TYPICAL CHARACTERISTICS

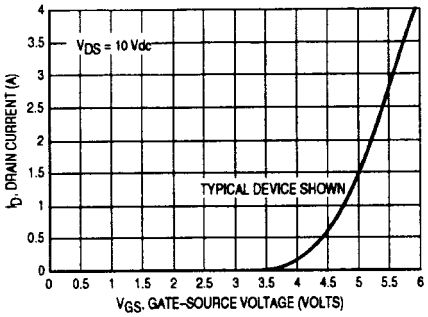

Figure 8. Drain Current versus Gate Voltage

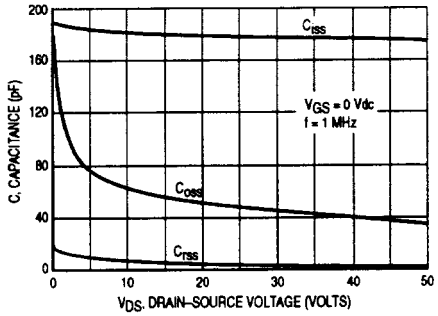

Figure 9. Capacitance versus Voltage

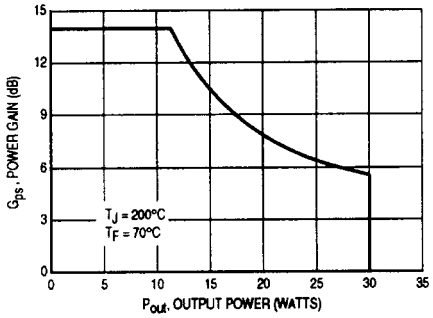

Figure 10. DC Safe Operating Area

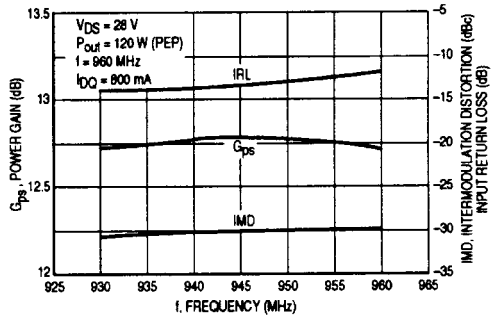

Figure 11. Broadband Circuit Performance

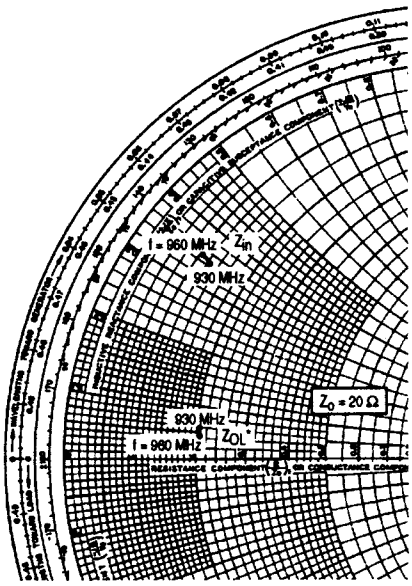

V_{CC} = 28 V, I_{DQ} = 2 × 400 mA, P_{out} = 120 Watts (PEP)

f MHz	Z_{in} Ω	Z_{OL}^* Ω
930	2.5 + j6.9	4.3 + j1.2
945	2.5 + j7.0	4.3 + j1.0
960	2.2 + j7.1	4.3 + j0.9

Z_{in} = Conjugate of impedance.

Z_{OL}^* = Conjugate of the optimum load impedance at a given output power, voltage, IMD, bias current, efficiency and frequency.

Note: Z_{OL}^* was chosen based on tradeoffs between gain, output power, drain efficiency and intermodulation performance. Impedances shown represent a single channel (1/2 of MRF186) impedance measurement.

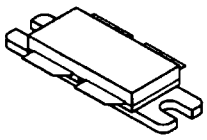
The RF Line
NPN Silicon RF Power Transistor

MRF899

150 W, 900 MHz
RF POWER
TRANSISTOR
NPN SILICON

Designed for 26 Volt UHF large–signal, common emitter, Class AB linear amplifier applications in industrial and commercial FM/AM equipment operating in the range 800–960 MHz.

- Specified 26 Volt, 900 MHz Characteristics
  Output Power = 150 Watts (PEP)
  Minimum Gain = 8.0 dB @ 900 MHz, Class AB
  Minimum Efficiency = 35% @ 900 MHz, 150 Watts (PEP)
  Maximum Intermodulation Distortion –28 dBc @ 150 Watts (PEP)
- Characterized with Series Equivalent Large–Signal Parameters from 800 to 960 MHz
- Silicon Nitride Passivated
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 26 Vdc, and Rated Output Power
- Gold Metallized, Emitter Ballasted for Long Life and Resistance to Metal Migration
- Circuit board photomaster available upon request by contacting RF Tactical Marketing in Phoenix, AZ.



CASE 375A–01, STYLE 1

MAXIMUM RATINGS

Rating	Symbol	Value	Unit
Collector–Emitter Voltage	V_{CEO}	28	Vdc

AMPLIFIER DESIGN WITH BJTs AND FETs

3-1 PROPERTIES OF AMPLIFIERS

3-1-1 Introduction

The goal of this chapter is to move from the details on the semiconductor devices themselves to our first practical application. One of the more interesting features of amplifiers is that they can easily become what will be covered in Chapter 5: *oscillators*. This is due to the high gain of the devices, unaccounted for parasitic elements, and other design flaws. The amplifiers we need will fall into three categories:

- Low-noise amplifiers
- High-gain amplifiers
- Medium- to high-power amplifiers

See Figure 3-1. The low-noise amplifier always operates in Class A, typically at 15–20% of its maximum useful current. The high-gain amplifier can operate in Class A, as well as Class B (mostly push–pull). The higher dc current for the same device results in a higher noise figure and more gain, and ultimately more output power. Class C operating mode is really reserved for either FM transmissions or constant-carrier modes like CW. Some of the modern digital modulation types are sensitive to phase distortion rather than amplitude changes and because of the resulting output spectrum designers have stayed away from Class C operation.

Some of these amplifiers, such as bipolar versions, can be dc-coupled with very few difficulties; others, like those in the FET families, will cause more headaches. An interesting example, although much too high in frequency for the purpose of this book, is shown in Figures 3-2, 3-3, 3-4, and 3-5. It shows a three-stage amplifier that has noise feedback for the first two stages and resistive feedback for the output stage. These are the three types of amplifiers, regardless of technology, we will be evaluating. The achievement of accurate noise analysis of this circuit, reported in Rohde et al. [1], marked the first time a complete

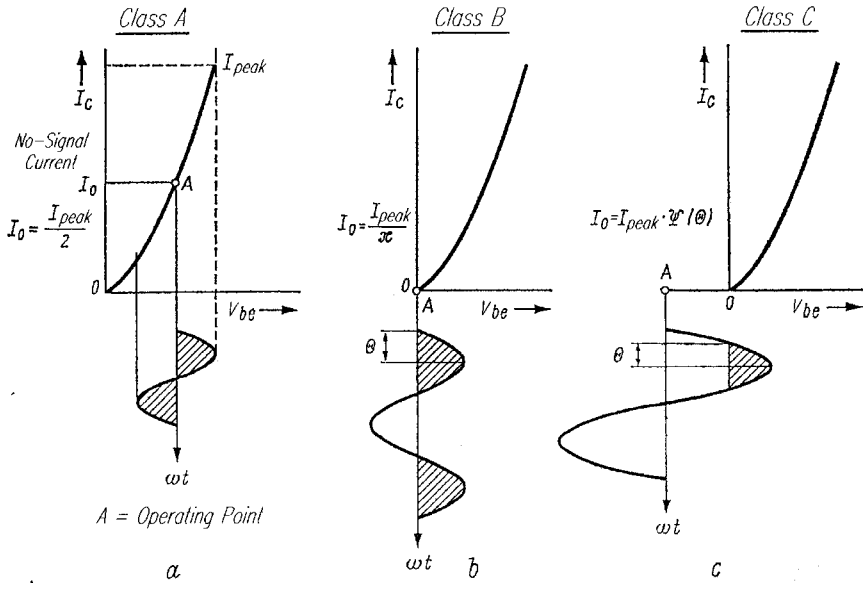

Figure 3-1 Definition of Class A, B, and C operation and resulting bias, including conduction angle (Θ, to be discussed in Section 3-2-2). The transfer characteristic can be either quadratic or exponential. This results in different distortion but does not change the basic operating mode.

linear noise model with essentially no frequency limitation had been developed. Its accuracy depends solely on the accuracy of the element values of the linear equivalent circuit, which can be obtained from measured *S*-parameters by an optimization process. Needless to say, this technique is also applicable at lower frequencies, such as 1.5–3 GHz, and its deviation from measured values has never been worse than 0.2 dB or, relative to the noise figure, 10% expressed in dB.

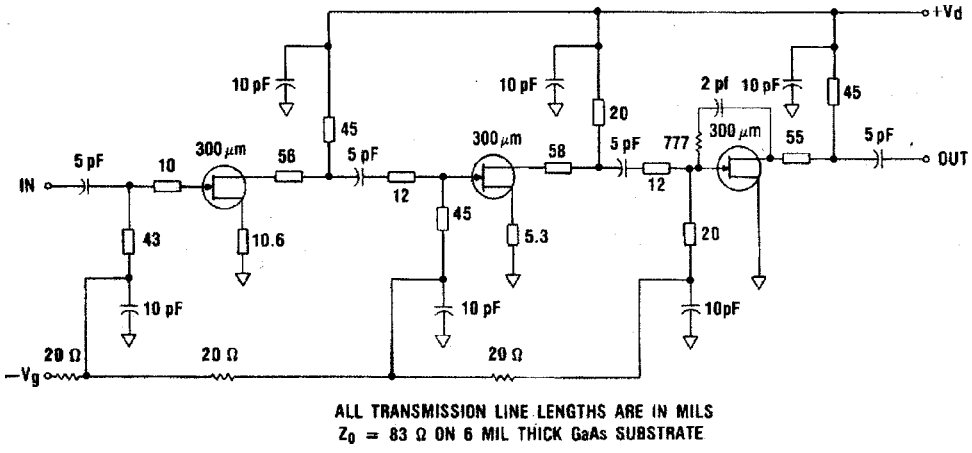

Figure 3-2 Schematic of the X-band GaAs monolithic low-noise amplifier (Texas Instruments EG8021). For reasons of linearity, all three stages operate in Class A.

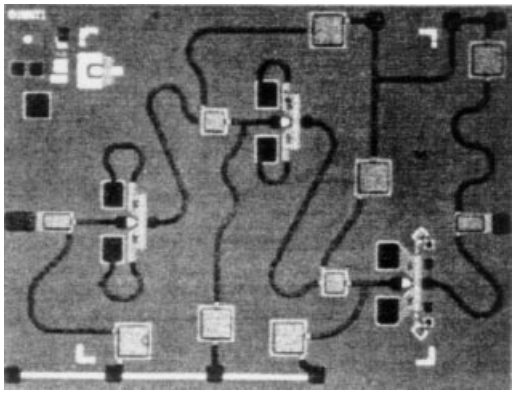

Figure 3-3 Photograph of the EG8021 monolithic amplifier chip. The area pictured is 0.09 inch by 0.12 inch in size.

The results of Figure 3-4 were obtained by using the linear FET model as supplied by Texas Instruments. It becomes somewhat obvious that a match for S_{11} of –60 dB is not likely. We then replaced the linear transistor with the SPICE-type nonlinear model, resulting in the responses shown in Figure 3-5. S_{11} now looks much more realistic in the center of the range, but at the same time exhibits a tendency toward instability at frequencies around 8 GHz. The actual circuit, when measured, did not exhibit this potential instability; on the other hand,

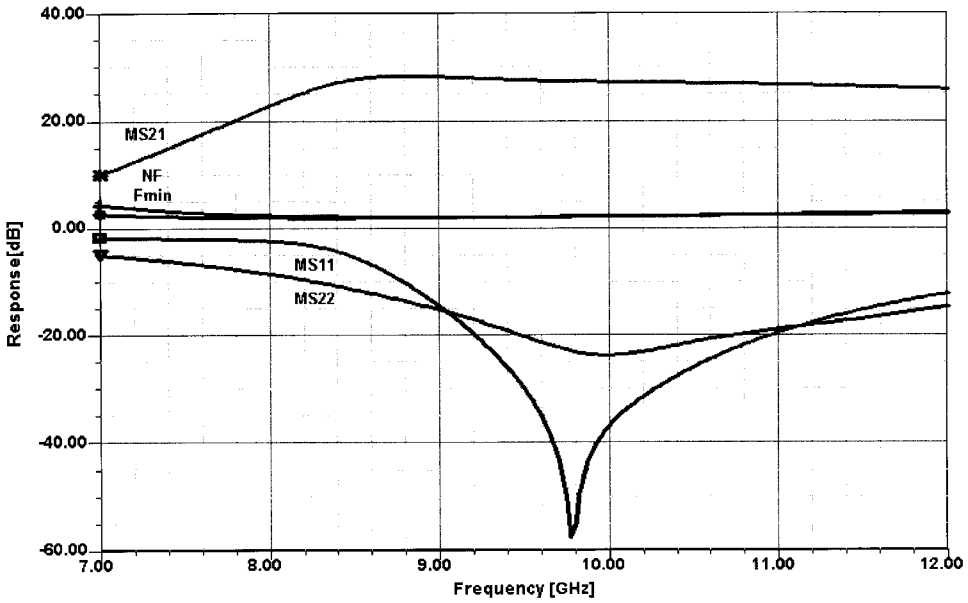

Figure 3-4 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the TI linear FET model. The values at 10 GHz are: F_{min}, 2.20 dB; NF, 2.21 dB; S_{11}, –36.8 dB; S_{21}, 27.2 dB; and S_{22}, –23.7 dB.

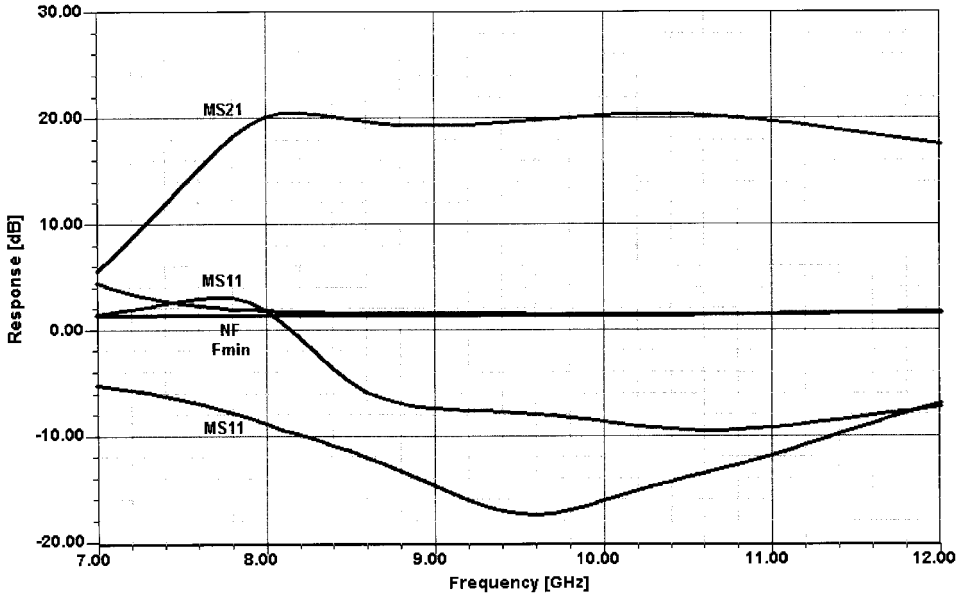

Figure 3-5 Simulated F_{min}, noise figure, S_{11}, S_{21}, and S_{22} responses for the three-stage GaAsFET amplifier using the nonlinear FET model. The values at 10 GHz are: F_{min}, 1.53 dB; NF, 1.65 dB; S_{11}, –8.5 dB; S_{21}, 20.3 dB; and S_{22}, –15.9 dB.

the noise figure and gain agreed quite well. The discrepancies between the results with the linear and nonlinear models emphasize the importance of accurate device modeling.

Figure 3-6 shows a wideband amplifier, specifically a distributed amplifier, that covers 1–20 GHz. Figure 3-7 shows its simulated frequency-dependent gain, matching, and noise performance. The example given here as the upper frequency for wireless systems is rapidly expanding and the technology to accommodate this is already in place. Modern CAD tools can handle such high frequencies accurately, which means one can trust them at the significantly lower wireless frequencies of 500 MHz to 3 GHz. Above 1500 MHz, one really should model using distributed elements. We will come to this later in this chapter.

Input/output and interstage matching will become another challenging task, specifically if one requires sufficient bandwidth. As circuits become more complex and as the operating frequency increases, passive components play an increasingly important role; the use of

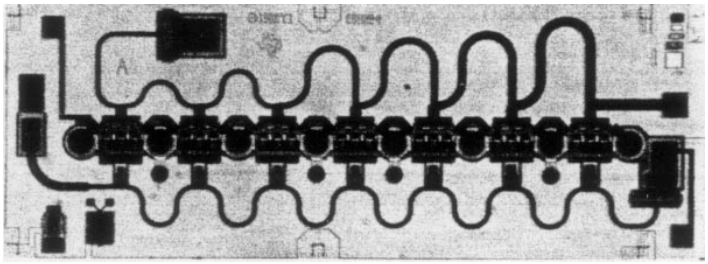

Figure 3-6 Photo of the 1–20-GHz distributed amplifier.

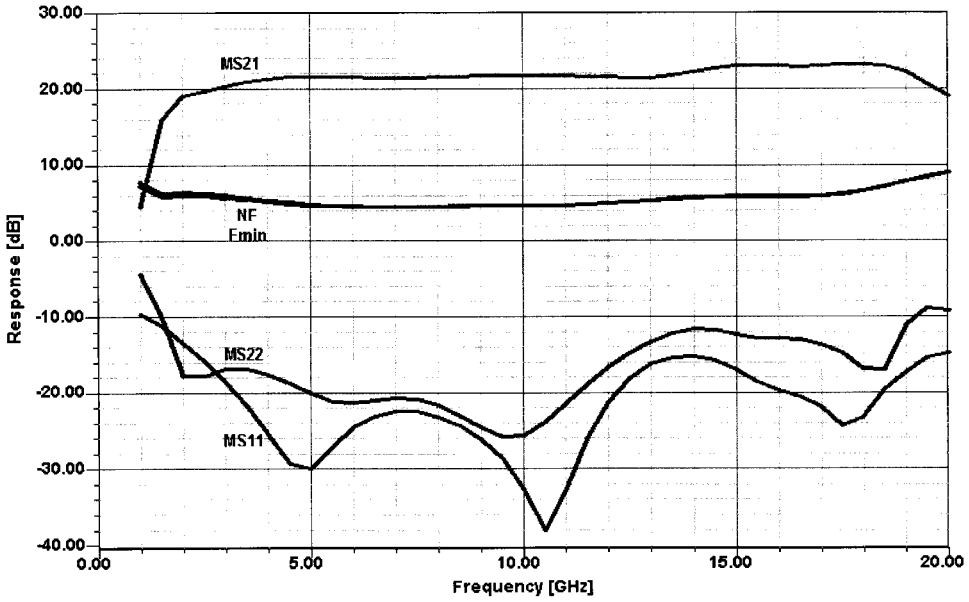

Figure 3-7 Simulated F_{min}, NF, S_{11}, S_{21}, and S_{22} responses. At the center of the range, the following numbers were found: F_{min}, 4.80 dB; NF, 4.80 dB; S_{11}, –32.8 dB; S_{21}, 21.8 dB; and S_{11}, –25.2 dB.

distributed elements is practically a necessity above 1500 MHz. For this reason, we begin this chapter by covering the application of transistors as amplifiers, following this with a discussion of the surrounding external circuitry, such as transmission lines, inductors, capacitors, and resistors. Monolithic ICs on silicon are a totally different ball game, and neither of the authors has sufficient expertise in this area. For this reason, we refer readers who will concentrate on MMIC design to the literature mentioned at the end of this chapter.

The goal of the applications presented here is to address, where possible, high-performance wireless stages that are less subject to constraints of space, power consumption, and cost, than portable/mobile applications. This is consistent with our preface, in which we have clearly stated our goal. The designers of handsets typically cannot consider the full variety of circuits we will present here. These types of stages (low noise, high gain and power) frequently will be used with filtering, and we will give some examples of input filters, including a tracking high-performance design.

A key topic besides the frequently mentioned gain is the whole noise issue. We will give the reader a complete introduction to this important area, followed by a similar introduction to the gain and matching of transistors. *Caution*: The majority of applications published go through the exercise of using *S*-parameters manually to design low-noise and small-signal amplifiers. While we have been tempted to repeat the information found in several textbooks, we feel that today's engineers will have access to CAD tools one way or another. It is highly unlikely that readers will undertake the inefficient process of going through all the design steps manually (a procedure that can take days); hopefully, engineers will resort to a linear/nonlinear CAD tool to do so. Only for the purpose of summarizing the necessary steps will we provide the relevant information regarding gain, stability, and related topics, demonstrating their usefulness or possible misuse with a modern CAD tool—in our case,

the Serenade Design Environment product from Ansoft. At this time, several additional companies beside Ansoft and Hewlett-Packard have emerged, but it is dangerous to list all of them as they come and go.

3-1-2 Gain

In practical terms, when we talk about gain we mean the output power relative to the input power. The industry standard now uses 50 Ω; however, at the point at which we have to match high-impedance devices such as monolithic crystal filters where the impedance jumps, things are not so obvious. The transformation equation that allows us to transform from one impedance to another is

$$m = \sqrt{\frac{R_2}{R_1}} \tag{3-1}$$

This correction factor, m, is required to do the transformation from R_1 (50 Ω) to R_2 (e.g., 1.2 kΩ). It needs to be understood that while the power gain remains the same, the voltage gain requires this correction factor. Since the power gain is expressed as 10 log A, A being the loop gain, 20 log A is the voltage gain, both expressed in dB. The reason for 10 versus 20 is that the power gain is always the voltage squared, which accounts for the 2. As a reminder of these relationships we present the following:

Distinction: Power Ratios–Voltage Ratios

$$n \text{ dB} = 10 \log_{10}(P_2/P_1) \quad \xrightarrow{PP = V^2/Z} \quad n = 10 \log_{10}\left(\frac{V_2^2/Z_2}{V_1^2/Z_1}\right)\text{dB}$$

$$Z_2 = Z_1 \rightarrow n \text{ dB} = 10 \log_{10}(V_2^2/V_1^2) = 10 \log_{10}(V_2/V_1)^2$$

$$\Longrightarrow \boldsymbol{n \text{ dB} = 20 \log_{10}(V_2/V_1) \text{ dB}}$$

The gain is typically defined under the condition of real resistive source and load terminations, which means that all the available power is being supplied to the amplifier, and likewise through proper matching at the output all the available power is fed to the termination. This gain figure is typically measured at a single spot frequency, but since most amplifiers are not totally flat, one needs to specify the gain tolerances or gain flatness. A good number is x dB ± 0.5 dB gain variation. In the case of a narrowband amplifier, the gain typically is shaped like a tuned circuit or like a critically coupled bandpass filter frequency response, while in the case of a real wideband application, the desired gain has some kind of ripple, which is due to the various compensation components in the circuit. An extreme case of a wideband amplifier is a 6–18-GHz single-stage amplifier that uses some very clever matching. This is shown in the following example. Figure 3-8 shows the circuit diagram, and Figure 3-9 shows its frequency-dependent performance.

While this is a cute approach for generating a single-stage amplifier over such a wide bandwidth, in real life it is not acceptable. The reason for this is that neither S_{11} nor S_{22} meets any useful specifications over the entire range. Typically, S_{11}/S_{22} values are only a few dB, while in reality more than 10 dB is required. We have chosen this example to show that gain

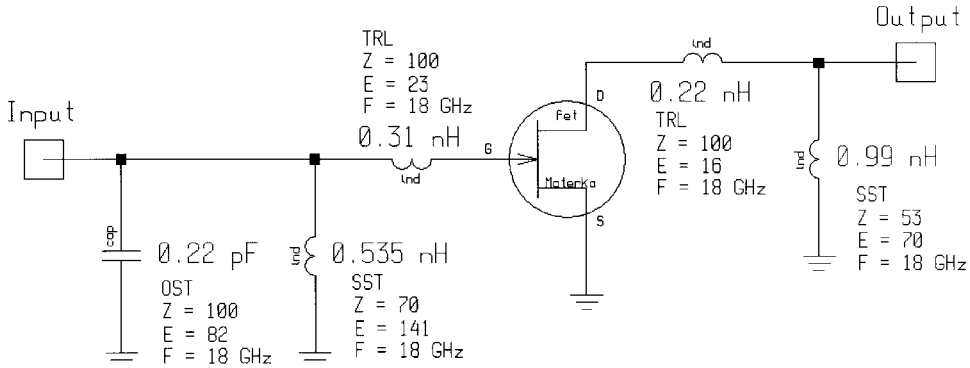

Figure 3-8 A 6–18-GHz FET amplifier.

and matching, depending on the circuit topology, are connected. We get similar results for the noise figure, whereby the best achievable noise figure ($F_{\min}$) and the actual 50-Ω noise figure are only a few dB apart; however, its frequency dependence in a wideband stage is certainly not acceptable.

Another parameter associated with gain is the stability factor K of the circuit. A value of $K > 1$ is mandatory to guarantee stability together with the S_{11} and S_{22} magnitudes being less than 1. Figure 3-10 plots the K stability factor, which for absolute stability must be >1, and maximum stable gain (MSG) as well as $G_{\max}$. It turns out that MSG is a highly artificial

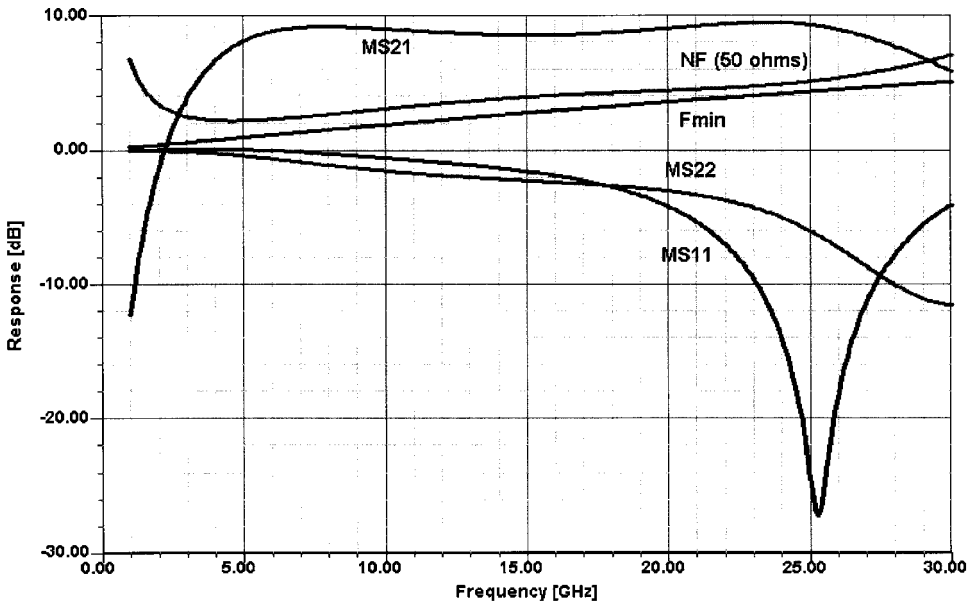

Figure 3-9 Frequency-dependent gain, matching, and noise performance of the amplifier shown in Figure 3-8.

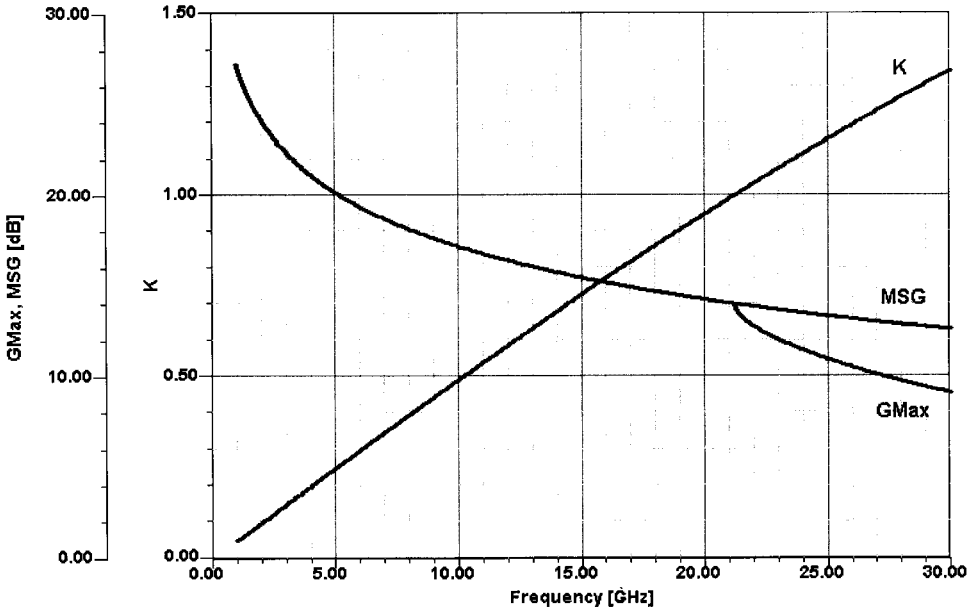

Figure 3-10 G_{max}, maximum stable gain (MSG), and K performance of the amplifier in Figure 3-8.

definition of stability that implies that input and output are terminated with pure resistances and then conjugately matched. There are four ways of achieving this resistive loading, either in the emitter as a shunt resistor between gate/drain or base/collector, or in parallel to the input and output to ground. Needless to say, this is not a real operating mode because it deteriorates both noise and gain. In our case, the entity G_{max} is a function of S_{12} of the circuit, not just the transistor, and depends highly on S_{12}. If we bring the system close to oscillation, then G_{max} will increase at the expense of bandwidth. Unfortunately, some of these microwave definitions of gain (see Table 3-1) have become widely used in industry without always being useful. Evaluating these equations for S_{12} is not legitimate because other quantities like K become infinite, and the entire system of equations falls apart. The power gain with input and output conjugately matched, or the transducer power gain for arbitrary source and load matching, still give more insight into the system.

In the above example, we specifically stated that the input and output VSWR was totally unacceptable, and this was due to a one-stage design. Figure 3-11 shows an amplifier chip built around two transistors with standard feedback techniques applied; Figures 3-12 and 3-13 show its frequency-dependent gain, matching, stability, and noise performance. This amplifier was one of the early examples of GaAsFET wideband amplifiers, but it is interesting because while it has wild (and wide) gain swings, it exhibits a fairly constant input and output impedance or reflection coefficient. A further evaluation of the circuit shows that not only is the circuit unconditionally stable, but that the maximum stable gain has an extremely high value based on essentially minimal S_{12}, the K factor is always significantly higher than 1, and G_{max} follows, to some degree, the actual gain response of the amplifier. (Ultimately, designers gave up on simple *RCL* feedback amplifiers for such a wide bandwidth, replacing them with distributed amplifiers previously called traveling wave amplifiers.) The problem of gain and stability starts at audiofrequency amplifiers, where the

Table 3-1 Nine power gains

Transducer power gain in 50-Ω system	$G_T = \lvert S_{21}\rvert^2$
Transducer power gain for arbitrary Γ_G and Γ_L	$G_T = \dfrac{(1-\lvert\Gamma_G\rvert^2)\,\lvert S_{21}\rvert^2\,(1-\lvert\Gamma_L\rvert^2)}{\lvert(1-S_{11}\Gamma_G)\,(1-S_{22}\Gamma_L)-S_{12}S_{21}\Gamma_G\Gamma_L\rvert^2}$
Unilateral transducer power gain	$G_{\mathrm{TU}} = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)\,(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2\lvert 1-S_{22}\Gamma_L\rvert^2}$
Power gain with input conjugate matched	$G = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_L\rvert^2)}{\lvert 1-S_{22}\Gamma_L\rvert^2(1-\lvert S'_{11}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{11}\rvert^2}$ (for $\Gamma_L = 0$)
Available power gain with output conjugate matched	$G_A = \dfrac{\lvert S_{21}\rvert^2(1-\lvert\Gamma_G\rvert^2)}{\lvert 1-S_{11}\Gamma_G\rvert^2(1-\lvert S'_{22}\rvert^2)} = \dfrac{\lvert S_{21}\rvert^2}{1-\lvert S_{22}\rvert^2}$ (for $\Gamma_G = 0$)
Maximum available power gain[a]	$G_{ma} = \left\lvert\dfrac{S_{21}}{S_{12}}\right\rvert\,(k-\sqrt{k^2-1})$
Maximum unilateral transducer power gain	$G_{\mathrm{TUmax}} = \dfrac{\lvert S_{21}\rvert^2}{(1-\lvert S_{11}\rvert^2)(1-\lvert S_{22}\rvert^2)}$
Maximum stable power gain	$G_{ms} = \dfrac{\lvert S_{21}\rvert}{\lvert S_{12}\rvert}$
Unilateral power gain	$U = \dfrac{1/2\lvert S_{21}/S_{12}-1\rvert^2}{k\lvert S_{21}/S_{12}\rvert-\mathrm{Re}(S_{21}/S_{12})}$

[a]Definition for $G_{\max}$: If $k > 1$, it is called G_{ma}, and if $k < 1$, it is called G_{ms}.

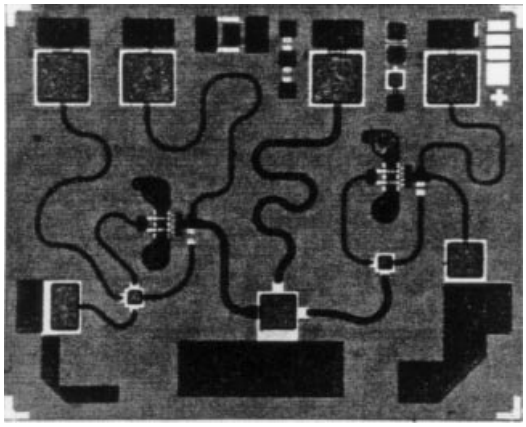

Figure 3-11 A two-stage, wideband feedback amplifier.

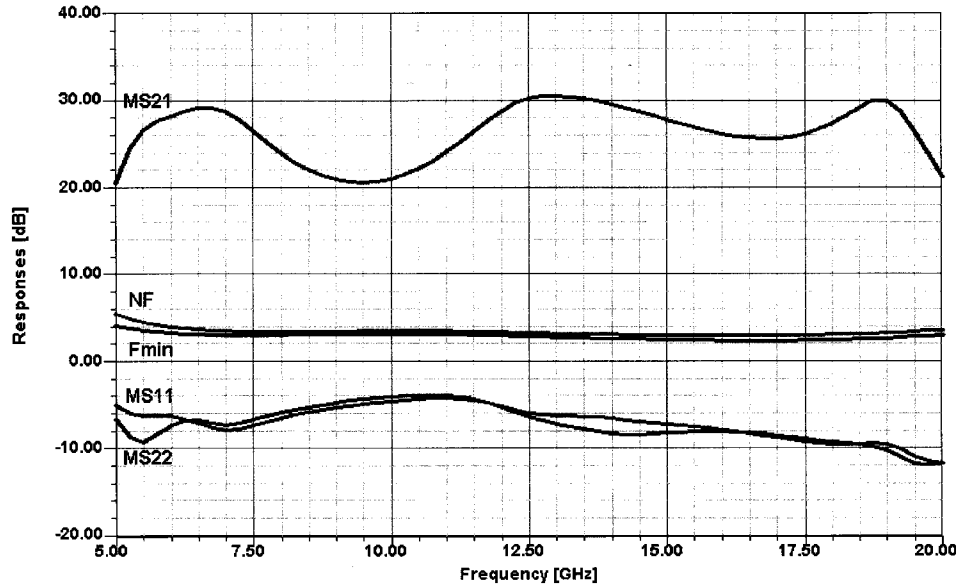

Figure 3-12 Frequency-dependent gain, matching, and noise performance for the amplifier in Figure 3-11.

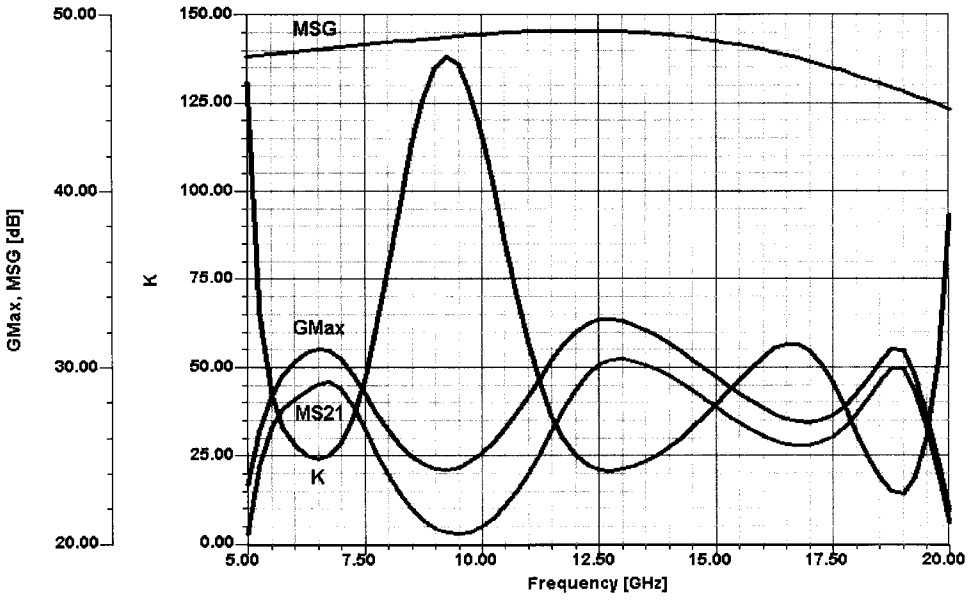

Figure 3-13 Frequency-dependent G_{max}, K, maximum stable gain, and gain performance for the amplifier in Figure 3-11.

motorboating phenomenon has been known for years, and the problem moves up in frequency with more modern technology and is largely dependent not only on the device and the circuit, but also on the layout. The motorboating effect has to do with ground loops and the fact that if the printed circuit traces from the power supply connection to the output power stage present too high a resistance, then at high currents the voltage will drop to a point below useful operation and then, as the volume is lowered, become stable again. In this case the amplitude of the signal through the amplifier controls the stability of the output stage. Needless to say, this most unpleasant effect applies to high-power stages for all output transistors, where we use Class B or C operation, meaning that the dc operating current as a function of output does not remain constant.

In terms of gain, there is also an important gain characteristic called *differential gain* and *differential phase*. These expressions were first used in television circuits, where linearity in both areas is an absolute must. The amplitude of the signal determines the black and white contrast, and the phase determines the color. As an example, transmitting an image of one of our presidents playing golf in California to the New York area is done by many microwave hops. Any multipath reception, such as that caused by reflection from airplanes, may have little effect on the signal amplitude, but the resulting phase shift can transform a green lawn to a red lawn if a total shift of 180° occurs. Given a particular operating point, if the 1-dB compression point of multiple amplifiers in the chain is approached or exceeded, their differential gain, which is defined by the IEEE as "the difference between (a) the ratio of the output of a small high-frequency sine-wave signal at two different levels of a low-frequency signal on which it is superimposed, and (b) unity," may increase. This mode of saturation charges all the capacitances of the amplifier transistors, causing huge phase shifts that result in the known problem of changing colors. The same applies, of course, in test equipment amplifiers, in which such changes cannot be tolerated. A somewhat similar, but not quite the same, problem is spectral regrowth [evaluated in terms of adjacent-channel power ratio (ACPR)], which is also due to nonlinearities. The question of linearity has already been covered in detail in Chapter 1. Needless to say, any overdrive condition also changes an amplifier's input and output SWR.

3-1-3 Noise Figure (NF)*

Introduction. In this section we look at the best way to describe noise in active devices (black boxes). Even when a two-port is linear, the output waveform will differ from the input, because of the failure to transmit all spectral components with equal gain (or attenuation) and delay. By careful design of the two-port, or by limitation of the bandwidth of the input waveform, such distortions can largely be avoided. However, noise generated within the two-port can still change the waveform of the output signal. In a linear passive two-port, noise arises only from the losses in the two-port; thermodynamic considerations indicate that such losses result in the random changes that we call noise. When the two-port contains active devices, such as transistors, there are other noise mechanisms present. A very important consideration in a system is the amount of noise that it adds to the transmitted signal. This is often judged by the ratio of the output signal power to the output noise power

*Section 3-1-3 is reprinted from Chapter 2 of George D. Vendelin, Anthony M. Pavio, and Ulrich L. Rohde, *Microwave Circuit Design Using Linear and Nonlinear Techniques*, copyright 1990 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

(S/N). The ratio of signal plus noise power to noise power [$(S + N)/N$] is generally easier to measure and approaches S/N when the signal is large.

In the evaluation of a two-port it is important to know the amount of noise added to a signal passing through it. An important parameter for expressing this characteristic is the noise factor. The signal energy coming from a generator or antenna is amplified or attenuated in passing from the input to the output of a two-port, as is the noise that accompanies the input signal energy. A system generally includes a cascade of two-port networks that constitute one overall two-port that amplifies the signal to a high-enough power level for its intended use. The *noise factor* of a system is defined as the ratio of signal-to-noise ratios available at input and output:

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}} \geq 1 \tag{3-2}$$

The noise figure (or factor) of a receiver is an easily measured quantity that describes the signal-to-noise ratio reduction of that receiver.

When this ratio of powers is converted to decibels, it is generally referred to as the *noise figure* rather than noise factor. Various conventions are used to distinguish the symbols used for noise factor and noise figure. Here we use F to represent the noise factor and NF to represent the noise figure, although the terms are usually used interchangeably.

For an amplifier with the power gain G, the noise factor can be rearranged as

$$F = \frac{S_i/N_i}{GS_i/G(N_i + N_a)} \tag{3-3}$$

when N_a is the additional noise power added by the amplifier referred to the input. This can be computed to be

$$F = 1 + N_a/N_i \tag{3-4}$$

The noise factor is often replaced by the noise figure (NF), which is defined in decibels as

$$\text{NF} = 10 \log_{10} F \tag{3-5}$$

In applications like satellite receivers, the noise factor becomes such a small number that it is inconvenient to work with. Many people have adopted the use of an equivalent noise temperature for a circuit to remedy this situation. Since the thermal noise power available from a resistor at temperature T_e is

$$N = kT_eB \tag{3-6}$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), T_e is the effective temperature in kelvins, and B is the bandwidth in hertz. The equation above may be used to associate an effective noise temperature with circuits containing more than just thermal noise sources. This allows Eq. (3-4) to be written as

$$F = 1 + \frac{kT_eB}{kT_0B} = 1 + \frac{T_e}{T_0} \tag{3-7}$$

where T_e is the effective noise temperature of the circuit and T_0 is the temperature of the generator resistor in kelvins. The noise temperature T_e now characterizes our circuit noise contribution and can directly be related to the noise factor.

Assuming a reference noise temperature of 290 K (–273 + 290 = 17 °C), let us determine the noise temperature of the system with a noise factor of 2.6 (4.15 dB):

$$T_e = (2.6 - 1)\ (290) = 464 \text{ K}$$

This temperature T_e should not be confused with the environmental operating temperature T_0. It is quite common to operate low-noise amplifiers with T_e below 100 K at an ambient temperature of 290 K.

Signal-to-Noise Ratio. Let us consider the signal-to-noise ratio of power delivered from a generator to a load as shown in Figure 3-14. The signal power delivered to the input is given by

$$S_{\text{in}} = P_{\text{in}} = \frac{E_g^2 \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-8}$$

where E_g is the rms voltage of the input signal supplied to the system, and the noise power supplied to the input is expressed by

$$N_{\text{in}} = \frac{\overline{v_n^2} \text{Re}(Z_{\text{in}})}{|Z_g + Z_{\text{in}}|^2} \tag{3-9}$$

where the noise power at the input is provided by the noise energy of the real part of Z_g. The input impedance Z of the system in the form $Z = R_{\text{in}} + jX_{\text{in}}$ is assumed to be complex.

The Johnson noise of a resistor [here $\text{Re}(Z_g)$], given by the mean-square voltage

$$\overline{v_n^2} = 4kTRB \tag{3-10}$$

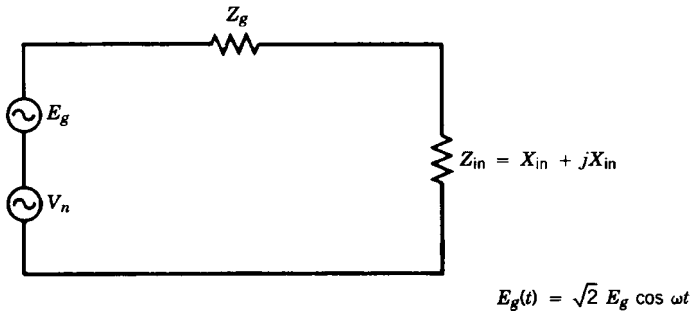

Figure 3-14 Combination of signal and noise voltages supplied to a complex termination.

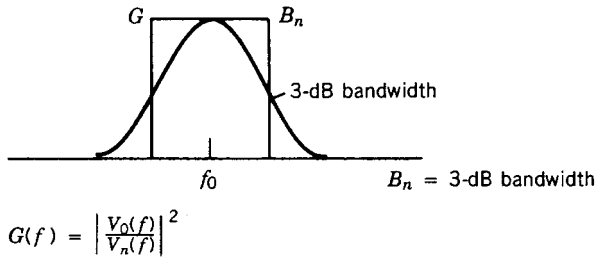
where k (Boltzmann's constant) = 1.38×10^{-23} J/K, T is the absolute temperature of the resistor, and B is the bandwidth, is sufficiently small that the resistive component of impedance does not change. The available signal power from the generator has a lower limit, even if the signal is attenuated by the highest possible attenuation. The generator resistor acts as a Johnson noise generator, its power being

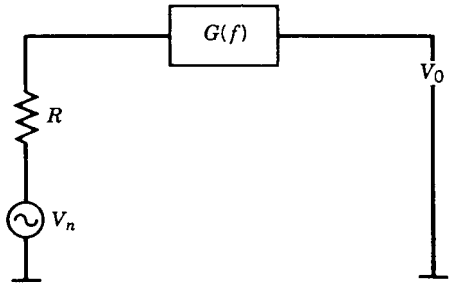
$$P_A = \frac{4kTRB}{4R} = kTB \tag{3-11}$$

where k is Boltzmann's constant, T is the absolute temperature, and B is the bandwidth. This power is the maximum available output power.

For an ambient temperature of 290 K, $kT = 4 \times 10^{-21}$ W/Hz. This expression is also given as kT = –204 dBW/Hz = –174 dBm/Hz = –114 dBm/MHz. We can combine Eqs. (3-8) to (3-10) to obtain

$$\left(\frac{S}{N}\right)_{\text{in}} = \frac{E_g^2}{4kT\text{Re}(Z_g)B} \tag{3-12}$$





$$V_0^2 = \int_0^\infty 4kT_0RG(f)\,dF$$
$$= 4kT_0R \int_0^\infty G(f)\,dF$$
$$B_n = \frac{1}{G} \int_0^\infty G(f)\,dF$$
B_n = noise bandwidth

Figure 3-15 Graphical and mathematical explanations of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

This is the value of *S/N* contributed by the generator, which does not include the noise generated by the load, in this case $\mathrm{Re}(Z_{\mathrm{in}})$, which would need to be included in the measurement of the total *S/N* across the input impedance.

A critical parameter is the noise bandwidth, B_n, which is defined as the equivalent bandwidth, as shown in Figure 3-15. For reasons of group delay correction, most practical filters have round rather than sharp corners. The noise figure measurements shown later can be used to determine the "integrated" bandwidth, which is B_n.

An active system such as a combination of amplifiers and mixers will add noise to the input signals, and the noise factor that describes this is defined as the *S/N* ratio at the input to the *S/N* ratio at the output, which is always greater than unity [2]. In practice, a certain minimum signal-to-noise ratio is required for operation. For example, in a communication system such a minimum is required for intelligible transmission, either voice or data. For high-performance TV reception, to provide a noise-free picture to the eye, a typical requirement is for a 60-dB *S/N*. In the case of a TV system, a large dynamic range is required, as well as a very large bandwidth to reproduce all colors truthfully and all shades from high-intensity white to black. Good systems will have a bandwidth of 8 MHz or more.

Noise Figure Measurements. Some of the noise equations are based on mathematical models and physics. To understand some of these expressions, it is useful to look at a practical system, with amplifiers, that has to be evaluated.

Let us look at Figure 3-16, which consists of a signal generator, the system or device under test (DUT), and a selective receiver with a built-in root-mean-square (rms) voltmeter to determine the signal and noise voltages. It is necessary that the system have enough gain so that the noise voltage supplied by the generator will be indicated [3].

If we assume that our selective receiver is a video noise meter calibrated in rms voltage levels, we can perform two measurements. With an input termination connected to the TV system (typically, 75 Ω for cable TV, 50 Ω for satellite TV), the noise receiver/meter will read a value for proper termination that can easily be calculated. Since one-half of the mean-square noise voltage appears across the input,

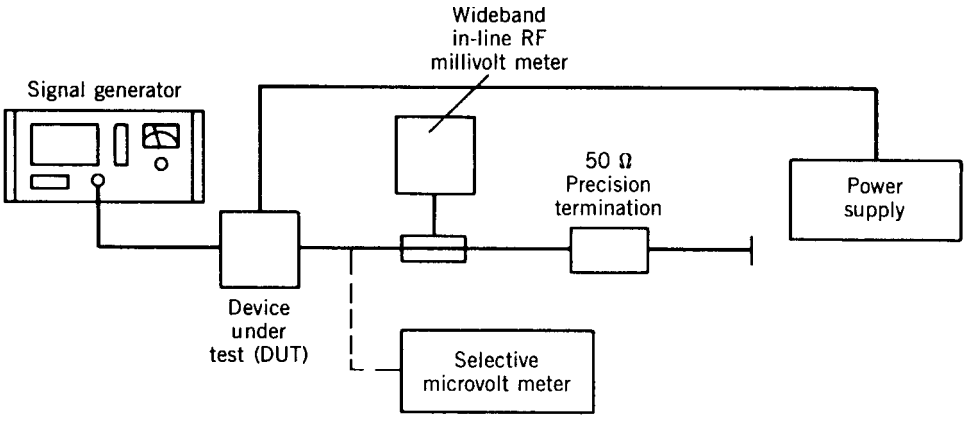


Figure 3-16 Test setup to measure signal-to-noise ratio.

$$v_{\text{in}} = \frac{v_n}{2} = \frac{\sqrt{4kTRB}}{2} \tag{3-13}$$

With $B = 10$ MHz, $T = 290$ K (T is always expressed in absolute temperature; $T_0 = -273$ °C), and $k = 1.38 \times 10^{-23}$ J/K, then for $R = 75\ \Omega$,

$$v_{\text{in}} = \frac{v_n}{2} = 1.73\ \mu\text{V} \tag{3-14}$$

where the rms noise voltage has been referred to the input port. We can verify this with our first measurement.

Now we increase the input voltage of the signal generator to a value that indicates a 60-dB *S/N* ratio at the output port. This should be about

$$E_g = \frac{v_n}{2}\sqrt{F} \times 1000 = 1.73\sqrt{F} \quad \text{mV}$$

where F is the noise factor of the receiver. For a receiver noise factor of 10, we would obtain $E_g = 5.48$ mV (rms value). If the noise energy equivalent to a noise factor of F is assumed, we need $\sqrt{F}$ times more voltage. For a 60-dB ratio, this means that $E_g = 1000 \times (v_n/2) \times \sqrt{F}$.

As they are done here, over a power range of 60 dB, the measurements can be performed over such a wide range only if special equipment is available. In cases where the internal detector of a piece of communication equipment is used, the signal-to-noise ratio measurements are performed over much smaller power ranges.

Let us assume that for the above-mentioned case ($F = 10$) we find a *S/N* ratio of 10 dB at the output for an input signal of 5.47 μV. By rewriting Eq. (3-7) as

$$E_g = \frac{v_n}{2}\sqrt{F} = \sqrt{KTRBF} \tag{3-15}$$

with F being the noise factor, we can solve for F with

$$F = \frac{P_s}{P_n} = \frac{E_g^2/R}{kTB} \tag{3-16}$$

While the input power from the thermal energy of the input termination resistor was $kTB = 4 \times 10^{-4}$ W, the input power required for the 10-dB *S/N* ratio was

$$P_s = \frac{(5.47 \times 10^{-6})^2}{75} = 3.98 \times 10^{-13}\ \text{W} \tag{3-17}$$

The noise factor is defined as the ratio P_s/P_n:

$$F = \frac{3.98 \times 10^{-13}}{4 \times 10^{-14}} = 10 \tag{3-18}$$

which is the proof.

This method is used more frequently at the 3-dB point, or double the input power if the dynamic range of the detector is small or only a linear indicator is available. Because of hum and other pickup, this is not an easy measurement. Using a signal generator is very expensive because in a laboratory or production environment a wide frequency range requires several generators.

Another method is the use of a wideband noise generator. Modern gas discharge diodes or avalanche diodes are available that provide essentially white noise energy over a large frequency range. These microwave diodes typically have an output of 30 dB above kT when switched on and kT when switched off. To provide good matching at microwave frequencies, a 15-dB attenuator is cascaded. This means that the noise power of the source in the ON condition is about 15 dB above kT.

In the early 1960s, low-cost noise figure test equipment was built around vacuum diodes whose operating range was limited to 1200 MHz due to the resonance effects of the structure. Today, automatic noise gain analyzers use calibrated solid-state noise sources up to 26.5 GHz. It appears that the upper frequency limit has to do with matching, and the lower-frequency limit with $1/f$ noise.

Noisy Two-Port Description. Based on the convention by Rothe and Dalke [4], any linear two-port can be in the form shown in Figure 3-17. This general case of a noisy two-port can be redrawn showing noise sources at the input and at the output. Figure 3-17b shows this in admittance form and Figure 3-17c in impedance form. The internal noise sources are assumed to produce very small currents and voltages, and we assume that linear two-port equations are valid. The internal noise contributions have been expressed by using external noise sources:

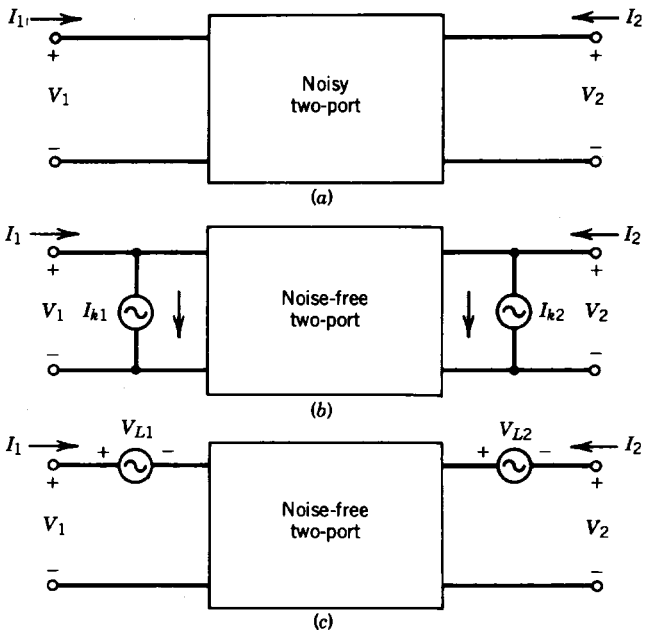

Figure 3-17 Noisy linear two-ports: (a) general form, (b) admittance form, and (c) impedance form.

$$I_1 = y_{11}V_1 + y_{12}V_2 + I_{K1}$$
$$I_2 = y_{21}V_1 + y_{22}V_2 + I_{K2} \tag{3-19}$$

$$V_1 = z_{11}I_1 + z_{12}I_2 + V_{L1}$$
$$V_2 = z_{21}I_1 + z_{22}I_2 + V_{L2} \tag{3-20}$$

where the external noise sources are I_{K1}, I_{K2}, V_{L1}, and V_{L2}.

Since we want to describe our noisy circuit in terms of the noise figure, the *ABCD*-matrix description will be more convenient since it refers both noise sources to the input of the two-port [5]. This representation is given below (note the change in direction of I_2):

$$V_1 = AV_2 + BI_2 + V_A$$
$$I_1 = CV_2 + DI_2 + I_A \tag{3-21}$$

where V_A and I_A are the external noise sources.

It is important to remember that all of these matrix representations are interrelated. For example, the noise sources for the *ABCD*-matrix description can be obtained from the *z*-matrix representation shown in Eq. (3-20). This transformation is

$$V_A = -\frac{I_{K2}}{y_{21}} = V_{L1} - \frac{V_{L2}z_{11}}{z_{21}} \tag{3-22}$$

$$I_A = I_{K1} - \frac{I_{K2}y_{11}}{y_{21}} = -\frac{V_{L2}}{z_{21}} \tag{3-23}$$

The *ABCD* representation is particularly useful because it allows us to define a noise temperature for the two-port referenced to the input. The two-port itself (shown in Figure 3-18) is assumed to be noise-free.

In the past, *z* and *y* parameters have been used, but in microwave applications it has become common to use *S*-parameter definitions. This is shown in Figure 3-19. The previous equations can be rewritten in their new form using *S*-parameters:

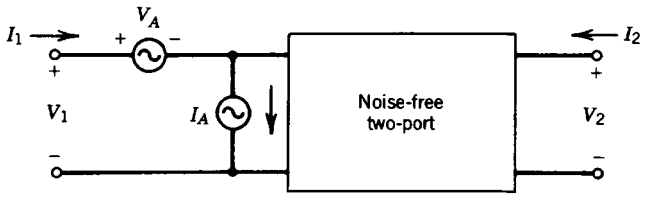

Figure 3-18 Chain-matrix form of linear noisy two-ports.

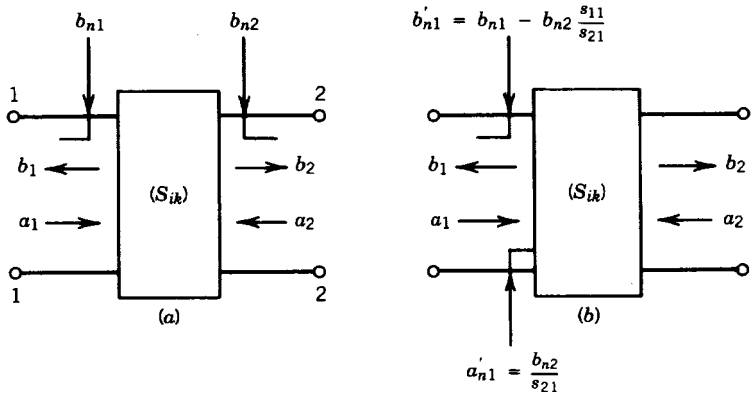

Figure 3-19 *S*-parameter form of linear noisy two-ports.

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \begin{bmatrix} b_{n1} \\ b_{n2} \end{bmatrix} \tag{3-24}$$

There are different physical origins for the various sources of noise. Typically, thermal noise is generated by resistances and loss in the circuit or transistor, whereas shot noise is generated by current flowing through semiconductor junctions and vacuum tubes. Since these many sources of noise are represented by only two noise sources at the device input, the two equivalent noise sources are often a complicated combination of the circuit internal noise sources. Often, some fraction of V_A and I_A is related to the same noise source. This means that V_A and I_A are not independent in general. Before we can use V_A and I_A to calculate the noise figure of the two-port, we must calculate the correlation between the V_A and I_A shown in Figure 3-18.

The noise source V_A represents all the device noise referred to the input when the generator impedance is zero; that is, when the input is short-circuited. The noise source I_A represents all the device noise referred to the input when the generator admittance is zero; that is, the input is open-circuited.

The correlation of these two noise sources considerably complicates analysis. By defining a correlation admittance, we can simplify the mathematics and get some physical intuition for the relationship between noise figure and generator admittance. Since some fraction of I_A will be correlated with V_A, we split I_A into correlated and uncorrelated parts as follows:

$$I_A = I_n + I_u \tag{3-25}$$

I_u is the part of I_A uncorrelated with V_A. Since I_n is correlated with V_A, we can say that I_n is proportional to V_A and the constant of proportionality is the correlation admittance:

$$I_n = Y_{\text{cor}} V_A \tag{3-26}$$

This leads us to

$$I_A = Y_{\text{cor}} V_A + I_u \tag{3-27}$$

The following derivation of noise figure will use the correlation admittance. Y_{cor} is not a physical component located somewhere in the circuit. Y_{cor} is a complex number derived by correlating the random variables I_A and V_A. To calculate Y_{cor}, we multiply each side of Eq. (3-27) by V_A^* and average the result. This gives

$$\overline{V_A^* I_A} = Y_{\text{cor}} \overline{V_A^2} \tag{3-28}$$

where the I_u term averaged to zero since it was uncorrelated with V_A. The correlation admittance is thus given by

$$Y_{\text{cor}} = \frac{\overline{V_A^* I_A}}{V_A^2} \tag{3-29}$$

Often, people use the term "correlation coefficient." This normalized quantity is defined as

$$c = \frac{\overline{V_A^* I_A}}{\sqrt{\overline{V_A^2} I_A^2}} = Y_{\text{cor}} \sqrt{\frac{\overline{V_A^2}}{I_A^2}} \tag{3-30}$$

Note that the dual of this admittance description is the impedance description. Thus, the impedance representation has the same equations as above with Y replaced by Z, I replaced by V, and V replaced by I.

V_A and I_A represent internal noise sources in the form of a voltage source acting in series with the input voltage and a source of current flowing in parallel with the input current. This representation conveniently leads to the four noise parameters needed to describe the noise performance of the two-port. Again using the Nyquist formula, the open-circuit voltage of a resistor at the temperature T is

$$\overline{V_A^2} = 4kTRB \tag{3-31}$$

This voltage is a mean-square fluctuation (or spectral density). It is the method used to calculate the noise identity. We could also define a noise equivalent resistance for a noise voltage as

$$R_n = \frac{\overline{V_A^2}}{4kTB} \tag{3-32}$$

The resistor R_n is not a physical resistor but can be used to simulate different portions of the noise equivalent circuit.

In a similar manner a mean-square current fluctuation can be represented in terms of an equivalent noise conductance G_n, which is defined by

$$G_n = \frac{\overline{I_A^2}}{4kTB} \tag{3-33}$$

and

$$G_u = \frac{\overline{I_u^2}}{4kTB} \tag{3-34}$$

for the case of the uncorrelated noise component. The input generator to the two-port has a similar contribution:

$$G_G = \frac{I_G^2}{4kTB} \tag{3-35}$$

with Y_G being the generator admittance and G_G being the real part. With the definition of F above, we can write

$$F = 1 + \left| \frac{I_A + Y_G V_A}{I_G} \right|^2 \tag{3-36}$$

The use of the voltage V_A and the current I_A has allowed us to combine all the effects of the internal noise sources.

We can use the previously defined [Eq. (3-29)] correlation admittance, $Y_{\text{cor}} = G_{\text{cor}} + jB_{\text{cor}}$, to simplify Eq. (3-36). First, we determine the total noise current:

$$\overline{I_A^2} = 4kT(|Y_{\text{cor}}|^2 R_n + G_u)B \tag{3-37}$$

where R_n and G_u are defined in Eqs. (3-32) and (3-34). The noise factor can now be determined:

$$F = 1 + \frac{G_u}{G_g} + \frac{R_n}{G_g}[(G_G + G_{\text{cor}})^2 + (B_G + B_{\text{cor}})^2] \tag{3-38}$$

$$F = 1 + \frac{R_u}{R_g} + \frac{G_n}{R_g}[(R_G + R_{\text{cor}})^2 + (X_G + X_{\text{cor}})^2] \tag{3-39}$$

The noise factor is a function of various elements, and the optimum impedance for the best noise figure can be determined by minimizing F with respect to generator reactance and resistance. This gives

$$R_{0n} = \sqrt{\frac{R_u}{G_n} + R_{\text{cor}}^2} \tag{3-40}$$

$$X_{0n} = -X_{\text{cor}} \tag{3-41}$$

and

$$F_{\min} = 1 + 2G_n R_{\text{cor}} + 2\sqrt{R_u G_n + (G_n R_{\text{cor}})^2} \tag{3-42}$$

(To distinguish between optimum noise and optimum power, we have introduced the convention 0*n* instead of the more familiar abbreviation *opt*.) At this point we see that the optimum condition for minimum noise figure is not a conjugate power match at the input port. We can explain this by recognizing that the noise source V_A and I_A represent all the

two-port noise, not just the thermal noise of the input port. We should observe that the optimum generator susceptance, $-X_{corr}$, will minimize the noise contribution of the two noise generators.

In rearranging for conversion to S parameters, we write

$$F = F_{\min} + \frac{g_n}{R_G}|Z_G - Z_{0n}|^2 \tag{3-43}$$

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-44}$$

From the definition of the reflection coefficient,

$$\Gamma_G = \frac{Y_0 - Y_G}{Y_0 + Y_G} \tag{3-45}$$

and with

$$g_G = \frac{G_G}{Y_0} \tag{3-46}$$

$$r_n = \frac{R_n}{Z_0} \tag{3-47}$$

the normalized equivalent noise resistance,

$$F = F_{\min} + \frac{4r_n|\Gamma_G - \Gamma_{0n}|^2}{g_G(1 - |\Gamma|^2)|1 + \Gamma_{0n}|^2} \tag{3-48}$$

$$r_n = (F_{50} - F_{\min})\frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-49}$$

$$\Gamma_{0n} = \frac{Z_{0n} - Z_0}{Z_{0n} + Z_0} \tag{3-50}$$

The noise performance of any linear two-port can now be determined if the values of the four noise parameters, $F_{\min}$, r_n (= $R_n/50$), and Γ_{0n} (magnitude and phase), are known.

Figure 3-20 shows the noise factor of a high-frequency transistor as a function of B_g for G_g = constant and as a function of G_g for $B_g = B_{opt}$.

Noise Figure of Cascaded Networks. In a system with many circuits connected in cascade (Figure 3-21), we must consider the contributions of the various circuits. In considering the equivalent noise resistor R_n in series with the input circuit,

$$F = \frac{R_G + R_n}{R_G} \tag{3-51}$$

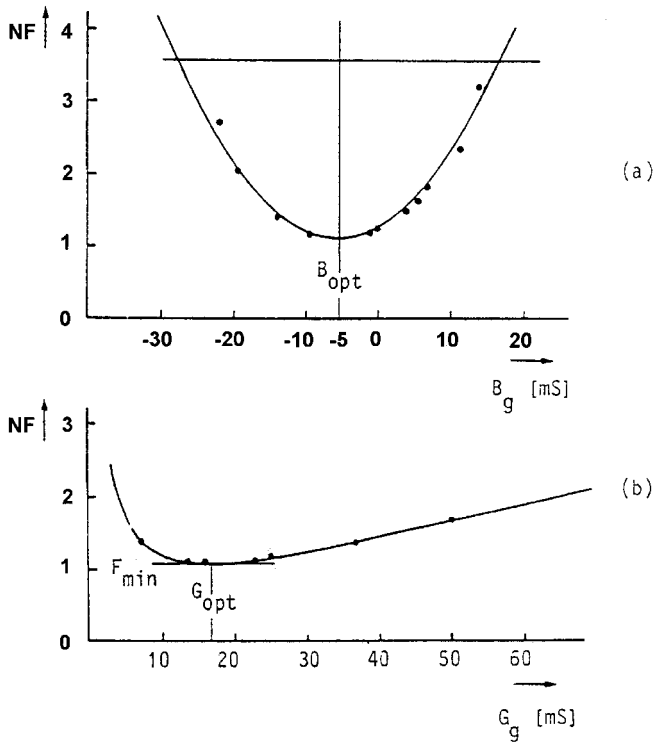

Figure 3-20 Noise factor in high-frequency BJTs for $f = 600$ MHz: (a) as a function of B_g for G_g = constant and (b) as a function of G_g for $B_g = B_{opt}$.

$$F = 1 + \frac{R_n}{R_G} \tag{3-52}$$

The excess noise added by the circuit is R_n/R_G.

In considering two cascaded circuits a and b, by definition the available noise at the output of b is

$$N_{ab} = F_{ab} G_{ab} kTB \tag{3-53}$$

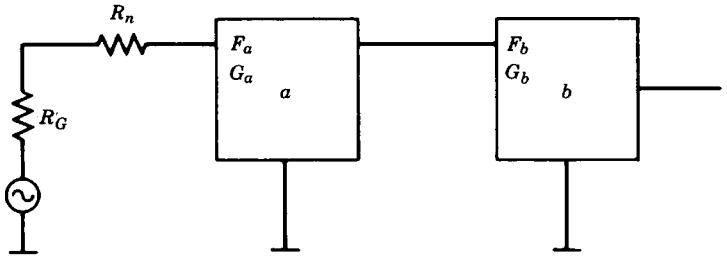

Figure 3-21 Cascaded noisy two-ports with the noise factors F_a and F_b and the gain figures G_a and G_b.

with B the equivalent noise bandwidth in which the noise is measured. The total available gain G is the product of the individual available gains, so

$$N_{ab} = F_{ab} G_a G_b kTB \tag{3-54}$$

The available noise from network a at the output of network b is

$$N_{a/b} = N_a G_b = F_a G_a G_b kTB \tag{3-55}$$

The available noise added by network b (its excess noise) is

$$N_{b/b} = (F_b - 1) G_b kTB \tag{3-56}$$

The total available noise N_{ab} is the sum of the available noise contributed by the two networks:

$$\begin{aligned} N_{ab} &= N_{a/b} + N_{b/b} = F_a G_a G_b kTB + (F_b - 1) G_b kTB \\ &= \left(F_a + \frac{F_b - 1}{G_a} \right) G_a G_b kTB \end{aligned} \tag{3-57}$$

$$F_{ab} = F_a + \frac{F_b - 1}{G_a} \tag{3-58}$$

For any number of circuits, this can be extended to

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \frac{F_4 - 1}{G_1 G_2 G_3} + \cdots \tag{3-59}$$

When considering a long chain of cascaded amplifiers, there will be a minimum noise figure achievable for this chain. This is a figure of merit and was proposed by Haus and Adler [6]. It is calculated by rearranging Eq. (3-59):

$$(F_{\text{tot}})_{\min} = (F_{\min} - 1) + \frac{F_{\min} - 1}{G_A} + \frac{F_{\min} - 1}{G_A^2} + \cdots + 1 \tag{3-60}$$

where $F_{\min}$ is the minimum noise figure for each stage and G_A is the available power gain of the identical stages. Using

$$\frac{1}{1 - X} = 1 + X + X^2 + \cdots \tag{3-61}$$

we find a quantity $(F_{\text{tot}} - 1)$, which is defined as the noise measure M. The minimum noise measure

$$(F_{\text{tot}})_{\min} - 1 = \frac{F_{\min} - 1}{1 - 1/G_A} = M_{\min} \tag{3-62}$$

refers to the noise of an infinite chain of optimally tuned, low-noise stages, so it represents a lower limit on the noise of an amplifier.

The minimum noise measure $M_{\min}$ is an invariant parameter and is not affected by feedback. It is somewhat similar to a gain–bandwidth product, in its use as a system invariant. The minimum noise measure is achieved when the amplifier is tuned for the available power gain and $\Gamma_G = \Gamma_{0n}$, given by Eq. (3-50).

Influence of External Parasitic Elements. Mounting an active two-port such as a transistor usually adds stray capacitance and lead inductance to the device, as shown in Figure 3-22. These external components consisting of transmission lines and parasitic reactances modify the noise parameters and the gain. Some researchers have published the results of these parasitic effects and have made manual computations or used some limited computer programs.

In a paper by Fukui [7], an attempt was made to determine the necessary equations, but the formulas are too involved even for pocket calculators. A more generic study by Iversen [8] is also very involved because of the various matrix manipulations and is more suitable for a computer. Besser's paper [9] in the *IEEE MTT-S* in 1975 and Vendelin's paper [10] in the same issue have shown for the first time some practical results using computers and even optimization methods, using an early version of COMPACT. The intention of these investigations was to find feedback that modifies the device noise and scattering parameters such that a noise match could also provide a low-input VSWR. It can be seen from these discussions that some feedback, besides resulting in some gain reduction, may improve the noise matching at the input for a limited frequency range.

A more recent paper by Suter [11] based on a report by Hartmann and Strutt [12] has given a simple transformation starting from the *S*-parameters and the noise parameters from common-source (or common-emitter) measurements. The noise parameters for the "packaged" device are calculated. This means that the parameters for the "new" device, including

the common-gate (or common-base) case, are calculated. The equations are device dependent. They are valid for any active two-port.

A transformation matrix, n, may be used to combine the noise sources of the various circuit configurations. The transformation matrix parameters are given in Table 3-2 for series feedback, shunt feedback, and the common-gate (base) case, which will be important for oscillator analysis. The transformation matrix gives the new noise parameters as follows:

$$R'_n = R_n|n_{11} + n_{12}Y_{\text{cor}}|^2 + G_n|n_{12}|^2 \tag{3-63}$$

$$G'_n = \frac{G_nR_n}{R'_n}|n_{11}n_{22} - n_{12}n_{21}|^2 \tag{3-64}$$

$$Y'_{\text{cor}} = \frac{R_n}{R'_n}(n_{21} + n_{22}Y_{\text{cor}})(n^*_{11} + n^*_{12}Y^*_{\text{cor}}) + \frac{G_n}{R'_n}n_{22}n^*_{12} \tag{3-65}$$

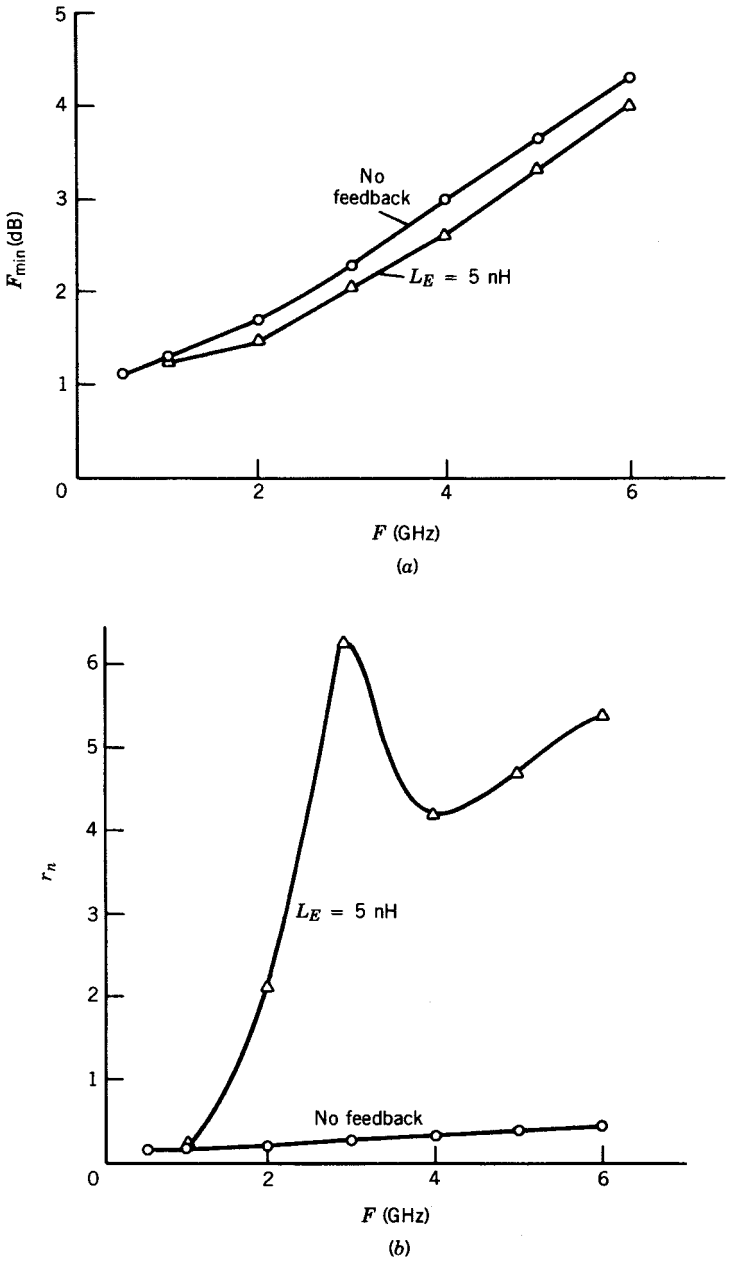

Figure 3-23 Noise parameters versus feedback for the AT-41435 silicon bipolar transistor: (a) F_{min} versus frequency and feedback; (b) r_n versus frequency and feedback; (c) Γ_{0n} versus frequency and feedback.

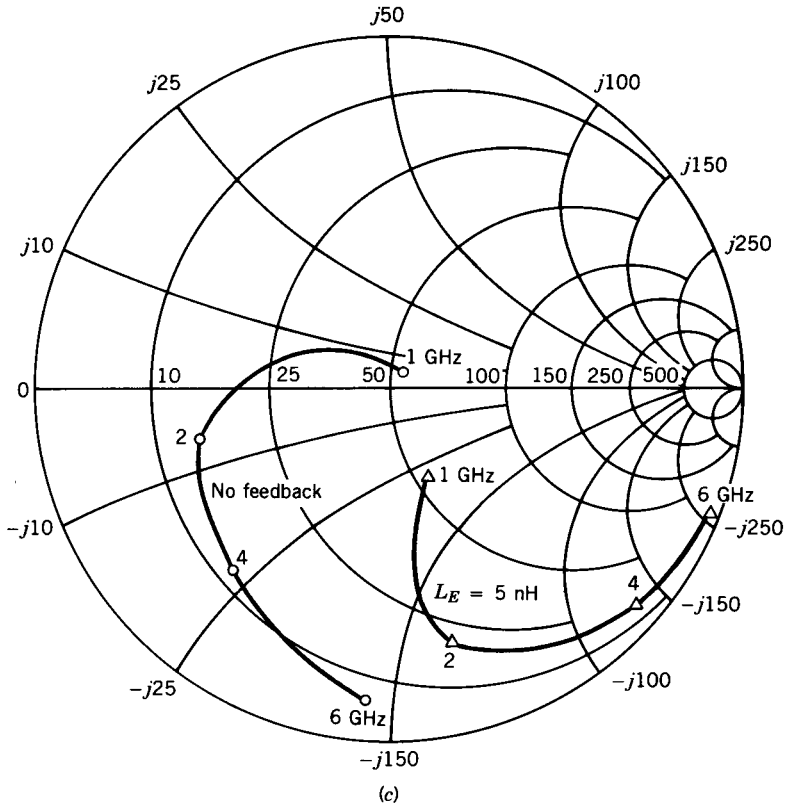

Figure 3-23 (*Continued*)

A final transformation to the more common noise-parameter format given by Eq. (3-44) is still needed [10]:

$$F_{\min} = 1 + 2R_n'(G_{\text{cor}}' + G_{0n}') \tag{3-66}$$

$$R_n = R_n' \tag{3-67}$$

$$G_{0n} = \sqrt{\frac{G_n'}{R_n'} + G_{\text{cor}}'^2} \tag{3-68}$$

$$B_{0n} = -B_{\text{cor}}' \tag{3-69}$$

Figure 3-23 shows the noise figure as a function of external feedback for a low-noise microwave bipolar transistor, the AT-41435.

Bias-Dependent Noise Parameters. Since we have elaborated on the effect of parasitics, it is now useful to point out that noise is also a strong function of bias point and frequency. Figure 3-24 shows the noise figure expressed in dB as a function of different dc currents and frequencies for a BFP420 BJT by Siemens. A change in the collector voltage will also affect the noise parameters, not quite as strongly as shown here, but still significantly. The reason

[a]Input matched for minimum noise figure, output for maximum gain.
[b]$Z_S = Z_L = 50\ \Omega$.

for the turning point of the noise figure has to do with the fact that for lower currents the f_T cutoff frequency has not reached its peak yet, and therefore the noise increases. The increase of the noise at higher currents is due to the Schottky noise calculated from the equation

$$P_n = 2Iq \tag{3-70}$$

where P_n is the noise power, I is the saturation, collector, or drain current, and q is the charge of an electron (1.60×10^{-19} coulomb).

Table 3-3 shows the common-emitter noise parameters for the BFP420.

Noise Circles. From the section entitled "Influence of External Parasitic Elements," we see that the noise factor is a strong function of the generator admittance (or impedance) presented to the input terminals of the noisy two-port. Noise tuning is used to change the values of the input admittance to obtain the best noise performance. There is a range of values of input reflection coefficient over which the noise figure is constant. In plotting these points of constant noise figure, we obtain the so-called noise circles, which can be drawn on the Smith chart Γ_G plane [13]. Starting with the noise equation [see Eq. (3-44)] for a 50-Ω generator impedance, we find that

$$F_{50} = F_{\min} + 4r_n \frac{|\Gamma_{0n}|^2}{|1 + \Gamma_{0n}|^2} \tag{3-71}$$

We want to find the position of the reflection coefficient on the Smith chart, as in the case of the gain circles, for which F is constant. First we rearrange Eq. (3-67) to read

$$r_n = (F_{50} - F_{\min}) \frac{|1 + \Gamma_{0n}|^2}{4|\Gamma_{0n}|^2} \tag{3-72}$$

By introducing

$$N_i = \frac{F_i - F_{\min}}{4r_n} |1 + \Gamma_{0n}|^2 \tag{3-73}$$

we can find an expression for a circle of constant noise figure as introduced by Rothe and Dahlke [4] (see also Fukui [13]). The center for the noise circle is

$$C_i = \frac{|\Gamma_{0n}|}{1 + N_i} \tag{3-74}$$

and the radius is

$$r_i = \frac{\sqrt{N_i^2 + N_i(1 - |\Gamma_{0n}|^2)}}{1 + N_i} \tag{3-75}$$

with the definition of N used previously. However, if we consider only the minimum noise figure for a given device, we will not obtain the minimum noise figure for the multistage amplifier system. This was explained when the noise measure was introduced. (See Figure 3-25.) Therefore, a better way to design the amplifier would be to use circles at constant noise measure instead of circles of constant noise figure. This was recently done by Poole

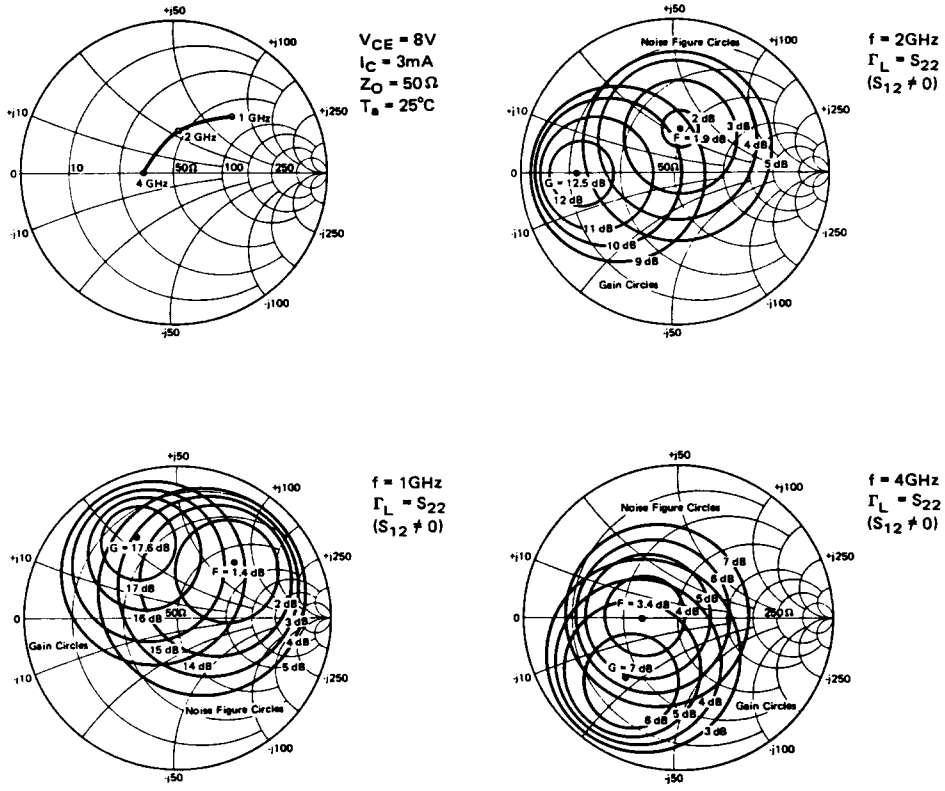

Figure 3-25 Typical noise figure circles and gain circles.

and Paul [14]. They derived the expressions for the noise measure circles as a function of S parameters, noise parameters, and Γ_G, using

$$G_A = \frac{|S_{21}|^2(1 - |\Gamma_G|^2)}{(1 - |S_{22}|^2) + |\Gamma_G|^2 (|S_{11}|^2 - |\Delta|^2) - 2\,\mathrm{Re}(\Gamma_G C_1)} \tag{3-76}$$

where

$$C_1 = S_{11} - S_{22}^* \Delta$$

$$\Delta = S_{11}S_{22} - S_{12}S_{11}$$

In terms of the generator reflection coefficient, the noise measure can be expressed as

$$M = [(F_{\min} - 1)(1 - |\Gamma_G|^2)|S_{21}|^2|1 + \Gamma_{0n}|^2 + 4r_n|S_{21}|^2|\Gamma_G - \Gamma_{0n}|^2]$$

$$\times \left\{|1 + \Gamma_{0n}|^2[|S_{21}|^2(1 - |\Gamma_G|^2) - (1 - |S_{22}|^2) - |\Gamma_G|^2(|S_{11}|^2 - |\Delta|^2) + 2\,\mathrm{Re}(\Gamma_G C_1)]\right\}^{-1} \tag{3-77}$$

Equation (3-77) can be shown to represent circles in the source reflection coefficient plane described by the following:

$$|\Gamma_G|^2 + |\Gamma_m|^2 - \Gamma_G\Gamma_m^* - \Gamma_G^*\Gamma_m = r_m^2 \tag{3-78}$$

The centers and radii of the constant-noise-measure circles are given by

$$C_m = \frac{M|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-79}$$

$$r_m = \frac{\sqrt{M^2M_a + MM_b + M_c}}{M|1 + \Gamma_{0n}|^2 P + |S_{21}|^2(4r_n - W)} \tag{3-80}$$

where

$$P = |S_{21}|^2 + |S_{11}|^2 - |\Delta|^2$$

$$Q = |S_{21}|^2 + |S_{22}|^2 - 1$$

$$W = |1 + \Gamma_{0n}|^2(F_{\min} - 1)$$

$$M_a = |1 + \Gamma_{0n}|^4(PQ + |C_1|^2)$$

$$M_b = |1 + \Gamma_{0n}|^2|S_{21}|^2[8r_n\,\mathrm{Re}(\Gamma_{0n}C_1)$$

$$- (4r_n|\Gamma_{0n}|^2 + W)P - (W - 4r_n)Q]$$

$$M_c = |S_{21}|^4[W - 4r_n(1 - |\Gamma_{0n}|^2)]$$

The value of the minimum noise measure can be found by considering the noise measure circle of zero radius; that is, set r_m equal to zero in Eq. (3-80). This results in

$$M_{\min} = \frac{-M_b \pm \sqrt{M_b^2 - 4M_a M_c}}{2M_a} \tag{3-81}$$

Equation (3-81) yields the same value of $M_{\min}$ as would have been obtained by using the immittance parameter equation given by Fukui [13] and can, therefore, be considered as the reflection coefficient plane analog of Fukui's expression. The elimination of the need for the parameter R_{eg}, however, results in a considerable simplification as compared with the earlier approach [13].

The value of the minimum noise measure is taken as the smallest nonnegative value of $M_{\min}$ given by Eq. (3-81). The source reflection coefficient that results in the minimum noise measure can now be obtained by employing Eq. (3-79):

$$\Gamma_{0m} = \frac{M_{\min}|1 + \Gamma_{0n}|^2 C_1^* + 4r_n|S_{21}|^2\Gamma_{0n}}{M_{\min}|1 + \Gamma_{0n}|^2 P + |S_{21}|^2\,(4r_n - W)} \tag{3-82}$$

The output reflection coefficient of the device, when Γ_{0m} is presented to the input port, is given by

$$S'_{22} = \frac{S_{22} - \Delta\Gamma_{0m}}{1 - S_{11}\Gamma_{0m}} \tag{3-83}$$

Noise Correlation in Linear Two-Ports Using Correlation Matrices. In the introduction to two-port noise theory, it was indicated that noise correlation matrices form a general technique for calculating noise in n-port networks. Haus and Adler [6] have described the theory behind this technique. In 1976, Hillbrand and Russer [15] published equations and transformations that aid in supplying this method to two-port CAD.

This method is useful because it forms a base from which we can rigorously calculate the noise of linear two-ports combined in arbitrary ways. For many representations, the method of combining the noise parameters is as simple as that for combining the circuit element matrices. In addition, noise correlation matrices can be used to calculate the noise in linear frequency conversion circuits. The following is an introduction to this subject.

A linear, noisy two-port can be modeled as a noise-free two-port with two additional noise sources. These noise sources must be chosen so that they add directly to the resulting vector of the representation, as shown in Eqs. (3-84) and (3-85) and Figure 3-17:

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-84}$$

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \tag{3-85}$$

where the i and v vectors indicate noise sources for the y and z representations, respectively. This two-port example can be extended to n-ports in a straightforward, obvious way.

Since the noise vector for any representation is a random variable, it is much more convenient to work with the noise correlation matrix. The correlation matrix gives us deterministic numbers with which to calculate. The correlation matrix is formed by taking the mean value of the outer product of the noise vector. This is equivalent to multiplying the noise vector by its adjoint (complex conjugate transpose) and averaging the result:

$$\langle \bar{i}\ \bar{i}^{+} \rangle = \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] = \begin{bmatrix} \langle i_1 i_1^* \rangle & \langle i_1 i_2^* \rangle \\ \langle i_1^* i_2 \rangle & \langle i_2 i_2^* \rangle \end{bmatrix} + [C_y] \tag{3-86}$$

where the angular brackets denote the average value.

Note that the diagonal terms are the "power" spectrum of each noise source and the off-diagonal terms are complex conjugates of each other and represent the "cross-power" spectra of the noise sources. "Power" is used because these magnitude-squared quantities are proportional to power.

To use these correlation matrices in circuit analysis, we must know how to combine them and how to convert them between various representations. An example using y matrices will illustrate the method for combining two-ports and their correlation matrices. Given two matrices y and y', when we parallel them we have the same port voltages, and the terminal currents add (Figure 3-26):

$$\begin{aligned} I_1 &= y_{11}V_1 + y_{12}V_2 + y'_{11}V_1 + y'_{12}V_2 + i_1 + i'_1 \\ I_2 &= y_{21}V_1 + y_{22}V_2 + y'_{21}V_1 + y'_{22}V_2 + i_2 + i'_2 \end{aligned} \tag{3-87}$$

or

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} + y'_{11} & y_{12} + y'_{12} \\ y_{21} + y'_{21} & y_{22} + y'_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 + i'_1 \\ i_2 + i'_2 \end{bmatrix} \tag{3-88}$$

Here we can see that the noise current vectors add just as the y parameters add. Converting the new noise vector to a correlation matrix yields

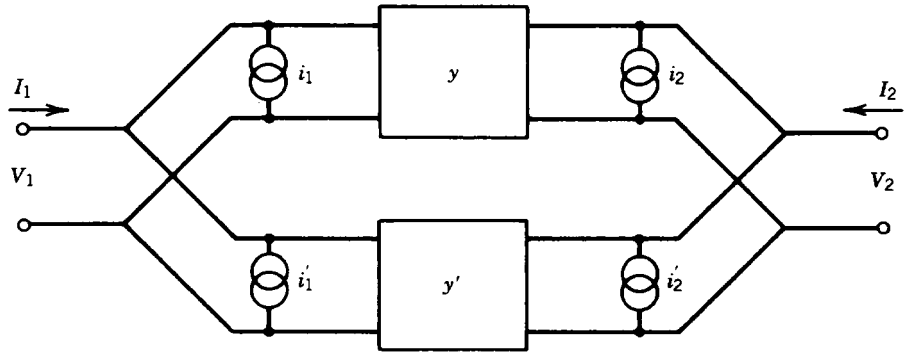

Figure 3-26 Parallel combination of two-ports using y parameters.

$$\langle \bar{i}_{\text{new}} \bar{i}^{+}_{\text{new}} \rangle = \left\langle \begin{bmatrix} i_1 + i_1' \\ i_2 + i_2' \end{bmatrix} [i_1^* + i_1'^* \quad i_2 i_2'^*] \right\rangle \tag{3-89}$$

$$= \begin{bmatrix} \langle i_1 i_1^* \rangle + \langle i_1' i_1'^* \rangle & \langle i_1 i_2^* \rangle + \langle i_1' i_2'^* \rangle \\ \langle i_2 i_1^* \rangle + \langle i_2' i_1'^* \rangle & \langle i_2 i_2^* \rangle + \langle i_2' i_2'^* \rangle \end{bmatrix} \tag{3-90}$$

The noise sources from different two-ports must be uncorrelated, so there are no cross products of different two-ports. By inspection, Eq. (3-90) is just the addition of the correlation matrices for the individual two-ports, so

$$[C_{y\text{new}}] = [C_y] + [C_y'] \tag{3-91}$$

The same holds true for g, h, and z parameters, but $ABCD$ parameters have the more complicated form shown below. If

$$[A_{\text{new}}] = [A][A'] \tag{3-92}$$

then

$$[C_{A\text{new}}] = \{C_A] + [A]\,[C_{A'}]\,[A]^{+} \tag{3-93}$$

The transformation of one representation to another is best illustrated by an example. Let us transform the correlation matrix for a Y representation to a Z representation. Starting with

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = [Y] \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} + \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \tag{3-94}$$

we can move the noise vector to the left side and invert y:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 - i_1 \\ I_2 - i_2 \end{bmatrix} = [Y^{-1}] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Y^{-1}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-95}$$

Table 3-4 π Noise matrix $T_{\alpha\beta}$ transformation

		Original Form (α Form)					
		Y		Z		A	
Resulting Form (β Form)	Y	1	0	y_{11}	y_{12}	$-y_{11}$	1
		0	1	y_{21}	y_{22}	$-y_{21}$	0
	Z	z_{11}	z_{12}	1	0	1	$-z_{11}$
		z_{21}	z_{22}	0	1	0	$-z_{21}$
	A	0	A_{12}	1	$-A_{11}$	1	0
		1	A_{22}	0	$-A_{21}$	0	1

Since $(Y)^{-1} = (Z)$, we have

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = [Z] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} + [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-96}$$

so

$$= [Z] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} = [T_{yz}] \begin{bmatrix} -i_1 \\ -i_2 \end{bmatrix} \tag{3-97}$$

where the signs of i_1 and i_2 are superfluous since they will cancel when the correlation matrix is formed. Here the transformation of the Y noise current vector to the Z noise voltage vector is done simply by multiplying by (Z). Other transformations are shown in Table 3-4.

To obtain the noise correlation matrix, we again form the mean of the outer product:

$$\langle vv^+ \rangle = \begin{bmatrix} \langle v_1 v_1^* \rangle & \langle v_1 v_2^* \rangle \\ \rangle v_1^* v_2 \rangle & \langle v_2 v_2^* \rangle \end{bmatrix} = [Z] \left\langle \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} [i_1^* \quad i_2^*] \right\rangle [Z]^+ \tag{3-98}$$

or

$$[C_z] = [Z]\,[C_y]\,[Z]^+ \tag{3-99}$$

where

$$v^+ = [i_1^* \quad i_2^*]\,[Z]^+ \tag{3-100}$$

This is called a congruence transformation. The key to all of these derivations is the construction of a correlation matrix from the noise vector, as shown in Eq. (3-90).

These correlation matrices may easily be derived from the circuit matrices of passive circuits with only thermal noise sources. For example,

$$[C_z] = 2kT\Delta f\,\mathrm{Re}([Z]) \tag{3-101}$$

and

$$[C_y] = 2kT\Delta f\,\mathrm{Re}([Y]) \tag{3-102}$$

The $2kT$ factor comes from the double-sided spectrum of thermal noise. The correlation matrix from the $ABCD$ matrix may be related to the noise figure, as shown by Hillbrand and Russer [15]. We have

$$F = 1 + \frac{\overline{Y}[C_a]\overline{Y}^+}{2kT\,\mathrm{Re}(Y_G)} \tag{3-103}$$

where

$$\overline{Y} = \begin{bmatrix} Y_G \\ 1 \end{bmatrix}$$

Expressing the noise factor in terms of the correlation matrix, we obtain a complete formula:

$$F = 1 + \frac{C_{22}^{A}(f) + 2\,\mathrm{Re}\{Y_g(f)\,C_{12}^{A}(f)\} + |Y_g(f)|^2\,C_{11}^{A}(f)}{2kT_0\,\mathrm{Re}\{Y_g(f)\}} \tag{3-104}$$

Once we transform this in the Y parameter form, we obtain the following equation:

$$F(f) = F_{\min}(f) + \frac{R_n(f)|Y_{\mathrm{opt}}(f) - Y_g(f)|^2}{\mathrm{Re}\{Y_g(f)\}} \tag{3-105}$$

It should be noted that all these values are frequency dependent, as expressed in this equation.

The *ABCD* correlation matrix can be written in terms of the noise figure parameters as (double-sided spectrum)

$$[C_a] = 2kT\begin{bmatrix} R_n & \dfrac{F_0 - 1}{2} - R_n Y_{0n}^{*} \\ \dfrac{F_0 - 1}{2} - R_n Y_{0n} & R_n|Y_{0n}|^2 \end{bmatrix} \tag{3-106}$$

The noise correlation matrix method forms an easy and rigorous technique for handling noise in networks. This technique allows us to calculate the total noise for complicated networks by combining the noise matrices of subcircuits. It should be remembered that although noise correlation matrices apply to n-port networks, noise figure calculations apply only to pairs of ports. The parameters of the C_a matrix can be used to give the noise parameters:

$$Y_{0n} = \sqrt{\frac{C_{ii*}}{C_{uu*}} - \left[\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right)\right]^2} + j\,\mathrm{Im}\left(\frac{C_{ui*}}{C_{uu*}}\right) \tag{3-107}$$

$$F_0 = 1 + \frac{C_{ui*} + C_{uu*}Y_{0n}^{*}}{kT} \tag{3-108}$$

$$R_u = C_{uu*} \tag{3-109}$$

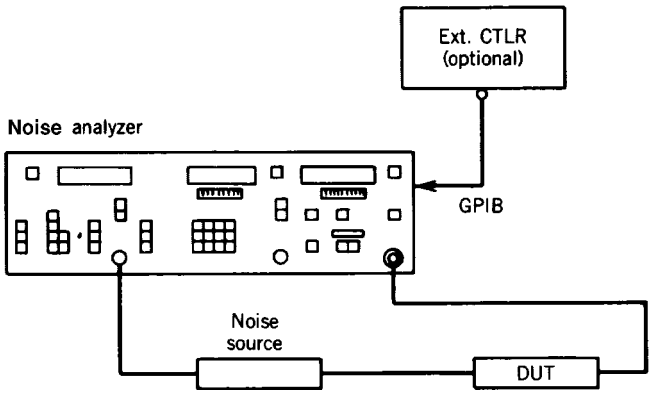

Figure 3-27 Noise figure measurement.

Noise Figure Test Equipment. Figure 3-27 shows the block diagram of a noise test setup. It includes the noise source and the other components. The metering unit has a special detector that is linear and over a certain dynamic range measures linear power. The tunable receiver covers a wide frequency range (e.g., 10–1800 MHz) and controls the noise source. The receiver is a double-conversion superheterodyne configuration with sufficient image rejection to avoid double-sideband noise measurements that would give the wrong results.

These receivers are microprocessor controlled and the measurement is a two-step procedure. The first is a calibration step that measures the noise figure of the receiver system and a reference power level. Then the device under test (DUT) is inserted and the system noise figure and total output power are measured. The noise factor is calculated by

$$F_1 = F_{\text{system}} - \frac{F_2 - 1}{G_1} \tag{3-110}$$

and the gain is given by the change in output power from the reference level [16]. The noise of the system is calculated by measuring the total noise power with the noise source on and off. With the excess noise ratio (ENR) known [16],

$$F_{\text{system}} = \frac{\text{ENR}}{Y - 1} \tag{3-111}$$

The noise bandwidth is usually set by the bandwidth of the receiver, which is assumed to be constant over the linear range. The ENR of the noise source is given by

$$\text{ENR} = \frac{T_{\text{hot}}}{T_{\text{cold}}} - 1 \tag{3-112}$$

where T_{cold} is usually room temperature (290 K). This ENR number is about 15 dB for noise sources with a 15-dB pad and 5 dB for noise sources with a 25-dB pad. Since both gain and noise were stored in the initial calibration, a noise/gain sweep can be performed.

For frequencies above 1800 MHz, we can extend the range with the help of the external signal generators, as shown in Figure 3-28. As shown, a filter ahead of the external mixer reduces the noise energy in the image band. If the DUT has a very broad frequency range

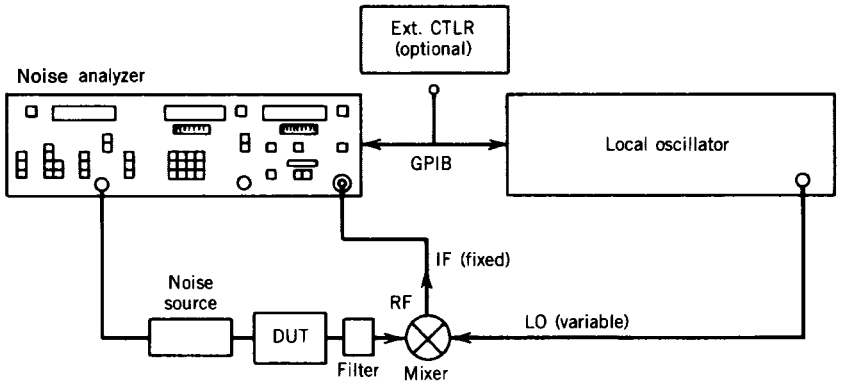

Figure 3-28 Single-sideband (SSB) noise figure measurements using an external mixer.

and has flat gain and noise over that range, a double-sideband (DSB) measurement is possible, with the image-rejection filter removed. However, a single-sideband (SSB) measurement is always more accurate [17].

How To Determine the Noise Parameters. The noise figure of a linear two-port network as a function of source admittance may be represented by

$$F = F_{\min} + \frac{R_n}{G_G}\left[(G_{0n} - G_G)^2 + (B_{0n} - B_G)^2\right] \tag{3-113}$$

where $G_G + jB_G$ = generator admittance presented to the input of the two-port
$G_{0n} + jB_{0n}$ = generator admittance at which optimum noise figure occurs
R_n = empirical constant relating sensitivity of the noise figure to generator admittance, with dimensions of resistance

It may be noted that for an arbitrary noise figure measurement with a known generator admittance, Eq. (3-113) has four unknowns—$F_{\min}$, R_n, G_{0n}, and B_{0n}. By choosing four known values of generator admittance, a set of four linear equations is formed and solutions of the four unknowns can be found [18, 19]. Eq. (3-113) may be transformed to

$$F = F_{\min} + \frac{R_n|Y_{0n}|^2}{G_G} - 2R_nG_{0n} + \frac{R_n|Y_G|^2}{G_G} - 2R_nB_{0n}\frac{B_G}{G_G} \tag{3-114}$$

or

$$F = F_{\min} + \frac{R_n}{G_G}|Y_G - Y_{0n}|^2 \tag{3-115}$$

Let

$$X_1 = F_{\min} - 2R_nG_{0n}$$

$$X_2 = R_n|Y_{0n}|^2$$

$$X_3 = R_n$$

$$X_4 = R_nB_{0n}$$

Then the generalized equation may be written

$$F_i = X_1 + \frac{1}{G_{si}}X_2 + \frac{|Y_{si}|^2}{G_{si}}X_3 - 2\frac{G_{si}}{B_{si}}X_4 \tag{3-116}$$

or, in matrix form,

$$[F] = [A]\,[X] \tag{3-117}$$

and the solution becomes

$$[X] = [A]^{-1}\,[F] \tag{3-118}$$

These parameters completely characterize the noise behavior of the linear two-port network. Direct measurement of these noise parameters by this method would be possible only if the receiver on the output of the two-port were noiseless and insensitive to its input admittance. In actual practice, the receiver itself behaves as a noisy two-port network and can be characterized in the same manner. What is actually being measured is the system noise figure of the two-port and the receiver. Thus, it becomes apparent that to do a complete two-port noise characterization, the gain of the two-port must be measured [20]. In addition, any losses in the input-matching networks must be carefully accounted for, because they add directly to the measured noise figure reading [21].

3-1-4 Linearity

Consistent with the elaborate discussion of linearity questions above, here is a quick refresher on what must be considered in amplifiers.

Dynamic Range, Compression, and IMD. An amplifier's dynamic range is related to the minimum discernible signal and the 1-dB compression point according to the equation

$$DR_n = \frac{(n-1)(IP_{n(\text{in})} - MDS)}{n} \tag{3-119}$$

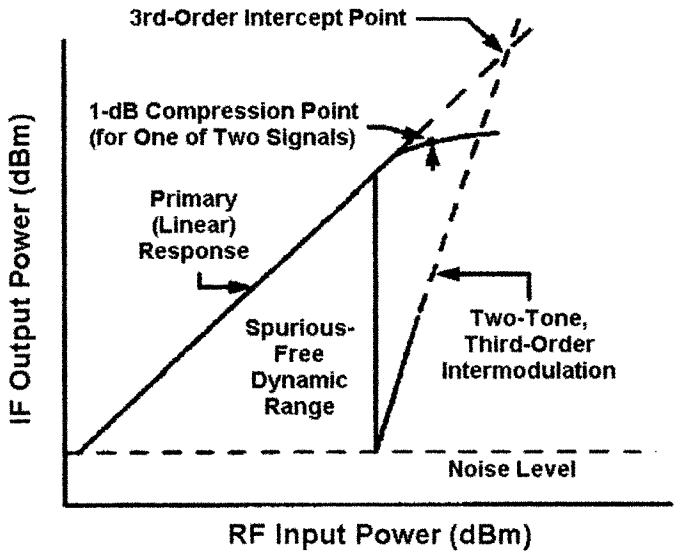

Figure 3-29 Amplifier linearity evaluation, including compression and two-tone IMD dynamic range. $P_{-1\text{dB}}$ for a single-tone cannot be read directly from this graph because the values shown are the result of two equal-power tones.

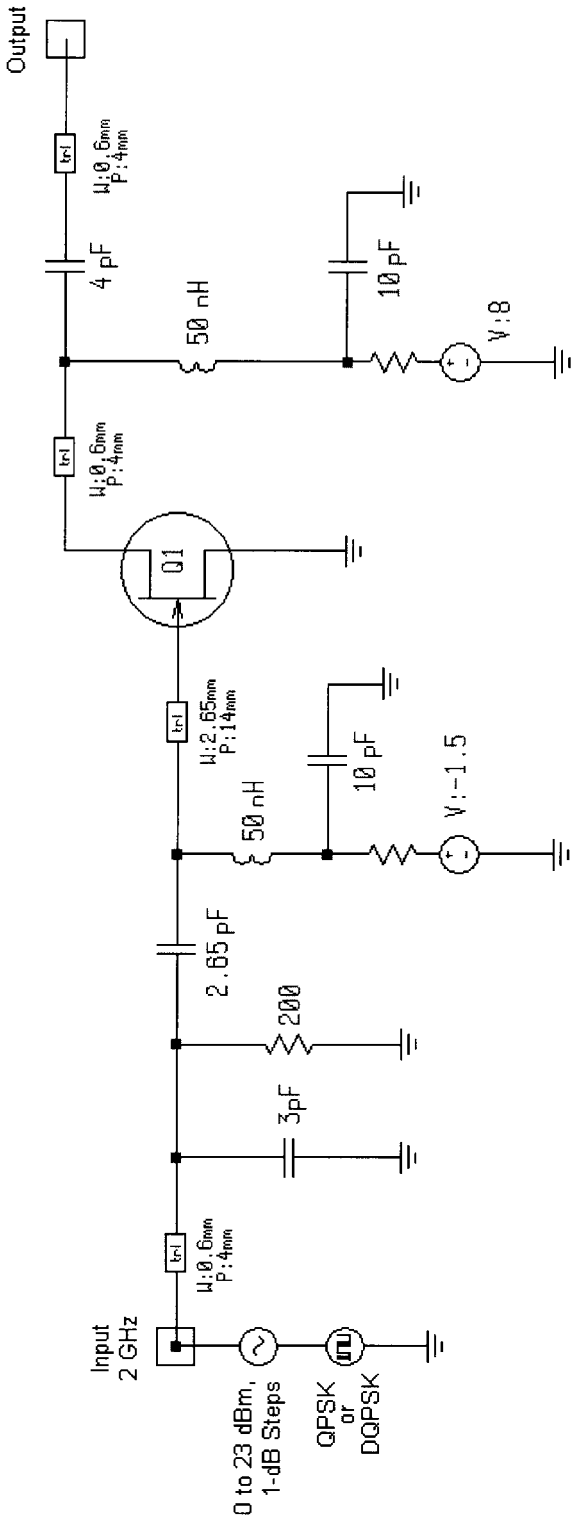

Figure 3-30 The power amplifier schematic.

where DR is the dynamic range in decibels, n is the order, $IP_{(in)}$ is the input intercept power in dBm, and MDS is the minimum detectable signal power in dBm. Once the 1-dB compression point is known, it is a fair assumption that the third-order intercept point, expressed in dBm, is 10 dB above this.

The intermodulation distortion gives the quality of an amplifier to withstand multiple signals without generating large intermodulation products or when using amplitude-modulated signals (cross-modulation). Figure 3-29 provides a quick reminder of IMD issues.

In some amplifiers, we would like to have control over the gain. While the better way to control gain while obtaining high linearity is a PIN-diode attenuator, special AGC circuits have become part of the amplifiers. Figure 3-48 shows a circuit of the SL610, made by Plessey, which has an AGC input provision. The noise figure of the PIN-diode attenuator is essentially equal to its attenuation. The AGC in multistage amplifiers is distributed over several stages and there is a lesser correlation between noise and AGC than in purely passive attenuators.

Special Case of Linearity Requirements for Digital Modulation. For cellular telephone systems we use digital modulation formats, such as QPSK and π/4-DQPSK, that combine phase and amplitude modulation. Amplifiers handling such signals must be carefully characterized and designed if adequate amplitude and phase linearity are to be maintained.

Examples of Power Amplifiers: Looking into the Effects of Distortion. This example presents modulation analysis using QPSK in a 2-GHz power amplifier (Figure 3-30). The simple amplifier was designed using the electronic Smith Tool of Serenade to determine the matching network for a narrowband design. The example demonstrates setup of modulation analysis and available results.

Siemens among others provides integrated amplifiers based on the concept depicted in Figure 3-30, the most popular ones being the CGY96 and CGY94. For the purpose of measurements, these amplifiers were actually put on a breadboard. Figure 3-31 shows the big brother, the CGY96. It is a GaAs MMIC intended as a power amplifier for GSM Class 4 phones with 3.2 W (35 dBm) at 3.5 V at an overall power added efficiency of 50%. Table 3-5 shows its electrical characteristics.

For the purpose of our experiments, we considered the CGY94 because it requires less external peripheral circuits. Table 3-6 shows its electrical characteristics. For those of us interested in seeing part of the internal circuit, Figure 3-32 shows the chip. This two-stage amplifier uses an interesting internal feedback scheme. Its schematic is shown in Figure 3-33.

For the purpose of looking at the waveforms, we will continue with the single-stage amplifier (Figure 3-30) and then compare the measured versus predicted performance of this CGY94-based amplifier.

A modulation source is connected to the RF source at the input port of the amplifier. The RF source specifies the carrier power (or voltage or current) and the modulation source specifies the modulation format and properties of the modulated signal.

A brief review of the modulation source used in this example indicates the following properties:

Property	Value	Description
NB	128	Number of bits
BR	1.2288E6	Bit rate
N	8	Number of samples per bit
BW1	590.E3	One-sided bandwidth of the main channel in the PIB or P1IB calculation
FS1	740.E3	Start baseband frequency of the fist adjacent channel
BW2	590.E3	One-sided bandwidth of the main channel in the P2IB calculation
FS2	1990.E3	Start baseband frequency of the second adjacent channel
BW3	590.E3	One-sided bandwidth of the main channel in the P3IB calculation
FS3	3240.E3	Start baseband frequency of the third adjacent channel
M	4	Order of the signal space; M = 4 is QPSK
DLY	0.0	Fractional bit delay
IASC	1.0	I channel amplitude scale; multiplier for the I waveform to model amplitude imbalance
QASC	1.0	Q channel amplitude scale; multiplier for the Q waveform to model amplitude imbalance
LPF	3	Baseband low-pass filter; 3 = root-raised cosine filter
LPFC	665.E3	–3 dB cutoff frequency of LPF
LPFN	3	Number of resonators if LPF = 1
LPFR	0.35	Roll-off factor if LPF = 3 or LPF = 4
FILE	N/A	File name of user-defined modulated signal file

The modulation source is a QPSK stream with a bit rate of 1.2288 Mbps. A total of 128 bits will be analyzed, and each bit is sampled eight times to construct an accurate analog waveform. The BW and FS parameters are defined here to specify the main (in-band) channel and adjacent channel for ACPR calculations. Imbalance of the I and Q amplitudes and phases can be described by the IASC, QASC, and DLY parameters, if desired. The modulation signal

is often filtered, and several types of filters are available. Here a root-raised cosine filter is used with a cutoff frequency of 665 kHz and a roll-off factor of 0.35.

Analysis. Figure 3-34 shows the compression characteristics of the amplifier as the available RF source power (a sinusoid) is swept. Note that P_{-1dB} is 11.5 dBm referred to the input and 28.5 dBm referred to the output. We will look at modulation characteristics in the linear region of operation at a source power of 0 dBm, and the nonlinear region at a source power of 20 dBm.

Next, we will view the voltage across the transistor to examine its behavior under compression. Figure 3-35 shows the drain–source voltage of the FET as the source power is swept. It is clear from this graph that clipping due to pinchoff and forward-gate conduction

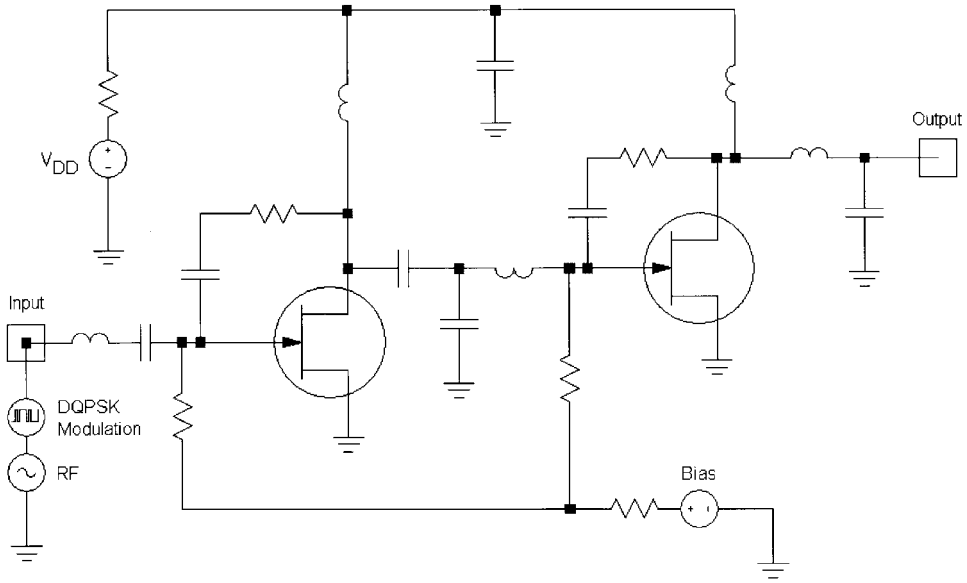

Figure 3-33 Schematic of the CGY94 GaAs MMIC power amplifier.

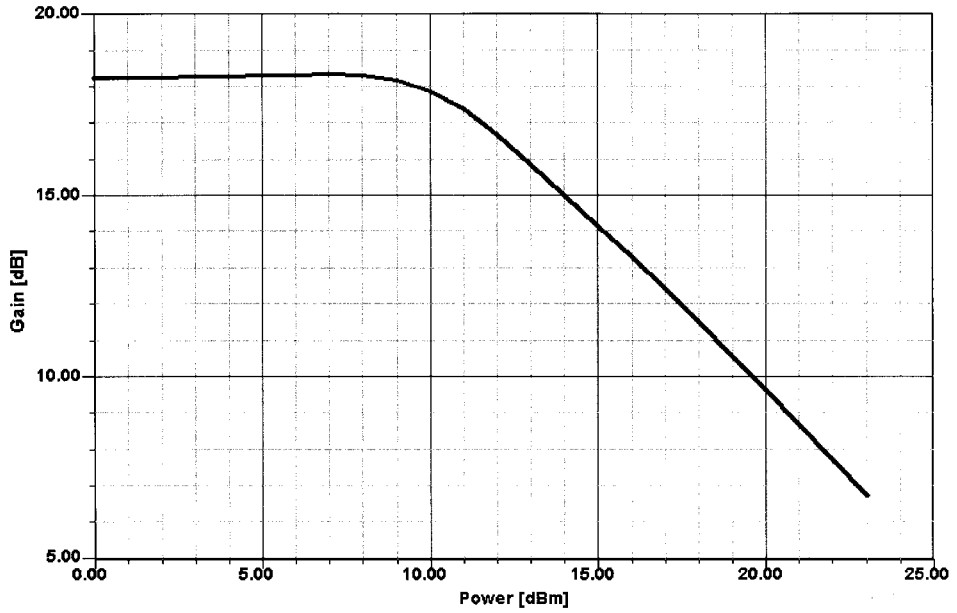

Figure 3-34 Single-tone RF power sweep analysis of the FET amplifier.

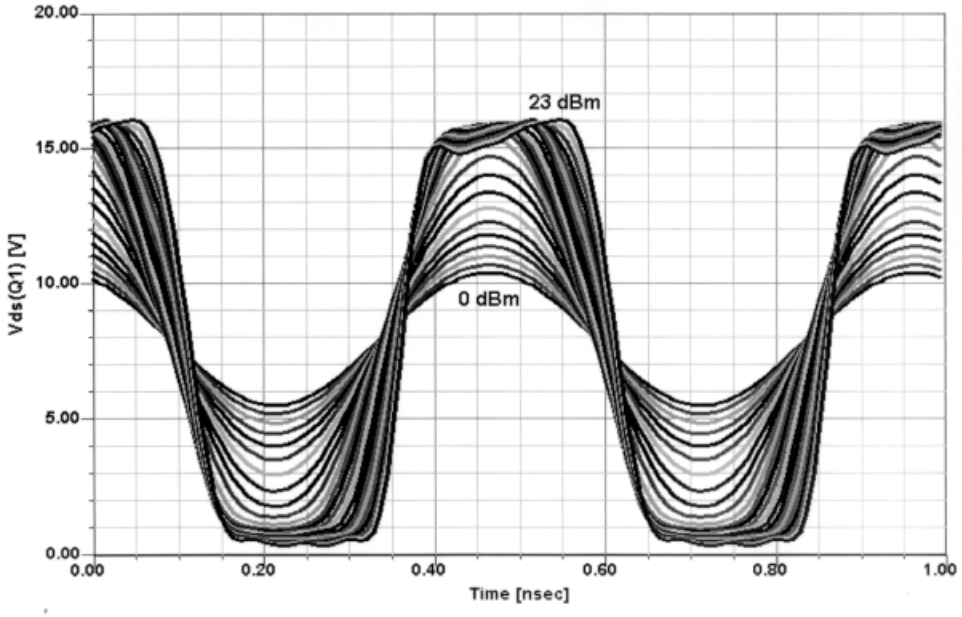

Figure 3-35 V_{DS} of the FET versus RF source power.

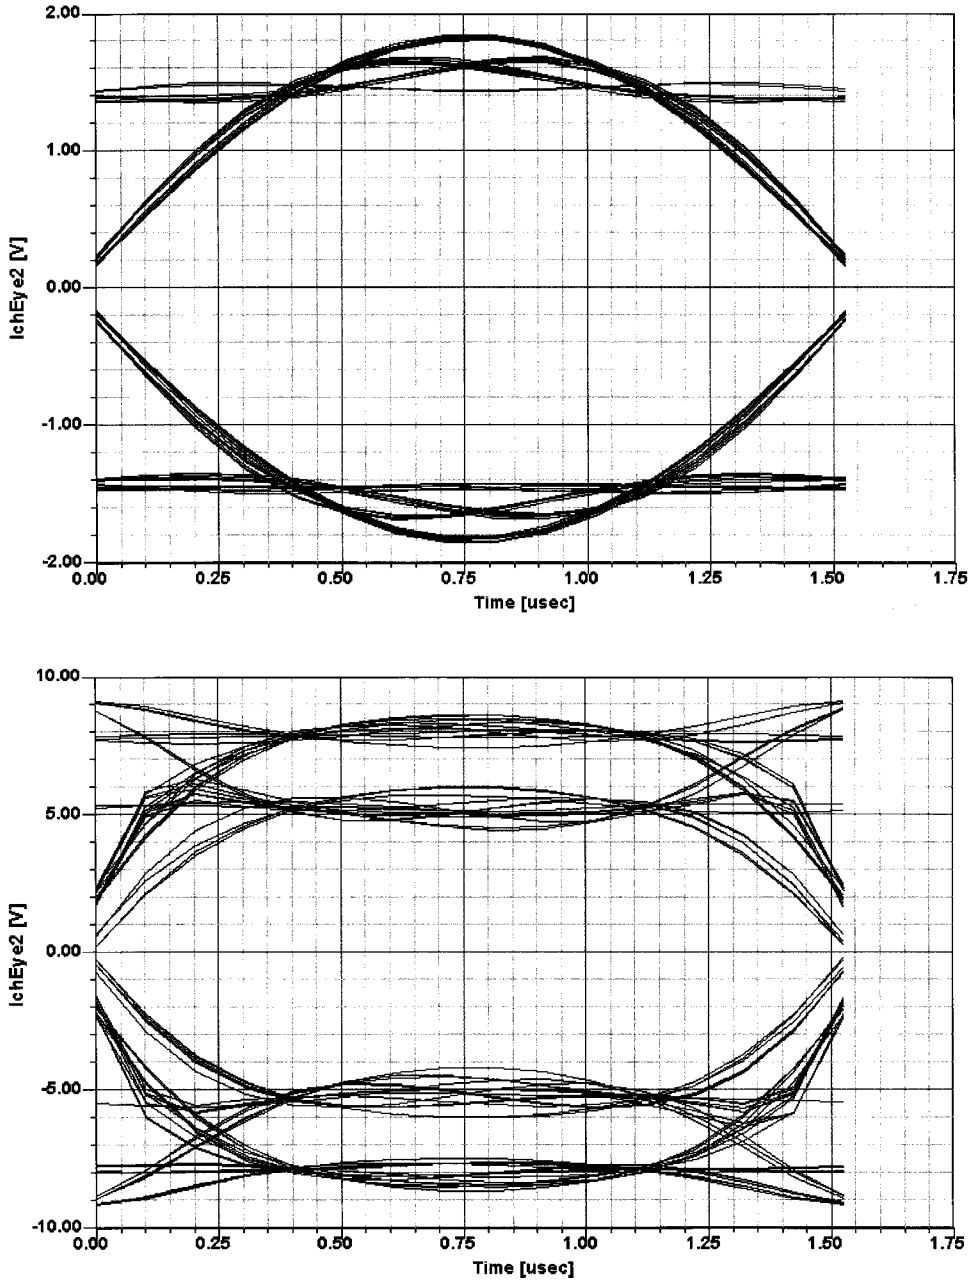

Figure 3-36 Eye diagrams of the I channel for source powers of (a) 0 dBm and (b) 20 dBm.

is limiting the performance of the device. A phase shift of the voltage waveform as power is increased is also apparent. The combination of the power compression and phase shift, or AM to PM conversion, will be used in the modulation analysis to determine the overall distortion of the modulated signal.

The output available from modulation analysis includes:

- I and Q channel waveforms
- Eye and constellation diagrams
- Spectral plots
- ACPR, in-band, and adjacent power

Figure 3-36 shows the eye diagrams for the 128-bit QPSK signal at two RF source powers, 0 and 20 dBm. Operating linearly at 0 dBm input, the amplifier doesn't distort the eye and it remains wide open. Note that in this example the filter bandwidth doesn't produce any intersymbol interference, as evidenced by the open eye. At an input power of 20 dBm, the amplifier compresses the signal, and distortion in the eye is evident.

We can also view the modulation spectrum at these two power levels to investigate the intermodulation distortion and spectral regrowth that takes place. Figure 3-37 shows the spectral plots. The lower trace corresponds to 0 dBm source power and shows almost no regrowth, while the upper trace at 20 dBm source power shows considerable regrowth.

The uncorrupted modulation source can also be shown. This corresponds to the source as a pure voltage without any circuit influence.

Now we evaluate the CGY94 board in a similar fashion. Figure 3-38 shows the waveform used for CAD purposes. Needless to say, such a signal cannot be produced by any signal

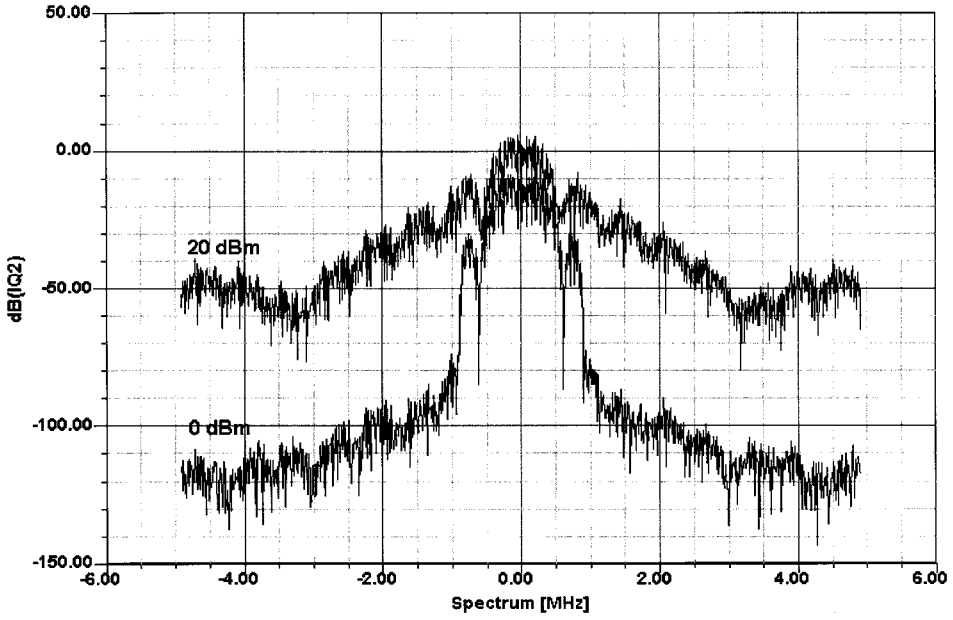

Figure 3-37 Spectrum of the modulation signal at the amplifier output. Source powers are 0 and 20 dBm.

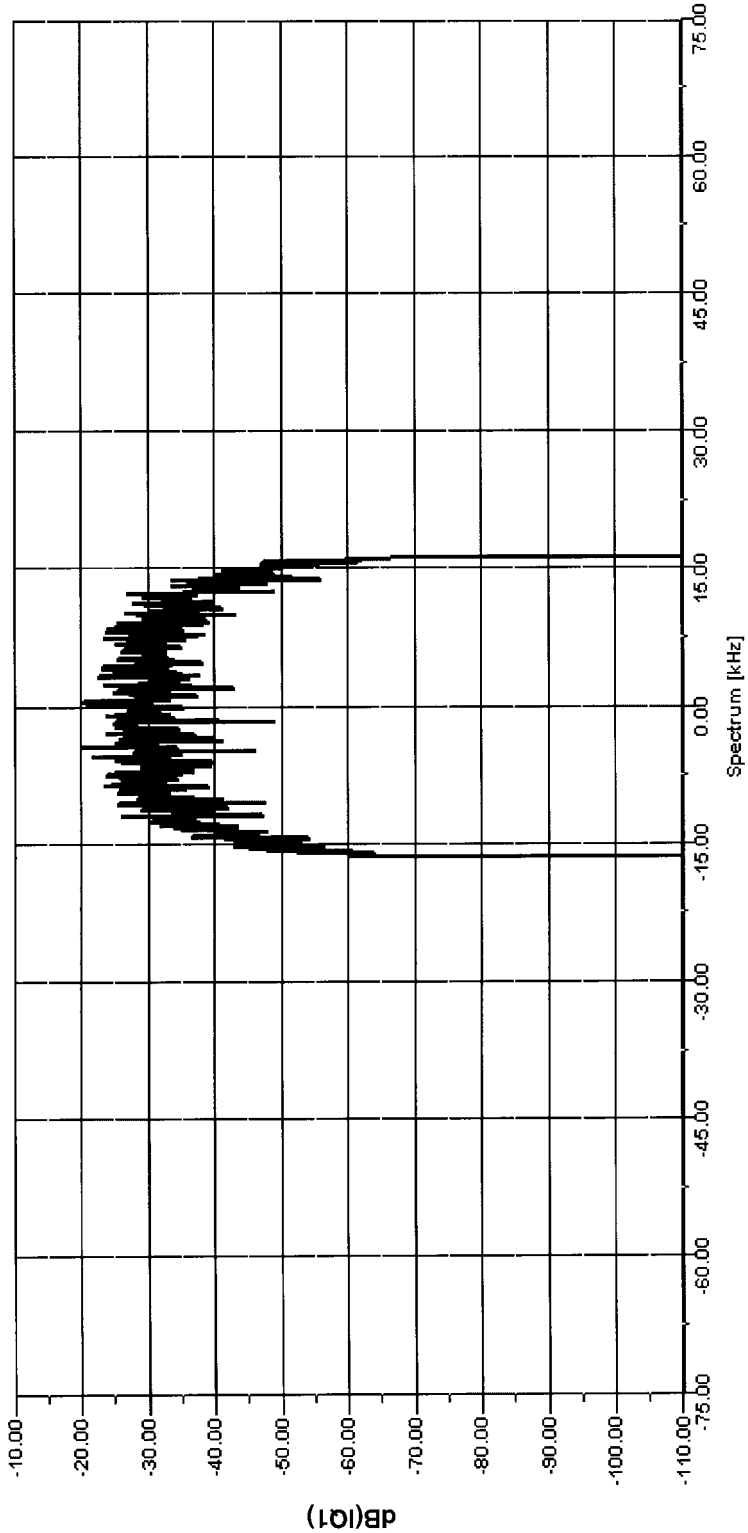

Figure 3-38 Simulated signal used for CAD analysis of the CGY94 amplifier.

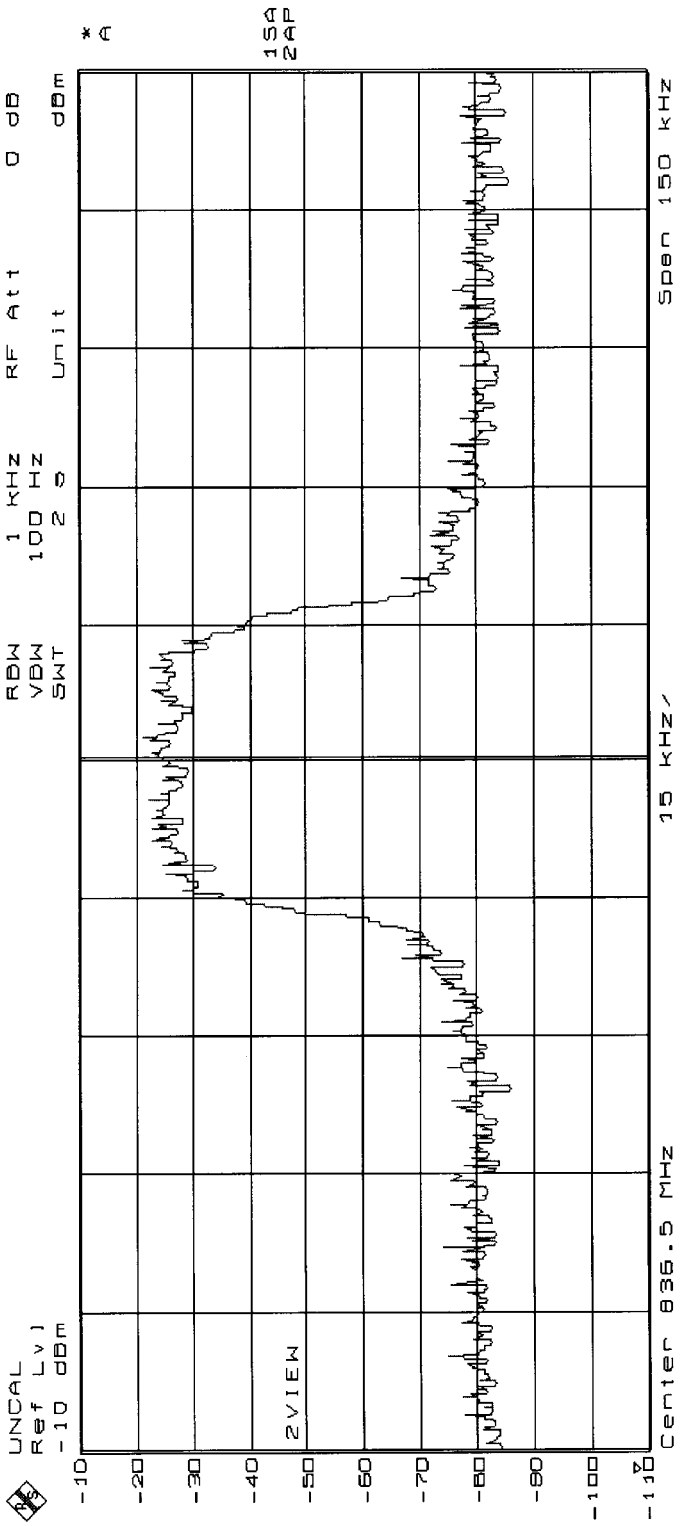

Figure 3-39 Real signal used for testing the actual amplifier.

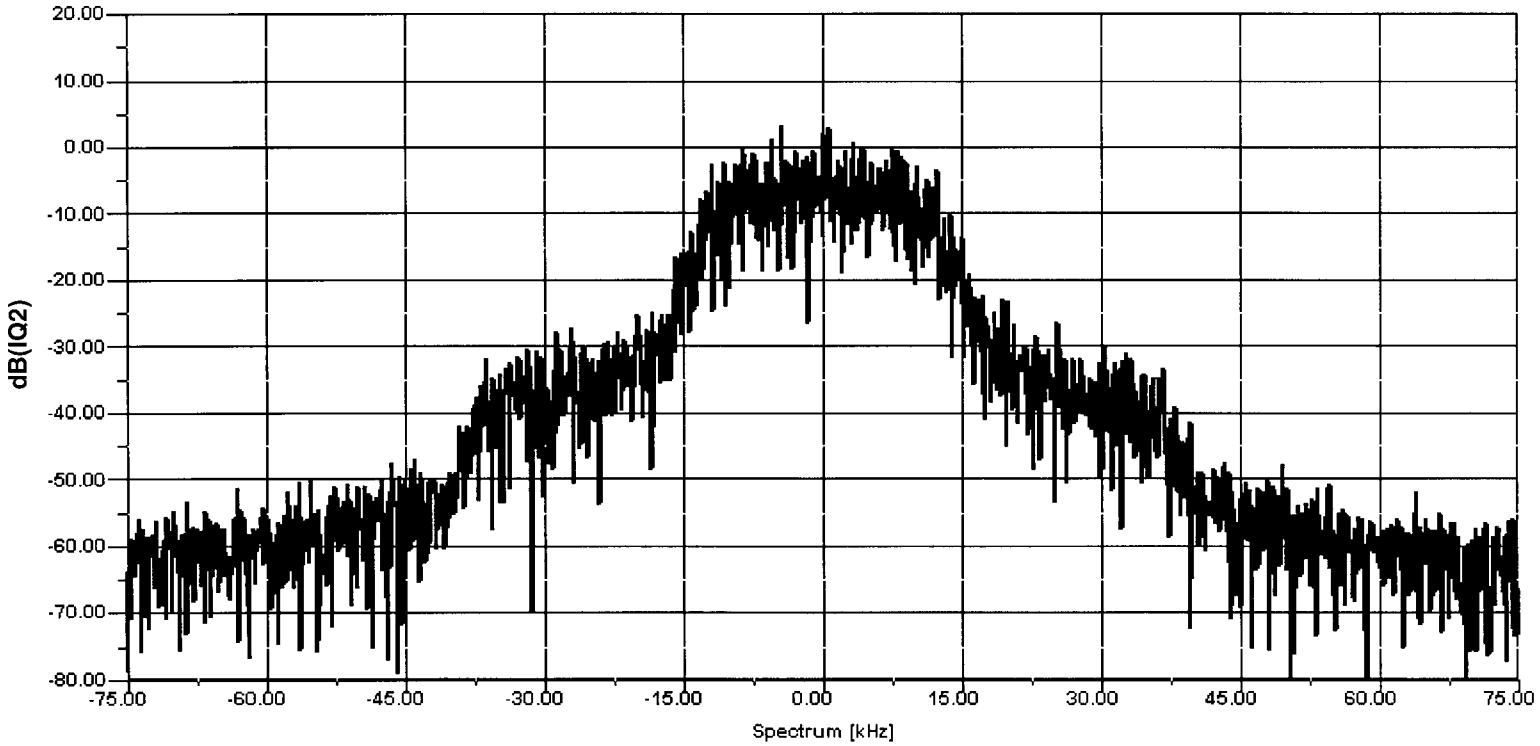

Figure 3-40 Spectral regrowth predicted by the simulation.

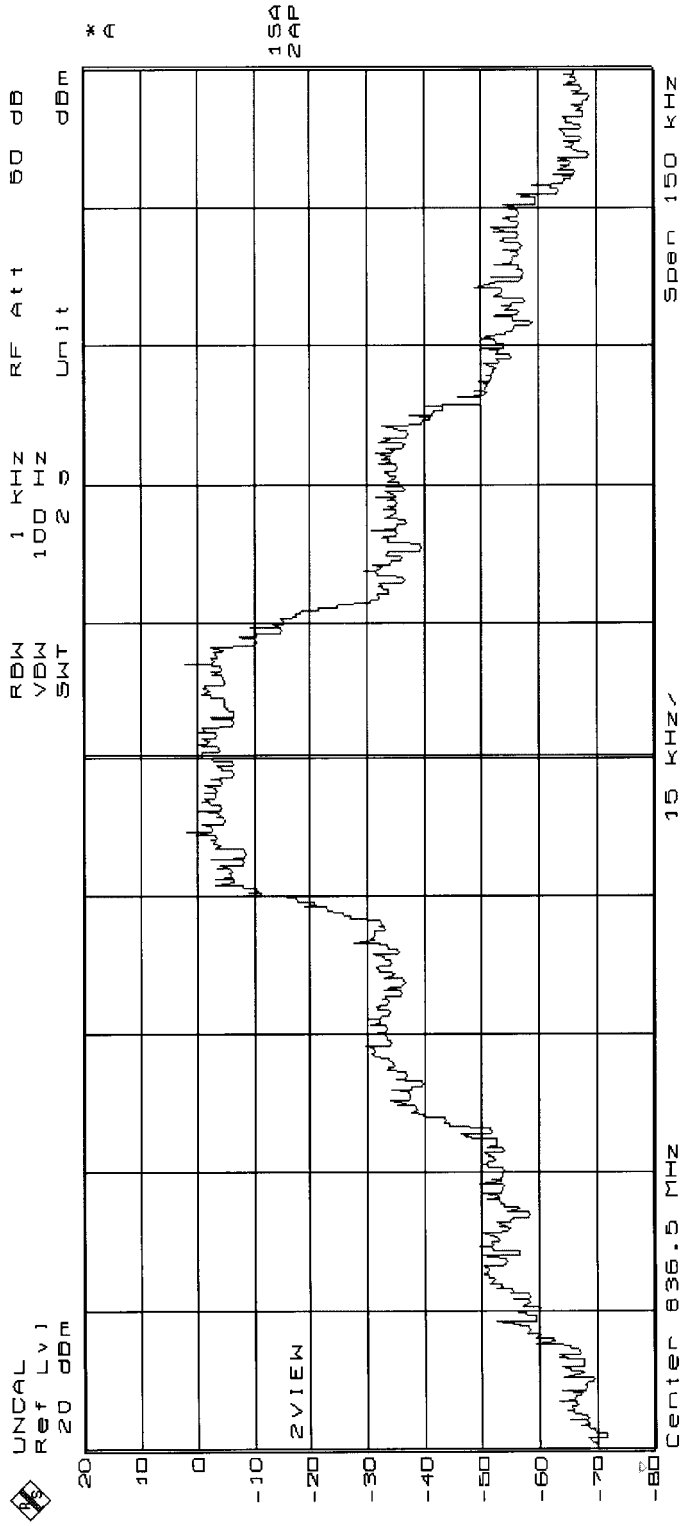

Figure 3-41 Measured spectral regrowth of the CGY94 amplifier.

generator. The one generated by an actual signal generator is shown in Figure 3-39. The wideband noise is around –80 dBm and the input level is about –25 dBm, consistent with the simulation signal. Looking at the output, Figure 3-40 shows the simulated signal with the expected increase in bandwidth. This is due to the nonlinearity of the amplifier and is consistent with Figure 3-37 for the single-stage amplifier. The actual measured output for the CGY94 shown in Figure 3-41 is quite close to its simulated output, indicating that the mathematical approach used for simulating is correct. This is only one example; in reality, many more waveforms can be analyzed and predicted using this method. Figure 3-41 shows essentially three distinct steps, which are sufficiently close to the response shown in the simulation. A dynamic range of 70 dB, while displayed in Figures 3-40 and 3-41, is not really necessary for good-quality transmission, and the discrepancy between the two pictures is in part due to the limited modeling quality of the active device as provided by the company that did the parameter extraction for this transistor.

Another useful view to aid in the understanding of the compression and distortion within the amplifier is to look at the magnitude of the complex waveform. Since the signal is composed of the in-phase and quadrature-phase components it is represented as

$$s(t) = i(t) + j \cdot q(t) \tag{3-120}$$

The time-domain magnitude is written

$$|s(t)| = \sqrt{i(t)^2 + q(t)^2} \tag{3-121}$$

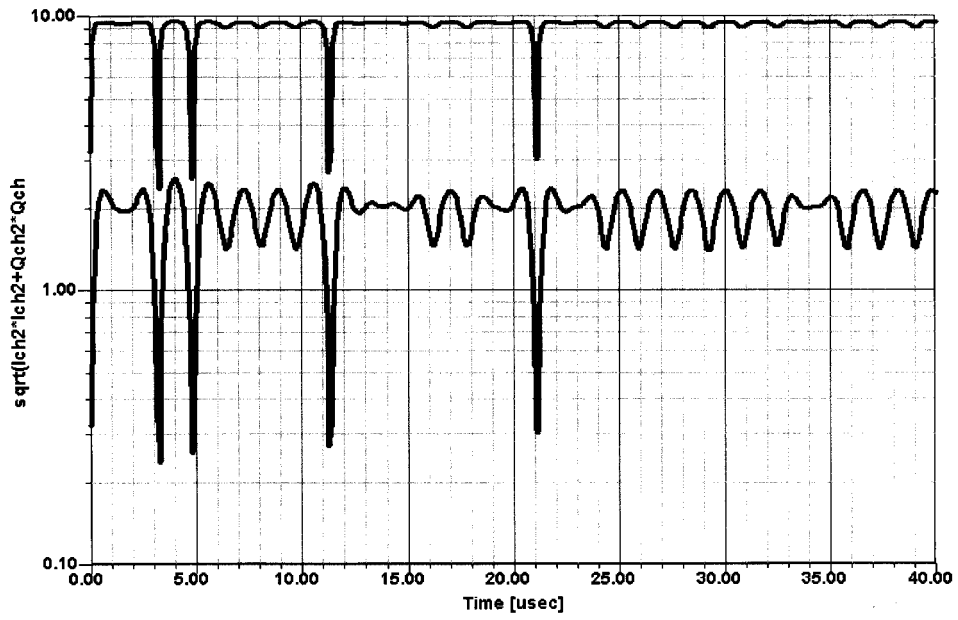

Figure 3-42 Time-domain magnitude of the complex modulation signal at source powers of 0 and 20 dBm.

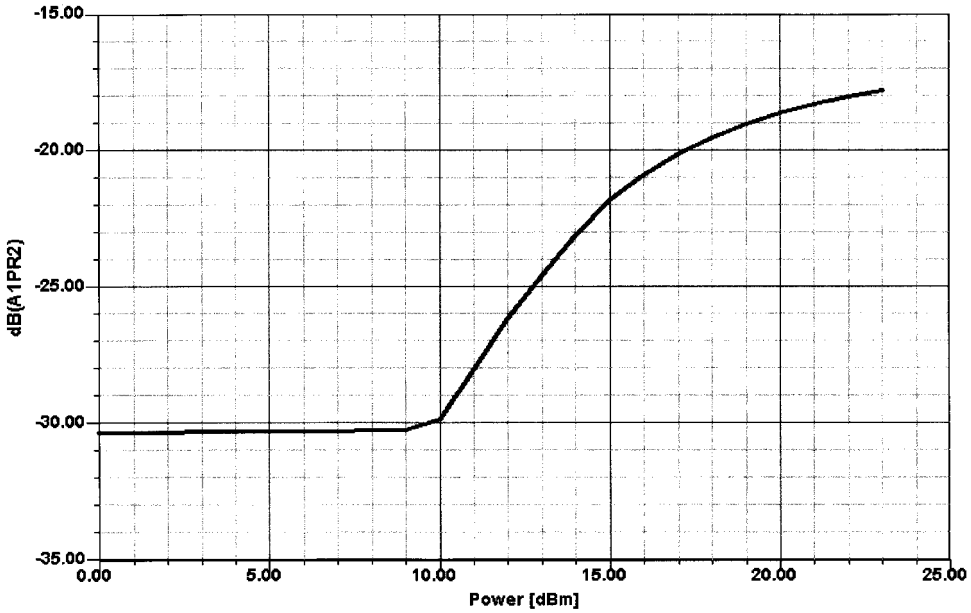

Figure 3-43 Adjacent-channel power ratio as function of RF source power.

Figure 3-42 shows the magnitude at source powers of 0 and 20 dBm. The *X* axis has been rescaled to 40 μs for improved viewing. Note the significant compression of the 20-dBm waveform at the higher signal levels. It is clear from this view that the signal is severely distorted.

We can also compute the adjacent-channel power ratio (ACPR) against the RF power sweep. ACPR is the ratio of the adjacent-channel power to the in-band channel power. The bandwidth (BW) and adjacent-channel start frequency (FS) are used for this calculation. For accurate ACPR calculation, a large number of bits are needed. This example uses 128 bits so the computation time is short, but 512 or more bits should be used for a more accurate computation.

Figure 3-43 shows the ACPR as a function of RF source power. The ACPR is nearly constant (and nonzero due to the gradual skirt of the baseband filter and inherent spillover to the adjacent channel) up to the P_{-1dB} compression point . As the intermodulation products spill into the adjacent channel and spectral regrowth occurs, the ACPR degrades.

π/4-DQPSK Circuit Analysis. Next, we will examine the same amplifier using a π/4-DQPSK modulation source. The task is identical to the previous one except for the source and the number of bits. The number of bits for this project has been increased from 128 to 256. Figure 3-44 shows the eye diagrams from this modulation format, at source powers of 0 and 20 dBm. The distortion and related intersymbol interference are clearly evident.

The constellation plot at 0 dBm is shown in Figure 3-45.

It may be interesting to take a look at the different waveforms currently in use. Figure 3-46 shows a spectrum analyzer picture of the most popular ones.

For reasons of time-division management, the European standard, GSM, which is now offered by Omnipoint at the 1.8-GHz band in the United States, uses gating to reduce the actual bandwidth of the spectrum. Figure 3-47 compares the GSM signal with and without gating.

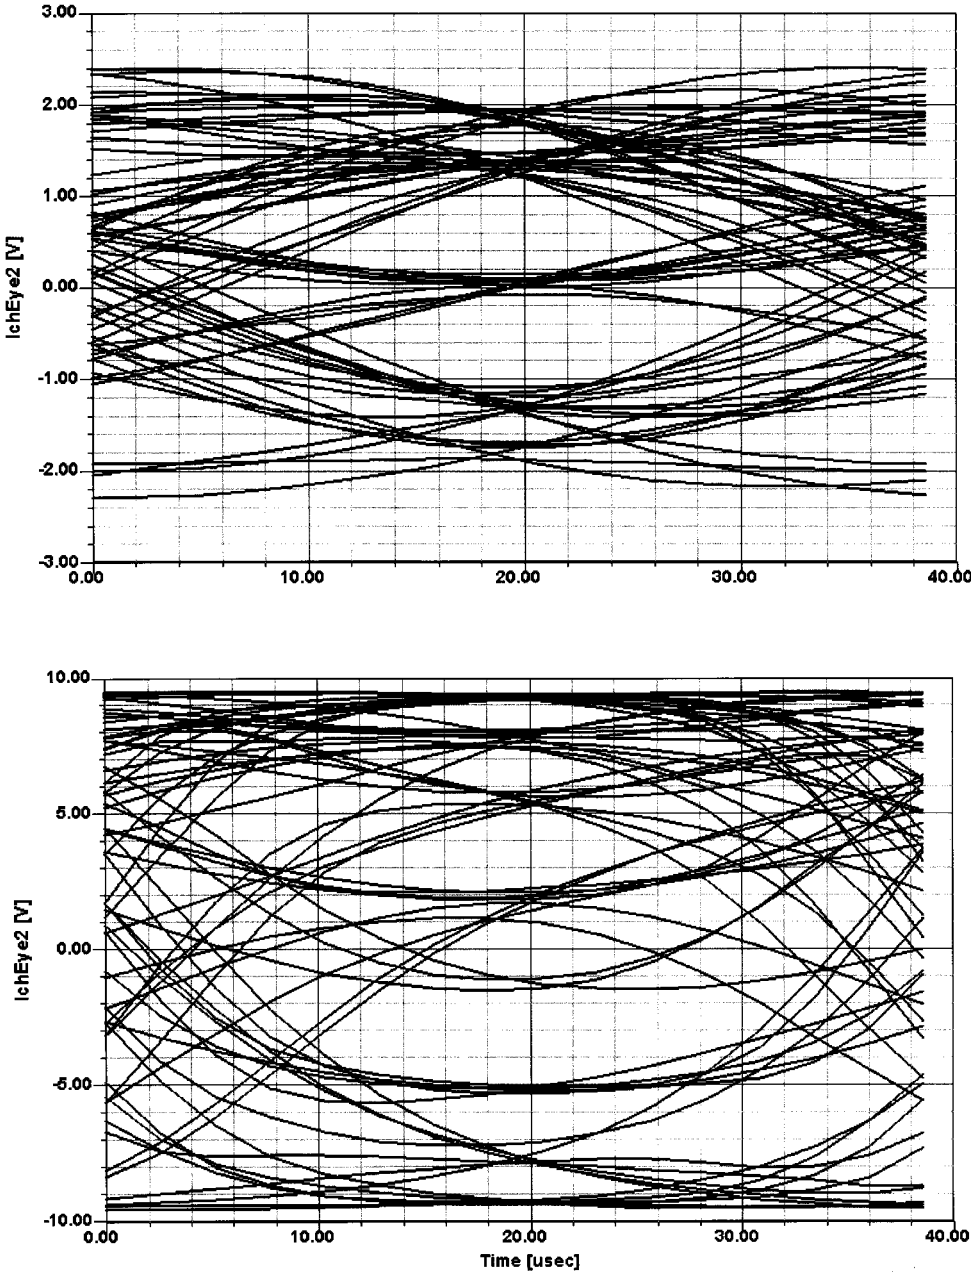

Figure 3-44 Eye diagrams for $\pi/4$-DQPSK at source powers of (a) 0 dBm and (b) 20 dBm. The distortion and related intersymbol interference are clearly visible.

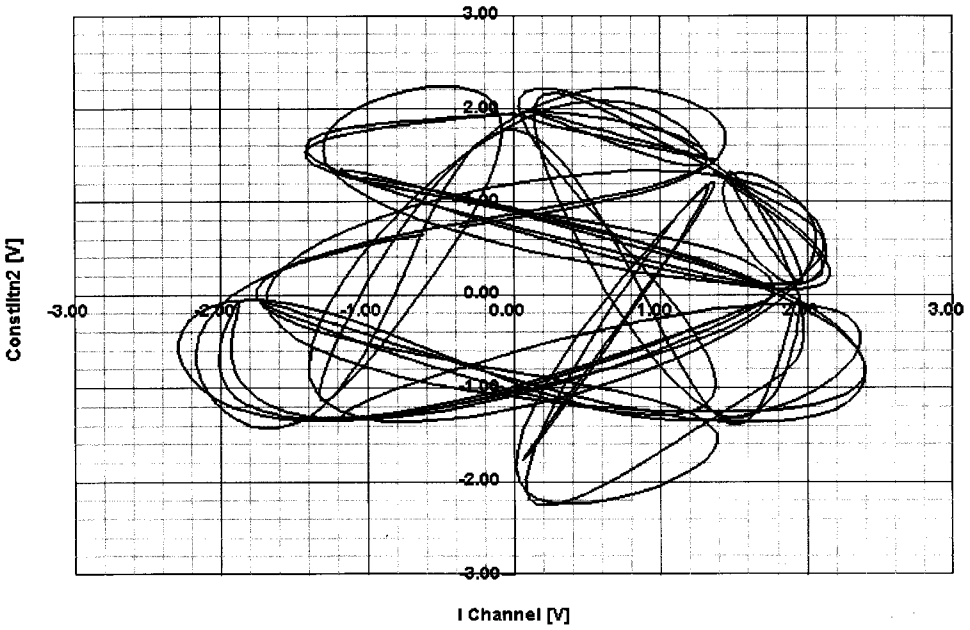

Figure 3-45 Constellation diagram for π/4-DQPSK at Port 2 and 0-dBm source power.

3-1-5 AGC

Many wireless systems consist of an up conversion or down conversion using an intermediate frequency, typically 10% or less of the receiving frequency (the FM broadcast IF has been set at 10.7 MHz for the same reason).

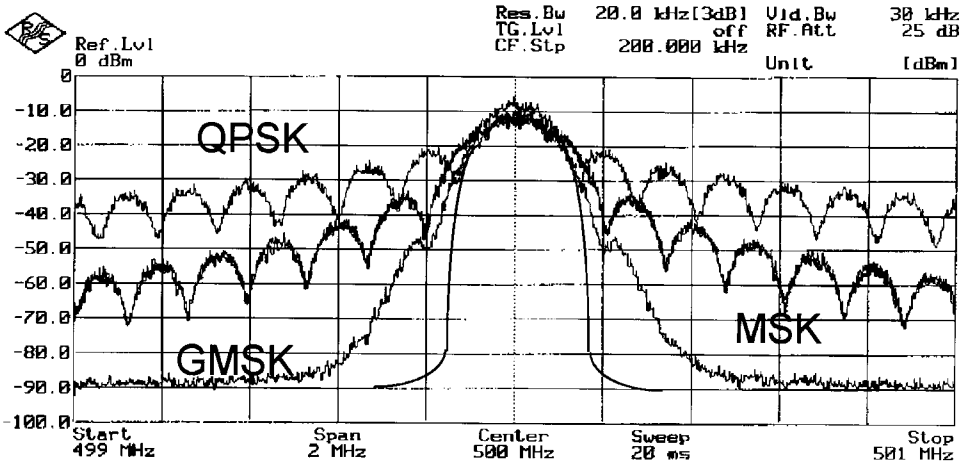

Figure 3-46 Spectrogram showing the characteristics of MSK, GMSK, and QPSK.

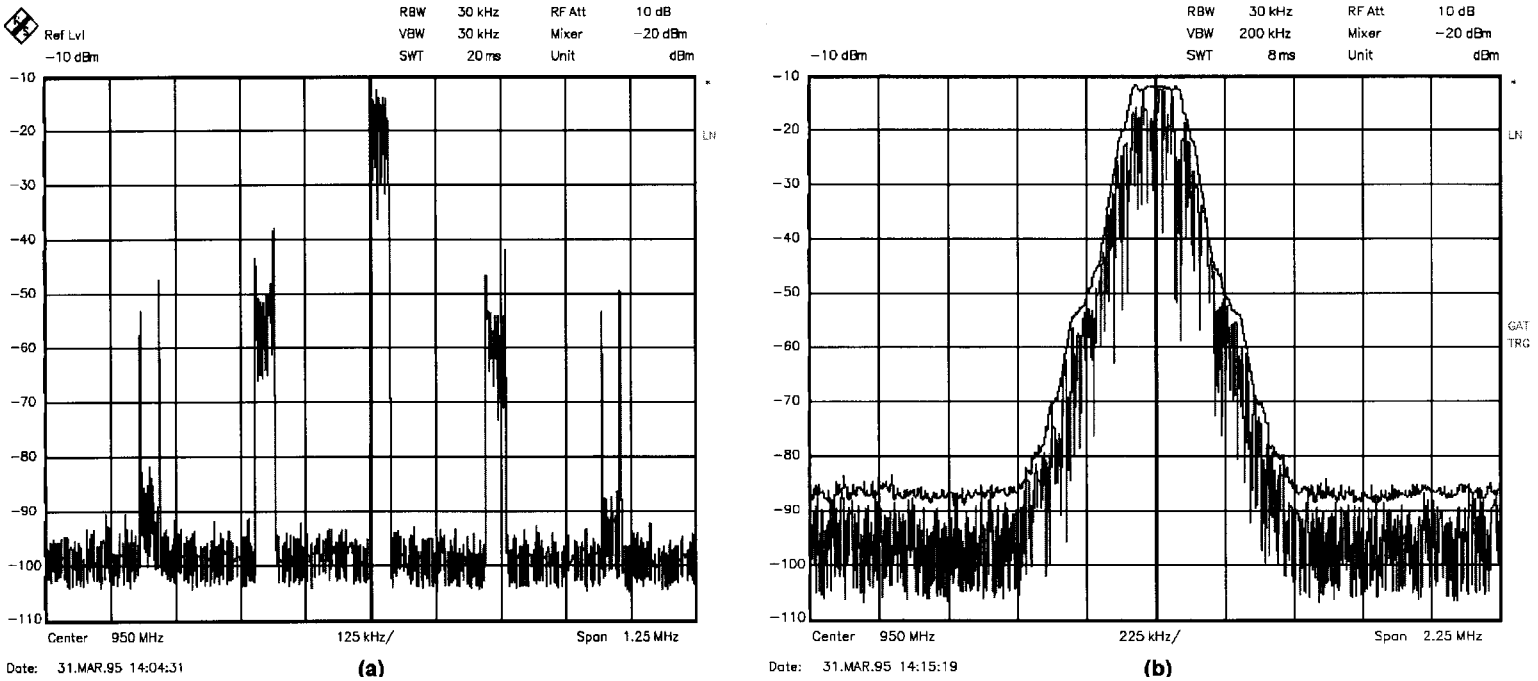

Figure 3-47 Pulsed GSM signal (a) without gating and (b) with gating.

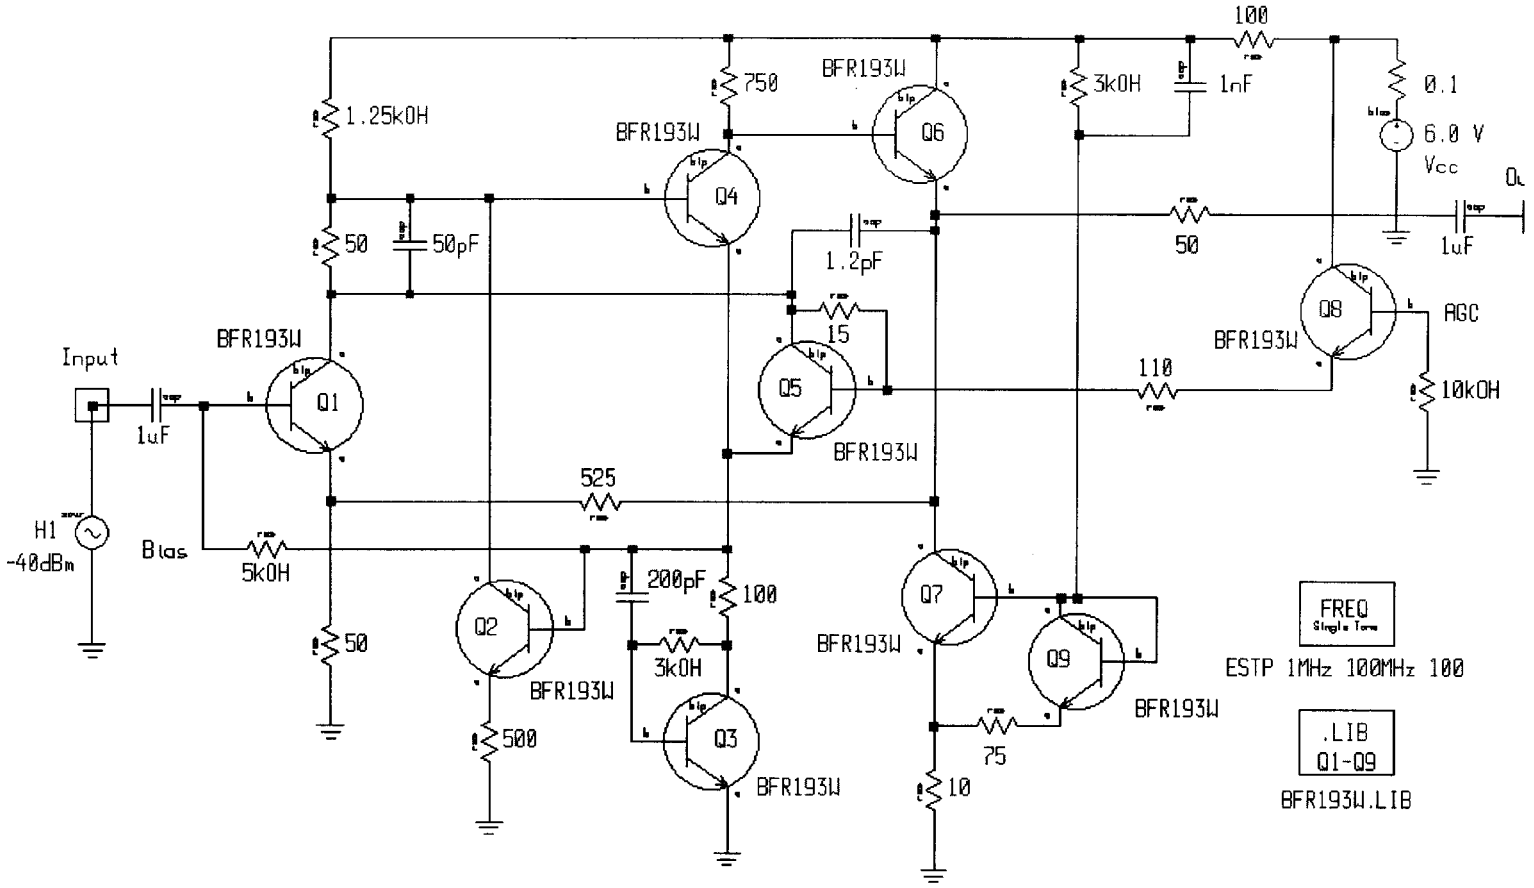

Figure 3-48 Schematic of the Plessey SL610 wideband amplifier with AGC. The 75-Ω resistor in the emitter of Q9 had to be added to obtain the appropriate dc current.

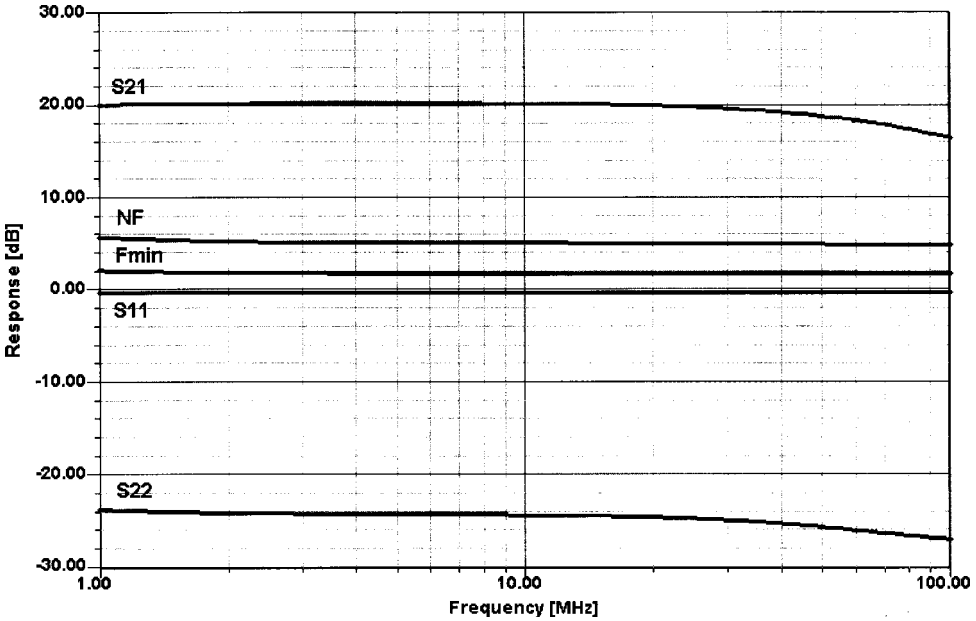

Figure 3-49 Simulated frequency response of the Plessey SL610 wideband amplifier IC with AGC = 0 V.

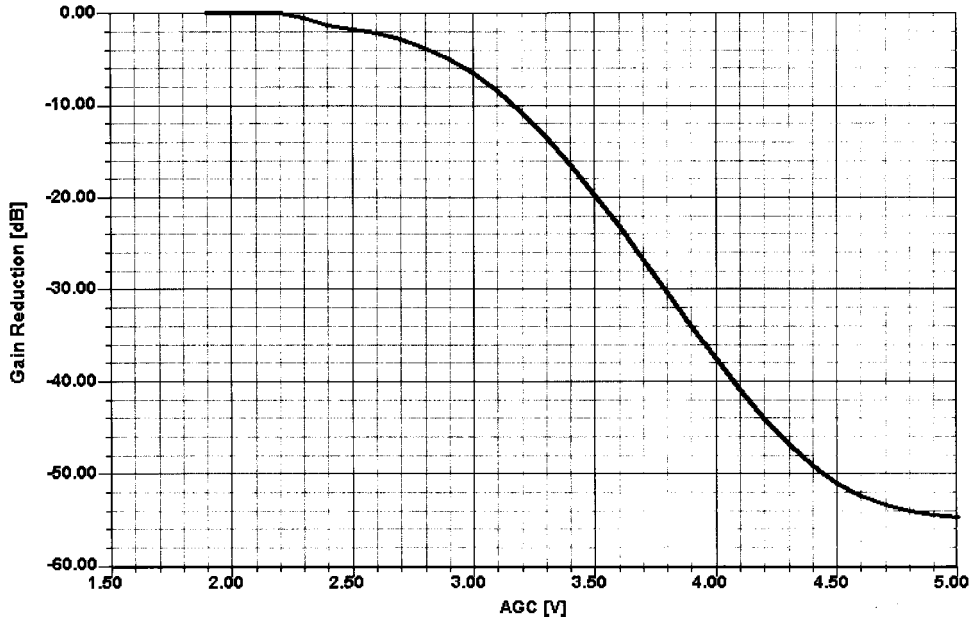

Figure 3-50 Simulated gain reduction versus AGC of the Plessey SL610 wideband amplifier IC.

Table 3-7 CGY121A features

- Variable gain amplifier (MMIC amplifier) for mobile communication
- Typical gain control range over 50 dB
- Positive control voltage
- 50-Ω input and output matched
- Low power consumption
- Operating voltage range: 2.7–6 V
- Frequency range 800 MHz to 2.5 GHz

We therefore will show two amplifiers with AGC and available data. The first one is a wideband amplifier type SL610, which has been manufactured by Plessey; its current fate is unknown. However, since we put the circuit into the simulator it provides significant insight into the operation of such AGC stages. Figure 3-48 shows the actual schematic of the SL610 entered in Ansoft's Serenade Design Environment for simulation.

The AGC action is derived from Q8 through Q5, which, together with Q4, forms a differential amplifier. Each consecutive stage (Q1, Q4, Q6) has increasing current, totaling about 20 mA; the last transistor takes about 13 mA. Based on the feedback surrounding the transistors, the actual transistor characteristics are less important. We have shown this by putting much higher f_T devices into the circuit than were available for the original design (20 years ago). The circuit is still interesting today because of its good large-signal-handling capability.

Table 3-8 CGY121A electrical characteristics at 900 MHz and 1.8 GHz

Characteristics	Symbol	Minimum	Typical	Maximum	Unit
(T_A 25 °C, f = 900 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	17	19	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	11	—	dB

Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm
(T_A 25 °C, f = 1800 MHz, V_g = –4 V, $RS = RL$ = 50 Ω unless otherwise specified)					
Power gain V_d = 3 V; I = 45 mA; V_{con} = 3 V	G	15.5	17.5	—	dB
Input return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{in}	—	10	—	dB
Output return loss V_d = 3 V; I = 45 mA; V_{con} = 3 V	RL_{out}	—	8.5	—	dB
Gain control range V_{con} = 3 V ... 0 V; V_d = 3 V; I = 45 mA	dG	48	53	—	dB
1-dB gain compression V_d = 3 V; I = 45 mA; V_{con} = 3 V	P_{1dB}	—	14	—	dBm

Figure 3-49 shows the amplifier's frequency response which is extremely close to the measured data. The good simulation also can be seen from comparing the published AGC curve with the one we found in the simulation. The bias of the first transistor remains essentially constant, resulting in a noise figure more independent of the AGC than the PIN-diode attenuator, and also stabilizes the input impedance as a function of AGC. Figure 3-50 shows the SL610's predicted AGC response.

The same requirement is applicable for the wireless frequency range. Tables 3-7 and 3-8 and Figures 3-51 through 3-54 present specifications for the recently introduced CGY121A GaAs MMIC by Infineon Technologies AG, formerly the Semiconductor Group part of Siemens AG.

3-1-6 Bias and Power Voltage and Current (Power Consumption)

Biasing of transistors operating in Class A or B follows some standard rules. The only deviation from this tends to be when the operating voltage is very low, below 3 V, because then the luxury of using voltage drops for good dc stability as a function of temperature disappears. (We will discuss low-voltage design in detail in Section 3-2-6.) In our simple example (Figure 3-55), we are operating from a 12-V power supply, and the first rule of thumb is to make sure that the voltage between the emitter and ground is at least 0.7 V. This is necessary to compensate the base–emitter junction threshold voltage, which decreases by about 2 mV/°C as the temperature increases. A larger voltage drop in the emitter–ground connection greatly reduces the influence. In this amplifier the emitter–ground path consists of an emitter unbypassed resistor of 10 Ω in series with a bypassed 501-Ω resistor, resulting in an overall voltage drop of 2.6. We could reduce the supply voltage by about 1.9 V at the collector side and still maintain a safety margin of 0.7 V at the emitter–ground connection. The current 2.6 V, so to speak, is overkill.

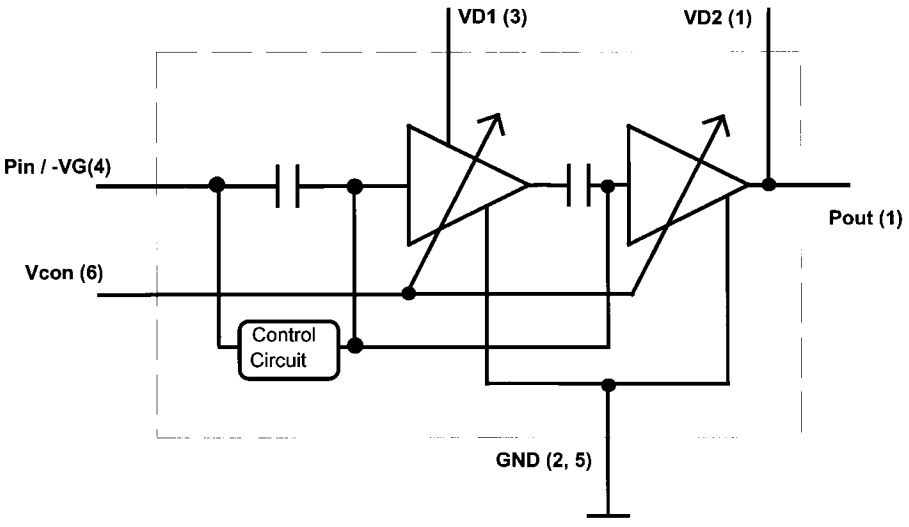

Figure 3-51 Functional block diagram of the gain-controllable CGY121A GaAs MMIC. Gain control is achieved by applying 0–3 V dc to the Vcon pin.

R3	6.8 Ω

Figure 3-52 CGY121A 900-MHz application circuit and parts list.

On the collector side, for an *RC* type of amplifier, it is not a bad idea to set the collector voltage at about half the supply, which allows the RF swing to be half the supply voltage. In this case, we have violated the rule because of our 2.6-V drop. Assuming we had chosen a 0.7-V drop, then the collector–emitter voltage would be 6.3 V available for the swing. The choice of 5 mA for the transistor has come from a combination of good linearity and low noise figure. While the 10-Ω unbypassed resistor will grade the noise figure somewhat, it reduces the emitter-current-dependent distortion. The base–emitter diffusion resistance equals 26 mV/5 mA, or roughly 5 Ω. The 10-Ω resistor is twofold larger and therefore adds to the linearity and to the noise.

To determine the base bias resistor it is a good assumption that the current going through the two resistors (in our case, 8.2 and 3.3 kΩ) is about 10% (or a slightly higher fraction) of

Figure 3-53 CGY121A 1.9-GHz application circuit and parts list.

the collector current. Since the dc current gain of the transistor is typically between 50 and 100, it is sufficient if the current through the resistive network is between 5 and 10 times higher than the dc bias current taken off the network. This type of bias scheme is only valid for Class A to AB_1. Later, we will see that for monolithic circuits, additional transistors will be used to generate the required voltage drops. Lately, combinations of *npn* and *pnp* transistors have become popular to avoid using any resistance in the emitter for dc biasing purposes. Figure 3-56 shows such a circuit. This, of course, invites thermal runaway. To minimize the circuitry, there are bias ICs, such as the Siemens BCR400R, now available. Figures 3-57 and 3-58 show its application in biasing BJTs and FETs, respectively; it can also be used to control PIN-diode bias current for TR antenna switching, as shown in Figure 3-59.

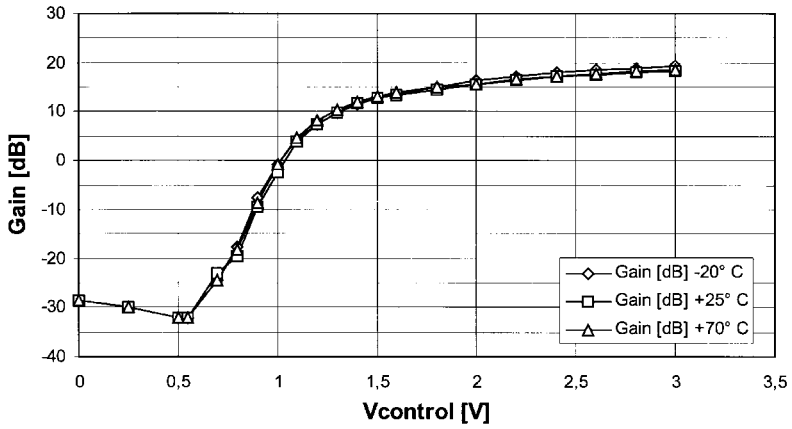

Figure 3-54 CGY121A gain versus $V_{control}$ at 1.9 GHz.

To validate this, we have used the Serenade 8.0 CAD tool, which has a built-in bias- and temperature-dependent noise model for BJTs and FETs. The SPICE-type dc analysis determines the actual currents, which were mentioned above. By maintaining the same bias and just bypassing both emitter resistors at the same time, the set of curves shown in Figure 3-60 will be obtained. As an exercise, we recommend the user to determine the optimum generator impedance for F_{min} with a 10-Ω resistor. Again, both the emitter current and collector voltage affect the noise figure, the intermodulation, and f_T. If a transistor is used

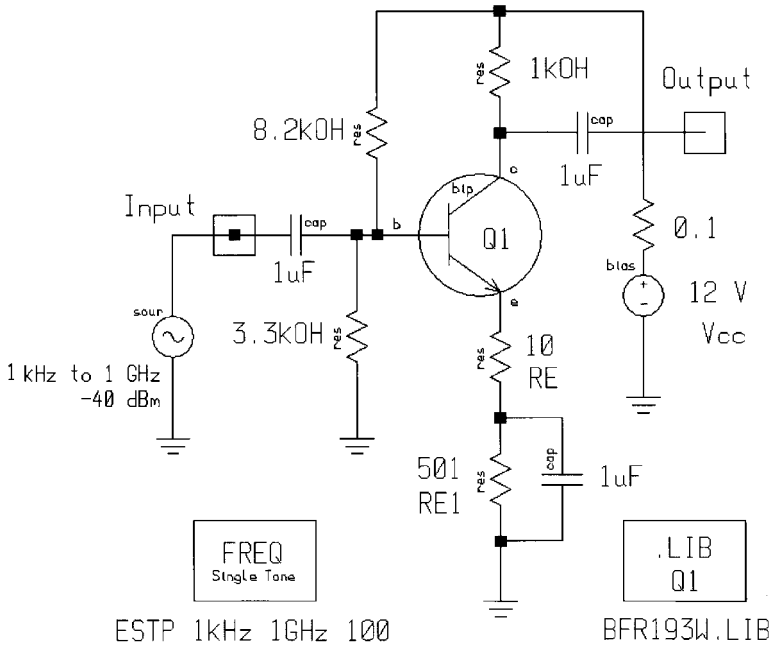

Figure 3-55 BJT amplifier example.

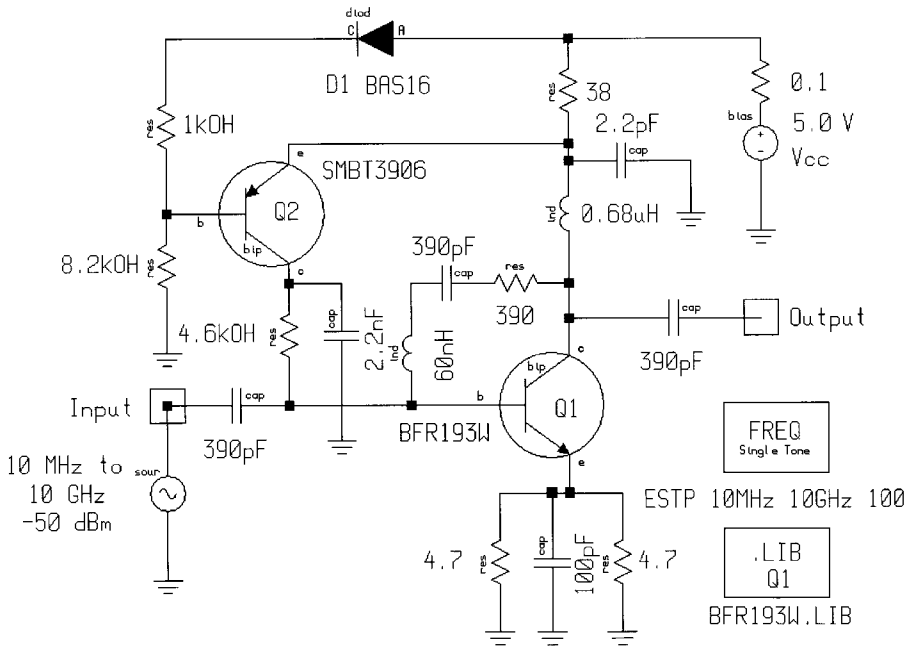

Figure 3-56 Wideband amplifier with active biasing. The 4.7-Ω resistors in the BFR193W emitter compensate the circuit's gain at low frequencies.

that is intended to be operated at significantly higher currents, then f_T will suffer while the other two parameters are less affected.

The dc input power translates into thermal dissipation, and Figure 3-60 is a plot of the noise figure as a function of temperature with and without emitter feedback. The heavy dc stabilization prevents a significant effect on the other parameters. The actual dc shift is from 5.0 to 5.2 mA for a temperature change of 70 K.

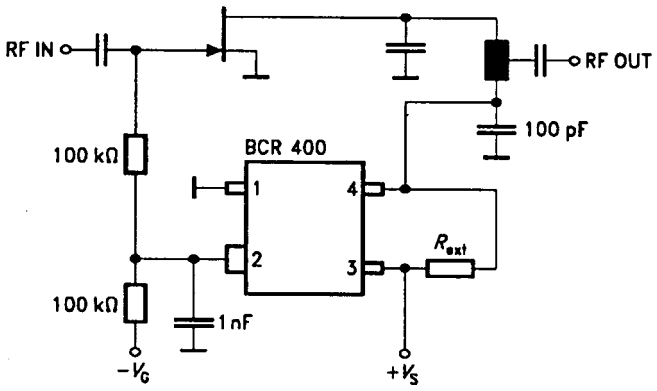

Figure 3-57 The Siemens BCR400 bias controller applied to a GaAsFET.

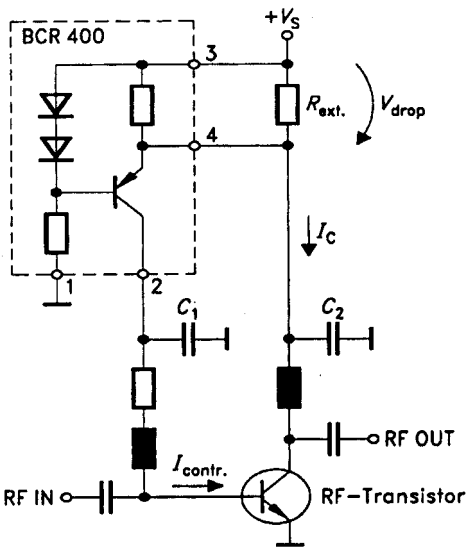

Figure 3-58 The Siemens BCR400 bias controller applied to a BJT.

As far as FETs are concerned, the enhancement types, typically PMOS, can use a similar type of bias, while the NMOS types complicate the designer's life as they require a negative gate voltage. For low-noise operation, these devices are operated somewhat close to the pinchoff voltage. Putting a source resistor in place causes mostly headaches simply because the gain is so high that the transistors are always ready to find a frequency at which they love to oscillate. The transistor will look for every possible parasitic to turn the amplifier into an oscillator.

3-2 AMPLIFIER GAIN, STABILITY, AND MATCHING

Most semiconductor manufacturers describe their devices these days by providing either their *S* parameters (small-signal) or SPICE-type parameters (large-signal). One of our headaches in writing this book has been that many of the published models don't translate

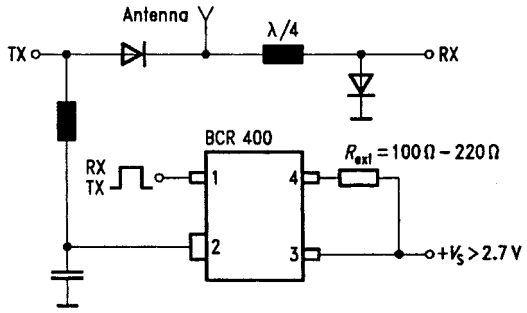

Figure 3-59 The Siemens BCR400 bias controller applied to TR switching.

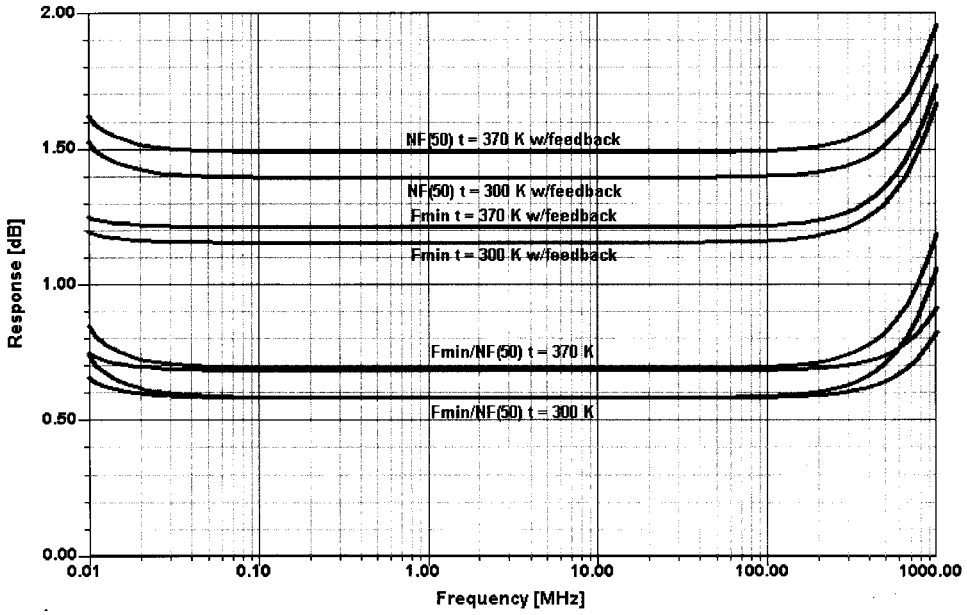

Figure 3-60 F_{min} and NF for the amplifier in Figure 3-55, with and without emitter feedback, at 300 and 370 K.

from large signal to small signal without giving unexpected or false results. Despite the availability of tools to do it right, many companies still can only provide data that are practically inadequate, and unfortunately the CAD manufacturers then get the blame for results for which they are not really responsible.

Tables 3-9 and 3-10 show typical data for a bipolar transistor (the BFP420 by Siemens). The next section presents a summary of the derivation and use of *S* parameters as published by Hewlett-Packard and others.

3-2-1 Scattering Parameter Relationships

Scattering (*S*) parameters characterize a network in terms of incident and reflected waves (Figures 3-61 and 3-62).

$$b_1 = s_{11}a_1 + s_{12}a_2 \tag{3-122}$$

$$b_2 = s_{21}a_1 + s_{22}a_2 \tag{3-123}$$

Notice that

$$s_{11} = \frac{b_1}{a_1} = \frac{V_1/I_1 - Z_0}{V_1/I_1 + Z_0} = \frac{Z_1 - Z_0}{Z_1 + Z_0} \tag{3-124}$$

and

Table 3-9 BFP420 common-emitter *S* parameters[a]

[a]Input matched for minimum noise figure, output for maximum gain.
[b]$Z_S = Z_L = 50\ \Omega$.

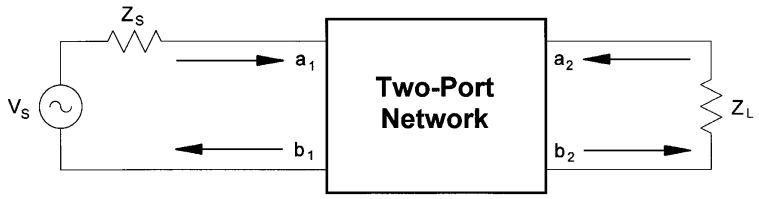

Figure 3-61 *S* parameters characterize a network (a two-port is shown) in terms of incident waves (a_1, a_2) and reflected waves (b_1, b_2). Figure 3-62 shows the flow graph for this network.

$$Z_1 = Z_0 \frac{(1 + s_{11})}{(1 - s_{11})} \tag{3-125}$$

where $Z_1 = V_1/I_1$ is the input impedance at Port 1.

This relationship between reflection coefficient and impedance is the basis of the Smith Chart transmission-line calculator. Consequently, the reflection coefficients S_{11} and S_{22} can be plotted on Smith charts, converted directly to impedance, and easily manipulated to determine matching networks for optimizing a circuit design.

The above equations show one of the important advantages of *S* parameters: They are simply gains and reflection coefficients, both familiar quantities to engineers. By comparison, some of the *Y* parameters described earlier in the article are not so familiar. For example, the *Y* parameter corresponding to insertion gain S_{21} is the "forward transadmittance," Y_{21}. Clearly, insertion gain gives by far the greater insight into the operation of the network.

S parameters are simply related to power gain and mismatch loss, quantities that are often of more interest than the corresponding voltage functions:

$$|s_{11}|^2 = \frac{\text{Power reflected from the network input}}{\text{Power incident on the network input}} \tag{3-126}$$

$$|s_{21}|^2 = \frac{\text{Power delivered to a } Z_0 \text{ load}}{\text{Power available from } Z_0 \text{ source}} \tag{3-127}$$

$$|s_{12}|^2 = \text{Reverse transducer power gain with } Z_0 \text{ load and source.} \tag{3-128}$$

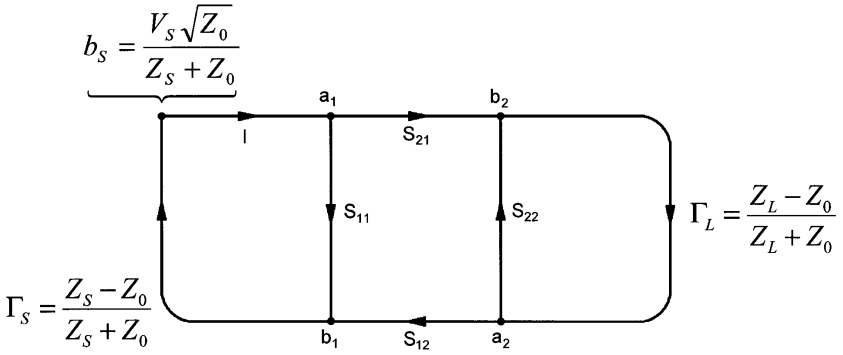

Figure 3-62 Flow graph for the network shown in Figure 3-61.

$$|s_{22}|^2 = \frac{\text{Power reflected from the network output}}{\text{Power incident on the network output}} \tag{3-129}$$

From this we obtain:
Input reflection coefficient with arbitrary Z_L:

$$s'_{11} = s_{11} + \frac{s_{12}s_{21}\Gamma_L}{1 - s_{22}\Gamma_L} \tag{3-130}$$

Output reflection coefficient with arbitrary Z_S:

$$s'_{22} = s_{22} + \frac{s_{12}s_{21}\Gamma_S}{1 - s_{11}\Gamma_S} \tag{3-131}$$

Voltage gain with arbitrary Z_L and Z_S:

$$A_V = \frac{V_2}{V_1} = \frac{s_{21}(1 + \Gamma_L)}{(1 - s_{22}\Gamma_L)(1 + s'_{11})} \tag{3-132}$$

$$\text{Power gain} = \frac{\text{Power delivered to load}}{\text{Power input to network}}:$$

$$G = \frac{|s_{21}|^2 (1 - |\Gamma_L|^2)}{(1 - |s_{11}|^2) + |\Gamma_L|^2 (|s_{22}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_L N)} \tag{3-133}$$

$$\text{Available power gain} = \frac{\text{Power available from network}}{\text{Power available from source}}:$$

$$G_A = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)}{(1 - |s_{22}|^2) + |\Gamma_S|^2 (|s_{11}|^2 - |D|^2) - 2\,\text{Re}\,(\Gamma_S M)} \tag{3-134}$$

$$\text{Transducer power gain} = \frac{\text{Power delivered to load}}{\text{Power available from source}}:$$

$$G_T = \frac{|s_{21}|^2 (1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|(1 - s_{11}\Gamma_S)(1 - s_{22}\Gamma_L) - s_{12}s_{21}\Gamma_L\Gamma_S|^2} \tag{3-135}$$

Unilateral transducer power gain ($S_{12} = 0$):

$$G_{Tu} = \frac{|s_{21}|^2(1 - |\Gamma_S|^2)(1 - |\Gamma_L|^2)}{|1 - s_{11}\Gamma_S|^2|1 - s_{22}\Gamma_L|^2}$$

$$= G_0 G_1 G_2 \tag{3-136}$$

$$G_0 = |s_{21}|^2 \tag{3-137}$$

$$G_1 = \frac{1 - |\Gamma_S|^2}{|1 - s_{11}\Gamma_S|^2} \tag{3-138}$$

$$G_2 = \frac{1 - |\Gamma_L|^2}{|1 - s_{22}\Gamma_L|^2} \tag{3-139}$$

Maximum unilateral transducer power gain when $|S_{11}| < 1$ and $|S_{22}| < 1$:

$$G_u = \frac{|s_{21}|^2}{|(1 - |s_{11}|^2)(1 - |s_{22}|)^2|}$$

$$= G_0\, G_{1\max}\, G_{2\max} \tag{3-140}$$

$$G_{i\max} = \frac{1}{1 - |s_{ii}|^2} \quad i = 1, 2 \tag{3-141}$$

Constant-gain circles (unilateral case: $S_{12} = 0$):

- Center of constant-gain circle is on line between center of Smith Chart and point representing S_{ii}^*
- Distance of center of circle from center of Smith Chart:

$$r_i = \frac{g_i |s_{ii}|}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-142}$$

- Radius of circle:

$$\rho_i = \frac{\sqrt{1 - g_i}(1 - |s_{ii}|^2)}{1 - |s_{ii}|^2(1 - g_i)} \tag{3-143}$$

where $i = 1, 2$ and

$$g_i = \frac{G_i}{G_{i\max}} = G_i(1 - |s_{ii}|^2) \tag{3-144}$$

Unilateral figure of merit:

$$u = \frac{|s_{11}s_{22}s_{12}s_{21}|}{|(1 - |s_{11}|^2)(1 - |s_{22}|^2)|} \tag{3-145}$$

Error limits of unilateral gain calculation:

$$\frac{1}{(1 + u^2)} < \frac{G_T}{G_{Tu}} < \frac{1}{(1 - u^2)} \tag{3-146}$$

Conditions for absolute stability. No passive source or load will cause a network to oscillate if a, b, and c are all satisfied:

$$\text{a.}\quad |s_{11}| < 1, |s_{22}| < 1 \tag{3-147}$$

$$\text{b.} \quad \left| \frac{|s_{12}s_{21}| - |M^*|}{|s_{11}|^2 - |D|^2} \right| > 1 \tag{3-148}$$

$$\text{c.} \quad \left| \frac{|s_{12}s_{21}| - |N^*|}{|s_{22}|^2 - |D|^2} \right| > 1 \tag{3-149}$$

where

$$D = s_{11}s_{22} - s_{12}s_{21} \tag{3-150}$$

$$M = s_{11} - Ds_{22}^* \tag{3-151}$$

$$N = s_{22} - Ds_{11}^* \tag{3-152}$$

Condition that a two-port network can be simultaneously matched with a positive real source and load:

$$K > 1 \tag{3-153}$$

$$K = \frac{1 + |D|^2 - |s_{11}|^2 - |s_{22}|^2}{2|s_{12}s_{21}|} \tag{3-154}$$

Source and load for simultaneous match

$$\Gamma_{mS} = M^* \left[\frac{B_1 \pm \sqrt{B_1^2 - 4|M|^2}}{2|M|^2} \right] \tag{3-155}$$

$$\Gamma_{mL} = N^* \left[\frac{B_2 \pm \sqrt{B_2^2 - 4|N|^2}}{2|N|^2} \right] \tag{3-156}$$

where

$$B_1 = 1 + |s_{11}|^2 - |s_{22}|^2 - |D|^2 \tag{3-157}$$

$$B_2 = 1 + |s_{22}|^2 - |s_{11}|^2 - |D|^2 \tag{3-158}$$

Maximum available power gain. If $K > 1$,

$$G_{A\max} = \left| \frac{s_{21}}{s_{12}} (K \pm \sqrt{K^2 - 1}) \right| \tag{3-159}$$

In conclusion, *a two-port network (active or passive) is unconditionally stable* when

$$K > 1$$

$$|S_{12}S_{21}| < 1 - |S_{11}|^2$$

and

$$|S_{12}S_{21}| < 1 - |S_{22}|^2$$

3-2-2 Low-Noise Amplifiers

A low-noise amplifier combines a low noise figure, reasonable gain, and stability without oscillation over its entire useful frequency range. These amplifiers are typically operated in Class A, which is characterized by a bias point more or less at the center of maximum current and voltage capability of the device used, and by RF current and voltages that are sufficiently small relative to the bias point that the bias point does not shift. This means that an amplifier operating at, say, 3 V and 1 mA for low-noise, high-gain operation will not be Class A if the RF current is larger than 0.1% of the current or the voltage swing is more than 0.1% of the current swing. These amplifiers can be designed using standard linear *S* parameters, which are (hopefully) available from the device manufacturer for the bias point of interest. If suitable *S* parameters are not available, we must resort to a CAD tool that allows us to determine a device's bias point as a function of its bias network and to generate small-signal *S* parameters for the device. With suitable *S* parameters in hand, and assuming the amplifier will be frequency selective, we then connect tuned circuits to the input and output to provide matching.

In designing amplifiers, the "power gain" of a circuit is mentioned frequently. This is actually deceptive because power gain is somewhat associated with dc power dissipation, and in considering it, we are on the verge of discussing large-signal performance. Therefore it would be better to define the power gain as a function of operating mode, such as "Class A power gain." We have also outlined that there is a difference between noise matching and gain matching. If we can be allowed to step back into the vacuum-tube era for a moment, the reader should be reminded that the difference between power gain and noise matching had to do with the grid-plate feedback capacitance which, via the Miller effect, showed up in parallel with the input. This actually detunes the input slightly off-center relative to the best gain. The reason for this is that as the feedback increases, Y_{12} or S_{12} starts playing a role, and the frequently assumed unilateral case no longer exists. The difference between noise matching and gain matching increases as a function of frequency. It can be brought closer together if appropriate reactive feedback is used. The two choices are: (1) increase the emitter or source inductance or (2) slightly increase the base-to-collector/gate-to-drain capacitance. Needless to say, the penalty for this is potential instability, and a sweep must be done from a few megahertz to several gigahertz to make sure the stage doesn't "take off."

The most efficiency this circuit provides is 50%; even this is a theoretical limit if one tries to keep distortion under control.

While the equation $P_{\text{OUT}} = (V_{\text{bat}} - V_{\text{sat}})^2/2R_L$ is valid, it really applies only to power amplifiers in the sense that for Class A, high-gain operation R_L can be made significantly higher as the absolute power output is not the important item. While the supply voltage V_{bat} is always known, the saturation voltage V_{sat} has to be obtained by the load line dc analysis. Note: The RF saturation voltage is always higher than the dc one. When looking at Figure 3-63, it becomes obvious that the conducting angle is 180°, which implies that the entire sine wave at the input is reproduced as an essentially undistorted sine wave at the output.

We can now calculate the components of the distorted current in separating them into the dc component, the fundamental frequency, and its first and second harmonics:

$$\text{Fundamental} \quad i_{c1} = i_{\text{peak}} \cdot f_1(\Theta) \tag{3-160}$$

$$\text{Second harmonic} \quad i_{c2} = i_{\text{peak}} \cdot f_2(\Theta) \tag{3-161}$$

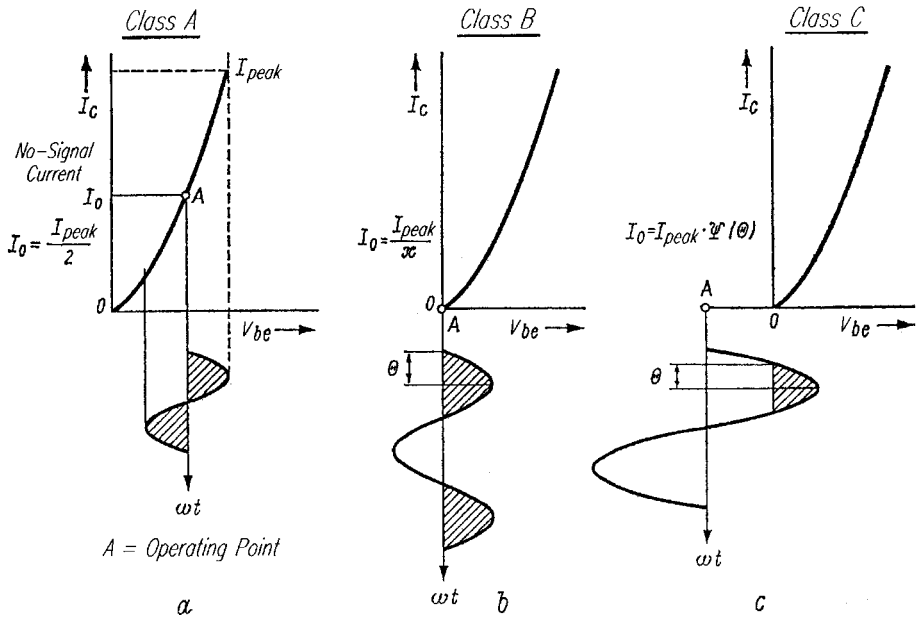

Figure 3-63 Definitions of Class A, B, and C operation, including conduction angle (Θ). Figure 3-64 shows the determination of Θ.

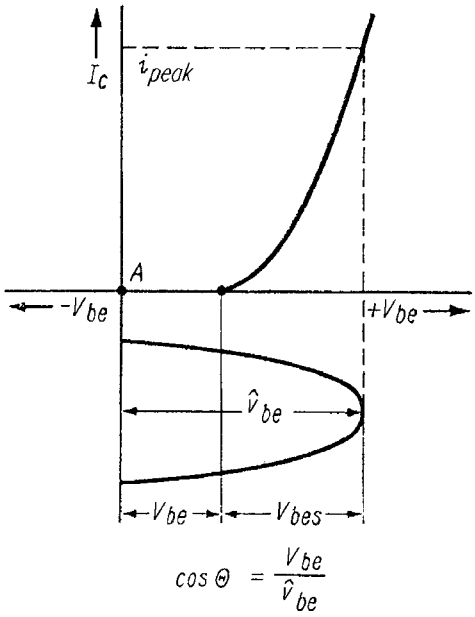

Figure 3-64 Determination of the conduction angle Θ from the base threshold voltage V_{be} and the base RF voltage $\hat{v}_{be}$.

$$\text{Third harmonic} \quad i_{c3} = i_{\text{peak}} \cdot f_3(\Theta) \tag{3-162}$$

For the collector dc current we obtain

$$I_c = i_{\text{peak}} \cdot \Psi(\Theta) \tag{3-163}$$

The frequency-dependent currents are a function of the conduction angle Θ. Figure 3-65 shows these transfer characteristics as a function of the conduction angle for a square-law dynamic transfer function; for higher-order transfer functions, the values don't change much. Tables for this can be found in various sources, including Clark and Hess [47]. Since the transistors exhibit a mixture of an exponential and a linear transfer characteristic (due to the unwanted parasitic emitter/source and collector/drain resistances when building the device), the plot in figure 3-65 is sufficiently valid for practical purposes. This function plot allows us to determine the amplitude of the current at various frequencies once the conducting angle has been set. For example, for Θ = 70°, the maximum collector current is $i_{\text{peak}} = I_c/0.253$, meaning that the peak current of the transistor is approximately four times larger than the dc value one would measure. Once the peak collector current is known, the fundamental and harmonic currents can be calculated:

$$i_{c1} = \frac{I_c}{0.253} f_1(\Theta)$$

$$i_{c1} = \frac{I_c}{0.253} 0.436$$

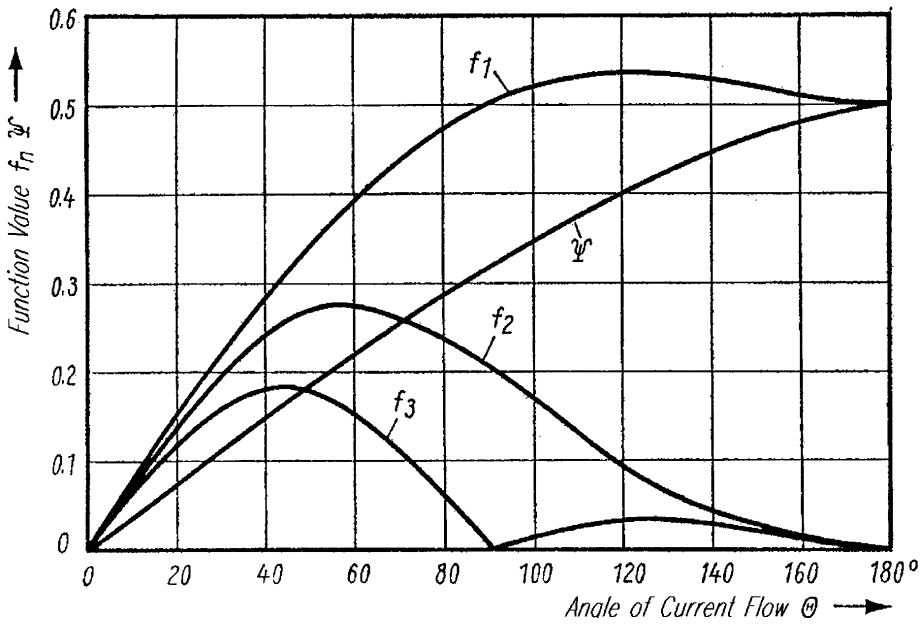

Figure 3-65 Function values for the fundamental, second harmonic, third harmonic, and dc components (f_1, f_2, f_3, and Ψ, respectively) versus device conduction angle.

In order to obtain i_{c2} and i_{c3} one needs to do the same calculations as above with the appropriate functions for f_2 and f_3.

It becomes obvious that the distorted collector current generates a lot of harmonics, which definitely requires sufficient low-pass filtering at the output, even for Class A operation. We already stated that for Class A operation the conduction angle is 180° while it is 90° for Class B operation. The conduction angle for Class C operation can be solved from the ratio of the knee voltage V_{be} and the peak value of the ac voltage at the base. We find

$$\cos \Theta = \frac{V_{be}}{\hat{V}_{be}} \tag{3-164}$$

where $\Theta = 90°$ and $V_{be} = 0$. Given the voltage V_{bes}, which determines the peak collector current (up to i_c peak), we can calculate the effective RF voltage at the base as

$$\hat{v}_{be} = \frac{v_{bes}}{1 - \cos \Theta} \tag{3-165}$$

Therefore, the peak value of v_b becomes v_{bes} for $\Theta = 90°$.

The necessary base voltage V_{be} for maximum current is obtained by the transistor model. Then one finds the threshold voltage at which the transistor becomes conductive and by using Eqs. (3-164) and (3-165) it can be checked whether this results in the appropriate conducting angle. An example for this will be shown in the high-power stage section.

Design Guidelines. The design of a one-stage amplifier consists of finding

- An input lossless matching network M_1
- An input lossless matching network M_2

so that the maximum or desired transistor gain is achieved over the operating bandwidth of the amplifier. Usually, the common-emitter or common-source configuration is chosen for highest gain per stage. If the stability factor K is greater than unity, these two networks can be found to give the maximum available gain $G_{\max}$. If the stability factor is less than or equal to unity, the amplifier could be terminated in a matching structure that causes oscillation; that is, $G_{\max}$ is infinite. This should be avoided by locating the regions of instability in the Γ_G and Γ_L planes. The input and output terminations (Γ_G and Γ_L) must be designed to avoid the instability regions. Usually, these unstable regions are near the conjugate match for S_{11} and S_{22}. Thus, a stable amplifier will require some input and/or output mismatch if K is less than or equal to unity.

There are at least two alternative approaches for potentially unstable amplifiers:

1. Add resistive matching elements to make $K \geq 1$ and $G_{\max} \approx G_{ms}$.
2. Add feedback to make $K \geq 1$ and $G_{\max \approx Gms}$.

For narrowband amplifiers, it is usually recommended that one accept a transistor with $K < 1$, design the amplifier for a gain approaching G_{ms}, and ensure that the Γ_G and Γ_L terminations provide stability at all frequencies, both inside and outside the amplifier passband.

The design of an amplifier would usually have the following specifications:

Gain and gain flatness
Bandwidth and center frequency ($f_2 - f_1, f_0$)
Noise figure
Linear output power
Input reflection coefficient ($VSWR_{in}$)
Output reflection coefficient ($VSWR_{out}$)
Bias voltage and current

For small-signal amplifiers, the small-signal S parameters are sufficient to complete the design. After selecting an appropriate transistor based on these specifications, a one-stage amplifier design should be considered if sufficient gain can be achieved; otherwise, a two-stage amplifier should be designed.

The circuit topology should be chosen to allow dc bias for the transistor. Usually, RF short-circuited stubs are placed near the transistor to allow dc biasing. If the topology does not allow dc bias, a broadband bias choke or high-resistance bias circuit that does not affect the amplifier performance must be used.

The following steps can be tabulated for the design of a one-stage amplifier (see Figure 3.66):

1. Select a transistor based on a datasheet description of the S parameters, noise figure, and linear output power.
2. Calculate K and G_{max} or G_{ms} versus frequency.
3. For $K > 1$, select the topologies that match the input and output (and allow dc biasing) at the upper band edge f_2. Ideally, this will give G_{max} and $S'_{11} = S'_{22} = 0$. Usually, $S_{12} = 0$ is assumed for the initial design. Next, the topology may be varied to flatten gain versus frequency at the expense of S'_{11} and S'_{22}.
4. For $K < 1$, plot the regions of instability on the Γ_G and Γ_L planes and select topologies that partially match the input and output at the upper band edge and avoid the unstable regions. The gain will approach G_{ms} as an upper limit. Next, the topology may be varied to flatten gain versus frequency.
5. After finding initial M_1 and M_2, plot the amplifier S parameters versus frequency; make adjustments in topology until the specifications for gain, input reflection coefficient, and output reflection are satisfied. Also plot Γ_G and Γ_L versus frequency to verify amplifier stability.
6. Design the dc bias circuit. Lay out the elements of the complete amplifier and check realizability.

As a beginning point in an amplifier design, the circuit topologies may be designed with the assumption that S_{12} is zero. Later, an exact design procedure will be described that includes the topologies with terminations in the stable region.

Design Examples. Throughout this book we always address the issue that we have to separate the battery-operated handheld applications and the more stationary designs like those for base stations. In the case of the handheld or low-voltage applications, the dynamic range requirements are significantly less than the front-end of a base station requires.

NE68133 Matched Amplifier. We will first consider the design of a low-voltage, low-current, low-noise amplifier based on the NEC BJT NE68133. This device was chosen

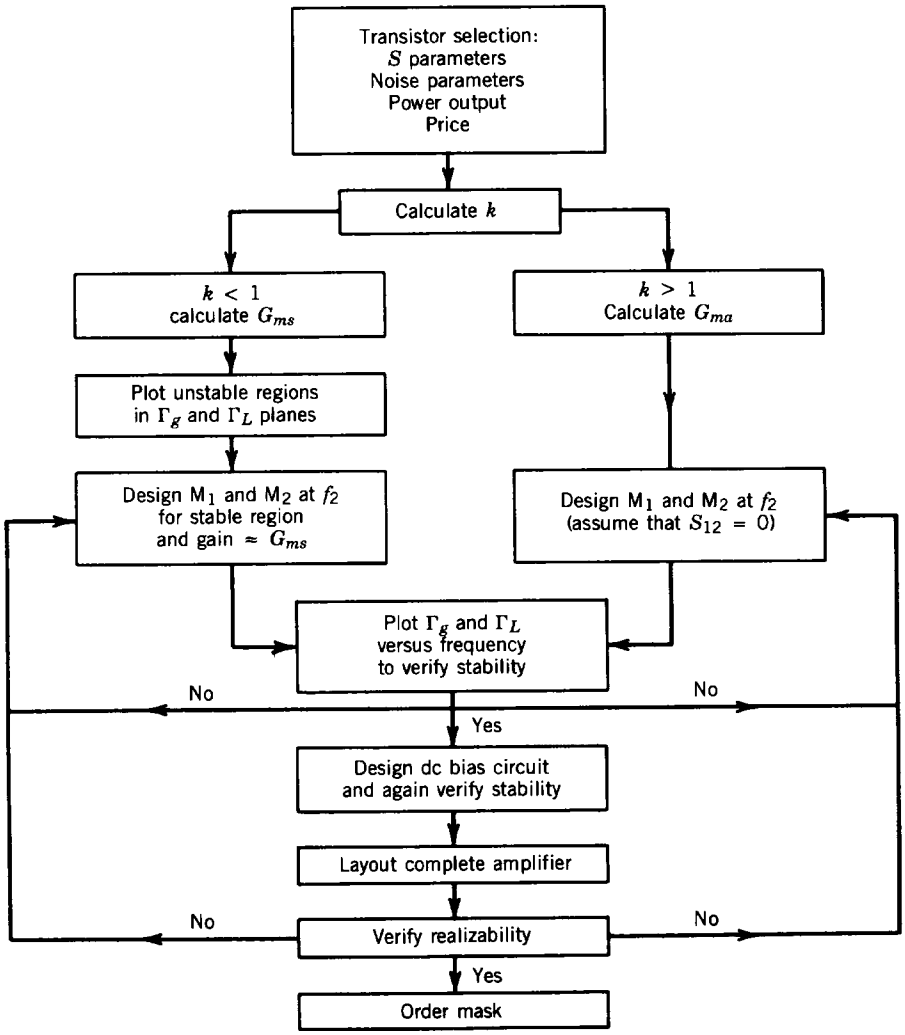

Figure 3-66 Simplified amplifier design procedure.

because it is unconditionally stable, has a minimum noise figure of about 1.2 dB at 7 mA, has 15.5 dB gain, and has an f_T of 8 GHz. While it is possible to start the design based on the published S and noise parameters, we will choose also to involve the nonlinear model, as this allows us more freedom in selecting the bias point including the collector voltage. The actual topology of the amplifier is shown in Figure 3-67.

Determining appropriate values for the input and output matching networks is essential to finalizing the design. The next several figures illustrate matching-network syntheses undertaken with the interactive Smith Tool in Ansoft's Serenade Design Environment. We evaluate the point of tangency as well as stability circles in the source and load planes, indicating that our impedance match will result in a stable amplifier.

In Figure 3-68, the center circle (with 1.1 marker) refers to the noise circle for which the noise figure of 1.1 dB can be obtained. The left circle (with the 14.3 marker) corresponds to

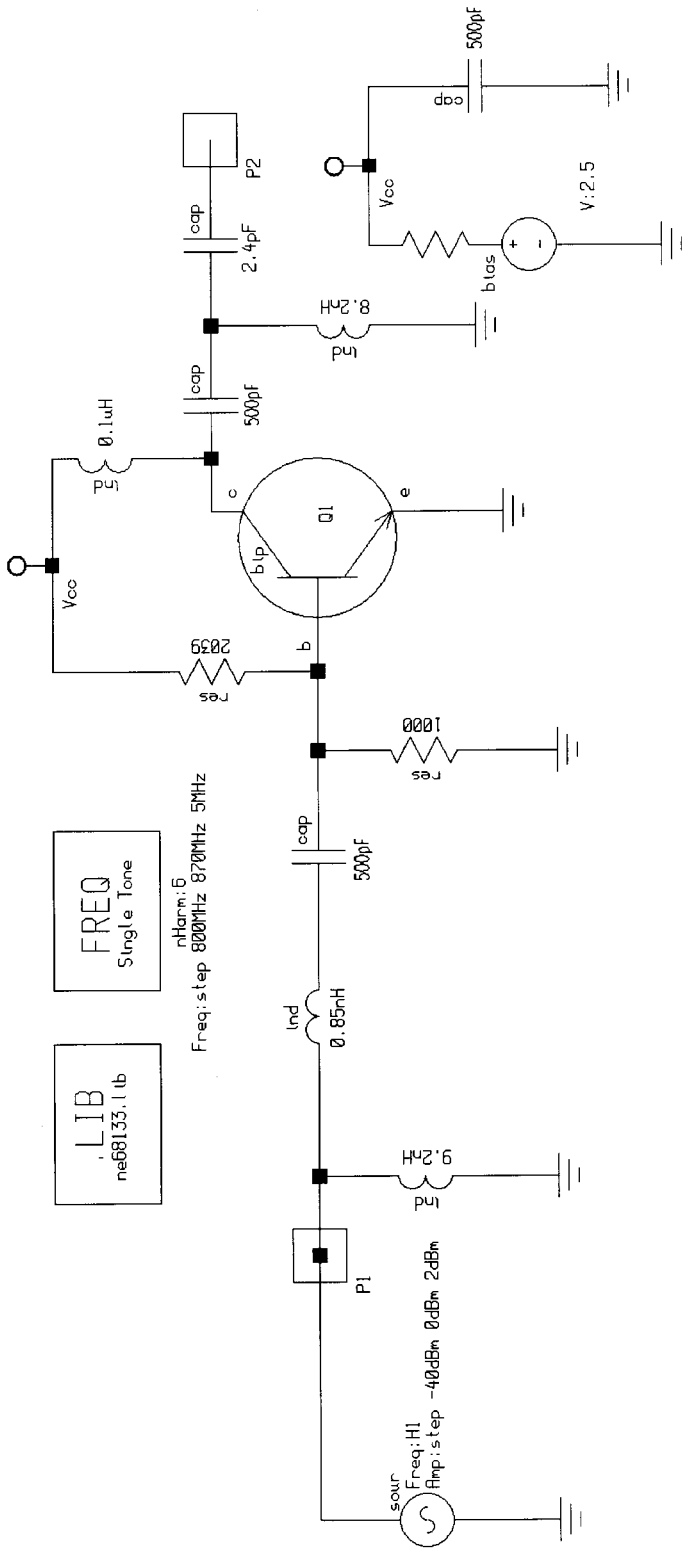

Figure 3-67 The NE68133 low-noise amplifier.

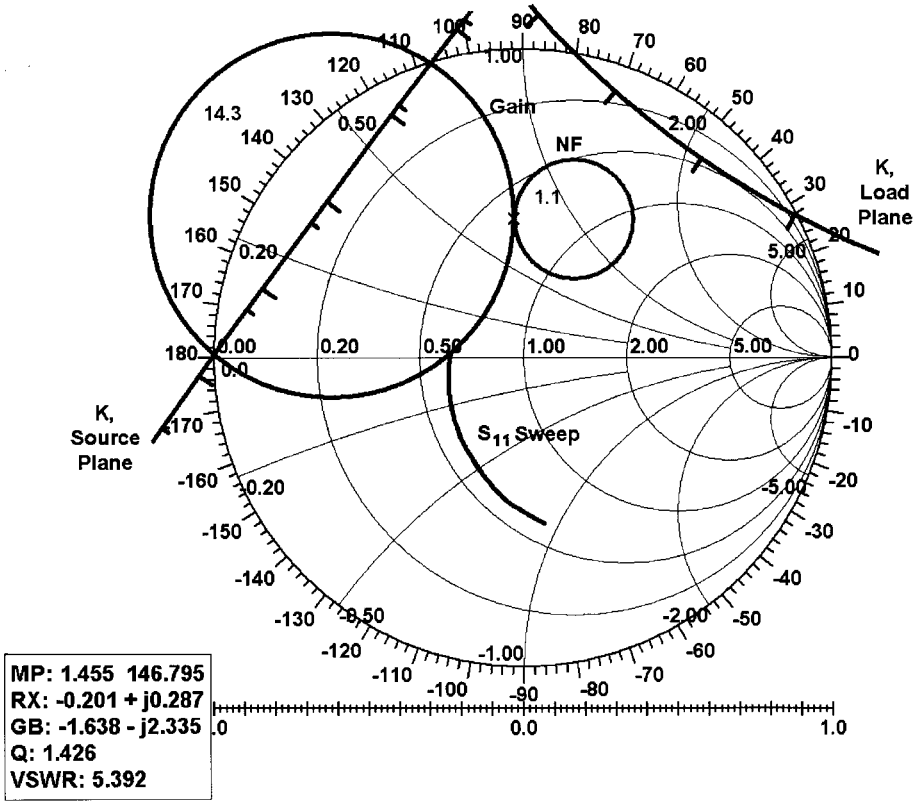

Figure 3-68 Display from the interactive Smith Tool, showing circles for gain, noise figure, and source- and load-plane stability, as well as a sweep of S_{11} versus frequency. In synthesizing an input matching circuit, we choose a single working frequency and work from the chart's origin to the point of tangency between the gain and noise figure circles. See Figure 3-69.

source-plane terminations that correspond to 14.3 dB of available gain. In order to get the required noise figure *and* gain, the input termination must be at the point of tangency of both circles. The arc touching the X axis close to 0.50 is the amplifier's S_{11} response from 800 to 875 MHz. The shallow arc that nearly bisects the 14.3-dB gain circle is actually a portion of the source-plane stability circle; the arc at the top right is a portion of the load-plane stability circle. Because we will be terminating the amplifier input with a value inside the source-plane stability circle, and terminating the amplifier output with a value outside the load-plane stability circle, the amplifier will be unconditionally stable at the frequency at which the match is obtained.

The next task is to obtain the values for the network circuit that matches the input for the 1.1-dB noise figure. A noise matching will not result in the best possible S_{11} matching (Figure 3-69). This translates into an inductor of 9.2 nH to ground and a series inductor of 0.85 nH based on the large-signal model of the NE68133 at the chosen bias point.

After we have determined our input matching network, it is time to find the output matching (Figure 3-70). First, find the termination point on the output plane that corresponds to 14.3-dB gain and 1.1-dB NF at the input plane. The output gain circle goes through the

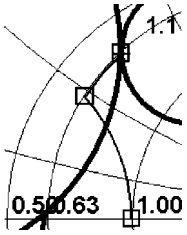

Figure 3-69 Input matching-network extraction, assuming lossless matching components and no parasitic effects.

1.1-dB NF circle at two points, and for reasons of easy matching we selected the lower point. The next step is to find the conjugate reflection coefficient $\Gamma_L = S_{22}^*$. This is the lower square marker in Figure 3-70. The remaining task is to find the matching network that brings this value to 50 Ω. By doing so, we first obtain a shunt inductance $L_{\text{shunt}} = 8.2$ nH and a series capacitor $C_{\text{series}} = 2.4$ pF. Again, these are the values applicable to the large-signal equivalent circuit.

The careful reader will have noticed that we have been avoiding the issue of small-signal exact matching using the manufacturer-supplied parameters. If this is done, the narrow band response shown in Figure 3-71 will be obtained. Therefore, we must optimize the circuit for a better frequency response to obtain the one shown in Figure 3-72.

After this optimization, we were well able to meet the specification of a center band gain of 14 dB and a corresponding NF of 1.1 dB. To show the flatness of the gain, Figure 3-73 shows a gain variation in the range of 0.25 dB.

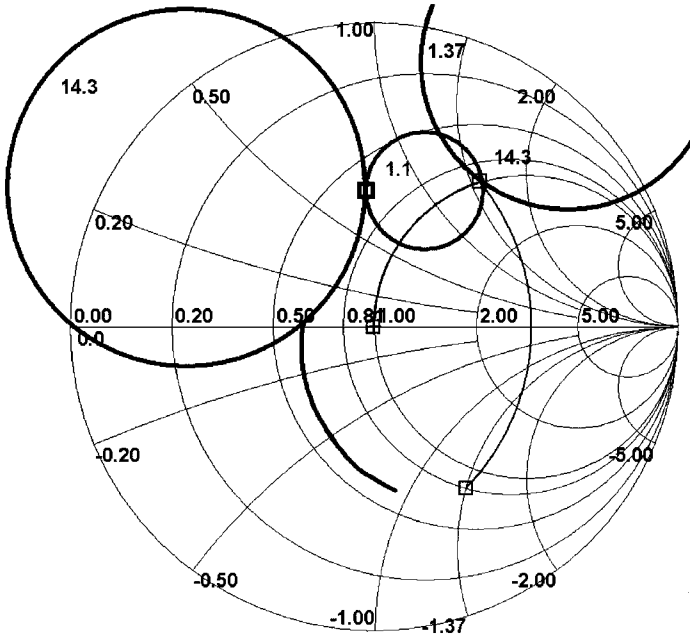

Figure 3-70 Output matching-network extraction.

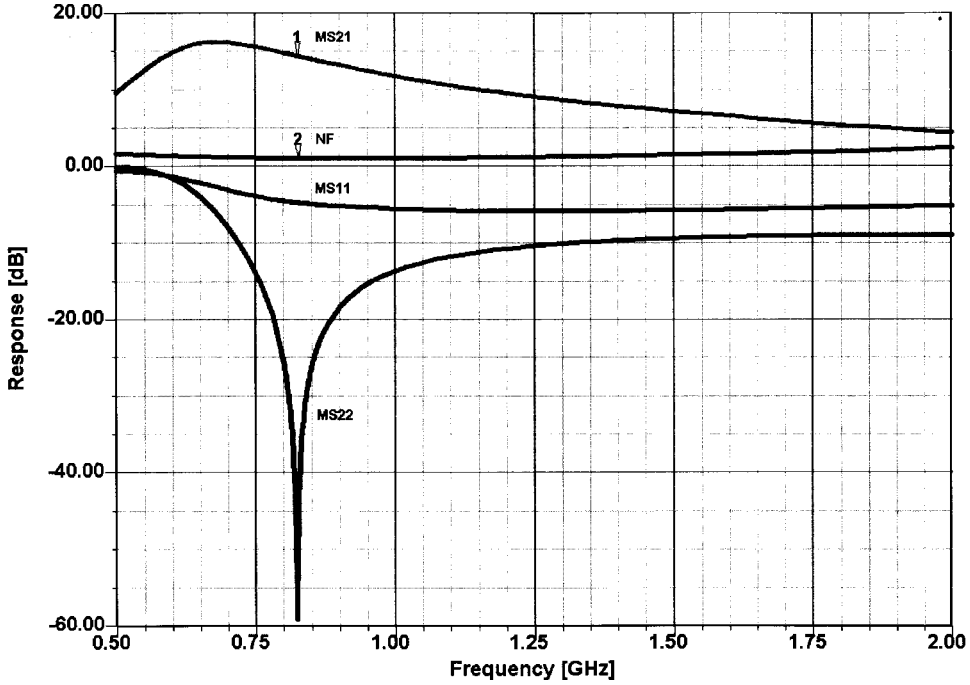

Figure 3-71 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-67.

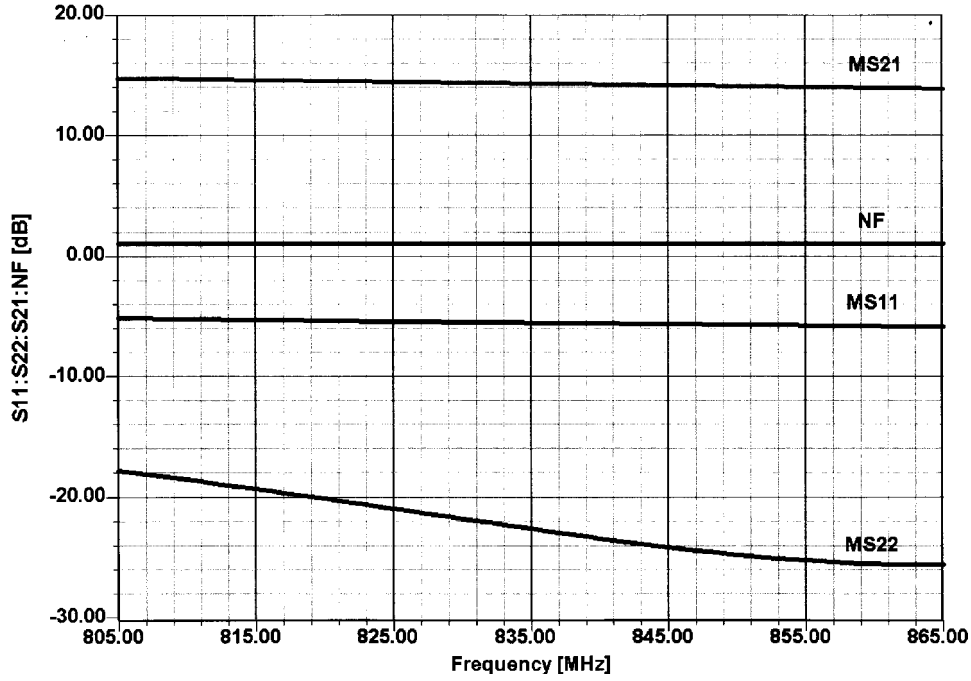

Figure 3-72 Optimized performance of input/output reflection, gain, and noise figure.

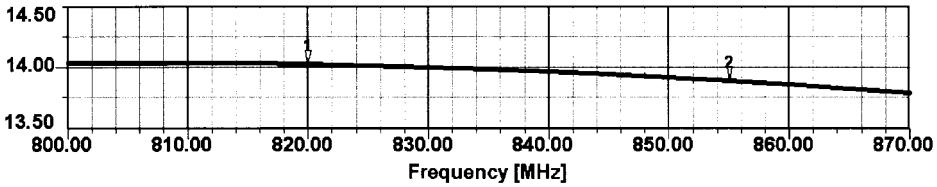

Figure 3-73 High-resolution display of gain as a function of frequency.

The next step is to look into the large-signal performance. The first order of business is to determine the third-order intercept point, which is based on a two-tone analysis. Given the fact that we run the device at low voltage and at a just-reasonable current, the actual intercept point of +13.5 dBm is quite a good number. Figure 3-74 shows the fundamental and third-order outputs. The crossover point between the two, as shown in Chapter 1, is defined as the third-order intercept point. If we had chosen the third harmonic output rather than the fundamental, we would have shown the fifth-order intercept point. The second-order IMD product ($f_1 \pm f_2$) typically can be minimized by input selectivity.

How an amplifier's linearity affects its ability to preserve the characteristics of digital signals is a major concern in wireless design. Figures 3-75 and 3-76 show constellation diagrams with the amplifier handling a PSK signal at drive levels of –40 dBm and +10 dBm, respectively. As expected, we see significant distortion at the higher drive levels due to circuit nonlinearities.

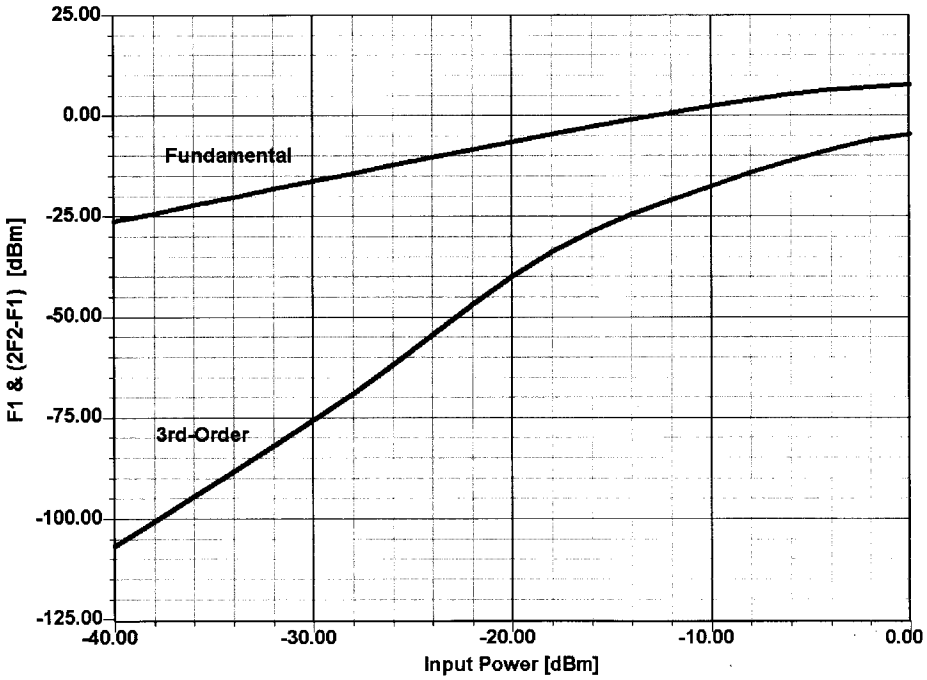

Figure 3-74 Simulated fundamental and third-order IMD outputs of the NE68133 amplifier.

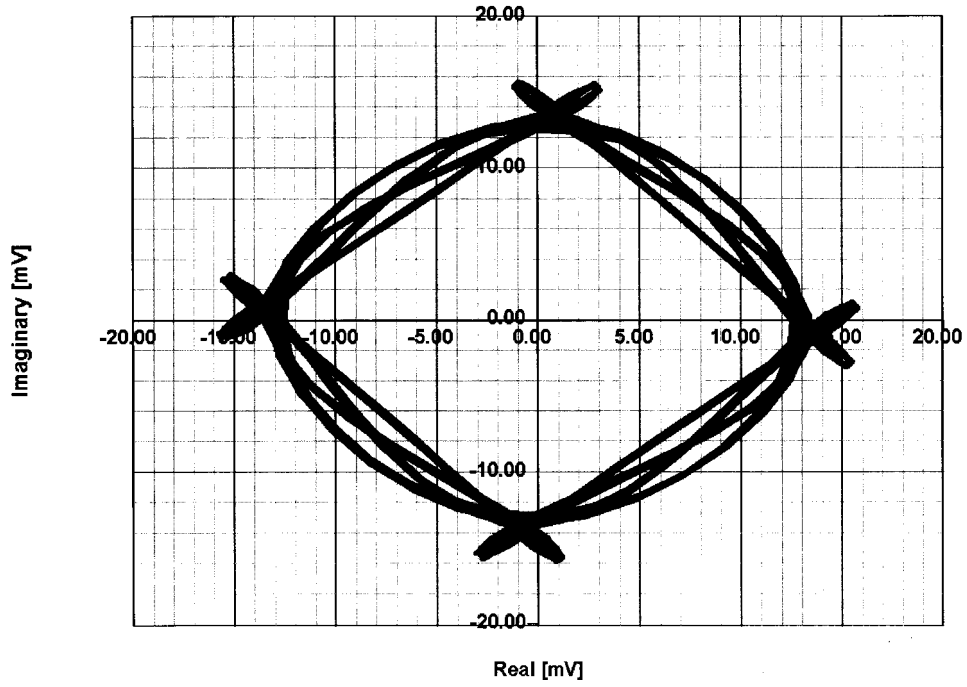

Figure 3-75 Output constellation at –40-dBm input.

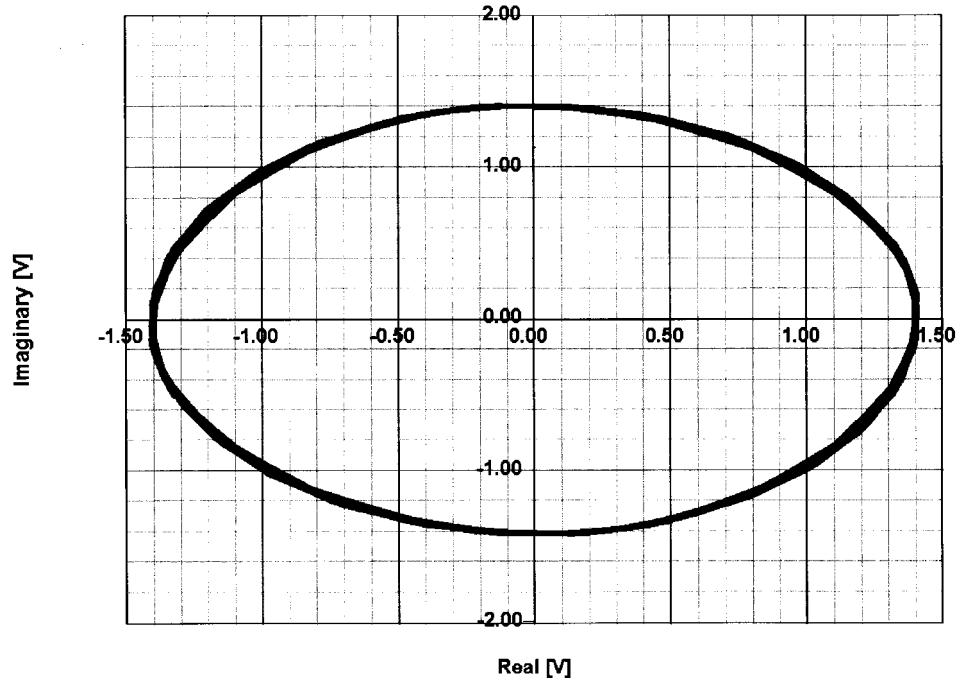

Figure 3-76 Output constellation at 10-dBm input.

BFP420 Matched Amplifier. The NE68133 has an attractive f_T of 8 GHz, but if more gain is needed, one may play with the concept of using a much "hotter" device, such as the BFP420. Recall that the NEC device was unconditionally stable, and our first worry is how the Siemens BFP420 will behave.

A study of Figure 3-77 shows that indeed the NEC device had to be stable all over and therefore was a good basis for a risk-free design. Things change dramatically with the BFP420, for which the K factor is essentially less than 1 up to a corner frequency of 2.75 GHz, where the transistor becomes unconditionally stable. Around 1.75 GHz, the K factor for the NEC transistor barely touches 1. We explained earlier that $G_{\max}$ deviating from the maximum stable gain is a more realistic number, since the conditions for maximum stable gain involve feedback and conjugate matching.

To improve the stability of the BFP420, we will now set out to use the same topology as the previous amplifier but with a resistive feedback between base and collector (Figure 3-78). A good value for this is always somewhere around 200–500 Ω. It must be remembered that this voltage feedback also stabilizes the input and output impedance and reduces the Miller effect because of the feedback being resistive and more dominant.

While the first example covered a fairly narrow frequency band, we are now attempting to cover a much wider frequency range; specifically, from 1.5 to 3 GHz reasonable gain and noise. This, by definition, requires a much higher gain-bandwidth product, and the simple matching network at the input and output provides a nonoptimal input and output matching (Figure 3-79). The feedback introduces some additional noise. This application shows the limits of single-stage UHF/SHF amplifiers with feedback.

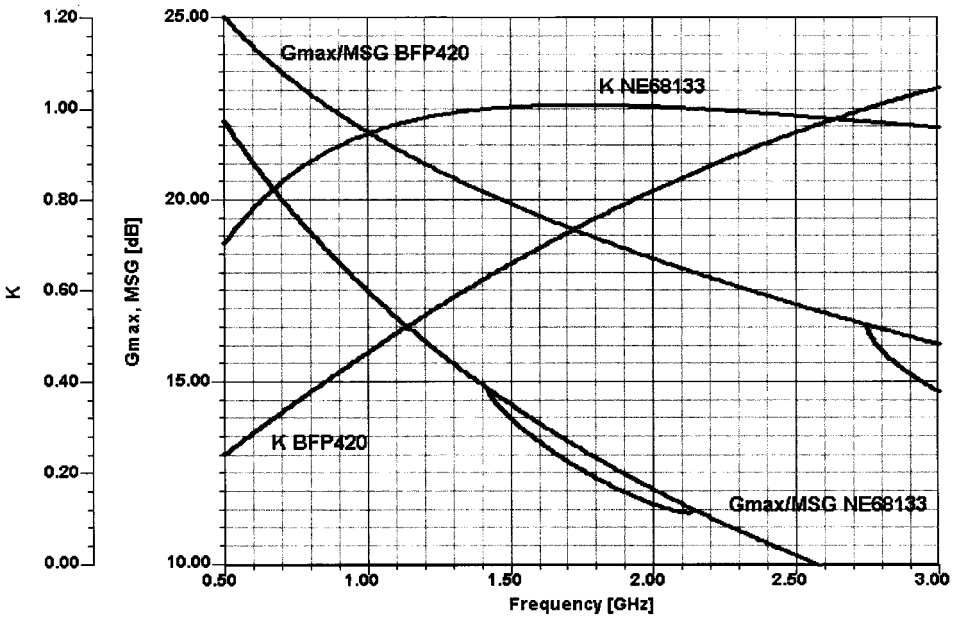

Figure 3-77 Comparison of K, $G_{\max}$, and maximum stable gain (MSG) for the NE68133 and BPF420 BJTs.

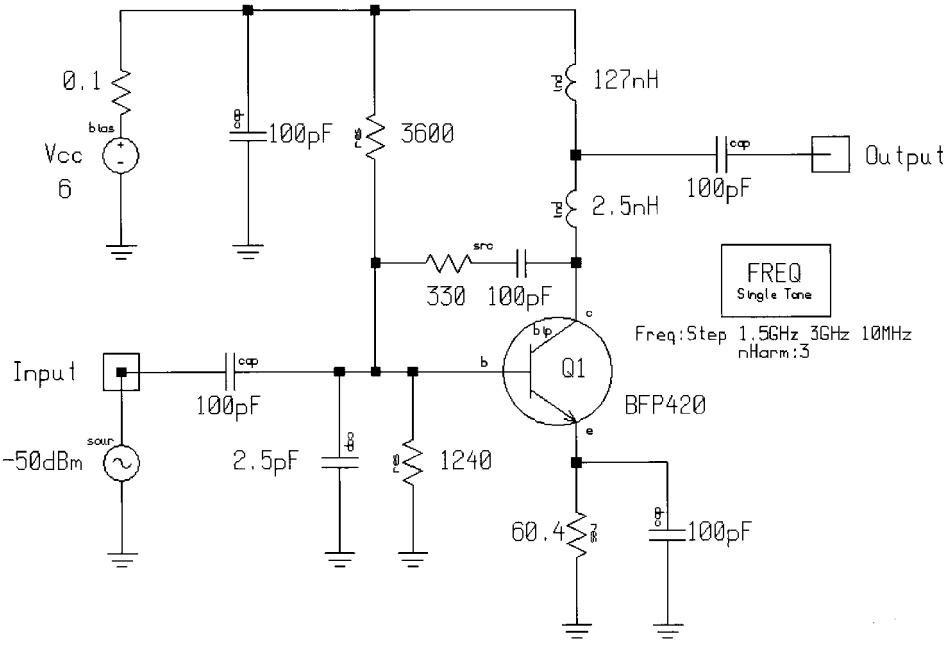

Figure 3-78 BFP420 amplifier with resistive voltage feedback from collector to base.

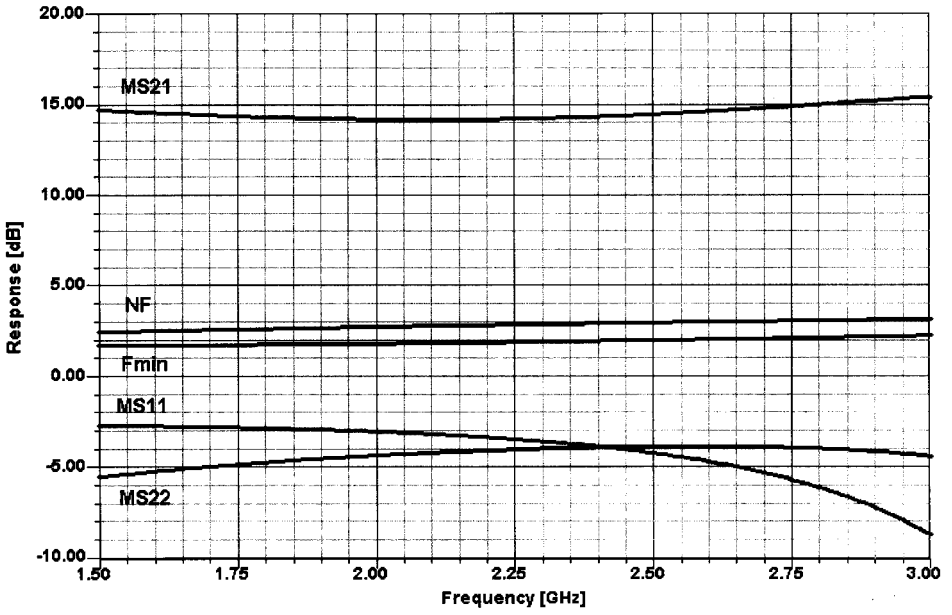

Figure 3-79 Frequency-dependent gain, matching, and noise performance of the BFP420 feedback amplifier.

Narrowband BFP420 Amplifier. Our next attempt will be to design a narrowband input stage that combines very high selectivity with good noise figure. This can only be achieved by using two tuned single-stage resonators with capacitive/magnetic coupling. The following amplifier is tailored to have a center frequency of 900 MHz. The transistor will operate at 12 V/10 mA to have a sufficient dynamic range. The input selectivity is achieved by the use of two top-coupled tuned circuits, followed by a BFP420 (Figure 3-80). The first order of business is to determine the input tuned circuit. The tuning capacitance for the two tuned circuits is arbitrarily set to a manageable 2 pF (small values have too much tolerances and larger values will require smaller inductances, resulting in lower Q). The reactance of the first tuned circuit is

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi \times 9\text{E}8 \times 2\text{E}{-}12} = 88.42\ \Omega$$

The necessary inductance for resonance will be

$$\omega L = 88.42$$

or

$$L = 88.42/\omega = 88.42/(2\pi \times 9\text{E}8) = 15.64\ \text{nH}$$

We will make both tuned circuits identical, but with different loaded Qs. By multiplying 88.42 times the loaded Q (20 for the input resonator and 50 for the output resonator), the resulting parallel-resonant resistance is $88.42 \times 20 = 1768\ \Omega$ at 900 MHz (for the input resonator) and $88.42 \times 50 = 4421\ \Omega$ (for the output resonator). These values are achieved by loading the input with the 50-Ω source and by loading the output with the input of the transistor. Therefore, the input transformation ratio $m_1 = 1768.4/50 = 35.37$. At the output, the equivalent number $m_2 = 4421/50 = 88.42$. For the purpose of simulation, and because it is extremely difficult to find the physical location of the appropriate tap on an air-wound coil for the necessary impedance, we do this "on paper" by incorporating an ideal transformer. We are also going to show later the actual transmission-line-based filter and its modeling. This filter will have a higher insertion loss based on the PC-board material used.

Using our nonlinear simulator, in small-signal ac mode, we obtain the frequency response and noise figure shown in Figure 3-81. In actually building this circuit, there is another problem besides these transformers—the top-coupling capacitor. We have used a grounded-T configuration to obtain a practically realizable value of 36 pF, whose lead inductance will not influence the circuit. (The actual coupling capacitance value for top coupling without the T configuration would have 0.1 pF. We would like to see this value repeatably realized.)

If the actual noise would be calculated relative to the output tuned circuit, the equivalent noise resistor R_n of 5 Ω would now be multiplied by m_2, resulting in 442 Ω. Fortunately, the Serenade simulator has a highly accurate BJT noise model that is both bias and temperature dependent, so the simulator will give us the answer directly.

We have not put any matching circuit at the output and leave this task to the reader. In practice, the slight tilt in the MS_{21} curve in Figure 3-81 would be tuned out. Also note that the minimum noise figure ($F_{\min}$) and the actual 50-Ω noise figure (NF) agree somewhat off center. This has to do with the Miller effect, which results in the well-known difference between noise matching and input-gain matching. By varying the coupling capacitor to move from the overcoupled response, which gives a low noise figure, to a critically coupled

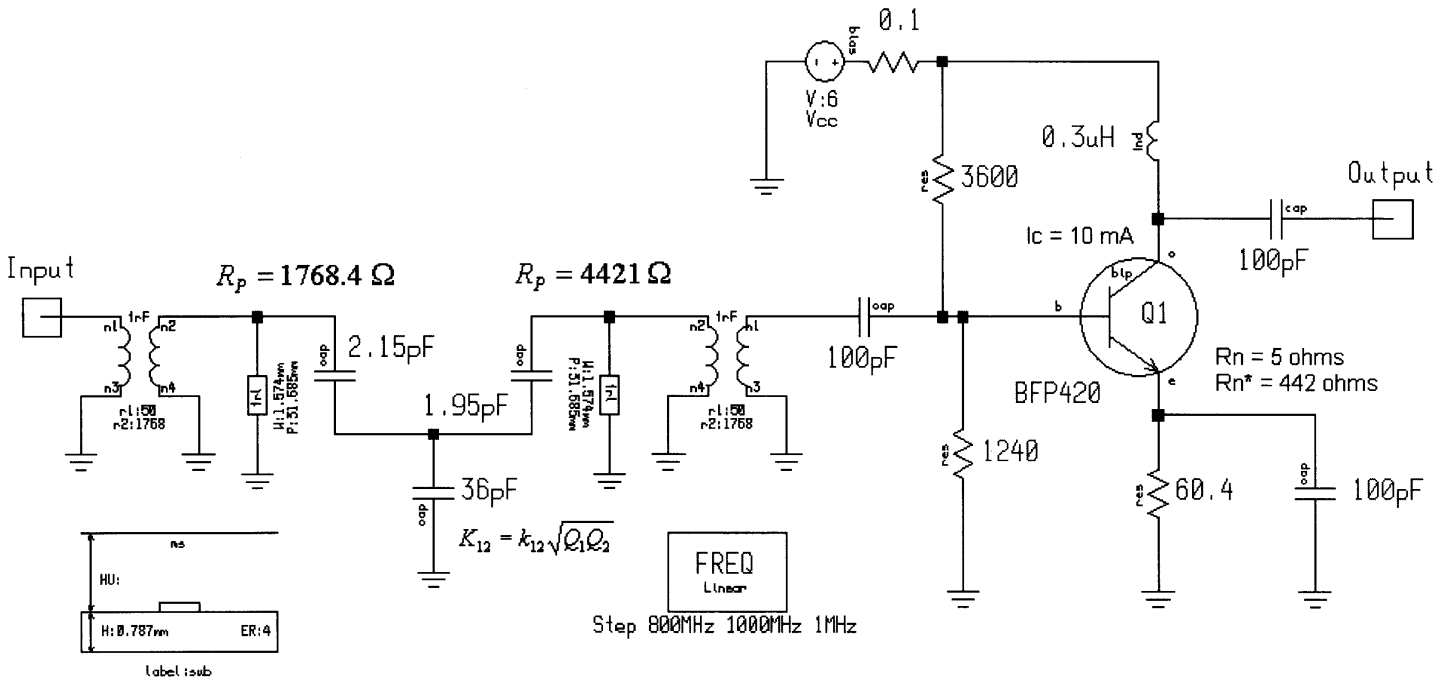

Figure 3-80 BFP420 amplifier with narrowband input filtering. Ideal transformers are used to match the filter's input and output to the input port and the BFP420 base, respectively.

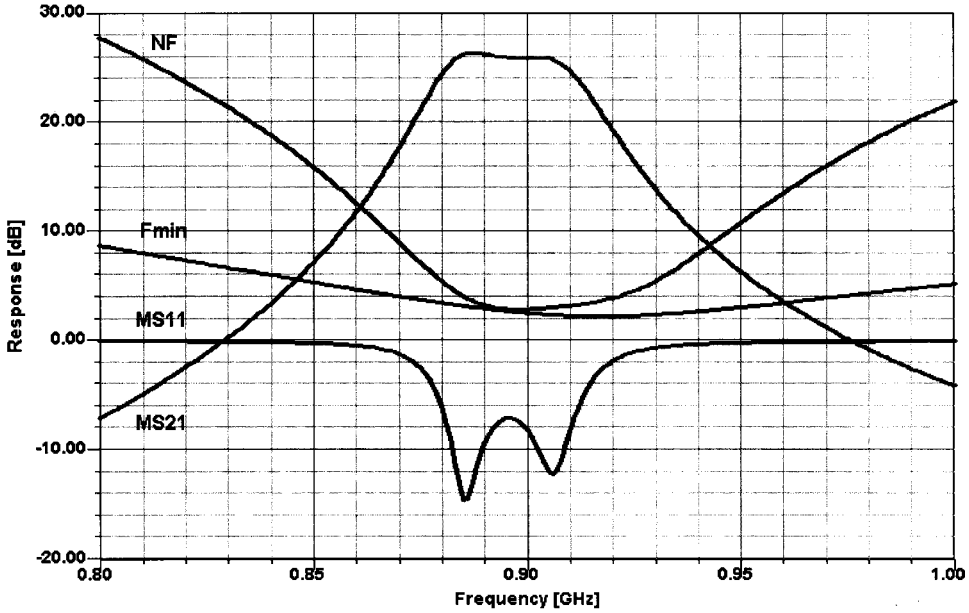

Figure 3-81 Frequency-dependent gain, matching, and noise performance of the narrowband BFP420 amplifier.

response ($K = 1$), we get significantly better selectivity and narrow bandwidth (at the obvious expense of the noise figure) as shown in Figure 3-82.

