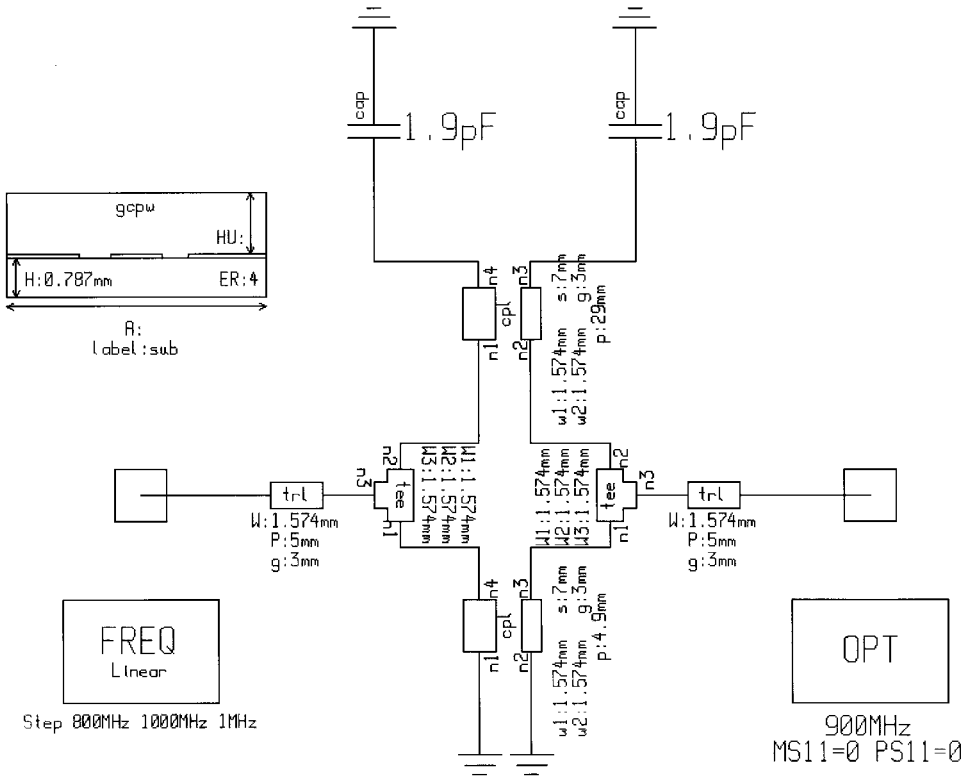

Figure 3-83 Input filter using distributed-element resonators and matching.

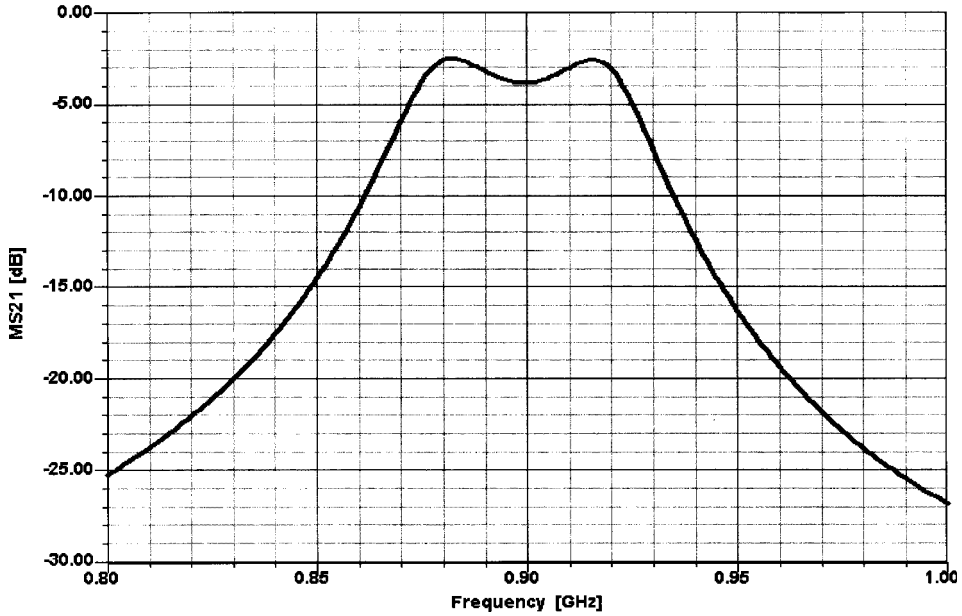

Figure 3-84 Gain versus frequency response for the distributed-element filter.

At the end of this chapter we will have a chance to discuss passive elements as needed for microwave frequencies, and one should consider frequencies above 1500 MHz as microwave frequencies.

GaAsFET Feedback Amplifier. The implementations we have shown so far have been based on bipolar transistors. Figure 3-85 shows a single-stage feedback amplifier using a GaAsFET. The feedback is based around an *LRC* network and some attempts at matching at the input and output are made. Figure 3-86 shows its frequency-dependent gain, matching, and noise performance.

3-2-3 High-Gain Amplifiers

In most cases, high-gain amplifiers receive an already amplified signal, which means we are less concerned about the signal-to-noise ratio but remain concerned about distortion. To reduce distortion, we have two options: (1) increase the dc current in the active device, which always improves the current-related distortion; and (2) add some voltage feedback, which reduces the voltage distortion. In simple terms again, only current feedback can reduce the current-related distortion of a square-law or exponential transfer characteristic and only voltage feedback can reduce the effect of overdrive as a function of the load, but only to some degree. Its main purpose remains to reduce the input impedance to useful values, specifically for FETs, since current feedback increases the input and output impedances. Some ultrasensitive circuits still require Class A operation, but now at higher current levels; these are typically CATV applications, and there are several transistors available that can be operated at 5–15 V but at 60 mA or higher. Because of the higher power consumption, this excludes handheld cordless or cellular telephones. The same circuit as used before (Figure 3-85) for

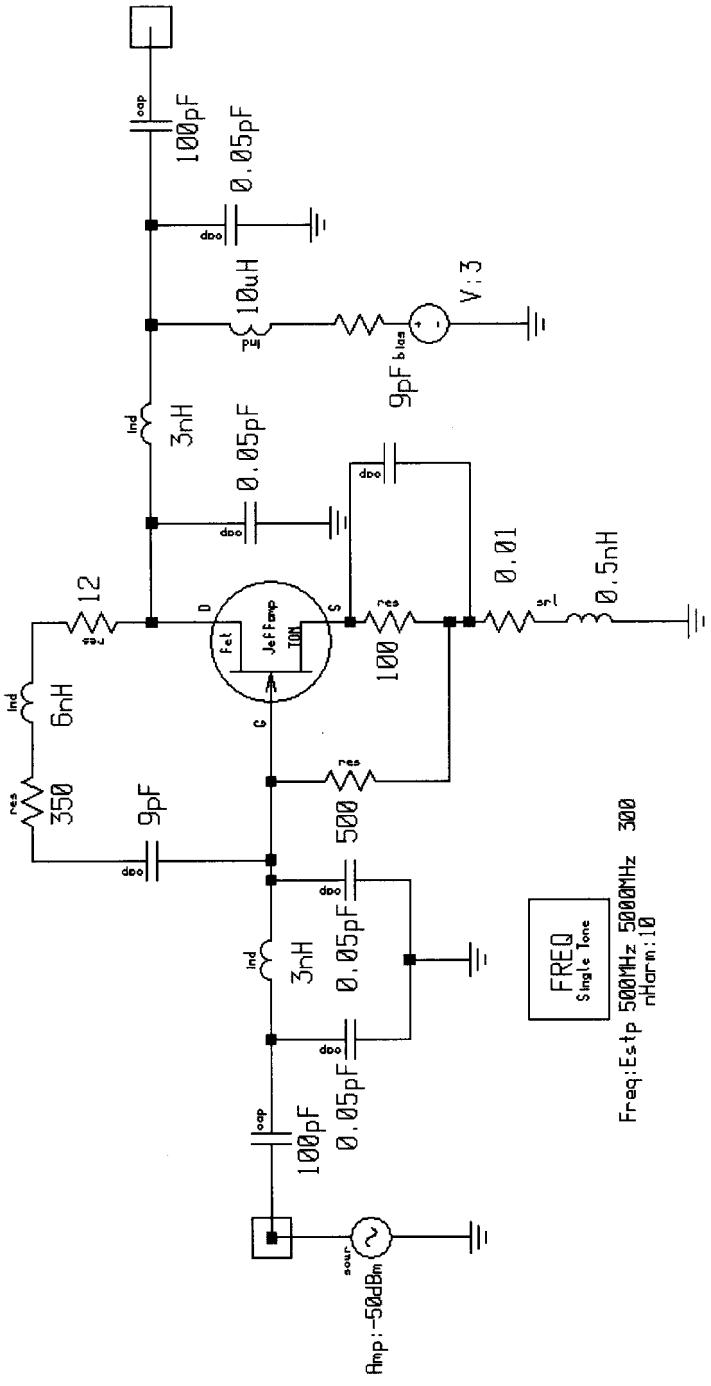

Figure 3-85 GaAsFET feedback amplifier.

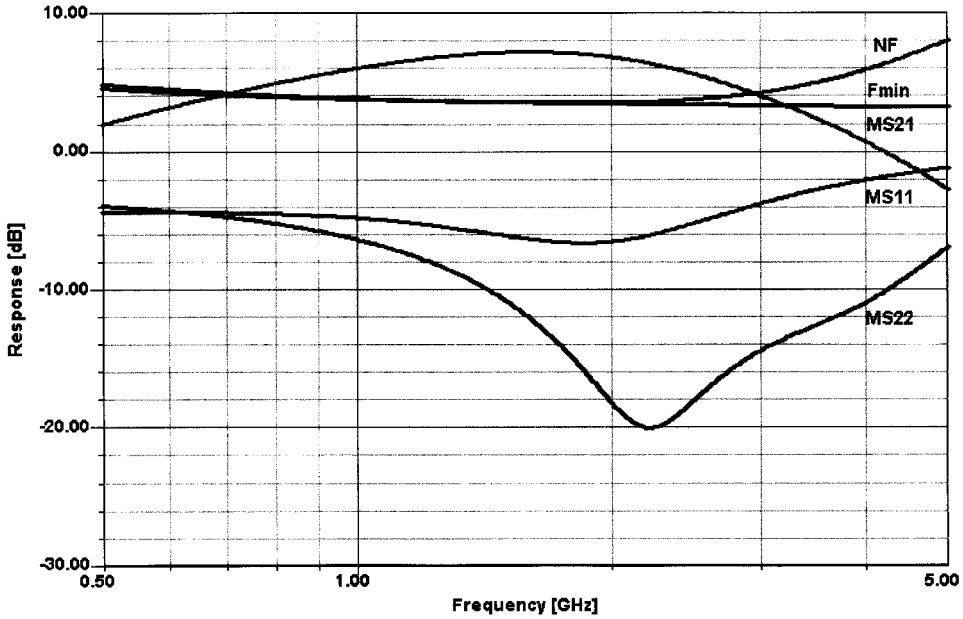

Figure 3-86 Frequency-dependent gain, matching, and noise responses for the GaAsFET amplifier.

Class A operation now can be operated at a higher current, which automatically increases the gain and the noise figure and reduces distortion. This is based on the fact that the transconductance (g_m) increases at higher currents. The second transistor in the TI circuit achieves this by being in reality a larger device, which could be modeled by several transistors, like the first stage, in parallel. This automatically increases the dc current by the scaling factor. The same is even more true for the output stage. Likewise, bipolar transistors can also be scaled. A visual inspection of some transistors in their packages will reveal that they are really not just one transistor, but several operating in parallel, each with its own ballast resistors (for bipolar transistors) or other means (for FETs).

Using tuned circuits rather than wideband matching, it is possible to go to Class AB or B operation. Class AB is really a hybrid between A and B, and Class B is probably better known. Figure 3-63 shows the Class B operating point. Most Class B stages are operated in push–pull because, together with the tuned circuit, one-half of the cycle is supplied by the other transistor. The definition of Class B operation is a conducting angle of 90° (see Figure 3-63). At this point it should be noted that some older texts define the conducting angle as being twice the value we have defined in this chapter.

Without going into further details, the highest efficiency in Class B operation is 78.5%. Based on the fact that modern wireless applications generally use a hybrid of amplitude and angle modulation, pure Class C operation finds little application today because of the severe nonlinear distortion it introduces. A Class B stage has less "power gain" than a Class A stage but provides much more output power. We have already mentioned the problem associated with characterizing a Class A stage in terms of power gain. That's the only time Kirchhoff's equations are valid, meaning that the sums of all currents and voltages have to be zero. Because Kirchhoff's equations do not consider nonlinearities and harmonic contributions,

the very moment we move into considering medium- and higher-power amplifiers, the nonlinearities will dominate and the performance of the stage is best analyzed with a high-quality circuit simulator with the appropriate dynamic range and good modeling capability. Without question, this applies to Class C operation also. As pointed out previously, the high-gain amplifier is optimized for gain rather than noise figure and typically requires more collector or drain current. This can easily be seen by rebiasing the FET amplifier as shown above to a significantly higher value of 33 mA. This is accomplished by changing the source resistor down to 3 Ω. As a result of this, we obtain the gain, matching, and noise figure responses shown in Figure 3-87.

It may be a surprise to the reader that the actual noise figure now is less than that shown in Figure 3-86. This device is now operating at 33 mA; the reason for this has to do with the fact that if the transconductance is too low, the noise figure also increases, and the NF curve for the FET has a similar-looking current-dependent minimum—a curve that is frequently not supplied by the manufacturer. This amplifier, now operating at 33 mA, should have quite good large-signal capabilities; we will examine this shortly.

Another interesting piece of information is the display of the dc I–V curves with the "load line." Since we have reactances in the circuit, we do not see a line but rather an ellipse, indicating the storage of energy. (The actual load line would be a line through the two foci of the ellipse.) This curve allows us to see immediately that at this operating point the transistor is neither going into current saturation nor becoming voltage limiting. The input power can be increased further until such a condition exists. Figure 3-88 shows the dc I–V curve for the amplifier shown in Figure 3-85.

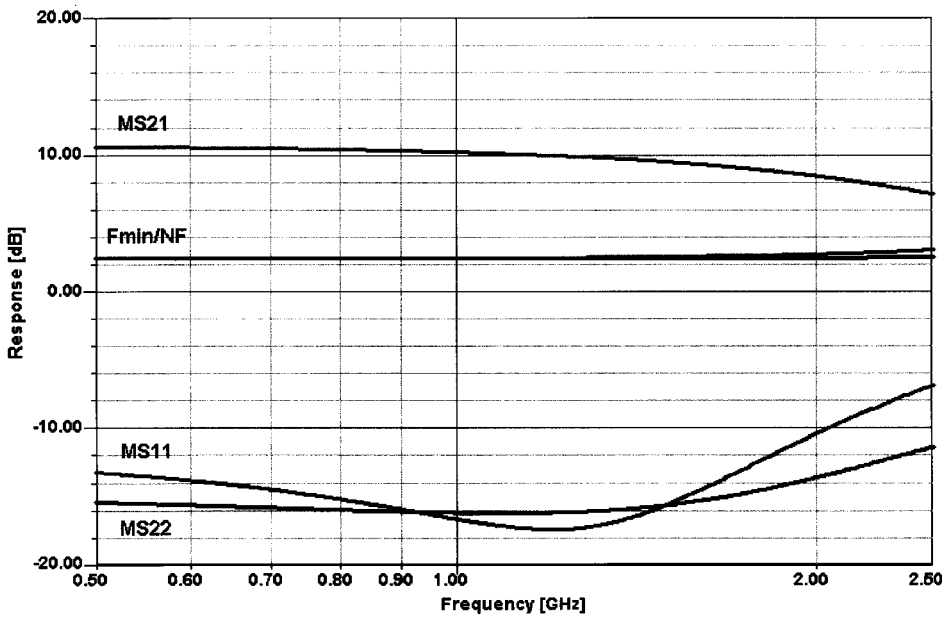

Figure 3-87 Frequency-dependent gain, matching, and noise performance for the GaAsFET amplifier of Figure 3-85 rebiased for a drain current of 33 mA.

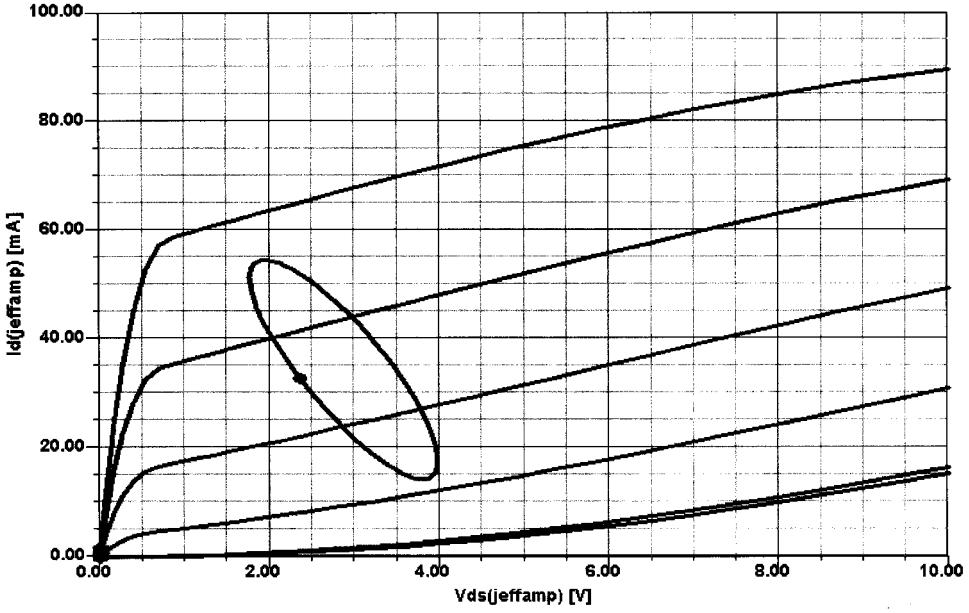

Figure 3-88 The dc *I–V* curves for the GaAsFET operating at I_D = 33 mA, including the ac load line. The load line is an ellipse rather than a straight line for the reason described in the text.

Besides looking for the adjacent-channel power ratio (ACPR), the other traditionally important points are third-order intercept point and the equivalent of a multitone simulation, as used for CATV application but relevant to the multisignal environment of wireless applications. Figure 3-89 shows the determination of the amplifier's third-order intercept point. It is most important for the reader to understand that very low values for input and output level have to be used to determine the crossover point. If this advice is not followed, totally erroneous numbers can occur.

Since an antenna supplies a large number of signals (this is true of handheld radios as well as base-station sites), a three-tone standard has been adopted as a good approximation of multisignal operation. This standard is in accordance with the German DIN 45004E,3.3 three-tone measurement. The requirement is that the intermodulation distortion products at the output are better than 60 dB suppressed relative to the largest of the three tones. One tone is used as the reference, and the other two tones are 6 dB less. This measurement has been derived from television, whereby the video transmitter, based on the vestigial sideband power, is 6 dB above the two sidebands produced by the FM sound transmitter using a modulation index of 5. The result of a three-tone test can be seen in Figure 3-90. This amplifier clearly meets the DIN specification for linearity at input levels up to –9/–15 dBm at the input.

Bipolar transistors are also quite popular for this purpose. Figure 3-91 shows a single-stage amplifier with an intrinsic transistor and all the other "hidden" intrinsics, normally not visible, added. The three diodes belong to those intrinsic elements, which are needed for accurate microwave modeling but which are not provided by the standard nonlinear models. The reader will see that we went into great detail to model all the necessary parts. This feedback amplifier, whose frequency response is shown in Figure 3-92, has been quite

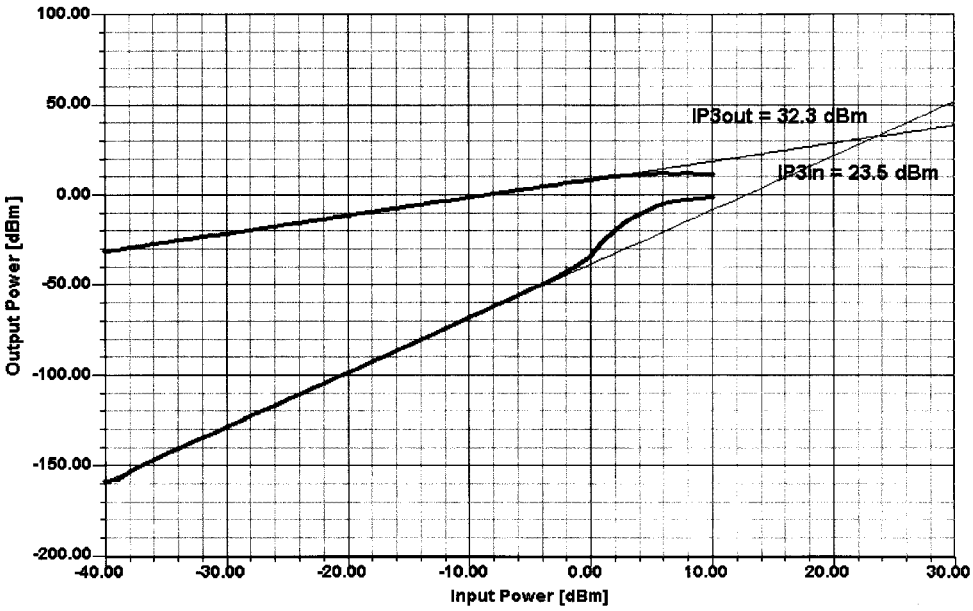

Figure 3-89 Determination of the third-order intercept point based on a two-tone measurement using tones spaced at 5% of the operating frequency (1.8 GHz).

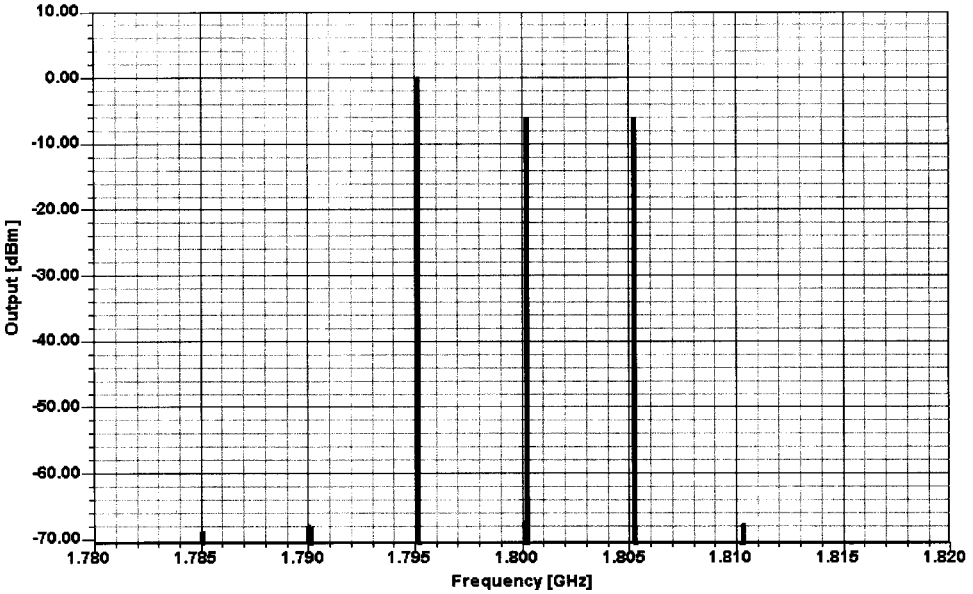

Figure 3-90 Simulated three-tone analysis of the GaAsFET amplifier with $I_D = 33$ mA.

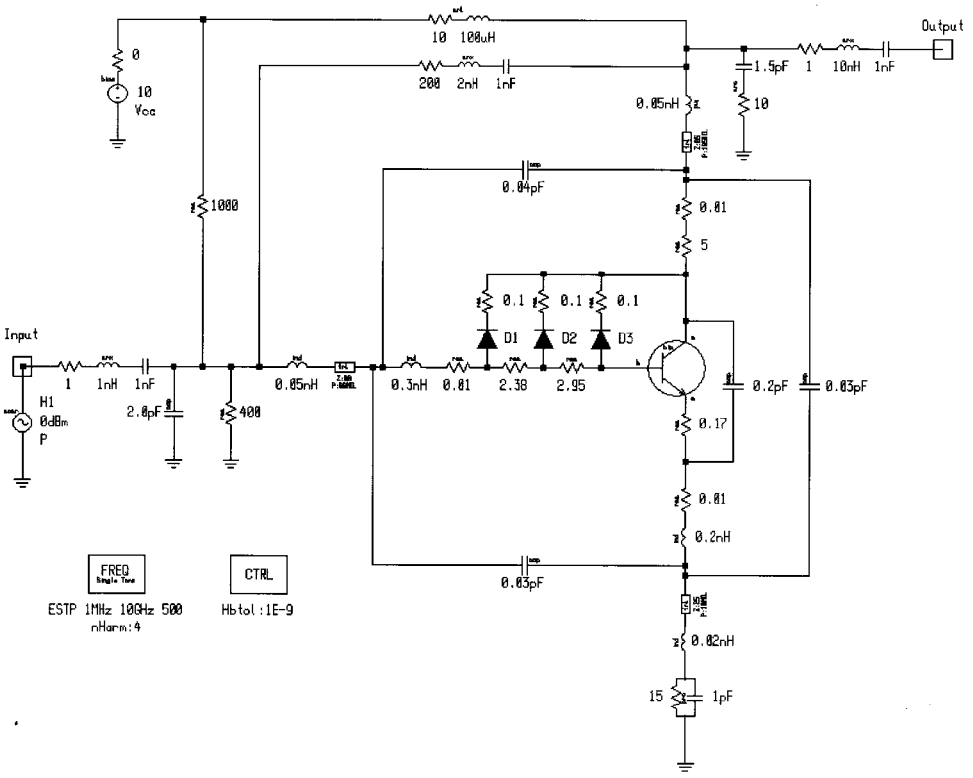

Figure 3-91 A high-linearity single-transistor amplifier modeled in great detail.

difficult to design, but there are monolithic circuits available where the higher gain–bandwidth product is being used to advantage.

Figure 3-92 shows the predicted frequency-dependent gain, matching, and noise figure at a bias point of 108 mA at 10 V. Using the same DIN three-tone test procedure, Figure 3-93 shows the expected good result.

Since this test requires two equal signals and one larger signal, we need to expect one IMD product larger than the rest. We have set our window for a dynamic range of 70 dB, and yes, in the lower left corner, we can see the product between the first two signals, while the other products are below the –50 dB level.

As a little task, Figure 3-94 shows a simple amplifier, based on a modern Siemens transistor, which is a feedback amplifier with fewer modeling details surrounding the transistor. Its associated frequency-dependent performance is shown in Figure 3-95. Interested readers are invited to improve its performance by using their skills and intuition.

Permitting higher currents and actually combining two transistors leads to our first MMIC. The following simulation is based on the MGA64135. Needless to say, there are some compensation networks inside the MMIC and distributed elements that affect the frequency response. However, with this arrangement, it is possible to obtain an appreciable gain at our wireless frequencies. The noise figure, based on the feedback, however, it not too impressive. This is a problem that occurs with most feedback amplifiers, which try to minimize the distortion and yet would like to keep the noise figure down. Figure 3-96 shows the schematic

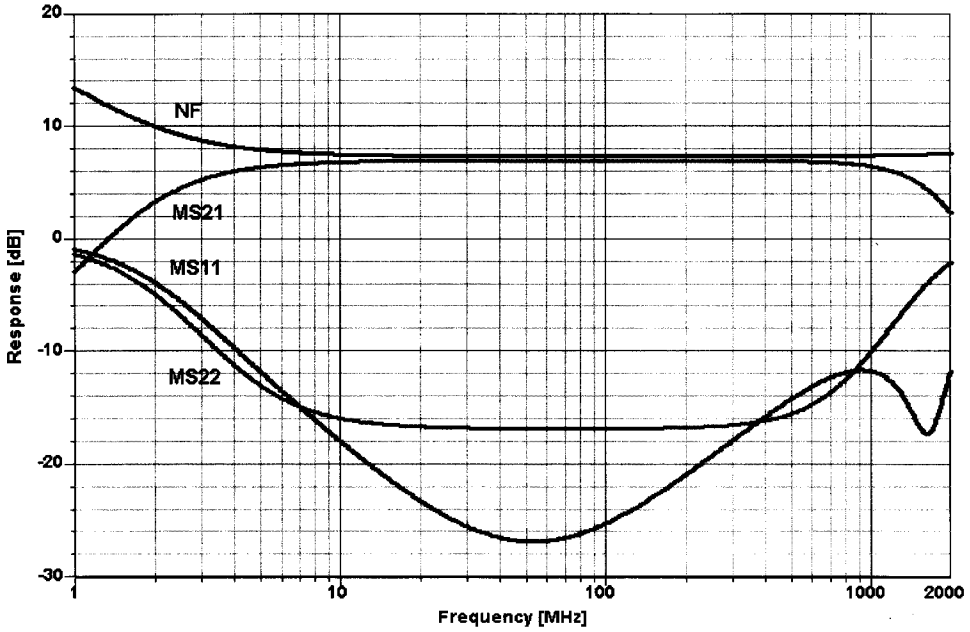

Figure 3-92 Simulated frequency-dependent gain, matching, and noise figure performance of the circuit in Figure 3-91.

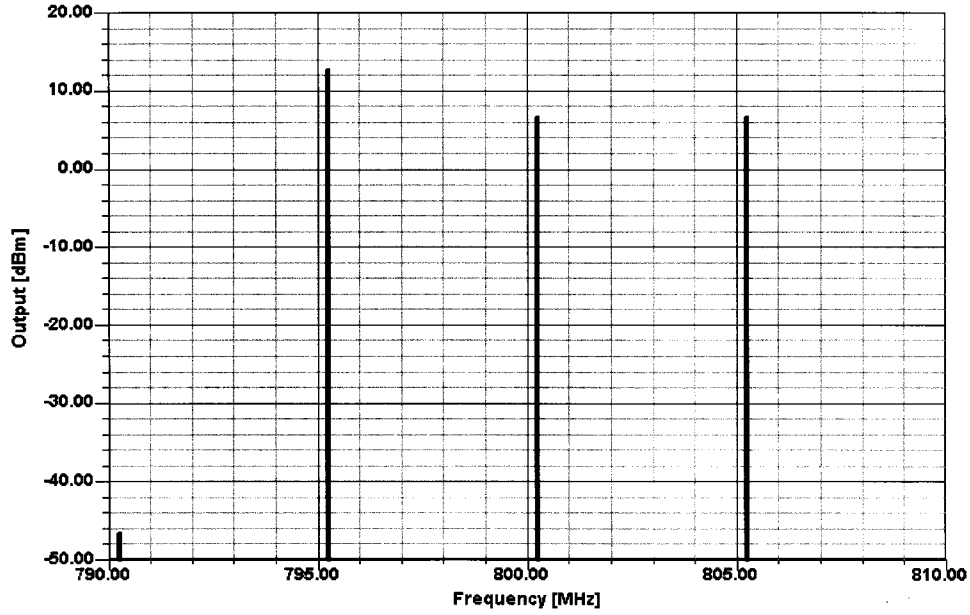

Figure 3-93 Simulated three-tone output spectrum of the amplifier in Figure 3-91.

of the GaAs MMIC; Figure 3-97 shows its frequency-dependent gain, matching, and noise performance; Figure 3-98 shows its two-tone response, which is used to obtain the intercept point ($IP_{3,in}$ = 8.5 dBm, $IP_{3,out}$ = 22 dBm); and, finally, Figure 3-99 shows the three-tone test results at an input RF level of –21/–27 dBm. While the gain–bandwidth product is considerably larger than the single-stage amplifier we examined before, the intercept point and three-tone performance do not reach the same values. As a general rule, the dynamic

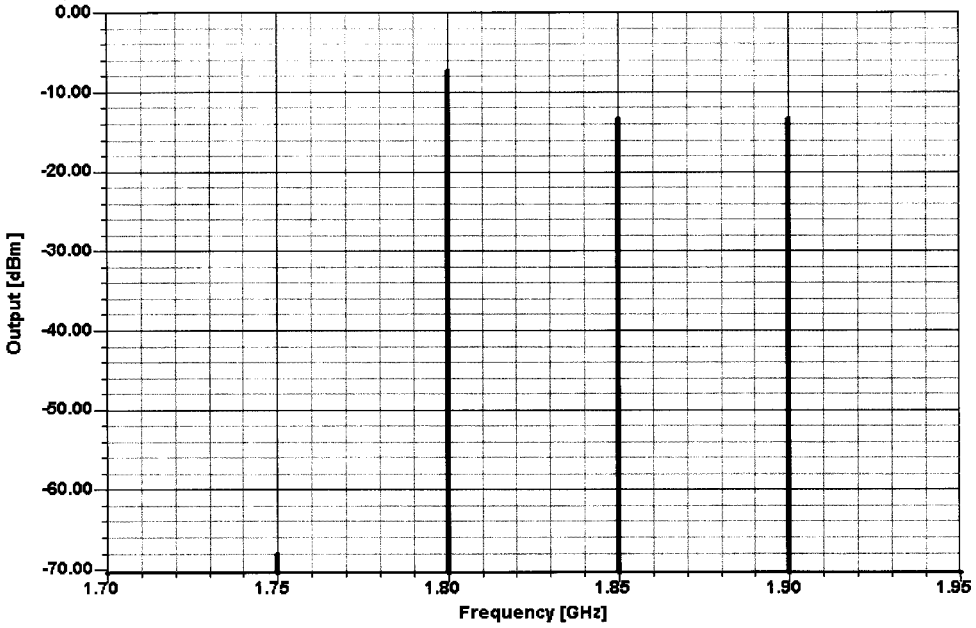

Figure 3-99 Simulated three-tone test of the MGA64135 MMIC. The test tones were 1.80 GHz (–21 dBm), 1.85 GHz (–27 dBm), and 1.90 GHz (–27 dBm). The 1.75-GHz IMD product is down 60.5 dB relative to the 1.80-GHz signal.

range is directly proportional to the power dissipated in the devices: specifically, the current. As explained earlier several times, the first-order nonlinearity comes from the voltage-to-current transfer characteristic, such as the transconductance itself, and can only be improved by a combination of resistive feedback in the emitter/source and by high currents. At these dc levels, the base–emitter (gate–source) junction gets linearized because the differential values are getting smaller compared to the parasitic loss resistances, including external dc/RF feedback. Once again, the voltage feedback reduces the voltage clipping but is initially more responsible for the input and output matching.

3-2-4 Low-Voltage Open-Collector Design [22–25]*

Why R_C Acts Like a Source Resistor. An open-collector output allows a designer the flexibility to choose the value of the R_C resistor. Choice of this resistor value not only sets the dc bias point of the device but also defines the source impedance value. Figure 3-100 shows the ac model of the transistor. Converting the output structure by applying a Norton and Thevenin transformation, one can conclude that R_C becomes the source resistance. Thus, by choosing R_C to be equal to the load, maximum power transfer will then occur.

Figure 3-101 shows an active transistor with collector and base resistors. From basic transistor theory, Eq. A in Figure 3-101 is generated and has the same form as the general equation for a straight line ($y = mx + b$).

Figure 3-101 Basic transistor analysis.

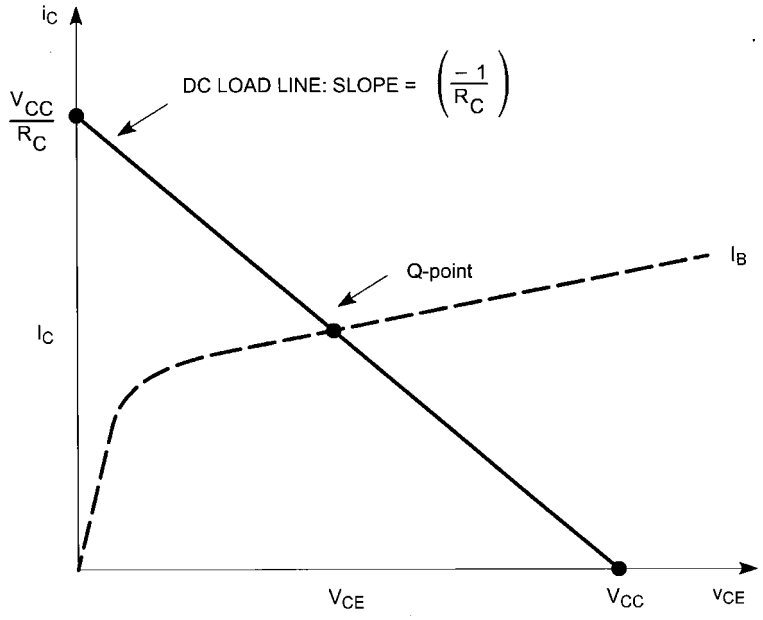

Figure 3-102 Load line and Q-point graph.

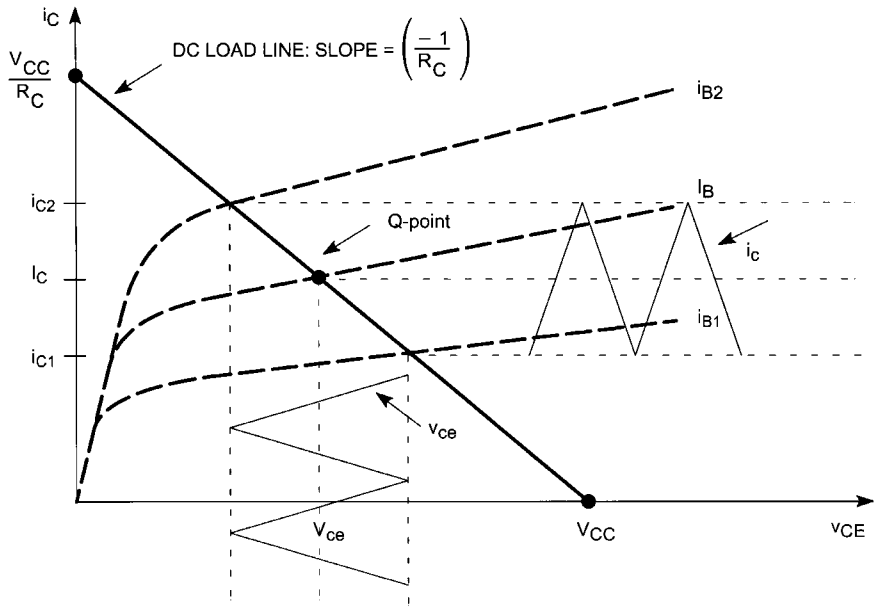

Figure 3-103 Graphical analysis for the circuitry in Figure 3-101.

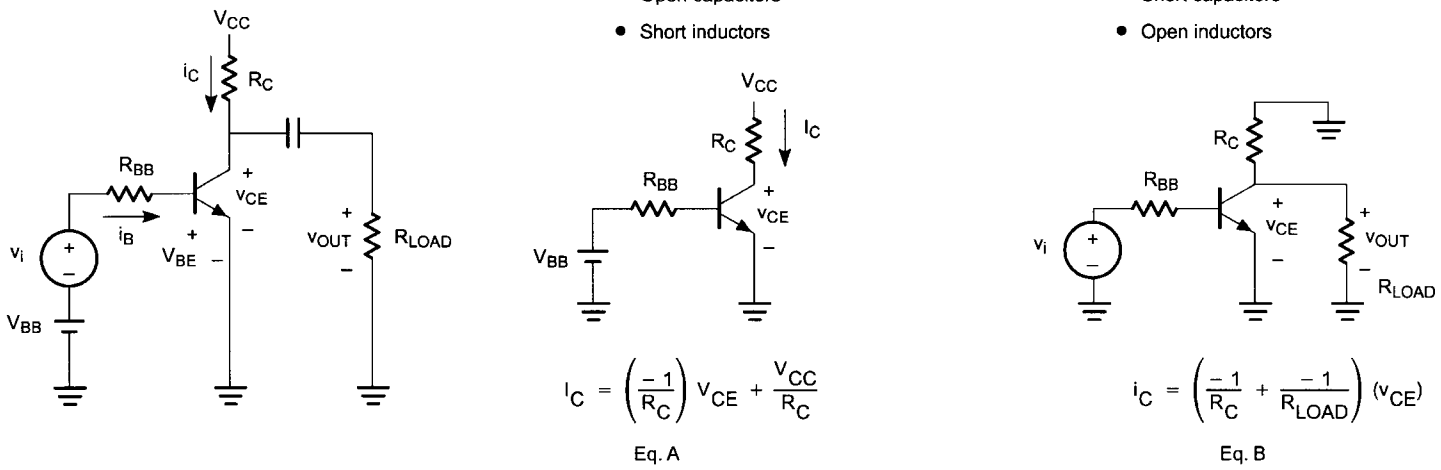

Figure 3-104 Basic transistor analysis with R_{LOAD}.

The slope of the dc load line is generated by the value of the collector resistor ($m = (1/R_C)$ and is shown in Figure 3-102. For a given small-signal base current, the collector current is shown by the dotted curve. The intersection of the dotted curve and the dc load line is called the *quiescent point* (Q-point) and dc bias determinant. The location of the Q-point is important because it determines whether the transistor is operated in the cutoff, active, or saturation region(s). In most cases, the Q-point should be in the active region because this is where the transistor acts like an amplifier.

Figure 3-103 shows the ac collector–emitter voltage (V_{CE}) output swing with respect to an ac collector current (I_C). Collector current is determined by the ac voltage presented to the input transistor's base (v_i) because it affects the base current (i_b), which then affects i_c. This is how v_i is amplified and seen at the output. Recall that this is with no external load (R_{LOAD}) present at the collector. Since no load is present, the slope of the ac load line is identical to that of the dc load line as seen in Eqs. A and B of Figure 3-101 ($m = -1/R_C$).

Open Collector with R_{LOAD}. A filter with some known input impedance is a typical load for the output of the transistor. For simplicity, we will assume a resistive load (R_{LOAD}) and neglect any reactance. Since a resistive load is used (see Figure 3-104), the ac output swing is measured at V_{OUT} or V_{CE}.

A dc blocking capacitor is used between the R_{LOAD} and the V_{CE} output to assure that the Q-point is not influenced by R_{LOAD}. It is also necessary to avoid passing dc to the load in applications where the load is a SAW filter. However, R_{LOAD} will affect the ac load line, which is seen in Eq. B in Figure 3-104. Note that the V_{CE} voltage swing is reduced; thus, the V_{OUT} signal is reduced (see Figure 3-105).

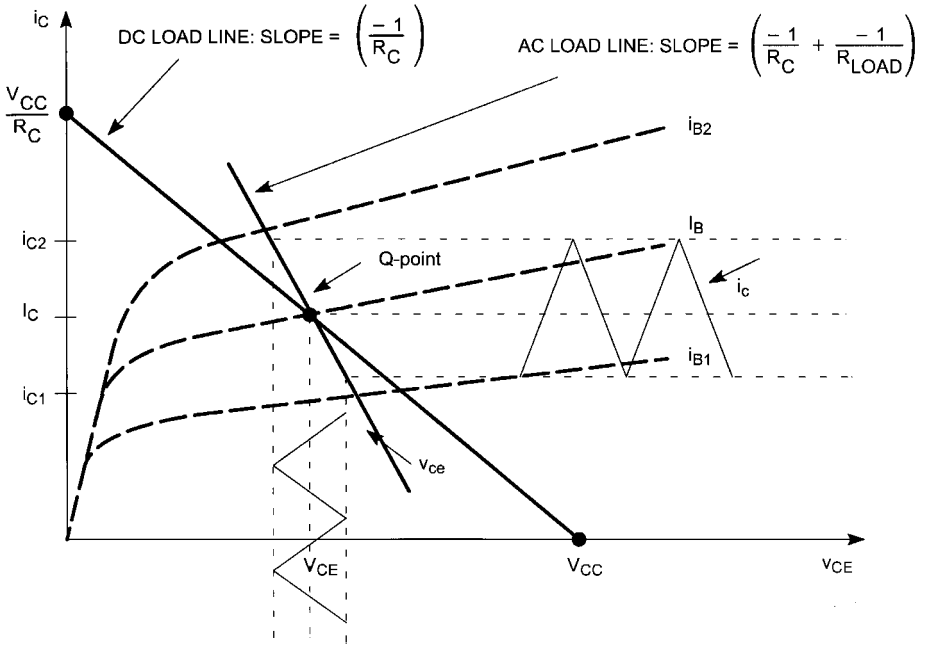

Figure 3-105 Graphical analysis for the circuitry in Figure 3-104. The ac load line intersects the Q point, and the slope is steeper than the dc load line due to R_{LOAD}, which makes V_{CE} smaller.

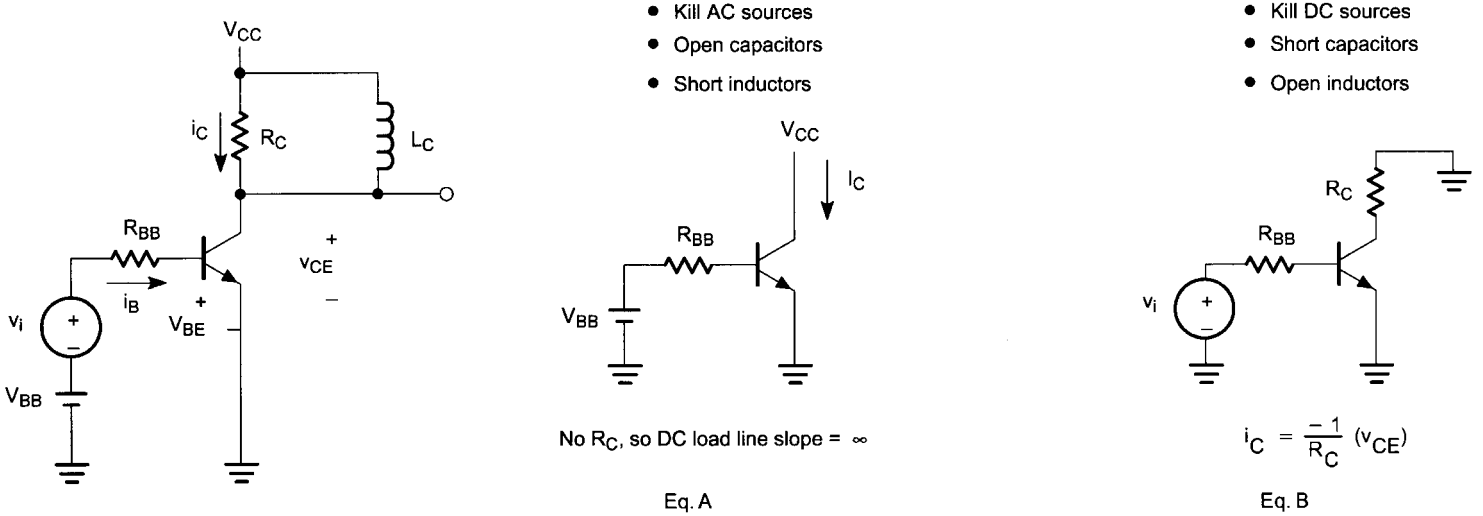

Figure 3-106 Basic transistor analysis with inductor added to collector.

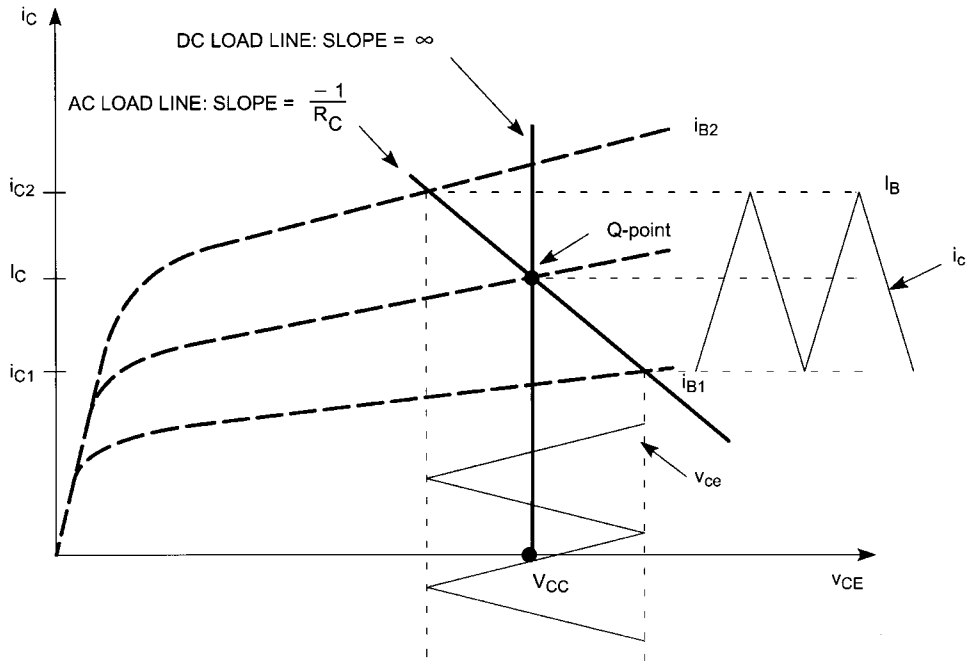

Figure 3-107 Graphical analysis for the circuitry in Figure 3-106.

Since the values of R_C and R_{LOAD} affect the ac load line slope, the value chosen is important. The higher the impedance of R_{LOAD} and R_C, the greater the ac output swing will be at the output, which means more conversion gain in a mixer. This is due to the slope getting flatter, thus allowing for more output swing.

Open Collector with Inductor (L_C). Adding an inductor in parallel with R_C can increase the ac output signal V_{CE}. Figure 3-106 shows the dc and ac analyses of this circuit configuration. In Eq. A in Figure 3-106, there is no R_C influence because the inductor acts like a short in the dc condition. This means the slope of the dc load is infinite and causes the Q-point to be centered around $V_{CC,}$ thus moving it to the right of the curve. The ac load line slope is set only by R_C because no load is present. Note that it has the same ac load line slope as the first condition in Eq. B of Figure 3-101.

Referring to Figure 3-107, one might notice that the base current (ac and dc) curves spread open as V_{CE} increases. This is caused by a noninfinite Early voltage (see Figure 3-108), which causes the collector current to be dependent on V_{CE}. Taking advantage of this nonideal condition, the peak-to-peak ac output swing V_{CE} can thereby be increased by moving the dc Q-point to the right due to the wider spreading between the curves corresponding to different base currents. Figure 3-109 combines Figures 3-103 and 3-107 to show the different ac output signals with different Q-points.

Looking at the ac output level, one might ask how the V_{CE} peak voltage can exceed the supply voltage V_{CC}. Recall that the inductor is an energy-storing device ($v = L\ di/dt$). Therefore, total instantaneous voltage is V_{CC} plus the voltage contribution of the inductor.

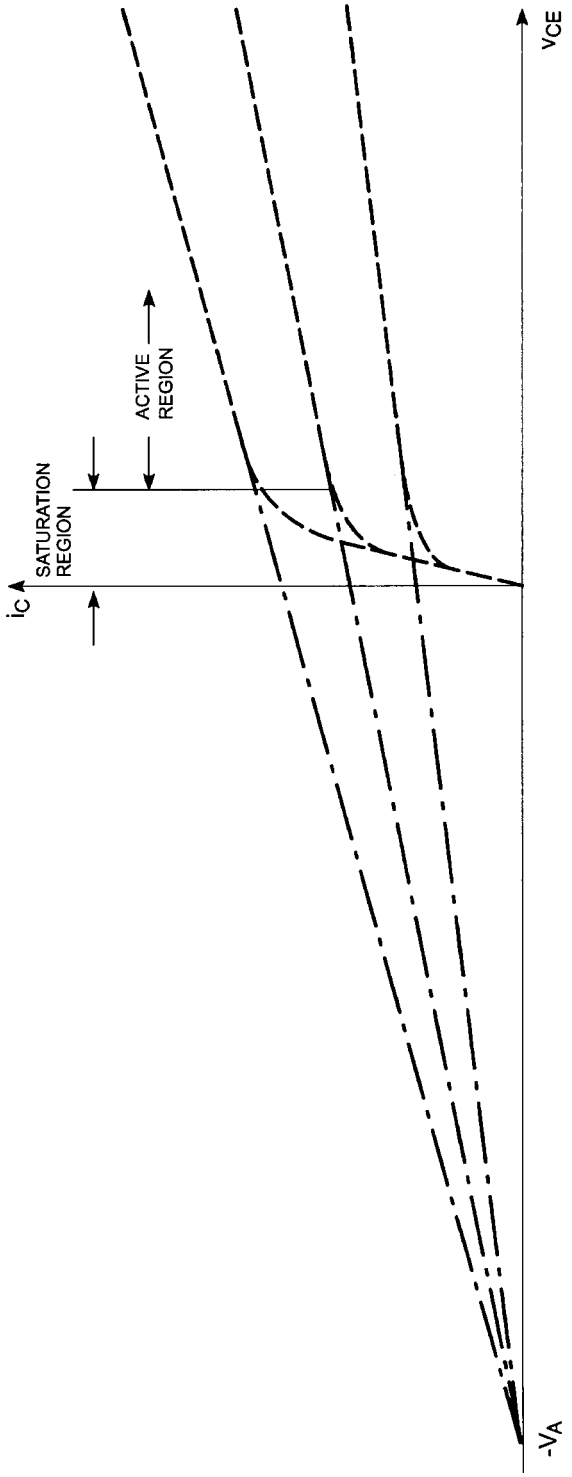

Figure 3-108 Graphical representation of Early voltage effect.

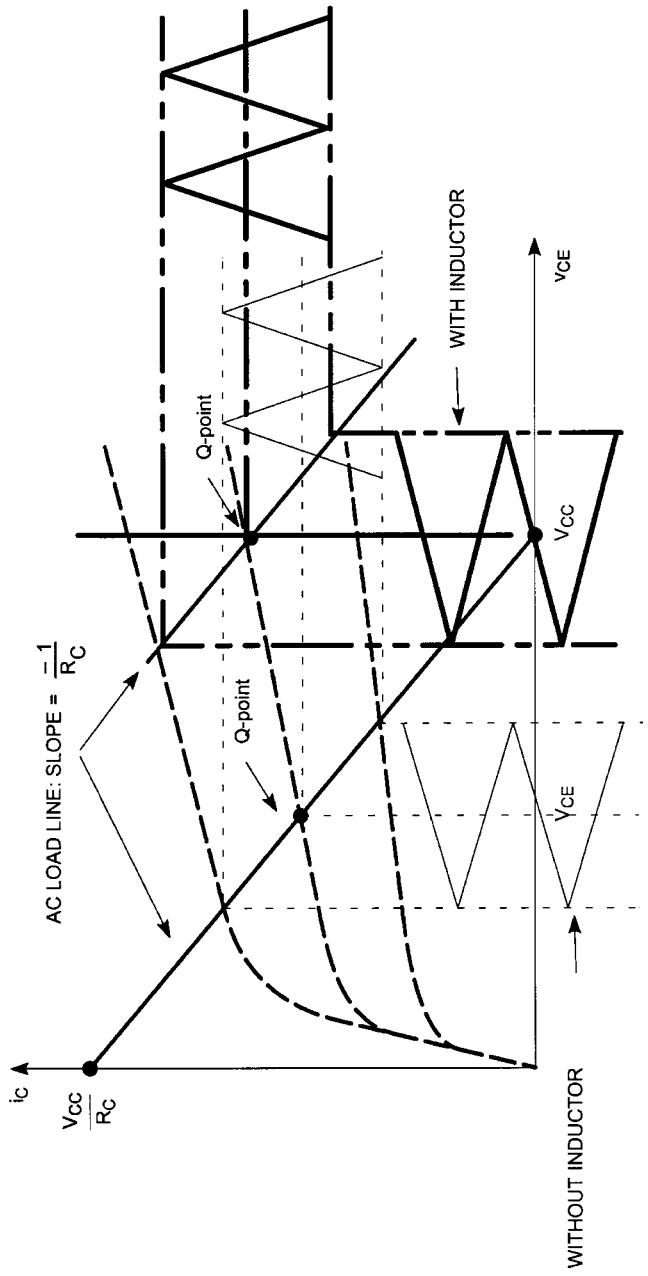

Figure 3-109 Comparison of open-collector circuit with inductor versus without inductor.

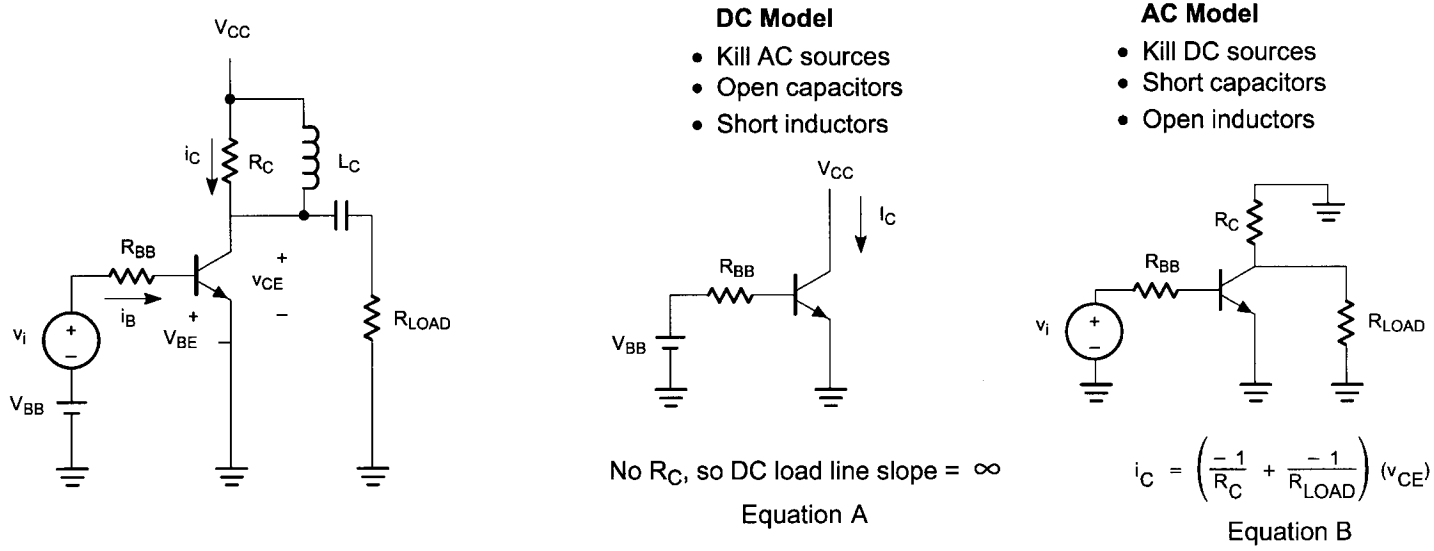

Figure 3-110 Basic transistor analysis with inductor and R_{LOAD}.

Open Collector with Inductor (L_C) and R_{LOAD}. Figure 3-110 shows the dc and ac analyses with the inductor and load resistor. Again, from the dc analysis, the inductor causes R_C to be nonexistent so the dc load line is vertical. In the ac analysis, the ac load line slope is influenced by both R_C and R_{LOAD} (see Eq. B in Figure 3-110). The ac load line slope is the same as the example of the open collector without the inductor. Figure 3-111 shows the response for the open collector with L_C and R_{LOAD}. Figure 3-112 combines Figures 3-105 and 3-111 showing the increase in ac output swing.

In conclusion, for the load line, R_C plays a role in setting up the bias-determined Q-point as well as the ac source impedance. However, when an inductor is placed in parallel with R_C, a different Q-point is set and the ac source impedance is altered. Moving the Q-point takes advantage of the transistor's nonideal i_c dependence on V_{CE} to get more signal output without having to change the base current. Since R_C is in parallel with R_{LOAD} in the ac condition, it influences the ac load line slope.

Flexible Matching Circuit [25]. A useful variation of the open-collector matching concepts previously outlined provided the capability of delivering equal power to two unequal resistive loads. This allows the power delivered to the load to be measured indirectly at another test point in the circuit where the impedance can be defined arbitrarily. If this impedance is defined to be 50 Ω, a spectrum analyzer can easily be placed directly into the circuit. This is an excellent troubleshooting technique and a valuable option to have available in high production environments.

Figure 3-113 shows the schematic for this flexible matching circuit. In this circuit, C_B functions only as a dc blocking capacitor and presents a negligible impedance at the frequency of interest. Recall from the previous open-collector matching discussions that,

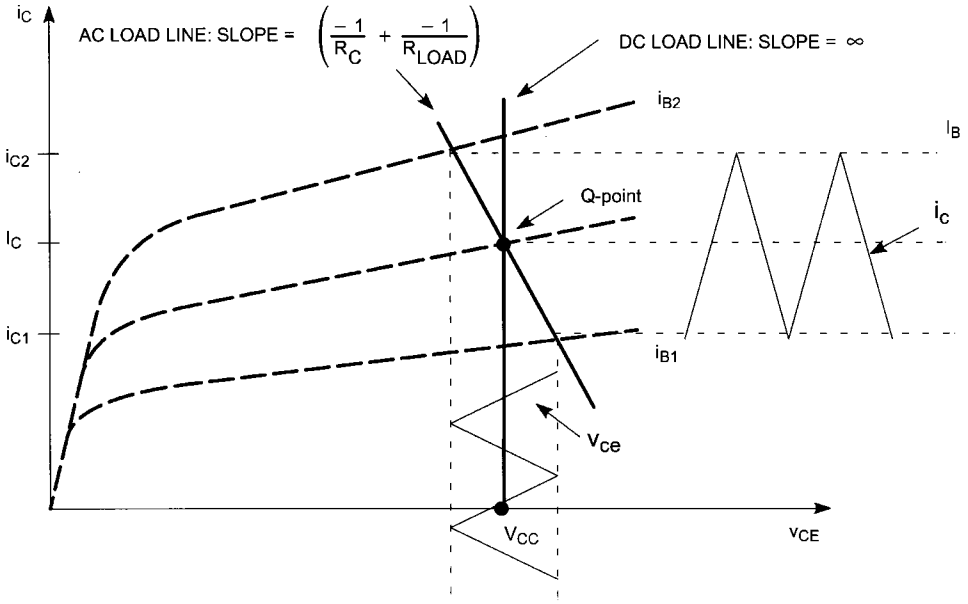

Figure 3-111 Graphical analysis for the circuitry in Figure 3-110.

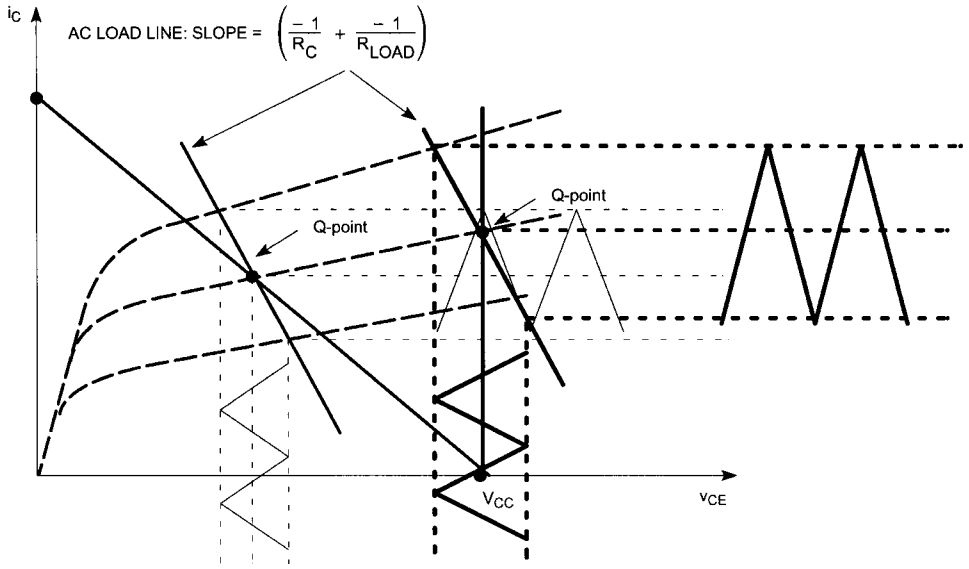

Figure 3-112 Comparison of open-collector R_{LOAD} circuit with inductor versus without inductor.

when R_C is placed in parallel with an inductor, it has no effect on the Q-point but does influence the slope of the ac load line as

$$\text{Slope} = \frac{-1}{R_C} + \frac{-1}{R_{\text{LOAD}}} \tag{3-166}$$

The capacitor C_S not only functions as a dc blocking capacitor but is also chosen such that the impedance presented by the combination of L, R_C, and C_S is equal to R_{LOAD} for optimum power transfer. The analysis is done in the following manner. First, note that inductor L is connected to V_{CC}, which is an affective ac ground. So L can be redrawn to ground. Next, R_C and C_S are converted to their parallel equivalent values as shown in Figure 3-114.

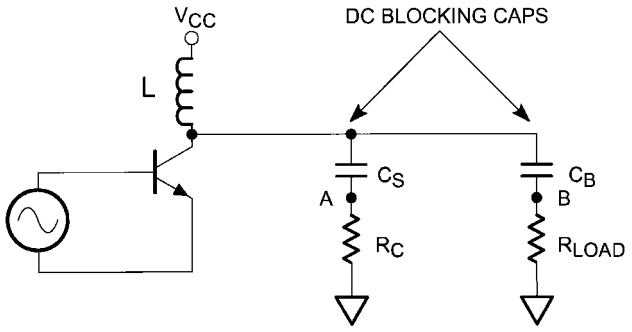

Figure 3-113 Flexible matching circuit.

Figure 3-114 Converting from series to parallel configuration.

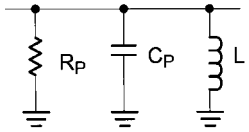

Figure 3-115 Converting from series to parallel configuration. Goal: Find L_C and C_p such that R_p looks like the R_{LOAD} value at the resonant frequency.

The resulting parallel *LCR* circuit is shown in Figure 3-115. At resonance, the parallel L–C_P combination will be an effective open circuit leaving only R_P. R_P is then simply chosen to be equal to R_{LOAD}.

Starting with the most simple transistor configuration and using *RC* types of dc-coupled amplifier circuits, we next present an overview of possible configurations for this application.

3-3 SINGLE-STAGE FEEDBACK AMPLIFIERS

This amplifier (Figure 3-116) is a standard minimal configuration amplifier with reduction of current distortion because of the emitter feedback. The voltage gain is

$$\text{VG} = \frac{R_L}{(26\text{mV})/I_C + R_e} \tag{3-167}$$

where R_L is the total load seen at the collector.

The feedback amplifier in Figure 3-117 uses voltage feedback to "correct" the input and output impedance to be close to 50 Ω but does not improve the current distortion. The voltage gain of this circuit is

$$\text{VG} = \frac{R_F}{R_g} \tag{3-168}$$

$$R_{\text{IN}} = R_{\text{OUT}}$$

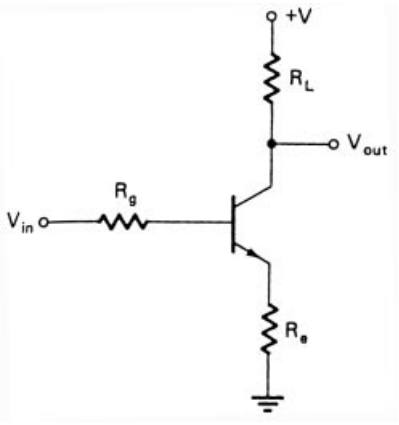

Figure 3-116 Single-stage amplifier with current feedback (provided by R_e).

$$= R_F R_D \quad \text{with} \quad R_D = \frac{26\text{mV}}{I_C} \tag{3-169}$$

Example. For $I_C = 10$ mA $\rightarrow R_D = 2.6\ \Omega$ and assuming $R_F = 200\ \Omega$, the input resistance $R_{\text{IN}} = 22.63\ \Omega$. The gain is calculated by getting the inverse of $R_D = g_m = 0.39$ A/V. Once this is multiplied with the output impedance of 22.63 Ω, the resulting gain becomes 10 log (8.6) or 9.3 dB. The gain can be increased by either using a larger collector current or a larger feedback resistor. It should be reminded that this circuit does not improve the distortion caused by the base–emitter junction.

To reduce the current distortion as well, we use the circuit shown in Figure 3-118, which contains both types of feedback. In reality, the collector–base resistor is frequently split into an unbypassed section responsible for the feedback and a larger resistor responsible for the appropriate biasing. The example circuit in Figure 3-119 shows this.

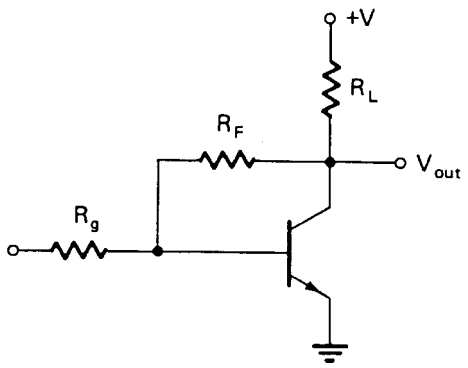

Figure 3-117 Single-stage amplifier with voltage feedback (provided by R_F).

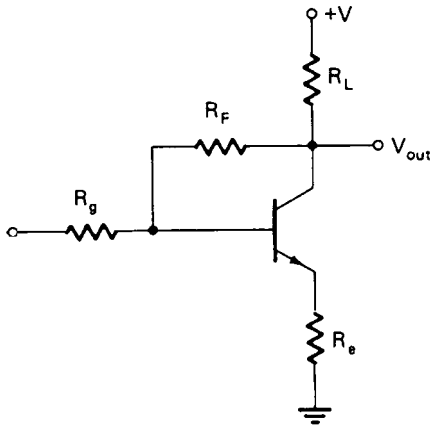

Figure 3-118 Single-stage amplifier with voltage and current feedback.

By using two of the fairly recent BFP420 transistors in parallel, and balancing the transistors by using the appropriate emitter resistors (which in total will result in 10 Ω) plus the bypassed value, we obtain the frequency-dependent gain, matching, and noise responses shown in Figure 3-120. To determine the appropriate feedback resistor R_F, we recommend the formula

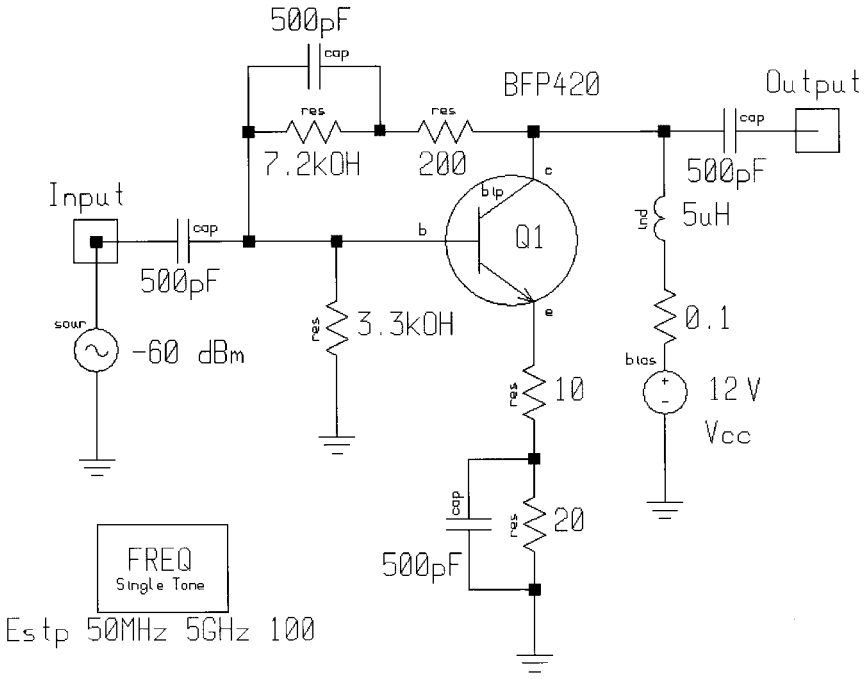

Figure 3-119 Practical amplifier circuit showing voltage and current feedback, and illustrating how reactances (in this case, 500-pF bypass capacitors) and multiple resistors can be used to provide different ac and dc resistances for the paths from collector to base and emitter to ground.

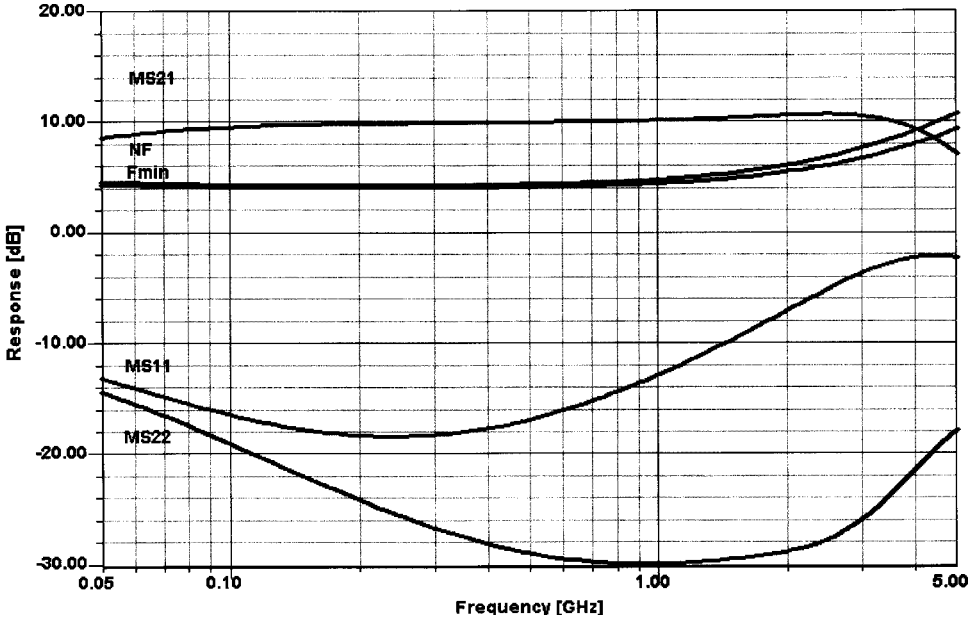

Figure 3-120 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-119.

$$R_F = \frac{(Z_{\text{in}}\, Z_{\text{out}})}{R_E} \tag{3-170}$$

This equation requires some additional comments. The combined shunt and series feedback only work as long as a sufficient transconductance is provided. In other words, there must be enough open-loop gain that will be reduced to obtain more bandwidth. A necessary condition for this approach, which really comes from the frequency range of less than 30 MHz, is that

$$Z_{\text{in}} = \frac{26\ \text{mV}}{I_C}\,\beta >> R_F \tag{3-171}$$

This requires a minimum transconductance of

$$g_m = \frac{1 + S_{21}}{Z_{\text{in}}} \tag{3-172}$$

where S_{21} must be a negative number that reflects the 180° phase shift. Of course, life becomes interesting when S_{21} goes through 1, but it (hopefully) never becomes negative and larger than 1 at the same time.

Example. The BFP420 has been used here frequently. A 10-dB gain would require an S_{21} of 3.16 ($\sqrt{10}$); therefore, we need to inspect the datasheet, which shows that the magnitude

of S_{21} is 3.16 around 4.5 GHz, yet the phase shift has changed from 180° to around 20°. In order to design an amplifier, we now set

$$R_F = Z_{\text{in}}(1 + |S_{21}|) \tag{3-173}$$

which is valid until S_{21} becomes too small. For a given 10 dB or 3.16 for S_{21}, the resulting RF is 4.16×50, or 208 Ω. The transconductance under these conditions becomes

$$g_m = \frac{1 + |S_{21}|}{Z_0} \tag{3-174}$$

where $Z_0 = 50$ Ω (the desired input impedance). g_m now becomes 83.2 mS. We now test the input and find

$$\frac{\beta}{g_m} = Z_{\text{in}} = \frac{50}{0.0832} = 600\ \Omega \tag{3-175}$$

Therefore, the emitter feedback resistor is not necessary to meet the previously mentioned condition whereby the input impedance needs to be higher than RF. Assuming the transconductance now is 0.00832, or 10% of the previous value, the input impedance would be 60 Ω, no longer meeting the prescribed requirement. Therefore, we need an unbypassed emitter resistor that fulfills the equation

$$R_E = \frac{Z_0^2}{R_F} - \frac{1}{g_{m_{\text{dc}}}} \tag{3-176}$$

where

$$g_{m_{\text{dc}}} = \frac{1 - S_{21_{\text{max}}}}{Z_0} \tag{3-177}$$

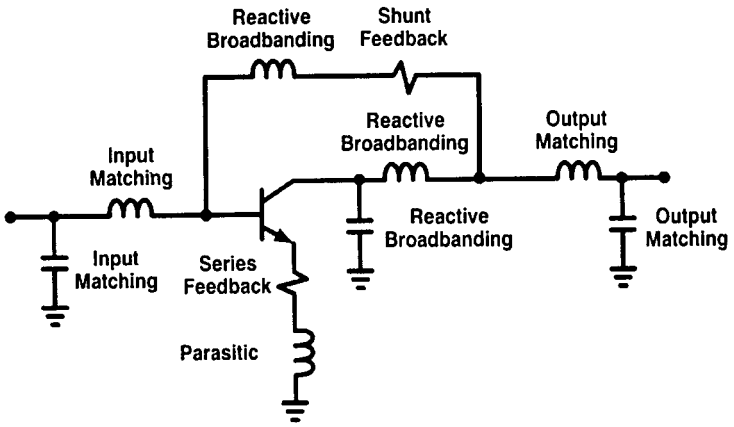

Figure 3-121 Elements of a feedback amplifier.

Again, the reader should be cautioned that in the common-emitter circuit, there is a 180° phase shift, and therefore $S_{21_{\max}}$ is a negative quantity, resulting in reality in

$$g_{m_{\text{dc}}} = \frac{1 + S_{21_{\max}}}{Z_0}$$

In our case,

$$g_{m_{\text{dc}}} = \frac{-S_{21}}{2Z_0} = \frac{38}{2 \times 50} = \frac{38}{100} = 0.38$$

so

$$R_E = \frac{50^2}{208} - \frac{1}{0.38} = 12 - 2.6 = 9.4\ \Omega \tag{3-178}$$

In practice, the designer would use a 10-Ω resistor.

Since the gain of the transistor continues to fall as a function of frequency, one can compensate to a degree for the cutoff frequency by putting an inductance in series that follows the equation

$$L_F = \frac{R_F}{2\pi f_{3\text{dB}}} \tag{3-179}$$

Assuming $f_{3\text{dB}}$ = 2 GHz, the resulting series inductance L_F = 16.6 nH. Basically, the same applies to circuits where the second transistor is used as an emitter follower to feed the signal back from the collector to the base of the first transistor.

In summary (see Figure 3-121):

- Resistive negative feedback at lower frequencies reduces open-loop gain and simultaneously matches input and output.
- Reactive elements set the gain and matching at high frequencies. Feedback is reduced at high frequencies.
- Emitter bypass capacitors are not used, as they would destroy the impedance match.

This is equally valid for FETs.

The next level of complexity can be reached by using two transistors with dc feedback.

3-3-1 Lossless or Noiseless Feedback

All the amplifiers shown above are based on a combination of resistive and reactive feedback. The very moment resistive feedback is used, the noise figure increases, as does the intercept point. As long as the intercept point increases overproportionally compared to the noise figure, this is an acceptable method. However, there are many cases in which an extremely low noise figure and a higher than normally achievable intercept point are required. To avoid this degradation of performance, Norton of Anzac developed a negative feedback structure based on the capabilities of the ferrite transformer. This patented technique (U.S. Patent Nos. 3,624,536 and 3,891,934, since expired), known as *lossless feedback*, provides lower noise figure and higher linear output than can be achieved using resistive feedback with the same transistor. Transformer feedback is used in which the transformer in the feedback network acts as a directional coupler. The coupling ratio between the input and output of the coupler

determines the magnitude of the feedback, and hence the gain. Across the frequency band over which the transformer operates as intended, the feedback is negative due to the in-phase coupling and the inversion of the active device.

This technique was used in amplifiers ranging from 5 to 500 MHz, 20 to 1000 MHz, and 300 to 1800 MHz. The difficulty associated with this type of amplifier is the fact that it is based on transformers that use twisted pairs of wires as transmission lines. In some implementations used at higher frequencies, actual directional couplers were used at the expense of bandwidth; in these circuits, the coupling was determined by the spacing of the coupler lines rather than transformer turns ratio. These microstrip couplers have much narrower bandwidths than transformers and are fairly large.

Another headache with the lossless feedback design is the fact that many of these transistor configurations are used in either grounded-base or grounded-emitter with transistors that have f_T values of 25 GHz and higher. Such devices are very hot, and achieving freedom from oscillation over a wide frequency range is a continuing problem, even for the circuits we have shown so far. A similar clever technique has been implemented in the termination-insensitive mixer, which we will examine in Chapter 4.

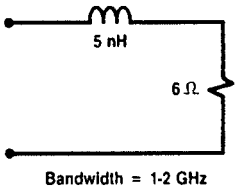
3-3-2 Broadband Matching

The circuitry above has enabled us to extend the frequency range of the amplifier and avoid the normal sharp cutoff. According to Fano [26], there is a limit to the bandwidth of matching. The concept is that impedance plus bandwidth determines the ability to match, since there is a Q of the circuit and there is a Q of the device. The following equations are valid:

$$|\rho_{\text{Bode}}| = e^{-(\pi Q_T / Q_{BP})} \tag{3-180}$$

$$Q_T = \frac{\sqrt{f_1 f_2}}{f_2 - f_1} \tag{3-181}$$

$$Q_{BP} = \frac{\text{Im}(Z)}{\text{Re}(Z)} = \frac{X_s}{R_s} \tag{3-182}$$



$$Q_{BP} = \frac{2\pi\sqrt{(2\text{ GHz})(1\text{ GHz})(5\text{ nH})}}{6\,\Omega} = 7.40$$

$$Q_T = \frac{\sqrt{(2\text{ GHz})(1\text{ GHz})}}{(2\text{ GHz} - 1\text{ GHz})} = 1.414$$

$$|\rho_{\text{Bode}}| = e^{-\left(\frac{\pi(1.414)}{7.40}\right)} = .549$$

$$\text{VSWR}_{\text{Bode}} = \frac{1 + .549}{1 - .549} = 3.43 : 1$$

Figure 3-122 Broadband matching example showing the Bode limit.

Figure 3-122 shows an example. This combination results in a VSWR of 3.43, which for practical purposes is already too high. The workaround is special circuitry (such as exponentially staggered impedance jumps in the matching network like 50 Ω > 20 Ω > 7 Ω > 3 Ω). This means we first transform the 50-Ω source of load impedance down to 3 Ω, and then look for a matching network that matches the transistor output/input, which is within a few ohms of 3 Ω. A detailed discussion of such matching can be found in the "Numerical Design" portion of Section 3-12-2 under the title "Broadband Matching Using Bandpass-Filter Networks—High-Q Case."

3-4 TWO-STAGE AMPLIFIERS

There are two popular configurations that have been used mostly for low-frequency applications. The first one (Figure 3-123, implemented in the circuit shown in Figure 3-124) shows a nice high-frequency performance assuming the emitter and collector currents are essentially the same. As for distortion products, this circuit behaves equivalently to the shunt impedance example from Figures 3-118 and 3-119, with the additional gain of the second transistor. Its frequency matching and noise performance are also shown, in Figure 3-125.

The next two-stage circuit (Figure 3-126, implemented in Figure 3-127) uses the collector current of the second stage as the feedback to the first. Proper biasing of this circuit is quite difficult and interactive. Figure 3-128 shows the frequency-dependent gain, matching, and noise figure. We believe that this circuit can be optimized further, but we leave such investigations to the reader.

A *cascode* amplifier is a special form of two-stage circuit. Although a cascaded pair acts like a single transistor, its merits are in its reduced feedback and resulting higher gain–bandwidth product. Figure 3-129 shows a simple cascode application that assumes the presence

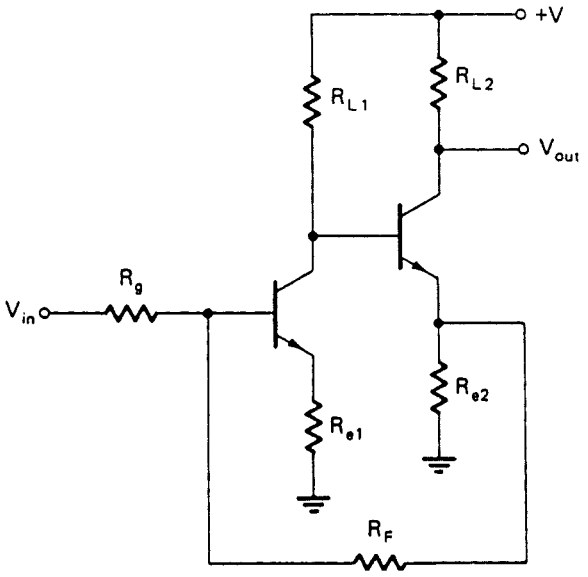


Figure 3-123 Two-stage amplifier with voltage feedback.

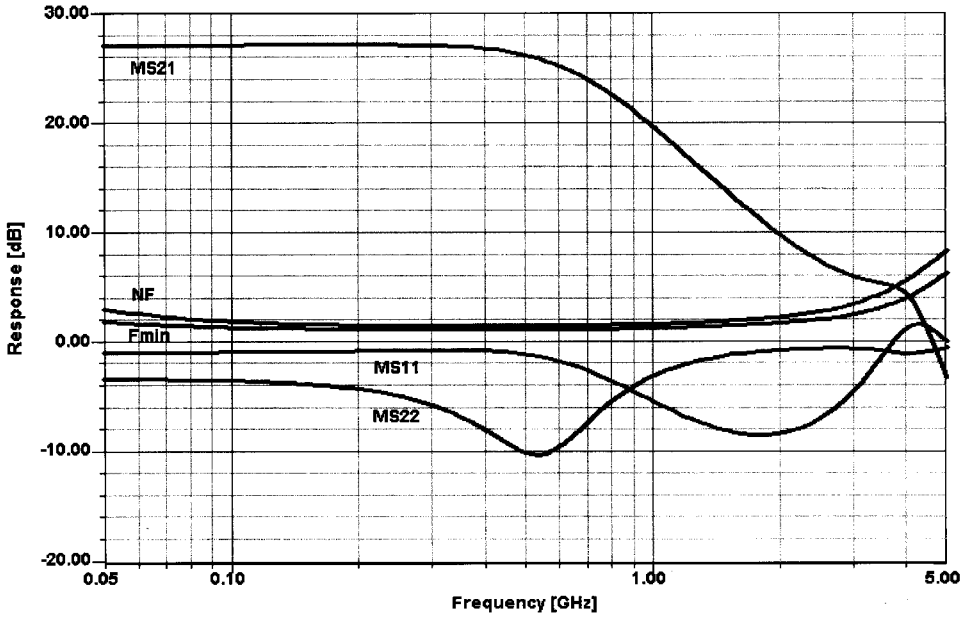

Figure 3-128 Gain, matching, and noise performance of the amplifier in Figure 3-127.

of an output transformer that absorbs the output capacitance. Figure 3-130 shows this circuit's frequency-dependent gain, matching, and noise performance.

It has been obvious to us that most published wireless application circuits are evaluated on a no-input-selectivity basis; that is, their reported performance does not take into account the filtering that is usually present in practical implementations. Evaluated in this way, a low-noise design may achieve a noise figure of less than 2 dB—1.2 dB or so is typical—but this is misleading because filters and connectors introduce insertion loss, resulting in a higher noise figure.

The cascode is a nice preamplifier combination. It combines (depending on the transistor) a low noise figure with essentially no feedback. Since the output of a grounded-base transistor provides a high-impedance source, this configuration is ideal to work into the SAW filters frequently used in wireless applications at the operating frequency. Special transistor pairs are available for use in cascode; as can be seen from this example, not every transistor combination is ideal. This one gives a higher noise figure than wanted and at frequencies above 2 GHz it tends to show possible instabilities. Both Siemens and Motorola are now offering transistors appropriate for these cascodes. Mostly, one would resort to transistors of less-exotic cutoff frequencies to guarantee stability. Typically, grounded-base/gate transistors tend to become oscillators, specifically because this configuration, like the emitter follower, allows a higher operating frequency while maintaining the same gain–bandwidth product; the actual gain for the last two circuit configurations is less. A grounded-base/gate stage has a high voltage gain and the emitter/source follower has power gain at low impedance levels. We invite our readers to experiment with the capacitor from the base of Q1 to ground in Figure 3-129 to get an interesting education about these transistors and their willingness to oscillate.

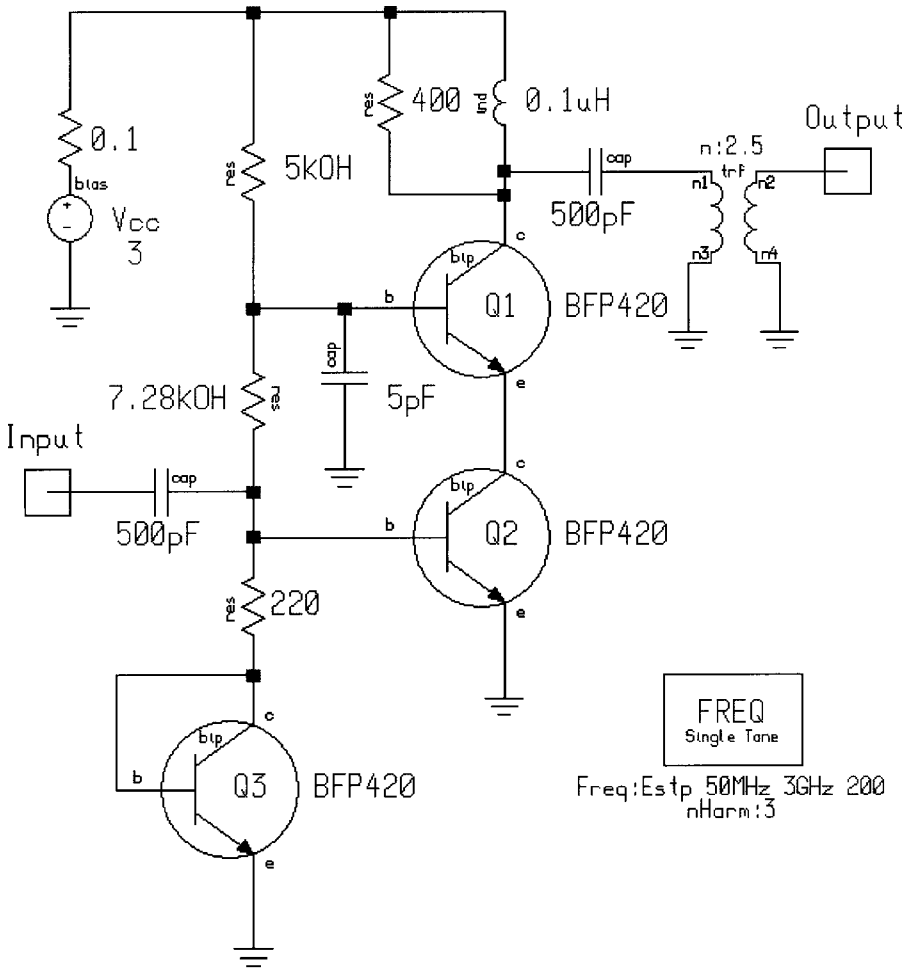

Figure 3-129 Schematic of the cascode amplifier.

The MC13144 is an example of a commercially available VHF to 2-GHz low-noise amplifier with programmable bias. As can be seen from Table 3-11, it is ideal for the 900-MHz range and its programmable gain/bias makes it very attractive. This design (Figure 3-131) is based on the cascode mentioned above and, because of high integration, uses many transistors for bias and level shifting.

The 900-MHz application circuit in Figure 3-132 shows the required external components for a successful design. Input and output are made tunable. The 5.6- and 39-nH inductances can be made from small air-wound coils. The output ceramic filter provides the necessary selectivity ahead of the mixer. With such a highly selective device in the input, the noise figure would deteriorate too much. The antenna is rarely in the vicinity of sufficiently strong transmitters to require such strong input filtering.

There are two more interesting applications for two-stage amplifiers: The one implemented in the Hewlett-Packard MSA-0735 MMIC has become a quite common one, and its usefulness up to higher frequencies depends mostly on the cutoff frequency of the transistors,

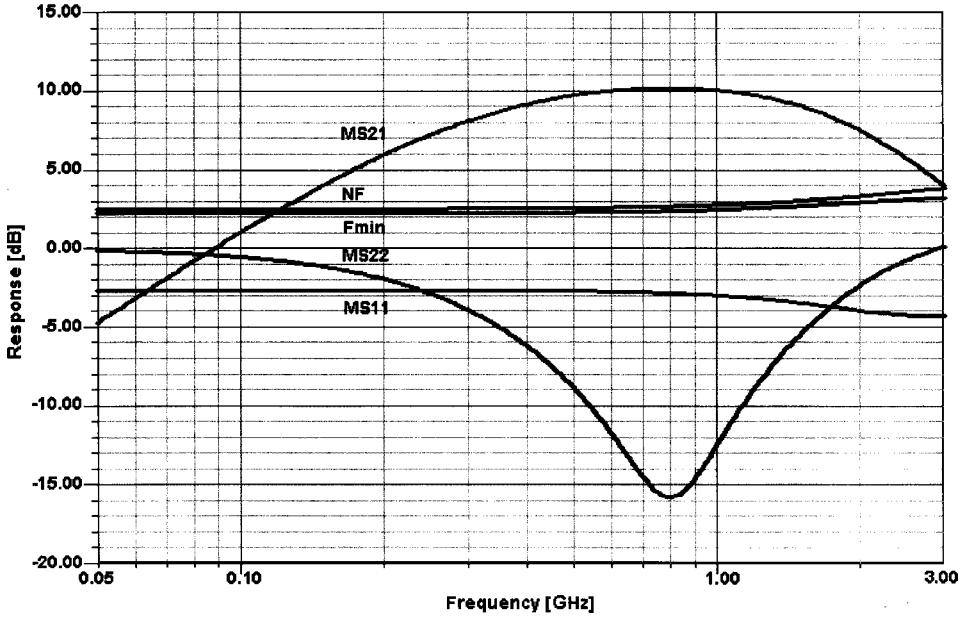

Figure 3-130 Frequency-dependent gain, matching, and noise performance of the cascode amplifier.

their parasitics, and the phase shift of the gain. The typical configuration is shown in Figure 3-133, and its frequency-dependent gain, match, and noise figure in Figure 3-134. There is an increase of S_{22} at higher frequencies; this indicates unwanted phase shift in the circuit. Some manufacturers hide the compensation circuits to overcome such peaking; most of the schematics shown by the manufacturers are really intended only to show operating principles, with proprietary details omitted.

Thanks to the properties of GaAs transistors, we can extend the frequency range significantly. The amplifier we are about to look at goes back several years and is described in great detail in Goyal [27]. Essentially what we have, seen in Figure 3-135, is an FET version of Figure 3-127. The main goal of this circuit was to have an all-monolithic circuit, avoiding all ac coupling and accomplishing all matching and interaction with dc coupling. The transistor Q1 is the main gain stage, which has the transistor Q2 as an active load. The output impedance of Q2 is $1/g_m$—typically in the area of 50–200 Ω, depending on the biasing,

Table 3-11 MC13144 features

Gain at 900 MHz, 17 dB
Noise figure at 900 MHz, 1.4 dB
P_{-1dB}, −7.0 dBm
$IP_{3,in}$, −5.0 dBm
Low operating supply voltage (1.8–6.0 Vdc)
Programmable bias with Enable 1 and Enable 2. [Enable 1 and Enable 2 programmed high for optimal noise figure and gain associated with NF. Enable can be overridden for external bias programming (up to 15 mA.)]

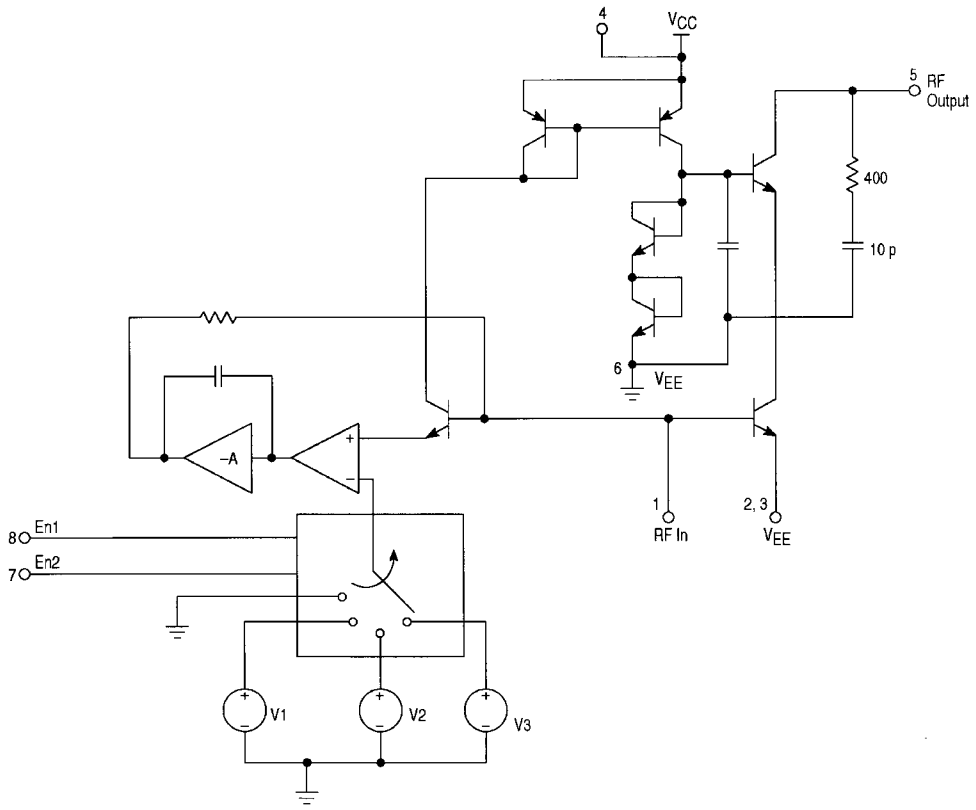

Figure 3-131 Schematic of the Motorola MC13144 cascode LNA.

which affects the transconductance. Transistor Q3 has the same function as an emitter/source follower; again, its dc bias determines its transconductance and therefore its output impedance. (Given this, a device that has a transconductance of 20 mS, or close to it, would establish a very good output match to 50 Ω.) The drains of Q1 and Q5 are at approximately 3.5 V. The diodes at the source of Q3 are level shifters that must shift the dc voltage at the gate of Q5 and at the drain of Q4 to approximately −1.5 V relative to ground—the necessary bias condition for Q1 and Q5. The standard shunt feedback circuit would show resistive feedback between the drain of Q1 (gate of Q2) and the gate of Q1; in the previous examples, we calculated the magic value of this part to be about 200 Ω. Adding in parallel to Q1 the transistor Q5 allows the designer to use a feedback scheme that isolates the feedback loop from the input. Dc-wise, the two transistors are tied together via a 10-kΩ resistor, which can be included in the actual packaged device. Insufficient information was published to allow us to duplicate the design, considering all the intricacies involved (we somewhat object to the fact that even in the *IEEE MTT-S Transactions*, so little information is given about the actual implementation of this design—using space constraints as an excuse—that its educational value is usually minimal); it shows a new principle without revealing the design steps necessary to obtain a practical circuit. Several variations of this type of circuit are available; the literature is full of discussions about them. The magnitude of the feedback is set by the ratio of the width of Q5 to that of Q1. Typical values for the Q5/Q1 ratio range

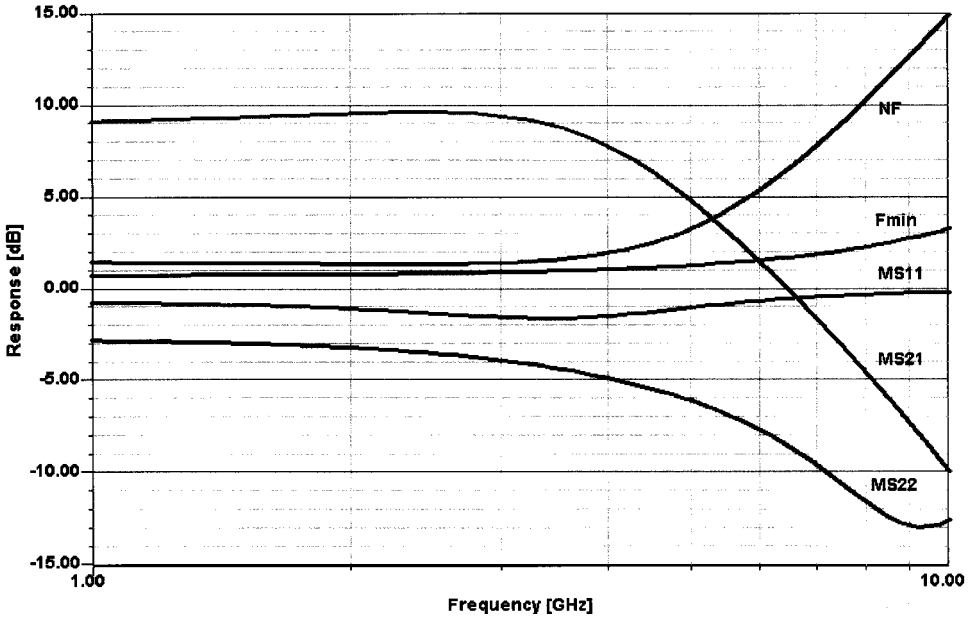

Figure 3-136 Frequency-dependent gain, matching, and noise performance of the dc-coupled GaAsFET amplifier.

from 0.15 to 0.30. In simulation, sizing the devices can best be accomplished by using the scaling factor for the FET model.

One of our questions was: "What would the perfect input termination for Q1 be?" By using an ideal transformer and playing with its turns ratio (needless to say, we did this with CAD), we determined experimentally that, relative to the gate, 200 Ω and a series inductor of 5–8 nH—the sort of details that designers often avoid telling their audiences—gave the ideal frequency response. Overall, we believe that the inventor of this circuit can be quite proud of the overall performance. The FETs we chose were taken from the Texas Instruments nonlinear foundry library; however, any similar device from another company would have worked equally well. The feedback loop used in this IC is an example of an approach frequently referred to as *active feedback*. The performance of this amplifier can be evaluated from Figure 3-136, which shows the frequency-dependent gain, matching, and noise figures (even including F_{min}).

3-5 AMPLIFIERS WITH THREE OR MORE STAGES

Most three-stage amplifiers are obtained by adding another buffer or power-gain stage to the previously described principal designs. As an example, we decided to evaluate the recent NEC UPC2749 IC, a silicon MMIC intended for application as a low-noise 1900-MHz amplifier operating at 3 V. Table 3-12 briefly summarizes its electrical specifications.

Table 3-12 NEC UPC2749 electrical characteristics

(T_A = 25 °C, $Z_L = Z_S$ = 50 Ω, V_{CC} = 3.0 V)			
	Part Number Package Outline		UPC2749T TO6
Symbols	Parameters and Conditions	Units	Typical
I_{CC}	Circuit current (no signal)	mA	6
G_S	Small-signal gain, f = 900 MHz dB	14.5	
	f = 1900 MHz	dB	16
f_{corner}	–3-dB Gain corner frequency	GHz	2.9
P_{1dB}	1 dB Compressed output power at 1900 MHz	dBm	–12.5
P_{SAT}	Saturated output power, f = 1900 MHz	dBm	–6
NF	Noise figure, f = 900 MHz	dB	3.2
	f = 1900 MHz	dB	4.0
RL_{IN}	Input return loss, f = 1900 MHz	dB	10
RL_{OUT}	Output return loss, f = 1900 MHz	dB	12.5
ISOL	Isolation, f = 1900 MHz	dB	30
OIP_3	SSB output third-order intercept, f_1 = 500 MHz, f_2 = 510 MHz	dBm	–3
	f_1 = 1000 MHz, f_2 = 1010 MHz	dBm	–3
	f_1 = 1900 MHz, f_2 = 1902 MHz	dBm	–3.5
	f_1 = 2000 MHz, f_2 = 2010 MHz	dBm	–4
$R_{TH(J-A)}$	Thermal resistance (junction to ambient)		
	Free air	°C/W	
	Mounted on a 50 × 50 × 1.6 mm epoxy glass PWB	°C/W	

In modeling the UPC2749's three transistors, we chose to use our favorite, the BFP420, which is not without its headaches at the higher frequencies. Figure 3-137 shows the circuit diagram, which closely resembles the one published by NEC; again, the only hard facts we had were the IC's basic circuit topology, gain, and dc current. Given those numbers, we staggered the current in the three devices by setting them at 0.64 mA for the first stage, 1.85 mA for the second stage, and 3 mA for the third stage. It should be noted that the two output transistors are not unlike the approach used for the Hewlett-Packard MSA-0735 (Figure 3-133). Taking (hopefully) all the right assumptions, we end up with a design that closely resembles the manufacturer's specifications for both power consumption, gain, and noise. This can be verified by looking at the results plotted in Figure 3-138.

The final example is a more complex derivative of the Philips NE/SA5204A amplifier, which was intended for standard 6-V operation and has a fairly "normal" circuit arrangement. This can be seen from Figure 3-139. A much more elaborate cousin of this is the low-voltage NEC UPC2710 amplifier. According to its specifications, it operates at 5 V but has significantly more gain than the NE/SA5204. Table 3-13 shows its electrical specifications and Figure 3-140 shows its measured gain as published by the manufacturer.

The actual interior of the circuit is shown in Figure 3-141. It consists of the standard preamplifier and then a Darlington configuration with the collectors tied together. The middle section of the circuit acts as a power supply responsible for the bias relative to the emitter of the first transistor influencing the rest of the circuit as well. Since NEC mentioned that they use their NESAT III process (f_T of 20 GHz at V_{ce} = 3) in producing the UPC2710T and we

obtained some information regarding it, we decided to use our standard BFP420 (f_T of 25 GHz; see the datasheet in Chapter 2) for the purpose of simulation.

In our effort to simulate this circuit, we chose a combination of values that pretty much complies with the manufacturer's published specifications, but S_{22} is not close, as shown in Figure 3-142. We stopped at this point and invite our readers with CAD capabilities to provide the final touch in meeting all the published specifications for the circuit. We are particularly

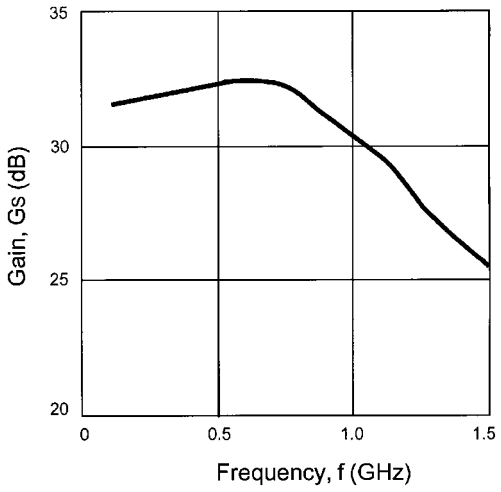

Figure 3-140 Manufacturer-supplied gain versus frequency for the NEC UPC2710T MMIC.

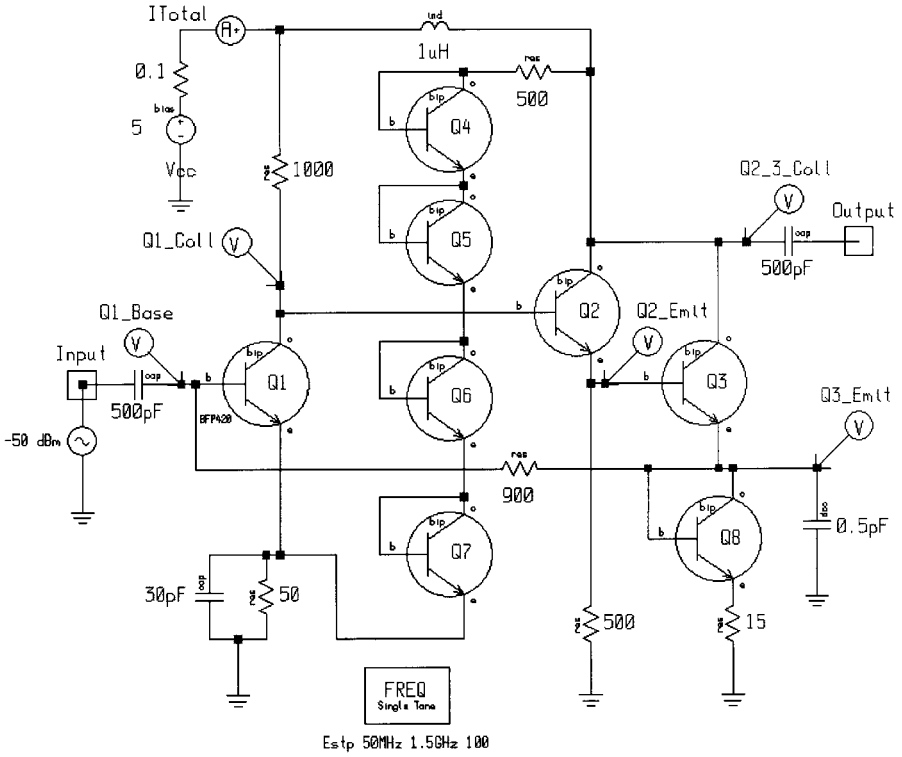

Figure 3-141 Schematic of the UPC2710T silicon MMIC entered for simulation.

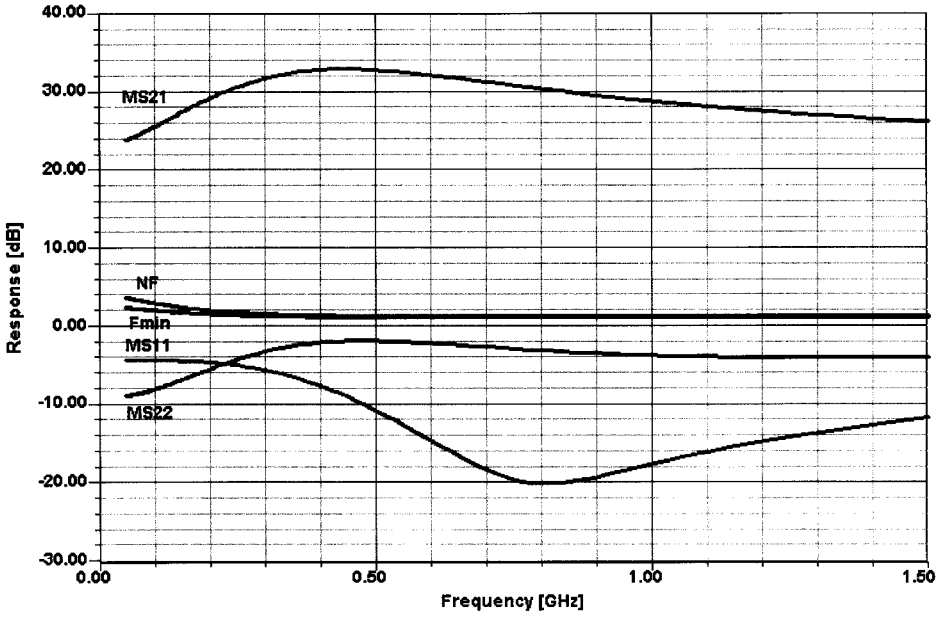

Figure 3-142 Simulated gain, match, and noise performance of the UPC2710T.

recommending such an effort because it shows very nicely the interaction of all the circuit elements in a fairly drastic way. Because of this, we admire the IC design even more, since the manufacturer has to sell a pretty consistent amplifier as a function of different production runs.

3-5-1 Stability of Multistage Amplifiers

Stability, needless to say, is a big issue, and the delay of the various stages adds to the phase shift, resulting in possible instabilities. The fact that S_{11} and/or S_{22} can become larger than 0 (in dB) means there is the potential of oscillating, depending on the reactances available. If a cable of inappropriate length is added, hell will break loose. Figure 3-143 shows the dangerous peaking of our simulation of the Philips NE5204A, in which the internal compensation was intentionally not assumed correctly. We will all agree that the high-end performance of this amplifier can generate high anxiety. As the production process of the aging device becomes more modern—meaning that transistors with much higher f_T will be the basis for the production—it will become quite difficult to maintain a previously achieved stability. This, by the way, applies also to discrete transistors, which for reasons of economics and multiple manufacturers will be improved over time. Such evolution results in generally smaller base-spreading resistances and capacitances, and other parameter changes, which, overall, cause headaches in manufacturing. We will leave the topic of three-stage amplifiers on this note.

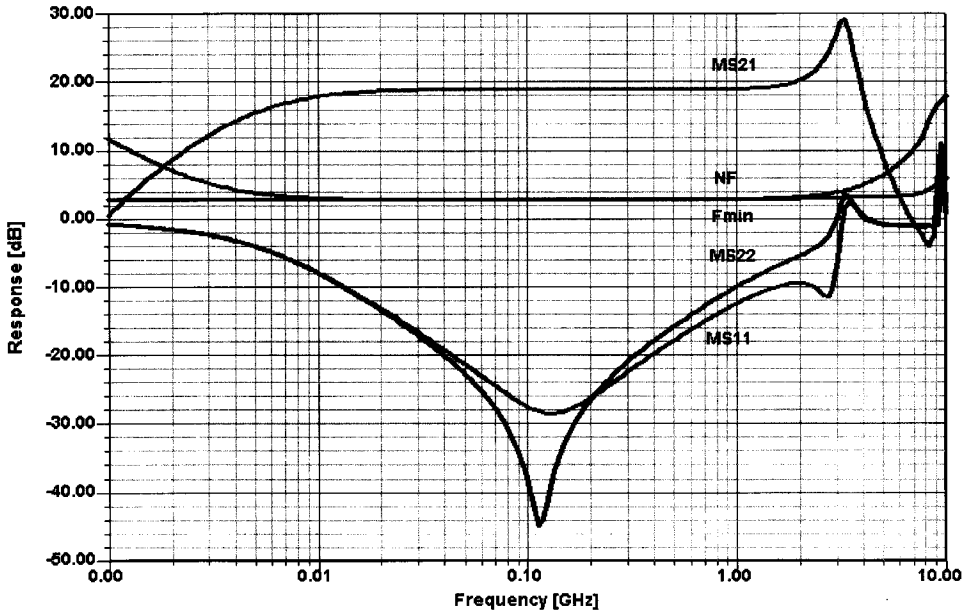

Figure 3-143 Simulated gain, match, and noise performance of the NE5204A IC.

3-6 A NOVEL APPROACH TO VOLTAGE-CONTROLLED TUNED FILTERS INCLUDING CAD VALIDATION [28]

Modern receivers control input stages as well as the oscillator band and frequency by electrical rather than mechanical means. Tuning is accomplished by voltage-sensitive capacitors (varactor diodes), and band switching by diodes with low forward conductance. Since the wireless band (essentially 400 MHz to 2.4 GHz) is so full of strong signals, the use of a tracking filter is desired as a solution to improve the performance and prevent second-order IMD products or other undesired overload effects. The dc control voltage needed for the filter can easily be derived from the VCO control voltage. There may be a small dc offset, depending on the IF used.

3-6-1 Diode Performance

The capacitance versus voltage curves of a varactor diode depend on the variation of the impurity density with the distance from the junction. When the distribution is constant, there is an "abrupt junction" and capacitance follows the law

$$C = \frac{K}{(V_d + V)^{1/2}} \tag{3-183}$$

where V_d is the contact potential of the diode and V is applied voltage.

Such a junction is well approximated by an alloyed junction diode. Other impurity distribution profiles give rise to other variations, and the above equation is usually modified to

$$C = \frac{K}{(V_d + V)^n} \tag{3-184}$$

where n depends on the diffusion profile and $C_0 = K/V_d^n$.

A so-called graded junction, having a linear decrease in impurity density with the distance from the junction, has a value of n. This is approximated in a diffused junction.

In all cases these are theoretical equations, and limitations on the control of the impurity pattern can result in a curve that does not have such a simple expression. In this case, the coefficient n is thought of as varying with voltage. If the impurity density increases away from the junction, a value of n higher than 0.5 can be obtained. Such junctions are called hyperabrupt. A typical n value for a hyperabrupt junction is about 0.75. Such capacitors are used primarily to achieve a large tuning range for a given voltage change. Figure 3-144 shows the capacitance–voltage variation for the abrupt and graded junctions as well as for a particular hyperabrupt-junction diode. Varactor diodes are available from a number of manufacturers, such as Motorola, Siemens, and Philips. Maximum values range from a few to several hundred picofarads, and useful capacitance ratios range from about 5 to 15.

Figure 3-145 shows three typical circuits that are used with varactor tuning diodes. In all cases, the voltage is applied through a large resistor R_e or, better, an RF choke in series with a small resistor. The resistance is shunted across the lower diode and may be converted to a shunt load resistor across the inductance to estimate Q. The diode also has losses that may result in lowering the circuit Q at high capacitance, when the frequency is sufficiently high. This must be considered in the circuit design.

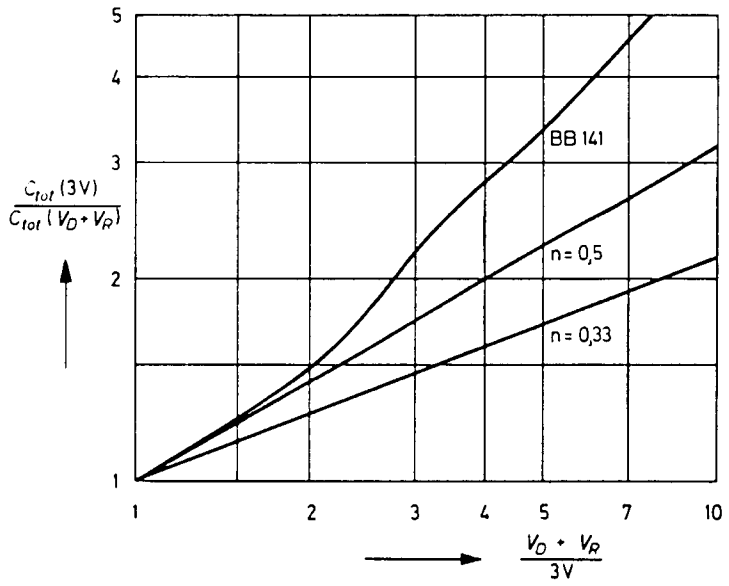

Figure 3-144 Voltage-dependent change of capacitance of different types of diodes. The BB141 is a hyperabrupt-junction diode with $n = 0.75$.

The frequency-dependent performance is not determined solely by applying the dc tuning voltage to Eq. (3-184). If the RF voltage is sufficient to drive the diode into conduction on peaks, an average current will flow in the circuits of Figure 3-145, which will increase the bias voltage. The current is impulsive, giving rise to various harmonics of the circuit. Even in the absence of conduction, Eq. (3-184) deals only with the small-signal capacitance. When the RF voltage varies over a relatively large range, the capacitance changes. In this case, Eq. (3-184) must be changed to

$$\frac{dQ}{dV} = \frac{K}{(V + V_d)^n} \tag{3-185}$$

Here Q is the charge on the capacitor. When this relation is substituted in the circuit differential equation, it produces a nonlinear differential equation, dependent on the parameter n. Thus, the varactor my generate direct current and harmonics of the fundamental frequency. Unless the diodes are driven into conduction at some point in the cycle, the direct current must remain zero.

The current of Figure 3-145c can be shown to eliminate the even harmonics, and it permits a substantially larger RF voltage without conduction than either circuit in Figure 3-145a or 3-145b. When $n = 0.5$, only the second harmonic is generated by the capacitor, and this can be eliminated by the back-to-back connection of the diode pair. Integrating Eq. (3-185), we find

$$Q + Q_A = \frac{K}{1 - n}(V + V_d)^{1-n}$$

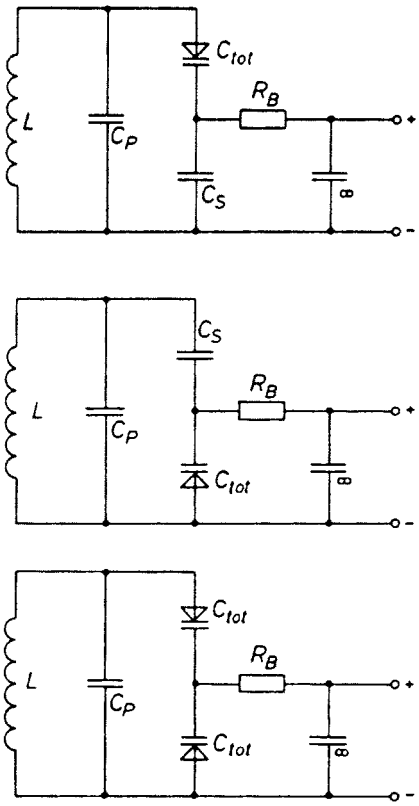

Figure 3-145 Various configurations to apply tuning diodes in a tuned circuit. The bottom version shows the lowest distortion.

$$= \frac{C_v}{1-n}(V + V_d) \tag{3-186}$$

C_v is the value of Eq. (3-184) for applied voltage V, and Q_A is a constant of integration. By letting $V = V_1 + v$ and $Q = Q_1 + q$, where the lowercase letters represent the varying RF and the uppercase letters indicate the values of bias when RF is absent, it follows that

$$q + Q_1 + Q_A = \frac{K}{1-n}[v + (V_1 + V_d)]^{1-n} \tag{3-187}$$

$$1 + \frac{v}{V'} = \left(1 + \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-188}$$

where $V' = V_1 + V_d$ and $Q' = Q_1 + Q_A$. For the back-to-back connection of identical diodes, $K_{11} = K_{12} = K_1$, $V_1' = V_2' = V'$, $Q_1' = Q_2' = Q'$, $q = q_1 = -q_2$, and $v = v_1 - v_2$. Here the new subscripts 1 and 2 refer to the top and bottom diodes, respectively; v is the RF voltage across

the pair in series, and q is the charge transferred through the pair in series. This notation results in

$$\frac{v}{V'} \equiv \frac{v_1 - v_2}{V'} = \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} - \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-189}$$

For all n, this eliminates the even powers of q, and hence the even harmonics. This can be shown by expanding Eq. (3-189) in a series expansion and performing term by term combination of the equal powers of q. In the particular case $n = \frac{1}{2}$, $v/V' = 4q/Q'$, and the circuit becomes linear.

The equations hold as long as the absolute value of v_1/V' is less than unity, so that there is no conduction. At the point of conduction, the total value of v/V' may be calculated by noting that when $v_1/V' = 1$, $q/Q' = -1$, so $q_2/Q' = 1$, $v_2/V = 3$, and $v/V = -4$. The single-diode circuits conduct at $v/V' = -1$, so the peak RF voltage should not exceed this. The back-to-back configuration can provide a fourfold increase in RF voltage handling over the single diode. For all values of n, the back-to-back configuration allows an increase in the peak-to-peak voltage without conduction. For some hyperabrupt values of n, such that $1/(1 - n)$ is an integer, many of the higher-order odd harmonics are eliminated, although only $n = \frac{1}{2}$ provides elimination of the third harmonic. For example, $n = \frac{2}{3}$ results in $1/(1 - n) = 3$. The fifth harmonic and higher odd harmonics are eliminated, and the peak-to-peak RF without conduction is increased eightfold; for $n = \frac{3}{4}$ the harmonics 7 and above are eliminated, and the RF peak is increased 16 times. It must be noted in these cases that the RF peak at the fundamental may not increase so much, since the RF voltage includes the harmonic voltages.

Since the equations are only approximate, not all harmonics are eliminated, and the RF voltage at conduction, for the back-to-back circuit, may be different from that predicted. For example, abrupt-junction diodes tend to have n of about 0.46–0.48 rather than exactly 0.5. Hyperabrupt junctions tend to have substantial changes in n with voltage. The diode illustrated in Figure 3-144 shows a variation from about 0.6 at low bias to about 0.9 at higher voltages, with wiggles from 0.67 to 1.1 in the midrange. The value of V_d for varactor diodes tends to be in the vicinity of 0.7 V.

3-6-2 A VHF Example

The application of tuning diodes in double-tuned circuits in TV tuners has been common practice for many years. Figure 3-146 shows the circuit diagram. The input impedance of 50 Ω gets transformed up to 10 kΩ. The tuned circuits consist of the 0.3-μH inductor and two sets of antiparallel diodes. By dividing the RF current in the tuned circuit and using several diodes instead of just one pair, intermodulation distortion is reduced.

The coupling between the two tuned circuits is tuned via the 6-nH inductor that is common to both circuits. This type of inductance is usually printed on the circuit board. The diode parameters used for this application were equivalent to the Siemens BB515 diode. The frequency response of this circuit is shown in Figure 3-147.

The coupling is less than critical. This results in an insertion loss of about 2 dB and relatively steep passband sides. Once the circuit's large-signal performance (Figure 3-148) is seen, a third-order intercept point of about –2 dBm is not so unexpected. The reason for this poor performance is the high impedance (high L/C ratio), which provides a large RF voltage swing across the diodes. A better approach appears to be using even more diodes and at the same time changing the impedance ratio (L/C ratio).

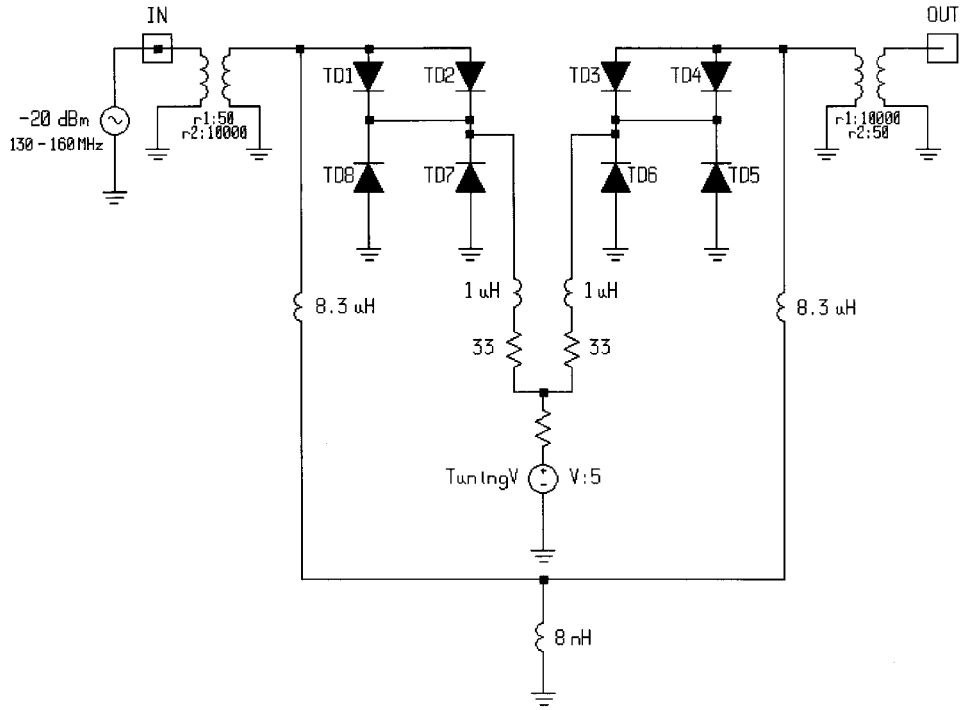

Figure 3-146 Double-tuned filter at 161 MHz using hyperabrupt-junction tuning diodes. By using several parallel diodes, the IMD performance improves.

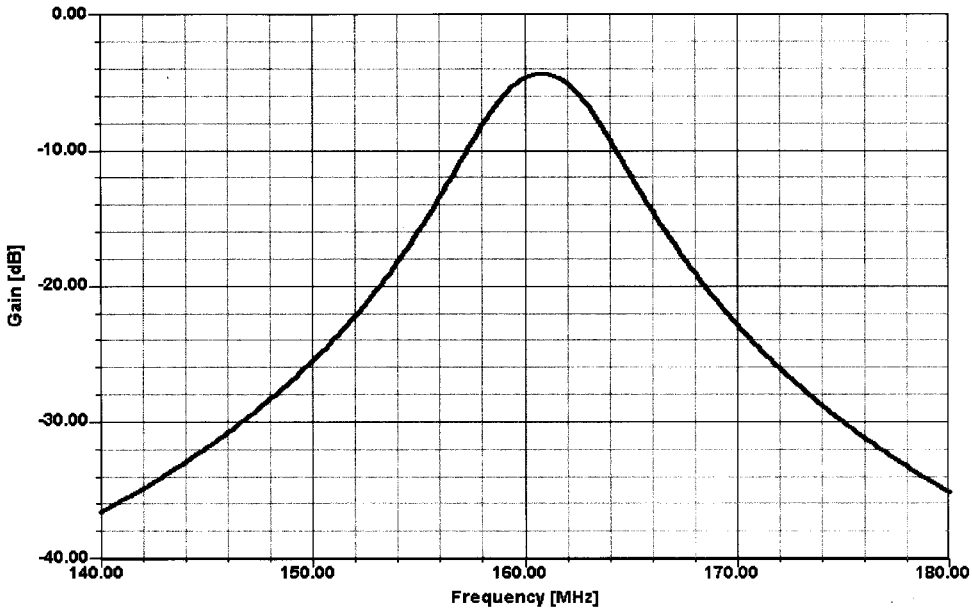

Figure 3-147 Frequency response of the tuned filter shown in Figure 3-146. The circuit is undercoupled (less than transitional coupling); $Q \times k < 1$.

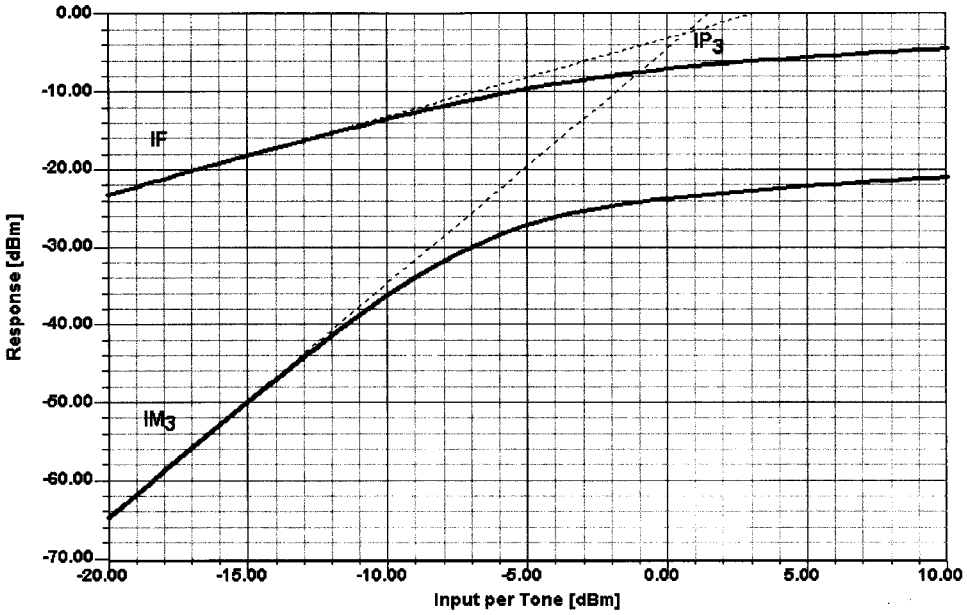

Figure 3-148 Prediction of intercept point of the double-tuned circuit shown in Figure 3-146. Note the compression of both the input signal and the IMD product.

3-6-3 An HF/VHF Voltage-Controlled Filter

The above example used a step-up procedure typically done by a tap at the input and output inductance. This method allows an impedance transformation; however, if one desires to change it into a series-tuned arrangement, it has to be done with a transformer. The large-signal conditions in the frequency range from 10 to 30 MHz on a medium- to large-sized antenna are equivalent to, if not worse than, the conditions for VHF operation. The only exception would be line of sight into the transmitter such as a tower in the middle of the city. Examples of such hostile conditions would be any large city, such as Munich, New York, Miami, Chicago, and San Francisco, where the authors had significant experience with intermodulation distortion problems.

By translating the circuit into a low-impedance-drive arrangement, building it symmetrically, and reducing the tuning range somewhat by capacitors and many series diode pairs, the filter's large-signal performance was significantly improved. The tuning diodes had about 125 pF at 1 Vdc per unit. Initial tests trying to use a high-capacitance diode, such as the BB112, resulted in much higher IMD products. The B112 has a 1-V capacitance of 470 pF down to about 20 pF at 8 V. Standard diodes show about 30 pF at 1 V, while the diodes used in the experiment had a 125-pF capacitance at 1 V. These experimental diodes were made available from a well-known manufacturer for this evaluation. Figure 3-149 shows the circuit diagram.

A step-down transformer drives the tuned circuit with a source impedance of 12.5 Ω. The circuit is symmetrical. There are two 0.8-μH inductors and 2×5 diodes in the loop. The output of the circuit is transformed back up to 50 Ω. The tuning voltage is supplied via a heavily filtered arrangement. This circuit has actually been implemented in Rohde & Schwarz field strength meter equipment. They guarantee an intercept point of about +20 dBm. The selectivity of these circuits is quite reasonable and mostly intended to reduce

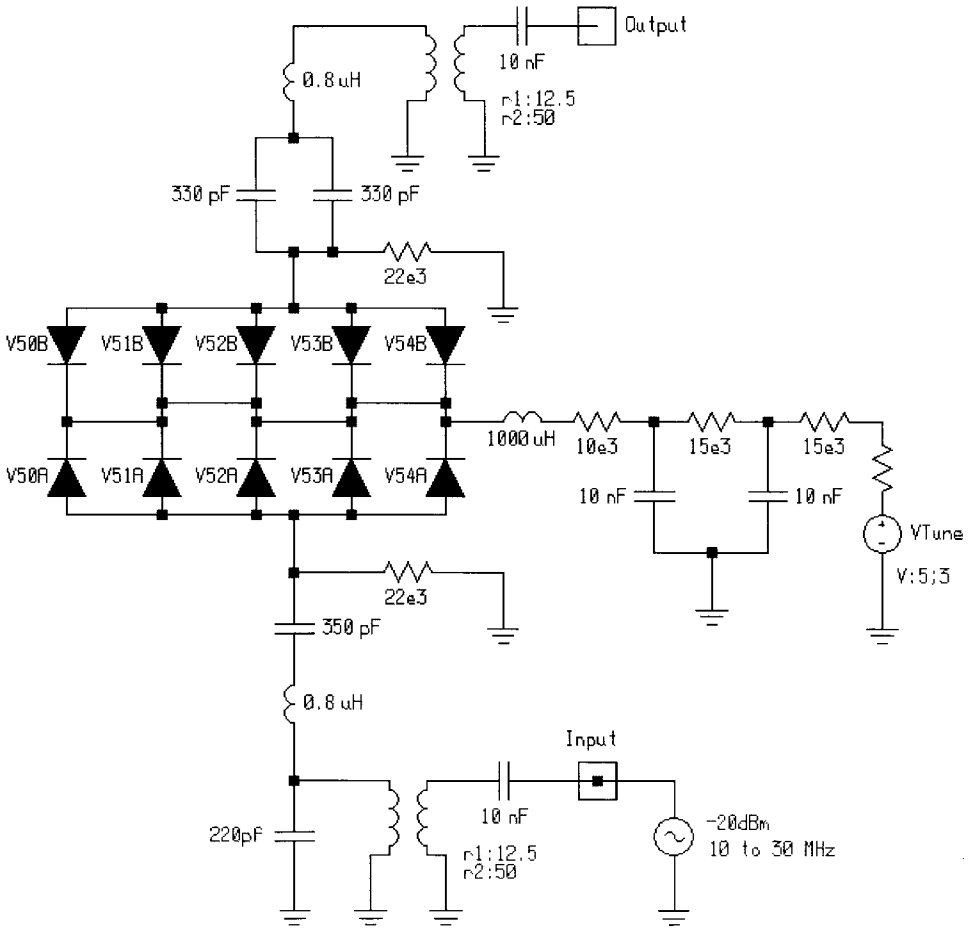

Figure 3-149 High dynamic range of a 10–20-MHz filter.

second-order intermodulation distortion products by about 10 dB, at the same time having a high third-order intercept point. Figure 3-150 shows the selectivity curves at two different tuning voltages.

The most interesting number, however, is the third-order intercept point (already determined as about 20 dBm), which still had to be simulated. This sometimes sounds like a contradiction: Once the measured values are available and are acceptable, why would one want—or, rather, need—to do a simulation besides the necessity to develop a high-input intercept filter? It was desirable to validate the nonlinear models and prove that the above-mentioned equations will hold true. This type of simulation is now more difficult because the number of nonlinear elements went from four to ten, and some numerical problems, such as convergence difficulties, can be expected, and the effect of harmonic frequency cancellation (compensation) can also be seen. By using diode combinations that result in $1(1 - n)$, n being an integer number, these IMD products can drastically be reduced. This implies that each of the five diode pairs has a selected value for n to meet this condition. Later, a final attempt will be made to improve the first VHF filter with the proper diode combinations.

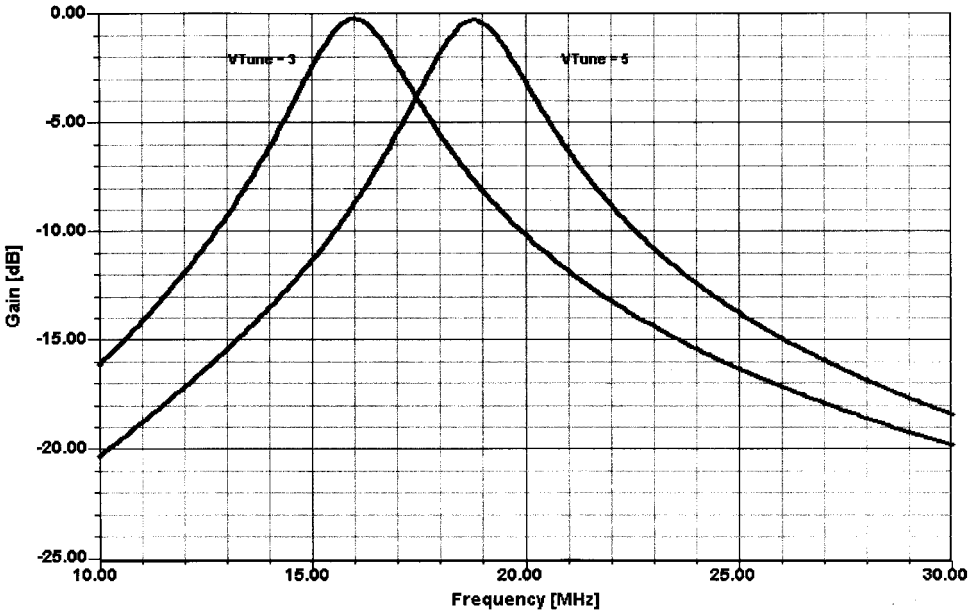

Figure 3-150 Frequency response of the filter shown in Figure 3-149. Filters of this type are intended to reduce second-order IMD by providing about 20-dB suppression at half the center frequency.

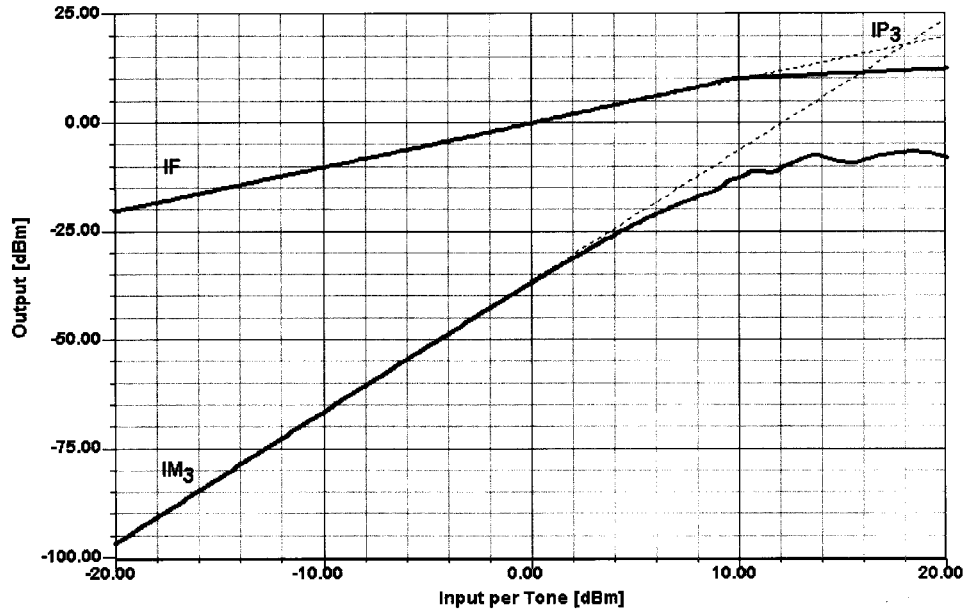

Figure 3-151 Prediction of third-order intercept point of the filter shown in Figure 3-149. The reason for the curves on the IMD plot lies in the interaction between the ten nonlinear devices.

Figure 3-151 shows the calculation of third-order intercept point for the arrangement shown in Figure 3-149. This number has now increased to +18 dBm. The difference between selection and measurement is approximately 2 dB. The reason for this more pessimistic value compared to the measured value probably has to do with slight variations of the exponent of the diodes' voltage-dependent capacitance. Therefore, the authors consider both the circuit performance and the simulation accuracy to be extremely good. This type of circuit, as mentioned earlier, has wide application in oscillator circuits. Danzeisen of Rohde & Schwarz was probably the first to have used this type of circuit by paralleling many diodes for improved performance.

3-6-4 Improving the VHF Filter

By selecting the appropriate diode combinations and circuit modifications as shown in Figure 3-152, a significant IMD improvement of the circuit shown in Figure 3-146 is obtained. A special shunt arrangement of several diodes with different exponents has been developed, which allows its value to be "adjusted." This circuit, for which a patent has been applied, showed an improvement from –2 dBm to 32 dBm. The same high operating Q was maintained. Figure 3-153 shows the frequency response after the modification. Note that a coupling slightly greater than critical ($Q \times k = 1.1$) has been selected.

3-6-5 Conclusion

After explaining some of the nonlinearities in mathematical terms, we have given some examples of voltage-tuned circuits and discussed their large-signal performance. This section has also shown that modern CAD tools can accurately predict the performance of such circuits.

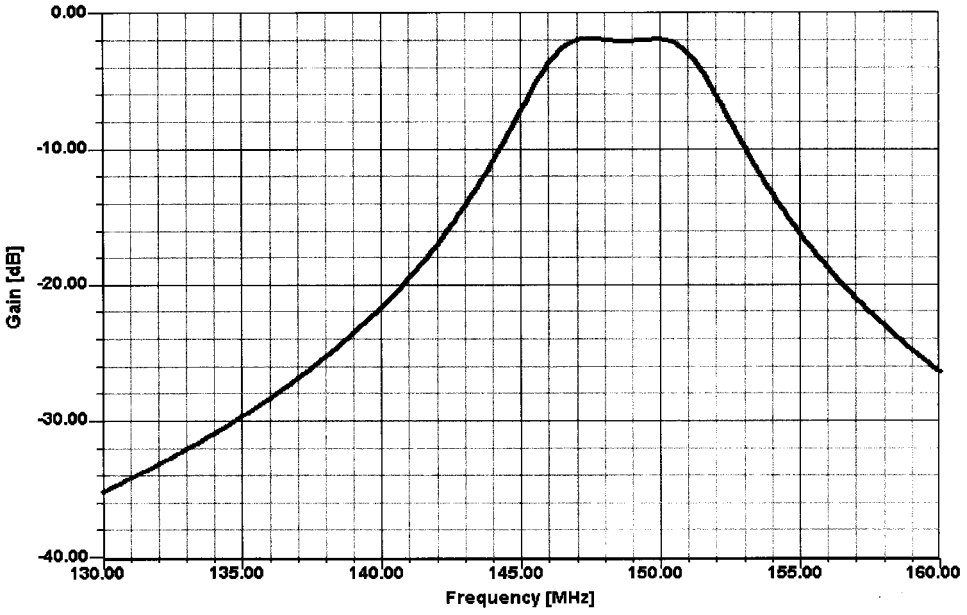

Figure 3-152 The frequency response of the improved circuit derived from Figure 3-146.

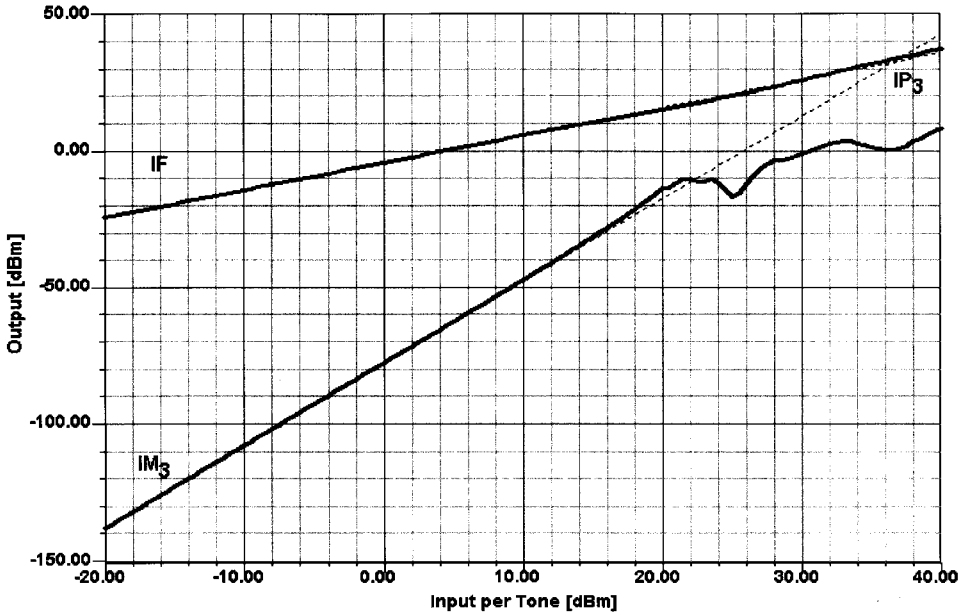

Figure 3-153 Predicted IMD performance of the improved version of the circuit shown in Figure 3-146. This type of improvement is significant for all applications. A patent is in the process of being obtained for this; therefore, the circuit cannot be disclosed at present.

3-7 DIFFERENTIAL AMPLIFIERS

The differential amplifier (Figure 3-154) goes back many years and also was the first step from TTL to ECL. The differential amplifier consists of an emitter follower (Q1) and a grounded-base stage (Q2). The constant-current generator (Q3) between ground and the emitters of Q1 and Q2 determines the current for these stages; the dc operating currents of Q1 and Q1 are the same. Most modern integrated circuits use this differential amplifier in one way or another.

If the circuit is operated about its point of symmetry, the dc component of the current through either Q1 or Q2 remains half of the emitter constant current through Q3 for all symmetrical driving signals. In addition, for input signals that are aperiodic, no even harmonics are generated. This assumes that the stage is driven symmetrically at both inputs. In our case, the differential amplifier has its second stage grounded, meaning that there is a base-to-ground capacitor, and the stage is asymmetrically fed. As the input voltage is increased, the differential stage becomes a limiter, which limits the current between plus and minus I_S, with I_S being the source current. The resulting output will become a square wave. This stage can also be used as a line receiver, translating a sine wave to an output logic suitable for driving emitter-coupled logic (ECL) stages.

One can assume that the differential amplifier has a transconductance of

$$g_m = \frac{\alpha g_{\text{in}}}{2} \tag{3-190}$$

where α is the ratio of collector to emitter current. Within the limits of the output being a sine wave, this stage has very low distortion. The output current now is determined by

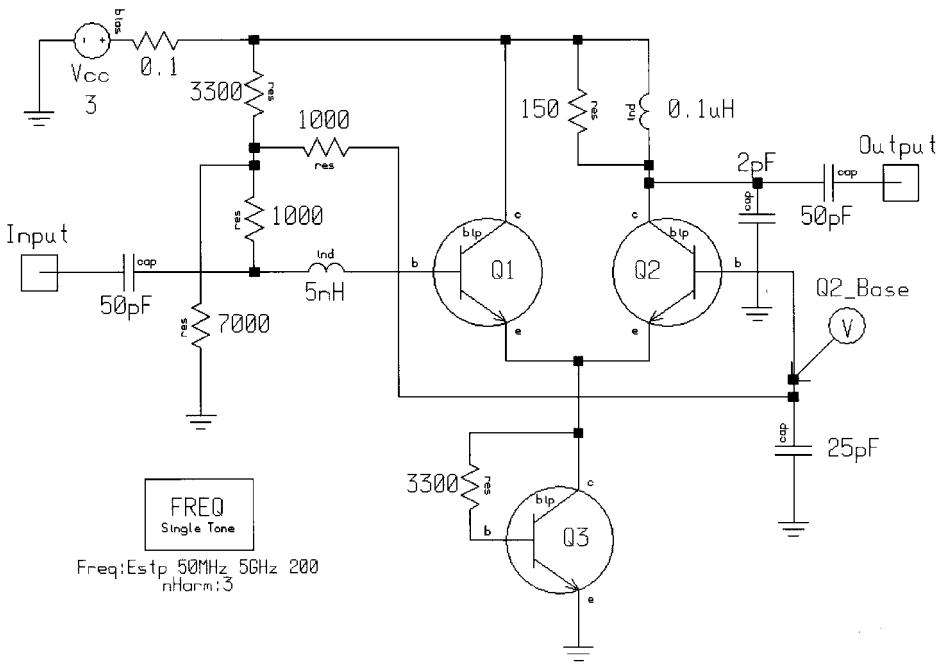

Figure 3-154 The differential amplifier schematic. The transistors are Siemens BFP420s. Figure 3-155 shows the circuit's frequency-dependent gain, matching, and noise performance.

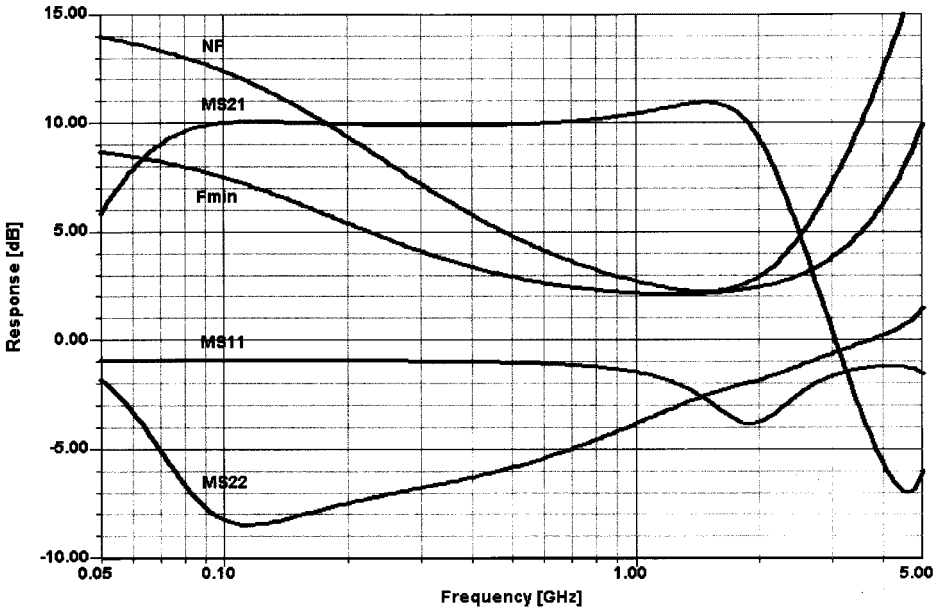

Figure 3-155 Frequency-dependent gain, matching, and noise performance of the differential amplifier.

$$i = \frac{I_{\text{in}}}{2} \tanh\left(\frac{x}{2} \cos \omega t\right) \tag{3-191}$$

where ωt is the input frequency and I_{in} is the current forced by Q3. The reason why the transconductance has to be divided by 2 comes from the fact that the current is split into two equal components for Q1 and Q2. Multiplying the new transconductance with the output load gives the voltage gain of this amplifier; its power gain can be obtained by multiplying this with $\sqrt{\text{output resistance} \div \text{load resistance}}$.

Having done the linear analysis and having learned that because of the hyperbolic tangent functions this amplifier can also be used as a line receiver, and converting sinusoidal waves to square waves, it may be useful to take a closer look at these issues. If we take a CAD oscilloscope, we see the resulting output waveform being a nonequal duty cycle output voltage, which results in high harmonic content. The amount of harmonic content can be controlled by the drive power and by the actual bias. Figure 3-156 shows the resulting output waveform.

If we now switch to a CAD spectrum analyzer, we can evaluate the harmonic content (Figure 3-157). Figure 3-158 shows the output transistor's dc I–V curves and ac load line under these conditions. Based on the previously defined conducting angle of the differential amplifier, one can optimize for harmonic content. Therefore, it is logical at this point to look at frequency multipliers, as they are sometimes needed. Finally, we are curious to see the so-called load line of the output transistor, which is, based on the interaction of all the stages, not looking the same way as the expected one, which we know from previous amplifier examples. Part of the reason for this is that for a certain voltage range, the collector voltage is in the negative region, and all kinds of saturation effects result in this surprising waveform. By reducing the input power, one would obtain a more "expected" load line. We invite readers with CAD capabilities to play with this example, as it gives a lot of insight into the operation of ECL stages.

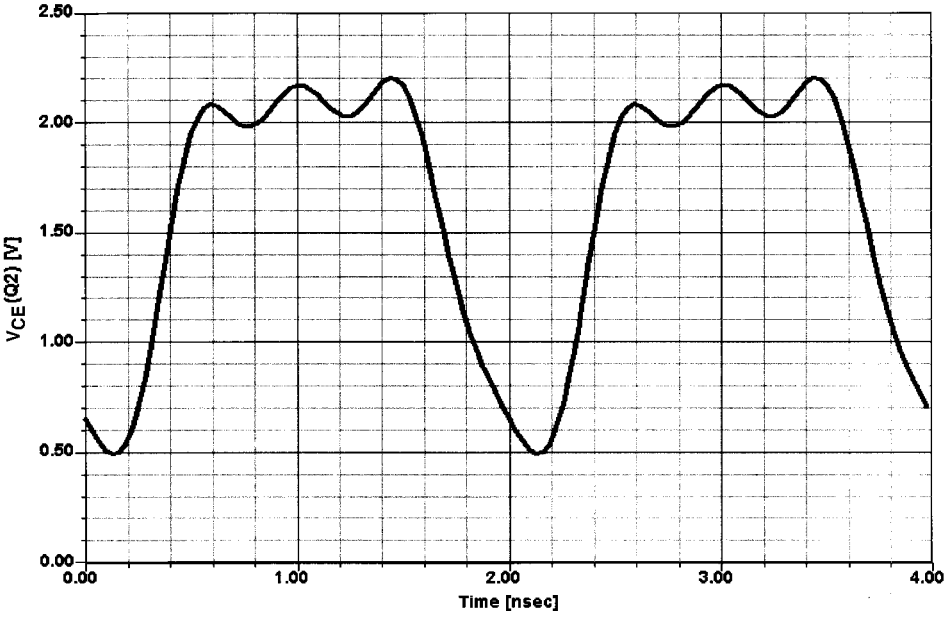

Figure 3-156 V_{CE} versus time for output transistor Q2 with a drive of 10 dBm.

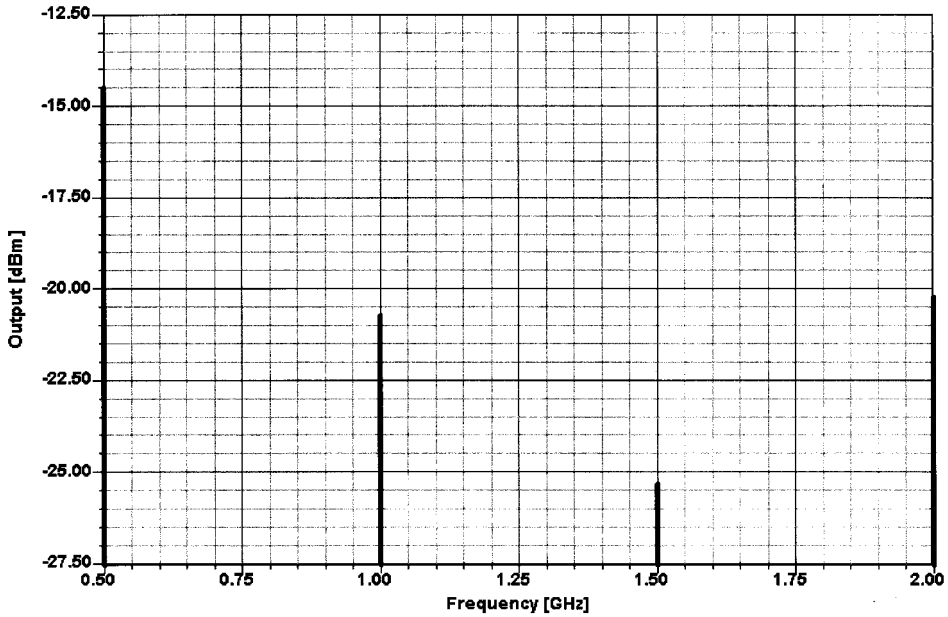

Figure 3-157 Output spectrum of the differential amplifier with a drive of 10 dBm. The biasing is not optimal for frequency multiplication.

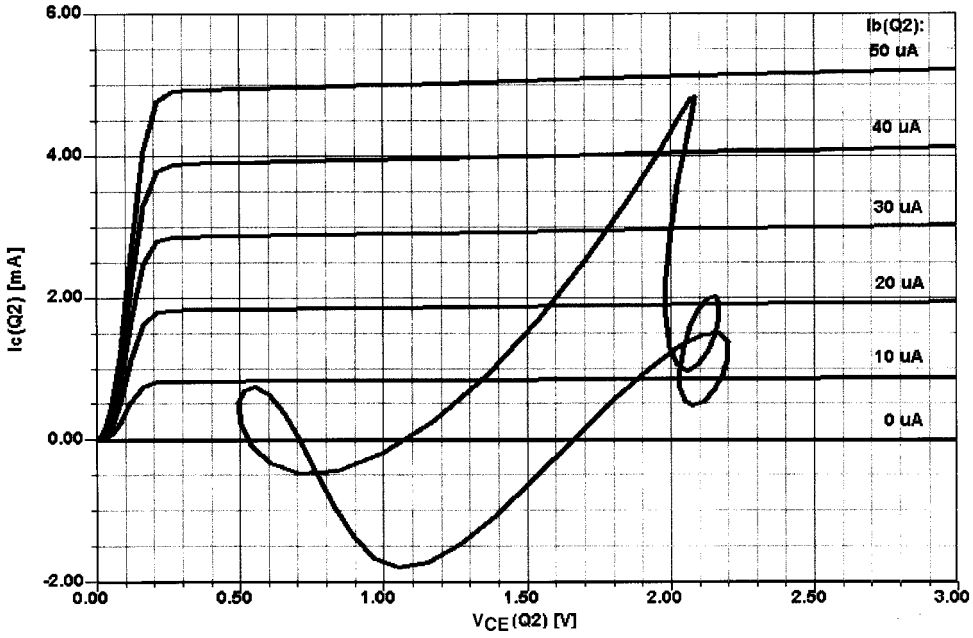

Figure 3-158 The dc *I–V* curves and ac load line for output transistor Q2 with a drive of 10 dBm.

3-8 FREQUENCY DOUBLERS

Having seen that the harmonic content invites us to bias a stage from Class A into Class B or C if our goal is a harmonically rich current, we will now evaluate a single stage that will be biased close to cutoff and driven by a relatively low frequency (500 MHz). To obtain the best results, we will use a parallel notch filter in the output, followed by a high-pass matching circuit to "catch" the desired harmonic. The input frequency is heavily suppressed by the notch filter. Based on its finite Q, there is a limited range over which this frequency can be varied with constant subharmonic attenuation. Figure 3-159 will be our test circuit.

This circuit consists of a bias transistor, Q2. This method has been discussed before and solves the temperature-dependent bias emitter thermal runaway problems through "temperature compensation." The purists among our readers may point out that the currents drawn by Q1 and Q2 are not quite identical (which would give 100% cancellation), but the approach shown is sufficient to do its job. Also, we have chosen a Class AB operation point, which is defined by Q1's 1-mA dc standing current. The conducting angle has not been optimized for the second harmonic—a task that the interested reader can do by using the conducting angle relationship shown at the beginning of this chapter. To give readers with access to nonlinear CAD some homework, we have not set this at the optimum point.

The second transistor, here called Q1 (because of its importance at RF), has a matching network at the input. This is recommended for optimum energy transfer. The matching condition can be validated by examining Figure 3-160. If we look at the higher frequency response, the input shows a possible trend of oscillation (negative loss); this could actually be eliminated by using a low-pass filter at the input instead of the high-pass filter used now. Findings of this type always make us nervous, and we hope that the nonlinear models are sufficiently accurate at higher frequencies to predict such behavior correctly. In the case of the FET doubler mentioned in Chapter 2, we found that the device modeling done by Compact (now Ansoft) gave the best results, the university answers were fairly close, and the device manufacturer data were worst. We have since become highly skeptical about device modeling unless we can validate it ourselves. Synergy Microwave has a complete set of test equipment in the laboratory, including network and spectrum analyzers with special software created by Rohde & Schwarz that can be used in addition to the Scout program to do in-house validation. This was achieved by the use of nonlinear optimization at a drive level of 0 dBm. One could say that this is similar to using a load-pull approach at the input, and then resorting to the large-signal S parameters obtained. Another note of caution: Capacitors at these low values tend to have a very large percentage error; for instance, a 1-pF capacitor, if not selected carefully, can vary between 0.7 and 1.3 pF—a 50% error. Needless to say, this is not acceptable for useful production.

The output consists of a high-pass filter and a notch filter with the purpose of reducing the subharmonic significantly. We have again done this on purpose, leaving room for the reader to come up with a more inventive output circuit like a Cauer-type (same as elliptical) low-pass filter with discrete notches at higher harmonics of the input frequency, such as 1.5 GHz, 2 GHz, and so on. In addition, we have shown three ways how to implement the inductance for the notch filter. This is equally applicable for other inductors in this value range. As frequency increases, this becomes more interesting but one needs to remember that many materials like silicon and gallium arsenide are extremely lossy. The same inductor approach has been used in Figure 5-61 of Chapter 5. For silicon, even the manufacturer becomes an issue. Figure 3-161 shows a top view of a "rectangular" inductor that actually approaches the spiral inductor; its implementation can be seen in Figure 3-162. Modeling this was a

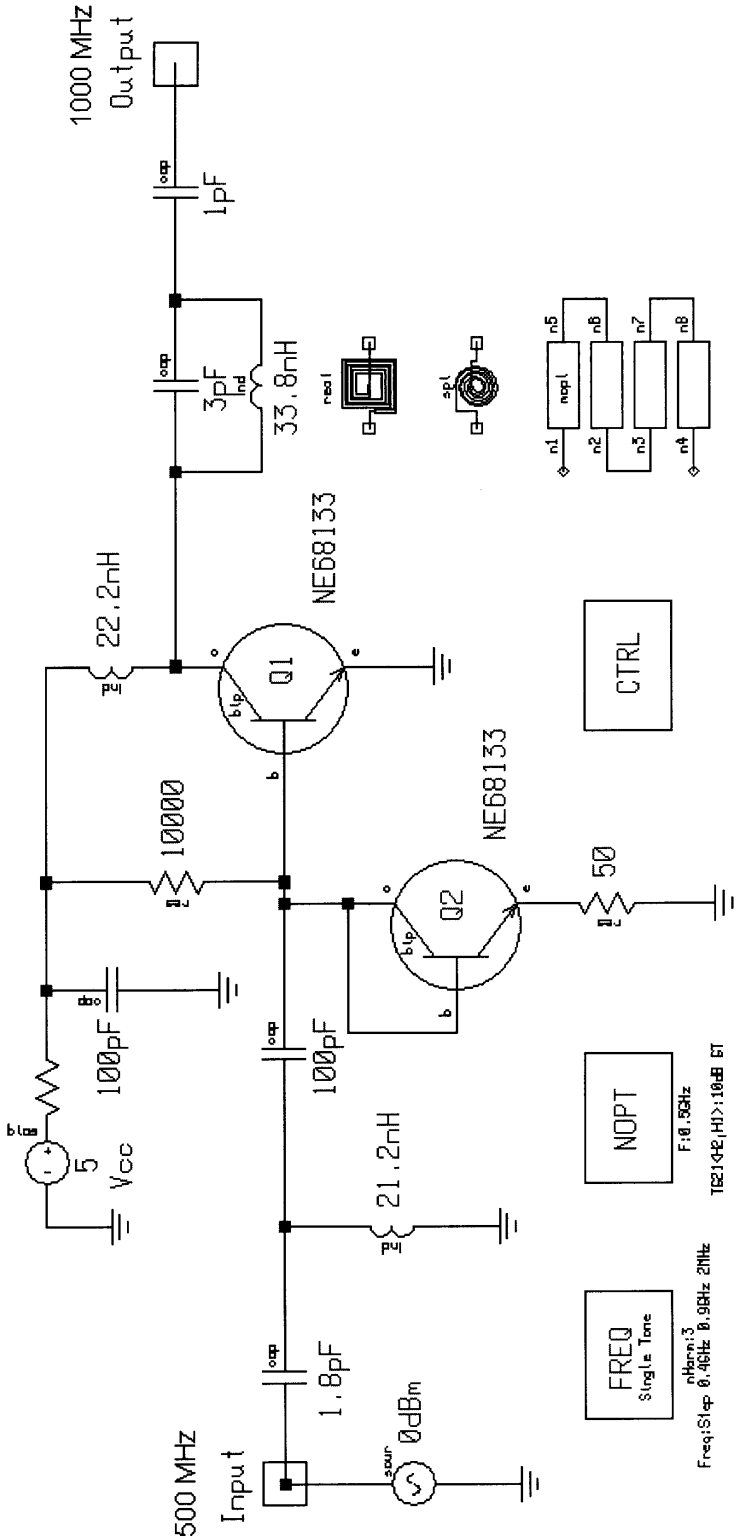

Figure 3-159 BJT frequency doubler schematic. A parallel-tuned trap in Q1's collector attenuates fundamental feedthrough.

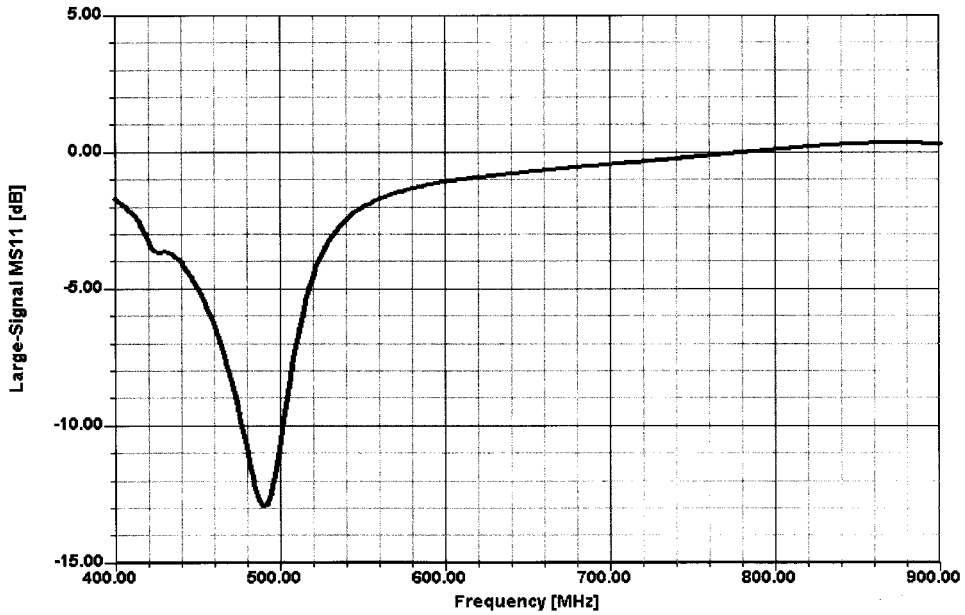

Figure 3-160 Large-signal MS_{11} for the BJT doubler. Note the positive region above 800 MHz.

nightmare, and during our Compact days, we actually had to modify the electromagnetic simulator to accommodate this and get results where measurements and simulation agreed. Figure 3-163 shows the measured and simulated Q as a function of frequency of a silicon-based inductor. In the case of other materials, such as PC board or GaAs, the models in the CAD tools are sufficient to predict the losses of the inductors. Following this initial exercise, Motorola then developed an improved silicon spiral inductor; its frequency-dependent Q is shown in Figure 3-164. Note that this Q was measured and not simulated.

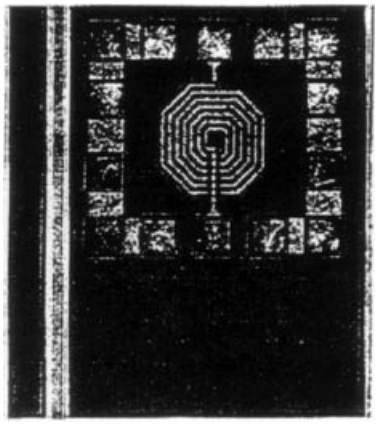

Figure 3-161 A 6.5-turn spiral inductor in silicon.

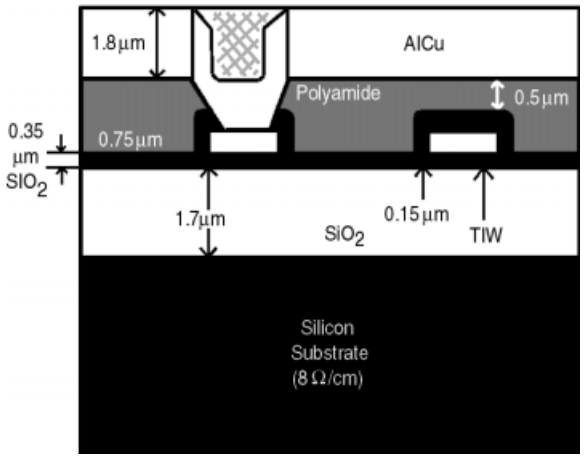

Figure 3-162 Cross section of the silicon inductor.

One of the reasons why we use a transistor multiplier is that we expect gain (because of the square-law characteristic, an FET would have been better tailored for a doubler); therefore, we have "measured" the gain of this circuit while driving it with 0 dBm. Another important factor is that, because of the way the CAD tool displays it, the gain is referenced to the 500-MHz input. Mentioning this is important; otherwise, the reader may look for the 1-GHz gain, which does not exist. Figure 3-165 shows the doubler gain.

By now we are curious to see the doubler in action, and by reviewing Figure 3-166 we can see the output spectrum. The output spectrum validates the statement that the output circuit, while doing a marvelous job of removing the 500-MHz input frequency, does not cure the problem of unwanted multiples of the input frequency. Again, a Cauer low-pass filter, while introducing some possible additional loss, should be considered for this circuit to have a bandpass response. On the other hand, many oscillators have very little harmonic suppression, and the same type of postfiltering needs to be considered. There are two-transistor solutions available also, such as push–push for frequency doubling (push–pull would

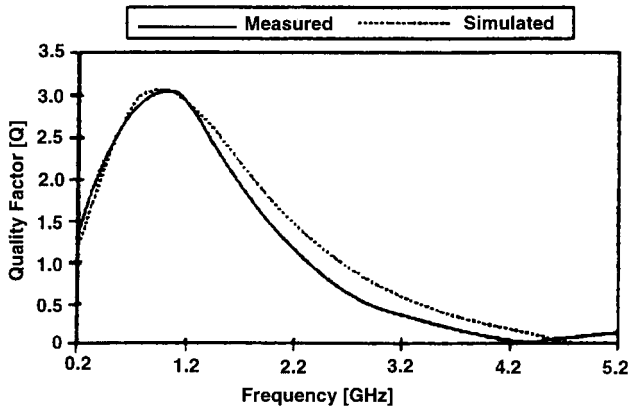

Figure 3-163 Measured and simulated *Q* versus frequency for the simulated inductor.

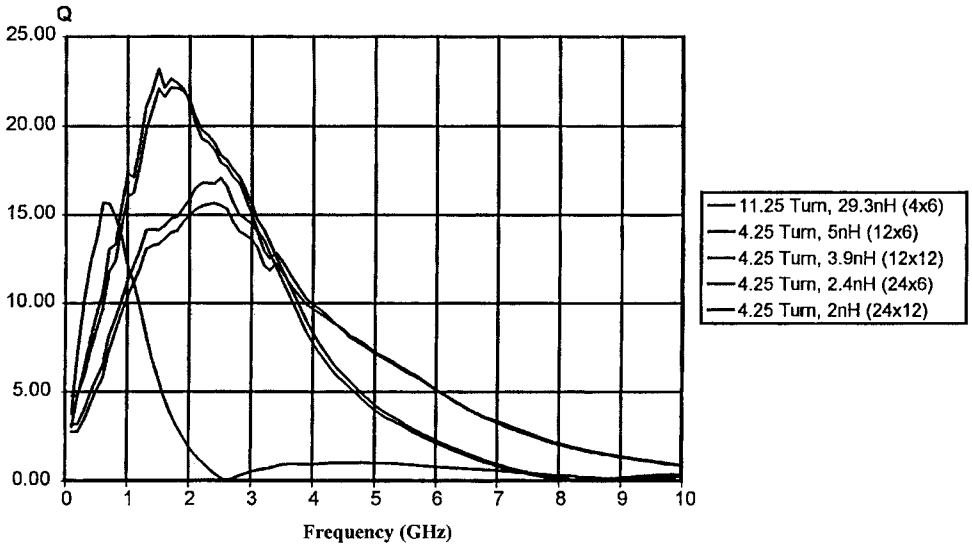

Figure 3-164 *Q* versus frequency for Motorola improved inductor.

eliminate the desired second harmonic quite well). Actually, two diodes could also have been used for doubling, but since this requires transformers and a postamplifier, we have shown the preferred application. The only advantage of the diode application is that it is wideband, while this BJT circuit, as we have just learned, must be made narrowband for reasons of spectral purity.

Finally, we are curious to see the actual operating state of this amplifier, and this can be done by analyzing the load line (Figure 3-167). This is as complicated as the analysis for the differential amplifier. Because of the stored energy in the various tuned circuits, the load line looks quite impressive and would probably be difficult to predict without a nonlinear CAD tool.

3-9 MULTISTAGE AMPLIFIERS WITH AUTOMATIC GAIN CONTROL (AGC)

Having discussed the basic differential amplifier, we will now evaluate the performance of the MC1350/1490 video amplifier chip from Motorola. Most of the circuitry in the chip is self-explanatory. Figure 3-168 shows its inner circuit, and Figure 3-169 show a recommended application. By grounding one side of the input, we effectively get the same performance as the differential amplifier just discussed, with one difference being that the input is now fed to the constant-current generator. To minimize the distortion at the two lower transistors, they are decoupled by a 66-Ω resistor. Figure 3-170 shows the frequency-dependent gain, matching, and noise figure. Since this particular device has been specifically designed for AGC purposes, we also show in Figure 3-171 its gain reduction versus applied AGC voltage.

3-10 BIASING

A lot has been written about biasing, and since the purpose of this book is not to focus too much on dc, the following examples including RF consequences have been selected and considered sufficient. Early application reports by Motorola and others have provided a wealth of data. As a side effect of the introduction of the wireless era, we find that the engineers are so pressed for time that the number of complete application reports has approached zero. This is one of the reasons why we have tried to minimize the mathematical basis of this book (some is still needed), while still providing practical assistance. Figure 3-172 shows a textbook type of approach for RF.

In order to decouple the transistor from the biasing, we use RF chokes and dc decoupling (bypass) capacitors. This is the technique used in previous examples, so one might ask, "What's new?" As frequency increases, these inductors are either not manufacturable or have such a low Q that their use becomes questionable. This is the point where one may introduce the so-called distributed elements.

Figure 3-173 shows the very same circuit but resorting to distributed rather than lumped elements. The newly introduced elements (part of any good, up-to-date CAD tool; see element library for how to use their physical element descriptions) are described next.

- *Transmission Line.* Any printed connection between two points on a circuit board is a transmission line (Figure 3-174). Its characteristic electrical impedance is a function of the square root of the dielectric constant (ε_r), the width, metallization, thickness and height above substrate of the line, and the loss tangent of the substrate. Since lines frequently have to be laid out in the form of curved connections or have a bend in their direction, we have to add elements capable of describing the high-frequency conse-

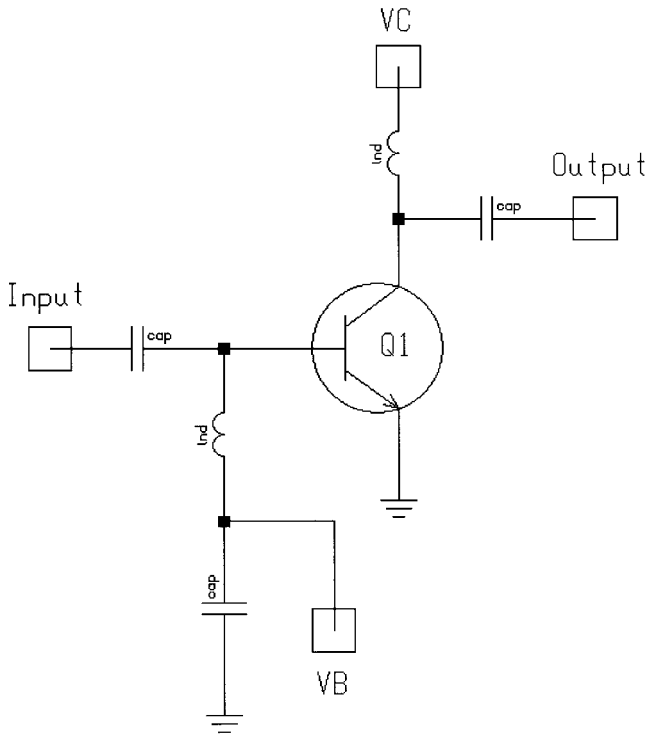

Figure 3-172 Simple BJT RF amplifier with lumped elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

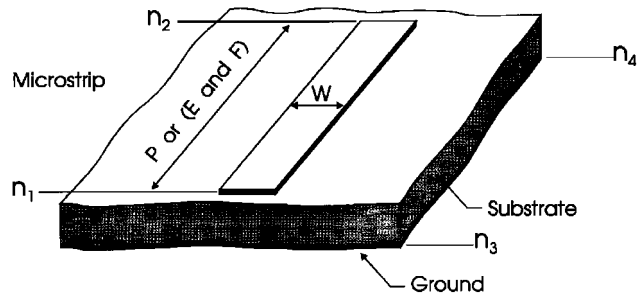

Figure 3-174 Transmission line in microstrip.

quences of such connections. Figures 3-175 and 3-176 show mitered and radial bend elements that perform this function.

- T *Junction, Cross, and* Y *Junction.* By the time a point like a collector or base, or its FET equivalent, spreads out into connections with other elements, we need additional modeling capability to describe ⊤ connections, crossings, and Y junctions. Figures 3-177, 3-178, and 3-179 show the way in which these connections must be modeled.

If the need exists, the standard inductances must be replaced with a transmission line whose length is λ/8 at the operating frequency. At higher frequencies, these transmission lines, however, then go into λ/4 resonant mode and later become capacitive. This type of design makes it fairly narrowband. A way around this is the use of printed inductors, as shown in Figures 3-180 and 3-181.

These inductors have a self-resonant frequency similar to the transmission line mentioned above, but the safety margin is significantly higher.

Talking about printed inductors, a logical extension of this is the printed transmission-line-based transformer, as shown in Figure 3-182. One can consider this as two interlaced rectangular inductors and, based on the substrate material, they are useful over a wide frequency range. Besides being used as a transformer, they can also be used to transit from

unbalanced to balanced transmission provided that the difference in length from a connection point of view does not cause any problems (this is a layout issue).

A popular form of combining stages is the so-called Lange coupler (Figure 3-183) invented by the German Julius Lange. It is one of the major contributions in wideband applications.

Useful application of the Lange coupler probably starts at 4 GHz. It consists of parallel transmission lines with the appropriate connections as shown. Lange couplers are typically built with four, six, and eight fingers. The Ansoft Serenade product has a Lange coupler synthesis program that can be used to gain more insight into this coupler's application. We assume that other modern software has similar capabilities.

Where meander-type inductors are necessary, a neat way to implement and simulate them is to use the multiple coupled lines element (Figure 3-184) of the Serenade product, which both quickly and accurately calculates the behavior of the meander, including self-resonances and losses. We made use of this arrangement in our previous examples.

- *Interdigital Capacitors.* The issue of tolerances of small capacitors already has been brought up. The interdigital capacitor can be made on printed circuit board material as

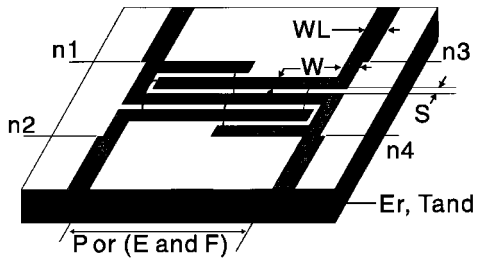

Figure 3-183 Four-strip Lange coupler.

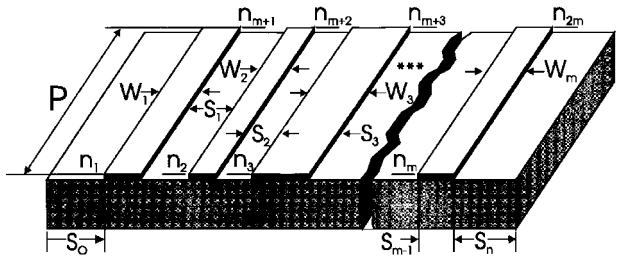

Figure 3-184 Multiple coupled lines element in microstrip.

well as gallium arsenide, and if its dimensions are continuous with the transmission-line width it does not cause any abrupt changes in impedance. This type of capacitor permits one to obtain very small values. An alternative to this is the use of transmission lines with a length of $\frac{3}{8}\lambda$. We learned earlier that a transmission line is inductive at frequencies below its fundamental resonance, is resistive at below resonance, and becomes capacitive above resonance. Again, bandwidth is also an issue. An interdigital capacitor consists of a number of parallel fingers as shown in Figure 3-185, and its capacitance can be varied by adjusting the number of fingers and their spacing. The advantage of the interdigital capacitor compared to discrete components is its low variation in value.

- *Radial Stubs.* The radial stub (Figure 3-186) is not much different from a $\lambda/4$ resonator, but its bandwidth is much greater than a simple transmission line. This is another way to ground the "cold" side of a transmission line or part of a circuit that needs to be grounded for RF. Of course, the interdigital capacitor comes in a version that is a combination of a capacitor and a via hole.
- *Via Holes.* The "cold" end of the transmission line, being considered either an inductor or a capacitor, needs to be connected to a sufficiently large copper backplane. One very efficient way to do this, especially if there is not enough copper left on the top of the board, is the use of via holes (Figure 3-187). One could theoretically generate

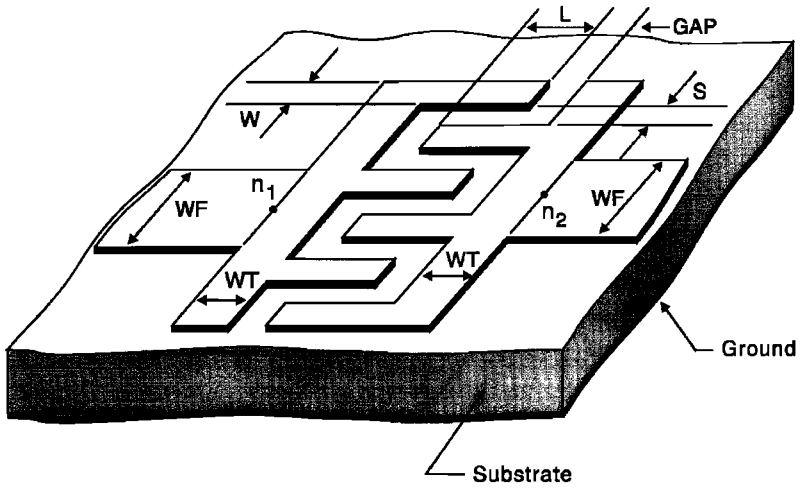

Figure 3-185 Interdigital capacitor.

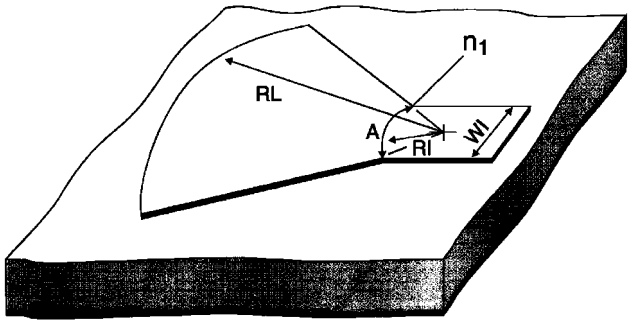

Figure 3-186 Radial stub.

a via hole with a rivet, but most manufacturing processes don't allow this; the normal solution is to use plated-through holes left open. In PC boards, via holes are typically cylindrical; on substrates like GaAs, they may be conical.

- *Correction Elements.* Although the behavior of an actual circuit proceeds regardless of our ability to measure and describe it, we do not enjoy this luxury in simulating circuit behavior in software. In a simulator, effects that are insufficiently described will be inaccurately simulated. For instance, segments of high-impedance transmission line (e.g., 120 Ω) are frequently used for dc feeds and RF chokes. In predicting the effect of a transition from 120-Ω line to 50-Ω line, a simulator must be alerted to the discontinuity so it can do the necessary mathematical corrections to account for the impedance jump. To do this, a specific circuit element, the STEP (Figure 3-188), must be inserted between the 120-Ω and 50-Ω line elements in the simulation circuit file. In addition to substrate data, we characterize a STEP by providing the widths of its input and output lines. The element itself has no physical length.

A similar correction is necessary if a transmission line is used as a resonator or just "left open" at one end. Such a transmission line tends to radiate and, because of its high-impedance properties, it reacts differently as far as its electrical length is concerned. A zero-length one-port element, the OPEN (Figure 3-189), must be added to such a line for mathematically correct calculation.

We end this excursion into distributed elements here. Interested readers may want to obtain a CD containing the element library of their favorite CAD tools that combine capabilities in the microwave area with a full set of distributed circuit elements. It is most important to keep

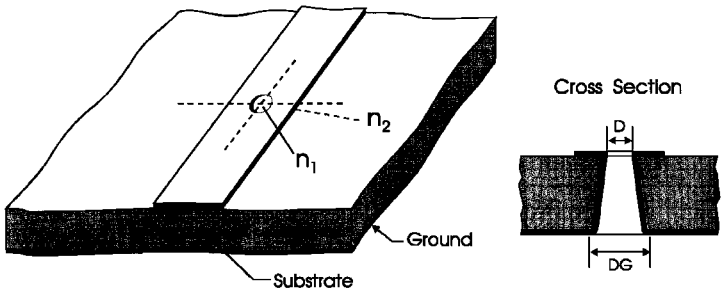

Figure 3-187 Via hole.

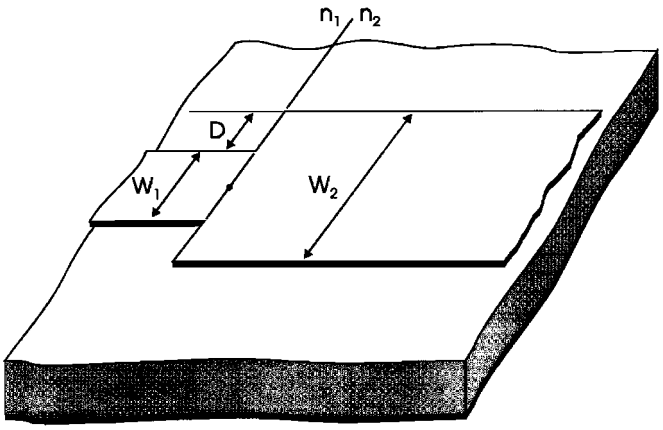

Figure 3-188 The STEP element tells the simulator to calculate the effects of joining transmission lines of differing characteristics.

in mind that, as frequency increases, we rapidly move into the area where we must consider all these distributed elements to achieve accurate simulations—even if doing so makes simulation a painful and time-consuming effort.

Finally, anyone who adventures into this area *must* obtain a foundry manual from the company that will build the integrated circuit or hybrid under design. There are basically two foundries, one applicable for MOS technology and one for GaAs. In the case of the bipolar transistor, the foundry service is not yet well-established. While we were able to interest one German company and one U.S. company in generating a custom bipolar IC within the activities of this book, the only "open" foundry we know of for bipolar (actually HBT) technology is the one operated by TRW. As of 1999, this seems to be the leading company for BJT-related products, and many currently available ICs have been developed with this foundry service.

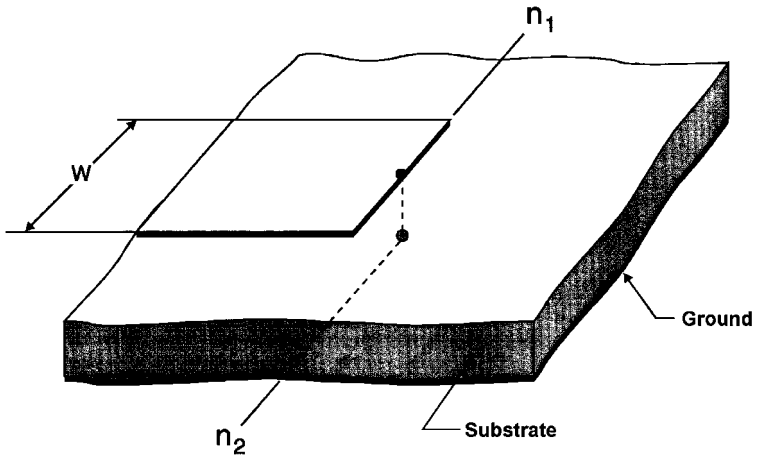

Figure 3-189 The OPEN element tells the simulator to calculate the effects of leaving the end of a transmission line unconnected.

We mention the issue of foundries here again because each foundry has its own proprietary approach to modeling discontinuities. The availability of a foundry service somewhat eases the requirement that a designer be fully up to speed on the nuances of discontinuities, because a foundry's designer service will help customers account for all relevant parasitics or discontinuities in their designs. In addition, there are tables of *S* parameters for standard cells of either capacitors, resistors, or inductors. The designer may then be forced to adjust the circuit so that it will work with a particular inductance value or value of another component within the resolution of the table that describes these elements. Information on the active parts, such as diodes and transistors, was given in Chapter 2.

3-10-1 RF Biasing

Applying the knowledge we have just acquired about distributed elements, Figure 3-190 shows a somewhat exaggerated case of using the various elements. While it is consistent with the simple RF case with which we started, modeling of this type is certainly necessary at higher frequencies. Many but not all of the elements we have just described are used, but we have not solved the question of the actual dc biasing.

3-10-2 dc Biasing

The following discussion is the recommended procedure for biasing a transistor. We will start with the collector current (in our example, Figure 3-191, 10 mA). To separate RF and dc, we have a combination of a load resistor (R_L) and an inductance (L_C). Information about this operation was given already in Section 3-2-6. The emitter resistor should have a voltage

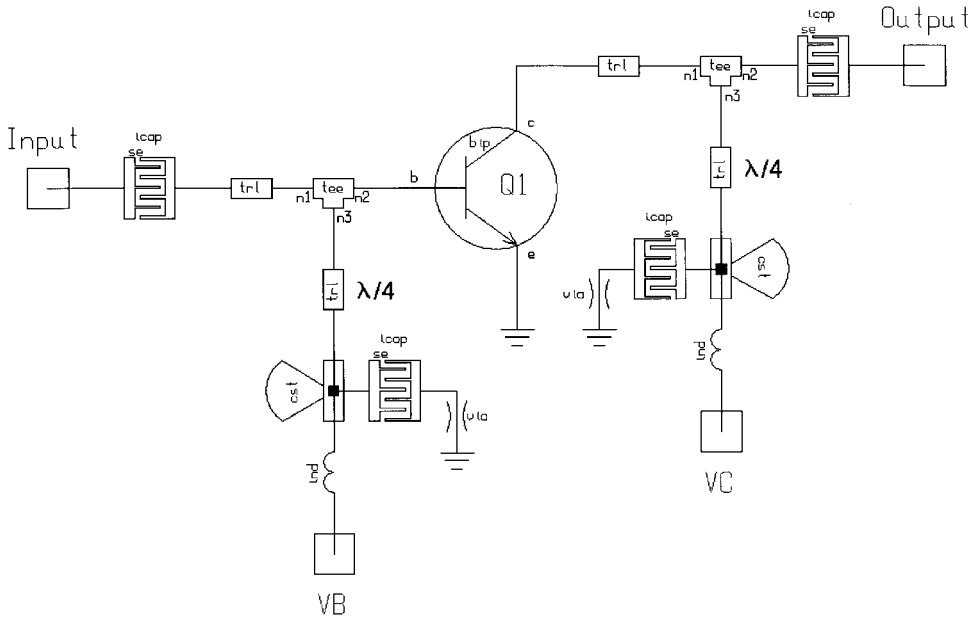

Figure 3-190 Simple BJT RF amplifier with distributed elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

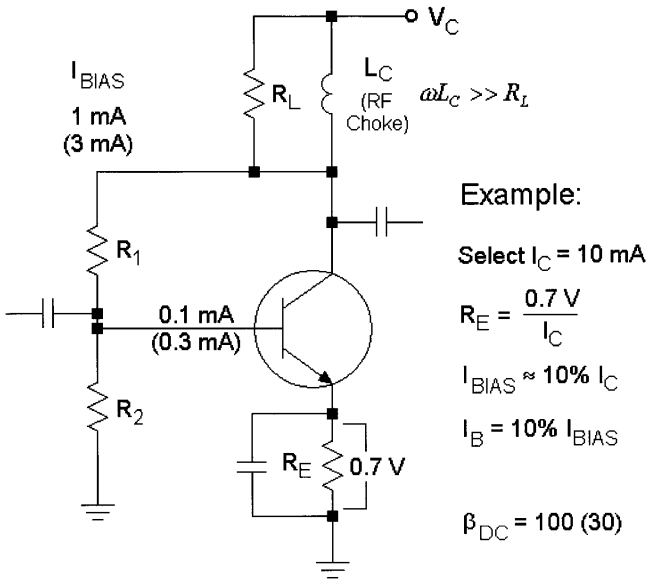

Figure 3-191 A dc biasing example.

drop of about 0.7 V, and therefore the emitter resistor is $0.7/I_C$. The next assumption is that the transistor has a dc current gain of 100, and therefore we decide to have the bias resistor chain (R_1 and R_2) draw 10% of I_C, or 1 mA. Assuming a collector voltage of 5 V, the value of $R_1 + R_2$ has to be 5 kΩ to result in the required 1 mA. Because the base current now is 10% of the divider current, the base will draw 0.1 mA. The voltage across R_2 has to be the voltage drop across R_E (0.7 V) + V_{BE}, which is also 0.7 V, or 1.4 V. Given the 1 mA, R_2 = 1.4/1E–3 = 1.4 kΩ. R_1 therefore is 5 kΩ – 1.4 kΩ = 3.6 kΩ. This concludes the calculation.

In the case of a dc beta of only 30, we need to raise I_{BIAS} from 1 mA to 3 mA since the base current now will be 0.3 mA. This changes the resistor values. $R_1 + R_2$ = 5 V/3 mA = (rounded) 1.6 kΩ. Following the same approach, we need 1.4/3E–3 = (rounded) 470 Ω. This makes R_1 = 1600 Ω – 470 Ω = (rounded) 1100 Ω. These roundings were necessary because resistors can only be bought in certain resistance steps.

However, for low battery voltages, the 0.7 V between the emitter and ground cannot be wasted. Therefore, a dc stabilization circuit, to which we have already referred, will be considered next. Figure 3-192 shows a combination of an RF transistor, Q1, and a dc stabilization transistor, Q2. The most important thing about this circuit is the fact that the difference between the supply voltage and the collector of Q1 is 0.3 V, which is approximately half of the voltage we had to "waste" across R_E in the above-mentioned circuit. Plus, the voltage drop is now in the collector, and given the fact that we feed Q1's collector through the inductor of a quasi-tuned circuit rather than through only a resistor, we get a much higher voltage swing. The base–collector diode temperature dependency of Q2 is compensated for with the silicon diode feeding the base. It is also fascinating to see that, because of the low currents, both the voltage drop of the diode and V_{BE} of Q2 are about the same, and yet Q1, operating at a reasonable current, shows the expected 0.7–0.8 V V_{BE}. We have supplied all the necessary dc voltages to give the reader an incentive to calculate the mechanism of this stabilization. The key equation to this is to determine the current in the voltage divider feeding

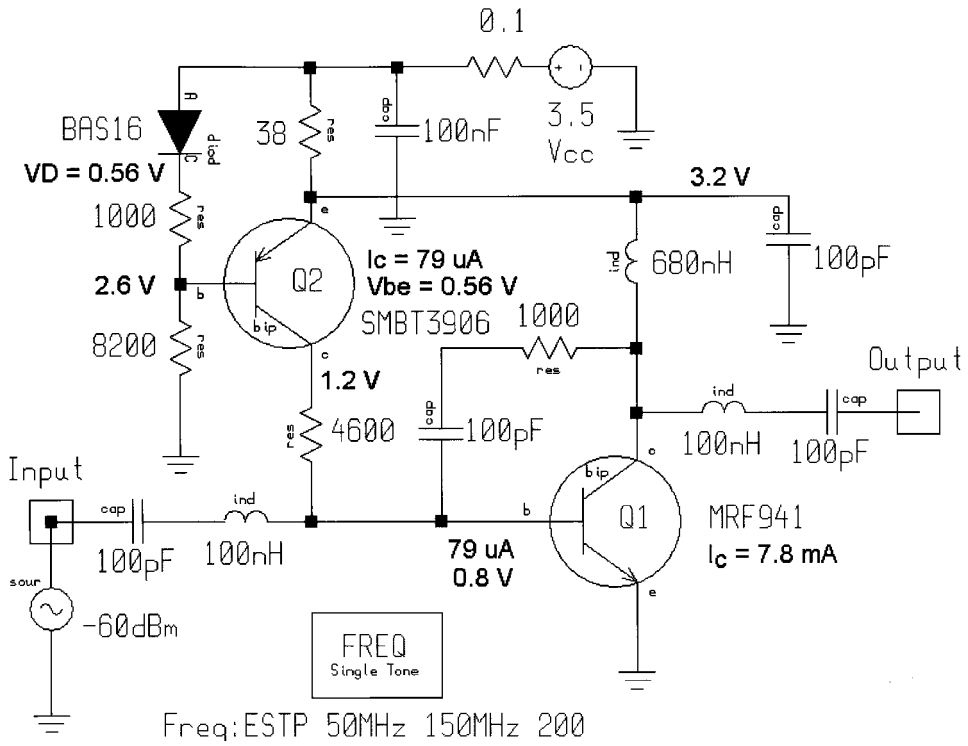

Figure 3-192 An RF amplifier with active biasing. (After the low-noise amplifier circuit in [29].)

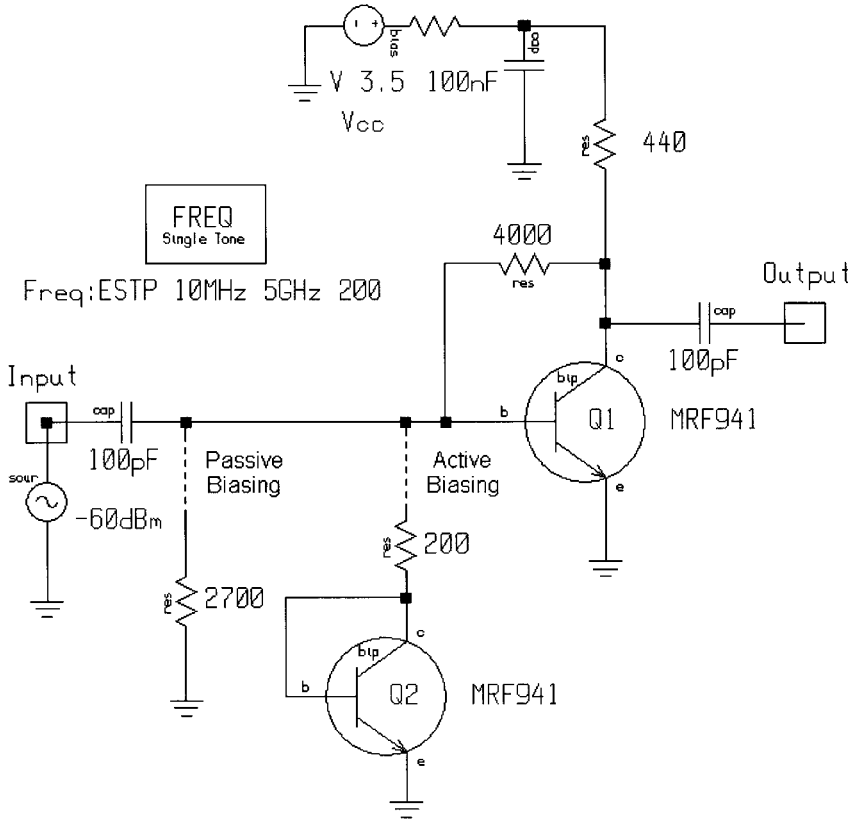

Figure 3-195 Amplifier stage (I_C = 3 mA) showing active and passive bias alternatives.

Q2, and proceeding from there. On the other hand, having a nice CAD tool that provides insight into the dc voltages and allows the addition of dc voltage probes makes life much easier. To prove that this circuit actually works, Figure 3-193 shows its frequency-dependent gain, matching, and noise figure performance. It is based on a Motorola application, which had excessive voltage drop for Q1 and which we have improved to be suitable for low-voltage operation [29].

Integrated active bias solutions are also available. Figure 3-194 shows the Siemens BCR400 active bias controller applied to a BJT; it can also be applied to FETs and TR switching diodes, as we saw in Figures 3-57 and 3-59, respectively.

3-10-3 dc Biasing of IC-Type Amplifiers

In integrated circuits, we do not have the unlimited flexibility described earlier. This results frequently in constant-current sources or transistors being used as diodes for biasing purposes. Our first suspicion is that this is going to cause a lot of noise in the IC; Figure 3-195 shows a test example.

As suspected, choosing the same bias point of 3 mA, the noise figure using active bias is quite a bit higher than the passive one, as shown in Figure 3-196.

3-11 PUSH–PULL/PARALLEL AMPLIFIERS

Since it is practically impossible to obtain $S_{11} = S_{22} = 0$, using a combiner at the input and output reduces the problem. Figure 3-197 shows the 3-dB hybrid approach. It has a practical

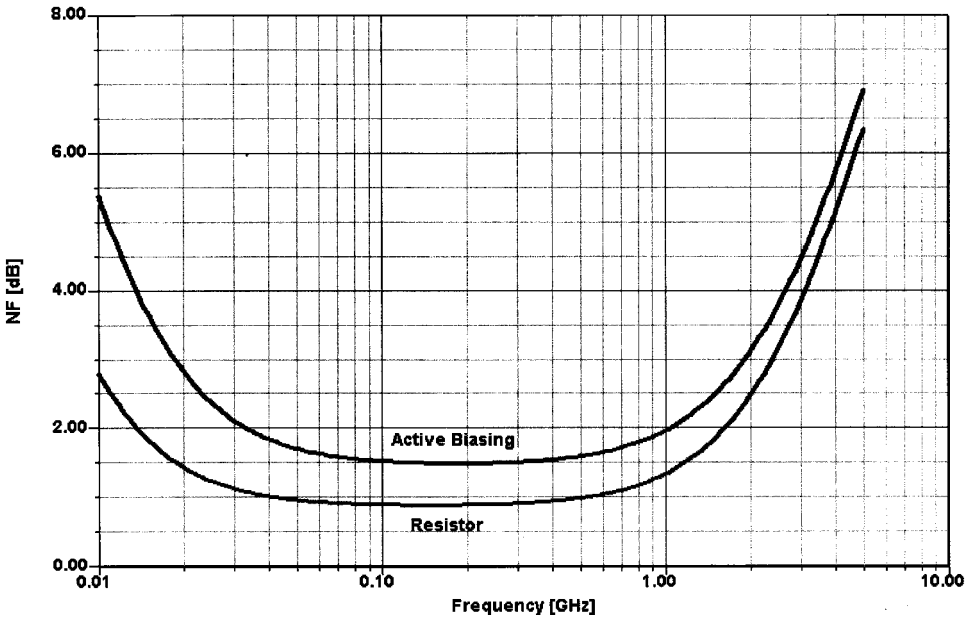

Figure 3-196 Frequency-dependent noise figure of the amplifier circuit shown in Figure 3-195. The active biasing curve is considerably noisier.

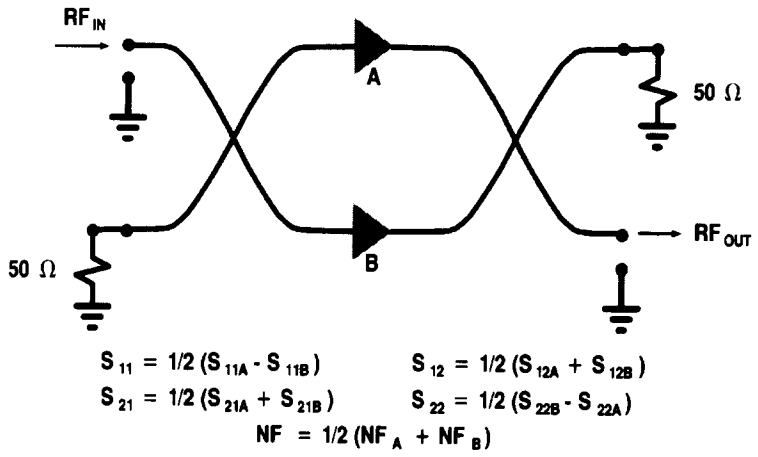

Figure 3-197 Combining power with 3-dB hybrid couplers.

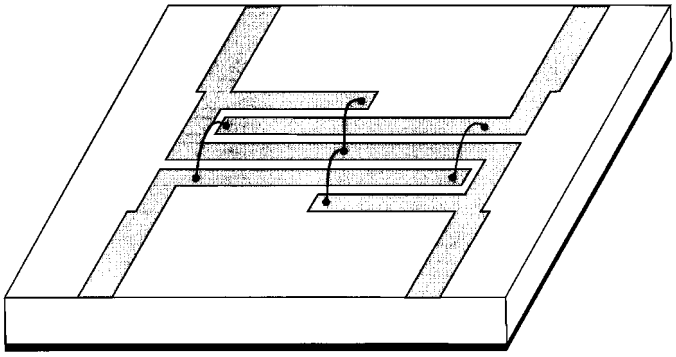

Figure 3-198 Four-strip version of the Lange coupler, a broadband 90° hybrid.

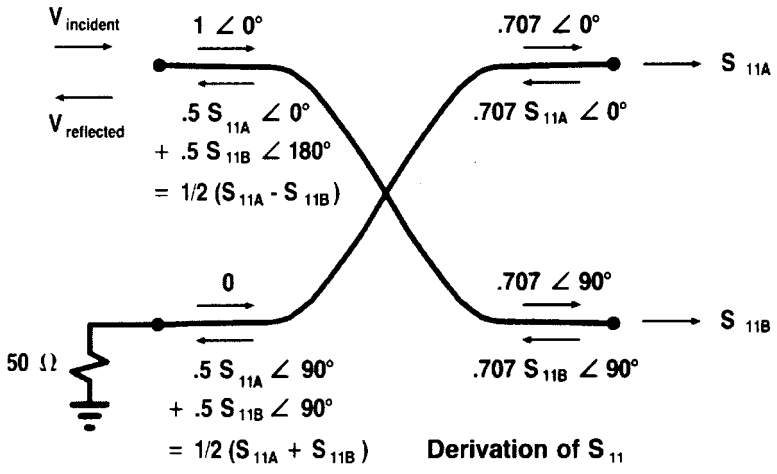

Figure 3-199 3-dB hybrids. This analysis method may be applied to any coupler.