Since we somewhat compromised by not providing the reader with an actual input and output coupling that can be built, and furthermore, because the inductance in question (15.26 nH) is hard to realize with a high Q, we now show the printed circuit approach for the input filter. By using a Teflon-based material for the PC board, the losses would be less; however, the radiation would be more because ε would go down to 2.1 from the value we used (4). It is also convenient to introduce this filter to show that at higher frequencies, where lumped elements are really no longer available, one has to switch to distributed elements. A list of the commonly used distributed elements will be shown later; the transmission line and T junction are probably the most frequently used elements, followed by spiral and rectangular inductors, and bends.

The actual implementation of the input filter on a printed circuit board requires distributed elements (Figure 3-83). In practice, one has two parallel coupled lines with a tap somewhere toward the ground connection and, for modeling accuracy, we have to introduce a T junction with the appropriate impedance of 50 Ω for the input and a different impedance (if necessary) for the output. The coupling mechanism now is magnetic coupling, since no one can physically change the distance between the transmission lines by tuning some mechanical elements, one has to get it right the first time. This can only be achieved with a high-precision simulator. The reason why these simulators are so expensive is the investment of research time and personnel to produce valid models over a huge frequency and impedance range. Since we are now curious about the frequency response, we have plotted in Figure 3-84 the frequency response, which shows a higher (expected) insertion loss. The PC-board material is partially responsible for this.

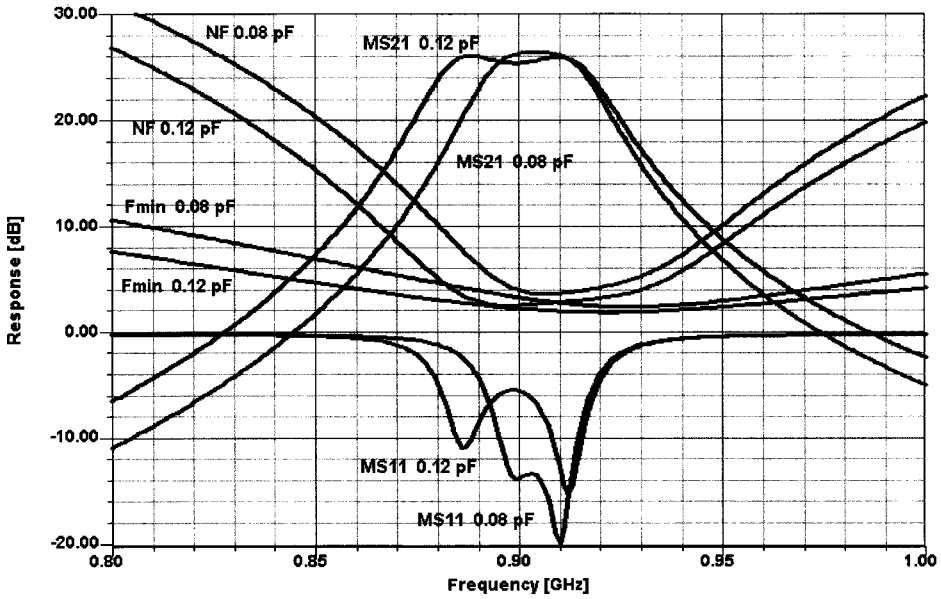

Figure 3-82 Comparison of filter responses with critical coupling (0.08-pF response) and overcoupling (0.12-pF response).

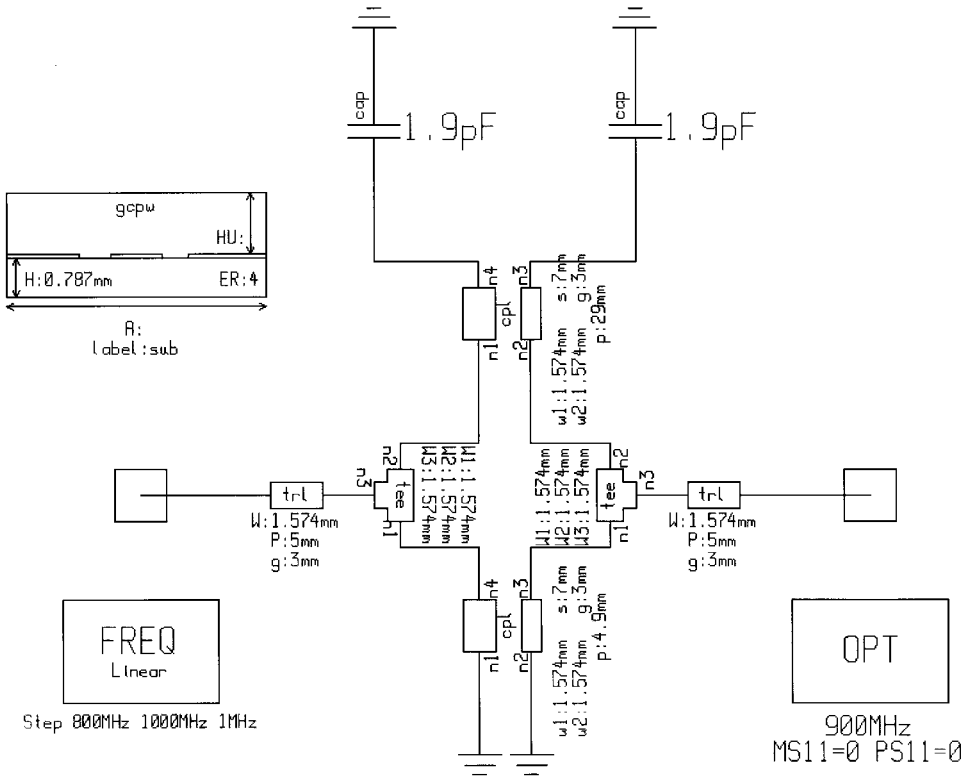

Figure 3-83 Input filter using distributed-element resonators and matching.

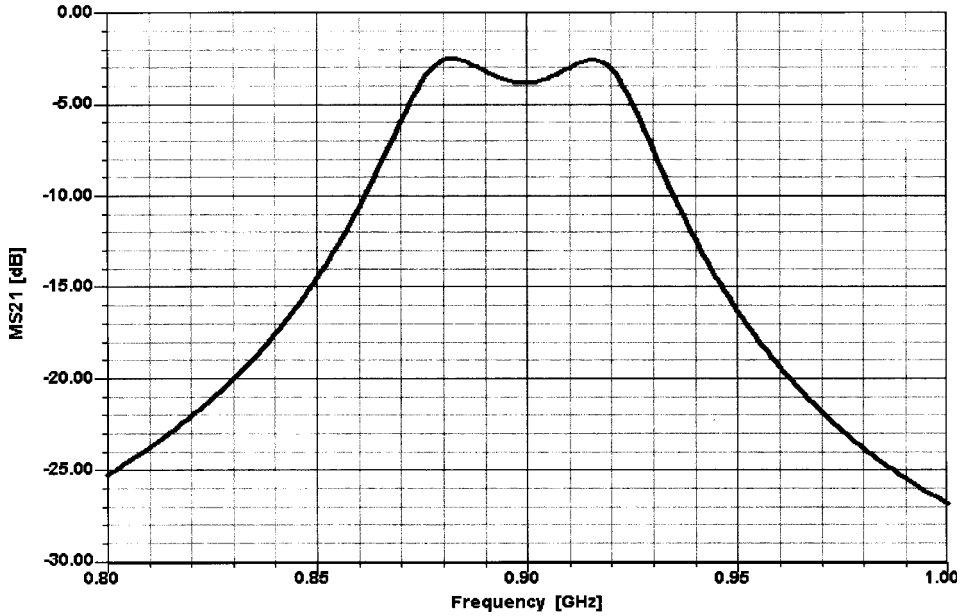

Figure 3-84 Gain versus frequency response for the distributed-element filter.

At the end of this chapter we will have a chance to discuss passive elements as needed for microwave frequencies, and one should consider frequencies above 1500 MHz as microwave frequencies.

GaAsFET Feedback Amplifier. The implementations we have shown so far have been based on bipolar transistors. Figure 3-85 shows a single-stage feedback amplifier using a GaAsFET. The feedback is based around an *LRC* network and some attempts at matching at the input and output are made. Figure 3-86 shows its frequency-dependent gain, matching, and noise performance.

3-2-3 High-Gain Amplifiers

In most cases, high-gain amplifiers receive an already amplified signal, which means we are less concerned about the signal-to-noise ratio but remain concerned about distortion. To reduce distortion, we have two options: (1) increase the dc current in the active device, which always improves the current-related distortion; and (2) add some voltage feedback, which reduces the voltage distortion. In simple terms again, only current feedback can reduce the current-related distortion of a square-law or exponential transfer characteristic and only voltage feedback can reduce the effect of overdrive as a function of the load, but only to some degree. Its main purpose remains to reduce the input impedance to useful values, specifically for FETs, since current feedback increases the input and output impedances. Some ultrasensitive circuits still require Class A operation, but now at higher current levels; these are typically CATV applications, and there are several transistors available that can be operated at 5–15 V but at 60 mA or higher. Because of the higher power consumption, this excludes handheld cordless or cellular telephones. The same circuit as used before (Figure 3-85) for

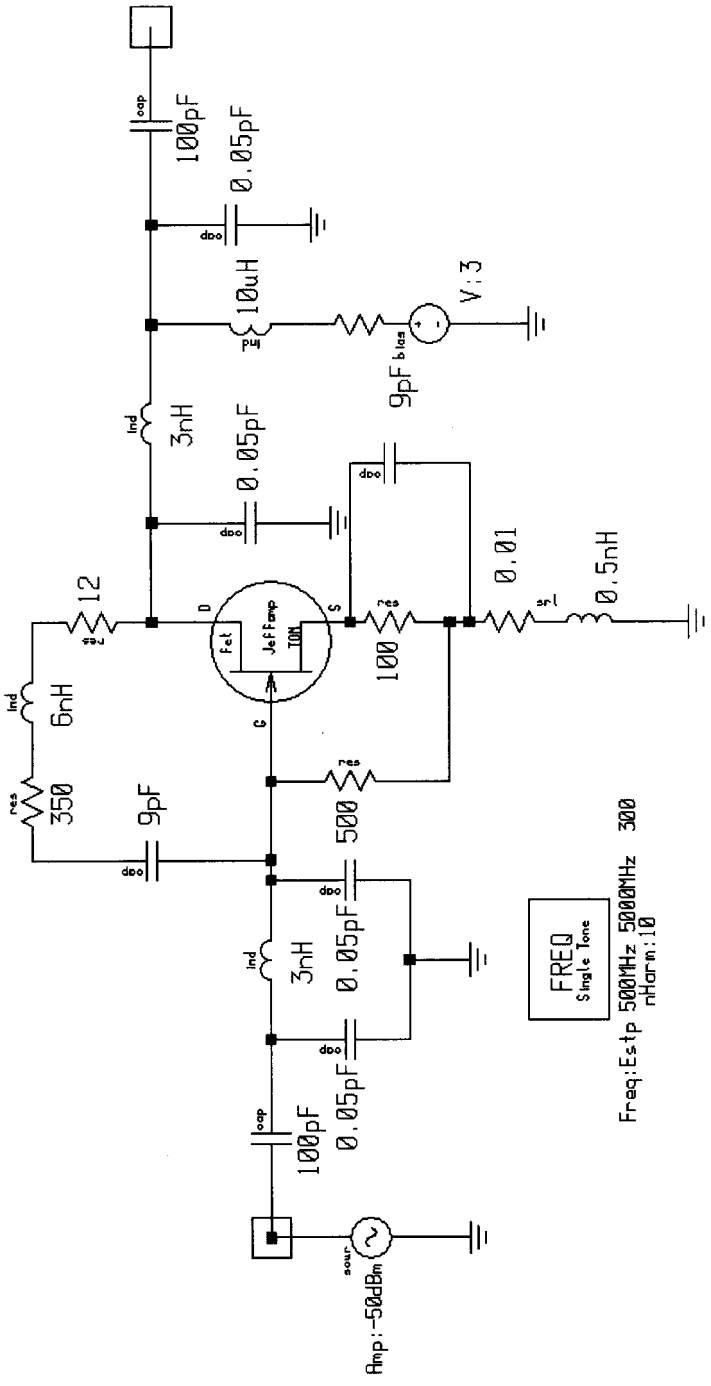

Figure 3-85 GaAsFET feedback amplifier.

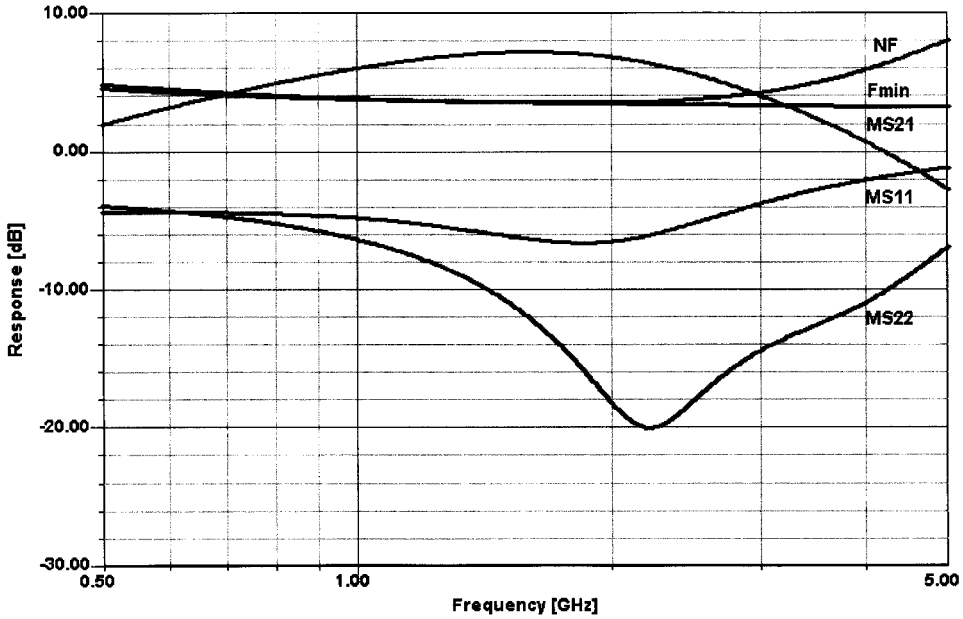

Figure 3-86 Frequency-dependent gain, matching, and noise responses for the GaAsFET amplifier.

Class A operation now can be operated at a higher current, which automatically increases the gain and the noise figure and reduces distortion. This is based on the fact that the transconductance (g_m) increases at higher currents. The second transistor in the TI circuit achieves this by being in reality a larger device, which could be modeled by several transistors, like the first stage, in parallel. This automatically increases the dc current by the scaling factor. The same is even more true for the output stage. Likewise, bipolar transistors can also be scaled. A visual inspection of some transistors in their packages will reveal that they are really not just one transistor, but several operating in parallel, each with its own ballast resistors (for bipolar transistors) or other means (for FETs).

Using tuned circuits rather than wideband matching, it is possible to go to Class AB or B operation. Class AB is really a hybrid between A and B, and Class B is probably better known. Figure 3-63 shows the Class B operating point. Most Class B stages are operated in push–pull because, together with the tuned circuit, one-half of the cycle is supplied by the other transistor. The definition of Class B operation is a conducting angle of 90° (see Figure 3-63). At this point it should be noted that some older texts define the conducting angle as being twice the value we have defined in this chapter.

Without going into further details, the highest efficiency in Class B operation is 78.5%. Based on the fact that modern wireless applications generally use a hybrid of amplitude and angle modulation, pure Class C operation finds little application today because of the severe nonlinear distortion it introduces. A Class B stage has less "power gain" than a Class A stage but provides much more output power. We have already mentioned the problem associated with characterizing a Class A stage in terms of power gain. That's the only time Kirchhoff's equations are valid, meaning that the sums of all currents and voltages have to be zero. Because Kirchhoff's equations do not consider nonlinearities and harmonic contributions,

the very moment we move into considering medium- and higher-power amplifiers, the nonlinearities will dominate and the performance of the stage is best analyzed with a high-quality circuit simulator with the appropriate dynamic range and good modeling capability. Without question, this applies to Class C operation also. As pointed out previously, the high-gain amplifier is optimized for gain rather than noise figure and typically requires more collector or drain current. This can easily be seen by rebiasing the FET amplifier as shown above to a significantly higher value of 33 mA. This is accomplished by changing the source resistor down to 3 Ω. As a result of this, we obtain the gain, matching, and noise figure responses shown in Figure 3-87.

It may be a surprise to the reader that the actual noise figure now is less than that shown in Figure 3-86. This device is now operating at 33 mA; the reason for this has to do with the fact that if the transconductance is too low, the noise figure also increases, and the NF curve for the FET has a similar-looking current-dependent minimum—a curve that is frequently not supplied by the manufacturer. This amplifier, now operating at 33 mA, should have quite good large-signal capabilities; we will examine this shortly.

Another interesting piece of information is the display of the dc I–V curves with the "load line." Since we have reactances in the circuit, we do not see a line but rather an ellipse, indicating the storage of energy. (The actual load line would be a line through the two foci of the ellipse.) This curve allows us to see immediately that at this operating point the transistor is neither going into current saturation nor becoming voltage limiting. The input power can be increased further until such a condition exists. Figure 3-88 shows the dc I–V curve for the amplifier shown in Figure 3-85.

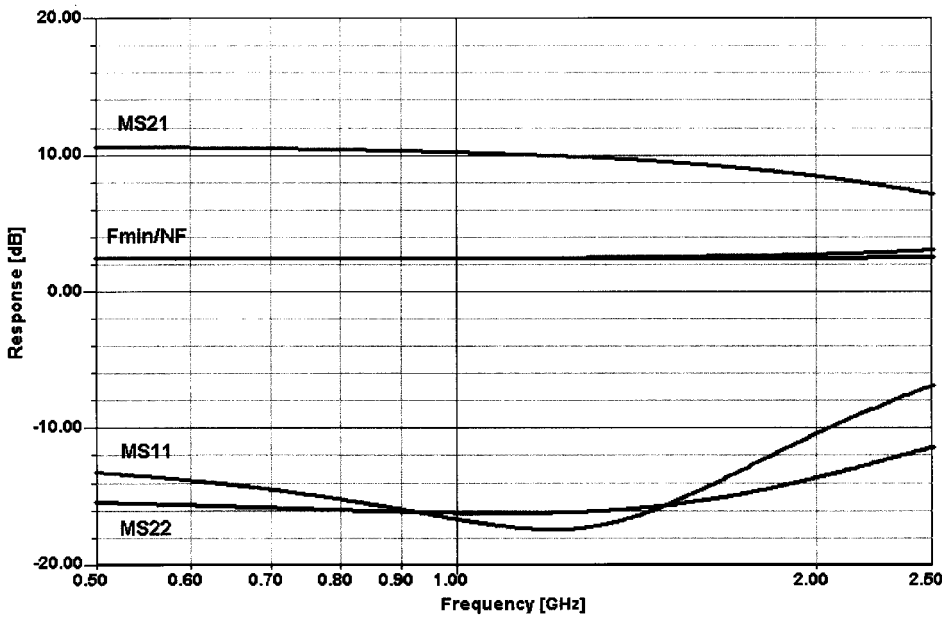

Figure 3-87 Frequency-dependent gain, matching, and noise performance for the GaAsFET amplifier of Figure 3-85 rebiased for a drain current of 33 mA.

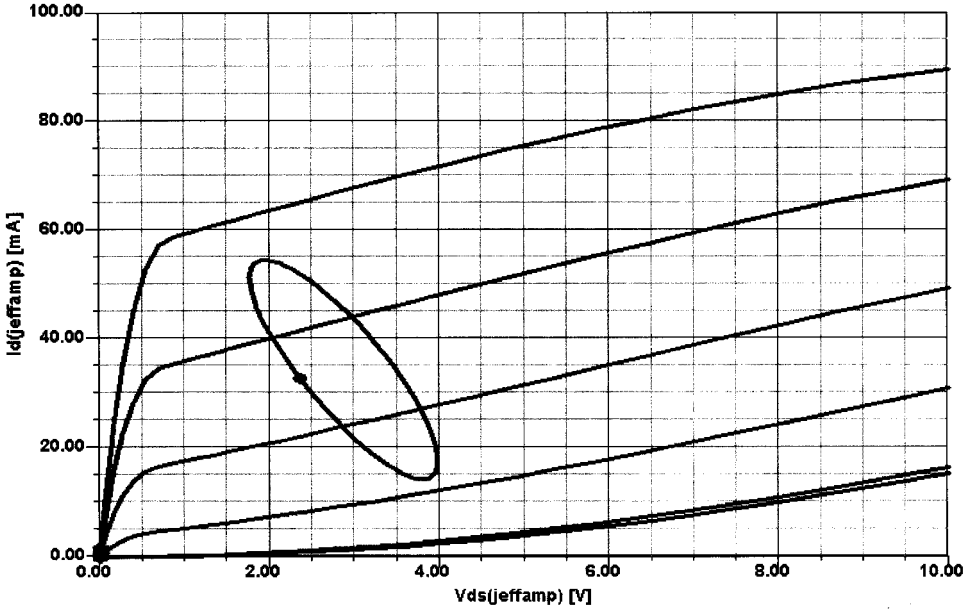

Figure 3-88 The dc *I–V* curves for the GaAsFET operating at I_D = 33 mA, including the ac load line. The load line is an ellipse rather than a straight line for the reason described in the text.

Besides looking for the adjacent-channel power ratio (ACPR), the other traditionally important points are third-order intercept point and the equivalent of a multitone simulation, as used for CATV application but relevant to the multisignal environment of wireless applications. Figure 3-89 shows the determination of the amplifier's third-order intercept point. It is most important for the reader to understand that very low values for input and output level have to be used to determine the crossover point. If this advice is not followed, totally erroneous numbers can occur.

Since an antenna supplies a large number of signals (this is true of handheld radios as well as base-station sites), a three-tone standard has been adopted as a good approximation of multisignal operation. This standard is in accordance with the German DIN 45004E,3.3 three-tone measurement. The requirement is that the intermodulation distortion products at the output are better than 60 dB suppressed relative to the largest of the three tones. One tone is used as the reference, and the other two tones are 6 dB less. This measurement has been derived from television, whereby the video transmitter, based on the vestigial sideband power, is 6 dB above the two sidebands produced by the FM sound transmitter using a modulation index of 5. The result of a three-tone test can be seen in Figure 3-90. This amplifier clearly meets the DIN specification for linearity at input levels up to –9/–15 dBm at the input.

Bipolar transistors are also quite popular for this purpose. Figure 3-91 shows a single-stage amplifier with an intrinsic transistor and all the other "hidden" intrinsics, normally not visible, added. The three diodes belong to those intrinsic elements, which are needed for accurate microwave modeling but which are not provided by the standard nonlinear models. The reader will see that we went into great detail to model all the necessary parts. This feedback amplifier, whose frequency response is shown in Figure 3-92, has been quite

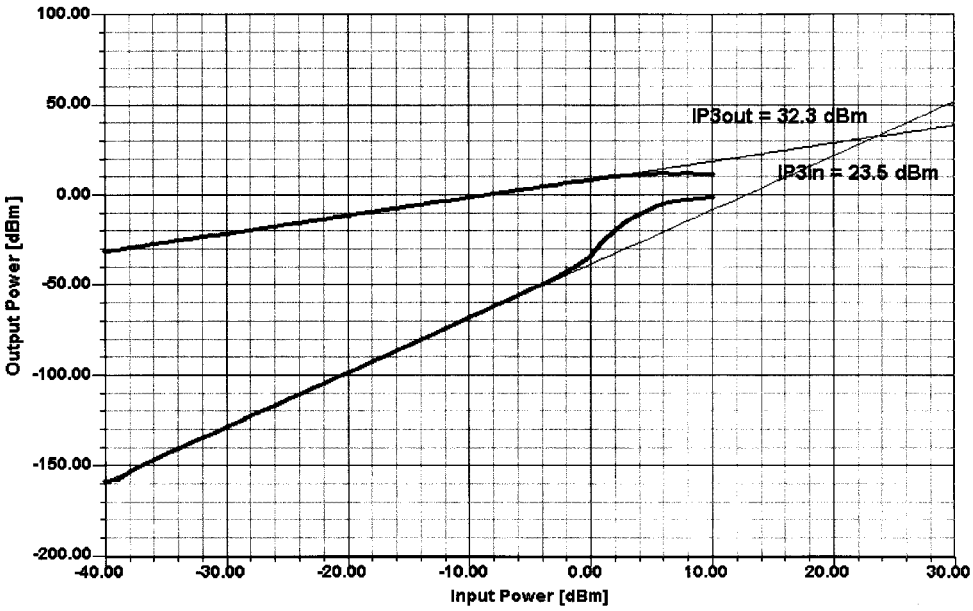

Figure 3-89 Determination of the third-order intercept point based on a two-tone measurement using tones spaced at 5% of the operating frequency (1.8 GHz).

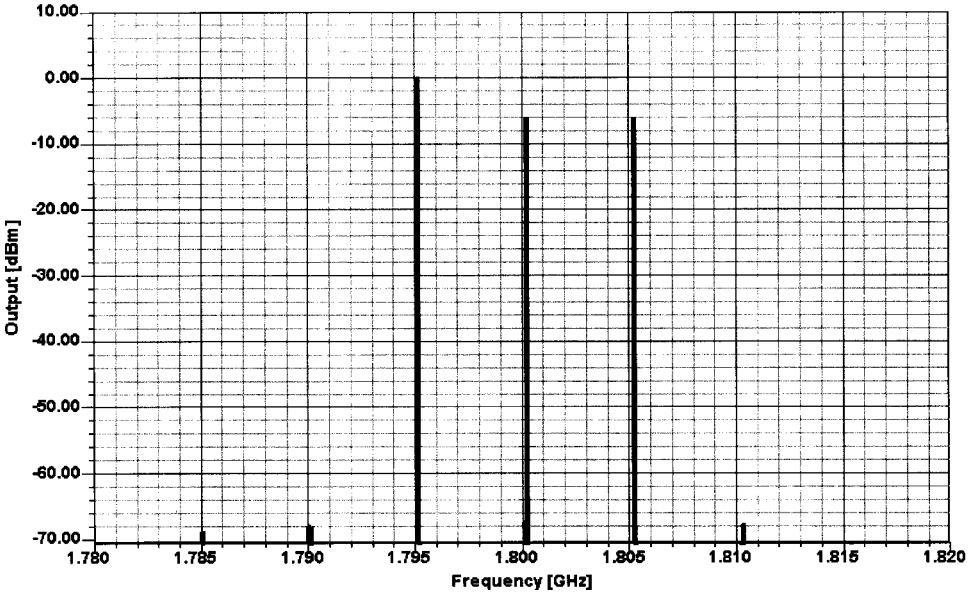

Figure 3-90 Simulated three-tone analysis of the GaAsFET amplifier with $I_D = 33$ mA.

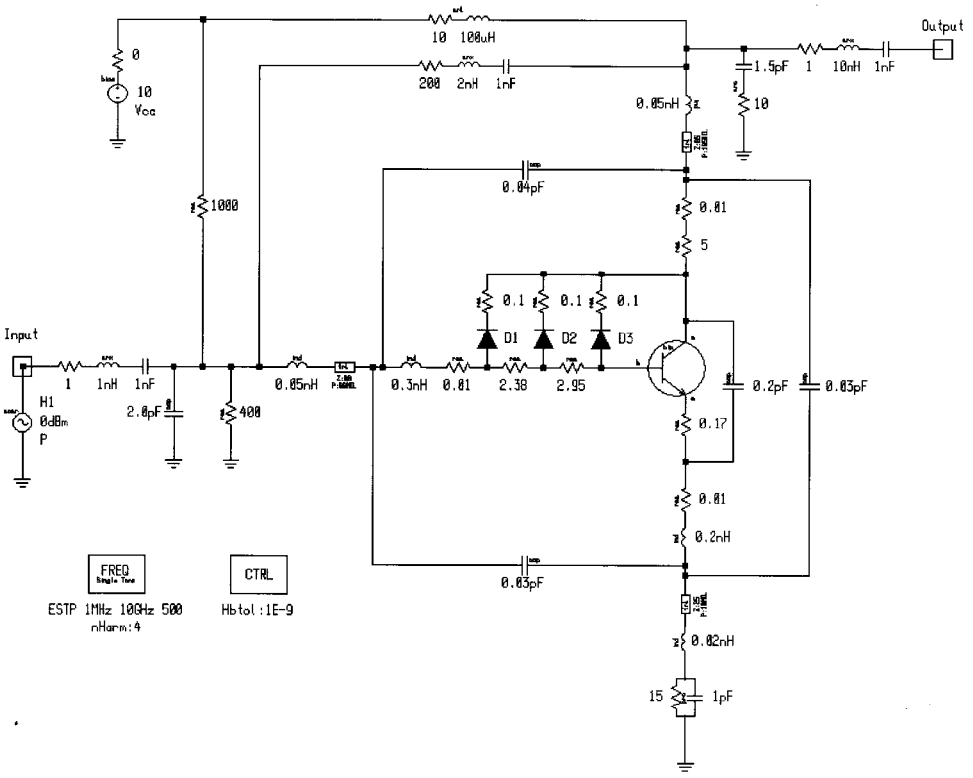

Figure 3-91 A high-linearity single-transistor amplifier modeled in great detail.

difficult to design, but there are monolithic circuits available where the higher gain–bandwidth product is being used to advantage.

Figure 3-92 shows the predicted frequency-dependent gain, matching, and noise figure at a bias point of 108 mA at 10 V. Using the same DIN three-tone test procedure, Figure 3-93 shows the expected good result.

Since this test requires two equal signals and one larger signal, we need to expect one IMD product larger than the rest. We have set our window for a dynamic range of 70 dB, and yes, in the lower left corner, we can see the product between the first two signals, while the other products are below the –50 dB level.

As a little task, Figure 3-94 shows a simple amplifier, based on a modern Siemens transistor, which is a feedback amplifier with fewer modeling details surrounding the transistor. Its associated frequency-dependent performance is shown in Figure 3-95. Interested readers are invited to improve its performance by using their skills and intuition.

Permitting higher currents and actually combining two transistors leads to our first MMIC. The following simulation is based on the MGA64135. Needless to say, there are some compensation networks inside the MMIC and distributed elements that affect the frequency response. However, with this arrangement, it is possible to obtain an appreciable gain at our wireless frequencies. The noise figure, based on the feedback, however, it not too impressive. This is a problem that occurs with most feedback amplifiers, which try to minimize the distortion and yet would like to keep the noise figure down. Figure 3-96 shows the schematic

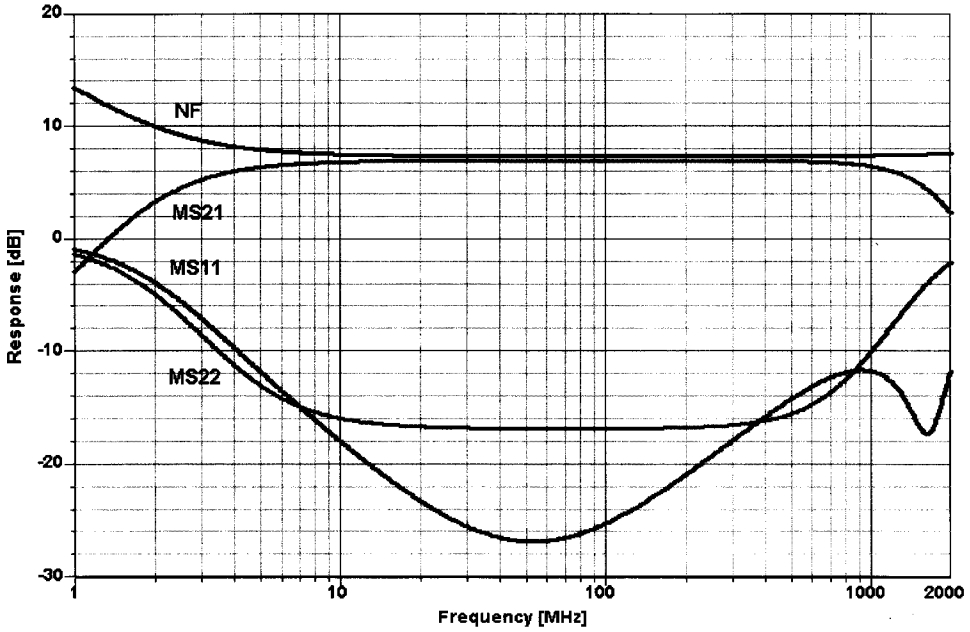

Figure 3-92 Simulated frequency-dependent gain, matching, and noise figure performance of the circuit in Figure 3-91.

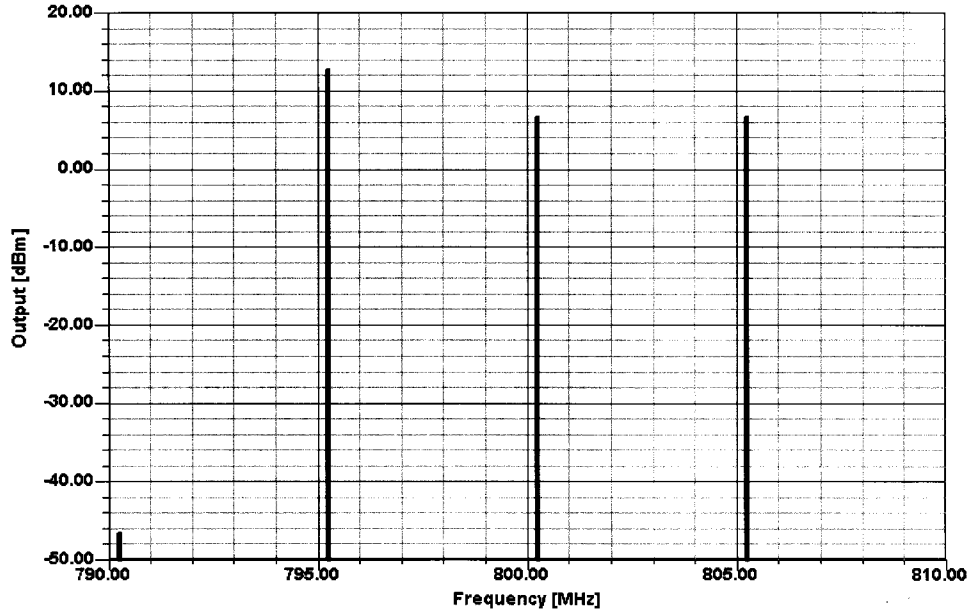

Figure 3-93 Simulated three-tone output spectrum of the amplifier in Figure 3-91.

of the GaAs MMIC; Figure 3-97 shows its frequency-dependent gain, matching, and noise performance; Figure 3-98 shows its two-tone response, which is used to obtain the intercept point ($IP_{3,in}$ = 8.5 dBm, $IP_{3,out}$ = 22 dBm); and, finally, Figure 3-99 shows the three-tone test results at an input RF level of –21/–27 dBm. While the gain–bandwidth product is considerably larger than the single-stage amplifier we examined before, the intercept point and three-tone performance do not reach the same values. As a general rule, the dynamic

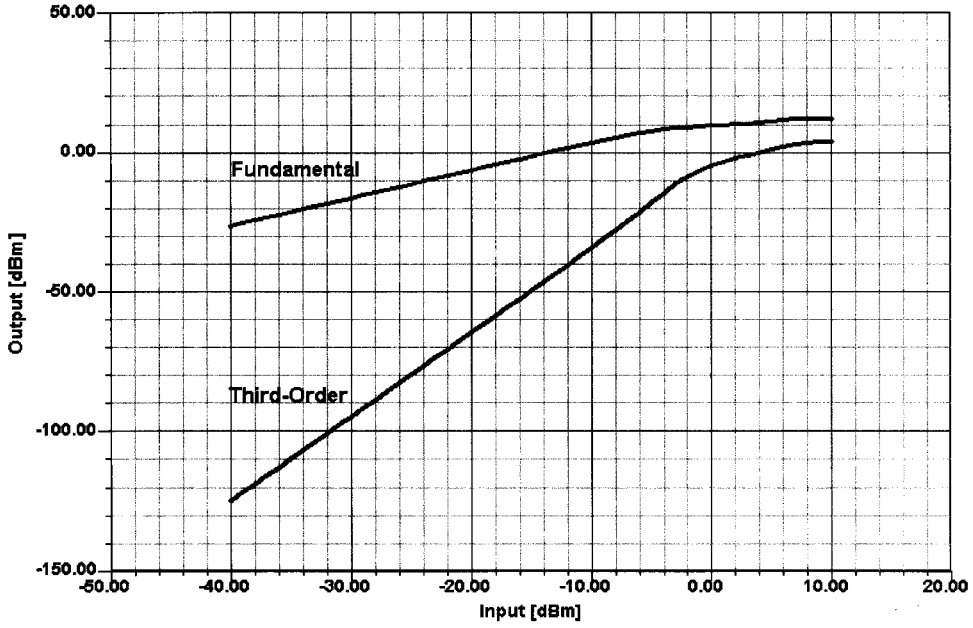

Figure 3-98 Simulated two-tone testing of the MGA64135 MMIC amplifier. $IP_{3,in}$ = 8.5 dBm and $IP_{3,out}$ = 22 dBm.

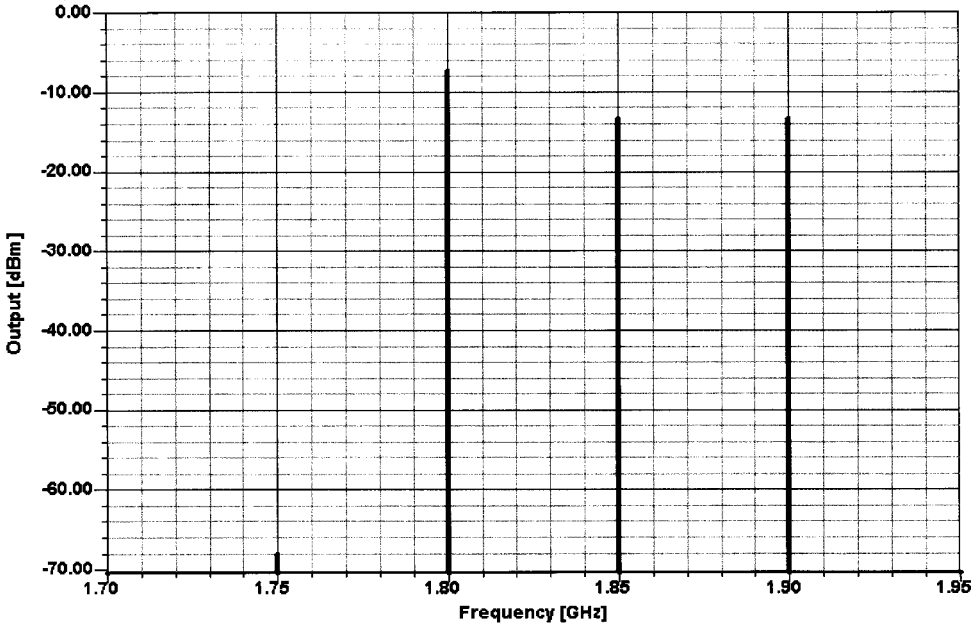

Figure 3-99 Simulated three-tone test of the MGA64135 MMIC. The test tones were 1.80 GHz (–21 dBm), 1.85 GHz (–27 dBm), and 1.90 GHz (–27 dBm). The 1.75-GHz IMD product is down 60.5 dB relative to the 1.80-GHz signal.

range is directly proportional to the power dissipated in the devices: specifically, the current. As explained earlier several times, the first-order nonlinearity comes from the voltage-to-current transfer characteristic, such as the transconductance itself, and can only be improved by a combination of resistive feedback in the emitter/source and by high currents. At these dc levels, the base–emitter (gate–source) junction gets linearized because the differential values are getting smaller compared to the parasitic loss resistances, including external dc/RF feedback. Once again, the voltage feedback reduces the voltage clipping but is initially more responsible for the input and output matching.

3-2-4 Low-Voltage Open-Collector Design [22–25]*

Why R_C Acts Like a Source Resistor. An open-collector output allows a designer the flexibility to choose the value of the R_C resistor. Choice of this resistor value not only sets the dc bias point of the device but also defines the source impedance value. Figure 3-100 shows the ac model of the transistor. Converting the output structure by applying a Norton and Thevenin transformation, one can conclude that R_C becomes the source resistance. Thus, by choosing R_C to be equal to the load, maximum power transfer will then occur.

Figure 3-101 shows an active transistor with collector and base resistors. From basic transistor theory, Eq. A in Figure 3-101 is generated and has the same form as the general equation for a straight line ($y = mx + b$).

Figure 3-101 Basic transistor analysis.

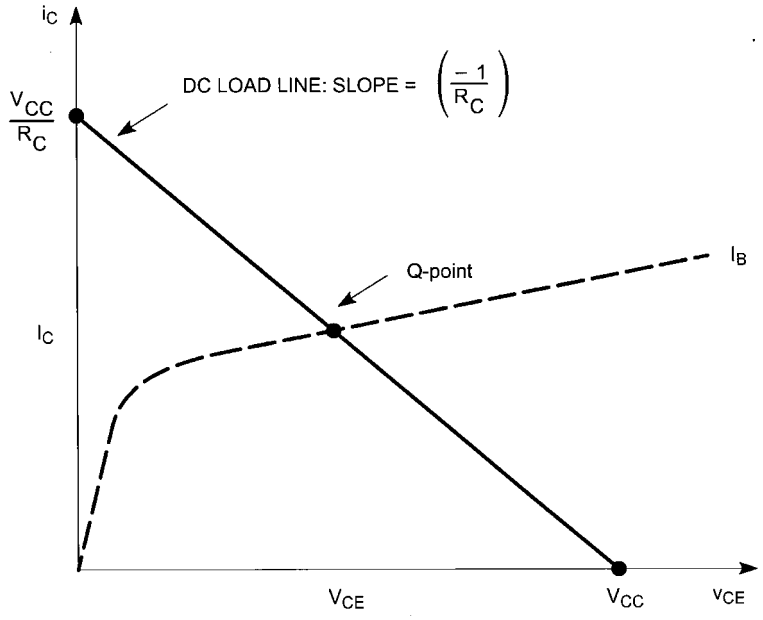

Figure 3-102 Load line and Q-point graph.

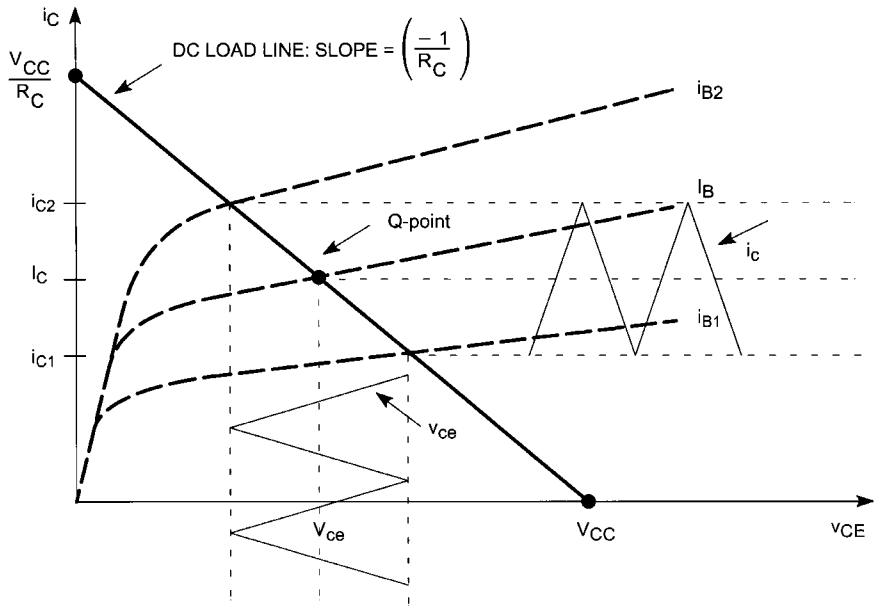

Figure 3-103 Graphical analysis for the circuitry in Figure 3-101.

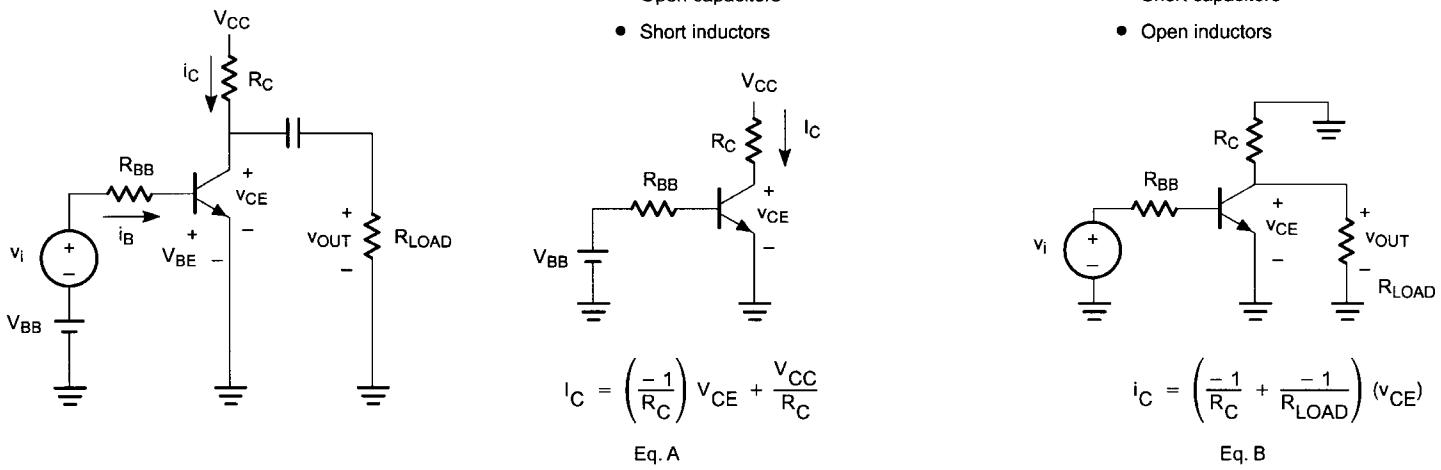

Figure 3-104 Basic transistor analysis with R_{LOAD}.

The slope of the dc load line is generated by the value of the collector resistor ($m = (1/R_C)$ and is shown in Figure 3-102. For a given small-signal base current, the collector current is shown by the dotted curve. The intersection of the dotted curve and the dc load line is called the *quiescent point* (Q-point) and dc bias determinant. The location of the Q-point is important because it determines whether the transistor is operated in the cutoff, active, or saturation region(s). In most cases, the Q-point should be in the active region because this is where the transistor acts like an amplifier.

Figure 3-103 shows the ac collector–emitter voltage (V_{CE}) output swing with respect to an ac collector current (I_C). Collector current is determined by the ac voltage presented to the input transistor's base (v_i) because it affects the base current (i_b), which then affects i_c. This is how v_i is amplified and seen at the output. Recall that this is with no external load (R_{LOAD}) present at the collector. Since no load is present, the slope of the ac load line is identical to that of the dc load line as seen in Eqs. A and B of Figure 3-101 ($m = -1/R_C$).

Open Collector with R_{LOAD}. A filter with some known input impedance is a typical load for the output of the transistor. For simplicity, we will assume a resistive load (R_{LOAD}) and neglect any reactance. Since a resistive load is used (see Figure 3-104), the ac output swing is measured at V_{OUT} or V_{CE}.

A dc blocking capacitor is used between the R_{LOAD} and the V_{CE} output to assure that the Q-point is not influenced by R_{LOAD}. It is also necessary to avoid passing dc to the load in applications where the load is a SAW filter. However, R_{LOAD} will affect the ac load line, which is seen in Eq. B in Figure 3-104. Note that the V_{CE} voltage swing is reduced; thus, the V_{OUT} signal is reduced (see Figure 3-105).

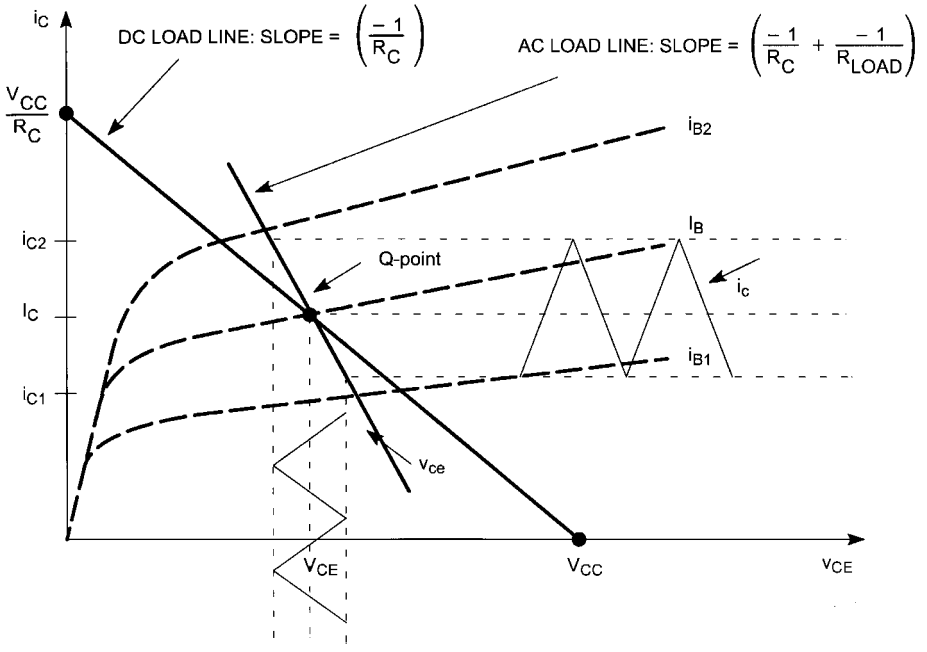

Figure 3-105 Graphical analysis for the circuitry in Figure 3-104. The ac load line intersects the Q point, and the slope is steeper than the dc load line due to R_{LOAD}, which makes V_{CE} smaller.

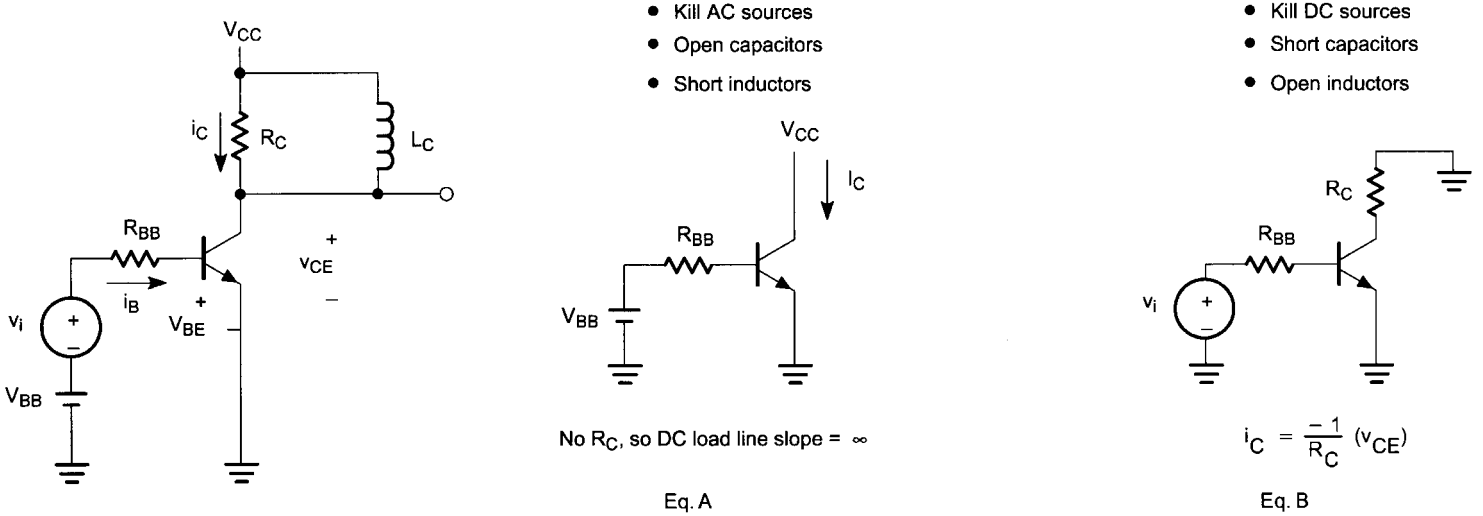

Figure 3-106 Basic transistor analysis with inductor added to collector.

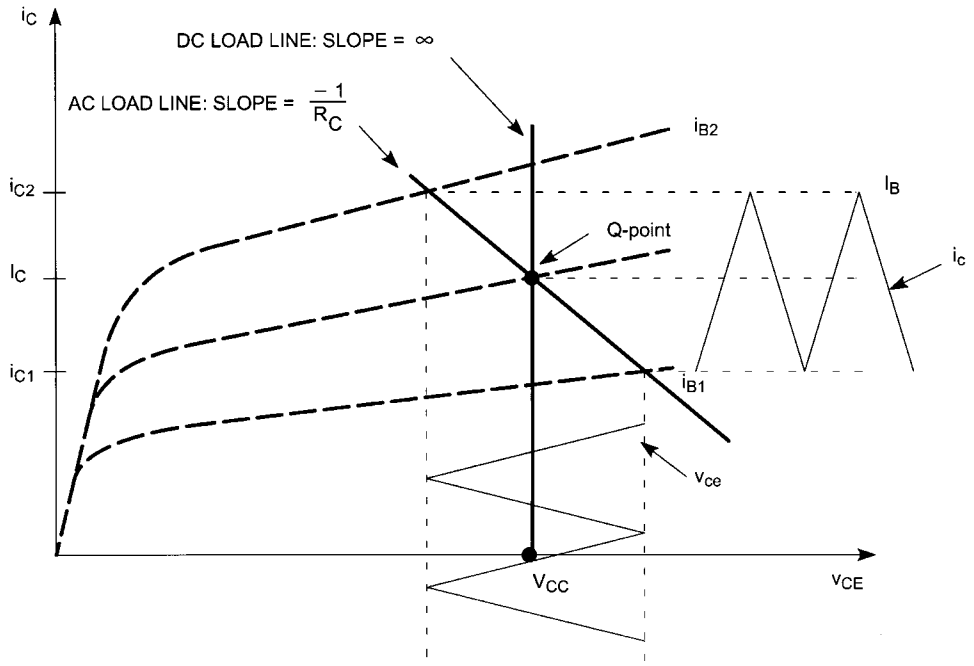

Figure 3-107 Graphical analysis for the circuitry in Figure 3-106.

Since the values of R_C and R_{LOAD} affect the ac load line slope, the value chosen is important. The higher the impedance of R_{LOAD} and R_C, the greater the ac output swing will be at the output, which means more conversion gain in a mixer. This is due to the slope getting flatter, thus allowing for more output swing.

Open Collector with Inductor (L_C). Adding an inductor in parallel with R_C can increase the ac output signal V_{CE}. Figure 3-106 shows the dc and ac analyses of this circuit configuration. In Eq. A in Figure 3-106, there is no R_C influence because the inductor acts like a short in the dc condition. This means the slope of the dc load is infinite and causes the Q-point to be centered around $V_{CC,}$ thus moving it to the right of the curve. The ac load line slope is set only by R_C because no load is present. Note that it has the same ac load line slope as the first condition in Eq. B of Figure 3-101.

Referring to Figure 3-107, one might notice that the base current (ac and dc) curves spread open as V_{CE} increases. This is caused by a noninfinite Early voltage (see Figure 3-108), which causes the collector current to be dependent on V_{CE}. Taking advantage of this nonideal condition, the peak-to-peak ac output swing V_{CE} can thereby be increased by moving the dc Q-point to the right due to the wider spreading between the curves corresponding to different base currents. Figure 3-109 combines Figures 3-103 and 3-107 to show the different ac output signals with different Q-points.

Looking at the ac output level, one might ask how the V_{CE} peak voltage can exceed the supply voltage V_{CC}. Recall that the inductor is an energy-storing device ($v = L\ di/dt$). Therefore, total instantaneous voltage is V_{CC} plus the voltage contribution of the inductor.

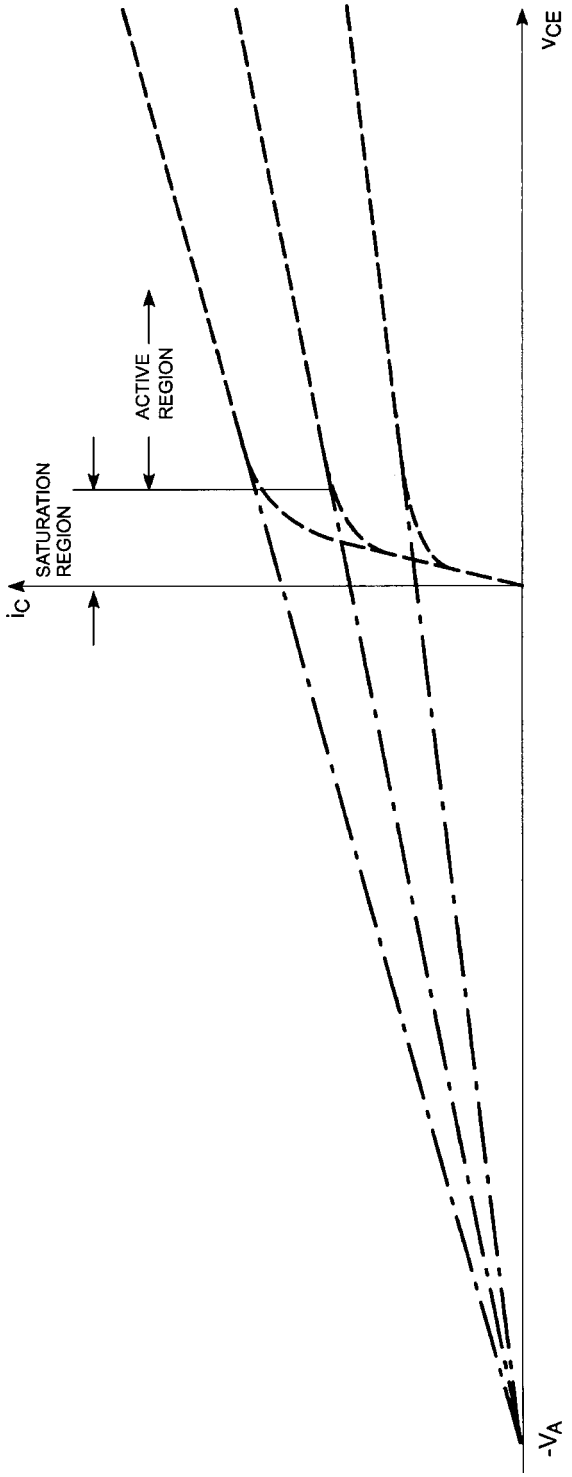

Figure 3-108 Graphical representation of Early voltage effect.

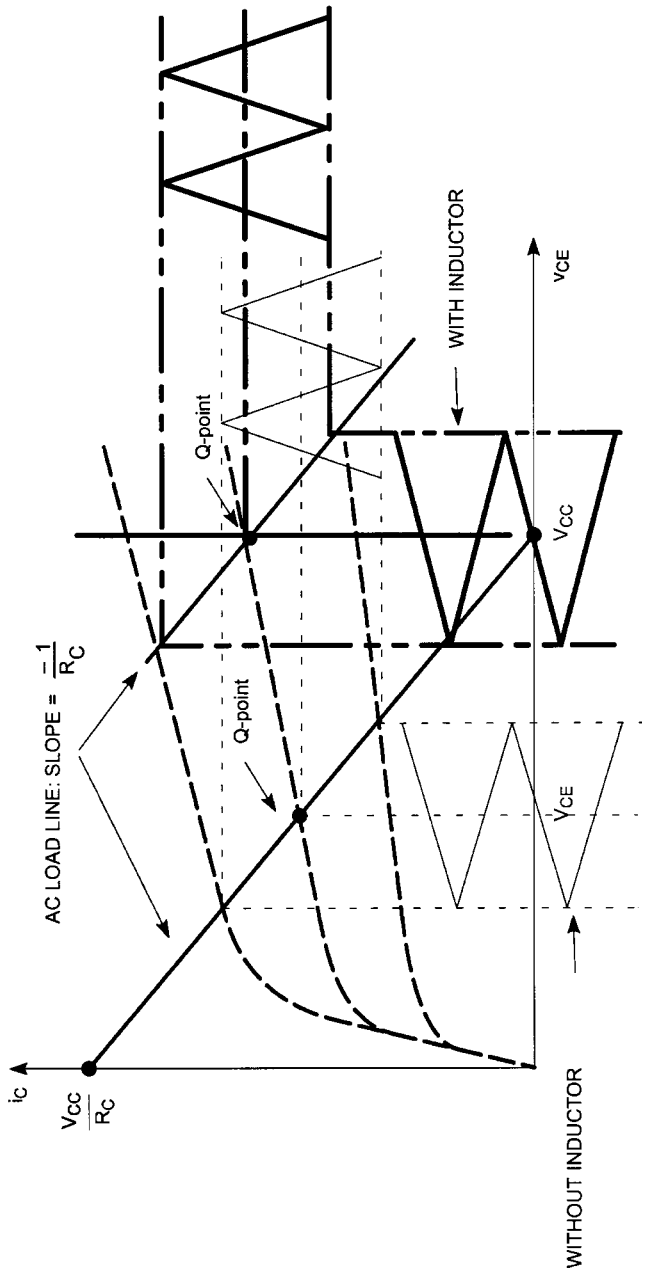

Figure 3-109 Comparison of open-collector circuit with inductor versus without inductor.

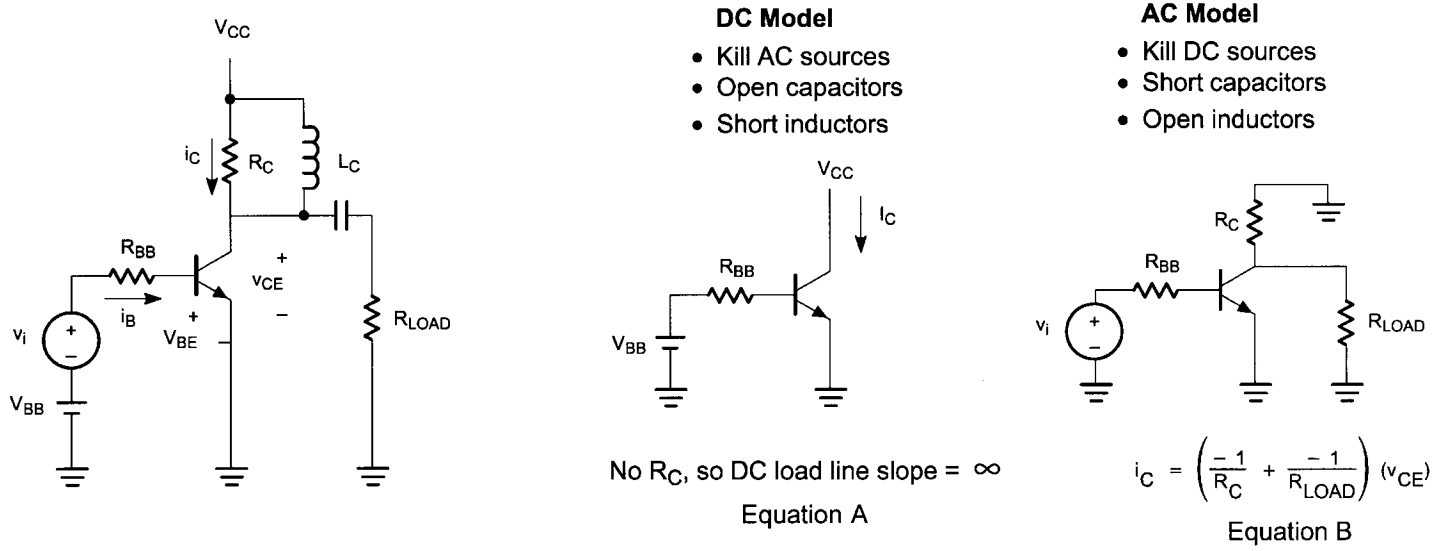

Figure 3-110 Basic transistor analysis with inductor and R_{LOAD}.

Open Collector with Inductor (L_C) and R_{LOAD}. Figure 3-110 shows the dc and ac analyses with the inductor and load resistor. Again, from the dc analysis, the inductor causes R_C to be nonexistent so the dc load line is vertical. In the ac analysis, the ac load line slope is influenced by both R_C and R_{LOAD} (see Eq. B in Figure 3-110). The ac load line slope is the same as the example of the open collector without the inductor. Figure 3-111 shows the response for the open collector with L_C and R_{LOAD}. Figure 3-112 combines Figures 3-105 and 3-111 showing the increase in ac output swing.

In conclusion, for the load line, R_C plays a role in setting up the bias-determined Q-point as well as the ac source impedance. However, when an inductor is placed in parallel with R_C, a different Q-point is set and the ac source impedance is altered. Moving the Q-point takes advantage of the transistor's nonideal i_c dependence on V_{CE} to get more signal output without having to change the base current. Since R_C is in parallel with R_{LOAD} in the ac condition, it influences the ac load line slope.

Flexible Matching Circuit [25]. A useful variation of the open-collector matching concepts previously outlined provided the capability of delivering equal power to two unequal resistive loads. This allows the power delivered to the load to be measured indirectly at another test point in the circuit where the impedance can be defined arbitrarily. If this impedance is defined to be 50 Ω, a spectrum analyzer can easily be placed directly into the circuit. This is an excellent troubleshooting technique and a valuable option to have available in high production environments.

Figure 3-113 shows the schematic for this flexible matching circuit. In this circuit, C_B functions only as a dc blocking capacitor and presents a negligible impedance at the frequency of interest. Recall from the previous open-collector matching discussions that,

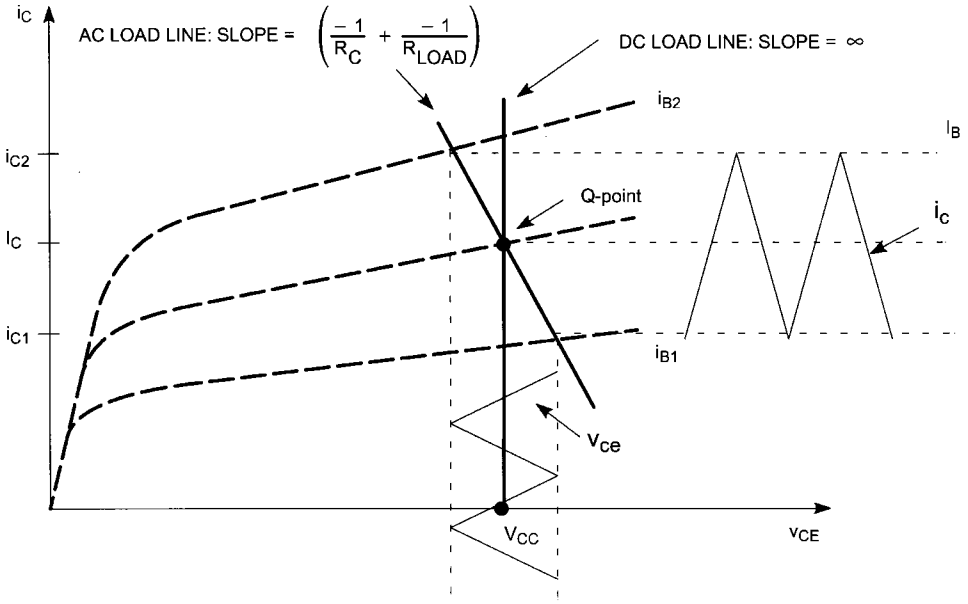

Figure 3-111 Graphical analysis for the circuitry in Figure 3-110.

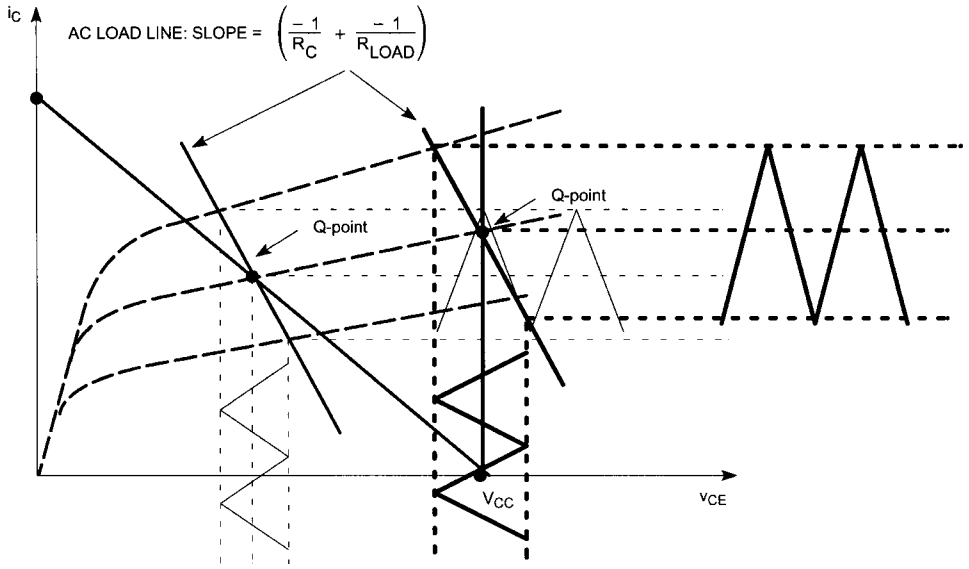

Figure 3-112 Comparison of open-collector R_{LOAD} circuit with inductor versus without inductor.

when R_C is placed in parallel with an inductor, it has no effect on the Q-point but does influence the slope of the ac load line as

$$\text{Slope} = \frac{-1}{R_C} + \frac{-1}{R_{\text{LOAD}}} \tag{3-166}$$

The capacitor C_S not only functions as a dc blocking capacitor but is also chosen such that the impedance presented by the combination of L, R_C, and C_S is equal to R_{LOAD} for optimum power transfer. The analysis is done in the following manner. First, note that inductor L is connected to V_{CC}, which is an affective ac ground. So L can be redrawn to ground. Next, R_C and C_S are converted to their parallel equivalent values as shown in Figure 3-114.

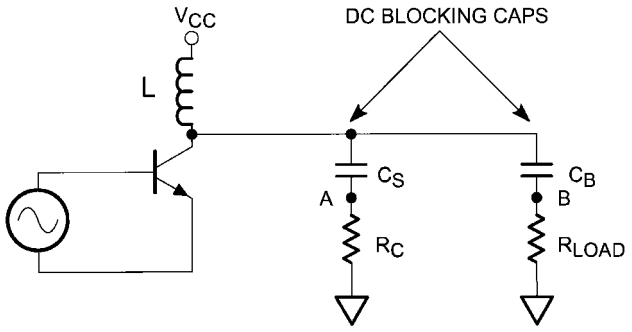

Figure 3-113 Flexible matching circuit.

Figure 3-114 Converting from series to parallel configuration.

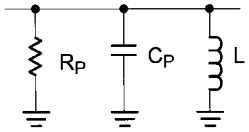

Figure 3-115 Converting from series to parallel configuration. Goal: Find L_C and C_p such that R_p looks like the R_{LOAD} value at the resonant frequency.

The resulting parallel *LCR* circuit is shown in Figure 3-115. At resonance, the parallel L–C_P combination will be an effective open circuit leaving only R_P. R_P is then simply chosen to be equal to R_{LOAD}.

Starting with the most simple transistor configuration and using *RC* types of dc-coupled amplifier circuits, we next present an overview of possible configurations for this application.

3-3 SINGLE-STAGE FEEDBACK AMPLIFIERS

This amplifier (Figure 3-116) is a standard minimal configuration amplifier with reduction of current distortion because of the emitter feedback. The voltage gain is

$$\text{VG} = \frac{R_L}{(26\text{mV})/I_C + R_e} \tag{3-167}$$

where R_L is the total load seen at the collector.

The feedback amplifier in Figure 3-117 uses voltage feedback to "correct" the input and output impedance to be close to 50 Ω but does not improve the current distortion. The voltage gain of this circuit is

$$\text{VG} = \frac{R_F}{R_g} \tag{3-168}$$

$$R_{\text{IN}} = R_{\text{OUT}}$$

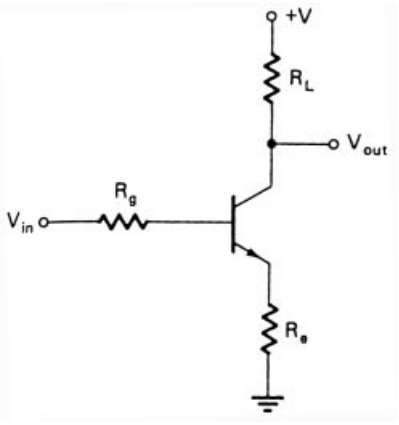

Figure 3-116 Single-stage amplifier with current feedback (provided by R_e).

$$= R_F R_D \quad \text{with} \quad R_D = \frac{26\text{mV}}{I_C} \tag{3-169}$$

Example. For $I_C = 10$ mA $\rightarrow R_D = 2.6\ \Omega$ and assuming $R_F = 200\ \Omega$, the input resistance $R_{\text{IN}} = 22.63\ \Omega$. The gain is calculated by getting the inverse of $R_D = g_m = 0.39$ A/V. Once this is multiplied with the output impedance of 22.63 Ω, the resulting gain becomes 10 log (8.6) or 9.3 dB. The gain can be increased by either using a larger collector current or a larger feedback resistor. It should be reminded that this circuit does not improve the distortion caused by the base–emitter junction.

To reduce the current distortion as well, we use the circuit shown in Figure 3-118, which contains both types of feedback. In reality, the collector–base resistor is frequently split into an unbypassed section responsible for the feedback and a larger resistor responsible for the appropriate biasing. The example circuit in Figure 3-119 shows this.

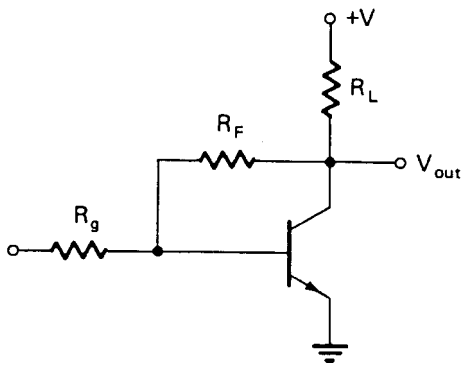

Figure 3-117 Single-stage amplifier with voltage feedback (provided by R_F).

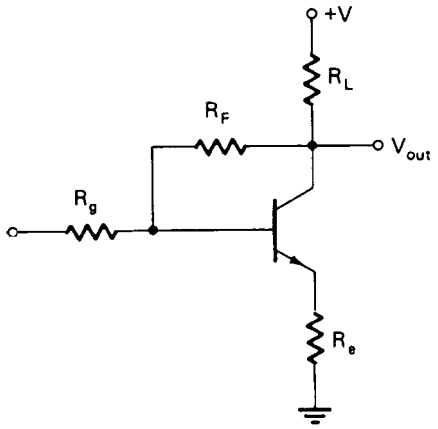

Figure 3-118 Single-stage amplifier with voltage and current feedback.

By using two of the fairly recent BFP420 transistors in parallel, and balancing the transistors by using the appropriate emitter resistors (which in total will result in 10 Ω) plus the bypassed value, we obtain the frequency-dependent gain, matching, and noise responses shown in Figure 3-120. To determine the appropriate feedback resistor R_F, we recommend the formula

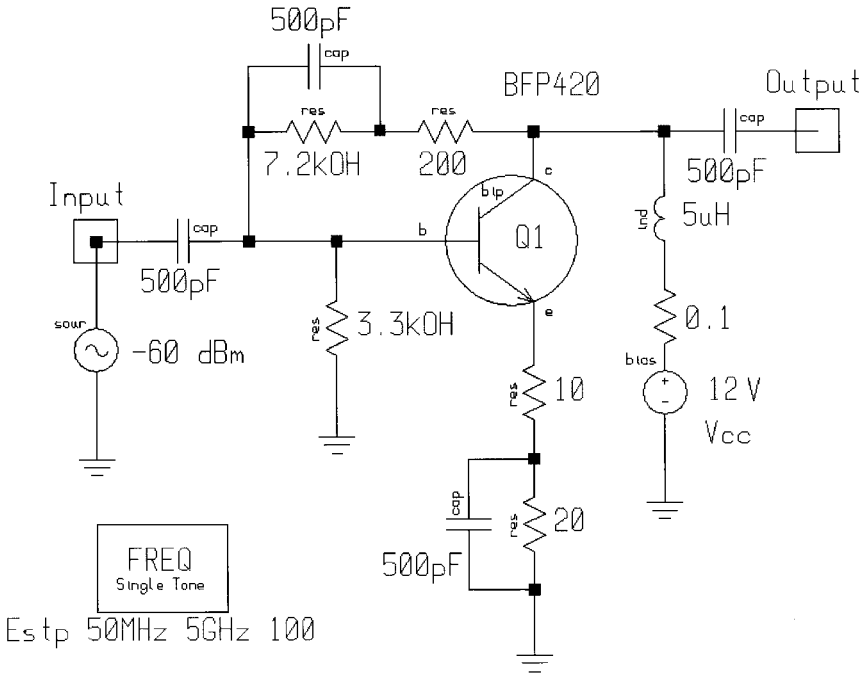

Figure 3-119 Practical amplifier circuit showing voltage and current feedback, and illustrating how reactances (in this case, 500-pF bypass capacitors) and multiple resistors can be used to provide different ac and dc resistances for the paths from collector to base and emitter to ground.

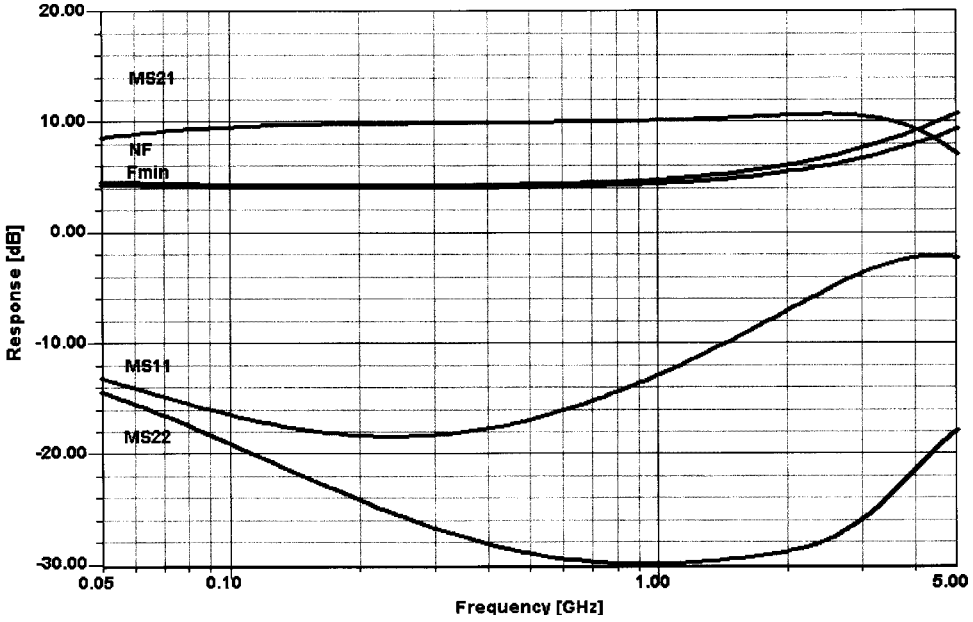

Figure 3-120 Frequency-dependent gain, matching, and noise performance of the circuit in Figure 3-119.

$$R_F = \frac{(Z_{\text{in}}\, Z_{\text{out}})}{R_E} \tag{3-170}$$

This equation requires some additional comments. The combined shunt and series feedback only work as long as a sufficient transconductance is provided. In other words, there must be enough open-loop gain that will be reduced to obtain more bandwidth. A necessary condition for this approach, which really comes from the frequency range of less than 30 MHz, is that

$$Z_{\text{in}} = \frac{26\ \text{mV}}{I_C}\,\beta >> R_F \tag{3-171}$$

This requires a minimum transconductance of

$$g_m = \frac{1 + S_{21}}{Z_{\text{in}}} \tag{3-172}$$

where S_{21} must be a negative number that reflects the 180° phase shift. Of course, life becomes interesting when S_{21} goes through 1, but it (hopefully) never becomes negative and larger than 1 at the same time.

Example. The BFP420 has been used here frequently. A 10-dB gain would require an S_{21} of 3.16 ($\sqrt{10}$); therefore, we need to inspect the datasheet, which shows that the magnitude

of S_{21} is 3.16 around 4.5 GHz, yet the phase shift has changed from 180° to around 20°. In order to design an amplifier, we now set

$$R_F = Z_{\text{in}}(1 + |S_{21}|) \tag{3-173}$$

which is valid until S_{21} becomes too small. For a given 10 dB or 3.16 for S_{21}, the resulting RF is 4.16×50, or 208 Ω. The transconductance under these conditions becomes

$$g_m = \frac{1 + |S_{21}|}{Z_0} \tag{3-174}$$

where $Z_0 = 50$ Ω (the desired input impedance). g_m now becomes 83.2 mS. We now test the input and find

$$\frac{\beta}{g_m} = Z_{\text{in}} = \frac{50}{0.0832} = 600\ \Omega \tag{3-175}$$

Therefore, the emitter feedback resistor is not necessary to meet the previously mentioned condition whereby the input impedance needs to be higher than RF. Assuming the transconductance now is 0.00832, or 10% of the previous value, the input impedance would be 60 Ω, no longer meeting the prescribed requirement. Therefore, we need an unbypassed emitter resistor that fulfills the equation

$$R_E = \frac{Z_0^2}{R_F} - \frac{1}{g_{m_{\text{dc}}}} \tag{3-176}$$

where

$$g_{m_{\text{dc}}} = \frac{1 - S_{21_{\text{max}}}}{Z_0} \tag{3-177}$$

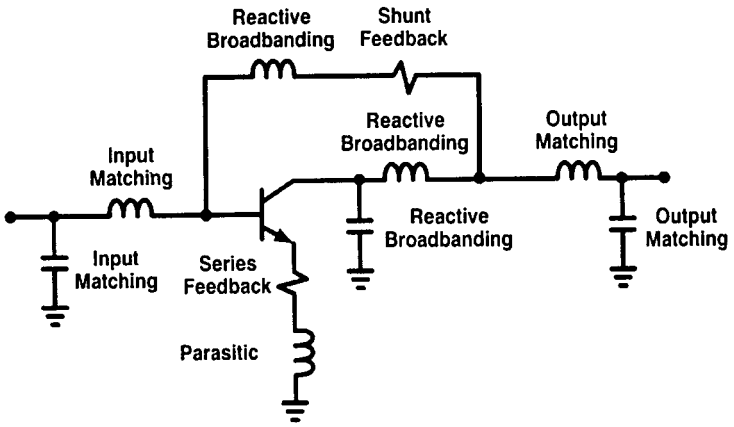

Figure 3-121 Elements of a feedback amplifier.

Again, the reader should be cautioned that in the common-emitter circuit, there is a 180° phase shift, and therefore $S_{21_{\max}}$ is a negative quantity, resulting in reality in

$$g_{m_{\text{dc}}} = \frac{1 + S_{21_{\max}}}{Z_0}$$

In our case,

$$g_{m_{\text{dc}}} = \frac{-S_{21}}{2Z_0} = \frac{38}{2 \times 50} = \frac{38}{100} = 0.38$$

so

$$R_E = \frac{50^2}{208} - \frac{1}{0.38} = 12 - 2.6 = 9.4\ \Omega \tag{3-178}$$

In practice, the designer would use a 10-Ω resistor.

Since the gain of the transistor continues to fall as a function of frequency, one can compensate to a degree for the cutoff frequency by putting an inductance in series that follows the equation

$$L_F = \frac{R_F}{2\pi f_{3\text{dB}}} \tag{3-179}$$

Assuming $f_{3\text{dB}}$ = 2 GHz, the resulting series inductance L_F = 16.6 nH. Basically, the same applies to circuits where the second transistor is used as an emitter follower to feed the signal back from the collector to the base of the first transistor.

In summary (see Figure 3-121):

- Resistive negative feedback at lower frequencies reduces open-loop gain and simultaneously matches input and output.
- Reactive elements set the gain and matching at high frequencies. Feedback is reduced at high frequencies.
- Emitter bypass capacitors are not used, as they would destroy the impedance match.

This is equally valid for FETs.

The next level of complexity can be reached by using two transistors with dc feedback.

3-3-1 Lossless or Noiseless Feedback

All the amplifiers shown above are based on a combination of resistive and reactive feedback. The very moment resistive feedback is used, the noise figure increases, as does the intercept point. As long as the intercept point increases overproportionally compared to the noise figure, this is an acceptable method. However, there are many cases in which an extremely low noise figure and a higher than normally achievable intercept point are required. To avoid this degradation of performance, Norton of Anzac developed a negative feedback structure based on the capabilities of the ferrite transformer. This patented technique (U.S. Patent Nos. 3,624,536 and 3,891,934, since expired), known as *lossless feedback*, provides lower noise figure and higher linear output than can be achieved using resistive feedback with the same transistor. Transformer feedback is used in which the transformer in the feedback network acts as a directional coupler. The coupling ratio between the input and output of the coupler

determines the magnitude of the feedback, and hence the gain. Across the frequency band over which the transformer operates as intended, the feedback is negative due to the in-phase coupling and the inversion of the active device.

This technique was used in amplifiers ranging from 5 to 500 MHz, 20 to 1000 MHz, and 300 to 1800 MHz. The difficulty associated with this type of amplifier is the fact that it is based on transformers that use twisted pairs of wires as transmission lines. In some implementations used at higher frequencies, actual directional couplers were used at the expense of bandwidth; in these circuits, the coupling was determined by the spacing of the coupler lines rather than transformer turns ratio. These microstrip couplers have much narrower bandwidths than transformers and are fairly large.

Another headache with the lossless feedback design is the fact that many of these transistor configurations are used in either grounded-base or grounded-emitter with transistors that have f_T values of 25 GHz and higher. Such devices are very hot, and achieving freedom from oscillation over a wide frequency range is a continuing problem, even for the circuits we have shown so far. A similar clever technique has been implemented in the termination-insensitive mixer, which we will examine in Chapter 4.

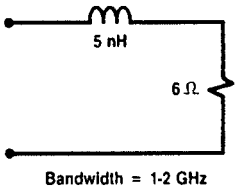
3-3-2 Broadband Matching

The circuitry above has enabled us to extend the frequency range of the amplifier and avoid the normal sharp cutoff. According to Fano [26], there is a limit to the bandwidth of matching. The concept is that impedance plus bandwidth determines the ability to match, since there is a Q of the circuit and there is a Q of the device. The following equations are valid:

$$|\rho_{\text{Bode}}| = e^{-(\pi Q_T / Q_{BP})} \tag{3-180}$$

$$Q_T = \frac{\sqrt{f_1 f_2}}{f_2 - f_1} \tag{3-181}$$

$$Q_{BP} = \frac{\text{Im}(Z)}{\text{Re}(Z)} = \frac{X_s}{R_s} \tag{3-182}$$



$$Q_{BP} = \frac{2\pi\sqrt{(2\text{ GHz})(1\text{ GHz})(5\text{ nH})}}{6\,\Omega} = 7.40$$

$$Q_T = \frac{\sqrt{(2\text{ GHz})(1\text{ GHz})}}{(2\text{ GHz} - 1\text{ GHz})} = 1.414$$

$$|\rho_{\text{Bode}}| = e^{-\left(\frac{\pi(1.414)}{7.40}\right)} = .549$$

$$\text{VSWR}_{\text{Bode}} = \frac{1 + .549}{1 - .549} = 3.43 : 1$$

Figure 3-122 Broadband matching example showing the Bode limit.

Figure 3-122 shows an example. This combination results in a VSWR of 3.43, which for practical purposes is already too high. The workaround is special circuitry (such as exponentially staggered impedance jumps in the matching network like 50 Ω > 20 Ω > 7 Ω > 3 Ω). This means we first transform the 50-Ω source of load impedance down to 3 Ω, and then look for a matching network that matches the transistor output/input, which is within a few ohms of 3 Ω. A detailed discussion of such matching can be found in the "Numerical Design" portion of Section 3-12-2 under the title "Broadband Matching Using Bandpass-Filter Networks—High-Q Case."

3-4 TWO-STAGE AMPLIFIERS

There are two popular configurations that have been used mostly for low-frequency applications. The first one (Figure 3-123, implemented in the circuit shown in Figure 3-124) shows a nice high-frequency performance assuming the emitter and collector currents are essentially the same. As for distortion products, this circuit behaves equivalently to the shunt impedance example from Figures 3-118 and 3-119, with the additional gain of the second transistor. Its frequency matching and noise performance are also shown, in Figure 3-125.

The next two-stage circuit (Figure 3-126, implemented in Figure 3-127) uses the collector current of the second stage as the feedback to the first. Proper biasing of this circuit is quite difficult and interactive. Figure 3-128 shows the frequency-dependent gain, matching, and noise figure. We believe that this circuit can be optimized further, but we leave such investigations to the reader.

A *cascode* amplifier is a special form of two-stage circuit. Although a cascaded pair acts like a single transistor, its merits are in its reduced feedback and resulting higher gain–bandwidth product. Figure 3-129 shows a simple cascode application that assumes the presence

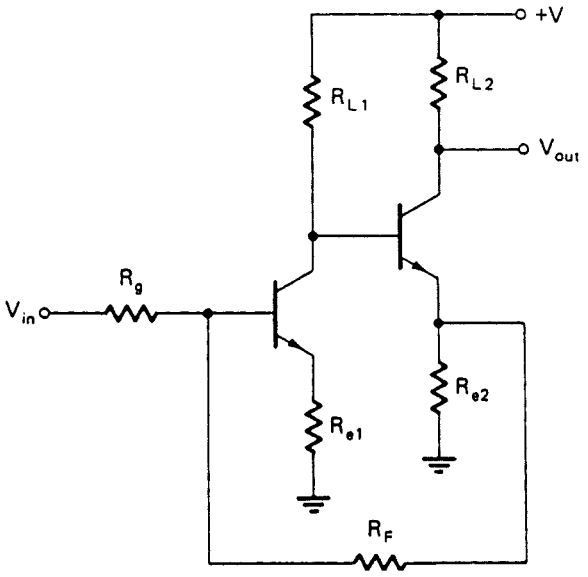


Figure 3-123 Two-stage amplifier with voltage feedback.

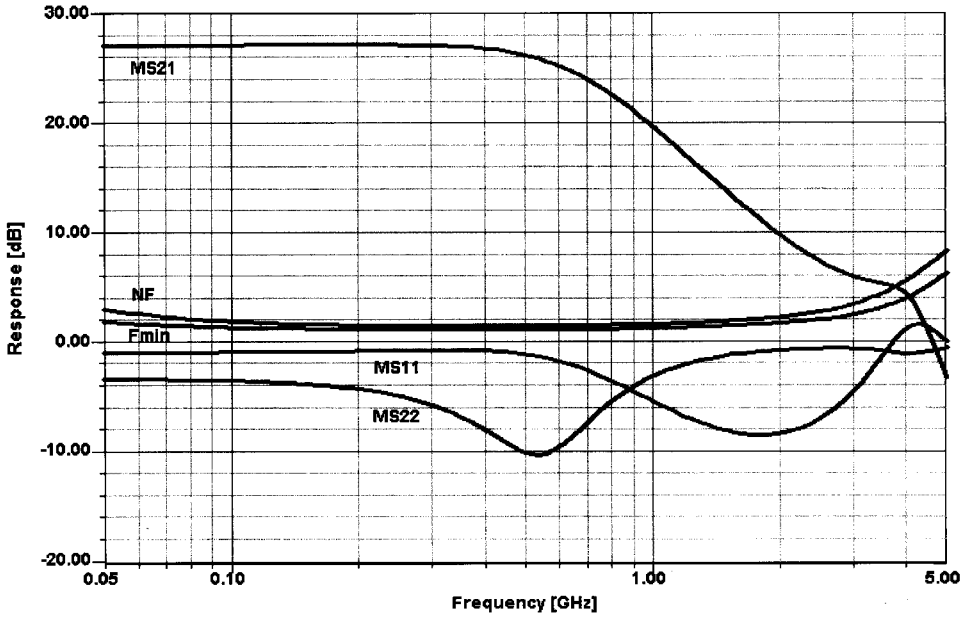

Figure 3-128 Gain, matching, and noise performance of the amplifier in Figure 3-127.

of an output transformer that absorbs the output capacitance. Figure 3-130 shows this circuit's frequency-dependent gain, matching, and noise performance.

It has been obvious to us that most published wireless application circuits are evaluated on a no-input-selectivity basis; that is, their reported performance does not take into account the filtering that is usually present in practical implementations. Evaluated in this way, a low-noise design may achieve a noise figure of less than 2 dB—1.2 dB or so is typical—but this is misleading because filters and connectors introduce insertion loss, resulting in a higher noise figure.

The cascode is a nice preamplifier combination. It combines (depending on the transistor) a low noise figure with essentially no feedback. Since the output of a grounded-base transistor provides a high-impedance source, this configuration is ideal to work into the SAW filters frequently used in wireless applications at the operating frequency. Special transistor pairs are available for use in cascode; as can be seen from this example, not every transistor combination is ideal. This one gives a higher noise figure than wanted and at frequencies above 2 GHz it tends to show possible instabilities. Both Siemens and Motorola are now offering transistors appropriate for these cascodes. Mostly, one would resort to transistors of less-exotic cutoff frequencies to guarantee stability. Typically, grounded-base/gate transistors tend to become oscillators, specifically because this configuration, like the emitter follower, allows a higher operating frequency while maintaining the same gain–bandwidth product; the actual gain for the last two circuit configurations is less. A grounded-base/gate stage has a high voltage gain and the emitter/source follower has power gain at low impedance levels. We invite our readers to experiment with the capacitor from the base of Q1 to ground in Figure 3-129 to get an interesting education about these transistors and their willingness to oscillate.

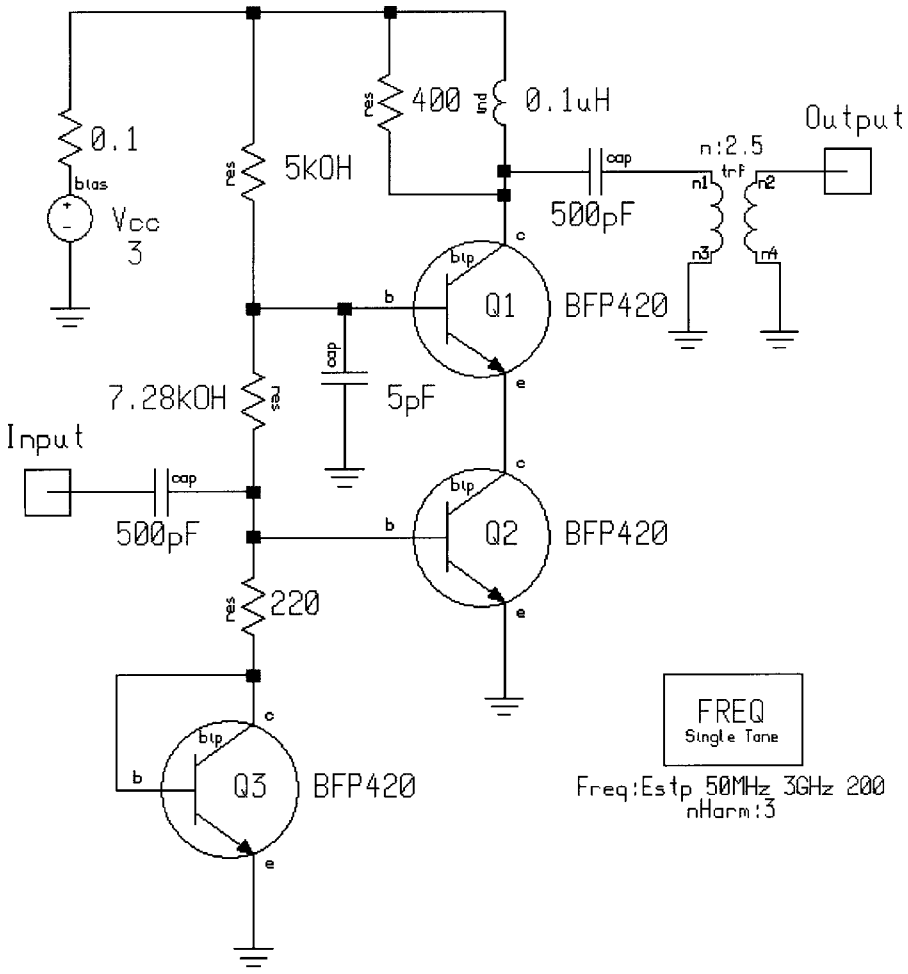

Figure 3-129 Schematic of the cascode amplifier.

The MC13144 is an example of a commercially available VHF to 2-GHz low-noise amplifier with programmable bias. As can be seen from Table 3-11, it is ideal for the 900-MHz range and its programmable gain/bias makes it very attractive. This design (Figure 3-131) is based on the cascode mentioned above and, because of high integration, uses many transistors for bias and level shifting.

The 900-MHz application circuit in Figure 3-132 shows the required external components for a successful design. Input and output are made tunable. The 5.6- and 39-nH inductances can be made from small air-wound coils. The output ceramic filter provides the necessary selectivity ahead of the mixer. With such a highly selective device in the input, the noise figure would deteriorate too much. The antenna is rarely in the vicinity of sufficiently strong transmitters to require such strong input filtering.

There are two more interesting applications for two-stage amplifiers: The one implemented in the Hewlett-Packard MSA-0735 MMIC has become a quite common one, and its usefulness up to higher frequencies depends mostly on the cutoff frequency of the transistors,

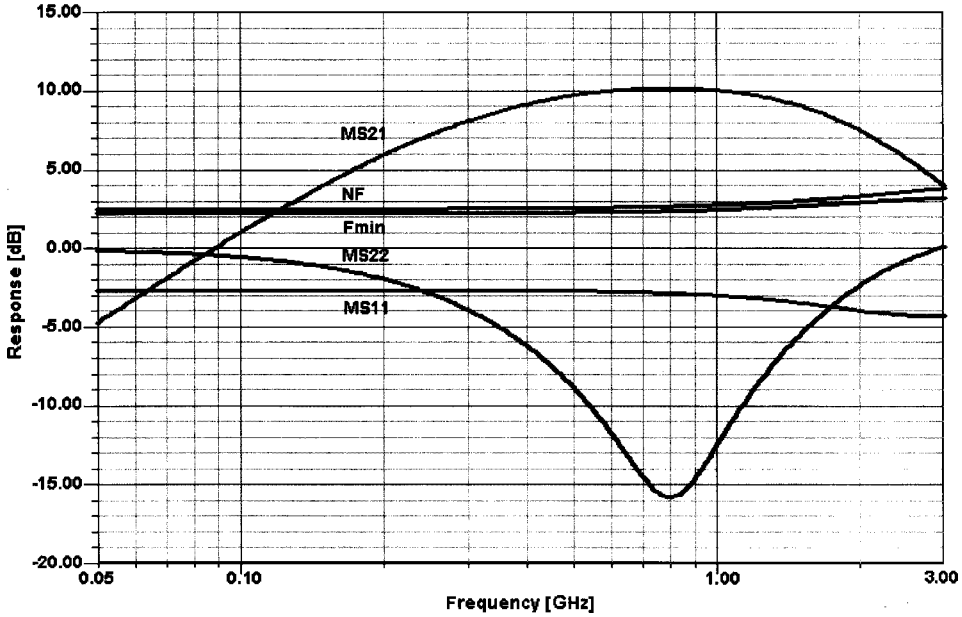

Figure 3-130 Frequency-dependent gain, matching, and noise performance of the cascode amplifier.

their parasitics, and the phase shift of the gain. The typical configuration is shown in Figure 3-133, and its frequency-dependent gain, match, and noise figure in Figure 3-134. There is an increase of S_{22} at higher frequencies; this indicates unwanted phase shift in the circuit. Some manufacturers hide the compensation circuits to overcome such peaking; most of the schematics shown by the manufacturers are really intended only to show operating principles, with proprietary details omitted.

Thanks to the properties of GaAs transistors, we can extend the frequency range significantly. The amplifier we are about to look at goes back several years and is described in great detail in Goyal [27]. Essentially what we have, seen in Figure 3-135, is an FET version of Figure 3-127. The main goal of this circuit was to have an all-monolithic circuit, avoiding all ac coupling and accomplishing all matching and interaction with dc coupling. The transistor Q1 is the main gain stage, which has the transistor Q2 as an active load. The output impedance of Q2 is $1/g_m$—typically in the area of 50–200 Ω, depending on the biasing,

Table 3-11 MC13144 features

Gain at 900 MHz, 17 dB
Noise figure at 900 MHz, 1.4 dB

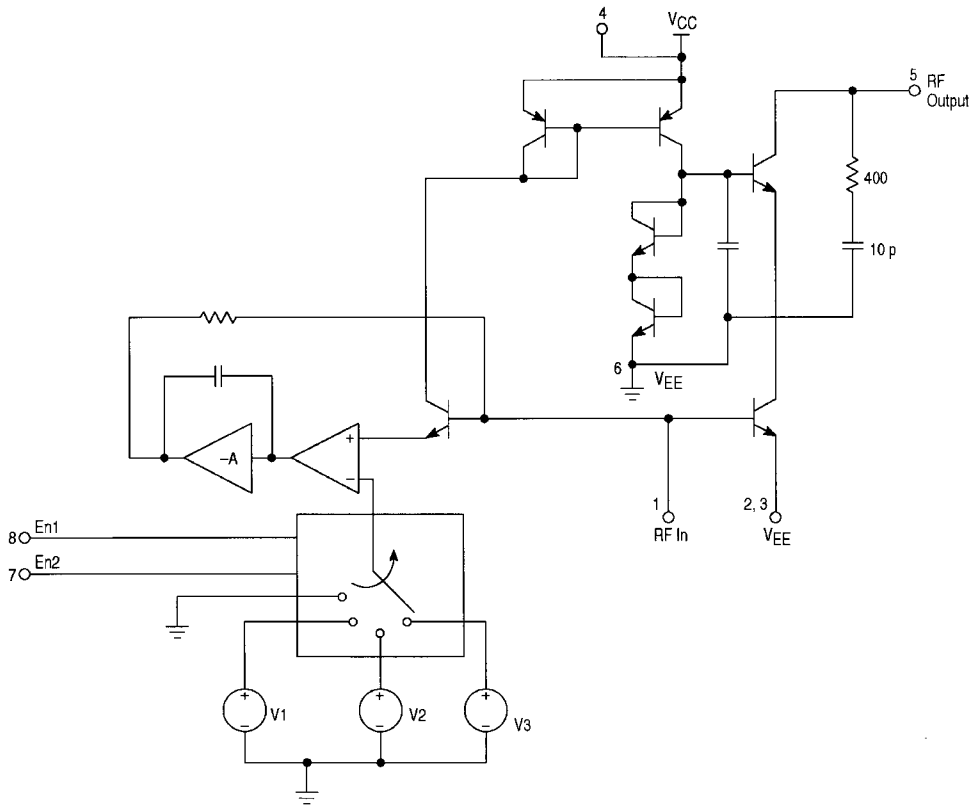

Figure 3-131 Schematic of the Motorola MC13144 cascode LNA.

which affects the transconductance. Transistor Q3 has the same function as an emitter/source follower; again, its dc bias determines its transconductance and therefore its output impedance. (Given this, a device that has a transconductance of 20 mS, or close to it, would establish a very good output match to 50 Ω.) The drains of Q1 and Q5 are at approximately 3.5 V. The diodes at the source of Q3 are level shifters that must shift the dc voltage at the gate of Q5 and at the drain of Q4 to approximately −1.5 V relative to ground—the necessary bias condition for Q1 and Q5. The standard shunt feedback circuit would show resistive feedback between the drain of Q1 (gate of Q2) and the gate of Q1; in the previous examples, we calculated the magic value of this part to be about 200 Ω. Adding in parallel to Q1 the transistor Q5 allows the designer to use a feedback scheme that isolates the feedback loop from the input. Dc-wise, the two transistors are tied together via a 10-kΩ resistor, which can be included in the actual packaged device. Insufficient information was published to allow us to duplicate the design, considering all the intricacies involved (we somewhat object to the fact that even in the *IEEE MTT-S Transactions*, so little information is given about the actual implementation of this design—using space constraints as an excuse—that its educational value is usually minimal); it shows a new principle without revealing the design steps necessary to obtain a practical circuit. Several variations of this type of circuit are available; the literature is full of discussions about them. The magnitude of the feedback is set by the ratio of the width of Q5 to that of Q1. Typical values for the Q5/Q1 ratio range

from 0.15 to 0.30. In simulation, sizing the devices can best be accomplished by using the scaling factor for the FET model.

One of our questions was: "What would the perfect input termination for Q1 be?" By using an ideal transformer and playing with its turns ratio (needless to say, we did this with CAD), we determined experimentally that, relative to the gate, 200 Ω and a series inductor of 5–8 nH—the sort of details that designers often avoid telling their audiences—gave the ideal frequency response. Overall, we believe that the inventor of this circuit can be quite proud of the overall performance. The FETs we chose were taken from the Texas Instruments nonlinear foundry library; however, any similar device from another company would have worked equally well. The feedback loop used in this IC is an example of an approach frequently referred to as *active feedback*. The performance of this amplifier can be evaluated from Figure 3-136, which shows the frequency-dependent gain, matching, and noise figures (even including F_{min}).

3-5 AMPLIFIERS WITH THREE OR MORE STAGES

Most three-stage amplifiers are obtained by adding another buffer or power-gain stage to the previously described principal designs. As an example, we decided to evaluate the recent NEC UPC2749 IC, a silicon MMIC intended for application as a low-noise 1900-MHz amplifier operating at 3 V. Table 3-12 briefly summarizes its electrical specifications.

Table 3-12 NEC UPC2749 electrical characteristics

(T_A = 25 °C, $Z_L = Z_S$ = 50 Ω, V_{CC} = 3.0 V)			
	Part Number Package Outline		UPC2749T TO6
Symbols	Parameters and Conditions	Units	Typical
I_{CC}	Circuit current (no signal)	mA	6
G_S	Small-signal gain, f = 900 MHz dB	14.5	
	f = 1900 MHz	dB	16
f_{corner}	–3-dB Gain corner frequency	GHz	2.9
P_{1dB}	1 dB Compressed output power at 1900 MHz	dBm	–12.5
P_{SAT}	Saturated output power, f = 1900 MHz	dBm	–6
NF	Noise figure, f = 900 MHz	dB	3.2
	f = 1900 MHz	dB	4.0
RL_{IN}	Input return loss, f = 1900 MHz	dB	10
RL_{OUT}	Output return loss, f = 1900 MHz	dB	12.5
ISOL	Isolation, f = 1900 MHz	dB	30
OIP_3	SSB output third-order intercept, f_1 = 500 MHz, f_2 = 510 MHz	dBm	–3
	f_1 = 1000 MHz, f_2 = 1010 MHz	dBm	–3
	f_1 = 1900 MHz, f_2 = 1902 MHz	dBm	–3.5
	f_1 = 2000 MHz, f_2 = 2010 MHz	dBm	–4
$R_{TH(J-A)}$	Thermal resistance (junction to ambient)		
	Free air	°C/W	
	Mounted on a 50 × 50 × 1.6 mm epoxy glass PWB	°C/W	

In modeling the UPC2749's three transistors, we chose to use our favorite, the BFP420, which is not without its headaches at the higher frequencies. Figure 3-137 shows the circuit diagram, which closely resembles the one published by NEC; again, the only hard facts we had were the IC's basic circuit topology, gain, and dc current. Given those numbers, we staggered the current in the three devices by setting them at 0.64 mA for the first stage, 1.85 mA for the second stage, and 3 mA for the third stage. It should be noted that the two output transistors are not unlike the approach used for the Hewlett-Packard MSA-0735 (Figure 3-133). Taking (hopefully) all the right assumptions, we end up with a design that closely resembles the manufacturer's specifications for both power consumption, gain, and noise. This can be verified by looking at the results plotted in Figure 3-138.

The final example is a more complex derivative of the Philips NE/SA5204A amplifier, which was intended for standard 6-V operation and has a fairly "normal" circuit arrangement. This can be seen from Figure 3-139. A much more elaborate cousin of this is the low-voltage NEC UPC2710 amplifier. According to its specifications, it operates at 5 V but has significantly more gain than the NE/SA5204. Table 3-13 shows its electrical specifications and Figure 3-140 shows its measured gain as published by the manufacturer.

The actual interior of the circuit is shown in Figure 3-141. It consists of the standard preamplifier and then a Darlington configuration with the collectors tied together. The middle section of the circuit acts as a power supply responsible for the bias relative to the emitter of the first transistor influencing the rest of the circuit as well. Since NEC mentioned that they use their NESAT III process (f_T of 20 GHz at V_{ce} = 3) in producing the UPC2710T and we

R_{TH}	Thermal resistance (junction to ambient)	°C/W	

obtained some information regarding it, we decided to use our standard BFP420 (f_T of 25 GHz; see the datasheet in Chapter 2) for the purpose of simulation.

In our effort to simulate this circuit, we chose a combination of values that pretty much complies with the manufacturer's published specifications, but S_{22} is not close, as shown in Figure 3-142. We stopped at this point and invite our readers with CAD capabilities to provide the final touch in meeting all the published specifications for the circuit. We are particularly

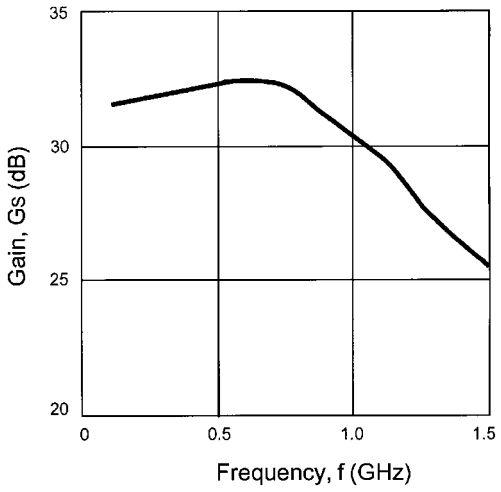

Figure 3-140 Manufacturer-supplied gain versus frequency for the NEC UPC2710T MMIC.

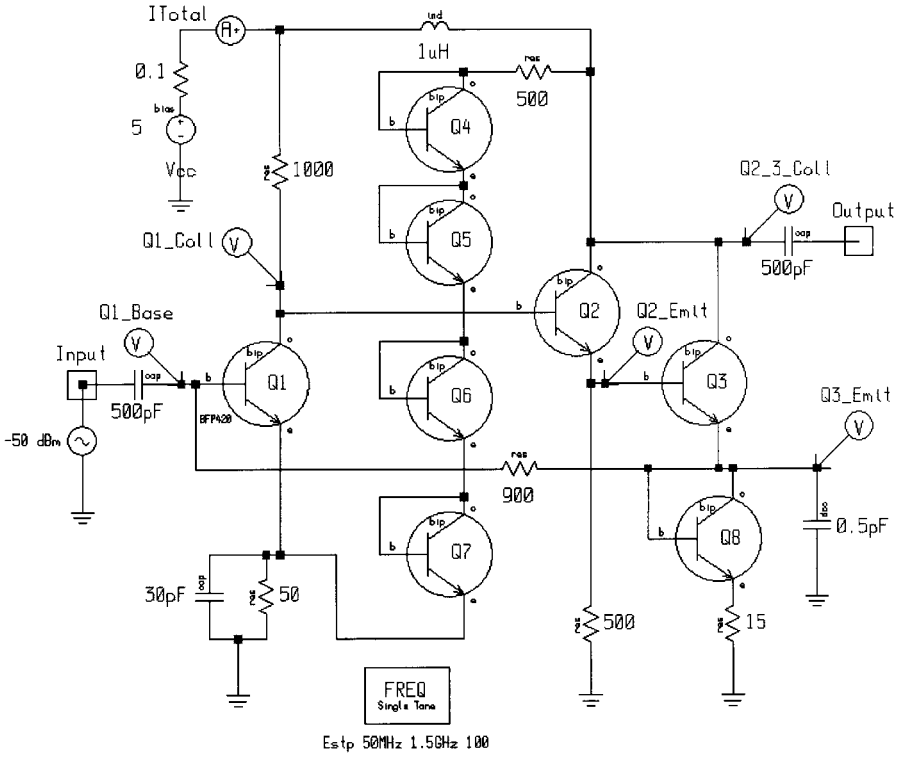

Figure 3-141 Schematic of the UPC2710T silicon MMIC entered for simulation.

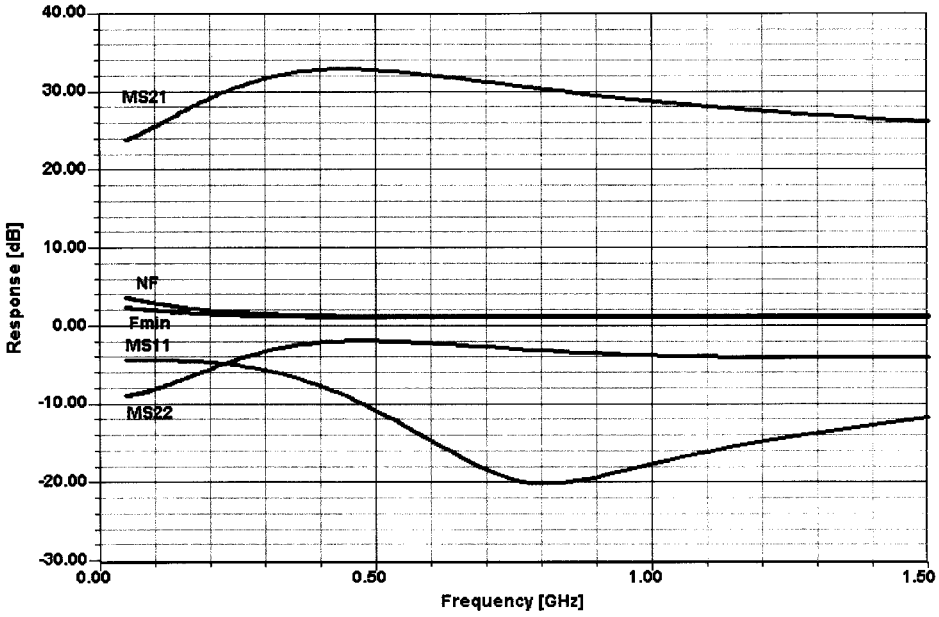

Figure 3-142 Simulated gain, match, and noise performance of the UPC2710T.

recommending such an effort because it shows very nicely the interaction of all the circuit elements in a fairly drastic way. Because of this, we admire the IC design even more, since the manufacturer has to sell a pretty consistent amplifier as a function of different production runs.

3-5-1 Stability of Multistage Amplifiers

Stability, needless to say, is a big issue, and the delay of the various stages adds to the phase shift, resulting in possible instabilities. The fact that S_{11} and/or S_{22} can become larger than 0 (in dB) means there is the potential of oscillating, depending on the reactances available. If a cable of inappropriate length is added, hell will break loose. Figure 3-143 shows the dangerous peaking of our simulation of the Philips NE5204A, in which the internal compensation was intentionally not assumed correctly. We will all agree that the high-end performance of this amplifier can generate high anxiety. As the production process of the aging device becomes more modern—meaning that transistors with much higher f_T will be the basis for the production—it will become quite difficult to maintain a previously achieved stability. This, by the way, applies also to discrete transistors, which for reasons of economics and multiple manufacturers will be improved over time. Such evolution results in generally smaller base-spreading resistances and capacitances, and other parameter changes, which, overall, cause headaches in manufacturing. We will leave the topic of three-stage amplifiers on this note.

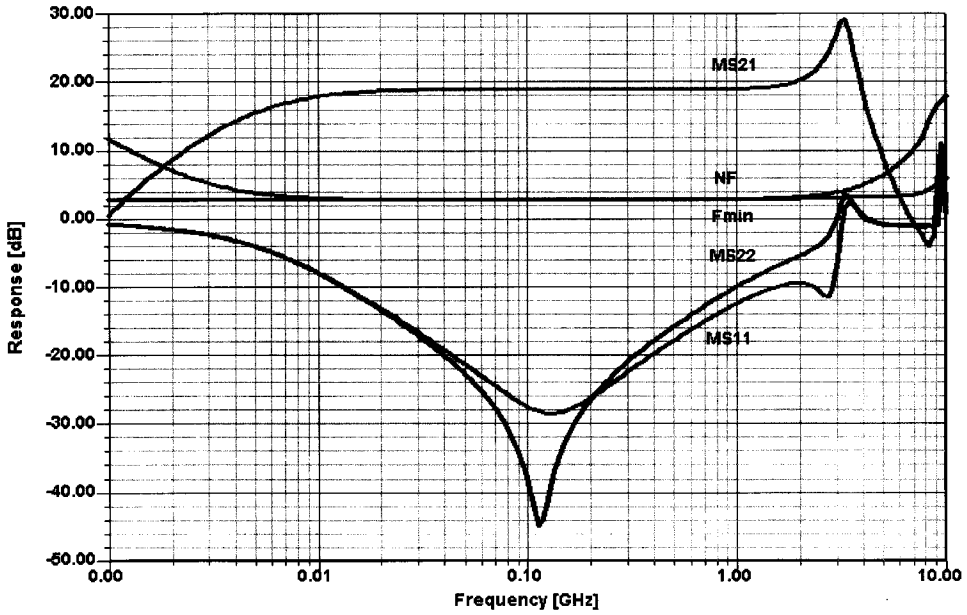

Figure 3-143 Simulated gain, match, and noise performance of the NE5204A IC.

3-6 A NOVEL APPROACH TO VOLTAGE-CONTROLLED TUNED FILTERS INCLUDING CAD VALIDATION [28]

Modern receivers control input stages as well as the oscillator band and frequency by electrical rather than mechanical means. Tuning is accomplished by voltage-sensitive capacitors (varactor diodes), and band switching by diodes with low forward conductance. Since the wireless band (essentially 400 MHz to 2.4 GHz) is so full of strong signals, the use of a tracking filter is desired as a solution to improve the performance and prevent second-order IMD products or other undesired overload effects. The dc control voltage needed for the filter can easily be derived from the VCO control voltage. There may be a small dc offset, depending on the IF used.

3-6-1 Diode Performance

The capacitance versus voltage curves of a varactor diode depend on the variation of the impurity density with the distance from the junction. When the distribution is constant, there is an "abrupt junction" and capacitance follows the law

$$C = \frac{K}{(V_d + V)^{1/2}} \tag{3-183}$$

where V_d is the contact potential of the diode and V is applied voltage.

Such a junction is well approximated by an alloyed junction diode. Other impurity distribution profiles give rise to other variations, and the above equation is usually modified to

$$C = \frac{K}{(V_d + V)^n} \tag{3-184}$$

where n depends on the diffusion profile and $C_0 = K/V_d^n$.

A so-called graded junction, having a linear decrease in impurity density with the distance from the junction, has a value of n. This is approximated in a diffused junction.

In all cases these are theoretical equations, and limitations on the control of the impurity pattern can result in a curve that does not have such a simple expression. In this case, the coefficient n is thought of as varying with voltage. If the impurity density increases away from the junction, a value of n higher than 0.5 can be obtained. Such junctions are called hyperabrupt. A typical n value for a hyperabrupt junction is about 0.75. Such capacitors are used primarily to achieve a large tuning range for a given voltage change. Figure 3-144 shows the capacitance–voltage variation for the abrupt and graded junctions as well as for a particular hyperabrupt-junction diode. Varactor diodes are available from a number of manufacturers, such as Motorola, Siemens, and Philips. Maximum values range from a few to several hundred picofarads, and useful capacitance ratios range from about 5 to 15.

Figure 3-145 shows three typical circuits that are used with varactor tuning diodes. In all cases, the voltage is applied through a large resistor R_e or, better, an RF choke in series with a small resistor. The resistance is shunted across the lower diode and may be converted to a shunt load resistor across the inductance to estimate Q. The diode also has losses that may result in lowering the circuit Q at high capacitance, when the frequency is sufficiently high. This must be considered in the circuit design.

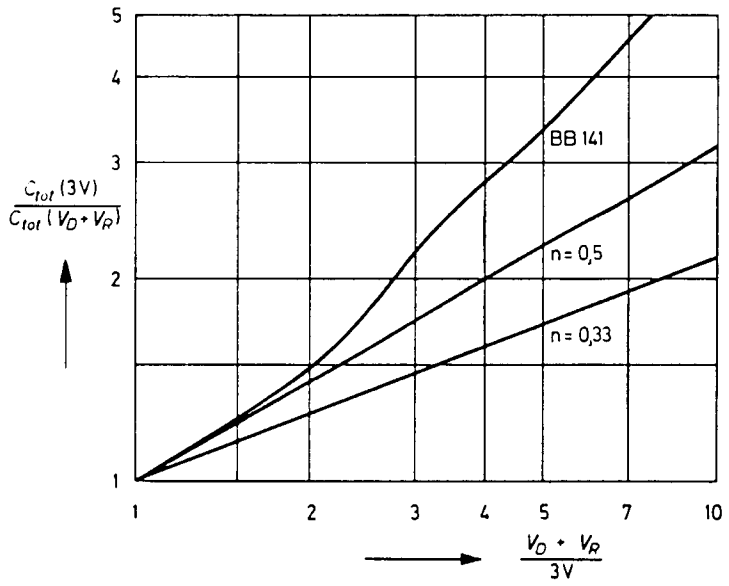

Figure 3-144 Voltage-dependent change of capacitance of different types of diodes. The BB141 is a hyperabrupt-junction diode with $n = 0.75$.

The frequency-dependent performance is not determined solely by applying the dc tuning voltage to Eq. (3-184). If the RF voltage is sufficient to drive the diode into conduction on peaks, an average current will flow in the circuits of Figure 3-145, which will increase the bias voltage. The current is impulsive, giving rise to various harmonics of the circuit. Even in the absence of conduction, Eq. (3-184) deals only with the small-signal capacitance. When the RF voltage varies over a relatively large range, the capacitance changes. In this case, Eq. (3-184) must be changed to

$$\frac{dQ}{dV} = \frac{K}{(V + V_d)^n} \tag{3-185}$$

Here Q is the charge on the capacitor. When this relation is substituted in the circuit differential equation, it produces a nonlinear differential equation, dependent on the parameter n. Thus, the varactor my generate direct current and harmonics of the fundamental frequency. Unless the diodes are driven into conduction at some point in the cycle, the direct current must remain zero.

The current of Figure 3-145c can be shown to eliminate the even harmonics, and it permits a substantially larger RF voltage without conduction than either circuit in Figure 3-145a or 3-145b. When $n = 0.5$, only the second harmonic is generated by the capacitor, and this can be eliminated by the back-to-back connection of the diode pair. Integrating Eq. (3-185), we find

$$Q + Q_A = \frac{K}{1 - n}(V + V_d)^{1-n}$$

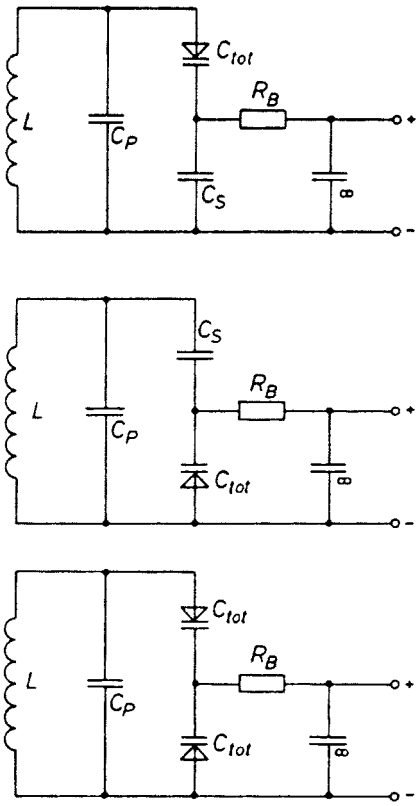

Figure 3-145 Various configurations to apply tuning diodes in a tuned circuit. The bottom version shows the lowest distortion.

$$= \frac{C_v}{1-n}(V + V_d) \tag{3-186}$$

C_v is the value of Eq. (3-184) for applied voltage V, and Q_A is a constant of integration. By letting $V = V_1 + v$ and $Q = Q_1 + q$, where the lowercase letters represent the varying RF and the uppercase letters indicate the values of bias when RF is absent, it follows that

$$q + Q_1 + Q_A = \frac{K}{1-n}[v + (V_1 + V_d)]^{1-n} \tag{3-187}$$

$$1 + \frac{v}{V'} = \left(1 + \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-188}$$

where $V' = V_1 + V_d$ and $Q' = Q_1 + Q_A$. For the back-to-back connection of identical diodes, $K_{11} = K_{12} = K_1$, $V_1' = V_2' = V'$, $Q_1' = Q_2' = Q'$, $q = q_1 = -q_2$, and $v = v_1 - v_2$. Here the new subscripts 1 and 2 refer to the top and bottom diodes, respectively; v is the RF voltage across

the pair in series, and q is the charge transferred through the pair in series. This notation results in

$$\frac{v}{V'} \equiv \frac{v_1 - v_2}{V'} = \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} - \left(1 - \frac{q}{Q'}\right)^{1/(1-n)} \tag{3-189}$$

For all n, this eliminates the even powers of q, and hence the even harmonics. This can be shown by expanding Eq. (3-189) in a series expansion and performing term by term combination of the equal powers of q. In the particular case $n = \frac{1}{2}$, $v/V' = 4q/Q'$, and the circuit becomes linear.

The equations hold as long as the absolute value of v_1/V' is less than unity, so that there is no conduction. At the point of conduction, the total value of v/V' may be calculated by noting that when $v_1/V' = 1$, $q/Q' = -1$, so $q_2/Q' = 1$, $v_2/V = 3$, and $v/V = -4$. The single-diode circuits conduct at $v/V' = -1$, so the peak RF voltage should not exceed this. The back-to-back configuration can provide a fourfold increase in RF voltage handling over the single diode. For all values of n, the back-to-back configuration allows an increase in the peak-to-peak voltage without conduction. For some hyperabrupt values of n, such that $1/(1 - n)$ is an integer, many of the higher-order odd harmonics are eliminated, although only $n = \frac{1}{2}$ provides elimination of the third harmonic. For example, $n = \frac{2}{3}$ results in $1/(1 - n) = 3$. The fifth harmonic and higher odd harmonics are eliminated, and the peak-to-peak RF without conduction is increased eightfold; for $n = \frac{3}{4}$ the harmonics 7 and above are eliminated, and the RF peak is increased 16 times. It must be noted in these cases that the RF peak at the fundamental may not increase so much, since the RF voltage includes the harmonic voltages.

Since the equations are only approximate, not all harmonics are eliminated, and the RF voltage at conduction, for the back-to-back circuit, may be different from that predicted. For example, abrupt-junction diodes tend to have n of about 0.46–0.48 rather than exactly 0.5. Hyperabrupt junctions tend to have substantial changes in n with voltage. The diode illustrated in Figure 3-144 shows a variation from about 0.6 at low bias to about 0.9 at higher voltages, with wiggles from 0.67 to 1.1 in the midrange. The value of V_d for varactor diodes tends to be in the vicinity of 0.7 V.

3-6-2 A VHF Example

The application of tuning diodes in double-tuned circuits in TV tuners has been common practice for many years. Figure 3-146 shows the circuit diagram. The input impedance of 50 Ω gets transformed up to 10 kΩ. The tuned circuits consist of the 0.3-μH inductor and two sets of antiparallel diodes. By dividing the RF current in the tuned circuit and using several diodes instead of just one pair, intermodulation distortion is reduced.

The coupling between the two tuned circuits is tuned via the 6-nH inductor that is common to both circuits. This type of inductance is usually printed on the circuit board. The diode parameters used for this application were equivalent to the Siemens BB515 diode. The frequency response of this circuit is shown in Figure 3-147.

The coupling is less than critical. This results in an insertion loss of about 2 dB and relatively steep passband sides. Once the circuit's large-signal performance (Figure 3-148) is seen, a third-order intercept point of about –2 dBm is not so unexpected. The reason for this poor performance is the high impedance (high L/C ratio), which provides a large RF voltage swing across the diodes. A better approach appears to be using even more diodes and at the same time changing the impedance ratio (L/C ratio).

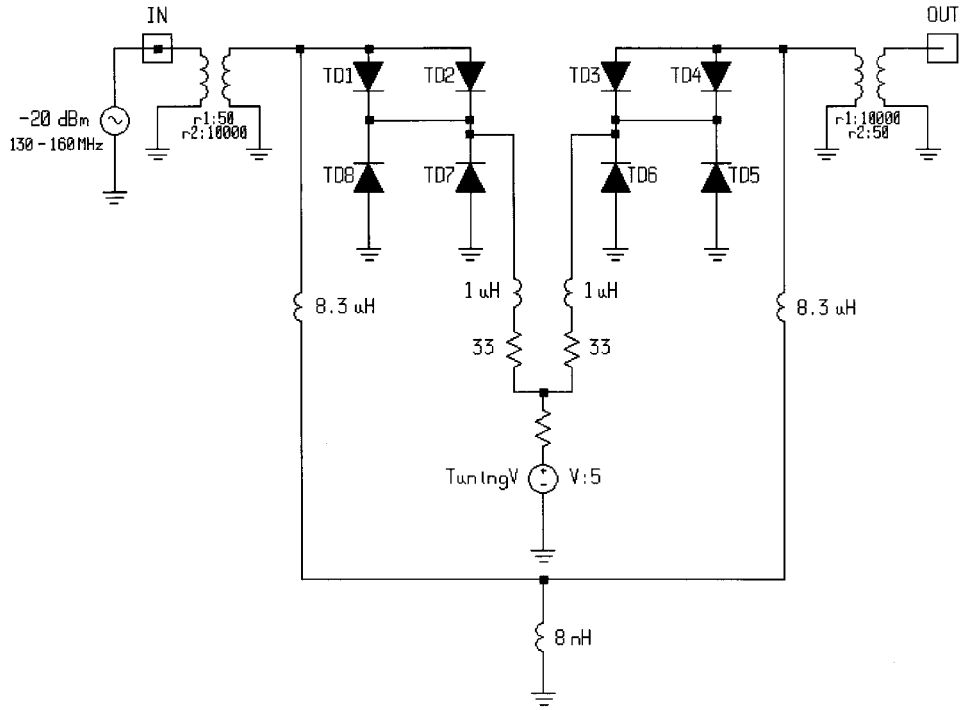

Figure 3-146 Double-tuned filter at 161 MHz using hyperabrupt-junction tuning diodes. By using several parallel diodes, the IMD performance improves.

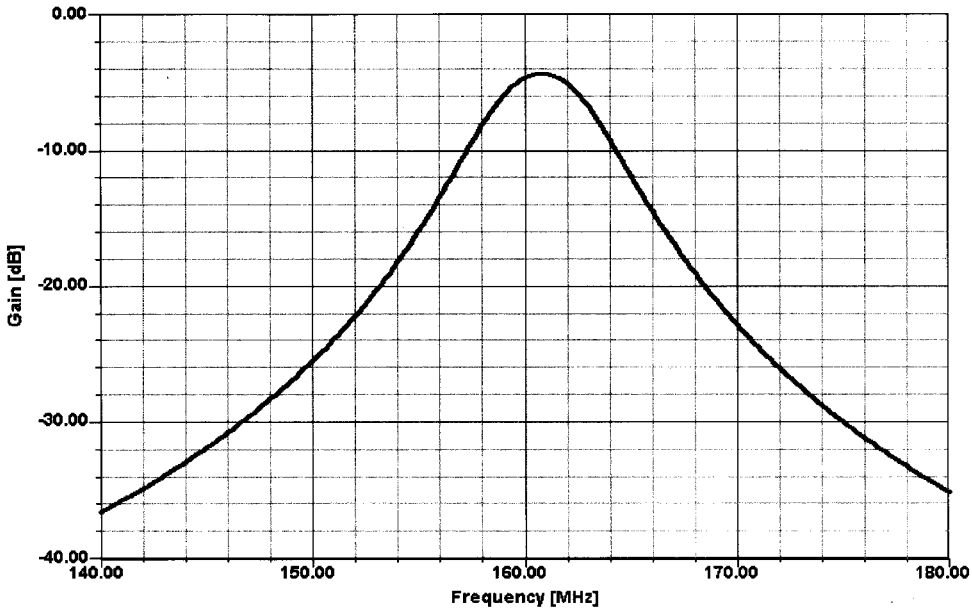

Figure 3-147 Frequency response of the tuned filter shown in Figure 3-146. The circuit is undercoupled (less than transitional coupling); $Q \times k < 1$.

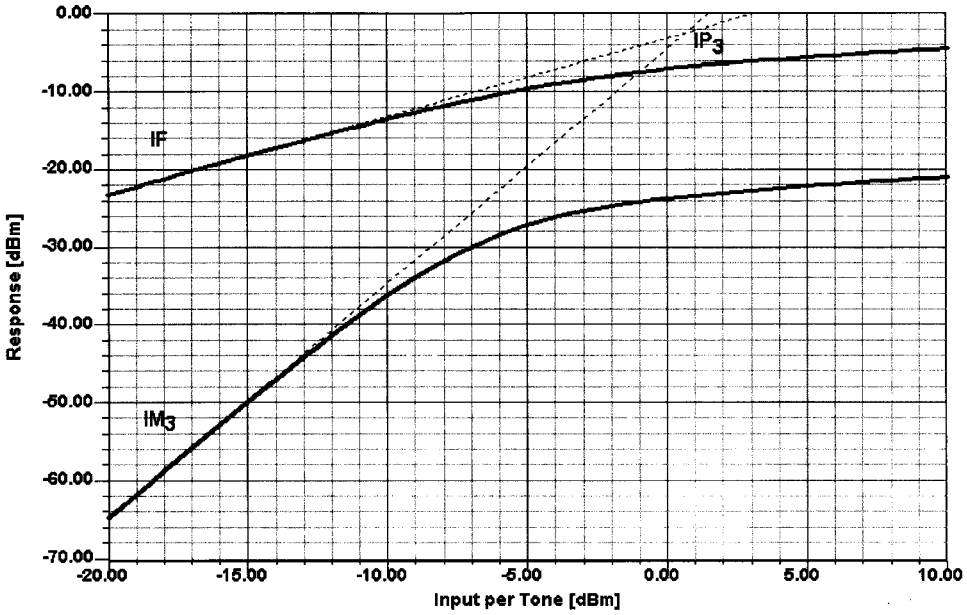

Figure 3-148 Prediction of intercept point of the double-tuned circuit shown in Figure 3-146. Note the compression of both the input signal and the IMD product.

3-6-3 An HF/VHF Voltage-Controlled Filter

The above example used a step-up procedure typically done by a tap at the input and output inductance. This method allows an impedance transformation; however, if one desires to change it into a series-tuned arrangement, it has to be done with a transformer. The large-signal conditions in the frequency range from 10 to 30 MHz on a medium- to large-sized antenna are equivalent to, if not worse than, the conditions for VHF operation. The only exception would be line of sight into the transmitter such as a tower in the middle of the city. Examples of such hostile conditions would be any large city, such as Munich, New York, Miami, Chicago, and San Francisco, where the authors had significant experience with intermodulation distortion problems.

By translating the circuit into a low-impedance-drive arrangement, building it symmetrically, and reducing the tuning range somewhat by capacitors and many series diode pairs, the filter's large-signal performance was significantly improved. The tuning diodes had about 125 pF at 1 Vdc per unit. Initial tests trying to use a high-capacitance diode, such as the BB112, resulted in much higher IMD products. The B112 has a 1-V capacitance of 470 pF down to about 20 pF at 8 V. Standard diodes show about 30 pF at 1 V, while the diodes used in the experiment had a 125-pF capacitance at 1 V. These experimental diodes were made available from a well-known manufacturer for this evaluation. Figure 3-149 shows the circuit diagram.

A step-down transformer drives the tuned circuit with a source impedance of 12.5 Ω. The circuit is symmetrical. There are two 0.8-μH inductors and 2×5 diodes in the loop. The output of the circuit is transformed back up to 50 Ω. The tuning voltage is supplied via a heavily filtered arrangement. This circuit has actually been implemented in Rohde & Schwarz field strength meter equipment. They guarantee an intercept point of about +20 dBm. The selectivity of these circuits is quite reasonable and mostly intended to reduce

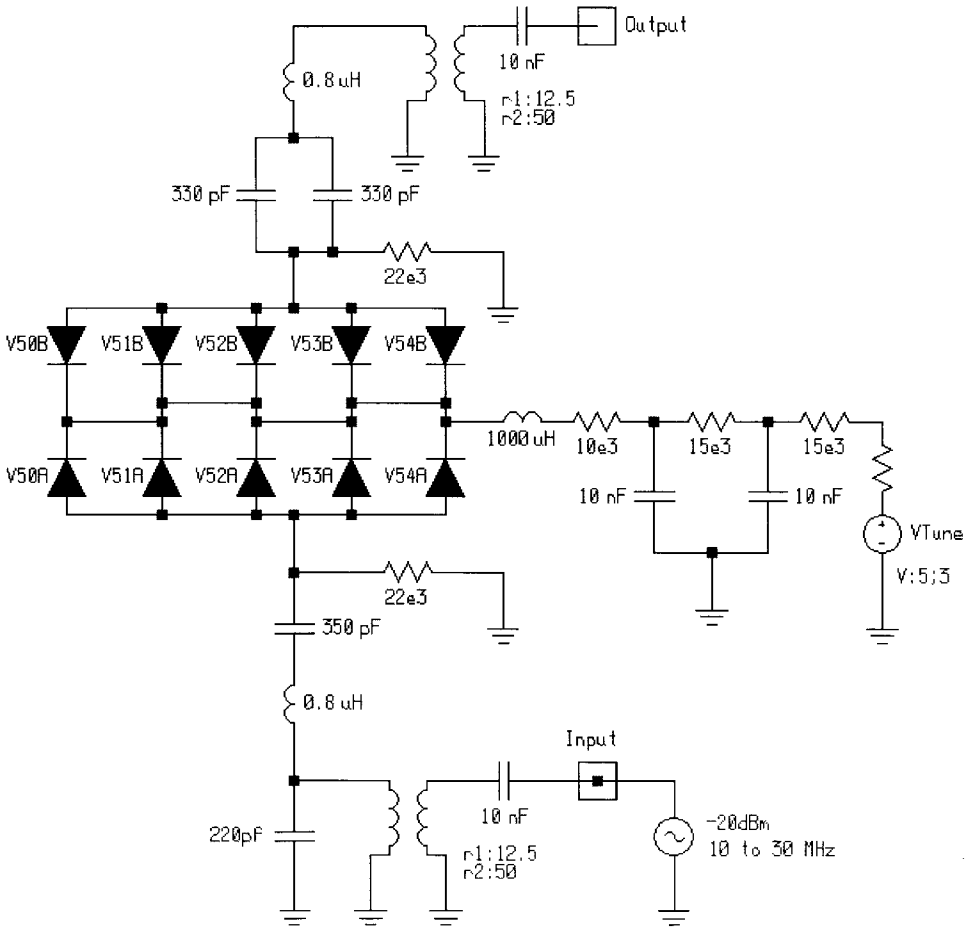

Figure 3-149 High dynamic range of a 10–20-MHz filter.

second-order intermodulation distortion products by about 10 dB, at the same time having a high third-order intercept point. Figure 3-150 shows the selectivity curves at two different tuning voltages.

The most interesting number, however, is the third-order intercept point (already determined as about 20 dBm), which still had to be simulated. This sometimes sounds like a contradiction: Once the measured values are available and are acceptable, why would one want—or, rather, need—to do a simulation besides the necessity to develop a high-input intercept filter? It was desirable to validate the nonlinear models and prove that the above-mentioned equations will hold true. This type of simulation is now more difficult because the number of nonlinear elements went from four to ten, and some numerical problems, such as convergence difficulties, can be expected, and the effect of harmonic frequency cancellation (compensation) can also be seen. By using diode combinations that result in $1(1 - n)$, n being an integer number, these IMD products can drastically be reduced. This implies that each of the five diode pairs has a selected value for n to meet this condition. Later, a final attempt will be made to improve the first VHF filter with the proper diode combinations.

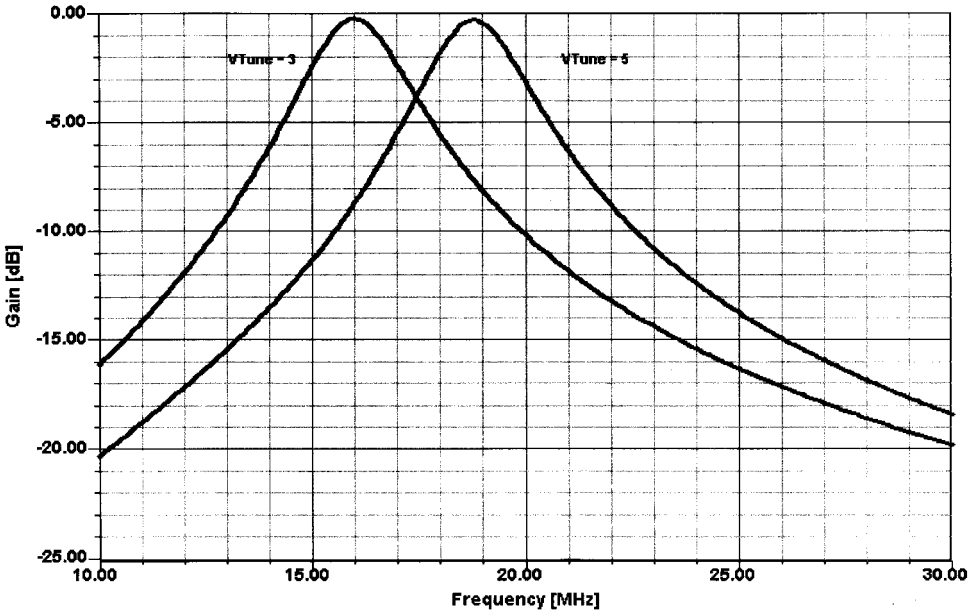

Figure 3-150 Frequency response of the filter shown in Figure 3-149. Filters of this type are intended to reduce second-order IMD by providing about 20-dB suppression at half the center frequency.

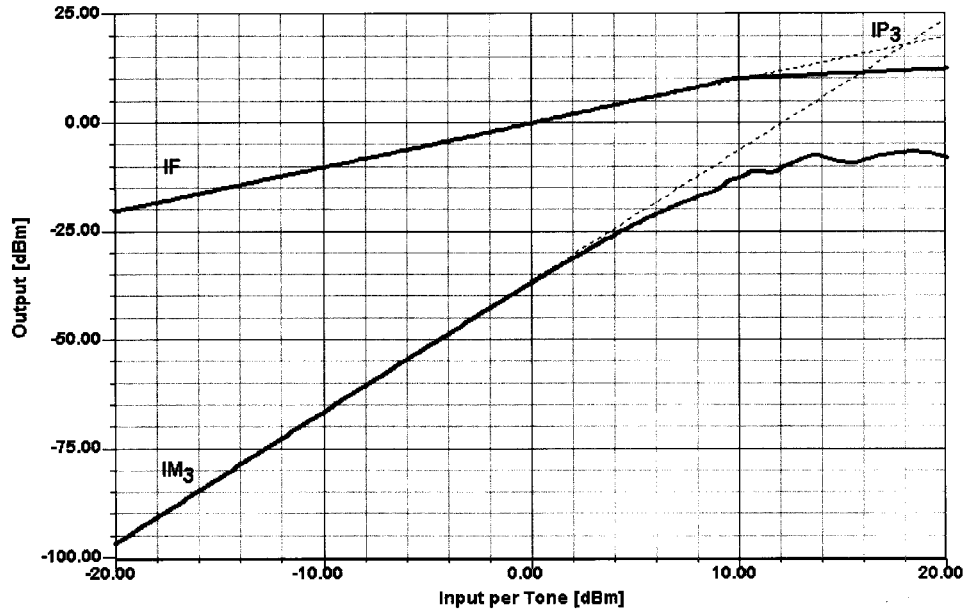

Figure 3-151 Prediction of third-order intercept point of the filter shown in Figure 3-149. The reason for the curves on the IMD plot lies in the interaction between the ten nonlinear devices.

Figure 3-151 shows the calculation of third-order intercept point for the arrangement shown in Figure 3-149. This number has now increased to +18 dBm. The difference between selection and measurement is approximately 2 dB. The reason for this more pessimistic value compared to the measured value probably has to do with slight variations of the exponent of the diodes' voltage-dependent capacitance. Therefore, the authors consider both the circuit performance and the simulation accuracy to be extremely good. This type of circuit, as mentioned earlier, has wide application in oscillator circuits. Danzeisen of Rohde & Schwarz was probably the first to have used this type of circuit by paralleling many diodes for improved performance.

3-6-4 Improving the VHF Filter

By selecting the appropriate diode combinations and circuit modifications as shown in Figure 3-152, a significant IMD improvement of the circuit shown in Figure 3-146 is obtained. A special shunt arrangement of several diodes with different exponents has been developed, which allows its value to be "adjusted." This circuit, for which a patent has been applied, showed an improvement from –2 dBm to 32 dBm. The same high operating Q was maintained. Figure 3-153 shows the frequency response after the modification. Note that a coupling slightly greater than critical ($Q \times k = 1.1$) has been selected.

3-6-5 Conclusion

After explaining some of the nonlinearities in mathematical terms, we have given some examples of voltage-tuned circuits and discussed their large-signal performance. This section has also shown that modern CAD tools can accurately predict the performance of such circuits.

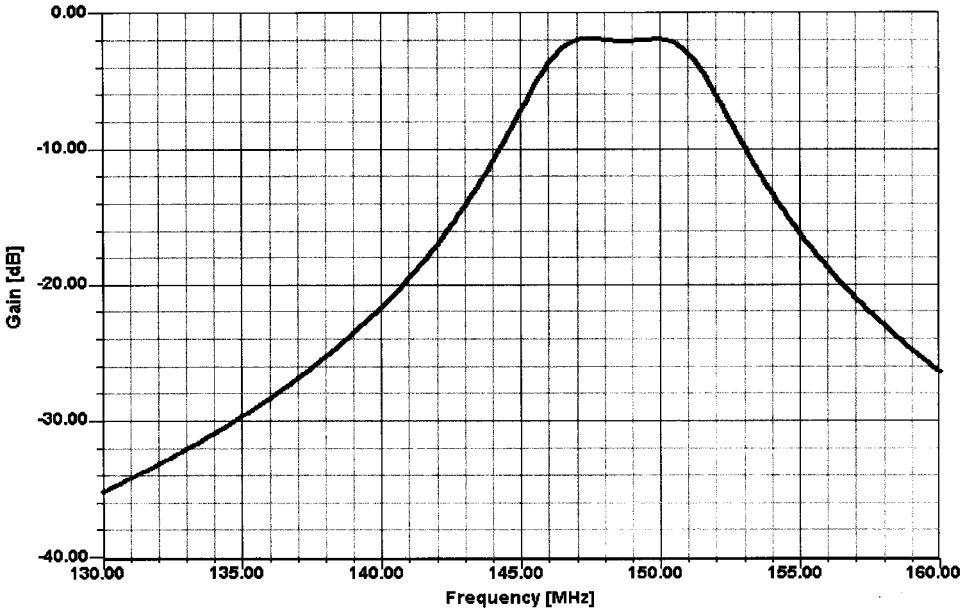

Figure 3-152 The frequency response of the improved circuit derived from Figure 3-146.

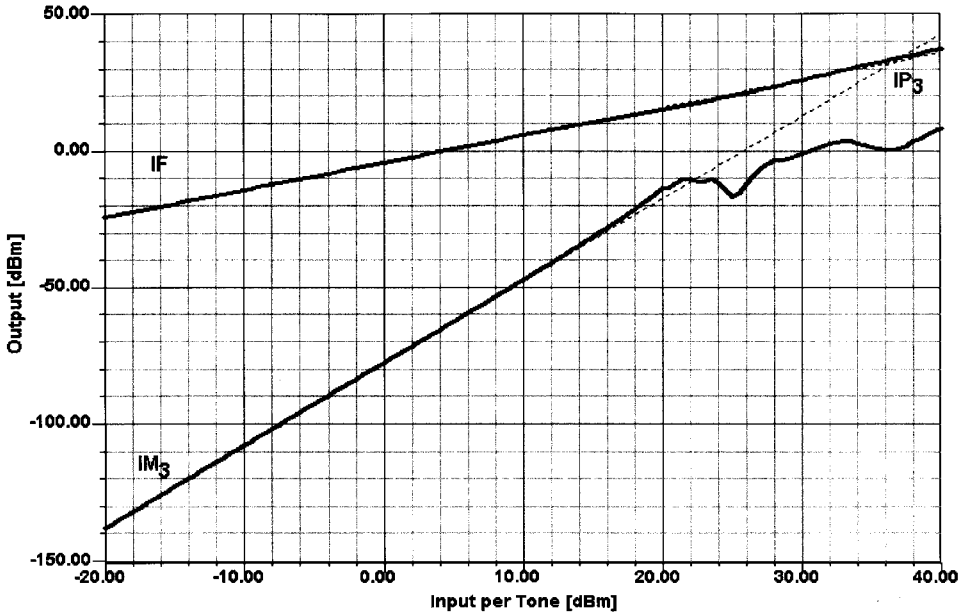

Figure 3-153 Predicted IMD performance of the improved version of the circuit shown in Figure 3-146. This type of improvement is significant for all applications. A patent is in the process of being obtained for this; therefore, the circuit cannot be disclosed at present.

3-7 DIFFERENTIAL AMPLIFIERS

The differential amplifier (Figure 3-154) goes back many years and also was the first step from TTL to ECL. The differential amplifier consists of an emitter follower (Q1) and a grounded-base stage (Q2). The constant-current generator (Q3) between ground and the emitters of Q1 and Q2 determines the current for these stages; the dc operating currents of Q1 and Q1 are the same. Most modern integrated circuits use this differential amplifier in one way or another.

If the circuit is operated about its point of symmetry, the dc component of the current through either Q1 or Q2 remains half of the emitter constant current through Q3 for all symmetrical driving signals. In addition, for input signals that are aperiodic, no even harmonics are generated. This assumes that the stage is driven symmetrically at both inputs. In our case, the differential amplifier has its second stage grounded, meaning that there is a base-to-ground capacitor, and the stage is asymmetrically fed. As the input voltage is increased, the differential stage becomes a limiter, which limits the current between plus and minus I_S, with I_S being the source current. The resulting output will become a square wave. This stage can also be used as a line receiver, translating a sine wave to an output logic suitable for driving emitter-coupled logic (ECL) stages.

One can assume that the differential amplifier has a transconductance of

$$g_m = \frac{\alpha g_{\text{in}}}{2} \tag{3-190}$$

where α is the ratio of collector to emitter current. Within the limits of the output being a sine wave, this stage has very low distortion. The output current now is determined by

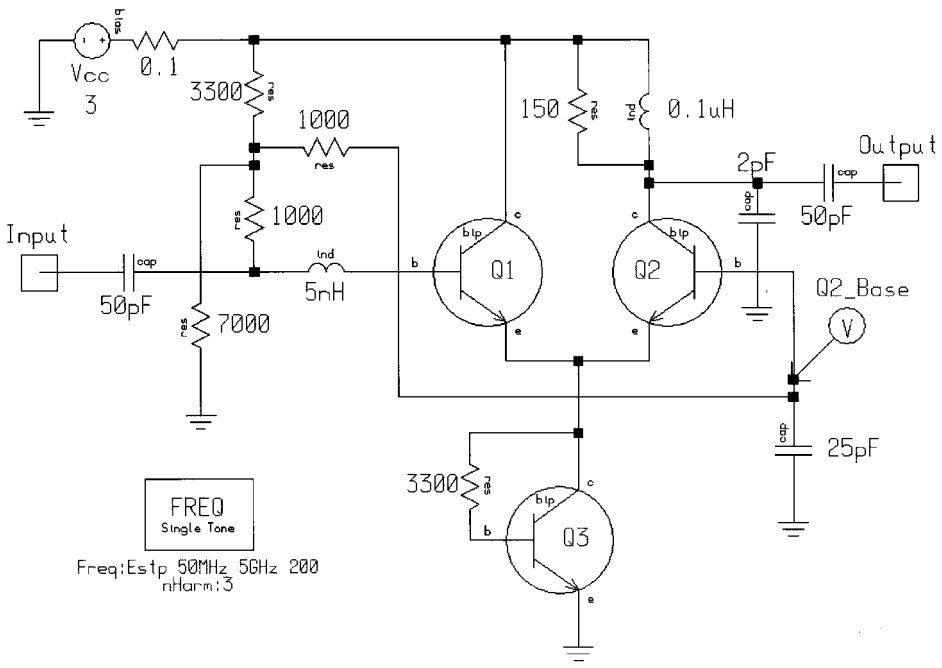

Figure 3-154 The differential amplifier schematic. The transistors are Siemens BFP420s. Figure 3-155 shows the circuit's frequency-dependent gain, matching, and noise performance.

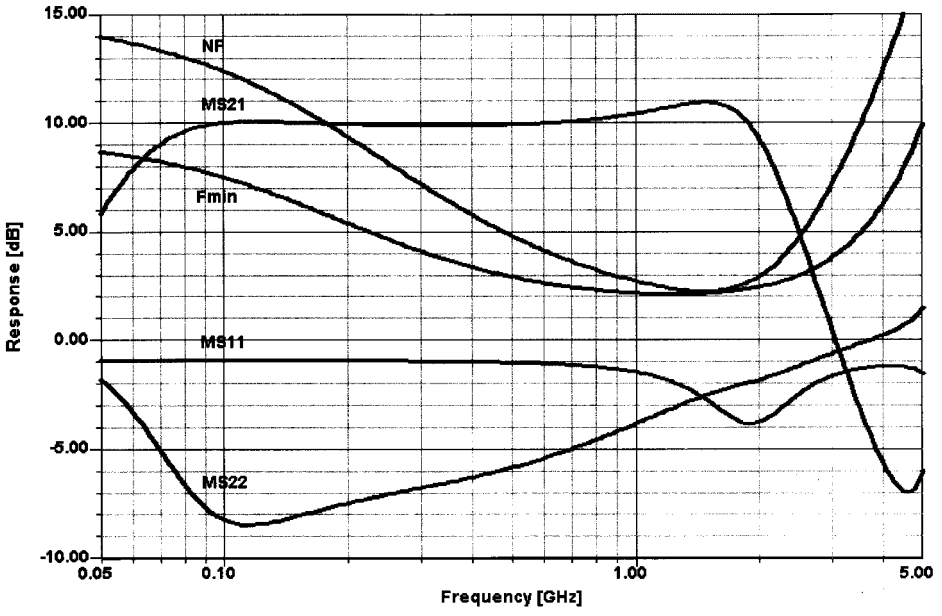

Figure 3-155 Frequency-dependent gain, matching, and noise performance of the differential amplifier.

$$i = \frac{I_{\text{in}}}{2} \tanh\left(\frac{x}{2} \cos \omega t\right) \tag{3-191}$$

where ωt is the input frequency and I_{in} is the current forced by Q3. The reason why the transconductance has to be divided by 2 comes from the fact that the current is split into two equal components for Q1 and Q2. Multiplying the new transconductance with the output load gives the voltage gain of this amplifier; its power gain can be obtained by multiplying this with $\sqrt{\text{output resistance} \div \text{load resistance}}$.

Having done the linear analysis and having learned that because of the hyperbolic tangent functions this amplifier can also be used as a line receiver, and converting sinusoidal waves to square waves, it may be useful to take a closer look at these issues. If we take a CAD oscilloscope, we see the resulting output waveform being a nonequal duty cycle output voltage, which results in high harmonic content. The amount of harmonic content can be controlled by the drive power and by the actual bias. Figure 3-156 shows the resulting output waveform.

If we now switch to a CAD spectrum analyzer, we can evaluate the harmonic content (Figure 3-157). Figure 3-158 shows the output transistor's dc I–V curves and ac load line under these conditions. Based on the previously defined conducting angle of the differential amplifier, one can optimize for harmonic content. Therefore, it is logical at this point to look at frequency multipliers, as they are sometimes needed. Finally, we are curious to see the so-called load line of the output transistor, which is, based on the interaction of all the stages, not looking the same way as the expected one, which we know from previous amplifier examples. Part of the reason for this is that for a certain voltage range, the collector voltage is in the negative region, and all kinds of saturation effects result in this surprising waveform. By reducing the input power, one would obtain a more "expected" load line. We invite readers with CAD capabilities to play with this example, as it gives a lot of insight into the operation of ECL stages.

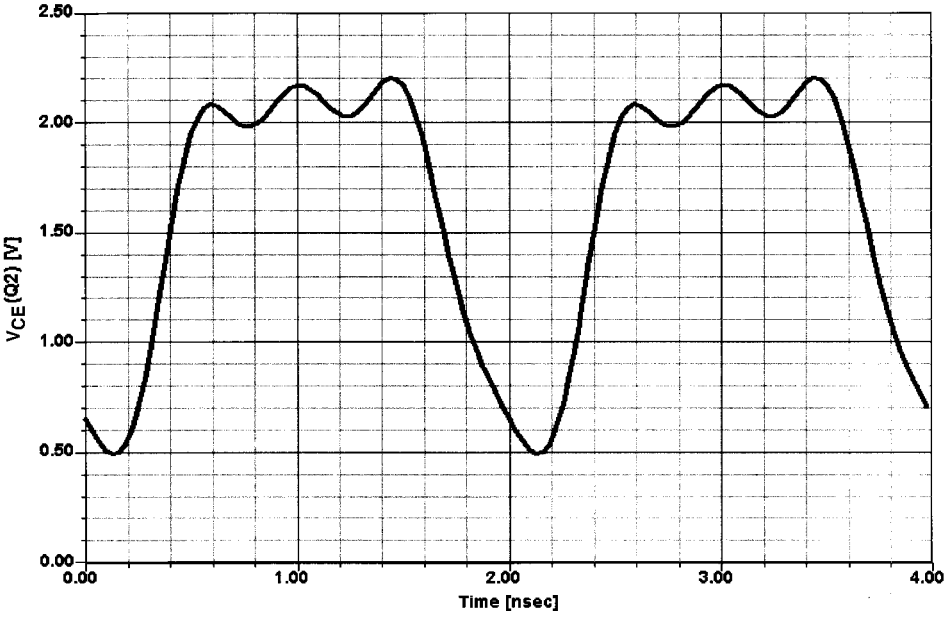

Figure 3-156 V_{CE} versus time for output transistor Q2 with a drive of 10 dBm.

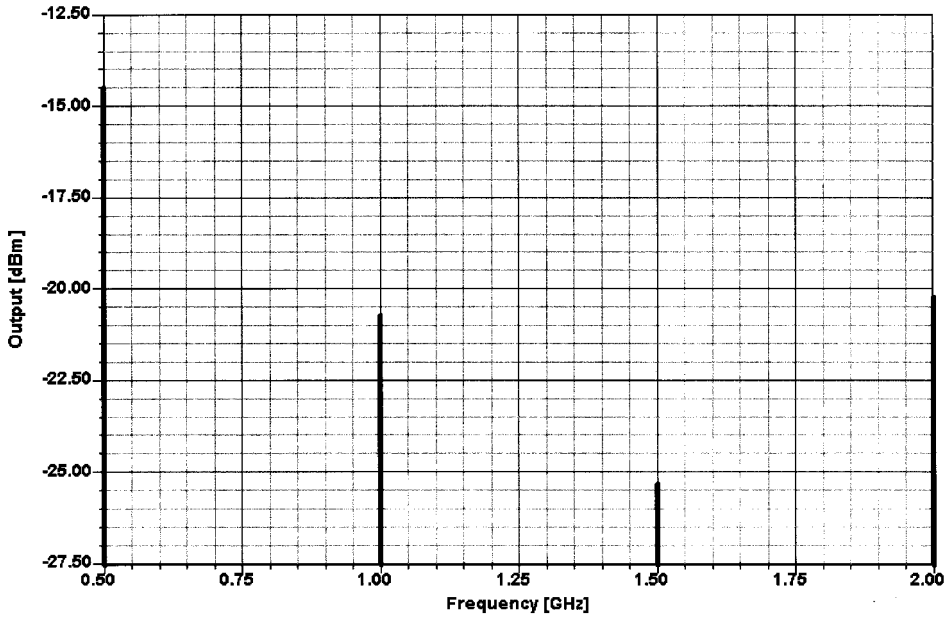

Figure 3-157 Output spectrum of the differential amplifier with a drive of 10 dBm. The biasing is not optimal for frequency multiplication.

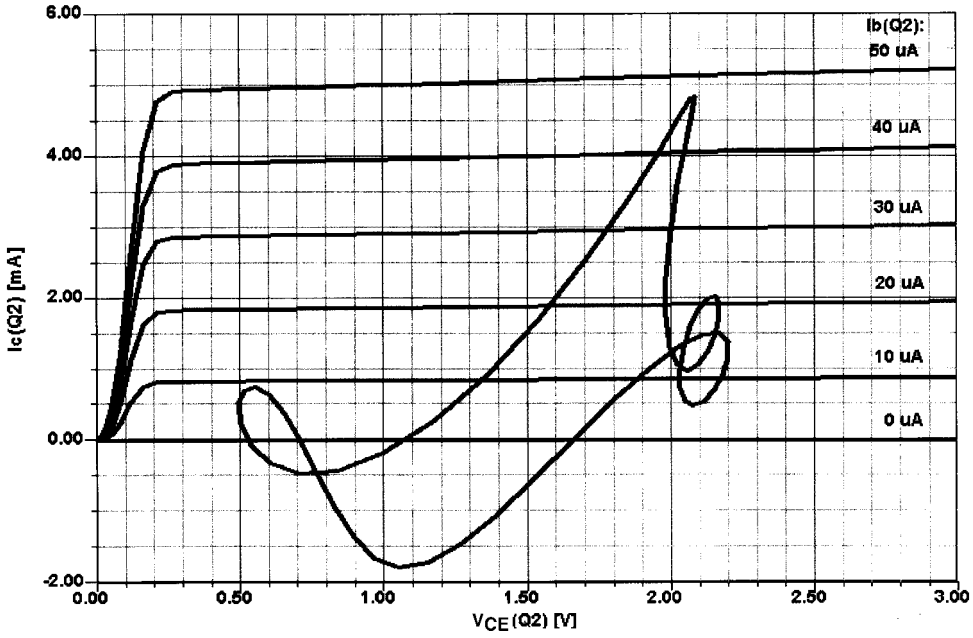

Figure 3-158 The dc *I–V* curves and ac load line for output transistor Q2 with a drive of 10 dBm.

3-8 FREQUENCY DOUBLERS

Having seen that the harmonic content invites us to bias a stage from Class A into Class B or C if our goal is a harmonically rich current, we will now evaluate a single stage that will be biased close to cutoff and driven by a relatively low frequency (500 MHz). To obtain the best results, we will use a parallel notch filter in the output, followed by a high-pass matching circuit to "catch" the desired harmonic. The input frequency is heavily suppressed by the notch filter. Based on its finite Q, there is a limited range over which this frequency can be varied with constant subharmonic attenuation. Figure 3-159 will be our test circuit.

This circuit consists of a bias transistor, Q2. This method has been discussed before and solves the temperature-dependent bias emitter thermal runaway problems through "temperature compensation." The purists among our readers may point out that the currents drawn by Q1 and Q2 are not quite identical (which would give 100% cancellation), but the approach shown is sufficient to do its job. Also, we have chosen a Class AB operation point, which is defined by Q1's 1-mA dc standing current. The conducting angle has not been optimized for the second harmonic—a task that the interested reader can do by using the conducting angle relationship shown at the beginning of this chapter. To give readers with access to nonlinear CAD some homework, we have not set this at the optimum point.

The second transistor, here called Q1 (because of its importance at RF), has a matching network at the input. This is recommended for optimum energy transfer. The matching condition can be validated by examining Figure 3-160. If we look at the higher frequency response, the input shows a possible trend of oscillation (negative loss); this could actually be eliminated by using a low-pass filter at the input instead of the high-pass filter used now. Findings of this type always make us nervous, and we hope that the nonlinear models are sufficiently accurate at higher frequencies to predict such behavior correctly. In the case of the FET doubler mentioned in Chapter 2, we found that the device modeling done by Compact (now Ansoft) gave the best results, the university answers were fairly close, and the device manufacturer data were worst. We have since become highly skeptical about device modeling unless we can validate it ourselves. Synergy Microwave has a complete set of test equipment in the laboratory, including network and spectrum analyzers with special software created by Rohde & Schwarz that can be used in addition to the Scout program to do in-house validation. This was achieved by the use of nonlinear optimization at a drive level of 0 dBm. One could say that this is similar to using a load-pull approach at the input, and then resorting to the large-signal S parameters obtained. Another note of caution: Capacitors at these low values tend to have a very large percentage error; for instance, a 1-pF capacitor, if not selected carefully, can vary between 0.7 and 1.3 pF—a 50% error. Needless to say, this is not acceptable for useful production.

The output consists of a high-pass filter and a notch filter with the purpose of reducing the subharmonic significantly. We have again done this on purpose, leaving room for the reader to come up with a more inventive output circuit like a Cauer-type (same as elliptical) low-pass filter with discrete notches at higher harmonics of the input frequency, such as 1.5 GHz, 2 GHz, and so on. In addition, we have shown three ways how to implement the inductance for the notch filter. This is equally applicable for other inductors in this value range. As frequency increases, this becomes more interesting but one needs to remember that many materials like silicon and gallium arsenide are extremely lossy. The same inductor approach has been used in Figure 5-61 of Chapter 5. For silicon, even the manufacturer becomes an issue. Figure 3-161 shows a top view of a "rectangular" inductor that actually approaches the spiral inductor; its implementation can be seen in Figure 3-162. Modeling this was a

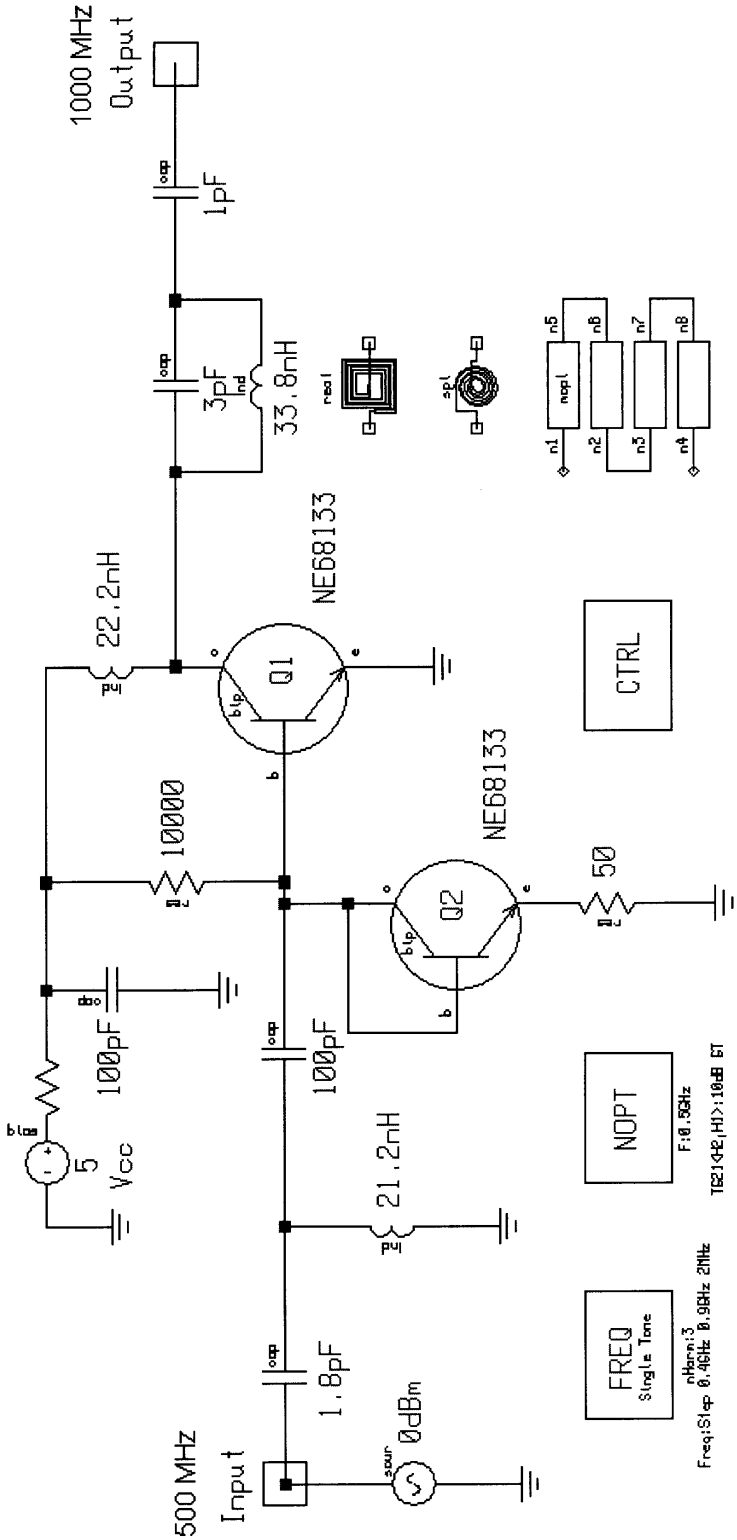

Figure 3-159 BJT frequency doubler schematic. A parallel-tuned trap in Q1's collector attenuates fundamental feedthrough.

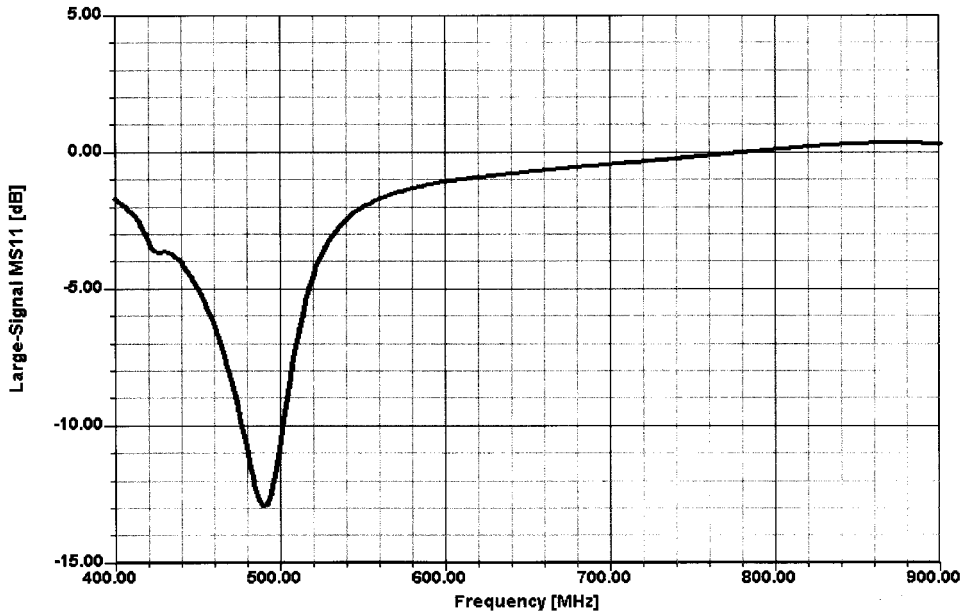

Figure 3-160 Large-signal MS_{11} for the BJT doubler. Note the positive region above 800 MHz.

nightmare, and during our Compact days, we actually had to modify the electromagnetic simulator to accommodate this and get results where measurements and simulation agreed. Figure 3-163 shows the measured and simulated Q as a function of frequency of a silicon-based inductor. In the case of other materials, such as PC board or GaAs, the models in the CAD tools are sufficient to predict the losses of the inductors. Following this initial exercise, Motorola then developed an improved silicon spiral inductor; its frequency-dependent Q is shown in Figure 3-164. Note that this Q was measured and not simulated.

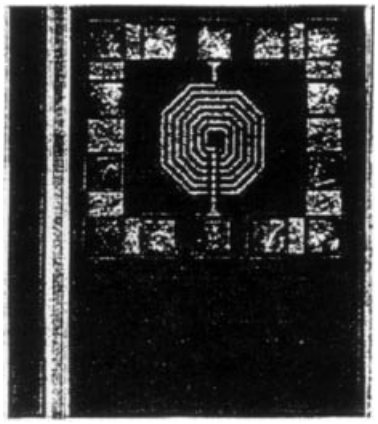

Figure 3-161 A 6.5-turn spiral inductor in silicon.

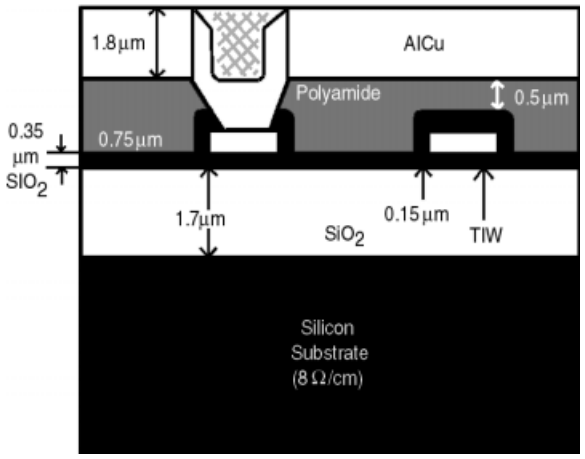

Figure 3-162 Cross section of the silicon inductor.

One of the reasons why we use a transistor multiplier is that we expect gain (because of the square-law characteristic, an FET would have been better tailored for a doubler); therefore, we have "measured" the gain of this circuit while driving it with 0 dBm. Another important factor is that, because of the way the CAD tool displays it, the gain is referenced to the 500-MHz input. Mentioning this is important; otherwise, the reader may look for the 1-GHz gain, which does not exist. Figure 3-165 shows the doubler gain.

By now we are curious to see the doubler in action, and by reviewing Figure 3-166 we can see the output spectrum. The output spectrum validates the statement that the output circuit, while doing a marvelous job of removing the 500-MHz input frequency, does not cure the problem of unwanted multiples of the input frequency. Again, a Cauer low-pass filter, while introducing some possible additional loss, should be considered for this circuit to have a bandpass response. On the other hand, many oscillators have very little harmonic suppression, and the same type of postfiltering needs to be considered. There are two-transistor solutions available also, such as push–push for frequency doubling (push–pull would

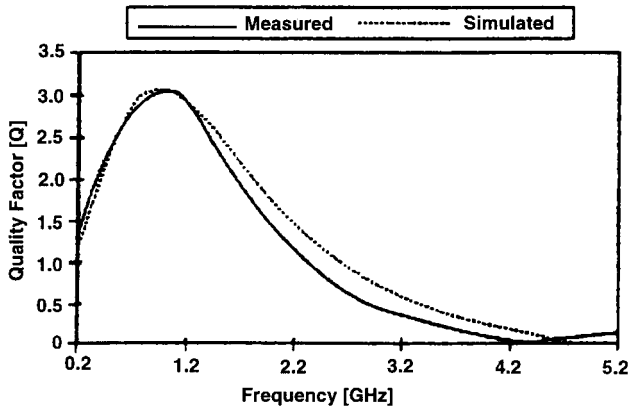

Figure 3-163 Measured and simulated *Q* versus frequency for the simulated inductor.

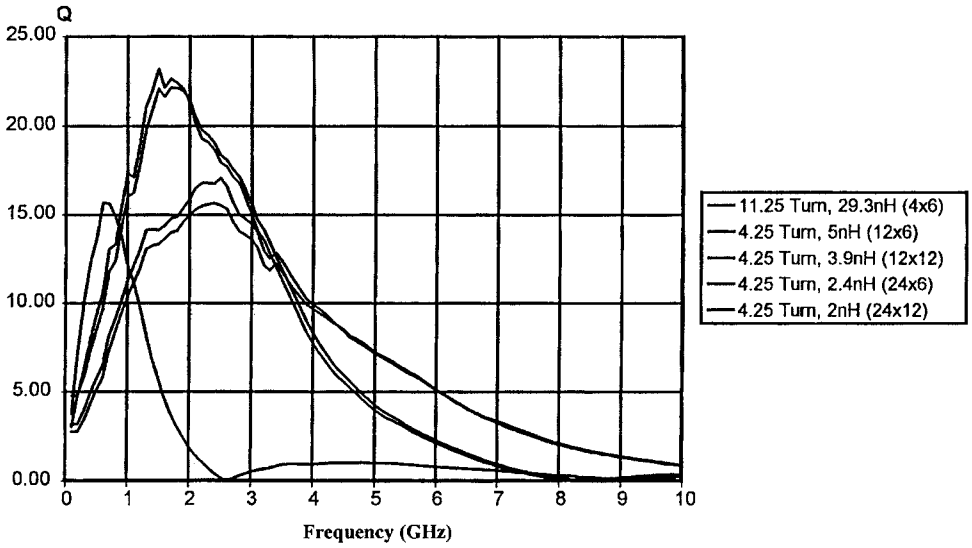

Figure 3-164 *Q* versus frequency for Motorola improved inductor.

eliminate the desired second harmonic quite well). Actually, two diodes could also have been used for doubling, but since this requires transformers and a postamplifier, we have shown the preferred application. The only advantage of the diode application is that it is wideband, while this BJT circuit, as we have just learned, must be made narrowband for reasons of spectral purity.

Finally, we are curious to see the actual operating state of this amplifier, and this can be done by analyzing the load line (Figure 3-167). This is as complicated as the analysis for the differential amplifier. Because of the stored energy in the various tuned circuits, the load line looks quite impressive and would probably be difficult to predict without a nonlinear CAD tool.

3-9 MULTISTAGE AMPLIFIERS WITH AUTOMATIC GAIN CONTROL (AGC)

Having discussed the basic differential amplifier, we will now evaluate the performance of the MC1350/1490 video amplifier chip from Motorola. Most of the circuitry in the chip is self-explanatory. Figure 3-168 shows its inner circuit, and Figure 3-169 show a recommended application. By grounding one side of the input, we effectively get the same performance as the differential amplifier just discussed, with one difference being that the input is now fed to the constant-current generator. To minimize the distortion at the two lower transistors, they are decoupled by a 66-Ω resistor. Figure 3-170 shows the frequency-dependent gain, matching, and noise figure. Since this particular device has been specifically designed for AGC purposes, we also show in Figure 3-171 its gain reduction versus applied AGC voltage.

3-10 BIASING

A lot has been written about biasing, and since the purpose of this book is not to focus too much on dc, the following examples including RF consequences have been selected and considered sufficient. Early application reports by Motorola and others have provided a wealth of data. As a side effect of the introduction of the wireless era, we find that the engineers are so pressed for time that the number of complete application reports has approached zero. This is one of the reasons why we have tried to minimize the mathematical basis of this book (some is still needed), while still providing practical assistance. Figure 3-172 shows a textbook type of approach for RF.

In order to decouple the transistor from the biasing, we use RF chokes and dc decoupling (bypass) capacitors. This is the technique used in previous examples, so one might ask, "What's new?" As frequency increases, these inductors are either not manufacturable or have such a low Q that their use becomes questionable. This is the point where one may introduce the so-called distributed elements.

Figure 3-173 shows the very same circuit but resorting to distributed rather than lumped elements. The newly introduced elements (part of any good, up-to-date CAD tool; see element library for how to use their physical element descriptions) are described next.

- *Transmission Line.* Any printed connection between two points on a circuit board is a transmission line (Figure 3-174). Its characteristic electrical impedance is a function of the square root of the dielectric constant (ε_r), the width, metallization, thickness and height above substrate of the line, and the loss tangent of the substrate. Since lines frequently have to be laid out in the form of curved connections or have a bend in their direction, we have to add elements capable of describing the high-frequency conse-

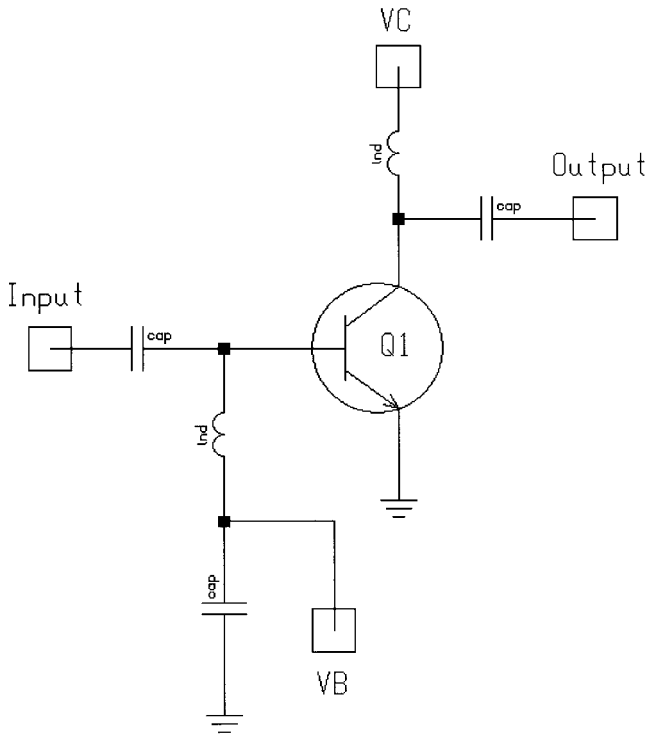

Figure 3-172 Simple BJT RF amplifier with lumped elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

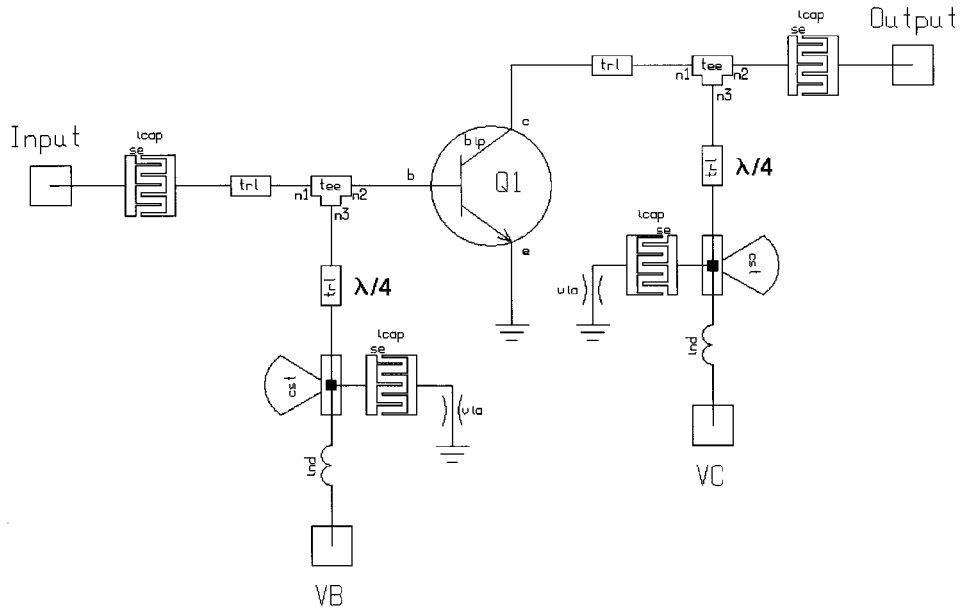

Figure 3-173 Simple BJT RF amplifier with distributed elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

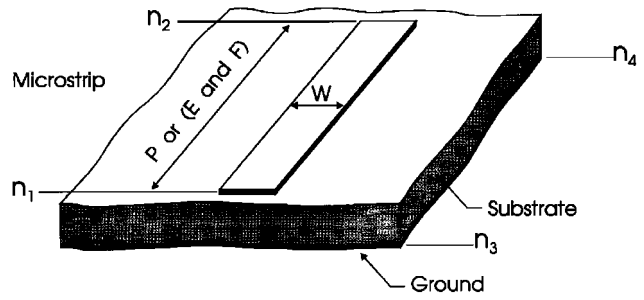

Figure 3-174 Transmission line in microstrip.

quences of such connections. Figures 3-175 and 3-176 show mitered and radial bend elements that perform this function.

- T *Junction, Cross, and* Y *Junction.* By the time a point like a collector or base, or its FET equivalent, spreads out into connections with other elements, we need additional modeling capability to describe ⊤ connections, crossings, and Y junctions. Figures 3-177, 3-178, and 3-179 show the way in which these connections must be modeled.

If the need exists, the standard inductances must be replaced with a transmission line whose length is λ/8 at the operating frequency. At higher frequencies, these transmission lines, however, then go into λ/4 resonant mode and later become capacitive. This type of design makes it fairly narrowband. A way around this is the use of printed inductors, as shown in Figures 3-180 and 3-181.

These inductors have a self-resonant frequency similar to the transmission line mentioned above, but the safety margin is significantly higher.

Talking about printed inductors, a logical extension of this is the printed transmission-line-based transformer, as shown in Figure 3-182. One can consider this as two interlaced rectangular inductors and, based on the substrate material, they are useful over a wide frequency range. Besides being used as a transformer, they can also be used to transit from

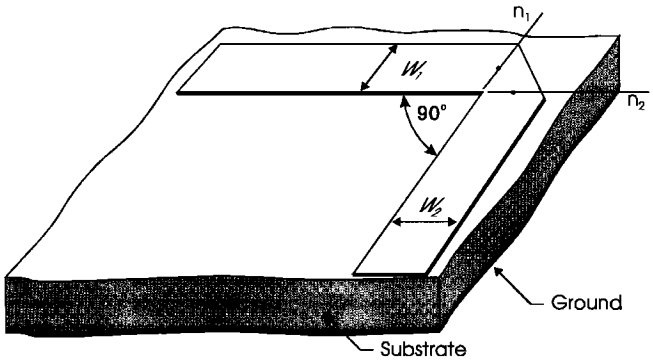

Figure 3-175 Mitered bend.

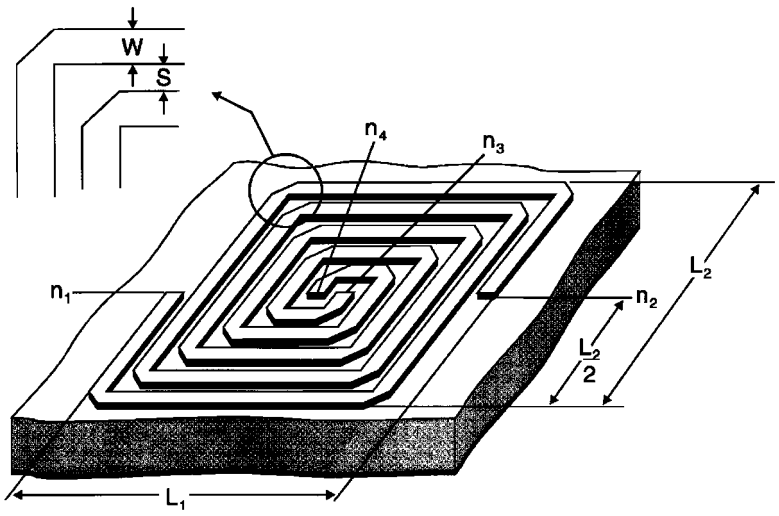

Figure 3-182 Transformer in microstrip.

unbalanced to balanced transmission provided that the difference in length from a connection point of view does not cause any problems (this is a layout issue).

A popular form of combining stages is the so-called Lange coupler (Figure 3-183) invented by the German Julius Lange. It is one of the major contributions in wideband applications.

Useful application of the Lange coupler probably starts at 4 GHz. It consists of parallel transmission lines with the appropriate connections as shown. Lange couplers are typically built with four, six, and eight fingers. The Ansoft Serenade product has a Lange coupler synthesis program that can be used to gain more insight into this coupler's application. We assume that other modern software has similar capabilities.

Where meander-type inductors are necessary, a neat way to implement and simulate them is to use the multiple coupled lines element (Figure 3-184) of the Serenade product, which both quickly and accurately calculates the behavior of the meander, including self-resonances and losses. We made use of this arrangement in our previous examples.

- *Interdigital Capacitors.* The issue of tolerances of small capacitors already has been brought up. The interdigital capacitor can be made on printed circuit board material as

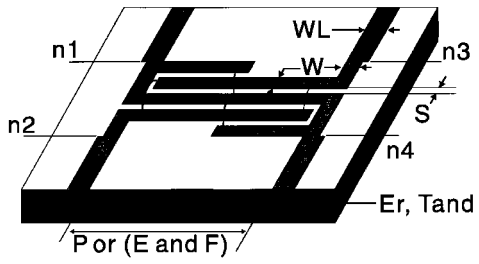

Figure 3-183 Four-strip Lange coupler.

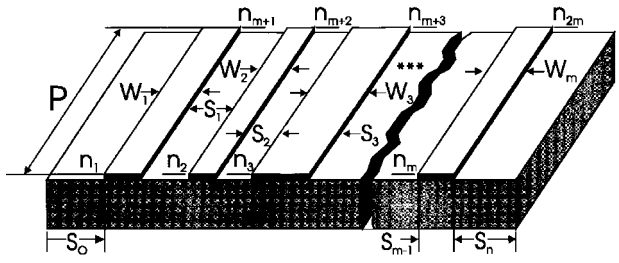

Figure 3-184 Multiple coupled lines element in microstrip.

well as gallium arsenide, and if its dimensions are continuous with the transmission-line width it does not cause any abrupt changes in impedance. This type of capacitor permits one to obtain very small values. An alternative to this is the use of transmission lines with a length of $\frac{3}{8}\lambda$. We learned earlier that a transmission line is inductive at frequencies below its fundamental resonance, is resistive at below resonance, and becomes capacitive above resonance. Again, bandwidth is also an issue. An interdigital capacitor consists of a number of parallel fingers as shown in Figure 3-185, and its capacitance can be varied by adjusting the number of fingers and their spacing. The advantage of the interdigital capacitor compared to discrete components is its low variation in value.

- *Radial Stubs.* The radial stub (Figure 3-186) is not much different from a $\lambda/4$ resonator, but its bandwidth is much greater than a simple transmission line. This is another way to ground the "cold" side of a transmission line or part of a circuit that needs to be grounded for RF. Of course, the interdigital capacitor comes in a version that is a combination of a capacitor and a via hole.
- *Via Holes.* The "cold" end of the transmission line, being considered either an inductor or a capacitor, needs to be connected to a sufficiently large copper backplane. One very efficient way to do this, especially if there is not enough copper left on the top of the board, is the use of via holes (Figure 3-187). One could theoretically generate

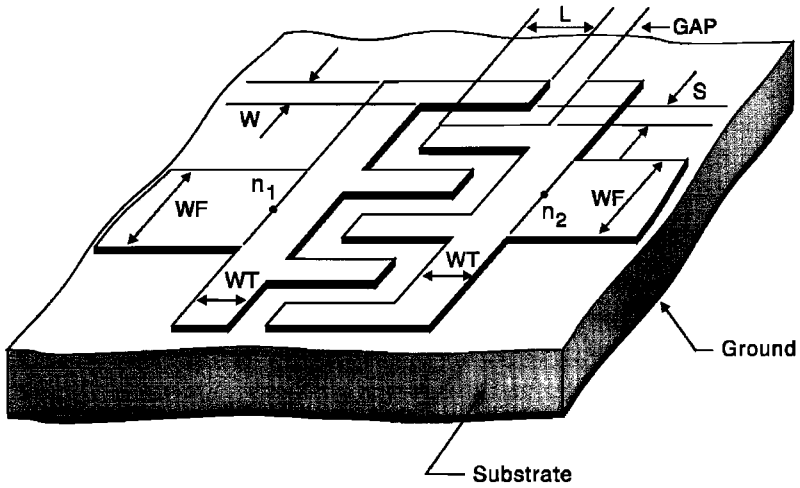

Figure 3-185 Interdigital capacitor.

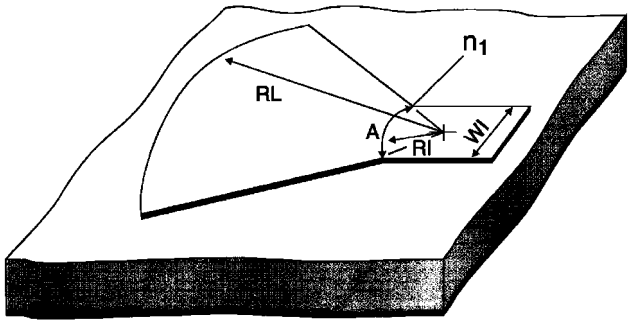

Figure 3-186 Radial stub.

a via hole with a rivet, but most manufacturing processes don't allow this; the normal solution is to use plated-through holes left open. In PC boards, via holes are typically cylindrical; on substrates like GaAs, they may be conical.

- *Correction Elements.* Although the behavior of an actual circuit proceeds regardless of our ability to measure and describe it, we do not enjoy this luxury in simulating circuit behavior in software. In a simulator, effects that are insufficiently described will be inaccurately simulated. For instance, segments of high-impedance transmission line (e.g., 120 Ω) are frequently used for dc feeds and RF chokes. In predicting the effect of a transition from 120-Ω line to 50-Ω line, a simulator must be alerted to the discontinuity so it can do the necessary mathematical corrections to account for the impedance jump. To do this, a specific circuit element, the STEP (Figure 3-188), must be inserted between the 120-Ω and 50-Ω line elements in the simulation circuit file. In addition to substrate data, we characterize a STEP by providing the widths of its input and output lines. The element itself has no physical length.

A similar correction is necessary if a transmission line is used as a resonator or just "left open" at one end. Such a transmission line tends to radiate and, because of its high-impedance properties, it reacts differently as far as its electrical length is concerned. A zero-length one-port element, the OPEN (Figure 3-189), must be added to such a line for mathematically correct calculation.

We end this excursion into distributed elements here. Interested readers may want to obtain a CD containing the element library of their favorite CAD tools that combine capabilities in the microwave area with a full set of distributed circuit elements. It is most important to keep

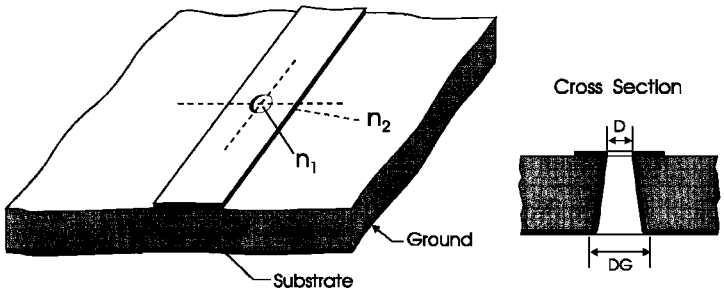

Figure 3-187 Via hole.

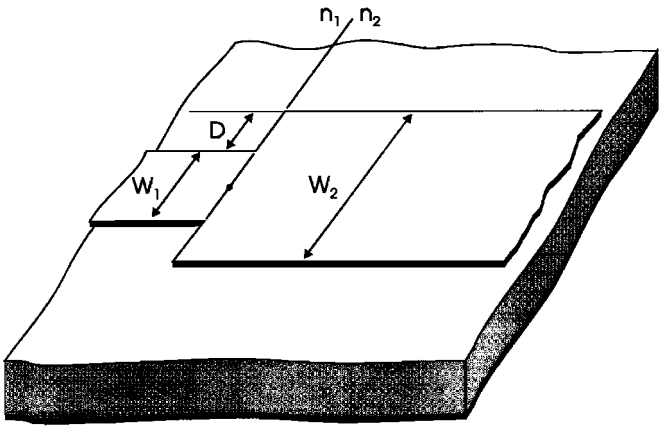

Figure 3-188 The STEP element tells the simulator to calculate the effects of joining transmission lines of differing characteristics.

in mind that, as frequency increases, we rapidly move into the area where we must consider all these distributed elements to achieve accurate simulations—even if doing so makes simulation a painful and time-consuming effort.

Finally, anyone who adventures into this area *must* obtain a foundry manual from the company that will build the integrated circuit or hybrid under design. There are basically two foundries, one applicable for MOS technology and one for GaAs. In the case of the bipolar transistor, the foundry service is not yet well-established. While we were able to interest one German company and one U.S. company in generating a custom bipolar IC within the activities of this book, the only "open" foundry we know of for bipolar (actually HBT) technology is the one operated by TRW. As of 1999, this seems to be the leading company for BJT-related products, and many currently available ICs have been developed with this foundry service.

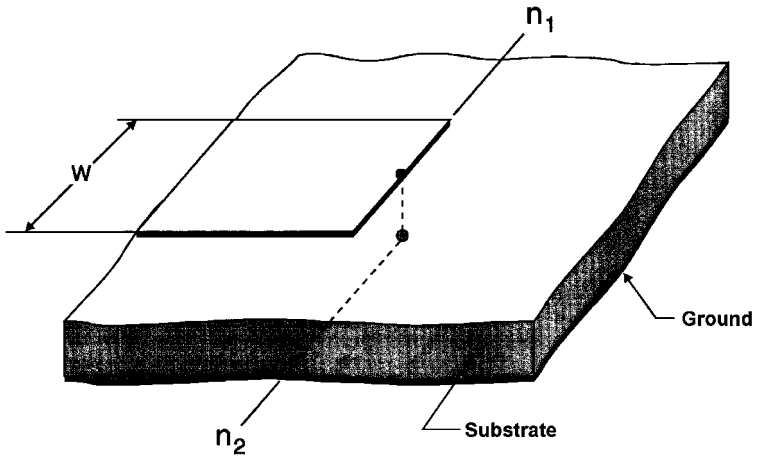

Figure 3-189 The OPEN element tells the simulator to calculate the effects of leaving the end of a transmission line unconnected.

We mention the issue of foundries here again because each foundry has its own proprietary approach to modeling discontinuities. The availability of a foundry service somewhat eases the requirement that a designer be fully up to speed on the nuances of discontinuities, because a foundry's designer service will help customers account for all relevant parasitics or discontinuities in their designs. In addition, there are tables of *S* parameters for standard cells of either capacitors, resistors, or inductors. The designer may then be forced to adjust the circuit so that it will work with a particular inductance value or value of another component within the resolution of the table that describes these elements. Information on the active parts, such as diodes and transistors, was given in Chapter 2.

3-10-1 RF Biasing

Applying the knowledge we have just acquired about distributed elements, Figure 3-190 shows a somewhat exaggerated case of using the various elements. While it is consistent with the simple RF case with which we started, modeling of this type is certainly necessary at higher frequencies. Many but not all of the elements we have just described are used, but we have not solved the question of the actual dc biasing.

3-10-2 dc Biasing

The following discussion is the recommended procedure for biasing a transistor. We will start with the collector current (in our example, Figure 3-191, 10 mA). To separate RF and dc, we have a combination of a load resistor (R_L) and an inductance (L_C). Information about this operation was given already in Section 3-2-6. The emitter resistor should have a voltage

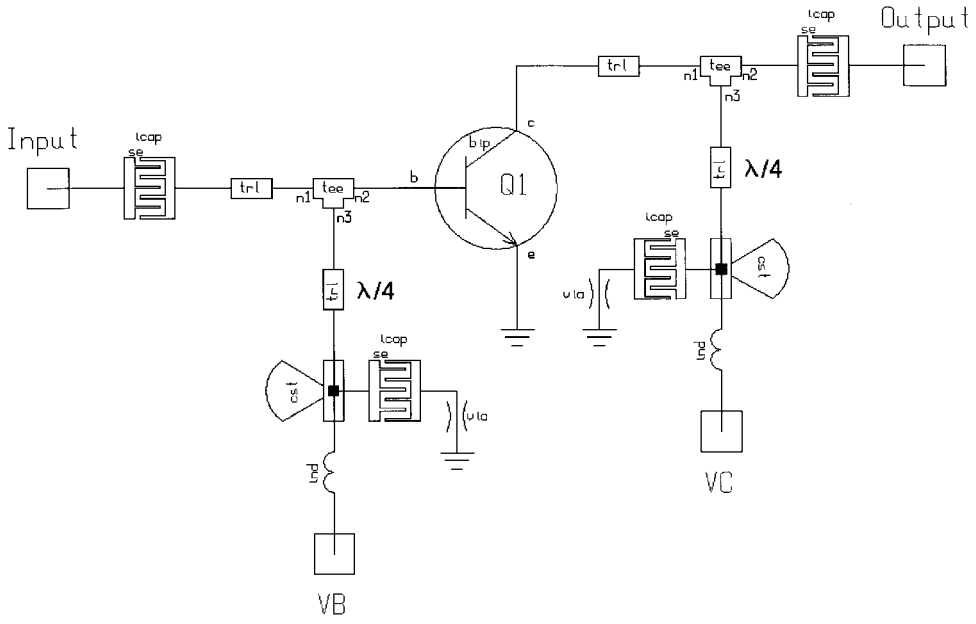

Figure 3-190 Simple BJT RF amplifier with distributed elements used for bypassing and dc blocking, and for base bias and collector supply feeds.

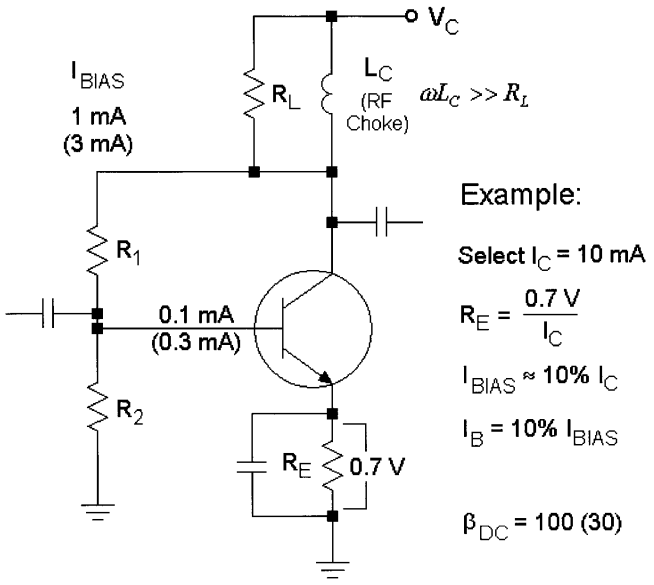

Figure 3-191 A dc biasing example.

drop of about 0.7 V, and therefore the emitter resistor is $0.7/I_C$. The next assumption is that the transistor has a dc current gain of 100, and therefore we decide to have the bias resistor chain (R_1 and R_2) draw 10% of I_C, or 1 mA. Assuming a collector voltage of 5 V, the value of $R_1 + R_2$ has to be 5 kΩ to result in the required 1 mA. Because the base current now is 10% of the divider current, the base will draw 0.1 mA. The voltage across R_2 has to be the voltage drop across R_E (0.7 V) + V_{BE}, which is also 0.7 V, or 1.4 V. Given the 1 mA, R_2 = 1.4/1E–3 = 1.4 kΩ. R_1 therefore is 5 kΩ – 1.4 kΩ = 3.6 kΩ. This concludes the calculation.

In the case of a dc beta of only 30, we need to raise I_{BIAS} from 1 mA to 3 mA since the base current now will be 0.3 mA. This changes the resistor values. $R_1 + R_2$ = 5 V/3 mA = (rounded) 1.6 kΩ. Following the same approach, we need 1.4/3E–3 = (rounded) 470 Ω. This makes R_1 = 1600 Ω – 470 Ω = (rounded) 1100 Ω. These roundings were necessary because resistors can only be bought in certain resistance steps.

However, for low battery voltages, the 0.7 V between the emitter and ground cannot be wasted. Therefore, a dc stabilization circuit, to which we have already referred, will be considered next. Figure 3-192 shows a combination of an RF transistor, Q1, and a dc stabilization transistor, Q2. The most important thing about this circuit is the fact that the difference between the supply voltage and the collector of Q1 is 0.3 V, which is approximately half of the voltage we had to "waste" across R_E in the above-mentioned circuit. Plus, the voltage drop is now in the collector, and given the fact that we feed Q1's collector through the inductor of a quasi-tuned circuit rather than through only a resistor, we get a much higher voltage swing. The base–collector diode temperature dependency of Q2 is compensated for with the silicon diode feeding the base. It is also fascinating to see that, because of the low currents, both the voltage drop of the diode and V_{BE} of Q2 are about the same, and yet Q1, operating at a reasonable current, shows the expected 0.7–0.8 V V_{BE}. We have supplied all the necessary dc voltages to give the reader an incentive to calculate the mechanism of this stabilization. The key equation to this is to determine the current in the voltage divider feeding

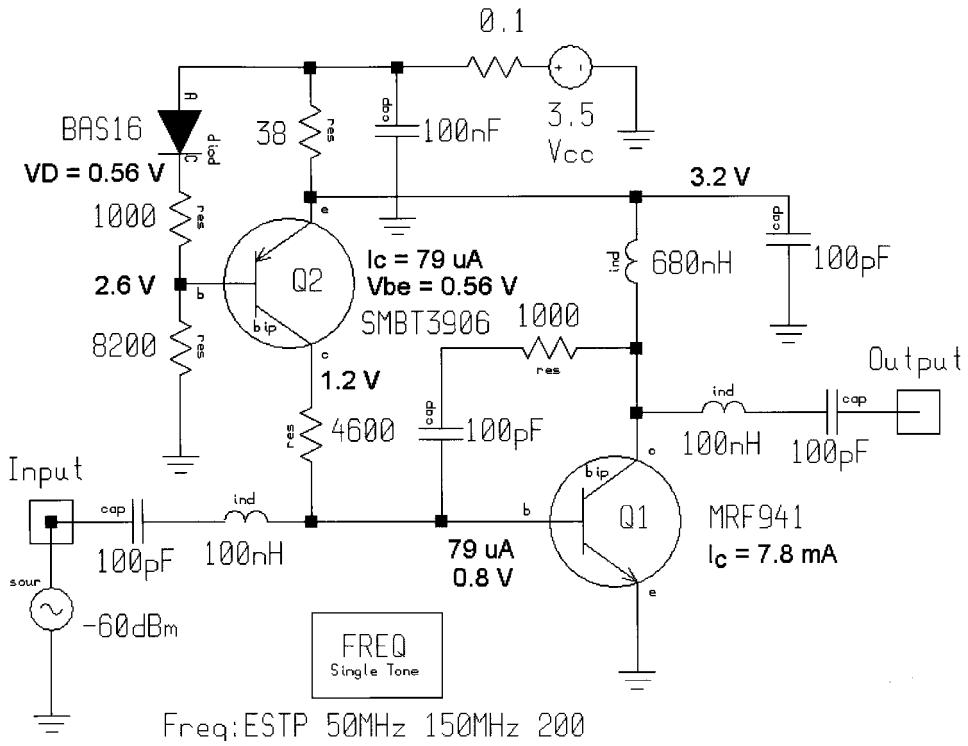

Figure 3-192 An RF amplifier with active biasing. (After the low-noise amplifier circuit in [29].)

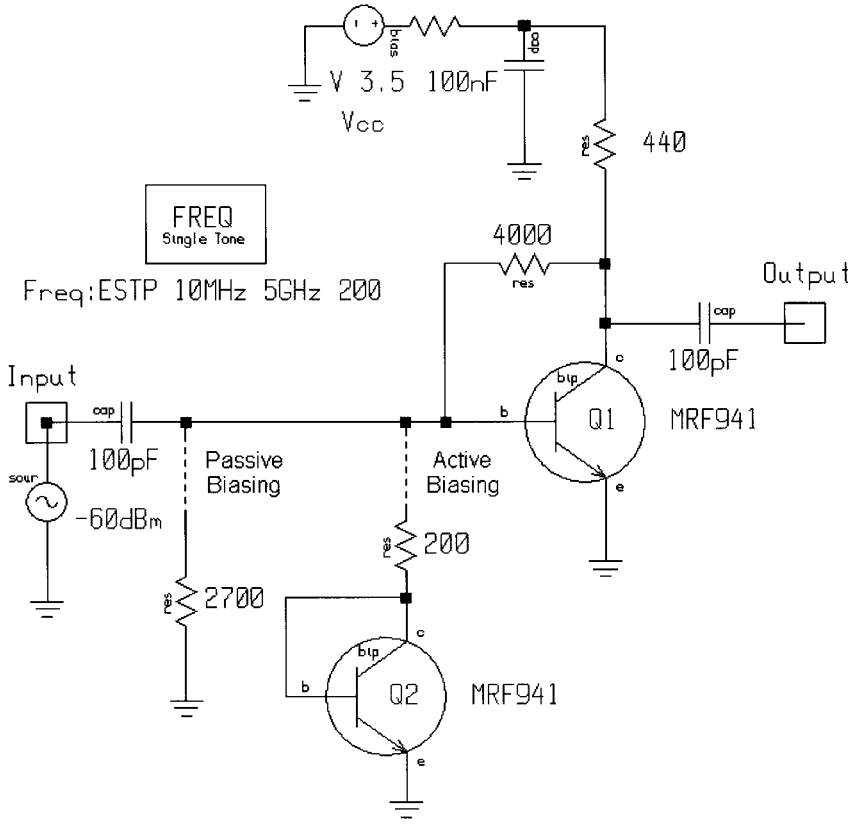

Figure 3-195 Amplifier stage (I_C = 3 mA) showing active and passive bias alternatives.

Q2, and proceeding from there. On the other hand, having a nice CAD tool that provides insight into the dc voltages and allows the addition of dc voltage probes makes life much easier. To prove that this circuit actually works, Figure 3-193 shows its frequency-dependent gain, matching, and noise figure performance. It is based on a Motorola application, which had excessive voltage drop for Q1 and which we have improved to be suitable for low-voltage operation [29].

Integrated active bias solutions are also available. Figure 3-194 shows the Siemens BCR400 active bias controller applied to a BJT; it can also be applied to FETs and TR switching diodes, as we saw in Figures 3-57 and 3-59, respectively.

3-10-3 dc Biasing of IC-Type Amplifiers

In integrated circuits, we do not have the unlimited flexibility described earlier. This results frequently in constant-current sources or transistors being used as diodes for biasing purposes. Our first suspicion is that this is going to cause a lot of noise in the IC; Figure 3-195 shows a test example.

As suspected, choosing the same bias point of 3 mA, the noise figure using active bias is quite a bit higher than the passive one, as shown in Figure 3-196.

3-11 PUSH–PULL/PARALLEL AMPLIFIERS

Since it is practically impossible to obtain $S_{11} = S_{22} = 0$, using a combiner at the input and output reduces the problem. Figure 3-197 shows the 3-dB hybrid approach. It has a practical

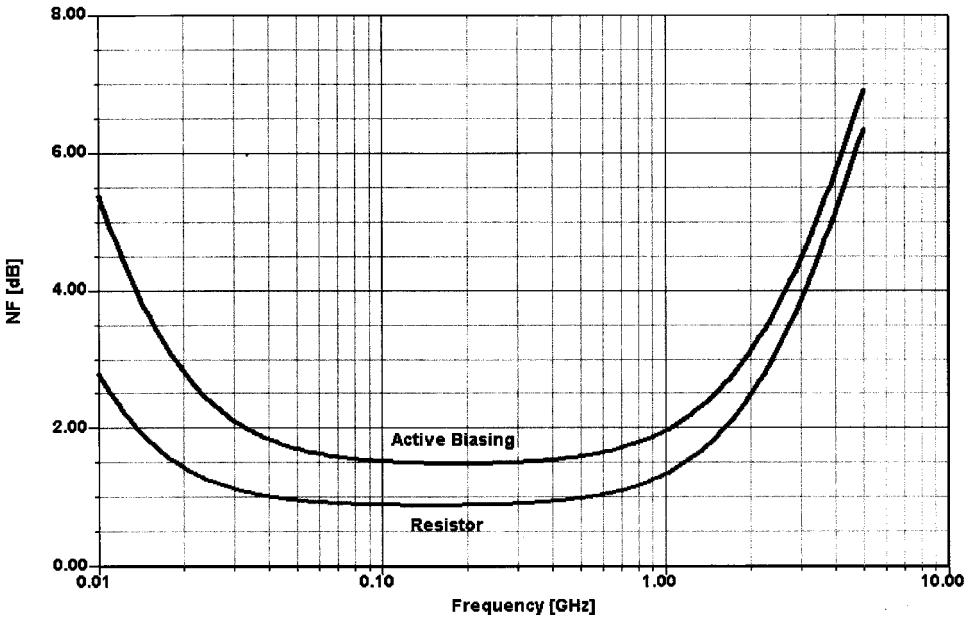

Figure 3-196 Frequency-dependent noise figure of the amplifier circuit shown in Figure 3-195. The active biasing curve is considerably noisier.

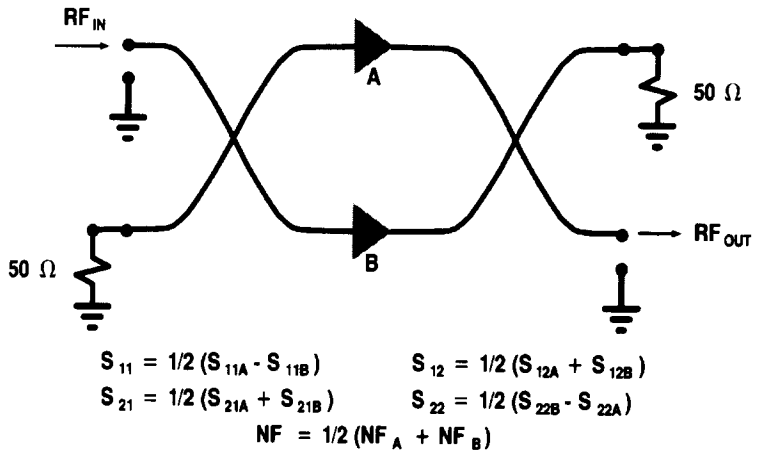

Figure 3-197 Combining power with 3-dB hybrid couplers.

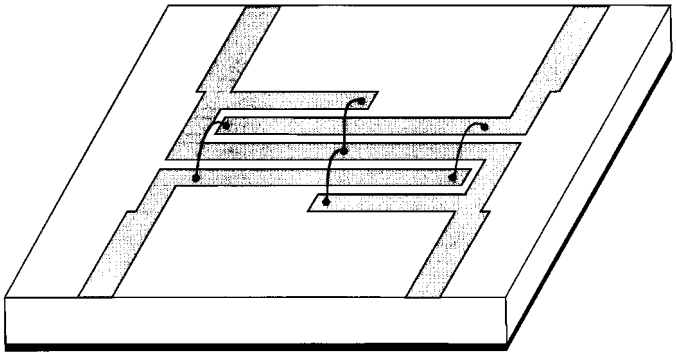

Figure 3-198 Four-strip version of the Lange coupler, a broadband 90° hybrid.

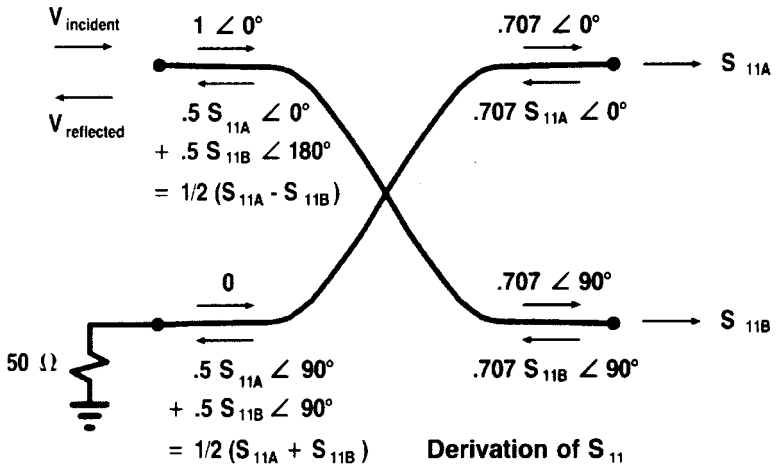

Figure 3-199 3-dB hybrids. This analysis method may be applied to any coupler.

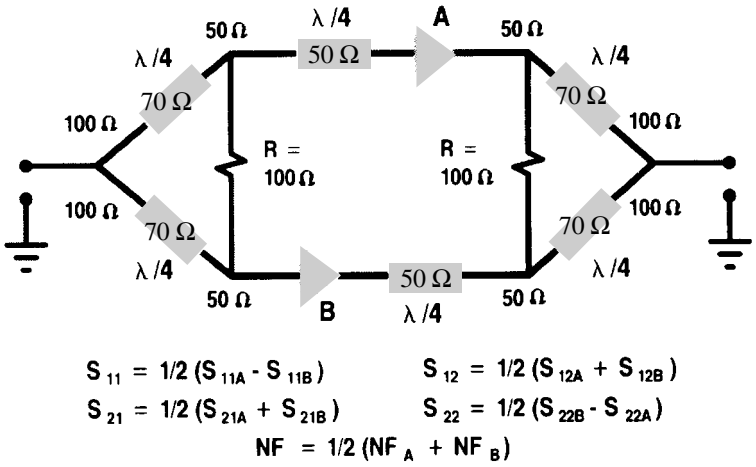

Figure 3-200 Wilkinson divider/combiners.

bandwidth limit of about 4:1; its advantage is that it is compact and ideal for cascading. If one stage opens, P_{OUT} and gain drop only 6 dB; however, it does not protect against load mismatch. A recommended distributed form is the Lange coupler (Figure 3-198). To analyze this approach, Figure 3-199 shows the resulting impedances and necessary phase shifts. If a Wilkinson coupler [30] is used instead of the 3-dB hybrid, the bandwidth is reduced. The Wilkinson coupler is larger in size than the 3-dB hybrid but more easily realized, leading to lower cost. Figure 3-200 shows the actual impedances necessary for matching, with A1 and A2 being the actual amplifiers combined.

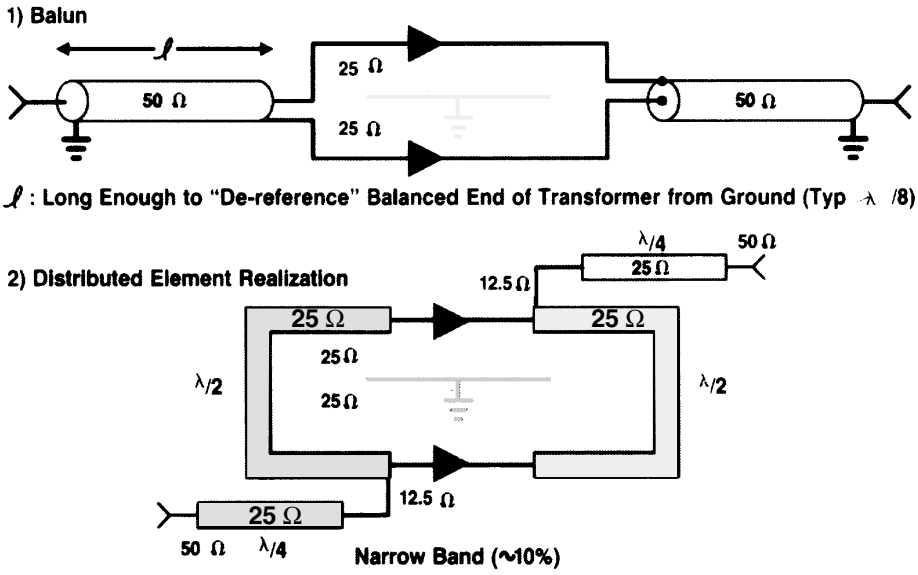

Figure 3-201 Push–pull amplifiers.

The solution for push–pull amplifiers resorts to a balun with the following results obtained: Bandwidths of greater than one decade are achievable; the balun structure gives 4:1 impedance advantage; there is no isolation; $S_{11} \neq 0$, $S_{22} \neq 0$; and cancellation of even-order products is provided.

Since most amplifiers have 50-Ω rather than 25-Ω impedances, Figure 3-201 shows a circuit that matches 25 Ω to 50 Ω on both sides. Since the standard amplifier operates at 50 Ω rather than 25 Ω, an additional network may be necessary to transform the impedance up to 50 Ω again. A similar problem occurs at the amplifier output.

3-12 POWER AMPLIFIERS

Power amplifiers are devices that are tasked to transform as much dc power into RF/microwave power as possible. Depending on the technology, devices are available that can produce at least 100 W up to 2 GHz. Since the transconductance of FETs at conducting angles of less than 180° becomes very small, the actual power gain sharply decreases compared to Class A operation while the power-added efficiency is optimized to values of 55% (Class B) or so. The dissipation of these devices is, of course, quite high, while in Class B operation this is even more of an issue. Power devices in Class C are dying to have big heat sinks to survive. One of the nice things about FETs is a much reduced thermal runaway effect compared to their bipolar brothers.

Power amplifier classes are defined in terms of the device conduction angle and/or the type of device operation:

Class A	"Linear" operation; 180° conduction angle
Class AB	"Linear" operation; conduction angle between 90° and 180°
Class B	"Linear" operation; 90° conduction angle
Class C	Fixed drive; less than 90° conduction angle
Class D	Switched operation, conduction range may vary with time from 0° to 180° or may be fixed.

There are also Classes E and F, which are currently under evaluation and showing some promising results.

Figure 3-202 shows Class C operation. The output of the amplifier is a current pulse train, which frequently leads to misunderstanding as to the calculation of its load. Given the fact that the amplifier is a current generator, it is silly to assume one has to do a conjugate matching looking backward into the amplifier. This is the condition for Class A operation. Unfortunately, this is still not understood by some engineers, but we hope we can clear this up today. The theoretical efficiency is 89.7% at a conducting angle of less than 180°; in practice, efficiencies more than 85% are not obtainable. (All of these efficiencies are those of the device itself; losses in matching networks are not taken into account in these efficiency values.) Considering optimal gain and optimal output power, the conducting angle actually settles somewhere between 100° and 140°. Again, the power gain in Class C operation is less than in Class A and Class B operation.

3-12-1 Example 1: 7-W Class C BJT Amplifier for 1.6 GHz

The following demonstrates how to design a 1.6-GHz, 7-W amplifier operating in Class C. We need to point out again that all modulation forms that contain the information in both

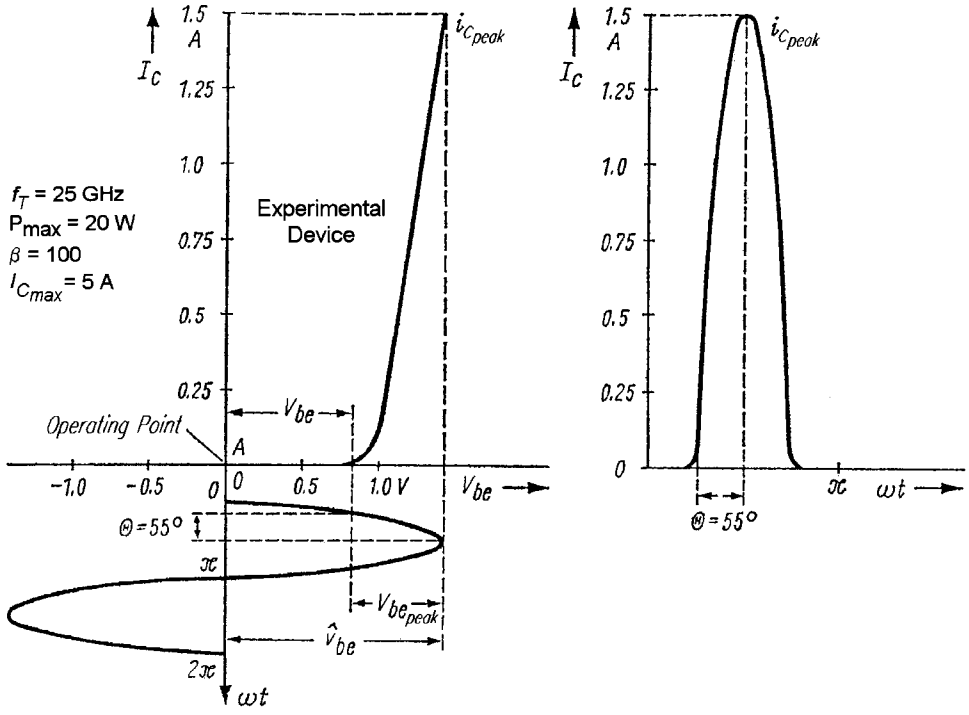

Figure 3-202 Output current as a function of drive voltage, taking into consideration the knee voltage of the base–emitter *pn* junction. The output is a series of current pulses with a duty cycle determined by the conduction angle.

amplitude and phase require more linearity than Class C affords. Needless to say, this affects the efficiency; therefore, at a later point we will also show a Class AB power amplifier. This is a tutorial, so we will present a UHF example and walk the reader through all the problems involved in the design. The selection of the transistor is done by first looking at the f_T, which in our case should be at least 4–5 GHz. The first order of business is to define the point of operation for the output amplifier. To do this, we need to determine the maximum voltage and current values supplied by the manufacturer. We have chosen a device that operates at 28 V and can sustain a peak collector current of 1.5 A. Figure 3-202 lets us determine the conducting angle Θ from the I_C/V_{BE} plane. This figure shows on the left side the I_C/V_{BE} plane and the necessary voltage to drive the amplifier.

Initially, we assume that the base–emitter junction is operated without any bias ($V_{BE} = 0$). The dc I–V curve shows that the collector current starts at about 650 mV. The amplifier itself, therefore, is already in Class C operation. For full output power, the drive voltage $V_{BE,\text{peak}}$ has to be 1.14 V. Therefore, the conducting angle can be determined by

$$\cos \Theta = \frac{V_{BE}}{\hat{\boldsymbol{v}}_{BE}} = \frac{0.65}{1.14} = 0.57$$

$$\cos 0.57 = 55^\circ$$

V_{BE} is the dc voltage at which the transistor starts conducting. From Figure 3-65 and Eqs. (3-160), (3-161), and (3-162), the fundamental current i_{c1} can be determined from

$$i_{c1} = i_{\text{peak}} \cdot f_1(\Theta)$$

or

$$i_{c1} = 1.5 \text{ A} \times 0.36 = 0.54 \text{ A}$$

The average collector dc current can be determined from

$$i_{c2} = i_{\text{peak}} \cdot f_2(\Theta)$$

or

$$i_{c2} = 1.5 \text{ A} \times 0.21 = 0.315 \text{ A}$$

The collector saturation voltage $V_{CE(\text{sat})}$, unfortunately, is around 2–3 V; for the purpose of the calculation, we assume that the saturation voltage is 3 V, and, therefore, we can assume that the maximum collector ac voltage $\hat{v}_{CE} \approx (V_B - 3) = 25$.

The appropriate collector load has to be

$$R_C = \frac{\hat{v}_{CE}}{i_{C1}} = \frac{25}{0.54} = 46.3 \ \Omega$$

The maximum output power is

$$P_{\text{out}} = \frac{(V_{CE} - V_{CE(\text{sat})})^2}{2R_C} = \frac{625}{92.6} = 6.75 \text{ W}$$

The only way to increase the power would be to have a smaller collector load at a higher current. In this family of Motorola transistors, there was no 10-W transistor; that's why we have chosen a 20-W experimental device, which for this purpose is overkill. The theoretical efficiency of the amplifier is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{6.75 \text{ W}}{0.315 \times 28} = 85\%$$

If the saturation voltage would be less, our efficiency would automatically increase, since for the given load, the actual output power would increase (6.75 W $\rightarrow$ 7.5 W). Assuming that this stage would operate at 1900 MHz with a gain of roughly 22 dB, the required drive would be significantly less than the output power, or roughly 40 mW. For the purpose of the following calculations, we will assume that the drive power is 0.7 W. The total dissipation of the device now adds up to be

$$P_T = P_{\text{in(dc)}} - P_{\text{out}} + P_{\text{drive}}$$

$$P_T = (28 \times 0.315) - 6.75 + 0.7 = 2.77$$

Power-added efficiency is derived from this. Knowing the power dissipation, one can calculate a thermal resistance R_{therm} of the heat sink and the transistor:

$$R_{\text{therm}} = \frac{T_J - T_A}{P_T}$$

Where T_J is the device junction temperature and T_A is the ambient temperature. For a maximum ambient temperature of 60 °C and a maximum junction temperature of 150 °C, the thermal resistance is

$$R_{\text{therm}} = \frac{120 - 60}{2.77} = 21.7\ ^\circ\text{C/W}$$

R_{therm} is the sum of thermal resistance of the transistor and its package, and the thermal resistance between the transistor package and the heat sink, and the thermal resistance between the heat sink and the ambient air. Therefore,

$$R_{\text{therm}} = R_{\text{th(case)}} + R_{\text{th(case/heat sink)}} + R_{\text{th(heat sink)}}$$

The required thermal resistance of the heat sink is calculated from

$$R_{\text{th(heat sink)}} = 21.7 - 10 - 1.4 = 15.6\ ^\circ\text{C/W}$$

Assuming an aluminum heat sink (a 2-mm-thick plate), the required heat-sink surface area A (cm^2) is

$$A = \frac{1}{\alpha R_{\text{th(heat sink)}}}; \quad \alpha \approx 1.5\ \frac{\text{mW}}{^\circ\text{Ccm}^2}$$

Therefore, the required area is

$$A = \frac{1}{1.5 \times 0.0156} = 42.7\ \text{cm}^2$$

The next task is to match both the input and output to the (most likely) 50-Ω source and termination. The following section will guide us through the procedure. The input impedance Z_{11} (after some lengthy search) was found to be $1 + j10\ \Omega$. This means that the input consists of the base-spreading resistance (approximately 1 Ω) and an input capacitance, which because of phase shift now turns out to be inductive. Since the popular method for input matching these days is a pi configuration, we are going to use a simple pi filter both for input and output matching. There are several equations in the literature that give the values for the two capacitors and inductors; most of them result in an incorrect resonance frequency. Since we have access to software tools, we decided to take three approximate values and use the optimizer to give us the appropriate matching. The only remaining variable in such an approach is the bandwidth. If we specify $S_{21} = 1$ and $S_{11} = 0$ (100% energy transfer and perfect return loss), we will realize that this is possible at only one frequency. We therefore need to identify a frequency band or bandwidth over which an acceptable match is needed. As the bandwidth increases, the match for such a simple circuit will get poorer; there are not enough elements available to do better. In this case, we took the center frequency ±100 MHz.

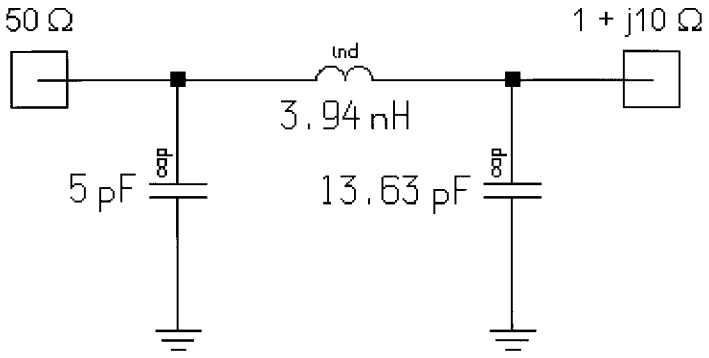

Figure 3-203 Input matching network for the amplifier used in this tutorial.

Figures 3-203 and 3-204 show the actual circuit with the element values and the resulting input match. Likewise, we did the same thing at the output, but the actual resulting dynamic output capacitance is not known *a priori*. For low frequencies, the integral equation gives a value of $2C_{CE}$; however, practical tests in frequencies above 500 MHz show that the actual increase is only 1.3 times the dc output capacitance. Therefore, we decided to design the filter with no output capacitance assumed, and the input capacitance of about 5 pF must be reduced for proper reactive matching. Mathematically, this could result in a negative number, specifically if the resulting output capacitance exceeds the 5-pF value. To compensate for this, one needs to use an RF choke that tunes out the resulting dynamic output capacitance and then one can revert to the original 5 pF as calculated.

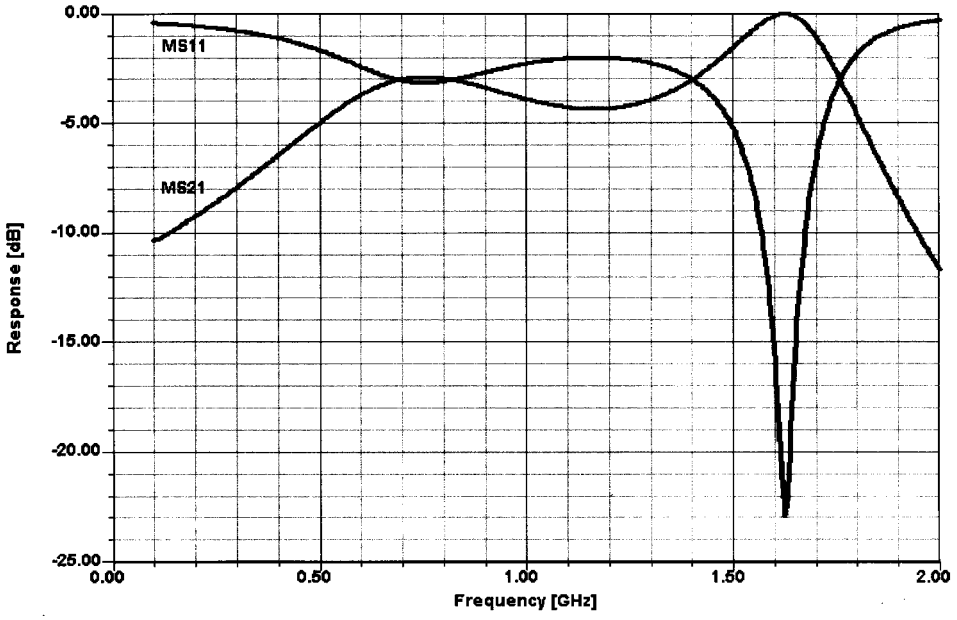

Figure 3-204 Frequency response of the input matching network.

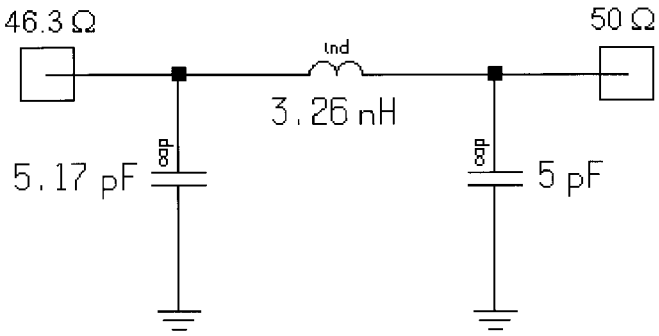

Figure 3-205 Output matching network for the amplifier.

The selection of the actual component is another issue, because these capacitors need to handle several amperes of RF current. It is not always easy to find capacitors with the appropriate value that can handle the current. The inductors can be printed. The paragraph following this section therefore will deal with the issue of how to translate the lumped values into distributed values, which will make the current handling much easier (we hope).

For this, we did the same optimizing approach by using a 50-Ω source and a 46.3-Ω load. Figures 3-205 and 3-206 show the circuit with the appropriate values and its simulated frequency-dependent responses.

The next step is to connect the input and output matching network to an "actual" transistor. This is a point where difficulties arise, since very few, if any, companies provide SPICE-type

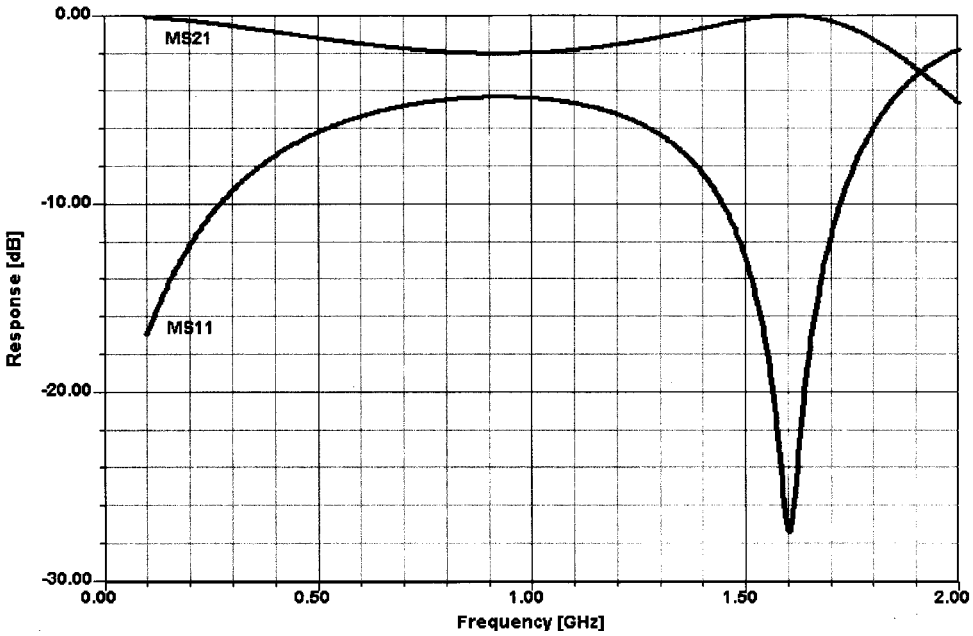

Figure 3-206 Frequency response of the output matching network.

parameters for transistors operating at currents of more than 200 mA. Figures 3-207 and 3-208 show the overall schematic and frequency response of the actual amplifier with all filters connected. Figure 3-209 details the amplifier's peak gain response. If more bandwidth is needed, the matching circuit must be increased in complexity, as will be shown in the following section.

Now is a good time to look at the final results of our simulation, which is based on the various assumptions as outlined above. Figure 3-210 shows the dc *I–V* curves with a straight load line and no reactances. This was accomplished by using a wideband transformer instead of an output matching circuit. Figure 3-211, however, shows the "load line" that results when the transformer is replaced with a real matching network. Based on the harmonics content and its improper termination, one can see how the output load line opens and shows ringing in the low-current area. If we expect to see the saturation voltage, we will be disappointed because the saturation voltage is frequency dependent (increases with frequency) and this figure gives an erroneous impression. Hence, we show dc *I–V* curves. To display the conduction angle, which we showed previously, we examine the output current as a function of time at a drive level of +16.5 dBm (Figure 3-212). During the negative half, the transistor is not conducting as predicted, so this validates our assumptions. Next, we are interested in determining the power gain. Therefore, we look at the output spectrum for a drive level of +16.5 dBm (Figure 3-213). It shows an output level of 38.6 dBm. If we subtract the drive level (16.5 dBm) from this, we see that the power gain is 22.1 dB at this drive level. Since we are used to thinking in watts, Figure 3-214 shows the absolute output power and the harmonics prior to filtering. Figure 3-215 shows the output spectrum after replacing the transformer with a simple pi output network.

During the conduction period, there will be a voltage across the transistor 180° out of phase, as shown in Figure 3-216. Finally, to highlight the nonlinearity of a Class C amplifier, Figure 3-217 shows the amplifier's output power versus drive, and Figure 3-218 shows the amplifier's gain versus drive. When the transistor turns on is clearly evident.

A particular difficulty arises in the case of FETs, where the charge energy makes for a difference between dc and pulsed measurements. Figure 3-219 shows this. Some of the more modern transistors, such as SiGe types, may need some pulsing also; as can be seen in Figure 3-219, even depending on the pulsing, one may get different dc *I–V* curves. This area is still under investigation, and even the "experts" do not agree on all aspects of this. In real life, it turns out that a lot of experimentation is the answer. Anyone who thinks that a pure CAD approach will give the right design answers immediately will encounter many surprises! This is not a fault of the CAD tools—assuming that they are properly engineered—but rather the availability of appropriately "tweaked" models for high-power applications, and the willingness of device suppliers to standardize on certain models and support them.

Because of the difficulties involved in cooling transistors under test and simulating RF pulse and CW conditions, depending on the application, manufacturers have so far stayed away from investing money in this area. The designer must therefore resort to application notes published by device manufacturers. Because even slight layer changes can have a large impact on the frequency response of a given device, application-note-based designs can run into difficulty if a device's fabrication has significantly evolved since the publication of its application notes.

Given the multitude of models outlined in Chapter 2, the CAD user is sometimes left hanging as to which is the best model to use. The latest indications are that the MEXTRAM (*m*ost *e*xquisite *t*ransistor *m*odel), developed by the University of Delft, Holland, with Philips of Holland, shows the most promising result, specifically in the area of IMD products. While

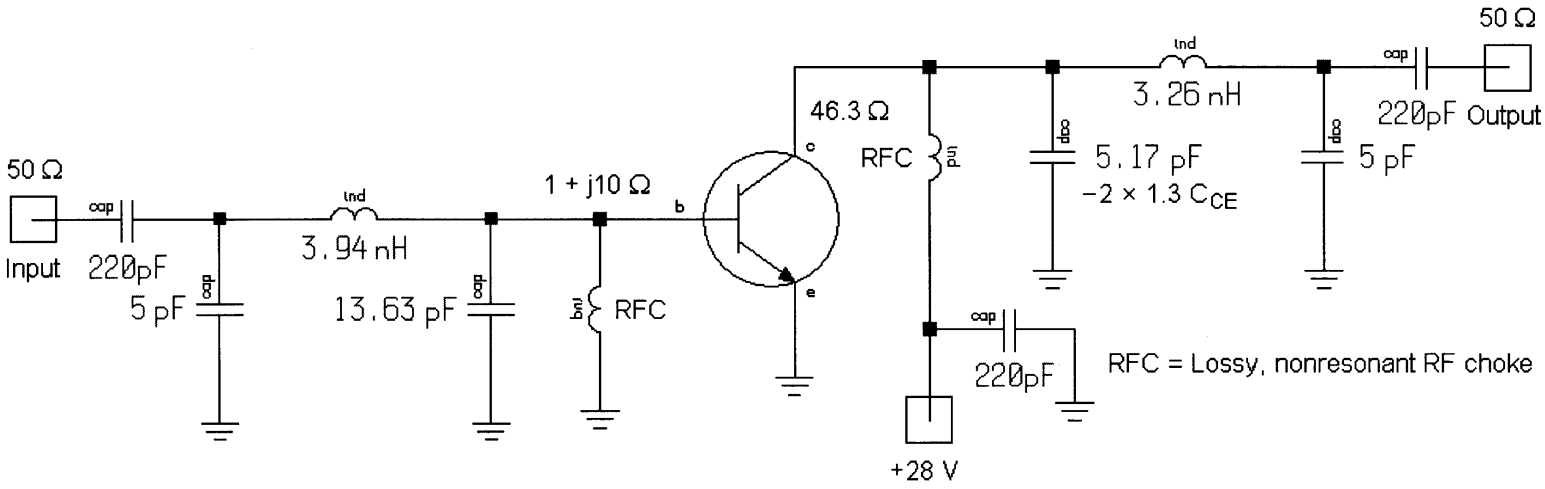

Figure 3-207 Actual schematic of our experimental 1.6-GHz amplifier. The RF chokes have enough RF losses not to be resonant and yet don't load the circuit. This is frequently accomplished with either ferrite beads or resistors in parallel with the chokes.

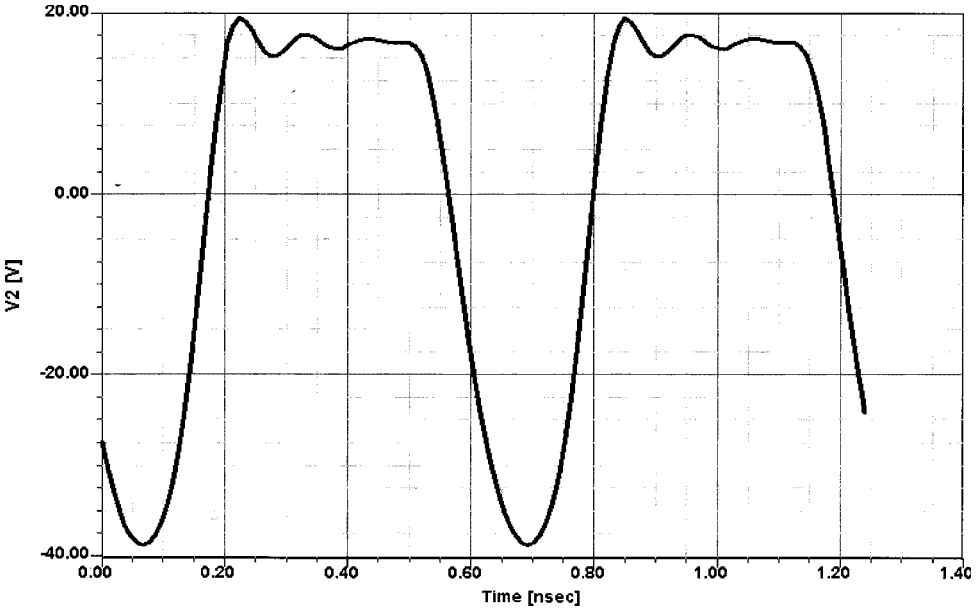

Figure 3-216 Output voltage at the collector. The voltage is asymmetrical compared to 0; this is important in the selection of a device capable of handling these voltages.

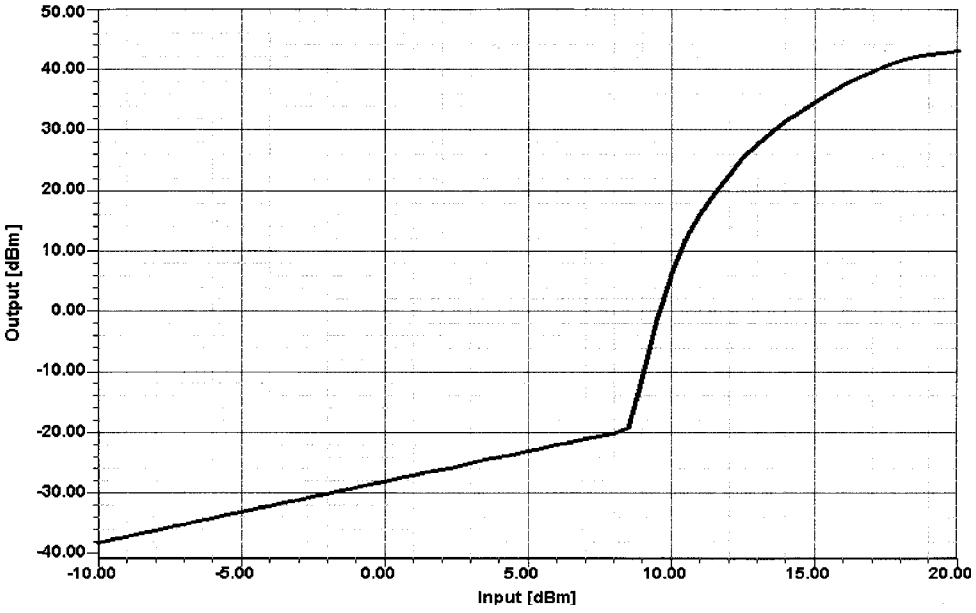

Figure 3-217 Output power versus input power for the Class C amplifier. Until the transistor turns on (at a drive level of about 8.5 dBm), only fedthrough power appears at the output.

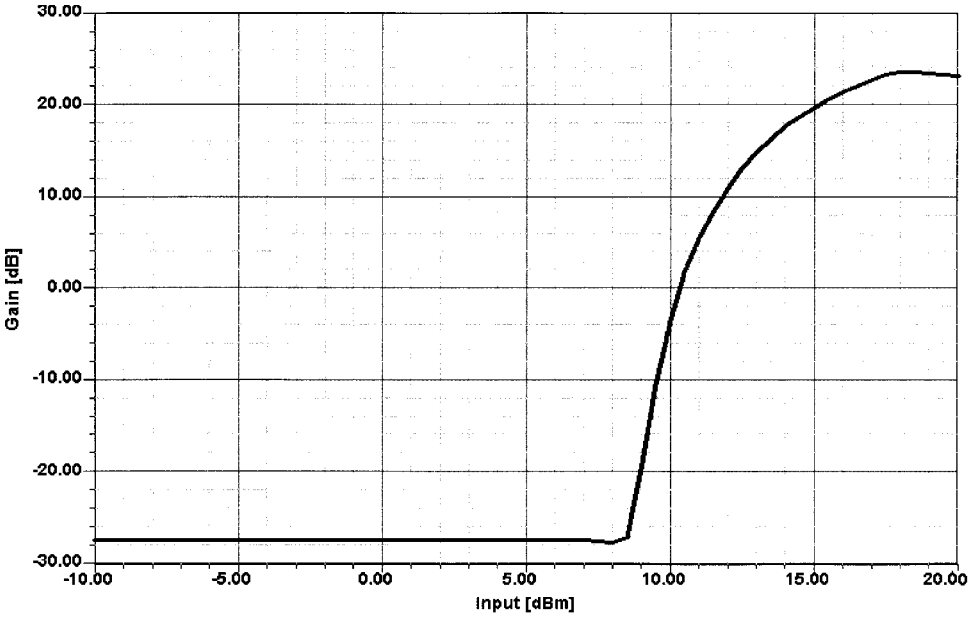

Figure 3-218 Amplifier gain as a function of drive. It is evident that one needs to cross the 0.65-V point for the transistor to become conductive and show gain. The initial amplification as a function of drive shows a very steep curve that then levels off and drops as the amplifier moves into saturation.

other later models have up to seven internal nodes, MEXTRAM fortunately uses only five. (The MEXTRAM model actually consists of three transistors, which makes modeling fun.) Power-added efficiency simulation is not available, since the MEXTRAM model was developed for small-signal applications, meaning circuits that operate at less than 100 mW of RF output power.

As if the absence of trustworthy high-power device models is not challenge enough, in developing this 1.6-GHz Class C amplifier example, we ran into another complication: Using a CAD optimizer to simultaneously match the circuit's input and output networks failed because of the device's input-impedance variation with drive. Every matching adjustment that improved the drive to the device resulted in an input-impedance change that reduced the drive to the device! In the end, the optimizer couldn't keep up. In actually building such a circuit, one would make the matching-network values adjustable on the initial breadboard and then, with the necessary input drive level applied, iteratively adjust the input and output matching for the desired output level. It appears that the CAD program could not handle such a degree of nonlinearity.

We then went to the approach of using large-signal *S* parameters at a drive level slightly less than 16 dBm, but this detuned the input filter, resulting in a poorer input match than the one initially predicted. Likewise, the output matching, which in a power stage must result in maximum output power rather than a conjugate match, was less impressive. The large-signal *S* parameters at the output for a power amplifier are somewhat dubious because Class C operation generates so many harmonics that the output termination will reflect a lot of energy and, depending on the output filter topology, different results can be expected. We firmly believe that there will be further mathematical improvement in the CAD tools, and we very much invite

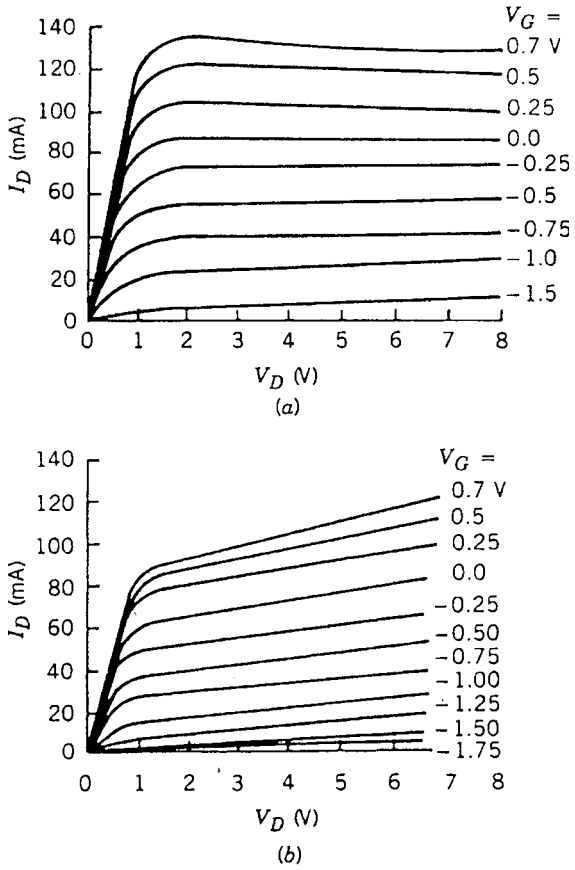

Figure 3-219 Comparison of FET drain current characteristics obtained from (a) pulsed *I–V* and (b) rectified sine-wave evaluation. The rectified sine-wave curves can be considered equivalent to curves obtained at dc.

our readers to use such a nonlinear example to test their tools, provided that a high-power model becomes available in this power range.

It has been rumored that the load-pull technique, rather than the application of large-signal *S* parameters, is a vehicle to solve such matching problems. However, the load-pull technique is really applied only to the fundamental frequency and does not deal with the issue of harmonics of the output current. More details about the load-pull technique and its capabilities are found in Appendix B.

Actual measurements of amplifiers of this type show that our simulated efficiency and drive level come quite close to reality, but at a frequency somewhat offset from that chosen for the design. As an example, the input and output filters tuned at 1.4 GHz instead of 1.6 GHz using the large-signal *S* parameters. Again, an iterative process, similar to manually trimming a prototype, will give a similar result. This is consistent with our earlier statement that most final designs are really hand-tweaked, and that CAD can only bring us close, but not all the way, to a good solution. For passive problems, the CAD does a significantly better job; the nonlinear cases are the ones that still cause headaches.

3-12-2 Impedance Matching Networks Applied to RF Power Transistors*

Introduction. Some graphical and numerical methods of impedance matching will be reviewed here. The examples given refer to high-frequency power amplifiers.

Although matching networks normally take the form of filters and therefore are also useful to provide frequency discrimination, this aspect will be considered only as a corollary of the matching circuit.

Matching is necessary for the best possible energy transfer from stage to stage. In RF power transistors, the input impedance is of low value, decreasing as the power increases or as the chip size becomes larger. This impedance must be matched either to a generator—of generally 50-Ω internal impedance—or to a preceding stage. Impedance matching has to be made between two complex impedances, which makes the design still more difficult, especially if matching must be accomplished over a wide frequency band.

Device Parameters

Input Impedance. The general shape of the input impedance of RF power transistors is as shown in Figure 3-220. It is a large-signal parameter, expressed here by the parallel combination of a resistance R_p and a reactance X_p [31].

The equivalent circuit shown in Figure 3-221 accounts for the behavior illustrated in Figure 3-220. With the presently used stripline or flange packaging, most of the power devices for VHF low band will have their R_p and X_p values below the series resonant point f_s. The input impedance will be essentially capacitive.

Most of the VHF high-band transistors will have the series-resonant frequency within their operating range; that is, they will be purely resistive at one single frequency f_s, which the parallel-resonant frequency f_p will be outside.

Parameters for 1- or 2-GHz transistors will be beyond f_s and approach f_p. They show a high value of R_p and X_p with inductive character.

A parameter that is very often used to judge on the broadband capabilities of a device is the input Q or Q_{IN}, defined simply as the ratio R_p/X_p. Practically, Q_{IN} ranges around 1 or less for VHF devices and around 5 or more for microwave transistors.

Q_{IN} is an important parameter to consider for broadband matching. Matching networks normally are low-pass or pseudo-low-pass filters. If Q_{IN} is high, it can be necessary to use bandpass filter-type matching networks and to allow insertion losses. But broadband matching is still possible. This will be discussed later.

Output Impedance. The output impedance of RF power transistors, as given by all manufacturers' datasheets, generally consists of only a capacitance C_{OUT}. The internal resistance of the transistor is supposed to be much higher than the load and is normally neglected. In the case of a relatively low internal resistance, the efficiency of the device would decrease by the factor

$$1 + R_L/R_T \tag{3-192}$$

*Based on Motorola application note AN-721 ("Impedance Matching Networks Applied to RF Power Transistors"). Copyright of Motorola; used by permission.

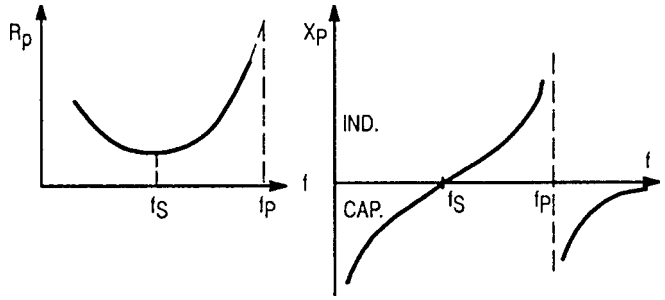

Figure 3-220 Input impedance of RF power transistors as a function of frequency.

where R_L is the load resistance, seen at the collector–emitter terminals, and R_T is the internal transistor resistance equal to

$$\frac{1}{\omega_T (C_{TC} + C_{DC})} \tag{3-193}$$

defined as a single parameter, where ω_T is the transit angular frequency and C_{TC} and C_{DC} are the transition and diffusion capacitances, respectively, at the collector junction.

The output capacitance, C_{OUT}, which is a large-signal parameter, is related to the small-signal parameter C_{CB}, the collector–base transition capacitance.

Since a junction capacitance varies with the applied voltage, C_{OUT} differs from C_{CB} in that it has to be averaged over the total voltage swing. For an abrupt junction and assuming certain simplifications, $C_{\text{OUT}} = 2C_{CB}$.

Figure 3-222 shows the variation of C_{OUT} with frequency. C_{OUT} decreases partly due to the presence of the collector lead inductance, but mainly because of the fact that the base–emitter diode does not shut off anymore when the operating frequency approaches the transit frequency, f_T.

Output Load. In the absence of a more precise indication, the output load R_L is taken as

$$R_L = \frac{[V_{CC} - V_{CE(\text{sat})}]^2}{2P_{\text{OUT}}} \tag{3-194}$$

with $V_{CE(\text{sat})}$ equal to 2 or 3 V, increasing with frequency.

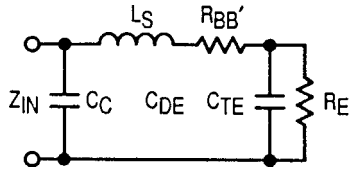

Figure 3-221 Equivalent circuit for the input impedance. R_E is the emitter diffusion resistance; C_{DE} and C_{TE} are the diffusion and transition capacitances, respectively, of the emitter junction; $R_{BB'}$ is the base-spreading resistance; C_C is the package capacitance; and L_S is the base lead inductance.

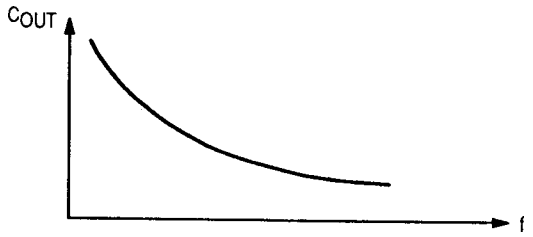

Figure 3-222 Output capacitance C_{OUT} as a function of frequency.

The above equation just expresses a well-known relation, but it also shows that the load, in first approximation, is not related to the device, except for $V_{CE(sat)}$. The load value is primarily dictated by the required output power and the peak voltage; it is not matched to the output impedance of the device.

At high frequencies this approximation becomes less exact, and for microwave devices the load that must be presented to the device is indicated on the datasheet.

Strictly speaking, impedance matching is accomplished only at the input. Interstage and load matching are more impedance transformations of the device input impedance and of the load into a value R_L (sometimes with additional reactive component) that depends essentially on the power demanded and the supply voltage.

Matching Networks. In the following, matching networks will be described by the order of complexity. These are ladder-type reactance networks. The different reactance values will be calculated and determined graphically. Increasing the number of reactances broadens the bandwidth. However, matching networks consisting of more than four reactances are rare. Above four reactances, the improvement is small.

Numerical Design

TWO-RESISTANCE NETWORKS. Resistance terminations will first be considered. Figure 3-223 shows the reactive L section and the terminations to be matched.

Matching or exact transformation from R_2 into R_1 occurs at a single frequency f_0. At f_0, X_1 and X_2 are equal to

$$X_1 = \pm R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = R_1 \frac{1}{\sqrt{n-1}} \tag{3-195}$$

$$X_2 = \mp \sqrt{R_2(R_1 - R_{2)}} = R_1 \frac{\sqrt{n-1}}{1} \tag{3-196}$$

At f_0, $X_1X_2 = R_1R_2$. X_1 and X_2 must be of opposite sign. The shunt reactance is in parallel with the larger resistance.

The frequency response of the L section is shown in Figure 3-224, where the normalized current is plotted as a function of the normalized frequency.

If X_1 is capacitive and consequently X_2 is inductive, then

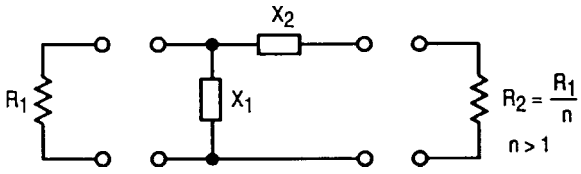

Figure 3-223 Two-reactance matching network.

$$X_1 = -\frac{f_0}{f} R_1 \sqrt{\frac{R_2}{R_1 - R_2}} = -\frac{f_0}{f} R_1 \frac{1}{\sqrt{n-1}} \tag{3-197}$$

and

$$X_2 = \frac{f}{f_0} \sqrt{R_2(R_1 - R_2)} = \frac{f}{f_0} R_1 \frac{\sqrt{n-1}}{1} \tag{3-198}$$

The normalized current absolute value is equal to

$$\left|\frac{I_2}{I_0}\right| = \frac{2\sqrt{n}}{\sqrt{(n-1)^2 \cdot (f/f_0)^4 - 2\,(f/f_0)^2 + (n+1)^2}} \tag{3-199}$$

where $I_0 = \sqrt{n}E/2R_1$ and is plotted in Figure 3-224 [32].

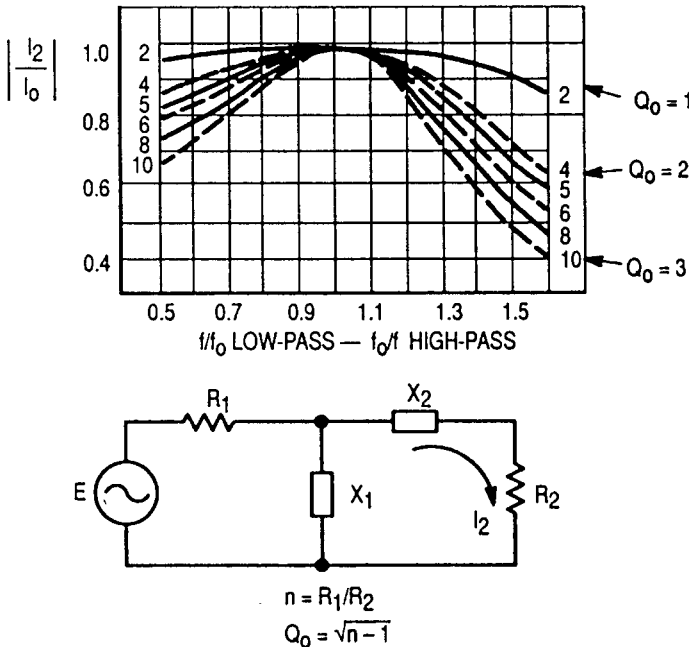

Figure 3-224 Normalized frequency response for the L section in low-pass or high-pass form.

If X_1 is inductive and consequently X_2 is capacitive, the only change required is a replacement of f by f_0 and vice versa. The L section has low-pass form in the first case and high-pass form in the second case.

The Q of the circuit at f_0 is equal to

$$Q_0 = \frac{X_2}{R_2} = \frac{R_1}{X_1} = \sqrt{n-1} \tag{3-200}$$

For a given transformation ratio n, there is only one possible value of Q. On the other hand, there are two symmetrical solutions for the network that can be either a low-pass filter or a high-pass filter.

The frequency f_0 does not need to be the center frequency, $(f_1 + f_2) / 2$, of the desired band limited by f_1 and f_2. In fact, as can be seen from the low-pass configuration of Figure 3-224, it may be interesting to shift f_0 toward the high-band edge frequency f_2 to obtain a larger bandwidth w, where

$$w = \frac{2(f_1 + f_2)}{f_2 - f_1} \tag{3-201}$$

This will, however, be at the expense of poor harmonic rejection.

Example. For a transformation ratio of $n = 4$, we can determine the following values from the above relations:

Bandwidth w	0.1	0.3
Maximum insertion losses	0.025	0.2
X_1/R_1	1.730	1.712

If the terminations R_1 and R_2 have a reactive component X, the latter may be taken as part of the external resistance as shown in Figure 3-225. This compensation is applicable as long as

$$Q_{int} = \frac{X_{\text{int}}}{R_2} \quad \text{or} \quad \frac{R_1}{X_{\text{int}}} < n - 1 \tag{3-202}$$

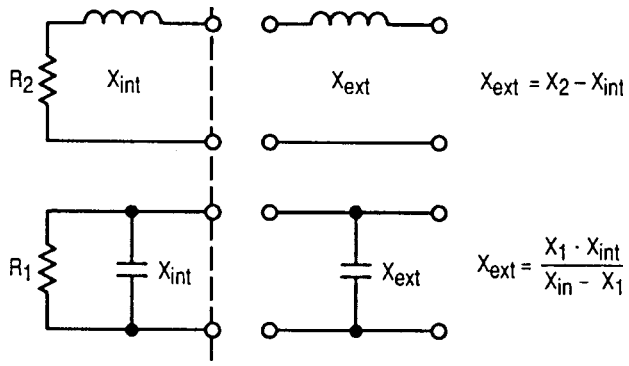

Figure 3-225 Termination reactance compensation.

Tables giving reactance values can be found in Matthaei et al. [33, 34].

USE OF TRANSMISSION LINES AND INDUCTORS. In the preceding section, the inductance was expected to be realized by a lumped element. A transmission line can be used instead (Figure 3-226).

As can be seen from the computed selectivity curves (Figure 3-227) for the two configurations, transmission lines result in a larger bandwidth. The gain is important for a transmission line having a length $L = \lambda/4$ ($\Theta = 90°$) and a characteristic impedance $Z_0 = \sqrt{R_1 R_2}$. It is not significant for lines short with respect to $\lambda/4$. One will notice that there is an infinity of solutions, one for each value of C, when using transmission lines.

THREE-REACTANCE MATCHING NETWORKS. The networks that will be investigated are shown in Figure 3-228. They are made of three reactances alternately connected in series and shunt.

A three-reactance configuration allows the designer to make the quality factor (Q) of the circuit and the transformation ratio $n = R_2/R_1$ independent of each other and consequently to choose the selectivity between certain limits.

For narrowband designs, one can use the following formulas (see [35], where tables are given):

Network (a)

$$X_{C1} = R_1/Q \quad Q \text{ must be selected first} \tag{3-203}$$

$$X_{C2} = R_2 \sqrt{\frac{R_1 R_2}{(Q^2 + 1) - R_1/R_2}} \tag{3-204}$$

$$X_L = \frac{QR_1 + (R_1 R_2/X_{C2})}{Q^2 + 1} \tag{3-205}$$

Network (b)

$$X_{L1} = R_1 Q \quad Q \text{ must be selected first} \tag{3-206}$$

$$X_{L2} = R_2 B \tag{3-207}$$

$$A = R_1(1 + Q^2) \tag{3-208}$$

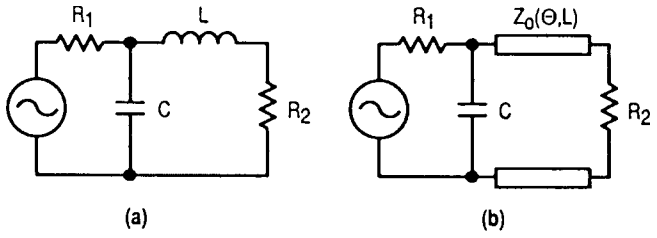

Figure 3-226 Use of a transmission line in the L section.

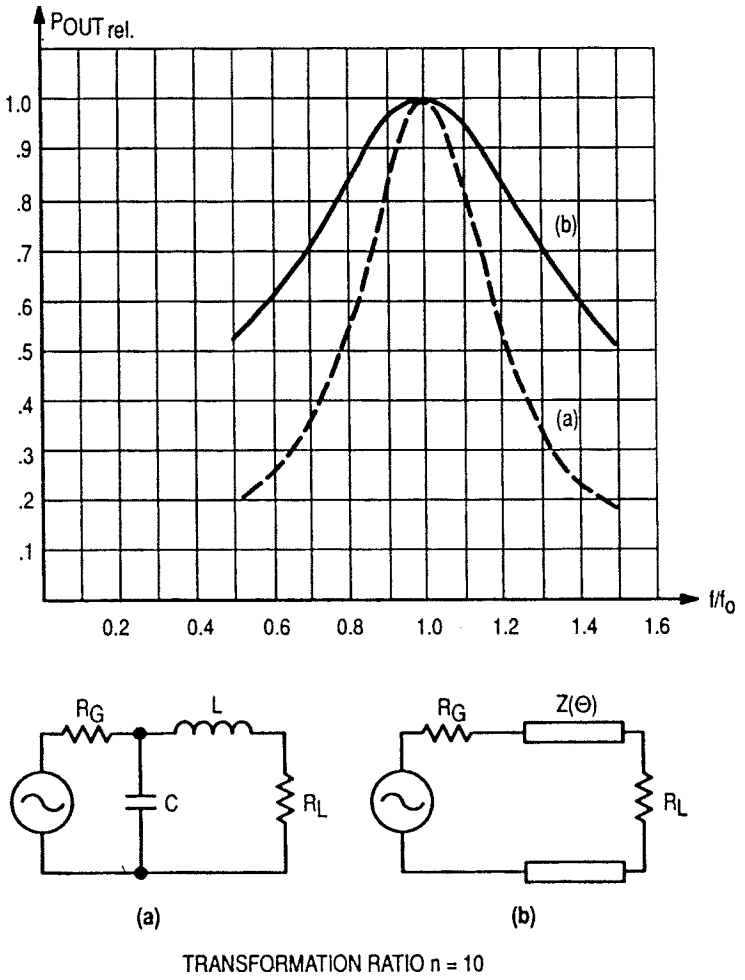

Figure 3-227 Bandwidth of the L section for $n = 10$ (a) with lumped constants and (b) with transmission line (λ/4).

$$X_{C1} = \frac{A}{Q + B} \tag{3-209}$$

$$B = \sqrt{\frac{A}{R_2} - 1} \tag{3-210}$$

Network (c)

$$X_{L1} = QR_1 \quad Q \text{ must be selected first} \tag{3-211}$$

$$X_{C2} = AR_2 \tag{3-212}$$

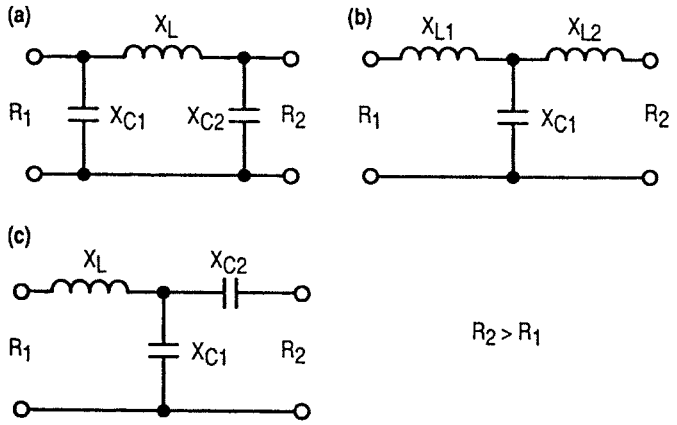

Figure 3-228 Three-reactance matching networks.

$$A = \sqrt{\frac{R_1(1+Q^2)}{R_2} - 1} \tag{3-213}$$

$$X_{C1} = \frac{B}{Q - A} \tag{3-214}$$

$$B = R_1(1+Q^2) \tag{3-215}$$

The network that yields the most-practical component values should be selected for a given application.

The three-reactance networks can be thought of as being formed of an L section (two reactances) and of a compensation reactance. The L section essentially performs the impedance transformation, while the additional reactance compensates for the reactive part of the transformed impedance over a certain frequency band.

Figure 3-229 shows a representation in the Z plane of the circuit of Figure 3-228a split into two parts: $R_1 - C_1 - L_1$ and $C_2 - R_2$. Exact transformation from R_1 into R_2 occurs at the points of intersection M and N. Impedances are then conjugate, or $Z' = R' + jX'$ and $Z'' = R'' + jX''$ with $R' = R''$ and $X' = -X''$.

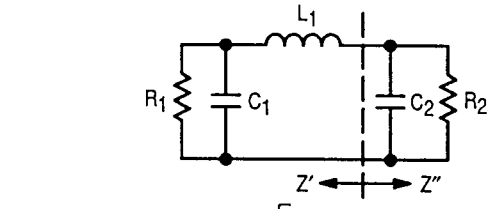
The only possible solution is obtained when X' and $-X''$ are tangential to each other. For the dashed curve, representing another value of L_1 or C_1, a wider frequency band could be expected at the expense of some ripple inside the band. However, this can only be reached with four reactances, as will be shown below.

With a three-reactance configuration, there are not enough degrees of freedom to permit $X' = -X''$ and simultaneously obtain the same variation of frequency on both curves from point M' to point N'. Exact transformation can, therefore, be obtained at only one frequency.

The values of the three reactances can be calculated by making

$$X' = -X'', \quad R' = R'', \quad \text{and} \frac{dX'}{dR'} = -\frac{dX''}{dR''} \tag{3-216}$$

The general solution of these equations leads to complicated calculations. Therefore, computed tables should be used.



$$Z' = \frac{R_1}{1 + \omega^2 R_1^2 C_1^2} + j\omega \left[L1 - \frac{R_1^2 C_1}{1 + \omega^2 R_1^2 C_1^2} \right] = R' + jX'$$

$$Z'' = \frac{R_2}{1 + \omega^2 C_2^2 R_2^2} - \frac{j\omega^2 C_2 R_2^2}{1 + \omega^2 C_2^2 R_2^2} = R'' + jX''$$

$$|x'| = \left(\frac{L_1}{C_1 R_1^2} - \frac{R'}{R_1} \right) \sqrt{\frac{R_1}{R'} - 1}$$

$$|x''| = \sqrt{R' R_2 - R'^2}$$

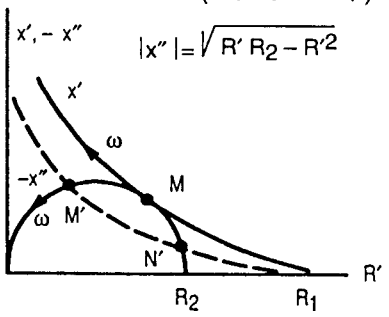


Figure 3-229 *Z*-plane representation of the circuit of Figure 3-228a.

One will note from Figure 3-229 that the compensation reactance contributes somewhat to the impedance transformation; that is, R' varies when going from M to R_2.

The circuit of Figure 3-228b is dual with respect to the first one and gives exactly the same results in a *Y*-plane representation. The circuit of Figure 3-228c is somewhat different since only one intersection M exists, as shown in Figure 3-230. Narrower frequency bands must be expected from this configuration. The widest band is obtained for $C_1 = \infty$.

Again, if one of the terminations has a reactive component, the latter can be taken as a part of the matching network, provided that it is not too large (see Figure 3-227).

FOUR-REACTANCE NETWORKS. Four-reactance networks are used essentially for broadband matching. The networks that will be considered in the following consist of two two-reactance sections in cascade. Some networks have pseudo-low-pass filter character; others, bandpass filter character. In principle, the former show narrower bandwidth since they extend the impedance transformation to very low frequencies unnecessarily, while the latter ensure good matching over a wide frequency band around the center frequency only (see Figure 3-233).

The two-reactance sections used in the networks in Figure 3-231 have either transformation properties or compensation properties. Impedance transformation is obtained with one series reactance and one shunt reactance. Compensation is made with both reactances in series or in shunt. If two cascaded transformation networks are used, transformation is accomplished partly by each one.

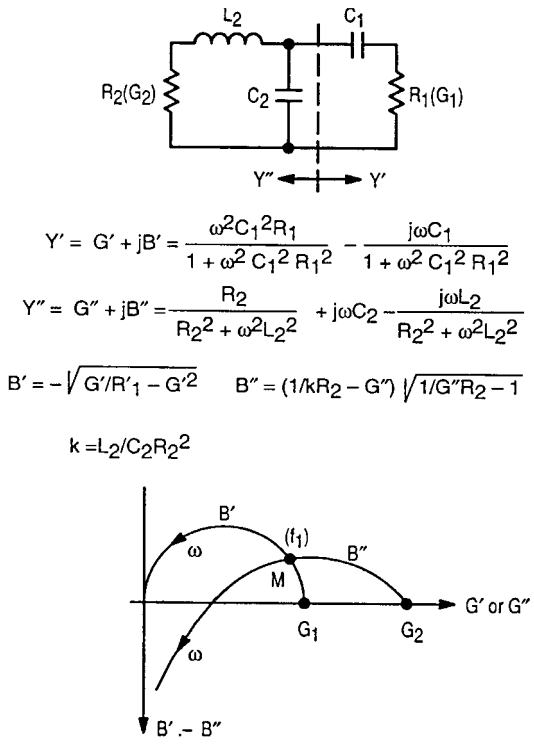

Figure 3-230 *Y*-plane representation of the circuit of Figure 3-228c.

With four-reactance networks there are two frequencies, f_1 and f_2, at which the transformation from R_1 into R_2 is exact. These frequencies may also coincide. For the network in Figure 3-231b, for instance, at point M, R_1 or R_2 is transformed into $\sqrt{R_1R_2}$ when both frequencies fall together. At all points (M), Z_1 and Z_2 are conjugate if the transformation is exact.

In the case of Figure 3-231b, the reactances are easily calculated for equal frequencies:

$$X_1 = \frac{R_1}{\sqrt{(n-1)^{1/2}}} \tag{3-217}$$

$$X_2 = R_1\sqrt{\frac{n^{1/2}-1}{n}} \tag{3-218}$$

$$X_1X_4 = R_1R_2 = X_2X_3 \tag{3-219}$$

$$X_3 = \frac{R_1}{\sqrt{n(n^{1/2}-1)}} \tag{3-220}$$

$$X_4 = \frac{R_1}{n}\sqrt{n^{1/2}-1} \tag{3-221}$$

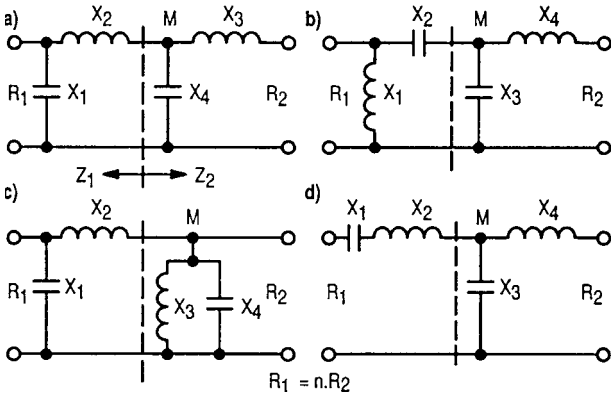

Figure 3-231 Four-reactance networks.

For the network in Figure 3-231a, normally at point M, Z_1 and Z_2 are complex. This pseudo-low-pass filter has been computed elsewhere [33]. Many tables can be found in the literature for networks of four and more reactances having Chebyshev character or maximally flat response [33, 34, 36].

Figure 3-232 shows the transformation path from R_1 to R_2 for networks (a) and (b) in Figure 3-231 on a Smith Chart.

Case (a) of Figure 3-232 has been calculated using tables in Matthaei [34]. Case (b) has been obtained from the relationship given above for $X_1, \ldots, X_4$. Both apply for a transformation ratio equal to 10 and for $R_1 = 1$. There is no simple relationship for $X_1', \ldots, X_4'$ of network (b) if f_1 is made different from f_2 for larger bandwidth. Figure 3-233 shows the respective bandwidths of networks (a) and (b) for the circuits shown in Figure 3-232.

If the terminations include a reactive component, the computed values for X_1 or X_4 may be adjusted to compensate for this.

For configuration (a), it can be seen from Figure 3-232 that, in the considered case, the Q values are equal to 1.6. For configuration (b), Q_1', which is equal to Q_2', is fixed for each transformation ratio

n	2	4	8	10	16
$Q'_1 = Q'_2$	0.65	1	1.35	1.46	1.73

$$Q' = \sqrt{n^{1/2} - 1} \qquad (3\text{-}222)$$

The maximum value of reactance that the terminations may have for use in this configuration can be determined from the above values of Q'.

If R_1 is the load resistance of a transistor, the internal transistor resistance may not be equal to R_1. In this case, the selectivity curve will be different from the curves given in Figure 3-233. Figure 3-234 shows the selectivity for networks (a) and (b) when the source resistance R_1 is infinite. From Figure 3-234 it can be seen that network (a) is more sensitive to changes in R_1 than network (b).

As mentioned earlier, the four-reactance network can also be thought of as two cascaded two-reactance sections: one used for transformation, the other for compensation. Figure 3-235 shows commonly used compensation networks, together with the associated L section.

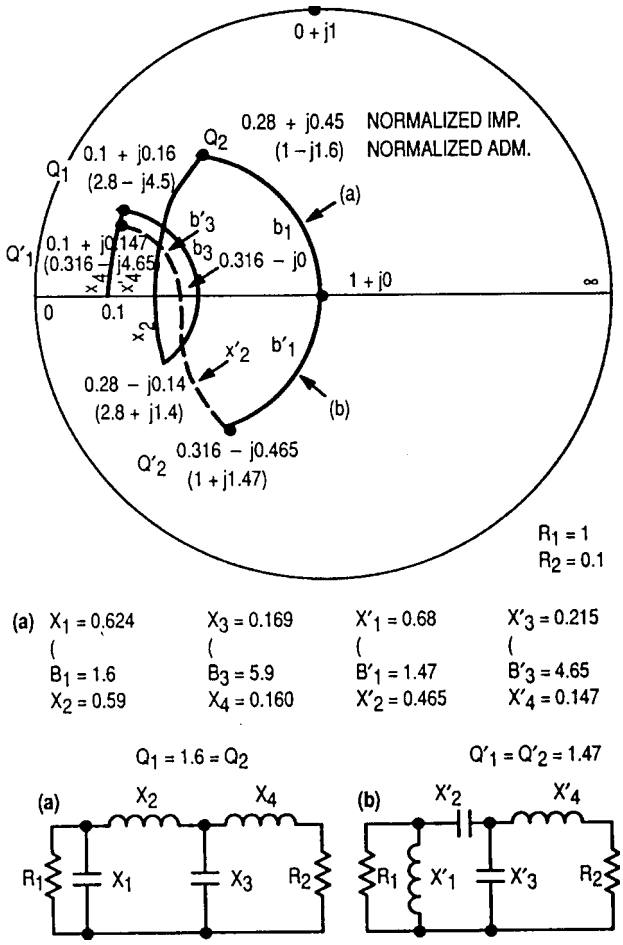

Figure 3-232 Transformation paths for networks (a) and (b).

The circuit of Figure 3-235a can be compared to the three-reactance network shown in Figure 3-228c. The difference is that capacitor C_2 of that circuit has been replaced by an *LC* circuit. The resulting improvement can be seen by comparing Figure 3-236 with Figure 3-230.

By adding one reactance, exact impedance transformation is achieved at two frequencies. It is now possible to choose component values such that the point of intersection M' occurs at the same frequency f_1 on both curves and simultaneously that N' occurs at the same frequency f_2 on both curves. Among the infinite number of possible intersections, only one allows the achievement of this.

When M' and N' coincide in M, the new $dX'/df = dX''/df$ condition can be added to the condition $X' = -X''$ (for three-reactance networks) and similarly $R' = R''$ and $dR'/df = dR''/df$.

Again, a general solution of the above equations leads to still more complicated calculations than in the case of three-reactance networks. Therefore, tables are preferable [33, 34, 36].

The circuit of Figure 3-235b is the dual of the circuit of Figure 3-233a and does not need to be treated separately. It gives exactly the same results in the *Z* plane. Figure 3-235c shows a higher-order compensation requiring six reactive elements.

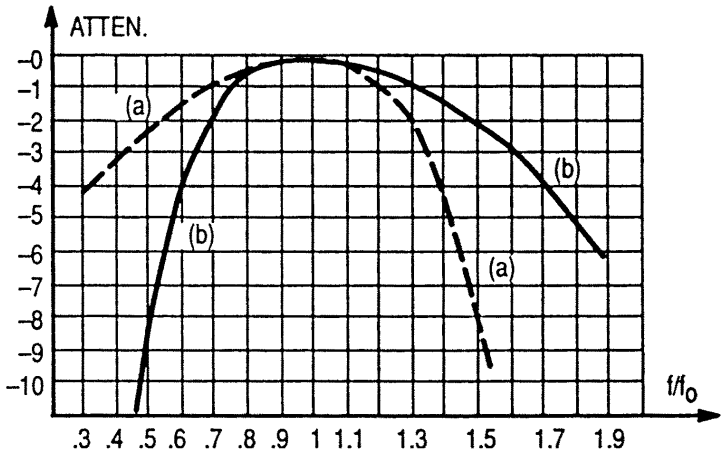

Figure 3-233 Selectivity curves for networks (a) and (b) of Figure 3-232.

The above-discussed matching networks employing compensation circuits result in narrower bandwidths than the former solutions (see p. 573) using two transformation sections. A matching arrangement with higher-order compensation, such as in Figure 3-235c, is not recommended. Better use can be made of the large number of reactive elements by using them all for transformation.

When the above configurations are realized using short portions of transmission lines, the equations or the usual tables no longer apply. The calculations must be carried out on a computer because of their complexity. However, a graphical method can be used (see the next section) that will consist essentially in tracing a transformation path on the Z–Y chart using the computed lumped element values and replacing it by the closest path obtained with distributed constants. The bandwidth change is not significant as long as short portions of lines are used.

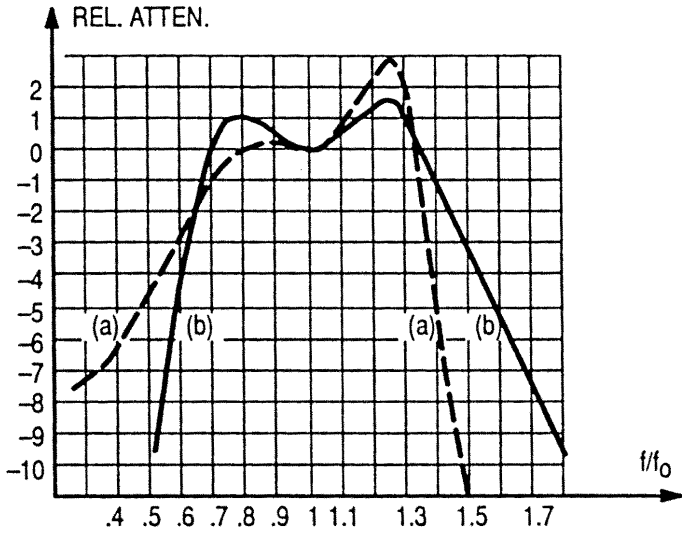

Figure 3-234 Selectivity curves for networks (a) and (b) of Figure 3-232 with infinite R_1.

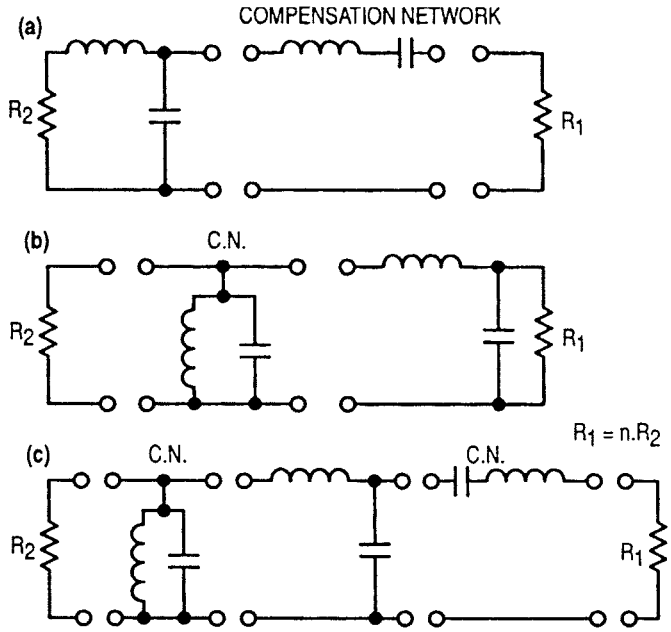

Figure 3-235 Compensation networks used with an L section.

MATCHING NETWORKS USING QUARTER-WAVE TRANSFORMERS. At sufficiently high frequencies, where λ/4-long lines of practical size can be realized, broadband transformations can easily be accomplished by the use of one or more λ/4 sections. Figure 3-237 summarizes the main relations for (a) one-section and (b) two-section transformations. A compensation network can be realized using a λ/2-long transmission line. Figures 3-238 and 3-239 show the selectivity curves for different transformation ratios and section numbers.

EXPONENTIAL LINES. Exponential lines have largely frequency-independent transformation properties. The characteristic impedance of such lines varies exponentially with their length l:

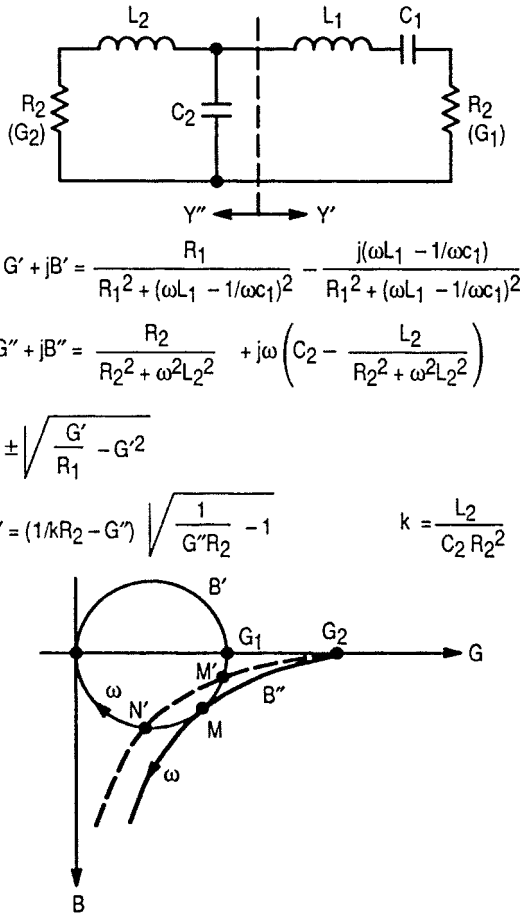
$$Z = Z_0 e^{kl} \tag{3-223}$$

where k is a constant, but these properties are preserved only if k is small.

BROADBAND MATCHING USING BANDPASS FILTER NETWORKS—HIGHQ CASE. The above circuits are applicable to devices having low input or output Q, if broadband matching is required. Generally, if the impedances to be matched can be represented, for instance, by a resistor R in series with an inductor L (sometimes a capacitor C) within the band of interest and if L is sufficiently low, the latter can be incorporated into the first inductor in the matching network. This is also valid if the representation consists of a shunt combination of a resistor and a reactance.

Practically, this is feasible for Q values around 1 or 2. For higher Q values or for input impedances consisting of a series or parallel resonant circuit (see Figure 3-221), as it appears to be for large bandwidths, a different treatment must be followed.

Let us first recall that, as shown by Bode [37] and Fano [38], limitations exist on the impedance matching of a complex load. In the example of Figure 3-240, the load to be matched consists of a capacitor C and a resistor R in shunt.



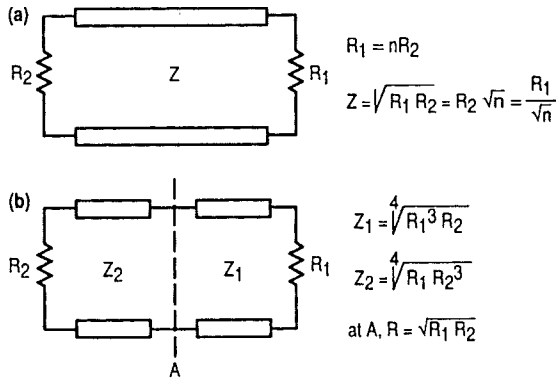
$$Y' = G' + jB' = \frac{R_1}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2} - \frac{j(\omega L_1 - 1/\omega c_1)}{R_1^2 + (\omega L_1 - 1/\omega c_1)^2}$$

$$Y'' = G'' + jB'' = \frac{R_2}{R_2^2 + \omega^2 L_2^2} + j\omega\left(C_2 - \frac{L_2}{R_2^2 + \omega^2 L_2^2}\right)$$

$$B' = \pm\sqrt{\frac{G'}{R_1} - G'^2}$$

$$B'' = (1/kR_2 - G'')\sqrt{\frac{1}{G''R_2} - 1} \qquad k = \frac{L_2}{C_2 R_2^2}$$

Figure 3-236 *Y*-plane representation of the circuit of Figure 3-235a.



$$R_1 = nR_2$$

$$Z = \sqrt{R_1 R_2} = R_2\sqrt{n} = \frac{R_1}{\sqrt{n}}$$

$$Z_1 = \sqrt[4]{R_1^3 R_2}$$

$$Z_2 = \sqrt[4]{R_1 R_2^3}$$

$$\text{at A, } R = \sqrt{R_1 R_2}$$

Figure 3-237 Transformation networks using λ/4-long transmission lines.

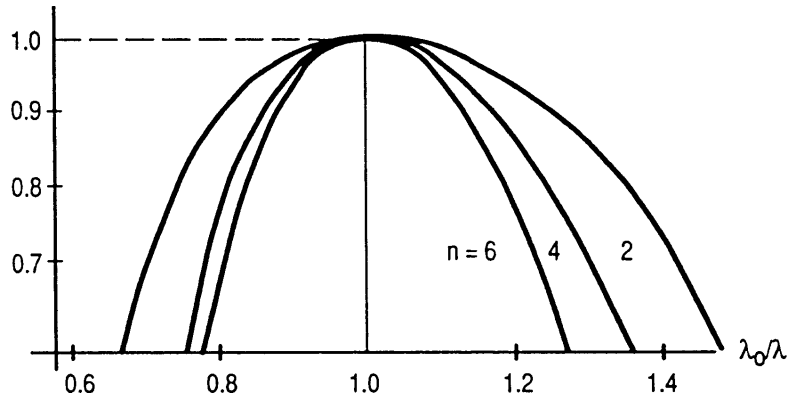


Figure 3-238 Selectivity curves for two λ/4-section networks at different transformation ratios.

The reflection coefficient between the transformed load and generator is equal to

$$\Gamma = \frac{Z_{\text{IN}} - R_G}{Z_{\text{IN}} + R_G} \tag{3-224}$$

When $\Gamma = 0$, there is perfect matching; when $\Gamma = 1$, there is total reflection. The ratio of reflected to incident power is

$$\frac{P_r}{P_i} = |\Gamma|^2 \tag{3-225}$$

The fundamental limitation on the matching takes the form

$$\int_{\omega=0}^{\infty} \ln\left(\frac{1}{|\Gamma|}\right) d\omega \le \frac{\pi}{RC} \qquad \text{Bode equation} \tag{3-226}$$

and is represented in Figure 3-241.

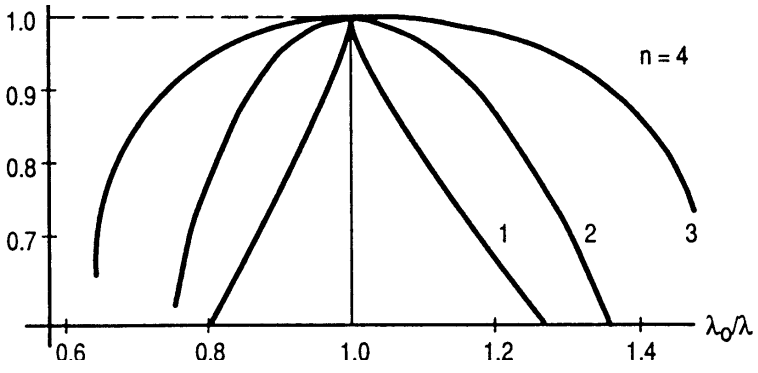

Figure 3-239 Selectivity curves for one, two, and three λ/4 sections.

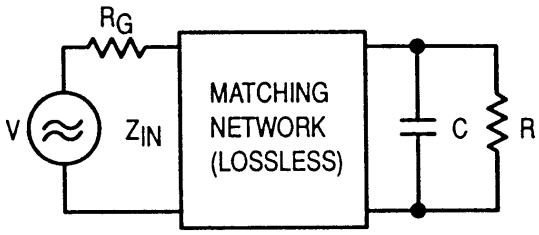

Figure 3-240 General matching conditions.

The meaning of the Bode equation is that the area S under the curve cannot be greater than π/RC and, therefore, if matching is required over a certain bandwidth, this can only be done at the expense of less power transfer within the band. Thus, power transfer and bandwidth appear as interchangeable quantities.

It is evident that the best utilization of the area S is obtained when $|\Gamma|$ is kept constant over the desired band ω_c and made equal to 1 over the rest of the spectrum. Then

$$|\Gamma| = e^{-\pi/\omega_c RC} \tag{3-227}$$

within the band and no power transfer happens outside. A network fulfilling this requirement cannot be obtained in practice because an infinite number of reactive elements would be necessary.

If the attenuation is plotted versus frequency for practical cases, one may expect to have curves like the ones shown in Figure 3-242 for a low-pass filter having Chebyshev character.

For a given complex load, an extension of the bandwidth from ω_1 to ω_2 is possible only with a simultaneous increase of the attenuation a. This is especially noticeable for Q values exceeding 1 or 2 (see Figure 3-243). Thus, devices having relatively high input Q values are usable for broadband operation, provided the consequent higher attenuation or reflection introduced is acceptable.

For average insertion losses or attenuation a (neglecting the ripple), the attenuation decreases if the number n of the network element increases. But above $n = 4$, the improvement is small. For a given attenuation a and bandwidth, the larger the n the smaller the ripple; for a given attenuation, the larger the n the larger the bandwidth.

Computations show that for $Q < 1$ and $n \leq 3$, the attenuation is below 0.1 dB (approximately). The impedance transformation ratio is not free here. The network is a

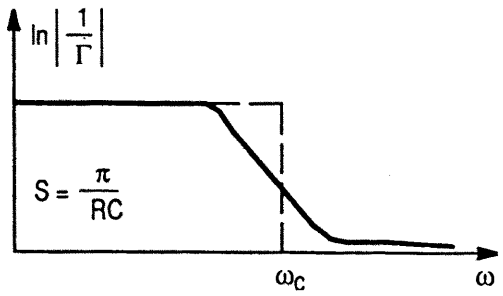

Figure 3-241 Representation of the Bode equation.

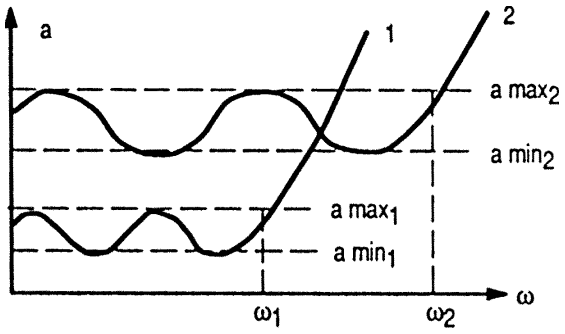

Figure 3-242 Attenuation versus angular frequency for different bandwidths with the same load.

true low-pass filter. For a given load, the optimum generator impedance will result from the computation.

Before impedance transformation is introduced, a conversion of the low-pass prototype into a bandpass filter network must be made. Figure 3-244 summarizes the main relations for this conversion. r is the conversion factor. For the bandpass filter, $Q_{\text{IN max}}$, or the maximum possible input Q of the device to be matched, has been increased by the factor r (from Figure 3-244, $Q'_{\text{IN max}} = rQ_{\text{IN max}}$).

Impedance inverters will be used for impedance transformation. These networks are suitable for insertion into a bandpass filter without affecting the transmission characteristics.

Figure 3-245 shows four impedance inverters. Note that one of the reactances is negative and must be combined in the bandpass network with a reactance of at least equal positive value. Insertion of the inverter can be made at any convenient place [32, 39].

When using the bandpass filter for matching the input impedance of a transistor, reactances $L'_1C'_1$ should be made to resonate at ω_0 by addition of a convenient series reactance.

As stated earlier, the series combination of R_0, L'_1 and C'_1 normally constitutes the equivalent input network of a transistor when considered over a large bandwidth. This is a good approximation up to about 500 MHz.

In practice, the normal procedure for using a bandpass filter matching network will be the following:

1. For a given bandwidth center frequency and input impedance of a device to be matched—for example, 50 Ω—first determine Q'_{IN} from the datasheet as

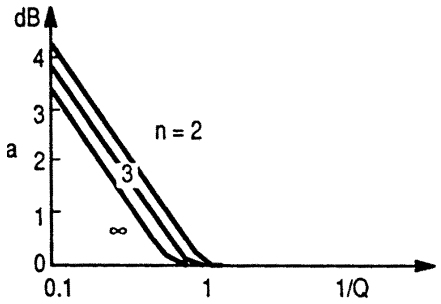

Figure 3-243 Insertion losses as a function of 1/*Q*.

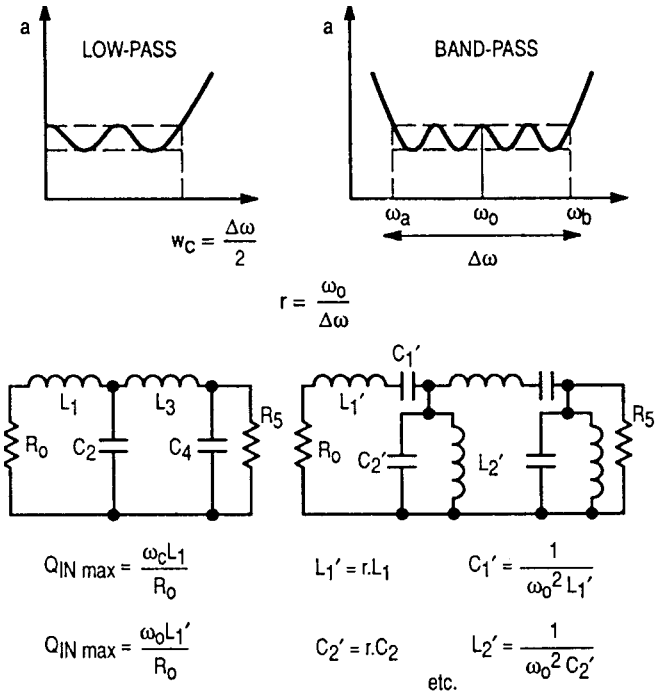

Figure 3-244 Conversion from low-pass filter into bandpass filter.

$$\frac{\omega_0 L_1'}{R_0} \tag{3-228}$$

after having eventually added a series reactor for centering.

2. Convert the equivalent circuit $R_0 L_1' C_1'$ into a low-pass prototype $R_0 L_1$ and calculate Q_{IN} using the formulas of Figure 3-244.
3. Determine the other reactance values from tables [33] for the desired bandwidth.
4. Convert the element values found by Step 3 into series- or parallel-resonant circuit parameters.
5. Insert the impedance inverter in any convenient place.

In the above discussions, the gain roll-off has not been taken into account. This is of normal use for moderate bandwidths (e.g., 30%). However, several methods can be employed to obtain a constant gain within the band despite the intrinsic gain decrease of a transistor with frequency. Tables have been computed elsewhere [40] for matching networks approximating 6 dB/octave attenuation versus frequency.

Another method consists of using the above-mentioned network and then adding a compensation circuit, as shown in Figure 3-246.

Resonance ω_b is placed at the high edge of the frequency band. Choosing Q correctly, roll-off can be made 6 dB/octave. The response of the circuit of Figure 3-246 is expressed by

$$\frac{1}{1 + Q^2(\omega/\omega_b - \omega_b/\omega)^2} \tag{3-229}$$

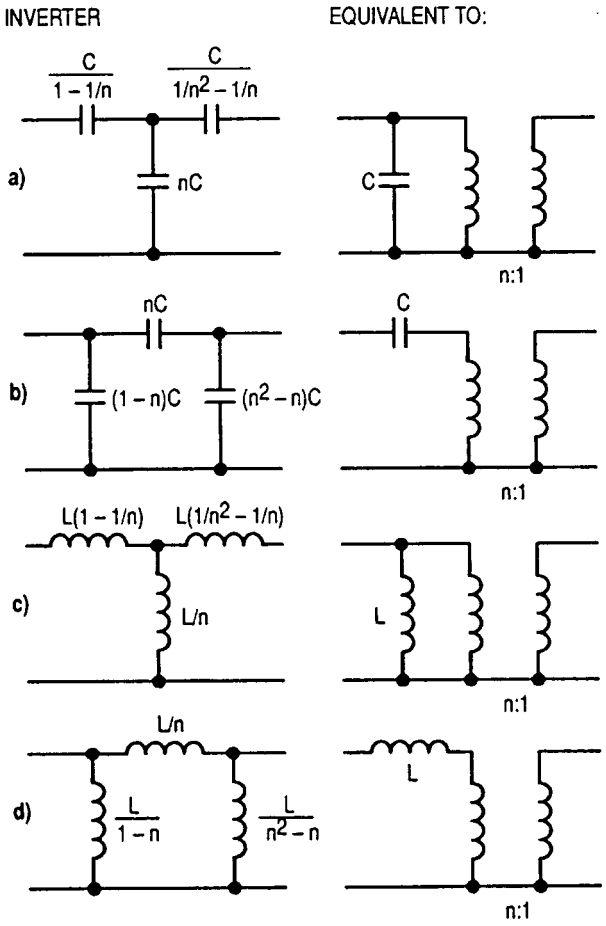

Figure 3-245 Impedance inverters.

where $\omega < \omega_b$. This must be equal to ω/ω_b for 6 dB/octave attenuation.

At the other band edge a, exact compensation can be obtained if

$$Q = \frac{(\omega_b/\omega_a)^2 - 1}{\omega_a/\omega_b - (\omega_b/\omega_a)^2} \tag{3-230}$$

There are several methods available for synthesis of matching networks. They should not be confused with filters because they can be either high-pass, low-pass, or bandpass, and their main purpose is to match one complex impedance to another. In many cases, one of the terminations happens to be 50 Ω and real, but this is just a "lucky" case of the general approach. An excellent paper on this [41] refers to the "real frequency" technique. Another equally important publication is the one by Cuthbert [42], since followed by his book [43]. Two more good references are Vendelin et al. [44] and Potter [45].

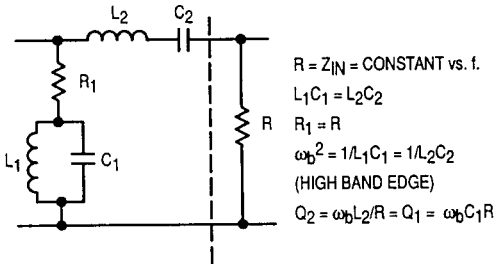

Figure 3-246 Roll-off compensation network.

3-12-3 Example 2: Low-Noise Amplifier Using Distributed Elements

In our previous examples, the amplifiers were built around lumped elements. Since a transmission line length of less than $\lambda/4$ is an inductor and $\frac{3}{4}\lambda$ is a capacitor, the whole amplifier can be built around microstrip technology.

If anyone wonders why we are going to show a low-noise amplifier in the middle of the power section, the reason is that we will select a low-power Siemens transistor, which, being operated in Class A, has an intercept point of +30 dBm and can easily achieve a noise figure of less than 2 dB. Such an amplifier is attractive when feeding an input stage from an antenna that sees many signals and curtails the bandwidth with an input filter of good selectivity that needs a good output termination, which in many cases works against the achievement of a good noise figure because when designing for best noise figure the input impedance of the transistor stage is far from 50 Ω.

First, we will start with the textbook approach and use the Smith diagram to obtain the best noise figure of which the device is capable. Figure 3-247 shows the actual approach to input and output matching.

We start our design by querying the Smith Tool about the minimum noise figure and the gain that comes with it. We mark the point of the lowest noise figure (labeled Γ_{opt}). The small

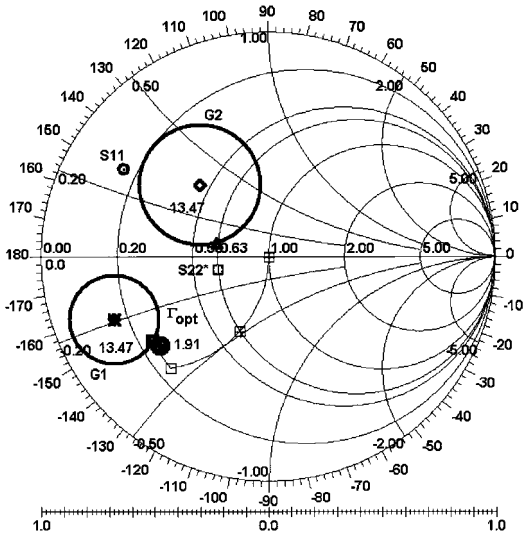

Figure 3-247 Input and output matches for 13.47 dB of gain and NF = 1.91 dB as displayed by the interactive Smith Tool.

noise circle yields the location for Γ_{opt} and tells us the minimum noise figure is going to be 1.91 dB. (By the way, this assumes no further losses, even in soldering the transistor to the PC board.) Then we construct the input gain circle (G1), which touches Γ_{opt} and turns out to represent 13.47 dB of available gain.

The next step is to find a matching network between Γ_{opt} and the 50-Ω source impedance. Immediately there is a conflict: If we look at S_{11}, which is the input reflection coefficient shown in the Smith diagram, it is on the other side of the complex plane and sufficiently far away, indicating that there is going to be quite a difference between noise matching and power-gain matching. We have two options for matching the input: Either we start from the origin and move toward the position of Γ_{opt}, or we start with Γ_{opt} and go to 50 Ω. Depending on the direction in which we do this, the result can be different topologies, such as a high-pass or low-pass filter. The high-pass filter is obtained by starting with Γ_{opt}; the low-pass topology is obtained by starting at the 50-Ω point. The Smith Tool then provides us with the corresponding values of capacitors and inductors after the transformation has been accomplished.

The final step is to do the same type of matching at the output. We start with S_{22}, and either select S_{22}^* (the complex conjugate for highest gain) or S_{22load}. As a rule, the second one is always a lower impedance (in terms of the real part) than the conjugate match. This graphic procedure is somewhat trial and error. As to the topology, a high-pass match should be preferred at the input and a low-pass match at the output. The reason for this is that the high-pass filter will tend to protect the stage from the enormous number of signals present below 1 GHz; using a low-pass filter at the output suppresses unwanted harmonics that the amplifier may generate. Figure 3-248 shows one of the approaches we like best simply because it gives a good input termination and we were trying for a simultaneous match for best noise figure and power gain.

The way we were able to achieve this was to take advantage of the existing feedback in the transistor and select a less-than-optimal output termination but gaining at the input. Taking advantage of the Miller effect, we rotate the phase angle of the feedback with the load to move the optimum noise and gain matching points closer. The danger in this is that the circuit is now highly sensitive to both input and output termination. The output *must* see 50 Ω to maintain this good input match, but since the second transistor stage can now be optimized for best input match, a two-stage combination can be configured to meet this

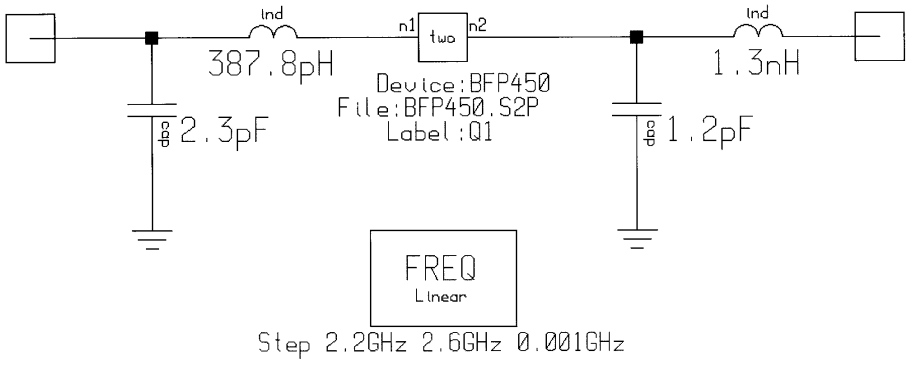

Figure 3-248 A 2.4-GHz amplifier using a BFP450 transistor and lumped-element input and output matching.

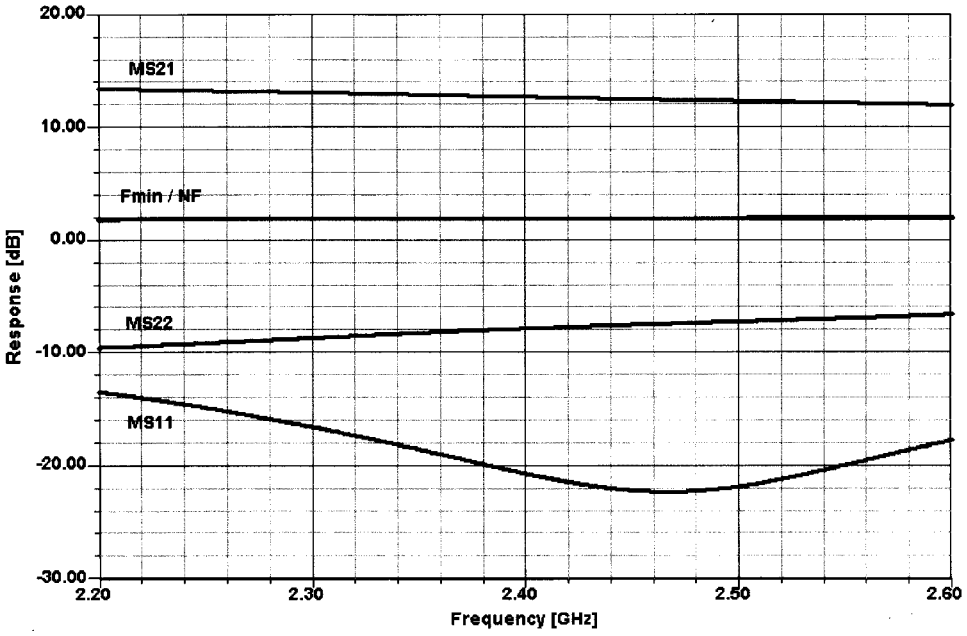

Figure 3-249 Frequency-dependent gain, matching, and noise characteristics of the matched high-dynamic-range BFP450 2.4-GHz amplifier.

requirement. Also, let us not forget that the device is running at 50 mA and as far as bipolar transistors are concerned, this is probably the best amplifier combination we have seen for getting the highest dynamic range and lowest noise figure. The resulting gain, matching, and noise figure characteristics are shown in Figure 3-249.

Now we turn to using distributed elements and at the same time use a shunt feedback at the output; to be specific, we will load it with 150 Ω. The reason for this is to be able to obtain a good compromise at the input that will depend less on the output and at the same

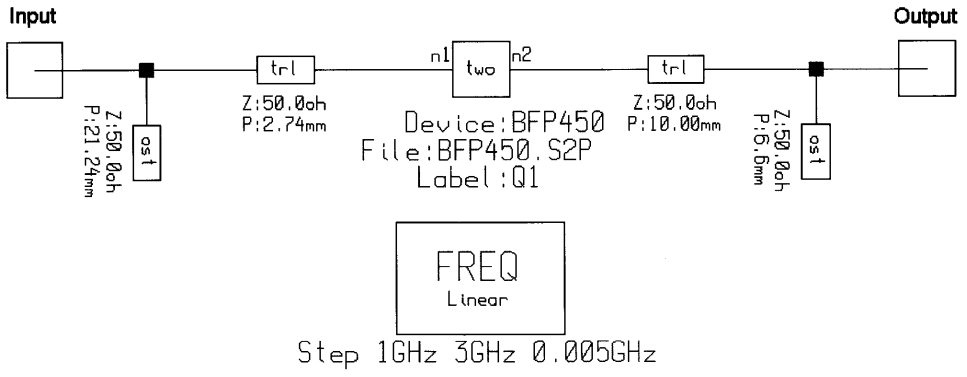

Figure 3-250 Distributed-element input and output matching for the 2.4-GHz BFP450 amplifier.

time improve the S_{22} matching at the output. The procedure for doing the matching with a transmission line offers only certain degrees of freedom, while doing the matching with lumped elements allows the choice of series or parallel inductors or capacitors. In the case of a transmission line, we have open stubs, shorted stubs, and transmission lines. This may result in somewhat more complex matching schemes. On the positive side, they can easily be trimmed, are reproducible, and certainly cost less than exotic capacitors, which need to have small tolerances and to be able to handle high RF currents.

The resulting input and output matching is shown in Figure 3-250, and its frequency response in Figure 3-251. We were able to maintain a good input and output match with an insignificant deterioration of the noise figure.

Since this is a high-dynamic-range amplifier, we also show its predicted two-tone response in Figure 3-252. The manufacturer specifies an $IP_{3,in}$ of 29 dB for a bias point of $V_{CE} = 3$ V and $I_C = 50$ mA with $Z_S = Z_{S,opt}$ and $Z_L = Z_{L,opt}$ at 1.8 GHz. Significantly, however, the manufacturer-supplied nonlinear BFP450 library we used exhibits considerably different characteristics at $V_{CE} = 4$ V and $I_C = 50$ mA than those reflected in the corresponding S parameters supplied by the same manufacturer. In our circuit, the S parameters resulted in about 13.5 dB of gain (based on a compromise between matching for optimum noise and maximum gain) versus about 9.5 dB of gain for the nonlinear library (match optimized for maximum gain). The difference between the 2.4-GHz F_{min} values returned for the two modeling approaches is similarly striking: 1.90 dB for the bare S parameter set and 7.76 dB for the bare nonlinear library biased to $V_{CE} = 4$ V and $I_C = 50$ mA. Clearly, the nonlinear modeling of the BFP450 needs work!

Having fully evaluated the amplifier at 2.4 GHz as a working example, we note that this frequency is used by radio amateurs for some applications. We will therefore supply

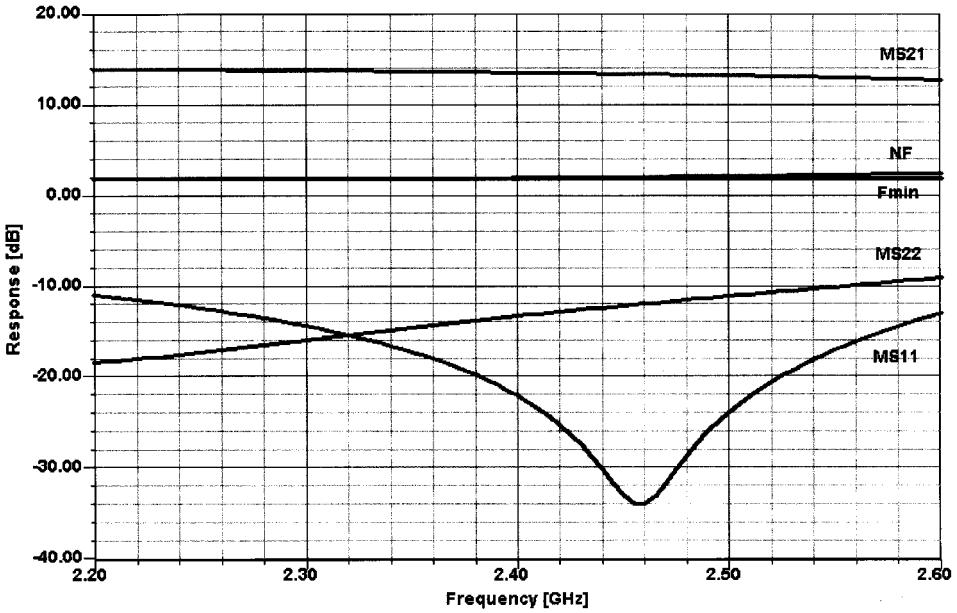

Figure 3-251 Predicted frequency-dependent gain, matching, and noise performance for the BFP450 amplifier with distributed-element matching.

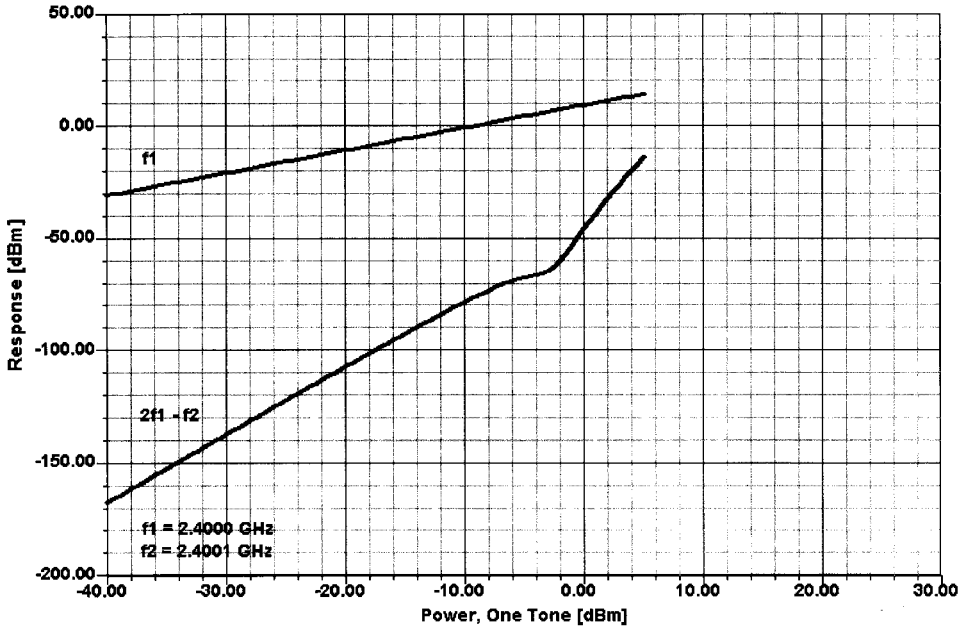

Figure 3-252 Predicted two-tone response of the BFP450 amplifier with the circuit adjusted for maximum gain (9.5 dB): $IP_{3,in} \approx 28.5$ dBm and $IP_{3,out} \approx 38$ dBm. That this version's gain is significantly lower than that of the *S*-parameter-based equivalent illustrates the need for better accuracy in parameter extraction.

examples for 432 and 1296 MHz, popular spot frequencies in the amateur 70- and 23-cm bands, respectively. Figures 3-253 and 3-254 show the 432-MHz version's schematic and frequency-dependent responses. Figures 3-255 and 3-256 show the schematic and frequency-dependent responses for the 1296-MHz version.

Using a bipolar transistor that operates at much less current, the noise figure can be improved at the expense of the dynamic range/intercept point. It is possible to reduce the noise figure by about 1 dB or so, but the reduction in intercept point will be much more dramatic. Another choice is the use of GaAsFETs for this application, but their matching in comparable circuits has been described as a nightmare simply because the devices have too much gain and very high input impedances (essentially 0.2 pF in series with 3 Ω) combined with reasonable output impedances in the vicinity of 240 Ω. Here is a wide field in which engineers can experiment and examine price/performance and performance/real estate issues. GaAsFETs also tend to require more than 30–40 mA to be alive, and even the low operating voltage of 4–5 V makes the device consume a lot of dc power.

3-12-4 Example 3: 1-W Amplifier Using the CLY15

The following is an application showing a fairly wideband amplifier with +30 dBm (1 W) output. We need to point out that in accordance with the various digital modulation modes used with this amplifier, this is not continuous operation, but a much less than 1:1 duty cycle operation. The device would probably not survive operating at full output under CW conditions. This is subject to a discussion with the manufacturer, Siemens, who has not

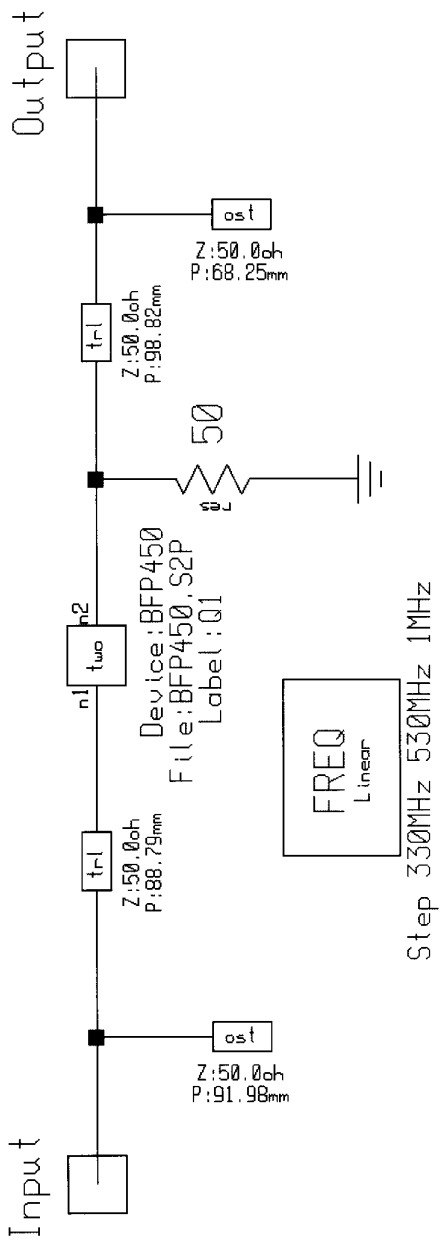

Figure 3-253 Schematic of BPF450 amplifier for 432 MHz. Because f_T = 25 GHz for the BFP450, at this lower frequency we must shunt the device output with a 50-Ω resistor to maintain stability.

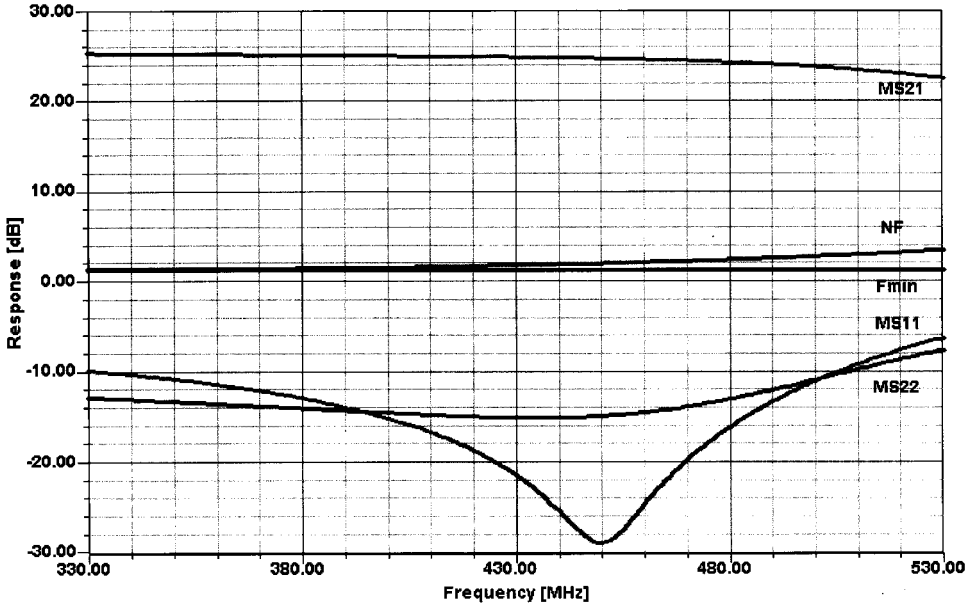

Figure 3-254 Frequency-dependent gain, matching, and noise performance for the BPF450 amplifier at 432 MHz. As with the circuit in Figure 3-253, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

released sufficient data for us to make a judgment as to the CLY15's continuous power capability. Since there is no useful large-signal model available at the time of this writing, we will design this Class A amplifier using large dc bias *S* parameters. In the actual design there will be some cut-and-try, but we find that in this type of application this is still the best way of handling the design.

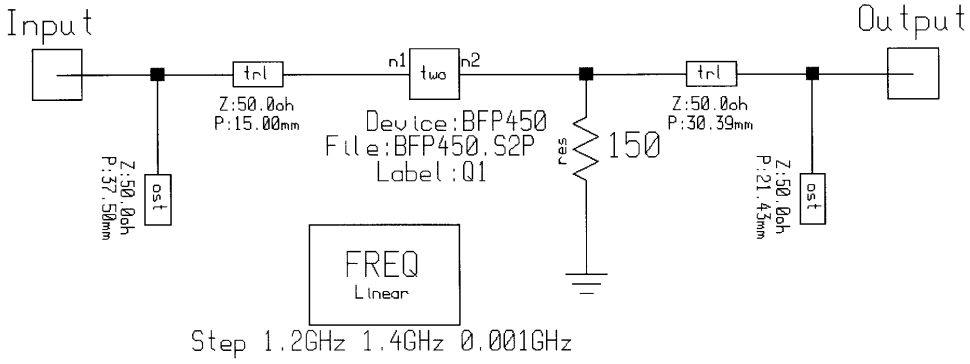

Figure 3-255 Schematic of the BPF450 amplifier for 1296 MHz. A loading resistor is still necessary to ensure stability, but because the transistor exhibits less gain at this frequency than at 432 MHz, we can increase the loading resistor to 150 Ω.

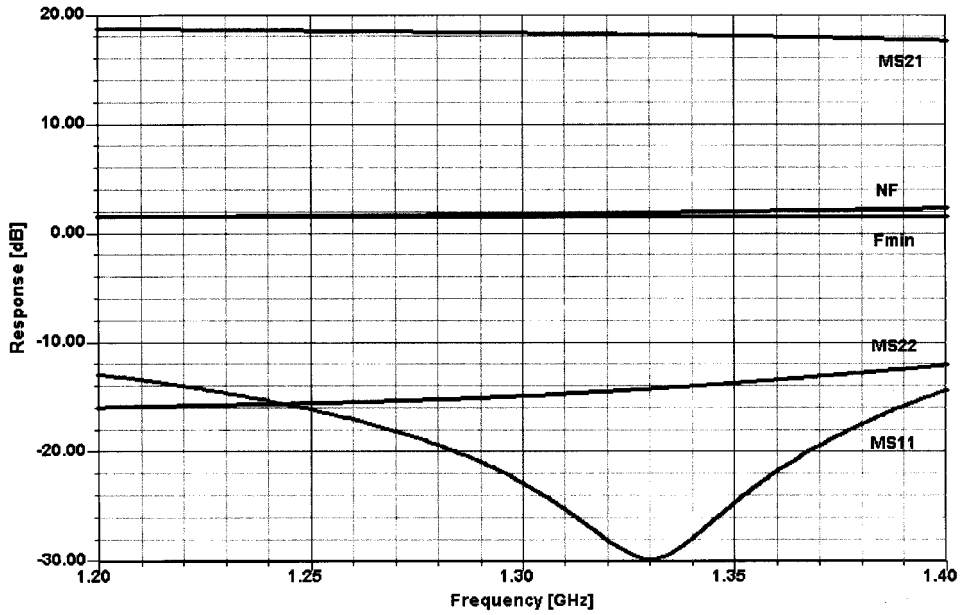

Figure 3-256 Frequency-dependent gain, matching, and noise responses of the BFP450 amplifier at 1296 MHz. As with the two previous versions, the input and output network values have been chosen to achieve a low NF and good input matching at the expense of the output match.

The CLY15 (gate width 16 mm) is the largest of a series of Siemens GaAsFETs; it was already mentioned in Chapter 2, where its datasheet is reproduced. Its device family also includes the CLY2 (gate width 2 mm), CLY5 (4 mm), and CLY10 (8 mm). It is possible that bigger devices will be offered in the future. One of the most critical parameters will be the saturation voltage; from the datasheet of the CLY15, we can see that at 1.5 A the saturation voltage is approximately 1 V. This drop of 1 V includes losses that result from other parasitic elements; the dc *I–V* curve (Figure 3-257a) indicates a saturation voltage of 0.75. Since we aim for 1-W output power, the resistive portion of the load will be $(5 - 1)^2 / (1 \times 2) = 8\ \Omega$. This assumes a supply voltage of 5 V.

The next step is to design the input and output matching network. Previewing the *S* parameters, it will be noticed that they are essentially inductive, which means that the input match, using lumped elements, will result in a combination of capacitors at both the input and the output. Figures 3-258 and 3-259 show the ways in which the input and output matches were done on the Smith diagram resulting in lumped matching elements. Inspecting the lumped input matching, we find the following. We start with S_{11}, which is in the lower part of the Smith diagram, and determine its conjugate match, S_{11}^*. We already pointed out that this device is inductive, which means that matching it from the conjugate point will require two capacitors. The first one is a series capacitor, as identified in the Smith diagram, and followed by a shunt capacitor to transform the impedance to 50 Ω. A close inspection of the Smith diagram shows that the resulting point is not quite on S_{11}; it is an iterative process to exactly find the crossover point, yet the input match of better than 20 dB is more than acceptable.

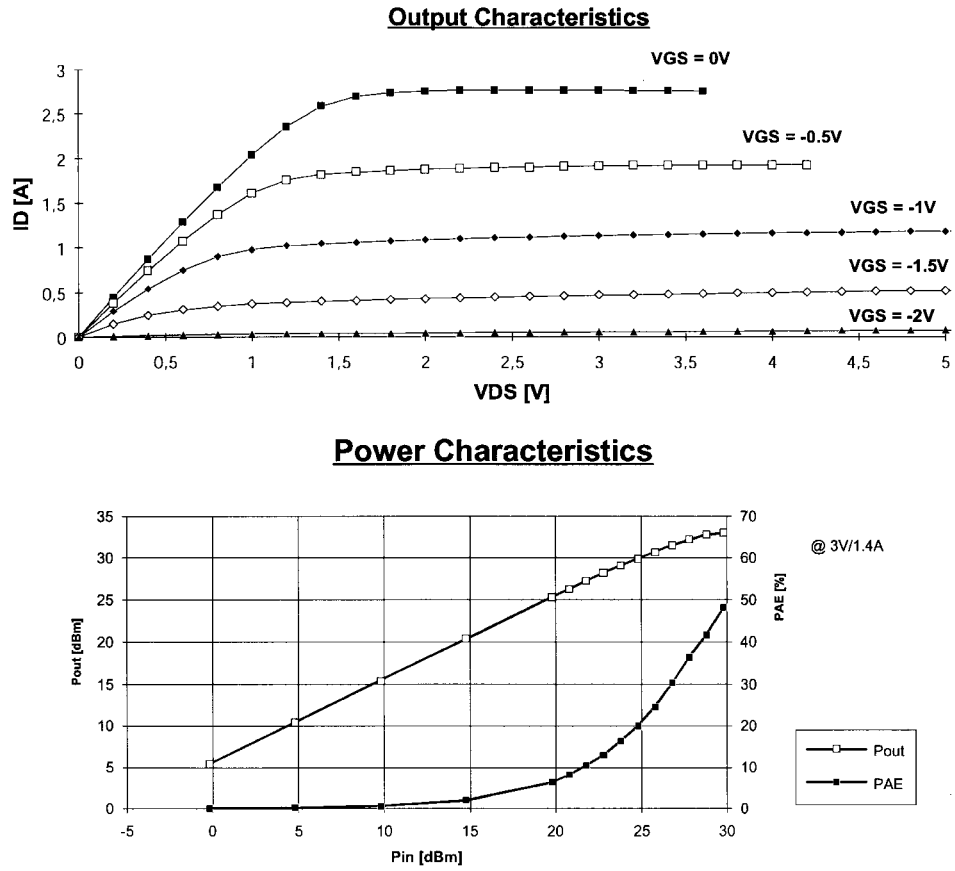

Figure 3-257 Output and power characteristics for the CLY15 medium-power GaAsFET.

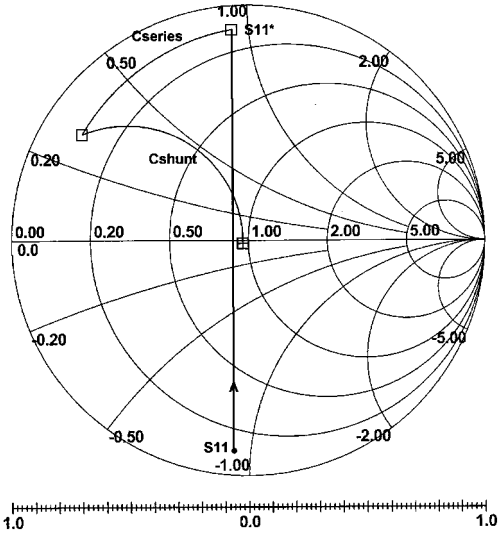

Figure 3-258 Input match for S_{11}^{*} using lumped elements.

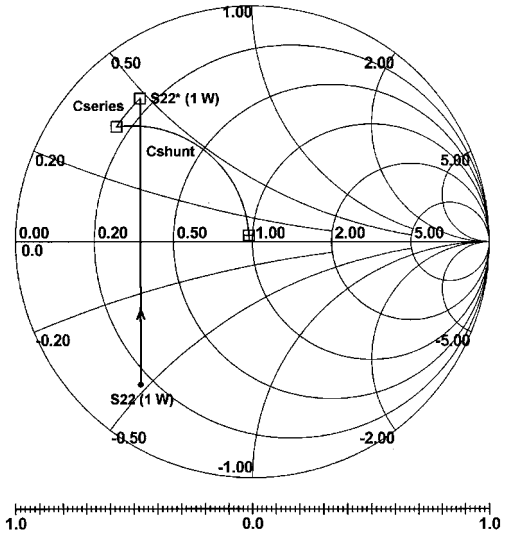

Figure 3-259 Output match for S_{22}^* (1 W) using ideal lumped elements.

As far as the output is concerned, we use the same technique by moving from S_{22} to S_{22}^*. S_{22} has been determined from the required output power; as we showed above, the real portion is 8 Ω. Using the lumped elements, the matching technique is identical; we first need to use a series capacitor and then a shunt capacitor for the transformation. The arc for the series capacitor this time is much longer, resulting in a series capacitance of 11.2 pF instead of the 2.1-pF capacitance used at the input. The actual schematic is shown Figure 3-260. The drawback of lumped elements is that it is not practical to buy components that can handle the heavy RF currents that flow in the input and output networks. Taking the values obtained

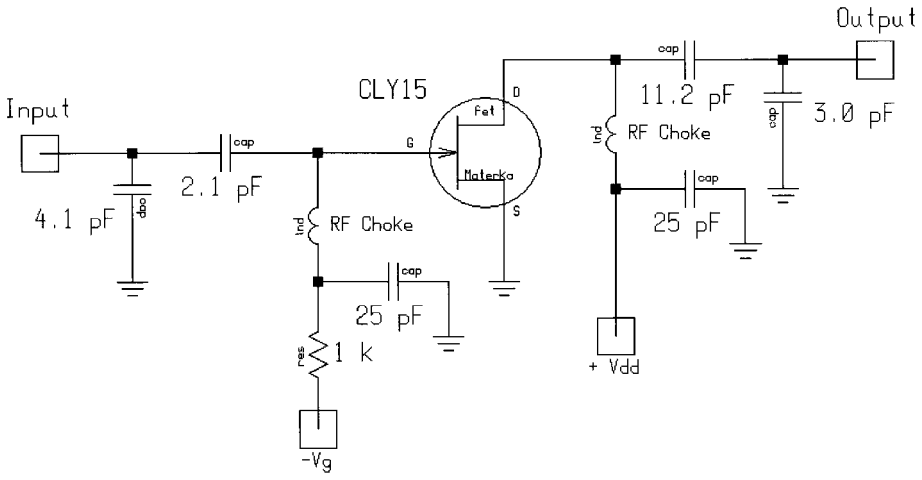

Figure 3-260 The complete amplifier using the CLY15 medium-power GaAsFET, with lumped-element input and output matching.

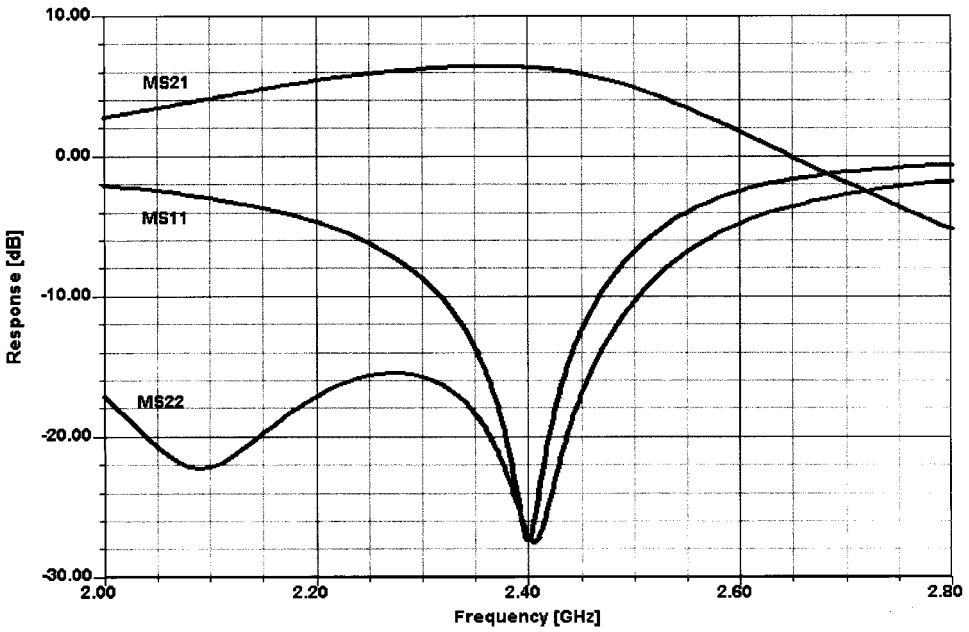

Figure 3-261 Frequency-dependent gain and matching responses of the CLY15 amplifier using ideal lumped elements.

from the lumped input and output matching approach, Figure 3-261 shows the resulting frequency response.

The next step is to provide the same matching condition using distributed elements, which of course have the advantage that they can be printed on the PC board. Instead of using ideal elements, we used a loss tangent of 2E–3, or a Q of 500. The manufacturer of the R4000 material (Rogers) provided this specification. Now we start with the same approach by moving from S_{11} to S_{11}^*. From there, we use an open stub with a transmission-line impedance of 50 Ω, followed by a transmission line to the point in the left lower corner, and, finally, a shorted transmission-line stub allows the 50-Ω matching. For this amplifier, we are not looking for noise matching but for input and output power matching. Figure 3-262 shows this match on the Smith Chart.

At the output, the procedure is again similar: We move from the S_{11} for 1 W to a conjugate value, then use an open stub that acts like a capacitor until we cross the real axis; finally, a λ/4 transmission line is used to match from approximately 75 Ω to 50 Ω. Figure 3-263 shows this match on the Smith Chart. This concludes the distributed matching design for the CLY15 amplifier.

Finally, the complete circuit using distributed elements is shown in Figure 3-264. From a dc point of view, we took advantage of the incoming shorted stub by using a transmission line of the appropriate length and a bypass capacitor to ground. This allows us to feed the gate with the required negative voltage without interfering with the frequency response of the amplifier. When evaluating the total frequency response (Figure 3-265), we noticed that this circuit seems to have a higher Q than the lumped equivalent. Again, to obtain a wider bandwidth more transformation stages will be needed. We leave this task to the interested reader.

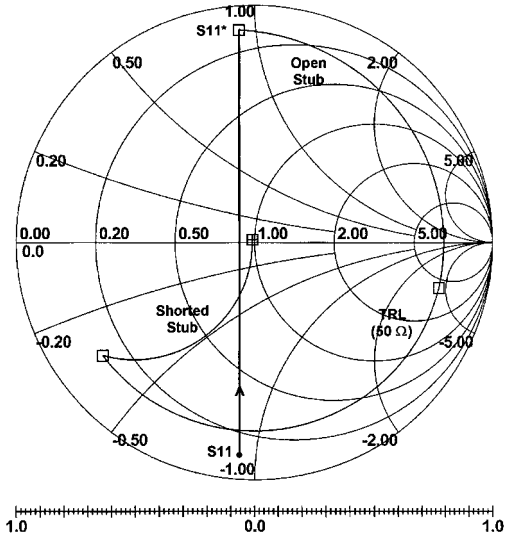

Figure 3-262 Input match for S_{11}^* (1 W) using distributed elements.

The 1-dB bandwidth of the amplifier using distributed, lossy elements is 120 MHz. If a wider bandwidth is required, matching networks with more elements are required. Because of the gain–bandwidth product, the peak gain for such a wider-bandwidth arrangement will be less than this narrowband example.

Having used a lumped to distributed transformation, we next present a power amplifier that uses coaxial lines, baluns, and other transformation steps capable of handling the increased power requirement.

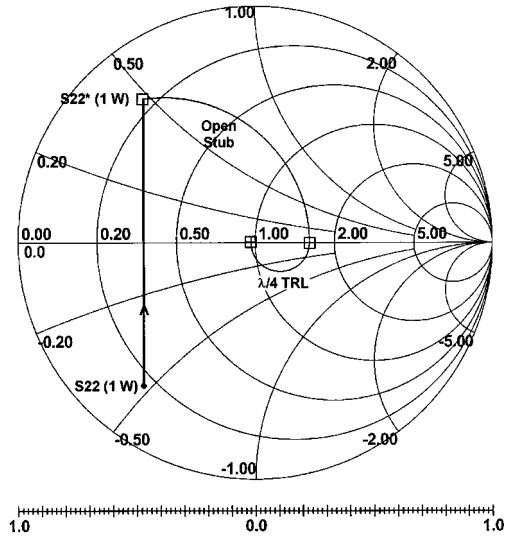

Figure 3-263 Output match for S_{22}^* (1 W) using distributed elements.

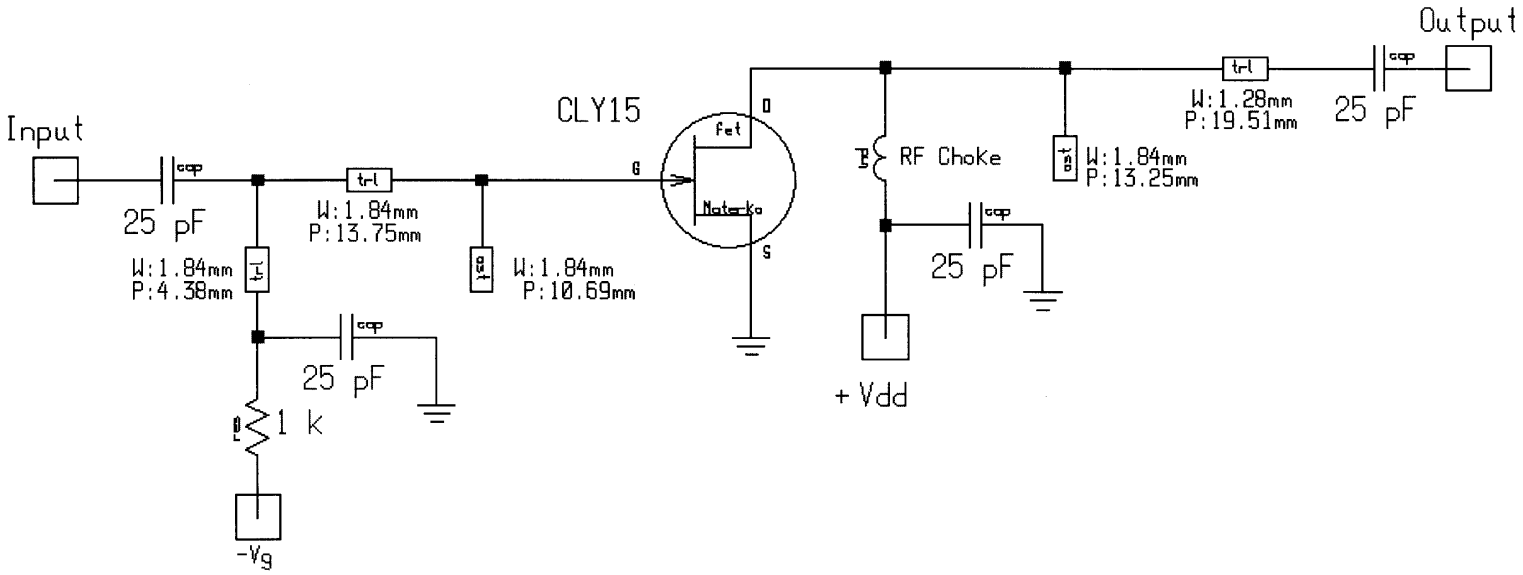

Figure 3-264 The complete amplifier using the CLY15 medium-power GaAsFET, with distributed-element input and output matching.

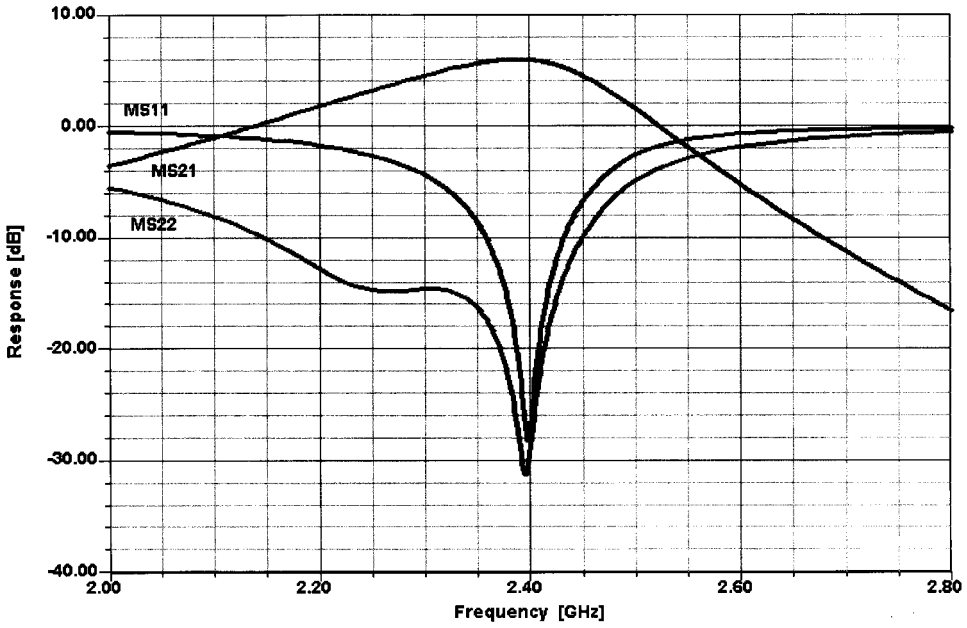

Figure 3-265 Frequency-dependent gain and matching using distributed, lossy elements.

3-12-5 Example 4: 90-W Push–Pull BJT Amplifier at 430 MHz

The last complete application we want to examine is a 90-W output, push–pull amplifier using two TRW transistors (that are no longer made—an all-too-frequent occurrence after a design is complete, resulting in a scramble for replacements). Figure 3-266 shows the circuit diagram of this UHF transistor amplifier, and Figure 3-267 shows its mechanical design. The amplifier requires 28 Vdc and will draw approximately 6 A, requiring 15 W of drive at 438 MHz. This amplifier operates in Class AB, which means it is not limited to amplifying FM and other angle-modulated signals, and can accommodate even single-sideband (SSB) operation.

The drive power coming from the source connected to the input N connector (15 W) is fed through a short piece of coaxial cable to the PC board sitting on top of the heat sink. To change from single ended to push–pull, a 50-Ω coaxial cable is coiled to provide sufficient electrical length to act as a balun that provides two symmetrical paths through the amplifier. The RC section of 10 Ω in parallel with a 220-pF capacitor stabilizes the amplifier at lower frequencies, while at higher frequencies the 10-Ω resistor has no contribution. There are two independent 4:1 transformers, one for each section; they are built using 25-Ω coaxial cable with a set of two binocular ferrite cores to force the transformation. The dc supply is also fed to the transistors at this point. The stabilization circuit consists of a temperature monitor using the *pn* junction of a transistor, side-mounted on the heat sink, and a combination of operational amplifiers and adjustments. This guarantees proper, temperature-independent biasing. The 4:1 input baluns result in 12.5 Ω impedance, or 3.125 Ω per transistor. Since the input impedance at this drive level is somewhere in the vicinity of $[(1 \ldots 2) + j(3 \ldots 5)]$ Ω; the final matching is accomplished by an *RC* section in which the inductance is actually printed

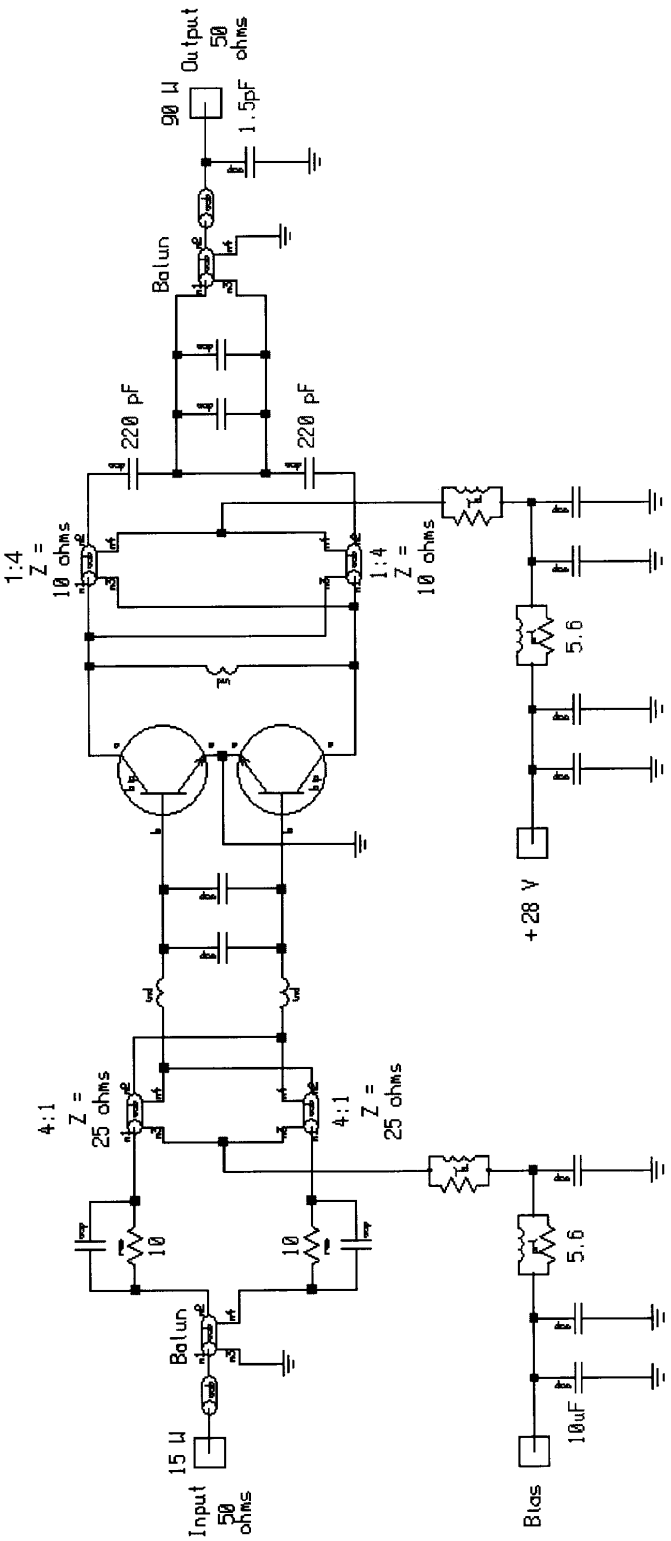

Figure 3-266 Circuit diagram of the 90-W, push–pull, 438-MHz linear amplifier.

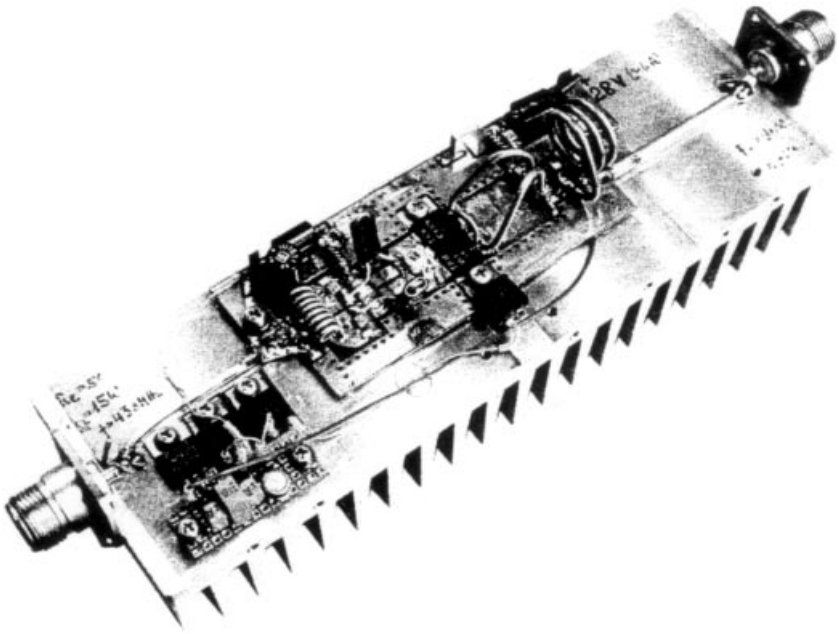

Figure 3-267 Mechanical assembly of the 90-W amplifier shown in Figure 3-266.

and the shunt capacitor across is soldered from base to base as close to the transistor bodies as possible. A ceramic-dielectric variable capacitor in parallel with this allows fine tuning.

The output consists of an inductor from collector to collector that tunes out the capacitive reactance and makes the transistor output impedance real. We then follow the same pattern by taking a 1:4 transformer, but this time built using 10-Ω rigid line instead of 25-Ω rigid line. Together with the output capacitance, prior to the output balun, this is a medium-bandwidth matching arrangement that transforms up to 50 Ω. The collector impedance per collector had to be $(28 - 2)^2/2 \times 90$, resulting in roughly 3.8 Ω—not that different from the input match at the balun point. This way, the matching networks at the input and output can be identical. At the output of the matching network, another coiled 50-Ω coaxial cable serves as balun; because it must operate at the 90-W level, larger-diameter line was used than in the input balun. Finally, another section of rigid line is used to connect the output balun on the PC board to the output N connector. The output capacitor again helps in the transformation.

Both the base and collector voltage supplies are heavily filtered using ferrite-bead-based RF chokes and heavy wire inductors wound on low-impedance resistors. A fairly large number of these amplifiers were actually built and are still in use.

3-12-6 Quasiparallel Transistors for Improved Linearity

Some applications require really low intermodulation distortion. One of the authors (Rohde), during his tenure at RCA Government Systems Division, and his team developed a parallel-device topology that is somewhat similar to the conventional parallel approach but shows vastly increased linearity. In creating higher-power devices, manufacturers parallel several transistors in one package, connecting them in a clever way so the overall drive, dissipation, and output power are equally divided between all the devices. Special nickel–chromium

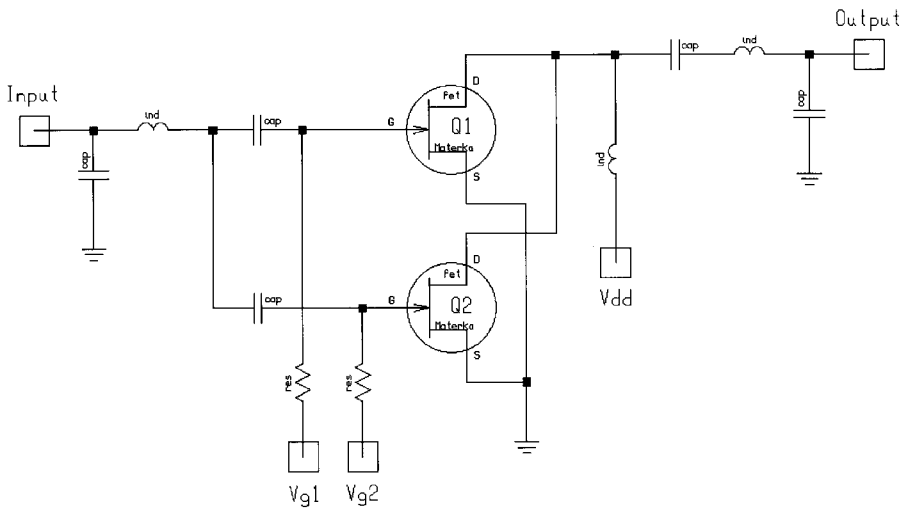

Figure 3-268 The quasiparallel amplifier topology looks like a standard parallel amplifier. Biasing the devices to different operating points nets an improvement in IMD performance.

ballasting resistors in the many fingers of the emitter connections of the multiple internal devices equalize any differences among the transistors while increasing the saturation voltage by only a small amount. In our high-linearity design, we used two transistors in parallel, one being biased somewhere between Class A and B, and the second one somewhere between Class B and C (Figure 3-268). The exact bias voltages and operating points had to be found through experiment. In practice, Q1, the "initially on" transistor, is driven to a point close to that at which its IMD products would increase. Q2 is biased such that at this same drive level it adds to the output power.

We frequently referred to this configuration as "turbocharged." The IMD products at full output power were down 40–45 dB, compared to 26–30 dB for a single transistor. While such an arrangement shows superior IMD performance, because of the somewhat abrupt kick-in of the second transistor, the transconductance response is semismooth, a characteristic that might make alert readers think that IMD will occur at this point. On the other hand, the transconductance for Q1, in effect, saturates or stays constant, so when the transconductance responses of both transistors are overlaid, the result is a smooth response overall.

This technique has been validated up to 100 W and up to at least 50 MHz. Its drawbacks include the need for two transistors with their associated costs, additional real estate, and higher input and output capacitances. Nonetheless, considering that MOS transistors capable of operation to 1 GHz were unavailable when this technique was developed, we believe that it should be revisited.

The Class D and higher operating modes require a large number of additional components and will make the efficiency higher (selective in frequency), but not necessarily reduce the IMD products. A further point of consideration is that it is incorrect to assume that reducing the input level to a given Class A will necessarily reduce its IMD products. As with tubes, the closer one gets to the knee, even in Class A operation, the worse the IMD. (This phenomenon was particularly troublesome in systems using 1-kW amplifiers up to 150 MHz;

underdrive with the intent of getting better IMD performance produced just the opposite result.) If a wide power range is considered, we recommend using a bias scheme that includes sufficient intelligence to find the best operating point.

Another hot amplifier issue is that of IMD as a function of load impedance. If an amplifier is used at output power considerably below its design value, its load impedance will be too low and, depending on the circuit configuration, the result may be additional IMD.

3-12-7 Distribution Amplifiers

It is not uncommon that a signal from a particular source like an antenna has to be distributed to several places. A condominium is a typical situation in which energy from a main signal source must be split for distribution to a larger number of users—there must be enough voltage or power to produce a noise-free picture. An amplifer capable of doing this is a *distribution* amplifier, not to be confused with a *distributed* (or traveling-wave) amplifier, such as that shown earlier in this chapter in Figure 3-6. An interesting means of achieving this is to use multiple Wilkinson couplers following an amplifier. Figure 3-269 shows an arrangement that makes heavy use of multiple power dividers to provide multiple outputs. Theoretically, the reverse is also possible: If we want to collect energy from a number of sources and combine them, as on a cable, we can use Wilkinson couplers at the *input* of a gain block. Note, however, that depending on the level and number of the combined signals, this may put enormous strain on the linearity of the amplifier. What we want to avoid is a lot of distortion, which, in the case of television, will show up as color confetti in the noise and signal.

3-12-8 Stability Analysis of a Power Amplifier

One of the hidden pitfalls in narrowband circuit design is that a circuit may be unstable outside the frequency range of interest. Circuits containing structures built from distributed elements, which exhibit multiple resonances, can be particularly susceptible to such instabilities. In this example, we analyze the stability of a simple FET power amplifier designed using small-signal concepts and the interactive Smith Tool utility in Ansoft's Serenade

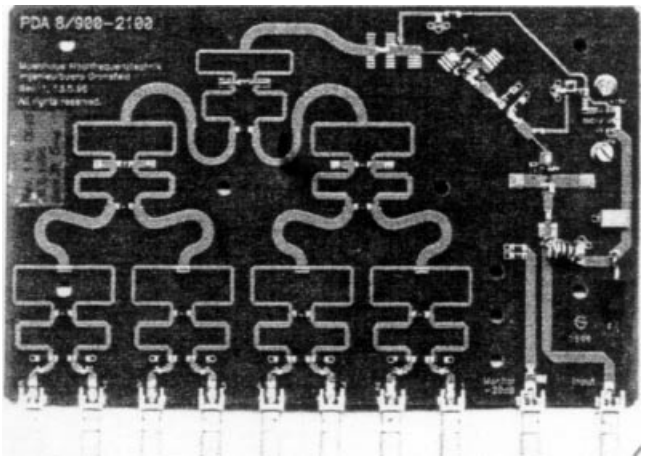

Figure 3-269 Distribution amplifier showing the use of multiple Wilkinson power dividers.

Design Environment. The evaluation shows how K-factor analysis alone is not sufficient to check for stability of a design.

Small-Signal ac Analysis. We begin by taking the Figure 3-270 amplifier, which was designed for about 16 dB of gain at 2.2 GHz. Due to the very low, capacitive input impedance of the FET and the proximity of the source-plane gain circles and stability circles to the edge of the Smith Chart, the matching network attempts to transform 50 Ω to an impedance of approximately $(2.5 + j15)$ Ω. The impedance lies close to the stability circles at 2 GHz but remains in a stable region. The bias point selected (–3.5 V) is chosen for Class AB operation. Higher linear gain can be achieved by reducing the gate voltage to –2.0 V; at this bias point, the amplifier gain will increase to about 19 dB.

First, we will do a small-signal ac analysis and examine the S parameters and K and B_1 factors [see Eqs. (3-154) and (3-157), respectively] from 1 GHz to 6 GHz—well beyond the bandwidth of the design. Figure 3-271 shows the circuit's frequency-dependent gain and matching characteristics.

If we examine B_1 and the stability factor K, we see that the amplifier is not unconditionally stable in the 2.2-GHz passband as shown in Figure 3-272. K dips slightly below 1, although B_1 remains above zero. In practice, a slight change in design would be required to bring K above 1 and remove this potential instability. However, for our example, this is of no consequence, as we shall see below.

Nyquist Stability Analysis. Now we will utilize a Nyquist stability analysis to check the stability of the amplifier. To fully realize the advantages of a Nyquist stability analysis, we must sweep frequency over a very wide range. We want to be able to pick up instabilities at *any* frequency, not just near the design frequency. In this example we sweep from 1 kHz to 20 GHz. A start frequency of 1 kHz is chosen so we can determine the starting point of the Nyquist plot and we ensure that any low-frequency resonances are picked up. The stop frequency is chosen past the f_{max} of the transistor (where we know it cannot oscillate).

The analysis results are shown in polar plot form in Figure 3-273 and in magnitude–angle form in Figure 3-274. The polar graph shows the real and imaginary parts of the system determinant as frequency is swept. The magnitude–angle graph shows the magnitude and cumulative angle (no cut at ±180°) of the system determinant as frequency is swept. The key to interpreting these graphs lies in the following statement drawn from the Nyquist criterion:

The circuit will be unstable if the Nyquist plot encircles the origin in a clockwise direction.

The term "unstable" refers to the existence of natural frequencies lying in the right-half of the complex frequency plane (RHP). These natural frequencies on the RHP will cause oscillations. To encircle the origin in a clockwise direction means that the Nyquist plot will travel in a clockwise path, cross the negative real axis, and continue to completely surround the origin. If the path appears to encircle the origin but then "unravels" itself in a counter-clockwise direction, the origin is not actually encircled. Figure 3-273 shows that the origin is not encircled and therefore this circuit is stable.

The magnitude–angle plot can assist in determining if a clockwise encirclement has actually been made with the help of the following:

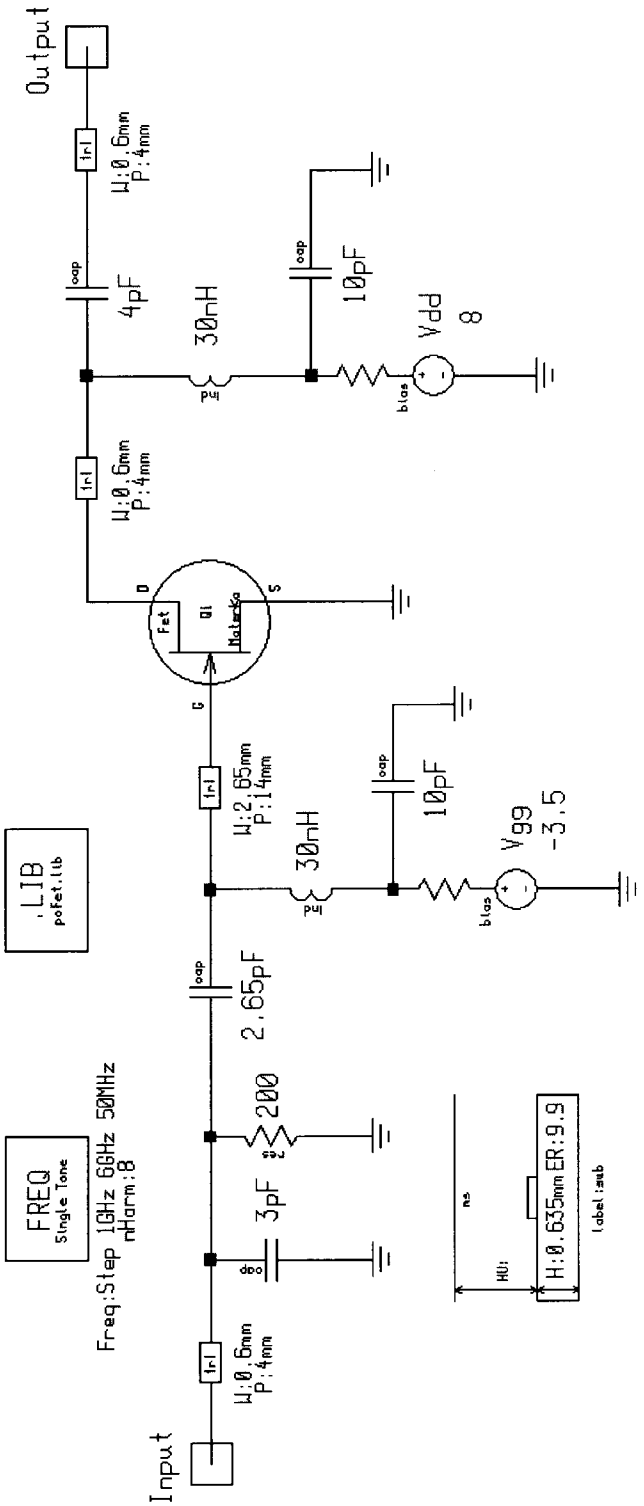

Figure 3-270 A 2.2-GHz amplifier design for stability analysis.

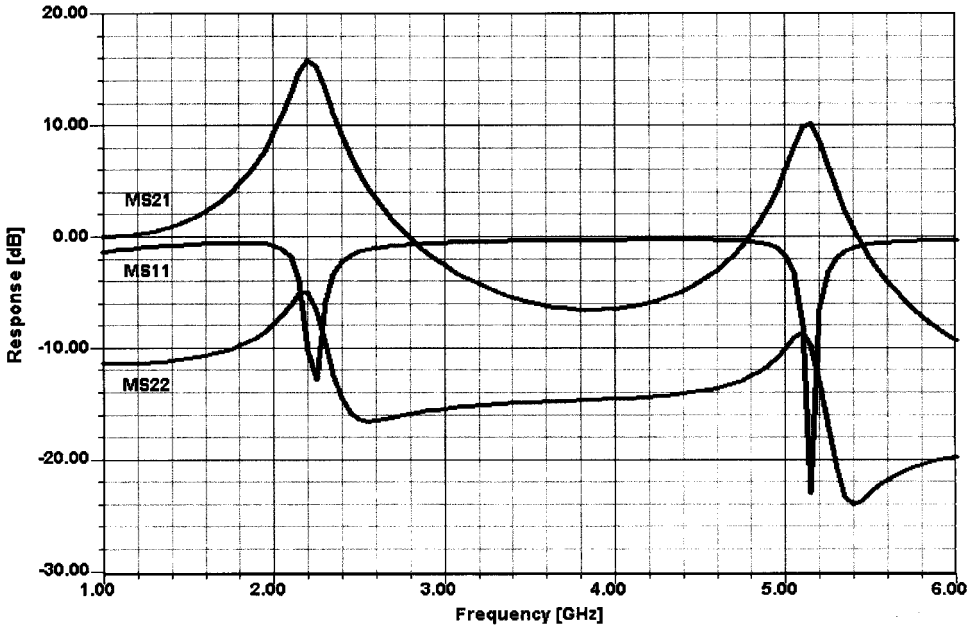

Figure 3-271 Frequency-dependent gain and matching characteristics of the amplifier. Although the circuit is designed for 2.2-GHz operation, the periodic responses of its distributed-element-based input and output matching networks result in a second gain peak near 5.1 GHz. As we shall see, however, instabilities may result at frequencies that cannot be intuited from this graph.

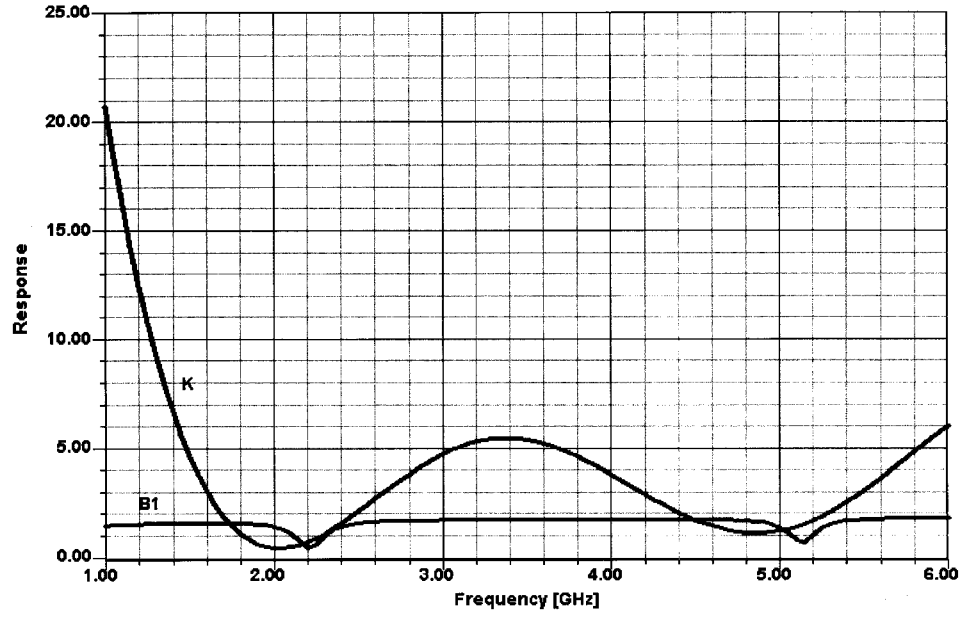

Figure 3-272 K and B_1 for the 2.2-GHz amplifier.

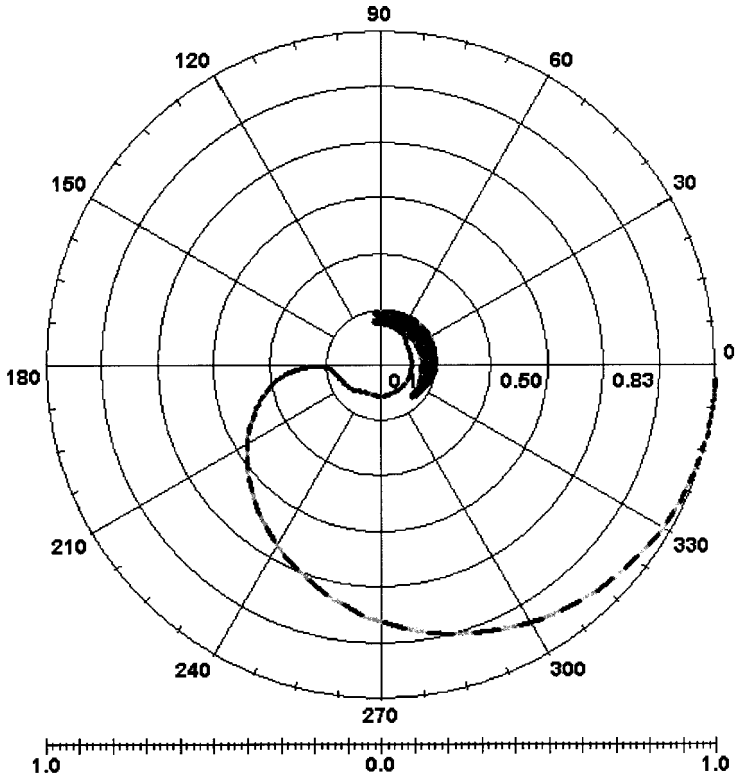

Figure 3-273 Polar Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

- To travel in a clockwise direction on a polar chart means to decrease phase angle. On a magnitude–angle plot, the phase will become more negative as frequency is increased (although it may not be monotonic).
- If the path crosses the negative real axis on the polar chart, it will cross –180° on the magnitude–angle plot.
- Encirclement will occur if the phase angle continues to decrease to, say, –360°. If "unraveling" occurs, the phase angle will not stay below –360°. Figure 3-274 clearly shows that the phase angle decreases to about –180° but does not decrease any more. Rather, the angle returns to a positive value and oscillates between about –40° and +100°. Therefore an encirclement did not occur, and the circuit is stable.

An Unstable Case. Let us now change the gate bias to –2 V—a value that increases the amplifier gain enough to cause instability. Figures 3-275 and 3-276 show the results. From Figure 3-275 we can see that the origin is encircled in a clockwise direction. Figure 3-276 confirms this since the phase angle goes through –180° and continues without unraveling.

Approximate Frequency of Oscillation. The frequency where the Nyquist plot crosses –180° is often the approximate frequency of the unstable right-half-plane zeros and provides an estimate of the potential oscillation. For this example, there is a sharp crossing at 200 MHz that is characteristic of a circuit resonance. Note that the frequency is not related

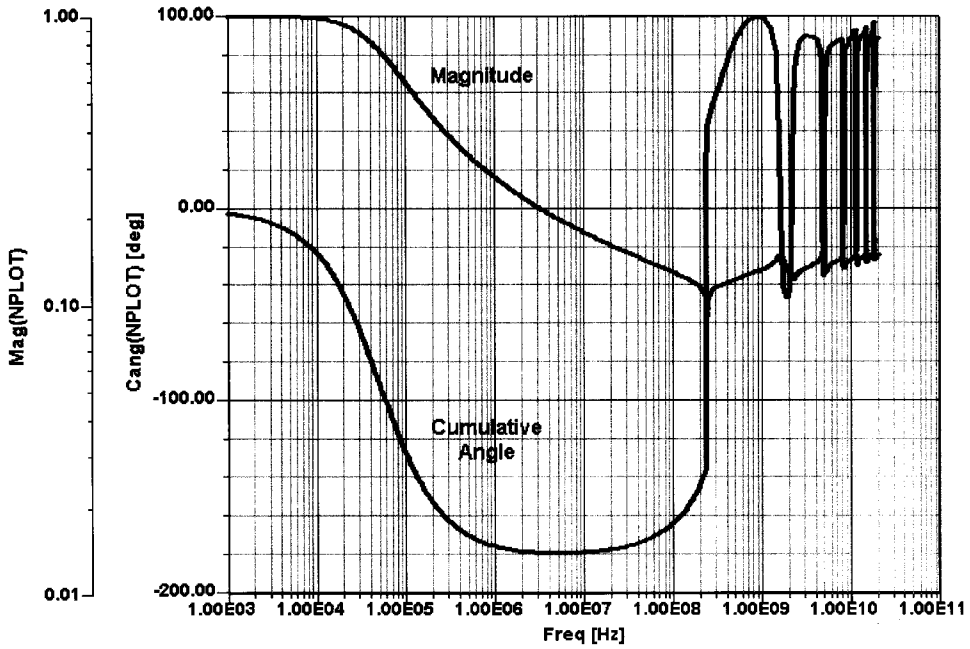

Figure 3-274 Magnitude and cumulative angle Nyquist plot for the 2.2-GHz amplifier covering 1 kHz to 20 GHz.

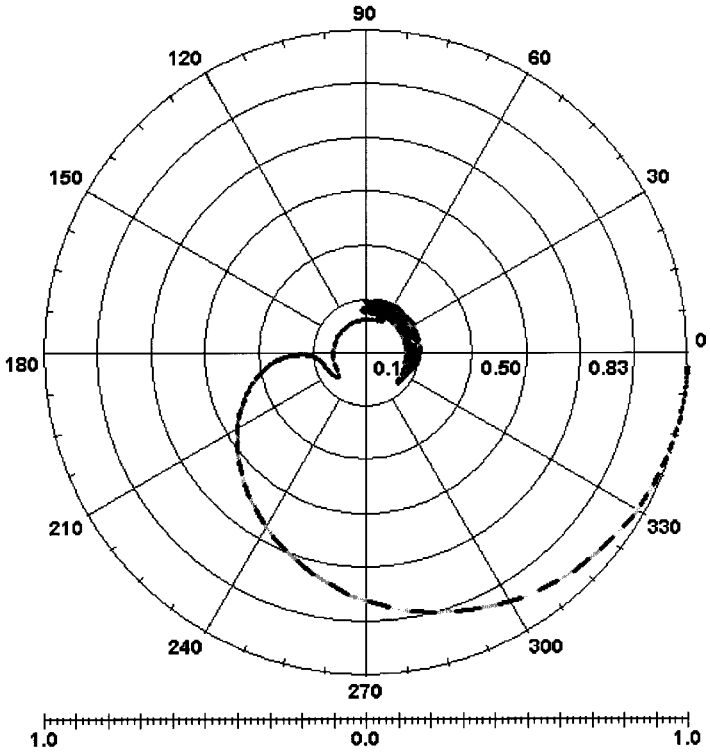

Figure 3-275 Polar Nyquist plot of the unstable amplifier.

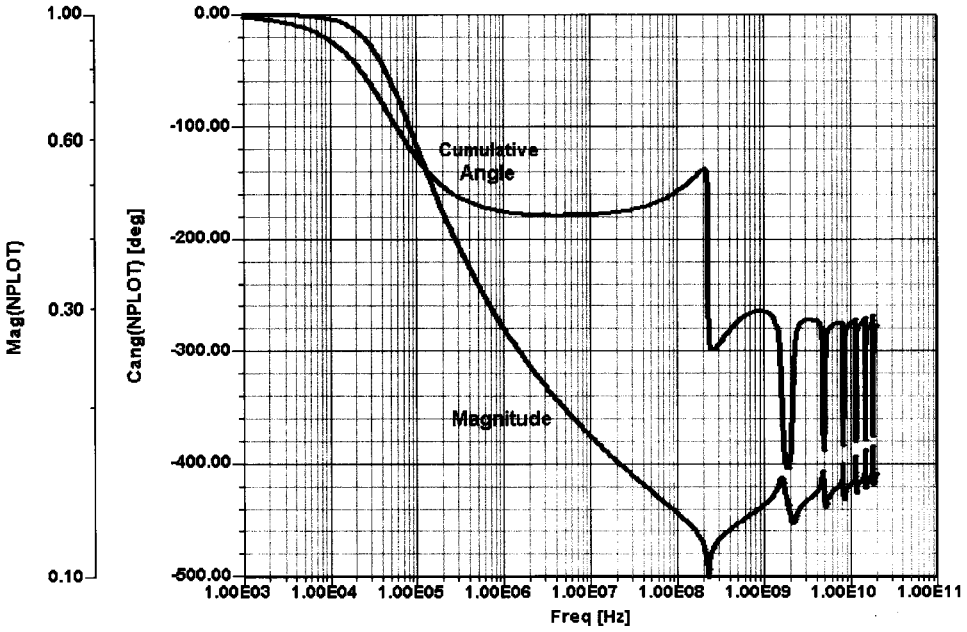

Figure 3-276 Magnitude–cumulative angle Nyquist plot of the unstable amplifier.

to a resonant frequency in a rigorous mathematical fashion, but it has been our experience that this frequency approximates the resonant frequency. To confirm the circuit's readiness for oscillation in the vicinity of this frequency, we evaluate it with Serenade's Oscillator Design Aid from 10 MHz to 1 GHz. The Design Aid finds an initial resonant frequency near 230.6 MHz—not too far from the –180° crossing frequency of 200 MHz of the Nyquist plot. Figure 3-277 shows this point.

Oscillator analysis finds a final oscillation frequency of 228.48 MHz. Figure 3-278 shows the resulting output spectrum at Port 2. At this point we decided to do a quick jump into Chapter 5 and take advantage of the CAD capability to predict the resulting phase noise, which is shown in Figure 3-279. As we compare this with other measured results, the approximately 228-MHz oscillator has a poor phase noise since the same phase noise is achievable at 1 GHz and higher. We remind the reader that this is an unwanted effect, but all of us who have built amplifiers will have experienced either low-frequency oscillations (motorboating) or very-high-frequency oscillation, sometimes caused by the components in the immediate vicinity of the transistor itself and found somewhere above 3 GHz. This case is really a demonstration case; a closer look reveals that the transconductance required for this condition is unrealistically high; but nonetheless it is a good example to demonstrate the stability issue.

Where Does Oscillation Begin? An interesting question to solve now is, "What gate bias voltage is needed for oscillation to begin?" Ansoft's Serenade Design Environment includes oscillator synchronous stability analysis, which uses a modification of the harmonic-balance technique to determine critical points, such as the voltage needed to "turn on" an oscillator. Mathematically, this is called a *Hopf bifurcation* because the behavior of

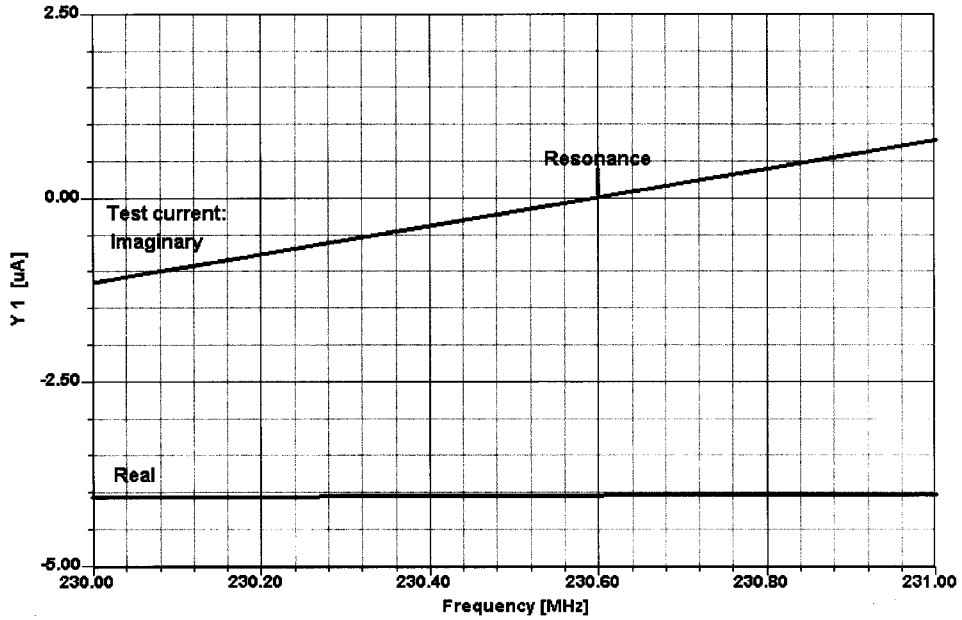

Figure 3-277 Graph from Serenade Oscillator Design Aid analysis of the amplifier. A resonant frequency is indicated where the imaginary part of the test current equals zero and the real part is negative.

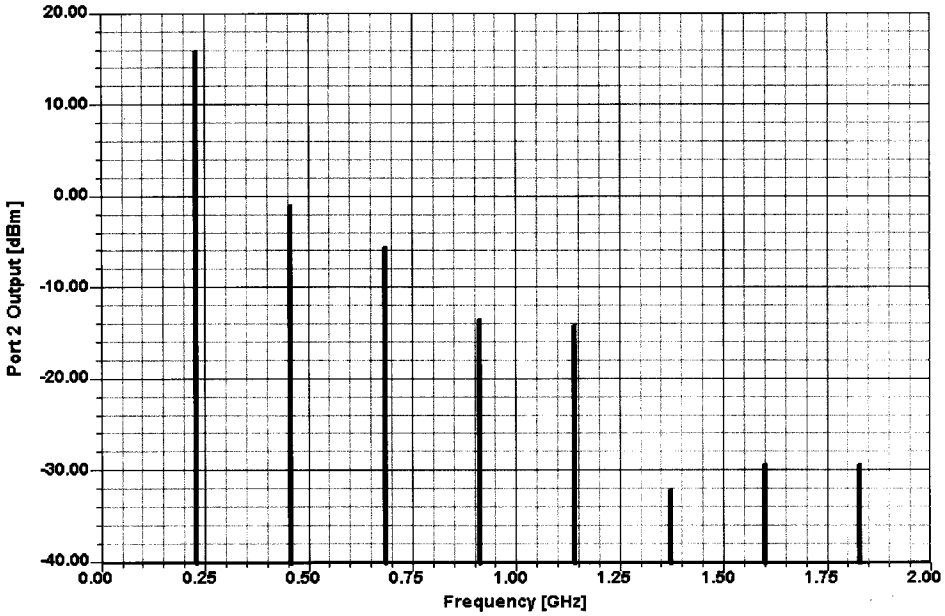

Figure 3-278 Predicted output spectrum of the unintended oscillator.

the circuit changes dramatically from a dc steady state to an oscillatory response. Figure 3-280 shows this effect by plotting output power versus gate bias. The turning point at –3.2 V (22 mW) is clearly visible, as is the bifurcation at –3.1 V (0 mW output).

Figure 3-280 can be interpreted as follows:

1. If the bias voltage is increased from, say, –4.0 V, the circuit will begin to oscillate at the bifurcation voltage and the output power will jump to 26 mW.
2. If the circuit is oscillating and the voltage is decreased from –2.0 V, the circuit will cease oscillating at the turning voltage of –3.2 V.
3. The branch between the turning point and the bifurcation point is unstable and cannot be realized in practice. This forms a hysteresis loop around points (–3.1 V, 0 mW), (–3.1 V, 26 mW), (–3.2 V, 22 mW), and (–3.2 V, 0 mW).

This amplifier stability analysis section is based on the stability analysis examples provided by Ansoft for the Serenade Design Environment.

An interesting example that combines both CAD and the feed-forward amplifier technique can be found in the Serenade Design Environment system simulator examples manual. This technique has been under evaluation for the last two years, but our feeling is that not enough measured data at frequencies above 500 MHz with reliable performance information have yet been made available in the literature. Along these lines, work done at Ansoft under a U.S. Air Force contract has provided very good insight into high-efficiency amplifiers at microwave frequencies [46].

3-13 POWER AMPLIFIER DATASHEETS AND MANUFACTURER-RECOMMENDED APPLICATIONS

Having discussed the various aspects of BJTs and FETs, we have decided to use MOS examples from Ericsson and Motorola, and a bipolar example from Motorola, as good examples to show the technology required to build high-power transistor amplifiers in this frequency range. In the following pages, we reproduce, with permission, datasheets for Ericsson's PTF 10009 FET and Motorola's MRF186 FET, followed by Motorola's MRF899 BJT.

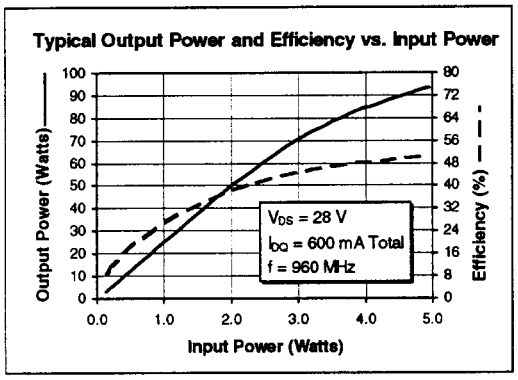
ERICSSON

PTF 10009
85 Watts, 1.0 GHz
LDMOS Field Effect Transistor

Description

The 10009 is a common source N-channel enhancement-mode lateral MOSFET intended for large signal amplifier applications to 1.0 GHz. It is rated at 85 watts minimum output power. Nitride surface passivation and gold metallization are used to ensure excellent device lifetime and reliability. 100% lot traceability is standard.

- Performance at 960 MHz, 28 Volts
  - Output Power = 85 Watts
  - Power Gain = 13.0 dB Typ
  - Efficiency = 50% Typ
- Gold Metallized
- Silicon Nitride Passivated
- Excellent Thermal Stability



Package 20230

RF Power Field-Effect Transistor
N–Channel Enhancement–Mode Lateral MOSFET

MRF186

120 W, 1.0 GHz
28 VOLTS
LATERAL N–CHANNEL
BROADBAND
RF POWER MOSFET

Designed for broadband commercial and industrial applications at frequencies from 800 MHz to 1.0 GHz. The high gain and broadband performance of this device makes it ideal for large–signal, common source amplifier applications in 28 volt base station equipment.

- Guaranteed Performance @ 960 MHz, 28 Volts
  Output Power — 120 Watts (PEP)
  Power Gain — 11 dB
  Efficiency — 30%
  Intermodulation Distortion — –28 dBc
- Excellent Thermal Stability
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 28 Vdc, 960 MHz, 120 Watts CW

The RF Line
NPN Silicon RF Power Transistor

MRF899

150 W, 900 MHz
RF POWER
TRANSISTOR
NPN SILICON

Designed for 26 Volt UHF large–signal, common emitter, Class AB linear amplifier applications in industrial and commercial FM/AM equipment operating in the range 800–960 MHz.

- Specified 26 Volt, 900 MHz Characteristics
  Output Power = 150 Watts (PEP)
  Minimum Gain = 8.0 dB @ 900 MHz, Class AB
  Minimum Efficiency = 35% @ 900 MHz, 150 Watts (PEP)
  Maximum Intermodulation Distortion –28 dBc @ 150 Watts (PEP)
- Characterized with Series Equivalent Large–Signal Parameters from 800 to 960 MHz
- Silicon Nitride Passivated
- 100% Tested for Load Mismatch Stress at all Phase Angles with 5:1 VSWR @ 26 Vdc, and Rated Output Power
- Gold Metallized, Emitter Ballasted for Long Life and Resistance to Metal Migration
- Circuit board photomaster available upon request by contacting RF Tactical Marketing in Phoenix, AZ.

MIXER DESIGN

4-1 INTRODUCTION

Radiocommunication requires that we shift a baseband information signal to a frequency or frequencies suitable for electromagnetic propagation to the desired destination. At the destination, we reverse this process, shifting the received radiofrequency (RF) signal back to baseband to allow the recovery of the information it contains. This frequency-shifting function is traditionally known as *mixing*; the stages that perform it are known as *mixers*. Any device that exhibits amplitude-nonlinear behavior can serve as a mixer, for, as we saw in Section 1-6-2, nonlinear distortion results in the production, from the signals present at the input of a device, of signals at new frequencies. Even a rusty screw or bolt on an antenna element can act as a mixer, producing unwanted IMD products that appear at the receiver input.

Although mixers are equally important in wireless transmission and reception, traditional mixer terminology favors the receiving case because mixing was first applied as such in receiving applications. Thus, the signal to be frequency shifted is applied to the mixer's RF port, and the frequency-shifting power or voltage [from a *local oscillator* (*LO*)] is applied to the mixer's LO port, resulting in two outputs at the mixer's *intermediate frequency* (*IF*) port. If the wanted IF is lower than the RF signal, the mixer is a *downconverter*; if the wanted IF is higher than the RF, the mixer is an *upconverter*. *Converter* may also be used as a term for a single stage that simultaneously acts as mixer and LO.

For a given RF signal, an ideal mixer with a perfect LO (i.e., an LO with no harmonics and no noise sidebands) would produce only two IF outputs: one at the frequency sum of the RF and LO, and another at the frequency difference between the RF and LO. Filtering can be used to select the desired IF product and reject the unwanted one, which is sometimes referred to as the *IF image*.

The simultaneous generation of LO + RF and LO – RF outputs results not from a departure of mixer performance from the ideal, but from the mathematics of mixing itself. Another unavoidable mixing artifact, the *RF image* response, also results from the mathematics of mixing rather than mixer nonideality. Just as a given RF/LO combination produces two IF outputs (LO + RF and LO – RF, the IF and IF image), the mixer will produce output at the

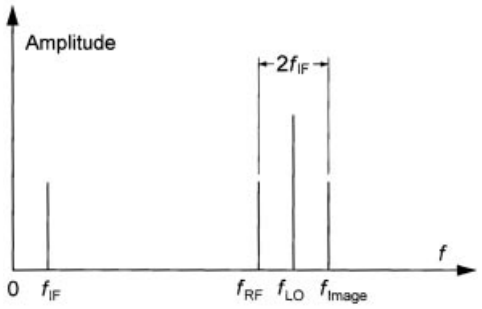

Figure 4-1 Relationship between a mixer's image and desired-signal responses. The image is $2f_{IF}$ away from the desired signal.

desired IF (LO + RF *or* LO – RF) in response to *two* possible RF inputs: one at LO + IF and another at LO (IF (Figure 4-1). The undesired response, the *RF image* (traditionally referred to merely as the *image*), is $2f_{IF}$ removed from the desired response. Even if no human-generated signals exist at the RF image frequency, reducing a mixer's RF image response can be important because noise at that frequency, including that produced by circuitry between the mixer and antenna, will still be mixed to the desired IF, degrading the signal-to-noise ratio. Filtering and phasing techniques can be used to reduce the RF or IF image responses: filtering if the image is sufficiently removed from the desired response that filtering will provide the necessary rejection; phasing if the desired and image responses are insufficiently spaced for filtering to work, as in the case of a double-conversion receiver in which signals at a high first IF (e.g., 50–70 MHz) must be converted to a very low first IF, such as 25 kHz.

The output of every real mixer includes a vast number of additional unwanted products, including noise, the fundamentals of the mixer's RF and LO signals and their harmonics, and the sums and differences of the RF and LO and their harmonics. Intermodulation distortion between multiple signals present at the RF port and IF output resulting from the mixing to IF of LO noise-sideband energy by strong adjacent signals (*reciprocal mixing*, Section 1-6-2) further complicate a mixer's output spectrum and may compromise system performance.

All mixers are *multipliers* in the sense that the various new outputs they produce can be described mathematically as the multiplicative products of their inputs. From an implementation standpoint, however, a given mixer circuit can be characterized as additive or multiplicative depending on how RF and LO signals are applied to it. Additive mixing occurs

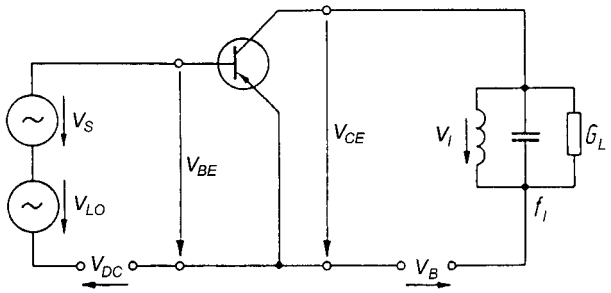

Figure 4-2 Additive mixing in a BJT [1].

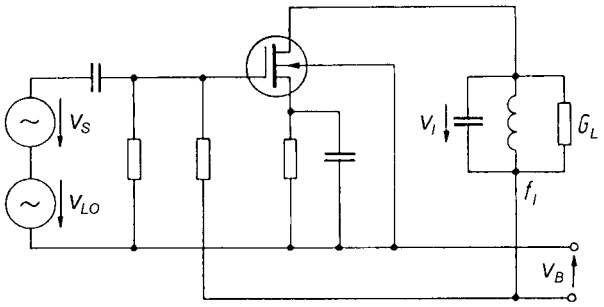

Figure 4-3 Additive mixing in a single-gate MOSFET [1].

when the RF and LO signals are applied to the same input port, as in Figures 4-2 and 4-3. Multiplicative mixing occurs when the RF and LO signals are applied to separate ports, as in Figure 4-4. As a rule, multiplicative mixers afford better isolation between their LO and RF ports than additive mixers, and this enhanced interport isolation is their principal merit. Multiplicative mixing does not in itself suppress unwanted products; the spurious response of a basic multiplicative mixer cell is poor unless it is used in a push–pull or quad configuration.

Let us now consider the basic theory of mixers. Mixing is achieved by the application of two signals to a nonlinear device. Depending on the particular device, the nonlinear characteristic may differ. However, it can generally be expressed in the form

$$I = K(V + v_1 + v_2)^n \tag{4-1}$$

The exponent n is not necessarily an integer, V may be a dc offset voltage, and the signal voltages v_1 and v_2 may be expressed as $v_1 = V_1 \sin(\omega_1 t)$ and $v_2 = V_2 \sin(\omega_2 t)$.

When $n = 2$, Eq. (4-1) may then be written as

$$I = K[V + V_1 \sin(\omega_1 t) + V_2 \sin(\omega_2 t)]^2 \tag{4-2}$$

This assumes the use of a device with a square-law characteristic. A different exponent will result in the generation of other mixing products, but this is not relevant for a basic understanding of the process. Expanding Eq. (4-2), we find

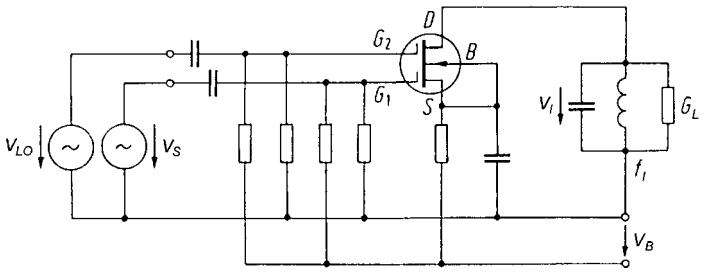

Figure 4-4 Multiplicative mixing in a dual-gate MOSFET. A dual-gate device is actually two single-gate devices in series [1].

$$I = K[V^2 + V_1^2 \sin^2(\omega_1 t) + V_2^2 \sin^2(\omega_2 t) + 2\,VV_1 \sin(\omega_1 t)$$

$$+ 2\,VV_2 \sin(\omega_2 t) + 2\,V_2V_1 \sin(\omega_2 t) \sin(\omega_1 t)] \tag{4-3}$$

The output comprises a direct current and a number of alternating current contributions. We are interested only in that portion of the current that generates the IF; so, if we neglect those terms that do not include both V_1 and V_2, we may write

$$I_{\text{IF}} = 2\,KV_1V_2 \sin(\omega_1 t) \sin(\omega_2 t)$$

$$I_{\text{IF}} = KV_2V_1\{\cos[(\omega_2 - \omega_1)t] - \cos[(\omega_2 + \omega_1)t]\} \tag{4-4}$$

This means that, at the output, we have the sum and difference signals available, and the one of interest may be selected by the IF filter.

4-2 PROPERTIES OF MIXERS

4-2-1 Conversion Gain/Loss

Even though a mixer works by means of the amplitude-nonlinear behavior in its device(s), we generally want (and expect) it to act as a linear frequency shifter. The degree to which the frequency-shifted signal is attenuated or amplified is an important mixer property. *Conversion gain* can be positive or negative; by convention, negative conversion gains are often stated as *conversion loss*.

In the case of a diode (passive) mixer , the insertion loss is calculated from the various loss components:

$$\text{Loss (dB)} = \text{Conversion loss} + \text{Transformer loss}$$

$$+ \text{Losses due to harmonic generation} + \text{Diode loss} \tag{4-5}$$

In the case of a double-balanced mixer (DBM), we must add the transformer losses (on both sides) and the diode losses as well as the mixer sideband conversion, which accounts, by definition, for 3 dB. Ideally, the mixer produces only one upper and one lower sideband, which results in the 3-dB loss compared to the input signal. Also, the input and output transformers add about 0.75 dB on each side, and of course there are the diode losses because of the series resistances of the diodes.

Figure 4-5 shows the equivalent circuit of a diode. It consists of a series (loss) resistor R_S and a time-variable electronic resistor, typically called the *diffusion resistance*, R_D, which equals 26 mV/I_D, and a capacitance C_D shunting R_D. C_D can be found from

$$C_D = \frac{W^2}{2D}\frac{I_D}{V_T} \tag{4-6}$$

where D is the diffusion constant, a material-dependent value, and W is the physical width. The average value for R_D is somewhere between the calculated value of 26 mV/I_D and some

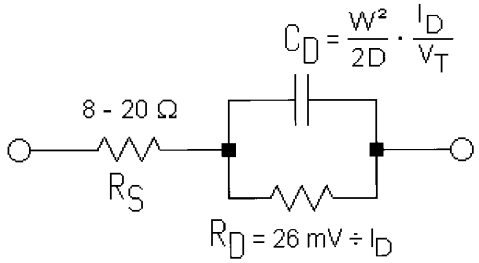

Figure 4-5 Equivalent circuit of a mixer diode.

leakage current, simply because it is generated by a rectification mechanism, which turns the LO power into an RF current and then into a combination of dc and RF currents.

We can calculate the diode loss according to

$$\text{Diode loss (db)} = \log 10\left(\frac{50 + (2 \times R_S)}{50}\right) \tag{4-7}$$

Assuming that $R_S = 8\ \Omega$, the diode loss for a diode-ring mixer is

$$\text{Diode loss (db)} = \log 10\left(\frac{50 + (2 \times 8)}{50}\right) = 0.5\ \text{dB} \tag{4-8}$$

From Eq. (4-5), the insertion loss for this mixer is therefore

$$\begin{aligned}\text{Loss (dB)} &= 3\ \text{dB (Conversion loss)} + 1.5\ \text{dB (Transformer loss)} \\ &\quad + 1\ \text{dB (Losses from harmonic generation)} + 0.5\ \text{dB (Diode loss)} \\ &= 6\ \text{dB}\end{aligned} \tag{4-9}$$

This assumes mixing at the fundamental frequency. Sometimes the diode loss resistor R_S is as high as 25 Ω per arm (as in a MOSFET switch), or 50 Ω total. This now results in

$$\text{Loss (dB)} = 3\ \text{dB} + 1.5\ \text{dB} + 1\ \text{dB} + 3\ \text{dB} = 8.5\ \text{dB} \quad \text{(Insertion loss)} \tag{4-10}$$

Since the value of R_S is partially determined by the threshold voltage of the diode and the diode diffusion resistance, R_D, a wide range of values can be noticed for different drive levels and mixer topologies. Figure 4-5 shows a shunt capacitance C_D, the so-called *diode diffusion capacitance*. When the diode is conducting, the influence of this nonlinearity is frequency dependent, which adds to the insertion loss. In this discussion we have not considered its frequency dependency. At wireless frequencies, modern Schottky diodes, also frequently called *hot-carrier* diodes, are operated far from their cutoff frequency, resulting in less than 1 dB of additional losses. There are also mixers with special circuitry to terminate the IF image. This is done with a diplexer circuit or equivalent circuitry. This makes insertion loss values as low as 4 dB possible; however, the large-signal condition or intercept point suffers.

4-2-2 Noise Figure

Like any network, a mixer contributes noise to the signals that it frequency-shifts. The degree to which a mixer's noise degrades the signal-to-noise ratio (see Section 1-7-1) of the signals it frequency-shifts is evaluated in terms of noise factor and noise figure as discussed in a subsection of Section 1-7-1 entitled "Noise Figure of Cascaded Networks."

For a long time, the literature has stated that the noise figure of a passive mixer, which is pretty much independent of its circuit arrangement, is equal to the mixer's insertion loss. But this neglects the influence of the white-noise contribution of the mixer's diode(s). This is ironic, considering that RF noise generators were long based on thermionic diodes operated in saturation (the 5722 noise diode was a popular type, as in the Rohde & Schwarz SKTU). Such a diode's noise power output can readily be determined from its saturation current. On the other hand, all Schottky diodes, while conducting, generate white noise that follows the same principle as above. This fact has been recognized by only a few companies that make modern noise-measurement equipment. Modern noise-measurement devices measure the noise figure of a system by a "hot and cold" technique, an approach based on knowledge of the absolute noise energy emitted under hot conditions (conductance). This method has the advantage that it can be used up to several tens of gigahertz, while the old vacuum-tube-based noise generators ran out of steam at around 1 GHz due to the inability to match the tube to the 50-Ω termination. This was typically accomplished by connecting a 50-Ω resistor between anode and ground (without dc connection), followed by a low-pass filter, which would match the tube capacitance and other parasitics to the required termination of 50 Ω, purely resistive.

In reality, we can take the loss calculation from above and add the Schottky noise generated by the diodes as they are driven by the local oscillator.

If a Schottky diode is used as a noise generator in the conductive mode, it generates a continuous frequency spectrum, possibly up to several gigahertz. There is a mathematical relationship between the noise power spectrum emitted by the diode and the time-averaged current of this diode, which generates the noise. If the noise source impedance is set (typically 50 Ω), the available noise power can be calculated according to

$$I_R = \sqrt{2e \times I_s \times \Delta f} \tag{4-11}$$

where $e = 1.6 \times 10^{-19}$ coulombs
I_s = saturation current of the diode
Δf = effective noise bandwidth

For $S_{11} = 0$ or proper termination of this circuit ($R_G = R_{term}$),

$$P_R = \left(\frac{I_R}{2}\right)^2 \times R_i$$

$$= \frac{e}{2} \times I_s \times \Delta f \times R_i \tag{4-12}$$

Calculated at a bandwidth of 1 Hz,

$$\frac{P_R}{\Delta f} = \frac{e}{2} \times I_s \times R_i \tag{4-13}$$

If

$$\frac{P_R}{\Delta f} = kT_0 \times F \tag{4-14}$$

the noise factor becomes

$$F = \frac{e \times I_s \times R_i}{2kT_0} \tag{4-15}$$

If the values for e and kT_0 are inserted,

$$F = 20 \times I_D \times \frac{26 \text{ mV}}{I_D} + \frac{R_S + R_G}{2R_G} \tag{4-16}$$

Example. Assume the passive mixer mentioned above with its 6-dB insertion loss is considered and a dc current of 15 mA results as a function of the LO drive. Since I_D gets canceled, the noise factor (F) of the diode portion equals

$$F = 20 \times I_D \times \frac{26 \text{ mV}}{I_d} + \frac{R_S + R_G}{2R_G}$$

$$= 0.52 + 0.58$$

$$= 1.1 \tag{4-17}$$

The noise figure, NF, is 10 log F, or 0.413 dB. Now this number and the insertion loss must be added. The resulting noise figure would be 6.413 dB. This is consistent with published measurement data.

Exact Mathematical Nonlinear Approach. The exact noise factor of a real mixer is computed by the formula

$$F = \frac{N_0(\omega_{\text{IF}}) + kT_0}{K_B T_0 G_{Tc}(\omega_{\text{RF}})} \tag{4-18}$$

where $N_0(\omega_{\text{IF}})$ = total noise power (per unit bandwidth) delivered to the IF load at intermediate frequency
K_B = Boltzmann's constant
T_0 = reference temperature (290 or 300 K is commonly used)
$G_{Tc}(\omega_{\text{RF}})$ = transducer conversion gain from ω_{RF} to ω_{IF}.

Let us now further elaborate on Eq. (4-18). We may write

$$N_0(\omega_{\text{IF}}) = N_S(\omega_{\text{IF}}) + N_{\text{INT}}(\omega_{\text{IF}}) + N_L(\omega_{\text{IF}}) + kT_0 \tag{4-19}$$

where N_S is noise generated by the RF source resistance and transferred to the IF load through frequency conversion, N_{INT} is noise generated internally to the mixer, and N_L is noise generated by the IF termination. If the source resistance is held at temperature T_0, N_S will basically originate from noise generated at the RF and image frequencies, which are transferred to the IF with approximately the same conversion gain, plus a relatively small contribution transferred from other sidebands with a smaller conversion gain. We may then write synthetically

$$N_S(\omega_{\text{IF}}) = 2aK_BT_0G_{Tc}(\omega_{\text{RF}}) \tag{4-20}$$

where a is a coefficient slightly larger than 1. $N_{\text{INT}}(\omega_{\text{RF}})$ is generated by transformer losses, by the diode Schottky noise, and by the diode resistive parasitics, and, in principle, it may take on any value; in particular, it may be zero if both the transformers and the diodes are ideal (i.e., if the latter are pure nonlinear resistors). As for $N_L(\omega_{\text{IF}})$, by Nyquist's theorem the IF load resistor R_L may be described as a noiseless resistor in series with a noise voltage source whose mean-square voltage (per unit bandwidth) is

$$|V_L|^2 = 4K_BT_LR_L \tag{4-21}$$

where T_L is the IF termination temperature. If the IF load is driven by a source with an output impedance $Z_{\text{out}}(\omega_{\text{IF}})$, the noise power actually delivered to the load will obviously be

$$N_{\text{out}} = \frac{4K_BT_LR_L^2}{|Z_{\text{out}}(\omega_{\text{IF}}) + R_L|^2} \tag{4-22}$$

In addition to N_{out}, the thermal noise originating from the IF termination delivered to the IF load at ω_{IF} will also include contributions from other sidebands that are backconverted by the mixer nonlinearities with a relatively small conversion gain. Thus, we may write

$$N_L(\omega_{\text{IF}}) = \frac{4bK_BT_LR_L^2}{|Z_{\text{out}}(\omega_{\text{IF}}) + R_L|^2} \tag{4-23}$$

where b is slightly larger than 1. If we now introduce the mixer conversion loss, namely,

$$L_C = \frac{1}{G_{Tc}(\omega_{\text{RF}})} \tag{4-24}$$

and combine Eq. (4-18) with Eqs. (4-19), (4-20), and (4-23), we finally get the noise factor expression:

$$F = 2a + \frac{N_{\text{INT}}(\omega_{\text{IF}}) + kT}{K_BT_0}L_C + \frac{4bT_LR_L^2}{T_0|Z_{\text{out}}(\omega_{\text{IF}}) + R_L|^2}L_C \tag{4-25}$$

In the normal region of operation of the mixer (sufficient LO drive) we may assume

Table 4-1 Noise figure and conversion gain versus LO power for a diode DBM

LO Power (dBm)	NF (dB)	Conversion Gain (dB)
–10.0	45.3486	–45.1993
–8.0	32.7714	–32.5264
–6.0	19.8529	–19.2862
–4.0	12.1154	–11.3228
–2.0	8.85188	–8.05585
0.0	7.26969	–6.51561
2.0	6.42344	–5.69211
4.0	5.85357	–5.15404
6.0	5.50914	–4.84439
8.0	5.31796	–4.66871
10.0	5.19081	–4.54960
12.0	5.08660	–4.45887
14.0	4.99530	–4.38806
16.0	4.91716	–4.33322
18.0	4.85920	–4.29407
20.0	4.82031	–4.26763

$$Z_{\text{out}}(\omega_{\text{IF}})R_L \tag{4-26}$$

so that Eq. (4-25) becomes

$$F = 2a + \frac{N_{\text{INT}}(\omega_{\text{IF}}) + kT}{K_B T_0} L_C + \frac{bT_L}{T_0} L_C \tag{4-27}$$

Multiplying $\log_{10} F$ by 10 gives us the exact mixer noise figure in dB.

The method just discussed is the basis for the far noise calculation for oscillators as mentioned in Chapter 5, in which it is referred to as conversion noise. This includes the AM-to-PM conversion noise.

Table 4-1 shows how the noise figure and conversion gain vary with LO power for a generic diode DBM (Figure 4-6). "Starving" a diode mixer by decreasing its LO drive rapidly degrades its performance in all respects.

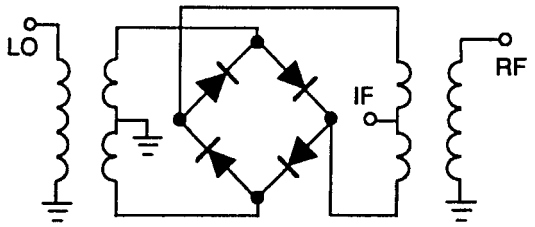

Figure 4-6 Generic diode DBM.

SSB Versus DSB Noise Figure. In radiocommunication, we typically use mixers as "single-sideband" devices; that is, we are interested in only one of the two possible RF inputs ($f_{LO} + f_{IF}$ or $f_{LO} - f_{IF}$) that produce output at the desired IF. The unused input is the *RF image* or simply *image*. A mixer's RF image response can be important even if no human-generated signals are present at f_{image} because noise there, including that produced by the mixer's RF-port termination, will be converted to the IF, possibly compromising the system's signal-to-noise ratio. As a result of this and the IEEE definition of noise figure [2], which, for a mixer, considers only the noise associated with a system's principal frequency transformation, some controversy exists about the definition and measurement of mixer noise figure. IEEE's NF definition for mixers assumes *no* noise contribution at f_{image}, not even from the mixer's RF-port termination at that frequency; yet, by convention (and out of necessity, since an absolutely noiseless $T = 0\,f_{image}$ termination is unavailable on the average test bench), the noise figures we measure always include *some* noise at f_{image}, even if, as a result of filtering, it arises only from the mixer's RF-port termination. The NF measurements and simulations presented in this book reflect this conventional SSB NF scenario. Stephen Maas [3] provides in-depth material on these issues, including the importance of double-sideband NF for some systems, and the limitations of NF as a figure of merit.

4-2-3 Linearity

The 1-dB Compression Point. Like other networks, a mixer is amplitude-nonlinear above a certain input level; above this point, the output level fails to track input-level changes proportionally. This figure of merit, P_{-1dB}, identifies the single-tone input-signal level at which the output of the mixer has fallen 1 dB below the expected output level. The 1-dB compression point in a conventional double-balanced diode mixer is approximately 6 dB below the LO power. For lower distortion mixers, it is usually 3 dB below the LO power.

The 1-dB Desensitization Point. This specification is another figure of merit similar to the 1-dB compression point. However, the 1-dB desensitization point refers to the level of an interfering (undesired) input signal that causes a 1-dB decrease in nominal conversion gain for the desired signal. For a diode-ring DBM, the 1-dB desensitization point is usually 2–3 dB below the 1-dB compression point.

Dynamic Range. The dynamic range of any RF/wireless system can be defined as the difference between the 1-dB compression point and the minimum discernible signal (MDS). These two points are specified in units of power (dBm), giving dynamic range in dB. When the RF input level approaches the 1-dB compression point, harmonic and intermodulation products begin to interfere with the system performance. High dynamic range is obviously desirable, but cost, power consumption, system complexity, and reliability must also be considered.

Harmonic Intermodulation Products (HIPs). These are spurious products that are harmonically related to the f_{LO} and f_{RF} input signals.

$$\text{HIP} = Mf_{LO} + Nf_{RF} \tag{4-28}$$

Table 4-2 Typical spurious responses of high-level double-balanced mixer (decibels below $f_{LO} \pm f_{RF}$ response)

RF Input Signal Harmonics		f_{LO}	$2f_{LO}$	$3f_{LO}$	$4f_{LO}$	$5f_{LO}$	$6f_{LO}$	$7f_{LO}$	$8f_{LO}$
$8f_{RF}$	100	100	100	100	100	100	100	100	100
$7f_{RF}$	100	97	102	95	100	100	100	90	100
$6f_{RF}$	100	92	97	95	100	100	95	100	100
$5f_{RF}$	90	84	86	72	92	70	95	70	92
$4f_{RF}$	90	84	97	86	97	90	100	90	92
$3f_{RF}$	75	63	66	72	72	58	86	58	80
$2f_{RF}$	70	72	72	70	82	62	75	75	100
f_{RF}	60	0	35	15	37	37	45	40	50
		60	60	70	72	72	62	70	70

Table 4-2 shows relative harmonic intermodulation product levels for a high-level diode DBM.

Intermodulation Distortion (IMD). Nonlinearities in the mixer devices give rise to intermodulation distortion products whenever two or more signals are applied to the mixer's RF port. Testing this behavior with two (usually closely spaced) input signals of equal magnitude can return several figures of merit depending on how the results are interpreted. A mixer's third-order output intercept point ($IP_{3,out}$) is defined as the output power level where the spurious signals generated by $(2f_{RF1} \pm f_{RF2}) \pm f_{LO}$ and $(f_{RF1} \pm 2f_{RF2}) \pm f_{LO}$ are equal in amplitude to the desired output signal as shown in Figure 4-7.

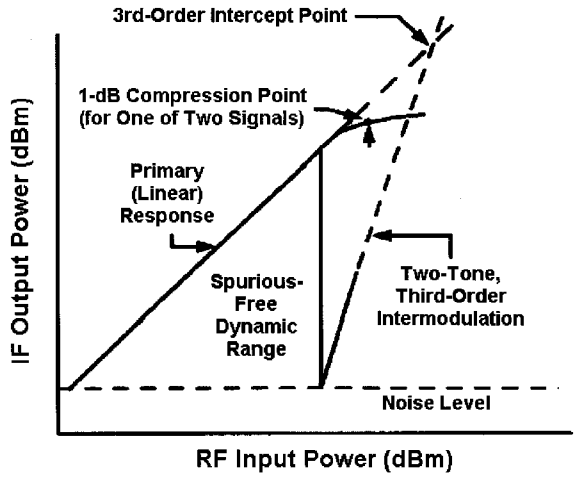

Figure 4-7 Mixer linearity evaluation, including compression and two-tone IMD dynamic range. P_{-1dB} for a single tone cannot be read directly from this graph because the values shown are the result of two-equal-tone drive.

The third-order input intercept point, $IP_{3,in}$—IP_3 referred to the input level—is of particularly useful value and is the most commonly used mixer IMD figure of merit. $IP_{3,in}$ can be calculated according to

$$IP_{n,in} = IMR \div (n - 1) + \text{Input power (dBm)} \tag{4-29}$$

where *IMR* is the intermodulation ratio (the difference in dB between the desired output and the spurious signal), and n is the IM order—in this case, 3. In a conventional diode double-balanced mixer, $IP_{3,in}$ is approximately 14 dB above the single-tone 1-dB compression point (P_{-1dB})—approximately 8 dB greater than the local oscillator power. As will be seen later, this does not apply to feedback-active mixers. They have their own agenda: Above a particular input level, their IMD products increase almost exponentially.

Although designers are usually more concerned with odd-order IM performance, second-order IM can be important in wideband systems (systems that operate over a 2:1 or greater bandwidth) as discussed in Section 1-7-2.

4-2-4 LO Drive Level

A mixer's specifications are usually guaranteed at a particular LO drive level, usually specified as a dBm value that may be qualified with a tolerance. Insufficient LO drive degrades mixer performance; excessive LO drive degrades performance and may damage mixer devices. Commercially available diode mixers are often classified by LO drive level; for example, a "Level 17" mixer requires 17 dBm of LO drive.

4-2-5 Interport Isolation

In a mixer, isolation is defined as the attenuation in dB between a signal input at any port and its level as measured at any other port. High isolation numbers are desirable. Figure 4-8 shows LO-to-IF and LO-to-RF isolation versus frequency for a triple-balanced diode DBM. Isolation is dependent mainly on transformer and physical symmetry and device balance, but the level of signals applied to the mixer also plays a role, as shown in Figure 4-9.

4-2-6 Port VSWR

The load presented by a mixer's ports to the outside world can be of critical importance to a designer. For example, high LO-port VSWR may result in inefficient use of available LO power, resulting in LO starvation (underdrive) that degrades the mixer's performance. Figure 4-10 shows LO-port VSWR versus frequency for a high-level diode DBM with two values of LO power. Like interport isolation, port VSWR can vary with the level of the signal applied.

4-2-7 dc Offset

Isolation between ports plays a major role in reducing dc offset in a mixer. Like isolation, dc offset is a measure of the imbalance of the mixer. In phase-detector and phase-modulator applications, dc offset is a critical parameter.

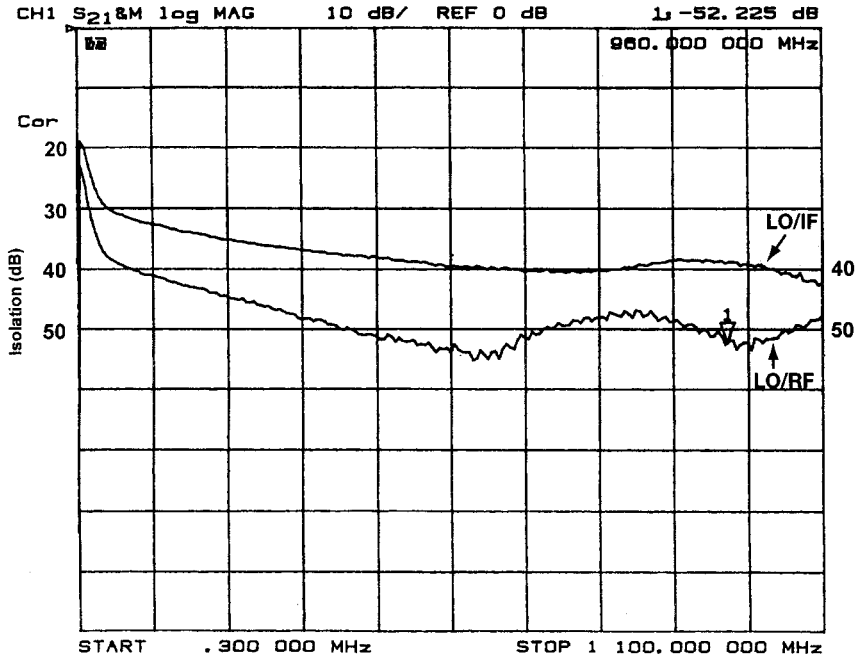

Figure 4-8 LO–IF and LO–RF isolation versus frequency for a high-level triple-balanced diode mixer. The periodic roughness of the traces is a measurement-system artifact, proving that even sophisticated FFT-based instruments are not perfect.

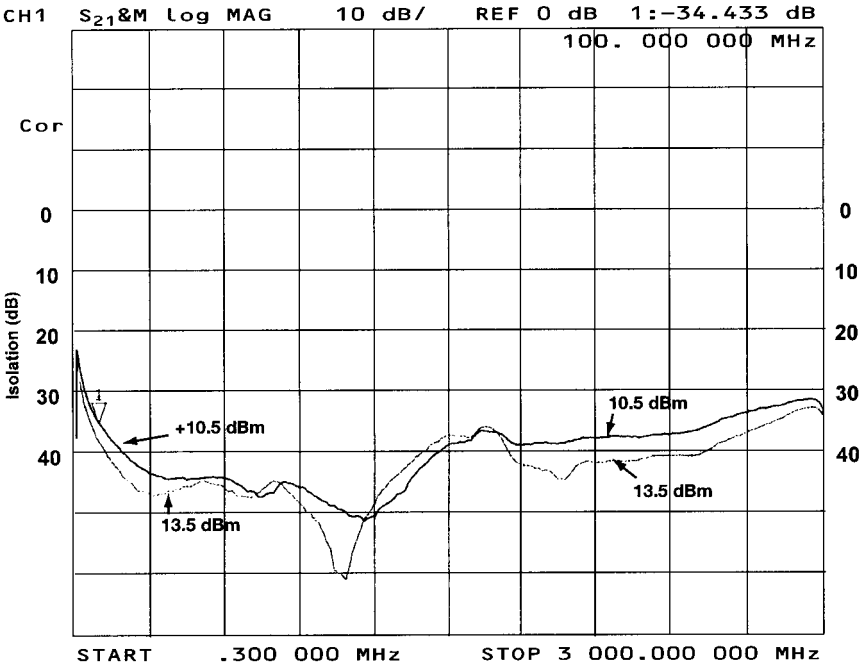

Figure 4-9 LO–IF isolation versus frequency and LO drive level for a high-level diode DBM.

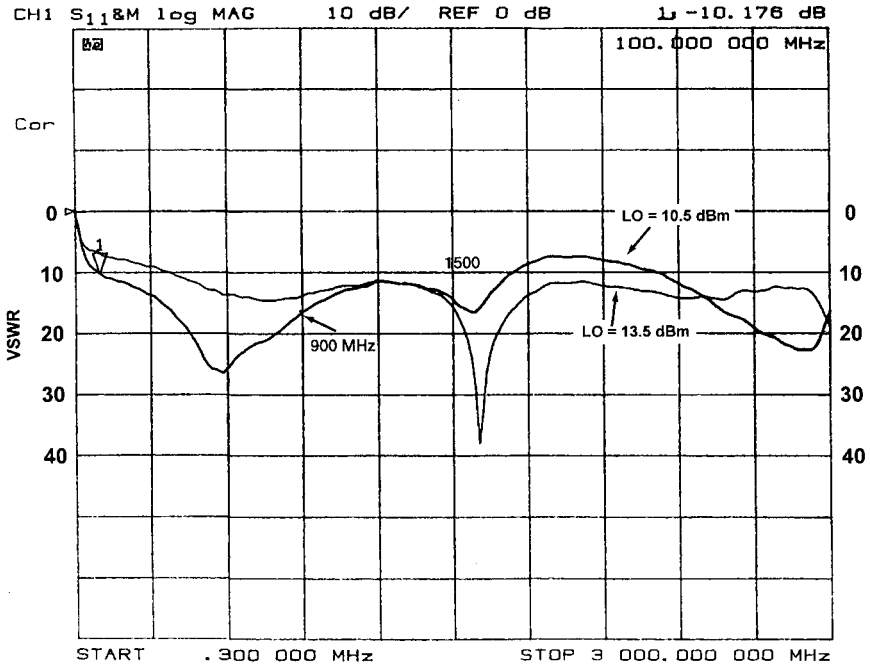

Figure 4-10 LO-port VSWR versus frequency for a high-level diode DBM.

4-2-8 dc Polarity

Unless otherwise specified, mixers with dc output are designed to have negative polarity when RF and LO signals are of equal phase.

4-2-9 Power Consumption

Circuit power consumption is always important, but in battery-powered wireless designs it is *critical.* Mixer choice may be significant in determining a system's power consumption, sometimes in ways that seem paradoxical at first glance. For instance, a passive mixer might seem to be a power-smart choice because it consumes *no* power—until we factor in the power consumption of the circuitry needed to provide the (often considerable) LO power a passive mixer requires. If a mixer requires a broadband resistive termination that will be provided by a postmixer amplifier operating at a high standing current, the power consumption of the amplifier stage must be considered as well. Evaluating the suitability of a given mixer type to a task therefore requires a grasp of its ecology as well as its specifications.

4-3 DIODE MIXERS

Passive mixers based on diode switches are common in base-station applications, where their high dynamic range and 50-Ω port impedances overcome objections to their inherent conversion loss, unsuitability to integration, and relatively high LO-power requirement. As we'll discuss later, FET-based passive mixers are overcoming some of these limitations in portable/mobile wireless applications.

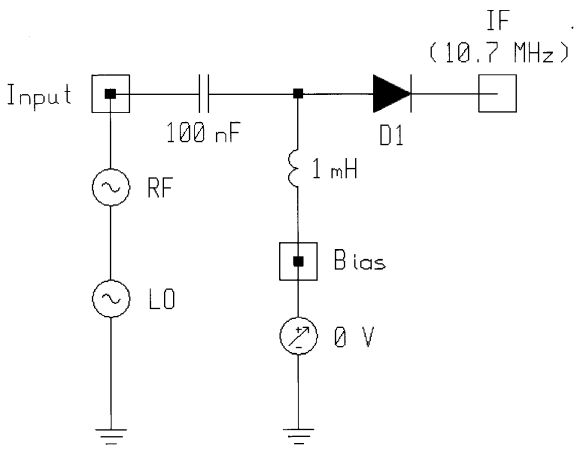

Figure 4-11 Schematic of the single-diode mixer. The circuit's 50-Ω output termination serves as the diode's dc return, as well as completing the circuit for RF, LO, and IF.

4-3-1 Single-Diode Mixer

Figure 4-11 shows the schematic of a simplistic single-diode mixer. The LO and RF signals are applied in series to the diode, with no effort made to match the sources to the diode or isolate the sources from each other. The LO and RF signals are both present in the diode simultaneously, so the mixing performed is additive. The LO signal switches the diode on and off, gating the RF signal to the circuit's output at the LO frequency. In this simple circuit, the output port's 50-Ω resistance serves as the diode's ac load and dc return. Because we want the diode to operate as a linear switch with respect to the RF signal, the diode should turn on hard and turn off as completely as possible, and the LO, not the RF source, should switch the diode on and off. The upper frequency limit of the circuit will depend on how rapidly the diode can switch between the on and off states. The LO can be only so strong before the diode's dissipation limits are exceeded; the RF source can be only so strong relative to the LO before it begins to play a role in switching the diode on and off. The LO must therefore be considerably stronger than the RF source—20 dB or more for low-distortion applications.

Figure 4-12 shows how the single-diode mixer's conversion gain and noise figure vary with applied LO power. Figure 4-13 shows the mixer's output spectrum.

Tables 4-3, 4-4, and 4-5 present sample data on diodes suitable for mixer service. The manufacturer's full datasheet on the Siemens BAT14-099 follows.

The simple single-diode-mixer circuit shown in Figure 4-11 is intended only as an illustration of the basic behavior of diode mixer behavior. A practical single-diode mixer would include filtering at its RF, LO, and IF ports—RF filtering for image rejection, reduced LO radiation and optimum matching of the RF source to the diode; LO filtering to keep RF out of the LO and optimally match the LO to the diode; and IF filtering to optimally match the diode to its IF (and IF image) load, preferably while providing some rejection of the mixer's unwanted outputs, the strongest (and most potentially troublesome) of which is the LO signal. Detail on the design of single-diode mixers can be found in Zinke and Brunswig [4].

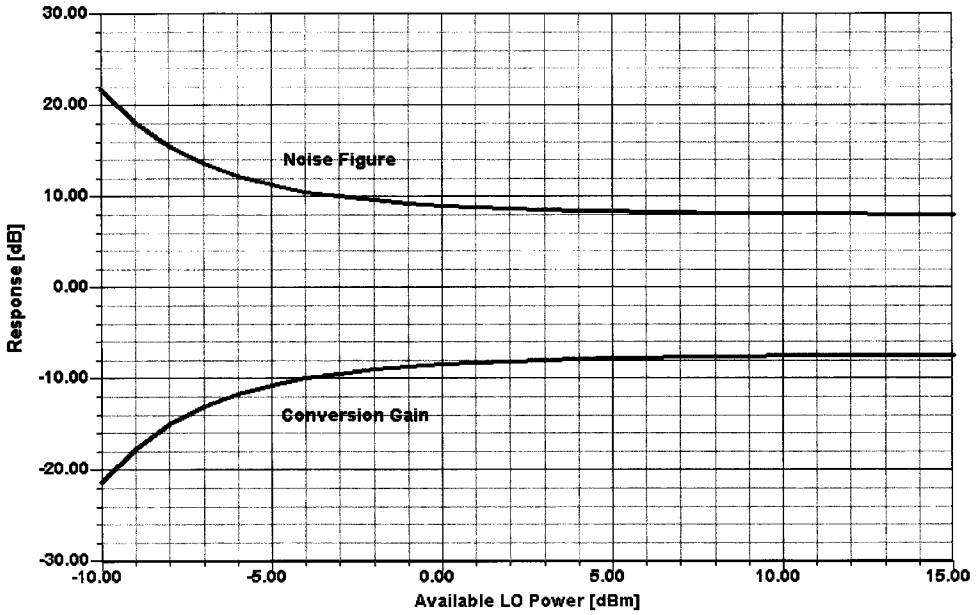

Figure 4-12 Conversion gain and noise figure versus LO power for the single-diode mixer. The values reported are worse than those predicted by theory because RF, LO, and IF matching has not been attempted. In this analysis, LO = 310.7 MHz (–10 to 25 dBm), RF = 300 MHz (–50 dBm), and IF = 10.7 MHz.

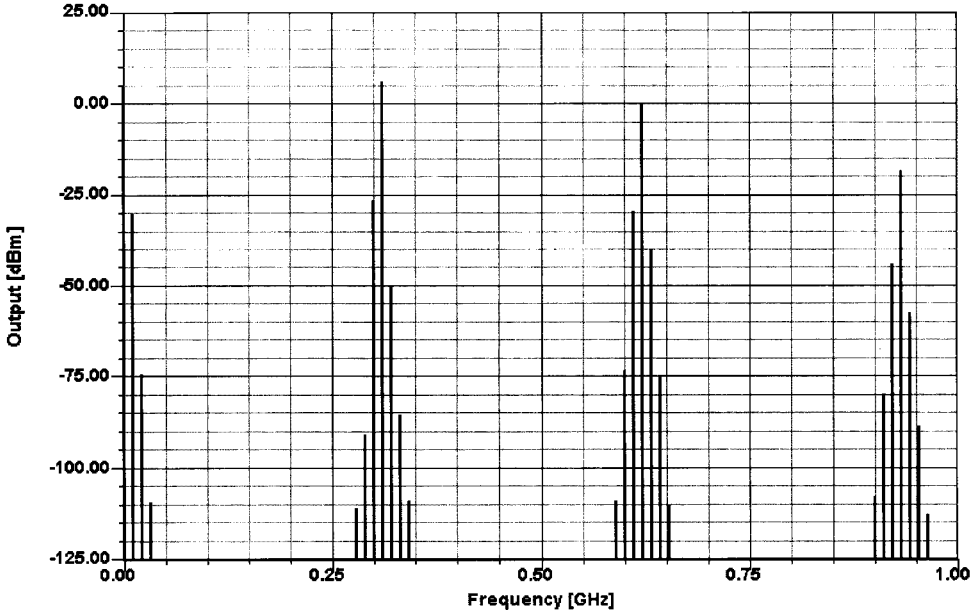

Figure 4-13 Output spectrum of the single-diode mixer. Three LO harmonics and 3 LO sidebands were used in this analysis. In this analysis, LO = 310.7 MHz (13 dBm), RF = 300 MHz (–20 dBm), and IF = 10.7 MHz.

4-3-2 Single-Balanced Mixer

Figure 4-14 shows the schematic of a two-diode, *single-balanced* mixer (SBM). Unlike the single-diode mixer, it performs multiplicative mixing because its RF and LO signals are applied to different ports. In this more commonly seen two-diode mixer configuration, a balanced transformer drives the diodes out of phase for the LO and in phase for signals present at the RF port. Figure 4-15 shows how this mixer's conversion gain and noise figure vary with applied LO power. Figure 4-16 shows how the mixer's conversion gain and noise figure vary with frequency for a constant LO power.

The two-diode mixer is used mostly in the frequency range above 1 GHz in a manner akin to a phase discriminator, using step-recovery diodes in the LO feed for enhanced harmonic mixing. Such mixers are mainly used in medium-cost spectrum analyzers or microwave receivers up to several tens of gigahertz, with the necessary transformers and baluns printed on the circuit board. With perfectly matched diodes and perfect transformer and constructional symmetry, no LO energy arrives at the IF and RF ports, and there is only slight attenuation between the RF and IF ports. Both building and computer modeling such a mixer are impossible: building, because perfectly matched diodes and perfect transformer and constructional symmetry cannot be achieved in practice; computer modeling, because floating-point mathematics runs out of gas in handling the infinite amplitude spread involved in calculating the perfect cancellation of the LO signal as it travels to the RF and IF ports. That said, Figure 4-17 compares the mixer's *quasi*-ideal port-to-port isolation (matched diodes, a perfect transformer, no stray inductances and capacitances, and a 10-MΩ resistors

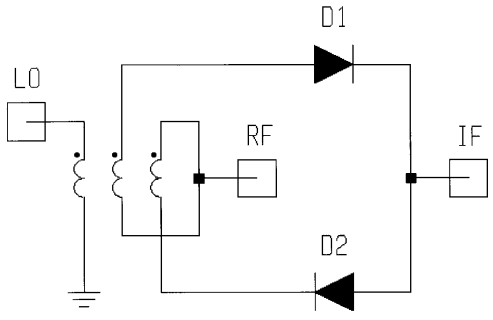

Figure 4-14 Schematic of the two-diode (also known as *single-balanced*) mixer.

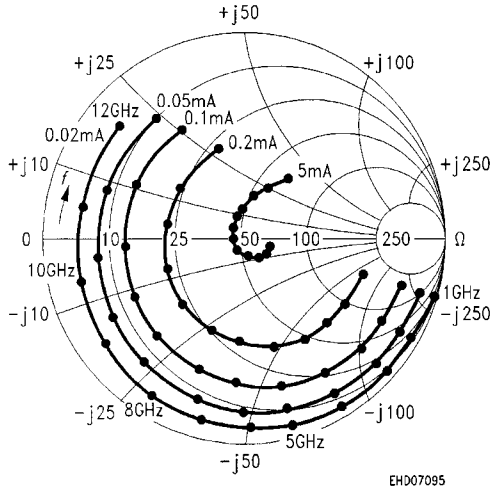

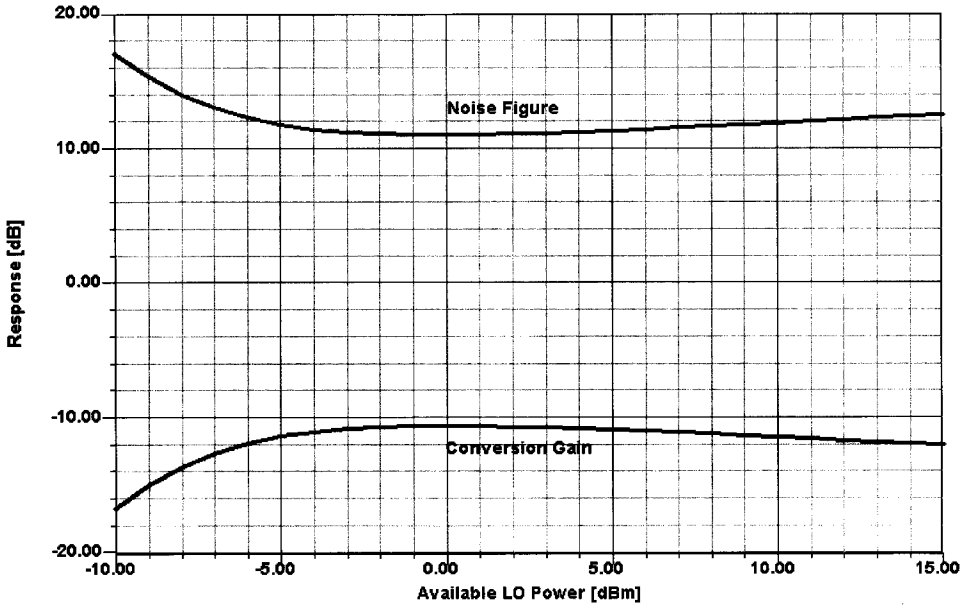

Figure 4-15 How the nonideal mixer's conversion gain and noise figure vary with available LO power. In this analysis, LO = 500 MHz (13 dBm), RF = 500.455 MHz (–20 dBm), and IF = 455 kHz.

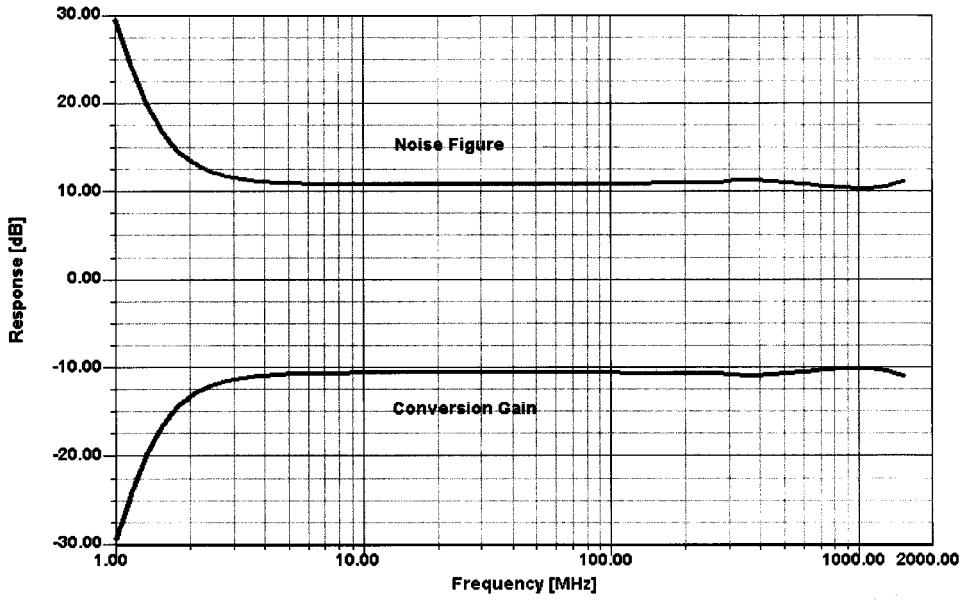

Figure 4-16 How the nonideal two-diode mixer's conversion gain and noise figure vary with frequency for a constant LO power. In this analysis, LO = 1–1500 MHz (2 dBm), RF = 1.455–1500.455 MHz (–40 dBm), and IF = 455 kHz.

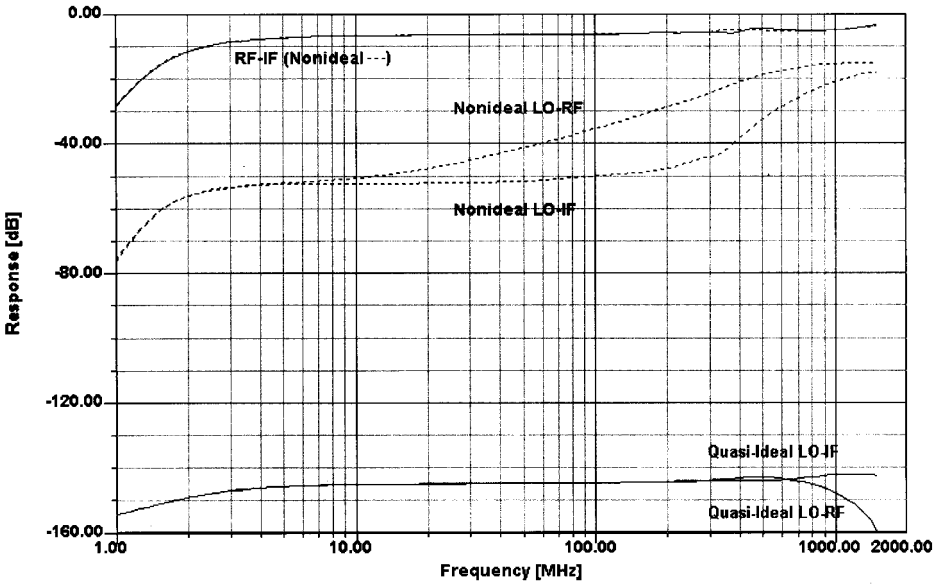

Figure 4-17 Port-to-port isolation of the quasi-ideal (identical diodes and no stray capacitance) and nonideal (slightly mismatched diodes and 0.5 pF of stray capacitance between the upper terminal of the middle transformer winding and ground) two-diode mixer. In this analysis, LO = 1–1500 MHz (2 dBm), RF = 1.455–1500.455 MHz (–40 dBm), and IF = 455 kHz.

connected from port to port) and nonideal port-to-port isolation (slightly mismatched diodes and 0.5 pF between the upper terminal of the middle winding and ground).

Figures 4-18a and 4-18b show the mixer's output spectrum for the quasi-ideal and nonideal cases, respectively.

Subharmonically Pumped Single-Balanced Mixer. Figure 4-19 shows a single-balanced mixer with a difference: antiparallel diode pairs take the place of single diodes, the RF and IF are buffered from each other only by filtering, and the LO is applied at one-half the frequency necessary to provide the desired frequency conversion. The RF-to-IF isolation is limited to that provided by the series input and output filtering, but the LO-to-IF isolation is higher at f_{LO} and much higher at $2f_{LO}$ than that achievable with a DBM with the LO signal at $2f_{LO}$(Figure 4-20). Although the example shown is for an up converting HF receiver, this technique finds application well into the microwave range as the basis for I/Q modulators, in which carrier leakage must be reduced to a level difficult to achieve with conventional DBMs [5–10].

4-3-3 Diode-Ring Mixer

Adding two more diodes and another transformer to the single-balanced mixer results in a double-balanced mixer (DBM) as shown in Figure 4-21. A DBM's frequency response is largely determined by the frequency response of its transformers, which act as transmission lines. The low-frequency limit is determined by the inductance of the transformer windings, the reactance of which, at the lowest frequency of interest, should be at least four times the impedance at which the transformer operates. The upper frequency limit is determined

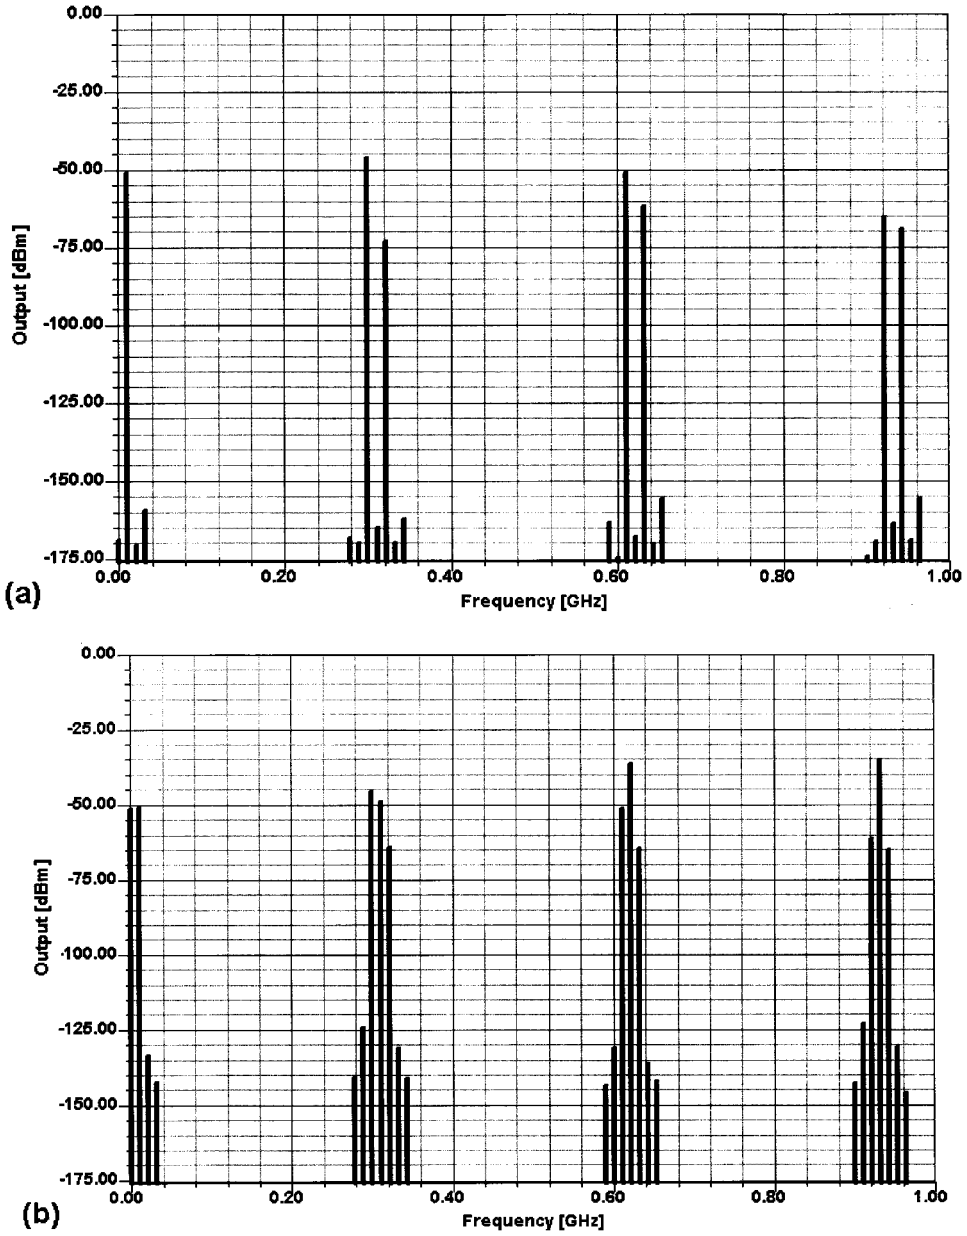

Figure 4-18 The nonideal mixer's output spectrum with (a) identical diodes and no stray capacitance and (b) slightly mismatched diodes and 0.5 pF of stray capacitance between the upper terminal of the middle transformer winding and ground. In these analyses, LO = 310.7 MHz (2 dBm), RF = 300.0 MHz (–40 dBm), and IF = 10.7 MHz. Four LO harmonics and 3 LO sidebands were used.

mainly by the degradation of the transformers' transmission-line behavior at higher frequencies, although the increasing importance of diode capacitance also plays a role.

A DBM's interport isolation is determined by the symmetry of its transformers, diodes, and physical construction. In practice, the effects of diode mismatch can be minimized by

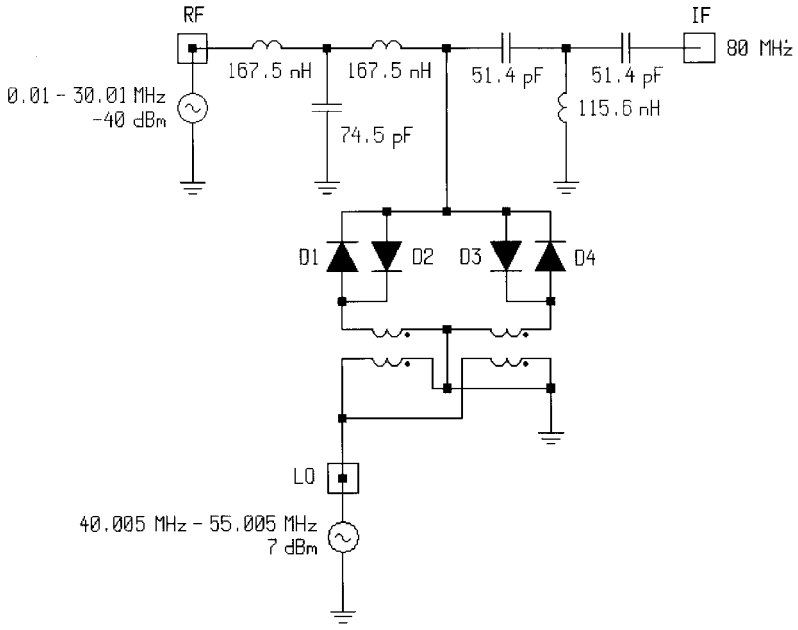

Figure 4-19 A subharmonically pumped single-balanced mixer using antiparallel diode pairs. The LO operates from 40.005 to 55.005 MHz to mix 0.01–30.01-MHz RF to an IF of 80 MHz.

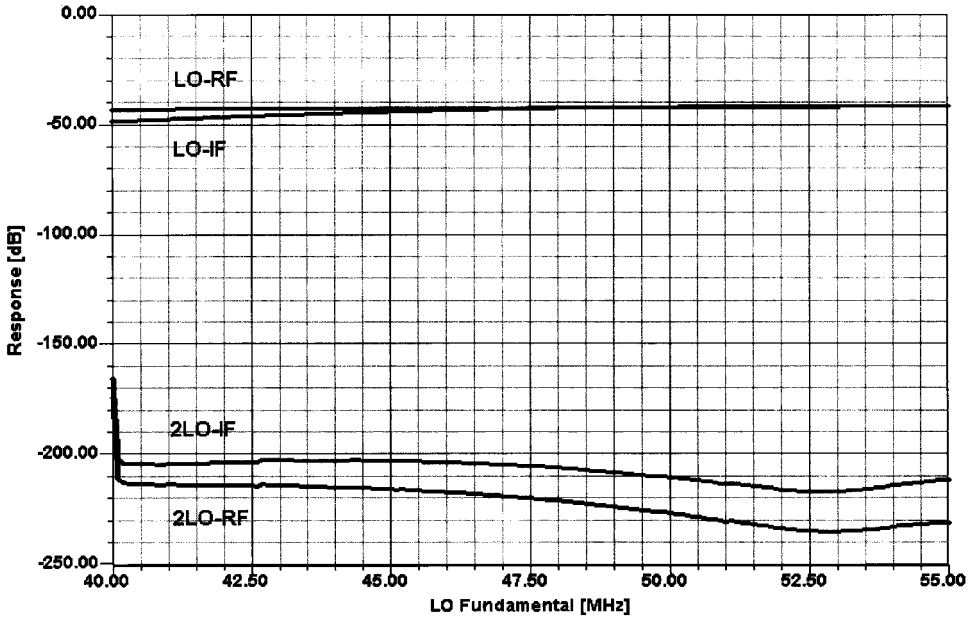

Figure 4-20 Simulated interport isolation of the subharmonic SBM. For realism, the diodes and transformers are slightly mismatched.

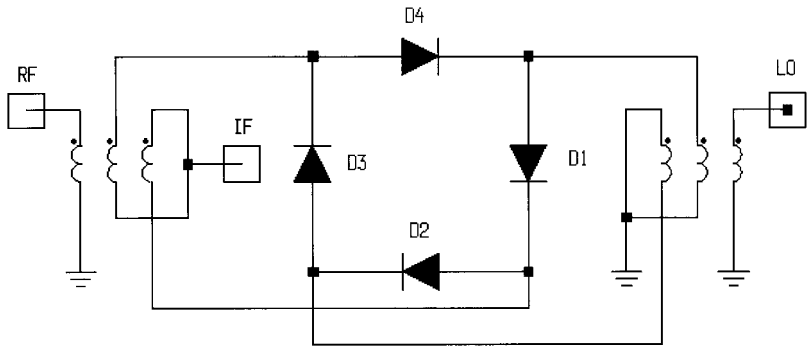

Figure 4-21 Schematic of the diode-ring double-balanced mixer.

using a dual diode, such as—in the case of the BAT15—the BAT15-099, the maximum V_F spread between the diodes being specified as 20 mV.

Figure 4-22 shows how the DBM's conversion gain and noise figure vary with applied LO power. Figure 4-23 shows how the DBM's conversion gain and noise figure vary with frequency for an LO power of 7 dBm, with quasi-ideal and nonideal balance. Figure 4-24 shows how the DBM's port-to-port isolation differs with quasi-ideal and nonideal balance for an LO power of 7 dBm. Figure 4-25 shows how the DBM's RF- and LO-port return losses vary with frequency; the sharp peak corresponds to a resonance caused by one of the stray capacitances added to simulate less-than-ideal balance in the modeled mixer.

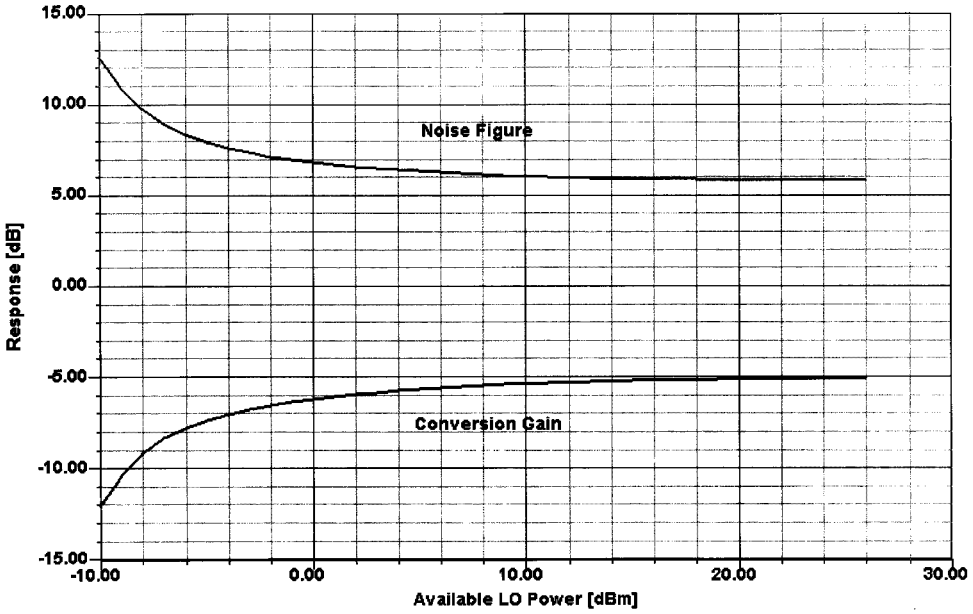

Figure 4-22 DBM conversion gain and noise figure versus LO power. In this analysis, LO = 310.7 MHz (–10 to 26 dBm), RF = 300 MHz (–40 dBm) and IF = 10.7 MHz.

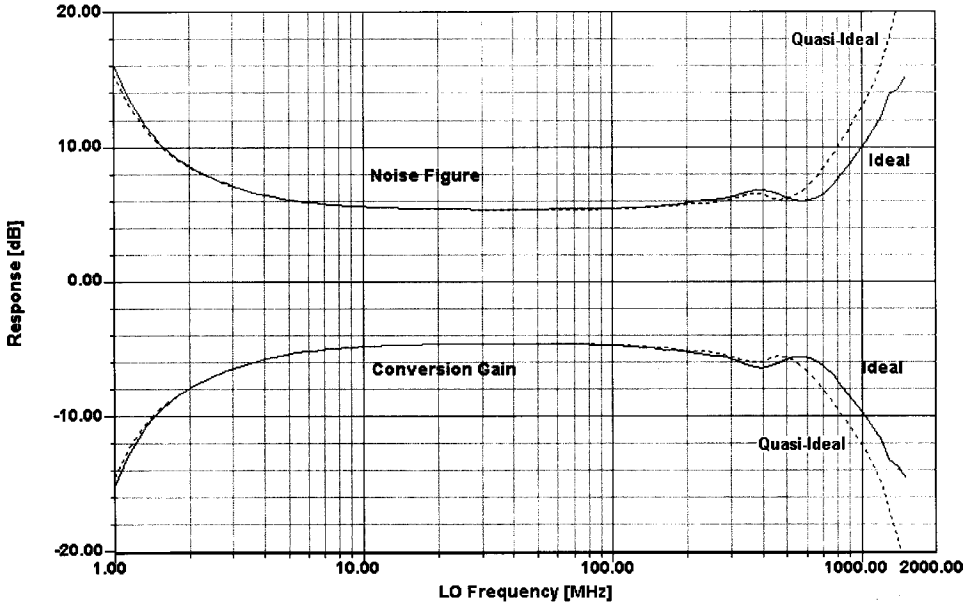

Figure 4-23 This plot of conversion gain (CG) and noise figure (NF) versus frequency for quasi-ideally and nonideally balanced versions of the same DBM reveals that balance plays a relatively minor role in the CG and NF performance achieved. In these analyses, the LO (–7 dBm) sweeps from 1 to 1500 MHz and the RF (–40 dBm) sweeps from 1.455 to 1500.455 MHz to produce an IF of 455 kHz.

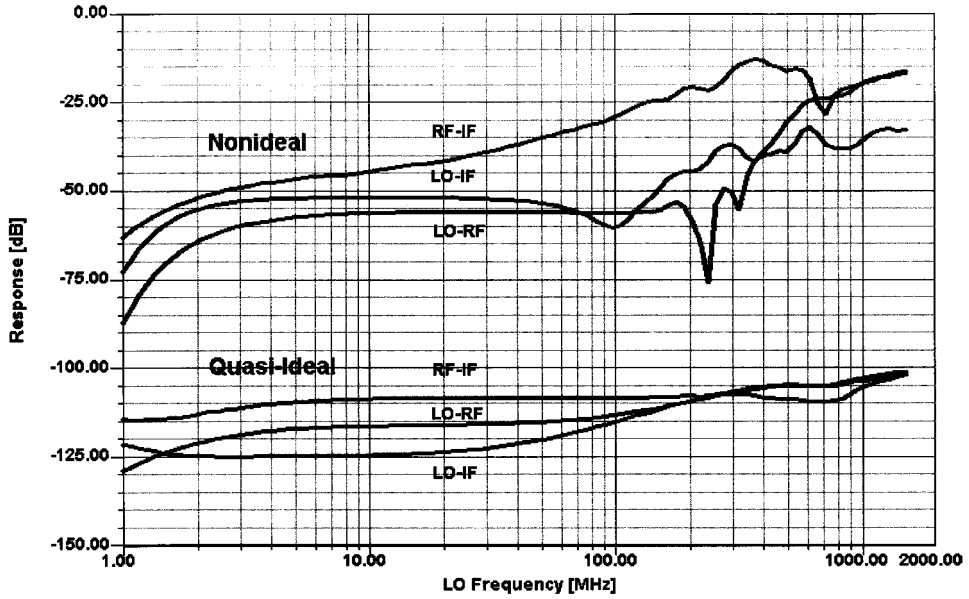

Figure 4-24 Interport isolation for DBMs with quasi-ideal and nonideal balance. In these analyses, the LO (–7 dBm) sweeps from 1 to 1500 MHz and the RF (–40 dBm) sweeps from 1.455 to 1500.455 MHz to produce an IF of 455 kHz.

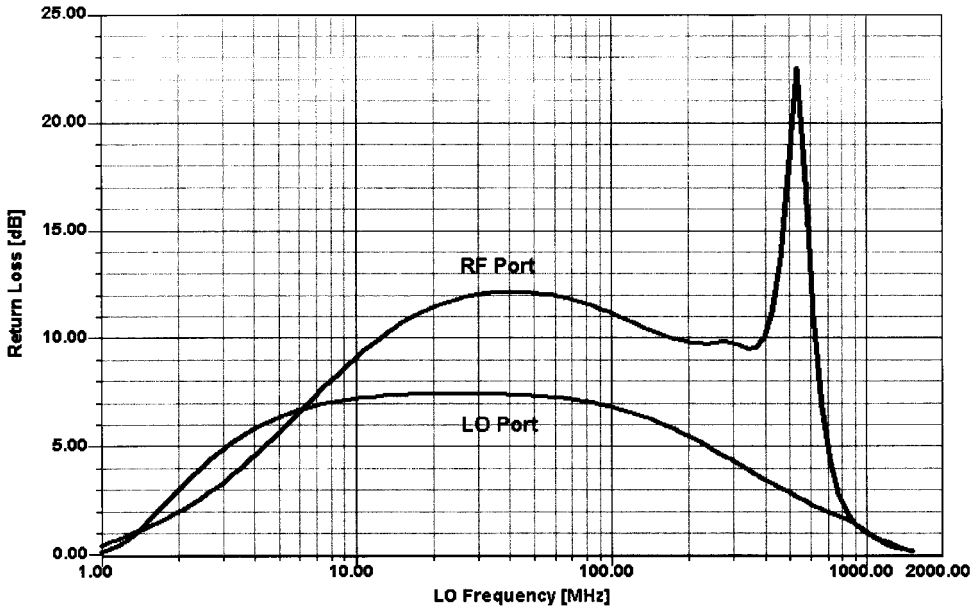

Figure 4-25 Return loss versus frequency for the DBM's RF and LO ports. The sharp peak results from a stray resonance.

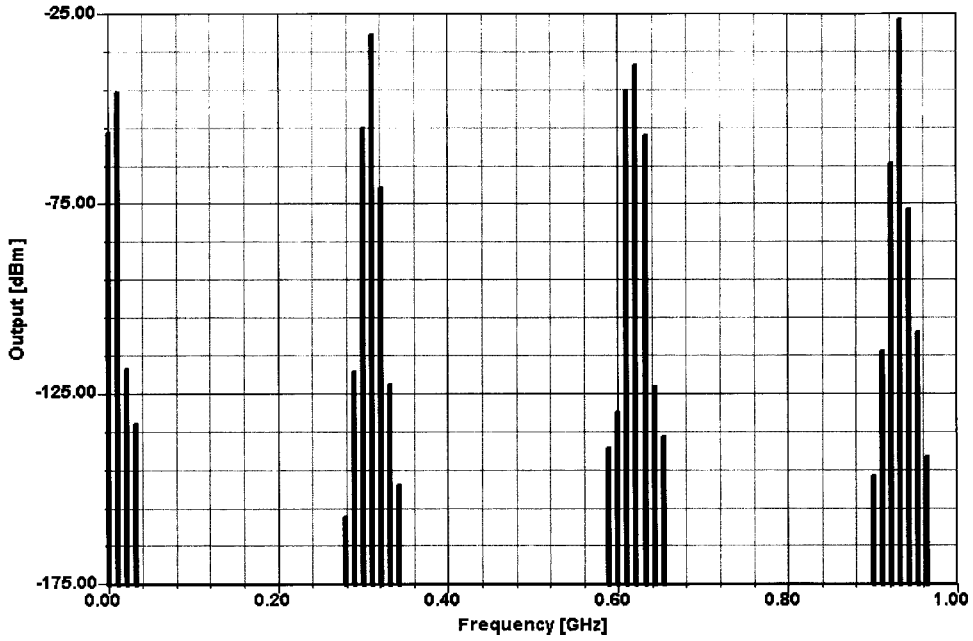

Figure 4-26 Output spectrum of a nonideally balanced DBM. In this analysis, LO = 310.7 MHz (–7 dBm) and RF = 300 MHz (–40 dBm) for an IF of 10.7 MHz. Four LO harmonics and three LO sidebands were used.

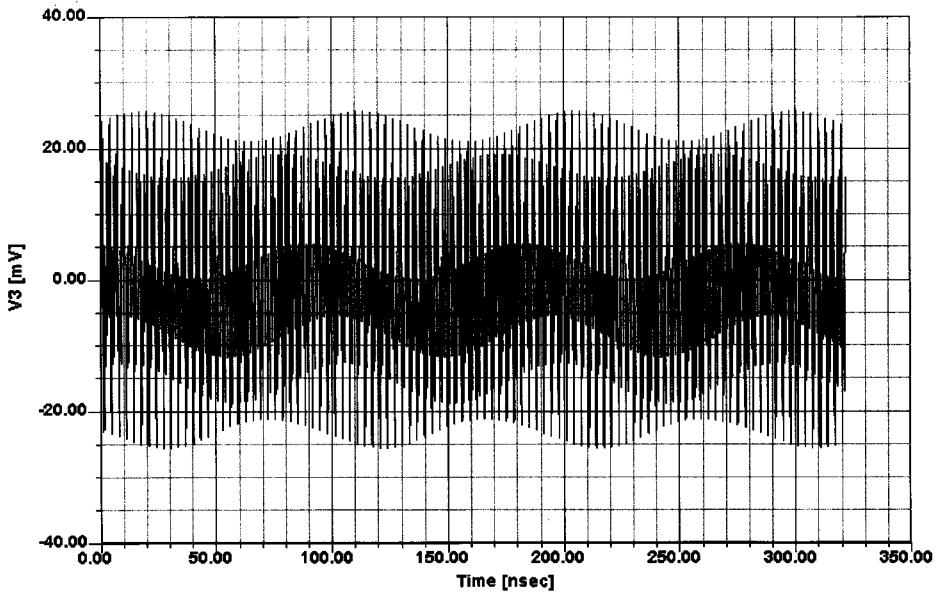

Figure 4-27 IF-port voltage waveform of the DBM over 100 cycles of the LO signal. The 310.7-MHz LO and 10.7-MHz IF components are clearly evident.

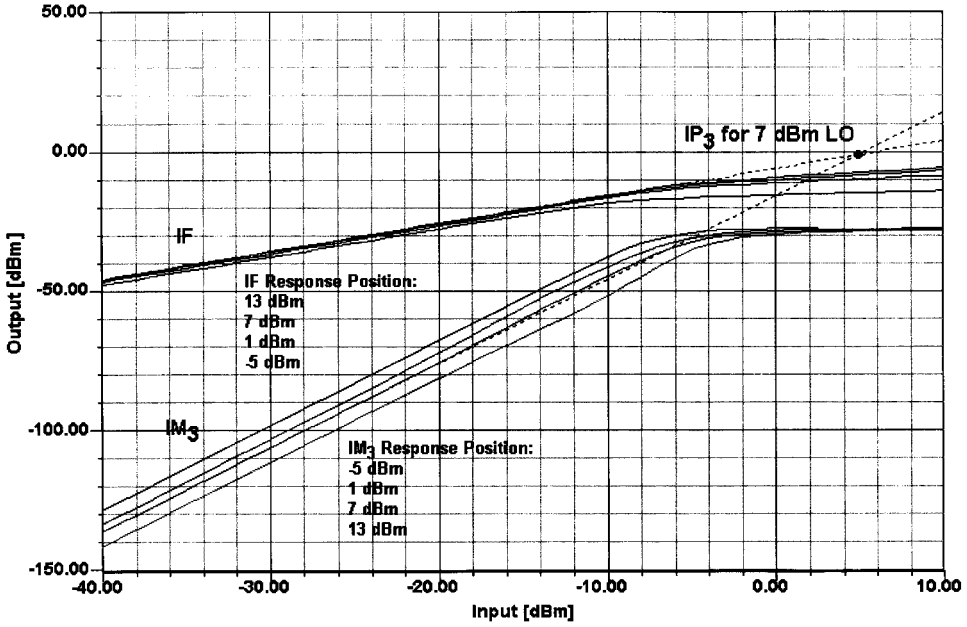

Figure 4-28 Diode DBM IF and IM_3 outputs versus RF power for four LO-drive levels. The responses for LO = 7 dBm have been extrapolated to show IP_3. Within limits, varying a mixer's LO drive affects its linear IF output relatively little while significantly affecting IMD. See Figure 4-29. For all four analyses, LO = 310.7 MHz, RF1 = 300.0 MHz (–40 to 10 dBm), and RF2 = 300.3 MHz (–40 to 10 dBm); four LO harmonics and three LO sidebands were used.

Figure 4-26 shows the DBM's output spectrum. Figure 4-27 shows the DBM's output waveform over 50 cycles of the LO signal.

Two-tone testing of the DBM allows us to characterize its IP_3 figures of merit. Figure 4-28 shows the nonideal DBM's IF and IM_3 responses for LO powers of –5, 1, 7, and 13 dBm. Figure 4-29 details how the DBM's IP_3 increases with LO drive, and Figure 4-30 shows the desired IF outputs and close third-order spurs near 10.7 MHz. Figure 4-31 shows the DBM's output voltage over 100 cycles of the LO signal, and Figure 4-32 shows the anode–cathode voltage of one of the ring's diodes, also over 100 LO cycles, both under two-tone IMD test conditions.

A double-balanced mixer, unless it is termination insensitive, is extremely sensitive to nonresistive termination. This is because the transmission-line transformers do not operate properly when they are not properly terminated, and the reflected power generates high voltage across the diodes. This effect results in much higher distortion levels than in a properly terminated transformer.

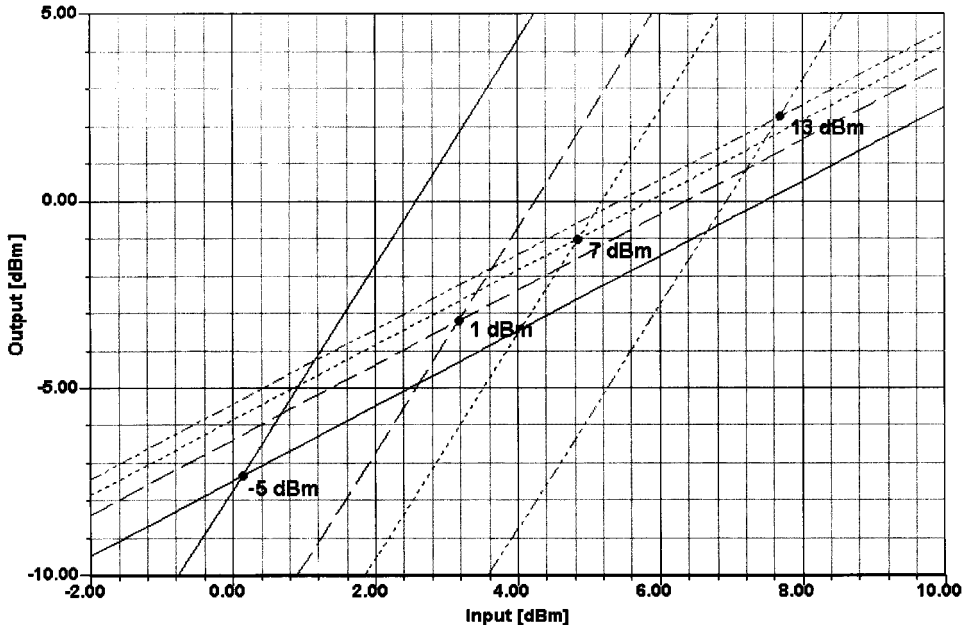

Figure 4-29 Extrapolating the responses for all four LO levels represented in Figure 4-28 shows how varying a diode DBM's LO drive shifts its third-order intercept point. Although these curves indicate that the simulated mixer's IP_3 generally increases with LO drive, the improvement in IP_3 is not as great as we might expect. The reason for this is that these four analyses, as well as the other diode-mixer analyses in this chapter, were done using diode models with a threshold voltage (V_J) of 0.23. If high-level diodes with a V_J of about 0.8 V had been used, $IP_{3,out}$ for the 13-dBm LO case shown here would increase to +13 dBm. $IP_{3,in}$ for the 13-dBm LO case would turn out to be 13 dBm + insertion loss = 13 dBm + 7 dB = 20 dBm. The issue of diode damage aside, attempting to increase IP_3 merely by driving a low- or medium-barrier diode harder eventually results in diminishing returns. High-barrier diodes are essential in getting the best IP_3 performance with high LO drive.

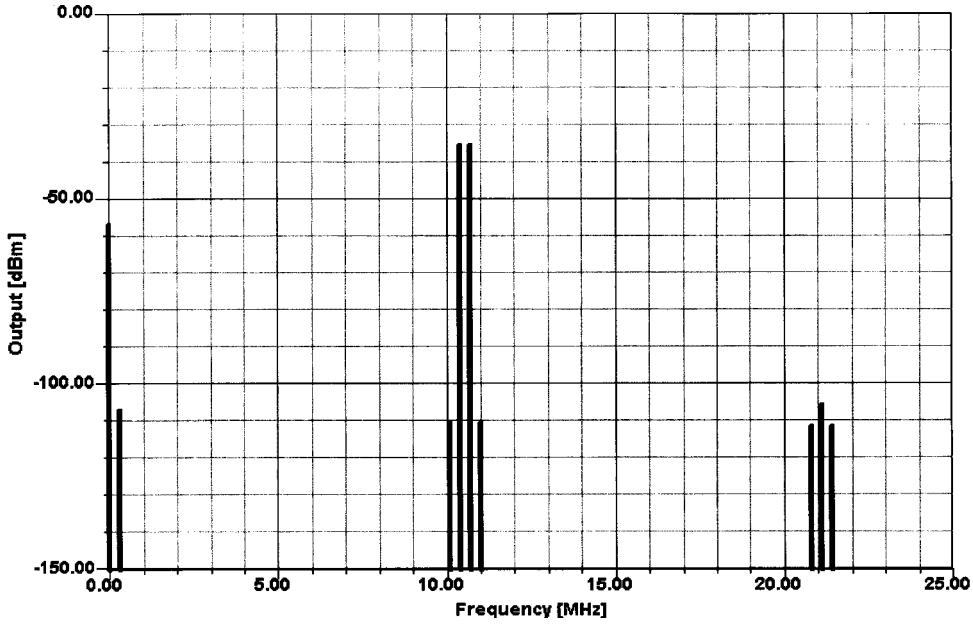

Figure 4-30 The DBM's output in the 11-MHz region during two-tone testing. The third-order products are clearly visible above and below the desired output signals. The test conditions for this analysis are those for Figure 4-28 with LO = 13 dBm.

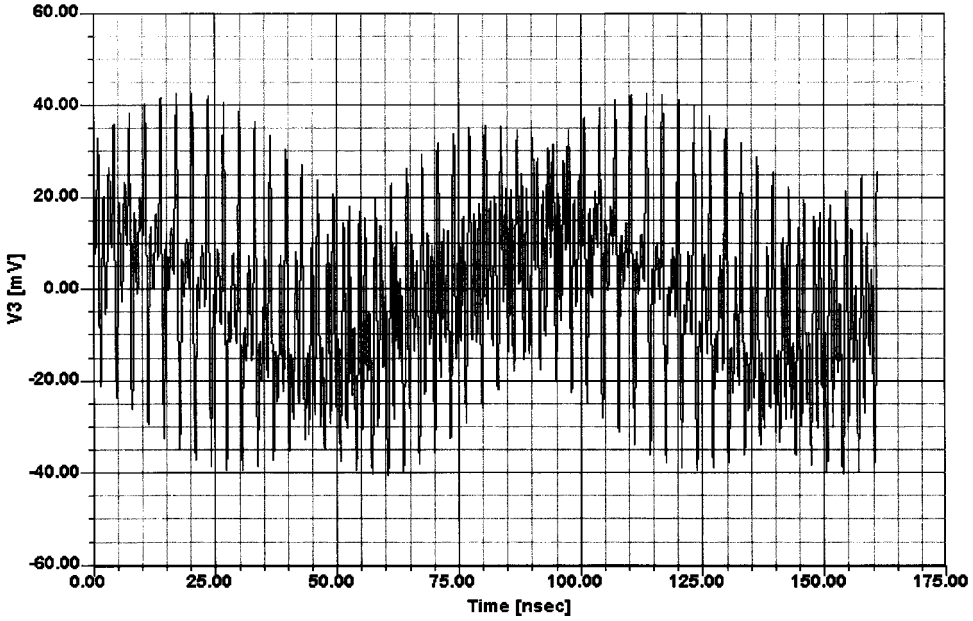

Figure 4-31 The DBM's IF-output voltage over 50 cycles of the LO signal. The test conditions for this analysis are those for Figure 4-28 with LO = 13 dBm.

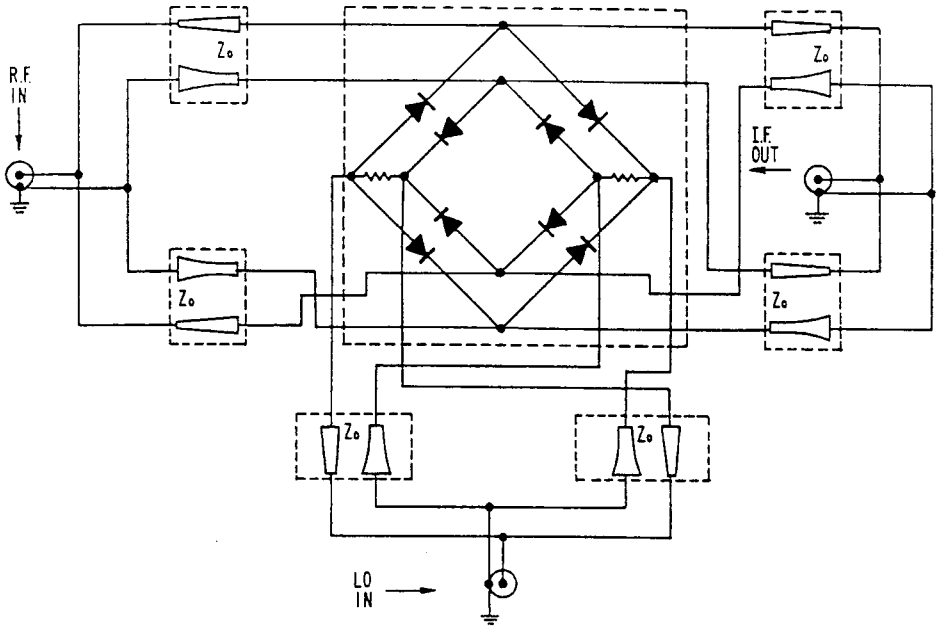

Figure 4-33 Example of a termination-insensitive mixer from U.S. Patent No. 4,224,572 (Adams-Russell Co., 1980) [11].

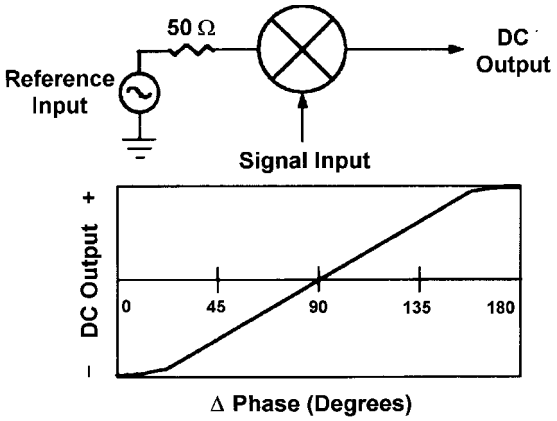

Figure 4-34 A mixer with a dc-coupled IF port can be used as a phase detector.

Termination-Insensitive Mixer. Figure 4-33 shows a mixer circuit that tolerates a fairly high VSWR at its output without significant degradation of its third-order IM performance [11].

Phase Detector. Theoretically, any mixer with a dc-coupled IF port can be used as a phase detector. When two signals of equal frequency are applied simultaneously to the reference and incoming signal ports, the phase detector produces a dc output at the IF port proportional to the cosine of the phase difference (Figure 4-34).

Binary Phase Shift Keying (BPSK) Modulator. Binary phase modulation occurs when a positive and negative signal current shifts the RF carrier between 0° and 180°. Figure 4-35 shows a double-balanced mixer operating as a BPSK modulator.

Quadrature Phase Shift Keying (QPSK) Modulator. A typical QPSK modulator consists of two biphase modulators, a 90° divider, and a 0° power combiner as shown. Data inputs at the control ports will cause the carrier to shift between 0°, 90°, 180°, and 270° as shown in Figure 4-36.

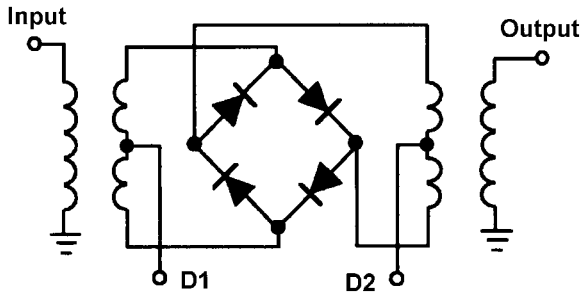

Figure 4-35 A diode-ring mixer as phase modulator.

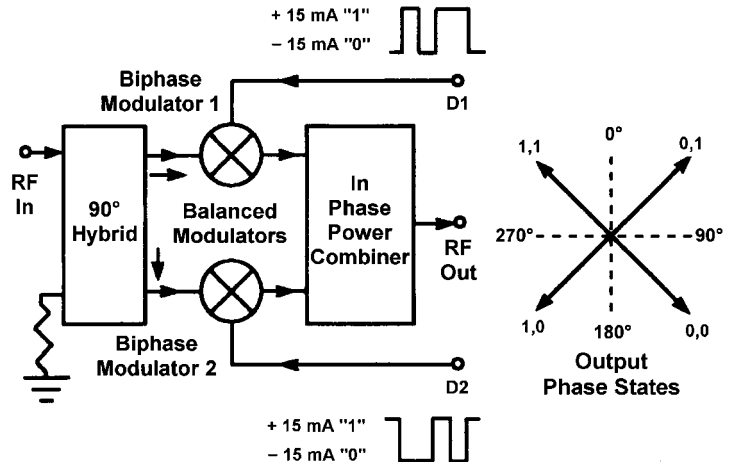

Figure 4-36 Two biphase modulators form the basis for a QPSK modulator.

Quadrature IF Mixer. A quadrature IF mixer produces two IF outputs in phase quadrature. Its basic structure consists of two double-balanced mixers, a 90° splitter, and a 0° splitter. The basic block diagram is shown in Figure 4-37.

Image-Reject Mixer. The image-reject mixer consists of a basic quadrature IF mixer with an additional 90° hybrid at the IF ports as shown in Figure 4-38. The primary function is to differentiate between the real signal and the image signal. This type of device is especially useful in applications where the desired RF signal and image are so close in frequency that rejecting the image with filtering is not practical.

Diode Attenuator/Switch. A ring of PIN diodes can be used as electronic attenuators by applying variable forward bias to the diodes (Figure 4-39). Maximum attenuation is achieved when the current at the control port is zero. The maximum attenuation is the isolation between the input and output ports. Minimum attenuation (insertion loss) is achieved when the IF-port current is 20-mA.

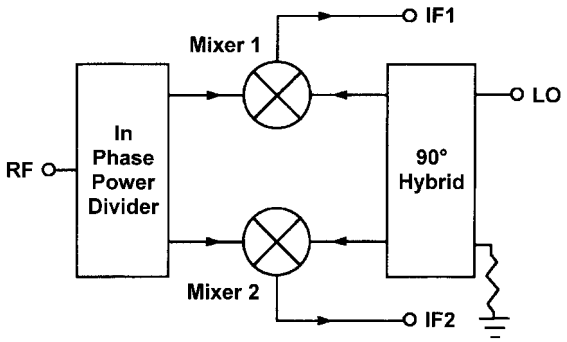

Figure 4-37 Quadrature mixer.

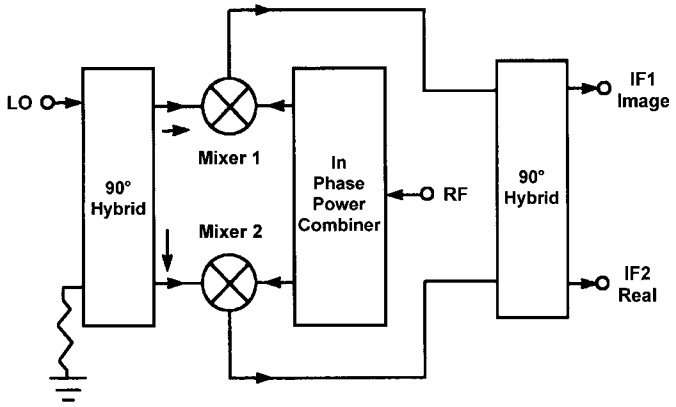

Figure 4-38 An image-reject mixer uses phasing to differentiate between its LO + IF and LO – RF IF outputs.

Single-Sideband (SSB) or In-Phase/Quadrature (I/Q) Modulator. SSB or I/Q modulators are useful in discriminating and removing the lower sideband (LSB) or upper sideband (USB) generated during frequency conversion, especially when the sidebands are very close in frequency and attenuation of one of the sidebands cannot be achieved with filtering. This is the case with audio and video modulation, where signals from dc to 10 MHz must be converted to a higher frequency that is appropriate for transmission. In such cases, both sidebands will be very close in frequency to the carrier frequency. With an I/Q modulator, one of the sidebands is easily canceled or attenuated along with its carrier.

Attenuation of the carrier has been the most troublesome aspect in the design of passive I/Q modulators. Isolation between the local oscillator (LO) port and the RF port of the mixers, which is the main parameter in determining carrier rejection, is usually insufficient at frequencies above 200 MHz.

I/Q modulator designs basically consist of two double-balanced mixers (Figure 4-40). The mixers are fed at the LO ports by a carrier phase-shifted through a 90° hybrid. Thus, the carrier signal's relative phase is 0° to one mixer and 90° to the other mixer. Modulation signals are fed externally in phase quadrature to the two mixers' IF ports. The mixers' modulated output signals are combined through a two-way, in-phase power divider/combiner.

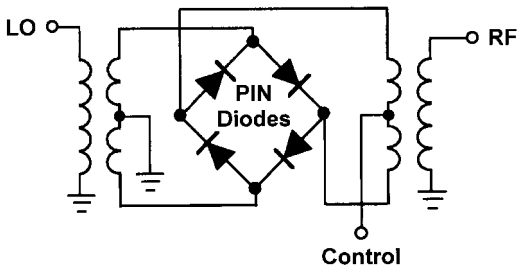

Figure 4-39 A diode DBM can be used as a dc-controlled attenuator if PIN diodes are used instead of Schottky devices in its ring.

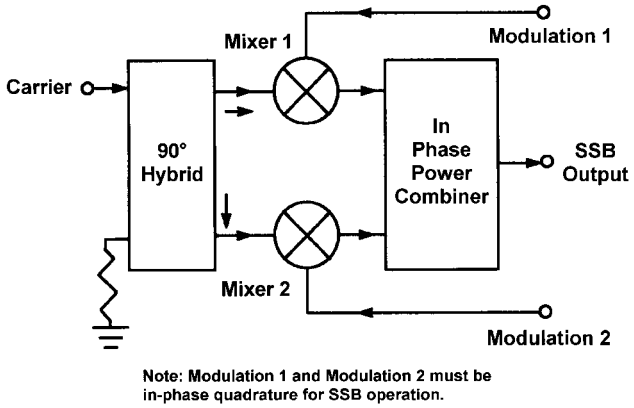

Figure 4-40 An SSB modulator matches two high-frequency mixers, a 90° hybrid, and an in-phase power combiner to produce an SSB output signal.

The circuit forms a phase-cancellation network to one of the sidebands and a phase-addition network to the other sideband. The carrier is somewhat attenuated and is directly dependent on the inherent LO-to-RF isolation of the mixers and the modulating signal level. In industry-standard I/Q modulators, USB suppression results when the first modulation port (Modulation 1) is fed with a signal that is 90° in advance of the signal feeding the second modulation port (Modulation 2). Opposite phasing can be arranged by changing the internal phase polarity of the mixers or by interchanging the 90° hybrid output ports to the LO ports of the mixers.

The phase and amplitude imbalances between the various components used in the manufacturing of the I/Q modulators must be tightly maintained for optimum SSB rejection. Matching of the two mixers for conversion loss and insertion phase is extremely critical, since differences in these parameters will add to amplitude- and phase-imbalance errors. The 90° hybrid in the LO port must be in nearly perfect phase quadrature.

Phase- and amplitude-imbalance errors adversely affect sideband suppression (Figure 4-41). In most cases, a typical passive I/Q modulator operates with a carrier input level of +10 dBm, which is required to drive the diodes in the mixers to operate in the linear range. The dynamic range of these mixers can be improved significantly by using diodes with a higher barrier height. The LO signal in this case must be increased in order to drive these diodes into conduction in their linear range.

Carrier rejection is also a problem when designing an SSB modulator, since only a few decibels of suppression can be achieved in standard high-frequency models. In the past, the major contributor to carrier suppression was the inherent LO-to-RF isolation through the mixers. Unfortunately, this isolation is usually poor at cellular frequencies (800–1000 MHz), where at least 25 dB of carrier rejection is necessary. In some cases, designers feed a small amount of dc into the IF ports to control the carrier rejection, which complicates the driver circuitry and calls for temperature compensation when operating at different temperatures.

As an example, an SSB modulator is assumed to operate with +10-dBm LO drive with each modulating signal at –10 dBm and in phase quadrature to each other when applied to the modulating ports (MOD 1 and MOD 2). The result will be a modulated signal at –16 dBm, assuming 6-dB conversion loss. For 20-dB carrier rejection with respect to the desired

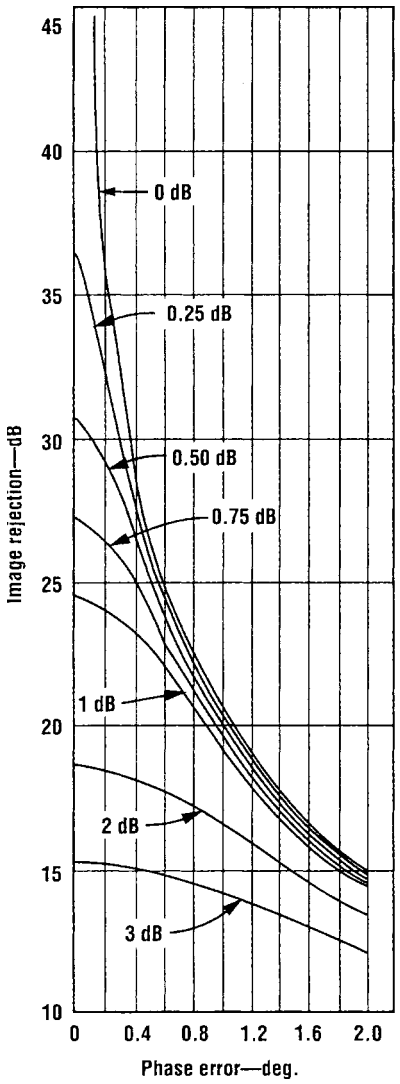

Figure 4-41 The level of SSB rejection improves as the phase- and amplitude-imbalance performance of an SSB modulator improves.

modulated signal, the carrier must be at –36 dBm, which translates to LO-to-RF isolation of 46 dB.

By employing a subharmonic approach, the performance of SSB modulators can be extended beyond the limits of conventional designs as reported by Joshi [7]. The approach is based on the use of subharmonic mixers in place of fundamental-frequency mixers and is applicable from about 140 to 3000 MHz. Subharmonic mixers use antiparallel diode pairs in their construction [12–14]. Matched antiparallel diode pairs used in single-ended or single-balanced mixer configurations cancel even-order intermodulation products (such as $2f_{LO} \times 2f_{RF}$, $3f_{LO} \times 3f_{RF}$, etc.) at all ports.

Single-ended mixers lack the port-to-port isolation needed for SSB modulator applications. Odd-order products of the RF and LO frequencies (even $f_{LO}\times$ odd f_{RF}) and (odd

$f_{LO} \times$ even f_{RF}) appear on all ports, requiring extensive filtering for satisfactory performance. For a single-balanced mixer, even harmonics of the LO combining with odd harmonics of the RF appear at the IF port, whereas odd harmonics of the LO combining with even harmonics of the RF appear at the RF and IF ports. This assumes that a balanced transformer is placed at the LO port, which is a logical choice due to the fact that the highest level signal appears at the LO port. Since the desired odd-order IF products appear at both the RF and IF ports, a need arises for a diplexing network to isolate the RF and IF signals.

The subharmonic modulator design provides a unique way to isolate the RF and IF signals. A single-balanced harmonic mixer offers good LO-to-RF and LO-to-IF isolation but poor RF-to-IF isolation. Fortunately, harmonically related signals are spaced well apart in the frequency spectrum, simplifying filtering of harmonically related signals.

Harmonic mixing also works well with low LO power levels, with somewhat lower 1-dB compression on the RF port than with fundamental-frequency mixing. The ability to operate with LO frequencies that are a fraction of the carrier frequency (1/2, 1/4, 1/6, etc.) significantly reduces the cost of an LO source, especially at higher frequencies. Also, using lower-frequency LO sources helps avoid the signal-leakage problems inherent with higher-frequency LO sources. Minimizing signal leakage, especially at higher frequencies, becomes expensive and bulky. Subharmonic mixing offers several advantages:

- The technique offers the ability to operate at LO frequencies that are 1/2, 1/4, or 1/6 of the carrier frequency. For example, for an IF of 100 MHz at an RF of 2 GHz, the LO can be $(2000 \pm 100) \div 2 = 950$ or 1050 MHz.
- The LO's even harmonics are strongly attenuated.
- The filtering requirements for fundamental frequency and odd harmonic signals of the LO are not critical.
- The cost of generating the LO is reduced due to the fact that the LO frequency need only be a fraction of the carrier frequency.

As an example of the performance improvements possible with the subharmonic mixers, units were evaluated at both cellular (935–960 MHz) and PCN/PCS (1.8–1.9 GHz) bands.

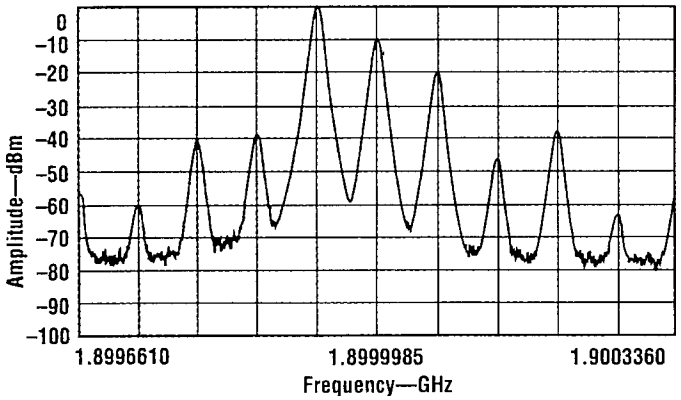

Figure 4-42 This plot of carrier and sideband rejection was measured for a conventional SSB modulator operating at 1.9 GHz.

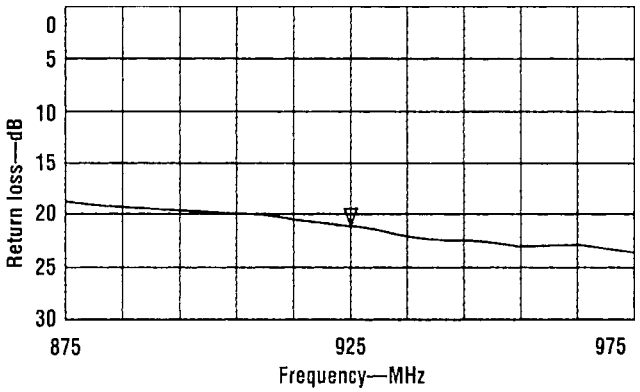

Figure 4-43 The SSB modulator's return loss as measured at the local oscillator (LO) port.

For a conventional SSB modulator at 1.9 GHz fed with +10-dBm modulation signals, carrier rejection is barely 10 dB (Figure 4-42).

Sideband rejection can be improved by tuning, but the carrier rejection is controlled by the LO-to-RF isolation of the double-balanced mixers. Conventional double-balanced mixers with high isolation at cellular and PCN bands are very expensive and large when special techniques are used to improve LO-to-RF isolation. In contrast, the subharmonic nature of the new approach allows the use of lower-frequency, less-expensive components in the modulators' construction.

The subharmonic modulators offer an improvement of more than 15 dB in carrier suppression compared to the conventional approach.

The measured VSWR (return loss) at the LO and RF ports is better than 1.50:1 (Figures 4-43 and 4-44). Measurements made on a cellular-band SSB modulator reveal carrier rejection on the order of 40 dB. Typical insertion loss is 7 dB while sideband rejection is 30 dB (Figure 4-45).

By virtue of harmonic mixing, even-order mixing products are attenuated by about 30 dB with respect to the desired modulated output signal. The fundamental-frequency feedthrough into the output port is approximately 5 dB lower than the desired modulated signal, whereas

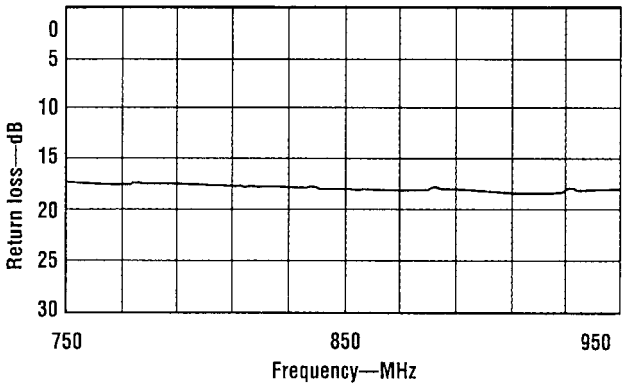

Figure 4-44 The novel harmonic SSB modulator's return loss as measured at the RF port.

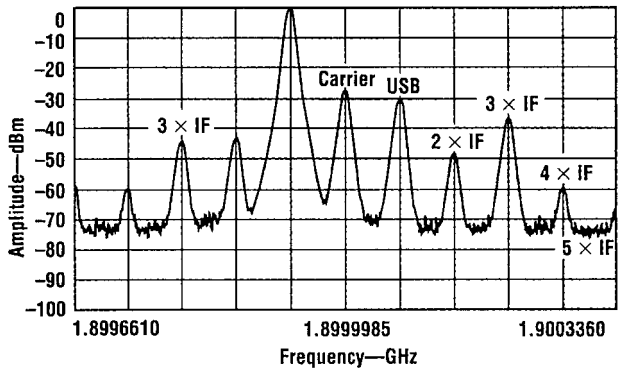

Figure 4-45 Plot of carrier and sideband rejection as measured for the novel harmonic SSB modulator operating at cellular frequencies.

the fourth harmonic mixing with the modulating signal is approximately 10 dB lower. Typical loss for fourth harmonic mixing is 17–19 dB while maintaining 30 dB of carrier rejection.

Since harmonically related products are well-spaced in frequency, filtering undesired signals is relatively inexpensive using standard octave-bandwidth filters. Low-cost commercial bandpass filters typically offer better than 40–50-dB attenuation of unwanted harmonic signals. Constant-impedance bandpass filters offering good impedance match at desired

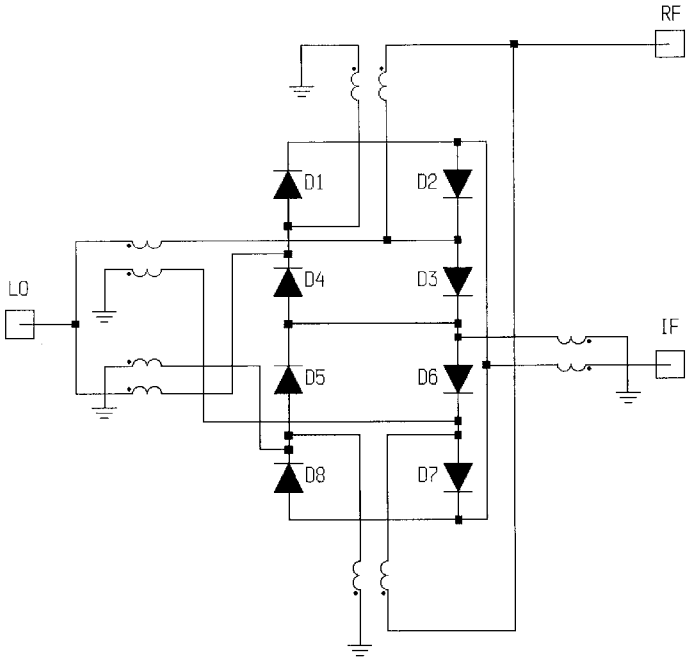

Figure 4-46 A triple-balanced diode mixer. A limitation of this configuration is that the internal dc common connections associated with its RF and LO transformers disallow usable IF response down to dc.

stopbands can also be used in cases where harmonically related products require impedance termination within a system.