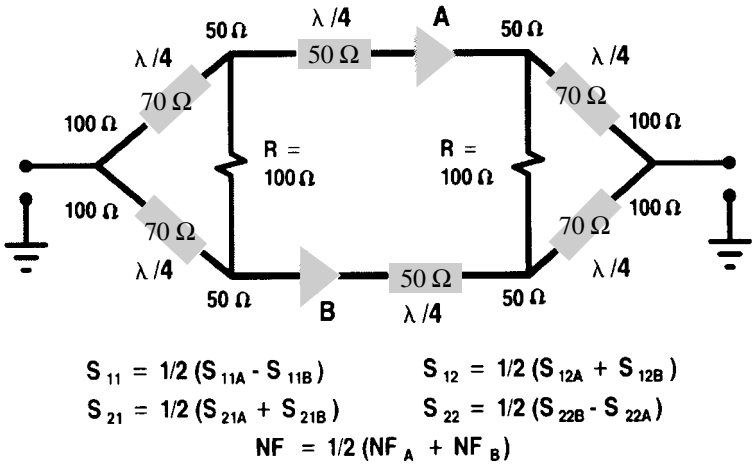

Figure 3-200 Wilkinson divider/combiners.

bandwidth limit of about 4:1; its advantage is that it is compact and ideal for cascading. If one stage opens, P_{OUT} and gain drop only 6 dB; however, it does not protect against load mismatch. A recommended distributed form is the Lange coupler (Figure 3-198). To analyze this approach, Figure 3-199 shows the resulting impedances and necessary phase shifts. If a Wilkinson coupler [30] is used instead of the 3-dB hybrid, the bandwidth is reduced. The Wilkinson coupler is larger in size than the 3-dB hybrid but more easily realized, leading to lower cost. Figure 3-200 shows the actual impedances necessary for matching, with A1 and A2 being the actual amplifiers combined.

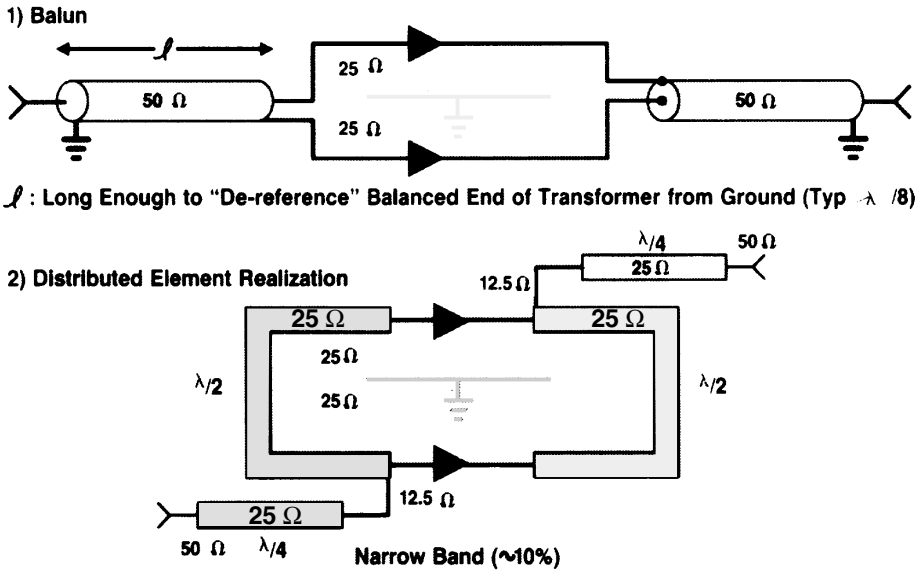

Figure 3-201 Push–pull amplifiers.

The solution for push–pull amplifiers resorts to a balun with the following results obtained: Bandwidths of greater than one decade are achievable; the balun structure gives 4:1 impedance advantage; there is no isolation; $S_{11} \neq 0$, $S_{22} \neq 0$; and cancellation of even-order products is provided.

Since most amplifiers have 50-Ω rather than 25-Ω impedances, Figure 3-201 shows a circuit that matches 25 Ω to 50 Ω on both sides. Since the standard amplifier operates at 50 Ω rather than 25 Ω, an additional network may be necessary to transform the impedance up to 50 Ω again. A similar problem occurs at the amplifier output.

3-12 POWER AMPLIFIERS

Power amplifiers are devices that are tasked to transform as much dc power into RF/microwave power as possible. Depending on the technology, devices are available that can produce at least 100 W up to 2 GHz. Since the transconductance of FETs at conducting angles of less than 180° becomes very small, the actual power gain sharply decreases compared to Class A operation while the power-added efficiency is optimized to values of 55% (Class B) or so. The dissipation of these devices is, of course, quite high, while in Class B operation this is even more of an issue. Power devices in Class C are dying to have big heat sinks to survive. One of the nice things about FETs is a much reduced thermal runaway effect compared to their bipolar brothers.

Power amplifier classes are defined in terms of the device conduction angle and/or the type of device operation:

Class A	"Linear" operation; 180° conduction angle
Class AB	"Linear" operation; conduction angle between 90° and 180°
Class B	"Linear" operation; 90° conduction angle
Class C	Fixed drive; less than 90° conduction angle
Class D	Switched operation, conduction range may vary with time from 0° to 180° or may be fixed.

There are also Classes E and F, which are currently under evaluation and showing some promising results.

Figure 3-202 shows Class C operation. The output of the amplifier is a current pulse train, which frequently leads to misunderstanding as to the calculation of its load. Given the fact that the amplifier is a current generator, it is silly to assume one has to do a conjugate matching looking backward into the amplifier. This is the condition for Class A operation. Unfortunately, this is still not understood by some engineers, but we hope we can clear this up today. The theoretical efficiency is 89.7% at a conducting angle of less than 180°; in practice, efficiencies more than 85% are not obtainable. (All of these efficiencies are those of the device itself; losses in matching networks are not taken into account in these efficiency values.) Considering optimal gain and optimal output power, the conducting angle actually settles somewhere between 100° and 140°. Again, the power gain in Class C operation is less than in Class A and Class B operation.

3-12-1 Example 1: 7-W Class C BJT Amplifier for 1.6 GHz

The following demonstrates how to design a 1.6-GHz, 7-W amplifier operating in Class C. We need to point out again that all modulation forms that contain the information in both

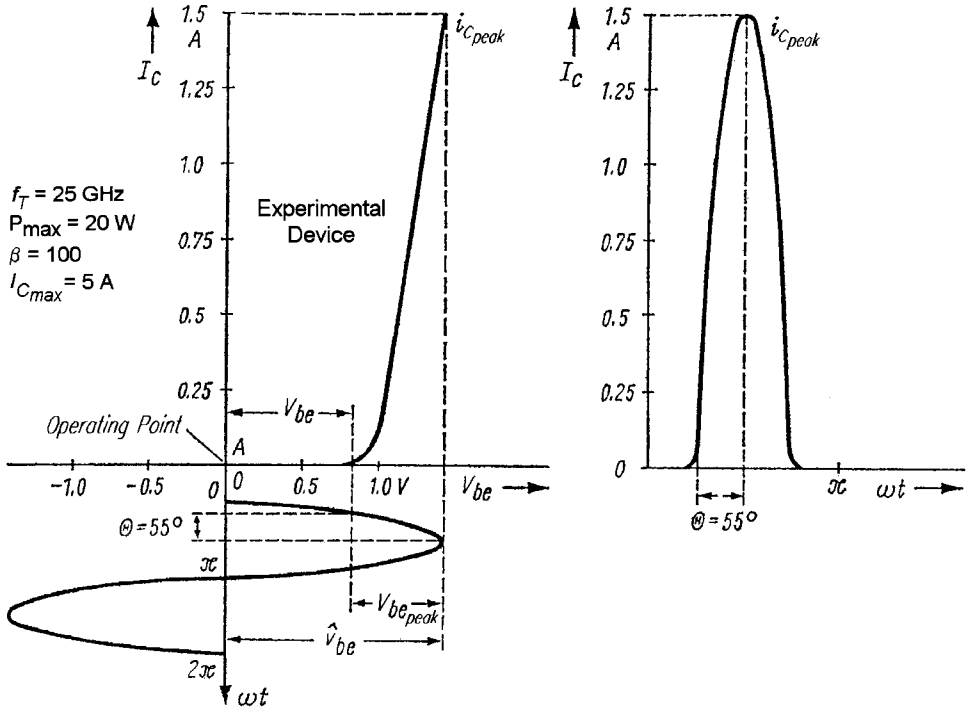

Figure 3-202 Output current as a function of drive voltage, taking into consideration the knee voltage of the base–emitter *pn* junction. The output is a series of current pulses with a duty cycle determined by the conduction angle.

amplitude and phase require more linearity than Class C affords. Needless to say, this affects the efficiency; therefore, at a later point we will also show a Class AB power amplifier. This is a tutorial, so we will present a UHF example and walk the reader through all the problems involved in the design. The selection of the transistor is done by first looking at the f_T, which in our case should be at least 4–5 GHz. The first order of business is to define the point of operation for the output amplifier. To do this, we need to determine the maximum voltage and current values supplied by the manufacturer. We have chosen a device that operates at 28 V and can sustain a peak collector current of 1.5 A. Figure 3-202 lets us determine the conducting angle Θ from the I_C/V_{BE} plane. This figure shows on the left side the I_C/V_{BE} plane and the necessary voltage to drive the amplifier.

Initially, we assume that the base–emitter junction is operated without any bias ($V_{BE} = 0$). The dc I–V curve shows that the collector current starts at about 650 mV. The amplifier itself, therefore, is already in Class C operation. For full output power, the drive voltage $V_{BE,\text{peak}}$ has to be 1.14 V. Therefore, the conducting angle can be determined by

$$\cos \Theta = \frac{V_{BE}}{\hat{\boldsymbol{v}}_{BE}} = \frac{0.65}{1.14} = 0.57$$

$$\cos 0.57 = 55^\circ$$

V_{BE} is the dc voltage at which the transistor starts conducting. From Figure 3-65 and Eqs. (3-160), (3-161), and (3-162), the fundamental current i_{c1} can be determined from

$$i_{c1} = i_{\text{peak}} \cdot f_1(\Theta)$$

or

$$i_{c1} = 1.5 \text{ A} \times 0.36 = 0.54 \text{ A}$$

The average collector dc current can be determined from

$$i_{c2} = i_{\text{peak}} \cdot f_2(\Theta)$$

or

$$i_{c2} = 1.5 \text{ A} \times 0.21 = 0.315 \text{ A}$$

The collector saturation voltage $V_{CE(\text{sat})}$, unfortunately, is around 2–3 V; for the purpose of the calculation, we assume that the saturation voltage is 3 V, and, therefore, we can assume that the maximum collector ac voltage $\hat{v}_{CE} \approx (V_B - 3) = 25$.

The appropriate collector load has to be

$$R_C = \frac{\hat{v}_{CE}}{i_{C1}} = \frac{25}{0.54} = 46.3 \ \Omega$$

The maximum output power is

$$P_{\text{out}} = \frac{(V_{CE} - V_{CE(\text{sat})})^2}{2R_C} = \frac{625}{92.6} = 6.75 \text{ W}$$

The only way to increase the power would be to have a smaller collector load at a higher current. In this family of Motorola transistors, there was no 10-W transistor; that's why we have chosen a 20-W experimental device, which for this purpose is overkill. The theoretical efficiency of the amplifier is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{6.75 \text{ W}}{0.315 \times 28} = 85\%$$

If the saturation voltage would be less, our efficiency would automatically increase, since for the given load, the actual output power would increase (6.75 W $\rightarrow$ 7.5 W). Assuming that this stage would operate at 1900 MHz with a gain of roughly 22 dB, the required drive would be significantly less than the output power, or roughly 40 mW. For the purpose of the following calculations, we will assume that the drive power is 0.7 W. The total dissipation of the device now adds up to be

$$P_T = P_{\text{in(dc)}} - P_{\text{out}} + P_{\text{drive}}$$

$$P_T = (28 \times 0.315) - 6.75 + 0.7 = 2.77$$

Power-added efficiency is derived from this. Knowing the power dissipation, one can calculate a thermal resistance R_{therm} of the heat sink and the transistor:

$$R_{\text{therm}} = \frac{T_J - T_A}{P_T}$$

Where T_J is the device junction temperature and T_A is the ambient temperature. For a maximum ambient temperature of 60 °C and a maximum junction temperature of 150 °C, the thermal resistance is

$$R_{\text{therm}} = \frac{120 - 60}{2.77} = 21.7\ ^\circ\text{C/W}$$

R_{therm} is the sum of thermal resistance of the transistor and its package, and the thermal resistance between the transistor package and the heat sink, and the thermal resistance between the heat sink and the ambient air. Therefore,

$$R_{\text{therm}} = R_{\text{th(case)}} + R_{\text{th(case/heat sink)}} + R_{\text{th(heat sink)}}$$

The required thermal resistance of the heat sink is calculated from

$$R_{\text{th(heat sink)}} = 21.7 - 10 - 1.4 = 15.6\ ^\circ\text{C/W}$$

Assuming an aluminum heat sink (a 2-mm-thick plate), the required heat-sink surface area A (cm^2) is

$$A = \frac{1}{\alpha R_{\text{th(heat sink)}}}; \quad \alpha \approx 1.5\ \frac{\text{mW}}{^\circ\text{Ccm}^2}$$

Therefore, the required area is

$$A = \frac{1}{1.5 \times 0.0156} = 42.7\ \text{cm}^2$$

The next task is to match both the input and output to the (most likely) 50-Ω source and termination. The following section will guide us through the procedure. The input impedance Z_{11} (after some lengthy search) was found to be $1 + j10\ \Omega$. This means that the input consists of the base-spreading resistance (approximately 1 Ω) and an input capacitance, which because of phase shift now turns out to be inductive. Since the popular method for input matching these days is a pi configuration, we are going to use a simple pi filter both for input and output matching. There are several equations in the literature that give the values for the two capacitors and inductors; most of them result in an incorrect resonance frequency. Since we have access to software tools, we decided to take three approximate values and use the optimizer to give us the appropriate matching. The only remaining variable in such an approach is the bandwidth. If we specify $S_{21} = 1$ and $S_{11} = 0$ (100% energy transfer and perfect return loss), we will realize that this is possible at only one frequency. We therefore need to identify a frequency band or bandwidth over which an acceptable match is needed. As the bandwidth increases, the match for such a simple circuit will get poorer; there are not enough elements available to do better. In this case, we took the center frequency ±100 MHz.

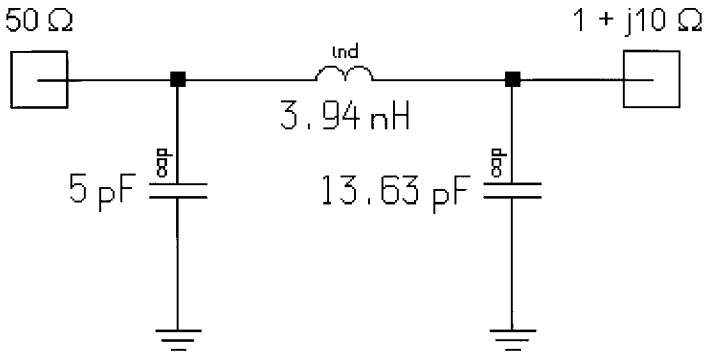

Figure 3-203 Input matching network for the amplifier used in this tutorial.

Figures 3-203 and 3-204 show the actual circuit with the element values and the resulting input match. Likewise, we did the same thing at the output, but the actual resulting dynamic output capacitance is not known *a priori*. For low frequencies, the integral equation gives a value of $2C_{CE}$; however, practical tests in frequencies above 500 MHz show that the actual increase is only 1.3 times the dc output capacitance. Therefore, we decided to design the filter with no output capacitance assumed, and the input capacitance of about 5 pF must be reduced for proper reactive matching. Mathematically, this could result in a negative number, specifically if the resulting output capacitance exceeds the 5-pF value. To compensate for this, one needs to use an RF choke that tunes out the resulting dynamic output capacitance and then one can revert to the original 5 pF as calculated.

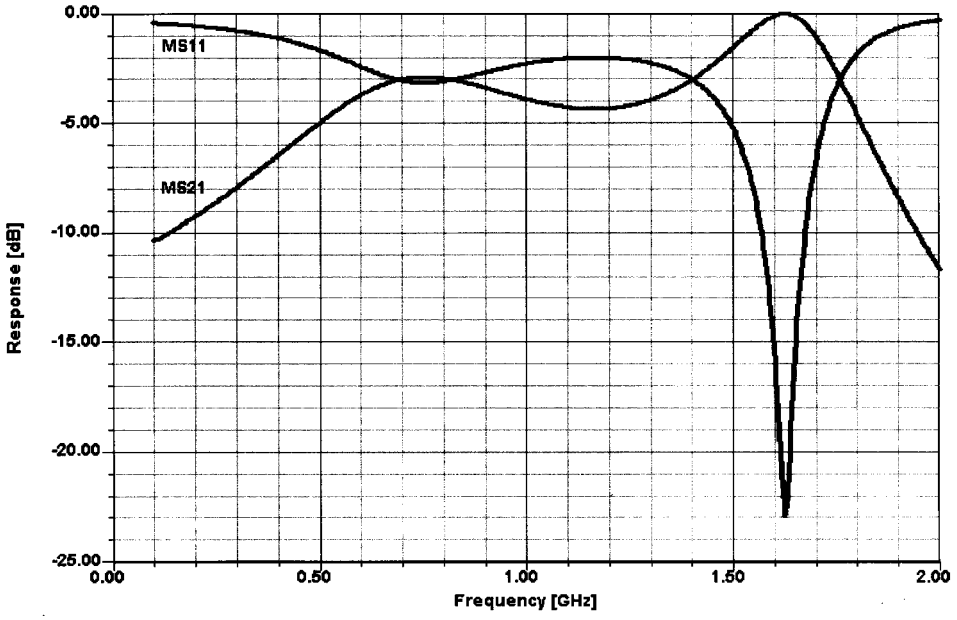

Figure 3-204 Frequency response of the input matching network.

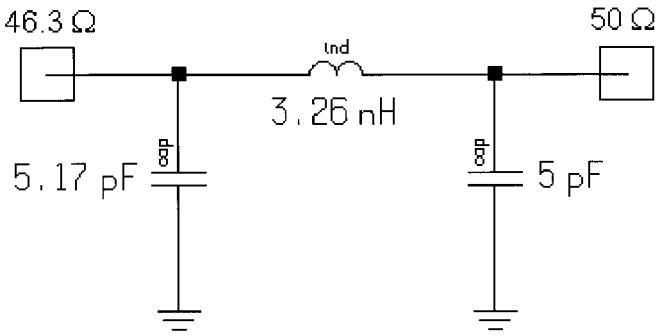

Figure 3-205 Output matching network for the amplifier.

The selection of the actual component is another issue, because these capacitors need to handle several amperes of RF current. It is not always easy to find capacitors with the appropriate value that can handle the current. The inductors can be printed. The paragraph following this section therefore will deal with the issue of how to translate the lumped values into distributed values, which will make the current handling much easier (we hope).

For this, we did the same optimizing approach by using a 50-Ω source and a 46.3-Ω load. Figures 3-205 and 3-206 show the circuit with the appropriate values and its simulated frequency-dependent responses.

The next step is to connect the input and output matching network to an "actual" transistor. This is a point where difficulties arise, since very few, if any, companies provide SPICE-type

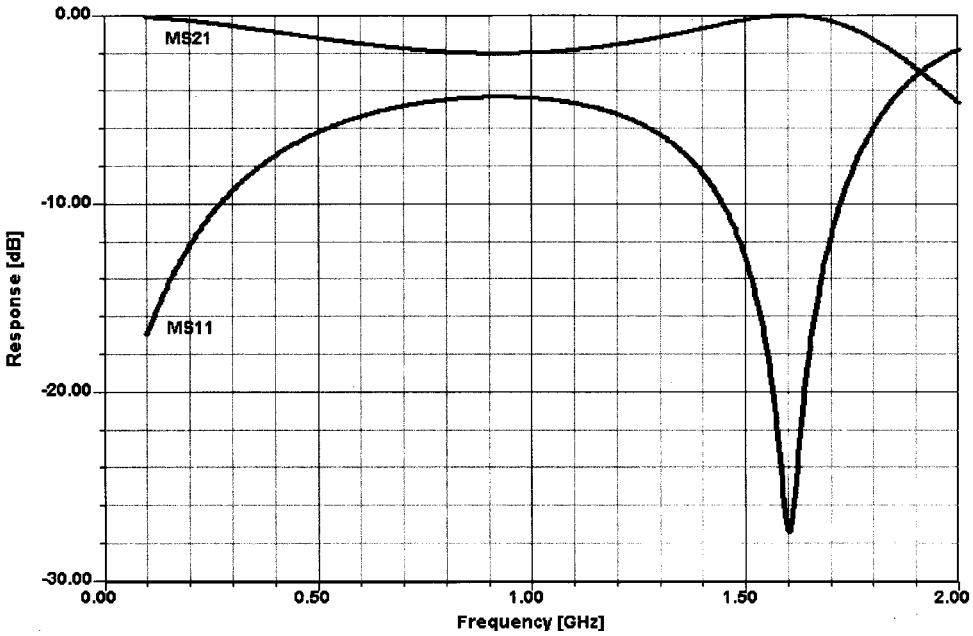

Figure 3-206 Frequency response of the output matching network.

parameters for transistors operating at currents of more than 200 mA. Figures 3-207 and 3-208 show the overall schematic and frequency response of the actual amplifier with all filters connected. Figure 3-209 details the amplifier's peak gain response. If more bandwidth is needed, the matching circuit must be increased in complexity, as will be shown in the following section.

Now is a good time to look at the final results of our simulation, which is based on the various assumptions as outlined above. Figure 3-210 shows the dc *I–V* curves with a straight load line and no reactances. This was accomplished by using a wideband transformer instead of an output matching circuit. Figure 3-211, however, shows the "load line" that results when the transformer is replaced with a real matching network. Based on the harmonics content and its improper termination, one can see how the output load line opens and shows ringing in the low-current area. If we expect to see the saturation voltage, we will be disappointed because the saturation voltage is frequency dependent (increases with frequency) and this figure gives an erroneous impression. Hence, we show dc *I–V* curves. To display the conduction angle, which we showed previously, we examine the output current as a function of time at a drive level of +16.5 dBm (Figure 3-212). During the negative half, the transistor is not conducting as predicted, so this validates our assumptions. Next, we are interested in determining the power gain. Therefore, we look at the output spectrum for a drive level of +16.5 dBm (Figure 3-213). It shows an output level of 38.6 dBm. If we subtract the drive level (16.5 dBm) from this, we see that the power gain is 22.1 dB at this drive level. Since we are used to thinking in watts, Figure 3-214 shows the absolute output power and the harmonics prior to filtering. Figure 3-215 shows the output spectrum after replacing the transformer with a simple pi output network.

During the conduction period, there will be a voltage across the transistor 180° out of phase, as shown in Figure 3-216. Finally, to highlight the nonlinearity of a Class C amplifier, Figure 3-217 shows the amplifier's output power versus drive, and Figure 3-218 shows the amplifier's gain versus drive. When the transistor turns on is clearly evident.

A particular difficulty arises in the case of FETs, where the charge energy makes for a difference between dc and pulsed measurements. Figure 3-219 shows this. Some of the more modern transistors, such as SiGe types, may need some pulsing also; as can be seen in Figure 3-219, even depending on the pulsing, one may get different dc *I–V* curves. This area is still under investigation, and even the "experts" do not agree on all aspects of this. In real life, it turns out that a lot of experimentation is the answer. Anyone who thinks that a pure CAD approach will give the right design answers immediately will encounter many surprises! This is not a fault of the CAD tools—assuming that they are properly engineered—but rather the availability of appropriately "tweaked" models for high-power applications, and the willingness of device suppliers to standardize on certain models and support them.

Because of the difficulties involved in cooling transistors under test and simulating RF pulse and CW conditions, depending on the application, manufacturers have so far stayed away from investing money in this area. The designer must therefore resort to application notes published by device manufacturers. Because even slight layer changes can have a large impact on the frequency response of a given device, application-note-based designs can run into difficulty if a device's fabrication has significantly evolved since the publication of its application notes.

Given the multitude of models outlined in Chapter 2, the CAD user is sometimes left hanging as to which is the best model to use. The latest indications are that the MEXTRAM (*m*ost *e*xquisite *t*ransistor *m*odel), developed by the University of Delft, Holland, with Philips of Holland, shows the most promising result, specifically in the area of IMD products. While

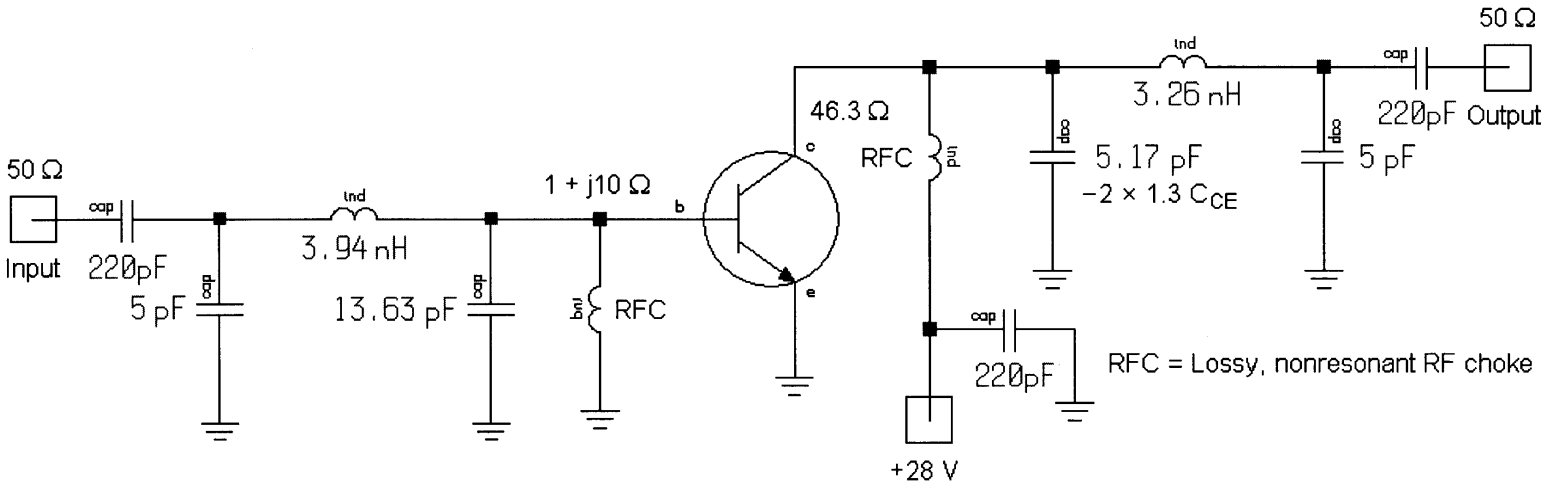

Figure 3-207 Actual schematic of our experimental 1.6-GHz amplifier. The RF chokes have enough RF losses not to be resonant and yet don't load the circuit. This is frequently accomplished with either ferrite beads or resistors in parallel with the chokes.

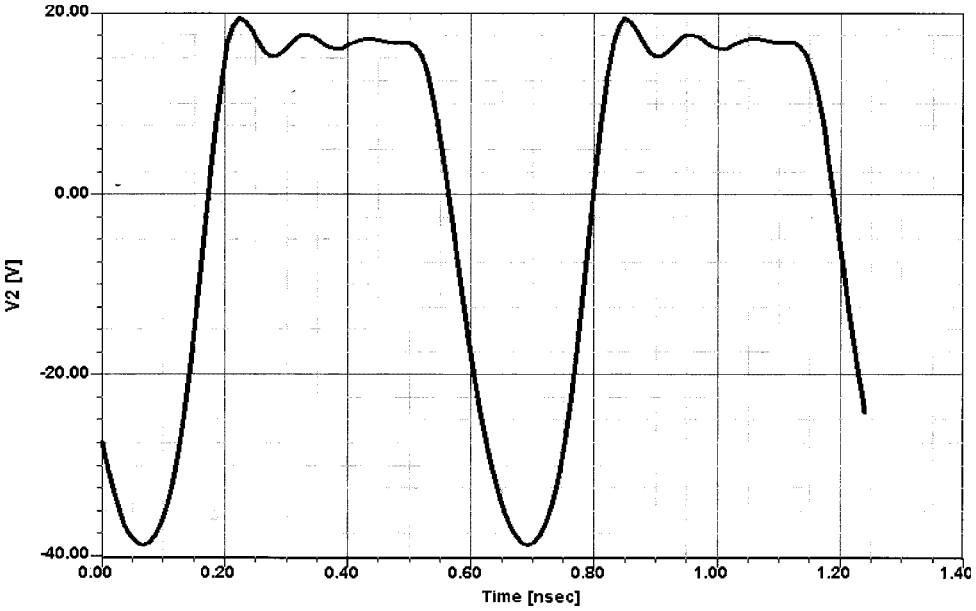

Figure 3-216 Output voltage at the collector. The voltage is asymmetrical compared to 0; this is important in the selection of a device capable of handling these voltages.

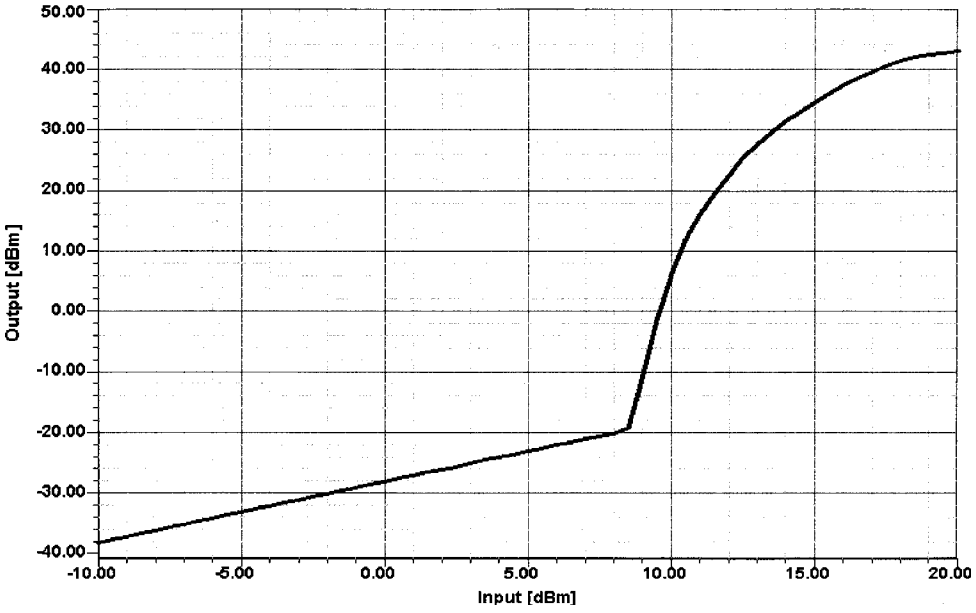

Figure 3-217 Output power versus input power for the Class C amplifier. Until the transistor turns on (at a drive level of about 8.5 dBm), only fedthrough power appears at the output.

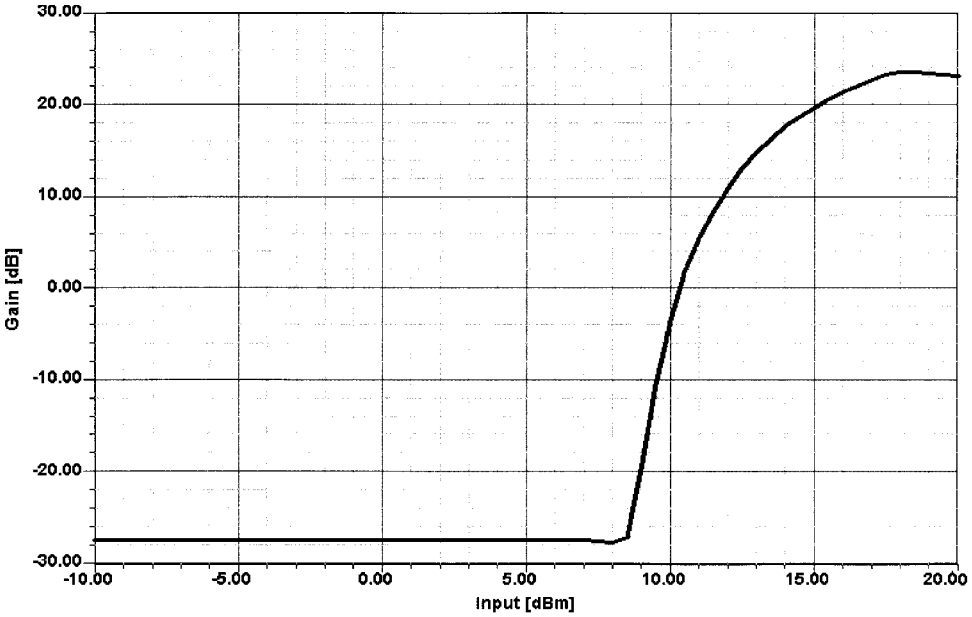

Figure 3-218 Amplifier gain as a function of drive. It is evident that one needs to cross the 0.65-V point for the transistor to become conductive and show gain. The initial amplification as a function of drive shows a very steep curve that then levels off and drops as the amplifier moves into saturation.

other later models have up to seven internal nodes, MEXTRAM fortunately uses only five. (The MEXTRAM model actually consists of three transistors, which makes modeling fun.) Power-added efficiency simulation is not available, since the MEXTRAM model was developed for small-signal applications, meaning circuits that operate at less than 100 mW of RF output power.

As if the absence of trustworthy high-power device models is not challenge enough, in developing this 1.6-GHz Class C amplifier example, we ran into another complication: Using a CAD optimizer to simultaneously match the circuit's input and output networks failed because of the device's input-impedance variation with drive. Every matching adjustment that improved the drive to the device resulted in an input-impedance change that reduced the drive to the device! In the end, the optimizer couldn't keep up. In actually building such a circuit, one would make the matching-network values adjustable on the initial breadboard and then, with the necessary input drive level applied, iteratively adjust the input and output matching for the desired output level. It appears that the CAD program could not handle such a degree of nonlinearity.

We then went to the approach of using large-signal *S* parameters at a drive level slightly less than 16 dBm, but this detuned the input filter, resulting in a poorer input match than the one initially predicted. Likewise, the output matching, which in a power stage must result in maximum output power rather than a conjugate match, was less impressive. The large-signal *S* parameters at the output for a power amplifier are somewhat dubious because Class C operation generates so many harmonics that the output termination will reflect a lot of energy and, depending on the output filter topology, different results can be expected. We firmly believe that there will be further mathematical improvement in the CAD tools, and we very much invite

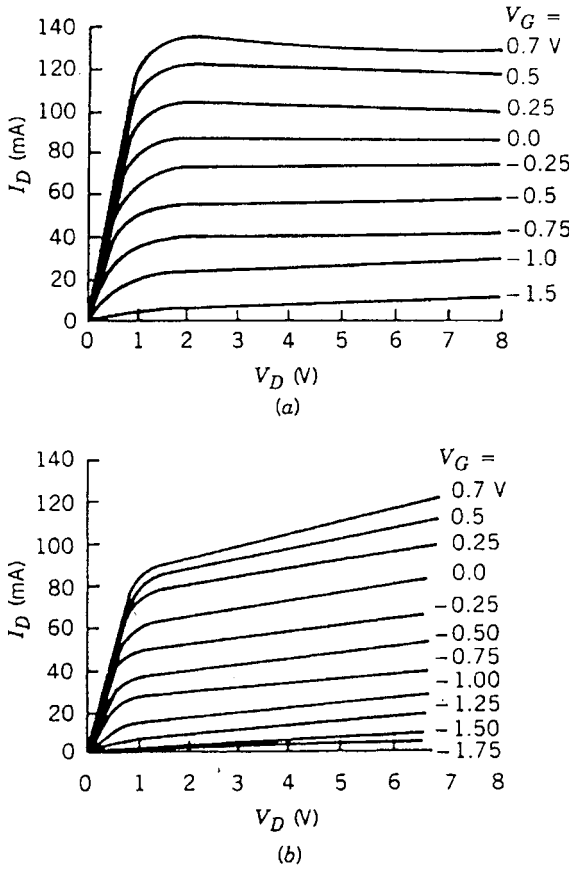

Figure 3-219 Comparison of FET drain current characteristics obtained from (a) pulsed *I–V* and (b) rectified sine-wave evaluation. The rectified sine-wave curves can be considered equivalent to curves obtained at dc.

our readers to use such a nonlinear example to test their tools, provided that a high-power model becomes available in this power range.

It has been rumored that the load-pull technique, rather than the application of large-signal *S* parameters, is a vehicle to solve such matching problems. However, the load-pull technique is really applied only to the fundamental frequency and does not deal with the issue of harmonics of the output current. More details about the load-pull technique and its capabilities are found in Appendix B.

Actual measurements of amplifiers of this type show that our simulated efficiency and drive level come quite close to reality, but at a frequency somewhat offset from that chosen for the design. As an example, the input and output filters tuned at 1.4 GHz instead of 1.6 GHz using the large-signal *S* parameters. Again, an iterative process, similar to manually trimming a prototype, will give a similar result. This is consistent with our earlier statement that most final designs are really hand-tweaked, and that CAD can only bring us close, but not all the way, to a good solution. For passive problems, the CAD does a significantly better job; the nonlinear cases are the ones that still cause headaches.

3-12-2 Impedance Matching Networks Applied to RF Power Transistors*

Introduction. Some graphical and numerical methods of impedance matching will be reviewed here. The examples given refer to high-frequency power amplifiers.

Although matching networks normally take the form of filters and therefore are also useful to provide frequency discrimination, this aspect will be considered only as a corollary of the matching circuit.

Matching is necessary for the best possible energy transfer from stage to stage. In RF power transistors, the input impedance is of low value, decreasing as the power increases or as the chip size becomes larger. This impedance must be matched either to a generator—of generally 50-Ω internal impedance—or to a preceding stage. Impedance matching has to be made between two complex impedances, which makes the design still more difficult, especially if matching must be accomplished over a wide frequency band.

Device Parameters

Input Impedance. The general shape of the input impedance of RF power transistors is as shown in Figure 3-220. It is a large-signal parameter, expressed here by the parallel combination of a resistance R_p and a reactance X_p [31].

The equivalent circuit shown in Figure 3-221 accounts for the behavior illustrated in Figure 3-220. With the presently used stripline or flange packaging, most of the power devices for VHF low band will have their R_p and X_p values below the series resonant point f_s. The input impedance will be essentially capacitive.

Most of the VHF high-band transistors will have the series-resonant frequency within their operating range; that is, they will be purely resistive at one single frequency f_s, which the parallel-resonant frequency f_p will be outside.

Parameters for 1- or 2-GHz transistors will be beyond f_s and approach f_p. They show a high value of R_p and X_p with inductive character.

A parameter that is very often used to judge on the broadband capabilities of a device is the input Q or Q_{IN}, defined simply as the ratio R_p/X_p. Practically, Q_{IN} ranges around 1 or less for VHF devices and around 5 or more for microwave transistors.

Q_{IN} is an important parameter to consider for broadband matching. Matching networks normally are low-pass or pseudo-low-pass filters. If Q_{IN} is high, it can be necessary to use bandpass filter-type matching networks and to allow insertion losses. But broadband matching is still possible. This will be discussed later.

Output Impedance. The output impedance of RF power transistors, as given by all manufacturers' datasheets, generally consists of only a capacitance C_{OUT}. The internal resistance of the transistor is supposed to be much higher than the load and is normally neglected. In the case of a relatively low internal resistance, the efficiency of the device would decrease by the factor

$$1 + R_L/R_T \tag{3-192}$$

*Based on Motorola application note AN-721 ("Impedance Matching Networks Applied to RF Power Transistors"). Copyright of Motorola; used by permission.

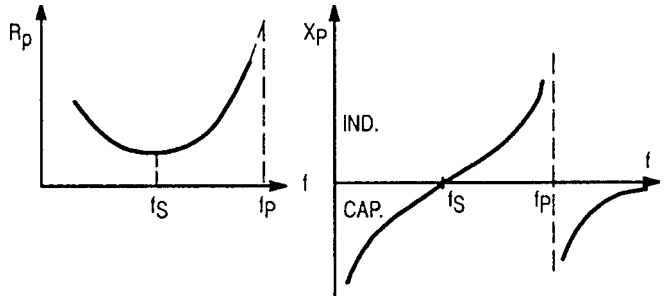

Figure 3-220 Input impedance of RF power transistors as a function of frequency.

where R_L is the load resistance, seen at the collector–emitter terminals, and R_T is the internal transistor resistance equal to

$$\frac{1}{\omega_T (C_{TC} + C_{DC})} \tag{3-193}$$

defined as a single parameter, where ω_T is the transit angular frequency and C_{TC} and C_{DC} are the transition and diffusion capacitances, respectively, at the collector junction.

The output capacitance, C_{OUT}, which is a large-signal parameter, is related to the small-signal parameter C_{CB}, the collector–base transition capacitance.

Since a junction capacitance varies with the applied voltage, C_{OUT} differs from C_{CB} in that it has to be averaged over the total voltage swing. For an abrupt junction and assuming certain simplifications, $C_{\text{OUT}} = 2C_{CB}$.

Figure 3-222 shows the variation of C_{OUT} with frequency. C_{OUT} decreases partly due to the presence of the collector lead inductance, but mainly because of the fact that the base–emitter diode does not shut off anymore when the operating frequency approaches the transit frequency, f_T.

Output Load. In the absence of a more precise indication, the output load R_L is taken as

$$R_L = \frac{[V_{CC} - V_{CE(\text{sat})}]^2}{2P_{\text{OUT}}} \tag{3-194}$$

with $V_{CE(\text{sat})}$ equal to 2 or 3 V, increasing with frequency.

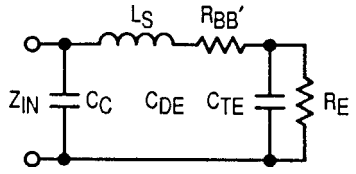

Figure 3-221 Equivalent circuit for the input impedance. R_E is the emitter diffusion resistance; C_{DE} and C_{TE} are the diffusion and transition capacitances, respectively, of the emitter junction; $R_{BB'}$ is the base-spreading resistance; C_C is the package capacitance; and L_S is the base lead inductance.

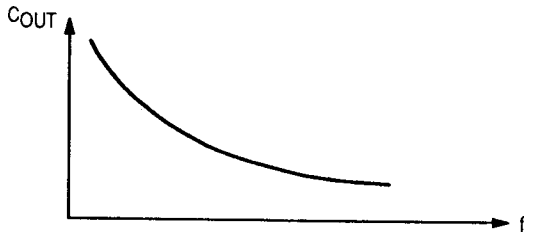

Figure 3-222 Output capacitance C_{OUT} as a function of frequency.

The above equation just expresses a well-known relation, but it also shows that the load, in first approximation, is not related to the device, except for $V_{CE(sat)}$. The load value is primarily dictated by the required output power and the peak voltage; it is not matched to the output impedance of the device.

At high frequencies this approximation becomes less exact, and for microwave devices the load that must be presented to the device is indicated on the datasheet.

Strictly speaking, impedance matching is accomplished only at the input. Interstage and load matching are more impedance transformations of the device input impedance and of the load into a value R_L (sometimes with additional reactive component) that depends essentially on the power demanded and the supply voltage.

Matching Networks. In the following, matching networks will be described by the order of complexity. These are ladder-type reactance networks. The different reactance values will be calculated and determined graphically. Increasing the number of reactances broadens the bandwidth. However, matching networks consisting of more than four reactances are rare. Above four reactances, the improvement is small.

Numerical Design

TWO-RESISTANCE NETWORKS. Resistance terminations will first be considered. Figure 3-223 shows the reactive L section and the terminations to be matched.

Matching or exact transformation from R_2 into R_1 occurs at a single frequency f_0. At f_0, X_1 and X_2 are equal to

$$X_1 = \pm R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = R_1 \frac{1}{\sqrt{n-1}} \tag{3-195}$$

$$X_2 = \mp \sqrt{R_2(R_1 - R_{2)}} = R_1 \frac{\sqrt{n-1}}{1} \tag{3-196}$$

At f_0, $X_1X_2 = R_1R_2$. X_1 and X_2 must be of opposite sign. The shunt reactance is in parallel with the larger resistance.

The frequency response of the L section is shown in Figure 3-224, where the normalized current is plotted as a function of the normalized frequency.

If X_1 is capacitive and consequently X_2 is inductive, then

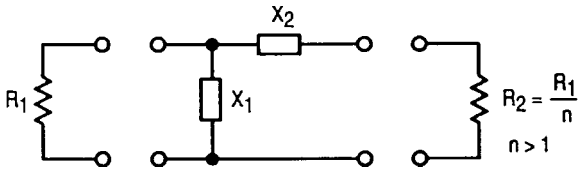

Figure 3-223 Two-reactance matching network.

$$X_1 = -\frac{f_0}{f} R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = -\frac{f_0}{f} R_1 \frac{1}{\sqrt{n-1}} \tag{3-197}$$

and

$$X_2 = \frac{f}{f_0} \sqrt{R_2(R_1 - R_2)} = \frac{f}{f_0} R_1 \frac{\sqrt{n-1}}{1} \tag{3-198}$$

The normalized current absolute value is equal to

$$\left|\frac{I_2}{I_0}\right| = \frac{2\sqrt{n}}{\sqrt{(n-1)^2 \cdot (f/f_0)^4 - 2\,(f/f_0)^2 + (n+1)^2}} \tag{3-199}$$

where $I_0 = \sqrt{n}E/2R_1$ and is plotted in Figure 3-224 [32].

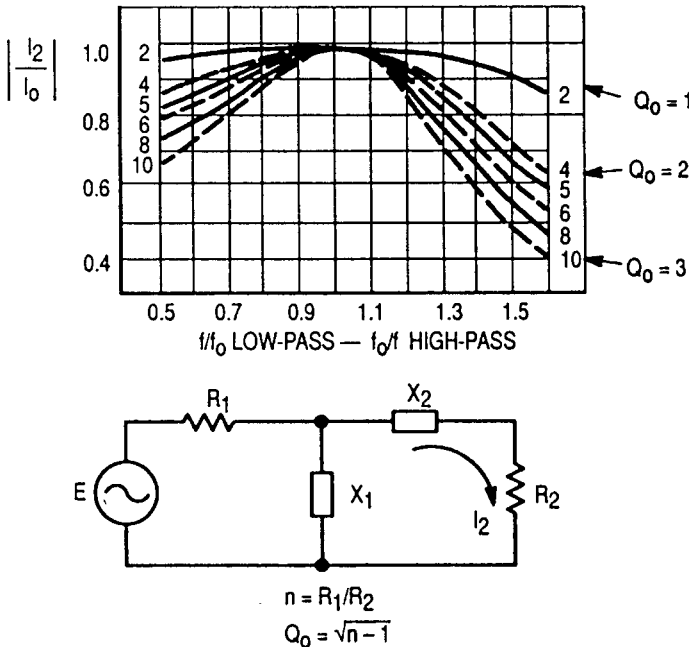

Figure 3-224 Normalized frequency response for the L section in low-pass or high-pass form.

If X_1 is inductive and consequently X_2 is capacitive, the only change required is a replacement of f by f_0 and vice versa. The L section has low-pass form in the first case and high-pass form in the second case.

The Q of the circuit at f_0 is equal to

$$Q_0 = \frac{X_2}{R_2} = \frac{R_1}{X_1} = \sqrt{n-1} \tag{3-200}$$

For a given transformation ratio n, there is only one possible value of Q. On the other hand, there are two symmetrical solutions for the network that can be either a low-pass filter or a high-pass filter.

The frequency f_0 does not need to be the center frequency, $(f_1 + f_2) / 2$, of the desired band limited by f_1 and f_2. In fact, as can be seen from the low-pass configuration of Figure 3-224, it may be interesting to shift f_0 toward the high-band edge frequency f_2 to obtain a larger bandwidth w, where

$$w = \frac{2(f_1 + f_2)}{f_2 - f_1} \tag{3-201}$$

This will, however, be at the expense of poor harmonic rejection.

Example. For a transformation ratio of $n = 4$, we can determine the following values from the above relations:

Bandwidth w	0.1	0.3
Maximum insertion losses	0.025	0.2
X_1/R_1	1.730	1.712

If the terminations R_1 and R_2 have a reactive component X, the latter may be taken as part of the external resistance as shown in Figure 3-225. This compensation is applicable as long as

$$Q_{int} = \frac{X_{\text{int}}}{R_2} \quad \text{or} \quad \frac{R_1}{X_{\text{int}}} < n - 1 \tag{3-202}$$

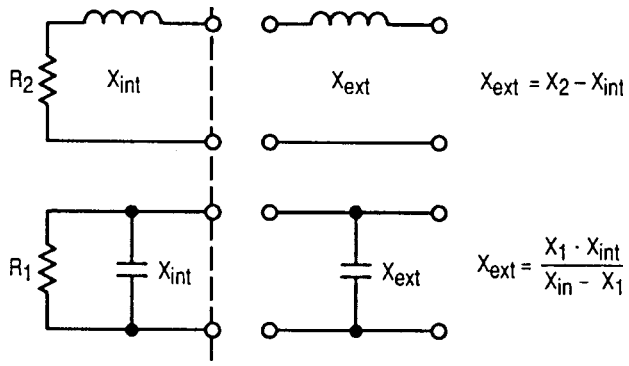

Figure 3-225 Termination reactance compensation.

Tables giving reactance values can be found in Matthaei et al. [33, 34].

USE OF TRANSMISSION LINES AND INDUCTORS. In the preceding section, the inductance was expected to be realized by a lumped element. A transmission line can be used instead (Figure 3-226).

As can be seen from the computed selectivity curves (Figure 3-227) for the two configurations, transmission lines result in a larger bandwidth. The gain is important for a transmission line having a length $L = \lambda/4$ ($\Theta = 90°$) and a characteristic impedance $Z_0 = \sqrt{R_1 R_2}$. It is not significant for lines short with respect to $\lambda/4$. One will notice that there is an infinity of solutions, one for each value of C, when using transmission lines.

THREE-REACTANCE MATCHING NETWORKS. The networks that will be investigated are shown in Figure 3-228. They are made of three reactances alternately connected in series and shunt.

A three-reactance configuration allows the designer to make the quality factor (Q) of the circuit and the transformation ratio $n = R_2/R_1$ independent of each other and consequently to choose the selectivity between certain limits.

For narrowband designs, one can use the following formulas (see [35], where tables are given):

Network (a)

$$X_{C1} = R_1/Q \quad Q \text{ must be selected first} \tag{3-203}$$

$$X_{C2} = R_2 \sqrt{\frac{R_1 R_2}{(Q^2 + 1) - R_1/R_2}} \tag{3-204}$$

$$X_L = \frac{QR_1 + (R_1 R_2/X_{C2})}{Q^2 + 1} \tag{3-205}$$

Network (b)

$$X_{L1} = R_1 Q \quad Q \text{ must be selected first} \tag{3-206}$$

$$X_{L2} = R_2 B \tag{3-207}$$

$$A = R_1(1 + Q^2) \tag{3-208}$$

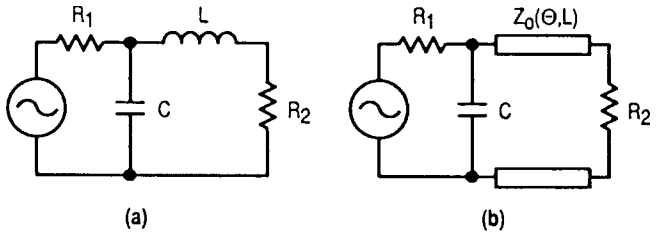

Figure 3-226 Use of a transmission line in the L section.

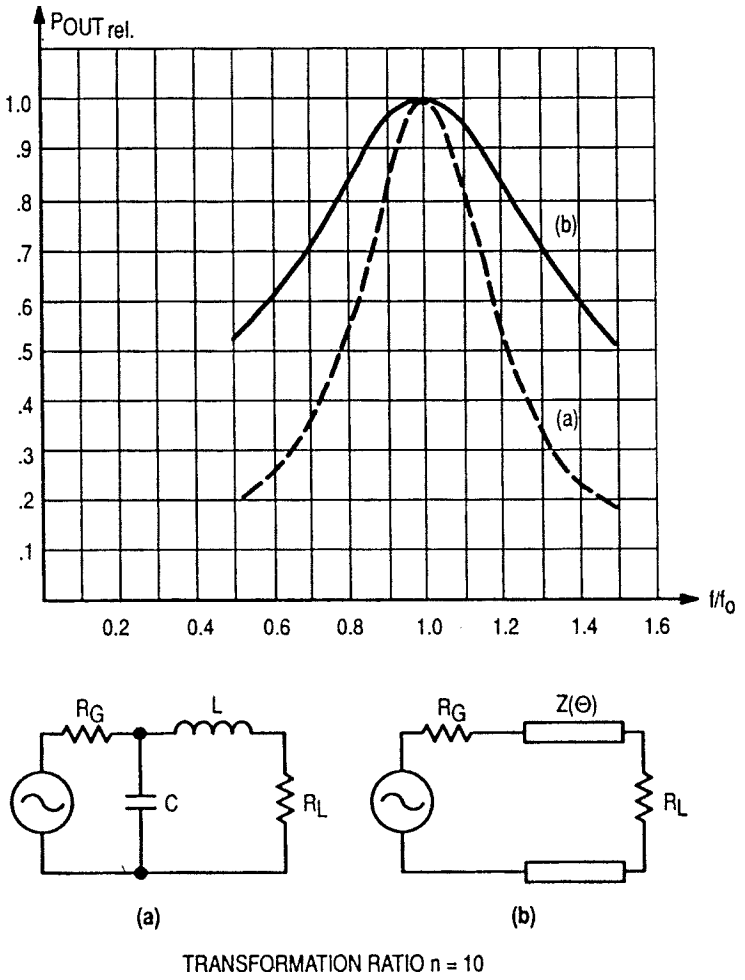

Figure 3-227 Bandwidth of the L section for $n = 10$ (a) with lumped constants and (b) with transmission line (λ/4).

$$X_{C1} = \frac{A}{Q + B} \tag{3-209}$$

$$B = \sqrt{\frac{A}{R_2} - 1} \tag{3-210}$$

Network (c)

$$X_{L1} = QR_1 \quad Q \text{ must be selected first} \tag{3-211}$$

$$X_{C2} = AR_2 \tag{3-212}$$

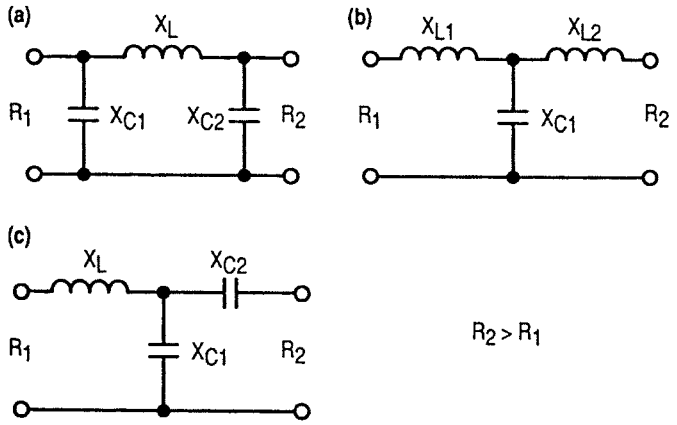

Figure 3-228 Three-reactance matching networks.

$$A = \sqrt{\frac{R_1(1+Q^2)}{R_2} - 1} \tag{3-213}$$

$$X_{C1} = \frac{B}{Q - A} \tag{3-214}$$

$$B = R_1(1+Q^2) \tag{3-215}$$

The network that yields the most-practical component values should be selected for a given application.

The three-reactance networks can be thought of as being formed of an L section (two reactances) and of a compensation reactance. The L section essentially performs the impedance transformation, while the additional reactance compensates for the reactive part of the transformed impedance over a certain frequency band.

Figure 3-229 shows a representation in the Z plane of the circuit of Figure 3-228a split into two parts: $R_1 - C_1 - L_1$ and $C_2 - R_2$. Exact transformation from R_1 into R_2 occurs at the points of intersection M and N. Impedances are then conjugate, or $Z' = R' + jX'$ and $Z'' = R'' + jX''$ with $R' = R''$ and $X' = -X''$.

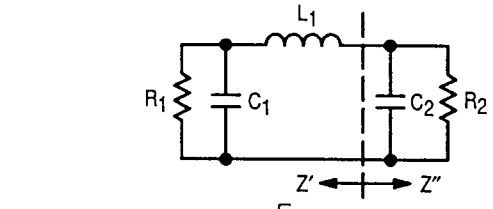
The only possible solution is obtained when X' and $-X''$ are tangential to each other. For the dashed curve, representing another value of L_1 or C_1, a wider frequency band could be expected at the expense of some ripple inside the band. However, this can only be reached with four reactances, as will be shown below.

With a three-reactance configuration, there are not enough degrees of freedom to permit $X' = -X''$ and simultaneously obtain the same variation of frequency on both curves from point M' to point N'. Exact transformation can, therefore, be obtained at only one frequency.

The values of the three reactances can be calculated by making

$$X' = -X'', \quad R' = R'', \quad \text{and} \frac{dX'}{dR'} = -\frac{dX''}{dR''} \tag{3-216}$$

The general solution of these equations leads to complicated calculations. Therefore, computed tables should be used.



$$Z' = \frac{R_1}{1 + \omega^2 R_1^2 C_1^2} + j\omega \left[L1 - \frac{R_1^2 C_1}{1 + \omega^2 R_1^2 C_1^2} \right] = R' + jX'$$

$$Z'' = \frac{R_2}{1 + \omega^2 C_2^2 R_2^2} - \frac{j\omega^2 C_2 R_2^2}{1 + \omega^2 C_2^2 R_2^2} = R'' + jX''$$

$$|x'| = \left(\frac{L_1}{C_1 R_1^2} - \frac{R'}{R_1} \right) \sqrt{\frac{R_1}{R'} - 1}$$

$$|x''| = \sqrt{R' R_2 - R'^2}$$

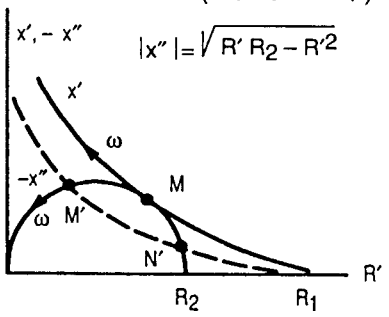


Figure 3-229 *Z*-plane representation of the circuit of Figure 3-228a.

One will note from Figure 3-229 that the compensation reactance contributes somewhat to the impedance transformation; that is, R' varies when going from M to R_2.

The circuit of Figure 3-228b is dual with respect to the first one and gives exactly the same results in a *Y*-plane representation. The circuit of Figure 3-228c is somewhat different since only one intersection M exists, as shown in Figure 3-230. Narrower frequency bands must be expected from this configuration. The widest band is obtained for $C_1 = \infty$.

Again, if one of the terminations has a reactive component, the latter can be taken as a part of the matching network, provided that it is not too large (see Figure 3-227).

FOUR-REACTANCE NETWORKS. Four-reactance networks are used essentially for broadband matching. The networks that will be considered in the following consist of two two-reactance sections in cascade. Some networks have pseudo-low-pass filter character; others, bandpass filter character. In principle, the former show narrower bandwidth since they extend the impedance transformation to very low frequencies unnecessarily, while the latter ensure good matching over a wide frequency band around the center frequency only (see Figure 3-233).

The two-reactance sections used in the networks in Figure 3-231 have either transformation properties or compensation properties. Impedance transformation is obtained with one series reactance and one shunt reactance. Compensation is made with both reactances in series or in shunt. If two cascaded transformation networks are used, transformation is accomplished partly by each one.

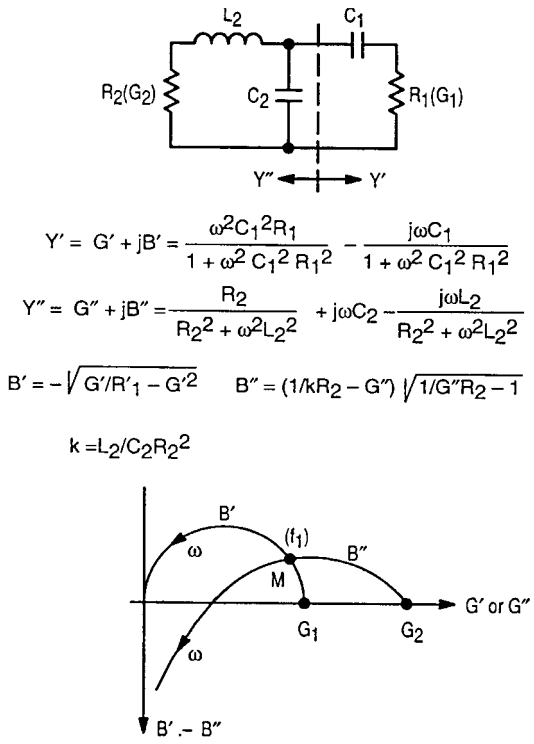

Figure 3-230 *Y*-plane representation of the circuit of Figure 3-228c.

With four-reactance networks there are two frequencies, f_1 and f_2, at which the transformation from R_1 into R_2 is exact. These frequencies may also coincide. For the network in Figure 3-231b, for instance, at point M, R_1 or R_2 is transformed into $\sqrt{R_1R_2}$ when both frequencies fall together. At all points (M), Z_1 and Z_2 are conjugate if the transformation is exact.

In the case of Figure 3-231b, the reactances are easily calculated for equal frequencies:

$$X_1 = \frac{R_1}{\sqrt{(n-1)^{1/2}}} \tag{3-217}$$

$$X_2 = R_1\sqrt{\frac{n^{1/2}-1}{n}} \tag{3-218}$$

$$X_1X_4 = R_1R_2 = X_2X_3 \tag{3-219}$$

$$X_3 = \frac{R_1}{\sqrt{n(n^{1/2}-1)}} \tag{3-220}$$

$$X_4 = \frac{R_1}{n}\sqrt{n^{1/2}-1} \tag{3-221}$$

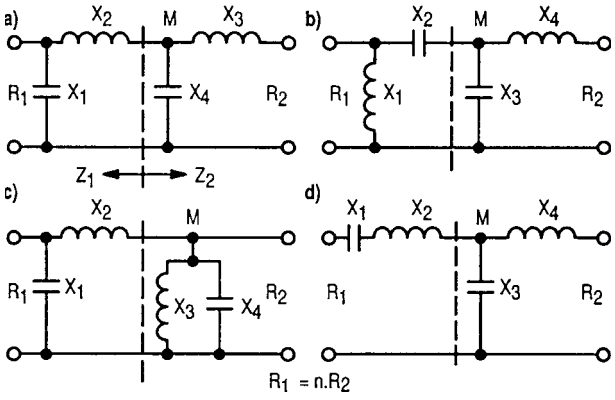

Figure 3-231 Four-reactance networks.

For the network in Figure 3-231a, normally at point M, Z_1 and Z_2 are complex. This pseudo-low-pass filter has been computed elsewhere [33]. Many tables can be found in the literature for networks of four and more reactances having Chebyshev character or maximally flat response [33, 34, 36].

Figure 3-232 shows the transformation path from R_1 to R_2 for networks (a) and (b) in Figure 3-231 on a Smith Chart.

Case (a) of Figure 3-232 has been calculated using tables in Matthaei [34]. Case (b) has been obtained from the relationship given above for $X_1, \ldots, X_4$. Both apply for a transformation ratio equal to 10 and for $R_1 = 1$. There is no simple relationship for $X_1', \ldots, X_4'$ of network (b) if f_1 is made different from f_2 for larger bandwidth. Figure 3-233 shows the respective bandwidths of networks (a) and (b) for the circuits shown in Figure 3-232.

If the terminations include a reactive component, the computed values for X_1 or X_4 may be adjusted to compensate for this.

For configuration (a), it can be seen from Figure 3-232 that, in the considered case, the Q values are equal to 1.6. For configuration (b), Q_1', which is equal to Q_2', is fixed for each transformation ratio

n	2	4	8	10	16
$Q'_1 = Q'_2$	0.65	1	1.35	1.46	1.73

$$Q' = \sqrt{n^{1/2} - 1} \qquad (3\text{-}222)$$

The maximum value of reactance that the terminations may have for use in this configuration can be determined from the above values of Q'.

If R_1 is the load resistance of a transistor, the internal transistor resistance may not be equal to R_1. In this case, the selectivity curve will be different from the curves given in Figure 3-233. Figure 3-234 shows the selectivity for networks (a) and (b) when the source resistance R_1 is infinite. From Figure 3-234 it can be seen that network (a) is more sensitive to changes in R_1 than network (b).

As mentioned earlier, the four-reactance network can also be thought of as two cascaded two-reactance sections: one used for transformation, the other for compensation. Figure 3-235 shows commonly used compensation networks, together with the associated L section.

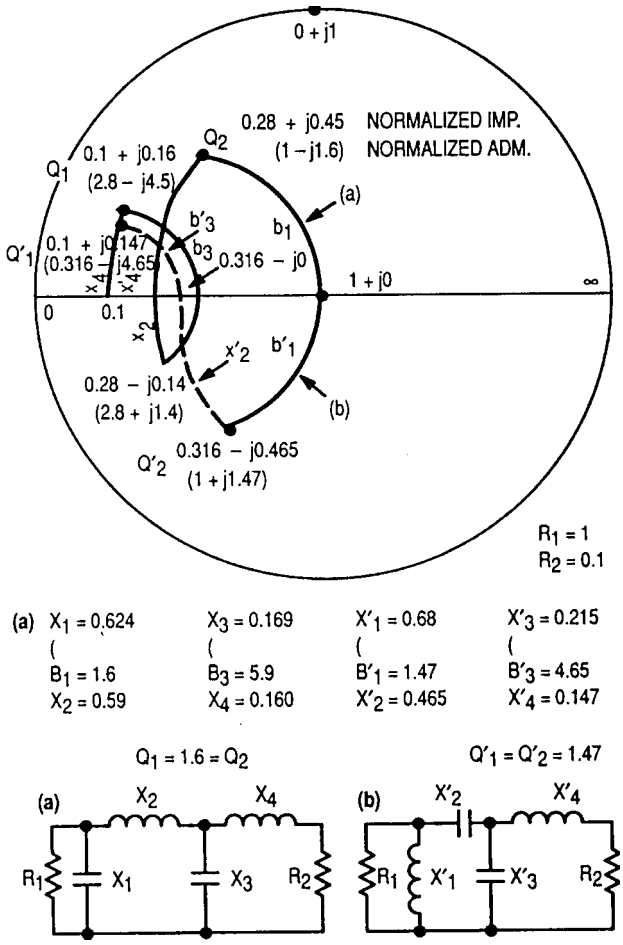

Figure 3-232 Transformation paths for networks (a) and (b).

The circuit of Figure 3-235a can be compared to the three-reactance network shown in Figure 3-228c. The difference is that capacitor C_2 of that circuit has been replaced by an *LC* circuit. The resulting improvement can be seen by comparing Figure 3-236 with Figure 3-230.

By adding one reactance, exact impedance transformation is achieved at two frequencies. It is now possible to choose component values such that the point of intersection M' occurs at the same frequency f_1 on both curves and simultaneously that N' occurs at the same frequency f_2 on both curves. Among the infinite number of possible intersections, only one allows the achievement of this.

When M' and N' coincide in M, the new $dX'/df = dX''/df$ condition can be added to the condition $X' = -X''$ (for three-reactance networks) and similarly $R' = R''$ and $dR'/df = dR''/df$.

Again, a general solution of the above equations leads to still more complicated calculations than in the case of three-reactance networks. Therefore, tables are preferable [33, 34, 36].

The circuit of Figure 3-235b is the dual of the circuit of Figure 3-233a and does not need to be treated separately. It gives exactly the same results in the *Z* plane. Figure 3-235c shows a higher-order compensation requiring six reactive elements.

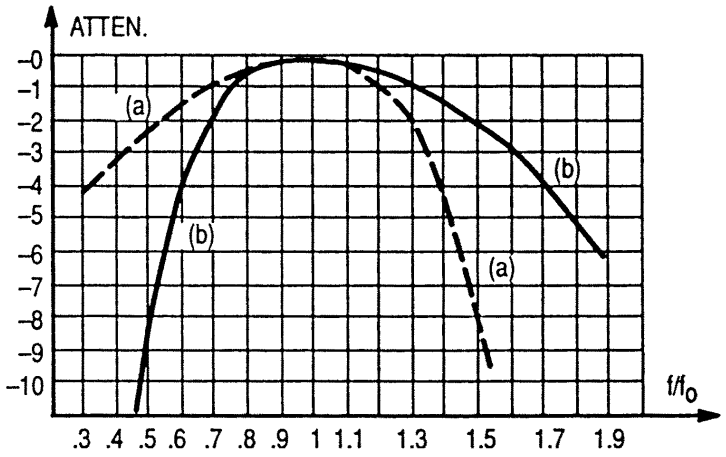

Figure 3-233 Selectivity curves for networks (a) and (b) of Figure 3-232.

The above-discussed matching networks employing compensation circuits result in narrower bandwidths than the former solutions (see p. 573) using two transformation sections. A matching arrangement with higher-order compensation, such as in Figure 3-235c, is not recommended. Better use can be made of the large number of reactive elements by using them all for transformation.

When the above configurations are realized using short portions of transmission lines, the equations or the usual tables no longer apply. The calculations must be carried out on a computer because of their complexity. However, a graphical method can be used (see the next section) that will consist essentially in tracing a transformation path on the Z–Y chart using the computed lumped element values and replacing it by the closest path obtained with distributed constants. The bandwidth change is not significant as long as short portions of lines are used.

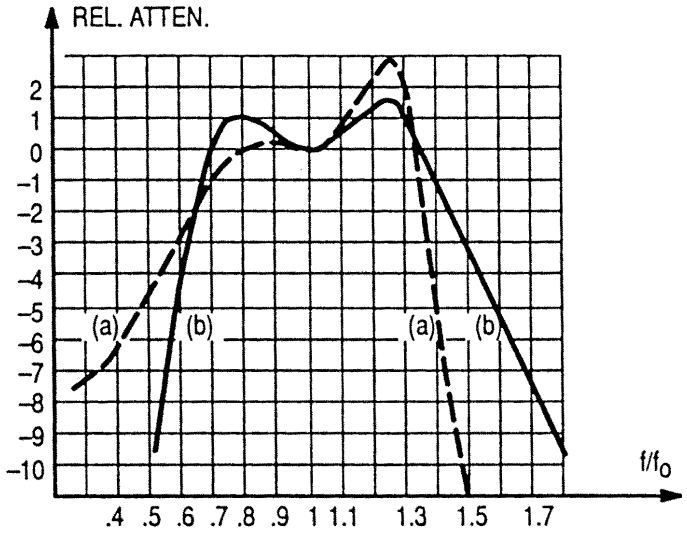

Figure 3-234 Selectivity curves for networks (a) and (b) of Figure 3-232 with infinite R_1.

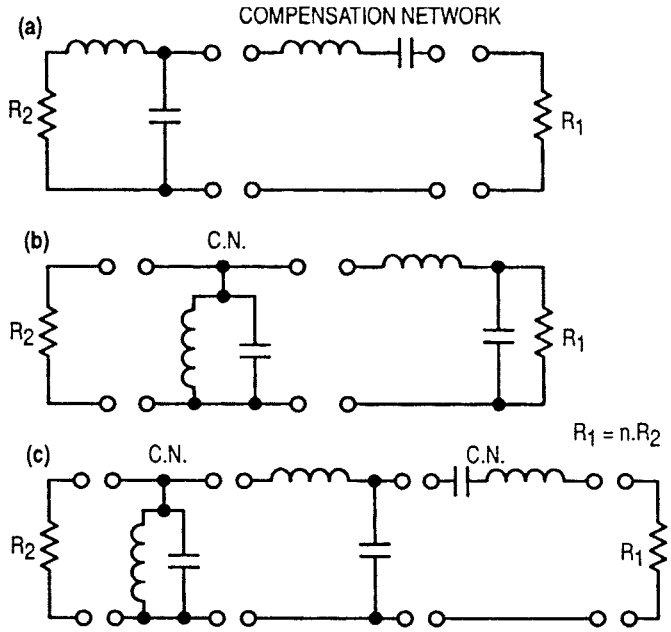

Figure 3-235 Compensation networks used with an L section.

MATCHING NETWORKS USING QUARTER-WAVE TRANSFORMERS. At sufficiently high frequencies, where λ/4-long lines of practical size can be realized, broadband transformations can easily be accomplished by the use of one or more λ/4 sections. Figure 3-237 summarizes the main relations for (a) one-section and (b) two-section transformations. A compensation network can be realized using a λ/2-long transmission line. Figures 3-238 and 3-239 show the selectivity curves for different transformation ratios and section numbers.

EXPONENTIAL LINES. Exponential lines have largely frequency-independent transformation properties. The characteristic impedance of such lines varies exponentially with their length l:

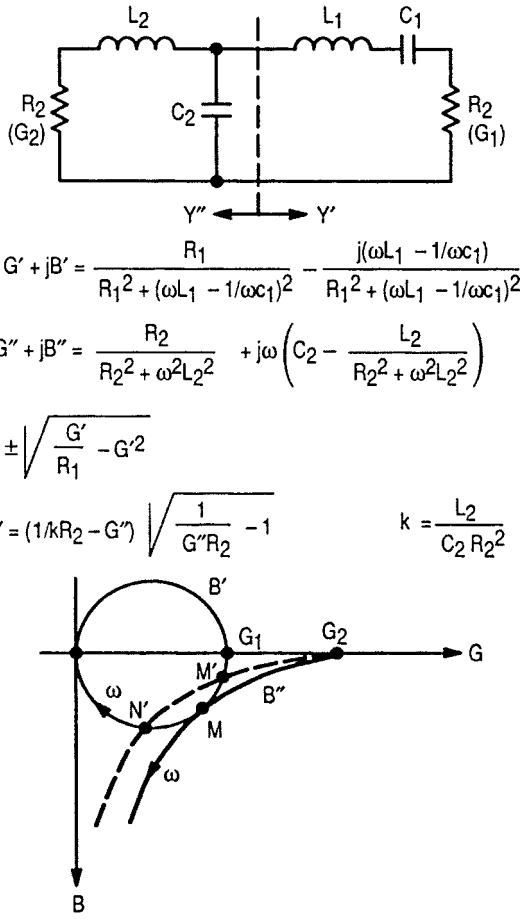
$$Z = Z_0 e^{kl} \tag{3-223}$$

where k is a constant, but these properties are preserved only if k is small.

BROADBAND MATCHING USING BANDPASS FILTER NETWORKS—HIGHQ CASE. The above circuits are applicable to devices having low input or output Q, if broadband matching is required. Generally, if the impedances to be matched can be represented, for instance, by a resistor R in series with an inductor L (sometimes a capacitor C) within the band of interest and if L is sufficiently low, the latter can be incorporated into the first inductor in the matching network. This is also valid if the representation consists of a shunt combination of a resistor and a reactance.

Practically, this is feasible for Q values around 1 or 2. For higher Q values or for input impedances consisting of a series or parallel resonant circuit (see Figure 3-221), as it appears to be for large bandwidths, a different treatment must be followed.

Let us first recall that, as shown by Bode [37] and Fano [38], limitations exist on the impedance matching of a complex load. In the example of Figure 3-240, the load to be matched consists of a capacitor C and a resistor R in shunt.



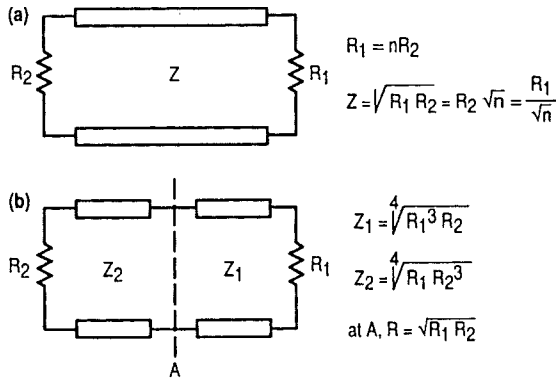
$$Y' = G' + jB' = \frac{R_1}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2} - \frac{j(\omega L_1 - 1/\omega c_1)}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2}$$

$$Y'' = G'' + jB'' = \frac{R_2}{R_2^2 + \omega^2 L_2^2} + j\omega\left(C_2 - \frac{L_2}{R_2^2 + \omega^2 L_2^2}\right)$$

$$B' = \pm\sqrt{\frac{G'}{R_1} - G'^2}$$

$$B'' = (1/kR_2 - G'')\sqrt{\frac{1}{G''R_2} - 1} \qquad k = \frac{L_2}{C_2 R_2^2}$$

Figure 3-236 *Y*-plane representation of the circuit of Figure 3-235a.



$$R_1 = nR_2$$

$$Z = \sqrt{R_1 R_2} = R_2\sqrt{n} = \frac{R_1}{\sqrt{n}}$$

$$Z_1 = \sqrt[4]{R_1^3 R_2}$$

$$Z_2 = \sqrt[4]{R_1 R_2^3}$$

$$\text{at A, } R = \sqrt{R_1 R_2}$$

Figure 3-237 Transformation networks using λ/4-long transmission lines.

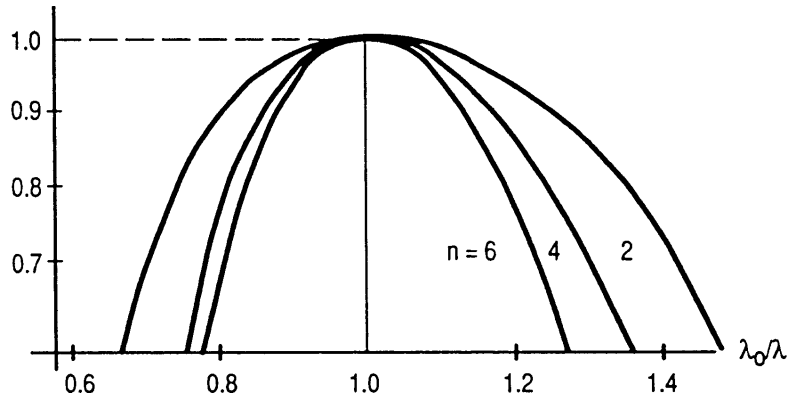


Figure 3-238 Selectivity curves for two λ/4-section networks at different transformation ratios.

The reflection coefficient between the transformed load and generator is equal to

$$\Gamma = \frac{Z_{\text{IN}} - R_G}{Z_{\text{IN}} + R_G} \tag{3-224}$$

When $\Gamma = 0$, there is perfect matching; when $\Gamma = 1$, there is total reflection. The ratio of reflected to incident power is

$$\frac{P_r}{P_i} = |\Gamma|^2 \tag{3-225}$$

The fundamental limitation on the matching takes the form

$$\int_{\omega=0}^{\infty} \ln\left(\frac{1}{|\Gamma|}\right) d\omega \le \frac{\pi}{RC} \qquad \text{Bode equation} \tag{3-226}$$

and is represented in Figure 3-241.

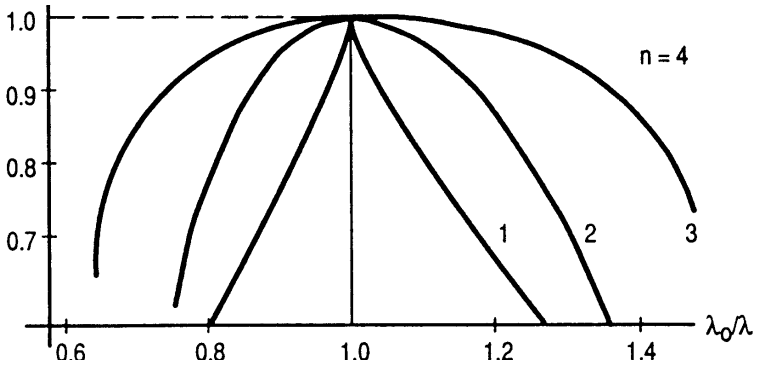

Figure 3-239 Selectivity curves for one, two, and three λ/4 sections.

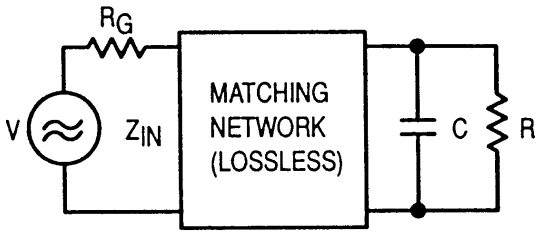

Figure 3-240 General matching conditions.

The meaning of the Bode equation is that the area S under the curve cannot be greater than π/RC and, therefore, if matching is required over a certain bandwidth, this can only be done at the expense of less power transfer within the band. Thus, power transfer and bandwidth appear as interchangeable quantities.

It is evident that the best utilization of the area S is obtained when $|\Gamma|$ is kept constant over the desired band ω_c and made equal to 1 over the rest of the spectrum. Then

$$|\Gamma| = e^{-\pi/\omega_c RC} \tag{3-227}$$

within the band and no power transfer happens outside. A network fulfilling this requirement cannot be obtained in practice because an infinite number of reactive elements would be necessary.

If the attenuation is plotted versus frequency for practical cases, one may expect to have curves like the ones shown in Figure 3-242 for a low-pass filter having Chebyshev character.

For a given complex load, an extension of the bandwidth from ω_1 to ω_2 is possible only with a simultaneous increase of the attenuation a. This is especially noticeable for Q values exceeding 1 or 2 (see Figure 3-243). Thus, devices having relatively high input Q values are usable for broadband operation, provided the consequent higher attenuation or reflection introduced is acceptable.

For average insertion losses or attenuation a (neglecting the ripple), the attenuation decreases if the number n of the network element increases. But above $n = 4$, the improvement is small. For a given attenuation a and bandwidth, the larger the n the smaller the ripple; for a given attenuation, the larger the n the larger the bandwidth.

Computations show that for $Q < 1$ and $n \leq 3$, the attenuation is below 0.1 dB (approximately). The impedance transformation ratio is not free here. The network is a

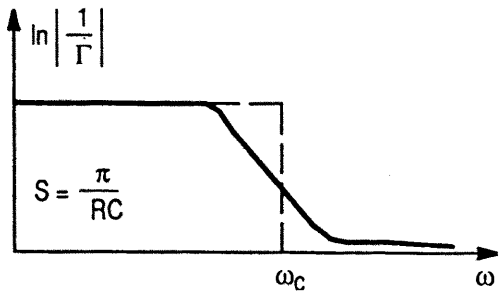

Figure 3-241 Representation of the Bode equation.

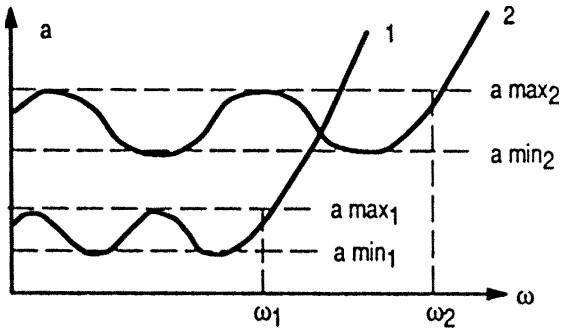

Figure 3-242 Attenuation versus angular frequency for different bandwidths with the same load.

true low-pass filter. For a given load, the optimum generator impedance will result from the computation.

Before impedance transformation is introduced, a conversion of the low-pass prototype into a bandpass filter network must be made. Figure 3-244 summarizes the main relations for this conversion. r is the conversion factor. For the bandpass filter, $Q_{\text{IN max}}$, or the maximum possible input Q of the device to be matched, has been increased by the factor r (from Figure 3-244, $Q'_{\text{IN max}} = rQ_{\text{IN max}}$).

Impedance inverters will be used for impedance transformation. These networks are suitable for insertion into a bandpass filter without affecting the transmission characteristics.

Figure 3-245 shows four impedance inverters. Note that one of the reactances is negative and must be combined in the bandpass network with a reactance of at least equal positive value. Insertion of the inverter can be made at any convenient place [32, 39].

When using the bandpass filter for matching the input impedance of a transistor, reactances $L'_1C'_1$ should be made to resonate at ω_0 by addition of a convenient series reactance.

As stated earlier, the series combination of R_0, L'_1 and C'_1 normally constitutes the equivalent input network of a transistor when considered over a large bandwidth. This is a good approximation up to about 500 MHz.

In practice, the normal procedure for using a bandpass filter matching network will be the following:

1. For a given bandwidth center frequency and input impedance of a device to be matched—for example, 50 Ω—first determine Q'_{IN} from the datasheet as

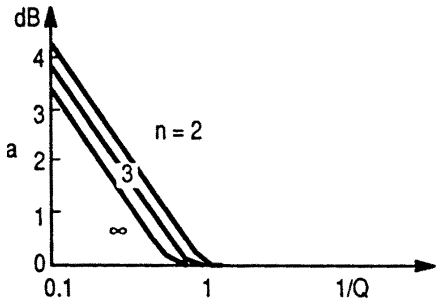

Figure 3-243 Insertion losses as a function of 1/*Q*.

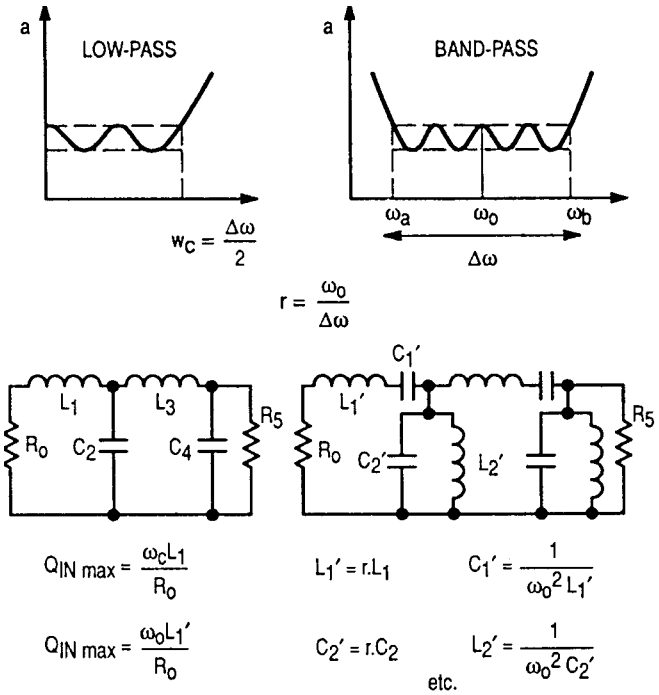

Figure 3-244 Conversion from low-pass filter into bandpass filter.

$$\frac{\omega_0 L_1'}{R_0} \tag{3-228}$$

after having eventually added a series reactor for centering.

2. Convert the equivalent circuit $R_0 L_1' C_1'$ into a low-pass prototype $R_0 L_1$ and calculate Q_{IN} using the formulas of Figure 3-244.
3. Determine the other reactance values from tables [33] for the desired bandwidth.
4. Convert the element values found by Step 3 into series- or parallel-resonant circuit parameters.
5. Insert the impedance inverter in any convenient place.

In the above discussions, the gain roll-off has not been taken into account. This is of normal use for moderate bandwidths (e.g., 30%). However, several methods can be employed to obtain a constant gain within the band despite the intrinsic gain decrease of a transistor with frequency. Tables have been computed elsewhere [40] for matching networks approximating 6 dB/octave attenuation versus frequency.

Another method consists of using the above-mentioned network and then adding a compensation circuit, as shown in Figure 3-246.

Resonance ω_b is placed at the high edge of the frequency band. Choosing Q correctly, roll-off can be made 6 dB/octave. The response of the circuit of Figure 3-246 is expressed by

$$\frac{1}{1 + Q^2(\omega/\omega_b - \omega_b/\omega)^2} \tag{3-229}$$

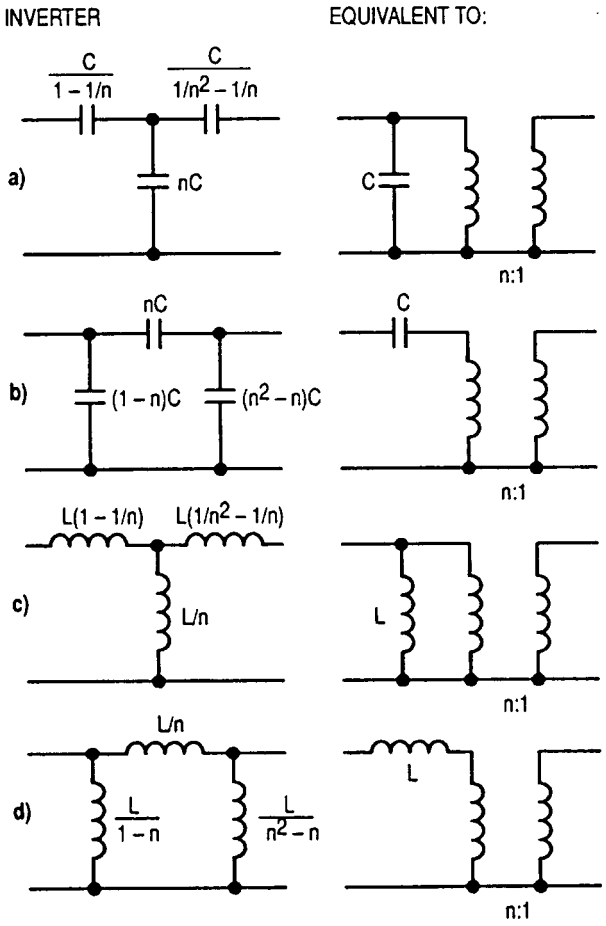

Figure 3-245 Impedance inverters.

where $\omega < \omega_b$. This must be equal to ω/ω_b for 6 dB/octave attenuation.

At the other band edge a, exact compensation can be obtained if

$$Q = \frac{(\omega_b/\omega_a)^2 - 1}{\omega_a/\omega_b - (\omega_b/\omega_a)^2} \tag{3-230}$$

There are several methods available for synthesis of matching networks. They should not be confused with filters because they can be either high-pass, low-pass, or bandpass, and their main purpose is to match one complex impedance to another. In many cases, one of the terminations happens to be 50 Ω and real, but this is just a "lucky" case of the general approach. An excellent paper on this [41] refers to the "real frequency" technique. Another equally important publication is the one by Cuthbert [42], since followed by his book [43]. Two more good references are Vendelin et al. [44] and Potter [45].

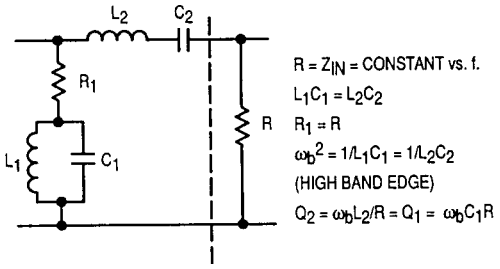

Figure 3-246 Roll-off compensation network.

3-12-3 Example 2: Low-Noise Amplifier Using Distributed Elements

In our previous examples, the amplifiers were built around lumped elements. Since a transmission line length of less than $\lambda/4$ is an inductor and $\frac{3}{4}\lambda$ is a capacitor, the whole amplifier can be built around microstrip technology.

If anyone wonders why we are going to show a low-noise amplifier in the middle of the power section, the reason is that we will select a low-power Siemens transistor, which, being operated in Class A, has an intercept point of +30 dBm and can easily achieve a noise figure of less than 2 dB. Such an amplifier is attractive when feeding an input stage from an antenna that sees many signals and curtails the bandwidth with an input filter of good selectivity that needs a good output termination, which in many cases works against the achievement of a good noise figure because when designing for best noise figure the input impedance of the transistor stage is far from 50 Ω.

First, we will start with the textbook approach and use the Smith diagram to obtain the best noise figure of which the device is capable. Figure 3-247 shows the actual approach to input and output matching.

We start our design by querying the Smith Tool about the minimum noise figure and the gain that comes with it. We mark the point of the lowest noise figure (labeled Γ_{opt}). The small

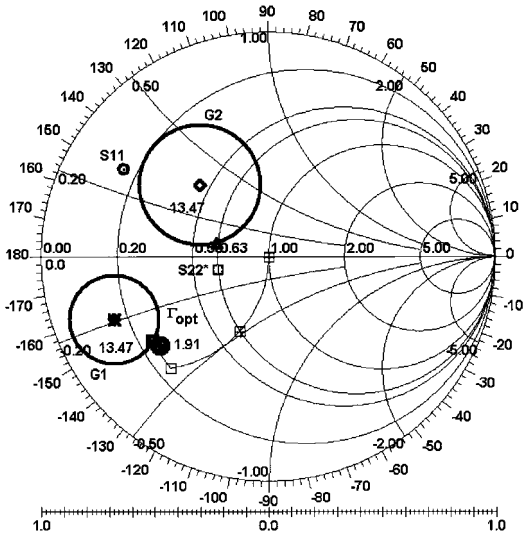

Figure 3-247 Input and output matches for 13.47 dB of gain and NF = 1.91 dB as displayed by the interactive Smith Tool.

noise circle yields the location for Γ_{opt} and tells us the minimum noise figure is going to be 1.91 dB. (By the way, this assumes no further losses, even in soldering the transistor to the PC board.) Then we construct the input gain circle (G1), which touches Γ_{opt} and turns out to represent 13.47 dB of available gain.

The next step is to find a matching network between Γ_{opt} and the 50-Ω source impedance. Immediately there is a conflict: If we look at S_{11}, which is the input reflection coefficient shown in the Smith diagram, it is on the other side of the complex plane and sufficiently far away, indicating that there is going to be quite a difference between noise matching and power-gain matching. We have two options for matching the input: Either we start from the origin and move toward the position of Γ_{opt}, or we start with Γ_{opt} and go to 50 Ω. Depending on the direction in which we do this, the result can be different topologies, such as a high-pass or low-pass filter. The high-pass filter is obtained by starting with Γ_{opt}; the low-pass topology is obtained by starting at the 50-Ω point. The Smith Tool then provides us with the corresponding values of capacitors and inductors after the transformation has been accomplished.

The final step is to do the same type of matching at the output. We start with S_{22}, and either select S_{22}^* (the complex conjugate for highest gain) or S_{22load}. As a rule, the second one is always a lower impedance (in terms of the real part) than the conjugate match. This graphic procedure is somewhat trial and error. As to the topology, a high-pass match should be preferred at the input and a low-pass match at the output. The reason for this is that the high-pass filter will tend to protect the stage from the enormous number of signals present below 1 GHz; using a low-pass filter at the output suppresses unwanted harmonics that the amplifier may generate. Figure 3-248 shows one of the approaches we like best simply because it gives a good input termination and we were trying for a simultaneous match for best noise figure and power gain.

The way we were able to achieve this was to take advantage of the existing feedback in the transistor and select a less-than-optimal output termination but gaining at the input. Taking advantage of the Miller effect, we rotate the phase angle of the feedback with the load to move the optimum noise and gain matching points closer. The danger in this is that the circuit is now highly sensitive to both input and output termination. The output *must* see 50 Ω to maintain this good input match, but since the second transistor stage can now be optimized for best input match, a two-stage combination can be configured to meet this

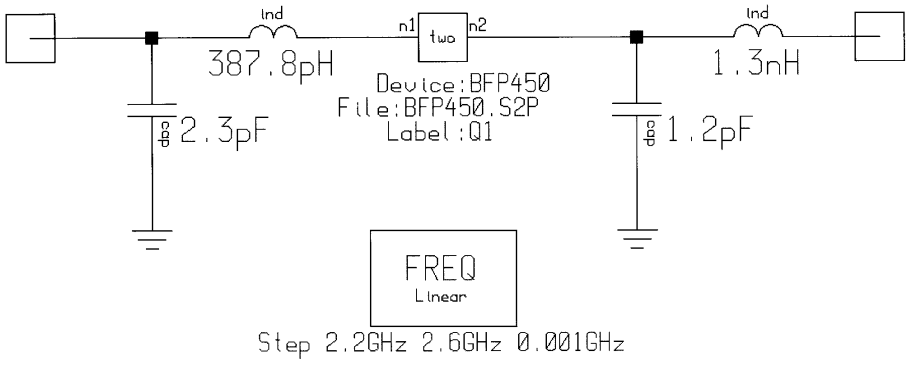

Figure 3-248 A 2.4-GHz amplifier using a BFP450 transistor and lumped-element input and output matching.

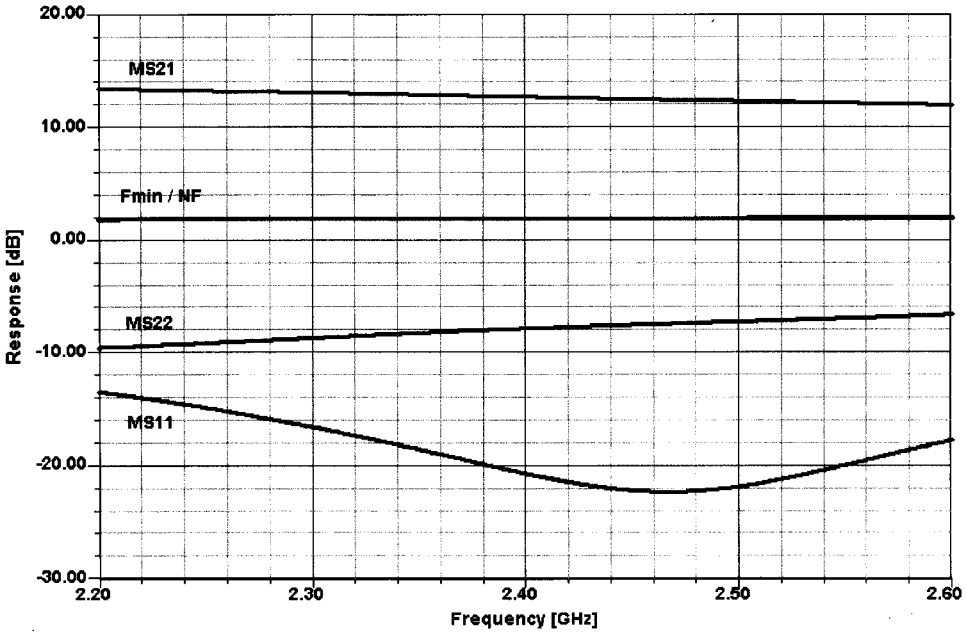

Figure 3-249 Frequency-dependent gain, matching, and noise characteristics of the matched high-dynamic-range BFP450 2.4-GHz amplifier.

requirement. Also, let us not forget that the device is running at 50 mA and as far as bipolar transistors are concerned, this is probably the best amplifier combination we have seen for getting the highest dynamic range and lowest noise figure. The resulting gain, matching, and noise figure characteristics are shown in Figure 3-249.

Now we turn to using distributed elements and at the same time use a shunt feedback at the output; to be specific, we will load it with 150 Ω. The reason for this is to be able to obtain a good compromise at the input that will depend less on the output and at the same

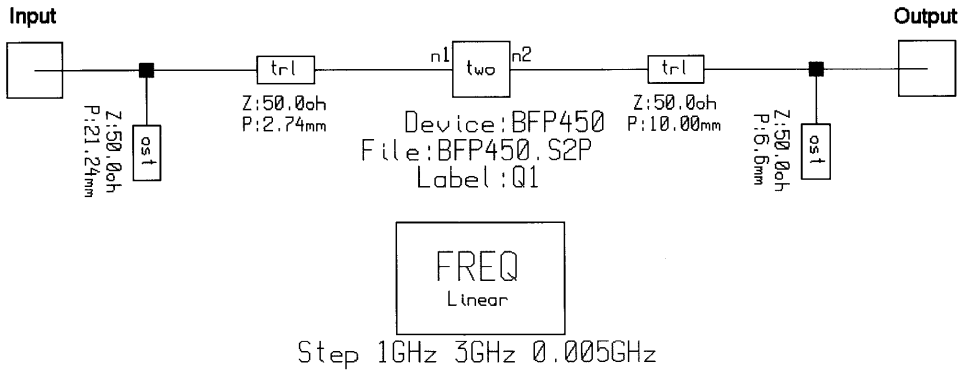

Figure 3-250 Distributed-element input and output matching for the 2.4-GHz BFP450 amplifier.

time improve the S_{22} matching at the output. The procedure for doing the matching with a transmission line offers only certain degrees of freedom, while doing the matching with lumped elements allows the choice of series or parallel inductors or capacitors. In the case of a transmission line, we have open stubs, shorted stubs, and transmission lines. This may result in somewhat more complex matching schemes. On the positive side, they can easily be trimmed, are reproducible, and certainly cost less than exotic capacitors, which need to have small tolerances and to be able to handle high RF currents.

The resulting input and output matching is shown in Figure 3-250, and its frequency response in Figure 3-251. We were able to maintain a good input and output match with an insignificant deterioration of the noise figure.

Since this is a high-dynamic-range amplifier, we also show its predicted two-tone response in Figure 3-252. The manufacturer specifies an $IP_{3,in}$ of 29 dB for a bias point of $V_{CE} = 3$ V and $I_C = 50$ mA with $Z_S = Z_{S,opt}$ and $Z_L = Z_{L,opt}$ at 1.8 GHz. Significantly, however, the manufacturer-supplied nonlinear BFP450 library we used exhibits considerably different characteristics at $V_{CE} = 4$ V and $I_C = 50$ mA than those reflected in the corresponding S parameters supplied by the same manufacturer. In our circuit, the S parameters resulted in about 13.5 dB of gain (based on a compromise between matching for optimum noise and maximum gain) versus about 9.5 dB of gain for the nonlinear library (match optimized for maximum gain). The difference between the 2.4-GHz F_{min} values returned for the two modeling approaches is similarly striking: 1.90 dB for the bare S parameter set and 7.76 dB for the bare nonlinear library biased to $V_{CE} = 4$ V and $I_C = 50$ mA. Clearly, the nonlinear modeling of the BFP450 needs work!

Having fully evaluated the amplifier at 2.4 GHz as a working example, we note that this frequency is used by radio amateurs for some applications. We will therefore supply

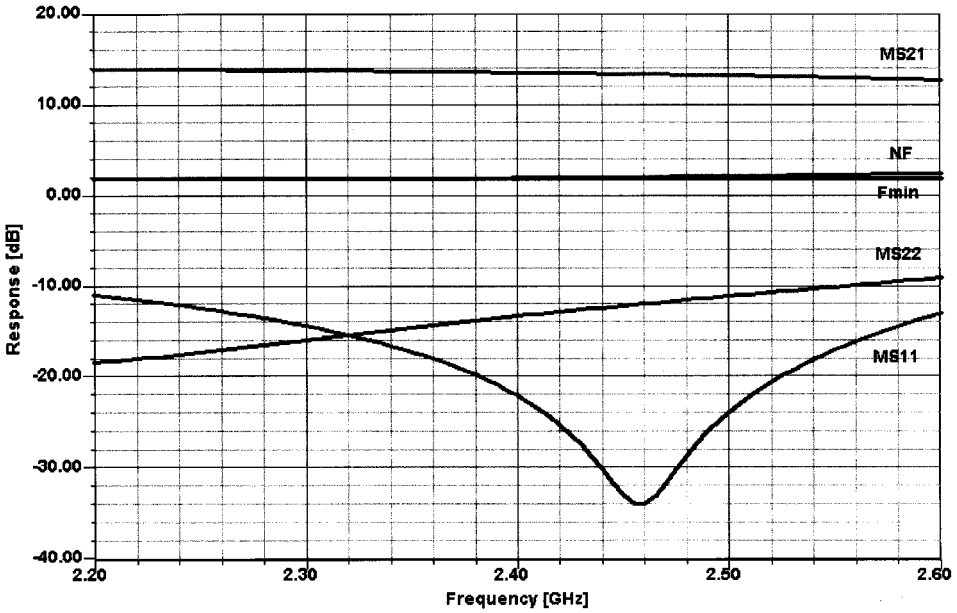

Figure 3-251 Predicted frequency-dependent gain, matching, and noise performance for the BFP450 amplifier with distributed-element matching.

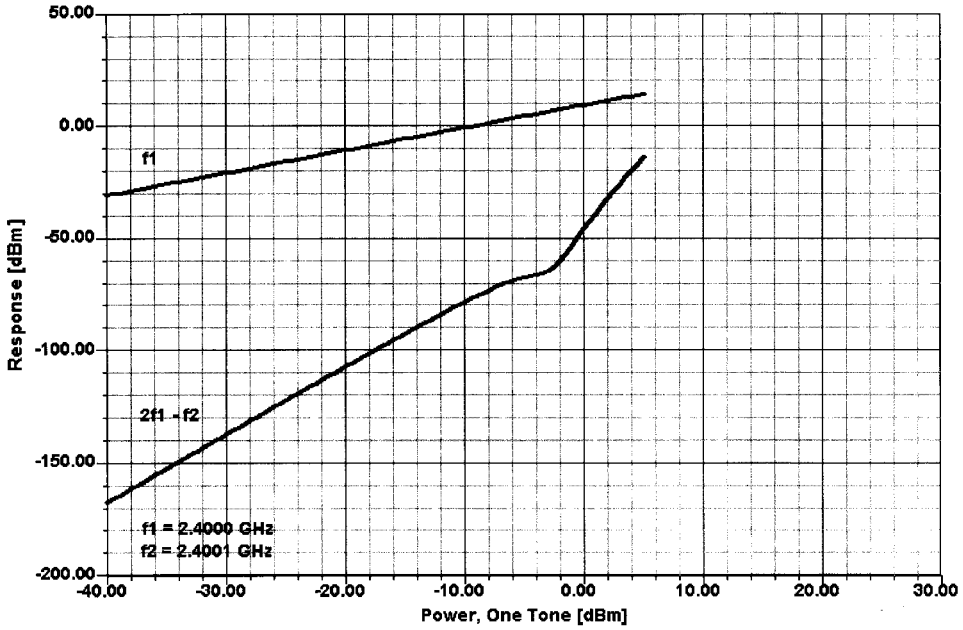

Figure 3-252 Predicted two-tone response of the BFP450 amplifier with the circuit adjusted for maximum gain (9.5 dB): $IP_{3,in} \approx 28.5$ dBm and $IP_{3,out} \approx 38$ dBm. That this version's gain is significantly lower than that of the *S*-parameter-based equivalent illustrates the need for better accuracy in parameter extraction.

examples for 432 and 1296 MHz, popular spot frequencies in the amateur 70- and 23-cm bands, respectively. Figures 3-253 and 3-254 show the 432-MHz version's schematic and frequency-dependent responses. Figures 3-255 and 3-256 show the schematic and frequency-dependent responses for the 1296-MHz version.

Using a bipolar transistor that operates at much less current, the noise figure can be improved at the expense of the dynamic range/intercept point. It is possible to reduce the noise figure by about 1 dB or so, but the reduction in intercept point will be much more dramatic. Another choice is the use of GaAsFETs for this application, but their matching in comparable circuits has been described as a nightmare simply because the devices have too much gain and very high input impedances (essentially 0.2 pF in series with 3 Ω) combined with reasonable output impedances in the vicinity of 240 Ω. Here is a wide field in which engineers can experiment and examine price/performance and performance/real estate issues. GaAsFETs also tend to require more than 30–40 mA to be alive, and even the low operating voltage of 4–5 V makes the device consume a lot of dc power.

3-12-4 Example 3: 1-W Amplifier Using the CLY15

The following is an application showing a fairly wideband amplifier with +30 dBm (1 W) output. We need to point out that in accordance with the various digital modulation modes used with this amplifier, this is not continuous operation, but a much less than 1:1 duty cycle operation. The device would probably not survive operating at full output under CW conditions. This is subject to a discussion with the manufacturer, Siemens, who has not

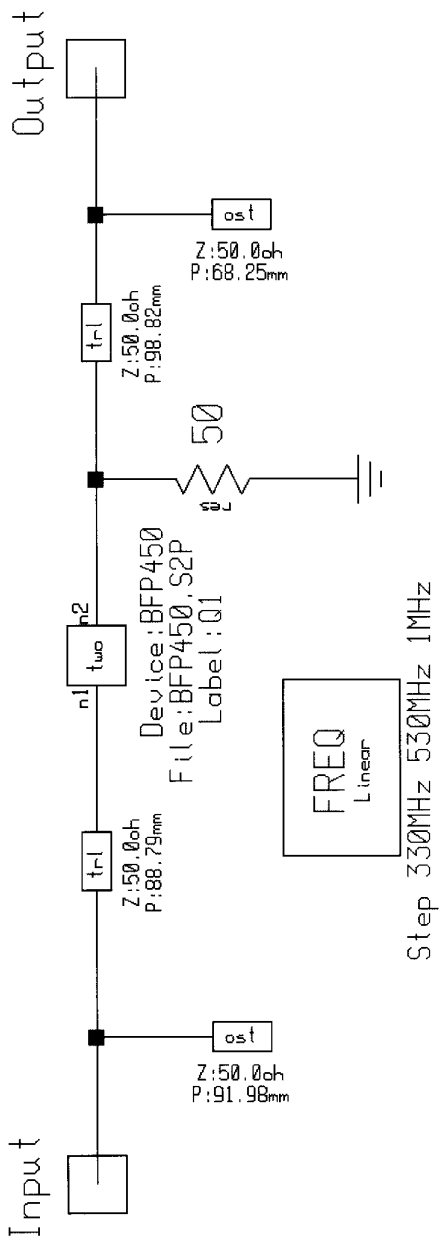

Figure 3-253 Schematic of BPF450 amplifier for 432 MHz. Because f_T = 25 GHz for the BFP450, at this lower frequency we must shunt the device output with a 50-Ω resistor to maintain stability.

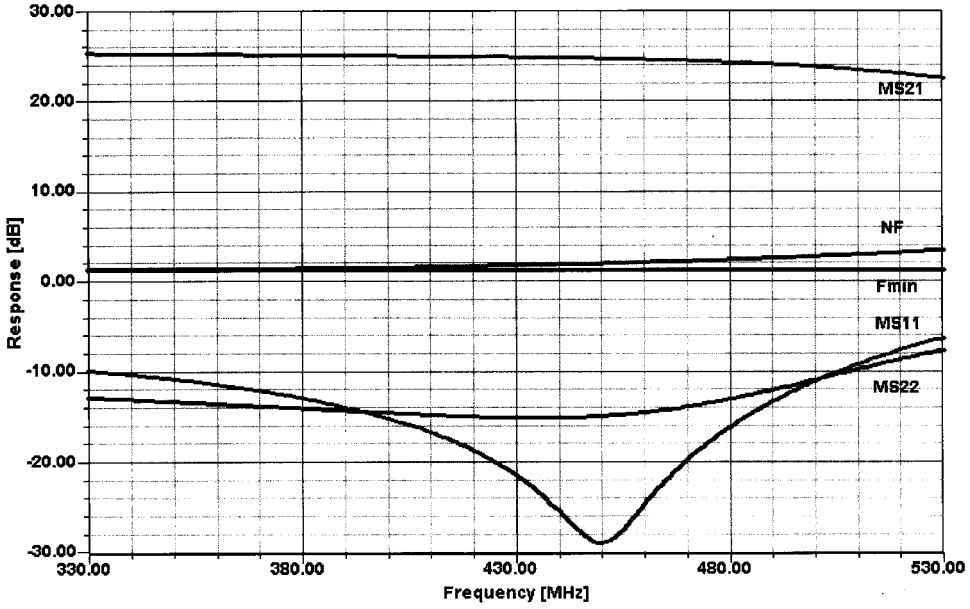

Figure 3-254 Frequency-dependent gain, matching, and noise performance for the BPF450 amplifier at 432 MHz. As with the circuit in Figure 3-253, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

released sufficient data for us to make a judgment as to the CLY15's continuous power capability. Since there is no useful large-signal model available at the time of this writing, we will design this Class A amplifier using large dc bias *S* parameters. In the actual design there will be some cut-and-try, but we find that in this type of application this is still the best way of handling the design.

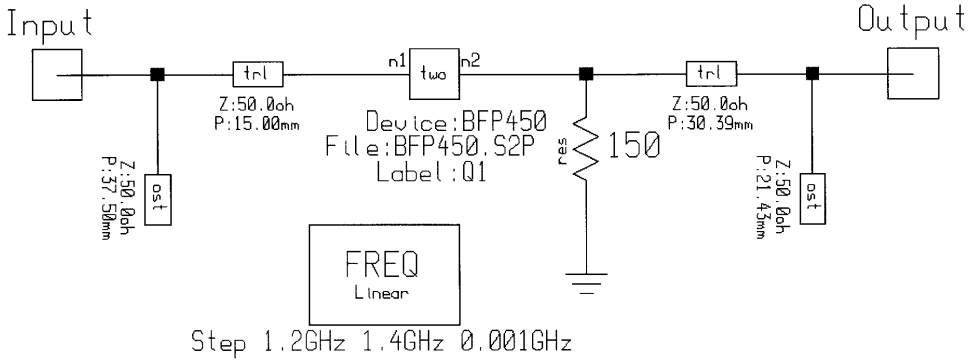

Figure 3-255 Schematic of the BPF450 amplifier for 1296 MHz. A loading resistor is still necessary to ensure stability, but because the transistor exhibits less gain at this frequency than at 432 MHz, we can increase the loading resistor to 150 Ω.

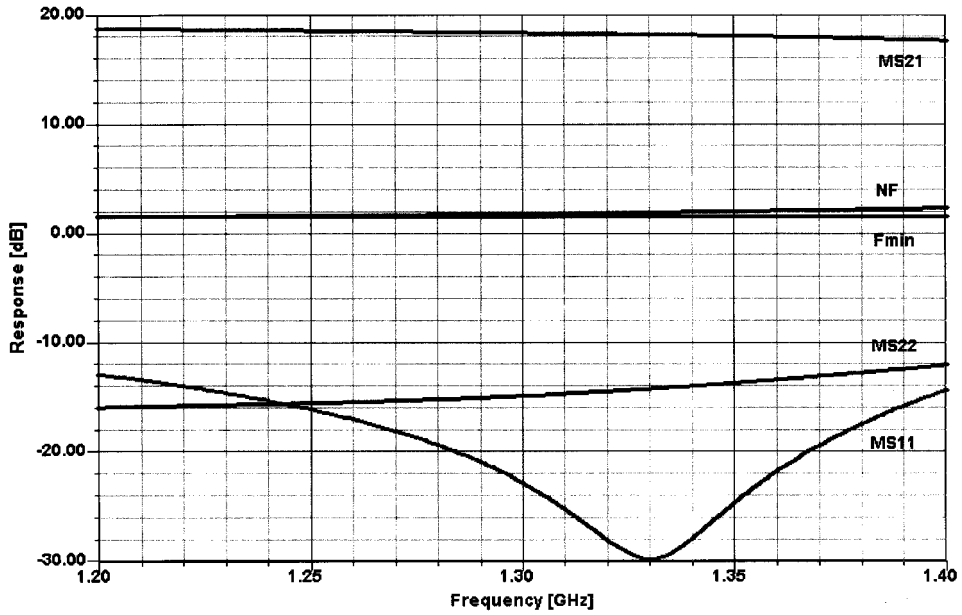

Figure 3-256 Frequency-dependent gain, matching, and noise responses of the BFP450 amplifier at 1296 MHz. As with the two previous versions, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

The CLY15 (gate width 16 mm) is the largest of a series of Siemens GaAsFETs; it was already mentioned in Chapter 2, where its datasheet is reproduced. Its device family also includes the CLY2 (gate width 2 mm), CLY5 (4 mm), and CLY10 (8 mm). It is possible that bigger devices will be offered in the future. One of the most critical parameters will be the saturation voltage; from the datasheet of the CLY15, we can see that at 1.5 A the saturation voltage is approximately 1 V. This drop of 1 V includes losses that result from other parasitic elements; the dc *I–V* curve (Figure 3-257a) indicates a saturation voltage of 0.75. Since we aim for 1-W output power, the resistive portion of the load will be $(5 - 1)^2 / (1 \times 2) = 8\ \Omega$. This assumes a supply voltage of 5 V.

The next step is to design the input and output matching network. Previewing the *S* parameters, it will be noticed that they are essentially inductive, which means that the input match, using lumped elements, will result in a combination of capacitors at both the input and the output. Figures 3-258 and 3-259 show the ways in which the input and output matches were done on the Smith diagram resulting in lumped matching elements. Inspecting the lumped input matching, we find the following. We start with S_{11}, which is in the lower part of the Smith diagram, and determine its conjugate match, S_{11}^*. We already pointed out that this device is inductive, which means that matching it from the conjugate point will require two capacitors. The first one is a series capacitor, as identified in the Smith diagram, and followed by a shunt capacitor to transform the impedance to 50 Ω. A close inspection of the Smith diagram shows that the resulting point is not quite on S_{11}; it is an iterative process to exactly find the crossover point, yet the input match of better than 20 dB is more than acceptable.

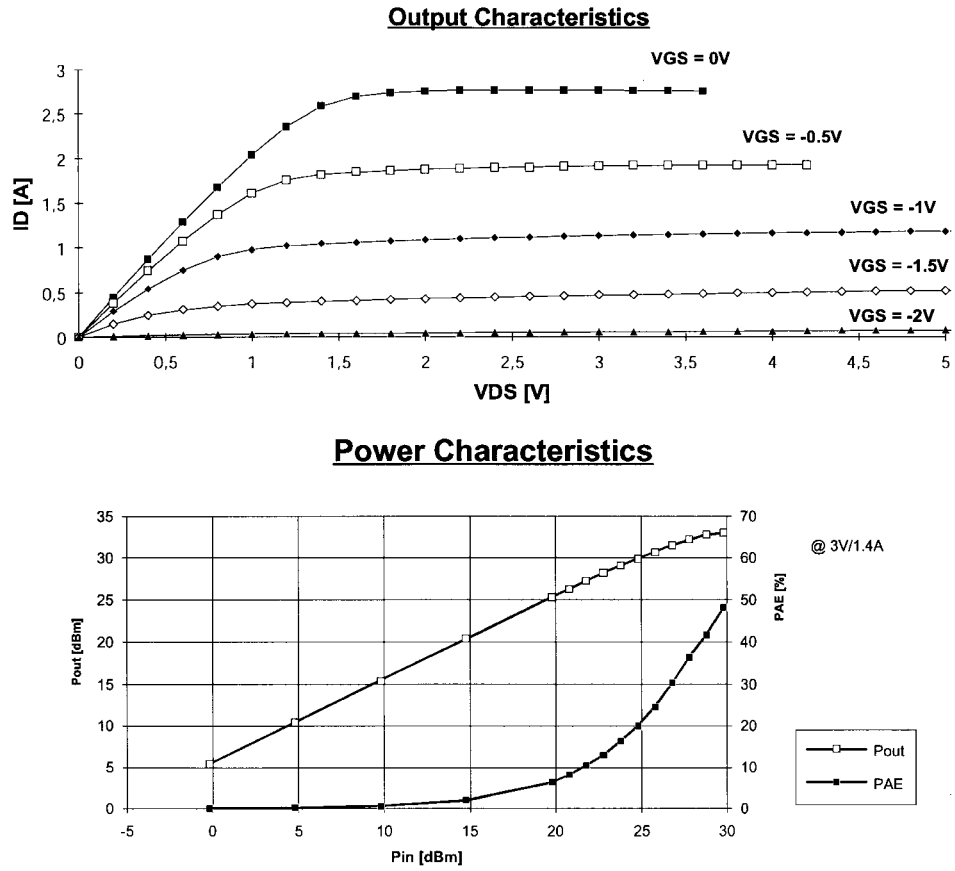

Figure 3-257 Output and power characteristics for the CLY15 medium-power GaAsFET.

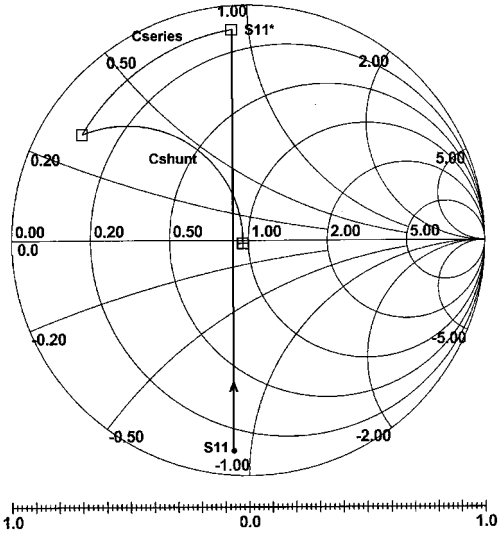

Figure 3-258 Input match for S_{11}^{*} using lumped elements.

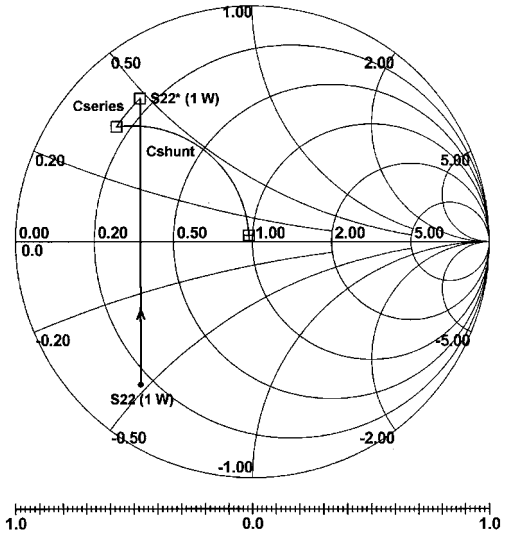

Figure 3-259 Output match for S_{22}^* (1 W) using ideal lumped elements.

As far as the output is concerned, we use the same technique by moving from S_{22} to S_{22}^*. S_{22} has been determined from the required output power; as we showed above, the real portion is 8 Ω. Using the lumped elements, the matching technique is identical; we first need to use a series capacitor and then a shunt capacitor for the transformation. The arc for the series capacitor this time is much longer, resulting in a series capacitance of 11.2 pF instead of the 2.1-pF capacitance used at the input. The actual schematic is shown Figure 3-260. The drawback of lumped elements is that it is not practical to buy components that can handle the heavy RF currents that flow in the input and output networks. Taking the values obtained

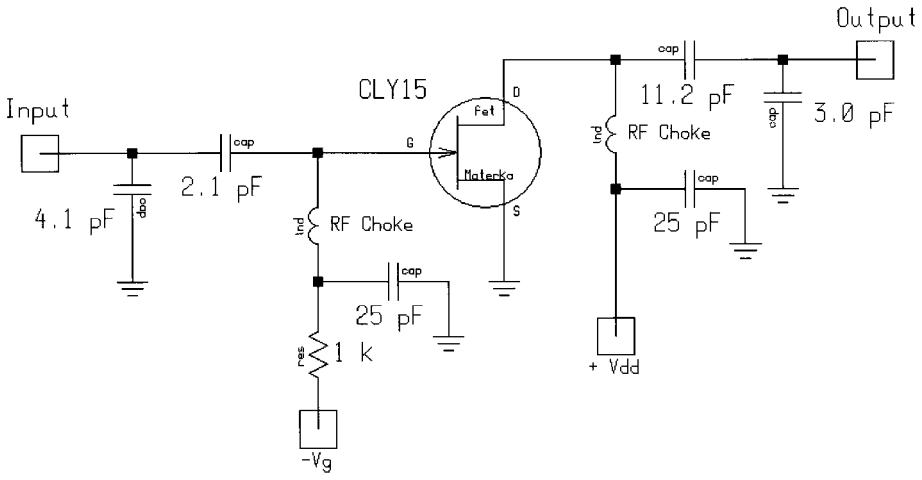

Figure 3-260 The complete amplifier using the CLY15 medium-power GaAsFET, with lumped-element input and output matching.

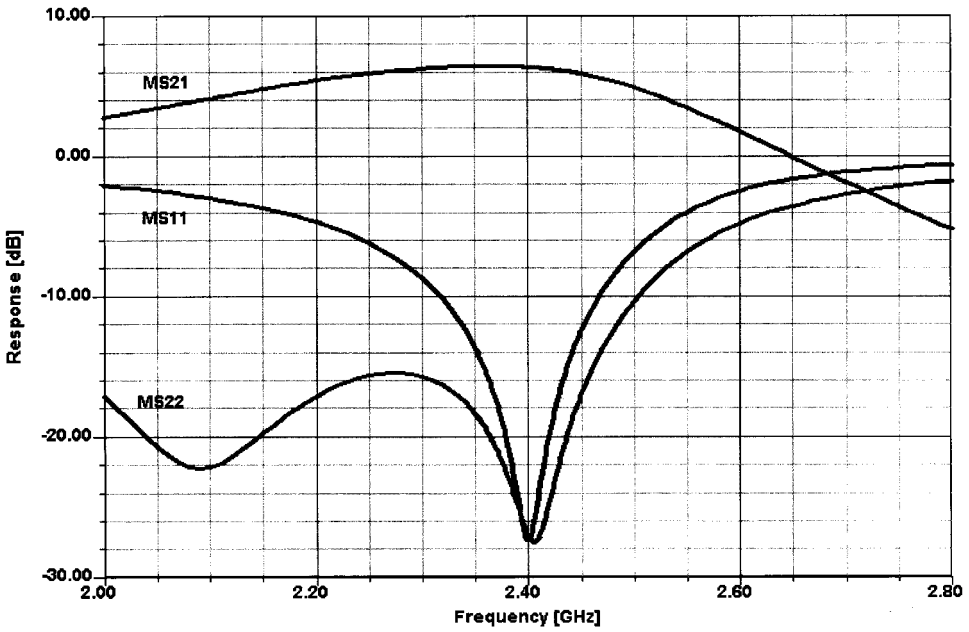

Figure 3-261 Frequency-dependent gain and matching responses of the CLY15 amplifier using ideal lumped elements.

from the lumped input and output matching approach, Figure 3-261 shows the resulting frequency response.

The next step is to provide the same matching condition using distributed elements, which of course have the advantage that they can be printed on the PC board. Instead of using ideal elements, we used a loss tangent of 2E–3, or a Q of 500. The manufacturer of the R4000 material (Rogers) provided this specification. Now we start with the same approach by moving from S_{11} to S_{11}^*. From there, we use an open stub with a transmission-line impedance of 50 Ω, followed by a transmission line to the point in the left lower corner, and, finally, a shorted transmission-line stub allows the 50-Ω matching. For this amplifier, we are not looking for noise matching but for input and output power matching. Figure 3-262 shows this match on the Smith Chart.

At the output, the procedure is again similar: We move from the S_{11} for 1 W to a conjugate value, then use an open stub that acts like a capacitor until we cross the real axis; finally, a λ/4 transmission line is used to match from approximately 75 Ω to 50 Ω. Figure 3-263 shows this match on the Smith Chart. This concludes the distributed matching design for the CLY15 amplifier.

Finally, the complete circuit using distributed elements is shown in Figure 3-264. From a dc point of view, we took advantage of the incoming shorted stub by using a transmission line of the appropriate length and a bypass capacitor to ground. This allows us to feed the gate with the required negative voltage without interfering with the frequency response of the amplifier. When evaluating the total frequency response (Figure 3-265), we noticed that this circuit seems to have a higher Q than the lumped equivalent. Again, to obtain a wider bandwidth more transformation stages will be needed. We leave this task to the interested reader.

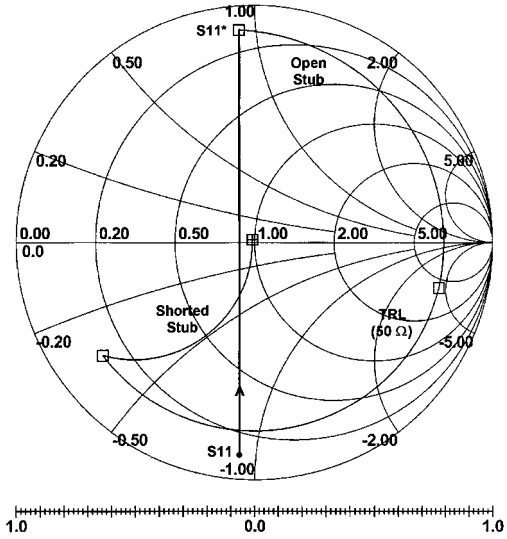

Figure 3-262 Input match for S_{11}^* (1 W) using distributed elements.

The 1-dB bandwidth of the amplifier using distributed, lossy elements is 120 MHz. If a wider bandwidth is required, matching networks with more elements are required. Because of the gain–bandwidth product, the peak gain for such a wider-bandwidth arrangement will be less than this narrowband example.

Having used a lumped to distributed transformation, we next present a power amplifier that uses coaxial lines, baluns, and other transformation steps capable of handling the increased power requirement.

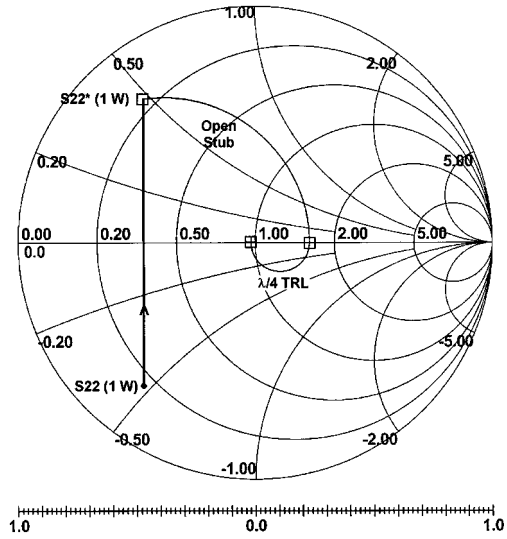

Figure 3-263 Output match for S_{22}^* (1 W) using distributed elements.

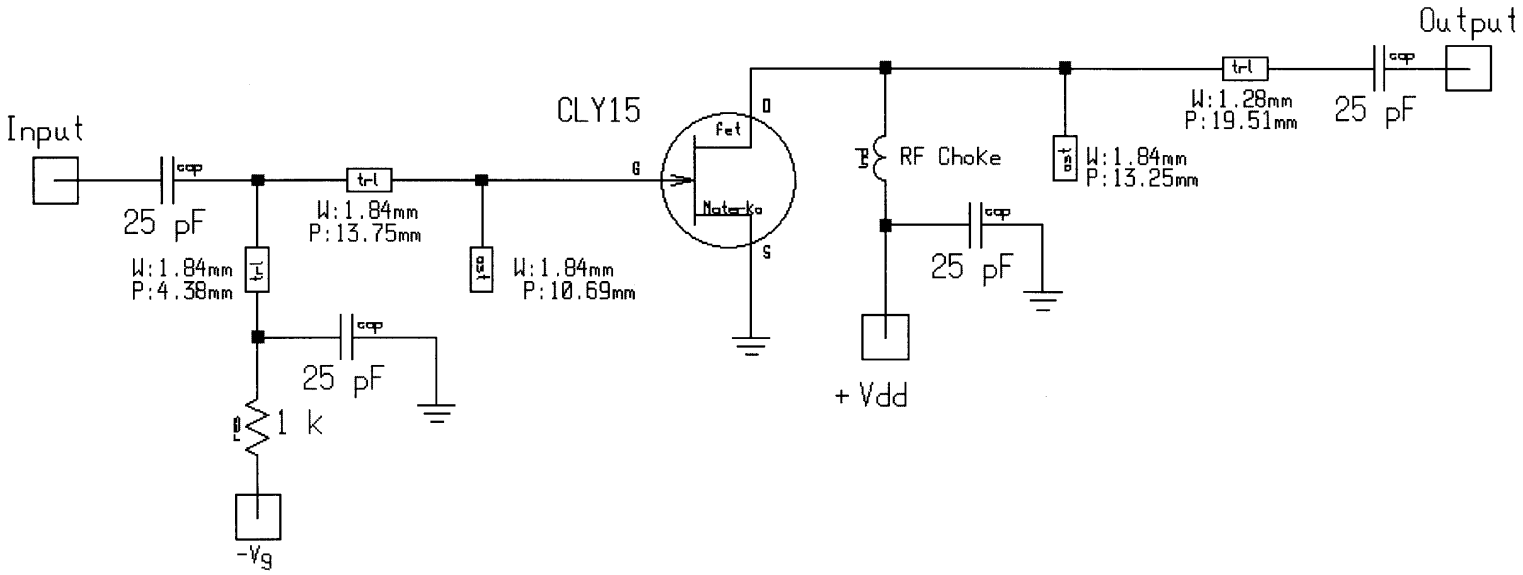

Figure 3-264 The complete amplifier using the CLY15 medium-power GaAsFET, with distributed-element input and output matching.

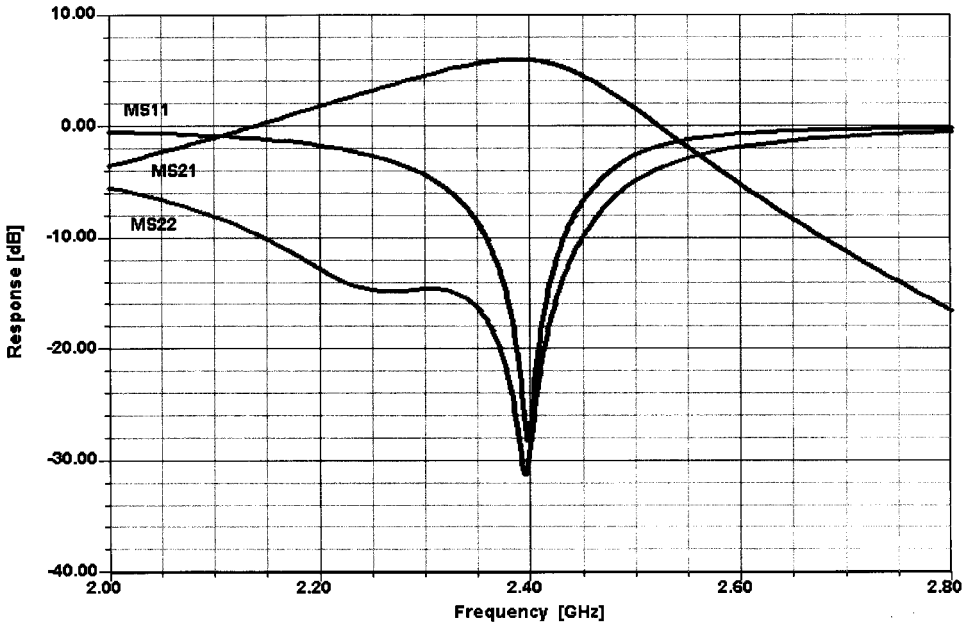

Figure 3-265 Frequency-dependent gain and matching using distributed, lossy elements.

3-12-5 Example 4: 90-W Push–Pull BJT Amplifier at 430 MHz

The last complete application we want to examine is a 90-W output, push–pull amplifier using two TRW transistors (that are no longer made—an all-too-frequent occurrence after a design is complete, resulting in a scramble for replacements). Figure 3-266 shows the circuit diagram of this UHF transistor amplifier, and Figure 3-267 shows its mechanical design. The amplifier requires 28 Vdc and will draw approximately 6 A, requiring 15 W of drive at 438 MHz. This amplifier operates in Class AB, which means it is not limited to amplifying FM and other angle-modulated signals, and can accommodate even single-sideband (SSB) operation.

The drive power coming from the source connected to the input N connector (15 W) is fed through a short piece of coaxial cable to the PC board sitting on top of the heat sink. To change from single ended to push–pull, a 50-Ω coaxial cable is coiled to provide sufficient electrical length to act as a balun that provides two symmetrical paths through the amplifier. The RC section of 10 Ω in parallel with a 220-pF capacitor stabilizes the amplifier at lower frequencies, while at higher frequencies the 10-Ω resistor has no contribution. There are two independent 4:1 transformers, one for each section; they are built using 25-Ω coaxial cable with a set of two binocular ferrite cores to force the transformation. The dc supply is also fed to the transistors at this point. The stabilization circuit consists of a temperature monitor using the *pn* junction of a transistor, side-mounted on the heat sink, and a combination of operational amplifiers and adjustments. This guarantees proper, temperature-independent biasing. The 4:1 input baluns result in 12.5 Ω impedance, or 3.125 Ω per transistor. Since the input impedance at this drive level is somewhere in the vicinity of $[(1 \ldots 2) + j(3 \ldots 5)]$ Ω; the final matching is accomplished by an *RC* section in which the inductance is actually printed

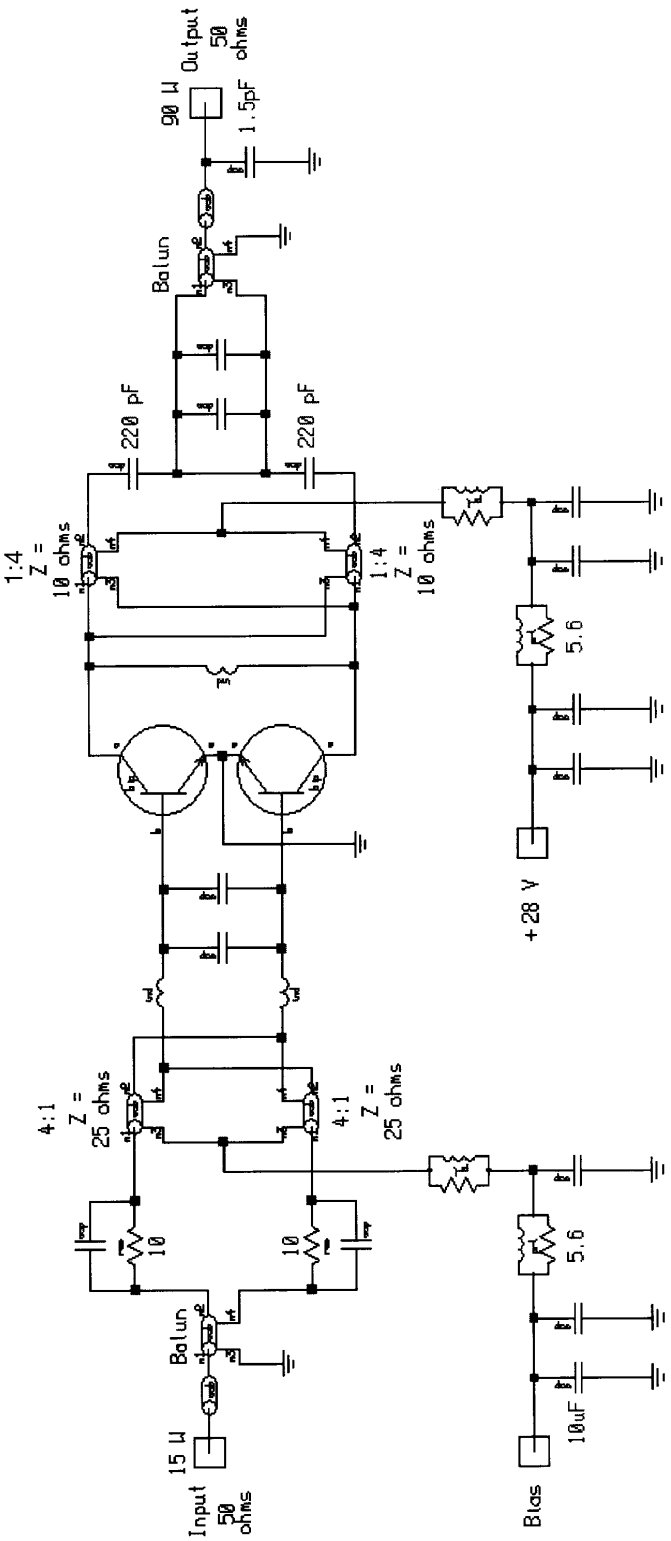

Figure 3-266 Circuit diagram of the 90-W, push–pull, 438-MHz linear amplifier.

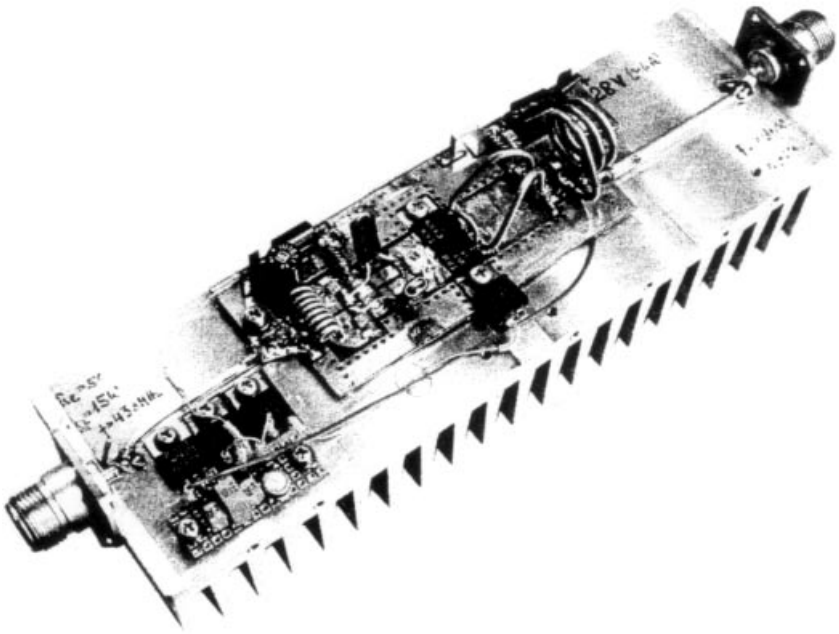

Figure 3-267 Mechanical assembly of the 90-W amplifier shown in Figure 3-266.

and the shunt capacitor across is soldered from base to base as close to the transistor bodies as possible. A ceramic-dielectric variable capacitor in parallel with this allows fine tuning.

The output consists of an inductor from collector to collector that tunes out the capacitive reactance and makes the transistor output impedance real. We then follow the same pattern by taking a 1:4 transformer, but this time built using 10-Ω rigid line instead of 25-Ω rigid line. Together with the output capacitance, prior to the output balun, this is a medium-bandwidth matching arrangement that transforms up to 50 Ω. The collector impedance per collector had to be $(28 - 2)^2/2 \times 90$, resulting in roughly 3.8 Ω—not that different from the input match at the balun point. This way, the matching networks at the input and output can be identical. At the output of the matching network, another coiled 50-Ω coaxial cable serves as balun; because it must operate at the 90-W level, larger-diameter line was used than in the input balun. Finally, another section of rigid line is used to connect the output balun on the PC board to the output N connector. The output capacitor again helps in the transformation.

Both the base and collector voltage supplies are heavily filtered using ferrite-bead-based RF chokes and heavy wire inductors wound on low-impedance resistors. A fairly large number of these amplifiers were actually built and are still in use.

3-12-6 Quasiparallel Transistors for Improved Linearity

Some applications require really low intermodulation distortion. One of the authors (Rohde), during his tenure at RCA Government Systems Division, and his team developed a parallel-device topology that is somewhat similar to the conventional parallel approach but shows vastly increased linearity. In creating higher-power devices, manufacturers parallel several transistors in one package, connecting them in a clever way so the overall drive, dissipation, and output power are equally divided between all the devices. Special nickel–chromium

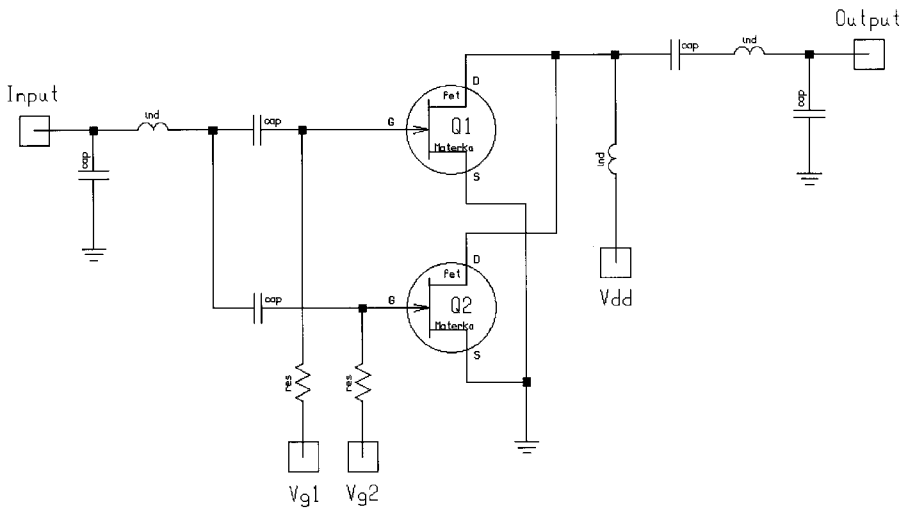

Figure 3-268 The quasiparallel amplifier topology looks like a standard parallel amplifier. Biasing the devices to different operating points nets an improvement in IMD performance.

ballasting resistors in the many fingers of the emitter connections of the multiple internal devices equalize any differences among the transistors while increasing the saturation voltage by only a small amount. In our high-linearity design, we used two transistors in parallel, one being biased somewhere between Class A and B, and the second one somewhere between Class B and C (Figure 3-268). The exact bias voltages and operating points had to be found through experiment. In practice, Q1, the "initially on" transistor, is driven to a point close to that at which its IMD products would increase. Q2 is biased such that at this same drive level it adds to the output power.

We frequently referred to this configuration as "turbocharged." The IMD products at full output power were down 40–45 dB, compared to 26–30 dB for a single transistor. While such an arrangement shows superior IMD performance, because of the somewhat abrupt kick-in of the second transistor, the transconductance response is semismooth, a characteristic that might make alert readers think that IMD will occur at this point. On the other hand, the transconductance for Q1, in effect, saturates or stays constant, so when the transconductance responses of both transistors are overlaid, the result is a smooth response overall.

This technique has been validated up to 100 W and up to at least 50 MHz. Its drawbacks include the need for two transistors with their associated costs, additional real estate, and higher input and output capacitances. Nonetheless, considering that MOS transistors capable of operation to 1 GHz were unavailable when this technique was developed, we believe that it should be revisited.

The Class D and higher operating modes require a large number of additional components and will make the efficiency higher (selective in frequency), but not necessarily reduce the IMD products. A further point of consideration is that it is incorrect to assume that reducing the input level to a given Class A will necessarily reduce its IMD products. As with tubes, the closer one gets to the knee, even in Class A operation, the worse the IMD. (This phenomenon was particularly troublesome in systems using 1-kW amplifiers up to 150 MHz;

underdrive with the intent of getting better IMD performance produced just the opposite result.) If a wide power range is considered, we recommend using a bias scheme that includes sufficient intelligence to find the best operating point.

Another hot amplifier issue is that of IMD as a function of load impedance. If an amplifier is used at output power considerably below its design value, its load impedance will be too low and, depending on the circuit configuration, the result may be additional IMD.

3-12-7 Distribution Amplifiers

It is not uncommon that a signal from a particular source like an antenna has to be distributed to several places. A condominium is a typical situation in which energy from a main signal source must be split for distribution to a larger number of users—there must be enough voltage or power to produce a noise-free picture. An amplifer capable of doing this is a *distribution* amplifier, not to be confused with a *distributed* (or traveling-wave) amplifier, such as that shown earlier in this chapter in Figure 3-6. An interesting means of achieving this is to use multiple Wilkinson couplers following an amplifier. Figure 3-269 shows an arrangement that makes heavy use of multiple power dividers to provide multiple outputs. Theoretically, the reverse is also possible: If we want to collect energy from a number of sources and combine them, as on a cable, we can use Wilkinson couplers at the *input* of a gain block. Note, however, that depending on the level and number of the combined signals, this may put enormous strain on the linearity of the amplifier. What we want to avoid is a lot of distortion, which, in the case of television, will show up as color confetti in the noise and signal.

3-12-8 Stability Analysis of a Power Amplifier

One of the hidden pitfalls in narrowband circuit design is that a circuit may be unstable outside the frequency range of interest. Circuits containing structures built from distributed elements, which exhibit multiple resonances, can be particularly susceptible to such instabilities. In this example, we analyze the stability of a simple FET power amplifier designed using small-signal concepts and the interactive Smith Tool utility in Ansoft's Serenade

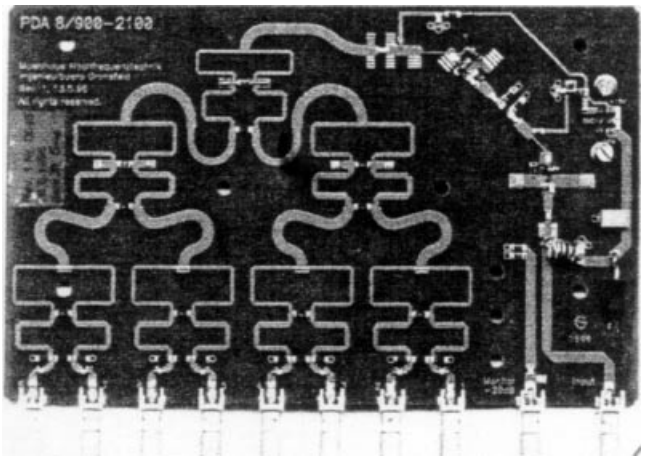

Figure 3-269 Distribution amplifier showing the use of multiple Wilkinson power dividers.

Design Environment. The evaluation shows how K-factor analysis alone is not sufficient to check for stability of a design.

Small-Signal ac Analysis. We begin by taking the Figure 3-270 amplifier, which was designed for about 16 dB of gain at 2.2 GHz. Due to the very low, capacitive input impedance of the FET and the proximity of the source-plane gain circles and stability circles to the edge of the Smith Chart, the matching network attempts to transform 50 Ω to an impedance of approximately $(2.5 + j15)$ Ω. The impedance lies close to the stability circles at 2 GHz but remains in a stable region. The bias point selected (–3.5 V) is chosen for Class AB operation. Higher linear gain can be achieved by reducing the gate voltage to –2.0 V; at this bias point, the amplifier gain will increase to about 19 dB.

First, we will do a small-signal ac analysis and examine the S parameters and K and B_1 factors [see Eqs. (3-154) and (3-157), respectively] from 1 GHz to 6 GHz—well beyond the bandwidth of the design. Figure 3-271 shows the circuit's frequency-dependent gain and matching characteristics.

If we examine B_1 and the stability factor K, we see that the amplifier is not unconditionally stable in the 2.2-GHz passband as shown in Figure 3-272. K dips slightly below 1, although B_1 remains above zero. In practice, a slight change in design would be required to bring K above 1 and remove this potential instability. However, for our example, this is of no consequence, as we shall see below.

Nyquist Stability Analysis. Now we will utilize a Nyquist stability analysis to check the stability of the amplifier. To fully realize the advantages of a Nyquist stability analysis, we must sweep frequency over a very wide range. We want to be able to pick up instabilities at *any* frequency, not just near the design frequency. In this example we sweep from 1 kHz to 20 GHz. A start frequency of 1 kHz is chosen so we can determine the starting point of the Nyquist plot and we ensure that any low-frequency resonances are picked up. The stop frequency is chosen past the f_{max} of the transistor (where we know it cannot oscillate).

The analysis results are shown in polar plot form in Figure 3-273 and in magnitude–angle form in Figure 3-274. The polar graph shows the real and imaginary parts of the system determinant as frequency is swept. The magnitude–angle graph shows the magnitude and cumulative angle (no cut at ±180°) of the system determinant as frequency is swept. The key to interpreting these graphs lies in the following statement drawn from the Nyquist criterion:

The circuit will be unstable if the Nyquist plot encircles the origin in a clockwise direction.

The term "unstable" refers to the existence of natural frequencies lying in the right-half of the complex frequency plane (RHP). These natural frequencies on the RHP will cause oscillations. To encircle the origin in a clockwise direction means that the Nyquist plot will travel in a clockwise path, cross the negative real axis, and continue to completely surround the origin. If the path appears to encircle the origin but then "unravels" itself in a counter-clockwise direction, the origin is not actually encircled. Figure 3-273 shows that the origin is not encircled and therefore this circuit is stable.

The magnitude–angle plot can assist in determining if a clockwise encirclement has actually been made with the help of the following:

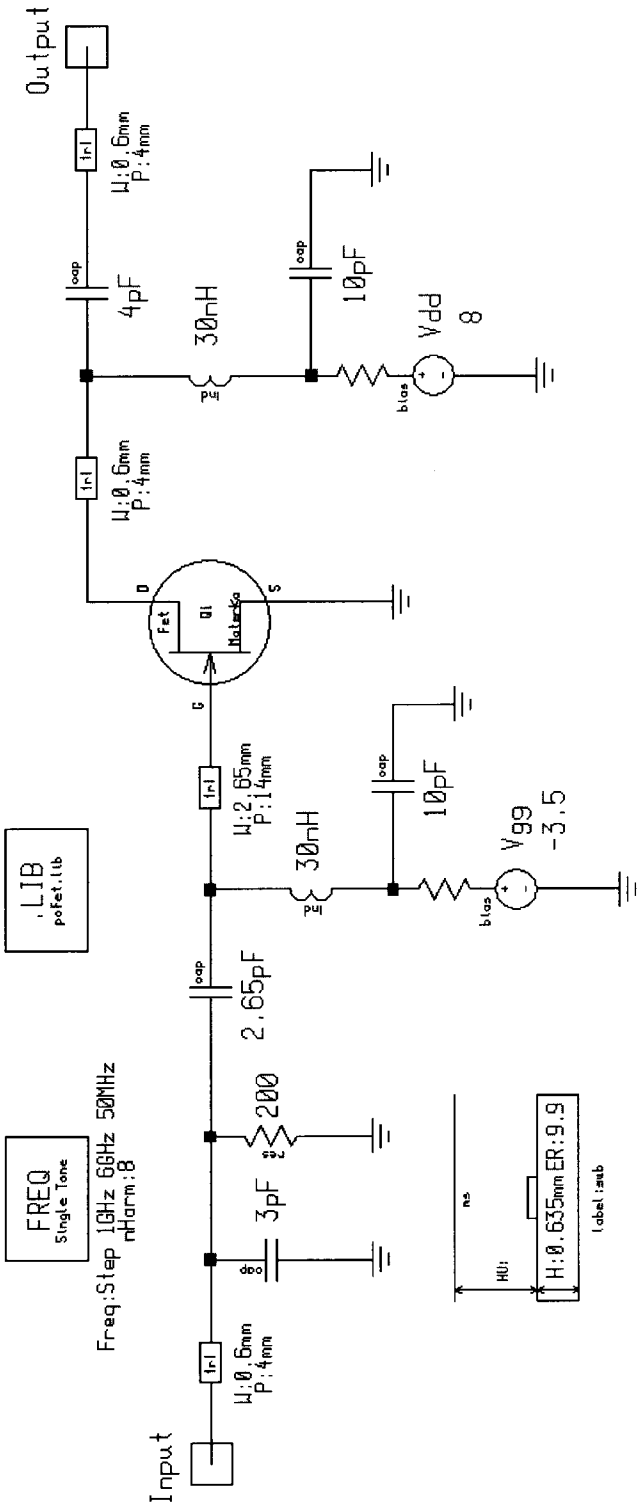

Figure 3-270 A 2.2-GHz amplifier design for stability analysis.

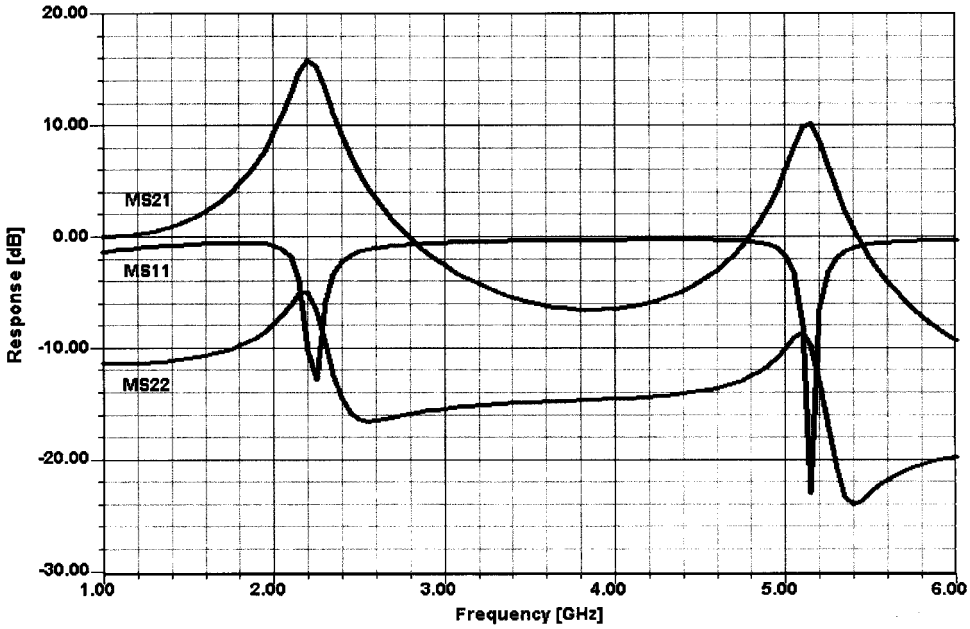

Figure 3-271 Frequency-dependent gain and matching characteristics of the amplifier. Although the circuit is designed for 2.2-GHz operation, the periodic responses of its distributed-element-based input and output matching networks result in a second gain peak near 5.1 GHz. As we shall see, however, instabilities may result at frequencies that cannot be intuited from this graph.

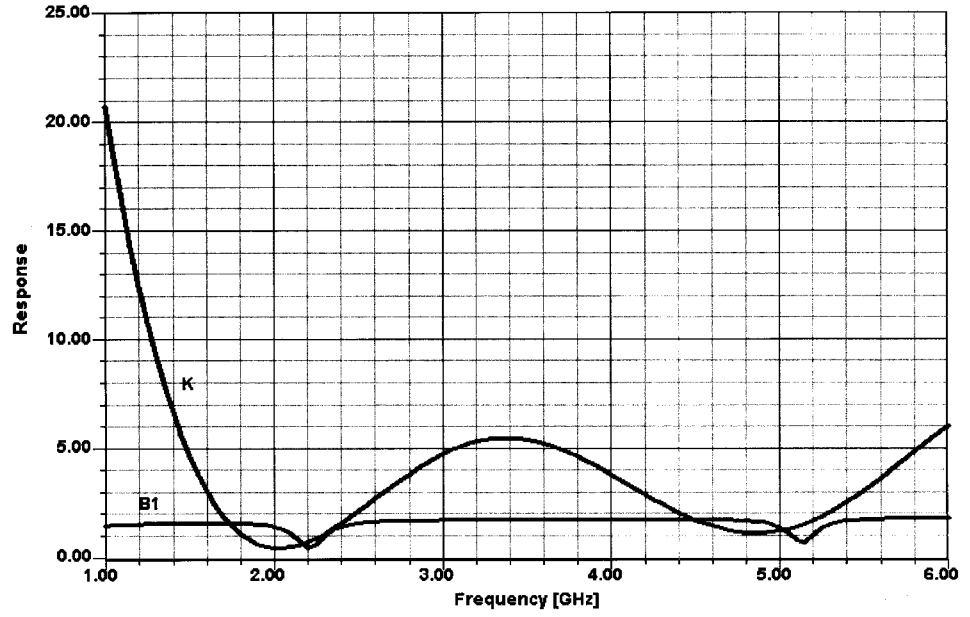

Figure 3-272 K and B_1 for the 2.2-GHz amplifier.

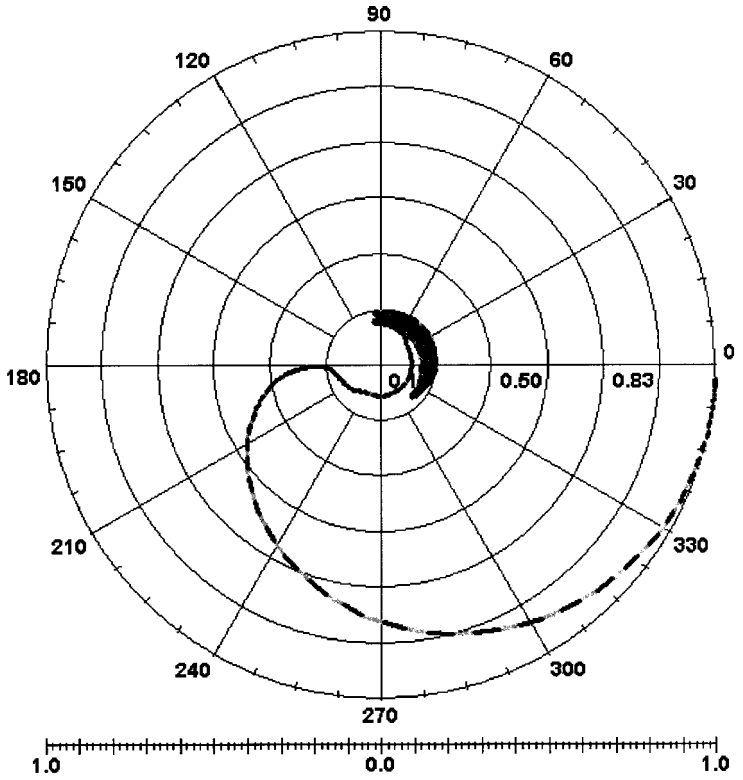

Figure 3-273 Polar Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

- To travel in a clockwise direction on a polar chart means to decrease phase angle. On a magnitude–angle plot, the phase will become more negative as frequency is increased (although it may not be monotonic).
- If the path crosses the negative real axis on the polar chart, it will cross –180° on the magnitude–angle plot.
- Encirclement will occur if the phase angle continues to decrease to, say, –360°. If "unraveling" occurs, the phase angle will not stay below –360°. Figure 3-274 clearly shows that the phase angle decreases to about –180° but does not decrease any more. Rather, the angle returns to a positive value and oscillates between about –40° and +100°. Therefore an encirclement did not occur, and the circuit is stable.

An Unstable Case. Let us now change the gate bias to –2 V—a value that increases the amplifier gain enough to cause instability. Figures 3-275 and 3-276 show the results. From Figure 3-275 we can see that the origin is encircled in a clockwise direction. Figure 3-276 confirms this since the phase angle goes through –180° and continues without unraveling.

Approximate Frequency of Oscillation. The frequency where the Nyquist plot crosses –180° is often the approximate frequency of the unstable right-half-plane zeros and provides an estimate of the potential oscillation. For this example, there is a sharp crossing at 200 MHz that is characteristic of a circuit resonance. Note that the frequency is not related

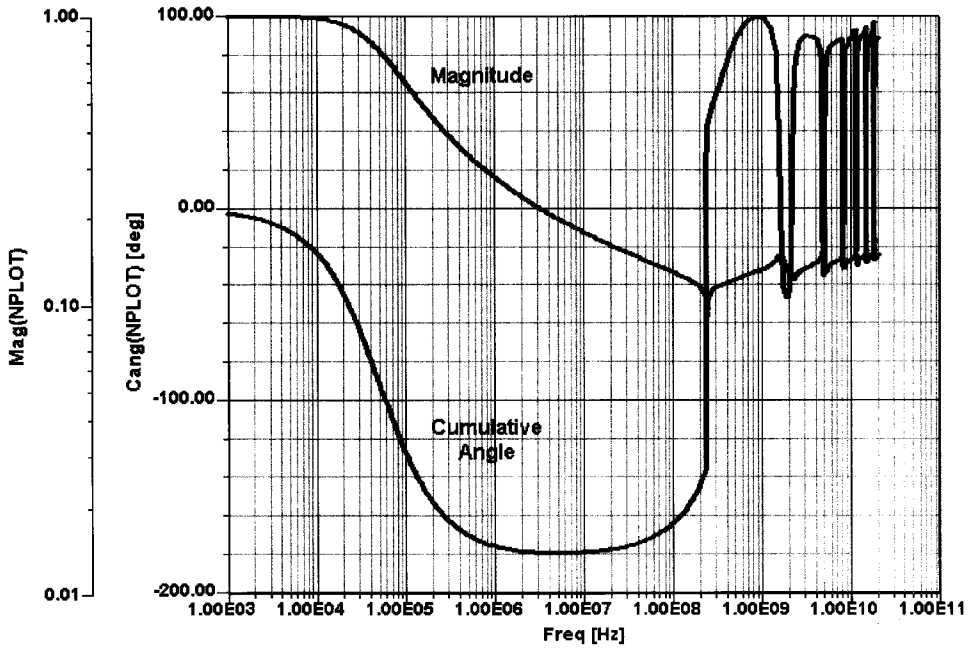

Figure 3-274 Magnitude and cumulative angle Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

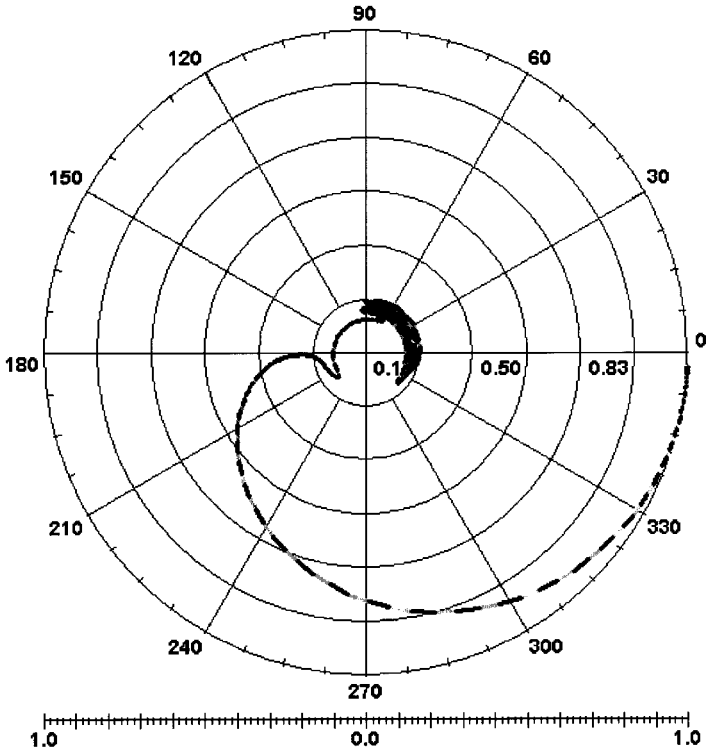

Figure 3-275 Polar Nyquist plot of the unstable amplifier.

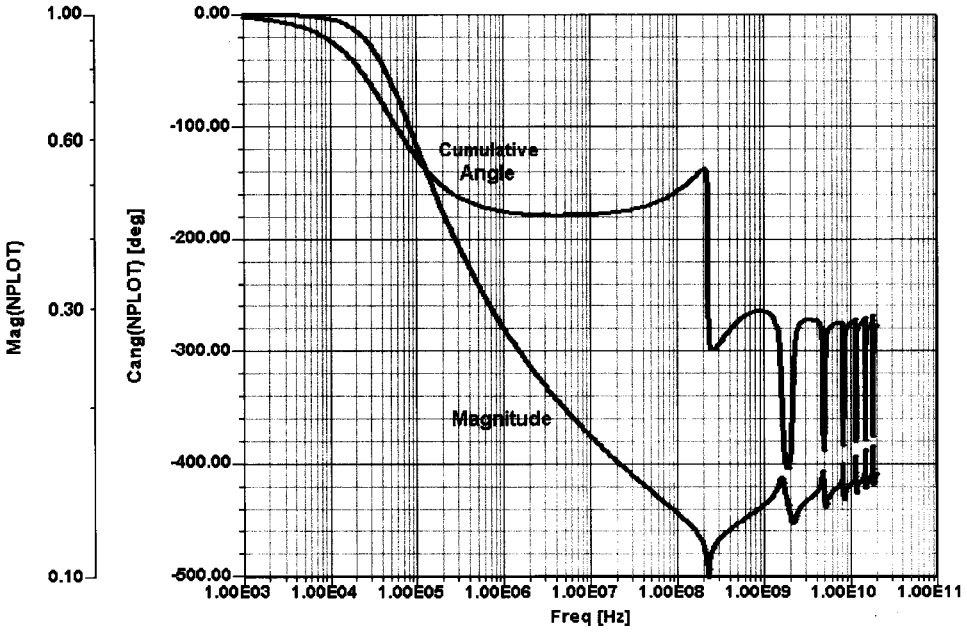

Figure 3-276 Magnitude–cumulative angle Nyquist plot of the unstable amplifier.

to a resonant frequency in a rigorous mathematical fashion, but it has been our experience that this frequency approximates the resonant frequency. To confirm the circuit's readiness for oscillation in the vicinity of this frequency, we evaluate it with Serenade's Oscillator Design Aid from 10 MHz to 1 GHz. The Design Aid finds an initial resonant frequency near 230.6 MHz—not too far from the –180° crossing frequency of 200 MHz of the Nyquist plot. Figure 3-277 shows this point.

Oscillator analysis finds a final oscillation frequency of 228.48 MHz. Figure 3-278 shows the resulting output spectrum at Port 2. At this point we decided to do a quick jump into Chapter 5 and take advantage of the CAD capability to predict the resulting phase noise, which is shown in Figure 3-279. As we compare this with other measured results, the approximately 228-MHz oscillator has a poor phase noise since the same phase noise is achievable at 1 GHz and higher. We remind the reader that this is an unwanted effect, but all of us who have built amplifiers will have experienced either low-frequency oscillations (motorboating) or very-high-frequency oscillation, sometimes caused by the components in the immediate vicinity of the transistor itself and found somewhere above 3 GHz. This case is really a demonstration case; a closer look reveals that the transconductance required for this condition is unrealistically high; but nonetheless it is a good example to demonstrate the stability issue.

Where Does Oscillation Begin? An interesting question to solve now is, "What gate bias voltage is needed for oscillation to begin?" Ansoft's Serenade Design Environment includes oscillator synchronous stability analysis, which uses a modification of the harmonic-balance technique to determine critical points, such as the voltage needed to "turn on" an oscillator. Mathematically, this is called a *Hopf bifurcation* because the behavior of

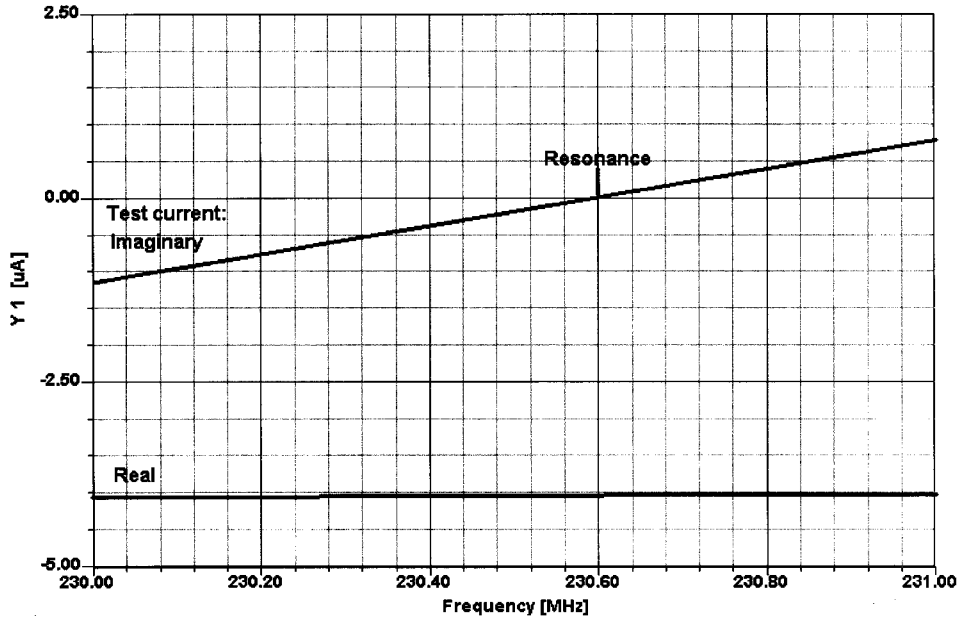

Figure 3-277 Graph from Serenade Oscillator Design Aid analysis of the amplifier. A resonant frequency is indicated where the imaginary part of the test current equals zero and the real part is negative.

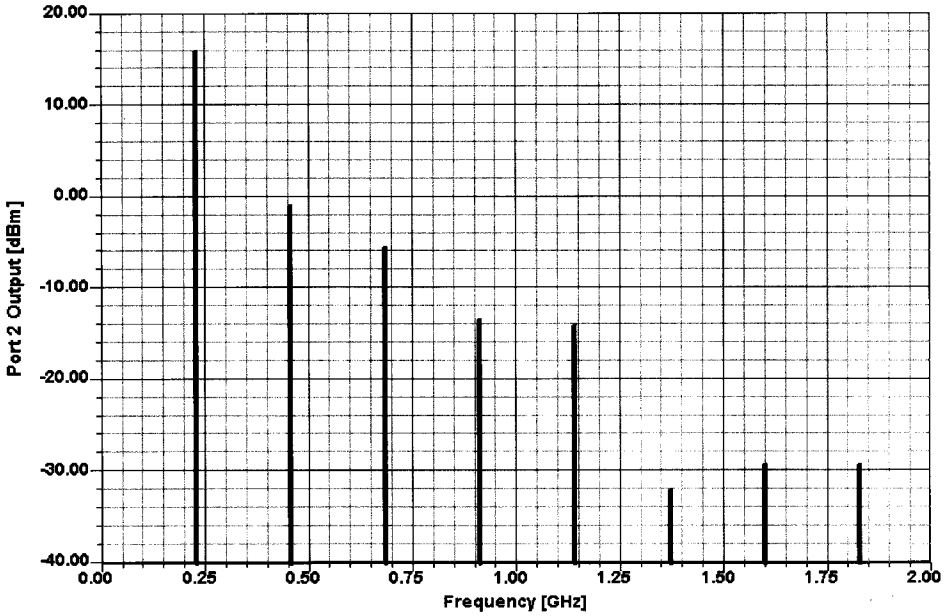

Figure 3-278 Predicted output spectrum of the unintended oscillator.

the circuit changes dramatically from a dc steady state to an oscillatory response. Figure 3-280 shows this effect by plotting output power versus gate bias. The turning point at –3.2 V (22 mW) is clearly visible, as is the bifurcation at –3.1 V (0 mW output).

Figure 3-280 can be interpreted as follows:

1. If the bias voltage is increased from, say, –4.0 V, the circuit will begin to oscillate at the bifurcation voltage and the output power will jump to 26 mW.
2. If the circuit is oscillating and the voltage is decreased from –2.0 V, the circuit will cease oscillating at the turning voltage of –3.2 V.
3. The branch between the turning point and the bifurcation point is unstable and cannot be realized in practice. This forms a hysteresis loop around points (–3.1 V, 0 mW), (–3.1 V, 26 mW), (–3.2 V, 22 mW), and (–3.2 V, 0 mW).

This amplifier stability analysis section is based on the stability analysis examples provided by Ansoft for the Serenade Design Environment.

An interesting example that combines both CAD and the feed-forward amplifier technique can be found in the Serenade Design Environment system simulator examples manual. This technique has been under evaluation for the last two years, but our feeling is that not enough measured data at frequencies above 500 MHz with reliable performance information have yet been made available in the literature. Along these lines, work done at Ansoft under a U.S. Air Force contract has provided very good insight into high-efficiency amplifiers at microwave frequencies [46].

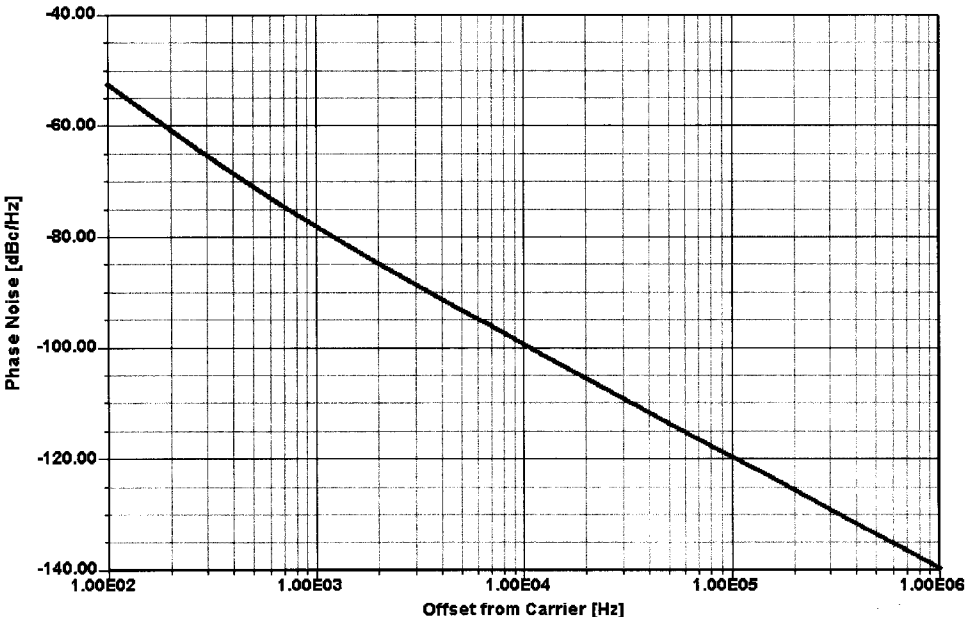

Figure 3-279 Predicted phase noise of the oscillating amplifier.

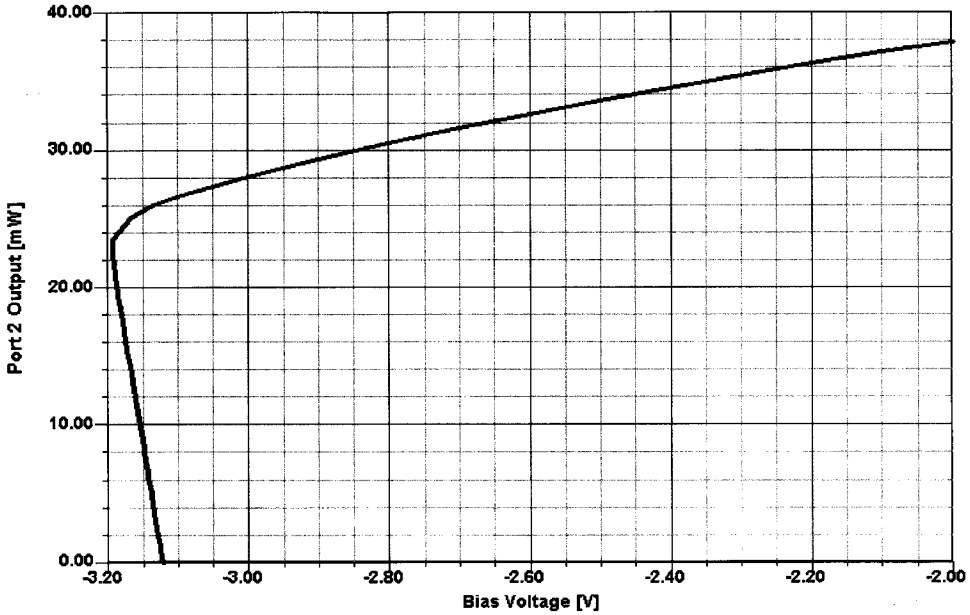

Figure 3-280 Output power versus gate bias for the unstable amplifier.

3-13 POWER AMPLIFIER DATASHEETS AND MANUFACTURER-RECOMMENDED APPLICATIONS

Having discussed the various aspects of BJTs and FETs, we have decided to use MOS examples from Ericsson and Motorola, and a bipolar example from Motorola, as good examples to show the technology required to build high-power transistor amplifiers in this frequency range. In the following pages, we reproduce, with permission, datasheets for Ericsson's PTF 10009 FET and Motorola's MRF186 FET, followed by Motorola's MRF899 BJT.

ERICSSON

PTF 10009
85 Watts, 1.0 GHz
LDMOS Field Effect Transistor

Description

The 10009 is a common source N-channel enhancement-mode lateral MOSFET intended for large signal amplifier applications to 1.0 GHz. It is rated at 85 watts minimum output power. Nitride surface passivation and gold metallization are used to ensure excellent device lifetime and reliability. 100% lot traceability is standard.

- Performance at 960 MHz, 28 Volts
  - Output Power = 85 Watts
  - Power Gain = 13.0 dB Typ
  - Efficiency = 50% Typ
- Gold Metallized
- Silicon Nitride Passivated
- Excellent Thermal Stability

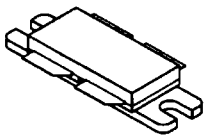
- Characterized with Series Equivalent Large–Signal Parameters from 800 to 960 MHz
- Silicon Nitride Passivated
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 26 Vdc, and Rated Output Power
- Gold Metallized, Emitter Ballasted for Long Life and Resistance to Metal Migration
- Circuit board photomaster available upon request by contacting RF Tactical Marketing in Phoenix, AZ.



CASE 375A–01, STYLE 1

MAXIMUM RATINGS

Rating	Symbol	Value	Unit
Collector–Emitter Voltage	V_{CEO}	28	Vdc
Collector–Emitter Voltage	V_{CES}	60	Vdc
Emitter–Base Voltage	V_{EBO}	4.0	Vdc
Collector–Current — Continuous	I_C	25	Adc
Total Device Dissipation @ T_C = 25°C Derate above 25°C	P_D	230 1.33	Watts W/°C
Storage Temperature Range	T_{stg}	–65 to +150	°C

THERMAL CHARACTERISTICS

Characteristic	Symbol	Max	Unit
Thermal Resistance, Junction to Case	$R_{\theta JC}$	0.75	°C/W

ELECTRICAL CHARACTERISTICS (T_C = 25°C unless otherwise noted.)

Characteristic	Symbol	Min	Typ	Max	Unit
OFF CHARACTERISTICS					
Collector–Emitter Breakdown Voltage (I_C = 100 mAdc, I_B = 0)	$V_{(BR)CEO}$	28	37	—	Vdc
Collector–Emitter Breakdown Voltage (I_C = 50 mAdc, V_{BE} = 0)	$V_{(BR)CES}$	60	85	—	Vdc
Emitter–Base Breakdown Voltage (I_E = 10 mAdc, I_C = 0)	$V_{(BR)EBO}$	4.0	4.9	—	Vdc
Collector Cutoff Current (V_{CE} = 30 Vdc, V_{BE} = 0)	I_{CES}	—	—	10	mAdc
ON CHARACTERISTICS					
DC Current Gain (I_{CE} = 1.0 Adc, V_{CE} = 5.0 Vdc)	h_{FE}	30	75	120	—
DYNAMIC CHARACTERISTICS					
Output Capacitance (V_{CB} = 26 Vdc, I_E = 0, f = 1.0 MHz) (1)	C_{ob}	—	75	—	pF

AMPLIFIER DESIGN WITH BJTs AND FETs

3-1 PROPERTIES OF AMPLIFIERS

3-1-1 Introduction

The goal of this chapter is to move from the details on the semiconductor devices themselves to our first practical application. One of the more interesting features of amplifiers is that they can easily become what will be covered in Chapter 5: *oscillators*. This is due to the high gain of the devices, unaccounted for parasitic elements, and other design flaws. The amplifiers we need will fall into three categories:

- Low-noise amplifiers
- High-gain amplifiers
- Medium- to high-power amplifiers

See Figure 3-1. The low-noise amplifier always operates in Class A, typically at 15–20% of its maximum useful current. The high-gain amplifier can operate in Class A, as well as Class B (mostly push–pull). The higher dc current for the same device results in a higher noise figure and more gain, and ultimately more output power. Class C operating mode is really reserved for either FM transmissions or constant-carrier modes like CW. Some of the modern digital modulation types are sensitive to phase distortion rather than amplitude changes and because of the resulting output spectrum designers have stayed away from Class C operation.

Some of these amplifiers, such as bipolar versions, can be dc-coupled with very few difficulties; others, like those in the FET families, will cause more headaches. An interesting example, although much too high in frequency for the purpose of this book, is shown in Figures 3-2, 3-3, 3-4, and 3-5. It shows a three-stage amplifier that has noise feedback for the first two stages and resistive feedback for the output stage. These are the three types of amplifiers, regardless of technology, we will be evaluating. The achievement of accurate noise analysis of this circuit, reported in Rohde et al. [1], marked the first time a complete

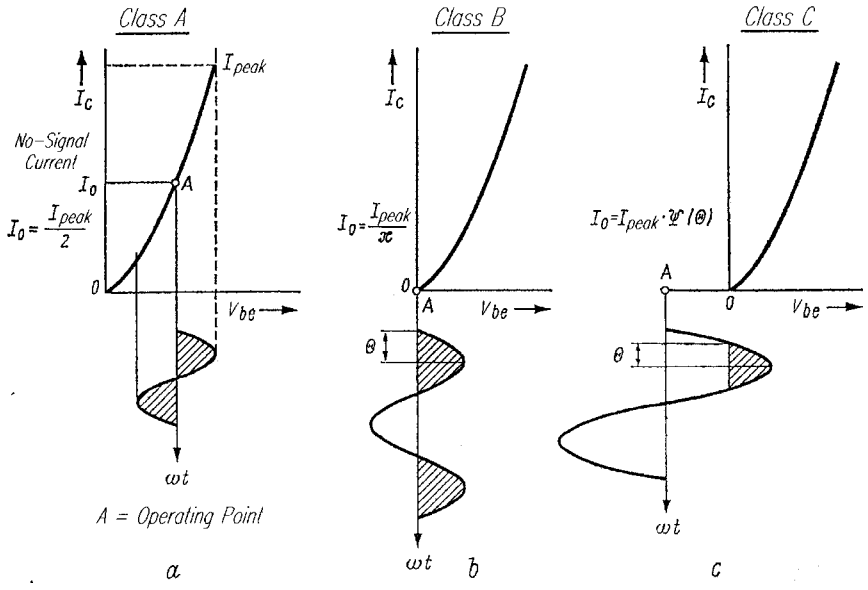

Figure 3-1 Definition of Class A, B, and C operation and resulting bias, including conduction angle (Θ, to be discussed in Section 3-2-2). The transfer characteristic can be either quadratic or exponential. This results in different distortion but does not change the basic operating mode.

linear noise model with essentially no frequency limitation had been developed. Its accuracy depends solely on the accuracy of the element values of the linear equivalent circuit, which can be obtained from measured *S*-parameters by an optimization process. Needless to say, this technique is also applicable at lower frequencies, such as 1.5–3 GHz, and its deviation from measured values has never been worse than 0.2 dB or, relative to the noise figure, 10% expressed in dB.

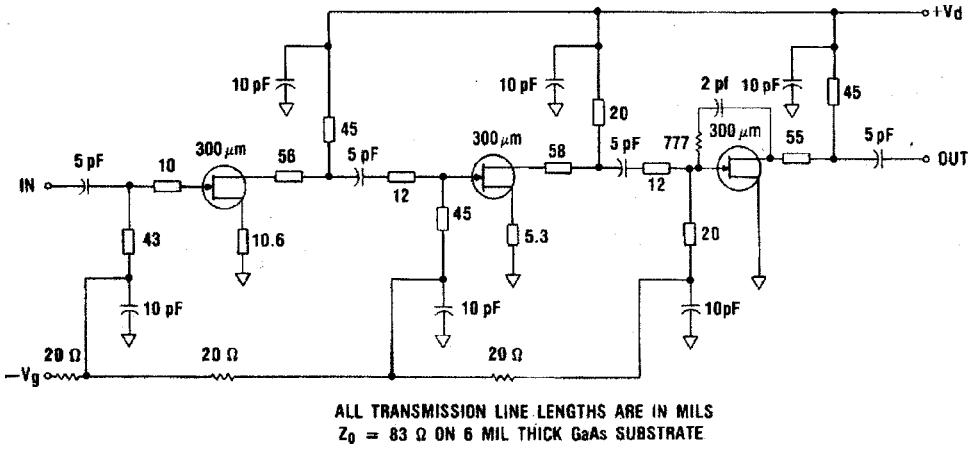

Figure 3-2 Schematic of the X-band GaAs monolithic low-noise amplifier (Texas Instruments EG8021). For reasons of linearity, all three stages operate in Class A.

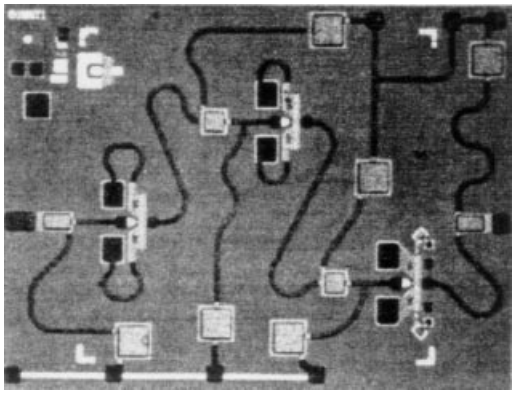

Figure 3-3 Photograph of the EG8021 monolithic amplifier chip. The area pictured is 0.09 inch by 0.12 inch in size.

The results of Figure 3-4 were obtained by using the linear FET model as supplied by Texas Instruments. It becomes somewhat obvious that a match for S_{11} of –60 dB is not likely. We then replaced the linear transistor with the SPICE-type nonlinear model, resulting in the responses shown in Figure 3-5. S_{11} now looks much more realistic in the center of the range, but at the same time exhibits a tendency toward instability at frequencies around 8 GHz. The actual circuit, when measured, did not exhibit this potential instability; on the other hand,

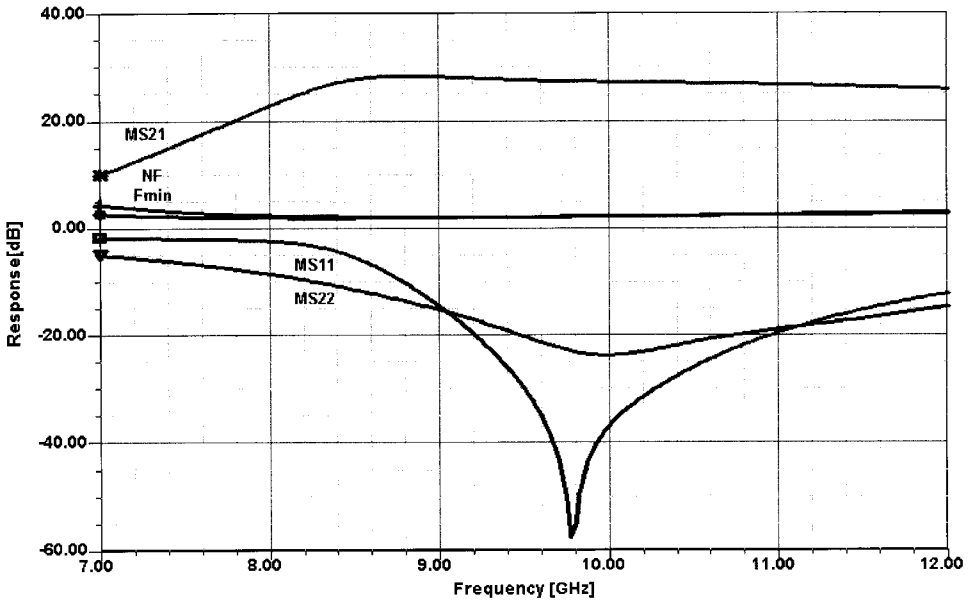

Figure 3-4 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the TI linear FET model. The values at 10 GHz are: F_{min}, 2.20 dB; NF, 2.21 dB; S_{11}, –36.8 dB; S_{21}, 27.2 dB; and S_{22}, –23.7 dB.

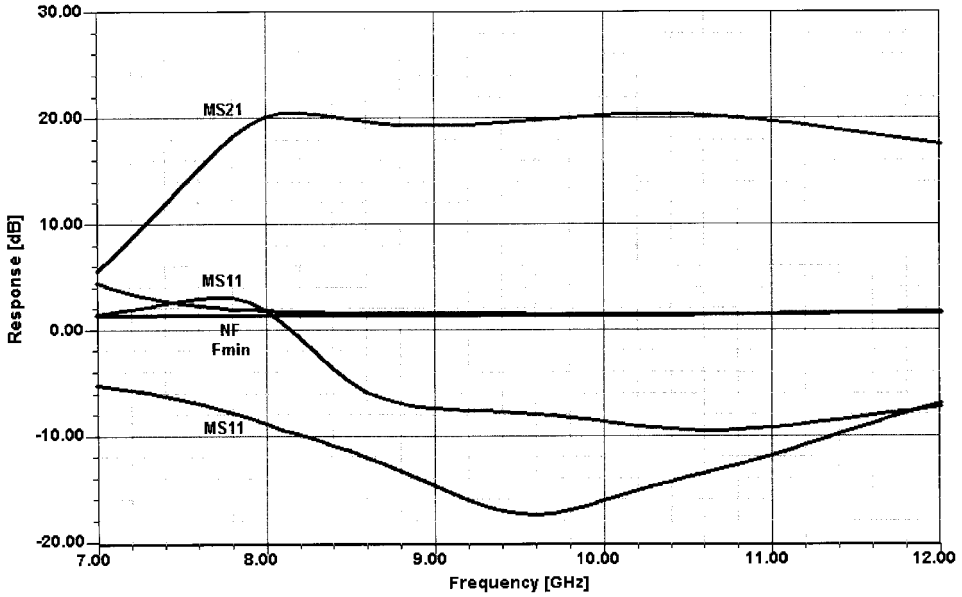

Figure 3-5 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the nonlinear FET model. The values at 10 GHz are: F_{min}, 1.53 dB; NF, 1.65 dB; S_{11}, –8.5 dB; S_{21}, 20.3 dB; and S_{22}, –15.9 dB.

the noise figure and gain agreed quite well. The discrepancies between the results with the linear and nonlinear models emphasize the importance of accurate device modeling.

Figure 3-6 shows a wideband amplifier, specifically a distributed amplifier, that covers 1–20 GHz. Figure 3-7 shows its simulated frequency-dependent gain, matching, and noise performance. The example given here as the upper frequency for wireless systems is rapidly expanding and the technology to accommodate this is already in place. Modern CAD tools can handle such high frequencies accurately, which means one can trust them at the significantly lower wireless frequencies of 500 MHz to 3 GHz. Above 1500 MHz, one really should model using distributed elements. We will come to this later in this chapter.

Input/output and interstage matching will become another challenging task, specifically if one requires sufficient bandwidth. As circuits become more complex and as the operating frequency increases, passive components play an increasingly important role; the use of

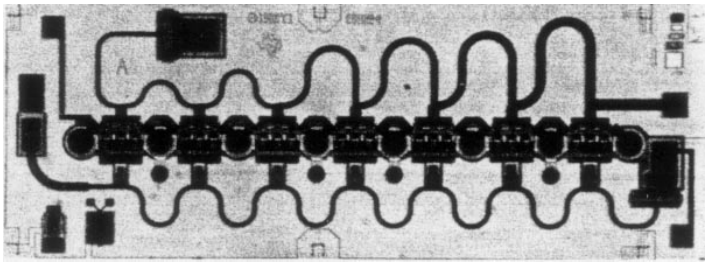

Figure 3-6 Photo of the 1–20-GHz distributed amplifier.

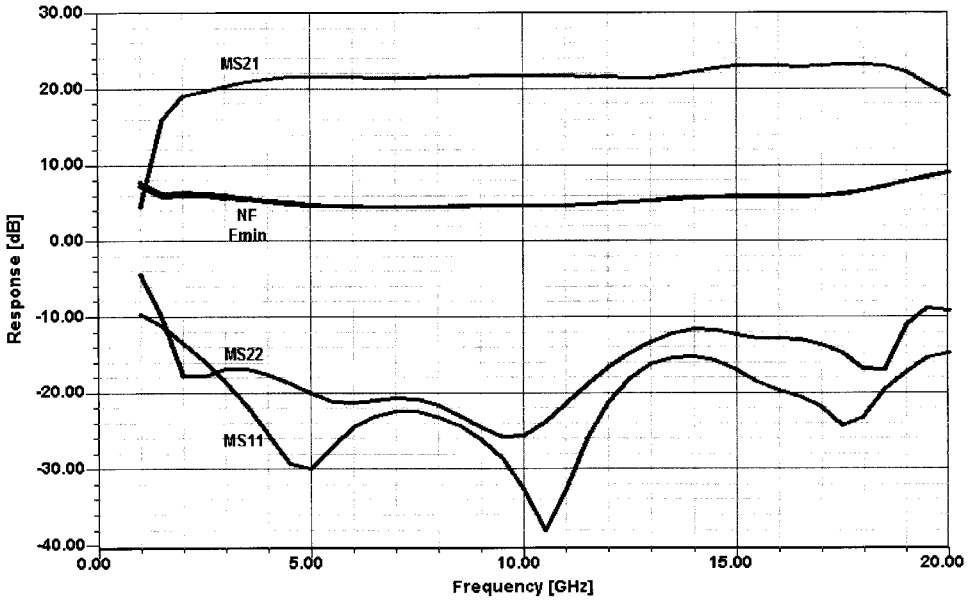

Figure 3-7 Simulated F_{min}, NF, S_{11}, S_{21}, and S_{22} responses. At the center of the range, the following numbers were found: F_{min}, 4.80 dB; NF, 4.80 dB; S_{11}, –32.8 dB; S_{21}, 21.8 dB; and S_{11}, –25.2 dB.

distributed elements is practically a necessity above 1500 MHz. For this reason, we begin this chapter by covering the application of transistors as amplifiers, following this with a discussion of the surrounding external circuitry, such as transmission lines, inductors, capacitors, and resistors. Monolithic ICs on silicon are a totally different ball game, and neither of the authors has sufficient expertise in this area. For this reason, we refer readers who will concentrate on MMIC design to the literature mentioned at the end of this chapter.

The goal of the applications presented here is to address, where possible, high-performance wireless stages that are less subject to constraints of space, power consumption, and cost, than portable/mobile applications. This is consistent with our preface, in which we have clearly stated our goal. The designers of handsets typically cannot consider the full variety of circuits we will present here. These types of stages (low noise, high gain and power) frequently will be used with filtering, and we will give some examples of input filters, including a tracking high-performance design.

A key topic besides the frequently mentioned gain is the whole noise issue. We will give the reader a complete introduction to this important area, followed by a similar introduction to the gain and matching of transistors. *Caution*: The majority of applications published go through the exercise of using *S*-parameters manually to design low-noise and small-signal amplifiers. While we have been tempted to repeat the information found in several textbooks, we feel that today's engineers will have access to CAD tools one way or another. It is highly unlikely that readers will undertake the inefficient process of going through all the design steps manually (a procedure that can take days); hopefully, engineers will resort to a linear/nonlinear CAD tool to do so. Only for the purpose of summarizing the necessary steps will we provide the relevant information regarding gain, stability, and related topics, demonstrating their usefulness or possible misuse with a modern CAD tool—in our case,

the Serenade Design Environment product from Ansoft. At this time, several additional companies beside Ansoft and Hewlett-Packard have emerged, but it is dangerous to list all of them as they come and go.

3-1-2 Gain

In practical terms, when we talk about gain we mean the output power relative to the input power. The industry standard now uses 50 Ω; however, at the point at which we have to match high-impedance devices such as monolithic crystal filters where the impedance jumps, things are not so obvious. The transformation equation that allows us to transform from one impedance to another is

$$m = \sqrt{\frac{R_2}{R_1}} \tag{3-1}$$

This correction factor, m, is required to do the transformation from R_1 (50 Ω) to R_2 (e.g., 1.2 kΩ). It needs to be understood that while the power gain remains the same, the voltage gain requires this correction factor. Since the power gain is expressed as 10 log A, A being the loop gain, 20 log A is the voltage gain, both expressed in dB. The reason for 10 versus 20 is that the power gain is always the voltage squared, which accounts for the 2. As a reminder of these relationships we present the following:

Distinction: Power Ratios–Voltage Ratios

$$n \text{ dB} = 10 \log_{10}(P_2/P_1) \quad \xrightarrow{PP = V^2/Z} \quad n = 10 \log_{10}\left(\frac{V_2^2/Z_2}{V_1^2/Z_1}\right)\text{dB}$$

$$Z_2 = Z_1 \rightarrow n \text{ dB} = 10 \log_{10}(V_2^2/V_1^2) = 10 \log_{10}(V_2/V_1)^2$$

$$\Longrightarrow \boldsymbol{n \text{ dB} = 20 \log_{10}(V_2/V_1) \text{ dB}}$$

The gain is typically defined under the condition of real resistive source and load terminations, which means that all the available power is being supplied to the amplifier, and likewise through proper matching at the output all the available power is fed to the termination. This gain figure is typically measured at a single spot frequency, but since most amplifiers are not totally flat, one needs to specify the gain tolerances or gain flatness. A good number is x dB ± 0.5 dB gain variation. In the case of a narrowband amplifier, the gain typically is shaped like a tuned circuit or like a critically coupled bandpass filter frequency response, while in the case of a real wideband application, the desired gain has some kind of ripple, which is due to the various compensation components in the circuit. An extreme case of a wideband amplifier is a 6–18-GHz single-stage amplifier that uses some very clever matching. This is shown in the following example. Figure 3-8 shows the circuit diagram, and Figure 3-9 shows its frequency-dependent performance.

While this is a cute approach for generating a single-stage amplifier over such a wide bandwidth, in real life it is not acceptable. The reason for this is that neither S_{11} nor S_{22} meets any useful specifications over the entire range. Typically, S_{11}/S_{22} values are only a few dB, while in reality more than 10 dB is required. We have chosen this example to show that gain

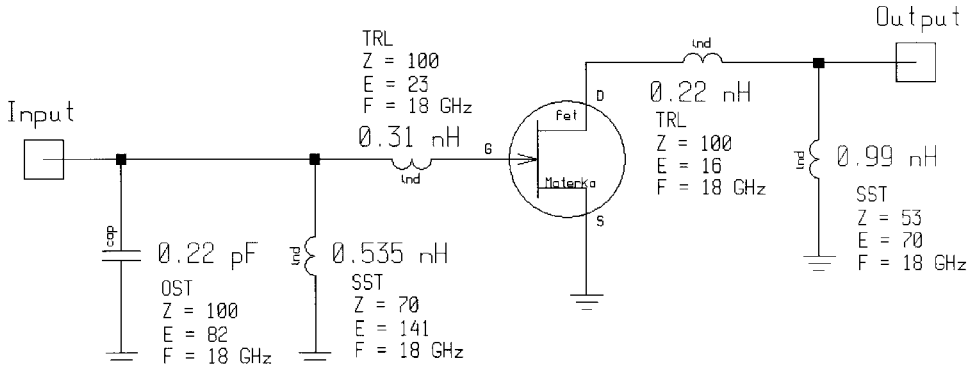

Figure 3-8 A 6–18-GHz FET amplifier.

and matching, depending on the circuit topology, are connected. We get similar results for the noise figure, whereby the best achievable noise figure ($F_{\min}$) and the actual 50-Ω noise figure are only a few dB apart; however, its frequency dependence in a wideband stage is certainly not acceptable.

Another parameter associated with gain is the stability factor K of the circuit. A value of $K > 1$ is mandatory to guarantee stability together with the S_{11} and S_{22} magnitudes being less than 1. Figure 3-10 plots the K stability factor, which for absolute stability must be >1, and maximum stable gain (MSG) as well as $G_{\max}$. It turns out that MSG is a highly artificial

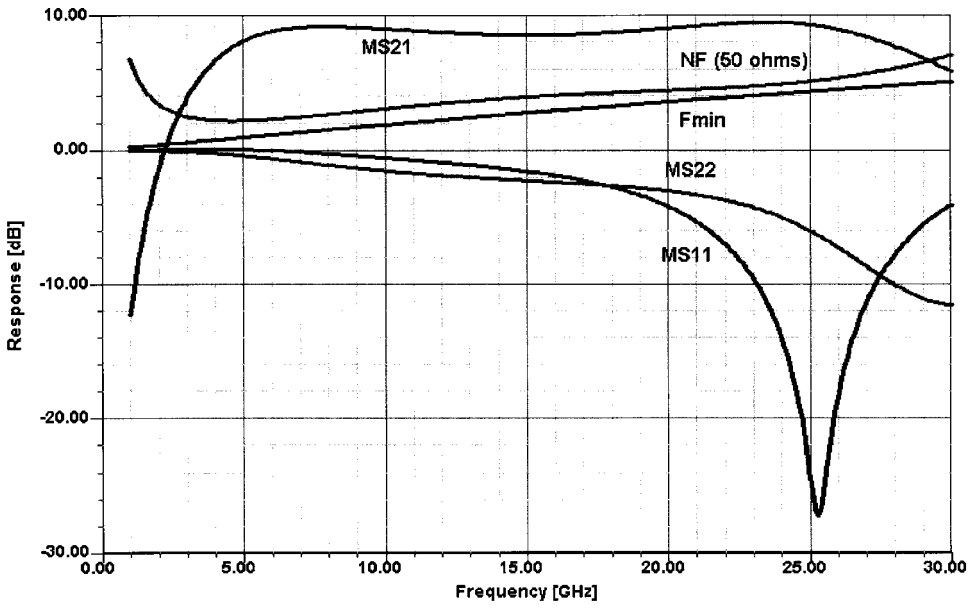

Figure 3-9 Frequency-dependent gain, matching, and noise performance of the amplifier shown in Figure 3-8.

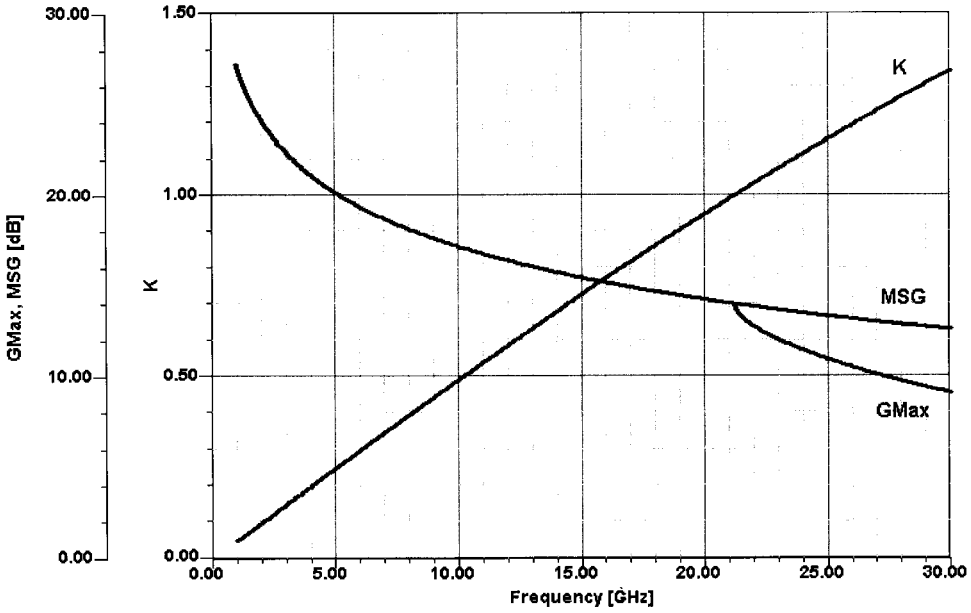

Figure 3-10 G_{max}, maximum stable gain (MSG), and K performance of the amplifier in Figure 3-8.

definition of stability that implies that input and output are terminated with pure resistances and then conjugately matched. There are four ways of achieving this resistive loading, either in the emitter as a shunt resistor between gate/drain or base/collector, or in parallel to the input and output to ground. Needless to say, this is not a real operating mode because it deteriorates both noise and gain. In our case, the entity G_{max} is a function of S_{12} of the circuit, not just the transistor, and depends highly on S_{12}. If we bring the system close to oscillation, then G_{max} will increase at the expense of bandwidth. Unfortunately, some of these microwave definitions of gain (see Table 3-1) have become widely used in industry without always being useful. Evaluating these equations for S_{12} is not legitimate because other quantities like K become infinite, and the entire system of equations falls apart. The power gain with input and output conjugately matched, or the transducer power gain for arbitrary source and load matching, still give more insight into the system.