The subharmonic modulator design is easily applied at custom frequencies. Conversion of an SSB modulator with output frequency corresponding to twice the LO frequency to one with output corresponding to four times the LO frequency requires only one component change, in the form of a signal-combining network at the modulator's output. Although the conversion loss of the fourth harmonic LO component mixing with the modulating signal is in the vicinity of 18 dB, the cost of generating the LO is drastically reduced with the subharmonic modulator. In spite of higher signal loss, the carrier rejection is still at least 30 dB at the fourth harmonic, and harmonically related products can be eliminated with an inexpensive filter.

Triple-Balanced Mixer. Two diode rings can be combined to form a double double-balanced mixer, or triple-balanced mixer (TBM), as shown in Figure 4-46. Triple-balanced mixers achieve higher dynamic range and interport isolation than double-balanced designs at the expense of LO power and increased complexity and size.

Figure 4-47 shows the interport isolation of the circuit in Figure 4-46 with the circuit configured in a less than ideally balanced form, with small variations in transformer-winding inductance and diode parameters introduced for more realistic modeling. Note that the mixer's interport isolation generally increases with frequency, rather than decreasing with frequency as with the DBM (Figure 4-24).

Rohde & Schwarz Subharmonically Pumped DBM. Figure 4-48 shows an example of a complete microwave diode mixer used as the input stage of a spectrum analyzer. Its LO is applied at 13.2 GHz, one-third the frequency necessary to mix the 40.1-GHz input

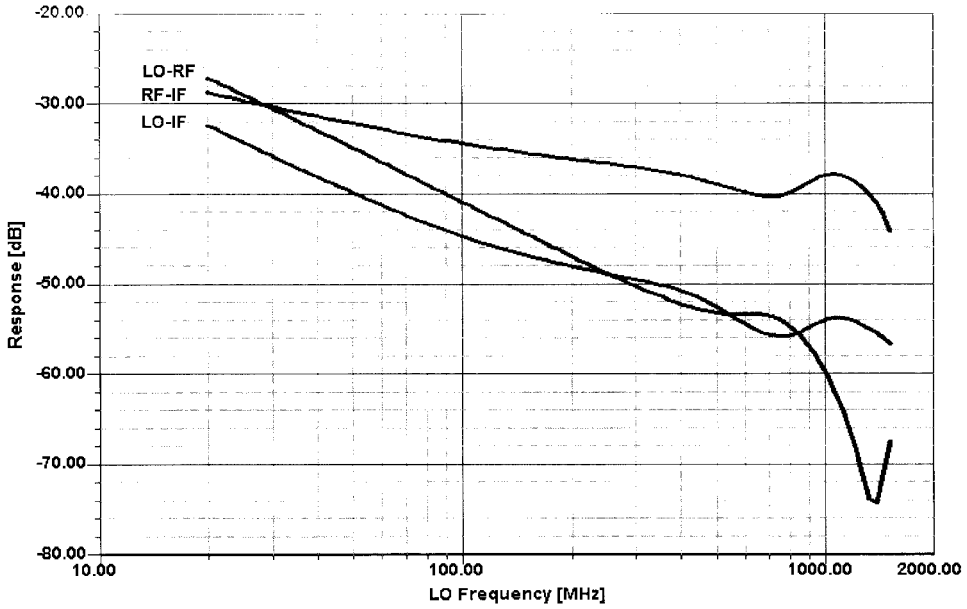

Figure 4-47 The triple-balanced mixer offers improved high-frequency isolation over a standard DBM.

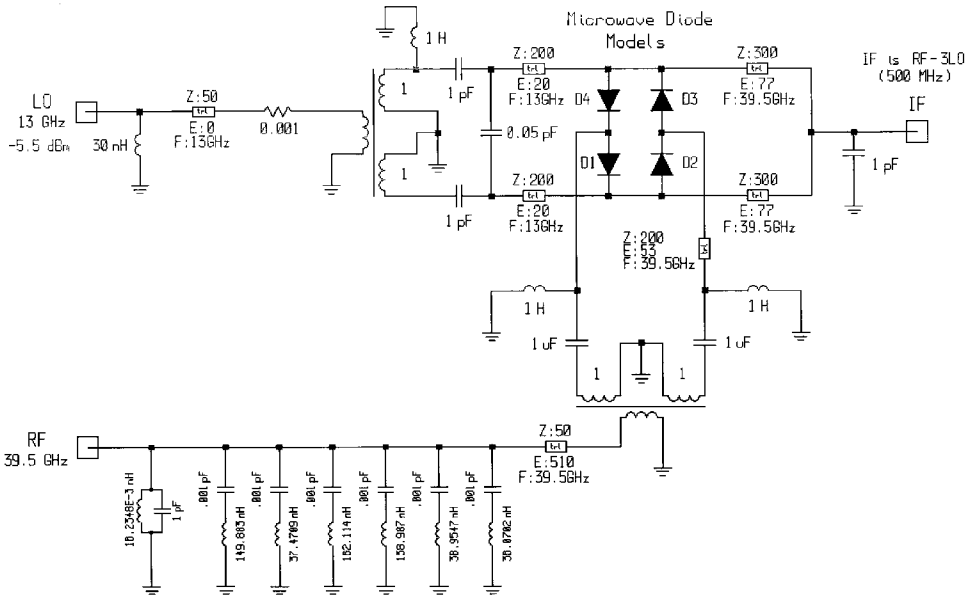

Figure 4-48 Schematic of the spectrum-analyzer mixer. The LO is applied at one-third the frequency necessary to mix the RF signal to the 500-MHz IF.

signal to the 500-MHz IF, with distortion in the diodes providing the 3× frequency multiplication. The circuit's conversion gain is –18.8 dB; its noise figure, 20.5 dB.

The subharmonic-drive technique exemplified by this mixer is important for another reason in addition to LO isolation. Depending on the application, directly generating a sufficiently phase-quiet LO signal at the higher wireless frequencies and on up into the microwave frequencies may not be feasible. In such cases, injecting the LO at a subharmonic of the desired LO frequency may provide better phase noise performance than a fundamental LO even though the phase noise of a frequency-multiplied source increases by $\log_{10} n$ dB, where n is the multiplication factor.

4-4 TRANSISTOR MIXERS

Diode mixers are lossy and termination-sensitive and require considerable LO power. Their attractiveness to designers of highly integrated wireless products is further reduced by their dependence on transformers for balance and port-to-port isolation. Transistor mixers are therefore used where high integration and reduced current drain are paramount—that is, in most non-base-station wireless applications.

Until ten years ago, single BJTs were commonly used in a simple additive-mixing arrangement, an example of which appears in Figure 4-49. Such a circuit behaves like a combination of a preamplifier and single-diode mixer. Single-BJT mixers were used in early AM–FM radios until 1980, and unfortunately in some handheld 2-meter and 70-cm ham equipment, to achieve the lowest possible power consumption. By definition, however, the presence of such a mixer also destroys any possibility of achieving a high intercept point. In

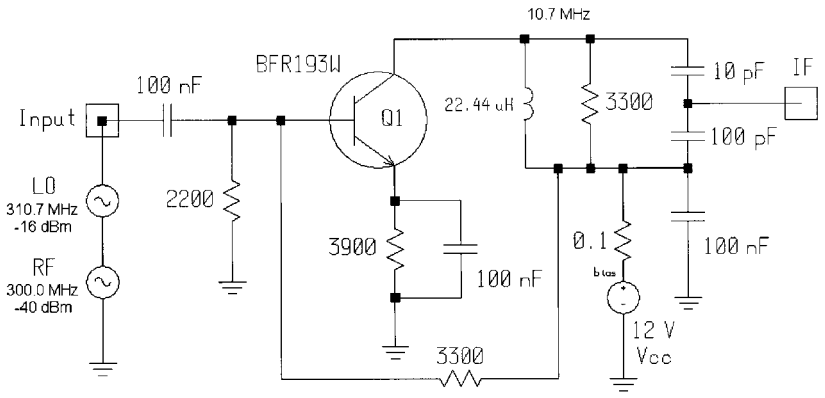

Figure 4-49 A single-BJT mixer.

addition to this, many combination frequencies occur despite elaborate input filtering. Although single-BJT mixers can exhibit considerable conversion gain (>10 dB), their dynamic range is restricted and their port-to-port isolation is poor. BJT mixers in today's competitive wireless designs use multiple transistors and are based almost exclusively on the Gilbert multiplier cell.

4-4-1 BJT Gilbert Cell

The classic active mixer (Figure 4-50), conceived by Barrie Gilbert in 1967, is the basis for most active mixers used in wireless products today. Figure 4-51 shows a Gilbert cell mixer implementation for analysis. Figure 4-52 shows its conversion gain and noise figure versus LO power. Figure 4-53 shows its IM_3 and IP_3 responses. As Gilbert wrote in a 1994 monograph [15]:

> This circuit is attractive because (a) it can be monolithically integrated with other signal-processing circuitry; (b) it can provide conversion gain, whereas a diode-ring mixer always has conversion loss; (c) it requires very low power to drive the LO port; (d) it provides excellent isolation between the signal ports; and (e) it is far less fussy about load-matching.

The two major advantages afforded by the Gilbert cell are port isolation (it should really be called a multiplicative mixer) and its significant reduction of even-order frequency combinations. As with the single-transistor mixer, the Gilbert cell does not particularly shine with high intercept point and low current consumption. Another major drawback is that it requires a high-impedance output, which gives the user headaches because most of the better filters are in 50-Ω technology, and only very simple monolithic filters offer input and output impedances around 1 kΩ. Impedances on this order can result in significant crosstalk in high-density circuit boards.

The reason the Gilbert cell can be so linear for small input signal levels is twofold: It is a differential amplifier and it makes use of the tanh function, which is linear over a wide range around the zero-crossing point [16]. Attempts have been made to increase the intercept point. The Plessey SL6440 IC was a special version of the Gilbert cell that achieved high $IP_{3,in}$ (+30 dBm) at the expense of dc current.

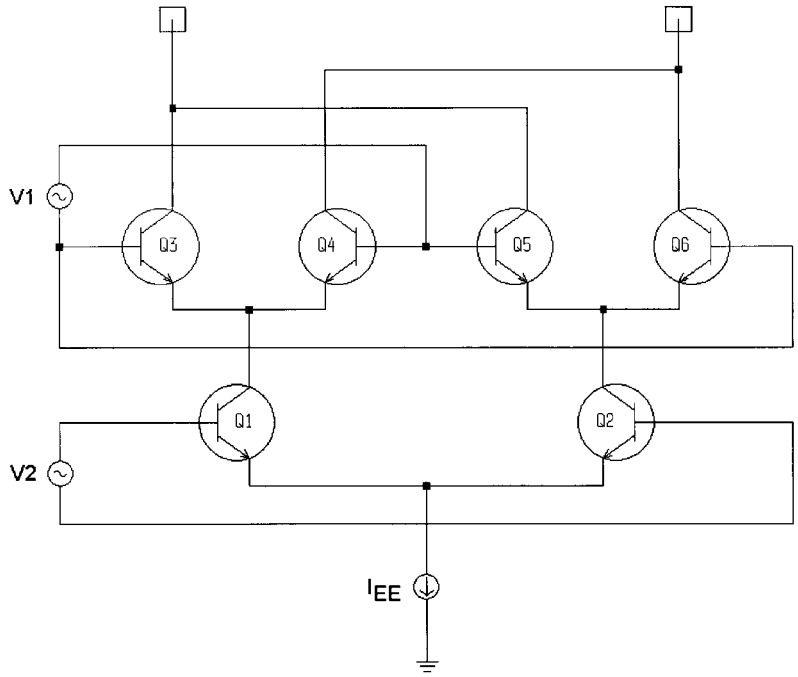

Figure 4-50 The basic Gilbert multiplier cell.

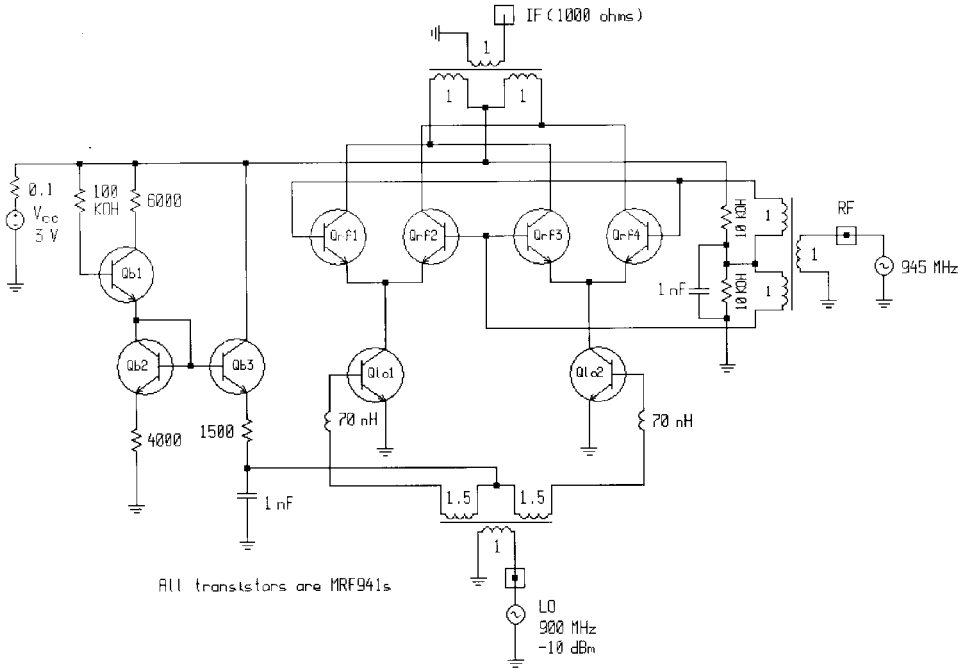

Figure 4-51 Gilbert cell mixer validation circuit.

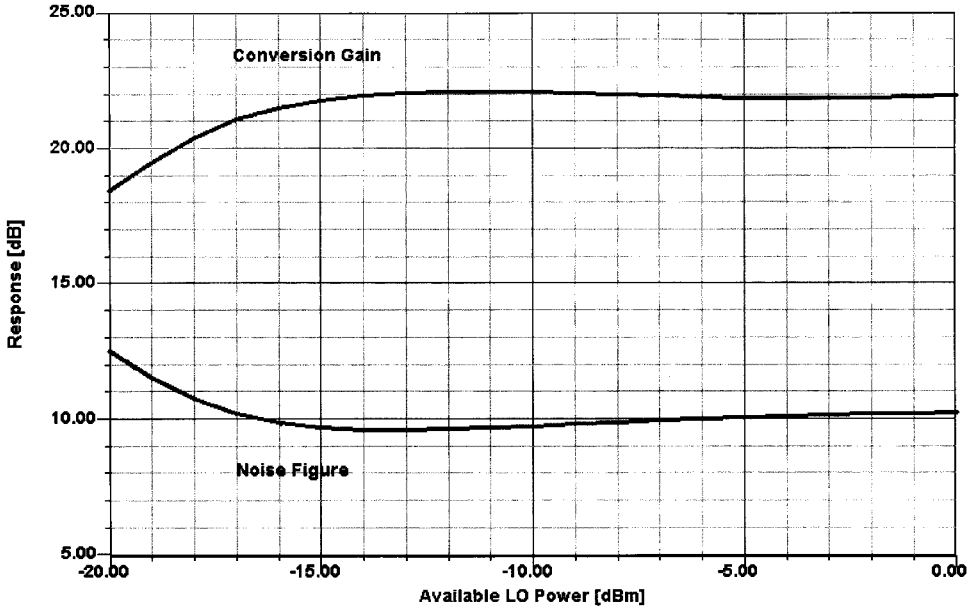

Figure 4-52 Conversion gain and noise figure versus LO power for the Gilbert cell mixer. In this analysis, LO = 900 MHz (–20 to 0 dBm) and RF = 945 MHz (–50 dBm) for an IF of 45 MHz.

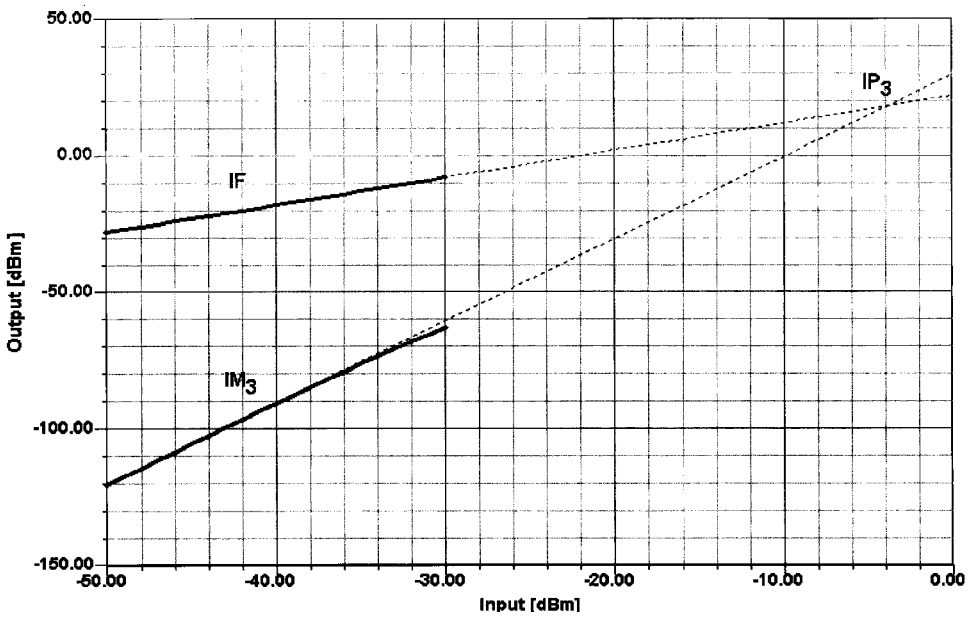

Figure 4-53 IM_3 and IP_3 responses for the BJT Gilbert cell mixer with RF signals at 945 and 946 MHz. In this analysis, LO = 900 MHz (–10 dBm), RF1 = 945 MHz (–50 to –30 dBm), and RF2 = 946 MHz (–50 to –30 dBm). Four LO harmonics and three LO sidebands were used.

Our suspicion, however, is that a combination of a modern double-balanced passive mixer using medium- to high-level diodes followed by a feedback FET amplifier, or even one of the late CATV transistors with f_T values of more than 25 GHz, would allow the achievement of a significantly higher intercept point. As pointed out in Chapter 3, CATV transistors are now available that combine a noise figure of less than 1 dB with a $IP_{3,in}$ of more than 30 dBm. Built-in push–pull structures using such transistors can achieve an $IP_{2,in}$ of 70 dBm, matching the numbers for the diode DBM. In Chapter 3 we learned that feedback always improves the dynamic range, mostly at the expense of gain, since the gain–bandwidth product gets reduced. Motorola has recently come out with a clever extension of its high-level preamplifier and modified it to become a mixer.

4-4-2 BJT Gilbert Cell with Feedback

Motorola's MC13143 low-power 2.4-GHz mixer IC uses a patented topology consisting of a Class-AB-biased Gilbert cell augmented by feedback. Its linearity can be programmed via

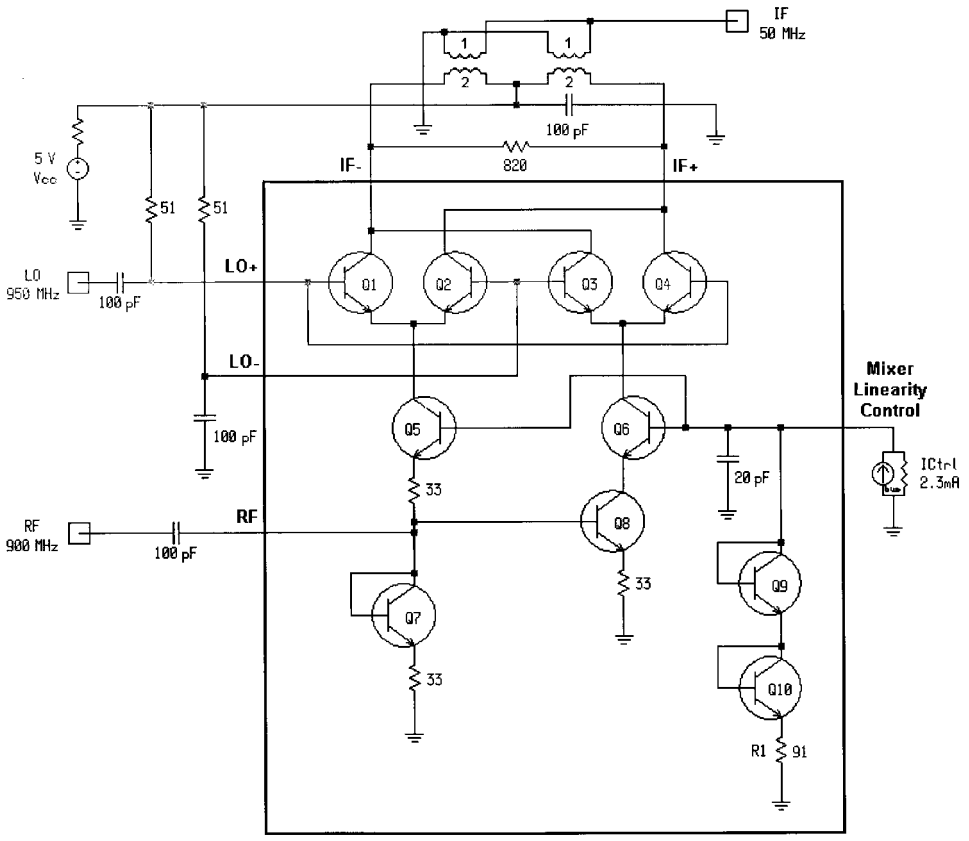

Figure 4-54 Motorola's MC13143 mixer IC uses dc feedback for improved linearity that can be programmed by applying a control current (0–2.3 mA) to its Mixer Linearity Control pin. Per Motorola, an $IP_{3,in}$ of 20 dBm may be achieved with a control current of 2.3 mA, at the expense of approximately 7 mA of additional supply current. In this validation circuit, R_1 (the resistor in Q10's emitter) has been adjusted for a total current drain (supply + linearity control) of 8 mA.

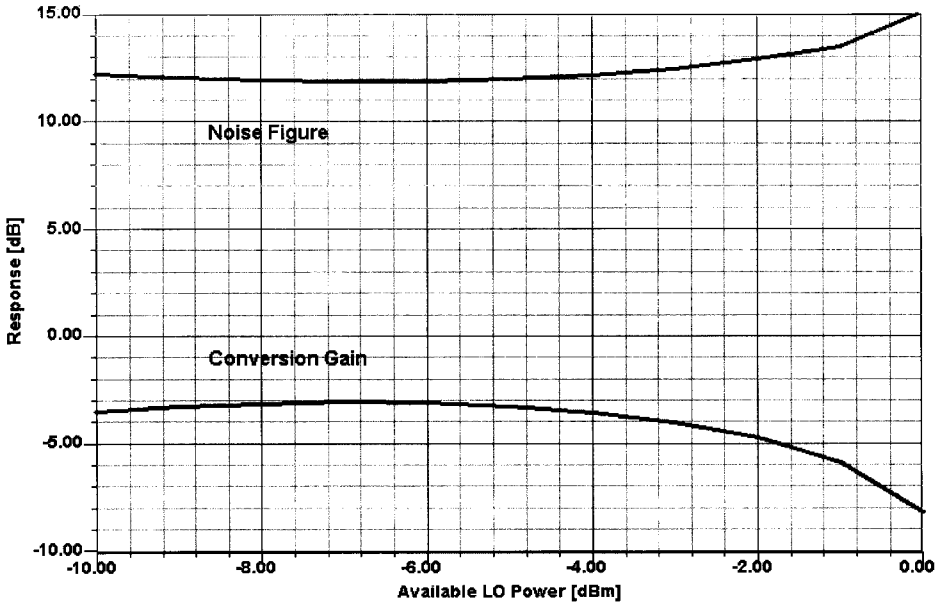

Figure 4-55 Calculated conversion gain and noise figure versus LO drive for the Motorola MC13143 IC operating at $V_{CC} = 2$. Motorola's specifications for the typical values of these characteristics are –5.0 dB and 12 dB, respectively, at an LO drive level of 0 dBm. The RF signal is at 900 MHz and the LO is at 950 MHz, for an IF of 50 MHz. In this analysis, LO = 950 MHz (–10 to 5 dBm) and RF = 901 MHz (–50 dBm) for an IF of 49 MHz.

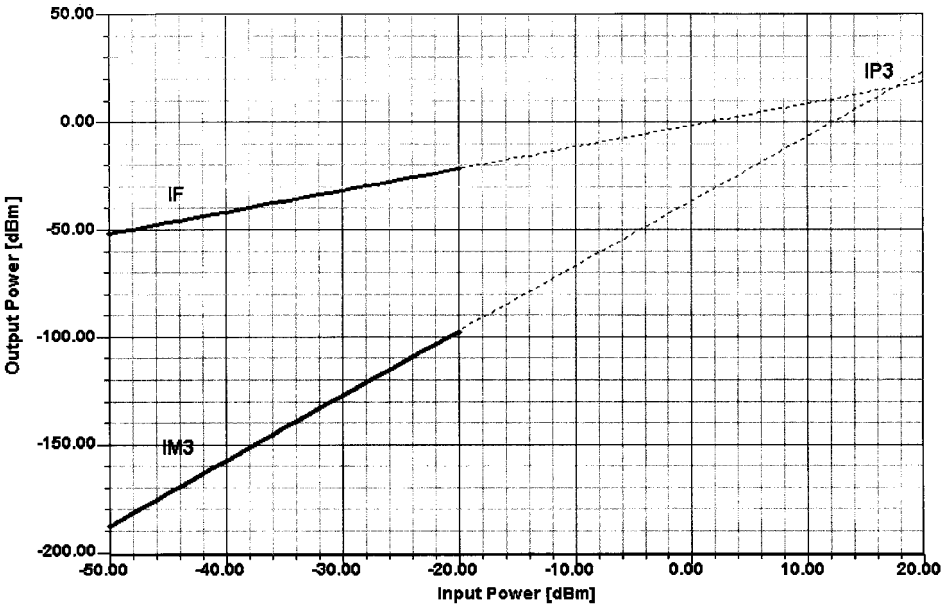

Figure 4-56 Calculated typical IF, IM_3, and IP_3 responses for the Motorola MC13143 mixer. In this analysis, LO = 950 MHz (–5 dBm), RF1 = 900 MHz (–50 to –20 dBm), and RF2 = 901 MHz (–50 to –20 dBm), and $V_{CC} = 5$. Four LO harmonics and three LO sidebands were used.

an external current source to achieve an $IP_{3,in}$ of 20 dBm at the expense of additional supply current.

The MC13143 contains 29 active transistors. Figure 4-54 shows the core of the MC13143 circuit reduced to its essentials and configured for computer analysis per Motorola's MC13143 test circuit. Figure 4-55 shows the circuit's conversion gain and noise figure versus LO drive, and Figure 4-56 shows the circuit's typical IF, IM_3, and IP_3 responses, both as calculated by Ansoft Corporation's Serenade 8.0 circuit simulator. A reproduction of the MC13143 datasheet, used by permission, follows.

In considering the approach used in the MC13143, one has to remember that feedback around many stages gives an IMD ripple, which means that the higher-order IPs are no longer a straight-line calculation. Above a certain level, the 3-dB/dB law fails, and as a result of this, the IMD characteristic can be as bad as 10 or 20 dB/dB—almost like a breakdown point.

High-frequency capability is an issue with silicon BJTs; the upper frequency limit of the technique is in the range of 3 GHz. Bipolar technology will be extended to 10 GHz by SiGe, but when these parts will be commercially available at competitive prices is currently unclear. There has not been enough published on the actual performance of Gilbert-cell-type mixers using SiGe transistors, but we assume that because of coupling on the silicon wafer, things are no longer as well behaved as we are used to at much lower frequencies.

4-4-3 FET Mixers

FETs, used in active and passive circuits, are still a popular solution for low-power integrated mixers up to 100 MHz (passive quad) and 1 GHz (dual-gate MOSFET). Cost-sensitive applications may require the use of a single-gate FET. These types of single-gate microwave mixers are frequently used to validate the quality of software but the user keeps forgetting this is a question of the quality of the model and not of the simulator. A good example of bad modeling is Figure 7.88 in Vendelin et al. [17]. Unfortunately, we have not seen the same circuit analyzed with modern tools, nor do the authors of the paper cited [18] provide sufficient details of the circuit and the transistor for us to do this ourselves.

Figure 4-57 shows a basic, active FET mixer. Like the single-diode and single-BJT mixers, it is additive, although it's common to lessen RF–LO interaction by injecting one signal at the gate and the other at the source as shown. Single-gate GaAs and LDMOS FETs are also used in this arrangement with gate biasing as appropriate to the device type. Figure 4-58 shows a dual-gate FET in an additive mixing configuration.

The linearity of FETs is based on the fact that a FET follows a square law and therefore the first derivative, its transconductance, is supposed to be constant. This is valid within a wide amplitude range. FET mixers have a noise figure similar to those found in bipolar mixers: typically around 6–9 dB, depending on the configuration. A FET mixer's intercept point is subject to load-impedance variations, with a purely resistive termination providing the best case. Terminating the mixer with a filter is problematic in that a filter looks purely resistive only within its 3-dB passband; in the transition band and beyond, the filter impedance rises rapidly and the mixer intercept point goes down. The best means devised so far to minimize this effect is to configure the FET output as a high-pass filter, using capacitive coupling from the output tuned circuit to a 50-(bandpass filter, as shown in Figure 4-59. Outside its passband, this impedance inverter acts more like a short circuit and maintains IMD products at a reasonable level. The alternative to this is the popular diplexer, which requires more components and has more insertion loss. The high-pass configuration has barely been mentioned in the literature.

MOTOROLA

Ultra Low Power DC - 2.4 GHz Linear Mixer

The MC13143 is a high compression linear mixer with single–ended RF input, differential IF output and differential LO inputs which consumes as little as 1.8 mW. A new circuit topology is used to achieve a high third order intermodulation intercept point, high linearity and high 1.0 dB output compression point while maintaining a linear 50 Ω input impedance. It is designed for Up or Down conversion anywhere from dc to 2.4 GHz.

Ultra Low Power: 1.0 mA @ V_{CC} = 1.8 to 6.5 V

- Wide Input Bandwidth: DC–2.4 GHz
- Wide Output Bandwidth: DC–2.4 GHz
- Wide LO Bandwidth: DC–2.4 GHz
- High Mixer Linearity: $P_{i1.0\ dB}$ = 3.0 dBm

Linearity Adjustment of up to IP_{3in} = 20 dBm

- 50 Ω Mixer Input
- Single–Ended Mixer Input
- Double Balanced Mixer Operation
- Differential Open Collector Mixer Output

MC13143

CIRCUIT DESCRIPTION

General

The MC13143 is a double–balanced Mixer. This device is designated for use as the frontend section in analog and digital FM systems such as Wireless Local Area Network (LAN), Digital European Cordless Telephone (DECT), PHS, PCS, GPS, Cellular, UHF and 800 MHz Special Mobile Radio (SMR), UHF Family Radio Services and 902 to 928 MHz cordless telephones. It features a mixer linearity control to preset or auto program the mixer dynamic range, an enable function and a wideband IF so the IC may be used either as a down converter or an up converter.

Current Regulation

Temperature compensating voltage independent current regulators provide typical supply current at 1.0 mA with no mixer linearity control current.

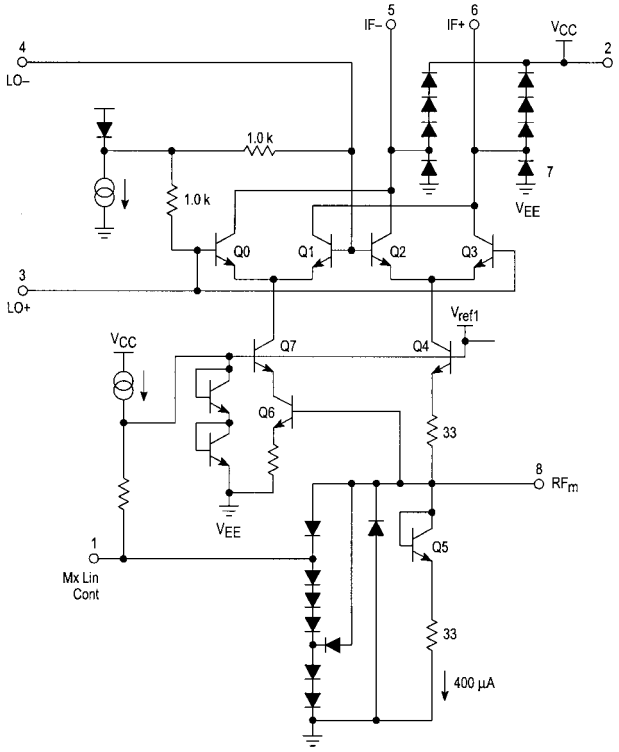
Mixer

The mixer is a unique and patented double–balanced four quadrant multiplier biased class AB allowing for programmable linearity control via an external current source. An input third order intercept point of 20 dBm may be achieved. All 3 ports of the mixer are designed to work up to 2.4 GHz. The mixer has a 50 Ω single–ended RF input and open collector differential IF outputs (see Internal Circuit Schematic for details). The linear gain of the mixer is approximately –5.0 dB with a SSB noise figure of 12 dB.

Local Oscillator

The local oscillator has differential input configuration that requires typically –10 dBm input from an external source to achieve the optimal mixer gain.

Figure 8. MC13143 Internal Circuit*



NOTE: * The MC13143 uses a unique and patented circuit topology.

MC13143

APPLICATIONS INFORMATION

Evaluation PC Board

The evaluation PCB is very versatile and is intended to be used across the entire useful frequency range of this device. The PC board is laid out to accommodate all SMT components on the circuit side (see Circuit Side Component Placement View).

Component Selection

The evaluation PC board is designed to accommodate specific components, while also being versatile enough to use components from various manufacturers. The circuit side placement view is illustrated for the components specified in the application circuit. The Component Placement View specifies particular components that were used to achieve the results shown in the typical curves and tables.

Mixer Input

The mixer input impedance is broadband 50 Ω for applications up to 2.4 GHz. It easily interfaces with a RF ceramic filter as shown in the application schematic.

Mixer Linearity Control

The mixer linearity control circuit accepts approximately 0 to 2.3 mA control current. An Input Third Order Intercept Point, IIP3 of 20 dBm may be achieved at 2.3 mA of control current (approximately 7.0 mA of additional supply current).

Local Oscillator Inputs

The differential LO inputs are internally biased at $V_{CC} - 1.0\ V_{BE}$; this is suitable for high voltage and high gain operation.

For low voltage operation, the inputs are taken to V_{CC} through 51 Ω.

IF Output

The IF is a differential open collector configuration which is designed to use over a wide frequency range for up conversion as well as down conversion.

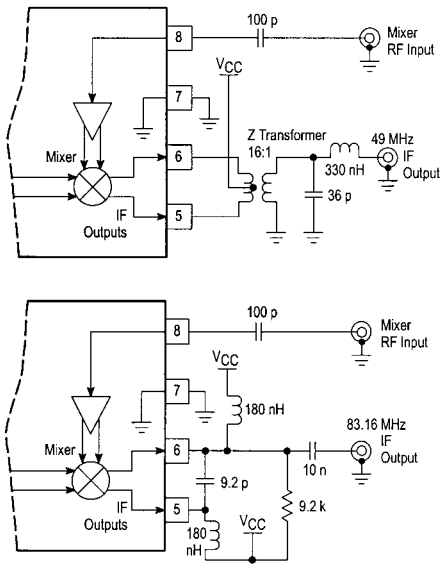
Input/Output Matching

It is desirable to use a RF ceramic or SAW filter before the mixer to provide image frequency rejection. The filter is selected based on cost, size and performance tradeoffs. Typical RF filters have 3.0 to 5.0 dB insertion loss. The PC board layout accommodates both ceramic and SAW RF filters which are offered by various suppliers such as Siemens, Toko and Murata.

Interface matching between the RF input, RF filter and the mixer will be required. The interface matching networks shown in the application circuit are designed for 50 Ω interfaces.

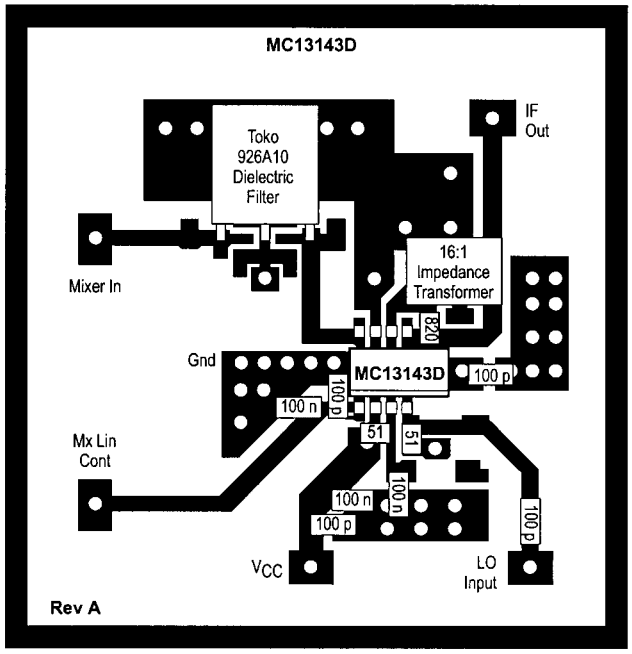
Differential to single–ended circuit configuration is shown in the test circuit. 6.0 dB of additional mixer gain can be achieved by conjugately matching the output of the MiniCircuits transformer to 50 Ω at the desired IF frequency. With narrowband IF output matching the mixer performance is 3.0 dB gain and 12 dB noise figure (see Narrowband 49 and 83 MHz IF Output Matching Options). Typical insertion loss of the Toko ceramic filter is 3.0 dB. Thus, the overall gain of the circuit is 0 dB with a 15 dB noise figure.

Figure 9. Narrowband IF Output Matching with 16:1 Z Transformer and LC Network



MC13143

Figure 10. Circuit Side Component Placement View



NOTES: 926.5 MHz preselect dielectric filter is Toko part # 4DFA–926A10; the 4DFA (2 and 3 pole SMD type) filters are available for applications in cellular and GSM, GPS, DECT, PHS, PCS and ISM bands at 902–928 MHz, 1.8–1.9 GHz at 2.4–2.5 GHz.

The PCB also accommodates a surface mount RF SAW filter in an eight or six pin ceramic package for the cellular base and handset frequencies. Recommended manufacturers are Siemens and Murata.

The PCB may also be used without a preselector filter; AC coupled to the mixer as shown in the test circuit schematic. All other external circuit components shown in the PCB layout above are the same as used in the test circuit schematic.

16:1 broadband impedance transformer is mini circuits part #TX16–R3T; it is in the leadless surface mount "TX" package. For a more selective narrowband match, a lowpass filter may be used after the transformer. The PCB is designed to accommodate lump inductors and capacitors in more selective narrowband matching of the mixer differential outputs to a single–ended output at a given IF frequency.

The local oscillator may also be driven in a differential configuration using a coaxial transformer. Recommended sources are the Toko Balun transformers type B4F, B5FL and B5F (SMD component).

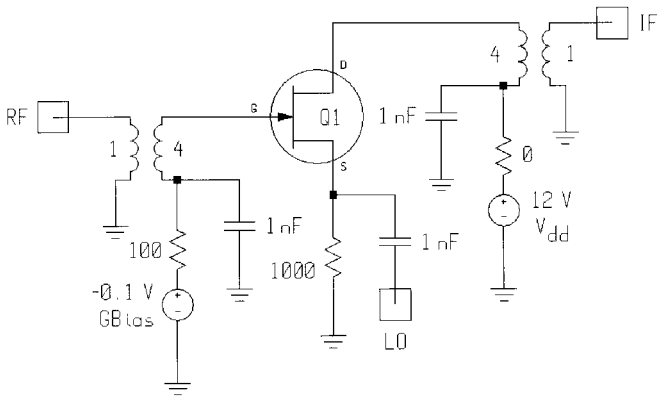


Figure 4-57 An additive JFET mixer cell using gate RF injection and source LO injection.

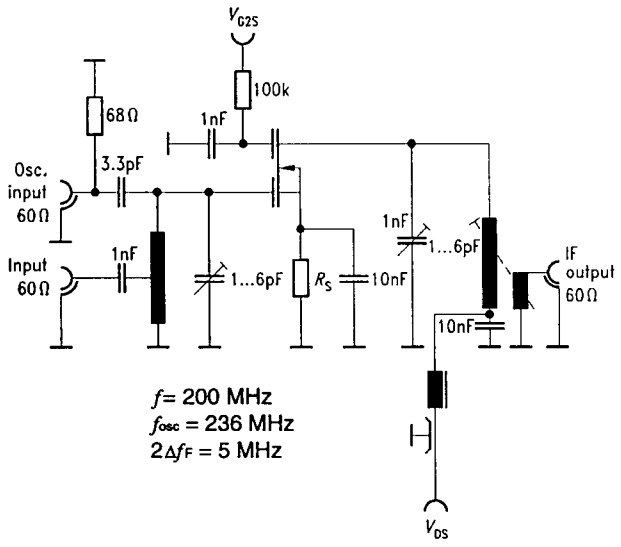

Figure 4-58 Test circuit for additive mixing using a dual-gate MOSFET.

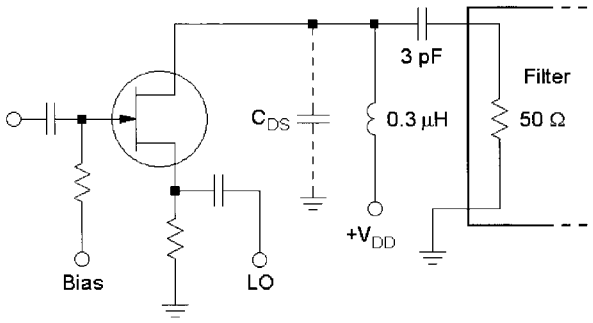

Figure 4-59 FET mixer output coupling that minimizes the effects of filter reactance outside the filter passband.

The active FET mixer achieves gain at the expense of intercept point; the difference can be as much as 20 dB. As an example, the passive MOSFET quad mixer, which is to be referenced, achieves an intercept point of greater than 40 dBm while similar active silicon FETs barely make 30 dBm. This 30-dBm performance is possible only at fairly low frequencies and requires careful selection and adjustment of the dc bias point of all transistors of the circuit. This performance also requires that the FETs be operated grounded-gate, which limits their gain. The other drawback of these active arrangements is that higher impedances at the output reduce the third-order intercept point overproportionally; as an example, a factor of two in impedance change can cost as much as 6 dB in the intercept point. In these discussions we assume that the IMD products are generated solely by the active device, and not by any passive devices, such as transformers. Actually, there are also some capacitors whose linearity varies with RF current—another unpleasant effect that is frequently overlooked.

On the other hand, one can use any FET as a passive device similar to a diode mixer, in which the source–drain channel gets switched on and off. This impedance modulation is somewhat similar to a diode mixer, but the gate electrode is isolated from both source and drain. It nonetheless falls into the category of additive mixers because there is sufficient interaction between gate and source, although the impedance at the gate changes significantly less than in an additive diode mixer. Implementation is a challenge in that building a high-performance passive FET mixer requires a pair or a quad of mixer cells that are sufficiently matched to suppress even-order IMD products. Intercept points, depending on the LO drive, vary between +20 and +45 dBm. The lower number is more applicable for microwave and RF frequencies, while the +45-dBm level is easily obtainable between and 5 and 30 MHz. It is necessary to remember that the FET is a voltage-driven switch, and LO matching becomes an issue: How do you generate 30 V peak-to-peak across a few picofarads over a wide frequency range? Physical layout can also be critical: Symmetry is not only important for the active devices, but also for the input, output, and LO circuit. We have seen cases where fractions of an inch in different lengths leading to the gate electrodes have cost up to 10 dB of IP_3—just because of the resulting lack of symmetry.

Figure 4-60 shows the circuit of Figure 4-57 modified to work with an LDMOS FET, the harmonic-balance version of the SPICE level 3 model. Figure 4-61 shows the LDMOS circuit's conversion gain and noise figure versus frequency. The "noisy" traces reflect the model's numerical problems. This model, which works up to about 0.8 μm and has been validated against the Motorola data and SPICE results, has already been made mathematically continuous but still shows the inability to properly model the real RF transistor. This is why more research needs to be done on RF and microwave applications for MOS in the modeling area. As can be seen from the references, several attempts have been made to improve the model, but the major headache remains with parameter extraction, and as the models get more complex, the modeling quality doesn't seem to improve as a linear function. The reader should be reminded of the load-pull measurement as outlined earlier.

Dual-Gate MOS/GaAs Mixers. Significantly better LO–RF isolation can be obtained by applying the RF to LO signals at separate gates of a dual-gate FET (Figure 4-62). The result is multiplicative mixing with fewer constraints on LO and RF filtering.

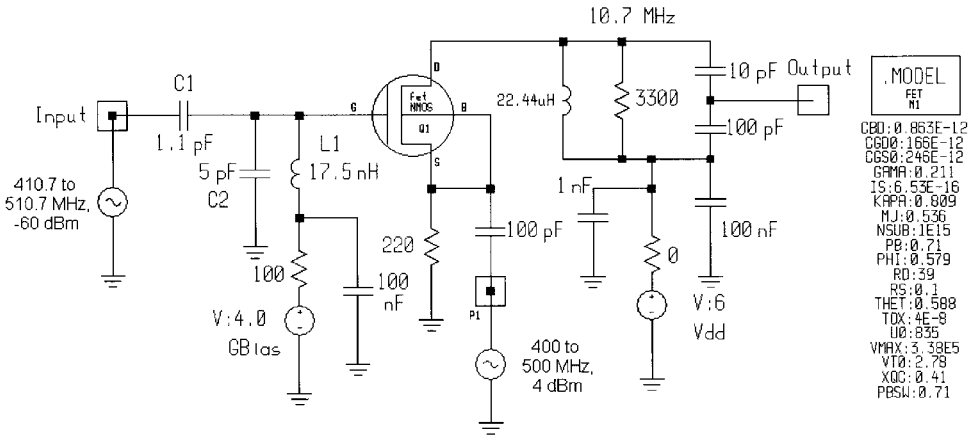

Figure 4-60 The N-JFET circuit of Figure 4-57 modified to work with an LDMOS FET.

4-4-4 MOSFET Gilbert Cell

The trend to go to smaller voltages has created some CMOS implementations of the Gilbert cell. While this may allow us to integrate reasonable mixers on the same chip, nobody should expect any miracles from these mixers. They are frequently starved in operating voltage and current and rarely fare better than a single diode mixer with proper drive level. On the other hand, the symmetry reduces some of the unwanted spurious frequencies and because of the high impedance, the actual RF power level is much less than the diode would need. There are so

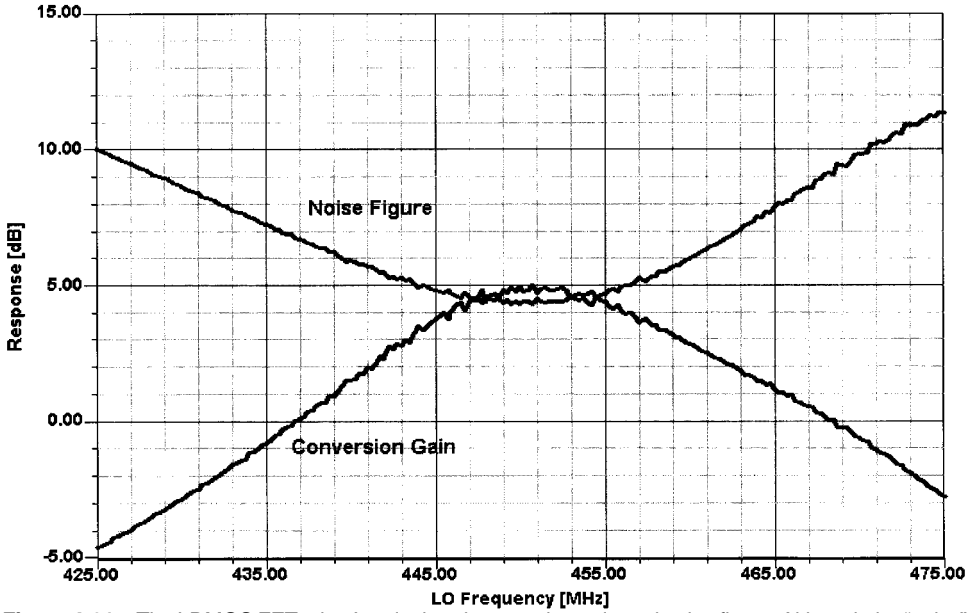

Figure 4-61 The LDMOS FET mixer's calculated conversion gain and noise figure. Although the "noisy" traces reflect numerical problems in the device model, the results can be put to good use in circuit design.

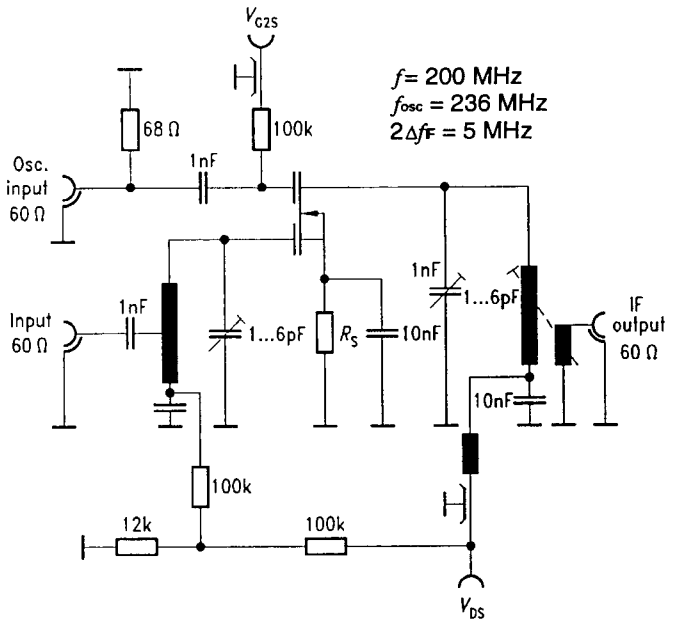

Figure 4-62 Test circuit for multiplicative mixing using a dual-gate MOSFET.

many CMOS transistors available in different processes that we cannot provide information about the general behavior, but this "low-cost" solution, as pointed out, is really only attractive because one can stay in the same technology while building the amplifier and other stages. Because of the flicker corner frequency of MOS, the noise figure of the mixer will be high compared to other devices, but not as bad as its GaAsFET brothers. In any case, to combine performance and simplicity, one needs to have a preamplifier that reduces the noise figure as well as the third-order intercept point of the mixer by the amount of preamplification.

4-4-5 GaAsFET Single-Gate Switch

In general, GaAsFET technology is the most expensive one. While GaAsFET competes with SiGe technology in frequency range at the time of this writing, it is a mature technology and well understood. The gallium arsenide wafers, however, are still unable to compete on a price basis with other technologies. There is a hybrid technology, silicon on sapphire, that also tries to go after the GaAsFET domain. The cutoff frequency of GaAsFET transistors is significantly higher than any other FETs, but the corner frequency f_c, also frequently referred to as flicker frequency, is somewhere between 10 and 100 MHz and therefore results in poor mixer performance from a noise figure point of view. The same applies, by the way, to oscillators. Another headache with GaAs is the low Q of the material, but this low Q gives transformers on GaAs a wider bandwidth. One of the pioneers of ICs for the wireless market is TriQuint, and we have been working with Wes Hayward of TriQuint in circuit analysis and validation. In doing so, we used some commercial and experimental circuits. In Chapter 3 we have already pointed out one amplifier that shows good agreement between measured and predicted data. By the time one has realized the entire circuit, including its associated biasing problems, even these circuits tend to grow. Figure 4-63 shows the circuit, which consists of an oscillator/amplifier, switching mixer, and a differential IF postamplifier.

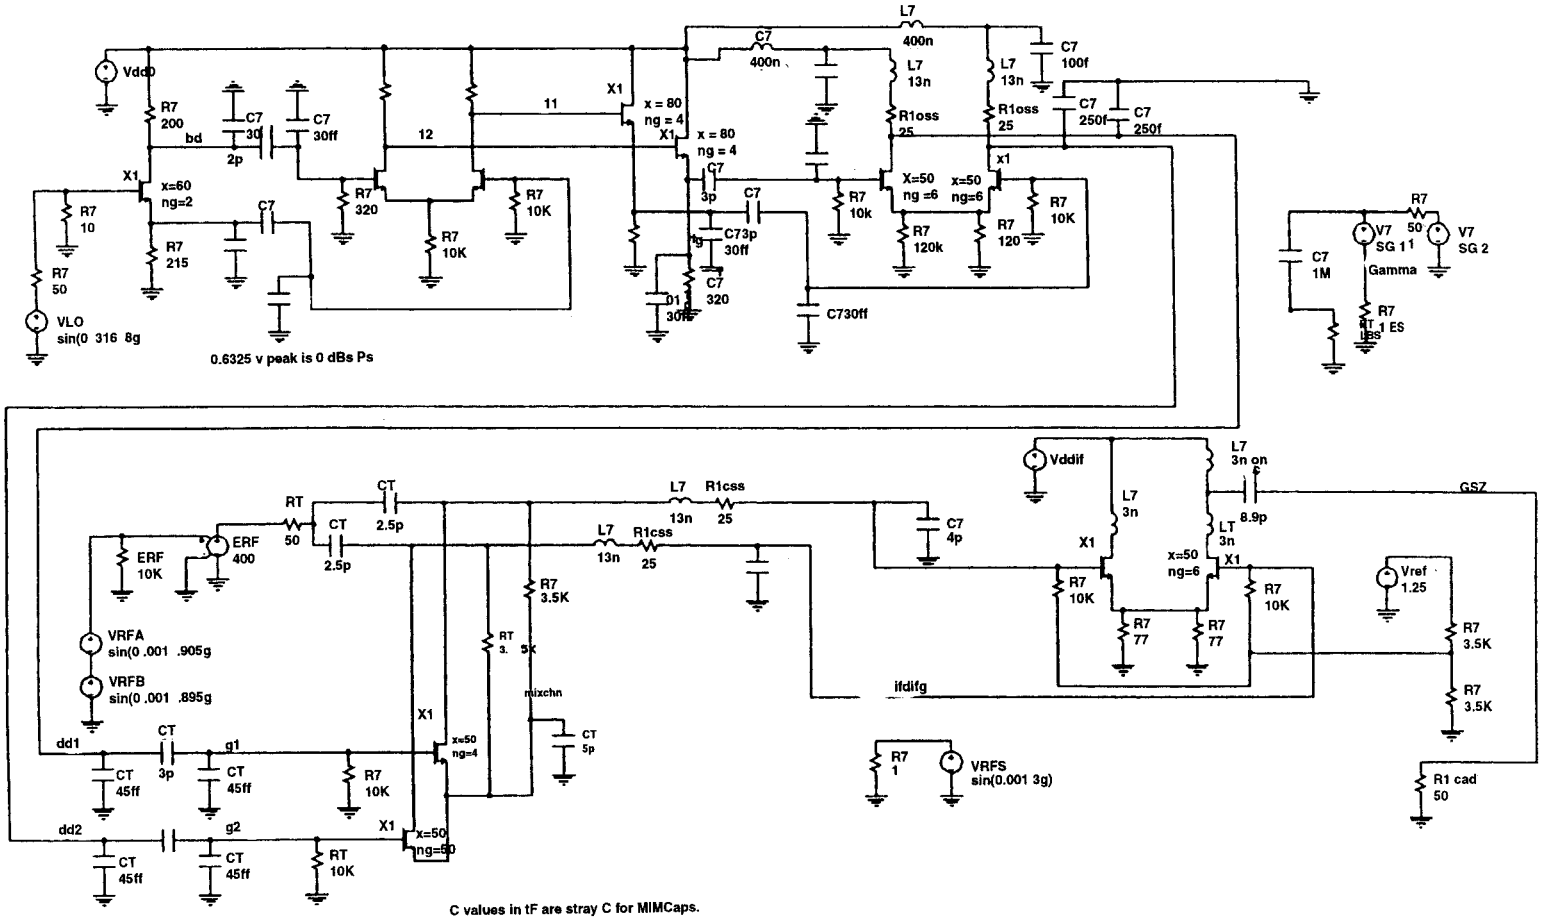

Figure 4-63 The complete switching mixer circuit.

Since the highest accuracy is needed to model these types of circuit, we found that only very recent simulators, such as Serenade 8 from Ansoft, can handle such a large number of FETs without barking at the user. Initially, we had all kinds of difficulties with these circuits because of the TriQuint TOM model, which had been developed for SPICE, and its IF/ELSE statements that made it mathematically discontinuous. The type of GaAsFETs used by TriQuint were both regular FETs and enhancement FETs, which require a positive voltage at the gate. Further details of this should be looked up in the foundry manual by TriQuint. In Chapter 2 we have shown some comparisons between different models and their prediction accuracy. Such converters need to resort to inductors in GaAs technology, and compared to other parts they become quite big (Figure 4-64).

In order to reduce some of the complexity in modeling and yet deal with the problems of mixers, a simpler mixer is needed that is a combination of a set of switching transistors and a postamplifier for the IF (Figure 4-65). The reader may notice that the small inductances of 15 nH have an extremely high loss modeled by a series resistor of 18 Ω. The first to recommend this type of switching mixers was probably Stephen Maas. The circuit diagram itself (Figure 4-65) is self-explanatory, but again we need to point out the resulting complexity.

The GaAsFET mixer giving the best performance on the market today is the Siemens model CMY210 (Figure 4-66). A reproduction of its datasheet, used by permission, follows the schematic.

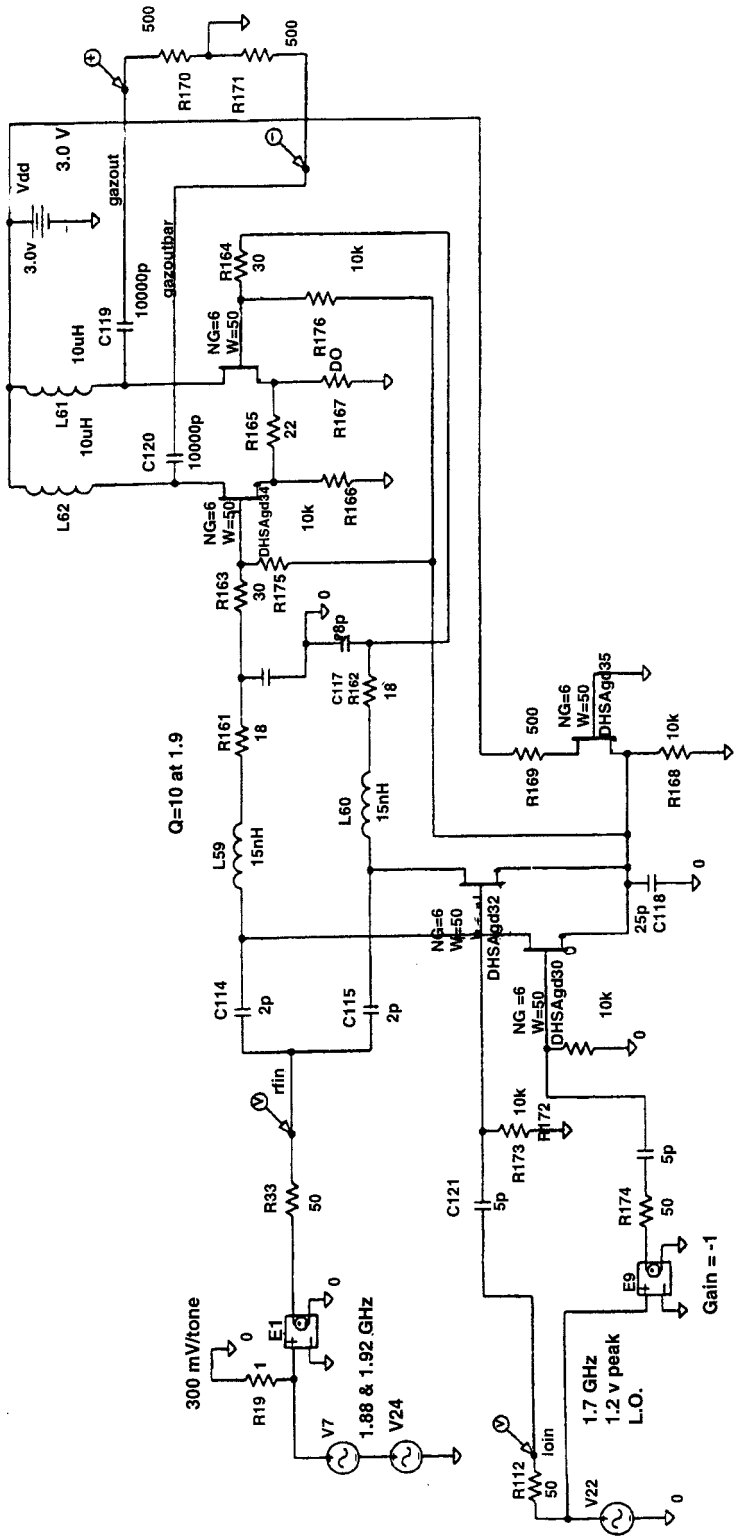

Figure 4-65 Simplified switching FET mixer.

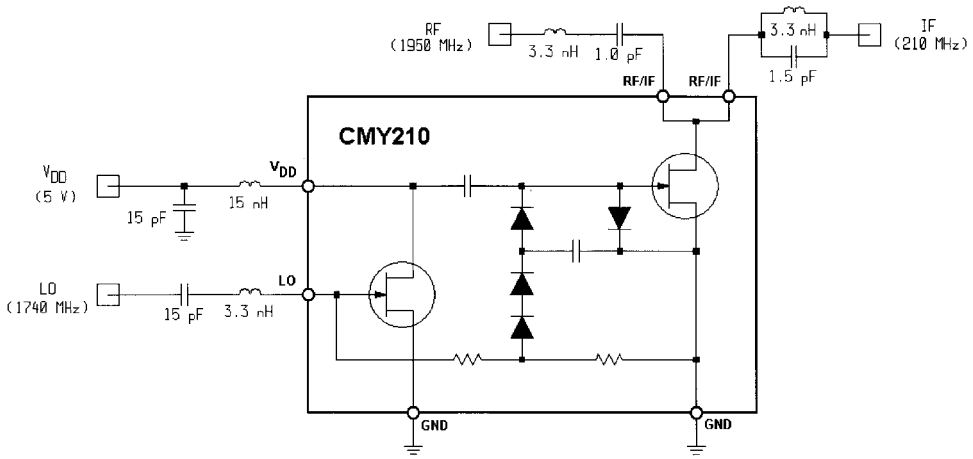

Figure 4-66 The Siemens CMY210 IC includes a shunt switch mixer and AGC-equipped LO amplifier for more constant LO drive. Despite its simplicity, this mixer achieves a typical $IP_{3,in}$ of 25 dBm.

The CMY210 circuit is a clever combination of a switching type of mixer with an automatic level control arrangement that provides the mixer with a reasonably constant drive level following the LO amplifier. Similar to cases we have shown, there is a clear relationship between the local oscillator power (invested dc power), and large-signal performance. This mixer externally has a series-tuned circuit at the input, which allows the UHF input signal

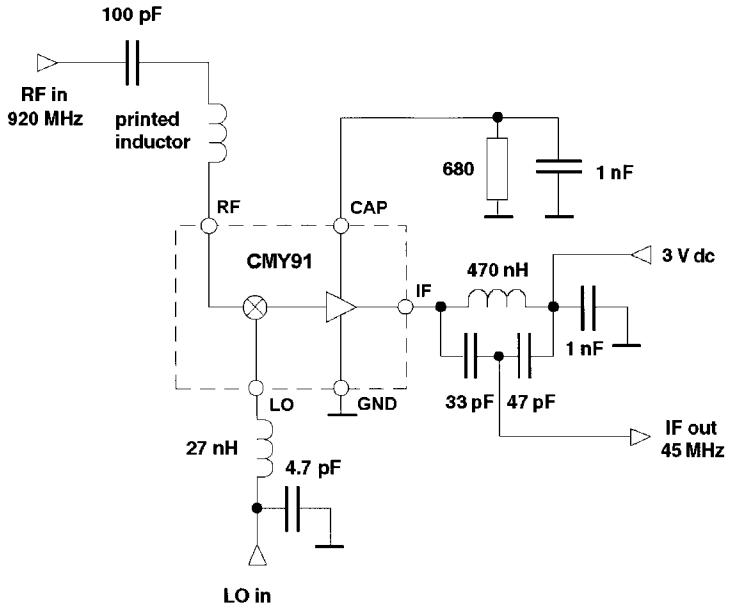

Figure 4-67 The CMY91 IC includes a postmixer amplifier instead of an AGC LO amplifier. Its $IP_{3,in}$ is typically –2 dBm (drain supply, 3 V at 1 mA) with no connection made to its CAP pin. In the configuration shown, its typical $IP_{3,in}$ is 0 dBm (drain supply, 3 V at 2.5 mA).

Notes for external elements:

L1, C1: Filter for upper frequency;
C2, L2: Filter for lower frequency;
each filter is a throughpath for the desired frequency (RF or IF) and isolates the other frequency (IF or RF) and its harmonics.
These two filters must be connected to pin 1 and pin 6 directly.
Parasitic capacitances at the ports 1 and 6 must be as small as possible.
L4 and C5 are optimized by indicating lowest I_{op} at used LO-frequency; same procedure for L3.
The ports 1, 3 and 6 must be DC open.

Approximate values of used elements for down- (or up-) conversion with a lower frequency of 10MHz to 120MHz (IF or RF; in or out); parasitics will cause deviations; therefore exact values will be defined by application, especially for *).

General description and notes:

The CMY 210 is an all port single ended general purpose Up- and Down-Converter.
It combines small conversion losses and excellent intermodulation characteristics with a low demand of LO- and DC-power.
The internal level controlled LO-Buffer enables a good performance over a wide LO level range.
The internal mixers principle with one port RF and IF requires a frequency separation at pin 1 and 6 respectively.

Note 1:
Best performance with lowest conversion loss is achieved when each circuit or device for the frequency separation meets the following requirements:

Input Filter: Throughpass for the signal to be mixed; reflection of the mixed signal and the harmonics of both.

Output Filter: Throughpass for the mixed signal and reflection of the signal to be mixed and the harmonics of both.

The impedance for the reflecting frequency range of each filter toward the ports 1 and 6 should be as high as possible.
In the simplest case a series- and a parallel- resonator circuit will meet these requirements but also others as appropriate drop in filters or micro stripline elements can be used.
The two branches with filters should meet immediately at the package leads of the port 1 and 6.
Parasitic capacitances at these ports must be kept as small as possible.
The mixer also can be driven with a source- and a load impedance different to 50Ω, but performance will degrade at larger deviations.

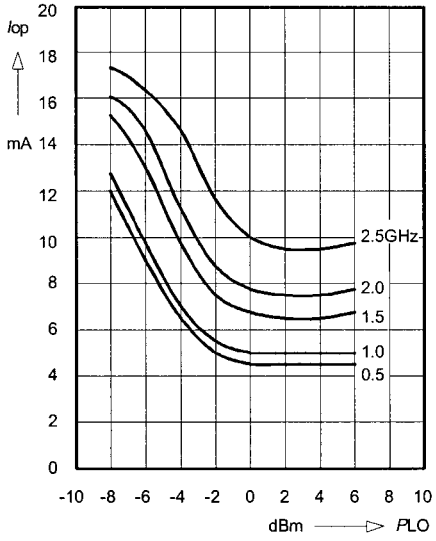
Note 2:
The LO-Buffer needs an external inductor L4 at port 4; the value of inductance depends on the LO frequency. It is tuned for minimum I_{op} consumption into port 4.
At lower LO frequencies it can be reduced by an additonal capacitor C5.

Note 3:
The LO Input impedance at Port 3 can be matched with a series inductor. It also can be tuned for a minimum current I_{op} into port 4. C3 is a DC blocking capacitor.
Since the input impedance of port 3 can be slightly negative at lower frequencies, the source reflection coefficient should be kept below 0.8 ($Z_0 = 50\ \Omega$) within this frequency range.

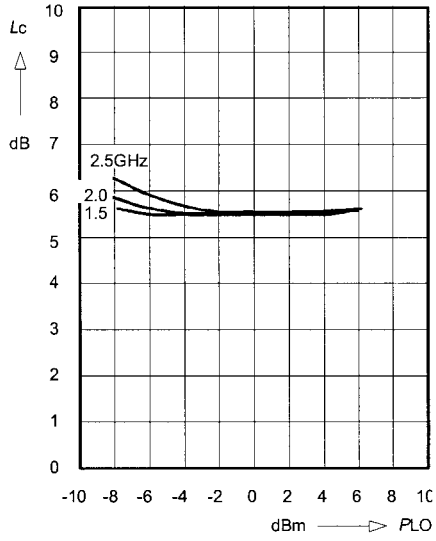
The Conversion Noise Figure Fssb is corresponding with the value of Conversion Loss L_c. The LO signal must be clean of noise and spurious at the frequencies $f_{LO} \pm f_{IF}$.

SIEMENS GaAs MMIC **CMY 210**

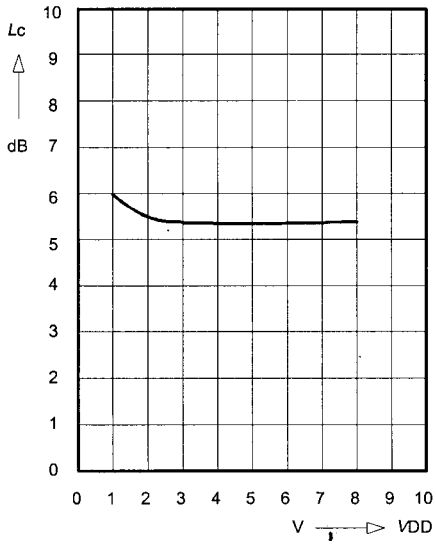
Operating Current $I_{op} = f(P_{LO})$
$V_{DD} = 3V$
f_{LO} = Parameter



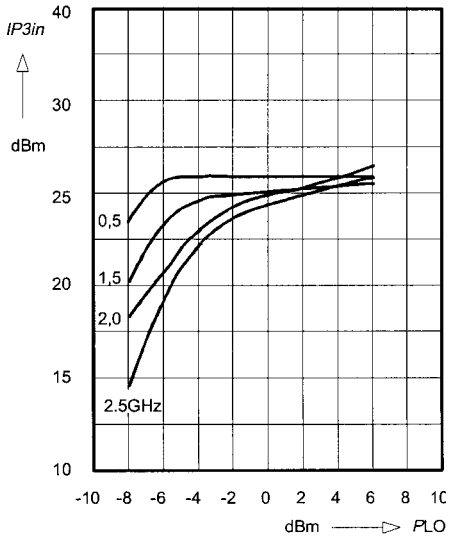
Conversion Loss $L_C = f(P_{LO})$
$V_{DD} = 3V$; $f_{IF} = 120MHz$
f_{LO} = Parameter



Conversion Loss $L_C = f(V_{DD})$
$P_{LO} = 0dBm$
$f_{LO} = 1500MHz$; $f_{IF} = 120MHz$

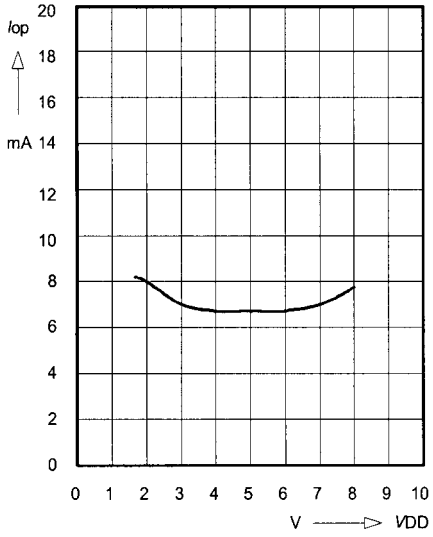


Third Order IP3 $IP3in = f(P_{LO})$
$P_{in} = 2$ x -3dBm; $f_{IF} = 40/45MHz$
$V_{DD} = 3V$; f_{LO} = Parameter;



SIEMENS GaAs MMIC **CMY 210**

Operating Current $I_{op} = f(V_{DD})$
P_{LO} = 0dBm
f_{LO} = 1500MHz



LO-Leakage at Port 1, 6 $P_{LO1,6} = f(f_{LO})$
P_{LO} = 0dBm
V_{DD} = 3V

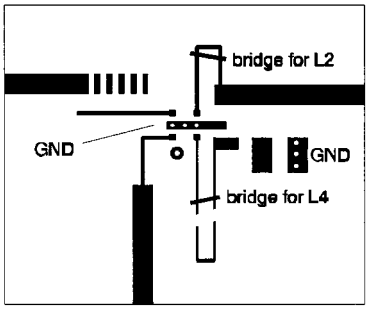
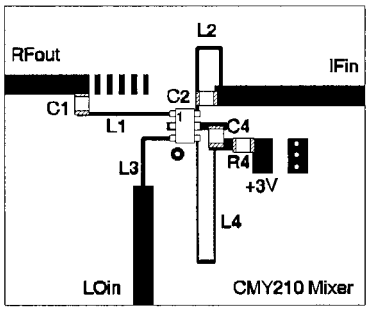
Additional informations and an example of a general purpose mixer pcb:

This general purpuse mixer demonstration board is used to show the performance of the CMY 210. The hints below will be helpful to achieve good intermodulation behaviour.



Material: Epoxy; size 24mm x 30mm; thickness 1mm

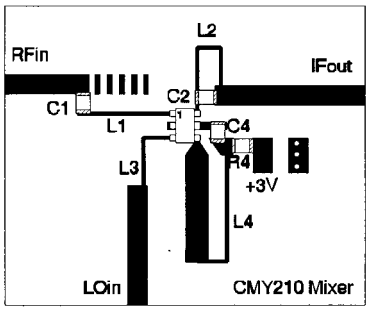
A good ground connection for CMY210 is necessary; here it is realized by 3 vias **under** the CMY 210 device. Best IM3 performance is obtained, when the capacitor C4 is grounded at the upper CMY 210 ground line without any additional vias (so the RF-Signal is encoupled from the LO-buffer best possible). Frequency tuning is done by selecting suitable capacitors C1 and C2, positioning C1 along the L1-line and by reducing the inductance of L2 and L4 by a bridge; unnecessary lines should be disconnected.



This example showes an up-converter.

The IM3 performance of upconverters mostly can be improved by tuning L4 slightly smaller then required for a minimum current consumption.

In other words, the resonant frequency of the buffer circuit at PIN4 (internal capacitor and L4) is tuned by L4 to a frequency slightly above the L.O.-frequency.



This example showes a down-converter.

Here an improved IM3-performance mostly can be obtained by a more capacitive load at CMY 210 port pin 4.
Here it is realized by a broader part of the L4 inductor line toward to port 4 and tuning L4 to a value sligthly smaller then for a minimum current consumption into port 4.

In other words, the resonant frequency of the buffer circuit at PIN4 (internal capacitor and L4) is tuned by L4 to a frequency slightly above the L.O.-frequency.

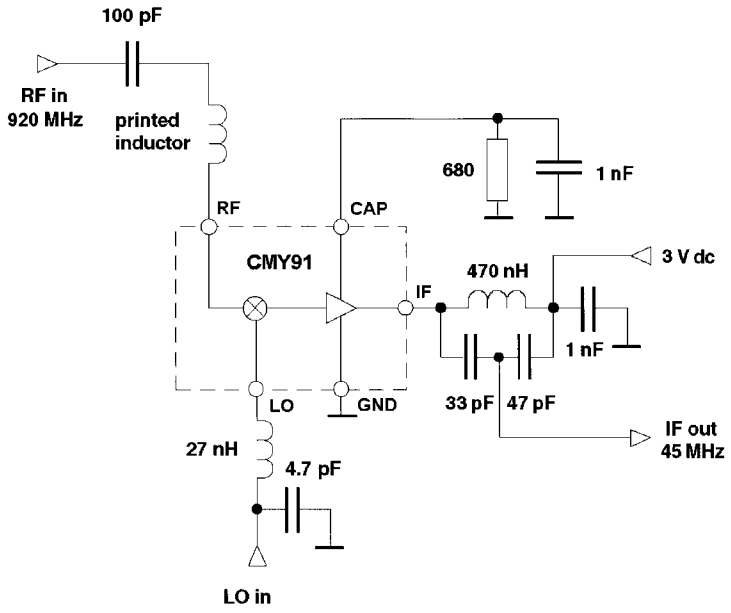


Figure 4-67 The CMY91 IC includes a postmixer amplifier instead of an AGC LO amplifier. Its $IP_{3,in}$ is typically –2 dBm (drain supply, 3 V at 1 mA) with no connection made to its CAP pin. In the configuration shown, its typical $IP_{3,in}$ is 0 dBm (drain supply, 3 V at 2.5 mA).

Table 4-6 Partial CMY91 specifications

Parameters		Symbol	Minimum	Typical	Maximum	Unit
Drain–source breakdown voltage						
I_{IF} = 500 µA	$V_{LO\text{-}GND}$ = 0 V					
$V_{RF\text{-}GND}$ = 4 V	CAP pin not connected	$V_{(BR)IF\text{-}GND}$	8	—	—	V
Drain current						
$V_{RF\text{-}GND}$ = 0 V	$V_{LO\text{-}GND}$ = 0 V					
$V_{IF\text{-}GND}$ = 3 V	CAP pin not connected	I_D	0.8	1	1.4	mA
Conversion gain						
f_{RF} = 920 MHz	f_{LO} = 965 MHz					
f_{IF} = 45 MHz	P_{LO} = –3 dBm	G_c	—	5.5	—	dB
Single-sideband noise figure						
f_{RF} = 920 MHz	f_{LO} = 965 MHz					
f_{IF} = 45 MHz	P_{LO} = –3 dBm	F_{SSB}	—	9	—	dB
Third-order intermodulation						
f_{RF} = 920 MHz	f_{LO} = 965 MHz					
f_{IF} = 45 MHz	P_{LO} = –3 dBm	IP_3	—	–2	—	dBm
LO/RF isolation						
f = 965 MHz		$Iso_{LO/RF}$	—	11	—	dB

T_A = 25 °C/V_D = 3 V; CAP pin connected to ground by 680-Ω resistor.

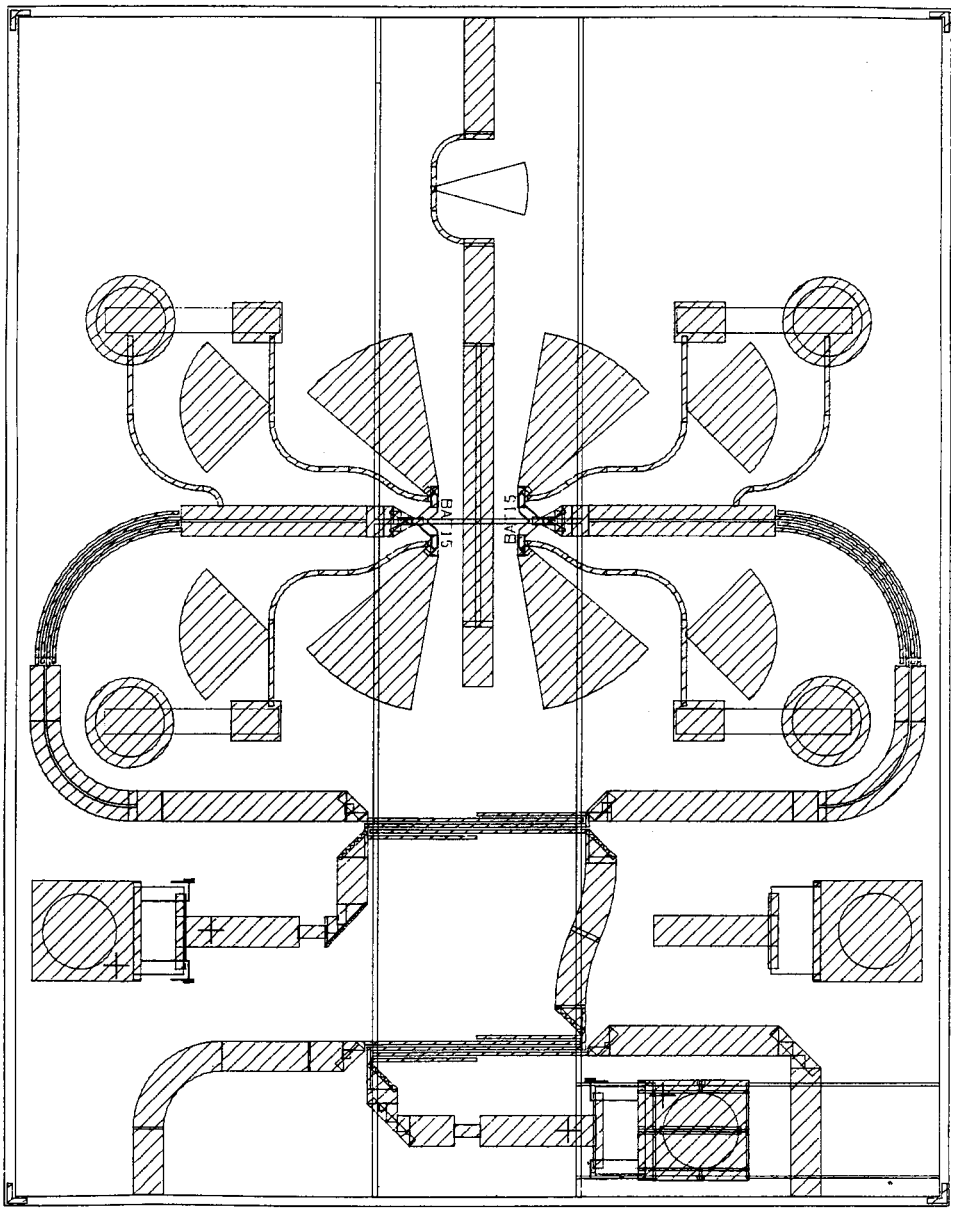

Figure 4-68 Layout of the 20-GHz diode mixer.

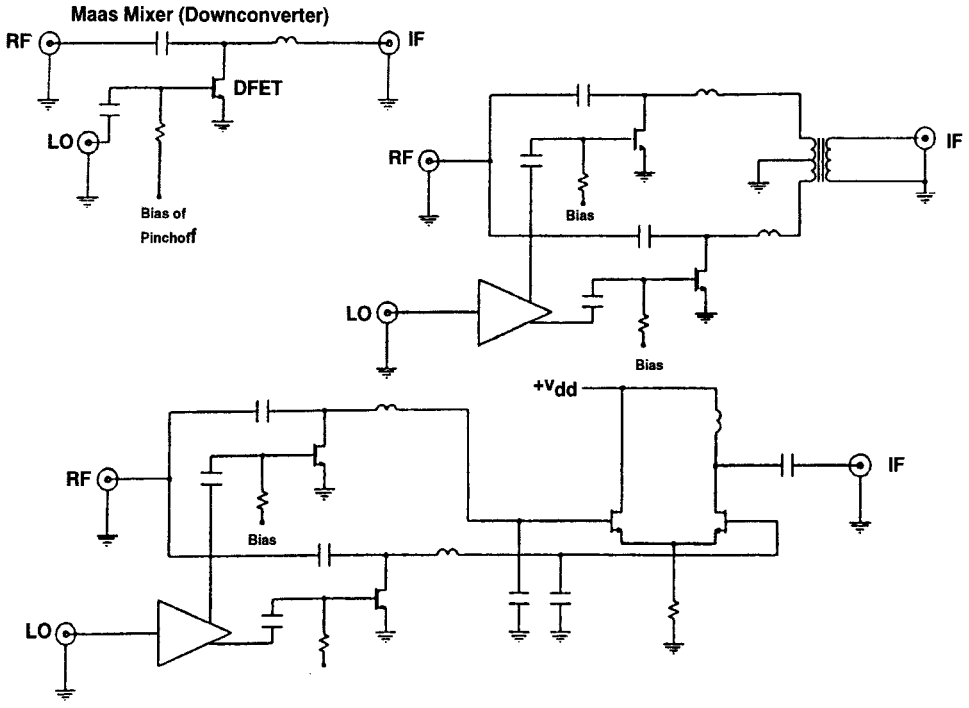

Figure 4-70a

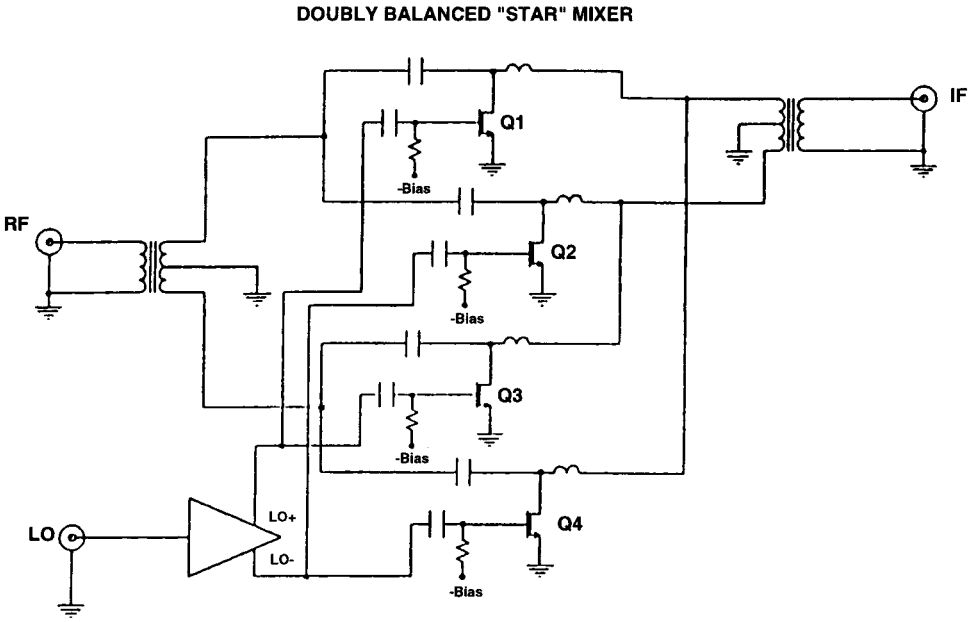

Figure 4-70b

to pass and has a parallel tuned circuit that keeps the input signal from getting into the IF stage. The resulting conversion loss of 5.5 dB is consistent with the example we presented before of 6 dB, and while the noise figure also is stated as 5.5 dB, that value is deceiving because it was determined using a 120-MHz IF. If an IF of 10 MHz or less was used, the noise figure would be tremendously worse. This is due to the frequently mentioned flicker-noise contribution. As a comparison, Figure 4-67 shows the predecessor to the CMY210, the CMY91, which includes a built-in IF amplifier. Table 4-6 shows its partial specifications. Since it has 5.5-dB gain, one can assume that the IF amplifier has something like 10 dB of gain, and the mixer portion, 6 dB losses. The resulting noise figure is the sum of the mixer noise figure and the IF amplifier noise figure. The IF transistor is probably not "noise matched" with the mixer, but the resulting 9-dB noise figure is not uncommon in this arrangement. Judging by previous examples, we would say that the noise figure of the mixer is somewhere around 6 dB, and therefore the mismatched (open at the input) IF amplifier has a noise figure of 3 dB, resulting in this total noise figure of 9 dB as stated. The third-order IP of –2 dBm is no match to the CMY210's $IP_{3,in}$ performance, which is typically 25 dBm.

For readers who are interested in what mixers look like when pushed well into the microwave region, we present the layout for a 20-GHz diode mixer. Figure 4-68 presents its layout, which includes radial stubs, circular stubs, and a Lange coupler. Figure 4-69 shows the layout implemented on a ceramic substrate.

As further food for thought and experimentation, Figure 4-70 presents mixer and related circuit notes as presented by Wes Hayward in TriQuint Semiconductor's GaAs Design Class.

HA Mixer Family Measurements

The mixers are all identical except for FET width. Mixers used the HA process and are half micron gate length. Bias was adjusted to best gain at +6 LO. The LO baluns were half wave lines of semi-rigid coax. F–LO = 1.65, RF = 1.9, and IF = 0.25 GHz. Input Power is –13 or –10 dBm RF. All measurements show downconversion results.

FET Width	P-av RF	P-LO dBm	P-out at IF	IMDR dB	Conv Gain dB	IP3-out dBm	IP3in dBm

MIXER DESIGN

4-1 INTRODUCTION

Radiocommunication requires that we shift a baseband information signal to a frequency or frequencies suitable for electromagnetic propagation to the desired destination. At the destination, we reverse this process, shifting the received radiofrequency (RF) signal back to baseband to allow the recovery of the information it contains. This frequency-shifting function is traditionally known as *mixing*; the stages that perform it are known as *mixers*. Any device that exhibits amplitude-nonlinear behavior can serve as a mixer, for, as we saw in Section 1-6-2, nonlinear distortion results in the production, from the signals present at the input of a device, of signals at new frequencies. Even a rusty screw or bolt on an antenna element can act as a mixer, producing unwanted IMD products that appear at the receiver input.

Although mixers are equally important in wireless transmission and reception, traditional mixer terminology favors the receiving case because mixing was first applied as such in receiving applications. Thus, the signal to be frequency shifted is applied to the mixer's RF port, and the frequency-shifting power or voltage [from a *local oscillator* (*LO*)] is applied to the mixer's LO port, resulting in two outputs at the mixer's *intermediate frequency* (*IF*) port. If the wanted IF is lower than the RF signal, the mixer is a *downconverter*; if the wanted IF is higher than the RF, the mixer is an *upconverter*. *Converter* may also be used as a term for a single stage that simultaneously acts as mixer and LO.

For a given RF signal, an ideal mixer with a perfect LO (i.e., an LO with no harmonics and no noise sidebands) would produce only two IF outputs: one at the frequency sum of the RF and LO, and another at the frequency difference between the RF and LO. Filtering can be used to select the desired IF product and reject the unwanted one, which is sometimes referred to as the *IF image*.

The simultaneous generation of LO + RF and LO – RF outputs results not from a departure of mixer performance from the ideal, but from the mathematics of mixing itself. Another unavoidable mixing artifact, the *RF image* response, also results from the mathematics of mixing rather than mixer nonideality. Just as a given RF/LO combination produces two IF outputs (LO + RF and LO – RF, the IF and IF image), the mixer will produce output at the

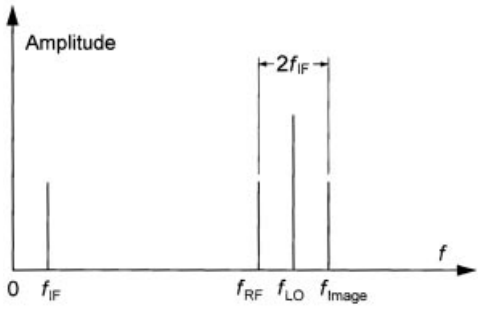

Figure 4-1 Relationship between a mixer's image and desired-signal responses. The image is $2f_{IF}$ away from the desired signal.

desired IF (LO + RF *or* LO – RF) in response to *two* possible RF inputs: one at LO + IF and another at LO (IF (Figure 4-1). The undesired response, the *RF image* (traditionally referred to merely as the *image*), is $2f_{IF}$ removed from the desired response. Even if no human-generated signals exist at the RF image frequency, reducing a mixer's RF image response can be important because noise at that frequency, including that produced by circuitry between the mixer and antenna, will still be mixed to the desired IF, degrading the signal-to-noise ratio. Filtering and phasing techniques can be used to reduce the RF or IF image responses: filtering if the image is sufficiently removed from the desired response that filtering will provide the necessary rejection; phasing if the desired and image responses are insufficiently spaced for filtering to work, as in the case of a double-conversion receiver in which signals at a high first IF (e.g., 50–70 MHz) must be converted to a very low first IF, such as 25 kHz.

The output of every real mixer includes a vast number of additional unwanted products, including noise, the fundamentals of the mixer's RF and LO signals and their harmonics, and the sums and differences of the RF and LO and their harmonics. Intermodulation distortion between multiple signals present at the RF port and IF output resulting from the mixing to IF of LO noise-sideband energy by strong adjacent signals (*reciprocal mixing*, Section 1-6-2) further complicate a mixer's output spectrum and may compromise system performance.

All mixers are *multipliers* in the sense that the various new outputs they produce can be described mathematically as the multiplicative products of their inputs. From an implementation standpoint, however, a given mixer circuit can be characterized as additive or multiplicative depending on how RF and LO signals are applied to it. Additive mixing occurs

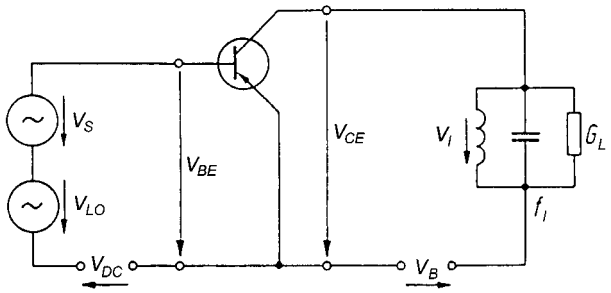

Figure 4-2 Additive mixing in a BJT [1].

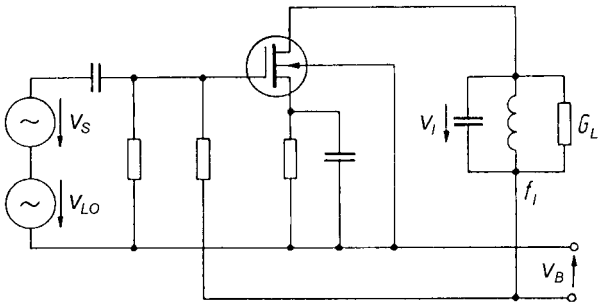

Figure 4-3 Additive mixing in a single-gate MOSFET [1].

when the RF and LO signals are applied to the same input port, as in Figures 4-2 and 4-3. Multiplicative mixing occurs when the RF and LO signals are applied to separate ports, as in Figure 4-4. As a rule, multiplicative mixers afford better isolation between their LO and RF ports than additive mixers, and this enhanced interport isolation is their principal merit. Multiplicative mixing does not in itself suppress unwanted products; the spurious response of a basic multiplicative mixer cell is poor unless it is used in a push–pull or quad configuration.

Let us now consider the basic theory of mixers. Mixing is achieved by the application of two signals to a nonlinear device. Depending on the particular device, the nonlinear characteristic may differ. However, it can generally be expressed in the form

$$I = K(V + v_1 + v_2)^n \tag{4-1}$$

The exponent n is not necessarily an integer, V may be a dc offset voltage, and the signal voltages v_1 and v_2 may be expressed as $v_1 = V_1 \sin(\omega_1 t)$ and $v_2 = V_2 \sin(\omega_2 t)$.

When $n = 2$, Eq. (4-1) may then be written as

$$I = K[V + V_1 \sin(\omega_1 t) + V_2 \sin(\omega_2 t)]^2 \tag{4-2}$$

This assumes the use of a device with a square-law characteristic. A different exponent will result in the generation of other mixing products, but this is not relevant for a basic understanding of the process. Expanding Eq. (4-2), we find

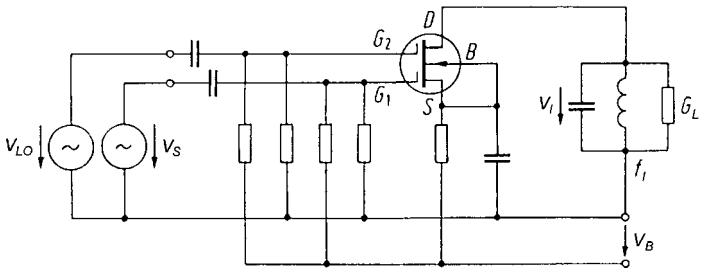

Figure 4-4 Multiplicative mixing in a dual-gate MOSFET. A dual-gate device is actually two single-gate devices in series [1].

$$I = K[V^2 + V_1^2 \sin^2(\omega_1 t) + V_2^2 \sin^2(\omega_2 t) + 2\,VV_1 \sin(\omega_1 t)$$

$$+ 2\,VV_2 \sin(\omega_2 t) + 2\,V_2V_1 \sin(\omega_2 t) \sin(\omega_1 t)] \tag{4-3}$$

The output comprises a direct current and a number of alternating current contributions. We are interested only in that portion of the current that generates the IF; so, if we neglect those terms that do not include both V_1 and V_2, we may write

$$I_{\text{IF}} = 2\,KV_1V_2 \sin(\omega_1 t) \sin(\omega_2 t)$$

$$I_{\text{IF}} = KV_2V_1\{\cos[(\omega_2 - \omega_1)t] - \cos[(\omega_2 + \omega_1)t]\} \tag{4-4}$$

This means that, at the output, we have the sum and difference signals available, and the one of interest may be selected by the IF filter.

4-2 PROPERTIES OF MIXERS

4-2-1 Conversion Gain/Loss

Even though a mixer works by means of the amplitude-nonlinear behavior in its device(s), we generally want (and expect) it to act as a linear frequency shifter. The degree to which the frequency-shifted signal is attenuated or amplified is an important mixer property. *Conversion gain* can be positive or negative; by convention, negative conversion gains are often stated as *conversion loss*.

In the case of a diode (passive) mixer , the insertion loss is calculated from the various loss components:

$$\text{Loss (dB)} = \text{Conversion loss} + \text{Transformer loss}$$

$$+ \text{Losses due to harmonic generation} + \text{Diode loss} \tag{4-5}$$

In the case of a double-balanced mixer (DBM), we must add the transformer losses (on both sides) and the diode losses as well as the mixer sideband conversion, which accounts, by definition, for 3 dB. Ideally, the mixer produces only one upper and one lower sideband, which results in the 3-dB loss compared to the input signal. Also, the input and output transformers add about 0.75 dB on each side, and of course there are the diode losses because of the series resistances of the diodes.

Figure 4-5 shows the equivalent circuit of a diode. It consists of a series (loss) resistor R_S and a time-variable electronic resistor, typically called the *diffusion resistance*, R_D, which equals 26 mV/I_D, and a capacitance C_D shunting R_D. C_D can be found from

$$C_D = \frac{W^2}{2D}\frac{I_D}{V_T} \tag{4-6}$$

where D is the diffusion constant, a material-dependent value, and W is the physical width. The average value for R_D is somewhere between the calculated value of 26 mV/I_D and some

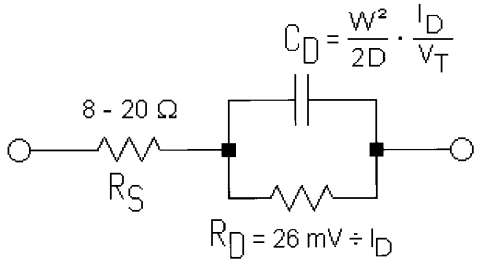

Figure 4-5 Equivalent circuit of a mixer diode.

leakage current, simply because it is generated by a rectification mechanism, which turns the LO power into an RF current and then into a combination of dc and RF currents.

We can calculate the diode loss according to

$$\text{Diode loss (db)} = \log 10\left(\frac{50 + (2 \times R_S)}{50}\right) \tag{4-7}$$

Assuming that $R_S = 8\ \Omega$, the diode loss for a diode-ring mixer is

$$\text{Diode loss (db)} = \log 10\left(\frac{50 + (2 \times 8)}{50}\right) = 0.5\ \text{dB} \tag{4-8}$$

From Eq. (4-5), the insertion loss for this mixer is therefore

$$\begin{aligned}\text{Loss (dB)} &= 3\ \text{dB (Conversion loss)} + 1.5\ \text{dB (Transformer loss)} \\ &\quad + 1\ \text{dB (Losses from harmonic generation)} + 0.5\ \text{dB (Diode loss)} \\ &= 6\ \text{dB}\end{aligned} \tag{4-9}$$

This assumes mixing at the fundamental frequency. Sometimes the diode loss resistor R_S is as high as 25 Ω per arm (as in a MOSFET switch), or 50 Ω total. This now results in

$$\text{Loss (dB)} = 3\ \text{dB} + 1.5\ \text{dB} + 1\ \text{dB} + 3\ \text{dB} = 8.5\ \text{dB} \quad \text{(Insertion loss)} \tag{4-10}$$

Since the value of R_S is partially determined by the threshold voltage of the diode and the diode diffusion resistance, R_D, a wide range of values can be noticed for different drive levels and mixer topologies. Figure 4-5 shows a shunt capacitance C_D, the so-called *diode diffusion capacitance*. When the diode is conducting, the influence of this nonlinearity is frequency dependent, which adds to the insertion loss. In this discussion we have not considered its frequency dependency. At wireless frequencies, modern Schottky diodes, also frequently called *hot-carrier* diodes, are operated far from their cutoff frequency, resulting in less than 1 dB of additional losses. There are also mixers with special circuitry to terminate the IF image. This is done with a diplexer circuit or equivalent circuitry. This makes insertion loss values as low as 4 dB possible; however, the large-signal condition or intercept point suffers.

4-2-2 Noise Figure

Like any network, a mixer contributes noise to the signals that it frequency-shifts. The degree to which a mixer's noise degrades the signal-to-noise ratio (see Section 1-7-1) of the signals it frequency-shifts is evaluated in terms of noise factor and noise figure as discussed in a subsection of Section 1-7-1 entitled "Noise Figure of Cascaded Networks."

For a long time, the literature has stated that the noise figure of a passive mixer, which is pretty much independent of its circuit arrangement, is equal to the mixer's insertion loss. But this neglects the influence of the white-noise contribution of the mixer's diode(s). This is ironic, considering that RF noise generators were long based on thermionic diodes operated in saturation (the 5722 noise diode was a popular type, as in the Rohde & Schwarz SKTU). Such a diode's noise power output can readily be determined from its saturation current. On the other hand, all Schottky diodes, while conducting, generate white noise that follows the same principle as above. This fact has been recognized by only a few companies that make modern noise-measurement equipment. Modern noise-measurement devices measure the noise figure of a system by a "hot and cold" technique, an approach based on knowledge of the absolute noise energy emitted under hot conditions (conductance). This method has the advantage that it can be used up to several tens of gigahertz, while the old vacuum-tube-based noise generators ran out of steam at around 1 GHz due to the inability to match the tube to the 50-Ω termination. This was typically accomplished by connecting a 50-Ω resistor between anode and ground (without dc connection), followed by a low-pass filter, which would match the tube capacitance and other parasitics to the required termination of 50 Ω, purely resistive.

In reality, we can take the loss calculation from above and add the Schottky noise generated by the diodes as they are driven by the local oscillator.

If a Schottky diode is used as a noise generator in the conductive mode, it generates a continuous frequency spectrum, possibly up to several gigahertz. There is a mathematical relationship between the noise power spectrum emitted by the diode and the time-averaged current of this diode, which generates the noise. If the noise source impedance is set (typically 50 Ω), the available noise power can be calculated according to

$$I_R = \sqrt{2e \times I_s \times \Delta f} \tag{4-11}$$

where $e = 1.6 \times 10^{-19}$ coulombs
I_s = saturation current of the diode
Δf = effective noise bandwidth

For $S_{11} = 0$ or proper termination of this circuit ($R_G = R_{term}$),

$$P_R = \left(\frac{I_R}{2}\right)^2 \times R_i$$

$$= \frac{e}{2} \times I_s \times \Delta f \times R_i \tag{4-12}$$

Calculated at a bandwidth of 1 Hz,

$$\frac{P_R}{\Delta f} = \frac{e}{2} \times I_s \times R_i \tag{4-13}$$

If

$$\frac{P_R}{\Delta f} = kT_0 \times F \tag{4-14}$$

the noise factor becomes

$$F = \frac{e \times I_s \times R_i}{2kT_0} \tag{4-15}$$

If the values for e and kT_0 are inserted,

$$F = 20 \times I_D \times \frac{26 \text{ mV}}{I_D} + \frac{R_S + R_G}{2R_G} \tag{4-16}$$

Example. Assume the passive mixer mentioned above with its 6-dB insertion loss is considered and a dc current of 15 mA results as a function of the LO drive. Since I_D gets canceled, the noise factor (F) of the diode portion equals

$$F = 20 \times I_D \times \frac{26 \text{ mV}}{I_d} + \frac{R_S + R_G}{2R_G}$$

$$= 0.52 + 0.58$$

$$= 1.1 \tag{4-17}$$

The noise figure, NF, is 10 log F, or 0.413 dB. Now this number and the insertion loss must be added. The resulting noise figure would be 6.413 dB. This is consistent with published measurement data.

Exact Mathematical Nonlinear Approach. The exact noise factor of a real mixer is computed by the formula

$$F = \frac{N_0(\omega_{\text{IF}}) + kT_0}{K_B T_0 G_{Tc}(\omega_{\text{RF}})} \tag{4-18}$$

where $N_0(\omega_{\text{IF}})$ = total noise power (per unit bandwidth) delivered to the IF load at intermediate frequency
K_B = Boltzmann's constant
T_0 = reference temperature (290 or 300 K is commonly used)
$G_{Tc}(\omega_{\text{RF}})$ = transducer conversion gain from ω_{RF} to ω_{IF}.

Let us now further elaborate on Eq. (4-18). We may write

$$N_0(\omega_{\text{IF}}) = N_S(\omega_{\text{IF}}) + N_{\text{INT}}(\omega_{\text{IF}}) + N_L(\omega_{\text{IF}}) + kT_0 \tag{4-19}$$

where N_S is noise generated by the RF source resistance and transferred to the IF load through frequency conversion, N_{INT} is noise generated internally to the mixer, and N_L is noise generated by the IF termination. If the source resistance is held at temperature T_0, N_S will basically originate from noise generated at the RF and image frequencies, which are transferred to the IF with approximately the same conversion gain, plus a relatively small contribution transferred from other sidebands with a smaller conversion gain. We may then write synthetically

$$N_S(\omega_{\text{IF}}) = 2aK_BT_0G_{Tc}(\omega_{\text{RF}}) \tag{4-20}$$

where a is a coefficient slightly larger than 1. $N_{\text{INT}}(\omega_{\text{RF}})$ is generated by transformer losses, by the diode Schottky noise, and by the diode resistive parasitics, and, in principle, it may take on any value; in particular, it may be zero if both the transformers and the diodes are ideal (i.e., if the latter are pure nonlinear resistors). As for $N_L(\omega_{\text{IF}})$, by Nyquist's theorem the IF load resistor R_L may be described as a noiseless resistor in series with a noise voltage source whose mean-square voltage (per unit bandwidth) is

$$|V_L|^2 = 4K_BT_LR_L \tag{4-21}$$

where T_L is the IF termination temperature. If the IF load is driven by a source with an output impedance $Z_{\text{out}}(\omega_{\text{IF}})$, the noise power actually delivered to the load will obviously be

$$N_{\text{out}} = \frac{4K_BT_LR_L^2}{|Z_{\text{out}}(\omega_{\text{IF}}) + R_L|^2} \tag{4-22}$$

In addition to N_{out}, the thermal noise originating from the IF termination delivered to the IF load at ω_{IF} will also include contributions from other sidebands that are backconverted by the mixer nonlinearities with a relatively small conversion gain. Thus, we may write

$$N_L(\omega_{\text{IF}}) = \frac{4bK_BT_LR_L^2}{|Z_{\text{out}}(\omega_{\text{IF}}) + R_L|^2} \tag{4-23}$$

where b is slightly larger than 1. If we now introduce the mixer conversion loss, namely,

$$L_C = \frac{1}{G_{Tc}(\omega_{\text{RF}})} \tag{4-24}$$

and combine Eq. (4-18) with Eqs. (4-19), (4-20), and (4-23), we finally get the noise factor expression:

$$F = 2a + \frac{N_{\text{INT}}(\omega_{\text{IF}}) + kT}{K_BT_0}L_C + \frac{4bT_LR_L^2}{T_0|Z_{\text{out}}(\omega_{\text{IF}}) + R_L|^2}L_C \tag{4-25}$$

In the normal region of operation of the mixer (sufficient LO drive) we may assume

Table 4-1 Noise figure and conversion gain versus LO power for a diode DBM

LO Power (dBm)	NF (dB)	Conversion Gain (dB)
–10.0	45.3486	–45.1993
–8.0	32.7714	–32.5264
–6.0	19.8529	–19.2862
–4.0	12.1154	–11.3228
–2.0	8.85188	–8.05585
0.0	7.26969	–6.51561
2.0	6.42344	–5.69211
4.0	5.85357	–5.15404
6.0	5.50914	–4.84439
8.0	5.31796	–4.66871
10.0	5.19081	–4.54960
12.0	5.08660	–4.45887
14.0	4.99530	–4.38806
16.0	4.91716	–4.33322
18.0	4.85920	–4.29407
20.0	4.82031	–4.26763

$$Z_{\text{out}}(\omega_{\text{IF}})R_L \tag{4-26}$$

so that Eq. (4-25) becomes

$$F = 2a + \frac{N_{\text{INT}}(\omega_{\text{IF}}) + kT}{K_B T_0} L_C + \frac{bT_L}{T_0} L_C \tag{4-27}$$

Multiplying $\log_{10} F$ by 10 gives us the exact mixer noise figure in dB.

The method just discussed is the basis for the far noise calculation for oscillators as mentioned in Chapter 5, in which it is referred to as conversion noise. This includes the AM-to-PM conversion noise.

Table 4-1 shows how the noise figure and conversion gain vary with LO power for a generic diode DBM (Figure 4-6). "Starving" a diode mixer by decreasing its LO drive rapidly degrades its performance in all respects.

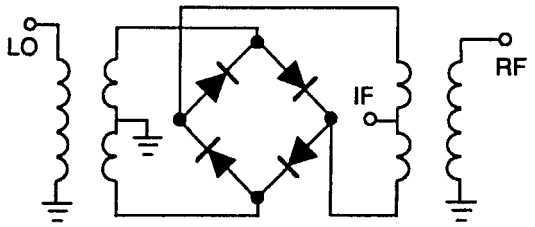

Figure 4-6 Generic diode DBM.

SSB Versus DSB Noise Figure. In radiocommunication, we typically use mixers as "single-sideband" devices; that is, we are interested in only one of the two possible RF inputs ($f_{LO} + f_{IF}$ or $f_{LO} - f_{IF}$) that produce output at the desired IF. The unused input is the *RF image* or simply *image*. A mixer's RF image response can be important even if no human-generated signals are present at f_{image} because noise there, including that produced by the mixer's RF-port termination, will be converted to the IF, possibly compromising the system's signal-to-noise ratio. As a result of this and the IEEE definition of noise figure [2], which, for a mixer, considers only the noise associated with a system's principal frequency transformation, some controversy exists about the definition and measurement of mixer noise figure. IEEE's NF definition for mixers assumes *no* noise contribution at f_{image}, not even from the mixer's RF-port termination at that frequency; yet, by convention (and out of necessity, since an absolutely noiseless $T = 0\,f_{image}$ termination is unavailable on the average test bench), the noise figures we measure always include *some* noise at f_{image}, even if, as a result of filtering, it arises only from the mixer's RF-port termination. The NF measurements and simulations presented in this book reflect this conventional SSB NF scenario. Stephen Maas [3] provides in-depth material on these issues, including the importance of double-sideband NF for some systems, and the limitations of NF as a figure of merit.

4-2-3 Linearity

The 1-dB Compression Point. Like other networks, a mixer is amplitude-nonlinear above a certain input level; above this point, the output level fails to track input-level changes proportionally. This figure of merit, P_{-1dB}, identifies the single-tone input-signal level at which the output of the mixer has fallen 1 dB below the expected output level. The 1-dB compression point in a conventional double-balanced diode mixer is approximately 6 dB below the LO power. For lower distortion mixers, it is usually 3 dB below the LO power.

The 1-dB Desensitization Point. This specification is another figure of merit similar to the 1-dB compression point. However, the 1-dB desensitization point refers to the level of an interfering (undesired) input signal that causes a 1-dB decrease in nominal conversion gain for the desired signal. For a diode-ring DBM, the 1-dB desensitization point is usually 2–3 dB below the 1-dB compression point.

Dynamic Range. The dynamic range of any RF/wireless system can be defined as the difference between the 1-dB compression point and the minimum discernible signal (MDS). These two points are specified in units of power (dBm), giving dynamic range in dB. When the RF input level approaches the 1-dB compression point, harmonic and intermodulation products begin to interfere with the system performance. High dynamic range is obviously desirable, but cost, power consumption, system complexity, and reliability must also be considered.

Harmonic Intermodulation Products (HIPs). These are spurious products that are harmonically related to the f_{LO} and f_{RF} input signals.

$$\text{HIP} = Mf_{LO} + Nf_{RF} \tag{4-28}$$

Table 4-2 Typical spurious responses of high-level double-balanced mixer (decibels below $f_{LO} \pm f_{RF}$ response)

RF Input Signal Harmonics		f_{LO}	$2f_{LO}$	$3f_{LO}$	$4f_{LO}$	$5f_{LO}$	$6f_{LO}$	$7f_{LO}$	$8f_{LO}$
$8f_{RF}$	100	100	100	100	100	100	100	100	100
$7f_{RF}$	100	97	102	95	100	100	100	90	100
$6f_{RF}$	100	92	97	95	100	100	95	100	100
$5f_{RF}$	90	84	86	72	92	70	95	70	92
$4f_{RF}$	90	84	97	86	97	90	100	90	92
$3f_{RF}$	75	63	66	72	72	58	86	58	80
$2f_{RF}$	70	72	72	70	82	62	75	75	100
f_{RF}	60	0	35	15	37	37	45	40	50
		60	60	70	72	72	62	70	70

Table 4-2 shows relative harmonic intermodulation product levels for a high-level diode DBM.

Intermodulation Distortion (IMD). Nonlinearities in the mixer devices give rise to intermodulation distortion products whenever two or more signals are applied to the mixer's RF port. Testing this behavior with two (usually closely spaced) input signals of equal magnitude can return several figures of merit depending on how the results are interpreted. A mixer's third-order output intercept point ($IP_{3,out}$) is defined as the output power level where the spurious signals generated by $(2f_{RF1} \pm f_{RF2}) \pm f_{LO}$ and $(f_{RF1} \pm 2f_{RF2}) \pm f_{LO}$ are equal in amplitude to the desired output signal as shown in Figure 4-7.

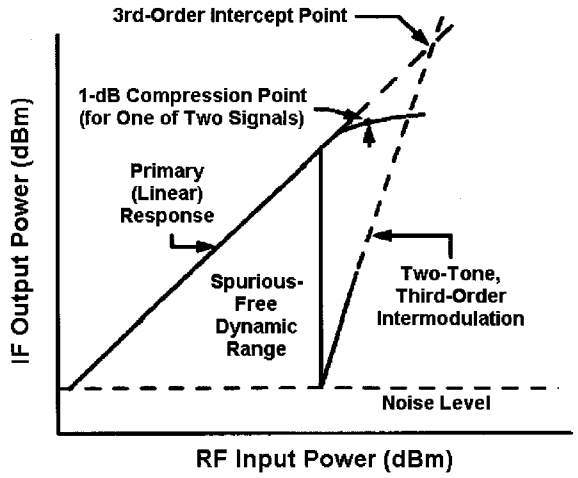

Figure 4-7 Mixer linearity evaluation, including compression and two-tone IMD dynamic range. P_{-1dB} for a single tone cannot be read directly from this graph because the values shown are the result of two-equal-tone drive.

The third-order input intercept point, $IP_{3,in}$—IP_3 referred to the input level—is of particularly useful value and is the most commonly used mixer IMD figure of merit. $IP_{3,in}$ can be calculated according to

$$IP_{n,in} = IMR \div (n - 1) + \text{Input power (dBm)} \tag{4-29}$$

where *IMR* is the intermodulation ratio (the difference in dB between the desired output and the spurious signal), and n is the IM order—in this case, 3. In a conventional diode double-balanced mixer, $IP_{3,in}$ is approximately 14 dB above the single-tone 1-dB compression point (P_{-1dB})—approximately 8 dB greater than the local oscillator power. As will be seen later, this does not apply to feedback-active mixers. They have their own agenda: Above a particular input level, their IMD products increase almost exponentially.

Although designers are usually more concerned with odd-order IM performance, second-order IM can be important in wideband systems (systems that operate over a 2:1 or greater bandwidth) as discussed in Section 1-7-2.

4-2-4 LO Drive Level

A mixer's specifications are usually guaranteed at a particular LO drive level, usually specified as a dBm value that may be qualified with a tolerance. Insufficient LO drive degrades mixer performance; excessive LO drive degrades performance and may damage mixer devices. Commercially available diode mixers are often classified by LO drive level; for example, a "Level 17" mixer requires 17 dBm of LO drive.

4-2-5 Interport Isolation

In a mixer, isolation is defined as the attenuation in dB between a signal input at any port and its level as measured at any other port. High isolation numbers are desirable. Figure 4-8 shows LO-to-IF and LO-to-RF isolation versus frequency for a triple-balanced diode DBM. Isolation is dependent mainly on transformer and physical symmetry and device balance, but the level of signals applied to the mixer also plays a role, as shown in Figure 4-9.

4-2-6 Port VSWR

The load presented by a mixer's ports to the outside world can be of critical importance to a designer. For example, high LO-port VSWR may result in inefficient use of available LO power, resulting in LO starvation (underdrive) that degrades the mixer's performance. Figure 4-10 shows LO-port VSWR versus frequency for a high-level diode DBM with two values of LO power. Like interport isolation, port VSWR can vary with the level of the signal applied.

4-2-7 dc Offset

Isolation between ports plays a major role in reducing dc offset in a mixer. Like isolation, dc offset is a measure of the imbalance of the mixer. In phase-detector and phase-modulator applications, dc offset is a critical parameter.

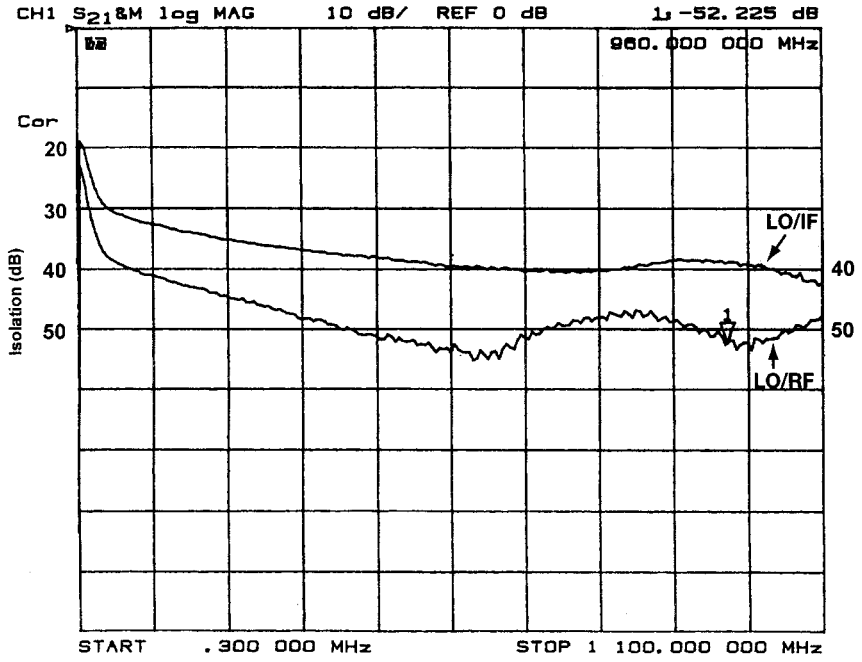

Figure 4-8 LO–IF and LO–RF isolation versus frequency for a high-level triple-balanced diode mixer. The periodic roughness of the traces is a measurement-system artifact, proving that even sophisticated FFT-based instruments are not perfect.

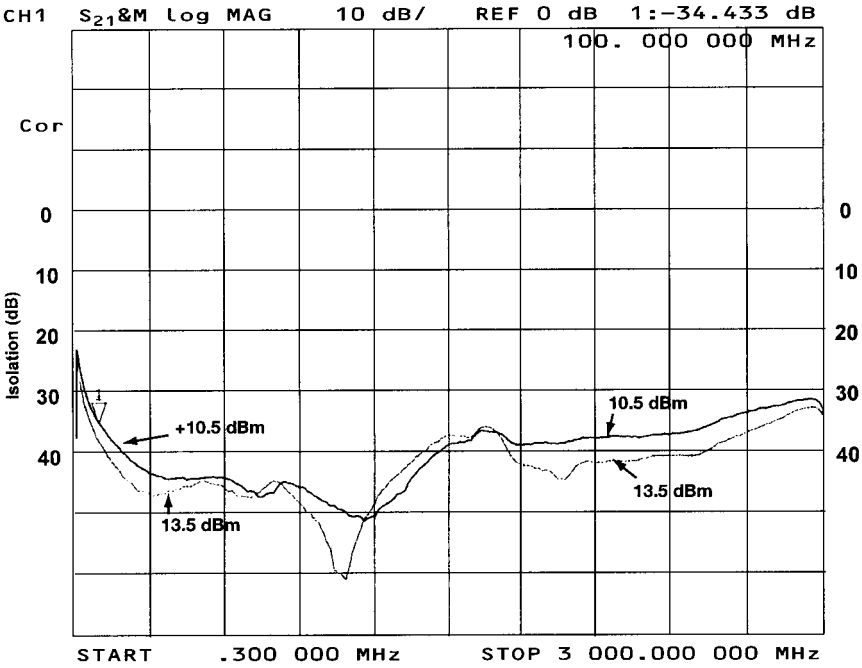

Figure 4-9 LO–IF isolation versus frequency and LO drive level for a high-level diode DBM.

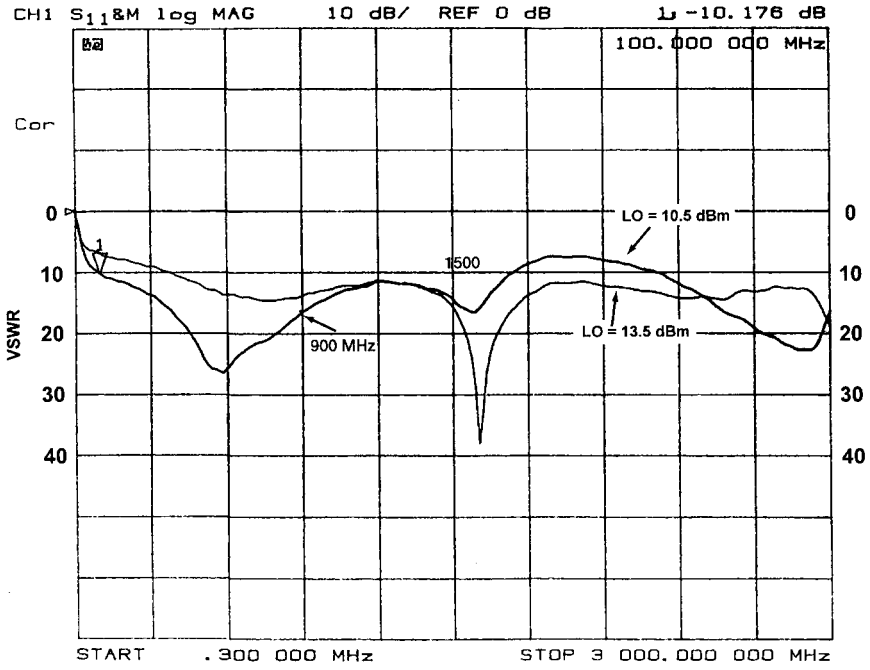

Figure 4-10 LO-port VSWR versus frequency for a high-level diode DBM.

4-2-8 dc Polarity

Unless otherwise specified, mixers with dc output are designed to have negative polarity when RF and LO signals are of equal phase.

4-2-9 Power Consumption

Circuit power consumption is always important, but in battery-powered wireless designs it is *critical.* Mixer choice may be significant in determining a system's power consumption, sometimes in ways that seem paradoxical at first glance. For instance, a passive mixer might seem to be a power-smart choice because it consumes *no* power—until we factor in the power consumption of the circuitry needed to provide the (often considerable) LO power a passive mixer requires. If a mixer requires a broadband resistive termination that will be provided by a postmixer amplifier operating at a high standing current, the power consumption of the amplifier stage must be considered as well. Evaluating the suitability of a given mixer type to a task therefore requires a grasp of its ecology as well as its specifications.

4-3 DIODE MIXERS

Passive mixers based on diode switches are common in base-station applications, where their high dynamic range and 50-Ω port impedances overcome objections to their inherent conversion loss, unsuitability to integration, and relatively high LO-power requirement. As we'll discuss later, FET-based passive mixers are overcoming some of these limitations in portable/mobile wireless applications.

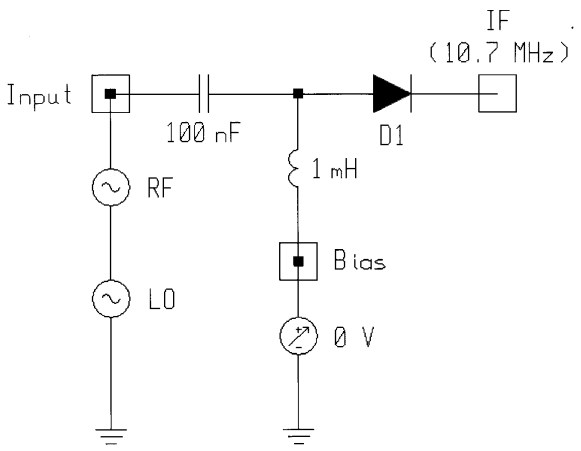

Figure 4-11 Schematic of the single-diode mixer. The circuit's 50-Ω output termination serves as the diode's dc return, as well as completing the circuit for RF, LO, and IF.

4-3-1 Single-Diode Mixer

Figure 4-11 shows the schematic of a simplistic single-diode mixer. The LO and RF signals are applied in series to the diode, with no effort made to match the sources to the diode or isolate the sources from each other. The LO and RF signals are both present in the diode simultaneously, so the mixing performed is additive. The LO signal switches the diode on and off, gating the RF signal to the circuit's output at the LO frequency. In this simple circuit, the output port's 50-Ω resistance serves as the diode's ac load and dc return. Because we want the diode to operate as a linear switch with respect to the RF signal, the diode should turn on hard and turn off as completely as possible, and the LO, not the RF source, should switch the diode on and off. The upper frequency limit of the circuit will depend on how rapidly the diode can switch between the on and off states. The LO can be only so strong before the diode's dissipation limits are exceeded; the RF source can be only so strong relative to the LO before it begins to play a role in switching the diode on and off. The LO must therefore be considerably stronger than the RF source—20 dB or more for low-distortion applications.

Figure 4-12 shows how the single-diode mixer's conversion gain and noise figure vary with applied LO power. Figure 4-13 shows the mixer's output spectrum.

Tables 4-3, 4-4, and 4-5 present sample data on diodes suitable for mixer service. The manufacturer's full datasheet on the Siemens BAT14-099 follows.

The simple single-diode-mixer circuit shown in Figure 4-11 is intended only as an illustration of the basic behavior of diode mixer behavior. A practical single-diode mixer would include filtering at its RF, LO, and IF ports—RF filtering for image rejection, reduced LO radiation and optimum matching of the RF source to the diode; LO filtering to keep RF out of the LO and optimally match the LO to the diode; and IF filtering to optimally match the diode to its IF (and IF image) load, preferably while providing some rejection of the mixer's unwanted outputs, the strongest (and most potentially troublesome) of which is the LO signal. Detail on the design of single-diode mixers can be found in Zinke and Brunswig [4].

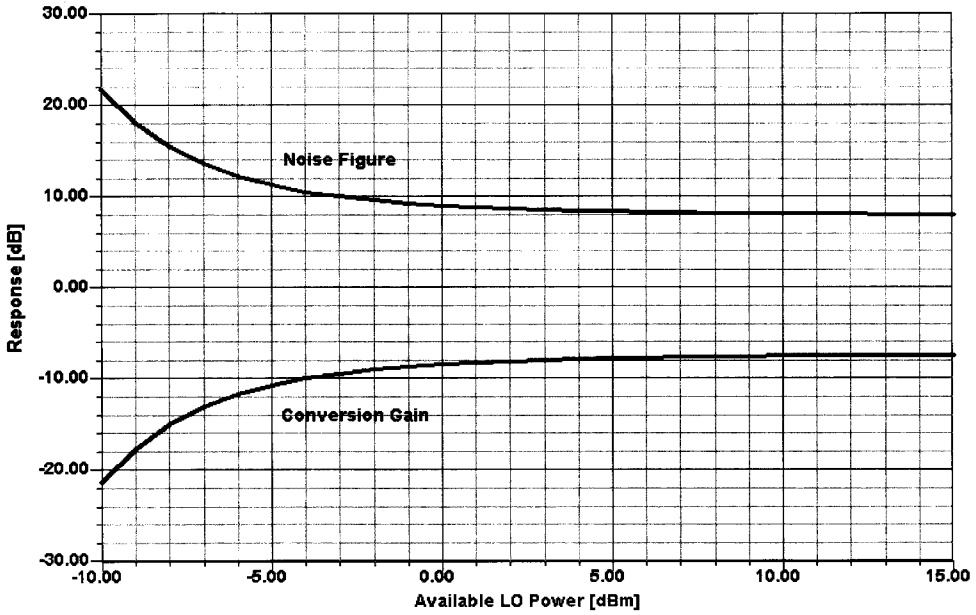

Figure 4-12 Conversion gain and noise figure versus LO power for the single-diode mixer. The values reported are worse than those predicted by theory because RF, LO, and IF matching has not been attempted. In this analysis, LO = 310.7 MHz (–10 to 25 dBm), RF = 300 MHz (–50 dBm), and IF = 10.7 MHz.

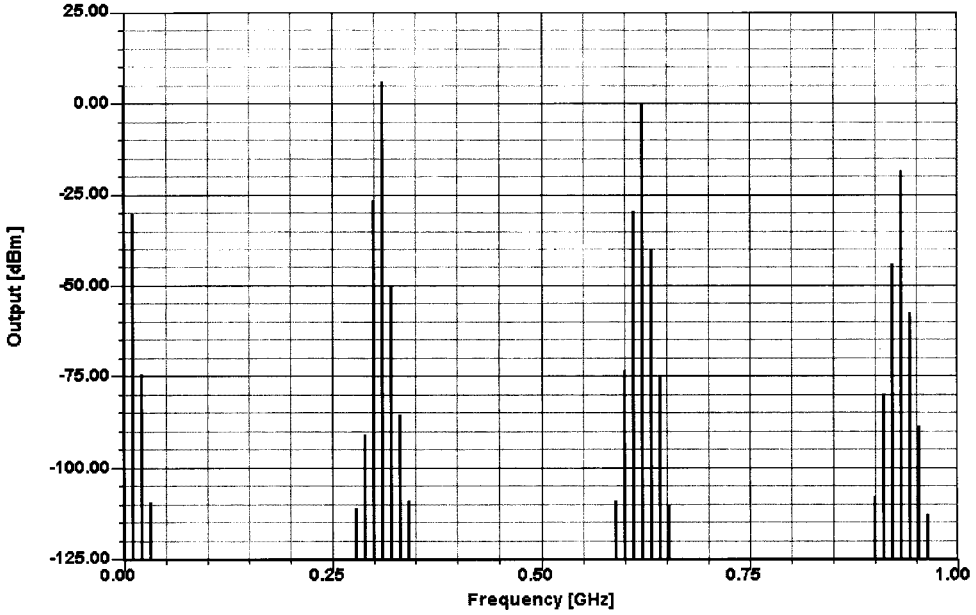

Figure 4-13 Output spectrum of the single-diode mixer. Three LO harmonics and 3 LO sidebands were used in this analysis. In this analysis, LO = 310.7 MHz (13 dBm), RF = 300 MHz (–20 dBm), and IF = 10.7 MHz.

4-3-2 Single-Balanced Mixer

Figure 4-14 shows the schematic of a two-diode, *single-balanced* mixer (SBM). Unlike the single-diode mixer, it performs multiplicative mixing because its RF and LO signals are applied to different ports. In this more commonly seen two-diode mixer configuration, a balanced transformer drives the diodes out of phase for the LO and in phase for signals present at the RF port. Figure 4-15 shows how this mixer's conversion gain and noise figure vary with applied LO power. Figure 4-16 shows how the mixer's conversion gain and noise figure vary with frequency for a constant LO power.

2. R_T is the slope resistance.

The two-diode mixer is used mostly in the frequency range above 1 GHz in a manner akin to a phase discriminator, using step-recovery diodes in the LO feed for enhanced harmonic mixing. Such mixers are mainly used in medium-cost spectrum analyzers or microwave receivers up to several tens of gigahertz, with the necessary transformers and baluns printed on the circuit board. With perfectly matched diodes and perfect transformer and constructional symmetry, no LO energy arrives at the IF and RF ports, and there is only slight attenuation between the RF and IF ports. Both building and computer modeling such a mixer are impossible: building, because perfectly matched diodes and perfect transformer and constructional symmetry cannot be achieved in practice; computer modeling, because floating-point mathematics runs out of gas in handling the infinite amplitude spread involved in calculating the perfect cancellation of the LO signal as it travels to the RF and IF ports. That said, Figure 4-17 compares the mixer's *quasi*-ideal port-to-port isolation (matched diodes, a perfect transformer, no stray inductances and capacitances, and a 10-MΩ resistors

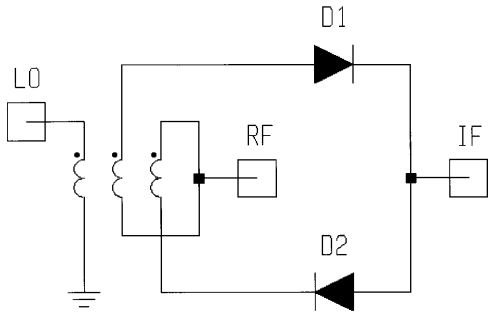

Figure 4-14 Schematic of the two-diode (also known as *single-balanced*) mixer.

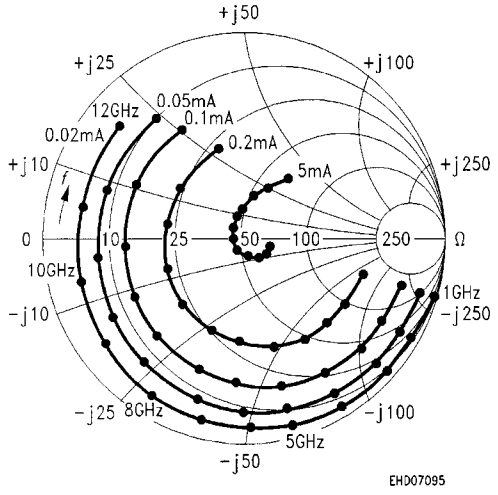

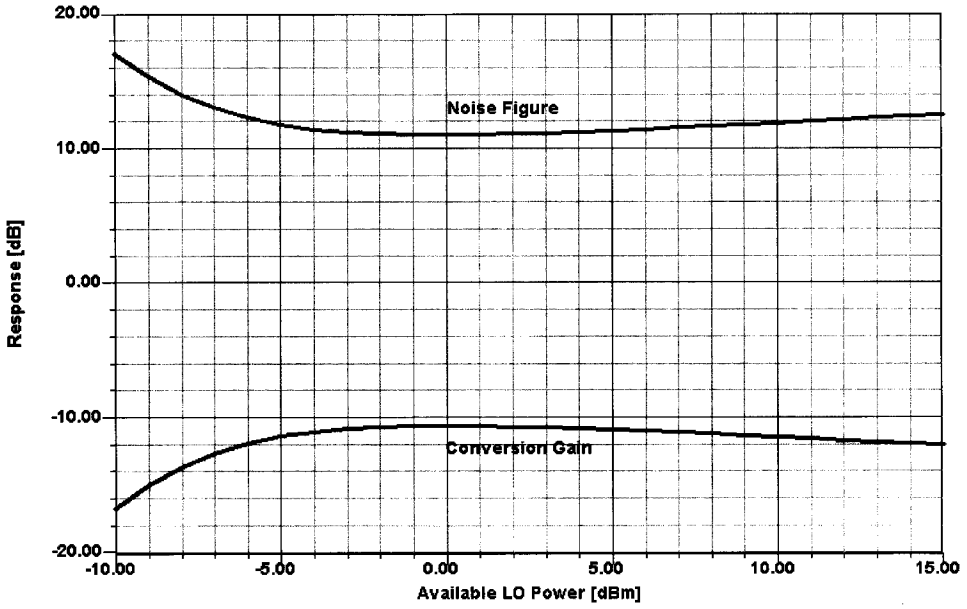

Figure 4-15 How the nonideal mixer's conversion gain and noise figure vary with available LO power. In this analysis, LO = 500 MHz (13 dBm), RF = 500.455 MHz (–20 dBm), and IF = 455 kHz.

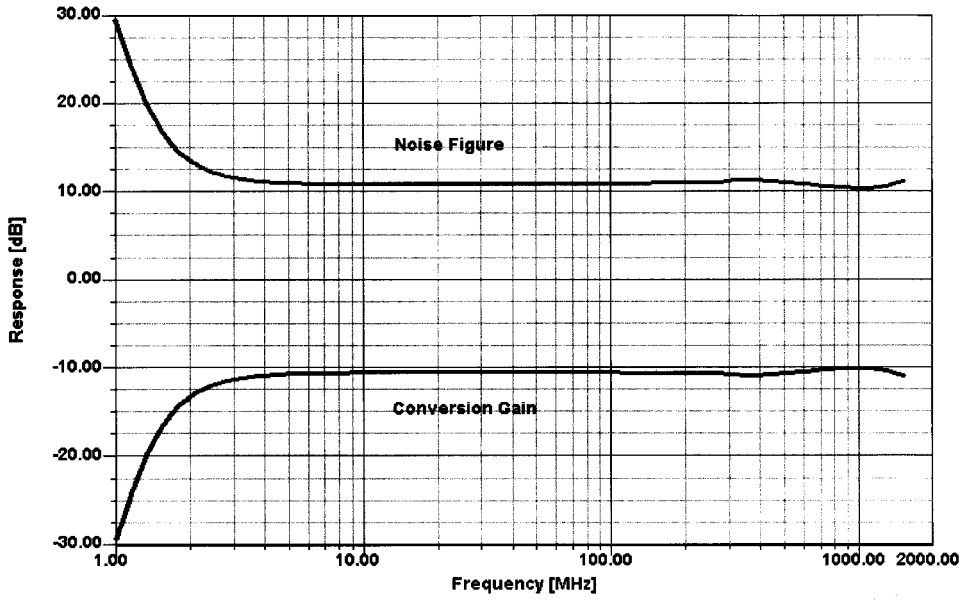

Figure 4-16 How the nonideal two-diode mixer's conversion gain and noise figure vary with frequency for a constant LO power. In this analysis, LO = 1–1500 MHz (2 dBm), RF = 1.455–1500.455 MHz (–40 dBm), and IF = 455 kHz.

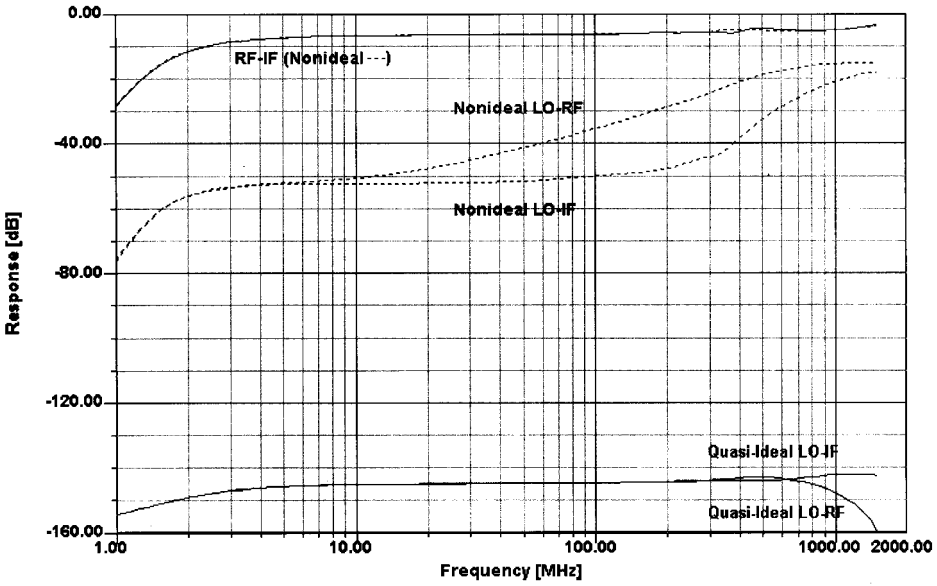

Figure 4-17 Port-to-port isolation of the quasi-ideal (identical diodes and no stray capacitance) and nonideal (slightly mismatched diodes and 0.5 pF of stray capacitance between the upper terminal of the middle transformer winding and ground) two-diode mixer. In this analysis, LO = 1–1500 MHz (2 dBm), RF = 1.455–1500.455 MHz (–40 dBm), and IF = 455 kHz.

connected from port to port) and nonideal port-to-port isolation (slightly mismatched diodes and 0.5 pF between the upper terminal of the middle winding and ground).

Figures 4-18a and 4-18b show the mixer's output spectrum for the quasi-ideal and nonideal cases, respectively.

Subharmonically Pumped Single-Balanced Mixer. Figure 4-19 shows a single-balanced mixer with a difference: antiparallel diode pairs take the place of single diodes, the RF and IF are buffered from each other only by filtering, and the LO is applied at one-half the frequency necessary to provide the desired frequency conversion. The RF-to-IF isolation is limited to that provided by the series input and output filtering, but the LO-to-IF isolation is higher at f_{LO} and much higher at $2f_{LO}$ than that achievable with a DBM with the LO signal at $2f_{LO}$(Figure 4-20). Although the example shown is for an up converting HF receiver, this technique finds application well into the microwave range as the basis for I/Q modulators, in which carrier leakage must be reduced to a level difficult to achieve with conventional DBMs [5–10].

4-3-3 Diode-Ring Mixer

Adding two more diodes and another transformer to the single-balanced mixer results in a double-balanced mixer (DBM) as shown in Figure 4-21. A DBM's frequency response is largely determined by the frequency response of its transformers, which act as transmission lines. The low-frequency limit is determined by the inductance of the transformer windings, the reactance of which, at the lowest frequency of interest, should be at least four times the impedance at which the transformer operates. The upper frequency limit is determined

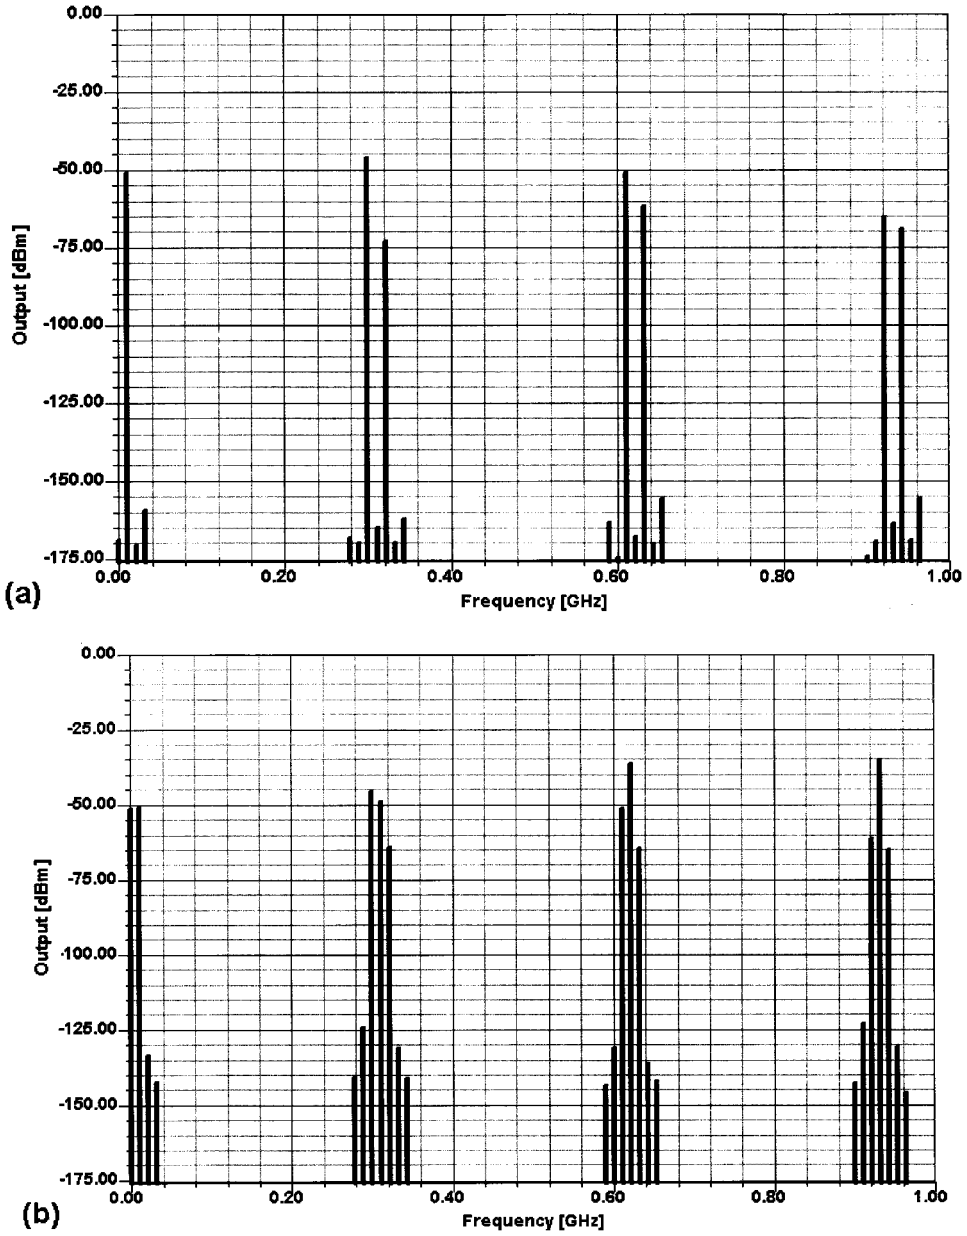

Figure 4-18 The nonideal mixer's output spectrum with (a) identical diodes and no stray capacitance and (b) slightly mismatched diodes and 0.5 pF of stray capacitance between the upper terminal of the middle transformer winding and ground. In these analyses, LO = 310.7 MHz (2 dBm), RF = 300.0 MHz (–40 dBm), and IF = 10.7 MHz. Four LO harmonics and 3 LO sidebands were used.

mainly by the degradation of the transformers' transmission-line behavior at higher frequencies, although the increasing importance of diode capacitance also plays a role.

A DBM's interport isolation is determined by the symmetry of its transformers, diodes, and physical construction. In practice, the effects of diode mismatch can be minimized by

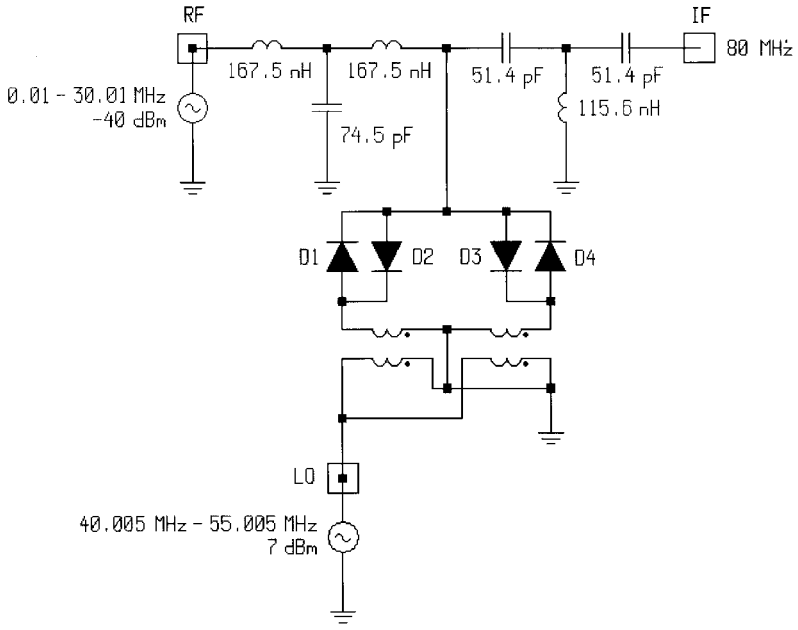

Figure 4-19 A subharmonically pumped single-balanced mixer using antiparallel diode pairs. The LO operates from 40.005 to 55.005 MHz to mix 0.01–30.01-MHz RF to an IF of 80 MHz.

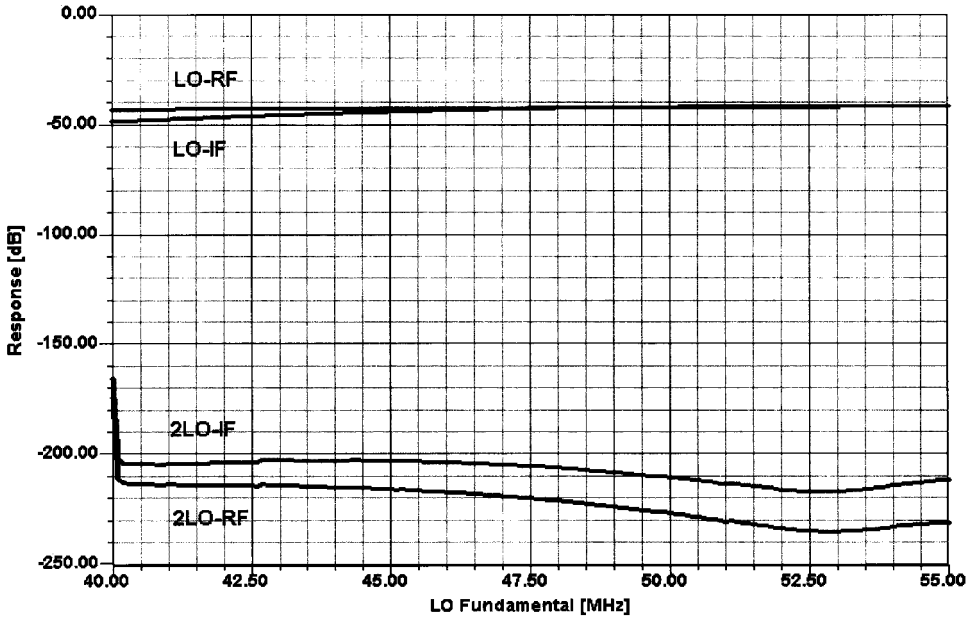

Figure 4-20 Simulated interport isolation of the subharmonic SBM. For realism, the diodes and transformers are slightly mismatched.

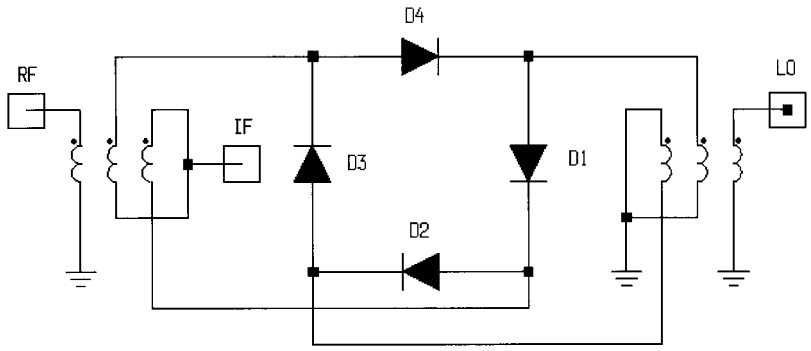

Figure 4-21 Schematic of the diode-ring double-balanced mixer.

using a dual diode, such as—in the case of the BAT15—the BAT15-099, the maximum V_F spread between the diodes being specified as 20 mV.

Figure 4-22 shows how the DBM's conversion gain and noise figure vary with applied LO power. Figure 4-23 shows how the DBM's conversion gain and noise figure vary with frequency for an LO power of 7 dBm, with quasi-ideal and nonideal balance. Figure 4-24 shows how the DBM's port-to-port isolation differs with quasi-ideal and nonideal balance for an LO power of 7 dBm. Figure 4-25 shows how the DBM's RF- and LO-port return losses vary with frequency; the sharp peak corresponds to a resonance caused by one of the stray capacitances added to simulate less-than-ideal balance in the modeled mixer.

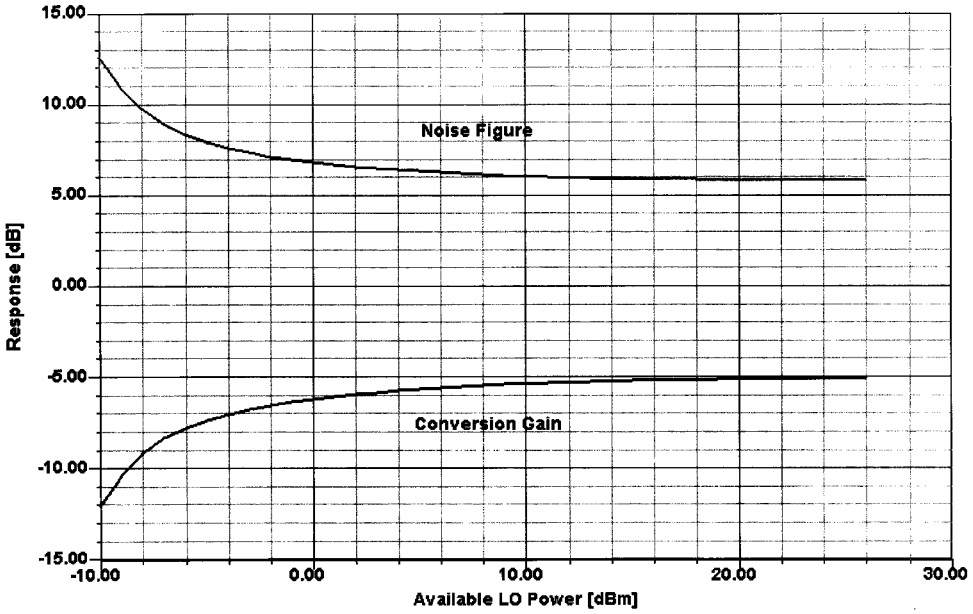

Figure 4-22 DBM conversion gain and noise figure versus LO power. In this analysis, LO = 310.7 MHz (–10 to 26 dBm), RF = 300 MHz (–40 dBm) and IF = 10.7 MHz.

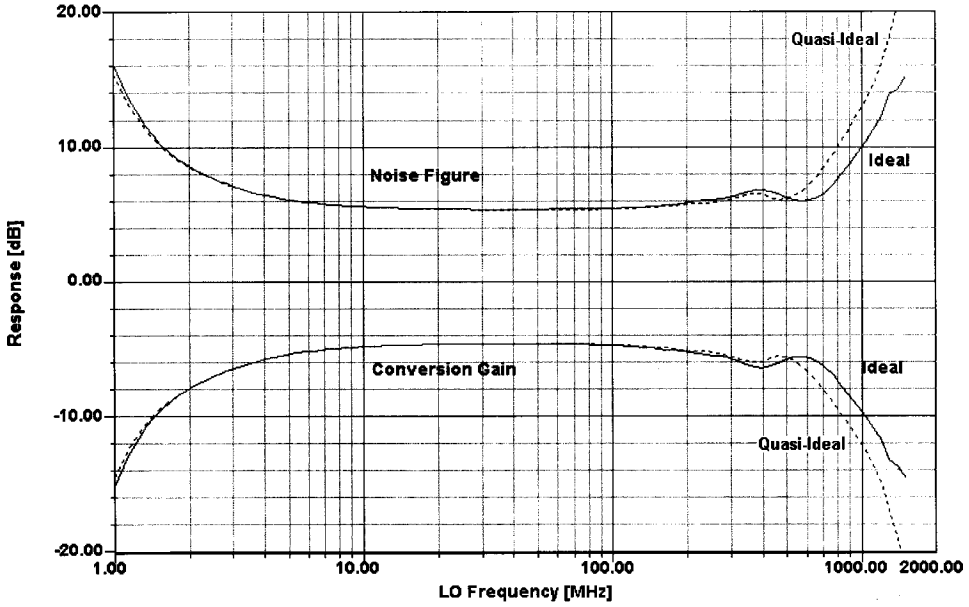

Figure 4-23 This plot of conversion gain (CG) and noise figure (NF) versus frequency for quasi-ideally and nonideally balanced versions of the same DBM reveals that balance plays a relatively minor role in the CG and NF performance achieved. In these analyses, the LO (–7 dBm) sweeps from 1 to 1500 MHz and the RF (–40 dBm) sweeps from 1.455 to 1500.455 MHz to produce an IF of 455 kHz.

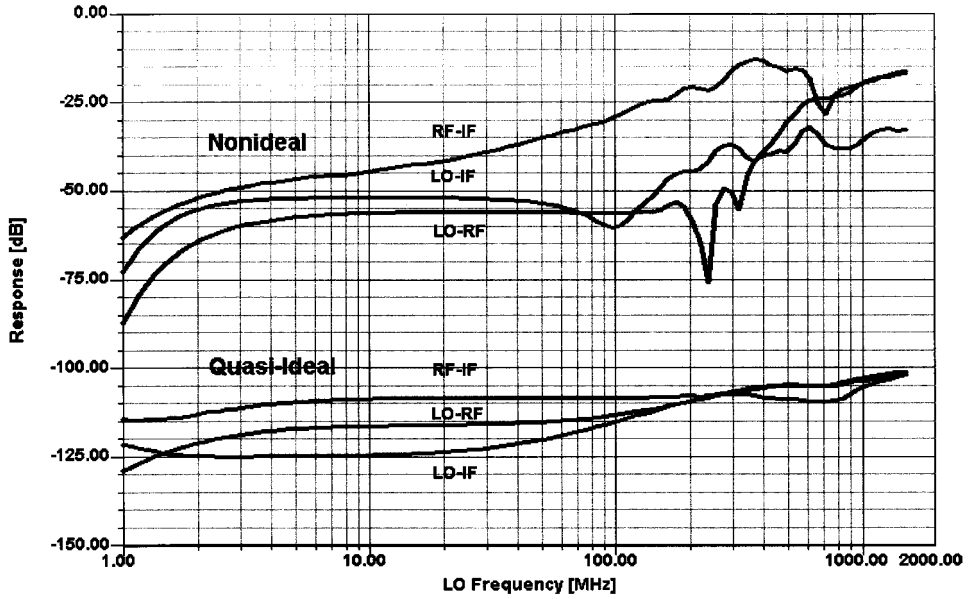

Figure 4-24 Interport isolation for DBMs with quasi-ideal and nonideal balance. In these analyses, the LO (–7 dBm) sweeps from 1 to 1500 MHz and the RF (–40 dBm) sweeps from 1.455 to 1500.455 MHz to produce an IF of 455 kHz.

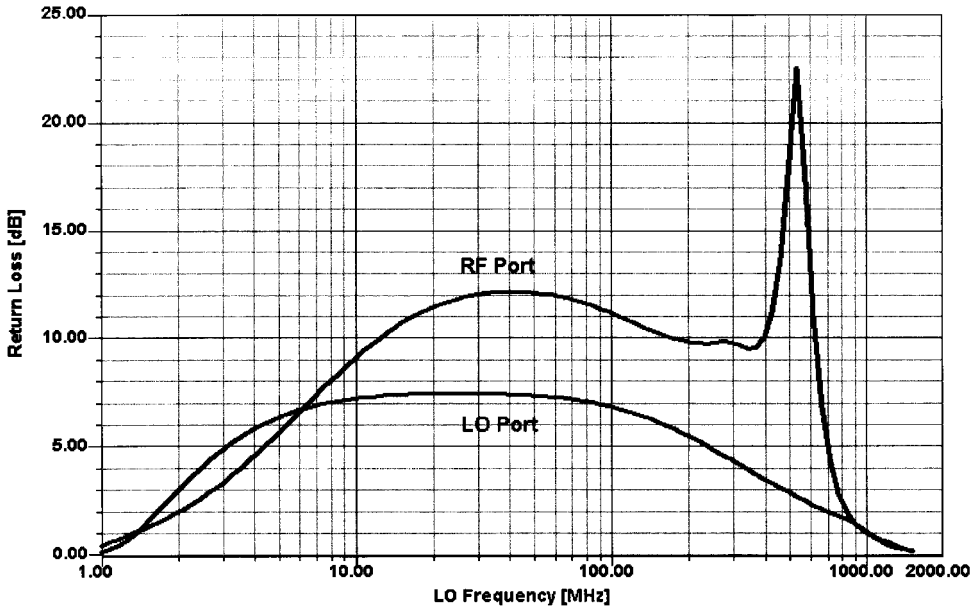

Figure 4-25 Return loss versus frequency for the DBM's RF and LO ports. The sharp peak results from a stray resonance.

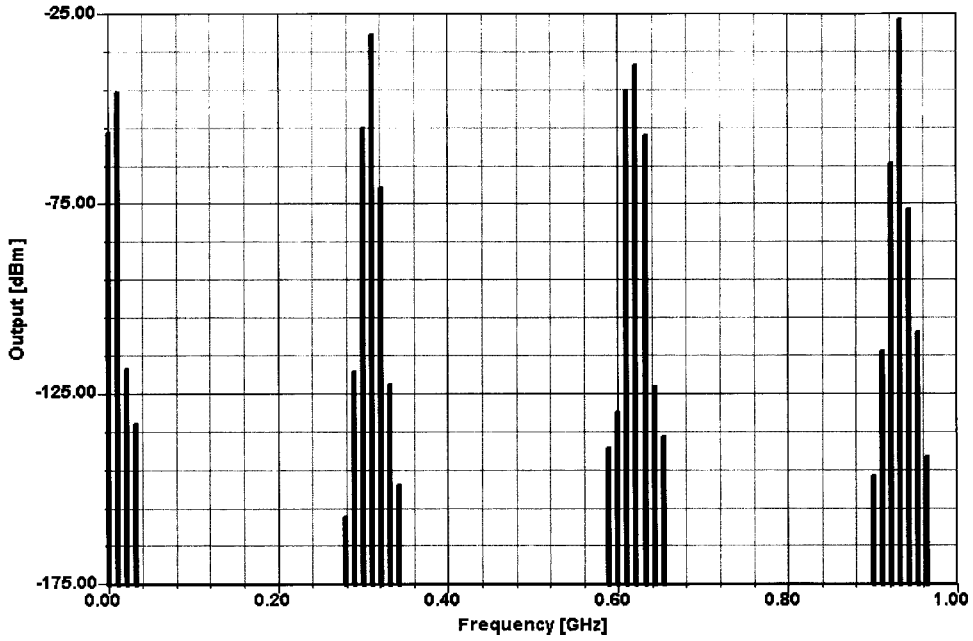

Figure 4-26 Output spectrum of a nonideally balanced DBM. In this analysis, LO = 310.7 MHz (–7 dBm) and RF = 300 MHz (–40 dBm) for an IF of 10.7 MHz. Four LO harmonics and three LO sidebands were used.

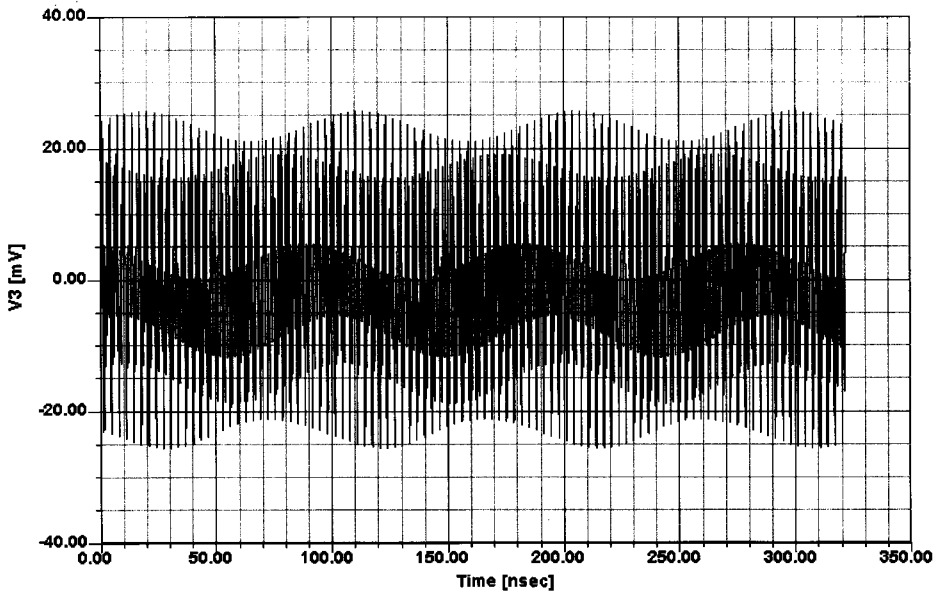

Figure 4-27 IF-port voltage waveform of the DBM over 100 cycles of the LO signal. The 310.7-MHz LO and 10.7-MHz IF components are clearly evident.

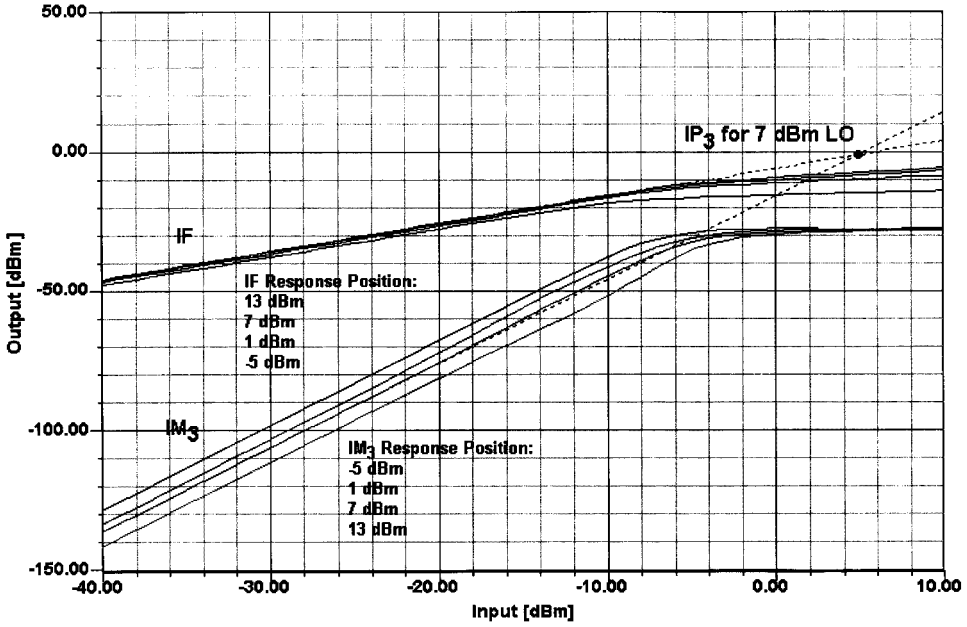

Figure 4-28 Diode DBM IF and IM_3 outputs versus RF power for four LO-drive levels. The responses for LO = 7 dBm have been extrapolated to show IP_3. Within limits, varying a mixer's LO drive affects its linear IF output relatively little while significantly affecting IMD. See Figure 4-29. For all four analyses, LO = 310.7 MHz, RF1 = 300.0 MHz (–40 to 10 dBm), and RF2 = 300.3 MHz (–40 to 10 dBm); four LO harmonics and three LO sidebands were used.

Figure 4-26 shows the DBM's output spectrum. Figure 4-27 shows the DBM's output waveform over 50 cycles of the LO signal.

Two-tone testing of the DBM allows us to characterize its IP_3 figures of merit. Figure 4-28 shows the nonideal DBM's IF and IM_3 responses for LO powers of –5, 1, 7, and 13 dBm. Figure 4-29 details how the DBM's IP_3 increases with LO drive, and Figure 4-30 shows the desired IF outputs and close third-order spurs near 10.7 MHz. Figure 4-31 shows the DBM's output voltage over 100 cycles of the LO signal, and Figure 4-32 shows the anode–cathode voltage of one of the ring's diodes, also over 100 LO cycles, both under two-tone IMD test conditions.

A double-balanced mixer, unless it is termination insensitive, is extremely sensitive to nonresistive termination. This is because the transmission-line transformers do not operate properly when they are not properly terminated, and the reflected power generates high voltage across the diodes. This effect results in much higher distortion levels than in a properly terminated transformer.

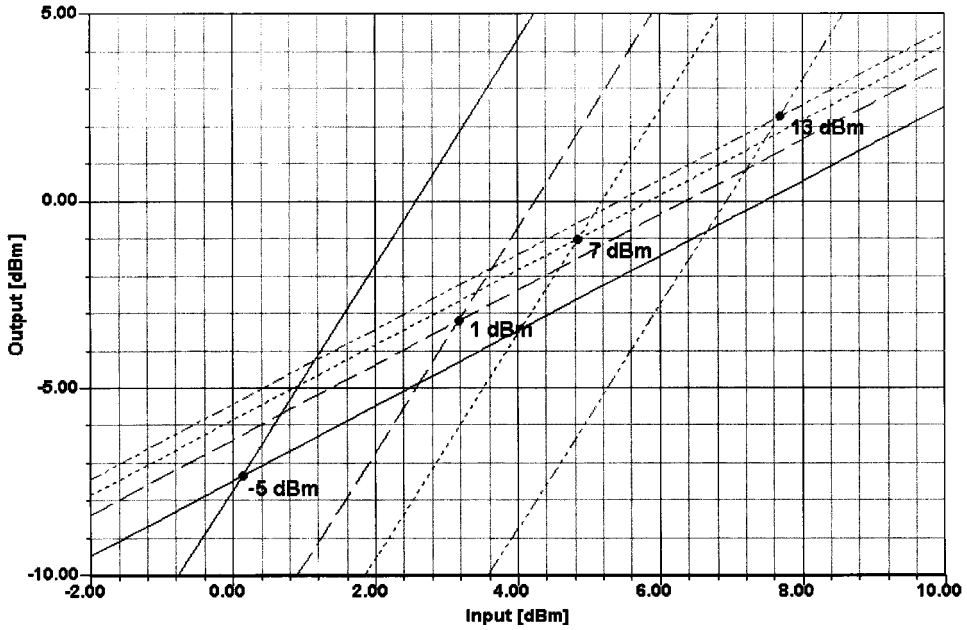

Figure 4-29 Extrapolating the responses for all four LO levels represented in Figure 4-28 shows how varying a diode DBM's LO drive shifts its third-order intercept point. Although these curves indicate that the simulated mixer's IP_3 generally increases with LO drive, the improvement in IP_3 is not as great as we might expect. The reason for this is that these four analyses, as well as the other diode-mixer analyses in this chapter, were done using diode models with a threshold voltage (V_J) of 0.23. If high-level diodes with a V_J of about 0.8 V had been used, $IP_{3,out}$ for the 13-dBm LO case shown here would increase to +13 dBm. $IP_{3,in}$ for the 13-dBm LO case would turn out to be 13 dBm + insertion loss = 13 dBm + 7 dB = 20 dBm. The issue of diode damage aside, attempting to increase IP_3 merely by driving a low- or medium-barrier diode harder eventually results in diminishing returns. High-barrier diodes are essential in getting the best IP_3 performance with high LO drive.

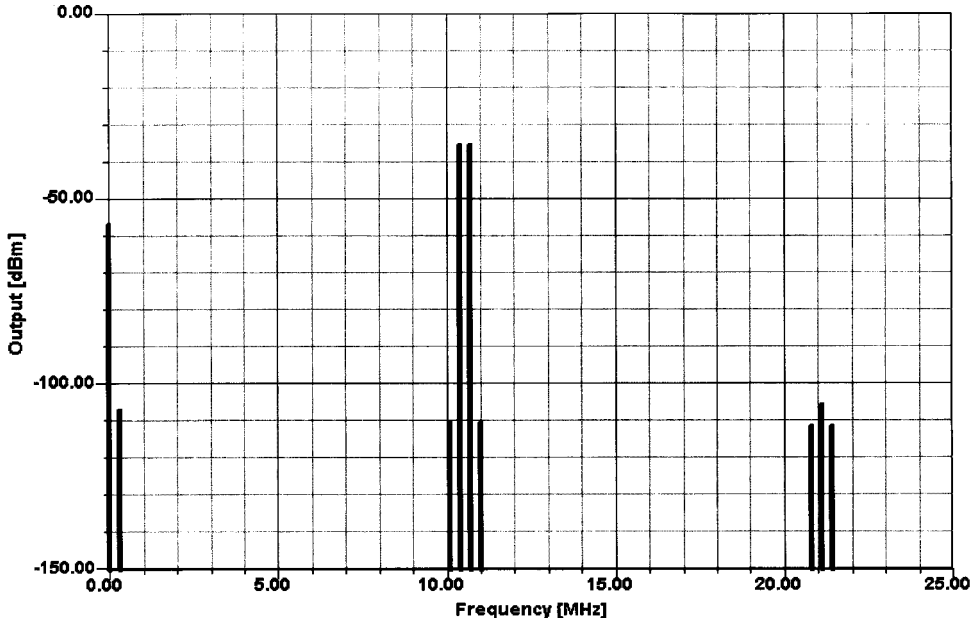

Figure 4-30 The DBM's output in the 11-MHz region during two-tone testing. The third-order products are clearly visible above and below the desired output signals. The test conditions for this analysis are those for Figure 4-28 with LO = 13 dBm.

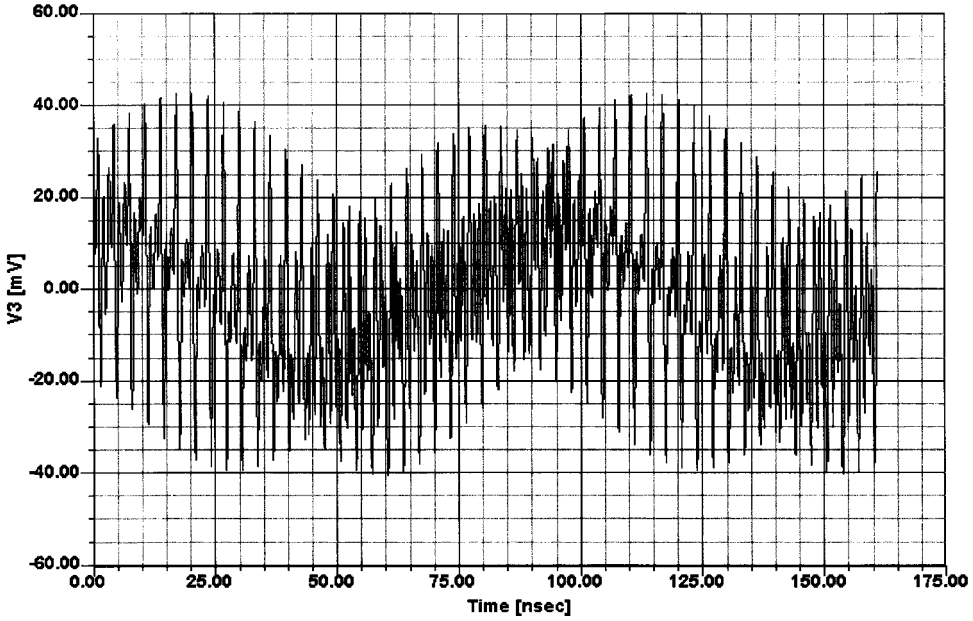

Figure 4-31 The DBM's IF-output voltage over 50 cycles of the LO signal. The test conditions for this analysis are those for Figure 4-28 with LO = 13 dBm.

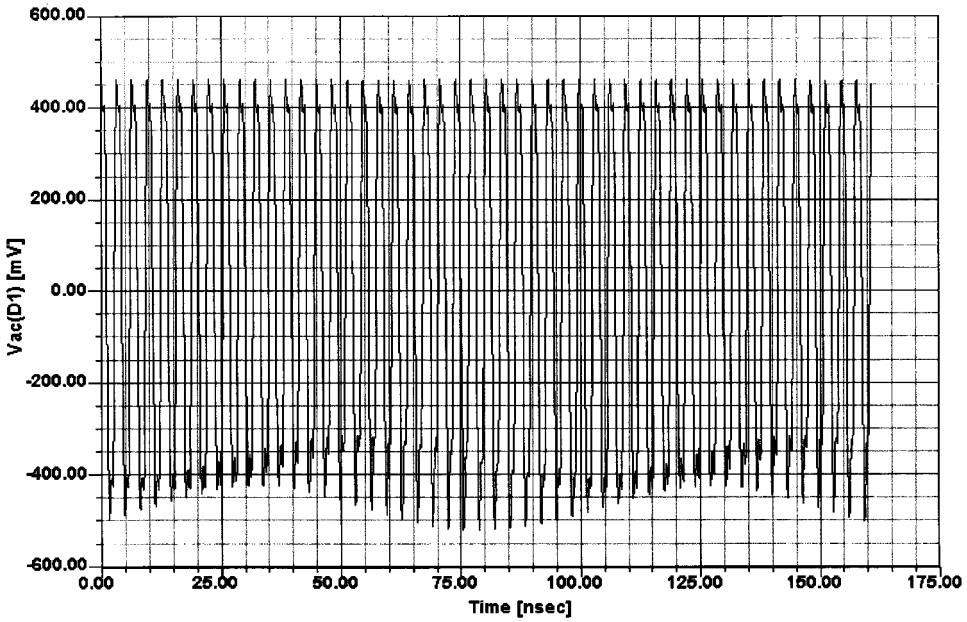

Figure 4-32 The anode-cathode voltage of one of the DBM's diodes, also over 50 LO cycles under two-tone IMD test conditions. The test conditions for this analysis are those for Figure 4-28 with LO = 13 dBm.

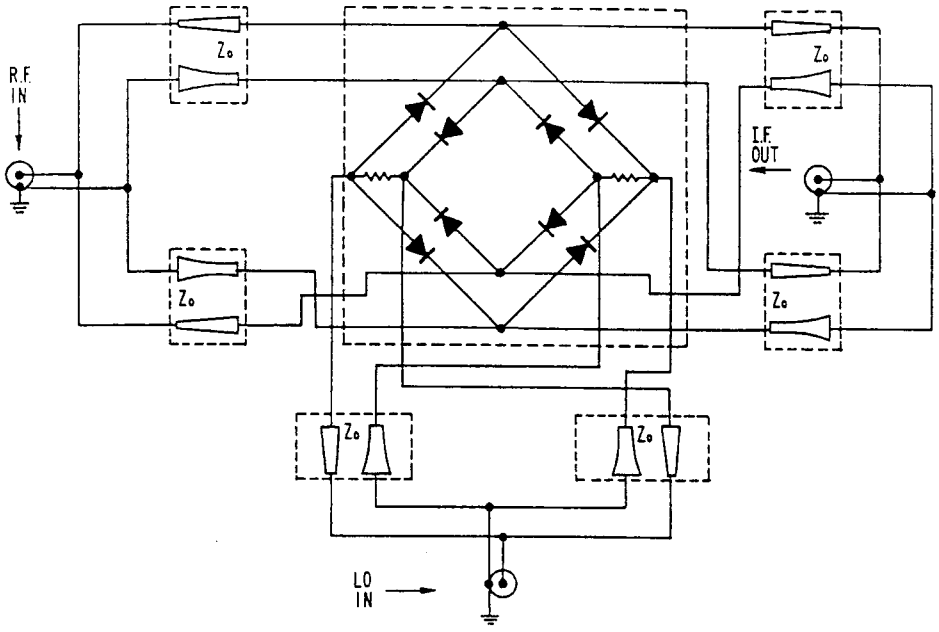

Figure 4-33 Example of a termination-insensitive mixer from U.S. Patent No. 4,224,572 (Adams-Russell Co., 1980) [11].

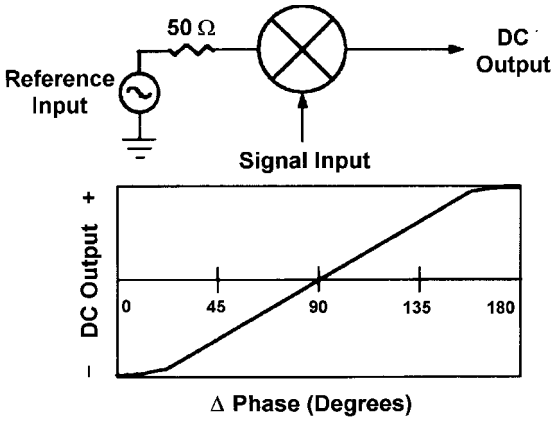

Figure 4-34 A mixer with a dc-coupled IF port can be used as a phase detector.

Termination-Insensitive Mixer. Figure 4-33 shows a mixer circuit that tolerates a fairly high VSWR at its output without significant degradation of its third-order IM performance [11].

Phase Detector. Theoretically, any mixer with a dc-coupled IF port can be used as a phase detector. When two signals of equal frequency are applied simultaneously to the reference and incoming signal ports, the phase detector produces a dc output at the IF port proportional to the cosine of the phase difference (Figure 4-34).

Binary Phase Shift Keying (BPSK) Modulator. Binary phase modulation occurs when a positive and negative signal current shifts the RF carrier between 0° and 180°. Figure 4-35 shows a double-balanced mixer operating as a BPSK modulator.

Quadrature Phase Shift Keying (QPSK) Modulator. A typical QPSK modulator consists of two biphase modulators, a 90° divider, and a 0° power combiner as shown. Data inputs at the control ports will cause the carrier to shift between 0°, 90°, 180°, and 270° as shown in Figure 4-36.

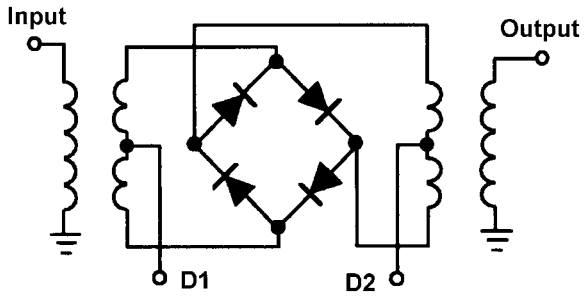

Figure 4-35 A diode-ring mixer as phase modulator.

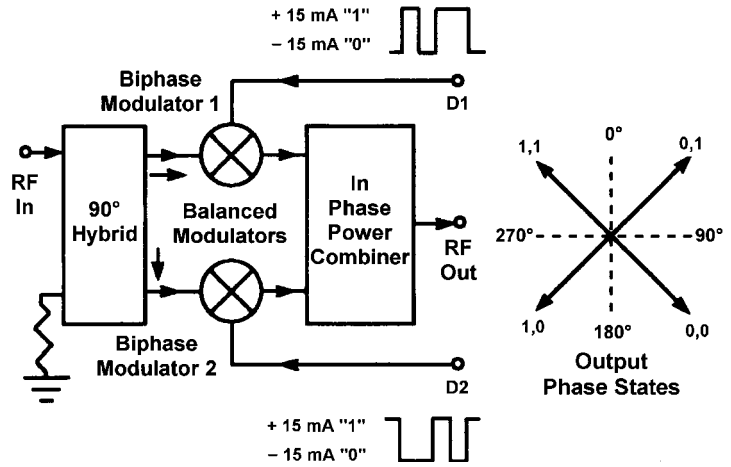

Figure 4-36 Two biphase modulators form the basis for a QPSK modulator.

Quadrature IF Mixer. A quadrature IF mixer produces two IF outputs in phase quadrature. Its basic structure consists of two double-balanced mixers, a 90° splitter, and a 0° splitter. The basic block diagram is shown in Figure 4-37.

Image-Reject Mixer. The image-reject mixer consists of a basic quadrature IF mixer with an additional 90° hybrid at the IF ports as shown in Figure 4-38. The primary function is to differentiate between the real signal and the image signal. This type of device is especially useful in applications where the desired RF signal and image are so close in frequency that rejecting the image with filtering is not practical.

Diode Attenuator/Switch. A ring of PIN diodes can be used as electronic attenuators by applying variable forward bias to the diodes (Figure 4-39). Maximum attenuation is achieved when the current at the control port is zero. The maximum attenuation is the isolation between the input and output ports. Minimum attenuation (insertion loss) is achieved when the IF-port current is 20-mA.

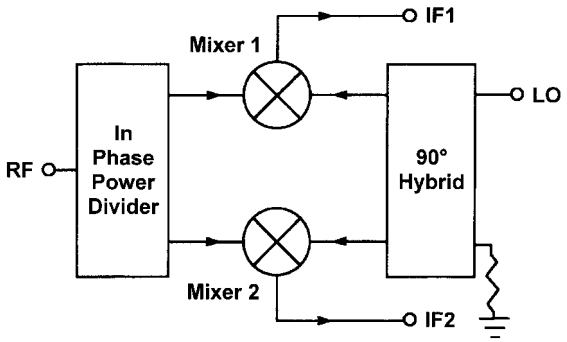

Figure 4-37 Quadrature mixer.

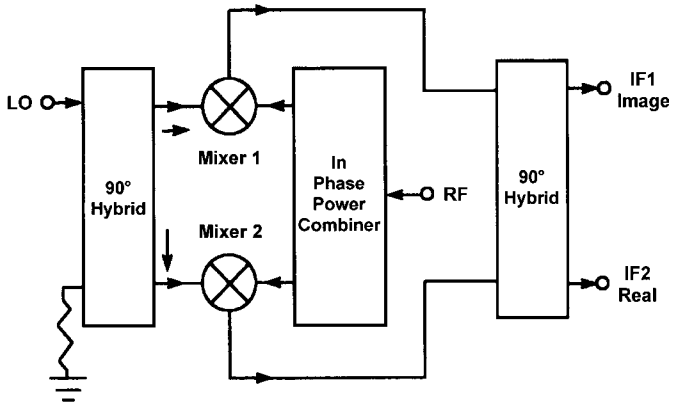

Figure 4-38 An image-reject mixer uses phasing to differentiate between its LO + IF and LO – RF IF outputs.

Single-Sideband (SSB) or In-Phase/Quadrature (I/Q) Modulator. SSB or I/Q modulators are useful in discriminating and removing the lower sideband (LSB) or upper sideband (USB) generated during frequency conversion, especially when the sidebands are very close in frequency and attenuation of one of the sidebands cannot be achieved with filtering. This is the case with audio and video modulation, where signals from dc to 10 MHz must be converted to a higher frequency that is appropriate for transmission. In such cases, both sidebands will be very close in frequency to the carrier frequency. With an I/Q modulator, one of the sidebands is easily canceled or attenuated along with its carrier.

Attenuation of the carrier has been the most troublesome aspect in the design of passive I/Q modulators. Isolation between the local oscillator (LO) port and the RF port of the mixers, which is the main parameter in determining carrier rejection, is usually insufficient at frequencies above 200 MHz.

I/Q modulator designs basically consist of two double-balanced mixers (Figure 4-40). The mixers are fed at the LO ports by a carrier phase-shifted through a 90° hybrid. Thus, the carrier signal's relative phase is 0° to one mixer and 90° to the other mixer. Modulation signals are fed externally in phase quadrature to the two mixers' IF ports. The mixers' modulated output signals are combined through a two-way, in-phase power divider/combiner.

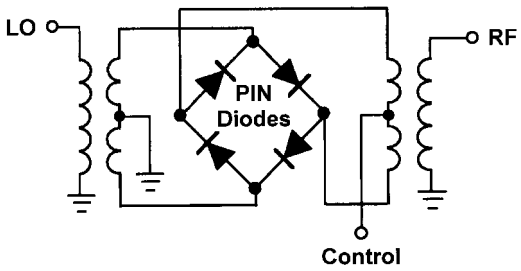

Figure 4-39 A diode DBM can be used as a dc-controlled attenuator if PIN diodes are used instead of Schottky devices in its ring.

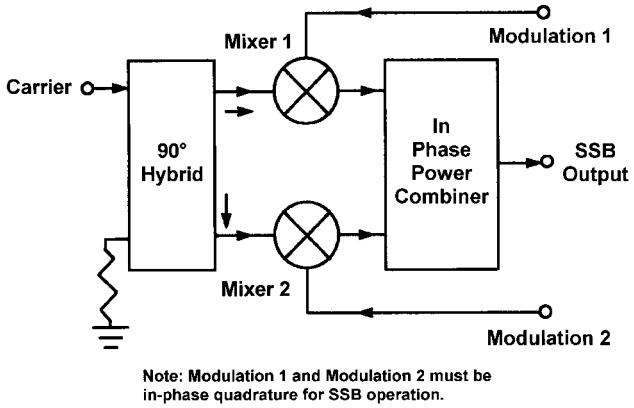

Figure 4-40 An SSB modulator matches two high-frequency mixers, a 90° hybrid, and an in-phase power combiner to produce an SSB output signal.

The circuit forms a phase-cancellation network to one of the sidebands and a phase-addition network to the other sideband. The carrier is somewhat attenuated and is directly dependent on the inherent LO-to-RF isolation of the mixers and the modulating signal level. In industry-standard I/Q modulators, USB suppression results when the first modulation port (Modulation 1) is fed with a signal that is 90° in advance of the signal feeding the second modulation port (Modulation 2). Opposite phasing can be arranged by changing the internal phase polarity of the mixers or by interchanging the 90° hybrid output ports to the LO ports of the mixers.

The phase and amplitude imbalances between the various components used in the manufacturing of the I/Q modulators must be tightly maintained for optimum SSB rejection. Matching of the two mixers for conversion loss and insertion phase is extremely critical, since differences in these parameters will add to amplitude- and phase-imbalance errors. The 90° hybrid in the LO port must be in nearly perfect phase quadrature.

Phase- and amplitude-imbalance errors adversely affect sideband suppression (Figure 4-41). In most cases, a typical passive I/Q modulator operates with a carrier input level of +10 dBm, which is required to drive the diodes in the mixers to operate in the linear range. The dynamic range of these mixers can be improved significantly by using diodes with a higher barrier height. The LO signal in this case must be increased in order to drive these diodes into conduction in their linear range.

Carrier rejection is also a problem when designing an SSB modulator, since only a few decibels of suppression can be achieved in standard high-frequency models. In the past, the major contributor to carrier suppression was the inherent LO-to-RF isolation through the mixers. Unfortunately, this isolation is usually poor at cellular frequencies (800–1000 MHz), where at least 25 dB of carrier rejection is necessary. In some cases, designers feed a small amount of dc into the IF ports to control the carrier rejection, which complicates the driver circuitry and calls for temperature compensation when operating at different temperatures.

As an example, an SSB modulator is assumed to operate with +10-dBm LO drive with each modulating signal at –10 dBm and in phase quadrature to each other when applied to the modulating ports (MOD 1 and MOD 2). The result will be a modulated signal at –16 dBm, assuming 6-dB conversion loss. For 20-dB carrier rejection with respect to the desired

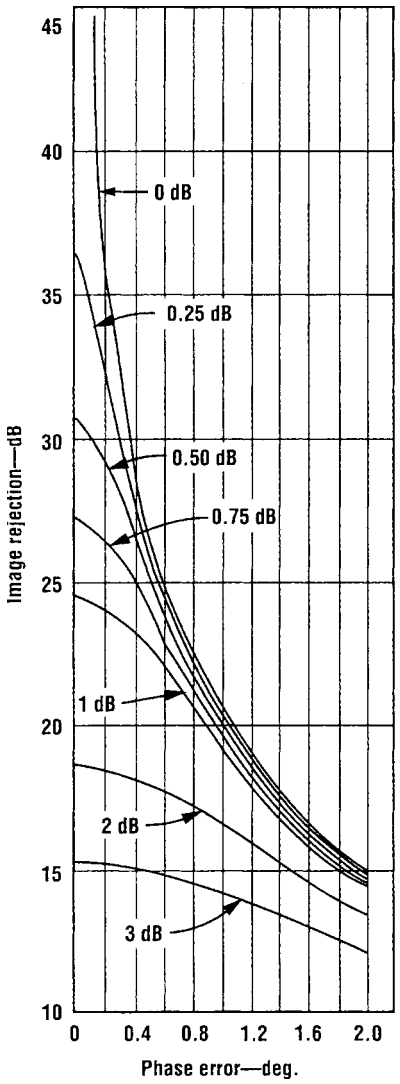

Figure 4-41 The level of SSB rejection improves as the phase- and amplitude-imbalance performance of an SSB modulator improves.

modulated signal, the carrier must be at –36 dBm, which translates to LO-to-RF isolation of 46 dB.

By employing a subharmonic approach, the performance of SSB modulators can be extended beyond the limits of conventional designs as reported by Joshi [7]. The approach is based on the use of subharmonic mixers in place of fundamental-frequency mixers and is applicable from about 140 to 3000 MHz. Subharmonic mixers use antiparallel diode pairs in their construction [12–14]. Matched antiparallel diode pairs used in single-ended or single-balanced mixer configurations cancel even-order intermodulation products (such as $2f_{LO} \times 2f_{RF}$, $3f_{LO} \times 3f_{RF}$, etc.) at all ports.

Single-ended mixers lack the port-to-port isolation needed for SSB modulator applications. Odd-order products of the RF and LO frequencies (even $f_{LO}\times$ odd f_{RF}) and (odd

$f_{LO} \times$ even f_{RF}) appear on all ports, requiring extensive filtering for satisfactory performance. For a single-balanced mixer, even harmonics of the LO combining with odd harmonics of the RF appear at the IF port, whereas odd harmonics of the LO combining with even harmonics of the RF appear at the RF and IF ports. This assumes that a balanced transformer is placed at the LO port, which is a logical choice due to the fact that the highest level signal appears at the LO port. Since the desired odd-order IF products appear at both the RF and IF ports, a need arises for a diplexing network to isolate the RF and IF signals.

The subharmonic modulator design provides a unique way to isolate the RF and IF signals. A single-balanced harmonic mixer offers good LO-to-RF and LO-to-IF isolation but poor RF-to-IF isolation. Fortunately, harmonically related signals are spaced well apart in the frequency spectrum, simplifying filtering of harmonically related signals.

Harmonic mixing also works well with low LO power levels, with somewhat lower 1-dB compression on the RF port than with fundamental-frequency mixing. The ability to operate with LO frequencies that are a fraction of the carrier frequency (1/2, 1/4, 1/6, etc.) significantly reduces the cost of an LO source, especially at higher frequencies. Also, using lower-frequency LO sources helps avoid the signal-leakage problems inherent with higher-frequency LO sources. Minimizing signal leakage, especially at higher frequencies, becomes expensive and bulky. Subharmonic mixing offers several advantages:

- The technique offers the ability to operate at LO frequencies that are 1/2, 1/4, or 1/6 of the carrier frequency. For example, for an IF of 100 MHz at an RF of 2 GHz, the LO can be $(2000 \pm 100) \div 2 = 950$ or 1050 MHz.
- The LO's even harmonics are strongly attenuated.
- The filtering requirements for fundamental frequency and odd harmonic signals of the LO are not critical.
- The cost of generating the LO is reduced due to the fact that the LO frequency need only be a fraction of the carrier frequency.

As an example of the performance improvements possible with the subharmonic mixers, units were evaluated at both cellular (935–960 MHz) and PCN/PCS (1.8–1.9 GHz) bands.

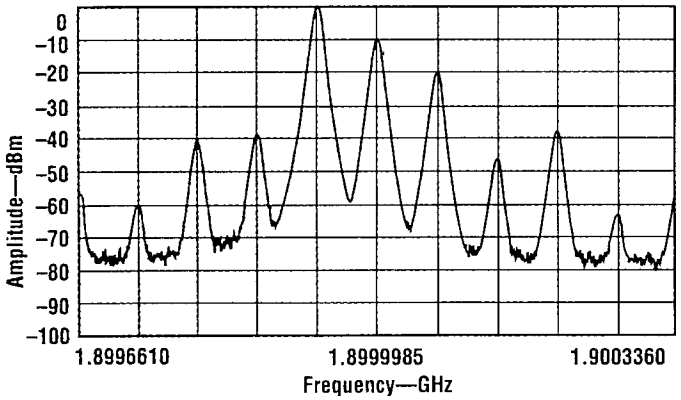

Figure 4-42 This plot of carrier and sideband rejection was measured for a conventional SSB modulator operating at 1.9 GHz.

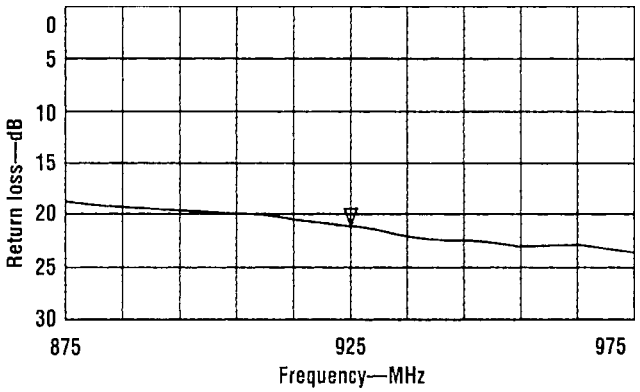

Figure 4-43 The SSB modulator's return loss as measured at the local oscillator (LO) port.

For a conventional SSB modulator at 1.9 GHz fed with +10-dBm modulation signals, carrier rejection is barely 10 dB (Figure 4-42).

Sideband rejection can be improved by tuning, but the carrier rejection is controlled by the LO-to-RF isolation of the double-balanced mixers. Conventional double-balanced mixers with high isolation at cellular and PCN bands are very expensive and large when special techniques are used to improve LO-to-RF isolation. In contrast, the subharmonic nature of the new approach allows the use of lower-frequency, less-expensive components in the modulators' construction.

The subharmonic modulators offer an improvement of more than 15 dB in carrier suppression compared to the conventional approach.

The measured VSWR (return loss) at the LO and RF ports is better than 1.50:1 (Figures 4-43 and 4-44). Measurements made on a cellular-band SSB modulator reveal carrier rejection on the order of 40 dB. Typical insertion loss is 7 dB while sideband rejection is 30 dB (Figure 4-45).

By virtue of harmonic mixing, even-order mixing products are attenuated by about 30 dB with respect to the desired modulated output signal. The fundamental-frequency feedthrough into the output port is approximately 5 dB lower than the desired modulated signal, whereas

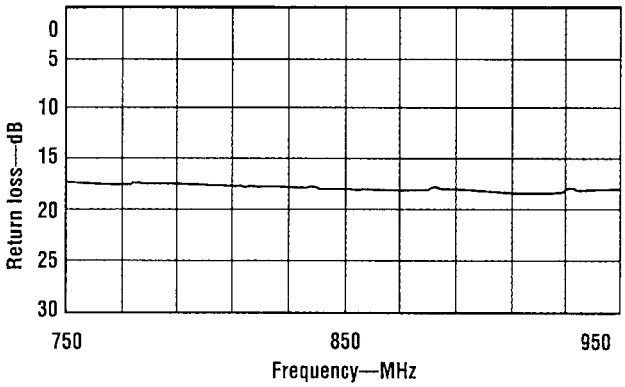

Figure 4-44 The novel harmonic SSB modulator's return loss as measured at the RF port.

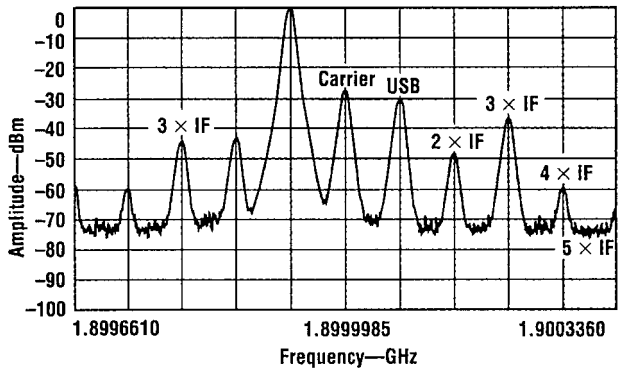

Figure 4-45 Plot of carrier and sideband rejection as measured for the novel harmonic SSB modulator operating at cellular frequencies.

the fourth harmonic mixing with the modulating signal is approximately 10 dB lower. Typical loss for fourth harmonic mixing is 17–19 dB while maintaining 30 dB of carrier rejection.

Since harmonically related products are well-spaced in frequency, filtering undesired signals is relatively inexpensive using standard octave-bandwidth filters. Low-cost commercial bandpass filters typically offer better than 40–50-dB attenuation of unwanted harmonic signals. Constant-impedance bandpass filters offering good impedance match at desired

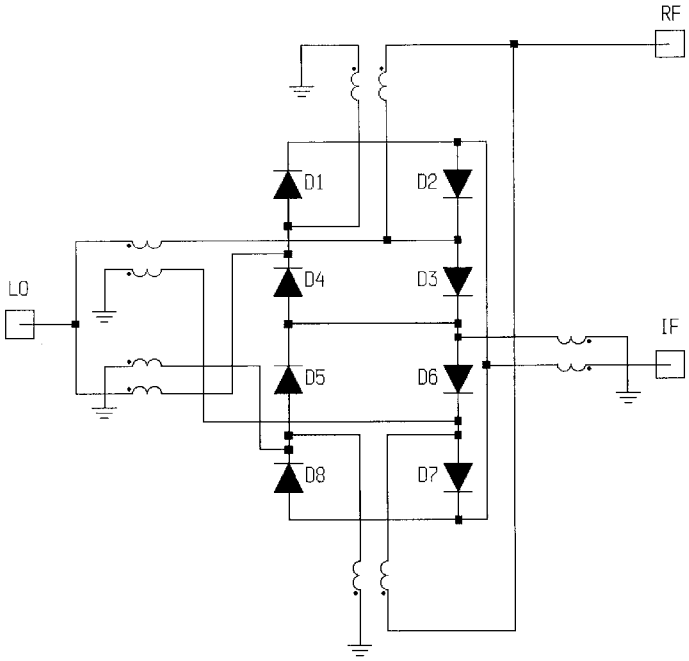

Figure 4-46 A triple-balanced diode mixer. A limitation of this configuration is that the internal dc common connections associated with its RF and LO transformers disallow usable IF response down to dc.

stopbands can also be used in cases where harmonically related products require impedance termination within a system.

The subharmonic modulator design is easily applied at custom frequencies. Conversion of an SSB modulator with output frequency corresponding to twice the LO frequency to one with output corresponding to four times the LO frequency requires only one component change, in the form of a signal-combining network at the modulator's output. Although the conversion loss of the fourth harmonic LO component mixing with the modulating signal is in the vicinity of 18 dB, the cost of generating the LO is drastically reduced with the subharmonic modulator. In spite of higher signal loss, the carrier rejection is still at least 30 dB at the fourth harmonic, and harmonically related products can be eliminated with an inexpensive filter.

Triple-Balanced Mixer. Two diode rings can be combined to form a double double-balanced mixer, or triple-balanced mixer (TBM), as shown in Figure 4-46. Triple-balanced mixers achieve higher dynamic range and interport isolation than double-balanced designs at the expense of LO power and increased complexity and size.

Figure 4-47 shows the interport isolation of the circuit in Figure 4-46 with the circuit configured in a less than ideally balanced form, with small variations in transformer-winding inductance and diode parameters introduced for more realistic modeling. Note that the mixer's interport isolation generally increases with frequency, rather than decreasing with frequency as with the DBM (Figure 4-24).

Rohde & Schwarz Subharmonically Pumped DBM. Figure 4-48 shows an example of a complete microwave diode mixer used as the input stage of a spectrum analyzer. Its LO is applied at 13.2 GHz, one-third the frequency necessary to mix the 40.1-GHz input

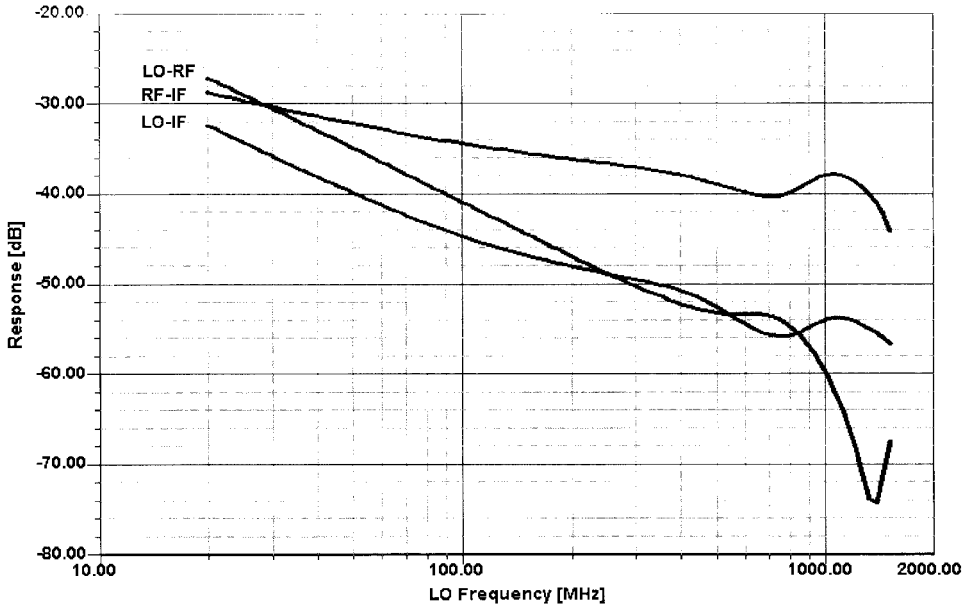

Figure 4-47 The triple-balanced mixer offers improved high-frequency isolation over a standard DBM.

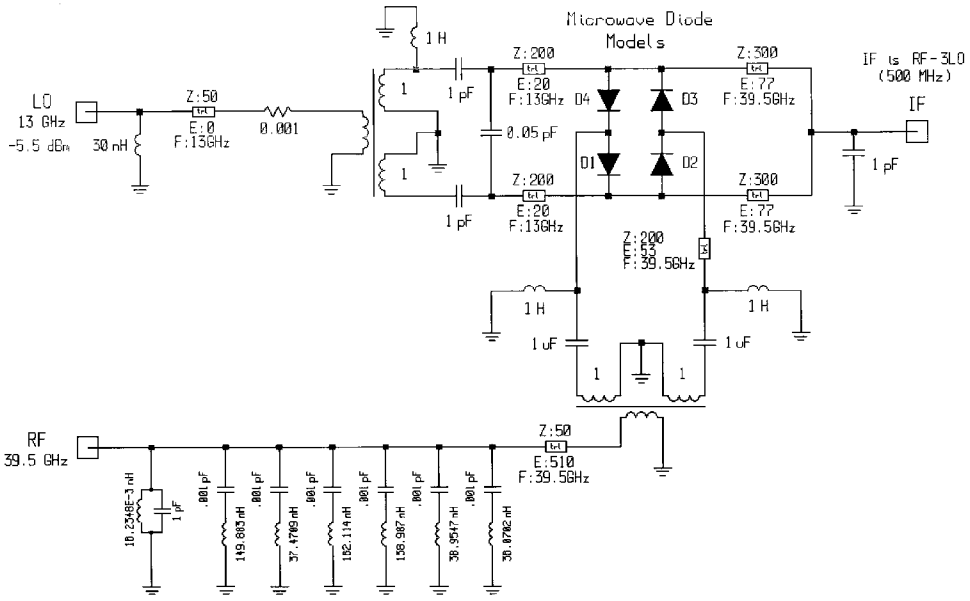

Figure 4-48 Schematic of the spectrum-analyzer mixer. The LO is applied at one-third the frequency necessary to mix the RF signal to the 500-MHz IF.

signal to the 500-MHz IF, with distortion in the diodes providing the 3× frequency multiplication. The circuit's conversion gain is –18.8 dB; its noise figure, 20.5 dB.

The subharmonic-drive technique exemplified by this mixer is important for another reason in addition to LO isolation. Depending on the application, directly generating a sufficiently phase-quiet LO signal at the higher wireless frequencies and on up into the microwave frequencies may not be feasible. In such cases, injecting the LO at a subharmonic of the desired LO frequency may provide better phase noise performance than a fundamental LO even though the phase noise of a frequency-multiplied source increases by $\log_{10} n$ dB, where n is the multiplication factor.

4-4 TRANSISTOR MIXERS

Diode mixers are lossy and termination-sensitive and require considerable LO power. Their attractiveness to designers of highly integrated wireless products is further reduced by their dependence on transformers for balance and port-to-port isolation. Transistor mixers are therefore used where high integration and reduced current drain are paramount—that is, in most non-base-station wireless applications.

Until ten years ago, single BJTs were commonly used in a simple additive-mixing arrangement, an example of which appears in Figure 4-49. Such a circuit behaves like a combination of a preamplifier and single-diode mixer. Single-BJT mixers were used in early AM–FM radios until 1980, and unfortunately in some handheld 2-meter and 70-cm ham equipment, to achieve the lowest possible power consumption. By definition, however, the presence of such a mixer also destroys any possibility of achieving a high intercept point. In

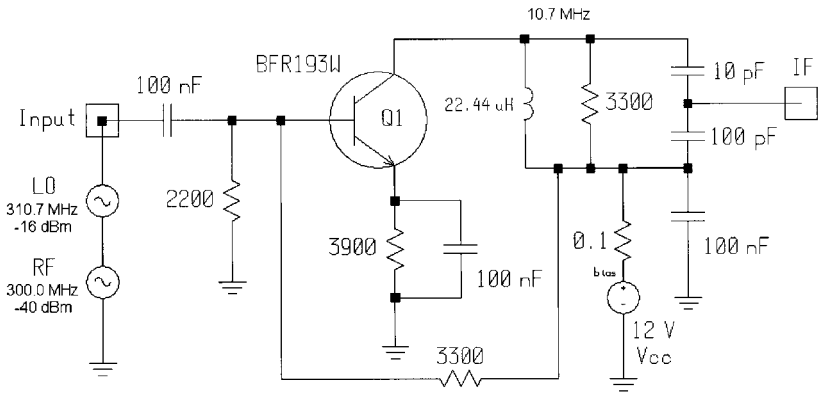

Figure 4-49 A single-BJT mixer.

addition to this, many combination frequencies occur despite elaborate input filtering. Although single-BJT mixers can exhibit considerable conversion gain (>10 dB), their dynamic range is restricted and their port-to-port isolation is poor. BJT mixers in today's competitive wireless designs use multiple transistors and are based almost exclusively on the Gilbert multiplier cell.

4-4-1 BJT Gilbert Cell

The classic active mixer (Figure 4-50), conceived by Barrie Gilbert in 1967, is the basis for most active mixers used in wireless products today. Figure 4-51 shows a Gilbert cell mixer implementation for analysis. Figure 4-52 shows its conversion gain and noise figure versus LO power. Figure 4-53 shows its IM_3 and IP_3 responses. As Gilbert wrote in a 1994 monograph [15]:

> This circuit is attractive because (a) it can be monolithically integrated with other signal-processing circuitry; (b) it can provide conversion gain, whereas a diode-ring mixer always has conversion loss; (c) it requires very low power to drive the LO port; (d) it provides excellent isolation between the signal ports; and (e) it is far less fussy about load-matching.

The two major advantages afforded by the Gilbert cell are port isolation (it should really be called a multiplicative mixer) and its significant reduction of even-order frequency combinations. As with the single-transistor mixer, the Gilbert cell does not particularly shine with high intercept point and low current consumption. Another major drawback is that it requires a high-impedance output, which gives the user headaches because most of the better filters are in 50-Ω technology, and only very simple monolithic filters offer input and output impedances around 1 kΩ. Impedances on this order can result in significant crosstalk in high-density circuit boards.

The reason the Gilbert cell can be so linear for small input signal levels is twofold: It is a differential amplifier and it makes use of the tanh function, which is linear over a wide range around the zero-crossing point [16]. Attempts have been made to increase the intercept point. The Plessey SL6440 IC was a special version of the Gilbert cell that achieved high $IP_{3,in}$ (+30 dBm) at the expense of dc current.

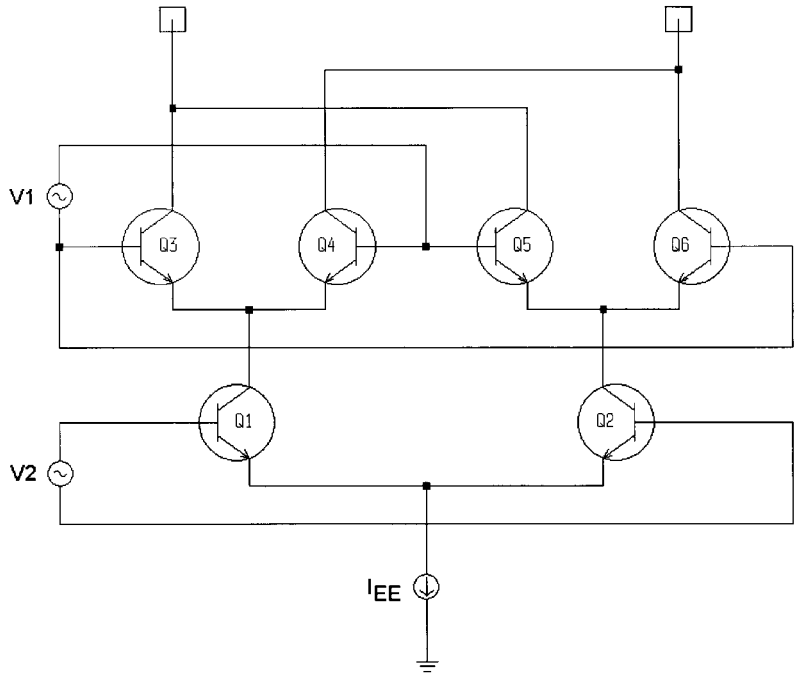

Figure 4-50 The basic Gilbert multiplier cell.

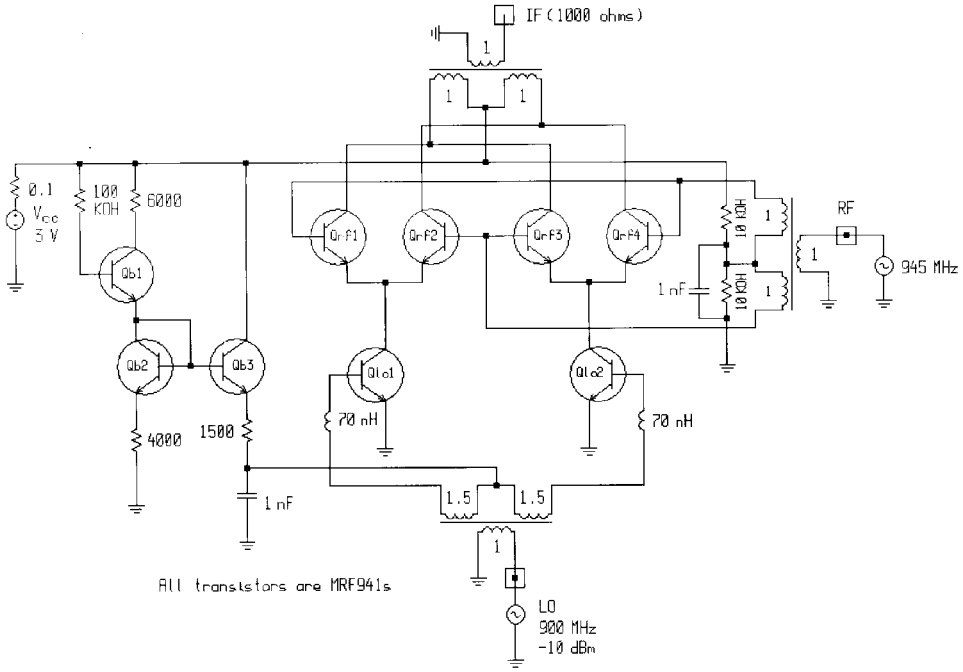

Figure 4-51 Gilbert cell mixer validation circuit.

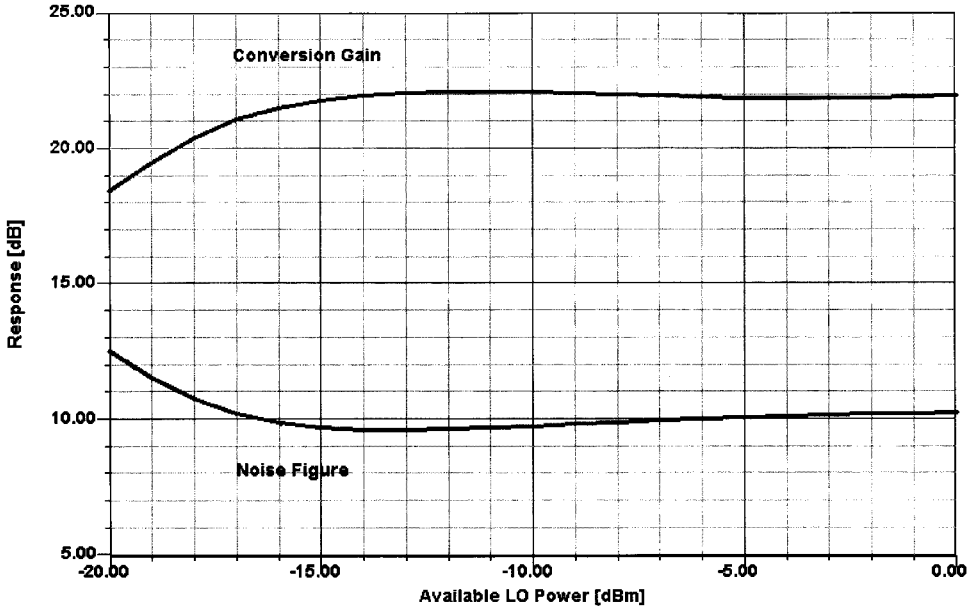

Figure 4-52 Conversion gain and noise figure versus LO power for the Gilbert cell mixer. In this analysis, LO = 900 MHz (–20 to 0 dBm) and RF = 945 MHz (–50 dBm) for an IF of 45 MHz.

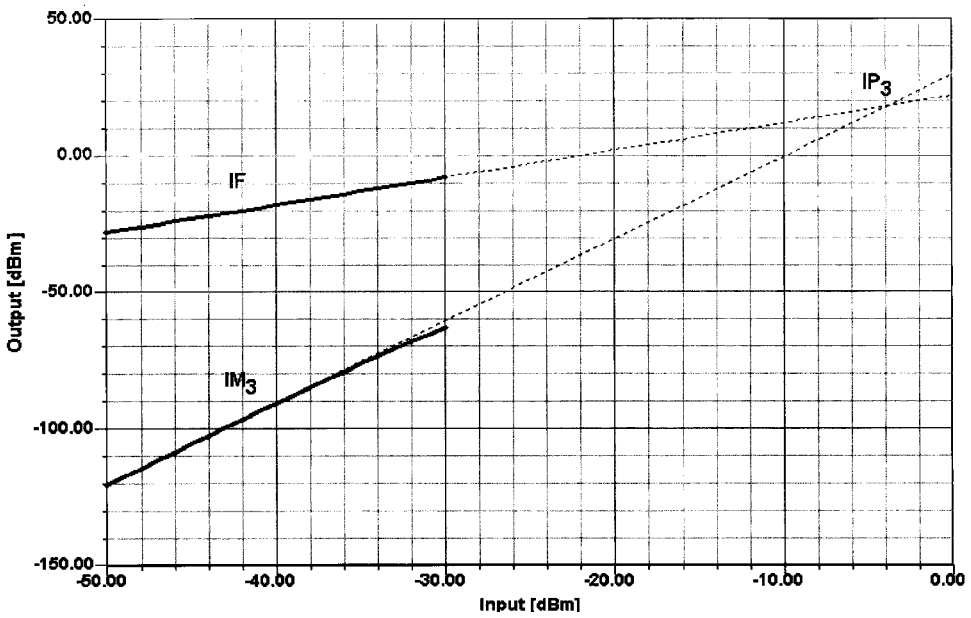

Figure 4-53 IM_3 and IP_3 responses for the BJT Gilbert cell mixer with RF signals at 945 and 946 MHz. In this analysis, LO = 900 MHz (–10 dBm), RF1 = 945 MHz (–50 to –30 dBm), and RF2 = 946 MHz (–50 to –30 dBm). Four LO harmonics and three LO sidebands were used.

Our suspicion, however, is that a combination of a modern double-balanced passive mixer using medium- to high-level diodes followed by a feedback FET amplifier, or even one of the late CATV transistors with f_T values of more than 25 GHz, would allow the achievement of a significantly higher intercept point. As pointed out in Chapter 3, CATV transistors are now available that combine a noise figure of less than 1 dB with a $IP_{3,in}$ of more than 30 dBm. Built-in push–pull structures using such transistors can achieve an $IP_{2,in}$ of 70 dBm, matching the numbers for the diode DBM. In Chapter 3 we learned that feedback always improves the dynamic range, mostly at the expense of gain, since the gain–bandwidth product gets reduced. Motorola has recently come out with a clever extension of its high-level preamplifier and modified it to become a mixer.

4-4-2 BJT Gilbert Cell with Feedback

Motorola's MC13143 low-power 2.4-GHz mixer IC uses a patented topology consisting of a Class-AB-biased Gilbert cell augmented by feedback. Its linearity can be programmed via

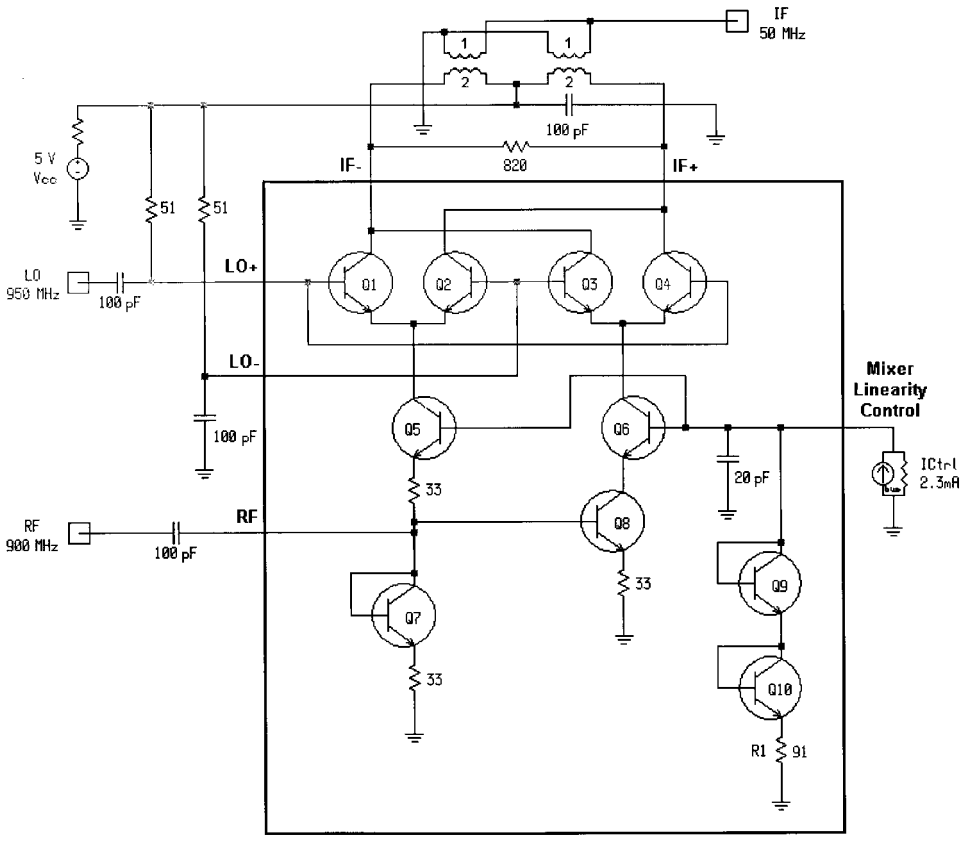

Figure 4-54 Motorola's MC13143 mixer IC uses dc feedback for improved linearity that can be programmed by applying a control current (0–2.3 mA) to its Mixer Linearity Control pin. Per Motorola, an $IP_{3,in}$ of 20 dBm may be achieved with a control current of 2.3 mA, at the expense of approximately 7 mA of additional supply current. In this validation circuit, R_1 (the resistor in Q10's emitter) has been adjusted for a total current drain (supply + linearity control) of 8 mA.

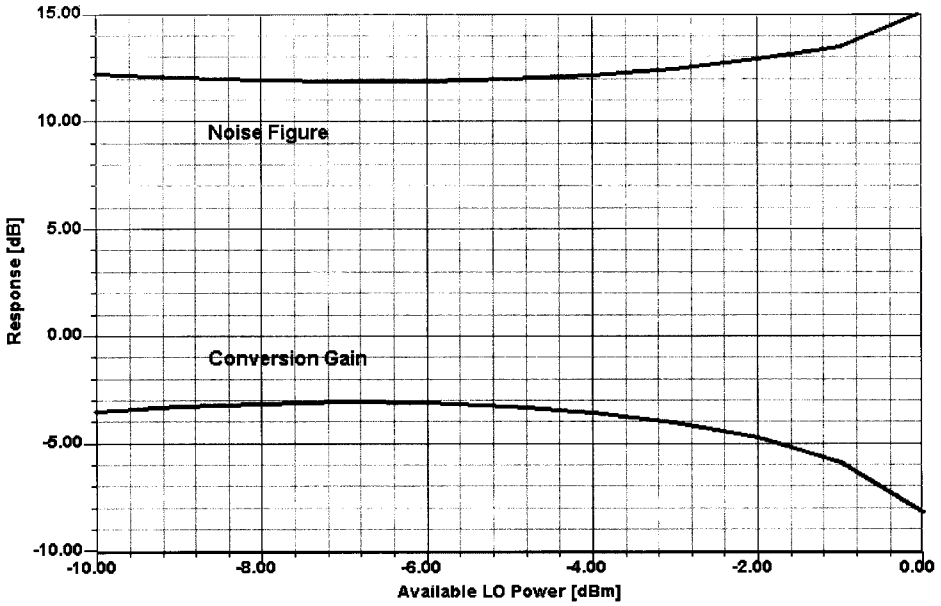

Figure 4-55 Calculated conversion gain and noise figure versus LO drive for the Motorola MC13143 IC operating at $V_{CC} = 2$. Motorola's specifications for the typical values of these characteristics are –5.0 dB and 12 dB, respectively, at an LO drive level of 0 dBm. The RF signal is at 900 MHz and the LO is at 950 MHz, for an IF of 50 MHz. In this analysis, LO = 950 MHz (–10 to 5 dBm) and RF = 901 MHz (–50 dBm) for an IF of 49 MHz.

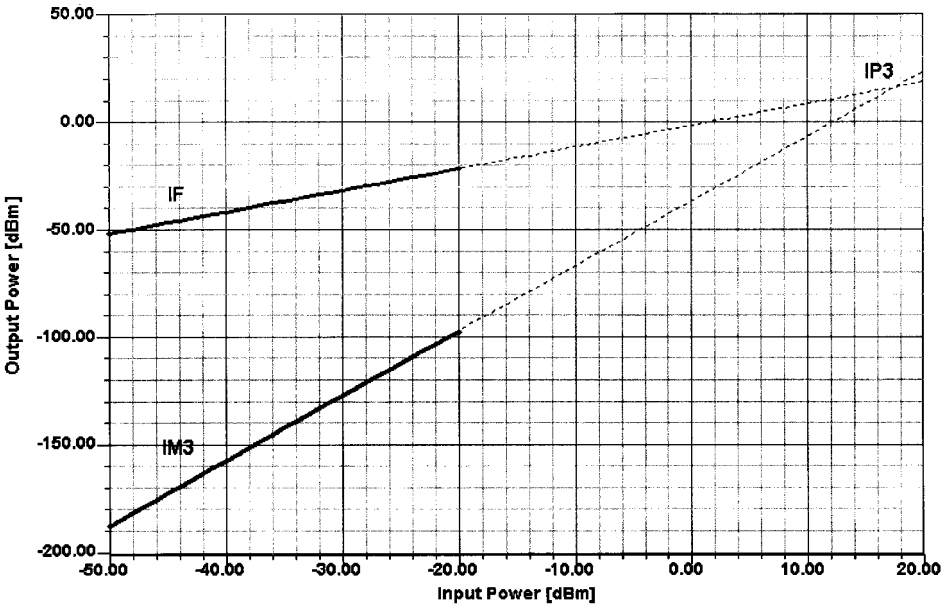

Figure 4-56 Calculated typical IF, IM_3, and IP_3 responses for the Motorola MC13143 mixer. In this analysis, LO = 950 MHz (–5 dBm), RF1 = 900 MHz (–50 to –20 dBm), and RF2 = 901 MHz (–50 to –20 dBm), and $V_{CC} = 5$. Four LO harmonics and three LO sidebands were used.

an external current source to achieve an $IP_{3,in}$ of 20 dBm at the expense of additional supply current.

The MC13143 contains 29 active transistors. Figure 4-54 shows the core of the MC13143 circuit reduced to its essentials and configured for computer analysis per Motorola's MC13143 test circuit. Figure 4-55 shows the circuit's conversion gain and noise figure versus LO drive, and Figure 4-56 shows the circuit's typical IF, IM_3, and IP_3 responses, both as calculated by Ansoft Corporation's Serenade 8.0 circuit simulator. A reproduction of the MC13143 datasheet, used by permission, follows.

In considering the approach used in the MC13143, one has to remember that feedback around many stages gives an IMD ripple, which means that the higher-order IPs are no longer a straight-line calculation. Above a certain level, the 3-dB/dB law fails, and as a result of this, the IMD characteristic can be as bad as 10 or 20 dB/dB—almost like a breakdown point.

High-frequency capability is an issue with silicon BJTs; the upper frequency limit of the technique is in the range of 3 GHz. Bipolar technology will be extended to 10 GHz by SiGe, but when these parts will be commercially available at competitive prices is currently unclear. There has not been enough published on the actual performance of Gilbert-cell-type mixers using SiGe transistors, but we assume that because of coupling on the silicon wafer, things are no longer as well behaved as we are used to at much lower frequencies.

4-4-3 FET Mixers

FETs, used in active and passive circuits, are still a popular solution for low-power integrated mixers up to 100 MHz (passive quad) and 1 GHz (dual-gate MOSFET). Cost-sensitive applications may require the use of a single-gate FET. These types of single-gate microwave mixers are frequently used to validate the quality of software but the user keeps forgetting this is a question of the quality of the model and not of the simulator. A good example of bad modeling is Figure 7.88 in Vendelin et al. [17]. Unfortunately, we have not seen the same circuit analyzed with modern tools, nor do the authors of the paper cited [18] provide sufficient details of the circuit and the transistor for us to do this ourselves.

Figure 4-57 shows a basic, active FET mixer. Like the single-diode and single-BJT mixers, it is additive, although it's common to lessen RF–LO interaction by injecting one signal at the gate and the other at the source as shown. Single-gate GaAs and LDMOS FETs are also used in this arrangement with gate biasing as appropriate to the device type. Figure 4-58 shows a dual-gate FET in an additive mixing configuration.

The linearity of FETs is based on the fact that a FET follows a square law and therefore the first derivative, its transconductance, is supposed to be constant. This is valid within a wide amplitude range. FET mixers have a noise figure similar to those found in bipolar mixers: typically around 6–9 dB, depending on the configuration. A FET mixer's intercept point is subject to load-impedance variations, with a purely resistive termination providing the best case. Terminating the mixer with a filter is problematic in that a filter looks purely resistive only within its 3-dB passband; in the transition band and beyond, the filter impedance rises rapidly and the mixer intercept point goes down. The best means devised so far to minimize this effect is to configure the FET output as a high-pass filter, using capacitive coupling from the output tuned circuit to a 50-(bandpass filter, as shown in Figure 4-59. Outside its passband, this impedance inverter acts more like a short circuit and maintains IMD products at a reasonable level. The alternative to this is the popular diplexer, which requires more components and has more insertion loss. The high-pass configuration has barely been mentioned in the literature.

MOTOROLA

Ultra Low Power DC - 2.4 GHz Linear Mixer

The MC13143 is a high compression linear mixer with single–ended RF input, differential IF output and differential LO inputs which consumes as little as 1.8 mW. A new circuit topology is used to achieve a high third order intermodulation intercept point, high linearity and high 1.0 dB output compression point while maintaining a linear 50 Ω input impedance. It is designed for Up or Down conversion anywhere from dc to 2.4 GHz.

Ultra Low Power: 1.0 mA @ V_{CC} = 1.8 to 6.5 V

- Wide Input Bandwidth: DC–2.4 GHz
- Wide Output Bandwidth: DC–2.4 GHz
- Wide LO Bandwidth: DC–2.4 GHz
- High Mixer Linearity: $P_{i1.0\ dB}$ = 3.0 dBm

Linearity Adjustment of up to IP_{3in} = 20 dBm

- 50 Ω Mixer Input
- Single–Ended Mixer Input
- Double Balanced Mixer Operation
- Differential Open Collector Mixer Output

MC13143

CIRCUIT DESCRIPTION

General

The MC13143 is a double–balanced Mixer. This device is designated for use as the frontend section in analog and digital FM systems such as Wireless Local Area Network (LAN), Digital European Cordless Telephone (DECT), PHS, PCS, GPS, Cellular, UHF and 800 MHz Special Mobile Radio (SMR), UHF Family Radio Services and 902 to 928 MHz cordless telephones. It features a mixer linearity control to preset or auto program the mixer dynamic range, an enable function and a wideband IF so the IC may be used either as a down converter or an up converter.

Current Regulation

Temperature compensating voltage independent current regulators provide typical supply current at 1.0 mA with no mixer linearity control current.

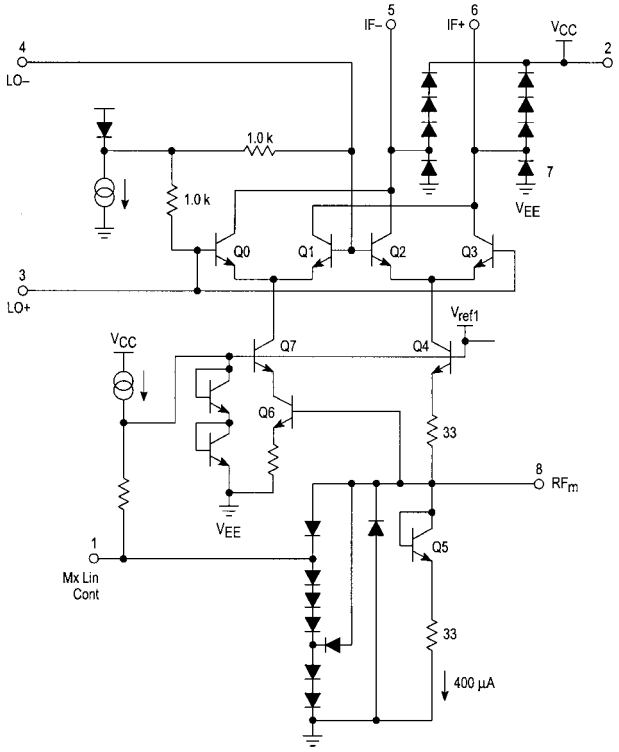
Mixer

The mixer is a unique and patented double–balanced four quadrant multiplier biased class AB allowing for programmable linearity control via an external current source. An input third order intercept point of 20 dBm may be achieved. All 3 ports of the mixer are designed to work up to 2.4 GHz. The mixer has a 50 Ω single–ended RF input and open collector differential IF outputs (see Internal Circuit Schematic for details). The linear gain of the mixer is approximately –5.0 dB with a SSB noise figure of 12 dB.

Local Oscillator

The local oscillator has differential input configuration that requires typically –10 dBm input from an external source to achieve the optimal mixer gain.

Figure 8. MC13143 Internal Circuit*



NOTE: * The MC13143 uses a unique and patented circuit topology.

MC13143

APPLICATIONS INFORMATION

Evaluation PC Board

The evaluation PCB is very versatile and is intended to be used across the entire useful frequency range of this device. The PC board is laid out to accommodate all SMT components on the circuit side (see Circuit Side Component Placement View).

Component Selection

The evaluation PC board is designed to accommodate specific components, while also being versatile enough to use components from various manufacturers. The circuit side placement view is illustrated for the components specified in the application circuit. The Component Placement View specifies particular components that were used to achieve the results shown in the typical curves and tables.

Mixer Input

The mixer input impedance is broadband 50 Ω for applications up to 2.4 GHz. It easily interfaces with a RF ceramic filter as shown in the application schematic.

Mixer Linearity Control

The mixer linearity control circuit accepts approximately 0 to 2.3 mA control current. An Input Third Order Intercept Point, IIP3 of 20 dBm may be achieved at 2.3 mA of control current (approximately 7.0 mA of additional supply current).

Local Oscillator Inputs

The differential LO inputs are internally biased at $V_{CC} - 1.0\ V_{BE}$; this is suitable for high voltage and high gain operation.

For low voltage operation, the inputs are taken to V_{CC} through 51 Ω.

IF Output

The IF is a differential open collector configuration which is designed to use over a wide frequency range for up conversion as well as down conversion.

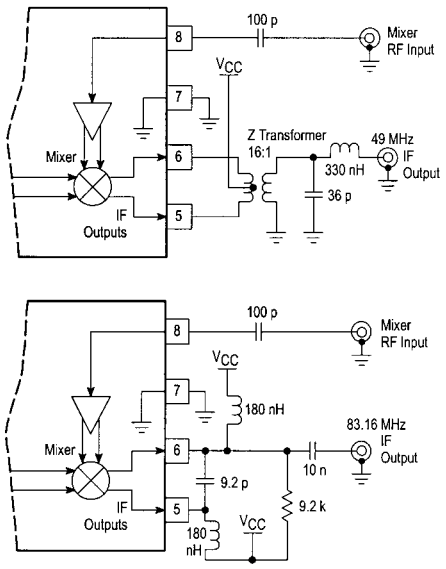
Input/Output Matching

It is desirable to use a RF ceramic or SAW filter before the mixer to provide image frequency rejection. The filter is selected based on cost, size and performance tradeoffs. Typical RF filters have 3.0 to 5.0 dB insertion loss. The PC board layout accommodates both ceramic and SAW RF filters which are offered by various suppliers such as Siemens, Toko and Murata.

Interface matching between the RF input, RF filter and the mixer will be required. The interface matching networks shown in the application circuit are designed for 50 Ω interfaces.

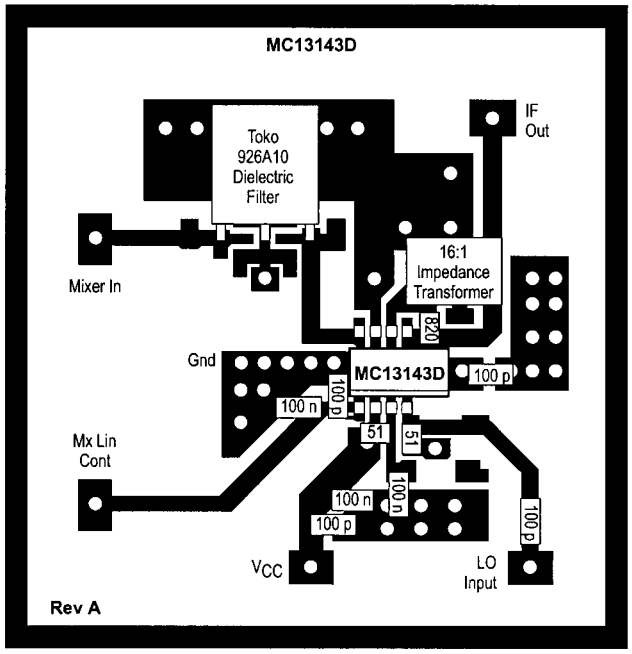
Differential to single–ended circuit configuration is shown in the test circuit. 6.0 dB of additional mixer gain can be achieved by conjugately matching the output of the MiniCircuits transformer to 50 Ω at the desired IF frequency. With narrowband IF output matching the mixer performance is 3.0 dB gain and 12 dB noise figure (see Narrowband 49 and 83 MHz IF Output Matching Options). Typical insertion loss of the Toko ceramic filter is 3.0 dB. Thus, the overall gain of the circuit is 0 dB with a 15 dB noise figure.

Figure 9. Narrowband IF Output Matching with 16:1 Z Transformer and LC Network



MC13143

Figure 10. Circuit Side Component Placement View



NOTES: 926.5 MHz preselect dielectric filter is Toko part # 4DFA–926A10; the 4DFA (2 and 3 pole SMD type) filters are available for applications in cellular and GSM, GPS, DECT, PHS, PCS and ISM bands at 902–928 MHz, 1.8–1.9 GHz at 2.4–2.5 GHz.

The PCB also accommodates a surface mount RF SAW filter in an eight or six pin ceramic package for the cellular base and handset frequencies. Recommended manufacturers are Siemens and Murata.

The PCB may also be used without a preselector filter; AC coupled to the mixer as shown in the test circuit schematic. All other external circuit components shown in the PCB layout above are the same as used in the test circuit schematic.

16:1 broadband impedance transformer is mini circuits part #TX16–R3T; it is in the leadless surface mount "TX" package. For a more selective narrowband match, a lowpass filter may be used after the transformer. The PCB is designed to accommodate lump inductors and capacitors in more selective narrowband matching of the mixer differential outputs to a single–ended output at a given IF frequency.

The local oscillator may also be driven in a differential configuration using a coaxial transformer. Recommended sources are the Toko Balun transformers type B4F, B5FL and B5F (SMD component).

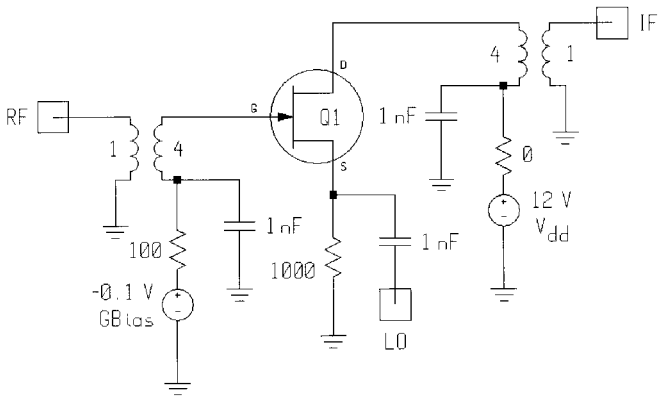


Figure 4-57 An additive JFET mixer cell using gate RF injection and source LO injection.

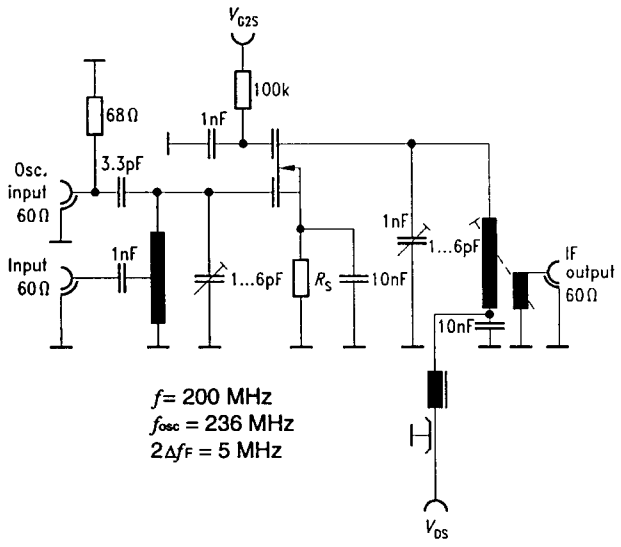

Figure 4-58 Test circuit for additive mixing using a dual-gate MOSFET.

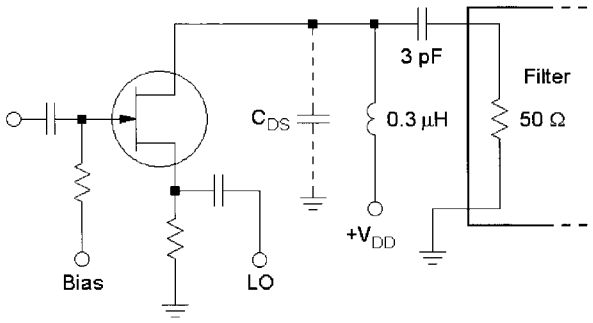

Figure 4-59 FET mixer output coupling that minimizes the effects of filter reactance outside the filter passband.

The active FET mixer achieves gain at the expense of intercept point; the difference can be as much as 20 dB. As an example, the passive MOSFET quad mixer, which is to be referenced, achieves an intercept point of greater than 40 dBm while similar active silicon FETs barely make 30 dBm. This 30-dBm performance is possible only at fairly low frequencies and requires careful selection and adjustment of the dc bias point of all transistors of the circuit. This performance also requires that the FETs be operated grounded-gate, which limits their gain. The other drawback of these active arrangements is that higher impedances at the output reduce the third-order intercept point overproportionally; as an example, a factor of two in impedance change can cost as much as 6 dB in the intercept point. In these discussions we assume that the IMD products are generated solely by the active device, and not by any passive devices, such as transformers. Actually, there are also some capacitors whose linearity varies with RF current—another unpleasant effect that is frequently overlooked.

On the other hand, one can use any FET as a passive device similar to a diode mixer, in which the source–drain channel gets switched on and off. This impedance modulation is somewhat similar to a diode mixer, but the gate electrode is isolated from both source and drain. It nonetheless falls into the category of additive mixers because there is sufficient interaction between gate and source, although the impedance at the gate changes significantly less than in an additive diode mixer. Implementation is a challenge in that building a high-performance passive FET mixer requires a pair or a quad of mixer cells that are sufficiently matched to suppress even-order IMD products. Intercept points, depending on the LO drive, vary between +20 and +45 dBm. The lower number is more applicable for microwave and RF frequencies, while the +45-dBm level is easily obtainable between and 5 and 30 MHz. It is necessary to remember that the FET is a voltage-driven switch, and LO matching becomes an issue: How do you generate 30 V peak-to-peak across a few picofarads over a wide frequency range? Physical layout can also be critical: Symmetry is not only important for the active devices, but also for the input, output, and LO circuit. We have seen cases where fractions of an inch in different lengths leading to the gate electrodes have cost up to 10 dB of IP_3—just because of the resulting lack of symmetry.

Figure 4-60 shows the circuit of Figure 4-57 modified to work with an LDMOS FET, the harmonic-balance version of the SPICE level 3 model. Figure 4-61 shows the LDMOS circuit's conversion gain and noise figure versus frequency. The "noisy" traces reflect the model's numerical problems. This model, which works up to about 0.8 μm and has been validated against the Motorola data and SPICE results, has already been made mathematically continuous but still shows the inability to properly model the real RF transistor. This is why more research needs to be done on RF and microwave applications for MOS in the modeling area. As can be seen from the references, several attempts have been made to improve the model, but the major headache remains with parameter extraction, and as the models get more complex, the modeling quality doesn't seem to improve as a linear function. The reader should be reminded of the load-pull measurement as outlined earlier.

Dual-Gate MOS/GaAs Mixers. Significantly better LO–RF isolation can be obtained by applying the RF to LO signals at separate gates of a dual-gate FET (Figure 4-62). The result is multiplicative mixing with fewer constraints on LO and RF filtering.

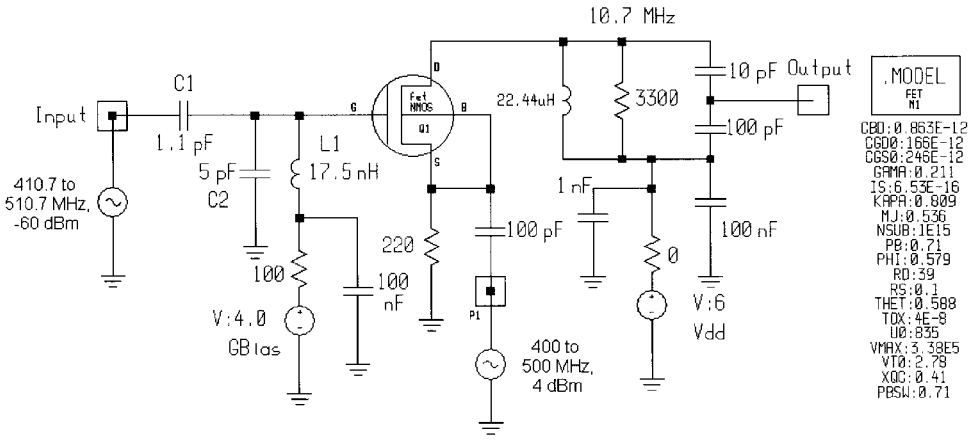

Figure 4-60 The N-JFET circuit of Figure 4-57 modified to work with an LDMOS FET.

4-4-4 MOSFET Gilbert Cell

The trend to go to smaller voltages has created some CMOS implementations of the Gilbert cell. While this may allow us to integrate reasonable mixers on the same chip, nobody should expect any miracles from these mixers. They are frequently starved in operating voltage and current and rarely fare better than a single diode mixer with proper drive level. On the other hand, the symmetry reduces some of the unwanted spurious frequencies and because of the high impedance, the actual RF power level is much less than the diode would need. There are so

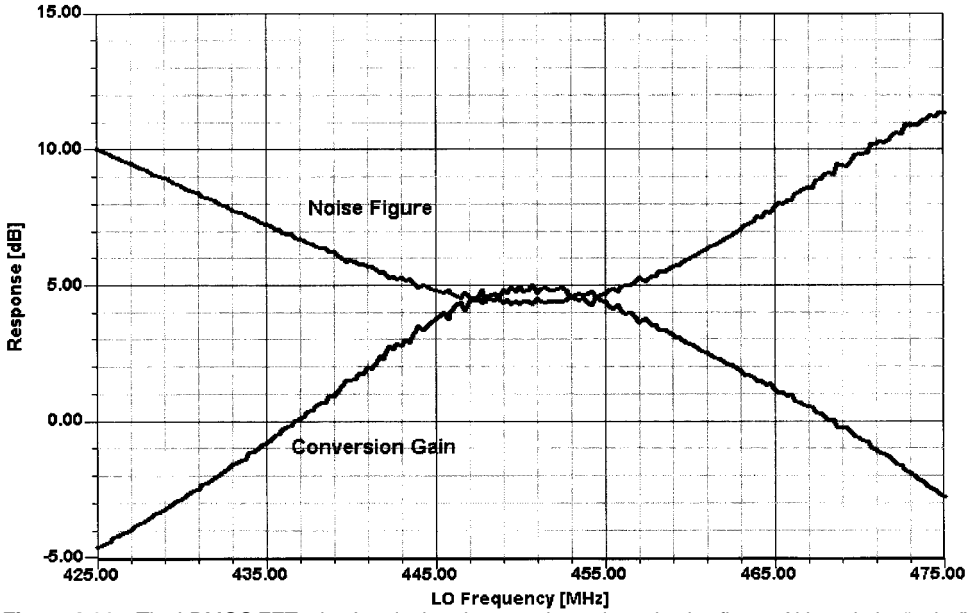

Figure 4-61 The LDMOS FET mixer's calculated conversion gain and noise figure. Although the "noisy" traces reflect numerical problems in the device model, the results can be put to good use in circuit design.

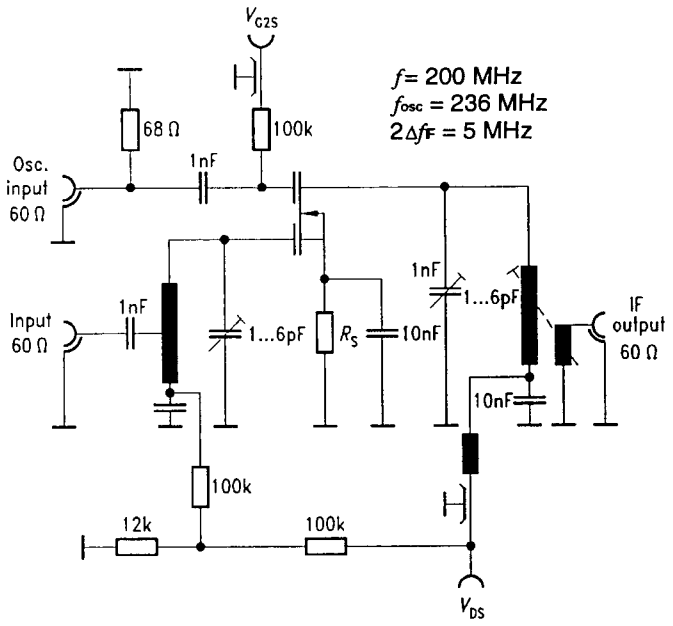

Figure 4-62 Test circuit for multiplicative mixing using a dual-gate MOSFET.

many CMOS transistors available in different processes that we cannot provide information about the general behavior, but this "low-cost" solution, as pointed out, is really only attractive because one can stay in the same technology while building the amplifier and other stages. Because of the flicker corner frequency of MOS, the noise figure of the mixer will be high compared to other devices, but not as bad as its GaAsFET brothers. In any case, to combine performance and simplicity, one needs to have a preamplifier that reduces the noise figure as well as the third-order intercept point of the mixer by the amount of preamplification.