In the above example, we specifically stated that the input and output VSWR was totally unacceptable, and this was due to a one-stage design. Figure 3-11 shows an amplifier chip built around two transistors with standard feedback techniques applied; Figures 3-12 and 3-13 show its frequency-dependent gain, matching, stability, and noise performance. This amplifier was one of the early examples of GaAsFET wideband amplifiers, but it is interesting because while it has wild (and wide) gain swings, it exhibits a fairly constant input and output impedance or reflection coefficient. A further evaluation of the circuit shows that not only is the circuit unconditionally stable, but that the maximum stable gain has an extremely high value based on essentially minimal S_{12}, the K factor is always significantly higher than 1, and G_{max} follows, to some degree, the actual gain response of the amplifier. (Ultimately, designers gave up on simple *RCL* feedback amplifiers for such a wide bandwidth, replacing them with distributed amplifiers previously called traveling wave amplifiers.) The problem of gain and stability starts at audiofrequency amplifiers, where the

Table 3-1 Nine power gains

Transducer power gain in 50-Ω system	$G_T = \lvert S_{21}\rvert^2$
Transducer power gain for arbitrary Γ_G and Γ_L	$G_T = \dfrac{(1-\lvert\Gamma_G\rvert^2)\,\lvert S_{21}\rvert^2\,(1-\lvert\Gamma_L\rvert^2)}{\lvert(1-S_{11}\Gamma_G)\,(1-S_{22}\Gamma_L)-S_{12}S_{21}\Gamma_G\Gamma_L\rvert^2}$
Unilateral transducer power gain	$G_{\mathrm{TU}} = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)\,(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2\lvert 1-S_{22}\Gamma_L\rvert^2}$
Power gain with input conjugate matched	$G = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{22}\Gamma_L\rvert^2(1-\lvert S'_{11}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{11}\rvert^2}$ (for $\Gamma_L = 0$)
Available power gain with output conjugate matched	$G_A = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2(1-\lvert S'_{22}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{22}\rvert^2}$ (for $\Gamma_G = 0$)
Maximum available power gain[a]	$G_{ma} = \left\lvert\dfrac{S_{21}}{S_{12}}\right\rvert\,(k-\sqrt{k^2-1})$
Maximum unilateral transducer power gain	$G_{\mathrm{TUmax}} = \dfrac{\lvert S_{21}\rvert^2}{(1-\lvert S_{11}\rvert^2)(1-\lvert S_{22}\rvert^2)}$
Maximum stable power gain	$G_{ms} = \dfrac{\lvert S_{21}\rvert}{\lvert S_{12}\rvert}$
Unilateral power gain	$U = \dfrac{1/2\lvert S_{21}/S_{12}-1\rvert^2}{k\lvert S_{21}/S_{12}\rvert-\mathrm{Re}(S_{21}/S_{12})}$

[a]Definition for $G_{\max}$: If $k > 1$, it is called G_{ma}, and if $k < 1$, it is called G_{ms}.

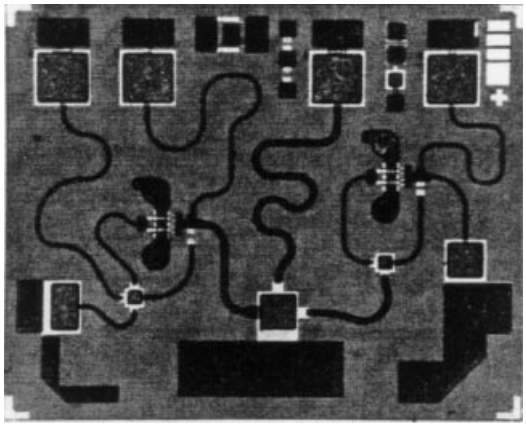

Figure 3-11 A two-stage, wideband feedback amplifier.

motorboating phenomenon has been known for years, and the problem moves up in frequency with more modern technology and is largely dependent not only on the device and the circuit, but also on the layout. The motorboating effect has to do with ground loops and the fact that if the printed circuit traces from the power supply connection to the output power stage present too high a resistance, then at high currents the voltage will drop to a point below useful operation and then, as the volume is lowered, become stable again. In this case the amplitude of the signal through the amplifier controls the stability of the output stage. Needless to say, this most unpleasant effect applies to high-power stages for all output transistors, where we use Class B or C operation, meaning that the dc operating current as a function of output does not remain constant.

In terms of gain, there is also an important gain characteristic called *differential gain* and *differential phase*. These expressions were first used in television circuits, where linearity in both areas is an absolute must. The amplitude of the signal determines the black and white contrast, and the phase determines the color. As an example, transmitting an image of one of our presidents playing golf in California to the New York area is done by many microwave hops. Any multipath reception, such as that caused by reflection from airplanes, may have little effect on the signal amplitude, but the resulting phase shift can transform a green lawn to a red lawn if a total shift of 180° occurs. Given a particular operating point, if the 1-dB compression point of multiple amplifiers in the chain is approached or exceeded, their differential gain, which is defined by the IEEE as "the difference between (a) the ratio of the output of a small high-frequency sine-wave signal at two different levels of a low-frequency signal on which it is superimposed, and (b) unity," may increase. This mode of saturation charges all the capacitances of the amplifier transistors, causing huge phase shifts that result in the known problem of changing colors. The same applies, of course, in test equipment amplifiers, in which such changes cannot be tolerated. A somewhat similar, but not quite the same, problem is spectral regrowth [evaluated in terms of adjacent-channel power ratio (ACPR)], which is also due to nonlinearities. The question of linearity has already been covered in detail in Chapter 1. Needless to say, any overdrive condition also changes an amplifier's input and output SWR.

3-1-3 Noise Figure (NF)*

Introduction. In this section we look at the best way to describe noise in active devices (black boxes). Even when a two-port is linear, the output waveform will differ from the input, because of the failure to transmit all spectral components with equal gain (or attenuation) and delay. By careful design of the two-port, or by limitation of the bandwidth of the input waveform, such distortions can largely be avoided. However, noise generated within the two-port can still change the waveform of the output signal. In a linear passive two-port, noise arises only from the losses in the two-port; thermodynamic considerations indicate that such losses result in the random changes that we call noise. When the two-port contains active devices, such as transistors, there are other noise mechanisms present. A very important consideration in a system is the amount of noise that it adds to the transmitted signal. This is often judged by the ratio of the output signal power to the output noise power

*Section 3-1-3 is reprinted from Chapter 2 of George D. Vendelin, Anthony M. Pavio, and Ulrich L. Rohde, *Microwave Circuit Design Using Linear and Nonlinear Techniques*, copyright 1990 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

(S/N). The ratio of signal plus noise power to noise power [$(S + N)/N$] is generally easier to measure and approaches S/N when the signal is large.

In the evaluation of a two-port it is important to know the amount of noise added to a signal passing through it. An important parameter for expressing this characteristic is the noise factor. The signal energy coming from a generator or antenna is amplified or attenuated in passing from the input to the output of a two-port, as is the noise that accompanies the input signal energy. A system generally includes a cascade of two-port networks that constitute one overall two-port that amplifies the signal to a high-enough power level for its intended use. The *noise factor* of a system is defined as the ratio of signal-to-noise ratios available at input and output:

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}} \geq 1 \tag{3-2}$$

The noise figure (or factor) of a receiver is an easily measured quantity that describes the signal-to-noise ratio reduction of that receiver.

When this ratio of powers is converted to decibels, it is generally referred to as the *noise figure* rather than noise factor. Various conventions are used to distinguish the symbols used for noise factor and noise figure. Here we use F to represent the noise factor and NF to represent the noise figure, although the terms are usually used interchangeably.

For an amplifier with the power gain G, the noise factor can be rearranged as

$$F = \frac{S_i/N_i}{GS_i/G(N_i + N_a)} \tag{3-3}$$

when N_a is the additional noise power added by the amplifier referred to the input. This can be computed to be

$$F = 1 + N_a/N_i \tag{3-4}$$

The noise factor is often replaced by the noise figure (NF), which is defined in decibels as

$$\text{NF} = 10 \log_{10} F \tag{3-5}$$

In applications like satellite receivers, the noise factor becomes such a small number that it is inconvenient to work with. Many people have adopted the use of an equivalent noise temperature for a circuit to remedy this situation. Since the thermal noise power available from a resistor at temperature T_e is

$$N = kT_eB \tag{3-6}$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), T_e is the effective temperature in kelvins, and B is the bandwidth in hertz. The equation above may be used to associate an effective noise temperature with circuits containing more than just thermal noise sources. This allows Eq. (3-4) to be written as

$$F = 1 + \frac{kT_eB}{kT_0B} = 1 + \frac{T_e}{T_0} \tag{3-7}$$

where T_e is the effective noise temperature of the circuit and T_0 is the temperature of the generator resistor in kelvins. The noise temperature T_e now characterizes our circuit noise contribution and can directly be related to the noise factor.

Assuming a reference noise temperature of 290 K (–273 + 290 = 17 °C), let us determine the noise temperature of the system with a noise factor of 2.6 (4.15 dB):

$$T_e = (2.6 - 1)\ (290) = 464 \text{ K}$$

This temperature T_e should not be confused with the environmental operating temperature T_0. It is quite common to operate low-noise amplifiers with T_e below 100 K at an ambient temperature of 290 K.

Signal-to-Noise Ratio. Let us consider the signal-to-noise ratio of power delivered from a generator to a load as shown in Figure 3-14. The signal power delivered to the input is given by

$$S_{\text{in}} = P_{\text{in}} = \frac{E_g^2 \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-8}$$

where E_g is the rms voltage of the input signal supplied to the system, and the noise power supplied to the input is expressed by

$$N_{\text{in}} = \frac{\overline{v_n^2} \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-9}$$

where the noise power at the input is provided by the noise energy of the real part of Z_g. The input impedance Z of the system in the form $Z = R_{\text{in}} + jX_{\text{in}}$ is assumed to be complex.

The Johnson noise of a resistor [here $\text{Re}(Z_g)$], given by the mean-square voltage

$$\overline{v_n^2} = 4kTRB \tag{3-10}$$

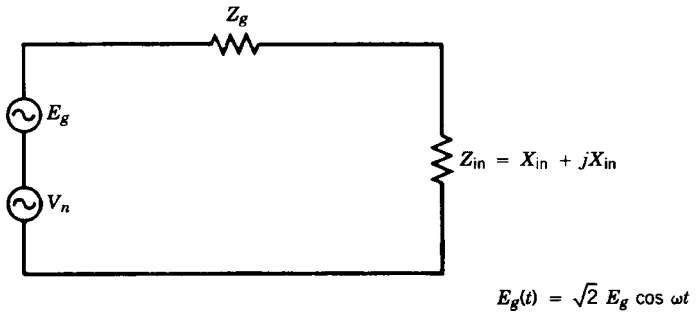

Figure 3-14 Combination of signal and noise voltages supplied to a complex termination.

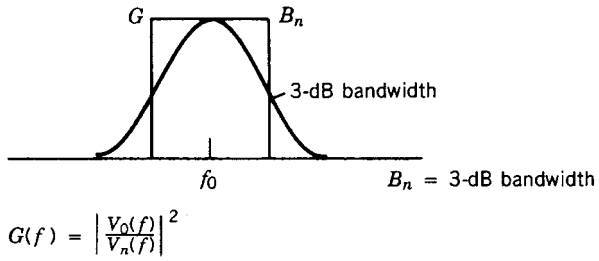
where k (Boltzmann's constant) = 1.38×10^{-23} J/K, T is the absolute temperature of the resistor, and B is the bandwidth, is sufficiently small that the resistive component of impedance does not change. The available signal power from the generator has a lower limit, even if the signal is attenuated by the highest possible attenuation. The generator resistor acts as a Johnson noise generator, its power being

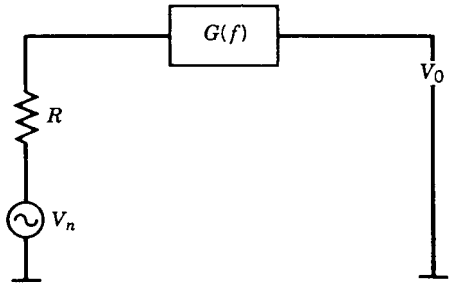
$$P_A = \frac{4kTRB}{4R} = kTB \tag{3-11}$$

where k is Boltzmann's constant, T is the absolute temperature, and B is the bandwidth. This power is the maximum available output power.

For an ambient temperature of 290 K, $kT = 4 \times 10^{-21}$ W/Hz. This expression is also given as kT = –204 dBW/Hz = –174 dBm/Hz = –114 dBm/MHz. We can combine Eqs. (3-8) to (3-10) to obtain

$$\left(\frac{S}{N}\right)_{\text{in}} = \frac{E_g^2}{4kT\text{Re}(Z_g)B} \tag{3-12}$$





$$V_0^2 = \int_0^\infty 4kT_0RG(f)\,dF$$
$$= 4kT_0R \int_0^\infty G(f)\,dF$$
$$B_n = \frac{1}{G} \int_0^\infty G(f)\,dF$$
B_n = noise bandwidth

Figure 3-15 Graphical and mathematical explanations of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

This is the value of *S/N* contributed by the generator, which does not include the noise generated by the load, in this case $\mathrm{Re}(Z_{\mathrm{in}})$, which would need to be included in the measurement of the total *S/N* across the input impedance.

A critical parameter is the noise bandwidth, B_n, which is defined as the equivalent bandwidth, as shown in Figure 3-15. For reasons of group delay correction, most practical filters have round rather than sharp corners. The noise figure measurements shown later can be used to determine the "integrated" bandwidth, which is B_n.

An active system such as a combination of amplifiers and mixers will add noise to the input signals, and the noise factor that describes this is defined as the *S/N* ratio at the input to the *S/N* ratio at the output, which is always greater than unity [2]. In practice, a certain minimum signal-to-noise ratio is required for operation. For example, in a communication system such a minimum is required for intelligible transmission, either voice or data. For high-performance TV reception, to provide a noise-free picture to the eye, a typical requirement is for a 60-dB *S/N*. In the case of a TV system, a large dynamic range is required, as well as a very large bandwidth to reproduce all colors truthfully and all shades from high-intensity white to black. Good systems will have a bandwidth of 8 MHz or more.

Noise Figure Measurements. Some of the noise equations are based on mathematical models and physics. To understand some of these expressions, it is useful to look at a practical system, with amplifiers, that has to be evaluated.

Let us look at Figure 3-16, which consists of a signal generator, the system or device under test (DUT), and a selective receiver with a built-in root-mean-square (rms) voltmeter to determine the signal and noise voltages. It is necessary that the system have enough gain so that the noise voltage supplied by the generator will be indicated [3].

If we assume that our selective receiver is a video noise meter calibrated in rms voltage levels, we can perform two measurements. With an input termination connected to the TV system (typically, 75 Ω for cable TV, 50 Ω for satellite TV), the noise receiver/meter will read a value for proper termination that can easily be calculated. Since one-half of the mean-square noise voltage appears across the input,

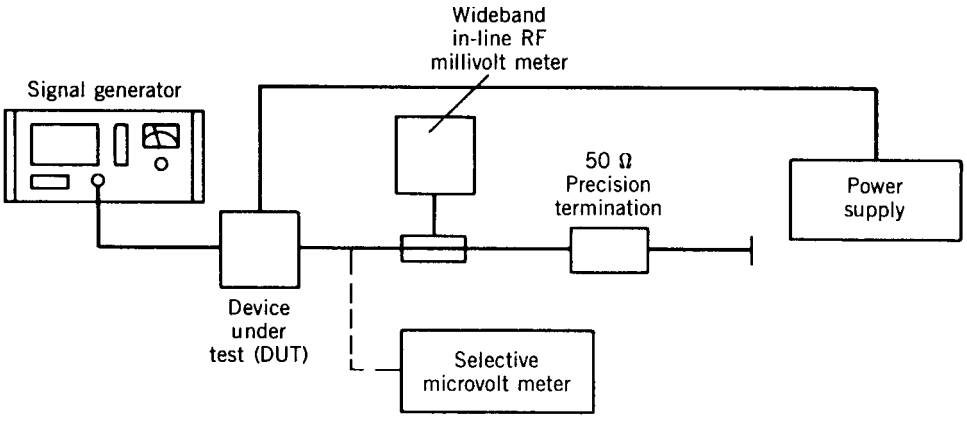


Figure 3-16 Test setup to measure signal-to-noise ratio.

$$v_{\text{in}} = \frac{v_n}{2} = \frac{\sqrt{4kTRB}}{2} \tag{3-13}$$

With $B = 10$ MHz, $T = 290$ K (T is always expressed in absolute temperature; $T_0 = -273$ °C), and $k = 1.38 \times 10^{-23}$ J/K, then for $R = 75\ \Omega$,

$$v_{\text{in}} = \frac{v_n}{2} = 1.73\ \mu\text{V} \tag{3-14}$$

where the rms noise voltage has been referred to the input port. We can verify this with our first measurement.

Now we increase the input voltage of the signal generator to a value that indicates a 60-dB *S/N* ratio at the output port. This should be about

$$E_g = \frac{v_n}{2}\sqrt{F} \times 1000 = 1.73\sqrt{F} \quad \text{mV}$$

where F is the noise factor of the receiver. For a receiver noise factor of 10, we would obtain $E_g = 5.48$ mV (rms value). If the noise energy equivalent to a noise factor of F is assumed, we need $\sqrt{F}$ times more voltage. For a 60-dB ratio, this means that $E_g = 1000 \times (v_n/2) \times \sqrt{F}$.

As they are done here, over a power range of 60 dB, the measurements can be performed over such a wide range only if special equipment is available. In cases where the internal detector of a piece of communication equipment is used, the signal-to-noise ratio measurements are performed over much smaller power ranges.

Let us assume that for the above-mentioned case ($F = 10$) we find a *S/N* ratio of 10 dB at the output for an input signal of 5.47 μV. By rewriting Eq. (3-7) as

$$E_g = \frac{v_n}{2}\sqrt{F} = \sqrt{KTRBF} \tag{3-15}$$

with F being the noise factor, we can solve for F with

$$F = \frac{P_s}{P_n} = \frac{E_g^2/R}{kTB} \tag{3-16}$$

While the input power from the thermal energy of the input termination resistor was $kTB = 4 \times 10^{-4}$ W, the input power required for the 10-dB *S/N* ratio was

$$P_s = \frac{(5.47 \times 10^{-6})^2}{75} = 3.98 \times 10^{-13}\ \text{W} \tag{3-17}$$

The noise factor is defined as the ratio P_s/P_n:

$$F = \frac{3.98 \times 10^{-13}}{4 \times 10^{-14}} = 10 \tag{3-18}$$

which is the proof.

This method is used more frequently at the 3-dB point, or double the input power if the dynamic range of the detector is small or only a linear indicator is available. Because of hum and other pickup, this is not an easy measurement. Using a signal generator is very expensive because in a laboratory or production environment a wide frequency range requires several generators.

Another method is the use of a wideband noise generator. Modern gas discharge diodes or avalanche diodes are available that provide essentially white noise energy over a large frequency range. These microwave diodes typically have an output of 30 dB above kT when switched on and kT when switched off. To provide good matching at microwave frequencies, a 15-dB attenuator is cascaded. This means that the noise power of the source in the ON condition is about 15 dB above kT.

In the early 1960s, low-cost noise figure test equipment was built around vacuum diodes whose operating range was limited to 1200 MHz due to the resonance effects of the structure. Today, automatic noise gain analyzers use calibrated solid-state noise sources up to 26.5 GHz. It appears that the upper frequency limit has to do with matching, and the lower-frequency limit with $1/f$ noise.

Noisy Two-Port Description. Based on the convention by Rothe and Dalke [4], any linear two-port can be in the form shown in Figure 3-17. This general case of a noisy two-port can be redrawn showing noise sources at the input and at the output. Figure 3-17b shows this in admittance form and Figure 3-17c in impedance form. The internal noise sources are assumed to produce very small currents and voltages, and we assume that linear two-port equations are valid. The internal noise contributions have been expressed by using external noise sources:

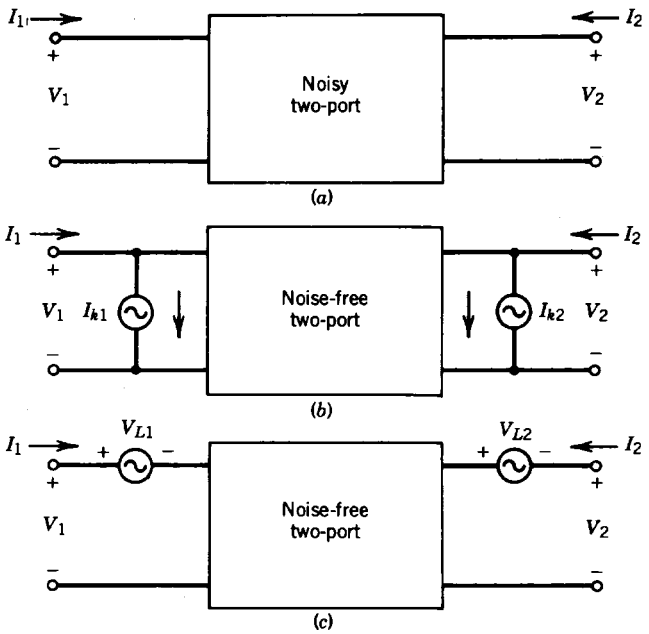

Figure 3-17 Noisy linear two-ports: (a) general form, (b) admittance form, and (c) impedance form.

$$I_1 = y_{11}V_1 + y_{12}V_2 + I_{K1}$$
$$I_2 = y_{21}V_1 + y_{22}V_2 + I_{K2} \tag{3-19}$$

$$V_1 = z_{11}I_1 + z_{12}I_2 + V_{L1}$$
$$V_2 = z_{21}I_1 + z_{22}I_2 + V_{L2} \tag{3-20}$$

where the external noise sources are I_{K1}, I_{K2}, V_{L1}, and V_{L2}.

Since we want to describe our noisy circuit in terms of the noise figure, the *ABCD*-matrix description will be more convenient since it refers both noise sources to the input of the two-port [5]. This representation is given below (note the change in direction of I_2):

$$V_1 = AV_2 + BI_2 + V_A$$
$$I_1 = CV_2 + DI_2 + I_A \tag{3-21}$$

where V_A and I_A are the external noise sources.

It is important to remember that all of these matrix representations are interrelated. For example, the noise sources for the *ABCD*-matrix description can be obtained from the *z*-matrix representation shown in Eq. (3-20). This transformation is

$$V_A = -\frac{I_{K2}}{y_{21}} = V_{L1} - \frac{V_{L2}z_{11}}{z_{21}} \tag{3-22}$$

$$I_A = I_{K1} - \frac{I_{K2}y_{11}}{y_{21}} = -\frac{V_{L2}}{z_{21}} \tag{3-23}$$

The *ABCD* representation is particularly useful because it allows us to define a noise temperature for the two-port referenced to the input. The two-port itself (shown in Figure 3-18) is assumed to be noise-free.

In the past, *z* and *y* parameters have been used, but in microwave applications it has become common to use *S*-parameter definitions. This is shown in Figure 3-19. The previous equations can be rewritten in their new form using *S*-parameters:

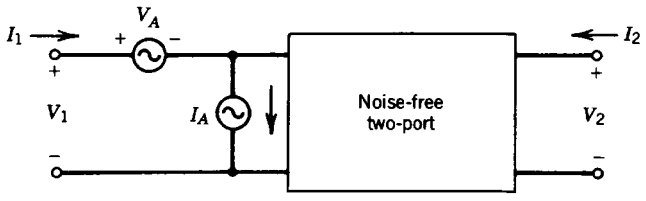

Figure 3-18 Chain-matrix form of linear noisy two-ports.

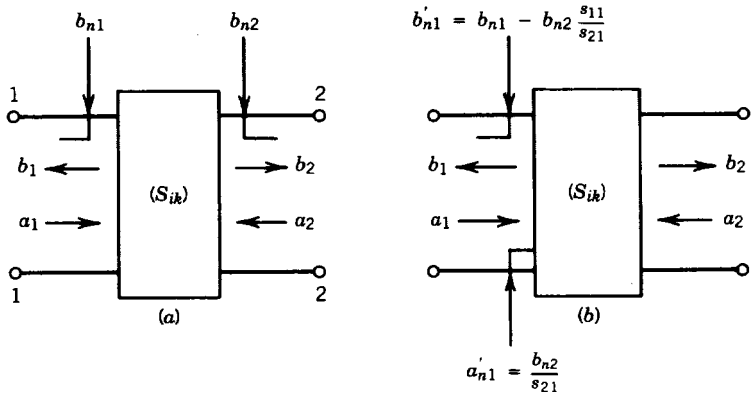

Figure 3-19 *S*-parameter form of linear noisy two-ports.

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \begin{bmatrix} b_{n1} \\ b_{n2} \end{bmatrix} \tag{3-24}$$

There are different physical origins for the various sources of noise. Typically, thermal noise is generated by resistances and loss in the circuit or transistor, whereas shot noise is generated by current flowing through semiconductor junctions and vacuum tubes. Since these many sources of noise are represented by only two noise sources at the device input, the two equivalent noise sources are often a complicated combination of the circuit internal noise sources. Often, some fraction of V_A and I_A is related to the same noise source. This means that V_A and I_A are not independent in general. Before we can use V_A and I_A to calculate the noise figure of the two-port, we must calculate the correlation between the V_A and I_A shown in Figure 3-18.

The noise source V_A represents all the device noise referred to the input when the generator impedance is zero; that is, when the input is short-circuited. The noise source I_A represents all the device noise referred to the input when the generator admittance is zero; that is, the input is open-circuited.

The correlation of these two noise sources considerably complicates analysis. By defining a correlation admittance, we can simplify the mathematics and get some physical intuition for the relationship between noise figure and generator admittance. Since some fraction of I_A will be correlated with V_A, we split I_A into correlated and uncorrelated parts as follows:

$$I_A = I_n + I_u \tag{3-25}$$

I_u is the part of I_A uncorrelated with V_A. Since I_n is correlated with V_A, we can say that I_n is proportional to V_A and the constant of proportionality is the correlation admittance:

$$I_n = Y_{\text{cor}} V_A \tag{3-26}$$

This leads us to

$$I_A = Y_{\text{cor}} V_A + I_u \tag{3-27}$$

The following derivation of noise figure will use the correlation admittance. Y_{cor} is not a physical component located somewhere in the circuit. Y_{cor} is a complex number derived by correlating the random variables I_A and V_A. To calculate Y_{cor}, we multiply each side of Eq. (3-27) by V_A^* and average the result. This gives

$$\overline{V_A^* I_A} = Y_{\text{cor}} \overline{V_A^2} \tag{3-28}$$

where the I_u term averaged to zero since it was uncorrelated with V_A. The correlation admittance is thus given by

$$Y_{\text{cor}} = \frac{\overline{V_A^* I_A}}{V_A^2} \tag{3-29}$$

Often, people use the term "correlation coefficient." This normalized quantity is defined as

$$c = \frac{\overline{V_A^* I_A}}{\sqrt{\overline{V_A^2} I_A^2}} = Y_{\text{cor}} \sqrt{\frac{\overline{V_A^2}}{I_A^2}} \tag{3-30}$$

Note that the dual of this admittance description is the impedance description. Thus, the impedance representation has the same equations as above with Y replaced by Z, I replaced by V, and V replaced by I.

V_A and I_A represent internal noise sources in the form of a voltage source acting in series with the input voltage and a source of current flowing in parallel with the input current. This representation conveniently leads to the four noise parameters needed to describe the noise performance of the two-port. Again using the Nyquist formula, the open-circuit voltage of a resistor at the temperature T is

$$\overline{V_A^2} = 4kTRB \tag{3-31}$$

This voltage is a mean-square fluctuation (or spectral density). It is the method used to calculate the noise identity. We could also define a noise equivalent resistance for a noise voltage as

$$R_n = \frac{\overline{V_A^2}}{4kTB} \tag{3-32}$$

The resistor R_n is not a physical resistor but can be used to simulate different portions of the noise equivalent circuit.

In a similar manner a mean-square current fluctuation can be represented in terms of an equivalent noise conductance G_n, which is defined by

$$G_n = \frac{\overline{I_A^2}}{4kTB} \tag{3-33}$$

and

$$G_u = \frac{\overline{I_u^2}}{4kTB} \tag{3-34}$$

for the case of the uncorrelated noise component. The input generator to the two-port has a similar contribution:

$$G_G = \frac{I_G^2}{4kTB} \tag{3-35}$$

with Y_G being the generator admittance and G_G being the real part. With the definition of F above, we can write

$$F = 1 + \left| \frac{I_A + Y_G V_A}{I_G} \right|^2 \tag{3-36}$$

The use of the voltage V_A and the current I_A has allowed us to combine all the effects of the internal noise sources.

We can use the previously defined [Eq. (3-29)] correlation admittance, $Y_{\text{cor}} = G_{\text{cor}} + jB_{\text{cor}}$, to simplify Eq. (3-36). First, we determine the total noise current:

$$\overline{I_A^2} = 4kT(|Y_{\text{cor}}|^2 R_n + G_u)B \tag{3-37}$$

where R_n and G_u are defined in Eqs. (3-32) and (3-34). The noise factor can now be determined:

$$F = 1 + \frac{G_u}{G_g} + \frac{R_n}{G_g}[(G_G + G_{\text{cor}})^2 + (B_G + B_{\text{cor}})^2] \tag{3-38}$$

$$F = 1 + \frac{R_u}{R_g} + \frac{G_n}{R_g}[(R_G + R_{\text{cor}})^2 + (X_G + X_{\text{cor}})^2] \tag{3-39}$$

The noise factor is a function of various elements, and the optimum impedance for the best noise figure can be determined by minimizing F with respect to generator reactance and resistance. This gives

$$R_{0n} = \sqrt{\frac{R_u}{G_n} + R_{\text{cor}}^2} \tag{3-40}$$

$$X_{0n} = -X_{\text{cor}} \tag{3-41}$$

and

$$F_{\min} = 1 + 2G_n R_{\text{cor}} + 2\sqrt{R_u G_n + (G_n R_{\text{cor}})^2} \tag{3-42}$$

(To distinguish between optimum noise and optimum power, we have introduced the convention 0*n* instead of the more familiar abbreviation *opt*.) At this point we see that the optimum condition for minimum noise figure is not a conjugate power match at the input port. We can explain this by recognizing that the noise source V_A and I_A represent all the

two-port noise, not just the thermal noise of the input port. We should observe that the optimum generator susceptance, $-X_{corr}$, will minimize the noise contribution of the two noise generators.

In rearranging for conversion to S parameters, we write

$$F = F_{\min} + \frac{g_n}{R_G}|Z_G - Z_{0n}|^2 \tag{3-43}$$

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-44}$$

From the definition of the reflection coefficient,

$$\Gamma_G = \frac{Y_0 - Y_G}{Y_0 + Y_G} \tag{3-45}$$

and with

$$g_G = \frac{G_G}{Y_0} \tag{3-46}$$

$$r_n = \frac{R_n}{Z_0} \tag{3-47}$$

the normalized equivalent noise resistance,

$$F = F_{\min} + \frac{4r_n|\Gamma_G - \Gamma_{0n}|^2}{g_G(1 - |\Gamma|^2)|1 + \Gamma_{0n}|^2} \tag{3-48}$$

$$r_n = (F_{50} - F_{\min})\frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-49}$$

$$\Gamma_{0n} = \frac{Z_{0n} - Z_0}{Z_{0n} + Z_0} \tag{3-50}$$

The noise performance of any linear two-port can now be determined if the values of the four noise parameters, $F_{\min}$, r_n (= $R_n/50$), and Γ_{0n} (magnitude and phase), are known.

Figure 3-20 shows the noise factor of a high-frequency transistor as a function of B_g for G_g = constant and as a function of G_g for $B_g = B_{opt}$.

Noise Figure of Cascaded Networks. In a system with many circuits connected in cascade (Figure 3-21), we must consider the contributions of the various circuits. In considering the equivalent noise resistor R_n in series with the input circuit,

$$F = \frac{R_G + R_n}{R_G} \tag{3-51}$$

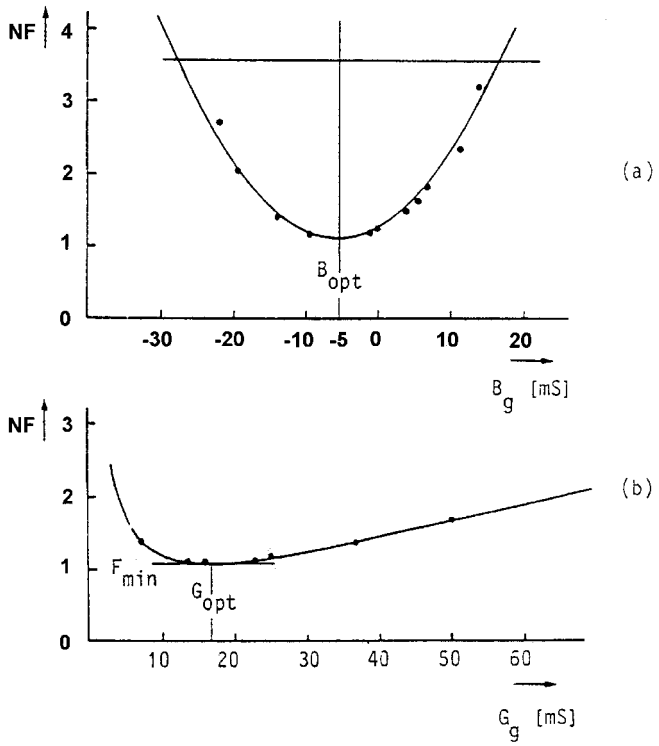

Figure 3-20 Noise factor in high-frequency BJTs for $f = 600$ MHz: (a) as a function of B_g for G_g = constant and (b) as a function of G_g for $B_g = B_{opt}$.

$$F = 1 + \frac{R_n}{R_G} \tag{3-52}$$

The excess noise added by the circuit is R_n/R_G.

In considering two cascaded circuits a and b, by definition the available noise at the output of b is

$$N_{ab} = F_{ab} G_{ab} kTB \tag{3-53}$$

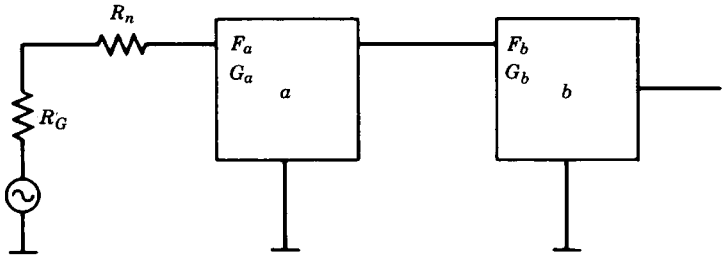

Figure 3-21 Cascaded noisy two-ports with the noise factors F_a and F_b and the gain figures G_a and G_b.

with B the equivalent noise bandwidth in which the noise is measured. The total available gain G is the product of the individual available gains, so

$$N_{ab} = F_{ab} G_a G_b kTB \tag{3-54}$$

The available noise from network a at the output of network b is

$$N_{a/b} = N_a G_b = F_a G_a G_b kTB \tag{3-55}$$

The available noise added by network b (its excess noise) is

$$N_{b/b} = (F_b - 1) G_b kTB \tag{3-56}$$

The total available noise N_{ab} is the sum of the available noise contributed by the two networks:

$$\begin{aligned} N_{ab} &= N_{a/b} + N_{b/b} = F_a G_a G_b kTB + (F_b - 1) G_b kTB \\ &= \left(F_a + \frac{F_b - 1}{G_a} \right) G_a G_b kTB \end{aligned} \tag{3-57}$$

$$F_{ab} = F_a + \frac{F_b - 1}{G_a} \tag{3-58}$$

For any number of circuits, this can be extended to

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \frac{F_4 - 1}{G_1 G_2 G_3} + \cdots \tag{3-59}$$

When considering a long chain of cascaded amplifiers, there will be a minimum noise figure achievable for this chain. This is a figure of merit and was proposed by Haus and Adler [6]. It is calculated by rearranging Eq. (3-59):

$$(F_{\text{tot}})_{\min} = (F_{\min} - 1) + \frac{F_{\min} - 1}{G_A} + \frac{F_{\min} - 1}{G_A^2} + \cdots + 1 \tag{3-60}$$

where $F_{\min}$ is the minimum noise figure for each stage and G_A is the available power gain of the identical stages. Using

$$\frac{1}{1 - X} = 1 + X + X^2 + \cdots \tag{3-61}$$

we find a quantity $(F_{\text{tot}} - 1)$, which is defined as the noise measure M. The minimum noise measure

$$(F_{\text{tot}})_{\min} - 1 = \frac{F_{\min} - 1}{1 - 1/G_A} = M_{\min} \tag{3-62}$$

refers to the noise of an infinite chain of optimally tuned, low-noise stages, so it represents a lower limit on the noise of an amplifier.

The minimum noise measure $M_{\min}$ is an invariant parameter and is not affected by feedback. It is somewhat similar to a gain–bandwidth product, in its use as a system invariant. The minimum noise measure is achieved when the amplifier is tuned for the available power gain and $\Gamma_G = \Gamma_{0n}$, given by Eq. (3-50).

Influence of External Parasitic Elements. Mounting an active two-port such as a transistor usually adds stray capacitance and lead inductance to the device, as shown in Figure 3-22. These external components consisting of transmission lines and parasitic reactances modify the noise parameters and the gain. Some researchers have published the results of these parasitic effects and have made manual computations or used some limited computer programs.

In a paper by Fukui [7], an attempt was made to determine the necessary equations, but the formulas are too involved even for pocket calculators. A more generic study by Iversen [8] is also very involved because of the various matrix manipulations and is more suitable for a computer. Besser's paper [9] in the *IEEE MTT-S* in 1975 and Vendelin's paper [10] in the same issue have shown for the first time some practical results using computers and even optimization methods, using an early version of COMPACT. The intention of these investigations was to find feedback that modifies the device noise and scattering parameters such that a noise match could also provide a low-input VSWR. It can be seen from these discussions that some feedback, besides resulting in some gain reduction, may improve the noise matching at the input for a limited frequency range.

A more recent paper by Suter [11] based on a report by Hartmann and Strutt [12] has given a simple transformation starting from the *S*-parameters and the noise parameters from common-source (or common-emitter) measurements. The noise parameters for the "packaged" device are calculated. This means that the parameters for the "new" device, including

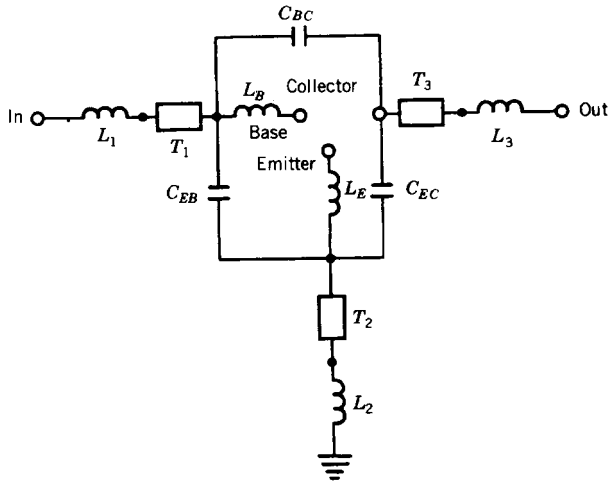

Figure 3-22 Equivalent circuit of the transistor package.

where

$$V = (1 + S_{11})(1 + S_{22}) - S_{12}S_{21}$$

$$C_3 = (1 - S_{11})(1 + S_{22}) + S_{12}S_{21}$$

$$C_4 = (1 + S_{11})(1 - S_{22}) + S_{12}S_{21}$$

$$[S]_{\text{DEVICE}} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} = \text{common-source } S \text{ parameters}$$

the common-gate (or common-base) case, are calculated. The equations are device dependent. They are valid for any active two-port.

A transformation matrix, n, may be used to combine the noise sources of the various circuit configurations. The transformation matrix parameters are given in Table 3-2 for series feedback, shunt feedback, and the common-gate (base) case, which will be important for oscillator analysis. The transformation matrix gives the new noise parameters as follows:

$$R'_n = R_n|n_{11} + n_{12}Y_{\text{cor}}|^2 + G_n|n_{12}|^2 \tag{3-63}$$

$$G'_n = \frac{G_nR_n}{R'_n}|n_{11}n_{22} - n_{12}n_{21}|^2 \tag{3-64}$$

$$Y'_{\text{cor}} = \frac{R_n}{R'_n}(n_{21} + n_{22}Y_{\text{cor}})(n^*_{11} + n^*_{12}Y^*_{\text{cor}}) + \frac{G_n}{R'_n}n_{22}n^*_{12} \tag{3-65}$$

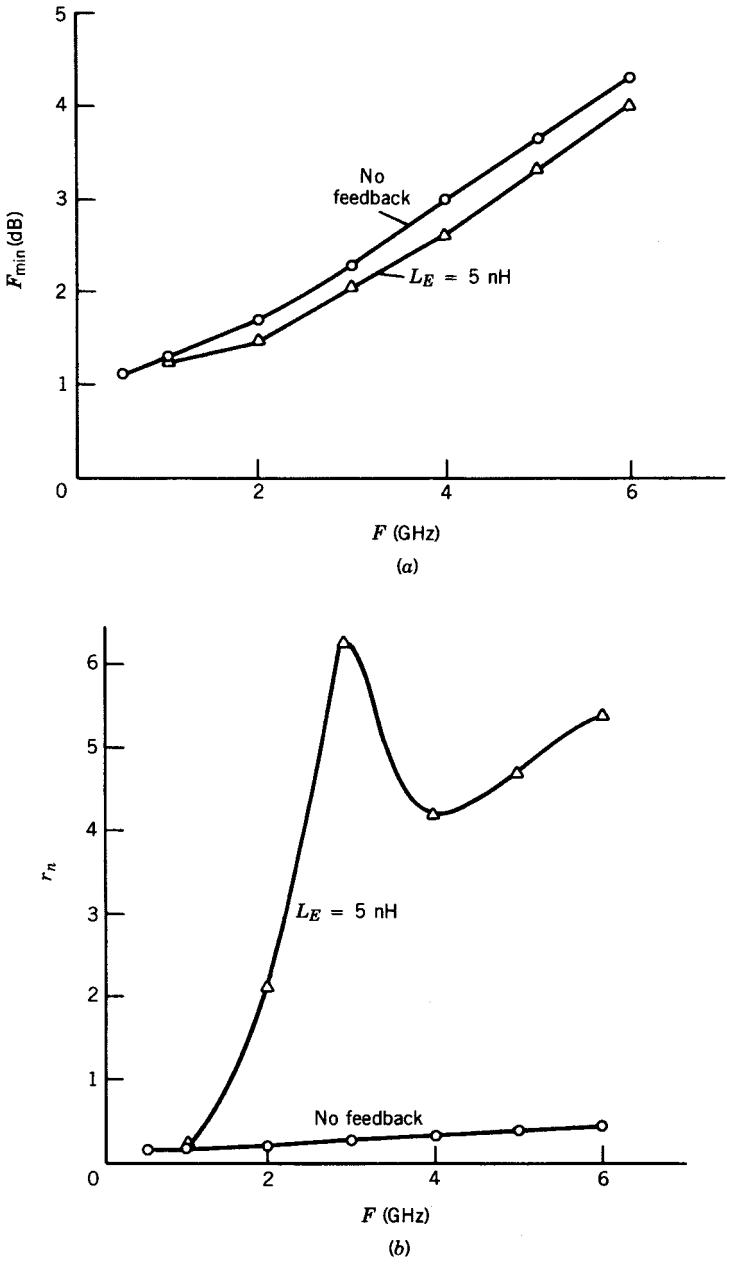

Figure 3-23 Noise parameters versus feedback for the AT-41435 silicon bipolar transistor: (a) F_{min} versus frequency and feedback; (b) r_n versus frequency and feedback; (c) Γ_{0n} versus frequency and feedback.

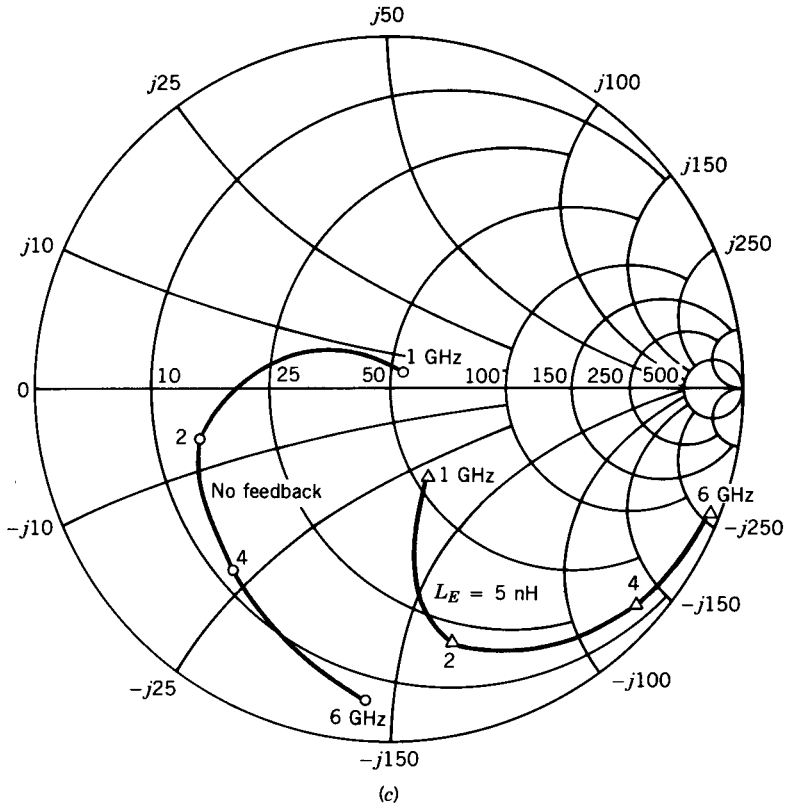

Figure 3-23 (*Continued*)

A final transformation to the more common noise-parameter format given by Eq. (3-44) is still needed [10]:

$$F_{\min} = 1 + 2R_n'(G_{\text{cor}}' + G_{0n}') \tag{3-66}$$

$$R_n = R_n' \tag{3-67}$$

$$G_{0n} = \sqrt{\frac{G_n'}{R_n'} + G_{\text{cor}}'^2} \tag{3-68}$$

$$B_{0n} = -B_{\text{cor}}' \tag{3-69}$$

Figure 3-23 shows the noise figure as a function of external feedback for a low-noise microwave bipolar transistor, the AT-41435.

Bias-Dependent Noise Parameters. Since we have elaborated on the effect of parasitics, it is now useful to point out that noise is also a strong function of bias point and frequency. Figure 3-24 shows the noise figure expressed in dB as a function of different dc currents and frequencies for a BFP420 BJT by Siemens. A change in the collector voltage will also affect the noise parameters, not quite as strongly as shown here, but still significantly. The reason

for the turning point of the noise figure has to do with the fact that for lower currents the f_T cutoff frequency has not reached its peak yet, and therefore the noise increases. The increase of the noise at higher currents is due to the Schottky noise calculated from the equation

$$P_n = 2Iq \tag{3-70}$$

where P_n is the noise power, I is the saturation, collector, or drain current, and q is the charge of an electron (1.60×10^{-19} coulomb).

Table 3-3 shows the common-emitter noise parameters for the BFP420.

Noise Circles. From the section entitled "Influence of External Parasitic Elements," we see that the noise factor is a strong function of the generator admittance (or impedance) presented to the input terminals of the noisy two-port. Noise tuning is used to change the values of the input admittance to obtain the best noise performance. There is a range of values of input reflection coefficient over which the noise figure is constant. In plotting these points of constant noise figure, we obtain the so-called noise circles, which can be drawn on the Smith chart Γ_G plane [13]. Starting with the noise equation [see Eq. (3-44)] for a 50-Ω generator impedance, we find that

$$F_{50} = F_{\min} + 4r_n \frac{|\Gamma_{0n}|^2}{|1 + \Gamma_{0n}|^2} \tag{3-71}$$

We want to find the position of the reflection coefficient on the Smith chart, as in the case of the gain circles, for which F is constant. First we rearrange Eq. (3-67) to read

$$r_n = (F_{50} - F_{\min}) \frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-72}$$

By introducing

$$N_i = \frac{F_i - F_{\min}}{4r_n} |1 + \Gamma_{0n}|^2 \tag{3-73}$$

we can find an expression for a circle of constant noise figure as introduced by Rothe and Dahlke [4] (see also Fukui [13]). The center for the noise circle is

$$C_i = \frac{|\Gamma_{0n}|}{1 + N_i} \tag{3-74}$$

and the radius is

$$r_i = \frac{\sqrt{N_i^2 + N_i(1 - |\Gamma_{0n}|^2)}}{1 + N_i} \tag{3-75}$$

with the definition of N used previously. However, if we consider only the minimum noise figure for a given device, we will not obtain the minimum noise figure for the multistage amplifier system. This was explained when the noise measure was introduced. (See Figure 3-25.) Therefore, a better way to design the amplifier would be to use circles at constant noise measure instead of circles of constant noise figure. This was recently done by Poole

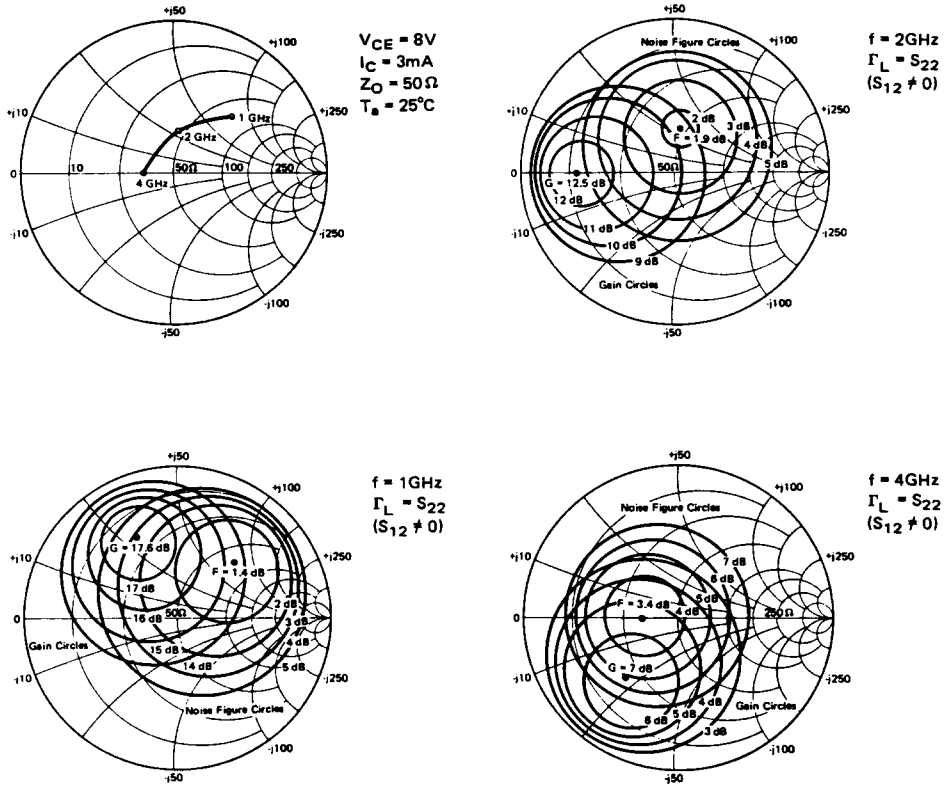

Figure 3-25 Typical noise figure circles and gain circles.

and Paul [14]. They derived the expressions for the noise measure circles as a function of S parameters, noise parameters, and Γ_G, using

$$G_A = \frac{|S_{21}|^2(1 - |\Gamma_G|^2)}{(1 - |S_{22}|^2) + |\Gamma_G|^2 (|S_{11}|^2 - |\Delta|^2) - 2\,\mathrm{Re}(\Gamma_G C_1)} \tag{3-76}$$

where

$$C_1 = S_{11} - S_{22}^* \Delta$$

$$\Delta = S_{11}S_{22} - S_{12}S_{11}$$

In terms of the generator reflection coefficient, the noise measure can be expressed as

$$M = [(F_{\min} - 1)(1 - |\Gamma_G|^2)|S_{21}|^2|1 + \Gamma_{0n}|^2 + 4r_n|S_{21}|^2|\Gamma_G - \Gamma_{0n}|^2]$$

$$\times \left\{|1 + \Gamma_{0n}|^2[|S_{21}|^2(1 - |\Gamma_G|^2) - (1 - |S_{22}|^2) - |\Gamma_G|^2(|S_{11}|^2 - |\Delta|^2) + 2\,\mathrm{Re}(\Gamma_G C_1)]\right\}^{-1} \tag{3-77}$$

Equation (3-77) can be shown to represent circles in the source reflection coefficient plane described by the following:

$$|\Gamma_G|^2 + |\Gamma_m|^2 - \Gamma_G\Gamma_m^* - \Gamma_G^*\Gamma_m = r_m^2 \tag{3-78}$$

The centers and radii of the constant-noise-measure circles are given by

$$C_m = \frac{M|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-79}$$

$$r_m = \frac{\sqrt{M^2M_a + MM_b + M_c}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-80}$$

where

$$P = |S_{21}|^2 + |S_{11}|^2 - |\Delta|^2$$

$$Q = |S_{21}|^2 + |S_{22}|^2 - 1$$

$$W = |1 + \Gamma_{0n}|^2(F_{\min} - 1)$$

$$M_a = |1 + \Gamma_{0n}|^4(PQ + |C_1|^2)$$

$$M_b = |1 + \Gamma_{0n}|^2|S_{21}|^2[8r_n\,\mathrm{Re}(\Gamma_{0n}C_1)$$

$$- (4r_n|\Gamma_{0n}|^2 + W)P - (W - 4r_n)Q]$$

$$M_c = |S_{21}|^4[W - 4r_n(1 - |\Gamma_{0n}|^2)]$$

The value of the minimum noise measure can be found by considering the noise measure circle of zero radius; that is, set r_m equal to zero in Eq. (3-80). This results in

$$M_{\min} = \frac{-M_b \pm \sqrt{M_b^2 - 4M_a M_c}}{2M_a} \tag{3-81}$$

Equation (3-81) yields the same value of $M_{\min}$ as would have been obtained by using the immittance parameter equation given by Fukui [13] and can, therefore, be considered as the reflection coefficient plane analog of Fukui's expression. The elimination of the need for the parameter R_{eg}, however, results in a considerable simplification as compared with the earlier approach [13].

The value of the minimum noise measure is taken as the smallest nonnegative value of $M_{\min}$ given by Eq. (3-81). The source reflection coefficient that results in the minimum noise measure can now be obtained by employing Eq. (3-79):

$$\Gamma_{0m} = \frac{M_{\min}|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M_{\min}|1 + \Gamma_{0n}|^2 P + |S_{21}|^2\,(4r_n - W)} \tag{3-82}$$

The output reflection coefficient of the device, when Γ_{0m} is presented to the input port, is given by

$$S'_{22} = \frac{S_{22} - \Delta\Gamma_{0m}}{1 - S_{11}\Gamma_{0m}} \tag{3-83}$$

Noise Correlation in Linear Two-Ports Using Correlation Matrices. In the introduction to two-port noise theory, it was indicated that noise correlation matrices form a general technique for calculating noise in n-port networks. Haus and Adler [6] have described the theory behind this technique. In 1976, Hillbrand and Russer [15] published equations and transformations that aid in supplying this method to two-port CAD.

This method is useful because it forms a base from which we can rigorously calculate the noise of linear two-ports combined in arbitrary ways. For many representations, the method of combining the noise parameters is as simple as that for combining the circuit element matrices. In addition, noise correlation matrices can be used to calculate the noise in linear frequency conversion circuits. The following is an introduction to this subject.

A linear, noisy two-port can be modeled as a noise-free two-port with two additional noise sources. These noise sources must be chosen so that they add directly to the resulting vector of the representation, as shown in Eqs. (3-84) and (3-85) and Figure 3-17:

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-84}$$

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \tag{3-85}$$

where the i and v vectors indicate noise sources for the y and z representations, respectively. This two-port example can be extended to n-ports in a straightforward, obvious way.

Since the noise vector for any representation is a random variable, it is much more convenient to work with the noise correlation matrix. The correlation matrix gives us deterministic numbers with which to calculate. The correlation matrix is formed by taking the mean value of the outer product of the noise vector. This is equivalent to multiplying the noise vector by its adjoint (complex conjugate transpose) and averaging the result:

$$\langle \bar{i}\ \bar{i}^{+} \rangle = \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] = \begin{bmatrix} \langle i_1 i_1^* \rangle & \langle i_1 i_2^* \rangle \\ \langle i_1^* i_2 \rangle & \langle i_2 i_2^* \rangle \end{bmatrix} + [C_y] \tag{3-86}$$

where the angular brackets denote the average value.

Note that the diagonal terms are the "power" spectrum of each noise source and the off-diagonal terms are complex conjugates of each other and represent the "cross-power" spectra of the noise sources. "Power" is used because these magnitude-squared quantities are proportional to power.

To use these correlation matrices in circuit analysis, we must know how to combine them and how to convert them between various representations. An example using y matrices will illustrate the method for combining two-ports and their correlation matrices. Given two matrices y and y', when we parallel them we have the same port voltages, and the terminal currents add (Figure 3-26):

$$\begin{aligned} I_1 &= y_{11}V_1 + y_{12}V_2 + y'_{11}V_1 + y'_{12}V_2 + i_1 + i'_1 \\ I_2 &= y_{21}V_1 + y_{22}V_2 + y'_{21}V_1 + y'_{22}V_2 + i_2 + i'_2 \end{aligned} \tag{3-87}$$

or

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} + y'_{11} & y_{12} + y'_{12} \\ y_{21} + y'_{21} & y_{22} + y'_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 + i'_1 \\ i_2 + i'_2 \end{bmatrix} \tag{3-88}$$

Here we can see that the noise current vectors add just as the y parameters add. Converting the new noise vector to a correlation matrix yields

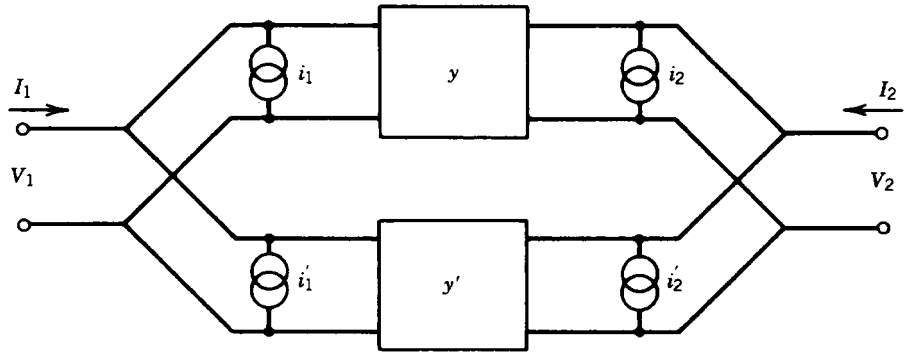

Figure 3-26 Parallel combination of two-ports using y parameters.

$$\langle \bar{i}_{\text{new}} \bar{i}^{+}_{\text{new}} \rangle = \left\langle \begin{bmatrix} i_1 + i_1' \\ i_2 + i_2' \end{bmatrix} [i_1^* + i_1'^* \quad i_2 i_2'^*] \right\rangle \tag{3-89}$$

$$= \begin{bmatrix} \langle i_1 i_1^* \rangle + \langle i_1' i_1'^* \rangle & \langle i_1 i_2^* \rangle + \langle i_1' i_2'^* \rangle \\ \langle i_2 i_1^* \rangle + \langle i_2' i_1'^* \rangle & \langle i_2 i_2^* \rangle + \langle i_2' i_2'^* \rangle \end{bmatrix} \tag{3-90}$$

The noise sources from different two-ports must be uncorrelated, so there are no cross products of different two-ports. By inspection, Eq. (3-90) is just the addition of the correlation matrices for the individual two-ports, so

$$[C_{y\text{new}}] = [C_y] + [C_y'] \tag{3-91}$$

The same holds true for g, h, and z parameters, but $ABCD$ parameters have the more complicated form shown below. If

$$[A_{\text{new}}] = [A][A'] \tag{3-92}$$

then

$$[C_{A\text{new}}] = \{C_A] + [A]\,[C_{A'}]\,[A]^{+} \tag{3-93}$$

The transformation of one representation to another is best illustrated by an example. Let us transform the correlation matrix for a Y representation to a Z representation. Starting with

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = [Y] \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-94}$$

we can move the noise vector to the left side and invert y:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 - i_1 \\ I_2 - i_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Y^{-1}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-95}$$

Table 3-4 π Noise matrix $T_{\alpha\beta}$ transformation

		Original Form (α Form)					
		Y		Z		A	
Resulting Form (β Form)	Y	1	0	y_{11}	y_{12}	$-y_{11}$	1
		0	1	y_{21}	y_{22}	$-y_{21}$	0
	Z	z_{11}	z_{12}	1	0	1	$-z_{11}$
		z_{21}	z_{22}	0	1	0	$-z_{21}$
	A	0	A_{12}	1	$-A_{11}$	1	0
		1	A_{22}	0	$-A_{21}$	0	1

Since $(Y)^{-1} = (Z)$, we have

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Z] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-96}$$

so

$$= [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} = [T_{yz}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-97}$$

where the signs of i_1 and i_2 are superfluous since they will cancel when the correlation matrix is formed. Here the transformation of the Y noise current vector to the Z noise voltage vector is done simply by multiplying by (Z). Other transformations are shown in Table 3-4.

To obtain the noise correlation matrix, we again form the mean of the outer product:

$$\langle vv^+ \rangle = \begin{bmatrix} \langle v_1 v_1^* \rangle & \langle v_1 v_2^* \rangle \\ \rangle v_1^* v_2 \rangle & \langle v_2 v_2^* \rangle \end{bmatrix} = [Z] \left\langle \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] \right\rangle [Z]^+ \tag{3-98}$$

or

$$[C_z] = [Z]\,[C_y]\,[Z]^+ \tag{3-99}$$

where

$$v^+ = [i_1^* \quad i_2^*]\,[Z]^+ \tag{3-100}$$

This is called a congruence transformation. The key to all of these derivations is the construction of a correlation matrix from the noise vector, as shown in Eq. (3-90).

These correlation matrices may easily be derived from the circuit matrices of passive circuits with only thermal noise sources. For example,

$$[C_z] = 2kT\Delta f\,\mathrm{Re}([Z]) \tag{3-101}$$

and

$$[C_y] = 2kT\Delta f\,\mathrm{Re}([Y]) \tag{3-102}$$

The $2kT$ factor comes from the double-sided spectrum of thermal noise. The correlation matrix from the $ABCD$ matrix may be related to the noise figure, as shown by Hillbrand and Russer [15]. We have

$$F = 1 + \frac{\overline{Y}[C_a]\overline{Y}^+}{2kT\,\mathrm{Re}(Y_G)} \tag{3-103}$$

where

$$\overline{Y} = \begin{bmatrix} Y_G \\ 1 \end{bmatrix}$$

Expressing the noise factor in terms of the correlation matrix, we obtain a complete formula:

$$F = 1 + \frac{C_{22}^{A}(f) + 2\,\mathrm{Re}\{Y_g(f)\,C_{12}^{A}(f)\} + |Y_g(f)|^2\,C_{11}^{A}(f)}{2kT_0\,\mathrm{Re}\{Y_g(f)\}} \tag{3-104}$$

Once we transform this in the Y parameter form, we obtain the following equation:

$$F(f) = F_{\min}(f) + \frac{R_n(f)|Y_{\mathrm{opt}}(f) - Y_g(f)|^2}{\mathrm{Re}\{Y_g(f)\}} \tag{3-105}$$

It should be noted that all these values are frequency dependent, as expressed in this equation.

The *ABCD* correlation matrix can be written in terms of the noise figure parameters as (double-sided spectrum)

$$[C_a] = 2kT\begin{bmatrix} R_n & \dfrac{F_0 - 1}{2} - R_n Y_{0n}^{*} \\ \dfrac{F_0 - 1}{2} - R_n Y_{0n} & R_n|Y_{0n}|^2 \end{bmatrix} \tag{3-106}$$

The noise correlation matrix method forms an easy and rigorous technique for handling noise in networks. This technique allows us to calculate the total noise for complicated networks by combining the noise matrices of subcircuits. It should be remembered that although noise correlation matrices apply to n-port networks, noise figure calculations apply only to pairs of ports. The parameters of the C_a matrix can be used to give the noise parameters:

$$Y_{0n} = \sqrt{\frac{C_{ii*}}{C_{uu*}} - \left[\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right)\right]^2} + j\,\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right) \tag{3-107}$$

$$F_0 = 1 + \frac{C_{ui*} + C_{uu*}Y_{0n}^{*}}{kT} \tag{3-108}$$

$$R_u = C_{uu*} \tag{3-109}$$

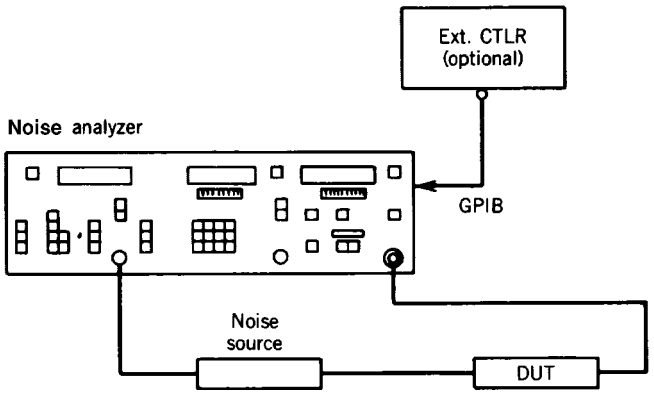

Figure 3-27 Noise figure measurement.

Noise Figure Test Equipment. Figure 3-27 shows the block diagram of a noise test setup. It includes the noise source and the other components. The metering unit has a special detector that is linear and over a certain dynamic range measures linear power. The tunable receiver covers a wide frequency range (e.g., 10–1800 MHz) and controls the noise source. The receiver is a double-conversion superheterodyne configuration with sufficient image rejection to avoid double-sideband noise measurements that would give the wrong results.

These receivers are microprocessor controlled and the measurement is a two-step procedure. The first is a calibration step that measures the noise figure of the receiver system and a reference power level. Then the device under test (DUT) is inserted and the system noise figure and total output power are measured. The noise factor is calculated by

$$F_1 = F_{\text{system}} - \frac{F_2 - 1}{G_1} \tag{3-110}$$

and the gain is given by the change in output power from the reference level [16]. The noise of the system is calculated by measuring the total noise power with the noise source on and off. With the excess noise ratio (ENR) known [16],

$$F_{\text{system}} = \frac{\text{ENR}}{Y - 1} \tag{3-111}$$

The noise bandwidth is usually set by the bandwidth of the receiver, which is assumed to be constant over the linear range. The ENR of the noise source is given by

$$\text{ENR} = \frac{T_{\text{hot}}}{T_{\text{cold}}} - 1 \tag{3-112}$$

where T_{cold} is usually room temperature (290 K). This ENR number is about 15 dB for noise sources with a 15-dB pad and 5 dB for noise sources with a 25-dB pad. Since both gain and noise were stored in the initial calibration, a noise/gain sweep can be performed.

For frequencies above 1800 MHz, we can extend the range with the help of the external signal generators, as shown in Figure 3-28. As shown, a filter ahead of the external mixer reduces the noise energy in the image band. If the DUT has a very broad frequency range

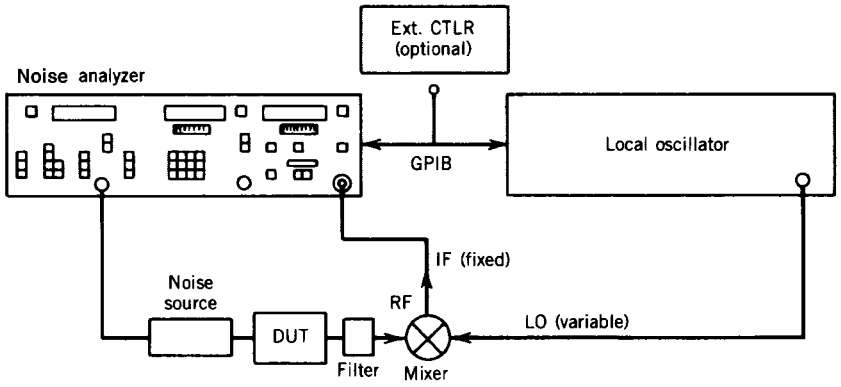

Figure 3-28 Single-sideband (SSB) noise figure measurements using an external mixer.

and has flat gain and noise over that range, a double-sideband (DSB) measurement is possible, with the image-rejection filter removed. However, a single-sideband (SSB) measurement is always more accurate [17].

How To Determine the Noise Parameters. The noise figure of a linear two-port network as a function of source admittance may be represented by

$$F = F_{\min} + \frac{R_n}{G_G}\left[(G_{0n} - G_G)^2 + (B_{0n} - B_G)^2\right] \tag{3-113}$$

where $G_G + jB_G$ = generator admittance presented to the input of the two-port
$G_{0n} + jB_{0n}$ = generator admittance at which optimum noise figure occurs
R_n = empirical constant relating sensitivity of the noise figure to generator admittance, with dimensions of resistance

It may be noted that for an arbitrary noise figure measurement with a known generator admittance, Eq. (3-113) has four unknowns—$F_{\min}$, R_n, G_{0n}, and B_{0n}. By choosing four known values of generator admittance, a set of four linear equations is formed and solutions of the four unknowns can be found [18, 19]. Eq. (3-113) may be transformed to

$$F = F_{\min} + \frac{R_n|Y_{0n}|^2}{G_G} - 2R_nG_{0n} + \frac{R_n|Y_G|^2}{G_G} - 2R_nB_{0n}\frac{B_G}{G_G} \tag{3-114}$$

or

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-115}$$

Let

$$X_1 = F_{\min} - 2R_nG_{0n}$$

$$X_2 = R_n|Y_{0n}|^2$$

$$X_3 = R_n$$

$$X_4 = R_nB_{0n}$$

Then the generalized equation may be written

$$F_i = X_1 + \frac{1}{G_{si}}X_2 + \frac{|Y_{si}|^2}{G_{si}}X_3 - 2\frac{G_{si}}{B_{si}}X_4 \tag{3-116}$$

or, in matrix form,

$$[F] = [A]\,[X] \tag{3-117}$$

and the solution becomes

$$[X] = [A]^{-1}\,[F] \tag{3-118}$$

These parameters completely characterize the noise behavior of the linear two-port network. Direct measurement of these noise parameters by this method would be possible only if the receiver on the output of the two-port were noiseless and insensitive to its input admittance. In actual practice, the receiver itself behaves as a noisy two-port network and can be characterized in the same manner. What is actually being measured is the system noise figure of the two-port and the receiver. Thus, it becomes apparent that to do a complete two-port noise characterization, the gain of the two-port must be measured [20]. In addition, any losses in the input-matching networks must be carefully accounted for, because they add directly to the measured noise figure reading [21].

3-1-4 Linearity

Consistent with the elaborate discussion of linearity questions above, here is a quick refresher on what must be considered in amplifiers.

Dynamic Range, Compression, and IMD. An amplifier's dynamic range is related to the minimum discernible signal and the 1-dB compression point according to the equation

$$DR_n = \frac{(n-1)(IP_{n(\text{in})} - MDS)}{n} \tag{3-119}$$

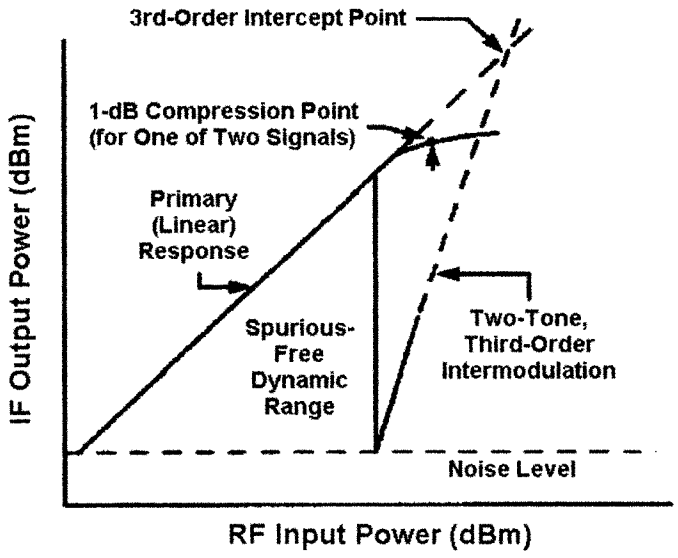

Figure 3-29 Amplifier linearity evaluation, including compression and two-tone IMD dynamic range. $P_{-1\text{dB}}$ for a single-tone cannot be read directly from this graph because the values shown are the result of two equal-power tones.

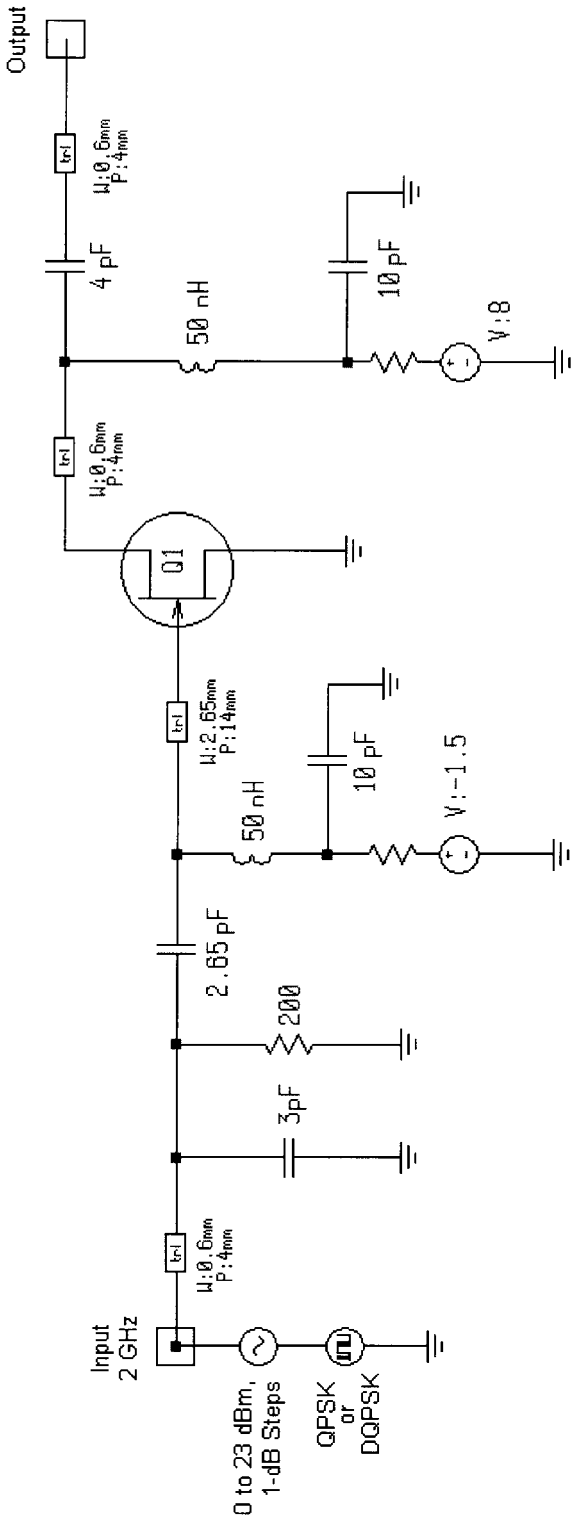

Figure 3-30 The power amplifier schematic.

where DR is the dynamic range in decibels, n is the order, $IP_{(in)}$ is the input intercept power in dBm, and MDS is the minimum detectable signal power in dBm. Once the 1-dB compression point is known, it is a fair assumption that the third-order intercept point, expressed in dBm, is 10 dB above this.

The intermodulation distortion gives the quality of an amplifier to withstand multiple signals without generating large intermodulation products or when using amplitude-modulated signals (cross-modulation). Figure 3-29 provides a quick reminder of IMD issues.

In some amplifiers, we would like to have control over the gain. While the better way to control gain while obtaining high linearity is a PIN-diode attenuator, special AGC circuits have become part of the amplifiers. Figure 3-48 shows a circuit of the SL610, made by Plessey, which has an AGC input provision. The noise figure of the PIN-diode attenuator is essentially equal to its attenuation. The AGC in multistage amplifiers is distributed over several stages and there is a lesser correlation between noise and AGC than in purely passive attenuators.

Special Case of Linearity Requirements for Digital Modulation. For cellular telephone systems we use digital modulation formats, such as QPSK and π/4-DQPSK, that combine phase and amplitude modulation. Amplifiers handling such signals must be carefully characterized and designed if adequate amplitude and phase linearity are to be maintained.

Examples of Power Amplifiers: Looking into the Effects of Distortion. This example presents modulation analysis using QPSK in a 2-GHz power amplifier (Figure 3-30). The simple amplifier was designed using the electronic Smith Tool of Serenade to determine the matching network for a narrowband design. The example demonstrates setup of modulation analysis and available results.

Siemens among others provides integrated amplifiers based on the concept depicted in Figure 3-30, the most popular ones being the CGY96 and CGY94. For the purpose of measurements, these amplifiers were actually put on a breadboard. Figure 3-31 shows the big brother, the CGY96. It is a GaAs MMIC intended as a power amplifier for GSM Class 4 phones with 3.2 W (35 dBm) at 3.5 V at an overall power added efficiency of 50%. Table 3-5 shows its electrical characteristics.

For the purpose of our experiments, we considered the CGY94 because it requires less external peripheral circuits. Table 3-6 shows its electrical characteristics. For those of us interested in seeing part of the internal circuit, Figure 3-32 shows the chip. This two-stage amplifier uses an interesting internal feedback scheme. Its schematic is shown in Figure 3-33.

For the purpose of looking at the waveforms, we will continue with the single-stage amplifier (Figure 3-30) and then compare the measured versus predicted performance of this CGY94-based amplifier.

A modulation source is connected to the RF source at the input port of the amplifier. The RF source specifies the carrier power (or voltage or current) and the modulation source specifies the modulation format and properties of the modulated signal.

A brief review of the modulation source used in this example indicates the following properties:

Property	Value	Description
NB	128	Number of bits
BR	1.2288E6	Bit rate
N	8	Number of samples per bit
BW1	590.E3	One-sided bandwidth of the main channel in the PIB or P1IB calculation
FS1	740.E3	Start baseband frequency of the fist adjacent channel
BW2	590.E3	One-sided bandwidth of the main channel in the P2IB calculation
FS2	1990.E3	Start baseband frequency of the second adjacent channel
BW3	590.E3	One-sided bandwidth of the main channel in the P3IB calculation
FS3	3240.E3	Start baseband frequency of the third adjacent channel
M	4	Order of the signal space; M = 4 is QPSK
DLY	0.0	Fractional bit delay
IASC	1.0	I channel amplitude scale; multiplier for the I waveform to model amplitude imbalance
QASC	1.0	Q channel amplitude scale; multiplier for the Q waveform to model amplitude imbalance
LPF	3	Baseband low-pass filter; 3 = root-raised cosine filter
LPFC	665.E3	–3 dB cutoff frequency of LPF
LPFN	3	Number of resonators if LPF = 1
LPFR	0.35	Roll-off factor if LPF = 3 or LPF = 4
FILE	N/A	File name of user-defined modulated signal file

The modulation source is a QPSK stream with a bit rate of 1.2288 Mbps. A total of 128 bits will be analyzed, and each bit is sampled eight times to construct an accurate analog waveform. The BW and FS parameters are defined here to specify the main (in-band) channel and adjacent channel for ACPR calculations. Imbalance of the I and Q amplitudes and phases can be described by the IASC, QASC, and DLY parameters, if desired. The modulation signal

is often filtered, and several types of filters are available. Here a root-raised cosine filter is used with a cutoff frequency of 665 kHz and a roll-off factor of 0.35.

Analysis. Figure 3-34 shows the compression characteristics of the amplifier as the available RF source power (a sinusoid) is swept. Note that P_{-1dB} is 11.5 dBm referred to the input and 28.5 dBm referred to the output. We will look at modulation characteristics in the linear region of operation at a source power of 0 dBm, and the nonlinear region at a source power of 20 dBm.

Next, we will view the voltage across the transistor to examine its behavior under compression. Figure 3-35 shows the drain–source voltage of the FET as the source power is swept. It is clear from this graph that clipping due to pinchoff and forward-gate conduction

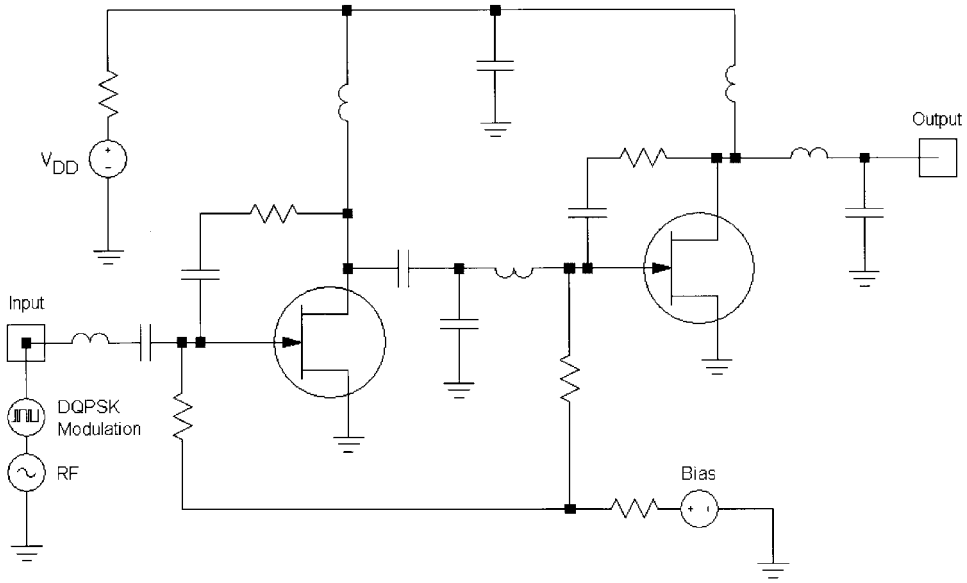

Figure 3-33 Schematic of the CGY94 GaAs MMIC power amplifier.

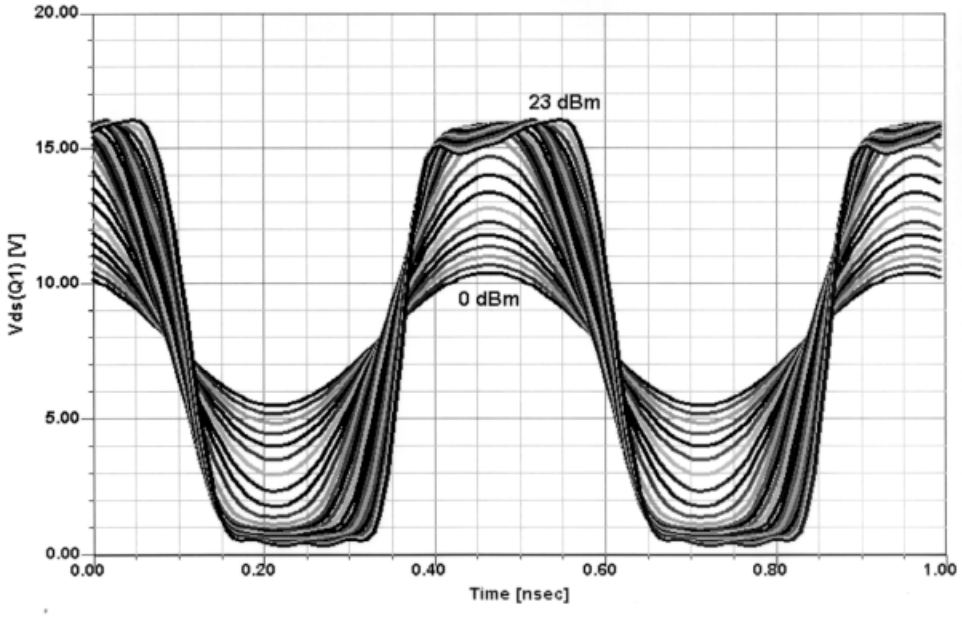

Figure 3-35 V_{DS} of the FET versus RF source power.

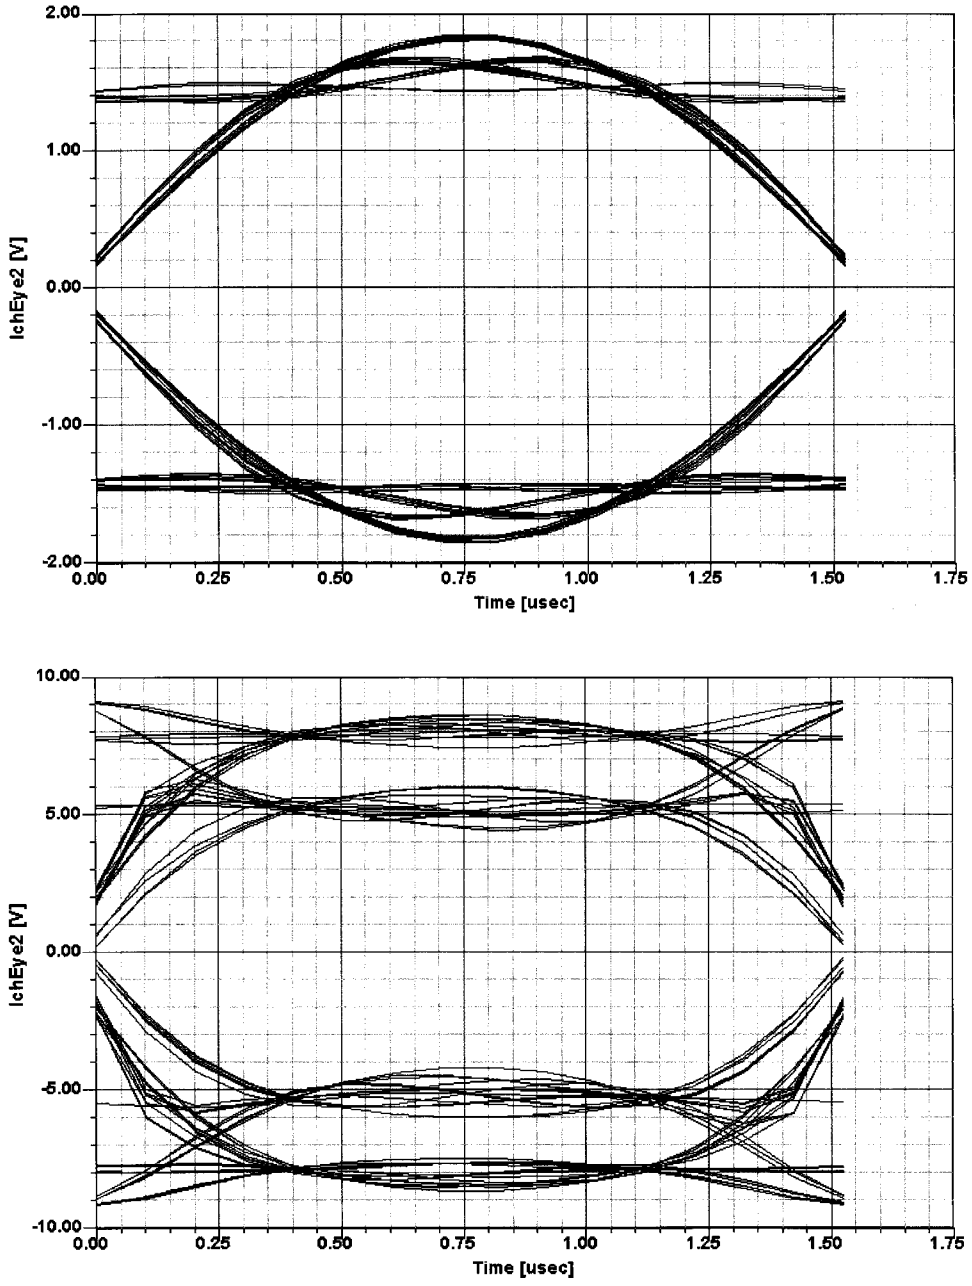

Figure 3-36 Eye diagrams of the I channel for source powers of (a) 0 dBm and (b) 20 dBm.

is limiting the performance of the device. A phase shift of the voltage waveform as power is increased is also apparent. The combination of the power compression and phase shift, or AM to PM conversion, will be used in the modulation analysis to determine the overall distortion of the modulated signal.

The output available from modulation analysis includes:

- I and Q channel waveforms
- Eye and constellation diagrams
- Spectral plots
- ACPR, in-band, and adjacent power

Figure 3-36 shows the eye diagrams for the 128-bit QPSK signal at two RF source powers, 0 and 20 dBm. Operating linearly at 0 dBm input, the amplifier doesn't distort the eye and it remains wide open. Note that in this example the filter bandwidth doesn't produce any intersymbol interference, as evidenced by the open eye. At an input power of 20 dBm, the amplifier compresses the signal, and distortion in the eye is evident.

We can also view the modulation spectrum at these two power levels to investigate the intermodulation distortion and spectral regrowth that takes place. Figure 3-37 shows the spectral plots. The lower trace corresponds to 0 dBm source power and shows almost no regrowth, while the upper trace at 20 dBm source power shows considerable regrowth.

The uncorrupted modulation source can also be shown. This corresponds to the source as a pure voltage without any circuit influence.

Now we evaluate the CGY94 board in a similar fashion. Figure 3-38 shows the waveform used for CAD purposes. Needless to say, such a signal cannot be produced by any signal

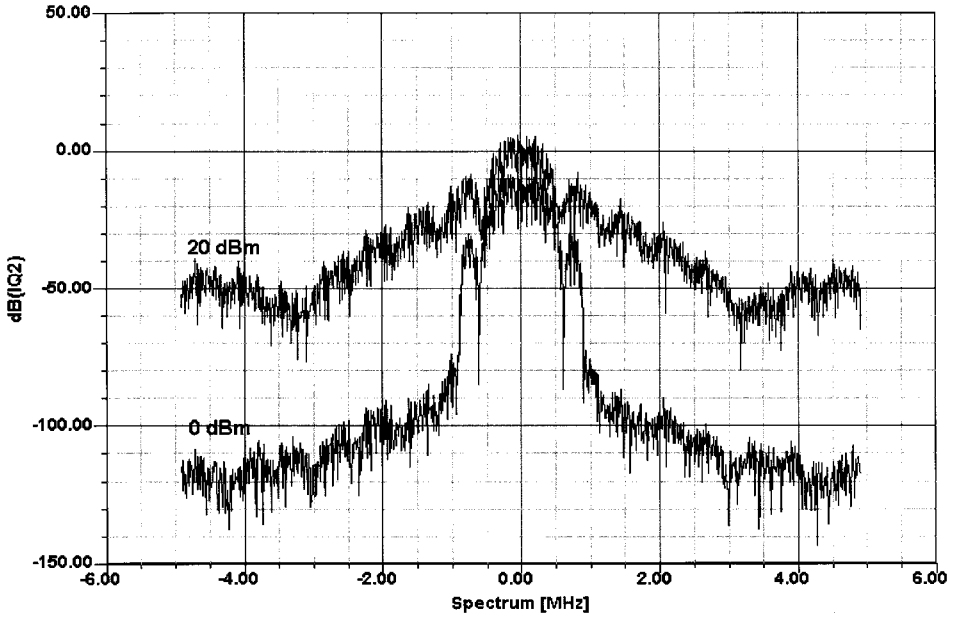

Figure 3-37 Spectrum of the modulation signal at the amplifier output. Source powers are 0 and 20 dBm.

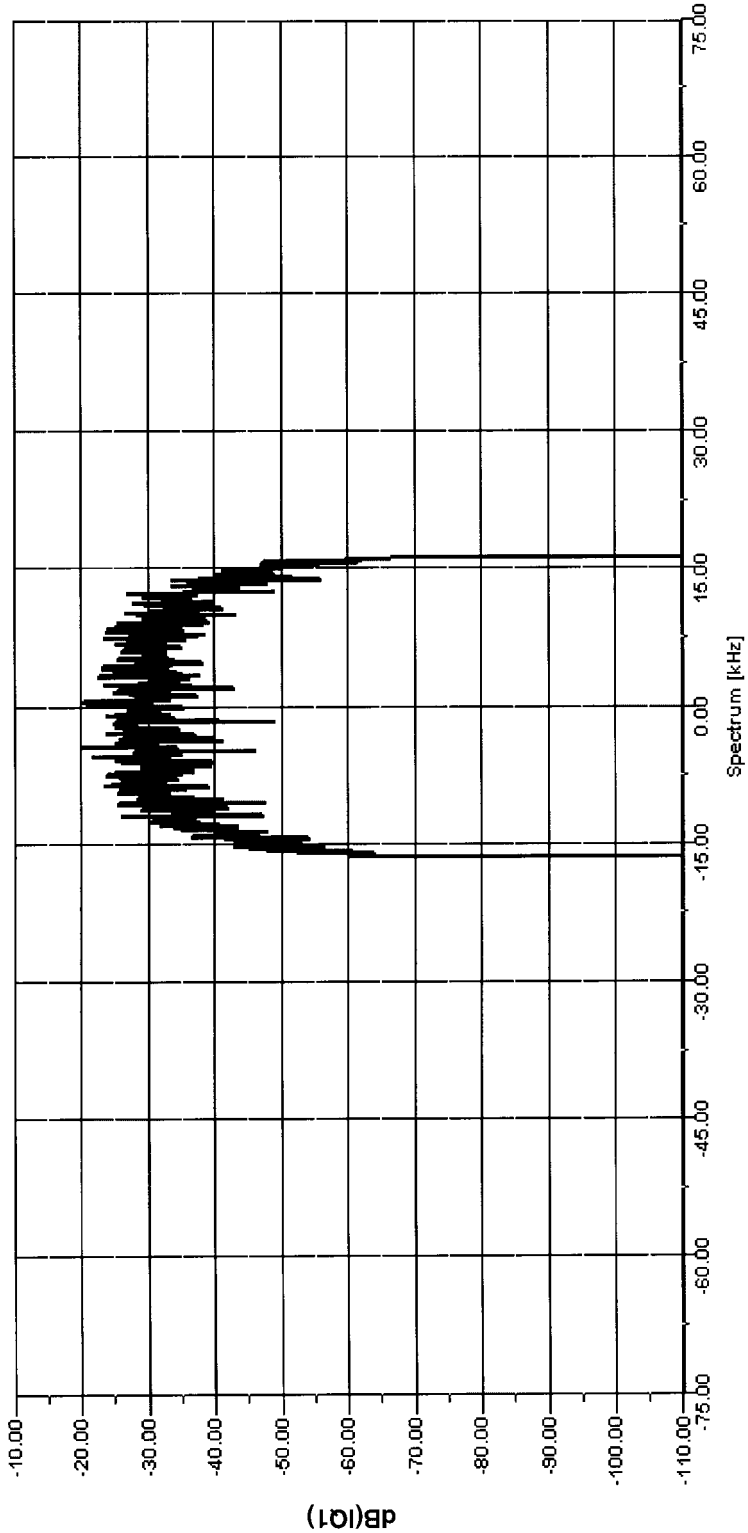

Figure 3-38 Simulated signal used for CAD analysis of the CGY94 amplifier.

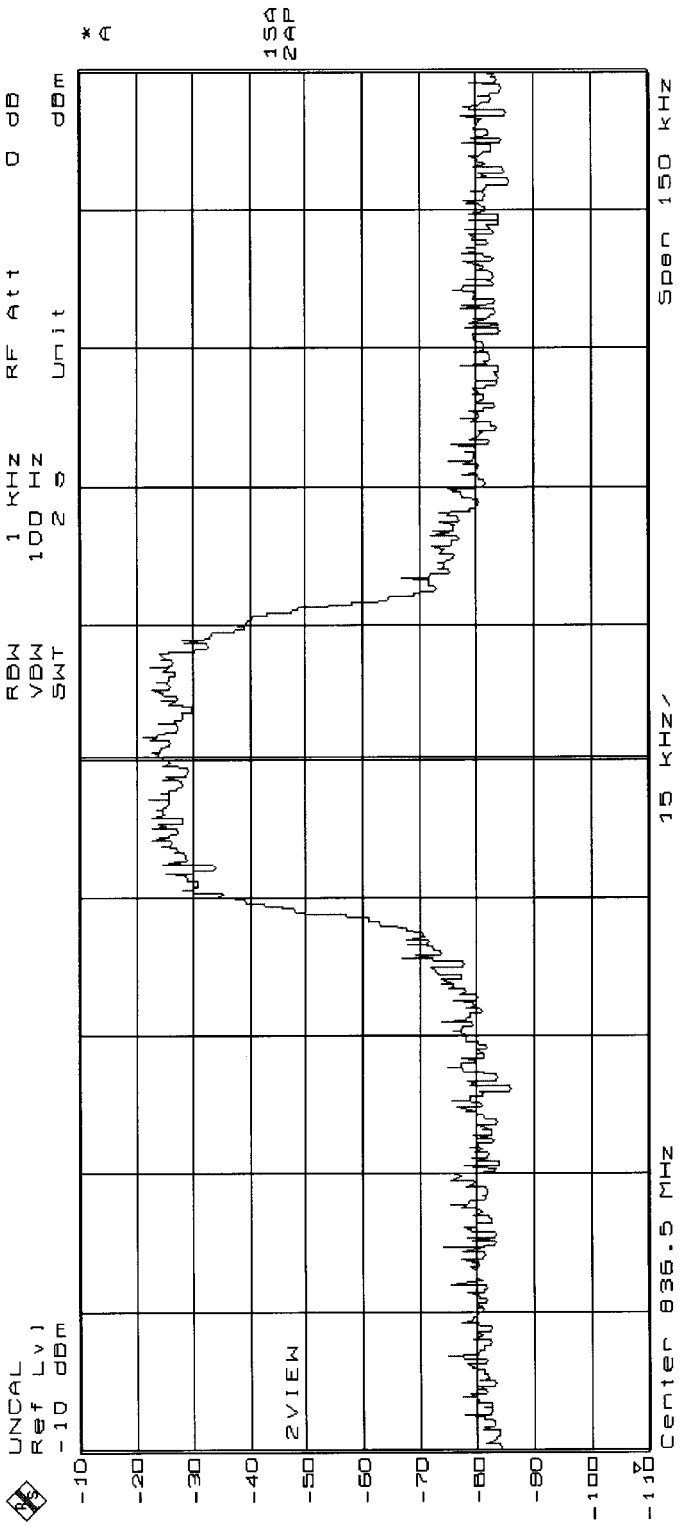

Figure 3-39 Real signal used for testing the actual amplifier.

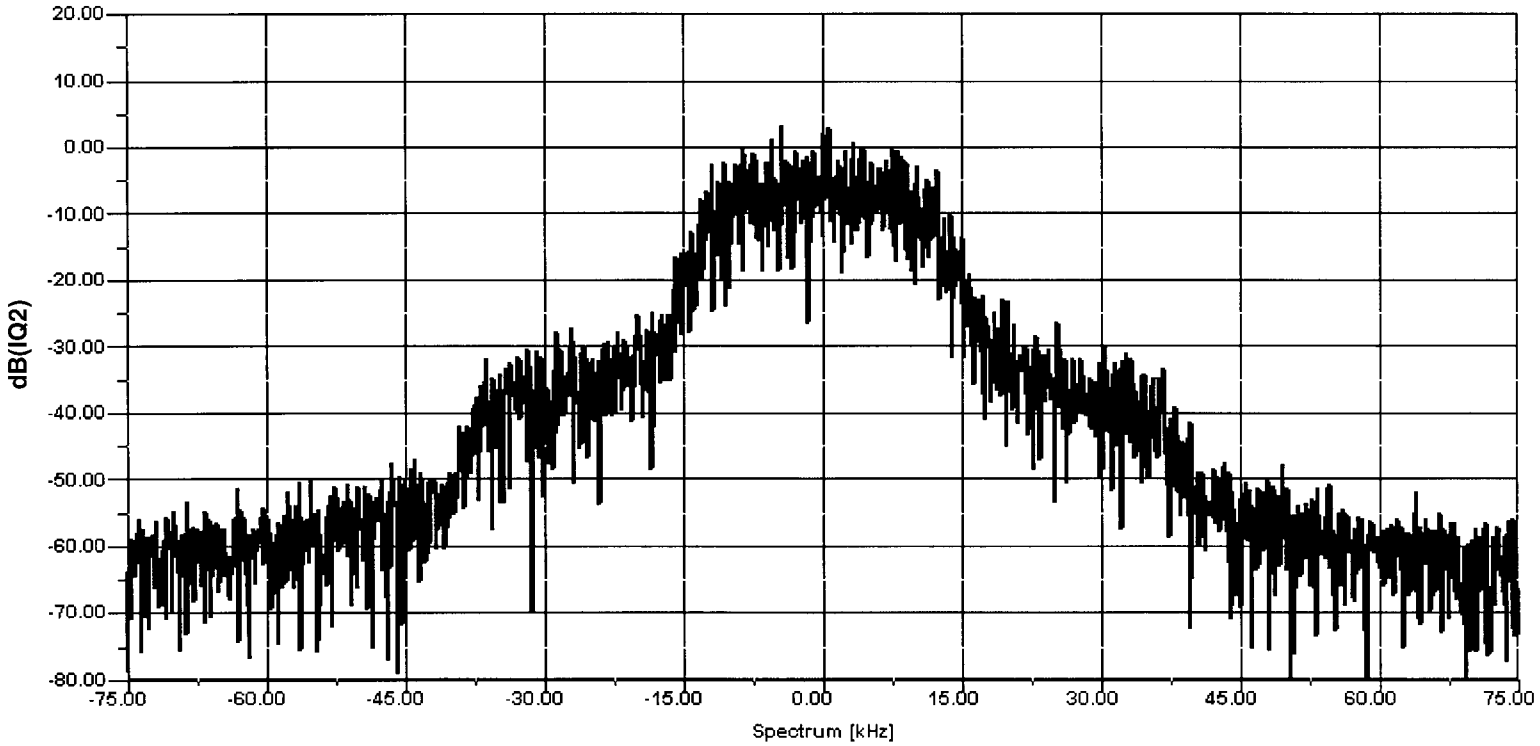

Figure 3-40 Spectral regrowth predicted by the simulation.

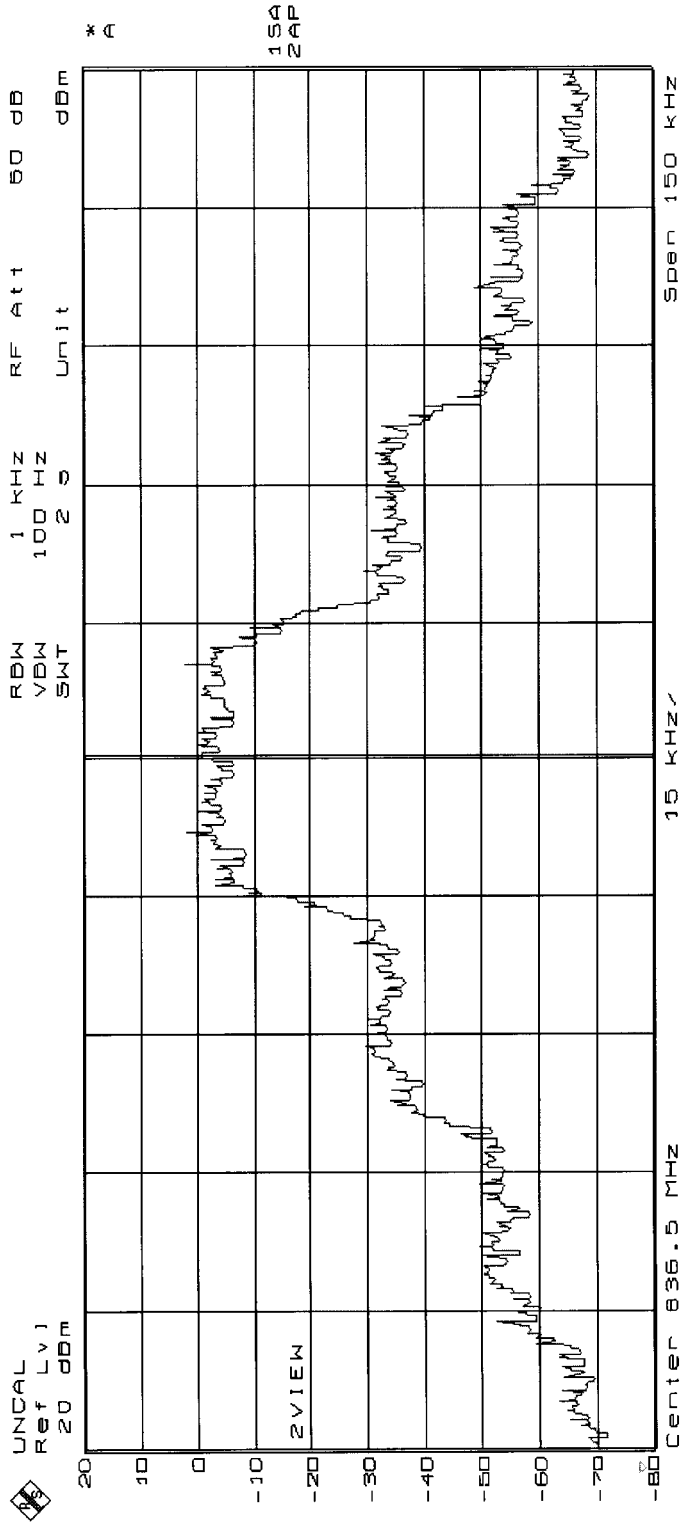

Figure 3-41 Measured spectral regrowth of the CGY94 amplifier.

generator. The one generated by an actual signal generator is shown in Figure 3-39. The wideband noise is around –80 dBm and the input level is about –25 dBm, consistent with the simulation signal. Looking at the output, Figure 3-40 shows the simulated signal with the expected increase in bandwidth. This is due to the nonlinearity of the amplifier and is consistent with Figure 3-37 for the single-stage amplifier. The actual measured output for the CGY94 shown in Figure 3-41 is quite close to its simulated output, indicating that the mathematical approach used for simulating is correct. This is only one example; in reality, many more waveforms can be analyzed and predicted using this method. Figure 3-41 shows essentially three distinct steps, which are sufficiently close to the response shown in the simulation. A dynamic range of 70 dB, while displayed in Figures 3-40 and 3-41, is not really necessary for good-quality transmission, and the discrepancy between the two pictures is in part due to the limited modeling quality of the active device as provided by the company that did the parameter extraction for this transistor.

Another useful view to aid in the understanding of the compression and distortion within the amplifier is to look at the magnitude of the complex waveform. Since the signal is composed of the in-phase and quadrature-phase components it is represented as

$$s(t) = i(t) + j \cdot q(t) \tag{3-120}$$

The time-domain magnitude is written

$$|s(t)| = \sqrt{i(t)^2 + q(t)^2} \tag{3-121}$$

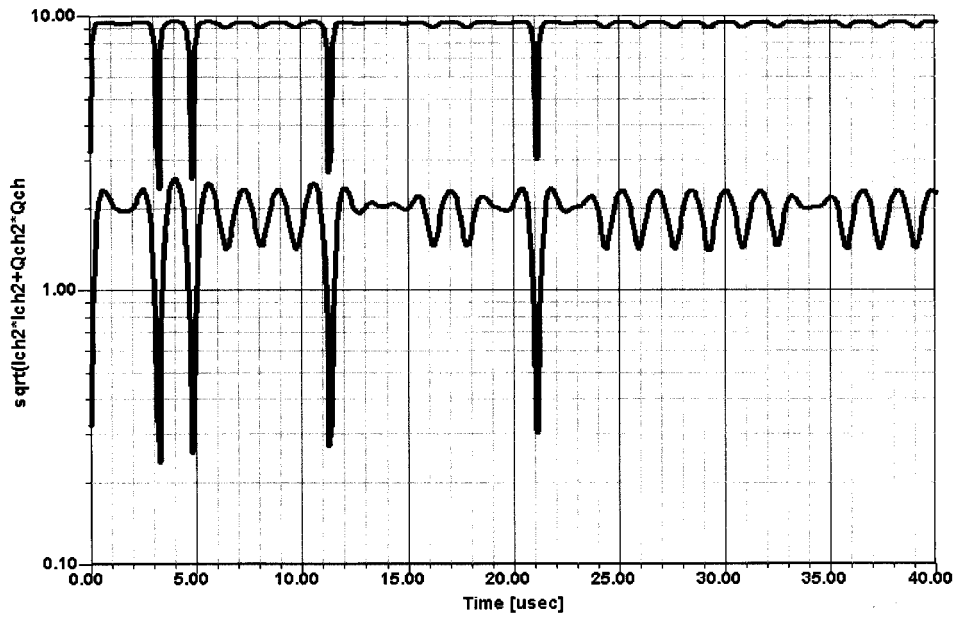

Figure 3-42 Time-domain magnitude of the complex modulation signal at source powers of 0 and 20 dBm.

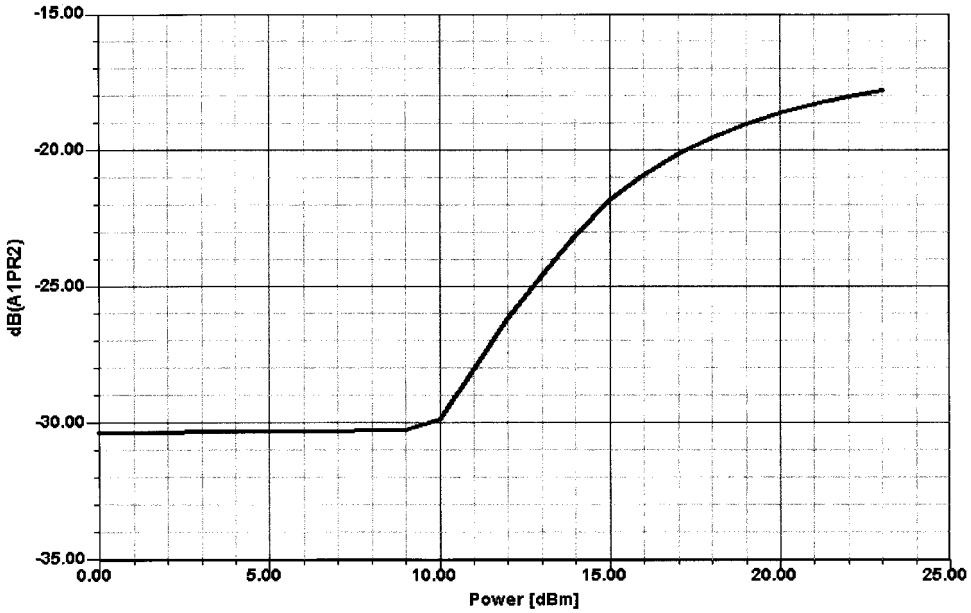

Figure 3-43 Adjacent-channel power ratio as function of RF source power.

Figure 3-42 shows the magnitude at source powers of 0 and 20 dBm. The *X* axis has been rescaled to 40 μs for improved viewing. Note the significant compression of the 20-dBm waveform at the higher signal levels. It is clear from this view that the signal is severely distorted.

We can also compute the adjacent-channel power ratio (ACPR) against the RF power sweep. ACPR is the ratio of the adjacent-channel power to the in-band channel power. The bandwidth (BW) and adjacent-channel start frequency (FS) are used for this calculation. For accurate ACPR calculation, a large number of bits are needed. This example uses 128 bits so the computation time is short, but 512 or more bits should be used for a more accurate computation.

Figure 3-43 shows the ACPR as a function of RF source power. The ACPR is nearly constant (and nonzero due to the gradual skirt of the baseband filter and inherent spillover to the adjacent channel) up to the P_{-1dB} compression point . As the intermodulation products spill into the adjacent channel and spectral regrowth occurs, the ACPR degrades.

π/4-DQPSK Circuit Analysis. Next, we will examine the same amplifier using a π/4-DQPSK modulation source. The task is identical to the previous one except for the source and the number of bits. The number of bits for this project has been increased from 128 to 256. Figure 3-44 shows the eye diagrams from this modulation format, at source powers of 0 and 20 dBm. The distortion and related intersymbol interference are clearly evident.

The constellation plot at 0 dBm is shown in Figure 3-45.

It may be interesting to take a look at the different waveforms currently in use. Figure 3-46 shows a spectrum analyzer picture of the most popular ones.

For reasons of time-division management, the European standard, GSM, which is now offered by Omnipoint at the 1.8-GHz band in the United States, uses gating to reduce the actual bandwidth of the spectrum. Figure 3-47 compares the GSM signal with and without gating.

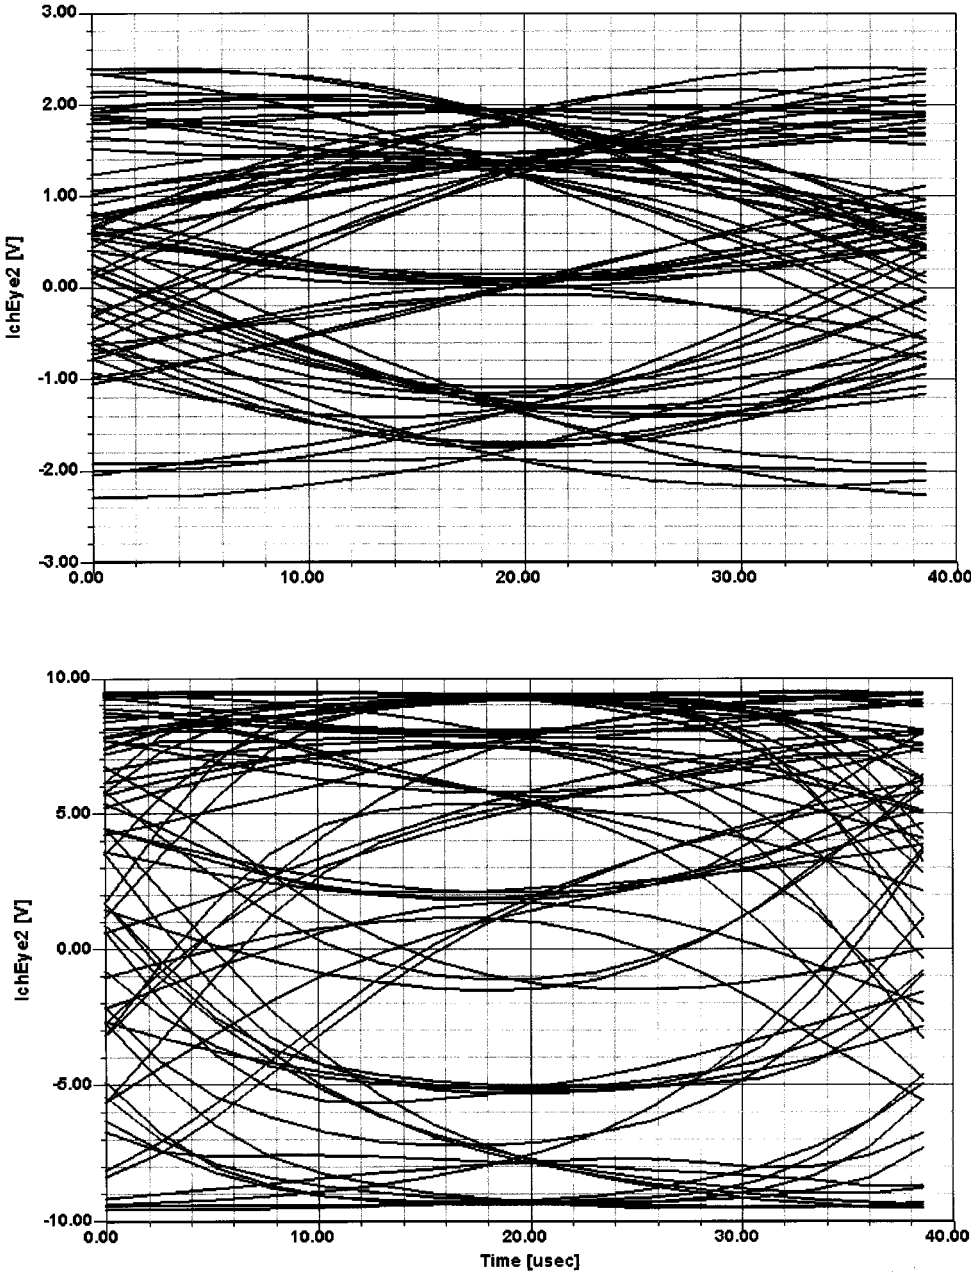

Figure 3-44 Eye diagrams for $\pi/4$-DQPSK at source powers of (a) 0 dBm and (b) 20 dBm. The distortion and related intersymbol interference are clearly visible.

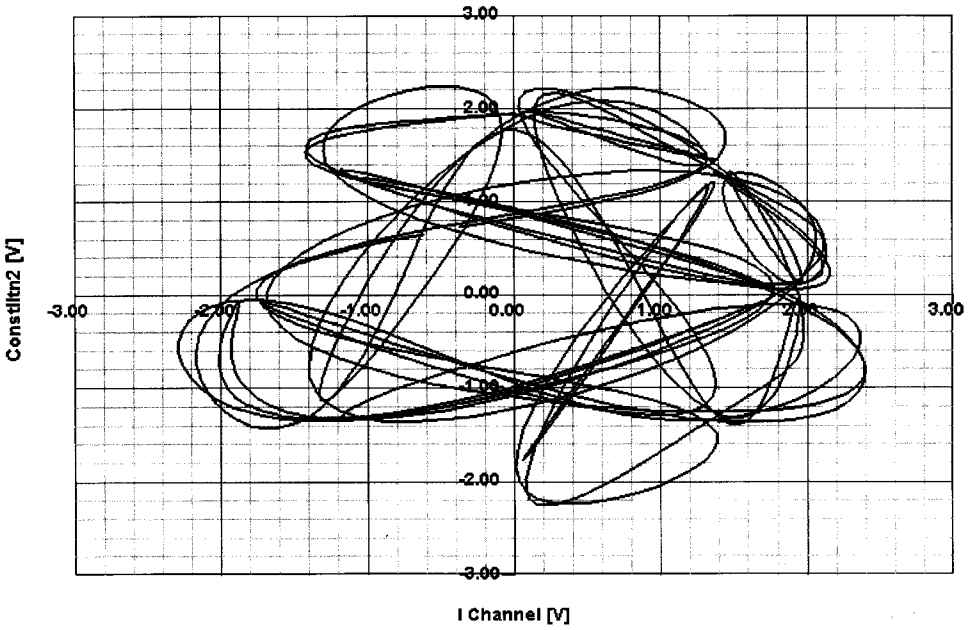

Figure 3-45 Constellation diagram for π/4-DQPSK at Port 2 and 0-dBm source power.

3-1-5 AGC

Many wireless systems consist of an up conversion or down conversion using an intermediate frequency, typically 10% or less of the receiving frequency (the FM broadcast IF has been set at 10.7 MHz for the same reason).

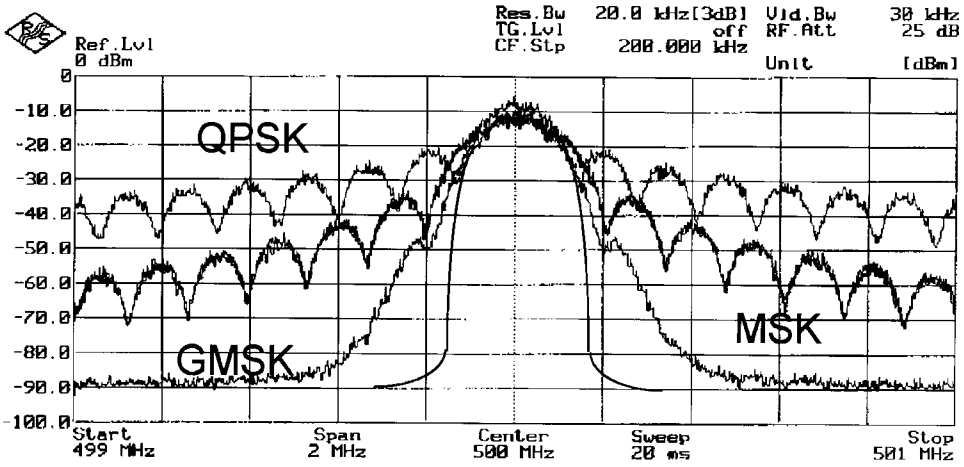

Figure 3-46 Spectrogram showing the characteristics of MSK, GMSK, and QPSK.

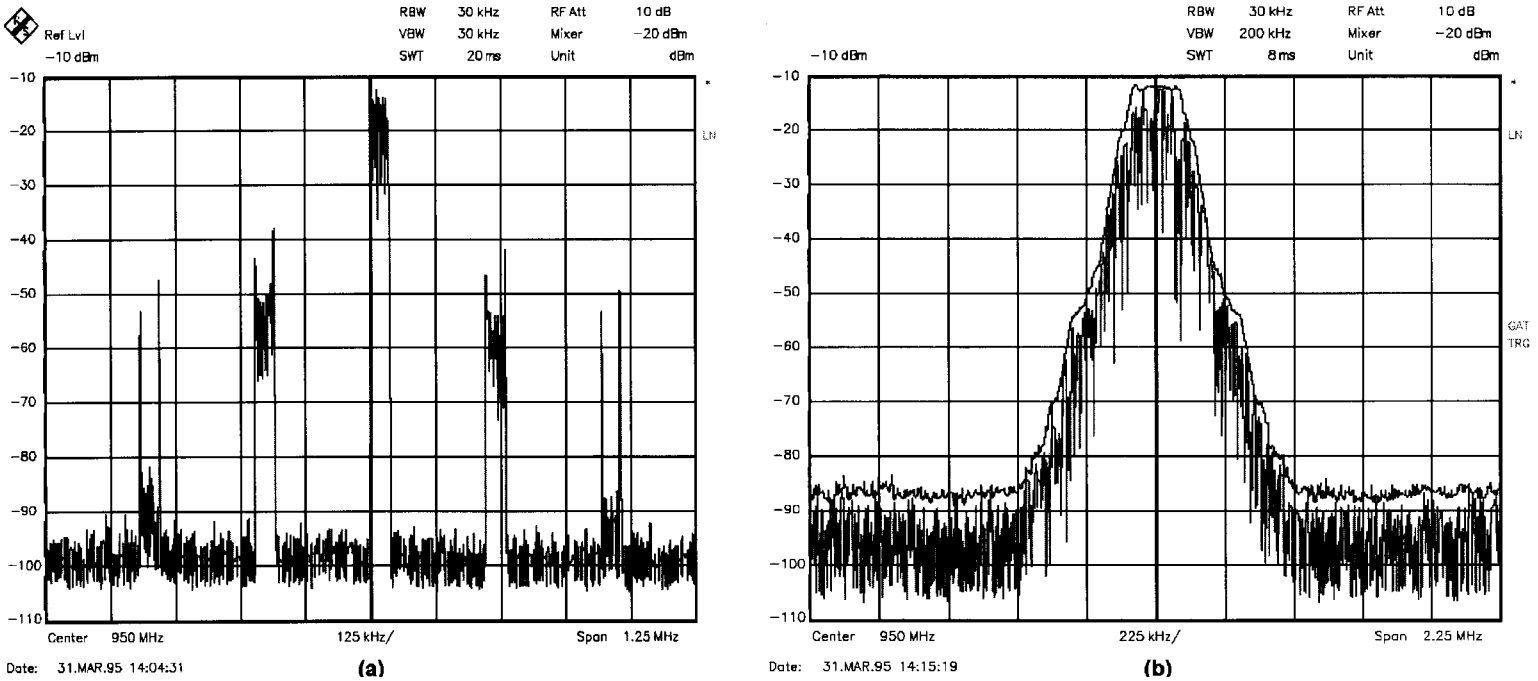

Figure 3-47 Pulsed GSM signal (a) without gating and (b) with gating.

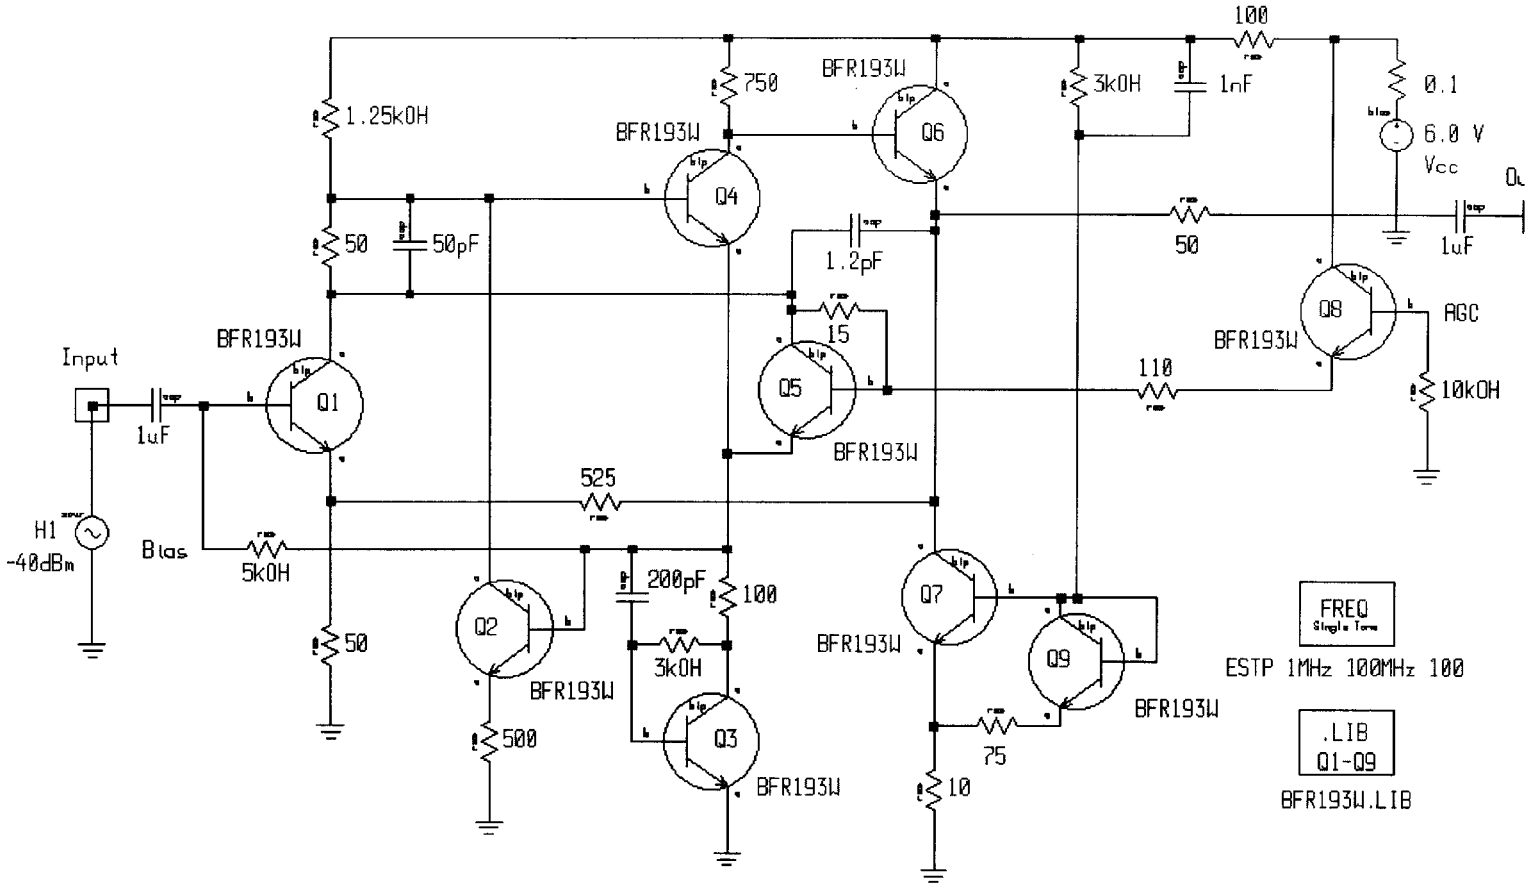

Figure 3-48 Schematic of the Plessey SL610 wideband amplifier with AGC. The 75-Ω resistor in the emitter of Q9 had to be added to obtain the appropriate dc current.

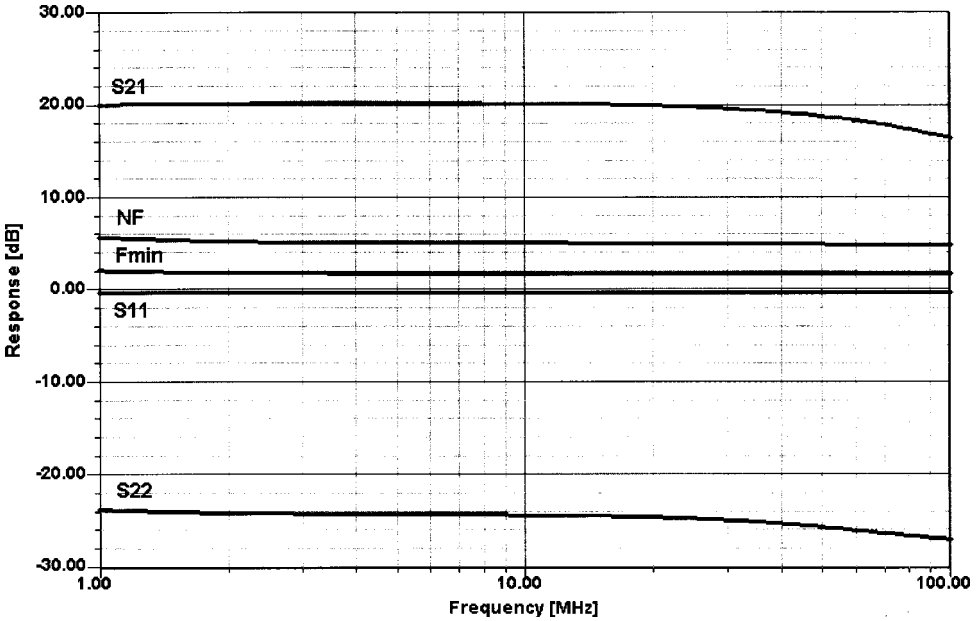

Figure 3-49 Simulated frequency response of the Plessey SL610 wideband amplifier IC with AGC = 0 V.

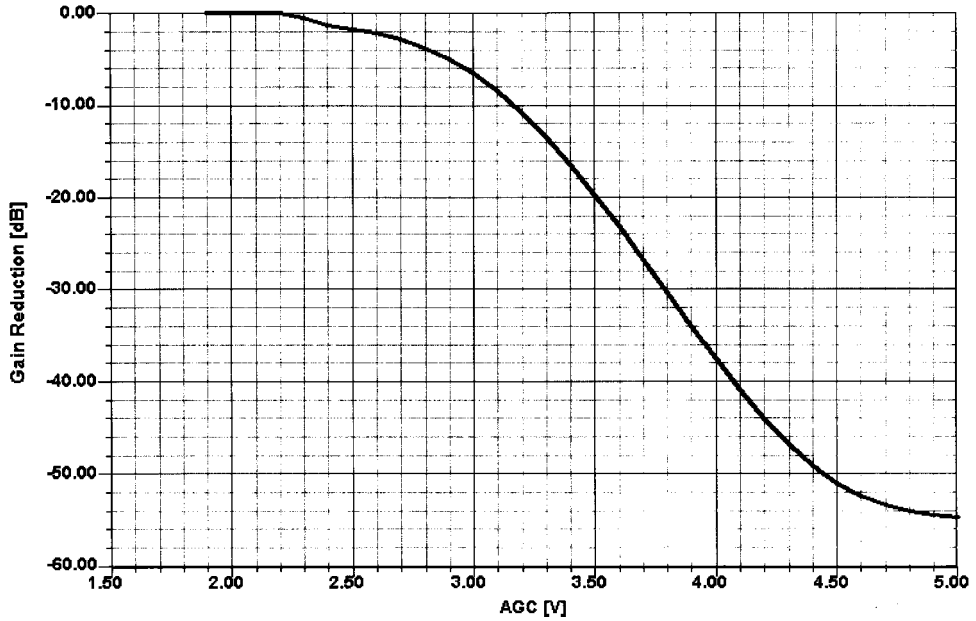

Figure 3-50 Simulated gain reduction versus AGC of the Plessey SL610 wideband amplifier IC.

Table 3-7 CGY121A features

- Variable gain amplifier (MMIC amplifier) for mobile communication
- Typical gain control range over 50 dB
- Positive control voltage
- 50-Ω input and output matched
- Low power consumption
- Operating voltage range: 2.7–6 V
- Frequency range 800 MHz to 2.5 GHz

We therefore will show two amplifiers with AGC and available data. The first one is a wideband amplifier type SL610, which has been manufactured by Plessey; its current fate is unknown. However, since we put the circuit into the simulator it provides significant insight into the operation of such AGC stages. Figure 3-48 shows the actual schematic of the SL610 entered in Ansoft's Serenade Design Environment for simulation.

The AGC action is derived from Q8 through Q5, which, together with Q4, forms a differential amplifier. Each consecutive stage (Q1, Q4, Q6) has increasing current, totaling about 20 mA; the last transistor takes about 13 mA. Based on the feedback surrounding the transistors, the actual transistor characteristics are less important. We have shown this by putting much higher f_T devices into the circuit than were available for the original design (20 years ago). The circuit is still interesting today because of its good large-signal-handling capability.

Table 3-8 CGY121A electrical characteristics at 900 MHz and 1.8 GHz

Characteristics	Symbol	Minimum	Typical	Maximum	Unit
(T_A 25 °C, f = 900 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	17	19	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	11	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	10	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm
(T_A 25 °C, f = 1800 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	15.5	17.5	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	10	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	8.5	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm

Figure 3-49 shows the amplifier's frequency response which is extremely close to the measured data. The good simulation also can be seen from comparing the published AGC curve with the one we found in the simulation. The bias of the first transistor remains essentially constant, resulting in a noise figure more independent of the AGC than the PIN-diode attenuator, and also stabilizes the input impedance as a function of AGC. Figure 3-50 shows the SL610's predicted AGC response.

The same requirement is applicable for the wireless frequency range. Tables 3-7 and 3-8 and Figures 3-51 through 3-54 present specifications for the recently introduced CGY121A GaAs MMIC by Infineon Technologies AG, formerly the Semiconductor Group part of Siemens AG.

3-1-6 Bias and Power Voltage and Current (Power Consumption)

Biasing of transistors operating in Class A or B follows some standard rules. The only deviation from this tends to be when the operating voltage is very low, below 3 V, because then the luxury of using voltage drops for good dc stability as a function of temperature disappears. (We will discuss low-voltage design in detail in Section 3-2-6.) In our simple example (Figure 3-55), we are operating from a 12-V power supply, and the first rule of thumb is to make sure that the voltage between the emitter and ground is at least 0.7 V. This is necessary to compensate the base–emitter junction threshold voltage, which decreases by about 2 mV/°C as the temperature increases. A larger voltage drop in the emitter–ground connection greatly reduces the influence. In this amplifier the emitter–ground path consists of an emitter unbypassed resistor of 10 Ω in series with a bypassed 501-Ω resistor, resulting in an overall voltage drop of 2.6. We could reduce the supply voltage by about 1.9 V at the collector side and still maintain a safety margin of 0.7 V at the emitter–ground connection. The current 2.6 V, so to speak, is overkill.

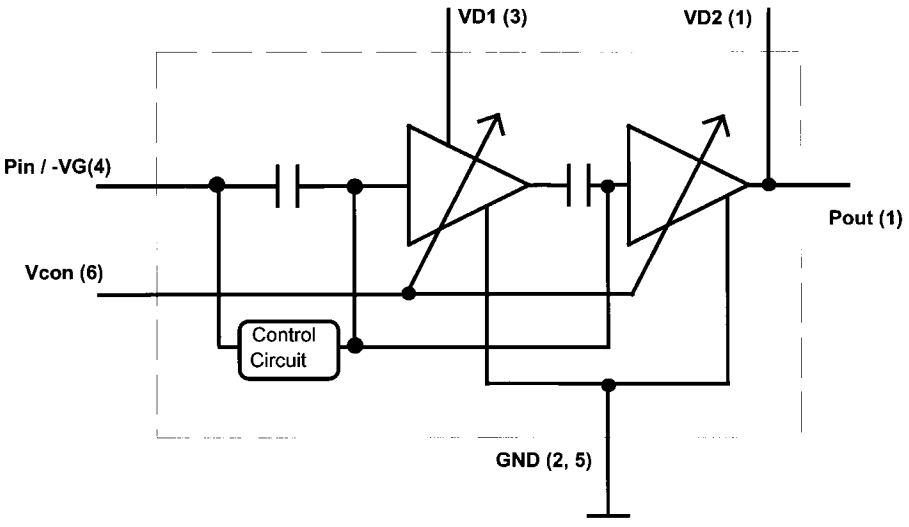

Figure 3-51 Functional block diagram of the gain-controllable CGY121A GaAs MMIC. Gain control is achieved by applying 0–3 V dc to the Vcon pin.

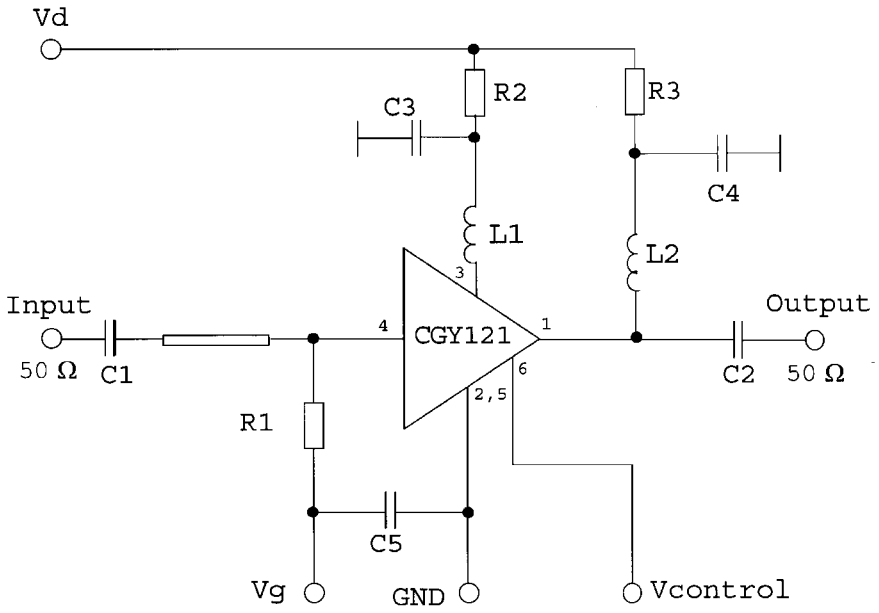

Parts List

Frequency	900 MHz
C1, C2 (Siemens Size 0603)	22 pF

R2 (Siemens B 54102-A1120-J60)	12 Ω
R3	6.8 Ω

Figure 3-52 CGY121A 900-MHz application circuit and parts list.

On the collector side, for an *RC* type of amplifier, it is not a bad idea to set the collector voltage at about half the supply, which allows the RF swing to be half the supply voltage. In this case, we have violated the rule because of our 2.6-V drop. Assuming we had chosen a 0.7-V drop, then the collector–emitter voltage would be 6.3 V available for the swing. The choice of 5 mA for the transistor has come from a combination of good linearity and low noise figure. While the 10-Ω unbypassed resistor will grade the noise figure somewhat, it reduces the emitter-current-dependent distortion. The base–emitter diffusion resistance equals 26 mV/5 mA, or roughly 5 Ω. The 10-Ω resistor is twofold larger and therefore adds to the linearity and to the noise.

To determine the base bias resistor it is a good assumption that the current going through the two resistors (in our case, 8.2 and 3.3 kΩ) is about 10% (or a slightly higher fraction) of

Figure 3-53 CGY121A 1.9-GHz application circuit and parts list.

the collector current. Since the dc current gain of the transistor is typically between 50 and 100, it is sufficient if the current through the resistive network is between 5 and 10 times higher than the dc bias current taken off the network. This type of bias scheme is only valid for Class A to AB_1. Later, we will see that for monolithic circuits, additional transistors will be used to generate the required voltage drops. Lately, combinations of *npn* and *pnp* transistors have become popular to avoid using any resistance in the emitter for dc biasing purposes. Figure 3-56 shows such a circuit. This, of course, invites thermal runaway. To minimize the circuitry, there are bias ICs, such as the Siemens BCR400R, now available. Figures 3-57 and 3-58 show its application in biasing BJTs and FETs, respectively; it can also be used to control PIN-diode bias current for TR antenna switching, as shown in Figure 3-59.

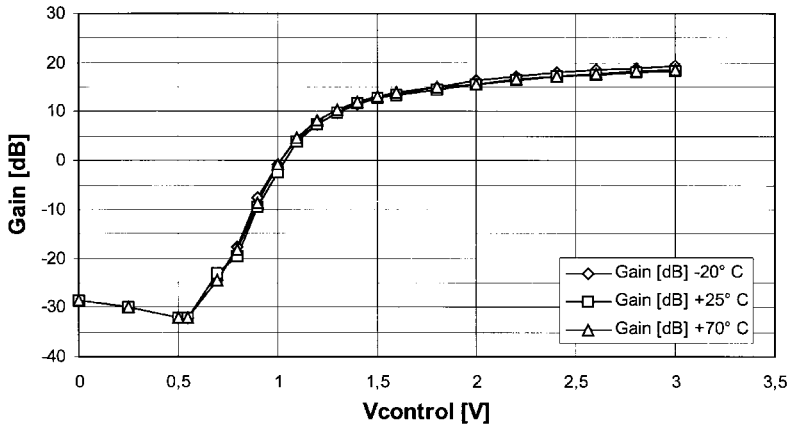

Figure 3-54 CGY121A gain versus $V_{control}$ at 1.9 GHz.

To validate this, we have used the Serenade 8.0 CAD tool, which has a built-in bias- and temperature-dependent noise model for BJTs and FETs. The SPICE-type dc analysis determines the actual currents, which were mentioned above. By maintaining the same bias and just bypassing both emitter resistors at the same time, the set of curves shown in Figure 3-60 will be obtained. As an exercise, we recommend the user to determine the optimum generator impedance for F_{min} with a 10-Ω resistor. Again, both the emitter current and collector voltage affect the noise figure, the intermodulation, and f_T. If a transistor is used

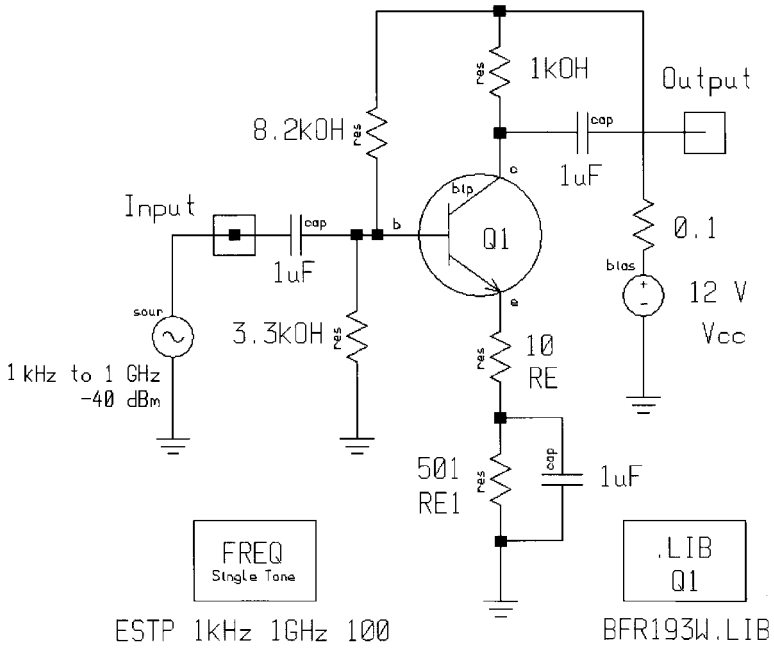

Figure 3-55 BJT amplifier example.

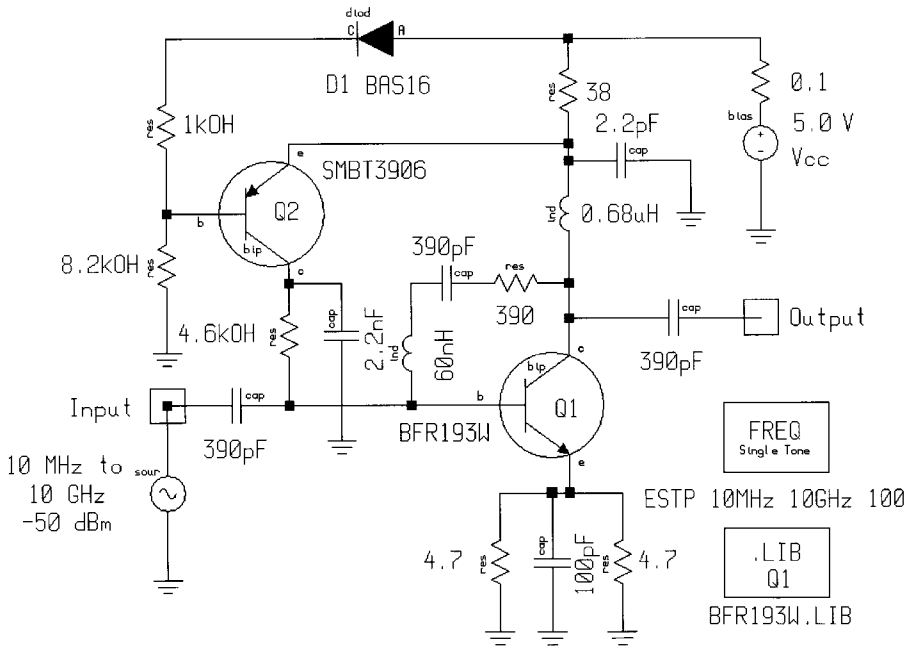

Figure 3-56 Wideband amplifier with active biasing. The 4.7-Ω resistors in the BFR193W emitter compensate the circuit's gain at low frequencies.

that is intended to be operated at significantly higher currents, then f_T will suffer while the other two parameters are less affected.

The dc input power translates into thermal dissipation, and Figure 3-60 is a plot of the noise figure as a function of temperature with and without emitter feedback. The heavy dc stabilization prevents a significant effect on the other parameters. The actual dc shift is from 5.0 to 5.2 mA for a temperature change of 70 K.

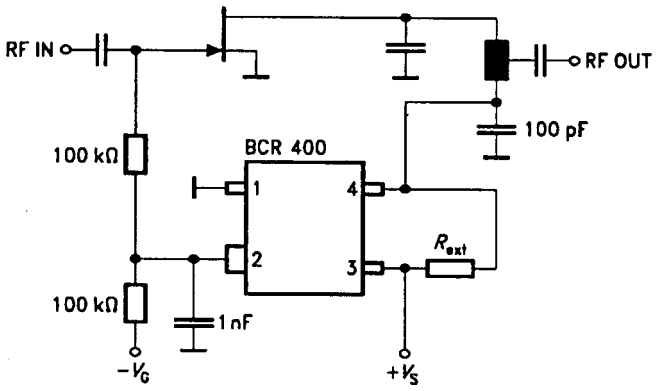

Figure 3-57 The Siemens BCR400 bias controller applied to a GaAsFET.

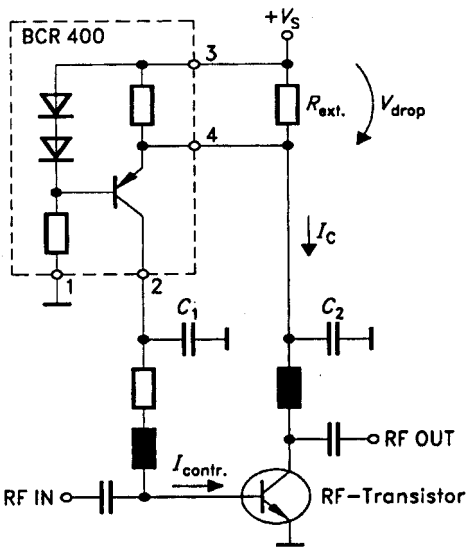

Figure 3-58 The Siemens BCR400 bias controller applied to a BJT.

As far as FETs are concerned, the enhancement types, typically PMOS, can use a similar type of bias, while the NMOS types complicate the designer's life as they require a negative gate voltage. For low-noise operation, these devices are operated somewhat close to the pinchoff voltage. Putting a source resistor in place causes mostly headaches simply because the gain is so high that the transistors are always ready to find a frequency at which they love to oscillate. The transistor will look for every possible parasitic to turn the amplifier into an oscillator.

3-2 AMPLIFIER GAIN, STABILITY, AND MATCHING

Most semiconductor manufacturers describe their devices these days by providing either their *S* parameters (small-signal) or SPICE-type parameters (large-signal). One of our headaches in writing this book has been that many of the published models don't translate

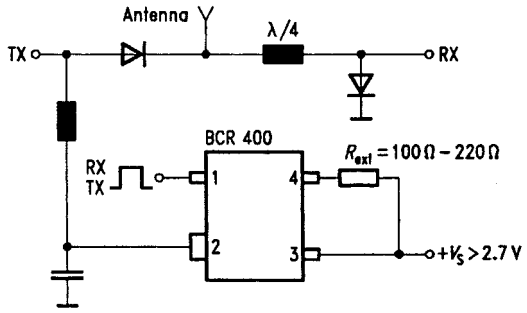

Figure 3-59 The Siemens BCR400 bias controller applied to TR switching.

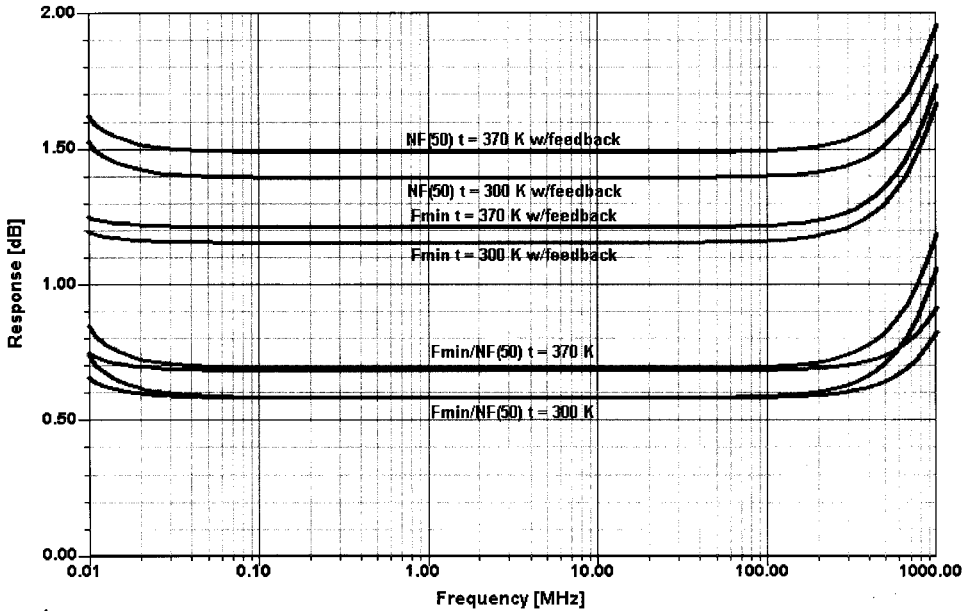

Figure 3-60 F_{min} and NF for the amplifier in Figure 3-55, with and without emitter feedback, at 300 and 370 K.

from large signal to small signal without giving unexpected or false results. Despite the availability of tools to do it right, many companies still can only provide data that are practically inadequate, and unfortunately the CAD manufacturers then get the blame for results for which they are not really responsible.

Tables 3-9 and 3-10 show typical data for a bipolar transistor (the BFP420 by Siemens). The next section presents a summary of the derivation and use of *S* parameters as published by Hewlett-Packard and others.

3-2-1 Scattering Parameter Relationships

Scattering (*S*) parameters characterize a network in terms of incident and reflected waves (Figures 3-61 and 3-62).

$$b_1 = s_{11}a_1 + s_{12}a_2 \tag{3-122}$$

$$b_2 = s_{21}a_1 + s_{22}a_2 \tag{3-123}$$

Notice that

$$s_{11} = \frac{b_1}{a_1} = \frac{V_1/I_1 - Z_0}{V_1/I_1 + Z_0} = \frac{Z_1 - Z_0}{Z_1 + Z_0} \tag{3-124}$$

and

Table 3-9 BFP420 common-emitter *S* parameters[a]

[a]Input matched for minimum noise figure, output for maximum gain.
[b]$Z_S = Z_L = 50\ \Omega$.

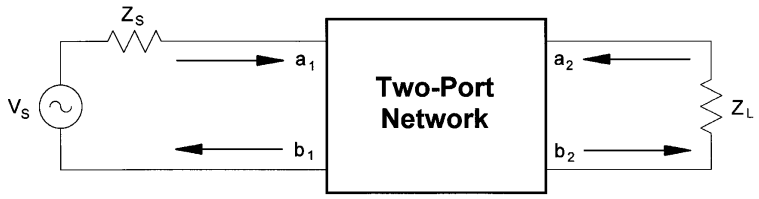

Figure 3-61 *S* parameters characterize a network (a two-port is shown) in terms of incident waves (a_1, a_2) and reflected waves (b_1, b_2). Figure 3-62 shows the flow graph for this network.

$$Z_1 = Z_0 \frac{(1 + s_{11})}{(1 - s_{11})} \tag{3-125}$$

where $Z_1 = V_1/I_1$ is the input impedance at Port 1.

This relationship between reflection coefficient and impedance is the basis of the Smith Chart transmission-line calculator. Consequently, the reflection coefficients S_{11} and S_{22} can be plotted on Smith charts, converted directly to impedance, and easily manipulated to determine matching networks for optimizing a circuit design.

The above equations show one of the important advantages of *S* parameters: They are simply gains and reflection coefficients, both familiar quantities to engineers. By comparison, some of the *Y* parameters described earlier in the article are not so familiar. For example, the *Y* parameter corresponding to insertion gain S_{21} is the "forward transadmittance," Y_{21}. Clearly, insertion gain gives by far the greater insight into the operation of the network.

S parameters are simply related to power gain and mismatch loss, quantities that are often of more interest than the corresponding voltage functions:

$$|s_{11}|^2 = \frac{\text{Power reflected from the network input}}{\text{Power incident on the network input}} \tag{3-126}$$

$$|s_{21}|^2 = \frac{\text{Power delivered to a } Z_0 \text{ load}}{\text{Power available from } Z_0 \text{ source}} \tag{3-127}$$

$$|s_{12}|^2 = \text{Reverse transducer power gain with } Z_0 \text{ load and source.} \tag{3-128}$$

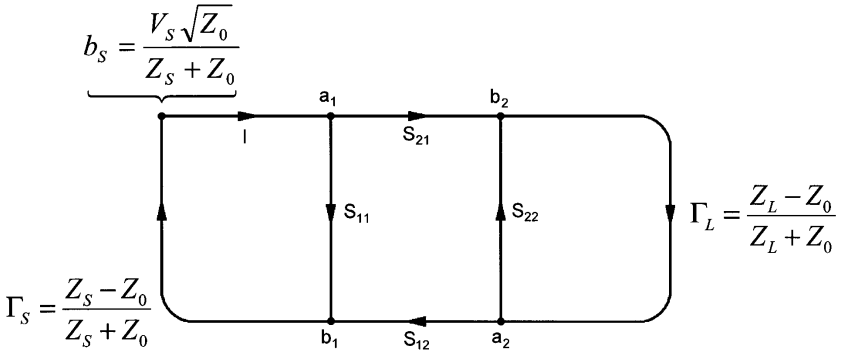

Figure 3-62 Flow graph for the network shown in Figure 3-61.

$$|s_{22}|^2 = \frac{\text{Power reflected from the network output}}{\text{Power incident on the network output}} \tag{3-129}$$

From this we obtain:
Input reflection coefficient with arbitrary Z_L:

$$s'_{11} = s_{11} + \frac{s_{12}s_{21}\Gamma_L}{1 - s_{22}\Gamma_L} \tag{3-130}$$

Output reflection coefficient with arbitrary Z_S:

$$s'_{22} = s_{22} + \frac{s_{12}s_{21}\Gamma_S}{1 - s_{11}\Gamma_S} \tag{3-131}$$

Voltage gain with arbitrary Z_L and Z_S:

$$A_V = \frac{V_2}{V_1} = \frac{s_{21}(1 + \Gamma_L)}{(1 - s_{22}\Gamma_L)(1 + s'_{11})} \tag{3-132}$$

$$\text{Power gain} = \frac{\text{Power delivered to load}}{\text{Power input to network}}:$$

$$G = \frac{|s_{21}|^2 (1 - |\Gamma_L|^2)}{(1 - |s_{11}|^2) + |\Gamma_L|^2 (|s_{22}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_L N)} \tag{3-133}$$

$$\text{Available power gain} = \frac{\text{Power available from network}}{\text{Power available from source}}:$$

$$G_A = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)}{(1 - |s_{22}|^2) + |\Gamma_S|^2 (|s_{11}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_S M)} \tag{3-134}$$

$$\text{Transducer power gain} = \frac{\text{Power delivered to load}}{\text{Power available from source}}:$$

$$G_T = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|(1 - s_{11}\Gamma_S)(1 - s_{22}\Gamma_L) - s_{12}s_{21}\Gamma_L\Gamma_S|^2} \tag{3-135}$$

Unilateral transducer power gain ($S_{12} = 0$):

$$G_{Tu} = \frac{|s_{21}|^2(1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|1 - s_{11}\Gamma_S|^2|1 - s_{22}\Gamma_L|^2}$$

$$= G_0 G_1 G_2 \tag{3-136}$$

$$G_0 = |s_{21}|^2 \tag{3-137}$$

$$G_1 = \frac{1 - |\Gamma_S|^2}{|1 - s_{11}\Gamma_S|^2} \tag{3-138}$$

$$G_2 = \frac{1 - |\Gamma_L|^2}{|1 - s_{22}\Gamma_L|^2} \tag{3-139}$$

Maximum unilateral transducer power gain when $|S_{11}| < 1$ and $|S_{22}| < 1$:

$$G_u = \frac{|s_{21}|^2}{|(1 - |s_{11}|^2)(1 - |s_{22}|)^2|}$$

$$= G_0\, G_{1\max}\, G_{2\max} \tag{3-140}$$

$$G_{i\max} = \frac{1}{1 - |s_{ii}|^2} \quad i = 1, 2 \tag{3-141}$$

Constant-gain circles (unilateral case: $S_{12} = 0$):

- Center of constant-gain circle is on line between center of Smith Chart and point representing S_{ii}^*
- Distance of center of circle from center of Smith Chart:

$$r_i = \frac{g_i |s_{ii}|}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-142}$$

- Radius of circle:

$$\rho_i = \frac{\sqrt{1 - g_i}(1 - |s_{ii}|^2)}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-143}$$

where $i = 1, 2$ and

$$g_i = \frac{G_i}{G_{i\max}} = G_i(1 - |s_{ii}|^2) \tag{3-144}$$

Unilateral figure of merit:

$$u = \frac{|s_{11}s_{22}s_{12}s_{21}|}{|(1 - |s_{11}|^2)(1 - |s_{22}|^2)|} \tag{3-145}$$

Error limits of unilateral gain calculation:

$$\frac{1}{(1 + u^2)} < \frac{G_T}{G_{Tu}} < \frac{1}{(1 - u^2)} \tag{3-146}$$

Conditions for absolute stability. No passive source or load will cause a network to oscillate if a, b, and c are all satisfied:

$$\text{a.}\quad |s_{11}| < 1, |s_{22}| < 1 \tag{3-147}$$

$$\text{b.} \quad \left| \frac{|s_{12}s_{21}| - |M^*|}{|s_{11}|^2 - |D|^2} \right| > 1 \tag{3-148}$$

$$\text{c.} \quad \left| \frac{|s_{12}s_{21}| - |N^*|}{|s_{22}|^2 - |D|^2} \right| > 1 \tag{3-149}$$

where

$$D = s_{11}s_{22} - s_{12}s_{21} \tag{3-150}$$

$$M = s_{11} - Ds_{22}^* \tag{3-151}$$

$$N = s_{22} - Ds_{11}^* \tag{3-152}$$

Condition that a two-port network can be simultaneously matched with a positive real source and load:

$$K > 1 \tag{3-153}$$

$$K = \frac{1 + |D|^2 - |s_{11}|^2 - |s_{22}|^2}{2|s_{12}s_{21}|} \tag{3-154}$$

Source and load for simultaneous match

$$\Gamma_{mS} = M^* \left[\frac{B_1 \pm \sqrt{B_1^2 - 4|M|^2}}{2|M|^2} \right] \tag{3-155}$$

$$\Gamma_{mL} = N^* \left[\frac{B_2 \pm \sqrt{B_2^2 - 4|N|^2}}{2|N|^2} \right] \tag{3-156}$$

where

$$B_1 = 1 + |s_{11}|^2 - |s_{22}|^2 - |D|^2 \tag{3-157}$$

$$B_2 = 1 + |s_{22}|^2 - |s_{11}|^2 - |D|^2 \tag{3-158}$$

Maximum available power gain. If $K > 1$,

$$G_{A\max} = \left| \frac{s_{21}}{s_{12}} (K \pm \sqrt{K^2 - 1}) \right| \tag{3-159}$$

In conclusion, *a two-port network (active or passive) is unconditionally stable* when

$$K > 1$$

$$|S_{12}S_{21}| < 1 - |S_{11}|^2$$

and

$$|S_{12}S_{21}| < 1 - |S_{22}|^2$$

3-2-2 Low-Noise Amplifiers

A low-noise amplifier combines a low noise figure, reasonable gain, and stability without oscillation over its entire useful frequency range. These amplifiers are typically operated in Class A, which is characterized by a bias point more or less at the center of maximum current and voltage capability of the device used, and by RF current and voltages that are sufficiently small relative to the bias point that the bias point does not shift. This means that an amplifier operating at, say, 3 V and 1 mA for low-noise, high-gain operation will not be Class A if the RF current is larger than 0.1% of the current or the voltage swing is more than 0.1% of the current swing. These amplifiers can be designed using standard linear *S* parameters, which are (hopefully) available from the device manufacturer for the bias point of interest. If suitable *S* parameters are not available, we must resort to a CAD tool that allows us to determine a device's bias point as a function of its bias network and to generate small-signal *S* parameters for the device. With suitable *S* parameters in hand, and assuming the amplifier will be frequency selective, we then connect tuned circuits to the input and output to provide matching.

In designing amplifiers, the "power gain" of a circuit is mentioned frequently. This is actually deceptive because power gain is somewhat associated with dc power dissipation, and in considering it, we are on the verge of discussing large-signal performance. Therefore it would be better to define the power gain as a function of operating mode, such as "Class A power gain." We have also outlined that there is a difference between noise matching and gain matching. If we can be allowed to step back into the vacuum-tube era for a moment, the reader should be reminded that the difference between power gain and noise matching had to do with the grid-plate feedback capacitance which, via the Miller effect, showed up in parallel with the input. This actually detunes the input slightly off-center relative to the best gain. The reason for this is that as the feedback increases, Y_{12} or S_{12} starts playing a role, and the frequently assumed unilateral case no longer exists. The difference between noise matching and gain matching increases as a function of frequency. It can be brought closer together if appropriate reactive feedback is used. The two choices are: (1) increase the emitter or source inductance or (2) slightly increase the base-to-collector/gate-to-drain capacitance. Needless to say, the penalty for this is potential instability, and a sweep must be done from a few megahertz to several gigahertz to make sure the stage doesn't "take off."

The most efficiency this circuit provides is 50%; even this is a theoretical limit if one tries to keep distortion under control.

While the equation $P_{\text{OUT}} = (V_{\text{bat}} - V_{\text{sat}})^2/2R_L$ is valid, it really applies only to power amplifiers in the sense that for Class A, high-gain operation R_L can be made significantly higher as the absolute power output is not the important item. While the supply voltage V_{bat} is always known, the saturation voltage V_{sat} has to be obtained by the load line dc analysis. Note: The RF saturation voltage is always higher than the dc one. When looking at Figure 3-63, it becomes obvious that the conducting angle is 180°, which implies that the entire sine wave at the input is reproduced as an essentially undistorted sine wave at the output.

We can now calculate the components of the distorted current in separating them into the dc component, the fundamental frequency, and its first and second harmonics:

$$\text{Fundamental} \quad i_{c1} = i_{\text{peak}} \cdot f_1(\Theta) \tag{3-160}$$

$$\text{Second harmonic} \quad i_{c2} = i_{\text{peak}} \cdot f_2(\Theta) \tag{3-161}$$

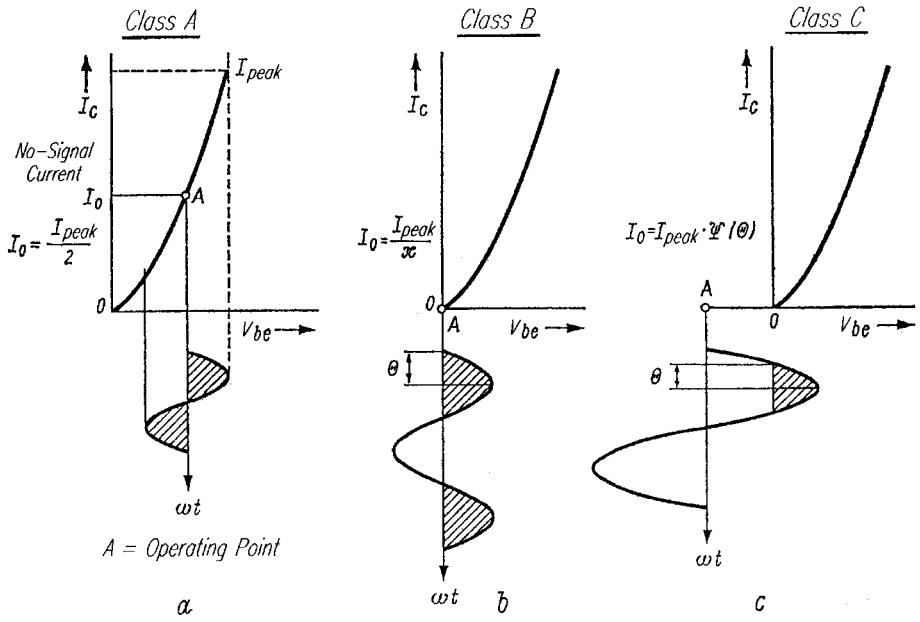

Figure 3-63 Definitions of Class A, B, and C operation, including conduction angle (Θ). Figure 3-64 shows the determination of Θ.

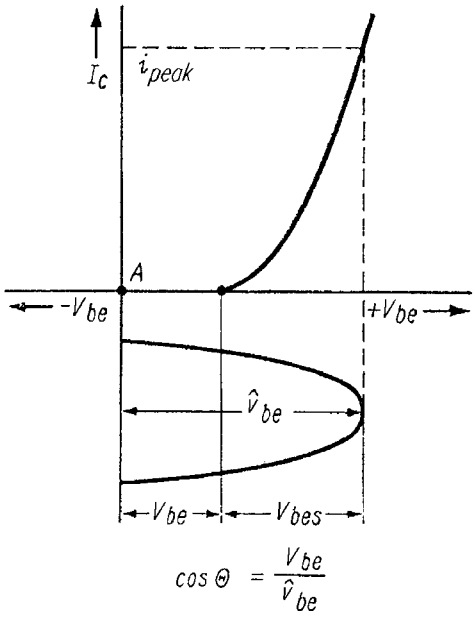

Figure 3-64 Determination of the conduction angle Θ from the base threshold voltage V_{be} and the base RF voltage $\hat{v}_{be}$.

$$\text{Third harmonic} \quad i_{c3} = i_{\text{peak}} \cdot f_3(\Theta) \tag{3-162}$$

For the collector dc current we obtain

$$I_c = i_{\text{peak}} \cdot \Psi(\Theta) \tag{3-163}$$

The frequency-dependent currents are a function of the conduction angle Θ. Figure 3-65 shows these transfer characteristics as a function of the conduction angle for a square-law dynamic transfer function; for higher-order transfer functions, the values don't change much. Tables for this can be found in various sources, including Clark and Hess [47]. Since the transistors exhibit a mixture of an exponential and a linear transfer characteristic (due to the unwanted parasitic emitter/source and collector/drain resistances when building the device), the plot in figure 3-65 is sufficiently valid for practical purposes. This function plot allows us to determine the amplitude of the current at various frequencies once the conducting angle has been set. For example, for Θ = 70°, the maximum collector current is $i_{\text{peak}} = I_c/0.253$, meaning that the peak current of the transistor is approximately four times larger than the dc value one would measure. Once the peak collector current is known, the fundamental and harmonic currents can be calculated:

$$i_{c1} = \frac{I_c}{0.253} f_1(\Theta)$$

$$i_{c1} = \frac{I_c}{0.253} 0.436$$

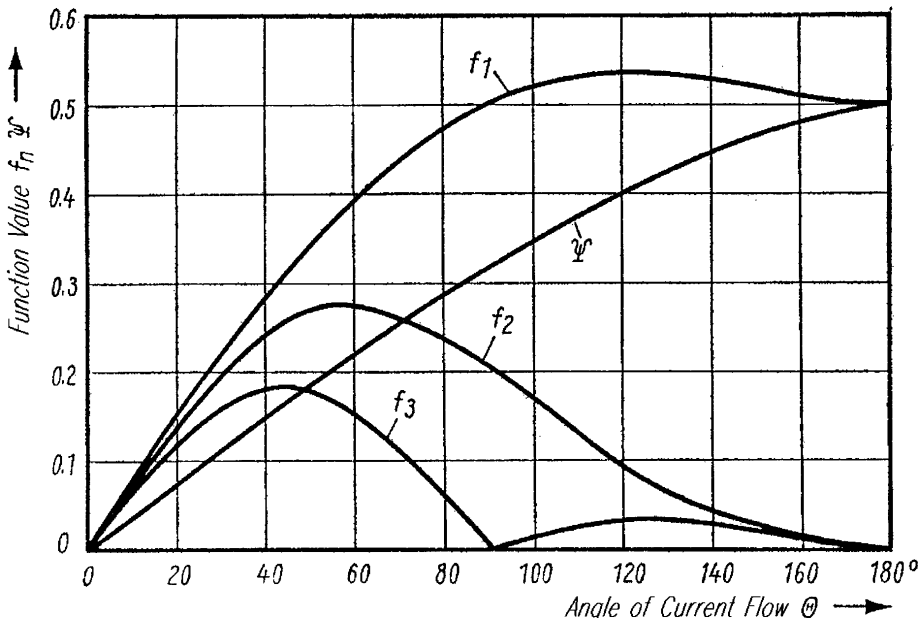

Figure 3-65 Function values for the fundamental, second harmonic, third harmonic, and dc components (f_1, f_2, f_3, and Ψ, respectively) versus device conduction angle.

In order to obtain i_{c2} and i_{c3} one needs to do the same calculations as above with the appropriate functions for f_2 and f_3.

It becomes obvious that the distorted collector current generates a lot of harmonics, which definitely requires sufficient low-pass filtering at the output, even for Class A operation. We already stated that for Class A operation the conduction angle is 180° while it is 90° for Class B operation. The conduction angle for Class C operation can be solved from the ratio of the knee voltage V_{be} and the peak value of the ac voltage at the base. We find

$$\cos \Theta = \frac{V_{be}}{\hat{V}_{be}} \tag{3-164}$$

where $\Theta = 90°$ and $V_{be} = 0$. Given the voltage V_{bes}, which determines the peak collector current (up to i_c peak), we can calculate the effective RF voltage at the base as

$$\hat{v}_{be} = \frac{v_{bes}}{1 - \cos \Theta} \tag{3-165}$$

Therefore, the peak value of v_b becomes v_{bes} for $\Theta = 90°$.

The necessary base voltage V_{be} for maximum current is obtained by the transistor model. Then one finds the threshold voltage at which the transistor becomes conductive and by using Eqs. (3-164) and (3-165) it can be checked whether this results in the appropriate conducting angle. An example for this will be shown in the high-power stage section.

Design Guidelines. The design of a one-stage amplifier consists of finding

- An input lossless matching network M_1
- An input lossless matching network M_2

so that the maximum or desired transistor gain is achieved over the operating bandwidth of the amplifier. Usually, the common-emitter or common-source configuration is chosen for highest gain per stage. If the stability factor K is greater than unity, these two networks can be found to give the maximum available gain $G_{\max}$. If the stability factor is less than or equal to unity, the amplifier could be terminated in a matching structure that causes oscillation; that is, $G_{\max}$ is infinite. This should be avoided by locating the regions of instability in the Γ_G and Γ_L planes. The input and output terminations (Γ_G and Γ_L) must be designed to avoid the instability regions. Usually, these unstable regions are near the conjugate match for S_{11} and S_{22}. Thus, a stable amplifier will require some input and/or output mismatch if K is less than or equal to unity.

There are at least two alternative approaches for potentially unstable amplifiers:

1. Add resistive matching elements to make $K \geq 1$ and $G_{\max} \approx G_{ms}$.
2. Add feedback to make $K \geq 1$ and $G_{\max \approx Gms}$.

For narrowband amplifiers, it is usually recommended that one accept a transistor with $K < 1$, design the amplifier for a gain approaching G_{ms}, and ensure that the Γ_G and Γ_L terminations provide stability at all frequencies, both inside and outside the amplifier passband.

The design of an amplifier would usually have the following specifications:

Gain and gain flatness
Bandwidth and center frequency ($f_2 - f_1, f_0$)
Noise figure
Linear output power
Input reflection coefficient ($VSWR_{in}$)
Output reflection coefficient ($VSWR_{out}$)
Bias voltage and current

For small-signal amplifiers, the small-signal S parameters are sufficient to complete the design. After selecting an appropriate transistor based on these specifications, a one-stage amplifier design should be considered if sufficient gain can be achieved; otherwise, a two-stage amplifier should be designed.

The circuit topology should be chosen to allow dc bias for the transistor. Usually, RF short-circuited stubs are placed near the transistor to allow dc biasing. If the topology does not allow dc bias, a broadband bias choke or high-resistance bias circuit that does not affect the amplifier performance must be used.

The following steps can be tabulated for the design of a one-stage amplifier (see Figure 3.66):

1. Select a transistor based on a datasheet description of the S parameters, noise figure, and linear output power.
2. Calculate K and G_{max} or G_{ms} versus frequency.
3. For $K > 1$, select the topologies that match the input and output (and allow dc biasing) at the upper band edge f_2. Ideally, this will give G_{max} and $S'_{11} = S'_{22} = 0$. Usually, $S_{12} = 0$ is assumed for the initial design. Next, the topology may be varied to flatten gain versus frequency at the expense of S'_{11} and S'_{22}.
4. For $K < 1$, plot the regions of instability on the Γ_G and Γ_L planes and select topologies that partially match the input and output at the upper band edge and avoid the unstable regions. The gain will approach G_{ms} as an upper limit. Next, the topology may be varied to flatten gain versus frequency.
5. After finding initial M_1 and M_2, plot the amplifier S parameters versus frequency; make adjustments in topology until the specifications for gain, input reflection coefficient, and output reflection are satisfied. Also plot Γ_G and Γ_L versus frequency to verify amplifier stability.
6. Design the dc bias circuit. Lay out the elements of the complete amplifier and check realizability.

As a beginning point in an amplifier design, the circuit topologies may be designed with the assumption that S_{12} is zero. Later, an exact design procedure will be described that includes the topologies with terminations in the stable region.

Design Examples. Throughout this book we always address the issue that we have to separate the battery-operated handheld applications and the more stationary designs like those for base stations. In the case of the handheld or low-voltage applications, the dynamic range requirements are significantly less than the front-end of a base station requires.

NE68133 Matched Amplifier. We will first consider the design of a low-voltage, low-current, low-noise amplifier based on the NEC BJT NE68133. This device was chosen

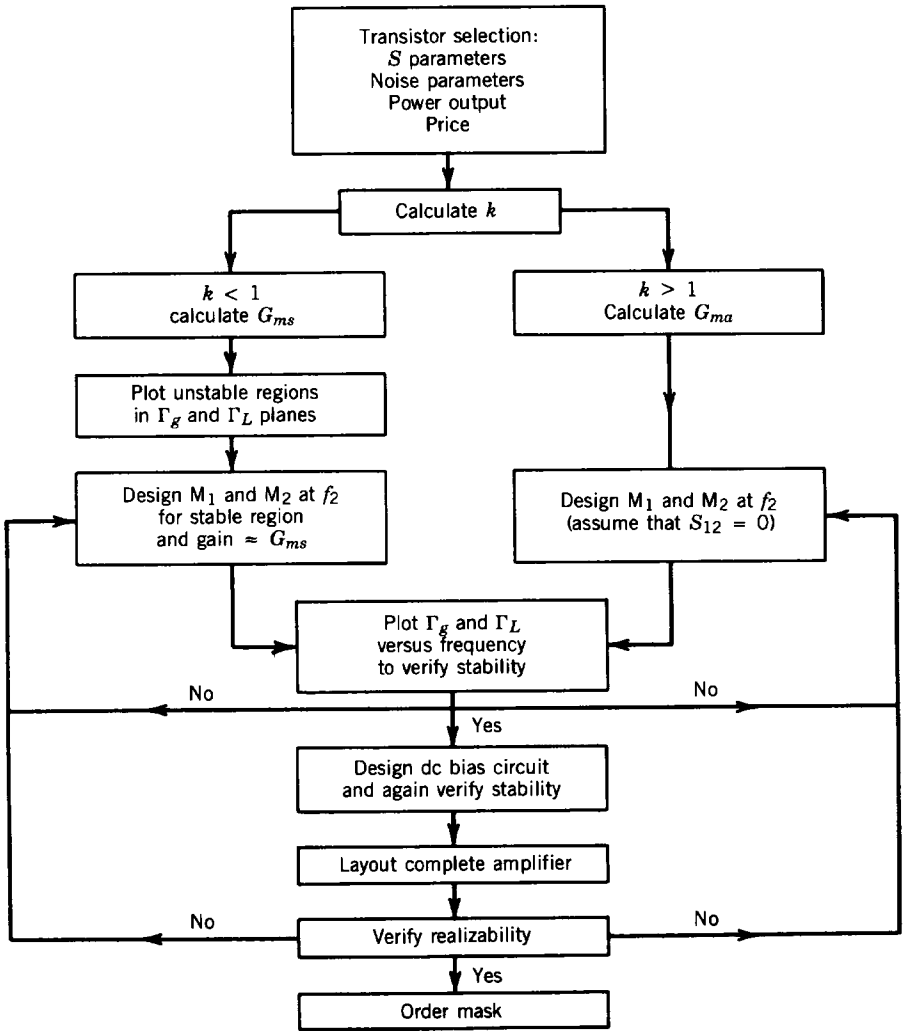

Figure 3-66 Simplified amplifier design procedure.

because it is unconditionally stable, has a minimum noise figure of about 1.2 dB at 7 mA, has 15.5 dB gain, and has an f_T of 8 GHz. While it is possible to start the design based on the published S and noise parameters, we will choose also to involve the nonlinear model, as this allows us more freedom in selecting the bias point including the collector voltage. The actual topology of the amplifier is shown in Figure 3-67.

Determining appropriate values for the input and output matching networks is essential to finalizing the design. The next several figures illustrate matching-network syntheses undertaken with the interactive Smith Tool in Ansoft's Serenade Design Environment. We evaluate the point of tangency as well as stability circles in the source and load planes, indicating that our impedance match will result in a stable amplifier.

In Figure 3-68, the center circle (with 1.1 marker) refers to the noise circle for which the noise figure of 1.1 dB can be obtained. The left circle (with the 14.3 marker) corresponds to

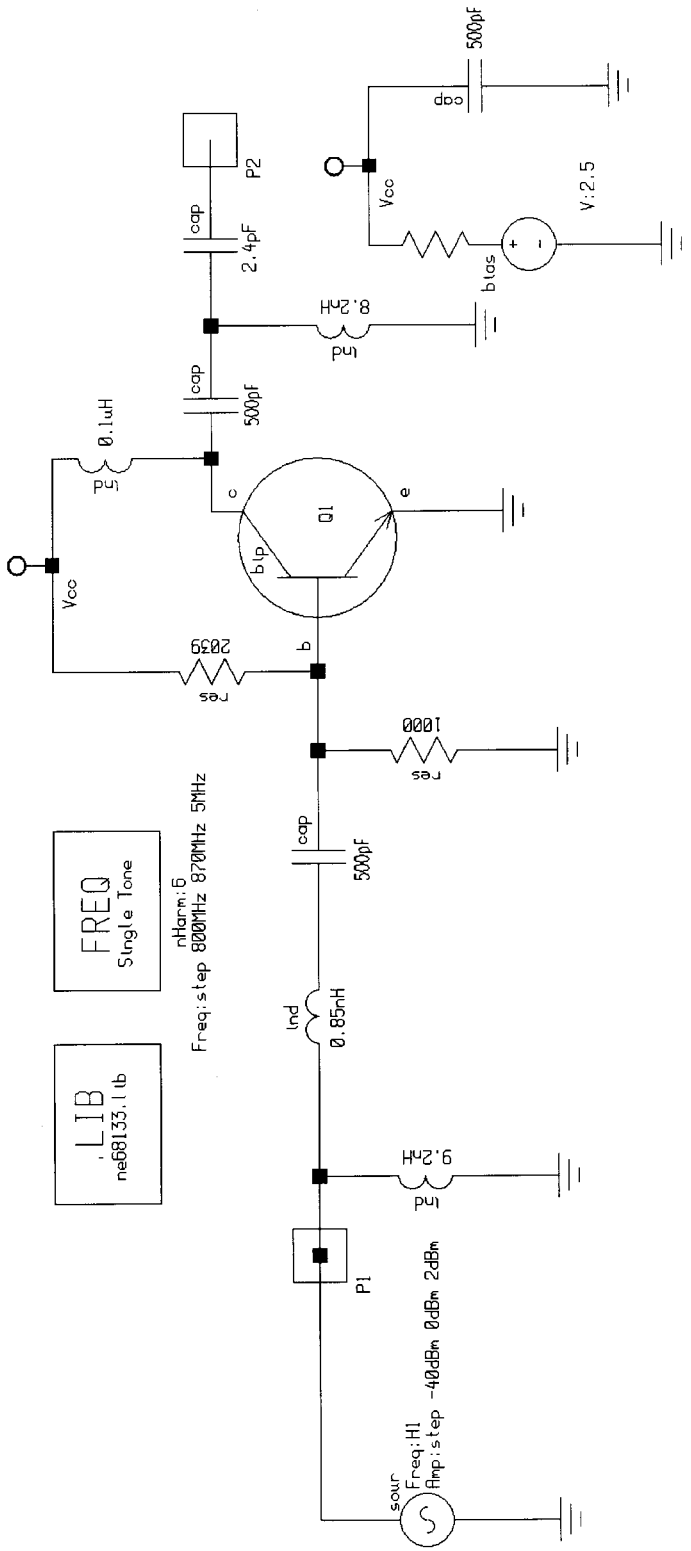

Figure 3-67 The NE68133 low-noise amplifier.

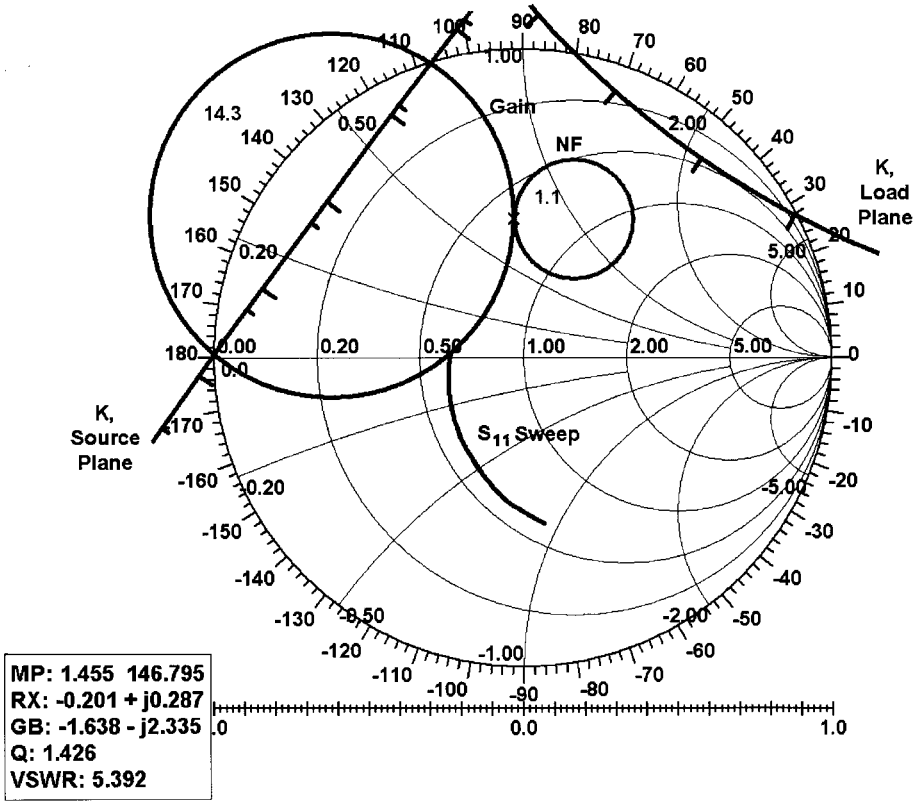

Figure 3-68 Display from the interactive Smith Tool, showing circles for gain, noise figure, and source- and load-plane stability, as well as a sweep of S_{11} versus frequency. In synthesizing an input matching circuit, we choose a single working frequency and work from the chart's origin to the point of tangency between the gain and noise figure circles. See Figure 3-69.

source-plane terminations that correspond to 14.3 dB of available gain. In order to get the required noise figure *and* gain, the input termination must be at the point of tangency of both circles. The arc touching the X axis close to 0.50 is the amplifier's S_{11} response from 800 to 875 MHz. The shallow arc that nearly bisects the 14.3-dB gain circle is actually a portion of the source-plane stability circle; the arc at the top right is a portion of the load-plane stability circle. Because we will be terminating the amplifier input with a value inside the source-plane stability circle, and terminating the amplifier output with a value outside the load-plane stability circle, the amplifier will be unconditionally stable at the frequency at which the match is obtained.

The next task is to obtain the values for the network circuit that matches the input for the 1.1-dB noise figure. A noise matching will not result in the best possible S_{11} matching (Figure 3-69). This translates into an inductor of 9.2 nH to ground and a series inductor of 0.85 nH based on the large-signal model of the NE68133 at the chosen bias point.

After we have determined our input matching network, it is time to find the output matching (Figure 3-70). First, find the termination point on the output plane that corresponds to 14.3-dB gain and 1.1-dB NF at the input plane. The output gain circle goes through the

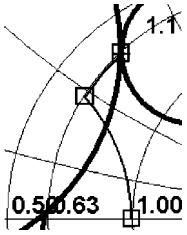

Figure 3-69 Input matching-network extraction, assuming lossless matching components and no parasitic effects.

1.1-dB NF circle at two points, and for reasons of easy matching we selected the lower point. The next step is to find the conjugate reflection coefficient $\Gamma_L = S_{22}^*$. This is the lower square marker in Figure 3-70. The remaining task is to find the matching network that brings this value to 50 Ω. By doing so, we first obtain a shunt inductance $L_{\text{shunt}} = 8.2$ nH and a series capacitor $C_{\text{series}} = 2.4$ pF. Again, these are the values applicable to the large-signal equivalent circuit.

The careful reader will have noticed that we have been avoiding the issue of small-signal exact matching using the manufacturer-supplied parameters. If this is done, the narrow band response shown in Figure 3-71 will be obtained. Therefore, we must optimize the circuit for a better frequency response to obtain the one shown in Figure 3-72.

After this optimization, we were well able to meet the specification of a center band gain of 14 dB and a corresponding NF of 1.1 dB. To show the flatness of the gain, Figure 3-73 shows a gain variation in the range of 0.25 dB.

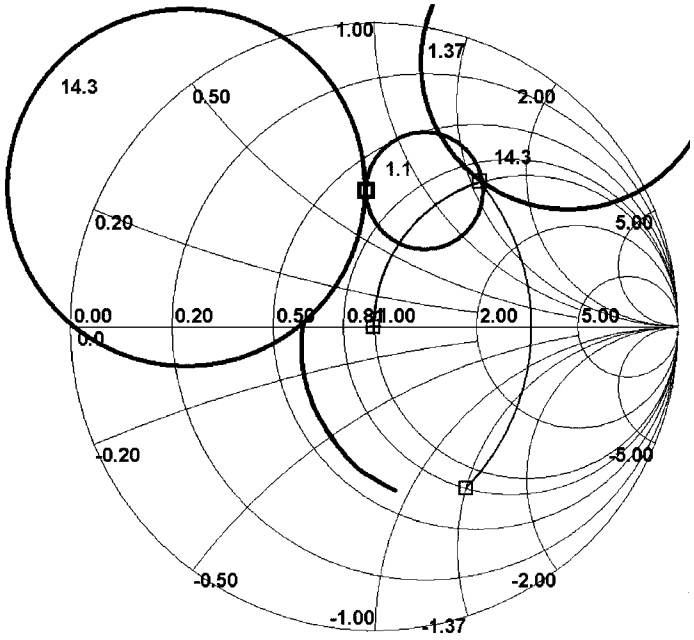

Figure 3-70 Output matching-network extraction.

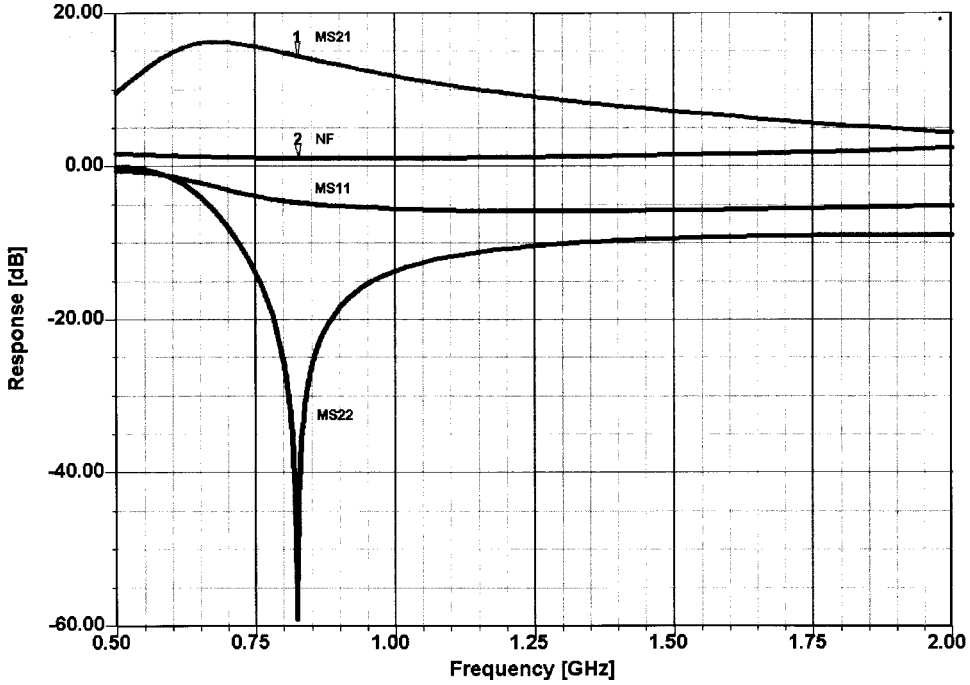

Figure 3-71 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-67.

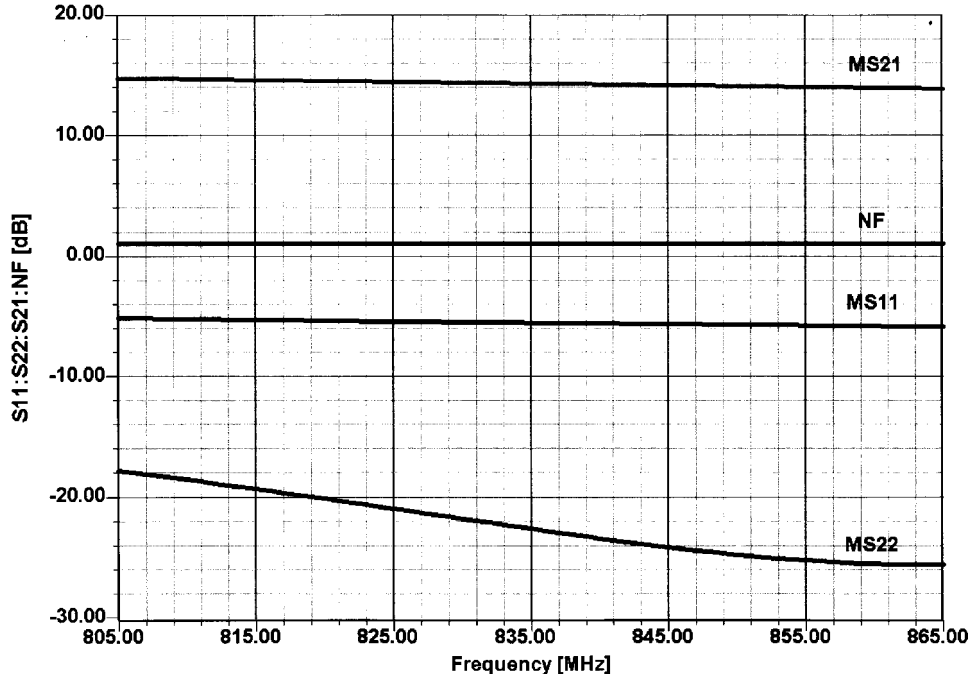

Figure 3-72 Optimized performance of input/output reflection, gain, and noise figure.

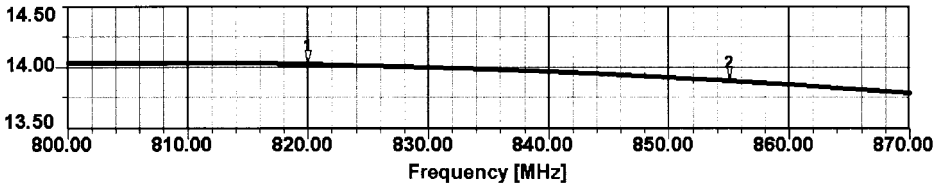

Figure 3-73 High-resolution display of gain as a function of frequency.

The next step is to look into the large-signal performance. The first order of business is to determine the third-order intercept point, which is based on a two-tone analysis. Given the fact that we run the device at low voltage and at a just-reasonable current, the actual intercept point of +13.5 dBm is quite a good number. Figure 3-74 shows the fundamental and third-order outputs. The crossover point between the two, as shown in Chapter 1, is defined as the third-order intercept point. If we had chosen the third harmonic output rather than the fundamental, we would have shown the fifth-order intercept point. The second-order IMD product ($f_1 \pm f_2$) typically can be minimized by input selectivity.

How an amplifier's linearity affects its ability to preserve the characteristics of digital signals is a major concern in wireless design. Figures 3-75 and 3-76 show constellation diagrams with the amplifier handling a PSK signal at drive levels of –40 dBm and +10 dBm, respectively. As expected, we see significant distortion at the higher drive levels due to circuit nonlinearities.

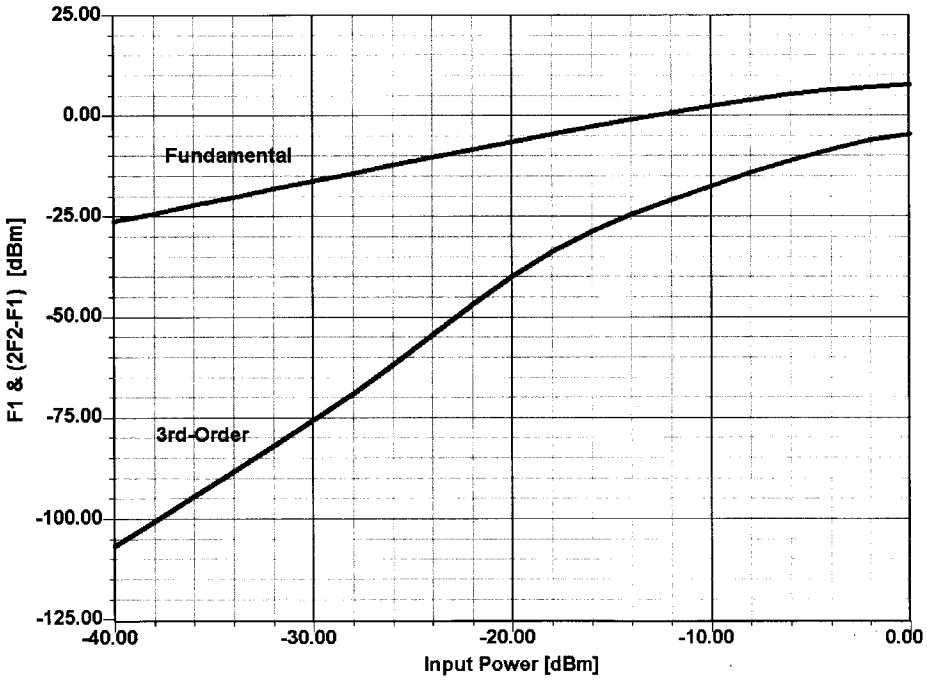

Figure 3-74 Simulated fundamental and third-order IMD outputs of the NE68133 amplifier.

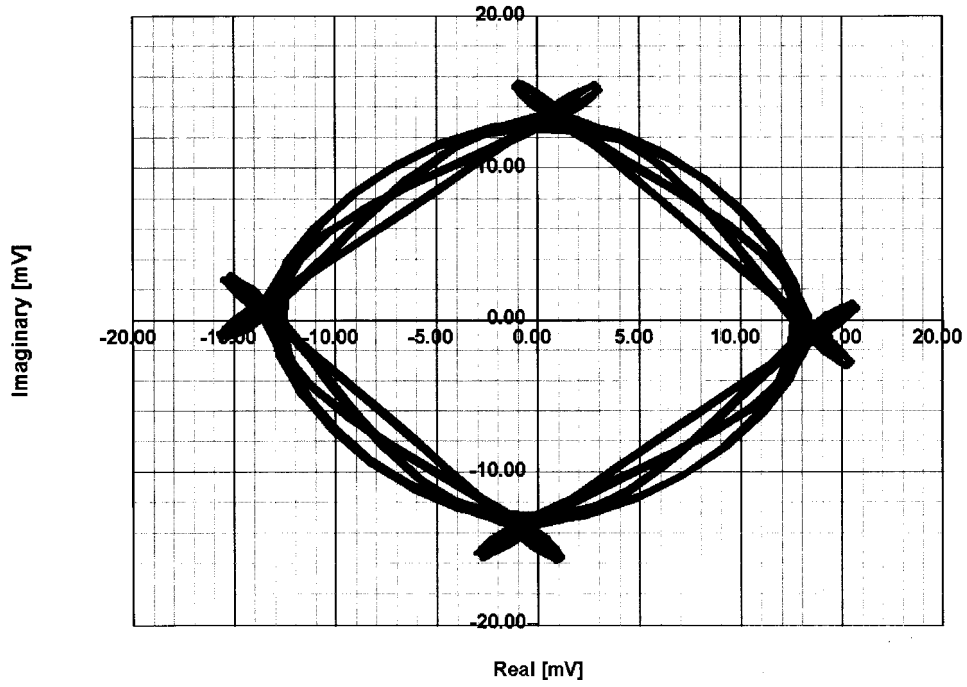

Figure 3-75 Output constellation at –40-dBm input.

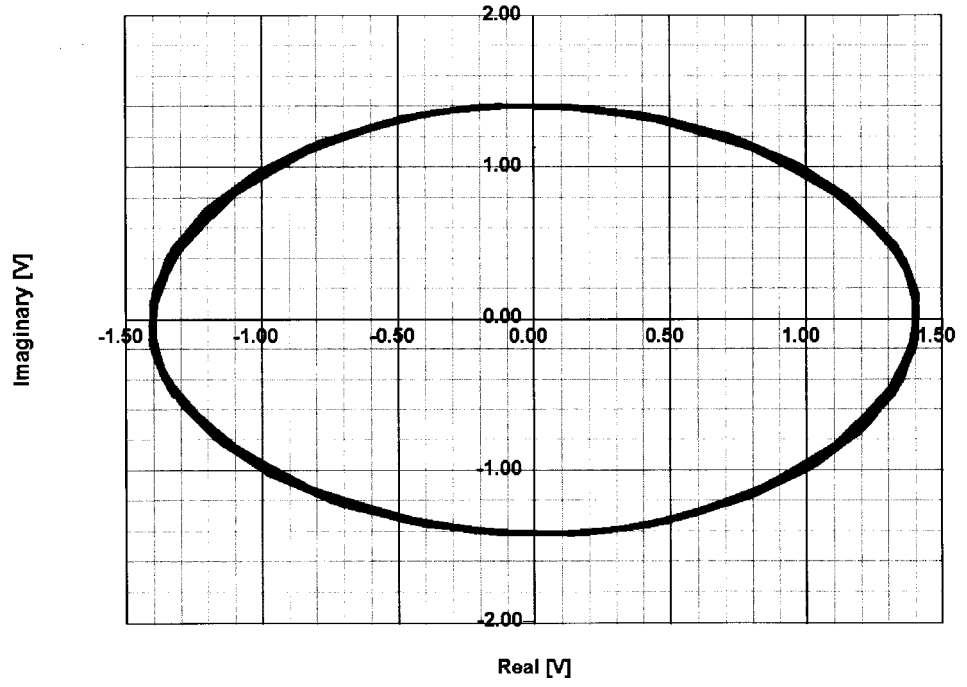

Figure 3-76 Output constellation at 10-dBm input.

BFP420 Matched Amplifier. The NE68133 has an attractive f_T of 8 GHz, but if more gain is needed, one may play with the concept of using a much "hotter" device, such as the BFP420. Recall that the NEC device was unconditionally stable, and our first worry is how the Siemens BFP420 will behave.

A study of Figure 3-77 shows that indeed the NEC device had to be stable all over and therefore was a good basis for a risk-free design. Things change dramatically with the BFP420, for which the K factor is essentially less than 1 up to a corner frequency of 2.75 GHz, where the transistor becomes unconditionally stable. Around 1.75 GHz, the K factor for the NEC transistor barely touches 1. We explained earlier that $G_{\max}$ deviating from the maximum stable gain is a more realistic number, since the conditions for maximum stable gain involve feedback and conjugate matching.

To improve the stability of the BFP420, we will now set out to use the same topology as the previous amplifier but with a resistive feedback between base and collector (Figure 3-78). A good value for this is always somewhere around 200–500 Ω. It must be remembered that this voltage feedback also stabilizes the input and output impedance and reduces the Miller effect because of the feedback being resistive and more dominant.

While the first example covered a fairly narrow frequency band, we are now attempting to cover a much wider frequency range; specifically, from 1.5 to 3 GHz reasonable gain and noise. This, by definition, requires a much higher gain-bandwidth product, and the simple matching network at the input and output provides a nonoptimal input and output matching (Figure 3-79). The feedback introduces some additional noise. This application shows the limits of single-stage UHF/SHF amplifiers with feedback.

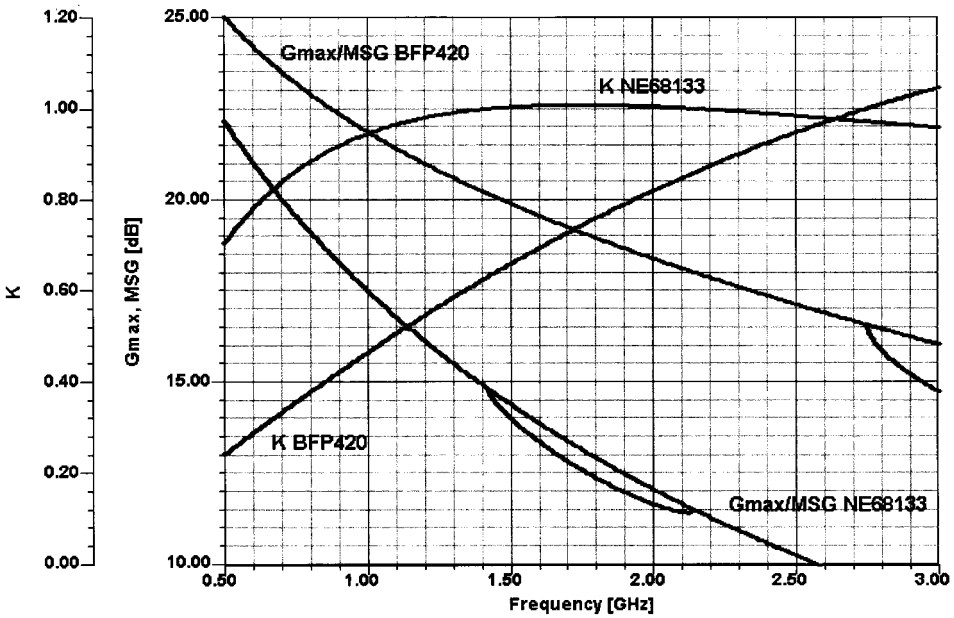

Figure 3-77 Comparison of K, $G_{\max}$, and maximum stable gain (MSG) for the NE68133 and BPF420 BJTs.

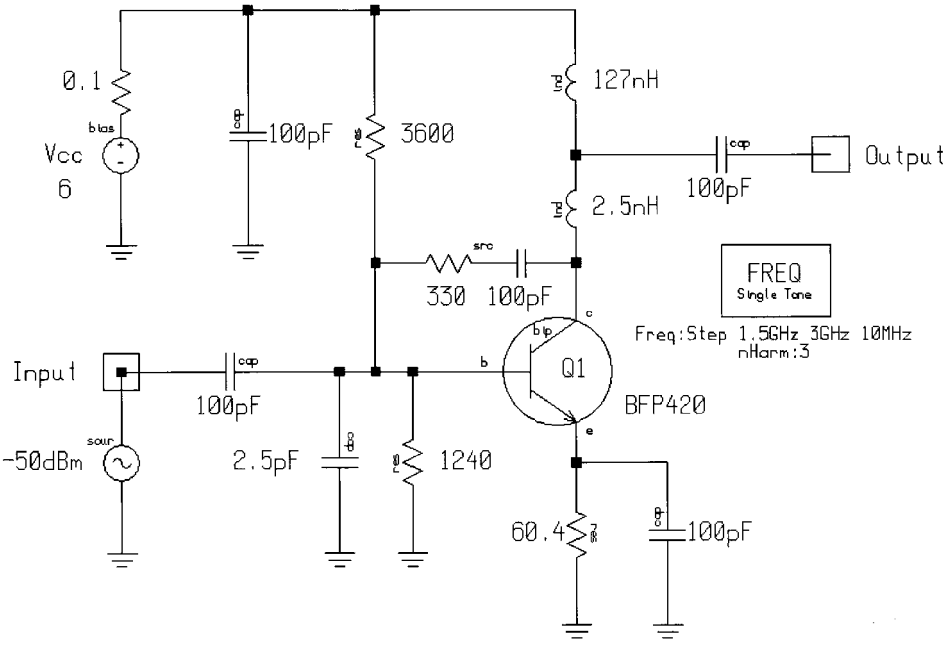

Figure 3-78 BFP420 amplifier with resistive voltage feedback from collector to base.