4-4-5 GaAsFET Single-Gate Switch

In general, GaAsFET technology is the most expensive one. While GaAsFET competes with SiGe technology in frequency range at the time of this writing, it is a mature technology and well understood. The gallium arsenide wafers, however, are still unable to compete on a price basis with other technologies. There is a hybrid technology, silicon on sapphire, that also tries to go after the GaAsFET domain. The cutoff frequency of GaAsFET transistors is significantly higher than any other FETs, but the corner frequency f_c, also frequently referred to as flicker frequency, is somewhere between 10 and 100 MHz and therefore results in poor mixer performance from a noise figure point of view. The same applies, by the way, to oscillators. Another headache with GaAs is the low Q of the material, but this low Q gives transformers on GaAs a wider bandwidth. One of the pioneers of ICs for the wireless market is TriQuint, and we have been working with Wes Hayward of TriQuint in circuit analysis and validation. In doing so, we used some commercial and experimental circuits. In Chapter 3 we have already pointed out one amplifier that shows good agreement between measured and predicted data. By the time one has realized the entire circuit, including its associated biasing problems, even these circuits tend to grow. Figure 4-63 shows the circuit, which consists of an oscillator/amplifier, switching mixer, and a differential IF postamplifier.

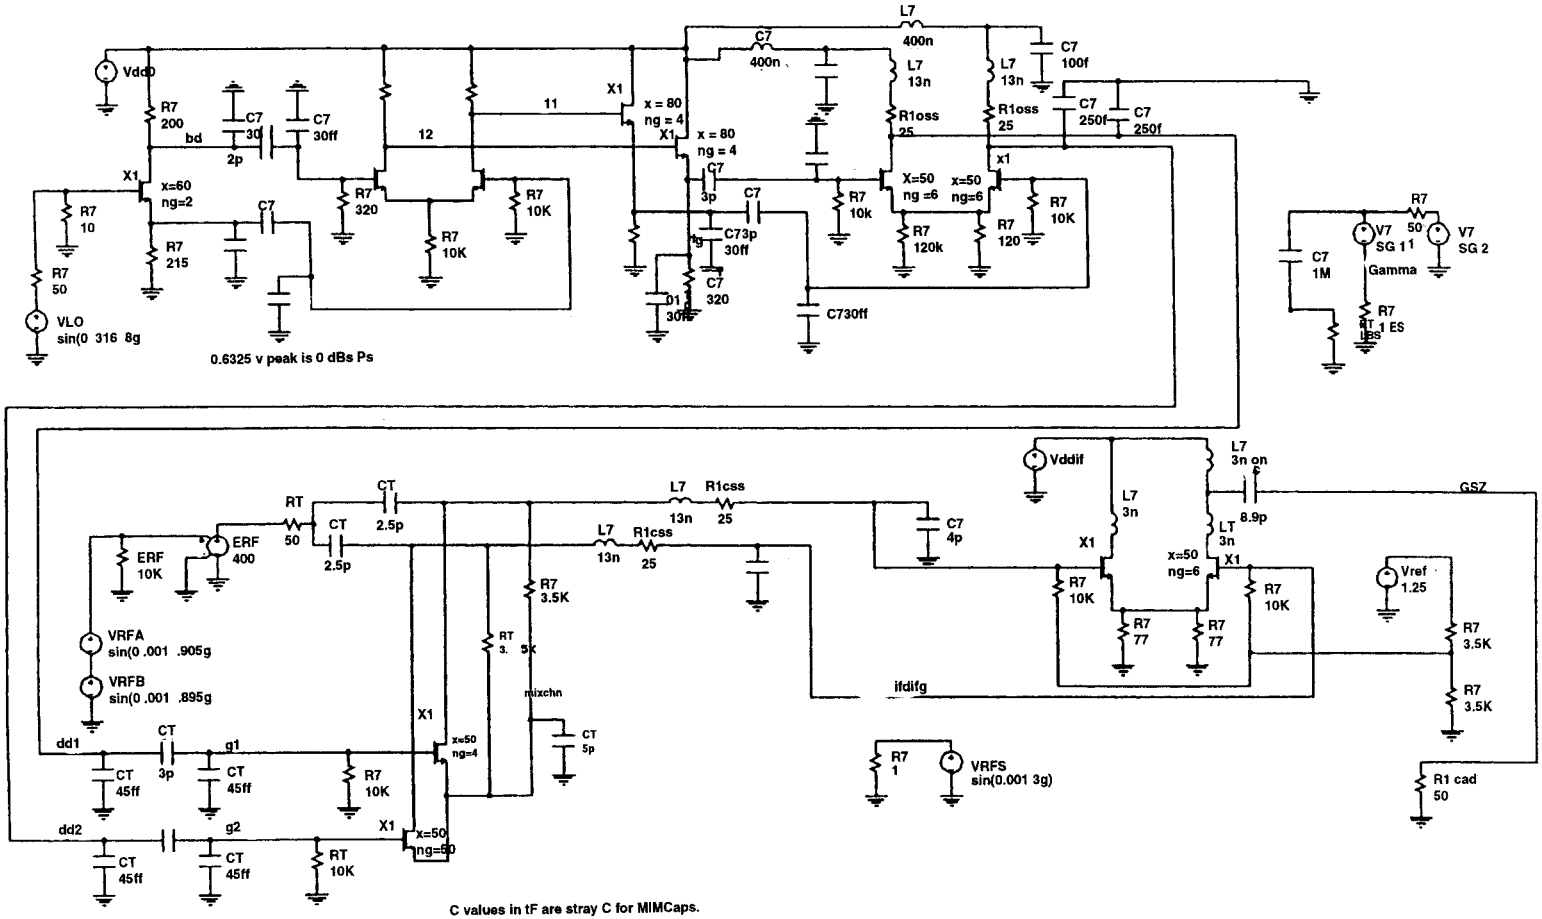

Figure 4-63 The complete switching mixer circuit.

Since the highest accuracy is needed to model these types of circuit, we found that only very recent simulators, such as Serenade 8 from Ansoft, can handle such a large number of FETs without barking at the user. Initially, we had all kinds of difficulties with these circuits because of the TriQuint TOM model, which had been developed for SPICE, and its IF/ELSE statements that made it mathematically discontinuous. The type of GaAsFETs used by TriQuint were both regular FETs and enhancement FETs, which require a positive voltage at the gate. Further details of this should be looked up in the foundry manual by TriQuint. In Chapter 2 we have shown some comparisons between different models and their prediction accuracy. Such converters need to resort to inductors in GaAs technology, and compared to other parts they become quite big (Figure 4-64).

In order to reduce some of the complexity in modeling and yet deal with the problems of mixers, a simpler mixer is needed that is a combination of a set of switching transistors and a postamplifier for the IF (Figure 4-65). The reader may notice that the small inductances of 15 nH have an extremely high loss modeled by a series resistor of 18 Ω. The first to recommend this type of switching mixers was probably Stephen Maas. The circuit diagram itself (Figure 4-65) is self-explanatory, but again we need to point out the resulting complexity.

The GaAsFET mixer giving the best performance on the market today is the Siemens model CMY210 (Figure 4-66). A reproduction of its datasheet, used by permission, follows the schematic.

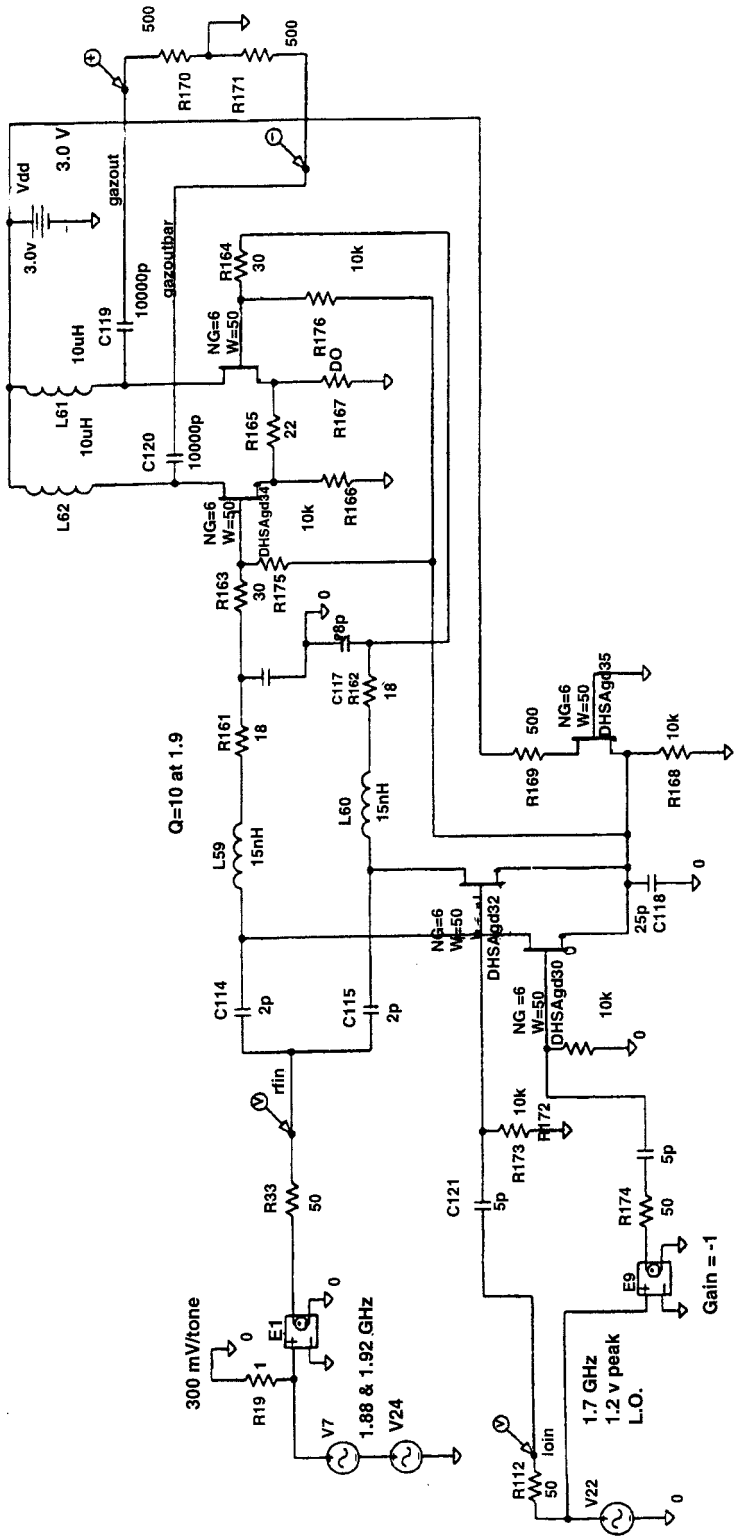

Figure 4-65 Simplified switching FET mixer.

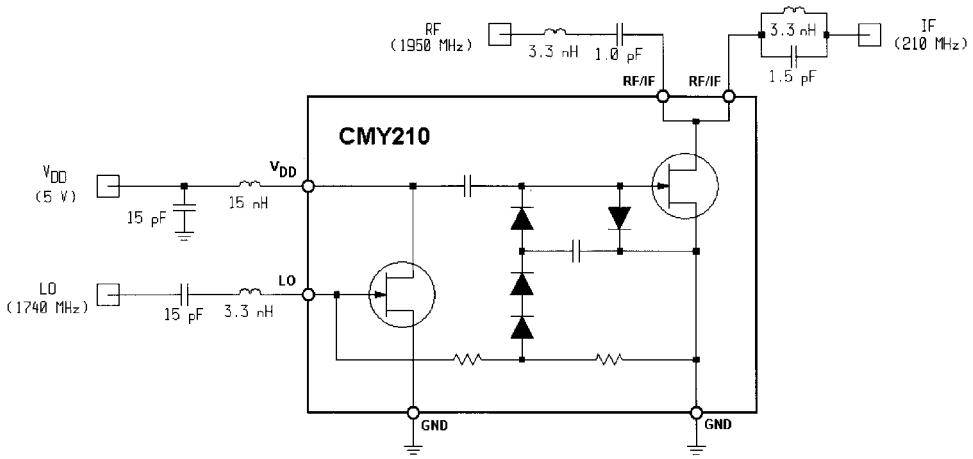

Figure 4-66 The Siemens CMY210 IC includes a shunt switch mixer and AGC-equipped LO amplifier for more constant LO drive. Despite its simplicity, this mixer achieves a typical $IP_{3,in}$ of 25 dBm.

The CMY210 circuit is a clever combination of a switching type of mixer with an automatic level control arrangement that provides the mixer with a reasonably constant drive level following the LO amplifier. Similar to cases we have shown, there is a clear relationship between the local oscillator power (invested dc power), and large-signal performance. This mixer externally has a series-tuned circuit at the input, which allows the UHF input signal

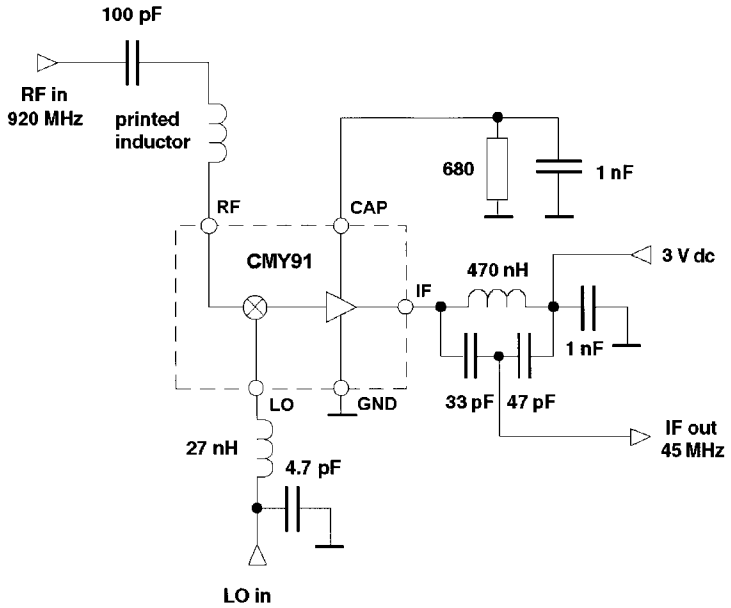

Figure 4-67 The CMY91 IC includes a postmixer amplifier instead of an AGC LO amplifier. Its $IP_{3,in}$ is typically –2 dBm (drain supply, 3 V at 1 mA) with no connection made to its CAP pin. In the configuration shown, its typical $IP_{3,in}$ is 0 dBm (drain supply, 3 V at 2.5 mA).

SIEMENS GaAs MMIC CMY 210

Preliminary Data

* **Ultralinear Mixer** with integrated LO-Buffer
* Very high **Input-IP3 of typical 25dBm**
* Very low **LO-Power demand of typ. 0dBm**
* Suited for Up- and Down-Conversion
* Wide LO-Frequency Range
  <500MHz to >2,5GHz
* Wide LO-Level Range
* Single ended Ports
* RF- and IF-Port Impedance 50 Ohm
* Operating Voltage Range: < 3 to 6V
* Very low Current Consumption of typical 7mA
* All Gold Metallisation

Notes for external elements:

L1, C1: Filter for upper frequency;
C2, L2: Filter for lower frequency;
each filter is a throughpath for the desired frequency (RF or IF) and isolates the other frequency (IF or RF) and its harmonics.
These two filters must be connected to pin 1 and pin 6 directly.
Parasitic capacitances at the ports 1 and 6 must be as small as possible.
L4 and C5 are optimized by indicating lowest I_{op} at used LO-frequency; same procedure for L3.
The ports 1, 3 and 6 must be DC open.

General description and notes:

The CMY 210 is an all port single ended general purpose Up- and Down-Converter.
It combines small conversion losses and excellent intermodulation characteristics with a low demand of LO- and DC-power.
The internal level controlled LO-Buffer enables a good performance over a wide LO level range.
The internal mixers principle with one port RF and IF requires a frequency separation at pin 1 and 6 respectively.

Note 1:
Best performance with lowest conversion loss is achieved when each circuit or device for the frequency separation meets the following requirements:

Input Filter: Throughpass for the signal to be mixed; reflection of the mixed signal and the harmonics of both.

Output Filter: Throughpass for the mixed signal and reflection of the signal to be mixed and the harmonics of both.

The impedance for the reflecting frequency range of each filter toward the ports 1 and 6 should be as high as possible.
In the simplest case a series- and a parallel- resonator circuit will meet these requirements but also others as appropriate drop in filters or micro stripline elements can be used.
The two branches with filters should meet immediately at the package leads of the port 1 and 6.
Parasitic capacitances at these ports must be kept as small as possible.
The mixer also can be driven with a source- and a load impedance different to 50Ω, but performance will degrade at larger deviations.

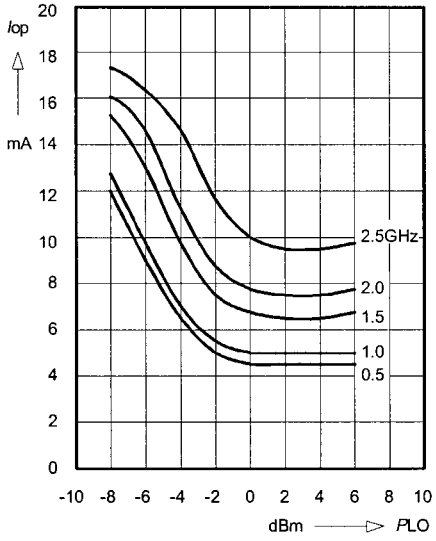
Note 2:
The LO-Buffer needs an external inductor L4 at port 4; the value of inductance depends on the LO frequency. It is tuned for minimum I_{op} consumption into port 4.
At lower LO frequencies it can be reduced by an additonal capacitor C5.

Note 3:
The LO Input impedance at Port 3 can be matched with a series inductor. It also can be tuned for a minimum current I_{op} into port 4. C3 is a DC blocking capacitor.
Since the input impedance of port 3 can be slightly negative at lower frequencies, the source reflection coefficient should be kept below 0.8 ($Z_0 = 50\ \Omega$) within this frequency range.

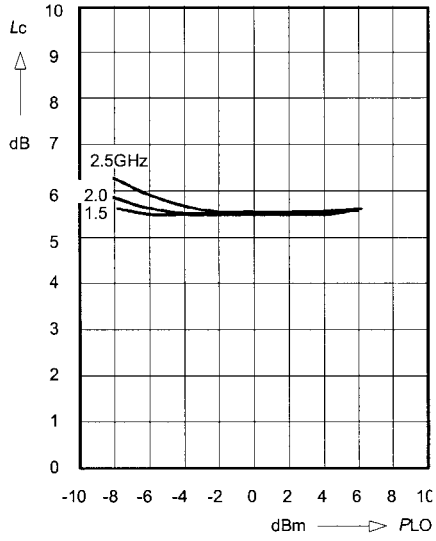
The Conversion Noise Figure Fssb is corresponding with the value of Conversion Loss L_c. The LO signal must be clean of noise and spurious at the frequencies $f_{LO} \pm f_{IF}$.

SIEMENS GaAs MMIC **CMY 210**

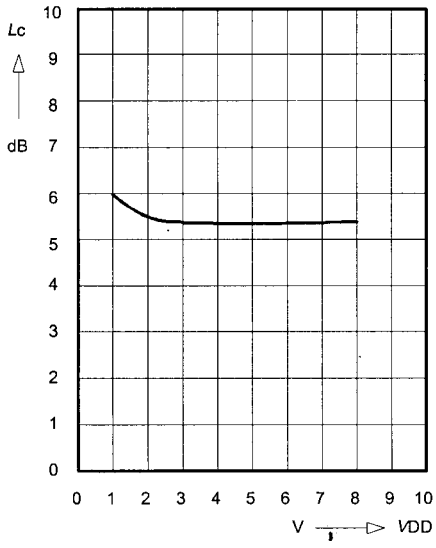
Operating Current $I_{op} = f(P_{LO})$
$V_{DD} = 3V$
f_{LO} = Parameter



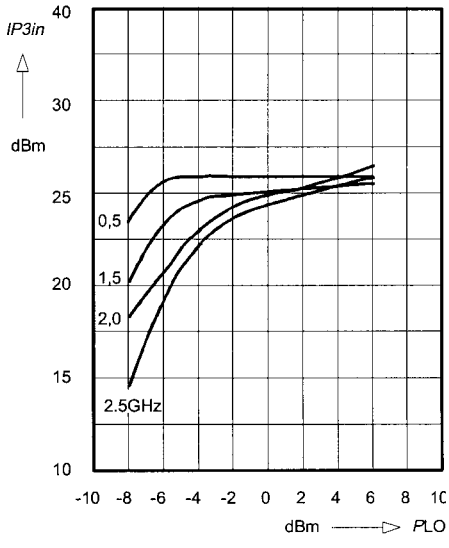
Conversion Loss $L_C = f(P_{LO})$
$V_{DD} = 3V$; $f_{IF} = 120MHz$
f_{LO} = Parameter



Conversion Loss $L_C = f(V_{DD})$
$P_{LO} = 0dBm$
$f_{LO} = 1500MHz$; $f_{IF} = 120MHz$

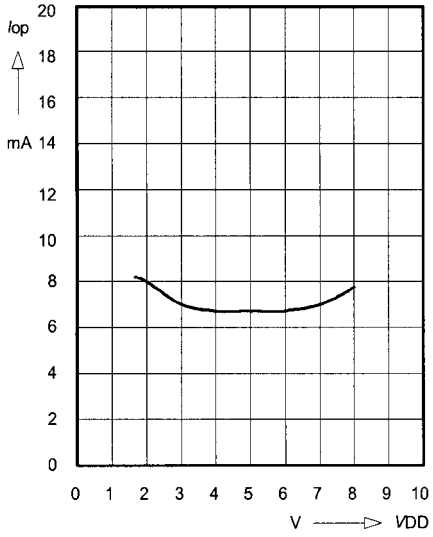


Third Order IP3 $IP3in = f(P_{LO})$
$P_{in} = 2$ x -3dBm; $f_{IF} = 40/45MHz$
$V_{DD} = 3V$; f_{LO} = Parameter;

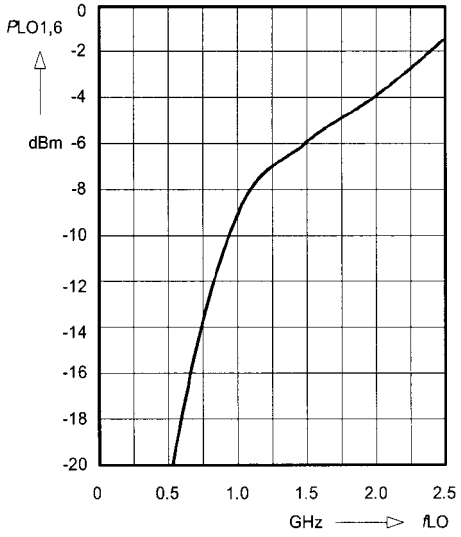


SIEMENS GaAs MMIC **CMY 210**

Operating Current $I_{op} = f(V_{DD})$
P_{LO} = 0dBm
f_{LO} = 1500MHz



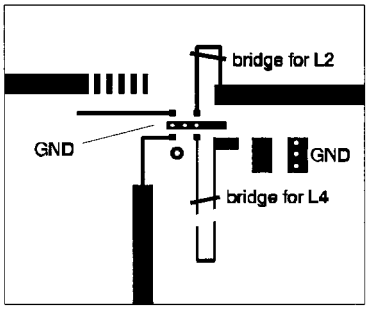
LO-Leakage at Port 1, 6 $P_{LO1,6} = f(f_{LO})$
P_{LO} = 0dBm
V_{DD} = 3V



SIEMENS GaAs MMIC **CMY 210**

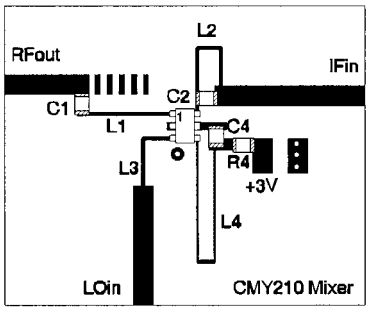
Additional informations and an example of a general purpose mixer pcb:

This general purpuse mixer demonstration board is used to show the performance of the CMY 210. The hints below will be helpful to achieve good intermodulation behaviour.



Material: Epoxy; size 24mm x 30mm; thickness 1mm

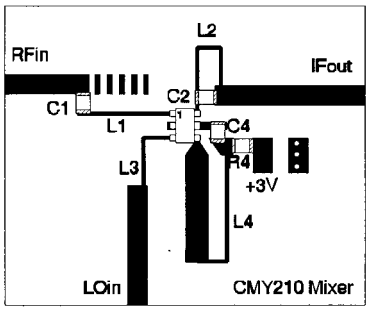
A good ground connection for CMY210 is necessary; here it is realized by 3 vias **under** the CMY 210 device. Best IM3 performance is obtained, when the capacitor C4 is grounded at the upper CMY 210 ground line without any additional vias (so the RF-Signal is encoupled from the LO-buffer best possible). Frequency tuning is done by selecting suitable capacitors C1 and C2, positioning C1 along the L1-line and by reducing the inductance of L2 and L4 by a bridge; unnecessary lines should be disconnected.



This example showes an up-converter.

The IM3 performance of upconverters mostly can be improved by tuning L4 slightly smaller then required for a minimum current consumption.

In other words, the resonant frequency of the buffer circuit at PIN4 (internal capacitor and L4) is tuned by L4 to a frequency slightly above the L.O.-frequency.



This example showes a down-converter.

Here an improved IM3-performance mostly can be obtained by a more capacitive load at CMY 210 port pin 4.
Here it is realized by a broader part of the L4 inductor line toward to port 4 and tuning L4 to a value sligthly smaller then for a minimum current consumption into port 4.

In other words, the resonant frequency of the buffer circuit at PIN4 (internal capacitor and L4) is tuned by L4 to a frequency slightly above the L.O.-frequency.

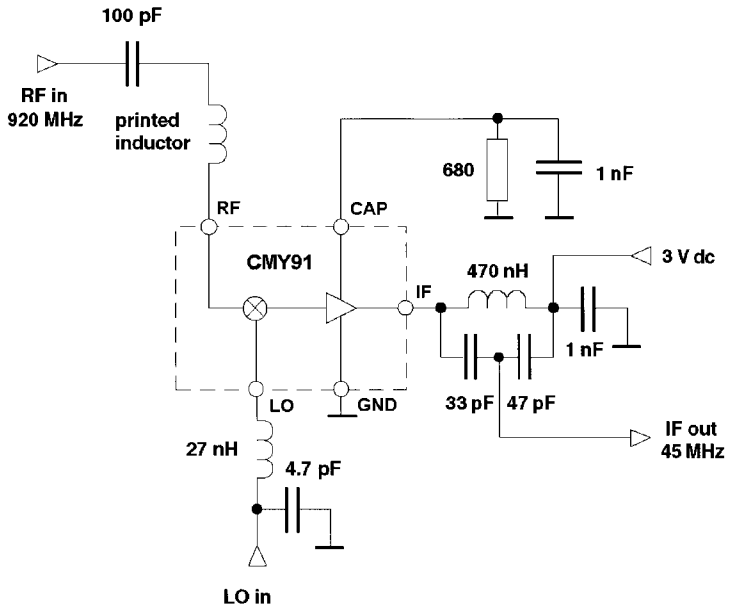


Figure 4-67 The CMY91 IC includes a postmixer amplifier instead of an AGC LO amplifier. Its $IP_{3,in}$ is typically –2 dBm (drain supply, 3 V at 1 mA) with no connection made to its CAP pin. In the configuration shown, its typical $IP_{3,in}$ is 0 dBm (drain supply, 3 V at 2.5 mA).

Table 4-6 Partial CMY91 specifications

Parameters		Symbol	Minimum	Typical	Maximum	Unit
Drain–source breakdown voltage						
I_{IF} = 500 µA	$V_{LO\text{-}GND}$ = 0 V					
$V_{RF\text{-}GND}$ = 4 V	CAP pin not connected	$V_{(BR)IF\text{-}GND}$	8	—	—	V
Drain current						
$V_{RF\text{-}GND}$ = 0 V	$V_{LO\text{-}GND}$ = 0 V					
$V_{IF\text{-}GND}$ = 3 V	CAP pin not connected	I_D	0.8	1	1.4	mA
Conversion gain						
f_{RF} = 920 MHz	f_{LO} = 965 MHz					
f_{IF} = 45 MHz	P_{LO} = –3 dBm	G_c	—	5.5	—	dB
Single-sideband noise figure						
f_{RF} = 920 MHz	f_{LO} = 965 MHz					
f_{IF} = 45 MHz	P_{LO} = –3 dBm	F_{SSB}	—	9	—	dB
Third-order intermodulation						
f_{RF} = 920 MHz	f_{LO} = 965 MHz					
f_{IF} = 45 MHz	P_{LO} = –3 dBm	IP_3	—	–2	—	dBm
LO/RF isolation						
f = 965 MHz		$Iso_{LO/RF}$	—	11	—	dB

T_A = 25 °C/V_D = 3 V; CAP pin connected to ground by 680-Ω resistor.

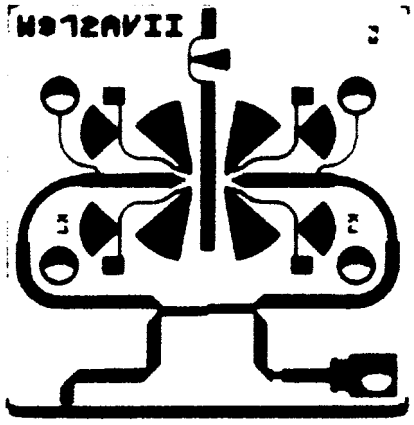

Figure 4-69 The 20-GHz diode mixer circuit board.

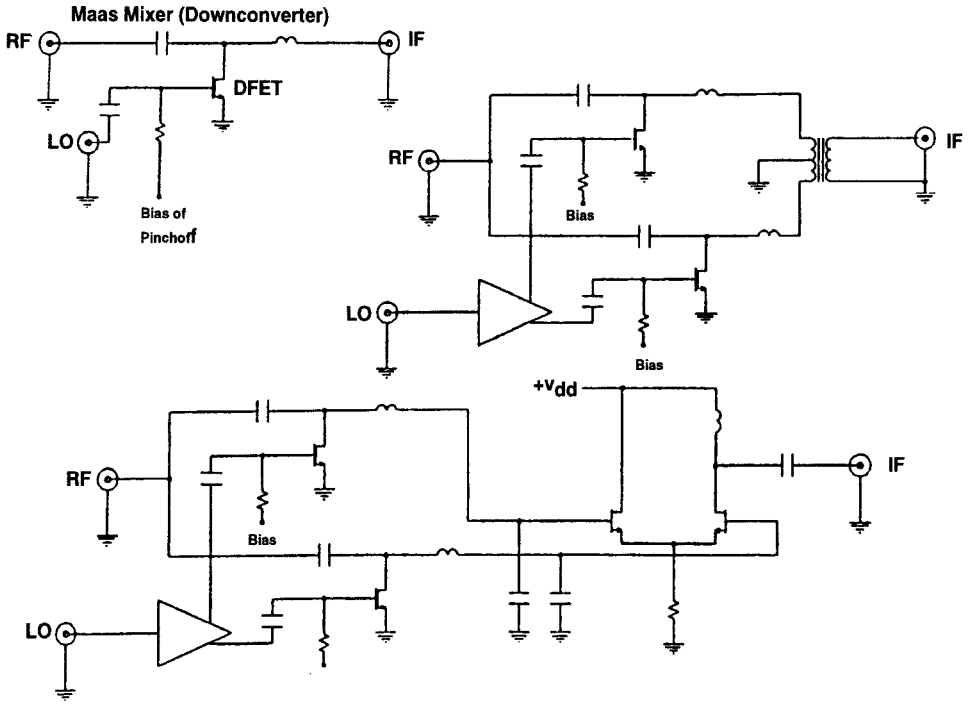

Figure 4-70a

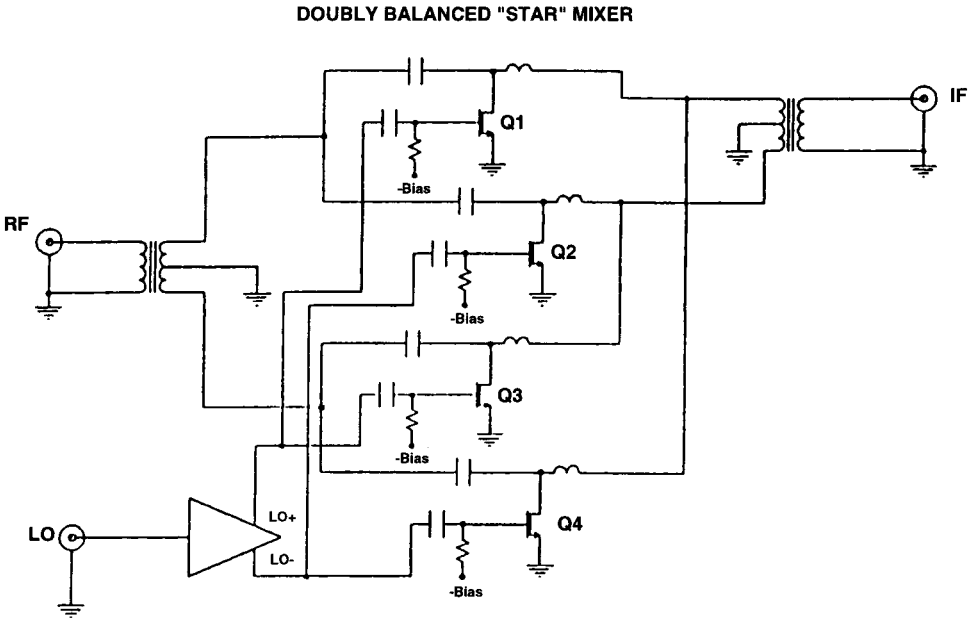

Figure 4-70b

to pass and has a parallel tuned circuit that keeps the input signal from getting into the IF stage. The resulting conversion loss of 5.5 dB is consistent with the example we presented before of 6 dB, and while the noise figure also is stated as 5.5 dB, that value is deceiving because it was determined using a 120-MHz IF. If an IF of 10 MHz or less was used, the noise figure would be tremendously worse. This is due to the frequently mentioned flicker-noise contribution. As a comparison, Figure 4-67 shows the predecessor to the CMY210, the CMY91, which includes a built-in IF amplifier. Table 4-6 shows its partial specifications. Since it has 5.5-dB gain, one can assume that the IF amplifier has something like 10 dB of gain, and the mixer portion, 6 dB losses. The resulting noise figure is the sum of the mixer noise figure and the IF amplifier noise figure. The IF transistor is probably not "noise matched" with the mixer, but the resulting 9-dB noise figure is not uncommon in this arrangement. Judging by previous examples, we would say that the noise figure of the mixer is somewhere around 6 dB, and therefore the mismatched (open at the input) IF amplifier has a noise figure of 3 dB, resulting in this total noise figure of 9 dB as stated. The third-order IP of –2 dBm is no match to the CMY210's $IP_{3,in}$ performance, which is typically 25 dBm.

For readers who are interested in what mixers look like when pushed well into the microwave region, we present the layout for a 20-GHz diode mixer. Figure 4-68 presents its layout, which includes radial stubs, circular stubs, and a Lange coupler. Figure 4-69 shows the layout implemented on a ceramic substrate.

As further food for thought and experimentation, Figure 4-70 presents mixer and related circuit notes as presented by Wes Hayward in TriQuint Semiconductor's GaAs Design Class.

HA Mixer Family Measurements

The mixers are all identical except for FET width. Mixers used the HA process and are half micron gate length. Bias was adjusted to best gain at +6 LO. The LO baluns were half wave lines of semi-rigid coax. F–LO = 1.65, RF = 1.9, and IF = 0.25 GHz. Input Power is –13 or –10 dBm RF. All measurements show downconversion results.

RF/WIRELESS OSCILLATORS

5-1 INTRODUCTION TO FREQUENCY CONTROL

Practically all modern telecommunication and test equipment uses frequency-control techniques based on *frequency synthesis*, the production of the many frequencies involved in a radiocommunication system's modulation, transmission, reception, and demodulation functions through the combination and mathematical manipulation of a very few input frequencies. Although the frequency synthesis techniques now ascendant in wireless systems—phase-locked loops and, less commonly, direct digital synthesizers—are fundamentally different, all are ultimately based on RF oscillators. This chapter covers oscillator theory, evaluation, and design.

Two types of oscillators are needed in a phase-locked-loop system (Figure 5-1). One, typically a *crystal oscillator*, generates the synthesizer's reference signal. As Figure 5-1 reflects, the reference oscillator may be built into the synthesizer IC in highly integrated systems. The other oscillator, a *voltage-controlled oscillator* (VCO), is varied in frequency by the system to produce the synthesizer's output signal. Although designing good oscillators remains somewhat like black magic or a special art, we will show that mathematics and CAD tools, applied in conjunction with practical experience, can keep the oscillator design process well under control.

5-2 BACKGROUND

The oscillator was probably first discovered by people who wanted to build an amplifier back in the vacuum-tube days. Its modern equivalent is shown in Figure 5-2. Here we see an active device, a bipolar transistor or field-effect transistor, with a tuned input and output circuit. Under ideal circumstances, the voltage at the input is 180° out of phase and the amplifier is "stable." Because of the unavoidable feedback capacitance, a certain amount of energy is transferred from the output to the input at about 90° out of phase. If one of the tuned circuits is detuned to the point where the phase shift is –180°, oscillation will occur. This means that the small energy from the output will be amplified, brought back to the input in phase and

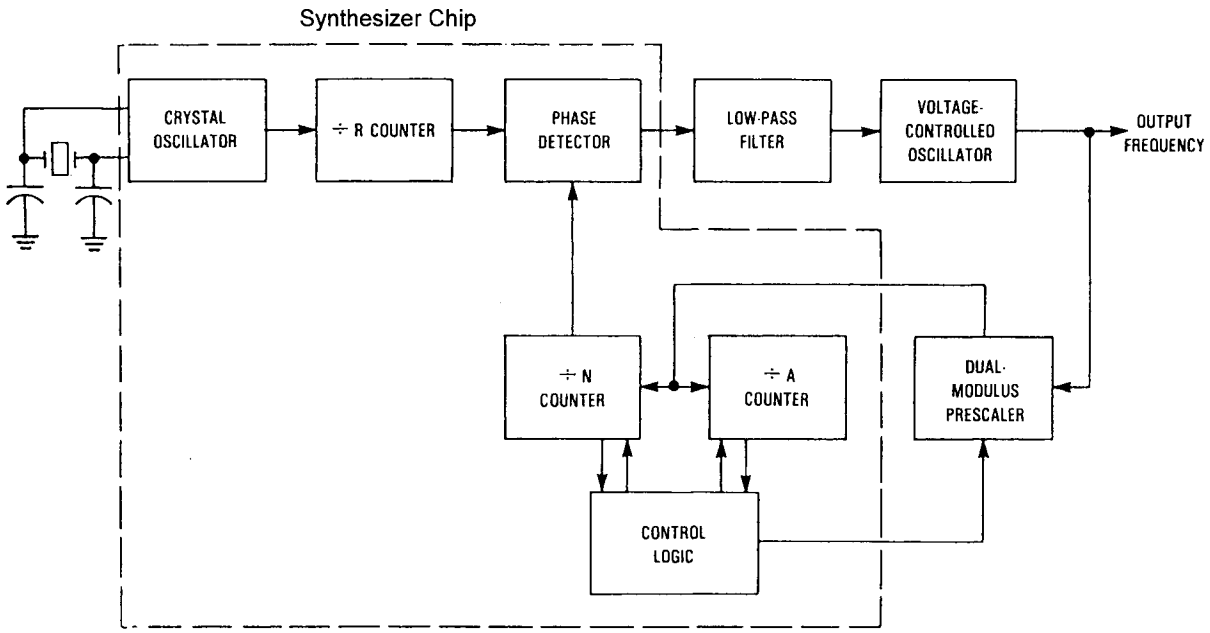

Figure 5-1 Block diagram of a modern, integrated frequency synthesizer. In this case, the designer has control over the VCO and the loop filter; the reference oscillator is part of the chip. In most cases (up to 2.5 GHz), the dual-modulus prescaler is inside the chip.

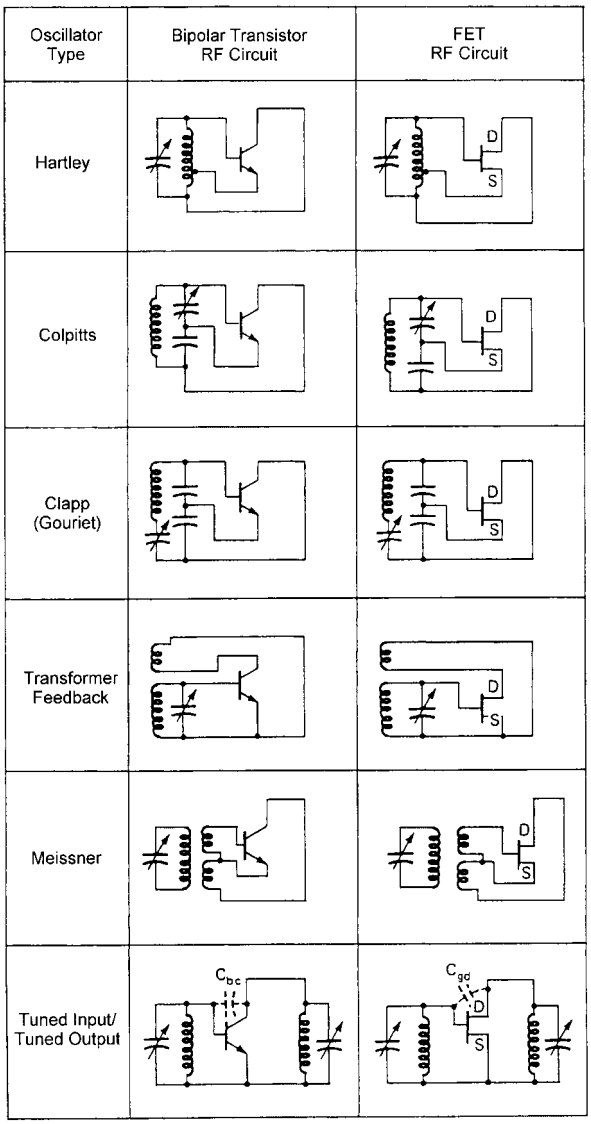

Figure 5-2 Schematic diagrams of RF connections for common oscillator circuits (dc and biasing circuits not shown) [1].

further amplified, causing the stage to "take off" and oscillate. Unless there is some mechanism to limit the amplitude of the oscillation at the input or output, its amplitude can theoretically increase to a level sufficient to destroy the device through breakdown effects or thermal runaway.

The criterion for oscillation was first described by Barkhausen [see Eq. (5-6) in the next section]. The conditions for oscillation exist when the feedback gain is high enough to cancel all losses and the difference between forward gain and reverse gain is less than zero. This implies also that oscillator circuits (Figure 5-2) provide a negative resistance, which is responsible for oscillation. The following mathematical treatment explains this.

5-3 OSCILLATOR DESIGN

A phase-locked loop generally has two oscillators: the oscillator at the output frequency and the reference oscillator. The reference oscillator at times can be another loop that is being mixed in, and the voltage-controlled oscillator (VCO) is controlled by either the reference or the oscillator loop. The VCO is one of the most important parts in a phase-locked-loop system, the performance of which is determined only by the loop filter at offsets inside the loop bandwidth, and only by the quality of the VCO design at offsets outside the loop bandwidth.

To some designers, VCO design appears to be magic. Shortly, we will go through the mathematics of the oscillator and some of its design criteria, but the results have only limited meaning. This is due to component tolerances, stray effects, and, most of all, nonlinear performance of the oscillator device, which can be modeled with only a certain degree of accuracy. However, after building oscillators for awhile, a certain feeling will be acquired for how to do this, and certain performance behavior will be predicted on a rule-of-thumb basis rather than on precise mathematical effort. For reasons of understanding, we will deal with the necessary mathematical equations, but we consider it essential to explain that these are only approximations.

5-3-1 Basics of Oscillators

An electronic oscillator is a device that converts dc power to a periodic output signal (ac power). If the output waveform is approximately sinusoidal, the oscillator is referred to as *sinusoidal.* There are many other oscillator types normally referred to as *relaxation* oscillators. For application in frequency synthesizers, we will explore only sinusoidal oscillators for reasons of purity and noise-sideband performance.

All oscillators are inherently nonlinear. Although the nonlinearity results in some distortion of the signal, linear analysis techniques can normally be used for the analysis and design of oscillators. Figure 5-3 shows, in block diagram form, the necessary components of an oscillator. It contains an amplifier with frequency-dependent forward loop gain $G(j\omega)$ and a frequency-dependent feedback network $H(j\omega)$.

The output voltage is given by

$$V_o = \frac{V_{\text{in}} G(j\omega)}{1 + G(j\omega)H(j\omega)} \tag{5-1}$$

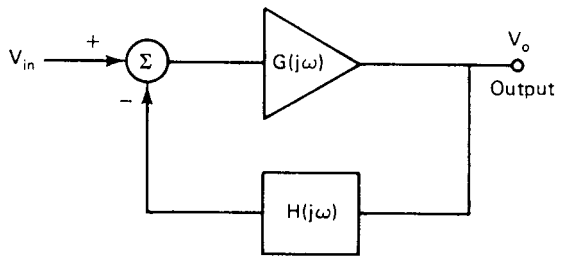

Figure 5-3 Block diagram of an oscillator showing forward and feedback loop components.

For an oscillator, the output V_o is nonzero even if the input signal $V_i = 0$. This can only be possible if the forward loop gain is infinite (which is not practical), or if the denominator

$$1 + G(j\omega)H(j\omega) = 0 \tag{5-2}$$

at some frequency ω_o. This leads to the well-known condition for oscillation (the *Nyquist criterion*), where at some frequency ω_o

$$G(j\omega_o)H(j\omega_o) = -1 \tag{5-3}$$

That is, the magnitude of the open-loop transfer function is equal to 1:

$$|G(j\omega_o)H(j\omega_o)| = 1 \tag{5-4}$$

and the phase shift is 180°:

$$\arg[G(j\omega_o)H(j\omega_o)] = 180° \tag{5-5}$$

This can be more simply expressed as follows: If in a negative-feedback system, the open-loop gain has a total phase shift of 180° at some frequency ω_o, the system will oscillate at that frequency provided that the open-loop gain is unity. If the gain is less than unity at the frequency where the phase shift is 180°, the system will be stable, whereas if the gain is greater than unity, the system will be unstable.

This statement is not correct for some complicated systems, but it is correct for those transfer functions normally encountered in oscillator design. The conditions for stability are also known as the *Barkhausen criteria*, which state that if the closed-loop transfer function is

$$\frac{V_o}{V_i} = \frac{\mu}{1 - \mu\beta} \tag{5-6}$$

the system will oscillate provided that $\mu\beta = 1$. This is equivalent to the Nyquist criterion, the difference being that the transfer function is written for a loop with positive feedback. Both versions state that the total phase shift around the loop must be 360° at the frequency of oscillation and the magnitude of the open-loop gain must be unity at that frequency.

The following analysis of the relatively simple oscillator shown in Figure 5-4 illustrates the design method. The linearized (and simplified) equivalent circuit of Figure 5-4 is given in Figure 5-5. h_{rb} has been neglected, and $1/h_{ob}$ has been assumed to be much greater than the load resistance R_L and is also ignored.

Note that the transistor is connected in the common-base configuration, which has no voltage phase inversion (the feedback is positive), so the conditions for oscillation are

$$|G(j\omega_o)H(j\omega_o) = 1| \tag{5-7}$$

and

$$\arg[G(j\omega_o)H(j\omega_o)] = 0° \tag{5-8}$$

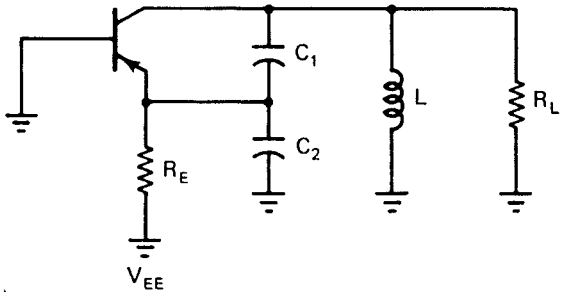

Figure 5-4 Oscillator with capacitive voltage divider.

The circuit analysis can greatly be simplified by assuming that

$$\frac{1}{\omega(C_2 + C_1)} << \frac{h_{ib}R_E}{h_{ib} + R_E} \tag{5-9}$$

and also that the Q of the load impedance is high. In this case the circuit reduces to that of Figure 5-6, where

$$V = \frac{V_o C_1}{C_1 + C_2} \tag{5-10}$$

and

$$R_{\text{eq}} = \frac{h_{ib}R_E}{h_{ib} + R_E}\left(\frac{C_1 + C_2}{C_1}\right)^2 \tag{5-11}$$

Figure 5-7 shows how the input impedance of an oscillator circuit—in this case, a BJT Colpitts oscillator minus its resonator—satisfies this condition for oscillation.

Then the forward gain

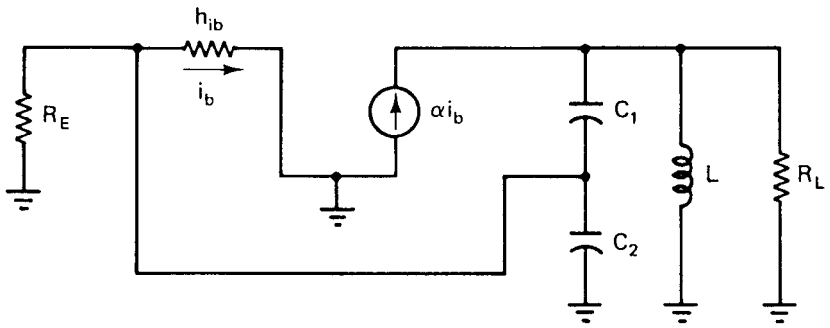

Figure 5-5 Linearized and simplified equivalent circuit of Figure 5-4.

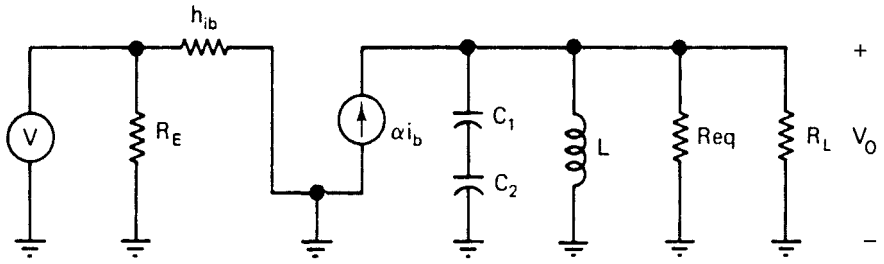

Figure 5-6 Further simplification of Figure 5-4, assuming high-impedance loads.

$$G(j\omega) = \frac{h_{fb}}{h_{ib}} Z_L = \frac{\alpha}{h_{ib}} Z_L \tag{5-12}$$

and

$$H(j\omega) = \frac{C_1}{C_1 + C_2} \tag{5-13}$$

where

$$Y_L = \frac{1}{Z_L} = \frac{1}{j\omega L} + \frac{1}{R_{\text{eq}}} + \frac{1}{R_L} + \frac{1}{j\omega C} \tag{5-14}$$

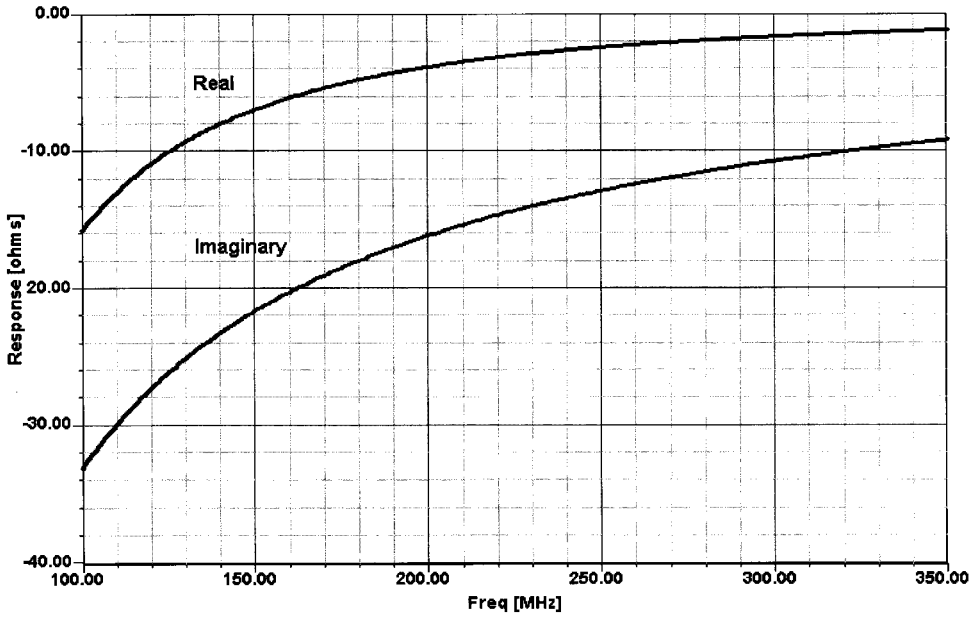

Figure 5-7 Calculated input impedance of a 200-MHz BJT Colpitts oscillator with its resonator removed. (Figure 5-46 shows an equivalent graph with the resonator present.)

A necessary condition for oscillation is that

$$\arg[G(j\omega)H(j\omega)] = 0^\circ \tag{5-15}$$

Since H does not depend on frequency in this example, if arg(GH) is zero, the phase shift of the load impedance Z_L must also be zero. This occurs only at the resonant frequency of the circuit,

$$\omega_o = \frac{1}{\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{5-16}$$

At this frequency

$$Z_L = \frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L} \tag{5-17}$$

and

$$GH = \frac{h_{fb}}{h_{ib}}\left(\frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L}\right)\frac{C_1}{C_1 + C_2} \tag{5-18}$$

The other condition for oscillation is the magnitude constraint that

$$G(j\omega)H(j\omega) = \frac{\alpha}{h_{ib}}\left(\frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L}\right)\frac{C_1}{C_1 + C_2} = 1 \tag{5-19}$$

Three-Reactance Oscillators. Although the block-diagram formulation of the stability criteria is an easy way to express stability mathematically, it is frequently not the easiest to apply since it is often difficult to identify the forward loop gain $G(j\omega)$ and the feedback ratio $H(j\omega)$ in electronic systems. A direct analysis of the circuit equations is frequently simpler than the block diagram interpretation (particularly for single-stage amplifiers). Figure 5-8 shows a generalized circuit for an electronic amplifier.

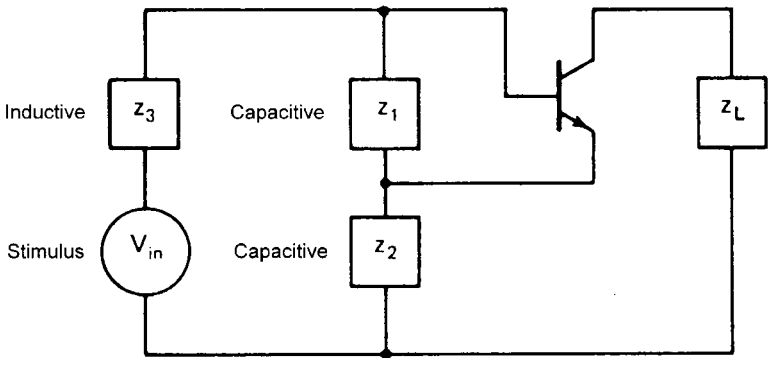

Figure 5-8 Generalized circuit for an oscillator using an amplifier model. Z_3 is inductive even with a capacitor in series with it.

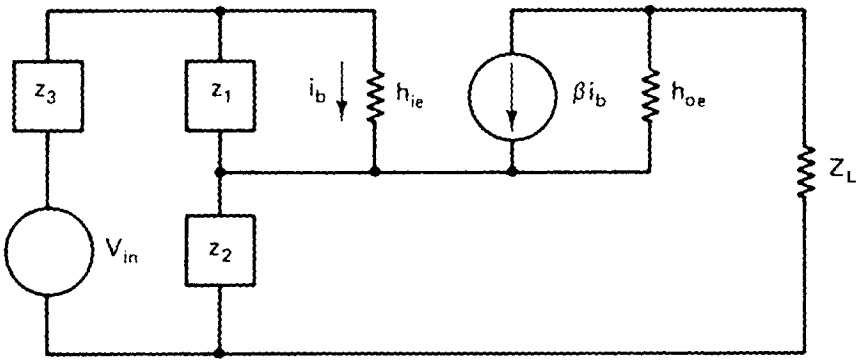

Figure 5-9 Small-signal equivalent circuit of Figure 5-8.

By inspecting Figure 5-8, one can see the three necessary reactances and the load. All other known circuits are derivatives of this by rotation. The small-signal equivalent circuit is given in Figure 5-9 (where h_{re} has been neglected).

Normally, h_{oe} can also be assumed sufficiently small and can be neglected. The loop equations are then

$$V_{\text{in}} = I_1(Z_3 + Z_1 + Z_2) - I_b Z_1 + \beta I_b Z_2 \tag{5-20}$$

$$0 = -I_1 Z_1 + I_b(h_{ie} + Z_1) \tag{5-21}$$

For the amplifier to oscillate, the currents I_b and I_1 must be nonzero even when $V_1 = 0$. This is only possible if the system determinant

$$\Delta = \begin{vmatrix} Z_3 + Z_1 + Z_2 & \beta Z_2 - Z_1 \\ -Z & h_{ie} + Z_1 \end{vmatrix} \tag{5-22}$$

is equal to 0. That is,

$$(Z_3 + Z_1 + Z_2)(h_{ie} + Z_1) - Z_1^2 + \beta Z_1 Z_2 = 0 \tag{5-23}$$

which reduces to

$$(Z_1 + Z_2 + Z_3)h_{fe} + Z_1 Z_2 \beta + Z_1(Z_2 + Z_3) = 0 \tag{5-24}$$

Assume for the moment that Z_1, Z_2, and Z_3 are purely reactive impedances. [It is easily seen that Eq. (5-24) does not have a solution if all three impedances are real.] Since both the real and imaginary parts must be zero, Eq. (5-24) is equivalent to the following equations if

$$h_{ie}(Z_1 + Z_2 + Z_3) = 0 \tag{5-25}$$

and

$$Z_1[(1 + \beta)Z_2 + Z_3] = 0 \tag{5-26}$$

Since β is real and positive, Z_2 and Z_3 must be of opposite sign for Eq. (5-26) to hold. That is,

$$(1 + \beta)Z_2 = -Z_3 \tag{5-27}$$

Therefore, since h_{ie} is nonzero, Eq. (5-25) reduces to

$$Z_1 + Z_2 - (1 + \beta)Z_2 = 0 \tag{5-28}$$

or

$$Z_1 = \beta Z_2 \qquad [C_1 < C_2; L_1 > L_2] \tag{5-29}$$

Thus, since β is positive, Z_1 and Z_2 will be reactances of the same kind. If Z_1 and Z_2 are capacitors, Z_3 is an inductor and the circuit is as shown in Figure 5-10. It is referred to as a *Colpitts* oscillator, named after the person who first described it.

If Z_1 and Z_2 are inductors and Z_3 is a capacitor as illustrated in Figure 5-11, the circuit is called a *Hartley* oscillator.

Example 1. Design a Colpitts circuit to oscillate at 200 MHz, using a transistor (operating at I_C = 6 mA dc) that has an input impedance

$$\text{Mag}(Z_{11}) = \frac{26 \text{ mV}}{I_C} \beta = 282\ \Omega (h_{ie} \triangleq Z_{11})$$

and

$$\beta_{RF} = 65; \quad \beta_{OSC} = 10 \quad \text{(large-signal condition)}$$

The oscillating transistor operates under large-signal conditions, generating harmonics in addition to the fundamental. Most of the transistor's current gain will come from dc biasing. β_{OSC}, its large-signal beta at the fundamental frequency of oscillation, must therefore be considerably less than β_{RF}, the small-signal, single-tone value, as the

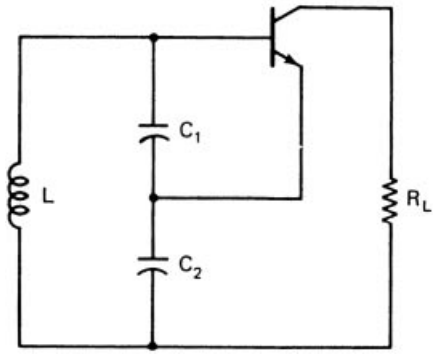

Figure 5-10 Colpitts oscillator.

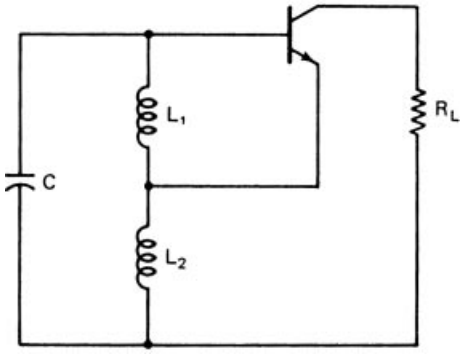

Figure 5-11 Hartley oscillator.

transistor's available current gain, β_0, is distributed among the dc, fundamental, and harmonic components present ($\beta_0 = \beta_{dc} + \beta_{OSC} + \beta_{OSC,F2} + \beta_{OSC,F3}\ldots$).

Solution: For the Colpitts circuit, Z_1 and Z_2 are capacitive reactances and Z_3 is an inductive reactance. Let $Z_2 = -j1.6\ \Omega$; then [Eq. (5-27)]

$$Z_3 = -(1 + \beta)Z_2 = -(1 + 10) \times (-1.6) \approx j17\ \Omega$$

and [Eq. (5-25)]

$$Z_1 = -(Z_2 + Z_3) \approx -j17\ \Omega$$

At 200 MHz, these impedances correspond to component values of $C_1 = 50$ pF, $C_2 = 500$ pF, and $L = 30$ nH. The oscillator will probably work with C_2 values larger than 500 pF, but at the loss of safety margin for tolerances in production, beta, temperature, and phase-noise performance. The completed circuit, except for biasing, is shown in Figure 5-12.

If Z_1, Z_2, Z_3, or h_{ie} is complex, the preceding analysis is more complicated, but the conditions for oscillation can still be obtained from Eq. (5-24). For example, if, in the Colpitts

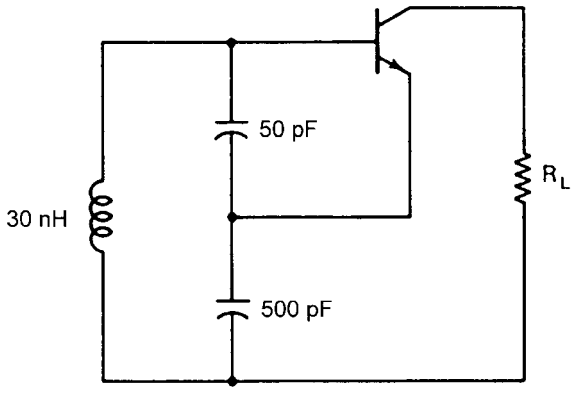

Figure 5-12 Design example of a Colpitts oscillator.

circuit, there is a resistor R in series with $L(Z_3 = R + j\omega L)$, Eq. (5-24) reduces to two equations:

$$h_{ie}\left(\omega L - \frac{1}{\omega C_1} - \frac{1}{\omega C_2}\right) - \frac{R}{\omega C_1} = 0 \tag{5-30}$$

and

$$h_{ie}R - \frac{1+\beta}{\omega^2 C_1 C_2} + \frac{1}{\omega C_1}\omega L = 0 \tag{5-31}$$

Define

$$C_1' = \frac{C_1}{1 + R/h_{ie}} \tag{5-32}$$

The resonant frequency at which oscillations will occur is found from Eq. (5-30) to be

$$\omega_o = \frac{1}{\sqrt{L[C_1' C_2/(C_1' + C_2)]}} \tag{5-33}$$

and for oscillations to occur $R_e(h_{ie}) = R_e(Z_{11})$ must be less than or equal to

$$R_e(h_{ie}) \leq \frac{1+\beta}{\omega_o^2 C_1 C_2} - \frac{L}{C_1} \tag{5-34}$$

If R becomes too large, Eq. (5-32) cannot be satisfied and oscillations will stop. In general, it is advantageous to have

$$X_{C_1} X_{C_2} = \frac{1}{\omega^2 C_1 C_2} \tag{5-35}$$

with $X \triangleq 1/\omega c$ as large as possible, since R can be large. However, if C_1 and C_2 are too small (large and X_{C_1} and X_{C_2}), the input and output capacitances of the transistor, which shunt C_1 and C_2, respectively, become important. A good, stable design will always have C_1 and C_2 much larger than the transistor capacitances they shunt.

Example 2. In Example 1, will the circuit still oscillate if the inductor now has a $Q_u = 100$? If the transistor input capacitance is 5 pF, what effect will this have on the system?

Solution: In Example 1, $X_L = 17\ \Omega$, $C_1 = 50$ pF, and $C_2 = 500$ pF. Since $C_1 = 50$ pF, adding 5 pF in parallel will change the equivalent C to 55 pF. As the inductor $Q_u = 100$, the equivalent resistance R in series with the lossless inductor is

$$R = \frac{17}{100} = 0.17\ \Omega$$

The new resonant frequency can be determined from Eqs. (5-32) and (5-33):

$$C_1' = \frac{C_1}{1 + R/h_{ie}} = \frac{55}{1 + (0.17/280)} \approx \frac{55}{1.0006} = 54.96 \text{ pF}$$

and

$$f_o = \frac{1}{2\pi L[C_1' C_2/(C_1' + C_2)]^{1/2}} \cong 191.56 \text{ MHz}$$

The effect of the finite inductor Q causes a negligible change in the oscillating frequency compared to the effect of the transistor input capacitance, which reduces the resonant frequency 4.2%. Because the large-signal beta, β_{OSC}, is 10, there is enough loop gain to maintain oscillation.

Two-Port Oscillator. Although Eqs. (5-25) and (5-26) can be used to determine the exact expressions for oscillation, they are often difficult to use and add little insight into the design process. An alternative interpretation, although not as accurate, will now be presented. It is based on the fact that an ideal tuned circuit (infinite Q), once excited, will oscillate infinitely because there is no resistance element present to dissipate the energy. In the actual case where the inductor Q is finite, the oscillations die out because energy is dissipated in the resistance. It is the function of the amplifier to maintain oscillations by supplying an amount of energy equal to that dissipated. This source of energy can be interpreted as a negative resistor in series with the tuned circuit. If the total resistance is positive, the oscillations will die out, while the oscillation amplitude will increase if the total resistance is negative. To maintain oscillations, the two resistors must be of equal magnitude. To see how a negative resistance is realized, the input impedance of the circuit in Figure 5-13 will be derived.

If h_{oe} is sufficiently small ($h_{oe} << 1/R_L$), the equivalent circuit is as shown in Figure 5-13. The steady-state loop equations are

$$V_{\text{in}} = I_{\text{in}}(X_{C_1} + X_{C_2}) - I_b(X_{C_1} - \beta X_{C_2}) \tag{5-36}$$

$$0 = -I_{\text{in}}(X_{C_1}) + I_b(X_{C_1} + h_{ie}) \tag{5-37}$$

After I_b is eliminated from these two equations, Z_{in} is obtained as

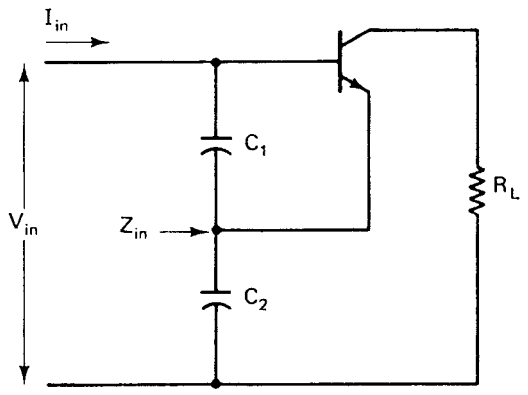

Figure 5-13 Calculation of input impedance of the negative-resistance oscillator.

$$Z_{\text{in}} = \frac{V_{\text{in}}}{I_{\text{in}}} = \frac{(1+\beta)X_{C_1}X_{C_2} + h_{ie}(X_{C_1} + X_{C_2})}{X_{C_1} + h_{ie}} \tag{5-38}$$

If $X_{C_1} << h_{ie}$, the input impedance is approximately equal to

$$Z_{\text{in}} \approx \frac{1+\beta}{h_{ie}} X_{C_1}X_{C_2} + (X_{C_1} + X_{C_2}) \tag{5-39}$$

$$Z_{\text{in}} \approx \frac{-g_m}{\omega^2 C_1 C_2} + \frac{1}{j\omega[C_1C_2/(C_1 + C_2)]} \tag{5-40}$$

That is, the input impedance of the circuit shown in Figure 5-14 is a negative resistor,

$$R = \frac{-g_m}{\omega^2 C_1 C_2} \tag{5-41}$$

in series with a capacitor,

$$C_{\text{in}} = \frac{C_1 C_2}{C_1 + C_2} \tag{5-42}$$

which is the series combination of the two capacitors.

With an inductor L (with the series resistance R_S) connected across the input, it is clear that the condition for sustained oscillation is

$$R_S = \frac{g_m}{\omega^2 C_1 C_2} \tag{5-43}$$

and the frequency of oscillation is

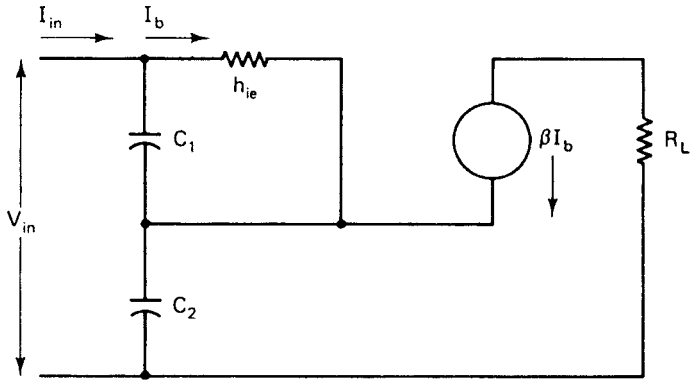

Figure 5-14 Equivalent small-signal circuit of Figure 5-13.

$$f_o = \frac{1}{2\pi\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{5-44}$$

This interpretation of the oscillator readily provides several guidelines that can be used in the design. First, C_1 should be as large as possible so that

$$X_{C_1} << h_{ie} \tag{5-45}$$

and C_2 is to be large so that

$$X_{C_2} << \frac{1}{h_{oe}} \tag{5-46}$$

When these two capacitors are large, the transistor base-to-emitter and collector-to-emitter capacitances will have a negligible effect on the circuit's performance. However, Eq. (5-43) limits the maximum value of the capacitances since

$$r \leq \frac{g_m}{\omega^2 C_1 C_2} \leq \frac{G}{\omega^2 C_1 C_2} \tag{5-47}$$

where G is the maximum value of g_m. For a given product of C_1 and C_2, the series capacitance is at maximum when $C_1 = C_2 = C_m$. Thus Eq. (5-47) can be written

$$\frac{1}{\omega C_m} > \sqrt{\frac{r}{G}} \tag{5-48}$$

This equation is important in that it shows that for oscillations to be maintained, the minimum permissible reactance $1/\omega C_m$ is a function of the resistance of the inductor and the transistor's mutual conductance, g_m.

An oscillator circuit known as the *Clapp circuit* or *Clapp–Gouriet circuit* is shown in Figure 5-15. This oscillator is equivalent to the one just discussed, but it has the practical advantage of being able to provide another degree of design freedom by making C_o much smaller than C_1 and C_2.

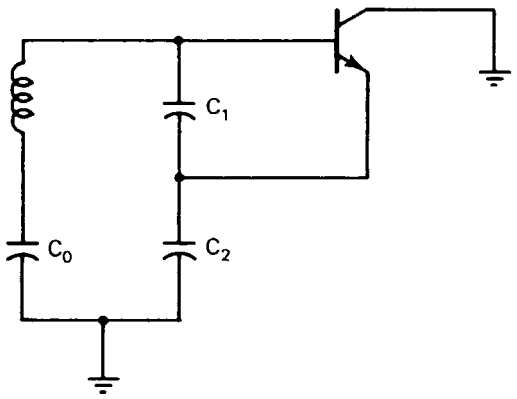

Figure 5-15 Circuit of a Clapp oscillator.

It is possible to use C_1 and C_2 to satisfy the condition of Eq. (5-47) and then adjust C_o for the desired frequency of oscillation ω_o, which is determined from

$$\omega_o L - \frac{1}{\omega_o C_o} - \frac{1}{\omega_o C_1} - \frac{1}{\omega_o C_2} = 0 \tag{5-49}$$

Amplitude Stability. Linearized analysis of the oscillator is convenient for determining the frequency but not the amplitude of the oscillation. The Nyquist stability criterion defines the frequency of oscillation as the frequency at which the loop phase shift is 360°, but it says nothing about the oscillation amplitude. If no provisions are taken to control the amplitude, it is susceptible to appreciable drift. Two frequently used methods for controlling the amplitude are operating the transistor in the nonlinear region or using a second stage for amplitude limiting. For the single-stage oscillator, amplitude limiting is accomplished by designing an unstable oscillator; that is, the loop gain is made greater than 1 at the frequency at which the phase shift is 180°. As the amplitude increases, the β of the transistor decreases, causing the loop gain to decrease until the amplitude stabilizes. This is a self-limiting oscillator. There are nonlinear analysis techniques predicting the amplitude of oscillation, but their results are approximate except in idealized cases, forcing the designer to resort to an empirical approach.

An example of a two-stage emitter-coupled oscillator is shown in Figure 5-16. In this circuit, amplitude stabilization occurs as a result of current limiting in the second stage. This circuit has the additional advantage that it has output terminals that are isolated from the feedback path. The emitter signal of Q_2, having a rich harmonic content, is normally used as output. Harmonics of the fundamental frequency can be extracted at the emitter of Q_2 by using an appropriately tuned circuit. Note that the collector of Q_2 is isolated from the feedback path.

Phase Stability. An oscillator has a frequency or phase stability that can be considered in two separate parts. First, there is *long-term* stability, in which the frequency changes over a period of minutes, hours, days, weeks, or even years. This frequency stability is normally limited by the circuit components' temperature coefficients and aging rates. The other part,

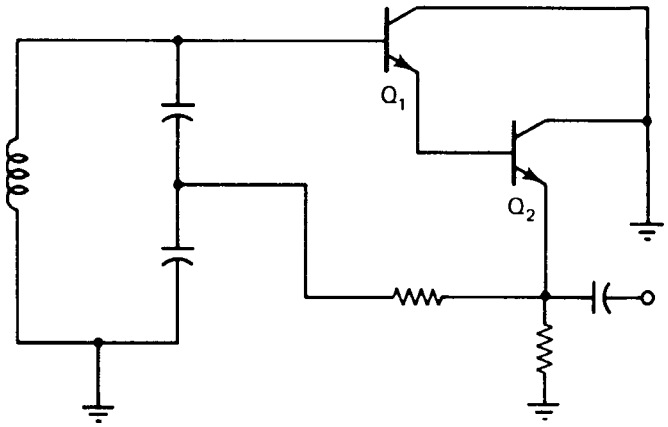

Figure 5-16 Two-stage, emitter-coupled oscillator.

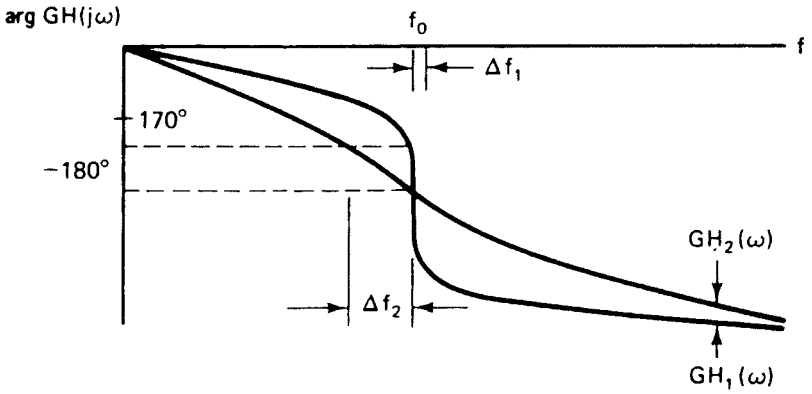

Figure 5-17 Phase plot of two open-loop systems with different resonator *Q* values.

short-term frequency stability, is measured in terms of seconds. One form of short-term instability is due to changes in phase of the system; here the term *phase stability* is used synonymously with frequency stability. It refers to how the frequency of oscillation reacts to small changes in phase shift of the open-loop system. It can be assumed that the system with the largest rate of change of phase versus frequency $d\phi/df$ will be the most stable in terms of frequency stability. Figure 5-17 shows the phase plots of two open-loop systems used in oscillators. At the system crossover frequency, the phase shift is −180°. If some external influence causes a shift in phase—say, it adds 10° of phase lag—the frequency will change until the total phase shift is again 0°. In this case, the frequency will decrease to the point where the open-loop phase shift is 170°. Figure 5-17 shows that Δf_2, the change in frequency associated with the 10° change in phase of GH_2, is greater than the change in frequency Δf_1, associated with the open-loop system GH_1, whose phase is changing more rapidly near the open-loop crossover frequency.

This qualitative discussion illustrates that $d\phi/df$ at $f = f_o$ is a measure of an oscillator's phase stability. It provides a good means of quantitatively comparing the phase stability of two oscillators. Consider the simple parallel tuned circuit shown in Figure 5-18.

For this circuit, the two-port is

$$\frac{V_o(j\omega)}{I(j\omega)} = \frac{R}{1 + jQ[(\omega/\omega_o) - (\omega_o/\omega)]} \tag{5-50}$$

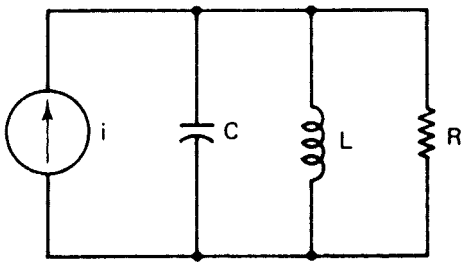

Figure 5-18 Parallel tuned circuit for phase-shift analysis.

where

$$\omega_o = \frac{1}{\sqrt{LC}} \quad \text{and} \quad Q = \frac{R}{\omega_o L} \tag{5-51}$$

The circuit phase shift is

$$\arg \frac{V_o}{I} = \theta = \tan^{-1} Q\left(\frac{\omega}{\omega_o} - \frac{\omega_o}{\omega}\right) \tag{5-52}$$

and

$$\frac{d\theta}{d\omega} = \frac{1/Q}{1/Q^2 + [(\omega^2 - \omega_o^2)/\omega_o\omega]^2} \frac{\omega^2 + \omega_o^2}{(\omega_o\omega)^2} \tag{5-53}$$

At the resonant frequency ω_o,

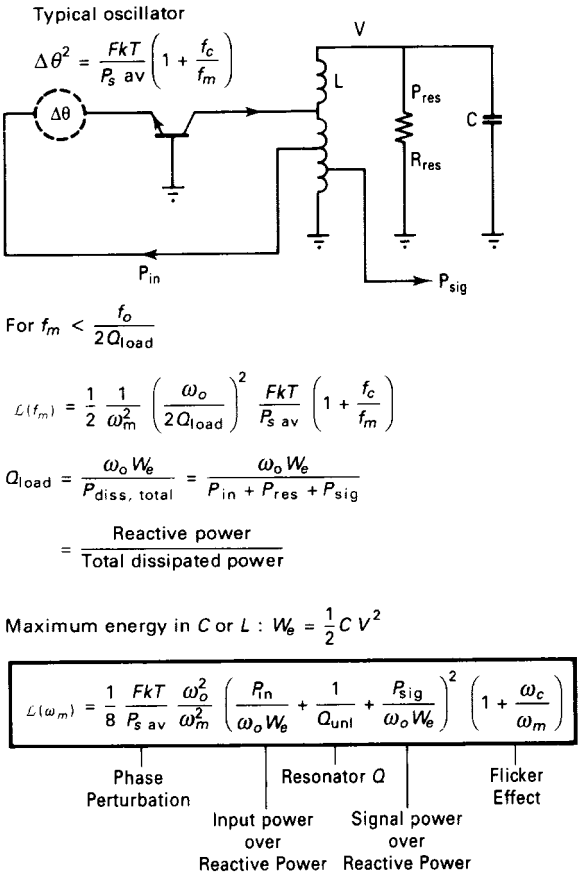

Figure 5-19 Diagram for a feedback oscillator illustrating the principles involved, and showing the key components considered in the phase noise calculation and its contribution.

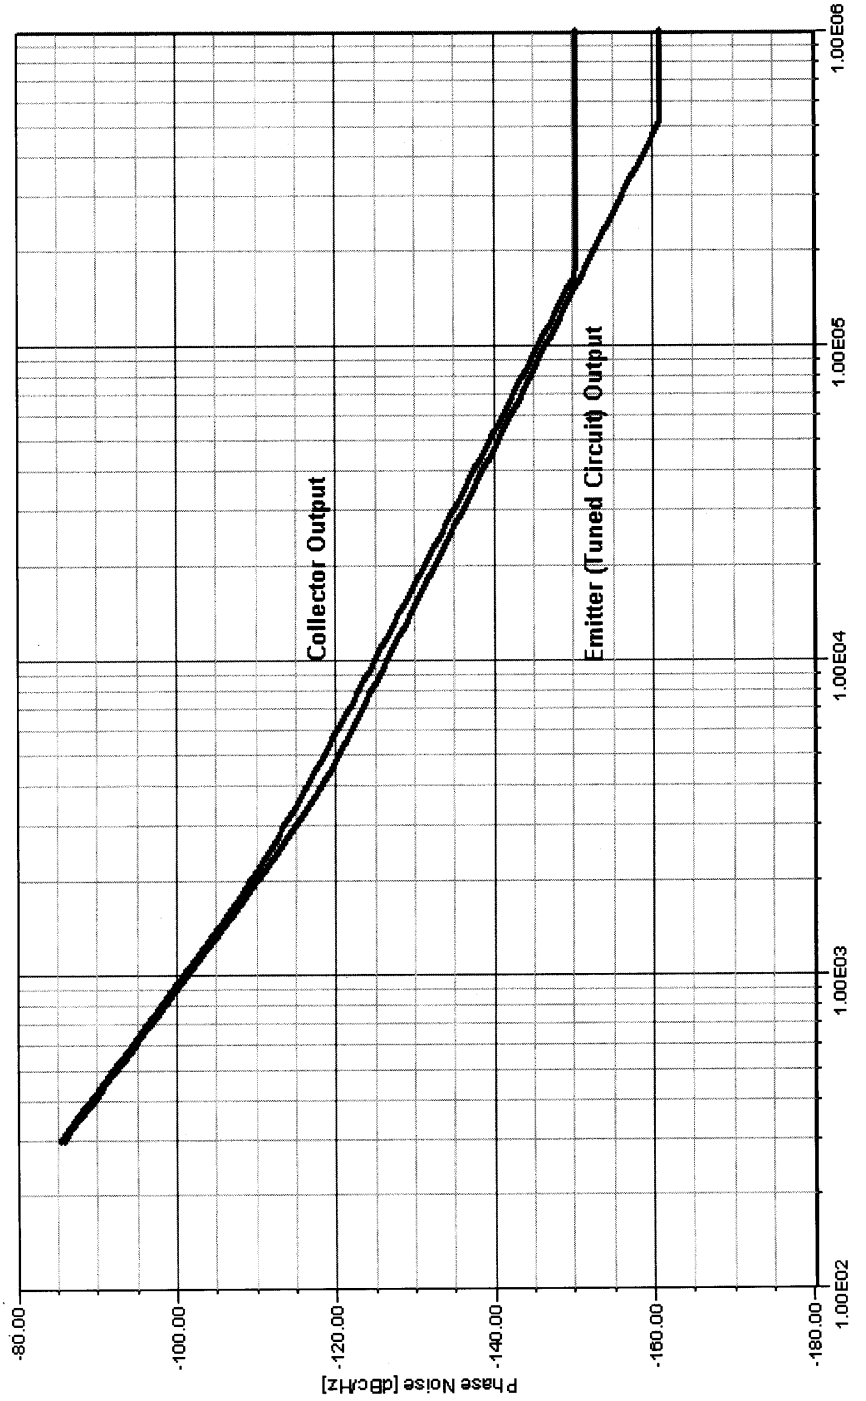

Figure 5-20 Phase noise with oscillator output taken from collector (upper trace) versus emitter (lower trace) of a BJT oscillator.

$$\left.\frac{dQ}{d\omega}\right|_{\omega=\omega_o} = \frac{2Q}{\omega_o} \tag{5-54}$$

The frequency stability factor S_F is defined as the change in phase $d\phi/d\omega$ divided by the normalized change in frequency $\Delta\omega/\omega_o$. That is,

$$S_F = 2Q \tag{5-55}$$

S_F is a measure of the short-term stability of an oscillator. Equation (5-54) indicates that the higher the circuit Q, the higher the stability factor. This is one reason for using high-Q circuits in oscillator circuits. Another reason is the ability of the tuned circuit to filter out undesired harmonics and noise.

The two oscillator types shown so far can be considered two-port oscillators because one port is responsible for oscillation and the other port supplies the output power. This type of output supposedly has better isolation (although this is not true at higher frequencies) but has a higher noise floor. A better way of extracting energy is shown in Figure 5-19.

These types of oscillators are essentially what is referred to as *two-port* oscillators. The name comes from the fact that the oscillating device has two ports, with the output energy taken from the output port, typically the collector or drain, while the tuned circuit is at the input port. For years, it was widely held that this type of design provided better isolation between the tuned circuit and termination; unfortunately, because of the Miller effect, this is not true. At the higher frequencies, changes in output-port loading affect the input port, resulting in *pulling*, a detuning effect that increases with frequency. In addition, taking the output from the collector or the drain results in a poorer signal-to-noise ratio than that achievable by extracting energy from the tuned circuit itself. The only real advantages the collector output provides are more power and higher efficiency, but definitely at the expense of phase noise, which is often referred to as *SSB phase noise* because it is expressed in terms of the decibel ratio of the noise power in a single (the upper or lower) noise sideband, in a 1-Hz bandwidth centered at a specified frequency offset from the oscillator carrier, to the carrier power. Figure 5-20 compares the phase noise of an oscillator with the energy taken off the collector and the tuned circuit; the difference is highly visible.

5-4 OSCILLATOR CIRCUITS

5-4-1 Hartley

Figure 5-21 shows the Hartley oscillator configuration, in which feedback is obtained by tapping the resonator. In practice, the resonator can consist of a single tapped inductor or two separate, magnetically uncoupled inductors, with feedback obtained at their junction.

5-4-2 Colpitts

Figure 5-22 shows the Colpitts oscillator configuration, in which feedback is obtained via a capacitive voltage divider.

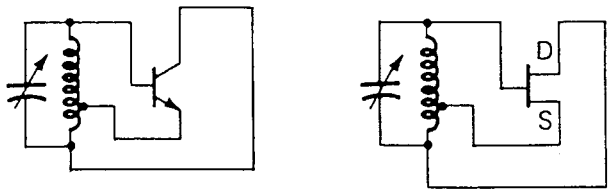

Figure 5-21 Hartley oscillator.

5-4-3 Clapp–Gouriet

Figure 5-23 shows the Clapp–Gouriet oscillator. Like the Colpitts, the Clapp–Gouriet obtains its feedback via a capacitive voltage divider; unlike the Colpitts, an additional capacitor series-tunes the resonator. The Pierce oscillator, a configuration used only with crystals, is a rotation of the Clapp–Gouriet oscillator in which the emitter is at RF ground.

5-5 DESIGN OF RF OSCILLATORS

5-5-1 General Thoughts on Transistor Oscillators

An estimate of the noise performance of an oscillator is

$$\mathcal{L}(\omega_m) = \frac{1}{8}\frac{FkT}{P_{s,\text{av}}}\frac{\omega_0^2}{\omega_m^2}\left(\frac{P_{\text{in}}}{\omega_0 W_e} + \frac{1}{Q_{\text{unl}}} + \frac{P_{\text{sig}}}{\omega_0 W_e}\right)^2\left(1 + \frac{\omega_c}{\omega_m}\right) \tag{5-56}$$

Phase perturbation

Resonator Q

Flicker effect

Input power/Reactive power ratio

Signal power/Reactive power ratio

We just state this here without presenting oscillator noise theory itself. (Also see Figure 5-19.) This equation is based on work done by Dieter Scherer of Hewlett-Packard about 1978. He was the first to introduce the flicker effect to the Leeson equation by adding the AM-to-PM

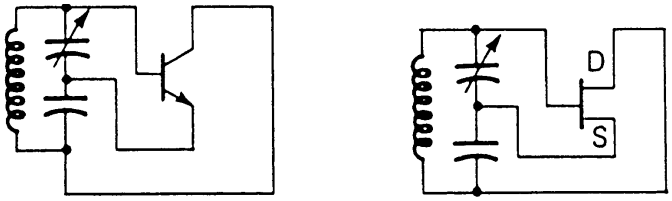

Figure 5-22 Colpitts oscillator.

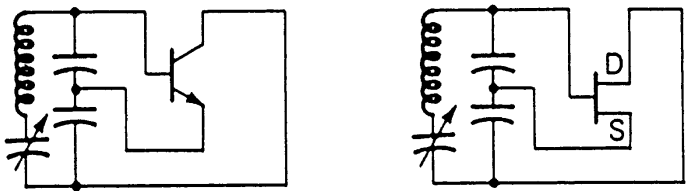

Figure 5-23 Clapp–Gouriet oscillator.

conversion effect, which is caused by the nonlinear capacitance of the active devices. This equation must be further expanded:

$$\pounds(f_m) = 10 \log\left\{\left[1 + \frac{f_0^2}{(2f_m Q_{\text{load}})^2}\right]\left(1 + \frac{f_c}{f_m}\right)\frac{FkT}{2P_{\text{sav}}} + \frac{2kTRK_0^2}{f_m^2}\right\} \tag{5-57}$$

where $\pounds(f_m)$ = ratio of sideband power in 1-Hz bandwidth at f_m to total power in dB
f_m = frequency offset
f_0 = center frequency
f_c = flicker frequency
Q_{load} = loaded Q of the tuned circuit
F = noise factor
$kT = 4.1 \times 10^{-21}$ at 300 K (room temperature)
P_{sav} = average power at oscillator output
R = equivalent noise resistance of tuning diode (typically 200 Ω to 10 kΩ)
K = oscillator voltage gain

The following table (from Motorola) shows the flicker corner frequency f_C as a function if I_C for a typical small-signal microwave BJT. $I_{C(\text{max})}$ of this transistor is about 10 mA.

I_C (mA)	f_C (kHz)
0.25	1
0.5	2.74
1	4.3
2	6.27
5	9.3

Note that f_C, which is defined by AF and KF in the SPICE model, increases with I_C. This gives us a clue about how f_C changes when a transistor oscillates. As a result of the bias-point shift that occurs during oscillation (see Example 1 of Section 5-3-1), an oscillating BJT's average I_C is higher than its small-signal I_C. KF is therefore higher for a given BJT operating as an oscillator than for the same transistor operating as a small-signal amplifier. This must be kept in mind when considering published f_C data, which are usually determined under small-signal conditions without being qualified as such. Determining a transistor's oscillating f_C is best done through measurement: Operate the device as a high-Q UHF oscillator (we

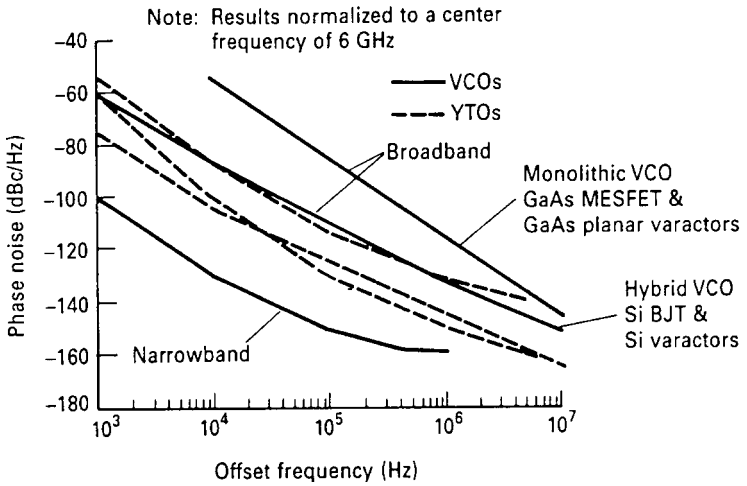

Figure 5-24 Phase noise of oscillators using different semiconductors and resonators.

suggest using a ceramic-resonator-based tank in the vicinity of 1 GHz), and measure its close-in (10 Hz to 10 kHz) phase noise versus offset from the carrier. f_C will correspond to a slight decrease in the slope of the phase noise versus offset curve. Generally, f_C varies with device type as follows: silicon JFETs, 50 Hz and higher; microwave RF BJTs, 1–10 kHz (as above); MOSFETs, 10–100 kHz; and GaAsFETs, 10–100 MHz. Figure 5-24 shows the phase noise of oscillators using different semiconductors and resonators.

Equation (5-57) is based on Rohde et al. [2]. The additional term introduces a distinction between a conventional oscillator and a VCO. Whether the voltage- or current-dependent capacitance is internal or external makes no difference; it simply affects the frequency.

For a more complete expression for a resonator oscillator's phase noise spectrum we can write

$$s_\phi(f_m) = \frac{\alpha_R F_0^4 + \alpha_E (F_0/2Q_L)^2}{f_m^3} + \frac{(2GFkT/P_0)\,(F_0/2Q_L)^2}{f_m^2} + \frac{2\alpha_R Q_L F_0^3}{f_m^2} + \frac{\alpha_E}{f_m} + \frac{2GFkT}{P_0} \tag{5-58}$$

where G = compressed power gain of the loop amplifier
F = noise factor of the loop amplifier
k = Boltzmann's constant
T = temperature in kelvins

P_0 = carrier power level (in watts) at the output of the loop amplifier
F_0 = carrier frequency in hertz
f_m = carrier offset frequency in hertz
$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop
α_R, α_E = flicker-noise constants for the resonator and loop amplifier, respectively.

In frequency synthesizers, we have no use for *LC* oscillators that do not include a tuning diode or diodes, but it may still be of interest to analyze the low-noise, fixed-tuned *LC* oscillator first and later make both elements, inductor and capacitor, variable.

Later, we will show the performance changes if we utilize the two possible ways of getting coarse and fine tuning in oscillators:

1. Use of tuning diodes.
2. Use of switching diodes.

We will spend some time looking at the effects that switching and tuning diodes have in a circuit because they will ultimately influence the noise performance more strongly than the transistor itself.

The reason is that the noise generated in tuning diodes will be superimposed on the noise generated in the circuit, while switching diodes have losses that cause a reduction of circuit *Q*. The selection of the proper tuning and switching diodes is important, as is the proper way of connecting them. As both types are modifications of the basic *LC* oscillator, we start with the *LC* oscillator itself.

Early signal generators as were offered by several companies (namely, Rohde & Schwarz, Hewlett-Packard, Boonton Electronics, or Marconi), if they are not synthesized, use an air-dielectric variable capacitor or, as in the case of one particular Hewlett-Packard generator, the Model HP8640, a tuned cavity.

Tuning here is accomplished by changing the value of an air-dielectric variable capacitor or changing the mechanical length of a quarter-wave resonator.

Using the equations shown previously, it is fairly easy to calculate the performance of oscillators and understand how they work, but this does not necessarily optimize their design. For *LC* oscillator applications in which noise performance is crucial, the oscillator shown in Figure 5-25, used in the famous Rohde & Schwarz SMDU, is the state of the art. Its noise performance is equivalent to the noise found in the cavity-tuned oscillator used in Hewlett-Packard's popular HP8640 signal generator, and because of the unique way a tuning diode is coupled to the circuit, its modulation capabilities are substantially superior to any of the signal generators currently offered. To develop such a circuit from design equations is not possible. This circuit is the result of many years of experience and research and looks fairly simple. The grounded-gate FET circuit provides the best performance because it fulfills the important requirements of Eq. (5-56).

The tuned circuit is not connected directly to the drain, but the drain is put on a tap of the oscillator section. Therefore, the actual voltage across the tuning capacitor is higher than the supply voltage, and thus the energy stored in the capacitor is much higher than in a circuit connected between the gate electrode and ground, as it is in a normal Colpitts oscillator. In addition, the high output impedance of the FET does not load the circuit, which also provides a reduced noise contribution. Since this oscillator is optimized for best frequency-modulation

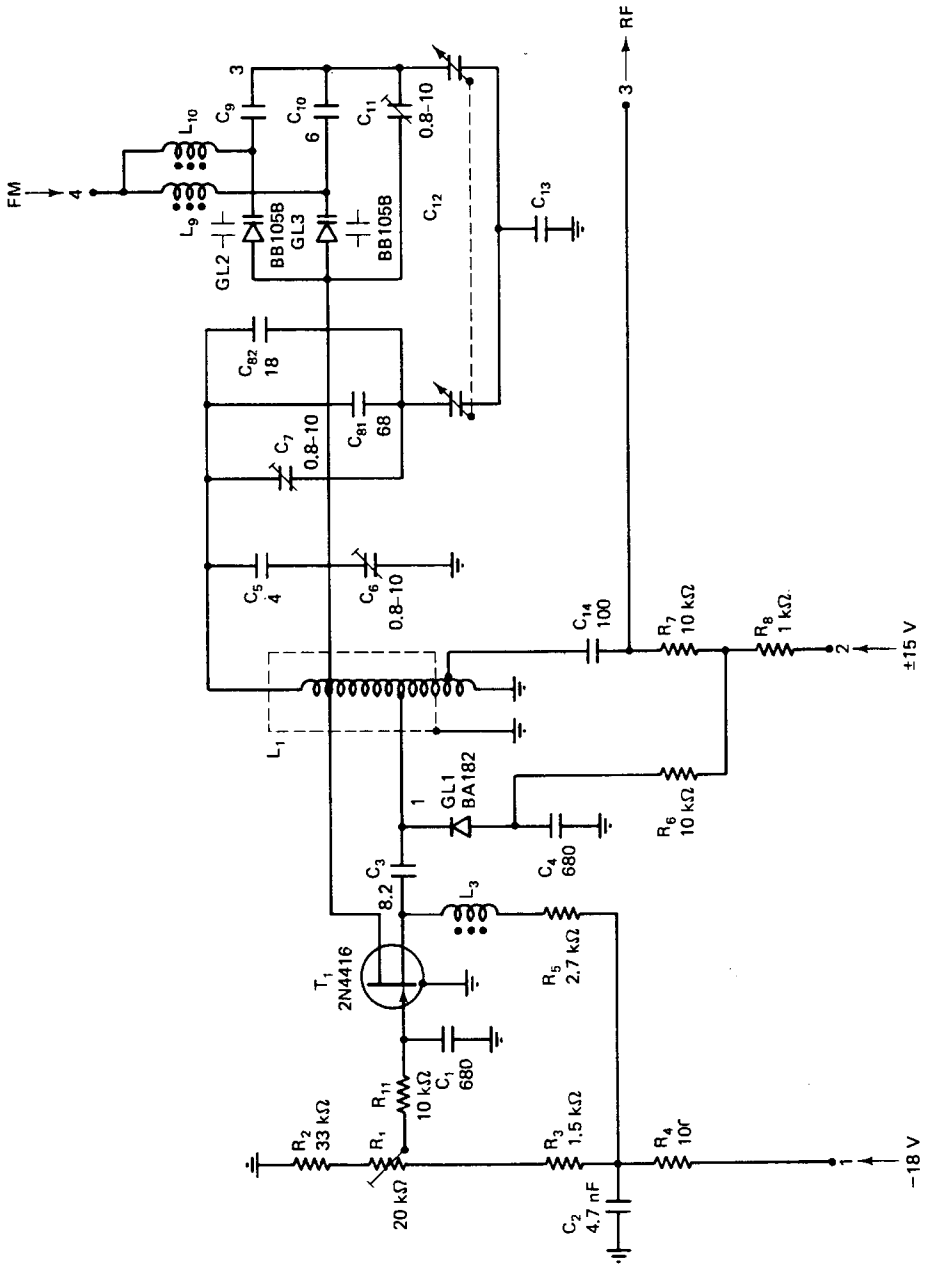

Figure 5-25 A 118–198-MHz oscillator from the Rohde & Schwarz SMDU signal generator.

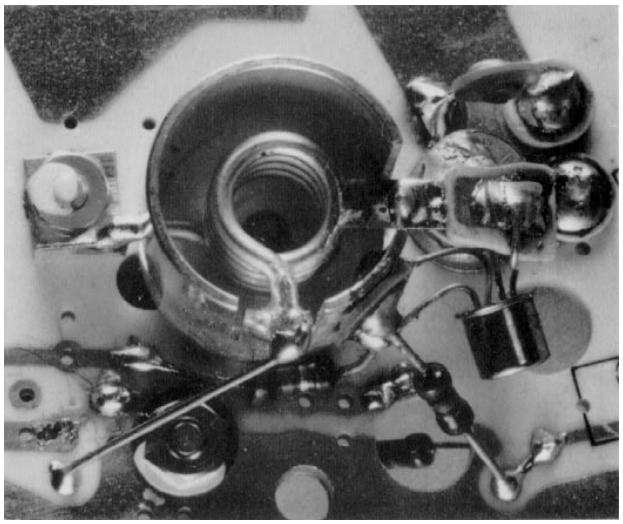

Figure 5-26 Photograph of the helical-resonator system from the Rohde & Schwarz SMDU signal generator.

performance in the FM frequency range, it becomes apparent that it fits the requirements of low-distortion stereo modulation.

For extremely critical blocking measurements in the 2-m region (140–160 MHz), the noise specification at 20 kHz off the carrier is of high importance, while the peak modulation typically does not exceed 5 kHz. Figure 5-25 shows the schematic of the oscillator section optimized for this frequency range.

Because of f_T limitations, it has been found experimentally that these *LC* oscillators, if based on silicon JFETs, should not be used above about 500 MHz; rather, a doubler stage should be employed. Analyzing the signal generators currently on the market, we find that their highest base band typically ranges from 200 to 500 MHz, with frequency doubling used to 1000 MHz. As can be seen in Figure 5-26, the mechanical layout of such an oscillator is extremely compact.

5-5-2 Two-Port Microwave/RF Oscillator Design

A common method for designing oscillators is to resonate the input port with a passive high-*Q* circuit at the desired frequency of resonance. It will be shown that if this is achieved with a load connected on the output port, the transistor is oscillating at both ports and is thus delivering power to the load port. The oscillator may be considered a two-port structure, with M_3 being the lossless resonating port and M_4 providing lossless matching such that all the external RF power is delivered to the load. See Figure 5-27. The resonating network has been described. Nominally, only parasitic resistance is present at the resonating port, since a high-*Q* resonance is desirable for minimizing oscillator noise. It is possible to have loads at both the input and output ports if such an application occurs, since the oscillator is oscillating at both ports simultaneously.

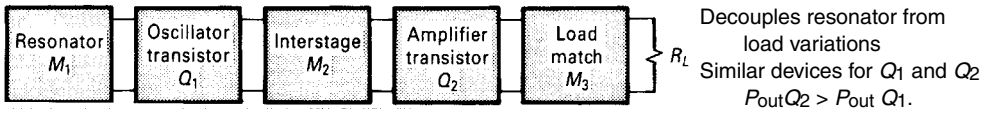

Figure 5-27 Buffered oscillator design.

The simultaneous oscillation condition is proved as follows. Assume that the oscillation condition is satisfied at port 1:

$$1/S'_{11} = \Gamma_G \tag{5-59}$$

Thus,

$$S'_{11} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} = \frac{S_{11} - D\Gamma_L}{1 - S_{22}\Gamma_L} \tag{5-60}$$

$$\frac{1}{S'_{11}} = \frac{1 - S_{22}\Gamma_L}{S_{11} - D\Gamma_L} = \Gamma_G \tag{5-61}$$

By expanding Eq. (5-61), we find

$$\begin{gathered} \Gamma_G S_{11} - D\Gamma_L\Gamma_G = 1 - S_{22}\Gamma_L \\ \Gamma_L(S_{22} - D\Gamma_G) = 1 - S_{11}\Gamma_G \\ \Gamma_L = \frac{1 - S_{11}\Gamma_G}{S_{22} - D\Gamma_G} \end{gathered} \tag{5-62}$$

Thus,

$$S'_{22} = S_{22} + \frac{S_{12}S_{21}\Gamma_G}{1 - S_{11}\Gamma_G} \tag{5-63}$$

$$\frac{1}{S'_{22}} = \frac{1 - S_{11}\Gamma_G}{S_{22} - D\Gamma_G} \tag{5-64}$$

Comparing Eqs. (5-62) and (5-64), we find

$$1/S'_{22} = \Gamma_L \tag{5-65}$$

which means that the oscillation condition is also satisfied at port 2; this completes the proof. Thus, if either port is oscillating, the other port must be oscillating as well. A load may appear at either or both ports, but normally the load is in Γ_L, the output termination. This result can be generalized to an n-port oscillator by showing that the oscillator is simultaneously oscillating at each port:

$$\Gamma_1 S'_{11} = \Gamma_2 S'_{22} = \Gamma_3 S'_{33} = \cdots = \Gamma_n S'_{nn} \tag{5-66}$$

Before concluding this section on two-port oscillator design, the buffered oscillator shown in Figure 5-27 must be considered. This design approach is used to provide the following:

1. A reduction in load-pulling, which is the change in oscillator frequency when the load reflection coefficient changes.
2. A load impedance that is more suitable to wideband applications ($k < 1$).
3. A higher output power from a working design, although the higher output power can also be achieved by using a larger oscillator transistor.
4. This type of oscillator is not optimized for low phase noise. However, buffered oscillator designs are quite common in wideband YIG applications, where changes in the load impedance must not change the generator frequency.

Two-port oscillator design may be summarized as follows:

1. Select a transistor with sufficient gain and output-power capability for the frequency of operation. This may be based on oscillator datasheets, amplifier performance, or *S*-parameter calculation.
2. Select a topology that gives $k < 1$ at the operating frequency. Add feedback if $k < 1$ has not been achieved.
3. Select an output load-matching circuit that gives $|S'_{11}| > 1$ over the desired frequency range. In the simplest case, this could be a 50-Ω load.
4. Resonate the input port with a lossless termination so that $\Gamma_G S'_{11} = 1$. The value of S'_{22} will be greater than unity with the input properly terminated.

In all cases, the transistor delivers power to a load and the input of the transistor. Practical considerations of realizability and dc biasing will determine the best design.

For both bipolar and FET oscillators, a common topology is the common-base or common-gate, since a common-lead inductance can be used to raise S_{22} to a large value, usually greater than unity even with a 50-Ω generator resistor. However, it is not necessary for the transistor S_{22} to be greater than unity, since the 50-Ω generator is not present in the oscillator design. The requirement for oscillation is $k < 1$; then resonating the input with a lossless termination will ensure that $|S'_{11}| > 1$.

A simple example will clarify the design procedure. A common-base bipolar transistor (HP2001) was selected to design a fixed-tuned oscillator at 2 GHz. The common-base *S*-parameters and stability factors are given in Table 5-1.

Using the load circuit in Figure 5-28, we see that the reflection coefficients are

Table 5-1 *S* parameters and stability factors (V_{CE} = 15 V, I_C = 25 mA)

$L_B = 0$	$L_B = 0.5$ nH
$S_{11} = 0.94 \angle 174°$	$1.04 \angle 173°$
$S_{21} = 1.90 \angle -28°$	$2.00 \angle -30°$
$S_{12} = 0.013 \angle 98°$	$0.043 \angle 153°$
$S_{22} = 1.01 \angle -17°$	$1.05 \angle -18°$
$k = -0.09$	-0.83

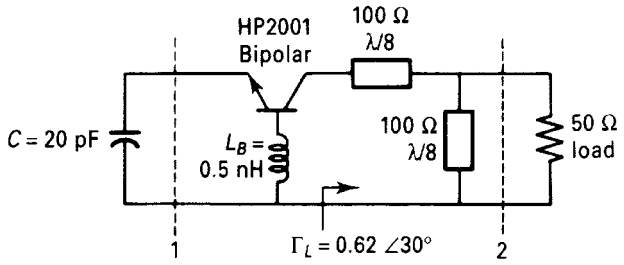

Figure 5-28 Oscillator example at 2 GHz.

$$\Gamma_L = 0.62\ \angle 30°$$

$$S'_{11} = 1.18\ \angle 173°$$

Thus, a resonating capacitance of G = 20 pF resonates the input port. In a YIG-tuned oscillator, this reactive element could be provided by the high-Q YIG element. For a dielectric-resonator oscillator (DRO), the puck would be placed to give $\Gamma_G \approx 1.0/\angle -173°$.

Another two-port design procedure is to resonate the Γ_G port and calculate S'_{22} until $|S'_{22}| > 1$, then design the load port to satisfy. This design procedure is summarized in Figure 5-29.

An example using this procedure at 4 GHz is given in Figure 5-30 using an AT41400 silicon bipolar chip in the common-base configuration with a convenient value of base and emitter

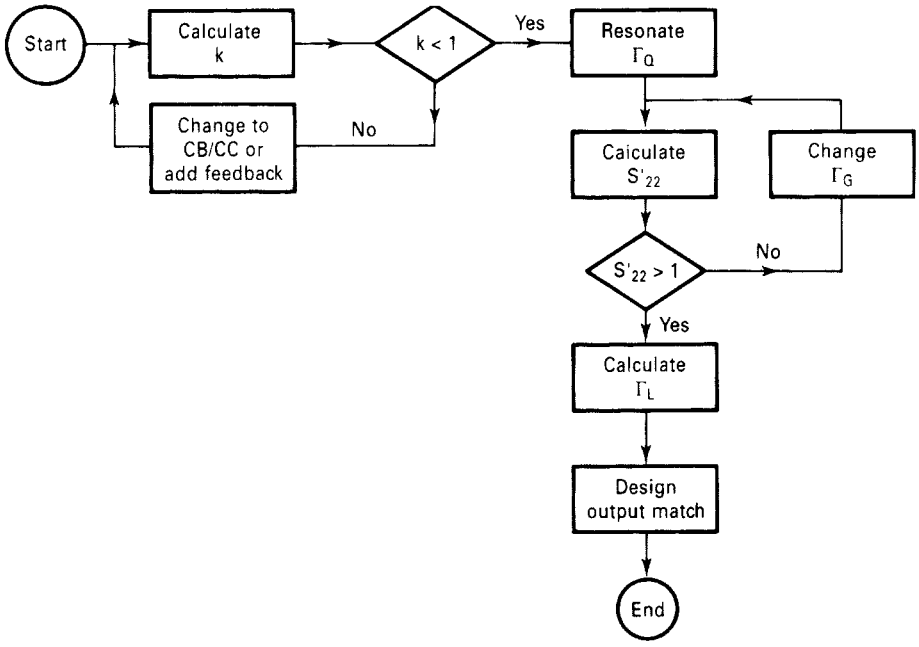

Figure 5-29 Oscillator design flowchart.

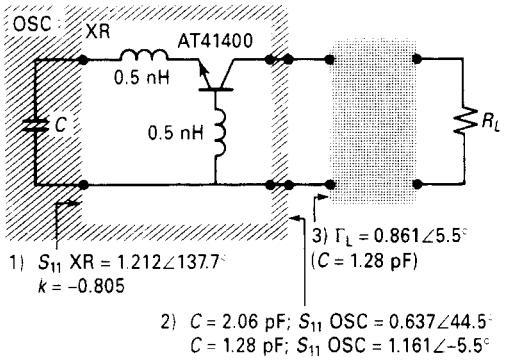

Figure 5-30 A 4-GHz lumped-resonator oscillator using the AT41400.

inductance of 0.5 nH. The feedback parameter is the base inductance, which can be varied if needed.

Since a lossless capacitor at 4 GHz of 2.06 pF gives $\Gamma_G = 1 - 0 \angle -137.7°$, this input termination is used to calculate S'_{22}, giving $S'_{22} = 0.637 \angle 44.5°$. This circuit will oscillate into any passive load. Varying the emitter capacitor about 20° on the Smith Chart to 1.28 pF gives $S'_{22} = 1.16 \angle -5.5°$, which will oscillate into a load of $\Gamma_L = 0.861 \angle 5.5°$. The completed lumped-element design is given in Figure 5-31.

5-5-3 Ceramic-Resonator Oscillators

An important application for a new class of resonators called ceramic resonators (CRs) has emerged for wireless applications. The CRs are similar to rigid coaxial cable, where the center conductor is connected at the end to the outside of the cable. These resonators are generally operating in quarter-wavelength mode and their characteristic impedance is approximately 10 Ω. Because their coaxial assemblies are made from a high-ε low-loss material with good silver plating throughout, the electromagnetic field is internally contained and therefore results in very little radiation. These resonators are therefore ideally suited for high-Q, high-density oscillators. The typical application for this resonator is VCOs ranging from not much more than 200 MHz up to about 3 or 4 GHz. At these high frequencies, the mechanical dimensions of the resonator become too tiny to offer any advantage. One of the

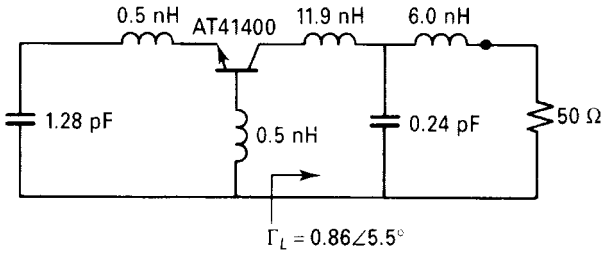

Figure 5-31 Completed lumped-resonator oscillator (LRO).

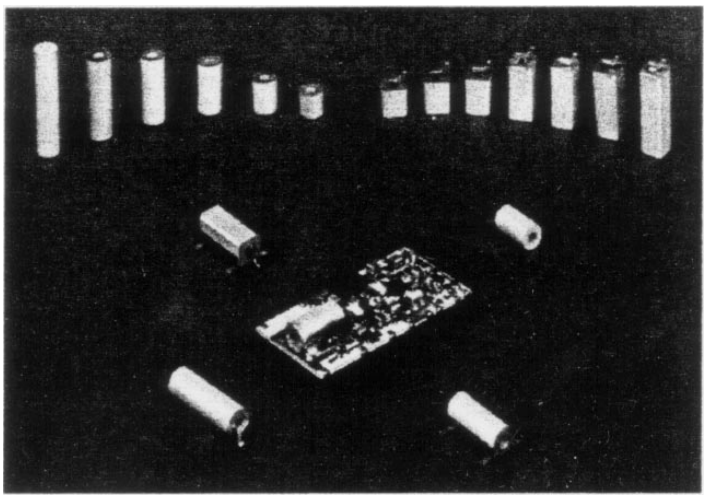

Figure 5-32 Ceramic resonators.

principal requirements is that the physical length is considerably larger than the diameter. If the frequency increases, this requirement can no longer be met.

Manufacturers supply ceramic resonators on a prefabricated basis. Figures 5-32 and 5-33 show the standard round/square packaging available and the typical dimensions for a ceramic resonator. Figure 5-34 shows a ceramic-resonator oscillator built on a ceramic substrate. The available material has a dielectric constant of 88 and is recommended for use in the 400–1500-MHz range. The next higher frequency range (800 MHz to 2.5 GHz) uses an ε of 38, while the top range (1–4.5 GHz) uses an ε of 21. Given the fact that ceramic resonators are prefabricated and have standard outside dimensions, the following quick calculation applies:

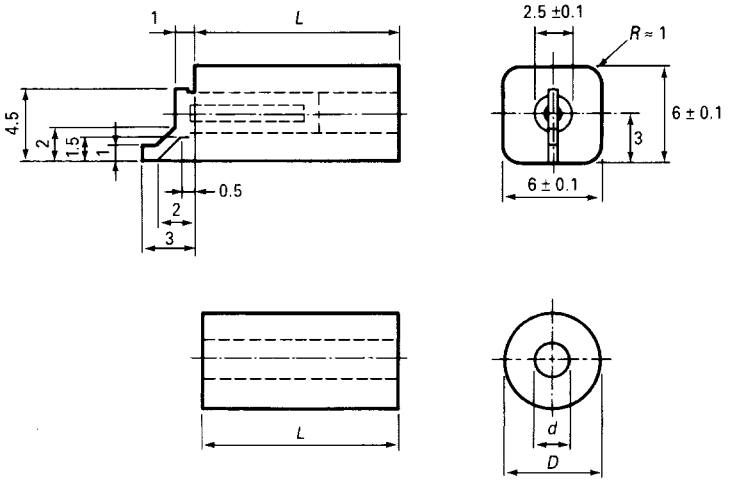

Figure 5-33 Standard round/square ceramic-resonator packaging and dimensions.

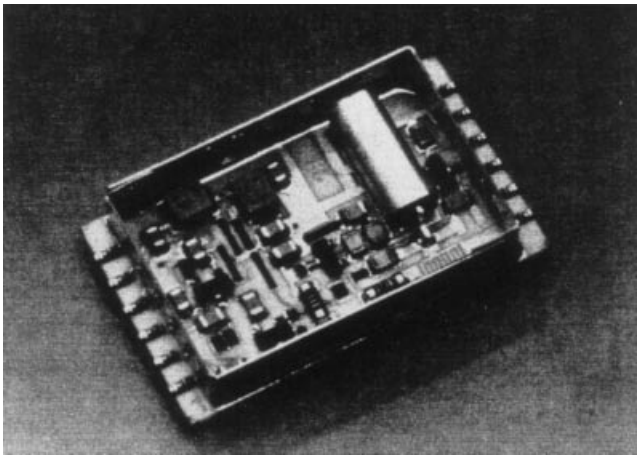

Figure 5-34 Modern ceramic-resonator oscillator for handheld cellular phones.

Relative dielectric constant of resonator material	$\varepsilon_r = 21$	$\varepsilon_r = 38$	$\varepsilon_r = 88$
Resonator length in millimeters	$l = \frac{16.6}{f}$	$l = \frac{12.6}{f}$	$l = \frac{8.2}{f}$
Temperature coefficient (ppm/°C)	10	6.5	8.5
Available temperature coefficients	–3 to +12	–3 to +12	–3 to +12
Typical resonator Q	800	500	400
Frequency range	1–4.5 GHz	800–2500 MHz	400–1500 MHz

Calculation of Equivalent Circuit. The equivalent parallel-resonant circuit afforded by a ceramic resonator has a resistance at resonance of

$$R_p = \frac{2(Z_0)^2}{R^* l} \tag{5-67}$$

where Z_0 = characteristic impedance of the resonator
l = mechanical length of the resonator
R^* = equivalent resistor due to metallization and other losses

As an example, one can calculate

$$C^* = \frac{2\pi\varepsilon_0\varepsilon_r}{\log_e(D/d)} = 55.61 \times 10^{-12}\,\frac{\varepsilon_r}{\log_e(D/d)} \tag{5-68}$$

and

$$L^* = \frac{\mu_r \mu_0}{2\pi} = \log_e\left(\frac{D}{d}\right) = 2 \times 10^{-7} \log_e\left(\frac{D}{d}\right) \tag{5-69}$$

$$Z_0 = 60\ \Omega \frac{1}{\sqrt{\varepsilon_r}} \log_e\left(\frac{D}{d}\right)$$

$$= 60 \frac{1}{\sqrt{88}} \log_e\left(\frac{6}{2.5}\right)$$

$$= 5.6\ \Omega \tag{5-70}$$

A practical example for $\varepsilon_r = 88$ and 450 MHz is

$$C_p = \frac{C^* l}{2} = 49.7\ \text{pF} \tag{5-71}$$

$$L_p = 8L^* l = 2.52\ \text{nH} \tag{5-72}$$

$$R_p = 2.5\ \text{k}\Omega \tag{5-73}$$

Figure 5-35 shows the schematic of a ceramic-resonator-based oscillator. Figures 5-36 and 5-37 show the simulated and measured phase noise of the oscillator.

By using ceramic-resonator-based oscillators in conjunction with miniature synthesizer chips, it is possible to build extremely small phase-locked-loop (PLL) systems for cellular telephone operation. Figure 5-38 shows one of the smallest currently available PLL-based synthesizers manufactured by Synergy Microwave Corporation. Because of the high-Q resonator, these types of oscillators exhibit extremely low phase noise. Values of better than –150 dBc/Hz at 1 MHz off the carrier are achievable. The ceramic resonator reduces the oscillator's sensitivity to microphonic effects and proximity effects caused by other components.

5-5-4 Using a Microstrip Inductor as the Oscillator Resonator*

A high-Q microstrip resonator [3–5] can be used to improve an oscillator's phase-noise performance. The following section, based on information in the Philips Semiconductors Application Note AN1777, describes the application of such a resonator in a BJT differential oscillator.

It can be seen from Eq. (5-56) that the phase noise is proportional to the term

$$\frac{1}{4Q_L^2} \tag{5-74}$$

This means that for any 10% increase in Q, we get something like 20% improvement in phase noise, which makes it most desirable to increase the Q. One way to reduce the loading of the

*Based on portions of the Philips Semiconductors/Signetics RF Communications Products Application Note AN1777, "Low-Voltage Front End Circuits: SA601, SA620," August 20, 1997. Used with permission.

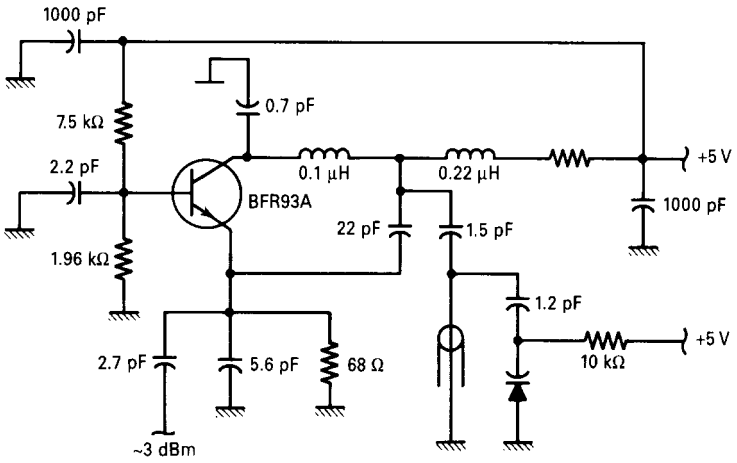

Figure 5-35 Schematic of a high-performance ceramic-resonator-based oscillator that can be used from 500 MHz to 2 GHz.

resonator is to tap the device down on the resonator. The underlying oscillator circuit is based on the differential type of oscillator found in ICs.

Increasing Loaded Q. Figure 5-39 shows the oscillator section of the Philips SA620 low-voltage front-end IC with a conventional second-order parallel-tuned tank circuit configured as the external resonator.

From the basic equations for parallel resonance, the resonator's loaded Q is given by

$$Q_L = R_P \left(\frac{C_T}{L_T} \right)^{1/2} \tag{5-75}$$

where

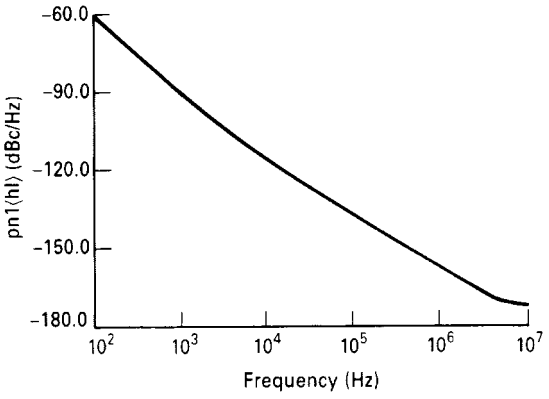

Figure 5-36 Simulated phase noise of an *npn* bipolar 1-GHz ceramic-resonator-based oscillator.

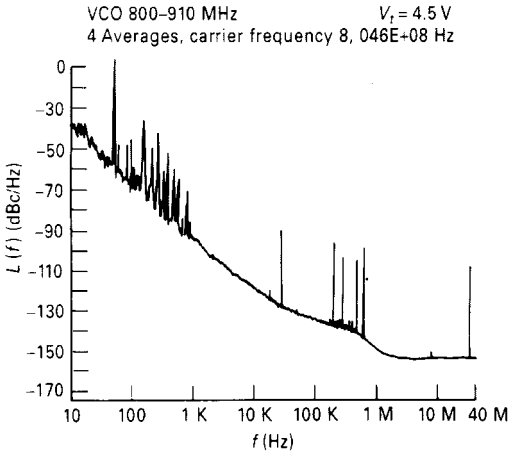

Figure 5-37 Measured phase noise of a ceramic-resonator-based oscillator.

$$R_P = R_T \| R_C = \left[\left(\frac{1}{R_T}\right) + \left(\frac{1}{R_C}\right)\right]^{-1} \tag{5-76}$$

represents the net shunt tank resistance appearing across the network at resonance. R_T represents losses in the inductance L_T and capacitance C_T (almost always dominated by inductor losses), and R_C is the active circuit's load impedance at resonance. Improving the quality of the tank components L_T and C_T (i.e., improving their Q) will increase R_T, but since R_C is low in the case of the SA620, the resulting increase in R_P is relatively small. We can

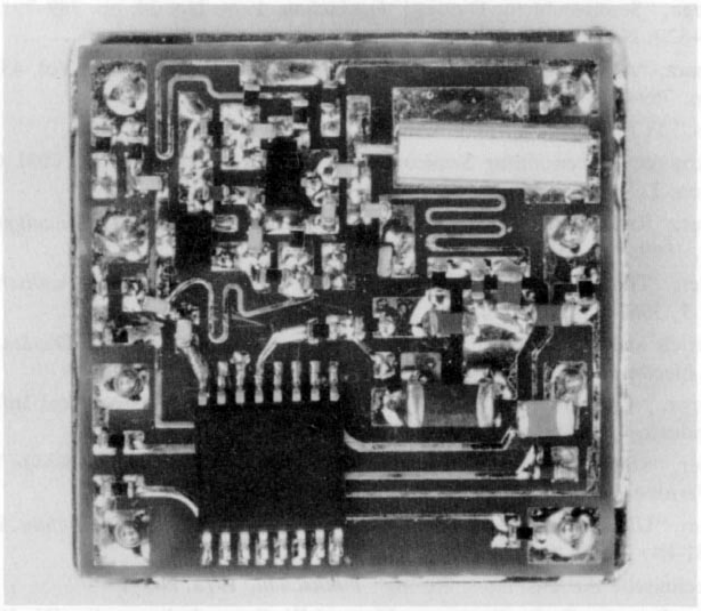

Figure 5-38 Miniature PLL-based synthesizer manufactured by Synergy Microwave Corporation.

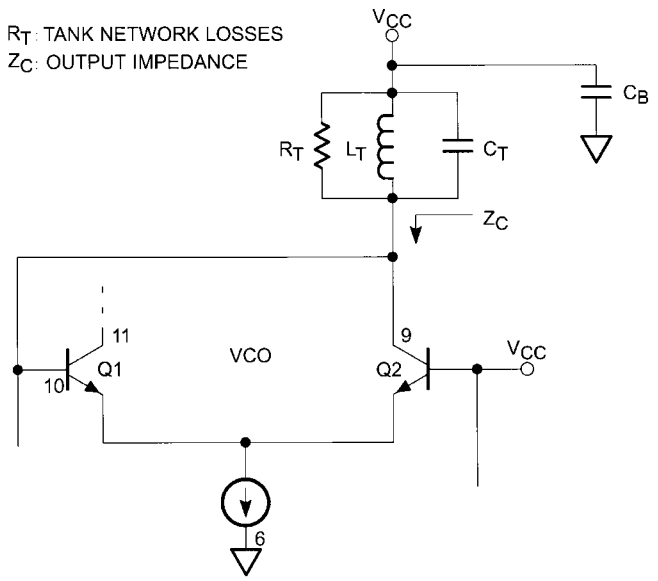

Figure 5-39 Oscillator portion of Philips SA620 front-end IC with external resonator.

increase R_P by decoupling Z_C from the tank circuit (note that R_C is the real part of Z_C at resonance). Decoupling this impedance by using either tapped-L or tapped-C tank configurations is possible. Inspection of the circuit shows that dc biasing is necessary for pins 9 and 10 (osc1 and osc2, respectively), so a tapped-C approach would require shunt-feeding these pins to V_{CC}. Thus, the most practical way is to employ a tapped-L network.

Figure 5-40 shows the basic tapped-L circuit. The effective multiplied shunt impedance at resonance across C_T is given by

$$\hat{R}_P = R_P\left[\left(\frac{L_{T2}}{L_{T1}}\right)+1\right]^{1/2} \tag{5-77}$$

with a corresponding increase in loaded Q:

$$Q_L = Q_L\left[\left(\frac{L_{T2}}{L_{T1}}\right)+1\right]^{1/2} \tag{5-78}$$

Feedback is caused by an RF voltage appearing across L_T, coupled through bypass capacitor C_B and its ground return to the cold end of the current source at pin 6. The significance of this path increases with frequency. At 900 MHz, it becomes very critical in obtaining stable oscillations and must be kept as short as possible. Attention to layout detail is pivotal here!

High-Q Microstrip Inductor. Realizing a stable tapped-L network using lumped surface-mount inductors is impractical due to their low unloaded Q and finite physical size. Another approach uses a high-Q short microstrip inductor. The conventional approach to microstrip resonators treats them as a length of transmission line terminated with a short that

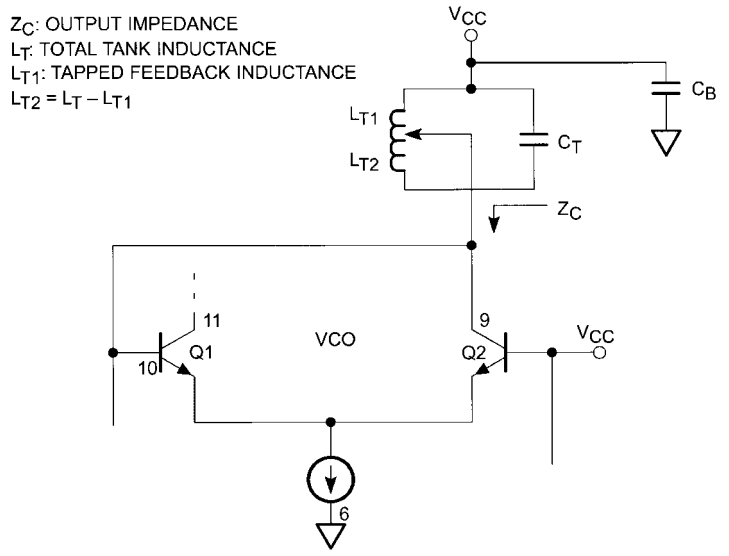

Figure 5-40 Oscillator portion of SA620 IC with tapped-microstrip resonator.

reflects back an inductance impedance that simulates a lumped inductor. The approach presented here deviates from this technique by specifically exploiting the very high unloaded Q attainable with short microstrip inductors, where we design for a large C/L ratio by making the microstrip a specific, but short, length. Resonance is achieved by replacing the short with whatever capacitance is needed for proper resonance. One equation for the inductance of a strip of metal having a length ℓ (mils) and width w (mils) is

$$L = [5.08\text{E} - 3]\,\ell\left[\ln\left(\frac{\ell}{w}\right) + 1.193\left(\frac{w}{\ell}\right)\right] \qquad \text{[3] (5-79)}$$

where L is in nH/mil. This technique results in a much shorter strip of metal for a given inductance. One intriguing property of microstrip inductors is that they are capable of very high unloaded Q values. An equation describing the quality factor for a "wide" microstrip is

$$Q_C = 0.63h[\sigma f_{\text{GHz}}]^{1/2} \qquad \text{[4] (5-80)}$$

where h is the dielectric thickness in centimeters, σ is the conductivity in S/m, and f is frequency in GHz. This equation predicts an unloaded Q exceeding 700 when silver-coated copper is used. Also, wide microstrip lines are defined as those whose strip width w to height h ratio is approximately greater than 1; that is, $w/h > 1$. The parallel capacitor formed by the metal strip over the ground plane should also be included and may be calculated by the classic formula and included in the total needed to resonate with the inductance result found from Eq. (5-79). This "strip" capacitance is given by

$$C_S = K\varepsilon_0\varepsilon_r\left(\frac{w\ell}{h}\right) \qquad \text{(5-81)}$$

where C_S is in farads, $\varepsilon_0 = 8.86\text{E} -12$ (F/cm) is the permittivity of free space, and ε_r is the relative dielectric constant of the substrate. A "fringe factor," K, is included to account for necessary fringing (estimated to be 2–15%). These equations are meant to provide insight into circuit behavior and should, therefore, be applied cautiously to specific applications.

UHF VCO Using the Tapped-Inductor Differential Oscillator at 900 MHz. The basic electrical circuit of this configuration is shown in Figure 5-41. Feedback occurs when sufficient RF voltage develops across the tap inductances L_{T1} and L_{T2} (due to tap 1 and tap 2, respectively); note that inductance is reckoned from the cold end of the tank at node A. Taps 1 and 2 should be as close as possible to pins 9 and 10, respectively. Also node A (cold end of tank) and node B (pin 6) must be as physically close together and exhibit as low an impedance as possible to discourage parasitic oscillations. This "inner loop," composed of L_{T2}, the inductance of connections between taps 1 and 2 and pins 9 and 10, respectively, and "stray" low-Q inductance between nodes A and B creates a parasitic loop that will support oscillation that no longer depends on the full tapped-L tank circuit. Oscillation based on this low-Q loop typically occurs well above 1.2 GHz and has been observed as high as 1.6 GHz, and exhibits very poor phase noise performance.

Another factor also affects this unwanted parasitic oscillation. As the full tank circuit's unloaded Q decreases, the circuit becomes conditionally stable and will eventually favor the parasitic loop exclusively. This occurs because the loaded Q of the tapped microstrip affects the magnitude of the RF voltage appearing across the entire tank. Thus, feedback at taps 1 and 2 is reduced as the Q decreases. This increases the likelihood of the parasitic inner loop controlling the oscillator, since its feedback voltage is largely independent of the microstrip tank Q.

Equation (5-80) shows that microstrip inductors are capable of very high unloaded Q values. This depends on a number of physical factors: frequency, dielectric thickness and

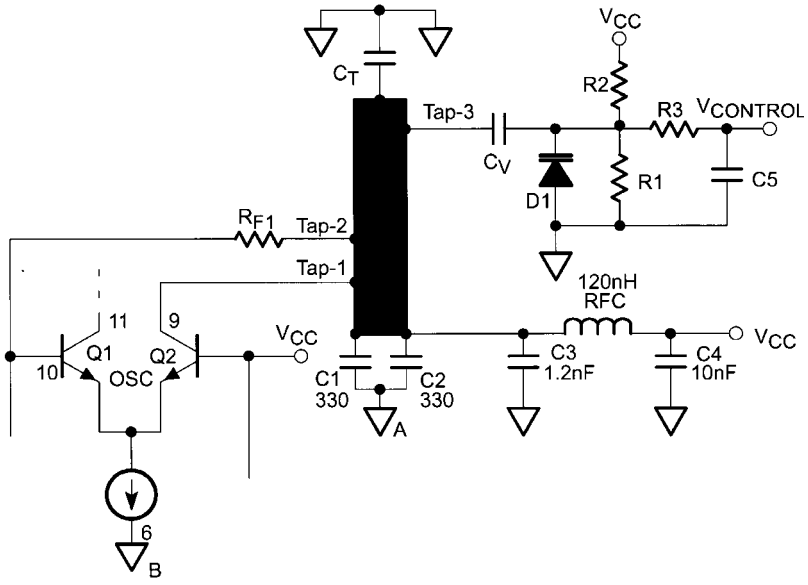

Figure 5-41 Differential oscillator with tapped-microstrip resonator.

quality, and the skin-depth conductance of the metal strip itself. For example, at 900 MHz, the unloaded Q of a silver-coated microstrip line is in the vicinity of 750. Coating the same line with lead (sloppy soldering can do it!) reduces the Q to less than 230. If the unloaded Q is too low, the loaded Q also drops. The circuit becomes conditionally stable and now may oscillate either at the higher parasitic-loop frequency or the desired lower frequency at which the entire microstrip tank resonates. Components should be connected by narrow traces closely connected to component leads to avoid soldering on the microstrip proper.

R_{F1} introduces necessary losses to control the inner-loop parasitic oscillation. Its size should be made as small as possible consistent with stability, startup, and good phase-noise performance. Since R_{F1} also decreases feedback, the oscillator's output falls as R_{F1} increases. Typically, experimental values from 4 to 30 Ω have proved sufficient.

Stability as a function of V_{CC} is a good way to assess conditional stability. Provided the microstrip tank has a high loaded Q, the oscillator's stability should be independent of V_{CC} down to less than 2.5 V or so. When loaded Q decreases sufficiently to favor the inner-loop parasitic, conditional stability will occur. This can readily be observed by increasing V_{CC} from about 1.0 V and noting whether the VCO frequency jumps back and forth unpredictably. Mixer and LO-port loading can also affect this condition and should be considered.

Dimensions for the microstrip resonator are based on several criteria. The strip must be "wide": Its width-to-height ratio must be on the order of 1 or greater. Minimum strip length seems to be about 200 mils for 62-mil-thick board. L/C ratios somewhere about 500 have yielded quite good results. Note that we usually specify the "L/C ratio" because it is always greater than 1, even though in a parallel-resonant circuit it appears in the Q equation as C/L. Thus, decreasing the "L/C ratio" by making the microstrip shorter helps the inductor's loaded Q, and the circuit's loaded Q_L, increase [see Eq. (5-75)]. However, the effect of the lower Q of C_T, even when using a high-Q surface-mount type, decreased the expected larger increase in the circuit's net loaded Q. Thus, the expected increase in Q_L may not be fully realizable. Assuming a 62-mil-thick board with FR5 dielectric, a strip 50 mils by 300 mils gave very good experimental results, where C_T was about 4.3 pF, with oscillation occurring from about 950 to 1000 MHz with various test boards. A shorter inductor designed to increase the C/L ratio requiring 7.5 pF experimentally resulted in only about 1–2-dB phase-noise improvement at 950 MHz. The reason for this is that as the microstrip inductor degenerates to a plain inductor, all of its advantages are lost.

Tap 1 may be anywhere between the cold end of the tank (where C_1 and C_2 are located) and tap 2. Tap 2 yields good results at about one-third the strip length. Making it too close to the cold end in an effort to increase Q_L will result in loss of control over the inner-loop parasitic. To keep Q_L as high as possible, C_T should be a high-Q surface-mount type. Differences greater than 5 dB in SSB phase noise have been observed between a generic NP0 surface-mount capacitor and a high-Q NP0 surface-mount capacitor.

Tap 3 can be at the end of the microstrip when C_T is connected. However, the tuning diode inevitably will cause a decrease in overall loaded Q, typically resulting in a phase-noise increase of as much as 5 dB. Moving it some distance down from the high end of the tank will decrease this effect and yield better results. A good starting point is about one-quarter down, or three-quarters of the length from the cold end of the tank. C_1 and C_2 are paralleled lower-value capacitors to yield a better low-impedance ground return to pin 6 (node B) since relatively large RF currents flow through them. Note that as Q_L increases, the peak circulating RF current will also increase, as will the RF voltage at the hot end of the microstrip. At 900 MHz, good results have been obtained when both are about 300 pF. The RF choke was chosen to be approximately series-resonant around 900 MHz, and constitutes the series feed path

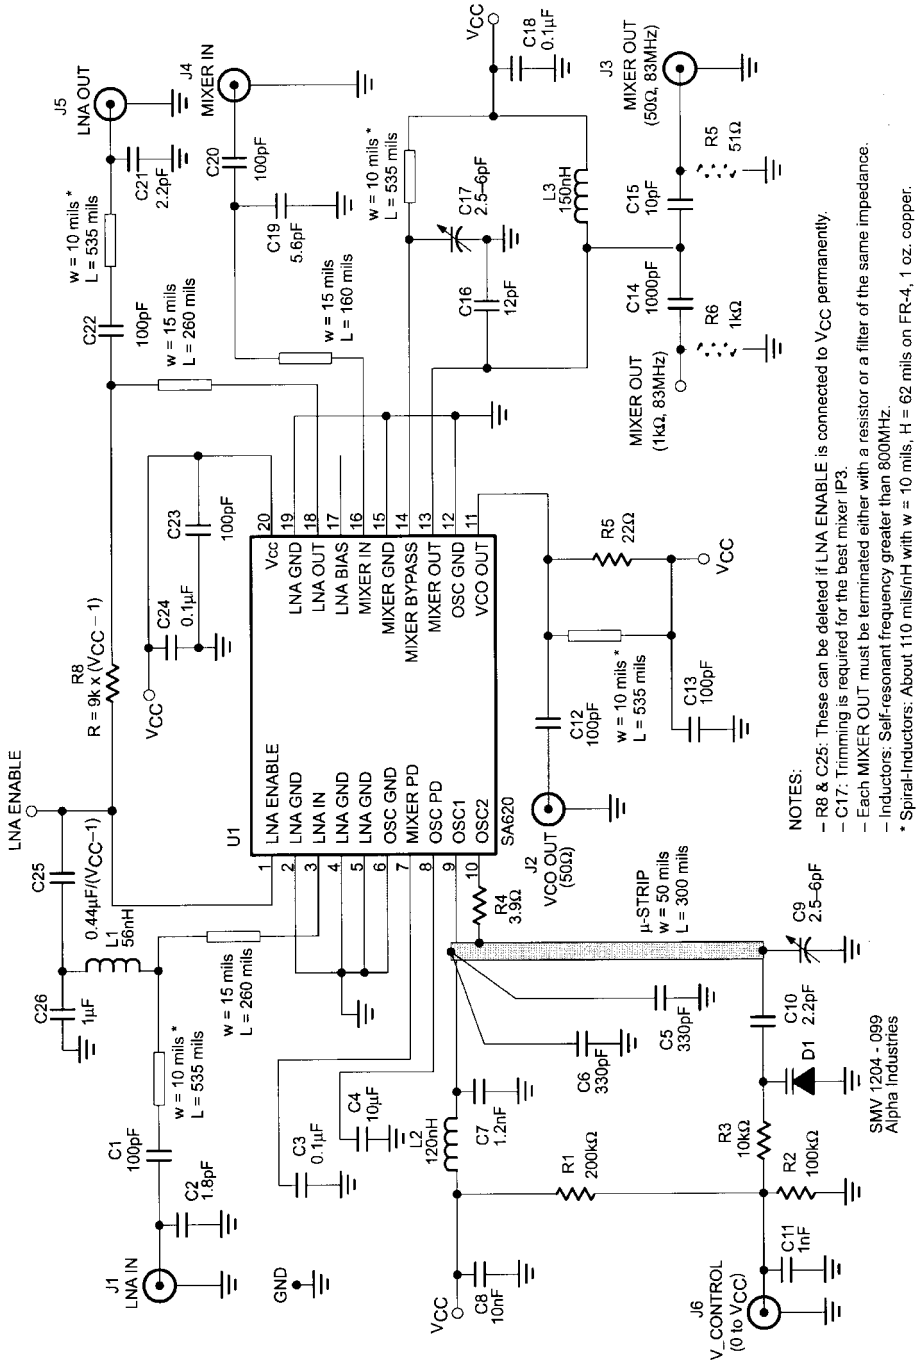

Figure 5-42 Philips SA620 application board schematic showing the tapped-microstrip resonator.

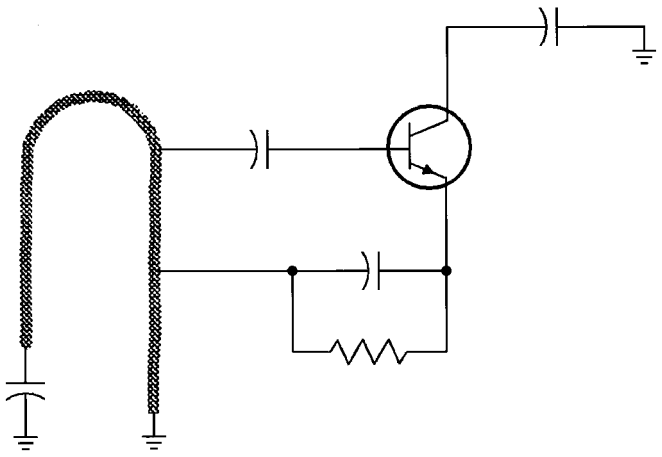

Figure 5-43 "Walking stick" microstrip Hartley resonator as used by Plextek in the 800–1500-MHz range. Below 800 MHz, the resonator's physical size becomes impractical; above 1500 MHz, the transistor's parasitic reactances make the Hartley configuration problematic.

for dc biasing. It may be possible to neglect this component entirely, provided that the PC-board connection to the cold end of the tank is very close to RF ground. Finally, note that shielding of the entire microstrip may be necessary to meet FCC Part 15 emission limitations (where applicable). Figure 5-42 shows one application of the tapped-microstrip oscillator with the Philips SA620 front-end IC.

5-5-5 Hartley Microstrip Resonator Oscillator

G. Smithson and S. Fitz of Plextek Communications Technology Consultants have reported on the construction of Hartley microstrip-resonator oscillators using thick-film techniques on ceramic (alumina) substrates for high-volume wireless products. The resonator in one such oscillator (Figure 5-43) exhibited an unloaded Q of approximately 80. Table 5-2 summarizes its phase noise versus tuning range with different tuning-diode configurations.

5-5-6 Crystal Oscillators

Most wireless applications do not require ultra-high-frequency stability that mandates the use of a primary standard, such as one based on cesium, or a secondary standard, such as one based on rubidium. For very stable oscillators at fixed or only slightly variable frequencies up to a few hundred megahertz, oscillators with piezoelectric resonators are generally used. A piezoelectric material transduces mechanical stress (deformation) to

Table 5-2 Achieved oscillator phase noise versus tuning range

Tuning Range, 0.5–3 V	Tuning Range, 1–3 V	Phase Noise at 20-kHz Offset

electrical stress (voltage), and vice versa. In noncritical applications up to 10 MHz, a piezoelectric ceramic may be used. The Q and temperature stability of such materials are relatively poor, however, so quartz is the resonator material of choice for temperature-stable, low-noise piezoelectric oscillators.

Just as an electrical resonator consisting of distributed L and C exhibits multiple electrical resonances, a physical piece of piezoelectric material, depending on its shape, exhibits multiple mechanical resonances. *Fundamental* resonance occurs at the frequency at which the crystal is one-half wavelength long; *overtone* resonances occur near odd multiples (3, 5, 7, etc.) of the fundamental. Figure 5-44 shows the electrical equivalent of a crystal. Table 5-3 presents examples of approximate parameters for several crystal types. Appropriate shaping and placement of the crystal's connecting electrodes, combined with suitable oscillator circuit design and adjustment, allow the selection or ehancement of a particular resonance for excitation.

Figure 5-45 shows a typical crystal oscillator circuit configuration, and the associated table supplies recommended values for the elements. This is in line with the chip manufacturer's recommendations for built-in oscillator circuits. Figure 5-46 shows how this oscillator's input impedance varies around resonance; Figure 5-47 shows its simulated phase noise. Placing a small resistance in series with the crystal (Figure 5-48) allows us to use the crystal as a high-Q filter, substantially improving the oscillator's spectral purity relative to that obtainable at the transistor emitter (Figure 5-49).

Some applications demand ultra-low-phase-noise crystal oscillators. Figures 5-50 and 5-51 show an appropriate circuit and its phase noise with and without the current-supplying hot carrier diode (HCD) used for noise reduction.

5-5-7 Voltage-Controlled Oscillators

A schematic of a ceramic-resonator-based VCO (Figure 5-35) has already been shown in the section on ceramic-resonator oscillators. To tune the oscillator within the required range,

	3 MHz	6 MHz	10 MHz	20 MHz	30 MHz
C_1 (pF)	330	270	180	82	43
C_2 (pF)	430	360	220	120	68
C_3 (pF)	39	43	43	36	32
Crystal C_L (pF)	32	32	30	20	15

C_3 is the approximate value needed to set oscillator on frequency using indicated crystal C_L.

Figure 5-45 A 3–30-MHz Colpitts crystal oscillator.

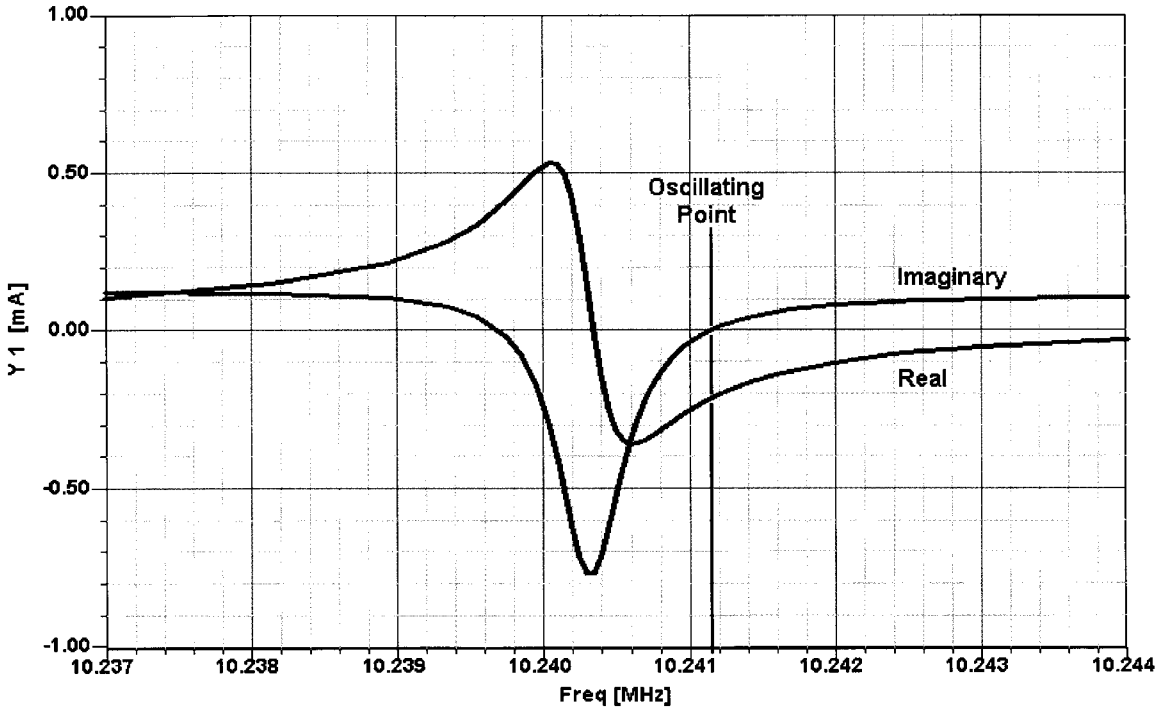

Figure 5-46 As with every oscillator, the crystal oscillator's input impedance is negative and real at resonance. This graph plots the real and imaginary components of the test voltage injected by the Oscillator Design Aid tool in Ansoft Serenade 8.0. Compare this graph with Figure 5-7, which plots an oscillator's input impedance with the resonator absent.

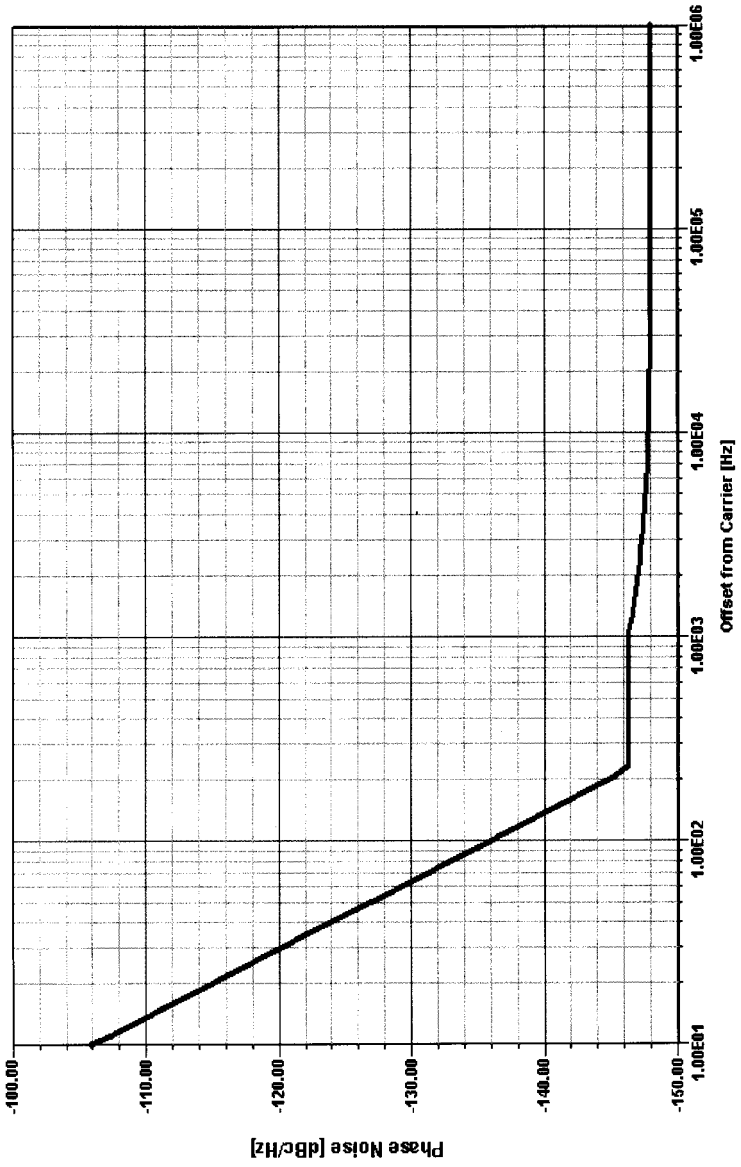

Figure 5-47 Simulated phase noise of the crystal oscillator.

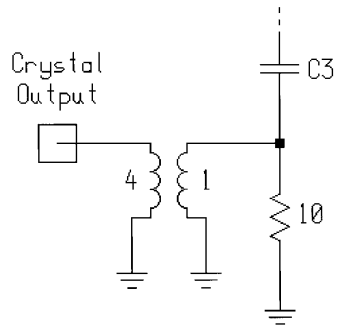

Figure 5-48 This alternative output tap uses the crystal's high selectivity for improved harmonic reduction.

tuning diodes are used. These diodes are often called *varactors* or *voltage-sensitive diodes.* By way of approximation, we can use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{5-82}$$

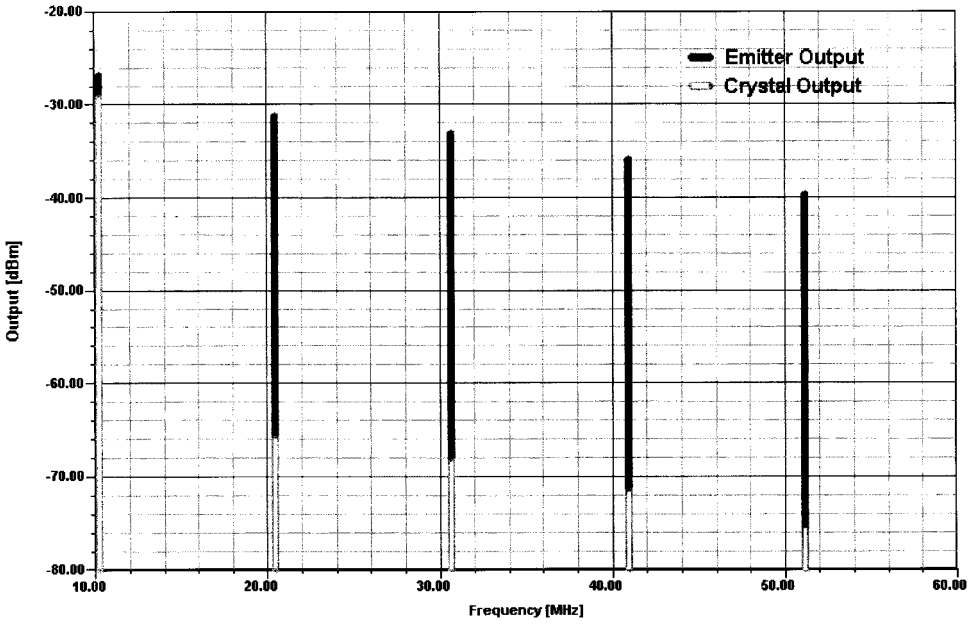

Figure 5-49 Comparison of the crystal oscillator's simulated output spectrum as obtained at the transistor emitter (dark gray, fundamental –26.7 dBm) and crystal (light gray, fundamental –29.1 dBm). At the emitter, the second harmonic is down only 4.3 dB relative to the carrier; at the crystal, the second harmonic is down 36 dB relative to the carrier.

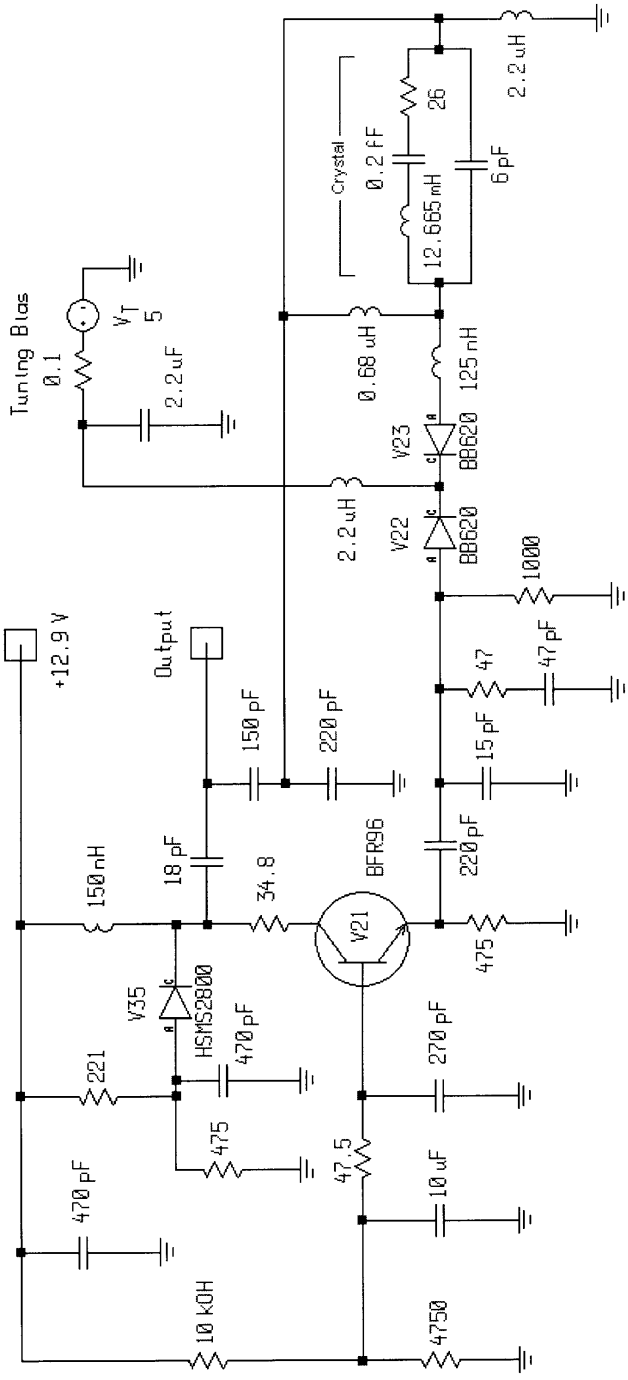

Figure 5-50 A 100-MHz VCXO suitable for ultra-low-phase-noise applications. The HSMS2800 hot-carrier diode (HCD) provides noise reduction.

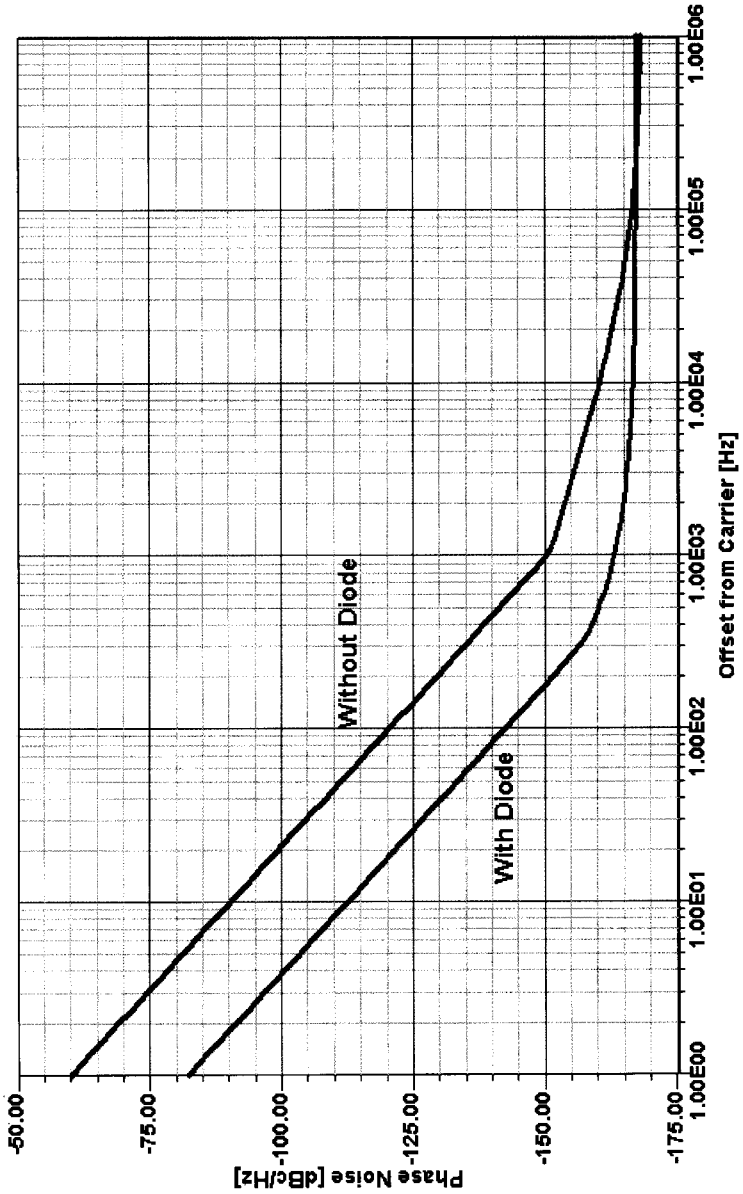

Figure 5-51 Phase noise of the VCXO with and without the noise-reduction diode.

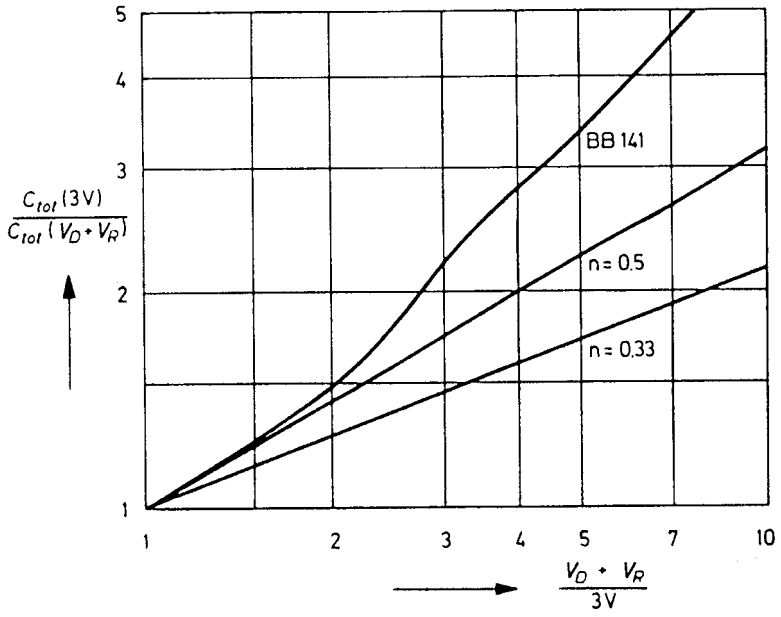

Figure 5-52 Capacitance–voltage characteristic for an alloyed capacitance diode ($n = 0.33$), a diffused capacitance diode ($n = 0.5$), and a wide-range tuning diode (BB141).

wherein all constants and all parameters determined by the manufacturing process are contained in K. The exponent is a measure of the slope of the capacitance/voltage characteristic and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction [6, 7]. Figure 5-52 shows the capacitance–voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation was developed that, although purely formal, describes the practical characteristic better than Eq. (5-82):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{5-83}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is the volt. The exponent m is much less dependent on voltage than the exponent n in Eq. (5-81).

The operating range of a capacitance diode or its useful capacitance ratio,

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R,\min})}{C_{\text{tot}}(V_{R,\max})} \tag{5-84}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage, either into the forward mode or the breakdown mode. Otherwise, rectification would take place, shifting the bias of the diode and considerably affecting its figure of merit.

There are several manufacturers of tuning diodes. Motorola is a typical supplier in this country; Siemens of Germany and Philips also provide good diodes. Table 5-4 and Figure 5-53 contain information for tuning diodes useful for our applications.

5-5-8 Diode-Tuned Resonant Circuits

Tuner Diode in Parallel-Resonant Circuit. Figures 5-54 and 5-55 illustrate two basic circuits for the tuning of parallel resonant circuits by means of capacitance diodes. In the circuit diagram of Figure 5-54, the tuning voltage is applied to the tuning diode via the bias resistor, R_B. Series-connected from the tuning diode to the top of the tank circuit is capacitor C_S, which completes the circuit for alternating current but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling resistor preceding the bias resistor is large enough to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_c. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_c = R_B \left(1 + \frac{C_{\text{tot}}}{C_S}\right)^2 \tag{5-85}$$

Table 5-4 Example tuning diodes (Siemens)

	Maximum Ratings		Characteristics (T_A = 25 °C)

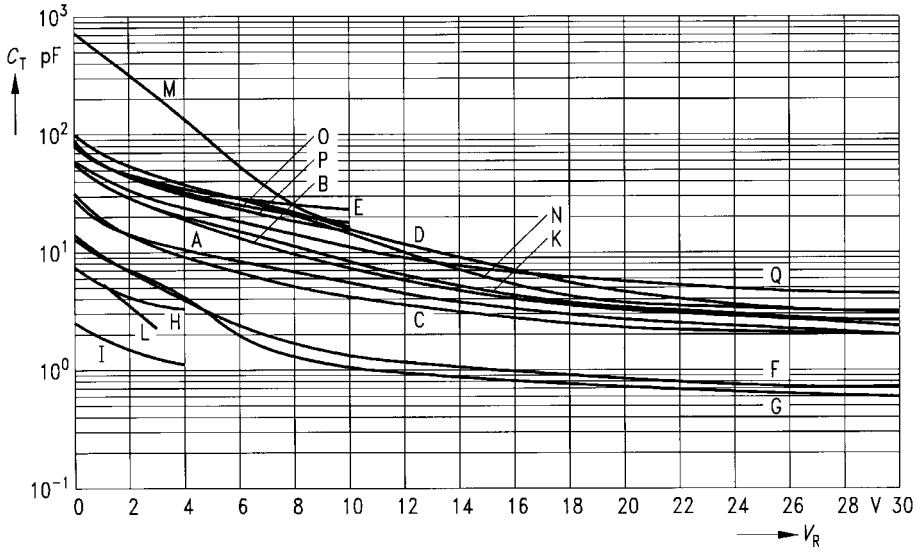

Figure 5-53 Diode capacitance C_T versus reverse voltage V_R for the diodes shown in Table 5-4. The curve labels correspond to the chip codes called out in the table.

If in this equation the diode capacitance is replaced by the resonator circuit frequency ω, we obtain

$$R_c = R_B \left(\frac{\omega^2 L C_S}{\omega^2 L (C_S + C_P) - 1} \right)^2 \tag{5-86}$$

In the circuit of Figure 5-55, the resonant circuit is tuned by two tuning diodes, which are connected in parallel via the coil for tuning purposes, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation acts in opposite directions in these diodes and, therefore, cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuning diodes, is transformed into the circuit at a constant ratio across the entire tuning range. Given two identical, loss-free tuning diodes, we obtain the expression

$$R_c = 4R_B \tag{5-87}$$

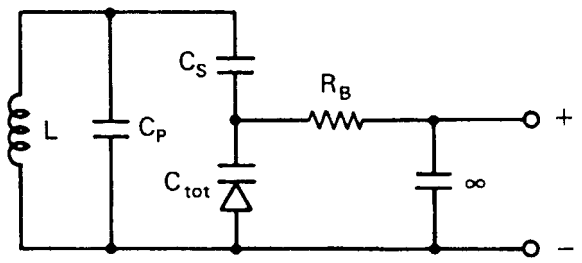

Figure 5-54 Parallel-resonant circuit with tuner diode, and bias resistor in parallel to the diode.

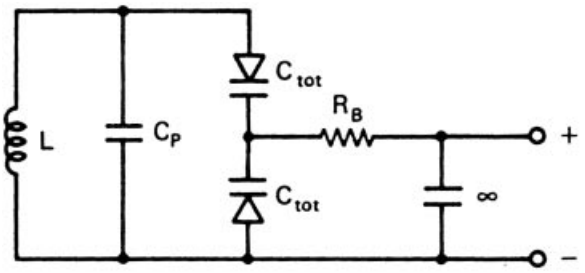

Figure 5-55 Parallel-resonant circuit with two tuning diodes.

Capacitances Connected in Parallel or in Series with the Tuning Diode. Figure 5-54 shows that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuning diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. If possible, the value of the series resistor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases—for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency—this is not possible, and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{tot} \frac{1}{1 + C_{tot}/C_S} \tag{5-88}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuning diode, increases to

$$Q^* = Q\left(1 + \frac{C_{tot}}{C_S}\right) \tag{5-89}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{max}}{C^*_{min}} = \frac{C_{max}}{C_{min}} \frac{1 + C_{min}/C_S}{1 + C_{max}/C_S} \tag{5-90}$$

where C_{max} and C_{min} are the maximum and minimum capacitances, respectively, of the tuner diode.

On the other hand, the advantage is gained that, due to the capacitive potential division, the amplitude of the alternating voltage applied to the tuner diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{tot}/C} \tag{5-91}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance C_{max} of the tuning diode and a higher useful capacitance ratio. The

influence exerted by the series capacitor, then, can actually be kept lower than Eq. (5-89) would suggest.

The parallel capacitance C_P that appears in Figures 5-54 and 5-55 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises in value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}}\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{5-92}$$

The Q of the effective tuning capacitance, derived from the Q of the tuning diode, is

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{5-93}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}}\,\frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{min}}} \tag{5-94}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the layout stage of the circuit design.

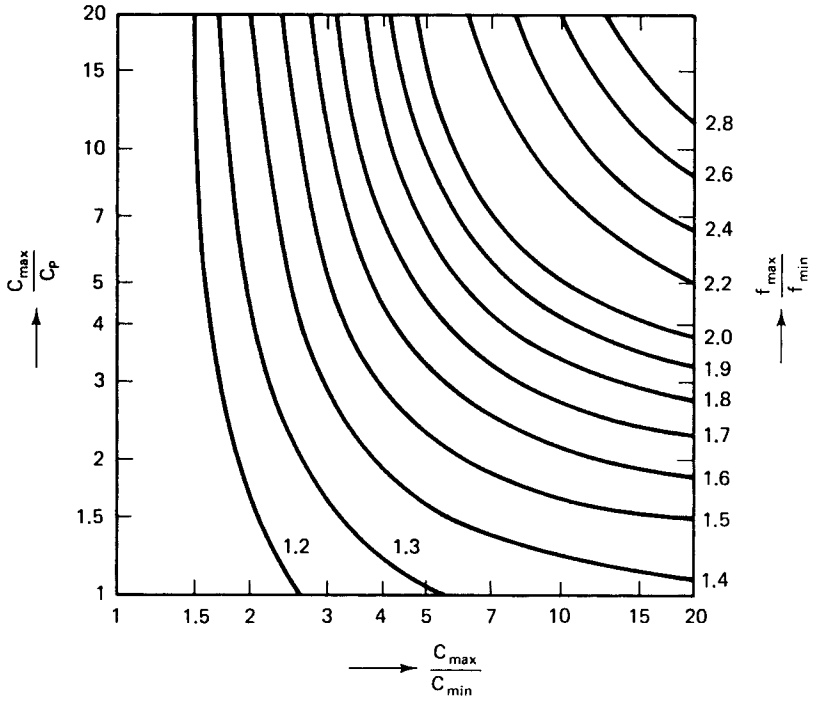

Figure 5-56 Diagram for determining capacitance ratio and maximum capacitance.

Tuning Range. The frequency range over which a parallel-resonant circuit (according to Figure 5-54) can be tuned by means of the tuning diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit. The ratio is

$$\frac{f_{\max}}{f_{\min}} = \left(\frac{1 + \dfrac{C_{\max}}{C_P(1 + C_{\max}/C_S)}}{1 + \dfrac{C_{\max}}{C_P(C_{\max}/C_{\min} + C_{\max}/C_S)}} \right)^{1/2} \tag{5-95}$$

In many cases, the value of the series capacitor can be chosen to be large enough for its effect to be negligible. In that case, Eq. (5-95) is simplified as follows:

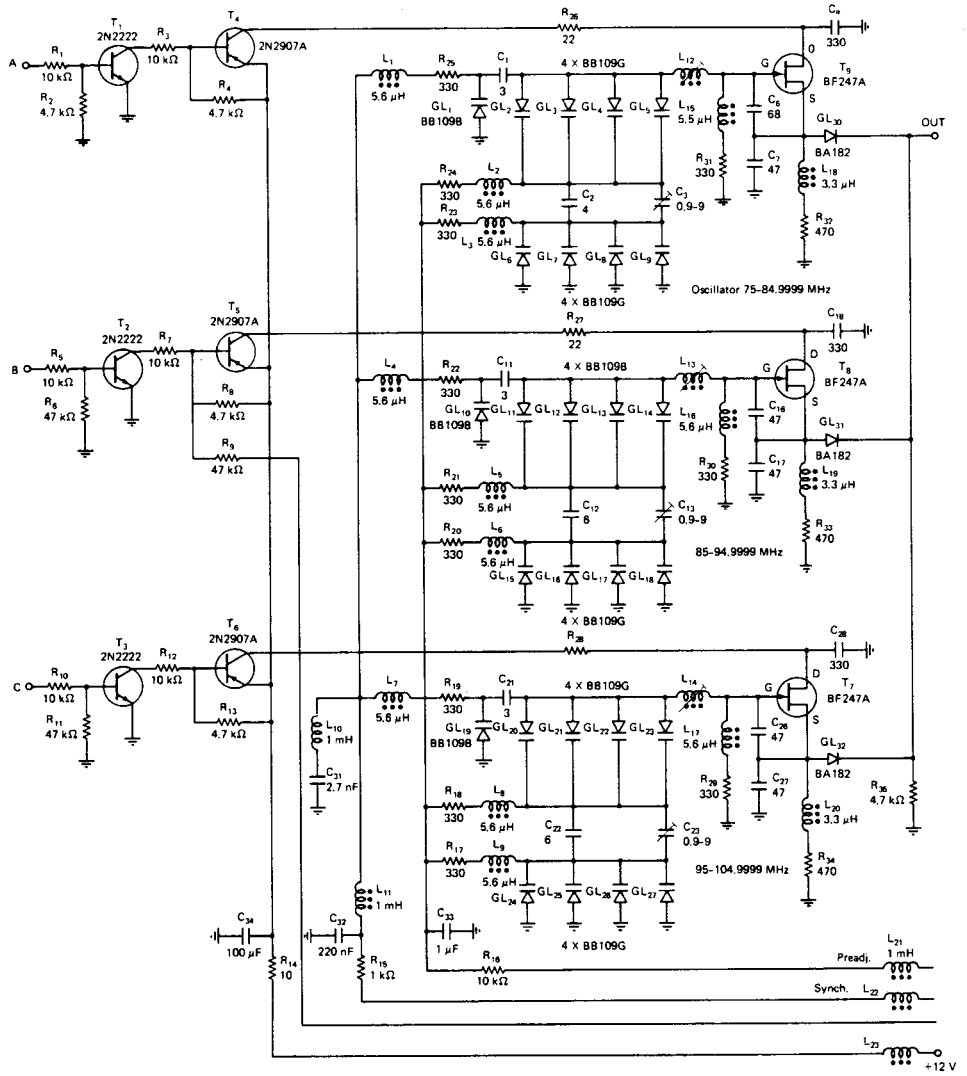

Figure 5-57 Oscillator and switching section of the Rohde & Schwarz ESH2/ESH3 test receiver.

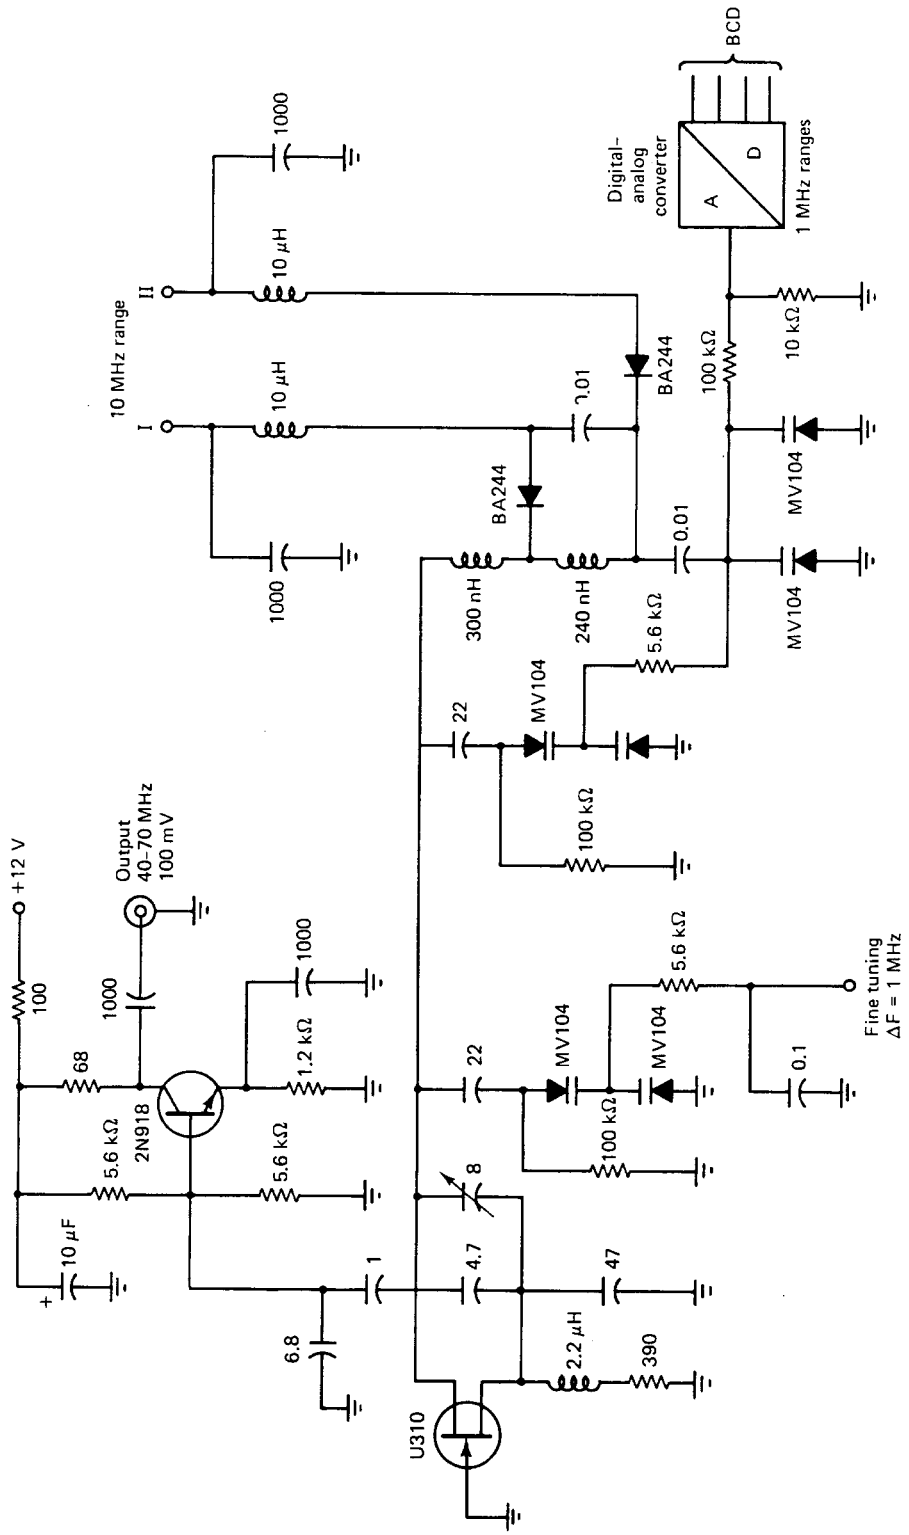

Figure 5-58 A 40–70-MHz VCO with two coarse-steering ranges and a fine-tuning range of 1 MHz.

$$\frac{f_{\max}}{f_{\min}} = \left(\frac{1 + C_{\max}/C_P}{1 + C_{\min}/C_P} \right)^{1/2} \tag{5-96}$$

From this equation, the diagram shown in Figure 5-56 is computed. With the aid of this diagram, the tuning diode parameters required for tuning a resonant circuit over a stipulated frequency range (i.e., the maximum capacitance and the capacitance ratio) can be determined. Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced accorded to Eq. (5-90).

Tracking. When several tuned circuits are used on the same frequency, diodes must be selected for perfect tracking.

5-5-9 Practical Circuits

Oscillators with Coarse and Fine Tuning. After so much theory, it may be nice to take a look at some practical circuits, such as the one shown in Figure 5-57. This oscillator is being used in the Rohde & Schwarz ESN/ESVN40 field-strength meter, and in the HF1030 receiver produced by Cubic Communications, San Diego. This circuit combines all the various techniques shown previously. A single diode is being used for fine-tuning a narrow range of less than 1 MHz; coarse tuning is achieved with the antiseries diodes.

Several unusual properties of this circuit are apparent:

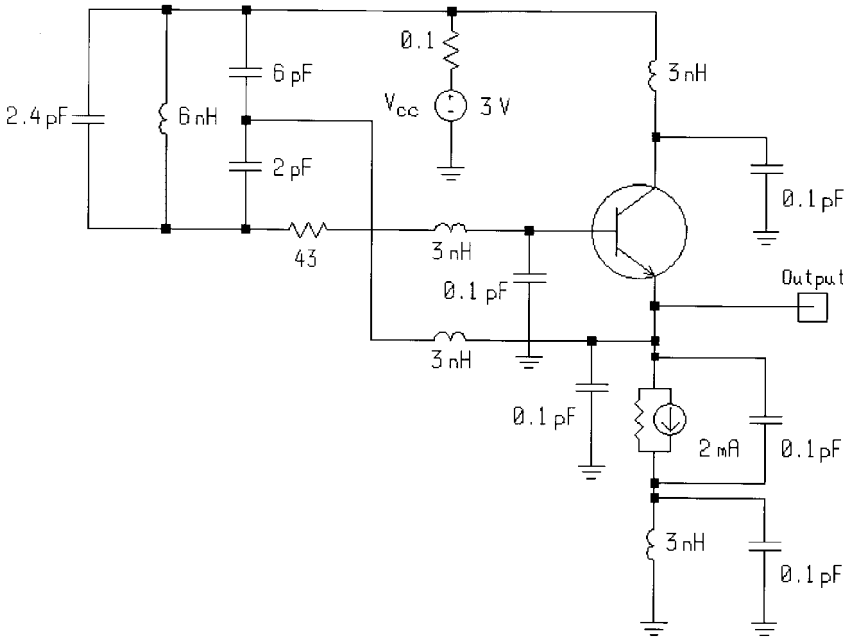

Figure 5-59 Schematic of the dc-coupled oscillator.

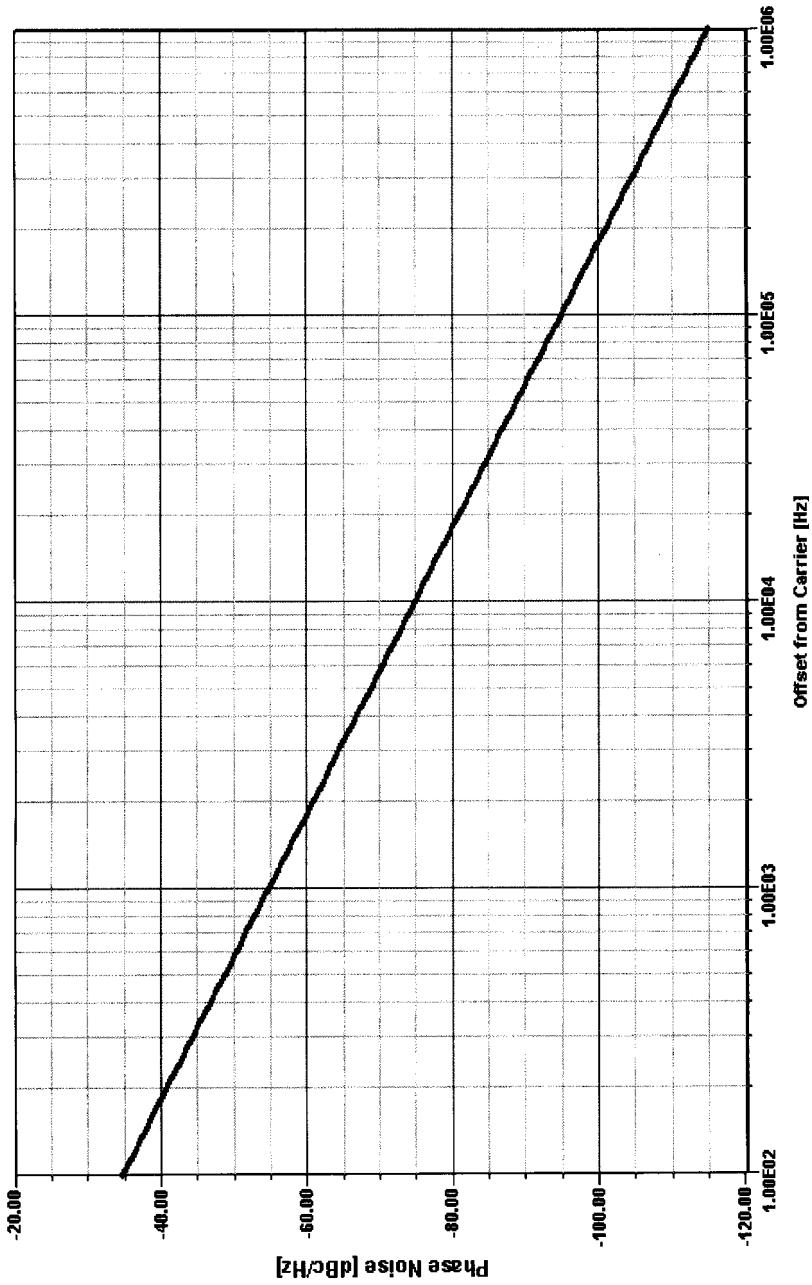

Figure 5-60 Phase noise of the dc-coupled oscillator operating at 897 MHz.

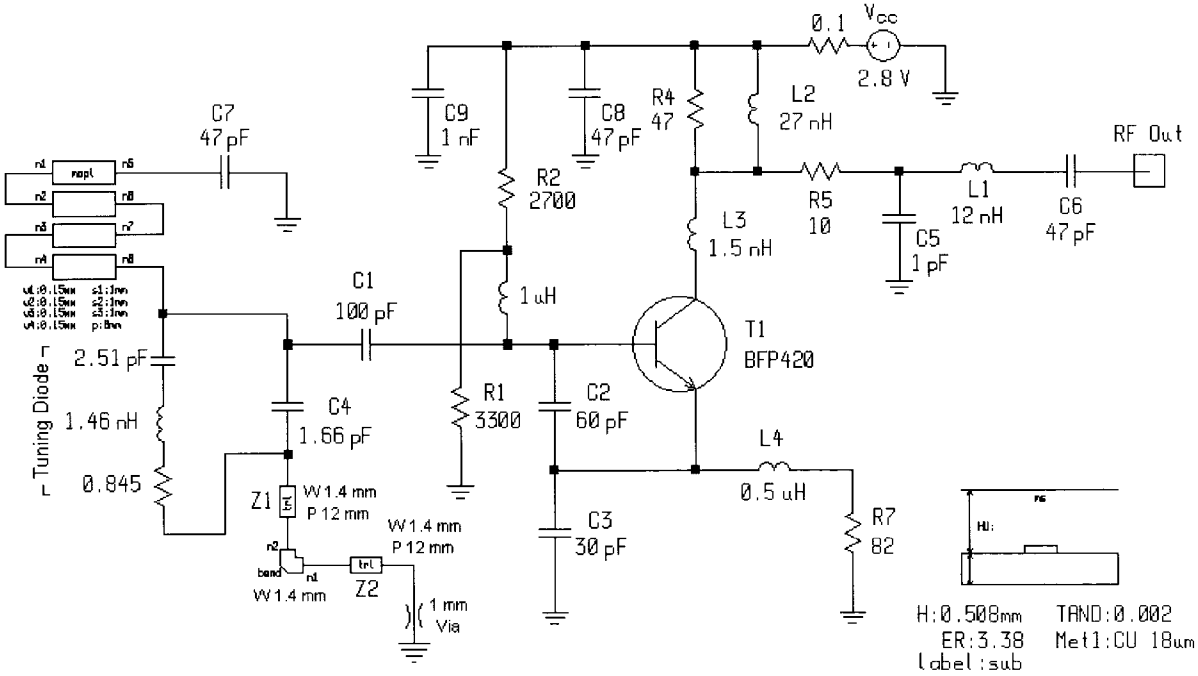

Figure 5-61 Schematic of the Siemens VCO. This oscillator (simulation) works with such high voltage-divider capacitances (C_2 and C_3) only because the circuit's large-signal transistor model, which was obtained under contract, exhibits unrealistically high gain at the frequency of oscillation. Actual capacitors with values on the order of those shown for C_2 and C_3 typically exhibit parasitic resistance and inductance of 0.3 Ω and 0.2 nH, respectively; the resulting series resonance would make any actual such capacitor act as an inductor at UHF. Obtaining practical "UHF useful" capacitances with values on the order of those shown for C_2 and C_3 would therefore necessitate the use of multiple, smaller-value capacitors in parallel—4 × 15 pF at C_2, for example.

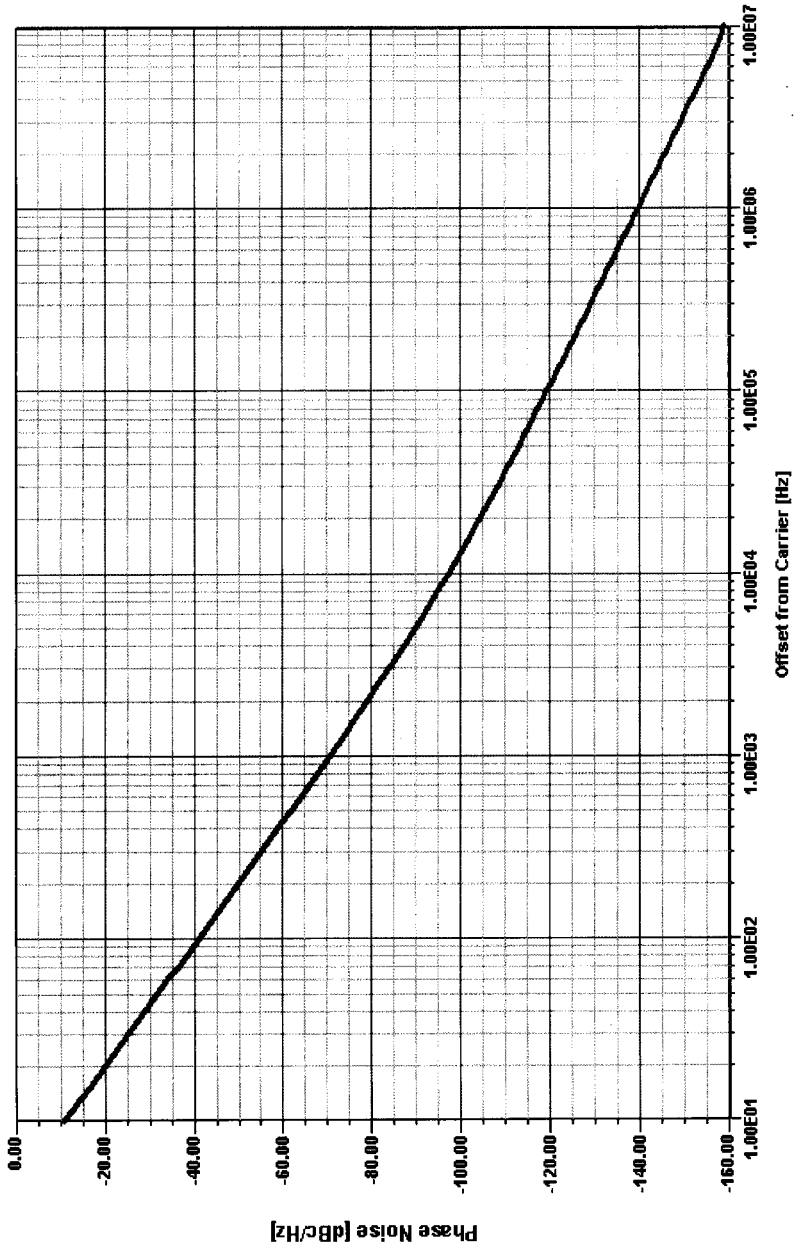

Figure 5-62 Simulated phase noise of the VCO. The frequency of oscillation is 1.052 GHz.

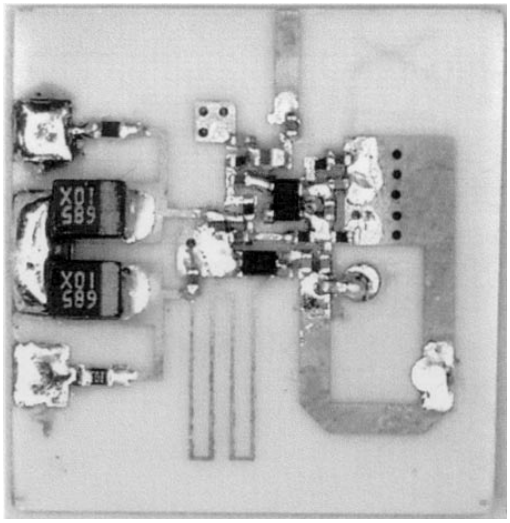

Figure 5-63 Implementation of the Siemens VCO.

1. The fine tuning is achieved with a tuning diode that has a much larger capacitance than that of the coupling capacitor in the circuit. The advantage of this technique is that the fixed capacitor and the tuning diode form a voltage divider, whereby the voltage across the tuning diode decreases as the capacitance increases. For larger values of the capacitance of the tuning diode, the Q changes and the gain K_0 increases. Because of the voltage division, the noise contribution and loading effect of the diode are reduced.
2. In the coarse-tuning circuit, several tuning diodes are used in parallel. The advantage of this circuit is a change in L/C ratio by using a higher C and storing more energy in the tuned circuit. There are no high-Q diodes available with such large capacitance values, and therefore preference is given to using several diodes in parallel rather than one tuning diode with a large capacitance, normally used only for AM (medium-frequency broadcast) tuner circuits.

We mentioned previously that, despite this, the coarse-tuning circuit will introduce noise outside the loop bandwidth, where it cannot be corrected. It is therefore preferable to incorporate switching diodes for segmenting ranges at the expense of switching current drain.

Figure 5-58 shows a circuit using a combined technique of tuning diodes for fine- and medium-resolution tuning, and coarse tuning with switching diodes.

dc-Coupled Oscillator. An interesting circuit that was cut out of an IC was supplied to us by David Lovelace of Motorola. Figure 5-59 shows the circuit and Figure 5-60 shows its phase noise. As a result of the constraints of integration, this BJT oscillator has no base bias circuitry in the conventional form. A fairly noisy performer, it ultimately was not used in production.

Siemens Colpitts Oscillator. A more elaborate approach that is essentially a standard Colpitts oscillator with a lot of detailed modeling is the oscillator of Figure 5-61, supplied

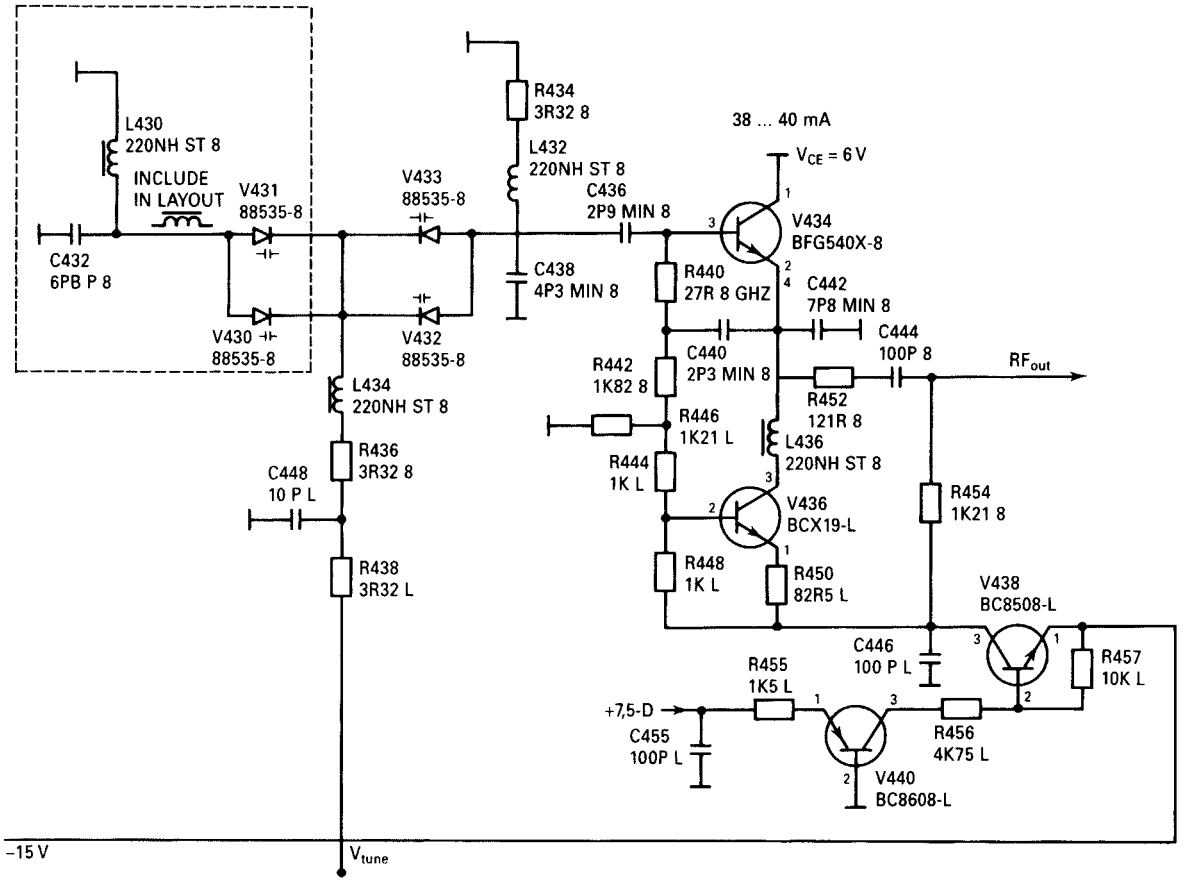

Figure 5-64 A recommended very-low-phase-noise VCO that operates in the 1-GHz region. The V436 stage is a constant-current generator responsible for improved phase-noise performance.

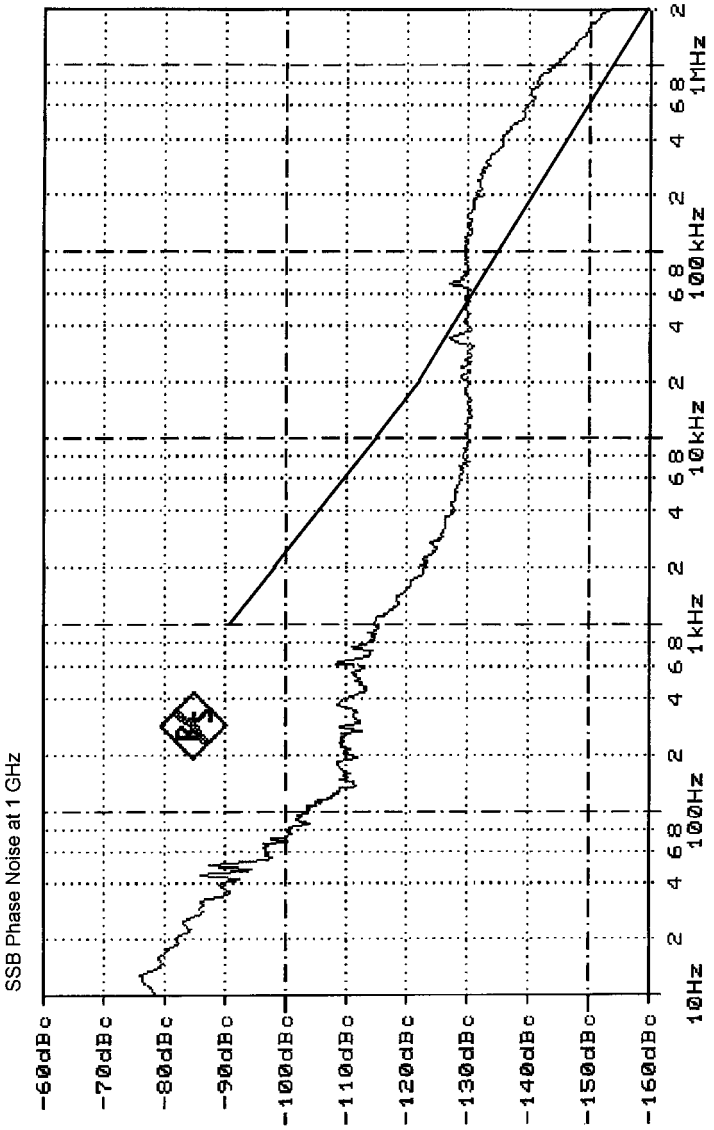

Figure 5-65 Phase noise of the low-noise VCO. The "ledges" from 100 Hz to 1 kHz and from 10 kHz to 100 kHz reflect the noise-cleanup effects of a dual-loop synthesizer; the superimposed line from 1 kHz to 2 MHz shows the oscillator's noise characteristic with both loops unlocked. The closed-loop response is noisier than the open-loop response at offsets above 60 kHz because a wide loop bandwidth is used to achieve a faster switching speed.

to us by Siemens. Considering its simplicity, its noise performance is good, as shown in Figure 5-62. Modeling this circuit involved the consideration of via holes and coupled lines. Figure 5-63 shows an actual implementation of this oscillator. The value of external emitter resistance (R7 in Figure 5-61) plays a critical role in determining a common-emitter Colpitts oscillator's upper frequency limit as described in Yeom [8].

dc-Stabilized Oscillator. For high-performance synthesizers, such as the Rohde & Schwarz series SMG/SMH, a dc-stabilized oscillator with fairly wide tuning range may be used. Figure 5-64 shows such an oscillator, the measured phase noise of which is shown in Figure 5-65. It should be noted that the output loop is magnetically coupled and therefore takes advantage of the inherent selectivity of the tuned circuit.

5-6 NOISE IN OSCILLATORS

In transmitters, oscillator noise can result in adjacent-channel interference and modulation errors; in receivers, oscillator noise can result in demodulation errors and degraded sensitivity and dynamic range. The specification, calculation, and reduction of oscillator noise are therefore of great importance in wireless system design.

5-6-1 Linear Approach to the Calculation of Oscillator Phase Noise

Since an oscillator can be viewed as an amplifier with feedback (Figure 5-66), it is helpful to examine the phase noise added to an amplifier that has a noise figure F. F is defined by [9]

$$F = \frac{(S/N)_{\text{in}}}{(S/N)_{\text{out}}} = \frac{N_{\text{out}}}{N_{\text{in}}G} = \frac{N_{\text{out}}}{GkTB} \tag{5-97}$$

$$N_{\text{out}} = FGkTB \tag{5-98}$$

$$N_{\text{in}} = kTB \tag{5-99}$$

where N_{in} is the total input noise power to a noise-free amplifier. The input phase noise in a 1-Hz bandwidth at any frequency $f_0 + f_m$ from the carrier produces a phase deviation given by (Figure 5-67)

$$\Delta\theta_{\text{peak}} = \frac{V_{n\,\text{RMS1}}}{V_{s,\text{av RMS}}} = \sqrt{\frac{fKT}{P_{s,\text{av}}}} \tag{5-100}$$

$$\Delta\theta_{\text{1RMS}} = \frac{1}{\sqrt{2}}\sqrt{\frac{FkT}{P_{s,\text{av}}}} \tag{5-101}$$

Since a correlated random phase-noise relation exists at $f_0 - f_m$, the total phase deviation becomes

$$\Delta\theta_{\text{RMS total}} = \sqrt{FkT/P_{s,\text{av}}} \tag{5-102}$$

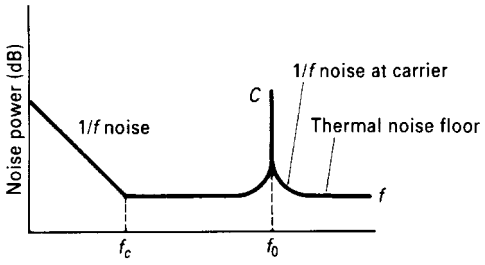

Figure 5-66 Noise power versus frequency of a transistor amplifier with an input signal applied.

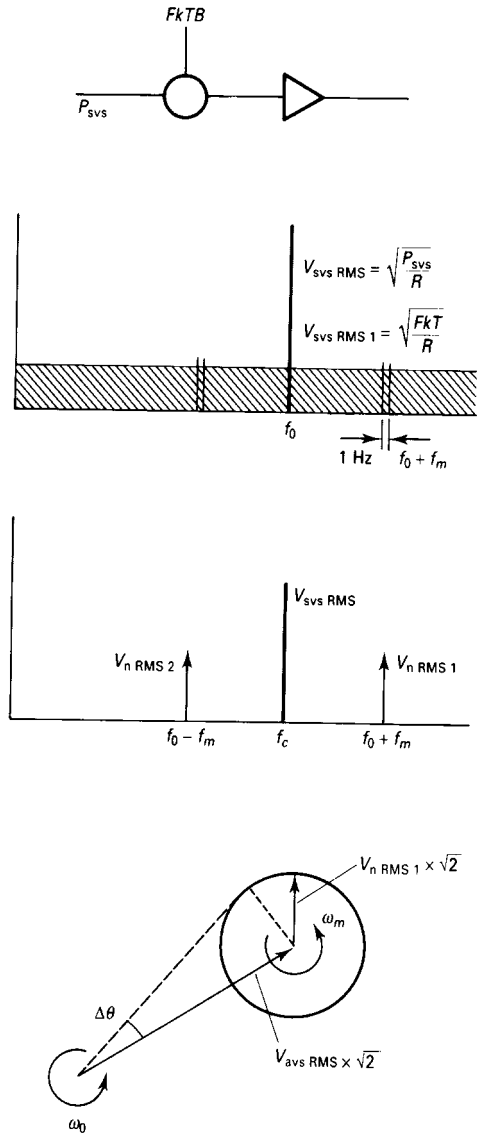

Figure 5-67 Phase noise added to carrier.

The spectral density of phase noise becomes

$$S_\theta(f_m) = \Delta\theta^2_{\text{RMS}} = FkTB/P_{s,\text{av}} \tag{5-103}$$

where $B = 1$ for a 1-Hz bandwidth. Using

$$kTB = -174 \text{ dBm/Hz} \qquad (B = 1) \tag{5-104}$$

allows a calculation of the spectral density of phase noise that is far removed from the carrier (i.e., at large values of f_m). This noise is the theoretical noise floor of the amplifier. For example, an amplifier with +10-dBm power at the input and a noise figure of 6 dB gives

$$S_\theta(f_m > f_c) = -174 \text{ dBm} + 6 \text{ dB} - 10 \text{ dBm} = -178 \text{ dBm} \tag{5-105}$$

Only if P_{OUT} is >0 dBm can we expect $\mathcal{L}$ (signal-to-noise ratio) to be greater than 174 dBc/Hz (1-Hz bandwidth). For a modulation frequency close to the carrier, $S_\theta(f_m)$ shows a flicker or $1/f$ component, which is empirically described by the corner frequency f_c. The phase noise can be modeled by a noise-free amplifier and a phase modulator at the input as shown in Figure 5-68.

The purity of the signal is degraded by the flicker noise at frequencies close to the carrier. The spectral phase noise can be described by

$$S_\theta(f_m) = \frac{FkTB}{P_{s,\text{av}}}\left(1 + \frac{f_c}{f_m}\right) \quad (B = 1) \tag{5-106}$$

No AM-to-PM conversion is considered in this equation. The oscillator may be modeled as an amplifier with feedback as shown in Figure 5-69. The phase noise at the input of the amplifier is affected by the bandwidth of the resonator in the oscillator circuit in the following way. The tank circuit or bandpass resonator has a low-pass transfer function

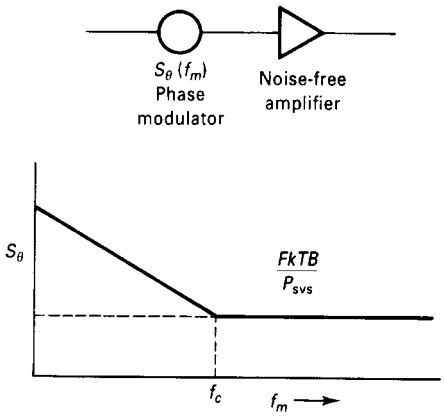

Figure 5-68 Phase noise modeled by a noise-free amplifier and phase modulator.

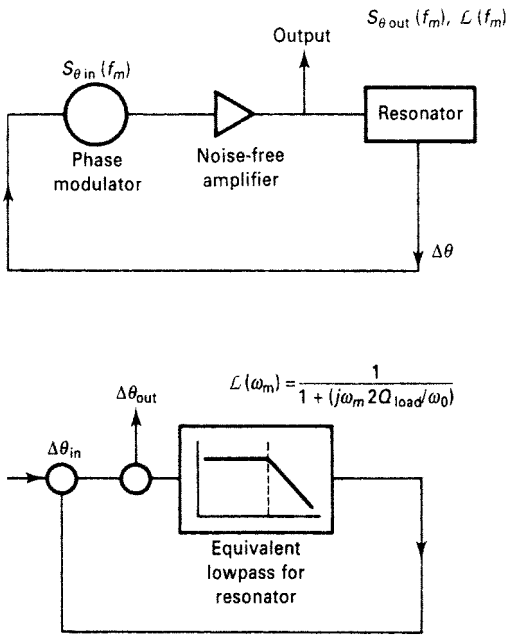

Figure 5-69 Equivalent feedback models of oscillator phase noise.

$$L(\omega_m) = \frac{1}{1 + j(2Q_L\omega_m/\omega_0)} \tag{5-107}$$

where

$$\omega_0/2Q_L = B/2 \tag{5-108}$$

is the half-bandwidth of the resonator. These equations describe the amplitude response of the bandpass resonator; the phase noise is transferred unattenuated through the resonator up to the half-bandwidth.

The closed-loop response of the phase feedback loop is given by

$$\Delta\theta_{\text{out}}(f_m) = \left(1 + \frac{\omega_0}{j2Q_L\omega_m}\right)\Delta\theta_{\text{in}}(f_m) \tag{5-109}$$

The power transfer becomes the phase spectral density

$$S_{\theta,\text{out}}(f_m) = \left[1 + \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right] S_{\theta,\text{in}}(f_m) \tag{5-110}$$

where $S_{\theta,\text{in}}$ was given by Eq. (5-106). Finally, $\mathcal{L}(f_m)$ is

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right] S_{\theta,\text{in}}(f_m) \tag{5-111}$$

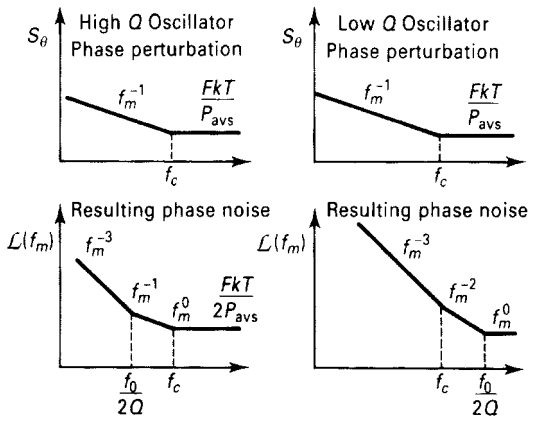

Figure 5-70 Equivalent feedback models of oscillator phase noise.

This equation describes the phase noise at the output of the amplifier (flicker corner frequency and AM-to-PM conversion are not considered). The phase perturbation $S_{\theta,\text{in}}$ at the input of the amplifier is enhanced by the positive phase feedback within the half-bandwidth of the resonator, $f_0/2Q_L$.

Depending on the relation between f_c and $f_0/2Q_L$, there are two cases of interest, as shown in Figure 5-70. For the low-Q case, the spectral phase noise is unaffected by the Q of the resonator, but the $\mathcal{L}(f_m)$ spectral density will show a $1/f^3$ and $1/f^2$ dependence close to the carrier. For the high-Q case, a region of $1/f^3$ and $1/f$ should be observed near the carrier. Substituting Eq. (5-106) into Eq. (5-111) gives an overall noise of

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{1}{f_m^2}\left(\frac{f}{2Q_L}\right)^2\right]\frac{FkT}{P_{s,\text{av}}}\left(1 + \frac{f_c}{f_m}\right)$$

$$= \frac{FkTB}{2P_{s,\text{av}}}\left[\frac{1}{f_m^3}\frac{f^2 f_c}{4Q_L^2} + \frac{1}{f_m^2}\left(\frac{f}{2Q_L}\right)^2 + \left(1 + \frac{f_c}{f_m}\right)\right] \text{dBc/Hz} \tag{5-112}$$

Examining Eq. (5-112) gives the four major causes of oscillator noise: the upconverted $1/f$ noise or flicker FM noise, the thermal FM noise, the flicker phase noise, and the thermal noise floor, respectively.

Q_L (loaded Q) can be expressed as

$$Q_L = \frac{\omega_o W_e}{P_{\text{diss,total}}} = \frac{\omega_o W_e}{P_{\text{in}} + P_{\text{res}} + P_{\text{sig}}} = \frac{\text{Reactive power}}{\text{Total dissipated power}} \tag{5-113}$$

where W_e is the reactive energy stored in L and C,

$$W_e = \frac{1}{2} CV^2 \tag{5-114}$$

$$P_{\text{res}} = \frac{\omega_o W_e}{Q_{\text{unl}}} \tag{5-115}$$

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{\omega_o^2}{4\omega_m^2}\left(\frac{P_{\text{in}}}{\omega_o W_e} + \frac{1}{Q_{\text{unl}}} + \frac{P_{\text{sig}}}{\omega_o W_e}\right)^2\right]\left(1 + \frac{\omega_c}{\omega_m}\right)\frac{FkT_o}{P_{\text{sav}}} \tag{5-116}$$

Input power/ Reactive power ratio

Resonator Q

Signal power/ Reactive power ratio

Flicker effect

Phase perturbation

This equation is extremely significant because it covers most of the causes of phase noise in oscillators. [AM-to-PM conversion must be added; see Eq. (5-56).] To minimize the phase noise, the following design rules apply:

1. Maximize the unloaded Q.
2. Maximize the reactive energy by means of a high RF voltage across the resonator and obtain a low L/C ratio. The limits are set by breakdown voltages of the active devices and the tuning diodes, and the forward-bias condition of the tuning diodes. If L becomes too high, the circuit degenerates into a squegging oscillator. Using lower L allows larger capacitance, which allows us to swamp the oscillating device's internal, nonlinear capacitance with external, linear capacitance, reducing the phase-noise degradation caused by the nonlinear capacitance. The ceramic-resonator oscillator best illustrates this approach, which may be hard to accomplish in discrete circuits because high-Q inductors with values above 1 nH cannot be built unless high-Q transmission lines or resonators are used.
3. Avoid saturation at all costs, and try to have either limiting or automatic gain control (AGC) without degradation of Q. Isolate the tuned circuit from the limiter or AGC circuit. Use tuning diodes in antiseries configurations to avoid forward bias.
4. Choose an active device with the lowest possible noise figure and flicker corner frequency. The noise figure of interest is the noise figure obtained with the actual impedance at which the device is operated. Using FETs rather than BJTs, it is preferable to deal with the equivalent noise voltage and noise currents rather than with the noise figure, since they are independent of source impedance. The noise figure improves as the ratio between source impedance and equivalent noise resistance increases. In addition, in a tuned circuit, the source impedance changes drastically as a function of the offset frequency, and this effect has to be considered. For low phase-noise operation, use a medium-power transistor. If you need your output power to be achieved at 6–9 mA, select a transistor with an $I_{C,\max}$ of 60–90 mA. Also avoid an f_T greater than 3× to 5× the operating frequency. To make transistors that are stable across their full frequency ranges, manufacturers add circuitry that makes the flicker corner frequency higher as f_T increases.

   The following transistors have the lowest noise figure:

   - BFG65/67 by Philips
   - BFR106/92; BFP405/420 by Siemens
   - 2SC3358/3356 by NEC
   - HXTR4105 by HP

- AT2100 (chip) by Avantek

Among the lowest-noise JFETs are the U310, 2N4416/17, and 2N5397.

In designing MMICs, one must resort to MESFETs, which are also referred to as GaAsFETs. They have a fairly high flicker frequency, which is typically around 10 MHz but can go up to as high as 100 MHz.

Table 5-5 shows equivalent circuits and measurement data for the Avantek AT2100 20-GHz *npn* silicon bipolar oscillator transistor. (Siemens of Germany is about to come out with 45-GHz f_T transistors, which will compete with SiGe transistors in the future.)

5. Phase perturbation can be minimized by using high-impedance devices such as FETs, where the signal-to-noise ratio of the signal voltage relative to the equivalent noise voltage can be made very high. This also indicates that in the case of a limiter, the limited voltage should be as high as possible.
6. Choose an active device with low flicker noise. The effect of flicker noise can be reduced through RF feedback. An unbypassed emitter resistor of 10–30 Ω in a bipolar circuit can improve the flicker noise by as much as 40 dB.

   The proper bias point of the active device is important, and precautions should be taken to prevent modulation of the input and output dynamic capacitances of the active device, which will cause amplitude-to-phase conversion and therefore introduce noise.
7. The energy should be coupled from the resonator rather than from another portion of the active device so that the resonator limits the bandwidth.
8. For microwave applications, the lowest-noise GaAsFETs are pseudomorphic HJ FETs. A reproduction of the datasheet of the NEC NE42484A, which is generally the state of the art today, follows; it is used with permission.

Equation (5-116) assumes that the phase perturbation and the flicker effect are the limiting factors, as practical use of such oscillators requires that an isolation amplifier must be used.

In the event that energy is taken directly from the resonator and the oscillator power can be increased, the signal-to-noise ratio can be increased above the theoretical limit of 174 dBc/Hz, due to the low-pass-filter effect of the tuned resonator. However, since this is mainly a theoretical assumption and does not represent a real-world system, this noise performance cannot be obtained. In an oscillator stage, even a total noise floor of –170 dBc/Hz is rarely achieved.

What other influences do we have that cause an oscillator's noise performance to degrade? So far, we have assumed that the Q of the tuned circuit is really determined only by the LC network and the loading effect of the transistor. In synthesizer applications, however, we find it necessary to add a tuning diode. The tuning diode has a substantially lower Q than that of a mica capacitor or even a ceramic capacitor. As a result of this, the noise sidebands change as a function of the additional loss. This is best expressed by adjusting the value for the loaded Q in Eq. (5-113).

There seems to be no precise mathematical way of predetermining the noise influence of a tuning diode, but the following approximation seems to give proper results:

$$\frac{1}{Q_{T,\text{load}}} = \frac{1}{Q_{\text{load}}} + \frac{1}{Q_{\text{diode}}} \tag{5-117}$$

[a]These equivalent circuits are provided only as first-order design aids. Their accuracy for critical designs at very high frequencies has not been validated.

[b]*S* parameters are from the linear equivalent circuit. Below 10 GHz, they have been fit to measurements of die on a standard carrier with one bond wire to the base and four wires to the emitter.

NEC

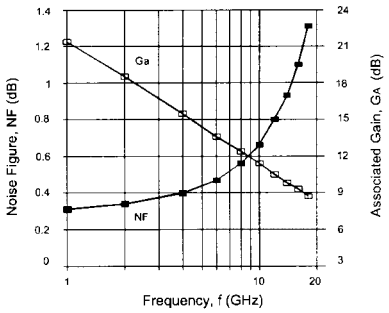
SUPER LOW NOISE PSEUDOMORPHIC HJ FET

NE42484A

FEATURES

- **VERY LOW NOISE FIGURE:** 0.8 dB TYP at 12 GHz
- **HIGH ASSOCIATED GAIN:** 10.5 dB TYP at 12 GHz
- **L_G = 0.35 µm, W_G = 200 µm**
- **LOW COST METAL CERAMIC PACKAGE**
- **TAPE & REEL PACKAGING OPTION AVAILABLE**

NOISE FIGURE & ASSOCIATED GAIN vs. FREQUENCY
V_{DS} = 2 V, I_{DS} = 10 mA



DESCRIPTION

The NE42484A is a pseudomorphic Hetero-Junction FET that uses the junction between Si-doped AlGaAs and undoped InGaAs to create very high mobility electrons. The device features mushroom shaped TiAl gates for decreased gate resistance and improved power handling capabilities. The mushroom gate also results in lower noise figure and high associated gain. This device is housed in an epoxy-sealed, metal/ceramic package and is intended for high volume consumer and industrial applications.

NEC's stringent quality assurance and test procedures ensure the highest reliability and performance.

Notes:
1. Typical values of noise figures and associated gain are those obtained when 50% of the devices from a large number of lots were individually measured in a circuit with the input individually tuned to obtain the minimum value. Maximum values are criteria established on the production line as a "go-no-go" screening tuned for the "generic" type but not for each specimen.
2. R_{TH} (channel to case) for package mounted on an infinite heat sink.

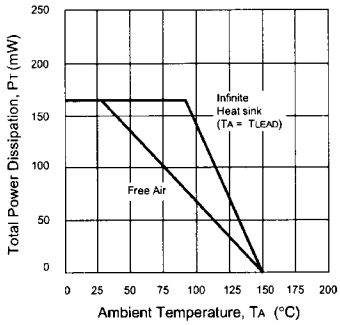
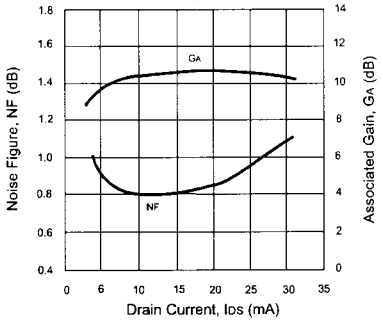
TOTAL POWER DISSIPATION vs. AMBIENT TEMPERATURE[1]

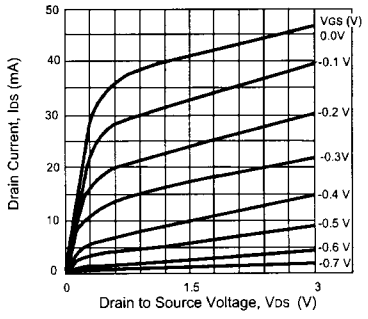


Note
1. If P_T exceeds the Free Air Value, reliable operation can be assured by measuring the worst-case temperature, $T_{(LEAD)}$, at the lead where heat flow is maximum (usually the source lead) and limiting T_A, P_T or $R_{TH\ (CKT)}$

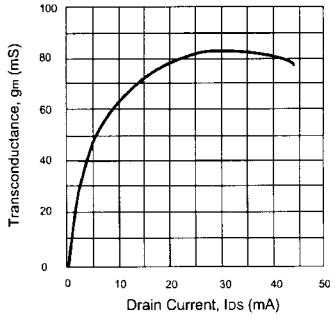
NOISE FIGURE AND ASSOCIATED GAIN vs. DRAIN CURRENT V_{DS} = 2 V, f = 12 GHz



DRAIN CURRENT vs. DRAIN TO SOURCE VOLTAGE



TRANSCONDUCTANCE vs. DRAIN CURRENT V_{DS} = 2.0 V



The tuning diode is specified to have a cutoff frequency $f_{\max}$, which is determined from the loss resistor R_S and the value of the junction capacitance as a function of voltage (e.g., measured at 3 V). This means that the voltage determines the Q and, consequently, the noise bandwidth.

5-6-2 AM-to-PM Conversion

We went into more detail in dealing with the mechanism and influence of tuning diodes in the voltage-controlled oscillators section, where we evaluated the various methods of building voltage-tunable oscillators using tuning diodes. In this section, we limit ourselves to practical results.

The loading effect of the tuning diode is due to losses, and these losses can be described by a resistor in parallel with the tuned circuit.

It is possible to define an equivalent noise $R_{a,\text{eq}}$ that, inserted in Nyquist's equation,

$$V_n = \sqrt{4kT_0R\,\Delta f} \tag{5-118}$$

where $kT_0 = 4.2 \times 10^{-21}$ at about 300 K, R is the equivalent noise resistor, and Δf is the bandwidth, determines an open-circuit noise voltage across the tuning diode. Practical values of $R_{a,\text{eq}}$ for carefully selected tuning diodes are in the vicinity of 200 Ω to 50 kΩ. If we now determine the noise voltage $V_n = \sqrt{4 \times 4.2 \times 10^{-21} \times 10{,}000}$, the resulting voltage value is 1.296×10^{-8} V $\sqrt{\text{Hz}}$.

This noise voltage generated from the tuning diode is now multiplied with the VCO gain K_0, resulting in the rms frequency deviation

$$(\Delta f_{\text{rms}}) = K_0 \times (1.296 \times 10^{-8}\ \text{V}) \text{ in 1-Hz bandwidth} \tag{5-119}$$

To translate this into an equivalent peak phase deviation,

$$\theta_d = \frac{K_0\sqrt{2}}{f_m}(1.296 \times 10^{-8}) \text{ rad in 1-Hz bandwidth} \tag{5-120}$$

or for a typical oscillator gain of 100 kHz/V,

$$\theta_d = \frac{0.00183}{f_m} \text{ rad in 1-Hz bandwidth} \tag{5-121}$$

For f_m = 25 kHz (typical spacing for adjacent-channel measurements for FM mobile radios), $\theta_c = 7.32 \times 10^{-8}$. This can be converted now into the SSB signal-to-noise ratio:

$$\mathcal{L}(f_m) = 20 \log_{10}\left(\frac{\theta_c}{2}\right) = -149 \text{ dBc/Hz} \tag{5-122}$$

For the typical oscillator gain of 10 MHz/V found in wireless applications, the resulting phase noise will be 20 dB worse [10 log (10 MHz ÷ 100 kHz)]. However, the best tuning diodes, like the BB104, have an R_n of 200 Ω instead of 10 kΩ, which again changes the picture. According to Eq. (5-118), with $kT_0 = 4.2 \times 10^{-21}$ the resulting noise voltage will be

$$V_n = \sqrt{4 \times 4.2 \times 10^{-21} \times 200}$$

$$= 1.833 \times 10^{-9} \text{ V}\sqrt{\text{Hz}} \tag{5-123}$$

From Eq. (5-114), the equivalent peak phase deviation for a gain of 10 MHz/V in a 1-Hz bandwidth is then

$$\theta_d = \frac{1 \times 10^7 \sqrt{2}}{f_m} (1.833 \times 10^{-9}) \text{ rad} \tag{5-124}$$

or

$$\theta_d = \frac{0.026}{f_m} \text{ rad in 1-Hz bandwidth} \tag{5-125}$$

With $f_m = 25$ kHz, $\theta_c = 1.04 \times 10^{-6}$. Expressing this as phase noise:

$$\mathcal{L}(f_m) = 20 \log_{10}\left(\frac{\theta_c}{2}\right) = -126 \text{ dBc/Hz} \tag{5-126}$$

The phase-noise value in Eq. (5-122) is that typically achieved in the Rohde & Schwarz SMDU or with the Hewlett-Packard 8640 signal generator and considered state-of-the-art for a free-running oscillator. It should be noted that both signal generators use a slightly different tuned circuit; the Rohde & Schwarz generator uses a helical resonator, whereas the Hewlett-Packard generator uses an electrically shortened quarter-wavelength cavity. Both generators are mechanically pretuned, and a tuning diode with a gain of about 100 kHz/V is used for AFC and frequency-modulation purposes. It is apparent that, because of the nonlinearity of the tuning diode, the gain is different for low dc voltages than for high dc voltages. The impact of this is that the noise varies with the tuning range.

If this oscillator had to be used for a synthesizer, its 1-MHz tuning range would be insufficient; therefore, a way had to be found to segment the band into the necessary ranges. In VCOs, this is typically done with switching diodes that allow the proper frequency bands to be selected. These switching diodes insert in parallel or series, depending on the circuit, with additional inductors or capacitors, depending on the design.

In low-energy-consuming circuits, the VCO frequently is divided into a coarse-tuning section using tuning diodes and a fine-tuning section with a tuning diode. In the coarse-tuning range, this results in very high gains, such as 1–10 MHz/V, for the diodes. The noise contribution of those diodes is therefore very high and can hardly be compensated by the loop. For low-noise applications, which automatically mean higher power consumption, it is unavoidable to use switching diodes.

Let us now examine some test results. Referring back to Eq. (5-106), Figure 5-71 shows the noise sideband performance as a function of Q, whereby the top curve with $Q_L = 100$ represents a somewhat poor oscillator and the lowest curve with $Q_L = 100{,}000$ probably represents a crystal oscillator where the unloaded Q of the crystal was in the vicinity of 3×10^6. Figure 5-72 shows the influence of flicker noise.

Corner frequencies of 10 Hz to 10 kHz have been selected, and it becomes apparent that around 1 kHz the influence is fairly dramatic, whereas the influence at 20 kHz off the carrier

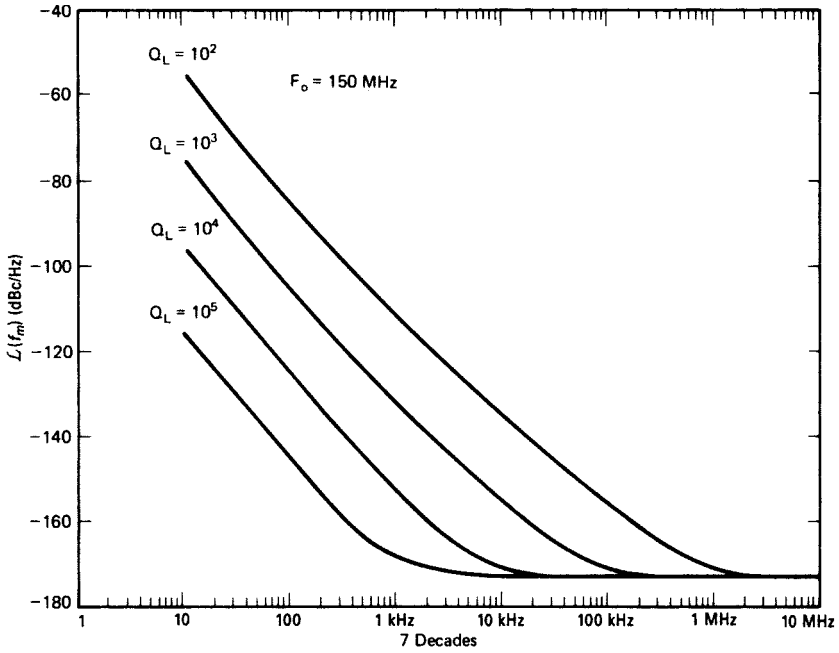


Figure 5-71 Noise sideband of an oscillator at 150 MHz as a function of the loaded Q of the resonator.

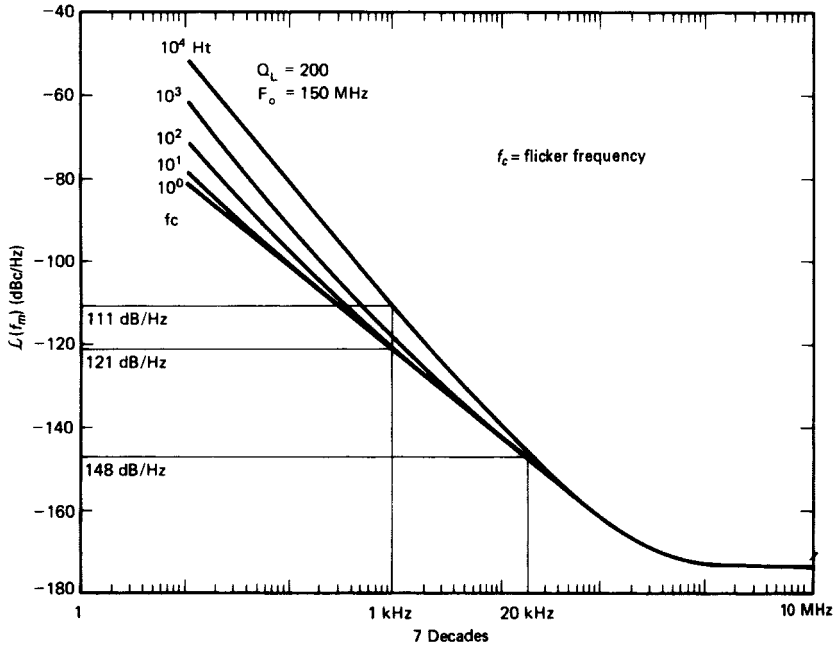

Figure 5-72 Noise-sideband performance as a function of the flicker frequency f_c varying from 10 Hz to 10 kHz.

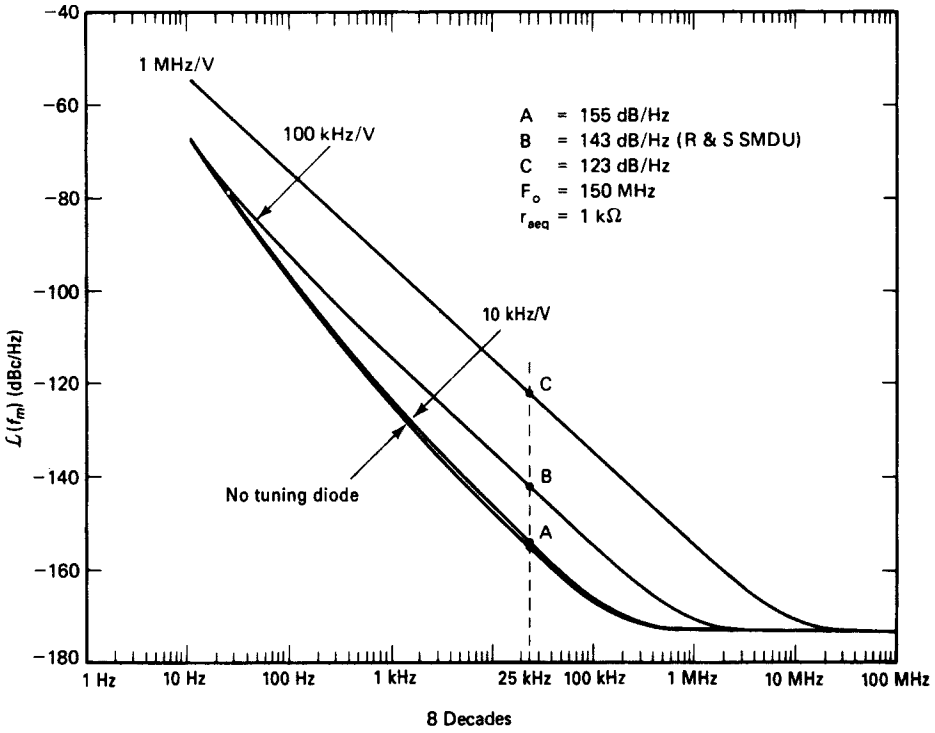

Figure 5-73 Noise-sideband performance of an oscillator at 150 MHz, showing the influence of various tuning diodes.

is not significant. Figures 5-73 and 5-74 show the influence of the tuning diodes on a high-Q oscillator.

Curve A in Figure 5-73 uses a lightly coupled tuning diode with a K_0 of 10 kHz/V; the lower curve is the noise performance without any diode. As a result, the two curves are almost identical, which can be seen from the somewhat smeared form of the graph. Curve B shows the influence of a tuning diode at 100 kHz/V and represents a value of −143 dBc/Hz from −155 dBc/Hz, already some deterioration. Curve C shows the noise if the tuning diode results in a 1-MHz/V VCO gain, and the noise sideband at 25 kHz has now deteriorated to −123 dBc/Hz. These curves speak for themselves.

Figure 5-74 shows how the phase noise of a 147-MHz VCO varies with the bias applied to its tuning diode. Because a tuning diode's Q increases with the reverse bias applied to it, we expect a VCO's phase-noise performance to improve, even if only slightly, as its tuning voltage is increased. Yet Figure 5-74 illustrates the reverse of this relationship. Inspecting this VCO's circuit (Figure 5-75), we see that the diode is in series with the circuit's 220-nH resonator. *All* of the RF current flowing through the resonator must flow through the relatively low-Q diode, and even small decreases in the diode's capacitance will significantly modify the tank's L/C ratio.

Graphing the diode's ac load line (Figure 5-76), we see that as the tuning voltage increases (i.e., as the tuning diode capacitance decreases), the RF voltage across the diode becomes disproportionately high. We note also that at every value of tuning voltage, the RF voltage across the diode goes positive (relative to the anode) during part of each cycle.

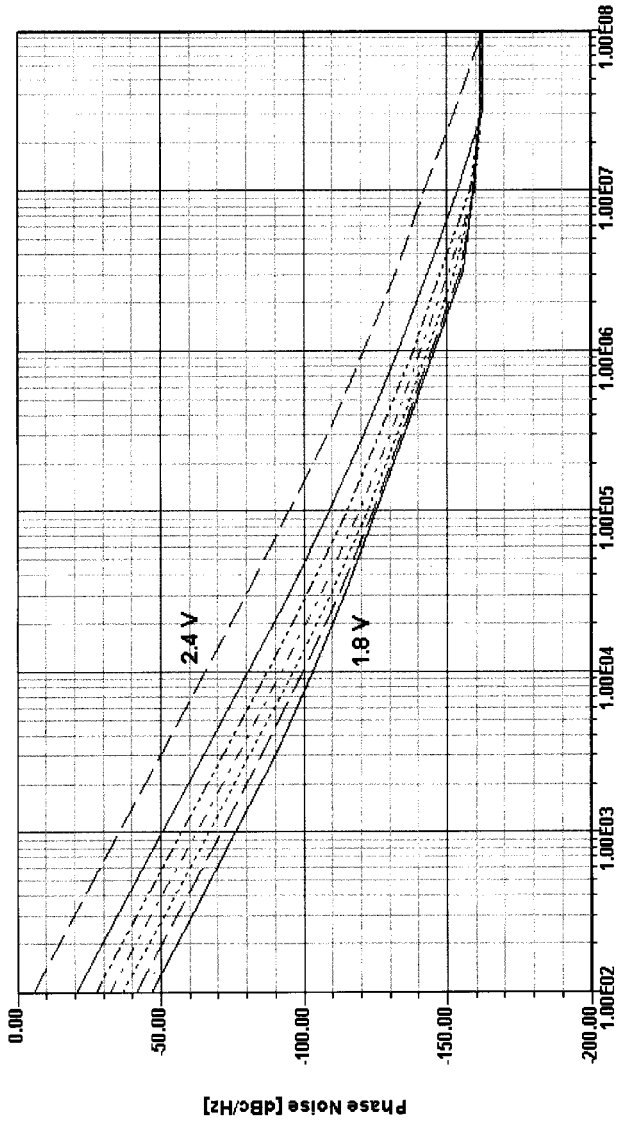

Figure 5-74 Noise-sideband performance of an oscillator at 147 MHz, showing the influence of a tuning diode operated at bias voltages from 1.8 to 2.4 V in 0.1-V increments.

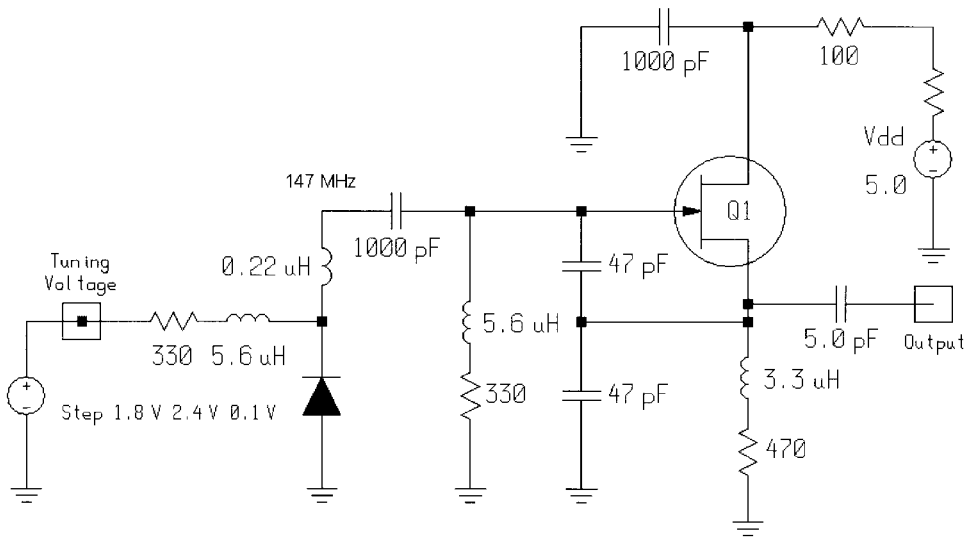

Figure 5-75 The VCO schematic. Because the tuning diode is in series with the resonator, it passes all of the tank's RF current and plays a disproportionately large role in determining the circuit's phase-noise performance.

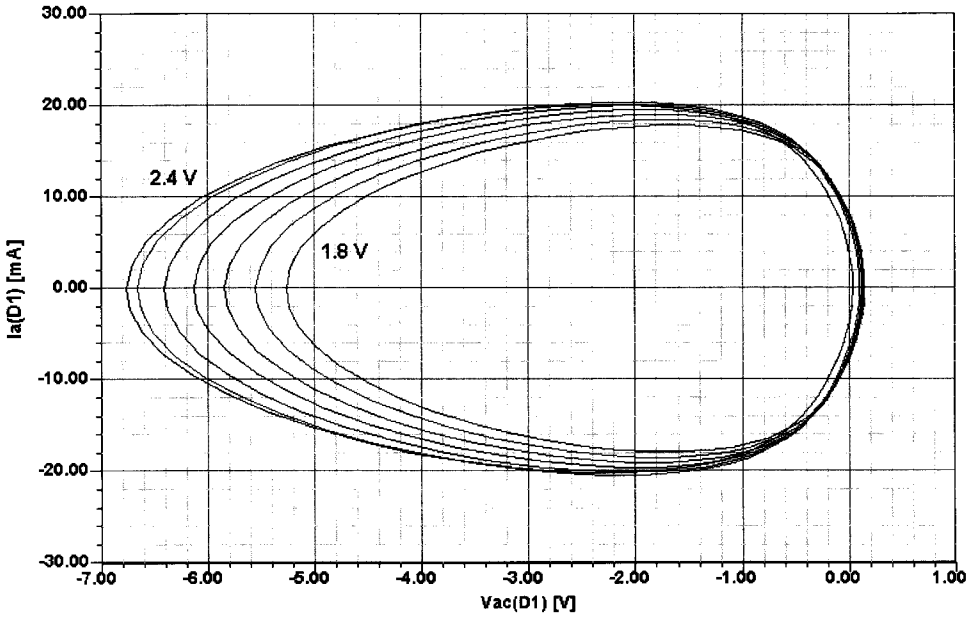

Figure 5-76 Graphing the tuning diode's ac load line reveals that increasing the diode's tuning bias (decreasing its capacitance) results in a disproportionally large increase in the RF voltage across the diode. At all tuning voltages, the RF voltage across the diode is slightly positive (relative to the anode) during part of each cycle.

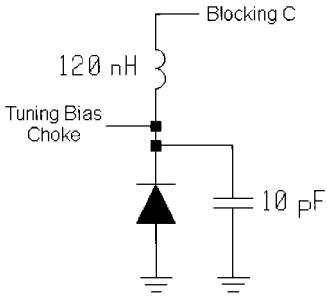

Figure 5-77 Adding capacitance across the tuning diode reduces the effect of its nonlinearities on phase-noise performance. We have also revalued the resonator to 120 nH to maintain oscillation near 147 MHz.

Modifying the oscillator tank to add capacitance in parallel with the tuning diode (Figure 5-77) reduces the tuning diode's effect on tank Q and L/C ratio, and therefore its contribution to phase noise. With this arrangement, we now see the expected relationship between tuning bias and phase noise: The higher the tuning bias, the lower the phase noise (Figure 5-78). Figure 5-79 shows that the diode's ac load line is now virtually unchanged across the tuning-voltage range. The RF voltage across the diode still goes positive (relative to the anode) during part of each cycle.

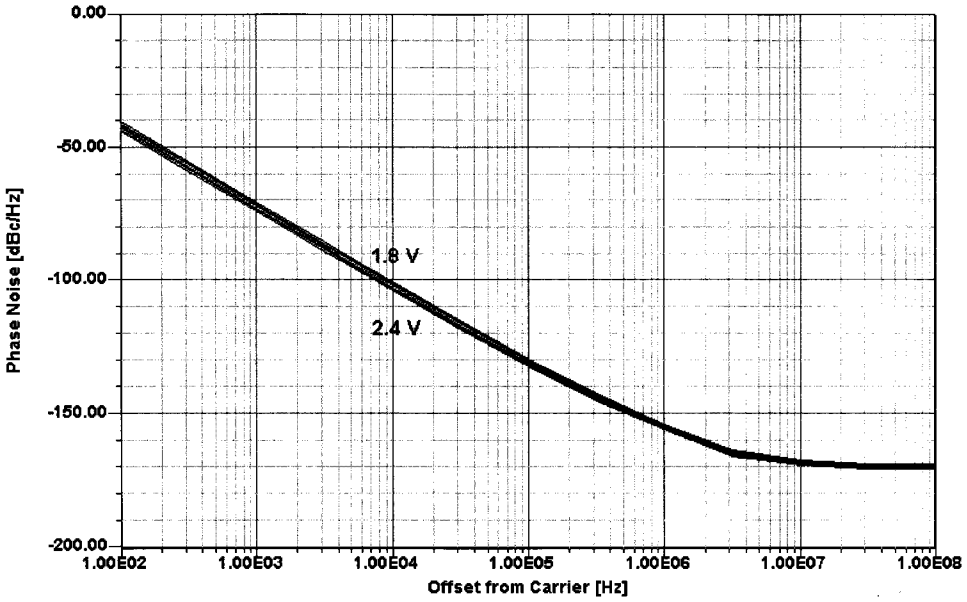

Figure 5-78 Now that the tuning diode passes only part of the tank's RF current, varying its capacitance does not result in the large change in phase-noise performance shown in Figure 5-74. Note also that the phase-noise-versus-tuning-bias relationship has reversed relative to that shown in Figure 5-74: The highest tuning voltage now corresponds to the lowest phase noise.

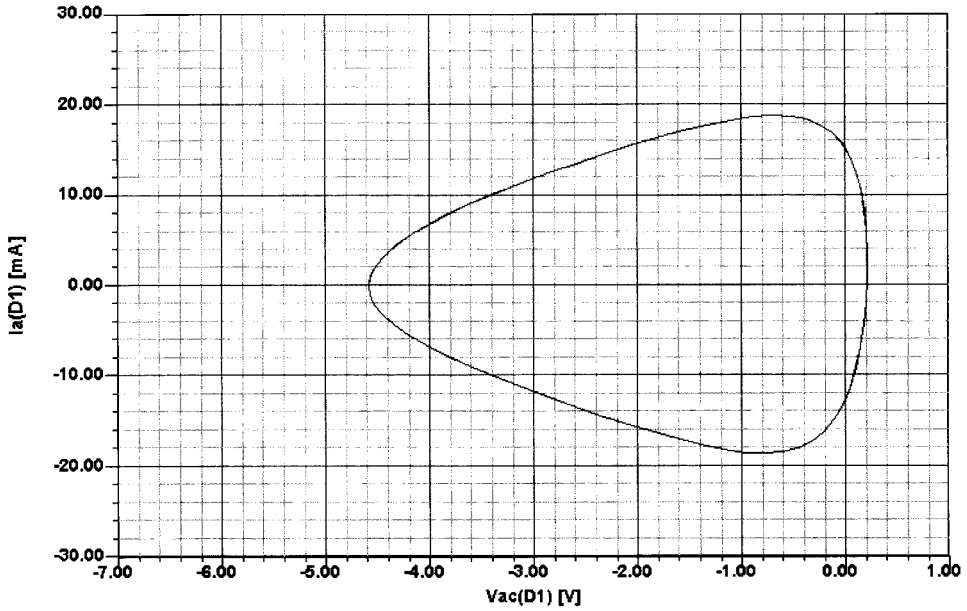

Figure 5-79 The ac load line for the tuning diode in Figure 5-77. Now the voltage swing across the diode is virtually the same at all tuning voltages. The RF voltage across the diode still goes positive (relative to the anode) during part of the cycle.

Figure 5-80 shows one more modification to the VCO tank. Now, the tuning diode is lightly coupled to the hot end of the tank, in parallel with the resonator. The result is phase-noise performance that is essentially unchanged across the 1.8–2.4-V tuning-voltage range. Figure 5-81 compares this circuit's phase-noise performance with the worst-case performance of the tank configurations in Figures 5-75 and 5-77. Figure 5-82 compares the diode ac load lines that correspond to the phase-noise curves in Figure 5-81. The best phase-noise performance corresponds to the diode ac load line that exhibits the narrowest voltage swing and never goes positive relative to the anode.

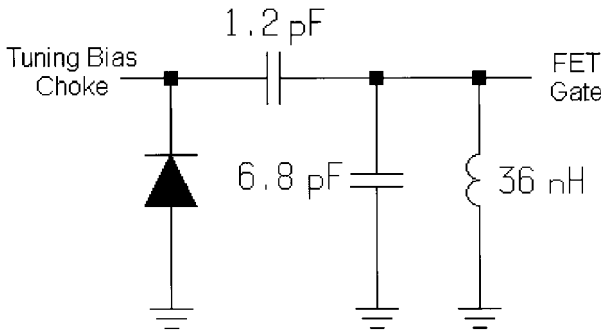

Figure 5-80 Tank circuit reconfigured as per Figure 5-54 to lightly couple the tuning diode in parallel with the resonator, with the resonator inductance again decreased to maintain oscillation near 147 MHz. The 1000-pF capacitor and gate choke of Figure 5-75 (5.6 μH in series with 330 Ω) are no longer needed.

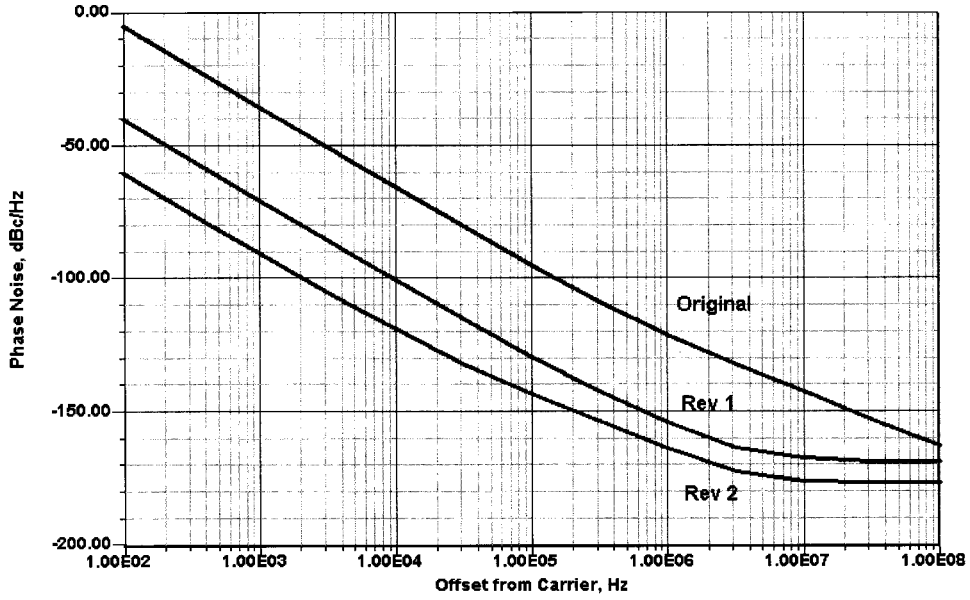

Figure 5-81 Comparison of worst-case phase-noise performance obtained with the tank configurations of Figures 5-75 (Original), 5-77 (Rev 1), and 5-80 (Rev 2).

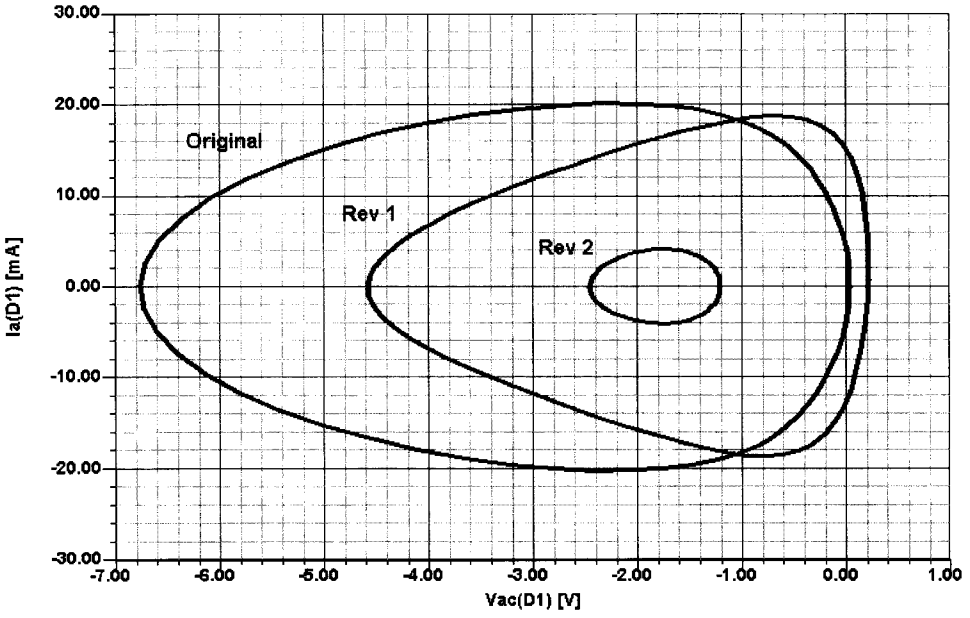

Figure 5-82 Comparison of the tuning diode's ac load line for the worst-case phase-noise curves of Figure 5-79.

It's important to keep in mind that we have not gained something for nothing in achieving the best phase-noise response in Figure 5-81. As we reduced the diode's phase-noise contribution, we also reduced the oscillator's tuning range—from 7.1% (Figure 5-75 circuit) to 1.8% (Figure 5-77 circuit) to 0.046% (Figure 5-80). Simultaneously optimizing phase-noise performance and tuning range requires a combination of techniques. First, we would maximize diode Q by using as high a tuning voltage as feasible. Second, we would use antiseries-connected diodes to minimize the RF voltage swing across them (Figure 5-55). Both of these techniques work against the achievement of wide tuning ranges by minimizing the capacitance swing that the diodes can contribute. As a result of this, and because hyperabrupt diodes are not available for the frequencies at which wireless VCOs operate, we would therefore use multiple antiseries diode pairs in parallel.

It is of interest to compare various oscillators. Figure 5-83 shows the performance of a 10-MHz crystal oscillator, a 40-MHz *LC* oscillator, the HP8640 cavity-tuned oscillator at 500 MHz, the 310–640-MHz switched-reactance oscillator of the HP8662 oscillator, and a 2–6-GHz YIG oscillator at 6 GHz.

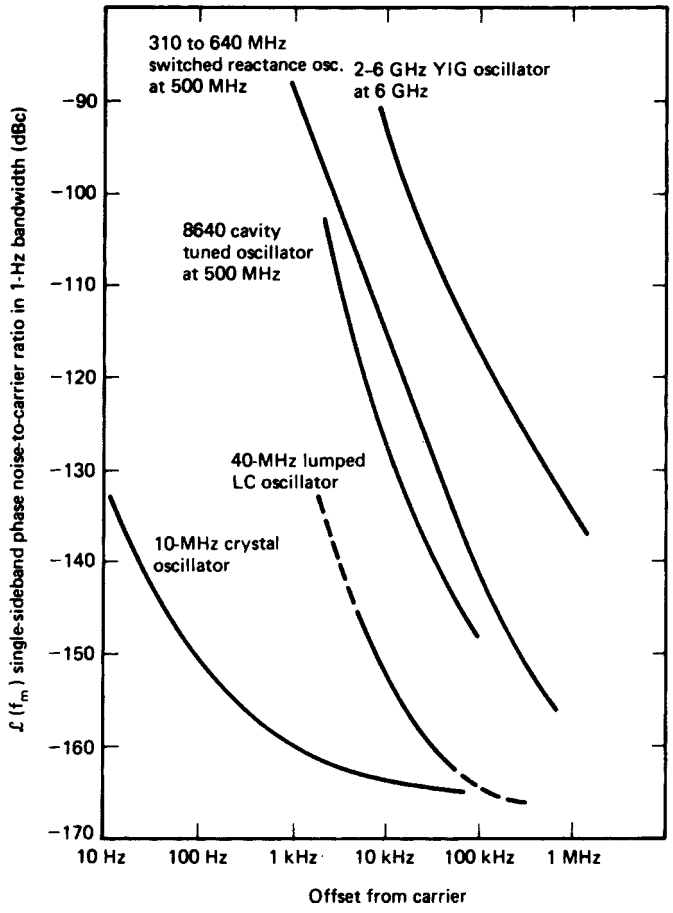

Figure 5-83 Comparison of noise-sideband performances of a crystal oscillator, *LC* oscillator, cavity-tuned oscillator, switched-reactance oscillator, and YIG oscillator.

5-6-3 Nonlinear Approach to the Calculation of Oscillator Phase Noise

The mechanism of noise generation in an oscillator combines the equivalent of frequency conversion (mixing) with the effect of AM-to-PM conversion. Therefore, to calculate oscillator phase noise, we must first be able to calculate the noise figure of a mixer. The following nonlinear approach is based on Ulrich L. Rohde, Chao-Ren Chang, and Jason Gerber, "Design and Optimization of Low-Noise Oscillators Using Nonlinear CAD Tools," *IEEE Frequency Control Symposium Proceedings*, 1994, pp. 548–554. This section presents the use of a novel algorithm for the computation of SSB carrier noise in free-running oscillators using the harmonic-balance (HB) nonlinear technique.

Traditional approaches relying on frequency conversion analysis are not sufficient to describe the complex physical behavior of a noisy oscillator. The accuracy of this nonlinear approach is based on the dynamic range of the harmonic-balance simulator and the quality of the parameter extraction for the active device. The algorithm described has also been verified with several examples up to millimeter wavelengths. This is the only algorithm that provides a complete and rigorous treatment of noise analysis for autonomous circuits.

Noise Generation in Oscillators. As shown earlier, the qualitative linearized picture of noise generation in oscillators is very well known [9]. The physical effects of random fluctuations taking place in the circuit are different depending on their spectral allocation with respect to the carrier:

- Noise components at low-frequency deviations result in frequency modulation of the carrier through mean square frequency fluctuation proportional to the available noise power.
- Noise components at high-frequency deviations result in phase modulation of the carrier through mean square phase fluctuation proportional to the available noise power.

We will demonstrate that the same conclusions can be derived quantitatively from the HB equations for an autonomous circuit.

Equivalent Representation of a Noisy Nonlinear Circuit. A general noisy nonlinear network can be described by the equivalent circuit shown in Figure 5-84. The circuit is divided into linear and nonlinear subnetworks as noise-free multiports. Noise generation is accounted for by connecting a set of noise voltage and noise current sources at the ports of the linear subnetwork [9–18].

Frequency Conversion Approach. The circuit supports a large-signal time-periodic steady state of fundamental angular frequency ω_0(carrier). Noise signals are small perturbations superimposed on the steady state, represented by families of pseudosinusoids located at the sidebands of the carrier harmonics. Therefore, the noise performance of the circuit is determined by the exchange of power among the sidebands of the unperturbed steady state through frequency conversion in the nonlinear subnetwork. Due to the perturbative assumption, the nonlinear subnetwork can be replaced with a multifrequency linear multiport described by a conversion matrix. The flow of noise signals can be computed by means of conventional linear circuit techniques.

The frequency conversion approach frequently used has limitations. The frequency-conversion approach is not sufficient to predict the noise performance of an autonomous

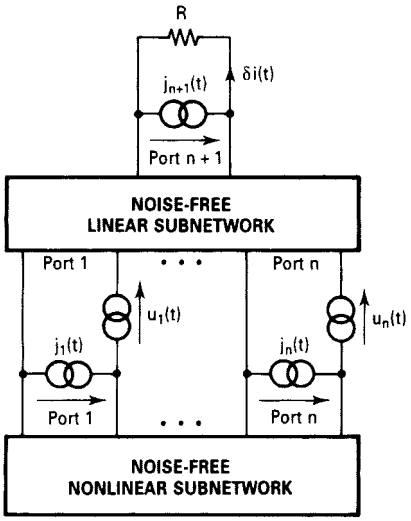

Figure 5-84 Equivalent circuit of a general noisy nonlinear network.

circuit. The spectral density of the output noise power and, consequently, the PM noise computed by the conversion analysis are proportional to the available power of the noise sources.

- In the presence of both thermal and flicker noise sources, PM noise increases as ω^{-1} for $\omega \to 0$ and tends to a finite limit for $\omega \to \infty$.
- Frequency conversion analysis correctly predicts the far-carrier noise behavior of an oscillator and, in particular, the oscillator noise floor; it does not provide results consistent with the physical observations at low deviations from the carrier.

This inconsistency can be removed by adding the modulation noise analysis. In order to determine the far-away noise using the autonomous circuit perturbation analysis, the following applies.

The circuit supports a large-signal time-periodic autonomous regime. The circuit is perturbed by a set of small sources located at the carrier harmonics and at the sidebands at a deviation ω from carrier harmonics. The perturbation of the circuit state (δX_B, δX_H) is given by the uncoupled sets of equations:

$$\frac{\partial E_B}{\partial E_B}\,\delta X_B = J_B(\omega) \tag{5-127}$$

$$\frac{\partial E_H}{\partial E_H}\,\delta X_H = J_H(\omega) \tag{5-128}$$

where E_B, E_H = vectors of HB errors
X_B, X_H = vectors of state-variable (SV) harmonics (since the circuit is autonomous, one of the entries X is replaced by the fundamental frequency ω_0)
J_B, J_H = vectors of forcing terms

The subscripts *B* and *H* denote sidebands and carrier harmonics, respectively.

For a spot noise analysis at a frequency ω, the noise sources can be interpreted in either of two ways:

- Pseudosinusoids with random amplitude and phase located at the sidebands. This noise generation mechanism is described by Eq. (5-127), which is essentially a frequency conversion equation relating the sideband harmonics of the state variables and of the noise sources. This description is exactly equivalent to the one provided by the frequency conversion approach. This mechanism is referred to as *conversion noise* [19–21].
- Sinusoids located at the carrier harmonics and randomly phase and amplitude modulated by pseudosinusoidal noise at frequency ω. This noise generation mechanism is described by Eq. (5-128), which describes noise-induced jitter of the circuit-state, represented by the vector δX_H. The modulated perturbing signals are represented by replacing the entries of J_H with the complex modulation laws. This mechanism is referred to as *modulation noise.* One of the entries of δX_H is $\delta\omega_0$, where $\delta\omega_0(\omega)$ is the phasor of the pseudosinusoidal components of the fundamental frequency fluctuations in a 1-Hz band at frequency ω. Equation (5-128) provides a frequency jitter with a mean square value proportional to the available noise power. In the presence of both thermal and flicker noise, PM noise increases as ω^{-3} for $\omega \to 0$ and tends to 0 for $\omega \to \infty$. Modulation noise analysis correctly describes the noise behavior of an oscillator at low deviations from the carrier and does not provide results consistent with physical observations at high deviations from the carrier.

The combination of both phenomena explains the noise in the oscillator shown in Figure 5-85, where the near-carrier noise dominates below ω_X and far-carrier noise dominates above ω_X. Figure 5-86 (itemized form) shows the noise sources as they are applied at the IF. We have arbitrarily defined the low oscillator output as IF. This applies to the conversion matrix calculation.

Figure 5-87 shows the contributions that have to be taken into consideration for calculation of the noise at the output. The accuracy of the calculation of the phase noise depends highly on the quality of the parameter extraction for the nonlinear device; in particular, high-frequency phenomena must be modeled properly. In addition, the flicker noise contribution is essential. This is also valid for mixer noise analysis.

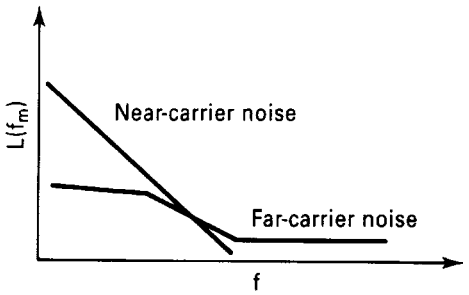

Figure 5-85 Oscillator noise components.

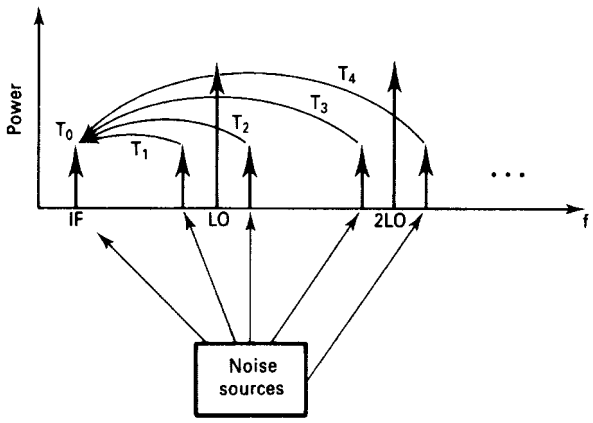

Figure 5-86 Noise sources where the noise at each sideband contributes to the output noise at the IF through frequency conversion.

Figure 5-88 shows the measured phase noise at 10 kHz of the carrier of an 800-MHz oscillator and the simulated result. The good agreement between measured and predicted data is worth noticing. At currents above 5 mA, the simulation becomes inaccurate as breakdown effects occur that were not part of the simulation.

Conversion Noise Analysis. The actual mathematics used to calculate the noise result (Ansoft Serenade 8.*x*) are as follows.

kth Harmonic PM Noise

$$\langle |\delta\Phi_k(\omega)|^2 \rangle = \frac{N_k(\omega) - N_{-k}(\omega) - 2\,\mathrm{Re}[C_k(\omega)]}{R|I_k^{SS}|^2} \tag{5-129}$$

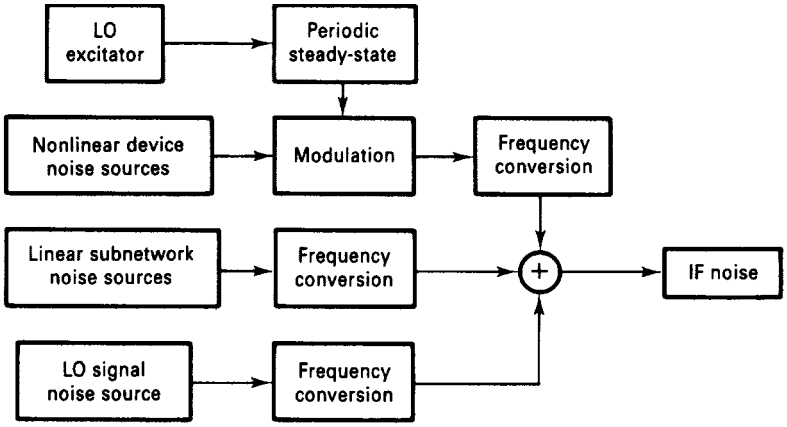

Figure 5-87 Noise mechanisms.

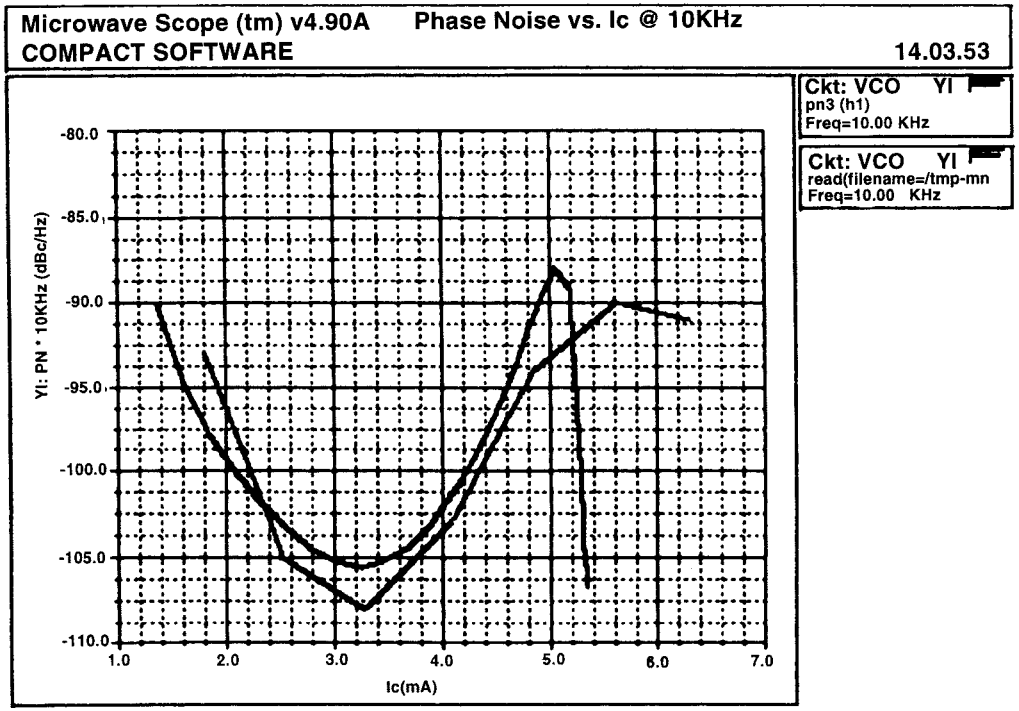

Figure 5-88 Bias-dependent measured and predicted phase noise at 10 kHz off the carrier of an 800-MHz oscillator.

kth Harmonic AM Noise

$$\langle |\delta A_k(\omega)|^2 \rangle = 2\,\frac{N_k(\omega) - N_{-k}(\omega) + 2\,\mathrm{Re}[C_k(\omega)]}{R|I_k^{SS}|^2} \tag{5-130}$$

kth Harmonic PM–AM Correlation Coefficient

$$C_k^{\mathrm{PMAM}}(\omega) = \langle \delta\Phi_k(\omega)\delta A_k(\omega)^* \rangle = -\sqrt{2}\,\frac{2\,\mathrm{Im}[C_k(\omega)] + j[N_k(\omega) - N_{-k}(\omega)]}{R|I_k^{SS|^2}} \tag{5-131}$$

where

$N_k(\omega)$, $N_{-k}(\omega)$ = noise power spectral densities at the upper and lower sidebands of the kth harmonic
$C_k(\omega)$ = normalized correlation coefficient of the upper and lower sidebands of the kth carrier harmonic
R = load resistance
I_k^{SS} = kth harmonic of the steady-state current through the load

Modulation Noise Analysis

kth Harmonic PM Noise

$$\langle |\delta\Phi_k(\omega)|^2 \rangle = \frac{k^2}{\omega^2}\,\mathrm{T}_F\,\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_F^t \tag{5-132}$$

kth Harmonic AM Noise

$$\langle |\delta A_k(\omega)|^2 \rangle = \frac{2}{|I_k^{SS}|^2}\,\mathrm{T}_{Ak}\,\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_{Ak}^t \tag{5-133}$$

kth Harmonic PM–AM Correlation Coefficient

$$C_k^{\mathrm{PMAM}}(\omega) = \langle \delta\Phi_k(\omega)\delta A_k(\omega)^* \rangle = \frac{k\sqrt{2}}{j\omega|I_K^{SS}|^2}\,\mathrm{T}_F\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_{Ak}^t \tag{5-134}$$

where $\mathrm{J}_H(\omega)$ = vector of Norton equivalent of the noise sources
T_F = frequency transfer matrix
I_k^{SS} = kth harmonic of the steady-state current through the load

Experimental Variations. We will look at two examples where we compare predicted and measured data. Figure 5-89 shows the abbreviated circuit of a 10-MHz crystal oscillator. It uses a high-precision, high-Q crystal made by companies such as Bliley. Oscillators like this are intended for use as frequency and low-phase-noise standards. In this case, the circuit under consideration is part of the HP3048 phase-noise measurement system.

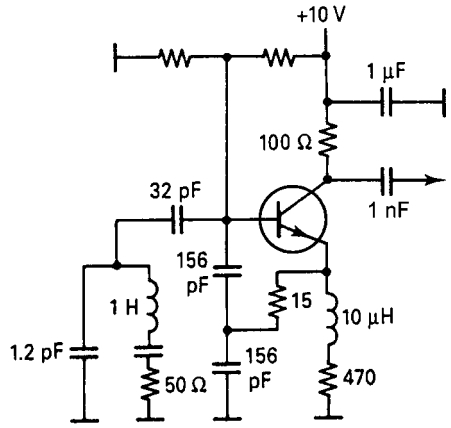

Figure 5-89 Abbreviated circuit of a 10-MHz crystal oscillator.

Figure 5-90 shows the measured phase noise of this HP frequency standard, and Figure 5-91 shows the phase noise predicted using the mathematical approach outlined above.

In cooperation with Motorola, we also analyzed an 800-MHz VCO. In this case, we also did the parameter extraction for the Motorola transistor. Figure 5-92 shows the circuit, a Colpitts oscillator that uses RF feedback in the form of a 15-Ω resistor and a capacitive

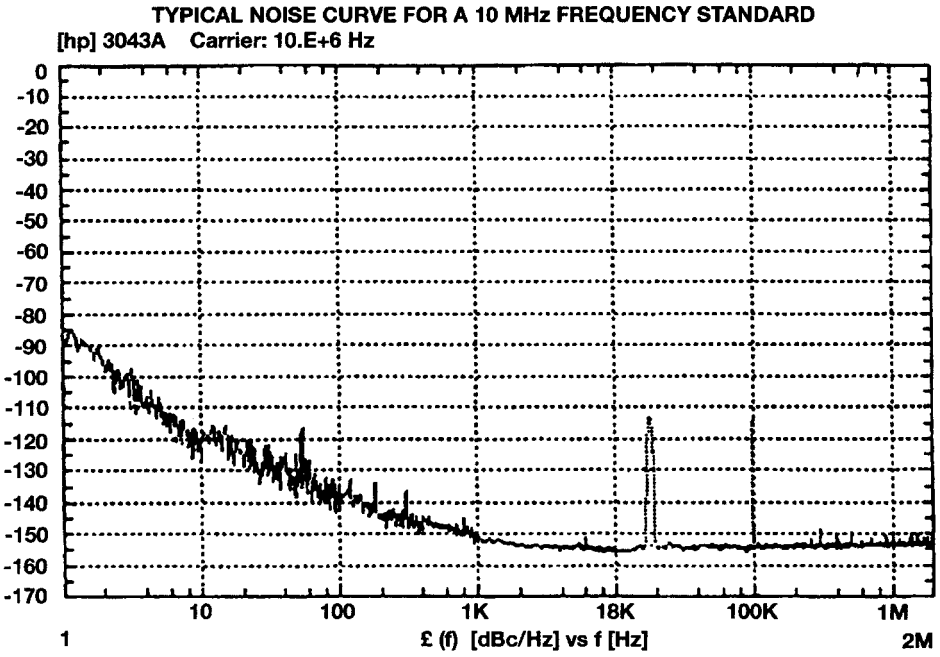

Figure 5-90 Measured phase noise for this frequency standard by HP.

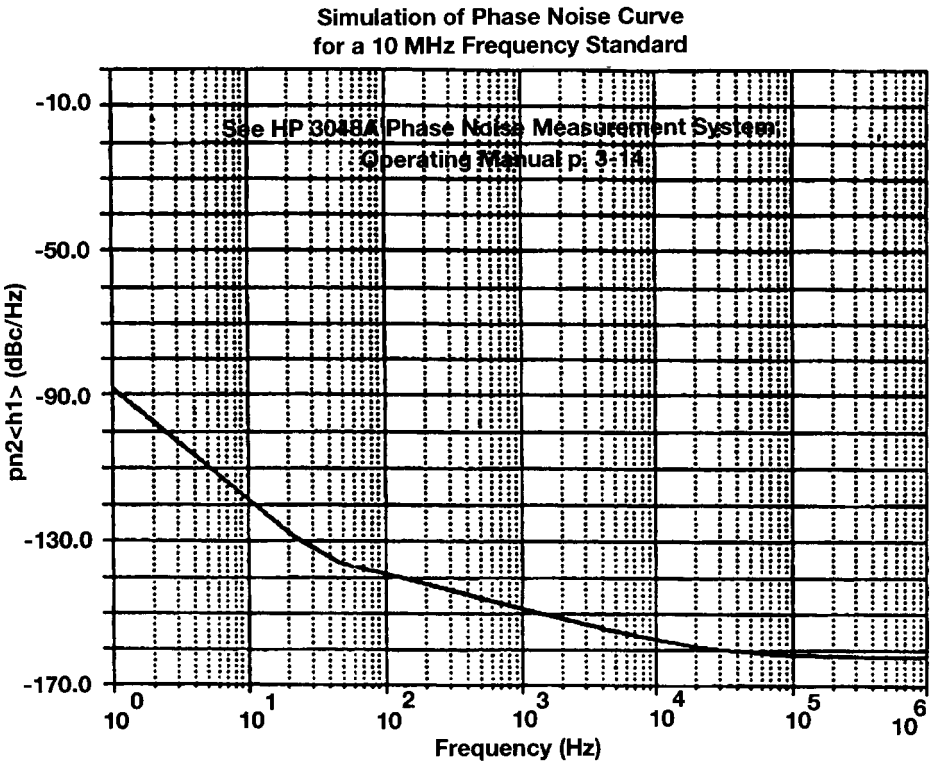

Figure 5-91 Simulated phase noise of the oscillator shown in Figure 5-89.

voltage divider consisting of 1 pF between the BJT's base and the feedback resistor, and 1 pF between the feedback resistor and common. Also, the tuned circuit is loosely coupled to this part of the transistor circuit. Figure 5-93 shows a comparison between predicted and measured phase noise for this oscillator. Figures 5-94, 5-95, and 5-96 show the oscillator's predicted output waveform, spectrum, and dc I–V and ac load line responses, respectively.

Phase Noise Optimization. By allowing the simulator's optimizer to vary the oscillator's feedback and dc operating point, phase noise can be improved. The values that were allowed to vary were the values of the capacitors in the feedback voltage divider, the value of a negative-feedback resistor (starting value, 15 Ω) that reduces AM–PM conversion, and the emitter resistor, which changes the transistor's dc bias and therefore affects its bias-dependent flicker noise. Figure 5-97 shows the improvement of the 800-MHz VCO as previously shown. While the close-in phase noise can be improved drastically by approximately 32 dB, the far-out noise at 20 MHz and beyond is deteriorated. This is due to the resistive feedback, which reduces AM-to-PM conversion [22–24].

In testing an oscillator's resistance to frequency pushing (frequency shift with supply-voltage changes), variations in phase noise can be observed. Phase noise is also bias dependent,

and this fact can be used for phase-noise optimization. Figure 5-98 shows the phase noise of an oscillator as its supply voltage is varied.

Summary. This section has demonstrated the power of harmonic-balance simulation in the design of low-phase-noise oscillators. The simulator can be used to accurately predict close-in and far-out phase noise based on the contribution of the transistor, the loaded Q of the resonator, and, in the case of a VCO, the contribution of the tuning diode.

This is the first time that a bias-dependent noise model for both FETs and bipolar transistors has been developed and used for this type of application, in which optimization is allowed to vary circuit components and the bias point for best performance.

Practical examples ranging from a 10-MHz crystal oscillator to a 1-GHz CR oscillator have been supplied. The theoretical background for the nonlinear oscillator and its validation have been presented.

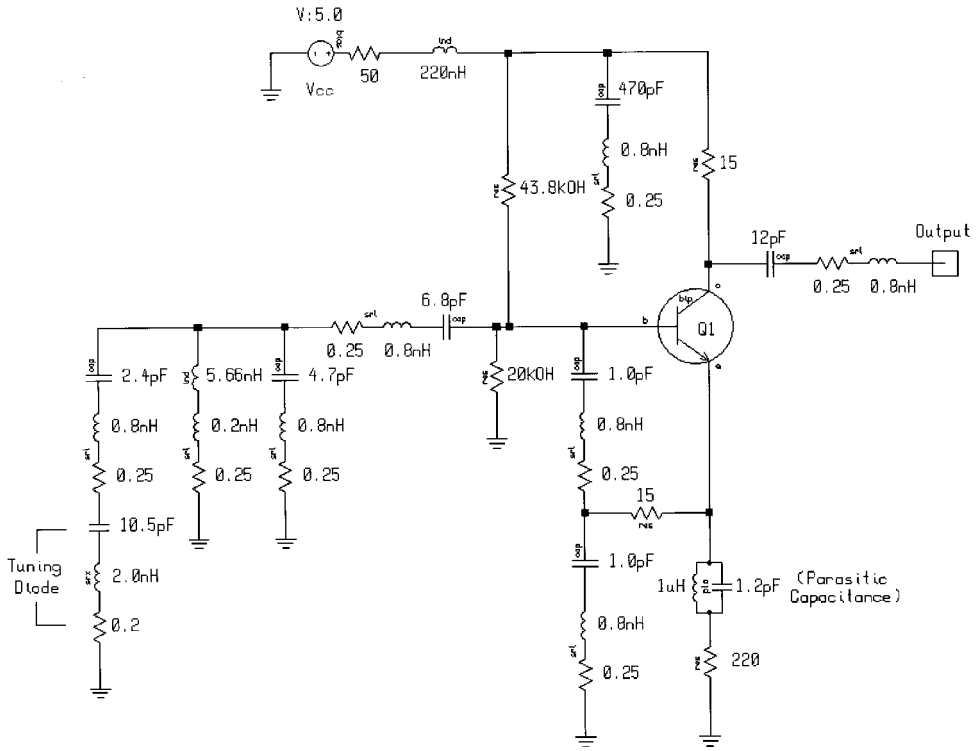

Figure 5-92 Colpitts oscillator that uses RF negative feedback between the emitter and capacitive voltage divider. To be realistic, we used actual components rather than ideal ones. The suppliers for the capacitors and inductors provide some typical values for the parasitics. The major changes are 0.8 nH and 0.25 Ω in series with the capacitors. The same thing applies for the main inductance, which has a parasitic connection inductance of 0.2 nH in series with a 0.25-Ω resistance. These types of parasitics are valid for a fairly large range of components assembled in surface-mount applications. Most engineers model the circuit only by assuming lossy devices, not adding these important parasitics. One of the side-effects we have noticed is that the output power is more realistic and, needless to say, the simulated phase noise agrees quite well with measured data. This circuit can also serve as an example for modeling amplifiers and mixers using surface-mount components.

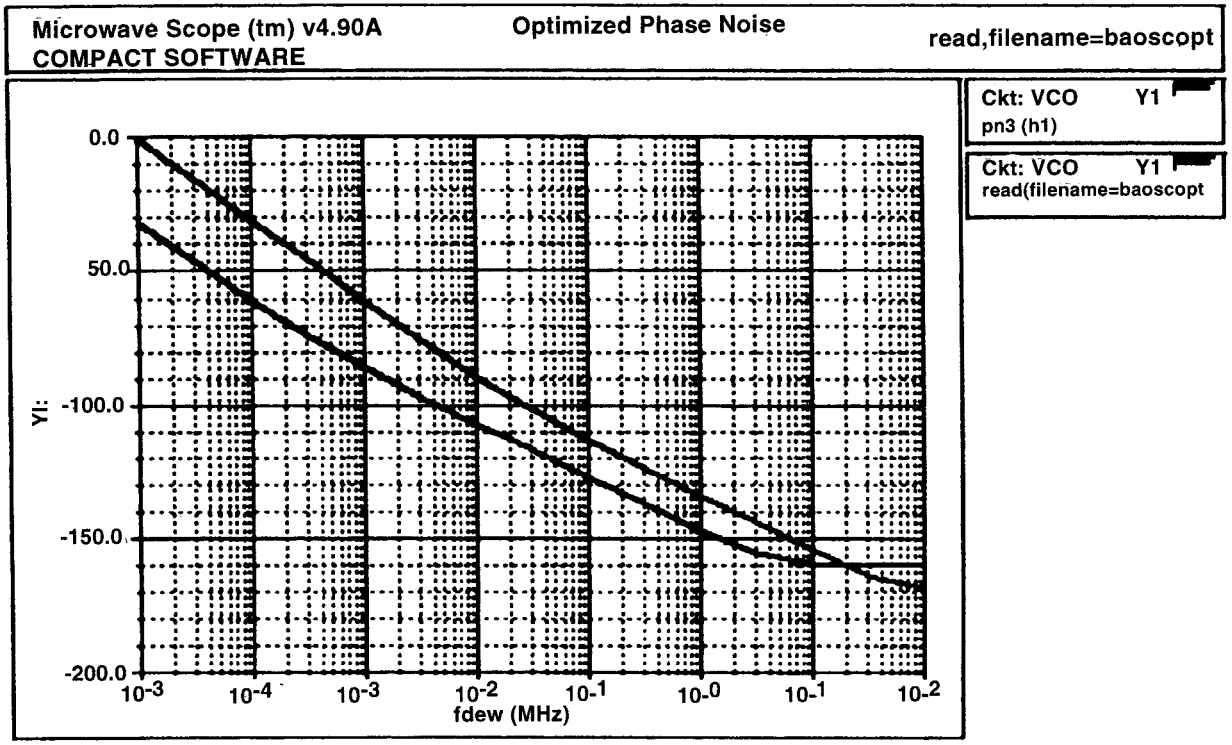

Figure 5-97 Phase noise of the 800-MHz VCO before and after optimization.

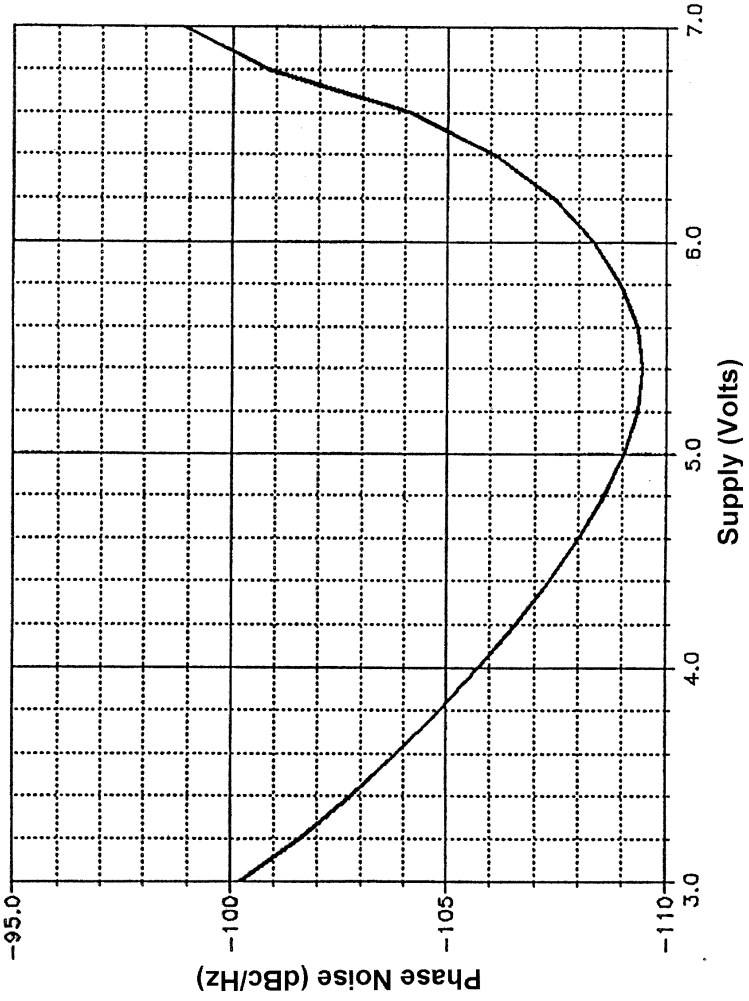

Figure 5-98 Calculated phase noise as a function of the supply voltage for a BJT oscillator. The graph shows a distinct minimum for a particular bias, which could be translated into a collector current change. Such phase-noise minimization could also be accomplished by changing just the voltage applied to the bias portion of the oscillator.

Acknowledgment. This research work for nonlinear operation in oscillators, partly sponsored by the U.S. Department of Defense MIMIC program, was performed in cooperation with Professor Vittorio Rizzoli's group of the Department of Electrical Engineering, Information and Systems Engineering at the University of Bologna, Italy, and the Motorola Portable Products Division, Florida, as well as the engineering team of Ansoft Corporation in New Jersey.

5-7 OSCILLATORS IN PRACTICE

5-7-1 Oscillator Specifications

Although we have tended to emphasize phase noise as a critical indicator of oscillator quality, phase noise is only one of a number of oscillator performance criteria that must be considered in wireless system design. In addition to phase noise, the following characteristics are used by commercial companies to describe oscillator performance:

Frequency Pushing. Frequency pushing characterizes the degree to which an oscillator's frequency is affected by its supply voltage. A sudden current surge caused by activating a transceiver's RF power amplifier may produce a spike on the VCO's dc power supply and a consequent frequency jump. Like tuning sensitivity (below), pushing is specified in frequency/voltage form and is tested by varying the VCO's dc supply voltage (typically ± 1 V) with its tuning voltage held constant.

Harmonic Output Power. The harmonic content is measured relative to the output power. Typical values are 20 dB or more suppression relative to the fundamental. This suppression can be improved by additional filtering.

Output Power. The output power of the oscillator, typically expressed in dBm, is measured into a 50-Ω load. The output power is always combined with a specification for flatness or variation. A typical specification would be 0 dBm ± 1 dB.

Output Power as a Function of Temperature. All active circuits vary in performance as a function of temperature. An oscillator's output power over a temperature range should vary less than a specified value, such as 1 dB.

Post-tuning Drift. After a voltage step is applied to the tuning diode input, the oscillator frequency may continue to change until it settles to a final value. This post-tuning drift is one of the parameters that limits the bandwidth of the VCO input.

Power Consumption. This characteristic conveys the dc power, usually specified in milliwatts and sometimes qualified by operating voltage, required by the oscillator.

Sensitivity to Load Changes. To keep costs down, many wireless applications use a VCO alone, without the buffering action of a high reverse-isolation amplifier stage. In such applications, *frequency pulling*, the change of frequency resulting from partially reactive loads, is an important oscillator characteristic. Pulling is commonly specified in terms of the frequency shift that occurs when the oscillator is connected to a load that exhibits a non-unity VSWR (such as 1.75, usually referenced to 50 Ω), compared to the frequency that results with a unity VSWR load (usually 50 Ω). Frequency pulling must be minimized, especially in cases where power stages are close to the VCO unit

and short pulses may affect the output frequency. Such feedback may make phase locking impossible.

Spurious Outputs. A VCO's spurious output specification, expressed in decibels, enumerates the strength of unwanted and nonharmonically related components relative to the oscillator fundamental. Because a stable, properly designed oscillator is inherently clean, such *spurs* are typically introduced only by external sources in the form of radiated or conducted interference. See *harmonic output power.*

Temperature Drift. Although the synthesizer is responsible for locking and maintaining the oscillator's frequency, the VCO's frequency change as a function of temperature is a critical parameter and must be specified. Its value varies between 10 kHz/°C to several hundred kHz/°C depending on the center frequency and tuning range.

Tuning Characteristic. This specification shows the relationship, depicted as a graph, between a VCO's operating frequency and the tuning voltage applied. Ideally, the correspondence between operating frequency and tuning voltage is linear. See *tuning linearity.*

Tuning Linearity. For stable synthesizers, a constant deviation of frequency versus tuning voltage is desirable. It is also important to make sure that there are no breaks in the tuning range—for example, that the oscillator does not stop operating with a tuning voltage of 0 V. See *tuning characteristic.*

Tuning Sensitivity, Tuning Performance. This characteristic, typically expressed in megahertz per volt (MHz/V), enumerates how much a VCO's frequency changes per unit of tuning-voltage change.

Tuning Speed. This characteristic is defined as the time necessary for the VCO to reach 90% of its final frequency on the application of a tuning-voltage step. Tuning speed depends on the internal components between the input pin and tuning diode—including, among other things, the capacitance present at the input port. The input port's parasitic elements determine the VCO's maximum possible modulation bandwidth.

5-7-2 More Practical Circuits

Because of the need for integration, we will present three IC oscillators of increasing complexity. The circuit in Figure 5-99 is found in early Siemens ICs. Figure 5-100 shows its phase-noise performance.

Figure 5-101 shows the basic push–pull oscillator topology underlying the circuit in Figure 5-99. The omission of the current source and active bias components improves the simpler circuit's phase-noise performance over that of the circuit shown in Figure 5-99. Figure 5-102 compares the phase noise of this basic circuit to the integrated version in Figure 5-99.

Figure 5-103 is for those who speculate on the possibility of replacing the BJTs in Figure 5-101 with LDMOS FETs or JFETs. Figure 5-104 compares its phase noise to that of the BJT case. The rule of thumb is that FETs do not have enough gain for high-Q oscillation in oscillators above 400 MHz, and bipolar transistors are a better choice. Because of their higher flicker noise contribution, GaAsFETs should be considered only at frequencies above 4 or 5 GHz.

Figure 5-105 shows a circuit based on two differential amplifiers and frequently found in Gilbert cell IC applications. Figure 5-106 shows its phase-noise performance.

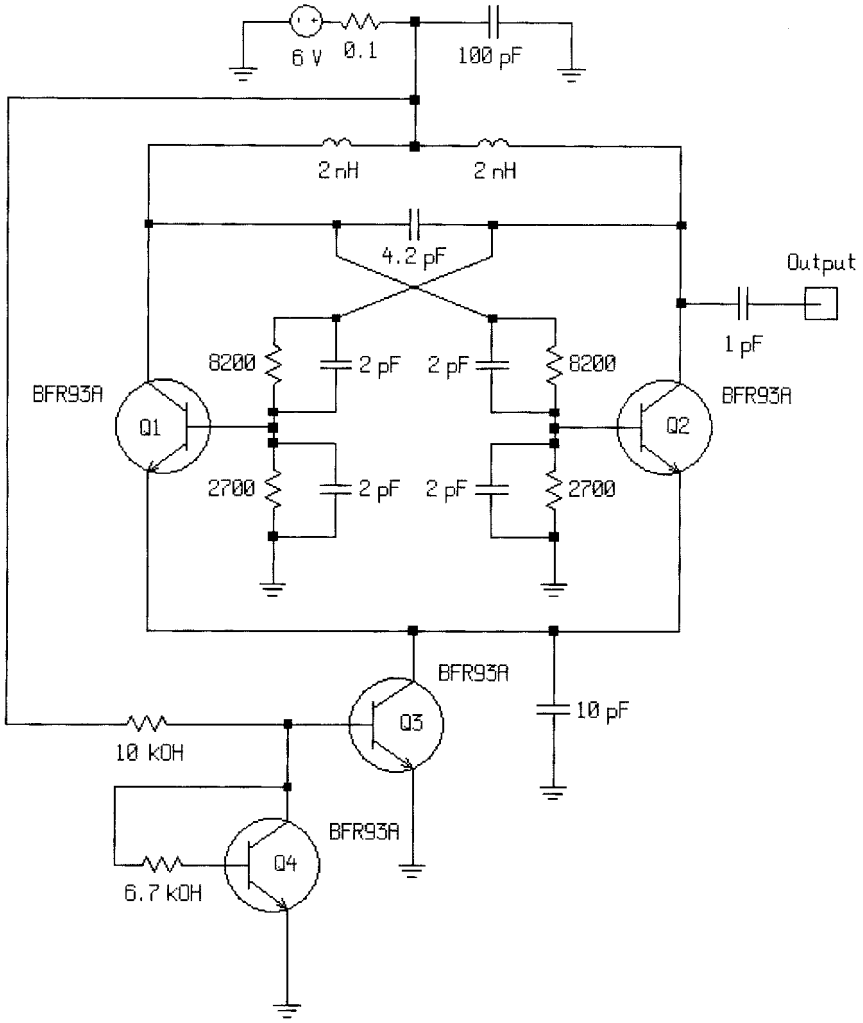

Figure 5-99 Schematic of the Siemens IC oscillator.

Figure 5-107 is a validation circuit that demonstrates a comparison of measured phase-noise performance versus its prediction by circuit simulation software. The circuit is based on the core of Motorola's MC12148 ECL oscillator IC, the topology of which is derived from the superseded MC1648. Motorola specifies the MC12148's typical phase-noise performance as –90 dBc/Hz at an offset of 25 kHz. The close agreement between the measured and simulated results highlights the value of state-of-the-art CAD tools in wireless oscillator design (Figure 5-108).

Figure 5-108 presents the results of *two* simulations: one with ideal L and C components, and another with realistic values specified for these reactances. In using a circuit

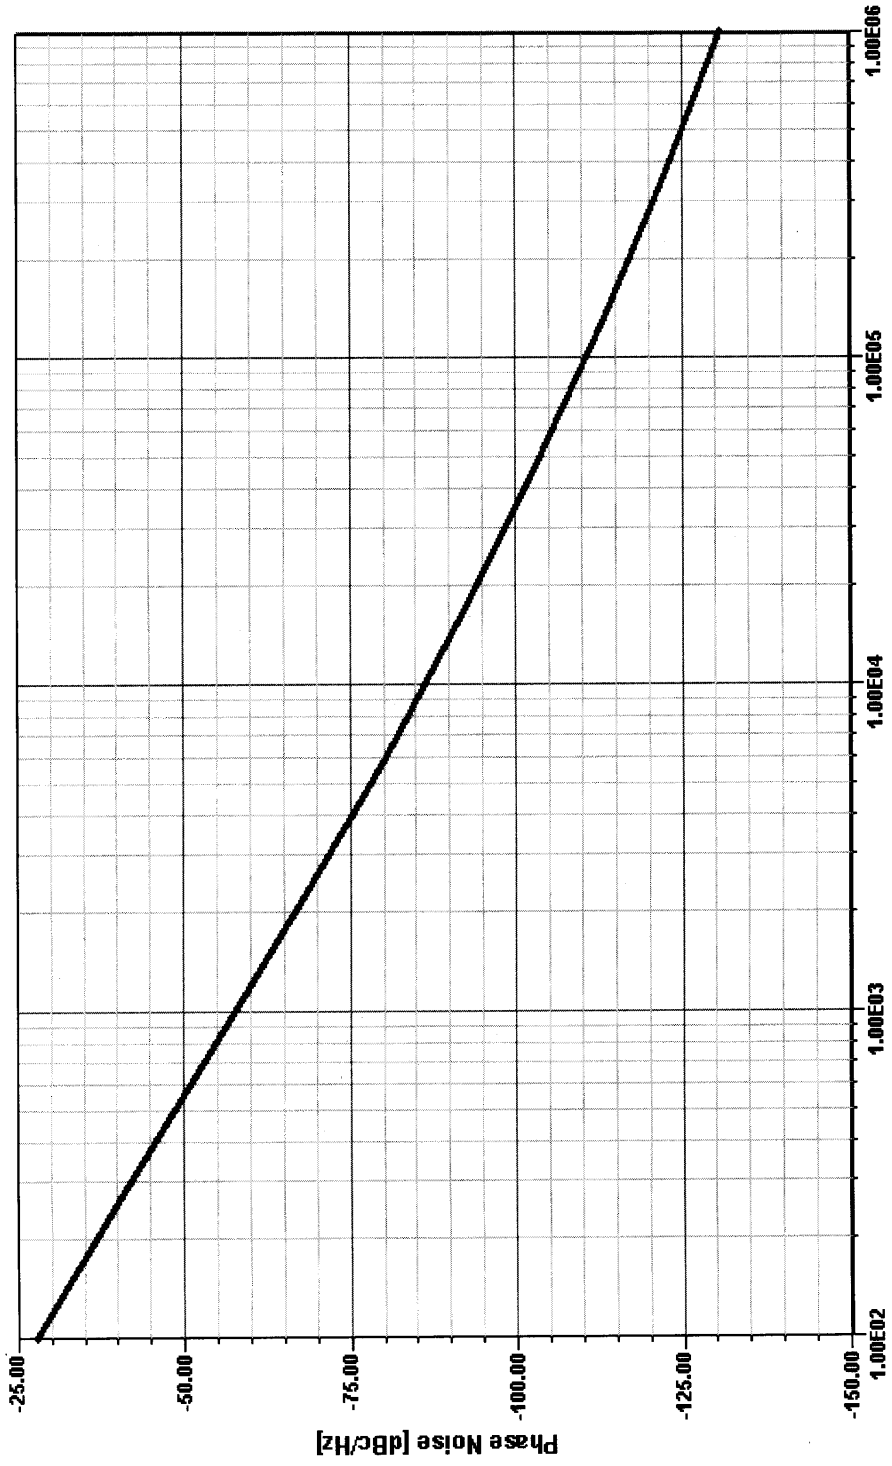

Figure 5-100 Phase noise of the Siemens IC oscillator. The frequency of oscillation is 1.051 GHz.

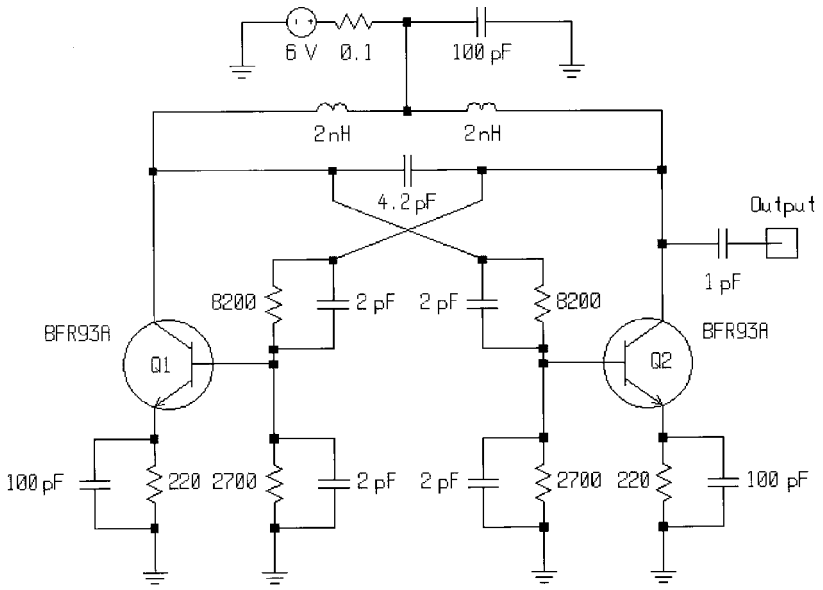

Figure 5-101 Basic push–pull oscillator underlying the circuit shown in Figure 5-99.

simulator to validate and compare oscillator topologies, it's important to start with ideal components because we are interested in comparing the inherent phase-noise performance of various circuits—particularly the role played by the nonlinear reactances in active devices. Because the Q values of practical components are so low in the microwave range (very generally, 200–300 for capacitors and 60–70 for inductors), the inherent merits of one topology, or one device, over another would be masked by loading effects if we conducted our investigations using nonideal reactances. Once initial evaluation is completed, realistic Q values should be specified for increased accuracy in phase-noise, output-power, and output-spectrum simulations.

Finally, as evidence of how moving from lumped to distributed techniques can improve oscillator performance at frequencies where *LC* tanks become problematic, Figure 5-109 compares, for a simulated BJT Colpitts oscillator operating at 2.3 GHz, the difference in phase-noise performance obtainable with a resonator consisting of an ideal 2-nH inductor and a $\frac{1}{4}\lambda$ transmission line (11 Ω, 90° long at 2.6 GHz, attenuation 0.1 dB/m) with the transistor biased by constant-current and constant-voltage sources.

Silicon/GaAs-Based Integrated VCOs and Possible Difficulties. Due to process variations, the center frequency of the VCO cannot be repeated without trimming. Trimming can be avoided by making the VCO gain large enough to compensate for tank circuit variations, but this degrades phase-noise performance and increases the VCO susceptibility to unwanted spurs. For example, a VCO with a gain of 10 MHz/V has a phase noise of –80 dBc/Hz at 10 kHz, while a VCO with a gain of 75 MHz/V has a phase noise of only –60 dBc/Hz at 10 kHz. All but the tank inductors are integrated.

Tank inductors are generally not integrated for reasons of size and Q. The area of a 1-nH inductor is approximately 42,000 mm^2, which is ~3.5% of a typical IC; the area of a 10-nH

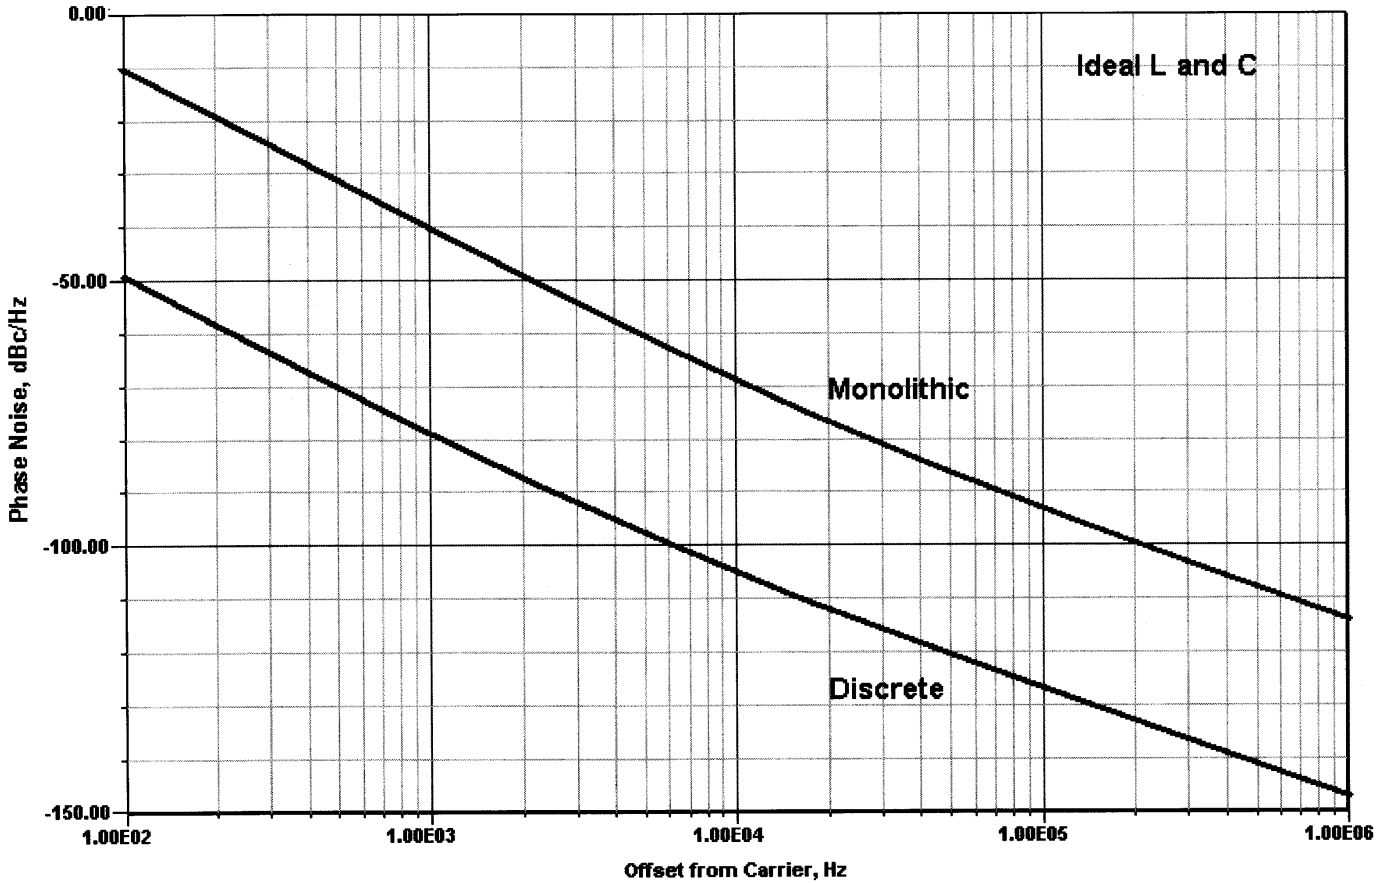

Figure 5-102 The basic version of the oscillator (Discrete curve) is a better phase-noise performer than the integrated version (Monolithic curve). The frequency of oscillation is 1.039 GHz.

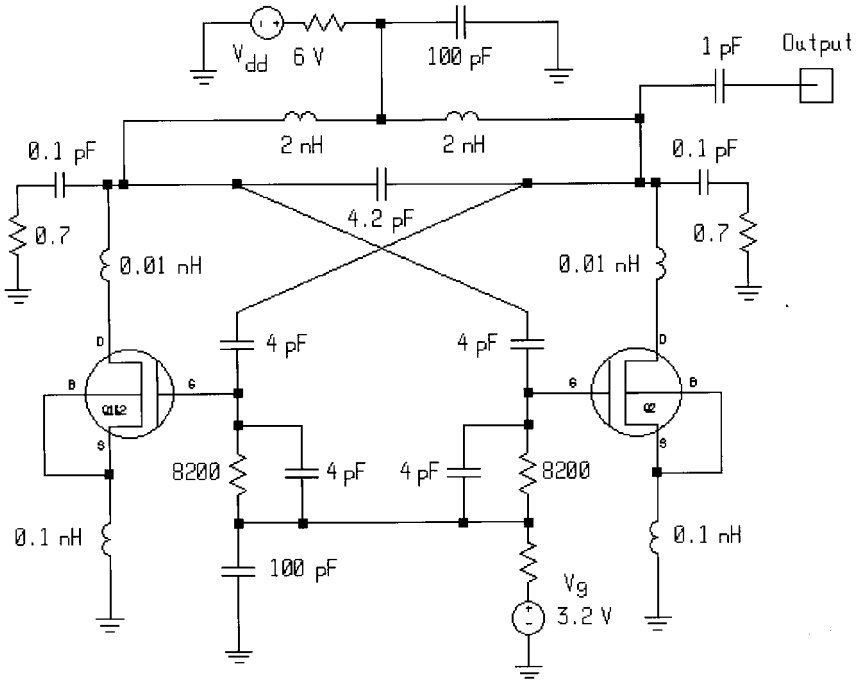

Figure 5-103 A 1.04-GHz push–pull oscillator using LDMOS FETs instead of BJTs. (LDMOS FET parameters courtesy of David K. Lovelace, Motorola, Inc.)

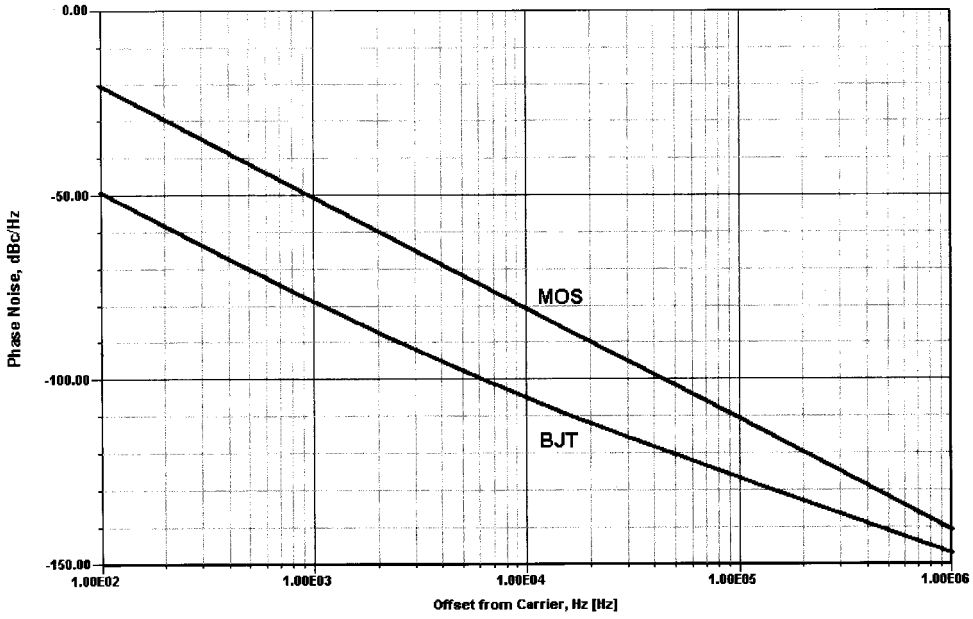

Figure 5-104 Phase-noise comparison of the BJT and MOSFET oscillators.

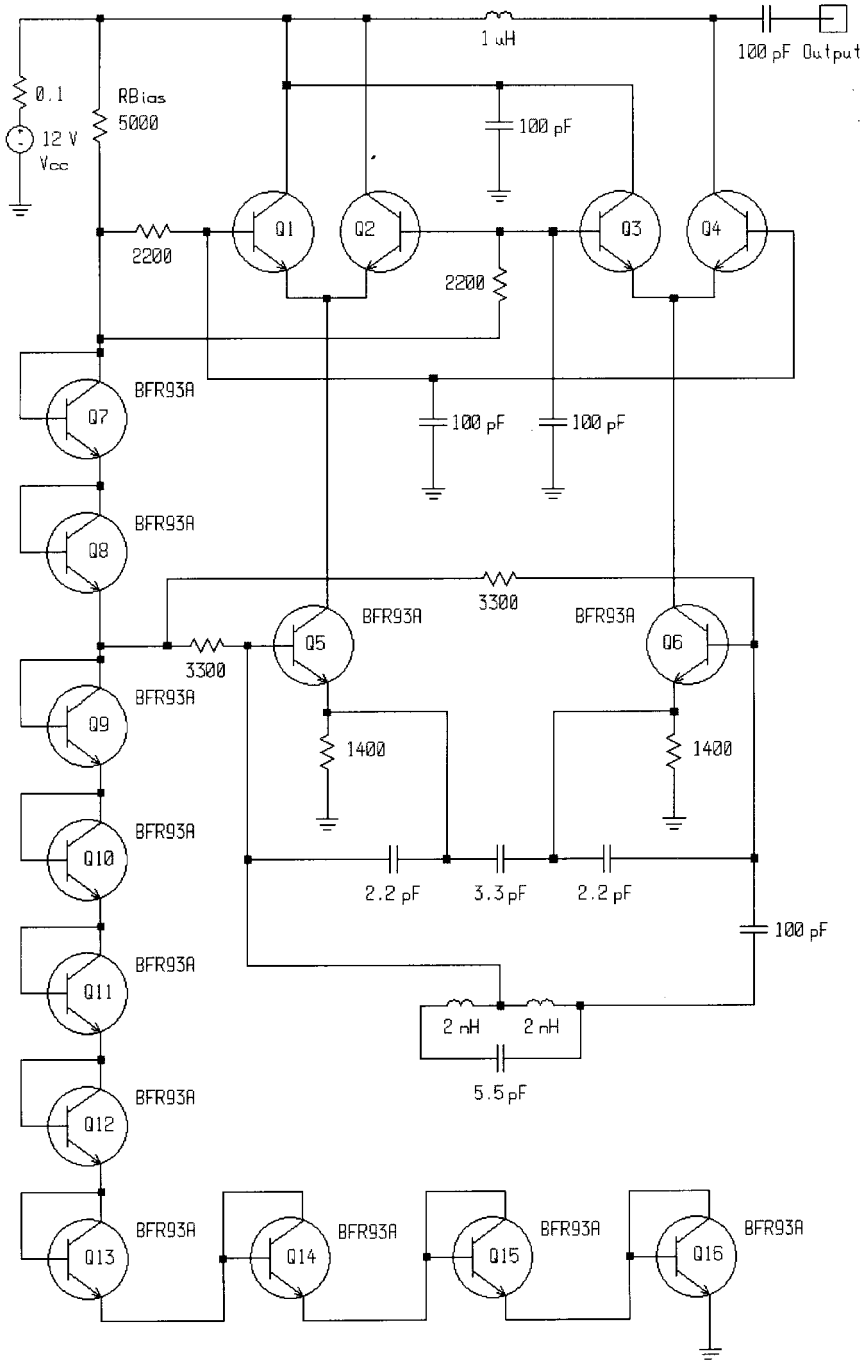

Figure 5-105 A 1.022-GHz IC oscillator based on two differential amplifiers. With an RF signal fed to the bases of Q_1–Q_4 and Q_2–Q_3 in push–pull, and IF output extracted from the collectors of Q_1–Q_3 and Q_2–Q_4 in push–pull, the circuit would act as a Gilbert cell converter. In the circuit shown, we have modified the differential amplifiers' collector circuitry to give single-ended output and avoid cancellation of the oscillator signal.

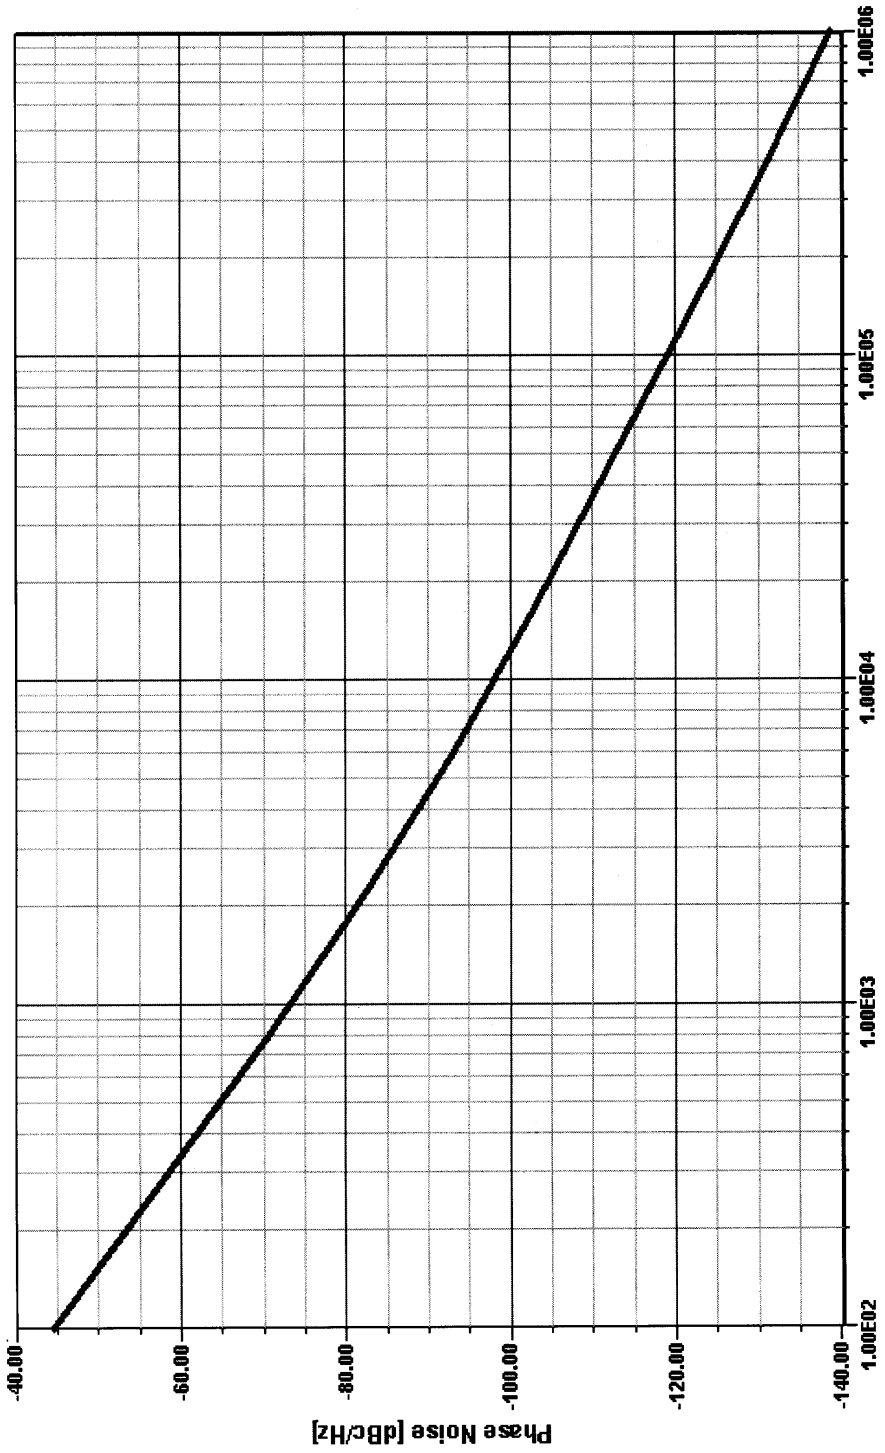

Figure 5-106 Phase noise of the two-differential-amplifier oscillator circuit.

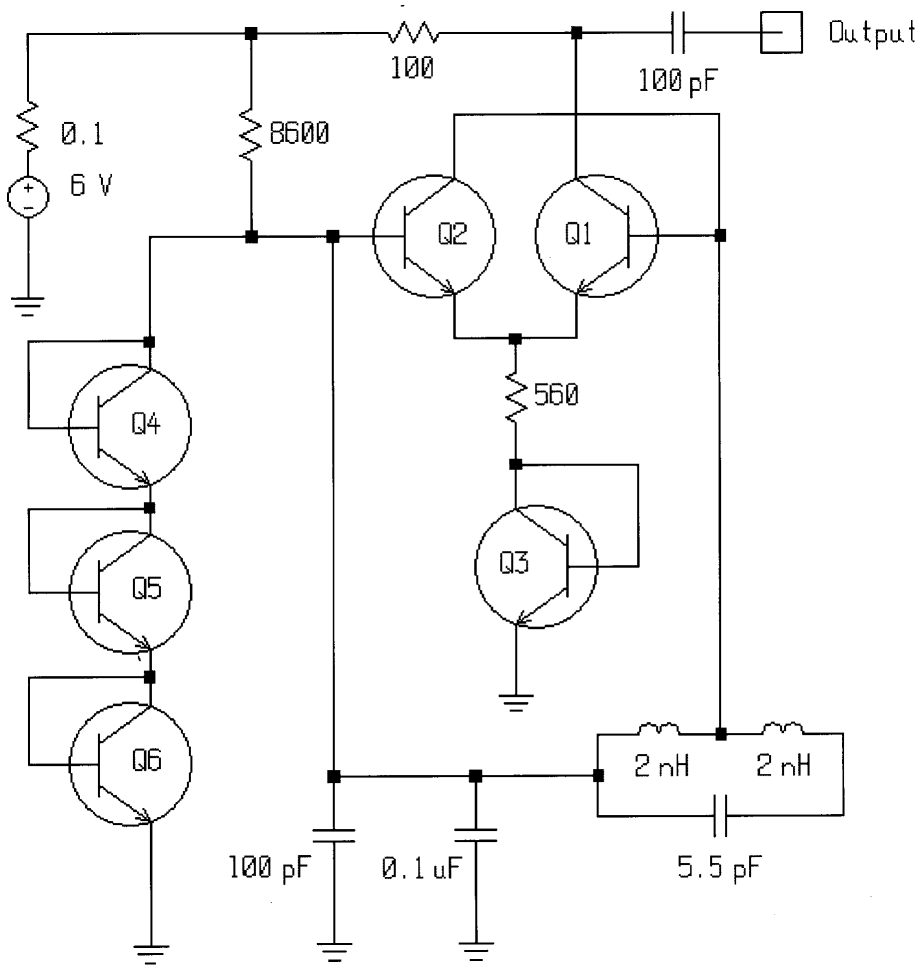

Figure 5-107 This validation circuit models the oscillator topology at the core of Motorola's MC12148 ECL oscillator IC.

inductor is approximately 167,000 mm^2, which is ~14% of a typical IC. For GaAs substrate, the resulting Q would be about 5; for silicon, as we already saw, 20 is already a very high value.

The customer can use PCB traces for the required inductance instead of external surface-mount inductors (cost: $0.03 each, most expensive passive component!). It must be pointed out that even for a nonintegrated approach, the higher VCO gain is noisier by definition. This was explained in Section 5-6-2. These problems are not unique to silicon; they apply to GaAs also. Figure 5-110 shows the size relationship of on-chip capacitors and inductors compared to the actual transistor; therefore, on-chip inductors should really be avoided for reasons of space and Q. Just imagine how the picture would change if the 1.1-nH inductor had to be 11 nH instead! It would dominate the IC area, and therefore the IC cost as well.

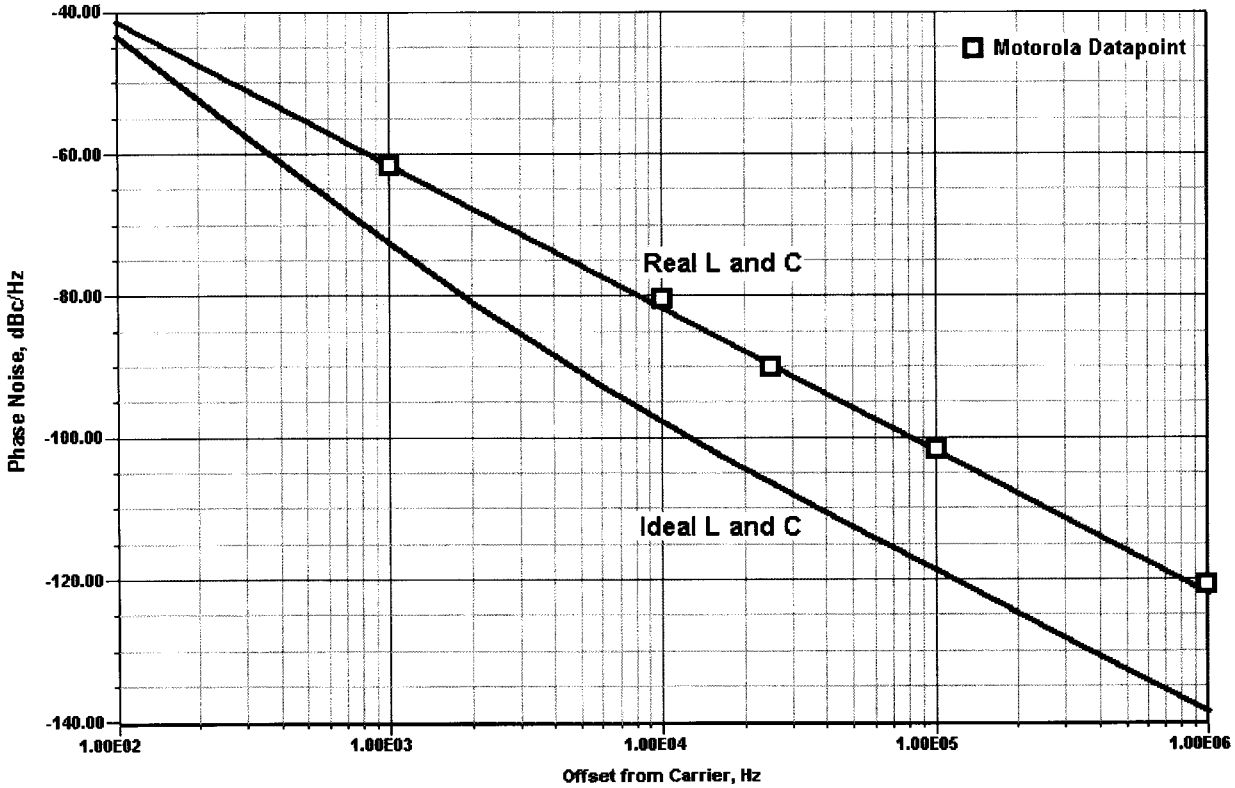

Figure 5-108 Comparison of measured versus simulated phase noise of the MC12148 differential oscillator. The simulation (1.016 GHz) predicts a phase noise of –89.54 dBc/Hz at an offset of 10 kHz (Real L and C curve), which agrees well with Motorola's specification of –89.54 dBc/Hz (typical at 930 MHz) at this offset. The Ideal L and C curve plots the simulation's phase-noise performance with ideal reactances, as opposed to the Real L and C curve, which graphs the results with realistic Q values specified for its reactive components ($Q = 250$ for its C values and $Q = 65$ for its L, all at 1 GHz).

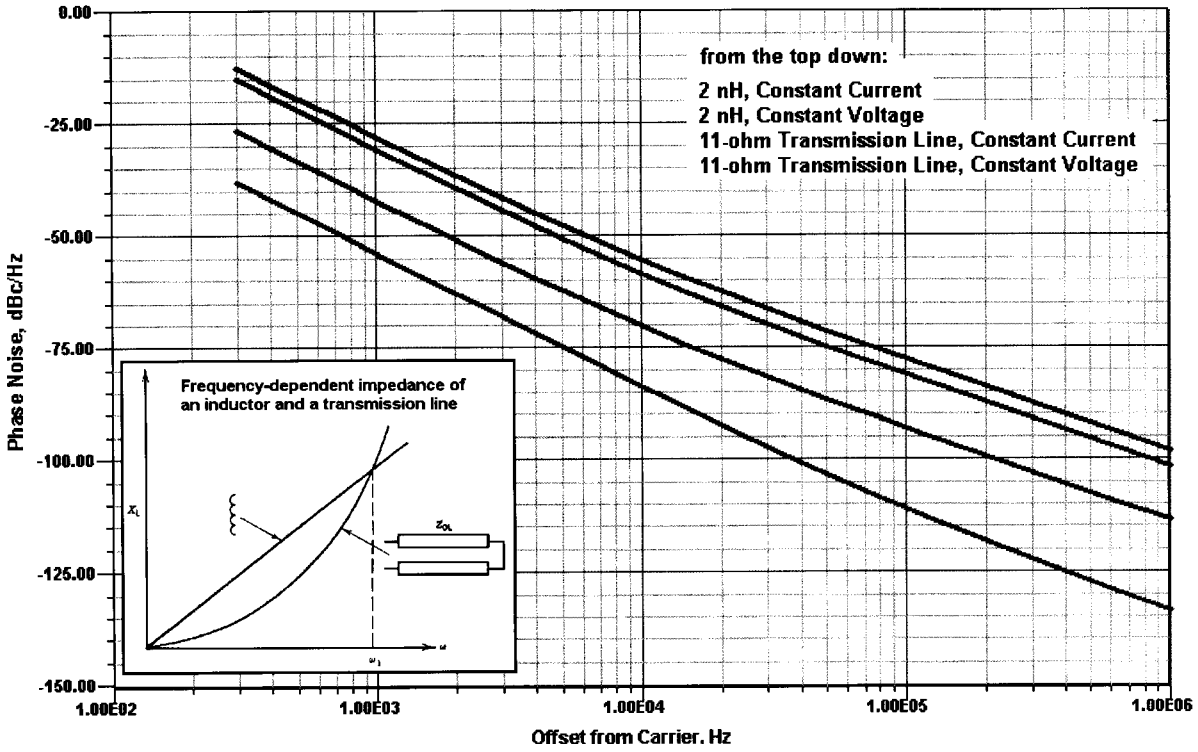

Figure 5-109 Phase-noise performance of a 2.3-GHz BJT oscillator with a resonator consisting of an inductor (2 nH) and a 1/4 λ transmission line (11 Ω, approximating the behavior of a dielectric resonator) with bias from a constant-current source and a low-impedance, resistive constant-voltage source.

5-8 DESIGN OF RF OSCILLATORS USING CAD

5-8-1 Harmonic-Balance Simulation

HB analysis performs steady-state analysis of periodically excited circuits. The circuit to be analyzed is split into linear and nonlinear subcircuits. The linear subcircuit is calculated in the frequency domain. Features of this aspect of the HB process include:

- Use of distributed models in the spectral domain
- Matrix formulation that can enable reduction of internal nodes
- Major speed advantage
- Straightforward intermodulation and mixer analysis

The nonlinear subcircuit is calculated in the time domain. Features of this aspect of the HB process include:

- Nonlinear models derived directly from device physics
- Intuitive, easy, and logical circuit representation

Figure 5-111 diagrams this approach for a MESFET amplifier. Figure 5-112 charts a general-purpose nonlinear design algorithm that includes optimization. Modern analysis tools that must provide accurate phase-noise calculation should be based on the principle of harmonic balance. Figure 5-113 shows a BJT microwave oscillator entered into the schematic-capture module of a commercially available HB simulator (Ansoft Serenade 8.0); Figure 5-114 shows this oscillator's simulated phase noise. By the way, HB analysis can also handle mixers.

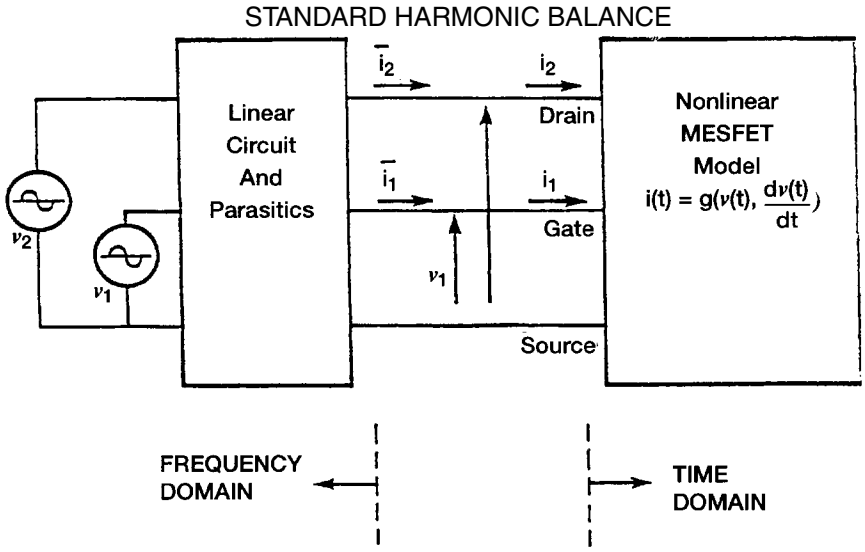

Figure 5-111 MESFET circuit partitioned into linear and nonlinear subcircuits for harmonic-balance analysis. Applied gate and drain voltages, and relevant terminal voltages and currents, are indicated.

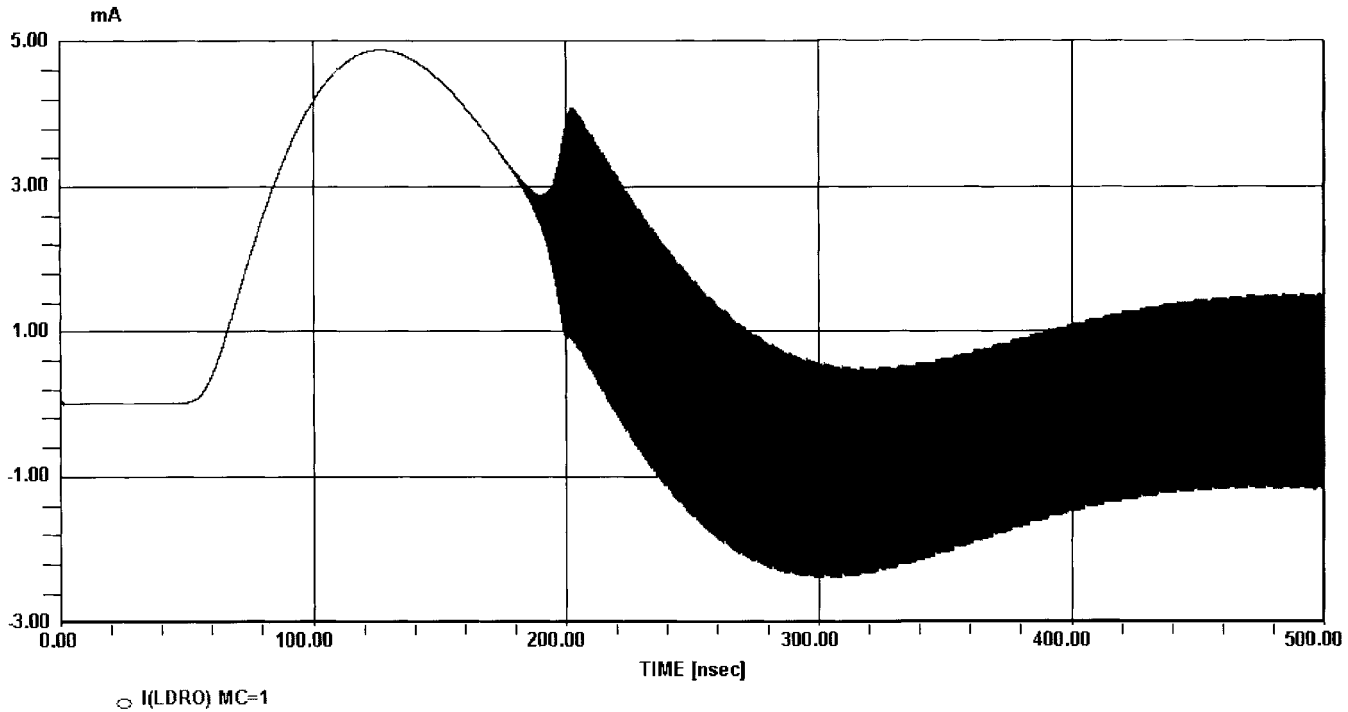

Figure 5-117 Current through the BJT DRO's equivalent resonator inductance from startup to amplitude stabilization.

5-8-2 Time-Domain Simulation

SPICE, a general-purpose simulation program capable of nonlinear dc, linear ac, and nonlinear transient analysis, is probably the most common of the time-domain methods used for nonlinear circuit analysis. Its ability to represent arbitrary time-domain waveforms and model time delays, level shifts, and the sinking and sourcing characteristics of such circuits have made it the simulator of choice for digital designers concerned with analog issues. SPICE's application in RF, microwave, and wireless circuit design is limited by its difficulties with simulating multitone excitations, and coupling and transmission-line effects—including losses, parasitics, and dispersion for distributed elements—and its inefficiency in simulating steady-state conditions.

One area in which SPICE's transient analysis capabilities can be particularly useful to RF and wireless designers is the simulation of oscillator startup. To illustrate this, we present a 3.8-GHz dielectric resonator oscillator modeled with Ansoft Corporation's Super-Spice simulator. Figure 5-115 shows how the oscillator's S_{11} response, positive throughout the simulation's frequency span of 3–5 GHz, peaks at 3.77 GHz. Figure 5-116 shows the oscillator's output voltage as the circuit starts oscillating and amplitude-stabilizes; Figure 5-117 shows the current through the equivalent inductance of the circuit's dielectric resonator across the same time span.

5-9 PHASE-NOISE IMPROVEMENTS OF INTEGRATED RF AND MILLIMETER-WAVE OSCILLATORS *

5-9-1 Introduction

The generation of microwave and millimeter-wave frequencies can be done by lower-frequency VCOs multiplied up in frequency, such as that provided by comb generators; by using hybrid GaAsFET-based oscillators with external resonators; or—for the best phase noise obtainable—YIG oscillators whose physical size and cost do not always provide a practical solution. A significant improvement in oscillator noise performance can be obtained with a novel feedback circuit that uses internally generated noise and cancels the close-in noise in a bandwidth of up to 1 MHz. This results in a phase noise improvement of more than 15 dB at microwave frequencies for the same topology, and the feedback system can be made part of the biasing circuit. This feedback circuit can be used over a wide frequency range and works well at VHF/UHF frequencies and in the millimeter-wave area.

5-9-2 Review of Noise Analysis

Section 5-6 of this chapter covered noise in oscillators in detail, so we will merely review oscillator noise issues here. The first linear model for a basic oscillator, without considering semiconductor noise, was developed by Leeson in 1966 [9] and has been quoted in numerous applications.

The phase noise of a VCO is completely determined by

*This section is based on a paper given at the Fifth International Workshop on Integrated Nonlinear Microwave and Millimeterwave Circuits, sponsored by IEEE at Gerhard-Mercator University, Duisburg, Germany, October 1–2, 1998.

$$£(f_m) = 10 \log\left\{\left[1 + \frac{f_0^2}{(2f_m Q_{\text{load}})^2}\right]\left(1 + \frac{f_c}{f_m}\right)\frac{FkT}{2P_{s,\text{av}}} + \frac{2kTRK_0^2}{f_m^2}\right\} \tag{5-135}$$

where $£(f_m)$ = ratio of sideband power in a 1-Hz bandwidth at f_m to total power in dB
f_m = frequency offset
f_0 = center frequency
f_c = flicker frequency
Q_{load} = loaded Q of the tuned circuit
F = noise factor
$kT = 4.1 \times 10^{-21}$ at 300 K (room temperature)
$P_{s,\text{av}}$ = average power at oscillator output
R = equivalent noise resistance of tuning diode (typically 200 Ω to 10 kΩ)
K_0 = oscillator voltage gain

When adding an isolating amplifier the noise of an *LC* oscillator is determined by

$$S_\phi(f_m) = [a_R F_0^4 + a_E(F_0/2Q_L)^2]/f_m^3$$
$$+ [(2GFkT/P_0)(F_0/2Q_L)^2]/f_m^2$$
$$+ 2a_R Q_L F_0^3/f_m^2$$
$$+ a_E/f_m + 2GFkT/P_0$$

where G = compressed power gain of the loop amplifier
F = noise factor of the loop amplifier
k = Boltzmann's constant
T = temperature in kelvins
P_0 = carrier power level (in watts) at the output of the loop amplifier
F_0 = carrier frequency in hertz
f_m = carrier offset frequency in hertz
$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop
a_R, a_E = flicker noise constants for the resonator and loop amplifier, respectively

In 1978, Dieter Scherer from Hewlett-Packard added the $(1 + f_c/f_m)$ term, which addresses the 1/*f* noise or flicker corner frequency [25]. The 1/*f* frequency phenomenon is based on the surface effects inside the semiconductor and varies from 50 Hz for silicon FETs, to 5 kHz and more for silicon microwave bipolar transistors, to 1 MHz and higher for GaAsFETs. As a rule of thumb, one can state that the higher the frequency of operation, the higher the f_T for the active device, the higher the flicker corner frequency will be. Figure 5-118 shows the spectral distribution as a function of offset frequency. This linearization was first discovered by individuals from NIST, formerly the National Bureau of Standards, in Boulder, Colorado. The left corner is dominated by the flicker corner frequency and the oscillator itself shows at the output a combination of modulation and conversion

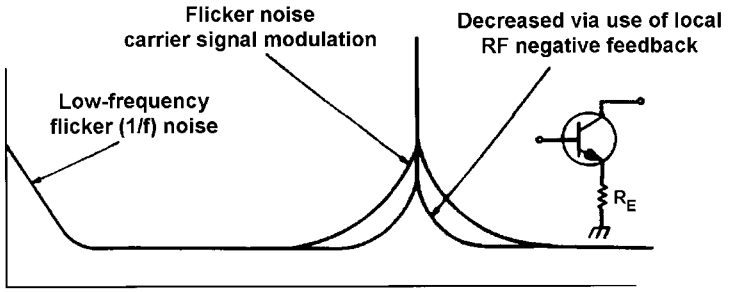

Figure 5-118 Reduction of transistor flicker-of-phase noise via use of local negative feedback (emitter resistance), showing, for a BJT, the flicker noise or corner frequency, as well as the phase noise that results from the flicker noise. The negative feedback from the unbypassed emitter resistor reduces the flicker noise by up to 40 dB [26, 27].

noise. In addition to the $1/f$ noise, the real-life oscillator exhibits a wideband noise, which is due to nonlinearities—specifically, the AM-to-PM conversion resulting from nonlinear capacitance and transconductance of the transistor. This complete linear "noise equation" was first published by Rohde et al. [2]. Therefore, the noise model for the transistor had to be enhanced by describing this mechanism. Essentially, it is equal to a tuning diode coupled to the resonator, which is modulated by thermal noise, and therefore results in a higher phase-noise contribution than the oscillator itself. This noise equation also has Q playing a major role. The phase noise, therefore, ignoring other frequencies, is proportional to $1/Q^2$. In monolithic circuits, the loss of transmission lines, which determines the Q, is related to the substrate material. One has little choice of material, particularly in microwave and millimeter-wave oscillators. Printed resonators sadly provide low Q at these frequencies. A similar problem related to the material is the choices of tuning diodes. In many, if not all, cases, one uses a GaAsFET with the gate connected to the drain or to the source as a tuning diode, and the resulting Q is also disappointing.

The example in Figure 5-118 takes advantage of a microwave bipolar transistor and also is applicable for heterojunction bipolar transistors (HBTs). The transconductance of the bipolar transistor, which is approximately 39 mA/V, increases to values up to 20 times larger than exhibited by GaAsFETs. This method of using negative feedback reduces the gain of the GaAsFET too much and is, therefore, not applicable.

5-9-3 Workarounds

When looking at the modes of operation of test sets for phase-noise measurement, the one method that requires only one signal generator is most desirable. Based on the frequency discriminator method, it uses a cable of appropriate length that acts as a delay line. The oscillator under test drives a double-balanced mixer [one port directly (LO port)] and drives the RF port "delayed" via the delay line cable, and the mixer is therefore driven by the same frequency with a different phase. This setup has been used for phase-noise measurements very successfully. One can easily connect a low-noise FFT-based audio spectrum analyzer to the mixer output and measure the signal-to-noise ratio as a function of offset. With modern FFT analyzers available up to 10 MHz and higher, a fast and reliable measurement can be done. The length of the cable determines the frequency range over which an accurate

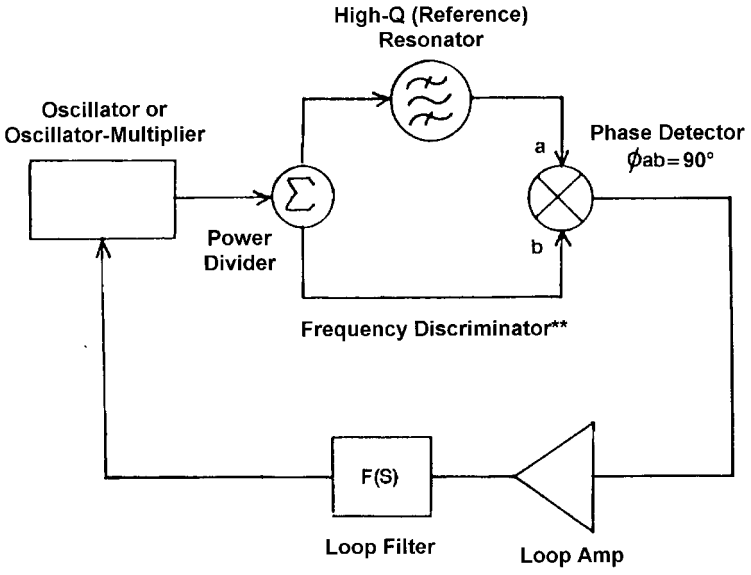
measurement is possible. This phase-noise information (dc and ac voltage) at the output can be used to modulate the VCO and improve the phase noise in the frequency range over which this method is applicable. Fluke and other companies have built signal generators based on this principle to improve the phase noise. The drawback of this method is that the delay line acts like a band-limiting filter, and, therefore, one cannot compensate over a large range of frequencies. The delay line in question, responsible for the phase shift, can also be substituted by a high-Q resonator. By closing the loop, one can "clean up" the phase noise of the device under test (DUT). The difficulty with this is that it requires an external high-Q resonator. One might as well use the same resonator for the oscillator. Therefore, this method is not suitable for MMICs. See Figure 5-119 for more details.

As far as the actual measurement is concerned, one has to observe certain limitations of the test setup as explained in Figure 5-120. When using the delay line instead of a high-Q resonator (low loss is assumed for coaxial cable), one needs to determine the physical length of the cable. The physical length of the cable determines the delay and, therefore, the discriminator noise floor as a function of the offset frequency. Typically, 8 feet of RG-8/U cable results in a delay of 12 ns. As can be seen from Figure 5-121, it is advisable to have several lengths of cable depending on the range of frequency for which one wants to do the measurements under different lengths of cable [28].

Since we are primarily concerned about the flicker noise, here is another, similar, approach to "cleaning up" the flicker noise, as shown in Figure 5-122. The bandwidth over which this technique works depends on the bandwidth of the phase detector system, which can be made fairly wide. A derivative of this will provide a useful solution.

5-9-4 Reduction of Flicker Noise

From inspecting a device datasheet, one is always pleasantly surprised about very low spot noise figures, while the 1/f corner frequency is rarely specified at all. The mechanism that



**Resonator may be operated in reflection mode as well as transmission mode.

Figure 5-119 AFC stabilization of an external oscillator.

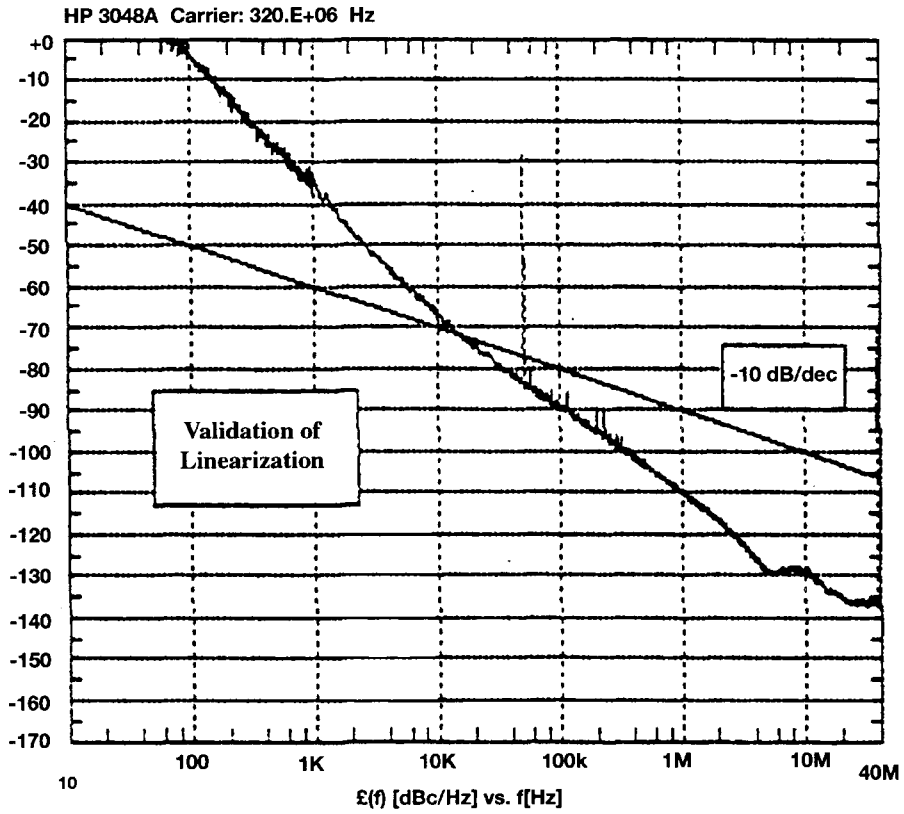


Figure 5-120 Display of a typical phase-noise measurement using the delay line principle. This method is only applicable where $x = \sin(x)$. The measurements above the solid line violate this relationship and therefore are not valid.

transforms the noise, which is generated by the $1/f$ contribution into what we referred to as modulation noise, is the AM-to-PM conversion. If one could "linearize" the transistor, the flicker noise effect would drastically be reduced.

Figure 5-123 shows two variations on an approach that is consistent with the previous method. In Figure 5-123a, the noise across the 56-Ω emitter resistor of oscillator transistor Q1 is sampled, amplified and inverted in Q2, and used to modulate Q1's base voltage. A low-frequency, general-purpose *npn* transistor (BC848C) is used at Q2. A high-frequency, higher-power transistor (BFR93A) is used at Q1; an HBT could also be used. Figure 5-123b shows the same approach using a variation of the *pnp* active biasing circuit shown in Figure 3-192. Figure 5-124 shows the phase-noise performance for the circuit of Figure 5-123a.

5-9-5 Applications to Integrated Oscillators

Figure 5-125 shows a silicon-based BiCMOS technology wireless oscillator. The three big inductors can be seen easily. This design by Motorola is a good candidate for using this innovative technology. Applying this feedback technology, we measure the phase noise shown in Figure 5-126.

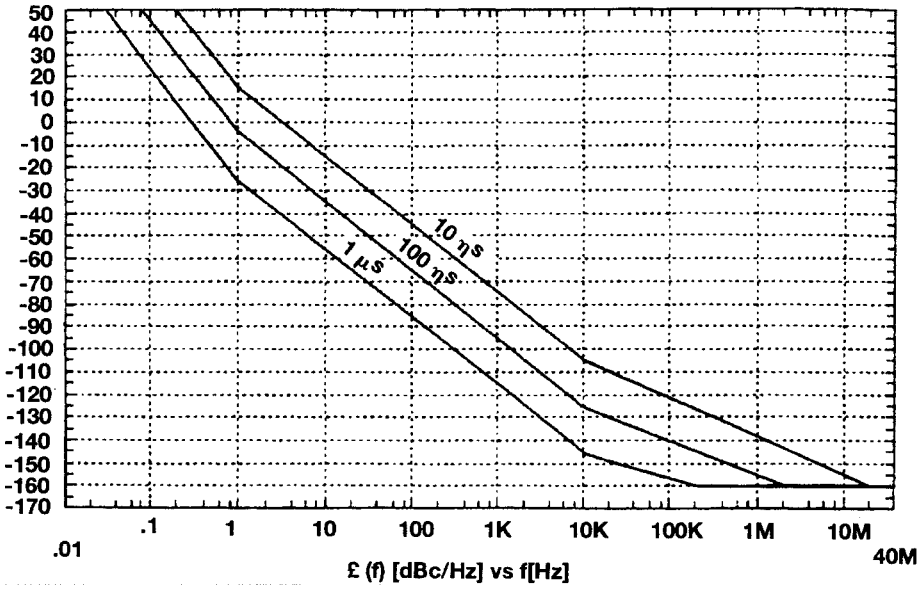

Figure 5-121 Dynamic range as a function of cable delay. A delay of 1 μs is ideal for microwave frequencies.

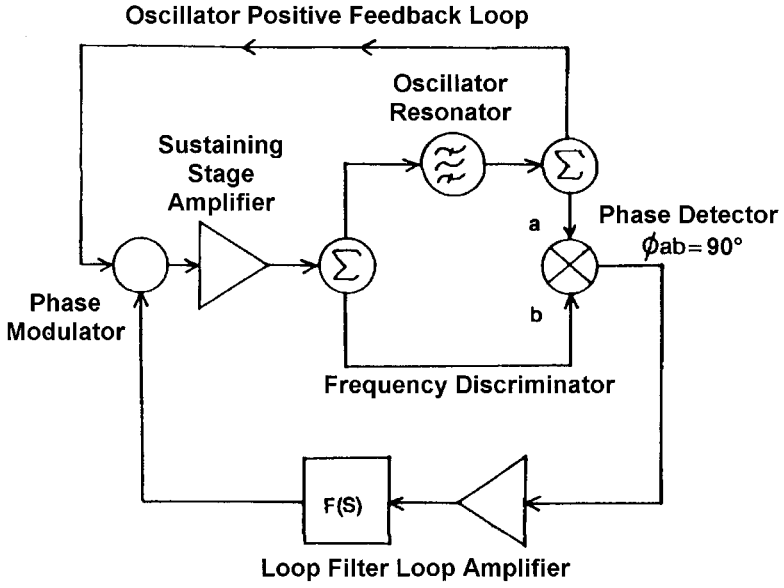

Figure 5-122 Noise reduction in an oscillator whose signal flicker-of-frequency noise is primarily due to sustaining stage flicker-of-phase noise. A phase perturbation in the sustaining stage produces a frequency change in the oscillator, which produces a change in the signal phase shift through the resonator detected as the phase detector. The resonator may be operated simultaneously in transmission line and reflection modes in the oscillator in the oscillator and discriminator portions of the circuit, respectively.

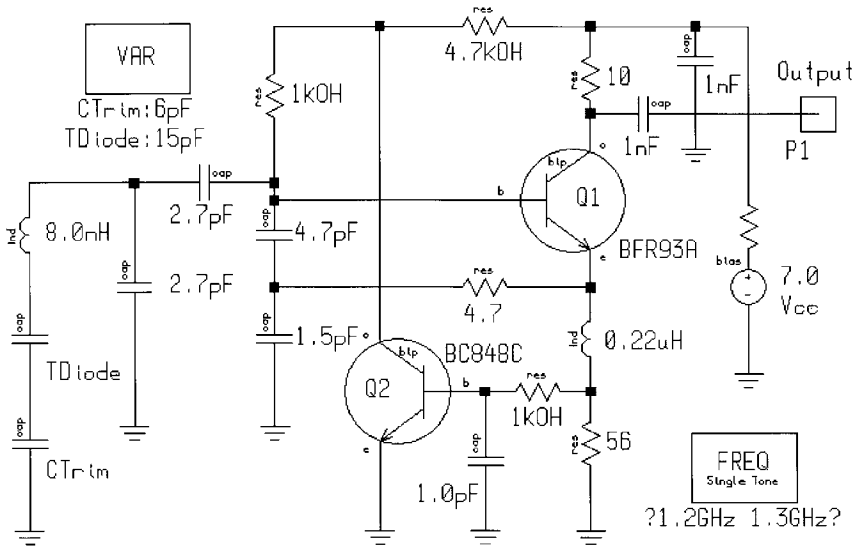
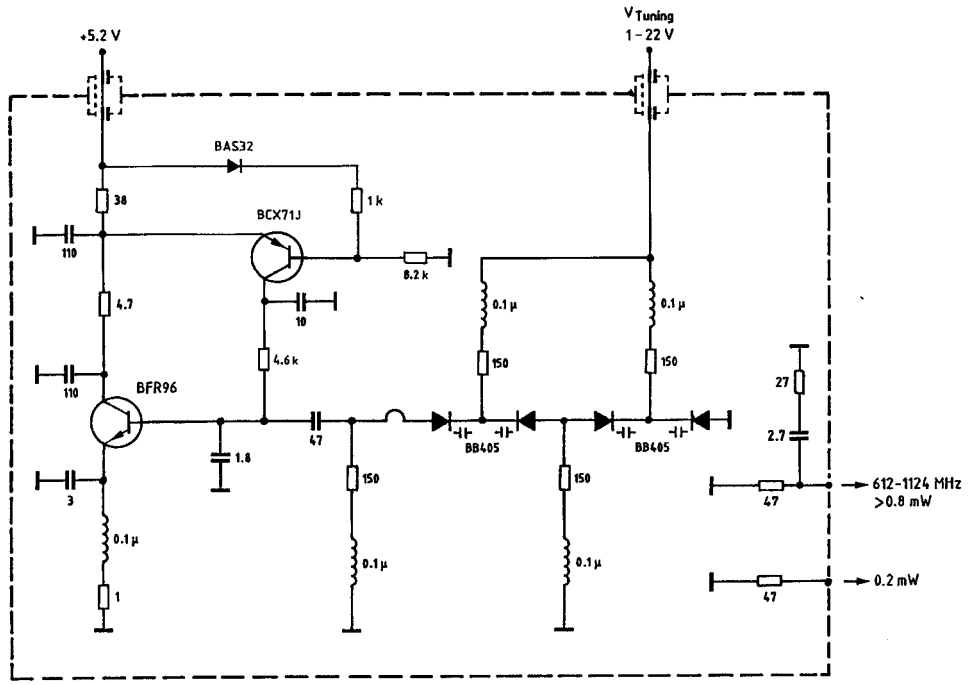


(a)



(b)

Figure 5-123 BJT-based oscillators with noise feedback. (a) The noise sampling is done in the transistor emitter; (b) the noise sampling is done in the collector using a variation of the active biasing circuit shown in Figure 5-124.

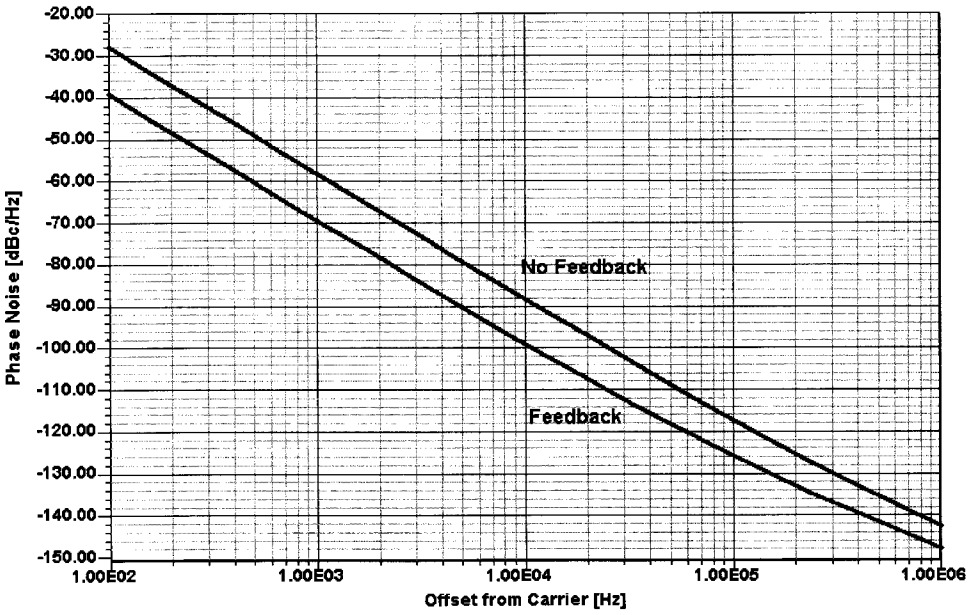


Figure 5-124 Phase noise of the oscillator in Figure 5-123a with and without noise feedback.

Moving up into the millimeter-wave area, one of the target oscillators is the Ka-band MMIC voltage-controlled oscillator designed for Ka-band smart munitions applications (Figure 5-127). This voltage-controlled oscillator MMIC employs 0.25-μm gate length, double-heterojunction, pseudomorphic, high-electron-mobility transistor (PHEMT) technology. This is a custom chip developed by Martin Marietta under the U.S. Government MMIC program. Ansoft Serenade tools were used in this design.

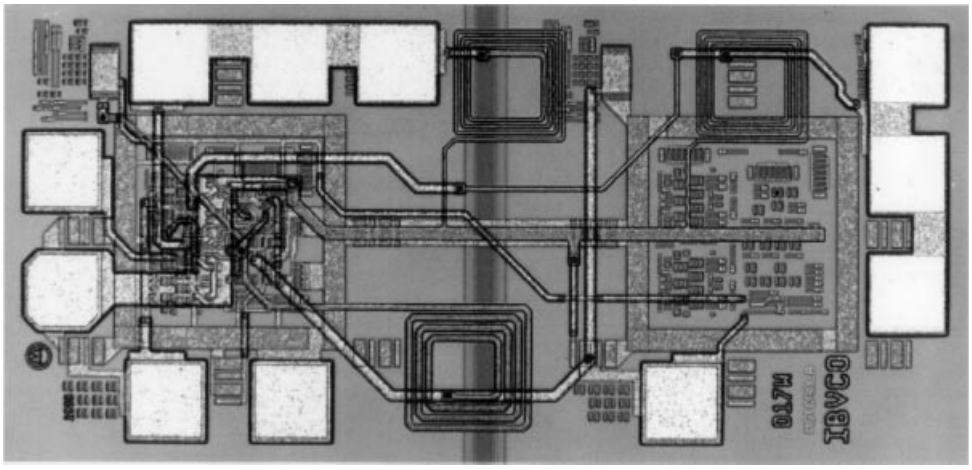

Figure 5-125 Layout of the Motorola 800-MHz monolithic differential oscillator IC in Si technology.

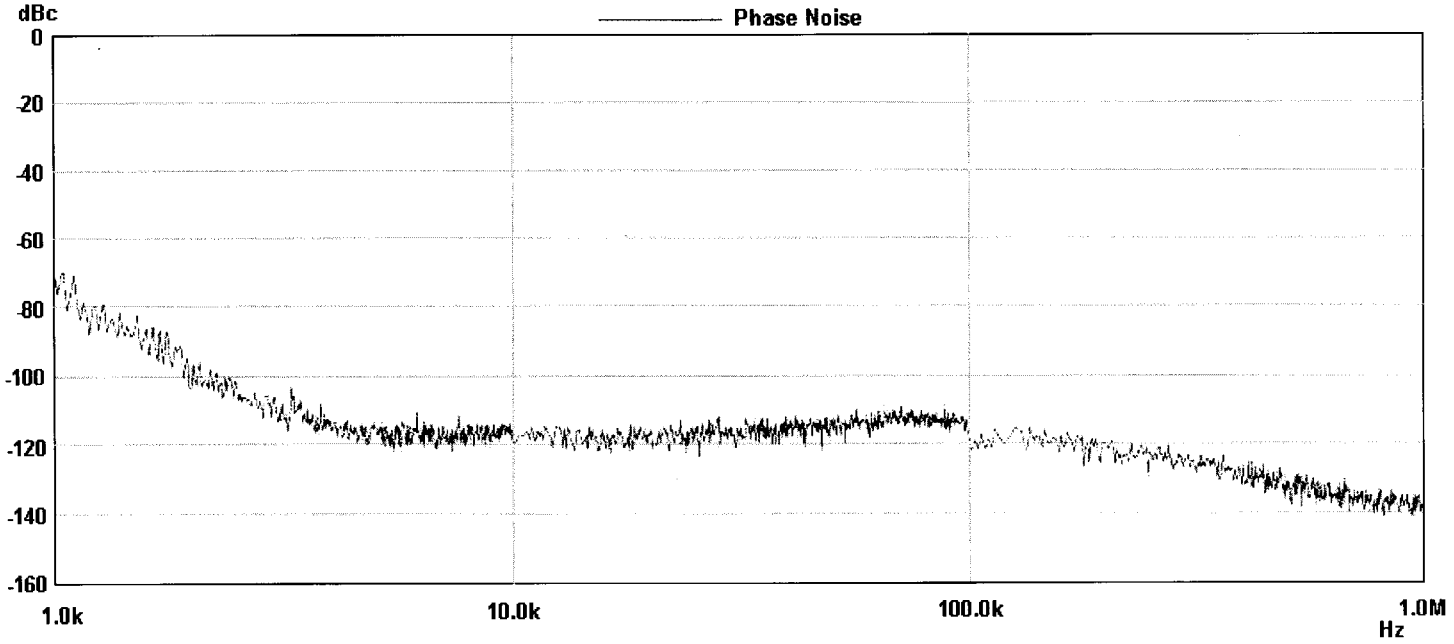

Figure 5-126 Phase noise of the oscillator of Figure 5-125. The noise floor is limited by the on-board isolation amplifier.

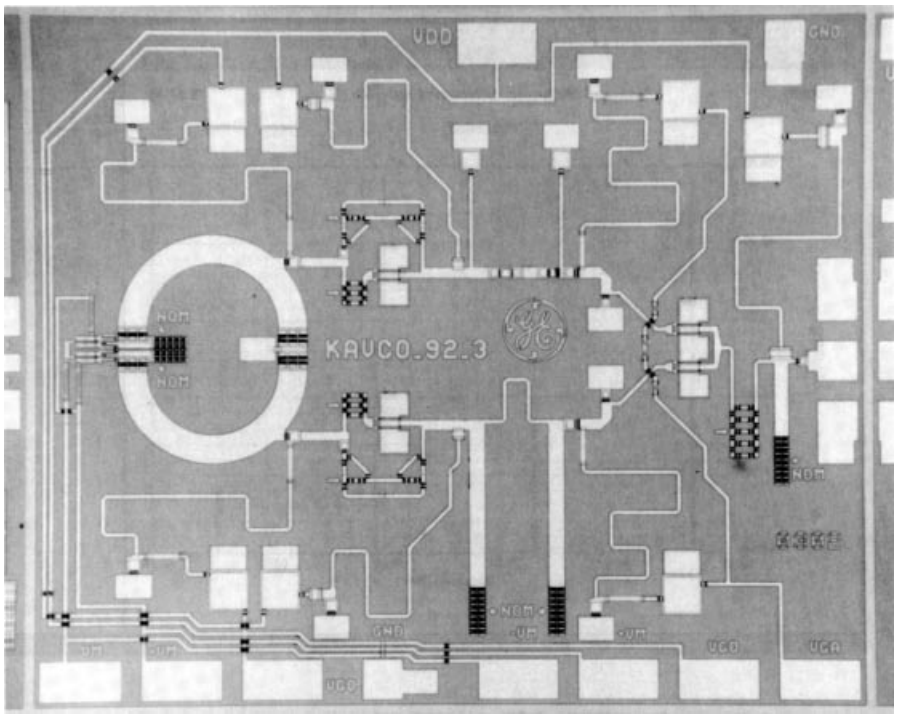

Figure 5-127 Layout of the Ka-band voltage-controlled oscillator.

Features

- Fundamental-mode, differential-ring VCO
- Electronically tunable
- Output power greater than 16 dBm
- Power-added efficiency (PAE) of 13%
- Compact size for easy integration with power amplifier
- 0.25-μm pseudomorphic HEMTs

Specifications

- Frequency range: Ka band
- Output power: 16 dBm minimum

When applying the same technology as shown in the previous bipolar example, the phase noise can be reduced significantly. Since field-effect transistors require a negative gate voltage, it is possible to sample the noise in the drain current using a resistor, amplify the noise with an appropriate loop amplifier, and modulate the gate voltage within a 1-MHz bandwidth.

A spectrum analyzer measurement of this oscillator type, as shown in Figure 5-128, indicates a phase noise of −78.6 dBc/Hz at an offset frequency of 100 kHz at a center frequency of 38 GHz, while the closed-loop phase noise of Figure 5-129 using the compen-

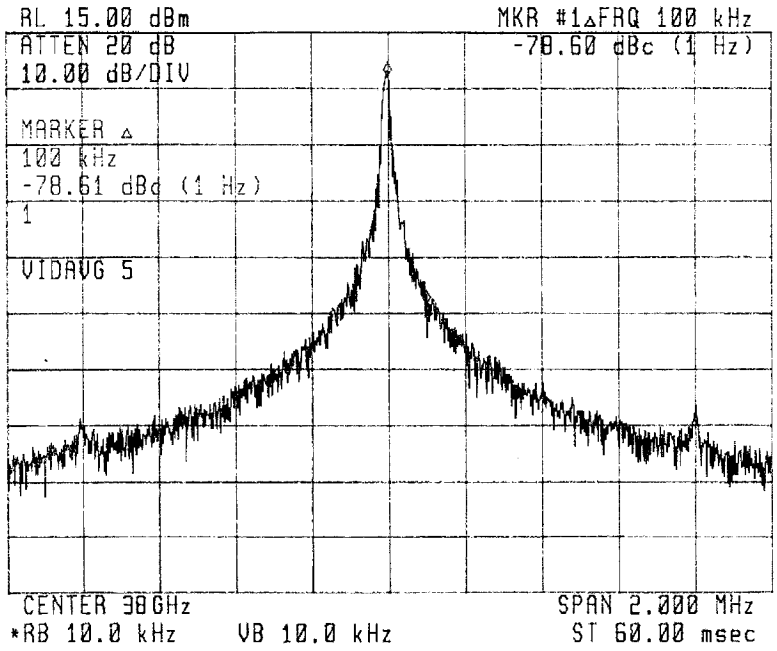

Figure 5-128 Spectrogram of the 38-GHz free-running push–pull VCO shown in Figure 5-127.

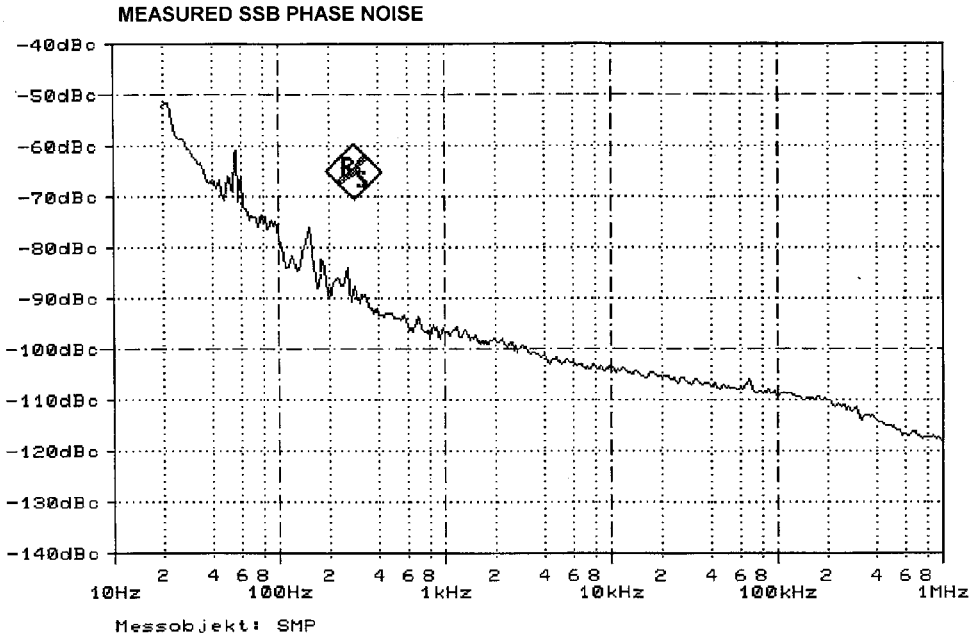

Figure 5-129 Phase-noise performance of a 38-GHz oscillator with phase-noise “clean-up” system.

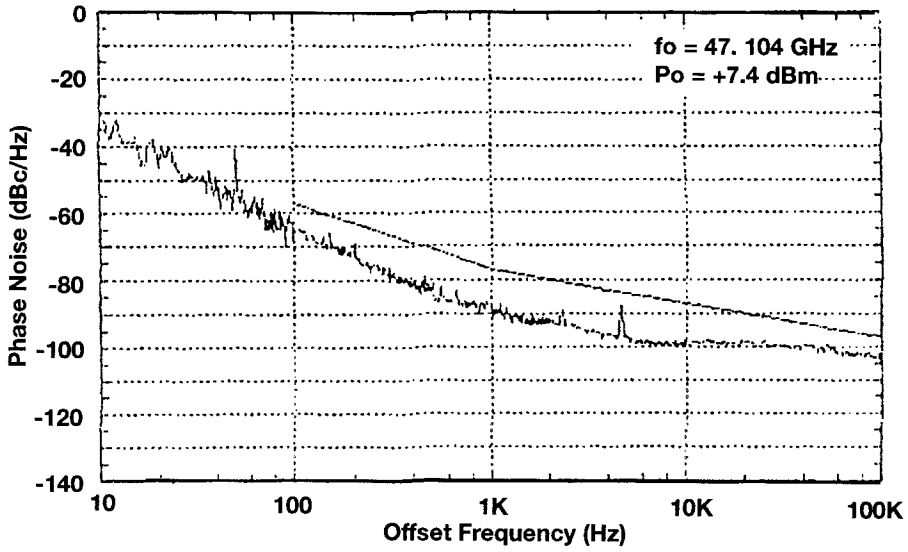

Figure 5-130 A 47-GHz loop-stabilized VCO with phase-noise performance similar to that of Figure 5-129.

sation scheme indicates a phase noise of about −108 dBc/Hz at 100 kHz. This is consistent with reported results from other researchers who have used complicated phase-locked loops to achieve similar performance as seen in Figure 5-130.

5-9-6 Summary

A novel method of improving the phase noise of oscillators has been demonstrated. This approach works well for low-frequency oscillators such as 1000 MHz up to the millimeter-wave range. It only requires an additional wideband dc biasing circuit, which applies noise feedback. The correctness of the theory has been demonstrated by appropriate validation.

RF/WIRELESS OSCILLATORS

5-1 INTRODUCTION TO FREQUENCY CONTROL

Practically all modern telecommunication and test equipment uses frequency-control techniques based on *frequency synthesis*, the production of the many frequencies involved in a radiocommunication system's modulation, transmission, reception, and demodulation functions through the combination and mathematical manipulation of a very few input frequencies. Although the frequency synthesis techniques now ascendant in wireless systems—phase-locked loops and, less commonly, direct digital synthesizers—are fundamentally different, all are ultimately based on RF oscillators. This chapter covers oscillator theory, evaluation, and design.

Two types of oscillators are needed in a phase-locked-loop system (Figure 5-1). One, typically a *crystal oscillator*, generates the synthesizer's reference signal. As Figure 5-1 reflects, the reference oscillator may be built into the synthesizer IC in highly integrated systems. The other oscillator, a *voltage-controlled oscillator* (VCO), is varied in frequency by the system to produce the synthesizer's output signal. Although designing good oscillators remains somewhat like black magic or a special art, we will show that mathematics and CAD tools, applied in conjunction with practical experience, can keep the oscillator design process well under control.

5-2 BACKGROUND

The oscillator was probably first discovered by people who wanted to build an amplifier back in the vacuum-tube days. Its modern equivalent is shown in Figure 5-2. Here we see an active device, a bipolar transistor or field-effect transistor, with a tuned input and output circuit. Under ideal circumstances, the voltage at the input is 180° out of phase and the amplifier is "stable." Because of the unavoidable feedback capacitance, a certain amount of energy is transferred from the output to the input at about 90° out of phase. If one of the tuned circuits is detuned to the point where the phase shift is –180°, oscillation will occur. This means that the small energy from the output will be amplified, brought back to the input in phase and

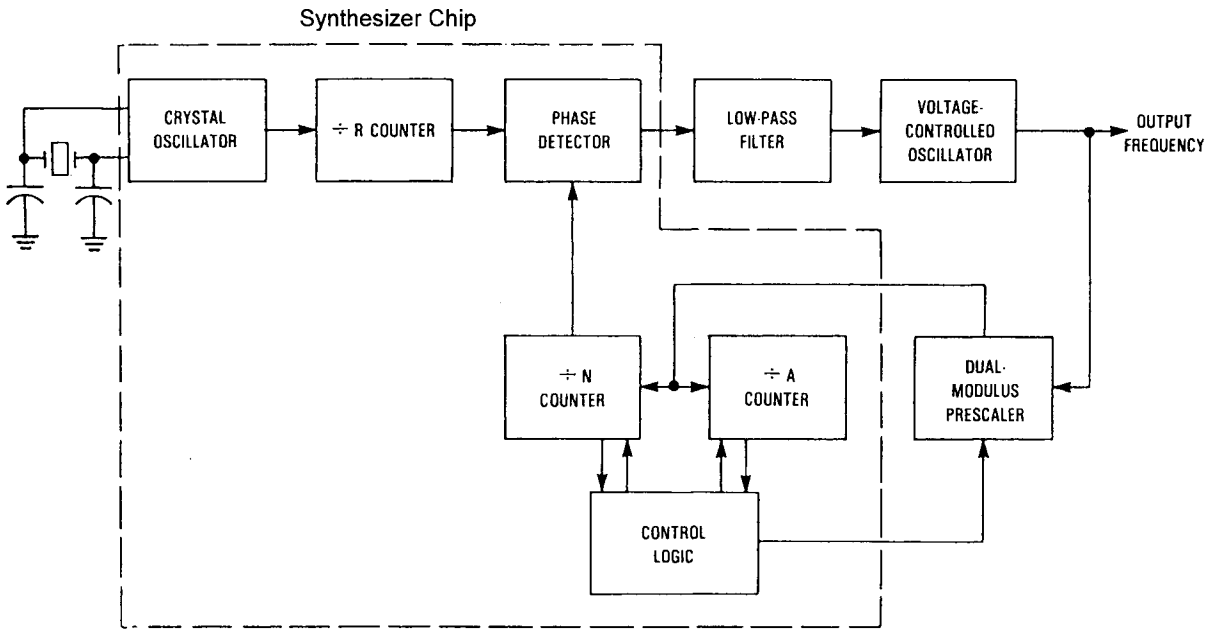

Figure 5-1 Block diagram of a modern, integrated frequency synthesizer. In this case, the designer has control over the VCO and the loop filter; the reference oscillator is part of the chip. In most cases (up to 2.5 GHz), the dual-modulus prescaler is inside the chip.

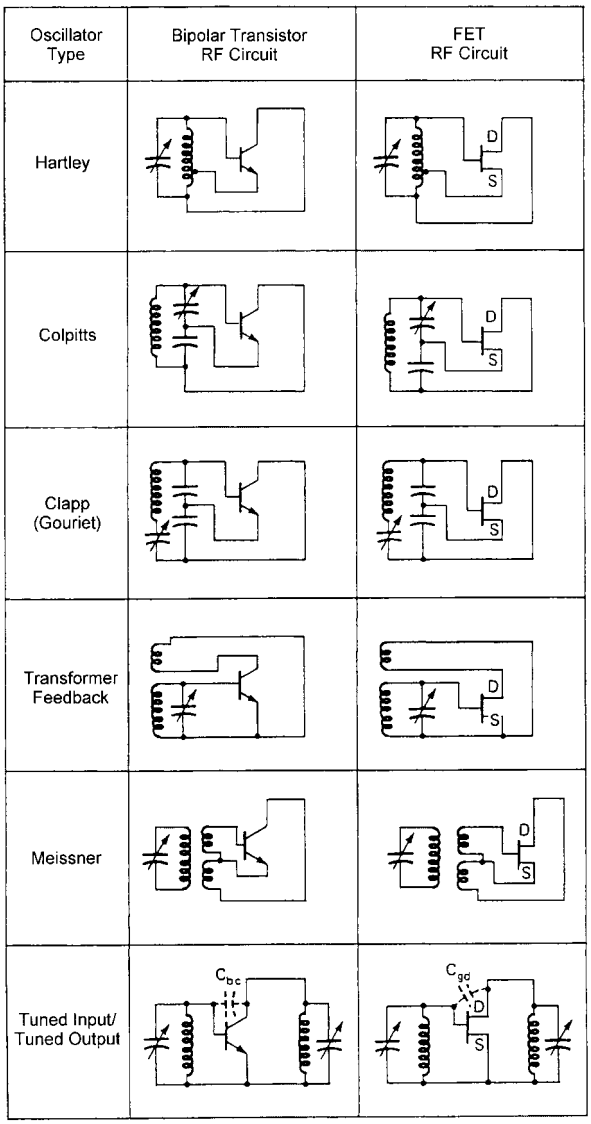

Figure 5-2 Schematic diagrams of RF connections for common oscillator circuits (dc and biasing circuits not shown) [1].

further amplified, causing the stage to "take off" and oscillate. Unless there is some mechanism to limit the amplitude of the oscillation at the input or output, its amplitude can theoretically increase to a level sufficient to destroy the device through breakdown effects or thermal runaway.

The criterion for oscillation was first described by Barkhausen [see Eq. (5-6) in the next section]. The conditions for oscillation exist when the feedback gain is high enough to cancel all losses and the difference between forward gain and reverse gain is less than zero. This implies also that oscillator circuits (Figure 5-2) provide a negative resistance, which is responsible for oscillation. The following mathematical treatment explains this.

5-3 OSCILLATOR DESIGN

A phase-locked loop generally has two oscillators: the oscillator at the output frequency and the reference oscillator. The reference oscillator at times can be another loop that is being mixed in, and the voltage-controlled oscillator (VCO) is controlled by either the reference or the oscillator loop. The VCO is one of the most important parts in a phase-locked-loop system, the performance of which is determined only by the loop filter at offsets inside the loop bandwidth, and only by the quality of the VCO design at offsets outside the loop bandwidth.

To some designers, VCO design appears to be magic. Shortly, we will go through the mathematics of the oscillator and some of its design criteria, but the results have only limited meaning. This is due to component tolerances, stray effects, and, most of all, nonlinear performance of the oscillator device, which can be modeled with only a certain degree of accuracy. However, after building oscillators for awhile, a certain feeling will be acquired for how to do this, and certain performance behavior will be predicted on a rule-of-thumb basis rather than on precise mathematical effort. For reasons of understanding, we will deal with the necessary mathematical equations, but we consider it essential to explain that these are only approximations.

5-3-1 Basics of Oscillators

An electronic oscillator is a device that converts dc power to a periodic output signal (ac power). If the output waveform is approximately sinusoidal, the oscillator is referred to as *sinusoidal.* There are many other oscillator types normally referred to as *relaxation* oscillators. For application in frequency synthesizers, we will explore only sinusoidal oscillators for reasons of purity and noise-sideband performance.

All oscillators are inherently nonlinear. Although the nonlinearity results in some distortion of the signal, linear analysis techniques can normally be used for the analysis and design of oscillators. Figure 5-3 shows, in block diagram form, the necessary components of an oscillator. It contains an amplifier with frequency-dependent forward loop gain $G(j\omega)$ and a frequency-dependent feedback network $H(j\omega)$.

The output voltage is given by

$$V_o = \frac{V_{\text{in}} G(j\omega)}{1 + G(j\omega)H(j\omega)} \tag{5-1}$$

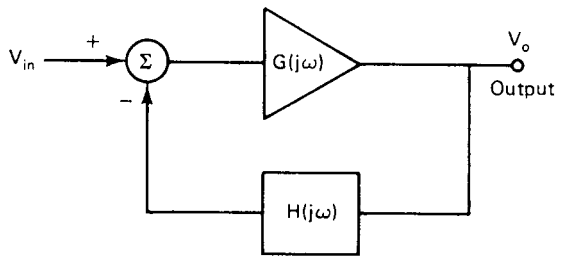

Figure 5-3 Block diagram of an oscillator showing forward and feedback loop components.

For an oscillator, the output V_o is nonzero even if the input signal $V_i = 0$. This can only be possible if the forward loop gain is infinite (which is not practical), or if the denominator

$$1 + G(j\omega)H(j\omega) = 0 \tag{5-2}$$

at some frequency ω_o. This leads to the well-known condition for oscillation (the *Nyquist criterion*), where at some frequency ω_o

$$G(j\omega_o)H(j\omega_o) = -1 \tag{5-3}$$

That is, the magnitude of the open-loop transfer function is equal to 1:

$$|G(j\omega_o)H(j\omega_o)| = 1 \tag{5-4}$$

and the phase shift is 180°:

$$\arg[G(j\omega_o)H(j\omega_o)] = 180° \tag{5-5}$$

This can be more simply expressed as follows: If in a negative-feedback system, the open-loop gain has a total phase shift of 180° at some frequency ω_o, the system will oscillate at that frequency provided that the open-loop gain is unity. If the gain is less than unity at the frequency where the phase shift is 180°, the system will be stable, whereas if the gain is greater than unity, the system will be unstable.

This statement is not correct for some complicated systems, but it is correct for those transfer functions normally encountered in oscillator design. The conditions for stability are also known as the *Barkhausen criteria*, which state that if the closed-loop transfer function is

$$\frac{V_o}{V_i} = \frac{\mu}{1 - \mu\beta} \tag{5-6}$$

the system will oscillate provided that $\mu\beta = 1$. This is equivalent to the Nyquist criterion, the difference being that the transfer function is written for a loop with positive feedback. Both versions state that the total phase shift around the loop must be 360° at the frequency of oscillation and the magnitude of the open-loop gain must be unity at that frequency.

The following analysis of the relatively simple oscillator shown in Figure 5-4 illustrates the design method. The linearized (and simplified) equivalent circuit of Figure 5-4 is given in Figure 5-5. h_{rb} has been neglected, and $1/h_{ob}$ has been assumed to be much greater than the load resistance R_L and is also ignored.

Note that the transistor is connected in the common-base configuration, which has no voltage phase inversion (the feedback is positive), so the conditions for oscillation are

$$|G(j\omega_o)H(j\omega_o) = 1| \tag{5-7}$$

and

$$\arg[G(j\omega_o)H(j\omega_o)] = 0° \tag{5-8}$$

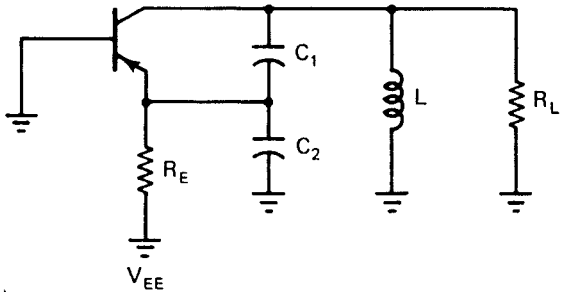

Figure 5-4 Oscillator with capacitive voltage divider.

The circuit analysis can greatly be simplified by assuming that

$$\frac{1}{\omega(C_2 + C_1)} << \frac{h_{ib}R_E}{h_{ib} + R_E} \tag{5-9}$$

and also that the Q of the load impedance is high. In this case the circuit reduces to that of Figure 5-6, where

$$V = \frac{V_o C_1}{C_1 + C_2} \tag{5-10}$$

and

$$R_{\text{eq}} = \frac{h_{ib}R_E}{h_{ib} + R_E}\left(\frac{C_1 + C_2}{C_1}\right)^2 \tag{5-11}$$

Figure 5-7 shows how the input impedance of an oscillator circuit—in this case, a BJT Colpitts oscillator minus its resonator—satisfies this condition for oscillation.

Then the forward gain

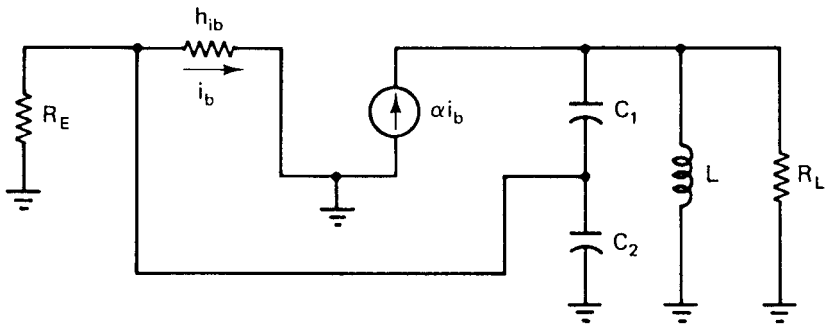

Figure 5-5 Linearized and simplified equivalent circuit of Figure 5-4.

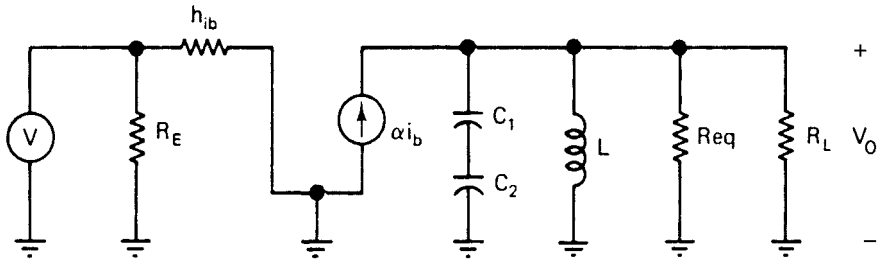

Figure 5-6 Further simplification of Figure 5-4, assuming high-impedance loads.

$$G(j\omega) = \frac{h_{fb}}{h_{ib}} Z_L = \frac{\alpha}{h_{ib}} Z_L \tag{5-12}$$

and

$$H(j\omega) = \frac{C_1}{C_1 + C_2} \tag{5-13}$$

where

$$Y_L = \frac{1}{Z_L} = \frac{1}{j\omega L} + \frac{1}{R_{\text{eq}}} + \frac{1}{R_L} + \frac{1}{j\omega C} \tag{5-14}$$

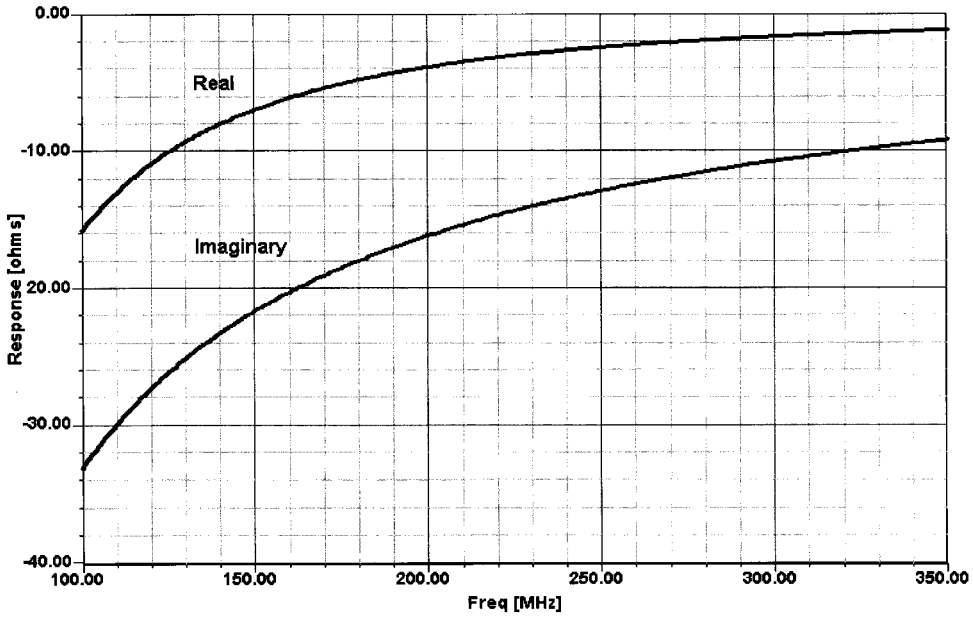

Figure 5-7 Calculated input impedance of a 200-MHz BJT Colpitts oscillator with its resonator removed. (Figure 5-46 shows an equivalent graph with the resonator present.)

A necessary condition for oscillation is that

$$\arg[G(j\omega)H(j\omega)] = 0^\circ \tag{5-15}$$

Since H does not depend on frequency in this example, if arg(GH) is zero, the phase shift of the load impedance Z_L must also be zero. This occurs only at the resonant frequency of the circuit,

$$\omega_o = \frac{1}{\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{5-16}$$

At this frequency

$$Z_L = \frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L} \tag{5-17}$$

and

$$GH = \frac{h_{fb}}{h_{ib}}\left(\frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L}\right)\frac{C_1}{C_1 + C_2} \tag{5-18}$$

The other condition for oscillation is the magnitude constraint that

$$G(j\omega)H(j\omega) = \frac{\alpha}{h_{ib}}\left(\frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L}\right)\frac{C_1}{C_1 + C_2} = 1 \tag{5-19}$$

Three-Reactance Oscillators. Although the block-diagram formulation of the stability criteria is an easy way to express stability mathematically, it is frequently not the easiest to apply since it is often difficult to identify the forward loop gain $G(j\omega)$ and the feedback ratio $H(j\omega)$ in electronic systems. A direct analysis of the circuit equations is frequently simpler than the block diagram interpretation (particularly for single-stage amplifiers). Figure 5-8 shows a generalized circuit for an electronic amplifier.

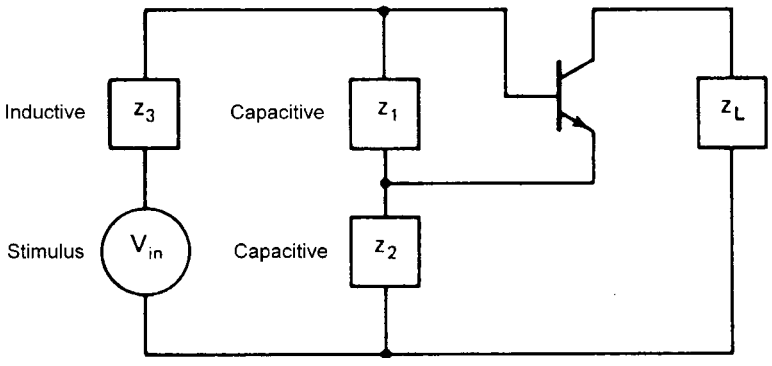

Figure 5-8 Generalized circuit for an oscillator using an amplifier model. Z_3 is inductive even with a capacitor in series with it.

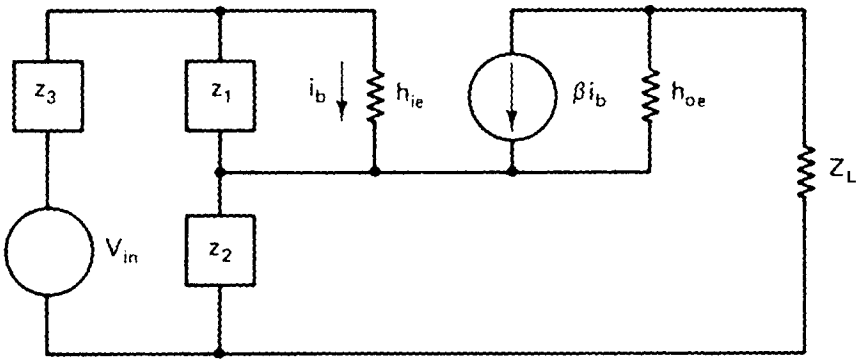

Figure 5-9 Small-signal equivalent circuit of Figure 5-8.

By inspecting Figure 5-8, one can see the three necessary reactances and the load. All other known circuits are derivatives of this by rotation. The small-signal equivalent circuit is given in Figure 5-9 (where h_{re} has been neglected).

Normally, h_{oe} can also be assumed sufficiently small and can be neglected. The loop equations are then

$$V_{\text{in}} = I_1(Z_3 + Z_1 + Z_2) - I_b Z_1 + \beta I_b Z_2 \tag{5-20}$$

$$0 = -I_1 Z_1 + I_b(h_{ie} + Z_1) \tag{5-21}$$

For the amplifier to oscillate, the currents I_b and I_1 must be nonzero even when $V_1 = 0$. This is only possible if the system determinant

$$\Delta = \begin{vmatrix} Z_3 + Z_1 + Z_2 & \beta Z_2 - Z_1 \\ -Z & h_{ie} + Z_1 \end{vmatrix} \tag{5-22}$$

is equal to 0. That is,

$$(Z_3 + Z_1 + Z_2)(h_{ie} + Z_1) - Z_1^2 + \beta Z_1 Z_2 = 0 \tag{5-23}$$

which reduces to

$$(Z_1 + Z_2 + Z_3)h_{fe} + Z_1 Z_2 \beta + Z_1(Z_2 + Z_3) = 0 \tag{5-24}$$

Assume for the moment that Z_1, Z_2, and Z_3 are purely reactive impedances. [It is easily seen that Eq. (5-24) does not have a solution if all three impedances are real.] Since both the real and imaginary parts must be zero, Eq. (5-24) is equivalent to the following equations if

$$h_{ie}(Z_1 + Z_2 + Z_3) = 0 \tag{5-25}$$

and

$$Z_1[(1 + \beta)Z_2 + Z_3] = 0 \tag{5-26}$$

Since β is real and positive, Z_2 and Z_3 must be of opposite sign for Eq. (5-26) to hold. That is,

$$(1 + \beta)Z_2 = -Z_3 \tag{5-27}$$

Therefore, since h_{ie} is nonzero, Eq. (5-25) reduces to

$$Z_1 + Z_2 - (1 + \beta)Z_2 = 0 \tag{5-28}$$

or

$$Z_1 = \beta Z_2 \qquad [C_1 < C_2; L_1 > L_2] \tag{5-29}$$

Thus, since β is positive, Z_1 and Z_2 will be reactances of the same kind. If Z_1 and Z_2 are capacitors, Z_3 is an inductor and the circuit is as shown in Figure 5-10. It is referred to as a *Colpitts* oscillator, named after the person who first described it.

If Z_1 and Z_2 are inductors and Z_3 is a capacitor as illustrated in Figure 5-11, the circuit is called a *Hartley* oscillator.

Example 1. Design a Colpitts circuit to oscillate at 200 MHz, using a transistor (operating at I_C = 6 mA dc) that has an input impedance

$$\text{Mag}(Z_{11}) = \frac{26 \text{ mV}}{I_C} \beta = 282\ \Omega (h_{ie} \triangleq Z_{11})$$

and

$$\beta_{RF} = 65; \quad \beta_{OSC} = 10 \quad \text{(large-signal condition)}$$

The oscillating transistor operates under large-signal conditions, generating harmonics in addition to the fundamental. Most of the transistor's current gain will come from dc biasing. β_{OSC}, its large-signal beta at the fundamental frequency of oscillation, must therefore be considerably less than β_{RF}, the small-signal, single-tone value, as the

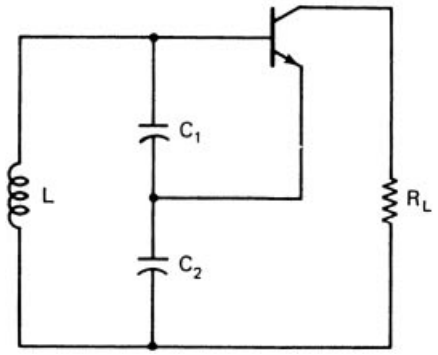

Figure 5-10 Colpitts oscillator.

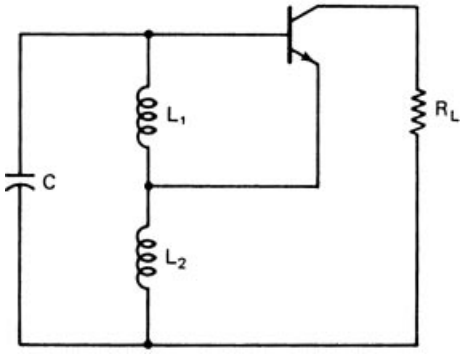

Figure 5-11 Hartley oscillator.

transistor's available current gain, β_0, is distributed among the dc, fundamental, and harmonic components present ($\beta_0 = \beta_{dc} + \beta_{OSC} + \beta_{OSC,F2} + \beta_{OSC,F3}\ldots$).

Solution: For the Colpitts circuit, Z_1 and Z_2 are capacitive reactances and Z_3 is an inductive reactance. Let $Z_2 = -j1.6\ \Omega$; then [Eq. (5-27)]

$$Z_3 = -(1 + \beta)Z_2 = -(1 + 10) \times (-1.6) \approx j17\ \Omega$$

and [Eq. (5-25)]

$$Z_1 = -(Z_2 + Z_3) \approx -j17\ \Omega$$

At 200 MHz, these impedances correspond to component values of $C_1 = 50$ pF, $C_2 = 500$ pF, and $L = 30$ nH. The oscillator will probably work with C_2 values larger than 500 pF, but at the loss of safety margin for tolerances in production, beta, temperature, and phase-noise performance. The completed circuit, except for biasing, is shown in Figure 5-12.

If Z_1, Z_2, Z_3, or h_{ie} is complex, the preceding analysis is more complicated, but the conditions for oscillation can still be obtained from Eq. (5-24). For example, if, in the Colpitts

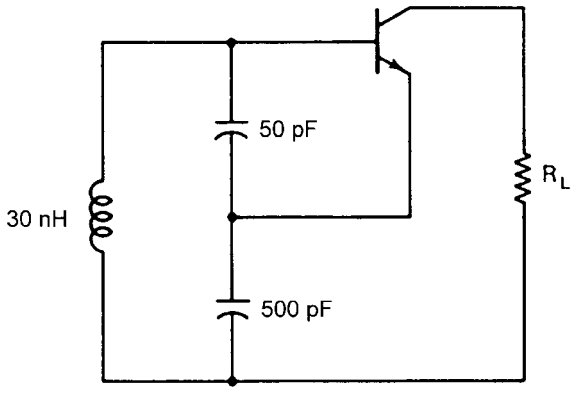

Figure 5-12 Design example of a Colpitts oscillator.

circuit, there is a resistor R in series with $L(Z_3 = R + j\omega L)$, Eq. (5-24) reduces to two equations:

$$h_{ie}\left(\omega L - \frac{1}{\omega C_1} - \frac{1}{\omega C_2}\right) - \frac{R}{\omega C_1} = 0 \tag{5-30}$$

and

$$h_{ie}R - \frac{1+\beta}{\omega^2 C_1 C_2} + \frac{1}{\omega C_1}\omega L = 0 \tag{5-31}$$

Define

$$C_1' = \frac{C_1}{1 + R/h_{ie}} \tag{5-32}$$

The resonant frequency at which oscillations will occur is found from Eq. (5-30) to be

$$\omega_o = \frac{1}{\sqrt{L[C_1' C_2/(C_1' + C_2)]}} \tag{5-33}$$

and for oscillations to occur $R_e(h_{ie}) = R_e(Z_{11})$ must be less than or equal to

$$R_e(h_{ie}) \leq \frac{1+\beta}{\omega_o^2 C_1 C_2} - \frac{L}{C_1} \tag{5-34}$$

If R becomes too large, Eq. (5-32) cannot be satisfied and oscillations will stop. In general, it is advantageous to have

$$X_{C_1} X_{C_2} = \frac{1}{\omega^2 C_1 C_2} \tag{5-35}$$

with $X \triangleq 1/\omega c$ as large as possible, since R can be large. However, if C_1 and C_2 are too small (large and X_{C_1} and X_{C_2}), the input and output capacitances of the transistor, which shunt C_1 and C_2, respectively, become important. A good, stable design will always have C_1 and C_2 much larger than the transistor capacitances they shunt.

Example 2. In Example 1, will the circuit still oscillate if the inductor now has a $Q_u = 100$? If the transistor input capacitance is 5 pF, what effect will this have on the system?

Solution: In Example 1, $X_L = 17\ \Omega$, $C_1 = 50$ pF, and $C_2 = 500$ pF. Since $C_1 = 50$ pF, adding 5 pF in parallel will change the equivalent C to 55 pF. As the inductor $Q_u = 100$, the equivalent resistance R in series with the lossless inductor is

$$R = \frac{17}{100} = 0.17\ \Omega$$

The new resonant frequency can be determined from Eqs. (5-32) and (5-33):

$$C_1' = \frac{C_1}{1 + R/h_{ie}} = \frac{55}{1 + (0.17/280)} \approx \frac{55}{1.0006} = 54.96 \text{ pF}$$

and

$$f_o = \frac{1}{2\pi L[C_1' C_2/(C_1' + C_2)]^{1/2}} \cong 191.56 \text{ MHz}$$

The effect of the finite inductor Q causes a negligible change in the oscillating frequency compared to the effect of the transistor input capacitance, which reduces the resonant frequency 4.2%. Because the large-signal beta, β_{OSC}, is 10, there is enough loop gain to maintain oscillation.

Two-Port Oscillator. Although Eqs. (5-25) and (5-26) can be used to determine the exact expressions for oscillation, they are often difficult to use and add little insight into the design process. An alternative interpretation, although not as accurate, will now be presented. It is based on the fact that an ideal tuned circuit (infinite Q), once excited, will oscillate infinitely because there is no resistance element present to dissipate the energy. In the actual case where the inductor Q is finite, the oscillations die out because energy is dissipated in the resistance. It is the function of the amplifier to maintain oscillations by supplying an amount of energy equal to that dissipated. This source of energy can be interpreted as a negative resistor in series with the tuned circuit. If the total resistance is positive, the oscillations will die out, while the oscillation amplitude will increase if the total resistance is negative. To maintain oscillations, the two resistors must be of equal magnitude. To see how a negative resistance is realized, the input impedance of the circuit in Figure 5-13 will be derived.

If h_{oe} is sufficiently small ($h_{oe} << 1/R_L$), the equivalent circuit is as shown in Figure 5-13. The steady-state loop equations are

$$V_{\text{in}} = I_{\text{in}}(X_{C_1} + X_{C_2}) - I_b(X_{C_1} - \beta X_{C_2}) \tag{5-36}$$

$$0 = -I_{\text{in}}(X_{C_1}) + I_b(X_{C_1} + h_{ie}) \tag{5-37}$$

After I_b is eliminated from these two equations, Z_{in} is obtained as

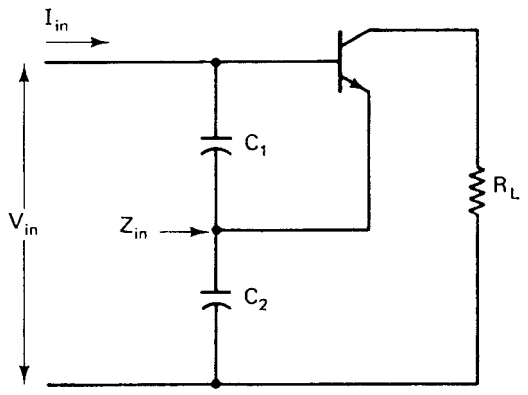

Figure 5-13 Calculation of input impedance of the negative-resistance oscillator.

$$Z_{\text{in}} = \frac{V_{\text{in}}}{I_{\text{in}}} = \frac{(1+\beta)X_{C_1}X_{C_2} + h_{ie}(X_{C_1} + X_{C_2})}{X_{C_1} + h_{ie}} \tag{5-38}$$

If $X_{C_1} << h_{ie}$, the input impedance is approximately equal to

$$Z_{\text{in}} \approx \frac{1+\beta}{h_{ie}} X_{C_1}X_{C_2} + (X_{C_1} + X_{C_2}) \tag{5-39}$$

$$Z_{\text{in}} \approx \frac{-g_m}{\omega^2 C_1 C_2} + \frac{1}{j\omega[C_1C_2/(C_1 + C_2)]} \tag{5-40}$$

That is, the input impedance of the circuit shown in Figure 5-14 is a negative resistor,

$$R = \frac{-g_m}{\omega^2 C_1 C_2} \tag{5-41}$$

in series with a capacitor,

$$C_{\text{in}} = \frac{C_1 C_2}{C_1 + C_2} \tag{5-42}$$

which is the series combination of the two capacitors.

With an inductor L (with the series resistance R_S) connected across the input, it is clear that the condition for sustained oscillation is

$$R_S = \frac{g_m}{\omega^2 C_1 C_2} \tag{5-43}$$

and the frequency of oscillation is

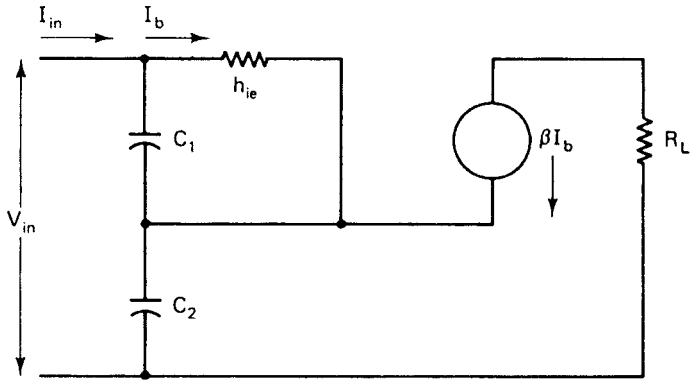

Figure 5-14 Equivalent small-signal circuit of Figure 5-13.

$$f_o = \frac{1}{2\pi\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{5-44}$$

This interpretation of the oscillator readily provides several guidelines that can be used in the design. First, C_1 should be as large as possible so that

$$X_{C_1} << h_{ie} \tag{5-45}$$

and C_2 is to be large so that

$$X_{C_2} << \frac{1}{h_{oe}} \tag{5-46}$$

When these two capacitors are large, the transistor base-to-emitter and collector-to-emitter capacitances will have a negligible effect on the circuit's performance. However, Eq. (5-43) limits the maximum value of the capacitances since

$$r \leq \frac{g_m}{\omega^2 C_1 C_2} \leq \frac{G}{\omega^2 C_1 C_2} \tag{5-47}$$

where G is the maximum value of g_m. For a given product of C_1 and C_2, the series capacitance is at maximum when $C_1 = C_2 = C_m$. Thus Eq. (5-47) can be written

$$\frac{1}{\omega C_m} > \sqrt{\frac{r}{G}} \tag{5-48}$$

This equation is important in that it shows that for oscillations to be maintained, the minimum permissible reactance $1/\omega C_m$ is a function of the resistance of the inductor and the transistor's mutual conductance, g_m.

An oscillator circuit known as the *Clapp circuit* or *Clapp–Gouriet circuit* is shown in Figure 5-15. This oscillator is equivalent to the one just discussed, but it has the practical advantage of being able to provide another degree of design freedom by making C_o much smaller than C_1 and C_2.

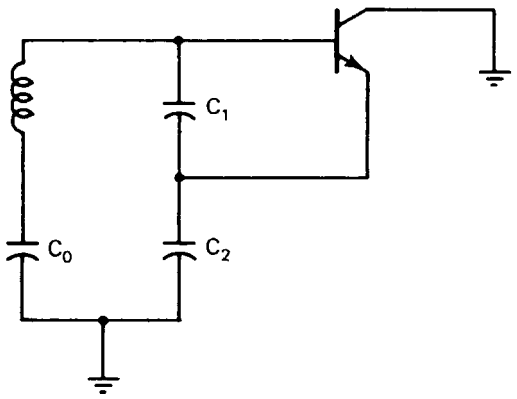

Figure 5-15 Circuit of a Clapp oscillator.

It is possible to use C_1 and C_2 to satisfy the condition of Eq. (5-47) and then adjust C_o for the desired frequency of oscillation ω_o, which is determined from

$$\omega_o L - \frac{1}{\omega_o C_o} - \frac{1}{\omega_o C_1} - \frac{1}{\omega_o C_2} = 0 \tag{5-49}$$

Amplitude Stability. Linearized analysis of the oscillator is convenient for determining the frequency but not the amplitude of the oscillation. The Nyquist stability criterion defines the frequency of oscillation as the frequency at which the loop phase shift is 360°, but it says nothing about the oscillation amplitude. If no provisions are taken to control the amplitude, it is susceptible to appreciable drift. Two frequently used methods for controlling the amplitude are operating the transistor in the nonlinear region or using a second stage for amplitude limiting. For the single-stage oscillator, amplitude limiting is accomplished by designing an unstable oscillator; that is, the loop gain is made greater than 1 at the frequency at which the phase shift is 180°. As the amplitude increases, the β of the transistor decreases, causing the loop gain to decrease until the amplitude stabilizes. This is a self-limiting oscillator. There are nonlinear analysis techniques predicting the amplitude of oscillation, but their results are approximate except in idealized cases, forcing the designer to resort to an empirical approach.

An example of a two-stage emitter-coupled oscillator is shown in Figure 5-16. In this circuit, amplitude stabilization occurs as a result of current limiting in the second stage. This circuit has the additional advantage that it has output terminals that are isolated from the feedback path. The emitter signal of Q_2, having a rich harmonic content, is normally used as output. Harmonics of the fundamental frequency can be extracted at the emitter of Q_2 by using an appropriately tuned circuit. Note that the collector of Q_2 is isolated from the feedback path.

Phase Stability. An oscillator has a frequency or phase stability that can be considered in two separate parts. First, there is *long-term* stability, in which the frequency changes over a period of minutes, hours, days, weeks, or even years. This frequency stability is normally limited by the circuit components' temperature coefficients and aging rates. The other part,

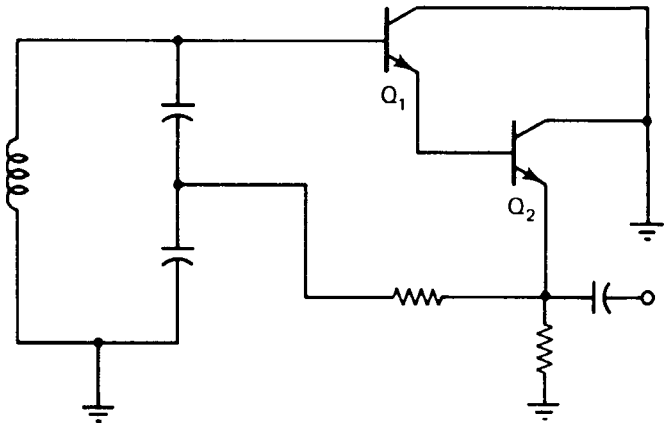

Figure 5-16 Two-stage, emitter-coupled oscillator.

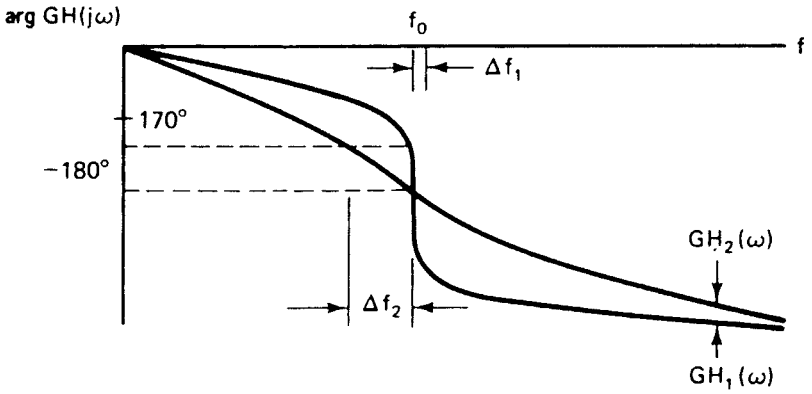

Figure 5-17 Phase plot of two open-loop systems with different resonator *Q* values.

short-term frequency stability, is measured in terms of seconds. One form of short-term instability is due to changes in phase of the system; here the term *phase stability* is used synonymously with frequency stability. It refers to how the frequency of oscillation reacts to small changes in phase shift of the open-loop system. It can be assumed that the system with the largest rate of change of phase versus frequency $d\phi/df$ will be the most stable in terms of frequency stability. Figure 5-17 shows the phase plots of two open-loop systems used in oscillators. At the system crossover frequency, the phase shift is −180°. If some external influence causes a shift in phase—say, it adds 10° of phase lag—the frequency will change until the total phase shift is again 0°. In this case, the frequency will decrease to the point where the open-loop phase shift is 170°. Figure 5-17 shows that Δf_2, the change in frequency associated with the 10° change in phase of GH_2, is greater than the change in frequency Δf_1, associated with the open-loop system GH_1, whose phase is changing more rapidly near the open-loop crossover frequency.

This qualitative discussion illustrates that $d\phi/df$ at $f = f_o$ is a measure of an oscillator's phase stability. It provides a good means of quantitatively comparing the phase stability of two oscillators. Consider the simple parallel tuned circuit shown in Figure 5-18.

For this circuit, the two-port is

$$\frac{V_o(j\omega)}{I(j\omega)} = \frac{R}{1 + jQ[(\omega/\omega_o) - (\omega_o/\omega)]} \tag{5-50}$$

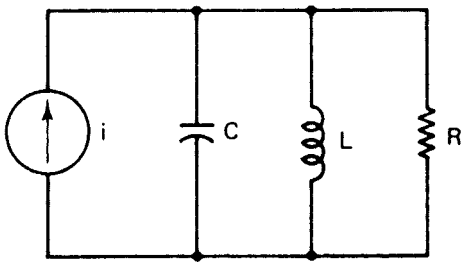

Figure 5-18 Parallel tuned circuit for phase-shift analysis.

where

$$\omega_o = \frac{1}{\sqrt{LC}} \quad \text{and} \quad Q = \frac{R}{\omega_o L} \tag{5-51}$$

The circuit phase shift is

$$\arg \frac{V_o}{I} = \theta = \tan^{-1} Q\left(\frac{\omega}{\omega_o} - \frac{\omega_o}{\omega}\right) \tag{5-52}$$

and

$$\frac{d\theta}{d\omega} = \frac{1/Q}{1/Q^2 + [(\omega^2 - \omega_o^2)/\omega_o\omega]^2} \frac{\omega^2 + \omega_o^2}{(\omega_o\omega)^2} \tag{5-53}$$

At the resonant frequency ω_o,

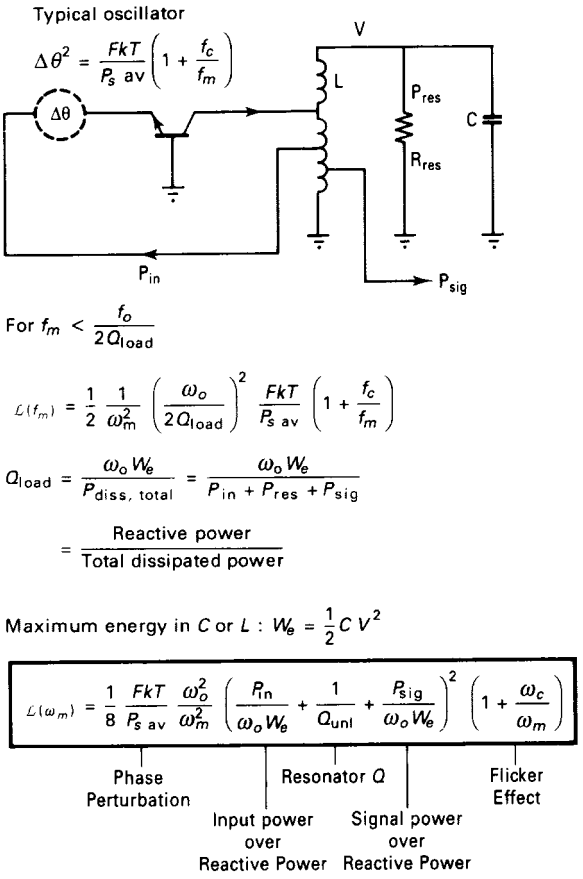

Figure 5-19 Diagram for a feedback oscillator illustrating the principles involved, and showing the key components considered in the phase noise calculation and its contribution.

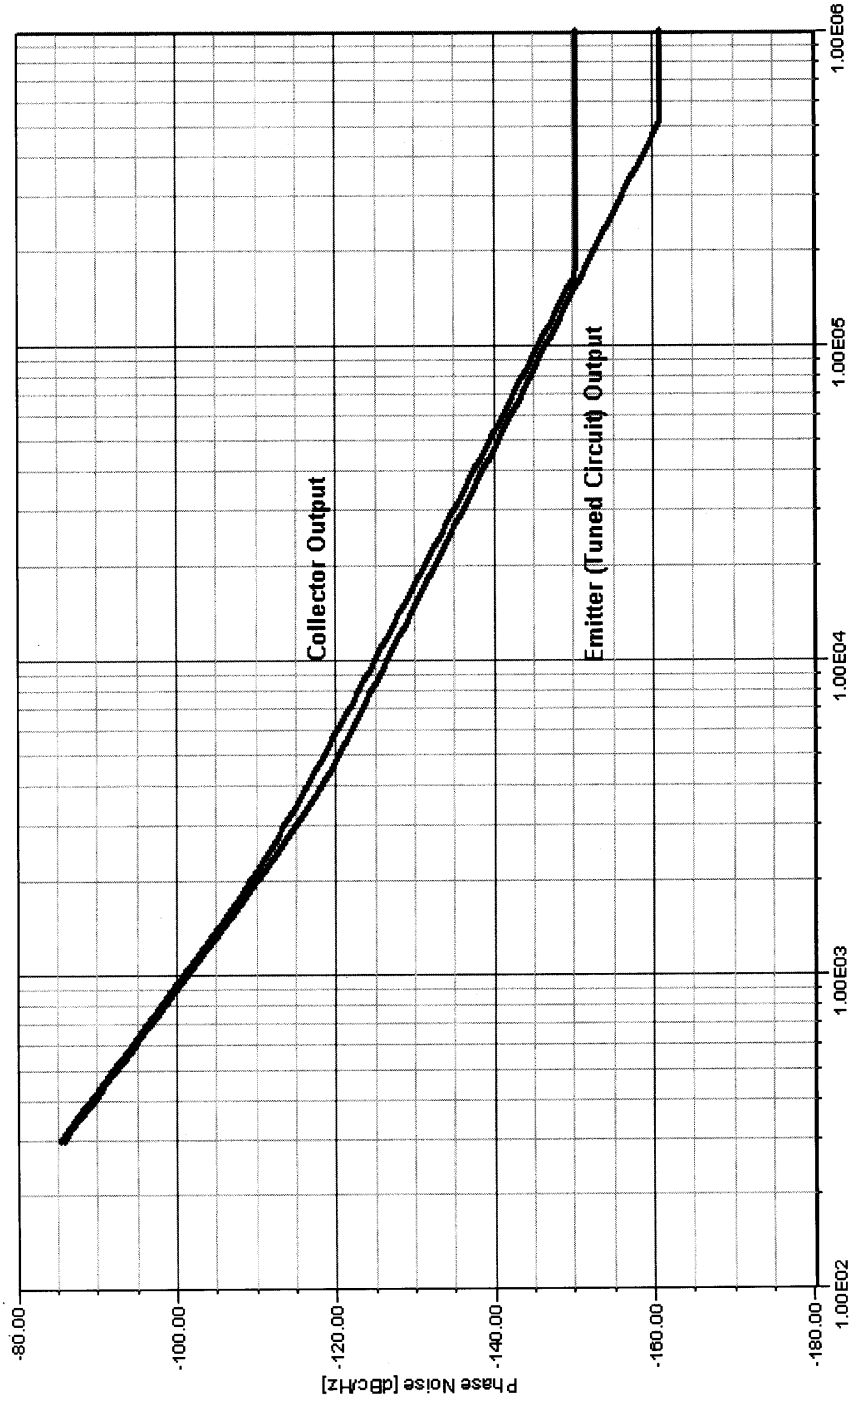

Figure 5-20 Phase noise with oscillator output taken from collector (upper trace) versus emitter (lower trace) of a BJT oscillator.

$$\left.\frac{dQ}{d\omega}\right|_{\omega=\omega_o} = \frac{2Q}{\omega_o} \tag{5-54}$$

The frequency stability factor S_F is defined as the change in phase $d\phi/d\omega$ divided by the normalized change in frequency $\Delta\omega/\omega_o$. That is,

$$S_F = 2Q \tag{5-55}$$

S_F is a measure of the short-term stability of an oscillator. Equation (5-54) indicates that the higher the circuit Q, the higher the stability factor. This is one reason for using high-Q circuits in oscillator circuits. Another reason is the ability of the tuned circuit to filter out undesired harmonics and noise.

The two oscillator types shown so far can be considered two-port oscillators because one port is responsible for oscillation and the other port supplies the output power. This type of output supposedly has better isolation (although this is not true at higher frequencies) but has a higher noise floor. A better way of extracting energy is shown in Figure 5-19.

These types of oscillators are essentially what is referred to as *two-port* oscillators. The name comes from the fact that the oscillating device has two ports, with the output energy taken from the output port, typically the collector or drain, while the tuned circuit is at the input port. For years, it was widely held that this type of design provided better isolation between the tuned circuit and termination; unfortunately, because of the Miller effect, this is not true. At the higher frequencies, changes in output-port loading affect the input port, resulting in *pulling*, a detuning effect that increases with frequency. In addition, taking the output from the collector or the drain results in a poorer signal-to-noise ratio than that achievable by extracting energy from the tuned circuit itself. The only real advantages the collector output provides are more power and higher efficiency, but definitely at the expense of phase noise, which is often referred to as *SSB phase noise* because it is expressed in terms of the decibel ratio of the noise power in a single (the upper or lower) noise sideband, in a 1-Hz bandwidth centered at a specified frequency offset from the oscillator carrier, to the carrier power. Figure 5-20 compares the phase noise of an oscillator with the energy taken off the collector and the tuned circuit; the difference is highly visible.

5-4 OSCILLATOR CIRCUITS

5-4-1 Hartley

Figure 5-21 shows the Hartley oscillator configuration, in which feedback is obtained by tapping the resonator. In practice, the resonator can consist of a single tapped inductor or two separate, magnetically uncoupled inductors, with feedback obtained at their junction.

5-4-2 Colpitts

Figure 5-22 shows the Colpitts oscillator configuration, in which feedback is obtained via a capacitive voltage divider.

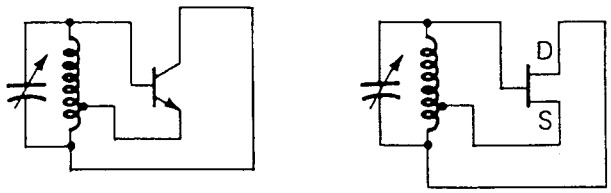

Figure 5-21 Hartley oscillator.

5-4-3 Clapp–Gouriet

Figure 5-23 shows the Clapp–Gouriet oscillator. Like the Colpitts, the Clapp–Gouriet obtains its feedback via a capacitive voltage divider; unlike the Colpitts, an additional capacitor series-tunes the resonator. The Pierce oscillator, a configuration used only with crystals, is a rotation of the Clapp–Gouriet oscillator in which the emitter is at RF ground.

5-5 DESIGN OF RF OSCILLATORS

5-5-1 General Thoughts on Transistor Oscillators

An estimate of the noise performance of an oscillator is

$$\mathcal{L}(\omega_m) = \frac{1}{8}\frac{FkT}{P_{s,\text{av}}}\frac{\omega_0^2}{\omega_m^2}\left(\frac{P_{\text{in}}}{\omega_0 W_e} + \frac{1}{Q_{\text{unl}}} + \frac{P_{\text{sig}}}{\omega_0 W_e}\right)^2\left(1 + \frac{\omega_c}{\omega_m}\right) \tag{5-56}$$

Phase perturbation

Resonator Q

Flicker effect

Input power/Reactive power ratio

Signal power/Reactive power ratio

We just state this here without presenting oscillator noise theory itself. (Also see Figure 5-19.) This equation is based on work done by Dieter Scherer of Hewlett-Packard about 1978. He was the first to introduce the flicker effect to the Leeson equation by adding the AM-to-PM

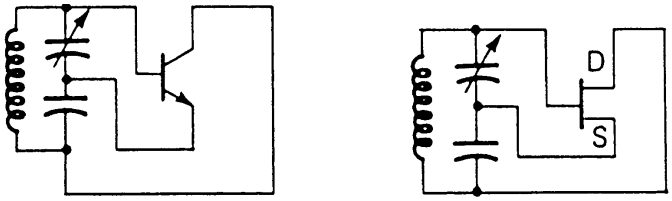

Figure 5-22 Colpitts oscillator.

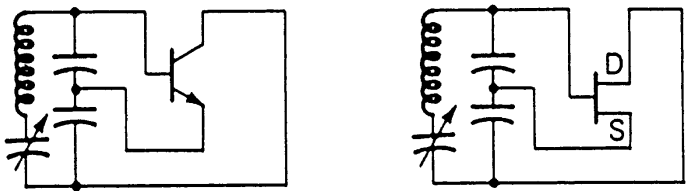

Figure 5-23 Clapp–Gouriet oscillator.

conversion effect, which is caused by the nonlinear capacitance of the active devices. This equation must be further expanded:

$$\pounds(f_m) = 10 \log\left\{\left[1 + \frac{f_0^2}{(2f_m Q_{\text{load}})^2}\right]\left(1 + \frac{f_c}{f_m}\right)\frac{FkT}{2P_{\text{sav}}} + \frac{2kTRK_0^2}{f_m^2}\right\} \tag{5-57}$$

where $\pounds(f_m)$ = ratio of sideband power in 1-Hz bandwidth at f_m to total power in dB
f_m = frequency offset
f_0 = center frequency
f_c = flicker frequency
Q_{load} = loaded Q of the tuned circuit
F = noise factor
$kT = 4.1 \times 10^{-21}$ at 300 K (room temperature)
P_{sav} = average power at oscillator output
R = equivalent noise resistance of tuning diode (typically 200 Ω to 10 kΩ)
K = oscillator voltage gain

The following table (from Motorola) shows the flicker corner frequency f_C as a function if I_C for a typical small-signal microwave BJT. $I_{C(\text{max})}$ of this transistor is about 10 mA.

I_C (mA)	f_C (kHz)
0.25	1
0.5	2.74
1	4.3
2	6.27
5	9.3

Note that f_C, which is defined by AF and KF in the SPICE model, increases with I_C. This gives us a clue about how f_C changes when a transistor oscillates. As a result of the bias-point shift that occurs during oscillation (see Example 1 of Section 5-3-1), an oscillating BJT's average I_C is higher than its small-signal I_C. KF is therefore higher for a given BJT operating as an oscillator than for the same transistor operating as a small-signal amplifier. This must be kept in mind when considering published f_C data, which are usually determined under small-signal conditions without being qualified as such. Determining a transistor's oscillating f_C is best done through measurement: Operate the device as a high-Q UHF oscillator (we

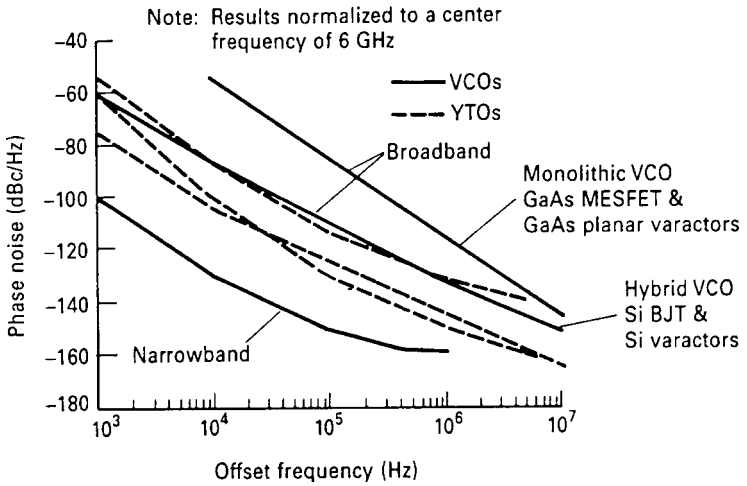

Figure 5-24 Phase noise of oscillators using different semiconductors and resonators.

suggest using a ceramic-resonator-based tank in the vicinity of 1 GHz), and measure its close-in (10 Hz to 10 kHz) phase noise versus offset from the carrier. f_C will correspond to a slight decrease in the slope of the phase noise versus offset curve. Generally, f_C varies with device type as follows: silicon JFETs, 50 Hz and higher; microwave RF BJTs, 1–10 kHz (as above); MOSFETs, 10–100 kHz; and GaAsFETs, 10–100 MHz. Figure 5-24 shows the phase noise of oscillators using different semiconductors and resonators.

Equation (5-57) is based on Rohde et al. [2]. The additional term introduces a distinction between a conventional oscillator and a VCO. Whether the voltage- or current-dependent capacitance is internal or external makes no difference; it simply affects the frequency.

For a more complete expression for a resonator oscillator's phase noise spectrum we can write

$$s_\phi(f_m) = \frac{\alpha_R F_0^4 + \alpha_E (F_0/2Q_L)^2}{f_m^3} + \frac{(2GFkT/P_0)\,(F_0/2Q_L)^2}{f_m^2} + \frac{2\alpha_R Q_L F_0^3}{f_m^2} + \frac{\alpha_E}{f_m} + \frac{2GFkT}{P_0} \tag{5-58}$$

where G = compressed power gain of the loop amplifier
F = noise factor of the loop amplifier
k = Boltzmann's constant
T = temperature in kelvins

P_0 = carrier power level (in watts) at the output of the loop amplifier
F_0 = carrier frequency in hertz
f_m = carrier offset frequency in hertz
$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop
α_R, α_E = flicker-noise constants for the resonator and loop amplifier, respectively.

In frequency synthesizers, we have no use for *LC* oscillators that do not include a tuning diode or diodes, but it may still be of interest to analyze the low-noise, fixed-tuned *LC* oscillator first and later make both elements, inductor and capacitor, variable.

Later, we will show the performance changes if we utilize the two possible ways of getting coarse and fine tuning in oscillators:

1. Use of tuning diodes.
2. Use of switching diodes.

We will spend some time looking at the effects that switching and tuning diodes have in a circuit because they will ultimately influence the noise performance more strongly than the transistor itself.

The reason is that the noise generated in tuning diodes will be superimposed on the noise generated in the circuit, while switching diodes have losses that cause a reduction of circuit *Q*. The selection of the proper tuning and switching diodes is important, as is the proper way of connecting them. As both types are modifications of the basic *LC* oscillator, we start with the *LC* oscillator itself.

Early signal generators as were offered by several companies (namely, Rohde & Schwarz, Hewlett-Packard, Boonton Electronics, or Marconi), if they are not synthesized, use an air-dielectric variable capacitor or, as in the case of one particular Hewlett-Packard generator, the Model HP8640, a tuned cavity.

Tuning here is accomplished by changing the value of an air-dielectric variable capacitor or changing the mechanical length of a quarter-wave resonator.

Using the equations shown previously, it is fairly easy to calculate the performance of oscillators and understand how they work, but this does not necessarily optimize their design. For *LC* oscillator applications in which noise performance is crucial, the oscillator shown in Figure 5-25, used in the famous Rohde & Schwarz SMDU, is the state of the art. Its noise performance is equivalent to the noise found in the cavity-tuned oscillator used in Hewlett-Packard's popular HP8640 signal generator, and because of the unique way a tuning diode is coupled to the circuit, its modulation capabilities are substantially superior to any of the signal generators currently offered. To develop such a circuit from design equations is not possible. This circuit is the result of many years of experience and research and looks fairly simple. The grounded-gate FET circuit provides the best performance because it fulfills the important requirements of Eq. (5-56).

The tuned circuit is not connected directly to the drain, but the drain is put on a tap of the oscillator section. Therefore, the actual voltage across the tuning capacitor is higher than the supply voltage, and thus the energy stored in the capacitor is much higher than in a circuit connected between the gate electrode and ground, as it is in a normal Colpitts oscillator. In addition, the high output impedance of the FET does not load the circuit, which also provides a reduced noise contribution. Since this oscillator is optimized for best frequency-modulation

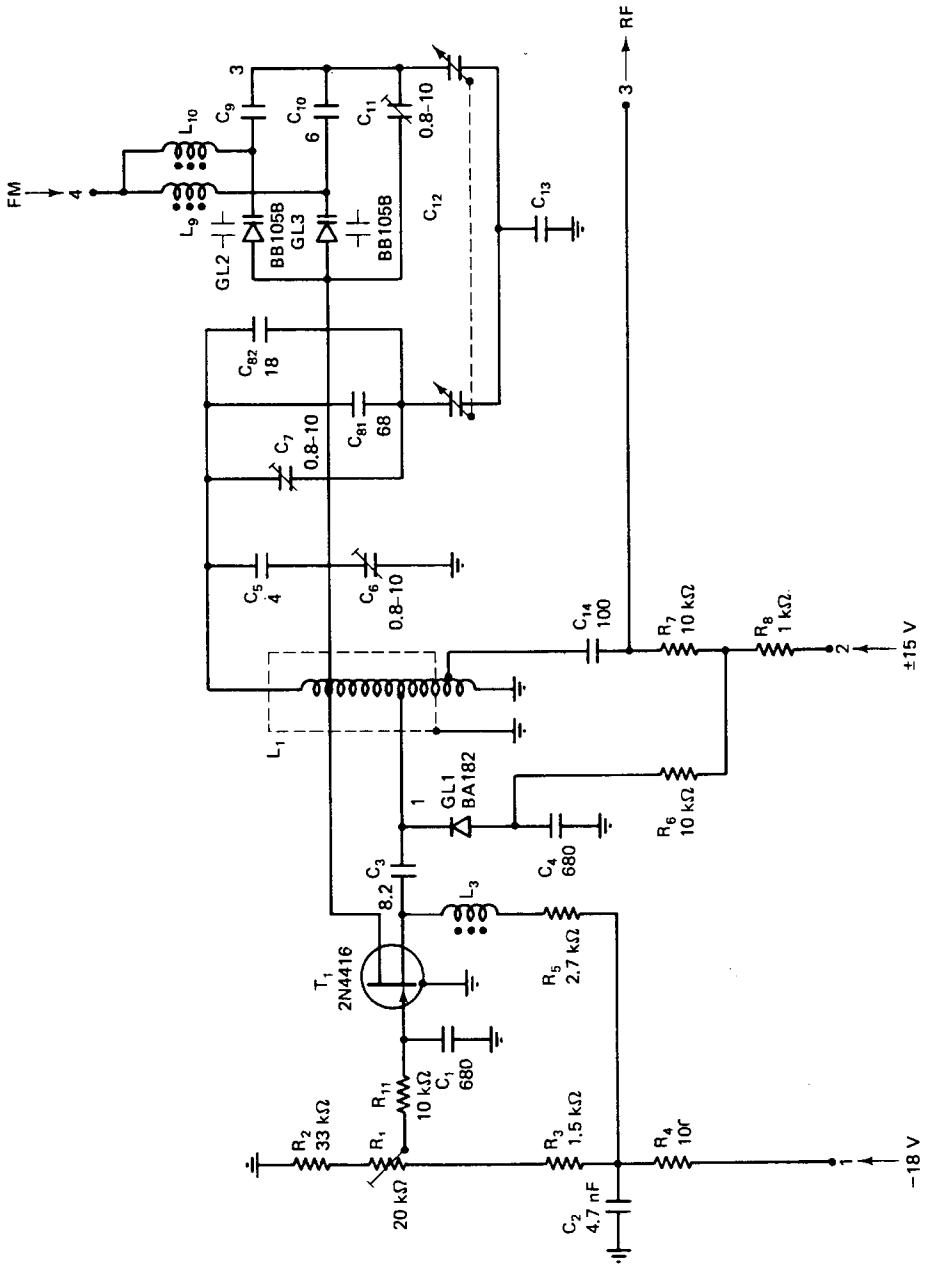

Figure 5-25 A 118–198-MHz oscillator from the Rohde & Schwarz SMDU signal generator.

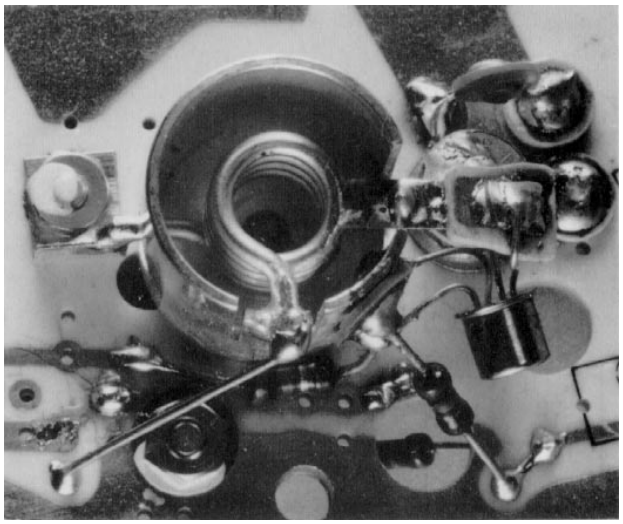

Figure 5-26 Photograph of the helical-resonator system from the Rohde & Schwarz SMDU signal generator.

performance in the FM frequency range, it becomes apparent that it fits the requirements of low-distortion stereo modulation.

For extremely critical blocking measurements in the 2-m region (140–160 MHz), the noise specification at 20 kHz off the carrier is of high importance, while the peak modulation typically does not exceed 5 kHz. Figure 5-25 shows the schematic of the oscillator section optimized for this frequency range.

Because of f_T limitations, it has been found experimentally that these *LC* oscillators, if based on silicon JFETs, should not be used above about 500 MHz; rather, a doubler stage should be employed. Analyzing the signal generators currently on the market, we find that their highest base band typically ranges from 200 to 500 MHz, with frequency doubling used to 1000 MHz. As can be seen in Figure 5-26, the mechanical layout of such an oscillator is extremely compact.

5-5-2 Two-Port Microwave/RF Oscillator Design

A common method for designing oscillators is to resonate the input port with a passive high-*Q* circuit at the desired frequency of resonance. It will be shown that if this is achieved with a load connected on the output port, the transistor is oscillating at both ports and is thus delivering power to the load port. The oscillator may be considered a two-port structure, with M_3 being the lossless resonating port and M_4 providing lossless matching such that all the external RF power is delivered to the load. See Figure 5-27. The resonating network has been described. Nominally, only parasitic resistance is present at the resonating port, since a high-*Q* resonance is desirable for minimizing oscillator noise. It is possible to have loads at both the input and output ports if such an application occurs, since the oscillator is oscillating at both ports simultaneously.

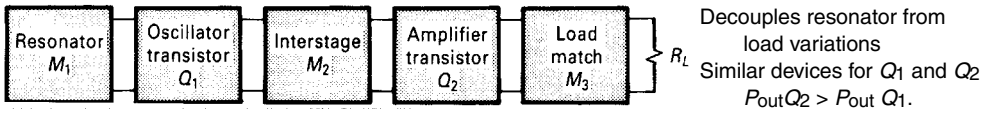

Figure 5-27 Buffered oscillator design.

The simultaneous oscillation condition is proved as follows. Assume that the oscillation condition is satisfied at port 1:

$$1/S'_{11} = \Gamma_G \tag{5-59}$$

Thus,

$$S'_{11} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} = \frac{S_{11} - D\Gamma_L}{1 - S_{22}\Gamma_L} \tag{5-60}$$

$$\frac{1}{S'_{11}} = \frac{1 - S_{22}\Gamma_L}{S_{11} - D\Gamma_L} = \Gamma_G \tag{5-61}$$

By expanding Eq. (5-61), we find

$$\begin{gathered} \Gamma_G S_{11} - D\Gamma_L\Gamma_G = 1 - S_{22}\Gamma_L \\ \Gamma_L(S_{22} - D\Gamma_G) = 1 - S_{11}\Gamma_G \\ \Gamma_L = \frac{1 - S_{11}\Gamma_G}{S_{22} - D\Gamma_G} \end{gathered} \tag{5-62}$$

Thus,

$$S'_{22} = S_{22} + \frac{S_{12}S_{21}\Gamma_G}{1 - S_{11}\Gamma_G} \tag{5-63}$$

$$\frac{1}{S'_{22}} = \frac{1 - S_{11}\Gamma_G}{S_{22} - D\Gamma_G} \tag{5-64}$$

Comparing Eqs. (5-62) and (5-64), we find

$$1/S'_{22} = \Gamma_L \tag{5-65}$$

which means that the oscillation condition is also satisfied at port 2; this completes the proof. Thus, if either port is oscillating, the other port must be oscillating as well. A load may appear at either or both ports, but normally the load is in Γ_L, the output termination. This result can be generalized to an n-port oscillator by showing that the oscillator is simultaneously oscillating at each port:

$$\Gamma_1 S'_{11} = \Gamma_2 S'_{22} = \Gamma_3 S'_{33} = \cdots = \Gamma_n S'_{nn} \tag{5-66}$$

Before concluding this section on two-port oscillator design, the buffered oscillator shown in Figure 5-27 must be considered. This design approach is used to provide the following:

1. A reduction in load-pulling, which is the change in oscillator frequency when the load reflection coefficient changes.
2. A load impedance that is more suitable to wideband applications ($k < 1$).
3. A higher output power from a working design, although the higher output power can also be achieved by using a larger oscillator transistor.
4. This type of oscillator is not optimized for low phase noise. However, buffered oscillator designs are quite common in wideband YIG applications, where changes in the load impedance must not change the generator frequency.

Two-port oscillator design may be summarized as follows:

1. Select a transistor with sufficient gain and output-power capability for the frequency of operation. This may be based on oscillator datasheets, amplifier performance, or *S*-parameter calculation.
2. Select a topology that gives $k < 1$ at the operating frequency. Add feedback if $k < 1$ has not been achieved.
3. Select an output load-matching circuit that gives $|S'_{11}| > 1$ over the desired frequency range. In the simplest case, this could be a 50-Ω load.
4. Resonate the input port with a lossless termination so that $\Gamma_G S'_{11} = 1$. The value of S'_{22} will be greater than unity with the input properly terminated.

In all cases, the transistor delivers power to a load and the input of the transistor. Practical considerations of realizability and dc biasing will determine the best design.

For both bipolar and FET oscillators, a common topology is the common-base or common-gate, since a common-lead inductance can be used to raise S_{22} to a large value, usually greater than unity even with a 50-Ω generator resistor. However, it is not necessary for the transistor S_{22} to be greater than unity, since the 50-Ω generator is not present in the oscillator design. The requirement for oscillation is $k < 1$; then resonating the input with a lossless termination will ensure that $|S'_{11}| > 1$.

A simple example will clarify the design procedure. A common-base bipolar transistor (HP2001) was selected to design a fixed-tuned oscillator at 2 GHz. The common-base *S*-parameters and stability factors are given in Table 5-1.

Using the load circuit in Figure 5-28, we see that the reflection coefficients are

Table 5-1 *S* parameters and stability factors (V_{CE} = 15 V, I_C = 25 mA)

$L_B = 0$	$L_B = 0.5$ nH
$S_{11} = 0.94 \angle 174°$	$1.04 \angle 173°$
$S_{21} = 1.90 \angle -28°$	$2.00 \angle -30°$
$S_{12} = 0.013 \angle 98°$	$0.043 \angle 153°$
$S_{22} = 1.01 \angle -17°$	$1.05 \angle -18°$
$k = -0.09$	-0.83

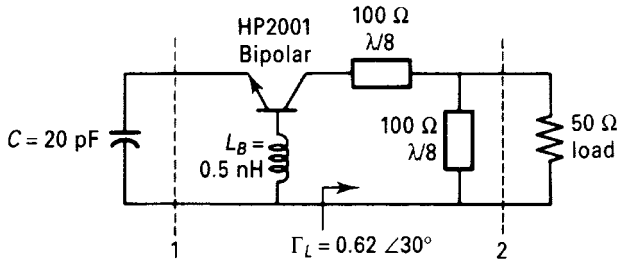

Figure 5-28 Oscillator example at 2 GHz.

$$\Gamma_L = 0.62\ \angle 30°$$

$$S'_{11} = 1.18\ \angle 173°$$

Thus, a resonating capacitance of G = 20 pF resonates the input port. In a YIG-tuned oscillator, this reactive element could be provided by the high-Q YIG element. For a dielectric-resonator oscillator (DRO), the puck would be placed to give $\Gamma_G \approx 1.0/\angle -173°$.

Another two-port design procedure is to resonate the Γ_G port and calculate S'_{22} until $|S'_{22}| > 1$, then design the load port to satisfy. This design procedure is summarized in Figure 5-29.

An example using this procedure at 4 GHz is given in Figure 5-30 using an AT41400 silicon bipolar chip in the common-base configuration with a convenient value of base and emitter

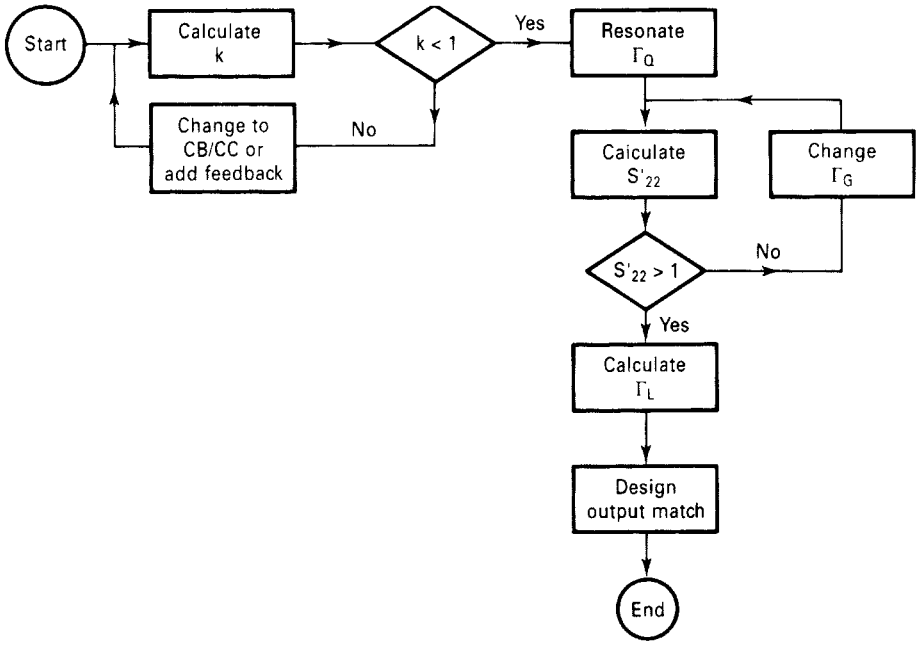

Figure 5-29 Oscillator design flowchart.

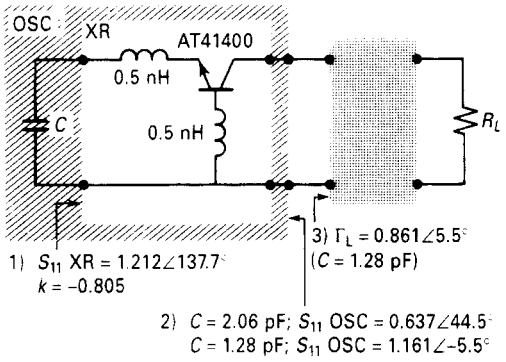

Figure 5-30 A 4-GHz lumped-resonator oscillator using the AT41400.

inductance of 0.5 nH. The feedback parameter is the base inductance, which can be varied if needed.

Since a lossless capacitor at 4 GHz of 2.06 pF gives $\Gamma_G = 1 - 0 \angle -137.7°$, this input termination is used to calculate S'_{22}, giving $S'_{22} = 0.637 \angle 44.5°$. This circuit will oscillate into any passive load. Varying the emitter capacitor about 20° on the Smith Chart to 1.28 pF gives $S'_{22} = 1.16 \angle -5.5°$, which will oscillate into a load of $\Gamma_L = 0.861 \angle 5.5°$. The completed lumped-element design is given in Figure 5-31.

5-5-3 Ceramic-Resonator Oscillators

An important application for a new class of resonators called ceramic resonators (CRs) has emerged for wireless applications. The CRs are similar to rigid coaxial cable, where the center conductor is connected at the end to the outside of the cable. These resonators are generally operating in quarter-wavelength mode and their characteristic impedance is approximately 10 Ω. Because their coaxial assemblies are made from a high-ε low-loss material with good silver plating throughout, the electromagnetic field is internally contained and therefore results in very little radiation. These resonators are therefore ideally suited for high-Q, high-density oscillators. The typical application for this resonator is VCOs ranging from not much more than 200 MHz up to about 3 or 4 GHz. At these high frequencies, the mechanical dimensions of the resonator become too tiny to offer any advantage. One of the

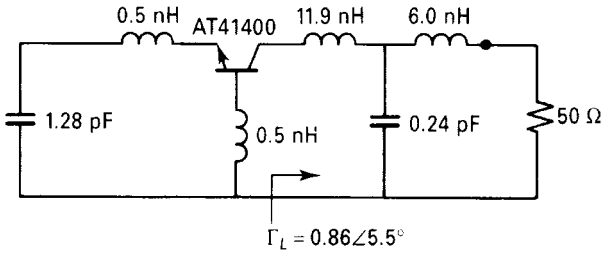

Figure 5-31 Completed lumped-resonator oscillator (LRO).

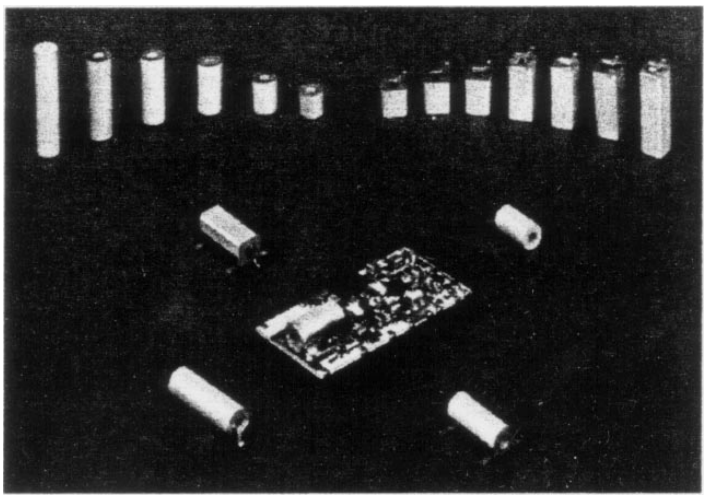

Figure 5-32 Ceramic resonators.

principal requirements is that the physical length is considerably larger than the diameter. If the frequency increases, this requirement can no longer be met.

Manufacturers supply ceramic resonators on a prefabricated basis. Figures 5-32 and 5-33 show the standard round/square packaging available and the typical dimensions for a ceramic resonator. Figure 5-34 shows a ceramic-resonator oscillator built on a ceramic substrate. The available material has a dielectric constant of 88 and is recommended for use in the 400–1500-MHz range. The next higher frequency range (800 MHz to 2.5 GHz) uses an ε of 38, while the top range (1–4.5 GHz) uses an ε of 21. Given the fact that ceramic resonators are prefabricated and have standard outside dimensions, the following quick calculation applies:

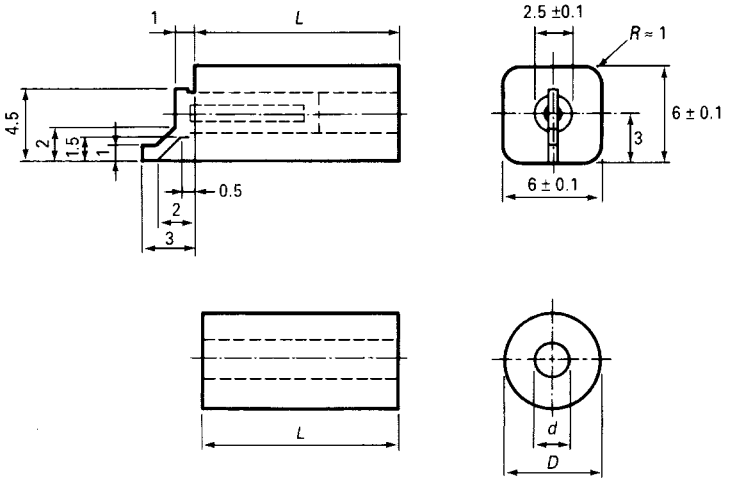

Figure 5-33 Standard round/square ceramic-resonator packaging and dimensions.

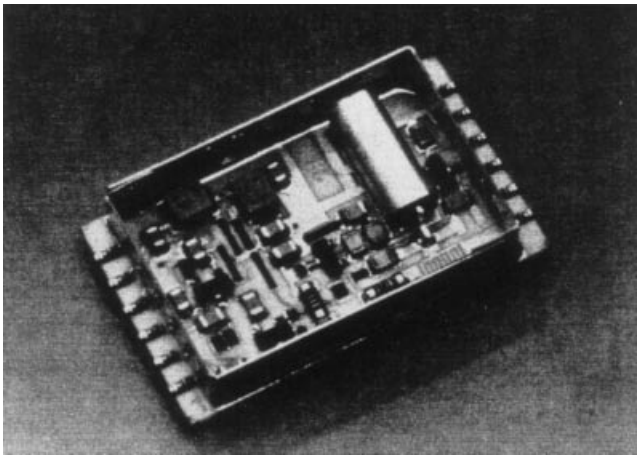

Figure 5-34 Modern ceramic-resonator oscillator for handheld cellular phones.

Relative dielectric constant of resonator material	$\varepsilon_r = 21$	$\varepsilon_r = 38$	$\varepsilon_r = 88$
Resonator length in millimeters	$l = \frac{16.6}{f}$	$l = \frac{12.6}{f}$	$l = \frac{8.2}{f}$
Temperature coefficient (ppm/°C)	10	6.5	8.5
Available temperature coefficients	–3 to +12	–3 to +12	–3 to +12
Typical resonator Q	800	500	400
Frequency range	1–4.5 GHz	800–2500 MHz	400–1500 MHz

Calculation of Equivalent Circuit. The equivalent parallel-resonant circuit afforded by a ceramic resonator has a resistance at resonance of

$$R_p = \frac{2(Z_0)^2}{R^* l} \tag{5-67}$$

where Z_0 = characteristic impedance of the resonator
l = mechanical length of the resonator
R^* = equivalent resistor due to metallization and other losses

As an example, one can calculate

$$C^* = \frac{2\pi\varepsilon_0\varepsilon_r}{\log_e(D/d)} = 55.61 \times 10^{-12}\,\frac{\varepsilon_r}{\log_e(D/d)} \tag{5-68}$$

and

$$L^* = \frac{\mu_r \mu_0}{2\pi} = \log_e\left(\frac{D}{d}\right) = 2 \times 10^{-7} \log_e\left(\frac{D}{d}\right) \tag{5-69}$$

$$Z_0 = 60\ \Omega \frac{1}{\sqrt{\varepsilon_r}} \log_e\left(\frac{D}{d}\right)$$

$$= 60 \frac{1}{\sqrt{88}} \log_e\left(\frac{6}{2.5}\right)$$

$$= 5.6\ \Omega \tag{5-70}$$

A practical example for $\varepsilon_r = 88$ and 450 MHz is

$$C_p = \frac{C^* l}{2} = 49.7\ \text{pF} \tag{5-71}$$

$$L_p = 8L^* l = 2.52\ \text{nH} \tag{5-72}$$

$$R_p = 2.5\ \text{k}\Omega \tag{5-73}$$

Figure 5-35 shows the schematic of a ceramic-resonator-based oscillator. Figures 5-36 and 5-37 show the simulated and measured phase noise of the oscillator.

By using ceramic-resonator-based oscillators in conjunction with miniature synthesizer chips, it is possible to build extremely small phase-locked-loop (PLL) systems for cellular telephone operation. Figure 5-38 shows one of the smallest currently available PLL-based synthesizers manufactured by Synergy Microwave Corporation. Because of the high-Q resonator, these types of oscillators exhibit extremely low phase noise. Values of better than –150 dBc/Hz at 1 MHz off the carrier are achievable. The ceramic resonator reduces the oscillator's sensitivity to microphonic effects and proximity effects caused by other components.

5-5-4 Using a Microstrip Inductor as the Oscillator Resonator*

A high-Q microstrip resonator [3–5] can be used to improve an oscillator's phase-noise performance. The following section, based on information in the Philips Semiconductors Application Note AN1777, describes the application of such a resonator in a BJT differential oscillator.

It can be seen from Eq. (5-56) that the phase noise is proportional to the term

$$\frac{1}{4Q_L^2} \tag{5-74}$$

This means that for any 10% increase in Q, we get something like 20% improvement in phase noise, which makes it most desirable to increase the Q. One way to reduce the loading of the

*Based on portions of the Philips Semiconductors/Signetics RF Communications Products Application Note AN1777, "Low-Voltage Front End Circuits: SA601, SA620," August 20, 1997. Used with permission.

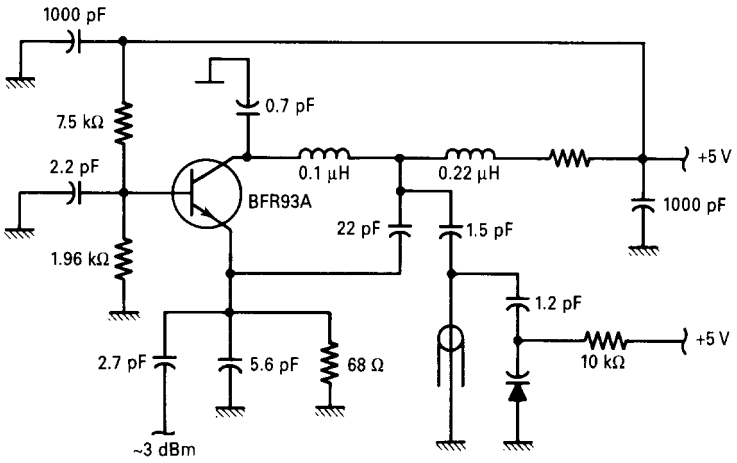

Figure 5-35 Schematic of a high-performance ceramic-resonator-based oscillator that can be used from 500 MHz to 2 GHz.

resonator is to tap the device down on the resonator. The underlying oscillator circuit is based on the differential type of oscillator found in ICs.

Increasing Loaded Q. Figure 5-39 shows the oscillator section of the Philips SA620 low-voltage front-end IC with a conventional second-order parallel-tuned tank circuit configured as the external resonator.

From the basic equations for parallel resonance, the resonator's loaded Q is given by

$$Q_L = R_P \left(\frac{C_T}{L_T} \right)^{1/2} \tag{5-75}$$

where

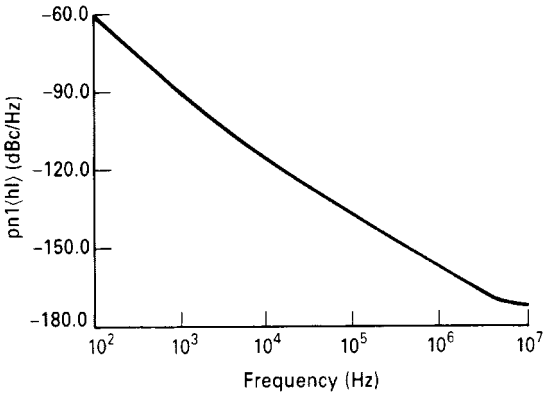

Figure 5-36 Simulated phase noise of an *npn* bipolar 1-GHz ceramic-resonator-based oscillator.

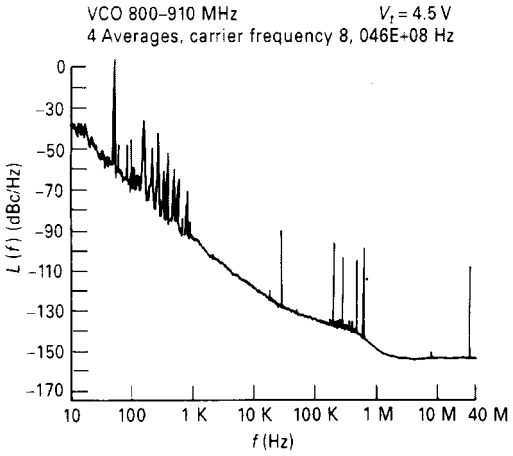

Figure 5-37 Measured phase noise of a ceramic-resonator-based oscillator.

$$R_P = R_T \| R_C = \left[\left(\frac{1}{R_T}\right) + \left(\frac{1}{R_C}\right)\right]^{-1} \tag{5-76}$$

represents the net shunt tank resistance appearing across the network at resonance. R_T represents losses in the inductance L_T and capacitance C_T (almost always dominated by inductor losses), and R_C is the active circuit's load impedance at resonance. Improving the quality of the tank components L_T and C_T (i.e., improving their Q) will increase R_T, but since R_C is low in the case of the SA620, the resulting increase in R_P is relatively small. We can

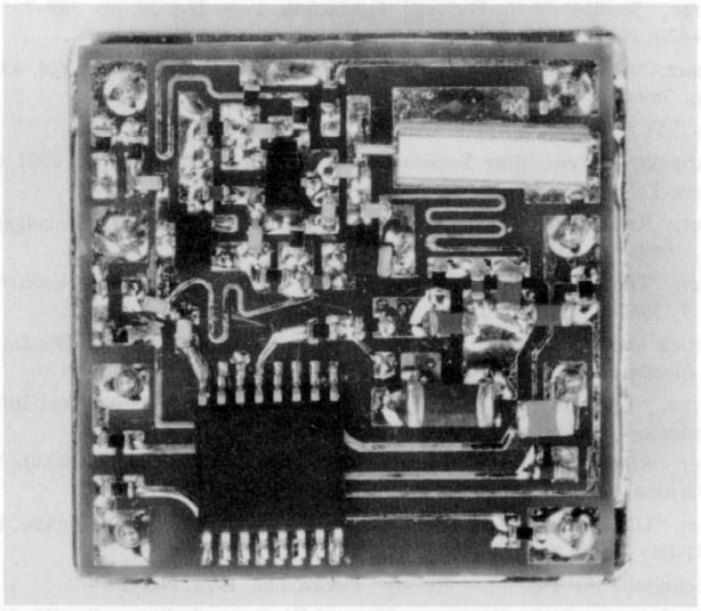

Figure 5-38 Miniature PLL-based synthesizer manufactured by Synergy Microwave Corporation.

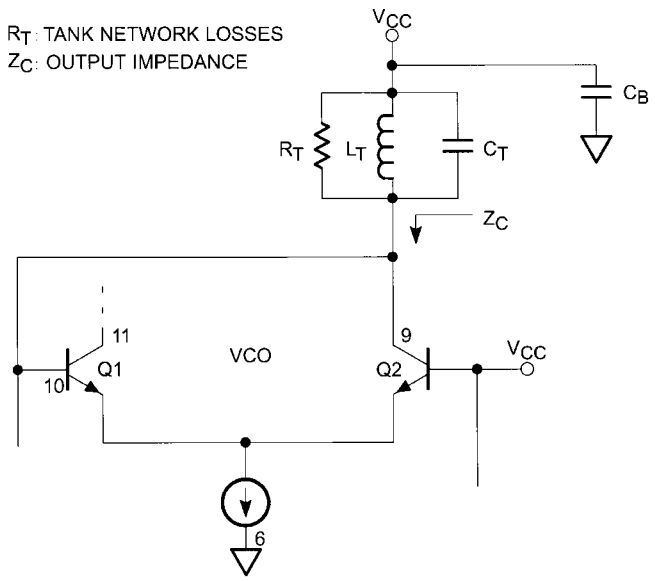

Figure 5-39 Oscillator portion of Philips SA620 front-end IC with external resonator.

increase R_P by decoupling Z_C from the tank circuit (note that R_C is the real part of Z_C at resonance). Decoupling this impedance by using either tapped-L or tapped-C tank configurations is possible. Inspection of the circuit shows that dc biasing is necessary for pins 9 and 10 (osc1 and osc2, respectively), so a tapped-C approach would require shunt-feeding these pins to V_{CC}. Thus, the most practical way is to employ a tapped-L network.

Figure 5-40 shows the basic tapped-L circuit. The effective multiplied shunt impedance at resonance across C_T is given by

$$\hat{R}_P = R_P\left[\left(\frac{L_{T2}}{L_{T1}}\right)+1\right]^{1/2} \tag{5-77}$$

with a corresponding increase in loaded Q:

$$Q_L = Q_L\left[\left(\frac{L_{T2}}{L_{T1}}\right)+1\right]^{1/2} \tag{5-78}$$

Feedback is caused by an RF voltage appearing across L_T, coupled through bypass capacitor C_B and its ground return to the cold end of the current source at pin 6. The significance of this path increases with frequency. At 900 MHz, it becomes very critical in obtaining stable oscillations and must be kept as short as possible. Attention to layout detail is pivotal here!

High-Q Microstrip Inductor. Realizing a stable tapped-L network using lumped surface-mount inductors is impractical due to their low unloaded Q and finite physical size. Another approach uses a high-Q short microstrip inductor. The conventional approach to microstrip resonators treats them as a length of transmission line terminated with a short that

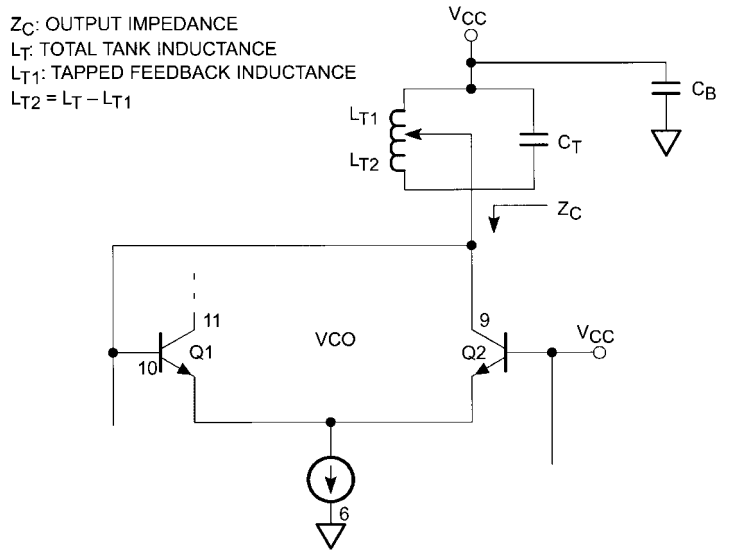

Figure 5-40 Oscillator portion of SA620 IC with tapped-microstrip resonator.

reflects back an inductance impedance that simulates a lumped inductor. The approach presented here deviates from this technique by specifically exploiting the very high unloaded Q attainable with short microstrip inductors, where we design for a large C/L ratio by making the microstrip a specific, but short, length. Resonance is achieved by replacing the short with whatever capacitance is needed for proper resonance. One equation for the inductance of a strip of metal having a length ℓ (mils) and width w (mils) is

$$L = [5.08\text{E} - 3]\,\ell\left[\ln\left(\frac{\ell}{w}\right) + 1.193\left(\frac{w}{\ell}\right)\right] \qquad \text{[3] (5-79)}$$

where L is in nH/mil. This technique results in a much shorter strip of metal for a given inductance. One intriguing property of microstrip inductors is that they are capable of very high unloaded Q values. An equation describing the quality factor for a "wide" microstrip is

$$Q_C = 0.63h[\sigma f_{\text{GHz}}]^{1/2} \qquad \text{[4] (5-80)}$$

where h is the dielectric thickness in centimeters, σ is the conductivity in S/m, and f is frequency in GHz. This equation predicts an unloaded Q exceeding 700 when silver-coated copper is used. Also, wide microstrip lines are defined as those whose strip width w to height h ratio is approximately greater than 1; that is, $w/h > 1$. The parallel capacitor formed by the metal strip over the ground plane should also be included and may be calculated by the classic formula and included in the total needed to resonate with the inductance result found from Eq. (5-79). This "strip" capacitance is given by

$$C_S = K\varepsilon_0\varepsilon_r\left(\frac{w\ell}{h}\right) \qquad \text{(5-81)}$$

where C_S is in farads, $\varepsilon_0 = 8.86\text{E} -12$ (F/cm) is the permittivity of free space, and ε_r is the relative dielectric constant of the substrate. A "fringe factor," K, is included to account for necessary fringing (estimated to be 2–15%). These equations are meant to provide insight into circuit behavior and should, therefore, be applied cautiously to specific applications.

UHF VCO Using the Tapped-Inductor Differential Oscillator at 900 MHz. The basic electrical circuit of this configuration is shown in Figure 5-41. Feedback occurs when sufficient RF voltage develops across the tap inductances L_{T1} and L_{T2} (due to tap 1 and tap 2, respectively); note that inductance is reckoned from the cold end of the tank at node A. Taps 1 and 2 should be as close as possible to pins 9 and 10, respectively. Also node A (cold end of tank) and node B (pin 6) must be as physically close together and exhibit as low an impedance as possible to discourage parasitic oscillations. This "inner loop," composed of L_{T2}, the inductance of connections between taps 1 and 2 and pins 9 and 10, respectively, and "stray" low-Q inductance between nodes A and B creates a parasitic loop that will support oscillation that no longer depends on the full tapped-L tank circuit. Oscillation based on this low-Q loop typically occurs well above 1.2 GHz and has been observed as high as 1.6 GHz, and exhibits very poor phase noise performance.

Another factor also affects this unwanted parasitic oscillation. As the full tank circuit's unloaded Q decreases, the circuit becomes conditionally stable and will eventually favor the parasitic loop exclusively. This occurs because the loaded Q of the tapped microstrip affects the magnitude of the RF voltage appearing across the entire tank. Thus, feedback at taps 1 and 2 is reduced as the Q decreases. This increases the likelihood of the parasitic inner loop controlling the oscillator, since its feedback voltage is largely independent of the microstrip tank Q.

Equation (5-80) shows that microstrip inductors are capable of very high unloaded Q values. This depends on a number of physical factors: frequency, dielectric thickness and

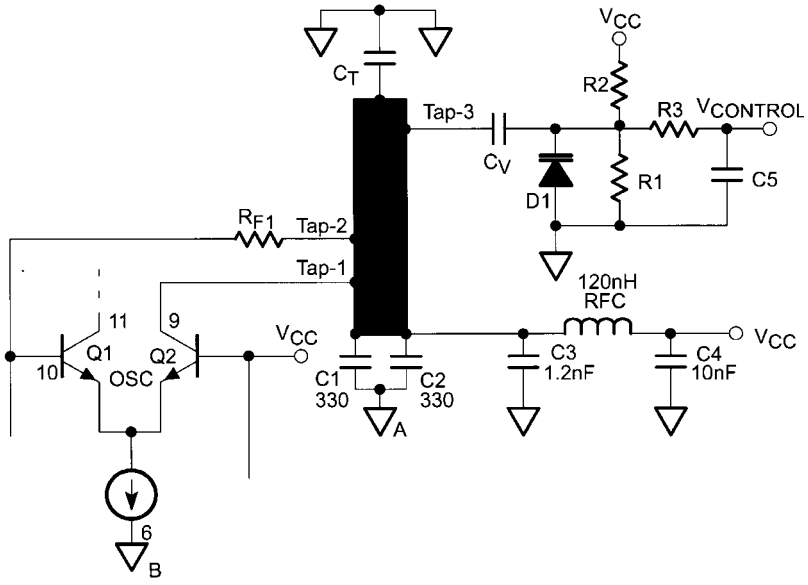

Figure 5-41 Differential oscillator with tapped-microstrip resonator.

quality, and the skin-depth conductance of the metal strip itself. For example, at 900 MHz, the unloaded Q of a silver-coated microstrip line is in the vicinity of 750. Coating the same line with lead (sloppy soldering can do it!) reduces the Q to less than 230. If the unloaded Q is too low, the loaded Q also drops. The circuit becomes conditionally stable and now may oscillate either at the higher parasitic-loop frequency or the desired lower frequency at which the entire microstrip tank resonates. Components should be connected by narrow traces closely connected to component leads to avoid soldering on the microstrip proper.

R_{F1} introduces necessary losses to control the inner-loop parasitic oscillation. Its size should be made as small as possible consistent with stability, startup, and good phase-noise performance. Since R_{F1} also decreases feedback, the oscillator's output falls as R_{F1} increases. Typically, experimental values from 4 to 30 Ω have proved sufficient.

Stability as a function of V_{CC} is a good way to assess conditional stability. Provided the microstrip tank has a high loaded Q, the oscillator's stability should be independent of V_{CC} down to less than 2.5 V or so. When loaded Q decreases sufficiently to favor the inner-loop parasitic, conditional stability will occur. This can readily be observed by increasing V_{CC} from about 1.0 V and noting whether the VCO frequency jumps back and forth unpredictably. Mixer and LO-port loading can also affect this condition and should be considered.

Dimensions for the microstrip resonator are based on several criteria. The strip must be "wide": Its width-to-height ratio must be on the order of 1 or greater. Minimum strip length seems to be about 200 mils for 62-mil-thick board. L/C ratios somewhere about 500 have yielded quite good results. Note that we usually specify the "L/C ratio" because it is always greater than 1, even though in a parallel-resonant circuit it appears in the Q equation as C/L. Thus, decreasing the "L/C ratio" by making the microstrip shorter helps the inductor's loaded Q, and the circuit's loaded Q_L, increase [see Eq. (5-75)]. However, the effect of the lower Q of C_T, even when using a high-Q surface-mount type, decreased the expected larger increase in the circuit's net loaded Q. Thus, the expected increase in Q_L may not be fully realizable. Assuming a 62-mil-thick board with FR5 dielectric, a strip 50 mils by 300 mils gave very good experimental results, where C_T was about 4.3 pF, with oscillation occurring from about 950 to 1000 MHz with various test boards. A shorter inductor designed to increase the C/L ratio requiring 7.5 pF experimentally resulted in only about 1–2-dB phase-noise improvement at 950 MHz. The reason for this is that as the microstrip inductor degenerates to a plain inductor, all of its advantages are lost.

Tap 1 may be anywhere between the cold end of the tank (where C_1 and C_2 are located) and tap 2. Tap 2 yields good results at about one-third the strip length. Making it too close to the cold end in an effort to increase Q_L will result in loss of control over the inner-loop parasitic. To keep Q_L as high as possible, C_T should be a high-Q surface-mount type. Differences greater than 5 dB in SSB phase noise have been observed between a generic NP0 surface-mount capacitor and a high-Q NP0 surface-mount capacitor.

Tap 3 can be at the end of the microstrip when C_T is connected. However, the tuning diode inevitably will cause a decrease in overall loaded Q, typically resulting in a phase-noise increase of as much as 5 dB. Moving it some distance down from the high end of the tank will decrease this effect and yield better results. A good starting point is about one-quarter down, or three-quarters of the length from the cold end of the tank. C_1 and C_2 are paralleled lower-value capacitors to yield a better low-impedance ground return to pin 6 (node B) since relatively large RF currents flow through them. Note that as Q_L increases, the peak circulating RF current will also increase, as will the RF voltage at the hot end of the microstrip. At 900 MHz, good results have been obtained when both are about 300 pF. The RF choke was chosen to be approximately series-resonant around 900 MHz, and constitutes the series feed path

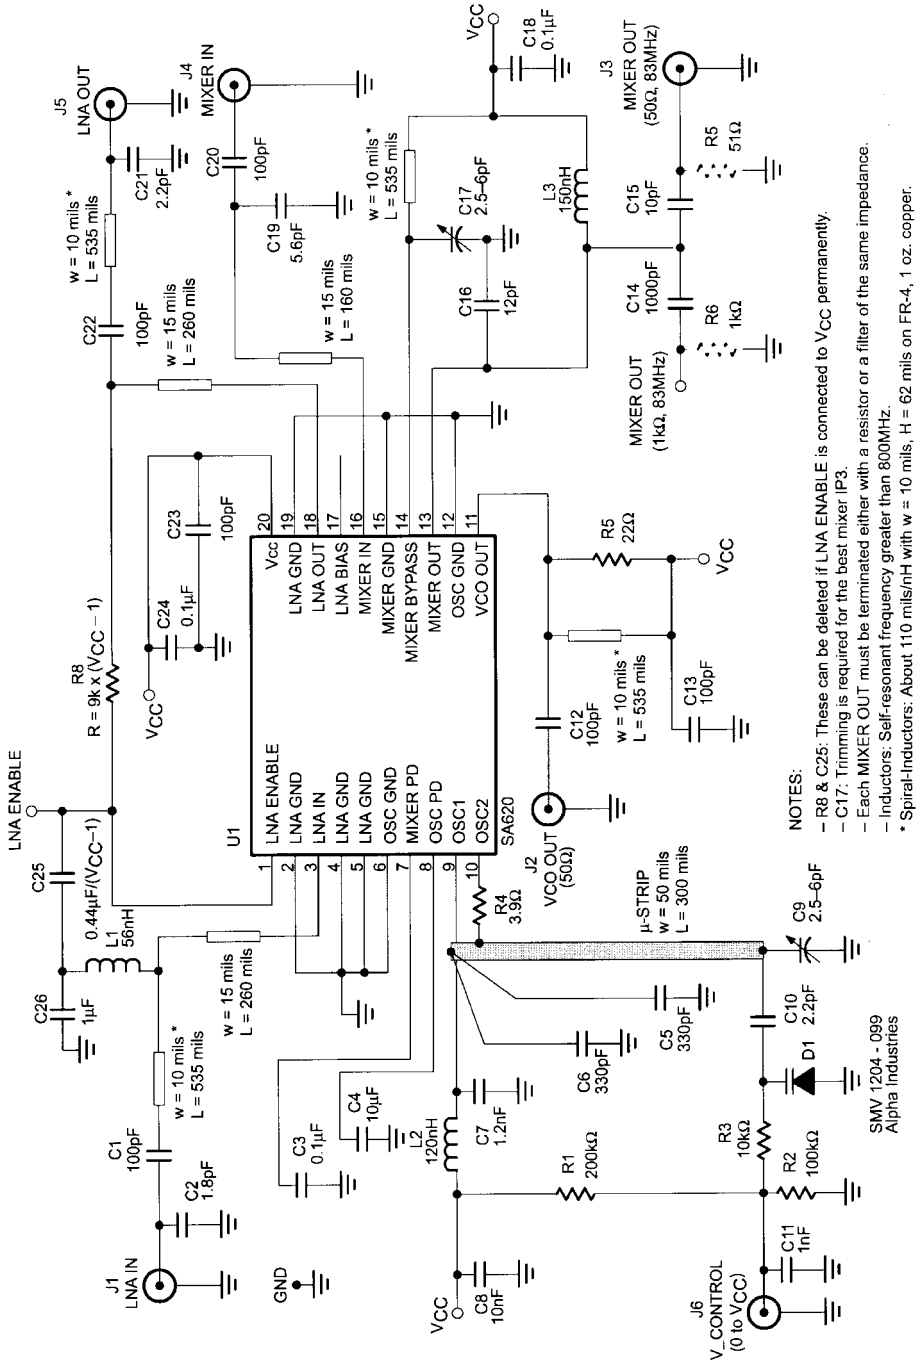

Figure 5-42 Philips SA620 application board schematic showing the tapped-microstrip resonator.

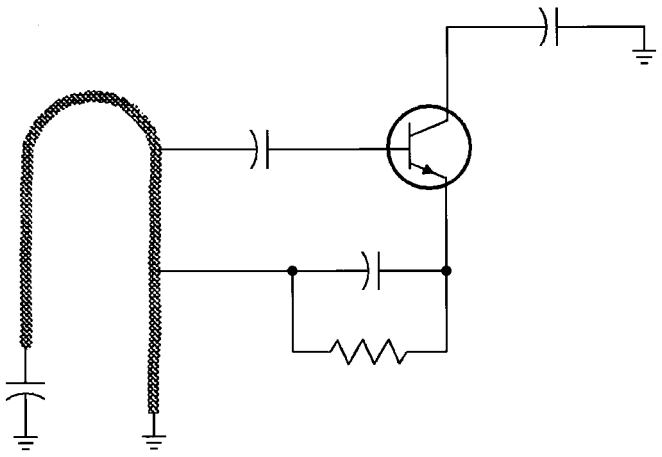

Figure 5-43 "Walking stick" microstrip Hartley resonator as used by Plextek in the 800–1500-MHz range. Below 800 MHz, the resonator's physical size becomes impractical; above 1500 MHz, the transistor's parasitic reactances make the Hartley configuration problematic.

for dc biasing. It may be possible to neglect this component entirely, provided that the PC-board connection to the cold end of the tank is very close to RF ground. Finally, note that shielding of the entire microstrip may be necessary to meet FCC Part 15 emission limitations (where applicable). Figure 5-42 shows one application of the tapped-microstrip oscillator with the Philips SA620 front-end IC.

5-5-5 Hartley Microstrip Resonator Oscillator

G. Smithson and S. Fitz of Plextek Communications Technology Consultants have reported on the construction of Hartley microstrip-resonator oscillators using thick-film techniques on ceramic (alumina) substrates for high-volume wireless products. The resonator in one such oscillator (Figure 5-43) exhibited an unloaded Q of approximately 80. Table 5-2 summarizes its phase noise versus tuning range with different tuning-diode configurations.

5-5-6 Crystal Oscillators

Most wireless applications do not require ultra-high-frequency stability that mandates the use of a primary standard, such as one based on cesium, or a secondary standard, such as one based on rubidium. For very stable oscillators at fixed or only slightly variable frequencies up to a few hundred megahertz, oscillators with piezoelectric resonators are generally used. A piezoelectric material transduces mechanical stress (deformation) to

Table 5-2 Achieved oscillator phase noise versus tuning range

Tuning Range, 0.5–3 V	Tuning Range, 1–3 V	Phase Noise at 20-kHz Offset
23%	16%	–100 dBc/Hz
16%	11%	–103 dBc/Hz
10%	8%	–106 dBc/Hz

electrical stress (voltage), and vice versa. In noncritical applications up to 10 MHz, a piezoelectric ceramic may be used. The Q and temperature stability of such materials are relatively poor, however, so quartz is the resonator material of choice for temperature-stable, low-noise piezoelectric oscillators.

Just as an electrical resonator consisting of distributed L and C exhibits multiple electrical resonances, a physical piece of piezoelectric material, depending on its shape, exhibits multiple mechanical resonances. *Fundamental* resonance occurs at the frequency at which the crystal is one-half wavelength long; *overtone* resonances occur near odd multiples (3, 5, 7, etc.) of the fundamental. Figure 5-44 shows the electrical equivalent of a crystal. Table 5-3 presents examples of approximate parameters for several crystal types. Appropriate shaping and placement of the crystal's connecting electrodes, combined with suitable oscillator circuit design and adjustment, allow the selection or ehancement of a particular resonance for excitation.

Figure 5-45 shows a typical crystal oscillator circuit configuration, and the associated table supplies recommended values for the elements. This is in line with the chip manufacturer's recommendations for built-in oscillator circuits. Figure 5-46 shows how this oscillator's input impedance varies around resonance; Figure 5-47 shows its simulated phase noise. Placing a small resistance in series with the crystal (Figure 5-48) allows us to use the crystal as a high-Q filter, substantially improving the oscillator's spectral purity relative to that obtainable at the transistor emitter (Figure 5-49).

Some applications demand ultra-low-phase-noise crystal oscillators. Figures 5-50 and 5-51 show an appropriate circuit and its phase noise with and without the current-supplying hot carrier diode (HCD) used for noise reduction.

5-5-7 Voltage-Controlled Oscillators

A schematic of a ceramic-resonator-based VCO (Figure 5-35) has already been shown in the section on ceramic-resonator oscillators. To tune the oscillator within the required range,

	3 MHz	6 MHz	10 MHz	20 MHz	30 MHz
C_1 (pF)	330	270	180	82	43
C_2 (pF)	430	360	220	120	68
C_3 (pF)	39	43	43	36	32
Crystal C_L (pF)	32	32	30	20	15

C_3 is the approximate value needed to set oscillator on frequency using indicated crystal C_L.

Figure 5-45 A 3–30-MHz Colpitts crystal oscillator.

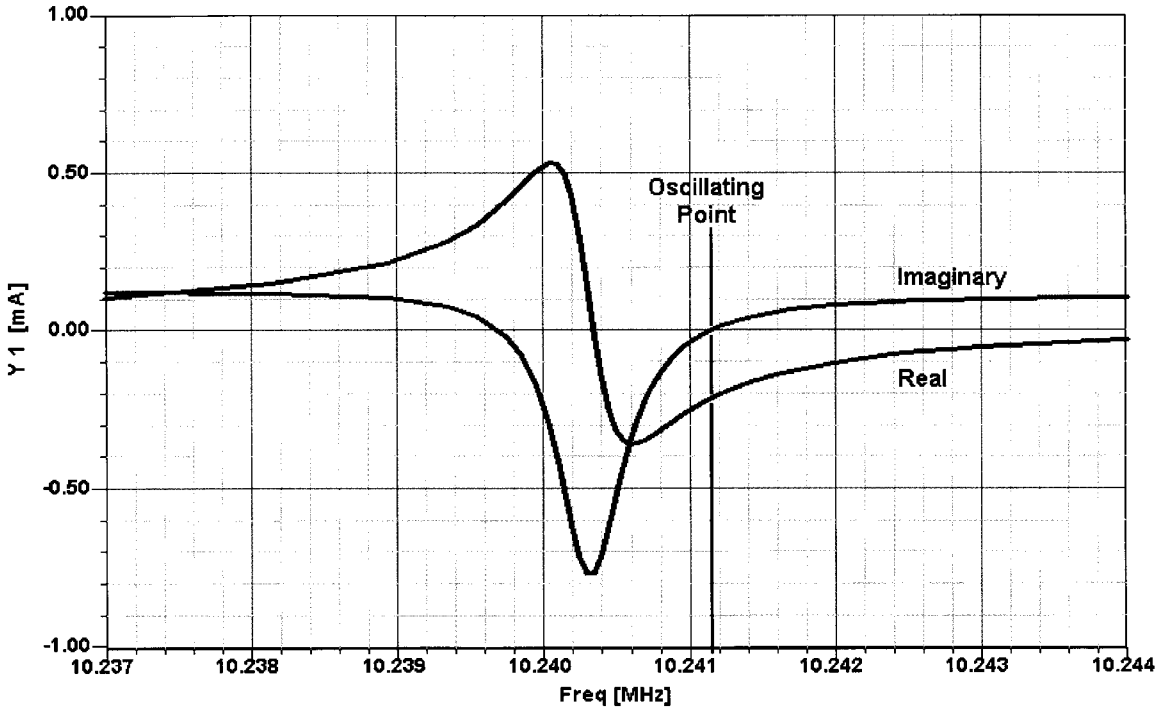

Figure 5-46 As with every oscillator, the crystal oscillator's input impedance is negative and real at resonance. This graph plots the real and imaginary components of the test voltage injected by the Oscillator Design Aid tool in Ansoft Serenade 8.0. Compare this graph with Figure 5-7, which plots an oscillator's input impedance with the resonator absent.

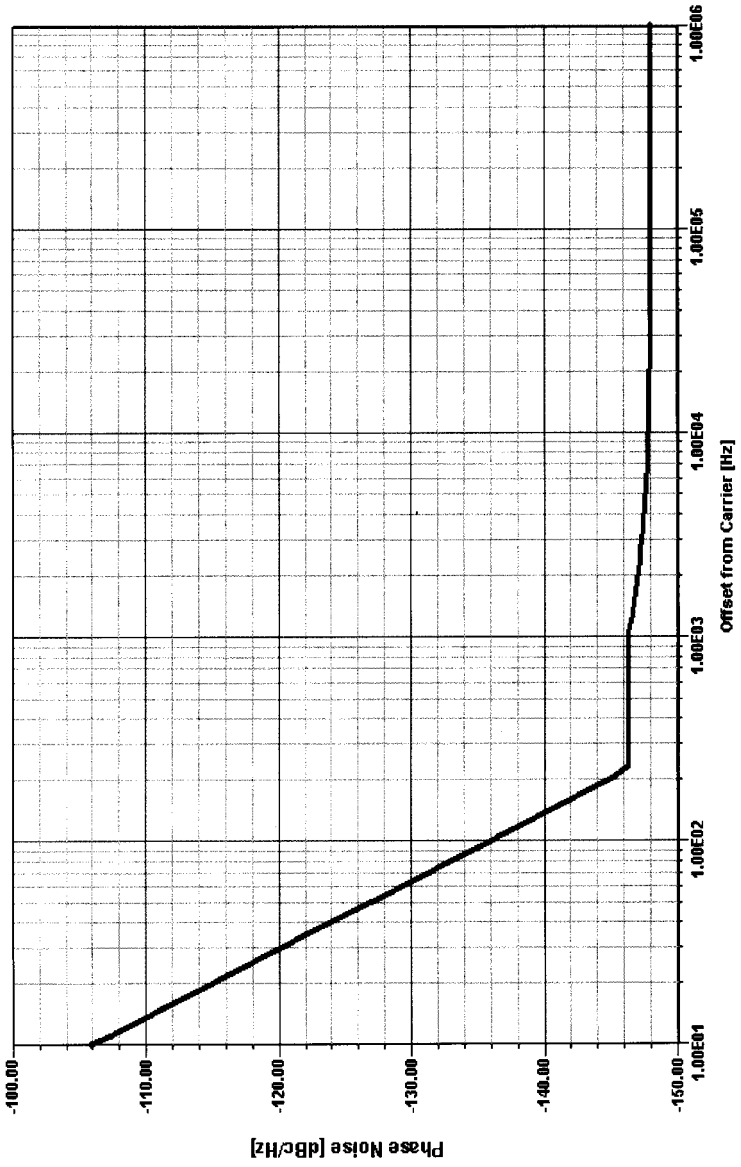

Figure 5-47 Simulated phase noise of the crystal oscillator.

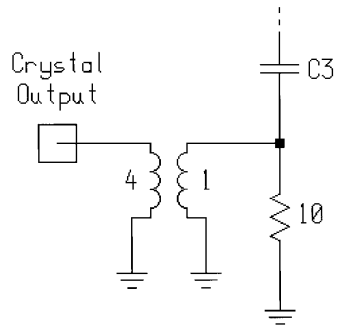

Figure 5-48 This alternative output tap uses the crystal's high selectivity for improved harmonic reduction.

tuning diodes are used. These diodes are often called *varactors* or *voltage-sensitive diodes.* By way of approximation, we can use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{5-82}$$

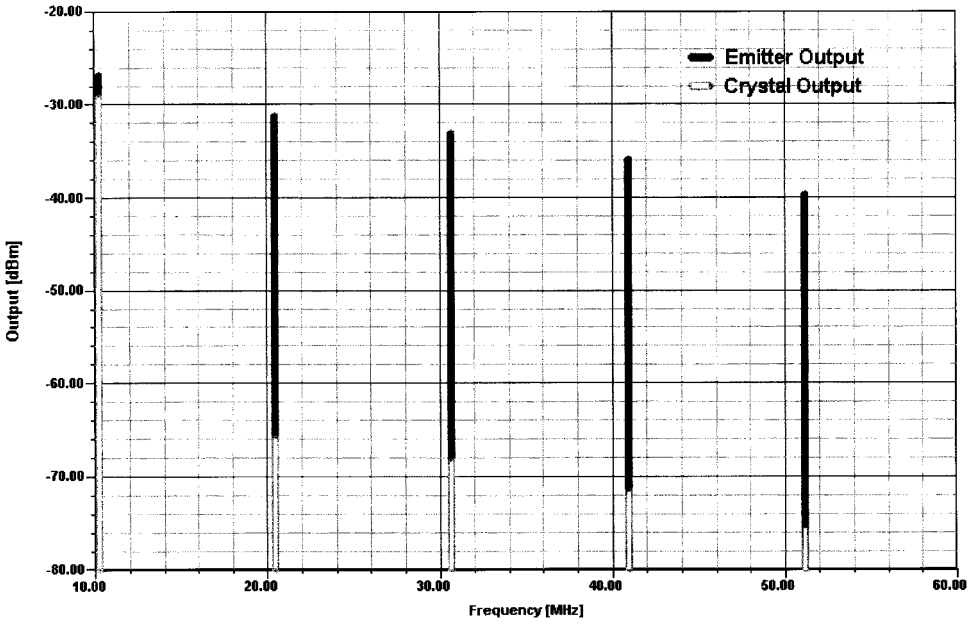

Figure 5-49 Comparison of the crystal oscillator's simulated output spectrum as obtained at the transistor emitter (dark gray, fundamental –26.7 dBm) and crystal (light gray, fundamental –29.1 dBm). At the emitter, the second harmonic is down only 4.3 dB relative to the carrier; at the crystal, the second harmonic is down 36 dB relative to the carrier.

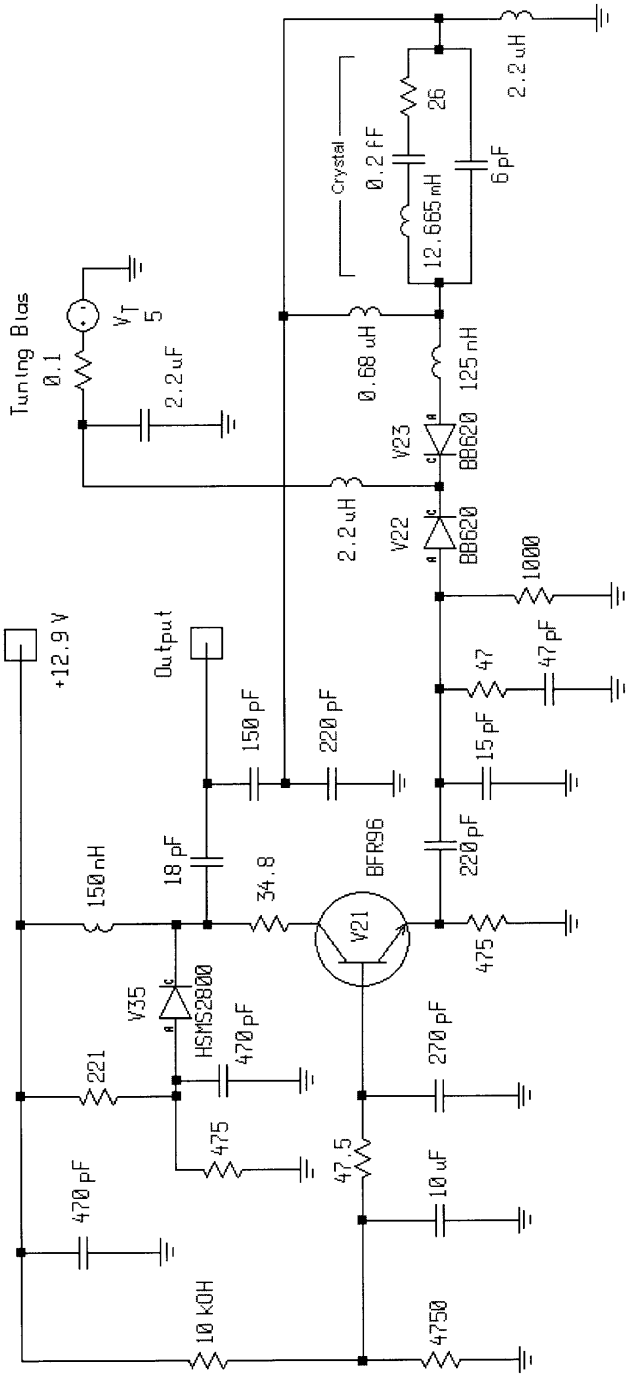

Figure 5-50 A 100-MHz VCXO suitable for ultra-low-phase-noise applications. The HSMS2800 hot-carrier diode (HCD) provides noise reduction.

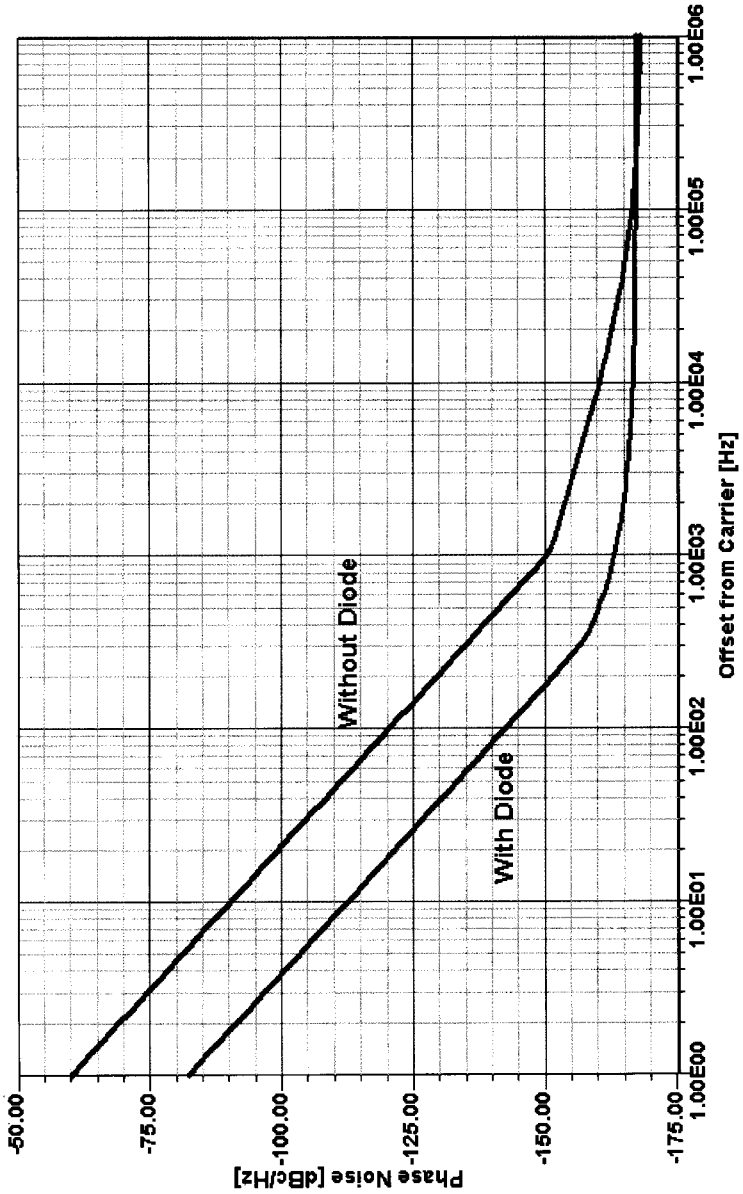

Figure 5-51 Phase noise of the VCXO with and without the noise-reduction diode.