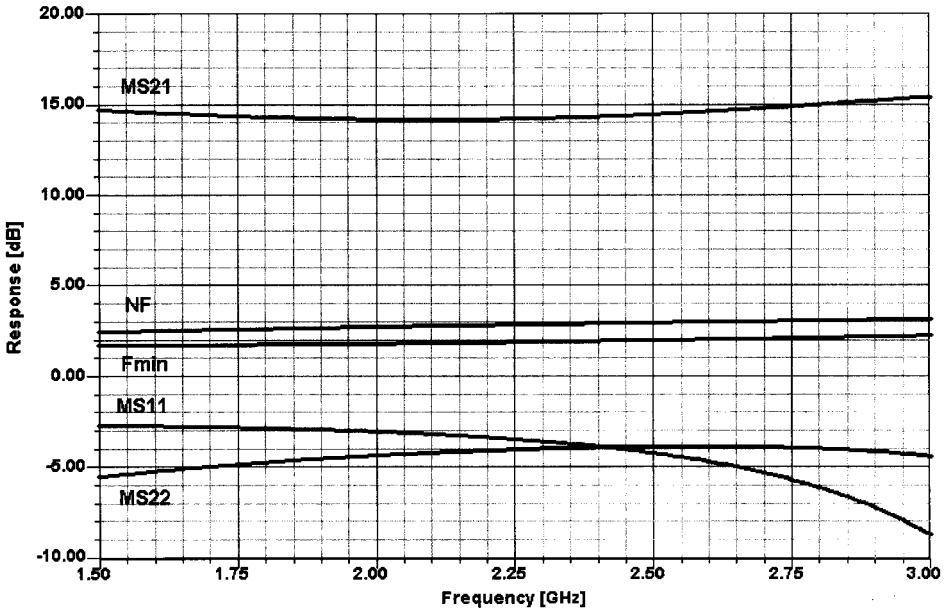

Figure 3-79 Frequency-dependent gain, matching, and noise performance of the BFP420 feedback amplifier.

Narrowband BFP420 Amplifier. Our next attempt will be to design a narrowband input stage that combines very high selectivity with good noise figure. This can only be achieved by using two tuned single-stage resonators with capacitive/magnetic coupling. The following amplifier is tailored to have a center frequency of 900 MHz. The transistor will operate at 12 V/10 mA to have a sufficient dynamic range. The input selectivity is achieved by the use of two top-coupled tuned circuits, followed by a BFP420 (Figure 3-80). The first order of business is to determine the input tuned circuit. The tuning capacitance for the two tuned circuits is arbitrarily set to a manageable 2 pF (small values have too much tolerances and larger values will require smaller inductances, resulting in lower Q). The reactance of the first tuned circuit is

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi \times 9\text{E}8 \times 2\text{E}{-}12} = 88.42\ \Omega$$

The necessary inductance for resonance will be

$$\omega L = 88.42$$

or

$$L = 88.42/\omega = 88.42/(2\pi \times 9\text{E}8) = 15.64\ \text{nH}$$

We will make both tuned circuits identical, but with different loaded Qs. By multiplying 88.42 times the loaded Q (20 for the input resonator and 50 for the output resonator), the resulting parallel-resonant resistance is $88.42 \times 20 = 1768\ \Omega$ at 900 MHz (for the input resonator) and $88.42 \times 50 = 4421\ \Omega$ (for the output resonator). These values are achieved by loading the input with the 50-Ω source and by loading the output with the input of the transistor. Therefore, the input transformation ratio $m_1 = 1768.4/50 = 35.37$. At the output, the equivalent number $m_2 = 4421/50 = 88.42$. For the purpose of simulation, and because it is extremely difficult to find the physical location of the appropriate tap on an air-wound coil for the necessary impedance, we do this "on paper" by incorporating an ideal transformer. We are also going to show later the actual transmission-line-based filter and its modeling. This filter will have a higher insertion loss based on the PC-board material used.

Using our nonlinear simulator, in small-signal ac mode, we obtain the frequency response and noise figure shown in Figure 3-81. In actually building this circuit, there is another problem besides these transformers—the top-coupling capacitor. We have used a grounded-T configuration to obtain a practically realizable value of 36 pF, whose lead inductance will not influence the circuit. (The actual coupling capacitance value for top coupling without the T configuration would have 0.1 pF. We would like to see this value repeatably realized.)

If the actual noise would be calculated relative to the output tuned circuit, the equivalent noise resistor R_n of 5 Ω would now be multiplied by m_2, resulting in 442 Ω. Fortunately, the Serenade simulator has a highly accurate BJT noise model that is both bias and temperature dependent, so the simulator will give us the answer directly.

We have not put any matching circuit at the output and leave this task to the reader. In practice, the slight tilt in the MS_{21} curve in Figure 3-81 would be tuned out. Also note that the minimum noise figure ($F_{\min}$) and the actual 50-Ω noise figure (NF) agree somewhat off center. This has to do with the Miller effect, which results in the well-known difference between noise matching and input-gain matching. By varying the coupling capacitor to move from the overcoupled response, which gives a low noise figure, to a critically coupled

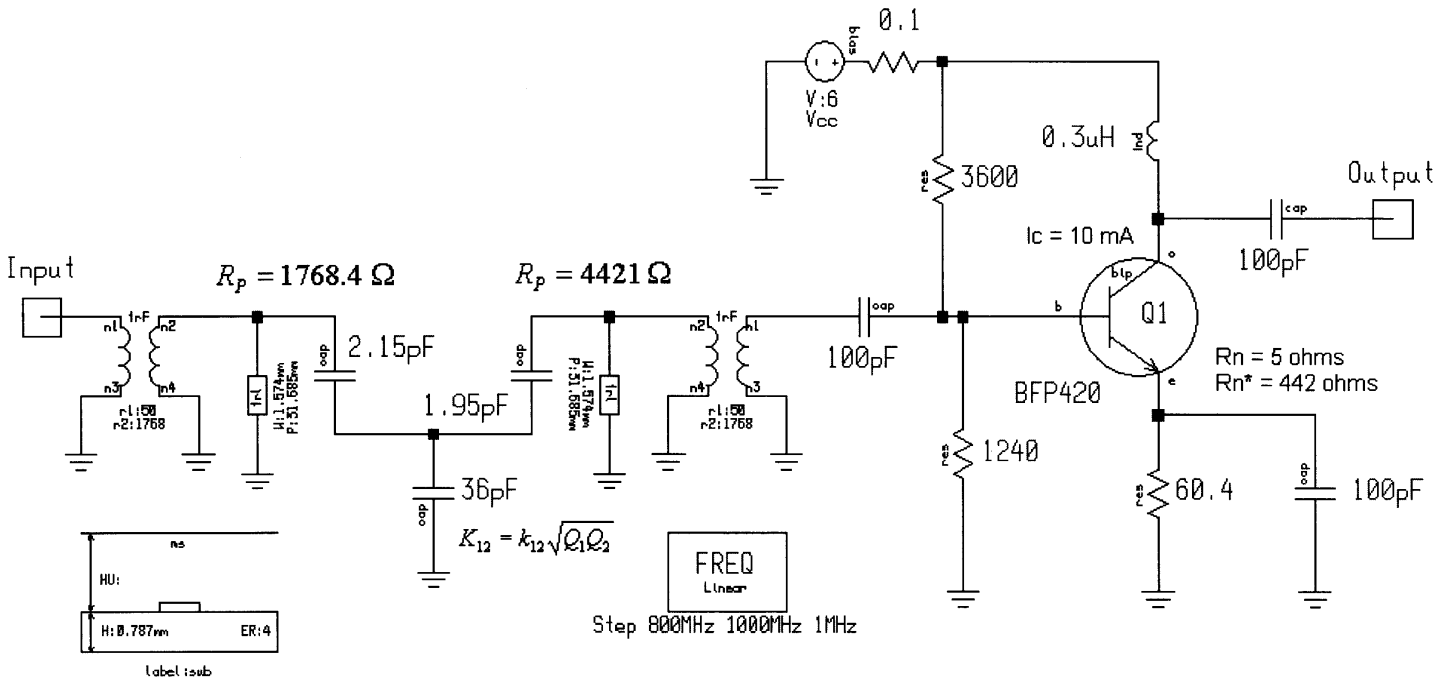

Figure 3-80 BFP420 amplifier with narrowband input filtering. Ideal transformers are used to match the filter's input and output to the input port and the BFP420 base, respectively.

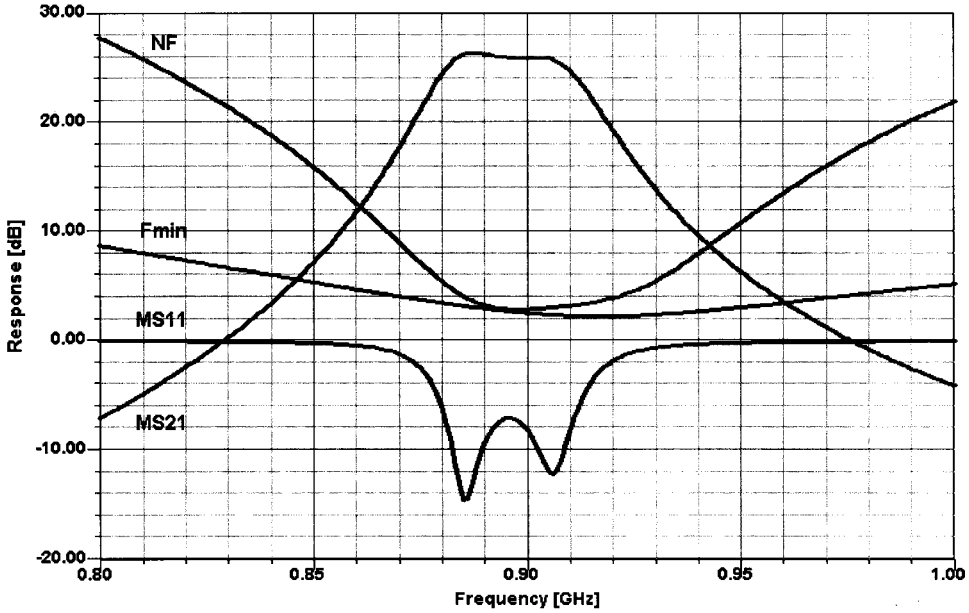

Figure 3-81 Frequency-dependent gain, matching, and noise performance of the narrowband BFP420 amplifier.

response ($K = 1$), we get significantly better selectivity and narrow bandwidth (at the obvious expense of the noise figure) as shown in Figure 3-82.

Since we somewhat compromised by not providing the reader with an actual input and output coupling that can be built, and furthermore, because the inductance in question (15.26 nH) is hard to realize with a high Q, we now show the printed circuit approach for the input filter. By using a Teflon-based material for the PC board, the losses would be less; however, the radiation would be more because ε would go down to 2.1 from the value we used (4). It is also convenient to introduce this filter to show that at higher frequencies, where lumped elements are really no longer available, one has to switch to distributed elements. A list of the commonly used distributed elements will be shown later; the transmission line and T junction are probably the most frequently used elements, followed by spiral and rectangular inductors, and bends.

The actual implementation of the input filter on a printed circuit board requires distributed elements (Figure 3-83). In practice, one has two parallel coupled lines with a tap somewhere toward the ground connection and, for modeling accuracy, we have to introduce a T junction with the appropriate impedance of 50 Ω for the input and a different impedance (if necessary) for the output. The coupling mechanism now is magnetic coupling, since no one can physically change the distance between the transmission lines by tuning some mechanical elements, one has to get it right the first time. This can only be achieved with a high-precision simulator. The reason why these simulators are so expensive is the investment of research time and personnel to produce valid models over a huge frequency and impedance range. Since we are now curious about the frequency response, we have plotted in Figure 3-84 the frequency response, which shows a higher (expected) insertion loss. The PC-board material is partially responsible for this.

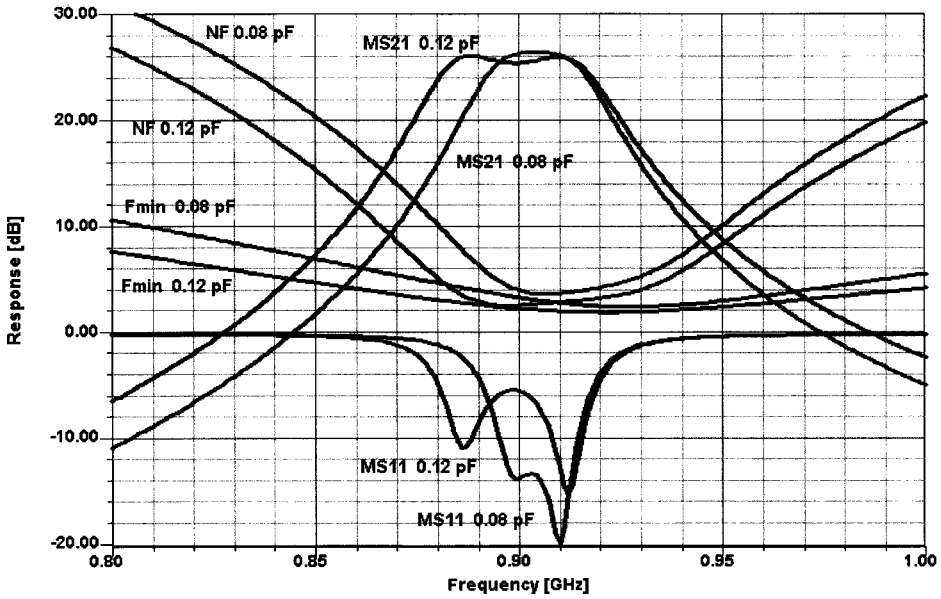

Figure 3-82 Comparison of filter responses with critical coupling (0.08-pF response) and overcoupling (0.12-pF response).

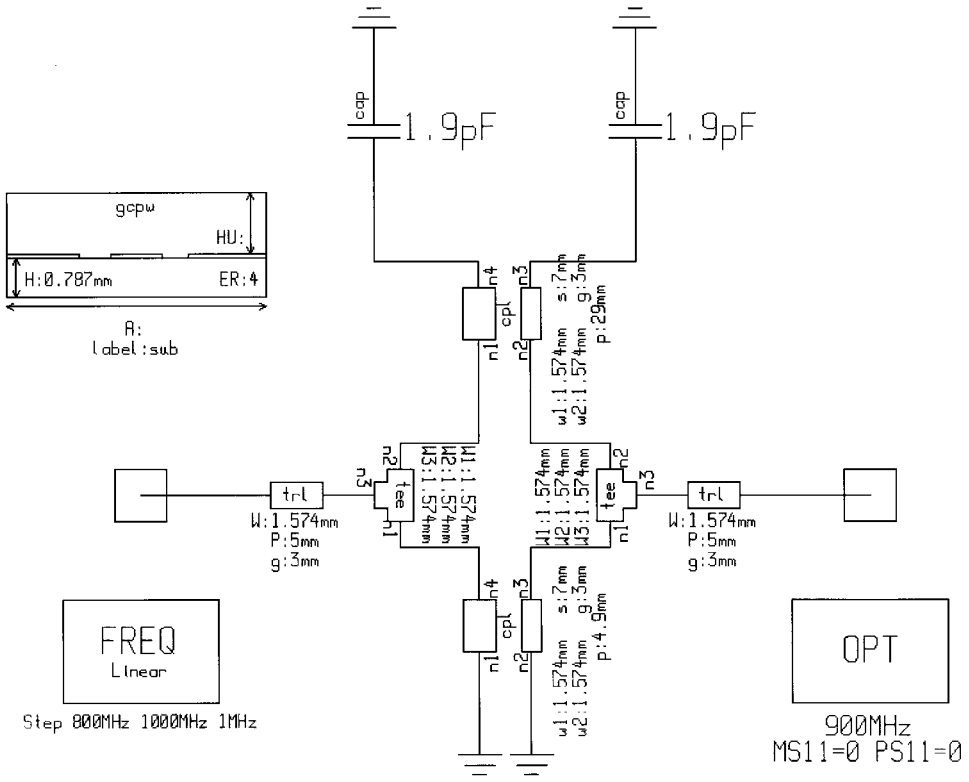

Figure 3-83 Input filter using distributed-element resonators and matching.

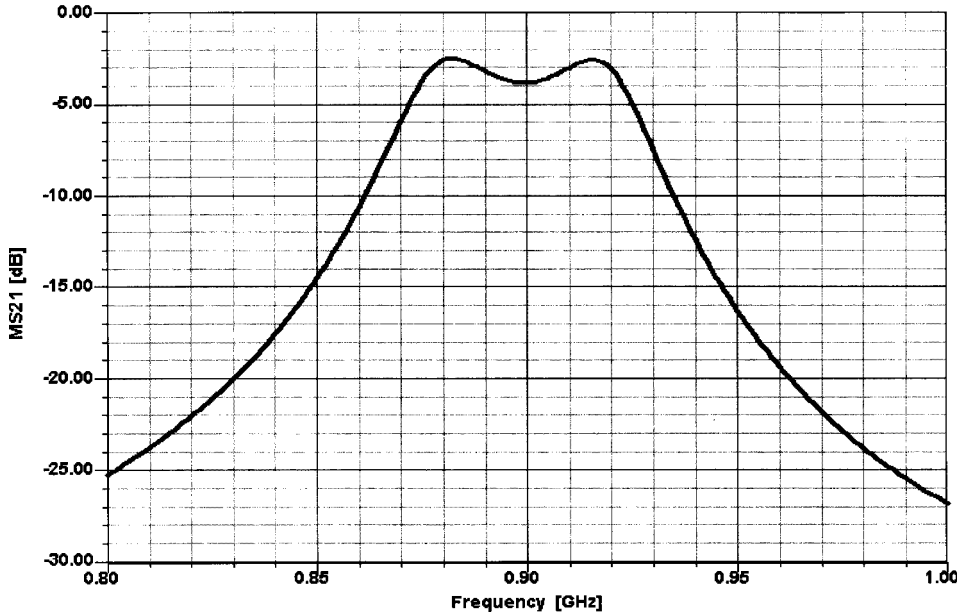

Figure 3-84 Gain versus frequency response for the distributed-element filter.

At the end of this chapter we will have a chance to discuss passive elements as needed for microwave frequencies, and one should consider frequencies above 1500 MHz as microwave frequencies.

GaAsFET Feedback Amplifier. The implementations we have shown so far have been based on bipolar transistors. Figure 3-85 shows a single-stage feedback amplifier using a GaAsFET. The feedback is based around an *LRC* network and some attempts at matching at the input and output are made. Figure 3-86 shows its frequency-dependent gain, matching, and noise performance.

3-2-3 High-Gain Amplifiers

In most cases, high-gain amplifiers receive an already amplified signal, which means we are less concerned about the signal-to-noise ratio but remain concerned about distortion. To reduce distortion, we have two options: (1) increase the dc current in the active device, which always improves the current-related distortion; and (2) add some voltage feedback, which reduces the voltage distortion. In simple terms again, only current feedback can reduce the current-related distortion of a square-law or exponential transfer characteristic and only voltage feedback can reduce the effect of overdrive as a function of the load, but only to some degree. Its main purpose remains to reduce the input impedance to useful values, specifically for FETs, since current feedback increases the input and output impedances. Some ultrasensitive circuits still require Class A operation, but now at higher current levels; these are typically CATV applications, and there are several transistors available that can be operated at 5–15 V but at 60 mA or higher. Because of the higher power consumption, this excludes handheld cordless or cellular telephones. The same circuit as used before (Figure 3-85) for

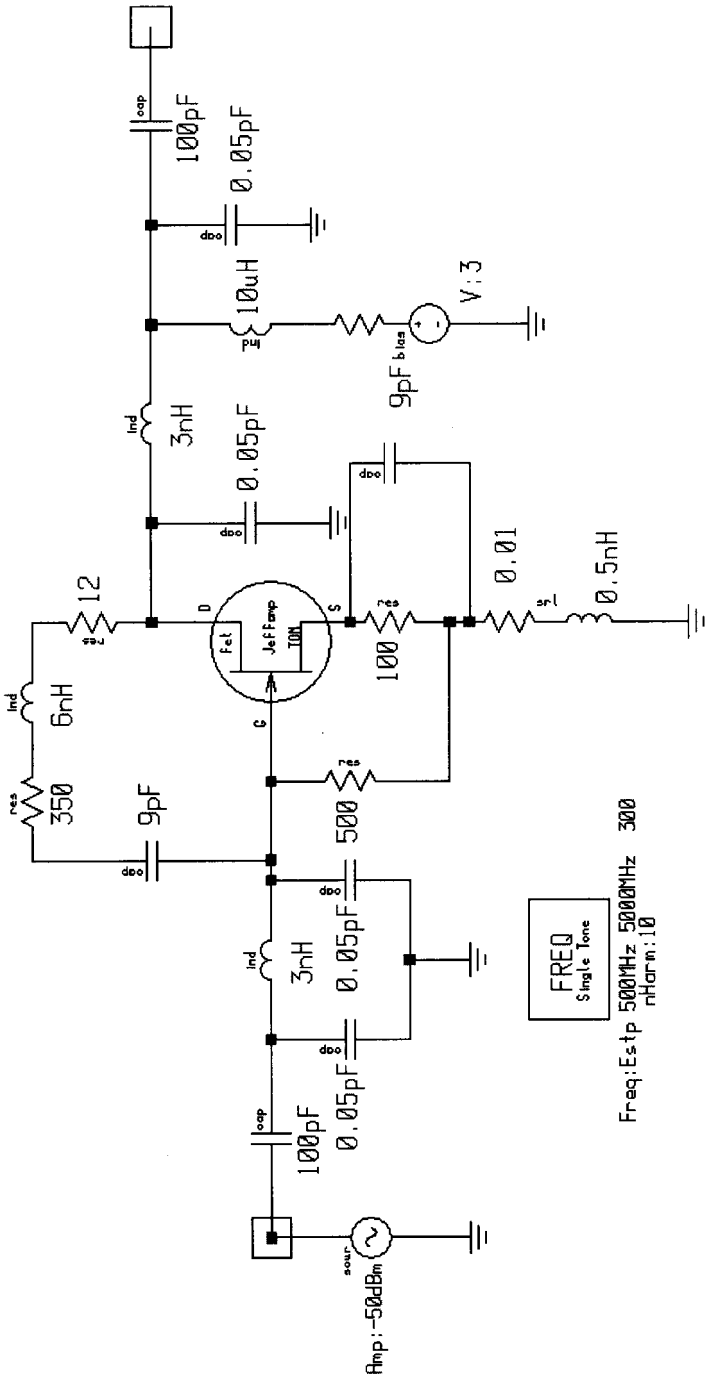

Figure 3-85 GaAsFET feedback amplifier.

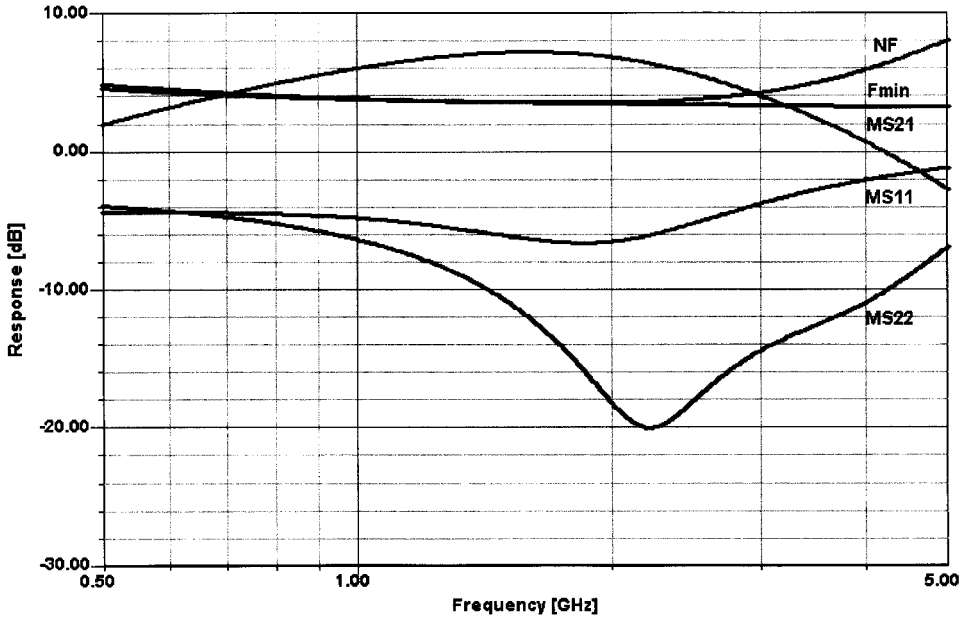

Figure 3-86 Frequency-dependent gain, matching, and noise responses for the GaAsFET amplifier.

Class A operation now can be operated at a higher current, which automatically increases the gain and the noise figure and reduces distortion. This is based on the fact that the transconductance (g_m) increases at higher currents. The second transistor in the TI circuit achieves this by being in reality a larger device, which could be modeled by several transistors, like the first stage, in parallel. This automatically increases the dc current by the scaling factor. The same is even more true for the output stage. Likewise, bipolar transistors can also be scaled. A visual inspection of some transistors in their packages will reveal that they are really not just one transistor, but several operating in parallel, each with its own ballast resistors (for bipolar transistors) or other means (for FETs).

Using tuned circuits rather than wideband matching, it is possible to go to Class AB or B operation. Class AB is really a hybrid between A and B, and Class B is probably better known. Figure 3-63 shows the Class B operating point. Most Class B stages are operated in push–pull because, together with the tuned circuit, one-half of the cycle is supplied by the other transistor. The definition of Class B operation is a conducting angle of 90° (see Figure 3-63). At this point it should be noted that some older texts define the conducting angle as being twice the value we have defined in this chapter.

Without going into further details, the highest efficiency in Class B operation is 78.5%. Based on the fact that modern wireless applications generally use a hybrid of amplitude and angle modulation, pure Class C operation finds little application today because of the severe nonlinear distortion it introduces. A Class B stage has less "power gain" than a Class A stage but provides much more output power. We have already mentioned the problem associated with characterizing a Class A stage in terms of power gain. That's the only time Kirchhoff's equations are valid, meaning that the sums of all currents and voltages have to be zero. Because Kirchhoff's equations do not consider nonlinearities and harmonic contributions,

the very moment we move into considering medium- and higher-power amplifiers, the nonlinearities will dominate and the performance of the stage is best analyzed with a high-quality circuit simulator with the appropriate dynamic range and good modeling capability. Without question, this applies to Class C operation also. As pointed out previously, the high-gain amplifier is optimized for gain rather than noise figure and typically requires more collector or drain current. This can easily be seen by rebiasing the FET amplifier as shown above to a significantly higher value of 33 mA. This is accomplished by changing the source resistor down to 3 Ω. As a result of this, we obtain the gain, matching, and noise figure responses shown in Figure 3-87.

It may be a surprise to the reader that the actual noise figure now is less than that shown in Figure 3-86. This device is now operating at 33 mA; the reason for this has to do with the fact that if the transconductance is too low, the noise figure also increases, and the NF curve for the FET has a similar-looking current-dependent minimum—a curve that is frequently not supplied by the manufacturer. This amplifier, now operating at 33 mA, should have quite good large-signal capabilities; we will examine this shortly.

Another interesting piece of information is the display of the dc I–V curves with the "load line." Since we have reactances in the circuit, we do not see a line but rather an ellipse, indicating the storage of energy. (The actual load line would be a line through the two foci of the ellipse.) This curve allows us to see immediately that at this operating point the transistor is neither going into current saturation nor becoming voltage limiting. The input power can be increased further until such a condition exists. Figure 3-88 shows the dc I–V curve for the amplifier shown in Figure 3-85.

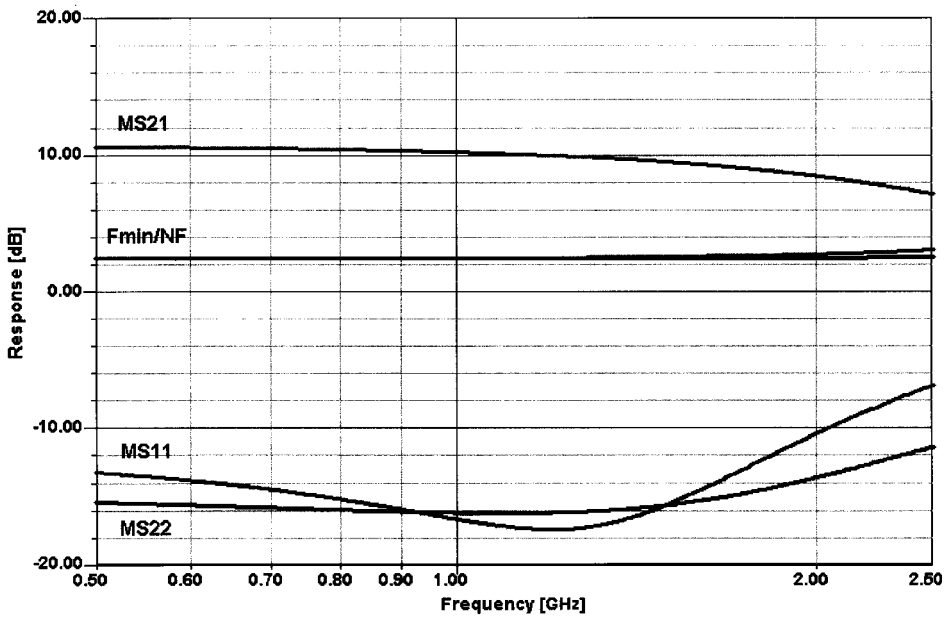

Figure 3-87 Frequency-dependent gain, matching, and noise performance for the GaAsFET amplifier of Figure 3-85 rebiased for a drain current of 33 mA.

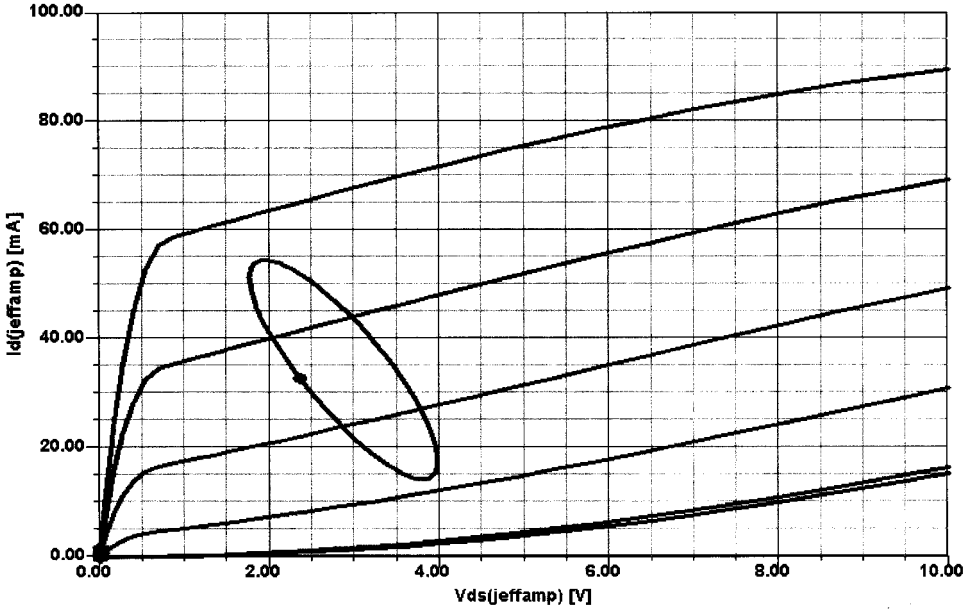

Figure 3-88 The dc *I–V* curves for the GaAsFET operating at I_D = 33 mA, including the ac load line. The load line is an ellipse rather than a straight line for the reason described in the text.

Besides looking for the adjacent-channel power ratio (ACPR), the other traditionally important points are third-order intercept point and the equivalent of a multitone simulation, as used for CATV application but relevant to the multisignal environment of wireless applications. Figure 3-89 shows the determination of the amplifier's third-order intercept point. It is most important for the reader to understand that very low values for input and output level have to be used to determine the crossover point. If this advice is not followed, totally erroneous numbers can occur.

Since an antenna supplies a large number of signals (this is true of handheld radios as well as base-station sites), a three-tone standard has been adopted as a good approximation of multisignal operation. This standard is in accordance with the German DIN 45004E,3.3 three-tone measurement. The requirement is that the intermodulation distortion products at the output are better than 60 dB suppressed relative to the largest of the three tones. One tone is used as the reference, and the other two tones are 6 dB less. This measurement has been derived from television, whereby the video transmitter, based on the vestigial sideband power, is 6 dB above the two sidebands produced by the FM sound transmitter using a modulation index of 5. The result of a three-tone test can be seen in Figure 3-90. This amplifier clearly meets the DIN specification for linearity at input levels up to –9/–15 dBm at the input.

Bipolar transistors are also quite popular for this purpose. Figure 3-91 shows a single-stage amplifier with an intrinsic transistor and all the other "hidden" intrinsics, normally not visible, added. The three diodes belong to those intrinsic elements, which are needed for accurate microwave modeling but which are not provided by the standard nonlinear models. The reader will see that we went into great detail to model all the necessary parts. This feedback amplifier, whose frequency response is shown in Figure 3-92, has been quite

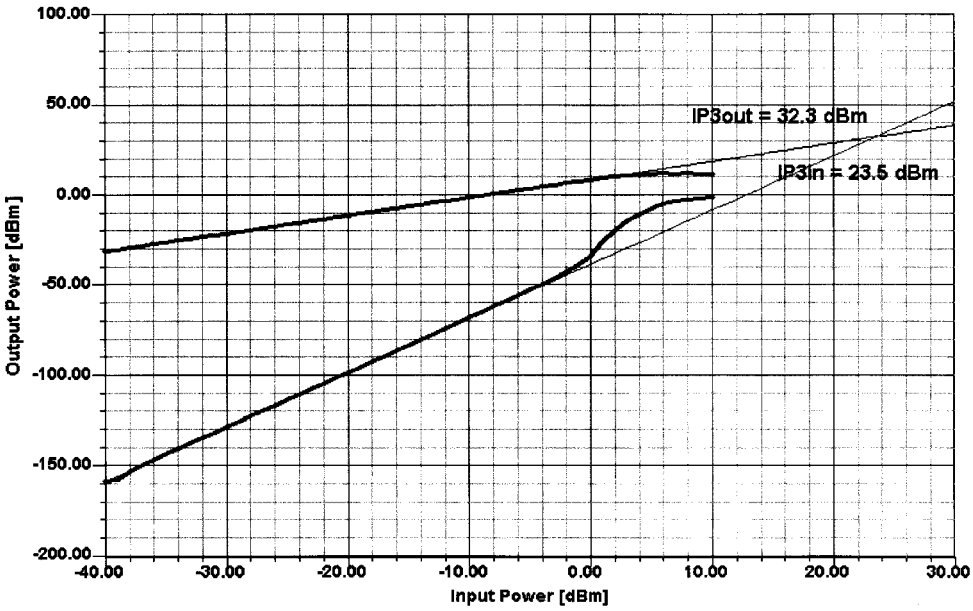

Figure 3-89 Determination of the third-order intercept point based on a two-tone measurement using tones spaced at 5% of the operating frequency (1.8 GHz).

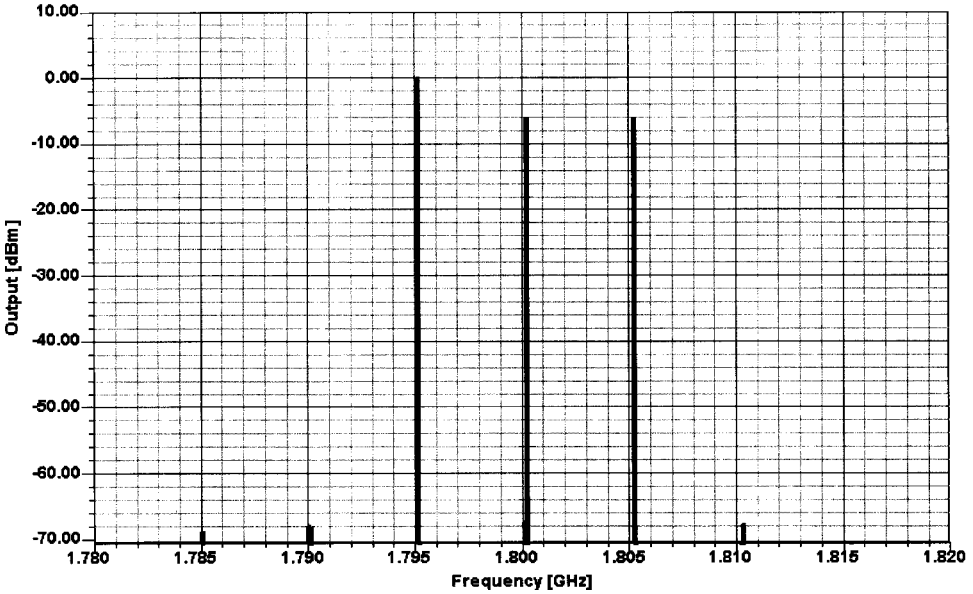

Figure 3-90 Simulated three-tone analysis of the GaAsFET amplifier with $I_D = 33$ mA.

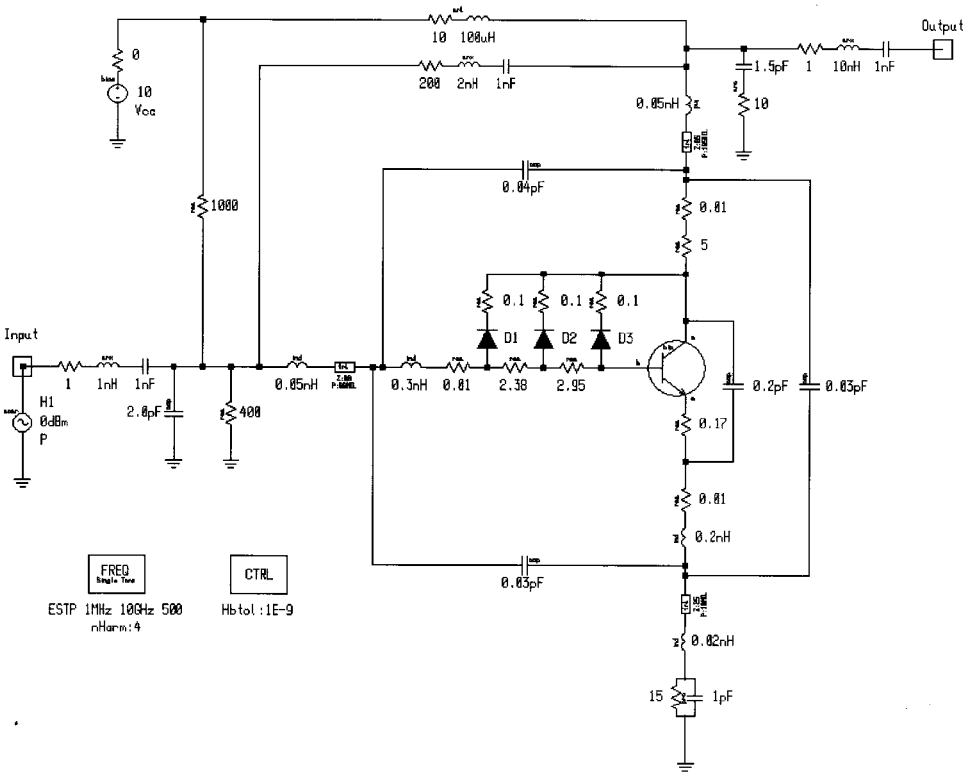

Figure 3-91 A high-linearity single-transistor amplifier modeled in great detail.

difficult to design, but there are monolithic circuits available where the higher gain–bandwidth product is being used to advantage.

Figure 3-92 shows the predicted frequency-dependent gain, matching, and noise figure at a bias point of 108 mA at 10 V. Using the same DIN three-tone test procedure, Figure 3-93 shows the expected good result.

Since this test requires two equal signals and one larger signal, we need to expect one IMD product larger than the rest. We have set our window for a dynamic range of 70 dB, and yes, in the lower left corner, we can see the product between the first two signals, while the other products are below the –50 dB level.

As a little task, Figure 3-94 shows a simple amplifier, based on a modern Siemens transistor, which is a feedback amplifier with fewer modeling details surrounding the transistor. Its associated frequency-dependent performance is shown in Figure 3-95. Interested readers are invited to improve its performance by using their skills and intuition.

Permitting higher currents and actually combining two transistors leads to our first MMIC. The following simulation is based on the MGA64135. Needless to say, there are some compensation networks inside the MMIC and distributed elements that affect the frequency response. However, with this arrangement, it is possible to obtain an appreciable gain at our wireless frequencies. The noise figure, based on the feedback, however, it not too impressive. This is a problem that occurs with most feedback amplifiers, which try to minimize the distortion and yet would like to keep the noise figure down. Figure 3-96 shows the schematic

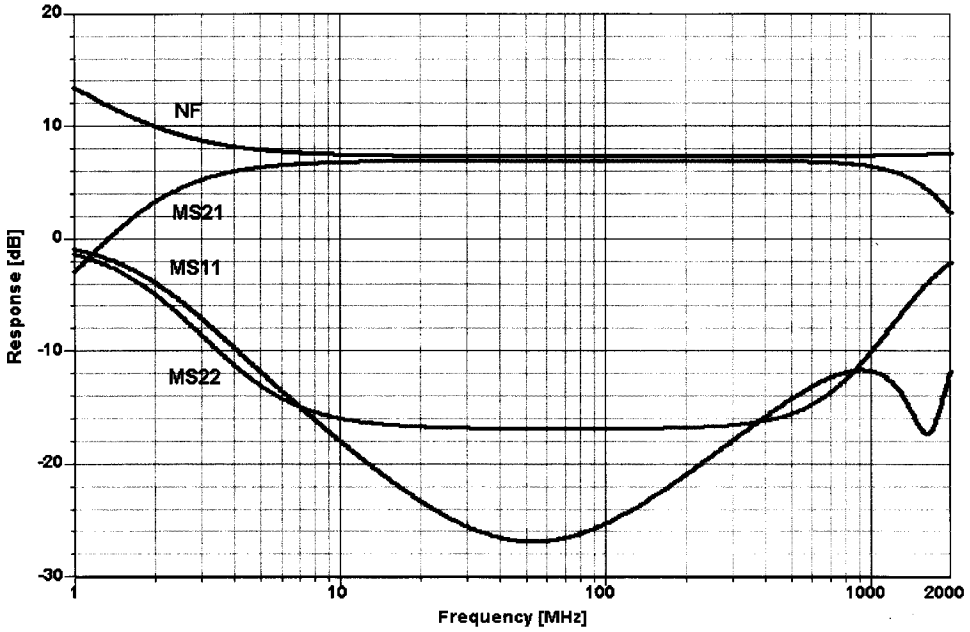

Figure 3-92 Simulated frequency-dependent gain, matching, and noise figure performance of the circuit in Figure 3-91.

of the GaAs MMIC; Figure 3-97 shows its frequency-dependent gain, matching, and noise performance; Figure 3-98 shows its two-tone response, which is used to obtain the intercept point ($IP_{3,in}$ = 8.5 dBm, $IP_{3,out}$ = 22 dBm); and, finally, Figure 3-99 shows the three-tone test results at an input RF level of –21/–27 dBm. While the gain–bandwidth product is considerably larger than the single-stage amplifier we examined before, the intercept point and three-tone performance do not reach the same values. As a general rule, the dynamic

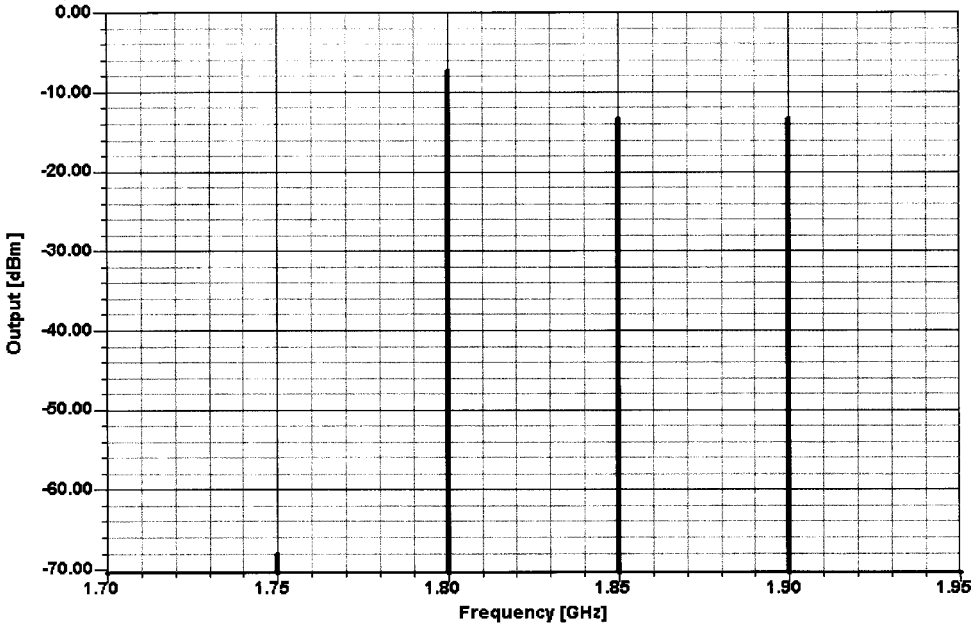

Figure 3-99 Simulated three-tone test of the MGA64135 MMIC. The test tones were 1.80 GHz (–21 dBm), 1.85 GHz (–27 dBm), and 1.90 GHz (–27 dBm). The 1.75-GHz IMD product is down 60.5 dB relative to the 1.80-GHz signal.

range is directly proportional to the power dissipated in the devices: specifically, the current. As explained earlier several times, the first-order nonlinearity comes from the voltage-to-current transfer characteristic, such as the transconductance itself, and can only be improved by a combination of resistive feedback in the emitter/source and by high currents. At these dc levels, the base–emitter (gate–source) junction gets linearized because the differential values are getting smaller compared to the parasitic loss resistances, including external dc/RF feedback. Once again, the voltage feedback reduces the voltage clipping but is initially more responsible for the input and output matching.

3-2-4 Low-Voltage Open-Collector Design [22–25]*

Why R_C Acts Like a Source Resistor. An open-collector output allows a designer the flexibility to choose the value of the R_C resistor. Choice of this resistor value not only sets the dc bias point of the device but also defines the source impedance value. Figure 3-100 shows the ac model of the transistor. Converting the output structure by applying a Norton and Thevenin transformation, one can conclude that R_C becomes the source resistance. Thus, by choosing R_C to be equal to the load, maximum power transfer will then occur.

Figure 3-101 shows an active transistor with collector and base resistors. From basic transistor theory, Eq. A in Figure 3-101 is generated and has the same form as the general equation for a straight line ($y = mx + b$).

Figure 3-101 Basic transistor analysis.

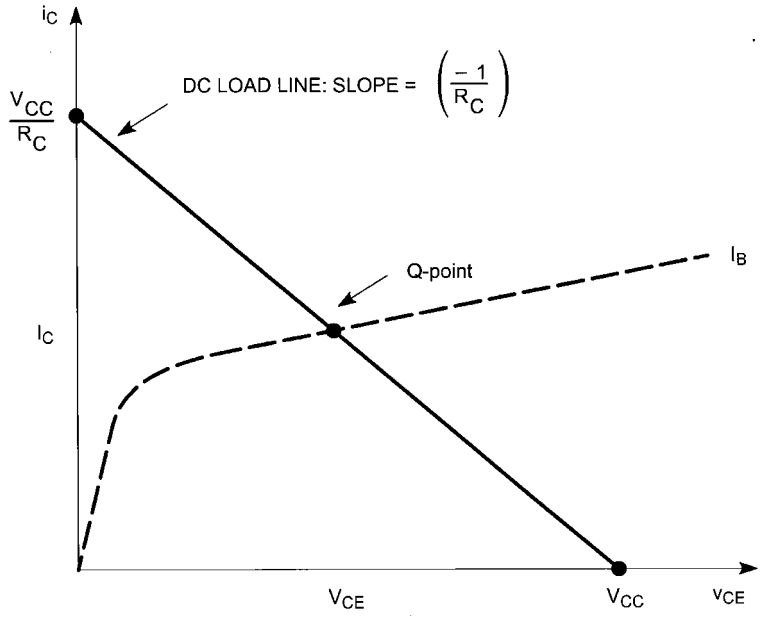

Figure 3-102 Load line and Q-point graph.

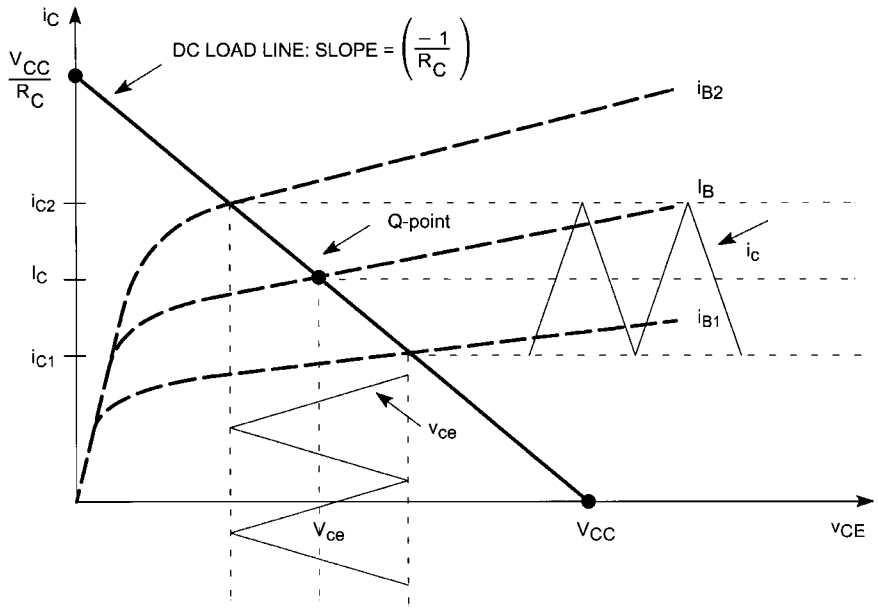

Figure 3-103 Graphical analysis for the circuitry in Figure 3-101.

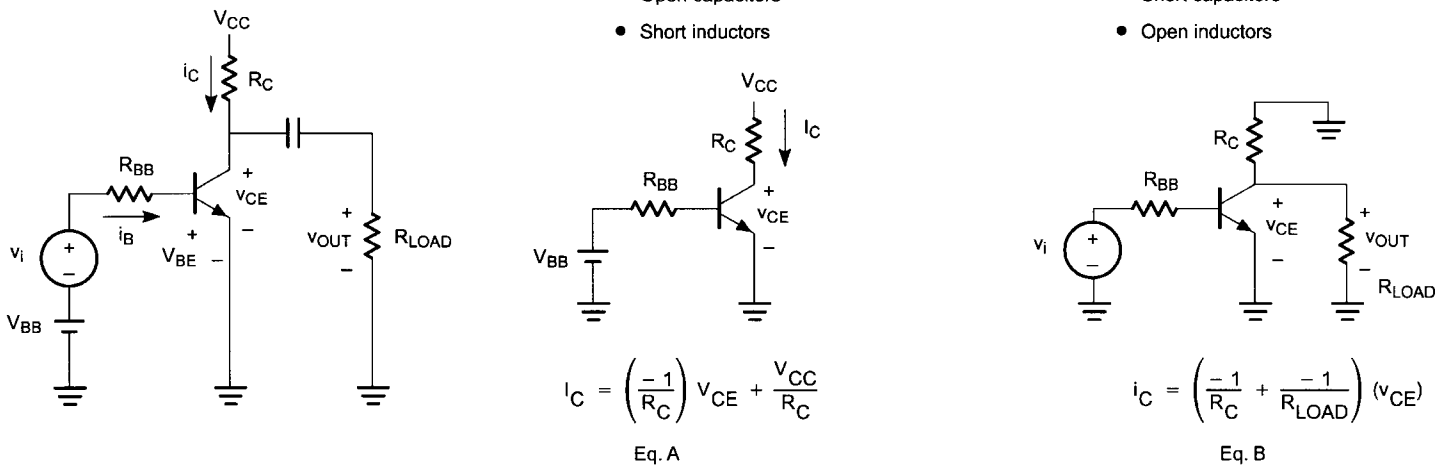

Figure 3-104 Basic transistor analysis with R_{LOAD}.

The slope of the dc load line is generated by the value of the collector resistor ($m = (1/R_C)$ and is shown in Figure 3-102. For a given small-signal base current, the collector current is shown by the dotted curve. The intersection of the dotted curve and the dc load line is called the *quiescent point* (Q-point) and dc bias determinant. The location of the Q-point is important because it determines whether the transistor is operated in the cutoff, active, or saturation region(s). In most cases, the Q-point should be in the active region because this is where the transistor acts like an amplifier.

Figure 3-103 shows the ac collector–emitter voltage (V_{CE}) output swing with respect to an ac collector current (I_C). Collector current is determined by the ac voltage presented to the input transistor's base (v_i) because it affects the base current (i_b), which then affects i_c. This is how v_i is amplified and seen at the output. Recall that this is with no external load (R_{LOAD}) present at the collector. Since no load is present, the slope of the ac load line is identical to that of the dc load line as seen in Eqs. A and B of Figure 3-101 ($m = -1/R_C$).

Open Collector with R_{LOAD}. A filter with some known input impedance is a typical load for the output of the transistor. For simplicity, we will assume a resistive load (R_{LOAD}) and neglect any reactance. Since a resistive load is used (see Figure 3-104), the ac output swing is measured at V_{OUT} or V_{CE}.

A dc blocking capacitor is used between the R_{LOAD} and the V_{CE} output to assure that the Q-point is not influenced by R_{LOAD}. It is also necessary to avoid passing dc to the load in applications where the load is a SAW filter. However, R_{LOAD} will affect the ac load line, which is seen in Eq. B in Figure 3-104. Note that the V_{CE} voltage swing is reduced; thus, the V_{OUT} signal is reduced (see Figure 3-105).

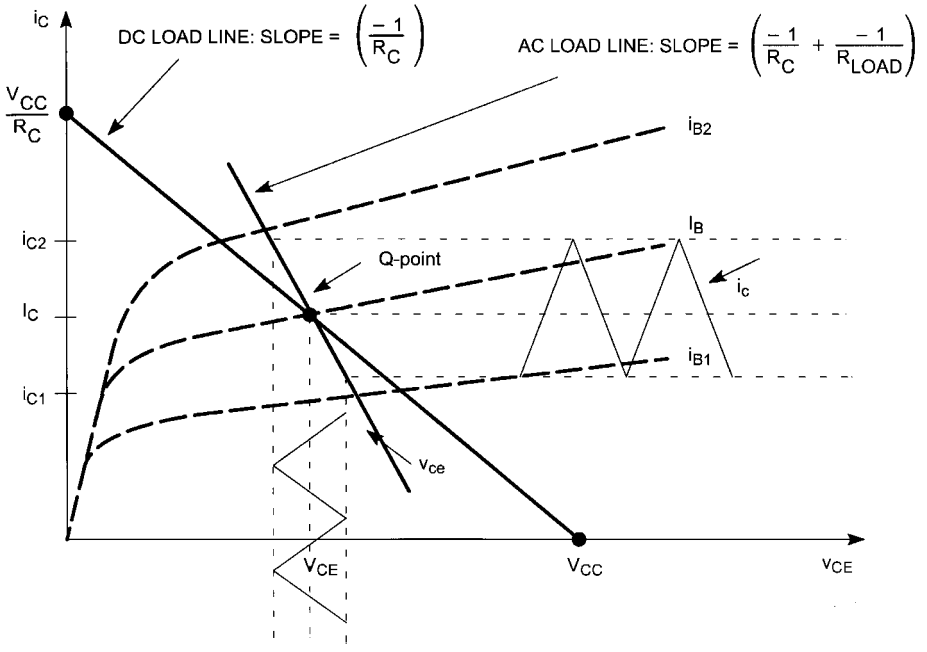

Figure 3-105 Graphical analysis for the circuitry in Figure 3-104. The ac load line intersects the Q point, and the slope is steeper than the dc load line due to R_{LOAD}, which makes V_{CE} smaller.

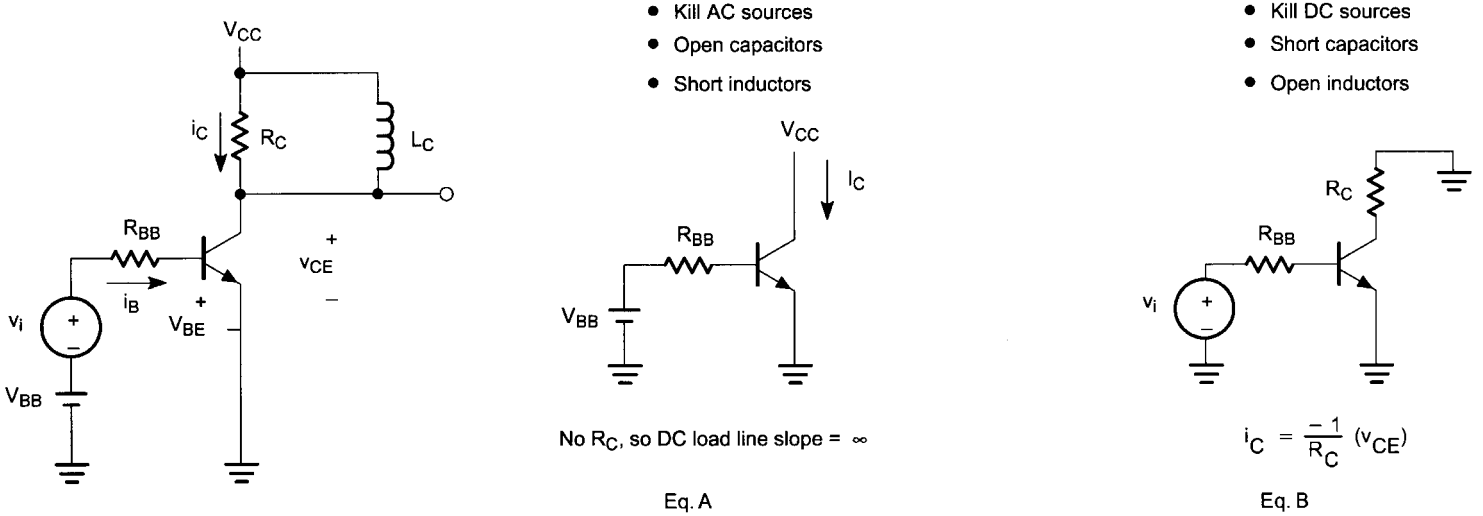

Figure 3-106 Basic transistor analysis with inductor added to collector.

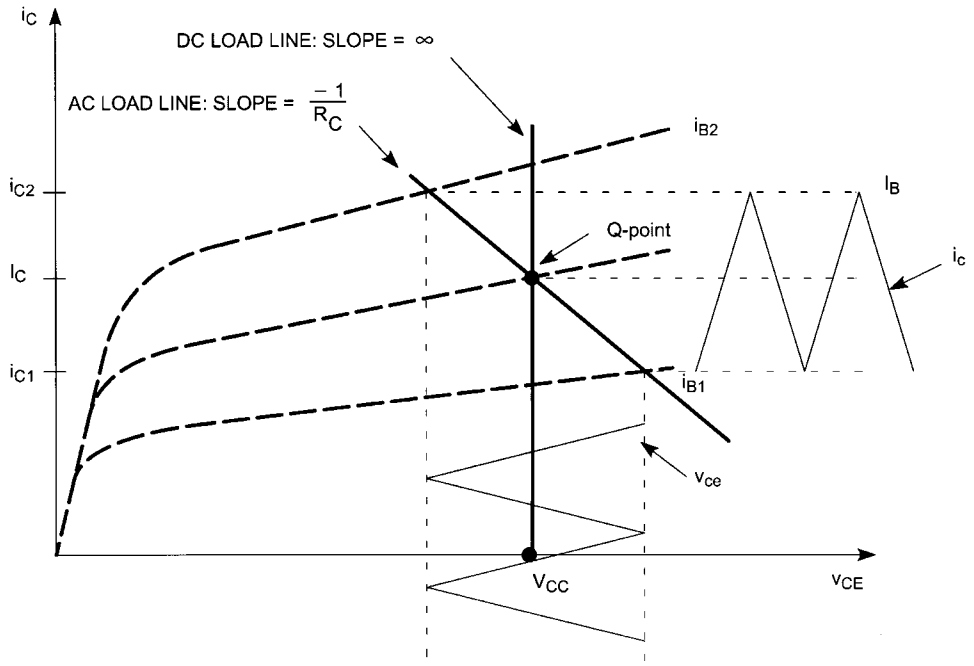

Figure 3-107 Graphical analysis for the circuitry in Figure 3-106.

Since the values of R_C and R_{LOAD} affect the ac load line slope, the value chosen is important. The higher the impedance of R_{LOAD} and R_C, the greater the ac output swing will be at the output, which means more conversion gain in a mixer. This is due to the slope getting flatter, thus allowing for more output swing.

Open Collector with Inductor (L_C). Adding an inductor in parallel with R_C can increase the ac output signal V_{CE}. Figure 3-106 shows the dc and ac analyses of this circuit configuration. In Eq. A in Figure 3-106, there is no R_C influence because the inductor acts like a short in the dc condition. This means the slope of the dc load is infinite and causes the Q-point to be centered around $V_{CC,}$ thus moving it to the right of the curve. The ac load line slope is set only by R_C because no load is present. Note that it has the same ac load line slope as the first condition in Eq. B of Figure 3-101.

Referring to Figure 3-107, one might notice that the base current (ac and dc) curves spread open as V_{CE} increases. This is caused by a noninfinite Early voltage (see Figure 3-108), which causes the collector current to be dependent on V_{CE}. Taking advantage of this nonideal condition, the peak-to-peak ac output swing V_{CE} can thereby be increased by moving the dc Q-point to the right due to the wider spreading between the curves corresponding to different base currents. Figure 3-109 combines Figures 3-103 and 3-107 to show the different ac output signals with different Q-points.

Looking at the ac output level, one might ask how the V_{CE} peak voltage can exceed the supply voltage V_{CC}. Recall that the inductor is an energy-storing device ($v = L\ di/dt$). Therefore, total instantaneous voltage is V_{CC} plus the voltage contribution of the inductor.

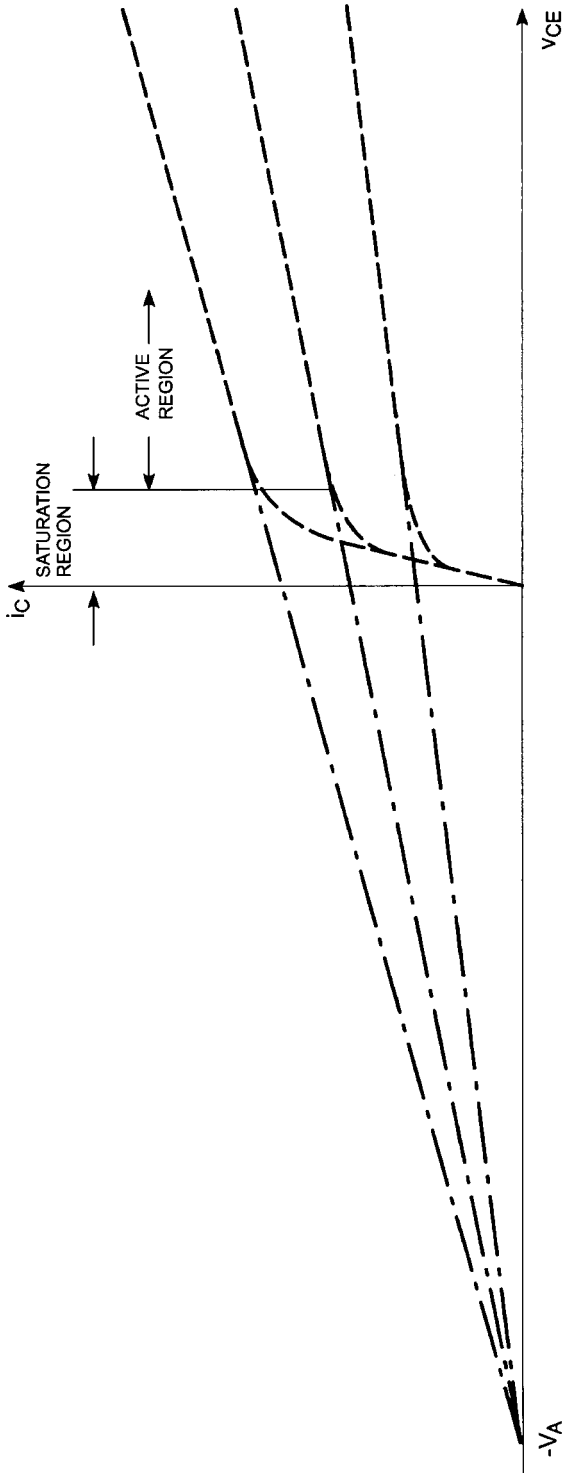

Figure 3-108 Graphical representation of Early voltage effect.

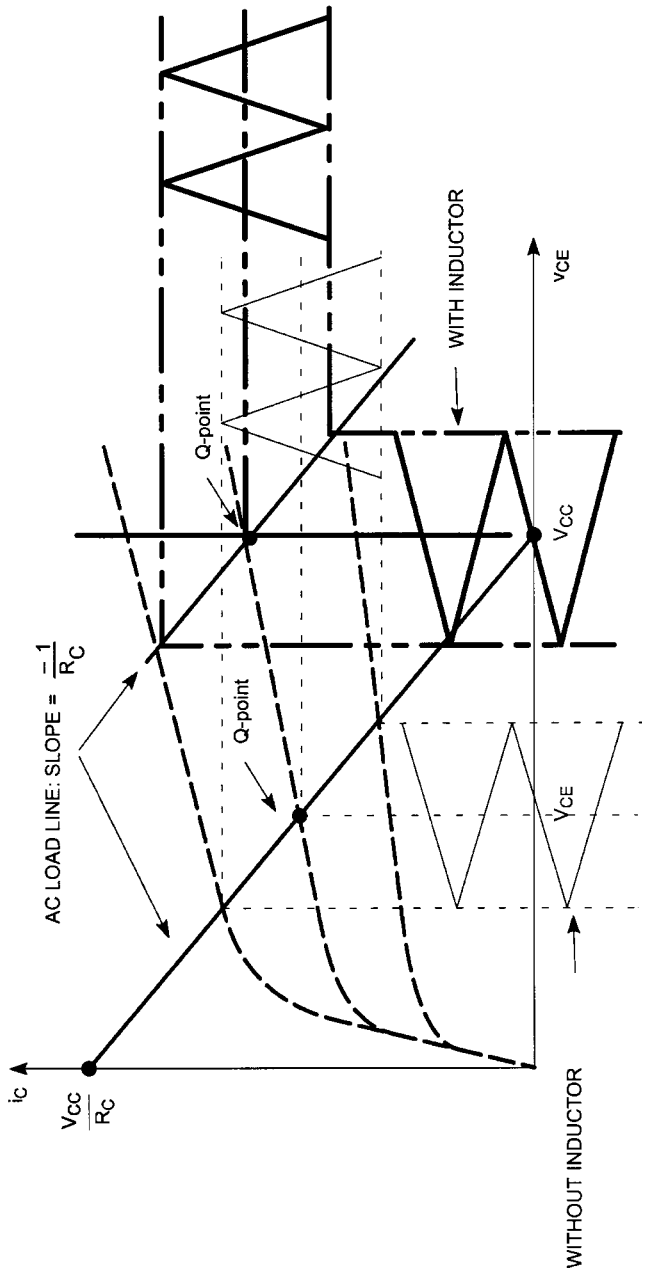

Figure 3-109 Comparison of open-collector circuit with inductor versus without inductor.

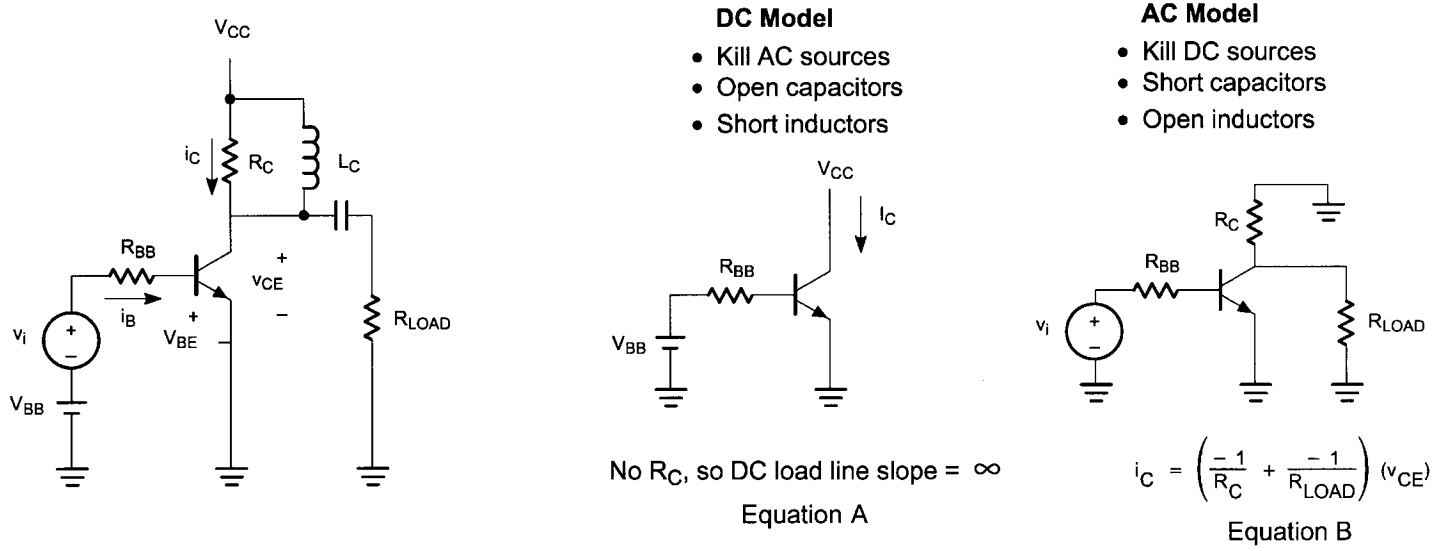

Figure 3-110 Basic transistor analysis with inductor and R_{LOAD}.

Open Collector with Inductor (L_C) and R_{LOAD}. Figure 3-110 shows the dc and ac analyses with the inductor and load resistor. Again, from the dc analysis, the inductor causes R_C to be nonexistent so the dc load line is vertical. In the ac analysis, the ac load line slope is influenced by both R_C and R_{LOAD} (see Eq. B in Figure 3-110). The ac load line slope is the same as the example of the open collector without the inductor. Figure 3-111 shows the response for the open collector with L_C and R_{LOAD}. Figure 3-112 combines Figures 3-105 and 3-111 showing the increase in ac output swing.

In conclusion, for the load line, R_C plays a role in setting up the bias-determined Q-point as well as the ac source impedance. However, when an inductor is placed in parallel with R_C, a different Q-point is set and the ac source impedance is altered. Moving the Q-point takes advantage of the transistor's nonideal i_c dependence on V_{CE} to get more signal output without having to change the base current. Since R_C is in parallel with R_{LOAD} in the ac condition, it influences the ac load line slope.

Flexible Matching Circuit [25]. A useful variation of the open-collector matching concepts previously outlined provided the capability of delivering equal power to two unequal resistive loads. This allows the power delivered to the load to be measured indirectly at another test point in the circuit where the impedance can be defined arbitrarily. If this impedance is defined to be 50 Ω, a spectrum analyzer can easily be placed directly into the circuit. This is an excellent troubleshooting technique and a valuable option to have available in high production environments.

Figure 3-113 shows the schematic for this flexible matching circuit. In this circuit, C_B functions only as a dc blocking capacitor and presents a negligible impedance at the frequency of interest. Recall from the previous open-collector matching discussions that,

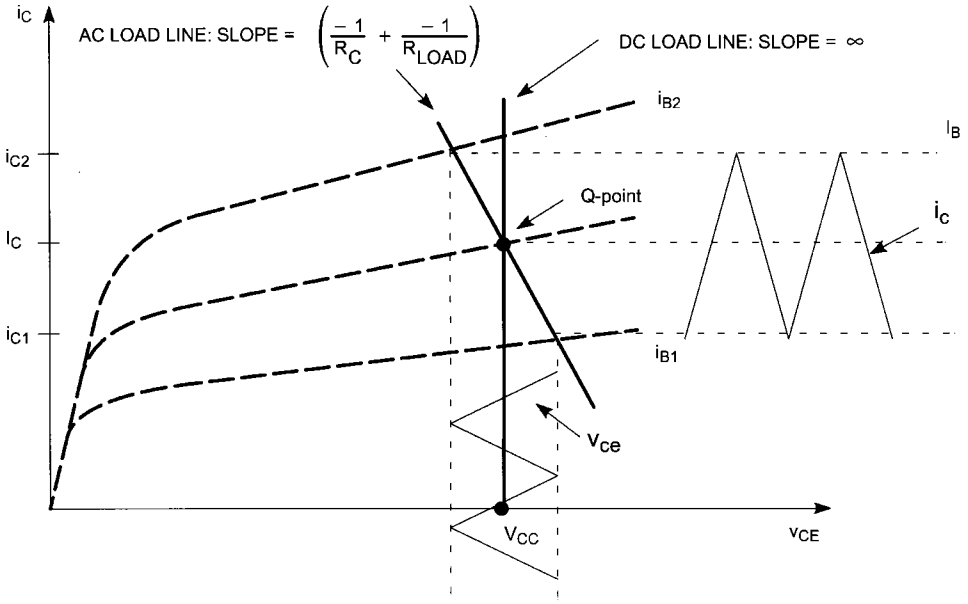

Figure 3-111 Graphical analysis for the circuitry in Figure 3-110.

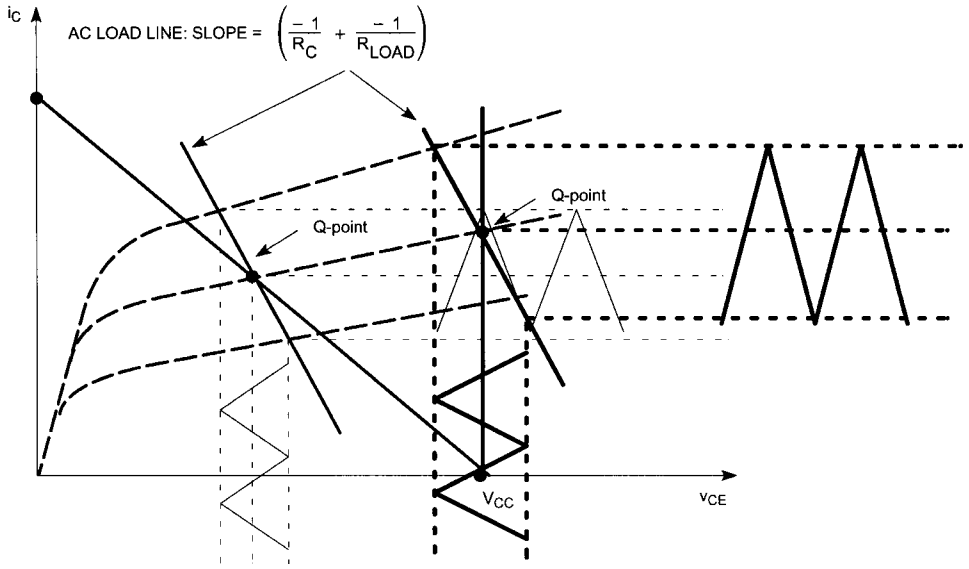

Figure 3-112 Comparison of open-collector R_{LOAD} circuit with inductor versus without inductor.

when R_C is placed in parallel with an inductor, it has no effect on the Q-point but does influence the slope of the ac load line as

$$\text{Slope} = \frac{-1}{R_C} + \frac{-1}{R_{\text{LOAD}}} \tag{3-166}$$

The capacitor C_S not only functions as a dc blocking capacitor but is also chosen such that the impedance presented by the combination of L, R_C, and C_S is equal to R_{LOAD} for optimum power transfer. The analysis is done in the following manner. First, note that inductor L is connected to V_{CC}, which is an affective ac ground. So L can be redrawn to ground. Next, R_C and C_S are converted to their parallel equivalent values as shown in Figure 3-114.

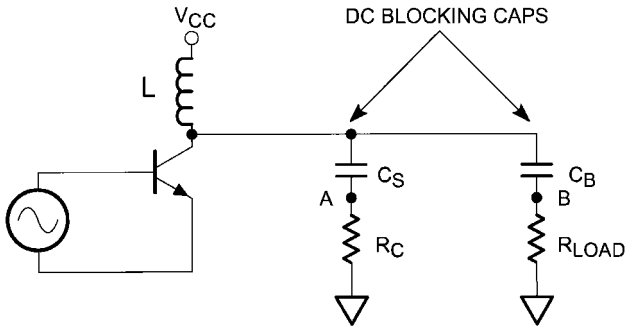

Figure 3-113 Flexible matching circuit.

Figure 3-114 Converting from series to parallel configuration.

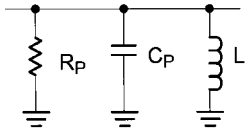

Figure 3-115 Converting from series to parallel configuration. Goal: Find L_C and C_p such that R_p looks like the R_{LOAD} value at the resonant frequency.

The resulting parallel *LCR* circuit is shown in Figure 3-115. At resonance, the parallel L–C_P combination will be an effective open circuit leaving only R_P. R_P is then simply chosen to be equal to R_{LOAD}.

Starting with the most simple transistor configuration and using *RC* types of dc-coupled amplifier circuits, we next present an overview of possible configurations for this application.

3-3 SINGLE-STAGE FEEDBACK AMPLIFIERS

This amplifier (Figure 3-116) is a standard minimal configuration amplifier with reduction of current distortion because of the emitter feedback. The voltage gain is

$$\text{VG} = \frac{R_L}{(26\text{mV})/I_C + R_e} \tag{3-167}$$

where R_L is the total load seen at the collector.

The feedback amplifier in Figure 3-117 uses voltage feedback to "correct" the input and output impedance to be close to 50 Ω but does not improve the current distortion. The voltage gain of this circuit is

$$\text{VG} = \frac{R_F}{R_g} \tag{3-168}$$

$$R_{\text{IN}} = R_{\text{OUT}}$$

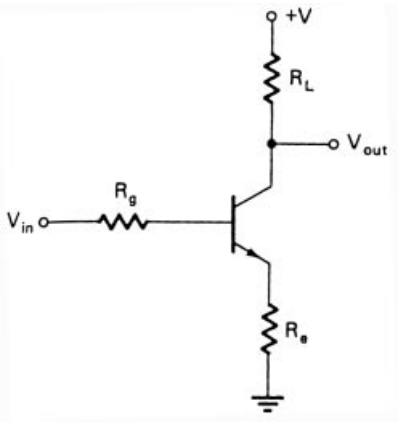

Figure 3-116 Single-stage amplifier with current feedback (provided by R_e).

$$= R_F R_D \quad \text{with} \quad R_D = \frac{26\text{mV}}{I_C} \tag{3-169}$$

Example. For $I_C = 10$ mA $\rightarrow R_D = 2.6\ \Omega$ and assuming $R_F = 200\ \Omega$, the input resistance $R_{\text{IN}} = 22.63\ \Omega$. The gain is calculated by getting the inverse of $R_D = g_m = 0.39$ A/V. Once this is multiplied with the output impedance of 22.63 Ω, the resulting gain becomes 10 log (8.6) or 9.3 dB. The gain can be increased by either using a larger collector current or a larger feedback resistor. It should be reminded that this circuit does not improve the distortion caused by the base–emitter junction.

To reduce the current distortion as well, we use the circuit shown in Figure 3-118, which contains both types of feedback. In reality, the collector–base resistor is frequently split into an unbypassed section responsible for the feedback and a larger resistor responsible for the appropriate biasing. The example circuit in Figure 3-119 shows this.

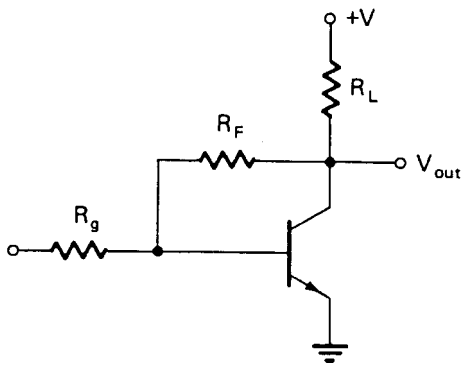

Figure 3-117 Single-stage amplifier with voltage feedback (provided by R_F).

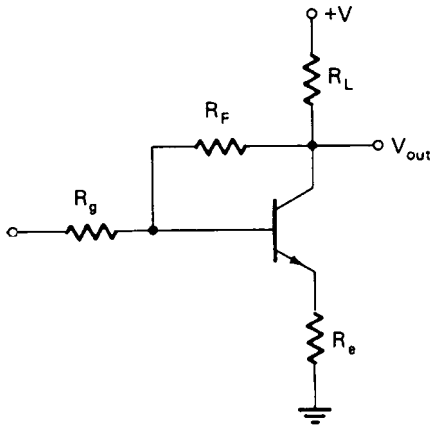

Figure 3-118 Single-stage amplifier with voltage and current feedback.

By using two of the fairly recent BFP420 transistors in parallel, and balancing the transistors by using the appropriate emitter resistors (which in total will result in 10 Ω) plus the bypassed value, we obtain the frequency-dependent gain, matching, and noise responses shown in Figure 3-120. To determine the appropriate feedback resistor R_F, we recommend the formula

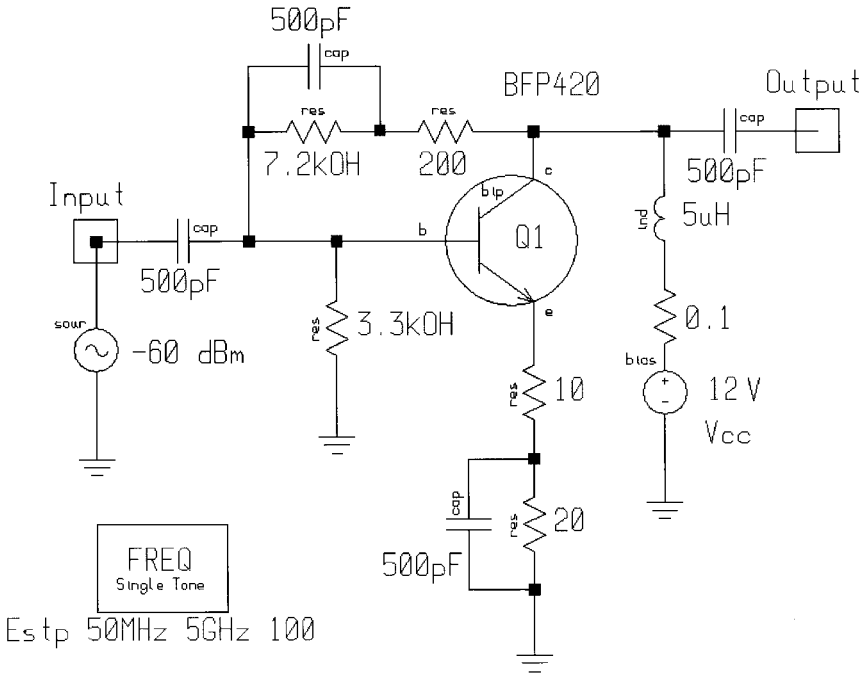

Figure 3-119 Practical amplifier circuit showing voltage and current feedback, and illustrating how reactances (in this case, 500-pF bypass capacitors) and multiple resistors can be used to provide different ac and dc resistances for the paths from collector to base and emitter to ground.

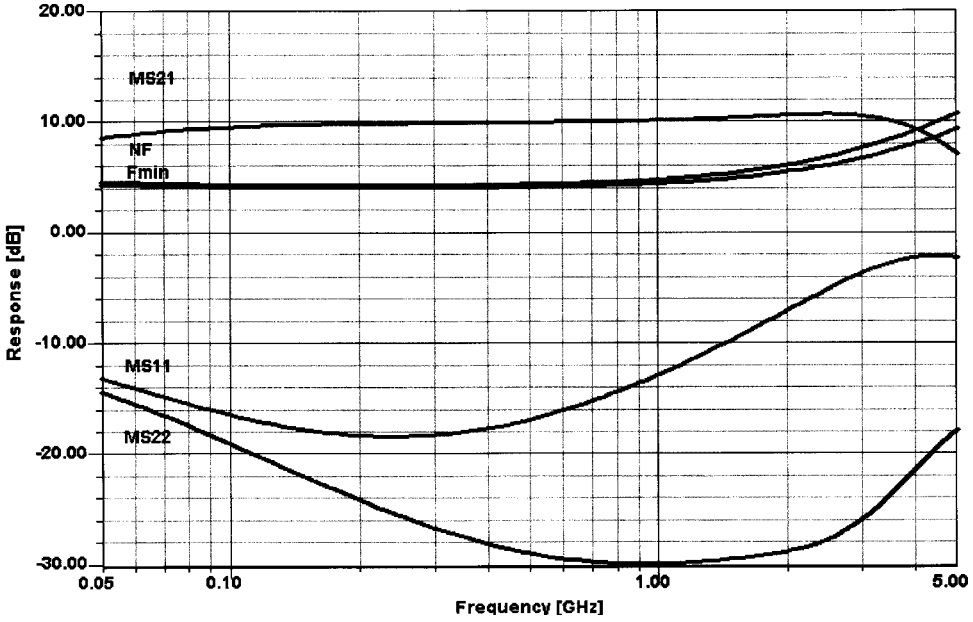

Figure 3-120 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-119.

$$R_F = \frac{(Z_{\text{in}}\, Z_{\text{out}})}{R_E} \tag{3-170}$$

This equation requires some additional comments. The combined shunt and series feedback only work as long as a sufficient transconductance is provided. In other words, there must be enough open-loop gain that will be reduced to obtain more bandwidth. A necessary condition for this approach, which really comes from the frequency range of less than 30 MHz, is that

$$Z_{\text{in}} = \frac{26\ \text{mV}}{I_C}\,\beta >> R_F \tag{3-171}$$

This requires a minimum transconductance of

$$g_m = \frac{1 + S_{21}}{Z_{\text{in}}} \tag{3-172}$$

where S_{21} must be a negative number that reflects the 180° phase shift. Of course, life becomes interesting when S_{21} goes through 1, but it (hopefully) never becomes negative and larger than 1 at the same time.

Example. The BFP420 has been used here frequently. A 10-dB gain would require an S_{21} of 3.16 ($\sqrt{10}$); therefore, we need to inspect the datasheet, which shows that the magnitude

of S_{21} is 3.16 around 4.5 GHz, yet the phase shift has changed from 180° to around 20°. In order to design an amplifier, we now set

$$R_F = Z_{\text{in}}(1 + |S_{21}|) \tag{3-173}$$

which is valid until S_{21} becomes too small. For a given 10 dB or 3.16 for S_{21}, the resulting RF is 4.16×50, or 208 Ω. The transconductance under these conditions becomes

$$g_m = \frac{1 + |S_{21}|}{Z_0} \tag{3-174}$$

where $Z_0 = 50$ Ω (the desired input impedance). g_m now becomes 83.2 mS. We now test the input and find

$$\frac{\beta}{g_m} = Z_{\text{in}} = \frac{50}{0.0832} = 600\ \Omega \tag{3-175}$$

Therefore, the emitter feedback resistor is not necessary to meet the previously mentioned condition whereby the input impedance needs to be higher than RF. Assuming the transconductance now is 0.00832, or 10% of the previous value, the input impedance would be 60 Ω, no longer meeting the prescribed requirement. Therefore, we need an unbypassed emitter resistor that fulfills the equation

$$R_E = \frac{Z_0^2}{R_F} - \frac{1}{g_{m_{\text{dc}}}} \tag{3-176}$$

where

$$g_{m_{\text{dc}}} = \frac{1 - S_{21_{\text{max}}}}{Z_0} \tag{3-177}$$

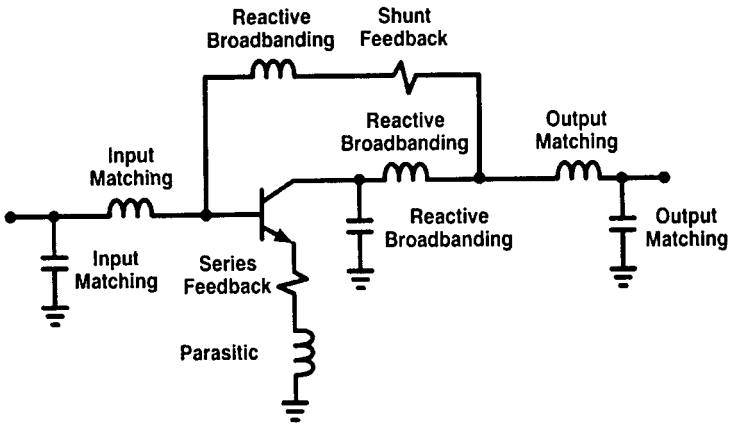

Figure 3-121 Elements of a feedback amplifier.

Again, the reader should be cautioned that in the common-emitter circuit, there is a 180° phase shift, and therefore $S_{21_{\max}}$ is a negative quantity, resulting in reality in

$$g_{m_{\text{dc}}} = \frac{1 + S_{21_{\max}}}{Z_0}$$

In our case,

$$g_{m_{\text{dc}}} = \frac{-S_{21}}{2Z_0} = \frac{38}{2 \times 50} = \frac{38}{100} = 0.38$$

so

$$R_E = \frac{50^2}{208} - \frac{1}{0.38} = 12 - 2.6 = 9.4\ \Omega \tag{3-178}$$

In practice, the designer would use a 10-Ω resistor.

Since the gain of the transistor continues to fall as a function of frequency, one can compensate to a degree for the cutoff frequency by putting an inductance in series that follows the equation

$$L_F = \frac{R_F}{2\pi f_{3\text{dB}}} \tag{3-179}$$

Assuming $f_{3\text{dB}}$ = 2 GHz, the resulting series inductance L_F = 16.6 nH. Basically, the same applies to circuits where the second transistor is used as an emitter follower to feed the signal back from the collector to the base of the first transistor.

In summary (see Figure 3-121):

- Resistive negative feedback at lower frequencies reduces open-loop gain and simultaneously matches input and output.
- Reactive elements set the gain and matching at high frequencies. Feedback is reduced at high frequencies.
- Emitter bypass capacitors are not used, as they would destroy the impedance match.

This is equally valid for FETs.

The next level of complexity can be reached by using two transistors with dc feedback.

3-3-1 Lossless or Noiseless Feedback

All the amplifiers shown above are based on a combination of resistive and reactive feedback. The very moment resistive feedback is used, the noise figure increases, as does the intercept point. As long as the intercept point increases overproportionally compared to the noise figure, this is an acceptable method. However, there are many cases in which an extremely low noise figure and a higher than normally achievable intercept point are required. To avoid this degradation of performance, Norton of Anzac developed a negative feedback structure based on the capabilities of the ferrite transformer. This patented technique (U.S. Patent Nos. 3,624,536 and 3,891,934, since expired), known as *lossless feedback*, provides lower noise figure and higher linear output than can be achieved using resistive feedback with the same transistor. Transformer feedback is used in which the transformer in the feedback network acts as a directional coupler. The coupling ratio between the input and output of the coupler

determines the magnitude of the feedback, and hence the gain. Across the frequency band over which the transformer operates as intended, the feedback is negative due to the in-phase coupling and the inversion of the active device.

This technique was used in amplifiers ranging from 5 to 500 MHz, 20 to 1000 MHz, and 300 to 1800 MHz. The difficulty associated with this type of amplifier is the fact that it is based on transformers that use twisted pairs of wires as transmission lines. In some implementations used at higher frequencies, actual directional couplers were used at the expense of bandwidth; in these circuits, the coupling was determined by the spacing of the coupler lines rather than transformer turns ratio. These microstrip couplers have much narrower bandwidths than transformers and are fairly large.

Another headache with the lossless feedback design is the fact that many of these transistor configurations are used in either grounded-base or grounded-emitter with transistors that have f_T values of 25 GHz and higher. Such devices are very hot, and achieving freedom from oscillation over a wide frequency range is a continuing problem, even for the circuits we have shown so far. A similar clever technique has been implemented in the termination-insensitive mixer, which we will examine in Chapter 4.

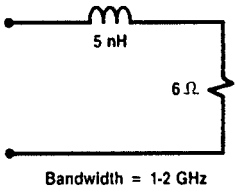
3-3-2 Broadband Matching

The circuitry above has enabled us to extend the frequency range of the amplifier and avoid the normal sharp cutoff. According to Fano [26], there is a limit to the bandwidth of matching. The concept is that impedance plus bandwidth determines the ability to match, since there is a Q of the circuit and there is a Q of the device. The following equations are valid:

$$|\rho_{\text{Bode}}| = e^{-(\pi Q_T / Q_{BP})} \tag{3-180}$$

$$Q_T = \frac{\sqrt{f_1 f_2}}{f_2 - f_1} \tag{3-181}$$

$$Q_{BP} = \frac{\text{Im}(Z)}{\text{Re}(Z)} = \frac{X_s}{R_s} \tag{3-182}$$



$$Q_{BP} = \frac{2\pi\sqrt{(2\text{ GHz})(1\text{ GHz})(5\text{ nH})}}{6\,\Omega} = 7.40$$

$$Q_T = \frac{\sqrt{(2\text{ GHz})(1\text{ GHz})}}{(2\text{ GHz} - 1\text{ GHz})} = 1.414$$

$$|\rho_{\text{Bode}}| = e^{-\left(\frac{\pi(1.414)}{7.40}\right)} = .549$$

$$\text{VSWR}_{\text{Bode}} = \frac{1 + .549}{1 - .549} = 3.43 : 1$$

Figure 3-122 Broadband matching example showing the Bode limit.

Figure 3-122 shows an example. This combination results in a VSWR of 3.43, which for practical purposes is already too high. The workaround is special circuitry (such as exponentially staggered impedance jumps in the matching network like 50 Ω > 20 Ω > 7 Ω > 3 Ω). This means we first transform the 50-Ω source of load impedance down to 3 Ω, and then look for a matching network that matches the transistor output/input, which is within a few ohms of 3 Ω. A detailed discussion of such matching can be found in the "Numerical Design" portion of Section 3-12-2 under the title "Broadband Matching Using Bandpass-Filter Networks—High-Q Case."

3-4 TWO-STAGE AMPLIFIERS

There are two popular configurations that have been used mostly for low-frequency applications. The first one (Figure 3-123, implemented in the circuit shown in Figure 3-124) shows a nice high-frequency performance assuming the emitter and collector currents are essentially the same. As for distortion products, this circuit behaves equivalently to the shunt impedance example from Figures 3-118 and 3-119, with the additional gain of the second transistor. Its frequency matching and noise performance are also shown, in Figure 3-125.

The next two-stage circuit (Figure 3-126, implemented in Figure 3-127) uses the collector current of the second stage as the feedback to the first. Proper biasing of this circuit is quite difficult and interactive. Figure 3-128 shows the frequency-dependent gain, matching, and noise figure. We believe that this circuit can be optimized further, but we leave such investigations to the reader.

A *cascode* amplifier is a special form of two-stage circuit. Although a cascaded pair acts like a single transistor, its merits are in its reduced feedback and resulting higher gain–bandwidth product. Figure 3-129 shows a simple cascode application that assumes the presence

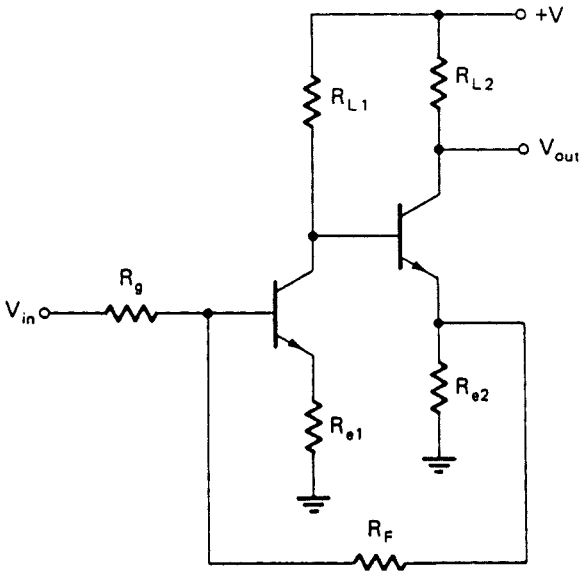


Figure 3-123 Two-stage amplifier with voltage feedback.

of an output transformer that absorbs the output capacitance. Figure 3-130 shows this circuit's frequency-dependent gain, matching, and noise performance.

It has been obvious to us that most published wireless application circuits are evaluated on a no-input-selectivity basis; that is, their reported performance does not take into account the filtering that is usually present in practical implementations. Evaluated in this way, a low-noise design may achieve a noise figure of less than 2 dB—1.2 dB or so is typical—but this is misleading because filters and connectors introduce insertion loss, resulting in a higher noise figure.

The cascode is a nice preamplifier combination. It combines (depending on the transistor) a low noise figure with essentially no feedback. Since the output of a grounded-base transistor provides a high-impedance source, this configuration is ideal to work into the SAW filters frequently used in wireless applications at the operating frequency. Special transistor pairs are available for use in cascode; as can be seen from this example, not every transistor combination is ideal. This one gives a higher noise figure than wanted and at frequencies above 2 GHz it tends to show possible instabilities. Both Siemens and Motorola are now offering transistors appropriate for these cascodes. Mostly, one would resort to transistors of less-exotic cutoff frequencies to guarantee stability. Typically, grounded-base/gate transistors tend to become oscillators, specifically because this configuration, like the emitter follower, allows a higher operating frequency while maintaining the same gain–bandwidth product; the actual gain for the last two circuit configurations is less. A grounded-base/gate stage has a high voltage gain and the emitter/source follower has power gain at low impedance levels. We invite our readers to experiment with the capacitor from the base of Q1 to ground in Figure 3-129 to get an interesting education about these transistors and their willingness to oscillate.

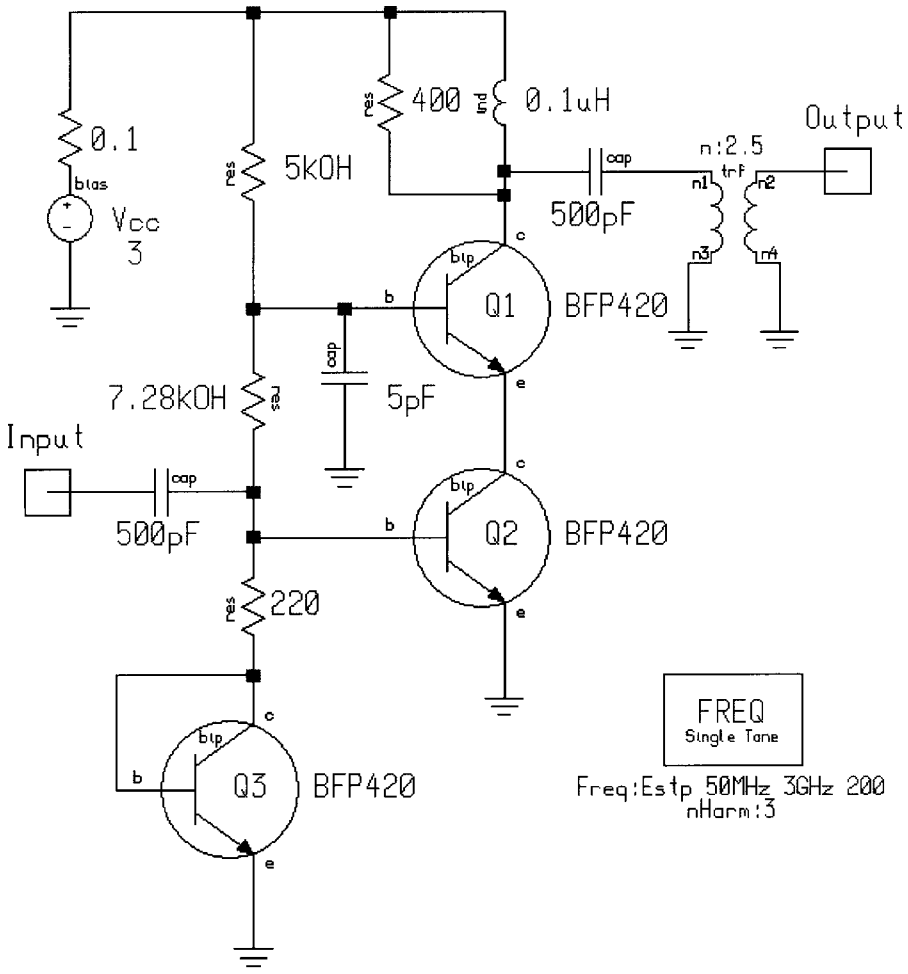

Figure 3-129 Schematic of the cascode amplifier.

The MC13144 is an example of a commercially available VHF to 2-GHz low-noise amplifier with programmable bias. As can be seen from Table 3-11, it is ideal for the 900-MHz range and its programmable gain/bias makes it very attractive. This design (Figure 3-131) is based on the cascode mentioned above and, because of high integration, uses many transistors for bias and level shifting.

The 900-MHz application circuit in Figure 3-132 shows the required external components for a successful design. Input and output are made tunable. The 5.6- and 39-nH inductances can be made from small air-wound coils. The output ceramic filter provides the necessary selectivity ahead of the mixer. With such a highly selective device in the input, the noise figure would deteriorate too much. The antenna is rarely in the vicinity of sufficiently strong transmitters to require such strong input filtering.

There are two more interesting applications for two-stage amplifiers: The one implemented in the Hewlett-Packard MSA-0735 MMIC has become a quite common one, and its usefulness up to higher frequencies depends mostly on the cutoff frequency of the transistors,

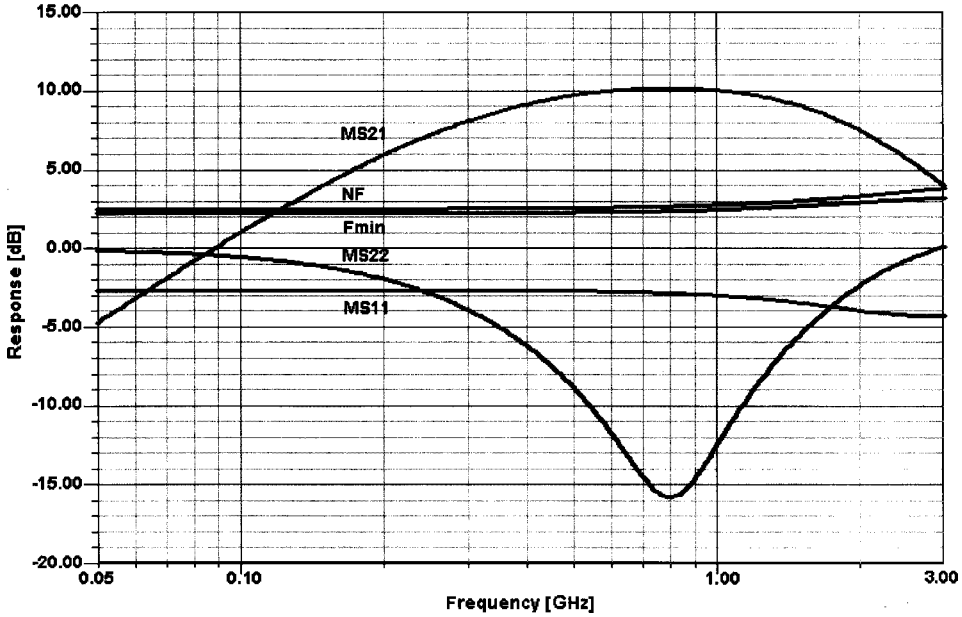

Figure 3-130 Frequency-dependent gain, matching, and noise performance of the cascode amplifier.

their parasitics, and the phase shift of the gain. The typical configuration is shown in Figure 3-133, and its frequency-dependent gain, match, and noise figure in Figure 3-134. There is an increase of S_{22} at higher frequencies; this indicates unwanted phase shift in the circuit. Some manufacturers hide the compensation circuits to overcome such peaking; most of the schematics shown by the manufacturers are really intended only to show operating principles, with proprietary details omitted.

Thanks to the properties of GaAs transistors, we can extend the frequency range significantly. The amplifier we are about to look at goes back several years and is described in great detail in Goyal [27]. Essentially what we have, seen in Figure 3-135, is an FET version of Figure 3-127. The main goal of this circuit was to have an all-monolithic circuit, avoiding all ac coupling and accomplishing all matching and interaction with dc coupling. The transistor Q1 is the main gain stage, which has the transistor Q2 as an active load. The output impedance of Q2 is $1/g_m$—typically in the area of 50–200 Ω, depending on the biasing,

Table 3-11 MC13144 features

Gain at 900 MHz, 17 dB
Noise figure at 900 MHz, 1.4 dB
P_{-1dB}, −7.0 dBm

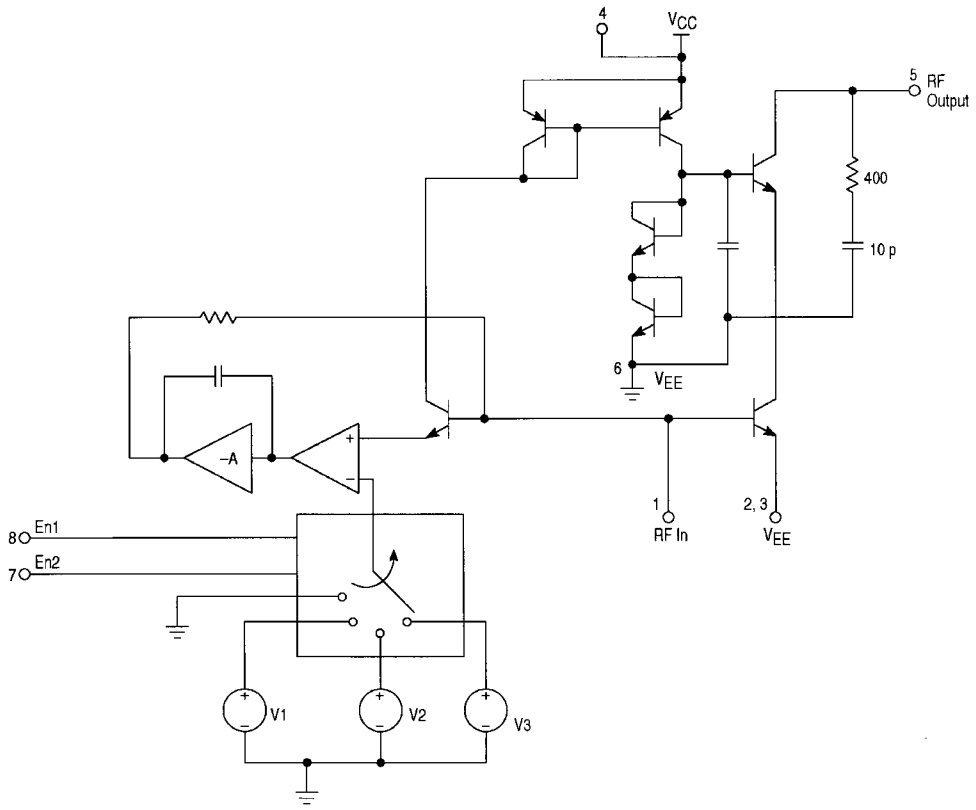

Figure 3-131 Schematic of the Motorola MC13144 cascode LNA.

which affects the transconductance. Transistor Q3 has the same function as an emitter/source follower; again, its dc bias determines its transconductance and therefore its output impedance. (Given this, a device that has a transconductance of 20 mS, or close to it, would establish a very good output match to 50 Ω.) The drains of Q1 and Q5 are at approximately 3.5 V. The diodes at the source of Q3 are level shifters that must shift the dc voltage at the gate of Q5 and at the drain of Q4 to approximately −1.5 V relative to ground—the necessary bias condition for Q1 and Q5. The standard shunt feedback circuit would show resistive feedback between the drain of Q1 (gate of Q2) and the gate of Q1; in the previous examples, we calculated the magic value of this part to be about 200 Ω. Adding in parallel to Q1 the transistor Q5 allows the designer to use a feedback scheme that isolates the feedback loop from the input. Dc-wise, the two transistors are tied together via a 10-kΩ resistor, which can be included in the actual packaged device. Insufficient information was published to allow us to duplicate the design, considering all the intricacies involved (we somewhat object to the fact that even in the *IEEE MTT-S Transactions*, so little information is given about the actual implementation of this design—using space constraints as an excuse—that its educational value is usually minimal); it shows a new principle without revealing the design steps necessary to obtain a practical circuit. Several variations of this type of circuit are available; the literature is full of discussions about them. The magnitude of the feedback is set by the ratio of the width of Q5 to that of Q1. Typical values for the Q5/Q1 ratio range

from 0.15 to 0.30. In simulation, sizing the devices can best be accomplished by using the scaling factor for the FET model.

One of our questions was: "What would the perfect input termination for Q1 be?" By using an ideal transformer and playing with its turns ratio (needless to say, we did this with CAD), we determined experimentally that, relative to the gate, 200 Ω and a series inductor of 5–8 nH—the sort of details that designers often avoid telling their audiences—gave the ideal frequency response. Overall, we believe that the inventor of this circuit can be quite proud of the overall performance. The FETs we chose were taken from the Texas Instruments nonlinear foundry library; however, any similar device from another company would have worked equally well. The feedback loop used in this IC is an example of an approach frequently referred to as *active feedback*. The performance of this amplifier can be evaluated from Figure 3-136, which shows the frequency-dependent gain, matching, and noise figures (even including F_{min}).

3-5 AMPLIFIERS WITH THREE OR MORE STAGES

Most three-stage amplifiers are obtained by adding another buffer or power-gain stage to the previously described principal designs. As an example, we decided to evaluate the recent NEC UPC2749 IC, a silicon MMIC intended for application as a low-noise 1900-MHz amplifier operating at 3 V. Table 3-12 briefly summarizes its electrical specifications.

Table 3-12 NEC UPC2749 electrical characteristics

(T_A = 25 °C, $Z_L = Z_S$ = 50 Ω, V_{CC} = 3.0 V)			
	Part Number Package Outline		UPC2749T TO6
Symbols	Parameters and Conditions	Units	Typical
I_{CC}	Circuit current (no signal)	mA	6
G_S	Small-signal gain, f = 900 MHz dB	14.5	
	f = 1900 MHz	dB	16
f_{corner}	–3-dB Gain corner frequency	GHz	2.9
P_{1dB}	1 dB Compressed output power at 1900 MHz	dBm	–12.5
P_{SAT}	Saturated output power, f = 1900 MHz	dBm	–6
NF	Noise figure, f = 900 MHz	dB	3.2
	f = 1900 MHz	dB	4.0
RL_{IN}	Input return loss, f = 1900 MHz	dB	10
RL_{OUT}	Output return loss, f = 1900 MHz	dB	12.5
ISOL	Isolation, f = 1900 MHz	dB	30
OIP_3	SSB output third-order intercept, f_1 = 500 MHz, f_2 = 510 MHz	dBm	–3
	f_1 = 1000 MHz, f_2 = 1010 MHz	dBm	–3
	f_1 = 1900 MHz, f_2 = 1902 MHz	dBm	–3.5
	f_1 = 2000 MHz, f_2 = 2010 MHz	dBm	–4
$R_{TH(J-A)}$	Thermal resistance (junction to ambient)		
	Free air	°C/W	
	Mounted on a 50 × 50 × 1.6 mm epoxy glass PWB	°C/W	

In modeling the UPC2749's three transistors, we chose to use our favorite, the BFP420, which is not without its headaches at the higher frequencies. Figure 3-137 shows the circuit diagram, which closely resembles the one published by NEC; again, the only hard facts we had were the IC's basic circuit topology, gain, and dc current. Given those numbers, we staggered the current in the three devices by setting them at 0.64 mA for the first stage, 1.85 mA for the second stage, and 3 mA for the third stage. It should be noted that the two output transistors are not unlike the approach used for the Hewlett-Packard MSA-0735 (Figure 3-133). Taking (hopefully) all the right assumptions, we end up with a design that closely resembles the manufacturer's specifications for both power consumption, gain, and noise. This can be verified by looking at the results plotted in Figure 3-138.

The final example is a more complex derivative of the Philips NE/SA5204A amplifier, which was intended for standard 6-V operation and has a fairly "normal" circuit arrangement. This can be seen from Figure 3-139. A much more elaborate cousin of this is the low-voltage NEC UPC2710 amplifier. According to its specifications, it operates at 5 V but has significantly more gain than the NE/SA5204. Table 3-13 shows its electrical specifications and Figure 3-140 shows its measured gain as published by the manufacturer.

The actual interior of the circuit is shown in Figure 3-141. It consists of the standard preamplifier and then a Darlington configuration with the collectors tied together. The middle section of the circuit acts as a power supply responsible for the bias relative to the emitter of the first transistor influencing the rest of the circuit as well. Since NEC mentioned that they use their NESAT III process (f_T of 20 GHz at V_{ce} = 3) in producing the UPC2710T and we

R_{TH}	Thermal resistance (junction to ambient)	°C/W	

obtained some information regarding it, we decided to use our standard BFP420 (f_T of 25 GHz; see the datasheet in Chapter 2) for the purpose of simulation.

In our effort to simulate this circuit, we chose a combination of values that pretty much complies with the manufacturer's published specifications, but S_{22} is not close, as shown in Figure 3-142. We stopped at this point and invite our readers with CAD capabilities to provide the final touch in meeting all the published specifications for the circuit. We are particularly

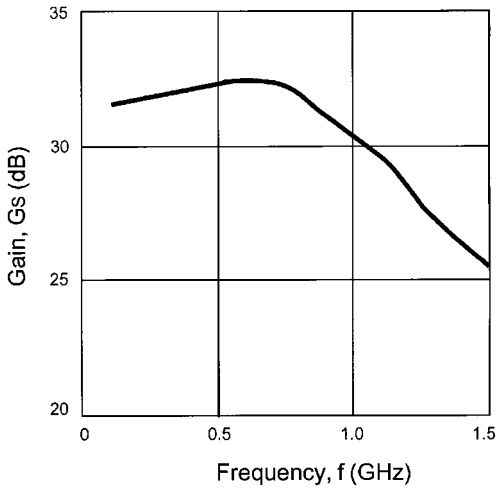

Figure 3-140 Manufacturer-supplied gain versus frequency for the NEC UPC2710T MMIC.

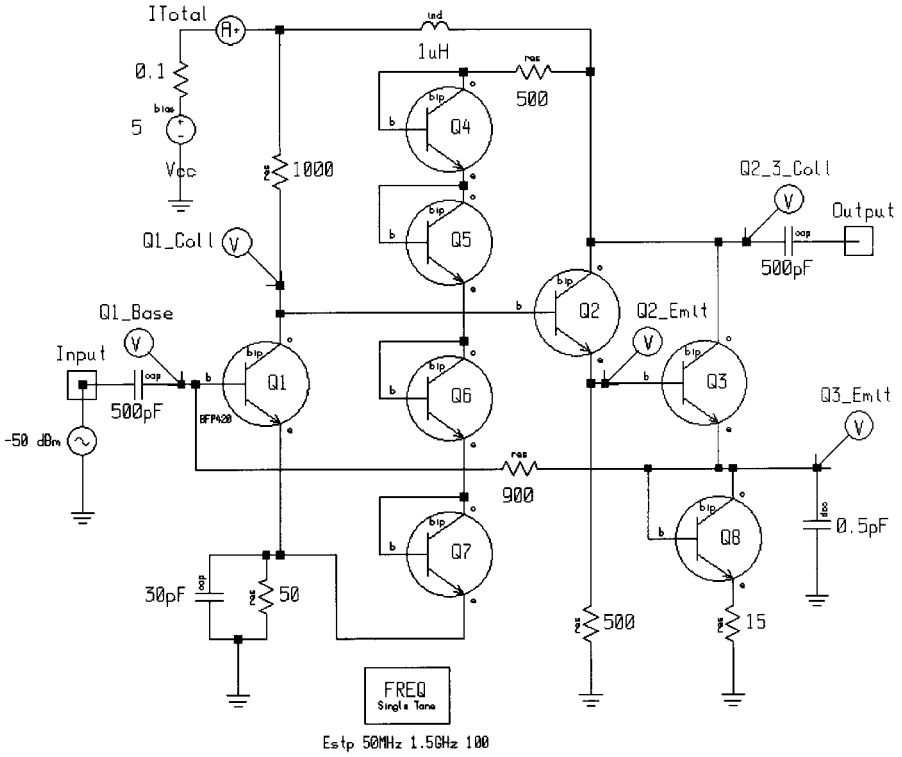

Figure 3-141 Schematic of the UPC2710T silicon MMIC entered for simulation.

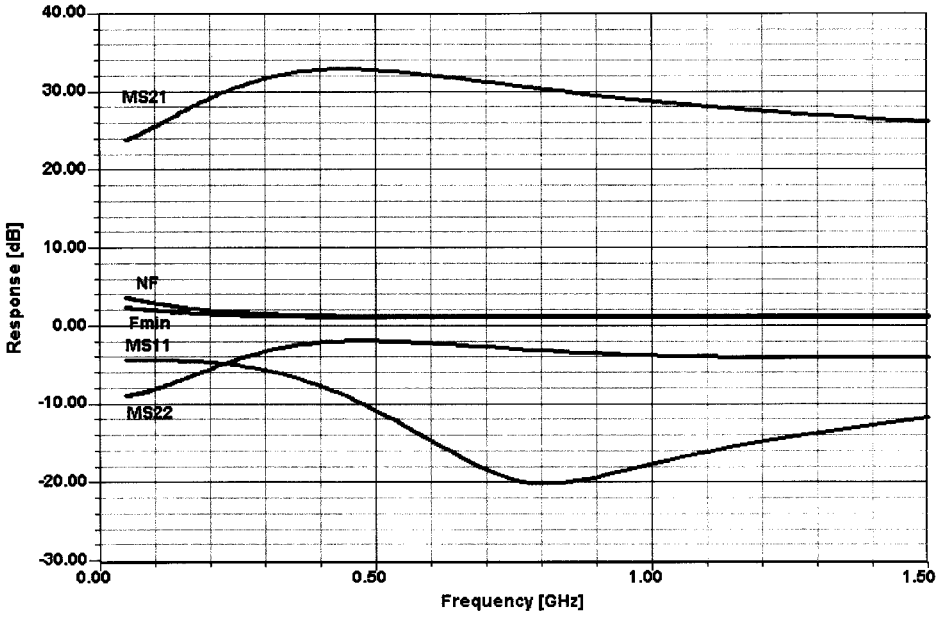

Figure 3-142 Simulated gain, match, and noise performance of the UPC2710T.

recommending such an effort because it shows very nicely the interaction of all the circuit elements in a fairly drastic way. Because of this, we admire the IC design even more, since the manufacturer has to sell a pretty consistent amplifier as a function of different production runs.

3-5-1 Stability of Multistage Amplifiers

Stability, needless to say, is a big issue, and the delay of the various stages adds to the phase shift, resulting in possible instabilities. The fact that S_{11} and/or S_{22} can become larger than 0 (in dB) means there is the potential of oscillating, depending on the reactances available. If a cable of inappropriate length is added, hell will break loose. Figure 3-143 shows the dangerous peaking of our simulation of the Philips NE5204A, in which the internal compensation was intentionally not assumed correctly. We will all agree that the high-end performance of this amplifier can generate high anxiety. As the production process of the aging device becomes more modern—meaning that transistors with much higher f_T will be the basis for the production—it will become quite difficult to maintain a previously achieved stability. This, by the way, applies also to discrete transistors, which for reasons of economics and multiple manufacturers will be improved over time. Such evolution results in generally smaller base-spreading resistances and capacitances, and other parameter changes, which, overall, cause headaches in manufacturing. We will leave the topic of three-stage amplifiers on this note.

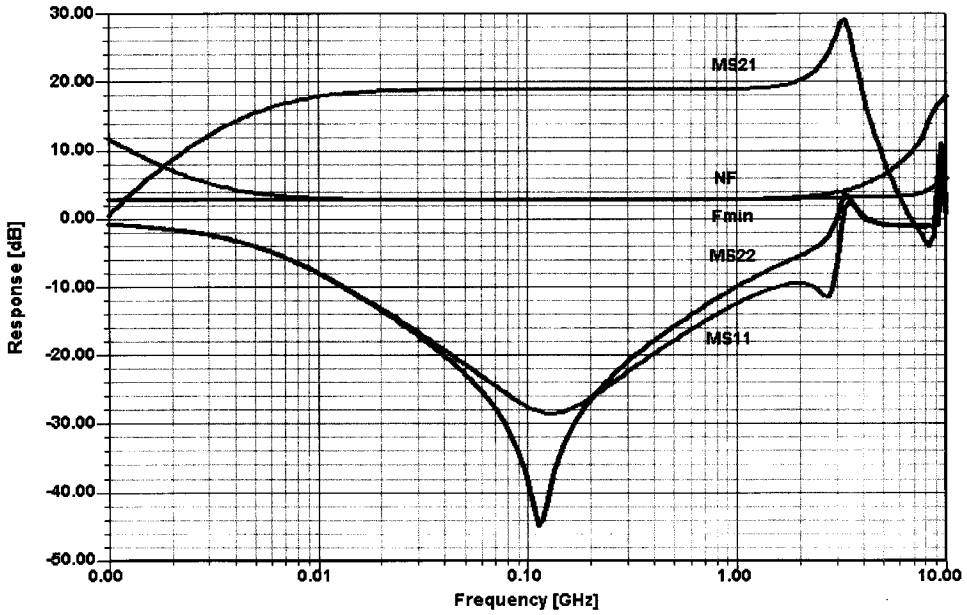

Figure 3-143 Simulated gain, match, and noise performance of the NE5204A IC.

3-6 A NOVEL APPROACH TO VOLTAGE-CONTROLLED TUNED FILTERS INCLUDING CAD VALIDATION [28]

Modern receivers control input stages as well as the oscillator band and frequency by electrical rather than mechanical means. Tuning is accomplished by voltage-sensitive capacitors (varactor diodes), and band switching by diodes with low forward conductance. Since the wireless band (essentially 400 MHz to 2.4 GHz) is so full of strong signals, the use of a tracking filter is desired as a solution to improve the performance and prevent second-order IMD products or other undesired overload effects. The dc control voltage needed for the filter can easily be derived from the VCO control voltage. There may be a small dc offset, depending on the IF used.

3-6-1 Diode Performance

The capacitance versus voltage curves of a varactor diode depend on the variation of the impurity density with the distance from the junction. When the distribution is constant, there is an "abrupt junction" and capacitance follows the law

$$C = \frac{K}{(V_d + V)^{1/2}} \tag{3-183}$$

where V_d is the contact potential of the diode and V is applied voltage.

Such a junction is well approximated by an alloyed junction diode. Other impurity distribution profiles give rise to other variations, and the above equation is usually modified to

$$C = \frac{K}{(V_d + V)^n} \tag{3-184}$$

where n depends on the diffusion profile and $C_0 = K/V_d^n$.

A so-called graded junction, having a linear decrease in impurity density with the distance from the junction, has a value of n. This is approximated in a diffused junction.

In all cases these are theoretical equations, and limitations on the control of the impurity pattern can result in a curve that does not have such a simple expression. In this case, the coefficient n is thought of as varying with voltage. If the impurity density increases away from the junction, a value of n higher than 0.5 can be obtained. Such junctions are called hyperabrupt. A typical n value for a hyperabrupt junction is about 0.75. Such capacitors are used primarily to achieve a large tuning range for a given voltage change. Figure 3-144 shows the capacitance–voltage variation for the abrupt and graded junctions as well as for a particular hyperabrupt-junction diode. Varactor diodes are available from a number of manufacturers, such as Motorola, Siemens, and Philips. Maximum values range from a few to several hundred picofarads, and useful capacitance ratios range from about 5 to 15.

Figure 3-145 shows three typical circuits that are used with varactor tuning diodes. In all cases, the voltage is applied through a large resistor R_e or, better, an RF choke in series with a small resistor. The resistance is shunted across the lower diode and may be converted to a shunt load resistor across the inductance to estimate Q. The diode also has losses that may result in lowering the circuit Q at high capacitance, when the frequency is sufficiently high. This must be considered in the circuit design.

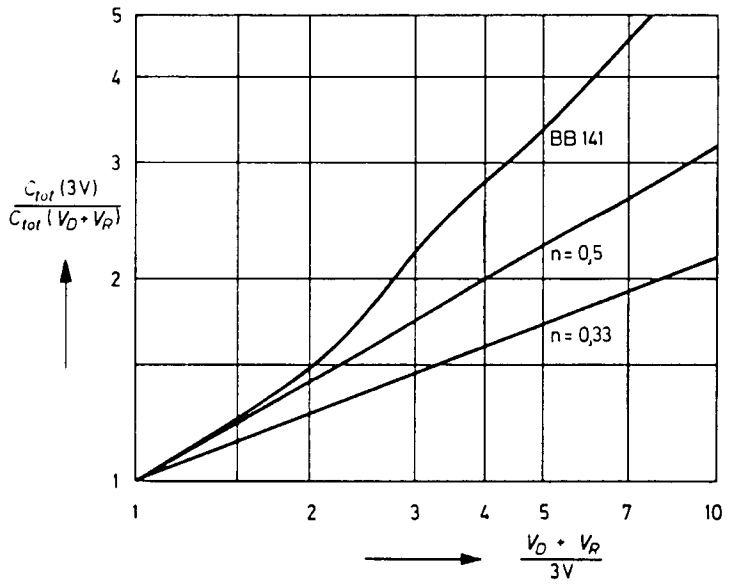

Figure 3-144 Voltage-dependent change of capacitance of different types of diodes. The BB141 is a hyperabrupt-junction diode with $n = 0.75$.

The frequency-dependent performance is not determined solely by applying the dc tuning voltage to Eq. (3-184). If the RF voltage is sufficient to drive the diode into conduction on peaks, an average current will flow in the circuits of Figure 3-145, which will increase the bias voltage. The current is impulsive, giving rise to various harmonics of the circuit. Even in the absence of conduction, Eq. (3-184) deals only with the small-signal capacitance. When the RF voltage varies over a relatively large range, the capacitance changes. In this case, Eq. (3-184) must be changed to

$$\frac{dQ}{dV} = \frac{K}{(V + V_d)^n} \tag{3-185}$$

Here Q is the charge on the capacitor. When this relation is substituted in the circuit differential equation, it produces a nonlinear differential equation, dependent on the parameter n. Thus, the varactor my generate direct current and harmonics of the fundamental frequency. Unless the diodes are driven into conduction at some point in the cycle, the direct current must remain zero.

The current of Figure 3-145c can be shown to eliminate the even harmonics, and it permits a substantially larger RF voltage without conduction than either circuit in Figure 3-145a or 3-145b. When $n = 0.5$, only the second harmonic is generated by the capacitor, and this can be eliminated by the back-to-back connection of the diode pair. Integrating Eq. (3-185), we find

$$Q + Q_A = \frac{K}{1 - n}(V + V_d)^{1-n}$$

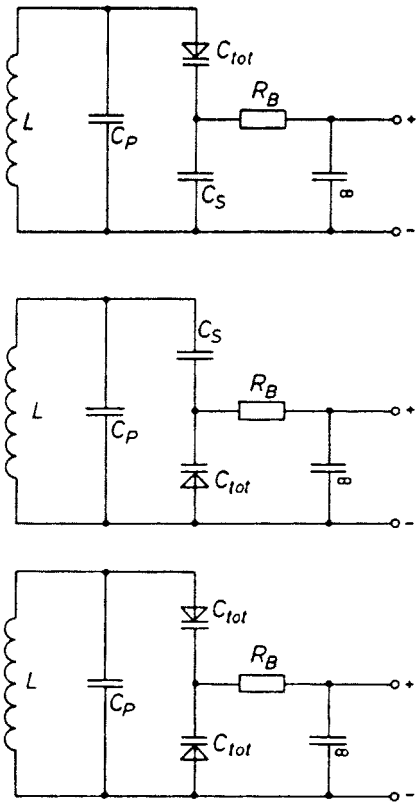

Figure 3-145 Various configurations to apply tuning diodes in a tuned circuit. The bottom version shows the lowest distortion.

$$= \frac{C_v}{1-n}(V + V_d) \tag{3-186}$$

C_v is the value of Eq. (3-184) for applied voltage V, and Q_A is a constant of integration. By letting $V = V_1 + v$ and $Q = Q_1 + q$, where the lowercase letters represent the varying RF and the uppercase letters indicate the values of bias when RF is absent, it follows that

$$q + Q_1 + Q_A = \frac{K}{1-n}[v + (V_1 + V_d)]^{1-n} \tag{3-187}$$

$$1 + \frac{v}{V'} = \left(1 + \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-188}$$

where $V' = V_1 + V_d$ and $Q' = Q_1 + Q_A$. For the back-to-back connection of identical diodes, $K_{11} = K_{12} = K_1$, $V_1' = V_2' = V'$, $Q_1' = Q_2' = Q'$, $q = q_1 = -q_2$, and $v = v_1 - v_2$. Here the new subscripts 1 and 2 refer to the top and bottom diodes, respectively; v is the RF voltage across

the pair in series, and q is the charge transferred through the pair in series. This notation results in

$$\frac{v}{V'} \equiv \frac{v_1 - v_2}{V'} = \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} - \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-189}$$

For all n, this eliminates the even powers of q, and hence the even harmonics. This can be shown by expanding Eq. (3-189) in a series expansion and performing term by term combination of the equal powers of q. In the particular case $n = \frac{1}{2}$, $v/V' = 4q/Q'$, and the circuit becomes linear.

The equations hold as long as the absolute value of v_1/V' is less than unity, so that there is no conduction. At the point of conduction, the total value of v/V' may be calculated by noting that when $v_1/V' = 1$, $q/Q' = -1$, so $q_2/Q' = 1$, $v_2/V = 3$, and $v/V = -4$. The single-diode circuits conduct at $v/V' = -1$, so the peak RF voltage should not exceed this. The back-to-back configuration can provide a fourfold increase in RF voltage handling over the single diode. For all values of n, the back-to-back configuration allows an increase in the peak-to-peak voltage without conduction. For some hyperabrupt values of n, such that $1/(1 - n)$ is an integer, many of the higher-order odd harmonics are eliminated, although only $n = \frac{1}{2}$ provides elimination of the third harmonic. For example, $n = \frac{2}{3}$ results in $1/(1 - n) = 3$. The fifth harmonic and higher odd harmonics are eliminated, and the peak-to-peak RF without conduction is increased eightfold; for $n = \frac{3}{4}$ the harmonics 7 and above are eliminated, and the RF peak is increased 16 times. It must be noted in these cases that the RF peak at the fundamental may not increase so much, since the RF voltage includes the harmonic voltages.

Since the equations are only approximate, not all harmonics are eliminated, and the RF voltage at conduction, for the back-to-back circuit, may be different from that predicted. For example, abrupt-junction diodes tend to have n of about 0.46–0.48 rather than exactly 0.5. Hyperabrupt junctions tend to have substantial changes in n with voltage. The diode illustrated in Figure 3-144 shows a variation from about 0.6 at low bias to about 0.9 at higher voltages, with wiggles from 0.67 to 1.1 in the midrange. The value of V_d for varactor diodes tends to be in the vicinity of 0.7 V.

3-6-2 A VHF Example

The application of tuning diodes in double-tuned circuits in TV tuners has been common practice for many years. Figure 3-146 shows the circuit diagram. The input impedance of 50 Ω gets transformed up to 10 kΩ. The tuned circuits consist of the 0.3-μH inductor and two sets of antiparallel diodes. By dividing the RF current in the tuned circuit and using several diodes instead of just one pair, intermodulation distortion is reduced.

The coupling between the two tuned circuits is tuned via the 6-nH inductor that is common to both circuits. This type of inductance is usually printed on the circuit board. The diode parameters used for this application were equivalent to the Siemens BB515 diode. The frequency response of this circuit is shown in Figure 3-147.

The coupling is less than critical. This results in an insertion loss of about 2 dB and relatively steep passband sides. Once the circuit's large-signal performance (Figure 3-148) is seen, a third-order intercept point of about –2 dBm is not so unexpected. The reason for this poor performance is the high impedance (high L/C ratio), which provides a large RF voltage swing across the diodes. A better approach appears to be using even more diodes and at the same time changing the impedance ratio (L/C ratio).

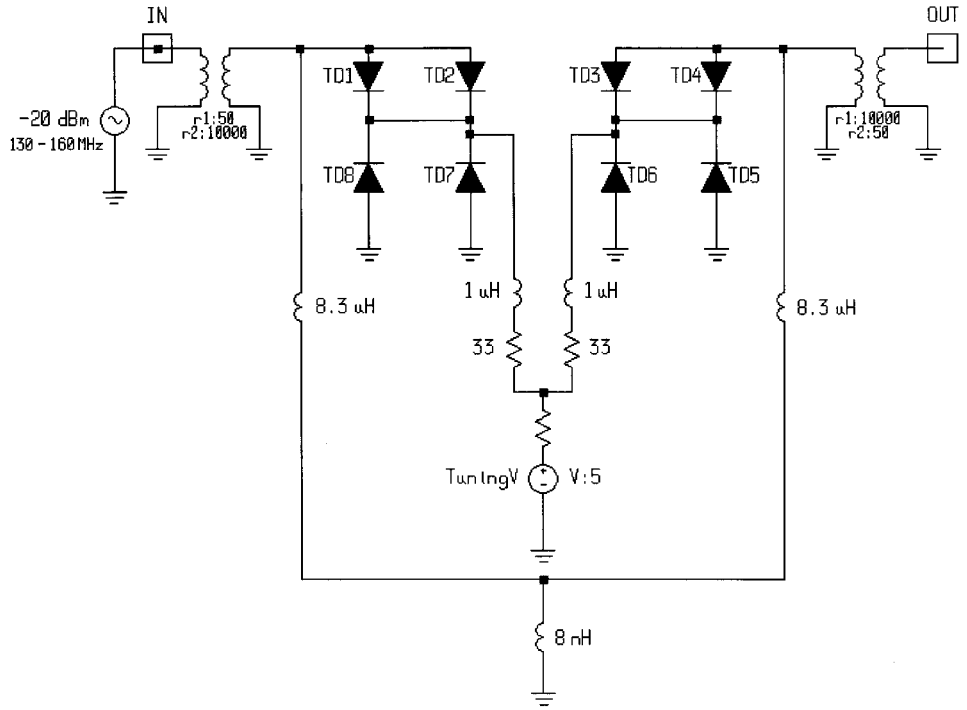

Figure 3-146 Double-tuned filter at 161 MHz using hyperabrupt-junction tuning diodes. By using several parallel diodes, the IMD performance improves.

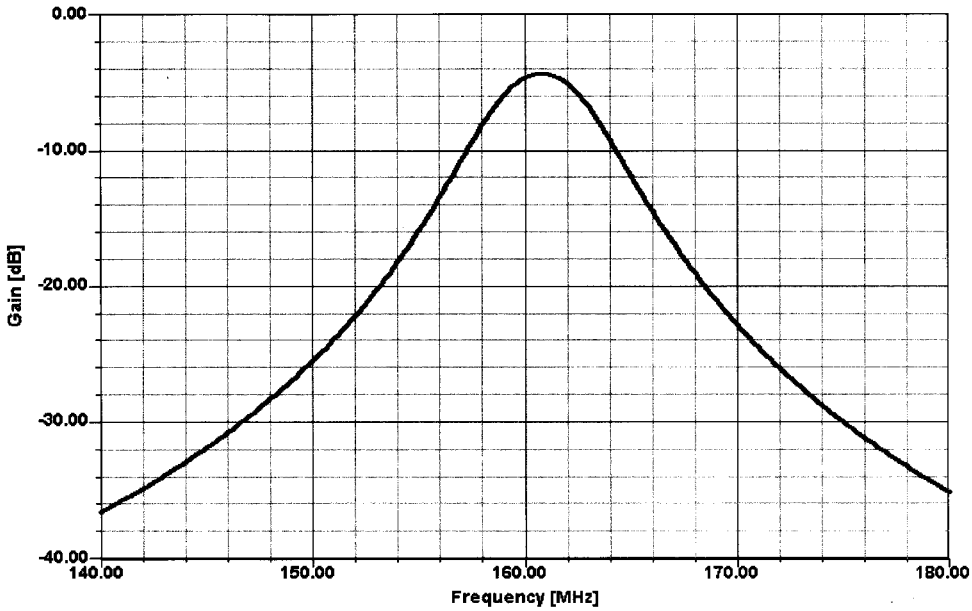

Figure 3-147 Frequency response of the tuned filter shown in Figure 3-146. The circuit is undercoupled (less than transitional coupling); $Q \times k < 1$.

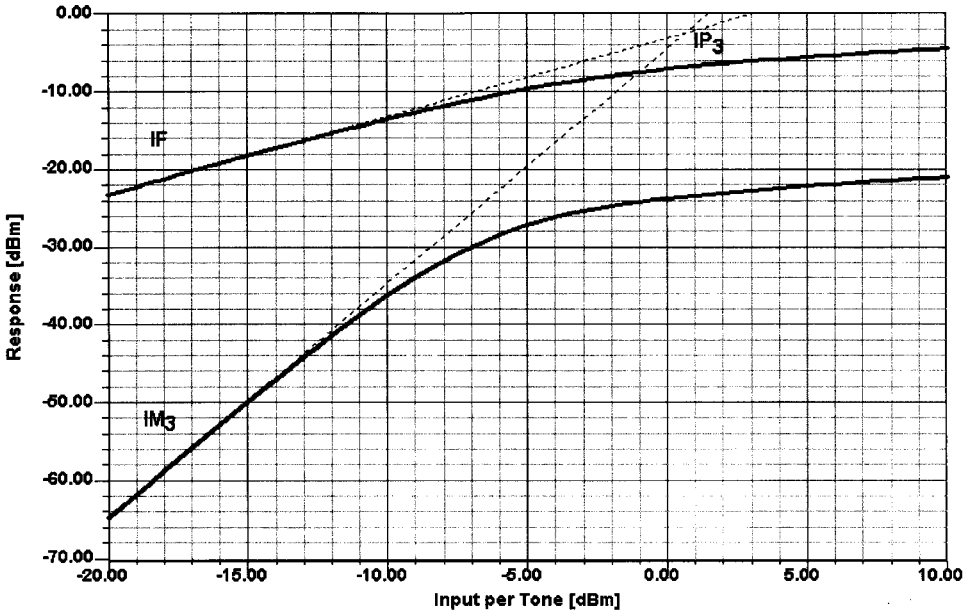

Figure 3-148 Prediction of intercept point of the double-tuned circuit shown in Figure 3-146. Note the compression of both the input signal and the IMD product.

3-6-3 An HF/VHF Voltage-Controlled Filter

The above example used a step-up procedure typically done by a tap at the input and output inductance. This method allows an impedance transformation; however, if one desires to change it into a series-tuned arrangement, it has to be done with a transformer. The large-signal conditions in the frequency range from 10 to 30 MHz on a medium- to large-sized antenna are equivalent to, if not worse than, the conditions for VHF operation. The only exception would be line of sight into the transmitter such as a tower in the middle of the city. Examples of such hostile conditions would be any large city, such as Munich, New York, Miami, Chicago, and San Francisco, where the authors had significant experience with intermodulation distortion problems.

By translating the circuit into a low-impedance-drive arrangement, building it symmetrically, and reducing the tuning range somewhat by capacitors and many series diode pairs, the filter's large-signal performance was significantly improved. The tuning diodes had about 125 pF at 1 Vdc per unit. Initial tests trying to use a high-capacitance diode, such as the BB112, resulted in much higher IMD products. The B112 has a 1-V capacitance of 470 pF down to about 20 pF at 8 V. Standard diodes show about 30 pF at 1 V, while the diodes used in the experiment had a 125-pF capacitance at 1 V. These experimental diodes were made available from a well-known manufacturer for this evaluation. Figure 3-149 shows the circuit diagram.

A step-down transformer drives the tuned circuit with a source impedance of 12.5 Ω. The circuit is symmetrical. There are two 0.8-μH inductors and 2×5 diodes in the loop. The output of the circuit is transformed back up to 50 Ω. The tuning voltage is supplied via a heavily filtered arrangement. This circuit has actually been implemented in Rohde & Schwarz field strength meter equipment. They guarantee an intercept point of about +20 dBm. The selectivity of these circuits is quite reasonable and mostly intended to reduce

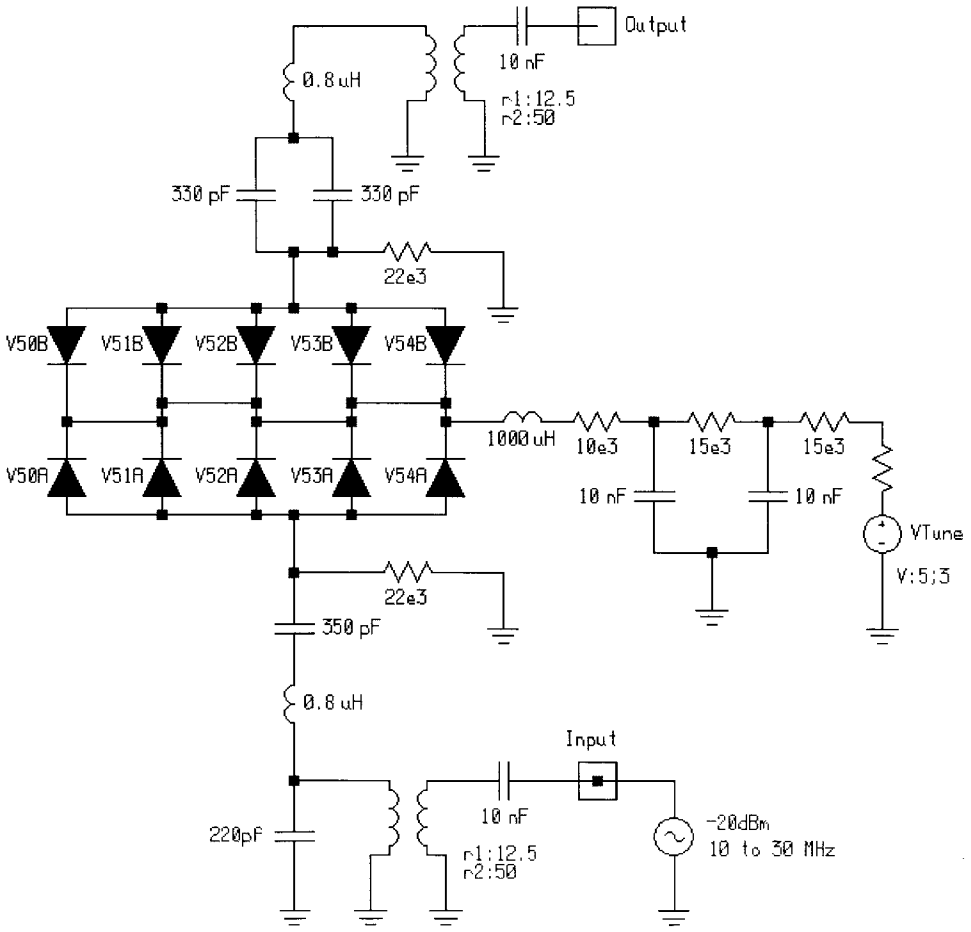

Figure 3-149 High dynamic range of a 10–20-MHz filter.

second-order intermodulation distortion products by about 10 dB, at the same time having a high third-order intercept point. Figure 3-150 shows the selectivity curves at two different tuning voltages.

The most interesting number, however, is the third-order intercept point (already determined as about 20 dBm), which still had to be simulated. This sometimes sounds like a contradiction: Once the measured values are available and are acceptable, why would one want—or, rather, need—to do a simulation besides the necessity to develop a high-input intercept filter? It was desirable to validate the nonlinear models and prove that the above-mentioned equations will hold true. This type of simulation is now more difficult because the number of nonlinear elements went from four to ten, and some numerical problems, such as convergence difficulties, can be expected, and the effect of harmonic frequency cancellation (compensation) can also be seen. By using diode combinations that result in $1(1 - n)$, n being an integer number, these IMD products can drastically be reduced. This implies that each of the five diode pairs has a selected value for n to meet this condition. Later, a final attempt will be made to improve the first VHF filter with the proper diode combinations.

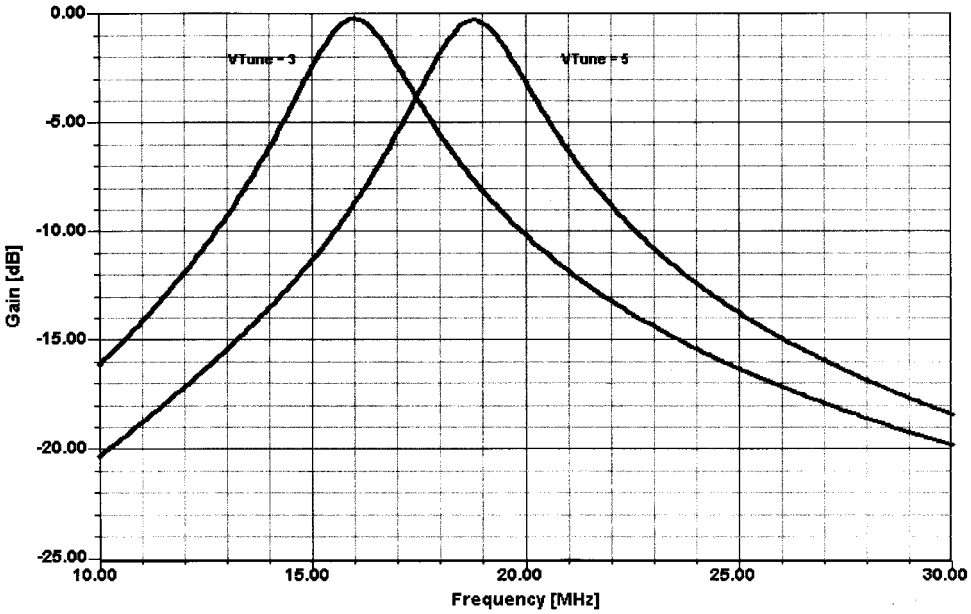

Figure 3-150 Frequency response of the filter shown in Figure 3-149. Filters of this type are intended to reduce second-order IMD by providing about 20-dB suppression at half the center frequency.

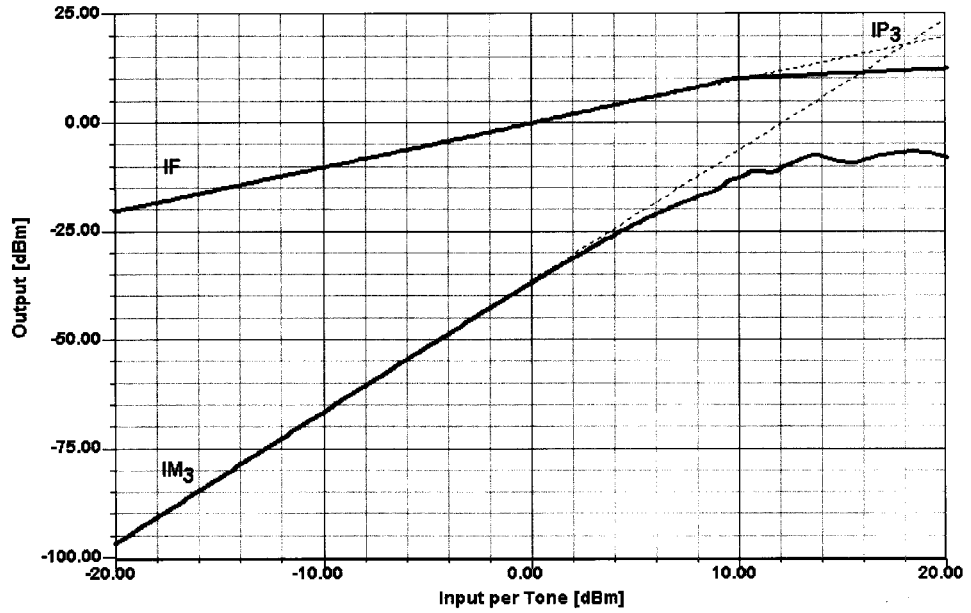

Figure 3-151 Prediction of third-order intercept point of the filter shown in Figure 3-149. The reason for the curves on the IMD plot lies in the interaction between the ten nonlinear devices.

Figure 3-151 shows the calculation of third-order intercept point for the arrangement shown in Figure 3-149. This number has now increased to +18 dBm. The difference between selection and measurement is approximately 2 dB. The reason for this more pessimistic value compared to the measured value probably has to do with slight variations of the exponent of the diodes' voltage-dependent capacitance. Therefore, the authors consider both the circuit performance and the simulation accuracy to be extremely good. This type of circuit, as mentioned earlier, has wide application in oscillator circuits. Danzeisen of Rohde & Schwarz was probably the first to have used this type of circuit by paralleling many diodes for improved performance.

3-6-4 Improving the VHF Filter

By selecting the appropriate diode combinations and circuit modifications as shown in Figure 3-152, a significant IMD improvement of the circuit shown in Figure 3-146 is obtained. A special shunt arrangement of several diodes with different exponents has been developed, which allows its value to be "adjusted." This circuit, for which a patent has been applied, showed an improvement from –2 dBm to 32 dBm. The same high operating Q was maintained. Figure 3-153 shows the frequency response after the modification. Note that a coupling slightly greater than critical ($Q \times k = 1.1$) has been selected.

3-6-5 Conclusion

After explaining some of the nonlinearities in mathematical terms, we have given some examples of voltage-tuned circuits and discussed their large-signal performance. This section has also shown that modern CAD tools can accurately predict the performance of such circuits.

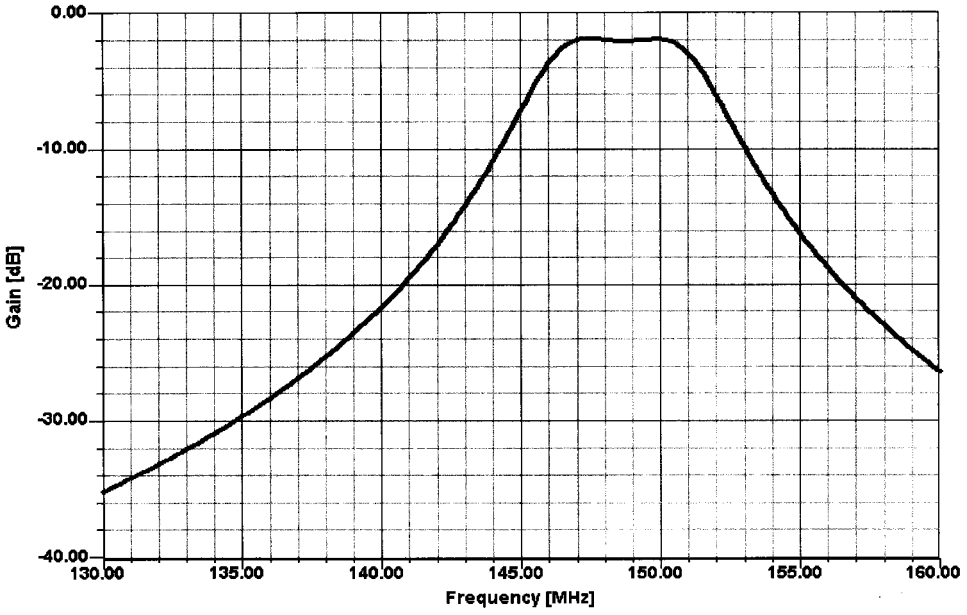

Figure 3-152 The frequency response of the improved circuit derived from Figure 3-146.

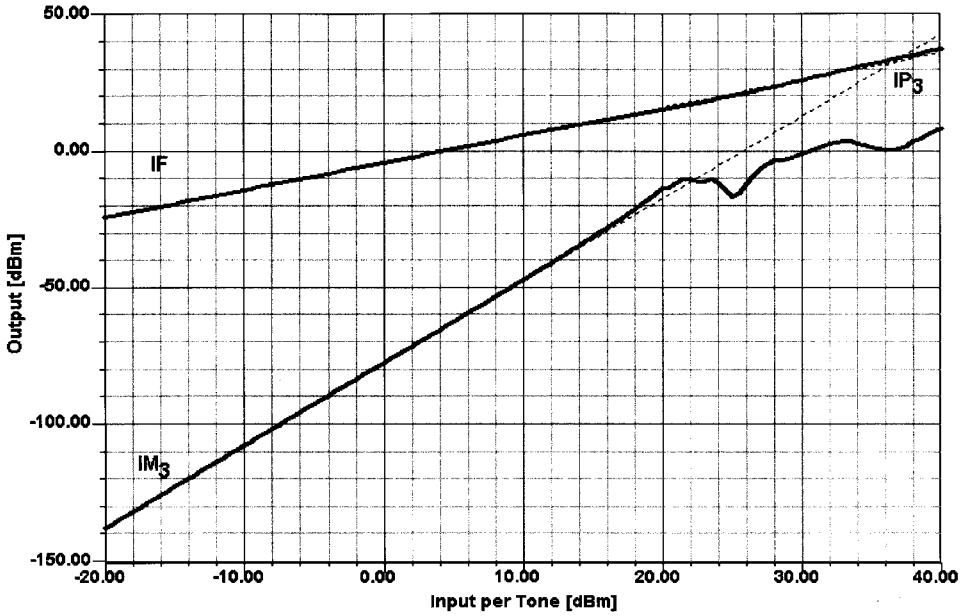

Figure 3-153 Predicted IMD performance of the improved version of the circuit shown in Figure 3-146. This type of improvement is significant for all applications. A patent is in the process of being obtained for this; therefore, the circuit cannot be disclosed at present.

3-7 DIFFERENTIAL AMPLIFIERS

The differential amplifier (Figure 3-154) goes back many years and also was the first step from TTL to ECL. The differential amplifier consists of an emitter follower (Q1) and a grounded-base stage (Q2). The constant-current generator (Q3) between ground and the emitters of Q1 and Q2 determines the current for these stages; the dc operating currents of Q1 and Q1 are the same. Most modern integrated circuits use this differential amplifier in one way or another.

If the circuit is operated about its point of symmetry, the dc component of the current through either Q1 or Q2 remains half of the emitter constant current through Q3 for all symmetrical driving signals. In addition, for input signals that are aperiodic, no even harmonics are generated. This assumes that the stage is driven symmetrically at both inputs. In our case, the differential amplifier has its second stage grounded, meaning that there is a base-to-ground capacitor, and the stage is asymmetrically fed. As the input voltage is increased, the differential stage becomes a limiter, which limits the current between plus and minus I_S, with I_S being the source current. The resulting output will become a square wave. This stage can also be used as a line receiver, translating a sine wave to an output logic suitable for driving emitter-coupled logic (ECL) stages.

One can assume that the differential amplifier has a transconductance of

$$g_m = \frac{\alpha g_{\text{in}}}{2} \tag{3-190}$$

where α is the ratio of collector to emitter current. Within the limits of the output being a sine wave, this stage has very low distortion. The output current now is determined by

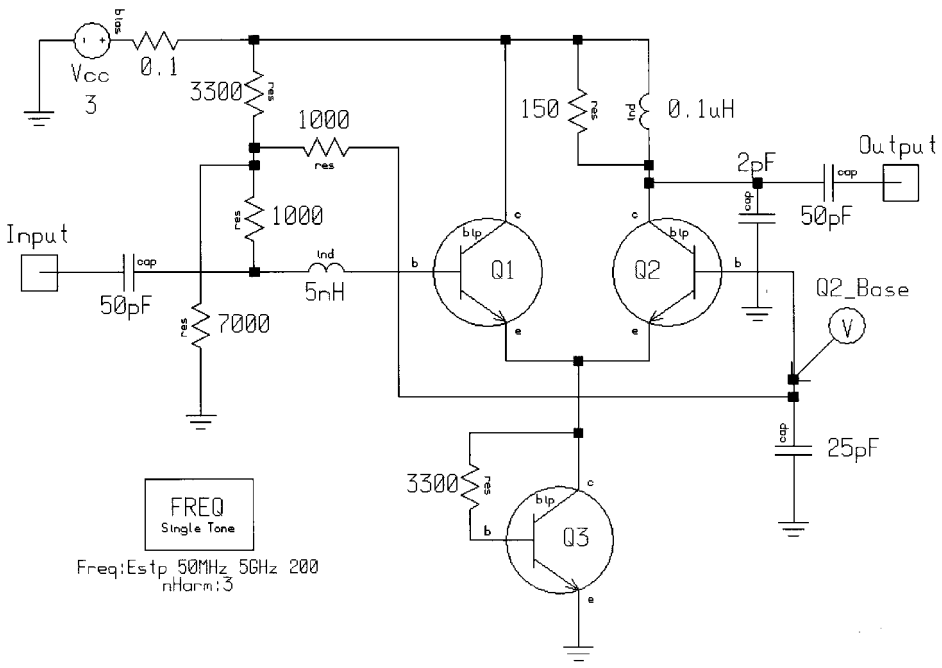

Figure 3-154 The differential amplifier schematic. The transistors are Siemens BFP420s. Figure 3-155 shows the circuit's frequency-dependent gain, matching, and noise performance.

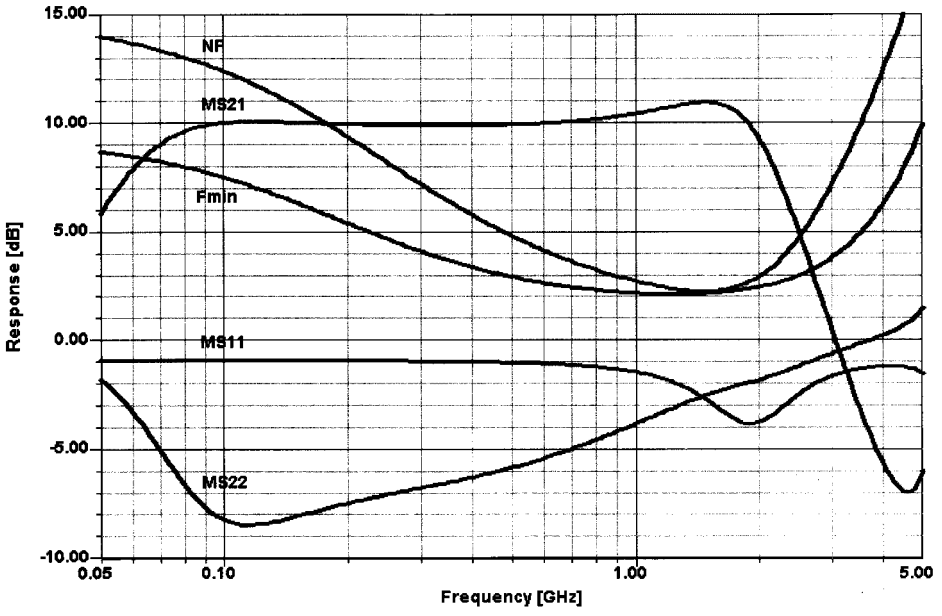

Figure 3-155 Frequency-dependent gain, matching, and noise performance of the differential amplifier.

$$i = \frac{I_{\text{in}}}{2} \tanh\left(\frac{x}{2} \cos \omega t\right) \tag{3-191}$$

where ωt is the input frequency and I_{in} is the current forced by Q3. The reason why the transconductance has to be divided by 2 comes from the fact that the current is split into two equal components for Q1 and Q2. Multiplying the new transconductance with the output load gives the voltage gain of this amplifier; its power gain can be obtained by multiplying this with $\sqrt{\text{output resistance} \div \text{load resistance}}$.

Having done the linear analysis and having learned that because of the hyperbolic tangent functions this amplifier can also be used as a line receiver, and converting sinusoidal waves to square waves, it may be useful to take a closer look at these issues. If we take a CAD oscilloscope, we see the resulting output waveform being a nonequal duty cycle output voltage, which results in high harmonic content. The amount of harmonic content can be controlled by the drive power and by the actual bias. Figure 3-156 shows the resulting output waveform.

If we now switch to a CAD spectrum analyzer, we can evaluate the harmonic content (Figure 3-157). Figure 3-158 shows the output transistor's dc I–V curves and ac load line under these conditions. Based on the previously defined conducting angle of the differential amplifier, one can optimize for harmonic content. Therefore, it is logical at this point to look at frequency multipliers, as they are sometimes needed. Finally, we are curious to see the so-called load line of the output transistor, which is, based on the interaction of all the stages, not looking the same way as the expected one, which we know from previous amplifier examples. Part of the reason for this is that for a certain voltage range, the collector voltage is in the negative region, and all kinds of saturation effects result in this surprising waveform. By reducing the input power, one would obtain a more "expected" load line. We invite readers with CAD capabilities to play with this example, as it gives a lot of insight into the operation of ECL stages.

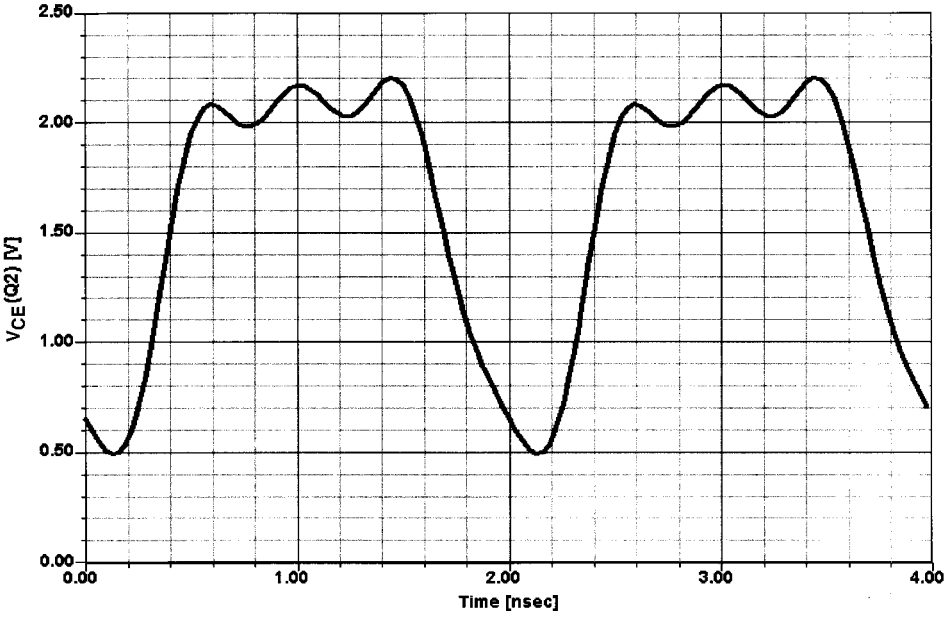

Figure 3-156 V_{CE} versus time for output transistor Q2 with a drive of 10 dBm.

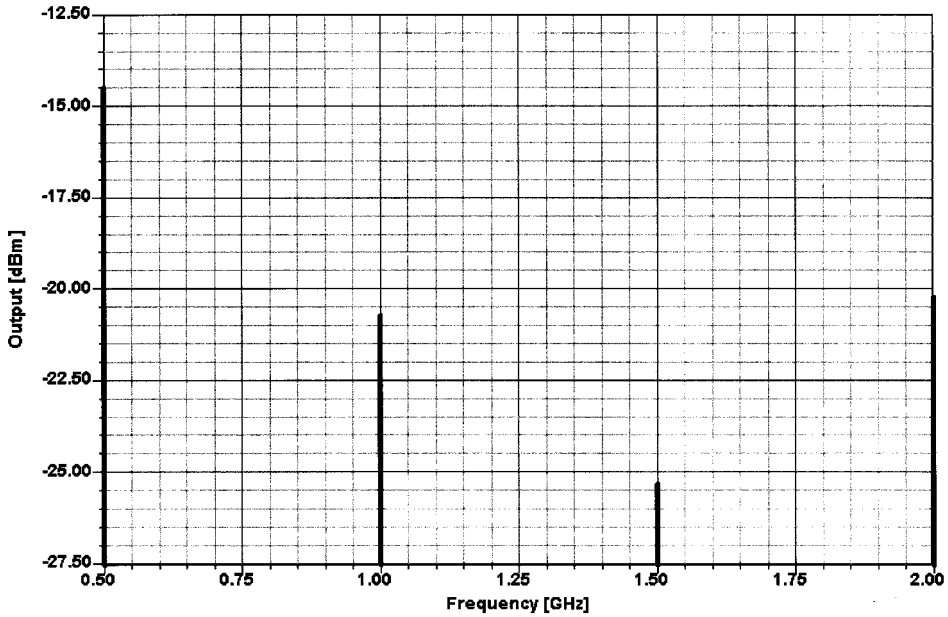

Figure 3-157 Output spectrum of the differential amplifier with a drive of 10 dBm. The biasing is not optimal for frequency multiplication.

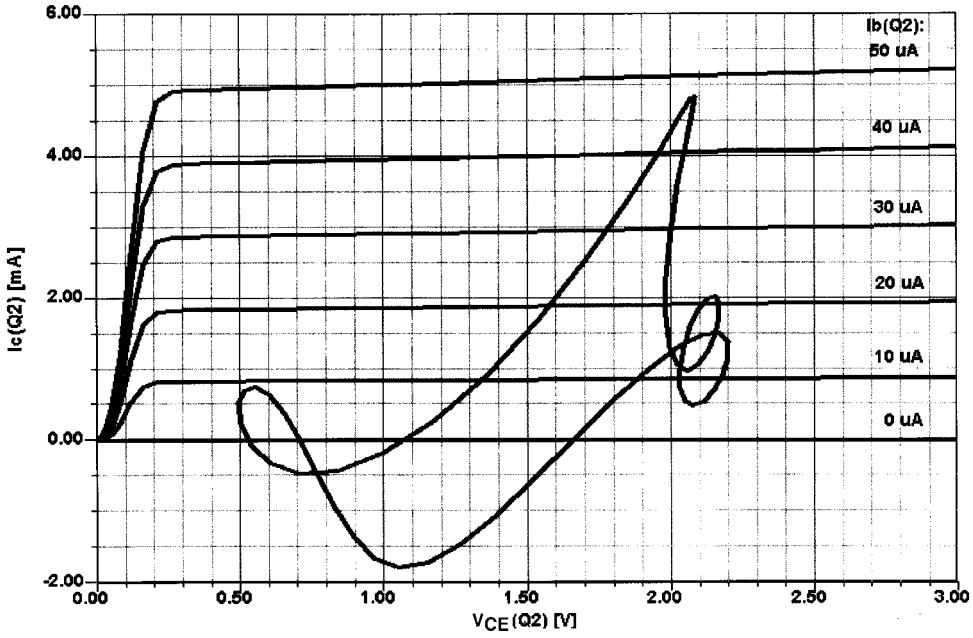

Figure 3-158 The dc *I–V* curves and ac load line for output transistor Q2 with a drive of 10 dBm.

3-8 FREQUENCY DOUBLERS

Having seen that the harmonic content invites us to bias a stage from Class A into Class B or C if our goal is a harmonically rich current, we will now evaluate a single stage that will be biased close to cutoff and driven by a relatively low frequency (500 MHz). To obtain the best results, we will use a parallel notch filter in the output, followed by a high-pass matching circuit to "catch" the desired harmonic. The input frequency is heavily suppressed by the notch filter. Based on its finite Q, there is a limited range over which this frequency can be varied with constant subharmonic attenuation. Figure 3-159 will be our test circuit.

This circuit consists of a bias transistor, Q2. This method has been discussed before and solves the temperature-dependent bias emitter thermal runaway problems through "temperature compensation." The purists among our readers may point out that the currents drawn by Q1 and Q2 are not quite identical (which would give 100% cancellation), but the approach shown is sufficient to do its job. Also, we have chosen a Class AB operation point, which is defined by Q1's 1-mA dc standing current. The conducting angle has not been optimized for the second harmonic—a task that the interested reader can do by using the conducting angle relationship shown at the beginning of this chapter. To give readers with access to nonlinear CAD some homework, we have not set this at the optimum point.

The second transistor, here called Q1 (because of its importance at RF), has a matching network at the input. This is recommended for optimum energy transfer. The matching condition can be validated by examining Figure 3-160. If we look at the higher frequency response, the input shows a possible trend of oscillation (negative loss); this could actually be eliminated by using a low-pass filter at the input instead of the high-pass filter used now. Findings of this type always make us nervous, and we hope that the nonlinear models are sufficiently accurate at higher frequencies to predict such behavior correctly. In the case of the FET doubler mentioned in Chapter 2, we found that the device modeling done by Compact (now Ansoft) gave the best results, the university answers were fairly close, and the device manufacturer data were worst. We have since become highly skeptical about device modeling unless we can validate it ourselves. Synergy Microwave has a complete set of test equipment in the laboratory, including network and spectrum analyzers with special software created by Rohde & Schwarz that can be used in addition to the Scout program to do in-house validation. This was achieved by the use of nonlinear optimization at a drive level of 0 dBm. One could say that this is similar to using a load-pull approach at the input, and then resorting to the large-signal S parameters obtained. Another note of caution: Capacitors at these low values tend to have a very large percentage error; for instance, a 1-pF capacitor, if not selected carefully, can vary between 0.7 and 1.3 pF—a 50% error. Needless to say, this is not acceptable for useful production.

The output consists of a high-pass filter and a notch filter with the purpose of reducing the subharmonic significantly. We have again done this on purpose, leaving room for the reader to come up with a more inventive output circuit like a Cauer-type (same as elliptical) low-pass filter with discrete notches at higher harmonics of the input frequency, such as 1.5 GHz, 2 GHz, and so on. In addition, we have shown three ways how to implement the inductance for the notch filter. This is equally applicable for other inductors in this value range. As frequency increases, this becomes more interesting but one needs to remember that many materials like silicon and gallium arsenide are extremely lossy. The same inductor approach has been used in Figure 5-61 of Chapter 5. For silicon, even the manufacturer becomes an issue. Figure 3-161 shows a top view of a "rectangular" inductor that actually approaches the spiral inductor; its implementation can be seen in Figure 3-162. Modeling this was a

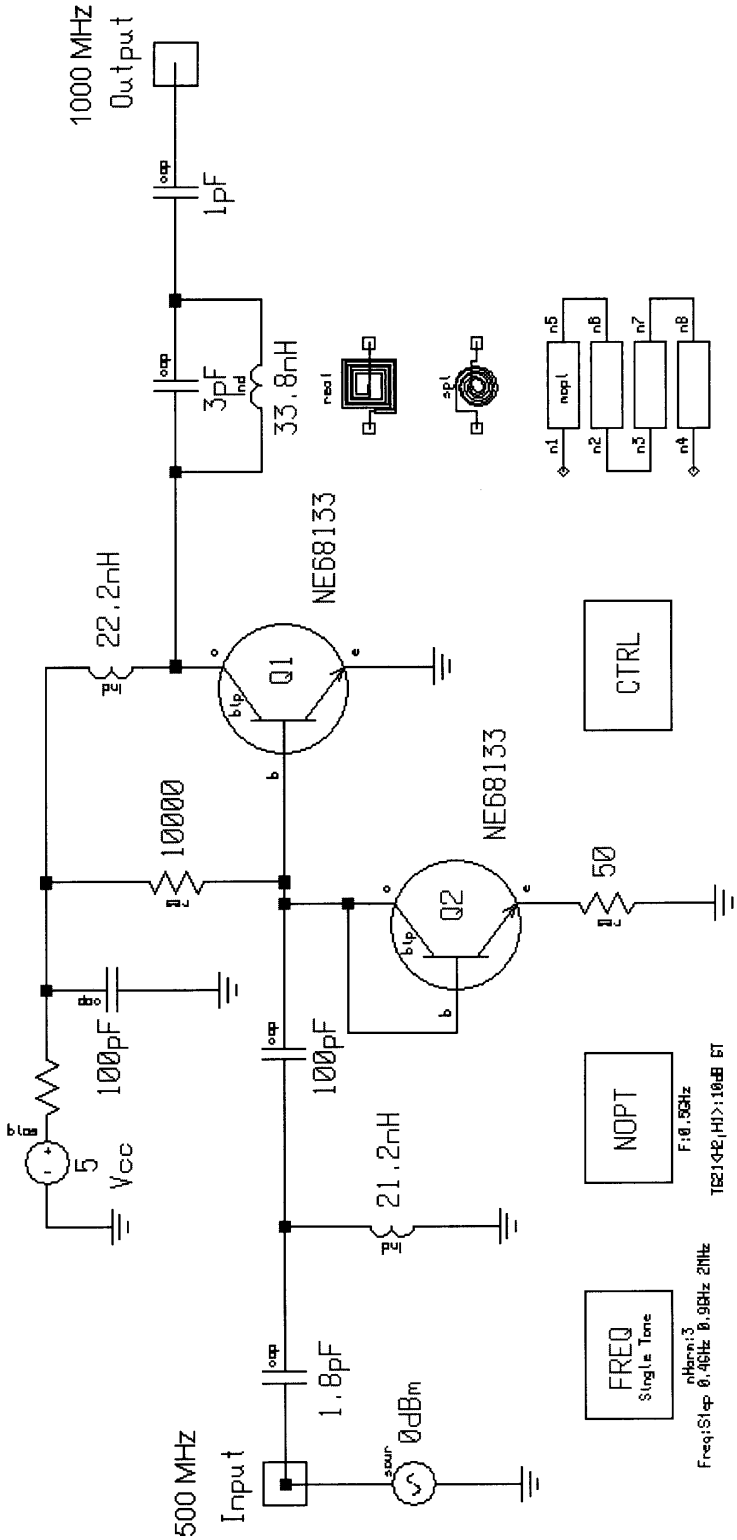

Figure 3-159 BJT frequency doubler schematic. A parallel-tuned trap in Q1's collector attenuates fundamental feedthrough.

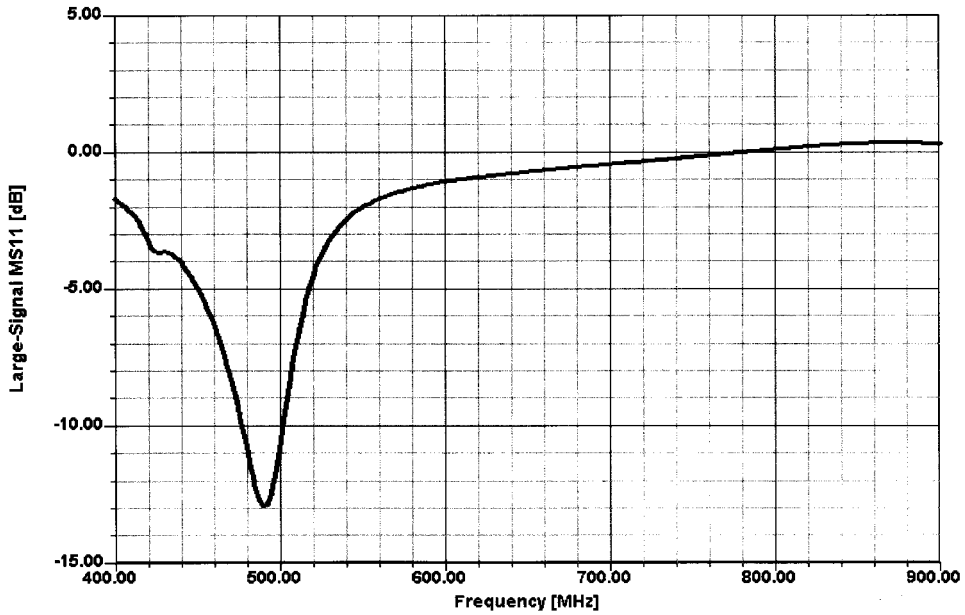

Figure 3-160 Large-signal MS_{11} for the BJT doubler. Note the positive region above 800 MHz.

nightmare, and during our Compact days, we actually had to modify the electromagnetic simulator to accommodate this and get results where measurements and simulation agreed. Figure 3-163 shows the measured and simulated Q as a function of frequency of a silicon-based inductor. In the case of other materials, such as PC board or GaAs, the models in the CAD tools are sufficient to predict the losses of the inductors. Following this initial exercise, Motorola then developed an improved silicon spiral inductor; its frequency-dependent Q is shown in Figure 3-164. Note that this Q was measured and not simulated.

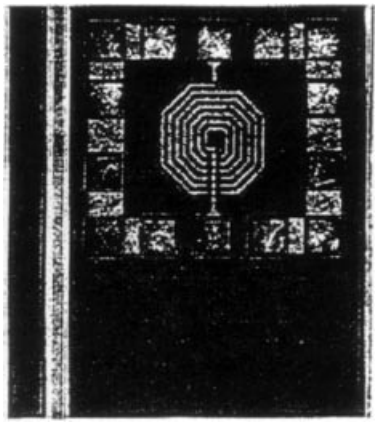

Figure 3-161 A 6.5-turn spiral inductor in silicon.

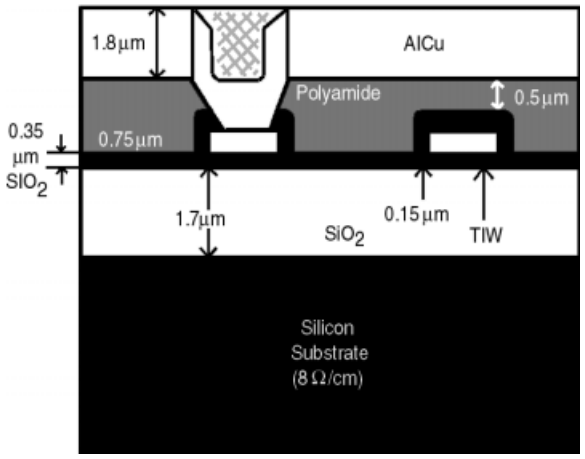

Figure 3-162 Cross section of the silicon inductor.

One of the reasons why we use a transistor multiplier is that we expect gain (because of the square-law characteristic, an FET would have been better tailored for a doubler); therefore, we have "measured" the gain of this circuit while driving it with 0 dBm. Another important factor is that, because of the way the CAD tool displays it, the gain is referenced to the 500-MHz input. Mentioning this is important; otherwise, the reader may look for the 1-GHz gain, which does not exist. Figure 3-165 shows the doubler gain.

By now we are curious to see the doubler in action, and by reviewing Figure 3-166 we can see the output spectrum. The output spectrum validates the statement that the output circuit, while doing a marvelous job of removing the 500-MHz input frequency, does not cure the problem of unwanted multiples of the input frequency. Again, a Cauer low-pass filter, while introducing some possible additional loss, should be considered for this circuit to have a bandpass response. On the other hand, many oscillators have very little harmonic suppression, and the same type of postfiltering needs to be considered. There are two-transistor solutions available also, such as push–push for frequency doubling (push–pull would

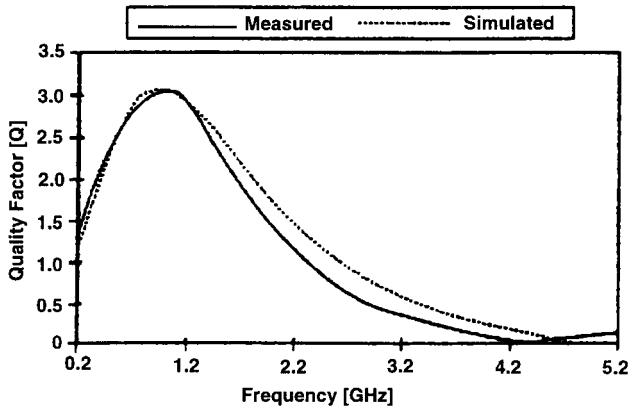

Figure 3-163 Measured and simulated *Q* versus frequency for the simulated inductor.

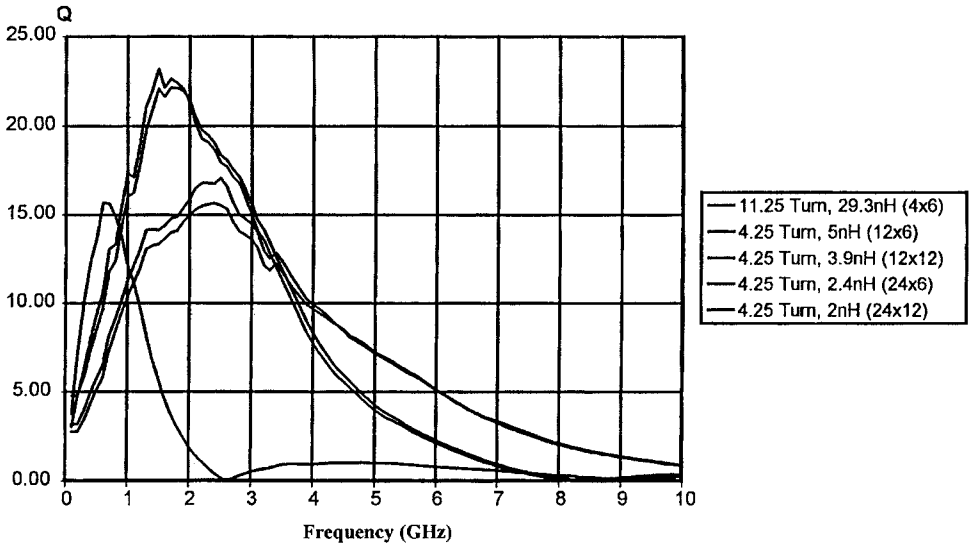

Figure 3-164 *Q* versus frequency for Motorola improved inductor.

eliminate the desired second harmonic quite well). Actually, two diodes could also have been used for doubling, but since this requires transformers and a postamplifier, we have shown the preferred application. The only advantage of the diode application is that it is wideband, while this BJT circuit, as we have just learned, must be made narrowband for reasons of spectral purity.

Finally, we are curious to see the actual operating state of this amplifier, and this can be done by analyzing the load line (Figure 3-167). This is as complicated as the analysis for the differential amplifier. Because of the stored energy in the various tuned circuits, the load line looks quite impressive and would probably be difficult to predict without a nonlinear CAD tool.

3-9 MULTISTAGE AMPLIFIERS WITH AUTOMATIC GAIN CONTROL (AGC)

Having discussed the basic differential amplifier, we will now evaluate the performance of the MC1350/1490 video amplifier chip from Motorola. Most of the circuitry in the chip is self-explanatory. Figure 3-168 shows its inner circuit, and Figure 3-169 show a recommended application. By grounding one side of the input, we effectively get the same performance as the differential amplifier just discussed, with one difference being that the input is now fed to the constant-current generator. To minimize the distortion at the two lower transistors, they are decoupled by a 66-Ω resistor. Figure 3-170 shows the frequency-dependent gain, matching, and noise figure. Since this particular device has been specifically designed for AGC purposes, we also show in Figure 3-171 its gain reduction versus applied AGC voltage.

3-10 BIASING

A lot has been written about biasing, and since the purpose of this book is not to focus too much on dc, the following examples including RF consequences have been selected and considered sufficient. Early application reports by Motorola and others have provided a wealth of data. As a side effect of the introduction of the wireless era, we find that the engineers are so pressed for time that the number of complete application reports has approached zero. This is one of the reasons why we have tried to minimize the mathematical basis of this book (some is still needed), while still providing practical assistance. Figure 3-172 shows a textbook type of approach for RF.

In order to decouple the transistor from the biasing, we use RF chokes and dc decoupling (bypass) capacitors. This is the technique used in previous examples, so one might ask, "What's new?" As frequency increases, these inductors are either not manufacturable or have such a low Q that their use becomes questionable. This is the point where one may introduce the so-called distributed elements.

Figure 3-173 shows the very same circuit but resorting to distributed rather than lumped elements. The newly introduced elements (part of any good, up-to-date CAD tool; see element library for how to use their physical element descriptions) are described next.

- *Transmission Line.* Any printed connection between two points on a circuit board is a transmission line (Figure 3-174). Its characteristic electrical impedance is a function of the square root of the dielectric constant (ε_r), the width, metallization, thickness and height above substrate of the line, and the loss tangent of the substrate. Since lines frequently have to be laid out in the form of curved connections or have a bend in their direction, we have to add elements capable of describing the high-frequency conse-

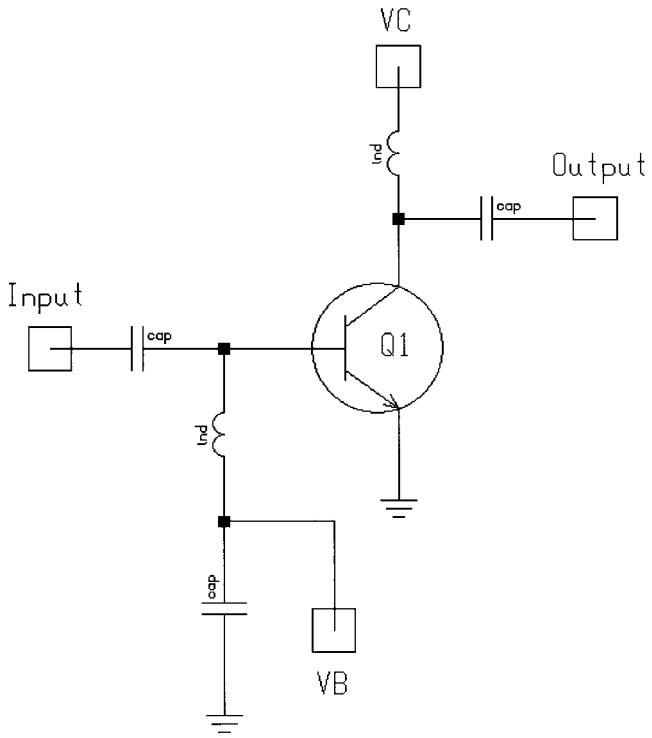

Figure 3-172 Simple BJT RF amplifier with lumped elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

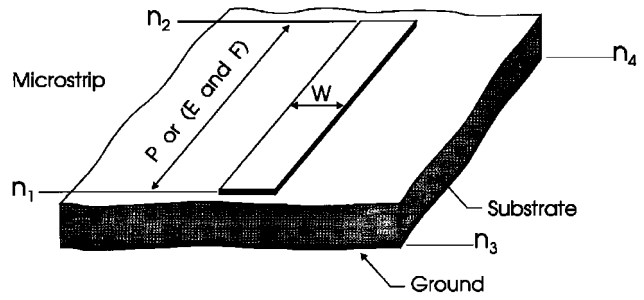

Figure 3-174 Transmission line in microstrip.

quences of such connections. Figures 3-175 and 3-176 show mitered and radial bend elements that perform this function.

- T *Junction, Cross, and* Y *Junction.* By the time a point like a collector or base, or its FET equivalent, spreads out into connections with other elements, we need additional modeling capability to describe ⊤ connections, crossings, and Y junctions. Figures 3-177, 3-178, and 3-179 show the way in which these connections must be modeled.

If the need exists, the standard inductances must be replaced with a transmission line whose length is λ/8 at the operating frequency. At higher frequencies, these transmission lines, however, then go into λ/4 resonant mode and later become capacitive. This type of design makes it fairly narrowband. A way around this is the use of printed inductors, as shown in Figures 3-180 and 3-181.

These inductors have a self-resonant frequency similar to the transmission line mentioned above, but the safety margin is significantly higher.

Talking about printed inductors, a logical extension of this is the printed transmission-line-based transformer, as shown in Figure 3-182. One can consider this as two interlaced rectangular inductors and, based on the substrate material, they are useful over a wide frequency range. Besides being used as a transformer, they can also be used to transit from

unbalanced to balanced transmission provided that the difference in length from a connection point of view does not cause any problems (this is a layout issue).

A popular form of combining stages is the so-called Lange coupler (Figure 3-183) invented by the German Julius Lange. It is one of the major contributions in wideband applications.

Useful application of the Lange coupler probably starts at 4 GHz. It consists of parallel transmission lines with the appropriate connections as shown. Lange couplers are typically built with four, six, and eight fingers. The Ansoft Serenade product has a Lange coupler synthesis program that can be used to gain more insight into this coupler's application. We assume that other modern software has similar capabilities.

Where meander-type inductors are necessary, a neat way to implement and simulate them is to use the multiple coupled lines element (Figure 3-184) of the Serenade product, which both quickly and accurately calculates the behavior of the meander, including self-resonances and losses. We made use of this arrangement in our previous examples.

- *Interdigital Capacitors.* The issue of tolerances of small capacitors already has been brought up. The interdigital capacitor can be made on printed circuit board material as

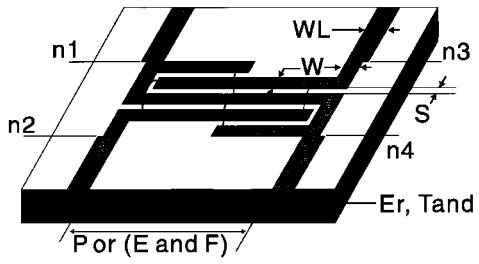

Figure 3-183 Four-strip Lange coupler.

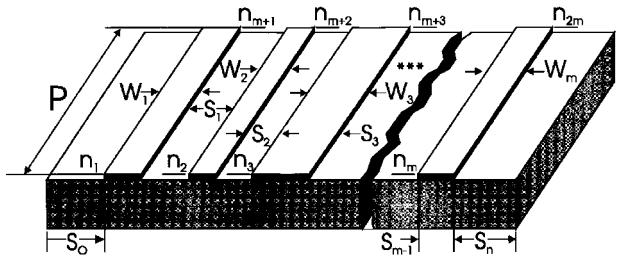

Figure 3-184 Multiple coupled lines element in microstrip.

well as gallium arsenide, and if its dimensions are continuous with the transmission-line width it does not cause any abrupt changes in impedance. This type of capacitor permits one to obtain very small values. An alternative to this is the use of transmission lines with a length of $\frac{3}{8}\lambda$. We learned earlier that a transmission line is inductive at frequencies below its fundamental resonance, is resistive at below resonance, and becomes capacitive above resonance. Again, bandwidth is also an issue. An interdigital capacitor consists of a number of parallel fingers as shown in Figure 3-185, and its capacitance can be varied by adjusting the number of fingers and their spacing. The advantage of the interdigital capacitor compared to discrete components is its low variation in value.

- *Radial Stubs.* The radial stub (Figure 3-186) is not much different from a $\lambda/4$ resonator, but its bandwidth is much greater than a simple transmission line. This is another way to ground the "cold" side of a transmission line or part of a circuit that needs to be grounded for RF. Of course, the interdigital capacitor comes in a version that is a combination of a capacitor and a via hole.
- *Via Holes.* The "cold" end of the transmission line, being considered either an inductor or a capacitor, needs to be connected to a sufficiently large copper backplane. One very efficient way to do this, especially if there is not enough copper left on the top of the board, is the use of via holes (Figure 3-187). One could theoretically generate

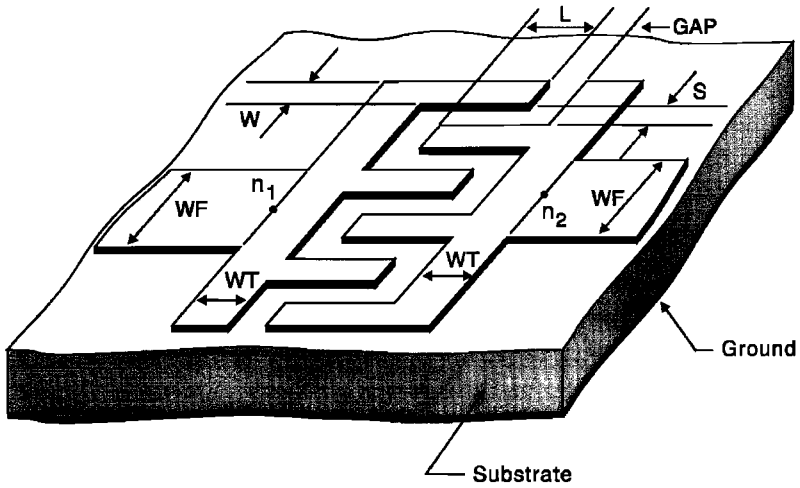

Figure 3-185 Interdigital capacitor.

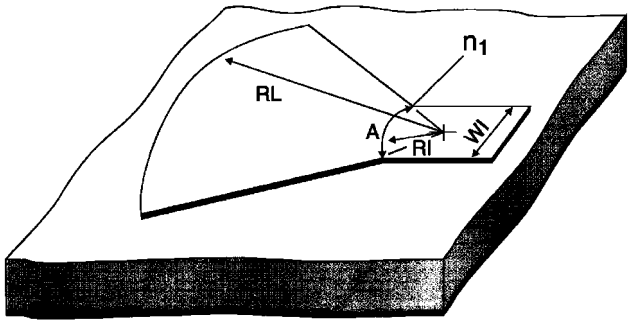

Figure 3-186 Radial stub.

a via hole with a rivet, but most manufacturing processes don't allow this; the normal solution is to use plated-through holes left open. In PC boards, via holes are typically cylindrical; on substrates like GaAs, they may be conical.

- *Correction Elements.* Although the behavior of an actual circuit proceeds regardless of our ability to measure and describe it, we do not enjoy this luxury in simulating circuit behavior in software. In a simulator, effects that are insufficiently described will be inaccurately simulated. For instance, segments of high-impedance transmission line (e.g., 120 Ω) are frequently used for dc feeds and RF chokes. In predicting the effect of a transition from 120-Ω line to 50-Ω line, a simulator must be alerted to the discontinuity so it can do the necessary mathematical corrections to account for the impedance jump. To do this, a specific circuit element, the STEP (Figure 3-188), must be inserted between the 120-Ω and 50-Ω line elements in the simulation circuit file. In addition to substrate data, we characterize a STEP by providing the widths of its input and output lines. The element itself has no physical length.

A similar correction is necessary if a transmission line is used as a resonator or just "left open" at one end. Such a transmission line tends to radiate and, because of its high-impedance properties, it reacts differently as far as its electrical length is concerned. A zero-length one-port element, the OPEN (Figure 3-189), must be added to such a line for mathematically correct calculation.

We end this excursion into distributed elements here. Interested readers may want to obtain a CD containing the element library of their favorite CAD tools that combine capabilities in the microwave area with a full set of distributed circuit elements. It is most important to keep

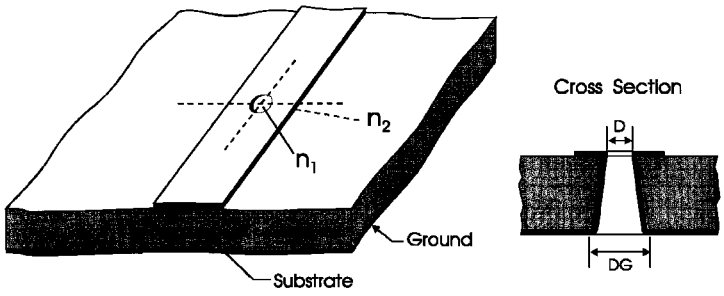

Figure 3-187 Via hole.

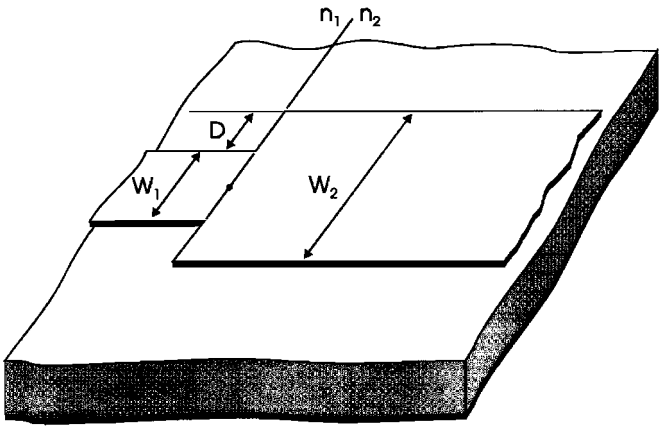

Figure 3-188 The STEP element tells the simulator to calculate the effects of joining transmission lines of differing characteristics.

in mind that, as frequency increases, we rapidly move into the area where we must consider all these distributed elements to achieve accurate simulations—even if doing so makes simulation a painful and time-consuming effort.

Finally, anyone who adventures into this area *must* obtain a foundry manual from the company that will build the integrated circuit or hybrid under design. There are basically two foundries, one applicable for MOS technology and one for GaAs. In the case of the bipolar transistor, the foundry service is not yet well-established. While we were able to interest one German company and one U.S. company in generating a custom bipolar IC within the activities of this book, the only "open" foundry we know of for bipolar (actually HBT) technology is the one operated by TRW. As of 1999, this seems to be the leading company for BJT-related products, and many currently available ICs have been developed with this foundry service.

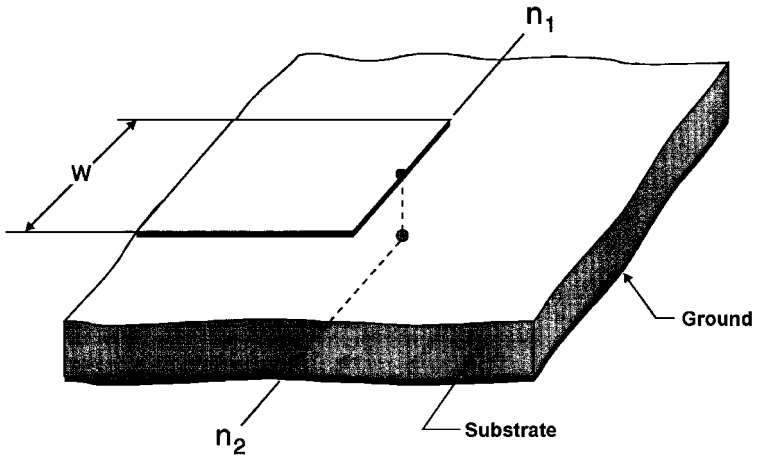

Figure 3-189 The OPEN element tells the simulator to calculate the effects of leaving the end of a transmission line unconnected.

We mention the issue of foundries here again because each foundry has its own proprietary approach to modeling discontinuities. The availability of a foundry service somewhat eases the requirement that a designer be fully up to speed on the nuances of discontinuities, because a foundry's designer service will help customers account for all relevant parasitics or discontinuities in their designs. In addition, there are tables of *S* parameters for standard cells of either capacitors, resistors, or inductors. The designer may then be forced to adjust the circuit so that it will work with a particular inductance value or value of another component within the resolution of the table that describes these elements. Information on the active parts, such as diodes and transistors, was given in Chapter 2.

3-10-1 RF Biasing

Applying the knowledge we have just acquired about distributed elements, Figure 3-190 shows a somewhat exaggerated case of using the various elements. While it is consistent with the simple RF case with which we started, modeling of this type is certainly necessary at higher frequencies. Many but not all of the elements we have just described are used, but we have not solved the question of the actual dc biasing.

3-10-2 dc Biasing

The following discussion is the recommended procedure for biasing a transistor. We will start with the collector current (in our example, Figure 3-191, 10 mA). To separate RF and dc, we have a combination of a load resistor (R_L) and an inductance (L_C). Information about this operation was given already in Section 3-2-6. The emitter resistor should have a voltage

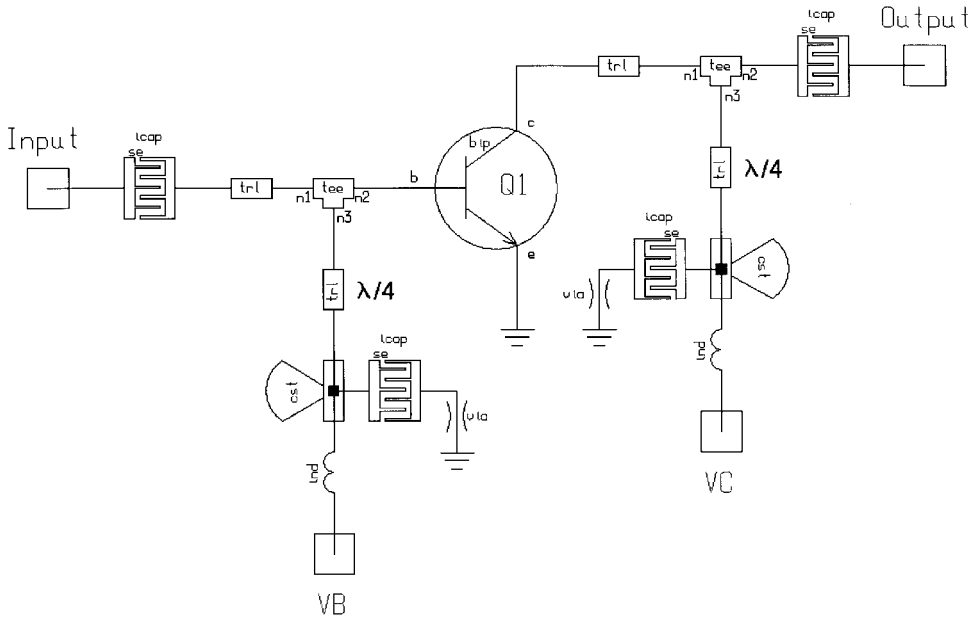

Figure 3-190 Simple BJT RF amplifier with distributed elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

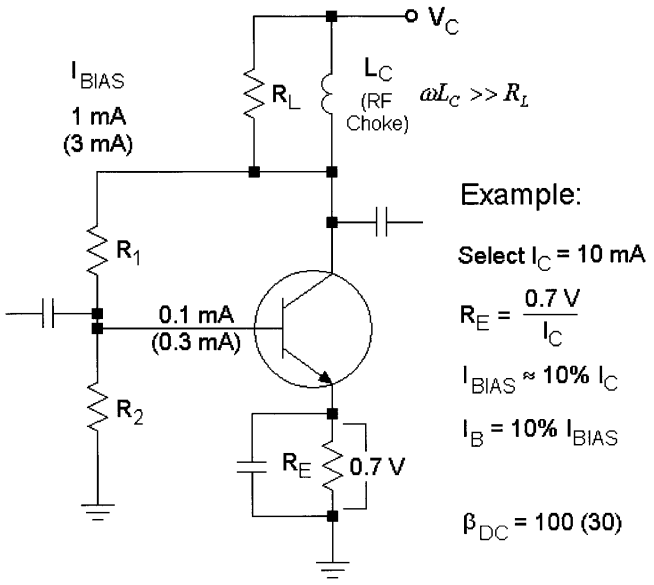

Figure 3-191 A dc biasing example.

drop of about 0.7 V, and therefore the emitter resistor is $0.7/I_C$. The next assumption is that the transistor has a dc current gain of 100, and therefore we decide to have the bias resistor chain (R_1 and R_2) draw 10% of I_C, or 1 mA. Assuming a collector voltage of 5 V, the value of $R_1 + R_2$ has to be 5 kΩ to result in the required 1 mA. Because the base current now is 10% of the divider current, the base will draw 0.1 mA. The voltage across R_2 has to be the voltage drop across R_E (0.7 V) + V_{BE}, which is also 0.7 V, or 1.4 V. Given the 1 mA, R_2 = 1.4/1E–3 = 1.4 kΩ. R_1 therefore is 5 kΩ – 1.4 kΩ = 3.6 kΩ. This concludes the calculation.

In the case of a dc beta of only 30, we need to raise I_{BIAS} from 1 mA to 3 mA since the base current now will be 0.3 mA. This changes the resistor values. $R_1 + R_2$ = 5 V/3 mA = (rounded) 1.6 kΩ. Following the same approach, we need 1.4/3E–3 = (rounded) 470 Ω. This makes R_1 = 1600 Ω – 470 Ω = (rounded) 1100 Ω. These roundings were necessary because resistors can only be bought in certain resistance steps.

However, for low battery voltages, the 0.7 V between the emitter and ground cannot be wasted. Therefore, a dc stabilization circuit, to which we have already referred, will be considered next. Figure 3-192 shows a combination of an RF transistor, Q1, and a dc stabilization transistor, Q2. The most important thing about this circuit is the fact that the difference between the supply voltage and the collector of Q1 is 0.3 V, which is approximately half of the voltage we had to "waste" across R_E in the above-mentioned circuit. Plus, the voltage drop is now in the collector, and given the fact that we feed Q1's collector through the inductor of a quasi-tuned circuit rather than through only a resistor, we get a much higher voltage swing. The base–collector diode temperature dependency of Q2 is compensated for with the silicon diode feeding the base. It is also fascinating to see that, because of the low currents, both the voltage drop of the diode and V_{BE} of Q2 are about the same, and yet Q1, operating at a reasonable current, shows the expected 0.7–0.8 V V_{BE}. We have supplied all the necessary dc voltages to give the reader an incentive to calculate the mechanism of this stabilization. The key equation to this is to determine the current in the voltage divider feeding

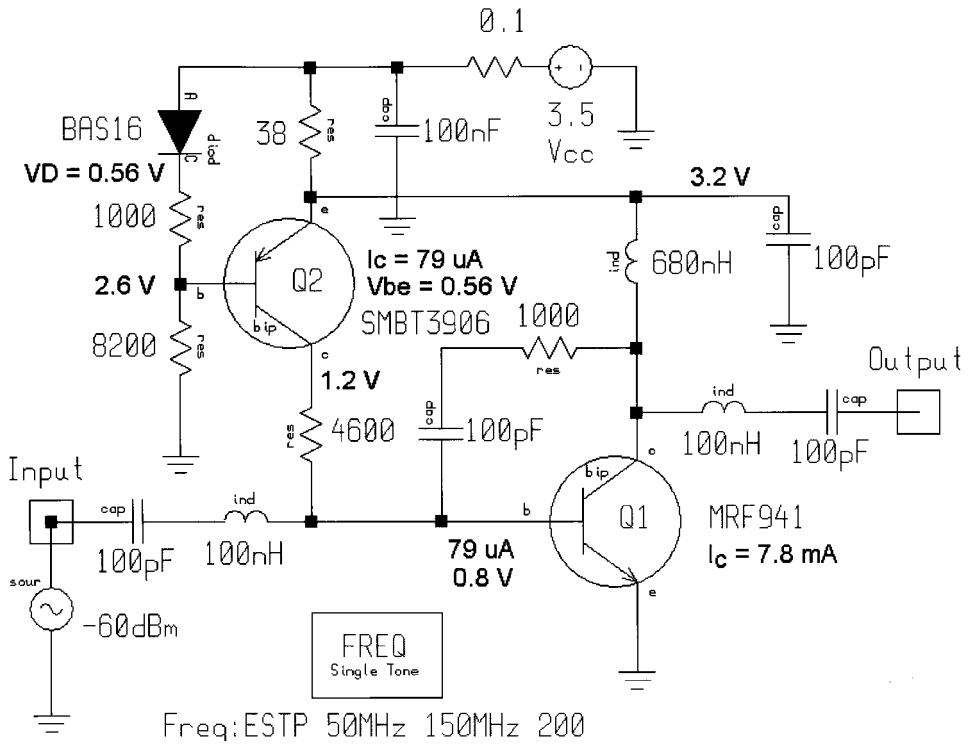

Figure 3-192 An RF amplifier with active biasing. (After the low-noise amplifier circuit in [29].)

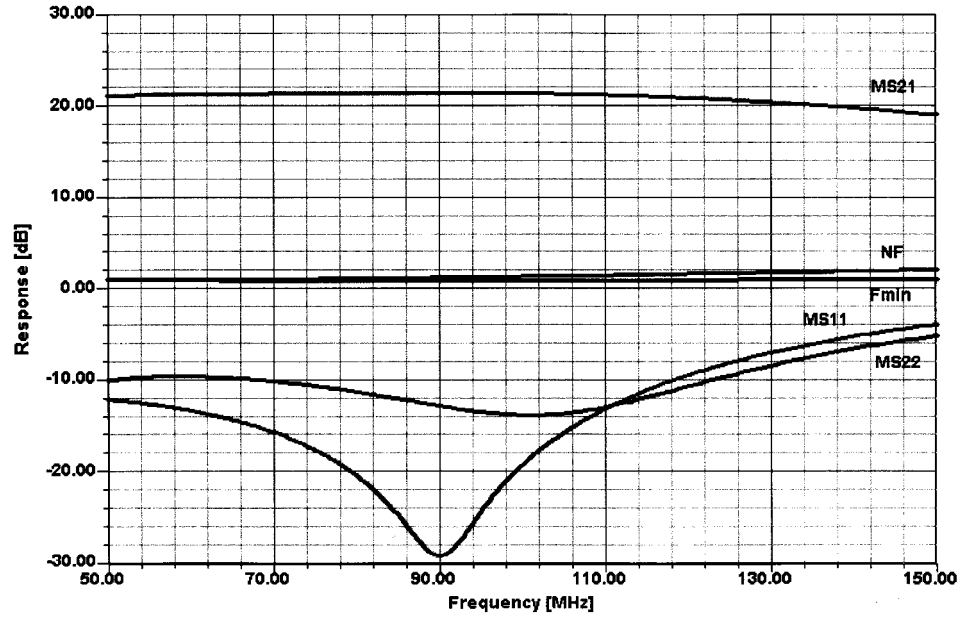

Figure 3-193 Frequency-dependent gain, matching, and noise responses for the amplifier in Figure 3-192.

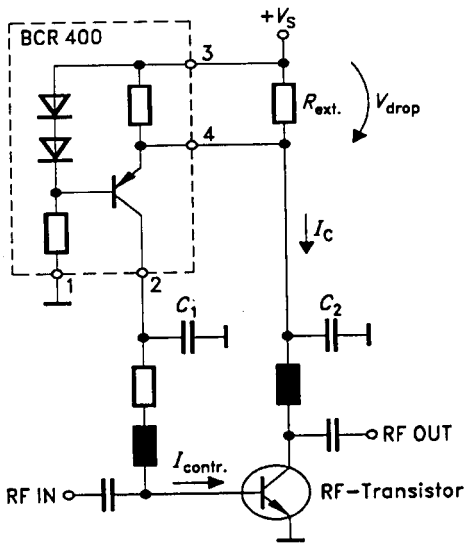

Figure 3-194 The Siemens BCR400 active bias controller can be applied to FETs as well as BJTs.

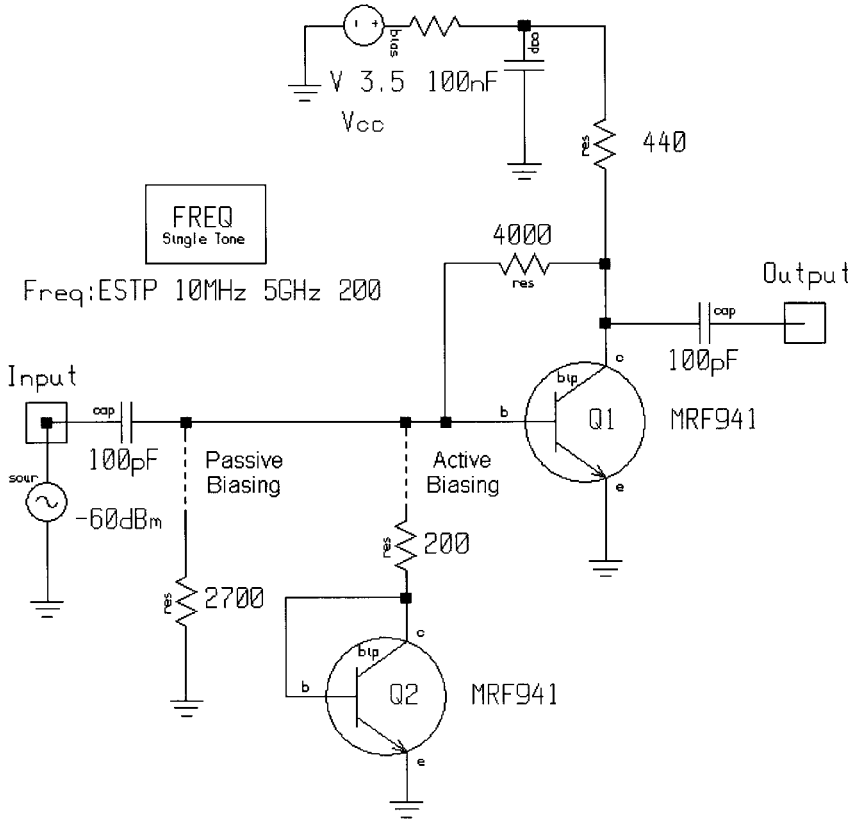

Figure 3-195 Amplifier stage (I_C = 3 mA) showing active and passive bias alternatives.

Q2, and proceeding from there. On the other hand, having a nice CAD tool that provides insight into the dc voltages and allows the addition of dc voltage probes makes life much easier. To prove that this circuit actually works, Figure 3-193 shows its frequency-dependent gain, matching, and noise figure performance. It is based on a Motorola application, which had excessive voltage drop for Q1 and which we have improved to be suitable for low-voltage operation [29].

Integrated active bias solutions are also available. Figure 3-194 shows the Siemens BCR400 active bias controller applied to a BJT; it can also be applied to FETs and TR switching diodes, as we saw in Figures 3-57 and 3-59, respectively.

3-10-3 dc Biasing of IC-Type Amplifiers

In integrated circuits, we do not have the unlimited flexibility described earlier. This results frequently in constant-current sources or transistors being used as diodes for biasing purposes. Our first suspicion is that this is going to cause a lot of noise in the IC; Figure 3-195 shows a test example.

As suspected, choosing the same bias point of 3 mA, the noise figure using active bias is quite a bit higher than the passive one, as shown in Figure 3-196.

3-11 PUSH–PULL/PARALLEL AMPLIFIERS

Since it is practically impossible to obtain $S_{11} = S_{22} = 0$, using a combiner at the input and output reduces the problem. Figure 3-197 shows the 3-dB hybrid approach. It has a practical

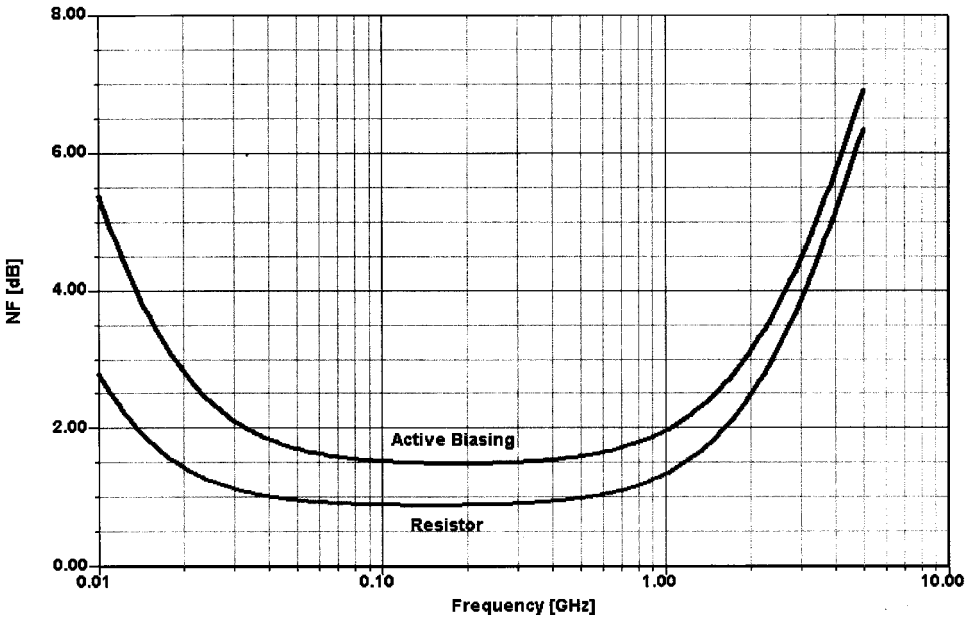

Figure 3-196 Frequency-dependent noise figure of the amplifier circuit shown in Figure 3-195. The active biasing curve is considerably noisier.

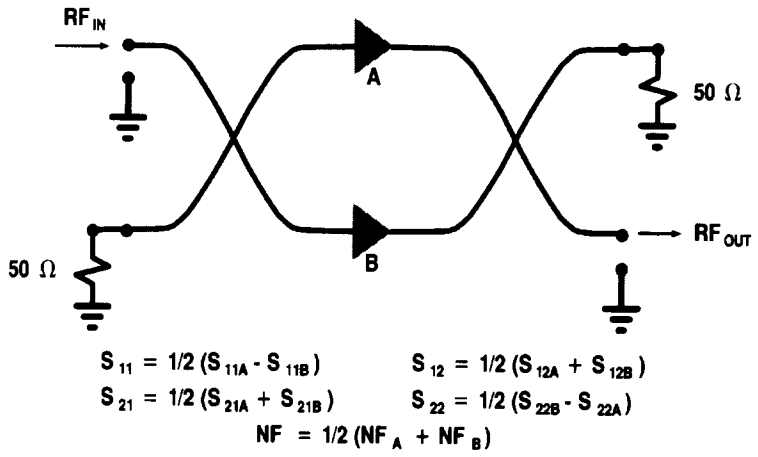

Figure 3-197 Combining power with 3-dB hybrid couplers.

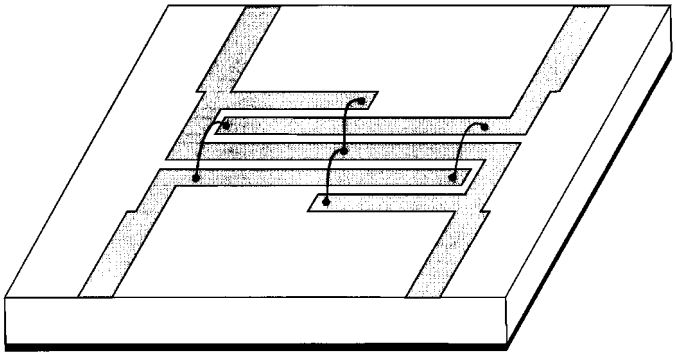

Figure 3-198 Four-strip version of the Lange coupler, a broadband 90° hybrid.

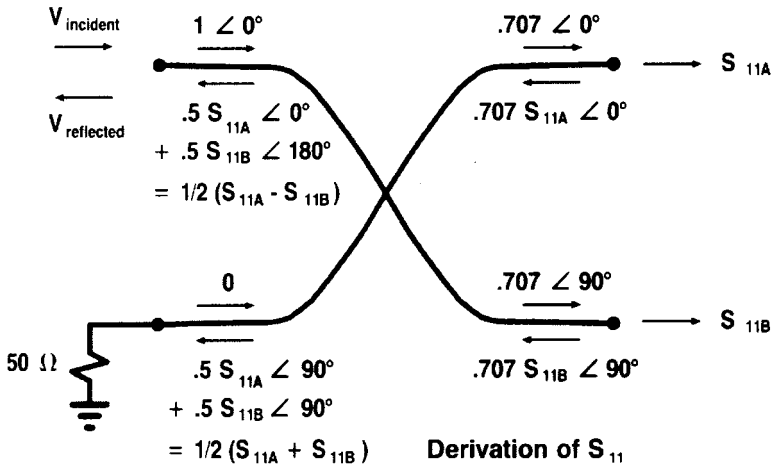

Figure 3-199 3-dB hybrids. This analysis method may be applied to any coupler.

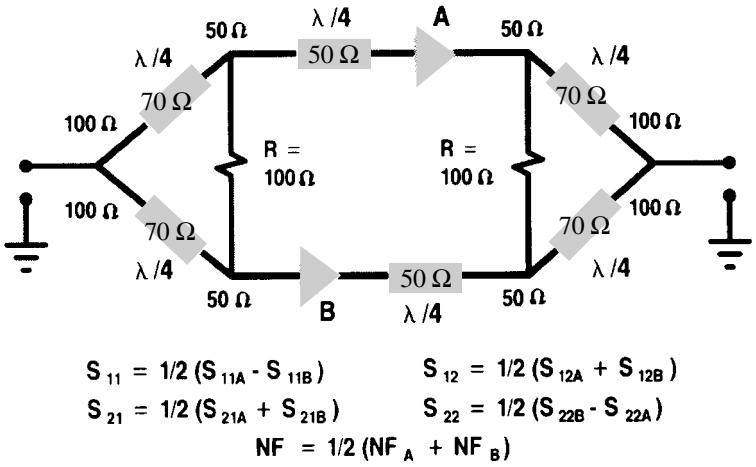

Figure 3-200 Wilkinson divider/combiners.

bandwidth limit of about 4:1; its advantage is that it is compact and ideal for cascading. If one stage opens, P_{OUT} and gain drop only 6 dB; however, it does not protect against load mismatch. A recommended distributed form is the Lange coupler (Figure 3-198). To analyze this approach, Figure 3-199 shows the resulting impedances and necessary phase shifts. If a Wilkinson coupler [30] is used instead of the 3-dB hybrid, the bandwidth is reduced. The Wilkinson coupler is larger in size than the 3-dB hybrid but more easily realized, leading to lower cost. Figure 3-200 shows the actual impedances necessary for matching, with A1 and A2 being the actual amplifiers combined.

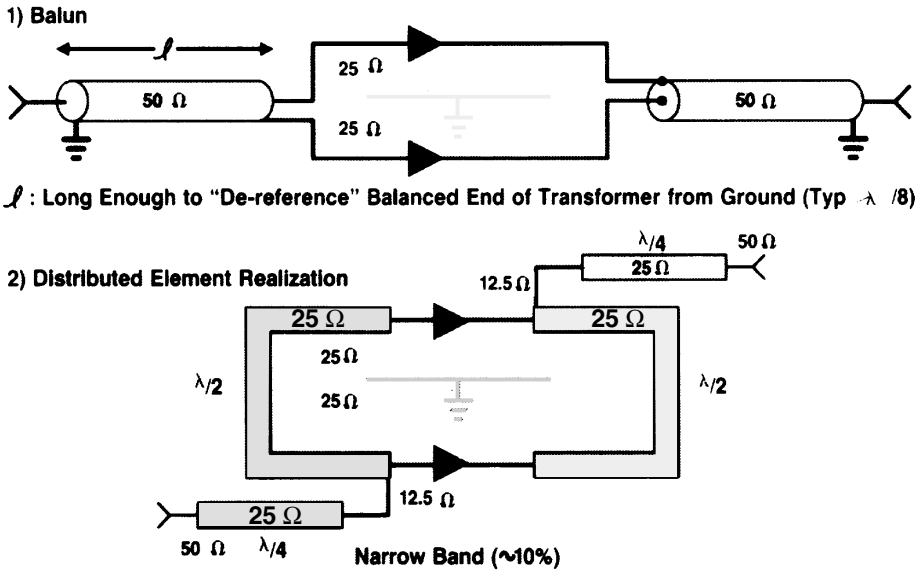

Figure 3-201 Push–pull amplifiers.

The solution for push–pull amplifiers resorts to a balun with the following results obtained: Bandwidths of greater than one decade are achievable; the balun structure gives 4:1 impedance advantage; there is no isolation; $S_{11} \neq 0$, $S_{22} \neq 0$; and cancellation of even-order products is provided.

Since most amplifiers have 50-Ω rather than 25-Ω impedances, Figure 3-201 shows a circuit that matches 25 Ω to 50 Ω on both sides. Since the standard amplifier operates at 50 Ω rather than 25 Ω, an additional network may be necessary to transform the impedance up to 50 Ω again. A similar problem occurs at the amplifier output.

3-12 POWER AMPLIFIERS

Power amplifiers are devices that are tasked to transform as much dc power into RF/microwave power as possible. Depending on the technology, devices are available that can produce at least 100 W up to 2 GHz. Since the transconductance of FETs at conducting angles of less than 180° becomes very small, the actual power gain sharply decreases compared to Class A operation while the power-added efficiency is optimized to values of 55% (Class B) or so. The dissipation of these devices is, of course, quite high, while in Class B operation this is even more of an issue. Power devices in Class C are dying to have big heat sinks to survive. One of the nice things about FETs is a much reduced thermal runaway effect compared to their bipolar brothers.

Power amplifier classes are defined in terms of the device conduction angle and/or the type of device operation:

Class A	"Linear" operation; 180° conduction angle
Class AB	"Linear" operation; conduction angle between 90° and 180°
Class B	"Linear" operation; 90° conduction angle
Class C	Fixed drive; less than 90° conduction angle
Class D	Switched operation, conduction range may vary with time from 0° to 180° or may be fixed.

There are also Classes E and F, which are currently under evaluation and showing some promising results.

Figure 3-202 shows Class C operation. The output of the amplifier is a current pulse train, which frequently leads to misunderstanding as to the calculation of its load. Given the fact that the amplifier is a current generator, it is silly to assume one has to do a conjugate matching looking backward into the amplifier. This is the condition for Class A operation. Unfortunately, this is still not understood by some engineers, but we hope we can clear this up today. The theoretical efficiency is 89.7% at a conducting angle of less than 180°; in practice, efficiencies more than 85% are not obtainable. (All of these efficiencies are those of the device itself; losses in matching networks are not taken into account in these efficiency values.) Considering optimal gain and optimal output power, the conducting angle actually settles somewhere between 100° and 140°. Again, the power gain in Class C operation is less than in Class A and Class B operation.

3-12-1 Example 1: 7-W Class C BJT Amplifier for 1.6 GHz

The following demonstrates how to design a 1.6-GHz, 7-W amplifier operating in Class C. We need to point out again that all modulation forms that contain the information in both

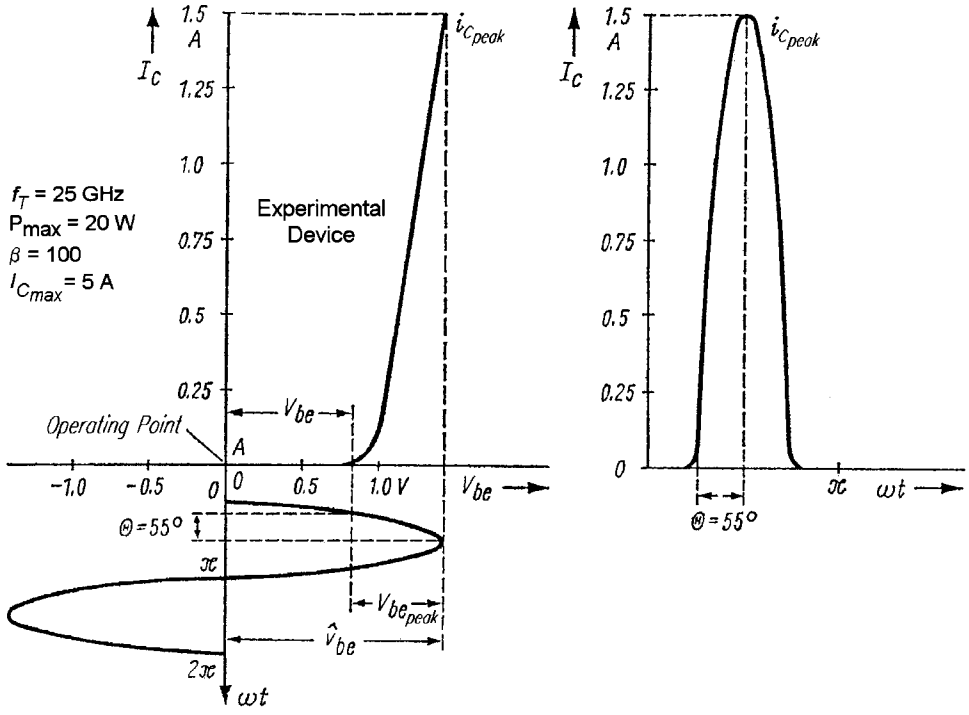

Figure 3-202 Output current as a function of drive voltage, taking into consideration the knee voltage of the base–emitter *pn* junction. The output is a series of current pulses with a duty cycle determined by the conduction angle.

amplitude and phase require more linearity than Class C affords. Needless to say, this affects the efficiency; therefore, at a later point we will also show a Class AB power amplifier. This is a tutorial, so we will present a UHF example and walk the reader through all the problems involved in the design. The selection of the transistor is done by first looking at the f_T, which in our case should be at least 4–5 GHz. The first order of business is to define the point of operation for the output amplifier. To do this, we need to determine the maximum voltage and current values supplied by the manufacturer. We have chosen a device that operates at 28 V and can sustain a peak collector current of 1.5 A. Figure 3-202 lets us determine the conducting angle Θ from the I_C/V_{BE} plane. This figure shows on the left side the I_C/V_{BE} plane and the necessary voltage to drive the amplifier.

Initially, we assume that the base–emitter junction is operated without any bias ($V_{BE} = 0$). The dc I–V curve shows that the collector current starts at about 650 mV. The amplifier itself, therefore, is already in Class C operation. For full output power, the drive voltage $V_{BE,\text{peak}}$ has to be 1.14 V. Therefore, the conducting angle can be determined by

$$\cos \Theta = \frac{V_{BE}}{\hat{\boldsymbol{v}}_{BE}} = \frac{0.65}{1.14} = 0.57$$

$$\cos 0.57 = 55^\circ$$

V_{BE} is the dc voltage at which the transistor starts conducting. From Figure 3-65 and Eqs. (3-160), (3-161), and (3-162), the fundamental current i_{c1} can be determined from

$$i_{c1} = i_{\text{peak}} \cdot f_1(\Theta)$$

or

$$i_{c1} = 1.5 \text{ A} \times 0.36 = 0.54 \text{ A}$$

The average collector dc current can be determined from

$$i_{c2} = i_{\text{peak}} \cdot f_2(\Theta)$$

or

$$i_{c2} = 1.5 \text{ A} \times 0.21 = 0.315 \text{ A}$$

The collector saturation voltage $V_{CE(\text{sat})}$, unfortunately, is around 2–3 V; for the purpose of the calculation, we assume that the saturation voltage is 3 V, and, therefore, we can assume that the maximum collector ac voltage $\hat{v}_{CE} \approx (V_B - 3) = 25$.

The appropriate collector load has to be

$$R_C = \frac{\hat{v}_{CE}}{i_{C1}} = \frac{25}{0.54} = 46.3 \ \Omega$$

The maximum output power is

$$P_{\text{out}} = \frac{(V_{CE} - V_{CE(\text{sat})})^2}{2R_C} = \frac{625}{92.6} = 6.75 \text{ W}$$

The only way to increase the power would be to have a smaller collector load at a higher current. In this family of Motorola transistors, there was no 10-W transistor; that's why we have chosen a 20-W experimental device, which for this purpose is overkill. The theoretical efficiency of the amplifier is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{6.75 \text{ W}}{0.315 \times 28} = 85\%$$

If the saturation voltage would be less, our efficiency would automatically increase, since for the given load, the actual output power would increase (6.75 W $\rightarrow$ 7.5 W). Assuming that this stage would operate at 1900 MHz with a gain of roughly 22 dB, the required drive would be significantly less than the output power, or roughly 40 mW. For the purpose of the following calculations, we will assume that the drive power is 0.7 W. The total dissipation of the device now adds up to be

$$P_T = P_{\text{in(dc)}} - P_{\text{out}} + P_{\text{drive}}$$

$$P_T = (28 \times 0.315) - 6.75 + 0.7 = 2.77$$

Power-added efficiency is derived from this. Knowing the power dissipation, one can calculate a thermal resistance R_{therm} of the heat sink and the transistor:

$$R_{\text{therm}} = \frac{T_J - T_A}{P_T}$$

Where T_J is the device junction temperature and T_A is the ambient temperature. For a maximum ambient temperature of 60 °C and a maximum junction temperature of 150 °C, the thermal resistance is

$$R_{\text{therm}} = \frac{120 - 60}{2.77} = 21.7\ ^\circ\text{C/W}$$

R_{therm} is the sum of thermal resistance of the transistor and its package, and the thermal resistance between the transistor package and the heat sink, and the thermal resistance between the heat sink and the ambient air. Therefore,

$$R_{\text{therm}} = R_{\text{th(case)}} + R_{\text{th(case/heat sink)}} + R_{\text{th(heat sink)}}$$

The required thermal resistance of the heat sink is calculated from

$$R_{\text{th(heat sink)}} = 21.7 - 10 - 1.4 = 15.6\ ^\circ\text{C/W}$$

Assuming an aluminum heat sink (a 2-mm-thick plate), the required heat-sink surface area A (cm^2) is

$$A = \frac{1}{\alpha R_{\text{th(heat sink)}}}; \quad \alpha \approx 1.5\ \frac{\text{mW}}{^\circ\text{Ccm}^2}$$

Therefore, the required area is

$$A = \frac{1}{1.5 \times 0.0156} = 42.7\ \text{cm}^2$$

The next task is to match both the input and output to the (most likely) 50-Ω source and termination. The following section will guide us through the procedure. The input impedance Z_{11} (after some lengthy search) was found to be $1 + j10\ \Omega$. This means that the input consists of the base-spreading resistance (approximately 1 Ω) and an input capacitance, which because of phase shift now turns out to be inductive. Since the popular method for input matching these days is a pi configuration, we are going to use a simple pi filter both for input and output matching. There are several equations in the literature that give the values for the two capacitors and inductors; most of them result in an incorrect resonance frequency. Since we have access to software tools, we decided to take three approximate values and use the optimizer to give us the appropriate matching. The only remaining variable in such an approach is the bandwidth. If we specify $S_{21} = 1$ and $S_{11} = 0$ (100% energy transfer and perfect return loss), we will realize that this is possible at only one frequency. We therefore need to identify a frequency band or bandwidth over which an acceptable match is needed. As the bandwidth increases, the match for such a simple circuit will get poorer; there are not enough elements available to do better. In this case, we took the center frequency ±100 MHz.

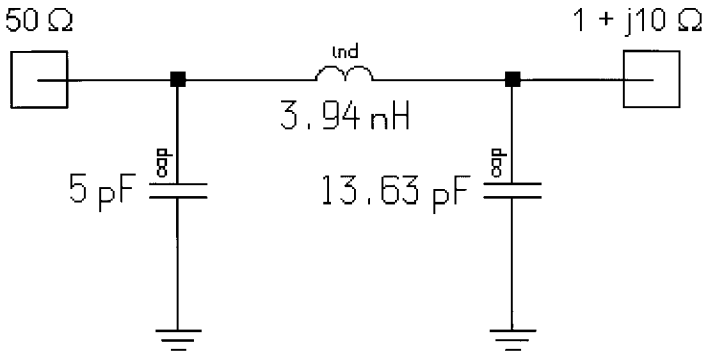

Figure 3-203 Input matching network for the amplifier used in this tutorial.

Figures 3-203 and 3-204 show the actual circuit with the element values and the resulting input match. Likewise, we did the same thing at the output, but the actual resulting dynamic output capacitance is not known *a priori*. For low frequencies, the integral equation gives a value of $2C_{CE}$; however, practical tests in frequencies above 500 MHz show that the actual increase is only 1.3 times the dc output capacitance. Therefore, we decided to design the filter with no output capacitance assumed, and the input capacitance of about 5 pF must be reduced for proper reactive matching. Mathematically, this could result in a negative number, specifically if the resulting output capacitance exceeds the 5-pF value. To compensate for this, one needs to use an RF choke that tunes out the resulting dynamic output capacitance and then one can revert to the original 5 pF as calculated.

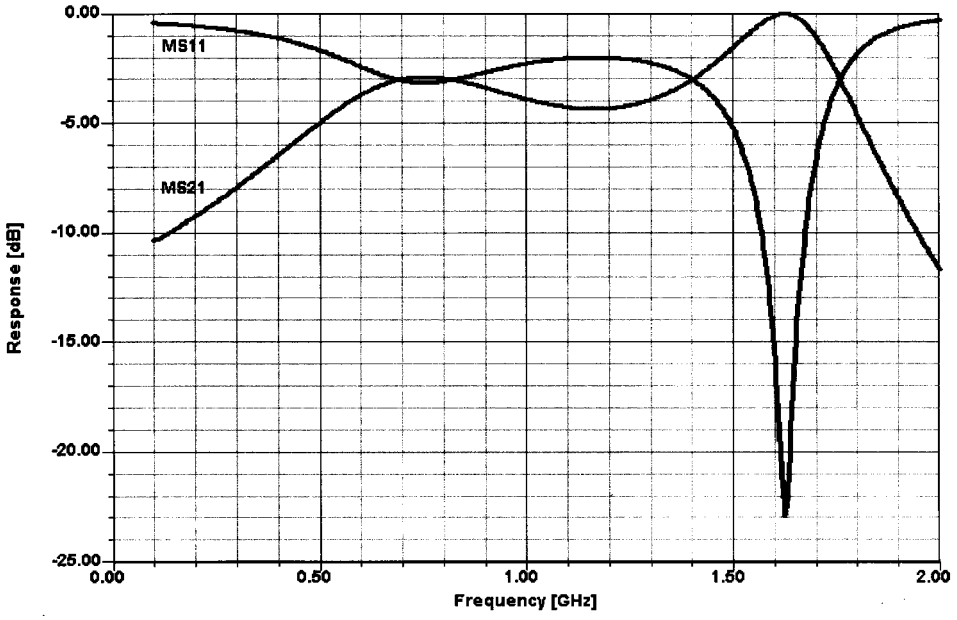

Figure 3-204 Frequency response of the input matching network.

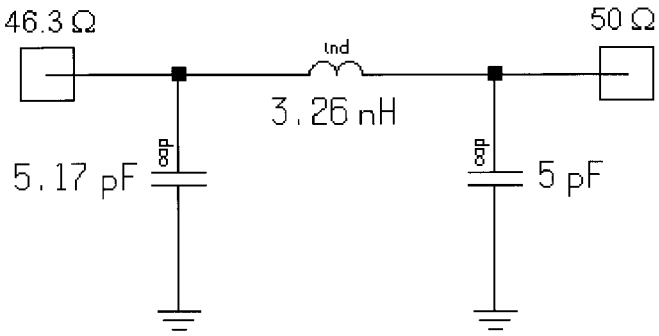

Figure 3-205 Output matching network for the amplifier.

The selection of the actual component is another issue, because these capacitors need to handle several amperes of RF current. It is not always easy to find capacitors with the appropriate value that can handle the current. The inductors can be printed. The paragraph following this section therefore will deal with the issue of how to translate the lumped values into distributed values, which will make the current handling much easier (we hope).

For this, we did the same optimizing approach by using a 50-Ω source and a 46.3-Ω load. Figures 3-205 and 3-206 show the circuit with the appropriate values and its simulated frequency-dependent responses.

The next step is to connect the input and output matching network to an "actual" transistor. This is a point where difficulties arise, since very few, if any, companies provide SPICE-type

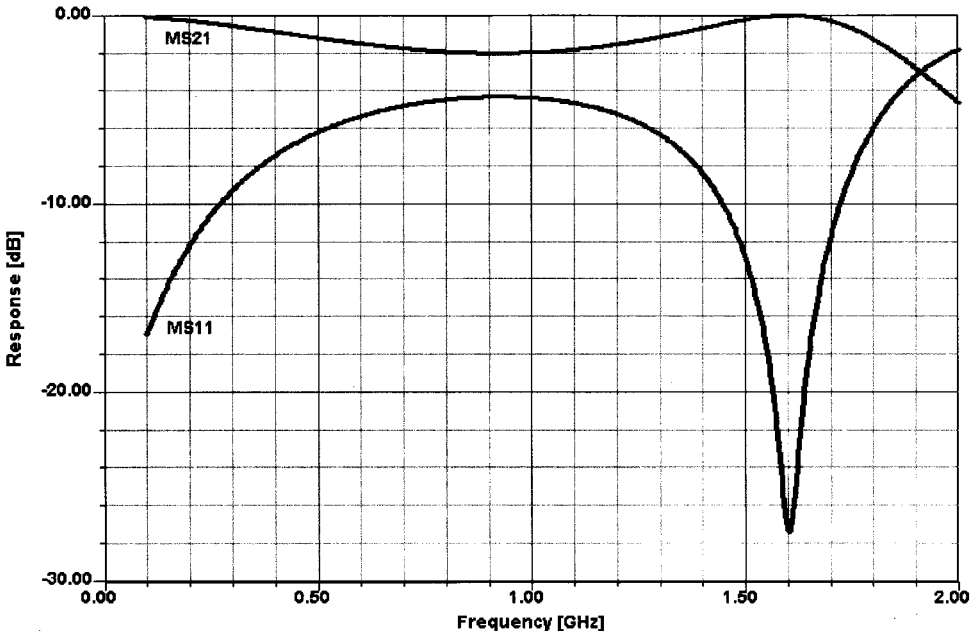

Figure 3-206 Frequency response of the output matching network.

parameters for transistors operating at currents of more than 200 mA. Figures 3-207 and 3-208 show the overall schematic and frequency response of the actual amplifier with all filters connected. Figure 3-209 details the amplifier's peak gain response. If more bandwidth is needed, the matching circuit must be increased in complexity, as will be shown in the following section.

Now is a good time to look at the final results of our simulation, which is based on the various assumptions as outlined above. Figure 3-210 shows the dc *I–V* curves with a straight load line and no reactances. This was accomplished by using a wideband transformer instead of an output matching circuit. Figure 3-211, however, shows the "load line" that results when the transformer is replaced with a real matching network. Based on the harmonics content and its improper termination, one can see how the output load line opens and shows ringing in the low-current area. If we expect to see the saturation voltage, we will be disappointed because the saturation voltage is frequency dependent (increases with frequency) and this figure gives an erroneous impression. Hence, we show dc *I–V* curves. To display the conduction angle, which we showed previously, we examine the output current as a function of time at a drive level of +16.5 dBm (Figure 3-212). During the negative half, the transistor is not conducting as predicted, so this validates our assumptions. Next, we are interested in determining the power gain. Therefore, we look at the output spectrum for a drive level of +16.5 dBm (Figure 3-213). It shows an output level of 38.6 dBm. If we subtract the drive level (16.5 dBm) from this, we see that the power gain is 22.1 dB at this drive level. Since we are used to thinking in watts, Figure 3-214 shows the absolute output power and the harmonics prior to filtering. Figure 3-215 shows the output spectrum after replacing the transformer with a simple pi output network.

During the conduction period, there will be a voltage across the transistor 180° out of phase, as shown in Figure 3-216. Finally, to highlight the nonlinearity of a Class C amplifier, Figure 3-217 shows the amplifier's output power versus drive, and Figure 3-218 shows the amplifier's gain versus drive. When the transistor turns on is clearly evident.

A particular difficulty arises in the case of FETs, where the charge energy makes for a difference between dc and pulsed measurements. Figure 3-219 shows this. Some of the more modern transistors, such as SiGe types, may need some pulsing also; as can be seen in Figure 3-219, even depending on the pulsing, one may get different dc *I–V* curves. This area is still under investigation, and even the "experts" do not agree on all aspects of this. In real life, it turns out that a lot of experimentation is the answer. Anyone who thinks that a pure CAD approach will give the right design answers immediately will encounter many surprises! This is not a fault of the CAD tools—assuming that they are properly engineered—but rather the availability of appropriately "tweaked" models for high-power applications, and the willingness of device suppliers to standardize on certain models and support them.

Because of the difficulties involved in cooling transistors under test and simulating RF pulse and CW conditions, depending on the application, manufacturers have so far stayed away from investing money in this area. The designer must therefore resort to application notes published by device manufacturers. Because even slight layer changes can have a large impact on the frequency response of a given device, application-note-based designs can run into difficulty if a device's fabrication has significantly evolved since the publication of its application notes.

Given the multitude of models outlined in Chapter 2, the CAD user is sometimes left hanging as to which is the best model to use. The latest indications are that the MEXTRAM (*m*ost *e*xquisite *t*ransistor *m*odel), developed by the University of Delft, Holland, with Philips of Holland, shows the most promising result, specifically in the area of IMD products. While

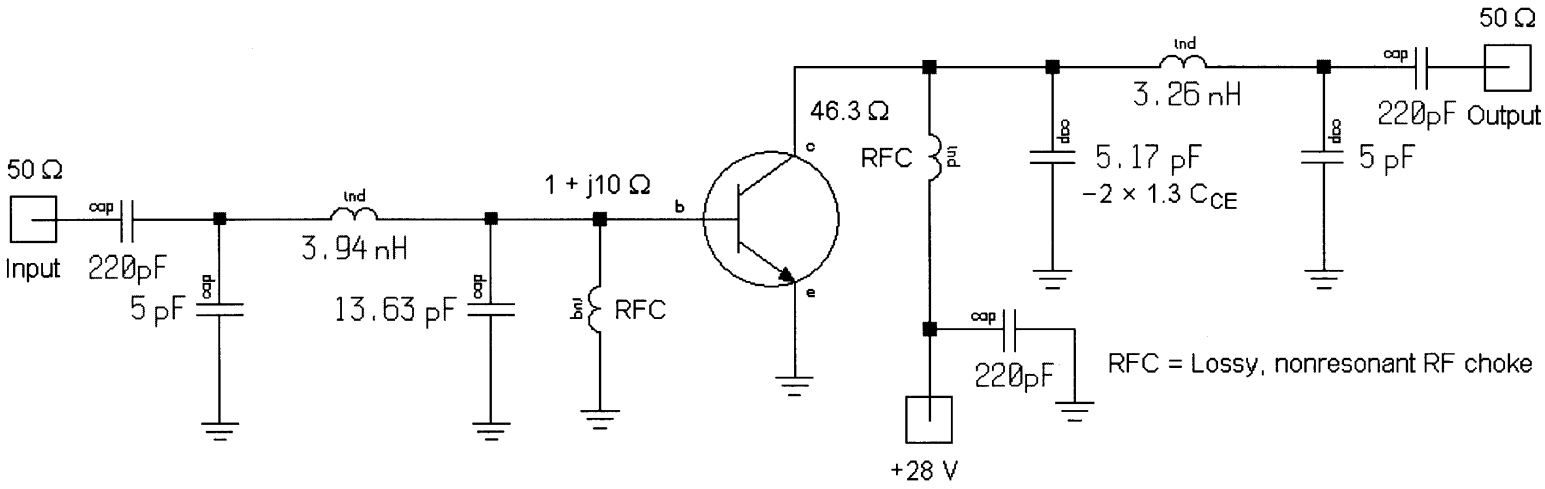

Figure 3-207 Actual schematic of our experimental 1.6-GHz amplifier. The RF chokes have enough RF losses not to be resonant and yet don't load the circuit. This is frequently accomplished with either ferrite beads or resistors in parallel with the chokes.

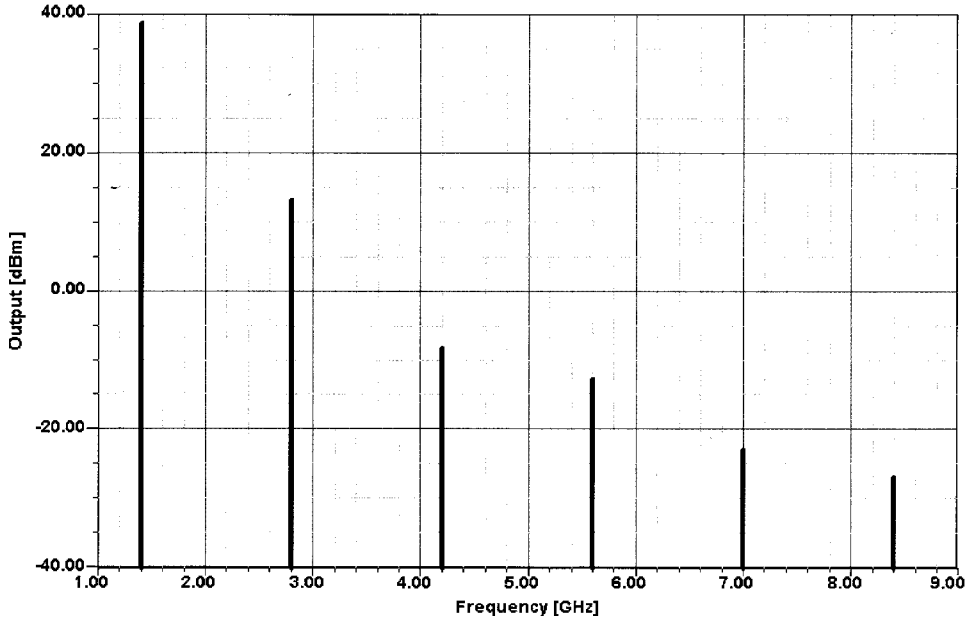

Figure 3-215 The output spectrum after replacing the transformer with a simple pi output network.

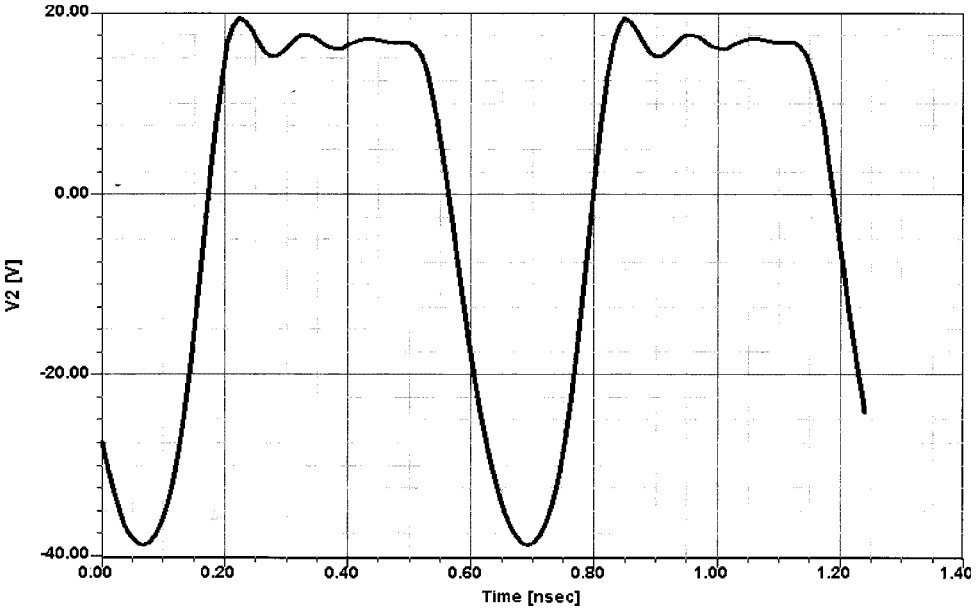

Figure 3-216 Output voltage at the collector. The voltage is asymmetrical compared to 0; this is important in the selection of a device capable of handling these voltages.

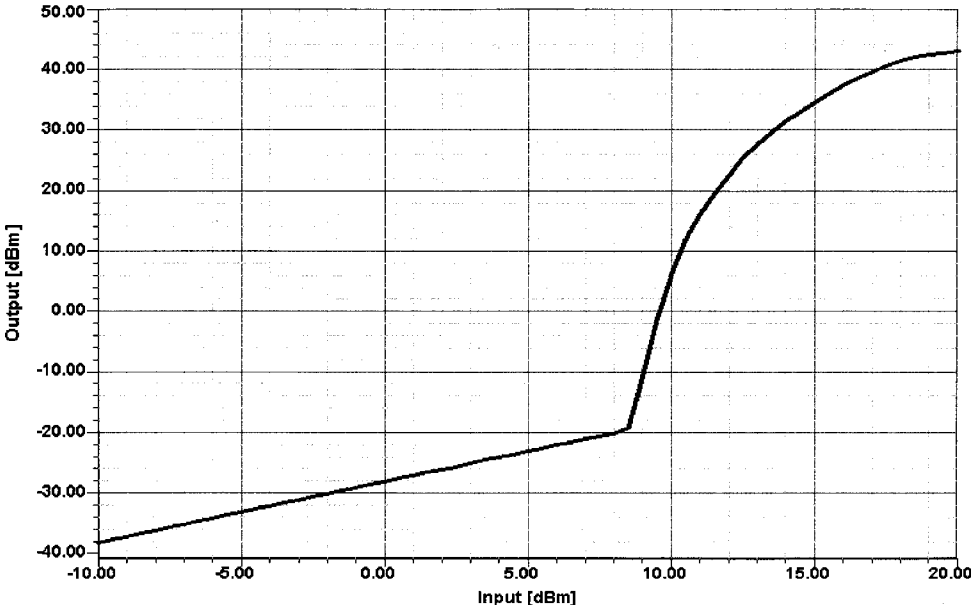

Figure 3-217 Output power versus input power for the Class C amplifier. Until the transistor turns on (at a drive level of about 8.5 dBm), only fedthrough power appears at the output.

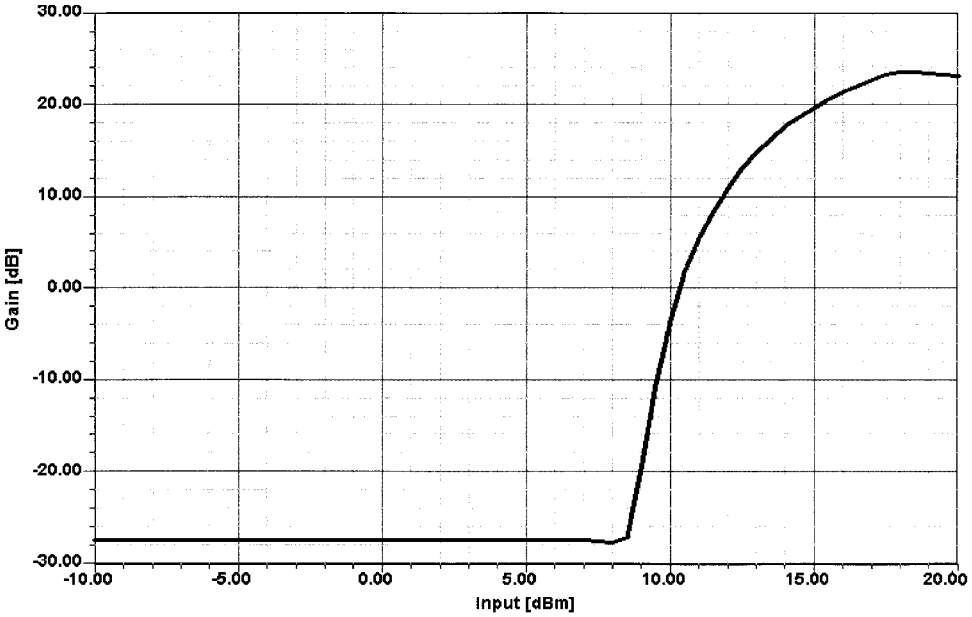

Figure 3-218 Amplifier gain as a function of drive. It is evident that one needs to cross the 0.65-V point for the transistor to become conductive and show gain. The initial amplification as a function of drive shows a very steep curve that then levels off and drops as the amplifier moves into saturation.

other later models have up to seven internal nodes, MEXTRAM fortunately uses only five. (The MEXTRAM model actually consists of three transistors, which makes modeling fun.) Power-added efficiency simulation is not available, since the MEXTRAM model was developed for small-signal applications, meaning circuits that operate at less than 100 mW of RF output power.

As if the absence of trustworthy high-power device models is not challenge enough, in developing this 1.6-GHz Class C amplifier example, we ran into another complication: Using a CAD optimizer to simultaneously match the circuit's input and output networks failed because of the device's input-impedance variation with drive. Every matching adjustment that improved the drive to the device resulted in an input-impedance change that reduced the drive to the device! In the end, the optimizer couldn't keep up. In actually building such a circuit, one would make the matching-network values adjustable on the initial breadboard and then, with the necessary input drive level applied, iteratively adjust the input and output matching for the desired output level. It appears that the CAD program could not handle such a degree of nonlinearity.

We then went to the approach of using large-signal *S* parameters at a drive level slightly less than 16 dBm, but this detuned the input filter, resulting in a poorer input match than the one initially predicted. Likewise, the output matching, which in a power stage must result in maximum output power rather than a conjugate match, was less impressive. The large-signal *S* parameters at the output for a power amplifier are somewhat dubious because Class C operation generates so many harmonics that the output termination will reflect a lot of energy and, depending on the output filter topology, different results can be expected. We firmly believe that there will be further mathematical improvement in the CAD tools, and we very much invite

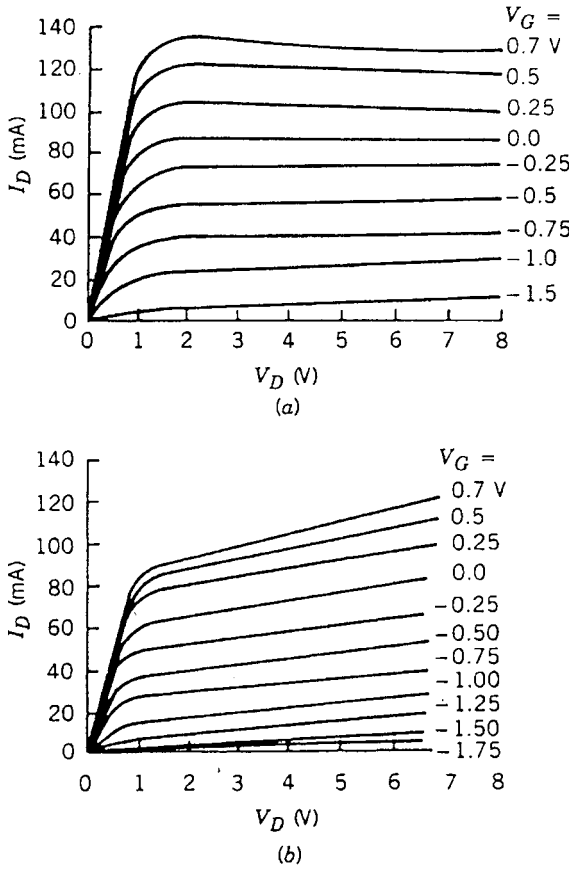

Figure 3-219 Comparison of FET drain current characteristics obtained from (a) pulsed *I–V* and (b) rectified sine-wave evaluation. The rectified sine-wave curves can be considered equivalent to curves obtained at dc.

our readers to use such a nonlinear example to test their tools, provided that a high-power model becomes available in this power range.

It has been rumored that the load-pull technique, rather than the application of large-signal *S* parameters, is a vehicle to solve such matching problems. However, the load-pull technique is really applied only to the fundamental frequency and does not deal with the issue of harmonics of the output current. More details about the load-pull technique and its capabilities are found in Appendix B.

Actual measurements of amplifiers of this type show that our simulated efficiency and drive level come quite close to reality, but at a frequency somewhat offset from that chosen for the design. As an example, the input and output filters tuned at 1.4 GHz instead of 1.6 GHz using the large-signal *S* parameters. Again, an iterative process, similar to manually trimming a prototype, will give a similar result. This is consistent with our earlier statement that most final designs are really hand-tweaked, and that CAD can only bring us close, but not all the way, to a good solution. For passive problems, the CAD does a significantly better job; the nonlinear cases are the ones that still cause headaches.

3-12-2 Impedance Matching Networks Applied to RF Power Transistors*

Introduction. Some graphical and numerical methods of impedance matching will be reviewed here. The examples given refer to high-frequency power amplifiers.

Although matching networks normally take the form of filters and therefore are also useful to provide frequency discrimination, this aspect will be considered only as a corollary of the matching circuit.

Matching is necessary for the best possible energy transfer from stage to stage. In RF power transistors, the input impedance is of low value, decreasing as the power increases or as the chip size becomes larger. This impedance must be matched either to a generator—of generally 50-Ω internal impedance—or to a preceding stage. Impedance matching has to be made between two complex impedances, which makes the design still more difficult, especially if matching must be accomplished over a wide frequency band.

Device Parameters

Input Impedance. The general shape of the input impedance of RF power transistors is as shown in Figure 3-220. It is a large-signal parameter, expressed here by the parallel combination of a resistance R_p and a reactance X_p [31].

The equivalent circuit shown in Figure 3-221 accounts for the behavior illustrated in Figure 3-220. With the presently used stripline or flange packaging, most of the power devices for VHF low band will have their R_p and X_p values below the series resonant point f_s. The input impedance will be essentially capacitive.

Most of the VHF high-band transistors will have the series-resonant frequency within their operating range; that is, they will be purely resistive at one single frequency f_s, which the parallel-resonant frequency f_p will be outside.

Parameters for 1- or 2-GHz transistors will be beyond f_s and approach f_p. They show a high value of R_p and X_p with inductive character.

A parameter that is very often used to judge on the broadband capabilities of a device is the input Q or Q_{IN}, defined simply as the ratio R_p/X_p. Practically, Q_{IN} ranges around 1 or less for VHF devices and around 5 or more for microwave transistors.

Q_{IN} is an important parameter to consider for broadband matching. Matching networks normally are low-pass or pseudo-low-pass filters. If Q_{IN} is high, it can be necessary to use bandpass filter-type matching networks and to allow insertion losses. But broadband matching is still possible. This will be discussed later.

Output Impedance. The output impedance of RF power transistors, as given by all manufacturers' datasheets, generally consists of only a capacitance C_{OUT}. The internal resistance of the transistor is supposed to be much higher than the load and is normally neglected. In the case of a relatively low internal resistance, the efficiency of the device would decrease by the factor

$$1 + R_L/R_T \tag{3-192}$$

*Based on Motorola application note AN-721 ("Impedance Matching Networks Applied to RF Power Transistors"). Copyright of Motorola; used by permission.

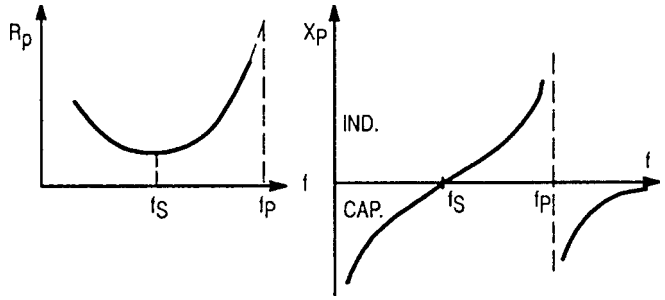

Figure 3-220 Input impedance of RF power transistors as a function of frequency.

where R_L is the load resistance, seen at the collector–emitter terminals, and R_T is the internal transistor resistance equal to

$$\frac{1}{\omega_T (C_{TC} + C_{DC})} \tag{3-193}$$

defined as a single parameter, where ω_T is the transit angular frequency and C_{TC} and C_{DC} are the transition and diffusion capacitances, respectively, at the collector junction.

The output capacitance, C_{OUT}, which is a large-signal parameter, is related to the small-signal parameter C_{CB}, the collector–base transition capacitance.

Since a junction capacitance varies with the applied voltage, C_{OUT} differs from C_{CB} in that it has to be averaged over the total voltage swing. For an abrupt junction and assuming certain simplifications, $C_{\text{OUT}} = 2C_{CB}$.

Figure 3-222 shows the variation of C_{OUT} with frequency. C_{OUT} decreases partly due to the presence of the collector lead inductance, but mainly because of the fact that the base–emitter diode does not shut off anymore when the operating frequency approaches the transit frequency, f_T.

Output Load. In the absence of a more precise indication, the output load R_L is taken as

$$R_L = \frac{[V_{CC} - V_{CE(\text{sat})}]^2}{2P_{\text{OUT}}} \tag{3-194}$$

with $V_{CE(\text{sat})}$ equal to 2 or 3 V, increasing with frequency.

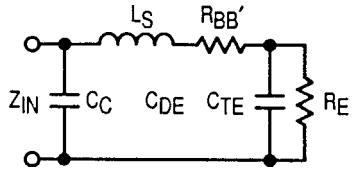

Figure 3-221 Equivalent circuit for the input impedance. R_E is the emitter diffusion resistance; C_{DE} and C_{TE} are the diffusion and transition capacitances, respectively, of the emitter junction; $R_{BB'}$ is the base-spreading resistance; C_C is the package capacitance; and L_S is the base lead inductance.

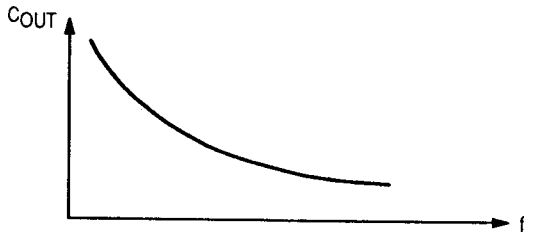

Figure 3-222 Output capacitance C_{OUT} as a function of frequency.

The above equation just expresses a well-known relation, but it also shows that the load, in first approximation, is not related to the device, except for $V_{CE(sat)}$. The load value is primarily dictated by the required output power and the peak voltage; it is not matched to the output impedance of the device.

At high frequencies this approximation becomes less exact, and for microwave devices the load that must be presented to the device is indicated on the datasheet.

Strictly speaking, impedance matching is accomplished only at the input. Interstage and load matching are more impedance transformations of the device input impedance and of the load into a value R_L (sometimes with additional reactive component) that depends essentially on the power demanded and the supply voltage.

Matching Networks. In the following, matching networks will be described by the order of complexity. These are ladder-type reactance networks. The different reactance values will be calculated and determined graphically. Increasing the number of reactances broadens the bandwidth. However, matching networks consisting of more than four reactances are rare. Above four reactances, the improvement is small.

Numerical Design

TWO-RESISTANCE NETWORKS. Resistance terminations will first be considered. Figure 3-223 shows the reactive L section and the terminations to be matched.

Matching or exact transformation from R_2 into R_1 occurs at a single frequency f_0. At f_0, X_1 and X_2 are equal to

$$X_1 = \pm R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = R_1 \frac{1}{\sqrt{n-1}} \tag{3-195}$$

$$X_2 = \mp \sqrt{R_2(R_1 - R_{2)}} = R_1 \frac{\sqrt{n-1}}{1} \tag{3-196}$$

At f_0, $X_1X_2 = R_1R_2$. X_1 and X_2 must be of opposite sign. The shunt reactance is in parallel with the larger resistance.

The frequency response of the L section is shown in Figure 3-224, where the normalized current is plotted as a function of the normalized frequency.

If X_1 is capacitive and consequently X_2 is inductive, then

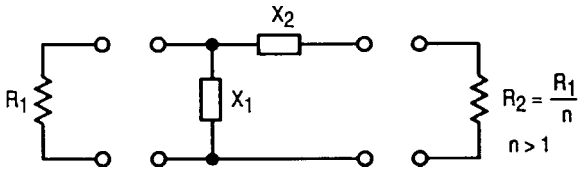

Figure 3-223 Two-reactance matching network.

$$X_1 = -\frac{f_0}{f} R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = -\frac{f_0}{f} R_1 \frac{1}{\sqrt{n-1}} \tag{3-197}$$

and

$$X_2 = \frac{f}{f_0} \sqrt{R_2(R_1 - R_2)} = \frac{f}{f_0} R_1 \frac{\sqrt{n-1}}{1} \tag{3-198}$$

The normalized current absolute value is equal to

$$\left|\frac{I_2}{I_0}\right| = \frac{2\sqrt{n}}{\sqrt{(n-1)^2 \cdot (f/f_0)^4 - 2\,(f/f_0)^2 + (n+1)^2}} \tag{3-199}$$

where $I_0 = \sqrt{n}E/2R_1$ and is plotted in Figure 3-224 [32].

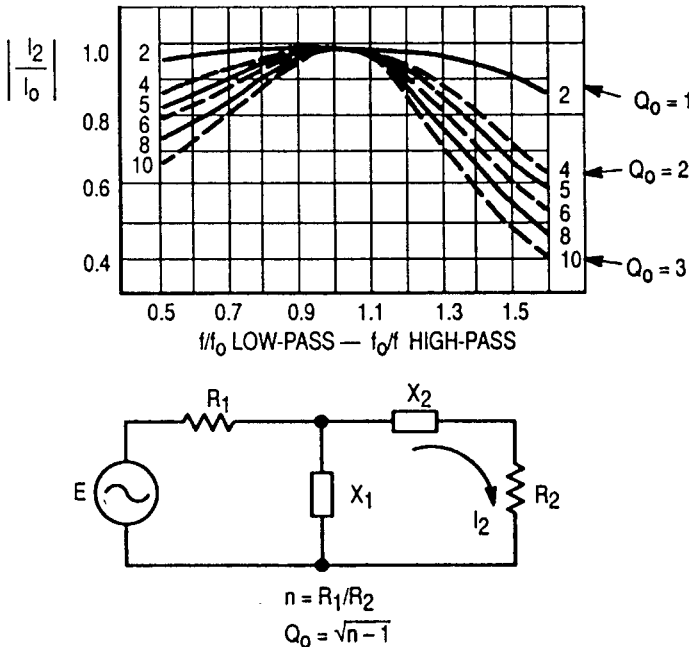

Figure 3-224 Normalized frequency response for the L section in low-pass or high-pass form.

If X_1 is inductive and consequently X_2 is capacitive, the only change required is a replacement of f by f_0 and vice versa. The L section has low-pass form in the first case and high-pass form in the second case.

The Q of the circuit at f_0 is equal to

$$Q_0 = \frac{X_2}{R_2} = \frac{R_1}{X_1} = \sqrt{n-1} \tag{3-200}$$

For a given transformation ratio n, there is only one possible value of Q. On the other hand, there are two symmetrical solutions for the network that can be either a low-pass filter or a high-pass filter.

The frequency f_0 does not need to be the center frequency, $(f_1 + f_2) / 2$, of the desired band limited by f_1 and f_2. In fact, as can be seen from the low-pass configuration of Figure 3-224, it may be interesting to shift f_0 toward the high-band edge frequency f_2 to obtain a larger bandwidth w, where

$$w = \frac{2(f_1 + f_2)}{f_2 - f_1} \tag{3-201}$$

This will, however, be at the expense of poor harmonic rejection.

Example. For a transformation ratio of $n = 4$, we can determine the following values from the above relations:

Bandwidth w	0.1	0.3
Maximum insertion losses	0.025	0.2
X_1/R_1	1.730	1.712

If the terminations R_1 and R_2 have a reactive component X, the latter may be taken as part of the external resistance as shown in Figure 3-225. This compensation is applicable as long as

$$Q_{int} = \frac{X_{\text{int}}}{R_2} \quad \text{or} \quad \frac{R_1}{X_{\text{int}}} < n - 1 \tag{3-202}$$

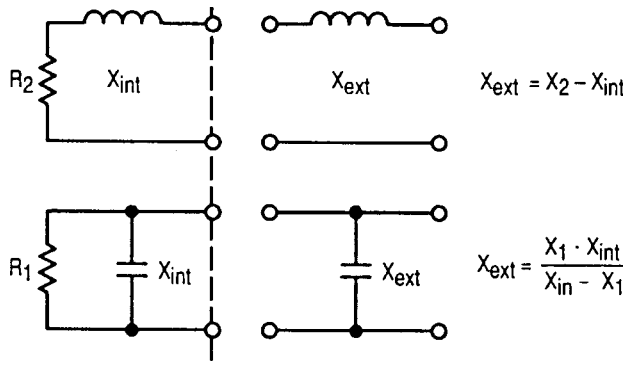

Figure 3-225 Termination reactance compensation.

Tables giving reactance values can be found in Matthaei et al. [33, 34].

USE OF TRANSMISSION LINES AND INDUCTORS. In the preceding section, the inductance was expected to be realized by a lumped element. A transmission line can be used instead (Figure 3-226).

As can be seen from the computed selectivity curves (Figure 3-227) for the two configurations, transmission lines result in a larger bandwidth. The gain is important for a transmission line having a length $L = \lambda/4$ ($\Theta = 90°$) and a characteristic impedance $Z_0 = \sqrt{R_1 R_2}$. It is not significant for lines short with respect to $\lambda/4$. One will notice that there is an infinity of solutions, one for each value of C, when using transmission lines.

THREE-REACTANCE MATCHING NETWORKS. The networks that will be investigated are shown in Figure 3-228. They are made of three reactances alternately connected in series and shunt.

A three-reactance configuration allows the designer to make the quality factor (Q) of the circuit and the transformation ratio $n = R_2/R_1$ independent of each other and consequently to choose the selectivity between certain limits.

For narrowband designs, one can use the following formulas (see [35], where tables are given):

Network (a)

$$X_{C1} = R_1/Q \quad Q \text{ must be selected first} \tag{3-203}$$

$$X_{C2} = R_2 \sqrt{\frac{R_1 R_2}{(Q^2 + 1) - R_1/R_2}} \tag{3-204}$$

$$X_L = \frac{QR_1 + (R_1 R_2/X_{C2})}{Q^2 + 1} \tag{3-205}$$

Network (b)

$$X_{L1} = R_1 Q \quad Q \text{ must be selected first} \tag{3-206}$$

$$X_{L2} = R_2 B \tag{3-207}$$

$$A = R_1(1 + Q^2) \tag{3-208}$$

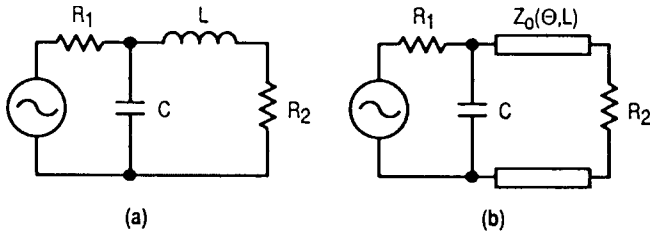

Figure 3-226 Use of a transmission line in the L section.

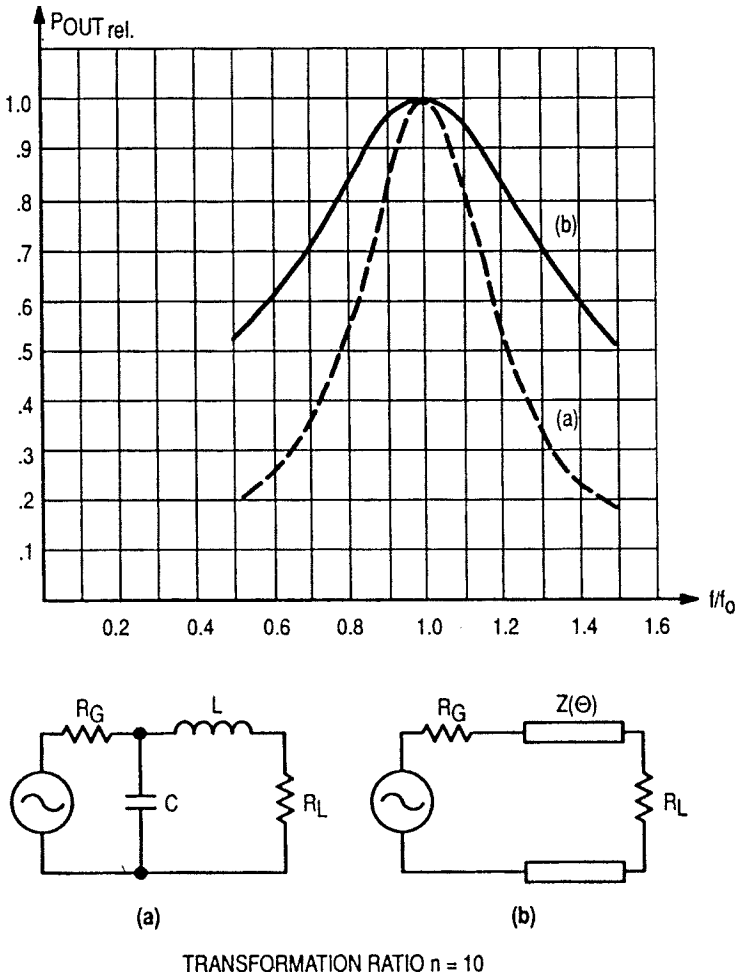

Figure 3-227 Bandwidth of the L section for $n = 10$ (a) with lumped constants and (b) with transmission line (λ/4).

$$X_{C1} = \frac{A}{Q + B} \tag{3-209}$$

$$B = \sqrt{\frac{A}{R_2} - 1} \tag{3-210}$$

Network (c)

$$X_{L1} = QR_1 \quad Q \text{ must be selected first} \tag{3-211}$$

$$X_{C2} = AR_2 \tag{3-212}$$

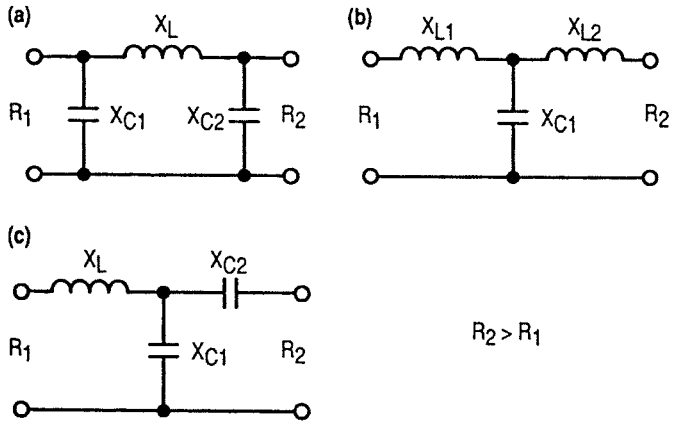

Figure 3-228 Three-reactance matching networks.

$$A = \sqrt{\frac{R_1(1+Q^2)}{R_2} - 1} \tag{3-213}$$

$$X_{C1} = \frac{B}{Q - A} \tag{3-214}$$

$$B = R_1(1+Q^2) \tag{3-215}$$

The network that yields the most-practical component values should be selected for a given application.

The three-reactance networks can be thought of as being formed of an L section (two reactances) and of a compensation reactance. The L section essentially performs the impedance transformation, while the additional reactance compensates for the reactive part of the transformed impedance over a certain frequency band.

Figure 3-229 shows a representation in the Z plane of the circuit of Figure 3-228a split into two parts: $R_1 - C_1 - L_1$ and $C_2 - R_2$. Exact transformation from R_1 into R_2 occurs at the points of intersection M and N. Impedances are then conjugate, or $Z' = R' + jX'$ and $Z'' = R'' + jX''$ with $R' = R''$ and $X' = -X''$.

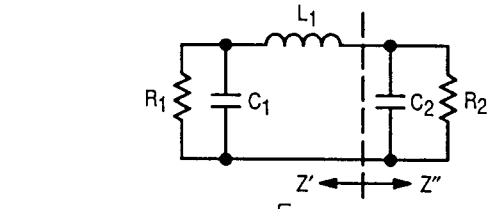
The only possible solution is obtained when X' and $-X''$ are tangential to each other. For the dashed curve, representing another value of L_1 or C_1, a wider frequency band could be expected at the expense of some ripple inside the band. However, this can only be reached with four reactances, as will be shown below.

With a three-reactance configuration, there are not enough degrees of freedom to permit $X' = -X''$ and simultaneously obtain the same variation of frequency on both curves from point M' to point N'. Exact transformation can, therefore, be obtained at only one frequency.

The values of the three reactances can be calculated by making

$$X' = -X'', \quad R' = R'', \quad \text{and} \frac{dX'}{dR'} = -\frac{dX''}{dR''} \tag{3-216}$$

The general solution of these equations leads to complicated calculations. Therefore, computed tables should be used.



$$Z' = \frac{R_1}{1 + \omega^2 R_1^2 C_1^2} + j\omega \left[L1 - \frac{R_1^2 C_1}{1 + \omega^2 R_1^2 C_1^2} \right] = R' + jX'$$

$$Z'' = \frac{R_2}{1 + \omega^2 C_2^2 R_2^2} - \frac{j\omega^2 C_2 R_2^2}{1 + \omega^2 C_2^2 R_2^2} = R'' + jX''$$

$$|x'| = \left(\frac{L_1}{C_1 R_1^2} - \frac{R'}{R_1} \right) \sqrt{\frac{R_1}{R'} - 1}$$

$$|x''| = \sqrt{R' R_2 - R'^2}$$

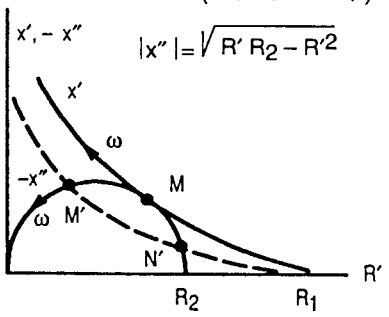


Figure 3-229 *Z*-plane representation of the circuit of Figure 3-228a.

One will note from Figure 3-229 that the compensation reactance contributes somewhat to the impedance transformation; that is, R' varies when going from M to R_2.

The circuit of Figure 3-228b is dual with respect to the first one and gives exactly the same results in a *Y*-plane representation. The circuit of Figure 3-228c is somewhat different since only one intersection M exists, as shown in Figure 3-230. Narrower frequency bands must be expected from this configuration. The widest band is obtained for $C_1 = \infty$.

Again, if one of the terminations has a reactive component, the latter can be taken as a part of the matching network, provided that it is not too large (see Figure 3-227).

FOUR-REACTANCE NETWORKS. Four-reactance networks are used essentially for broadband matching. The networks that will be considered in the following consist of two two-reactance sections in cascade. Some networks have pseudo-low-pass filter character; others, bandpass filter character. In principle, the former show narrower bandwidth since they extend the impedance transformation to very low frequencies unnecessarily, while the latter ensure good matching over a wide frequency band around the center frequency only (see Figure 3-233).

The two-reactance sections used in the networks in Figure 3-231 have either transformation properties or compensation properties. Impedance transformation is obtained with one series reactance and one shunt reactance. Compensation is made with both reactances in series or in shunt. If two cascaded transformation networks are used, transformation is accomplished partly by each one.

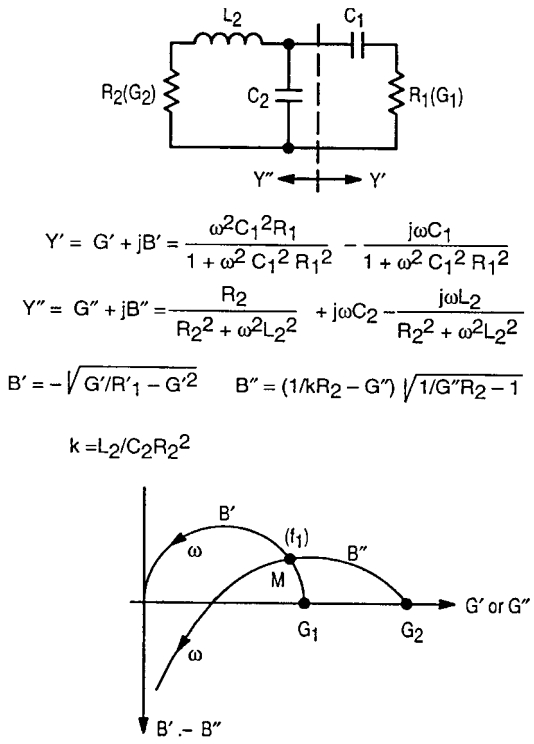

Figure 3-230 *Y*-plane representation of the circuit of Figure 3-228c.

With four-reactance networks there are two frequencies, f_1 and f_2, at which the transformation from R_1 into R_2 is exact. These frequencies may also coincide. For the network in Figure 3-231b, for instance, at point M, R_1 or R_2 is transformed into $\sqrt{R_1R_2}$ when both frequencies fall together. At all points (M), Z_1 and Z_2 are conjugate if the transformation is exact.

In the case of Figure 3-231b, the reactances are easily calculated for equal frequencies:

$$X_1 = \frac{R_1}{\sqrt{(n-1)^{1/2}}} \tag{3-217}$$

$$X_2 = R_1\sqrt{\frac{n^{1/2}-1}{n}} \tag{3-218}$$

$$X_1X_4 = R_1R_2 = X_2X_3 \tag{3-219}$$

$$X_3 = \frac{R_1}{\sqrt{n(n^{1/2}-1)}} \tag{3-220}$$

$$X_4 = \frac{R_1}{n}\sqrt{n^{1/2}-1} \tag{3-221}$$

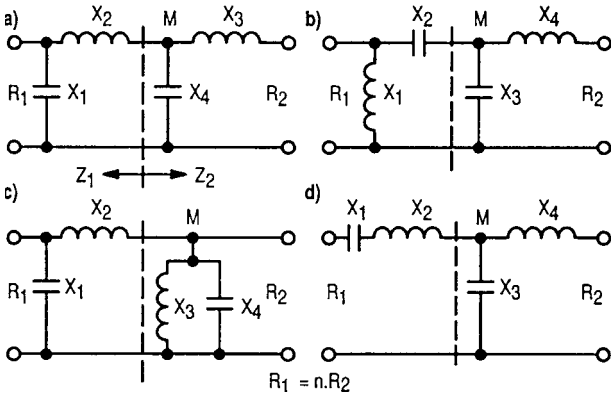

Figure 3-231 Four-reactance networks.

For the network in Figure 3-231a, normally at point M, Z_1 and Z_2 are complex. This pseudo-low-pass filter has been computed elsewhere [33]. Many tables can be found in the literature for networks of four and more reactances having Chebyshev character or maximally flat response [33, 34, 36].

Figure 3-232 shows the transformation path from R_1 to R_2 for networks (a) and (b) in Figure 3-231 on a Smith Chart.

Case (a) of Figure 3-232 has been calculated using tables in Matthaei [34]. Case (b) has been obtained from the relationship given above for $X_1, \ldots, X_4$. Both apply for a transformation ratio equal to 10 and for $R_1 = 1$. There is no simple relationship for $X_1', \ldots, X_4'$ of network (b) if f_1 is made different from f_2 for larger bandwidth. Figure 3-233 shows the respective bandwidths of networks (a) and (b) for the circuits shown in Figure 3-232.

If the terminations include a reactive component, the computed values for X_1 or X_4 may be adjusted to compensate for this.

For configuration (a), it can be seen from Figure 3-232 that, in the considered case, the Q values are equal to 1.6. For configuration (b), Q_1', which is equal to Q_2', is fixed for each transformation ratio

n	2	4	8	10	16
$Q'_1 = Q'_2$	0.65	1	1.35	1.46	1.73

$$Q' = \sqrt{n^{1/2} - 1} \qquad (3\text{-}222)$$

The maximum value of reactance that the terminations may have for use in this configuration can be determined from the above values of Q'.

If R_1 is the load resistance of a transistor, the internal transistor resistance may not be equal to R_1. In this case, the selectivity curve will be different from the curves given in Figure 3-233. Figure 3-234 shows the selectivity for networks (a) and (b) when the source resistance R_1 is infinite. From Figure 3-234 it can be seen that network (a) is more sensitive to changes in R_1 than network (b).

As mentioned earlier, the four-reactance network can also be thought of as two cascaded two-reactance sections: one used for transformation, the other for compensation. Figure 3-235 shows commonly used compensation networks, together with the associated L section.

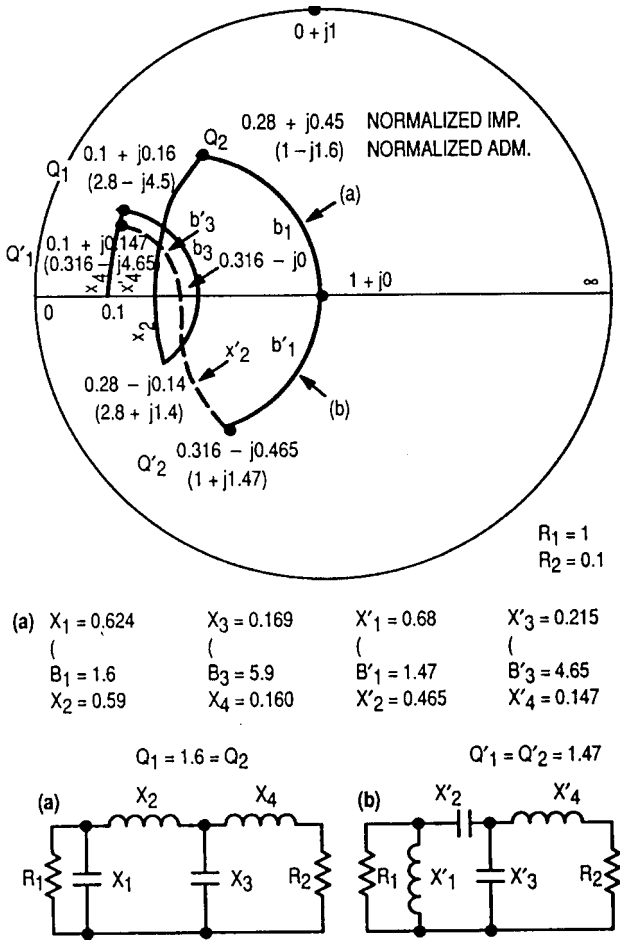

Figure 3-232 Transformation paths for networks (a) and (b).

The circuit of Figure 3-235a can be compared to the three-reactance network shown in Figure 3-228c. The difference is that capacitor C_2 of that circuit has been replaced by an *LC* circuit. The resulting improvement can be seen by comparing Figure 3-236 with Figure 3-230.

By adding one reactance, exact impedance transformation is achieved at two frequencies. It is now possible to choose component values such that the point of intersection M' occurs at the same frequency f_1 on both curves and simultaneously that N' occurs at the same frequency f_2 on both curves. Among the infinite number of possible intersections, only one allows the achievement of this.

When M' and N' coincide in M, the new $dX'/df = dX''/df$ condition can be added to the condition $X' = -X''$ (for three-reactance networks) and similarly $R' = R''$ and $dR'/df = dR''/df$.

Again, a general solution of the above equations leads to still more complicated calculations than in the case of three-reactance networks. Therefore, tables are preferable [33, 34, 36].

The circuit of Figure 3-235b is the dual of the circuit of Figure 3-233a and does not need to be treated separately. It gives exactly the same results in the *Z* plane. Figure 3-235c shows a higher-order compensation requiring six reactive elements.

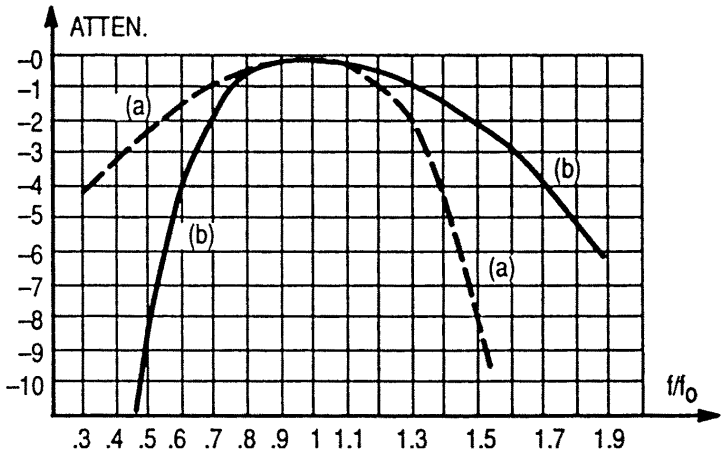

Figure 3-233 Selectivity curves for networks (a) and (b) of Figure 3-232.

The above-discussed matching networks employing compensation circuits result in narrower bandwidths than the former solutions (see p. 573) using two transformation sections. A matching arrangement with higher-order compensation, such as in Figure 3-235c, is not recommended. Better use can be made of the large number of reactive elements by using them all for transformation.

When the above configurations are realized using short portions of transmission lines, the equations or the usual tables no longer apply. The calculations must be carried out on a computer because of their complexity. However, a graphical method can be used (see the next section) that will consist essentially in tracing a transformation path on the Z–Y chart using the computed lumped element values and replacing it by the closest path obtained with distributed constants. The bandwidth change is not significant as long as short portions of lines are used.

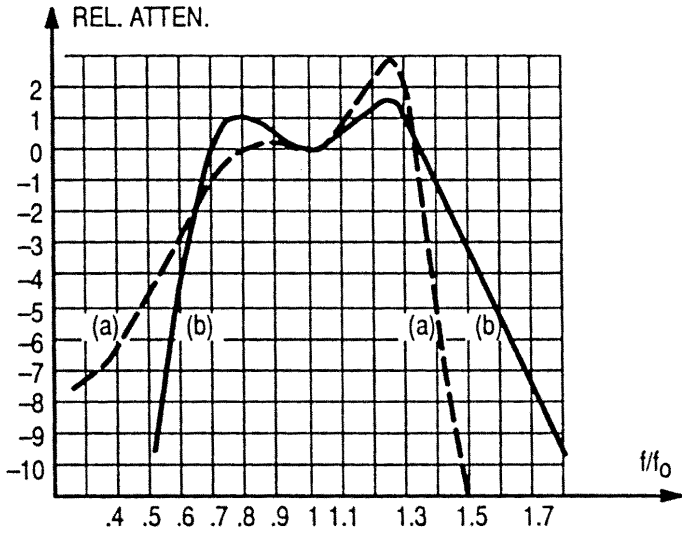

Figure 3-234 Selectivity curves for networks (a) and (b) of Figure 3-232 with infinite R_1.

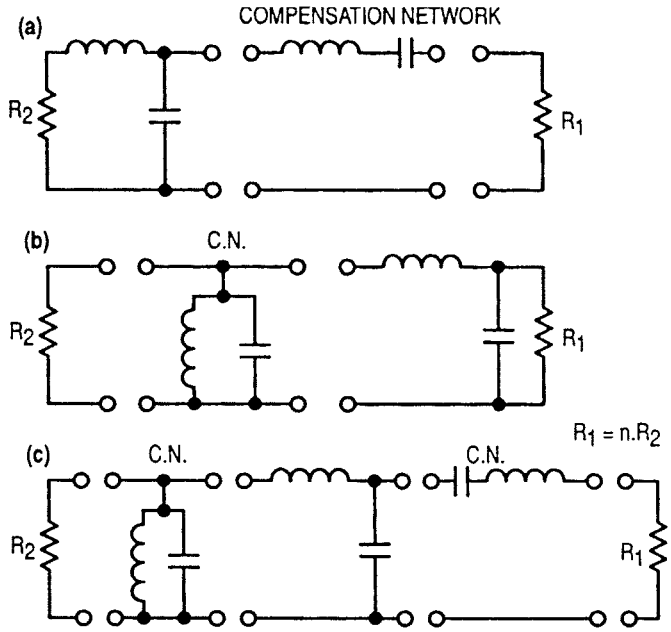

Figure 3-235 Compensation networks used with an L section.

MATCHING NETWORKS USING QUARTER-WAVE TRANSFORMERS. At sufficiently high frequencies, where λ/4-long lines of practical size can be realized, broadband transformations can easily be accomplished by the use of one or more λ/4 sections. Figure 3-237 summarizes the main relations for (a) one-section and (b) two-section transformations. A compensation network can be realized using a λ/2-long transmission line. Figures 3-238 and 3-239 show the selectivity curves for different transformation ratios and section numbers.

EXPONENTIAL LINES. Exponential lines have largely frequency-independent transformation properties. The characteristic impedance of such lines varies exponentially with their length l:

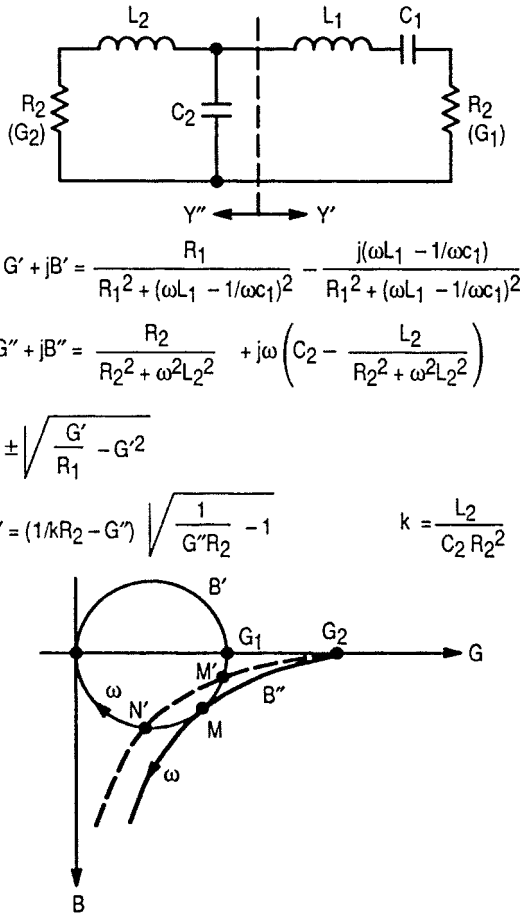
$$Z = Z_0 e^{kl} \tag{3-223}$$

where k is a constant, but these properties are preserved only if k is small.

BROADBAND MATCHING USING BANDPASS FILTER NETWORKS—HIGHQ CASE. The above circuits are applicable to devices having low input or output Q, if broadband matching is required. Generally, if the impedances to be matched can be represented, for instance, by a resistor R in series with an inductor L (sometimes a capacitor C) within the band of interest and if L is sufficiently low, the latter can be incorporated into the first inductor in the matching network. This is also valid if the representation consists of a shunt combination of a resistor and a reactance.

Practically, this is feasible for Q values around 1 or 2. For higher Q values or for input impedances consisting of a series or parallel resonant circuit (see Figure 3-221), as it appears to be for large bandwidths, a different treatment must be followed.

Let us first recall that, as shown by Bode [37] and Fano [38], limitations exist on the impedance matching of a complex load. In the example of Figure 3-240, the load to be matched consists of a capacitor C and a resistor R in shunt.



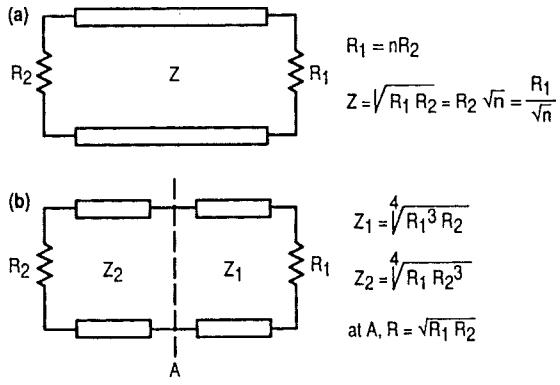
$$Y' = G' + jB' = \frac{R_1}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2} - \frac{j(\omega L_1 - 1/\omega c_1)}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2}$$

$$Y'' = G'' + jB'' = \frac{R_2}{R_2^2 + \omega^2 L_2^2} + j\omega\left(C_2 - \frac{L_2}{R_2^2 + \omega^2 L_2^2}\right)$$

$$B' = \pm\sqrt{\frac{G'}{R_1} - G'^2}$$

$$B'' = (1/kR_2 - G'')\sqrt{\frac{1}{G''R_2} - 1} \qquad k = \frac{L_2}{C_2 R_2^2}$$

Figure 3-236 *Y*-plane representation of the circuit of Figure 3-235a.



$$R_1 = nR_2$$

$$Z = \sqrt{R_1 R_2} = R_2\sqrt{n} = \frac{R_1}{\sqrt{n}}$$

$$Z_1 = \sqrt[4]{R_1^3 R_2}$$

$$Z_2 = \sqrt[4]{R_1 R_2^3}$$

$$\text{at A, } R = \sqrt{R_1 R_2}$$

Figure 3-237 Transformation networks using λ/4-long transmission lines.

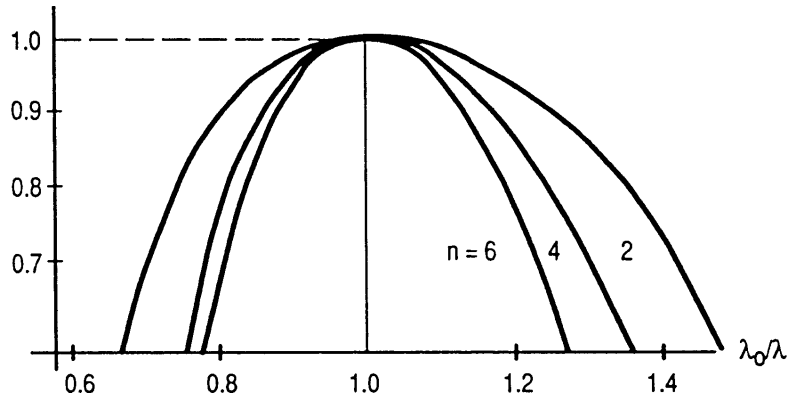


Figure 3-238 Selectivity curves for two λ/4-section networks at different transformation ratios.

The reflection coefficient between the transformed load and generator is equal to

$$\Gamma = \frac{Z_{\text{IN}} - R_G}{Z_{\text{IN}} + R_G} \tag{3-224}$$

When $\Gamma = 0$, there is perfect matching; when $\Gamma = 1$, there is total reflection. The ratio of reflected to incident power is

$$\frac{P_r}{P_i} = |\Gamma|^2 \tag{3-225}$$

The fundamental limitation on the matching takes the form

$$\int_{\omega=0}^{\infty} \ln\left(\frac{1}{|\Gamma|}\right) d\omega \le \frac{\pi}{RC} \qquad \text{Bode equation} \tag{3-226}$$

and is represented in Figure 3-241.

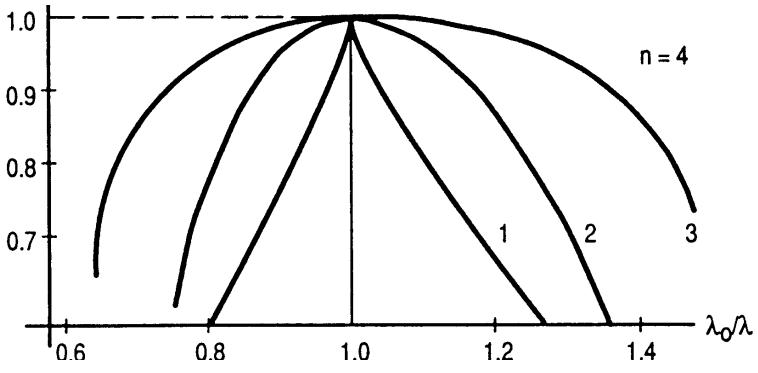

Figure 3-239 Selectivity curves for one, two, and three λ/4 sections.

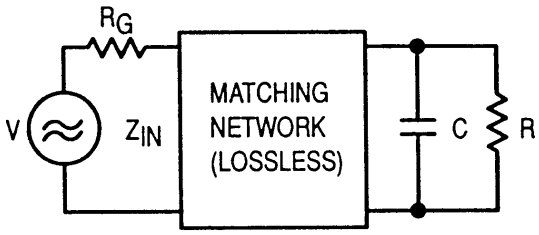

Figure 3-240 General matching conditions.

The meaning of the Bode equation is that the area S under the curve cannot be greater than π/RC and, therefore, if matching is required over a certain bandwidth, this can only be done at the expense of less power transfer within the band. Thus, power transfer and bandwidth appear as interchangeable quantities.

It is evident that the best utilization of the area S is obtained when $|\Gamma|$ is kept constant over the desired band ω_c and made equal to 1 over the rest of the spectrum. Then

$$|\Gamma| = e^{-\pi/\omega_c RC} \tag{3-227}$$

within the band and no power transfer happens outside. A network fulfilling this requirement cannot be obtained in practice because an infinite number of reactive elements would be necessary.

If the attenuation is plotted versus frequency for practical cases, one may expect to have curves like the ones shown in Figure 3-242 for a low-pass filter having Chebyshev character.

For a given complex load, an extension of the bandwidth from ω_1 to ω_2 is possible only with a simultaneous increase of the attenuation a. This is especially noticeable for Q values exceeding 1 or 2 (see Figure 3-243). Thus, devices having relatively high input Q values are usable for broadband operation, provided the consequent higher attenuation or reflection introduced is acceptable.

For average insertion losses or attenuation a (neglecting the ripple), the attenuation decreases if the number n of the network element increases. But above $n = 4$, the improvement is small. For a given attenuation a and bandwidth, the larger the n the smaller the ripple; for a given attenuation, the larger the n the larger the bandwidth.

Computations show that for $Q < 1$ and $n \leq 3$, the attenuation is below 0.1 dB (approximately). The impedance transformation ratio is not free here. The network is a

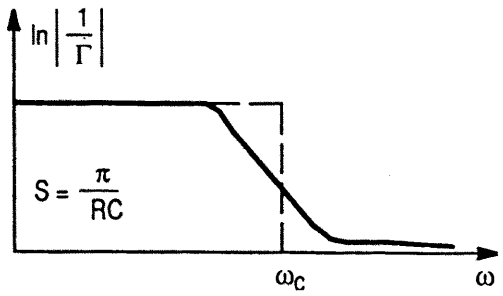

Figure 3-241 Representation of the Bode equation.

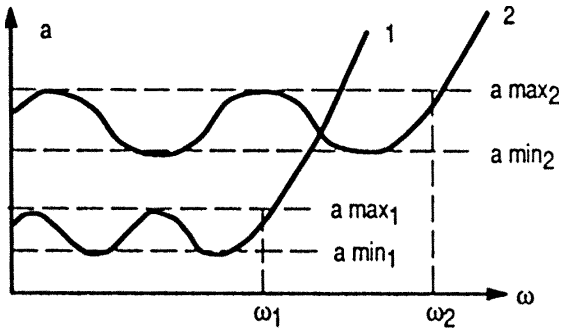

Figure 3-242 Attenuation versus angular frequency for different bandwidths with the same load.

true low-pass filter. For a given load, the optimum generator impedance will result from the computation.

Before impedance transformation is introduced, a conversion of the low-pass prototype into a bandpass filter network must be made. Figure 3-244 summarizes the main relations for this conversion. r is the conversion factor. For the bandpass filter, $Q_{\text{IN max}}$, or the maximum possible input Q of the device to be matched, has been increased by the factor r (from Figure 3-244, $Q'_{\text{IN max}} = rQ_{\text{IN max}}$).

Impedance inverters will be used for impedance transformation. These networks are suitable for insertion into a bandpass filter without affecting the transmission characteristics.

Figure 3-245 shows four impedance inverters. Note that one of the reactances is negative and must be combined in the bandpass network with a reactance of at least equal positive value. Insertion of the inverter can be made at any convenient place [32, 39].

When using the bandpass filter for matching the input impedance of a transistor, reactances $L'_1C'_1$ should be made to resonate at ω_0 by addition of a convenient series reactance.

As stated earlier, the series combination of R_0, L'_1 and C'_1 normally constitutes the equivalent input network of a transistor when considered over a large bandwidth. This is a good approximation up to about 500 MHz.

In practice, the normal procedure for using a bandpass filter matching network will be the following:

1. For a given bandwidth center frequency and input impedance of a device to be matched—for example, 50 Ω—first determine Q'_{IN} from the datasheet as

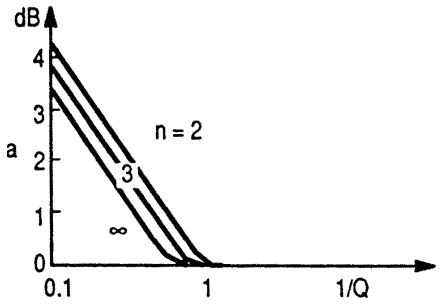

Figure 3-243 Insertion losses as a function of 1/*Q*.

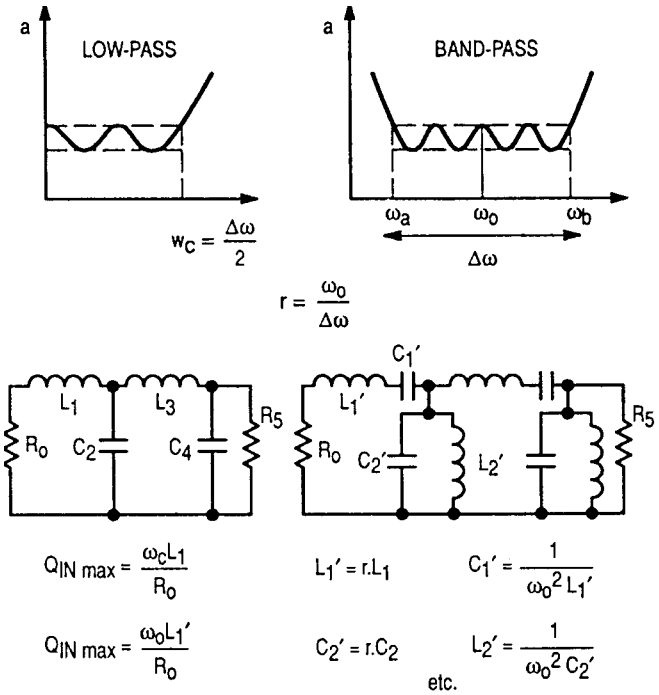

Figure 3-244 Conversion from low-pass filter into bandpass filter.

$$\frac{\omega_0 L_1'}{R_0} \tag{3-228}$$

after having eventually added a series reactor for centering.

2. Convert the equivalent circuit $R_0 L_1' C_1'$ into a low-pass prototype $R_0 L_1$ and calculate Q_{IN} using the formulas of Figure 3-244.
3. Determine the other reactance values from tables [33] for the desired bandwidth.
4. Convert the element values found by Step 3 into series- or parallel-resonant circuit parameters.
5. Insert the impedance inverter in any convenient place.

In the above discussions, the gain roll-off has not been taken into account. This is of normal use for moderate bandwidths (e.g., 30%). However, several methods can be employed to obtain a constant gain within the band despite the intrinsic gain decrease of a transistor with frequency. Tables have been computed elsewhere [40] for matching networks approximating 6 dB/octave attenuation versus frequency.

Another method consists of using the above-mentioned network and then adding a compensation circuit, as shown in Figure 3-246.

Resonance ω_b is placed at the high edge of the frequency band. Choosing Q correctly, roll-off can be made 6 dB/octave. The response of the circuit of Figure 3-246 is expressed by

$$\frac{1}{1 + Q^2(\omega/\omega_b - \omega_b/\omega)^2} \tag{3-229}$$

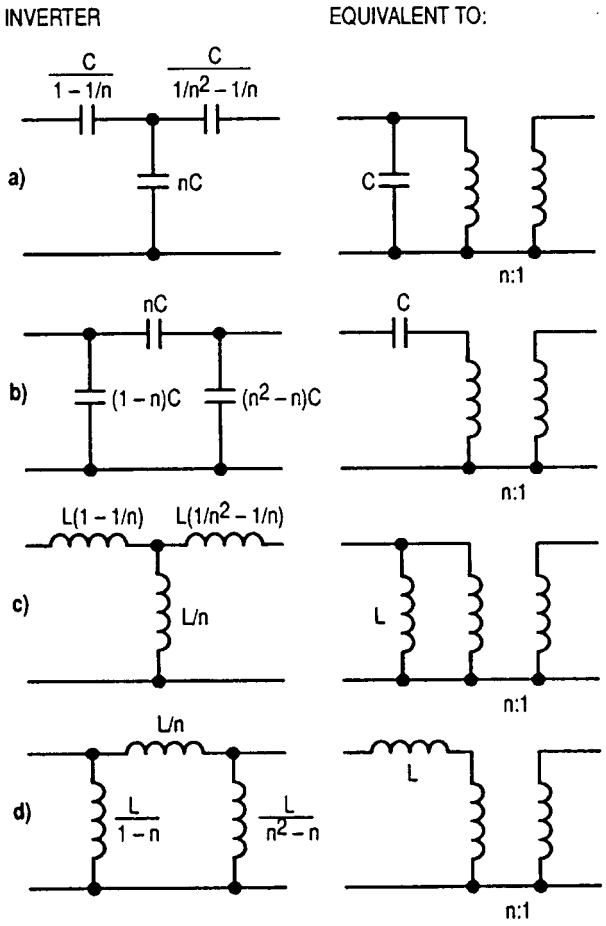

Figure 3-245 Impedance inverters.

where $\omega < \omega_b$. This must be equal to ω/ω_b for 6 dB/octave attenuation.

At the other band edge a, exact compensation can be obtained if

$$Q = \frac{(\omega_b/\omega_a)^2 - 1}{\omega_a/\omega_b - (\omega_b/\omega_a)^2} \tag{3-230}$$

There are several methods available for synthesis of matching networks. They should not be confused with filters because they can be either high-pass, low-pass, or bandpass, and their main purpose is to match one complex impedance to another. In many cases, one of the terminations happens to be 50 Ω and real, but this is just a "lucky" case of the general approach. An excellent paper on this [41] refers to the "real frequency" technique. Another equally important publication is the one by Cuthbert [42], since followed by his book [43]. Two more good references are Vendelin et al. [44] and Potter [45].

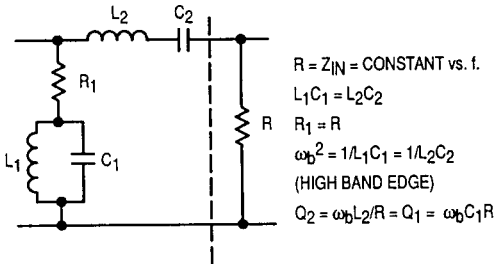

Figure 3-246 Roll-off compensation network.

3-12-3 Example 2: Low-Noise Amplifier Using Distributed Elements

In our previous examples, the amplifiers were built around lumped elements. Since a transmission line length of less than $\lambda/4$ is an inductor and $\frac{3}{4}\lambda$ is a capacitor, the whole amplifier can be built around microstrip technology.

If anyone wonders why we are going to show a low-noise amplifier in the middle of the power section, the reason is that we will select a low-power Siemens transistor, which, being operated in Class A, has an intercept point of +30 dBm and can easily achieve a noise figure of less than 2 dB. Such an amplifier is attractive when feeding an input stage from an antenna that sees many signals and curtails the bandwidth with an input filter of good selectivity that needs a good output termination, which in many cases works against the achievement of a good noise figure because when designing for best noise figure the input impedance of the transistor stage is far from 50 Ω.

First, we will start with the textbook approach and use the Smith diagram to obtain the best noise figure of which the device is capable. Figure 3-247 shows the actual approach to input and output matching.

We start our design by querying the Smith Tool about the minimum noise figure and the gain that comes with it. We mark the point of the lowest noise figure (labeled Γ_{opt}). The small

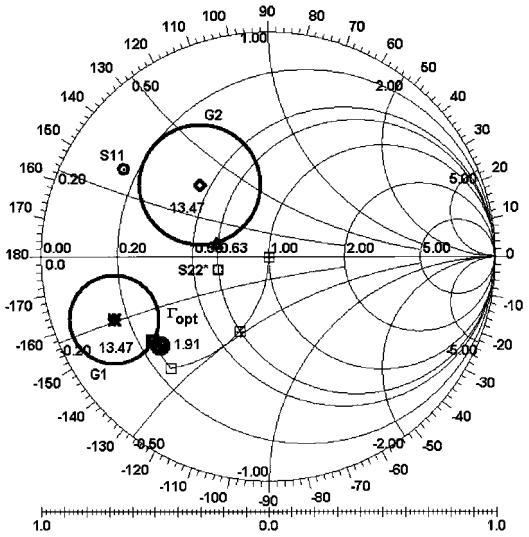

Figure 3-247 Input and output matches for 13.47 dB of gain and NF = 1.91 dB as displayed by the interactive Smith Tool.

noise circle yields the location for Γ_{opt} and tells us the minimum noise figure is going to be 1.91 dB. (By the way, this assumes no further losses, even in soldering the transistor to the PC board.) Then we construct the input gain circle (G1), which touches Γ_{opt} and turns out to represent 13.47 dB of available gain.

The next step is to find a matching network between Γ_{opt} and the 50-Ω source impedance. Immediately there is a conflict: If we look at S_{11}, which is the input reflection coefficient shown in the Smith diagram, it is on the other side of the complex plane and sufficiently far away, indicating that there is going to be quite a difference between noise matching and power-gain matching. We have two options for matching the input: Either we start from the origin and move toward the position of Γ_{opt}, or we start with Γ_{opt} and go to 50 Ω. Depending on the direction in which we do this, the result can be different topologies, such as a high-pass or low-pass filter. The high-pass filter is obtained by starting with Γ_{opt}; the low-pass topology is obtained by starting at the 50-Ω point. The Smith Tool then provides us with the corresponding values of capacitors and inductors after the transformation has been accomplished.

The final step is to do the same type of matching at the output. We start with S_{22}, and either select S_{22}^* (the complex conjugate for highest gain) or S_{22load}. As a rule, the second one is always a lower impedance (in terms of the real part) than the conjugate match. This graphic procedure is somewhat trial and error. As to the topology, a high-pass match should be preferred at the input and a low-pass match at the output. The reason for this is that the high-pass filter will tend to protect the stage from the enormous number of signals present below 1 GHz; using a low-pass filter at the output suppresses unwanted harmonics that the amplifier may generate. Figure 3-248 shows one of the approaches we like best simply because it gives a good input termination and we were trying for a simultaneous match for best noise figure and power gain.

The way we were able to achieve this was to take advantage of the existing feedback in the transistor and select a less-than-optimal output termination but gaining at the input. Taking advantage of the Miller effect, we rotate the phase angle of the feedback with the load to move the optimum noise and gain matching points closer. The danger in this is that the circuit is now highly sensitive to both input and output termination. The output *must* see 50 Ω to maintain this good input match, but since the second transistor stage can now be optimized for best input match, a two-stage combination can be configured to meet this

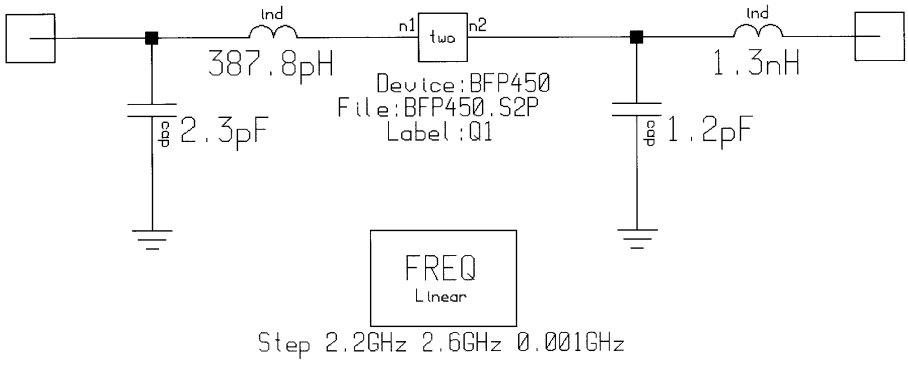

Figure 3-248 A 2.4-GHz amplifier using a BFP450 transistor and lumped-element input and output matching.

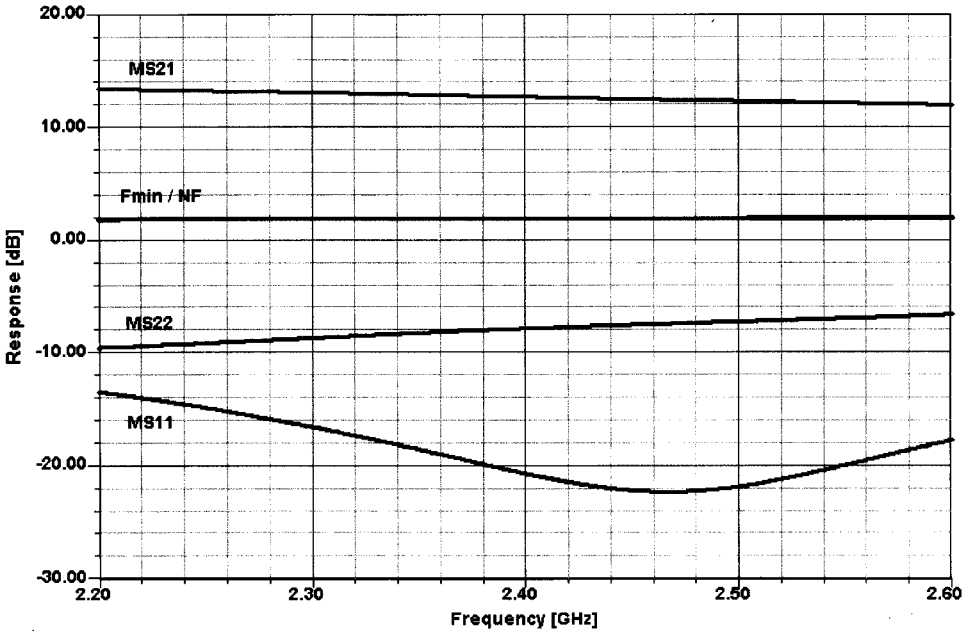

Figure 3-249 Frequency-dependent gain, matching, and noise characteristics of the matched high-dynamic-range BFP450 2.4-GHz amplifier.

requirement. Also, let us not forget that the device is running at 50 mA and as far as bipolar transistors are concerned, this is probably the best amplifier combination we have seen for getting the highest dynamic range and lowest noise figure. The resulting gain, matching, and noise figure characteristics are shown in Figure 3-249.

Now we turn to using distributed elements and at the same time use a shunt feedback at the output; to be specific, we will load it with 150 Ω. The reason for this is to be able to obtain a good compromise at the input that will depend less on the output and at the same

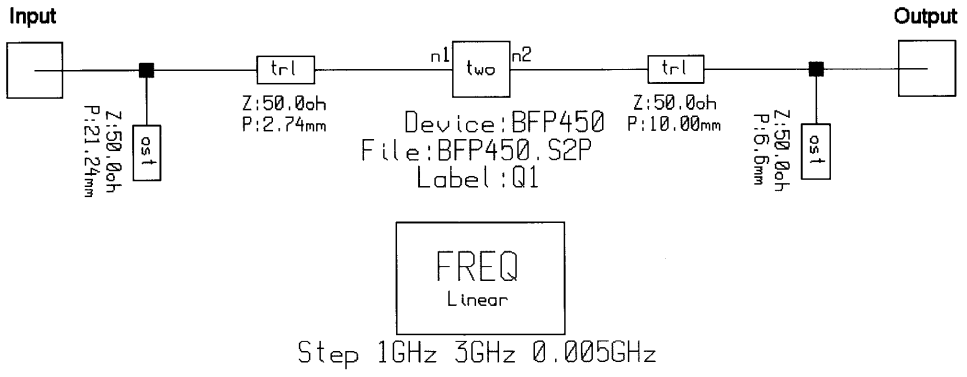

Figure 3-250 Distributed-element input and output matching for the 2.4-GHz BFP450 amplifier.

time improve the S_{22} matching at the output. The procedure for doing the matching with a transmission line offers only certain degrees of freedom, while doing the matching with lumped elements allows the choice of series or parallel inductors or capacitors. In the case of a transmission line, we have open stubs, shorted stubs, and transmission lines. This may result in somewhat more complex matching schemes. On the positive side, they can easily be trimmed, are reproducible, and certainly cost less than exotic capacitors, which need to have small tolerances and to be able to handle high RF currents.

The resulting input and output matching is shown in Figure 3-250, and its frequency response in Figure 3-251. We were able to maintain a good input and output match with an insignificant deterioration of the noise figure.

Since this is a high-dynamic-range amplifier, we also show its predicted two-tone response in Figure 3-252. The manufacturer specifies an $IP_{3,in}$ of 29 dB for a bias point of $V_{CE} = 3$ V and $I_C = 50$ mA with $Z_S = Z_{S,opt}$ and $Z_L = Z_{L,opt}$ at 1.8 GHz. Significantly, however, the manufacturer-supplied nonlinear BFP450 library we used exhibits considerably different characteristics at $V_{CE} = 4$ V and $I_C = 50$ mA than those reflected in the corresponding S parameters supplied by the same manufacturer. In our circuit, the S parameters resulted in about 13.5 dB of gain (based on a compromise between matching for optimum noise and maximum gain) versus about 9.5 dB of gain for the nonlinear library (match optimized for maximum gain). The difference between the 2.4-GHz F_{min} values returned for the two modeling approaches is similarly striking: 1.90 dB for the bare S parameter set and 7.76 dB for the bare nonlinear library biased to $V_{CE} = 4$ V and $I_C = 50$ mA. Clearly, the nonlinear modeling of the BFP450 needs work!

Having fully evaluated the amplifier at 2.4 GHz as a working example, we note that this frequency is used by radio amateurs for some applications. We will therefore supply

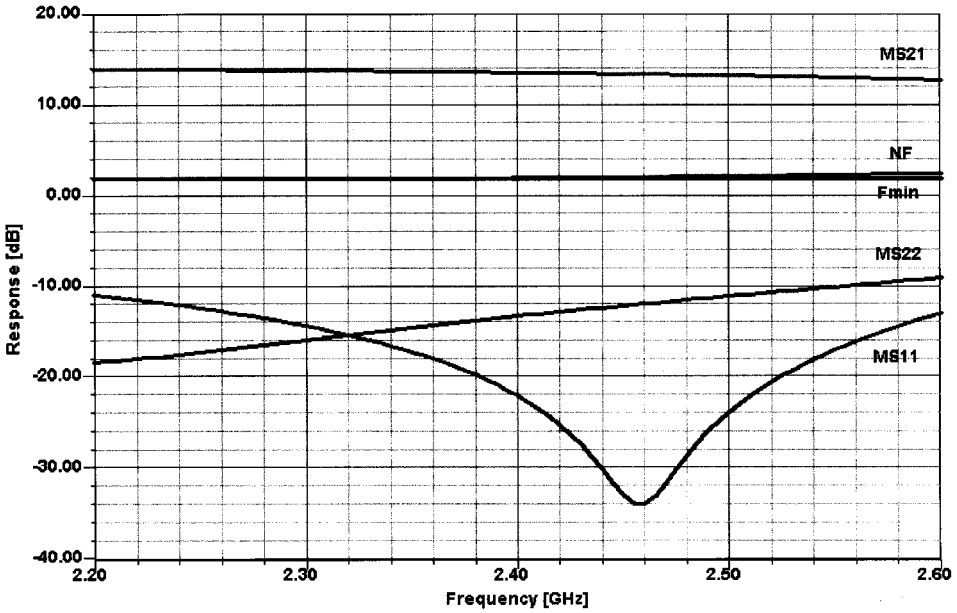

Figure 3-251 Predicted frequency-dependent gain, matching, and noise performance for the BFP450 amplifier with distributed-element matching.

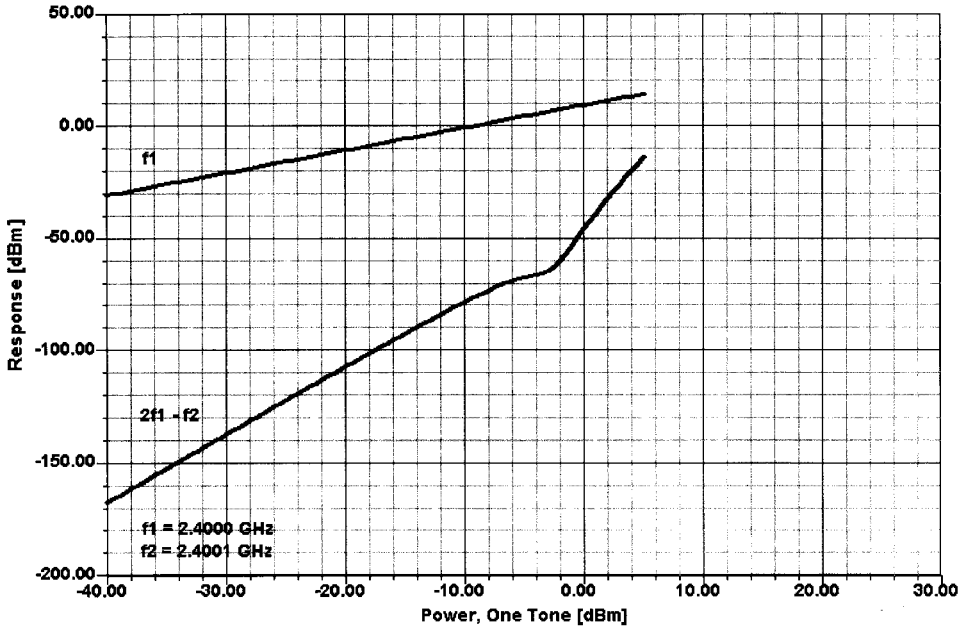

Figure 3-252 Predicted two-tone response of the BFP450 amplifier with the circuit adjusted for maximum gain (9.5 dB): $IP_{3,in} \approx 28.5$ dBm and $IP_{3,out} \approx 38$ dBm. That this version's gain is significantly lower than that of the *S*-parameter-based equivalent illustrates the need for better accuracy in parameter extraction.

examples for 432 and 1296 MHz, popular spot frequencies in the amateur 70- and 23-cm bands, respectively. Figures 3-253 and 3-254 show the 432-MHz version's schematic and frequency-dependent responses. Figures 3-255 and 3-256 show the schematic and frequency-dependent responses for the 1296-MHz version.

Using a bipolar transistor that operates at much less current, the noise figure can be improved at the expense of the dynamic range/intercept point. It is possible to reduce the noise figure by about 1 dB or so, but the reduction in intercept point will be much more dramatic. Another choice is the use of GaAsFETs for this application, but their matching in comparable circuits has been described as a nightmare simply because the devices have too much gain and very high input impedances (essentially 0.2 pF in series with 3 Ω) combined with reasonable output impedances in the vicinity of 240 Ω. Here is a wide field in which engineers can experiment and examine price/performance and performance/real estate issues. GaAsFETs also tend to require more than 30–40 mA to be alive, and even the low operating voltage of 4–5 V makes the device consume a lot of dc power.

3-12-4 Example 3: 1-W Amplifier Using the CLY15

The following is an application showing a fairly wideband amplifier with +30 dBm (1 W) output. We need to point out that in accordance with the various digital modulation modes used with this amplifier, this is not continuous operation, but a much less than 1:1 duty cycle operation. The device would probably not survive operating at full output under CW conditions. This is subject to a discussion with the manufacturer, Siemens, who has not

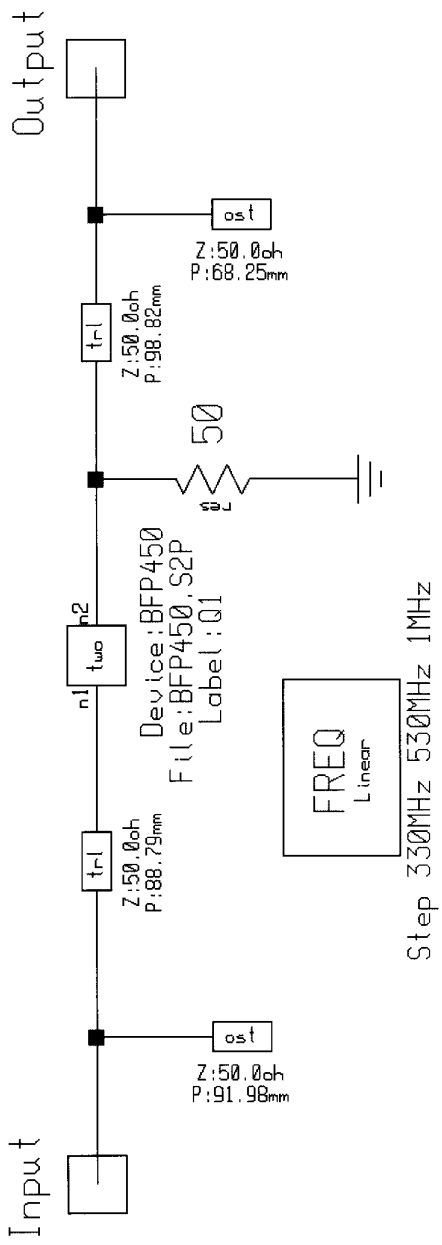

Figure 3-253 Schematic of BPF450 amplifier for 432 MHz. Because f_T = 25 GHz for the BFP450, at this lower frequency we must shunt the device output with a 50-Ω resistor to maintain stability.

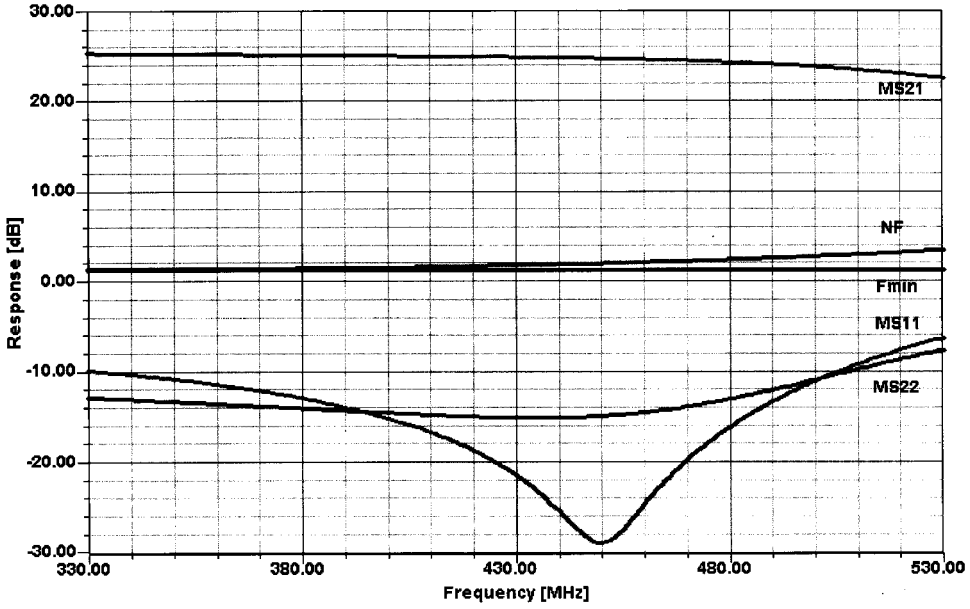

Figure 3-254 Frequency-dependent gain, matching, and noise performance for the BPF450 amplifier at 432 MHz. As with the circuit in Figure 3-253, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

released sufficient data for us to make a judgment as to the CLY15's continuous power capability. Since there is no useful large-signal model available at the time of this writing, we will design this Class A amplifier using large dc bias *S* parameters. In the actual design there will be some cut-and-try, but we find that in this type of application this is still the best way of handling the design.

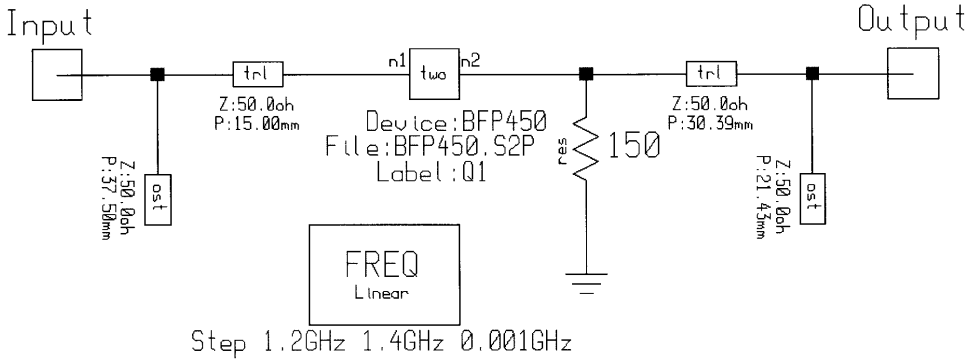

Figure 3-255 Schematic of the BPF450 amplifier for 1296 MHz. A loading resistor is still necessary to ensure stability, but because the transistor exhibits less gain at this frequency than at 432 MHz, we can increase the loading resistor to 150 Ω.

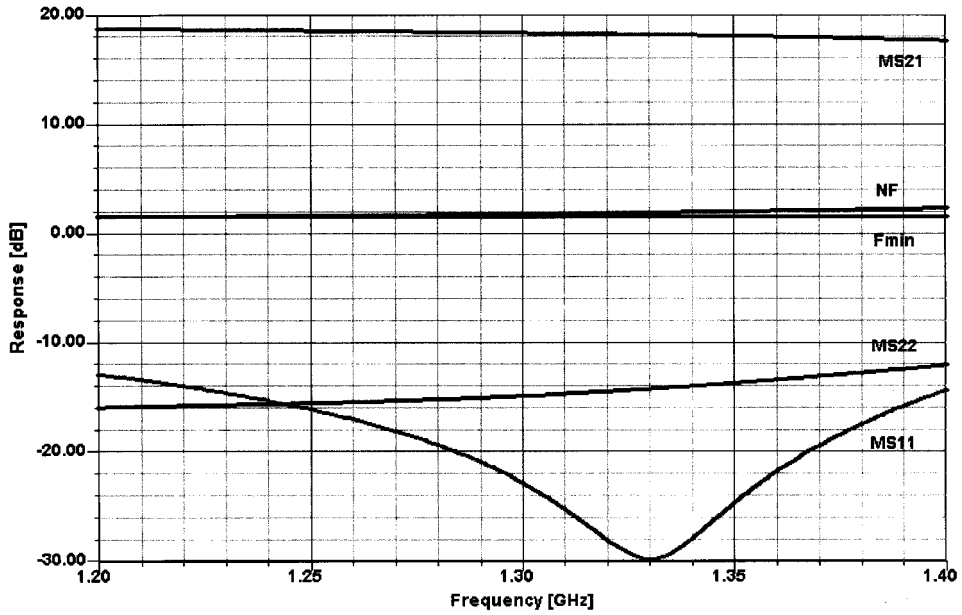

Figure 3-256 Frequency-dependent gain, matching, and noise responses of the BFP450 amplifier at 1296 MHz. As with the two previous versions, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

The CLY15 (gate width 16 mm) is the largest of a series of Siemens GaAsFETs; it was already mentioned in Chapter 2, where its datasheet is reproduced. Its device family also includes the CLY2 (gate width 2 mm), CLY5 (4 mm), and CLY10 (8 mm). It is possible that bigger devices will be offered in the future. One of the most critical parameters will be the saturation voltage; from the datasheet of the CLY15, we can see that at 1.5 A the saturation voltage is approximately 1 V. This drop of 1 V includes losses that result from other parasitic elements; the dc *I–V* curve (Figure 3-257a) indicates a saturation voltage of 0.75. Since we aim for 1-W output power, the resistive portion of the load will be $(5 - 1)^2 / (1 \times 2) = 8\ \Omega$. This assumes a supply voltage of 5 V.

The next step is to design the input and output matching network. Previewing the *S* parameters, it will be noticed that they are essentially inductive, which means that the input match, using lumped elements, will result in a combination of capacitors at both the input and the output. Figures 3-258 and 3-259 show the ways in which the input and output matches were done on the Smith diagram resulting in lumped matching elements. Inspecting the lumped input matching, we find the following. We start with S_{11}, which is in the lower part of the Smith diagram, and determine its conjugate match, S_{11}^*. We already pointed out that this device is inductive, which means that matching it from the conjugate point will require two capacitors. The first one is a series capacitor, as identified in the Smith diagram, and followed by a shunt capacitor to transform the impedance to 50 Ω. A close inspection of the Smith diagram shows that the resulting point is not quite on S_{11}; it is an iterative process to exactly find the crossover point, yet the input match of better than 20 dB is more than acceptable.

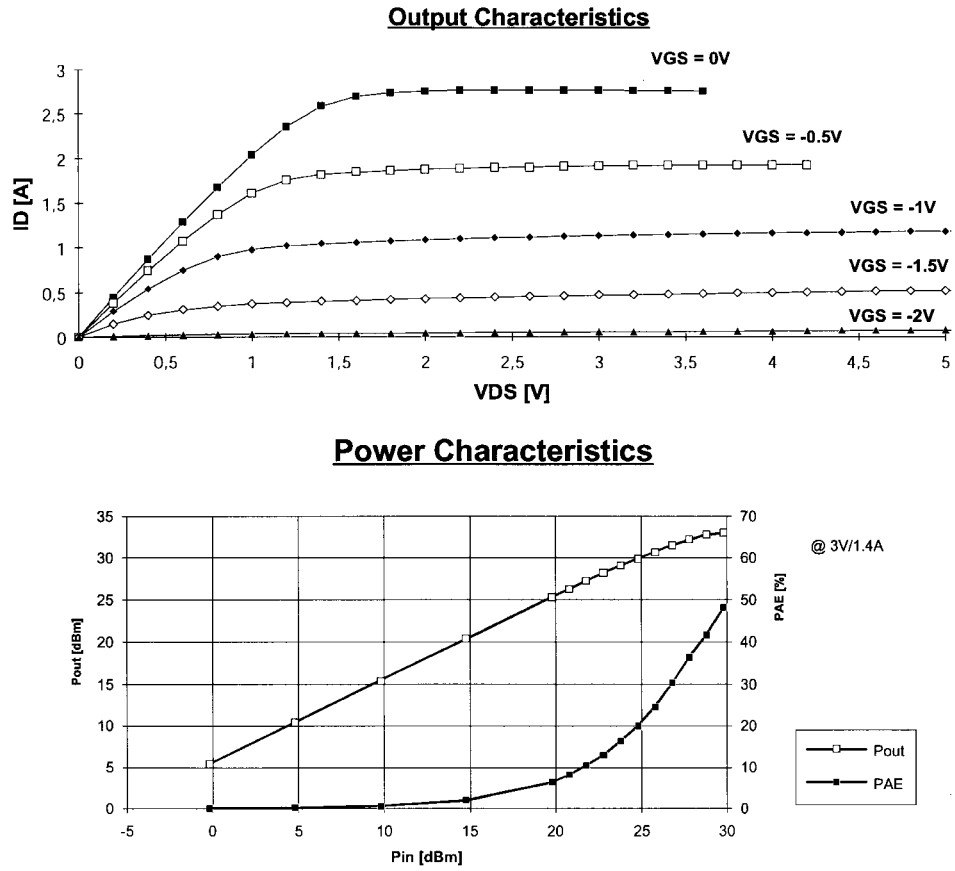

Figure 3-257 Output and power characteristics for the CLY15 medium-power GaAsFET.

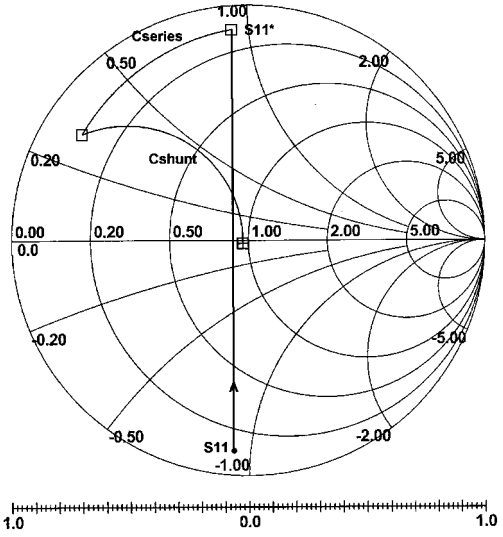

Figure 3-258 Input match for S_{11}^{*} using lumped elements.

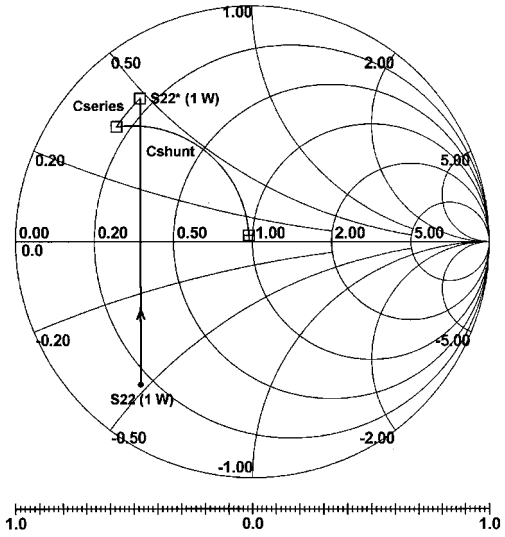

Figure 3-259 Output match for S_{22}^* (1 W) using ideal lumped elements.

As far as the output is concerned, we use the same technique by moving from S_{22} to S_{22}^*. S_{22} has been determined from the required output power; as we showed above, the real portion is 8 Ω. Using the lumped elements, the matching technique is identical; we first need to use a series capacitor and then a shunt capacitor for the transformation. The arc for the series capacitor this time is much longer, resulting in a series capacitance of 11.2 pF instead of the 2.1-pF capacitance used at the input. The actual schematic is shown Figure 3-260. The drawback of lumped elements is that it is not practical to buy components that can handle the heavy RF currents that flow in the input and output networks. Taking the values obtained

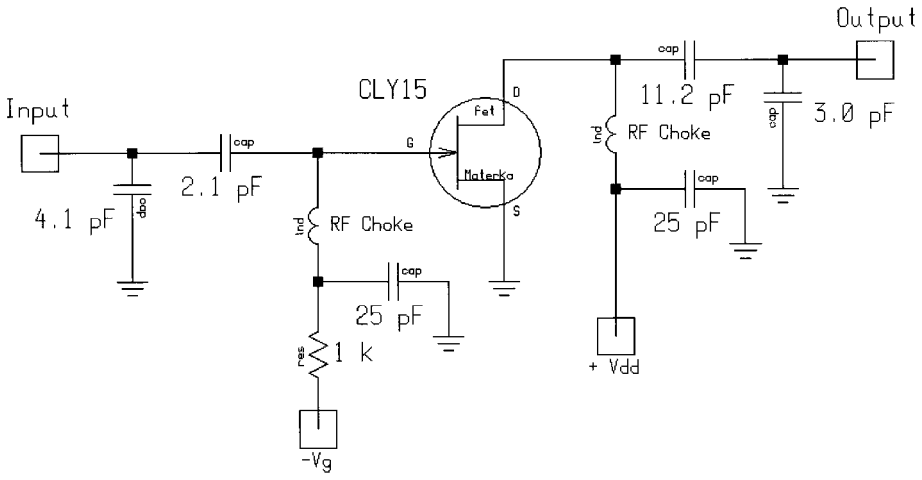

Figure 3-260 The complete amplifier using the CLY15 medium-power GaAsFET, with lumped-element input and output matching.

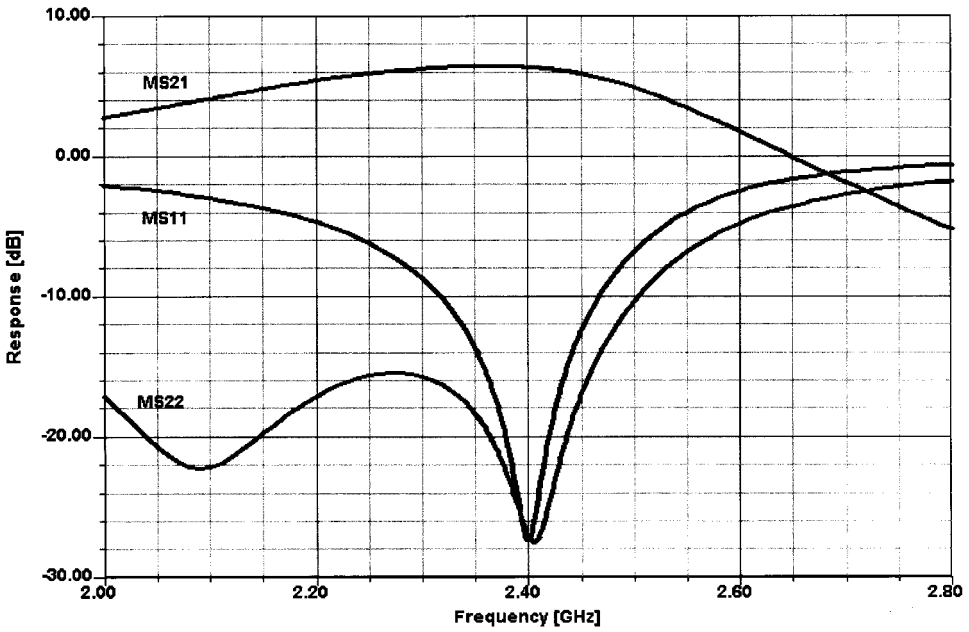

Figure 3-261 Frequency-dependent gain and matching responses of the CLY15 amplifier using ideal lumped elements.

from the lumped input and output matching approach, Figure 3-261 shows the resulting frequency response.

The next step is to provide the same matching condition using distributed elements, which of course have the advantage that they can be printed on the PC board. Instead of using ideal elements, we used a loss tangent of 2E–3, or a Q of 500. The manufacturer of the R4000 material (Rogers) provided this specification. Now we start with the same approach by moving from S_{11} to S_{11}^*. From there, we use an open stub with a transmission-line impedance of 50 Ω, followed by a transmission line to the point in the left lower corner, and, finally, a shorted transmission-line stub allows the 50-Ω matching. For this amplifier, we are not looking for noise matching but for input and output power matching. Figure 3-262 shows this match on the Smith Chart.

At the output, the procedure is again similar: We move from the S_{11} for 1 W to a conjugate value, then use an open stub that acts like a capacitor until we cross the real axis; finally, a λ/4 transmission line is used to match from approximately 75 Ω to 50 Ω. Figure 3-263 shows this match on the Smith Chart. This concludes the distributed matching design for the CLY15 amplifier.

Finally, the complete circuit using distributed elements is shown in Figure 3-264. From a dc point of view, we took advantage of the incoming shorted stub by using a transmission line of the appropriate length and a bypass capacitor to ground. This allows us to feed the gate with the required negative voltage without interfering with the frequency response of the amplifier. When evaluating the total frequency response (Figure 3-265), we noticed that this circuit seems to have a higher Q than the lumped equivalent. Again, to obtain a wider bandwidth more transformation stages will be needed. We leave this task to the interested reader.

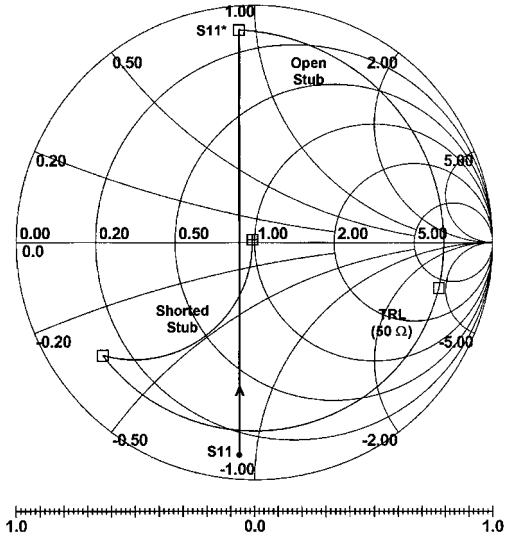

Figure 3-262 Input match for S_{11}^* (1 W) using distributed elements.

The 1-dB bandwidth of the amplifier using distributed, lossy elements is 120 MHz. If a wider bandwidth is required, matching networks with more elements are required. Because of the gain–bandwidth product, the peak gain for such a wider-bandwidth arrangement will be less than this narrowband example.

Having used a lumped to distributed transformation, we next present a power amplifier that uses coaxial lines, baluns, and other transformation steps capable of handling the increased power requirement.

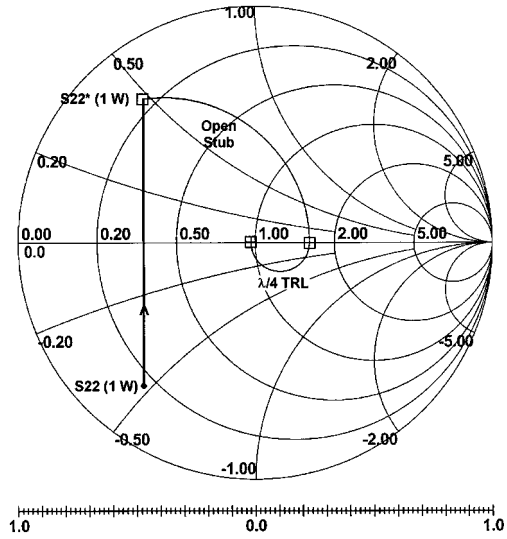

Figure 3-263 Output match for S_{22}^* (1 W) using distributed elements.

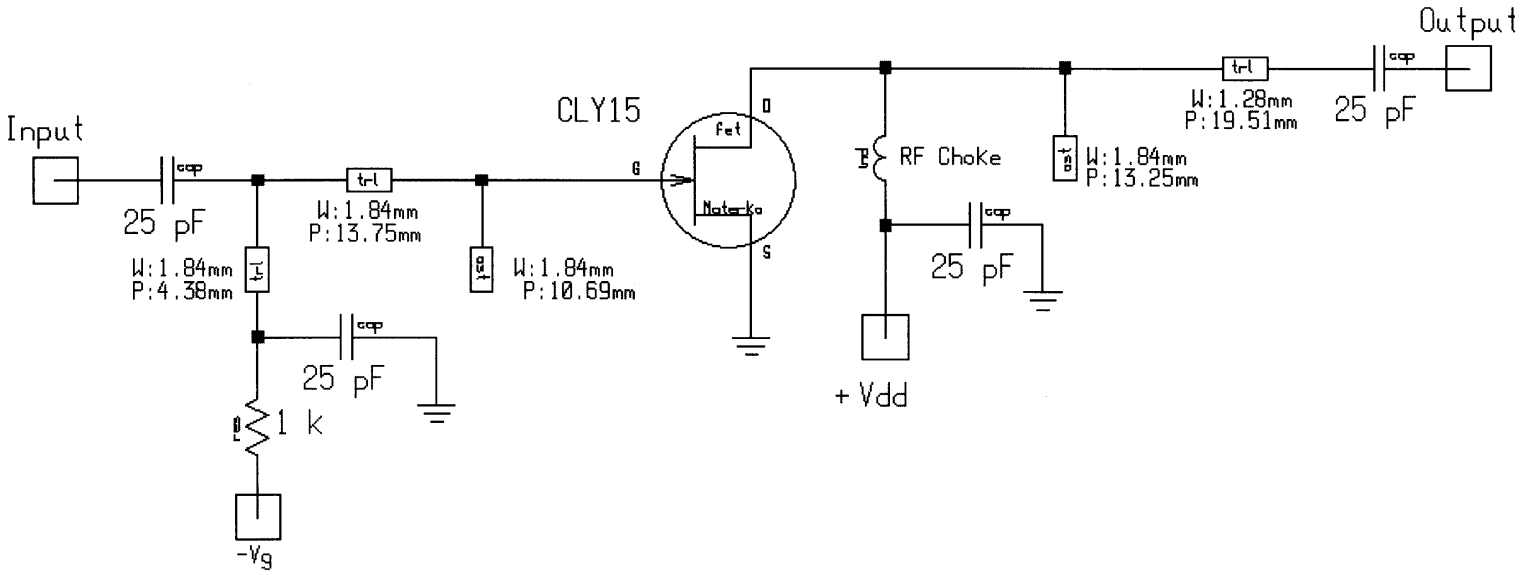

Figure 3-264 The complete amplifier using the CLY15 medium-power GaAsFET, with distributed-element input and output matching.

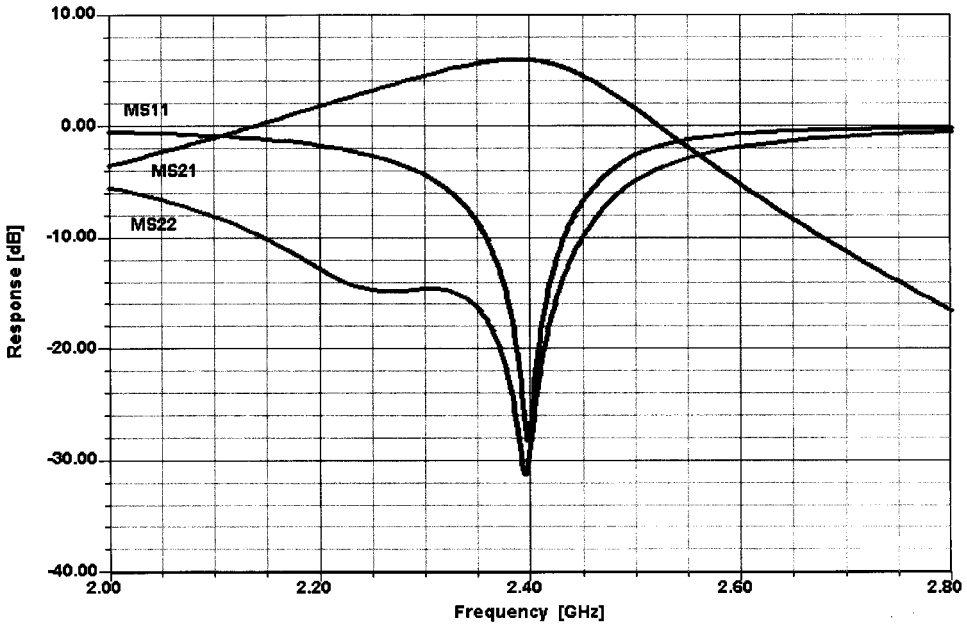

Figure 3-265 Frequency-dependent gain and matching using distributed, lossy elements.

3-12-5 Example 4: 90-W Push–Pull BJT Amplifier at 430 MHz

The last complete application we want to examine is a 90-W output, push–pull amplifier using two TRW transistors (that are no longer made—an all-too-frequent occurrence after a design is complete, resulting in a scramble for replacements). Figure 3-266 shows the circuit diagram of this UHF transistor amplifier, and Figure 3-267 shows its mechanical design. The amplifier requires 28 Vdc and will draw approximately 6 A, requiring 15 W of drive at 438 MHz. This amplifier operates in Class AB, which means it is not limited to amplifying FM and other angle-modulated signals, and can accommodate even single-sideband (SSB) operation.

The drive power coming from the source connected to the input N connector (15 W) is fed through a short piece of coaxial cable to the PC board sitting on top of the heat sink. To change from single ended to push–pull, a 50-Ω coaxial cable is coiled to provide sufficient electrical length to act as a balun that provides two symmetrical paths through the amplifier. The RC section of 10 Ω in parallel with a 220-pF capacitor stabilizes the amplifier at lower frequencies, while at higher frequencies the 10-Ω resistor has no contribution. There are two independent 4:1 transformers, one for each section; they are built using 25-Ω coaxial cable with a set of two binocular ferrite cores to force the transformation. The dc supply is also fed to the transistors at this point. The stabilization circuit consists of a temperature monitor using the *pn* junction of a transistor, side-mounted on the heat sink, and a combination of operational amplifiers and adjustments. This guarantees proper, temperature-independent biasing. The 4:1 input baluns result in 12.5 Ω impedance, or 3.125 Ω per transistor. Since the input impedance at this drive level is somewhere in the vicinity of $[(1 \ldots 2) + j(3 \ldots 5)]$ Ω; the final matching is accomplished by an *RC* section in which the inductance is actually printed

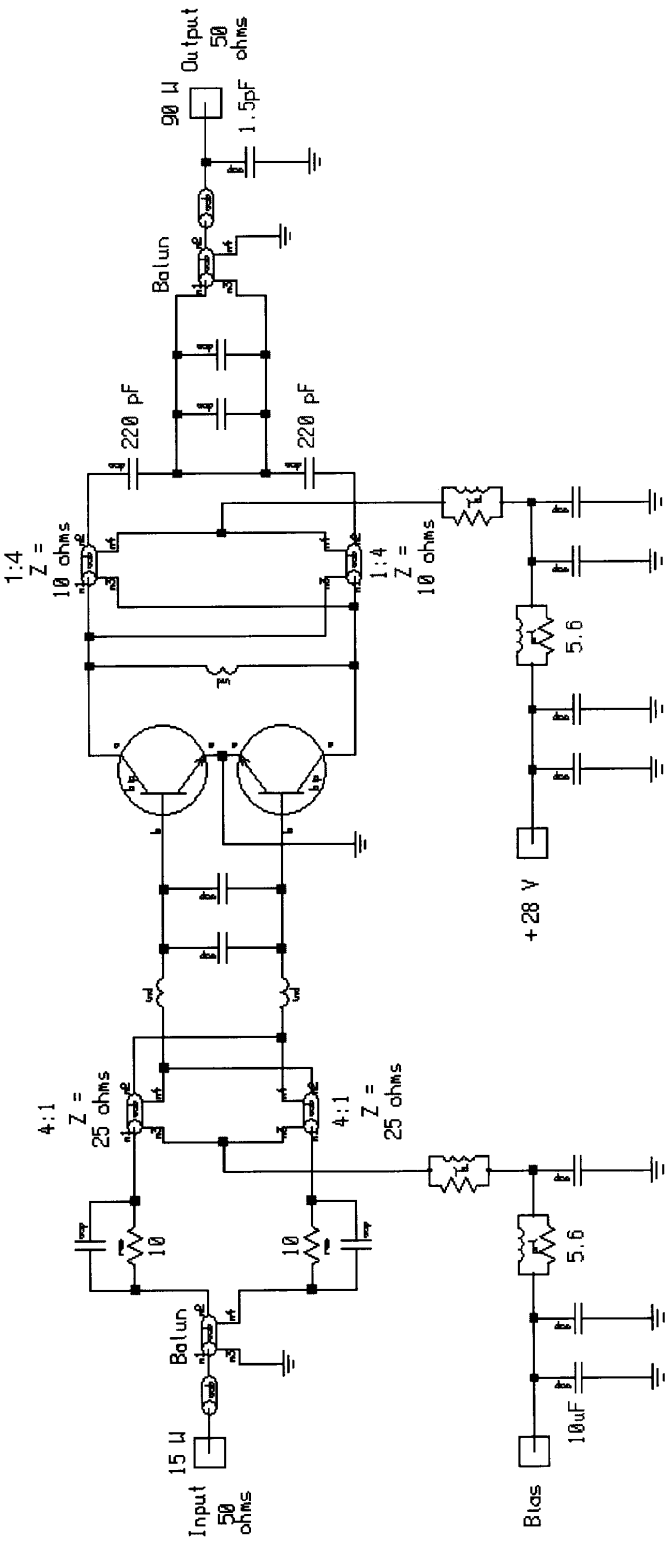

Figure 3-266 Circuit diagram of the 90-W, push–pull, 438-MHz linear amplifier.

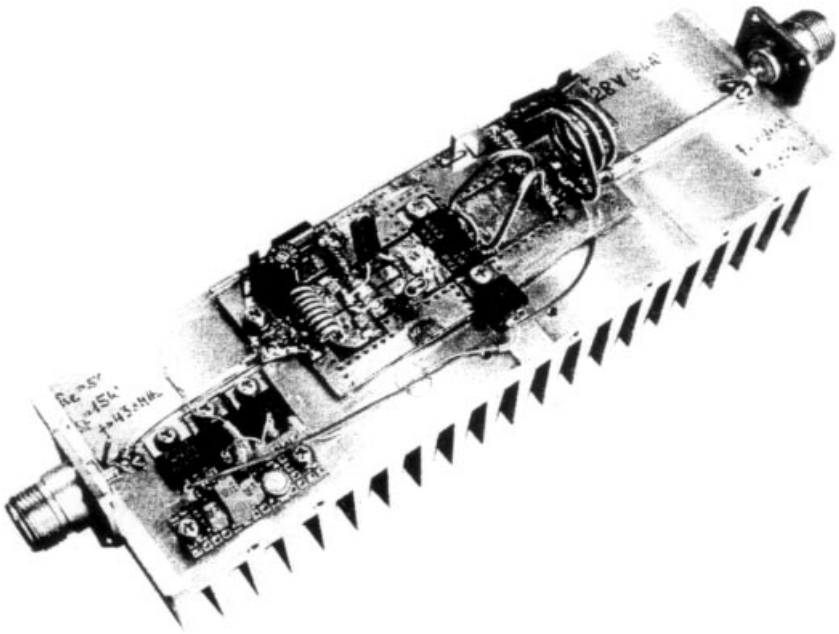

Figure 3-267 Mechanical assembly of the 90-W amplifier shown in Figure 3-266.

and the shunt capacitor across is soldered from base to base as close to the transistor bodies as possible. A ceramic-dielectric variable capacitor in parallel with this allows fine tuning.

The output consists of an inductor from collector to collector that tunes out the capacitive reactance and makes the transistor output impedance real. We then follow the same pattern by taking a 1:4 transformer, but this time built using 10-Ω rigid line instead of 25-Ω rigid line. Together with the output capacitance, prior to the output balun, this is a medium-bandwidth matching arrangement that transforms up to 50 Ω. The collector impedance per collector had to be $(28 - 2)^2/2 \times 90$, resulting in roughly 3.8 Ω—not that different from the input match at the balun point. This way, the matching networks at the input and output can be identical. At the output of the matching network, another coiled 50-Ω coaxial cable serves as balun; because it must operate at the 90-W level, larger-diameter line was used than in the input balun. Finally, another section of rigid line is used to connect the output balun on the PC board to the output N connector. The output capacitor again helps in the transformation.

Both the base and collector voltage supplies are heavily filtered using ferrite-bead-based RF chokes and heavy wire inductors wound on low-impedance resistors. A fairly large number of these amplifiers were actually built and are still in use.

3-12-6 Quasiparallel Transistors for Improved Linearity

Some applications require really low intermodulation distortion. One of the authors (Rohde), during his tenure at RCA Government Systems Division, and his team developed a parallel-device topology that is somewhat similar to the conventional parallel approach but shows vastly increased linearity. In creating higher-power devices, manufacturers parallel several transistors in one package, connecting them in a clever way so the overall drive, dissipation, and output power are equally divided between all the devices. Special nickel–chromium

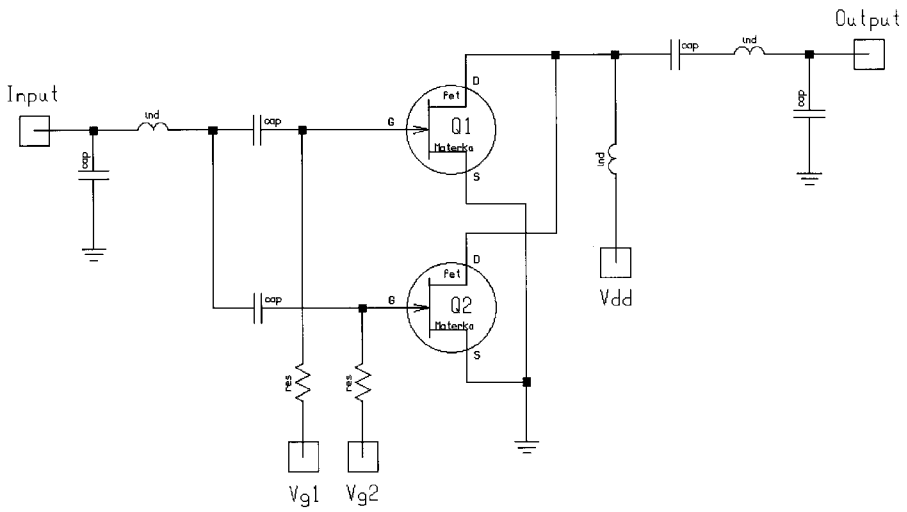

Figure 3-268 The quasiparallel amplifier topology looks like a standard parallel amplifier. Biasing the devices to different operating points nets an improvement in IMD performance.

ballasting resistors in the many fingers of the emitter connections of the multiple internal devices equalize any differences among the transistors while increasing the saturation voltage by only a small amount. In our high-linearity design, we used two transistors in parallel, one being biased somewhere between Class A and B, and the second one somewhere between Class B and C (Figure 3-268). The exact bias voltages and operating points had to be found through experiment. In practice, Q1, the "initially on" transistor, is driven to a point close to that at which its IMD products would increase. Q2 is biased such that at this same drive level it adds to the output power.

We frequently referred to this configuration as "turbocharged." The IMD products at full output power were down 40–45 dB, compared to 26–30 dB for a single transistor. While such an arrangement shows superior IMD performance, because of the somewhat abrupt kick-in of the second transistor, the transconductance response is semismooth, a characteristic that might make alert readers think that IMD will occur at this point. On the other hand, the transconductance for Q1, in effect, saturates or stays constant, so when the transconductance responses of both transistors are overlaid, the result is a smooth response overall.

This technique has been validated up to 100 W and up to at least 50 MHz. Its drawbacks include the need for two transistors with their associated costs, additional real estate, and higher input and output capacitances. Nonetheless, considering that MOS transistors capable of operation to 1 GHz were unavailable when this technique was developed, we believe that it should be revisited.

The Class D and higher operating modes require a large number of additional components and will make the efficiency higher (selective in frequency), but not necessarily reduce the IMD products. A further point of consideration is that it is incorrect to assume that reducing the input level to a given Class A will necessarily reduce its IMD products. As with tubes, the closer one gets to the knee, even in Class A operation, the worse the IMD. (This phenomenon was particularly troublesome in systems using 1-kW amplifiers up to 150 MHz;

underdrive with the intent of getting better IMD performance produced just the opposite result.) If a wide power range is considered, we recommend using a bias scheme that includes sufficient intelligence to find the best operating point.

Another hot amplifier issue is that of IMD as a function of load impedance. If an amplifier is used at output power considerably below its design value, its load impedance will be too low and, depending on the circuit configuration, the result may be additional IMD.

3-12-7 Distribution Amplifiers

It is not uncommon that a signal from a particular source like an antenna has to be distributed to several places. A condominium is a typical situation in which energy from a main signal source must be split for distribution to a larger number of users—there must be enough voltage or power to produce a noise-free picture. An amplifer capable of doing this is a *distribution* amplifier, not to be confused with a *distributed* (or traveling-wave) amplifier, such as that shown earlier in this chapter in Figure 3-6. An interesting means of achieving this is to use multiple Wilkinson couplers following an amplifier. Figure 3-269 shows an arrangement that makes heavy use of multiple power dividers to provide multiple outputs. Theoretically, the reverse is also possible: If we want to collect energy from a number of sources and combine them, as on a cable, we can use Wilkinson couplers at the *input* of a gain block. Note, however, that depending on the level and number of the combined signals, this may put enormous strain on the linearity of the amplifier. What we want to avoid is a lot of distortion, which, in the case of television, will show up as color confetti in the noise and signal.

3-12-8 Stability Analysis of a Power Amplifier

One of the hidden pitfalls in narrowband circuit design is that a circuit may be unstable outside the frequency range of interest. Circuits containing structures built from distributed elements, which exhibit multiple resonances, can be particularly susceptible to such instabilities. In this example, we analyze the stability of a simple FET power amplifier designed using small-signal concepts and the interactive Smith Tool utility in Ansoft's Serenade

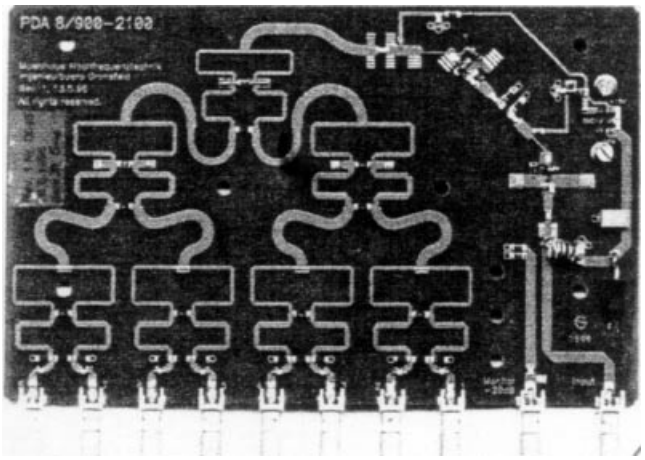

Figure 3-269 Distribution amplifier showing the use of multiple Wilkinson power dividers.

Design Environment. The evaluation shows how K-factor analysis alone is not sufficient to check for stability of a design.

Small-Signal ac Analysis. We begin by taking the Figure 3-270 amplifier, which was designed for about 16 dB of gain at 2.2 GHz. Due to the very low, capacitive input impedance of the FET and the proximity of the source-plane gain circles and stability circles to the edge of the Smith Chart, the matching network attempts to transform 50 Ω to an impedance of approximately $(2.5 + j15)$ Ω. The impedance lies close to the stability circles at 2 GHz but remains in a stable region. The bias point selected (–3.5 V) is chosen for Class AB operation. Higher linear gain can be achieved by reducing the gate voltage to –2.0 V; at this bias point, the amplifier gain will increase to about 19 dB.

First, we will do a small-signal ac analysis and examine the S parameters and K and B_1 factors [see Eqs. (3-154) and (3-157), respectively] from 1 GHz to 6 GHz—well beyond the bandwidth of the design. Figure 3-271 shows the circuit's frequency-dependent gain and matching characteristics.

If we examine B_1 and the stability factor K, we see that the amplifier is not unconditionally stable in the 2.2-GHz passband as shown in Figure 3-272. K dips slightly below 1, although B_1 remains above zero. In practice, a slight change in design would be required to bring K above 1 and remove this potential instability. However, for our example, this is of no consequence, as we shall see below.

Nyquist Stability Analysis. Now we will utilize a Nyquist stability analysis to check the stability of the amplifier. To fully realize the advantages of a Nyquist stability analysis, we must sweep frequency over a very wide range. We want to be able to pick up instabilities at *any* frequency, not just near the design frequency. In this example we sweep from 1 kHz to 20 GHz. A start frequency of 1 kHz is chosen so we can determine the starting point of the Nyquist plot and we ensure that any low-frequency resonances are picked up. The stop frequency is chosen past the f_{max} of the transistor (where we know it cannot oscillate).

The analysis results are shown in polar plot form in Figure 3-273 and in magnitude–angle form in Figure 3-274. The polar graph shows the real and imaginary parts of the system determinant as frequency is swept. The magnitude–angle graph shows the magnitude and cumulative angle (no cut at ±180°) of the system determinant as frequency is swept. The key to interpreting these graphs lies in the following statement drawn from the Nyquist criterion:

The circuit will be unstable if the Nyquist plot encircles the origin in a clockwise direction.

The term "unstable" refers to the existence of natural frequencies lying in the right-half of the complex frequency plane (RHP). These natural frequencies on the RHP will cause oscillations. To encircle the origin in a clockwise direction means that the Nyquist plot will travel in a clockwise path, cross the negative real axis, and continue to completely surround the origin. If the path appears to encircle the origin but then "unravels" itself in a counter-clockwise direction, the origin is not actually encircled. Figure 3-273 shows that the origin is not encircled and therefore this circuit is stable.

The magnitude–angle plot can assist in determining if a clockwise encirclement has actually been made with the help of the following:

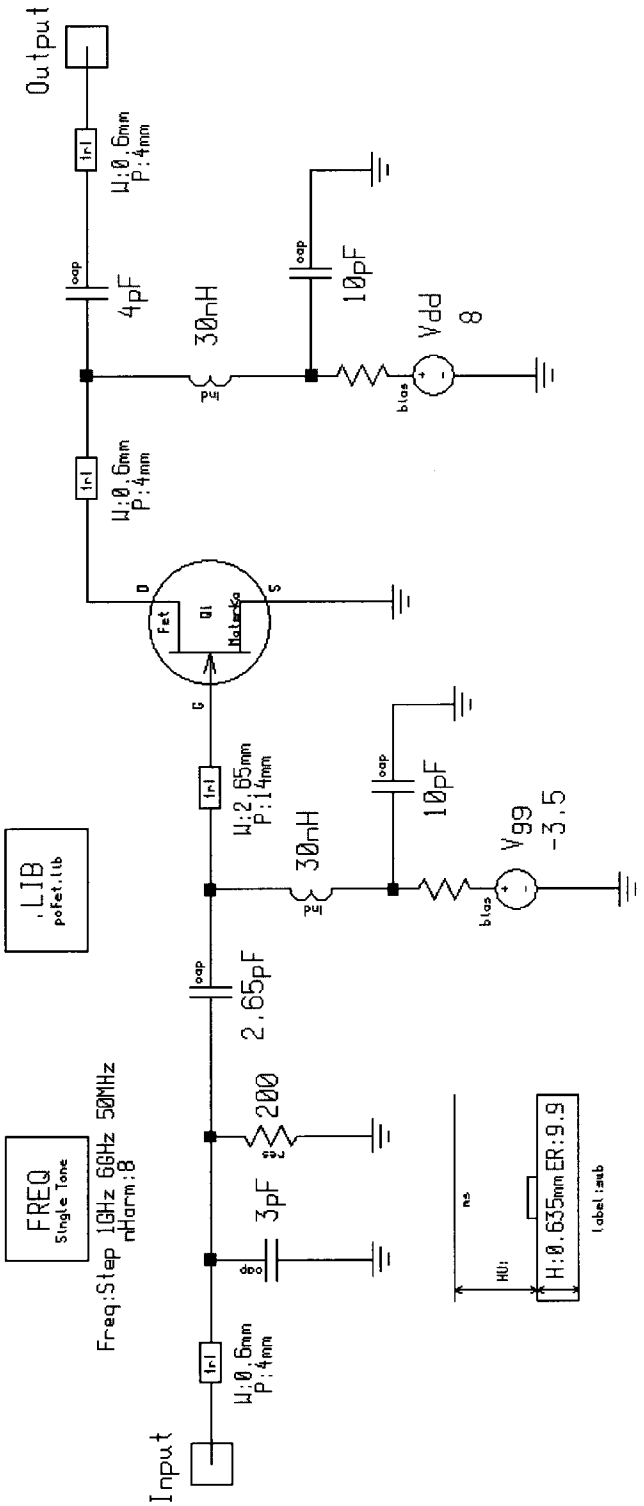

Figure 3-270 A 2.2-GHz amplifier design for stability analysis.

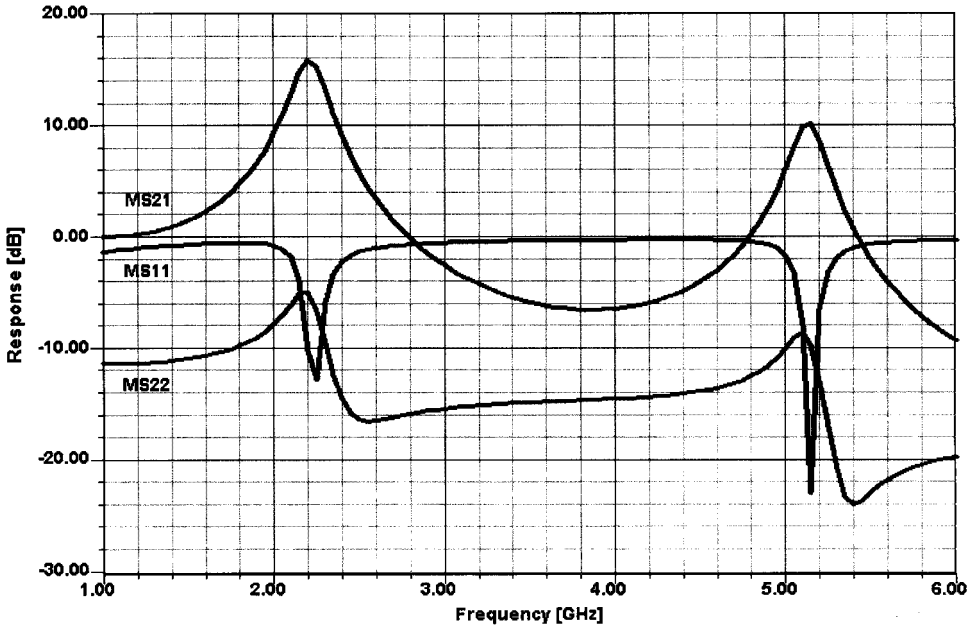

Figure 3-271 Frequency-dependent gain and matching characteristics of the amplifier. Although the circuit is designed for 2.2-GHz operation, the periodic responses of its distributed-element-based input and output matching networks result in a second gain peak near 5.1 GHz. As we shall see, however, instabilities may result at frequencies that cannot be intuited from this graph.

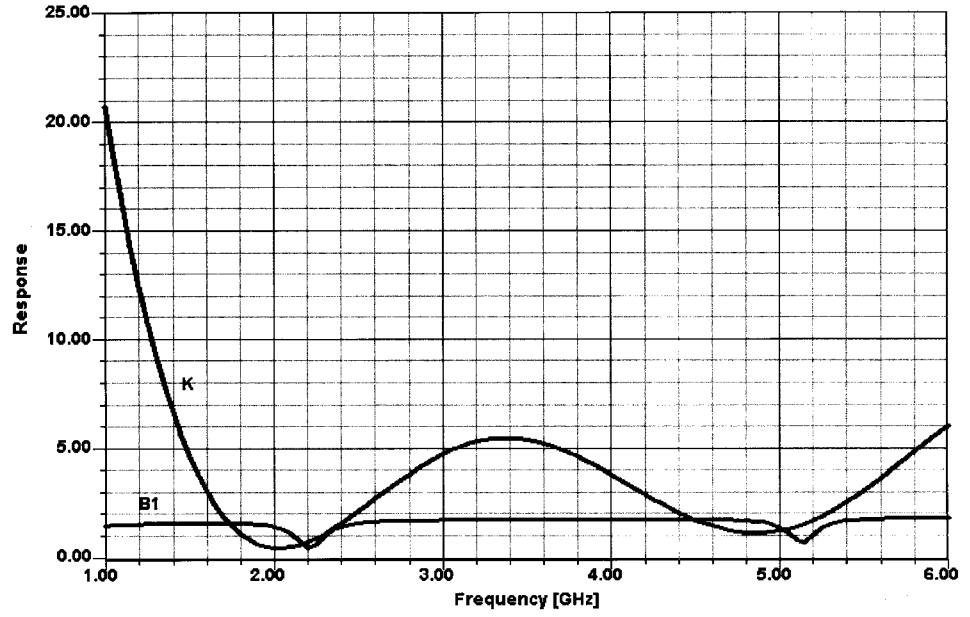

Figure 3-272 K and B_1 for the 2.2-GHz amplifier.

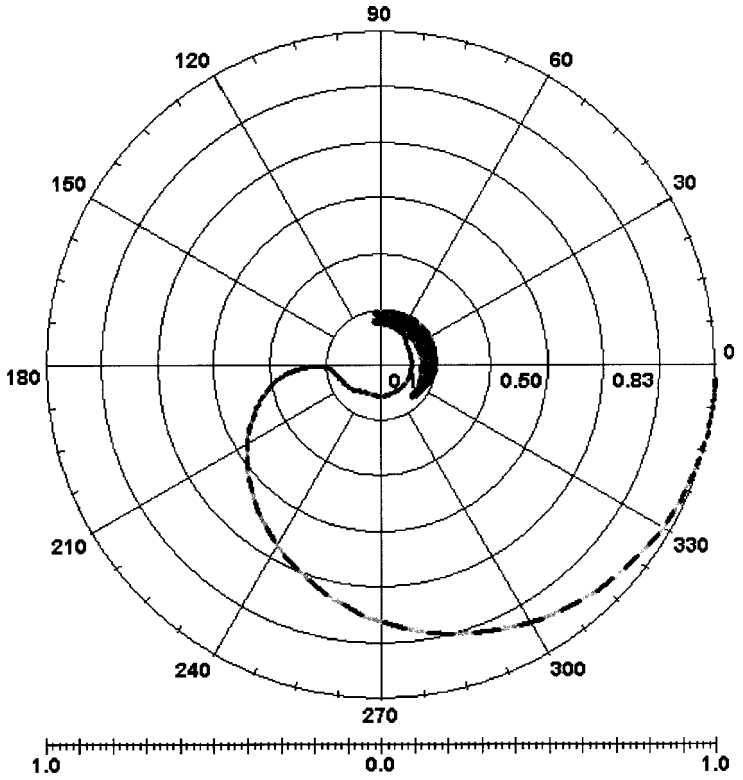

Figure 3-273 Polar Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

- To travel in a clockwise direction on a polar chart means to decrease phase angle. On a magnitude–angle plot, the phase will become more negative as frequency is increased (although it may not be monotonic).
- If the path crosses the negative real axis on the polar chart, it will cross –180° on the magnitude–angle plot.
- Encirclement will occur if the phase angle continues to decrease to, say, –360°. If "unraveling" occurs, the phase angle will not stay below –360°. Figure 3-274 clearly shows that the phase angle decreases to about –180° but does not decrease any more. Rather, the angle returns to a positive value and oscillates between about –40° and +100°. Therefore an encirclement did not occur, and the circuit is stable.

An Unstable Case. Let us now change the gate bias to –2 V—a value that increases the amplifier gain enough to cause instability. Figures 3-275 and 3-276 show the results. From Figure 3-275 we can see that the origin is encircled in a clockwise direction. Figure 3-276 confirms this since the phase angle goes through –180° and continues without unraveling.

Approximate Frequency of Oscillation. The frequency where the Nyquist plot crosses –180° is often the approximate frequency of the unstable right-half-plane zeros and provides an estimate of the potential oscillation. For this example, there is a sharp crossing at 200 MHz that is characteristic of a circuit resonance. Note that the frequency is not related

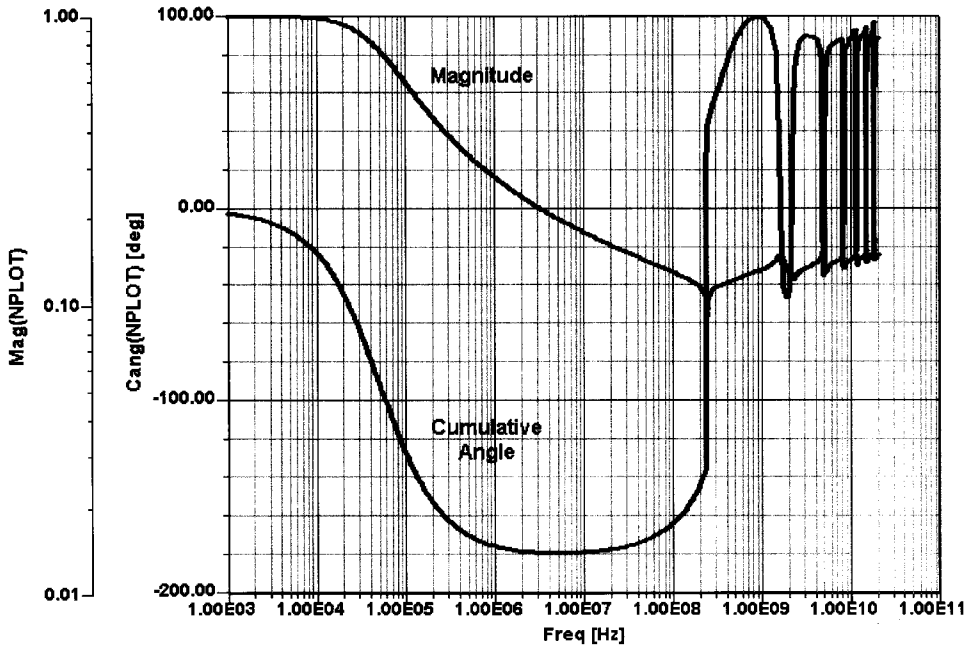

Figure 3-274 Magnitude and cumulative angle Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

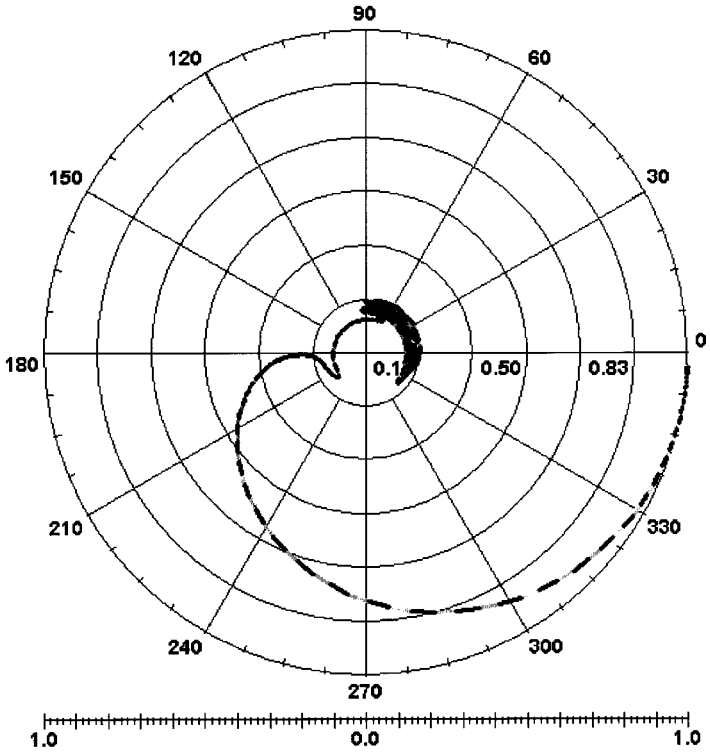

Figure 3-275 Polar Nyquist plot of the unstable amplifier.

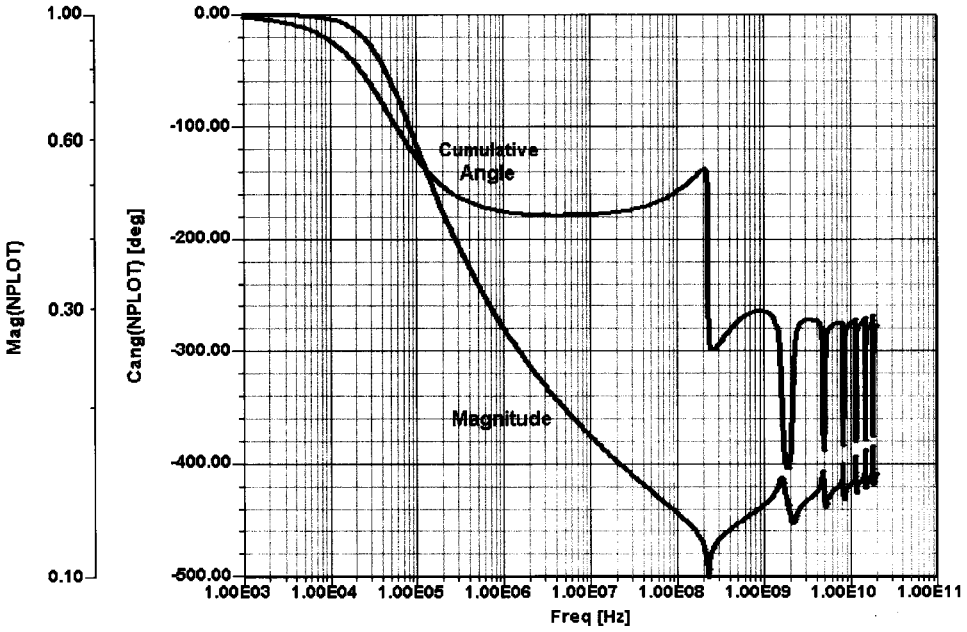

Figure 3-276 Magnitude–cumulative angle Nyquist plot of the unstable amplifier.

to a resonant frequency in a rigorous mathematical fashion, but it has been our experience that this frequency approximates the resonant frequency. To confirm the circuit's readiness for oscillation in the vicinity of this frequency, we evaluate it with Serenade's Oscillator Design Aid from 10 MHz to 1 GHz. The Design Aid finds an initial resonant frequency near 230.6 MHz—not too far from the –180° crossing frequency of 200 MHz of the Nyquist plot. Figure 3-277 shows this point.

Oscillator analysis finds a final oscillation frequency of 228.48 MHz. Figure 3-278 shows the resulting output spectrum at Port 2. At this point we decided to do a quick jump into Chapter 5 and take advantage of the CAD capability to predict the resulting phase noise, which is shown in Figure 3-279. As we compare this with other measured results, the approximately 228-MHz oscillator has a poor phase noise since the same phase noise is achievable at 1 GHz and higher. We remind the reader that this is an unwanted effect, but all of us who have built amplifiers will have experienced either low-frequency oscillations (motorboating) or very-high-frequency oscillation, sometimes caused by the components in the immediate vicinity of the transistor itself and found somewhere above 3 GHz. This case is really a demonstration case; a closer look reveals that the transconductance required for this condition is unrealistically high; but nonetheless it is a good example to demonstrate the stability issue.

Where Does Oscillation Begin? An interesting question to solve now is, "What gate bias voltage is needed for oscillation to begin?" Ansoft's Serenade Design Environment includes oscillator synchronous stability analysis, which uses a modification of the harmonic-balance technique to determine critical points, such as the voltage needed to "turn on" an oscillator. Mathematically, this is called a *Hopf bifurcation* because the behavior of

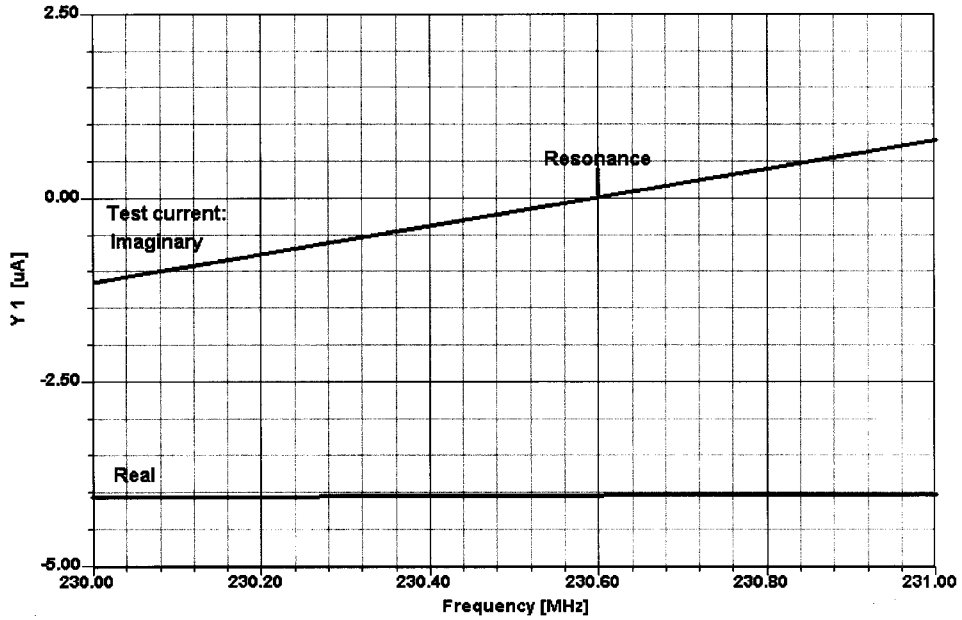

Figure 3-277 Graph from Serenade Oscillator Design Aid analysis of the amplifier. A resonant frequency is indicated where the imaginary part of the test current equals zero and the real part is negative.

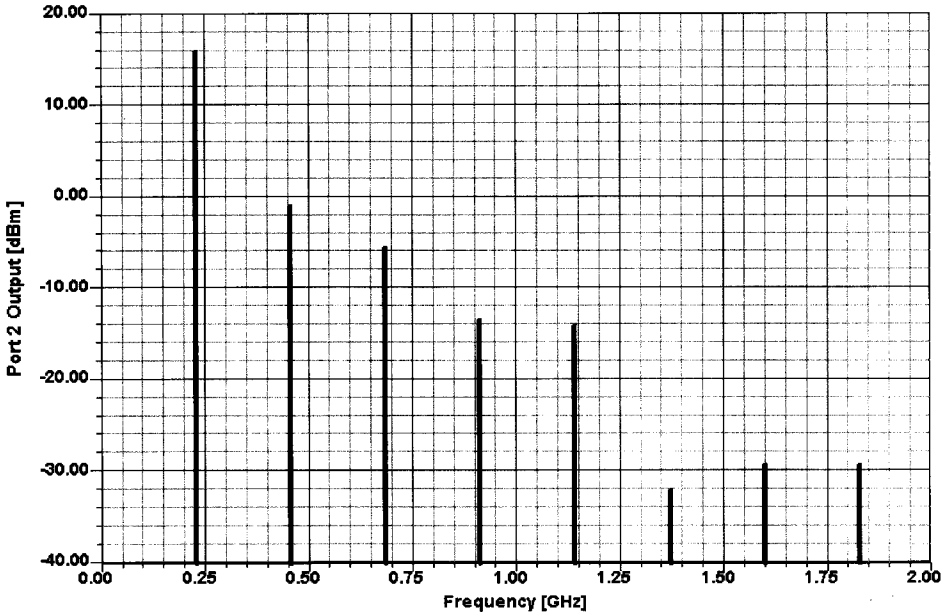

Figure 3-278 Predicted output spectrum of the unintended oscillator.

the circuit changes dramatically from a dc steady state to an oscillatory response. Figure 3-280 shows this effect by plotting output power versus gate bias. The turning point at –3.2 V (22 mW) is clearly visible, as is the bifurcation at –3.1 V (0 mW output).

Figure 3-280 can be interpreted as follows:

1. If the bias voltage is increased from, say, –4.0 V, the circuit will begin to oscillate at the bifurcation voltage and the output power will jump to 26 mW.
2. If the circuit is oscillating and the voltage is decreased from –2.0 V, the circuit will cease oscillating at the turning voltage of –3.2 V.
3. The branch between the turning point and the bifurcation point is unstable and cannot be realized in practice. This forms a hysteresis loop around points (–3.1 V, 0 mW), (–3.1 V, 26 mW), (–3.2 V, 22 mW), and (–3.2 V, 0 mW).

This amplifier stability analysis section is based on the stability analysis examples provided by Ansoft for the Serenade Design Environment.

An interesting example that combines both CAD and the feed-forward amplifier technique can be found in the Serenade Design Environment system simulator examples manual. This technique has been under evaluation for the last two years, but our feeling is that not enough measured data at frequencies above 500 MHz with reliable performance information have yet been made available in the literature. Along these lines, work done at Ansoft under a U.S. Air Force contract has provided very good insight into high-efficiency amplifiers at microwave frequencies [46].

3-13 POWER AMPLIFIER DATASHEETS AND MANUFACTURER-RECOMMENDED APPLICATIONS

Having discussed the various aspects of BJTs and FETs, we have decided to use MOS examples from Ericsson and Motorola, and a bipolar example from Motorola, as good examples to show the technology required to build high-power transistor amplifiers in this frequency range. In the following pages, we reproduce, with permission, datasheets for Ericsson's PTF 10009 FET and Motorola's MRF186 FET, followed by Motorola's MRF899 BJT.

ERICSSON

PTF 10009
85 Watts, 1.0 GHz
LDMOS Field Effect Transistor

Description

The 10009 is a common source N-channel enhancement-mode lateral MOSFET intended for large signal amplifier applications to 1.0 GHz. It is rated at 85 watts minimum output power. Nitride surface passivation and gold metallization are used to ensure excellent device lifetime and reliability. 100% lot traceability is standard.

- Performance at 960 MHz, 28 Volts
  - Output Power = 85 Watts
  - Power Gain = 13.0 dB Typ
  - Efficiency = 50% Typ
- Gold Metallized
- Silicon Nitride Passivated
- Excellent Thermal Stability

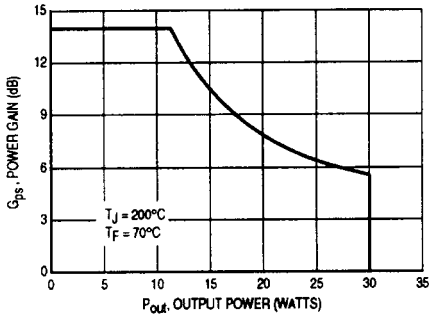

Figure 10. DC Safe Operating Area

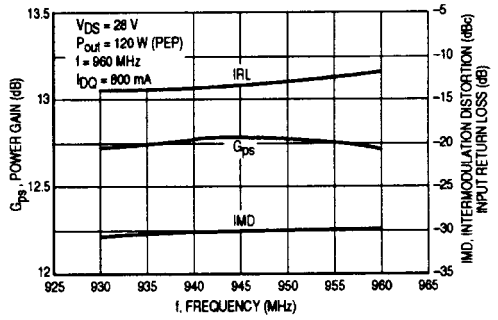

Figure 11. Broadband Circuit Performance

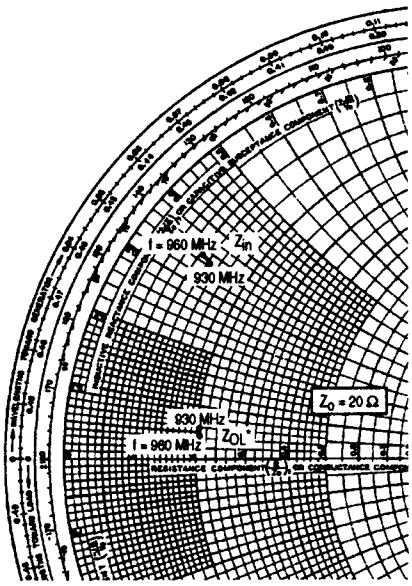

V_{CC} = 28 V, I_{DQ} = 2 × 400 mA, P_{out} = 120 Watts (PEP)

f MHz	Z_{in} Ω	Z_{OL}^* Ω
930	2.5 + j6.9	4.3 + j1.2
945	2.5 + j7.0	4.3 + j1.0
960	2.2 + j7.1	4.3 + j0.9

Z_{in} = Conjugate of impedance.

Z_{OL}^* = Conjugate of the optimum load impedance at a given output power, voltage, IMD, bias current, efficiency and frequency.

Note: Z_{OL}^* was chosen based on tradeoffs between gain, output power, drain efficiency and intermodulation performance. Impedances shown represent a single channel (1/2 of MRF186) impedance measurement.

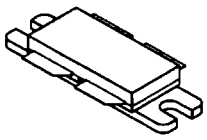
The RF Line
NPN Silicon RF Power Transistor

MRF899

150 W, 900 MHz
RF POWER
TRANSISTOR
NPN SILICON

Designed for 26 Volt UHF large–signal, common emitter, Class AB linear amplifier applications in industrial and commercial FM/AM equipment operating in the range 800–960 MHz.

- Specified 26 Volt, 900 MHz Characteristics
  Output Power = 150 Watts (PEP)
  Minimum Gain = 8.0 dB @ 900 MHz, Class AB
  Minimum Efficiency = 35% @ 900 MHz, 150 Watts (PEP)
  Maximum Intermodulation Distortion –28 dBc @ 150 Watts (PEP)
- Characterized with Series Equivalent Large–Signal Parameters from 800 to 960 MHz
- Silicon Nitride Passivated
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 26 Vdc, and Rated Output Power
- Gold Metallized, Emitter Ballasted for Long Life and Resistance to Metal Migration
- Circuit board photomaster available upon request by contacting RF Tactical Marketing in Phoenix, AZ.



CASE 375A–01, STYLE 1

MAXIMUM RATINGS

Rating	Symbol	Value	Unit
Collector–Emitter Voltage	V_{CEO}	28	Vdc
Collector–Emitter Voltage	V_{CES}	60	Vdc
Emitter–Base Voltage	V_{EBO}	4.0	Vdc
Collector–Current — Continuous	I_C	25	Adc

AMPLIFIER DESIGN WITH BJTs AND FETs

3-1 PROPERTIES OF AMPLIFIERS

3-1-1 Introduction

The goal of this chapter is to move from the details on the semiconductor devices themselves to our first practical application. One of the more interesting features of amplifiers is that they can easily become what will be covered in Chapter 5: *oscillators*. This is due to the high gain of the devices, unaccounted for parasitic elements, and other design flaws. The amplifiers we need will fall into three categories:

- Low-noise amplifiers
- High-gain amplifiers
- Medium- to high-power amplifiers

See Figure 3-1. The low-noise amplifier always operates in Class A, typically at 15–20% of its maximum useful current. The high-gain amplifier can operate in Class A, as well as Class B (mostly push–pull). The higher dc current for the same device results in a higher noise figure and more gain, and ultimately more output power. Class C operating mode is really reserved for either FM transmissions or constant-carrier modes like CW. Some of the modern digital modulation types are sensitive to phase distortion rather than amplitude changes and because of the resulting output spectrum designers have stayed away from Class C operation.

Some of these amplifiers, such as bipolar versions, can be dc-coupled with very few difficulties; others, like those in the FET families, will cause more headaches. An interesting example, although much too high in frequency for the purpose of this book, is shown in Figures 3-2, 3-3, 3-4, and 3-5. It shows a three-stage amplifier that has noise feedback for the first two stages and resistive feedback for the output stage. These are the three types of amplifiers, regardless of technology, we will be evaluating. The achievement of accurate noise analysis of this circuit, reported in Rohde et al. [1], marked the first time a complete

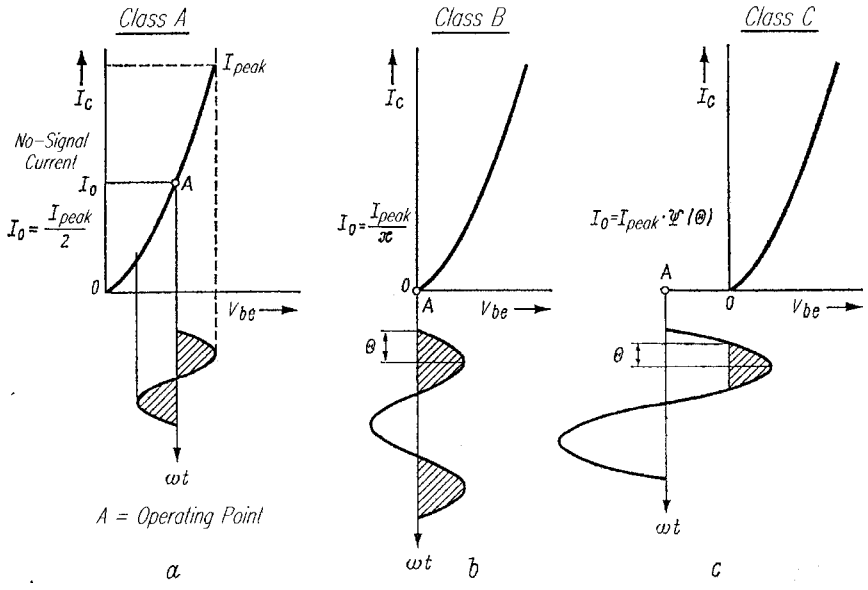

Figure 3-1 Definition of Class A, B, and C operation and resulting bias, including conduction angle (Θ, to be discussed in Section 3-2-2). The transfer characteristic can be either quadratic or exponential. This results in different distortion but does not change the basic operating mode.

linear noise model with essentially no frequency limitation had been developed. Its accuracy depends solely on the accuracy of the element values of the linear equivalent circuit, which can be obtained from measured *S*-parameters by an optimization process. Needless to say, this technique is also applicable at lower frequencies, such as 1.5–3 GHz, and its deviation from measured values has never been worse than 0.2 dB or, relative to the noise figure, 10% expressed in dB.

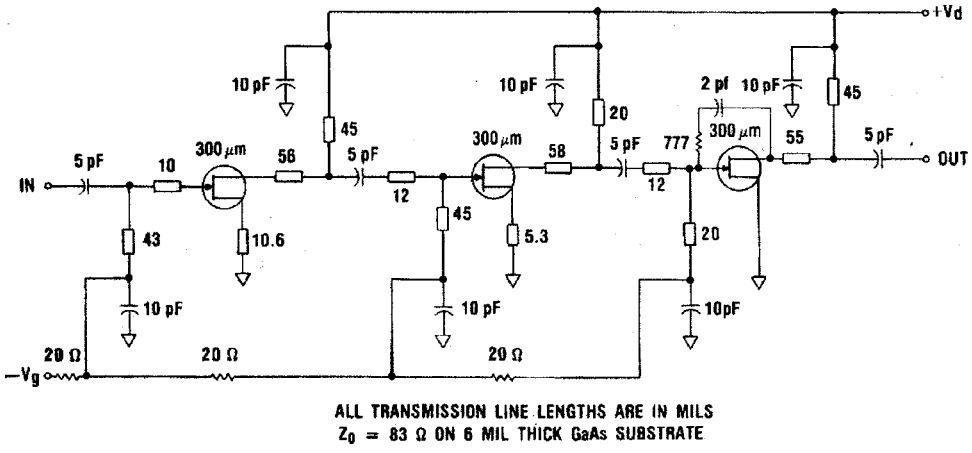

Figure 3-2 Schematic of the X-band GaAs monolithic low-noise amplifier (Texas Instruments EG8021). For reasons of linearity, all three stages operate in Class A.

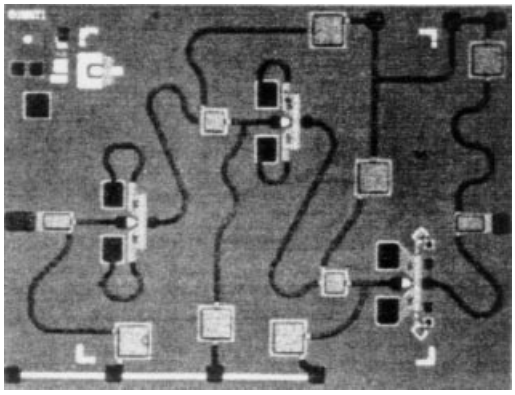

Figure 3-3 Photograph of the EG8021 monolithic amplifier chip. The area pictured is 0.09 inch by 0.12 inch in size.

The results of Figure 3-4 were obtained by using the linear FET model as supplied by Texas Instruments. It becomes somewhat obvious that a match for S_{11} of –60 dB is not likely. We then replaced the linear transistor with the SPICE-type nonlinear model, resulting in the responses shown in Figure 3-5. S_{11} now looks much more realistic in the center of the range, but at the same time exhibits a tendency toward instability at frequencies around 8 GHz. The actual circuit, when measured, did not exhibit this potential instability; on the other hand,

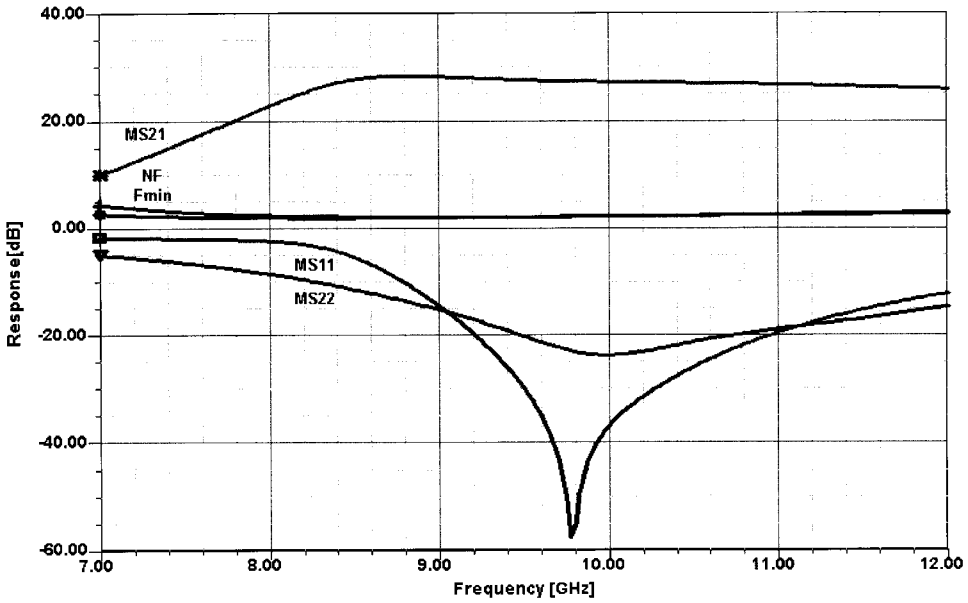

Figure 3-4 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the TI linear FET model. The values at 10 GHz are: F_{min}, 2.20 dB; NF, 2.21 dB; S_{11}, –36.8 dB; S_{21}, 27.2 dB; and S_{22}, –23.7 dB.

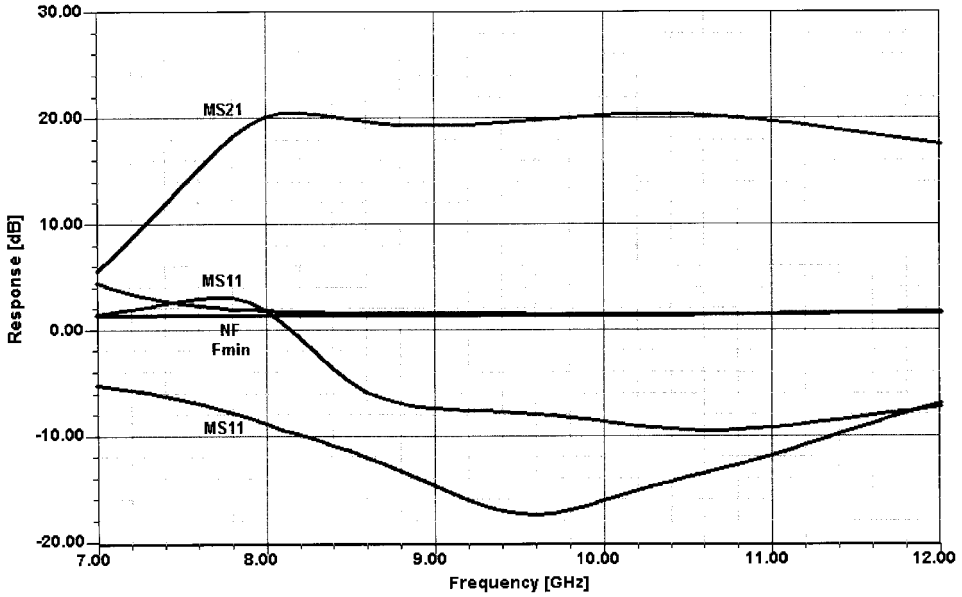

Figure 3-5 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the nonlinear FET model. The values at 10 GHz are: F_{min}, 1.53 dB; NF, 1.65 dB; S_{11}, –8.5 dB; S_{21}, 20.3 dB; and S_{22}, –15.9 dB.

the noise figure and gain agreed quite well. The discrepancies between the results with the linear and nonlinear models emphasize the importance of accurate device modeling.

Figure 3-6 shows a wideband amplifier, specifically a distributed amplifier, that covers 1–20 GHz. Figure 3-7 shows its simulated frequency-dependent gain, matching, and noise performance. The example given here as the upper frequency for wireless systems is rapidly expanding and the technology to accommodate this is already in place. Modern CAD tools can handle such high frequencies accurately, which means one can trust them at the significantly lower wireless frequencies of 500 MHz to 3 GHz. Above 1500 MHz, one really should model using distributed elements. We will come to this later in this chapter.

Input/output and interstage matching will become another challenging task, specifically if one requires sufficient bandwidth. As circuits become more complex and as the operating frequency increases, passive components play an increasingly important role; the use of

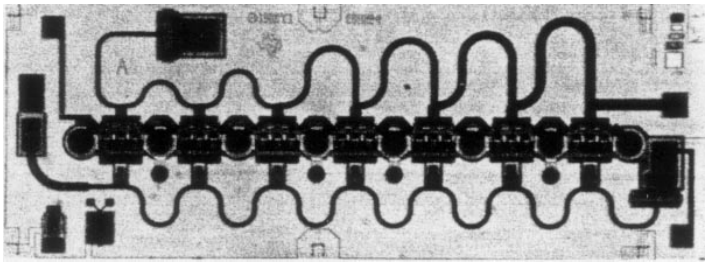

Figure 3-6 Photo of the 1–20-GHz distributed amplifier.

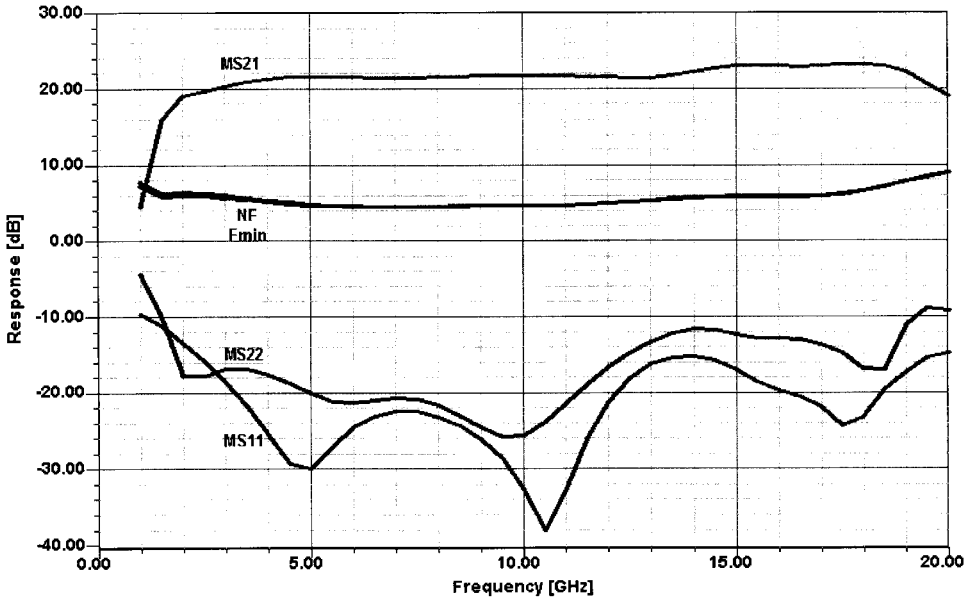

Figure 3-7 Simulated F_{min}, NF, S_{11}, S_{21}, and S_{22} responses. At the center of the range, the following numbers were found: F_{min}, 4.80 dB; NF, 4.80 dB; S_{11}, –32.8 dB; S_{21}, 21.8 dB; and S_{11}, –25.2 dB.

distributed elements is practically a necessity above 1500 MHz. For this reason, we begin this chapter by covering the application of transistors as amplifiers, following this with a discussion of the surrounding external circuitry, such as transmission lines, inductors, capacitors, and resistors. Monolithic ICs on silicon are a totally different ball game, and neither of the authors has sufficient expertise in this area. For this reason, we refer readers who will concentrate on MMIC design to the literature mentioned at the end of this chapter.

The goal of the applications presented here is to address, where possible, high-performance wireless stages that are less subject to constraints of space, power consumption, and cost, than portable/mobile applications. This is consistent with our preface, in which we have clearly stated our goal. The designers of handsets typically cannot consider the full variety of circuits we will present here. These types of stages (low noise, high gain and power) frequently will be used with filtering, and we will give some examples of input filters, including a tracking high-performance design.