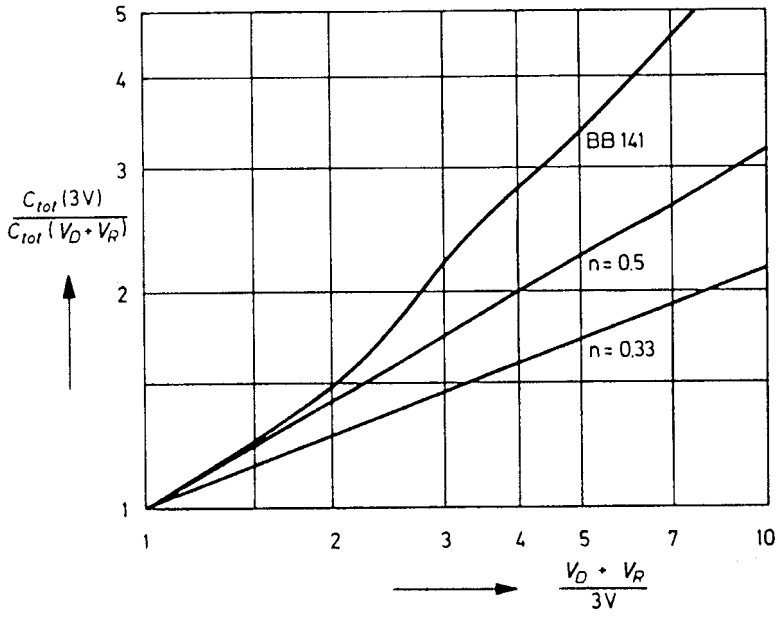

Figure 5-52 Capacitance–voltage characteristic for an alloyed capacitance diode ($n = 0.33$), a diffused capacitance diode ($n = 0.5$), and a wide-range tuning diode (BB141).

wherein all constants and all parameters determined by the manufacturing process are contained in K. The exponent is a measure of the slope of the capacitance/voltage characteristic and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction [6, 7]. Figure 5-52 shows the capacitance–voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation was developed that, although purely formal, describes the practical characteristic better than Eq. (5-82):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{5-83}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is the volt. The exponent m is much less dependent on voltage than the exponent n in Eq. (5-81).

The operating range of a capacitance diode or its useful capacitance ratio,

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R,\min})}{C_{\text{tot}}(V_{R,\max})} \tag{5-84}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage, either into the forward mode or the breakdown mode. Otherwise, rectification would take place, shifting the bias of the diode and considerably affecting its figure of merit.

There are several manufacturers of tuning diodes. Motorola is a typical supplier in this country; Siemens of Germany and Philips also provide good diodes. Table 5-4 and Figure 5-53 contain information for tuning diodes useful for our applications.

5-5-8 Diode-Tuned Resonant Circuits

Tuner Diode in Parallel-Resonant Circuit. Figures 5-54 and 5-55 illustrate two basic circuits for the tuning of parallel resonant circuits by means of capacitance diodes. In the circuit diagram of Figure 5-54, the tuning voltage is applied to the tuning diode via the bias resistor, R_B. Series-connected from the tuning diode to the top of the tank circuit is capacitor C_S, which completes the circuit for alternating current but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling resistor preceding the bias resistor is large enough to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_c. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_c = R_B \left(1 + \frac{C_{\text{tot}}}{C_S}\right)^2 \tag{5-85}$$

Table 5-4 Example tuning diodes (Siemens)

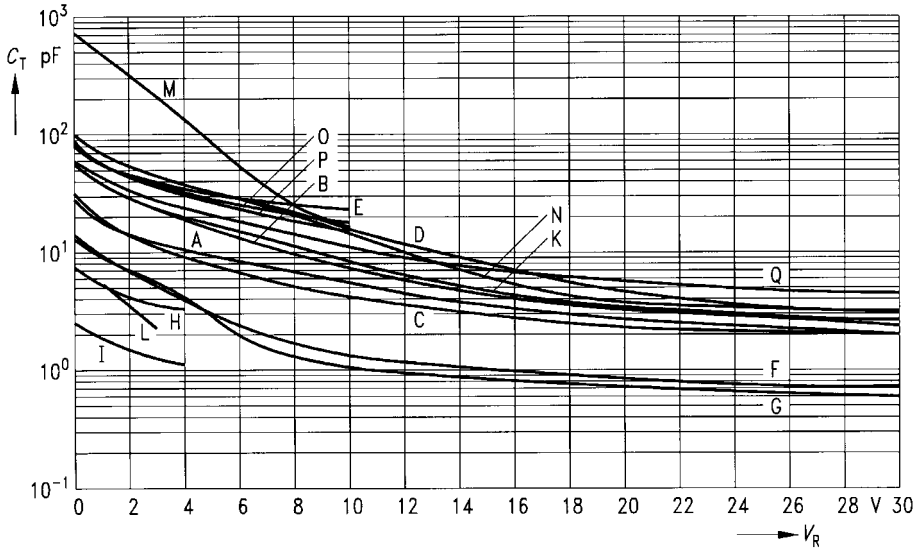

Figure 5-53 Diode capacitance C_T versus reverse voltage V_R for the diodes shown in Table 5-4. The curve labels correspond to the chip codes called out in the table.

If in this equation the diode capacitance is replaced by the resonator circuit frequency ω, we obtain

$$R_c = R_B \left(\frac{\omega^2 L C_S}{\omega^2 L (C_S + C_P) - 1} \right)^2 \tag{5-86}$$

In the circuit of Figure 5-55, the resonant circuit is tuned by two tuning diodes, which are connected in parallel via the coil for tuning purposes, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation acts in opposite directions in these diodes and, therefore, cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuning diodes, is transformed into the circuit at a constant ratio across the entire tuning range. Given two identical, loss-free tuning diodes, we obtain the expression

$$R_c = 4R_B \tag{5-87}$$

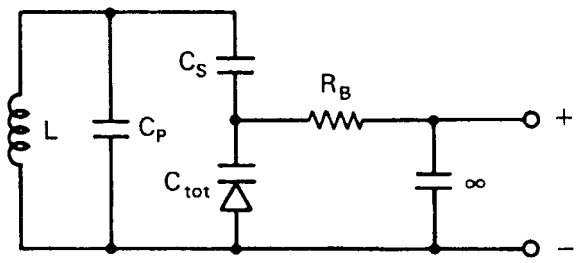

Figure 5-54 Parallel-resonant circuit with tuner diode, and bias resistor in parallel to the diode.

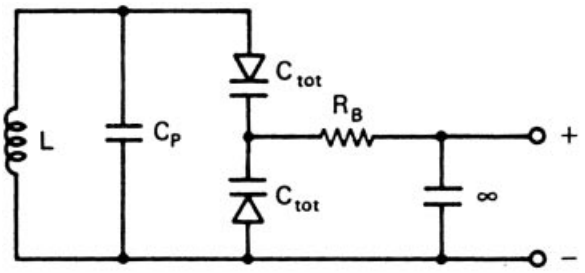

Figure 5-55 Parallel-resonant circuit with two tuning diodes.

Capacitances Connected in Parallel or in Series with the Tuning Diode. Figure 5-54 shows that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuning diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. If possible, the value of the series resistor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases—for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency—this is not possible, and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{tot} \frac{1}{1 + C_{tot}/C_S} \tag{5-88}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuning diode, increases to

$$Q^* = Q\left(1 + \frac{C_{tot}}{C_S}\right) \tag{5-89}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{max}}{C^*_{min}} = \frac{C_{max}}{C_{min}} \frac{1 + C_{min}/C_S}{1 + C_{max}/C_S} \tag{5-90}$$

where C_{max} and C_{min} are the maximum and minimum capacitances, respectively, of the tuner diode.

On the other hand, the advantage is gained that, due to the capacitive potential division, the amplitude of the alternating voltage applied to the tuner diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{tot}/C} \tag{5-91}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance C_{max} of the tuning diode and a higher useful capacitance ratio. The

influence exerted by the series capacitor, then, can actually be kept lower than Eq. (5-89) would suggest.

The parallel capacitance C_P that appears in Figures 5-54 and 5-55 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises in value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}}\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{5-92}$$

The Q of the effective tuning capacitance, derived from the Q of the tuning diode, is

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{5-93}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}}\,\frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{min}}} \tag{5-94}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the layout stage of the circuit design.

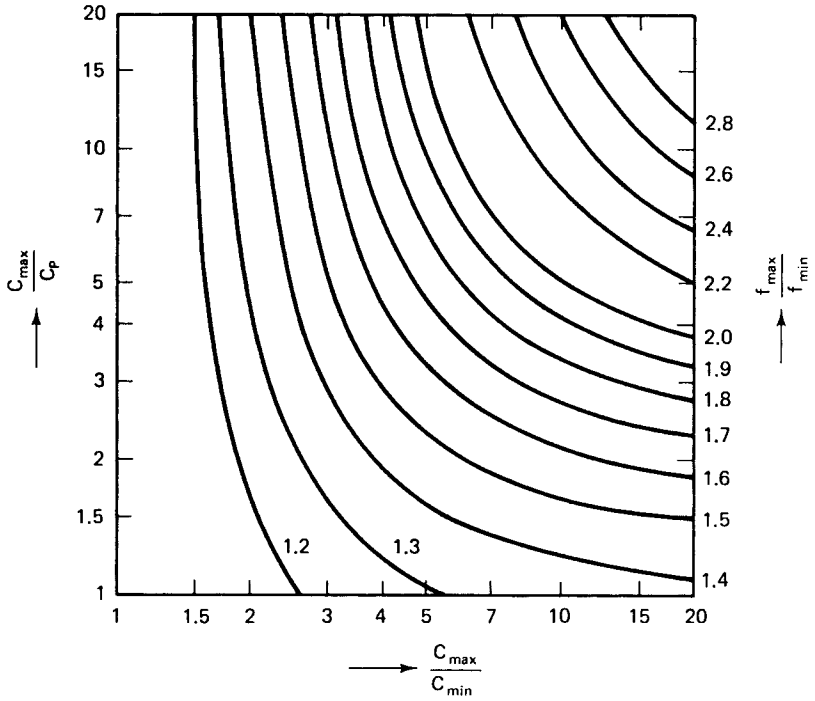

Figure 5-56 Diagram for determining capacitance ratio and maximum capacitance.

Tuning Range. The frequency range over which a parallel-resonant circuit (according to Figure 5-54) can be tuned by means of the tuning diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit. The ratio is

$$\frac{f_{\max}}{f_{\min}} = \left(\frac{1 + \dfrac{C_{\max}}{C_P(1 + C_{\max}/C_S)}}{1 + \dfrac{C_{\max}}{C_P(C_{\max}/C_{\min} + C_{\max}/C_S)}} \right)^{1/2} \tag{5-95}$$

In many cases, the value of the series capacitor can be chosen to be large enough for its effect to be negligible. In that case, Eq. (5-95) is simplified as follows:

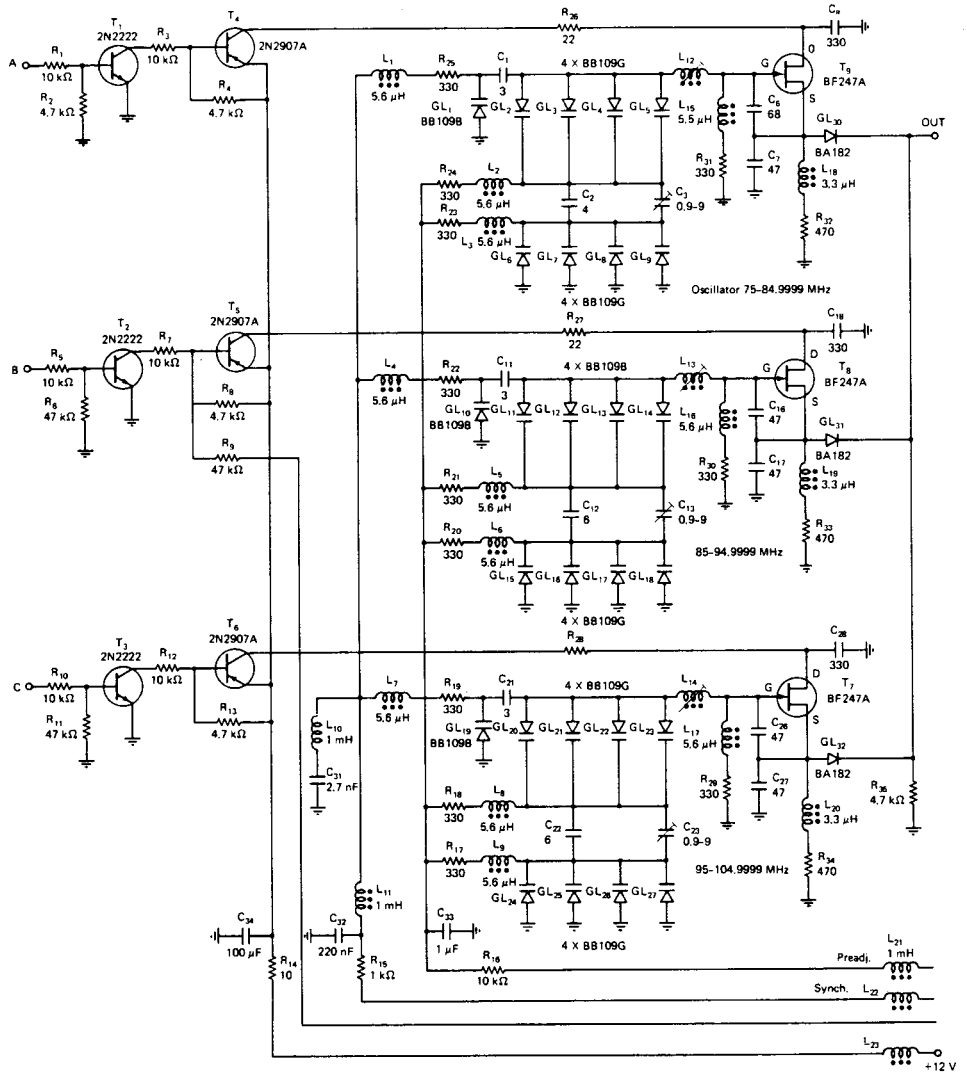

Figure 5-57 Oscillator and switching section of the Rohde & Schwarz ESH2/ESH3 test receiver.

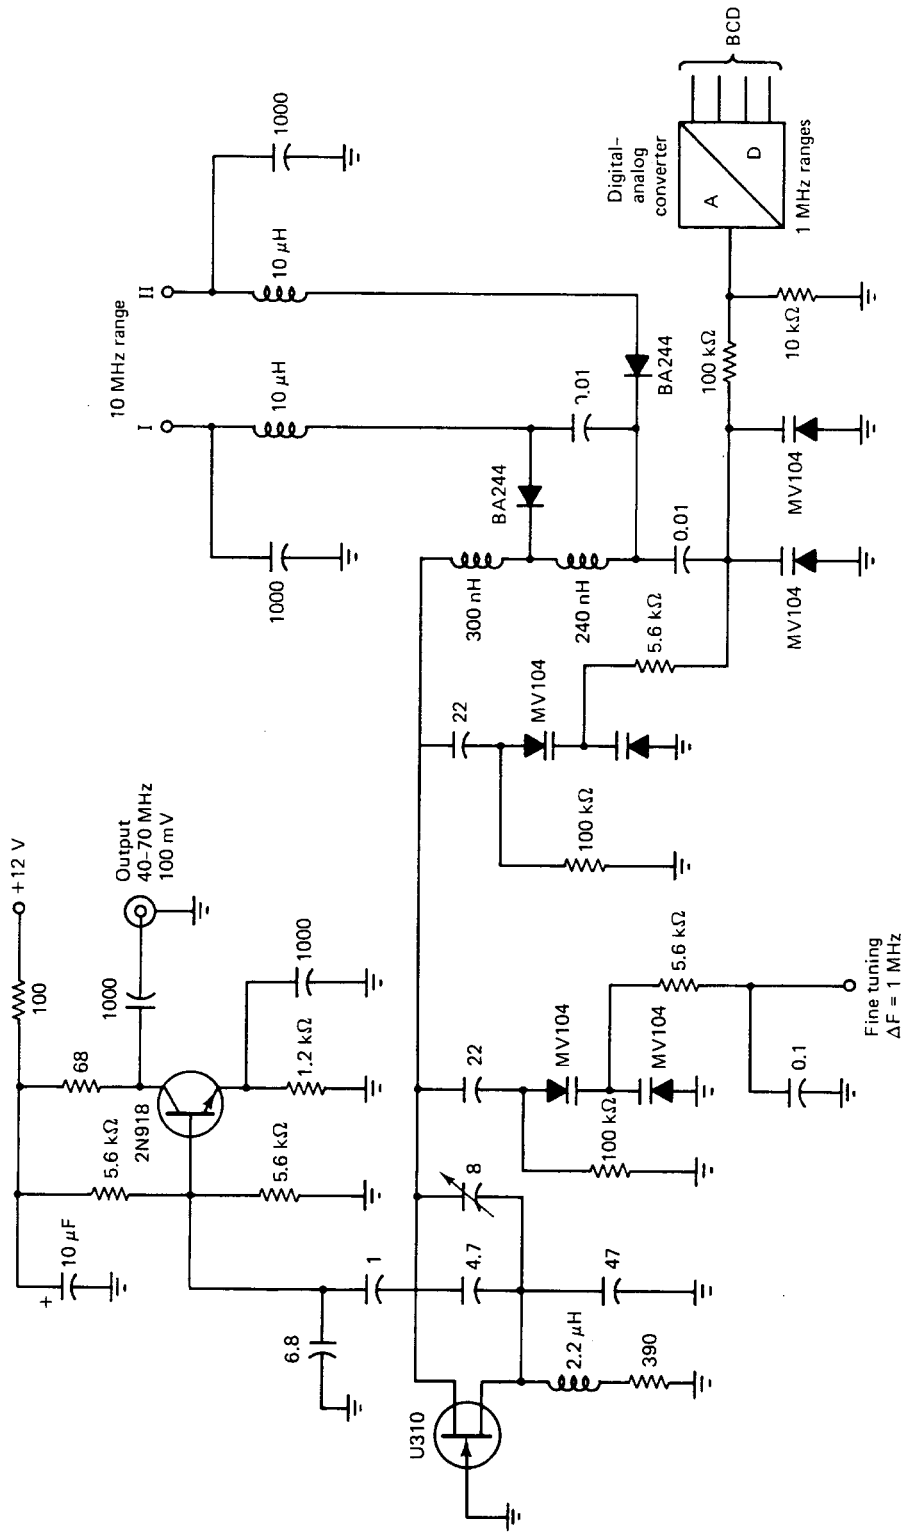

Figure 5-58 A 40–70-MHz VCO with two coarse-steering ranges and a fine-tuning range of 1 MHz.

$$\frac{f_{\max}}{f_{\min}} = \left(\frac{1 + C_{\max}/C_P}{1 + C_{\min}/C_P} \right)^{1/2} \tag{5-96}$$

From this equation, the diagram shown in Figure 5-56 is computed. With the aid of this diagram, the tuning diode parameters required for tuning a resonant circuit over a stipulated frequency range (i.e., the maximum capacitance and the capacitance ratio) can be determined. Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced accorded to Eq. (5-90).

Tracking. When several tuned circuits are used on the same frequency, diodes must be selected for perfect tracking.

5-5-9 Practical Circuits

Oscillators with Coarse and Fine Tuning. After so much theory, it may be nice to take a look at some practical circuits, such as the one shown in Figure 5-57. This oscillator is being used in the Rohde & Schwarz ESN/ESVN40 field-strength meter, and in the HF1030 receiver produced by Cubic Communications, San Diego. This circuit combines all the various techniques shown previously. A single diode is being used for fine-tuning a narrow range of less than 1 MHz; coarse tuning is achieved with the antiseries diodes.

Several unusual properties of this circuit are apparent:

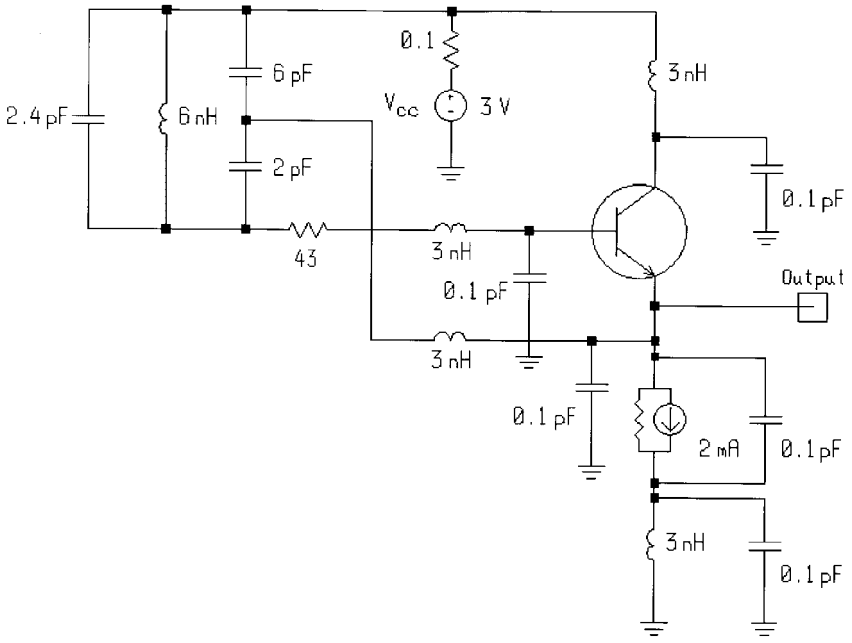

Figure 5-59 Schematic of the dc-coupled oscillator.

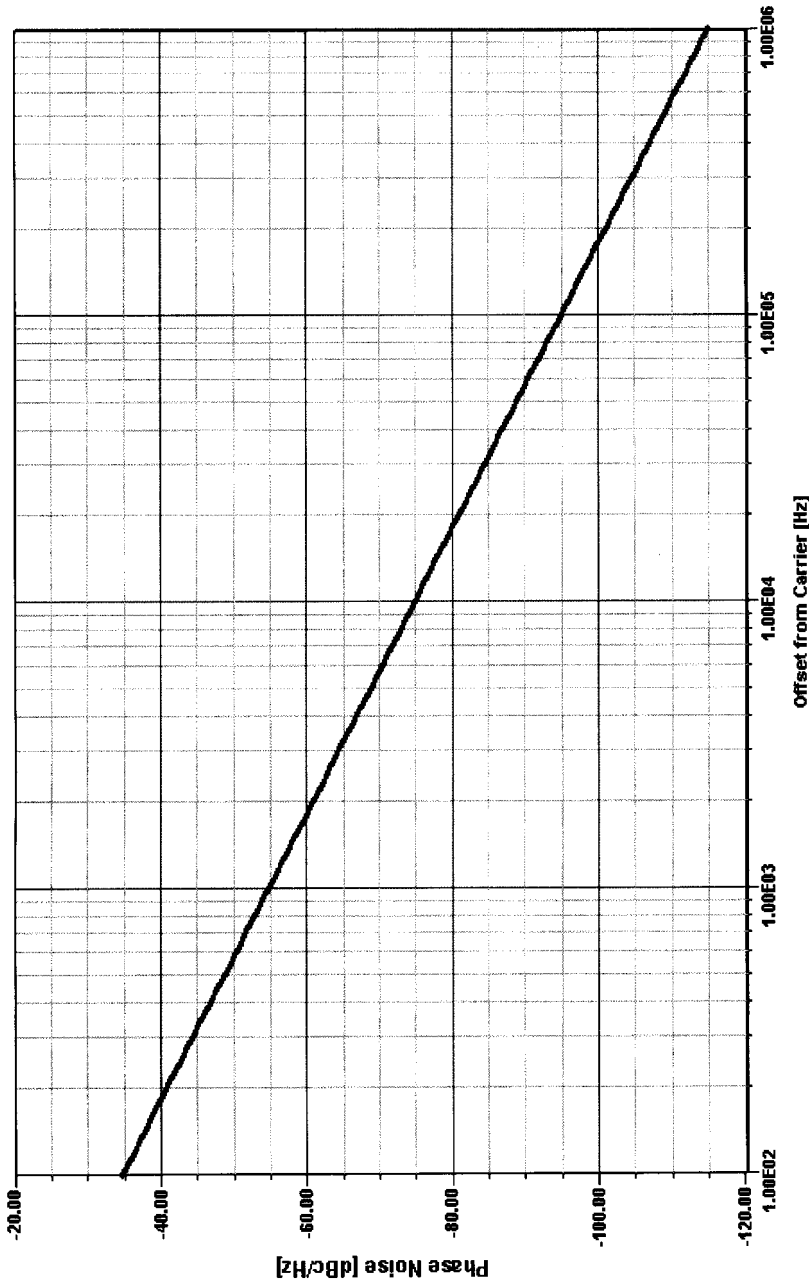

Figure 5-60 Phase noise of the dc-coupled oscillator operating at 897 MHz.

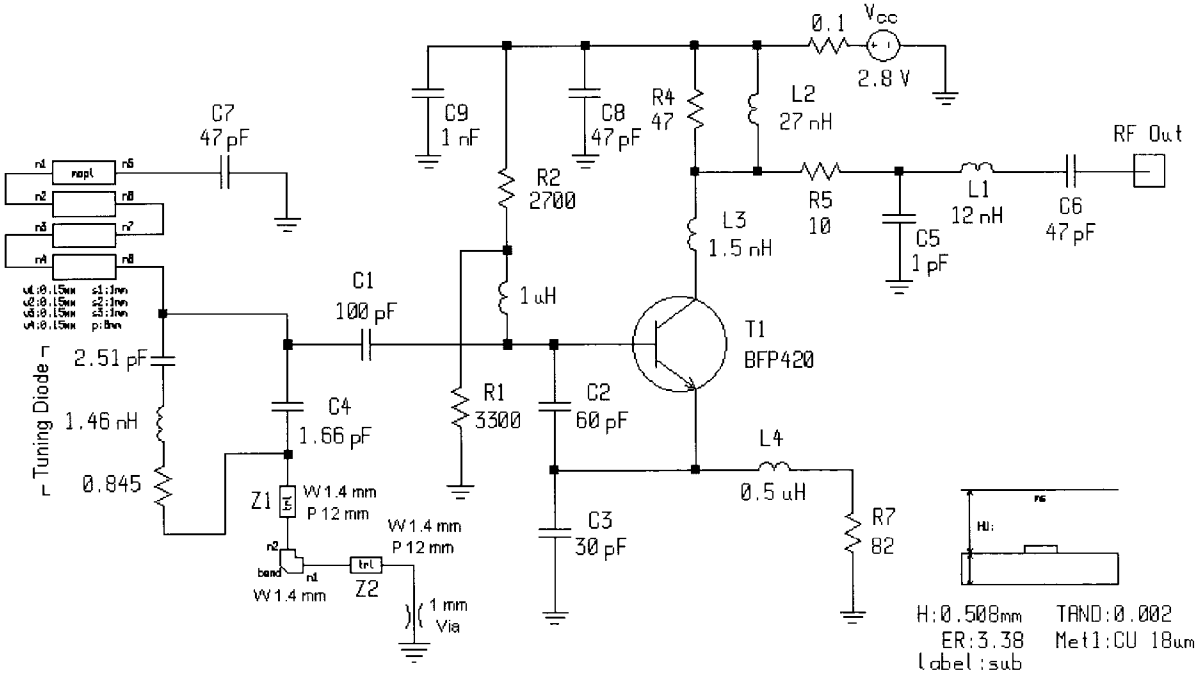

Figure 5-61 Schematic of the Siemens VCO. This oscillator (simulation) works with such high voltage-divider capacitances (C_2 and C_3) only because the circuit's large-signal transistor model, which was obtained under contract, exhibits unrealistically high gain at the frequency of oscillation. Actual capacitors with values on the order of those shown for C_2 and C_3 typically exhibit parasitic resistance and inductance of 0.3 Ω and 0.2 nH, respectively; the resulting series resonance would make any actual such capacitor act as an inductor at UHF. Obtaining practical "UHF useful" capacitances with values on the order of those shown for C_2 and C_3 would therefore necessitate the use of multiple, smaller-value capacitors in parallel—4 × 15 pF at C_2, for example.

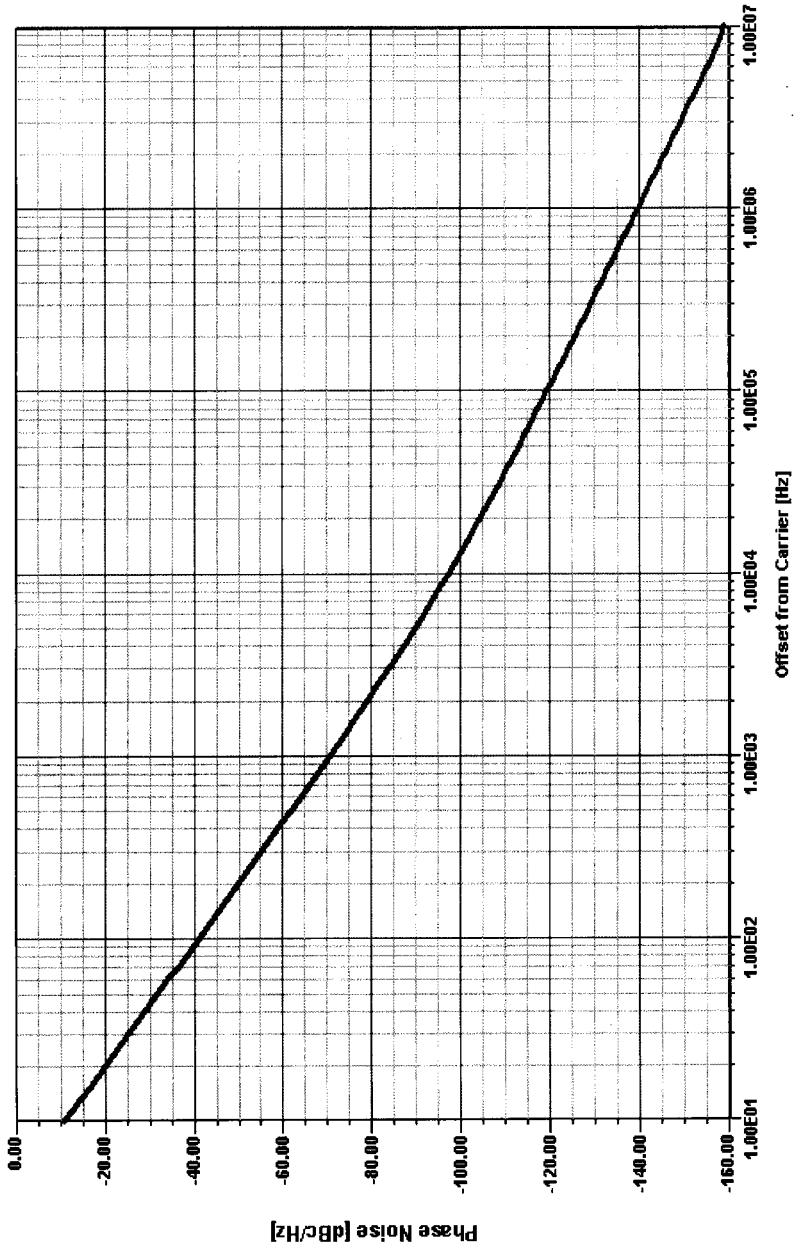

Figure 5-62 Simulated phase noise of the VCO. The frequency of oscillation is 1.052 GHz.

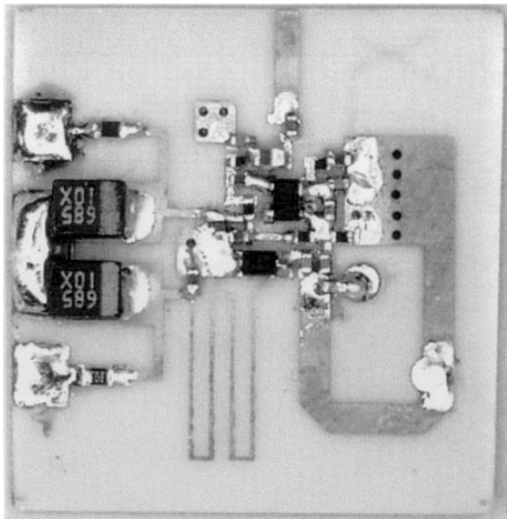

Figure 5-63 Implementation of the Siemens VCO.

1. The fine tuning is achieved with a tuning diode that has a much larger capacitance than that of the coupling capacitor in the circuit. The advantage of this technique is that the fixed capacitor and the tuning diode form a voltage divider, whereby the voltage across the tuning diode decreases as the capacitance increases. For larger values of the capacitance of the tuning diode, the Q changes and the gain K_0 increases. Because of the voltage division, the noise contribution and loading effect of the diode are reduced.
2. In the coarse-tuning circuit, several tuning diodes are used in parallel. The advantage of this circuit is a change in L/C ratio by using a higher C and storing more energy in the tuned circuit. There are no high-Q diodes available with such large capacitance values, and therefore preference is given to using several diodes in parallel rather than one tuning diode with a large capacitance, normally used only for AM (medium-frequency broadcast) tuner circuits.

We mentioned previously that, despite this, the coarse-tuning circuit will introduce noise outside the loop bandwidth, where it cannot be corrected. It is therefore preferable to incorporate switching diodes for segmenting ranges at the expense of switching current drain.

Figure 5-58 shows a circuit using a combined technique of tuning diodes for fine- and medium-resolution tuning, and coarse tuning with switching diodes.

dc-Coupled Oscillator. An interesting circuit that was cut out of an IC was supplied to us by David Lovelace of Motorola. Figure 5-59 shows the circuit and Figure 5-60 shows its phase noise. As a result of the constraints of integration, this BJT oscillator has no base bias circuitry in the conventional form. A fairly noisy performer, it ultimately was not used in production.

Siemens Colpitts Oscillator. A more elaborate approach that is essentially a standard Colpitts oscillator with a lot of detailed modeling is the oscillator of Figure 5-61, supplied

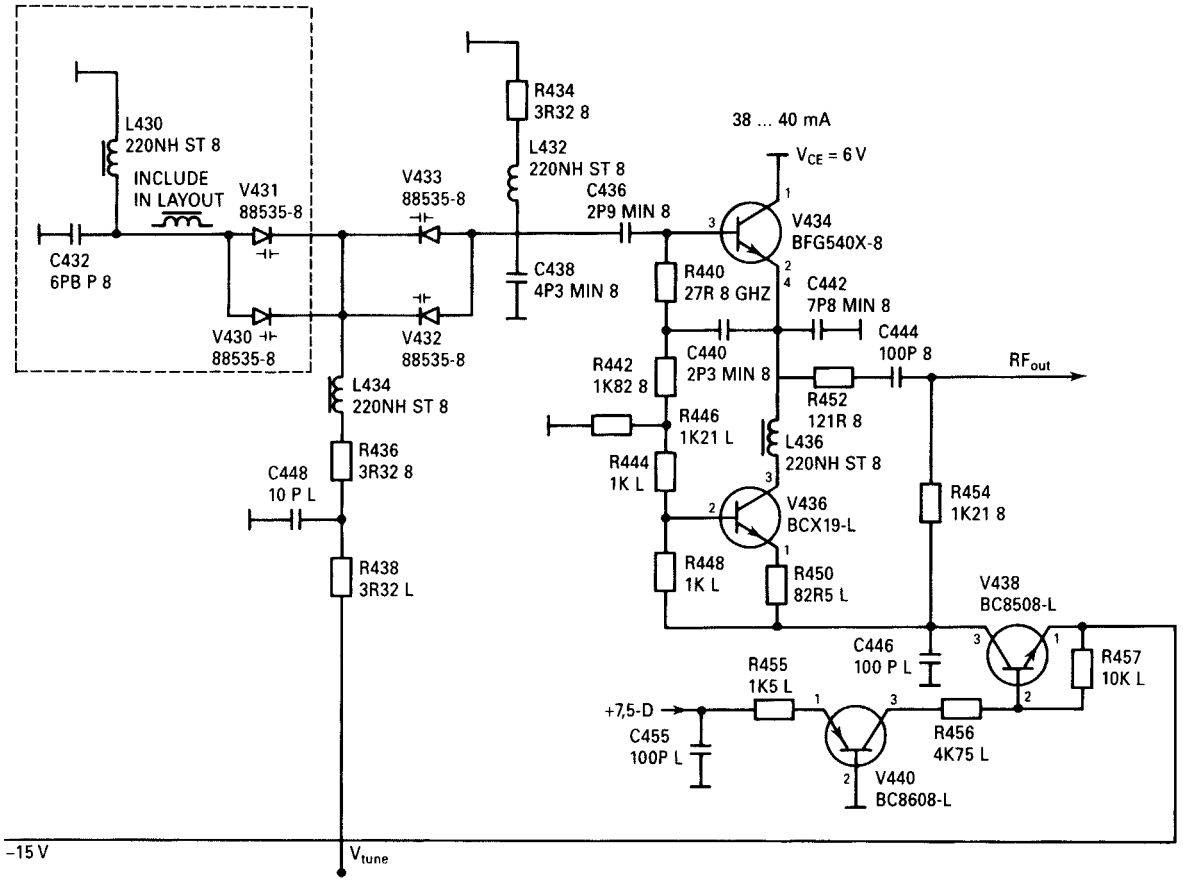

Figure 5-64 A recommended very-low-phase-noise VCO that operates in the 1-GHz region. The V436 stage is a constant-current generator responsible for improved phase-noise performance.

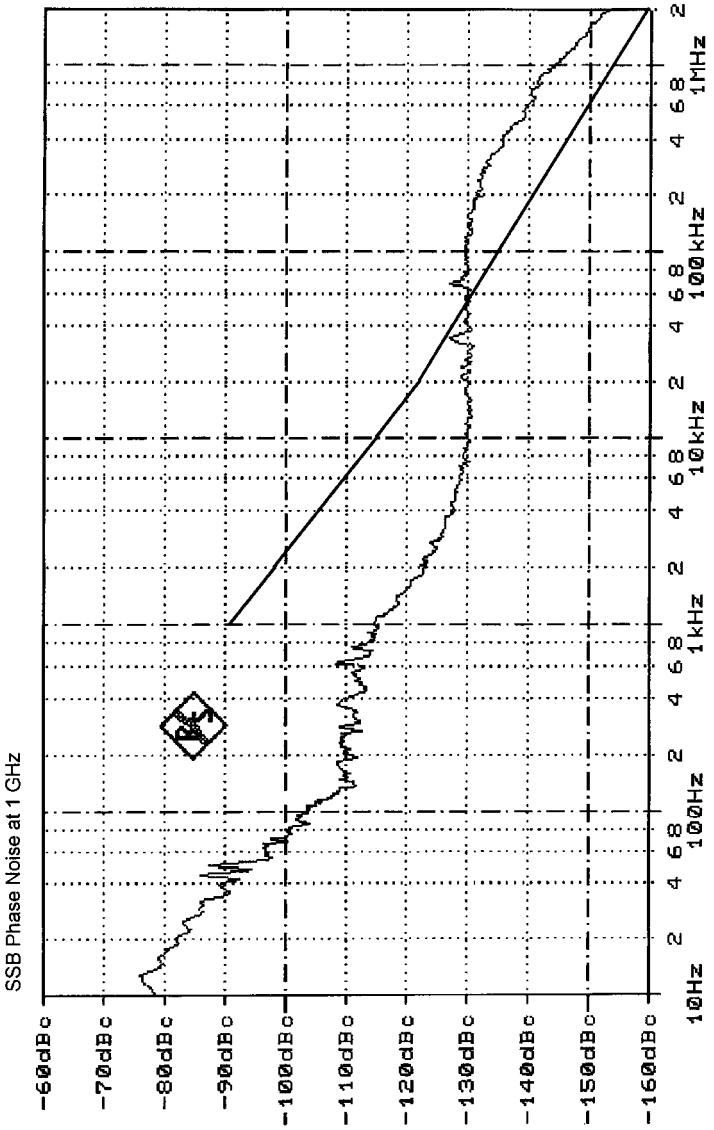

Figure 5-65 Phase noise of the low-noise VCO. The "ledges" from 100 Hz to 1 kHz and from 10 kHz to 100 kHz reflect the noise-cleanup effects of a dual-loop synthesizer; the superimposed line from 1 kHz to 2 MHz shows the oscillator's noise characteristic with both loops unlocked. The closed-loop response is noisier than the open-loop response at offsets above 60 kHz because a wide loop bandwidth is used to achieve a faster switching speed.

to us by Siemens. Considering its simplicity, its noise performance is good, as shown in Figure 5-62. Modeling this circuit involved the consideration of via holes and coupled lines. Figure 5-63 shows an actual implementation of this oscillator. The value of external emitter resistance (R7 in Figure 5-61) plays a critical role in determining a common-emitter Colpitts oscillator's upper frequency limit as described in Yeom [8].

dc-Stabilized Oscillator. For high-performance synthesizers, such as the Rohde & Schwarz series SMG/SMH, a dc-stabilized oscillator with fairly wide tuning range may be used. Figure 5-64 shows such an oscillator, the measured phase noise of which is shown in Figure 5-65. It should be noted that the output loop is magnetically coupled and therefore takes advantage of the inherent selectivity of the tuned circuit.

5-6 NOISE IN OSCILLATORS

In transmitters, oscillator noise can result in adjacent-channel interference and modulation errors; in receivers, oscillator noise can result in demodulation errors and degraded sensitivity and dynamic range. The specification, calculation, and reduction of oscillator noise are therefore of great importance in wireless system design.

5-6-1 Linear Approach to the Calculation of Oscillator Phase Noise

Since an oscillator can be viewed as an amplifier with feedback (Figure 5-66), it is helpful to examine the phase noise added to an amplifier that has a noise figure F. F is defined by [9]

$$F = \frac{(S/N)_{\text{in}}}{(S/N)_{\text{out}}} = \frac{N_{\text{out}}}{N_{\text{in}}G} = \frac{N_{\text{out}}}{GkTB} \tag{5-97}$$

$$N_{\text{out}} = FGkTB \tag{5-98}$$

$$N_{\text{in}} = kTB \tag{5-99}$$

where N_{in} is the total input noise power to a noise-free amplifier. The input phase noise in a 1-Hz bandwidth at any frequency $f_0 + f_m$ from the carrier produces a phase deviation given by (Figure 5-67)

$$\Delta\theta_{\text{peak}} = \frac{V_{n\,\text{RMS1}}}{V_{s,\text{av RMS}}} = \sqrt{\frac{fKT}{P_{s,\text{av}}}} \tag{5-100}$$

$$\Delta\theta_{\text{1RMS}} = \frac{1}{\sqrt{2}}\sqrt{\frac{FkT}{P_{s,\text{av}}}} \tag{5-101}$$

Since a correlated random phase-noise relation exists at $f_0 - f_m$, the total phase deviation becomes

$$\Delta\theta_{\text{RMS total}} = \sqrt{FkT/P_{s,\text{av}}} \tag{5-102}$$

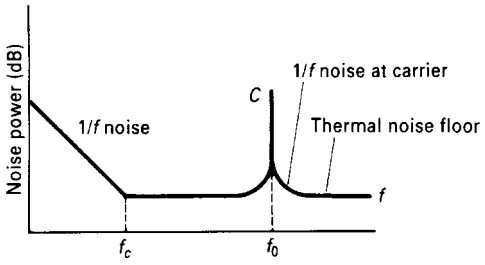

Figure 5-66 Noise power versus frequency of a transistor amplifier with an input signal applied.

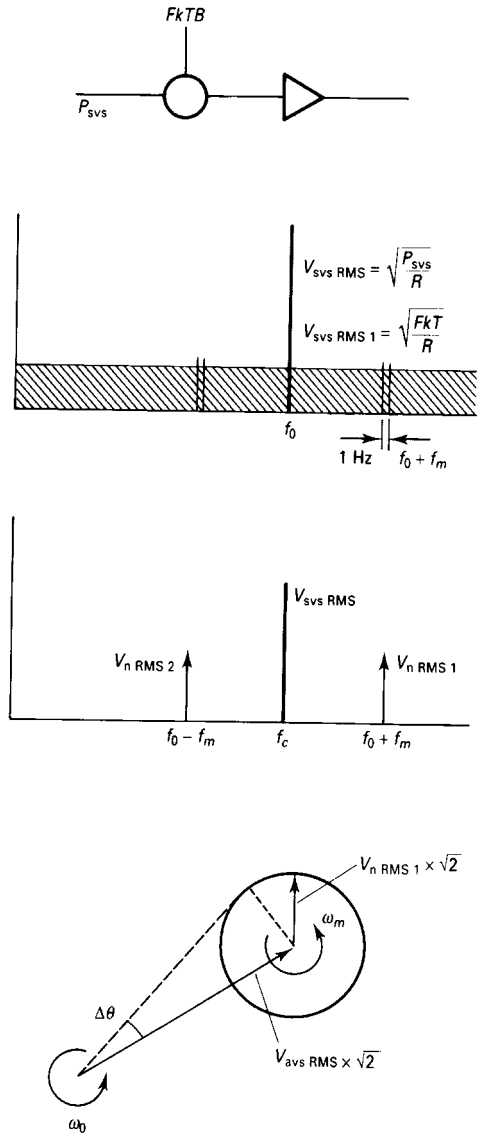

Figure 5-67 Phase noise added to carrier.

The spectral density of phase noise becomes

$$S_\theta(f_m) = \Delta\theta^2_{\text{RMS}} = FkTB/P_{s,\text{av}} \tag{5-103}$$

where $B = 1$ for a 1-Hz bandwidth. Using

$$kTB = -174 \text{ dBm/Hz} \qquad (B = 1) \tag{5-104}$$

allows a calculation of the spectral density of phase noise that is far removed from the carrier (i.e., at large values of f_m). This noise is the theoretical noise floor of the amplifier. For example, an amplifier with +10-dBm power at the input and a noise figure of 6 dB gives

$$S_\theta(f_m > f_c) = -174 \text{ dBm} + 6 \text{ dB} - 10 \text{ dBm} = -178 \text{ dBm} \tag{5-105}$$

Only if P_{OUT} is >0 dBm can we expect $\mathcal{L}$ (signal-to-noise ratio) to be greater than 174 dBc/Hz (1-Hz bandwidth). For a modulation frequency close to the carrier, $S_\theta(f_m)$ shows a flicker or $1/f$ component, which is empirically described by the corner frequency f_c. The phase noise can be modeled by a noise-free amplifier and a phase modulator at the input as shown in Figure 5-68.

The purity of the signal is degraded by the flicker noise at frequencies close to the carrier. The spectral phase noise can be described by

$$S_\theta(f_m) = \frac{FkTB}{P_{s,\text{av}}}\left(1 + \frac{f_c}{f_m}\right) \quad (B = 1) \tag{5-106}$$

No AM-to-PM conversion is considered in this equation. The oscillator may be modeled as an amplifier with feedback as shown in Figure 5-69. The phase noise at the input of the amplifier is affected by the bandwidth of the resonator in the oscillator circuit in the following way. The tank circuit or bandpass resonator has a low-pass transfer function

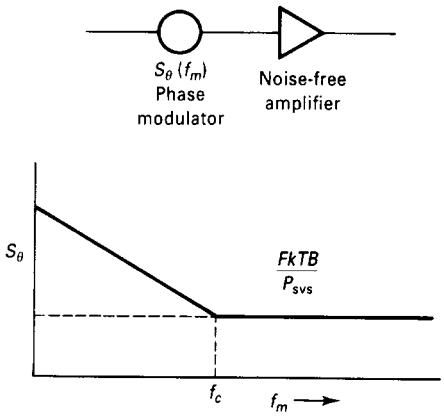

Figure 5-68 Phase noise modeled by a noise-free amplifier and phase modulator.

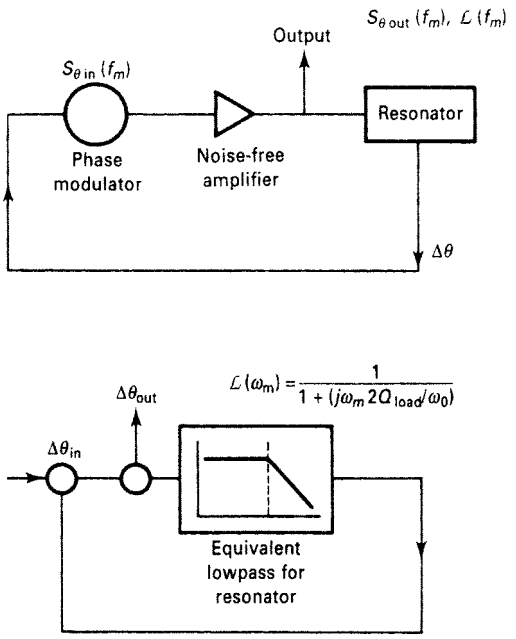

Figure 5-69 Equivalent feedback models of oscillator phase noise.

$$L(\omega_m) = \frac{1}{1 + j(2Q_L\omega_m/\omega_0)} \tag{5-107}$$

where

$$\omega_0/2Q_L = B/2 \tag{5-108}$$

is the half-bandwidth of the resonator. These equations describe the amplitude response of the bandpass resonator; the phase noise is transferred unattenuated through the resonator up to the half-bandwidth.

The closed-loop response of the phase feedback loop is given by

$$\Delta\theta_{\text{out}}(f_m) = \left(1 + \frac{\omega_0}{j2Q_L\omega_m}\right)\Delta\theta_{\text{in}}(f_m) \tag{5-109}$$

The power transfer becomes the phase spectral density

$$S_{\theta,\text{out}}(f_m) = \left[1 + \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right] S_{\theta,\text{in}}(f_m) \tag{5-110}$$

where $S_{\theta,\text{in}}$ was given by Eq. (5-106). Finally, $\mathcal{L}(f_m)$ is

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right] S_{\theta,\text{in}}(f_m) \tag{5-111}$$

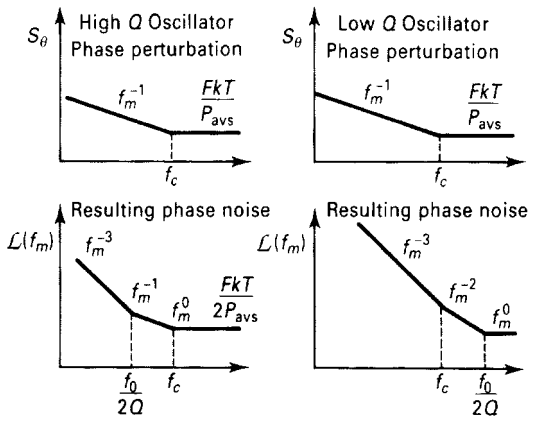

Figure 5-70 Equivalent feedback models of oscillator phase noise.

This equation describes the phase noise at the output of the amplifier (flicker corner frequency and AM-to-PM conversion are not considered). The phase perturbation $S_{\theta,\text{in}}$ at the input of the amplifier is enhanced by the positive phase feedback within the half-bandwidth of the resonator, $f_0/2Q_L$.

Depending on the relation between f_c and $f_0/2Q_L$, there are two cases of interest, as shown in Figure 5-70. For the low-Q case, the spectral phase noise is unaffected by the Q of the resonator, but the $\mathcal{L}(f_m)$ spectral density will show a $1/f^3$ and $1/f^2$ dependence close to the carrier. For the high-Q case, a region of $1/f^3$ and $1/f$ should be observed near the carrier. Substituting Eq. (5-106) into Eq. (5-111) gives an overall noise of

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{1}{f_m^2}\left(\frac{f}{2Q_L}\right)^2\right]\frac{FkT}{P_{s,\text{av}}}\left(1 + \frac{f_c}{f_m}\right)$$

$$= \frac{FkTB}{2P_{s,\text{av}}}\left[\frac{1}{f_m^3}\frac{f^2 f_c}{4Q_L^2} + \frac{1}{f_m^2}\left(\frac{f}{2Q_L}\right)^2 + \left(1 + \frac{f_c}{f_m}\right)\right] \text{dBc/Hz} \tag{5-112}$$

Examining Eq. (5-112) gives the four major causes of oscillator noise: the upconverted $1/f$ noise or flicker FM noise, the thermal FM noise, the flicker phase noise, and the thermal noise floor, respectively.

Q_L (loaded Q) can be expressed as

$$Q_L = \frac{\omega_o W_e}{P_{\text{diss,total}}} = \frac{\omega_o W_e}{P_{\text{in}} + P_{\text{res}} + P_{\text{sig}}} = \frac{\text{Reactive power}}{\text{Total dissipated power}} \tag{5-113}$$

where W_e is the reactive energy stored in L and C,

$$W_e = \frac{1}{2} CV^2 \tag{5-114}$$

$$P_{\text{res}} = \frac{\omega_o W_e}{Q_{\text{unl}}} \tag{5-115}$$

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{\omega_o^2}{4\omega_m^2}\left(\frac{P_{\text{in}}}{\omega_o W_e} + \frac{1}{Q_{\text{unl}}} + \frac{P_{\text{sig}}}{\omega_o W_e}\right)^2\right]\left(1 + \frac{\omega_c}{\omega_m}\right)\frac{FkT_o}{P_{\text{sav}}} \tag{5-116}$$

Input power/ Reactive power ratio

Resonator Q

Signal power/ Reactive power ratio

Flicker effect

Phase perturbation

This equation is extremely significant because it covers most of the causes of phase noise in oscillators. [AM-to-PM conversion must be added; see Eq. (5-56).] To minimize the phase noise, the following design rules apply:

1. Maximize the unloaded Q.
2. Maximize the reactive energy by means of a high RF voltage across the resonator and obtain a low L/C ratio. The limits are set by breakdown voltages of the active devices and the tuning diodes, and the forward-bias condition of the tuning diodes. If L becomes too high, the circuit degenerates into a squegging oscillator. Using lower L allows larger capacitance, which allows us to swamp the oscillating device's internal, nonlinear capacitance with external, linear capacitance, reducing the phase-noise degradation caused by the nonlinear capacitance. The ceramic-resonator oscillator best illustrates this approach, which may be hard to accomplish in discrete circuits because high-Q inductors with values above 1 nH cannot be built unless high-Q transmission lines or resonators are used.
3. Avoid saturation at all costs, and try to have either limiting or automatic gain control (AGC) without degradation of Q. Isolate the tuned circuit from the limiter or AGC circuit. Use tuning diodes in antiseries configurations to avoid forward bias.
4. Choose an active device with the lowest possible noise figure and flicker corner frequency. The noise figure of interest is the noise figure obtained with the actual impedance at which the device is operated. Using FETs rather than BJTs, it is preferable to deal with the equivalent noise voltage and noise currents rather than with the noise figure, since they are independent of source impedance. The noise figure improves as the ratio between source impedance and equivalent noise resistance increases. In addition, in a tuned circuit, the source impedance changes drastically as a function of the offset frequency, and this effect has to be considered. For low phase-noise operation, use a medium-power transistor. If you need your output power to be achieved at 6–9 mA, select a transistor with an $I_{C,\max}$ of 60–90 mA. Also avoid an f_T greater than 3× to 5× the operating frequency. To make transistors that are stable across their full frequency ranges, manufacturers add circuitry that makes the flicker corner frequency higher as f_T increases.

   The following transistors have the lowest noise figure:

   - BFG65/67 by Philips
   - BFR106/92; BFP405/420 by Siemens
   - 2SC3358/3356 by NEC
   - HXTR4105 by HP

- AT2100 (chip) by Avantek

Among the lowest-noise JFETs are the U310, 2N4416/17, and 2N5397.

In designing MMICs, one must resort to MESFETs, which are also referred to as GaAsFETs. They have a fairly high flicker frequency, which is typically around 10 MHz but can go up to as high as 100 MHz.

Table 5-5 shows equivalent circuits and measurement data for the Avantek AT2100 20-GHz *npn* silicon bipolar oscillator transistor. (Siemens of Germany is about to come out with 45-GHz f_T transistors, which will compete with SiGe transistors in the future.)

5. Phase perturbation can be minimized by using high-impedance devices such as FETs, where the signal-to-noise ratio of the signal voltage relative to the equivalent noise voltage can be made very high. This also indicates that in the case of a limiter, the limited voltage should be as high as possible.
6. Choose an active device with low flicker noise. The effect of flicker noise can be reduced through RF feedback. An unbypassed emitter resistor of 10–30 Ω in a bipolar circuit can improve the flicker noise by as much as 40 dB.

   The proper bias point of the active device is important, and precautions should be taken to prevent modulation of the input and output dynamic capacitances of the active device, which will cause amplitude-to-phase conversion and therefore introduce noise.
7. The energy should be coupled from the resonator rather than from another portion of the active device so that the resonator limits the bandwidth.
8. For microwave applications, the lowest-noise GaAsFETs are pseudomorphic HJ FETs. A reproduction of the datasheet of the NEC NE42484A, which is generally the state of the art today, follows; it is used with permission.

Equation (5-116) assumes that the phase perturbation and the flicker effect are the limiting factors, as practical use of such oscillators requires that an isolation amplifier must be used.

In the event that energy is taken directly from the resonator and the oscillator power can be increased, the signal-to-noise ratio can be increased above the theoretical limit of 174 dBc/Hz, due to the low-pass-filter effect of the tuned resonator. However, since this is mainly a theoretical assumption and does not represent a real-world system, this noise performance cannot be obtained. In an oscillator stage, even a total noise floor of –170 dBc/Hz is rarely achieved.

What other influences do we have that cause an oscillator's noise performance to degrade? So far, we have assumed that the Q of the tuned circuit is really determined only by the LC network and the loading effect of the transistor. In synthesizer applications, however, we find it necessary to add a tuning diode. The tuning diode has a substantially lower Q than that of a mica capacitor or even a ceramic capacitor. As a result of this, the noise sidebands change as a function of the additional loss. This is best expressed by adjusting the value for the loaded Q in Eq. (5-113).

There seems to be no precise mathematical way of predetermining the noise influence of a tuning diode, but the following approximation seems to give proper results:

$$\frac{1}{Q_{T,\text{load}}} = \frac{1}{Q_{\text{load}}} + \frac{1}{Q_{\text{diode}}} \tag{5-117}$$

[a]These equivalent circuits are provided only as first-order design aids. Their accuracy for critical designs at very high frequencies has not been validated.

[b]*S* parameters are from the linear equivalent circuit. Below 10 GHz, they have been fit to measurements of die on a standard carrier with one bond wire to the base and four wires to the emitter.

NEC

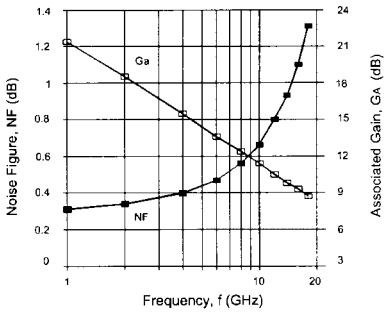
SUPER LOW NOISE PSEUDOMORPHIC HJ FET

NE42484A

FEATURES

- **VERY LOW NOISE FIGURE:** 0.8 dB TYP at 12 GHz
- **HIGH ASSOCIATED GAIN:** 10.5 dB TYP at 12 GHz
- **L_G = 0.35 µm, W_G = 200 µm**
- **LOW COST METAL CERAMIC PACKAGE**
- **TAPE & REEL PACKAGING OPTION AVAILABLE**

NOISE FIGURE & ASSOCIATED GAIN vs. FREQUENCY
V_{DS} = 2 V, I_{DS} = 10 mA



DESCRIPTION

The NE42484A is a pseudomorphic Hetero-Junction FET that uses the junction between Si-doped AlGaAs and undoped InGaAs to create very high mobility electrons. The device features mushroom shaped TiAl gates for decreased gate resistance and improved power handling capabilities. The mushroom gate also results in lower noise figure and high associated gain. This device is housed in an epoxy-sealed, metal/ceramic package and is intended for high volume consumer and industrial applications.

NEC's stringent quality assurance and test procedures ensure the highest reliability and performance.

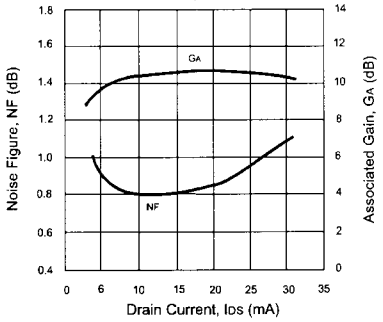
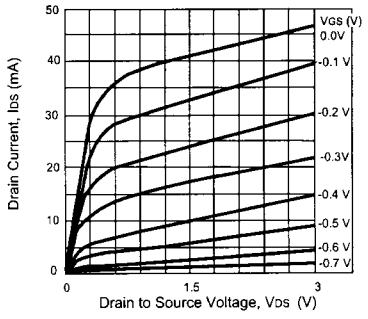
Note
1. If P_T exceeds the Free Air Value, reliable operation can be assured by measuring the worst-case temperature, $T_{(LEAD)}$, at the lead where heat flow is maximum (usually the source lead) and limiting T_A, P_T or $R_{TH\ (CKT)}$

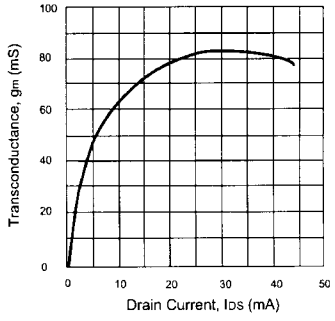
NOISE FIGURE AND ASSOCIATED GAIN vs. DRAIN CURRENT V_{DS} = 2 V, f = 12 GHz



DRAIN CURRENT vs. DRAIN TO SOURCE VOLTAGE



TRANSCONDUCTANCE vs. DRAIN CURRENT V_{DS} = 2.0 V



The tuning diode is specified to have a cutoff frequency $f_{\max}$, which is determined from the loss resistor R_S and the value of the junction capacitance as a function of voltage (e.g., measured at 3 V). This means that the voltage determines the Q and, consequently, the noise bandwidth.

5-6-2 AM-to-PM Conversion

We went into more detail in dealing with the mechanism and influence of tuning diodes in the voltage-controlled oscillators section, where we evaluated the various methods of building voltage-tunable oscillators using tuning diodes. In this section, we limit ourselves to practical results.

The loading effect of the tuning diode is due to losses, and these losses can be described by a resistor in parallel with the tuned circuit.

It is possible to define an equivalent noise $R_{a,\text{eq}}$ that, inserted in Nyquist's equation,

$$V_n = \sqrt{4kT_0R\,\Delta f} \tag{5-118}$$

where $kT_0 = 4.2 \times 10^{-21}$ at about 300 K, R is the equivalent noise resistor, and Δf is the bandwidth, determines an open-circuit noise voltage across the tuning diode. Practical values of $R_{a,\text{eq}}$ for carefully selected tuning diodes are in the vicinity of 200 Ω to 50 kΩ. If we now determine the noise voltage $V_n = \sqrt{4 \times 4.2 \times 10^{-21} \times 10{,}000}$, the resulting voltage value is 1.296×10^{-8} V $\sqrt{\text{Hz}}$.

This noise voltage generated from the tuning diode is now multiplied with the VCO gain K_0, resulting in the rms frequency deviation

$$(\Delta f_{\text{rms}}) = K_0 \times (1.296 \times 10^{-8}\ \text{V}) \text{ in 1-Hz bandwidth} \tag{5-119}$$

To translate this into an equivalent peak phase deviation,

$$\theta_d = \frac{K_0\sqrt{2}}{f_m}(1.296 \times 10^{-8}) \text{ rad in 1-Hz bandwidth} \tag{5-120}$$

or for a typical oscillator gain of 100 kHz/V,

$$\theta_d = \frac{0.00183}{f_m} \text{ rad in 1-Hz bandwidth} \tag{5-121}$$

For f_m = 25 kHz (typical spacing for adjacent-channel measurements for FM mobile radios), $\theta_c = 7.32 \times 10^{-8}$. This can be converted now into the SSB signal-to-noise ratio:

$$\mathcal{L}(f_m) = 20 \log_{10}\left(\frac{\theta_c}{2}\right) = -149 \text{ dBc/Hz} \tag{5-122}$$

For the typical oscillator gain of 10 MHz/V found in wireless applications, the resulting phase noise will be 20 dB worse [10 log (10 MHz ÷ 100 kHz)]. However, the best tuning diodes, like the BB104, have an R_n of 200 Ω instead of 10 kΩ, which again changes the picture. According to Eq. (5-118), with $kT_0 = 4.2 \times 10^{-21}$ the resulting noise voltage will be

$$V_n = \sqrt{4 \times 4.2 \times 10^{-21} \times 200}$$

$$= 1.833 \times 10^{-9} \text{ V}\sqrt{\text{Hz}} \tag{5-123}$$

From Eq. (5-114), the equivalent peak phase deviation for a gain of 10 MHz/V in a 1-Hz bandwidth is then

$$\theta_d = \frac{1 \times 10^7 \sqrt{2}}{f_m} (1.833 \times 10^{-9}) \text{ rad} \tag{5-124}$$

or

$$\theta_d = \frac{0.026}{f_m} \text{ rad in 1-Hz bandwidth} \tag{5-125}$$

With $f_m = 25$ kHz, $\theta_c = 1.04 \times 10^{-6}$. Expressing this as phase noise:

$$\mathcal{L}(f_m) = 20 \log_{10}\left(\frac{\theta_c}{2}\right) = -126 \text{ dBc/Hz} \tag{5-126}$$

The phase-noise value in Eq. (5-122) is that typically achieved in the Rohde & Schwarz SMDU or with the Hewlett-Packard 8640 signal generator and considered state-of-the-art for a free-running oscillator. It should be noted that both signal generators use a slightly different tuned circuit; the Rohde & Schwarz generator uses a helical resonator, whereas the Hewlett-Packard generator uses an electrically shortened quarter-wavelength cavity. Both generators are mechanically pretuned, and a tuning diode with a gain of about 100 kHz/V is used for AFC and frequency-modulation purposes. It is apparent that, because of the nonlinearity of the tuning diode, the gain is different for low dc voltages than for high dc voltages. The impact of this is that the noise varies with the tuning range.

If this oscillator had to be used for a synthesizer, its 1-MHz tuning range would be insufficient; therefore, a way had to be found to segment the band into the necessary ranges. In VCOs, this is typically done with switching diodes that allow the proper frequency bands to be selected. These switching diodes insert in parallel or series, depending on the circuit, with additional inductors or capacitors, depending on the design.

In low-energy-consuming circuits, the VCO frequently is divided into a coarse-tuning section using tuning diodes and a fine-tuning section with a tuning diode. In the coarse-tuning range, this results in very high gains, such as 1–10 MHz/V, for the diodes. The noise contribution of those diodes is therefore very high and can hardly be compensated by the loop. For low-noise applications, which automatically mean higher power consumption, it is unavoidable to use switching diodes.

Let us now examine some test results. Referring back to Eq. (5-106), Figure 5-71 shows the noise sideband performance as a function of Q, whereby the top curve with $Q_L = 100$ represents a somewhat poor oscillator and the lowest curve with $Q_L = 100{,}000$ probably represents a crystal oscillator where the unloaded Q of the crystal was in the vicinity of 3×10^6. Figure 5-72 shows the influence of flicker noise.

Corner frequencies of 10 Hz to 10 kHz have been selected, and it becomes apparent that around 1 kHz the influence is fairly dramatic, whereas the influence at 20 kHz off the carrier

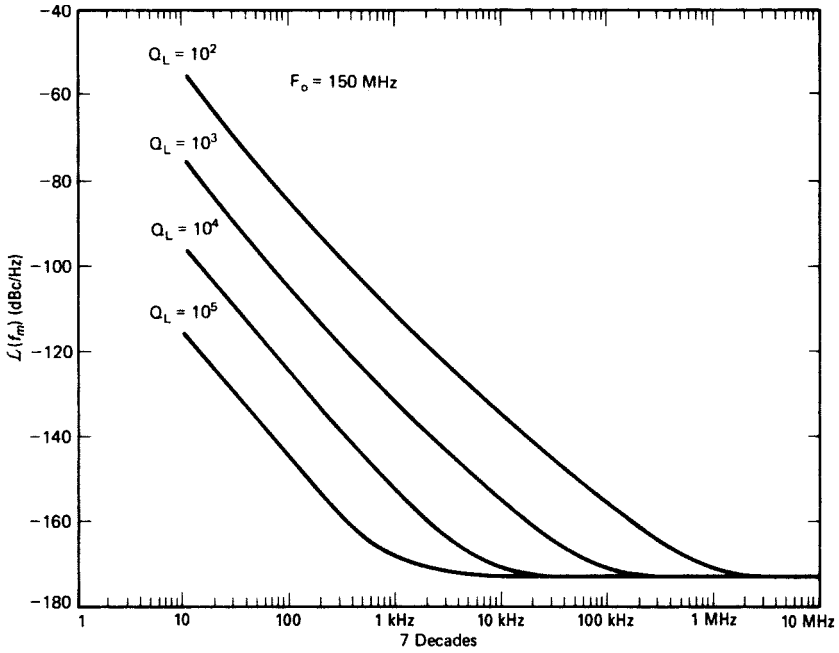


Figure 5-71 Noise sideband of an oscillator at 150 MHz as a function of the loaded Q of the resonator.

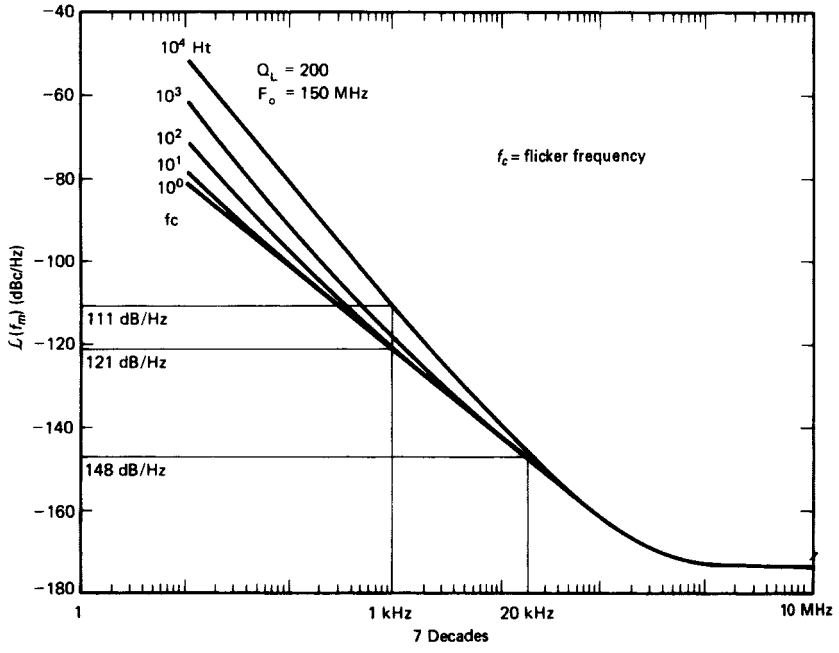

Figure 5-72 Noise-sideband performance as a function of the flicker frequency f_c varying from 10 Hz to 10 kHz.

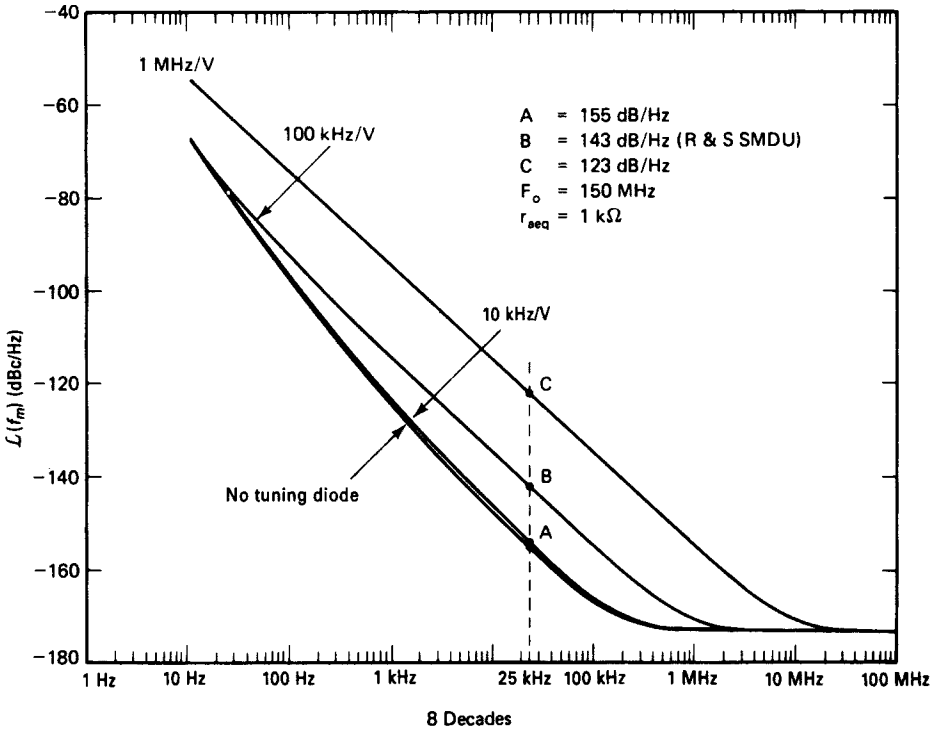

Figure 5-73 Noise-sideband performance of an oscillator at 150 MHz, showing the influence of various tuning diodes.

is not significant. Figures 5-73 and 5-74 show the influence of the tuning diodes on a high-Q oscillator.

Curve A in Figure 5-73 uses a lightly coupled tuning diode with a K_0 of 10 kHz/V; the lower curve is the noise performance without any diode. As a result, the two curves are almost identical, which can be seen from the somewhat smeared form of the graph. Curve B shows the influence of a tuning diode at 100 kHz/V and represents a value of −143 dBc/Hz from −155 dBc/Hz, already some deterioration. Curve C shows the noise if the tuning diode results in a 1-MHz/V VCO gain, and the noise sideband at 25 kHz has now deteriorated to −123 dBc/Hz. These curves speak for themselves.

Figure 5-74 shows how the phase noise of a 147-MHz VCO varies with the bias applied to its tuning diode. Because a tuning diode's Q increases with the reverse bias applied to it, we expect a VCO's phase-noise performance to improve, even if only slightly, as its tuning voltage is increased. Yet Figure 5-74 illustrates the reverse of this relationship. Inspecting this VCO's circuit (Figure 5-75), we see that the diode is in series with the circuit's 220-nH resonator. *All* of the RF current flowing through the resonator must flow through the relatively low-Q diode, and even small decreases in the diode's capacitance will significantly modify the tank's L/C ratio.

Graphing the diode's ac load line (Figure 5-76), we see that as the tuning voltage increases (i.e., as the tuning diode capacitance decreases), the RF voltage across the diode becomes disproportionately high. We note also that at every value of tuning voltage, the RF voltage across the diode goes positive (relative to the anode) during part of each cycle.

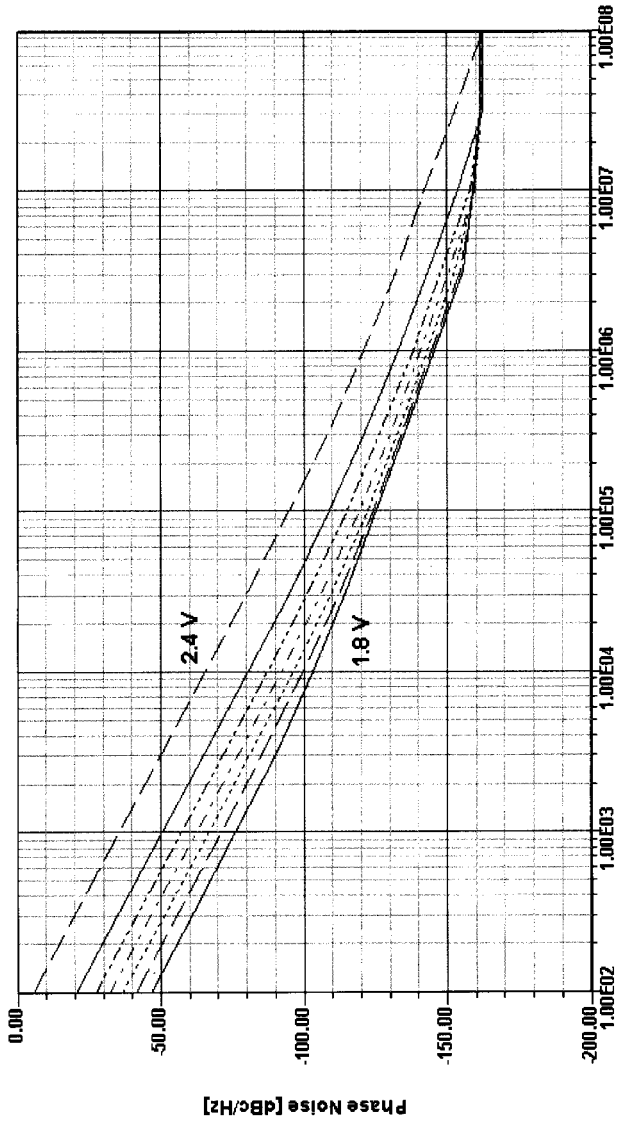

Figure 5-74 Noise-sideband performance of an oscillator at 147 MHz, showing the influence of a tuning diode operated at bias voltages from 1.8 to 2.4 V in 0.1-V increments.

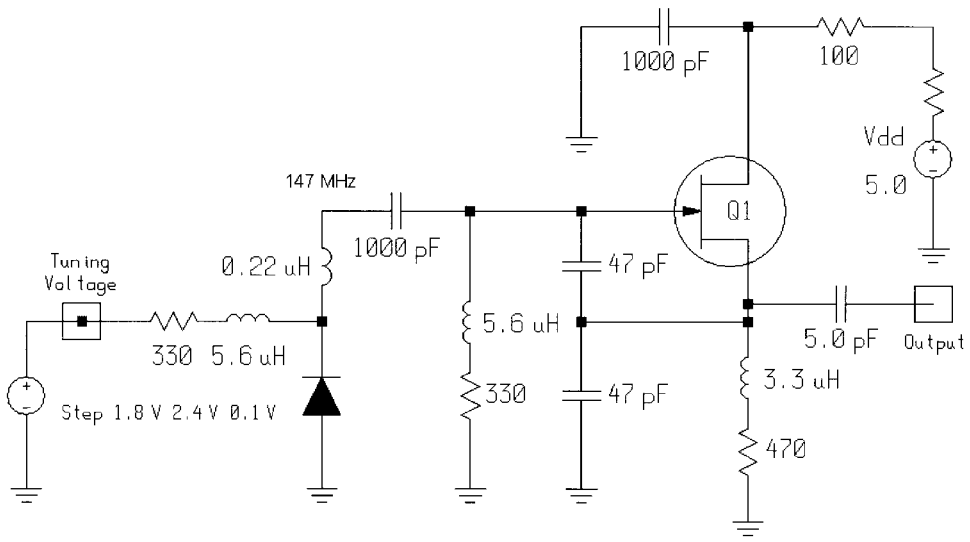

Figure 5-75 The VCO schematic. Because the tuning diode is in series with the resonator, it passes all of the tank's RF current and plays a disproportionately large role in determining the circuit's phase-noise performance.

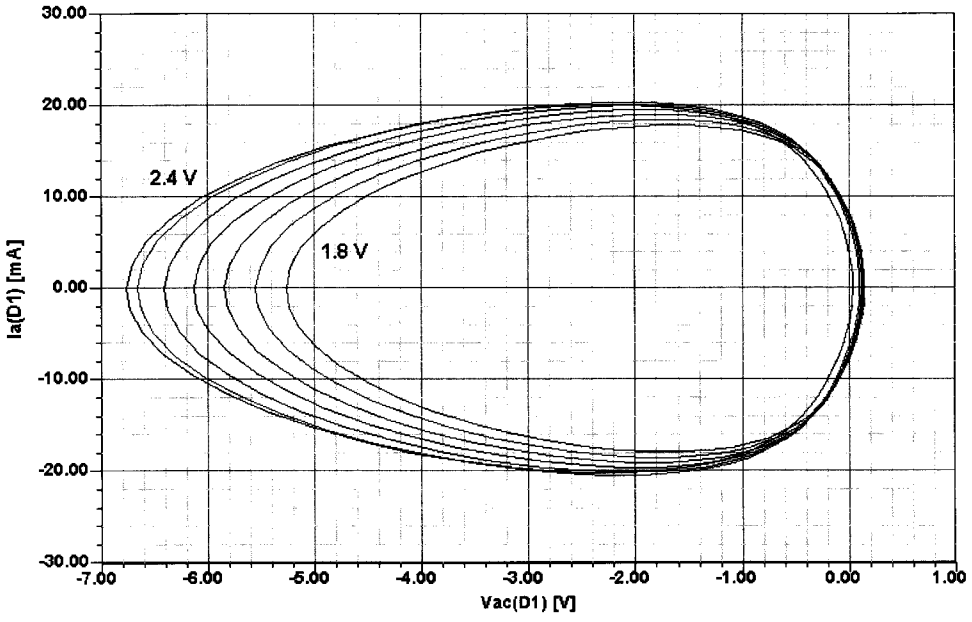

Figure 5-76 Graphing the tuning diode's ac load line reveals that increasing the diode's tuning bias (decreasing its capacitance) results in a disproportionally large increase in the RF voltage across the diode. At all tuning voltages, the RF voltage across the diode is slightly positive (relative to the anode) during part of each cycle.

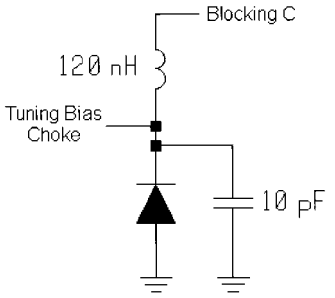

Figure 5-77 Adding capacitance across the tuning diode reduces the effect of its nonlinearities on phase-noise performance. We have also revalued the resonator to 120 nH to maintain oscillation near 147 MHz.

Modifying the oscillator tank to add capacitance in parallel with the tuning diode (Figure 5-77) reduces the tuning diode's effect on tank Q and L/C ratio, and therefore its contribution to phase noise. With this arrangement, we now see the expected relationship between tuning bias and phase noise: The higher the tuning bias, the lower the phase noise (Figure 5-78). Figure 5-79 shows that the diode's ac load line is now virtually unchanged across the tuning-voltage range. The RF voltage across the diode still goes positive (relative to the anode) during part of each cycle.

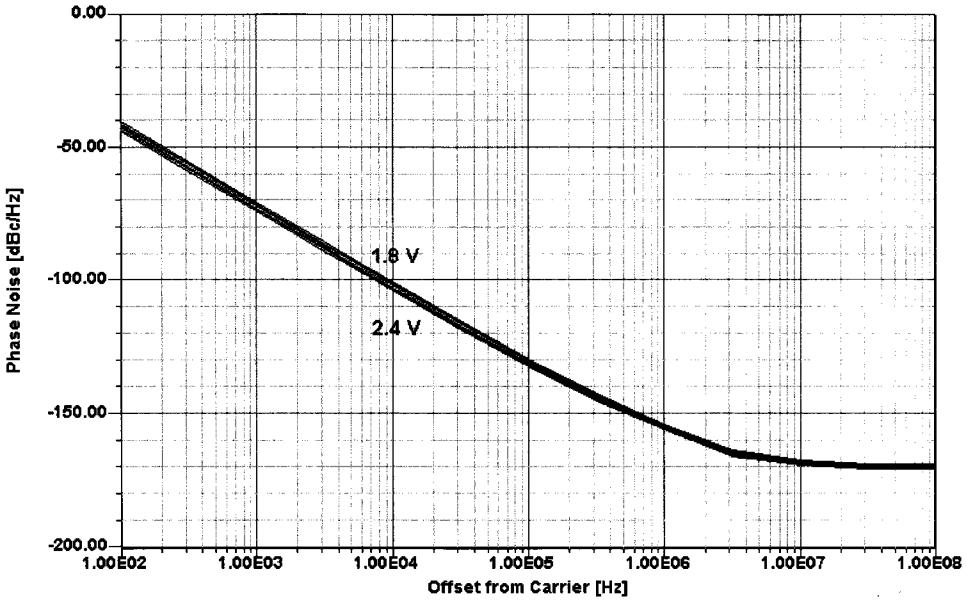

Figure 5-78 Now that the tuning diode passes only part of the tank's RF current, varying its capacitance does not result in the large change in phase-noise performance shown in Figure 5-74. Note also that the phase-noise-versus-tuning-bias relationship has reversed relative to that shown in Figure 5-74: The highest tuning voltage now corresponds to the lowest phase noise.

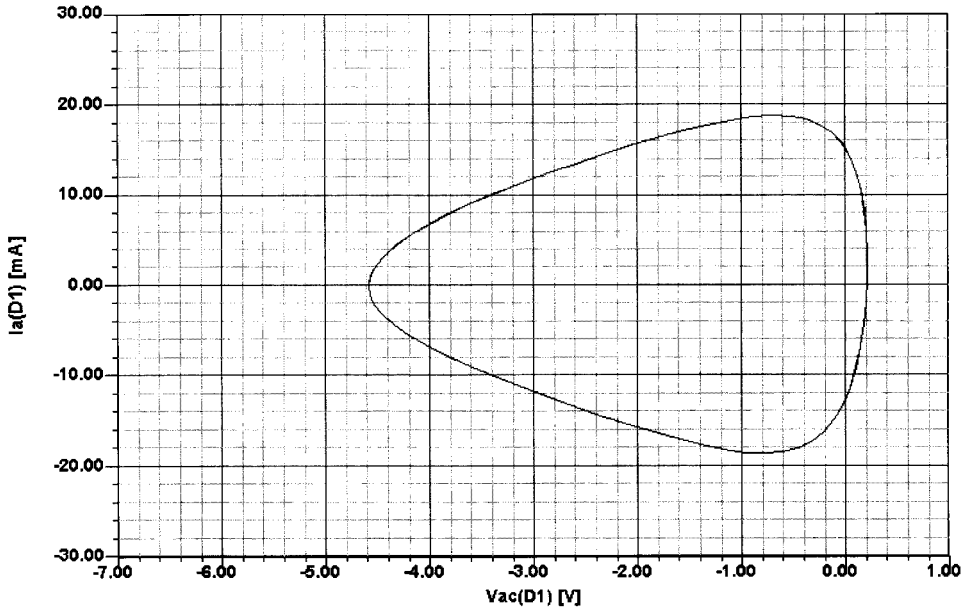

Figure 5-79 The ac load line for the tuning diode in Figure 5-77. Now the voltage swing across the diode is virtually the same at all tuning voltages. The RF voltage across the diode still goes positive (relative to the anode) during part of the cycle.

Figure 5-80 shows one more modification to the VCO tank. Now, the tuning diode is lightly coupled to the hot end of the tank, in parallel with the resonator. The result is phase-noise performance that is essentially unchanged across the 1.8–2.4-V tuning-voltage range. Figure 5-81 compares this circuit's phase-noise performance with the worst-case performance of the tank configurations in Figures 5-75 and 5-77. Figure 5-82 compares the diode ac load lines that correspond to the phase-noise curves in Figure 5-81. The best phase-noise performance corresponds to the diode ac load line that exhibits the narrowest voltage swing and never goes positive relative to the anode.

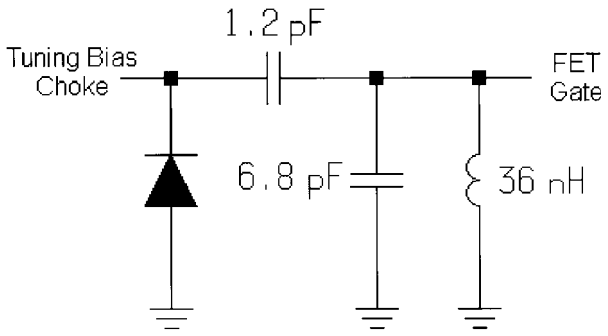

Figure 5-80 Tank circuit reconfigured as per Figure 5-54 to lightly couple the tuning diode in parallel with the resonator, with the resonator inductance again decreased to maintain oscillation near 147 MHz. The 1000-pF capacitor and gate choke of Figure 5-75 (5.6 μH in series with 330 Ω) are no longer needed.

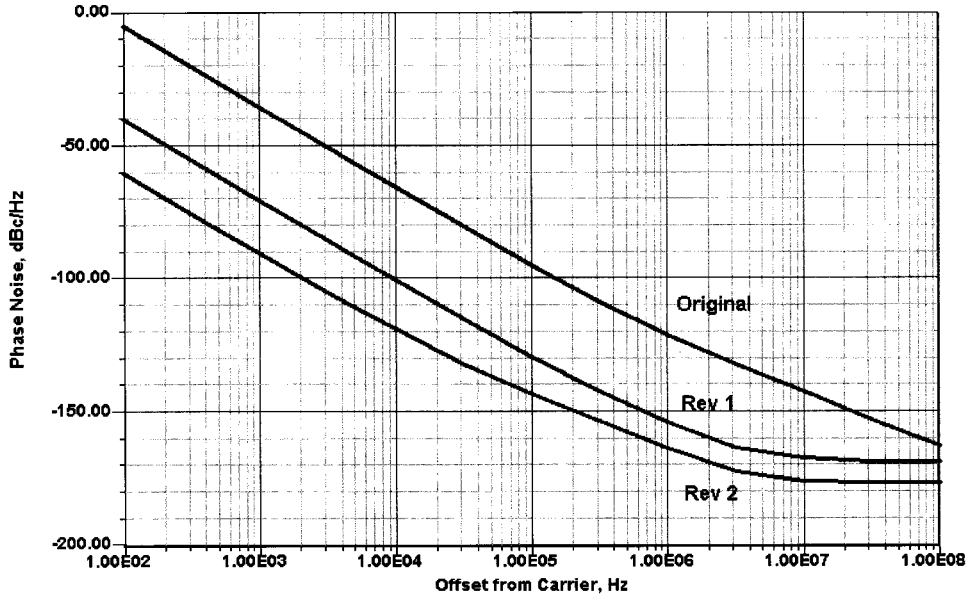

Figure 5-81 Comparison of worst-case phase-noise performance obtained with the tank configurations of Figures 5-75 (Original), 5-77 (Rev 1), and 5-80 (Rev 2).

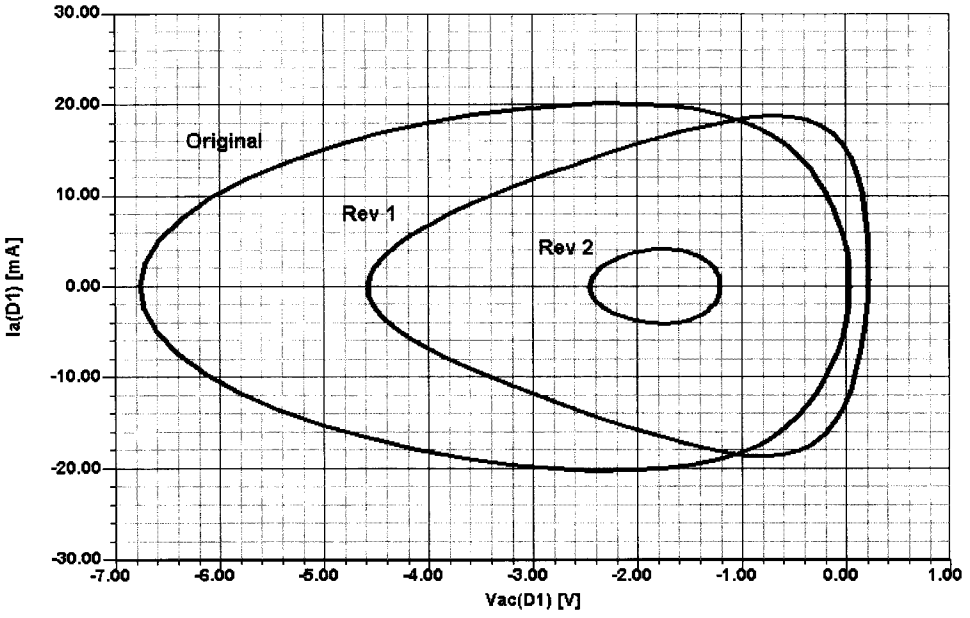

Figure 5-82 Comparison of the tuning diode's ac load line for the worst-case phase-noise curves of Figure 5-79.

It's important to keep in mind that we have not gained something for nothing in achieving the best phase-noise response in Figure 5-81. As we reduced the diode's phase-noise contribution, we also reduced the oscillator's tuning range—from 7.1% (Figure 5-75 circuit) to 1.8% (Figure 5-77 circuit) to 0.046% (Figure 5-80). Simultaneously optimizing phase-noise performance and tuning range requires a combination of techniques. First, we would maximize diode Q by using as high a tuning voltage as feasible. Second, we would use antiseries-connected diodes to minimize the RF voltage swing across them (Figure 5-55). Both of these techniques work against the achievement of wide tuning ranges by minimizing the capacitance swing that the diodes can contribute. As a result of this, and because hyperabrupt diodes are not available for the frequencies at which wireless VCOs operate, we would therefore use multiple antiseries diode pairs in parallel.

It is of interest to compare various oscillators. Figure 5-83 shows the performance of a 10-MHz crystal oscillator, a 40-MHz *LC* oscillator, the HP8640 cavity-tuned oscillator at 500 MHz, the 310–640-MHz switched-reactance oscillator of the HP8662 oscillator, and a 2–6-GHz YIG oscillator at 6 GHz.

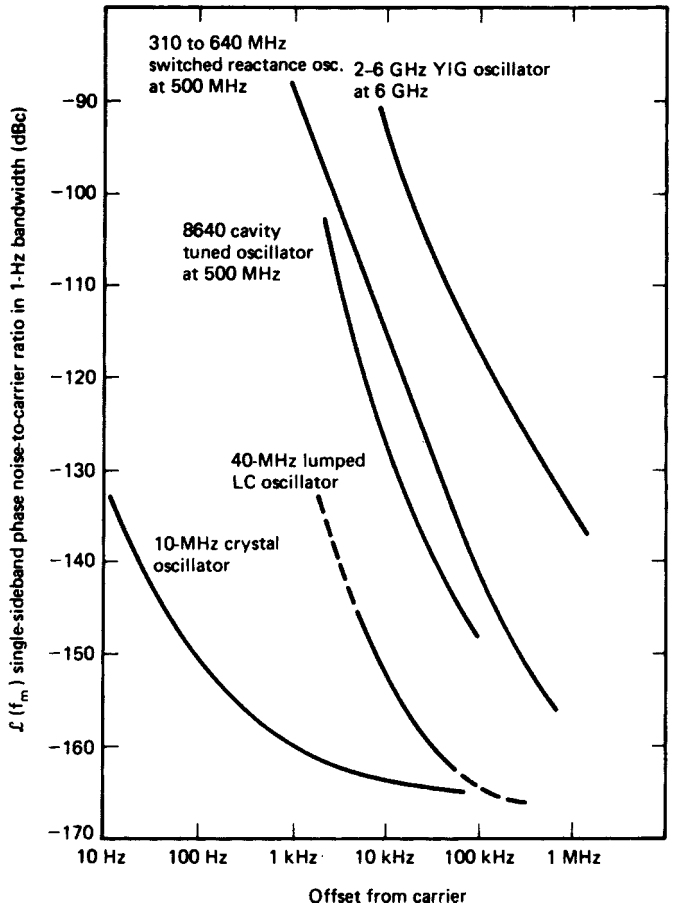

Figure 5-83 Comparison of noise-sideband performances of a crystal oscillator, *LC* oscillator, cavity-tuned oscillator, switched-reactance oscillator, and YIG oscillator.

5-6-3 Nonlinear Approach to the Calculation of Oscillator Phase Noise

The mechanism of noise generation in an oscillator combines the equivalent of frequency conversion (mixing) with the effect of AM-to-PM conversion. Therefore, to calculate oscillator phase noise, we must first be able to calculate the noise figure of a mixer. The following nonlinear approach is based on Ulrich L. Rohde, Chao-Ren Chang, and Jason Gerber, "Design and Optimization of Low-Noise Oscillators Using Nonlinear CAD Tools," *IEEE Frequency Control Symposium Proceedings*, 1994, pp. 548–554. This section presents the use of a novel algorithm for the computation of SSB carrier noise in free-running oscillators using the harmonic-balance (HB) nonlinear technique.

Traditional approaches relying on frequency conversion analysis are not sufficient to describe the complex physical behavior of a noisy oscillator. The accuracy of this nonlinear approach is based on the dynamic range of the harmonic-balance simulator and the quality of the parameter extraction for the active device. The algorithm described has also been verified with several examples up to millimeter wavelengths. This is the only algorithm that provides a complete and rigorous treatment of noise analysis for autonomous circuits.

Noise Generation in Oscillators. As shown earlier, the qualitative linearized picture of noise generation in oscillators is very well known [9]. The physical effects of random fluctuations taking place in the circuit are different depending on their spectral allocation with respect to the carrier:

- Noise components at low-frequency deviations result in frequency modulation of the carrier through mean square frequency fluctuation proportional to the available noise power.
- Noise components at high-frequency deviations result in phase modulation of the carrier through mean square phase fluctuation proportional to the available noise power.

We will demonstrate that the same conclusions can be derived quantitatively from the HB equations for an autonomous circuit.

Equivalent Representation of a Noisy Nonlinear Circuit. A general noisy nonlinear network can be described by the equivalent circuit shown in Figure 5-84. The circuit is divided into linear and nonlinear subnetworks as noise-free multiports. Noise generation is accounted for by connecting a set of noise voltage and noise current sources at the ports of the linear subnetwork [9–18].

Frequency Conversion Approach. The circuit supports a large-signal time-periodic steady state of fundamental angular frequency ω_0(carrier). Noise signals are small perturbations superimposed on the steady state, represented by families of pseudosinusoids located at the sidebands of the carrier harmonics. Therefore, the noise performance of the circuit is determined by the exchange of power among the sidebands of the unperturbed steady state through frequency conversion in the nonlinear subnetwork. Due to the perturbative assumption, the nonlinear subnetwork can be replaced with a multifrequency linear multiport described by a conversion matrix. The flow of noise signals can be computed by means of conventional linear circuit techniques.

The frequency conversion approach frequently used has limitations. The frequency-conversion approach is not sufficient to predict the noise performance of an autonomous

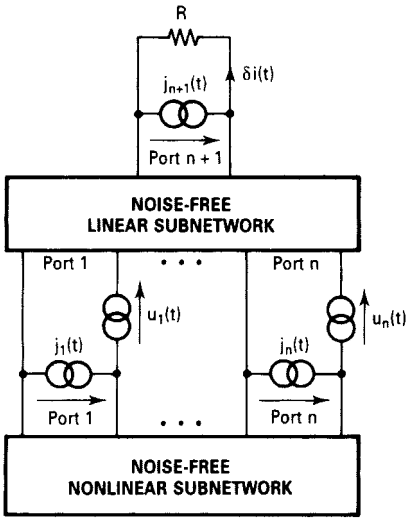

Figure 5-84 Equivalent circuit of a general noisy nonlinear network.

circuit. The spectral density of the output noise power and, consequently, the PM noise computed by the conversion analysis are proportional to the available power of the noise sources.

- In the presence of both thermal and flicker noise sources, PM noise increases as ω^{-1} for $\omega \to 0$ and tends to a finite limit for $\omega \to \infty$.
- Frequency conversion analysis correctly predicts the far-carrier noise behavior of an oscillator and, in particular, the oscillator noise floor; it does not provide results consistent with the physical observations at low deviations from the carrier.

This inconsistency can be removed by adding the modulation noise analysis. In order to determine the far-away noise using the autonomous circuit perturbation analysis, the following applies.

The circuit supports a large-signal time-periodic autonomous regime. The circuit is perturbed by a set of small sources located at the carrier harmonics and at the sidebands at a deviation ω from carrier harmonics. The perturbation of the circuit state (δX_B, δX_H) is given by the uncoupled sets of equations:

$$\frac{\partial E_B}{\partial E_B}\,\delta X_B = J_B(\omega) \tag{5-127}$$

$$\frac{\partial E_H}{\partial E_H}\,\delta X_H = J_H(\omega) \tag{5-128}$$

where E_B, E_H = vectors of HB errors
X_B, X_H = vectors of state-variable (SV) harmonics (since the circuit is autonomous, one of the entries X is replaced by the fundamental frequency ω_0)
J_B, J_H = vectors of forcing terms

The subscripts *B* and *H* denote sidebands and carrier harmonics, respectively.

For a spot noise analysis at a frequency ω, the noise sources can be interpreted in either of two ways:

- Pseudosinusoids with random amplitude and phase located at the sidebands. This noise generation mechanism is described by Eq. (5-127), which is essentially a frequency conversion equation relating the sideband harmonics of the state variables and of the noise sources. This description is exactly equivalent to the one provided by the frequency conversion approach. This mechanism is referred to as *conversion noise* [19–21].
- Sinusoids located at the carrier harmonics and randomly phase and amplitude modulated by pseudosinusoidal noise at frequency ω. This noise generation mechanism is described by Eq. (5-128), which describes noise-induced jitter of the circuit-state, represented by the vector δX_H. The modulated perturbing signals are represented by replacing the entries of J_H with the complex modulation laws. This mechanism is referred to as *modulation noise.* One of the entries of δX_H is $\delta\omega_0$, where $\delta\omega_0(\omega)$ is the phasor of the pseudosinusoidal components of the fundamental frequency fluctuations in a 1-Hz band at frequency ω. Equation (5-128) provides a frequency jitter with a mean square value proportional to the available noise power. In the presence of both thermal and flicker noise, PM noise increases as ω^{-3} for $\omega \to 0$ and tends to 0 for $\omega \to \infty$. Modulation noise analysis correctly describes the noise behavior of an oscillator at low deviations from the carrier and does not provide results consistent with physical observations at high deviations from the carrier.

The combination of both phenomena explains the noise in the oscillator shown in Figure 5-85, where the near-carrier noise dominates below ω_X and far-carrier noise dominates above ω_X. Figure 5-86 (itemized form) shows the noise sources as they are applied at the IF. We have arbitrarily defined the low oscillator output as IF. This applies to the conversion matrix calculation.

Figure 5-87 shows the contributions that have to be taken into consideration for calculation of the noise at the output. The accuracy of the calculation of the phase noise depends highly on the quality of the parameter extraction for the nonlinear device; in particular, high-frequency phenomena must be modeled properly. In addition, the flicker noise contribution is essential. This is also valid for mixer noise analysis.

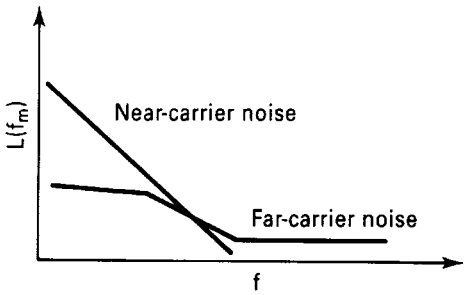

Figure 5-85 Oscillator noise components.

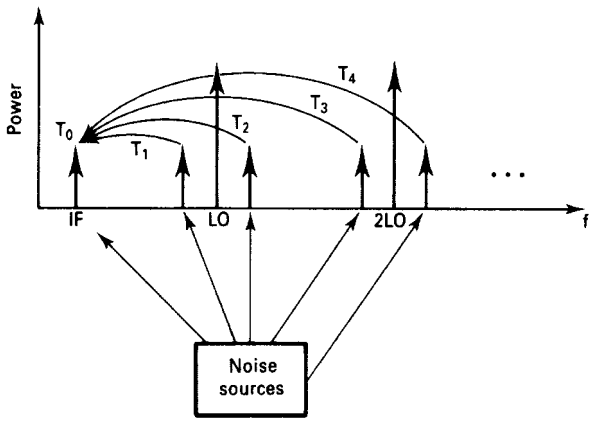

Figure 5-86 Noise sources where the noise at each sideband contributes to the output noise at the IF through frequency conversion.

Figure 5-88 shows the measured phase noise at 10 kHz of the carrier of an 800-MHz oscillator and the simulated result. The good agreement between measured and predicted data is worth noticing. At currents above 5 mA, the simulation becomes inaccurate as breakdown effects occur that were not part of the simulation.

Conversion Noise Analysis. The actual mathematics used to calculate the noise result (Ansoft Serenade 8.*x*) are as follows.

kth Harmonic PM Noise

$$\langle |\delta\Phi_k(\omega)|^2 \rangle = \frac{N_k(\omega) - N_{-k}(\omega) - 2\,\mathrm{Re}[C_k(\omega)]}{R|I_k^{SS}|^2} \tag{5-129}$$

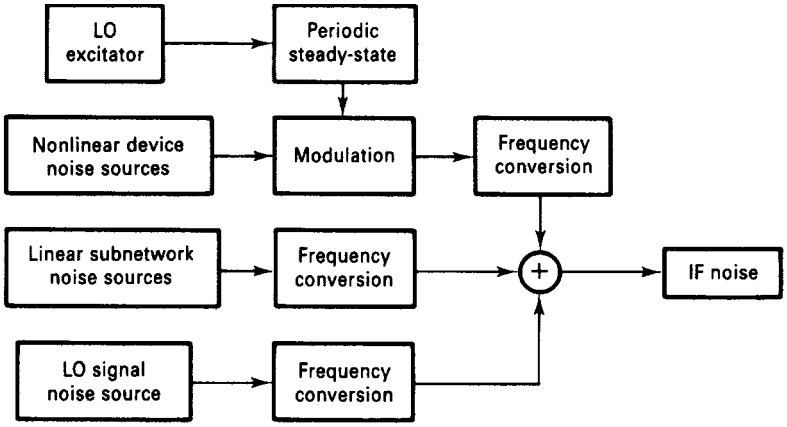

Figure 5-87 Noise mechanisms.

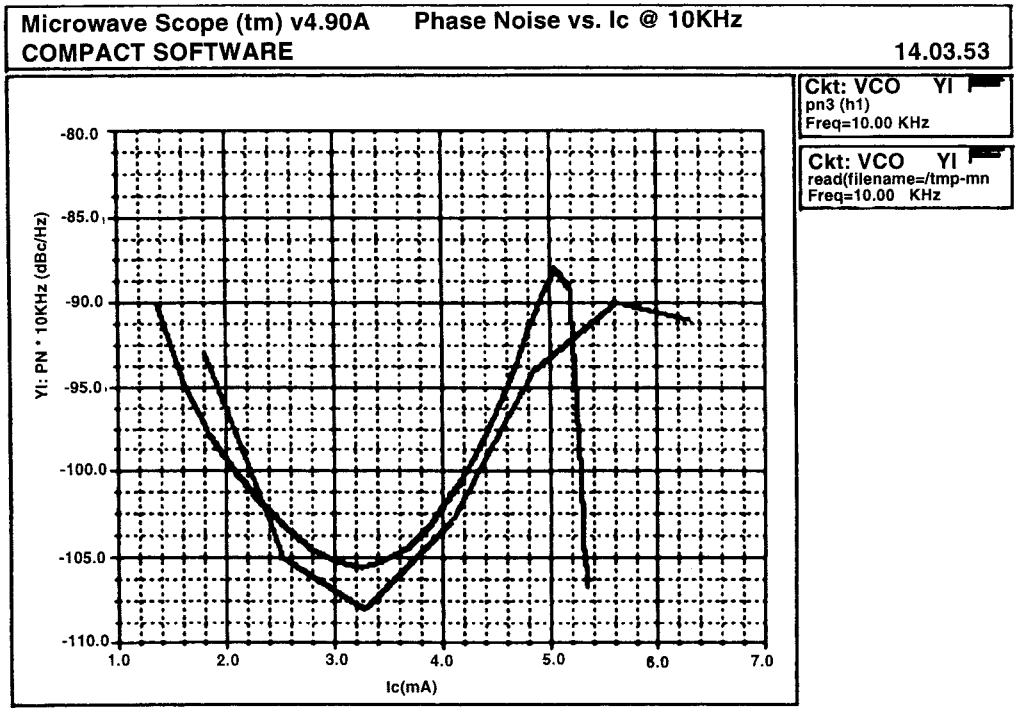

Figure 5-88 Bias-dependent measured and predicted phase noise at 10 kHz off the carrier of an 800-MHz oscillator.

kth Harmonic AM Noise

$$\langle |\delta A_k(\omega)|^2 \rangle = 2\,\frac{N_k(\omega) - N_{-k}(\omega) + 2\,\mathrm{Re}[C_k(\omega)]}{R|I_k^{SS}|^2} \tag{5-130}$$

kth Harmonic PM–AM Correlation Coefficient

$$C_k^{\mathrm{PMAM}}(\omega) = \langle \delta\Phi_k(\omega)\delta A_k(\omega)^* \rangle = -\sqrt{2}\,\frac{2\,\mathrm{Im}[C_k(\omega)] + j[N_k(\omega) - N_{-k}(\omega)]}{R|I_k^{SS|^2}} \tag{5-131}$$

where

$N_k(\omega)$, $N_{-k}(\omega)$ = noise power spectral densities at the upper and lower sidebands of the kth harmonic
$C_k(\omega)$ = normalized correlation coefficient of the upper and lower sidebands of the kth carrier harmonic
R = load resistance
I_k^{SS} = kth harmonic of the steady-state current through the load

Modulation Noise Analysis

kth Harmonic PM Noise

$$\langle |\delta\Phi_k(\omega)|^2 \rangle = \frac{k^2}{\omega^2}\,\mathrm{T}_F\,\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_F^t \tag{5-132}$$

kth Harmonic AM Noise

$$\langle |\delta A_k(\omega)|^2 \rangle = \frac{2}{|I_k^{SS}|^2}\,\mathrm{T}_{Ak}\,\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_{Ak}^t \tag{5-133}$$

kth Harmonic PM–AM Correlation Coefficient

$$C_k^{\mathrm{PMAM}}(\omega) = \langle \delta\Phi_k(\omega)\delta A_k(\omega)^* \rangle = \frac{k\sqrt{2}}{j\omega|I_K^{SS}|^2}\,\mathrm{T}_F\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_{Ak}^t \tag{5-134}$$

where $\mathrm{J}_H(\omega)$ = vector of Norton equivalent of the noise sources
T_F = frequency transfer matrix
I_k^{SS} = kth harmonic of the steady-state current through the load

Experimental Variations. We will look at two examples where we compare predicted and measured data. Figure 5-89 shows the abbreviated circuit of a 10-MHz crystal oscillator. It uses a high-precision, high-Q crystal made by companies such as Bliley. Oscillators like this are intended for use as frequency and low-phase-noise standards. In this case, the circuit under consideration is part of the HP3048 phase-noise measurement system.

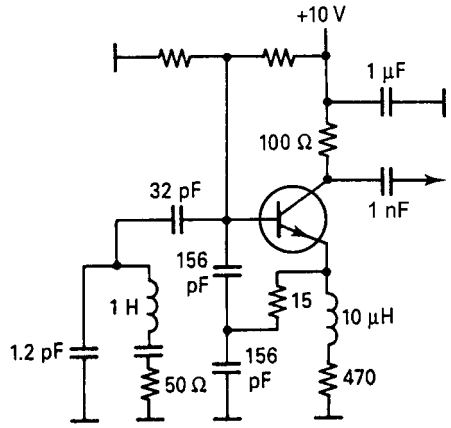

Figure 5-89 Abbreviated circuit of a 10-MHz crystal oscillator.

Figure 5-90 shows the measured phase noise of this HP frequency standard, and Figure 5-91 shows the phase noise predicted using the mathematical approach outlined above.

In cooperation with Motorola, we also analyzed an 800-MHz VCO. In this case, we also did the parameter extraction for the Motorola transistor. Figure 5-92 shows the circuit, a Colpitts oscillator that uses RF feedback in the form of a 15-Ω resistor and a capacitive

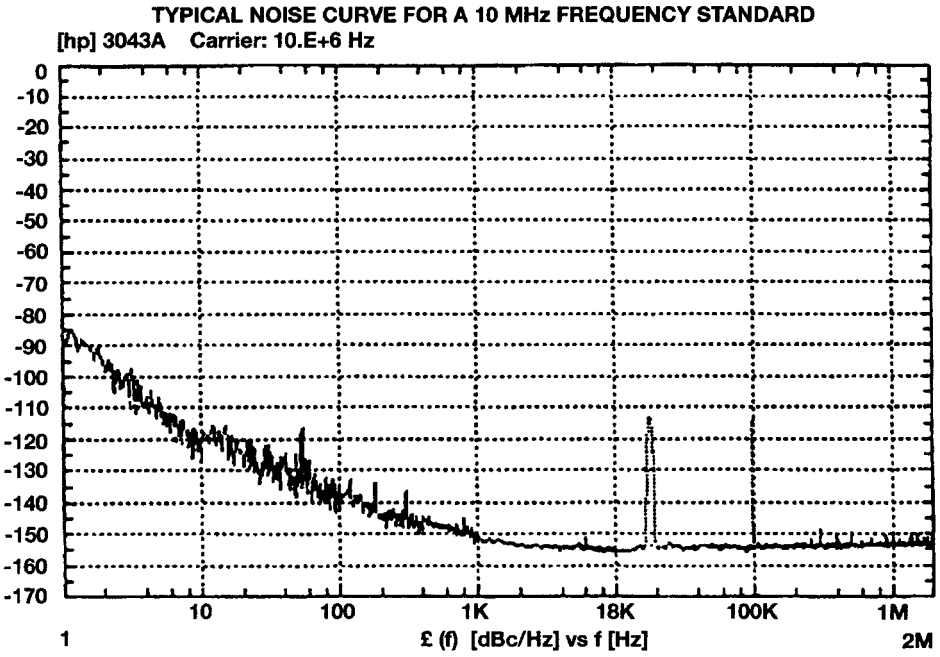

Figure 5-90 Measured phase noise for this frequency standard by HP.

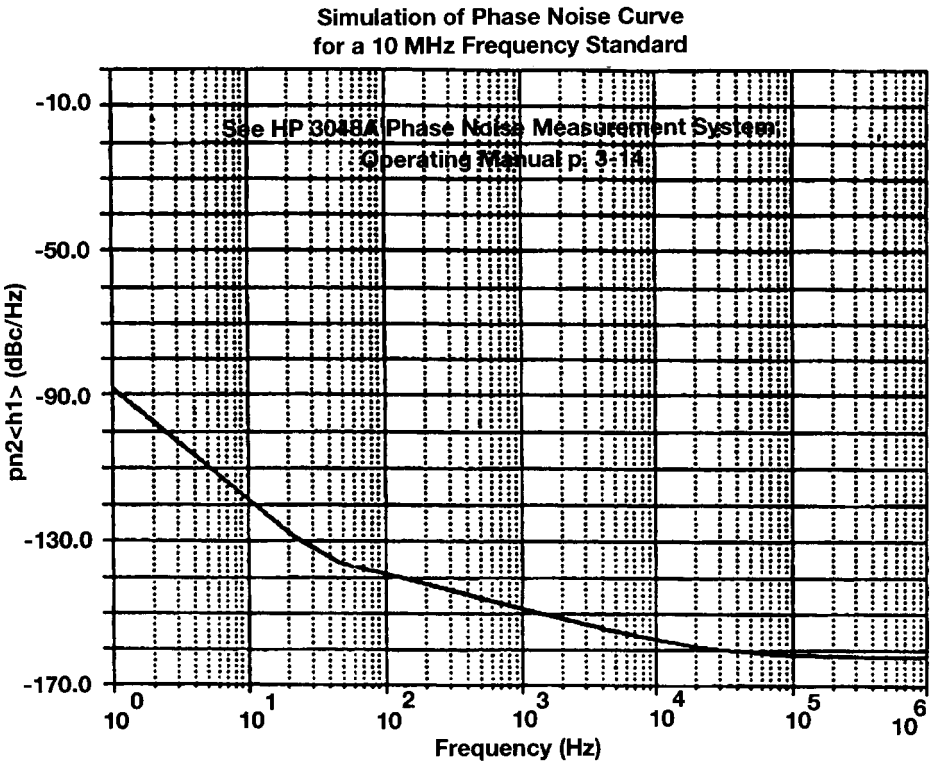

Figure 5-91 Simulated phase noise of the oscillator shown in Figure 5-89.

voltage divider consisting of 1 pF between the BJT's base and the feedback resistor, and 1 pF between the feedback resistor and common. Also, the tuned circuit is loosely coupled to this part of the transistor circuit. Figure 5-93 shows a comparison between predicted and measured phase noise for this oscillator. Figures 5-94, 5-95, and 5-96 show the oscillator's predicted output waveform, spectrum, and dc I–V and ac load line responses, respectively.

Phase Noise Optimization. By allowing the simulator's optimizer to vary the oscillator's feedback and dc operating point, phase noise can be improved. The values that were allowed to vary were the values of the capacitors in the feedback voltage divider, the value of a negative-feedback resistor (starting value, 15 Ω) that reduces AM–PM conversion, and the emitter resistor, which changes the transistor's dc bias and therefore affects its bias-dependent flicker noise. Figure 5-97 shows the improvement of the 800-MHz VCO as previously shown. While the close-in phase noise can be improved drastically by approximately 32 dB, the far-out noise at 20 MHz and beyond is deteriorated. This is due to the resistive feedback, which reduces AM-to-PM conversion [22–24].

In testing an oscillator's resistance to frequency pushing (frequency shift with supply-voltage changes), variations in phase noise can be observed. Phase noise is also bias dependent,

and this fact can be used for phase-noise optimization. Figure 5-98 shows the phase noise of an oscillator as its supply voltage is varied.

Summary. This section has demonstrated the power of harmonic-balance simulation in the design of low-phase-noise oscillators. The simulator can be used to accurately predict close-in and far-out phase noise based on the contribution of the transistor, the loaded Q of the resonator, and, in the case of a VCO, the contribution of the tuning diode.

This is the first time that a bias-dependent noise model for both FETs and bipolar transistors has been developed and used for this type of application, in which optimization is allowed to vary circuit components and the bias point for best performance.

Practical examples ranging from a 10-MHz crystal oscillator to a 1-GHz CR oscillator have been supplied. The theoretical background for the nonlinear oscillator and its validation have been presented.

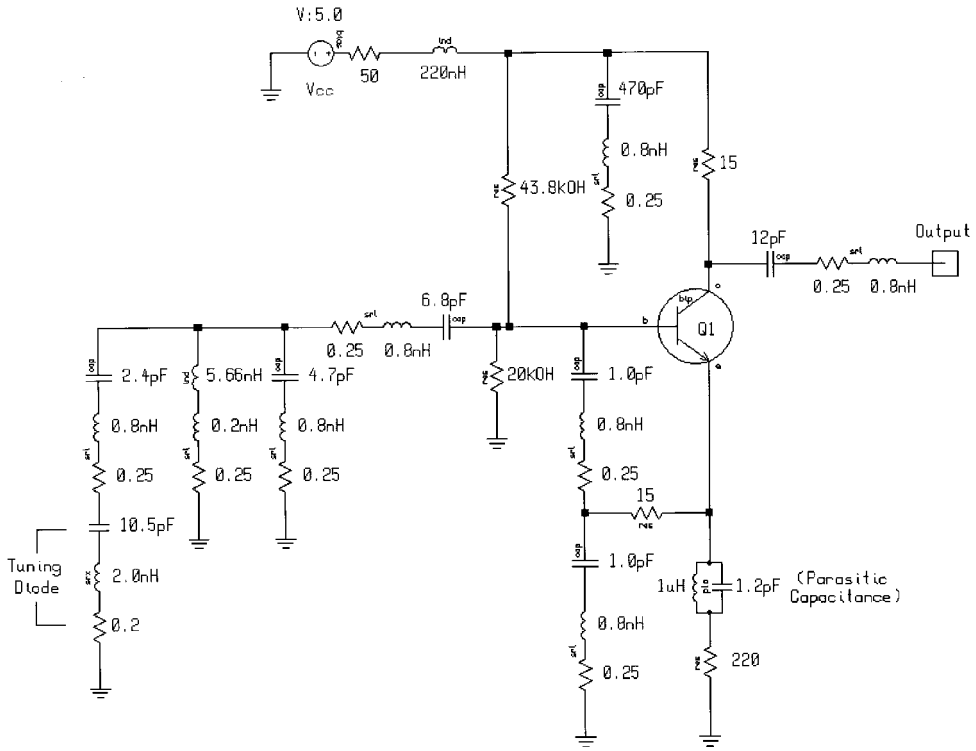

Figure 5-92 Colpitts oscillator that uses RF negative feedback between the emitter and capacitive voltage divider. To be realistic, we used actual components rather than ideal ones. The suppliers for the capacitors and inductors provide some typical values for the parasitics. The major changes are 0.8 nH and 0.25 Ω in series with the capacitors. The same thing applies for the main inductance, which has a parasitic connection inductance of 0.2 nH in series with a 0.25-Ω resistance. These types of parasitics are valid for a fairly large range of components assembled in surface-mount applications. Most engineers model the circuit only by assuming lossy devices, not adding these important parasitics. One of the side-effects we have noticed is that the output power is more realistic and, needless to say, the simulated phase noise agrees quite well with measured data. This circuit can also serve as an example for modeling amplifiers and mixers using surface-mount components.

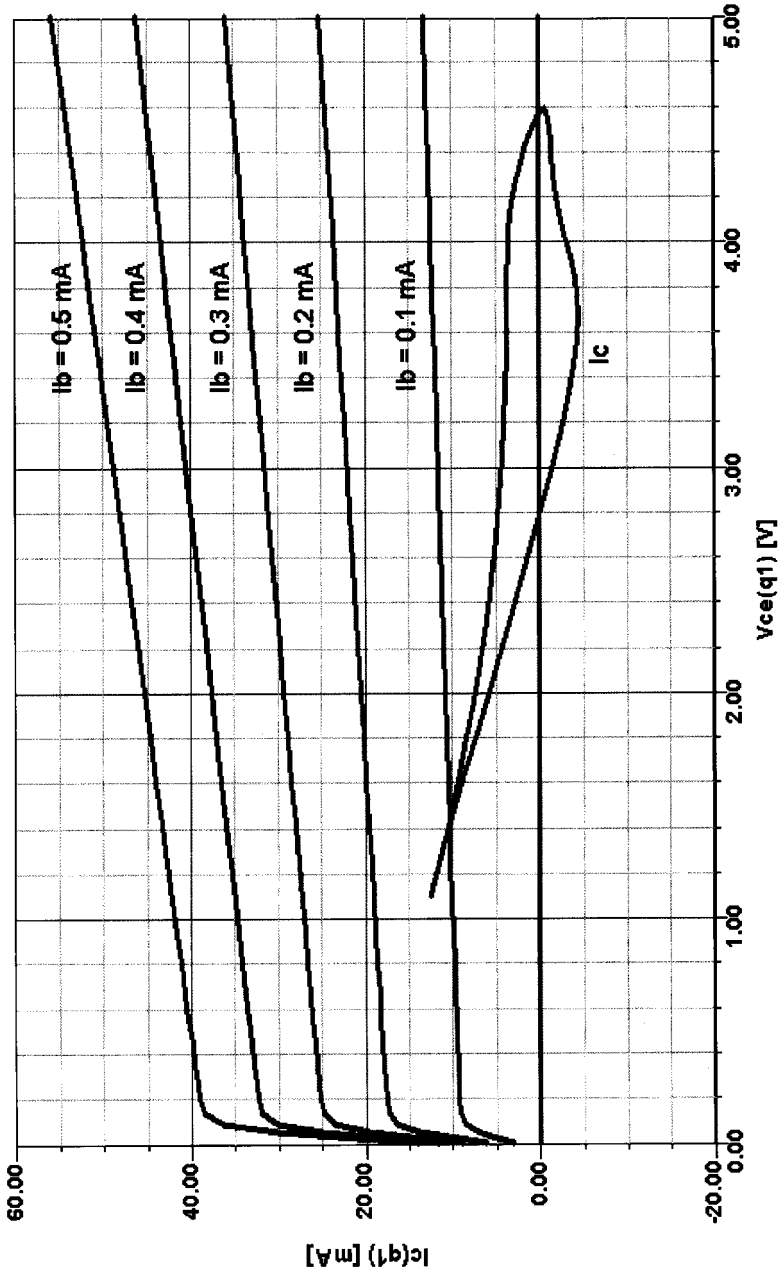

Figure 5-96 The ac load line and dc *I–V* curves for the transistor in the oscillator shown in Figure 5-92.

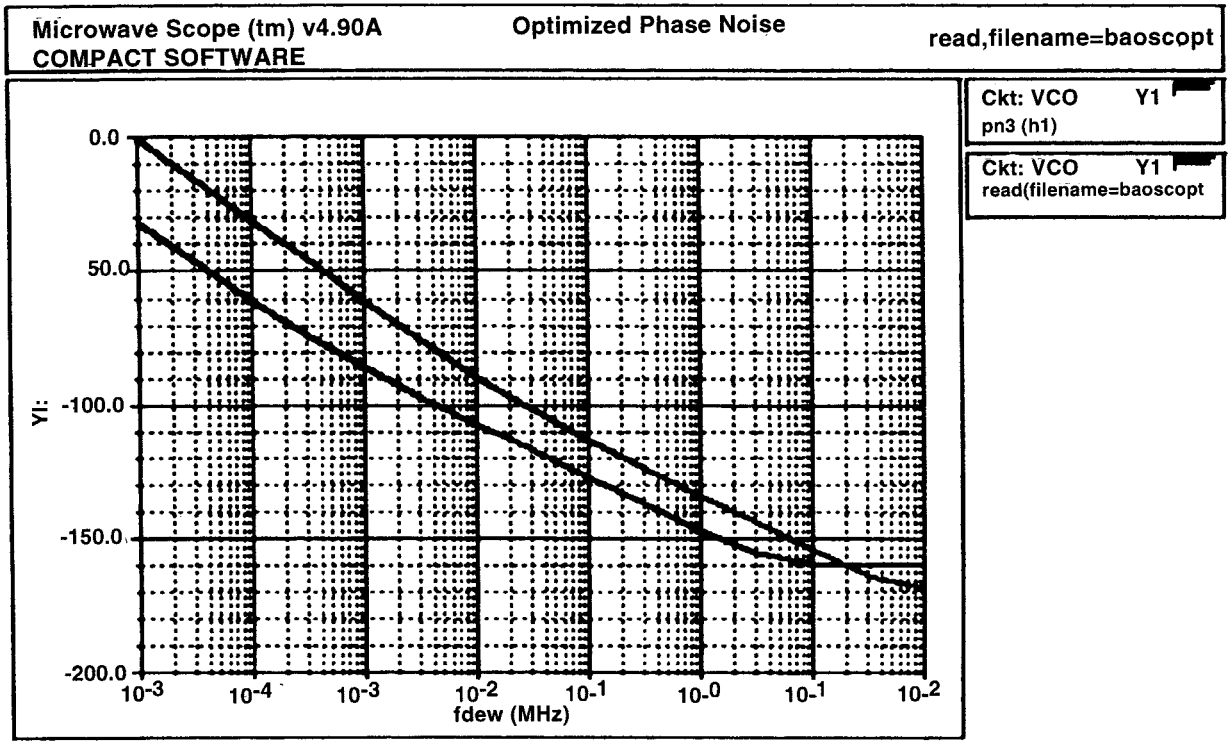

Figure 5-97 Phase noise of the 800-MHz VCO before and after optimization.

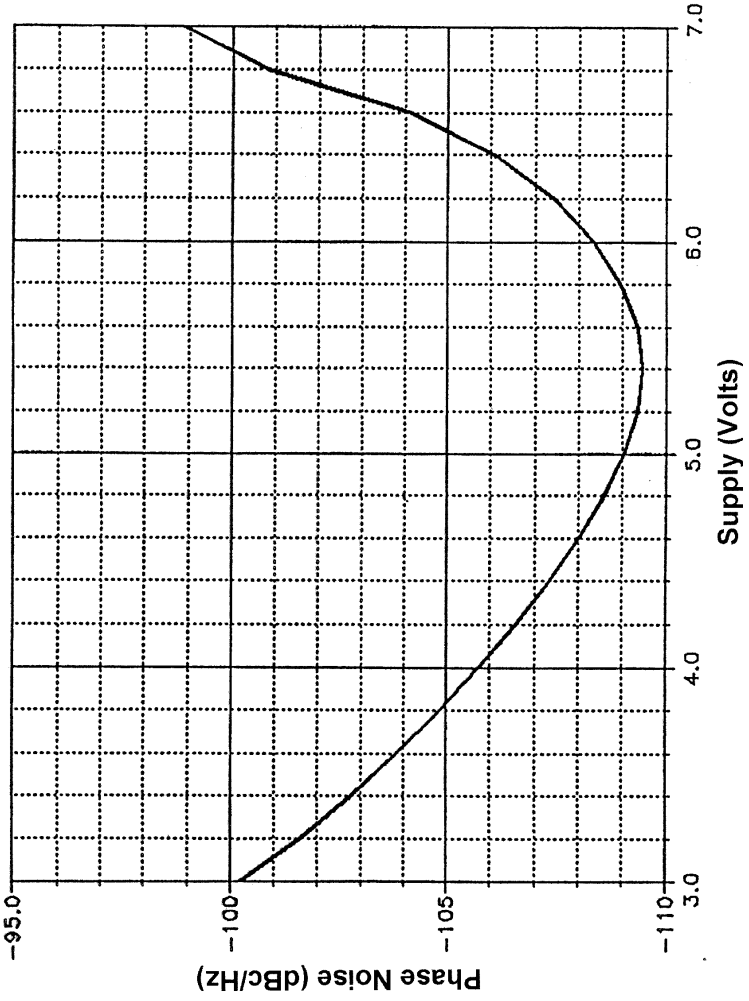

Figure 5-98 Calculated phase noise as a function of the supply voltage for a BJT oscillator. The graph shows a distinct minimum for a particular bias, which could be translated into a collector current change. Such phase-noise minimization could also be accomplished by changing just the voltage applied to the bias portion of the oscillator.

Acknowledgment. This research work for nonlinear operation in oscillators, partly sponsored by the U.S. Department of Defense MIMIC program, was performed in cooperation with Professor Vittorio Rizzoli's group of the Department of Electrical Engineering, Information and Systems Engineering at the University of Bologna, Italy, and the Motorola Portable Products Division, Florida, as well as the engineering team of Ansoft Corporation in New Jersey.

5-7 OSCILLATORS IN PRACTICE

5-7-1 Oscillator Specifications

Although we have tended to emphasize phase noise as a critical indicator of oscillator quality, phase noise is only one of a number of oscillator performance criteria that must be considered in wireless system design. In addition to phase noise, the following characteristics are used by commercial companies to describe oscillator performance:

Frequency Pushing. Frequency pushing characterizes the degree to which an oscillator's frequency is affected by its supply voltage. A sudden current surge caused by activating a transceiver's RF power amplifier may produce a spike on the VCO's dc power supply and a consequent frequency jump. Like tuning sensitivity (below), pushing is specified in frequency/voltage form and is tested by varying the VCO's dc supply voltage (typically ± 1 V) with its tuning voltage held constant.

Harmonic Output Power. The harmonic content is measured relative to the output power. Typical values are 20 dB or more suppression relative to the fundamental. This suppression can be improved by additional filtering.

Output Power. The output power of the oscillator, typically expressed in dBm, is measured into a 50-Ω load. The output power is always combined with a specification for flatness or variation. A typical specification would be 0 dBm ± 1 dB.

Output Power as a Function of Temperature. All active circuits vary in performance as a function of temperature. An oscillator's output power over a temperature range should vary less than a specified value, such as 1 dB.

Post-tuning Drift. After a voltage step is applied to the tuning diode input, the oscillator frequency may continue to change until it settles to a final value. This post-tuning drift is one of the parameters that limits the bandwidth of the VCO input.

Power Consumption. This characteristic conveys the dc power, usually specified in milliwatts and sometimes qualified by operating voltage, required by the oscillator.

Sensitivity to Load Changes. To keep costs down, many wireless applications use a VCO alone, without the buffering action of a high reverse-isolation amplifier stage. In such applications, *frequency pulling*, the change of frequency resulting from partially reactive loads, is an important oscillator characteristic. Pulling is commonly specified in terms of the frequency shift that occurs when the oscillator is connected to a load that exhibits a non-unity VSWR (such as 1.75, usually referenced to 50 Ω), compared to the frequency that results with a unity VSWR load (usually 50 Ω). Frequency pulling must be minimized, especially in cases where power stages are close to the VCO unit

and short pulses may affect the output frequency. Such feedback may make phase locking impossible.

Spurious Outputs. A VCO's spurious output specification, expressed in decibels, enumerates the strength of unwanted and nonharmonically related components relative to the oscillator fundamental. Because a stable, properly designed oscillator is inherently clean, such *spurs* are typically introduced only by external sources in the form of radiated or conducted interference. See *harmonic output power.*

Temperature Drift. Although the synthesizer is responsible for locking and maintaining the oscillator's frequency, the VCO's frequency change as a function of temperature is a critical parameter and must be specified. Its value varies between 10 kHz/°C to several hundred kHz/°C depending on the center frequency and tuning range.

Tuning Characteristic. This specification shows the relationship, depicted as a graph, between a VCO's operating frequency and the tuning voltage applied. Ideally, the correspondence between operating frequency and tuning voltage is linear. See *tuning linearity.*

Tuning Linearity. For stable synthesizers, a constant deviation of frequency versus tuning voltage is desirable. It is also important to make sure that there are no breaks in the tuning range—for example, that the oscillator does not stop operating with a tuning voltage of 0 V. See *tuning characteristic.*

Tuning Sensitivity, Tuning Performance. This characteristic, typically expressed in megahertz per volt (MHz/V), enumerates how much a VCO's frequency changes per unit of tuning-voltage change.

Tuning Speed. This characteristic is defined as the time necessary for the VCO to reach 90% of its final frequency on the application of a tuning-voltage step. Tuning speed depends on the internal components between the input pin and tuning diode—including, among other things, the capacitance present at the input port. The input port's parasitic elements determine the VCO's maximum possible modulation bandwidth.

5-7-2 More Practical Circuits

Because of the need for integration, we will present three IC oscillators of increasing complexity. The circuit in Figure 5-99 is found in early Siemens ICs. Figure 5-100 shows its phase-noise performance.

Figure 5-101 shows the basic push–pull oscillator topology underlying the circuit in Figure 5-99. The omission of the current source and active bias components improves the simpler circuit's phase-noise performance over that of the circuit shown in Figure 5-99. Figure 5-102 compares the phase noise of this basic circuit to the integrated version in Figure 5-99.

Figure 5-103 is for those who speculate on the possibility of replacing the BJTs in Figure 5-101 with LDMOS FETs or JFETs. Figure 5-104 compares its phase noise to that of the BJT case. The rule of thumb is that FETs do not have enough gain for high-Q oscillation in oscillators above 400 MHz, and bipolar transistors are a better choice. Because of their higher flicker noise contribution, GaAsFETs should be considered only at frequencies above 4 or 5 GHz.

Figure 5-105 shows a circuit based on two differential amplifiers and frequently found in Gilbert cell IC applications. Figure 5-106 shows its phase-noise performance.

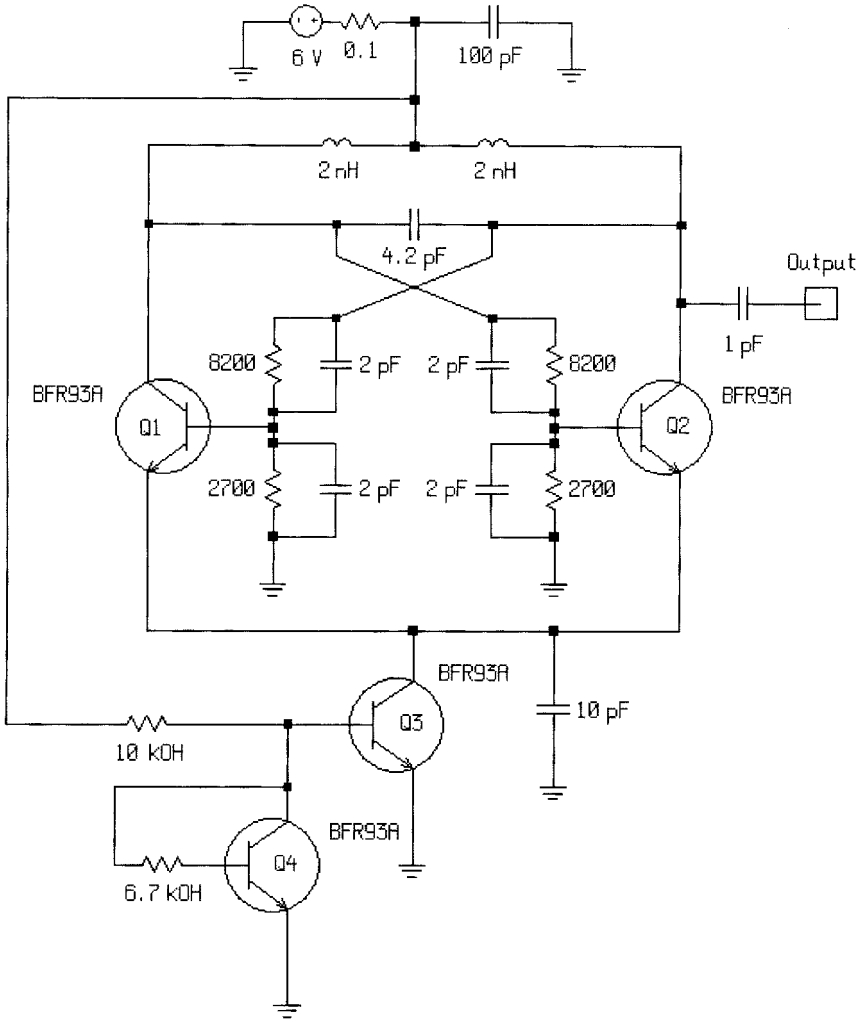

Figure 5-99 Schematic of the Siemens IC oscillator.

Figure 5-107 is a validation circuit that demonstrates a comparison of measured phase-noise performance versus its prediction by circuit simulation software. The circuit is based on the core of Motorola's MC12148 ECL oscillator IC, the topology of which is derived from the superseded MC1648. Motorola specifies the MC12148's typical phase-noise performance as –90 dBc/Hz at an offset of 25 kHz. The close agreement between the measured and simulated results highlights the value of state-of-the-art CAD tools in wireless oscillator design (Figure 5-108).

Figure 5-108 presents the results of *two* simulations: one with ideal L and C components, and another with realistic values specified for these reactances. In using a circuit

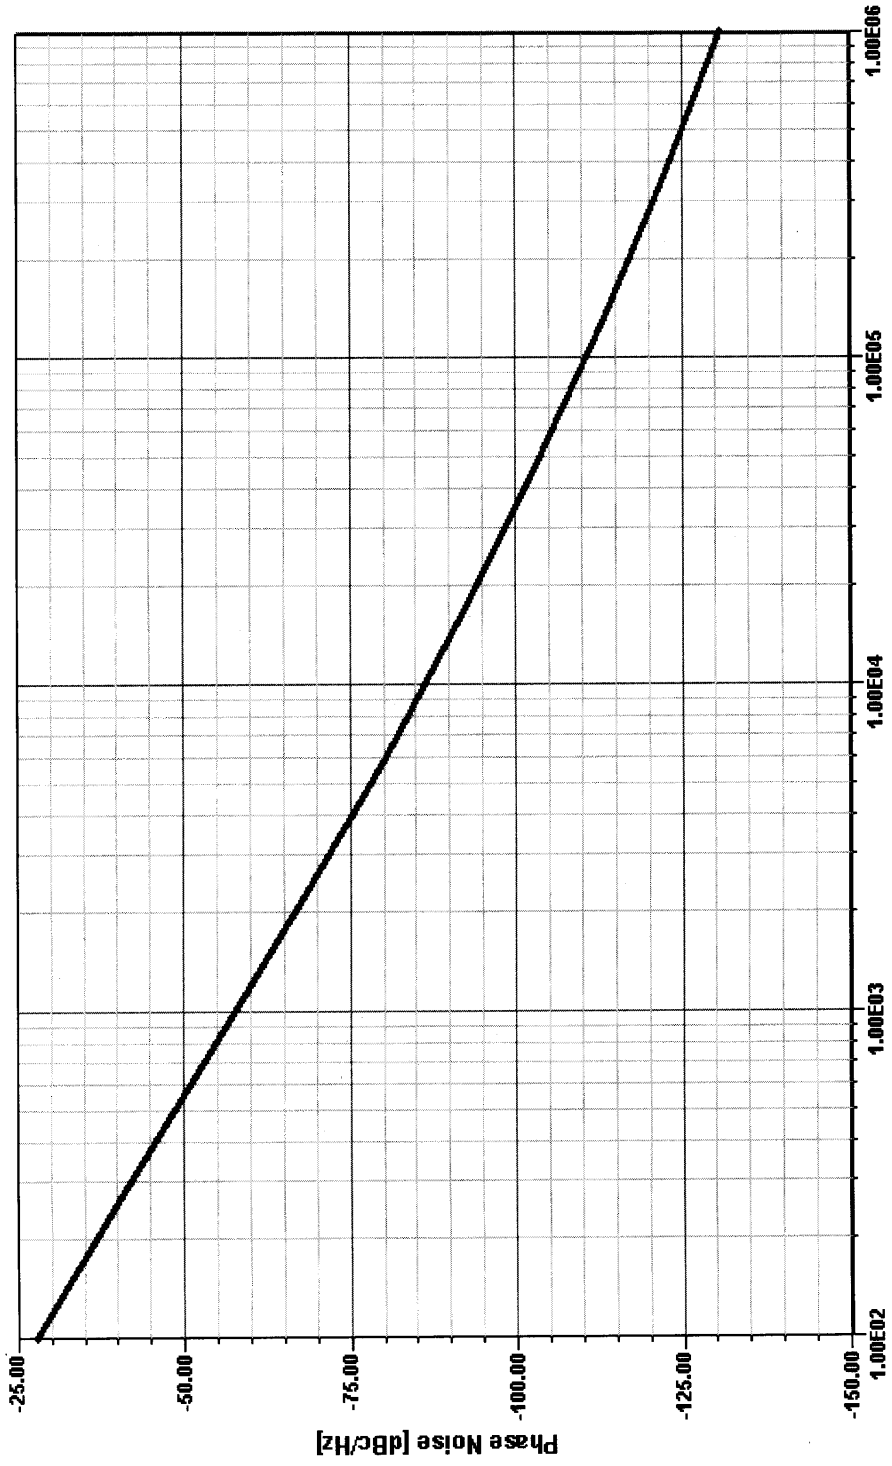

Figure 5-100 Phase noise of the Siemens IC oscillator. The frequency of oscillation is 1.051 GHz.

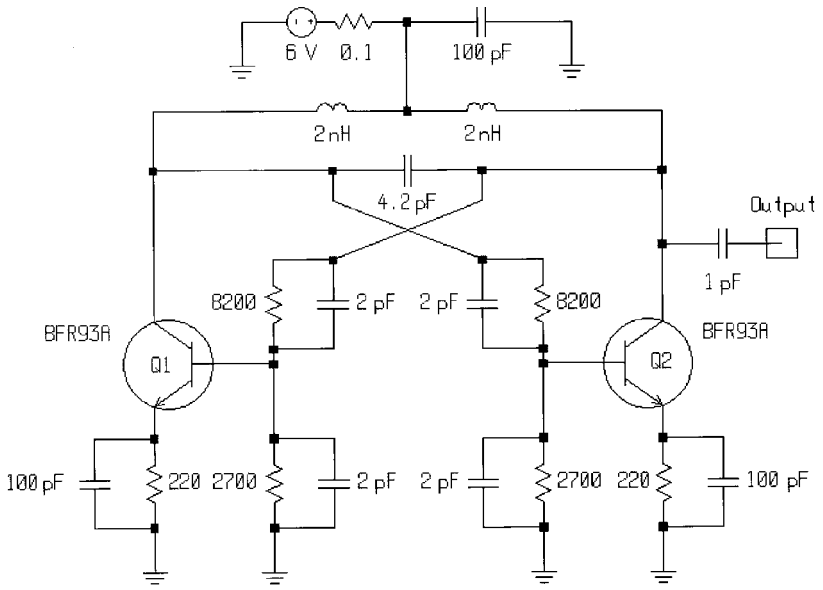

Figure 5-101 Basic push–pull oscillator underlying the circuit shown in Figure 5-99.

simulator to validate and compare oscillator topologies, it's important to start with ideal components because we are interested in comparing the inherent phase-noise performance of various circuits—particularly the role played by the nonlinear reactances in active devices. Because the Q values of practical components are so low in the microwave range (very generally, 200–300 for capacitors and 60–70 for inductors), the inherent merits of one topology, or one device, over another would be masked by loading effects if we conducted our investigations using nonideal reactances. Once initial evaluation is completed, realistic Q values should be specified for increased accuracy in phase-noise, output-power, and output-spectrum simulations.

Finally, as evidence of how moving from lumped to distributed techniques can improve oscillator performance at frequencies where *LC* tanks become problematic, Figure 5-109 compares, for a simulated BJT Colpitts oscillator operating at 2.3 GHz, the difference in phase-noise performance obtainable with a resonator consisting of an ideal 2-nH inductor and a $\frac{1}{4}\lambda$ transmission line (11 Ω, 90° long at 2.6 GHz, attenuation 0.1 dB/m) with the transistor biased by constant-current and constant-voltage sources.

Silicon/GaAs-Based Integrated VCOs and Possible Difficulties. Due to process variations, the center frequency of the VCO cannot be repeated without trimming. Trimming can be avoided by making the VCO gain large enough to compensate for tank circuit variations, but this degrades phase-noise performance and increases the VCO susceptibility to unwanted spurs. For example, a VCO with a gain of 10 MHz/V has a phase noise of –80 dBc/Hz at 10 kHz, while a VCO with a gain of 75 MHz/V has a phase noise of only –60 dBc/Hz at 10 kHz. All but the tank inductors are integrated.

Tank inductors are generally not integrated for reasons of size and Q. The area of a 1-nH inductor is approximately 42,000 mm^2, which is ~3.5% of a typical IC; the area of a 10-nH

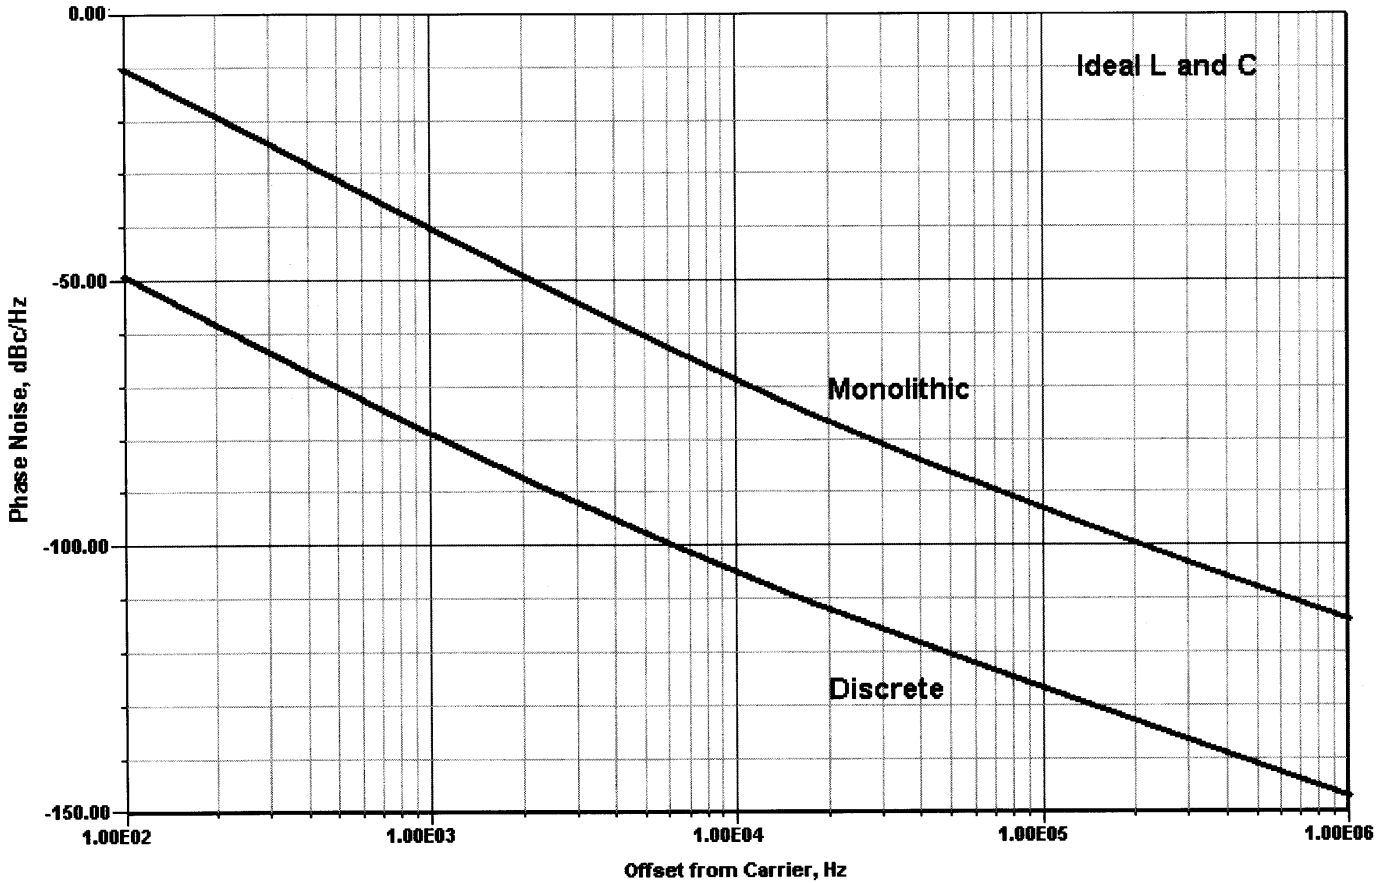

Figure 5-102 The basic version of the oscillator (Discrete curve) is a better phase-noise performer than the integrated version (Monolithic curve). The frequency of oscillation is 1.039 GHz.

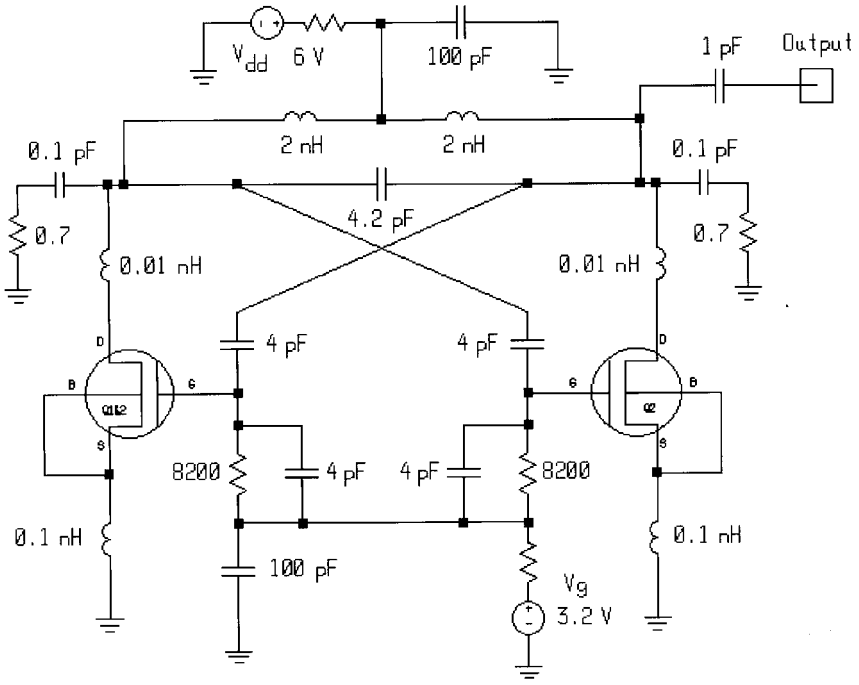

Figure 5-103 A 1.04-GHz push–pull oscillator using LDMOS FETs instead of BJTs. (LDMOS FET parameters courtesy of David K. Lovelace, Motorola, Inc.)

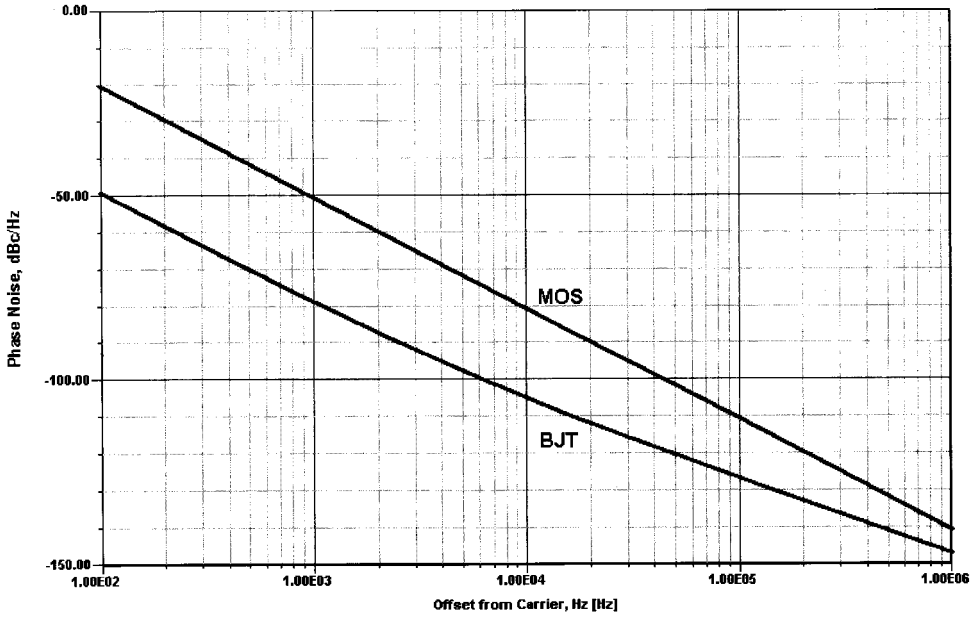

Figure 5-104 Phase-noise comparison of the BJT and MOSFET oscillators.

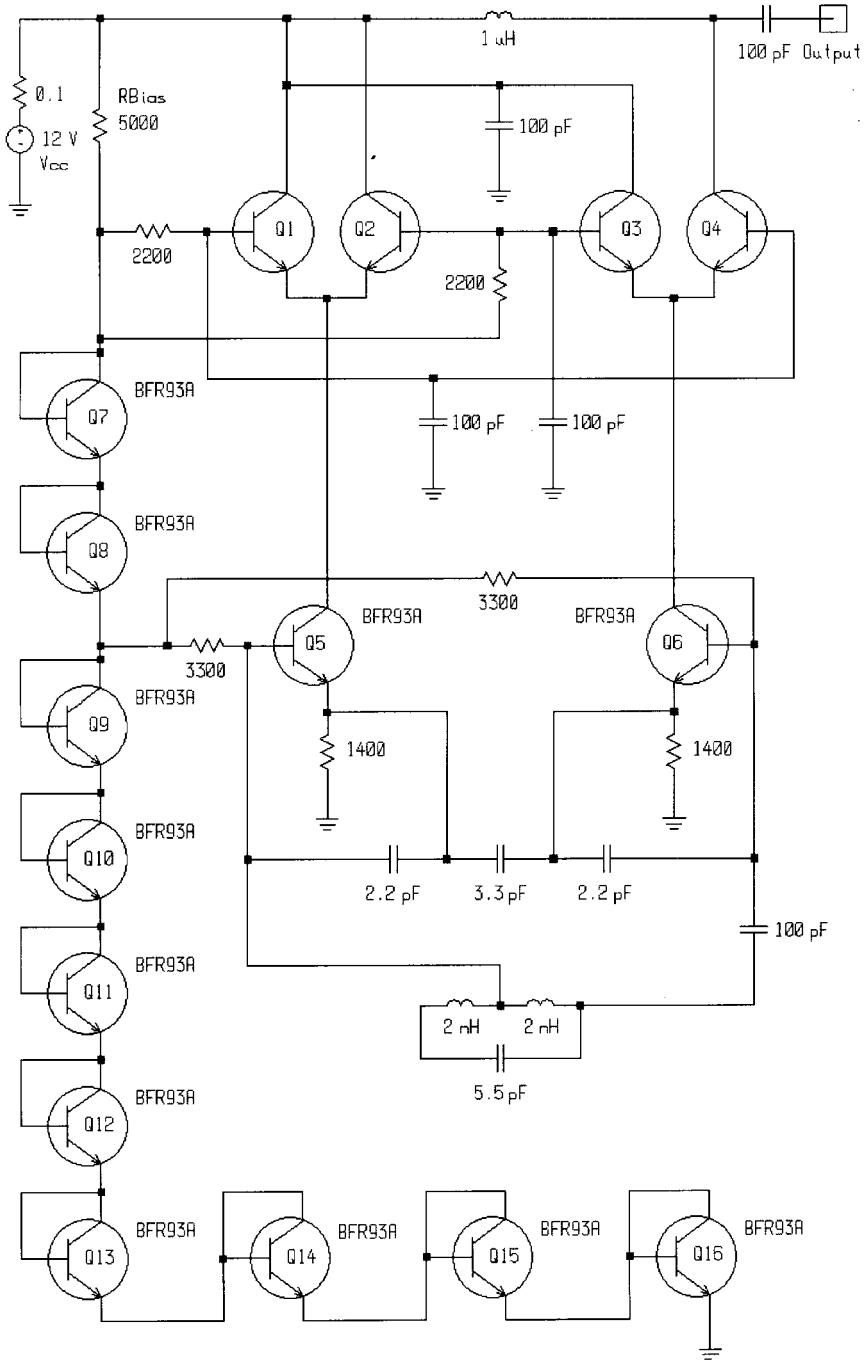

Figure 5-105 A 1.022-GHz IC oscillator based on two differential amplifiers. With an RF signal fed to the bases of Q_1–Q_4 and Q_2–Q_3 in push–pull, and IF output extracted from the collectors of Q_1–Q_3 and Q_2–Q_4 in push–pull, the circuit would act as a Gilbert cell converter. In the circuit shown, we have modified the differential amplifiers' collector circuitry to give single-ended output and avoid cancellation of the oscillator signal.

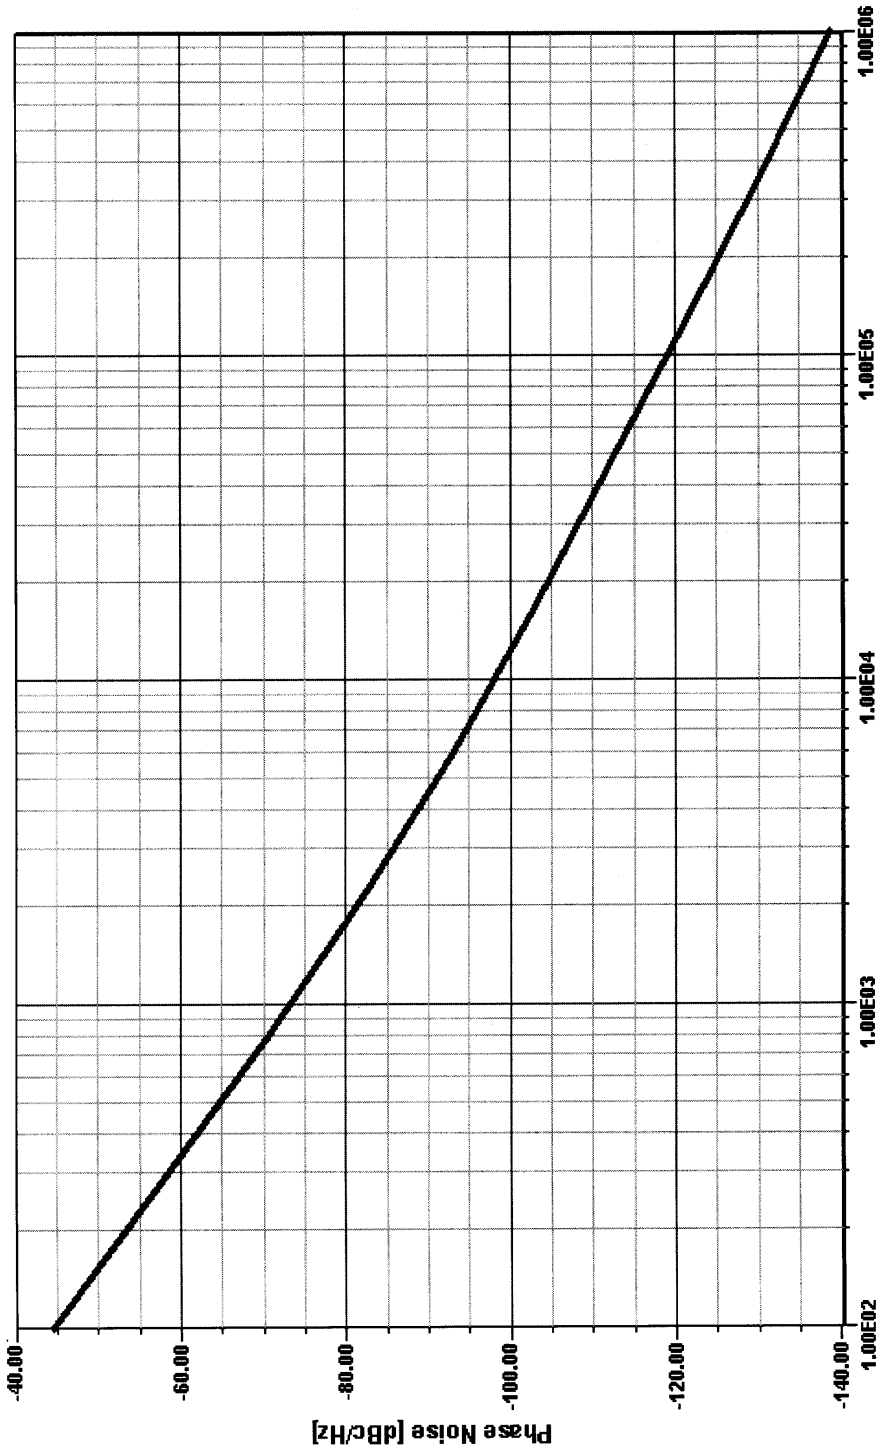

Figure 5-106 Phase noise of the two-differential-amplifier oscillator circuit.

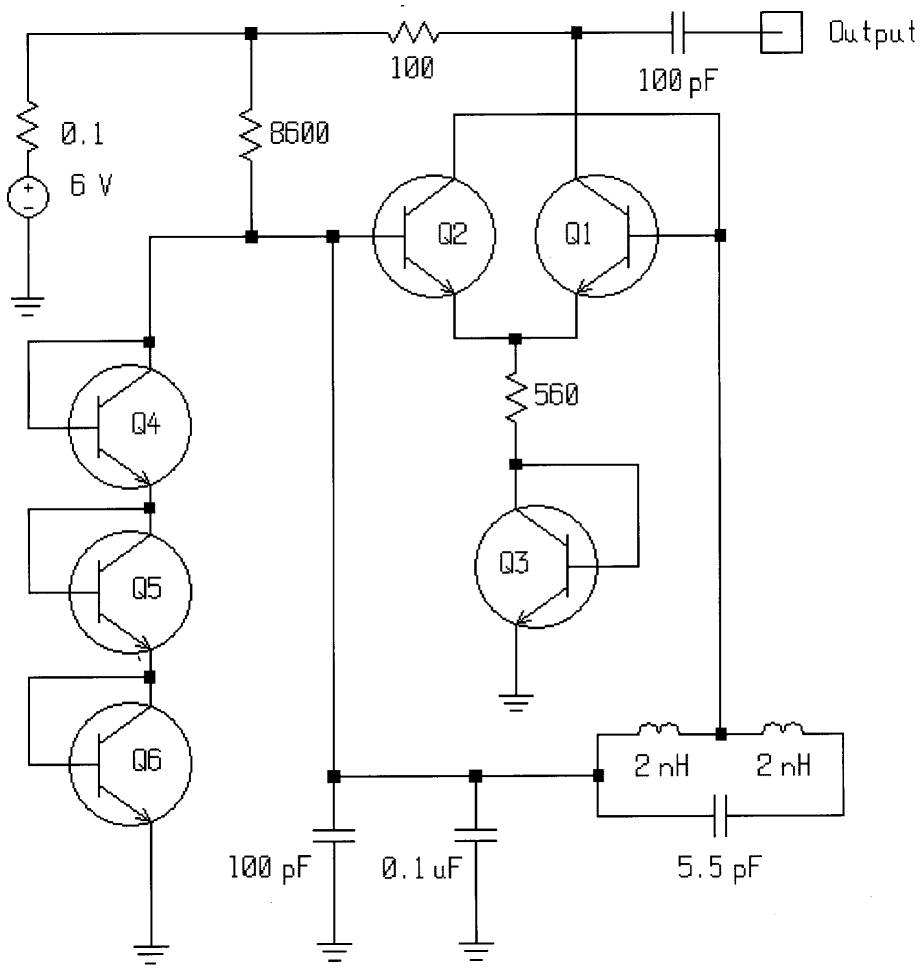

Figure 5-107 This validation circuit models the oscillator topology at the core of Motorola's MC12148 ECL oscillator IC.

inductor is approximately 167,000 mm^2, which is ~14% of a typical IC. For GaAs substrate, the resulting Q would be about 5; for silicon, as we already saw, 20 is already a very high value.

The customer can use PCB traces for the required inductance instead of external surface-mount inductors (cost: $0.03 each, most expensive passive component!). It must be pointed out that even for a nonintegrated approach, the higher VCO gain is noisier by definition. This was explained in Section 5-6-2. These problems are not unique to silicon; they apply to GaAs also. Figure 5-110 shows the size relationship of on-chip capacitors and inductors compared to the actual transistor; therefore, on-chip inductors should really be avoided for reasons of space and Q. Just imagine how the picture would change if the 1.1-nH inductor had to be 11 nH instead! It would dominate the IC area, and therefore the IC cost as well.

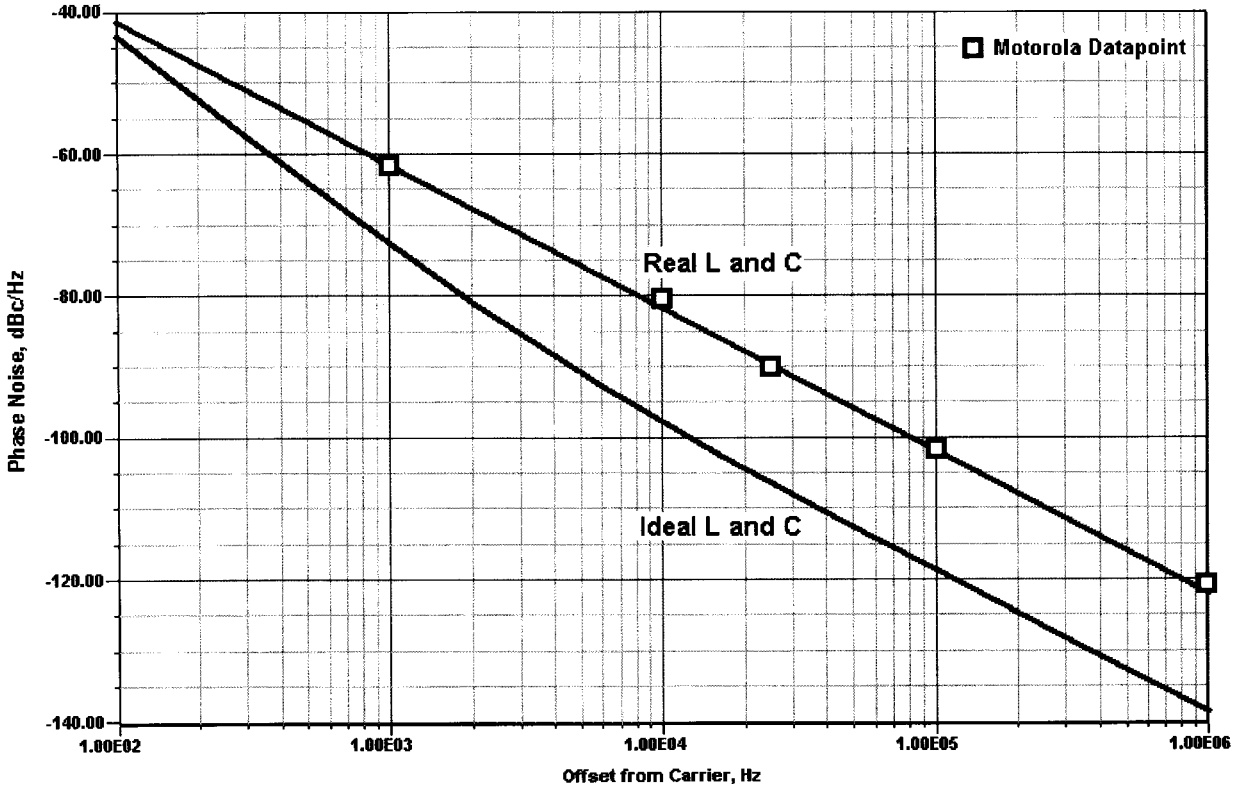

Figure 5-108 Comparison of measured versus simulated phase noise of the MC12148 differential oscillator. The simulation (1.016 GHz) predicts a phase noise of –89.54 dBc/Hz at an offset of 10 kHz (Real L and C curve), which agrees well with Motorola's specification of –89.54 dBc/Hz (typical at 930 MHz) at this offset. The Ideal L and C curve plots the simulation's phase-noise performance with ideal reactances, as opposed to the Real L and C curve, which graphs the results with realistic Q values specified for its reactive components ($Q = 250$ for its C values and $Q = 65$ for its L, all at 1 GHz).

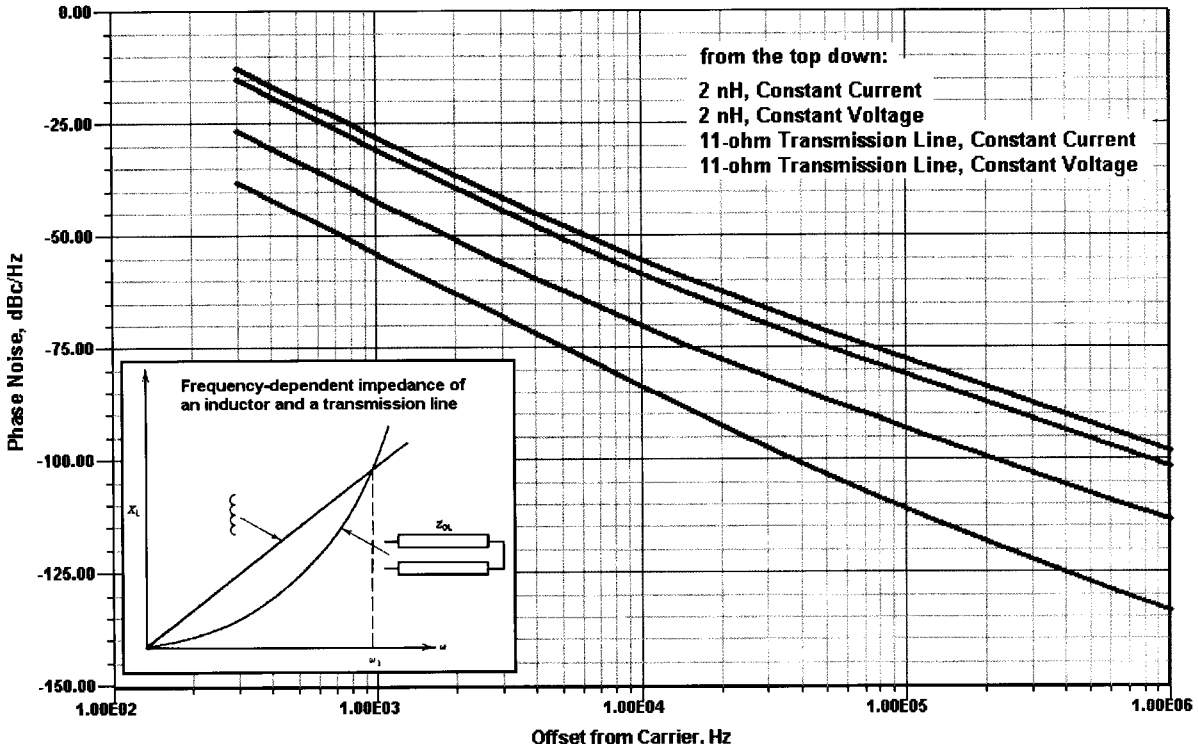

Figure 5-109 Phase-noise performance of a 2.3-GHz BJT oscillator with a resonator consisting of an inductor (2 nH) and a 1/4 λ transmission line (11 Ω, approximating the behavior of a dielectric resonator) with bias from a constant-current source and a low-impedance, resistive constant-voltage source.

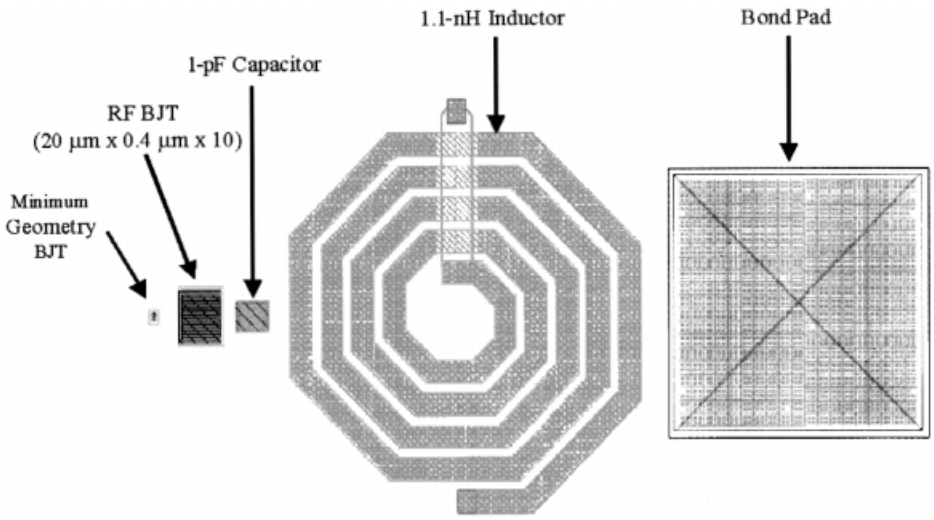

Figure 5-110 Same-scale comparison of space requirements for transistors, capacitors, inductors, and bond pads. For reference purposes, the coil diameter is 0.2 mm.

5-8 DESIGN OF RF OSCILLATORS USING CAD

5-8-1 Harmonic-Balance Simulation

HB analysis performs steady-state analysis of periodically excited circuits. The circuit to be analyzed is split into linear and nonlinear subcircuits. The linear subcircuit is calculated in the frequency domain. Features of this aspect of the HB process include:

- Use of distributed models in the spectral domain
- Matrix formulation that can enable reduction of internal nodes
- Major speed advantage
- Straightforward intermodulation and mixer analysis

The nonlinear subcircuit is calculated in the time domain. Features of this aspect of the HB process include:

- Nonlinear models derived directly from device physics
- Intuitive, easy, and logical circuit representation

Figure 5-111 diagrams this approach for a MESFET amplifier. Figure 5-112 charts a general-purpose nonlinear design algorithm that includes optimization. Modern analysis tools that must provide accurate phase-noise calculation should be based on the principle of harmonic balance. Figure 5-113 shows a BJT microwave oscillator entered into the schematic-capture module of a commercially available HB simulator (Ansoft Serenade 8.0); Figure 5-114 shows this oscillator's simulated phase noise. By the way, HB analysis can also handle mixers.

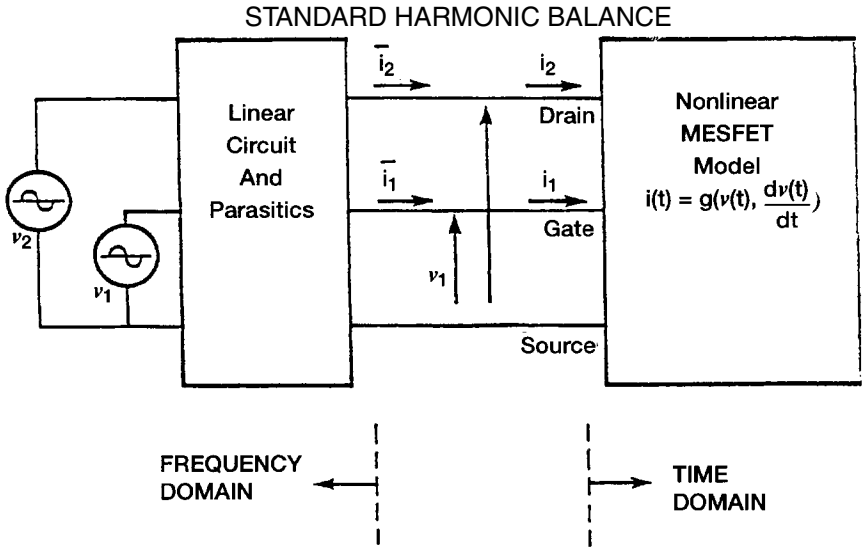

Figure 5-111 MESFET circuit partitioned into linear and nonlinear subcircuits for harmonic-balance analysis. Applied gate and drain voltages, and relevant terminal voltages and currents, are indicated.

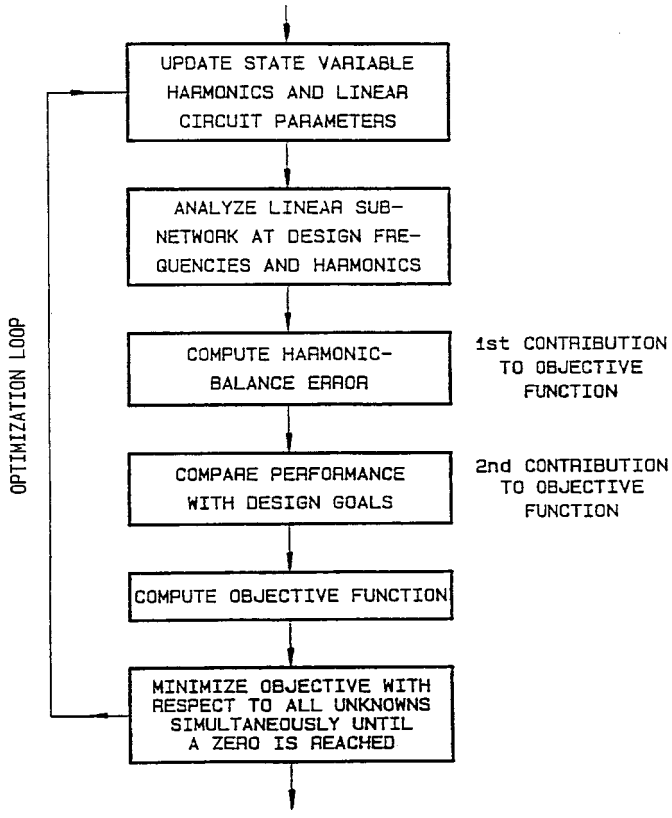

Figure 5-112 Flowchart of a general-purpose harmonic-balance design algorithm that includes optimization.

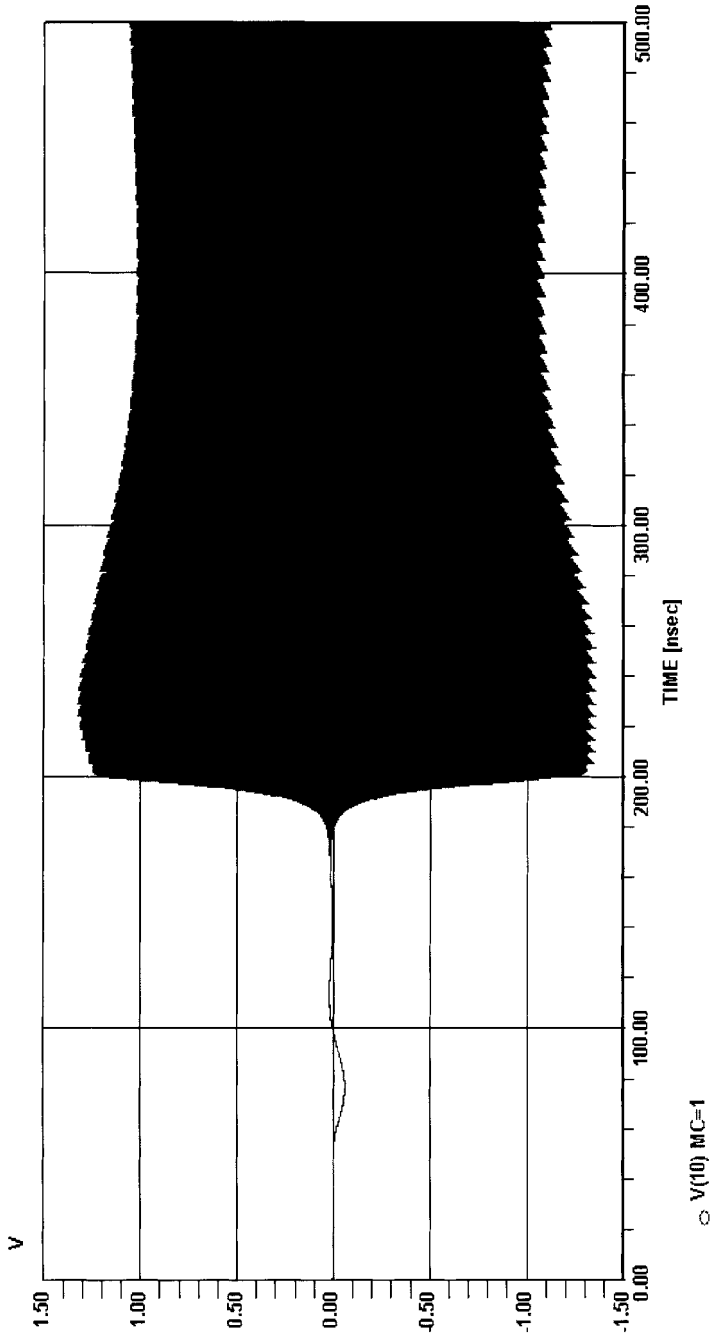

Figure 5-116 Output voltage of the BJT DRO as simulated by Super-Spice.

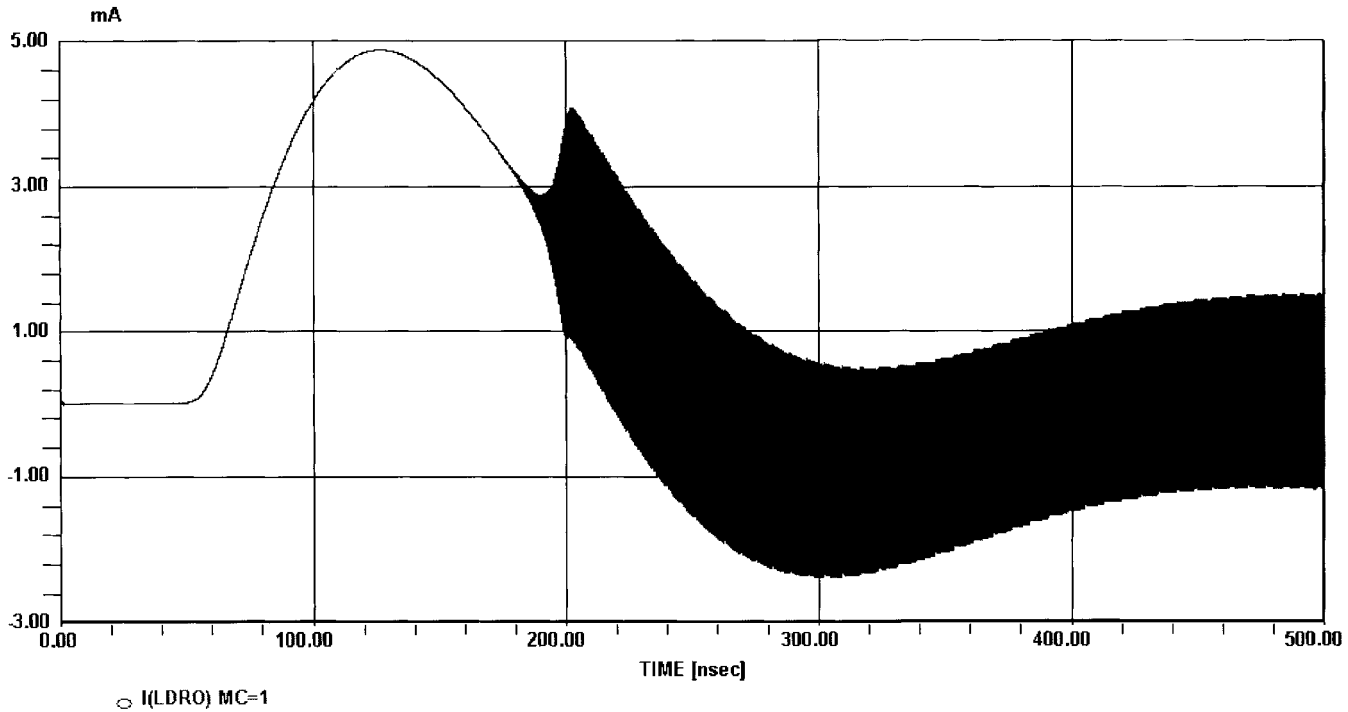

Figure 5-117 Current through the BJT DRO's equivalent resonator inductance from startup to amplitude stabilization.

5-8-2 Time-Domain Simulation

SPICE, a general-purpose simulation program capable of nonlinear dc, linear ac, and nonlinear transient analysis, is probably the most common of the time-domain methods used for nonlinear circuit analysis. Its ability to represent arbitrary time-domain waveforms and model time delays, level shifts, and the sinking and sourcing characteristics of such circuits have made it the simulator of choice for digital designers concerned with analog issues. SPICE's application in RF, microwave, and wireless circuit design is limited by its difficulties with simulating multitone excitations, and coupling and transmission-line effects—including losses, parasitics, and dispersion for distributed elements—and its inefficiency in simulating steady-state conditions.

One area in which SPICE's transient analysis capabilities can be particularly useful to RF and wireless designers is the simulation of oscillator startup. To illustrate this, we present a 3.8-GHz dielectric resonator oscillator modeled with Ansoft Corporation's Super-Spice simulator. Figure 5-115 shows how the oscillator's S_{11} response, positive throughout the simulation's frequency span of 3–5 GHz, peaks at 3.77 GHz. Figure 5-116 shows the oscillator's output voltage as the circuit starts oscillating and amplitude-stabilizes; Figure 5-117 shows the current through the equivalent inductance of the circuit's dielectric resonator across the same time span.

5-9 PHASE-NOISE IMPROVEMENTS OF INTEGRATED RF AND MILLIMETER-WAVE OSCILLATORS *

5-9-1 Introduction

The generation of microwave and millimeter-wave frequencies can be done by lower-frequency VCOs multiplied up in frequency, such as that provided by comb generators; by using hybrid GaAsFET-based oscillators with external resonators; or—for the best phase noise obtainable—YIG oscillators whose physical size and cost do not always provide a practical solution. A significant improvement in oscillator noise performance can be obtained with a novel feedback circuit that uses internally generated noise and cancels the close-in noise in a bandwidth of up to 1 MHz. This results in a phase noise improvement of more than 15 dB at microwave frequencies for the same topology, and the feedback system can be made part of the biasing circuit. This feedback circuit can be used over a wide frequency range and works well at VHF/UHF frequencies and in the millimeter-wave area.

5-9-2 Review of Noise Analysis

Section 5-6 of this chapter covered noise in oscillators in detail, so we will merely review oscillator noise issues here. The first linear model for a basic oscillator, without considering semiconductor noise, was developed by Leeson in 1966 [9] and has been quoted in numerous applications.

The phase noise of a VCO is completely determined by

*This section is based on a paper given at the Fifth International Workshop on Integrated Nonlinear Microwave and Millimeterwave Circuits, sponsored by IEEE at Gerhard-Mercator University, Duisburg, Germany, October 1–2, 1998.

$$£(f_m) = 10 \log\left\{\left[1 + \frac{f_0^2}{(2f_m Q_{\text{load}})^2}\right]\left(1 + \frac{f_c}{f_m}\right)\frac{FkT}{2P_{s,\text{av}}} + \frac{2kTRK_0^2}{f_m^2}\right\} \tag{5-135}$$

where $£(f_m)$ = ratio of sideband power in a 1-Hz bandwidth at f_m to total power in dB
f_m = frequency offset
f_0 = center frequency
f_c = flicker frequency
Q_{load} = loaded Q of the tuned circuit
F = noise factor
$kT = 4.1 \times 10^{-21}$ at 300 K (room temperature)
$P_{s,\text{av}}$ = average power at oscillator output
R = equivalent noise resistance of tuning diode (typically 200 Ω to 10 kΩ)
K_0 = oscillator voltage gain

When adding an isolating amplifier the noise of an *LC* oscillator is determined by

$$S_\phi(f_m) = [a_R F_0^4 + a_E(F_0/2Q_L)^2]/f_m^3$$
$$+ [(2GFkT/P_0)(F_0/2Q_L)^2]/f_m^2$$
$$+ 2a_R Q_L F_0^3/f_m^2$$
$$+ a_E/f_m + 2GFkT/P_0$$

where G = compressed power gain of the loop amplifier
F = noise factor of the loop amplifier
k = Boltzmann's constant
T = temperature in kelvins
P_0 = carrier power level (in watts) at the output of the loop amplifier
F_0 = carrier frequency in hertz
f_m = carrier offset frequency in hertz
$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop
a_R, a_E = flicker noise constants for the resonator and loop amplifier, respectively

In 1978, Dieter Scherer from Hewlett-Packard added the $(1 + f_c/f_m)$ term, which addresses the 1/*f* noise or flicker corner frequency [25]. The 1/*f* frequency phenomenon is based on the surface effects inside the semiconductor and varies from 50 Hz for silicon FETs, to 5 kHz and more for silicon microwave bipolar transistors, to 1 MHz and higher for GaAsFETs. As a rule of thumb, one can state that the higher the frequency of operation, the higher the f_T for the active device, the higher the flicker corner frequency will be. Figure 5-118 shows the spectral distribution as a function of offset frequency. This linearization was first discovered by individuals from NIST, formerly the National Bureau of Standards, in Boulder, Colorado. The left corner is dominated by the flicker corner frequency and the oscillator itself shows at the output a combination of modulation and conversion

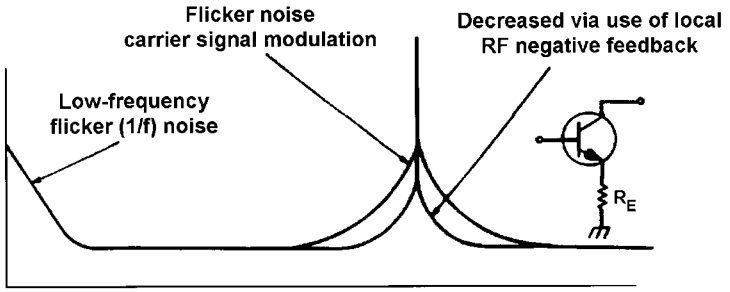

Figure 5-118 Reduction of transistor flicker-of-phase noise via use of local negative feedback (emitter resistance), showing, for a BJT, the flicker noise or corner frequency, as well as the phase noise that results from the flicker noise. The negative feedback from the unbypassed emitter resistor reduces the flicker noise by up to 40 dB [26, 27].

noise. In addition to the $1/f$ noise, the real-life oscillator exhibits a wideband noise, which is due to nonlinearities—specifically, the AM-to-PM conversion resulting from nonlinear capacitance and transconductance of the transistor. This complete linear "noise equation" was first published by Rohde et al. [2]. Therefore, the noise model for the transistor had to be enhanced by describing this mechanism. Essentially, it is equal to a tuning diode coupled to the resonator, which is modulated by thermal noise, and therefore results in a higher phase-noise contribution than the oscillator itself. This noise equation also has Q playing a major role. The phase noise, therefore, ignoring other frequencies, is proportional to $1/Q^2$. In monolithic circuits, the loss of transmission lines, which determines the Q, is related to the substrate material. One has little choice of material, particularly in microwave and millimeter-wave oscillators. Printed resonators sadly provide low Q at these frequencies. A similar problem related to the material is the choices of tuning diodes. In many, if not all, cases, one uses a GaAsFET with the gate connected to the drain or to the source as a tuning diode, and the resulting Q is also disappointing.

The example in Figure 5-118 takes advantage of a microwave bipolar transistor and also is applicable for heterojunction bipolar transistors (HBTs). The transconductance of the bipolar transistor, which is approximately 39 mA/V, increases to values up to 20 times larger than exhibited by GaAsFETs. This method of using negative feedback reduces the gain of the GaAsFET too much and is, therefore, not applicable.

5-9-3 Workarounds

When looking at the modes of operation of test sets for phase-noise measurement, the one method that requires only one signal generator is most desirable. Based on the frequency discriminator method, it uses a cable of appropriate length that acts as a delay line. The oscillator under test drives a double-balanced mixer [one port directly (LO port)] and drives the RF port "delayed" via the delay line cable, and the mixer is therefore driven by the same frequency with a different phase. This setup has been used for phase-noise measurements very successfully. One can easily connect a low-noise FFT-based audio spectrum analyzer to the mixer output and measure the signal-to-noise ratio as a function of offset. With modern FFT analyzers available up to 10 MHz and higher, a fast and reliable measurement can be done. The length of the cable determines the frequency range over which an accurate

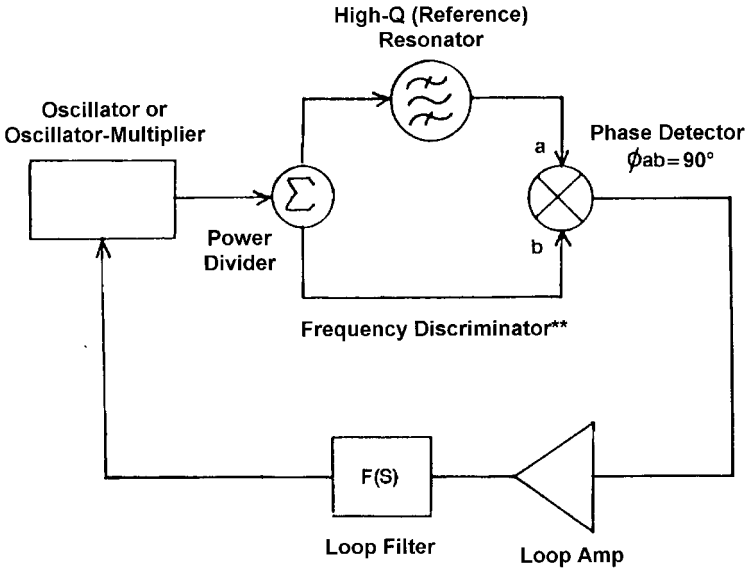
measurement is possible. This phase-noise information (dc and ac voltage) at the output can be used to modulate the VCO and improve the phase noise in the frequency range over which this method is applicable. Fluke and other companies have built signal generators based on this principle to improve the phase noise. The drawback of this method is that the delay line acts like a band-limiting filter, and, therefore, one cannot compensate over a large range of frequencies. The delay line in question, responsible for the phase shift, can also be substituted by a high-Q resonator. By closing the loop, one can "clean up" the phase noise of the device under test (DUT). The difficulty with this is that it requires an external high-Q resonator. One might as well use the same resonator for the oscillator. Therefore, this method is not suitable for MMICs. See Figure 5-119 for more details.

As far as the actual measurement is concerned, one has to observe certain limitations of the test setup as explained in Figure 5-120. When using the delay line instead of a high-Q resonator (low loss is assumed for coaxial cable), one needs to determine the physical length of the cable. The physical length of the cable determines the delay and, therefore, the discriminator noise floor as a function of the offset frequency. Typically, 8 feet of RG-8/U cable results in a delay of 12 ns. As can be seen from Figure 5-121, it is advisable to have several lengths of cable depending on the range of frequency for which one wants to do the measurements under different lengths of cable [28].

Since we are primarily concerned about the flicker noise, here is another, similar, approach to "cleaning up" the flicker noise, as shown in Figure 5-122. The bandwidth over which this technique works depends on the bandwidth of the phase detector system, which can be made fairly wide. A derivative of this will provide a useful solution.

5-9-4 Reduction of Flicker Noise

From inspecting a device datasheet, one is always pleasantly surprised about very low spot noise figures, while the 1/f corner frequency is rarely specified at all. The mechanism that



**Resonator may be operated in reflection mode as well as transmission mode.

Figure 5-119 AFC stabilization of an external oscillator.

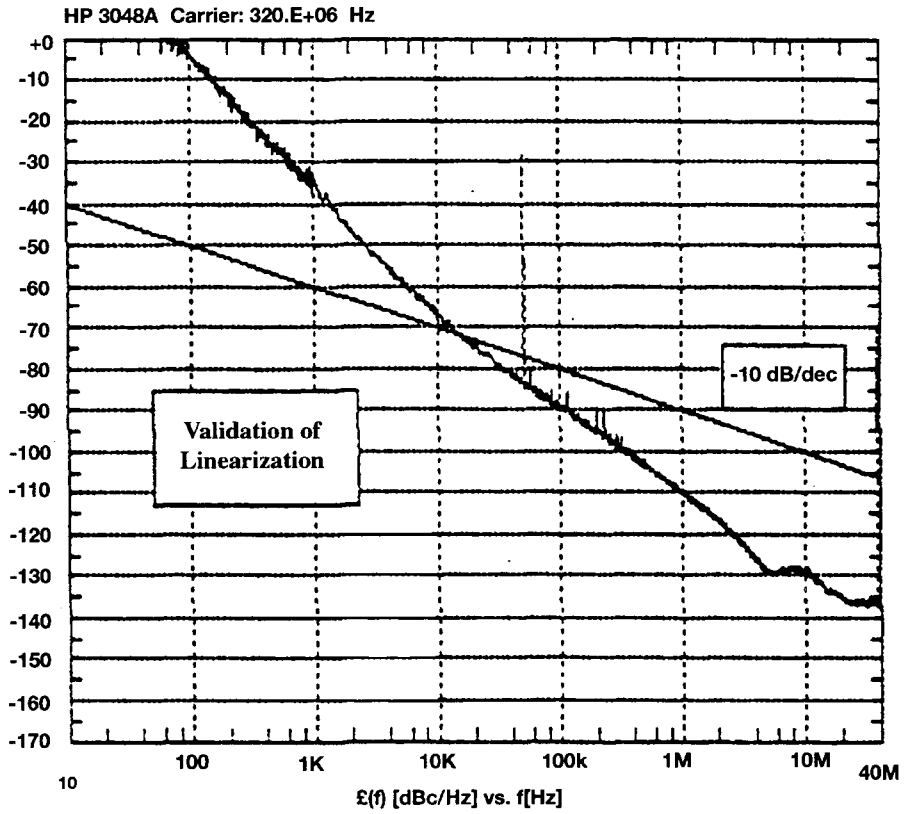


Figure 5-120 Display of a typical phase-noise measurement using the delay line principle. This method is only applicable where $x = \sin(x)$. The measurements above the solid line violate this relationship and therefore are not valid.

transforms the noise, which is generated by the $1/f$ contribution into what we referred to as modulation noise, is the AM-to-PM conversion. If one could "linearize" the transistor, the flicker noise effect would drastically be reduced.

Figure 5-123 shows two variations on an approach that is consistent with the previous method. In Figure 5-123a, the noise across the 56-Ω emitter resistor of oscillator transistor Q1 is sampled, amplified and inverted in Q2, and used to modulate Q1's base voltage. A low-frequency, general-purpose *npn* transistor (BC848C) is used at Q2. A high-frequency, higher-power transistor (BFR93A) is used at Q1; an HBT could also be used. Figure 5-123b shows the same approach using a variation of the *pnp* active biasing circuit shown in Figure 3-192. Figure 5-124 shows the phase-noise performance for the circuit of Figure 5-123a.

5-9-5 Applications to Integrated Oscillators

Figure 5-125 shows a silicon-based BiCMOS technology wireless oscillator. The three big inductors can be seen easily. This design by Motorola is a good candidate for using this innovative technology. Applying this feedback technology, we measure the phase noise shown in Figure 5-126.

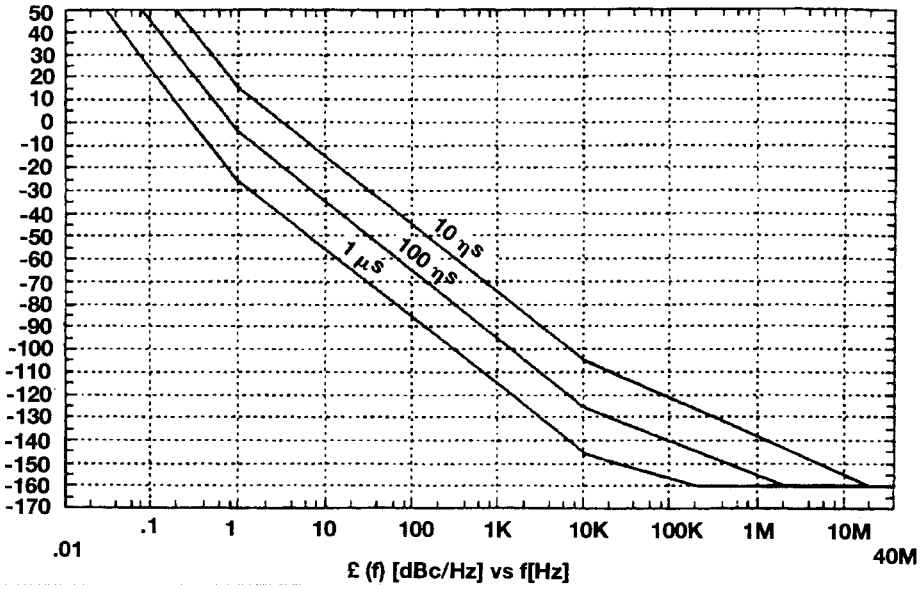

Figure 5-121 Dynamic range as a function of cable delay. A delay of 1 μs is ideal for microwave frequencies.

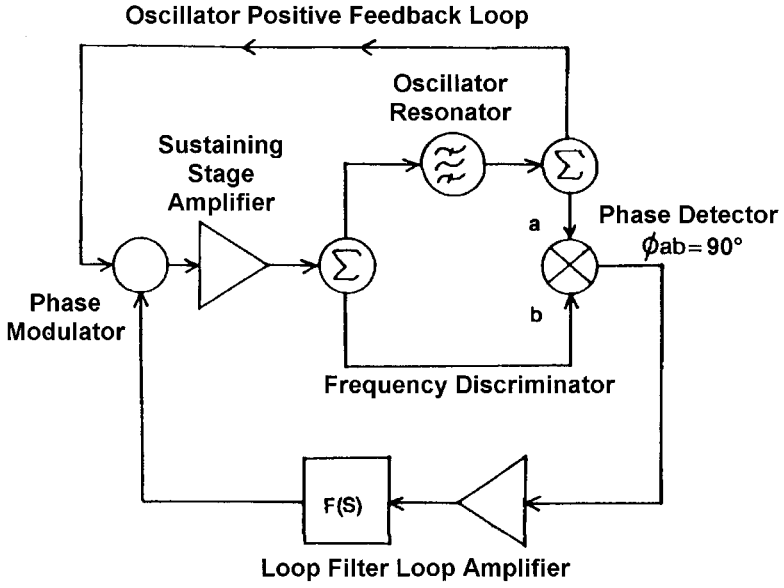

Figure 5-122 Noise reduction in an oscillator whose signal flicker-of-frequency noise is primarily due to sustaining stage flicker-of-phase noise. A phase perturbation in the sustaining stage produces a frequency change in the oscillator, which produces a change in the signal phase shift through the resonator detected as the phase detector. The resonator may be operated simultaneously in transmission line and reflection modes in the oscillator in the oscillator and discriminator portions of the circuit, respectively.

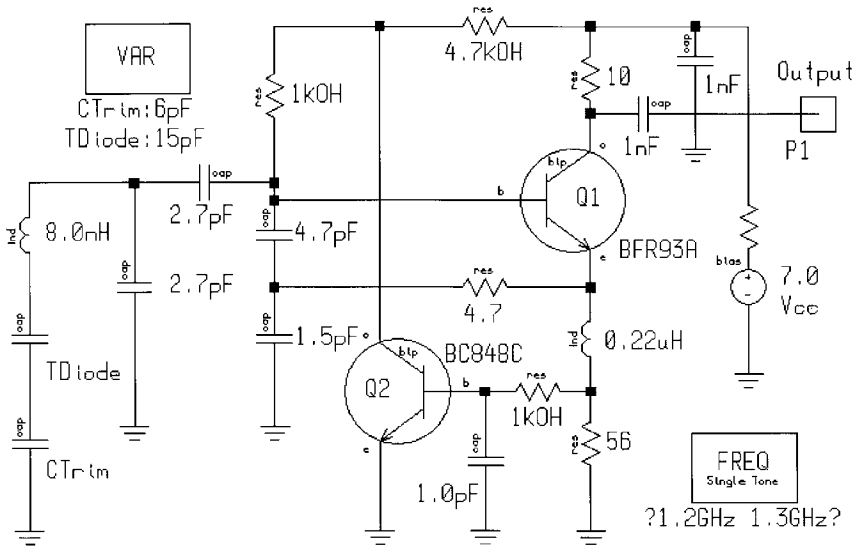
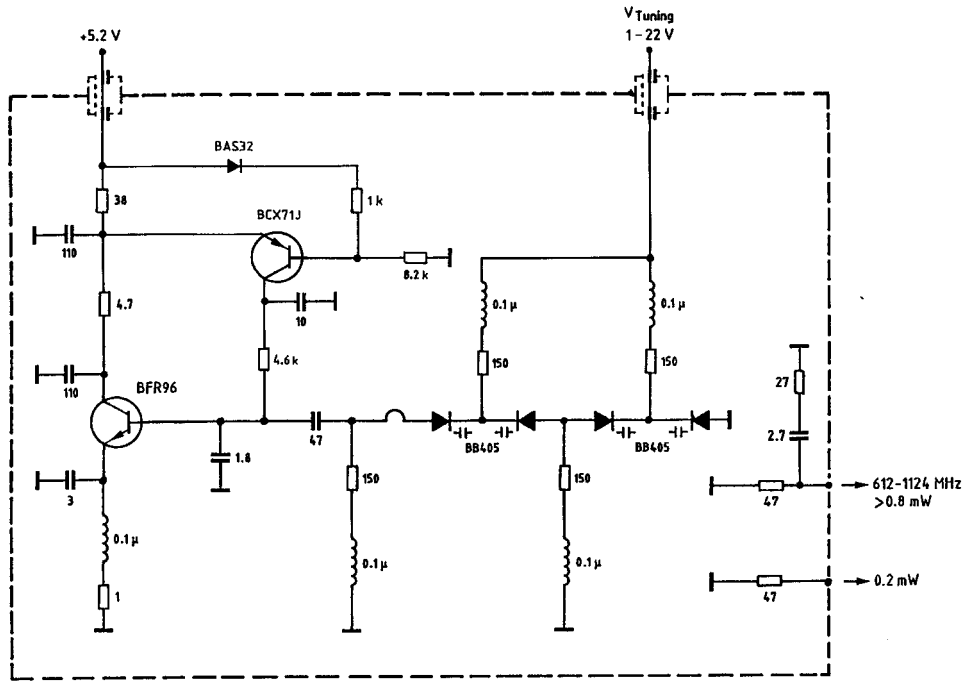


(a)



(b)

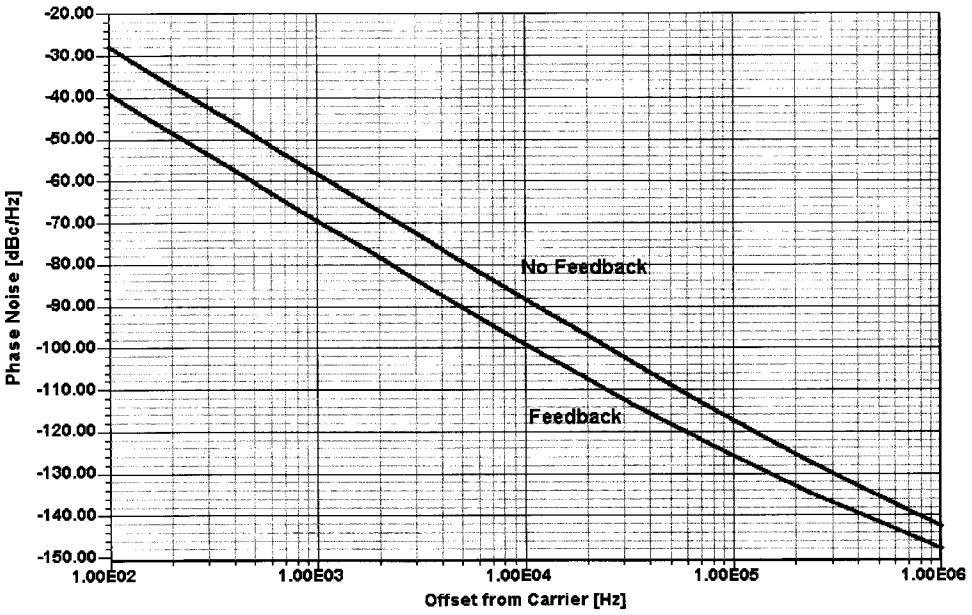

Figure 5-124 Phase noise of the oscillator in Figure 5-123a with and without noise feedback.

Moving up into the millimeter-wave area, one of the target oscillators is the Ka-band MMIC voltage-controlled oscillator designed for Ka-band smart munitions applications (Figure 5-127). This voltage-controlled oscillator MMIC employs 0.25-μm gate length, double-heterojunction, pseudomorphic, high-electron-mobility transistor (PHEMT) technology. This is a custom chip developed by Martin Marietta under the U.S. Government MMIC program. Ansoft Serenade tools were used in this design.

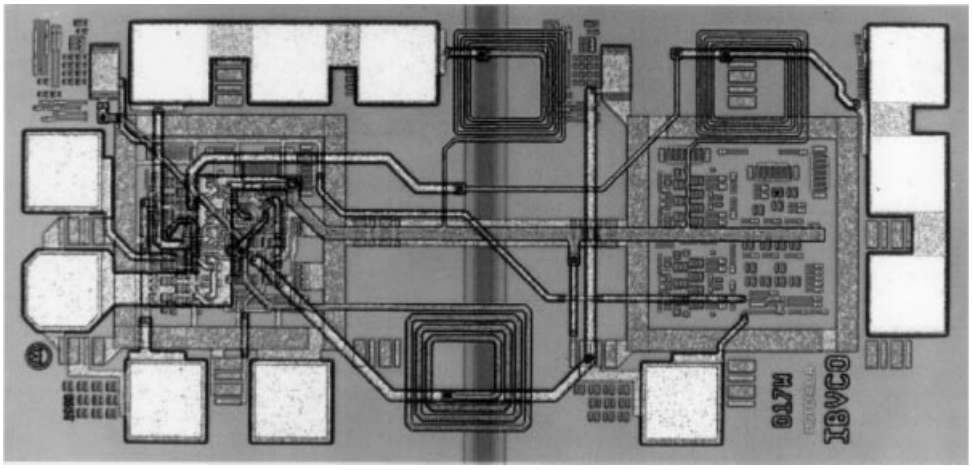

Figure 5-125 Layout of the Motorola 800-MHz monolithic differential oscillator IC in Si technology.

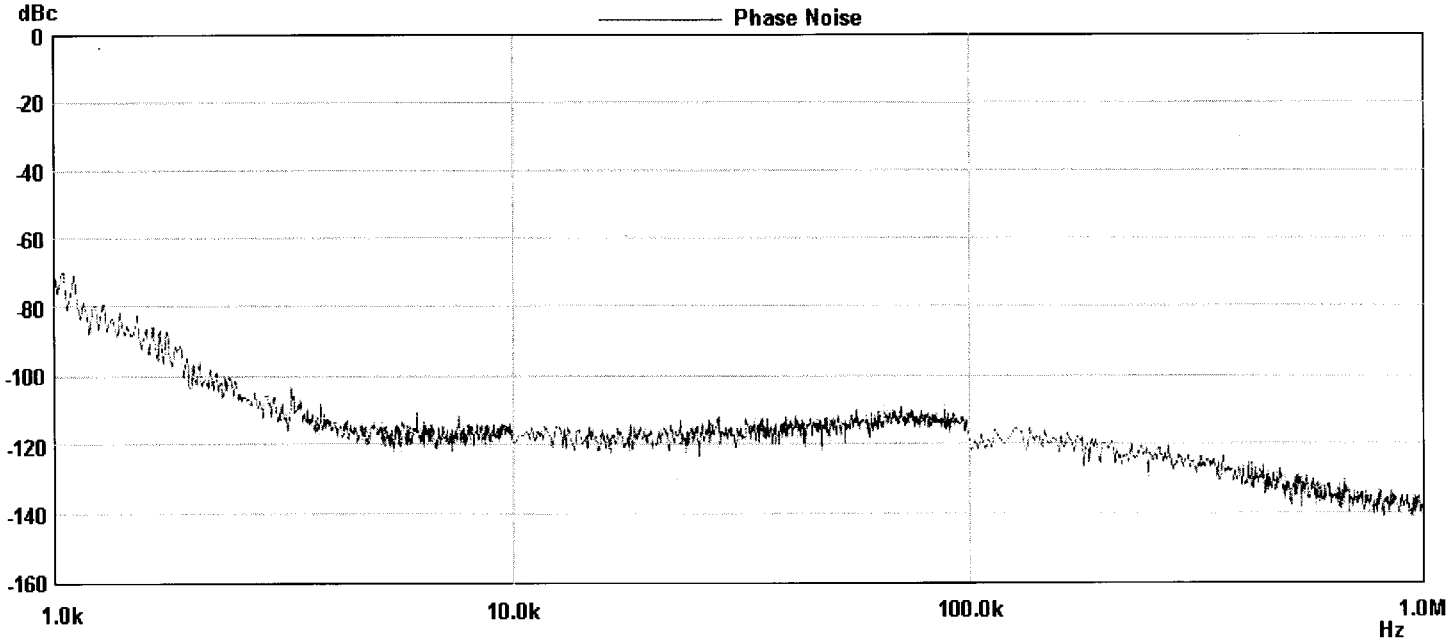

Figure 5-126 Phase noise of the oscillator of Figure 5-125. The noise floor is limited by the on-board isolation amplifier.

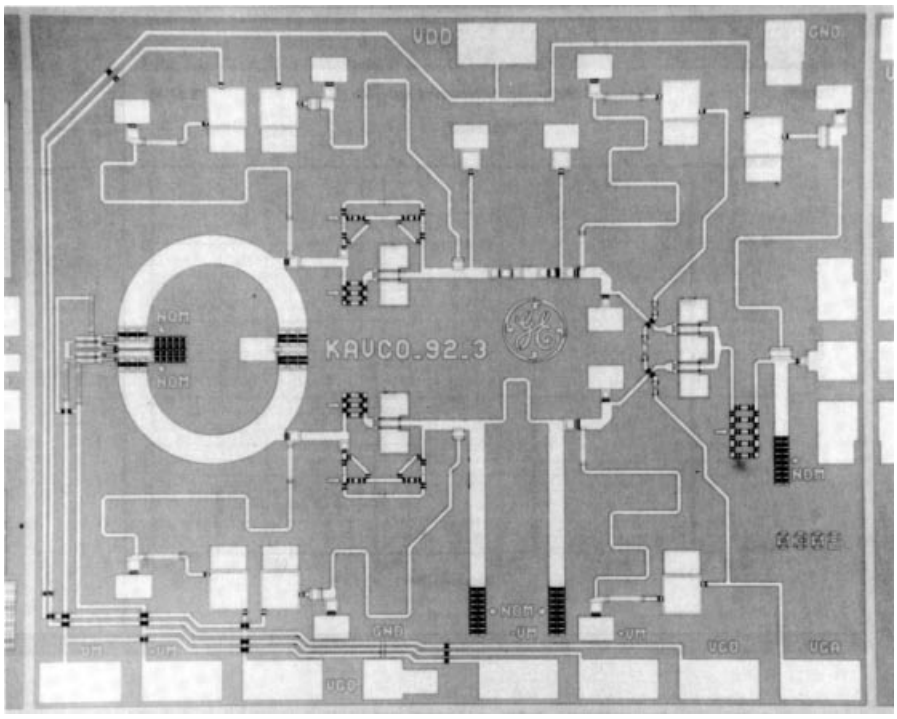

Figure 5-127 Layout of the Ka-band voltage-controlled oscillator.

Features

- Fundamental-mode, differential-ring VCO
- Electronically tunable
- Output power greater than 16 dBm
- Power-added efficiency (PAE) of 13%
- Compact size for easy integration with power amplifier
- 0.25-μm pseudomorphic HEMTs

Specifications

- Frequency range: Ka band
- Output power: 16 dBm minimum

When applying the same technology as shown in the previous bipolar example, the phase noise can be reduced significantly. Since field-effect transistors require a negative gate voltage, it is possible to sample the noise in the drain current using a resistor, amplify the noise with an appropriate loop amplifier, and modulate the gate voltage within a 1-MHz bandwidth.

A spectrum analyzer measurement of this oscillator type, as shown in Figure 5-128, indicates a phase noise of −78.6 dBc/Hz at an offset frequency of 100 kHz at a center frequency of 38 GHz, while the closed-loop phase noise of Figure 5-129 using the compen-

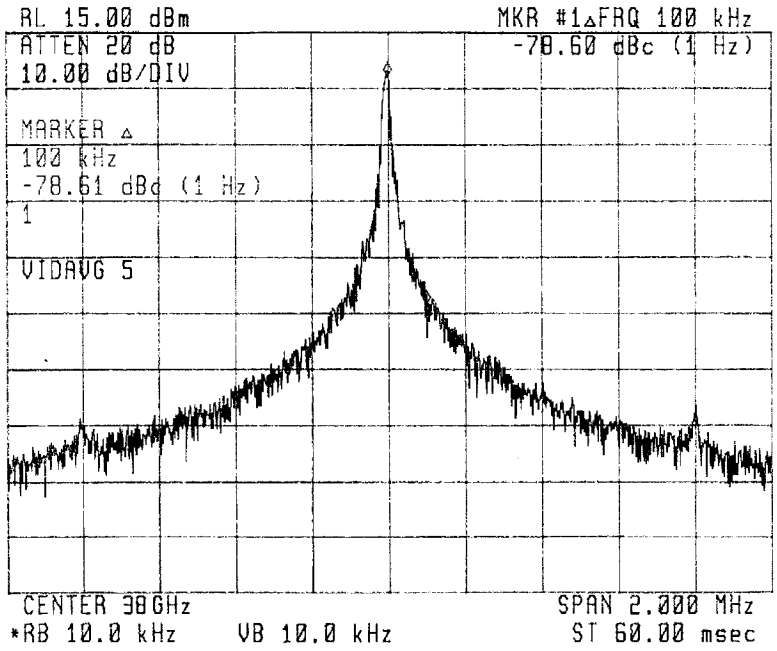

Figure 5-128 Spectrogram of the 38-GHz free-running push–pull VCO shown in Figure 5-127.

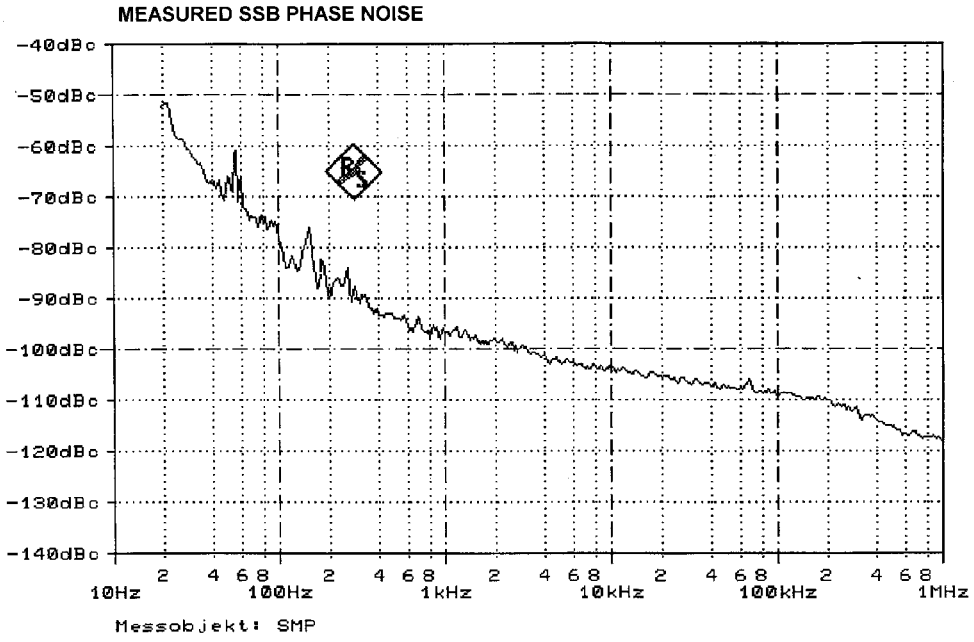

Figure 5-129 Phase-noise performance of a 38-GHz oscillator with phase-noise “clean-up” system.

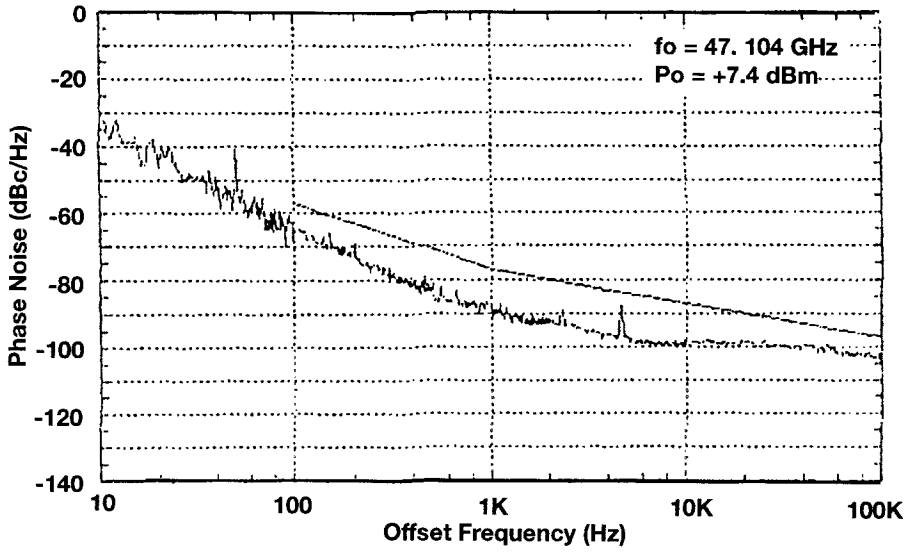

Figure 5-130 A 47-GHz loop-stabilized VCO with phase-noise performance similar to that of Figure 5-129.

sation scheme indicates a phase noise of about −108 dBc/Hz at 100 kHz. This is consistent with reported results from other researchers who have used complicated phase-locked loops to achieve similar performance as seen in Figure 5-130.

5-9-6 Summary

A novel method of improving the phase noise of oscillators has been demonstrated. This approach works well for low-frequency oscillators such as 1000 MHz up to the millimeter-wave range. It only requires an additional wideband dc biasing circuit, which applies noise feedback. The correctness of the theory has been demonstrated by appropriate validation.

RF/WIRELESS OSCILLATORS

5-1 INTRODUCTION TO FREQUENCY CONTROL

Practically all modern telecommunication and test equipment uses frequency-control techniques based on *frequency synthesis*, the production of the many frequencies involved in a radiocommunication system's modulation, transmission, reception, and demodulation functions through the combination and mathematical manipulation of a very few input frequencies. Although the frequency synthesis techniques now ascendant in wireless systems—phase-locked loops and, less commonly, direct digital synthesizers—are fundamentally different, all are ultimately based on RF oscillators. This chapter covers oscillator theory, evaluation, and design.

Two types of oscillators are needed in a phase-locked-loop system (Figure 5-1). One, typically a *crystal oscillator*, generates the synthesizer's reference signal. As Figure 5-1 reflects, the reference oscillator may be built into the synthesizer IC in highly integrated systems. The other oscillator, a *voltage-controlled oscillator* (VCO), is varied in frequency by the system to produce the synthesizer's output signal. Although designing good oscillators remains somewhat like black magic or a special art, we will show that mathematics and CAD tools, applied in conjunction with practical experience, can keep the oscillator design process well under control.

5-2 BACKGROUND

The oscillator was probably first discovered by people who wanted to build an amplifier back in the vacuum-tube days. Its modern equivalent is shown in Figure 5-2. Here we see an active device, a bipolar transistor or field-effect transistor, with a tuned input and output circuit. Under ideal circumstances, the voltage at the input is 180° out of phase and the amplifier is "stable." Because of the unavoidable feedback capacitance, a certain amount of energy is transferred from the output to the input at about 90° out of phase. If one of the tuned circuits is detuned to the point where the phase shift is –180°, oscillation will occur. This means that the small energy from the output will be amplified, brought back to the input in phase and

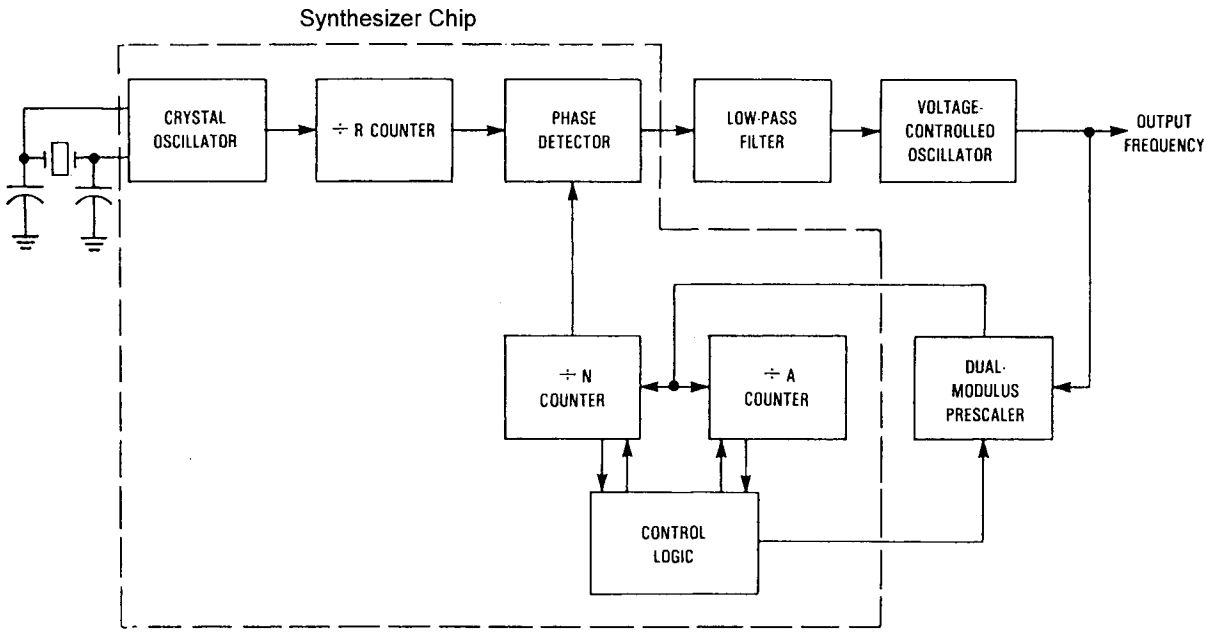

Figure 5-1 Block diagram of a modern, integrated frequency synthesizer. In this case, the designer has control over the VCO and the loop filter; the reference oscillator is part of the chip. In most cases (up to 2.5 GHz), the dual-modulus prescaler is inside the chip.

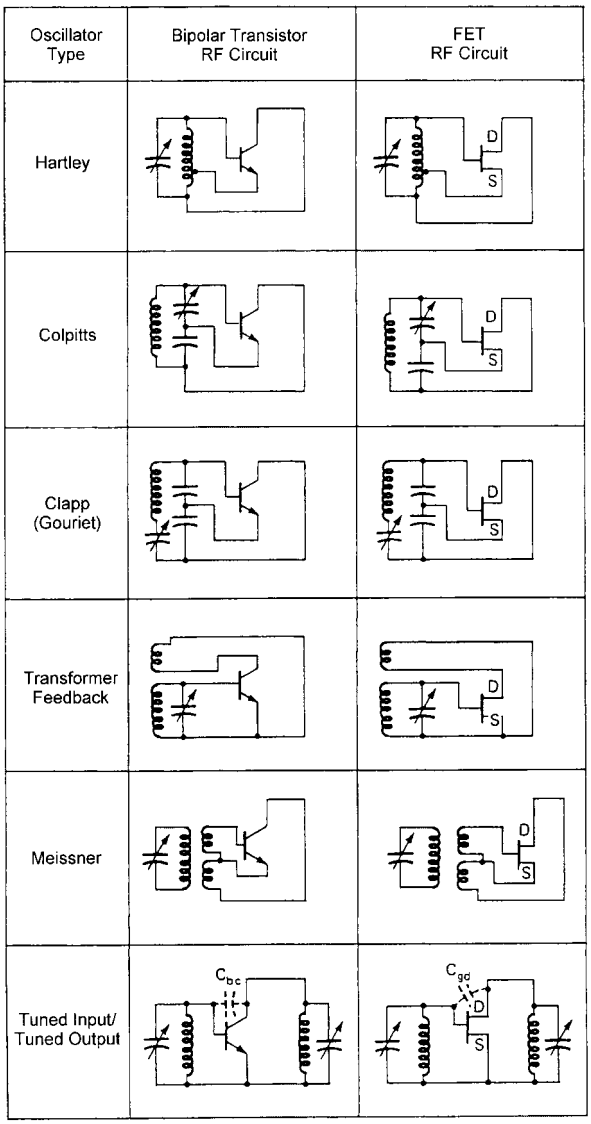

Figure 5-2 Schematic diagrams of RF connections for common oscillator circuits (dc and biasing circuits not shown) [1].

further amplified, causing the stage to "take off" and oscillate. Unless there is some mechanism to limit the amplitude of the oscillation at the input or output, its amplitude can theoretically increase to a level sufficient to destroy the device through breakdown effects or thermal runaway.

The criterion for oscillation was first described by Barkhausen [see Eq. (5-6) in the next section]. The conditions for oscillation exist when the feedback gain is high enough to cancel all losses and the difference between forward gain and reverse gain is less than zero. This implies also that oscillator circuits (Figure 5-2) provide a negative resistance, which is responsible for oscillation. The following mathematical treatment explains this.

5-3 OSCILLATOR DESIGN

A phase-locked loop generally has two oscillators: the oscillator at the output frequency and the reference oscillator. The reference oscillator at times can be another loop that is being mixed in, and the voltage-controlled oscillator (VCO) is controlled by either the reference or the oscillator loop. The VCO is one of the most important parts in a phase-locked-loop system, the performance of which is determined only by the loop filter at offsets inside the loop bandwidth, and only by the quality of the VCO design at offsets outside the loop bandwidth.

To some designers, VCO design appears to be magic. Shortly, we will go through the mathematics of the oscillator and some of its design criteria, but the results have only limited meaning. This is due to component tolerances, stray effects, and, most of all, nonlinear performance of the oscillator device, which can be modeled with only a certain degree of accuracy. However, after building oscillators for awhile, a certain feeling will be acquired for how to do this, and certain performance behavior will be predicted on a rule-of-thumb basis rather than on precise mathematical effort. For reasons of understanding, we will deal with the necessary mathematical equations, but we consider it essential to explain that these are only approximations.

5-3-1 Basics of Oscillators

An electronic oscillator is a device that converts dc power to a periodic output signal (ac power). If the output waveform is approximately sinusoidal, the oscillator is referred to as *sinusoidal.* There are many other oscillator types normally referred to as *relaxation* oscillators. For application in frequency synthesizers, we will explore only sinusoidal oscillators for reasons of purity and noise-sideband performance.

All oscillators are inherently nonlinear. Although the nonlinearity results in some distortion of the signal, linear analysis techniques can normally be used for the analysis and design of oscillators. Figure 5-3 shows, in block diagram form, the necessary components of an oscillator. It contains an amplifier with frequency-dependent forward loop gain $G(j\omega)$ and a frequency-dependent feedback network $H(j\omega)$.

The output voltage is given by

$$V_o = \frac{V_{\text{in}} G(j\omega)}{1 + G(j\omega)H(j\omega)} \tag{5-1}$$

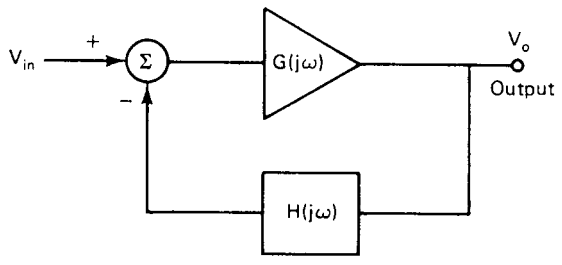

Figure 5-3 Block diagram of an oscillator showing forward and feedback loop components.

For an oscillator, the output V_o is nonzero even if the input signal $V_i = 0$. This can only be possible if the forward loop gain is infinite (which is not practical), or if the denominator

$$1 + G(j\omega)H(j\omega) = 0 \tag{5-2}$$

at some frequency ω_o. This leads to the well-known condition for oscillation (the *Nyquist criterion*), where at some frequency ω_o

$$G(j\omega_o)H(j\omega_o) = -1 \tag{5-3}$$

That is, the magnitude of the open-loop transfer function is equal to 1:

$$|G(j\omega_o)H(j\omega_o)| = 1 \tag{5-4}$$

and the phase shift is 180°:

$$\arg[G(j\omega_o)H(j\omega_o)] = 180° \tag{5-5}$$

This can be more simply expressed as follows: If in a negative-feedback system, the open-loop gain has a total phase shift of 180° at some frequency ω_o, the system will oscillate at that frequency provided that the open-loop gain is unity. If the gain is less than unity at the frequency where the phase shift is 180°, the system will be stable, whereas if the gain is greater than unity, the system will be unstable.

This statement is not correct for some complicated systems, but it is correct for those transfer functions normally encountered in oscillator design. The conditions for stability are also known as the *Barkhausen criteria*, which state that if the closed-loop transfer function is

$$\frac{V_o}{V_i} = \frac{\mu}{1 - \mu\beta} \tag{5-6}$$

the system will oscillate provided that $\mu\beta = 1$. This is equivalent to the Nyquist criterion, the difference being that the transfer function is written for a loop with positive feedback. Both versions state that the total phase shift around the loop must be 360° at the frequency of oscillation and the magnitude of the open-loop gain must be unity at that frequency.

The following analysis of the relatively simple oscillator shown in Figure 5-4 illustrates the design method. The linearized (and simplified) equivalent circuit of Figure 5-4 is given in Figure 5-5. h_{rb} has been neglected, and $1/h_{ob}$ has been assumed to be much greater than the load resistance R_L and is also ignored.

Note that the transistor is connected in the common-base configuration, which has no voltage phase inversion (the feedback is positive), so the conditions for oscillation are

$$|G(j\omega_o)H(j\omega_o) = 1| \tag{5-7}$$

and

$$\arg[G(j\omega_o)H(j\omega_o)] = 0° \tag{5-8}$$

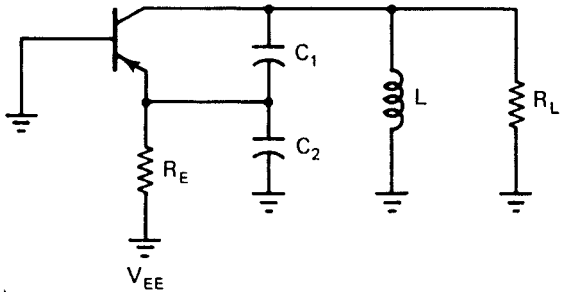

Figure 5-4 Oscillator with capacitive voltage divider.

The circuit analysis can greatly be simplified by assuming that

$$\frac{1}{\omega(C_2 + C_1)} << \frac{h_{ib}R_E}{h_{ib} + R_E} \tag{5-9}$$

and also that the Q of the load impedance is high. In this case the circuit reduces to that of Figure 5-6, where

$$V = \frac{V_o C_1}{C_1 + C_2} \tag{5-10}$$

and

$$R_{\text{eq}} = \frac{h_{ib}R_E}{h_{ib} + R_E}\left(\frac{C_1 + C_2}{C_1}\right)^2 \tag{5-11}$$

Figure 5-7 shows how the input impedance of an oscillator circuit—in this case, a BJT Colpitts oscillator minus its resonator—satisfies this condition for oscillation.

Then the forward gain

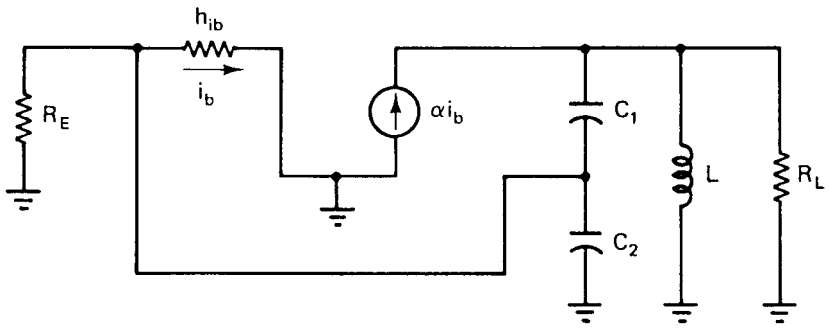

Figure 5-5 Linearized and simplified equivalent circuit of Figure 5-4.

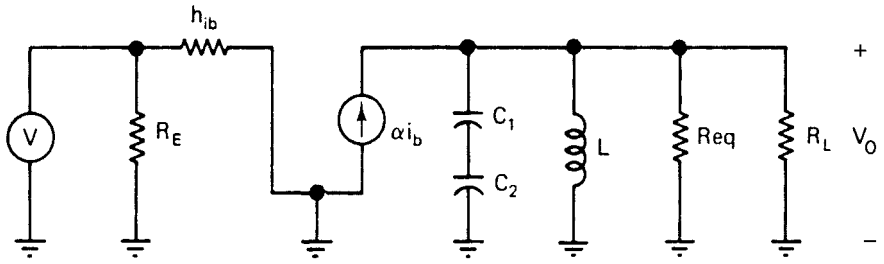

Figure 5-6 Further simplification of Figure 5-4, assuming high-impedance loads.

$$G(j\omega) = \frac{h_{fb}}{h_{ib}} Z_L = \frac{\alpha}{h_{ib}} Z_L \tag{5-12}$$

and

$$H(j\omega) = \frac{C_1}{C_1 + C_2} \tag{5-13}$$

where

$$Y_L = \frac{1}{Z_L} = \frac{1}{j\omega L} + \frac{1}{R_{\text{eq}}} + \frac{1}{R_L} + \frac{1}{j\omega C} \tag{5-14}$$

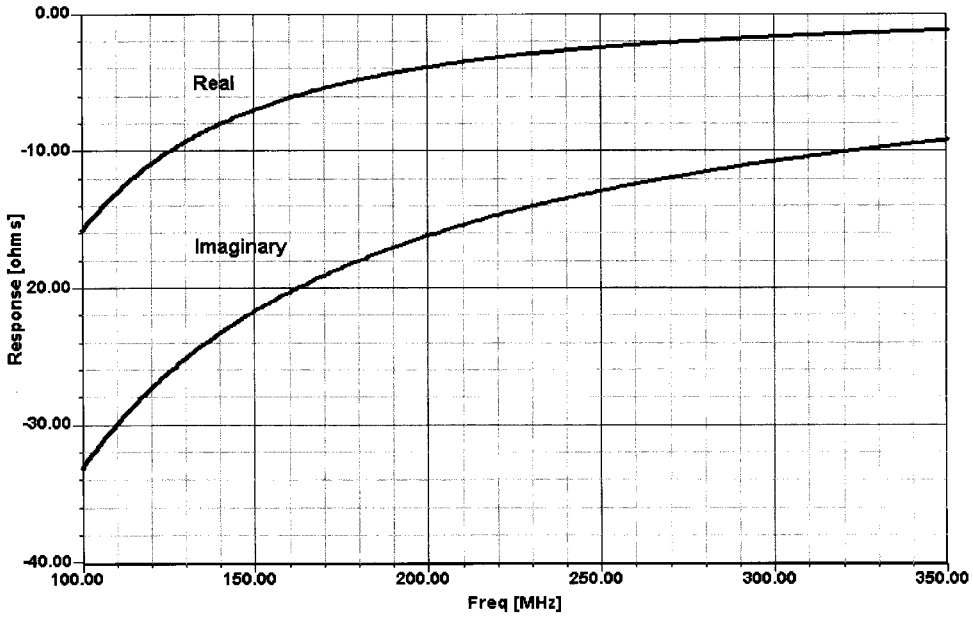

Figure 5-7 Calculated input impedance of a 200-MHz BJT Colpitts oscillator with its resonator removed. (Figure 5-46 shows an equivalent graph with the resonator present.)

A necessary condition for oscillation is that

$$\arg[G(j\omega)H(j\omega)] = 0^\circ \tag{5-15}$$

Since H does not depend on frequency in this example, if arg(GH) is zero, the phase shift of the load impedance Z_L must also be zero. This occurs only at the resonant frequency of the circuit,

$$\omega_o = \frac{1}{\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{5-16}$$

At this frequency

$$Z_L = \frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L} \tag{5-17}$$

and

$$GH = \frac{h_{fb}}{h_{ib}}\left(\frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L}\right)\frac{C_1}{C_1 + C_2} \tag{5-18}$$

The other condition for oscillation is the magnitude constraint that

$$G(j\omega)H(j\omega) = \frac{\alpha}{h_{ib}}\left(\frac{R_{\text{eq}}R_L}{R_{\text{eq}} + R_L}\right)\frac{C_1}{C_1 + C_2} = 1 \tag{5-19}$$

Three-Reactance Oscillators. Although the block-diagram formulation of the stability criteria is an easy way to express stability mathematically, it is frequently not the easiest to apply since it is often difficult to identify the forward loop gain $G(j\omega)$ and the feedback ratio $H(j\omega)$ in electronic systems. A direct analysis of the circuit equations is frequently simpler than the block diagram interpretation (particularly for single-stage amplifiers). Figure 5-8 shows a generalized circuit for an electronic amplifier.

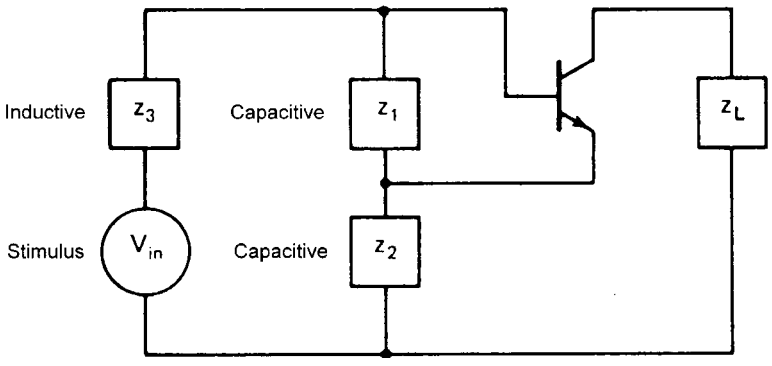

Figure 5-8 Generalized circuit for an oscillator using an amplifier model. Z_3 is inductive even with a capacitor in series with it.

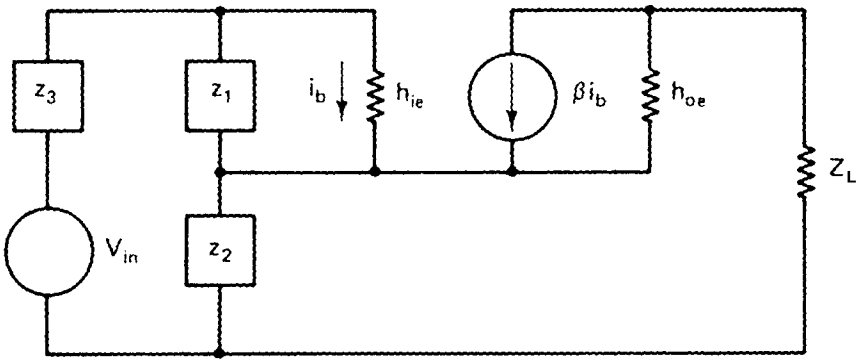

Figure 5-9 Small-signal equivalent circuit of Figure 5-8.

By inspecting Figure 5-8, one can see the three necessary reactances and the load. All other known circuits are derivatives of this by rotation. The small-signal equivalent circuit is given in Figure 5-9 (where h_{re} has been neglected).

Normally, h_{oe} can also be assumed sufficiently small and can be neglected. The loop equations are then

$$V_{\text{in}} = I_1(Z_3 + Z_1 + Z_2) - I_b Z_1 + \beta I_b Z_2 \tag{5-20}$$

$$0 = -I_1 Z_1 + I_b(h_{ie} + Z_1) \tag{5-21}$$

For the amplifier to oscillate, the currents I_b and I_1 must be nonzero even when $V_1 = 0$. This is only possible if the system determinant

$$\Delta = \begin{vmatrix} Z_3 + Z_1 + Z_2 & \beta Z_2 - Z_1 \\ -Z & h_{ie} + Z_1 \end{vmatrix} \tag{5-22}$$

is equal to 0. That is,

$$(Z_3 + Z_1 + Z_2)(h_{ie} + Z_1) - Z_1^2 + \beta Z_1 Z_2 = 0 \tag{5-23}$$

which reduces to

$$(Z_1 + Z_2 + Z_3)h_{fe} + Z_1 Z_2 \beta + Z_1(Z_2 + Z_3) = 0 \tag{5-24}$$

Assume for the moment that Z_1, Z_2, and Z_3 are purely reactive impedances. [It is easily seen that Eq. (5-24) does not have a solution if all three impedances are real.] Since both the real and imaginary parts must be zero, Eq. (5-24) is equivalent to the following equations if

$$h_{ie}(Z_1 + Z_2 + Z_3) = 0 \tag{5-25}$$

and

$$Z_1[(1 + \beta)Z_2 + Z_3] = 0 \tag{5-26}$$

Since β is real and positive, Z_2 and Z_3 must be of opposite sign for Eq. (5-26) to hold. That is,

$$(1 + \beta)Z_2 = -Z_3 \tag{5-27}$$

Therefore, since h_{ie} is nonzero, Eq. (5-25) reduces to

$$Z_1 + Z_2 - (1 + \beta)Z_2 = 0 \tag{5-28}$$

or

$$Z_1 = \beta Z_2 \qquad [C_1 < C_2; L_1 > L_2] \tag{5-29}$$

Thus, since β is positive, Z_1 and Z_2 will be reactances of the same kind. If Z_1 and Z_2 are capacitors, Z_3 is an inductor and the circuit is as shown in Figure 5-10. It is referred to as a *Colpitts* oscillator, named after the person who first described it.

If Z_1 and Z_2 are inductors and Z_3 is a capacitor as illustrated in Figure 5-11, the circuit is called a *Hartley* oscillator.

Example 1. Design a Colpitts circuit to oscillate at 200 MHz, using a transistor (operating at I_C = 6 mA dc) that has an input impedance

$$\text{Mag}(Z_{11}) = \frac{26 \text{ mV}}{I_C} \beta = 282\ \Omega (h_{ie} \triangleq Z_{11})$$

and

$$\beta_{RF} = 65; \quad \beta_{OSC} = 10 \quad \text{(large-signal condition)}$$

The oscillating transistor operates under large-signal conditions, generating harmonics in addition to the fundamental. Most of the transistor's current gain will come from dc biasing. β_{OSC}, its large-signal beta at the fundamental frequency of oscillation, must therefore be considerably less than β_{RF}, the small-signal, single-tone value, as the

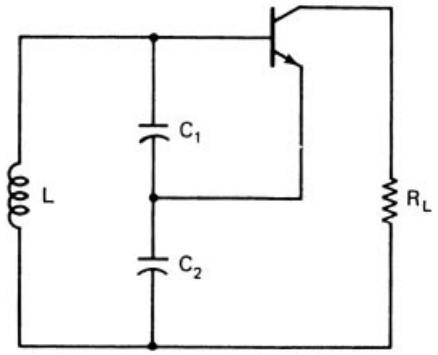

Figure 5-10 Colpitts oscillator.

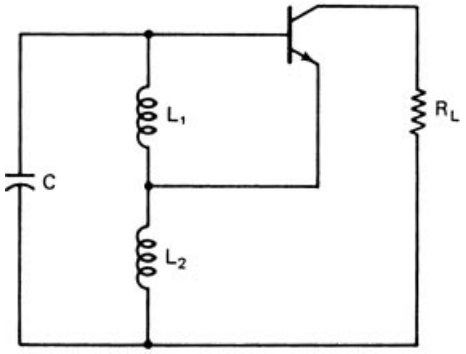

Figure 5-11 Hartley oscillator.

transistor's available current gain, β_0, is distributed among the dc, fundamental, and harmonic components present ($\beta_0 = \beta_{dc} + \beta_{OSC} + \beta_{OSC,F2} + \beta_{OSC,F3}\ldots$).

Solution: For the Colpitts circuit, Z_1 and Z_2 are capacitive reactances and Z_3 is an inductive reactance. Let $Z_2 = -j1.6\ \Omega$; then [Eq. (5-27)]

$$Z_3 = -(1 + \beta)Z_2 = -(1 + 10) \times (-1.6) \approx j17\ \Omega$$

and [Eq. (5-25)]

$$Z_1 = -(Z_2 + Z_3) \approx -j17\ \Omega$$

At 200 MHz, these impedances correspond to component values of $C_1 = 50$ pF, $C_2 = 500$ pF, and $L = 30$ nH. The oscillator will probably work with C_2 values larger than 500 pF, but at the loss of safety margin for tolerances in production, beta, temperature, and phase-noise performance. The completed circuit, except for biasing, is shown in Figure 5-12.

If Z_1, Z_2, Z_3, or h_{ie} is complex, the preceding analysis is more complicated, but the conditions for oscillation can still be obtained from Eq. (5-24). For example, if, in the Colpitts

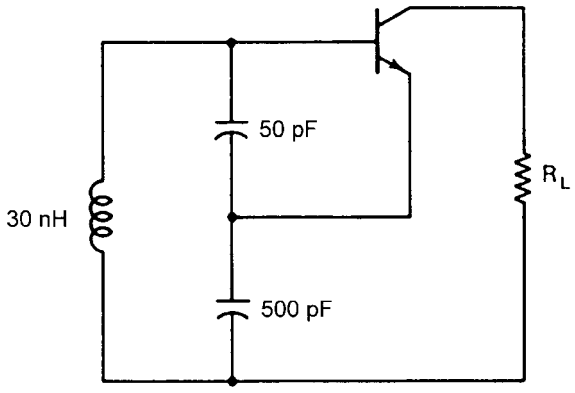

Figure 5-12 Design example of a Colpitts oscillator.

circuit, there is a resistor R in series with $L(Z_3 = R + j\omega L)$, Eq. (5-24) reduces to two equations:

$$h_{ie}\left(\omega L - \frac{1}{\omega C_1} - \frac{1}{\omega C_2}\right) - \frac{R}{\omega C_1} = 0 \tag{5-30}$$

and

$$h_{ie}R - \frac{1+\beta}{\omega^2 C_1 C_2} + \frac{1}{\omega C_1}\omega L = 0 \tag{5-31}$$

Define

$$C_1' = \frac{C_1}{1 + R/h_{ie}} \tag{5-32}$$

The resonant frequency at which oscillations will occur is found from Eq. (5-30) to be

$$\omega_o = \frac{1}{\sqrt{L[C_1' C_2/(C_1' + C_2)]}} \tag{5-33}$$

and for oscillations to occur $R_e(h_{ie}) = R_e(Z_{11})$ must be less than or equal to

$$R_e(h_{ie}) \leq \frac{1+\beta}{\omega_o^2 C_1 C_2} - \frac{L}{C_1} \tag{5-34}$$

If R becomes too large, Eq. (5-32) cannot be satisfied and oscillations will stop. In general, it is advantageous to have

$$X_{C_1} X_{C_2} = \frac{1}{\omega^2 C_1 C_2} \tag{5-35}$$

with $X \triangleq 1/\omega c$ as large as possible, since R can be large. However, if C_1 and C_2 are too small (large and X_{C_1} and X_{C_2}), the input and output capacitances of the transistor, which shunt C_1 and C_2, respectively, become important. A good, stable design will always have C_1 and C_2 much larger than the transistor capacitances they shunt.

Example 2. In Example 1, will the circuit still oscillate if the inductor now has a $Q_u = 100$? If the transistor input capacitance is 5 pF, what effect will this have on the system?

Solution: In Example 1, $X_L = 17\ \Omega$, $C_1 = 50$ pF, and $C_2 = 500$ pF. Since $C_1 = 50$ pF, adding 5 pF in parallel will change the equivalent C to 55 pF. As the inductor $Q_u = 100$, the equivalent resistance R in series with the lossless inductor is

$$R = \frac{17}{100} = 0.17\ \Omega$$

The new resonant frequency can be determined from Eqs. (5-32) and (5-33):

$$C_1' = \frac{C_1}{1 + R/h_{ie}} = \frac{55}{1 + (0.17/280)} \approx \frac{55}{1.0006} = 54.96 \text{ pF}$$

and

$$f_o = \frac{1}{2\pi L[C_1' C_2/(C_1' + C_2)]^{1/2}} \cong 191.56 \text{ MHz}$$

The effect of the finite inductor Q causes a negligible change in the oscillating frequency compared to the effect of the transistor input capacitance, which reduces the resonant frequency 4.2%. Because the large-signal beta, β_{OSC}, is 10, there is enough loop gain to maintain oscillation.