A key topic besides the frequently mentioned gain is the whole noise issue. We will give the reader a complete introduction to this important area, followed by a similar introduction to the gain and matching of transistors. *Caution*: The majority of applications published go through the exercise of using *S*-parameters manually to design low-noise and small-signal amplifiers. While we have been tempted to repeat the information found in several textbooks, we feel that today's engineers will have access to CAD tools one way or another. It is highly unlikely that readers will undertake the inefficient process of going through all the design steps manually (a procedure that can take days); hopefully, engineers will resort to a linear/nonlinear CAD tool to do so. Only for the purpose of summarizing the necessary steps will we provide the relevant information regarding gain, stability, and related topics, demonstrating their usefulness or possible misuse with a modern CAD tool—in our case,

the Serenade Design Environment product from Ansoft. At this time, several additional companies beside Ansoft and Hewlett-Packard have emerged, but it is dangerous to list all of them as they come and go.

3-1-2 Gain

In practical terms, when we talk about gain we mean the output power relative to the input power. The industry standard now uses 50 Ω; however, at the point at which we have to match high-impedance devices such as monolithic crystal filters where the impedance jumps, things are not so obvious. The transformation equation that allows us to transform from one impedance to another is

$$m = \sqrt{\frac{R_2}{R_1}} \tag{3-1}$$

This correction factor, m, is required to do the transformation from R_1 (50 Ω) to R_2 (e.g., 1.2 kΩ). It needs to be understood that while the power gain remains the same, the voltage gain requires this correction factor. Since the power gain is expressed as 10 log A, A being the loop gain, 20 log A is the voltage gain, both expressed in dB. The reason for 10 versus 20 is that the power gain is always the voltage squared, which accounts for the 2. As a reminder of these relationships we present the following:

Distinction: Power Ratios–Voltage Ratios

$$n \text{ dB} = 10 \log_{10}(P_2/P_1) \quad \xrightarrow{PP = V^2/Z} \quad n = 10 \log_{10}\left(\frac{V_2^2/Z_2}{V_1^2/Z_1}\right)\text{dB}$$

$$Z_2 = Z_1 \rightarrow n \text{ dB} = 10 \log_{10}(V_2^2/V_1^2) = 10 \log_{10}(V_2/V_1)^2$$

$$\Longrightarrow \boldsymbol{n \text{ dB} = 20 \log_{10}(V_2/V_1) \text{ dB}}$$

The gain is typically defined under the condition of real resistive source and load terminations, which means that all the available power is being supplied to the amplifier, and likewise through proper matching at the output all the available power is fed to the termination. This gain figure is typically measured at a single spot frequency, but since most amplifiers are not totally flat, one needs to specify the gain tolerances or gain flatness. A good number is x dB ± 0.5 dB gain variation. In the case of a narrowband amplifier, the gain typically is shaped like a tuned circuit or like a critically coupled bandpass filter frequency response, while in the case of a real wideband application, the desired gain has some kind of ripple, which is due to the various compensation components in the circuit. An extreme case of a wideband amplifier is a 6–18-GHz single-stage amplifier that uses some very clever matching. This is shown in the following example. Figure 3-8 shows the circuit diagram, and Figure 3-9 shows its frequency-dependent performance.

While this is a cute approach for generating a single-stage amplifier over such a wide bandwidth, in real life it is not acceptable. The reason for this is that neither S_{11} nor S_{22} meets any useful specifications over the entire range. Typically, S_{11}/S_{22} values are only a few dB, while in reality more than 10 dB is required. We have chosen this example to show that gain

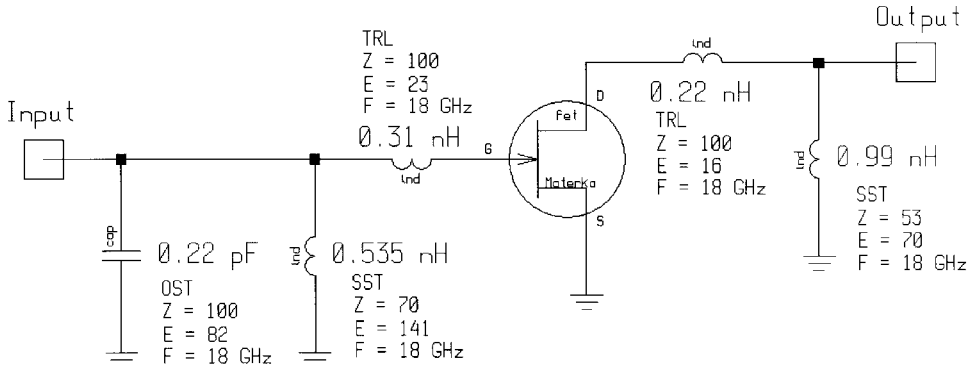

Figure 3-8 A 6–18-GHz FET amplifier.

and matching, depending on the circuit topology, are connected. We get similar results for the noise figure, whereby the best achievable noise figure ($F_{\min}$) and the actual 50-Ω noise figure are only a few dB apart; however, its frequency dependence in a wideband stage is certainly not acceptable.

Another parameter associated with gain is the stability factor K of the circuit. A value of $K > 1$ is mandatory to guarantee stability together with the S_{11} and S_{22} magnitudes being less than 1. Figure 3-10 plots the K stability factor, which for absolute stability must be >1, and maximum stable gain (MSG) as well as $G_{\max}$. It turns out that MSG is a highly artificial

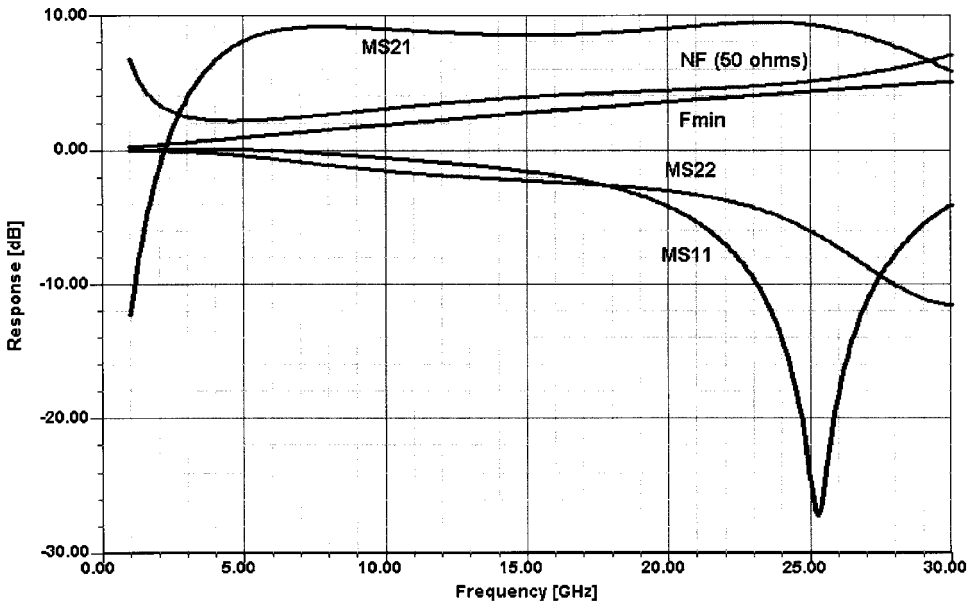

Figure 3-9 Frequency-dependent gain, matching, and noise performance of the amplifier shown in Figure 3-8.

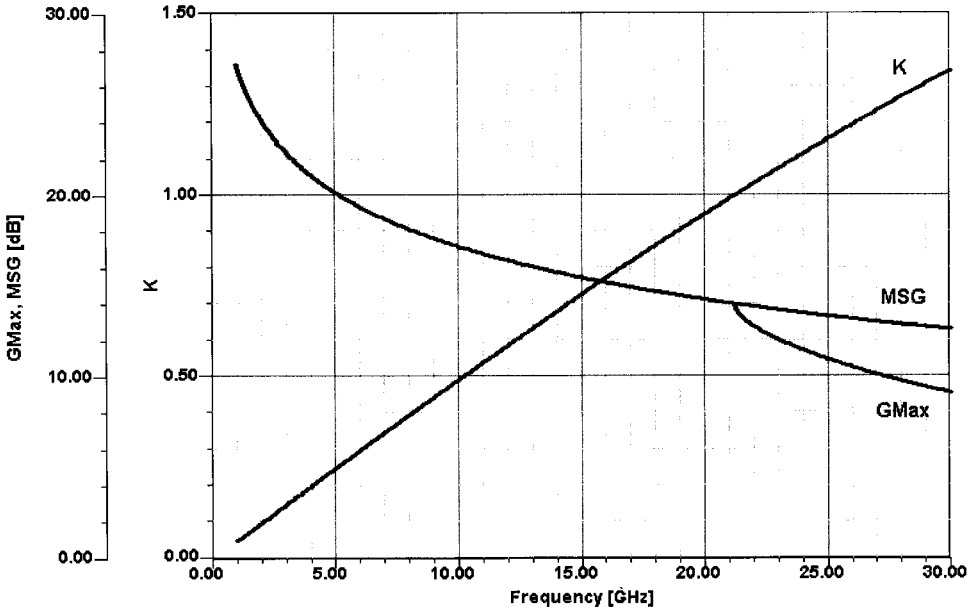

Figure 3-10 G_{max}, maximum stable gain (MSG), and K performance of the amplifier in Figure 3-8.

definition of stability that implies that input and output are terminated with pure resistances and then conjugately matched. There are four ways of achieving this resistive loading, either in the emitter as a shunt resistor between gate/drain or base/collector, or in parallel to the input and output to ground. Needless to say, this is not a real operating mode because it deteriorates both noise and gain. In our case, the entity G_{max} is a function of S_{12} of the circuit, not just the transistor, and depends highly on S_{12}. If we bring the system close to oscillation, then G_{max} will increase at the expense of bandwidth. Unfortunately, some of these microwave definitions of gain (see Table 3-1) have become widely used in industry without always being useful. Evaluating these equations for S_{12} is not legitimate because other quantities like K become infinite, and the entire system of equations falls apart. The power gain with input and output conjugately matched, or the transducer power gain for arbitrary source and load matching, still give more insight into the system.

In the above example, we specifically stated that the input and output VSWR was totally unacceptable, and this was due to a one-stage design. Figure 3-11 shows an amplifier chip built around two transistors with standard feedback techniques applied; Figures 3-12 and 3-13 show its frequency-dependent gain, matching, stability, and noise performance. This amplifier was one of the early examples of GaAsFET wideband amplifiers, but it is interesting because while it has wild (and wide) gain swings, it exhibits a fairly constant input and output impedance or reflection coefficient. A further evaluation of the circuit shows that not only is the circuit unconditionally stable, but that the maximum stable gain has an extremely high value based on essentially minimal S_{12}, the K factor is always significantly higher than 1, and G_{max} follows, to some degree, the actual gain response of the amplifier. (Ultimately, designers gave up on simple *RCL* feedback amplifiers for such a wide bandwidth, replacing them with distributed amplifiers previously called traveling wave amplifiers.) The problem of gain and stability starts at audiofrequency amplifiers, where the

Table 3-1 Nine power gains

Transducer power gain in 50-Ω system	$G_T = \lvert S_{21}\rvert^2$
Transducer power gain for arbitrary Γ_G and Γ_L	$G_T = \dfrac{(1-\lvert\Gamma_G\rvert^2)\,\lvert S_{21}\rvert^2\,(1-\lvert\Gamma_L\rvert^2)}{\lvert(1-S_{11}\Gamma_G)\,(1-S_{22}\Gamma_L)-S_{12}S_{21}\Gamma_G\Gamma_L\rvert^2}$
Unilateral transducer power gain	$G_{\mathrm{TU}} = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)\,(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2\lvert 1-S_{22}\Gamma_L\rvert^2}$
Power gain with input conjugate matched	$G = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{22}\Gamma_L\rvert^2(1-\lvert S'_{11}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{11}\rvert^2}$ (for $\Gamma_L = 0$)
Available power gain with output conjugate matched	$G_A = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2(1-\lvert S'_{22}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{22}\rvert^2}$ (for $\Gamma_G = 0$)
Maximum available power gain[a]	$G_{ma} = \left\lvert\dfrac{S_{21}}{S_{12}}\right\rvert\,(k-\sqrt{k^2-1})$
Maximum unilateral transducer power gain	$G_{\mathrm{TUmax}} = \dfrac{\lvert S_{21}\rvert^2}{(1-\lvert S_{11}\rvert^2)(1-\lvert S_{22}\rvert^2)}$
Maximum stable power gain	$G_{ms} = \dfrac{\lvert S_{21}\rvert}{\lvert S_{12}\rvert}$
Unilateral power gain	$U = \dfrac{1/2\lvert S_{21}/S_{12}-1\rvert^2}{k\lvert S_{21}/S_{12}\rvert-\mathrm{Re}(S_{21}/S_{12})}$

[a]Definition for $G_{\max}$: If $k > 1$, it is called G_{ma}, and if $k < 1$, it is called G_{ms}.

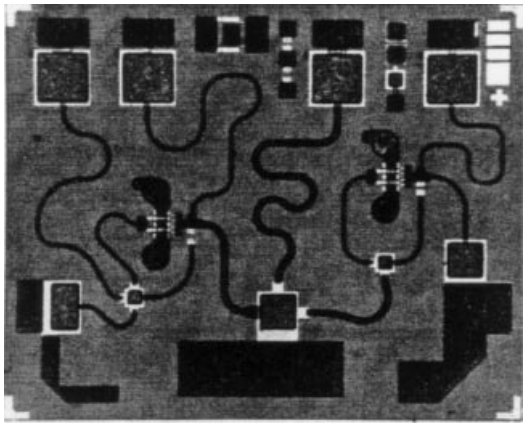

Figure 3-11 A two-stage, wideband feedback amplifier.

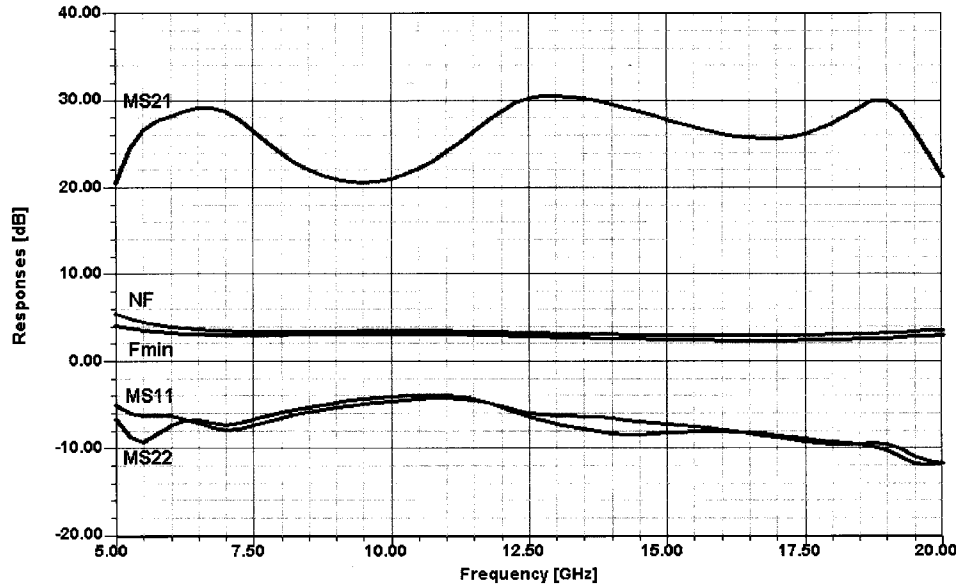

Figure 3-12 Frequency-dependent gain, matching, and noise performance for the amplifier in Figure 3-11.

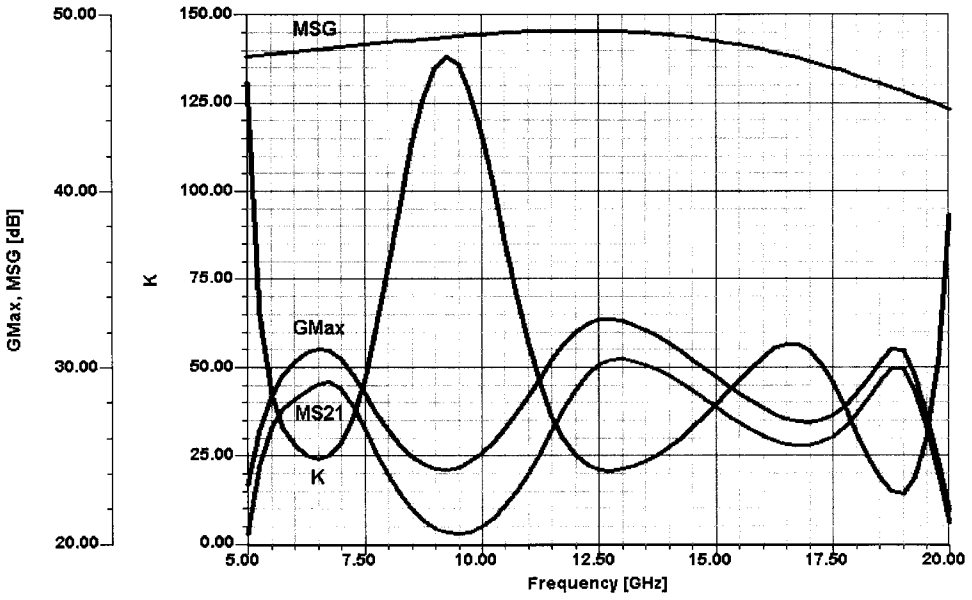

Figure 3-13 Frequency-dependent G_{max}, K, maximum stable gain, and gain performance for the amplifier in Figure 3-11.

motorboating phenomenon has been known for years, and the problem moves up in frequency with more modern technology and is largely dependent not only on the device and the circuit, but also on the layout. The motorboating effect has to do with ground loops and the fact that if the printed circuit traces from the power supply connection to the output power stage present too high a resistance, then at high currents the voltage will drop to a point below useful operation and then, as the volume is lowered, become stable again. In this case the amplitude of the signal through the amplifier controls the stability of the output stage. Needless to say, this most unpleasant effect applies to high-power stages for all output transistors, where we use Class B or C operation, meaning that the dc operating current as a function of output does not remain constant.

In terms of gain, there is also an important gain characteristic called *differential gain* and *differential phase*. These expressions were first used in television circuits, where linearity in both areas is an absolute must. The amplitude of the signal determines the black and white contrast, and the phase determines the color. As an example, transmitting an image of one of our presidents playing golf in California to the New York area is done by many microwave hops. Any multipath reception, such as that caused by reflection from airplanes, may have little effect on the signal amplitude, but the resulting phase shift can transform a green lawn to a red lawn if a total shift of 180° occurs. Given a particular operating point, if the 1-dB compression point of multiple amplifiers in the chain is approached or exceeded, their differential gain, which is defined by the IEEE as "the difference between (a) the ratio of the output of a small high-frequency sine-wave signal at two different levels of a low-frequency signal on which it is superimposed, and (b) unity," may increase. This mode of saturation charges all the capacitances of the amplifier transistors, causing huge phase shifts that result in the known problem of changing colors. The same applies, of course, in test equipment amplifiers, in which such changes cannot be tolerated. A somewhat similar, but not quite the same, problem is spectral regrowth [evaluated in terms of adjacent-channel power ratio (ACPR)], which is also due to nonlinearities. The question of linearity has already been covered in detail in Chapter 1. Needless to say, any overdrive condition also changes an amplifier's input and output SWR.

3-1-3 Noise Figure (NF)*

Introduction. In this section we look at the best way to describe noise in active devices (black boxes). Even when a two-port is linear, the output waveform will differ from the input, because of the failure to transmit all spectral components with equal gain (or attenuation) and delay. By careful design of the two-port, or by limitation of the bandwidth of the input waveform, such distortions can largely be avoided. However, noise generated within the two-port can still change the waveform of the output signal. In a linear passive two-port, noise arises only from the losses in the two-port; thermodynamic considerations indicate that such losses result in the random changes that we call noise. When the two-port contains active devices, such as transistors, there are other noise mechanisms present. A very important consideration in a system is the amount of noise that it adds to the transmitted signal. This is often judged by the ratio of the output signal power to the output noise power

*Section 3-1-3 is reprinted from Chapter 2 of George D. Vendelin, Anthony M. Pavio, and Ulrich L. Rohde, *Microwave Circuit Design Using Linear and Nonlinear Techniques*, copyright 1990 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

(S/N). The ratio of signal plus noise power to noise power [$(S + N)/N$] is generally easier to measure and approaches S/N when the signal is large.

In the evaluation of a two-port it is important to know the amount of noise added to a signal passing through it. An important parameter for expressing this characteristic is the noise factor. The signal energy coming from a generator or antenna is amplified or attenuated in passing from the input to the output of a two-port, as is the noise that accompanies the input signal energy. A system generally includes a cascade of two-port networks that constitute one overall two-port that amplifies the signal to a high-enough power level for its intended use. The *noise factor* of a system is defined as the ratio of signal-to-noise ratios available at input and output:

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}} \geq 1 \tag{3-2}$$

The noise figure (or factor) of a receiver is an easily measured quantity that describes the signal-to-noise ratio reduction of that receiver.

When this ratio of powers is converted to decibels, it is generally referred to as the *noise figure* rather than noise factor. Various conventions are used to distinguish the symbols used for noise factor and noise figure. Here we use F to represent the noise factor and NF to represent the noise figure, although the terms are usually used interchangeably.

For an amplifier with the power gain G, the noise factor can be rearranged as

$$F = \frac{S_i/N_i}{GS_i/G(N_i + N_a)} \tag{3-3}$$

when N_a is the additional noise power added by the amplifier referred to the input. This can be computed to be

$$F = 1 + N_a/N_i \tag{3-4}$$

The noise factor is often replaced by the noise figure (NF), which is defined in decibels as

$$\text{NF} = 10 \log_{10} F \tag{3-5}$$

In applications like satellite receivers, the noise factor becomes such a small number that it is inconvenient to work with. Many people have adopted the use of an equivalent noise temperature for a circuit to remedy this situation. Since the thermal noise power available from a resistor at temperature T_e is

$$N = kT_eB \tag{3-6}$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), T_e is the effective temperature in kelvins, and B is the bandwidth in hertz. The equation above may be used to associate an effective noise temperature with circuits containing more than just thermal noise sources. This allows Eq. (3-4) to be written as

$$F = 1 + \frac{kT_eB}{kT_0B} = 1 + \frac{T_e}{T_0} \tag{3-7}$$

where T_e is the effective noise temperature of the circuit and T_0 is the temperature of the generator resistor in kelvins. The noise temperature T_e now characterizes our circuit noise contribution and can directly be related to the noise factor.

Assuming a reference noise temperature of 290 K (–273 + 290 = 17 °C), let us determine the noise temperature of the system with a noise factor of 2.6 (4.15 dB):

$$T_e = (2.6 - 1)\ (290) = 464 \text{ K}$$

This temperature T_e should not be confused with the environmental operating temperature T_0. It is quite common to operate low-noise amplifiers with T_e below 100 K at an ambient temperature of 290 K.

Signal-to-Noise Ratio. Let us consider the signal-to-noise ratio of power delivered from a generator to a load as shown in Figure 3-14. The signal power delivered to the input is given by

$$S_{\text{in}} = P_{\text{in}} = \frac{E_g^2 \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-8}$$

where E_g is the rms voltage of the input signal supplied to the system, and the noise power supplied to the input is expressed by

$$N_{\text{in}} = \frac{\overline{v_n^2} \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-9}$$

where the noise power at the input is provided by the noise energy of the real part of Z_g. The input impedance Z of the system in the form $Z = R_{\text{in}} + jX_{\text{in}}$ is assumed to be complex.

The Johnson noise of a resistor [here $\text{Re}(Z_g)$], given by the mean-square voltage

$$\overline{v_n^2} = 4kTRB \tag{3-10}$$

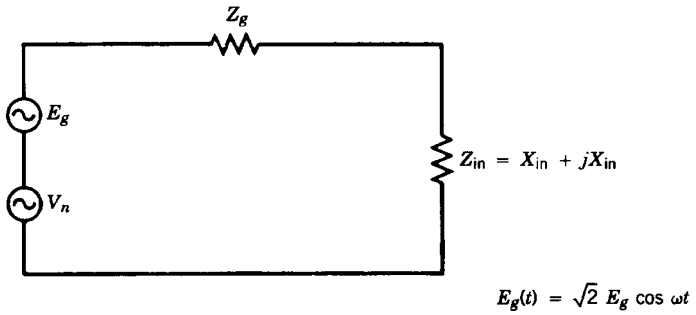

Figure 3-14 Combination of signal and noise voltages supplied to a complex termination.

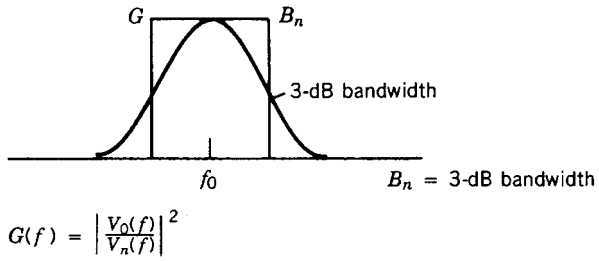
where k (Boltzmann's constant) = 1.38×10^{-23} J/K, T is the absolute temperature of the resistor, and B is the bandwidth, is sufficiently small that the resistive component of impedance does not change. The available signal power from the generator has a lower limit, even if the signal is attenuated by the highest possible attenuation. The generator resistor acts as a Johnson noise generator, its power being

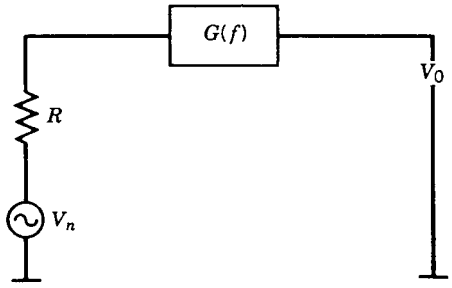
$$P_A = \frac{4kTRB}{4R} = kTB \tag{3-11}$$

where k is Boltzmann's constant, T is the absolute temperature, and B is the bandwidth. This power is the maximum available output power.

For an ambient temperature of 290 K, $kT = 4 \times 10^{-21}$ W/Hz. This expression is also given as kT = –204 dBW/Hz = –174 dBm/Hz = –114 dBm/MHz. We can combine Eqs. (3-8) to (3-10) to obtain

$$\left(\frac{S}{N}\right)_{\text{in}} = \frac{E_g^2}{4kT\text{Re}(Z_g)B} \tag{3-12}$$





$$V_0^2 = \int_0^\infty 4kT_0RG(f)\,dF$$
$$= 4kT_0R \int_0^\infty G(f)\,dF$$
$$B_n = \frac{1}{G} \int_0^\infty G(f)\,dF$$
B_n = noise bandwidth

Figure 3-15 Graphical and mathematical explanations of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

This is the value of *S/N* contributed by the generator, which does not include the noise generated by the load, in this case $\mathrm{Re}(Z_{\mathrm{in}})$, which would need to be included in the measurement of the total *S/N* across the input impedance.

A critical parameter is the noise bandwidth, B_n, which is defined as the equivalent bandwidth, as shown in Figure 3-15. For reasons of group delay correction, most practical filters have round rather than sharp corners. The noise figure measurements shown later can be used to determine the "integrated" bandwidth, which is B_n.

An active system such as a combination of amplifiers and mixers will add noise to the input signals, and the noise factor that describes this is defined as the *S/N* ratio at the input to the *S/N* ratio at the output, which is always greater than unity [2]. In practice, a certain minimum signal-to-noise ratio is required for operation. For example, in a communication system such a minimum is required for intelligible transmission, either voice or data. For high-performance TV reception, to provide a noise-free picture to the eye, a typical requirement is for a 60-dB *S/N*. In the case of a TV system, a large dynamic range is required, as well as a very large bandwidth to reproduce all colors truthfully and all shades from high-intensity white to black. Good systems will have a bandwidth of 8 MHz or more.

Noise Figure Measurements. Some of the noise equations are based on mathematical models and physics. To understand some of these expressions, it is useful to look at a practical system, with amplifiers, that has to be evaluated.

Let us look at Figure 3-16, which consists of a signal generator, the system or device under test (DUT), and a selective receiver with a built-in root-mean-square (rms) voltmeter to determine the signal and noise voltages. It is necessary that the system have enough gain so that the noise voltage supplied by the generator will be indicated [3].

If we assume that our selective receiver is a video noise meter calibrated in rms voltage levels, we can perform two measurements. With an input termination connected to the TV system (typically, 75 Ω for cable TV, 50 Ω for satellite TV), the noise receiver/meter will read a value for proper termination that can easily be calculated. Since one-half of the mean-square noise voltage appears across the input,

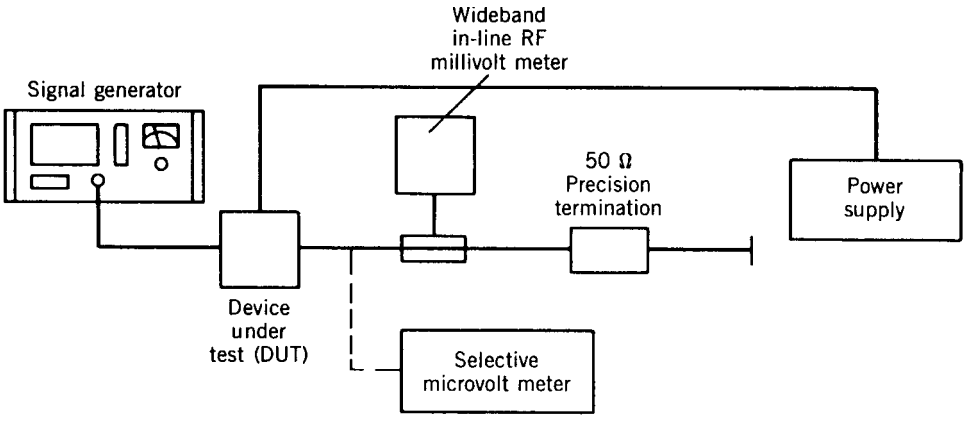


Figure 3-16 Test setup to measure signal-to-noise ratio.

$$v_{\text{in}} = \frac{v_n}{2} = \frac{\sqrt{4kTRB}}{2} \tag{3-13}$$

With $B = 10$ MHz, $T = 290$ K (T is always expressed in absolute temperature; $T_0 = -273$ °C), and $k = 1.38 \times 10^{-23}$ J/K, then for $R = 75\ \Omega$,

$$v_{\text{in}} = \frac{v_n}{2} = 1.73\ \mu\text{V} \tag{3-14}$$

where the rms noise voltage has been referred to the input port. We can verify this with our first measurement.

Now we increase the input voltage of the signal generator to a value that indicates a 60-dB *S/N* ratio at the output port. This should be about

$$E_g = \frac{v_n}{2}\sqrt{F} \times 1000 = 1.73\sqrt{F} \quad \text{mV}$$

where F is the noise factor of the receiver. For a receiver noise factor of 10, we would obtain $E_g = 5.48$ mV (rms value). If the noise energy equivalent to a noise factor of F is assumed, we need $\sqrt{F}$ times more voltage. For a 60-dB ratio, this means that $E_g = 1000 \times (v_n/2) \times \sqrt{F}$.

As they are done here, over a power range of 60 dB, the measurements can be performed over such a wide range only if special equipment is available. In cases where the internal detector of a piece of communication equipment is used, the signal-to-noise ratio measurements are performed over much smaller power ranges.

Let us assume that for the above-mentioned case ($F = 10$) we find a *S/N* ratio of 10 dB at the output for an input signal of 5.47 μV. By rewriting Eq. (3-7) as

$$E_g = \frac{v_n}{2}\sqrt{F} = \sqrt{KTRBF} \tag{3-15}$$

with F being the noise factor, we can solve for F with

$$F = \frac{P_s}{P_n} = \frac{E_g^2/R}{kTB} \tag{3-16}$$

While the input power from the thermal energy of the input termination resistor was $kTB = 4 \times 10^{-4}$ W, the input power required for the 10-dB *S/N* ratio was

$$P_s = \frac{(5.47 \times 10^{-6})^2}{75} = 3.98 \times 10^{-13}\ \text{W} \tag{3-17}$$

The noise factor is defined as the ratio P_s/P_n:

$$F = \frac{3.98 \times 10^{-13}}{4 \times 10^{-14}} = 10 \tag{3-18}$$

which is the proof.

This method is used more frequently at the 3-dB point, or double the input power if the dynamic range of the detector is small or only a linear indicator is available. Because of hum and other pickup, this is not an easy measurement. Using a signal generator is very expensive because in a laboratory or production environment a wide frequency range requires several generators.

Another method is the use of a wideband noise generator. Modern gas discharge diodes or avalanche diodes are available that provide essentially white noise energy over a large frequency range. These microwave diodes typically have an output of 30 dB above kT when switched on and kT when switched off. To provide good matching at microwave frequencies, a 15-dB attenuator is cascaded. This means that the noise power of the source in the ON condition is about 15 dB above kT.

In the early 1960s, low-cost noise figure test equipment was built around vacuum diodes whose operating range was limited to 1200 MHz due to the resonance effects of the structure. Today, automatic noise gain analyzers use calibrated solid-state noise sources up to 26.5 GHz. It appears that the upper frequency limit has to do with matching, and the lower-frequency limit with $1/f$ noise.

Noisy Two-Port Description. Based on the convention by Rothe and Dalke [4], any linear two-port can be in the form shown in Figure 3-17. This general case of a noisy two-port can be redrawn showing noise sources at the input and at the output. Figure 3-17b shows this in admittance form and Figure 3-17c in impedance form. The internal noise sources are assumed to produce very small currents and voltages, and we assume that linear two-port equations are valid. The internal noise contributions have been expressed by using external noise sources:

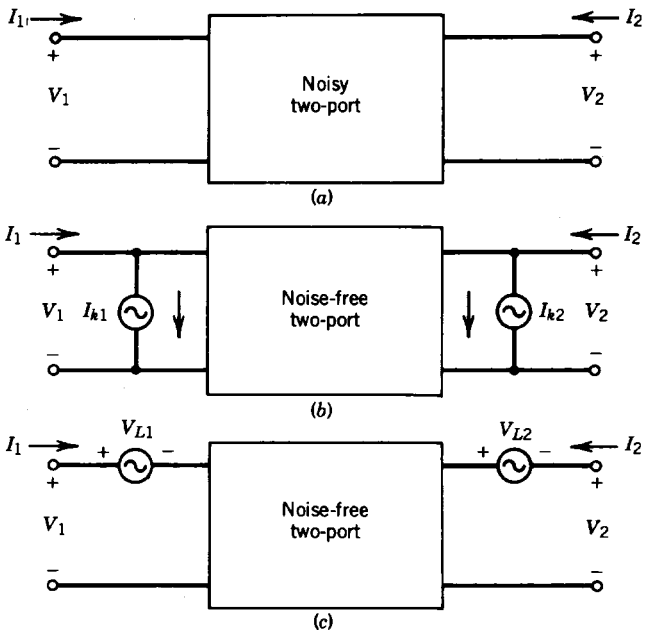

Figure 3-17 Noisy linear two-ports: (a) general form, (b) admittance form, and (c) impedance form.

$$I_1 = y_{11}V_1 + y_{12}V_2 + I_{K1}$$
$$I_2 = y_{21}V_1 + y_{22}V_2 + I_{K2} \tag{3-19}$$

$$V_1 = z_{11}I_1 + z_{12}I_2 + V_{L1}$$
$$V_2 = z_{21}I_1 + z_{22}I_2 + V_{L2} \tag{3-20}$$

where the external noise sources are I_{K1}, I_{K2}, V_{L1}, and V_{L2}.

Since we want to describe our noisy circuit in terms of the noise figure, the *ABCD*-matrix description will be more convenient since it refers both noise sources to the input of the two-port [5]. This representation is given below (note the change in direction of I_2):

$$V_1 = AV_2 + BI_2 + V_A$$
$$I_1 = CV_2 + DI_2 + I_A \tag{3-21}$$

where V_A and I_A are the external noise sources.

It is important to remember that all of these matrix representations are interrelated. For example, the noise sources for the *ABCD*-matrix description can be obtained from the *z*-matrix representation shown in Eq. (3-20). This transformation is

$$V_A = -\frac{I_{K2}}{y_{21}} = V_{L1} - \frac{V_{L2}z_{11}}{z_{21}} \tag{3-22}$$

$$I_A = I_{K1} - \frac{I_{K2}y_{11}}{y_{21}} = -\frac{V_{L2}}{z_{21}} \tag{3-23}$$

The *ABCD* representation is particularly useful because it allows us to define a noise temperature for the two-port referenced to the input. The two-port itself (shown in Figure 3-18) is assumed to be noise-free.

In the past, *z* and *y* parameters have been used, but in microwave applications it has become common to use *S*-parameter definitions. This is shown in Figure 3-19. The previous equations can be rewritten in their new form using *S*-parameters:

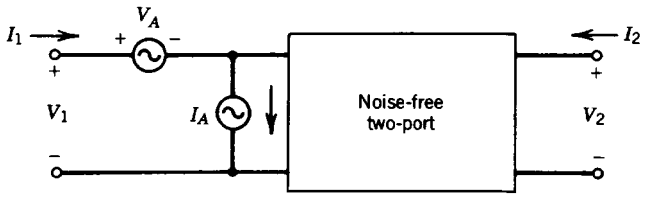

Figure 3-18 Chain-matrix form of linear noisy two-ports.

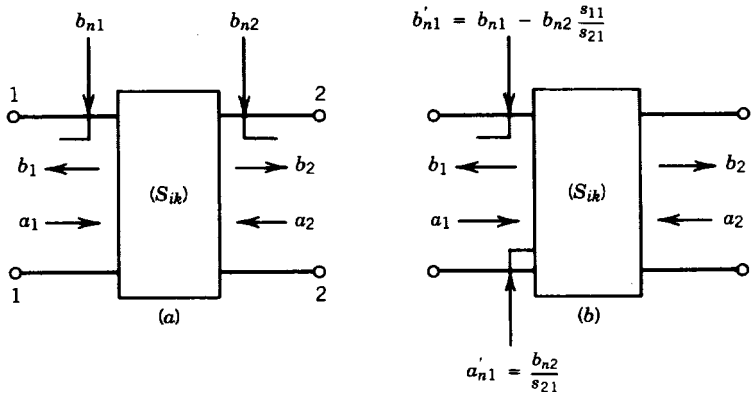

Figure 3-19 *S*-parameter form of linear noisy two-ports.

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \begin{bmatrix} b_{n1} \\ b_{n2} \end{bmatrix} \tag{3-24}$$

There are different physical origins for the various sources of noise. Typically, thermal noise is generated by resistances and loss in the circuit or transistor, whereas shot noise is generated by current flowing through semiconductor junctions and vacuum tubes. Since these many sources of noise are represented by only two noise sources at the device input, the two equivalent noise sources are often a complicated combination of the circuit internal noise sources. Often, some fraction of V_A and I_A is related to the same noise source. This means that V_A and I_A are not independent in general. Before we can use V_A and I_A to calculate the noise figure of the two-port, we must calculate the correlation between the V_A and I_A shown in Figure 3-18.

The noise source V_A represents all the device noise referred to the input when the generator impedance is zero; that is, when the input is short-circuited. The noise source I_A represents all the device noise referred to the input when the generator admittance is zero; that is, the input is open-circuited.

The correlation of these two noise sources considerably complicates analysis. By defining a correlation admittance, we can simplify the mathematics and get some physical intuition for the relationship between noise figure and generator admittance. Since some fraction of I_A will be correlated with V_A, we split I_A into correlated and uncorrelated parts as follows:

$$I_A = I_n + I_u \tag{3-25}$$

I_u is the part of I_A uncorrelated with V_A. Since I_n is correlated with V_A, we can say that I_n is proportional to V_A and the constant of proportionality is the correlation admittance:

$$I_n = Y_{\text{cor}} V_A \tag{3-26}$$

This leads us to

$$I_A = Y_{\text{cor}} V_A + I_u \tag{3-27}$$

The following derivation of noise figure will use the correlation admittance. Y_{cor} is not a physical component located somewhere in the circuit. Y_{cor} is a complex number derived by correlating the random variables I_A and V_A. To calculate Y_{cor}, we multiply each side of Eq. (3-27) by V_A^* and average the result. This gives

$$\overline{V_A^* I_A} = Y_{\text{cor}} \overline{V_A^2} \tag{3-28}$$

where the I_u term averaged to zero since it was uncorrelated with V_A. The correlation admittance is thus given by

$$Y_{\text{cor}} = \frac{\overline{V_A^* I_A}}{V_A^2} \tag{3-29}$$

Often, people use the term "correlation coefficient." This normalized quantity is defined as

$$c = \frac{\overline{V_A^* I_A}}{\sqrt{\overline{V_A^2} I_A^2}} = Y_{\text{cor}} \sqrt{\frac{\overline{V_A^2}}{I_A^2}} \tag{3-30}$$

Note that the dual of this admittance description is the impedance description. Thus, the impedance representation has the same equations as above with Y replaced by Z, I replaced by V, and V replaced by I.

V_A and I_A represent internal noise sources in the form of a voltage source acting in series with the input voltage and a source of current flowing in parallel with the input current. This representation conveniently leads to the four noise parameters needed to describe the noise performance of the two-port. Again using the Nyquist formula, the open-circuit voltage of a resistor at the temperature T is

$$\overline{V_A^2} = 4kTRB \tag{3-31}$$

This voltage is a mean-square fluctuation (or spectral density). It is the method used to calculate the noise identity. We could also define a noise equivalent resistance for a noise voltage as

$$R_n = \frac{\overline{V_A^2}}{4kTB} \tag{3-32}$$

The resistor R_n is not a physical resistor but can be used to simulate different portions of the noise equivalent circuit.

In a similar manner a mean-square current fluctuation can be represented in terms of an equivalent noise conductance G_n, which is defined by

$$G_n = \frac{\overline{I_A^2}}{4kTB} \tag{3-33}$$

and

$$G_u = \frac{\overline{I_u^2}}{4kTB} \tag{3-34}$$

for the case of the uncorrelated noise component. The input generator to the two-port has a similar contribution:

$$G_G = \frac{I_G^2}{4kTB} \tag{3-35}$$

with Y_G being the generator admittance and G_G being the real part. With the definition of F above, we can write

$$F = 1 + \left| \frac{I_A + Y_G V_A}{I_G} \right|^2 \tag{3-36}$$

The use of the voltage V_A and the current I_A has allowed us to combine all the effects of the internal noise sources.

We can use the previously defined [Eq. (3-29)] correlation admittance, $Y_{\text{cor}} = G_{\text{cor}} + jB_{\text{cor}}$, to simplify Eq. (3-36). First, we determine the total noise current:

$$\overline{I_A^2} = 4kT(|Y_{\text{cor}}|^2 R_n + G_u)B \tag{3-37}$$

where R_n and G_u are defined in Eqs. (3-32) and (3-34). The noise factor can now be determined:

$$F = 1 + \frac{G_u}{G_g} + \frac{R_n}{G_g}[(G_G + G_{\text{cor}})^2 + (B_G + B_{\text{cor}})^2] \tag{3-38}$$

$$F = 1 + \frac{R_u}{R_g} + \frac{G_n}{R_g}[(R_G + R_{\text{cor}})^2 + (X_G + X_{\text{cor}})^2] \tag{3-39}$$

The noise factor is a function of various elements, and the optimum impedance for the best noise figure can be determined by minimizing F with respect to generator reactance and resistance. This gives

$$R_{0n} = \sqrt{\frac{R_u}{G_n} + R_{\text{cor}}^2} \tag{3-40}$$

$$X_{0n} = -X_{\text{cor}} \tag{3-41}$$

and

$$F_{\min} = 1 + 2G_n R_{\text{cor}} + 2\sqrt{R_u G_n + (G_n R_{\text{cor}})^2} \tag{3-42}$$

(To distinguish between optimum noise and optimum power, we have introduced the convention 0*n* instead of the more familiar abbreviation *opt*.) At this point we see that the optimum condition for minimum noise figure is not a conjugate power match at the input port. We can explain this by recognizing that the noise source V_A and I_A represent all the

two-port noise, not just the thermal noise of the input port. We should observe that the optimum generator susceptance, $-X_{corr}$, will minimize the noise contribution of the two noise generators.

In rearranging for conversion to S parameters, we write

$$F = F_{\min} + \frac{g_n}{R_G}|Z_G - Z_{0n}|^2 \tag{3-43}$$

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-44}$$

From the definition of the reflection coefficient,

$$\Gamma_G = \frac{Y_0 - Y_G}{Y_0 + Y_G} \tag{3-45}$$

and with

$$g_G = \frac{G_G}{Y_0} \tag{3-46}$$

$$r_n = \frac{R_n}{Z_0} \tag{3-47}$$

the normalized equivalent noise resistance,

$$F = F_{\min} + \frac{4r_n|\Gamma_G - \Gamma_{0n}|^2}{g_G(1 - |\Gamma|^2)|1 + \Gamma_{0n}|^2} \tag{3-48}$$

$$r_n = (F_{50} - F_{\min})\frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-49}$$

$$\Gamma_{0n} = \frac{Z_{0n} - Z_0}{Z_{0n} + Z_0} \tag{3-50}$$

The noise performance of any linear two-port can now be determined if the values of the four noise parameters, $F_{\min}$, r_n (= $R_n/50$), and Γ_{0n} (magnitude and phase), are known.

Figure 3-20 shows the noise factor of a high-frequency transistor as a function of B_g for G_g = constant and as a function of G_g for $B_g = B_{opt}$.

Noise Figure of Cascaded Networks. In a system with many circuits connected in cascade (Figure 3-21), we must consider the contributions of the various circuits. In considering the equivalent noise resistor R_n in series with the input circuit,

$$F = \frac{R_G + R_n}{R_G} \tag{3-51}$$

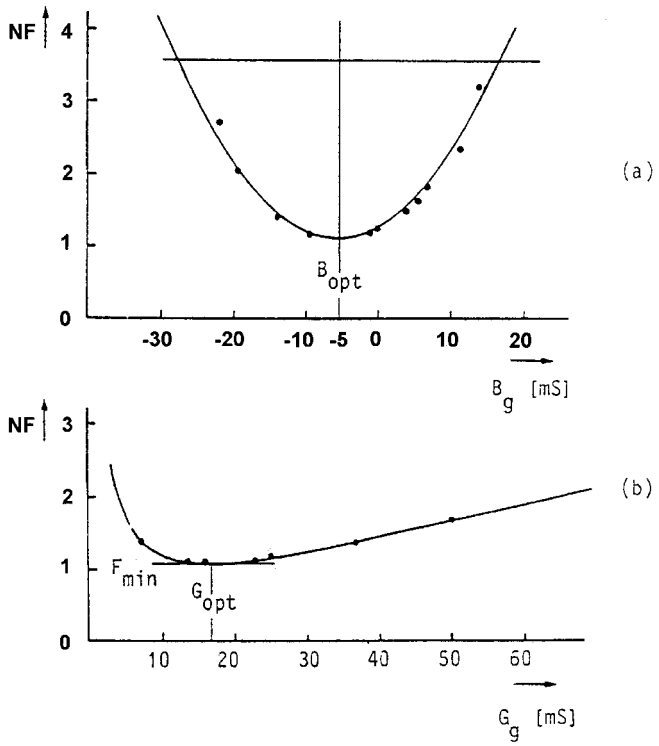

Figure 3-20 Noise factor in high-frequency BJTs for $f = 600$ MHz: (a) as a function of B_g for G_g = constant and (b) as a function of G_g for $B_g = B_{opt}$.

$$F = 1 + \frac{R_n}{R_G} \tag{3-52}$$

The excess noise added by the circuit is R_n/R_G.

In considering two cascaded circuits a and b, by definition the available noise at the output of b is

$$N_{ab} = F_{ab} G_{ab} kTB \tag{3-53}$$

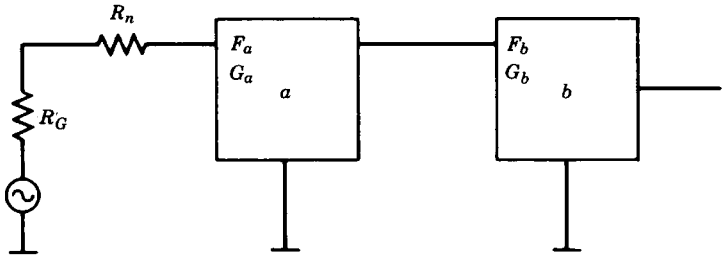

Figure 3-21 Cascaded noisy two-ports with the noise factors F_a and F_b and the gain figures G_a and G_b.

with B the equivalent noise bandwidth in which the noise is measured. The total available gain G is the product of the individual available gains, so

$$N_{ab} = F_{ab} G_a G_b kTB \tag{3-54}$$

The available noise from network a at the output of network b is

$$N_{a/b} = N_a G_b = F_a G_a G_b kTB \tag{3-55}$$

The available noise added by network b (its excess noise) is

$$N_{b/b} = (F_b - 1) G_b kTB \tag{3-56}$$

The total available noise N_{ab} is the sum of the available noise contributed by the two networks:

$$\begin{aligned} N_{ab} &= N_{a/b} + N_{b/b} = F_a G_a G_b kTB + (F_b - 1) G_b kTB \\ &= \left(F_a + \frac{F_b - 1}{G_a} \right) G_a G_b kTB \end{aligned} \tag{3-57}$$

$$F_{ab} = F_a + \frac{F_b - 1}{G_a} \tag{3-58}$$

For any number of circuits, this can be extended to

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \frac{F_4 - 1}{G_1 G_2 G_3} + \cdots \tag{3-59}$$

When considering a long chain of cascaded amplifiers, there will be a minimum noise figure achievable for this chain. This is a figure of merit and was proposed by Haus and Adler [6]. It is calculated by rearranging Eq. (3-59):

$$(F_{\text{tot}})_{\min} = (F_{\min} - 1) + \frac{F_{\min} - 1}{G_A} + \frac{F_{\min} - 1}{G_A^2} + \cdots + 1 \tag{3-60}$$

where $F_{\min}$ is the minimum noise figure for each stage and G_A is the available power gain of the identical stages. Using

$$\frac{1}{1 - X} = 1 + X + X^2 + \cdots \tag{3-61}$$

we find a quantity $(F_{\text{tot}} - 1)$, which is defined as the noise measure M. The minimum noise measure

$$(F_{\text{tot}})_{\min} - 1 = \frac{F_{\min} - 1}{1 - 1/G_A} = M_{\min} \tag{3-62}$$

refers to the noise of an infinite chain of optimally tuned, low-noise stages, so it represents a lower limit on the noise of an amplifier.

The minimum noise measure $M_{\min}$ is an invariant parameter and is not affected by feedback. It is somewhat similar to a gain–bandwidth product, in its use as a system invariant. The minimum noise measure is achieved when the amplifier is tuned for the available power gain and $\Gamma_G = \Gamma_{0n}$, given by Eq. (3-50).

Influence of External Parasitic Elements. Mounting an active two-port such as a transistor usually adds stray capacitance and lead inductance to the device, as shown in Figure 3-22. These external components consisting of transmission lines and parasitic reactances modify the noise parameters and the gain. Some researchers have published the results of these parasitic effects and have made manual computations or used some limited computer programs.

In a paper by Fukui [7], an attempt was made to determine the necessary equations, but the formulas are too involved even for pocket calculators. A more generic study by Iversen [8] is also very involved because of the various matrix manipulations and is more suitable for a computer. Besser's paper [9] in the *IEEE MTT-S* in 1975 and Vendelin's paper [10] in the same issue have shown for the first time some practical results using computers and even optimization methods, using an early version of COMPACT. The intention of these investigations was to find feedback that modifies the device noise and scattering parameters such that a noise match could also provide a low-input VSWR. It can be seen from these discussions that some feedback, besides resulting in some gain reduction, may improve the noise matching at the input for a limited frequency range.

A more recent paper by Suter [11] based on a report by Hartmann and Strutt [12] has given a simple transformation starting from the *S*-parameters and the noise parameters from common-source (or common-emitter) measurements. The noise parameters for the "packaged" device are calculated. This means that the parameters for the "new" device, including

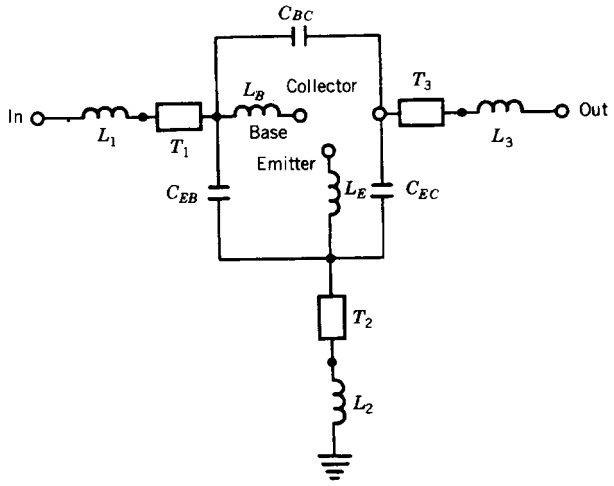

Figure 3-22 Equivalent circuit of the transistor package.

where

$$S'_{11} = S'_{22} = \frac{Z_P}{2 + Z_P}$$

(*continued*)

Table 3-2 (*Continued*)

$$S'_{12} = S'_{21} = \frac{2}{2 + Z_P}$$

$$P = (1 - S'_{11})(1 + S'_{22}) + S'_{12}S'_{21}$$

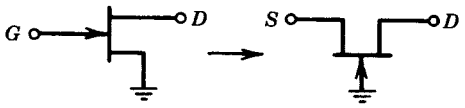
$$Q = (1 - S_{11})(1 + S_{22}) + S_{12}S_{21}$$

$$C_2 = (1 + S_{11})(1 + S_{22}) - S_{12}S_{21}$$

$$C'_2 = (1 + S'_{11})(1 + S'_{22}) - S'_{12}S'_{21}$$

$$[S]_{\text{DEVICE}} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}$$

Common Gate



$$[n] = \begin{bmatrix} n_{11} = \dfrac{2S_{21}}{-2S_{21} + C_4} & n_{12} = 0\ \Omega \\ n_{21} = \dfrac{1}{Z_0}\dfrac{C_3C_4 - 4S_{12}S_{21}}{V(-2S_{21} + C_4)}S & n_{22} = -1 \end{bmatrix}$$

where

$$V = (1 + S_{11})(1 + S_{22}) - S_{12}S_{21}$$

$$C_3 = (1 - S_{11})(1 + S_{22}) + S_{12}S_{21}$$

$$C_4 = (1 + S_{11})(1 - S_{22}) + S_{12}S_{21}$$

$$[S]_{\text{DEVICE}} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} = \text{common-source } S \text{ parameters}$$

the common-gate (or common-base) case, are calculated. The equations are device dependent. They are valid for any active two-port.

A transformation matrix, n, may be used to combine the noise sources of the various circuit configurations. The transformation matrix parameters are given in Table 3-2 for series feedback, shunt feedback, and the common-gate (base) case, which will be important for oscillator analysis. The transformation matrix gives the new noise parameters as follows:

$$R'_n = R_n|n_{11} + n_{12}Y_{\text{cor}}|^2 + G_n|n_{12}|^2 \tag{3-63}$$

$$G'_n = \frac{G_nR_n}{R'_n}|n_{11}n_{22} - n_{12}n_{21}|^2 \tag{3-64}$$

$$Y'_{\text{cor}} = \frac{R_n}{R'_n}(n_{21} + n_{22}Y_{\text{cor}})(n^*_{11} + n^*_{12}Y^*_{\text{cor}}) + \frac{G_n}{R'_n}n_{22}n^*_{12} \tag{3-65}$$

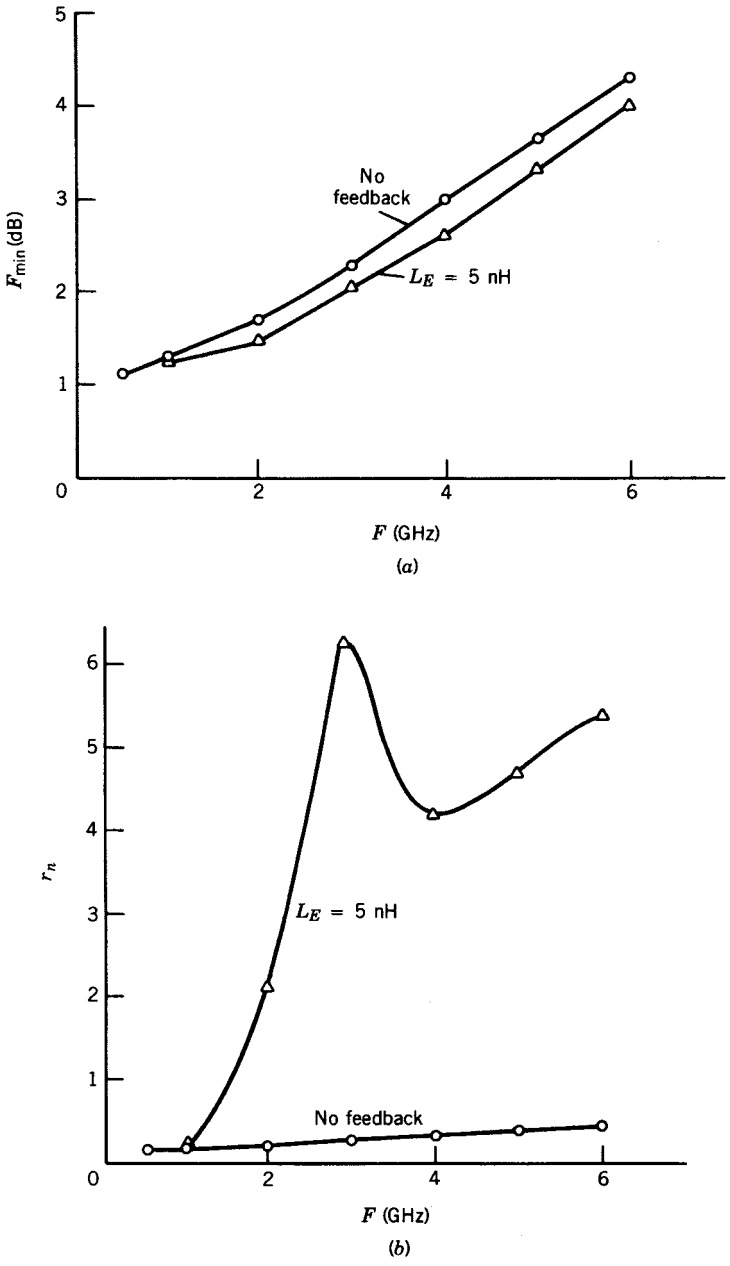

Figure 3-23 Noise parameters versus feedback for the AT-41435 silicon bipolar transistor: (a) F_{min} versus frequency and feedback; (b) r_n versus frequency and feedback; (c) Γ_{0n} versus frequency and feedback.

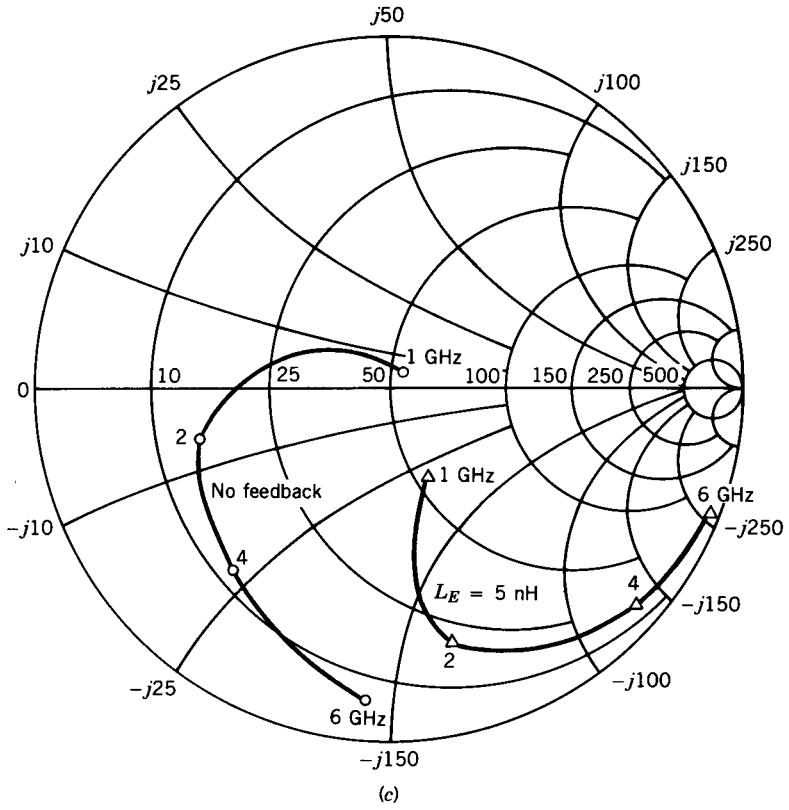

Figure 3-23 (*Continued*)

A final transformation to the more common noise-parameter format given by Eq. (3-44) is still needed [10]:

$$F_{\min} = 1 + 2R_n'(G_{\text{cor}}' + G_{0n}') \tag{3-66}$$

$$R_n = R_n' \tag{3-67}$$

$$G_{0n} = \sqrt{\frac{G_n'}{R_n'} + G_{\text{cor}}'^2} \tag{3-68}$$

$$B_{0n} = -B_{\text{cor}}' \tag{3-69}$$

Figure 3-23 shows the noise figure as a function of external feedback for a low-noise microwave bipolar transistor, the AT-41435.

Bias-Dependent Noise Parameters. Since we have elaborated on the effect of parasitics, it is now useful to point out that noise is also a strong function of bias point and frequency. Figure 3-24 shows the noise figure expressed in dB as a function of different dc currents and frequencies for a BFP420 BJT by Siemens. A change in the collector voltage will also affect the noise parameters, not quite as strongly as shown here, but still significantly. The reason

[b]$Z_S = Z_L = 50\ \Omega$.

for the turning point of the noise figure has to do with the fact that for lower currents the f_T cutoff frequency has not reached its peak yet, and therefore the noise increases. The increase of the noise at higher currents is due to the Schottky noise calculated from the equation

$$P_n = 2Iq \tag{3-70}$$

where P_n is the noise power, I is the saturation, collector, or drain current, and q is the charge of an electron (1.60×10^{-19} coulomb).

Table 3-3 shows the common-emitter noise parameters for the BFP420.

Noise Circles. From the section entitled "Influence of External Parasitic Elements," we see that the noise factor is a strong function of the generator admittance (or impedance) presented to the input terminals of the noisy two-port. Noise tuning is used to change the values of the input admittance to obtain the best noise performance. There is a range of values of input reflection coefficient over which the noise figure is constant. In plotting these points of constant noise figure, we obtain the so-called noise circles, which can be drawn on the Smith chart Γ_G plane [13]. Starting with the noise equation [see Eq. (3-44)] for a 50-Ω generator impedance, we find that

$$F_{50} = F_{\min} + 4r_n \frac{|\Gamma_{0n}|^2}{|1 + \Gamma_{0n}|^2} \tag{3-71}$$

We want to find the position of the reflection coefficient on the Smith chart, as in the case of the gain circles, for which F is constant. First we rearrange Eq. (3-67) to read

$$r_n = (F_{50} - F_{\min}) \frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-72}$$

By introducing

$$N_i = \frac{F_i - F_{\min}}{4r_n} |1 + \Gamma_{0n}|^2 \tag{3-73}$$

we can find an expression for a circle of constant noise figure as introduced by Rothe and Dahlke [4] (see also Fukui [13]). The center for the noise circle is

$$C_i = \frac{|\Gamma_{0n}|}{1 + N_i} \tag{3-74}$$

and the radius is

$$r_i = \frac{\sqrt{N_i^2 + N_i(1 - |\Gamma_{0n}|^2)}}{1 + N_i} \tag{3-75}$$

with the definition of N used previously. However, if we consider only the minimum noise figure for a given device, we will not obtain the minimum noise figure for the multistage amplifier system. This was explained when the noise measure was introduced. (See Figure 3-25.) Therefore, a better way to design the amplifier would be to use circles at constant noise measure instead of circles of constant noise figure. This was recently done by Poole

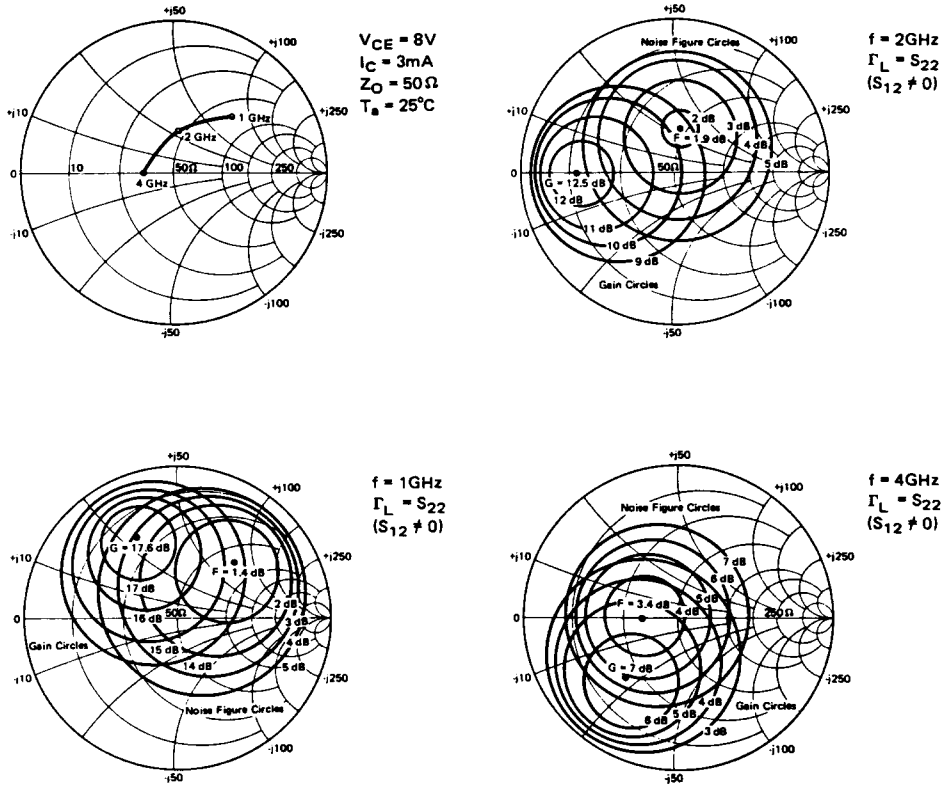

Figure 3-25 Typical noise figure circles and gain circles.

and Paul [14]. They derived the expressions for the noise measure circles as a function of S parameters, noise parameters, and Γ_G, using

$$G_A = \frac{|S_{21}|^2(1 - |\Gamma_G|^2)}{(1 - |S_{22}|^2) + |\Gamma_G|^2 (|S_{11}|^2 - |\Delta|^2) - 2\,\mathrm{Re}(\Gamma_G C_1)} \tag{3-76}$$

where

$$C_1 = S_{11} - S_{22}^* \Delta$$

$$\Delta = S_{11}S_{22} - S_{12}S_{11}$$

In terms of the generator reflection coefficient, the noise measure can be expressed as

$$M = [(F_{\min} - 1)(1 - |\Gamma_G|^2)|S_{21}|^2|1 + \Gamma_{0n}|^2 + 4r_n|S_{21}|^2|\Gamma_G - \Gamma_{0n}|^2]$$

$$\times \left\{|1 + \Gamma_{0n}|^2[|S_{21}|^2(1 - |\Gamma_G|^2) - (1 - |S_{22}|^2) - |\Gamma_G|^2(|S_{11}|^2 - |\Delta|^2) + 2\,\mathrm{Re}(\Gamma_G C_1)]\right\}^{-1} \tag{3-77}$$

Equation (3-77) can be shown to represent circles in the source reflection coefficient plane described by the following:

$$|\Gamma_G|^2 + |\Gamma_m|^2 - \Gamma_G\Gamma_m^* - \Gamma_G^*\Gamma_m = r_m^2 \tag{3-78}$$

The centers and radii of the constant-noise-measure circles are given by

$$C_m = \frac{M|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-79}$$

$$r_m = \frac{\sqrt{M^2M_a + MM_b + M_c}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-80}$$

where

$$P = |S_{21}|^2 + |S_{11}|^2 - |\Delta|^2$$

$$Q = |S_{21}|^2 + |S_{22}|^2 - 1$$

$$W = |1 + \Gamma_{0n}|^2(F_{\min} - 1)$$

$$M_a = |1 + \Gamma_{0n}|^4(PQ + |C_1|^2)$$

$$M_b = |1 + \Gamma_{0n}|^2|S_{21}|^2[8r_n\,\mathrm{Re}(\Gamma_{0n}C_1)$$

$$- (4r_n|\Gamma_{0n}|^2 + W)P - (W - 4r_n)Q]$$

$$M_c = |S_{21}|^4[W - 4r_n(1 - |\Gamma_{0n}|^2)]$$

The value of the minimum noise measure can be found by considering the noise measure circle of zero radius; that is, set r_m equal to zero in Eq. (3-80). This results in

$$M_{\min} = \frac{-M_b \pm \sqrt{M_b^2 - 4M_a M_c}}{2M_a} \tag{3-81}$$

Equation (3-81) yields the same value of $M_{\min}$ as would have been obtained by using the immittance parameter equation given by Fukui [13] and can, therefore, be considered as the reflection coefficient plane analog of Fukui's expression. The elimination of the need for the parameter R_{eg}, however, results in a considerable simplification as compared with the earlier approach [13].

The value of the minimum noise measure is taken as the smallest nonnegative value of $M_{\min}$ given by Eq. (3-81). The source reflection coefficient that results in the minimum noise measure can now be obtained by employing Eq. (3-79):

$$\Gamma_{0m} = \frac{M_{\min}|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M_{\min}|1 + \Gamma_{0n}|^2 P + |S_{21}|^2\,(4r_n - W)} \tag{3-82}$$

The output reflection coefficient of the device, when Γ_{0m} is presented to the input port, is given by

$$S'_{22} = \frac{S_{22} - \Delta\Gamma_{0m}}{1 - S_{11}\Gamma_{0m}} \tag{3-83}$$

Noise Correlation in Linear Two-Ports Using Correlation Matrices. In the introduction to two-port noise theory, it was indicated that noise correlation matrices form a general technique for calculating noise in n-port networks. Haus and Adler [6] have described the theory behind this technique. In 1976, Hillbrand and Russer [15] published equations and transformations that aid in supplying this method to two-port CAD.

This method is useful because it forms a base from which we can rigorously calculate the noise of linear two-ports combined in arbitrary ways. For many representations, the method of combining the noise parameters is as simple as that for combining the circuit element matrices. In addition, noise correlation matrices can be used to calculate the noise in linear frequency conversion circuits. The following is an introduction to this subject.

A linear, noisy two-port can be modeled as a noise-free two-port with two additional noise sources. These noise sources must be chosen so that they add directly to the resulting vector of the representation, as shown in Eqs. (3-84) and (3-85) and Figure 3-17:

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-84}$$

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \tag{3-85}$$

where the i and v vectors indicate noise sources for the y and z representations, respectively. This two-port example can be extended to n-ports in a straightforward, obvious way.

Since the noise vector for any representation is a random variable, it is much more convenient to work with the noise correlation matrix. The correlation matrix gives us deterministic numbers with which to calculate. The correlation matrix is formed by taking the mean value of the outer product of the noise vector. This is equivalent to multiplying the noise vector by its adjoint (complex conjugate transpose) and averaging the result:

$$\langle \bar{i}\ \bar{i}^{+} \rangle = \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] = \begin{bmatrix} \langle i_1 i_1^* \rangle & \langle i_1 i_2^* \rangle \\ \langle i_1^* i_2 \rangle & \langle i_2 i_2^* \rangle \end{bmatrix} + [C_y] \tag{3-86}$$

where the angular brackets denote the average value.

Note that the diagonal terms are the "power" spectrum of each noise source and the off-diagonal terms are complex conjugates of each other and represent the "cross-power" spectra of the noise sources. "Power" is used because these magnitude-squared quantities are proportional to power.

To use these correlation matrices in circuit analysis, we must know how to combine them and how to convert them between various representations. An example using y matrices will illustrate the method for combining two-ports and their correlation matrices. Given two matrices y and y', when we parallel them we have the same port voltages, and the terminal currents add (Figure 3-26):

$$\begin{aligned} I_1 &= y_{11}V_1 + y_{12}V_2 + y'_{11}V_1 + y'_{12}V_2 + i_1 + i'_1 \\ I_2 &= y_{21}V_1 + y_{22}V_2 + y'_{21}V_1 + y'_{22}V_2 + i_2 + i'_2 \end{aligned} \tag{3-87}$$

or

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} + y'_{11} & y_{12} + y'_{12} \\ y_{21} + y'_{21} & y_{22} + y'_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 + i'_1 \\ i_2 + i'_2 \end{bmatrix} \tag{3-88}$$

Here we can see that the noise current vectors add just as the y parameters add. Converting the new noise vector to a correlation matrix yields

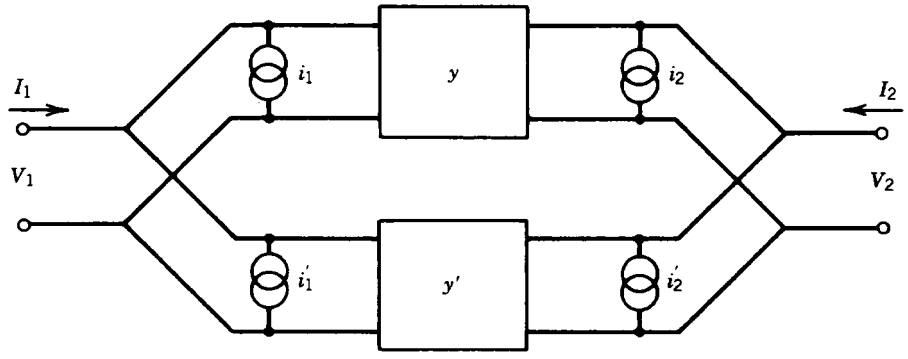

Figure 3-26 Parallel combination of two-ports using y parameters.

$$\langle \bar{i}_{\text{new}} \bar{i}^{+}_{\text{new}} \rangle = \left\langle \begin{bmatrix} i_1 + i_1' \\ i_2 + i_2' \end{bmatrix} [i_1^* + i_1'^* \quad i_2 i_2'^*] \right\rangle \tag{3-89}$$

$$= \begin{bmatrix} \langle i_1 i_1^* \rangle + \langle i_1' i_1'^* \rangle & \langle i_1 i_2^* \rangle + \langle i_1' i_2'^* \rangle \\ \langle i_2 i_1^* \rangle + \langle i_2' i_1'^* \rangle & \langle i_2 i_2^* \rangle + \langle i_2' i_2'^* \rangle \end{bmatrix} \tag{3-90}$$

The noise sources from different two-ports must be uncorrelated, so there are no cross products of different two-ports. By inspection, Eq. (3-90) is just the addition of the correlation matrices for the individual two-ports, so

$$[C_{y\text{new}}] = [C_y] + [C_y'] \tag{3-91}$$

The same holds true for g, h, and z parameters, but $ABCD$ parameters have the more complicated form shown below. If

$$[A_{\text{new}}] = [A][A'] \tag{3-92}$$

then

$$[C_{A\text{new}}] = \{C_A] + [A]\,[C_{A'}]\,[A]^{+} \tag{3-93}$$

The transformation of one representation to another is best illustrated by an example. Let us transform the correlation matrix for a Y representation to a Z representation. Starting with

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = [Y] \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-94}$$

we can move the noise vector to the left side and invert y:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 - i_1 \\ I_2 - i_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Y^{-1}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-95}$$

Table 3-4 π Noise matrix $T_{\alpha\beta}$ transformation

		Original Form (α Form)					
		Y		Z		A	
Resulting Form (β Form)	Y	1	0	y_{11}	y_{12}	$-y_{11}$	1
		0	1	y_{21}	y_{22}	$-y_{21}$	0
	Z	z_{11}	z_{12}	1	0	1	$-z_{11}$
		z_{21}	z_{22}	0	1	0	$-z_{21}$
	A	0	A_{12}	1	$-A_{11}$	1	0
		1	A_{22}	0	$-A_{21}$	0	1

Since $(Y)^{-1} = (Z)$, we have

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Z] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-96}$$

so

$$= [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} = [T_{yz}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-97}$$

where the signs of i_1 and i_2 are superfluous since they will cancel when the correlation matrix is formed. Here the transformation of the Y noise current vector to the Z noise voltage vector is done simply by multiplying by (Z). Other transformations are shown in Table 3-4.

To obtain the noise correlation matrix, we again form the mean of the outer product:

$$\langle vv^+ \rangle = \begin{bmatrix} \langle v_1 v_1^* \rangle & \langle v_1 v_2^* \rangle \\ \rangle v_1^* v_2 \rangle & \langle v_2 v_2^* \rangle \end{bmatrix} = [Z] \left\langle \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] \right\rangle [Z]^+ \tag{3-98}$$

or

$$[C_z] = [Z]\,[C_y]\,[Z]^+ \tag{3-99}$$

where

$$v^+ = [i_1^* \quad i_2^*]\,[Z]^+ \tag{3-100}$$

This is called a congruence transformation. The key to all of these derivations is the construction of a correlation matrix from the noise vector, as shown in Eq. (3-90).

These correlation matrices may easily be derived from the circuit matrices of passive circuits with only thermal noise sources. For example,

$$[C_z] = 2kT\Delta f\,\mathrm{Re}([Z]) \tag{3-101}$$

and

$$[C_y] = 2kT\Delta f\,\mathrm{Re}([Y]) \tag{3-102}$$

The $2kT$ factor comes from the double-sided spectrum of thermal noise. The correlation matrix from the $ABCD$ matrix may be related to the noise figure, as shown by Hillbrand and Russer [15]. We have

$$F = 1 + \frac{\overline{Y}[C_a]\overline{Y}^+}{2kT\,\mathrm{Re}(Y_G)} \tag{3-103}$$

where

$$\overline{Y} = \begin{bmatrix} Y_G \\ 1 \end{bmatrix}$$

Expressing the noise factor in terms of the correlation matrix, we obtain a complete formula:

$$F = 1 + \frac{C_{22}^{A}(f) + 2\,\mathrm{Re}\{Y_g(f)\,C_{12}^{A}(f)\} + |Y_g(f)|^2\,C_{11}^{A}(f)}{2kT_0\,\mathrm{Re}\{Y_g(f)\}} \tag{3-104}$$

Once we transform this in the Y parameter form, we obtain the following equation:

$$F(f) = F_{\min}(f) + \frac{R_n(f)|Y_{\mathrm{opt}}(f) - Y_g(f)|^2}{\mathrm{Re}\{Y_g(f)\}} \tag{3-105}$$

It should be noted that all these values are frequency dependent, as expressed in this equation.

The *ABCD* correlation matrix can be written in terms of the noise figure parameters as (double-sided spectrum)

$$[C_a] = 2kT\begin{bmatrix} R_n & \dfrac{F_0 - 1}{2} - R_n Y_{0n}^{*} \\ \dfrac{F_0 - 1}{2} - R_n Y_{0n} & R_n|Y_{0n}|^2 \end{bmatrix} \tag{3-106}$$

The noise correlation matrix method forms an easy and rigorous technique for handling noise in networks. This technique allows us to calculate the total noise for complicated networks by combining the noise matrices of subcircuits. It should be remembered that although noise correlation matrices apply to n-port networks, noise figure calculations apply only to pairs of ports. The parameters of the C_a matrix can be used to give the noise parameters:

$$Y_{0n} = \sqrt{\frac{C_{ii*}}{C_{uu*}} - \left[\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right)\right]^2} + j\,\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right) \tag{3-107}$$

$$F_0 = 1 + \frac{C_{ui*} + C_{uu*}Y_{0n}^{*}}{kT} \tag{3-108}$$

$$R_u = C_{uu*} \tag{3-109}$$

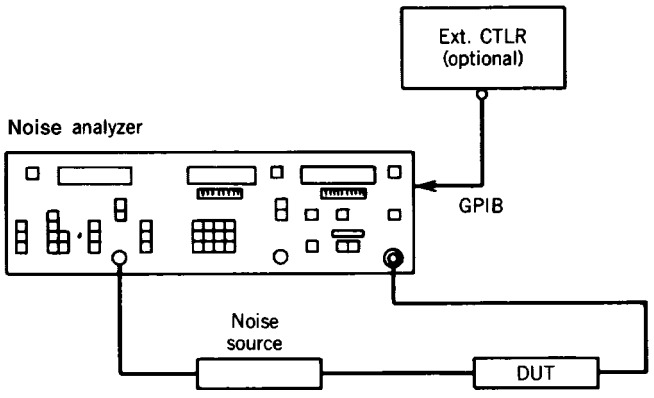

Figure 3-27 Noise figure measurement.

Noise Figure Test Equipment. Figure 3-27 shows the block diagram of a noise test setup. It includes the noise source and the other components. The metering unit has a special detector that is linear and over a certain dynamic range measures linear power. The tunable receiver covers a wide frequency range (e.g., 10–1800 MHz) and controls the noise source. The receiver is a double-conversion superheterodyne configuration with sufficient image rejection to avoid double-sideband noise measurements that would give the wrong results.

These receivers are microprocessor controlled and the measurement is a two-step procedure. The first is a calibration step that measures the noise figure of the receiver system and a reference power level. Then the device under test (DUT) is inserted and the system noise figure and total output power are measured. The noise factor is calculated by

$$F_1 = F_{\text{system}} - \frac{F_2 - 1}{G_1} \tag{3-110}$$

and the gain is given by the change in output power from the reference level [16]. The noise of the system is calculated by measuring the total noise power with the noise source on and off. With the excess noise ratio (ENR) known [16],

$$F_{\text{system}} = \frac{\text{ENR}}{Y - 1} \tag{3-111}$$

The noise bandwidth is usually set by the bandwidth of the receiver, which is assumed to be constant over the linear range. The ENR of the noise source is given by

$$\text{ENR} = \frac{T_{\text{hot}}}{T_{\text{cold}}} - 1 \tag{3-112}$$

where T_{cold} is usually room temperature (290 K). This ENR number is about 15 dB for noise sources with a 15-dB pad and 5 dB for noise sources with a 25-dB pad. Since both gain and noise were stored in the initial calibration, a noise/gain sweep can be performed.

For frequencies above 1800 MHz, we can extend the range with the help of the external signal generators, as shown in Figure 3-28. As shown, a filter ahead of the external mixer reduces the noise energy in the image band. If the DUT has a very broad frequency range

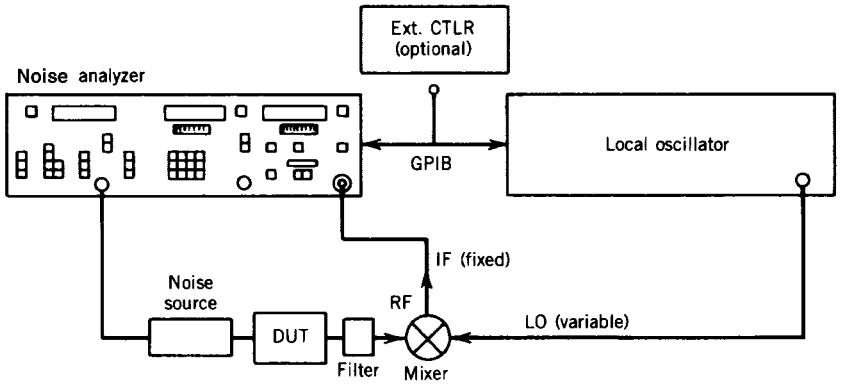

Figure 3-28 Single-sideband (SSB) noise figure measurements using an external mixer.

and has flat gain and noise over that range, a double-sideband (DSB) measurement is possible, with the image-rejection filter removed. However, a single-sideband (SSB) measurement is always more accurate [17].

How To Determine the Noise Parameters. The noise figure of a linear two-port network as a function of source admittance may be represented by

$$F = F_{\min} + \frac{R_n}{G_G}\left[(G_{0n} - G_G)^2 + (B_{0n} - B_G)^2\right] \tag{3-113}$$

where $G_G + jB_G$ = generator admittance presented to the input of the two-port
$G_{0n} + jB_{0n}$ = generator admittance at which optimum noise figure occurs
R_n = empirical constant relating sensitivity of the noise figure to generator admittance, with dimensions of resistance

It may be noted that for an arbitrary noise figure measurement with a known generator admittance, Eq. (3-113) has four unknowns—$F_{\min}$, R_n, G_{0n}, and B_{0n}. By choosing four known values of generator admittance, a set of four linear equations is formed and solutions of the four unknowns can be found [18, 19]. Eq. (3-113) may be transformed to

$$F = F_{\min} + \frac{R_n|Y_{0n}|^2}{G_G} - 2R_nG_{0n} + \frac{R_n|Y_G|^2}{G_G} - 2R_nB_{0n}\frac{B_G}{G_G} \tag{3-114}$$

or

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-115}$$

Let

$$X_1 = F_{\min} - 2R_nG_{0n}$$

$$X_2 = R_n|Y_{0n}|^2$$

$$X_3 = R_n$$

$$X_4 = R_nB_{0n}$$

Then the generalized equation may be written

$$F_i = X_1 + \frac{1}{G_{si}}X_2 + \frac{|Y_{si}|^2}{G_{si}}X_3 - 2\frac{G_{si}}{B_{si}}X_4 \tag{3-116}$$

or, in matrix form,

$$[F] = [A]\,[X] \tag{3-117}$$

and the solution becomes

$$[X] = [A]^{-1}\,[F] \tag{3-118}$$

These parameters completely characterize the noise behavior of the linear two-port network. Direct measurement of these noise parameters by this method would be possible only if the receiver on the output of the two-port were noiseless and insensitive to its input admittance. In actual practice, the receiver itself behaves as a noisy two-port network and can be characterized in the same manner. What is actually being measured is the system noise figure of the two-port and the receiver. Thus, it becomes apparent that to do a complete two-port noise characterization, the gain of the two-port must be measured [20]. In addition, any losses in the input-matching networks must be carefully accounted for, because they add directly to the measured noise figure reading [21].

3-1-4 Linearity

Consistent with the elaborate discussion of linearity questions above, here is a quick refresher on what must be considered in amplifiers.

Dynamic Range, Compression, and IMD. An amplifier's dynamic range is related to the minimum discernible signal and the 1-dB compression point according to the equation

$$DR_n = \frac{(n-1)(IP_{n(\text{in})} - MDS)}{n} \tag{3-119}$$

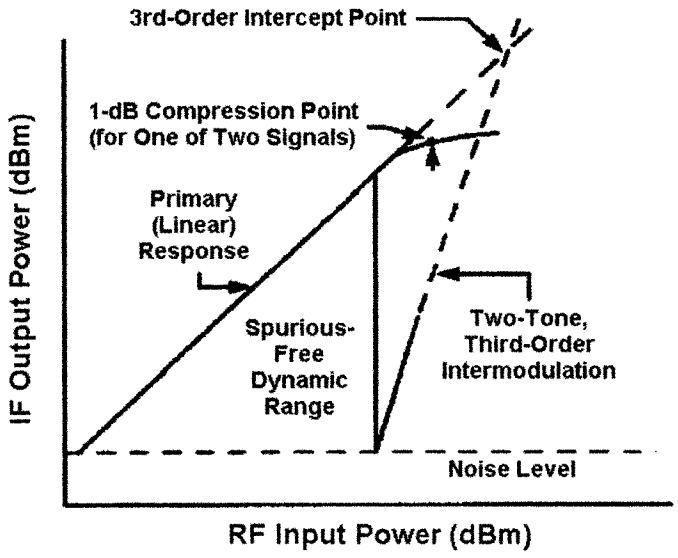

Figure 3-29 Amplifier linearity evaluation, including compression and two-tone IMD dynamic range. $P_{-1\text{dB}}$ for a single-tone cannot be read directly from this graph because the values shown are the result of two equal-power tones.

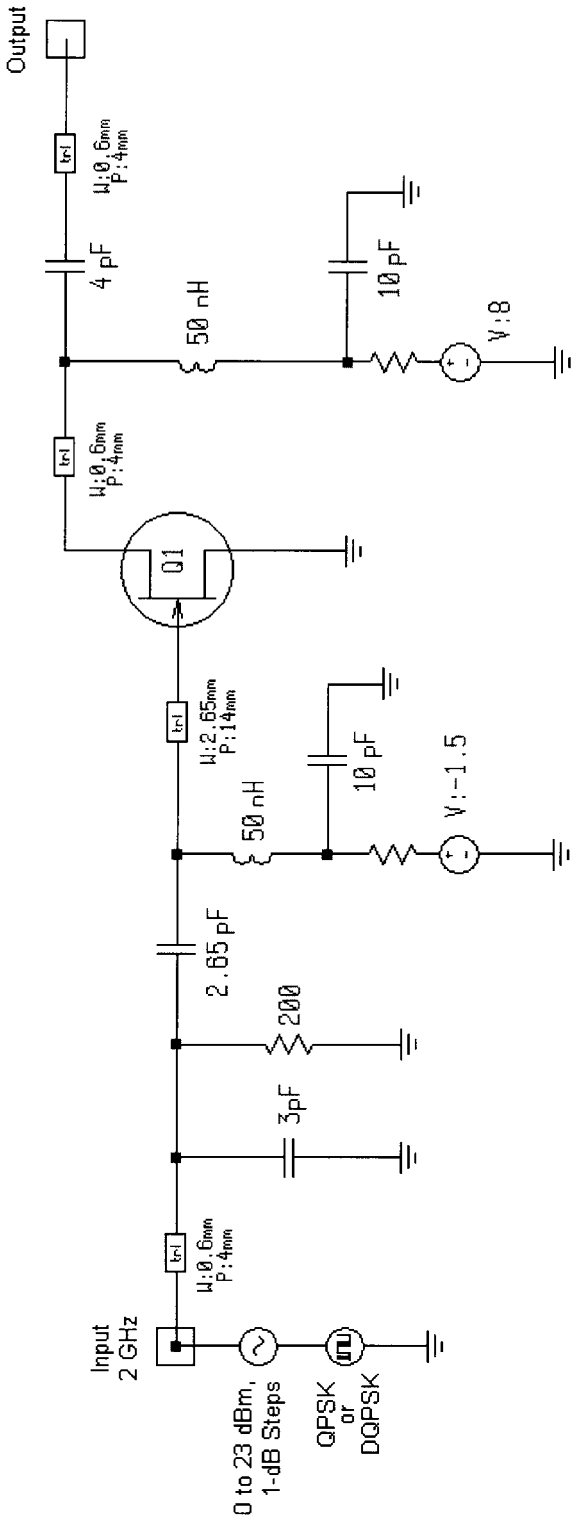

Figure 3-30 The power amplifier schematic.

where DR is the dynamic range in decibels, n is the order, $IP_{(in)}$ is the input intercept power in dBm, and MDS is the minimum detectable signal power in dBm. Once the 1-dB compression point is known, it is a fair assumption that the third-order intercept point, expressed in dBm, is 10 dB above this.

The intermodulation distortion gives the quality of an amplifier to withstand multiple signals without generating large intermodulation products or when using amplitude-modulated signals (cross-modulation). Figure 3-29 provides a quick reminder of IMD issues.

In some amplifiers, we would like to have control over the gain. While the better way to control gain while obtaining high linearity is a PIN-diode attenuator, special AGC circuits have become part of the amplifiers. Figure 3-48 shows a circuit of the SL610, made by Plessey, which has an AGC input provision. The noise figure of the PIN-diode attenuator is essentially equal to its attenuation. The AGC in multistage amplifiers is distributed over several stages and there is a lesser correlation between noise and AGC than in purely passive attenuators.

Special Case of Linearity Requirements for Digital Modulation. For cellular telephone systems we use digital modulation formats, such as QPSK and π/4-DQPSK, that combine phase and amplitude modulation. Amplifiers handling such signals must be carefully characterized and designed if adequate amplitude and phase linearity are to be maintained.

Examples of Power Amplifiers: Looking into the Effects of Distortion. This example presents modulation analysis using QPSK in a 2-GHz power amplifier (Figure 3-30). The simple amplifier was designed using the electronic Smith Tool of Serenade to determine the matching network for a narrowband design. The example demonstrates setup of modulation analysis and available results.

Siemens among others provides integrated amplifiers based on the concept depicted in Figure 3-30, the most popular ones being the CGY96 and CGY94. For the purpose of measurements, these amplifiers were actually put on a breadboard. Figure 3-31 shows the big brother, the CGY96. It is a GaAs MMIC intended as a power amplifier for GSM Class 4 phones with 3.2 W (35 dBm) at 3.5 V at an overall power added efficiency of 50%. Table 3-5 shows its electrical characteristics.

For the purpose of our experiments, we considered the CGY94 because it requires less external peripheral circuits. Table 3-6 shows its electrical characteristics. For those of us interested in seeing part of the internal circuit, Figure 3-32 shows the chip. This two-stage amplifier uses an interesting internal feedback scheme. Its schematic is shown in Figure 3-33.

For the purpose of looking at the waveforms, we will continue with the single-stage amplifier (Figure 3-30) and then compare the measured versus predicted performance of this CGY94-based amplifier.

A modulation source is connected to the RF source at the input port of the amplifier. The RF source specifies the carrier power (or voltage or current) and the modulation source specifies the modulation format and properties of the modulated signal.

A brief review of the modulation source used in this example indicates the following properties:

Property	Value	Description
NB	128	Number of bits
BR	1.2288E6	Bit rate
N	8	Number of samples per bit
BW1	590.E3	One-sided bandwidth of the main channel in the PIB or P1IB calculation
FS1	740.E3	Start baseband frequency of the fist adjacent channel
BW2	590.E3	One-sided bandwidth of the main channel in the P2IB calculation
FS2	1990.E3	Start baseband frequency of the second adjacent channel
BW3	590.E3	One-sided bandwidth of the main channel in the P3IB calculation
FS3	3240.E3	Start baseband frequency of the third adjacent channel
M	4	Order of the signal space; M = 4 is QPSK
DLY	0.0	Fractional bit delay
IASC	1.0	I channel amplitude scale; multiplier for the I waveform to model amplitude imbalance
QASC	1.0	Q channel amplitude scale; multiplier for the Q waveform to model amplitude imbalance
LPF	3	Baseband low-pass filter; 3 = root-raised cosine filter
LPFC	665.E3	–3 dB cutoff frequency of LPF
LPFN	3	Number of resonators if LPF = 1
LPFR	0.35	Roll-off factor if LPF = 3 or LPF = 4
FILE	N/A	File name of user-defined modulated signal file

The modulation source is a QPSK stream with a bit rate of 1.2288 Mbps. A total of 128 bits will be analyzed, and each bit is sampled eight times to construct an accurate analog waveform. The BW and FS parameters are defined here to specify the main (in-band) channel and adjacent channel for ACPR calculations. Imbalance of the I and Q amplitudes and phases can be described by the IASC, QASC, and DLY parameters, if desired. The modulation signal

is often filtered, and several types of filters are available. Here a root-raised cosine filter is used with a cutoff frequency of 665 kHz and a roll-off factor of 0.35.

Analysis. Figure 3-34 shows the compression characteristics of the amplifier as the available RF source power (a sinusoid) is swept. Note that P_{-1dB} is 11.5 dBm referred to the input and 28.5 dBm referred to the output. We will look at modulation characteristics in the linear region of operation at a source power of 0 dBm, and the nonlinear region at a source power of 20 dBm.

Next, we will view the voltage across the transistor to examine its behavior under compression. Figure 3-35 shows the drain–source voltage of the FET as the source power is swept. It is clear from this graph that clipping due to pinchoff and forward-gate conduction

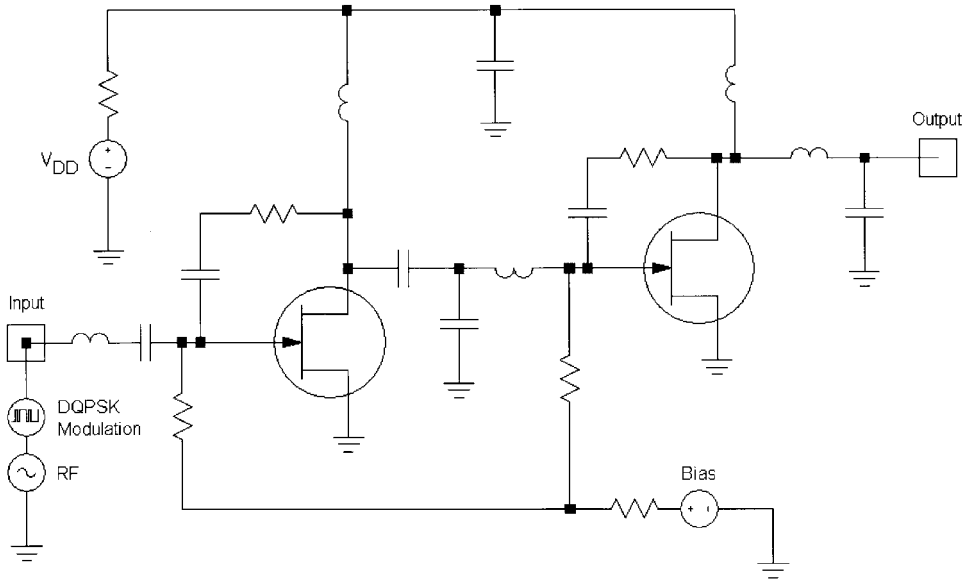

Figure 3-33 Schematic of the CGY94 GaAs MMIC power amplifier.

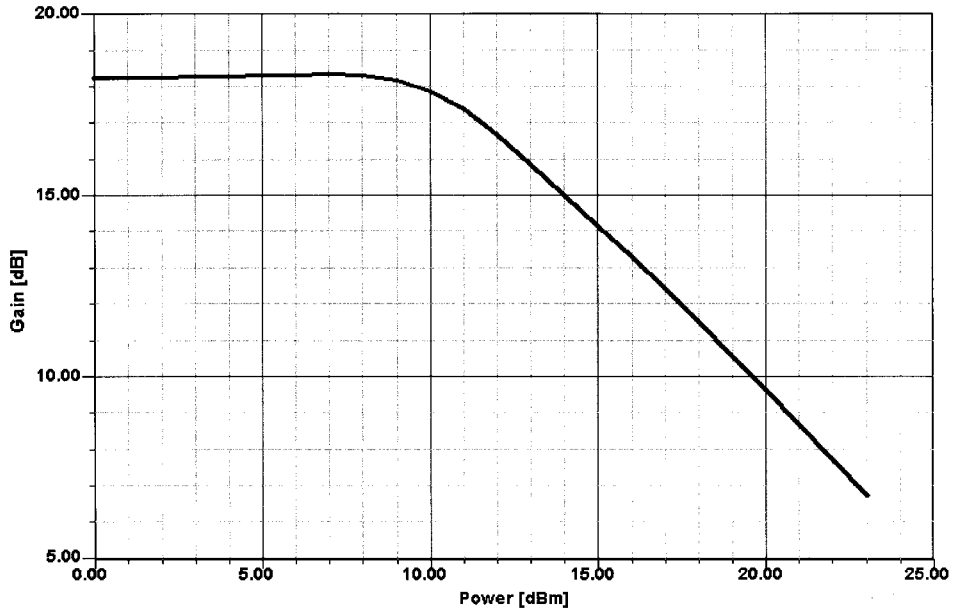

Figure 3-34 Single-tone RF power sweep analysis of the FET amplifier.

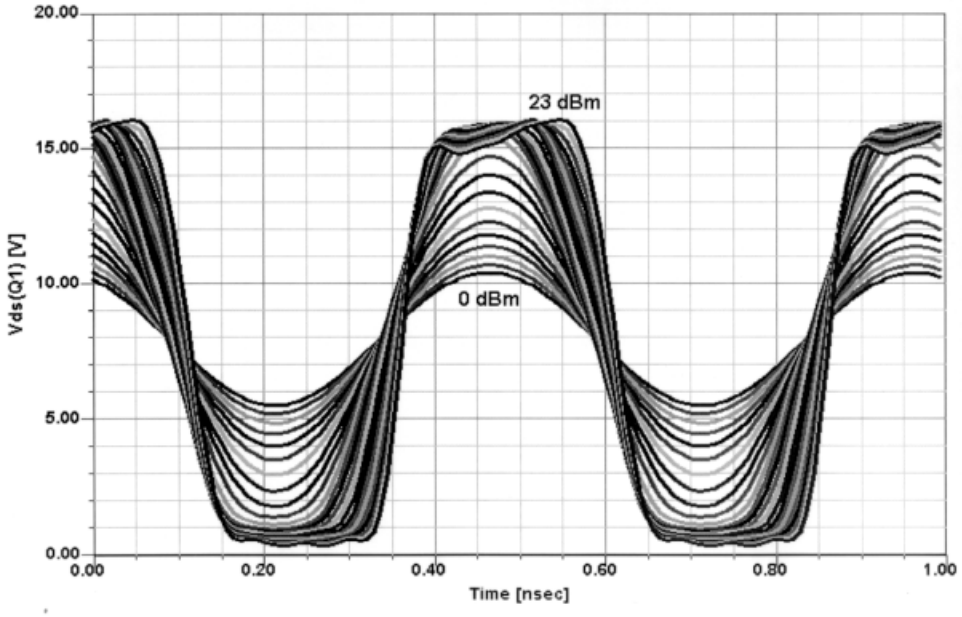

Figure 3-35 V_{DS} of the FET versus RF source power.

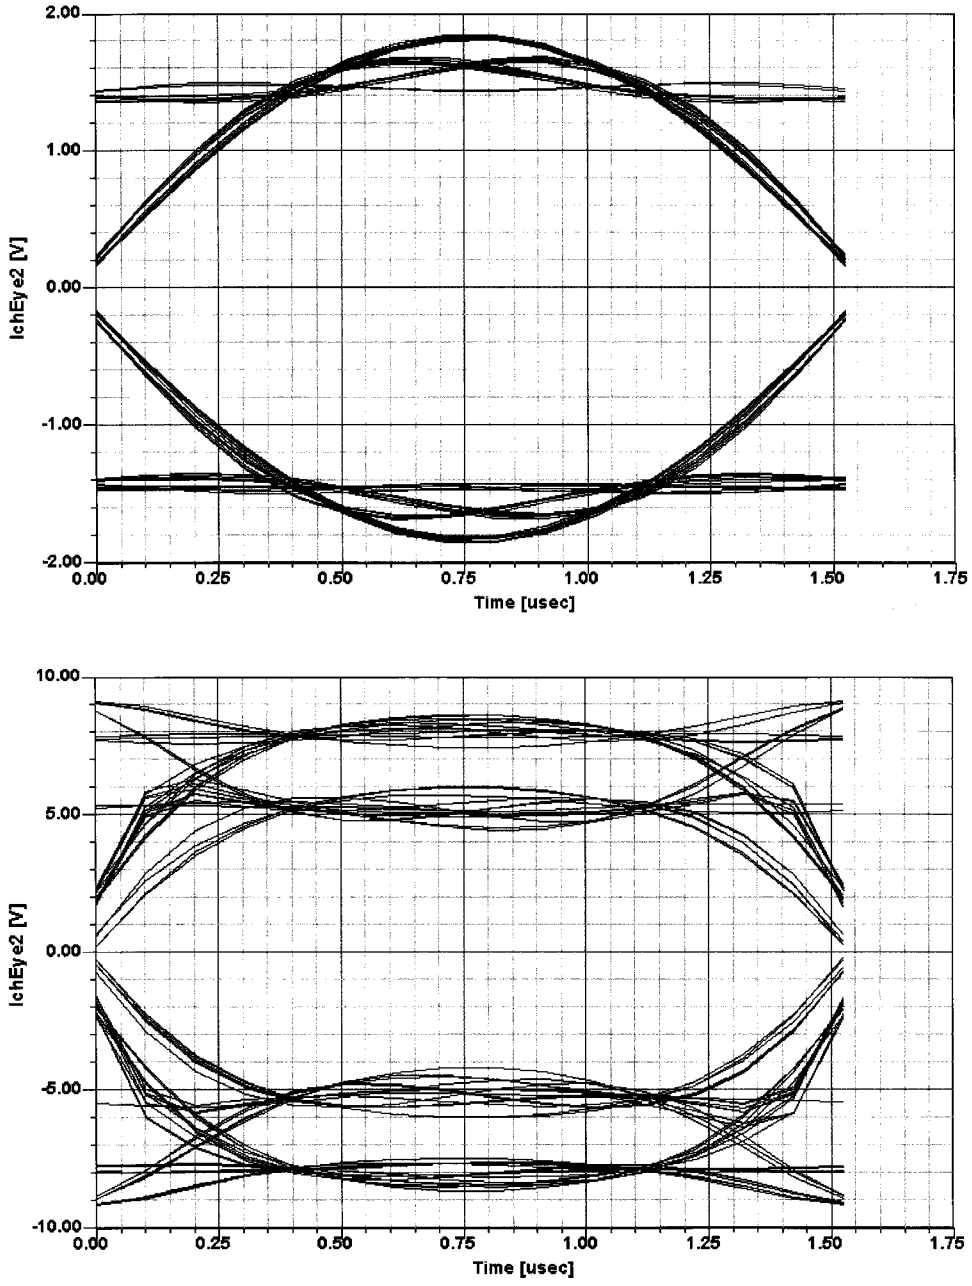

Figure 3-36 Eye diagrams of the I channel for source powers of (a) 0 dBm and (b) 20 dBm.

is limiting the performance of the device. A phase shift of the voltage waveform as power is increased is also apparent. The combination of the power compression and phase shift, or AM to PM conversion, will be used in the modulation analysis to determine the overall distortion of the modulated signal.

The output available from modulation analysis includes:

- I and Q channel waveforms
- Eye and constellation diagrams
- Spectral plots
- ACPR, in-band, and adjacent power

Figure 3-36 shows the eye diagrams for the 128-bit QPSK signal at two RF source powers, 0 and 20 dBm. Operating linearly at 0 dBm input, the amplifier doesn't distort the eye and it remains wide open. Note that in this example the filter bandwidth doesn't produce any intersymbol interference, as evidenced by the open eye. At an input power of 20 dBm, the amplifier compresses the signal, and distortion in the eye is evident.

We can also view the modulation spectrum at these two power levels to investigate the intermodulation distortion and spectral regrowth that takes place. Figure 3-37 shows the spectral plots. The lower trace corresponds to 0 dBm source power and shows almost no regrowth, while the upper trace at 20 dBm source power shows considerable regrowth.

The uncorrupted modulation source can also be shown. This corresponds to the source as a pure voltage without any circuit influence.

Now we evaluate the CGY94 board in a similar fashion. Figure 3-38 shows the waveform used for CAD purposes. Needless to say, such a signal cannot be produced by any signal

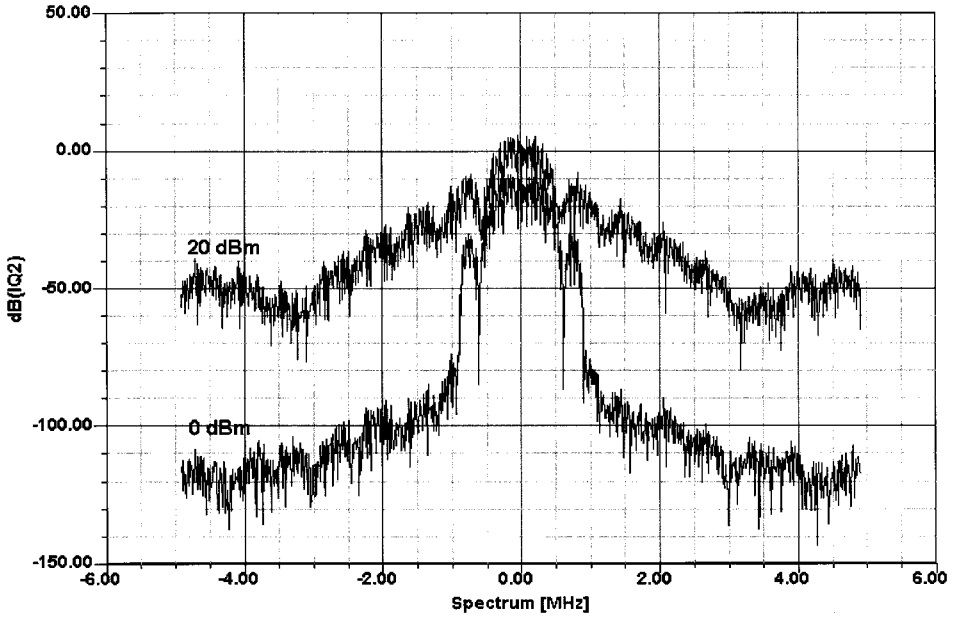

Figure 3-37 Spectrum of the modulation signal at the amplifier output. Source powers are 0 and 20 dBm.

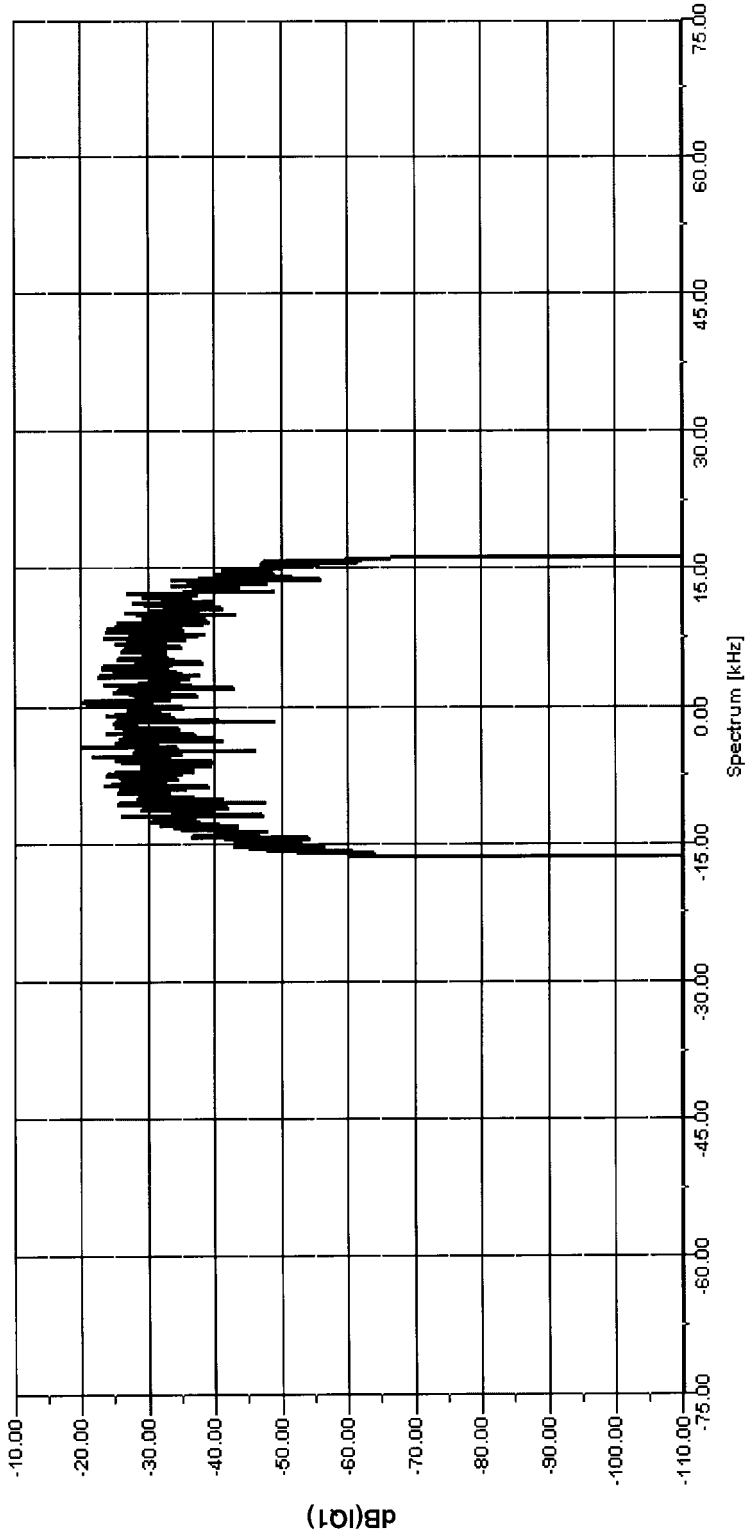

Figure 3-38 Simulated signal used for CAD analysis of the CGY94 amplifier.

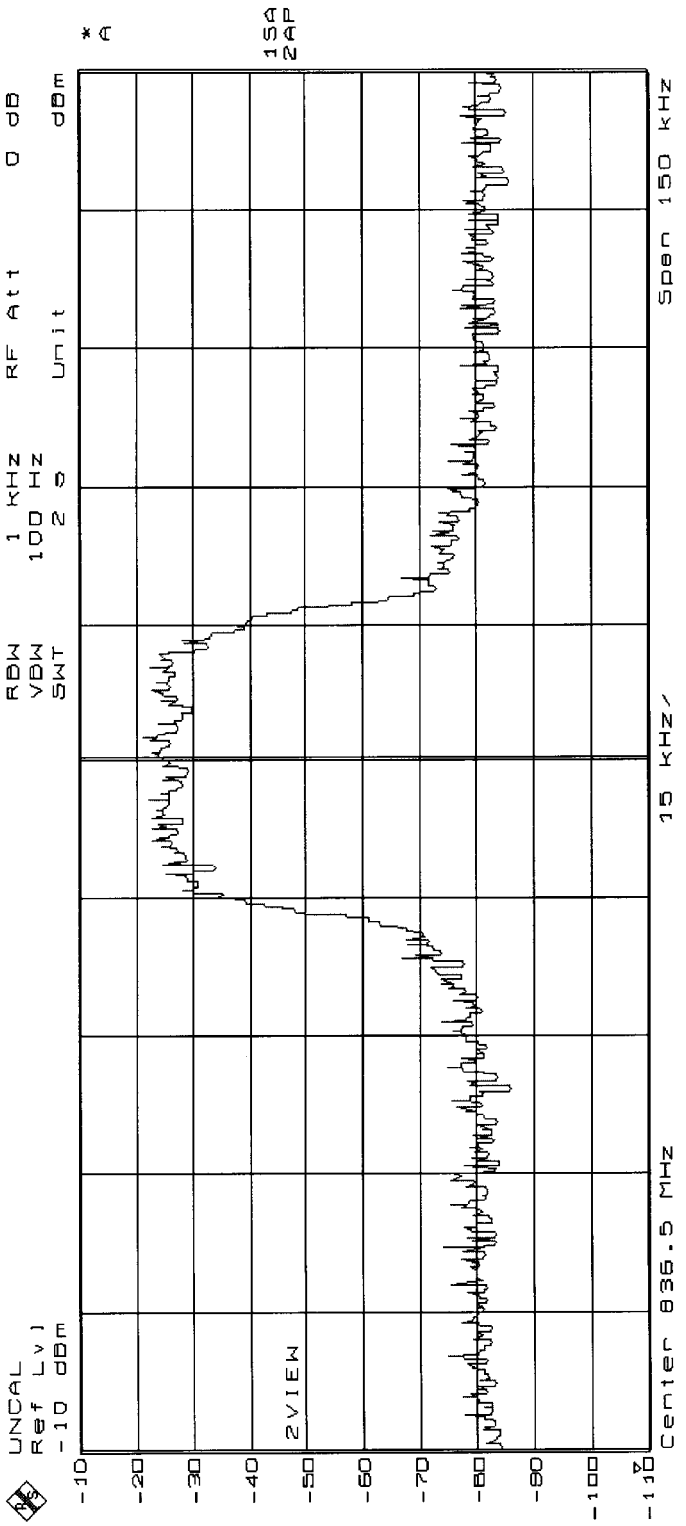

Figure 3-39 Real signal used for testing the actual amplifier.

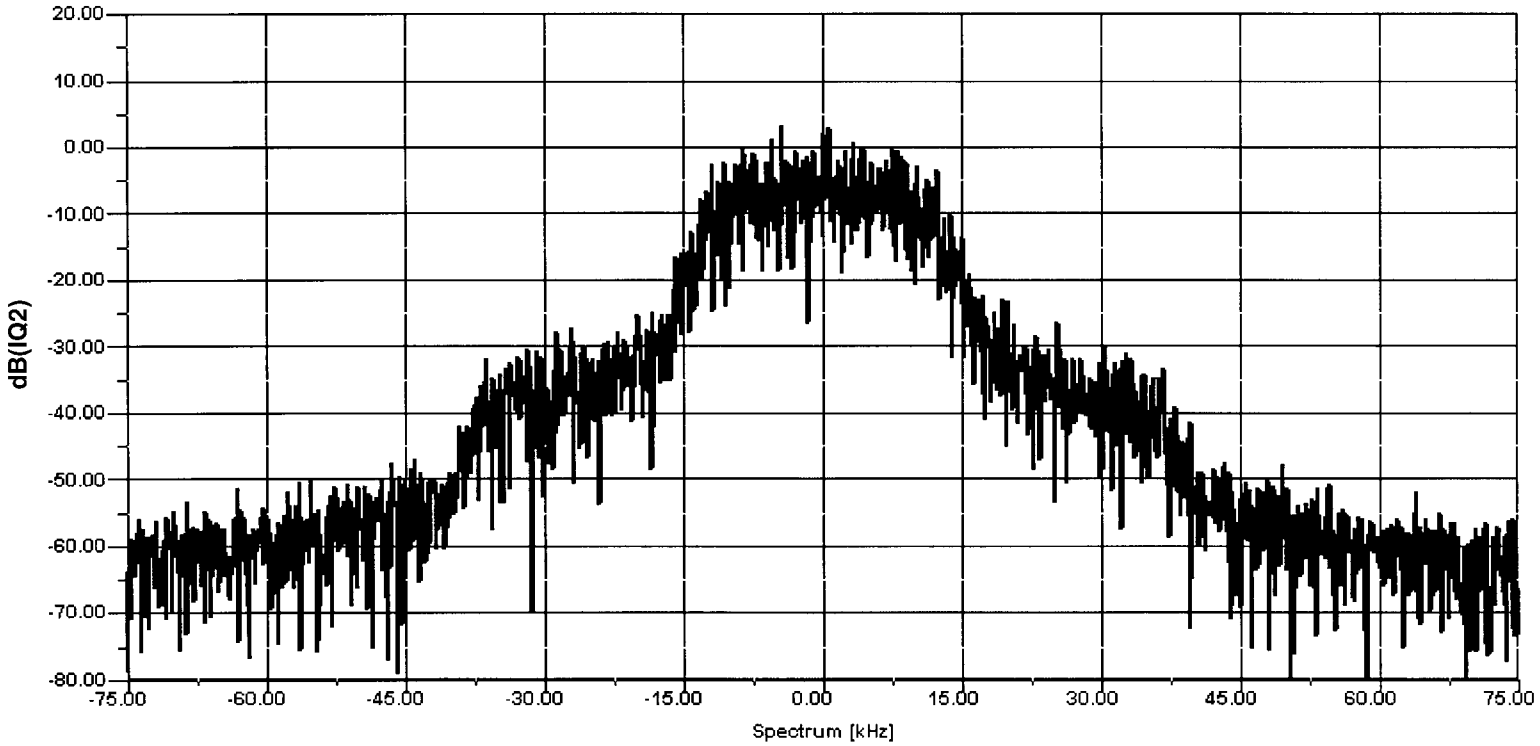

Figure 3-40 Spectral regrowth predicted by the simulation.

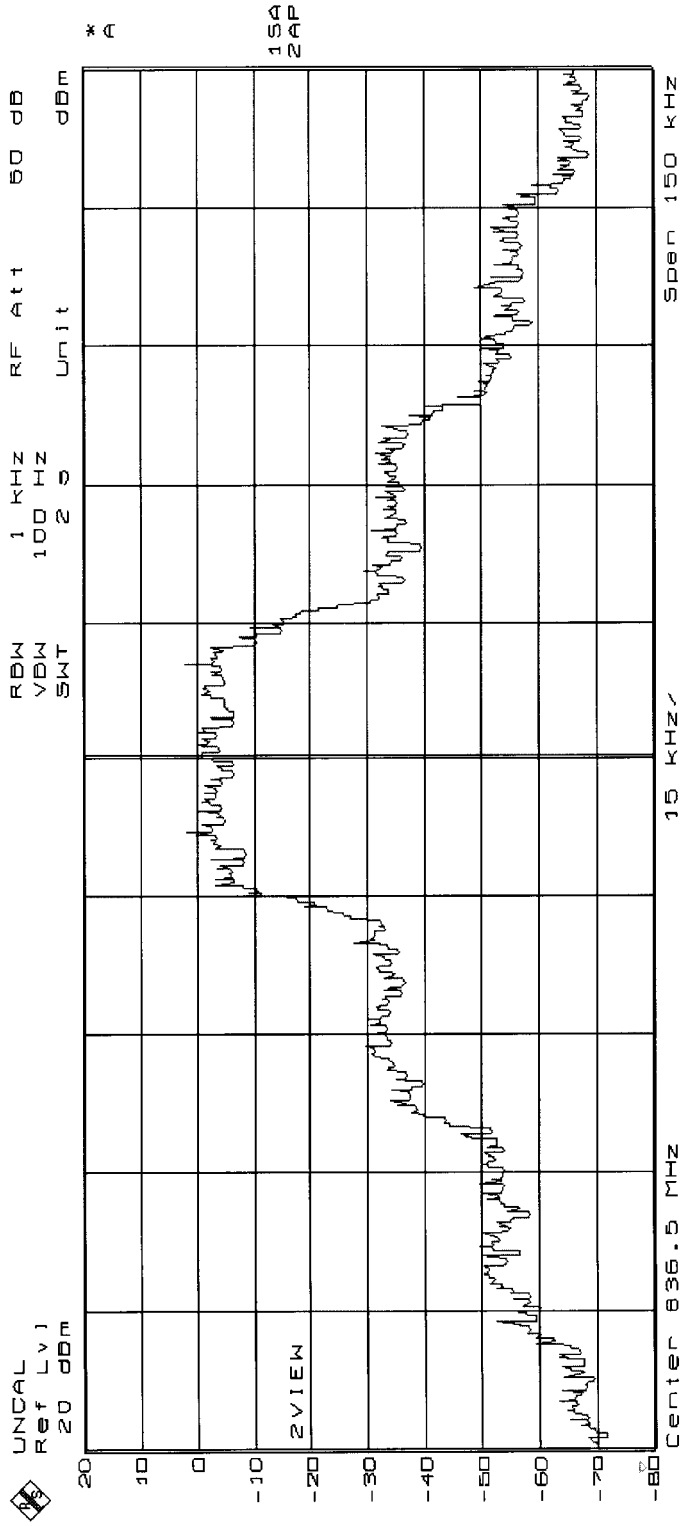

Figure 3-41 Measured spectral regrowth of the CGY94 amplifier.

generator. The one generated by an actual signal generator is shown in Figure 3-39. The wideband noise is around –80 dBm and the input level is about –25 dBm, consistent with the simulation signal. Looking at the output, Figure 3-40 shows the simulated signal with the expected increase in bandwidth. This is due to the nonlinearity of the amplifier and is consistent with Figure 3-37 for the single-stage amplifier. The actual measured output for the CGY94 shown in Figure 3-41 is quite close to its simulated output, indicating that the mathematical approach used for simulating is correct. This is only one example; in reality, many more waveforms can be analyzed and predicted using this method. Figure 3-41 shows essentially three distinct steps, which are sufficiently close to the response shown in the simulation. A dynamic range of 70 dB, while displayed in Figures 3-40 and 3-41, is not really necessary for good-quality transmission, and the discrepancy between the two pictures is in part due to the limited modeling quality of the active device as provided by the company that did the parameter extraction for this transistor.

Another useful view to aid in the understanding of the compression and distortion within the amplifier is to look at the magnitude of the complex waveform. Since the signal is composed of the in-phase and quadrature-phase components it is represented as

$$s(t) = i(t) + j \cdot q(t) \tag{3-120}$$

The time-domain magnitude is written

$$|s(t)| = \sqrt{i(t)^2 + q(t)^2} \tag{3-121}$$

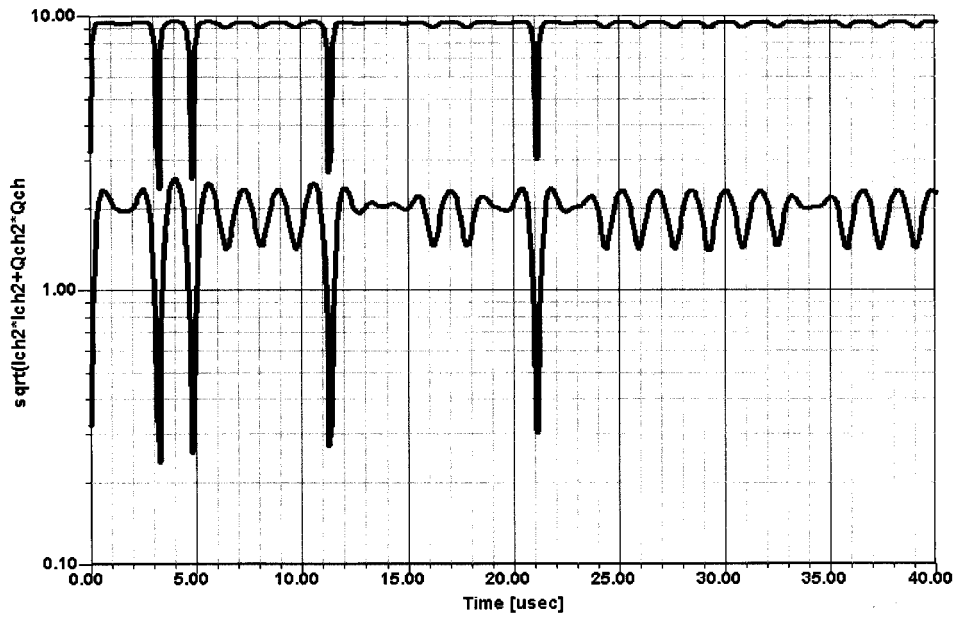

Figure 3-42 Time-domain magnitude of the complex modulation signal at source powers of 0 and 20 dBm.

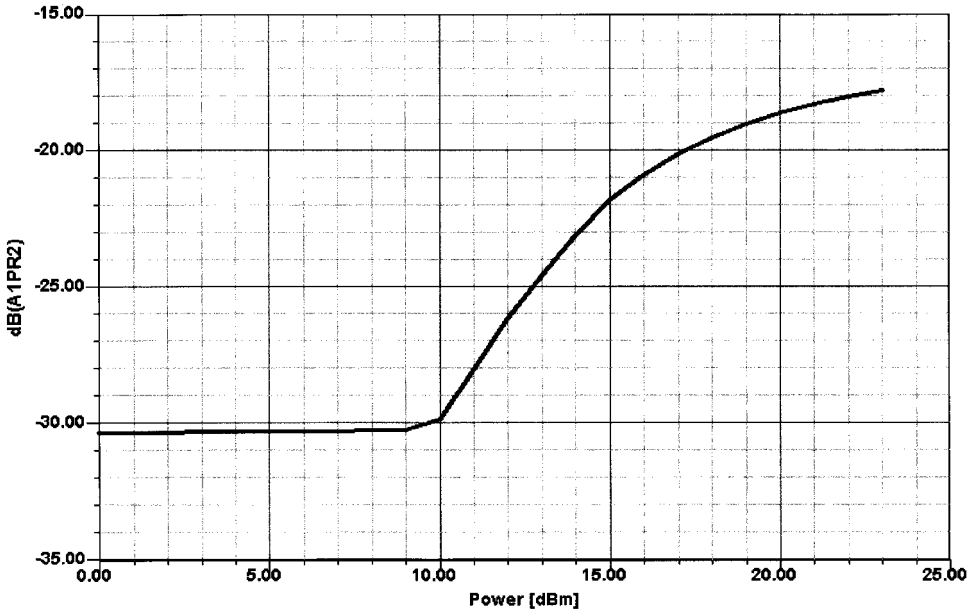

Figure 3-43 Adjacent-channel power ratio as function of RF source power.

Figure 3-42 shows the magnitude at source powers of 0 and 20 dBm. The *X* axis has been rescaled to 40 μs for improved viewing. Note the significant compression of the 20-dBm waveform at the higher signal levels. It is clear from this view that the signal is severely distorted.

We can also compute the adjacent-channel power ratio (ACPR) against the RF power sweep. ACPR is the ratio of the adjacent-channel power to the in-band channel power. The bandwidth (BW) and adjacent-channel start frequency (FS) are used for this calculation. For accurate ACPR calculation, a large number of bits are needed. This example uses 128 bits so the computation time is short, but 512 or more bits should be used for a more accurate computation.

Figure 3-43 shows the ACPR as a function of RF source power. The ACPR is nearly constant (and nonzero due to the gradual skirt of the baseband filter and inherent spillover to the adjacent channel) up to the P_{-1dB} compression point . As the intermodulation products spill into the adjacent channel and spectral regrowth occurs, the ACPR degrades.

π/4-DQPSK Circuit Analysis. Next, we will examine the same amplifier using a π/4-DQPSK modulation source. The task is identical to the previous one except for the source and the number of bits. The number of bits for this project has been increased from 128 to 256. Figure 3-44 shows the eye diagrams from this modulation format, at source powers of 0 and 20 dBm. The distortion and related intersymbol interference are clearly evident.

The constellation plot at 0 dBm is shown in Figure 3-45.

It may be interesting to take a look at the different waveforms currently in use. Figure 3-46 shows a spectrum analyzer picture of the most popular ones.

For reasons of time-division management, the European standard, GSM, which is now offered by Omnipoint at the 1.8-GHz band in the United States, uses gating to reduce the actual bandwidth of the spectrum. Figure 3-47 compares the GSM signal with and without gating.

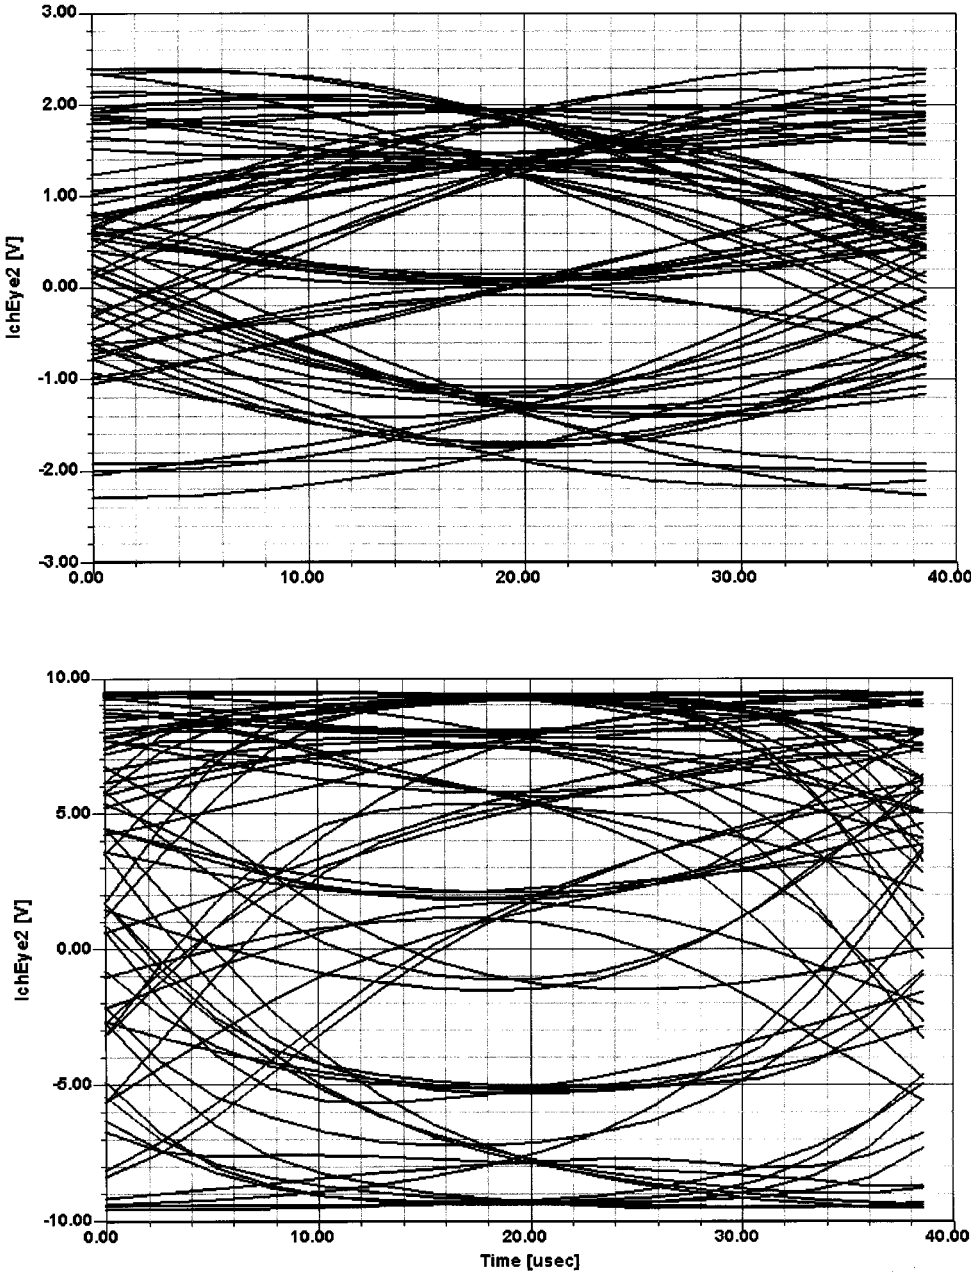

Figure 3-44 Eye diagrams for $\pi/4$-DQPSK at source powers of (a) 0 dBm and (b) 20 dBm. The distortion and related intersymbol interference are clearly visible.

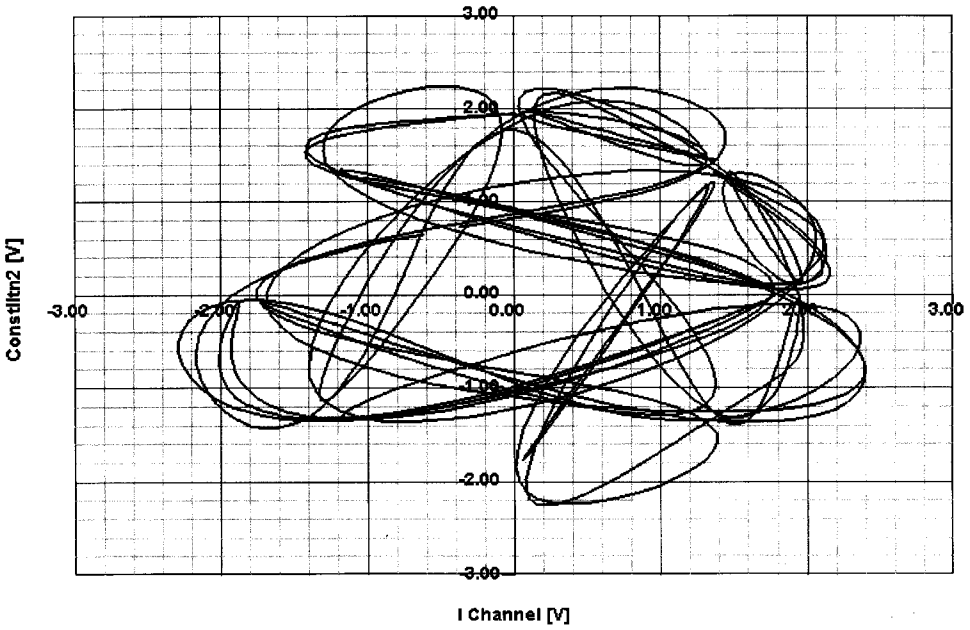

Figure 3-45 Constellation diagram for π/4-DQPSK at Port 2 and 0-dBm source power.

3-1-5 AGC

Many wireless systems consist of an up conversion or down conversion using an intermediate frequency, typically 10% or less of the receiving frequency (the FM broadcast IF has been set at 10.7 MHz for the same reason).

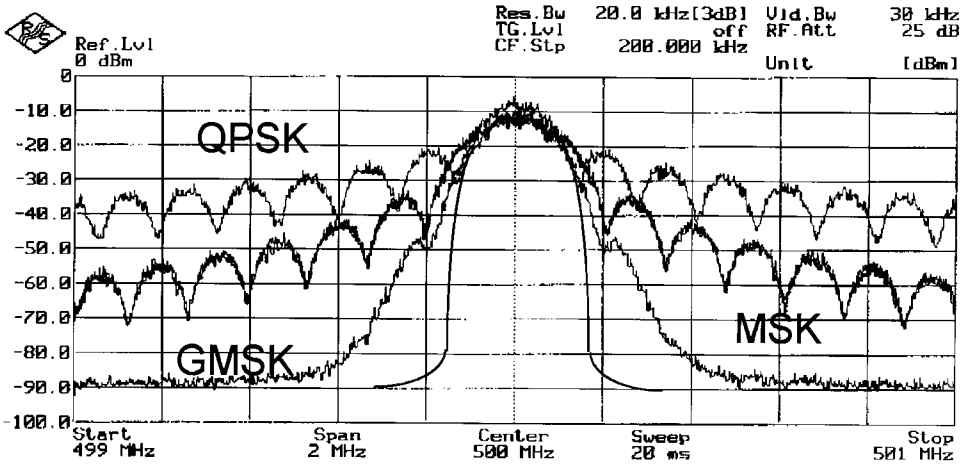

Figure 3-46 Spectrogram showing the characteristics of MSK, GMSK, and QPSK.

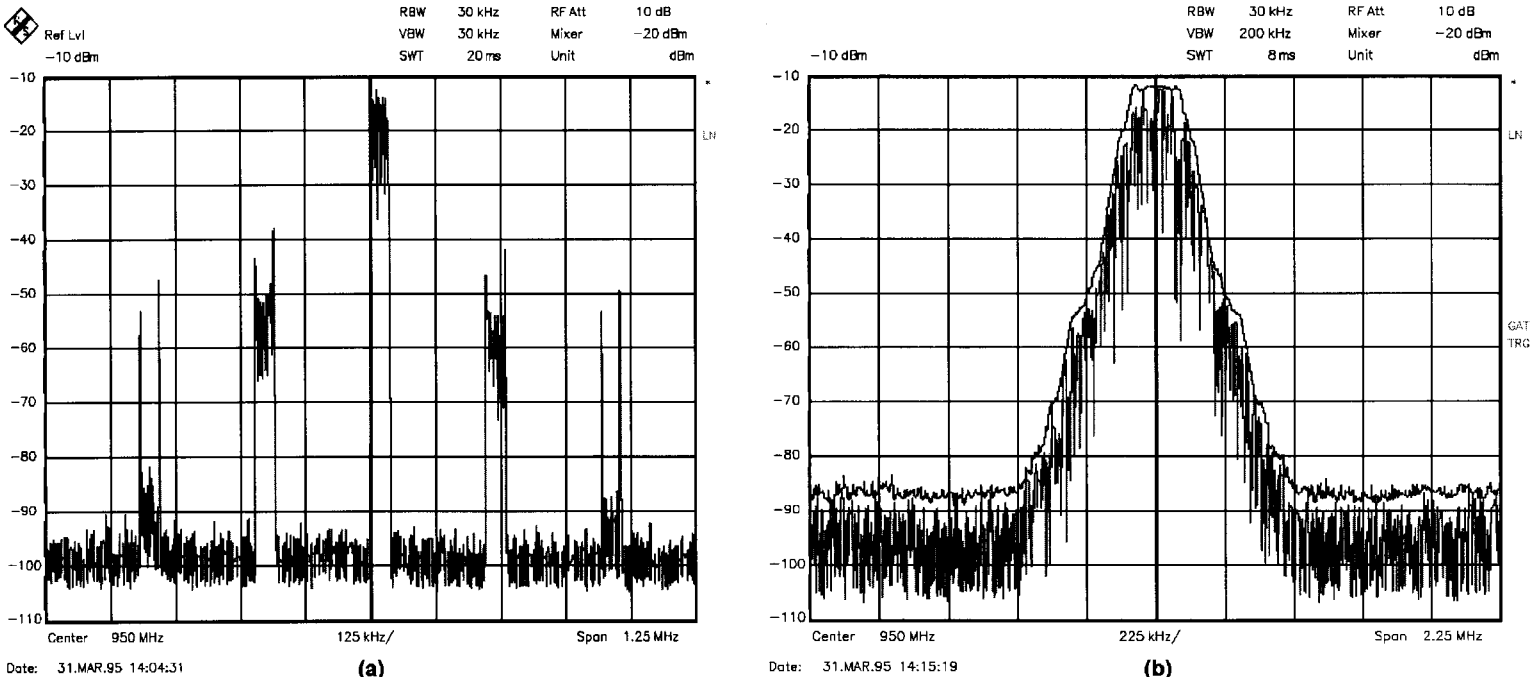

Figure 3-47 Pulsed GSM signal (a) without gating and (b) with gating.

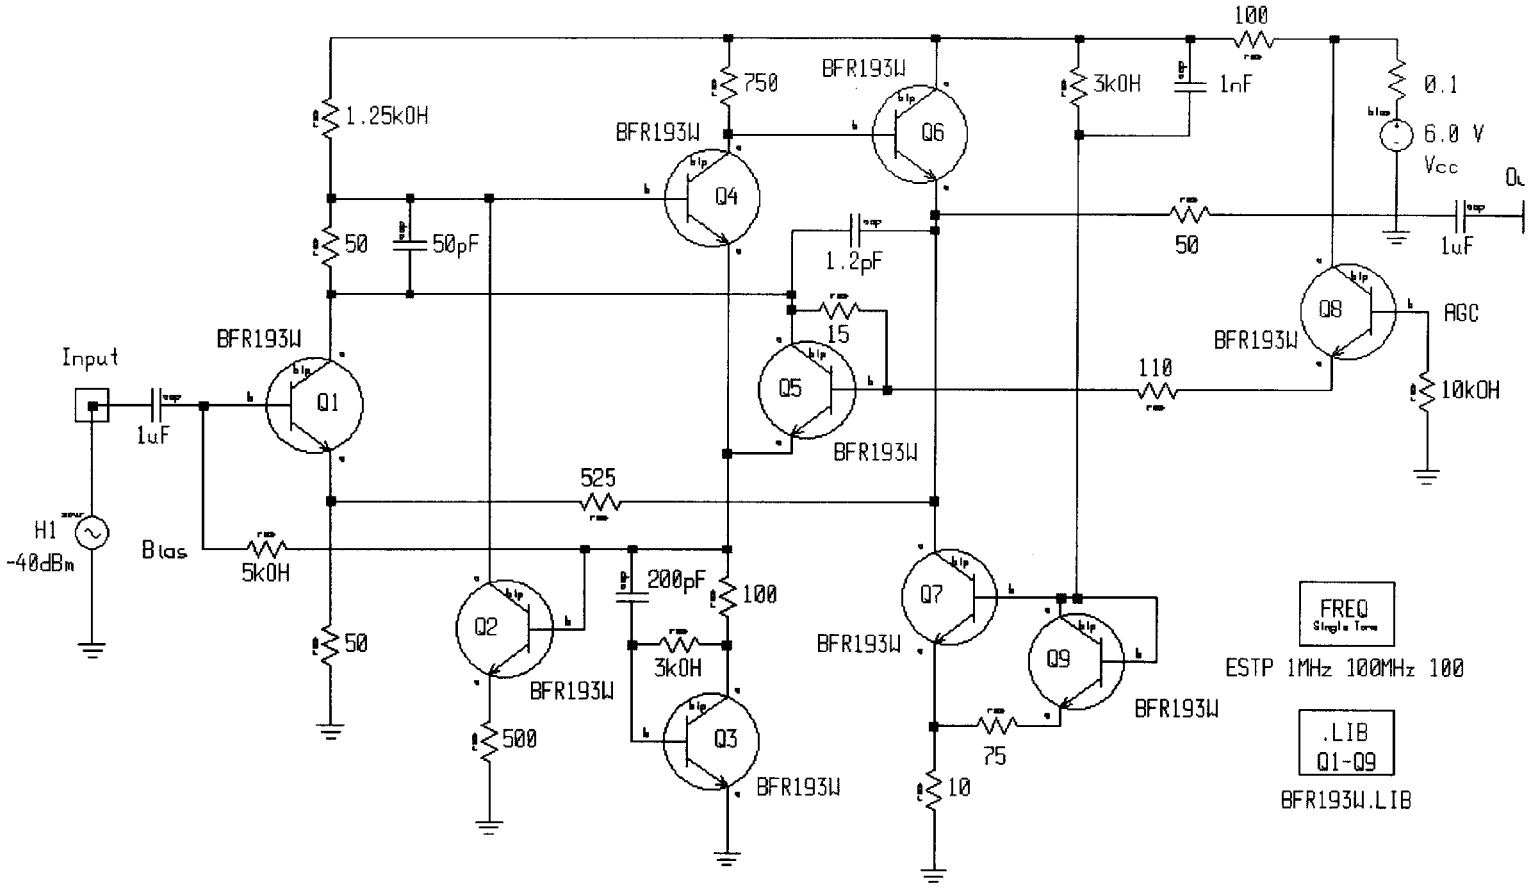

Figure 3-48 Schematic of the Plessey SL610 wideband amplifier with AGC. The 75-Ω resistor in the emitter of Q9 had to be added to obtain the appropriate dc current.

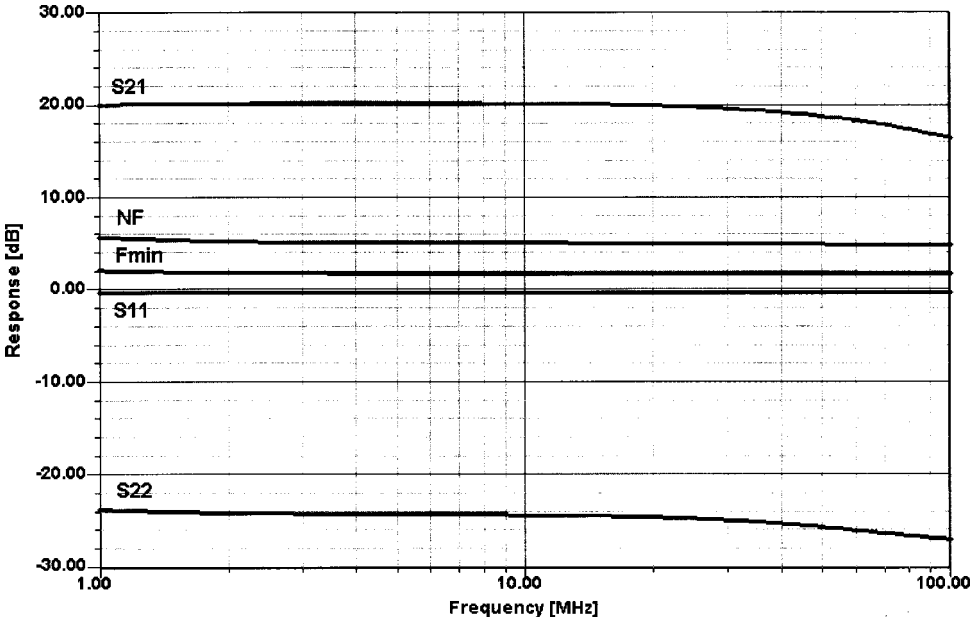

Figure 3-49 Simulated frequency response of the Plessey SL610 wideband amplifier IC with AGC = 0 V.

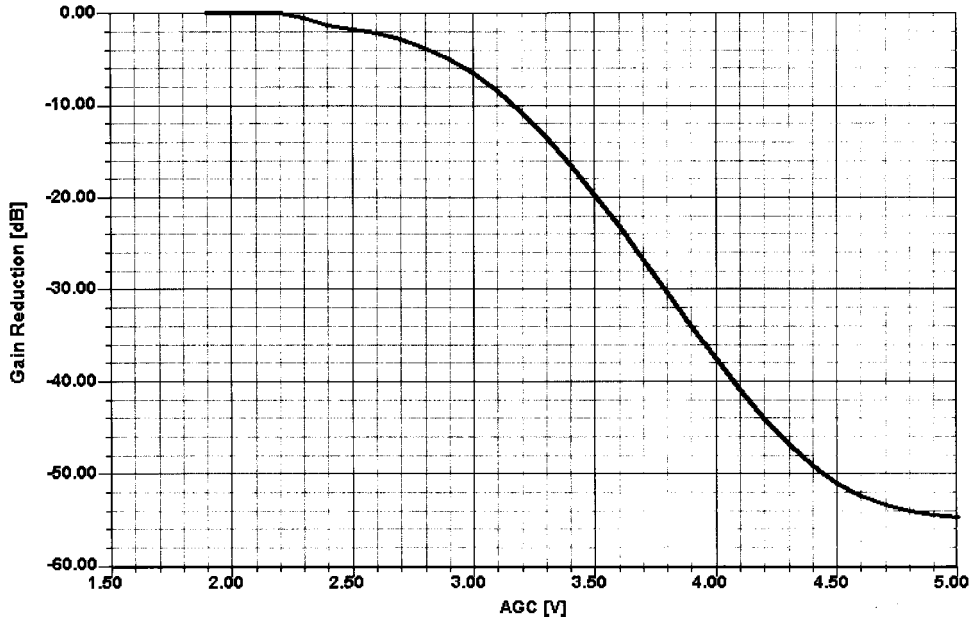

Figure 3-50 Simulated gain reduction versus AGC of the Plessey SL610 wideband amplifier IC.

Table 3-7 CGY121A features

- Variable gain amplifier (MMIC amplifier) for mobile communication
- Typical gain control range over 50 dB
- Positive control voltage
- 50-Ω input and output matched
- Low power consumption
- Operating voltage range: 2.7–6 V
- Frequency range 800 MHz to 2.5 GHz

We therefore will show two amplifiers with AGC and available data. The first one is a wideband amplifier type SL610, which has been manufactured by Plessey; its current fate is unknown. However, since we put the circuit into the simulator it provides significant insight into the operation of such AGC stages. Figure 3-48 shows the actual schematic of the SL610 entered in Ansoft's Serenade Design Environment for simulation.

The AGC action is derived from Q8 through Q5, which, together with Q4, forms a differential amplifier. Each consecutive stage (Q1, Q4, Q6) has increasing current, totaling about 20 mA; the last transistor takes about 13 mA. Based on the feedback surrounding the transistors, the actual transistor characteristics are less important. We have shown this by putting much higher f_T devices into the circuit than were available for the original design (20 years ago). The circuit is still interesting today because of its good large-signal-handling capability.

Table 3-8 CGY121A electrical characteristics at 900 MHz and 1.8 GHz

Characteristics	Symbol	Minimum	Typical	Maximum	Unit
(T_A 25 °C, f = 900 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	17	19	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	11	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	10	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm
(T_A 25 °C, f = 1800 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	15.5	17.5	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	10	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	8.5	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm

Figure 3-49 shows the amplifier's frequency response which is extremely close to the measured data. The good simulation also can be seen from comparing the published AGC curve with the one we found in the simulation. The bias of the first transistor remains essentially constant, resulting in a noise figure more independent of the AGC than the PIN-diode attenuator, and also stabilizes the input impedance as a function of AGC. Figure 3-50 shows the SL610's predicted AGC response.

The same requirement is applicable for the wireless frequency range. Tables 3-7 and 3-8 and Figures 3-51 through 3-54 present specifications for the recently introduced CGY121A GaAs MMIC by Infineon Technologies AG, formerly the Semiconductor Group part of Siemens AG.

3-1-6 Bias and Power Voltage and Current (Power Consumption)

Biasing of transistors operating in Class A or B follows some standard rules. The only deviation from this tends to be when the operating voltage is very low, below 3 V, because then the luxury of using voltage drops for good dc stability as a function of temperature disappears. (We will discuss low-voltage design in detail in Section 3-2-6.) In our simple example (Figure 3-55), we are operating from a 12-V power supply, and the first rule of thumb is to make sure that the voltage between the emitter and ground is at least 0.7 V. This is necessary to compensate the base–emitter junction threshold voltage, which decreases by about 2 mV/°C as the temperature increases. A larger voltage drop in the emitter–ground connection greatly reduces the influence. In this amplifier the emitter–ground path consists of an emitter unbypassed resistor of 10 Ω in series with a bypassed 501-Ω resistor, resulting in an overall voltage drop of 2.6. We could reduce the supply voltage by about 1.9 V at the collector side and still maintain a safety margin of 0.7 V at the emitter–ground connection. The current 2.6 V, so to speak, is overkill.

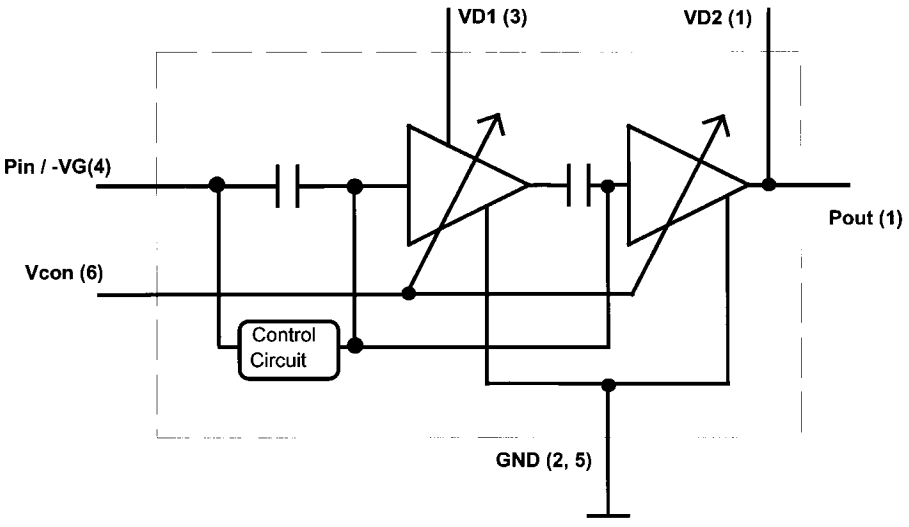

Figure 3-51 Functional block diagram of the gain-controllable CGY121A GaAs MMIC. Gain control is achieved by applying 0–3 V dc to the Vcon pin.

R2 (Siemens B 54102-A1120-J60)	12 Ω
R3	6.8 Ω

Figure 3-52 CGY121A 900-MHz application circuit and parts list.

On the collector side, for an *RC* type of amplifier, it is not a bad idea to set the collector voltage at about half the supply, which allows the RF swing to be half the supply voltage. In this case, we have violated the rule because of our 2.6-V drop. Assuming we had chosen a 0.7-V drop, then the collector–emitter voltage would be 6.3 V available for the swing. The choice of 5 mA for the transistor has come from a combination of good linearity and low noise figure. While the 10-Ω unbypassed resistor will grade the noise figure somewhat, it reduces the emitter-current-dependent distortion. The base–emitter diffusion resistance equals 26 mV/5 mA, or roughly 5 Ω. The 10-Ω resistor is twofold larger and therefore adds to the linearity and to the noise.

To determine the base bias resistor it is a good assumption that the current going through the two resistors (in our case, 8.2 and 3.3 kΩ) is about 10% (or a slightly higher fraction) of

Figure 3-53 CGY121A 1.9-GHz application circuit and parts list.

the collector current. Since the dc current gain of the transistor is typically between 50 and 100, it is sufficient if the current through the resistive network is between 5 and 10 times higher than the dc bias current taken off the network. This type of bias scheme is only valid for Class A to AB_1. Later, we will see that for monolithic circuits, additional transistors will be used to generate the required voltage drops. Lately, combinations of *npn* and *pnp* transistors have become popular to avoid using any resistance in the emitter for dc biasing purposes. Figure 3-56 shows such a circuit. This, of course, invites thermal runaway. To minimize the circuitry, there are bias ICs, such as the Siemens BCR400R, now available. Figures 3-57 and 3-58 show its application in biasing BJTs and FETs, respectively; it can also be used to control PIN-diode bias current for TR antenna switching, as shown in Figure 3-59.

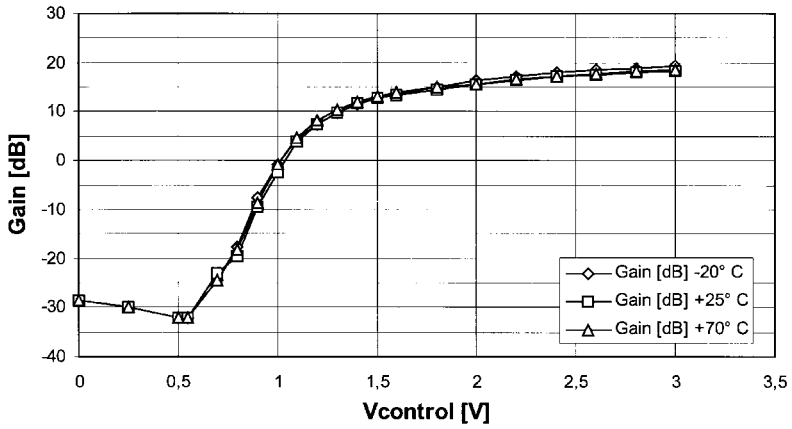

Figure 3-54 CGY121A gain versus $V_{control}$ at 1.9 GHz.

To validate this, we have used the Serenade 8.0 CAD tool, which has a built-in bias- and temperature-dependent noise model for BJTs and FETs. The SPICE-type dc analysis determines the actual currents, which were mentioned above. By maintaining the same bias and just bypassing both emitter resistors at the same time, the set of curves shown in Figure 3-60 will be obtained. As an exercise, we recommend the user to determine the optimum generator impedance for F_{min} with a 10-Ω resistor. Again, both the emitter current and collector voltage affect the noise figure, the intermodulation, and f_T. If a transistor is used

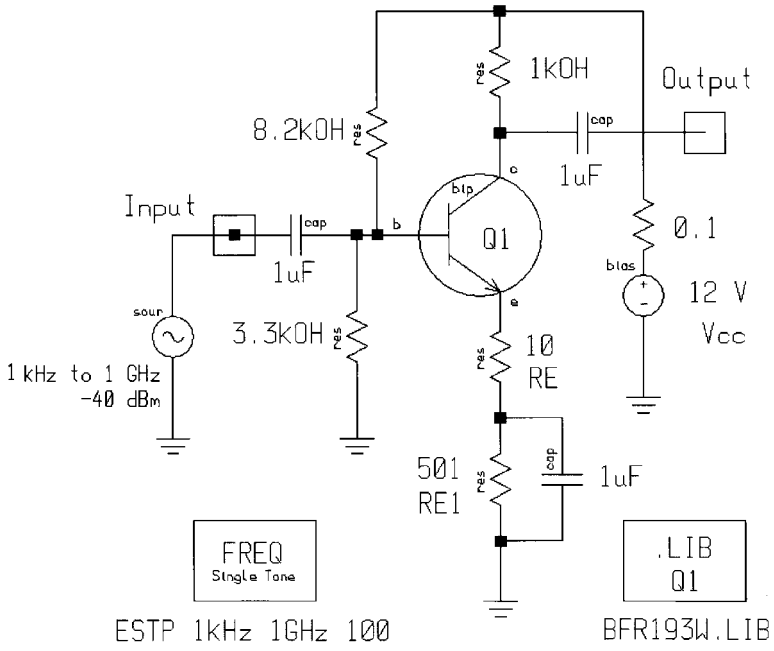

Figure 3-55 BJT amplifier example.

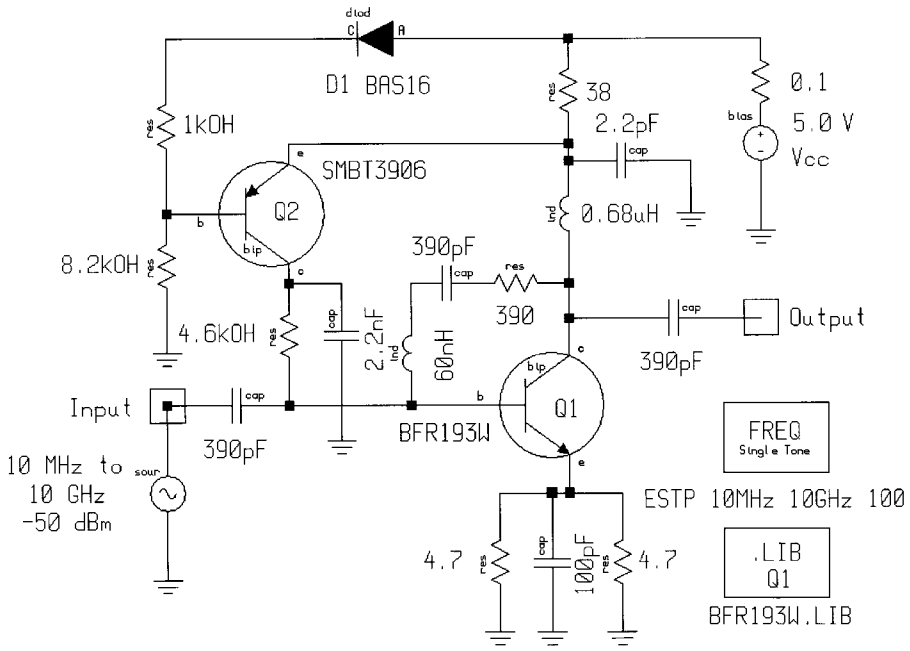

Figure 3-56 Wideband amplifier with active biasing. The 4.7-Ω resistors in the BFR193W emitter compensate the circuit's gain at low frequencies.

that is intended to be operated at significantly higher currents, then f_T will suffer while the other two parameters are less affected.

The dc input power translates into thermal dissipation, and Figure 3-60 is a plot of the noise figure as a function of temperature with and without emitter feedback. The heavy dc stabilization prevents a significant effect on the other parameters. The actual dc shift is from 5.0 to 5.2 mA for a temperature change of 70 K.

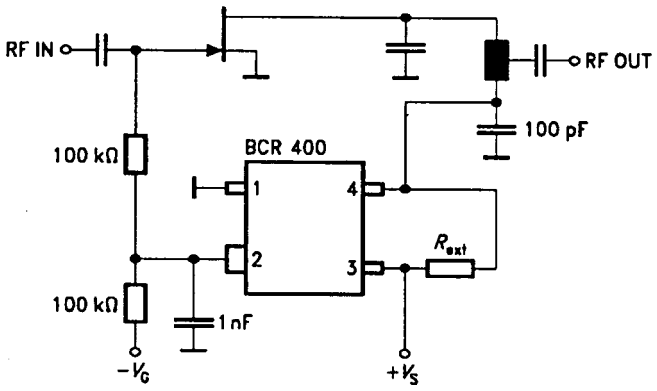

Figure 3-57 The Siemens BCR400 bias controller applied to a GaAsFET.

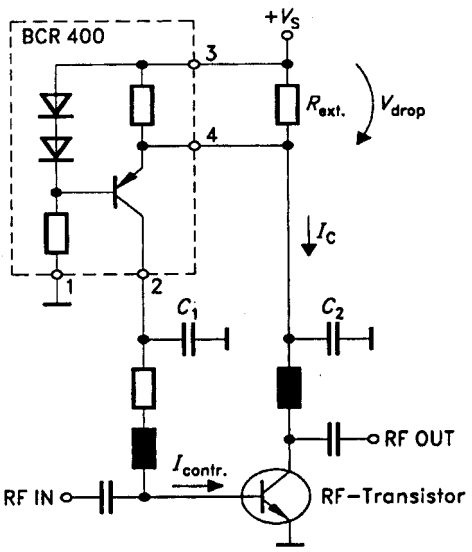

Figure 3-58 The Siemens BCR400 bias controller applied to a BJT.

As far as FETs are concerned, the enhancement types, typically PMOS, can use a similar type of bias, while the NMOS types complicate the designer's life as they require a negative gate voltage. For low-noise operation, these devices are operated somewhat close to the pinchoff voltage. Putting a source resistor in place causes mostly headaches simply because the gain is so high that the transistors are always ready to find a frequency at which they love to oscillate. The transistor will look for every possible parasitic to turn the amplifier into an oscillator.

3-2 AMPLIFIER GAIN, STABILITY, AND MATCHING

Most semiconductor manufacturers describe their devices these days by providing either their *S* parameters (small-signal) or SPICE-type parameters (large-signal). One of our headaches in writing this book has been that many of the published models don't translate

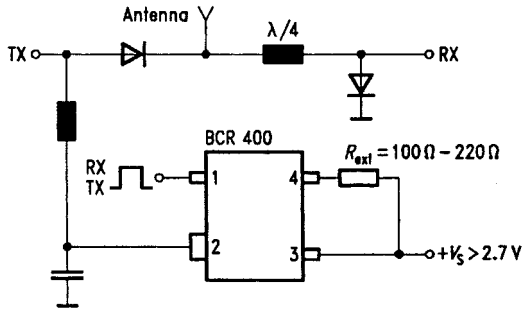

Figure 3-59 The Siemens BCR400 bias controller applied to TR switching.

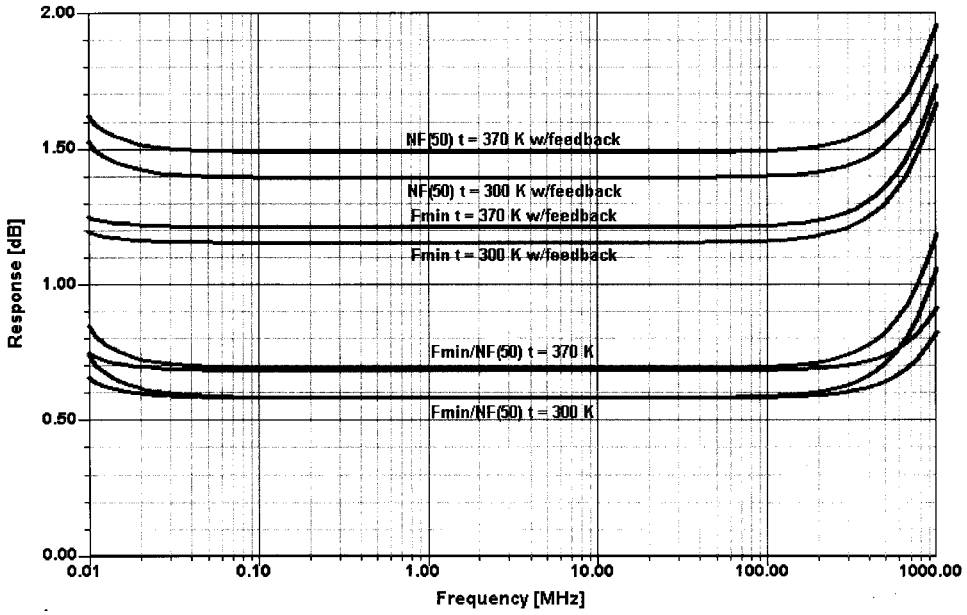

Figure 3-60 F_{min} and NF for the amplifier in Figure 3-55, with and without emitter feedback, at 300 and 370 K.

from large signal to small signal without giving unexpected or false results. Despite the availability of tools to do it right, many companies still can only provide data that are practically inadequate, and unfortunately the CAD manufacturers then get the blame for results for which they are not really responsible.

Tables 3-9 and 3-10 show typical data for a bipolar transistor (the BFP420 by Siemens). The next section presents a summary of the derivation and use of *S* parameters as published by Hewlett-Packard and others.

3-2-1 Scattering Parameter Relationships

Scattering (*S*) parameters characterize a network in terms of incident and reflected waves (Figures 3-61 and 3-62).

$$b_1 = s_{11}a_1 + s_{12}a_2 \tag{3-122}$$

$$b_2 = s_{21}a_1 + s_{22}a_2 \tag{3-123}$$

Notice that

$$s_{11} = \frac{b_1}{a_1} = \frac{V_1/I_1 - Z_0}{V_1/I_1 + Z_0} = \frac{Z_1 - Z_0}{Z_1 + Z_0} \tag{3-124}$$

and

[a]Input matched for minimum noise figure, output for maximum gain.
[b]$Z_S = Z_L = 50\ \Omega$.

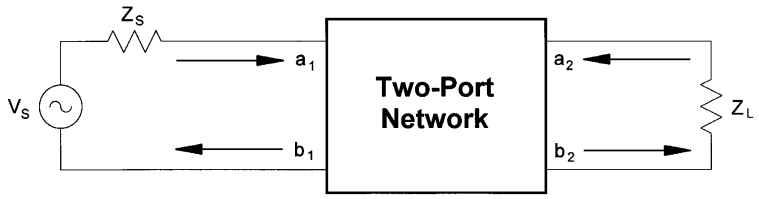

Figure 3-61 *S* parameters characterize a network (a two-port is shown) in terms of incident waves (a_1, a_2) and reflected waves (b_1, b_2). Figure 3-62 shows the flow graph for this network.

$$Z_1 = Z_0 \frac{(1 + s_{11})}{(1 - s_{11})} \tag{3-125}$$

where $Z_1 = V_1/I_1$ is the input impedance at Port 1.

This relationship between reflection coefficient and impedance is the basis of the Smith Chart transmission-line calculator. Consequently, the reflection coefficients S_{11} and S_{22} can be plotted on Smith charts, converted directly to impedance, and easily manipulated to determine matching networks for optimizing a circuit design.

The above equations show one of the important advantages of *S* parameters: They are simply gains and reflection coefficients, both familiar quantities to engineers. By comparison, some of the *Y* parameters described earlier in the article are not so familiar. For example, the *Y* parameter corresponding to insertion gain S_{21} is the "forward transadmittance," Y_{21}. Clearly, insertion gain gives by far the greater insight into the operation of the network.

S parameters are simply related to power gain and mismatch loss, quantities that are often of more interest than the corresponding voltage functions:

$$|s_{11}|^2 = \frac{\text{Power reflected from the network input}}{\text{Power incident on the network input}} \tag{3-126}$$

$$|s_{21}|^2 = \frac{\text{Power delivered to a } Z_0 \text{ load}}{\text{Power available from } Z_0 \text{ source}} \tag{3-127}$$

$$|s_{12}|^2 = \text{Reverse transducer power gain with } Z_0 \text{ load and source.} \tag{3-128}$$

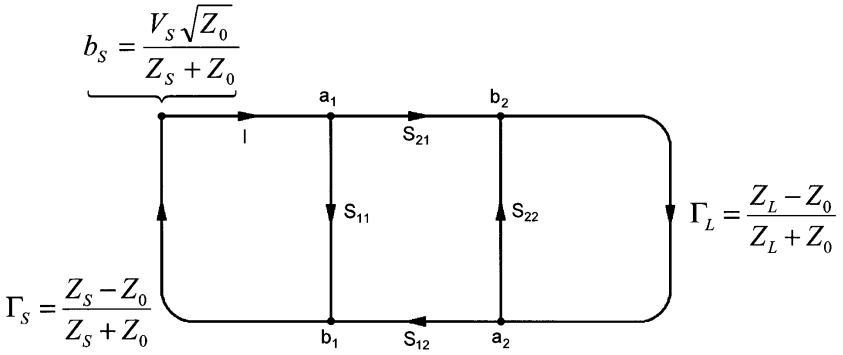

Figure 3-62 Flow graph for the network shown in Figure 3-61.

$$|s_{22}|^2 = \frac{\text{Power reflected from the network output}}{\text{Power incident on the network output}} \tag{3-129}$$

From this we obtain:
Input reflection coefficient with arbitrary Z_L:

$$s'_{11} = s_{11} + \frac{s_{12}s_{21}\Gamma_L}{1 - s_{22}\Gamma_L} \tag{3-130}$$

Output reflection coefficient with arbitrary Z_S:

$$s'_{22} = s_{22} + \frac{s_{12}s_{21}\Gamma_S}{1 - s_{11}\Gamma_S} \tag{3-131}$$

Voltage gain with arbitrary Z_L and Z_S:

$$A_V = \frac{V_2}{V_1} = \frac{s_{21}(1 + \Gamma_L)}{(1 - s_{22}\Gamma_L)(1 + s'_{11})} \tag{3-132}$$

$$\text{Power gain} = \frac{\text{Power delivered to load}}{\text{Power input to network}}:$$

$$G = \frac{|s_{21}|^2 (1 - |\Gamma_L|^2)}{(1 - |s_{11}|^2) + |\Gamma_L|^2 (|s_{22}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_L N)} \tag{3-133}$$

$$\text{Available power gain} = \frac{\text{Power available from network}}{\text{Power available from source}}:$$

$$G_A = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)}{(1 - |s_{22}|^2) + |\Gamma_S|^2 (|s_{11}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_S M)} \tag{3-134}$$

$$\text{Transducer power gain} = \frac{\text{Power delivered to load}}{\text{Power available from source}}:$$

$$G_T = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|(1 - s_{11}\Gamma_S)(1 - s_{22}\Gamma_L) - s_{12}s_{21}\Gamma_L\Gamma_S|^2} \tag{3-135}$$

Unilateral transducer power gain ($S_{12} = 0$):

$$G_{Tu} = \frac{|s_{21}|^2(1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|1 - s_{11}\Gamma_S|^2|1 - s_{22}\Gamma_L|^2}$$

$$= G_0 G_1 G_2 \tag{3-136}$$

$$G_0 = |s_{21}|^2 \tag{3-137}$$

$$G_1 = \frac{1 - |\Gamma_S|^2}{|1 - s_{11}\Gamma_S|^2} \tag{3-138}$$

$$G_2 = \frac{1 - |\Gamma_L|^2}{|1 - s_{22}\Gamma_L|^2} \tag{3-139}$$

Maximum unilateral transducer power gain when $|S_{11}| < 1$ and $|S_{22}| < 1$:

$$G_u = \frac{|s_{21}|^2}{|(1 - |s_{11}|^2)(1 - |s_{22}|)^2|}$$

$$= G_0\, G_{1\max}\, G_{2\max} \tag{3-140}$$

$$G_{i\max} = \frac{1}{1 - |s_{ii}|^2} \quad i = 1, 2 \tag{3-141}$$

Constant-gain circles (unilateral case: $S_{12} = 0$):

- Center of constant-gain circle is on line between center of Smith Chart and point representing S_{ii}^*
- Distance of center of circle from center of Smith Chart:

$$r_i = \frac{g_i |s_{ii}|}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-142}$$

- Radius of circle:

$$\rho_i = \frac{\sqrt{1 - g_i}(1 - |s_{ii}|^2)}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-143}$$

where $i = 1, 2$ and

$$g_i = \frac{G_i}{G_{i\max}} = G_i(1 - |s_{ii}|^2) \tag{3-144}$$

Unilateral figure of merit:

$$u = \frac{|s_{11}s_{22}s_{12}s_{21}|}{|(1 - |s_{11}|^2)(1 - |s_{22}|^2)|} \tag{3-145}$$

Error limits of unilateral gain calculation:

$$\frac{1}{(1 + u^2)} < \frac{G_T}{G_{Tu}} < \frac{1}{(1 - u^2)} \tag{3-146}$$

Conditions for absolute stability. No passive source or load will cause a network to oscillate if a, b, and c are all satisfied:

$$\text{a.}\quad |s_{11}| < 1, |s_{22}| < 1 \tag{3-147}$$

$$\text{b.} \quad \left| \frac{|s_{12}s_{21}| - |M^*|}{|s_{11}|^2 - |D|^2} \right| > 1 \tag{3-148}$$

$$\text{c.} \quad \left| \frac{|s_{12}s_{21}| - |N^*|}{|s_{22}|^2 - |D|^2} \right| > 1 \tag{3-149}$$

where

$$D = s_{11}s_{22} - s_{12}s_{21} \tag{3-150}$$

$$M = s_{11} - Ds_{22}^* \tag{3-151}$$

$$N = s_{22} - Ds_{11}^* \tag{3-152}$$

Condition that a two-port network can be simultaneously matched with a positive real source and load:

$$K > 1 \tag{3-153}$$

$$K = \frac{1 + |D|^2 - |s_{11}|^2 - |s_{22}|^2}{2|s_{12}s_{21}|} \tag{3-154}$$

Source and load for simultaneous match

$$\Gamma_{mS} = M^* \left[\frac{B_1 \pm \sqrt{B_1^2 - 4|M|^2}}{2|M|^2} \right] \tag{3-155}$$

$$\Gamma_{mL} = N^* \left[\frac{B_2 \pm \sqrt{B_2^2 - 4|N|^2}}{2|N|^2} \right] \tag{3-156}$$

where

$$B_1 = 1 + |s_{11}|^2 - |s_{22}|^2 - |D|^2 \tag{3-157}$$

$$B_2 = 1 + |s_{22}|^2 - |s_{11}|^2 - |D|^2 \tag{3-158}$$

Maximum available power gain. If $K > 1$,

$$G_{A\max} = \left| \frac{s_{21}}{s_{12}} (K \pm \sqrt{K^2 - 1}) \right| \tag{3-159}$$

In conclusion, *a two-port network (active or passive) is unconditionally stable* when

$$K > 1$$

$$|S_{12}S_{21}| < 1 - |S_{11}|^2$$

and

$$|S_{12}S_{21}| < 1 - |S_{22}|^2$$

3-2-2 Low-Noise Amplifiers

A low-noise amplifier combines a low noise figure, reasonable gain, and stability without oscillation over its entire useful frequency range. These amplifiers are typically operated in Class A, which is characterized by a bias point more or less at the center of maximum current and voltage capability of the device used, and by RF current and voltages that are sufficiently small relative to the bias point that the bias point does not shift. This means that an amplifier operating at, say, 3 V and 1 mA for low-noise, high-gain operation will not be Class A if the RF current is larger than 0.1% of the current or the voltage swing is more than 0.1% of the current swing. These amplifiers can be designed using standard linear *S* parameters, which are (hopefully) available from the device manufacturer for the bias point of interest. If suitable *S* parameters are not available, we must resort to a CAD tool that allows us to determine a device's bias point as a function of its bias network and to generate small-signal *S* parameters for the device. With suitable *S* parameters in hand, and assuming the amplifier will be frequency selective, we then connect tuned circuits to the input and output to provide matching.

In designing amplifiers, the "power gain" of a circuit is mentioned frequently. This is actually deceptive because power gain is somewhat associated with dc power dissipation, and in considering it, we are on the verge of discussing large-signal performance. Therefore it would be better to define the power gain as a function of operating mode, such as "Class A power gain." We have also outlined that there is a difference between noise matching and gain matching. If we can be allowed to step back into the vacuum-tube era for a moment, the reader should be reminded that the difference between power gain and noise matching had to do with the grid-plate feedback capacitance which, via the Miller effect, showed up in parallel with the input. This actually detunes the input slightly off-center relative to the best gain. The reason for this is that as the feedback increases, Y_{12} or S_{12} starts playing a role, and the frequently assumed unilateral case no longer exists. The difference between noise matching and gain matching increases as a function of frequency. It can be brought closer together if appropriate reactive feedback is used. The two choices are: (1) increase the emitter or source inductance or (2) slightly increase the base-to-collector/gate-to-drain capacitance. Needless to say, the penalty for this is potential instability, and a sweep must be done from a few megahertz to several gigahertz to make sure the stage doesn't "take off."

The most efficiency this circuit provides is 50%; even this is a theoretical limit if one tries to keep distortion under control.

While the equation $P_{\text{OUT}} = (V_{\text{bat}} - V_{\text{sat}})^2/2R_L$ is valid, it really applies only to power amplifiers in the sense that for Class A, high-gain operation R_L can be made significantly higher as the absolute power output is not the important item. While the supply voltage V_{bat} is always known, the saturation voltage V_{sat} has to be obtained by the load line dc analysis. Note: The RF saturation voltage is always higher than the dc one. When looking at Figure 3-63, it becomes obvious that the conducting angle is 180°, which implies that the entire sine wave at the input is reproduced as an essentially undistorted sine wave at the output.

We can now calculate the components of the distorted current in separating them into the dc component, the fundamental frequency, and its first and second harmonics:

$$\text{Fundamental} \quad i_{c1} = i_{\text{peak}} \cdot f_1(\Theta) \tag{3-160}$$

$$\text{Second harmonic} \quad i_{c2} = i_{\text{peak}} \cdot f_2(\Theta) \tag{3-161}$$

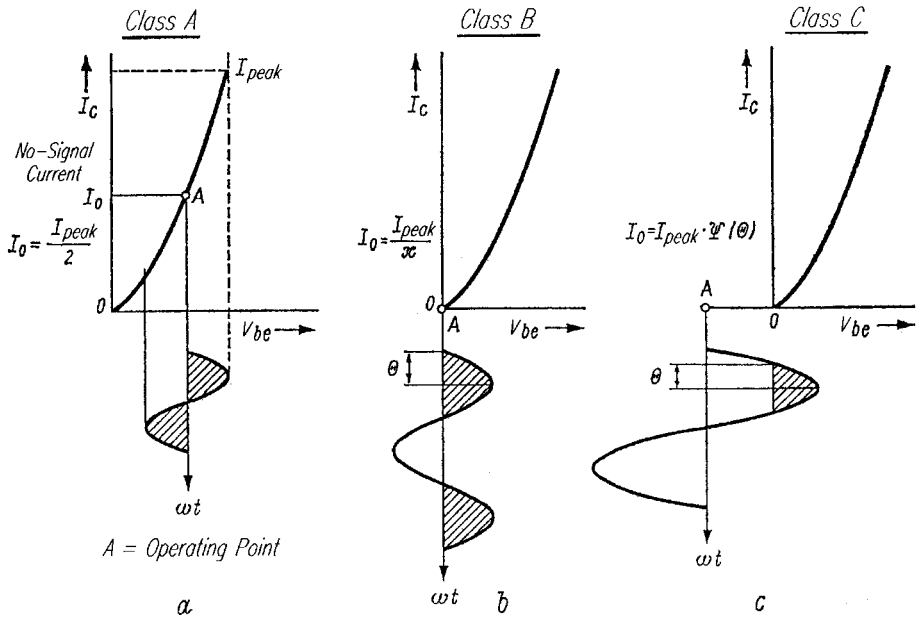

Figure 3-63 Definitions of Class A, B, and C operation, including conduction angle (Θ). Figure 3-64 shows the determination of Θ.

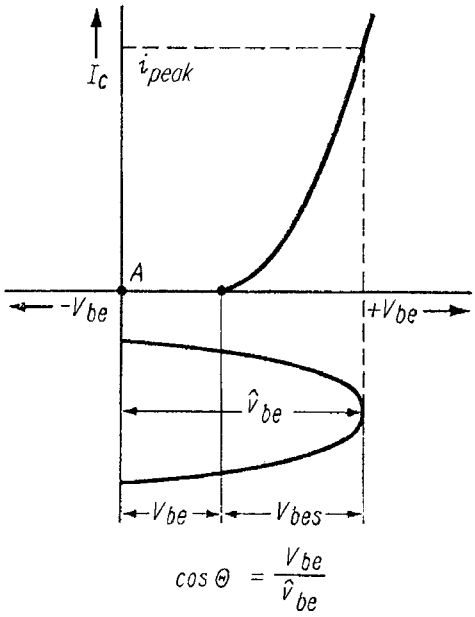

Figure 3-64 Determination of the conduction angle Θ from the base threshold voltage V_{be} and the base RF voltage $\hat{v}_{be}$.

$$\text{Third harmonic} \quad i_{c3} = i_{\text{peak}} \cdot f_3(\Theta) \tag{3-162}$$

For the collector dc current we obtain

$$I_c = i_{\text{peak}} \cdot \Psi(\Theta) \tag{3-163}$$

The frequency-dependent currents are a function of the conduction angle Θ. Figure 3-65 shows these transfer characteristics as a function of the conduction angle for a square-law dynamic transfer function; for higher-order transfer functions, the values don't change much. Tables for this can be found in various sources, including Clark and Hess [47]. Since the transistors exhibit a mixture of an exponential and a linear transfer characteristic (due to the unwanted parasitic emitter/source and collector/drain resistances when building the device), the plot in figure 3-65 is sufficiently valid for practical purposes. This function plot allows us to determine the amplitude of the current at various frequencies once the conducting angle has been set. For example, for Θ = 70°, the maximum collector current is $i_{\text{peak}} = I_c/0.253$, meaning that the peak current of the transistor is approximately four times larger than the dc value one would measure. Once the peak collector current is known, the fundamental and harmonic currents can be calculated:

$$i_{c1} = \frac{I_c}{0.253} f_1(\Theta)$$

$$i_{c1} = \frac{I_c}{0.253} 0.436$$

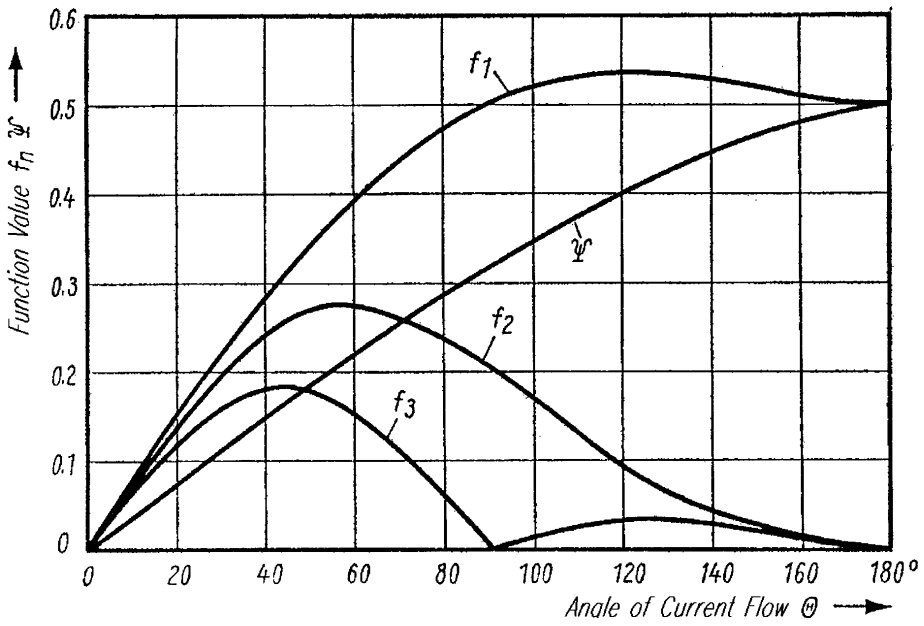

Figure 3-65 Function values for the fundamental, second harmonic, third harmonic, and dc components (f_1, f_2, f_3, and Ψ, respectively) versus device conduction angle.

In order to obtain i_{c2} and i_{c3} one needs to do the same calculations as above with the appropriate functions for f_2 and f_3.

It becomes obvious that the distorted collector current generates a lot of harmonics, which definitely requires sufficient low-pass filtering at the output, even for Class A operation. We already stated that for Class A operation the conduction angle is 180° while it is 90° for Class B operation. The conduction angle for Class C operation can be solved from the ratio of the knee voltage V_{be} and the peak value of the ac voltage at the base. We find

$$\cos \Theta = \frac{V_{be}}{\hat{V}_{be}} \tag{3-164}$$

where $\Theta = 90°$ and $V_{be} = 0$. Given the voltage V_{bes}, which determines the peak collector current (up to i_c peak), we can calculate the effective RF voltage at the base as

$$\hat{v}_{be} = \frac{v_{bes}}{1 - \cos \Theta} \tag{3-165}$$

Therefore, the peak value of v_b becomes v_{bes} for $\Theta = 90°$.

The necessary base voltage V_{be} for maximum current is obtained by the transistor model. Then one finds the threshold voltage at which the transistor becomes conductive and by using Eqs. (3-164) and (3-165) it can be checked whether this results in the appropriate conducting angle. An example for this will be shown in the high-power stage section.

Design Guidelines. The design of a one-stage amplifier consists of finding

- An input lossless matching network M_1
- An input lossless matching network M_2

so that the maximum or desired transistor gain is achieved over the operating bandwidth of the amplifier. Usually, the common-emitter or common-source configuration is chosen for highest gain per stage. If the stability factor K is greater than unity, these two networks can be found to give the maximum available gain $G_{\max}$. If the stability factor is less than or equal to unity, the amplifier could be terminated in a matching structure that causes oscillation; that is, $G_{\max}$ is infinite. This should be avoided by locating the regions of instability in the Γ_G and Γ_L planes. The input and output terminations (Γ_G and Γ_L) must be designed to avoid the instability regions. Usually, these unstable regions are near the conjugate match for S_{11} and S_{22}. Thus, a stable amplifier will require some input and/or output mismatch if K is less than or equal to unity.

There are at least two alternative approaches for potentially unstable amplifiers:

1. Add resistive matching elements to make $K \geq 1$ and $G_{\max} \approx G_{ms}$.
2. Add feedback to make $K \geq 1$ and $G_{\max \approx Gms}$.

For narrowband amplifiers, it is usually recommended that one accept a transistor with $K < 1$, design the amplifier for a gain approaching G_{ms}, and ensure that the Γ_G and Γ_L terminations provide stability at all frequencies, both inside and outside the amplifier passband.

The design of an amplifier would usually have the following specifications:

Gain and gain flatness
Bandwidth and center frequency ($f_2 - f_1, f_0$)
Noise figure
Linear output power
Input reflection coefficient ($VSWR_{in}$)
Output reflection coefficient ($VSWR_{out}$)
Bias voltage and current

For small-signal amplifiers, the small-signal S parameters are sufficient to complete the design. After selecting an appropriate transistor based on these specifications, a one-stage amplifier design should be considered if sufficient gain can be achieved; otherwise, a two-stage amplifier should be designed.

The circuit topology should be chosen to allow dc bias for the transistor. Usually, RF short-circuited stubs are placed near the transistor to allow dc biasing. If the topology does not allow dc bias, a broadband bias choke or high-resistance bias circuit that does not affect the amplifier performance must be used.

The following steps can be tabulated for the design of a one-stage amplifier (see Figure 3.66):

1. Select a transistor based on a datasheet description of the S parameters, noise figure, and linear output power.
2. Calculate K and G_{max} or G_{ms} versus frequency.
3. For $K > 1$, select the topologies that match the input and output (and allow dc biasing) at the upper band edge f_2. Ideally, this will give G_{max} and $S'_{11} = S'_{22} = 0$. Usually, $S_{12} = 0$ is assumed for the initial design. Next, the topology may be varied to flatten gain versus frequency at the expense of S'_{11} and S'_{22}.
4. For $K < 1$, plot the regions of instability on the Γ_G and Γ_L planes and select topologies that partially match the input and output at the upper band edge and avoid the unstable regions. The gain will approach G_{ms} as an upper limit. Next, the topology may be varied to flatten gain versus frequency.
5. After finding initial M_1 and M_2, plot the amplifier S parameters versus frequency; make adjustments in topology until the specifications for gain, input reflection coefficient, and output reflection are satisfied. Also plot Γ_G and Γ_L versus frequency to verify amplifier stability.
6. Design the dc bias circuit. Lay out the elements of the complete amplifier and check realizability.

As a beginning point in an amplifier design, the circuit topologies may be designed with the assumption that S_{12} is zero. Later, an exact design procedure will be described that includes the topologies with terminations in the stable region.

Design Examples. Throughout this book we always address the issue that we have to separate the battery-operated handheld applications and the more stationary designs like those for base stations. In the case of the handheld or low-voltage applications, the dynamic range requirements are significantly less than the front-end of a base station requires.

NE68133 Matched Amplifier. We will first consider the design of a low-voltage, low-current, low-noise amplifier based on the NEC BJT NE68133. This device was chosen

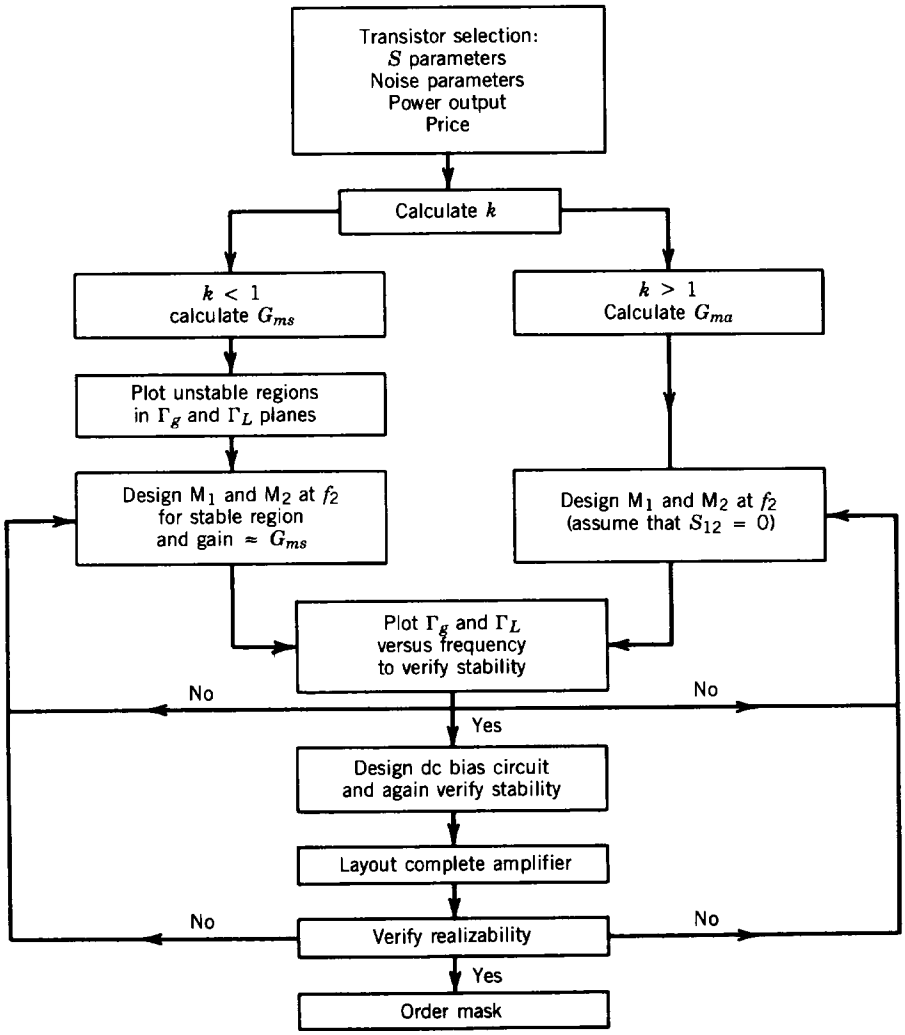

Figure 3-66 Simplified amplifier design procedure.

because it is unconditionally stable, has a minimum noise figure of about 1.2 dB at 7 mA, has 15.5 dB gain, and has an f_T of 8 GHz. While it is possible to start the design based on the published S and noise parameters, we will choose also to involve the nonlinear model, as this allows us more freedom in selecting the bias point including the collector voltage. The actual topology of the amplifier is shown in Figure 3-67.

Determining appropriate values for the input and output matching networks is essential to finalizing the design. The next several figures illustrate matching-network syntheses undertaken with the interactive Smith Tool in Ansoft's Serenade Design Environment. We evaluate the point of tangency as well as stability circles in the source and load planes, indicating that our impedance match will result in a stable amplifier.

In Figure 3-68, the center circle (with 1.1 marker) refers to the noise circle for which the noise figure of 1.1 dB can be obtained. The left circle (with the 14.3 marker) corresponds to

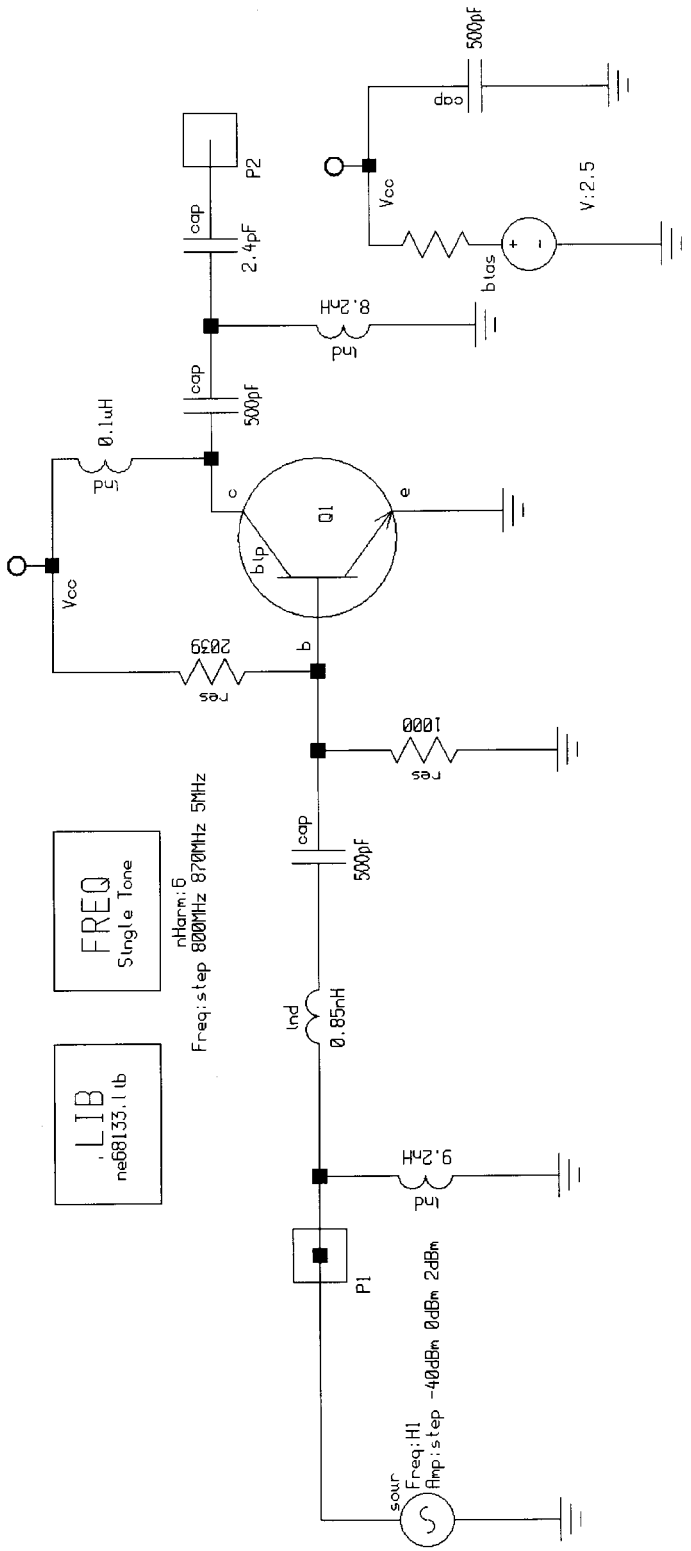

Figure 3-67 The NE68133 low-noise amplifier.

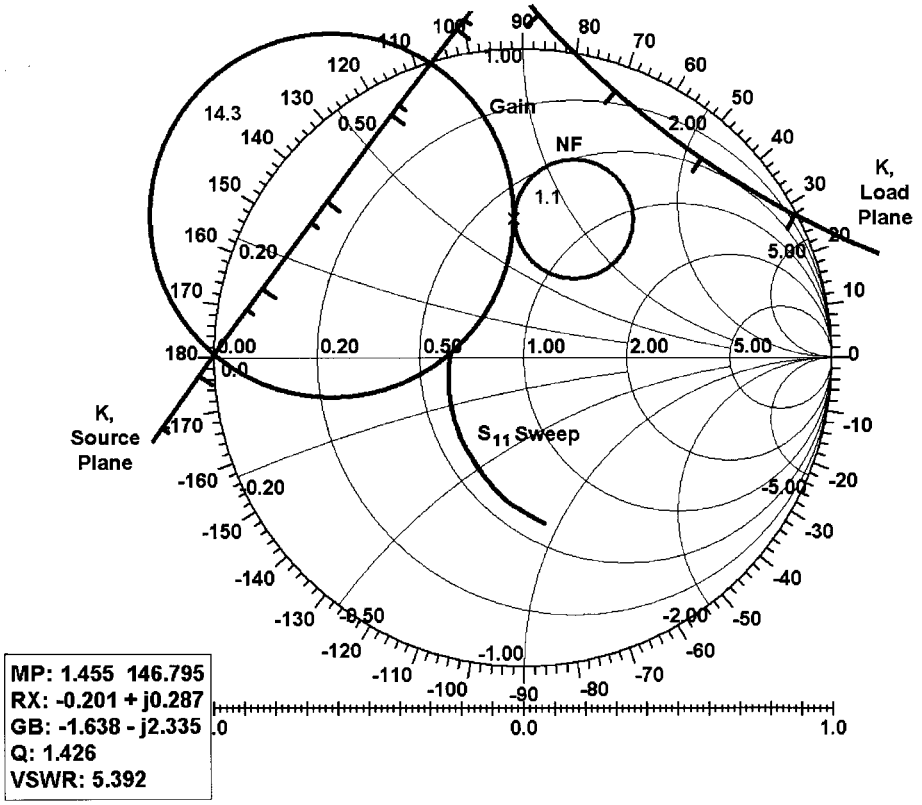

Figure 3-68 Display from the interactive Smith Tool, showing circles for gain, noise figure, and source- and load-plane stability, as well as a sweep of S_{11} versus frequency. In synthesizing an input matching circuit, we choose a single working frequency and work from the chart's origin to the point of tangency between the gain and noise figure circles. See Figure 3-69.

source-plane terminations that correspond to 14.3 dB of available gain. In order to get the required noise figure *and* gain, the input termination must be at the point of tangency of both circles. The arc touching the X axis close to 0.50 is the amplifier's S_{11} response from 800 to 875 MHz. The shallow arc that nearly bisects the 14.3-dB gain circle is actually a portion of the source-plane stability circle; the arc at the top right is a portion of the load-plane stability circle. Because we will be terminating the amplifier input with a value inside the source-plane stability circle, and terminating the amplifier output with a value outside the load-plane stability circle, the amplifier will be unconditionally stable at the frequency at which the match is obtained.

The next task is to obtain the values for the network circuit that matches the input for the 1.1-dB noise figure. A noise matching will not result in the best possible S_{11} matching (Figure 3-69). This translates into an inductor of 9.2 nH to ground and a series inductor of 0.85 nH based on the large-signal model of the NE68133 at the chosen bias point.

After we have determined our input matching network, it is time to find the output matching (Figure 3-70). First, find the termination point on the output plane that corresponds to 14.3-dB gain and 1.1-dB NF at the input plane. The output gain circle goes through the

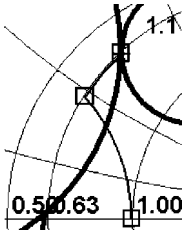

Figure 3-69 Input matching-network extraction, assuming lossless matching components and no parasitic effects.

1.1-dB NF circle at two points, and for reasons of easy matching we selected the lower point. The next step is to find the conjugate reflection coefficient $\Gamma_L = S_{22}^*$. This is the lower square marker in Figure 3-70. The remaining task is to find the matching network that brings this value to 50 Ω. By doing so, we first obtain a shunt inductance $L_{\text{shunt}} = 8.2$ nH and a series capacitor $C_{\text{series}} = 2.4$ pF. Again, these are the values applicable to the large-signal equivalent circuit.

The careful reader will have noticed that we have been avoiding the issue of small-signal exact matching using the manufacturer-supplied parameters. If this is done, the narrow band response shown in Figure 3-71 will be obtained. Therefore, we must optimize the circuit for a better frequency response to obtain the one shown in Figure 3-72.

After this optimization, we were well able to meet the specification of a center band gain of 14 dB and a corresponding NF of 1.1 dB. To show the flatness of the gain, Figure 3-73 shows a gain variation in the range of 0.25 dB.

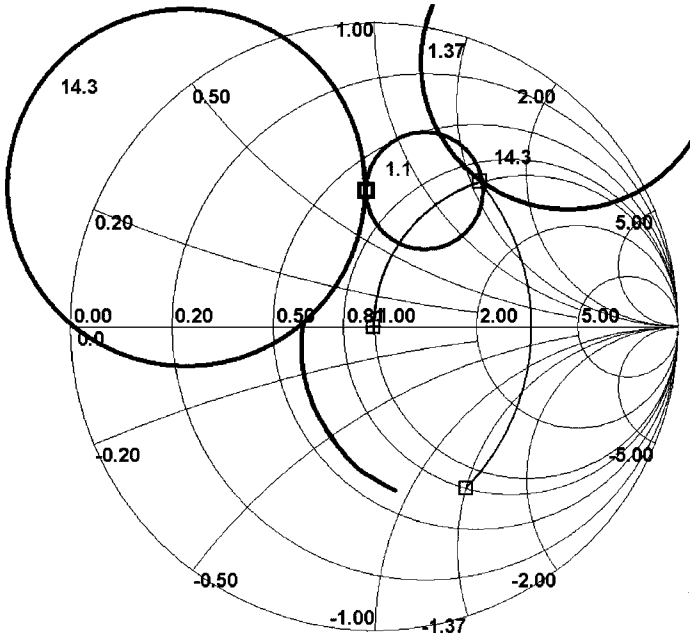

Figure 3-70 Output matching-network extraction.

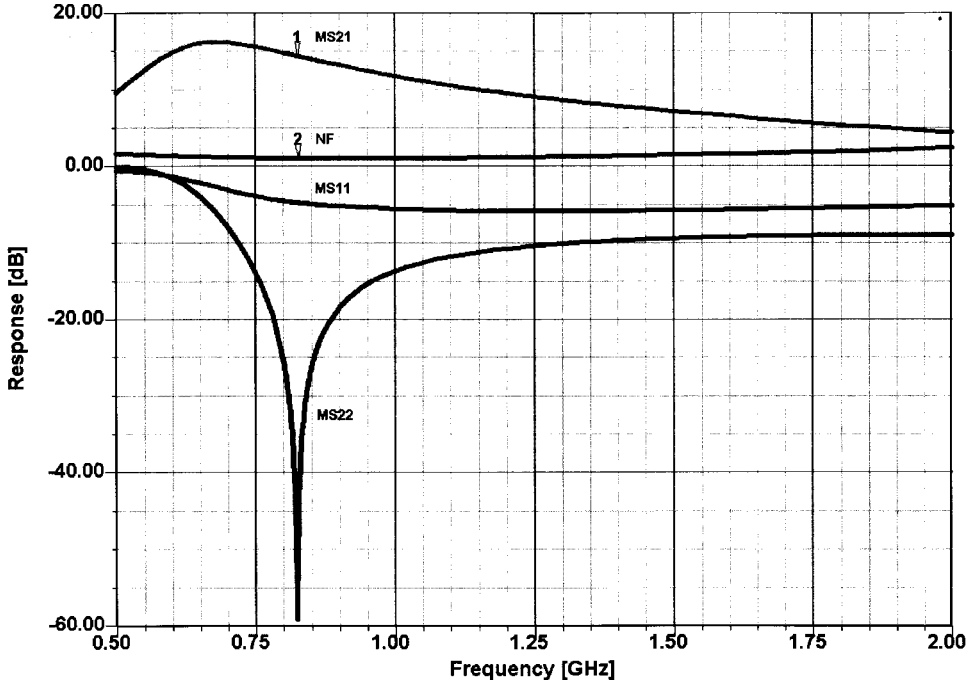

Figure 3-71 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-67.

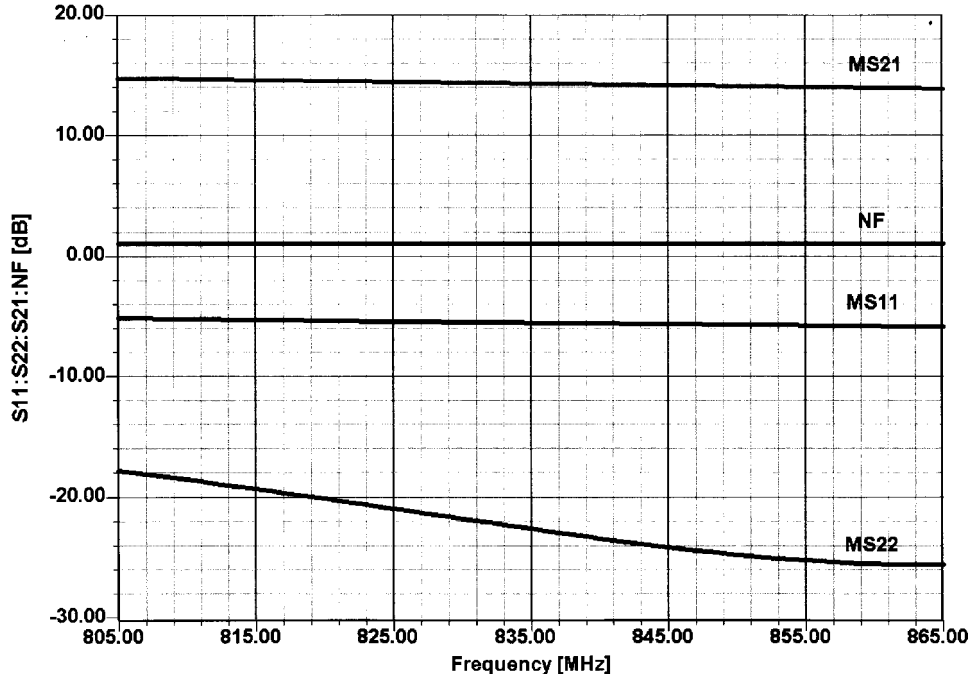

Figure 3-72 Optimized performance of input/output reflection, gain, and noise figure.

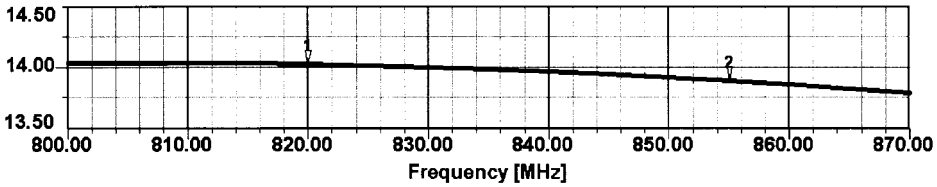

Figure 3-73 High-resolution display of gain as a function of frequency.

The next step is to look into the large-signal performance. The first order of business is to determine the third-order intercept point, which is based on a two-tone analysis. Given the fact that we run the device at low voltage and at a just-reasonable current, the actual intercept point of +13.5 dBm is quite a good number. Figure 3-74 shows the fundamental and third-order outputs. The crossover point between the two, as shown in Chapter 1, is defined as the third-order intercept point. If we had chosen the third harmonic output rather than the fundamental, we would have shown the fifth-order intercept point. The second-order IMD product ($f_1 \pm f_2$) typically can be minimized by input selectivity.

How an amplifier's linearity affects its ability to preserve the characteristics of digital signals is a major concern in wireless design. Figures 3-75 and 3-76 show constellation diagrams with the amplifier handling a PSK signal at drive levels of –40 dBm and +10 dBm, respectively. As expected, we see significant distortion at the higher drive levels due to circuit nonlinearities.

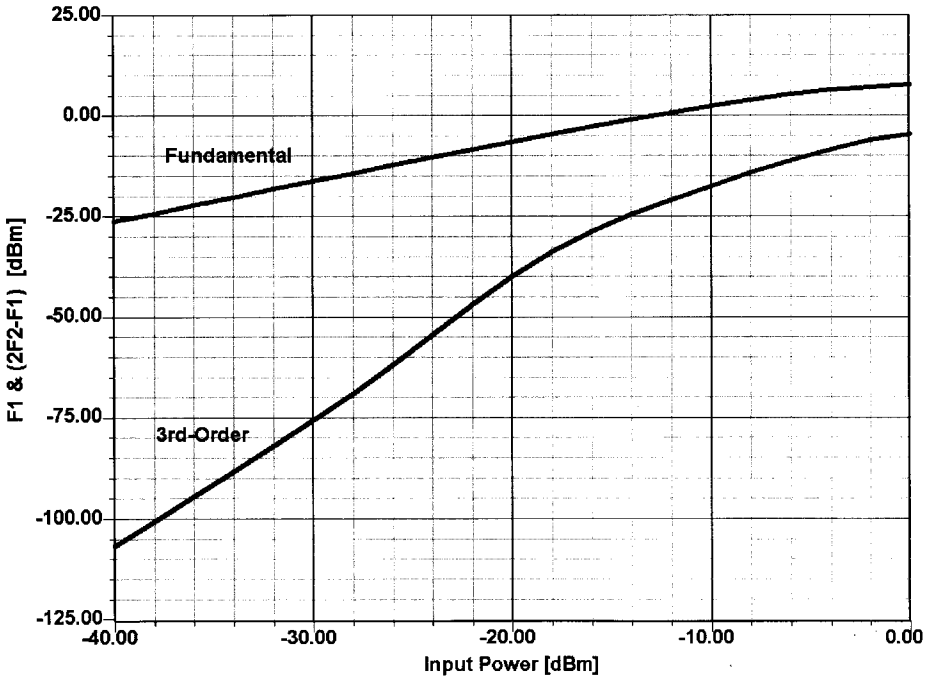

Figure 3-74 Simulated fundamental and third-order IMD outputs of the NE68133 amplifier.

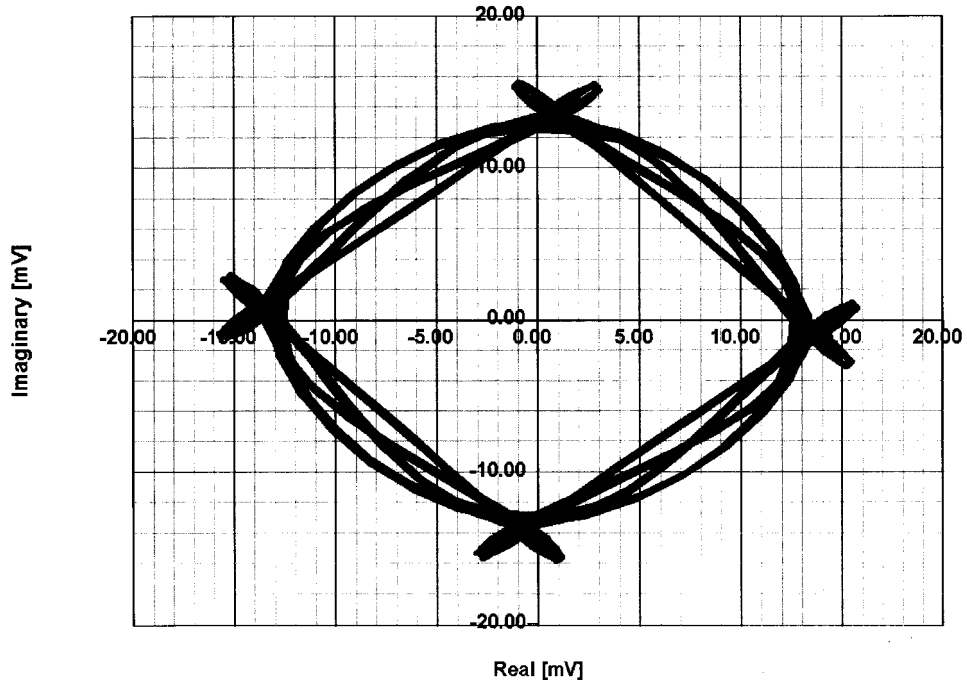

Figure 3-75 Output constellation at –40-dBm input.

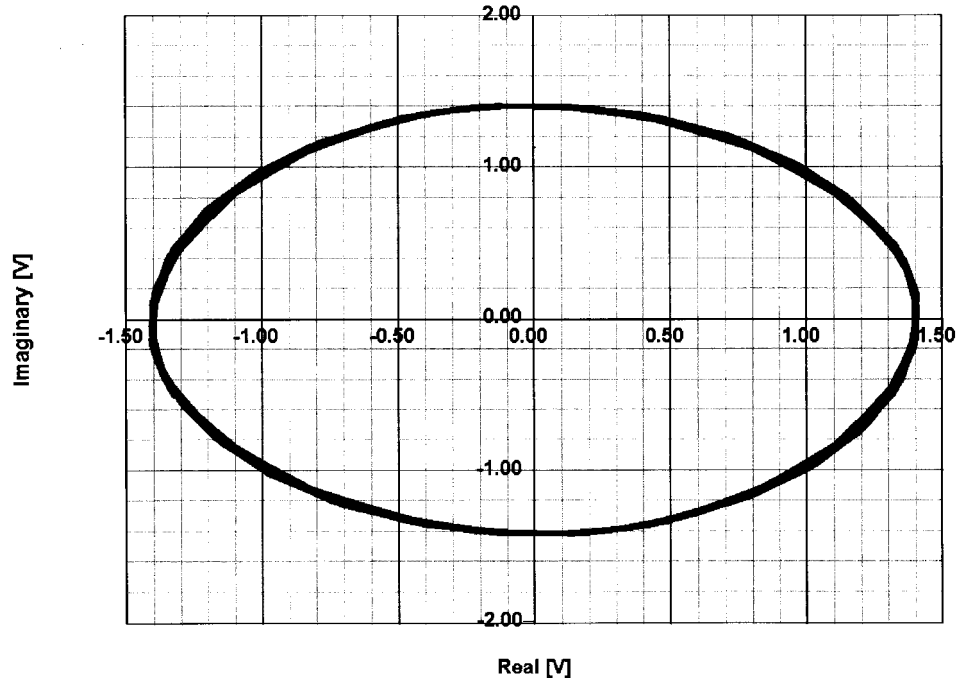

Figure 3-76 Output constellation at 10-dBm input.

BFP420 Matched Amplifier. The NE68133 has an attractive f_T of 8 GHz, but if more gain is needed, one may play with the concept of using a much "hotter" device, such as the BFP420. Recall that the NEC device was unconditionally stable, and our first worry is how the Siemens BFP420 will behave.

A study of Figure 3-77 shows that indeed the NEC device had to be stable all over and therefore was a good basis for a risk-free design. Things change dramatically with the BFP420, for which the K factor is essentially less than 1 up to a corner frequency of 2.75 GHz, where the transistor becomes unconditionally stable. Around 1.75 GHz, the K factor for the NEC transistor barely touches 1. We explained earlier that $G_{\max}$ deviating from the maximum stable gain is a more realistic number, since the conditions for maximum stable gain involve feedback and conjugate matching.

To improve the stability of the BFP420, we will now set out to use the same topology as the previous amplifier but with a resistive feedback between base and collector (Figure 3-78). A good value for this is always somewhere around 200–500 Ω. It must be remembered that this voltage feedback also stabilizes the input and output impedance and reduces the Miller effect because of the feedback being resistive and more dominant.

While the first example covered a fairly narrow frequency band, we are now attempting to cover a much wider frequency range; specifically, from 1.5 to 3 GHz reasonable gain and noise. This, by definition, requires a much higher gain-bandwidth product, and the simple matching network at the input and output provides a nonoptimal input and output matching (Figure 3-79). The feedback introduces some additional noise. This application shows the limits of single-stage UHF/SHF amplifiers with feedback.

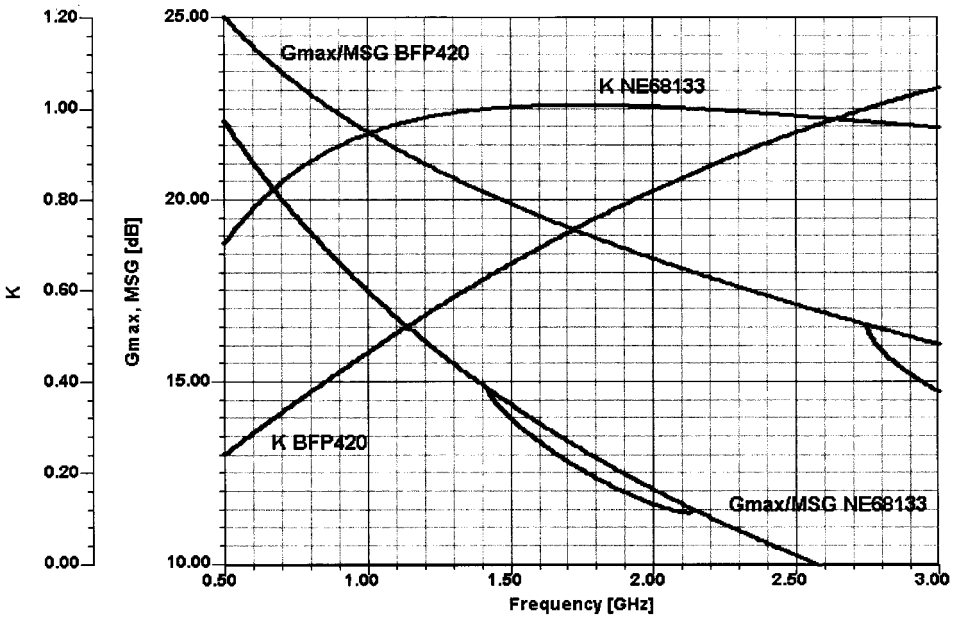

Figure 3-77 Comparison of K, $G_{\max}$, and maximum stable gain (MSG) for the NE68133 and BPF420 BJTs.

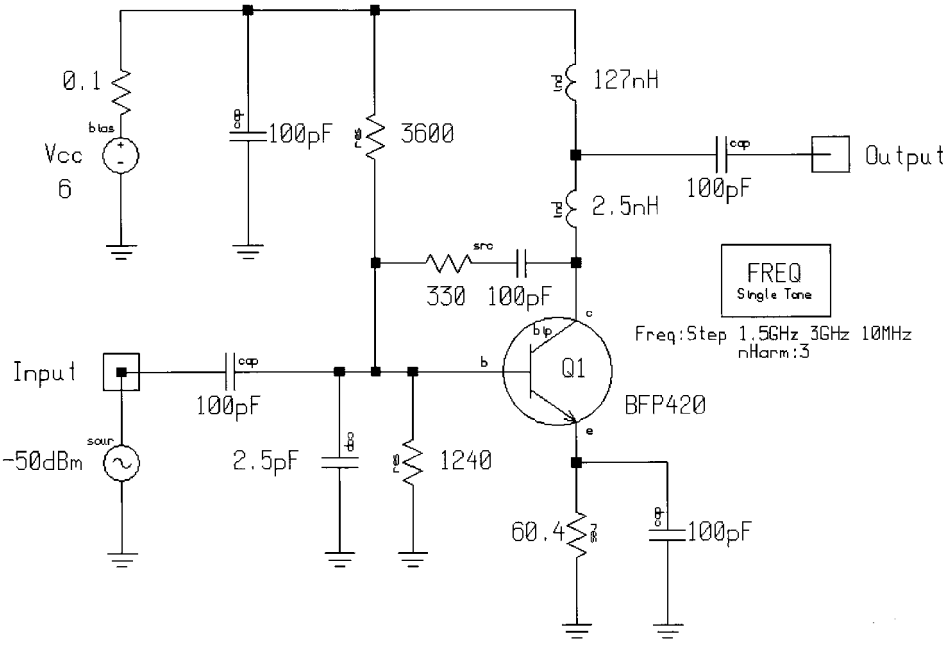

Figure 3-78 BFP420 amplifier with resistive voltage feedback from collector to base.

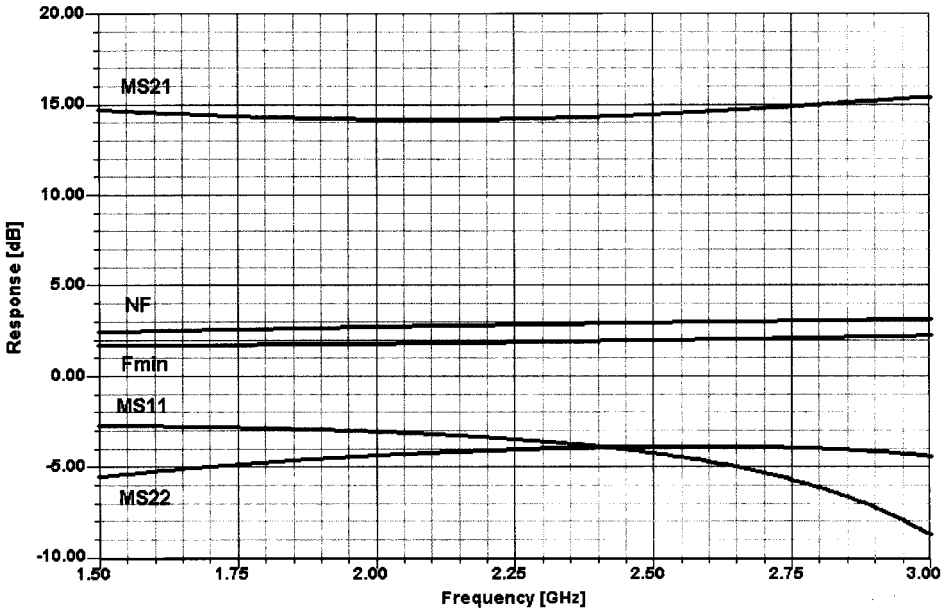

Figure 3-79 Frequency-dependent gain, matching, and noise performance of the BFP420 feedback amplifier.

Narrowband BFP420 Amplifier. Our next attempt will be to design a narrowband input stage that combines very high selectivity with good noise figure. This can only be achieved by using two tuned single-stage resonators with capacitive/magnetic coupling. The following amplifier is tailored to have a center frequency of 900 MHz. The transistor will operate at 12 V/10 mA to have a sufficient dynamic range. The input selectivity is achieved by the use of two top-coupled tuned circuits, followed by a BFP420 (Figure 3-80). The first order of business is to determine the input tuned circuit. The tuning capacitance for the two tuned circuits is arbitrarily set to a manageable 2 pF (small values have too much tolerances and larger values will require smaller inductances, resulting in lower Q). The reactance of the first tuned circuit is

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi \times 9\text{E}8 \times 2\text{E}{-}12} = 88.42\ \Omega$$

The necessary inductance for resonance will be

$$\omega L = 88.42$$

or

$$L = 88.42/\omega = 88.42/(2\pi \times 9\text{E}8) = 15.64\ \text{nH}$$

We will make both tuned circuits identical, but with different loaded Qs. By multiplying 88.42 times the loaded Q (20 for the input resonator and 50 for the output resonator), the resulting parallel-resonant resistance is $88.42 \times 20 = 1768\ \Omega$ at 900 MHz (for the input resonator) and $88.42 \times 50 = 4421\ \Omega$ (for the output resonator). These values are achieved by loading the input with the 50-Ω source and by loading the output with the input of the transistor. Therefore, the input transformation ratio $m_1 = 1768.4/50 = 35.37$. At the output, the equivalent number $m_2 = 4421/50 = 88.42$. For the purpose of simulation, and because it is extremely difficult to find the physical location of the appropriate tap on an air-wound coil for the necessary impedance, we do this "on paper" by incorporating an ideal transformer. We are also going to show later the actual transmission-line-based filter and its modeling. This filter will have a higher insertion loss based on the PC-board material used.

Using our nonlinear simulator, in small-signal ac mode, we obtain the frequency response and noise figure shown in Figure 3-81. In actually building this circuit, there is another problem besides these transformers—the top-coupling capacitor. We have used a grounded-T configuration to obtain a practically realizable value of 36 pF, whose lead inductance will not influence the circuit. (The actual coupling capacitance value for top coupling without the T configuration would have 0.1 pF. We would like to see this value repeatably realized.)

If the actual noise would be calculated relative to the output tuned circuit, the equivalent noise resistor R_n of 5 Ω would now be multiplied by m_2, resulting in 442 Ω. Fortunately, the Serenade simulator has a highly accurate BJT noise model that is both bias and temperature dependent, so the simulator will give us the answer directly.

We have not put any matching circuit at the output and leave this task to the reader. In practice, the slight tilt in the MS_{21} curve in Figure 3-81 would be tuned out. Also note that the minimum noise figure ($F_{\min}$) and the actual 50-Ω noise figure (NF) agree somewhat off center. This has to do with the Miller effect, which results in the well-known difference between noise matching and input-gain matching. By varying the coupling capacitor to move from the overcoupled response, which gives a low noise figure, to a critically coupled

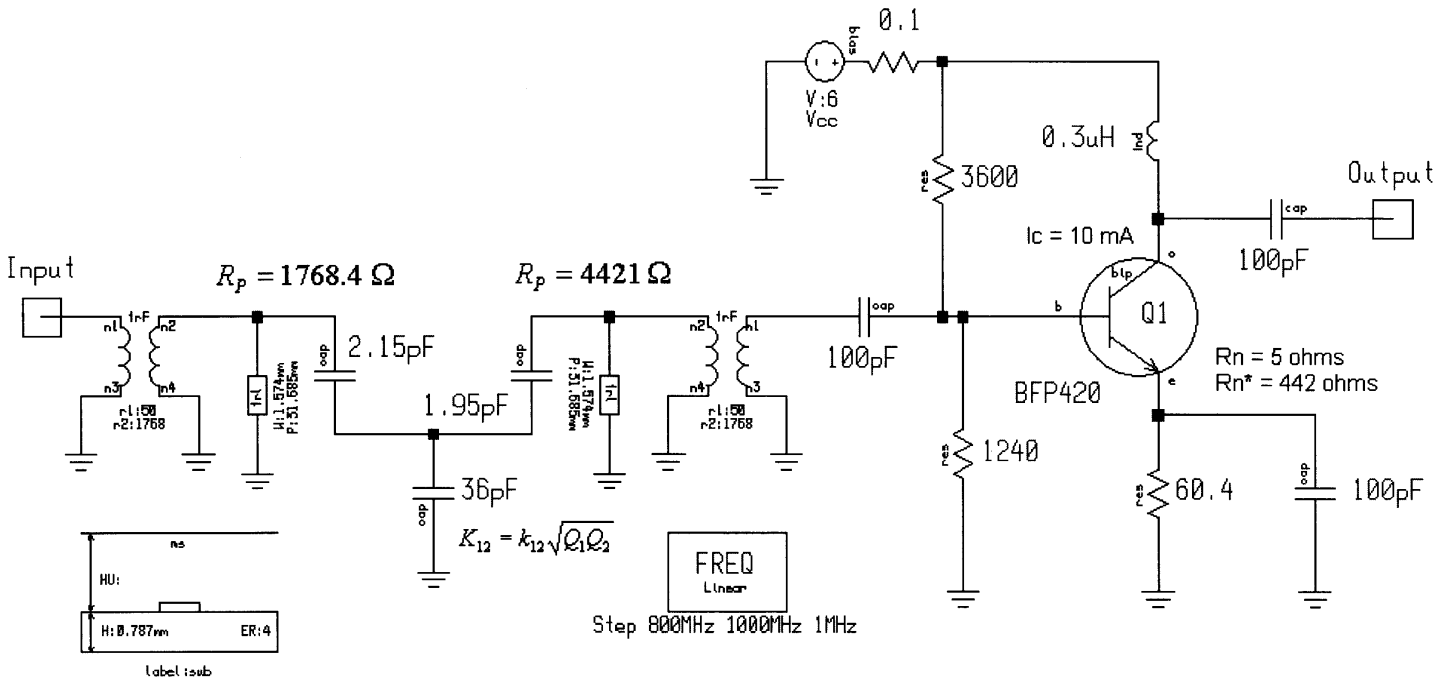

Figure 3-80 BFP420 amplifier with narrowband input filtering. Ideal transformers are used to match the filter's input and output to the input port and the BFP420 base, respectively.

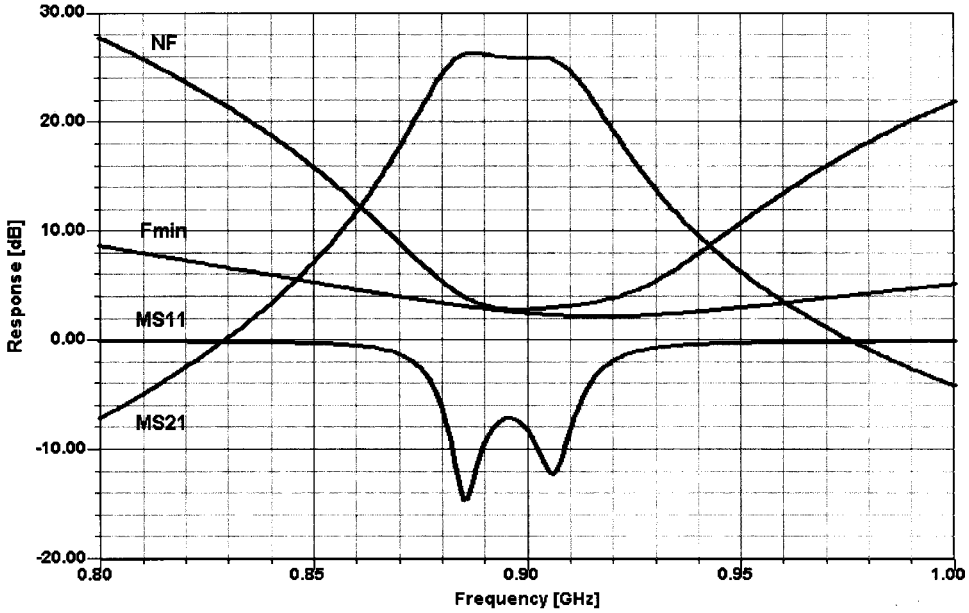

Figure 3-81 Frequency-dependent gain, matching, and noise performance of the narrowband BFP420 amplifier.

response ($K = 1$), we get significantly better selectivity and narrow bandwidth (at the obvious expense of the noise figure) as shown in Figure 3-82.

Since we somewhat compromised by not providing the reader with an actual input and output coupling that can be built, and furthermore, because the inductance in question (15.26 nH) is hard to realize with a high Q, we now show the printed circuit approach for the input filter. By using a Teflon-based material for the PC board, the losses would be less; however, the radiation would be more because ε would go down to 2.1 from the value we used (4). It is also convenient to introduce this filter to show that at higher frequencies, where lumped elements are really no longer available, one has to switch to distributed elements. A list of the commonly used distributed elements will be shown later; the transmission line and T junction are probably the most frequently used elements, followed by spiral and rectangular inductors, and bends.

The actual implementation of the input filter on a printed circuit board requires distributed elements (Figure 3-83). In practice, one has two parallel coupled lines with a tap somewhere toward the ground connection and, for modeling accuracy, we have to introduce a T junction with the appropriate impedance of 50 Ω for the input and a different impedance (if necessary) for the output. The coupling mechanism now is magnetic coupling, since no one can physically change the distance between the transmission lines by tuning some mechanical elements, one has to get it right the first time. This can only be achieved with a high-precision simulator. The reason why these simulators are so expensive is the investment of research time and personnel to produce valid models over a huge frequency and impedance range. Since we are now curious about the frequency response, we have plotted in Figure 3-84 the frequency response, which shows a higher (expected) insertion loss. The PC-board material is partially responsible for this.

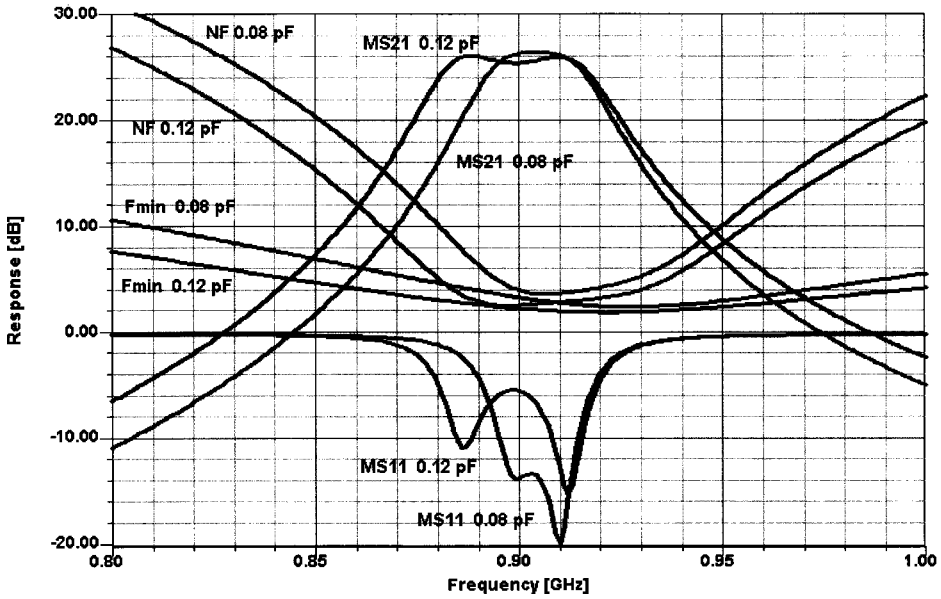

Figure 3-82 Comparison of filter responses with critical coupling (0.08-pF response) and overcoupling (0.12-pF response).

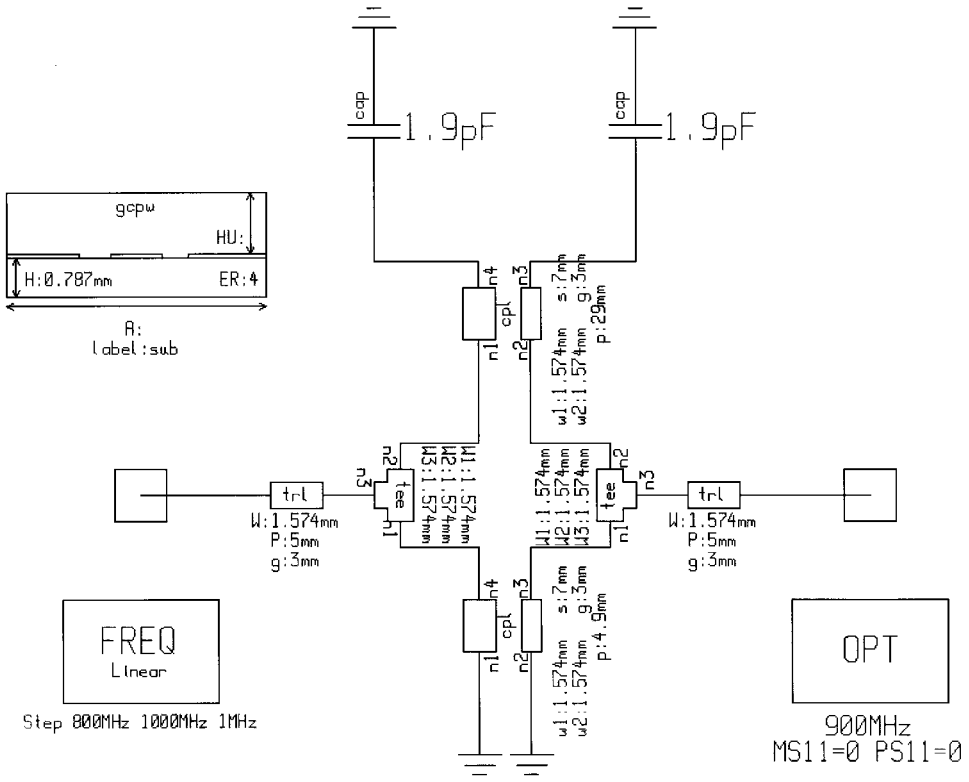

Figure 3-83 Input filter using distributed-element resonators and matching.

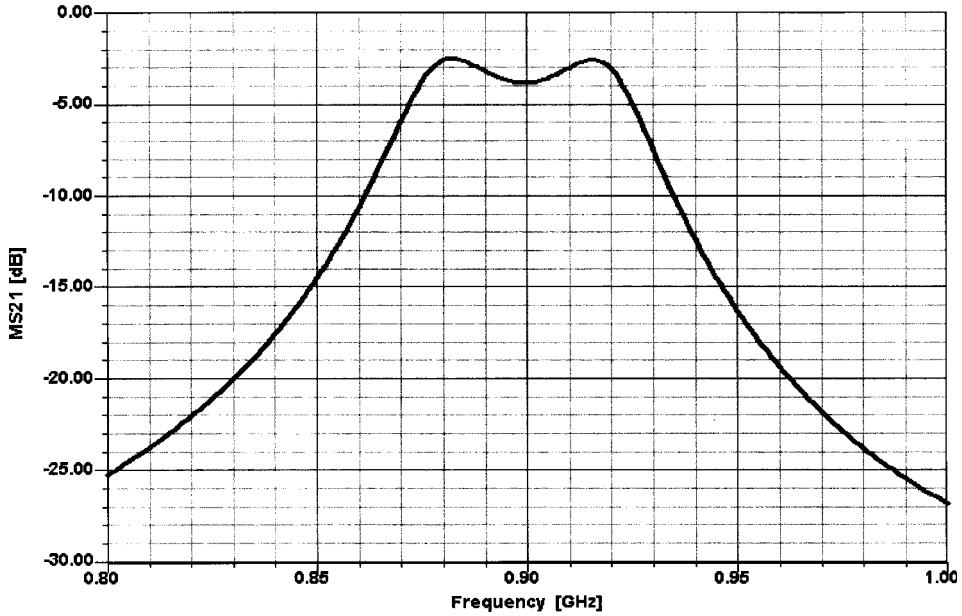

Figure 3-84 Gain versus frequency response for the distributed-element filter.

At the end of this chapter we will have a chance to discuss passive elements as needed for microwave frequencies, and one should consider frequencies above 1500 MHz as microwave frequencies.

GaAsFET Feedback Amplifier. The implementations we have shown so far have been based on bipolar transistors. Figure 3-85 shows a single-stage feedback amplifier using a GaAsFET. The feedback is based around an *LRC* network and some attempts at matching at the input and output are made. Figure 3-86 shows its frequency-dependent gain, matching, and noise performance.

3-2-3 High-Gain Amplifiers

In most cases, high-gain amplifiers receive an already amplified signal, which means we are less concerned about the signal-to-noise ratio but remain concerned about distortion. To reduce distortion, we have two options: (1) increase the dc current in the active device, which always improves the current-related distortion; and (2) add some voltage feedback, which reduces the voltage distortion. In simple terms again, only current feedback can reduce the current-related distortion of a square-law or exponential transfer characteristic and only voltage feedback can reduce the effect of overdrive as a function of the load, but only to some degree. Its main purpose remains to reduce the input impedance to useful values, specifically for FETs, since current feedback increases the input and output impedances. Some ultrasensitive circuits still require Class A operation, but now at higher current levels; these are typically CATV applications, and there are several transistors available that can be operated at 5–15 V but at 60 mA or higher. Because of the higher power consumption, this excludes handheld cordless or cellular telephones. The same circuit as used before (Figure 3-85) for

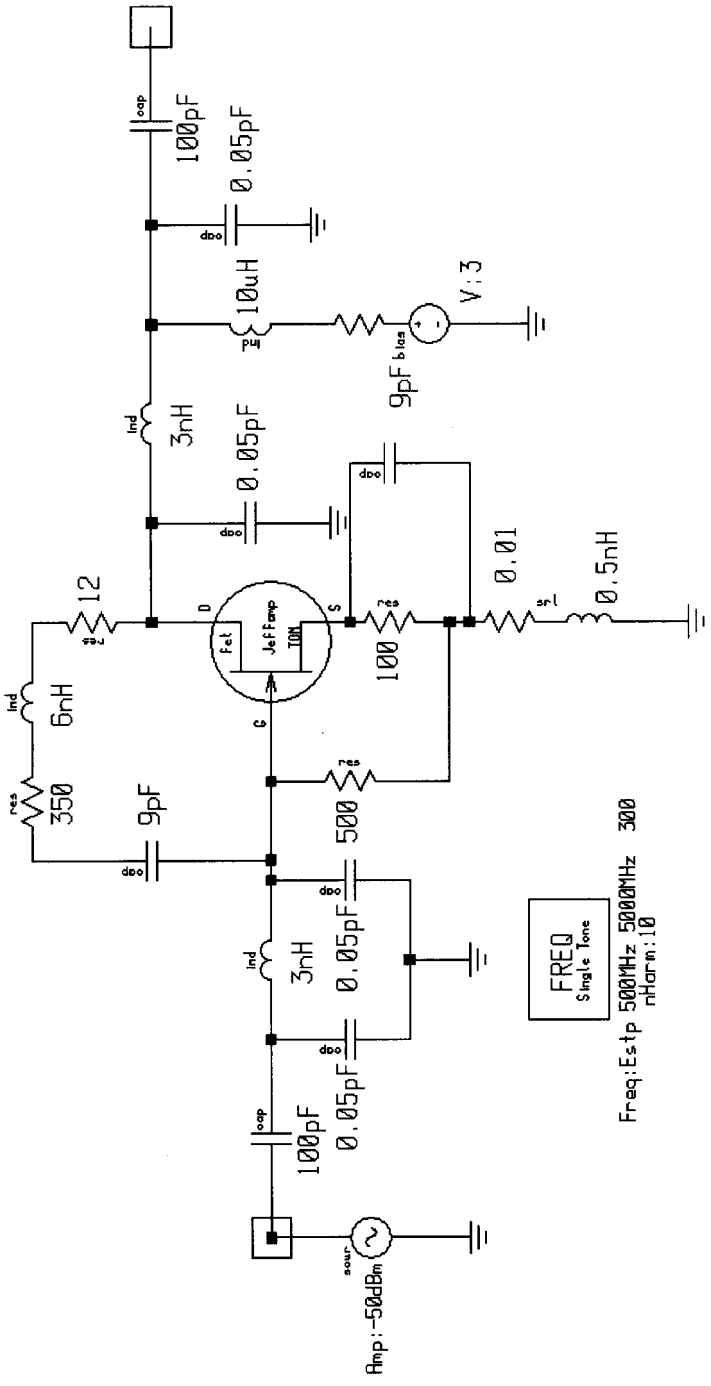

Figure 3-85 GaAsFET feedback amplifier.

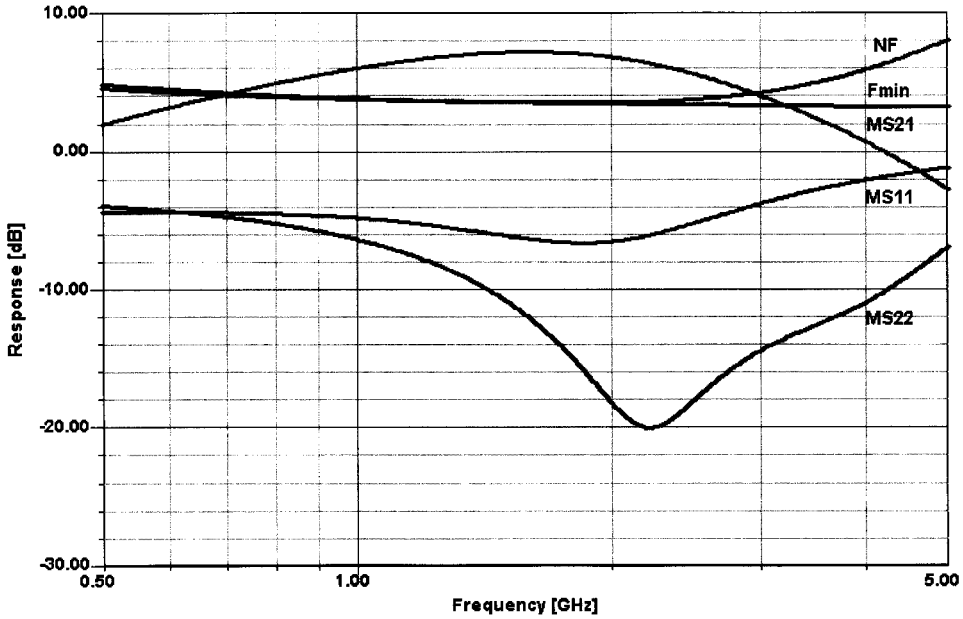

Figure 3-86 Frequency-dependent gain, matching, and noise responses for the GaAsFET amplifier.

Class A operation now can be operated at a higher current, which automatically increases the gain and the noise figure and reduces distortion. This is based on the fact that the transconductance (g_m) increases at higher currents. The second transistor in the TI circuit achieves this by being in reality a larger device, which could be modeled by several transistors, like the first stage, in parallel. This automatically increases the dc current by the scaling factor. The same is even more true for the output stage. Likewise, bipolar transistors can also be scaled. A visual inspection of some transistors in their packages will reveal that they are really not just one transistor, but several operating in parallel, each with its own ballast resistors (for bipolar transistors) or other means (for FETs).

Using tuned circuits rather than wideband matching, it is possible to go to Class AB or B operation. Class AB is really a hybrid between A and B, and Class B is probably better known. Figure 3-63 shows the Class B operating point. Most Class B stages are operated in push–pull because, together with the tuned circuit, one-half of the cycle is supplied by the other transistor. The definition of Class B operation is a conducting angle of 90° (see Figure 3-63). At this point it should be noted that some older texts define the conducting angle as being twice the value we have defined in this chapter.

Without going into further details, the highest efficiency in Class B operation is 78.5%. Based on the fact that modern wireless applications generally use a hybrid of amplitude and angle modulation, pure Class C operation finds little application today because of the severe nonlinear distortion it introduces. A Class B stage has less "power gain" than a Class A stage but provides much more output power. We have already mentioned the problem associated with characterizing a Class A stage in terms of power gain. That's the only time Kirchhoff's equations are valid, meaning that the sums of all currents and voltages have to be zero. Because Kirchhoff's equations do not consider nonlinearities and harmonic contributions,

the very moment we move into considering medium- and higher-power amplifiers, the nonlinearities will dominate and the performance of the stage is best analyzed with a high-quality circuit simulator with the appropriate dynamic range and good modeling capability. Without question, this applies to Class C operation also. As pointed out previously, the high-gain amplifier is optimized for gain rather than noise figure and typically requires more collector or drain current. This can easily be seen by rebiasing the FET amplifier as shown above to a significantly higher value of 33 mA. This is accomplished by changing the source resistor down to 3 Ω. As a result of this, we obtain the gain, matching, and noise figure responses shown in Figure 3-87.

It may be a surprise to the reader that the actual noise figure now is less than that shown in Figure 3-86. This device is now operating at 33 mA; the reason for this has to do with the fact that if the transconductance is too low, the noise figure also increases, and the NF curve for the FET has a similar-looking current-dependent minimum—a curve that is frequently not supplied by the manufacturer. This amplifier, now operating at 33 mA, should have quite good large-signal capabilities; we will examine this shortly.

Another interesting piece of information is the display of the dc I–V curves with the "load line." Since we have reactances in the circuit, we do not see a line but rather an ellipse, indicating the storage of energy. (The actual load line would be a line through the two foci of the ellipse.) This curve allows us to see immediately that at this operating point the transistor is neither going into current saturation nor becoming voltage limiting. The input power can be increased further until such a condition exists. Figure 3-88 shows the dc I–V curve for the amplifier shown in Figure 3-85.

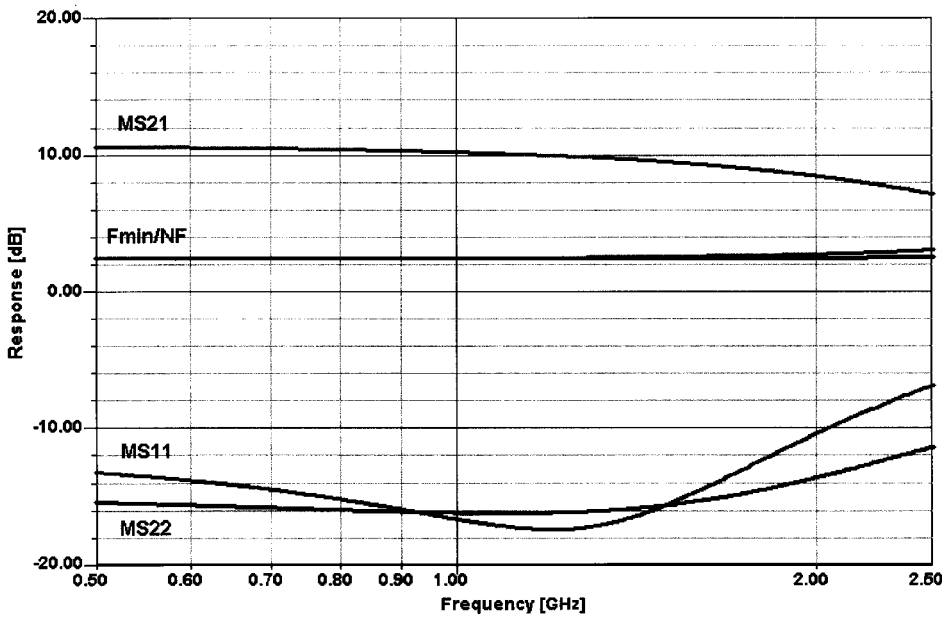

Figure 3-87 Frequency-dependent gain, matching, and noise performance for the GaAsFET amplifier of Figure 3-85 rebiased for a drain current of 33 mA.

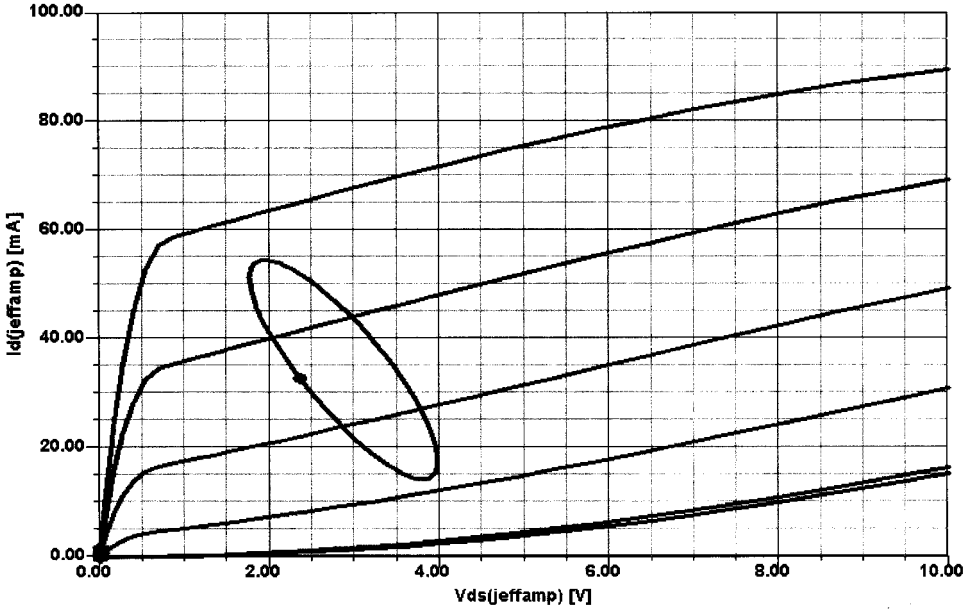

Figure 3-88 The dc *I–V* curves for the GaAsFET operating at I_D = 33 mA, including the ac load line. The load line is an ellipse rather than a straight line for the reason described in the text.

Besides looking for the adjacent-channel power ratio (ACPR), the other traditionally important points are third-order intercept point and the equivalent of a multitone simulation, as used for CATV application but relevant to the multisignal environment of wireless applications. Figure 3-89 shows the determination of the amplifier's third-order intercept point. It is most important for the reader to understand that very low values for input and output level have to be used to determine the crossover point. If this advice is not followed, totally erroneous numbers can occur.

Since an antenna supplies a large number of signals (this is true of handheld radios as well as base-station sites), a three-tone standard has been adopted as a good approximation of multisignal operation. This standard is in accordance with the German DIN 45004E,3.3 three-tone measurement. The requirement is that the intermodulation distortion products at the output are better than 60 dB suppressed relative to the largest of the three tones. One tone is used as the reference, and the other two tones are 6 dB less. This measurement has been derived from television, whereby the video transmitter, based on the vestigial sideband power, is 6 dB above the two sidebands produced by the FM sound transmitter using a modulation index of 5. The result of a three-tone test can be seen in Figure 3-90. This amplifier clearly meets the DIN specification for linearity at input levels up to –9/–15 dBm at the input.

Bipolar transistors are also quite popular for this purpose. Figure 3-91 shows a single-stage amplifier with an intrinsic transistor and all the other "hidden" intrinsics, normally not visible, added. The three diodes belong to those intrinsic elements, which are needed for accurate microwave modeling but which are not provided by the standard nonlinear models. The reader will see that we went into great detail to model all the necessary parts. This feedback amplifier, whose frequency response is shown in Figure 3-92, has been quite

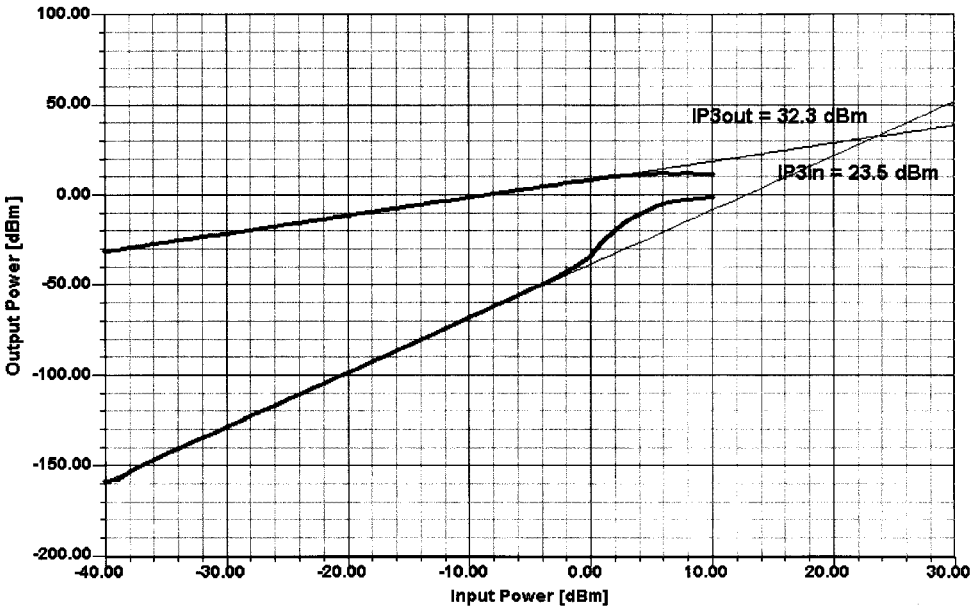

Figure 3-89 Determination of the third-order intercept point based on a two-tone measurement using tones spaced at 5% of the operating frequency (1.8 GHz).

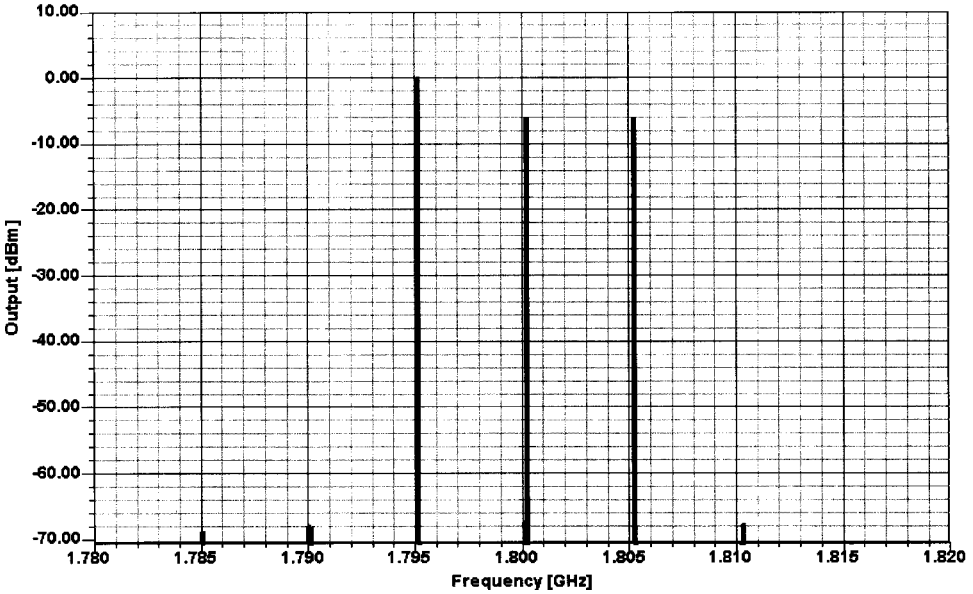

Figure 3-90 Simulated three-tone analysis of the GaAsFET amplifier with $I_D = 33$ mA.

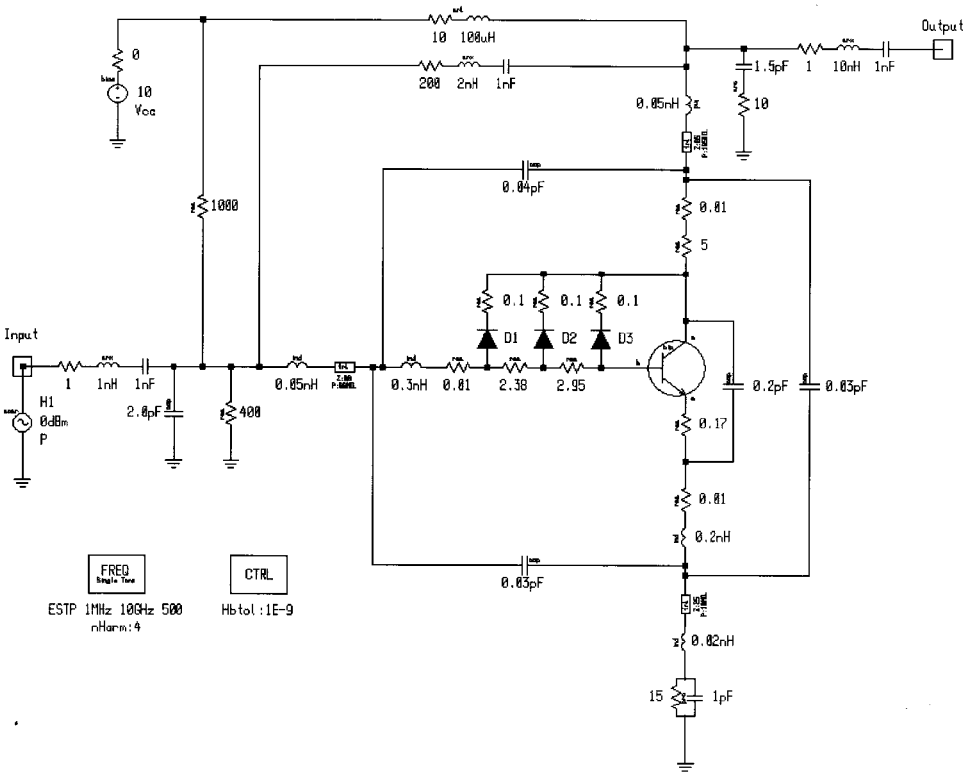

Figure 3-91 A high-linearity single-transistor amplifier modeled in great detail.

difficult to design, but there are monolithic circuits available where the higher gain–bandwidth product is being used to advantage.

Figure 3-92 shows the predicted frequency-dependent gain, matching, and noise figure at a bias point of 108 mA at 10 V. Using the same DIN three-tone test procedure, Figure 3-93 shows the expected good result.

Since this test requires two equal signals and one larger signal, we need to expect one IMD product larger than the rest. We have set our window for a dynamic range of 70 dB, and yes, in the lower left corner, we can see the product between the first two signals, while the other products are below the –50 dB level.

As a little task, Figure 3-94 shows a simple amplifier, based on a modern Siemens transistor, which is a feedback amplifier with fewer modeling details surrounding the transistor. Its associated frequency-dependent performance is shown in Figure 3-95. Interested readers are invited to improve its performance by using their skills and intuition.

Permitting higher currents and actually combining two transistors leads to our first MMIC. The following simulation is based on the MGA64135. Needless to say, there are some compensation networks inside the MMIC and distributed elements that affect the frequency response. However, with this arrangement, it is possible to obtain an appreciable gain at our wireless frequencies. The noise figure, based on the feedback, however, it not too impressive. This is a problem that occurs with most feedback amplifiers, which try to minimize the distortion and yet would like to keep the noise figure down. Figure 3-96 shows the schematic

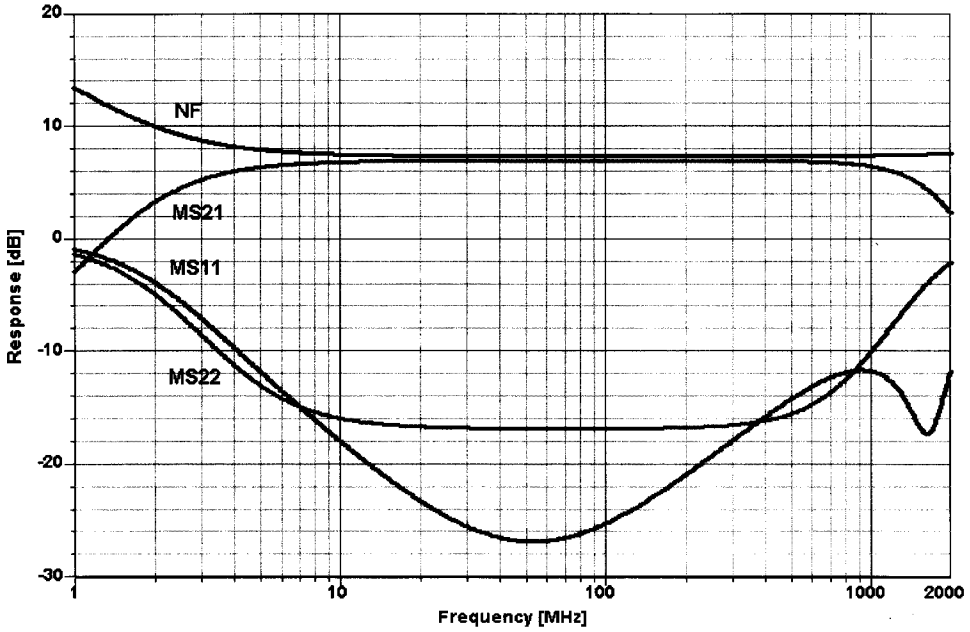

Figure 3-92 Simulated frequency-dependent gain, matching, and noise figure performance of the circuit in Figure 3-91.

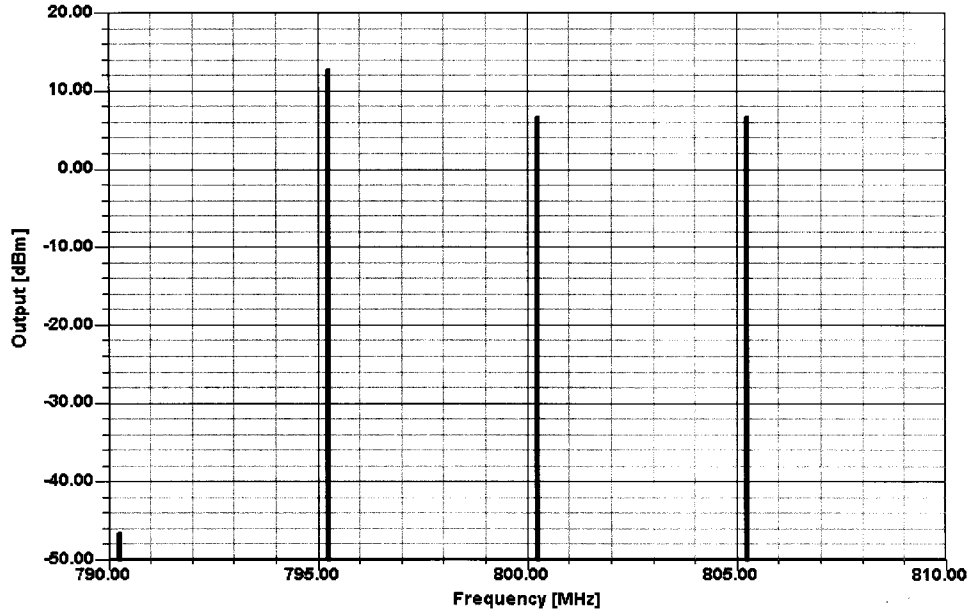

Figure 3-93 Simulated three-tone output spectrum of the amplifier in Figure 3-91.

of the GaAs MMIC; Figure 3-97 shows its frequency-dependent gain, matching, and noise performance; Figure 3-98 shows its two-tone response, which is used to obtain the intercept point ($IP_{3,in}$ = 8.5 dBm, $IP_{3,out}$ = 22 dBm); and, finally, Figure 3-99 shows the three-tone test results at an input RF level of –21/–27 dBm. While the gain–bandwidth product is considerably larger than the single-stage amplifier we examined before, the intercept point and three-tone performance do not reach the same values. As a general rule, the dynamic

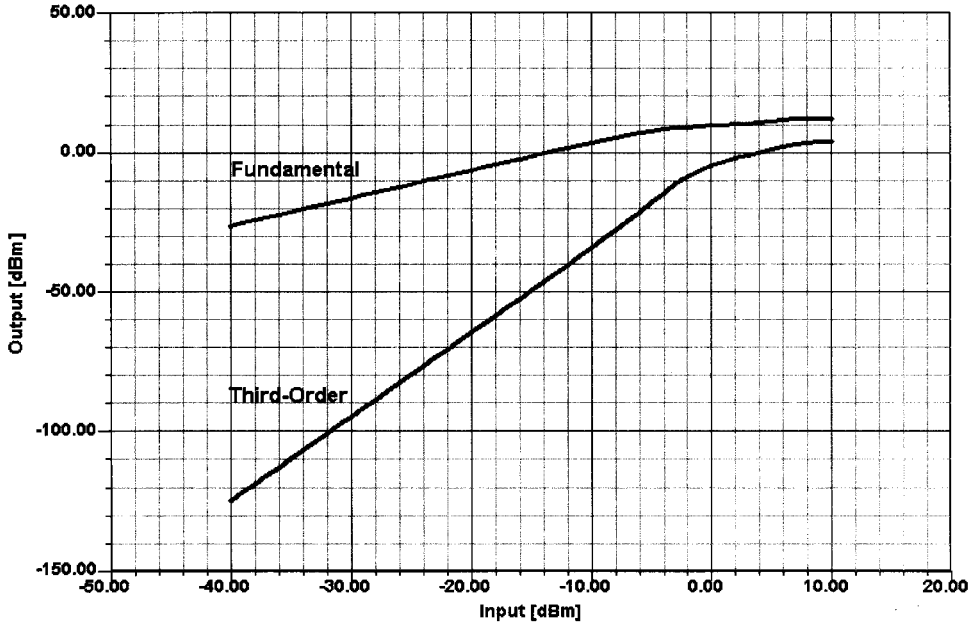

Figure 3-98 Simulated two-tone testing of the MGA64135 MMIC amplifier. $IP_{3,in}$ = 8.5 dBm and $IP_{3,out}$ = 22 dBm.

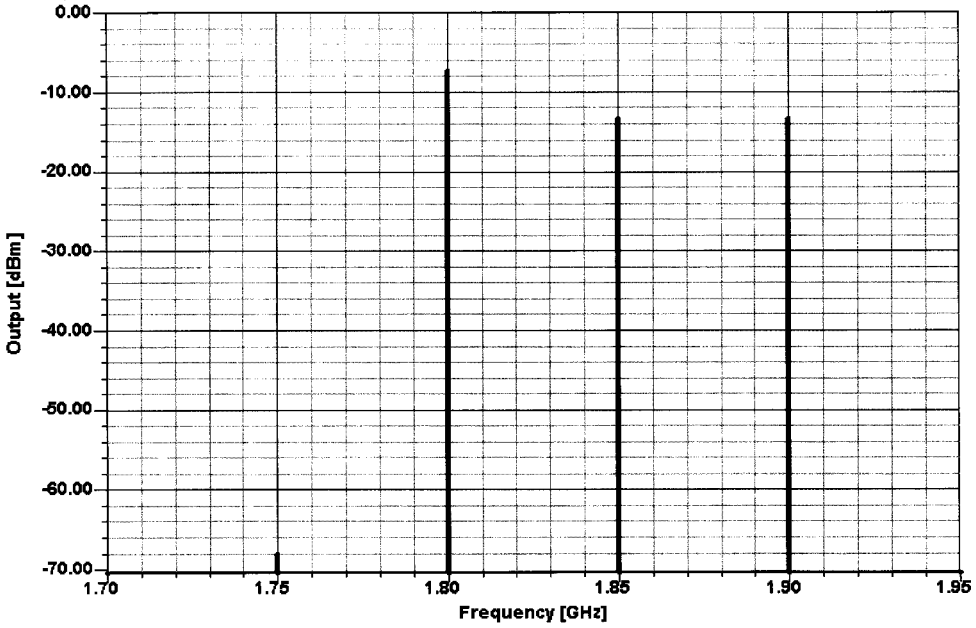

Figure 3-99 Simulated three-tone test of the MGA64135 MMIC. The test tones were 1.80 GHz (–21 dBm), 1.85 GHz (–27 dBm), and 1.90 GHz (–27 dBm). The 1.75-GHz IMD product is down 60.5 dB relative to the 1.80-GHz signal.

range is directly proportional to the power dissipated in the devices: specifically, the current. As explained earlier several times, the first-order nonlinearity comes from the voltage-to-current transfer characteristic, such as the transconductance itself, and can only be improved by a combination of resistive feedback in the emitter/source and by high currents. At these dc levels, the base–emitter (gate–source) junction gets linearized because the differential values are getting smaller compared to the parasitic loss resistances, including external dc/RF feedback. Once again, the voltage feedback reduces the voltage clipping but is initially more responsible for the input and output matching.

3-2-4 Low-Voltage Open-Collector Design [22–25]*

Why R_C Acts Like a Source Resistor. An open-collector output allows a designer the flexibility to choose the value of the R_C resistor. Choice of this resistor value not only sets the dc bias point of the device but also defines the source impedance value. Figure 3-100 shows the ac model of the transistor. Converting the output structure by applying a Norton and Thevenin transformation, one can conclude that R_C becomes the source resistance. Thus, by choosing R_C to be equal to the load, maximum power transfer will then occur.

Figure 3-101 shows an active transistor with collector and base resistors. From basic transistor theory, Eq. A in Figure 3-101 is generated and has the same form as the general equation for a straight line ($y = mx + b$).

Figure 3-101 Basic transistor analysis.

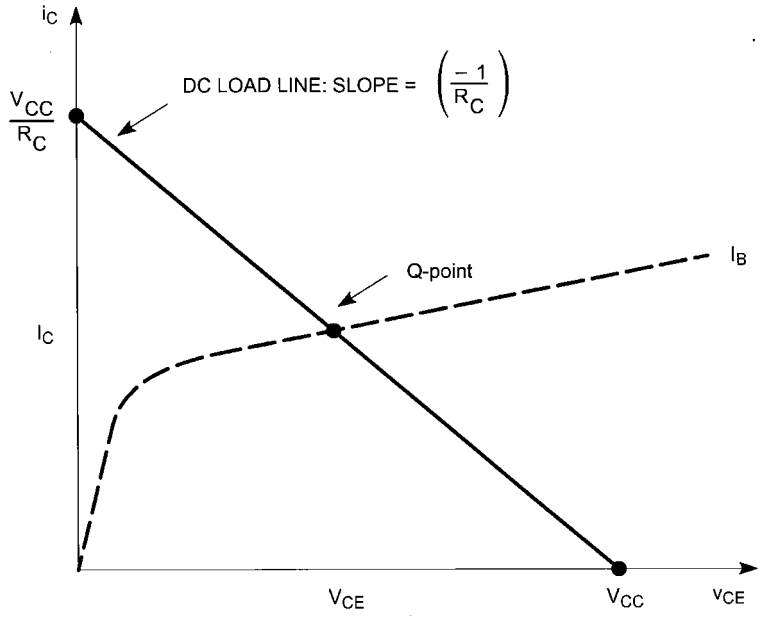

Figure 3-102 Load line and Q-point graph.

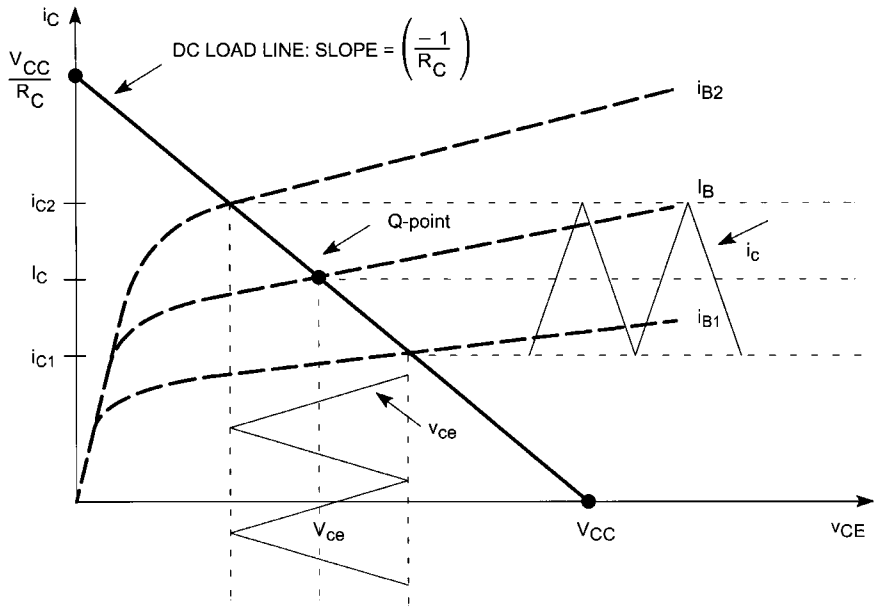

Figure 3-103 Graphical analysis for the circuitry in Figure 3-101.

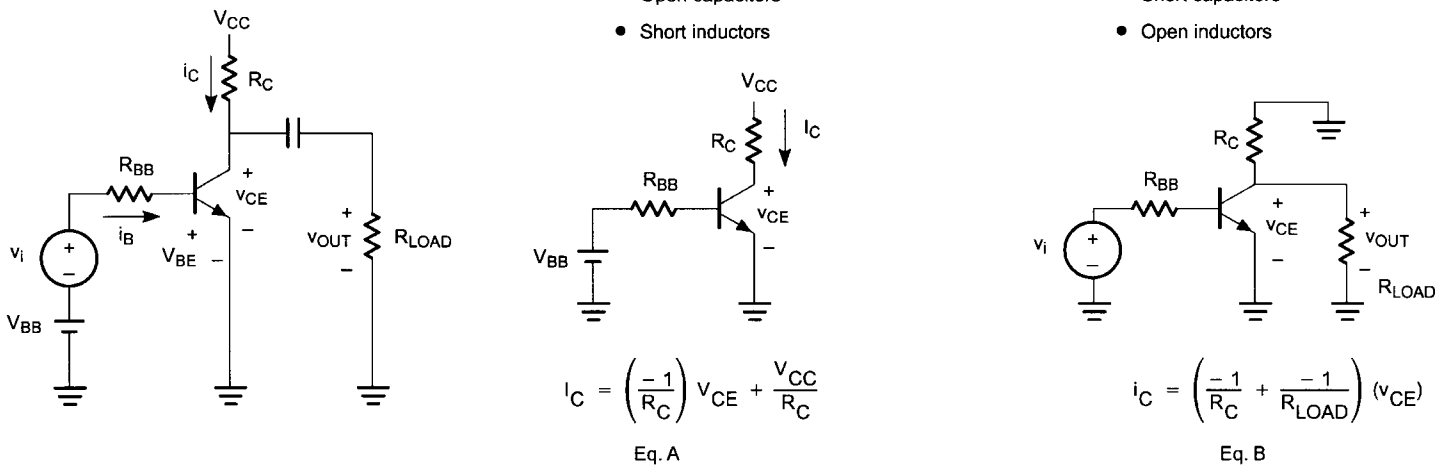

Figure 3-104 Basic transistor analysis with R_{LOAD}.

The slope of the dc load line is generated by the value of the collector resistor ($m = (1/R_C)$ and is shown in Figure 3-102. For a given small-signal base current, the collector current is shown by the dotted curve. The intersection of the dotted curve and the dc load line is called the *quiescent point* (Q-point) and dc bias determinant. The location of the Q-point is important because it determines whether the transistor is operated in the cutoff, active, or saturation region(s). In most cases, the Q-point should be in the active region because this is where the transistor acts like an amplifier.

Figure 3-103 shows the ac collector–emitter voltage (V_{CE}) output swing with respect to an ac collector current (I_C). Collector current is determined by the ac voltage presented to the input transistor's base (v_i) because it affects the base current (i_b), which then affects i_c. This is how v_i is amplified and seen at the output. Recall that this is with no external load (R_{LOAD}) present at the collector. Since no load is present, the slope of the ac load line is identical to that of the dc load line as seen in Eqs. A and B of Figure 3-101 ($m = -1/R_C$).

Open Collector with R_{LOAD}. A filter with some known input impedance is a typical load for the output of the transistor. For simplicity, we will assume a resistive load (R_{LOAD}) and neglect any reactance. Since a resistive load is used (see Figure 3-104), the ac output swing is measured at V_{OUT} or V_{CE}.

A dc blocking capacitor is used between the R_{LOAD} and the V_{CE} output to assure that the Q-point is not influenced by R_{LOAD}. It is also necessary to avoid passing dc to the load in applications where the load is a SAW filter. However, R_{LOAD} will affect the ac load line, which is seen in Eq. B in Figure 3-104. Note that the V_{CE} voltage swing is reduced; thus, the V_{OUT} signal is reduced (see Figure 3-105).

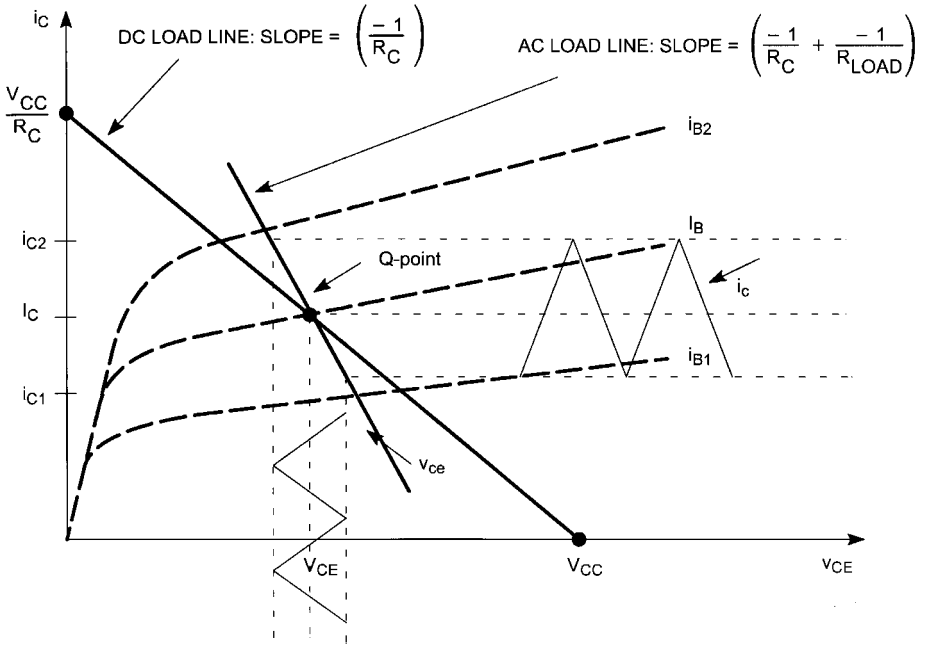

Figure 3-105 Graphical analysis for the circuitry in Figure 3-104. The ac load line intersects the Q point, and the slope is steeper than the dc load line due to R_{LOAD}, which makes V_{CE} smaller.

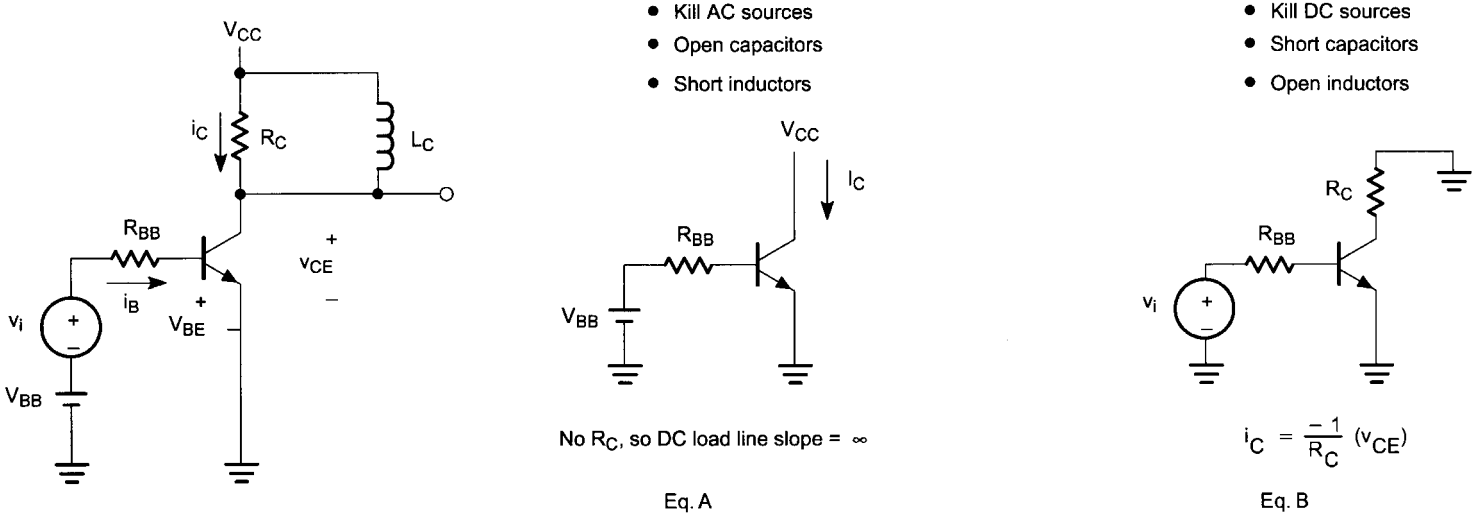

Figure 3-106 Basic transistor analysis with inductor added to collector.

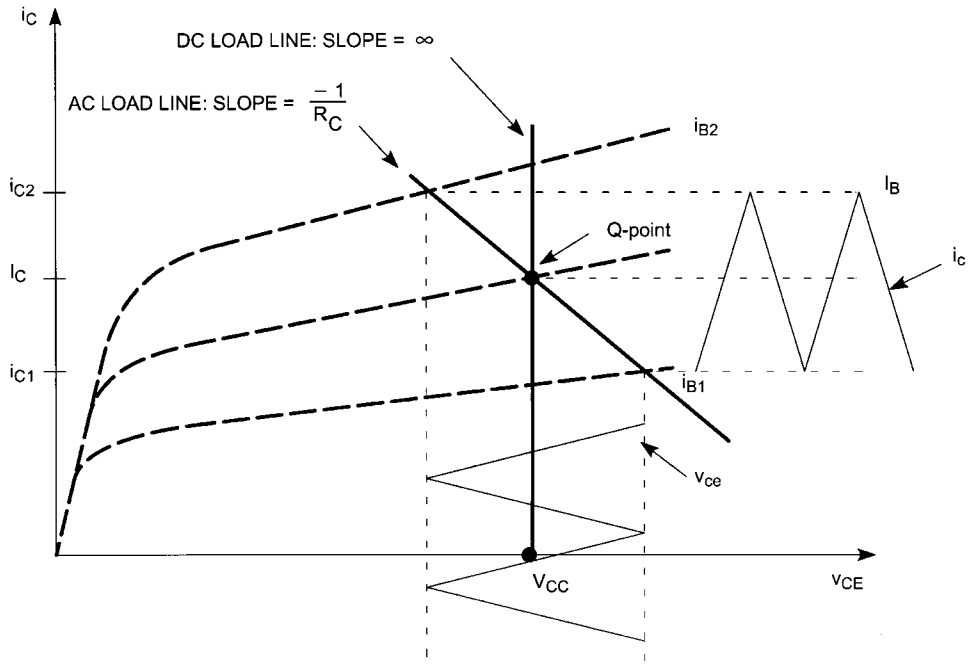

Figure 3-107 Graphical analysis for the circuitry in Figure 3-106.

Since the values of R_C and R_{LOAD} affect the ac load line slope, the value chosen is important. The higher the impedance of R_{LOAD} and R_C, the greater the ac output swing will be at the output, which means more conversion gain in a mixer. This is due to the slope getting flatter, thus allowing for more output swing.

Open Collector with Inductor (L_C). Adding an inductor in parallel with R_C can increase the ac output signal V_{CE}. Figure 3-106 shows the dc and ac analyses of this circuit configuration. In Eq. A in Figure 3-106, there is no R_C influence because the inductor acts like a short in the dc condition. This means the slope of the dc load is infinite and causes the Q-point to be centered around $V_{CC,}$ thus moving it to the right of the curve. The ac load line slope is set only by R_C because no load is present. Note that it has the same ac load line slope as the first condition in Eq. B of Figure 3-101.

Referring to Figure 3-107, one might notice that the base current (ac and dc) curves spread open as V_{CE} increases. This is caused by a noninfinite Early voltage (see Figure 3-108), which causes the collector current to be dependent on V_{CE}. Taking advantage of this nonideal condition, the peak-to-peak ac output swing V_{CE} can thereby be increased by moving the dc Q-point to the right due to the wider spreading between the curves corresponding to different base currents. Figure 3-109 combines Figures 3-103 and 3-107 to show the different ac output signals with different Q-points.

Looking at the ac output level, one might ask how the V_{CE} peak voltage can exceed the supply voltage V_{CC}. Recall that the inductor is an energy-storing device ($v = L\ di/dt$). Therefore, total instantaneous voltage is V_{CC} plus the voltage contribution of the inductor.

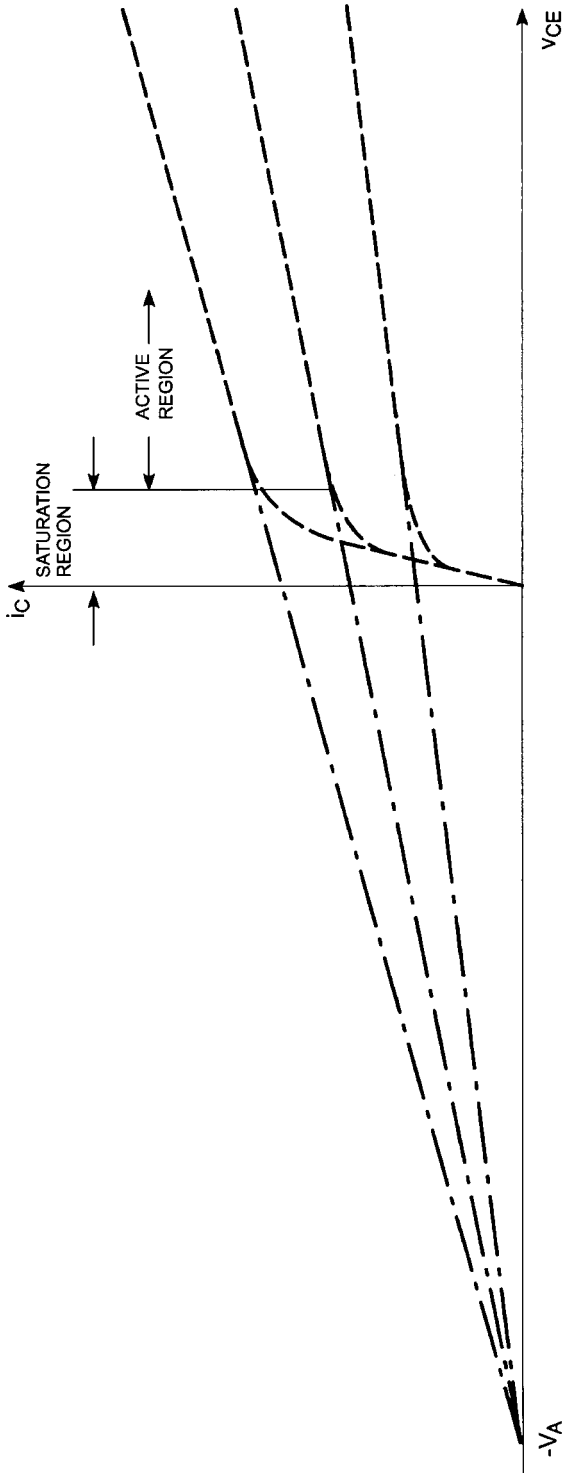

Figure 3-108 Graphical representation of Early voltage effect.

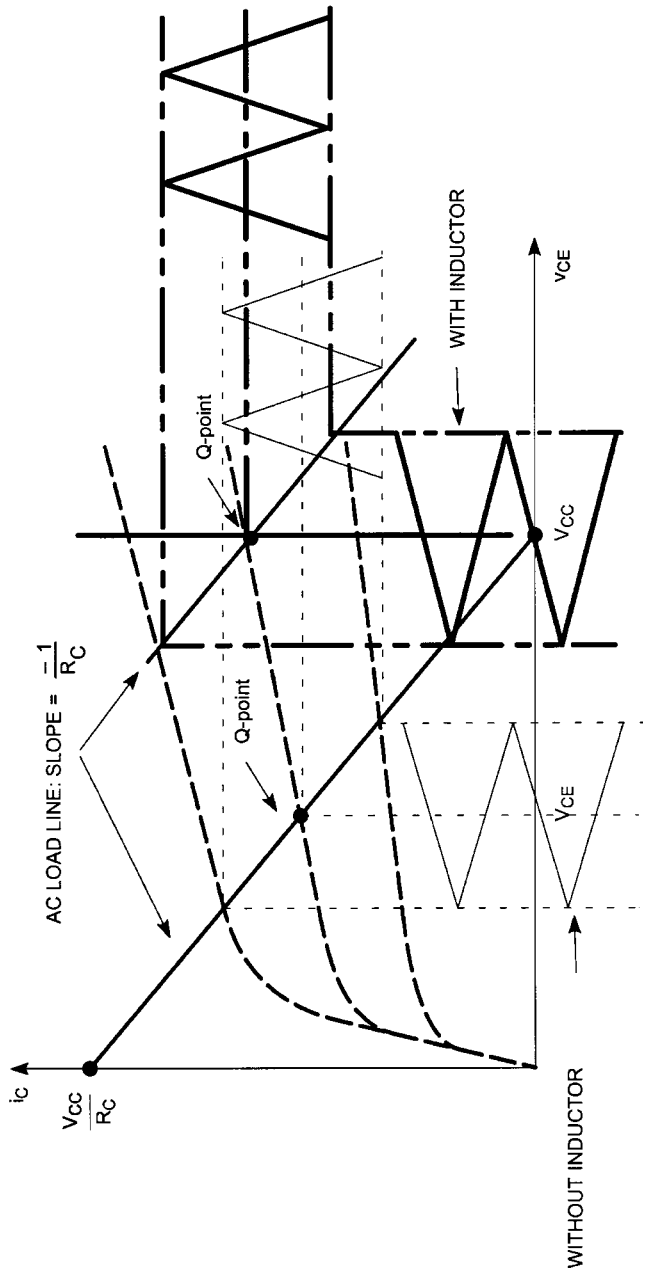

Figure 3-109 Comparison of open-collector circuit with inductor versus without inductor.

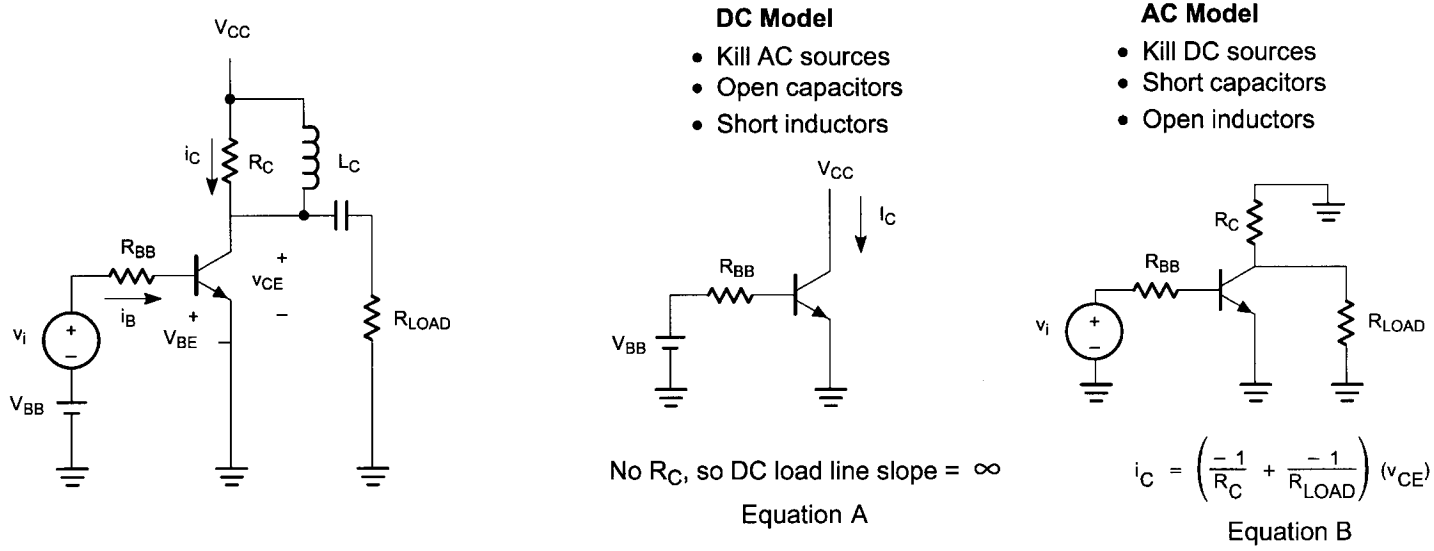

Figure 3-110 Basic transistor analysis with inductor and R_{LOAD}.

Open Collector with Inductor (L_C) and R_{LOAD}. Figure 3-110 shows the dc and ac analyses with the inductor and load resistor. Again, from the dc analysis, the inductor causes R_C to be nonexistent so the dc load line is vertical. In the ac analysis, the ac load line slope is influenced by both R_C and R_{LOAD} (see Eq. B in Figure 3-110). The ac load line slope is the same as the example of the open collector without the inductor. Figure 3-111 shows the response for the open collector with L_C and R_{LOAD}. Figure 3-112 combines Figures 3-105 and 3-111 showing the increase in ac output swing.

In conclusion, for the load line, R_C plays a role in setting up the bias-determined Q-point as well as the ac source impedance. However, when an inductor is placed in parallel with R_C, a different Q-point is set and the ac source impedance is altered. Moving the Q-point takes advantage of the transistor's nonideal i_c dependence on V_{CE} to get more signal output without having to change the base current. Since R_C is in parallel with R_{LOAD} in the ac condition, it influences the ac load line slope.

Flexible Matching Circuit [25]. A useful variation of the open-collector matching concepts previously outlined provided the capability of delivering equal power to two unequal resistive loads. This allows the power delivered to the load to be measured indirectly at another test point in the circuit where the impedance can be defined arbitrarily. If this impedance is defined to be 50 Ω, a spectrum analyzer can easily be placed directly into the circuit. This is an excellent troubleshooting technique and a valuable option to have available in high production environments.

Figure 3-113 shows the schematic for this flexible matching circuit. In this circuit, C_B functions only as a dc blocking capacitor and presents a negligible impedance at the frequency of interest. Recall from the previous open-collector matching discussions that,

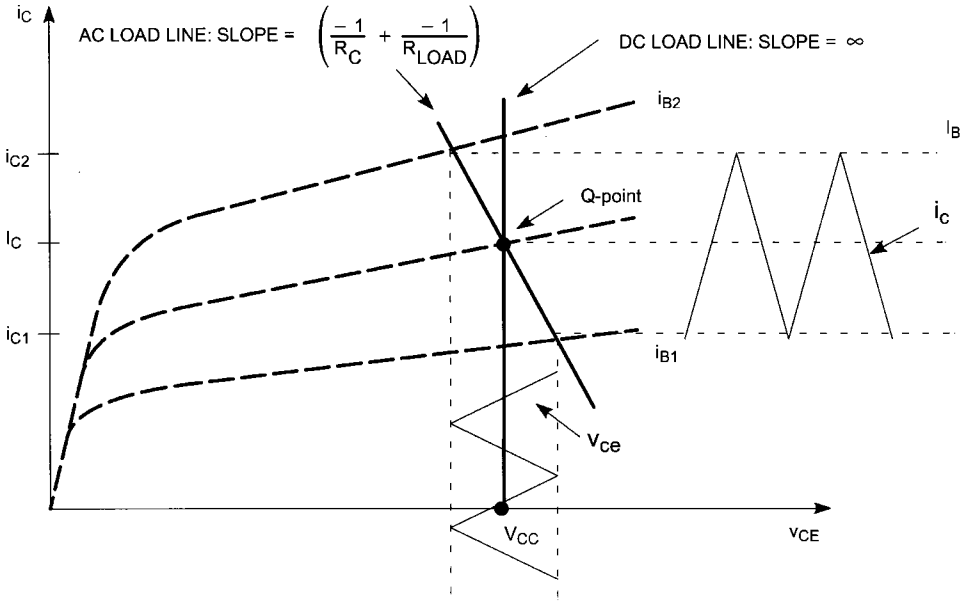

Figure 3-111 Graphical analysis for the circuitry in Figure 3-110.

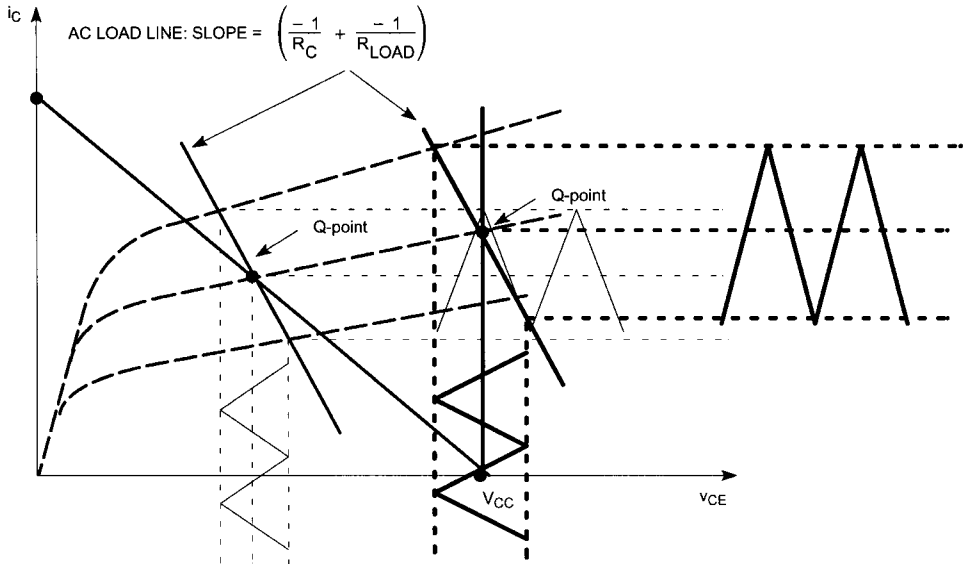

Figure 3-112 Comparison of open-collector R_{LOAD} circuit with inductor versus without inductor.

when R_C is placed in parallel with an inductor, it has no effect on the Q-point but does influence the slope of the ac load line as

$$\text{Slope} = \frac{-1}{R_C} + \frac{-1}{R_{\text{LOAD}}} \tag{3-166}$$

The capacitor C_S not only functions as a dc blocking capacitor but is also chosen such that the impedance presented by the combination of L, R_C, and C_S is equal to R_{LOAD} for optimum power transfer. The analysis is done in the following manner. First, note that inductor L is connected to V_{CC}, which is an affective ac ground. So L can be redrawn to ground. Next, R_C and C_S are converted to their parallel equivalent values as shown in Figure 3-114.

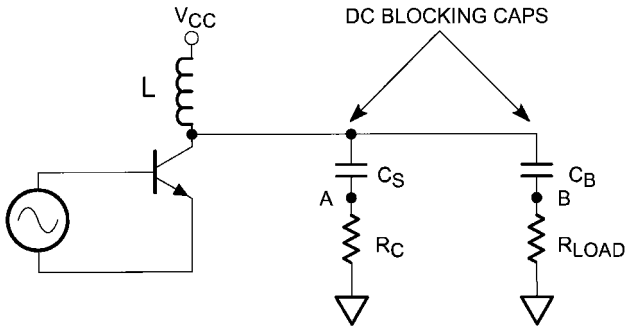

Figure 3-113 Flexible matching circuit.

Figure 3-114 Converting from series to parallel configuration.

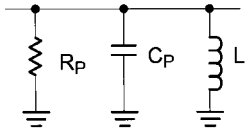

Figure 3-115 Converting from series to parallel configuration. Goal: Find L_C and C_p such that R_p looks like the R_{LOAD} value at the resonant frequency.

The resulting parallel *LCR* circuit is shown in Figure 3-115. At resonance, the parallel L–C_P combination will be an effective open circuit leaving only R_P. R_P is then simply chosen to be equal to R_{LOAD}.

Starting with the most simple transistor configuration and using *RC* types of dc-coupled amplifier circuits, we next present an overview of possible configurations for this application.

3-3 SINGLE-STAGE FEEDBACK AMPLIFIERS

This amplifier (Figure 3-116) is a standard minimal configuration amplifier with reduction of current distortion because of the emitter feedback. The voltage gain is

$$\text{VG} = \frac{R_L}{(26\text{mV})/I_C + R_e} \tag{3-167}$$

where R_L is the total load seen at the collector.

The feedback amplifier in Figure 3-117 uses voltage feedback to "correct" the input and output impedance to be close to 50 Ω but does not improve the current distortion. The voltage gain of this circuit is

$$\text{VG} = \frac{R_F}{R_g} \tag{3-168}$$

$$R_{\text{IN}} = R_{\text{OUT}}$$

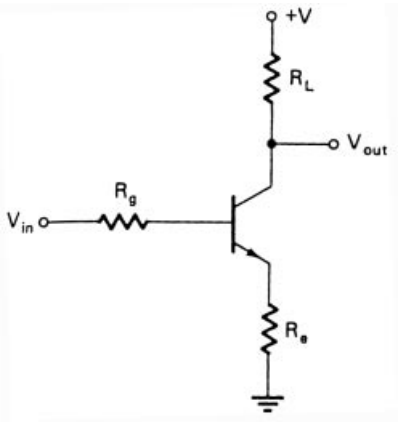

Figure 3-116 Single-stage amplifier with current feedback (provided by R_e).

$$= R_F R_D \quad \text{with} \quad R_D = \frac{26\text{mV}}{I_C} \tag{3-169}$$

Example. For $I_C = 10$ mA $\rightarrow R_D = 2.6\ \Omega$ and assuming $R_F = 200\ \Omega$, the input resistance $R_{\text{IN}} = 22.63\ \Omega$. The gain is calculated by getting the inverse of $R_D = g_m = 0.39$ A/V. Once this is multiplied with the output impedance of 22.63 Ω, the resulting gain becomes 10 log (8.6) or 9.3 dB. The gain can be increased by either using a larger collector current or a larger feedback resistor. It should be reminded that this circuit does not improve the distortion caused by the base–emitter junction.

To reduce the current distortion as well, we use the circuit shown in Figure 3-118, which contains both types of feedback. In reality, the collector–base resistor is frequently split into an unbypassed section responsible for the feedback and a larger resistor responsible for the appropriate biasing. The example circuit in Figure 3-119 shows this.

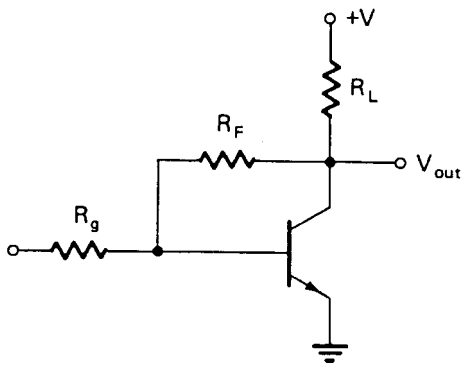

Figure 3-117 Single-stage amplifier with voltage feedback (provided by R_F).

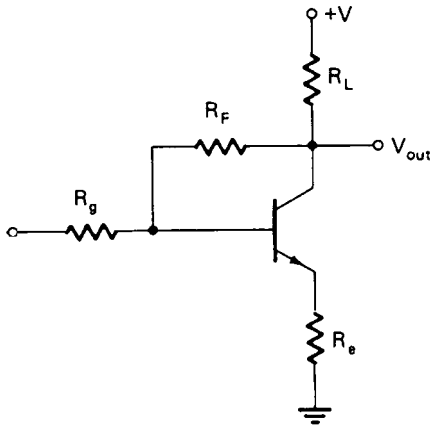

Figure 3-118 Single-stage amplifier with voltage and current feedback.

By using two of the fairly recent BFP420 transistors in parallel, and balancing the transistors by using the appropriate emitter resistors (which in total will result in 10 Ω) plus the bypassed value, we obtain the frequency-dependent gain, matching, and noise responses shown in Figure 3-120. To determine the appropriate feedback resistor R_F, we recommend the formula

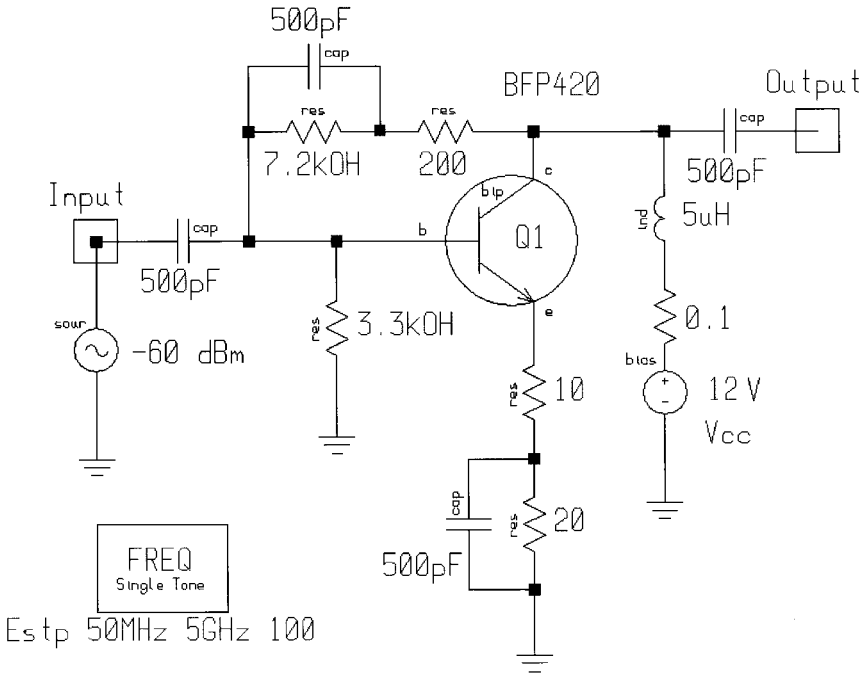

Figure 3-119 Practical amplifier circuit showing voltage and current feedback, and illustrating how reactances (in this case, 500-pF bypass capacitors) and multiple resistors can be used to provide different ac and dc resistances for the paths from collector to base and emitter to ground.

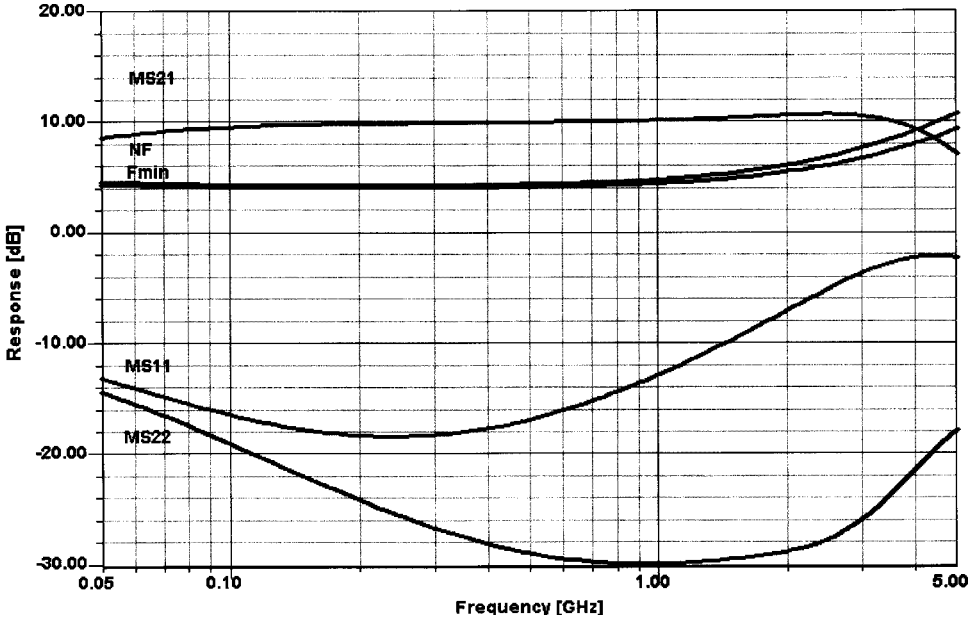

Figure 3-120 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-119.

$$R_F = \frac{(Z_{\text{in}}\, Z_{\text{out}})}{R_E} \tag{3-170}$$

This equation requires some additional comments. The combined shunt and series feedback only work as long as a sufficient transconductance is provided. In other words, there must be enough open-loop gain that will be reduced to obtain more bandwidth. A necessary condition for this approach, which really comes from the frequency range of less than 30 MHz, is that

$$Z_{\text{in}} = \frac{26\ \text{mV}}{I_C}\,\beta >> R_F \tag{3-171}$$

This requires a minimum transconductance of

$$g_m = \frac{1 + S_{21}}{Z_{\text{in}}} \tag{3-172}$$

where S_{21} must be a negative number that reflects the 180° phase shift. Of course, life becomes interesting when S_{21} goes through 1, but it (hopefully) never becomes negative and larger than 1 at the same time.

Example. The BFP420 has been used here frequently. A 10-dB gain would require an S_{21} of 3.16 ($\sqrt{10}$); therefore, we need to inspect the datasheet, which shows that the magnitude

of S_{21} is 3.16 around 4.5 GHz, yet the phase shift has changed from 180° to around 20°. In order to design an amplifier, we now set

$$R_F = Z_{\text{in}}(1 + |S_{21}|) \tag{3-173}$$

which is valid until S_{21} becomes too small. For a given 10 dB or 3.16 for S_{21}, the resulting RF is 4.16×50, or 208 Ω. The transconductance under these conditions becomes

$$g_m = \frac{1 + |S_{21}|}{Z_0} \tag{3-174}$$

where $Z_0 = 50$ Ω (the desired input impedance). g_m now becomes 83.2 mS. We now test the input and find

$$\frac{\beta}{g_m} = Z_{\text{in}} = \frac{50}{0.0832} = 600\ \Omega \tag{3-175}$$

Therefore, the emitter feedback resistor is not necessary to meet the previously mentioned condition whereby the input impedance needs to be higher than RF. Assuming the transconductance now is 0.00832, or 10% of the previous value, the input impedance would be 60 Ω, no longer meeting the prescribed requirement. Therefore, we need an unbypassed emitter resistor that fulfills the equation

$$R_E = \frac{Z_0^2}{R_F} - \frac{1}{g_{m_{\text{dc}}}} \tag{3-176}$$

where

$$g_{m_{\text{dc}}} = \frac{1 - S_{21_{\text{max}}}}{Z_0} \tag{3-177}$$

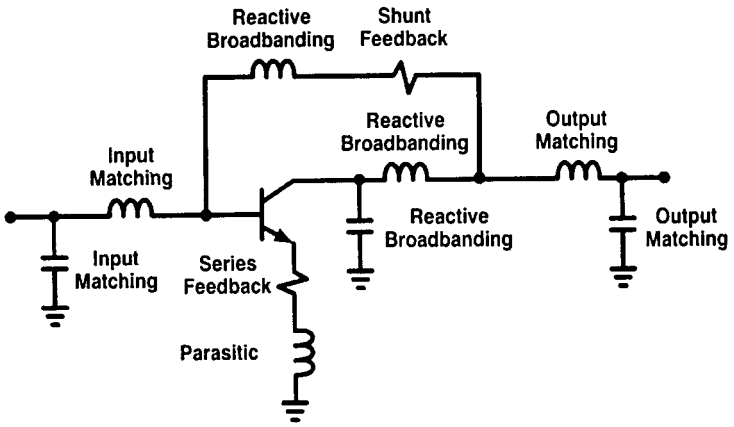

Figure 3-121 Elements of a feedback amplifier.

Again, the reader should be cautioned that in the common-emitter circuit, there is a 180° phase shift, and therefore $S_{21_{\max}}$ is a negative quantity, resulting in reality in

$$g_{m_{\text{dc}}} = \frac{1 + S_{21_{\max}}}{Z_0}$$

In our case,

$$g_{m_{\text{dc}}} = \frac{-S_{21}}{2Z_0} = \frac{38}{2 \times 50} = \frac{38}{100} = 0.38$$

so

$$R_E = \frac{50^2}{208} - \frac{1}{0.38} = 12 - 2.6 = 9.4\ \Omega \tag{3-178}$$

In practice, the designer would use a 10-Ω resistor.

Since the gain of the transistor continues to fall as a function of frequency, one can compensate to a degree for the cutoff frequency by putting an inductance in series that follows the equation

$$L_F = \frac{R_F}{2\pi f_{3\text{dB}}} \tag{3-179}$$

Assuming $f_{3\text{dB}}$ = 2 GHz, the resulting series inductance L_F = 16.6 nH. Basically, the same applies to circuits where the second transistor is used as an emitter follower to feed the signal back from the collector to the base of the first transistor.

In summary (see Figure 3-121):

- Resistive negative feedback at lower frequencies reduces open-loop gain and simultaneously matches input and output.
- Reactive elements set the gain and matching at high frequencies. Feedback is reduced at high frequencies.
- Emitter bypass capacitors are not used, as they would destroy the impedance match.

This is equally valid for FETs.

The next level of complexity can be reached by using two transistors with dc feedback.

3-3-1 Lossless or Noiseless Feedback

All the amplifiers shown above are based on a combination of resistive and reactive feedback. The very moment resistive feedback is used, the noise figure increases, as does the intercept point. As long as the intercept point increases overproportionally compared to the noise figure, this is an acceptable method. However, there are many cases in which an extremely low noise figure and a higher than normally achievable intercept point are required. To avoid this degradation of performance, Norton of Anzac developed a negative feedback structure based on the capabilities of the ferrite transformer. This patented technique (U.S. Patent Nos. 3,624,536 and 3,891,934, since expired), known as *lossless feedback*, provides lower noise figure and higher linear output than can be achieved using resistive feedback with the same transistor. Transformer feedback is used in which the transformer in the feedback network acts as a directional coupler. The coupling ratio between the input and output of the coupler

determines the magnitude of the feedback, and hence the gain. Across the frequency band over which the transformer operates as intended, the feedback is negative due to the in-phase coupling and the inversion of the active device.

This technique was used in amplifiers ranging from 5 to 500 MHz, 20 to 1000 MHz, and 300 to 1800 MHz. The difficulty associated with this type of amplifier is the fact that it is based on transformers that use twisted pairs of wires as transmission lines. In some implementations used at higher frequencies, actual directional couplers were used at the expense of bandwidth; in these circuits, the coupling was determined by the spacing of the coupler lines rather than transformer turns ratio. These microstrip couplers have much narrower bandwidths than transformers and are fairly large.

Another headache with the lossless feedback design is the fact that many of these transistor configurations are used in either grounded-base or grounded-emitter with transistors that have f_T values of 25 GHz and higher. Such devices are very hot, and achieving freedom from oscillation over a wide frequency range is a continuing problem, even for the circuits we have shown so far. A similar clever technique has been implemented in the termination-insensitive mixer, which we will examine in Chapter 4.

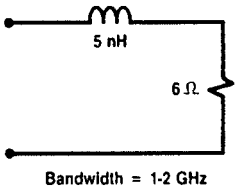
3-3-2 Broadband Matching

The circuitry above has enabled us to extend the frequency range of the amplifier and avoid the normal sharp cutoff. According to Fano [26], there is a limit to the bandwidth of matching. The concept is that impedance plus bandwidth determines the ability to match, since there is a Q of the circuit and there is a Q of the device. The following equations are valid:

$$|\rho_{\text{Bode}}| = e^{-(\pi Q_T / Q_{BP})} \tag{3-180}$$

$$Q_T = \frac{\sqrt{f_1 f_2}}{f_2 - f_1} \tag{3-181}$$

$$Q_{BP} = \frac{\text{Im}(Z)}{\text{Re}(Z)} = \frac{X_s}{R_s} \tag{3-182}$$



$$Q_{BP} = \frac{2\pi\sqrt{(2\text{ GHz})(1\text{ GHz})(5\text{ nH})}}{6\,\Omega} = 7.40$$

$$Q_T = \frac{\sqrt{(2\text{ GHz})(1\text{ GHz})}}{(2\text{ GHz} - 1\text{ GHz})} = 1.414$$

$$|\rho_{\text{Bode}}| = e^{-\left(\frac{\pi(1.414)}{7.40}\right)} = .549$$

$$\text{VSWR}_{\text{Bode}} = \frac{1 + .549}{1 - .549} = 3.43 : 1$$

Figure 3-122 Broadband matching example showing the Bode limit.

Figure 3-122 shows an example. This combination results in a VSWR of 3.43, which for practical purposes is already too high. The workaround is special circuitry (such as exponentially staggered impedance jumps in the matching network like 50 Ω > 20 Ω > 7 Ω > 3 Ω). This means we first transform the 50-Ω source of load impedance down to 3 Ω, and then look for a matching network that matches the transistor output/input, which is within a few ohms of 3 Ω. A detailed discussion of such matching can be found in the "Numerical Design" portion of Section 3-12-2 under the title "Broadband Matching Using Bandpass-Filter Networks—High-Q Case."

3-4 TWO-STAGE AMPLIFIERS

There are two popular configurations that have been used mostly for low-frequency applications. The first one (Figure 3-123, implemented in the circuit shown in Figure 3-124) shows a nice high-frequency performance assuming the emitter and collector currents are essentially the same. As for distortion products, this circuit behaves equivalently to the shunt impedance example from Figures 3-118 and 3-119, with the additional gain of the second transistor. Its frequency matching and noise performance are also shown, in Figure 3-125.

The next two-stage circuit (Figure 3-126, implemented in Figure 3-127) uses the collector current of the second stage as the feedback to the first. Proper biasing of this circuit is quite difficult and interactive. Figure 3-128 shows the frequency-dependent gain, matching, and noise figure. We believe that this circuit can be optimized further, but we leave such investigations to the reader.

A *cascode* amplifier is a special form of two-stage circuit. Although a cascaded pair acts like a single transistor, its merits are in its reduced feedback and resulting higher gain–bandwidth product. Figure 3-129 shows a simple cascode application that assumes the presence

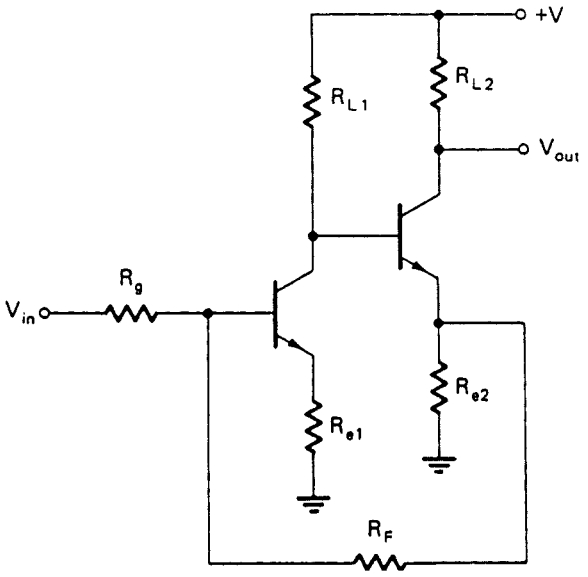


Figure 3-123 Two-stage amplifier with voltage feedback.

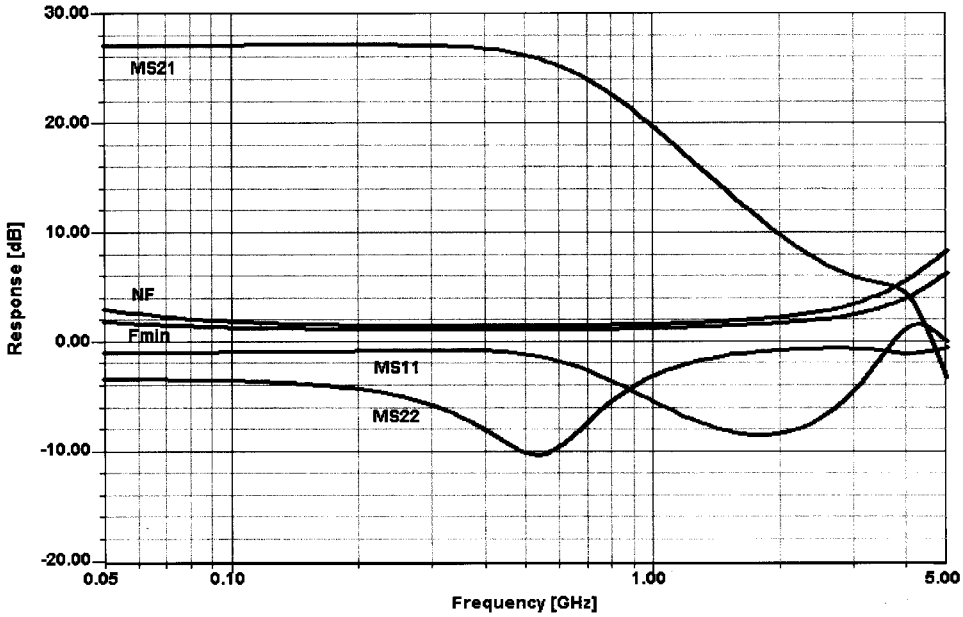

Figure 3-128 Gain, matching, and noise performance of the amplifier in Figure 3-127.

of an output transformer that absorbs the output capacitance. Figure 3-130 shows this circuit's frequency-dependent gain, matching, and noise performance.

It has been obvious to us that most published wireless application circuits are evaluated on a no-input-selectivity basis; that is, their reported performance does not take into account the filtering that is usually present in practical implementations. Evaluated in this way, a low-noise design may achieve a noise figure of less than 2 dB—1.2 dB or so is typical—but this is misleading because filters and connectors introduce insertion loss, resulting in a higher noise figure.

The cascode is a nice preamplifier combination. It combines (depending on the transistor) a low noise figure with essentially no feedback. Since the output of a grounded-base transistor provides a high-impedance source, this configuration is ideal to work into the SAW filters frequently used in wireless applications at the operating frequency. Special transistor pairs are available for use in cascode; as can be seen from this example, not every transistor combination is ideal. This one gives a higher noise figure than wanted and at frequencies above 2 GHz it tends to show possible instabilities. Both Siemens and Motorola are now offering transistors appropriate for these cascodes. Mostly, one would resort to transistors of less-exotic cutoff frequencies to guarantee stability. Typically, grounded-base/gate transistors tend to become oscillators, specifically because this configuration, like the emitter follower, allows a higher operating frequency while maintaining the same gain–bandwidth product; the actual gain for the last two circuit configurations is less. A grounded-base/gate stage has a high voltage gain and the emitter/source follower has power gain at low impedance levels. We invite our readers to experiment with the capacitor from the base of Q1 to ground in Figure 3-129 to get an interesting education about these transistors and their willingness to oscillate.

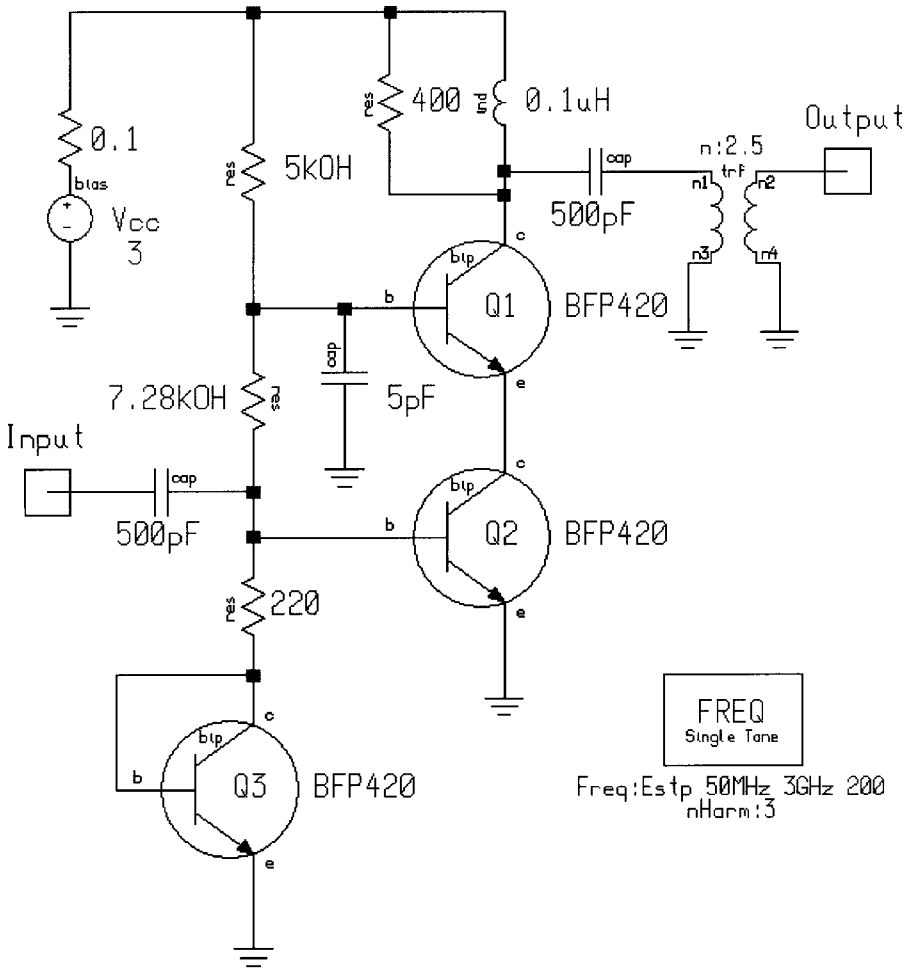

Figure 3-129 Schematic of the cascode amplifier.

The MC13144 is an example of a commercially available VHF to 2-GHz low-noise amplifier with programmable bias. As can be seen from Table 3-11, it is ideal for the 900-MHz range and its programmable gain/bias makes it very attractive. This design (Figure 3-131) is based on the cascode mentioned above and, because of high integration, uses many transistors for bias and level shifting.

The 900-MHz application circuit in Figure 3-132 shows the required external components for a successful design. Input and output are made tunable. The 5.6- and 39-nH inductances can be made from small air-wound coils. The output ceramic filter provides the necessary selectivity ahead of the mixer. With such a highly selective device in the input, the noise figure would deteriorate too much. The antenna is rarely in the vicinity of sufficiently strong transmitters to require such strong input filtering.

There are two more interesting applications for two-stage amplifiers: The one implemented in the Hewlett-Packard MSA-0735 MMIC has become a quite common one, and its usefulness up to higher frequencies depends mostly on the cutoff frequency of the transistors,

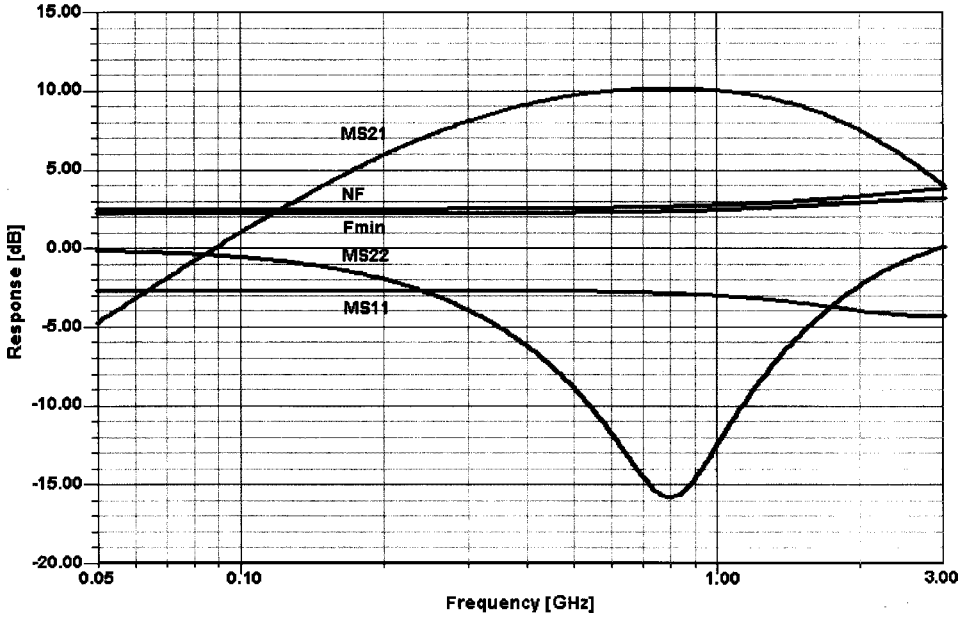

Figure 3-130 Frequency-dependent gain, matching, and noise performance of the cascode amplifier.

their parasitics, and the phase shift of the gain. The typical configuration is shown in Figure 3-133, and its frequency-dependent gain, match, and noise figure in Figure 3-134. There is an increase of S_{22} at higher frequencies; this indicates unwanted phase shift in the circuit. Some manufacturers hide the compensation circuits to overcome such peaking; most of the schematics shown by the manufacturers are really intended only to show operating principles, with proprietary details omitted.

Thanks to the properties of GaAs transistors, we can extend the frequency range significantly. The amplifier we are about to look at goes back several years and is described in great detail in Goyal [27]. Essentially what we have, seen in Figure 3-135, is an FET version of Figure 3-127. The main goal of this circuit was to have an all-monolithic circuit, avoiding all ac coupling and accomplishing all matching and interaction with dc coupling. The transistor Q1 is the main gain stage, which has the transistor Q2 as an active load. The output impedance of Q2 is $1/g_m$—typically in the area of 50–200 Ω, depending on the biasing,

Table 3-11 MC13144 features

Gain at 900 MHz, 17 dB
Noise figure at 900 MHz, 1.4 dB

$IP_{3,in}$, −5.0 dBm
Low operating supply voltage (1.8–6.0 Vdc)
Programmable bias with Enable 1 and Enable 2. [Enable 1 and Enable 2 programmed high for optimal noise figure and gain associated with NF. Enable can be overridden for external bias programming (up to 15 mA.)]

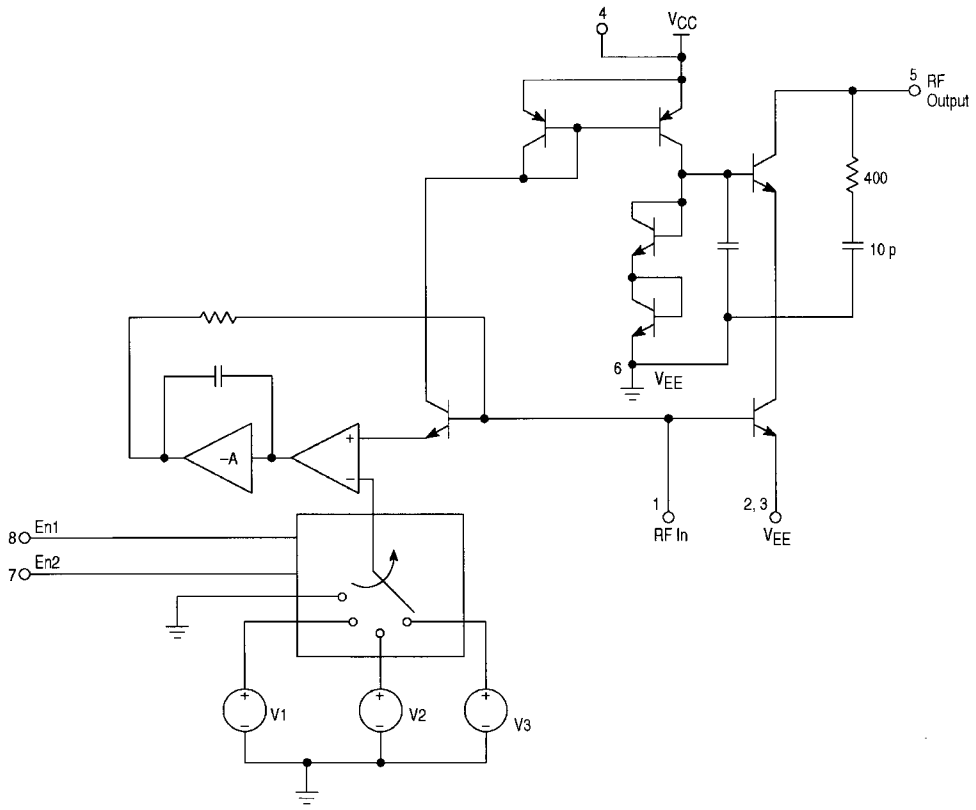

Figure 3-131 Schematic of the Motorola MC13144 cascode LNA.

which affects the transconductance. Transistor Q3 has the same function as an emitter/source follower; again, its dc bias determines its transconductance and therefore its output impedance. (Given this, a device that has a transconductance of 20 mS, or close to it, would establish a very good output match to 50 Ω.) The drains of Q1 and Q5 are at approximately 3.5 V. The diodes at the source of Q3 are level shifters that must shift the dc voltage at the gate of Q5 and at the drain of Q4 to approximately −1.5 V relative to ground—the necessary bias condition for Q1 and Q5. The standard shunt feedback circuit would show resistive feedback between the drain of Q1 (gate of Q2) and the gate of Q1; in the previous examples, we calculated the magic value of this part to be about 200 Ω. Adding in parallel to Q1 the transistor Q5 allows the designer to use a feedback scheme that isolates the feedback loop from the input. Dc-wise, the two transistors are tied together via a 10-kΩ resistor, which can be included in the actual packaged device. Insufficient information was published to allow us to duplicate the design, considering all the intricacies involved (we somewhat object to the fact that even in the *IEEE MTT-S Transactions*, so little information is given about the actual implementation of this design—using space constraints as an excuse—that its educational value is usually minimal); it shows a new principle without revealing the design steps necessary to obtain a practical circuit. Several variations of this type of circuit are available; the literature is full of discussions about them. The magnitude of the feedback is set by the ratio of the width of Q5 to that of Q1. Typical values for the Q5/Q1 ratio range

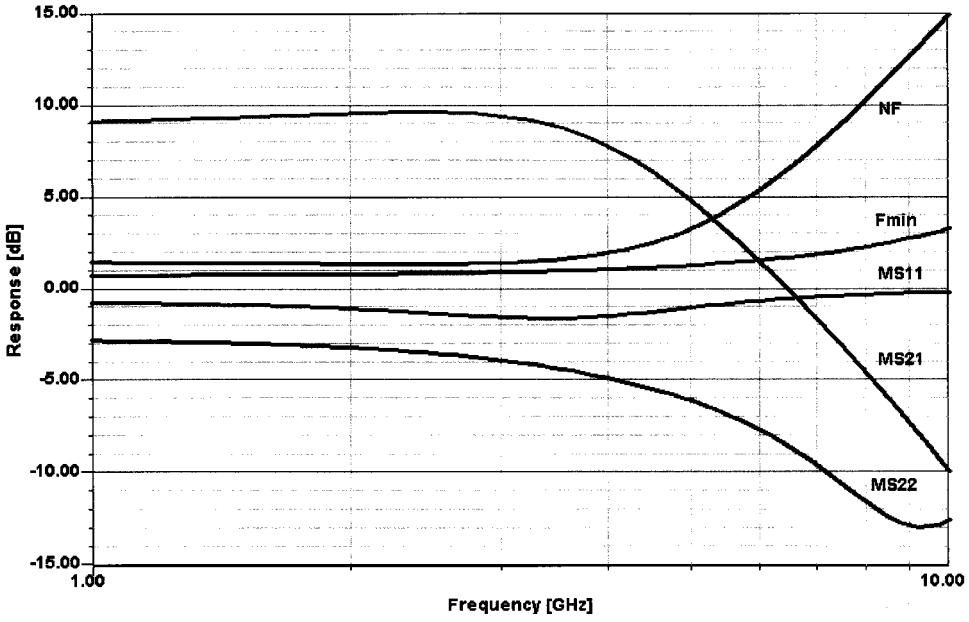

Figure 3-136 Frequency-dependent gain, matching, and noise performance of the dc-coupled GaAsFET amplifier.

from 0.15 to 0.30. In simulation, sizing the devices can best be accomplished by using the scaling factor for the FET model.

One of our questions was: "What would the perfect input termination for Q1 be?" By using an ideal transformer and playing with its turns ratio (needless to say, we did this with CAD), we determined experimentally that, relative to the gate, 200 Ω and a series inductor of 5–8 nH—the sort of details that designers often avoid telling their audiences—gave the ideal frequency response. Overall, we believe that the inventor of this circuit can be quite proud of the overall performance. The FETs we chose were taken from the Texas Instruments nonlinear foundry library; however, any similar device from another company would have worked equally well. The feedback loop used in this IC is an example of an approach frequently referred to as *active feedback*. The performance of this amplifier can be evaluated from Figure 3-136, which shows the frequency-dependent gain, matching, and noise figures (even including F_{min}).

3-5 AMPLIFIERS WITH THREE OR MORE STAGES

Most three-stage amplifiers are obtained by adding another buffer or power-gain stage to the previously described principal designs. As an example, we decided to evaluate the recent NEC UPC2749 IC, a silicon MMIC intended for application as a low-noise 1900-MHz amplifier operating at 3 V. Table 3-12 briefly summarizes its electrical specifications.

Table 3-12 NEC UPC2749 electrical characteristics

(T_A = 25 °C, $Z_L = Z_S$ = 50 Ω, V_{CC} = 3.0 V)			
	Part Number Package Outline		UPC2749T TO6
Symbols	Parameters and Conditions	Units	Typical
I_{CC}	Circuit current (no signal)	mA	6
G_S	Small-signal gain, f = 900 MHz dB	14.5	
	f = 1900 MHz	dB	16
f_{corner}	–3-dB Gain corner frequency	GHz	2.9
P_{1dB}	1 dB Compressed output power at 1900 MHz	dBm	–12.5
P_{SAT}	Saturated output power, f = 1900 MHz	dBm	–6
NF	Noise figure, f = 900 MHz	dB	3.2
	f = 1900 MHz	dB	4.0
RL_{IN}	Input return loss, f = 1900 MHz	dB	10
RL_{OUT}	Output return loss, f = 1900 MHz	dB	12.5
ISOL	Isolation, f = 1900 MHz	dB	30
OIP_3	SSB output third-order intercept, f_1 = 500 MHz, f_2 = 510 MHz	dBm	–3
	f_1 = 1000 MHz, f_2 = 1010 MHz	dBm	–3
	f_1 = 1900 MHz, f_2 = 1902 MHz	dBm	–3.5
	f_1 = 2000 MHz, f_2 = 2010 MHz	dBm	–4
$R_{TH(J-A)}$	Thermal resistance (junction to ambient)		
	Free air	°C/W	
	Mounted on a 50 × 50 × 1.6 mm epoxy glass PWB	°C/W	

In modeling the UPC2749's three transistors, we chose to use our favorite, the BFP420, which is not without its headaches at the higher frequencies. Figure 3-137 shows the circuit diagram, which closely resembles the one published by NEC; again, the only hard facts we had were the IC's basic circuit topology, gain, and dc current. Given those numbers, we staggered the current in the three devices by setting them at 0.64 mA for the first stage, 1.85 mA for the second stage, and 3 mA for the third stage. It should be noted that the two output transistors are not unlike the approach used for the Hewlett-Packard MSA-0735 (Figure 3-133). Taking (hopefully) all the right assumptions, we end up with a design that closely resembles the manufacturer's specifications for both power consumption, gain, and noise. This can be verified by looking at the results plotted in Figure 3-138.

The final example is a more complex derivative of the Philips NE/SA5204A amplifier, which was intended for standard 6-V operation and has a fairly "normal" circuit arrangement. This can be seen from Figure 3-139. A much more elaborate cousin of this is the low-voltage NEC UPC2710 amplifier. According to its specifications, it operates at 5 V but has significantly more gain than the NE/SA5204. Table 3-13 shows its electrical specifications and Figure 3-140 shows its measured gain as published by the manufacturer.

The actual interior of the circuit is shown in Figure 3-141. It consists of the standard preamplifier and then a Darlington configuration with the collectors tied together. The middle section of the circuit acts as a power supply responsible for the bias relative to the emitter of the first transistor influencing the rest of the circuit as well. Since NEC mentioned that they use their NESAT III process (f_T of 20 GHz at V_{ce} = 3) in producing the UPC2710T and we

R_{TH}	Thermal resistance (junction to ambient)	°C/W	

obtained some information regarding it, we decided to use our standard BFP420 (f_T of 25 GHz; see the datasheet in Chapter 2) for the purpose of simulation.

In our effort to simulate this circuit, we chose a combination of values that pretty much complies with the manufacturer's published specifications, but S_{22} is not close, as shown in Figure 3-142. We stopped at this point and invite our readers with CAD capabilities to provide the final touch in meeting all the published specifications for the circuit. We are particularly

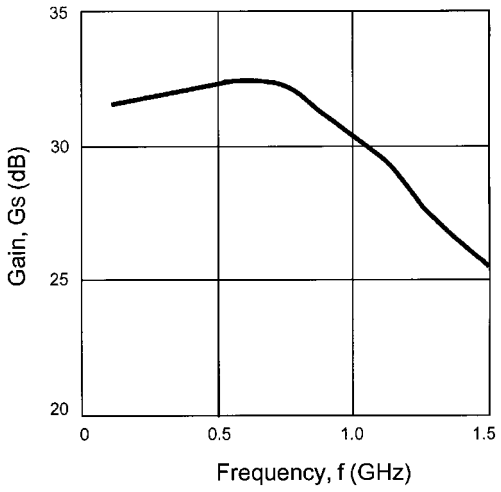

Figure 3-140 Manufacturer-supplied gain versus frequency for the NEC UPC2710T MMIC.

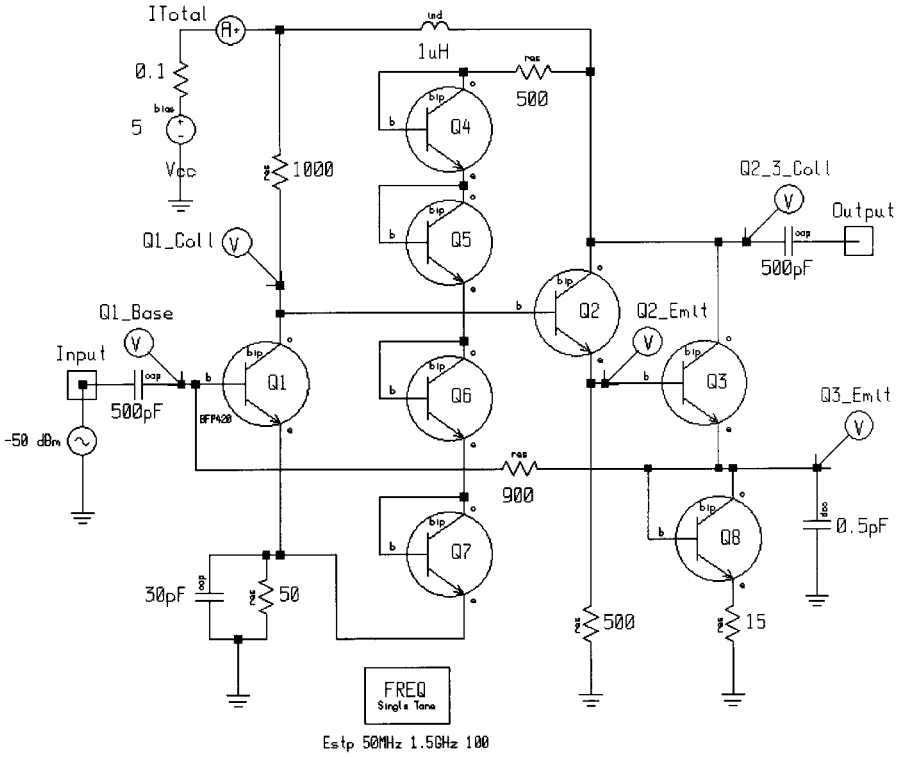

Figure 3-141 Schematic of the UPC2710T silicon MMIC entered for simulation.

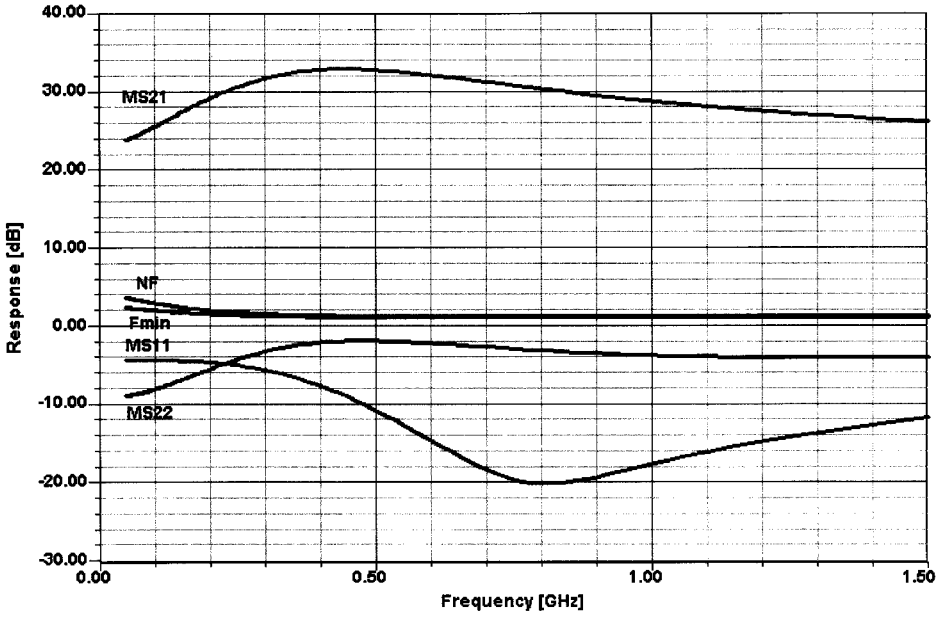

Figure 3-142 Simulated gain, match, and noise performance of the UPC2710T.

recommending such an effort because it shows very nicely the interaction of all the circuit elements in a fairly drastic way. Because of this, we admire the IC design even more, since the manufacturer has to sell a pretty consistent amplifier as a function of different production runs.

3-5-1 Stability of Multistage Amplifiers

Stability, needless to say, is a big issue, and the delay of the various stages adds to the phase shift, resulting in possible instabilities. The fact that S_{11} and/or S_{22} can become larger than 0 (in dB) means there is the potential of oscillating, depending on the reactances available. If a cable of inappropriate length is added, hell will break loose. Figure 3-143 shows the dangerous peaking of our simulation of the Philips NE5204A, in which the internal compensation was intentionally not assumed correctly. We will all agree that the high-end performance of this amplifier can generate high anxiety. As the production process of the aging device becomes more modern—meaning that transistors with much higher f_T will be the basis for the production—it will become quite difficult to maintain a previously achieved stability. This, by the way, applies also to discrete transistors, which for reasons of economics and multiple manufacturers will be improved over time. Such evolution results in generally smaller base-spreading resistances and capacitances, and other parameter changes, which, overall, cause headaches in manufacturing. We will leave the topic of three-stage amplifiers on this note.

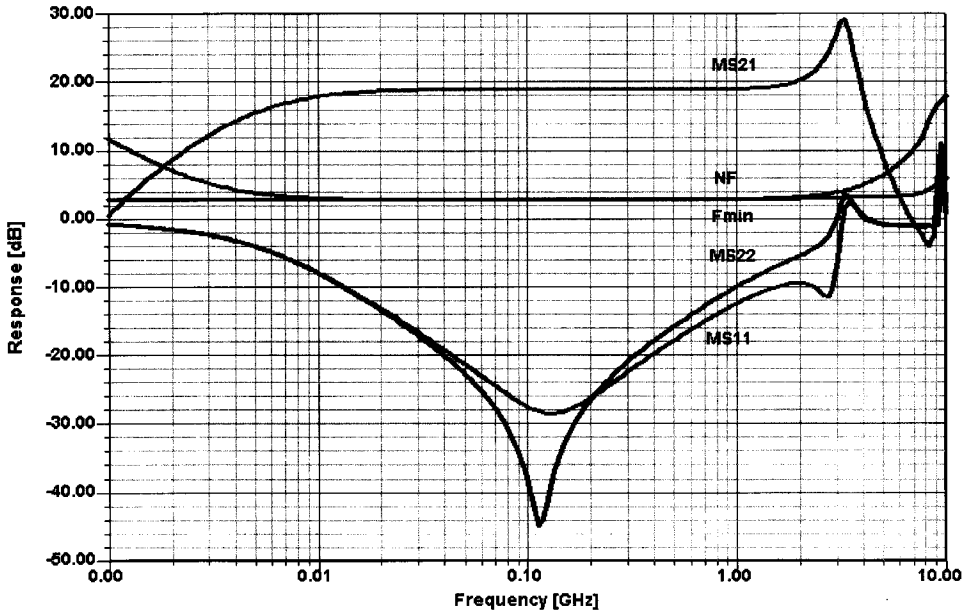

Figure 3-143 Simulated gain, match, and noise performance of the NE5204A IC.

3-6 A NOVEL APPROACH TO VOLTAGE-CONTROLLED TUNED FILTERS INCLUDING CAD VALIDATION [28]

Modern receivers control input stages as well as the oscillator band and frequency by electrical rather than mechanical means. Tuning is accomplished by voltage-sensitive capacitors (varactor diodes), and band switching by diodes with low forward conductance. Since the wireless band (essentially 400 MHz to 2.4 GHz) is so full of strong signals, the use of a tracking filter is desired as a solution to improve the performance and prevent second-order IMD products or other undesired overload effects. The dc control voltage needed for the filter can easily be derived from the VCO control voltage. There may be a small dc offset, depending on the IF used.

3-6-1 Diode Performance

The capacitance versus voltage curves of a varactor diode depend on the variation of the impurity density with the distance from the junction. When the distribution is constant, there is an "abrupt junction" and capacitance follows the law

$$C = \frac{K}{(V_d + V)^{1/2}} \tag{3-183}$$

where V_d is the contact potential of the diode and V is applied voltage.

Such a junction is well approximated by an alloyed junction diode. Other impurity distribution profiles give rise to other variations, and the above equation is usually modified to

$$C = \frac{K}{(V_d + V)^n} \tag{3-184}$$

where n depends on the diffusion profile and $C_0 = K/V_d^n$.

A so-called graded junction, having a linear decrease in impurity density with the distance from the junction, has a value of n. This is approximated in a diffused junction.

In all cases these are theoretical equations, and limitations on the control of the impurity pattern can result in a curve that does not have such a simple expression. In this case, the coefficient n is thought of as varying with voltage. If the impurity density increases away from the junction, a value of n higher than 0.5 can be obtained. Such junctions are called hyperabrupt. A typical n value for a hyperabrupt junction is about 0.75. Such capacitors are used primarily to achieve a large tuning range for a given voltage change. Figure 3-144 shows the capacitance–voltage variation for the abrupt and graded junctions as well as for a particular hyperabrupt-junction diode. Varactor diodes are available from a number of manufacturers, such as Motorola, Siemens, and Philips. Maximum values range from a few to several hundred picofarads, and useful capacitance ratios range from about 5 to 15.

Figure 3-145 shows three typical circuits that are used with varactor tuning diodes. In all cases, the voltage is applied through a large resistor R_e or, better, an RF choke in series with a small resistor. The resistance is shunted across the lower diode and may be converted to a shunt load resistor across the inductance to estimate Q. The diode also has losses that may result in lowering the circuit Q at high capacitance, when the frequency is sufficiently high. This must be considered in the circuit design.

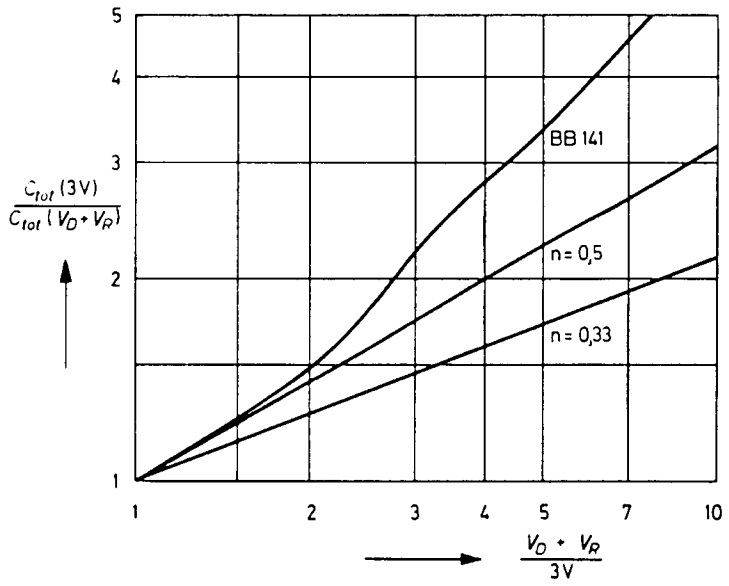

Figure 3-144 Voltage-dependent change of capacitance of different types of diodes. The BB141 is a hyperabrupt-junction diode with $n = 0.75$.

The frequency-dependent performance is not determined solely by applying the dc tuning voltage to Eq. (3-184). If the RF voltage is sufficient to drive the diode into conduction on peaks, an average current will flow in the circuits of Figure 3-145, which will increase the bias voltage. The current is impulsive, giving rise to various harmonics of the circuit. Even in the absence of conduction, Eq. (3-184) deals only with the small-signal capacitance. When the RF voltage varies over a relatively large range, the capacitance changes. In this case, Eq. (3-184) must be changed to

$$\frac{dQ}{dV} = \frac{K}{(V + V_d)^n} \tag{3-185}$$

Here Q is the charge on the capacitor. When this relation is substituted in the circuit differential equation, it produces a nonlinear differential equation, dependent on the parameter n. Thus, the varactor my generate direct current and harmonics of the fundamental frequency. Unless the diodes are driven into conduction at some point in the cycle, the direct current must remain zero.

The current of Figure 3-145c can be shown to eliminate the even harmonics, and it permits a substantially larger RF voltage without conduction than either circuit in Figure 3-145a or 3-145b. When $n = 0.5$, only the second harmonic is generated by the capacitor, and this can be eliminated by the back-to-back connection of the diode pair. Integrating Eq. (3-185), we find

$$Q + Q_A = \frac{K}{1 - n}(V + V_d)^{1-n}$$

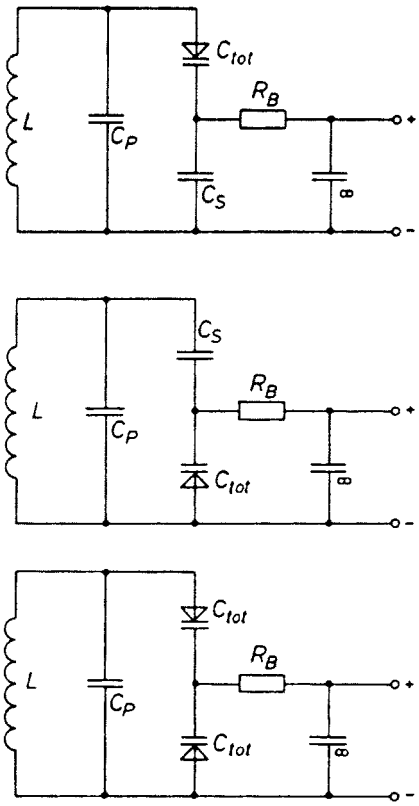

Figure 3-145 Various configurations to apply tuning diodes in a tuned circuit. The bottom version shows the lowest distortion.

$$= \frac{C_v}{1-n}(V + V_d) \tag{3-186}$$

C_v is the value of Eq. (3-184) for applied voltage V, and Q_A is a constant of integration. By letting $V = V_1 + v$ and $Q = Q_1 + q$, where the lowercase letters represent the varying RF and the uppercase letters indicate the values of bias when RF is absent, it follows that

$$q + Q_1 + Q_A = \frac{K}{1-n}[v + (V_1 + V_d)]^{1-n} \tag{3-187}$$

$$1 + \frac{v}{V'} = \left(1 + \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-188}$$

where $V' = V_1 + V_d$ and $Q' = Q_1 + Q_A$. For the back-to-back connection of identical diodes, $K_{11} = K_{12} = K_1$, $V_1' = V_2' = V'$, $Q_1' = Q_2' = Q'$, $q = q_1 = -q_2$, and $v = v_1 - v_2$. Here the new subscripts 1 and 2 refer to the top and bottom diodes, respectively; v is the RF voltage across

the pair in series, and q is the charge transferred through the pair in series. This notation results in

$$\frac{v}{V'} \equiv \frac{v_1 - v_2}{V'} = \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} - \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-189}$$

For all n, this eliminates the even powers of q, and hence the even harmonics. This can be shown by expanding Eq. (3-189) in a series expansion and performing term by term combination of the equal powers of q. In the particular case $n = \frac{1}{2}$, $v/V' = 4q/Q'$, and the circuit becomes linear.

The equations hold as long as the absolute value of v_1/V' is less than unity, so that there is no conduction. At the point of conduction, the total value of v/V' may be calculated by noting that when $v_1/V' = 1$, $q/Q' = -1$, so $q_2/Q' = 1$, $v_2/V = 3$, and $v/V = -4$. The single-diode circuits conduct at $v/V' = -1$, so the peak RF voltage should not exceed this. The back-to-back configuration can provide a fourfold increase in RF voltage handling over the single diode. For all values of n, the back-to-back configuration allows an increase in the peak-to-peak voltage without conduction. For some hyperabrupt values of n, such that $1/(1 - n)$ is an integer, many of the higher-order odd harmonics are eliminated, although only $n = \frac{1}{2}$ provides elimination of the third harmonic. For example, $n = \frac{2}{3}$ results in $1/(1 - n) = 3$. The fifth harmonic and higher odd harmonics are eliminated, and the peak-to-peak RF without conduction is increased eightfold; for $n = \frac{3}{4}$ the harmonics 7 and above are eliminated, and the RF peak is increased 16 times. It must be noted in these cases that the RF peak at the fundamental may not increase so much, since the RF voltage includes the harmonic voltages.

Since the equations are only approximate, not all harmonics are eliminated, and the RF voltage at conduction, for the back-to-back circuit, may be different from that predicted. For example, abrupt-junction diodes tend to have n of about 0.46–0.48 rather than exactly 0.5. Hyperabrupt junctions tend to have substantial changes in n with voltage. The diode illustrated in Figure 3-144 shows a variation from about 0.6 at low bias to about 0.9 at higher voltages, with wiggles from 0.67 to 1.1 in the midrange. The value of V_d for varactor diodes tends to be in the vicinity of 0.7 V.

3-6-2 A VHF Example

The application of tuning diodes in double-tuned circuits in TV tuners has been common practice for many years. Figure 3-146 shows the circuit diagram. The input impedance of 50 Ω gets transformed up to 10 kΩ. The tuned circuits consist of the 0.3-μH inductor and two sets of antiparallel diodes. By dividing the RF current in the tuned circuit and using several diodes instead of just one pair, intermodulation distortion is reduced.

The coupling between the two tuned circuits is tuned via the 6-nH inductor that is common to both circuits. This type of inductance is usually printed on the circuit board. The diode parameters used for this application were equivalent to the Siemens BB515 diode. The frequency response of this circuit is shown in Figure 3-147.

The coupling is less than critical. This results in an insertion loss of about 2 dB and relatively steep passband sides. Once the circuit's large-signal performance (Figure 3-148) is seen, a third-order intercept point of about –2 dBm is not so unexpected. The reason for this poor performance is the high impedance (high L/C ratio), which provides a large RF voltage swing across the diodes. A better approach appears to be using even more diodes and at the same time changing the impedance ratio (L/C ratio).

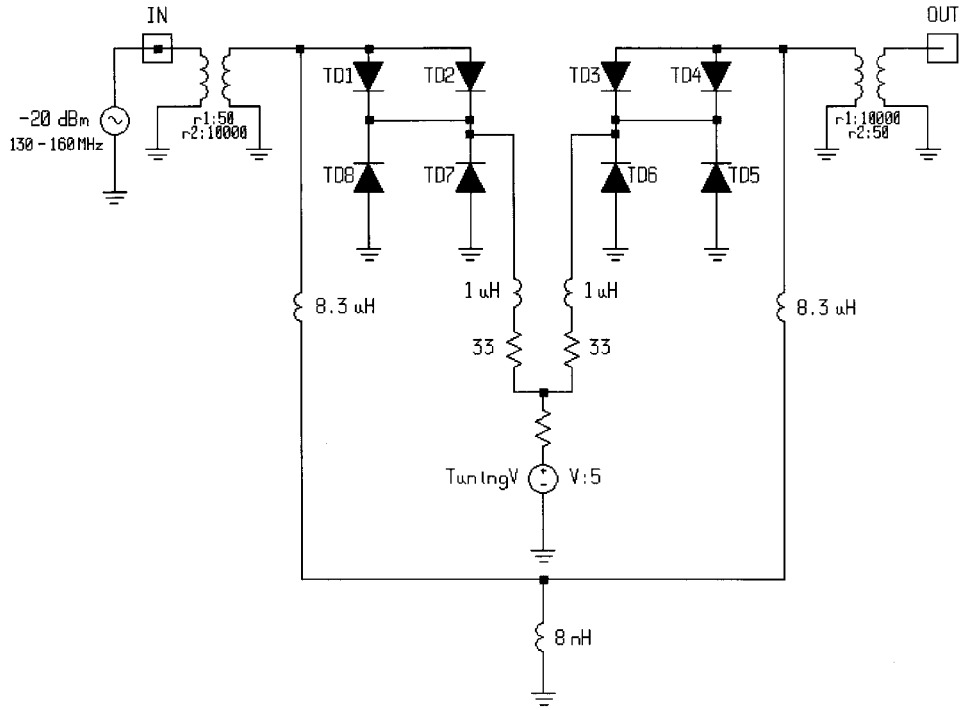

Figure 3-146 Double-tuned filter at 161 MHz using hyperabrupt-junction tuning diodes. By using several parallel diodes, the IMD performance improves.

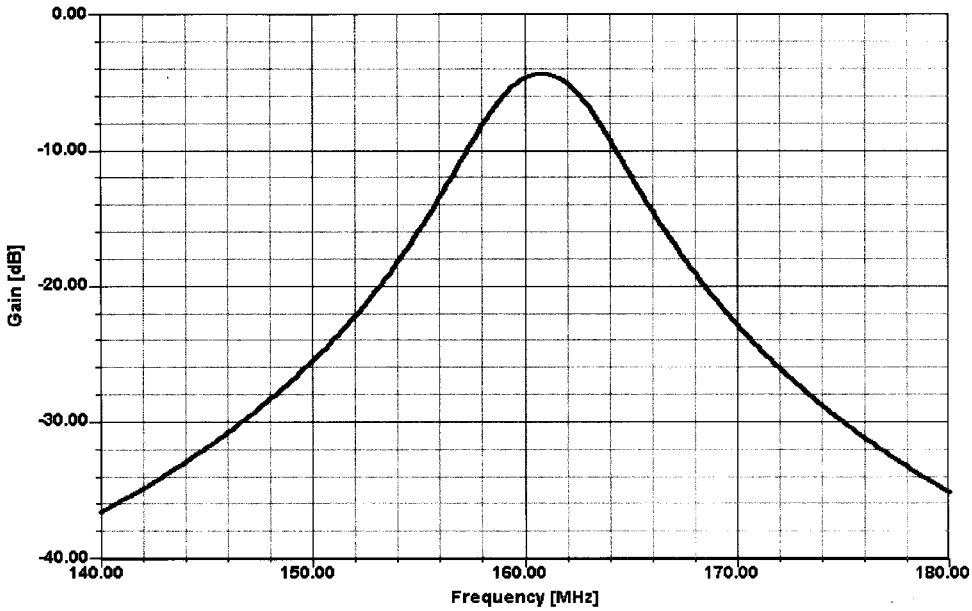

Figure 3-147 Frequency response of the tuned filter shown in Figure 3-146. The circuit is undercoupled (less than transitional coupling); $Q \times k < 1$.

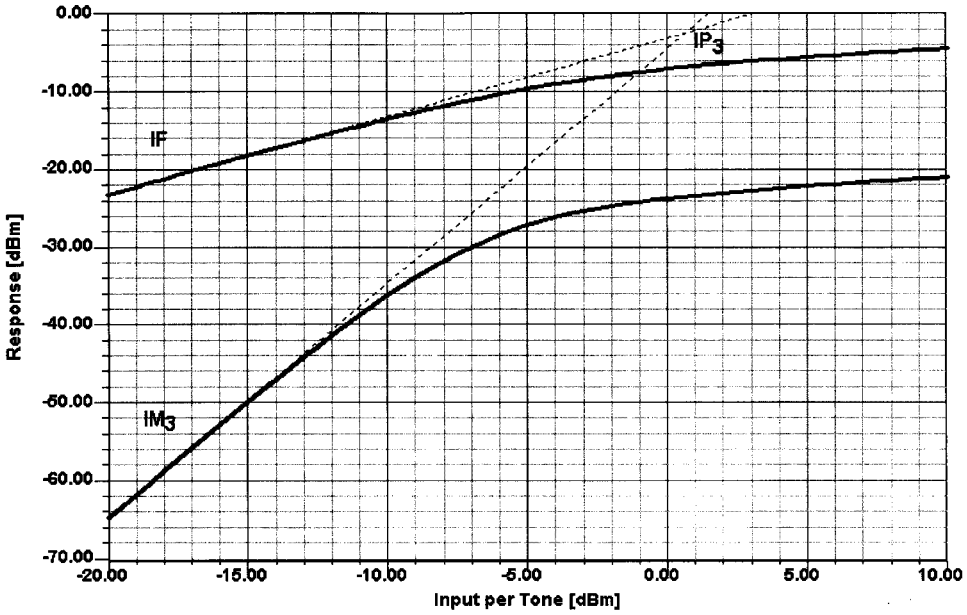

Figure 3-148 Prediction of intercept point of the double-tuned circuit shown in Figure 3-146. Note the compression of both the input signal and the IMD product.

3-6-3 An HF/VHF Voltage-Controlled Filter

The above example used a step-up procedure typically done by a tap at the input and output inductance. This method allows an impedance transformation; however, if one desires to change it into a series-tuned arrangement, it has to be done with a transformer. The large-signal conditions in the frequency range from 10 to 30 MHz on a medium- to large-sized antenna are equivalent to, if not worse than, the conditions for VHF operation. The only exception would be line of sight into the transmitter such as a tower in the middle of the city. Examples of such hostile conditions would be any large city, such as Munich, New York, Miami, Chicago, and San Francisco, where the authors had significant experience with intermodulation distortion problems.

By translating the circuit into a low-impedance-drive arrangement, building it symmetrically, and reducing the tuning range somewhat by capacitors and many series diode pairs, the filter's large-signal performance was significantly improved. The tuning diodes had about 125 pF at 1 Vdc per unit. Initial tests trying to use a high-capacitance diode, such as the BB112, resulted in much higher IMD products. The B112 has a 1-V capacitance of 470 pF down to about 20 pF at 8 V. Standard diodes show about 30 pF at 1 V, while the diodes used in the experiment had a 125-pF capacitance at 1 V. These experimental diodes were made available from a well-known manufacturer for this evaluation. Figure 3-149 shows the circuit diagram.

A step-down transformer drives the tuned circuit with a source impedance of 12.5 Ω. The circuit is symmetrical. There are two 0.8-μH inductors and 2×5 diodes in the loop. The output of the circuit is transformed back up to 50 Ω. The tuning voltage is supplied via a heavily filtered arrangement. This circuit has actually been implemented in Rohde & Schwarz field strength meter equipment. They guarantee an intercept point of about +20 dBm. The selectivity of these circuits is quite reasonable and mostly intended to reduce

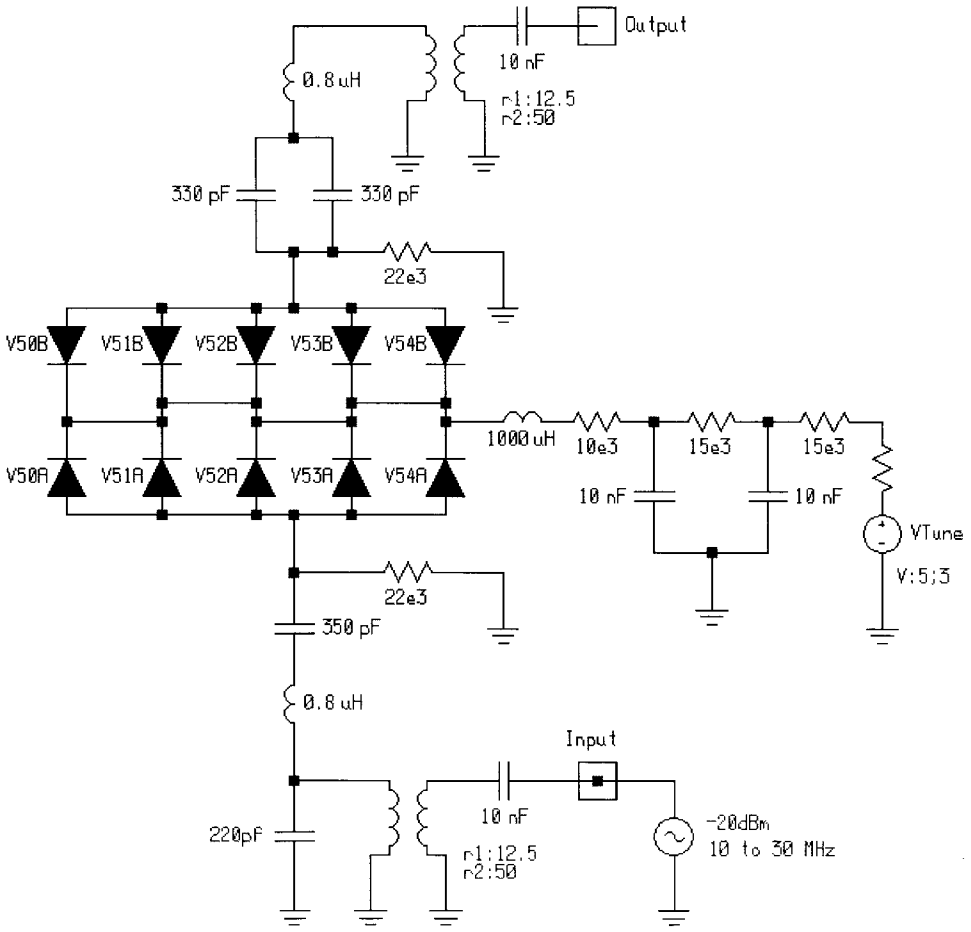

Figure 3-149 High dynamic range of a 10–20-MHz filter.

second-order intermodulation distortion products by about 10 dB, at the same time having a high third-order intercept point. Figure 3-150 shows the selectivity curves at two different tuning voltages.

The most interesting number, however, is the third-order intercept point (already determined as about 20 dBm), which still had to be simulated. This sometimes sounds like a contradiction: Once the measured values are available and are acceptable, why would one want—or, rather, need—to do a simulation besides the necessity to develop a high-input intercept filter? It was desirable to validate the nonlinear models and prove that the above-mentioned equations will hold true. This type of simulation is now more difficult because the number of nonlinear elements went from four to ten, and some numerical problems, such as convergence difficulties, can be expected, and the effect of harmonic frequency cancellation (compensation) can also be seen. By using diode combinations that result in $1(1 - n)$, n being an integer number, these IMD products can drastically be reduced. This implies that each of the five diode pairs has a selected value for n to meet this condition. Later, a final attempt will be made to improve the first VHF filter with the proper diode combinations.

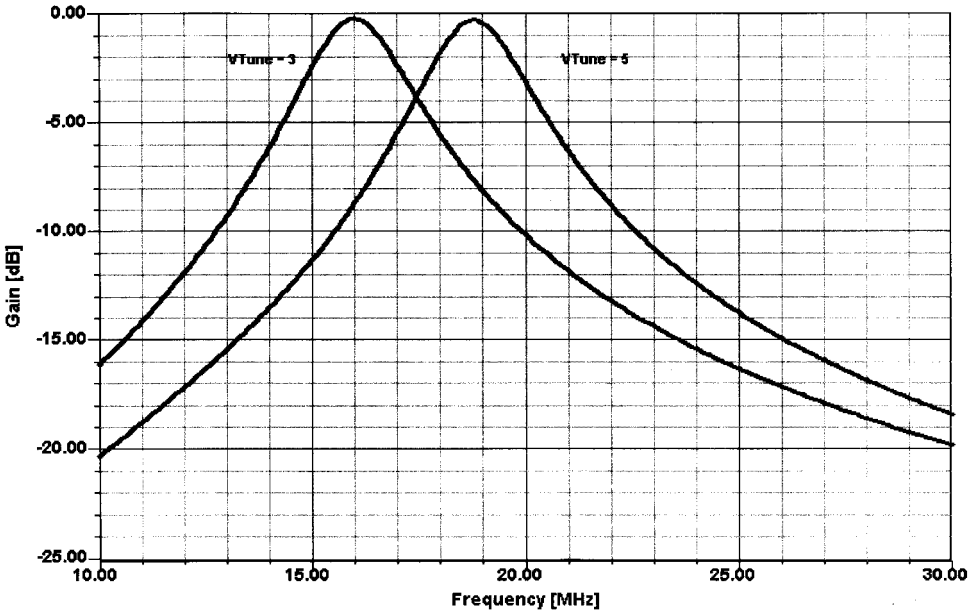

Figure 3-150 Frequency response of the filter shown in Figure 3-149. Filters of this type are intended to reduce second-order IMD by providing about 20-dB suppression at half the center frequency.

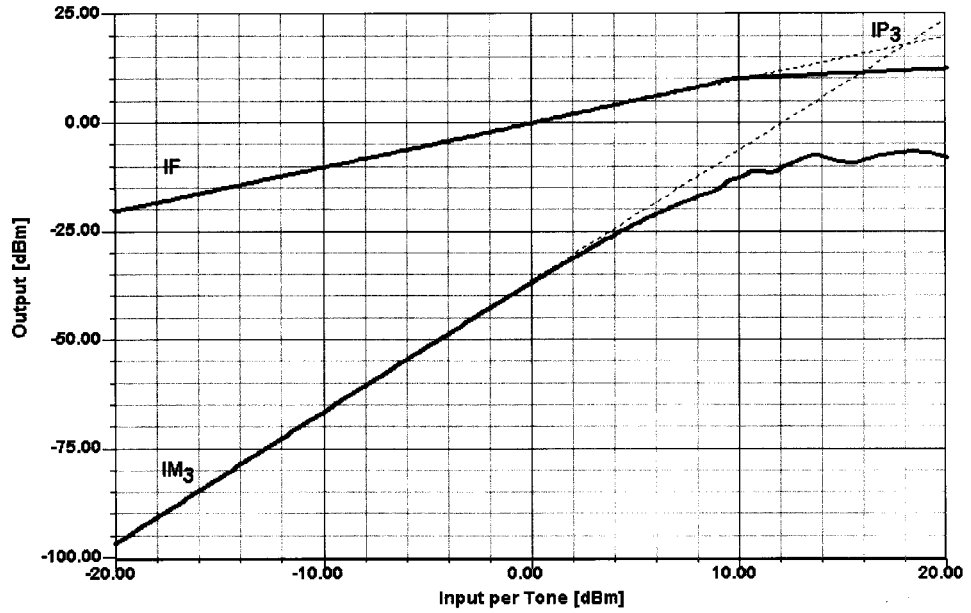

Figure 3-151 Prediction of third-order intercept point of the filter shown in Figure 3-149. The reason for the curves on the IMD plot lies in the interaction between the ten nonlinear devices.

Figure 3-151 shows the calculation of third-order intercept point for the arrangement shown in Figure 3-149. This number has now increased to +18 dBm. The difference between selection and measurement is approximately 2 dB. The reason for this more pessimistic value compared to the measured value probably has to do with slight variations of the exponent of the diodes' voltage-dependent capacitance. Therefore, the authors consider both the circuit performance and the simulation accuracy to be extremely good. This type of circuit, as mentioned earlier, has wide application in oscillator circuits. Danzeisen of Rohde & Schwarz was probably the first to have used this type of circuit by paralleling many diodes for improved performance.

3-6-4 Improving the VHF Filter

By selecting the appropriate diode combinations and circuit modifications as shown in Figure 3-152, a significant IMD improvement of the circuit shown in Figure 3-146 is obtained. A special shunt arrangement of several diodes with different exponents has been developed, which allows its value to be "adjusted." This circuit, for which a patent has been applied, showed an improvement from –2 dBm to 32 dBm. The same high operating Q was maintained. Figure 3-153 shows the frequency response after the modification. Note that a coupling slightly greater than critical ($Q \times k = 1.1$) has been selected.

3-6-5 Conclusion

After explaining some of the nonlinearities in mathematical terms, we have given some examples of voltage-tuned circuits and discussed their large-signal performance. This section has also shown that modern CAD tools can accurately predict the performance of such circuits.

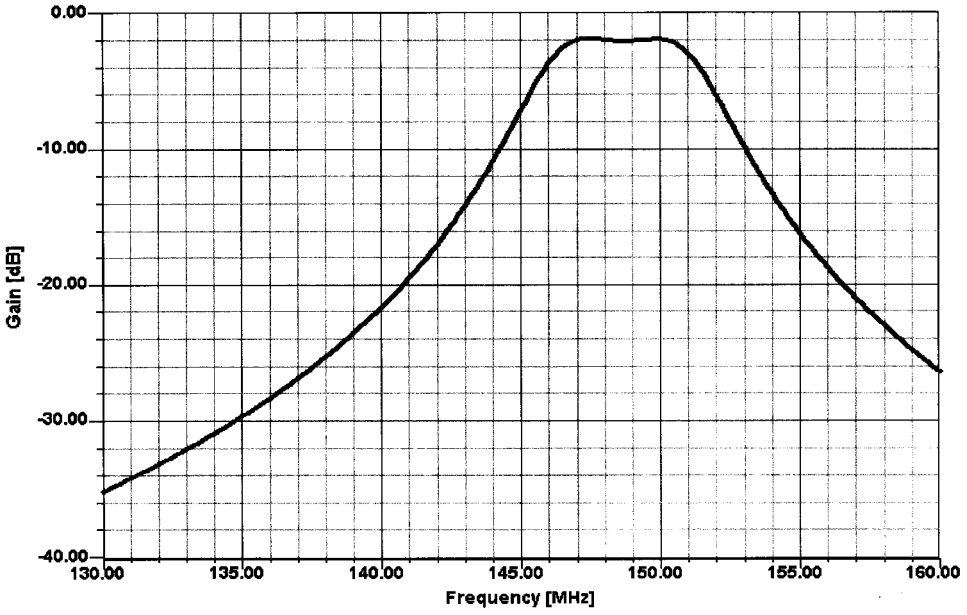

Figure 3-152 The frequency response of the improved circuit derived from Figure 3-146.

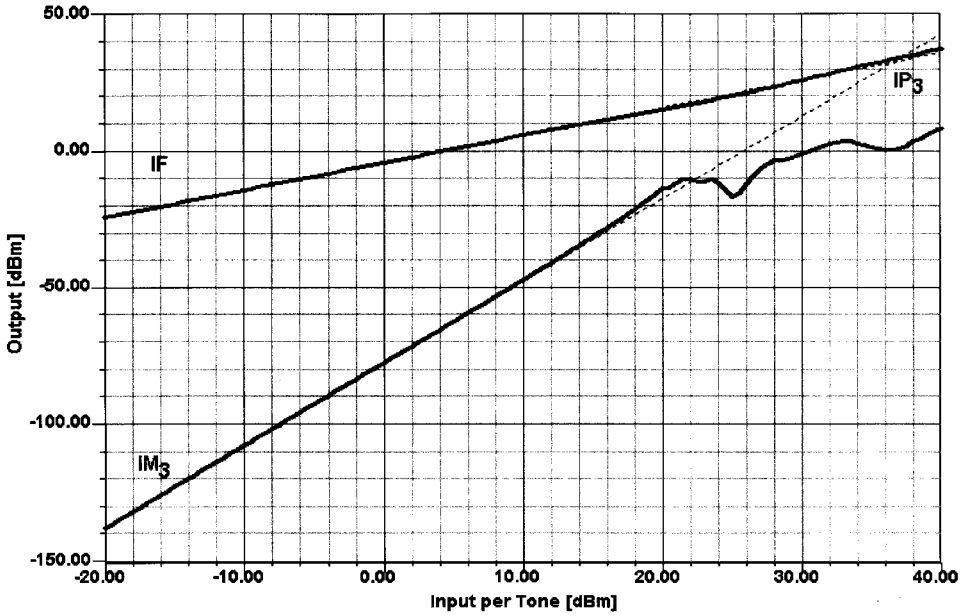

Figure 3-153 Predicted IMD performance of the improved version of the circuit shown in Figure 3-146. This type of improvement is significant for all applications. A patent is in the process of being obtained for this; therefore, the circuit cannot be disclosed at present.

3-7 DIFFERENTIAL AMPLIFIERS

The differential amplifier (Figure 3-154) goes back many years and also was the first step from TTL to ECL. The differential amplifier consists of an emitter follower (Q1) and a grounded-base stage (Q2). The constant-current generator (Q3) between ground and the emitters of Q1 and Q2 determines the current for these stages; the dc operating currents of Q1 and Q1 are the same. Most modern integrated circuits use this differential amplifier in one way or another.

If the circuit is operated about its point of symmetry, the dc component of the current through either Q1 or Q2 remains half of the emitter constant current through Q3 for all symmetrical driving signals. In addition, for input signals that are aperiodic, no even harmonics are generated. This assumes that the stage is driven symmetrically at both inputs. In our case, the differential amplifier has its second stage grounded, meaning that there is a base-to-ground capacitor, and the stage is asymmetrically fed. As the input voltage is increased, the differential stage becomes a limiter, which limits the current between plus and minus I_S, with I_S being the source current. The resulting output will become a square wave. This stage can also be used as a line receiver, translating a sine wave to an output logic suitable for driving emitter-coupled logic (ECL) stages.

One can assume that the differential amplifier has a transconductance of

$$g_m = \frac{\alpha g_{\text{in}}}{2} \tag{3-190}$$

where α is the ratio of collector to emitter current. Within the limits of the output being a sine wave, this stage has very low distortion. The output current now is determined by

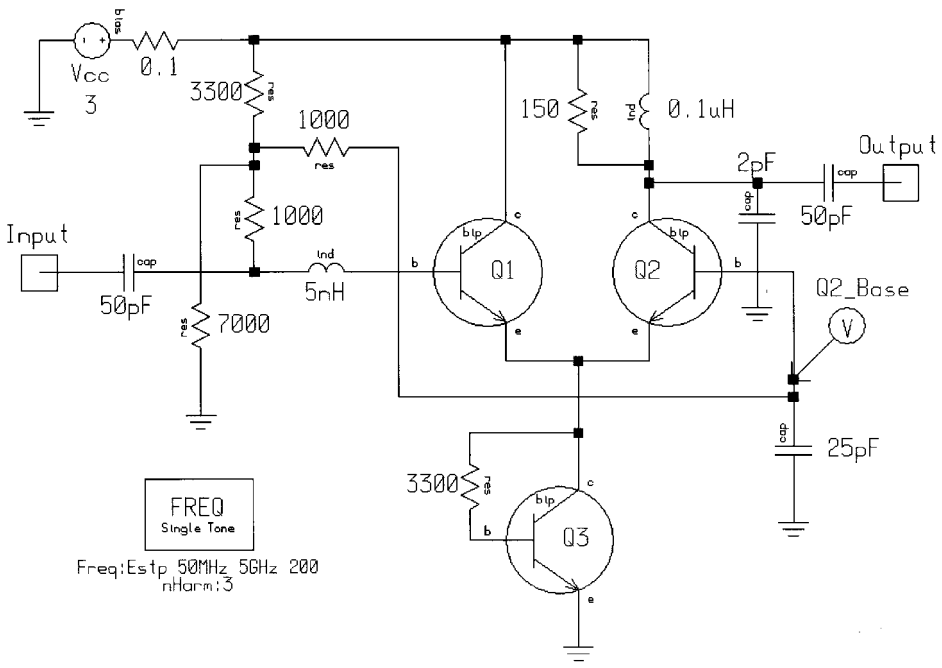

Figure 3-154 The differential amplifier schematic. The transistors are Siemens BFP420s. Figure 3-155 shows the circuit's frequency-dependent gain, matching, and noise performance.

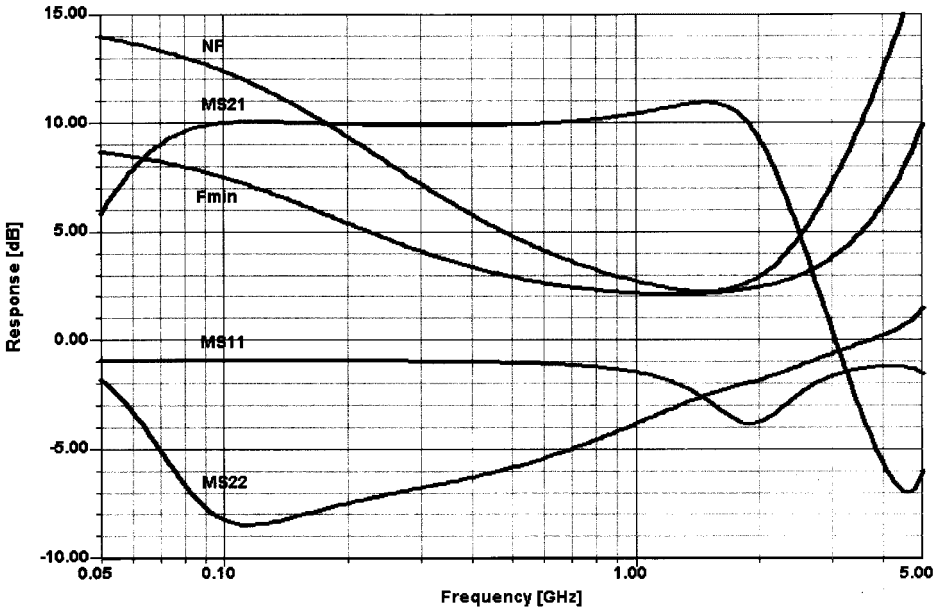

Figure 3-155 Frequency-dependent gain, matching, and noise performance of the differential amplifier.

$$i = \frac{I_{\text{in}}}{2} \tanh\left(\frac{x}{2} \cos \omega t\right) \tag{3-191}$$

where ωt is the input frequency and I_{in} is the current forced by Q3. The reason why the transconductance has to be divided by 2 comes from the fact that the current is split into two equal components for Q1 and Q2. Multiplying the new transconductance with the output load gives the voltage gain of this amplifier; its power gain can be obtained by multiplying this with $\sqrt{\text{output resistance} \div \text{load resistance}}$.

Having done the linear analysis and having learned that because of the hyperbolic tangent functions this amplifier can also be used as a line receiver, and converting sinusoidal waves to square waves, it may be useful to take a closer look at these issues. If we take a CAD oscilloscope, we see the resulting output waveform being a nonequal duty cycle output voltage, which results in high harmonic content. The amount of harmonic content can be controlled by the drive power and by the actual bias. Figure 3-156 shows the resulting output waveform.

If we now switch to a CAD spectrum analyzer, we can evaluate the harmonic content (Figure 3-157). Figure 3-158 shows the output transistor's dc I–V curves and ac load line under these conditions. Based on the previously defined conducting angle of the differential amplifier, one can optimize for harmonic content. Therefore, it is logical at this point to look at frequency multipliers, as they are sometimes needed. Finally, we are curious to see the so-called load line of the output transistor, which is, based on the interaction of all the stages, not looking the same way as the expected one, which we know from previous amplifier examples. Part of the reason for this is that for a certain voltage range, the collector voltage is in the negative region, and all kinds of saturation effects result in this surprising waveform. By reducing the input power, one would obtain a more "expected" load line. We invite readers with CAD capabilities to play with this example, as it gives a lot of insight into the operation of ECL stages.

3-8 FREQUENCY DOUBLERS

Having seen that the harmonic content invites us to bias a stage from Class A into Class B or C if our goal is a harmonically rich current, we will now evaluate a single stage that will be biased close to cutoff and driven by a relatively low frequency (500 MHz). To obtain the best results, we will use a parallel notch filter in the output, followed by a high-pass matching circuit to "catch" the desired harmonic. The input frequency is heavily suppressed by the notch filter. Based on its finite Q, there is a limited range over which this frequency can be varied with constant subharmonic attenuation. Figure 3-159 will be our test circuit.

This circuit consists of a bias transistor, Q2. This method has been discussed before and solves the temperature-dependent bias emitter thermal runaway problems through "temperature compensation." The purists among our readers may point out that the currents drawn by Q1 and Q2 are not quite identical (which would give 100% cancellation), but the approach shown is sufficient to do its job. Also, we have chosen a Class AB operation point, which is defined by Q1's 1-mA dc standing current. The conducting angle has not been optimized for the second harmonic—a task that the interested reader can do by using the conducting angle relationship shown at the beginning of this chapter. To give readers with access to nonlinear CAD some homework, we have not set this at the optimum point.

The second transistor, here called Q1 (because of its importance at RF), has a matching network at the input. This is recommended for optimum energy transfer. The matching condition can be validated by examining Figure 3-160. If we look at the higher frequency response, the input shows a possible trend of oscillation (negative loss); this could actually be eliminated by using a low-pass filter at the input instead of the high-pass filter used now. Findings of this type always make us nervous, and we hope that the nonlinear models are sufficiently accurate at higher frequencies to predict such behavior correctly. In the case of the FET doubler mentioned in Chapter 2, we found that the device modeling done by Compact (now Ansoft) gave the best results, the university answers were fairly close, and the device manufacturer data were worst. We have since become highly skeptical about device modeling unless we can validate it ourselves. Synergy Microwave has a complete set of test equipment in the laboratory, including network and spectrum analyzers with special software created by Rohde & Schwarz that can be used in addition to the Scout program to do in-house validation. This was achieved by the use of nonlinear optimization at a drive level of 0 dBm. One could say that this is similar to using a load-pull approach at the input, and then resorting to the large-signal S parameters obtained. Another note of caution: Capacitors at these low values tend to have a very large percentage error; for instance, a 1-pF capacitor, if not selected carefully, can vary between 0.7 and 1.3 pF—a 50% error. Needless to say, this is not acceptable for useful production.

The output consists of a high-pass filter and a notch filter with the purpose of reducing the subharmonic significantly. We have again done this on purpose, leaving room for the reader to come up with a more inventive output circuit like a Cauer-type (same as elliptical) low-pass filter with discrete notches at higher harmonics of the input frequency, such as 1.5 GHz, 2 GHz, and so on. In addition, we have shown three ways how to implement the inductance for the notch filter. This is equally applicable for other inductors in this value range. As frequency increases, this becomes more interesting but one needs to remember that many materials like silicon and gallium arsenide are extremely lossy. The same inductor approach has been used in Figure 5-61 of Chapter 5. For silicon, even the manufacturer becomes an issue. Figure 3-161 shows a top view of a "rectangular" inductor that actually approaches the spiral inductor; its implementation can be seen in Figure 3-162. Modeling this was a

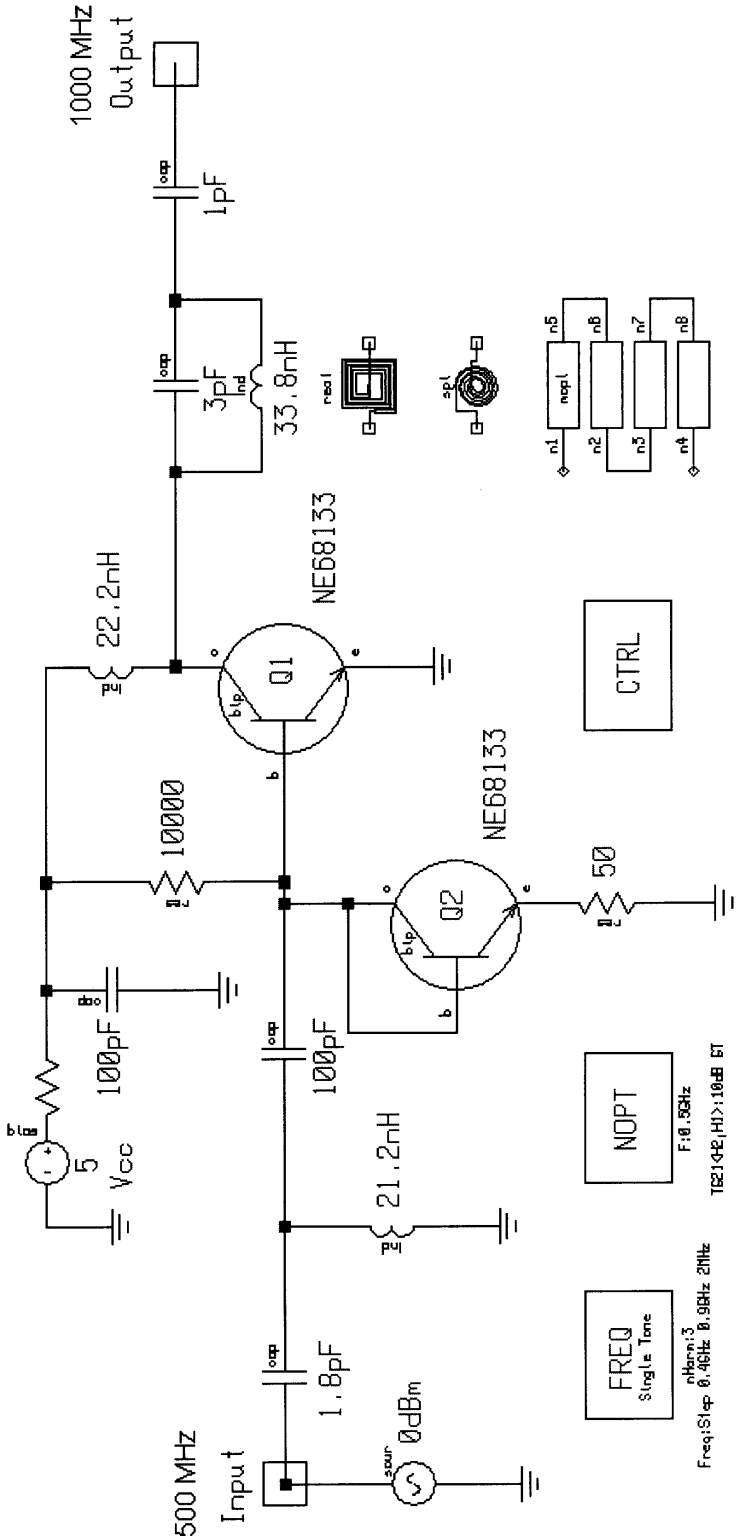

Figure 3-159 BJT frequency doubler schematic. A parallel-tuned trap in Q1's collector attenuates fundamental feedthrough.

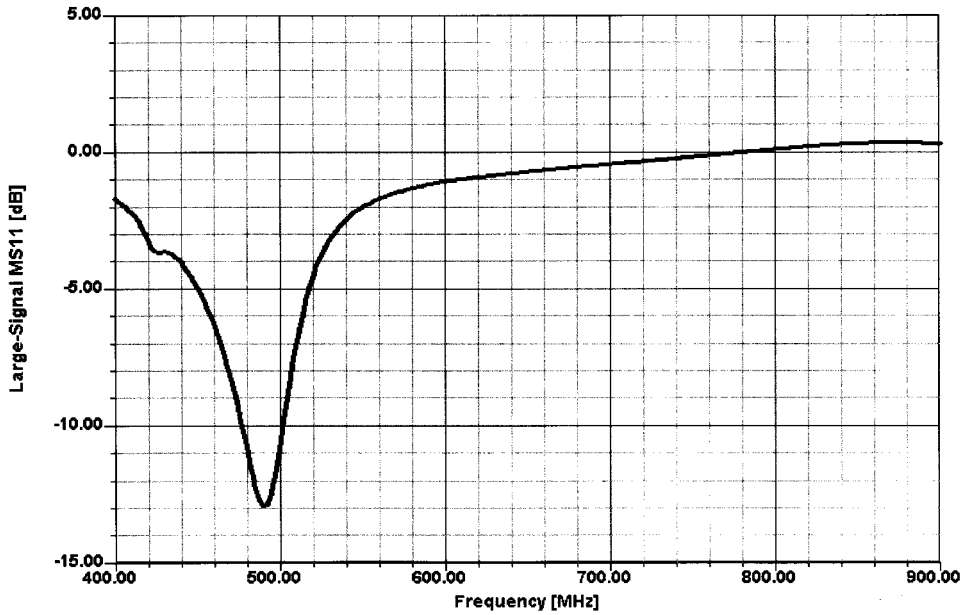

Figure 3-160 Large-signal MS_{11} for the BJT doubler. Note the positive region above 800 MHz.

nightmare, and during our Compact days, we actually had to modify the electromagnetic simulator to accommodate this and get results where measurements and simulation agreed. Figure 3-163 shows the measured and simulated Q as a function of frequency of a silicon-based inductor. In the case of other materials, such as PC board or GaAs, the models in the CAD tools are sufficient to predict the losses of the inductors. Following this initial exercise, Motorola then developed an improved silicon spiral inductor; its frequency-dependent Q is shown in Figure 3-164. Note that this Q was measured and not simulated.

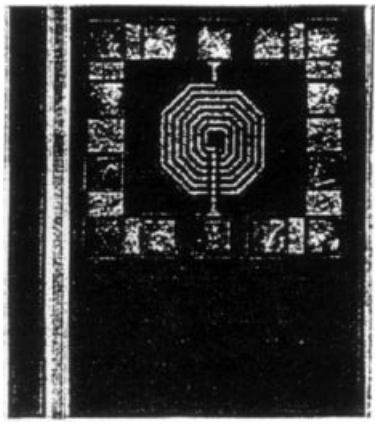

Figure 3-161 A 6.5-turn spiral inductor in silicon.

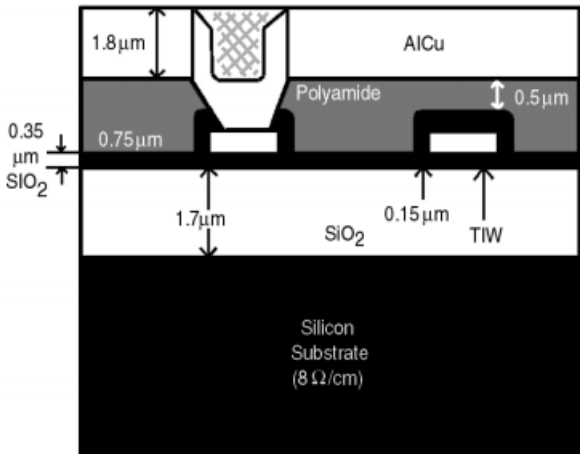

Figure 3-162 Cross section of the silicon inductor.

One of the reasons why we use a transistor multiplier is that we expect gain (because of the square-law characteristic, an FET would have been better tailored for a doubler); therefore, we have "measured" the gain of this circuit while driving it with 0 dBm. Another important factor is that, because of the way the CAD tool displays it, the gain is referenced to the 500-MHz input. Mentioning this is important; otherwise, the reader may look for the 1-GHz gain, which does not exist. Figure 3-165 shows the doubler gain.

By now we are curious to see the doubler in action, and by reviewing Figure 3-166 we can see the output spectrum. The output spectrum validates the statement that the output circuit, while doing a marvelous job of removing the 500-MHz input frequency, does not cure the problem of unwanted multiples of the input frequency. Again, a Cauer low-pass filter, while introducing some possible additional loss, should be considered for this circuit to have a bandpass response. On the other hand, many oscillators have very little harmonic suppression, and the same type of postfiltering needs to be considered. There are two-transistor solutions available also, such as push–push for frequency doubling (push–pull would

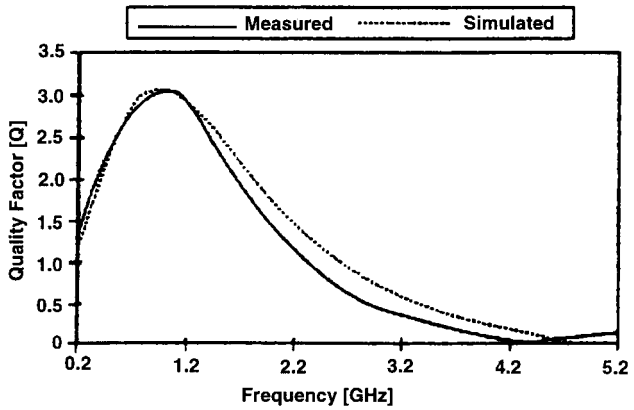

Figure 3-163 Measured and simulated *Q* versus frequency for the simulated inductor.

eliminate the desired second harmonic quite well). Actually, two diodes could also have been used for doubling, but since this requires transformers and a postamplifier, we have shown the preferred application. The only advantage of the diode application is that it is wideband, while this BJT circuit, as we have just learned, must be made narrowband for reasons of spectral purity.

Finally, we are curious to see the actual operating state of this amplifier, and this can be done by analyzing the load line (Figure 3-167). This is as complicated as the analysis for the differential amplifier. Because of the stored energy in the various tuned circuits, the load line looks quite impressive and would probably be difficult to predict without a nonlinear CAD tool.

3-9 MULTISTAGE AMPLIFIERS WITH AUTOMATIC GAIN CONTROL (AGC)

Having discussed the basic differential amplifier, we will now evaluate the performance of the MC1350/1490 video amplifier chip from Motorola. Most of the circuitry in the chip is self-explanatory. Figure 3-168 shows its inner circuit, and Figure 3-169 show a recommended application. By grounding one side of the input, we effectively get the same performance as the differential amplifier just discussed, with one difference being that the input is now fed to the constant-current generator. To minimize the distortion at the two lower transistors, they are decoupled by a 66-Ω resistor. Figure 3-170 shows the frequency-dependent gain, matching, and noise figure. Since this particular device has been specifically designed for AGC purposes, we also show in Figure 3-171 its gain reduction versus applied AGC voltage.

3-10 BIASING

A lot has been written about biasing, and since the purpose of this book is not to focus too much on dc, the following examples including RF consequences have been selected and considered sufficient. Early application reports by Motorola and others have provided a wealth of data. As a side effect of the introduction of the wireless era, we find that the engineers are so pressed for time that the number of complete application reports has approached zero. This is one of the reasons why we have tried to minimize the mathematical basis of this book (some is still needed), while still providing practical assistance. Figure 3-172 shows a textbook type of approach for RF.

In order to decouple the transistor from the biasing, we use RF chokes and dc decoupling (bypass) capacitors. This is the technique used in previous examples, so one might ask, "What's new?" As frequency increases, these inductors are either not manufacturable or have such a low Q that their use becomes questionable. This is the point where one may introduce the so-called distributed elements.

Figure 3-173 shows the very same circuit but resorting to distributed rather than lumped elements. The newly introduced elements (part of any good, up-to-date CAD tool; see element library for how to use their physical element descriptions) are described next.

- *Transmission Line.* Any printed connection between two points on a circuit board is a transmission line (Figure 3-174). Its characteristic electrical impedance is a function of the square root of the dielectric constant (ε_r), the width, metallization, thickness and height above substrate of the line, and the loss tangent of the substrate. Since lines frequently have to be laid out in the form of curved connections or have a bend in their direction, we have to add elements capable of describing the high-frequency conse-

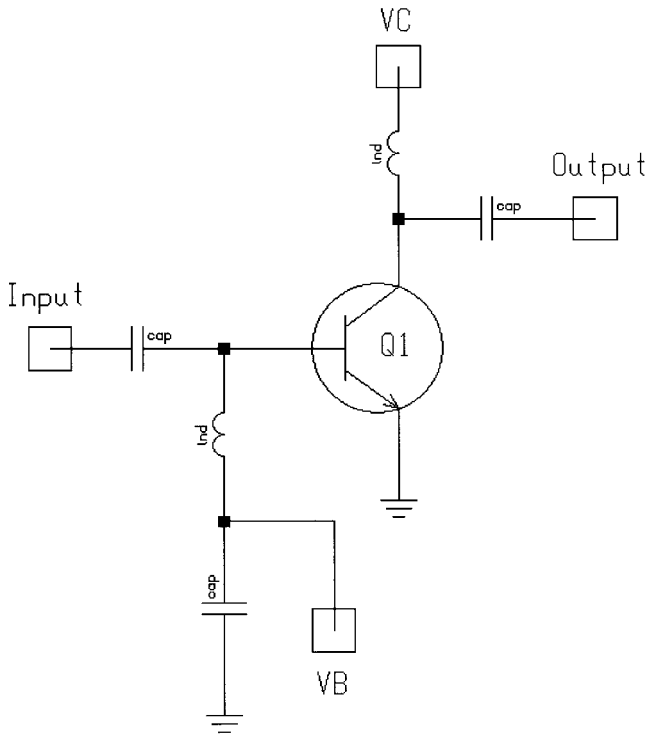

Figure 3-172 Simple BJT RF amplifier with lumped elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

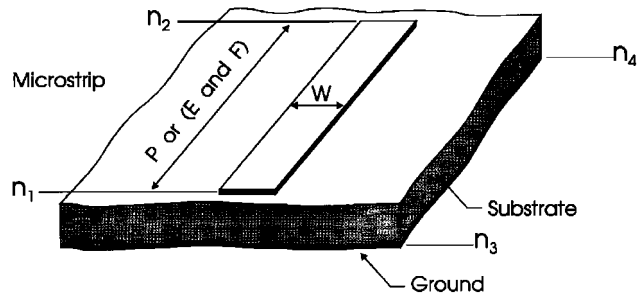

Figure 3-174 Transmission line in microstrip.

quences of such connections. Figures 3-175 and 3-176 show mitered and radial bend elements that perform this function.

- T *Junction, Cross, and* Y *Junction.* By the time a point like a collector or base, or its FET equivalent, spreads out into connections with other elements, we need additional modeling capability to describe ⊤ connections, crossings, and Y junctions. Figures 3-177, 3-178, and 3-179 show the way in which these connections must be modeled.

If the need exists, the standard inductances must be replaced with a transmission line whose length is λ/8 at the operating frequency. At higher frequencies, these transmission lines, however, then go into λ/4 resonant mode and later become capacitive. This type of design makes it fairly narrowband. A way around this is the use of printed inductors, as shown in Figures 3-180 and 3-181.

These inductors have a self-resonant frequency similar to the transmission line mentioned above, but the safety margin is significantly higher.

Talking about printed inductors, a logical extension of this is the printed transmission-line-based transformer, as shown in Figure 3-182. One can consider this as two interlaced rectangular inductors and, based on the substrate material, they are useful over a wide frequency range. Besides being used as a transformer, they can also be used to transit from

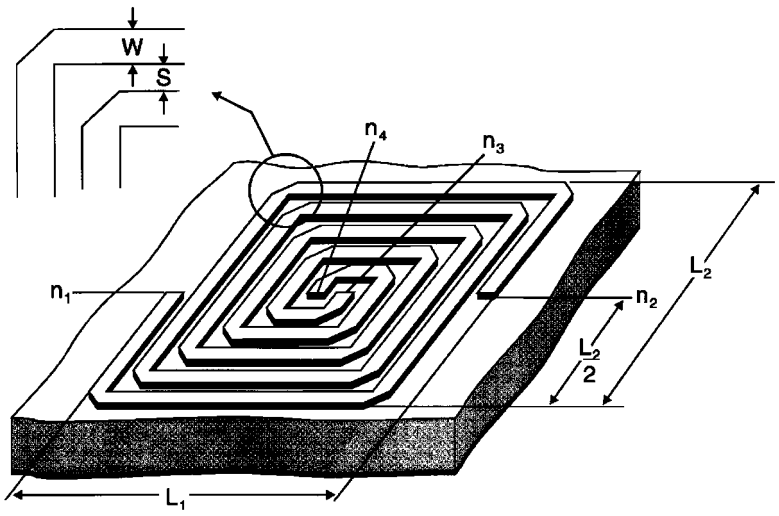

Figure 3-182 Transformer in microstrip.

unbalanced to balanced transmission provided that the difference in length from a connection point of view does not cause any problems (this is a layout issue).

A popular form of combining stages is the so-called Lange coupler (Figure 3-183) invented by the German Julius Lange. It is one of the major contributions in wideband applications.

Useful application of the Lange coupler probably starts at 4 GHz. It consists of parallel transmission lines with the appropriate connections as shown. Lange couplers are typically built with four, six, and eight fingers. The Ansoft Serenade product has a Lange coupler synthesis program that can be used to gain more insight into this coupler's application. We assume that other modern software has similar capabilities.

Where meander-type inductors are necessary, a neat way to implement and simulate them is to use the multiple coupled lines element (Figure 3-184) of the Serenade product, which both quickly and accurately calculates the behavior of the meander, including self-resonances and losses. We made use of this arrangement in our previous examples.

- *Interdigital Capacitors.* The issue of tolerances of small capacitors already has been brought up. The interdigital capacitor can be made on printed circuit board material as

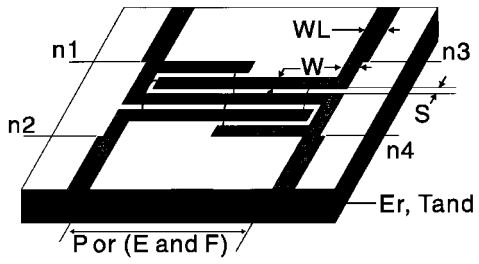

Figure 3-183 Four-strip Lange coupler.

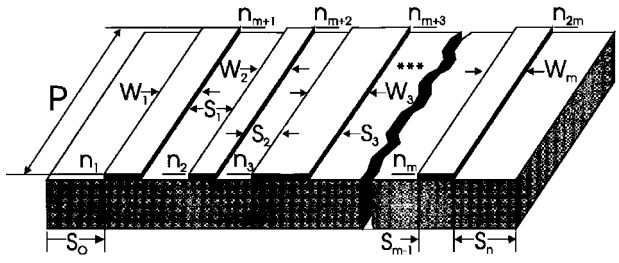

Figure 3-184 Multiple coupled lines element in microstrip.

well as gallium arsenide, and if its dimensions are continuous with the transmission-line width it does not cause any abrupt changes in impedance. This type of capacitor permits one to obtain very small values. An alternative to this is the use of transmission lines with a length of $\frac{3}{8}\lambda$. We learned earlier that a transmission line is inductive at frequencies below its fundamental resonance, is resistive at below resonance, and becomes capacitive above resonance. Again, bandwidth is also an issue. An interdigital capacitor consists of a number of parallel fingers as shown in Figure 3-185, and its capacitance can be varied by adjusting the number of fingers and their spacing. The advantage of the interdigital capacitor compared to discrete components is its low variation in value.

- *Radial Stubs.* The radial stub (Figure 3-186) is not much different from a $\lambda/4$ resonator, but its bandwidth is much greater than a simple transmission line. This is another way to ground the "cold" side of a transmission line or part of a circuit that needs to be grounded for RF. Of course, the interdigital capacitor comes in a version that is a combination of a capacitor and a via hole.
- *Via Holes.* The "cold" end of the transmission line, being considered either an inductor or a capacitor, needs to be connected to a sufficiently large copper backplane. One very efficient way to do this, especially if there is not enough copper left on the top of the board, is the use of via holes (Figure 3-187). One could theoretically generate

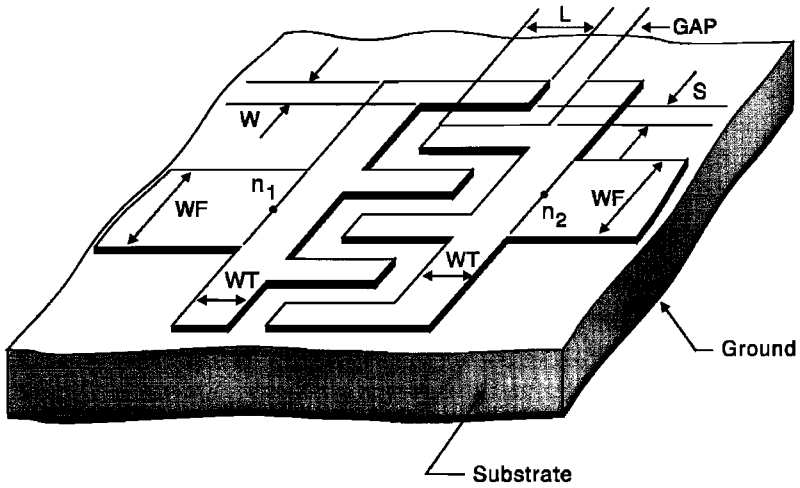

Figure 3-185 Interdigital capacitor.

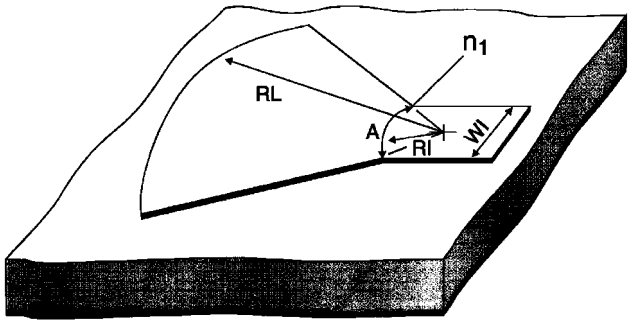

Figure 3-186 Radial stub.

a via hole with a rivet, but most manufacturing processes don't allow this; the normal solution is to use plated-through holes left open. In PC boards, via holes are typically cylindrical; on substrates like GaAs, they may be conical.

- *Correction Elements.* Although the behavior of an actual circuit proceeds regardless of our ability to measure and describe it, we do not enjoy this luxury in simulating circuit behavior in software. In a simulator, effects that are insufficiently described will be inaccurately simulated. For instance, segments of high-impedance transmission line (e.g., 120 Ω) are frequently used for dc feeds and RF chokes. In predicting the effect of a transition from 120-Ω line to 50-Ω line, a simulator must be alerted to the discontinuity so it can do the necessary mathematical corrections to account for the impedance jump. To do this, a specific circuit element, the STEP (Figure 3-188), must be inserted between the 120-Ω and 50-Ω line elements in the simulation circuit file. In addition to substrate data, we characterize a STEP by providing the widths of its input and output lines. The element itself has no physical length.

A similar correction is necessary if a transmission line is used as a resonator or just "left open" at one end. Such a transmission line tends to radiate and, because of its high-impedance properties, it reacts differently as far as its electrical length is concerned. A zero-length one-port element, the OPEN (Figure 3-189), must be added to such a line for mathematically correct calculation.

We end this excursion into distributed elements here. Interested readers may want to obtain a CD containing the element library of their favorite CAD tools that combine capabilities in the microwave area with a full set of distributed circuit elements. It is most important to keep

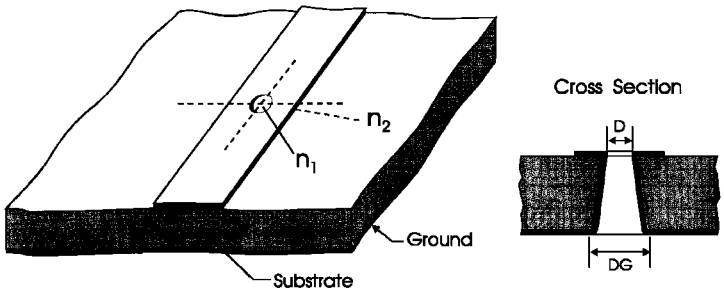

Figure 3-187 Via hole.

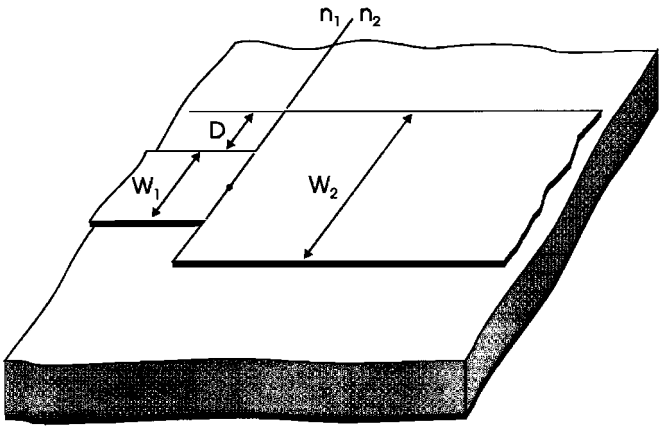

Figure 3-188 The STEP element tells the simulator to calculate the effects of joining transmission lines of differing characteristics.

in mind that, as frequency increases, we rapidly move into the area where we must consider all these distributed elements to achieve accurate simulations—even if doing so makes simulation a painful and time-consuming effort.

Finally, anyone who adventures into this area *must* obtain a foundry manual from the company that will build the integrated circuit or hybrid under design. There are basically two foundries, one applicable for MOS technology and one for GaAs. In the case of the bipolar transistor, the foundry service is not yet well-established. While we were able to interest one German company and one U.S. company in generating a custom bipolar IC within the activities of this book, the only "open" foundry we know of for bipolar (actually HBT) technology is the one operated by TRW. As of 1999, this seems to be the leading company for BJT-related products, and many currently available ICs have been developed with this foundry service.

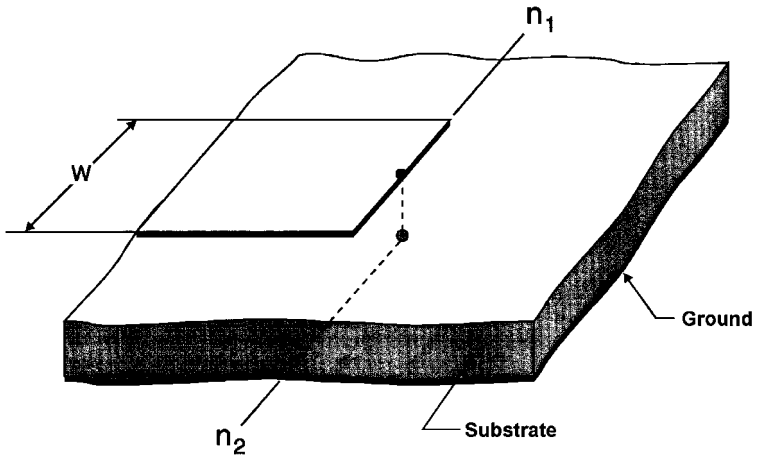

Figure 3-189 The OPEN element tells the simulator to calculate the effects of leaving the end of a transmission line unconnected.

We mention the issue of foundries here again because each foundry has its own proprietary approach to modeling discontinuities. The availability of a foundry service somewhat eases the requirement that a designer be fully up to speed on the nuances of discontinuities, because a foundry's designer service will help customers account for all relevant parasitics or discontinuities in their designs. In addition, there are tables of *S* parameters for standard cells of either capacitors, resistors, or inductors. The designer may then be forced to adjust the circuit so that it will work with a particular inductance value or value of another component within the resolution of the table that describes these elements. Information on the active parts, such as diodes and transistors, was given in Chapter 2.

3-10-1 RF Biasing

Applying the knowledge we have just acquired about distributed elements, Figure 3-190 shows a somewhat exaggerated case of using the various elements. While it is consistent with the simple RF case with which we started, modeling of this type is certainly necessary at higher frequencies. Many but not all of the elements we have just described are used, but we have not solved the question of the actual dc biasing.

3-10-2 dc Biasing

The following discussion is the recommended procedure for biasing a transistor. We will start with the collector current (in our example, Figure 3-191, 10 mA). To separate RF and dc, we have a combination of a load resistor (R_L) and an inductance (L_C). Information about this operation was given already in Section 3-2-6. The emitter resistor should have a voltage

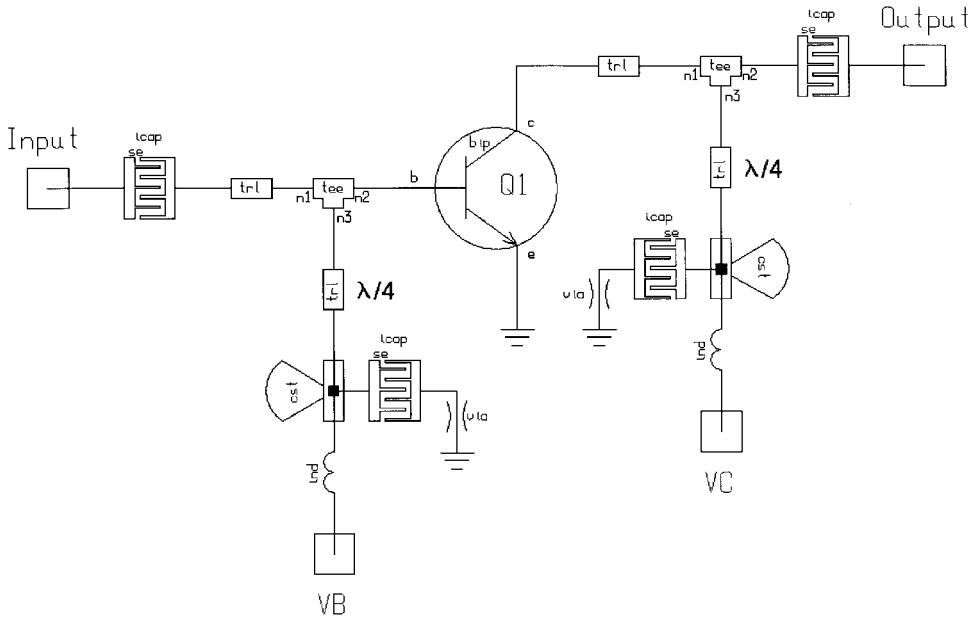

Figure 3-190 Simple BJT RF amplifier with distributed elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

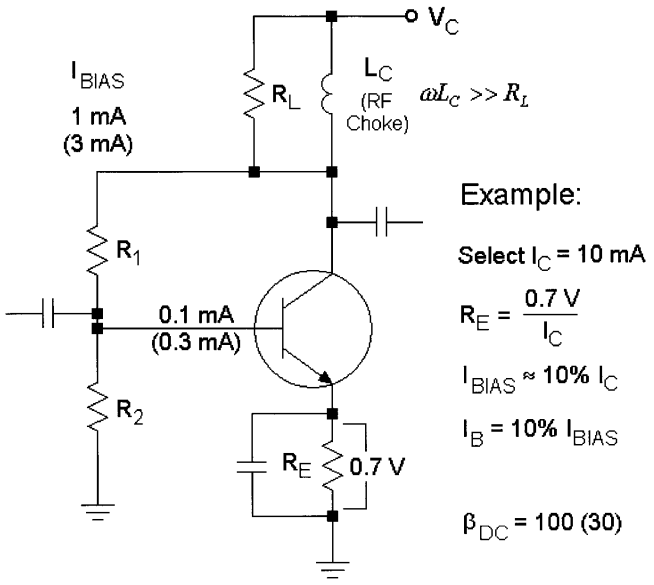

Figure 3-191 A dc biasing example.

drop of about 0.7 V, and therefore the emitter resistor is $0.7/I_C$. The next assumption is that the transistor has a dc current gain of 100, and therefore we decide to have the bias resistor chain (R_1 and R_2) draw 10% of I_C, or 1 mA. Assuming a collector voltage of 5 V, the value of $R_1 + R_2$ has to be 5 kΩ to result in the required 1 mA. Because the base current now is 10% of the divider current, the base will draw 0.1 mA. The voltage across R_2 has to be the voltage drop across R_E (0.7 V) + V_{BE}, which is also 0.7 V, or 1.4 V. Given the 1 mA, R_2 = 1.4/1E–3 = 1.4 kΩ. R_1 therefore is 5 kΩ – 1.4 kΩ = 3.6 kΩ. This concludes the calculation.

In the case of a dc beta of only 30, we need to raise I_{BIAS} from 1 mA to 3 mA since the base current now will be 0.3 mA. This changes the resistor values. $R_1 + R_2$ = 5 V/3 mA = (rounded) 1.6 kΩ. Following the same approach, we need 1.4/3E–3 = (rounded) 470 Ω. This makes R_1 = 1600 Ω – 470 Ω = (rounded) 1100 Ω. These roundings were necessary because resistors can only be bought in certain resistance steps.

However, for low battery voltages, the 0.7 V between the emitter and ground cannot be wasted. Therefore, a dc stabilization circuit, to which we have already referred, will be considered next. Figure 3-192 shows a combination of an RF transistor, Q1, and a dc stabilization transistor, Q2. The most important thing about this circuit is the fact that the difference between the supply voltage and the collector of Q1 is 0.3 V, which is approximately half of the voltage we had to "waste" across R_E in the above-mentioned circuit. Plus, the voltage drop is now in the collector, and given the fact that we feed Q1's collector through the inductor of a quasi-tuned circuit rather than through only a resistor, we get a much higher voltage swing. The base–collector diode temperature dependency of Q2 is compensated for with the silicon diode feeding the base. It is also fascinating to see that, because of the low currents, both the voltage drop of the diode and V_{BE} of Q2 are about the same, and yet Q1, operating at a reasonable current, shows the expected 0.7–0.8 V V_{BE}. We have supplied all the necessary dc voltages to give the reader an incentive to calculate the mechanism of this stabilization. The key equation to this is to determine the current in the voltage divider feeding

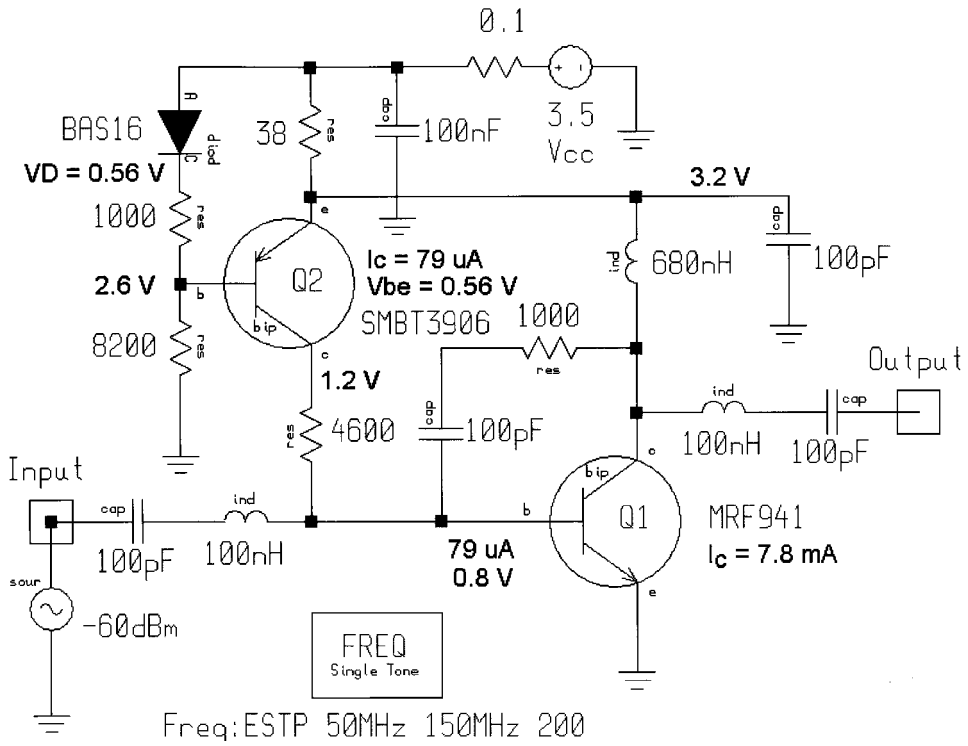

Figure 3-192 An RF amplifier with active biasing. (After the low-noise amplifier circuit in [29].)

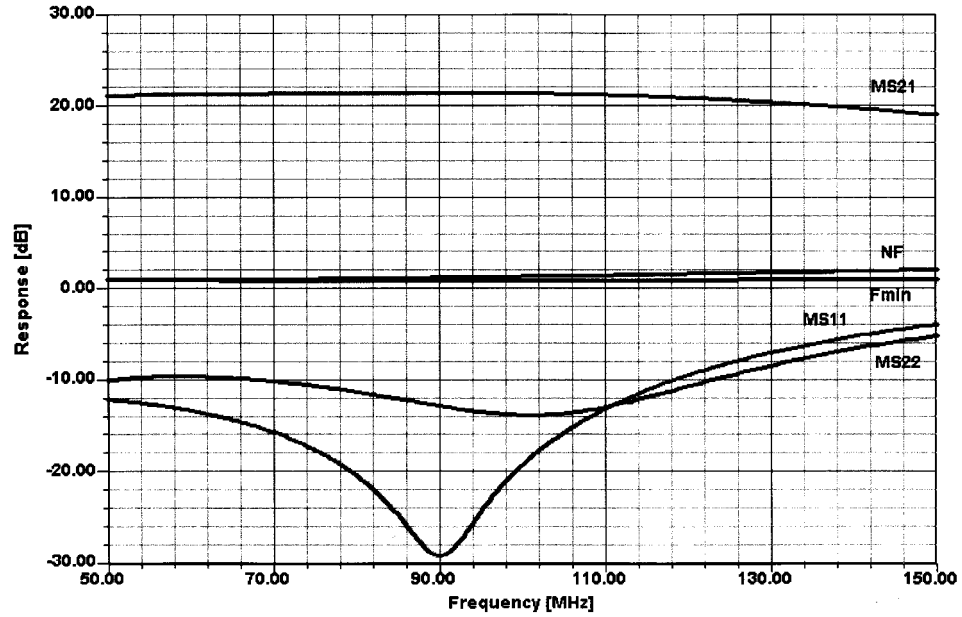

Figure 3-193 Frequency-dependent gain, matching, and noise responses for the amplifier in Figure 3-192.

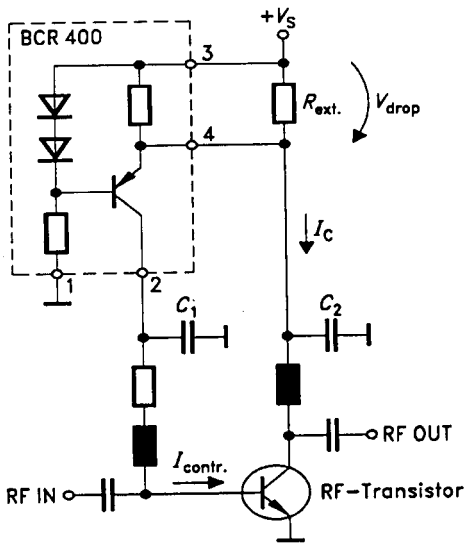

Figure 3-194 The Siemens BCR400 active bias controller can be applied to FETs as well as BJTs.

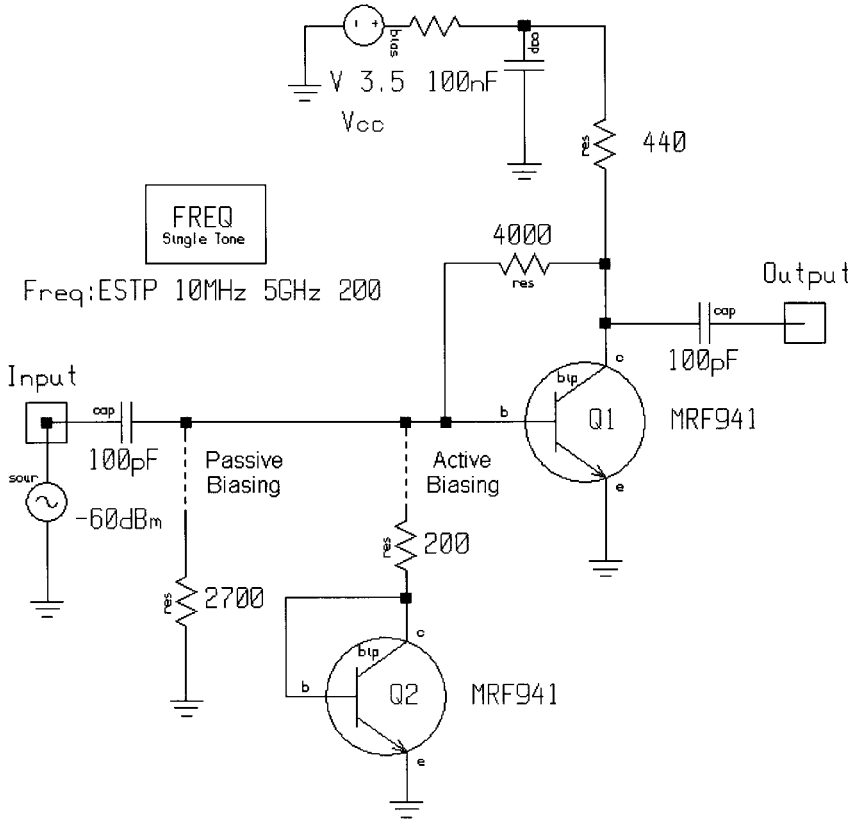

Figure 3-195 Amplifier stage (I_C = 3 mA) showing active and passive bias alternatives.

Q2, and proceeding from there. On the other hand, having a nice CAD tool that provides insight into the dc voltages and allows the addition of dc voltage probes makes life much easier. To prove that this circuit actually works, Figure 3-193 shows its frequency-dependent gain, matching, and noise figure performance. It is based on a Motorola application, which had excessive voltage drop for Q1 and which we have improved to be suitable for low-voltage operation [29].

Integrated active bias solutions are also available. Figure 3-194 shows the Siemens BCR400 active bias controller applied to a BJT; it can also be applied to FETs and TR switching diodes, as we saw in Figures 3-57 and 3-59, respectively.

3-10-3 dc Biasing of IC-Type Amplifiers

In integrated circuits, we do not have the unlimited flexibility described earlier. This results frequently in constant-current sources or transistors being used as diodes for biasing purposes. Our first suspicion is that this is going to cause a lot of noise in the IC; Figure 3-195 shows a test example.

As suspected, choosing the same bias point of 3 mA, the noise figure using active bias is quite a bit higher than the passive one, as shown in Figure 3-196.

3-11 PUSH–PULL/PARALLEL AMPLIFIERS

Since it is practically impossible to obtain $S_{11} = S_{22} = 0$, using a combiner at the input and output reduces the problem. Figure 3-197 shows the 3-dB hybrid approach. It has a practical

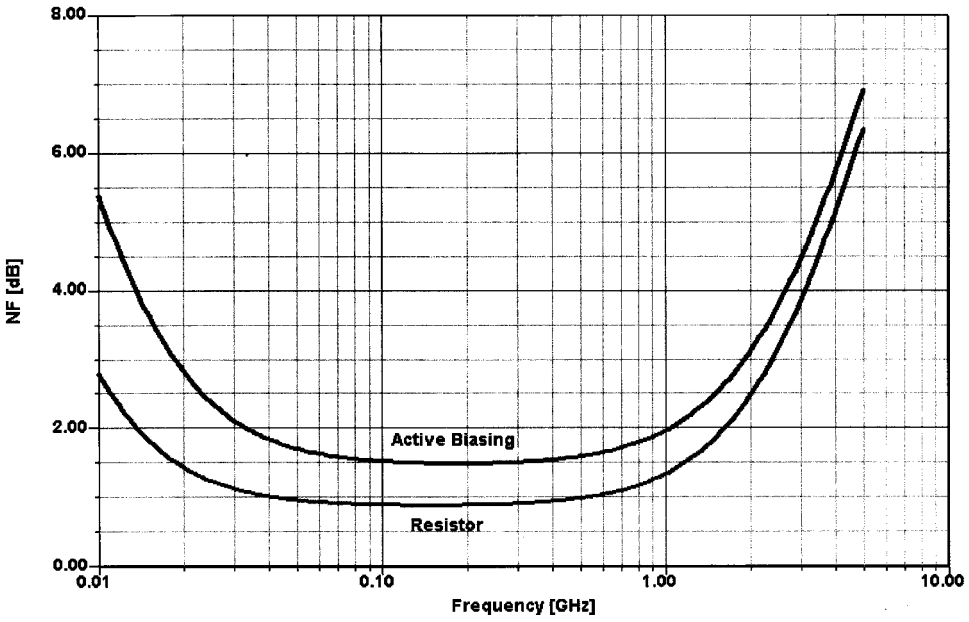

Figure 3-196 Frequency-dependent noise figure of the amplifier circuit shown in Figure 3-195. The active biasing curve is considerably noisier.

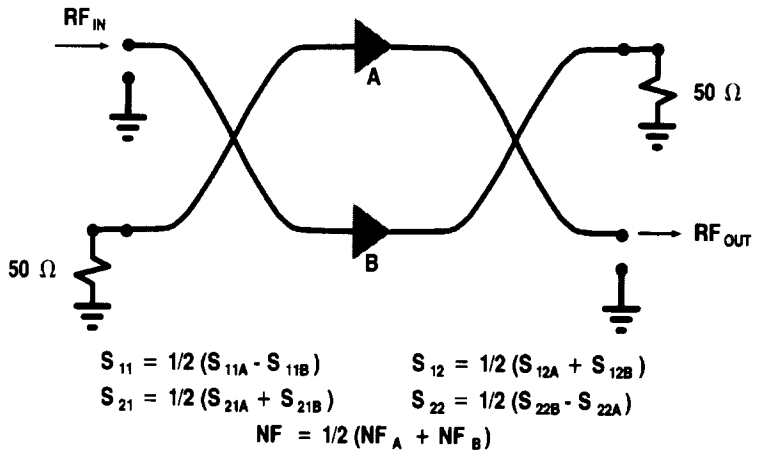

Figure 3-197 Combining power with 3-dB hybrid couplers.

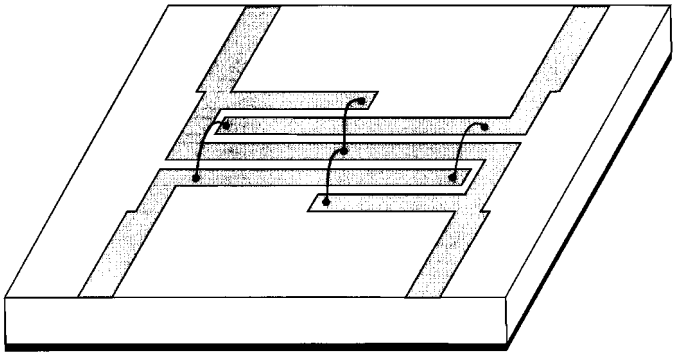

Figure 3-198 Four-strip version of the Lange coupler, a broadband 90° hybrid.

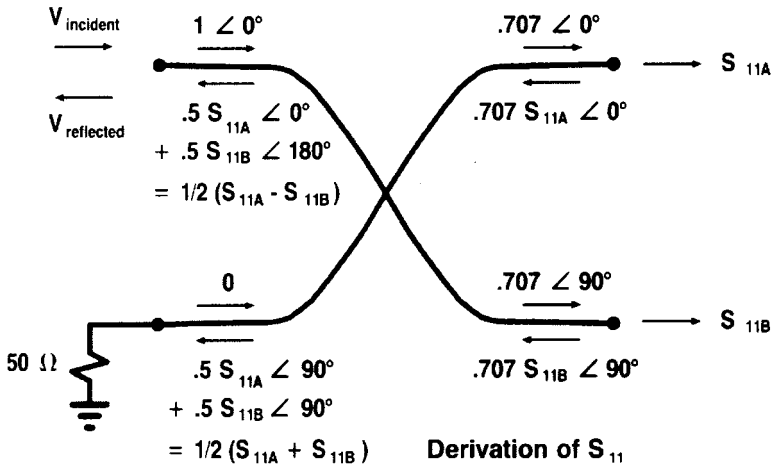

Figure 3-199 3-dB hybrids. This analysis method may be applied to any coupler.

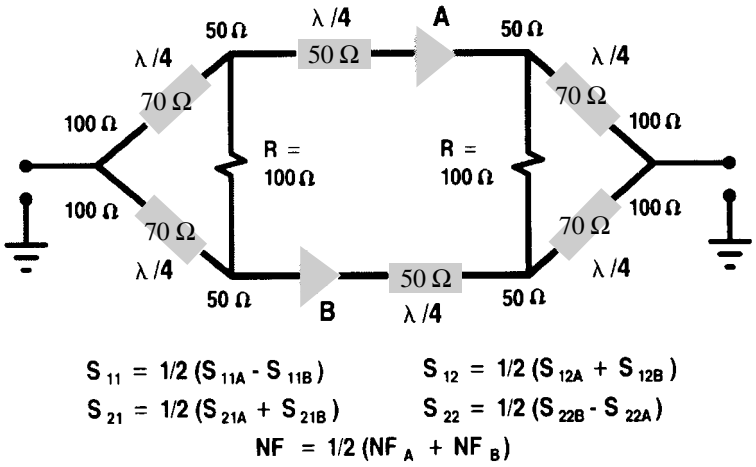

Figure 3-200 Wilkinson divider/combiners.

bandwidth limit of about 4:1; its advantage is that it is compact and ideal for cascading. If one stage opens, P_{OUT} and gain drop only 6 dB; however, it does not protect against load mismatch. A recommended distributed form is the Lange coupler (Figure 3-198). To analyze this approach, Figure 3-199 shows the resulting impedances and necessary phase shifts. If a Wilkinson coupler [30] is used instead of the 3-dB hybrid, the bandwidth is reduced. The Wilkinson coupler is larger in size than the 3-dB hybrid but more easily realized, leading to lower cost. Figure 3-200 shows the actual impedances necessary for matching, with A1 and A2 being the actual amplifiers combined.

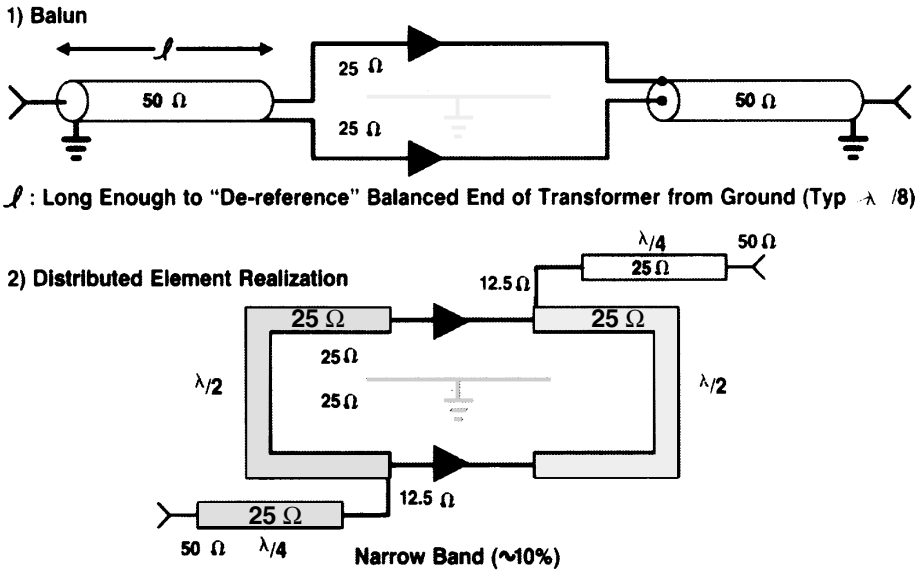

Figure 3-201 Push–pull amplifiers.

The solution for push–pull amplifiers resorts to a balun with the following results obtained: Bandwidths of greater than one decade are achievable; the balun structure gives 4:1 impedance advantage; there is no isolation; $S_{11} \neq 0$, $S_{22} \neq 0$; and cancellation of even-order products is provided.

Since most amplifiers have 50-Ω rather than 25-Ω impedances, Figure 3-201 shows a circuit that matches 25 Ω to 50 Ω on both sides. Since the standard amplifier operates at 50 Ω rather than 25 Ω, an additional network may be necessary to transform the impedance up to 50 Ω again. A similar problem occurs at the amplifier output.

3-12 POWER AMPLIFIERS

Power amplifiers are devices that are tasked to transform as much dc power into RF/microwave power as possible. Depending on the technology, devices are available that can produce at least 100 W up to 2 GHz. Since the transconductance of FETs at conducting angles of less than 180° becomes very small, the actual power gain sharply decreases compared to Class A operation while the power-added efficiency is optimized to values of 55% (Class B) or so. The dissipation of these devices is, of course, quite high, while in Class B operation this is even more of an issue. Power devices in Class C are dying to have big heat sinks to survive. One of the nice things about FETs is a much reduced thermal runaway effect compared to their bipolar brothers.

Power amplifier classes are defined in terms of the device conduction angle and/or the type of device operation:

Class A	"Linear" operation; 180° conduction angle
Class AB	"Linear" operation; conduction angle between 90° and 180°
Class B	"Linear" operation; 90° conduction angle
Class C	Fixed drive; less than 90° conduction angle
Class D	Switched operation, conduction range may vary with time from 0° to 180° or may be fixed.

There are also Classes E and F, which are currently under evaluation and showing some promising results.

Figure 3-202 shows Class C operation. The output of the amplifier is a current pulse train, which frequently leads to misunderstanding as to the calculation of its load. Given the fact that the amplifier is a current generator, it is silly to assume one has to do a conjugate matching looking backward into the amplifier. This is the condition for Class A operation. Unfortunately, this is still not understood by some engineers, but we hope we can clear this up today. The theoretical efficiency is 89.7% at a conducting angle of less than 180°; in practice, efficiencies more than 85% are not obtainable. (All of these efficiencies are those of the device itself; losses in matching networks are not taken into account in these efficiency values.) Considering optimal gain and optimal output power, the conducting angle actually settles somewhere between 100° and 140°. Again, the power gain in Class C operation is less than in Class A and Class B operation.

3-12-1 Example 1: 7-W Class C BJT Amplifier for 1.6 GHz

The following demonstrates how to design a 1.6-GHz, 7-W amplifier operating in Class C. We need to point out again that all modulation forms that contain the information in both

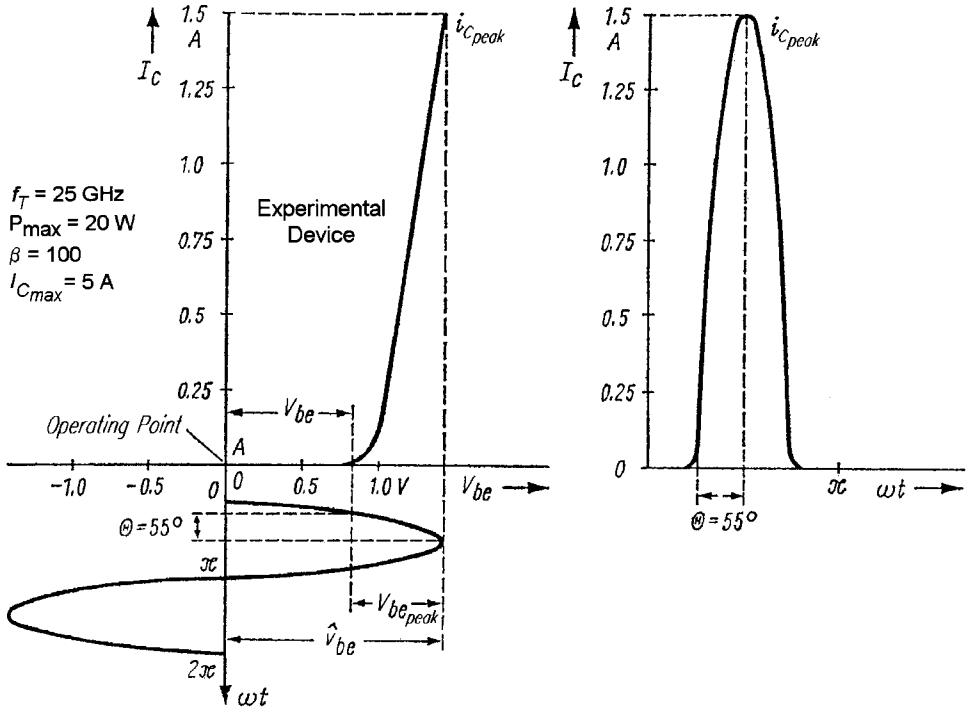

Figure 3-202 Output current as a function of drive voltage, taking into consideration the knee voltage of the base–emitter *pn* junction. The output is a series of current pulses with a duty cycle determined by the conduction angle.

amplitude and phase require more linearity than Class C affords. Needless to say, this affects the efficiency; therefore, at a later point we will also show a Class AB power amplifier. This is a tutorial, so we will present a UHF example and walk the reader through all the problems involved in the design. The selection of the transistor is done by first looking at the f_T, which in our case should be at least 4–5 GHz. The first order of business is to define the point of operation for the output amplifier. To do this, we need to determine the maximum voltage and current values supplied by the manufacturer. We have chosen a device that operates at 28 V and can sustain a peak collector current of 1.5 A. Figure 3-202 lets us determine the conducting angle Θ from the I_C/V_{BE} plane. This figure shows on the left side the I_C/V_{BE} plane and the necessary voltage to drive the amplifier.

Initially, we assume that the base–emitter junction is operated without any bias ($V_{BE} = 0$). The dc I–V curve shows that the collector current starts at about 650 mV. The amplifier itself, therefore, is already in Class C operation. For full output power, the drive voltage $V_{BE,\text{peak}}$ has to be 1.14 V. Therefore, the conducting angle can be determined by

$$\cos \Theta = \frac{V_{BE}}{\hat{\boldsymbol{v}}_{BE}} = \frac{0.65}{1.14} = 0.57$$

$$\cos 0.57 = 55^\circ$$

V_{BE} is the dc voltage at which the transistor starts conducting. From Figure 3-65 and Eqs. (3-160), (3-161), and (3-162), the fundamental current i_{c1} can be determined from

$$i_{c1} = i_{\text{peak}} \cdot f_1(\Theta)$$

or

$$i_{c1} = 1.5 \text{ A} \times 0.36 = 0.54 \text{ A}$$

The average collector dc current can be determined from

$$i_{c2} = i_{\text{peak}} \cdot f_2(\Theta)$$

or

$$i_{c2} = 1.5 \text{ A} \times 0.21 = 0.315 \text{ A}$$

The collector saturation voltage $V_{CE(\text{sat})}$, unfortunately, is around 2–3 V; for the purpose of the calculation, we assume that the saturation voltage is 3 V, and, therefore, we can assume that the maximum collector ac voltage $\hat{v}_{CE} \approx (V_B - 3) = 25$.

The appropriate collector load has to be

$$R_C = \frac{\hat{v}_{CE}}{i_{C1}} = \frac{25}{0.54} = 46.3 \ \Omega$$

The maximum output power is

$$P_{\text{out}} = \frac{(V_{CE} - V_{CE(\text{sat})})^2}{2R_C} = \frac{625}{92.6} = 6.75 \text{ W}$$

The only way to increase the power would be to have a smaller collector load at a higher current. In this family of Motorola transistors, there was no 10-W transistor; that's why we have chosen a 20-W experimental device, which for this purpose is overkill. The theoretical efficiency of the amplifier is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{6.75 \text{ W}}{0.315 \times 28} = 85\%$$

If the saturation voltage would be less, our efficiency would automatically increase, since for the given load, the actual output power would increase (6.75 W $\rightarrow$ 7.5 W). Assuming that this stage would operate at 1900 MHz with a gain of roughly 22 dB, the required drive would be significantly less than the output power, or roughly 40 mW. For the purpose of the following calculations, we will assume that the drive power is 0.7 W. The total dissipation of the device now adds up to be

$$P_T = P_{\text{in(dc)}} - P_{\text{out}} + P_{\text{drive}}$$

$$P_T = (28 \times 0.315) - 6.75 + 0.7 = 2.77$$

Power-added efficiency is derived from this. Knowing the power dissipation, one can calculate a thermal resistance R_{therm} of the heat sink and the transistor:

$$R_{\text{therm}} = \frac{T_J - T_A}{P_T}$$

Where T_J is the device junction temperature and T_A is the ambient temperature. For a maximum ambient temperature of 60 °C and a maximum junction temperature of 150 °C, the thermal resistance is

$$R_{\text{therm}} = \frac{120 - 60}{2.77} = 21.7\ ^\circ\text{C/W}$$

R_{therm} is the sum of thermal resistance of the transistor and its package, and the thermal resistance between the transistor package and the heat sink, and the thermal resistance between the heat sink and the ambient air. Therefore,

$$R_{\text{therm}} = R_{\text{th(case)}} + R_{\text{th(case/heat sink)}} + R_{\text{th(heat sink)}}$$

The required thermal resistance of the heat sink is calculated from

$$R_{\text{th(heat sink)}} = 21.7 - 10 - 1.4 = 15.6\ ^\circ\text{C/W}$$

Assuming an aluminum heat sink (a 2-mm-thick plate), the required heat-sink surface area A (cm^2) is

$$A = \frac{1}{\alpha R_{\text{th(heat sink)}}}; \quad \alpha \approx 1.5\ \frac{\text{mW}}{^\circ\text{Ccm}^2}$$

Therefore, the required area is

$$A = \frac{1}{1.5 \times 0.0156} = 42.7\ \text{cm}^2$$

The next task is to match both the input and output to the (most likely) 50-Ω source and termination. The following section will guide us through the procedure. The input impedance Z_{11} (after some lengthy search) was found to be $1 + j10\ \Omega$. This means that the input consists of the base-spreading resistance (approximately 1 Ω) and an input capacitance, which because of phase shift now turns out to be inductive. Since the popular method for input matching these days is a pi configuration, we are going to use a simple pi filter both for input and output matching. There are several equations in the literature that give the values for the two capacitors and inductors; most of them result in an incorrect resonance frequency. Since we have access to software tools, we decided to take three approximate values and use the optimizer to give us the appropriate matching. The only remaining variable in such an approach is the bandwidth. If we specify $S_{21} = 1$ and $S_{11} = 0$ (100% energy transfer and perfect return loss), we will realize that this is possible at only one frequency. We therefore need to identify a frequency band or bandwidth over which an acceptable match is needed. As the bandwidth increases, the match for such a simple circuit will get poorer; there are not enough elements available to do better. In this case, we took the center frequency ±100 MHz.

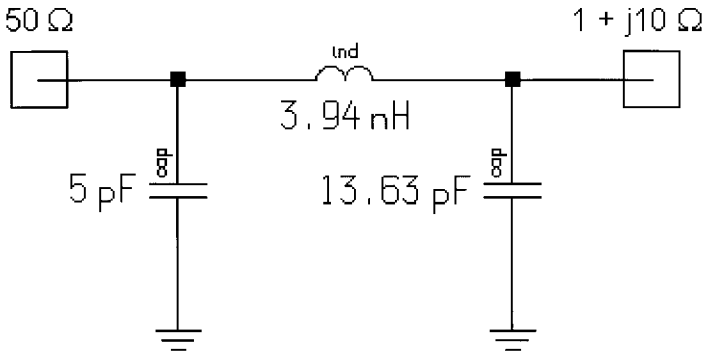

Figure 3-203 Input matching network for the amplifier used in this tutorial.

Figures 3-203 and 3-204 show the actual circuit with the element values and the resulting input match. Likewise, we did the same thing at the output, but the actual resulting dynamic output capacitance is not known *a priori*. For low frequencies, the integral equation gives a value of $2C_{CE}$; however, practical tests in frequencies above 500 MHz show that the actual increase is only 1.3 times the dc output capacitance. Therefore, we decided to design the filter with no output capacitance assumed, and the input capacitance of about 5 pF must be reduced for proper reactive matching. Mathematically, this could result in a negative number, specifically if the resulting output capacitance exceeds the 5-pF value. To compensate for this, one needs to use an RF choke that tunes out the resulting dynamic output capacitance and then one can revert to the original 5 pF as calculated.

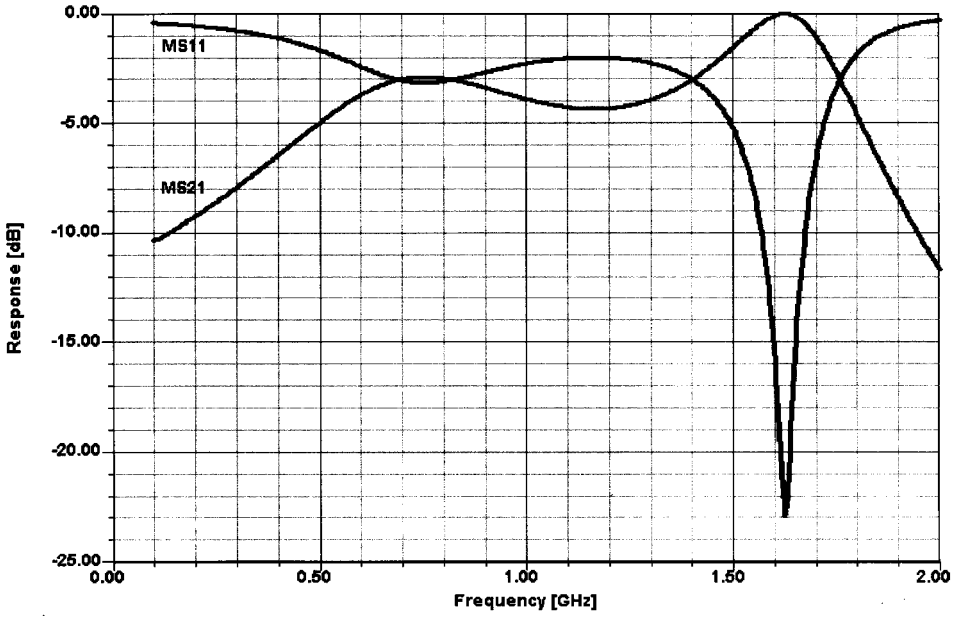

Figure 3-204 Frequency response of the input matching network.

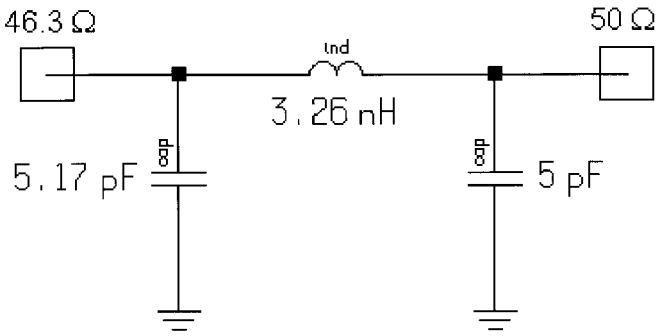

Figure 3-205 Output matching network for the amplifier.

The selection of the actual component is another issue, because these capacitors need to handle several amperes of RF current. It is not always easy to find capacitors with the appropriate value that can handle the current. The inductors can be printed. The paragraph following this section therefore will deal with the issue of how to translate the lumped values into distributed values, which will make the current handling much easier (we hope).

For this, we did the same optimizing approach by using a 50-Ω source and a 46.3-Ω load. Figures 3-205 and 3-206 show the circuit with the appropriate values and its simulated frequency-dependent responses.

The next step is to connect the input and output matching network to an "actual" transistor. This is a point where difficulties arise, since very few, if any, companies provide SPICE-type

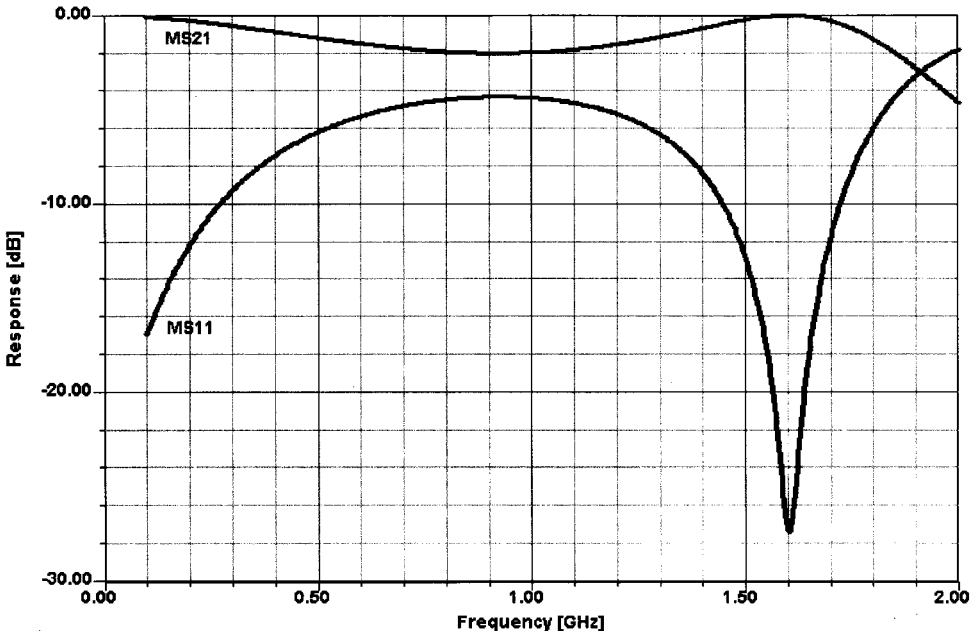

Figure 3-206 Frequency response of the output matching network.

parameters for transistors operating at currents of more than 200 mA. Figures 3-207 and 3-208 show the overall schematic and frequency response of the actual amplifier with all filters connected. Figure 3-209 details the amplifier's peak gain response. If more bandwidth is needed, the matching circuit must be increased in complexity, as will be shown in the following section.

Now is a good time to look at the final results of our simulation, which is based on the various assumptions as outlined above. Figure 3-210 shows the dc *I–V* curves with a straight load line and no reactances. This was accomplished by using a wideband transformer instead of an output matching circuit. Figure 3-211, however, shows the "load line" that results when the transformer is replaced with a real matching network. Based on the harmonics content and its improper termination, one can see how the output load line opens and shows ringing in the low-current area. If we expect to see the saturation voltage, we will be disappointed because the saturation voltage is frequency dependent (increases with frequency) and this figure gives an erroneous impression. Hence, we show dc *I–V* curves. To display the conduction angle, which we showed previously, we examine the output current as a function of time at a drive level of +16.5 dBm (Figure 3-212). During the negative half, the transistor is not conducting as predicted, so this validates our assumptions. Next, we are interested in determining the power gain. Therefore, we look at the output spectrum for a drive level of +16.5 dBm (Figure 3-213). It shows an output level of 38.6 dBm. If we subtract the drive level (16.5 dBm) from this, we see that the power gain is 22.1 dB at this drive level. Since we are used to thinking in watts, Figure 3-214 shows the absolute output power and the harmonics prior to filtering. Figure 3-215 shows the output spectrum after replacing the transformer with a simple pi output network.

During the conduction period, there will be a voltage across the transistor 180° out of phase, as shown in Figure 3-216. Finally, to highlight the nonlinearity of a Class C amplifier, Figure 3-217 shows the amplifier's output power versus drive, and Figure 3-218 shows the amplifier's gain versus drive. When the transistor turns on is clearly evident.

A particular difficulty arises in the case of FETs, where the charge energy makes for a difference between dc and pulsed measurements. Figure 3-219 shows this. Some of the more modern transistors, such as SiGe types, may need some pulsing also; as can be seen in Figure 3-219, even depending on the pulsing, one may get different dc *I–V* curves. This area is still under investigation, and even the "experts" do not agree on all aspects of this. In real life, it turns out that a lot of experimentation is the answer. Anyone who thinks that a pure CAD approach will give the right design answers immediately will encounter many surprises! This is not a fault of the CAD tools—assuming that they are properly engineered—but rather the availability of appropriately "tweaked" models for high-power applications, and the willingness of device suppliers to standardize on certain models and support them.

Because of the difficulties involved in cooling transistors under test and simulating RF pulse and CW conditions, depending on the application, manufacturers have so far stayed away from investing money in this area. The designer must therefore resort to application notes published by device manufacturers. Because even slight layer changes can have a large impact on the frequency response of a given device, application-note-based designs can run into difficulty if a device's fabrication has significantly evolved since the publication of its application notes.

Given the multitude of models outlined in Chapter 2, the CAD user is sometimes left hanging as to which is the best model to use. The latest indications are that the MEXTRAM (*m*ost *e*xquisite *t*ransistor *m*odel), developed by the University of Delft, Holland, with Philips of Holland, shows the most promising result, specifically in the area of IMD products. While

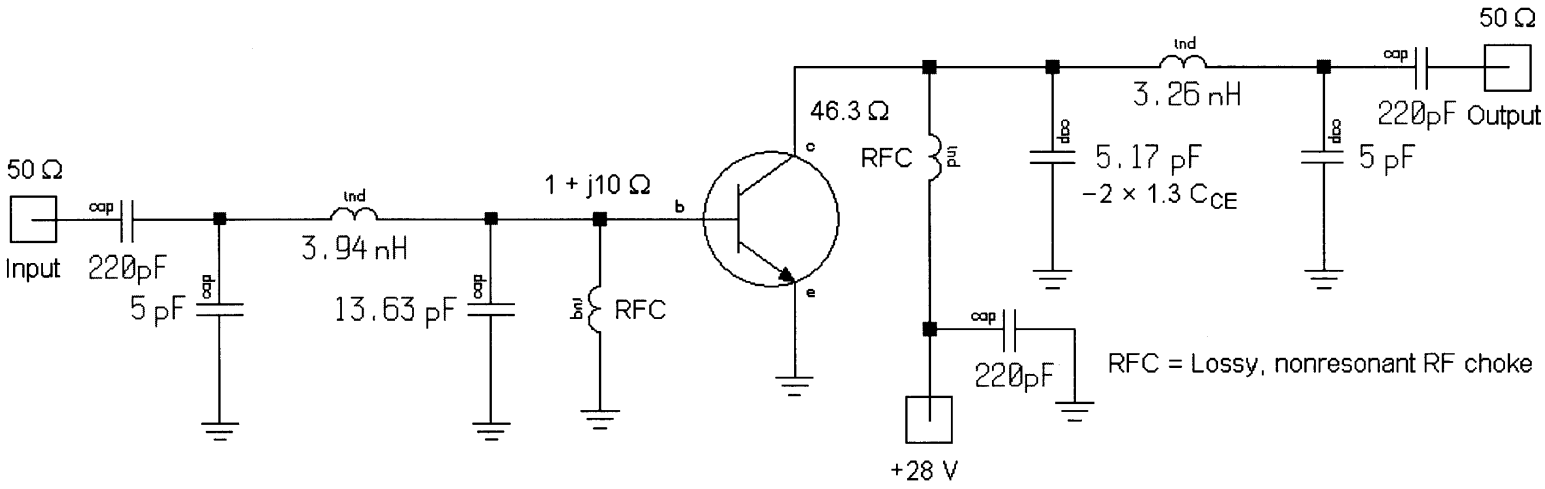

Figure 3-207 Actual schematic of our experimental 1.6-GHz amplifier. The RF chokes have enough RF losses not to be resonant and yet don't load the circuit. This is frequently accomplished with either ferrite beads or resistors in parallel with the chokes.

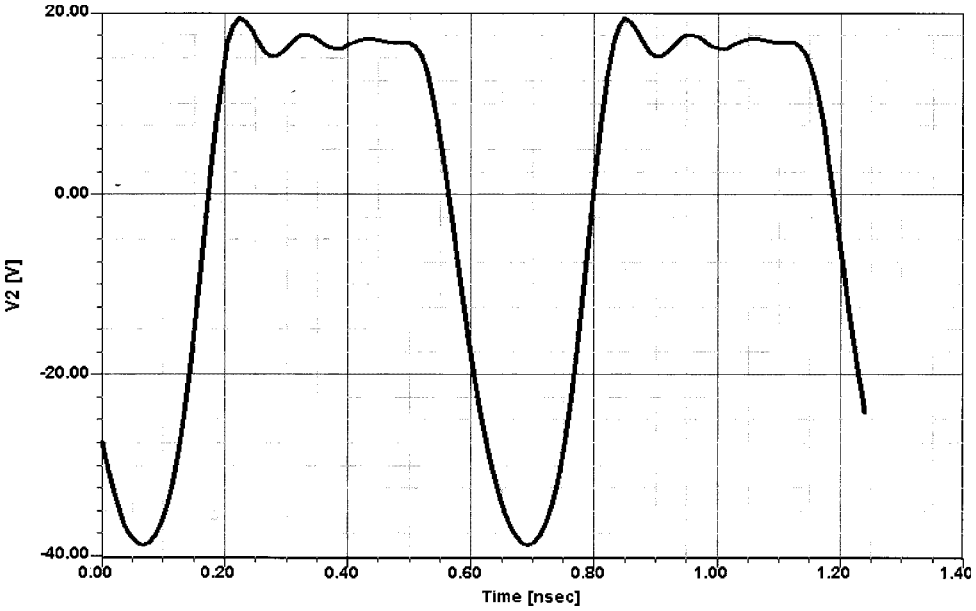

Figure 3-216 Output voltage at the collector. The voltage is asymmetrical compared to 0; this is important in the selection of a device capable of handling these voltages.

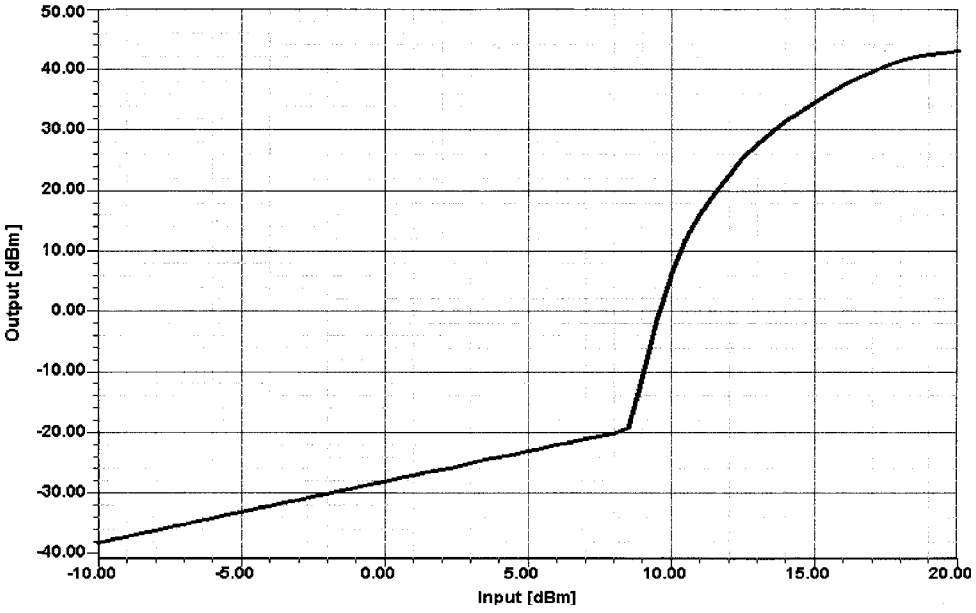

Figure 3-217 Output power versus input power for the Class C amplifier. Until the transistor turns on (at a drive level of about 8.5 dBm), only fedthrough power appears at the output.

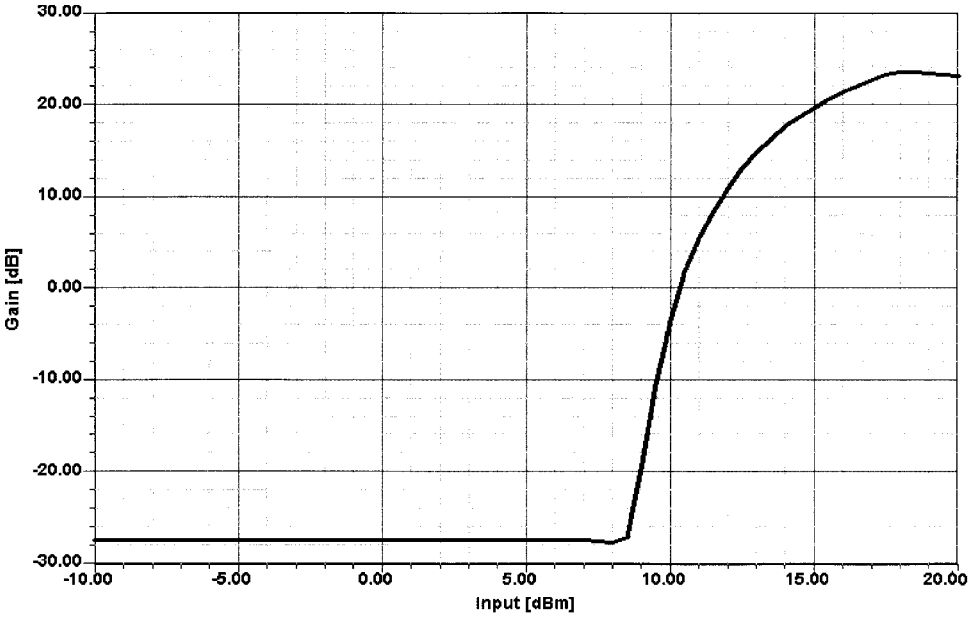

Figure 3-218 Amplifier gain as a function of drive. It is evident that one needs to cross the 0.65-V point for the transistor to become conductive and show gain. The initial amplification as a function of drive shows a very steep curve that then levels off and drops as the amplifier moves into saturation.

other later models have up to seven internal nodes, MEXTRAM fortunately uses only five. (The MEXTRAM model actually consists of three transistors, which makes modeling fun.) Power-added efficiency simulation is not available, since the MEXTRAM model was developed for small-signal applications, meaning circuits that operate at less than 100 mW of RF output power.

As if the absence of trustworthy high-power device models is not challenge enough, in developing this 1.6-GHz Class C amplifier example, we ran into another complication: Using a CAD optimizer to simultaneously match the circuit's input and output networks failed because of the device's input-impedance variation with drive. Every matching adjustment that improved the drive to the device resulted in an input-impedance change that reduced the drive to the device! In the end, the optimizer couldn't keep up. In actually building such a circuit, one would make the matching-network values adjustable on the initial breadboard and then, with the necessary input drive level applied, iteratively adjust the input and output matching for the desired output level. It appears that the CAD program could not handle such a degree of nonlinearity.

We then went to the approach of using large-signal *S* parameters at a drive level slightly less than 16 dBm, but this detuned the input filter, resulting in a poorer input match than the one initially predicted. Likewise, the output matching, which in a power stage must result in maximum output power rather than a conjugate match, was less impressive. The large-signal *S* parameters at the output for a power amplifier are somewhat dubious because Class C operation generates so many harmonics that the output termination will reflect a lot of energy and, depending on the output filter topology, different results can be expected. We firmly believe that there will be further mathematical improvement in the CAD tools, and we very much invite

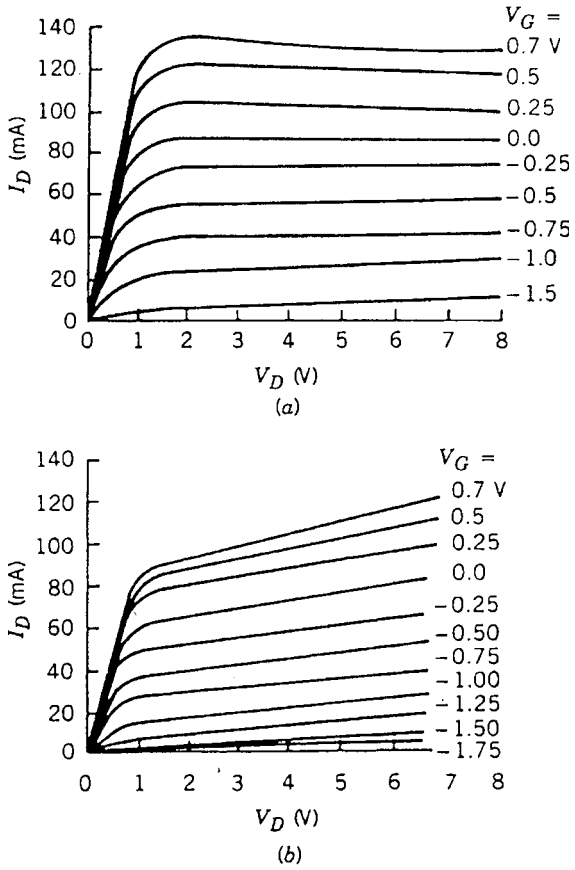

Figure 3-219 Comparison of FET drain current characteristics obtained from (a) pulsed *I–V* and (b) rectified sine-wave evaluation. The rectified sine-wave curves can be considered equivalent to curves obtained at dc.

our readers to use such a nonlinear example to test their tools, provided that a high-power model becomes available in this power range.

It has been rumored that the load-pull technique, rather than the application of large-signal *S* parameters, is a vehicle to solve such matching problems. However, the load-pull technique is really applied only to the fundamental frequency and does not deal with the issue of harmonics of the output current. More details about the load-pull technique and its capabilities are found in Appendix B.

Actual measurements of amplifiers of this type show that our simulated efficiency and drive level come quite close to reality, but at a frequency somewhat offset from that chosen for the design. As an example, the input and output filters tuned at 1.4 GHz instead of 1.6 GHz using the large-signal *S* parameters. Again, an iterative process, similar to manually trimming a prototype, will give a similar result. This is consistent with our earlier statement that most final designs are really hand-tweaked, and that CAD can only bring us close, but not all the way, to a good solution. For passive problems, the CAD does a significantly better job; the nonlinear cases are the ones that still cause headaches.

3-12-2 Impedance Matching Networks Applied to RF Power Transistors*

Introduction. Some graphical and numerical methods of impedance matching will be reviewed here. The examples given refer to high-frequency power amplifiers.

Although matching networks normally take the form of filters and therefore are also useful to provide frequency discrimination, this aspect will be considered only as a corollary of the matching circuit.

Matching is necessary for the best possible energy transfer from stage to stage. In RF power transistors, the input impedance is of low value, decreasing as the power increases or as the chip size becomes larger. This impedance must be matched either to a generator—of generally 50-Ω internal impedance—or to a preceding stage. Impedance matching has to be made between two complex impedances, which makes the design still more difficult, especially if matching must be accomplished over a wide frequency band.

Device Parameters

Input Impedance. The general shape of the input impedance of RF power transistors is as shown in Figure 3-220. It is a large-signal parameter, expressed here by the parallel combination of a resistance R_p and a reactance X_p [31].

The equivalent circuit shown in Figure 3-221 accounts for the behavior illustrated in Figure 3-220. With the presently used stripline or flange packaging, most of the power devices for VHF low band will have their R_p and X_p values below the series resonant point f_s. The input impedance will be essentially capacitive.

Most of the VHF high-band transistors will have the series-resonant frequency within their operating range; that is, they will be purely resistive at one single frequency f_s, which the parallel-resonant frequency f_p will be outside.

Parameters for 1- or 2-GHz transistors will be beyond f_s and approach f_p. They show a high value of R_p and X_p with inductive character.

A parameter that is very often used to judge on the broadband capabilities of a device is the input Q or Q_{IN}, defined simply as the ratio R_p/X_p. Practically, Q_{IN} ranges around 1 or less for VHF devices and around 5 or more for microwave transistors.

Q_{IN} is an important parameter to consider for broadband matching. Matching networks normally are low-pass or pseudo-low-pass filters. If Q_{IN} is high, it can be necessary to use bandpass filter-type matching networks and to allow insertion losses. But broadband matching is still possible. This will be discussed later.

Output Impedance. The output impedance of RF power transistors, as given by all manufacturers' datasheets, generally consists of only a capacitance C_{OUT}. The internal resistance of the transistor is supposed to be much higher than the load and is normally neglected. In the case of a relatively low internal resistance, the efficiency of the device would decrease by the factor

$$1 + R_L/R_T \tag{3-192}$$

*Based on Motorola application note AN-721 ("Impedance Matching Networks Applied to RF Power Transistors"). Copyright of Motorola; used by permission.

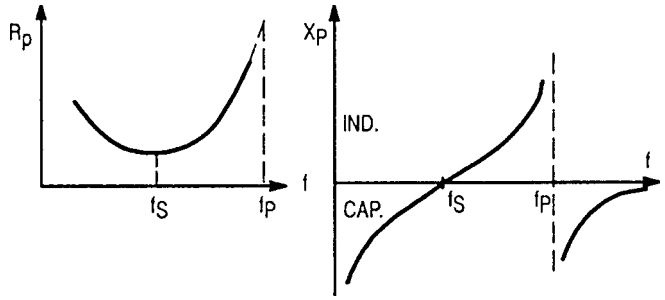

Figure 3-220 Input impedance of RF power transistors as a function of frequency.

where R_L is the load resistance, seen at the collector–emitter terminals, and R_T is the internal transistor resistance equal to

$$\frac{1}{\omega_T (C_{TC} + C_{DC})} \tag{3-193}$$

defined as a single parameter, where ω_T is the transit angular frequency and C_{TC} and C_{DC} are the transition and diffusion capacitances, respectively, at the collector junction.

The output capacitance, C_{OUT}, which is a large-signal parameter, is related to the small-signal parameter C_{CB}, the collector–base transition capacitance.

Since a junction capacitance varies with the applied voltage, C_{OUT} differs from C_{CB} in that it has to be averaged over the total voltage swing. For an abrupt junction and assuming certain simplifications, $C_{\text{OUT}} = 2C_{CB}$.

Figure 3-222 shows the variation of C_{OUT} with frequency. C_{OUT} decreases partly due to the presence of the collector lead inductance, but mainly because of the fact that the base–emitter diode does not shut off anymore when the operating frequency approaches the transit frequency, f_T.

Output Load. In the absence of a more precise indication, the output load R_L is taken as

$$R_L = \frac{[V_{CC} - V_{CE(\text{sat})}]^2}{2P_{\text{OUT}}} \tag{3-194}$$

with $V_{CE(\text{sat})}$ equal to 2 or 3 V, increasing with frequency.

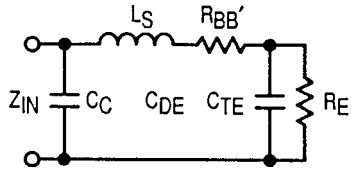

Figure 3-221 Equivalent circuit for the input impedance. R_E is the emitter diffusion resistance; C_{DE} and C_{TE} are the diffusion and transition capacitances, respectively, of the emitter junction; $R_{BB'}$ is the base-spreading resistance; C_C is the package capacitance; and L_S is the base lead inductance.

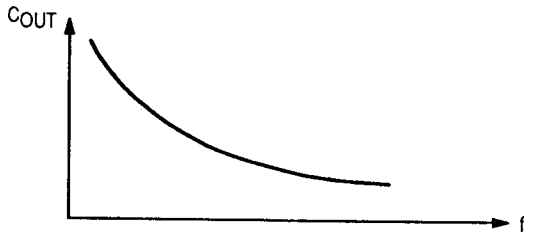

Figure 3-222 Output capacitance C_{OUT} as a function of frequency.

The above equation just expresses a well-known relation, but it also shows that the load, in first approximation, is not related to the device, except for $V_{CE(sat)}$. The load value is primarily dictated by the required output power and the peak voltage; it is not matched to the output impedance of the device.

At high frequencies this approximation becomes less exact, and for microwave devices the load that must be presented to the device is indicated on the datasheet.

Strictly speaking, impedance matching is accomplished only at the input. Interstage and load matching are more impedance transformations of the device input impedance and of the load into a value R_L (sometimes with additional reactive component) that depends essentially on the power demanded and the supply voltage.

Matching Networks. In the following, matching networks will be described by the order of complexity. These are ladder-type reactance networks. The different reactance values will be calculated and determined graphically. Increasing the number of reactances broadens the bandwidth. However, matching networks consisting of more than four reactances are rare. Above four reactances, the improvement is small.

Numerical Design

TWO-RESISTANCE NETWORKS. Resistance terminations will first be considered. Figure 3-223 shows the reactive L section and the terminations to be matched.

Matching or exact transformation from R_2 into R_1 occurs at a single frequency f_0. At f_0, X_1 and X_2 are equal to

$$X_1 = \pm R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = R_1 \frac{1}{\sqrt{n-1}} \tag{3-195}$$

$$X_2 = \mp \sqrt{R_2(R_1 - R_{2)}} = R_1 \frac{\sqrt{n-1}}{1} \tag{3-196}$$

At f_0, $X_1X_2 = R_1R_2$. X_1 and X_2 must be of opposite sign. The shunt reactance is in parallel with the larger resistance.

The frequency response of the L section is shown in Figure 3-224, where the normalized current is plotted as a function of the normalized frequency.

If X_1 is capacitive and consequently X_2 is inductive, then

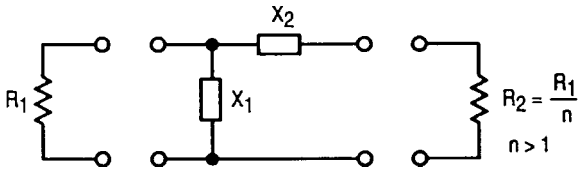

Figure 3-223 Two-reactance matching network.

$$X_1 = -\frac{f_0}{f} R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = -\frac{f_0}{f} R_1 \frac{1}{\sqrt{n-1}} \tag{3-197}$$

and

$$X_2 = \frac{f}{f_0} \sqrt{R_2(R_1 - R_2)} = \frac{f}{f_0} R_1 \frac{\sqrt{n-1}}{1} \tag{3-198}$$

The normalized current absolute value is equal to

$$\left|\frac{I_2}{I_0}\right| = \frac{2\sqrt{n}}{\sqrt{(n-1)^2 \cdot (f/f_0)^4 - 2\,(f/f_0)^2 + (n+1)^2}} \tag{3-199}$$

where $I_0 = \sqrt{n}E/2R_1$ and is plotted in Figure 3-224 [32].

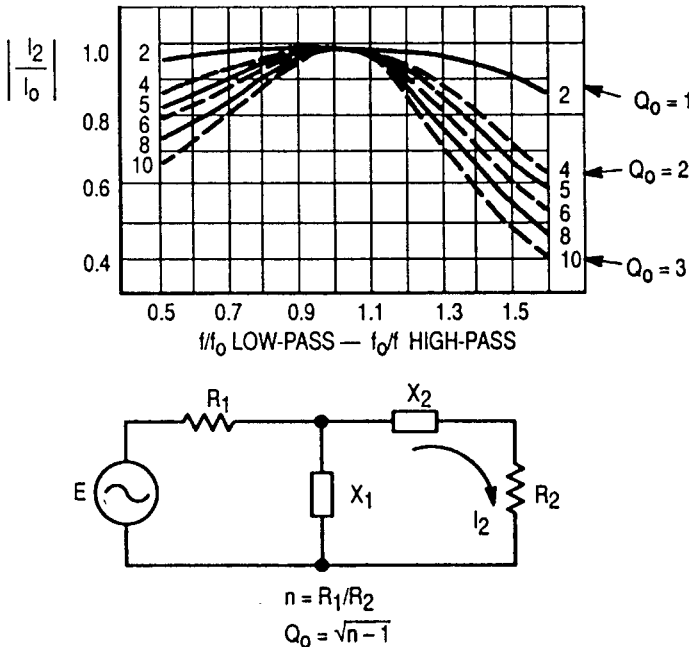

Figure 3-224 Normalized frequency response for the L section in low-pass or high-pass form.

If X_1 is inductive and consequently X_2 is capacitive, the only change required is a replacement of f by f_0 and vice versa. The L section has low-pass form in the first case and high-pass form in the second case.

The Q of the circuit at f_0 is equal to

$$Q_0 = \frac{X_2}{R_2} = \frac{R_1}{X_1} = \sqrt{n-1} \tag{3-200}$$

For a given transformation ratio n, there is only one possible value of Q. On the other hand, there are two symmetrical solutions for the network that can be either a low-pass filter or a high-pass filter.

The frequency f_0 does not need to be the center frequency, $(f_1 + f_2) / 2$, of the desired band limited by f_1 and f_2. In fact, as can be seen from the low-pass configuration of Figure 3-224, it may be interesting to shift f_0 toward the high-band edge frequency f_2 to obtain a larger bandwidth w, where

$$w = \frac{2(f_1 + f_2)}{f_2 - f_1} \tag{3-201}$$

This will, however, be at the expense of poor harmonic rejection.

Example. For a transformation ratio of $n = 4$, we can determine the following values from the above relations:

Bandwidth w	0.1	0.3
Maximum insertion losses	0.025	0.2
X_1/R_1	1.730	1.712

If the terminations R_1 and R_2 have a reactive component X, the latter may be taken as part of the external resistance as shown in Figure 3-225. This compensation is applicable as long as

$$Q_{int} = \frac{X_{\text{int}}}{R_2} \quad \text{or} \quad \frac{R_1}{X_{\text{int}}} < n - 1 \tag{3-202}$$

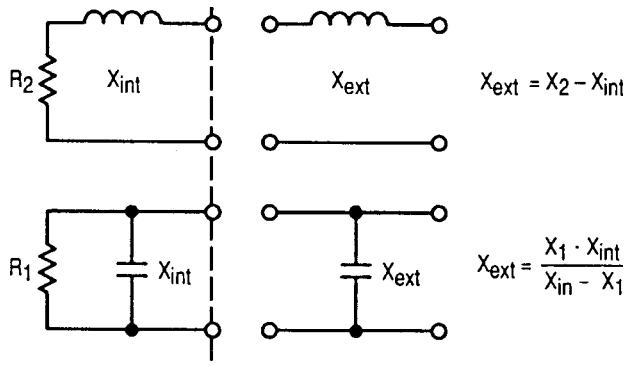

Figure 3-225 Termination reactance compensation.

Tables giving reactance values can be found in Matthaei et al. [33, 34].

USE OF TRANSMISSION LINES AND INDUCTORS. In the preceding section, the inductance was expected to be realized by a lumped element. A transmission line can be used instead (Figure 3-226).

As can be seen from the computed selectivity curves (Figure 3-227) for the two configurations, transmission lines result in a larger bandwidth. The gain is important for a transmission line having a length $L = \lambda/4$ ($\Theta = 90°$) and a characteristic impedance $Z_0 = \sqrt{R_1 R_2}$. It is not significant for lines short with respect to $\lambda/4$. One will notice that there is an infinity of solutions, one for each value of C, when using transmission lines.

THREE-REACTANCE MATCHING NETWORKS. The networks that will be investigated are shown in Figure 3-228. They are made of three reactances alternately connected in series and shunt.

A three-reactance configuration allows the designer to make the quality factor (Q) of the circuit and the transformation ratio $n = R_2/R_1$ independent of each other and consequently to choose the selectivity between certain limits.

For narrowband designs, one can use the following formulas (see [35], where tables are given):

Network (a)

$$X_{C1} = R_1/Q \quad Q \text{ must be selected first} \tag{3-203}$$

$$X_{C2} = R_2 \sqrt{\frac{R_1 R_2}{(Q^2 + 1) - R_1/R_2}} \tag{3-204}$$

$$X_L = \frac{QR_1 + (R_1 R_2/X_{C2})}{Q^2 + 1} \tag{3-205}$$

Network (b)

$$X_{L1} = R_1 Q \quad Q \text{ must be selected first} \tag{3-206}$$

$$X_{L2} = R_2 B \tag{3-207}$$

$$A = R_1(1 + Q^2) \tag{3-208}$$

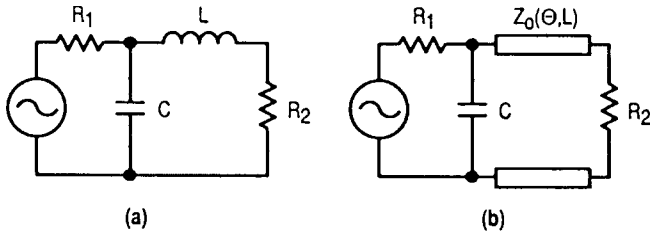

Figure 3-226 Use of a transmission line in the L section.

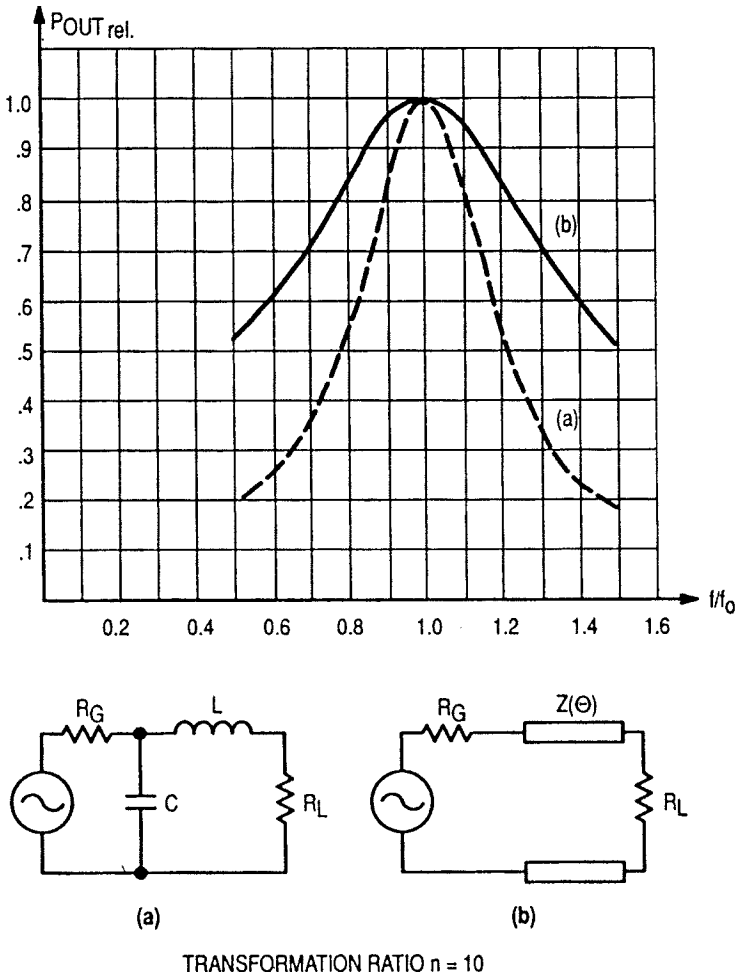

Figure 3-227 Bandwidth of the L section for $n = 10$ (a) with lumped constants and (b) with transmission line (λ/4).

$$X_{C1} = \frac{A}{Q + B} \tag{3-209}$$

$$B = \sqrt{\frac{A}{R_2} - 1} \tag{3-210}$$

Network (c)

$$X_{L1} = QR_1 \quad Q \text{ must be selected first} \tag{3-211}$$

$$X_{C2} = AR_2 \tag{3-212}$$

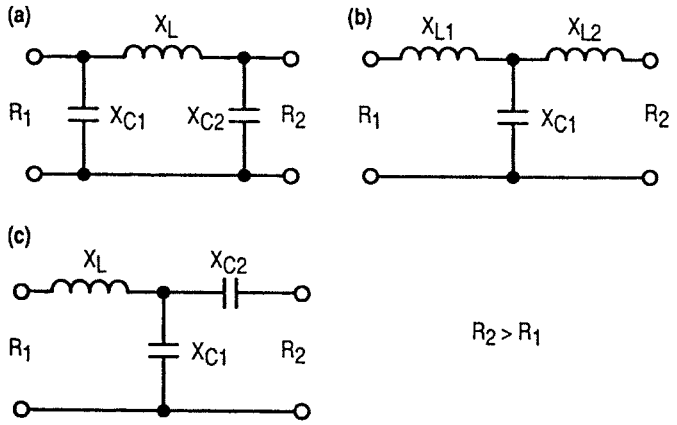

Figure 3-228 Three-reactance matching networks.

$$A = \sqrt{\frac{R_1(1+Q^2)}{R_2} - 1} \tag{3-213}$$

$$X_{C1} = \frac{B}{Q - A} \tag{3-214}$$

$$B = R_1(1+Q^2) \tag{3-215}$$

The network that yields the most-practical component values should be selected for a given application.

The three-reactance networks can be thought of as being formed of an L section (two reactances) and of a compensation reactance. The L section essentially performs the impedance transformation, while the additional reactance compensates for the reactive part of the transformed impedance over a certain frequency band.

Figure 3-229 shows a representation in the Z plane of the circuit of Figure 3-228a split into two parts: $R_1 - C_1 - L_1$ and $C_2 - R_2$. Exact transformation from R_1 into R_2 occurs at the points of intersection M and N. Impedances are then conjugate, or $Z' = R' + jX'$ and $Z'' = R'' + jX''$ with $R' = R''$ and $X' = -X''$.

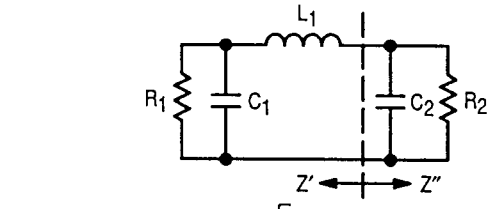
The only possible solution is obtained when X' and $-X''$ are tangential to each other. For the dashed curve, representing another value of L_1 or C_1, a wider frequency band could be expected at the expense of some ripple inside the band. However, this can only be reached with four reactances, as will be shown below.

With a three-reactance configuration, there are not enough degrees of freedom to permit $X' = -X''$ and simultaneously obtain the same variation of frequency on both curves from point M' to point N'. Exact transformation can, therefore, be obtained at only one frequency.

The values of the three reactances can be calculated by making

$$X' = -X'', \quad R' = R'', \quad \text{and} \frac{dX'}{dR'} = -\frac{dX''}{dR''} \tag{3-216}$$

The general solution of these equations leads to complicated calculations. Therefore, computed tables should be used.



$$Z' = \frac{R_1}{1 + \omega^2 R_1^2 C_1^2} + j\omega \left[L1 - \frac{R_1^2 C_1}{1 + \omega^2 R_1^2 C_1^2} \right] = R' + jX'$$

$$Z'' = \frac{R_2}{1 + \omega^2 C_2^2 R_2^2} - \frac{j\omega^2 C_2 R_2^2}{1 + \omega^2 C_2^2 R_2^2} = R'' + jX''$$

$$|x'| = \left(\frac{L_1}{C_1 R_1^2} - \frac{R'}{R_1} \right) \sqrt{\frac{R_1}{R'} - 1}$$

$$|x''| = \sqrt{R' R_2 - R'^2}$$

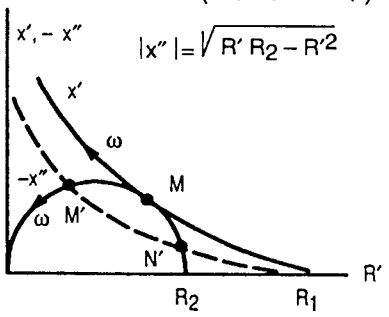


Figure 3-229 *Z*-plane representation of the circuit of Figure 3-228a.

One will note from Figure 3-229 that the compensation reactance contributes somewhat to the impedance transformation; that is, R' varies when going from M to R_2.

The circuit of Figure 3-228b is dual with respect to the first one and gives exactly the same results in a *Y*-plane representation. The circuit of Figure 3-228c is somewhat different since only one intersection M exists, as shown in Figure 3-230. Narrower frequency bands must be expected from this configuration. The widest band is obtained for $C_1 = \infty$.

Again, if one of the terminations has a reactive component, the latter can be taken as a part of the matching network, provided that it is not too large (see Figure 3-227).

FOUR-REACTANCE NETWORKS. Four-reactance networks are used essentially for broadband matching. The networks that will be considered in the following consist of two two-reactance sections in cascade. Some networks have pseudo-low-pass filter character; others, bandpass filter character. In principle, the former show narrower bandwidth since they extend the impedance transformation to very low frequencies unnecessarily, while the latter ensure good matching over a wide frequency band around the center frequency only (see Figure 3-233).

The two-reactance sections used in the networks in Figure 3-231 have either transformation properties or compensation properties. Impedance transformation is obtained with one series reactance and one shunt reactance. Compensation is made with both reactances in series or in shunt. If two cascaded transformation networks are used, transformation is accomplished partly by each one.

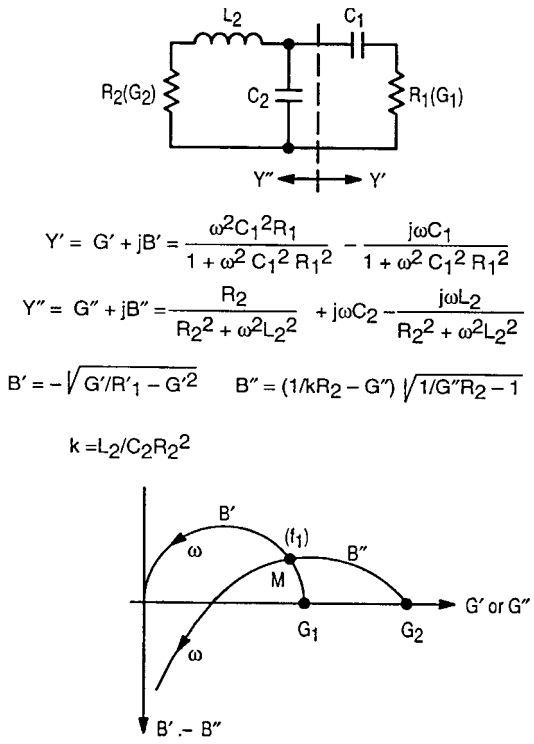

Figure 3-230 *Y*-plane representation of the circuit of Figure 3-228c.

With four-reactance networks there are two frequencies, f_1 and f_2, at which the transformation from R_1 into R_2 is exact. These frequencies may also coincide. For the network in Figure 3-231b, for instance, at point M, R_1 or R_2 is transformed into $\sqrt{R_1R_2}$ when both frequencies fall together. At all points (M), Z_1 and Z_2 are conjugate if the transformation is exact.

In the case of Figure 3-231b, the reactances are easily calculated for equal frequencies:

$$X_1 = \frac{R_1}{\sqrt{(n-1)^{1/2}}} \tag{3-217}$$

$$X_2 = R_1\sqrt{\frac{n^{1/2}-1}{n}} \tag{3-218}$$

$$X_1X_4 = R_1R_2 = X_2X_3 \tag{3-219}$$

$$X_3 = \frac{R_1}{\sqrt{n(n^{1/2}-1)}} \tag{3-220}$$

$$X_4 = \frac{R_1}{n}\sqrt{n^{1/2}-1} \tag{3-221}$$

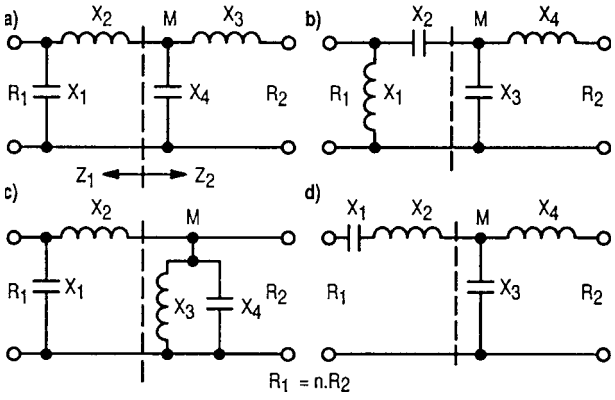

Figure 3-231 Four-reactance networks.

For the network in Figure 3-231a, normally at point M, Z_1 and Z_2 are complex. This pseudo-low-pass filter has been computed elsewhere [33]. Many tables can be found in the literature for networks of four and more reactances having Chebyshev character or maximally flat response [33, 34, 36].

Figure 3-232 shows the transformation path from R_1 to R_2 for networks (a) and (b) in Figure 3-231 on a Smith Chart.

Case (a) of Figure 3-232 has been calculated using tables in Matthaei [34]. Case (b) has been obtained from the relationship given above for $X_1, \ldots, X_4$. Both apply for a transformation ratio equal to 10 and for $R_1 = 1$. There is no simple relationship for $X_1', \ldots, X_4'$ of network (b) if f_1 is made different from f_2 for larger bandwidth. Figure 3-233 shows the respective bandwidths of networks (a) and (b) for the circuits shown in Figure 3-232.

If the terminations include a reactive component, the computed values for X_1 or X_4 may be adjusted to compensate for this.

For configuration (a), it can be seen from Figure 3-232 that, in the considered case, the Q values are equal to 1.6. For configuration (b), Q_1', which is equal to Q_2', is fixed for each transformation ratio

n	2	4	8	10	16
$Q'_1 = Q'_2$	0.65	1	1.35	1.46	1.73

$$Q' = \sqrt{n^{1/2} - 1} \qquad (3\text{-}222)$$

The maximum value of reactance that the terminations may have for use in this configuration can be determined from the above values of Q'.

If R_1 is the load resistance of a transistor, the internal transistor resistance may not be equal to R_1. In this case, the selectivity curve will be different from the curves given in Figure 3-233. Figure 3-234 shows the selectivity for networks (a) and (b) when the source resistance R_1 is infinite. From Figure 3-234 it can be seen that network (a) is more sensitive to changes in R_1 than network (b).

As mentioned earlier, the four-reactance network can also be thought of as two cascaded two-reactance sections: one used for transformation, the other for compensation. Figure 3-235 shows commonly used compensation networks, together with the associated L section.

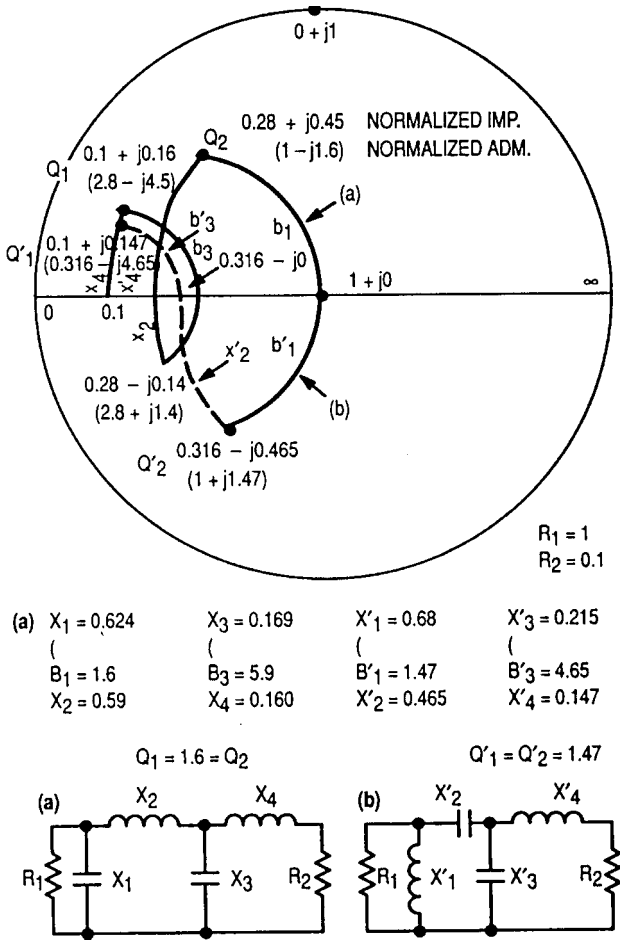

Figure 3-232 Transformation paths for networks (a) and (b).

The circuit of Figure 3-235a can be compared to the three-reactance network shown in Figure 3-228c. The difference is that capacitor C_2 of that circuit has been replaced by an *LC* circuit. The resulting improvement can be seen by comparing Figure 3-236 with Figure 3-230.

By adding one reactance, exact impedance transformation is achieved at two frequencies. It is now possible to choose component values such that the point of intersection M' occurs at the same frequency f_1 on both curves and simultaneously that N' occurs at the same frequency f_2 on both curves. Among the infinite number of possible intersections, only one allows the achievement of this.

When M' and N' coincide in M, the new $dX'/df = dX''/df$ condition can be added to the condition $X' = -X''$ (for three-reactance networks) and similarly $R' = R''$ and $dR'/df = dR''/df$.

Again, a general solution of the above equations leads to still more complicated calculations than in the case of three-reactance networks. Therefore, tables are preferable [33, 34, 36].

The circuit of Figure 3-235b is the dual of the circuit of Figure 3-233a and does not need to be treated separately. It gives exactly the same results in the *Z* plane. Figure 3-235c shows a higher-order compensation requiring six reactive elements.

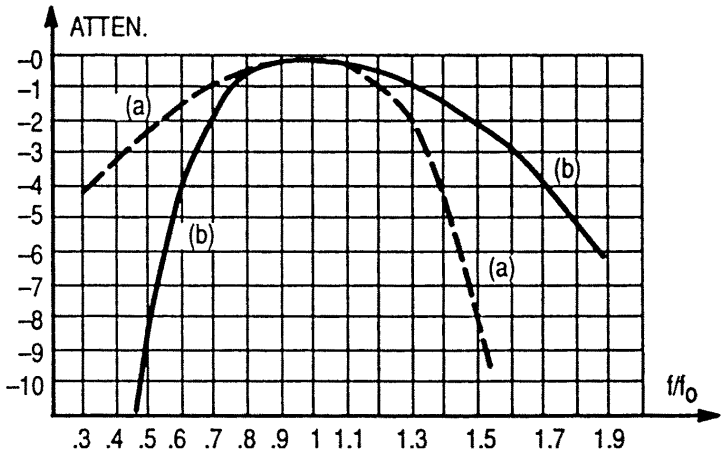

Figure 3-233 Selectivity curves for networks (a) and (b) of Figure 3-232.

The above-discussed matching networks employing compensation circuits result in narrower bandwidths than the former solutions (see p. 573) using two transformation sections. A matching arrangement with higher-order compensation, such as in Figure 3-235c, is not recommended. Better use can be made of the large number of reactive elements by using them all for transformation.

When the above configurations are realized using short portions of transmission lines, the equations or the usual tables no longer apply. The calculations must be carried out on a computer because of their complexity. However, a graphical method can be used (see the next section) that will consist essentially in tracing a transformation path on the Z–Y chart using the computed lumped element values and replacing it by the closest path obtained with distributed constants. The bandwidth change is not significant as long as short portions of lines are used.

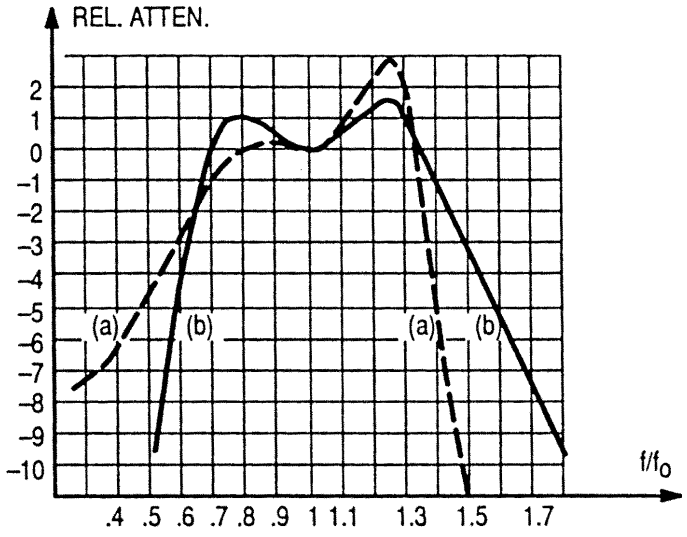

Figure 3-234 Selectivity curves for networks (a) and (b) of Figure 3-232 with infinite R_1.

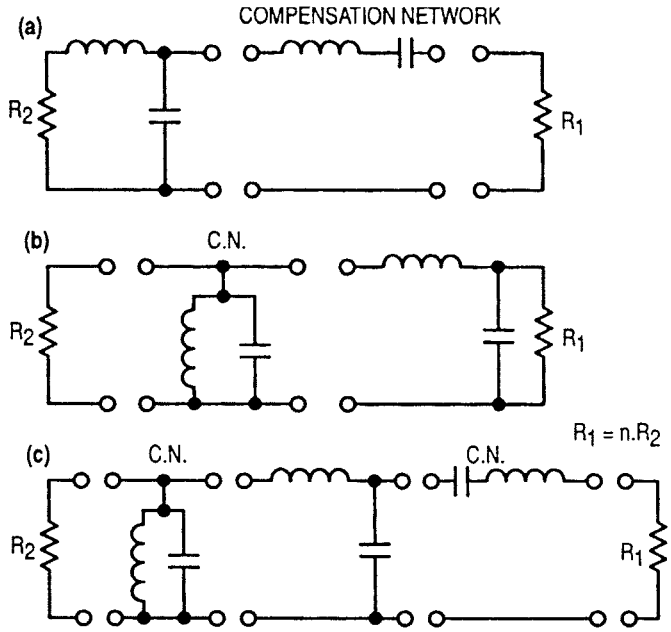

Figure 3-235 Compensation networks used with an L section.

MATCHING NETWORKS USING QUARTER-WAVE TRANSFORMERS. At sufficiently high frequencies, where λ/4-long lines of practical size can be realized, broadband transformations can easily be accomplished by the use of one or more λ/4 sections. Figure 3-237 summarizes the main relations for (a) one-section and (b) two-section transformations. A compensation network can be realized using a λ/2-long transmission line. Figures 3-238 and 3-239 show the selectivity curves for different transformation ratios and section numbers.

EXPONENTIAL LINES. Exponential lines have largely frequency-independent transformation properties. The characteristic impedance of such lines varies exponentially with their length l:

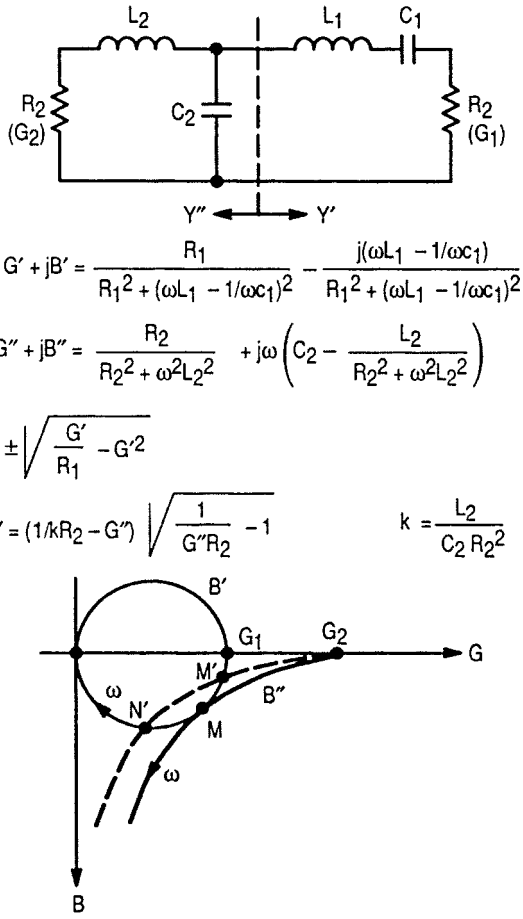
$$Z = Z_0 e^{kl} \tag{3-223}$$

where k is a constant, but these properties are preserved only if k is small.

BROADBAND MATCHING USING BANDPASS FILTER NETWORKS—HIGHQ CASE. The above circuits are applicable to devices having low input or output Q, if broadband matching is required. Generally, if the impedances to be matched can be represented, for instance, by a resistor R in series with an inductor L (sometimes a capacitor C) within the band of interest and if L is sufficiently low, the latter can be incorporated into the first inductor in the matching network. This is also valid if the representation consists of a shunt combination of a resistor and a reactance.

Practically, this is feasible for Q values around 1 or 2. For higher Q values or for input impedances consisting of a series or parallel resonant circuit (see Figure 3-221), as it appears to be for large bandwidths, a different treatment must be followed.

Let us first recall that, as shown by Bode [37] and Fano [38], limitations exist on the impedance matching of a complex load. In the example of Figure 3-240, the load to be matched consists of a capacitor C and a resistor R in shunt.



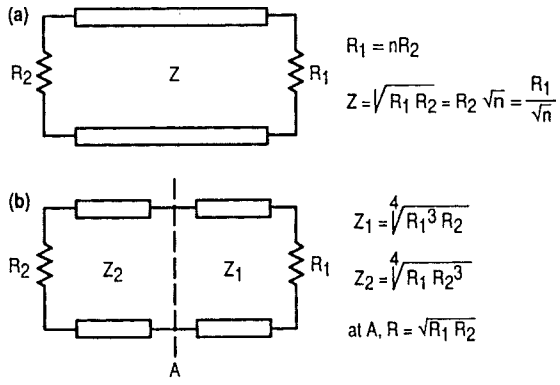
$$Y' = G' + jB' = \frac{R_1}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2} - \frac{j(\omega L_1 - 1/\omega c_1)}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2}$$

$$Y'' = G'' + jB'' = \frac{R_2}{R_2^2 + \omega^2 L_2^2} + j\omega\left(C_2 - \frac{L_2}{R_2^2 + \omega^2 L_2^2}\right)$$

$$B' = \pm\sqrt{\frac{G'}{R_1} - G'^2}$$

$$B'' = (1/kR_2 - G'')\sqrt{\frac{1}{G''R_2} - 1} \qquad k = \frac{L_2}{C_2 R_2^2}$$

Figure 3-236 *Y*-plane representation of the circuit of Figure 3-235a.



$$R_1 = nR_2$$

$$Z = \sqrt{R_1 R_2} = R_2\sqrt{n} = \frac{R_1}{\sqrt{n}}$$

$$Z_1 = \sqrt[4]{R_1^3 R_2}$$

$$Z_2 = \sqrt[4]{R_1 R_2^3}$$

$$\text{at A, } R = \sqrt{R_1 R_2}$$

Figure 3-237 Transformation networks using λ/4-long transmission lines.

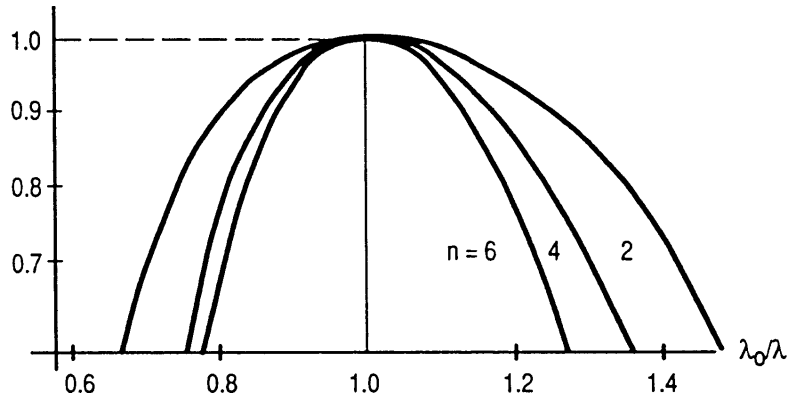


Figure 3-238 Selectivity curves for two λ/4-section networks at different transformation ratios.

The reflection coefficient between the transformed load and generator is equal to

$$\Gamma = \frac{Z_{\text{IN}} - R_G}{Z_{\text{IN}} + R_G} \tag{3-224}$$

When $\Gamma = 0$, there is perfect matching; when $\Gamma = 1$, there is total reflection. The ratio of reflected to incident power is

$$\frac{P_r}{P_i} = |\Gamma|^2 \tag{3-225}$$

The fundamental limitation on the matching takes the form

$$\int_{\omega=0}^{\infty} \ln\left(\frac{1}{|\Gamma|}\right) d\omega \le \frac{\pi}{RC} \qquad \text{Bode equation} \tag{3-226}$$

and is represented in Figure 3-241.

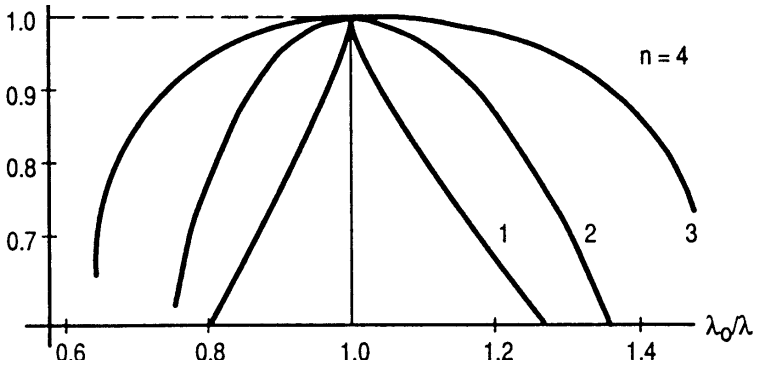

Figure 3-239 Selectivity curves for one, two, and three λ/4 sections.

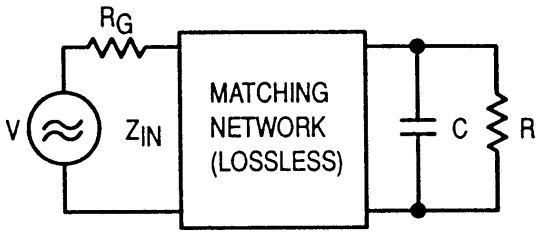

Figure 3-240 General matching conditions.

The meaning of the Bode equation is that the area S under the curve cannot be greater than π/RC and, therefore, if matching is required over a certain bandwidth, this can only be done at the expense of less power transfer within the band. Thus, power transfer and bandwidth appear as interchangeable quantities.

It is evident that the best utilization of the area S is obtained when $|\Gamma|$ is kept constant over the desired band ω_c and made equal to 1 over the rest of the spectrum. Then

$$|\Gamma| = e^{-\pi/\omega_c RC} \tag{3-227}$$

within the band and no power transfer happens outside. A network fulfilling this requirement cannot be obtained in practice because an infinite number of reactive elements would be necessary.

If the attenuation is plotted versus frequency for practical cases, one may expect to have curves like the ones shown in Figure 3-242 for a low-pass filter having Chebyshev character.

For a given complex load, an extension of the bandwidth from ω_1 to ω_2 is possible only with a simultaneous increase of the attenuation a. This is especially noticeable for Q values exceeding 1 or 2 (see Figure 3-243). Thus, devices having relatively high input Q values are usable for broadband operation, provided the consequent higher attenuation or reflection introduced is acceptable.

For average insertion losses or attenuation a (neglecting the ripple), the attenuation decreases if the number n of the network element increases. But above $n = 4$, the improvement is small. For a given attenuation a and bandwidth, the larger the n the smaller the ripple; for a given attenuation, the larger the n the larger the bandwidth.

Computations show that for $Q < 1$ and $n \leq 3$, the attenuation is below 0.1 dB (approximately). The impedance transformation ratio is not free here. The network is a

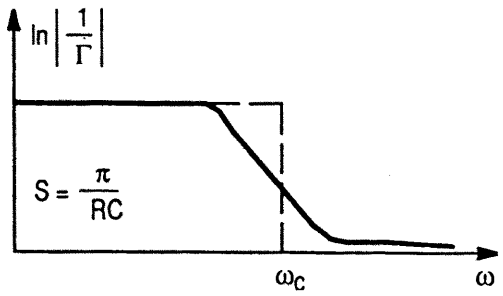

Figure 3-241 Representation of the Bode equation.

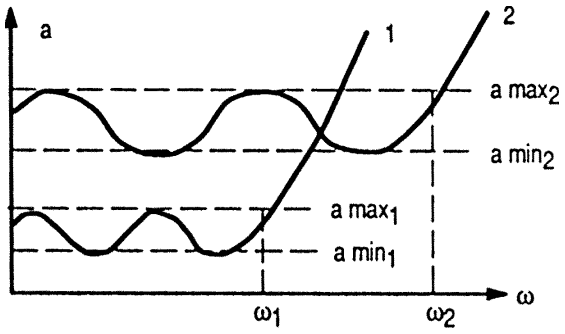

Figure 3-242 Attenuation versus angular frequency for different bandwidths with the same load.

true low-pass filter. For a given load, the optimum generator impedance will result from the computation.

Before impedance transformation is introduced, a conversion of the low-pass prototype into a bandpass filter network must be made. Figure 3-244 summarizes the main relations for this conversion. r is the conversion factor. For the bandpass filter, $Q_{\text{IN max}}$, or the maximum possible input Q of the device to be matched, has been increased by the factor r (from Figure 3-244, $Q'_{\text{IN max}} = rQ_{\text{IN max}}$).

Impedance inverters will be used for impedance transformation. These networks are suitable for insertion into a bandpass filter without affecting the transmission characteristics.

Figure 3-245 shows four impedance inverters. Note that one of the reactances is negative and must be combined in the bandpass network with a reactance of at least equal positive value. Insertion of the inverter can be made at any convenient place [32, 39].

When using the bandpass filter for matching the input impedance of a transistor, reactances $L'_1C'_1$ should be made to resonate at ω_0 by addition of a convenient series reactance.

As stated earlier, the series combination of R_0, L'_1 and C'_1 normally constitutes the equivalent input network of a transistor when considered over a large bandwidth. This is a good approximation up to about 500 MHz.

In practice, the normal procedure for using a bandpass filter matching network will be the following:

1. For a given bandwidth center frequency and input impedance of a device to be matched—for example, 50 Ω—first determine Q'_{IN} from the datasheet as

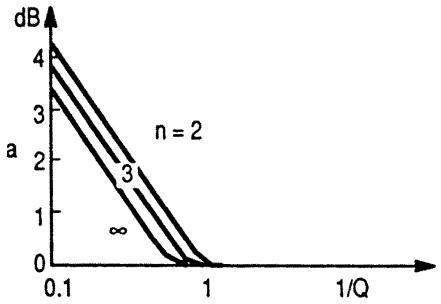

Figure 3-243 Insertion losses as a function of 1/*Q*.

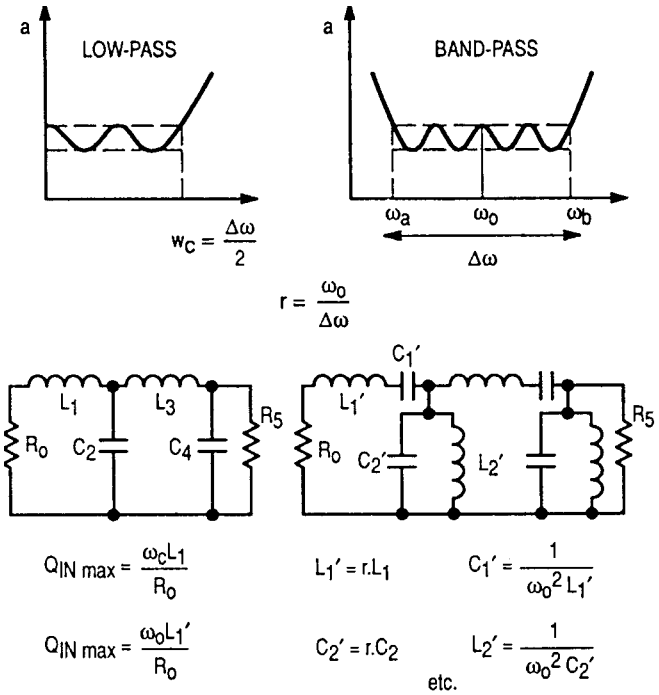

Figure 3-244 Conversion from low-pass filter into bandpass filter.

$$\frac{\omega_0 L_1'}{R_0} \tag{3-228}$$

after having eventually added a series reactor for centering.

2. Convert the equivalent circuit $R_0 L_1' C_1'$ into a low-pass prototype $R_0 L_1$ and calculate Q_{IN} using the formulas of Figure 3-244.
3. Determine the other reactance values from tables [33] for the desired bandwidth.
4. Convert the element values found by Step 3 into series- or parallel-resonant circuit parameters.
5. Insert the impedance inverter in any convenient place.

In the above discussions, the gain roll-off has not been taken into account. This is of normal use for moderate bandwidths (e.g., 30%). However, several methods can be employed to obtain a constant gain within the band despite the intrinsic gain decrease of a transistor with frequency. Tables have been computed elsewhere [40] for matching networks approximating 6 dB/octave attenuation versus frequency.

Another method consists of using the above-mentioned network and then adding a compensation circuit, as shown in Figure 3-246.

Resonance ω_b is placed at the high edge of the frequency band. Choosing Q correctly, roll-off can be made 6 dB/octave. The response of the circuit of Figure 3-246 is expressed by

$$\frac{1}{1 + Q^2(\omega/\omega_b - \omega_b/\omega)^2} \tag{3-229}$$

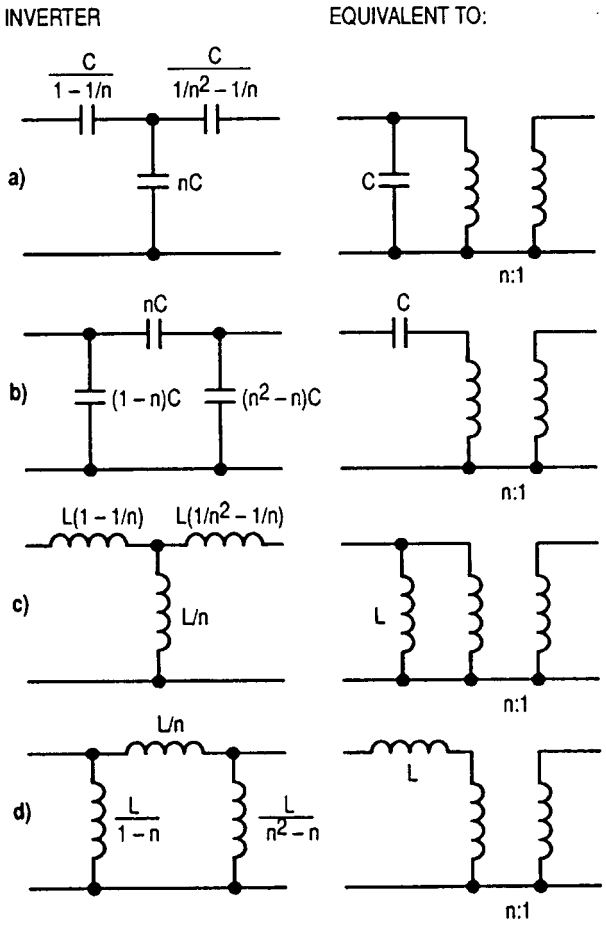

Figure 3-245 Impedance inverters.

where $\omega < \omega_b$. This must be equal to ω/ω_b for 6 dB/octave attenuation.

At the other band edge a, exact compensation can be obtained if

$$Q = \frac{(\omega_b/\omega_a)^2 - 1}{\omega_a/\omega_b - (\omega_b/\omega_a)^2} \tag{3-230}$$

There are several methods available for synthesis of matching networks. They should not be confused with filters because they can be either high-pass, low-pass, or bandpass, and their main purpose is to match one complex impedance to another. In many cases, one of the terminations happens to be 50 Ω and real, but this is just a "lucky" case of the general approach. An excellent paper on this [41] refers to the "real frequency" technique. Another equally important publication is the one by Cuthbert [42], since followed by his book [43]. Two more good references are Vendelin et al. [44] and Potter [45].

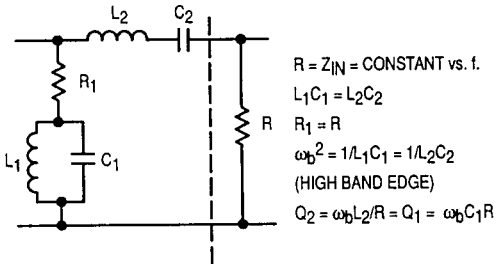

Figure 3-246 Roll-off compensation network.

3-12-3 Example 2: Low-Noise Amplifier Using Distributed Elements

In our previous examples, the amplifiers were built around lumped elements. Since a transmission line length of less than $\lambda/4$ is an inductor and $\frac{3}{4}\lambda$ is a capacitor, the whole amplifier can be built around microstrip technology.

If anyone wonders why we are going to show a low-noise amplifier in the middle of the power section, the reason is that we will select a low-power Siemens transistor, which, being operated in Class A, has an intercept point of +30 dBm and can easily achieve a noise figure of less than 2 dB. Such an amplifier is attractive when feeding an input stage from an antenna that sees many signals and curtails the bandwidth with an input filter of good selectivity that needs a good output termination, which in many cases works against the achievement of a good noise figure because when designing for best noise figure the input impedance of the transistor stage is far from 50 Ω.

First, we will start with the textbook approach and use the Smith diagram to obtain the best noise figure of which the device is capable. Figure 3-247 shows the actual approach to input and output matching.

We start our design by querying the Smith Tool about the minimum noise figure and the gain that comes with it. We mark the point of the lowest noise figure (labeled Γ_{opt}). The small

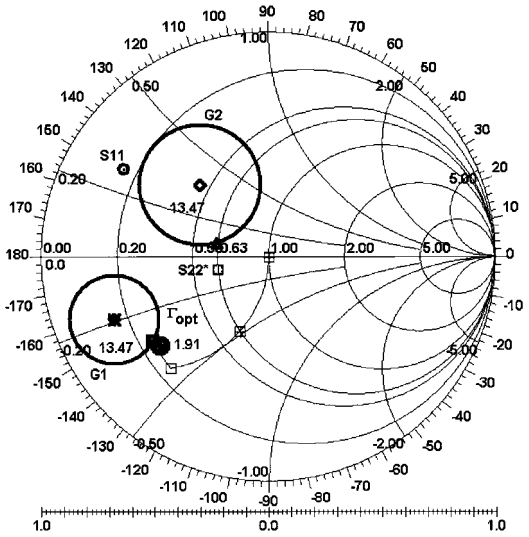

Figure 3-247 Input and output matches for 13.47 dB of gain and NF = 1.91 dB as displayed by the interactive Smith Tool.

noise circle yields the location for Γ_{opt} and tells us the minimum noise figure is going to be 1.91 dB. (By the way, this assumes no further losses, even in soldering the transistor to the PC board.) Then we construct the input gain circle (G1), which touches Γ_{opt} and turns out to represent 13.47 dB of available gain.

The next step is to find a matching network between Γ_{opt} and the 50-Ω source impedance. Immediately there is a conflict: If we look at S_{11}, which is the input reflection coefficient shown in the Smith diagram, it is on the other side of the complex plane and sufficiently far away, indicating that there is going to be quite a difference between noise matching and power-gain matching. We have two options for matching the input: Either we start from the origin and move toward the position of Γ_{opt}, or we start with Γ_{opt} and go to 50 Ω. Depending on the direction in which we do this, the result can be different topologies, such as a high-pass or low-pass filter. The high-pass filter is obtained by starting with Γ_{opt}; the low-pass topology is obtained by starting at the 50-Ω point. The Smith Tool then provides us with the corresponding values of capacitors and inductors after the transformation has been accomplished.

The final step is to do the same type of matching at the output. We start with S_{22}, and either select S_{22}^* (the complex conjugate for highest gain) or S_{22load}. As a rule, the second one is always a lower impedance (in terms of the real part) than the conjugate match. This graphic procedure is somewhat trial and error. As to the topology, a high-pass match should be preferred at the input and a low-pass match at the output. The reason for this is that the high-pass filter will tend to protect the stage from the enormous number of signals present below 1 GHz; using a low-pass filter at the output suppresses unwanted harmonics that the amplifier may generate. Figure 3-248 shows one of the approaches we like best simply because it gives a good input termination and we were trying for a simultaneous match for best noise figure and power gain.

The way we were able to achieve this was to take advantage of the existing feedback in the transistor and select a less-than-optimal output termination but gaining at the input. Taking advantage of the Miller effect, we rotate the phase angle of the feedback with the load to move the optimum noise and gain matching points closer. The danger in this is that the circuit is now highly sensitive to both input and output termination. The output *must* see 50 Ω to maintain this good input match, but since the second transistor stage can now be optimized for best input match, a two-stage combination can be configured to meet this

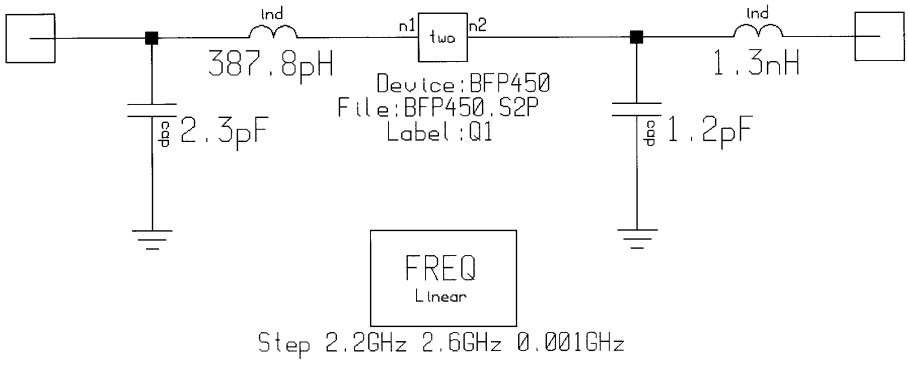

Figure 3-248 A 2.4-GHz amplifier using a BFP450 transistor and lumped-element input and output matching.

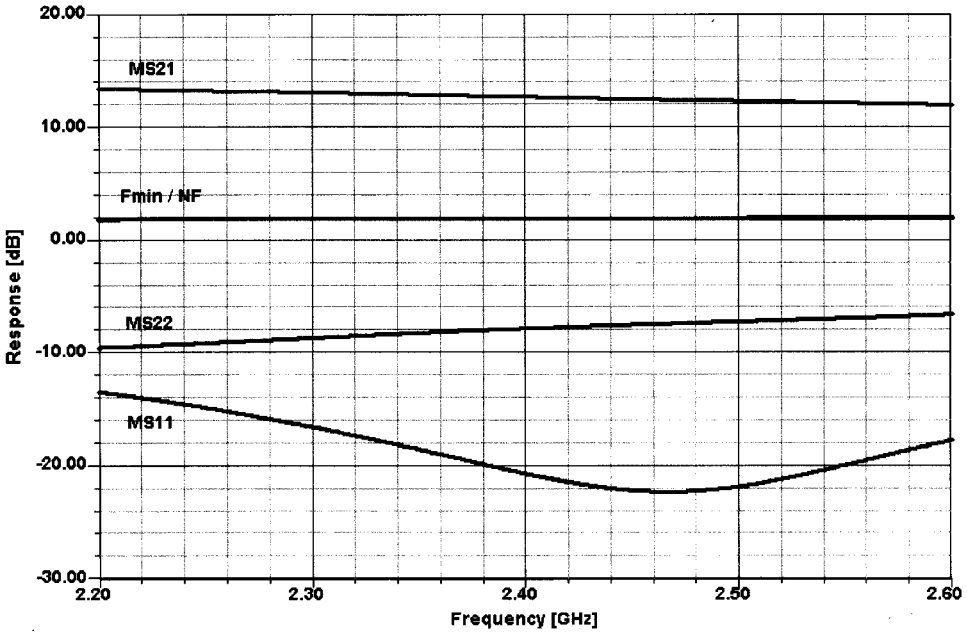

Figure 3-249 Frequency-dependent gain, matching, and noise characteristics of the matched high-dynamic-range BFP450 2.4-GHz amplifier.

requirement. Also, let us not forget that the device is running at 50 mA and as far as bipolar transistors are concerned, this is probably the best amplifier combination we have seen for getting the highest dynamic range and lowest noise figure. The resulting gain, matching, and noise figure characteristics are shown in Figure 3-249.

Now we turn to using distributed elements and at the same time use a shunt feedback at the output; to be specific, we will load it with 150 Ω. The reason for this is to be able to obtain a good compromise at the input that will depend less on the output and at the same

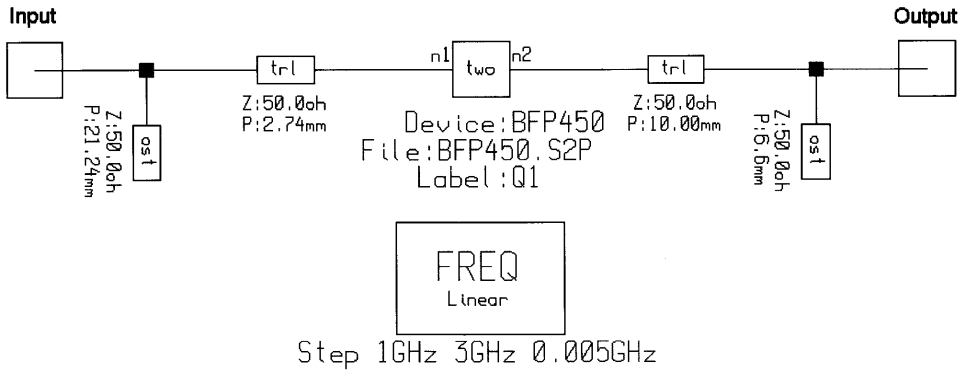

Figure 3-250 Distributed-element input and output matching for the 2.4-GHz BFP450 amplifier.

time improve the S_{22} matching at the output. The procedure for doing the matching with a transmission line offers only certain degrees of freedom, while doing the matching with lumped elements allows the choice of series or parallel inductors or capacitors. In the case of a transmission line, we have open stubs, shorted stubs, and transmission lines. This may result in somewhat more complex matching schemes. On the positive side, they can easily be trimmed, are reproducible, and certainly cost less than exotic capacitors, which need to have small tolerances and to be able to handle high RF currents.

The resulting input and output matching is shown in Figure 3-250, and its frequency response in Figure 3-251. We were able to maintain a good input and output match with an insignificant deterioration of the noise figure.

Since this is a high-dynamic-range amplifier, we also show its predicted two-tone response in Figure 3-252. The manufacturer specifies an $IP_{3,in}$ of 29 dB for a bias point of $V_{CE} = 3$ V and $I_C = 50$ mA with $Z_S = Z_{S,opt}$ and $Z_L = Z_{L,opt}$ at 1.8 GHz. Significantly, however, the manufacturer-supplied nonlinear BFP450 library we used exhibits considerably different characteristics at $V_{CE} = 4$ V and $I_C = 50$ mA than those reflected in the corresponding S parameters supplied by the same manufacturer. In our circuit, the S parameters resulted in about 13.5 dB of gain (based on a compromise between matching for optimum noise and maximum gain) versus about 9.5 dB of gain for the nonlinear library (match optimized for maximum gain). The difference between the 2.4-GHz F_{min} values returned for the two modeling approaches is similarly striking: 1.90 dB for the bare S parameter set and 7.76 dB for the bare nonlinear library biased to $V_{CE} = 4$ V and $I_C = 50$ mA. Clearly, the nonlinear modeling of the BFP450 needs work!

Having fully evaluated the amplifier at 2.4 GHz as a working example, we note that this frequency is used by radio amateurs for some applications. We will therefore supply

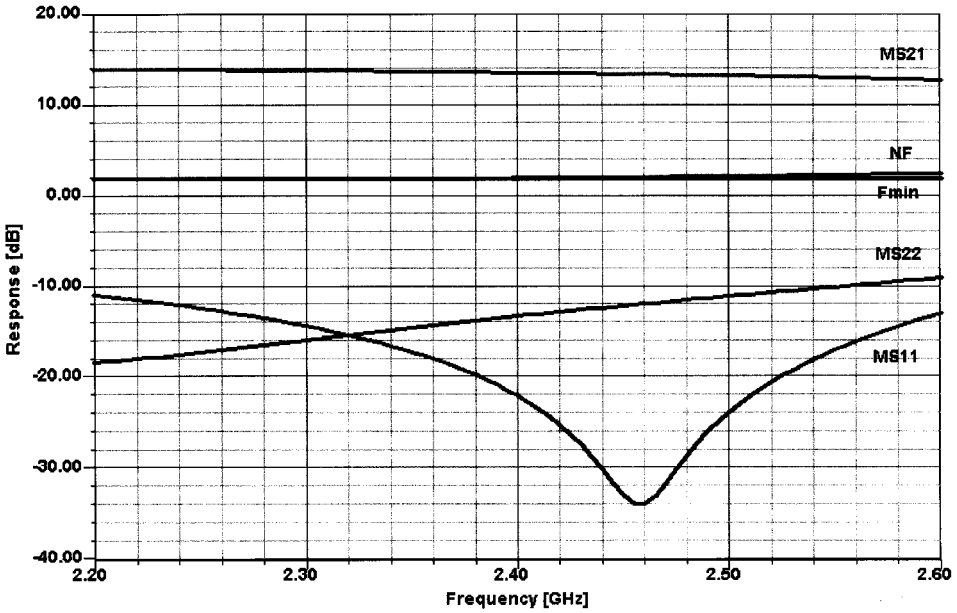

Figure 3-251 Predicted frequency-dependent gain, matching, and noise performance for the BFP450 amplifier with distributed-element matching.

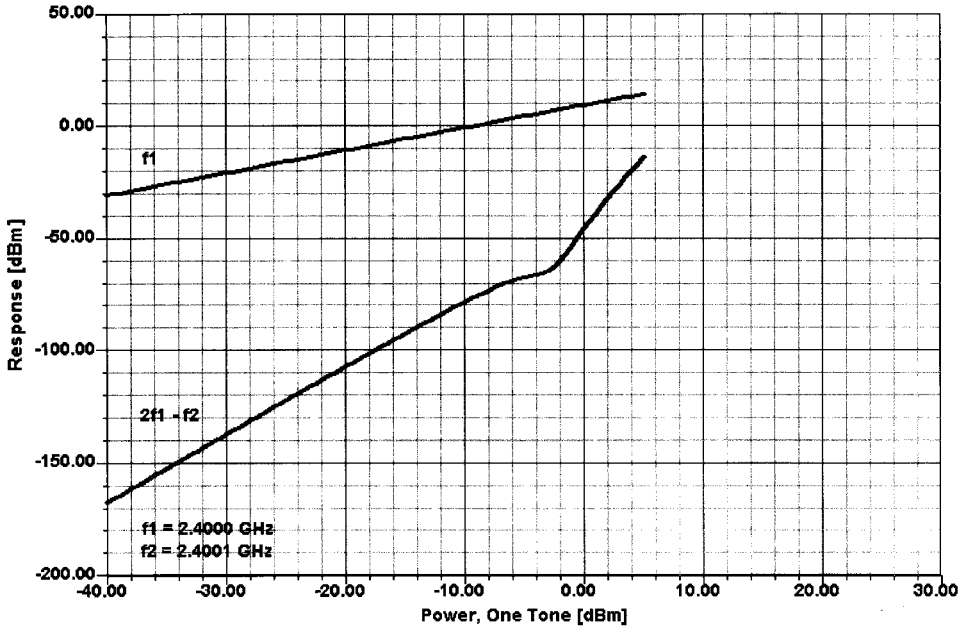

Figure 3-252 Predicted two-tone response of the BFP450 amplifier with the circuit adjusted for maximum gain (9.5 dB): $IP_{3,in} \approx 28.5$ dBm and $IP_{3,out} \approx 38$ dBm. That this version's gain is significantly lower than that of the *S*-parameter-based equivalent illustrates the need for better accuracy in parameter extraction.

examples for 432 and 1296 MHz, popular spot frequencies in the amateur 70- and 23-cm bands, respectively. Figures 3-253 and 3-254 show the 432-MHz version's schematic and frequency-dependent responses. Figures 3-255 and 3-256 show the schematic and frequency-dependent responses for the 1296-MHz version.

Using a bipolar transistor that operates at much less current, the noise figure can be improved at the expense of the dynamic range/intercept point. It is possible to reduce the noise figure by about 1 dB or so, but the reduction in intercept point will be much more dramatic. Another choice is the use of GaAsFETs for this application, but their matching in comparable circuits has been described as a nightmare simply because the devices have too much gain and very high input impedances (essentially 0.2 pF in series with 3 Ω) combined with reasonable output impedances in the vicinity of 240 Ω. Here is a wide field in which engineers can experiment and examine price/performance and performance/real estate issues. GaAsFETs also tend to require more than 30–40 mA to be alive, and even the low operating voltage of 4–5 V makes the device consume a lot of dc power.

3-12-4 Example 3: 1-W Amplifier Using the CLY15

The following is an application showing a fairly wideband amplifier with +30 dBm (1 W) output. We need to point out that in accordance with the various digital modulation modes used with this amplifier, this is not continuous operation, but a much less than 1:1 duty cycle operation. The device would probably not survive operating at full output under CW conditions. This is subject to a discussion with the manufacturer, Siemens, who has not

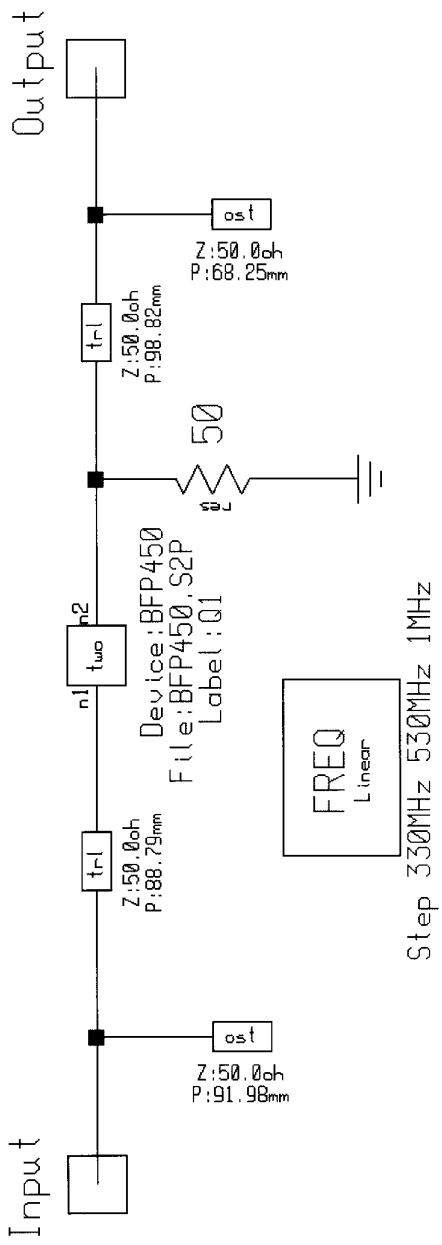

Figure 3-253 Schematic of BPF450 amplifier for 432 MHz. Because f_T = 25 GHz for the BFP450, at this lower frequency we must shunt the device output with a 50-Ω resistor to maintain stability.

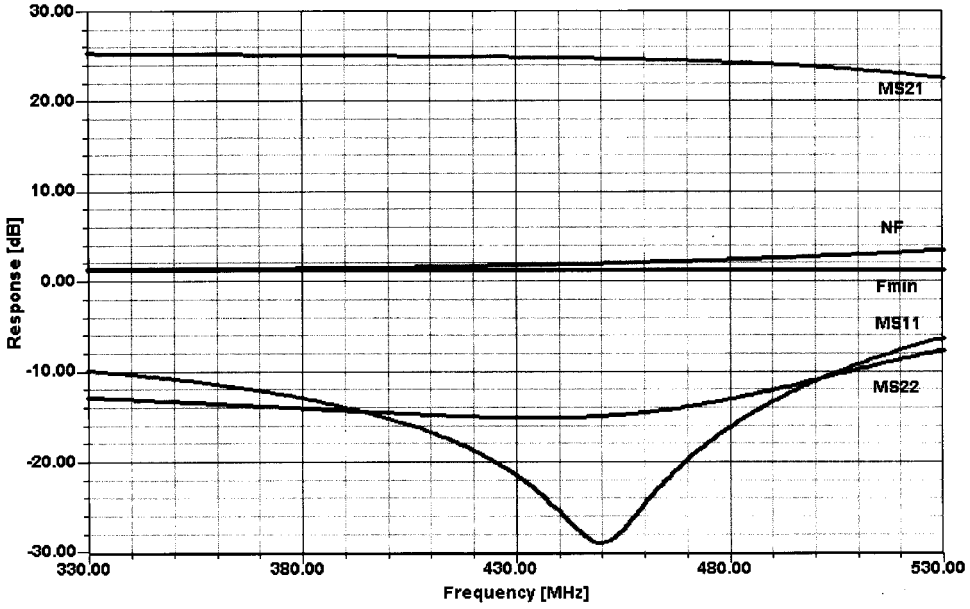

Figure 3-254 Frequency-dependent gain, matching, and noise performance for the BPF450 amplifier at 432 MHz. As with the circuit in Figure 3-253, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

released sufficient data for us to make a judgment as to the CLY15's continuous power capability. Since there is no useful large-signal model available at the time of this writing, we will design this Class A amplifier using large dc bias *S* parameters. In the actual design there will be some cut-and-try, but we find that in this type of application this is still the best way of handling the design.

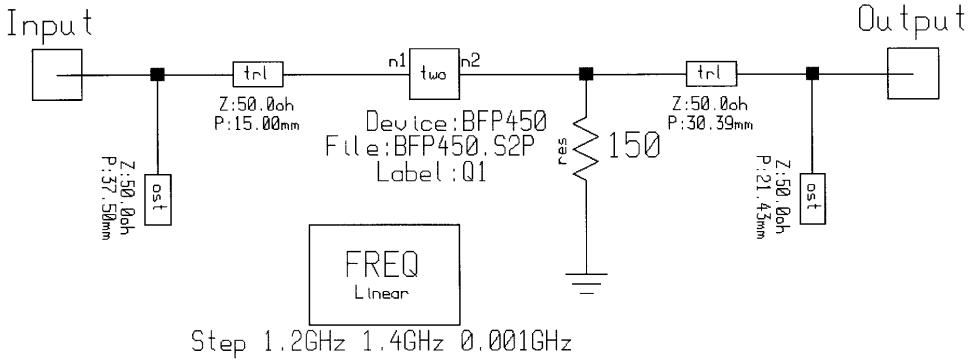

Figure 3-255 Schematic of the BPF450 amplifier for 1296 MHz. A loading resistor is still necessary to ensure stability, but because the transistor exhibits less gain at this frequency than at 432 MHz, we can increase the loading resistor to 150 Ω.

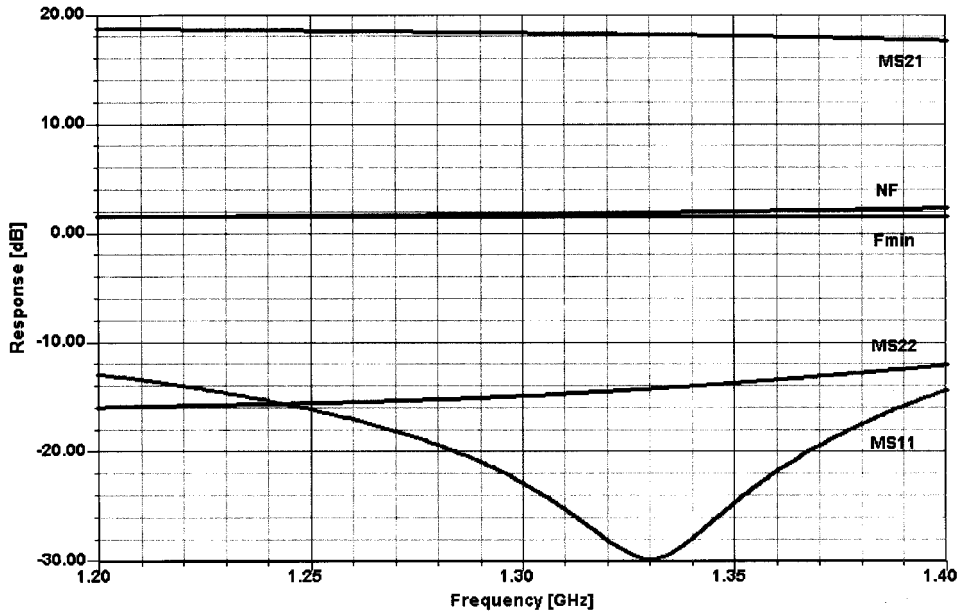

Figure 3-256 Frequency-dependent gain, matching, and noise responses of the BFP450 amplifier at 1296 MHz. As with the two previous versions, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

The CLY15 (gate width 16 mm) is the largest of a series of Siemens GaAsFETs; it was already mentioned in Chapter 2, where its datasheet is reproduced. Its device family also includes the CLY2 (gate width 2 mm), CLY5 (4 mm), and CLY10 (8 mm). It is possible that bigger devices will be offered in the future. One of the most critical parameters will be the saturation voltage; from the datasheet of the CLY15, we can see that at 1.5 A the saturation voltage is approximately 1 V. This drop of 1 V includes losses that result from other parasitic elements; the dc *I–V* curve (Figure 3-257a) indicates a saturation voltage of 0.75. Since we aim for 1-W output power, the resistive portion of the load will be $(5 - 1)^2 / (1 \times 2) = 8\ \Omega$. This assumes a supply voltage of 5 V.

The next step is to design the input and output matching network. Previewing the *S* parameters, it will be noticed that they are essentially inductive, which means that the input match, using lumped elements, will result in a combination of capacitors at both the input and the output. Figures 3-258 and 3-259 show the ways in which the input and output matches were done on the Smith diagram resulting in lumped matching elements. Inspecting the lumped input matching, we find the following. We start with S_{11}, which is in the lower part of the Smith diagram, and determine its conjugate match, S_{11}^*. We already pointed out that this device is inductive, which means that matching it from the conjugate point will require two capacitors. The first one is a series capacitor, as identified in the Smith diagram, and followed by a shunt capacitor to transform the impedance to 50 Ω. A close inspection of the Smith diagram shows that the resulting point is not quite on S_{11}; it is an iterative process to exactly find the crossover point, yet the input match of better than 20 dB is more than acceptable.

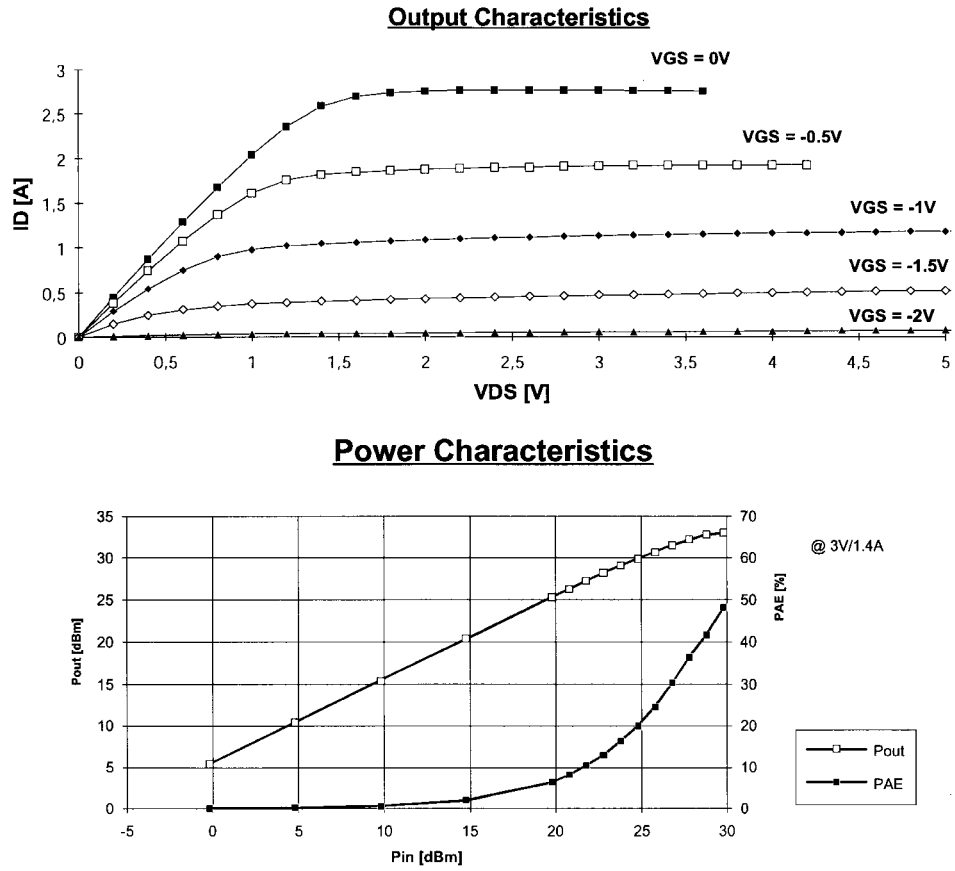

Figure 3-257 Output and power characteristics for the CLY15 medium-power GaAsFET.

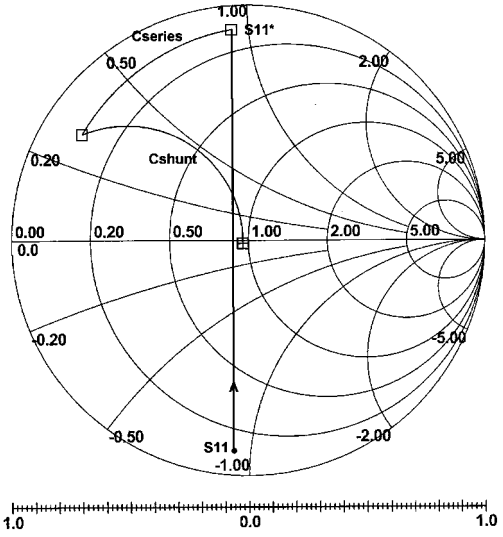

Figure 3-258 Input match for S_{11}^{*} using lumped elements.

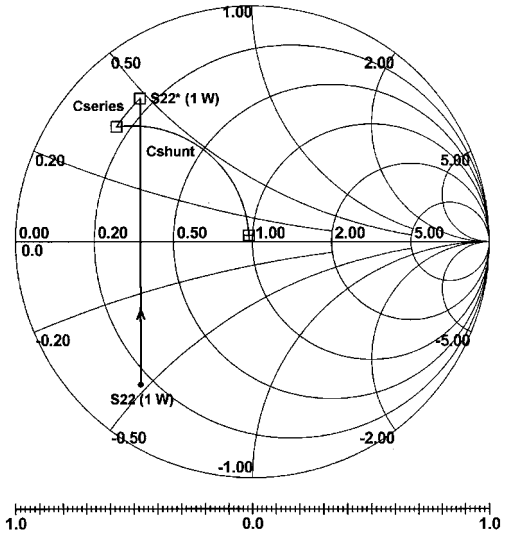

Figure 3-259 Output match for S_{22}^* (1 W) using ideal lumped elements.

As far as the output is concerned, we use the same technique by moving from S_{22} to S_{22}^*. S_{22} has been determined from the required output power; as we showed above, the real portion is 8 Ω. Using the lumped elements, the matching technique is identical; we first need to use a series capacitor and then a shunt capacitor for the transformation. The arc for the series capacitor this time is much longer, resulting in a series capacitance of 11.2 pF instead of the 2.1-pF capacitance used at the input. The actual schematic is shown Figure 3-260. The drawback of lumped elements is that it is not practical to buy components that can handle the heavy RF currents that flow in the input and output networks. Taking the values obtained

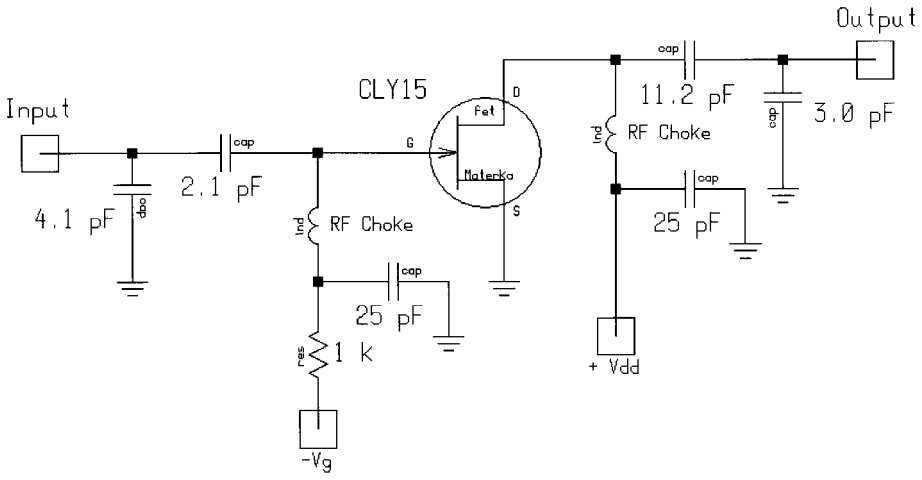

Figure 3-260 The complete amplifier using the CLY15 medium-power GaAsFET, with lumped-element input and output matching.

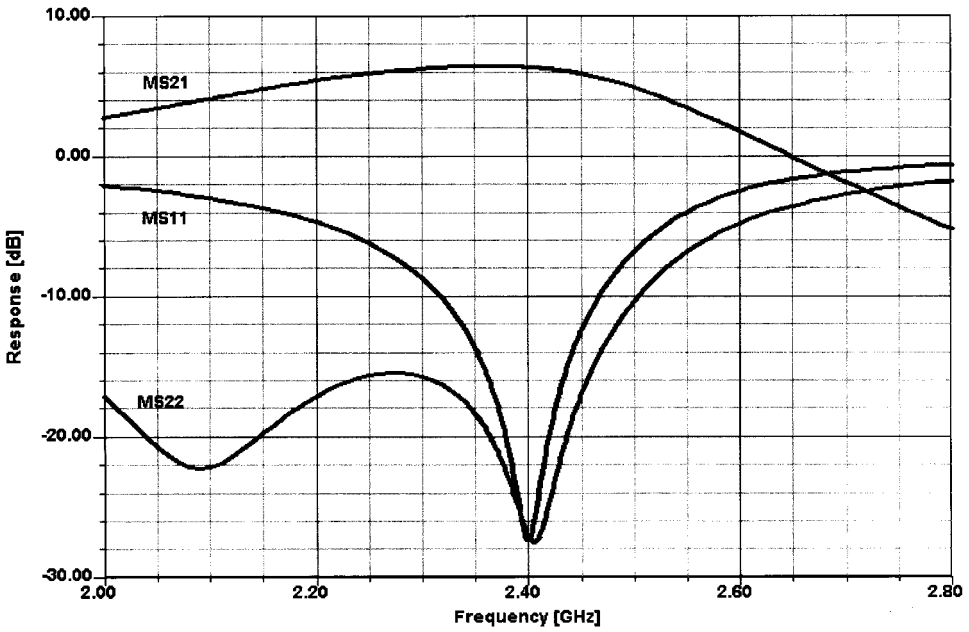

Figure 3-261 Frequency-dependent gain and matching responses of the CLY15 amplifier using ideal lumped elements.

from the lumped input and output matching approach, Figure 3-261 shows the resulting frequency response.

The next step is to provide the same matching condition using distributed elements, which of course have the advantage that they can be printed on the PC board. Instead of using ideal elements, we used a loss tangent of 2E–3, or a Q of 500. The manufacturer of the R4000 material (Rogers) provided this specification. Now we start with the same approach by moving from S_{11} to S_{11}^*. From there, we use an open stub with a transmission-line impedance of 50 Ω, followed by a transmission line to the point in the left lower corner, and, finally, a shorted transmission-line stub allows the 50-Ω matching. For this amplifier, we are not looking for noise matching but for input and output power matching. Figure 3-262 shows this match on the Smith Chart.

At the output, the procedure is again similar: We move from the S_{11} for 1 W to a conjugate value, then use an open stub that acts like a capacitor until we cross the real axis; finally, a λ/4 transmission line is used to match from approximately 75 Ω to 50 Ω. Figure 3-263 shows this match on the Smith Chart. This concludes the distributed matching design for the CLY15 amplifier.

Finally, the complete circuit using distributed elements is shown in Figure 3-264. From a dc point of view, we took advantage of the incoming shorted stub by using a transmission line of the appropriate length and a bypass capacitor to ground. This allows us to feed the gate with the required negative voltage without interfering with the frequency response of the amplifier. When evaluating the total frequency response (Figure 3-265), we noticed that this circuit seems to have a higher Q than the lumped equivalent. Again, to obtain a wider bandwidth more transformation stages will be needed. We leave this task to the interested reader.

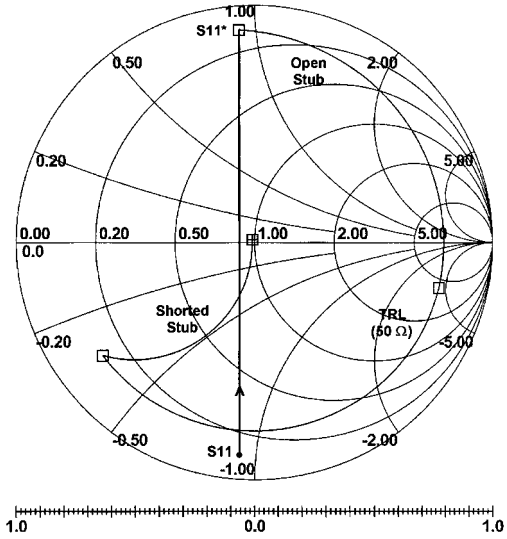

Figure 3-262 Input match for S_{11}^* (1 W) using distributed elements.

The 1-dB bandwidth of the amplifier using distributed, lossy elements is 120 MHz. If a wider bandwidth is required, matching networks with more elements are required. Because of the gain–bandwidth product, the peak gain for such a wider-bandwidth arrangement will be less than this narrowband example.

Having used a lumped to distributed transformation, we next present a power amplifier that uses coaxial lines, baluns, and other transformation steps capable of handling the increased power requirement.

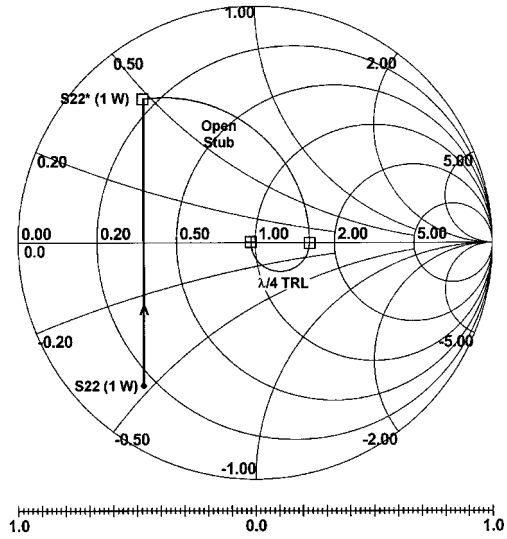

Figure 3-263 Output match for S_{22}^* (1 W) using distributed elements.

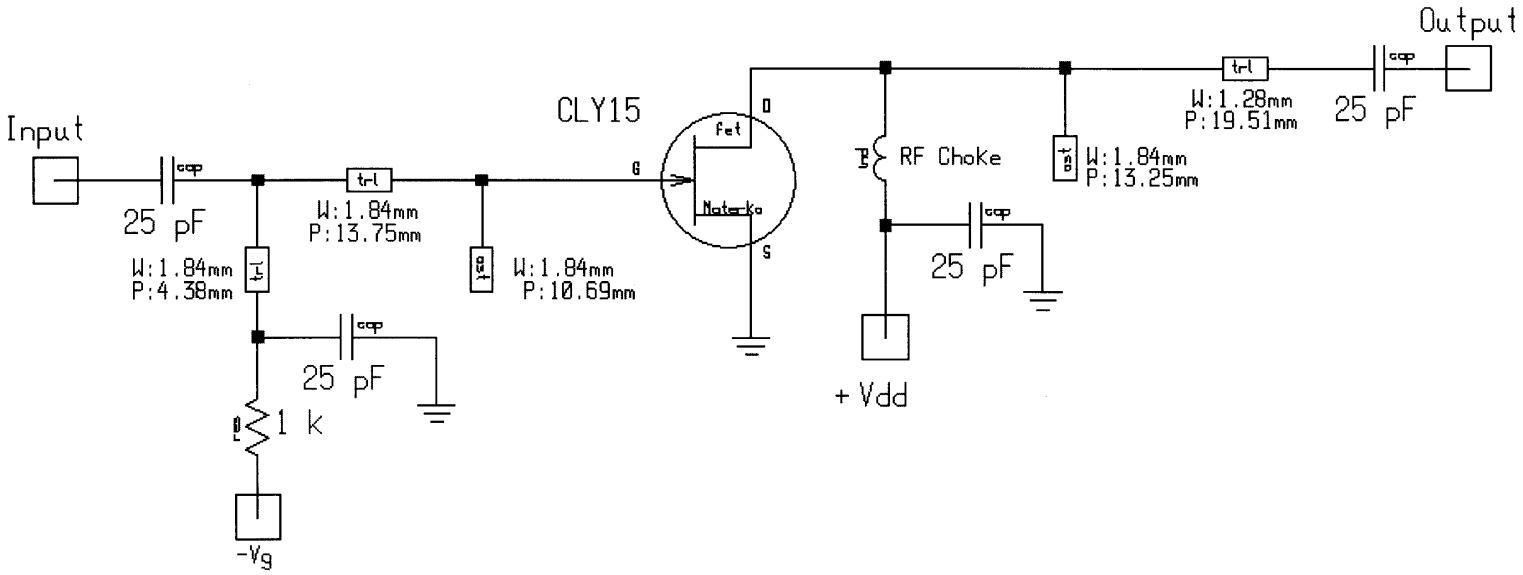

Figure 3-264 The complete amplifier using the CLY15 medium-power GaAsFET, with distributed-element input and output matching.

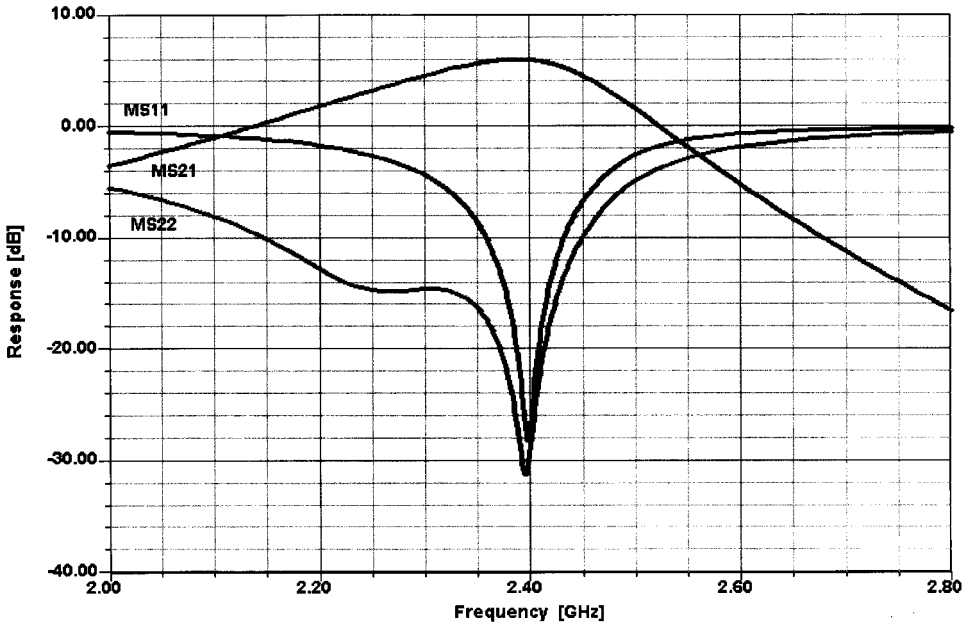

Figure 3-265 Frequency-dependent gain and matching using distributed, lossy elements.

3-12-5 Example 4: 90-W Push–Pull BJT Amplifier at 430 MHz

The last complete application we want to examine is a 90-W output, push–pull amplifier using two TRW transistors (that are no longer made—an all-too-frequent occurrence after a design is complete, resulting in a scramble for replacements). Figure 3-266 shows the circuit diagram of this UHF transistor amplifier, and Figure 3-267 shows its mechanical design. The amplifier requires 28 Vdc and will draw approximately 6 A, requiring 15 W of drive at 438 MHz. This amplifier operates in Class AB, which means it is not limited to amplifying FM and other angle-modulated signals, and can accommodate even single-sideband (SSB) operation.

The drive power coming from the source connected to the input N connector (15 W) is fed through a short piece of coaxial cable to the PC board sitting on top of the heat sink. To change from single ended to push–pull, a 50-Ω coaxial cable is coiled to provide sufficient electrical length to act as a balun that provides two symmetrical paths through the amplifier. The RC section of 10 Ω in parallel with a 220-pF capacitor stabilizes the amplifier at lower frequencies, while at higher frequencies the 10-Ω resistor has no contribution. There are two independent 4:1 transformers, one for each section; they are built using 25-Ω coaxial cable with a set of two binocular ferrite cores to force the transformation. The dc supply is also fed to the transistors at this point. The stabilization circuit consists of a temperature monitor using the *pn* junction of a transistor, side-mounted on the heat sink, and a combination of operational amplifiers and adjustments. This guarantees proper, temperature-independent biasing. The 4:1 input baluns result in 12.5 Ω impedance, or 3.125 Ω per transistor. Since the input impedance at this drive level is somewhere in the vicinity of $[(1 \ldots 2) + j(3 \ldots 5)]$ Ω; the final matching is accomplished by an *RC* section in which the inductance is actually printed

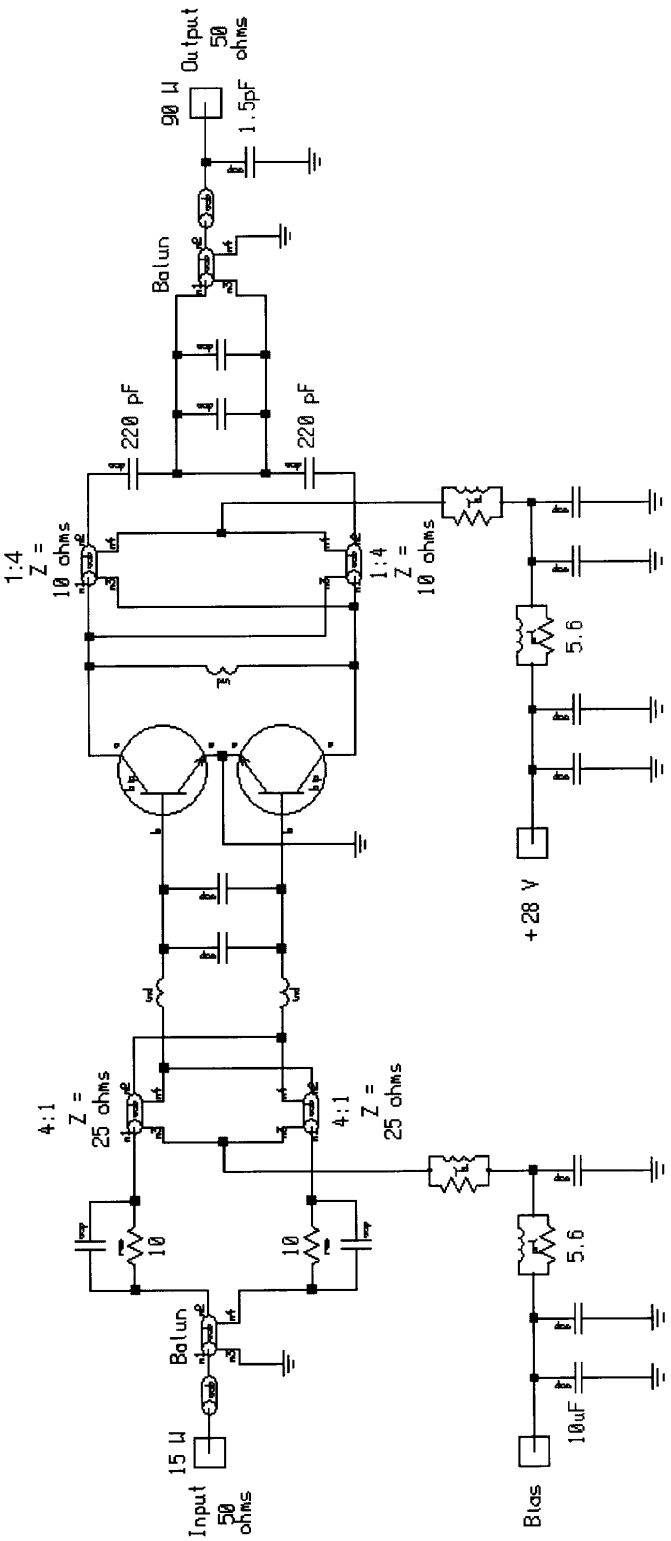

Figure 3-266 Circuit diagram of the 90-W, push–pull, 438-MHz linear amplifier.

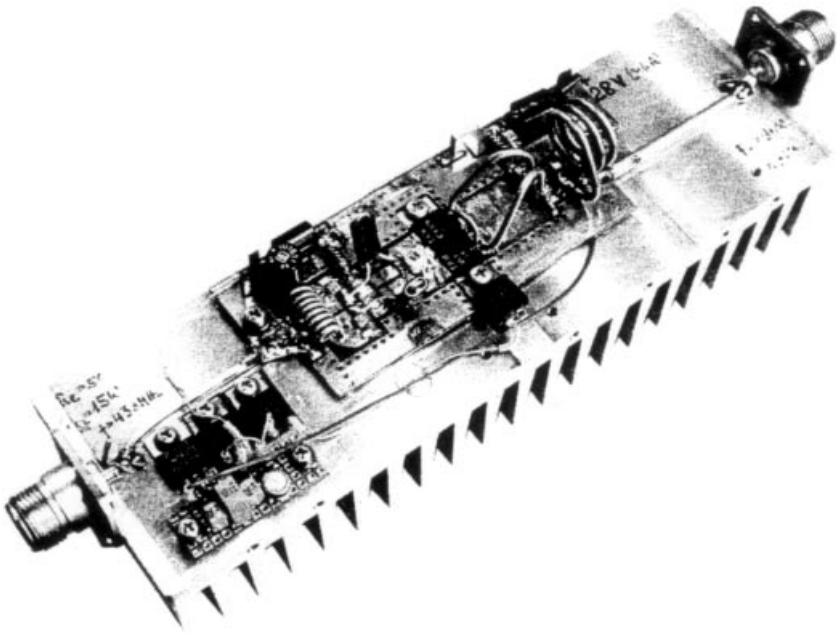

Figure 3-267 Mechanical assembly of the 90-W amplifier shown in Figure 3-266.

and the shunt capacitor across is soldered from base to base as close to the transistor bodies as possible. A ceramic-dielectric variable capacitor in parallel with this allows fine tuning.

The output consists of an inductor from collector to collector that tunes out the capacitive reactance and makes the transistor output impedance real. We then follow the same pattern by taking a 1:4 transformer, but this time built using 10-Ω rigid line instead of 25-Ω rigid line. Together with the output capacitance, prior to the output balun, this is a medium-bandwidth matching arrangement that transforms up to 50 Ω. The collector impedance per collector had to be $(28 - 2)^2/2 \times 90$, resulting in roughly 3.8 Ω—not that different from the input match at the balun point. This way, the matching networks at the input and output can be identical. At the output of the matching network, another coiled 50-Ω coaxial cable serves as balun; because it must operate at the 90-W level, larger-diameter line was used than in the input balun. Finally, another section of rigid line is used to connect the output balun on the PC board to the output N connector. The output capacitor again helps in the transformation.

Both the base and collector voltage supplies are heavily filtered using ferrite-bead-based RF chokes and heavy wire inductors wound on low-impedance resistors. A fairly large number of these amplifiers were actually built and are still in use.

3-12-6 Quasiparallel Transistors for Improved Linearity

Some applications require really low intermodulation distortion. One of the authors (Rohde), during his tenure at RCA Government Systems Division, and his team developed a parallel-device topology that is somewhat similar to the conventional parallel approach but shows vastly increased linearity. In creating higher-power devices, manufacturers parallel several transistors in one package, connecting them in a clever way so the overall drive, dissipation, and output power are equally divided between all the devices. Special nickel–chromium

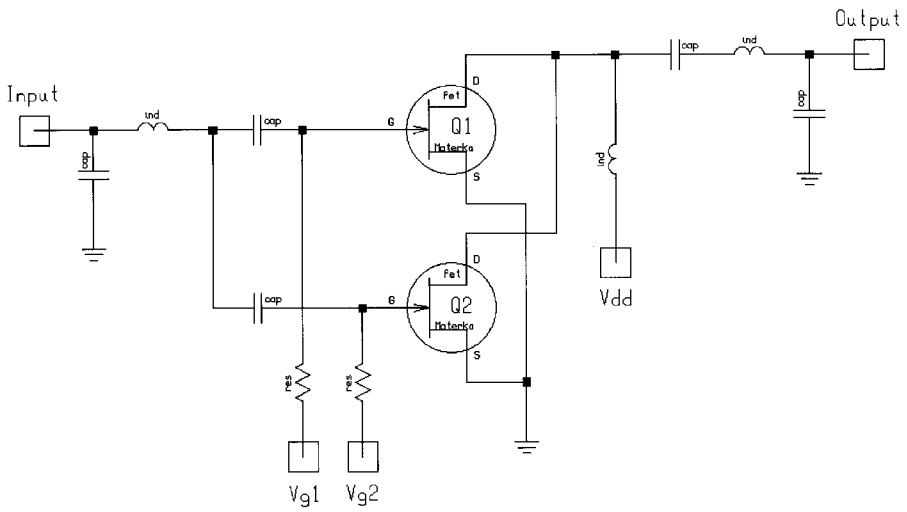

Figure 3-268 The quasiparallel amplifier topology looks like a standard parallel amplifier. Biasing the devices to different operating points nets an improvement in IMD performance.

ballasting resistors in the many fingers of the emitter connections of the multiple internal devices equalize any differences among the transistors while increasing the saturation voltage by only a small amount. In our high-linearity design, we used two transistors in parallel, one being biased somewhere between Class A and B, and the second one somewhere between Class B and C (Figure 3-268). The exact bias voltages and operating points had to be found through experiment. In practice, Q1, the "initially on" transistor, is driven to a point close to that at which its IMD products would increase. Q2 is biased such that at this same drive level it adds to the output power.

We frequently referred to this configuration as "turbocharged." The IMD products at full output power were down 40–45 dB, compared to 26–30 dB for a single transistor. While such an arrangement shows superior IMD performance, because of the somewhat abrupt kick-in of the second transistor, the transconductance response is semismooth, a characteristic that might make alert readers think that IMD will occur at this point. On the other hand, the transconductance for Q1, in effect, saturates or stays constant, so when the transconductance responses of both transistors are overlaid, the result is a smooth response overall.

This technique has been validated up to 100 W and up to at least 50 MHz. Its drawbacks include the need for two transistors with their associated costs, additional real estate, and higher input and output capacitances. Nonetheless, considering that MOS transistors capable of operation to 1 GHz were unavailable when this technique was developed, we believe that it should be revisited.

The Class D and higher operating modes require a large number of additional components and will make the efficiency higher (selective in frequency), but not necessarily reduce the IMD products. A further point of consideration is that it is incorrect to assume that reducing the input level to a given Class A will necessarily reduce its IMD products. As with tubes, the closer one gets to the knee, even in Class A operation, the worse the IMD. (This phenomenon was particularly troublesome in systems using 1-kW amplifiers up to 150 MHz;

underdrive with the intent of getting better IMD performance produced just the opposite result.) If a wide power range is considered, we recommend using a bias scheme that includes sufficient intelligence to find the best operating point.

Another hot amplifier issue is that of IMD as a function of load impedance. If an amplifier is used at output power considerably below its design value, its load impedance will be too low and, depending on the circuit configuration, the result may be additional IMD.

3-12-7 Distribution Amplifiers

It is not uncommon that a signal from a particular source like an antenna has to be distributed to several places. A condominium is a typical situation in which energy from a main signal source must be split for distribution to a larger number of users—there must be enough voltage or power to produce a noise-free picture. An amplifer capable of doing this is a *distribution* amplifier, not to be confused with a *distributed* (or traveling-wave) amplifier, such as that shown earlier in this chapter in Figure 3-6. An interesting means of achieving this is to use multiple Wilkinson couplers following an amplifier. Figure 3-269 shows an arrangement that makes heavy use of multiple power dividers to provide multiple outputs. Theoretically, the reverse is also possible: If we want to collect energy from a number of sources and combine them, as on a cable, we can use Wilkinson couplers at the *input* of a gain block. Note, however, that depending on the level and number of the combined signals, this may put enormous strain on the linearity of the amplifier. What we want to avoid is a lot of distortion, which, in the case of television, will show up as color confetti in the noise and signal.

3-12-8 Stability Analysis of a Power Amplifier

One of the hidden pitfalls in narrowband circuit design is that a circuit may be unstable outside the frequency range of interest. Circuits containing structures built from distributed elements, which exhibit multiple resonances, can be particularly susceptible to such instabilities. In this example, we analyze the stability of a simple FET power amplifier designed using small-signal concepts and the interactive Smith Tool utility in Ansoft's Serenade

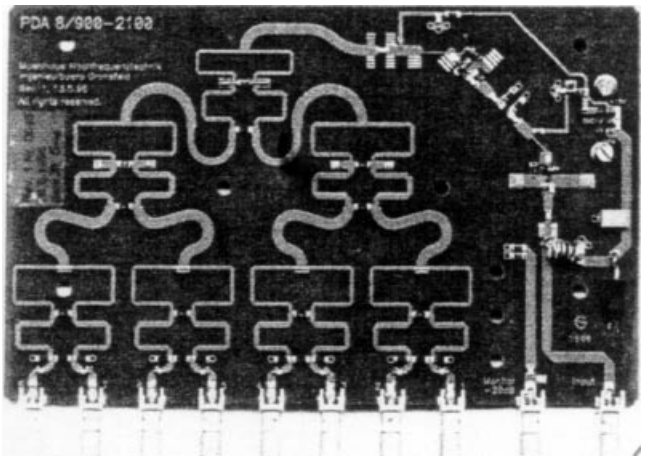

Figure 3-269 Distribution amplifier showing the use of multiple Wilkinson power dividers.

Design Environment. The evaluation shows how K-factor analysis alone is not sufficient to check for stability of a design.

Small-Signal ac Analysis. We begin by taking the Figure 3-270 amplifier, which was designed for about 16 dB of gain at 2.2 GHz. Due to the very low, capacitive input impedance of the FET and the proximity of the source-plane gain circles and stability circles to the edge of the Smith Chart, the matching network attempts to transform 50 Ω to an impedance of approximately $(2.5 + j15)$ Ω. The impedance lies close to the stability circles at 2 GHz but remains in a stable region. The bias point selected (–3.5 V) is chosen for Class AB operation. Higher linear gain can be achieved by reducing the gate voltage to –2.0 V; at this bias point, the amplifier gain will increase to about 19 dB.

First, we will do a small-signal ac analysis and examine the S parameters and K and B_1 factors [see Eqs. (3-154) and (3-157), respectively] from 1 GHz to 6 GHz—well beyond the bandwidth of the design. Figure 3-271 shows the circuit's frequency-dependent gain and matching characteristics.

If we examine B_1 and the stability factor K, we see that the amplifier is not unconditionally stable in the 2.2-GHz passband as shown in Figure 3-272. K dips slightly below 1, although B_1 remains above zero. In practice, a slight change in design would be required to bring K above 1 and remove this potential instability. However, for our example, this is of no consequence, as we shall see below.

Nyquist Stability Analysis. Now we will utilize a Nyquist stability analysis to check the stability of the amplifier. To fully realize the advantages of a Nyquist stability analysis, we must sweep frequency over a very wide range. We want to be able to pick up instabilities at *any* frequency, not just near the design frequency. In this example we sweep from 1 kHz to 20 GHz. A start frequency of 1 kHz is chosen so we can determine the starting point of the Nyquist plot and we ensure that any low-frequency resonances are picked up. The stop frequency is chosen past the f_{max} of the transistor (where we know it cannot oscillate).

The analysis results are shown in polar plot form in Figure 3-273 and in magnitude–angle form in Figure 3-274. The polar graph shows the real and imaginary parts of the system determinant as frequency is swept. The magnitude–angle graph shows the magnitude and cumulative angle (no cut at ±180°) of the system determinant as frequency is swept. The key to interpreting these graphs lies in the following statement drawn from the Nyquist criterion:

The circuit will be unstable if the Nyquist plot encircles the origin in a clockwise direction.

The term "unstable" refers to the existence of natural frequencies lying in the right-half of the complex frequency plane (RHP). These natural frequencies on the RHP will cause oscillations. To encircle the origin in a clockwise direction means that the Nyquist plot will travel in a clockwise path, cross the negative real axis, and continue to completely surround the origin. If the path appears to encircle the origin but then "unravels" itself in a counter-clockwise direction, the origin is not actually encircled. Figure 3-273 shows that the origin is not encircled and therefore this circuit is stable.

The magnitude–angle plot can assist in determining if a clockwise encirclement has actually been made with the help of the following:

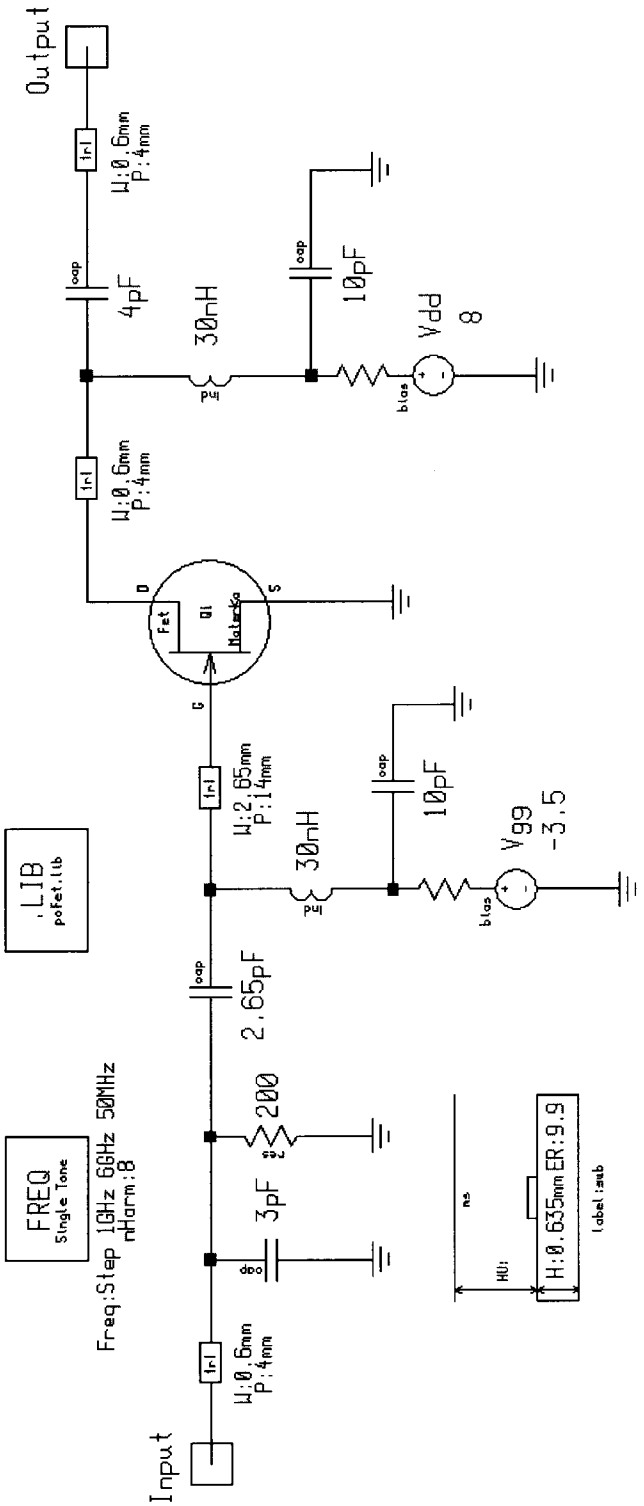

Figure 3-270 A 2.2-GHz amplifier design for stability analysis.

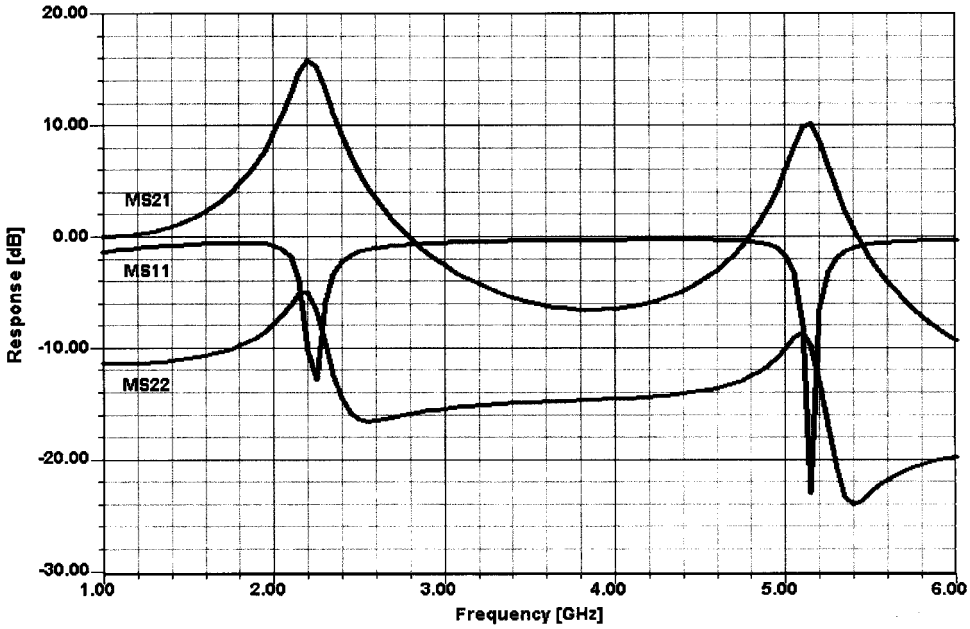

Figure 3-271 Frequency-dependent gain and matching characteristics of the amplifier. Although the circuit is designed for 2.2-GHz operation, the periodic responses of its distributed-element-based input and output matching networks result in a second gain peak near 5.1 GHz. As we shall see, however, instabilities may result at frequencies that cannot be intuited from this graph.

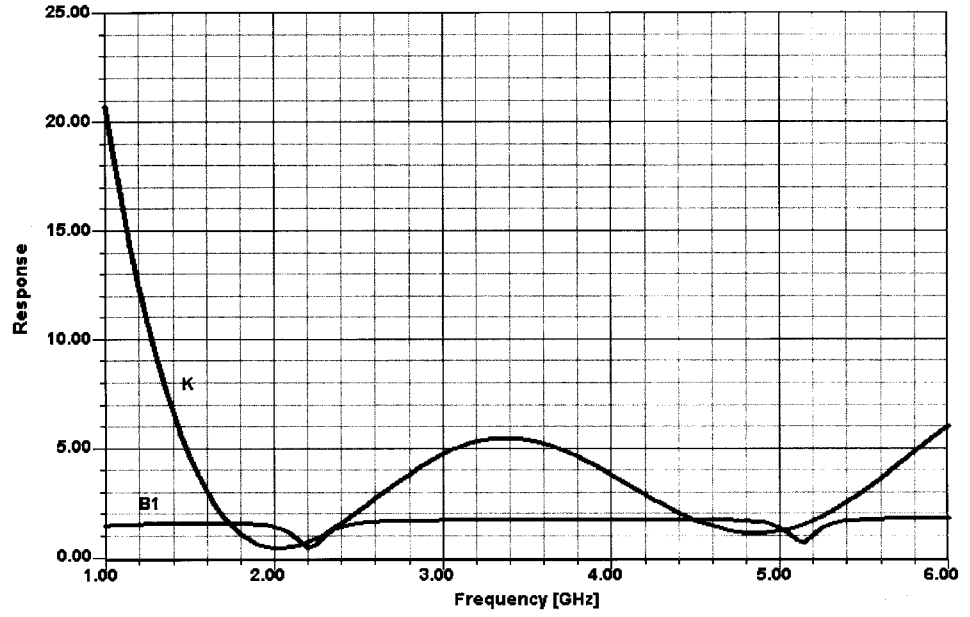

Figure 3-272 K and B_1 for the 2.2-GHz amplifier.

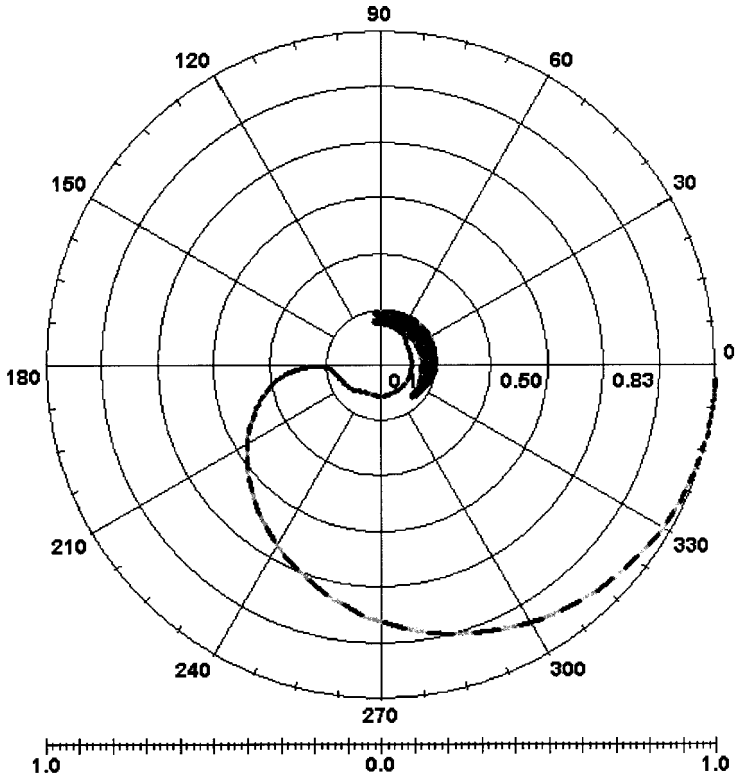

Figure 3-273 Polar Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

- To travel in a clockwise direction on a polar chart means to decrease phase angle. On a magnitude–angle plot, the phase will become more negative as frequency is increased (although it may not be monotonic).
- If the path crosses the negative real axis on the polar chart, it will cross –180° on the magnitude–angle plot.
- Encirclement will occur if the phase angle continues to decrease to, say, –360°. If "unraveling" occurs, the phase angle will not stay below –360°. Figure 3-274 clearly shows that the phase angle decreases to about –180° but does not decrease any more. Rather, the angle returns to a positive value and oscillates between about –40° and +100°. Therefore an encirclement did not occur, and the circuit is stable.

An Unstable Case. Let us now change the gate bias to –2 V—a value that increases the amplifier gain enough to cause instability. Figures 3-275 and 3-276 show the results. From Figure 3-275 we can see that the origin is encircled in a clockwise direction. Figure 3-276 confirms this since the phase angle goes through –180° and continues without unraveling.

Approximate Frequency of Oscillation. The frequency where the Nyquist plot crosses –180° is often the approximate frequency of the unstable right-half-plane zeros and provides an estimate of the potential oscillation. For this example, there is a sharp crossing at 200 MHz that is characteristic of a circuit resonance. Note that the frequency is not related

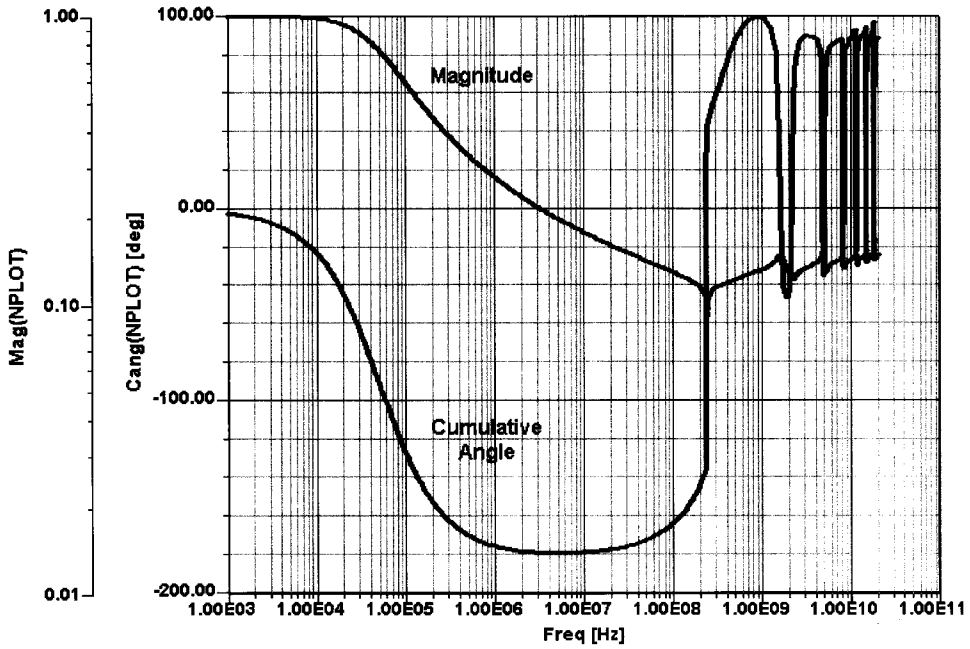

Figure 3-274 Magnitude and cumulative angle Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

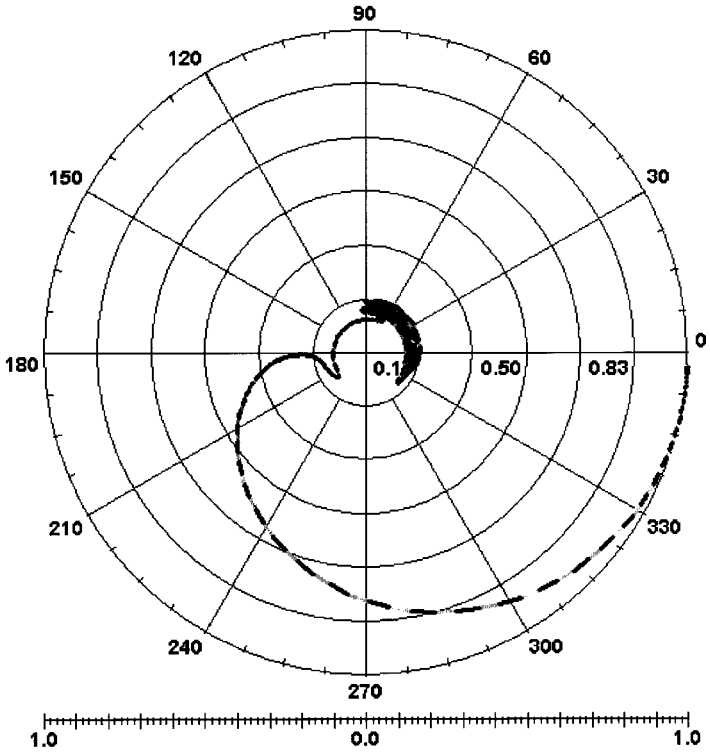

Figure 3-275 Polar Nyquist plot of the unstable amplifier.

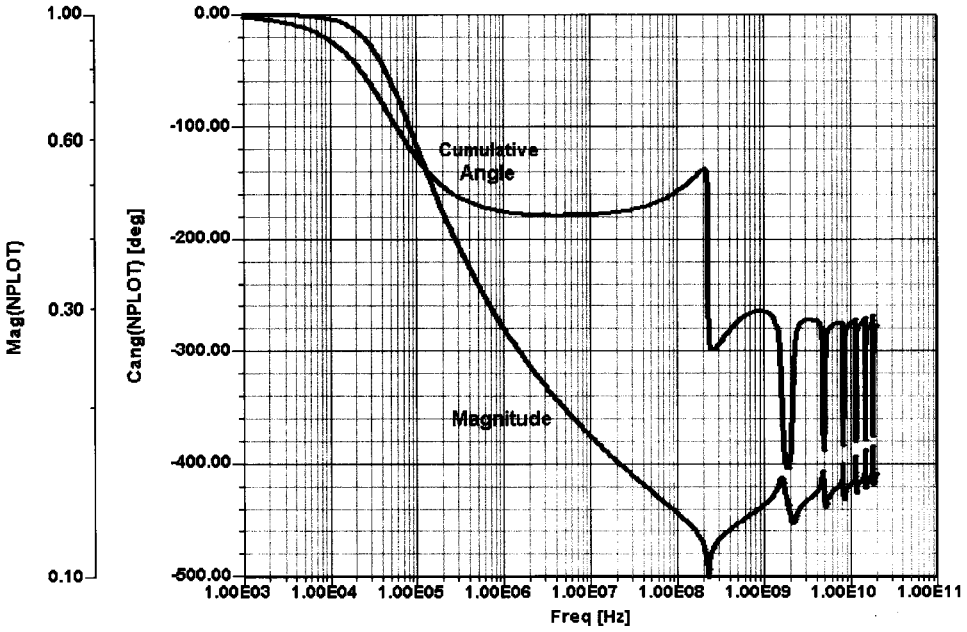

Figure 3-276 Magnitude–cumulative angle Nyquist plot of the unstable amplifier.

to a resonant frequency in a rigorous mathematical fashion, but it has been our experience that this frequency approximates the resonant frequency. To confirm the circuit's readiness for oscillation in the vicinity of this frequency, we evaluate it with Serenade's Oscillator Design Aid from 10 MHz to 1 GHz. The Design Aid finds an initial resonant frequency near 230.6 MHz—not too far from the –180° crossing frequency of 200 MHz of the Nyquist plot. Figure 3-277 shows this point.

Oscillator analysis finds a final oscillation frequency of 228.48 MHz. Figure 3-278 shows the resulting output spectrum at Port 2. At this point we decided to do a quick jump into Chapter 5 and take advantage of the CAD capability to predict the resulting phase noise, which is shown in Figure 3-279. As we compare this with other measured results, the approximately 228-MHz oscillator has a poor phase noise since the same phase noise is achievable at 1 GHz and higher. We remind the reader that this is an unwanted effect, but all of us who have built amplifiers will have experienced either low-frequency oscillations (motorboating) or very-high-frequency oscillation, sometimes caused by the components in the immediate vicinity of the transistor itself and found somewhere above 3 GHz. This case is really a demonstration case; a closer look reveals that the transconductance required for this condition is unrealistically high; but nonetheless it is a good example to demonstrate the stability issue.

Where Does Oscillation Begin? An interesting question to solve now is, "What gate bias voltage is needed for oscillation to begin?" Ansoft's Serenade Design Environment includes oscillator synchronous stability analysis, which uses a modification of the harmonic-balance technique to determine critical points, such as the voltage needed to "turn on" an oscillator. Mathematically, this is called a *Hopf bifurcation* because the behavior of

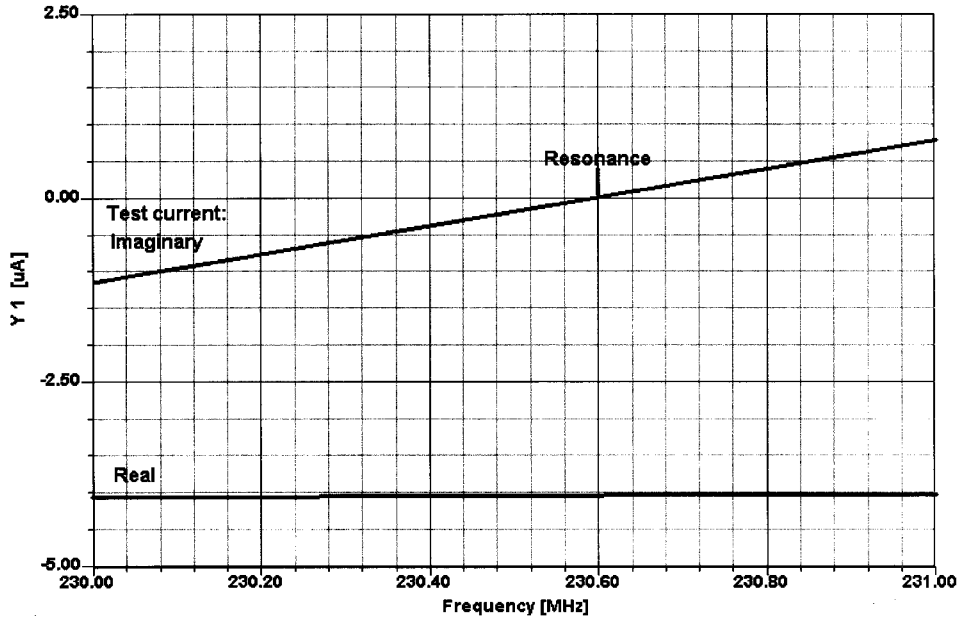

Figure 3-277 Graph from Serenade Oscillator Design Aid analysis of the amplifier. A resonant frequency is indicated where the imaginary part of the test current equals zero and the real part is negative.

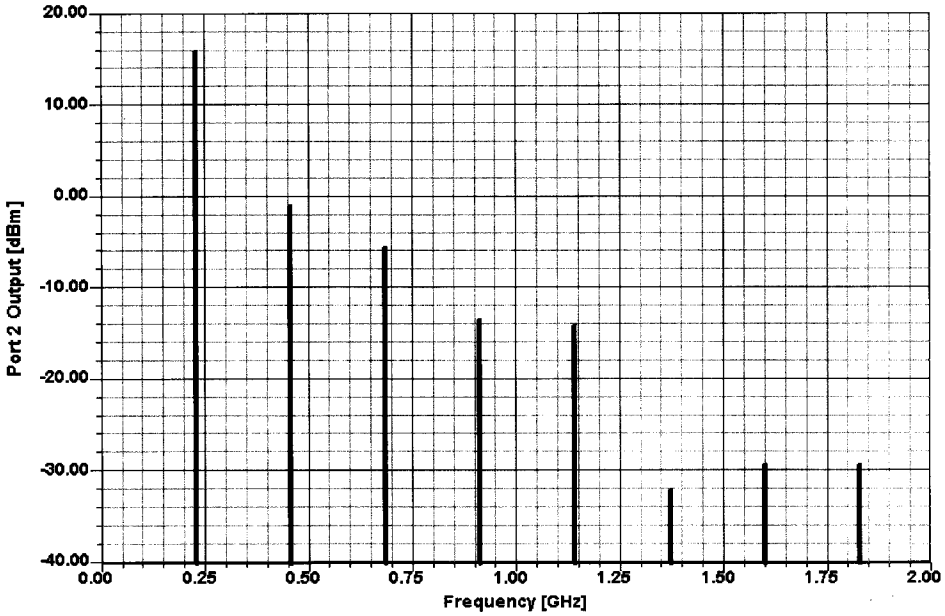

Figure 3-278 Predicted output spectrum of the unintended oscillator.

the circuit changes dramatically from a dc steady state to an oscillatory response. Figure 3-280 shows this effect by plotting output power versus gate bias. The turning point at –3.2 V (22 mW) is clearly visible, as is the bifurcation at –3.1 V (0 mW output).

Figure 3-280 can be interpreted as follows:

1. If the bias voltage is increased from, say, –4.0 V, the circuit will begin to oscillate at the bifurcation voltage and the output power will jump to 26 mW.
2. If the circuit is oscillating and the voltage is decreased from –2.0 V, the circuit will cease oscillating at the turning voltage of –3.2 V.
3. The branch between the turning point and the bifurcation point is unstable and cannot be realized in practice. This forms a hysteresis loop around points (–3.1 V, 0 mW), (–3.1 V, 26 mW), (–3.2 V, 22 mW), and (–3.2 V, 0 mW).

This amplifier stability analysis section is based on the stability analysis examples provided by Ansoft for the Serenade Design Environment.

An interesting example that combines both CAD and the feed-forward amplifier technique can be found in the Serenade Design Environment system simulator examples manual. This technique has been under evaluation for the last two years, but our feeling is that not enough measured data at frequencies above 500 MHz with reliable performance information have yet been made available in the literature. Along these lines, work done at Ansoft under a U.S. Air Force contract has provided very good insight into high-efficiency amplifiers at microwave frequencies [46].

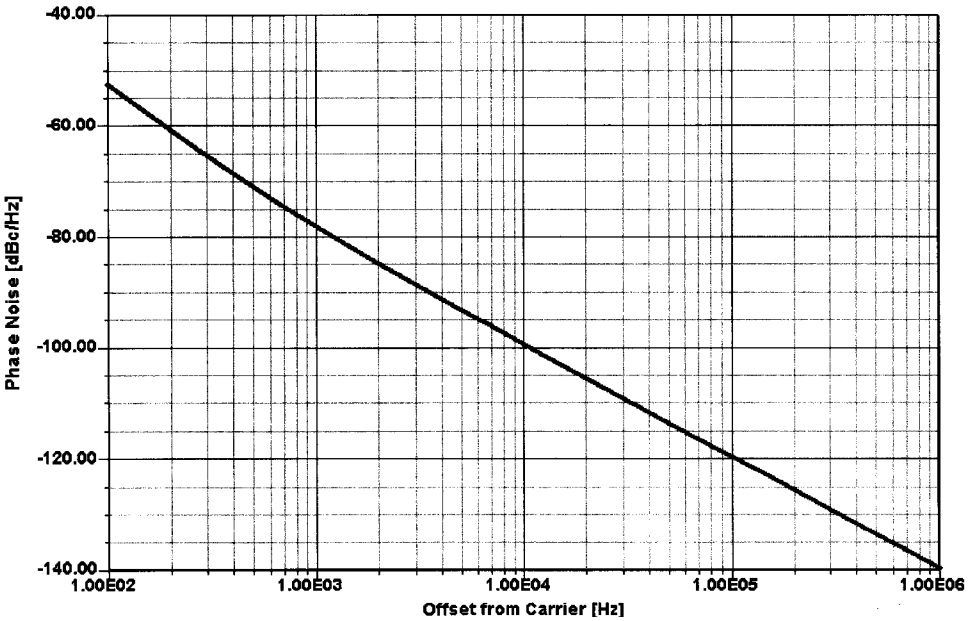

Figure 3-279 Predicted phase noise of the oscillating amplifier.

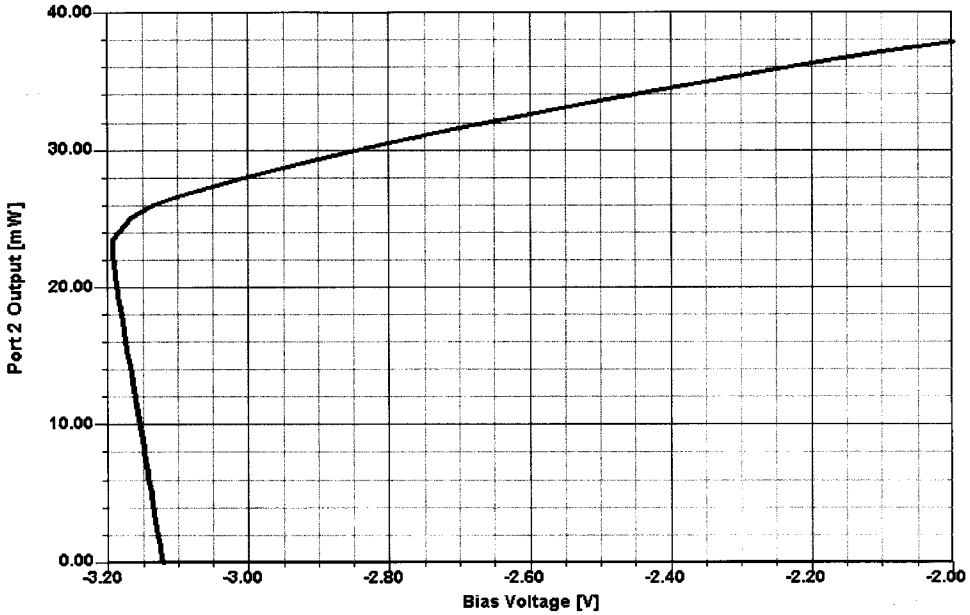

Figure 3-280 Output power versus gate bias for the unstable amplifier.

3-13 POWER AMPLIFIER DATASHEETS AND MANUFACTURER-RECOMMENDED APPLICATIONS

Having discussed the various aspects of BJTs and FETs, we have decided to use MOS examples from Ericsson and Motorola, and a bipolar example from Motorola, as good examples to show the technology required to build high-power transistor amplifiers in this frequency range. In the following pages, we reproduce, with permission, datasheets for Ericsson's PTF 10009 FET and Motorola's MRF186 FET, followed by Motorola's MRF899 BJT.

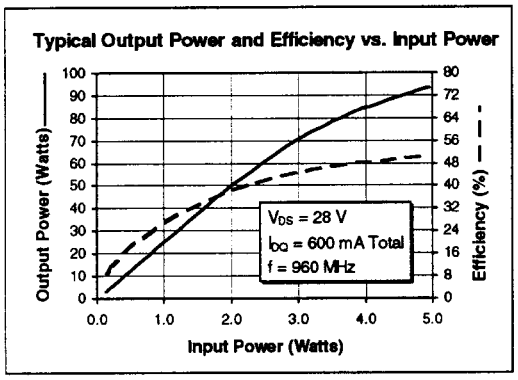
ERICSSON

PTF 10009
85 Watts, 1.0 GHz
LDMOS Field Effect Transistor

Description

The 10009 is a common source N-channel enhancement-mode lateral MOSFET intended for large signal amplifier applications to 1.0 GHz. It is rated at 85 watts minimum output power. Nitride surface passivation and gold metallization are used to ensure excellent device lifetime and reliability. 100% lot traceability is standard.

- Performance at 960 MHz, 28 Volts
  - Output Power = 85 Watts
  - Power Gain = 13.0 dB Typ
  - Efficiency = 50% Typ
- Gold Metallized
- Silicon Nitride Passivated
- Excellent Thermal Stability



Package 20230