Two-Port Oscillator. Although Eqs. (5-25) and (5-26) can be used to determine the exact expressions for oscillation, they are often difficult to use and add little insight into the design process. An alternative interpretation, although not as accurate, will now be presented. It is based on the fact that an ideal tuned circuit (infinite Q), once excited, will oscillate infinitely because there is no resistance element present to dissipate the energy. In the actual case where the inductor Q is finite, the oscillations die out because energy is dissipated in the resistance. It is the function of the amplifier to maintain oscillations by supplying an amount of energy equal to that dissipated. This source of energy can be interpreted as a negative resistor in series with the tuned circuit. If the total resistance is positive, the oscillations will die out, while the oscillation amplitude will increase if the total resistance is negative. To maintain oscillations, the two resistors must be of equal magnitude. To see how a negative resistance is realized, the input impedance of the circuit in Figure 5-13 will be derived.

If h_{oe} is sufficiently small ($h_{oe} << 1/R_L$), the equivalent circuit is as shown in Figure 5-13. The steady-state loop equations are

$$V_{\text{in}} = I_{\text{in}}(X_{C_1} + X_{C_2}) - I_b(X_{C_1} - \beta X_{C_2}) \tag{5-36}$$

$$0 = -I_{\text{in}}(X_{C_1}) + I_b(X_{C_1} + h_{ie}) \tag{5-37}$$

After I_b is eliminated from these two equations, Z_{in} is obtained as

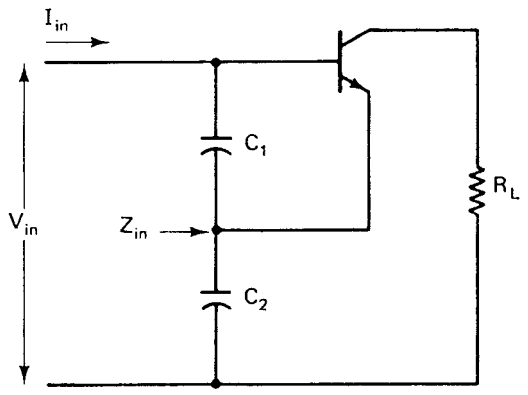

Figure 5-13 Calculation of input impedance of the negative-resistance oscillator.

$$Z_{\text{in}} = \frac{V_{\text{in}}}{I_{\text{in}}} = \frac{(1+\beta)X_{C_1}X_{C_2} + h_{ie}(X_{C_1} + X_{C_2})}{X_{C_1} + h_{ie}} \tag{5-38}$$

If $X_{C_1} << h_{ie}$, the input impedance is approximately equal to

$$Z_{\text{in}} \approx \frac{1+\beta}{h_{ie}} X_{C_1}X_{C_2} + (X_{C_1} + X_{C_2}) \tag{5-39}$$

$$Z_{\text{in}} \approx \frac{-g_m}{\omega^2 C_1 C_2} + \frac{1}{j\omega[C_1C_2/(C_1 + C_2)]} \tag{5-40}$$

That is, the input impedance of the circuit shown in Figure 5-14 is a negative resistor,

$$R = \frac{-g_m}{\omega^2 C_1 C_2} \tag{5-41}$$

in series with a capacitor,

$$C_{\text{in}} = \frac{C_1 C_2}{C_1 + C_2} \tag{5-42}$$

which is the series combination of the two capacitors.

With an inductor L (with the series resistance R_S) connected across the input, it is clear that the condition for sustained oscillation is

$$R_S = \frac{g_m}{\omega^2 C_1 C_2} \tag{5-43}$$

and the frequency of oscillation is

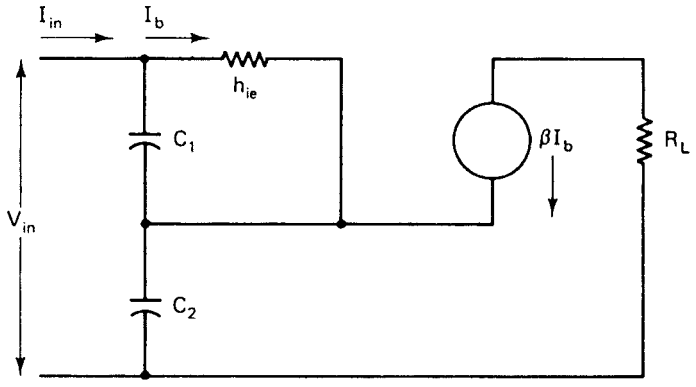

Figure 5-14 Equivalent small-signal circuit of Figure 5-13.

$$f_o = \frac{1}{2\pi\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{5-44}$$

This interpretation of the oscillator readily provides several guidelines that can be used in the design. First, C_1 should be as large as possible so that

$$X_{C_1} << h_{ie} \tag{5-45}$$

and C_2 is to be large so that

$$X_{C_2} << \frac{1}{h_{oe}} \tag{5-46}$$

When these two capacitors are large, the transistor base-to-emitter and collector-to-emitter capacitances will have a negligible effect on the circuit's performance. However, Eq. (5-43) limits the maximum value of the capacitances since

$$r \leq \frac{g_m}{\omega^2 C_1 C_2} \leq \frac{G}{\omega^2 C_1 C_2} \tag{5-47}$$

where G is the maximum value of g_m. For a given product of C_1 and C_2, the series capacitance is at maximum when $C_1 = C_2 = C_m$. Thus Eq. (5-47) can be written

$$\frac{1}{\omega C_m} > \sqrt{\frac{r}{G}} \tag{5-48}$$

This equation is important in that it shows that for oscillations to be maintained, the minimum permissible reactance $1/\omega C_m$ is a function of the resistance of the inductor and the transistor's mutual conductance, g_m.

An oscillator circuit known as the *Clapp circuit* or *Clapp–Gouriet circuit* is shown in Figure 5-15. This oscillator is equivalent to the one just discussed, but it has the practical advantage of being able to provide another degree of design freedom by making C_o much smaller than C_1 and C_2.

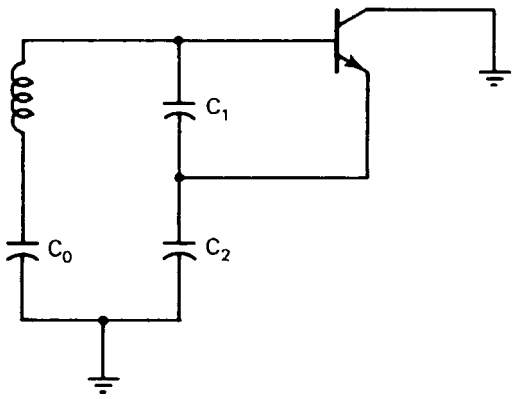

Figure 5-15 Circuit of a Clapp oscillator.

It is possible to use C_1 and C_2 to satisfy the condition of Eq. (5-47) and then adjust C_o for the desired frequency of oscillation ω_o, which is determined from

$$\omega_o L - \frac{1}{\omega_o C_o} - \frac{1}{\omega_o C_1} - \frac{1}{\omega_o C_2} = 0 \tag{5-49}$$

Amplitude Stability. Linearized analysis of the oscillator is convenient for determining the frequency but not the amplitude of the oscillation. The Nyquist stability criterion defines the frequency of oscillation as the frequency at which the loop phase shift is 360°, but it says nothing about the oscillation amplitude. If no provisions are taken to control the amplitude, it is susceptible to appreciable drift. Two frequently used methods for controlling the amplitude are operating the transistor in the nonlinear region or using a second stage for amplitude limiting. For the single-stage oscillator, amplitude limiting is accomplished by designing an unstable oscillator; that is, the loop gain is made greater than 1 at the frequency at which the phase shift is 180°. As the amplitude increases, the β of the transistor decreases, causing the loop gain to decrease until the amplitude stabilizes. This is a self-limiting oscillator. There are nonlinear analysis techniques predicting the amplitude of oscillation, but their results are approximate except in idealized cases, forcing the designer to resort to an empirical approach.

An example of a two-stage emitter-coupled oscillator is shown in Figure 5-16. In this circuit, amplitude stabilization occurs as a result of current limiting in the second stage. This circuit has the additional advantage that it has output terminals that are isolated from the feedback path. The emitter signal of Q_2, having a rich harmonic content, is normally used as output. Harmonics of the fundamental frequency can be extracted at the emitter of Q_2 by using an appropriately tuned circuit. Note that the collector of Q_2 is isolated from the feedback path.

Phase Stability. An oscillator has a frequency or phase stability that can be considered in two separate parts. First, there is *long-term* stability, in which the frequency changes over a period of minutes, hours, days, weeks, or even years. This frequency stability is normally limited by the circuit components' temperature coefficients and aging rates. The other part,

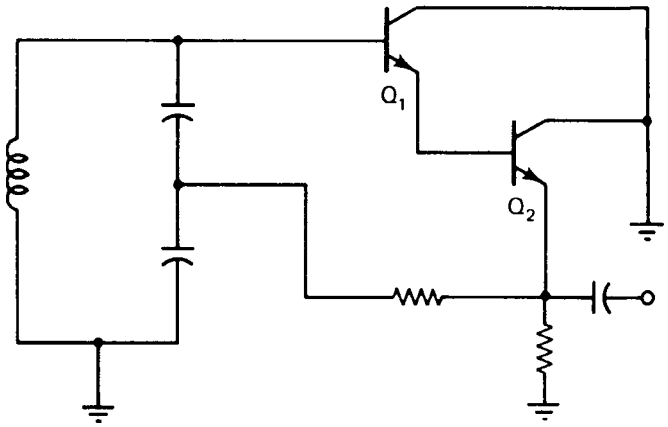

Figure 5-16 Two-stage, emitter-coupled oscillator.

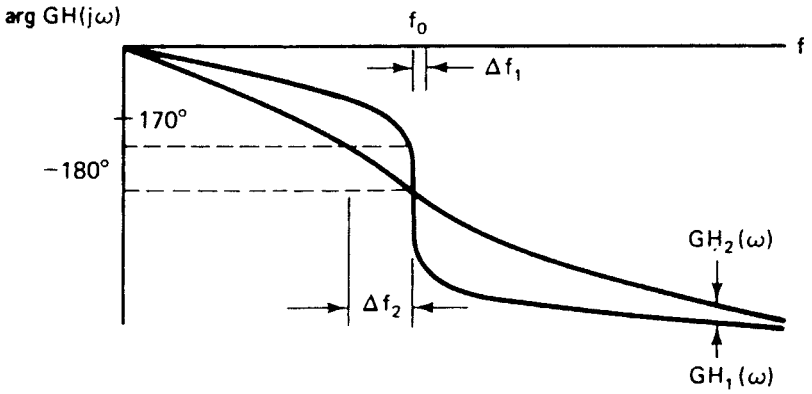

Figure 5-17 Phase plot of two open-loop systems with different resonator *Q* values.

short-term frequency stability, is measured in terms of seconds. One form of short-term instability is due to changes in phase of the system; here the term *phase stability* is used synonymously with frequency stability. It refers to how the frequency of oscillation reacts to small changes in phase shift of the open-loop system. It can be assumed that the system with the largest rate of change of phase versus frequency $d\phi/df$ will be the most stable in terms of frequency stability. Figure 5-17 shows the phase plots of two open-loop systems used in oscillators. At the system crossover frequency, the phase shift is −180°. If some external influence causes a shift in phase—say, it adds 10° of phase lag—the frequency will change until the total phase shift is again 0°. In this case, the frequency will decrease to the point where the open-loop phase shift is 170°. Figure 5-17 shows that Δf_2, the change in frequency associated with the 10° change in phase of GH_2, is greater than the change in frequency Δf_1, associated with the open-loop system GH_1, whose phase is changing more rapidly near the open-loop crossover frequency.

This qualitative discussion illustrates that $d\phi/df$ at $f = f_o$ is a measure of an oscillator's phase stability. It provides a good means of quantitatively comparing the phase stability of two oscillators. Consider the simple parallel tuned circuit shown in Figure 5-18.

For this circuit, the two-port is

$$\frac{V_o(j\omega)}{I(j\omega)} = \frac{R}{1 + jQ[(\omega/\omega_o) - (\omega_o/\omega)]} \tag{5-50}$$

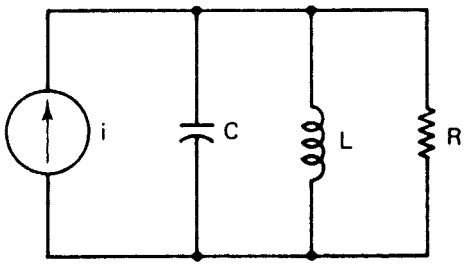

Figure 5-18 Parallel tuned circuit for phase-shift analysis.

where

$$\omega_o = \frac{1}{\sqrt{LC}} \quad \text{and} \quad Q = \frac{R}{\omega_o L} \tag{5-51}$$

The circuit phase shift is

$$\arg \frac{V_o}{I} = \theta = \tan^{-1} Q\left(\frac{\omega}{\omega_o} - \frac{\omega_o}{\omega}\right) \tag{5-52}$$

and

$$\frac{d\theta}{d\omega} = \frac{1/Q}{1/Q^2 + [(\omega^2 - \omega_o^2)/\omega_o\omega]^2} \frac{\omega^2 + \omega_o^2}{(\omega_o\omega)^2} \tag{5-53}$$

At the resonant frequency ω_o,

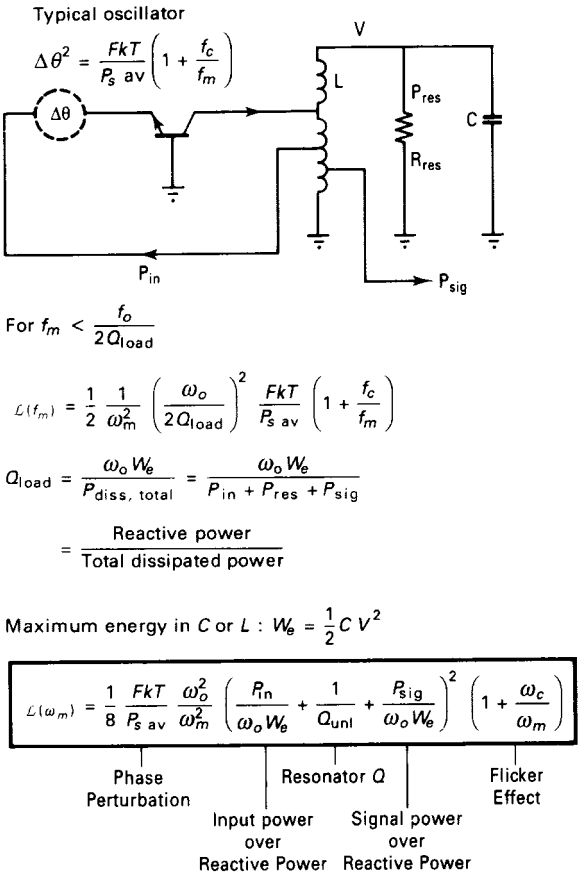

Figure 5-19 Diagram for a feedback oscillator illustrating the principles involved, and showing the key components considered in the phase noise calculation and its contribution.

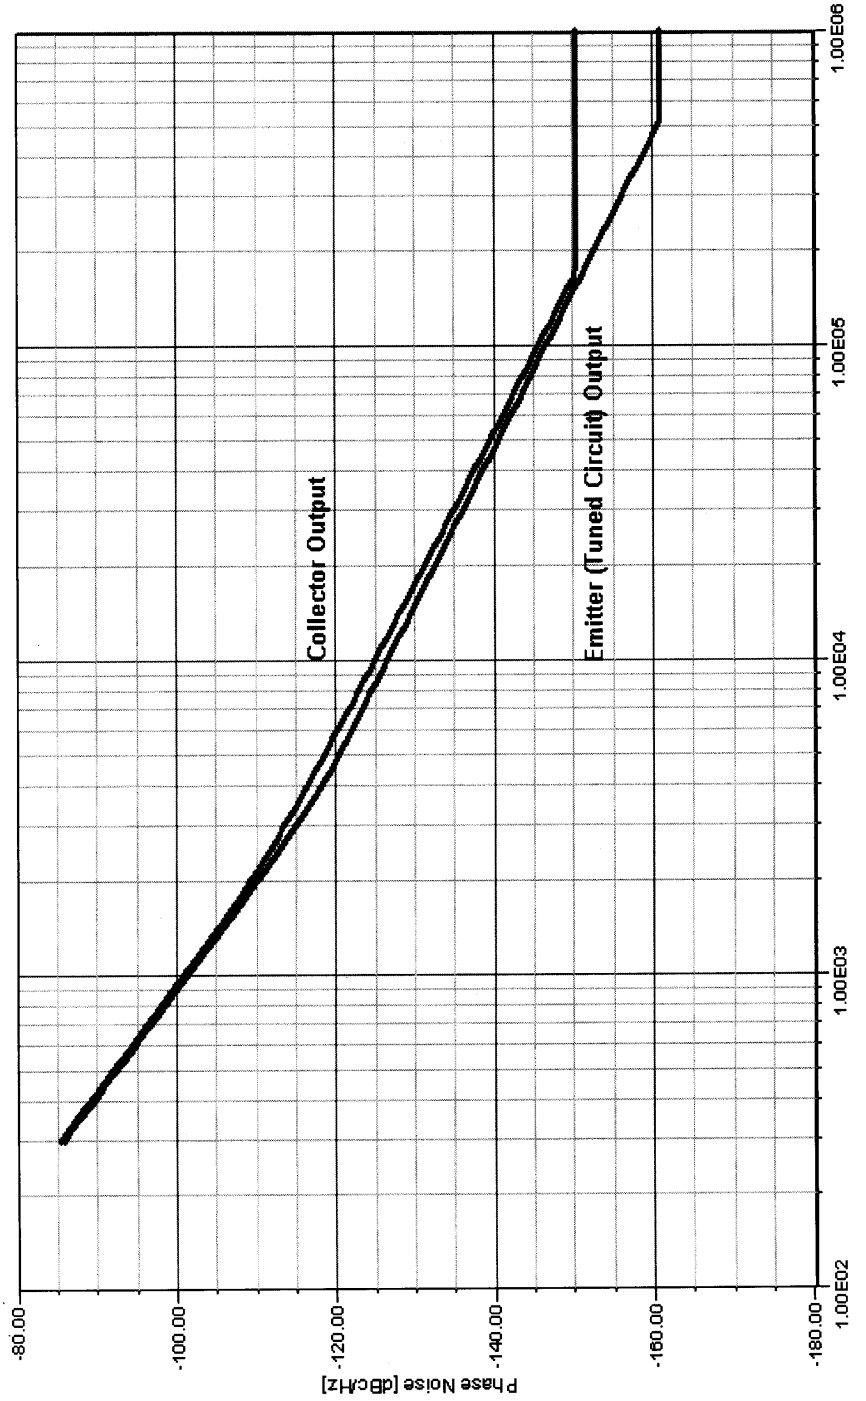

Figure 5-20 Phase noise with oscillator output taken from collector (upper trace) versus emitter (lower trace) of a BJT oscillator.

$$\left.\frac{dQ}{d\omega}\right|_{\omega=\omega_o} = \frac{2Q}{\omega_o} \tag{5-54}$$

The frequency stability factor S_F is defined as the change in phase $d\phi/d\omega$ divided by the normalized change in frequency $\Delta\omega/\omega_o$. That is,

$$S_F = 2Q \tag{5-55}$$

S_F is a measure of the short-term stability of an oscillator. Equation (5-54) indicates that the higher the circuit Q, the higher the stability factor. This is one reason for using high-Q circuits in oscillator circuits. Another reason is the ability of the tuned circuit to filter out undesired harmonics and noise.

The two oscillator types shown so far can be considered two-port oscillators because one port is responsible for oscillation and the other port supplies the output power. This type of output supposedly has better isolation (although this is not true at higher frequencies) but has a higher noise floor. A better way of extracting energy is shown in Figure 5-19.

These types of oscillators are essentially what is referred to as *two-port* oscillators. The name comes from the fact that the oscillating device has two ports, with the output energy taken from the output port, typically the collector or drain, while the tuned circuit is at the input port. For years, it was widely held that this type of design provided better isolation between the tuned circuit and termination; unfortunately, because of the Miller effect, this is not true. At the higher frequencies, changes in output-port loading affect the input port, resulting in *pulling*, a detuning effect that increases with frequency. In addition, taking the output from the collector or the drain results in a poorer signal-to-noise ratio than that achievable by extracting energy from the tuned circuit itself. The only real advantages the collector output provides are more power and higher efficiency, but definitely at the expense of phase noise, which is often referred to as *SSB phase noise* because it is expressed in terms of the decibel ratio of the noise power in a single (the upper or lower) noise sideband, in a 1-Hz bandwidth centered at a specified frequency offset from the oscillator carrier, to the carrier power. Figure 5-20 compares the phase noise of an oscillator with the energy taken off the collector and the tuned circuit; the difference is highly visible.

5-4 OSCILLATOR CIRCUITS

5-4-1 Hartley

Figure 5-21 shows the Hartley oscillator configuration, in which feedback is obtained by tapping the resonator. In practice, the resonator can consist of a single tapped inductor or two separate, magnetically uncoupled inductors, with feedback obtained at their junction.

5-4-2 Colpitts

Figure 5-22 shows the Colpitts oscillator configuration, in which feedback is obtained via a capacitive voltage divider.

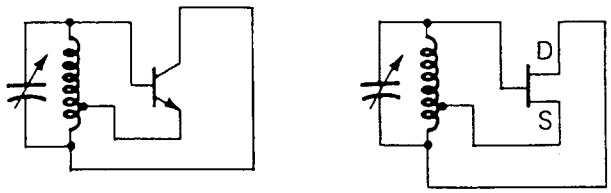

Figure 5-21 Hartley oscillator.

5-4-3 Clapp–Gouriet

Figure 5-23 shows the Clapp–Gouriet oscillator. Like the Colpitts, the Clapp–Gouriet obtains its feedback via a capacitive voltage divider; unlike the Colpitts, an additional capacitor series-tunes the resonator. The Pierce oscillator, a configuration used only with crystals, is a rotation of the Clapp–Gouriet oscillator in which the emitter is at RF ground.

5-5 DESIGN OF RF OSCILLATORS

5-5-1 General Thoughts on Transistor Oscillators

An estimate of the noise performance of an oscillator is

$$\mathcal{L}(\omega_m) = \frac{1}{8}\frac{FkT}{P_{s,\text{av}}}\frac{\omega_0^2}{\omega_m^2}\left(\frac{P_{\text{in}}}{\omega_0 W_e} + \frac{1}{Q_{\text{unl}}} + \frac{P_{\text{sig}}}{\omega_0 W_e}\right)^2\left(1 + \frac{\omega_c}{\omega_m}\right) \tag{5-56}$$

Phase perturbation

Resonator Q

Flicker effect

Input power/Reactive power ratio

Signal power/Reactive power ratio

We just state this here without presenting oscillator noise theory itself. (Also see Figure 5-19.) This equation is based on work done by Dieter Scherer of Hewlett-Packard about 1978. He was the first to introduce the flicker effect to the Leeson equation by adding the AM-to-PM

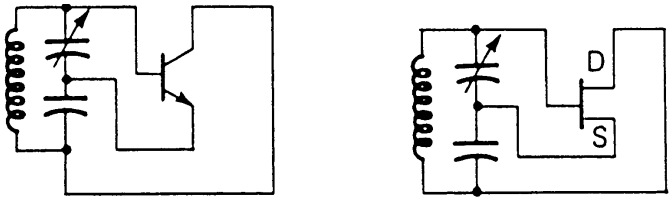

Figure 5-22 Colpitts oscillator.

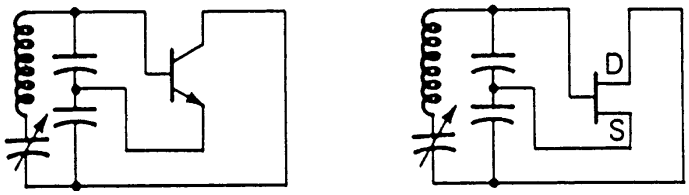

Figure 5-23 Clapp–Gouriet oscillator.

conversion effect, which is caused by the nonlinear capacitance of the active devices. This equation must be further expanded:

$$\pounds(f_m) = 10 \log\left\{\left[1 + \frac{f_0^2}{(2f_m Q_{\text{load}})^2}\right]\left(1 + \frac{f_c}{f_m}\right)\frac{FkT}{2P_{\text{sav}}} + \frac{2kTRK_0^2}{f_m^2}\right\} \tag{5-57}$$

where $\pounds(f_m)$ = ratio of sideband power in 1-Hz bandwidth at f_m to total power in dB
f_m = frequency offset
f_0 = center frequency
f_c = flicker frequency
Q_{load} = loaded Q of the tuned circuit
F = noise factor
$kT = 4.1 \times 10^{-21}$ at 300 K (room temperature)
P_{sav} = average power at oscillator output
R = equivalent noise resistance of tuning diode (typically 200 Ω to 10 kΩ)
K = oscillator voltage gain

The following table (from Motorola) shows the flicker corner frequency f_C as a function if I_C for a typical small-signal microwave BJT. $I_{C(\text{max})}$ of this transistor is about 10 mA.

I_C (mA)	f_C (kHz)
0.25	1
0.5	2.74
1	4.3
2	6.27
5	9.3

Note that f_C, which is defined by AF and KF in the SPICE model, increases with I_C. This gives us a clue about how f_C changes when a transistor oscillates. As a result of the bias-point shift that occurs during oscillation (see Example 1 of Section 5-3-1), an oscillating BJT's average I_C is higher than its small-signal I_C. KF is therefore higher for a given BJT operating as an oscillator than for the same transistor operating as a small-signal amplifier. This must be kept in mind when considering published f_C data, which are usually determined under small-signal conditions without being qualified as such. Determining a transistor's oscillating f_C is best done through measurement: Operate the device as a high-Q UHF oscillator (we

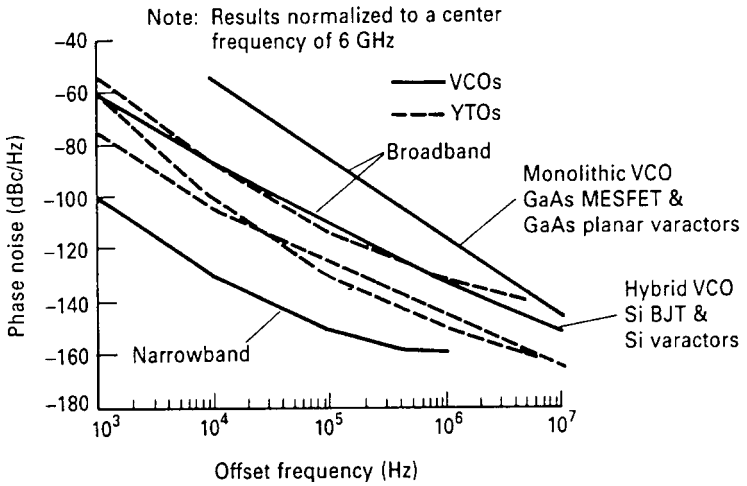

Figure 5-24 Phase noise of oscillators using different semiconductors and resonators.

suggest using a ceramic-resonator-based tank in the vicinity of 1 GHz), and measure its close-in (10 Hz to 10 kHz) phase noise versus offset from the carrier. f_C will correspond to a slight decrease in the slope of the phase noise versus offset curve. Generally, f_C varies with device type as follows: silicon JFETs, 50 Hz and higher; microwave RF BJTs, 1–10 kHz (as above); MOSFETs, 10–100 kHz; and GaAsFETs, 10–100 MHz. Figure 5-24 shows the phase noise of oscillators using different semiconductors and resonators.

Equation (5-57) is based on Rohde et al. [2]. The additional term introduces a distinction between a conventional oscillator and a VCO. Whether the voltage- or current-dependent capacitance is internal or external makes no difference; it simply affects the frequency.

For a more complete expression for a resonator oscillator's phase noise spectrum we can write

$$s_\phi(f_m) = \frac{\alpha_R F_0^4 + \alpha_E (F_0/2Q_L)^2}{f_m^3} + \frac{(2GFkT/P_0)\,(F_0/2Q_L)^2}{f_m^2} + \frac{2\alpha_R Q_L F_0^3}{f_m^2} + \frac{\alpha_E}{f_m} + \frac{2GFkT}{P_0} \tag{5-58}$$

where G = compressed power gain of the loop amplifier
F = noise factor of the loop amplifier
k = Boltzmann's constant
T = temperature in kelvins

P_0 = carrier power level (in watts) at the output of the loop amplifier
F_0 = carrier frequency in hertz
f_m = carrier offset frequency in hertz
$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop
α_R, α_E = flicker-noise constants for the resonator and loop amplifier, respectively.

In frequency synthesizers, we have no use for *LC* oscillators that do not include a tuning diode or diodes, but it may still be of interest to analyze the low-noise, fixed-tuned *LC* oscillator first and later make both elements, inductor and capacitor, variable.

Later, we will show the performance changes if we utilize the two possible ways of getting coarse and fine tuning in oscillators:

1. Use of tuning diodes.
2. Use of switching diodes.

We will spend some time looking at the effects that switching and tuning diodes have in a circuit because they will ultimately influence the noise performance more strongly than the transistor itself.

The reason is that the noise generated in tuning diodes will be superimposed on the noise generated in the circuit, while switching diodes have losses that cause a reduction of circuit *Q*. The selection of the proper tuning and switching diodes is important, as is the proper way of connecting them. As both types are modifications of the basic *LC* oscillator, we start with the *LC* oscillator itself.

Early signal generators as were offered by several companies (namely, Rohde & Schwarz, Hewlett-Packard, Boonton Electronics, or Marconi), if they are not synthesized, use an air-dielectric variable capacitor or, as in the case of one particular Hewlett-Packard generator, the Model HP8640, a tuned cavity.

Tuning here is accomplished by changing the value of an air-dielectric variable capacitor or changing the mechanical length of a quarter-wave resonator.

Using the equations shown previously, it is fairly easy to calculate the performance of oscillators and understand how they work, but this does not necessarily optimize their design. For *LC* oscillator applications in which noise performance is crucial, the oscillator shown in Figure 5-25, used in the famous Rohde & Schwarz SMDU, is the state of the art. Its noise performance is equivalent to the noise found in the cavity-tuned oscillator used in Hewlett-Packard's popular HP8640 signal generator, and because of the unique way a tuning diode is coupled to the circuit, its modulation capabilities are substantially superior to any of the signal generators currently offered. To develop such a circuit from design equations is not possible. This circuit is the result of many years of experience and research and looks fairly simple. The grounded-gate FET circuit provides the best performance because it fulfills the important requirements of Eq. (5-56).

The tuned circuit is not connected directly to the drain, but the drain is put on a tap of the oscillator section. Therefore, the actual voltage across the tuning capacitor is higher than the supply voltage, and thus the energy stored in the capacitor is much higher than in a circuit connected between the gate electrode and ground, as it is in a normal Colpitts oscillator. In addition, the high output impedance of the FET does not load the circuit, which also provides a reduced noise contribution. Since this oscillator is optimized for best frequency-modulation

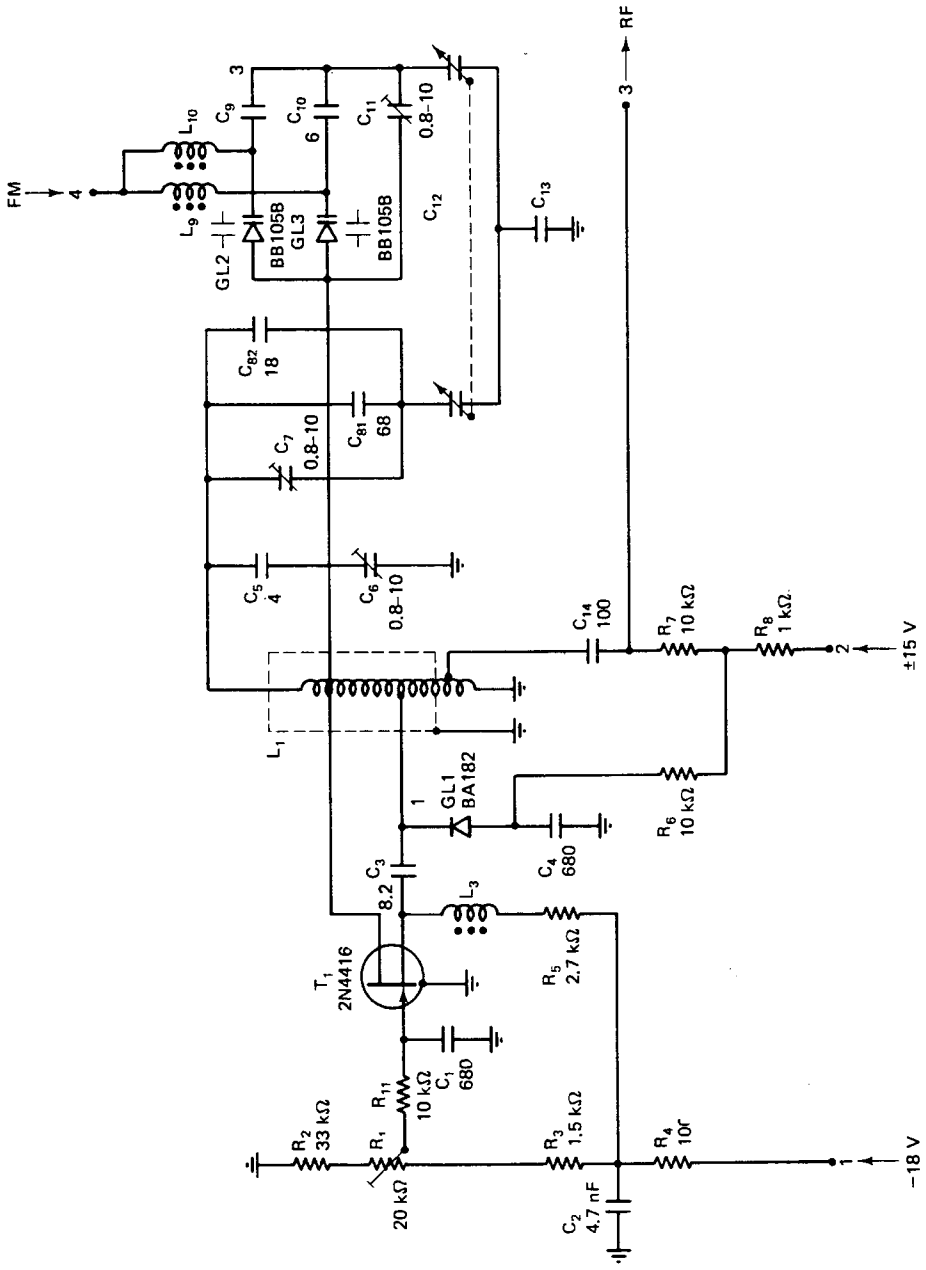

Figure 5-25 A 118–198-MHz oscillator from the Rohde & Schwarz SMDU signal generator.

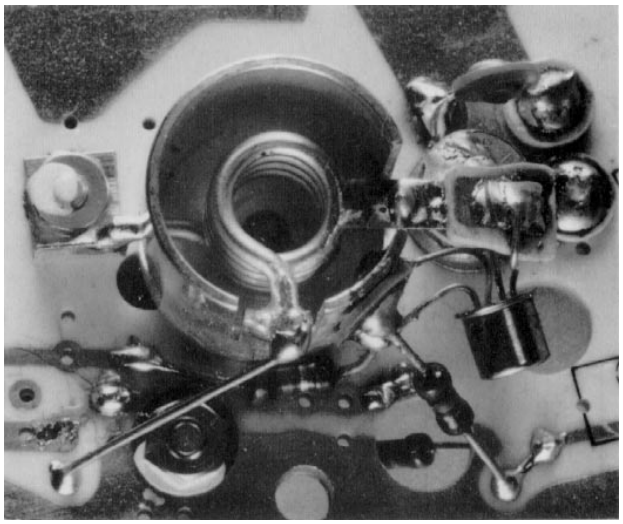

Figure 5-26 Photograph of the helical-resonator system from the Rohde & Schwarz SMDU signal generator.

performance in the FM frequency range, it becomes apparent that it fits the requirements of low-distortion stereo modulation.

For extremely critical blocking measurements in the 2-m region (140–160 MHz), the noise specification at 20 kHz off the carrier is of high importance, while the peak modulation typically does not exceed 5 kHz. Figure 5-25 shows the schematic of the oscillator section optimized for this frequency range.

Because of f_T limitations, it has been found experimentally that these *LC* oscillators, if based on silicon JFETs, should not be used above about 500 MHz; rather, a doubler stage should be employed. Analyzing the signal generators currently on the market, we find that their highest base band typically ranges from 200 to 500 MHz, with frequency doubling used to 1000 MHz. As can be seen in Figure 5-26, the mechanical layout of such an oscillator is extremely compact.

5-5-2 Two-Port Microwave/RF Oscillator Design

A common method for designing oscillators is to resonate the input port with a passive high-*Q* circuit at the desired frequency of resonance. It will be shown that if this is achieved with a load connected on the output port, the transistor is oscillating at both ports and is thus delivering power to the load port. The oscillator may be considered a two-port structure, with M_3 being the lossless resonating port and M_4 providing lossless matching such that all the external RF power is delivered to the load. See Figure 5-27. The resonating network has been described. Nominally, only parasitic resistance is present at the resonating port, since a high-*Q* resonance is desirable for minimizing oscillator noise. It is possible to have loads at both the input and output ports if such an application occurs, since the oscillator is oscillating at both ports simultaneously.

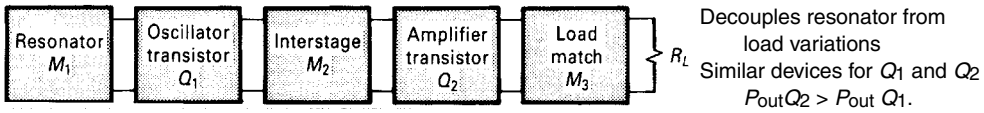

Figure 5-27 Buffered oscillator design.

The simultaneous oscillation condition is proved as follows. Assume that the oscillation condition is satisfied at port 1:

$$1/S'_{11} = \Gamma_G \tag{5-59}$$

Thus,

$$S'_{11} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} = \frac{S_{11} - D\Gamma_L}{1 - S_{22}\Gamma_L} \tag{5-60}$$

$$\frac{1}{S'_{11}} = \frac{1 - S_{22}\Gamma_L}{S_{11} - D\Gamma_L} = \Gamma_G \tag{5-61}$$

By expanding Eq. (5-61), we find

$$\begin{gathered} \Gamma_G S_{11} - D\Gamma_L\Gamma_G = 1 - S_{22}\Gamma_L \\ \Gamma_L(S_{22} - D\Gamma_G) = 1 - S_{11}\Gamma_G \\ \Gamma_L = \frac{1 - S_{11}\Gamma_G}{S_{22} - D\Gamma_G} \end{gathered} \tag{5-62}$$

Thus,

$$S'_{22} = S_{22} + \frac{S_{12}S_{21}\Gamma_G}{1 - S_{11}\Gamma_G} \tag{5-63}$$

$$\frac{1}{S'_{22}} = \frac{1 - S_{11}\Gamma_G}{S_{22} - D\Gamma_G} \tag{5-64}$$

Comparing Eqs. (5-62) and (5-64), we find

$$1/S'_{22} = \Gamma_L \tag{5-65}$$

which means that the oscillation condition is also satisfied at port 2; this completes the proof. Thus, if either port is oscillating, the other port must be oscillating as well. A load may appear at either or both ports, but normally the load is in Γ_L, the output termination. This result can be generalized to an n-port oscillator by showing that the oscillator is simultaneously oscillating at each port:

$$\Gamma_1 S'_{11} = \Gamma_2 S'_{22} = \Gamma_3 S'_{33} = \cdots = \Gamma_n S'_{nn} \tag{5-66}$$

Before concluding this section on two-port oscillator design, the buffered oscillator shown in Figure 5-27 must be considered. This design approach is used to provide the following:

1. A reduction in load-pulling, which is the change in oscillator frequency when the load reflection coefficient changes.
2. A load impedance that is more suitable to wideband applications ($k < 1$).
3. A higher output power from a working design, although the higher output power can also be achieved by using a larger oscillator transistor.
4. This type of oscillator is not optimized for low phase noise. However, buffered oscillator designs are quite common in wideband YIG applications, where changes in the load impedance must not change the generator frequency.

Two-port oscillator design may be summarized as follows:

1. Select a transistor with sufficient gain and output-power capability for the frequency of operation. This may be based on oscillator datasheets, amplifier performance, or *S*-parameter calculation.
2. Select a topology that gives $k < 1$ at the operating frequency. Add feedback if $k < 1$ has not been achieved.
3. Select an output load-matching circuit that gives $|S'_{11}| > 1$ over the desired frequency range. In the simplest case, this could be a 50-Ω load.
4. Resonate the input port with a lossless termination so that $\Gamma_G S'_{11} = 1$. The value of S'_{22} will be greater than unity with the input properly terminated.

In all cases, the transistor delivers power to a load and the input of the transistor. Practical considerations of realizability and dc biasing will determine the best design.

For both bipolar and FET oscillators, a common topology is the common-base or common-gate, since a common-lead inductance can be used to raise S_{22} to a large value, usually greater than unity even with a 50-Ω generator resistor. However, it is not necessary for the transistor S_{22} to be greater than unity, since the 50-Ω generator is not present in the oscillator design. The requirement for oscillation is $k < 1$; then resonating the input with a lossless termination will ensure that $|S'_{11}| > 1$.

A simple example will clarify the design procedure. A common-base bipolar transistor (HP2001) was selected to design a fixed-tuned oscillator at 2 GHz. The common-base *S*-parameters and stability factors are given in Table 5-1.

Using the load circuit in Figure 5-28, we see that the reflection coefficients are

Table 5-1 *S* parameters and stability factors (V_{CE} = 15 V, I_C = 25 mA)

$L_B = 0$	$L_B = 0.5$ nH
$S_{11} = 0.94 \angle 174°$	$1.04 \angle 173°$
$S_{21} = 1.90 \angle -28°$	$2.00 \angle -30°$
$S_{12} = 0.013 \angle 98°$	$0.043 \angle 153°$
$S_{22} = 1.01 \angle -17°$	$1.05 \angle -18°$
$k = -0.09$	-0.83

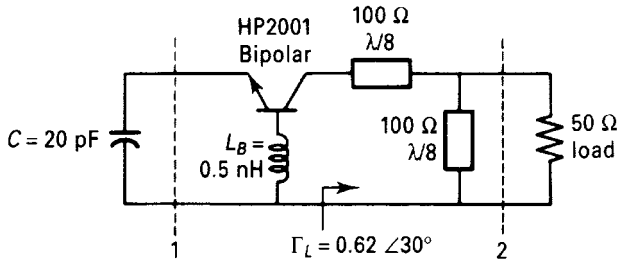

Figure 5-28 Oscillator example at 2 GHz.

$$\Gamma_L = 0.62\ \angle 30°$$

$$S'_{11} = 1.18\ \angle 173°$$

Thus, a resonating capacitance of G = 20 pF resonates the input port. In a YIG-tuned oscillator, this reactive element could be provided by the high-Q YIG element. For a dielectric-resonator oscillator (DRO), the puck would be placed to give $\Gamma_G \approx 1.0/\angle -173°$.

Another two-port design procedure is to resonate the Γ_G port and calculate S'_{22} until $|S'_{22}| > 1$, then design the load port to satisfy. This design procedure is summarized in Figure 5-29.

An example using this procedure at 4 GHz is given in Figure 5-30 using an AT41400 silicon bipolar chip in the common-base configuration with a convenient value of base and emitter

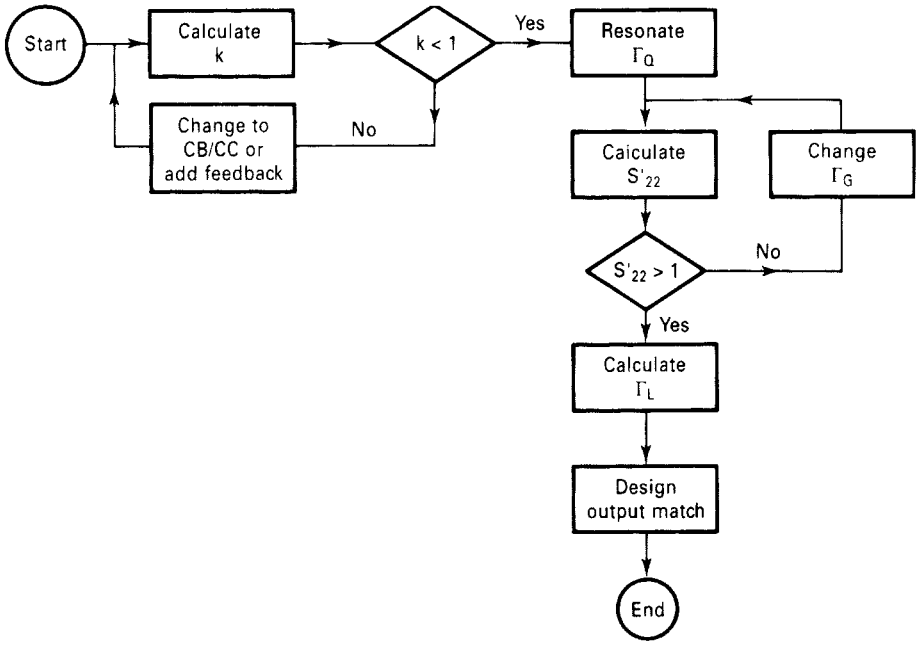

Figure 5-29 Oscillator design flowchart.

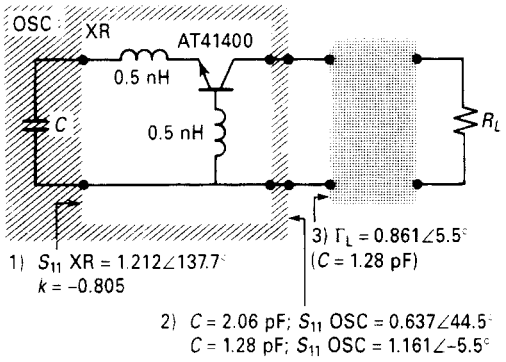

Figure 5-30 A 4-GHz lumped-resonator oscillator using the AT41400.

inductance of 0.5 nH. The feedback parameter is the base inductance, which can be varied if needed.

Since a lossless capacitor at 4 GHz of 2.06 pF gives $\Gamma_G = 1 - 0 \angle -137.7°$, this input termination is used to calculate S'_{22}, giving $S'_{22} = 0.637 \angle 44.5°$. This circuit will oscillate into any passive load. Varying the emitter capacitor about 20° on the Smith Chart to 1.28 pF gives $S'_{22} = 1.16 \angle -5.5°$, which will oscillate into a load of $\Gamma_L = 0.861 \angle 5.5°$. The completed lumped-element design is given in Figure 5-31.

5-5-3 Ceramic-Resonator Oscillators

An important application for a new class of resonators called ceramic resonators (CRs) has emerged for wireless applications. The CRs are similar to rigid coaxial cable, where the center conductor is connected at the end to the outside of the cable. These resonators are generally operating in quarter-wavelength mode and their characteristic impedance is approximately 10 Ω. Because their coaxial assemblies are made from a high-ε low-loss material with good silver plating throughout, the electromagnetic field is internally contained and therefore results in very little radiation. These resonators are therefore ideally suited for high-Q, high-density oscillators. The typical application for this resonator is VCOs ranging from not much more than 200 MHz up to about 3 or 4 GHz. At these high frequencies, the mechanical dimensions of the resonator become too tiny to offer any advantage. One of the

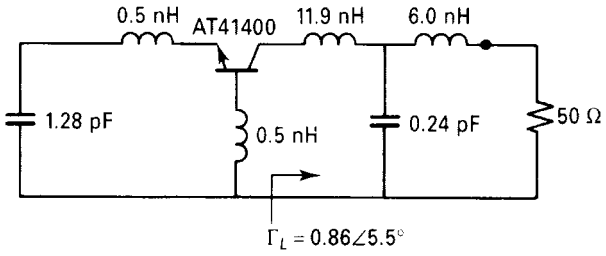

Figure 5-31 Completed lumped-resonator oscillator (LRO).

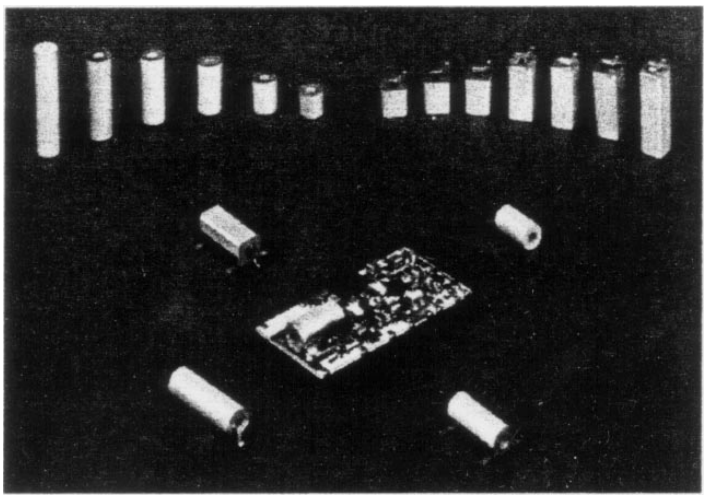

Figure 5-32 Ceramic resonators.

principal requirements is that the physical length is considerably larger than the diameter. If the frequency increases, this requirement can no longer be met.

Manufacturers supply ceramic resonators on a prefabricated basis. Figures 5-32 and 5-33 show the standard round/square packaging available and the typical dimensions for a ceramic resonator. Figure 5-34 shows a ceramic-resonator oscillator built on a ceramic substrate. The available material has a dielectric constant of 88 and is recommended for use in the 400–1500-MHz range. The next higher frequency range (800 MHz to 2.5 GHz) uses an ε of 38, while the top range (1–4.5 GHz) uses an ε of 21. Given the fact that ceramic resonators are prefabricated and have standard outside dimensions, the following quick calculation applies:

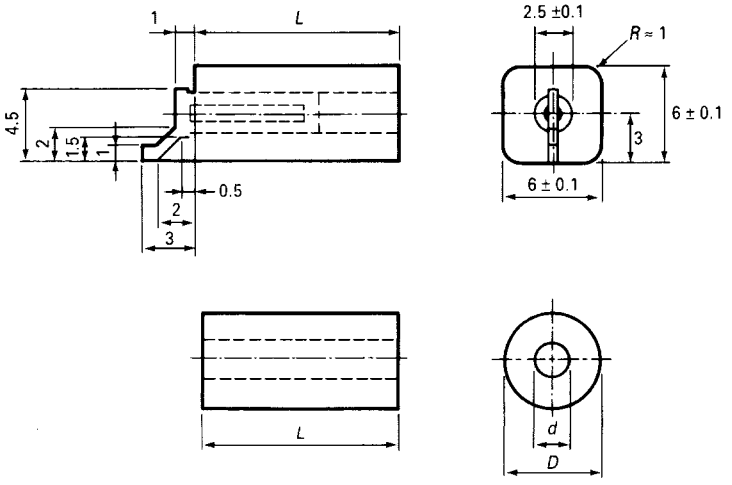

Figure 5-33 Standard round/square ceramic-resonator packaging and dimensions.

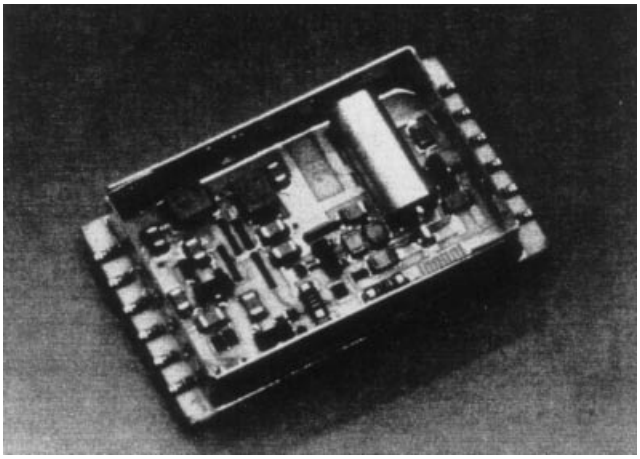

Figure 5-34 Modern ceramic-resonator oscillator for handheld cellular phones.

Relative dielectric constant of resonator material	$\varepsilon_r = 21$	$\varepsilon_r = 38$	$\varepsilon_r = 88$
Resonator length in millimeters	$l = \frac{16.6}{f}$	$l = \frac{12.6}{f}$	$l = \frac{8.2}{f}$
Temperature coefficient (ppm/°C)	10	6.5	8.5
Available temperature coefficients	–3 to +12	–3 to +12	–3 to +12
Typical resonator Q	800	500	400
Frequency range	1–4.5 GHz	800–2500 MHz	400–1500 MHz

Calculation of Equivalent Circuit. The equivalent parallel-resonant circuit afforded by a ceramic resonator has a resistance at resonance of

$$R_p = \frac{2(Z_0)^2}{R^* l} \tag{5-67}$$

where Z_0 = characteristic impedance of the resonator
l = mechanical length of the resonator
R^* = equivalent resistor due to metallization and other losses

As an example, one can calculate

$$C^* = \frac{2\pi\varepsilon_0\varepsilon_r}{\log_e(D/d)} = 55.61 \times 10^{-12}\,\frac{\varepsilon_r}{\log_e(D/d)} \tag{5-68}$$

and

$$L^* = \frac{\mu_r \mu_0}{2\pi} = \log_e\left(\frac{D}{d}\right) = 2 \times 10^{-7} \log_e\left(\frac{D}{d}\right) \tag{5-69}$$

$$Z_0 = 60\ \Omega \frac{1}{\sqrt{\varepsilon_r}} \log_e\left(\frac{D}{d}\right)$$

$$= 60 \frac{1}{\sqrt{88}} \log_e\left(\frac{6}{2.5}\right)$$

$$= 5.6\ \Omega \tag{5-70}$$

A practical example for $\varepsilon_r = 88$ and 450 MHz is

$$C_p = \frac{C^* l}{2} = 49.7\ \text{pF} \tag{5-71}$$

$$L_p = 8L^* l = 2.52\ \text{nH} \tag{5-72}$$

$$R_p = 2.5\ \text{k}\Omega \tag{5-73}$$

Figure 5-35 shows the schematic of a ceramic-resonator-based oscillator. Figures 5-36 and 5-37 show the simulated and measured phase noise of the oscillator.

By using ceramic-resonator-based oscillators in conjunction with miniature synthesizer chips, it is possible to build extremely small phase-locked-loop (PLL) systems for cellular telephone operation. Figure 5-38 shows one of the smallest currently available PLL-based synthesizers manufactured by Synergy Microwave Corporation. Because of the high-Q resonator, these types of oscillators exhibit extremely low phase noise. Values of better than –150 dBc/Hz at 1 MHz off the carrier are achievable. The ceramic resonator reduces the oscillator's sensitivity to microphonic effects and proximity effects caused by other components.

5-5-4 Using a Microstrip Inductor as the Oscillator Resonator*

A high-Q microstrip resonator [3–5] can be used to improve an oscillator's phase-noise performance. The following section, based on information in the Philips Semiconductors Application Note AN1777, describes the application of such a resonator in a BJT differential oscillator.

It can be seen from Eq. (5-56) that the phase noise is proportional to the term

$$\frac{1}{4Q_L^2} \tag{5-74}$$

This means that for any 10% increase in Q, we get something like 20% improvement in phase noise, which makes it most desirable to increase the Q. One way to reduce the loading of the

*Based on portions of the Philips Semiconductors/Signetics RF Communications Products Application Note AN1777, "Low-Voltage Front End Circuits: SA601, SA620," August 20, 1997. Used with permission.

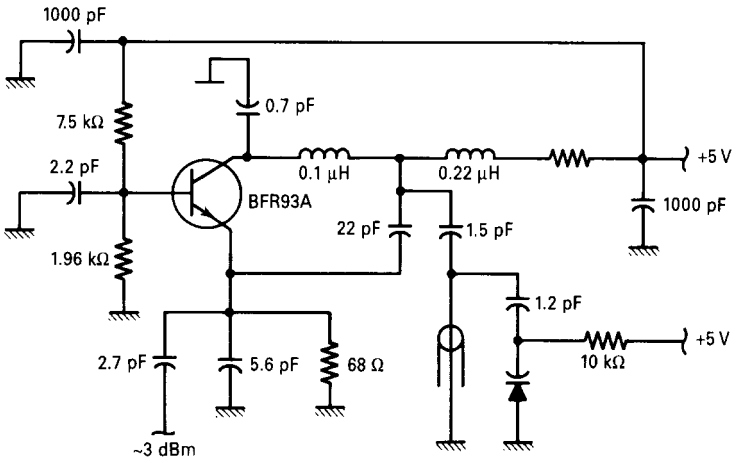

Figure 5-35 Schematic of a high-performance ceramic-resonator-based oscillator that can be used from 500 MHz to 2 GHz.

resonator is to tap the device down on the resonator. The underlying oscillator circuit is based on the differential type of oscillator found in ICs.

Increasing Loaded Q. Figure 5-39 shows the oscillator section of the Philips SA620 low-voltage front-end IC with a conventional second-order parallel-tuned tank circuit configured as the external resonator.

From the basic equations for parallel resonance, the resonator's loaded Q is given by

$$Q_L = R_P \left(\frac{C_T}{L_T} \right)^{1/2} \tag{5-75}$$

where

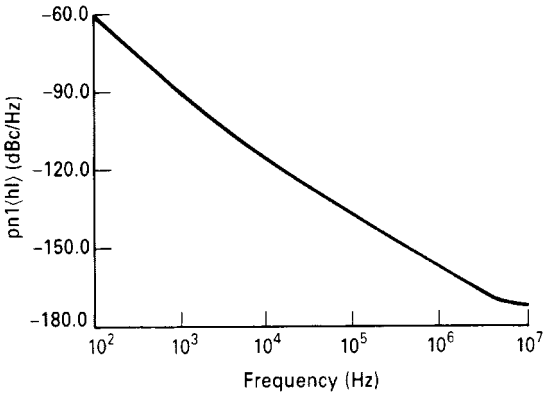

Figure 5-36 Simulated phase noise of an *npn* bipolar 1-GHz ceramic-resonator-based oscillator.

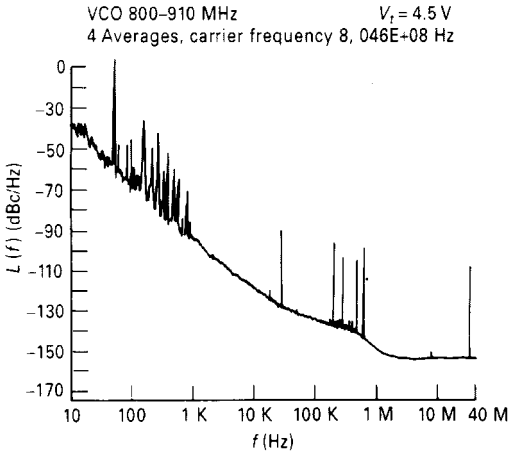

Figure 5-37 Measured phase noise of a ceramic-resonator-based oscillator.

$$R_P = R_T \| R_C = \left[\left(\frac{1}{R_T}\right) + \left(\frac{1}{R_C}\right)\right]^{-1} \tag{5-76}$$

represents the net shunt tank resistance appearing across the network at resonance. R_T represents losses in the inductance L_T and capacitance C_T (almost always dominated by inductor losses), and R_C is the active circuit's load impedance at resonance. Improving the quality of the tank components L_T and C_T (i.e., improving their Q) will increase R_T, but since R_C is low in the case of the SA620, the resulting increase in R_P is relatively small. We can

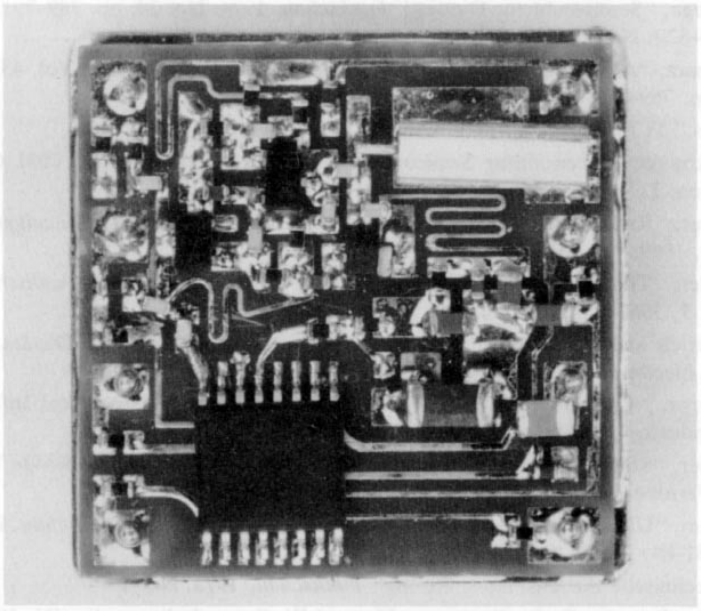

Figure 5-38 Miniature PLL-based synthesizer manufactured by Synergy Microwave Corporation.

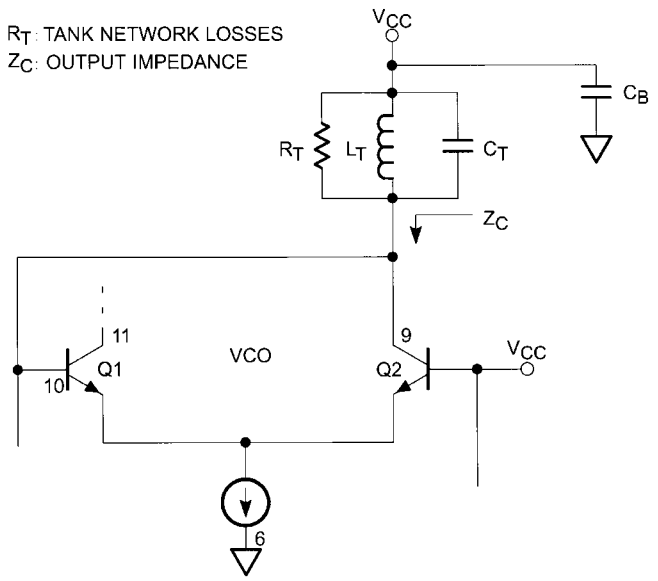

Figure 5-39 Oscillator portion of Philips SA620 front-end IC with external resonator.

increase R_P by decoupling Z_C from the tank circuit (note that R_C is the real part of Z_C at resonance). Decoupling this impedance by using either tapped-L or tapped-C tank configurations is possible. Inspection of the circuit shows that dc biasing is necessary for pins 9 and 10 (osc1 and osc2, respectively), so a tapped-C approach would require shunt-feeding these pins to V_{CC}. Thus, the most practical way is to employ a tapped-L network.

Figure 5-40 shows the basic tapped-L circuit. The effective multiplied shunt impedance at resonance across C_T is given by

$$\hat{R}_P = R_P\left[\left(\frac{L_{T2}}{L_{T1}}\right)+1\right]^{1/2} \tag{5-77}$$

with a corresponding increase in loaded Q:

$$Q_L = Q_L\left[\left(\frac{L_{T2}}{L_{T1}}\right)+1\right]^{1/2} \tag{5-78}$$

Feedback is caused by an RF voltage appearing across L_T, coupled through bypass capacitor C_B and its ground return to the cold end of the current source at pin 6. The significance of this path increases with frequency. At 900 MHz, it becomes very critical in obtaining stable oscillations and must be kept as short as possible. Attention to layout detail is pivotal here!

High-Q Microstrip Inductor. Realizing a stable tapped-L network using lumped surface-mount inductors is impractical due to their low unloaded Q and finite physical size. Another approach uses a high-Q short microstrip inductor. The conventional approach to microstrip resonators treats them as a length of transmission line terminated with a short that

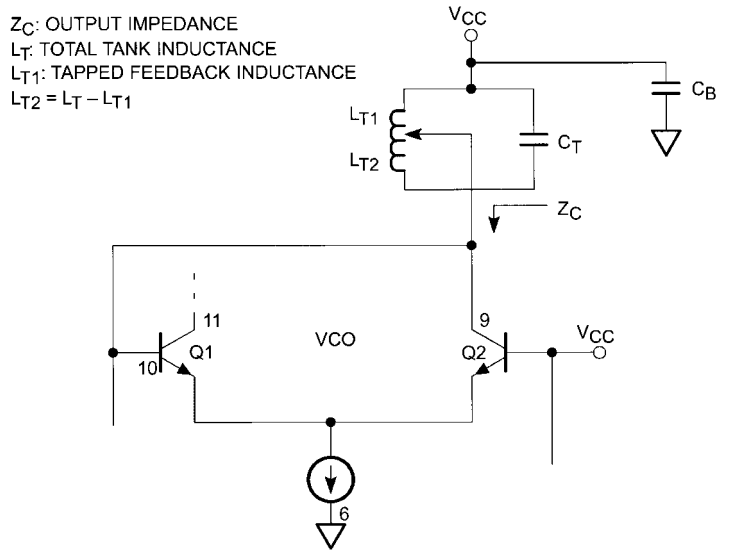

Figure 5-40 Oscillator portion of SA620 IC with tapped-microstrip resonator.

reflects back an inductance impedance that simulates a lumped inductor. The approach presented here deviates from this technique by specifically exploiting the very high unloaded Q attainable with short microstrip inductors, where we design for a large C/L ratio by making the microstrip a specific, but short, length. Resonance is achieved by replacing the short with whatever capacitance is needed for proper resonance. One equation for the inductance of a strip of metal having a length ℓ (mils) and width w (mils) is

$$L = [5.08\text{E} - 3]\,\ell\left[\ln\left(\frac{\ell}{w}\right) + 1.193\left(\frac{w}{\ell}\right)\right] \qquad \text{[3] (5-79)}$$

where L is in nH/mil. This technique results in a much shorter strip of metal for a given inductance. One intriguing property of microstrip inductors is that they are capable of very high unloaded Q values. An equation describing the quality factor for a "wide" microstrip is

$$Q_C = 0.63h[\sigma f_{\text{GHz}}]^{1/2} \qquad \text{[4] (5-80)}$$

where h is the dielectric thickness in centimeters, σ is the conductivity in S/m, and f is frequency in GHz. This equation predicts an unloaded Q exceeding 700 when silver-coated copper is used. Also, wide microstrip lines are defined as those whose strip width w to height h ratio is approximately greater than 1; that is, $w/h > 1$. The parallel capacitor formed by the metal strip over the ground plane should also be included and may be calculated by the classic formula and included in the total needed to resonate with the inductance result found from Eq. (5-79). This "strip" capacitance is given by

$$C_S = K\varepsilon_0\varepsilon_r\left(\frac{w\ell}{h}\right) \qquad \text{(5-81)}$$

where C_S is in farads, $\varepsilon_0 = 8.86\text{E} -12$ (F/cm) is the permittivity of free space, and ε_r is the relative dielectric constant of the substrate. A "fringe factor," K, is included to account for necessary fringing (estimated to be 2–15%). These equations are meant to provide insight into circuit behavior and should, therefore, be applied cautiously to specific applications.

UHF VCO Using the Tapped-Inductor Differential Oscillator at 900 MHz. The basic electrical circuit of this configuration is shown in Figure 5-41. Feedback occurs when sufficient RF voltage develops across the tap inductances L_{T1} and L_{T2} (due to tap 1 and tap 2, respectively); note that inductance is reckoned from the cold end of the tank at node A. Taps 1 and 2 should be as close as possible to pins 9 and 10, respectively. Also node A (cold end of tank) and node B (pin 6) must be as physically close together and exhibit as low an impedance as possible to discourage parasitic oscillations. This "inner loop," composed of L_{T2}, the inductance of connections between taps 1 and 2 and pins 9 and 10, respectively, and "stray" low-Q inductance between nodes A and B creates a parasitic loop that will support oscillation that no longer depends on the full tapped-L tank circuit. Oscillation based on this low-Q loop typically occurs well above 1.2 GHz and has been observed as high as 1.6 GHz, and exhibits very poor phase noise performance.

Another factor also affects this unwanted parasitic oscillation. As the full tank circuit's unloaded Q decreases, the circuit becomes conditionally stable and will eventually favor the parasitic loop exclusively. This occurs because the loaded Q of the tapped microstrip affects the magnitude of the RF voltage appearing across the entire tank. Thus, feedback at taps 1 and 2 is reduced as the Q decreases. This increases the likelihood of the parasitic inner loop controlling the oscillator, since its feedback voltage is largely independent of the microstrip tank Q.

Equation (5-80) shows that microstrip inductors are capable of very high unloaded Q values. This depends on a number of physical factors: frequency, dielectric thickness and

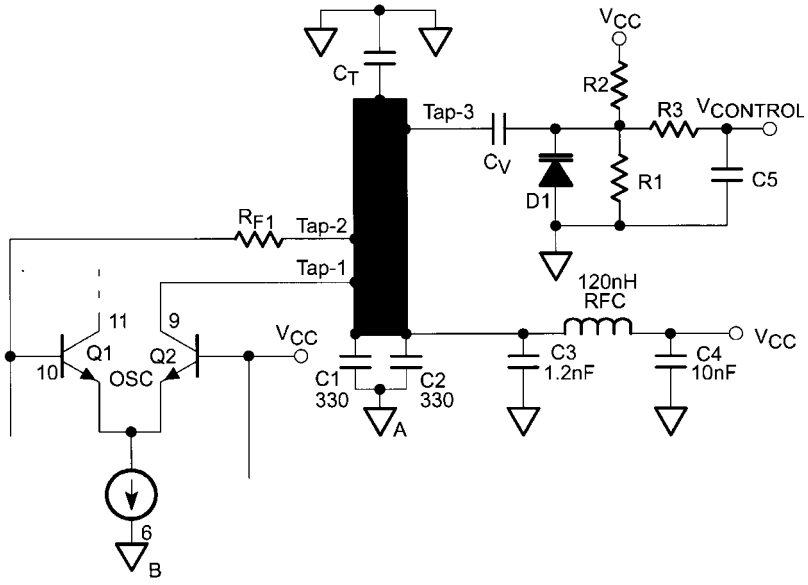

Figure 5-41 Differential oscillator with tapped-microstrip resonator.

quality, and the skin-depth conductance of the metal strip itself. For example, at 900 MHz, the unloaded Q of a silver-coated microstrip line is in the vicinity of 750. Coating the same line with lead (sloppy soldering can do it!) reduces the Q to less than 230. If the unloaded Q is too low, the loaded Q also drops. The circuit becomes conditionally stable and now may oscillate either at the higher parasitic-loop frequency or the desired lower frequency at which the entire microstrip tank resonates. Components should be connected by narrow traces closely connected to component leads to avoid soldering on the microstrip proper.

R_{F1} introduces necessary losses to control the inner-loop parasitic oscillation. Its size should be made as small as possible consistent with stability, startup, and good phase-noise performance. Since R_{F1} also decreases feedback, the oscillator's output falls as R_{F1} increases. Typically, experimental values from 4 to 30 Ω have proved sufficient.

Stability as a function of V_{CC} is a good way to assess conditional stability. Provided the microstrip tank has a high loaded Q, the oscillator's stability should be independent of V_{CC} down to less than 2.5 V or so. When loaded Q decreases sufficiently to favor the inner-loop parasitic, conditional stability will occur. This can readily be observed by increasing V_{CC} from about 1.0 V and noting whether the VCO frequency jumps back and forth unpredictably. Mixer and LO-port loading can also affect this condition and should be considered.

Dimensions for the microstrip resonator are based on several criteria. The strip must be "wide": Its width-to-height ratio must be on the order of 1 or greater. Minimum strip length seems to be about 200 mils for 62-mil-thick board. L/C ratios somewhere about 500 have yielded quite good results. Note that we usually specify the "L/C ratio" because it is always greater than 1, even though in a parallel-resonant circuit it appears in the Q equation as C/L. Thus, decreasing the "L/C ratio" by making the microstrip shorter helps the inductor's loaded Q, and the circuit's loaded Q_L, increase [see Eq. (5-75)]. However, the effect of the lower Q of C_T, even when using a high-Q surface-mount type, decreased the expected larger increase in the circuit's net loaded Q. Thus, the expected increase in Q_L may not be fully realizable. Assuming a 62-mil-thick board with FR5 dielectric, a strip 50 mils by 300 mils gave very good experimental results, where C_T was about 4.3 pF, with oscillation occurring from about 950 to 1000 MHz with various test boards. A shorter inductor designed to increase the C/L ratio requiring 7.5 pF experimentally resulted in only about 1–2-dB phase-noise improvement at 950 MHz. The reason for this is that as the microstrip inductor degenerates to a plain inductor, all of its advantages are lost.

Tap 1 may be anywhere between the cold end of the tank (where C_1 and C_2 are located) and tap 2. Tap 2 yields good results at about one-third the strip length. Making it too close to the cold end in an effort to increase Q_L will result in loss of control over the inner-loop parasitic. To keep Q_L as high as possible, C_T should be a high-Q surface-mount type. Differences greater than 5 dB in SSB phase noise have been observed between a generic NP0 surface-mount capacitor and a high-Q NP0 surface-mount capacitor.

Tap 3 can be at the end of the microstrip when C_T is connected. However, the tuning diode inevitably will cause a decrease in overall loaded Q, typically resulting in a phase-noise increase of as much as 5 dB. Moving it some distance down from the high end of the tank will decrease this effect and yield better results. A good starting point is about one-quarter down, or three-quarters of the length from the cold end of the tank. C_1 and C_2 are paralleled lower-value capacitors to yield a better low-impedance ground return to pin 6 (node B) since relatively large RF currents flow through them. Note that as Q_L increases, the peak circulating RF current will also increase, as will the RF voltage at the hot end of the microstrip. At 900 MHz, good results have been obtained when both are about 300 pF. The RF choke was chosen to be approximately series-resonant around 900 MHz, and constitutes the series feed path

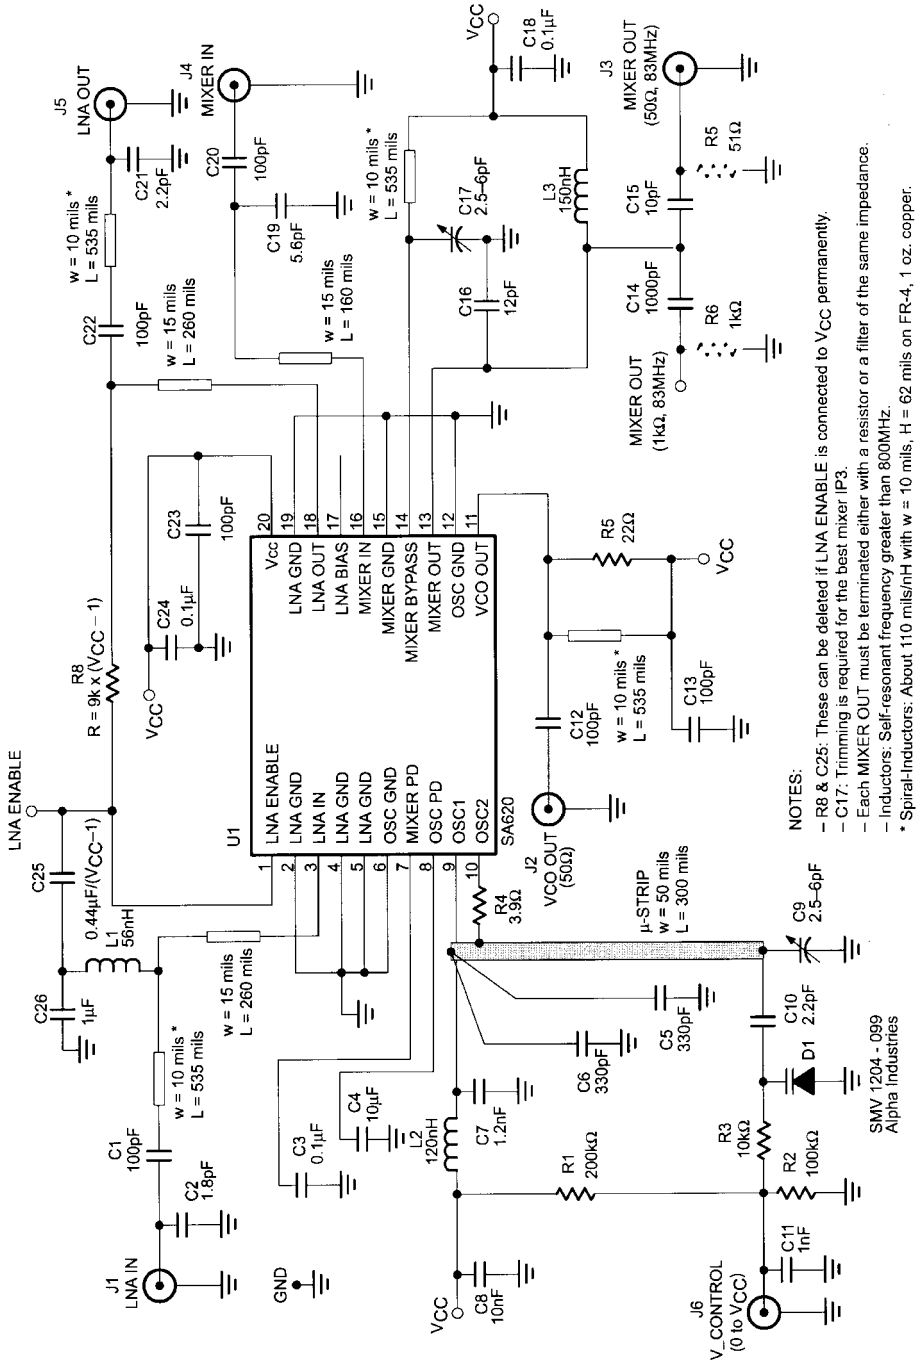

Figure 5-42 Philips SA620 application board schematic showing the tapped-microstrip resonator.

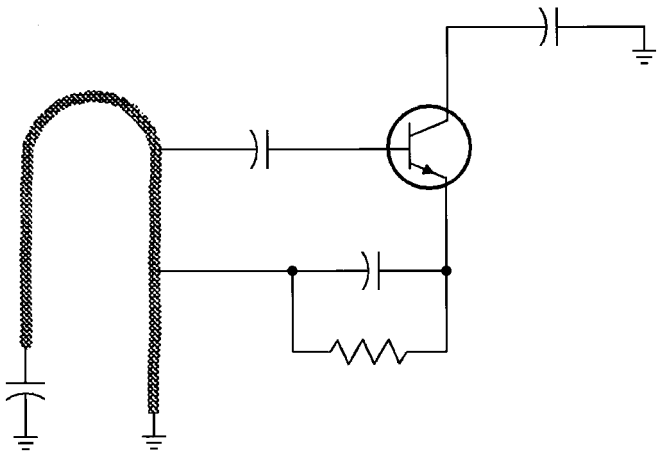

Figure 5-43 "Walking stick" microstrip Hartley resonator as used by Plextek in the 800–1500-MHz range. Below 800 MHz, the resonator's physical size becomes impractical; above 1500 MHz, the transistor's parasitic reactances make the Hartley configuration problematic.

for dc biasing. It may be possible to neglect this component entirely, provided that the PC-board connection to the cold end of the tank is very close to RF ground. Finally, note that shielding of the entire microstrip may be necessary to meet FCC Part 15 emission limitations (where applicable). Figure 5-42 shows one application of the tapped-microstrip oscillator with the Philips SA620 front-end IC.

5-5-5 Hartley Microstrip Resonator Oscillator

G. Smithson and S. Fitz of Plextek Communications Technology Consultants have reported on the construction of Hartley microstrip-resonator oscillators using thick-film techniques on ceramic (alumina) substrates for high-volume wireless products. The resonator in one such oscillator (Figure 5-43) exhibited an unloaded Q of approximately 80. Table 5-2 summarizes its phase noise versus tuning range with different tuning-diode configurations.

5-5-6 Crystal Oscillators

Most wireless applications do not require ultra-high-frequency stability that mandates the use of a primary standard, such as one based on cesium, or a secondary standard, such as one based on rubidium. For very stable oscillators at fixed or only slightly variable frequencies up to a few hundred megahertz, oscillators with piezoelectric resonators are generally used. A piezoelectric material transduces mechanical stress (deformation) to

Table 5-2 Achieved oscillator phase noise versus tuning range

Tuning Range, 0.5–3 V	Tuning Range, 1–3 V	Phase Noise at 20-kHz Offset
23%	16%	–100 dBc/Hz
16%	11%	–103 dBc/Hz
10%	8%	–106 dBc/Hz

electrical stress (voltage), and vice versa. In noncritical applications up to 10 MHz, a piezoelectric ceramic may be used. The Q and temperature stability of such materials are relatively poor, however, so quartz is the resonator material of choice for temperature-stable, low-noise piezoelectric oscillators.

Just as an electrical resonator consisting of distributed L and C exhibits multiple electrical resonances, a physical piece of piezoelectric material, depending on its shape, exhibits multiple mechanical resonances. *Fundamental* resonance occurs at the frequency at which the crystal is one-half wavelength long; *overtone* resonances occur near odd multiples (3, 5, 7, etc.) of the fundamental. Figure 5-44 shows the electrical equivalent of a crystal. Table 5-3 presents examples of approximate parameters for several crystal types. Appropriate shaping and placement of the crystal's connecting electrodes, combined with suitable oscillator circuit design and adjustment, allow the selection or ehancement of a particular resonance for excitation.

Figure 5-45 shows a typical crystal oscillator circuit configuration, and the associated table supplies recommended values for the elements. This is in line with the chip manufacturer's recommendations for built-in oscillator circuits. Figure 5-46 shows how this oscillator's input impedance varies around resonance; Figure 5-47 shows its simulated phase noise. Placing a small resistance in series with the crystal (Figure 5-48) allows us to use the crystal as a high-Q filter, substantially improving the oscillator's spectral purity relative to that obtainable at the transistor emitter (Figure 5-49).

Some applications demand ultra-low-phase-noise crystal oscillators. Figures 5-50 and 5-51 show an appropriate circuit and its phase noise with and without the current-supplying hot carrier diode (HCD) used for noise reduction.

5-5-7 Voltage-Controlled Oscillators

A schematic of a ceramic-resonator-based VCO (Figure 5-35) has already been shown in the section on ceramic-resonator oscillators. To tune the oscillator within the required range,

	3 MHz	6 MHz	10 MHz	20 MHz	30 MHz
C_1 (pF)	330	270	180	82	43
C_2 (pF)	430	360	220	120	68
C_3 (pF)	39	43	43	36	32
Crystal C_L (pF)	32	32	30	20	15

C_3 is the approximate value needed to set oscillator on frequency using indicated crystal C_L.

Figure 5-45 A 3–30-MHz Colpitts crystal oscillator.

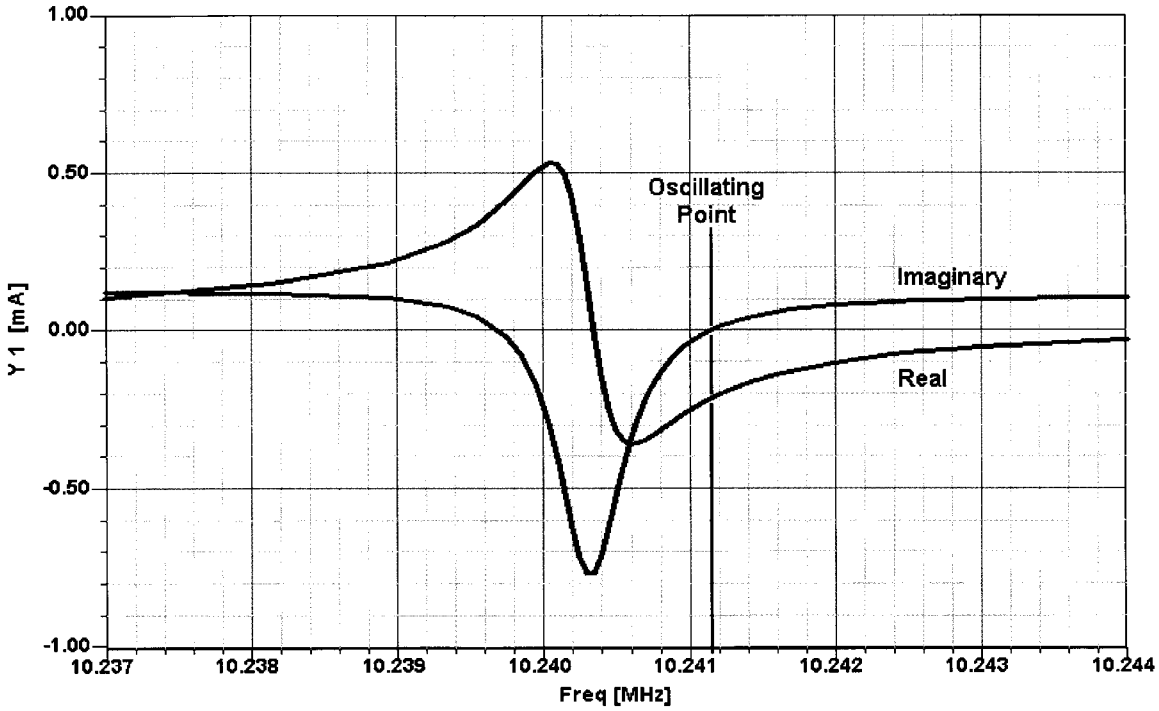

Figure 5-46 As with every oscillator, the crystal oscillator's input impedance is negative and real at resonance. This graph plots the real and imaginary components of the test voltage injected by the Oscillator Design Aid tool in Ansoft Serenade 8.0. Compare this graph with Figure 5-7, which plots an oscillator's input impedance with the resonator absent.

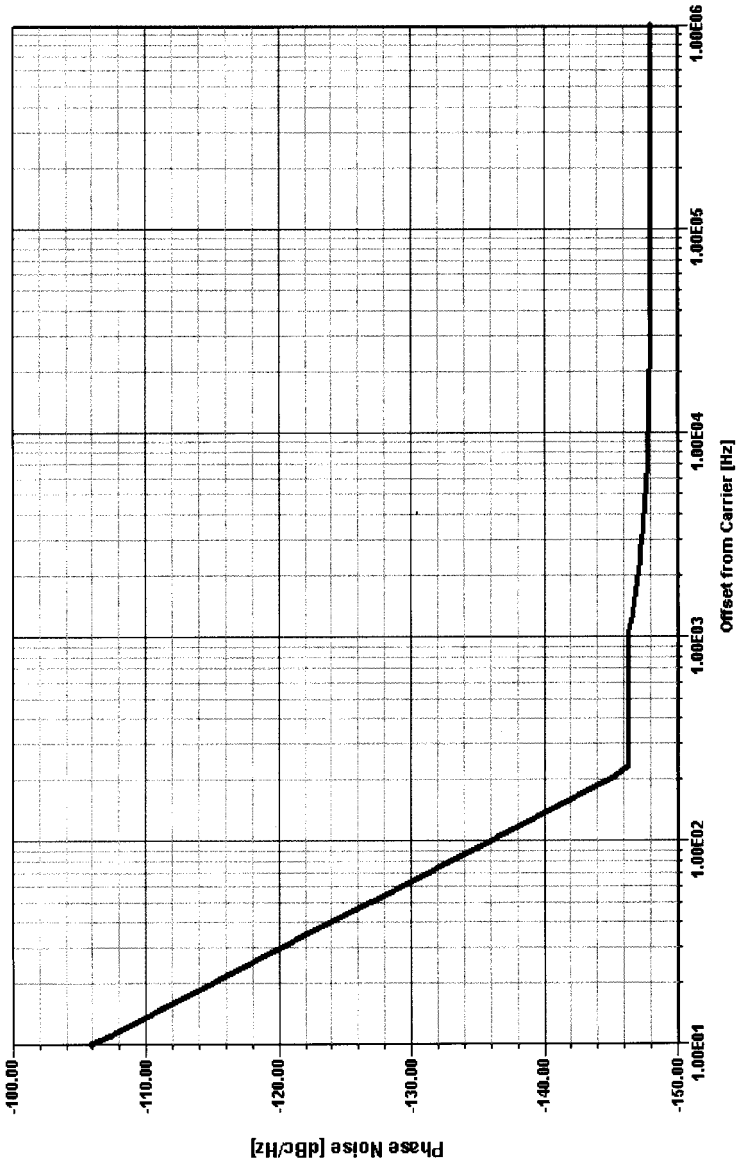

Figure 5-47 Simulated phase noise of the crystal oscillator.

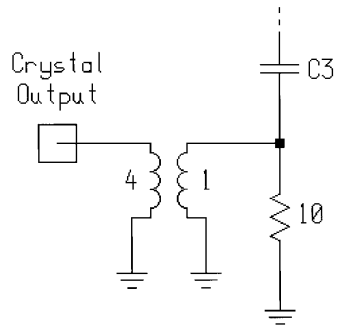

Figure 5-48 This alternative output tap uses the crystal's high selectivity for improved harmonic reduction.

tuning diodes are used. These diodes are often called *varactors* or *voltage-sensitive diodes.* By way of approximation, we can use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{5-82}$$

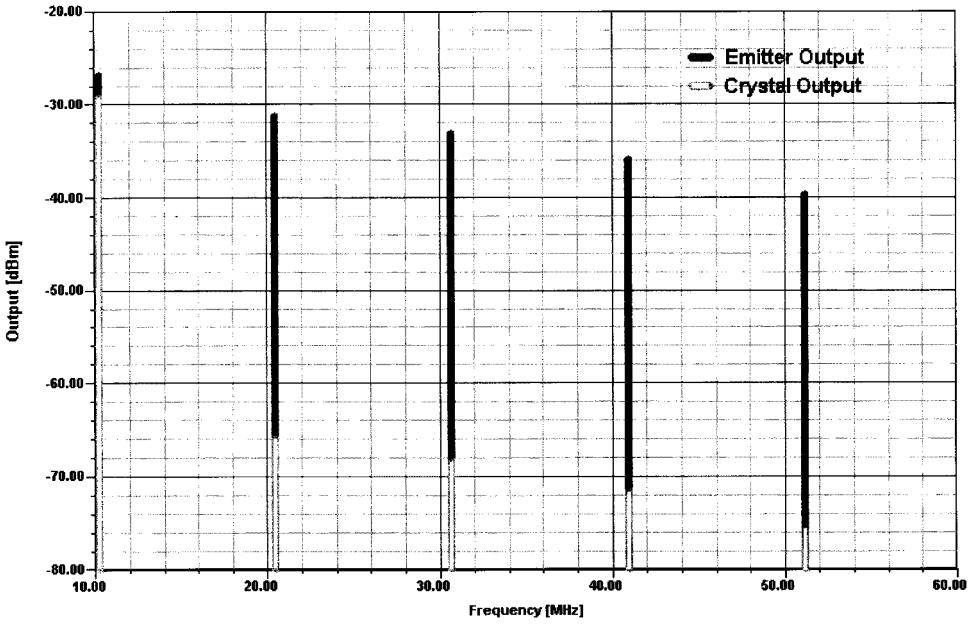

Figure 5-49 Comparison of the crystal oscillator's simulated output spectrum as obtained at the transistor emitter (dark gray, fundamental –26.7 dBm) and crystal (light gray, fundamental –29.1 dBm). At the emitter, the second harmonic is down only 4.3 dB relative to the carrier; at the crystal, the second harmonic is down 36 dB relative to the carrier.

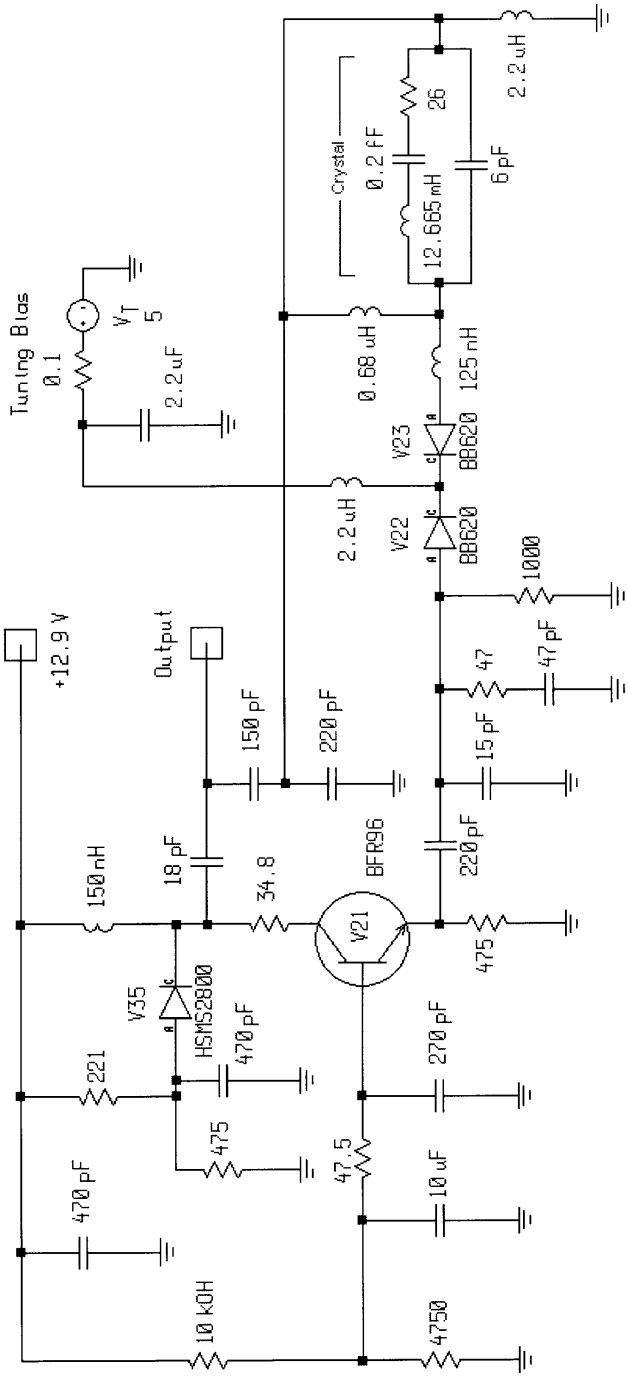

Figure 5-50 A 100-MHz VCXO suitable for ultra-low-phase-noise applications. The HSMS2800 hot-carrier diode (HCD) provides noise reduction.

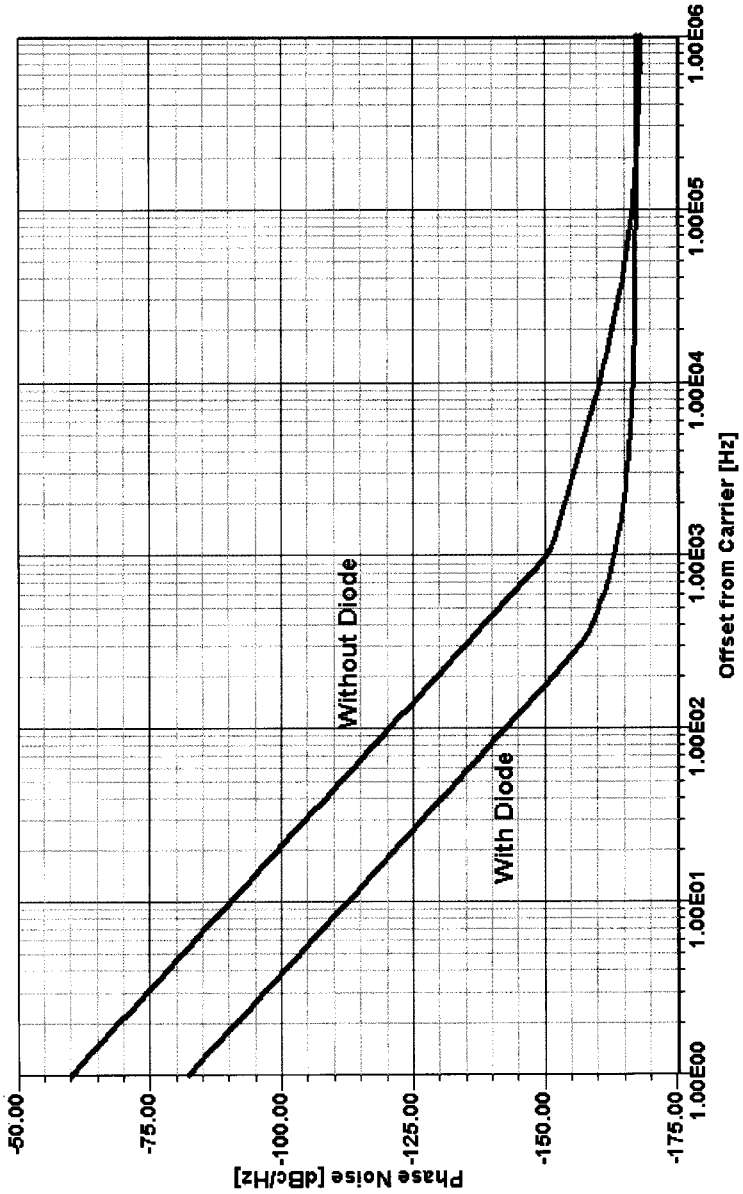

Figure 5-51 Phase noise of the VCXO with and without the noise-reduction diode.

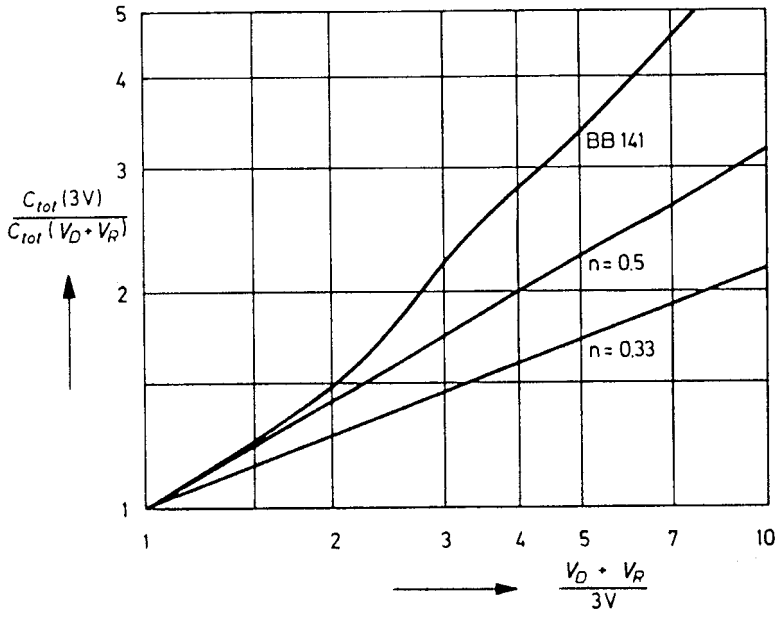

Figure 5-52 Capacitance–voltage characteristic for an alloyed capacitance diode ($n = 0.33$), a diffused capacitance diode ($n = 0.5$), and a wide-range tuning diode (BB141).

wherein all constants and all parameters determined by the manufacturing process are contained in K. The exponent is a measure of the slope of the capacitance/voltage characteristic and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction [6, 7]. Figure 5-52 shows the capacitance–voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation was developed that, although purely formal, describes the practical characteristic better than Eq. (5-82):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{5-83}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is the volt. The exponent m is much less dependent on voltage than the exponent n in Eq. (5-81).

The operating range of a capacitance diode or its useful capacitance ratio,

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R,\min})}{C_{\text{tot}}(V_{R,\max})} \tag{5-84}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage, either into the forward mode or the breakdown mode. Otherwise, rectification would take place, shifting the bias of the diode and considerably affecting its figure of merit.

There are several manufacturers of tuning diodes. Motorola is a typical supplier in this country; Siemens of Germany and Philips also provide good diodes. Table 5-4 and Figure 5-53 contain information for tuning diodes useful for our applications.

5-5-8 Diode-Tuned Resonant Circuits

Tuner Diode in Parallel-Resonant Circuit. Figures 5-54 and 5-55 illustrate two basic circuits for the tuning of parallel resonant circuits by means of capacitance diodes. In the circuit diagram of Figure 5-54, the tuning voltage is applied to the tuning diode via the bias resistor, R_B. Series-connected from the tuning diode to the top of the tank circuit is capacitor C_S, which completes the circuit for alternating current but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling resistor preceding the bias resistor is large enough to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_c. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_c = R_B \left(1 + \frac{C_{\text{tot}}}{C_S}\right)^2 \tag{5-85}$$

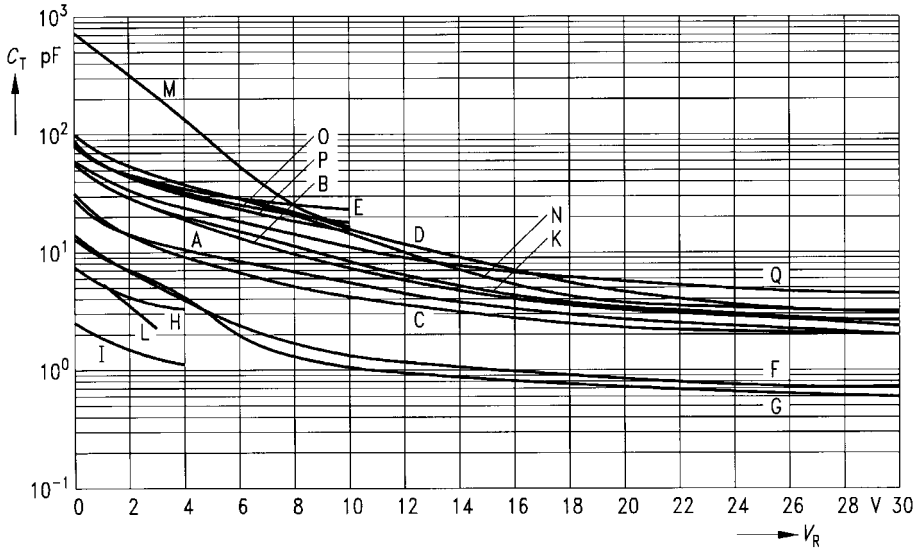

Figure 5-53 Diode capacitance C_T versus reverse voltage V_R for the diodes shown in Table 5-4. The curve labels correspond to the chip codes called out in the table.

If in this equation the diode capacitance is replaced by the resonator circuit frequency ω, we obtain

$$R_c = R_B \left(\frac{\omega^2 L C_S}{\omega^2 L (C_S + C_P) - 1} \right)^2 \tag{5-86}$$

In the circuit of Figure 5-55, the resonant circuit is tuned by two tuning diodes, which are connected in parallel via the coil for tuning purposes, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation acts in opposite directions in these diodes and, therefore, cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuning diodes, is transformed into the circuit at a constant ratio across the entire tuning range. Given two identical, loss-free tuning diodes, we obtain the expression

$$R_c = 4R_B \tag{5-87}$$

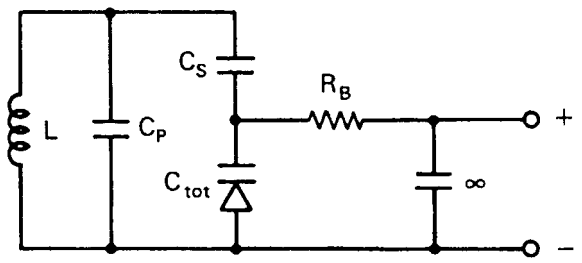

Figure 5-54 Parallel-resonant circuit with tuner diode, and bias resistor in parallel to the diode.

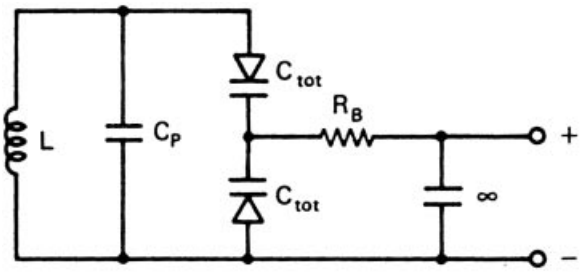

Figure 5-55 Parallel-resonant circuit with two tuning diodes.

Capacitances Connected in Parallel or in Series with the Tuning Diode. Figure 5-54 shows that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuning diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. If possible, the value of the series resistor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases—for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency—this is not possible, and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{tot} \frac{1}{1 + C_{tot}/C_S} \tag{5-88}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuning diode, increases to

$$Q^* = Q\left(1 + \frac{C_{tot}}{C_S}\right) \tag{5-89}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{max}}{C^*_{min}} = \frac{C_{max}}{C_{min}} \frac{1 + C_{min}/C_S}{1 + C_{max}/C_S} \tag{5-90}$$

where C_{max} and C_{min} are the maximum and minimum capacitances, respectively, of the tuner diode.

On the other hand, the advantage is gained that, due to the capacitive potential division, the amplitude of the alternating voltage applied to the tuner diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{tot}/C} \tag{5-91}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance C_{max} of the tuning diode and a higher useful capacitance ratio. The

influence exerted by the series capacitor, then, can actually be kept lower than Eq. (5-89) would suggest.

The parallel capacitance C_P that appears in Figures 5-54 and 5-55 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises in value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}}\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{5-92}$$

The Q of the effective tuning capacitance, derived from the Q of the tuning diode, is

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{5-93}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}}\,\frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{min}}} \tag{5-94}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the layout stage of the circuit design.

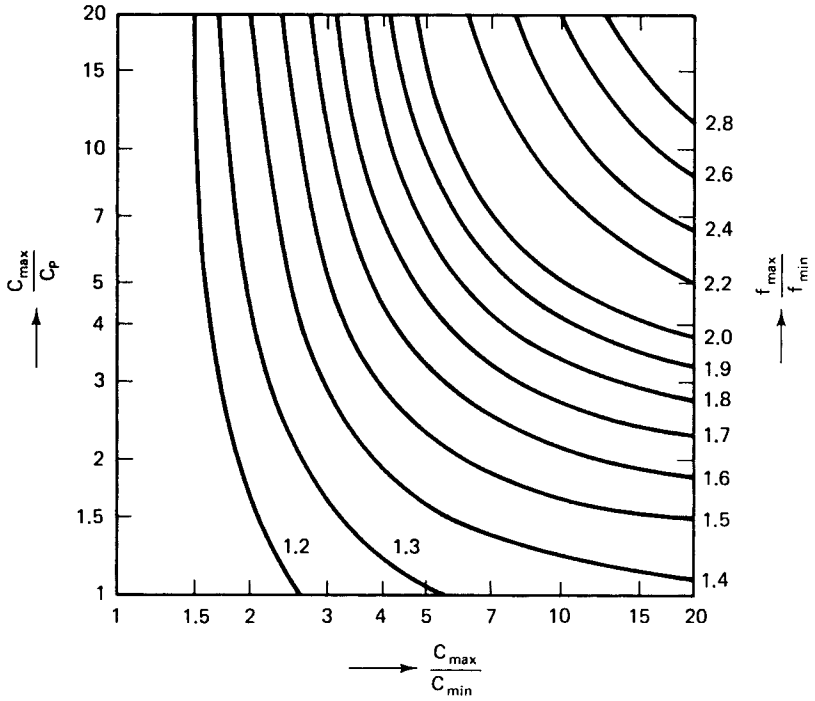

Figure 5-56 Diagram for determining capacitance ratio and maximum capacitance.

Tuning Range. The frequency range over which a parallel-resonant circuit (according to Figure 5-54) can be tuned by means of the tuning diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit. The ratio is

$$\frac{f_{\max}}{f_{\min}} = \left(\frac{1 + \dfrac{C_{\max}}{C_P(1 + C_{\max}/C_S)}}{1 + \dfrac{C_{\max}}{C_P(C_{\max}/C_{\min} + C_{\max}/C_S)}} \right)^{1/2} \tag{5-95}$$

In many cases, the value of the series capacitor can be chosen to be large enough for its effect to be negligible. In that case, Eq. (5-95) is simplified as follows:

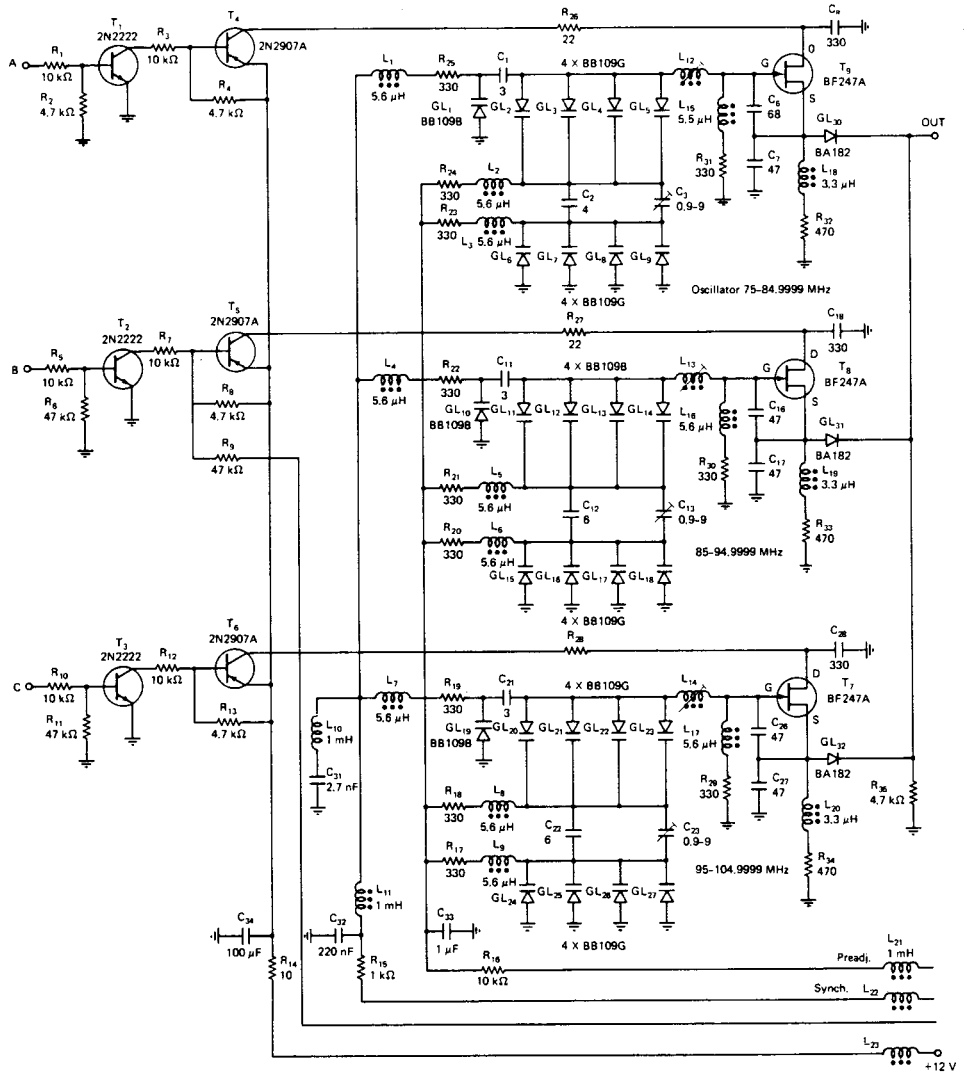

Figure 5-57 Oscillator and switching section of the Rohde & Schwarz ESH2/ESH3 test receiver.

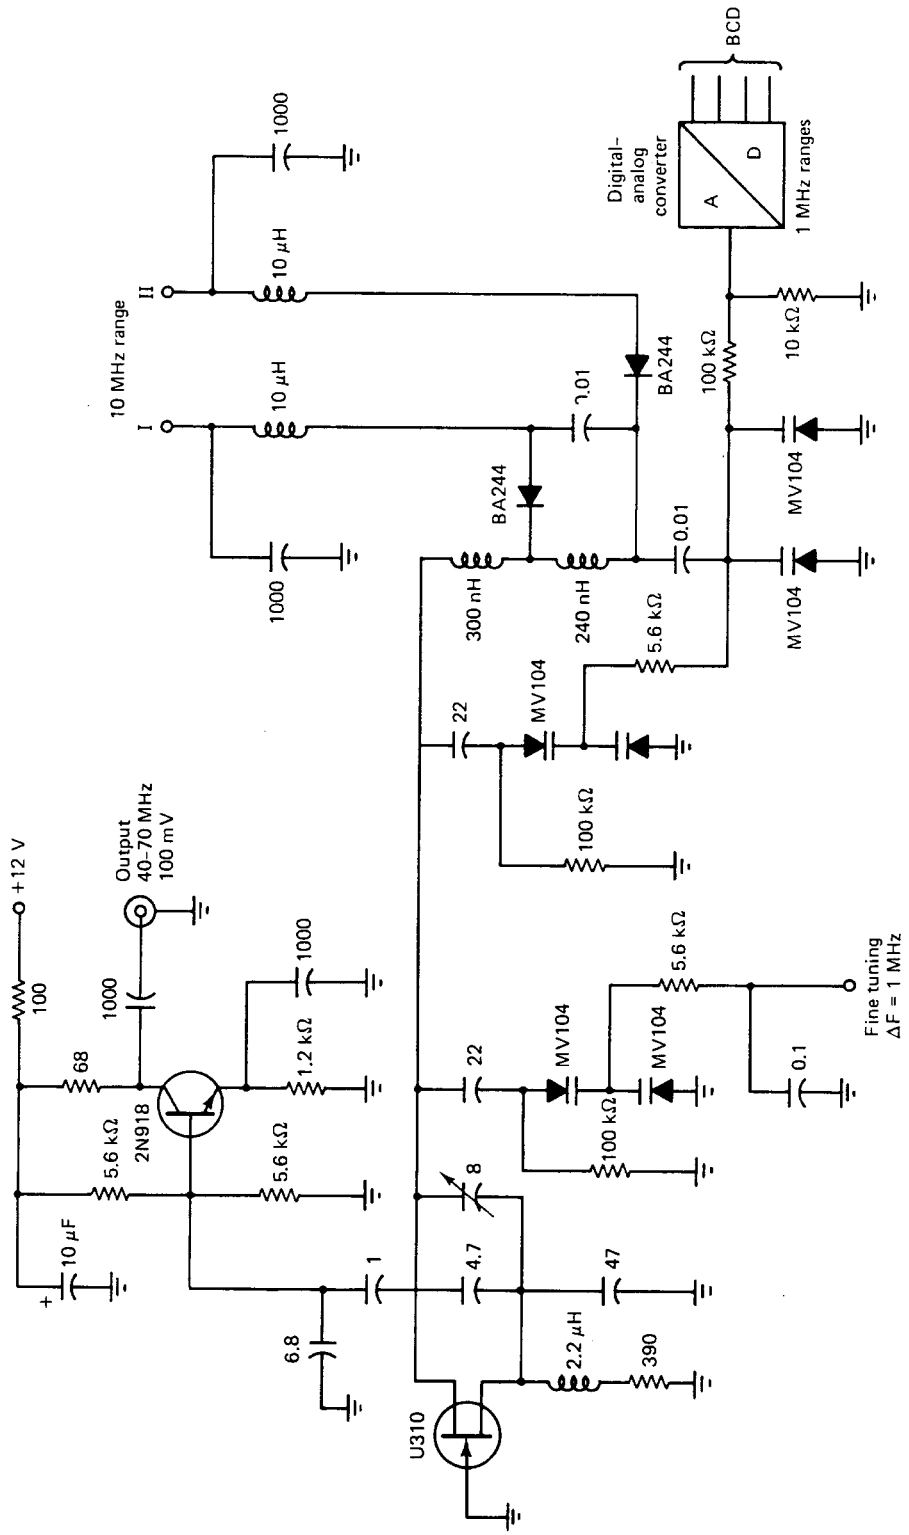

Figure 5-58 A 40–70-MHz VCO with two coarse-steering ranges and a fine-tuning range of 1 MHz.

$$\frac{f_{\max}}{f_{\min}} = \left(\frac{1 + C_{\max}/C_P}{1 + C_{\min}/C_P} \right)^{1/2} \tag{5-96}$$

From this equation, the diagram shown in Figure 5-56 is computed. With the aid of this diagram, the tuning diode parameters required for tuning a resonant circuit over a stipulated frequency range (i.e., the maximum capacitance and the capacitance ratio) can be determined. Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced accorded to Eq. (5-90).

Tracking. When several tuned circuits are used on the same frequency, diodes must be selected for perfect tracking.

5-5-9 Practical Circuits

Oscillators with Coarse and Fine Tuning. After so much theory, it may be nice to take a look at some practical circuits, such as the one shown in Figure 5-57. This oscillator is being used in the Rohde & Schwarz ESN/ESVN40 field-strength meter, and in the HF1030 receiver produced by Cubic Communications, San Diego. This circuit combines all the various techniques shown previously. A single diode is being used for fine-tuning a narrow range of less than 1 MHz; coarse tuning is achieved with the antiseries diodes.

Several unusual properties of this circuit are apparent:

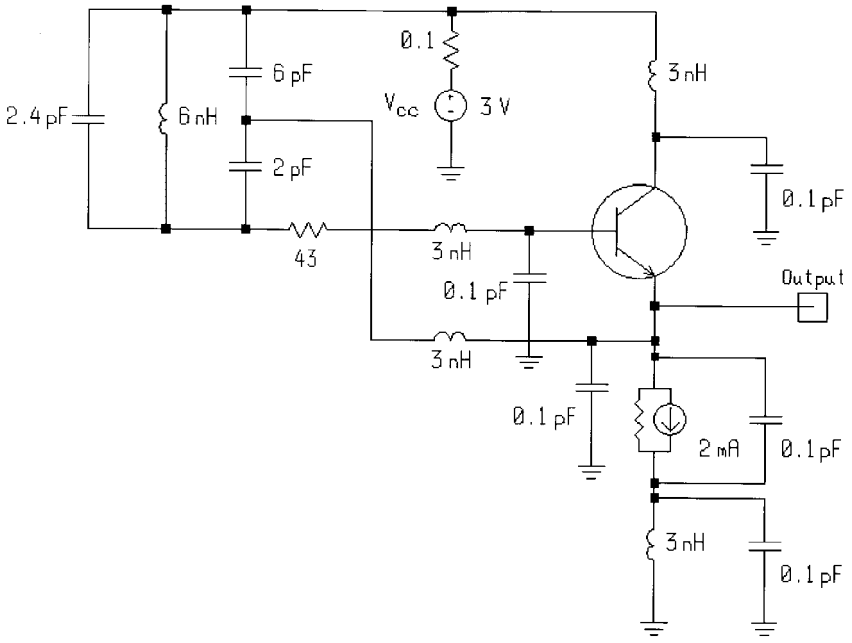

Figure 5-59 Schematic of the dc-coupled oscillator.

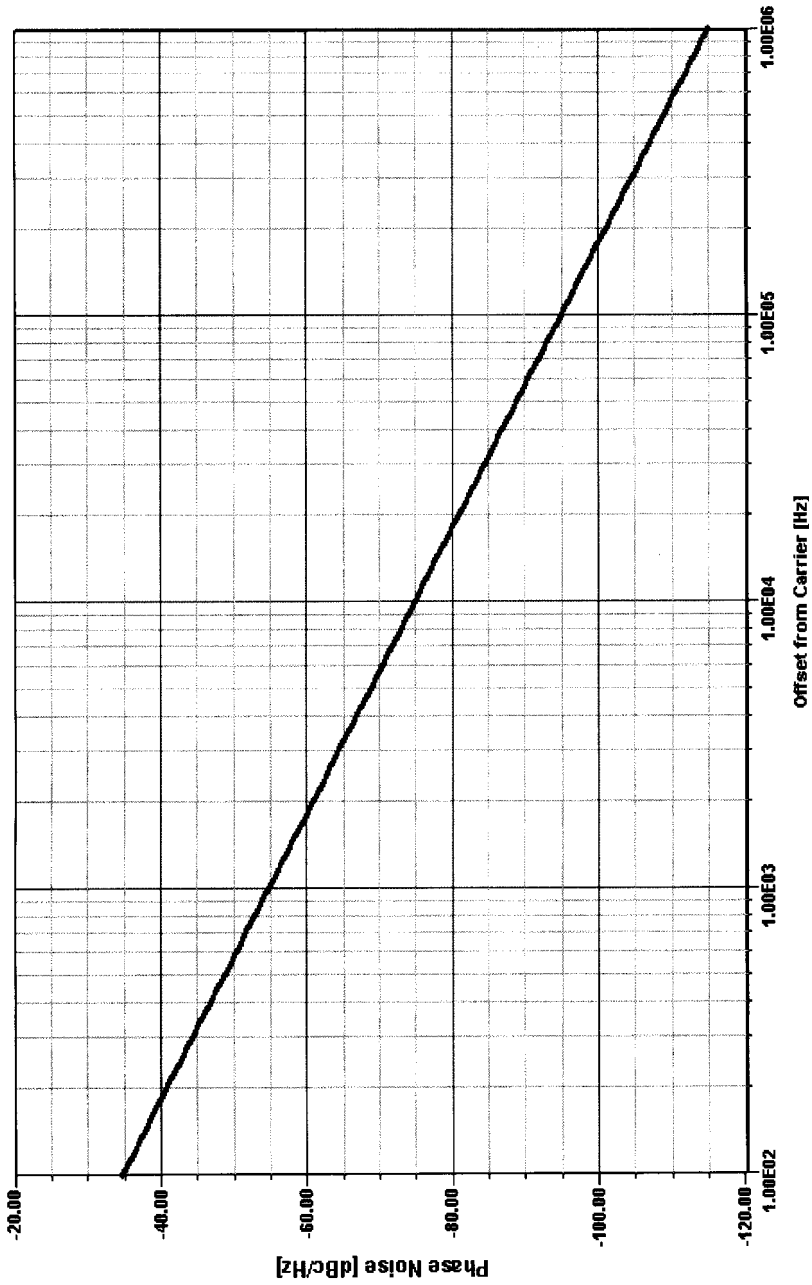

Figure 5-60 Phase noise of the dc-coupled oscillator operating at 897 MHz.

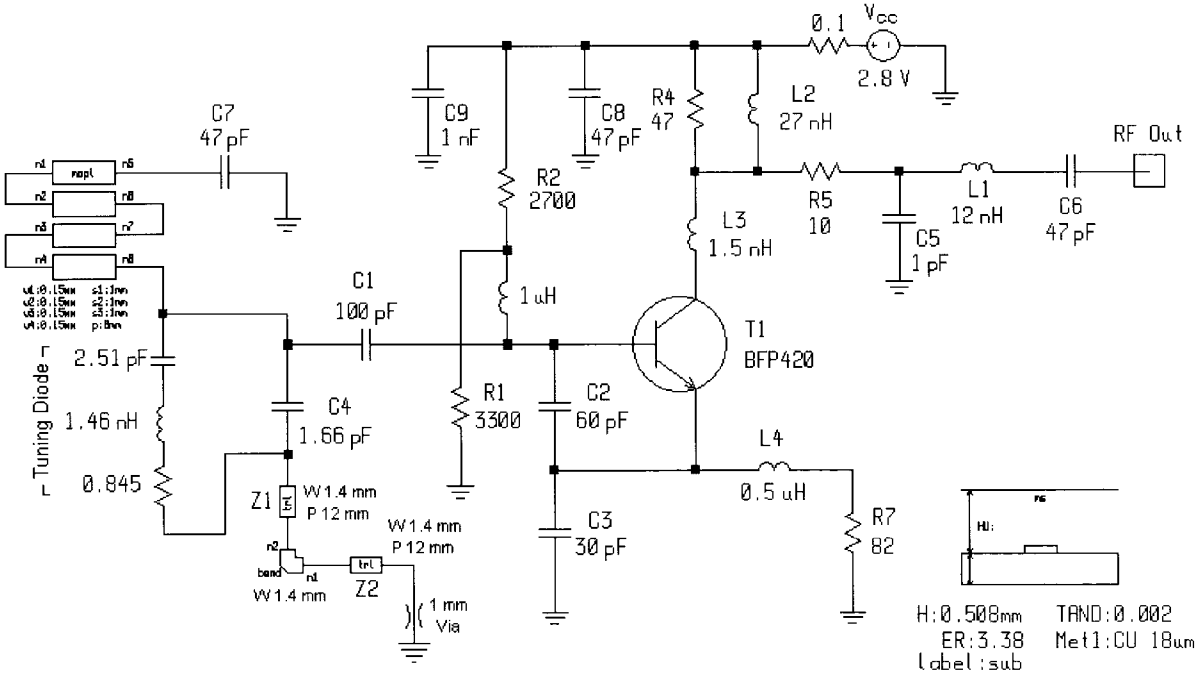

Figure 5-61 Schematic of the Siemens VCO. This oscillator (simulation) works with such high voltage-divider capacitances (C_2 and C_3) only because the circuit's large-signal transistor model, which was obtained under contract, exhibits unrealistically high gain at the frequency of oscillation. Actual capacitors with values on the order of those shown for C_2 and C_3 typically exhibit parasitic resistance and inductance of 0.3 Ω and 0.2 nH, respectively; the resulting series resonance would make any actual such capacitor act as an inductor at UHF. Obtaining practical "UHF useful" capacitances with values on the order of those shown for C_2 and C_3 would therefore necessitate the use of multiple, smaller-value capacitors in parallel—4 × 15 pF at C_2, for example.

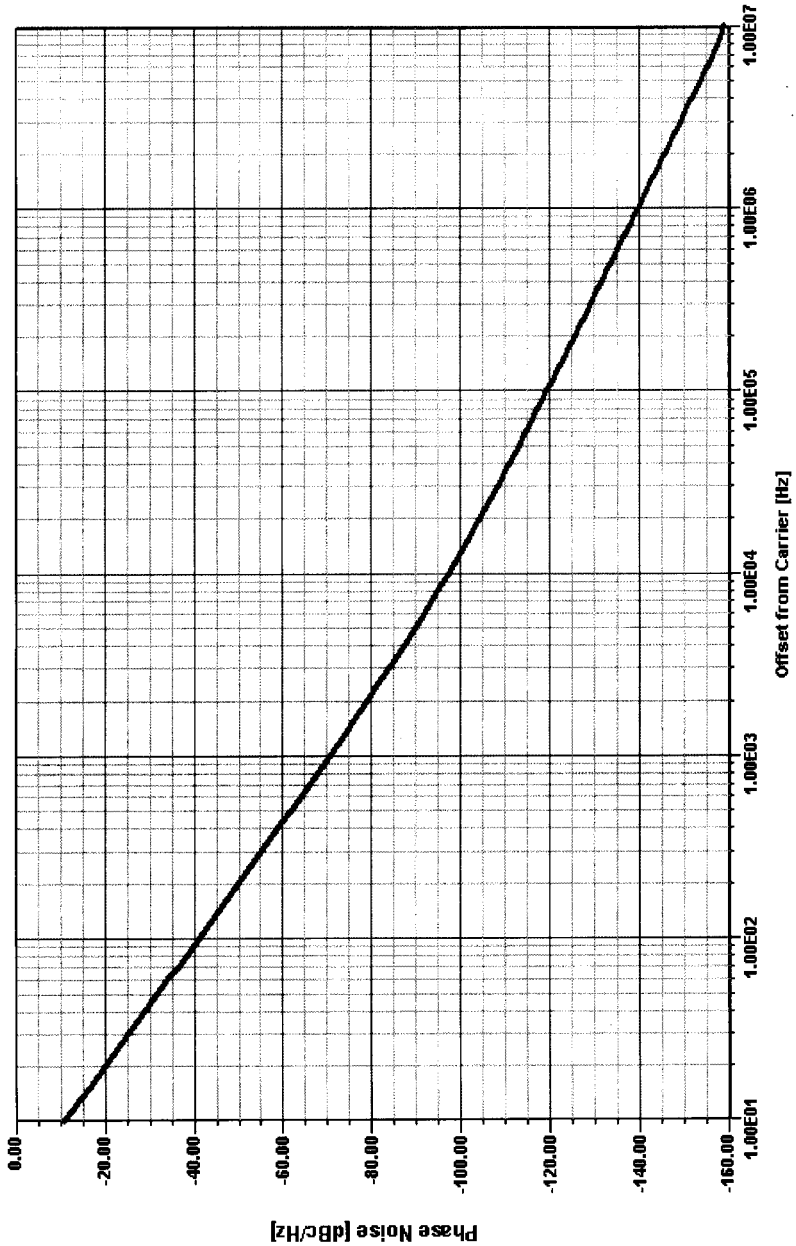

Figure 5-62 Simulated phase noise of the VCO. The frequency of oscillation is 1.052 GHz.

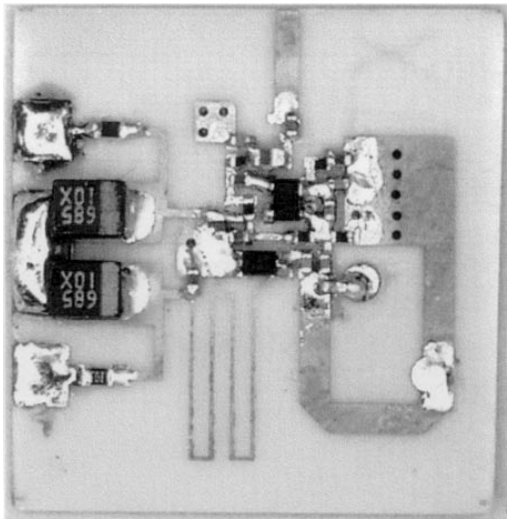

Figure 5-63 Implementation of the Siemens VCO.

1. The fine tuning is achieved with a tuning diode that has a much larger capacitance than that of the coupling capacitor in the circuit. The advantage of this technique is that the fixed capacitor and the tuning diode form a voltage divider, whereby the voltage across the tuning diode decreases as the capacitance increases. For larger values of the capacitance of the tuning diode, the Q changes and the gain K_0 increases. Because of the voltage division, the noise contribution and loading effect of the diode are reduced.
2. In the coarse-tuning circuit, several tuning diodes are used in parallel. The advantage of this circuit is a change in L/C ratio by using a higher C and storing more energy in the tuned circuit. There are no high-Q diodes available with such large capacitance values, and therefore preference is given to using several diodes in parallel rather than one tuning diode with a large capacitance, normally used only for AM (medium-frequency broadcast) tuner circuits.

We mentioned previously that, despite this, the coarse-tuning circuit will introduce noise outside the loop bandwidth, where it cannot be corrected. It is therefore preferable to incorporate switching diodes for segmenting ranges at the expense of switching current drain.

Figure 5-58 shows a circuit using a combined technique of tuning diodes for fine- and medium-resolution tuning, and coarse tuning with switching diodes.

dc-Coupled Oscillator. An interesting circuit that was cut out of an IC was supplied to us by David Lovelace of Motorola. Figure 5-59 shows the circuit and Figure 5-60 shows its phase noise. As a result of the constraints of integration, this BJT oscillator has no base bias circuitry in the conventional form. A fairly noisy performer, it ultimately was not used in production.

Siemens Colpitts Oscillator. A more elaborate approach that is essentially a standard Colpitts oscillator with a lot of detailed modeling is the oscillator of Figure 5-61, supplied

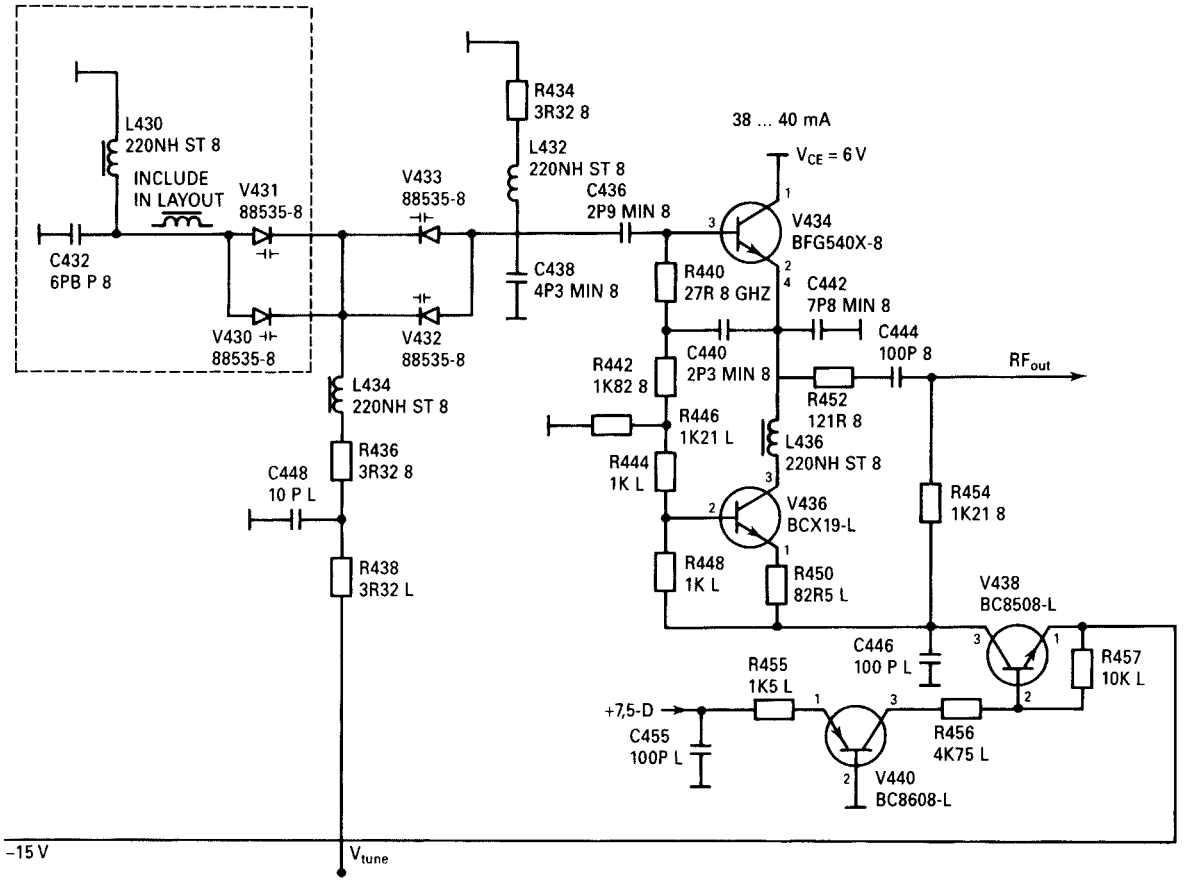

Figure 5-64 A recommended very-low-phase-noise VCO that operates in the 1-GHz region. The V436 stage is a constant-current generator responsible for improved phase-noise performance.

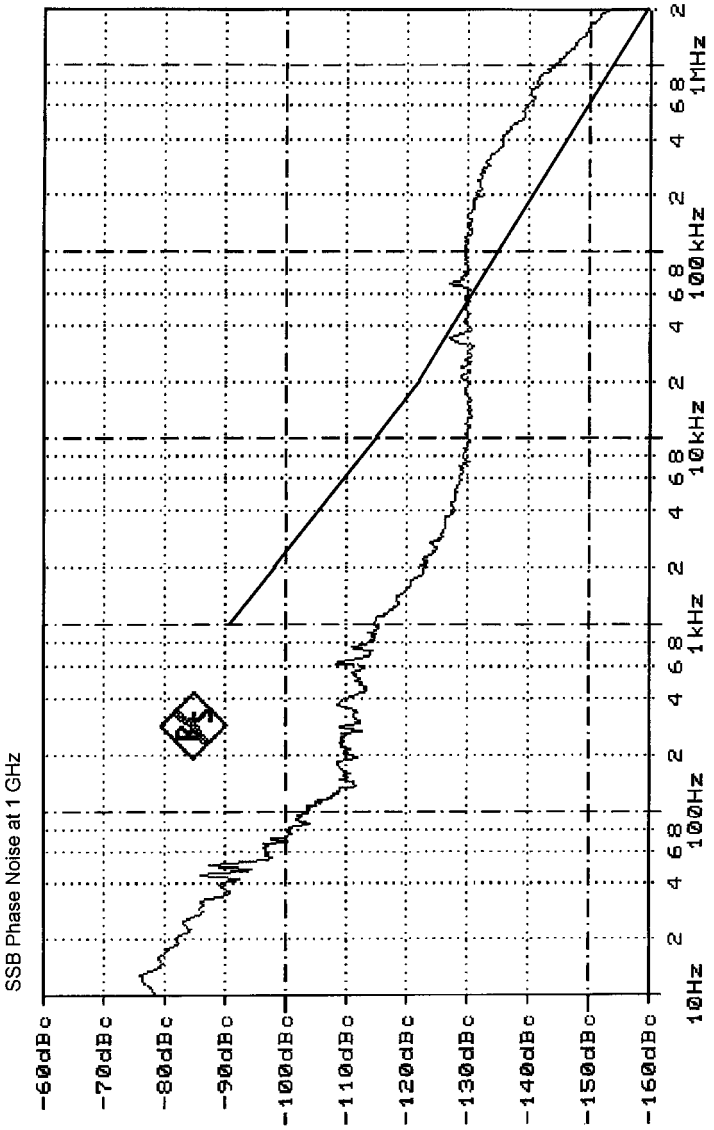

Figure 5-65 Phase noise of the low-noise VCO. The "ledges" from 100 Hz to 1 kHz and from 10 kHz to 100 kHz reflect the noise-cleanup effects of a dual-loop synthesizer; the superimposed line from 1 kHz to 2 MHz shows the oscillator's noise characteristic with both loops unlocked. The closed-loop response is noisier than the open-loop response at offsets above 60 kHz because a wide loop bandwidth is used to achieve a faster switching speed.

to us by Siemens. Considering its simplicity, its noise performance is good, as shown in Figure 5-62. Modeling this circuit involved the consideration of via holes and coupled lines. Figure 5-63 shows an actual implementation of this oscillator. The value of external emitter resistance (R7 in Figure 5-61) plays a critical role in determining a common-emitter Colpitts oscillator's upper frequency limit as described in Yeom [8].

dc-Stabilized Oscillator. For high-performance synthesizers, such as the Rohde & Schwarz series SMG/SMH, a dc-stabilized oscillator with fairly wide tuning range may be used. Figure 5-64 shows such an oscillator, the measured phase noise of which is shown in Figure 5-65. It should be noted that the output loop is magnetically coupled and therefore takes advantage of the inherent selectivity of the tuned circuit.

5-6 NOISE IN OSCILLATORS

In transmitters, oscillator noise can result in adjacent-channel interference and modulation errors; in receivers, oscillator noise can result in demodulation errors and degraded sensitivity and dynamic range. The specification, calculation, and reduction of oscillator noise are therefore of great importance in wireless system design.

5-6-1 Linear Approach to the Calculation of Oscillator Phase Noise

Since an oscillator can be viewed as an amplifier with feedback (Figure 5-66), it is helpful to examine the phase noise added to an amplifier that has a noise figure F. F is defined by [9]

$$F = \frac{(S/N)_{\text{in}}}{(S/N)_{\text{out}}} = \frac{N_{\text{out}}}{N_{\text{in}}G} = \frac{N_{\text{out}}}{GkTB} \tag{5-97}$$

$$N_{\text{out}} = FGkTB \tag{5-98}$$

$$N_{\text{in}} = kTB \tag{5-99}$$

where N_{in} is the total input noise power to a noise-free amplifier. The input phase noise in a 1-Hz bandwidth at any frequency $f_0 + f_m$ from the carrier produces a phase deviation given by (Figure 5-67)

$$\Delta\theta_{\text{peak}} = \frac{V_{n\,\text{RMS1}}}{V_{s,\text{av RMS}}} = \sqrt{\frac{fKT}{P_{s,\text{av}}}} \tag{5-100}$$

$$\Delta\theta_{\text{1RMS}} = \frac{1}{\sqrt{2}}\sqrt{\frac{FkT}{P_{s,\text{av}}}} \tag{5-101}$$

Since a correlated random phase-noise relation exists at $f_0 - f_m$, the total phase deviation becomes

$$\Delta\theta_{\text{RMS total}} = \sqrt{FkT/P_{s,\text{av}}} \tag{5-102}$$

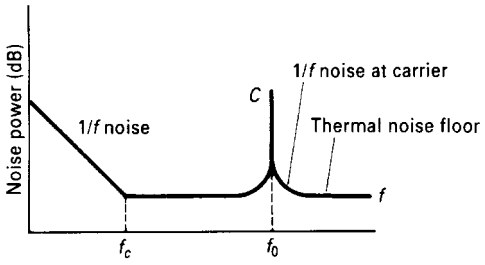

Figure 5-66 Noise power versus frequency of a transistor amplifier with an input signal applied.

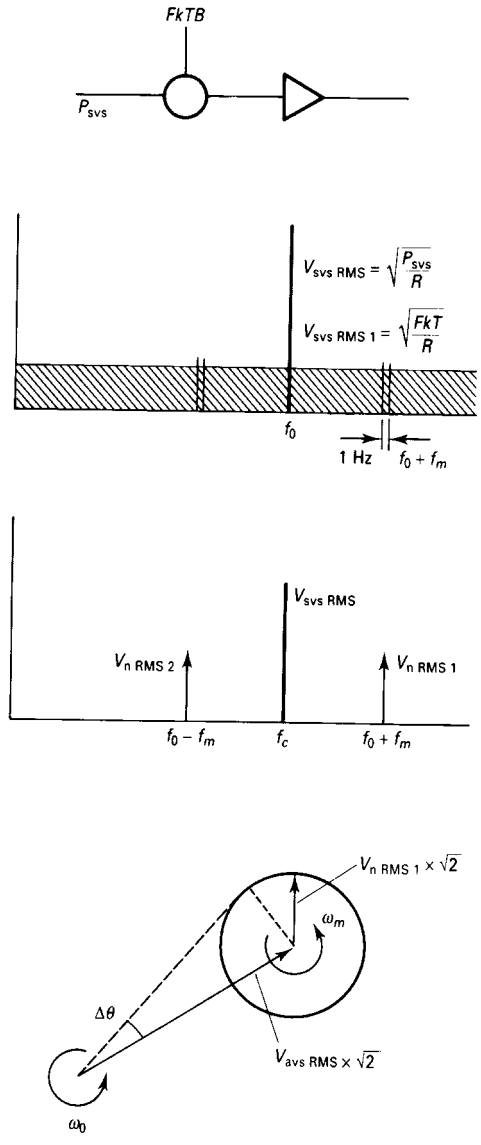

Figure 5-67 Phase noise added to carrier.

The spectral density of phase noise becomes

$$S_\theta(f_m) = \Delta\theta^2_{\text{RMS}} = FkTB/P_{s,\text{av}} \tag{5-103}$$

where $B = 1$ for a 1-Hz bandwidth. Using

$$kTB = -174 \text{ dBm/Hz} \qquad (B = 1) \tag{5-104}$$

allows a calculation of the spectral density of phase noise that is far removed from the carrier (i.e., at large values of f_m). This noise is the theoretical noise floor of the amplifier. For example, an amplifier with +10-dBm power at the input and a noise figure of 6 dB gives

$$S_\theta(f_m > f_c) = -174 \text{ dBm} + 6 \text{ dB} - 10 \text{ dBm} = -178 \text{ dBm} \tag{5-105}$$

Only if P_{OUT} is >0 dBm can we expect $\mathcal{L}$ (signal-to-noise ratio) to be greater than 174 dBc/Hz (1-Hz bandwidth). For a modulation frequency close to the carrier, $S_\theta(f_m)$ shows a flicker or $1/f$ component, which is empirically described by the corner frequency f_c. The phase noise can be modeled by a noise-free amplifier and a phase modulator at the input as shown in Figure 5-68.

The purity of the signal is degraded by the flicker noise at frequencies close to the carrier. The spectral phase noise can be described by

$$S_\theta(f_m) = \frac{FkTB}{P_{s,\text{av}}}\left(1 + \frac{f_c}{f_m}\right) \quad (B = 1) \tag{5-106}$$

No AM-to-PM conversion is considered in this equation. The oscillator may be modeled as an amplifier with feedback as shown in Figure 5-69. The phase noise at the input of the amplifier is affected by the bandwidth of the resonator in the oscillator circuit in the following way. The tank circuit or bandpass resonator has a low-pass transfer function

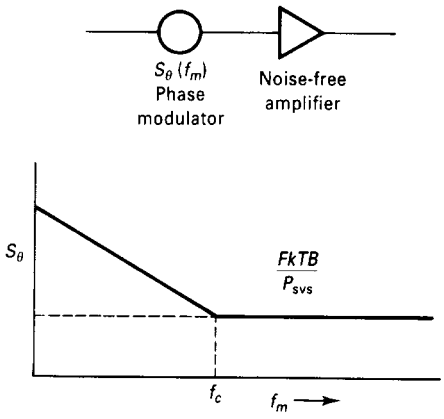

Figure 5-68 Phase noise modeled by a noise-free amplifier and phase modulator.

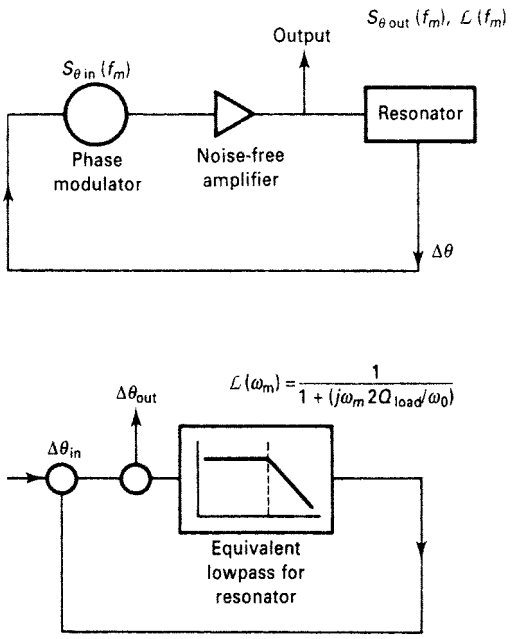

Figure 5-69 Equivalent feedback models of oscillator phase noise.

$$L(\omega_m) = \frac{1}{1 + j(2Q_L\omega_m/\omega_0)} \tag{5-107}$$

where

$$\omega_0/2Q_L = B/2 \tag{5-108}$$

is the half-bandwidth of the resonator. These equations describe the amplitude response of the bandpass resonator; the phase noise is transferred unattenuated through the resonator up to the half-bandwidth.

The closed-loop response of the phase feedback loop is given by

$$\Delta\theta_{\text{out}}(f_m) = \left(1 + \frac{\omega_0}{j2Q_L\omega_m}\right)\Delta\theta_{\text{in}}(f_m) \tag{5-109}$$

The power transfer becomes the phase spectral density

$$S_{\theta,\text{out}}(f_m) = \left[1 + \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right] S_{\theta,\text{in}}(f_m) \tag{5-110}$$

where $S_{\theta,\text{in}}$ was given by Eq. (5-106). Finally, $\mathcal{L}(f_m)$ is

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right] S_{\theta,\text{in}}(f_m) \tag{5-111}$$

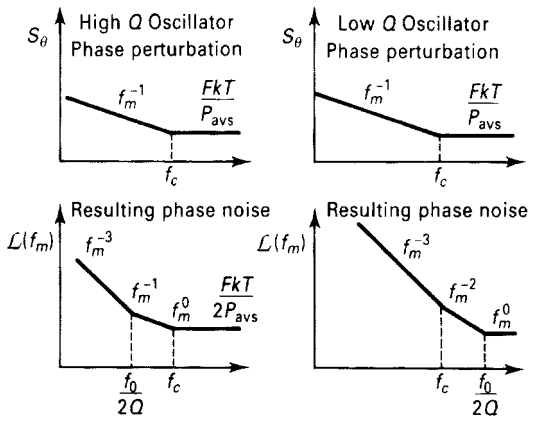

Figure 5-70 Equivalent feedback models of oscillator phase noise.

This equation describes the phase noise at the output of the amplifier (flicker corner frequency and AM-to-PM conversion are not considered). The phase perturbation $S_{\theta,\text{in}}$ at the input of the amplifier is enhanced by the positive phase feedback within the half-bandwidth of the resonator, $f_0/2Q_L$.

Depending on the relation between f_c and $f_0/2Q_L$, there are two cases of interest, as shown in Figure 5-70. For the low-Q case, the spectral phase noise is unaffected by the Q of the resonator, but the $\mathcal{L}(f_m)$ spectral density will show a $1/f^3$ and $1/f^2$ dependence close to the carrier. For the high-Q case, a region of $1/f^3$ and $1/f$ should be observed near the carrier. Substituting Eq. (5-106) into Eq. (5-111) gives an overall noise of

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{1}{f_m^2}\left(\frac{f}{2Q_L}\right)^2\right]\frac{FkT}{P_{s,\text{av}}}\left(1 + \frac{f_c}{f_m}\right)$$

$$= \frac{FkTB}{2P_{s,\text{av}}}\left[\frac{1}{f_m^3}\frac{f^2 f_c}{4Q_L^2} + \frac{1}{f_m^2}\left(\frac{f}{2Q_L}\right)^2 + \left(1 + \frac{f_c}{f_m}\right)\right] \text{dBc/Hz} \tag{5-112}$$

Examining Eq. (5-112) gives the four major causes of oscillator noise: the upconverted $1/f$ noise or flicker FM noise, the thermal FM noise, the flicker phase noise, and the thermal noise floor, respectively.

Q_L (loaded Q) can be expressed as

$$Q_L = \frac{\omega_o W_e}{P_{\text{diss,total}}} = \frac{\omega_o W_e}{P_{\text{in}} + P_{\text{res}} + P_{\text{sig}}} = \frac{\text{Reactive power}}{\text{Total dissipated power}} \tag{5-113}$$

where W_e is the reactive energy stored in L and C,

$$W_e = \frac{1}{2} CV^2 \tag{5-114}$$

$$P_{\text{res}} = \frac{\omega_o W_e}{Q_{\text{unl}}} \tag{5-115}$$

$$\mathcal{L}(f_m) = \frac{1}{2}\left[1 + \frac{\omega_o^2}{4\omega_m^2}\left(\frac{P_{\text{in}}}{\omega_o W_e} + \frac{1}{Q_{\text{unl}}} + \frac{P_{\text{sig}}}{\omega_o W_e}\right)^2\right]\left(1 + \frac{\omega_c}{\omega_m}\right)\frac{FkT_o}{P_{\text{sav}}} \tag{5-116}$$

Input power/ Reactive power ratio

Resonator Q

Signal power/ Reactive power ratio

Flicker effect

Phase perturbation

This equation is extremely significant because it covers most of the causes of phase noise in oscillators. [AM-to-PM conversion must be added; see Eq. (5-56).] To minimize the phase noise, the following design rules apply:

1. Maximize the unloaded Q.
2. Maximize the reactive energy by means of a high RF voltage across the resonator and obtain a low L/C ratio. The limits are set by breakdown voltages of the active devices and the tuning diodes, and the forward-bias condition of the tuning diodes. If L becomes too high, the circuit degenerates into a squegging oscillator. Using lower L allows larger capacitance, which allows us to swamp the oscillating device's internal, nonlinear capacitance with external, linear capacitance, reducing the phase-noise degradation caused by the nonlinear capacitance. The ceramic-resonator oscillator best illustrates this approach, which may be hard to accomplish in discrete circuits because high-Q inductors with values above 1 nH cannot be built unless high-Q transmission lines or resonators are used.
3. Avoid saturation at all costs, and try to have either limiting or automatic gain control (AGC) without degradation of Q. Isolate the tuned circuit from the limiter or AGC circuit. Use tuning diodes in antiseries configurations to avoid forward bias.
4. Choose an active device with the lowest possible noise figure and flicker corner frequency. The noise figure of interest is the noise figure obtained with the actual impedance at which the device is operated. Using FETs rather than BJTs, it is preferable to deal with the equivalent noise voltage and noise currents rather than with the noise figure, since they are independent of source impedance. The noise figure improves as the ratio between source impedance and equivalent noise resistance increases. In addition, in a tuned circuit, the source impedance changes drastically as a function of the offset frequency, and this effect has to be considered. For low phase-noise operation, use a medium-power transistor. If you need your output power to be achieved at 6–9 mA, select a transistor with an $I_{C,\max}$ of 60–90 mA. Also avoid an f_T greater than 3× to 5× the operating frequency. To make transistors that are stable across their full frequency ranges, manufacturers add circuitry that makes the flicker corner frequency higher as f_T increases.

   The following transistors have the lowest noise figure:

   - BFG65/67 by Philips
   - BFR106/92; BFP405/420 by Siemens
   - 2SC3358/3356 by NEC
   - HXTR4105 by HP

- AT2100 (chip) by Avantek

Among the lowest-noise JFETs are the U310, 2N4416/17, and 2N5397.

In designing MMICs, one must resort to MESFETs, which are also referred to as GaAsFETs. They have a fairly high flicker frequency, which is typically around 10 MHz but can go up to as high as 100 MHz.

Table 5-5 shows equivalent circuits and measurement data for the Avantek AT2100 20-GHz *npn* silicon bipolar oscillator transistor. (Siemens of Germany is about to come out with 45-GHz f_T transistors, which will compete with SiGe transistors in the future.)

5. Phase perturbation can be minimized by using high-impedance devices such as FETs, where the signal-to-noise ratio of the signal voltage relative to the equivalent noise voltage can be made very high. This also indicates that in the case of a limiter, the limited voltage should be as high as possible.
6. Choose an active device with low flicker noise. The effect of flicker noise can be reduced through RF feedback. An unbypassed emitter resistor of 10–30 Ω in a bipolar circuit can improve the flicker noise by as much as 40 dB.

   The proper bias point of the active device is important, and precautions should be taken to prevent modulation of the input and output dynamic capacitances of the active device, which will cause amplitude-to-phase conversion and therefore introduce noise.
7. The energy should be coupled from the resonator rather than from another portion of the active device so that the resonator limits the bandwidth.
8. For microwave applications, the lowest-noise GaAsFETs are pseudomorphic HJ FETs. A reproduction of the datasheet of the NEC NE42484A, which is generally the state of the art today, follows; it is used with permission.

Equation (5-116) assumes that the phase perturbation and the flicker effect are the limiting factors, as practical use of such oscillators requires that an isolation amplifier must be used.

In the event that energy is taken directly from the resonator and the oscillator power can be increased, the signal-to-noise ratio can be increased above the theoretical limit of 174 dBc/Hz, due to the low-pass-filter effect of the tuned resonator. However, since this is mainly a theoretical assumption and does not represent a real-world system, this noise performance cannot be obtained. In an oscillator stage, even a total noise floor of –170 dBc/Hz is rarely achieved.

What other influences do we have that cause an oscillator's noise performance to degrade? So far, we have assumed that the Q of the tuned circuit is really determined only by the LC network and the loading effect of the transistor. In synthesizer applications, however, we find it necessary to add a tuning diode. The tuning diode has a substantially lower Q than that of a mica capacitor or even a ceramic capacitor. As a result of this, the noise sidebands change as a function of the additional loss. This is best expressed by adjusting the value for the loaded Q in Eq. (5-113).

There seems to be no precise mathematical way of predetermining the noise influence of a tuning diode, but the following approximation seems to give proper results:

$$\frac{1}{Q_{T,\text{load}}} = \frac{1}{Q_{\text{load}}} + \frac{1}{Q_{\text{diode}}} \tag{5-117}$$

[a]These equivalent circuits are provided only as first-order design aids. Their accuracy for critical designs at very high frequencies has not been validated.

[b]*S* parameters are from the linear equivalent circuit. Below 10 GHz, they have been fit to measurements of die on a standard carrier with one bond wire to the base and four wires to the emitter.

NEC

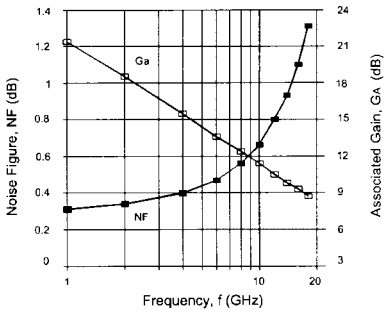
SUPER LOW NOISE PSEUDOMORPHIC HJ FET

NE42484A

FEATURES

- **VERY LOW NOISE FIGURE:** 0.8 dB TYP at 12 GHz
- **HIGH ASSOCIATED GAIN:** 10.5 dB TYP at 12 GHz
- **L_G = 0.35 µm, W_G = 200 µm**
- **LOW COST METAL CERAMIC PACKAGE**
- **TAPE & REEL PACKAGING OPTION AVAILABLE**

NOISE FIGURE & ASSOCIATED GAIN vs. FREQUENCY
V_{DS} = 2 V, I_{DS} = 10 mA



DESCRIPTION

The NE42484A is a pseudomorphic Hetero-Junction FET that uses the junction between Si-doped AlGaAs and undoped InGaAs to create very high mobility electrons. The device features mushroom shaped TiAl gates for decreased gate resistance and improved power handling capabilities. The mushroom gate also results in lower noise figure and high associated gain. This device is housed in an epoxy-sealed, metal/ceramic package and is intended for high volume consumer and industrial applications.

NEC's stringent quality assurance and test procedures ensure the highest reliability and performance.

ELECTRICAL CHARACTERISTICS (T_A = 25°C)

Notes:
1. Typical values of noise figures and associated gain are those obtained when 50% of the devices from a large number of lots were individually measured in a circuit with the input individually tuned to obtain the minimum value. Maximum values are criteria established on the production line as a "go-no-go" screening tuned for the "generic" type but not for each specimen.
2. R_{TH} (channel to case) for package mounted on an infinite heat sink.

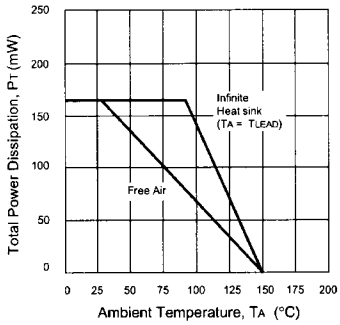
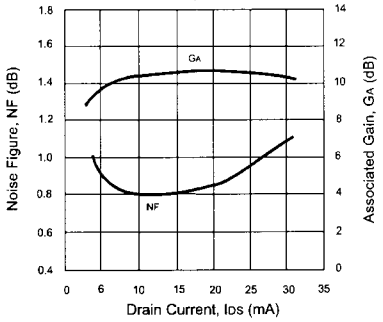
TYPICAL PERFORMANCE CURVES (T_A = 25°C)

TOTAL POWER DISSIPATION vs. AMBIENT TEMPERATURE[1]

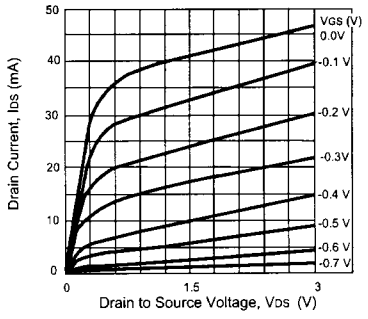


Note
1. If P_T exceeds the Free Air Value, reliable operation can be assured by measuring the worst-case temperature, $T_{(LEAD)}$, at the lead where heat flow is maximum (usually the source lead) and limiting T_A, P_T or $R_{TH\ (CKT)}$

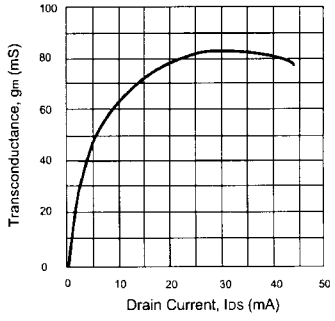
NOISE FIGURE AND ASSOCIATED GAIN vs. DRAIN CURRENT V_{DS} = 2 V, f = 12 GHz



DRAIN CURRENT vs. DRAIN TO SOURCE VOLTAGE



TRANSCONDUCTANCE vs. DRAIN CURRENT V_{DS} = 2.0 V



The tuning diode is specified to have a cutoff frequency $f_{\max}$, which is determined from the loss resistor R_S and the value of the junction capacitance as a function of voltage (e.g., measured at 3 V). This means that the voltage determines the Q and, consequently, the noise bandwidth.

5-6-2 AM-to-PM Conversion

We went into more detail in dealing with the mechanism and influence of tuning diodes in the voltage-controlled oscillators section, where we evaluated the various methods of building voltage-tunable oscillators using tuning diodes. In this section, we limit ourselves to practical results.

The loading effect of the tuning diode is due to losses, and these losses can be described by a resistor in parallel with the tuned circuit.

It is possible to define an equivalent noise $R_{a,\text{eq}}$ that, inserted in Nyquist's equation,

$$V_n = \sqrt{4kT_0R\,\Delta f} \tag{5-118}$$

where $kT_0 = 4.2 \times 10^{-21}$ at about 300 K, R is the equivalent noise resistor, and Δf is the bandwidth, determines an open-circuit noise voltage across the tuning diode. Practical values of $R_{a,\text{eq}}$ for carefully selected tuning diodes are in the vicinity of 200 Ω to 50 kΩ. If we now determine the noise voltage $V_n = \sqrt{4 \times 4.2 \times 10^{-21} \times 10{,}000}$, the resulting voltage value is 1.296×10^{-8} V $\sqrt{\text{Hz}}$.

This noise voltage generated from the tuning diode is now multiplied with the VCO gain K_0, resulting in the rms frequency deviation

$$(\Delta f_{\text{rms}}) = K_0 \times (1.296 \times 10^{-8}\ \text{V}) \text{ in 1-Hz bandwidth} \tag{5-119}$$

To translate this into an equivalent peak phase deviation,

$$\theta_d = \frac{K_0\sqrt{2}}{f_m}(1.296 \times 10^{-8}) \text{ rad in 1-Hz bandwidth} \tag{5-120}$$

or for a typical oscillator gain of 100 kHz/V,

$$\theta_d = \frac{0.00183}{f_m} \text{ rad in 1-Hz bandwidth} \tag{5-121}$$

For f_m = 25 kHz (typical spacing for adjacent-channel measurements for FM mobile radios), $\theta_c = 7.32 \times 10^{-8}$. This can be converted now into the SSB signal-to-noise ratio:

$$\mathcal{L}(f_m) = 20 \log_{10}\left(\frac{\theta_c}{2}\right) = -149 \text{ dBc/Hz} \tag{5-122}$$

For the typical oscillator gain of 10 MHz/V found in wireless applications, the resulting phase noise will be 20 dB worse [10 log (10 MHz ÷ 100 kHz)]. However, the best tuning diodes, like the BB104, have an R_n of 200 Ω instead of 10 kΩ, which again changes the picture. According to Eq. (5-118), with $kT_0 = 4.2 \times 10^{-21}$ the resulting noise voltage will be

$$V_n = \sqrt{4 \times 4.2 \times 10^{-21} \times 200}$$

$$= 1.833 \times 10^{-9} \text{ V}\sqrt{\text{Hz}} \tag{5-123}$$

From Eq. (5-114), the equivalent peak phase deviation for a gain of 10 MHz/V in a 1-Hz bandwidth is then

$$\theta_d = \frac{1 \times 10^7 \sqrt{2}}{f_m} (1.833 \times 10^{-9}) \text{ rad} \tag{5-124}$$

or

$$\theta_d = \frac{0.026}{f_m} \text{ rad in 1-Hz bandwidth} \tag{5-125}$$

With $f_m = 25$ kHz, $\theta_c = 1.04 \times 10^{-6}$. Expressing this as phase noise:

$$\mathcal{L}(f_m) = 20 \log_{10}\left(\frac{\theta_c}{2}\right) = -126 \text{ dBc/Hz} \tag{5-126}$$

The phase-noise value in Eq. (5-122) is that typically achieved in the Rohde & Schwarz SMDU or with the Hewlett-Packard 8640 signal generator and considered state-of-the-art for a free-running oscillator. It should be noted that both signal generators use a slightly different tuned circuit; the Rohde & Schwarz generator uses a helical resonator, whereas the Hewlett-Packard generator uses an electrically shortened quarter-wavelength cavity. Both generators are mechanically pretuned, and a tuning diode with a gain of about 100 kHz/V is used for AFC and frequency-modulation purposes. It is apparent that, because of the nonlinearity of the tuning diode, the gain is different for low dc voltages than for high dc voltages. The impact of this is that the noise varies with the tuning range.

If this oscillator had to be used for a synthesizer, its 1-MHz tuning range would be insufficient; therefore, a way had to be found to segment the band into the necessary ranges. In VCOs, this is typically done with switching diodes that allow the proper frequency bands to be selected. These switching diodes insert in parallel or series, depending on the circuit, with additional inductors or capacitors, depending on the design.

In low-energy-consuming circuits, the VCO frequently is divided into a coarse-tuning section using tuning diodes and a fine-tuning section with a tuning diode. In the coarse-tuning range, this results in very high gains, such as 1–10 MHz/V, for the diodes. The noise contribution of those diodes is therefore very high and can hardly be compensated by the loop. For low-noise applications, which automatically mean higher power consumption, it is unavoidable to use switching diodes.

Let us now examine some test results. Referring back to Eq. (5-106), Figure 5-71 shows the noise sideband performance as a function of Q, whereby the top curve with $Q_L = 100$ represents a somewhat poor oscillator and the lowest curve with $Q_L = 100{,}000$ probably represents a crystal oscillator where the unloaded Q of the crystal was in the vicinity of 3×10^6. Figure 5-72 shows the influence of flicker noise.

Corner frequencies of 10 Hz to 10 kHz have been selected, and it becomes apparent that around 1 kHz the influence is fairly dramatic, whereas the influence at 20 kHz off the carrier

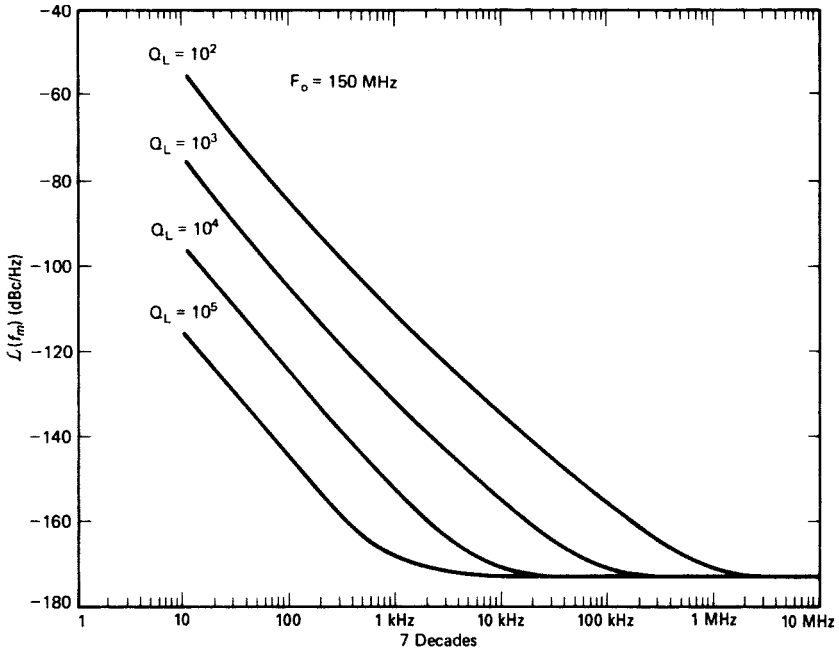


Figure 5-71 Noise sideband of an oscillator at 150 MHz as a function of the loaded Q of the resonator.

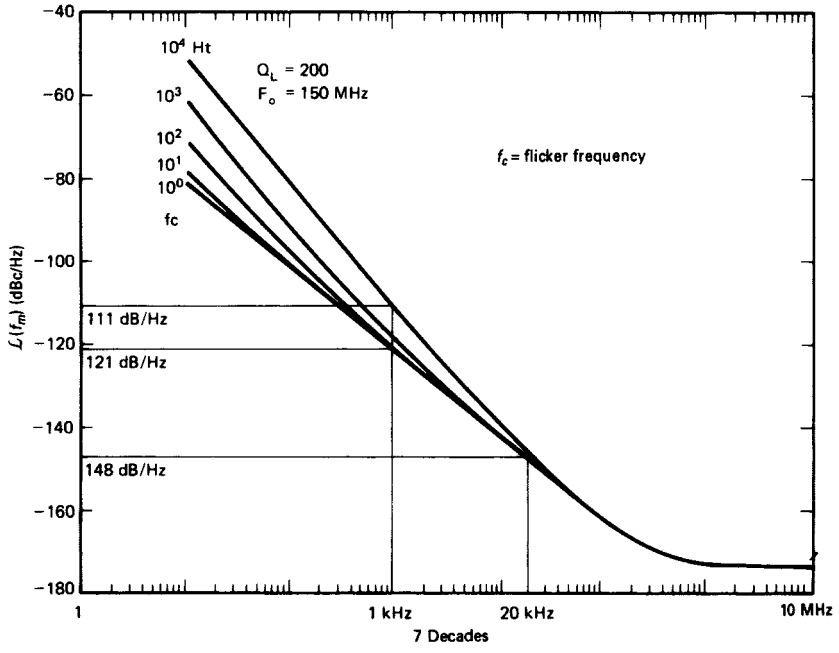

Figure 5-72 Noise-sideband performance as a function of the flicker frequency f_c varying from 10 Hz to 10 kHz.

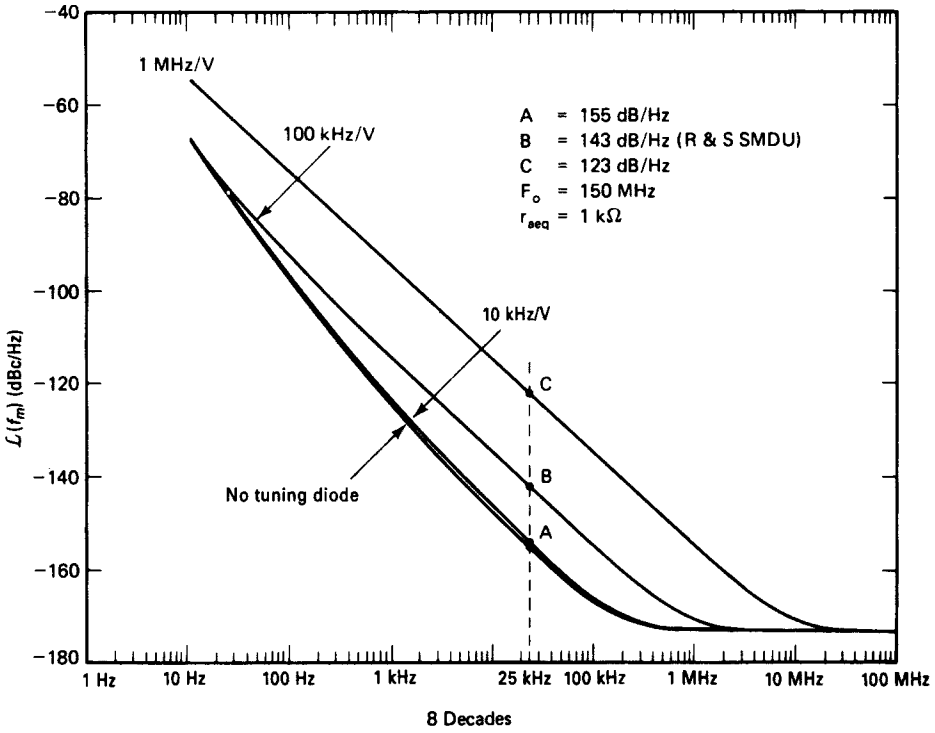

Figure 5-73 Noise-sideband performance of an oscillator at 150 MHz, showing the influence of various tuning diodes.

is not significant. Figures 5-73 and 5-74 show the influence of the tuning diodes on a high-Q oscillator.

Curve A in Figure 5-73 uses a lightly coupled tuning diode with a K_0 of 10 kHz/V; the lower curve is the noise performance without any diode. As a result, the two curves are almost identical, which can be seen from the somewhat smeared form of the graph. Curve B shows the influence of a tuning diode at 100 kHz/V and represents a value of −143 dBc/Hz from −155 dBc/Hz, already some deterioration. Curve C shows the noise if the tuning diode results in a 1-MHz/V VCO gain, and the noise sideband at 25 kHz has now deteriorated to −123 dBc/Hz. These curves speak for themselves.

Figure 5-74 shows how the phase noise of a 147-MHz VCO varies with the bias applied to its tuning diode. Because a tuning diode's Q increases with the reverse bias applied to it, we expect a VCO's phase-noise performance to improve, even if only slightly, as its tuning voltage is increased. Yet Figure 5-74 illustrates the reverse of this relationship. Inspecting this VCO's circuit (Figure 5-75), we see that the diode is in series with the circuit's 220-nH resonator. *All* of the RF current flowing through the resonator must flow through the relatively low-Q diode, and even small decreases in the diode's capacitance will significantly modify the tank's L/C ratio.

Graphing the diode's ac load line (Figure 5-76), we see that as the tuning voltage increases (i.e., as the tuning diode capacitance decreases), the RF voltage across the diode becomes disproportionately high. We note also that at every value of tuning voltage, the RF voltage across the diode goes positive (relative to the anode) during part of each cycle.

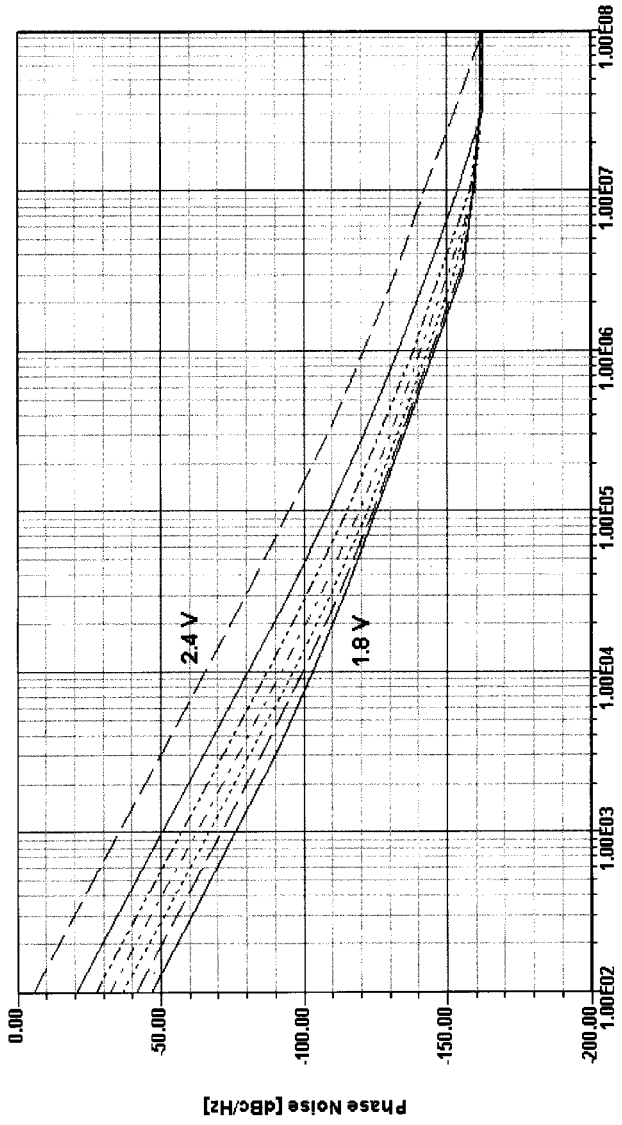

Figure 5-74 Noise-sideband performance of an oscillator at 147 MHz, showing the influence of a tuning diode operated at bias voltages from 1.8 to 2.4 V in 0.1-V increments.

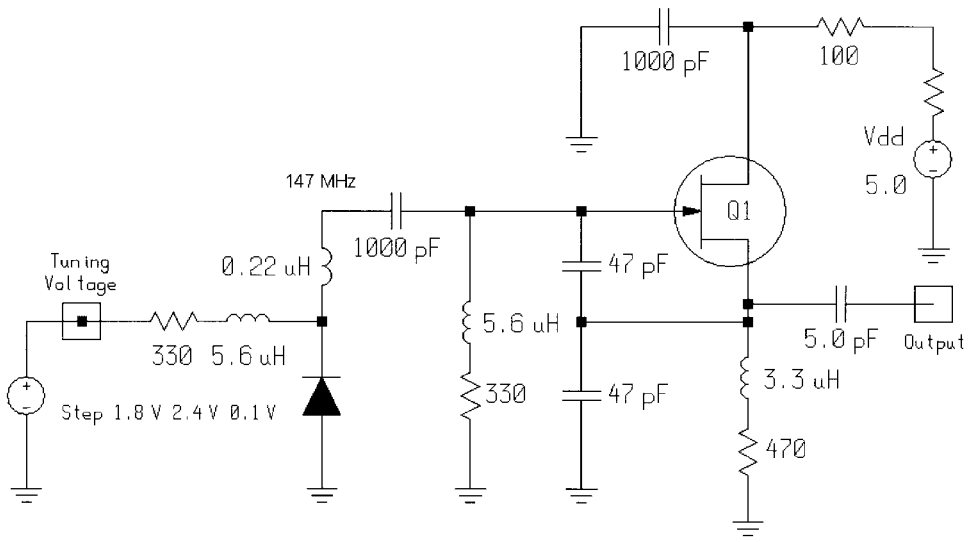

Figure 5-75 The VCO schematic. Because the tuning diode is in series with the resonator, it passes all of the tank's RF current and plays a disproportionately large role in determining the circuit's phase-noise performance.

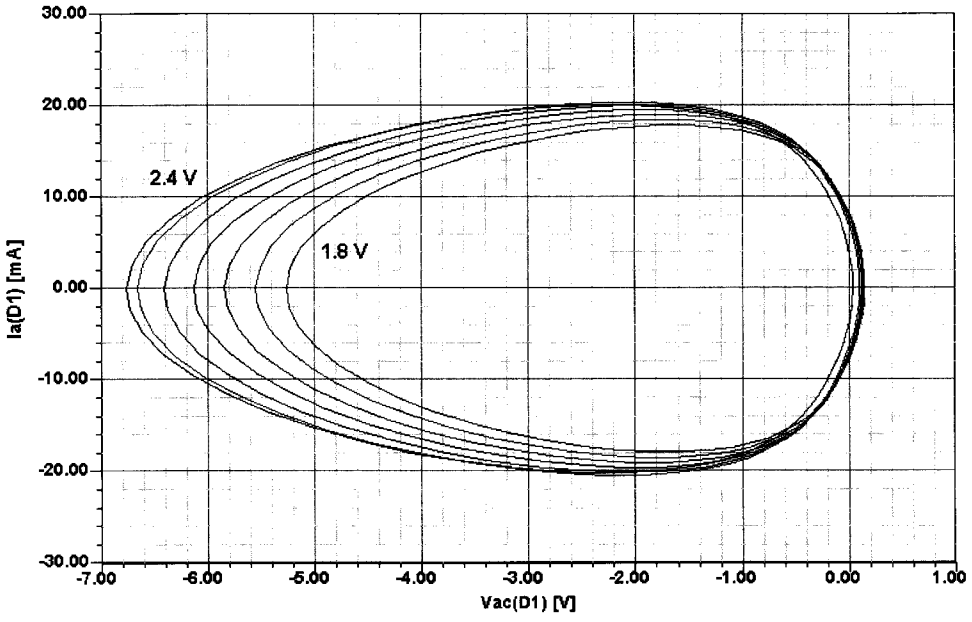

Figure 5-76 Graphing the tuning diode's ac load line reveals that increasing the diode's tuning bias (decreasing its capacitance) results in a disproportionally large increase in the RF voltage across the diode. At all tuning voltages, the RF voltage across the diode is slightly positive (relative to the anode) during part of each cycle.

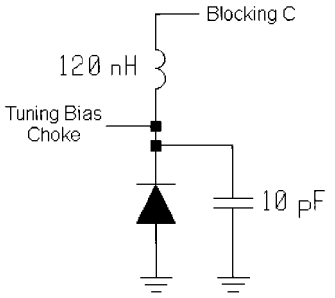

Figure 5-77 Adding capacitance across the tuning diode reduces the effect of its nonlinearities on phase-noise performance. We have also revalued the resonator to 120 nH to maintain oscillation near 147 MHz.

Modifying the oscillator tank to add capacitance in parallel with the tuning diode (Figure 5-77) reduces the tuning diode's effect on tank Q and L/C ratio, and therefore its contribution to phase noise. With this arrangement, we now see the expected relationship between tuning bias and phase noise: The higher the tuning bias, the lower the phase noise (Figure 5-78). Figure 5-79 shows that the diode's ac load line is now virtually unchanged across the tuning-voltage range. The RF voltage across the diode still goes positive (relative to the anode) during part of each cycle.

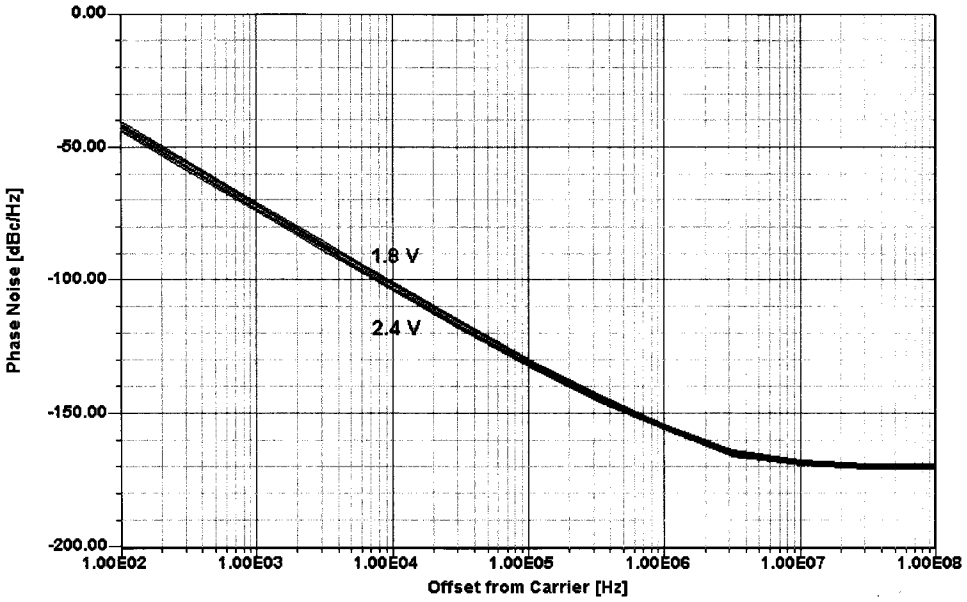

Figure 5-78 Now that the tuning diode passes only part of the tank's RF current, varying its capacitance does not result in the large change in phase-noise performance shown in Figure 5-74. Note also that the phase-noise-versus-tuning-bias relationship has reversed relative to that shown in Figure 5-74: The highest tuning voltage now corresponds to the lowest phase noise.

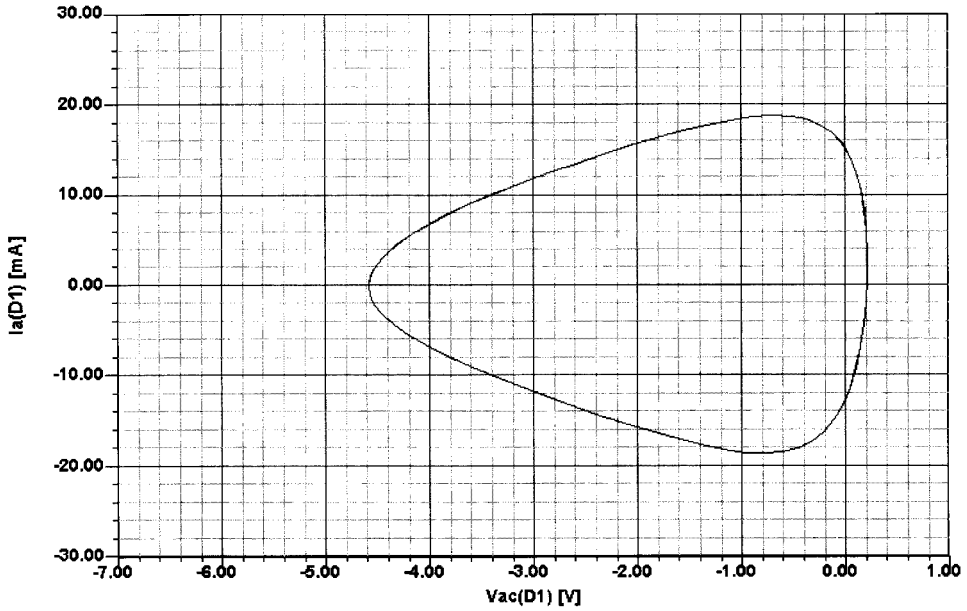

Figure 5-79 The ac load line for the tuning diode in Figure 5-77. Now the voltage swing across the diode is virtually the same at all tuning voltages. The RF voltage across the diode still goes positive (relative to the anode) during part of the cycle.

Figure 5-80 shows one more modification to the VCO tank. Now, the tuning diode is lightly coupled to the hot end of the tank, in parallel with the resonator. The result is phase-noise performance that is essentially unchanged across the 1.8–2.4-V tuning-voltage range. Figure 5-81 compares this circuit's phase-noise performance with the worst-case performance of the tank configurations in Figures 5-75 and 5-77. Figure 5-82 compares the diode ac load lines that correspond to the phase-noise curves in Figure 5-81. The best phase-noise performance corresponds to the diode ac load line that exhibits the narrowest voltage swing and never goes positive relative to the anode.

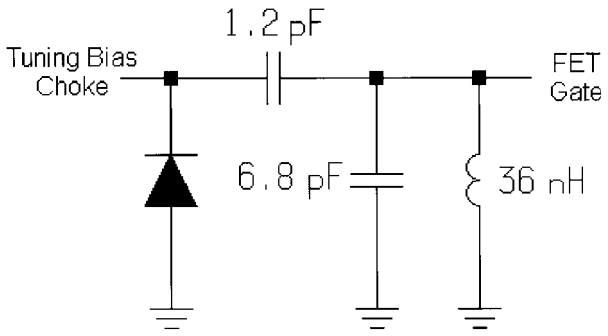

Figure 5-80 Tank circuit reconfigured as per Figure 5-54 to lightly couple the tuning diode in parallel with the resonator, with the resonator inductance again decreased to maintain oscillation near 147 MHz. The 1000-pF capacitor and gate choke of Figure 5-75 (5.6 μH in series with 330 Ω) are no longer needed.

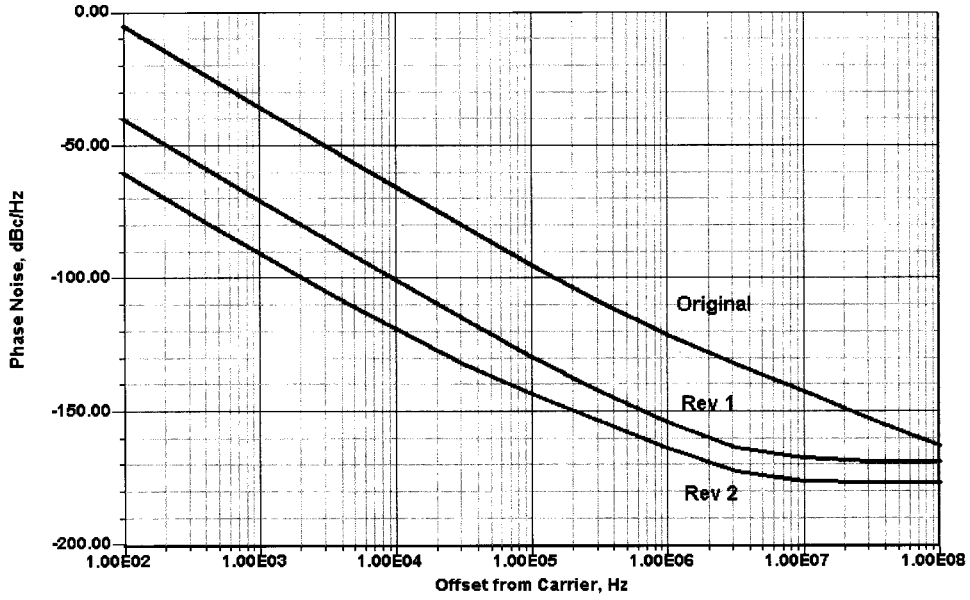

Figure 5-81 Comparison of worst-case phase-noise performance obtained with the tank configurations of Figures 5-75 (Original), 5-77 (Rev 1), and 5-80 (Rev 2).

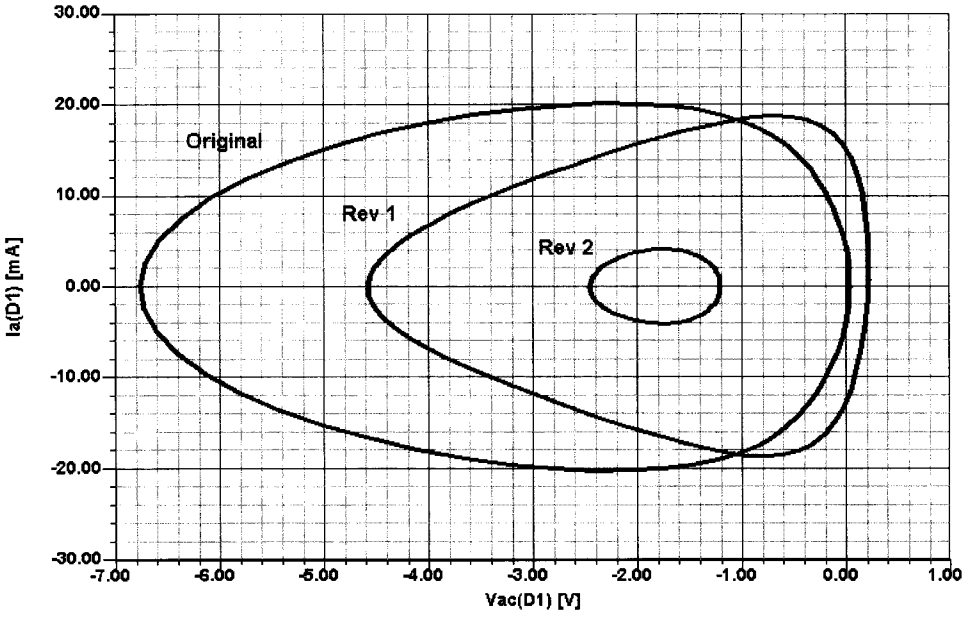

Figure 5-82 Comparison of the tuning diode's ac load line for the worst-case phase-noise curves of Figure 5-79.

It's important to keep in mind that we have not gained something for nothing in achieving the best phase-noise response in Figure 5-81. As we reduced the diode's phase-noise contribution, we also reduced the oscillator's tuning range—from 7.1% (Figure 5-75 circuit) to 1.8% (Figure 5-77 circuit) to 0.046% (Figure 5-80). Simultaneously optimizing phase-noise performance and tuning range requires a combination of techniques. First, we would maximize diode Q by using as high a tuning voltage as feasible. Second, we would use antiseries-connected diodes to minimize the RF voltage swing across them (Figure 5-55). Both of these techniques work against the achievement of wide tuning ranges by minimizing the capacitance swing that the diodes can contribute. As a result of this, and because hyperabrupt diodes are not available for the frequencies at which wireless VCOs operate, we would therefore use multiple antiseries diode pairs in parallel.

It is of interest to compare various oscillators. Figure 5-83 shows the performance of a 10-MHz crystal oscillator, a 40-MHz *LC* oscillator, the HP8640 cavity-tuned oscillator at 500 MHz, the 310–640-MHz switched-reactance oscillator of the HP8662 oscillator, and a 2–6-GHz YIG oscillator at 6 GHz.

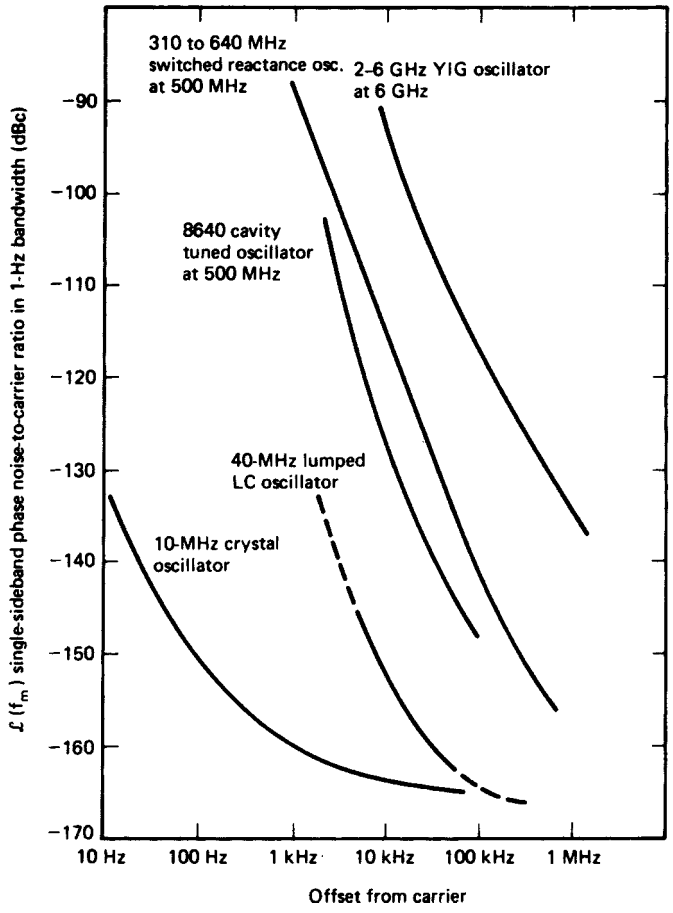

Figure 5-83 Comparison of noise-sideband performances of a crystal oscillator, *LC* oscillator, cavity-tuned oscillator, switched-reactance oscillator, and YIG oscillator.

5-6-3 Nonlinear Approach to the Calculation of Oscillator Phase Noise

The mechanism of noise generation in an oscillator combines the equivalent of frequency conversion (mixing) with the effect of AM-to-PM conversion. Therefore, to calculate oscillator phase noise, we must first be able to calculate the noise figure of a mixer. The following nonlinear approach is based on Ulrich L. Rohde, Chao-Ren Chang, and Jason Gerber, "Design and Optimization of Low-Noise Oscillators Using Nonlinear CAD Tools," *IEEE Frequency Control Symposium Proceedings*, 1994, pp. 548–554. This section presents the use of a novel algorithm for the computation of SSB carrier noise in free-running oscillators using the harmonic-balance (HB) nonlinear technique.

Traditional approaches relying on frequency conversion analysis are not sufficient to describe the complex physical behavior of a noisy oscillator. The accuracy of this nonlinear approach is based on the dynamic range of the harmonic-balance simulator and the quality of the parameter extraction for the active device. The algorithm described has also been verified with several examples up to millimeter wavelengths. This is the only algorithm that provides a complete and rigorous treatment of noise analysis for autonomous circuits.

Noise Generation in Oscillators. As shown earlier, the qualitative linearized picture of noise generation in oscillators is very well known [9]. The physical effects of random fluctuations taking place in the circuit are different depending on their spectral allocation with respect to the carrier:

- Noise components at low-frequency deviations result in frequency modulation of the carrier through mean square frequency fluctuation proportional to the available noise power.
- Noise components at high-frequency deviations result in phase modulation of the carrier through mean square phase fluctuation proportional to the available noise power.

We will demonstrate that the same conclusions can be derived quantitatively from the HB equations for an autonomous circuit.

Equivalent Representation of a Noisy Nonlinear Circuit. A general noisy nonlinear network can be described by the equivalent circuit shown in Figure 5-84. The circuit is divided into linear and nonlinear subnetworks as noise-free multiports. Noise generation is accounted for by connecting a set of noise voltage and noise current sources at the ports of the linear subnetwork [9–18].

Frequency Conversion Approach. The circuit supports a large-signal time-periodic steady state of fundamental angular frequency ω_0(carrier). Noise signals are small perturbations superimposed on the steady state, represented by families of pseudosinusoids located at the sidebands of the carrier harmonics. Therefore, the noise performance of the circuit is determined by the exchange of power among the sidebands of the unperturbed steady state through frequency conversion in the nonlinear subnetwork. Due to the perturbative assumption, the nonlinear subnetwork can be replaced with a multifrequency linear multiport described by a conversion matrix. The flow of noise signals can be computed by means of conventional linear circuit techniques.

The frequency conversion approach frequently used has limitations. The frequency-conversion approach is not sufficient to predict the noise performance of an autonomous

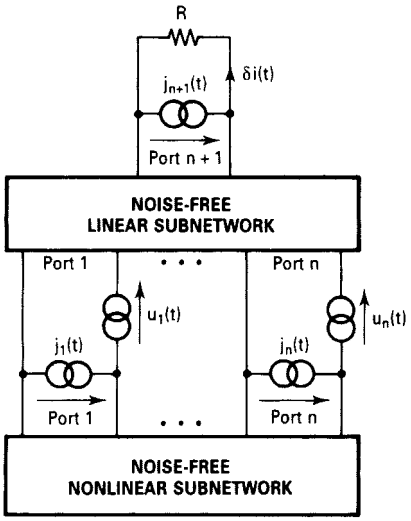

Figure 5-84 Equivalent circuit of a general noisy nonlinear network.

circuit. The spectral density of the output noise power and, consequently, the PM noise computed by the conversion analysis are proportional to the available power of the noise sources.

- In the presence of both thermal and flicker noise sources, PM noise increases as ω^{-1} for $\omega \to 0$ and tends to a finite limit for $\omega \to \infty$.
- Frequency conversion analysis correctly predicts the far-carrier noise behavior of an oscillator and, in particular, the oscillator noise floor; it does not provide results consistent with the physical observations at low deviations from the carrier.

This inconsistency can be removed by adding the modulation noise analysis. In order to determine the far-away noise using the autonomous circuit perturbation analysis, the following applies.

The circuit supports a large-signal time-periodic autonomous regime. The circuit is perturbed by a set of small sources located at the carrier harmonics and at the sidebands at a deviation ω from carrier harmonics. The perturbation of the circuit state (δX_B, δX_H) is given by the uncoupled sets of equations:

$$\frac{\partial E_B}{\partial E_B}\,\delta X_B = J_B(\omega) \tag{5-127}$$

$$\frac{\partial E_H}{\partial E_H}\,\delta X_H = J_H(\omega) \tag{5-128}$$

where E_B, E_H = vectors of HB errors
X_B, X_H = vectors of state-variable (SV) harmonics (since the circuit is autonomous, one of the entries X is replaced by the fundamental frequency ω_0)
J_B, J_H = vectors of forcing terms

The subscripts *B* and *H* denote sidebands and carrier harmonics, respectively.

For a spot noise analysis at a frequency ω, the noise sources can be interpreted in either of two ways:

- Pseudosinusoids with random amplitude and phase located at the sidebands. This noise generation mechanism is described by Eq. (5-127), which is essentially a frequency conversion equation relating the sideband harmonics of the state variables and of the noise sources. This description is exactly equivalent to the one provided by the frequency conversion approach. This mechanism is referred to as *conversion noise* [19–21].
- Sinusoids located at the carrier harmonics and randomly phase and amplitude modulated by pseudosinusoidal noise at frequency ω. This noise generation mechanism is described by Eq. (5-128), which describes noise-induced jitter of the circuit-state, represented by the vector δX_H. The modulated perturbing signals are represented by replacing the entries of J_H with the complex modulation laws. This mechanism is referred to as *modulation noise.* One of the entries of δX_H is $\delta\omega_0$, where $\delta\omega_0(\omega)$ is the phasor of the pseudosinusoidal components of the fundamental frequency fluctuations in a 1-Hz band at frequency ω. Equation (5-128) provides a frequency jitter with a mean square value proportional to the available noise power. In the presence of both thermal and flicker noise, PM noise increases as ω^{-3} for $\omega \to 0$ and tends to 0 for $\omega \to \infty$. Modulation noise analysis correctly describes the noise behavior of an oscillator at low deviations from the carrier and does not provide results consistent with physical observations at high deviations from the carrier.

The combination of both phenomena explains the noise in the oscillator shown in Figure 5-85, where the near-carrier noise dominates below ω_X and far-carrier noise dominates above ω_X. Figure 5-86 (itemized form) shows the noise sources as they are applied at the IF. We have arbitrarily defined the low oscillator output as IF. This applies to the conversion matrix calculation.

Figure 5-87 shows the contributions that have to be taken into consideration for calculation of the noise at the output. The accuracy of the calculation of the phase noise depends highly on the quality of the parameter extraction for the nonlinear device; in particular, high-frequency phenomena must be modeled properly. In addition, the flicker noise contribution is essential. This is also valid for mixer noise analysis.

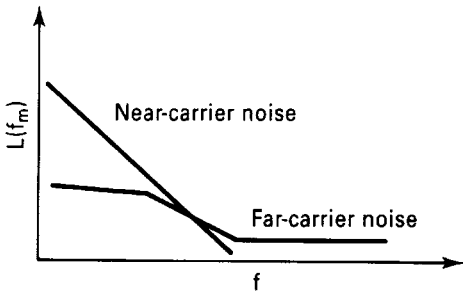

Figure 5-85 Oscillator noise components.

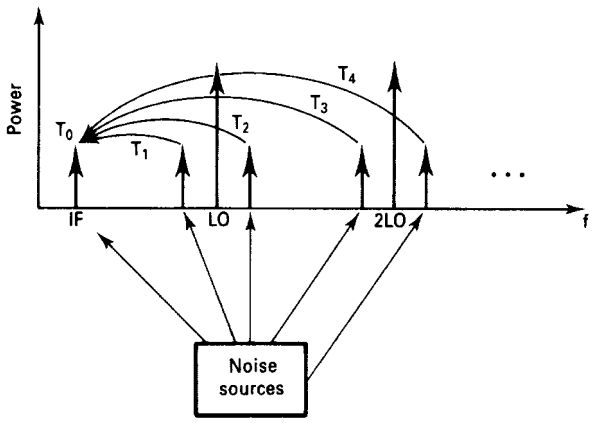

Figure 5-86 Noise sources where the noise at each sideband contributes to the output noise at the IF through frequency conversion.

Figure 5-88 shows the measured phase noise at 10 kHz of the carrier of an 800-MHz oscillator and the simulated result. The good agreement between measured and predicted data is worth noticing. At currents above 5 mA, the simulation becomes inaccurate as breakdown effects occur that were not part of the simulation.

Conversion Noise Analysis. The actual mathematics used to calculate the noise result (Ansoft Serenade 8.*x*) are as follows.

kth Harmonic PM Noise

$$\langle |\delta\Phi_k(\omega)|^2 \rangle = \frac{N_k(\omega) - N_{-k}(\omega) - 2\,\mathrm{Re}[C_k(\omega)]}{R|I_k^{SS}|^2} \tag{5-129}$$

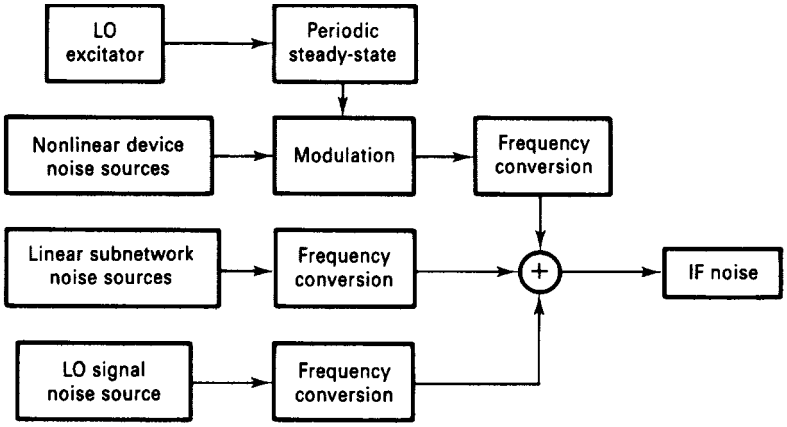

Figure 5-87 Noise mechanisms.

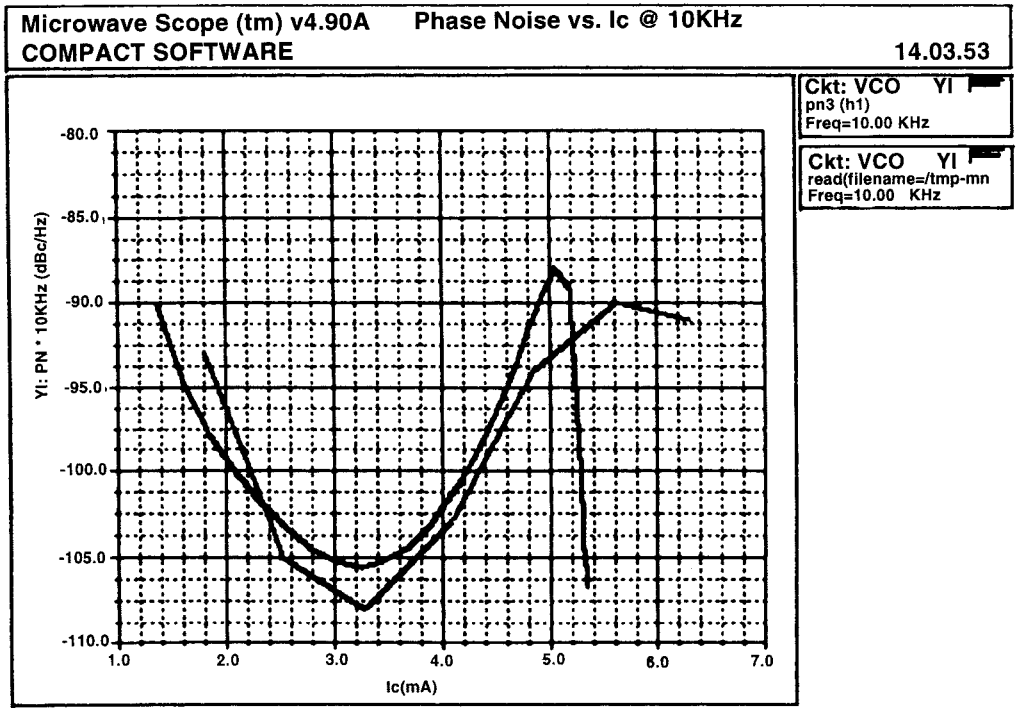

Figure 5-88 Bias-dependent measured and predicted phase noise at 10 kHz off the carrier of an 800-MHz oscillator.

kth Harmonic AM Noise

$$\langle |\delta A_k(\omega)|^2 \rangle = 2\,\frac{N_k(\omega) - N_{-k}(\omega) + 2\,\mathrm{Re}[C_k(\omega)]}{R|I_k^{SS}|^2} \tag{5-130}$$

kth Harmonic PM–AM Correlation Coefficient

$$C_k^{\mathrm{PMAM}}(\omega) = \langle \delta\Phi_k(\omega)\delta A_k(\omega)^* \rangle = -\sqrt{2}\,\frac{2\,\mathrm{Im}[C_k(\omega)] + j[N_k(\omega) - N_{-k}(\omega)]}{R|I_k^{SS|^2}} \tag{5-131}$$

where

$N_k(\omega)$, $N_{-k}(\omega)$ = noise power spectral densities at the upper and lower sidebands of the kth harmonic
$C_k(\omega)$ = normalized correlation coefficient of the upper and lower sidebands of the kth carrier harmonic
R = load resistance
I_k^{SS} = kth harmonic of the steady-state current through the load

Modulation Noise Analysis

kth Harmonic PM Noise

$$\langle |\delta\Phi_k(\omega)|^2 \rangle = \frac{k^2}{\omega^2}\,\mathrm{T}_F\,\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_F^t \tag{5-132}$$

kth Harmonic AM Noise

$$\langle |\delta A_k(\omega)|^2 \rangle = \frac{2}{|I_k^{SS}|^2}\,\mathrm{T}_{Ak}\,\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_{Ak}^t \tag{5-133}$$

kth Harmonic PM–AM Correlation Coefficient

$$C_k^{\mathrm{PMAM}}(\omega) = \langle \delta\Phi_k(\omega)\delta A_k(\omega)^* \rangle = \frac{k\sqrt{2}}{j\omega|I_K^{SS}|^2}\,\mathrm{T}_F\langle \mathrm{J}_H(\omega)\mathrm{J}_H^t(\omega)\rangle \mathrm{T}_{Ak}^t \tag{5-134}$$

where $\mathrm{J}_H(\omega)$ = vector of Norton equivalent of the noise sources
T_F = frequency transfer matrix
I_k^{SS} = kth harmonic of the steady-state current through the load

Experimental Variations. We will look at two examples where we compare predicted and measured data. Figure 5-89 shows the abbreviated circuit of a 10-MHz crystal oscillator. It uses a high-precision, high-Q crystal made by companies such as Bliley. Oscillators like this are intended for use as frequency and low-phase-noise standards. In this case, the circuit under consideration is part of the HP3048 phase-noise measurement system.

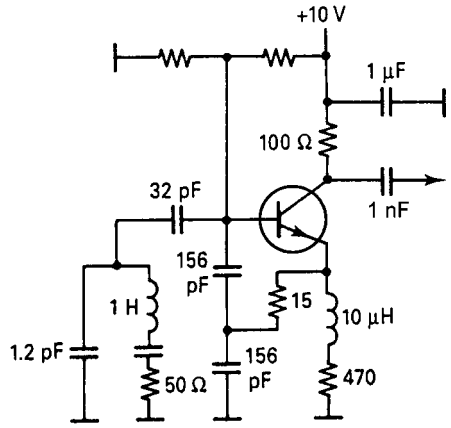

Figure 5-89 Abbreviated circuit of a 10-MHz crystal oscillator.

Figure 5-90 shows the measured phase noise of this HP frequency standard, and Figure 5-91 shows the phase noise predicted using the mathematical approach outlined above.

In cooperation with Motorola, we also analyzed an 800-MHz VCO. In this case, we also did the parameter extraction for the Motorola transistor. Figure 5-92 shows the circuit, a Colpitts oscillator that uses RF feedback in the form of a 15-Ω resistor and a capacitive

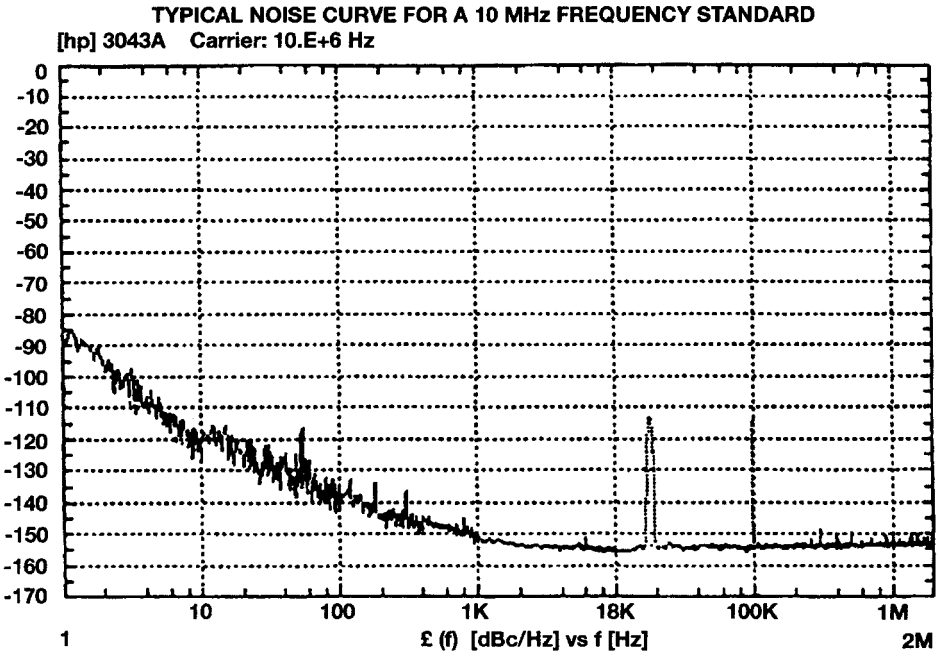

Figure 5-90 Measured phase noise for this frequency standard by HP.

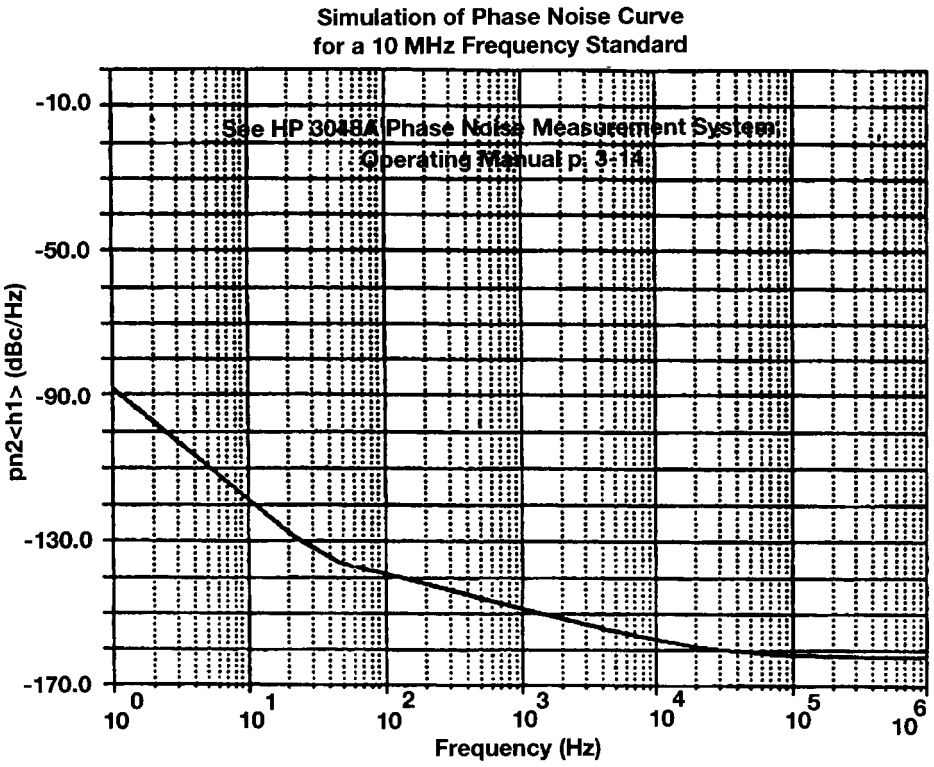

Figure 5-91 Simulated phase noise of the oscillator shown in Figure 5-89.

voltage divider consisting of 1 pF between the BJT's base and the feedback resistor, and 1 pF between the feedback resistor and common. Also, the tuned circuit is loosely coupled to this part of the transistor circuit. Figure 5-93 shows a comparison between predicted and measured phase noise for this oscillator. Figures 5-94, 5-95, and 5-96 show the oscillator's predicted output waveform, spectrum, and dc I–V and ac load line responses, respectively.

Phase Noise Optimization. By allowing the simulator's optimizer to vary the oscillator's feedback and dc operating point, phase noise can be improved. The values that were allowed to vary were the values of the capacitors in the feedback voltage divider, the value of a negative-feedback resistor (starting value, 15 Ω) that reduces AM–PM conversion, and the emitter resistor, which changes the transistor's dc bias and therefore affects its bias-dependent flicker noise. Figure 5-97 shows the improvement of the 800-MHz VCO as previously shown. While the close-in phase noise can be improved drastically by approximately 32 dB, the far-out noise at 20 MHz and beyond is deteriorated. This is due to the resistive feedback, which reduces AM-to-PM conversion [22–24].

In testing an oscillator's resistance to frequency pushing (frequency shift with supply-voltage changes), variations in phase noise can be observed. Phase noise is also bias dependent,

and this fact can be used for phase-noise optimization. Figure 5-98 shows the phase noise of an oscillator as its supply voltage is varied.

Summary. This section has demonstrated the power of harmonic-balance simulation in the design of low-phase-noise oscillators. The simulator can be used to accurately predict close-in and far-out phase noise based on the contribution of the transistor, the loaded Q of the resonator, and, in the case of a VCO, the contribution of the tuning diode.

This is the first time that a bias-dependent noise model for both FETs and bipolar transistors has been developed and used for this type of application, in which optimization is allowed to vary circuit components and the bias point for best performance.

Practical examples ranging from a 10-MHz crystal oscillator to a 1-GHz CR oscillator have been supplied. The theoretical background for the nonlinear oscillator and its validation have been presented.

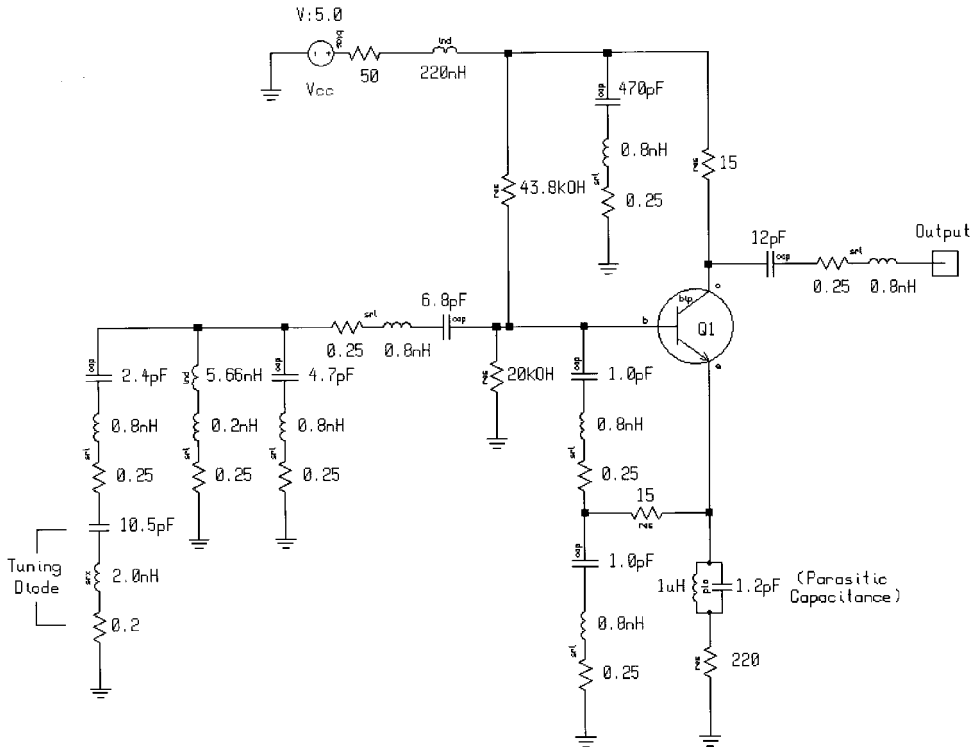

Figure 5-92 Colpitts oscillator that uses RF negative feedback between the emitter and capacitive voltage divider. To be realistic, we used actual components rather than ideal ones. The suppliers for the capacitors and inductors provide some typical values for the parasitics. The major changes are 0.8 nH and 0.25 Ω in series with the capacitors. The same thing applies for the main inductance, which has a parasitic connection inductance of 0.2 nH in series with a 0.25-Ω resistance. These types of parasitics are valid for a fairly large range of components assembled in surface-mount applications. Most engineers model the circuit only by assuming lossy devices, not adding these important parasitics. One of the side-effects we have noticed is that the output power is more realistic and, needless to say, the simulated phase noise agrees quite well with measured data. This circuit can also serve as an example for modeling amplifiers and mixers using surface-mount components.

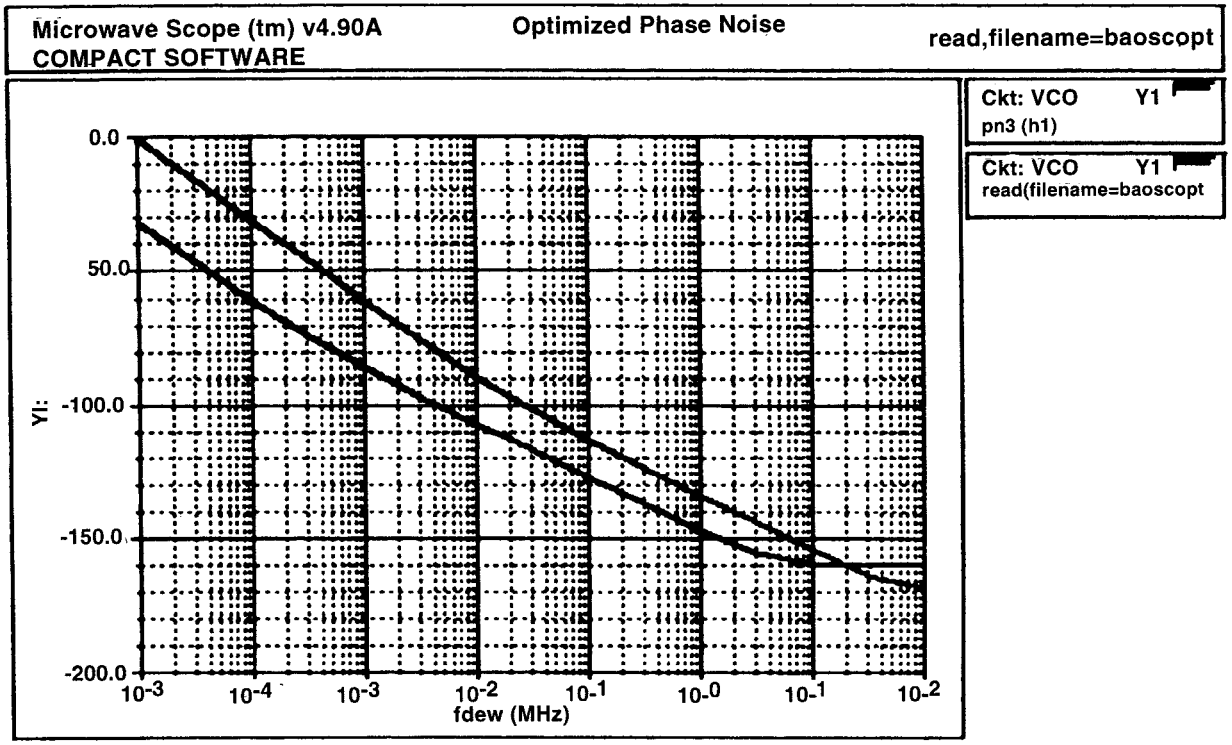

Figure 5-97 Phase noise of the 800-MHz VCO before and after optimization.

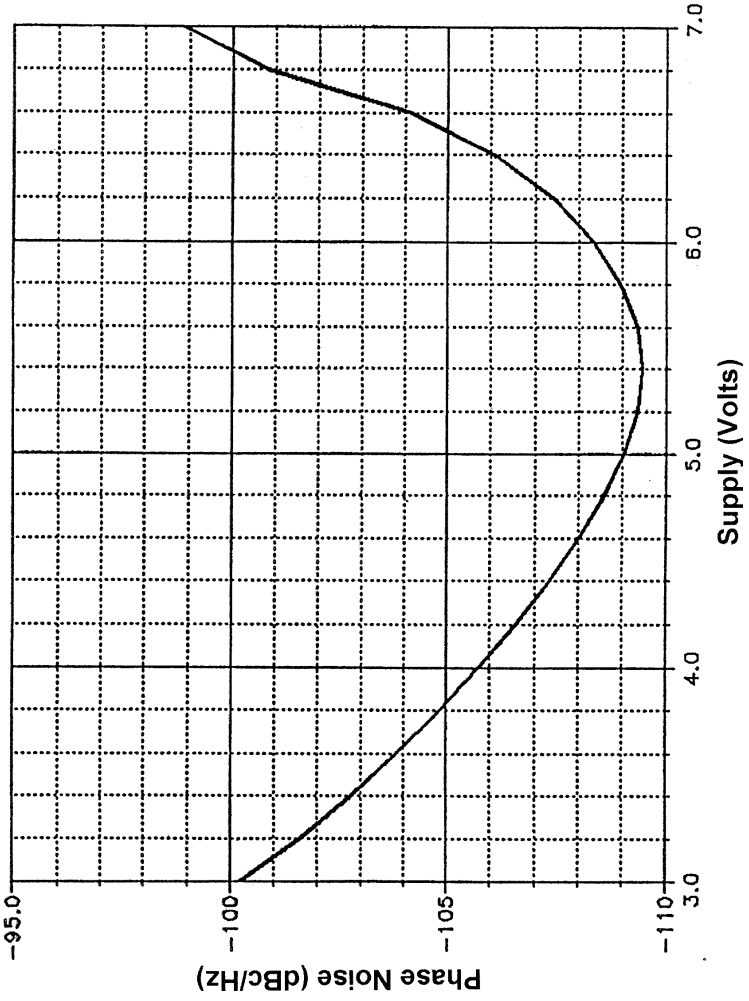

Figure 5-98 Calculated phase noise as a function of the supply voltage for a BJT oscillator. The graph shows a distinct minimum for a particular bias, which could be translated into a collector current change. Such phase-noise minimization could also be accomplished by changing just the voltage applied to the bias portion of the oscillator.

Acknowledgment. This research work for nonlinear operation in oscillators, partly sponsored by the U.S. Department of Defense MIMIC program, was performed in cooperation with Professor Vittorio Rizzoli's group of the Department of Electrical Engineering, Information and Systems Engineering at the University of Bologna, Italy, and the Motorola Portable Products Division, Florida, as well as the engineering team of Ansoft Corporation in New Jersey.

5-7 OSCILLATORS IN PRACTICE

5-7-1 Oscillator Specifications

Although we have tended to emphasize phase noise as a critical indicator of oscillator quality, phase noise is only one of a number of oscillator performance criteria that must be considered in wireless system design. In addition to phase noise, the following characteristics are used by commercial companies to describe oscillator performance:

Frequency Pushing. Frequency pushing characterizes the degree to which an oscillator's frequency is affected by its supply voltage. A sudden current surge caused by activating a transceiver's RF power amplifier may produce a spike on the VCO's dc power supply and a consequent frequency jump. Like tuning sensitivity (below), pushing is specified in frequency/voltage form and is tested by varying the VCO's dc supply voltage (typically ± 1 V) with its tuning voltage held constant.

Harmonic Output Power. The harmonic content is measured relative to the output power. Typical values are 20 dB or more suppression relative to the fundamental. This suppression can be improved by additional filtering.

Output Power. The output power of the oscillator, typically expressed in dBm, is measured into a 50-Ω load. The output power is always combined with a specification for flatness or variation. A typical specification would be 0 dBm ± 1 dB.

Output Power as a Function of Temperature. All active circuits vary in performance as a function of temperature. An oscillator's output power over a temperature range should vary less than a specified value, such as 1 dB.

Post-tuning Drift. After a voltage step is applied to the tuning diode input, the oscillator frequency may continue to change until it settles to a final value. This post-tuning drift is one of the parameters that limits the bandwidth of the VCO input.

Power Consumption. This characteristic conveys the dc power, usually specified in milliwatts and sometimes qualified by operating voltage, required by the oscillator.

Sensitivity to Load Changes. To keep costs down, many wireless applications use a VCO alone, without the buffering action of a high reverse-isolation amplifier stage. In such applications, *frequency pulling*, the change of frequency resulting from partially reactive loads, is an important oscillator characteristic. Pulling is commonly specified in terms of the frequency shift that occurs when the oscillator is connected to a load that exhibits a non-unity VSWR (such as 1.75, usually referenced to 50 Ω), compared to the frequency that results with a unity VSWR load (usually 50 Ω). Frequency pulling must be minimized, especially in cases where power stages are close to the VCO unit

and short pulses may affect the output frequency. Such feedback may make phase locking impossible.

Spurious Outputs. A VCO's spurious output specification, expressed in decibels, enumerates the strength of unwanted and nonharmonically related components relative to the oscillator fundamental. Because a stable, properly designed oscillator is inherently clean, such *spurs* are typically introduced only by external sources in the form of radiated or conducted interference. See *harmonic output power.*

Temperature Drift. Although the synthesizer is responsible for locking and maintaining the oscillator's frequency, the VCO's frequency change as a function of temperature is a critical parameter and must be specified. Its value varies between 10 kHz/°C to several hundred kHz/°C depending on the center frequency and tuning range.

Tuning Characteristic. This specification shows the relationship, depicted as a graph, between a VCO's operating frequency and the tuning voltage applied. Ideally, the correspondence between operating frequency and tuning voltage is linear. See *tuning linearity.*

Tuning Linearity. For stable synthesizers, a constant deviation of frequency versus tuning voltage is desirable. It is also important to make sure that there are no breaks in the tuning range—for example, that the oscillator does not stop operating with a tuning voltage of 0 V. See *tuning characteristic.*

Tuning Sensitivity, Tuning Performance. This characteristic, typically expressed in megahertz per volt (MHz/V), enumerates how much a VCO's frequency changes per unit of tuning-voltage change.

Tuning Speed. This characteristic is defined as the time necessary for the VCO to reach 90% of its final frequency on the application of a tuning-voltage step. Tuning speed depends on the internal components between the input pin and tuning diode—including, among other things, the capacitance present at the input port. The input port's parasitic elements determine the VCO's maximum possible modulation bandwidth.

5-7-2 More Practical Circuits

Because of the need for integration, we will present three IC oscillators of increasing complexity. The circuit in Figure 5-99 is found in early Siemens ICs. Figure 5-100 shows its phase-noise performance.

Figure 5-101 shows the basic push–pull oscillator topology underlying the circuit in Figure 5-99. The omission of the current source and active bias components improves the simpler circuit's phase-noise performance over that of the circuit shown in Figure 5-99. Figure 5-102 compares the phase noise of this basic circuit to the integrated version in Figure 5-99.

Figure 5-103 is for those who speculate on the possibility of replacing the BJTs in Figure 5-101 with LDMOS FETs or JFETs. Figure 5-104 compares its phase noise to that of the BJT case. The rule of thumb is that FETs do not have enough gain for high-Q oscillation in oscillators above 400 MHz, and bipolar transistors are a better choice. Because of their higher flicker noise contribution, GaAsFETs should be considered only at frequencies above 4 or 5 GHz.

Figure 5-105 shows a circuit based on two differential amplifiers and frequently found in Gilbert cell IC applications. Figure 5-106 shows its phase-noise performance.

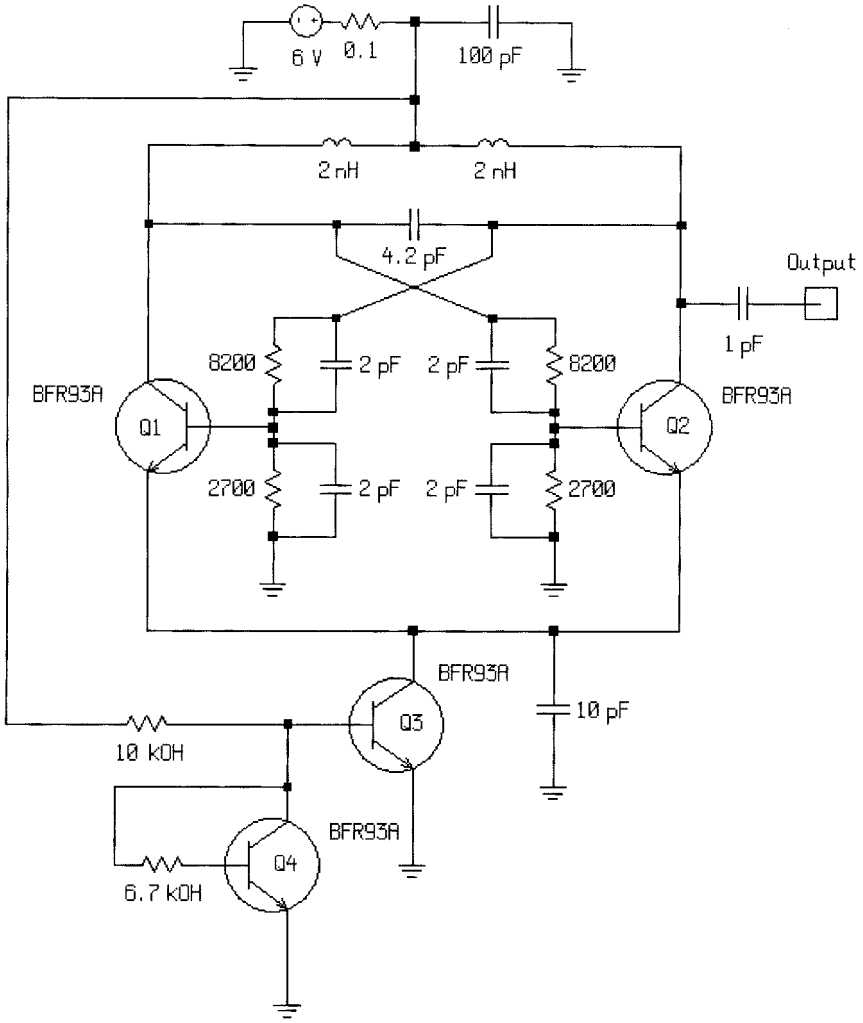

Figure 5-99 Schematic of the Siemens IC oscillator.

Figure 5-107 is a validation circuit that demonstrates a comparison of measured phase-noise performance versus its prediction by circuit simulation software. The circuit is based on the core of Motorola's MC12148 ECL oscillator IC, the topology of which is derived from the superseded MC1648. Motorola specifies the MC12148's typical phase-noise performance as –90 dBc/Hz at an offset of 25 kHz. The close agreement between the measured and simulated results highlights the value of state-of-the-art CAD tools in wireless oscillator design (Figure 5-108).

Figure 5-108 presents the results of *two* simulations: one with ideal L and C components, and another with realistic values specified for these reactances. In using a circuit

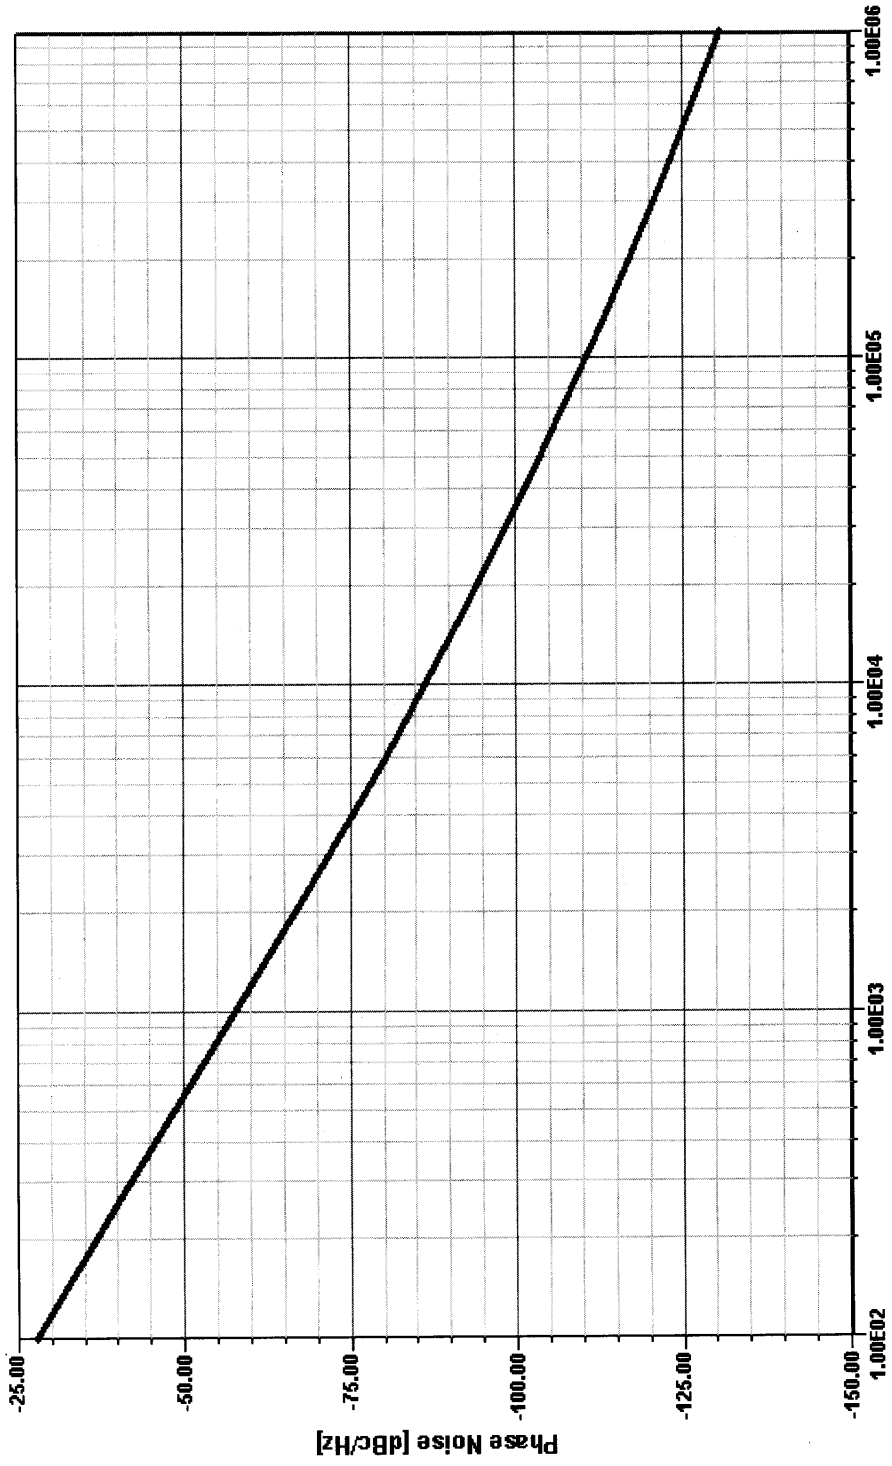

Figure 5-100 Phase noise of the Siemens IC oscillator. The frequency of oscillation is 1.051 GHz.

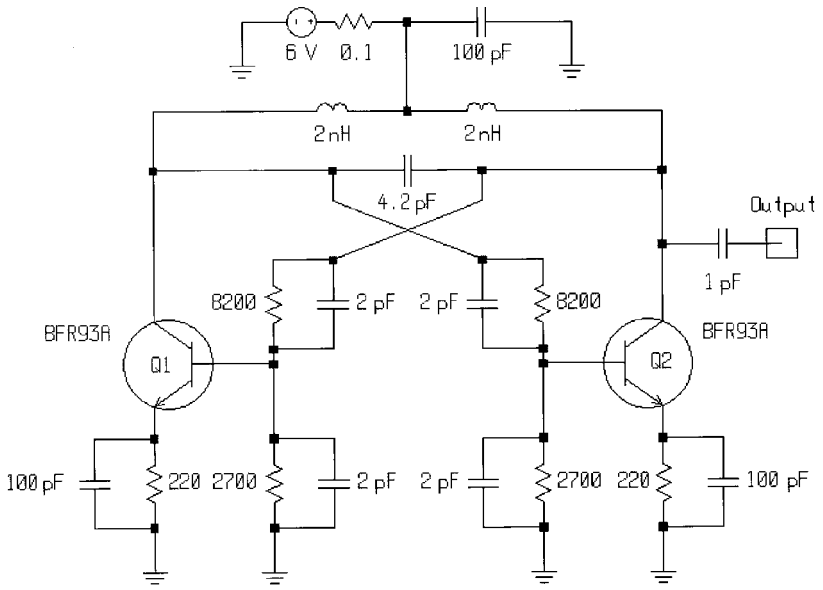

Figure 5-101 Basic push–pull oscillator underlying the circuit shown in Figure 5-99.

simulator to validate and compare oscillator topologies, it's important to start with ideal components because we are interested in comparing the inherent phase-noise performance of various circuits—particularly the role played by the nonlinear reactances in active devices. Because the Q values of practical components are so low in the microwave range (very generally, 200–300 for capacitors and 60–70 for inductors), the inherent merits of one topology, or one device, over another would be masked by loading effects if we conducted our investigations using nonideal reactances. Once initial evaluation is completed, realistic Q values should be specified for increased accuracy in phase-noise, output-power, and output-spectrum simulations.

Finally, as evidence of how moving from lumped to distributed techniques can improve oscillator performance at frequencies where *LC* tanks become problematic, Figure 5-109 compares, for a simulated BJT Colpitts oscillator operating at 2.3 GHz, the difference in phase-noise performance obtainable with a resonator consisting of an ideal 2-nH inductor and a $\frac{1}{4}\lambda$ transmission line (11 Ω, 90° long at 2.6 GHz, attenuation 0.1 dB/m) with the transistor biased by constant-current and constant-voltage sources.

Silicon/GaAs-Based Integrated VCOs and Possible Difficulties. Due to process variations, the center frequency of the VCO cannot be repeated without trimming. Trimming can be avoided by making the VCO gain large enough to compensate for tank circuit variations, but this degrades phase-noise performance and increases the VCO susceptibility to unwanted spurs. For example, a VCO with a gain of 10 MHz/V has a phase noise of –80 dBc/Hz at 10 kHz, while a VCO with a gain of 75 MHz/V has a phase noise of only –60 dBc/Hz at 10 kHz. All but the tank inductors are integrated.

Tank inductors are generally not integrated for reasons of size and Q. The area of a 1-nH inductor is approximately 42,000 mm^2, which is ~3.5% of a typical IC; the area of a 10-nH

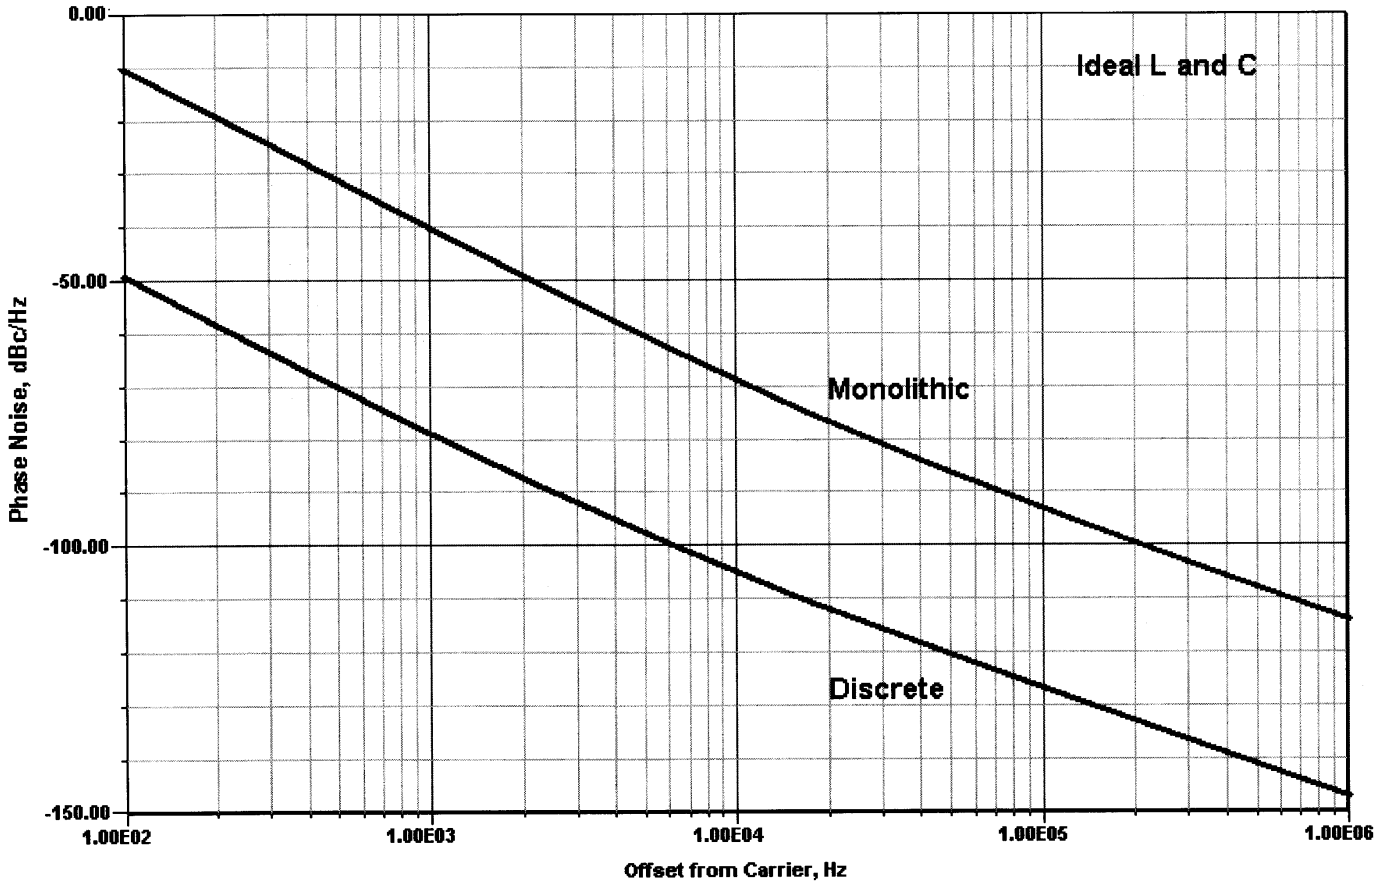

Figure 5-102 The basic version of the oscillator (Discrete curve) is a better phase-noise performer than the integrated version (Monolithic curve). The frequency of oscillation is 1.039 GHz.

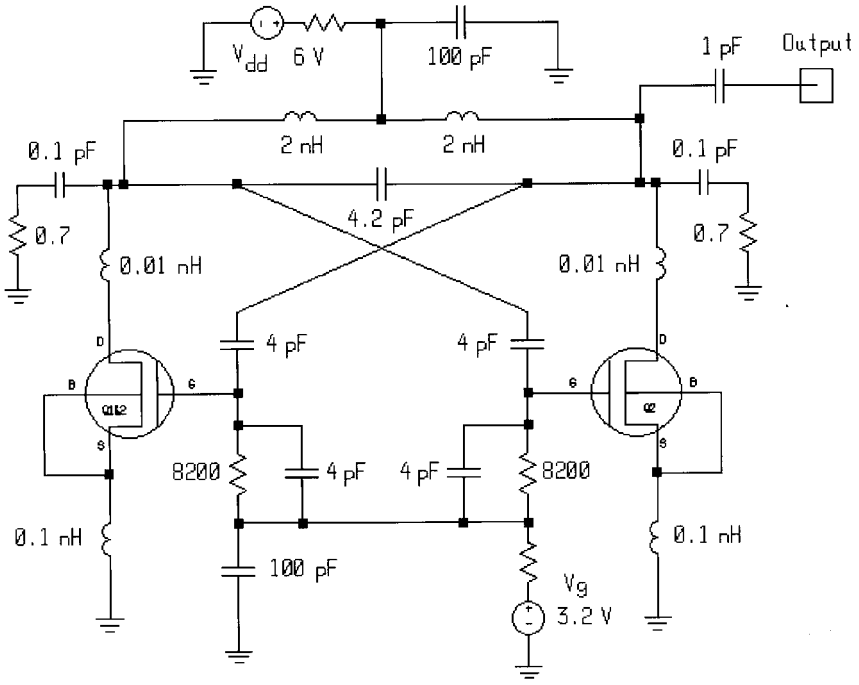

Figure 5-103 A 1.04-GHz push–pull oscillator using LDMOS FETs instead of BJTs. (LDMOS FET parameters courtesy of David K. Lovelace, Motorola, Inc.)

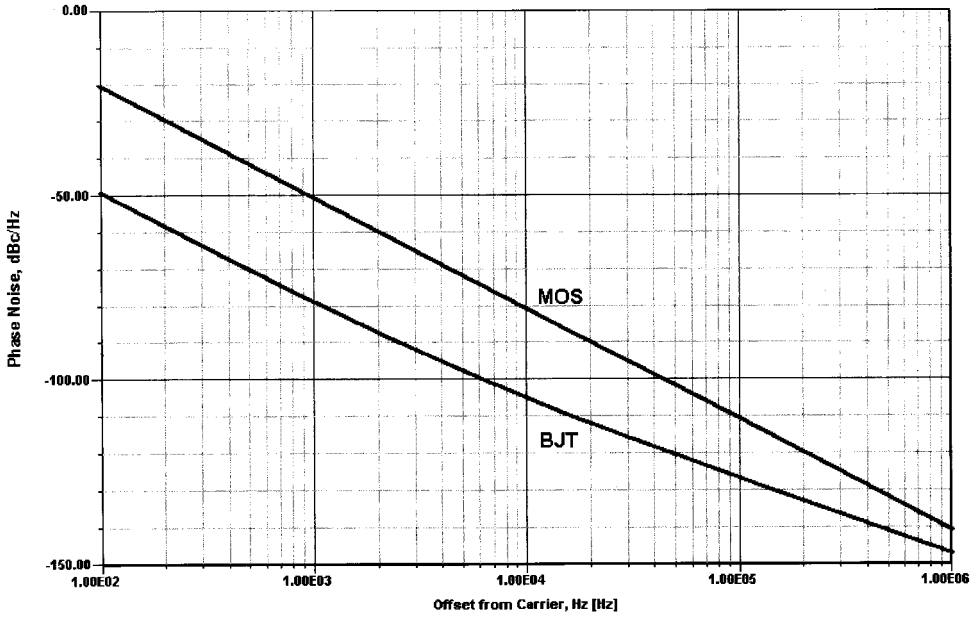

Figure 5-104 Phase-noise comparison of the BJT and MOSFET oscillators.

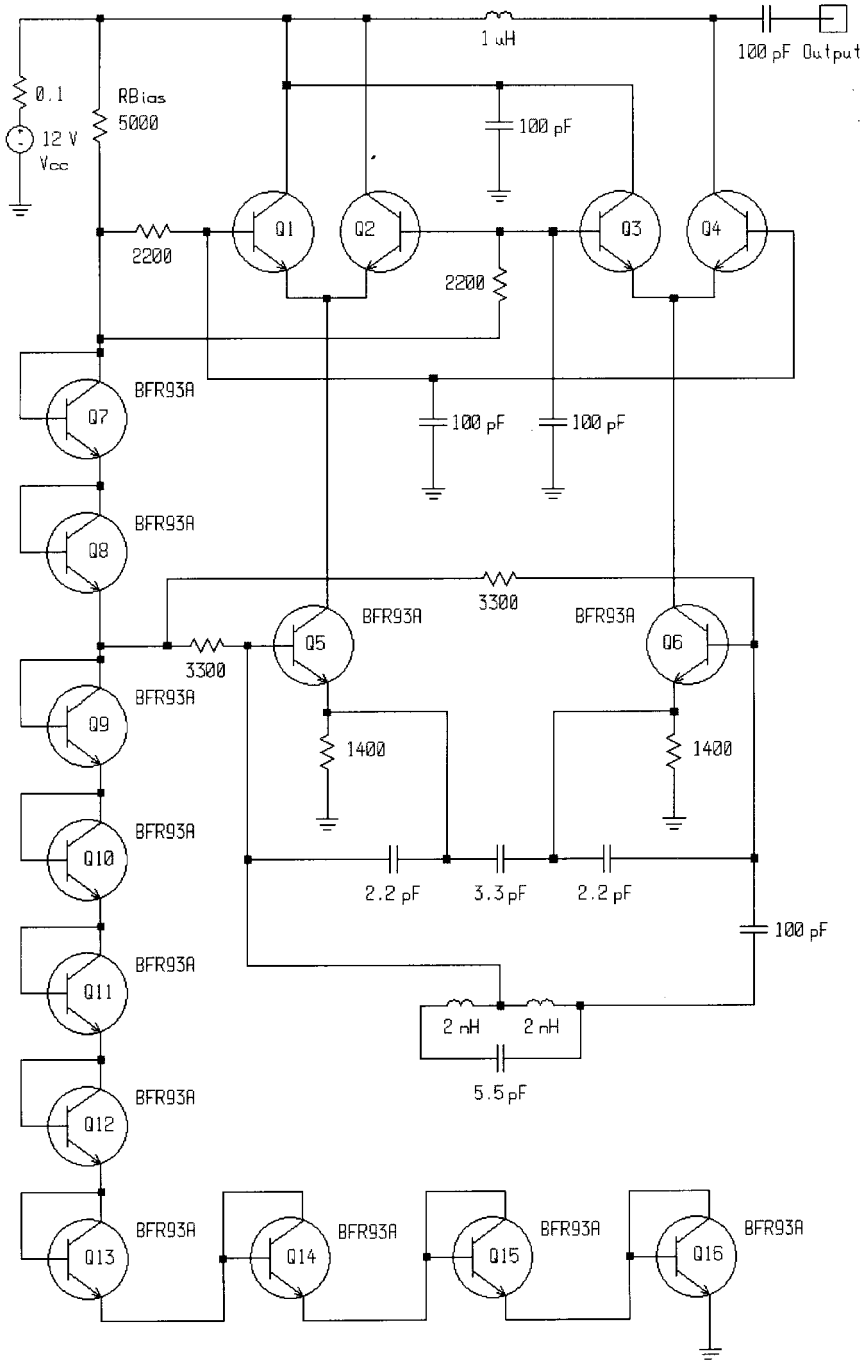

Figure 5-105 A 1.022-GHz IC oscillator based on two differential amplifiers. With an RF signal fed to the bases of Q_1–Q_4 and Q_2–Q_3 in push–pull, and IF output extracted from the collectors of Q_1–Q_3 and Q_2–Q_4 in push–pull, the circuit would act as a Gilbert cell converter. In the circuit shown, we have modified the differential amplifiers' collector circuitry to give single-ended output and avoid cancellation of the oscillator signal.

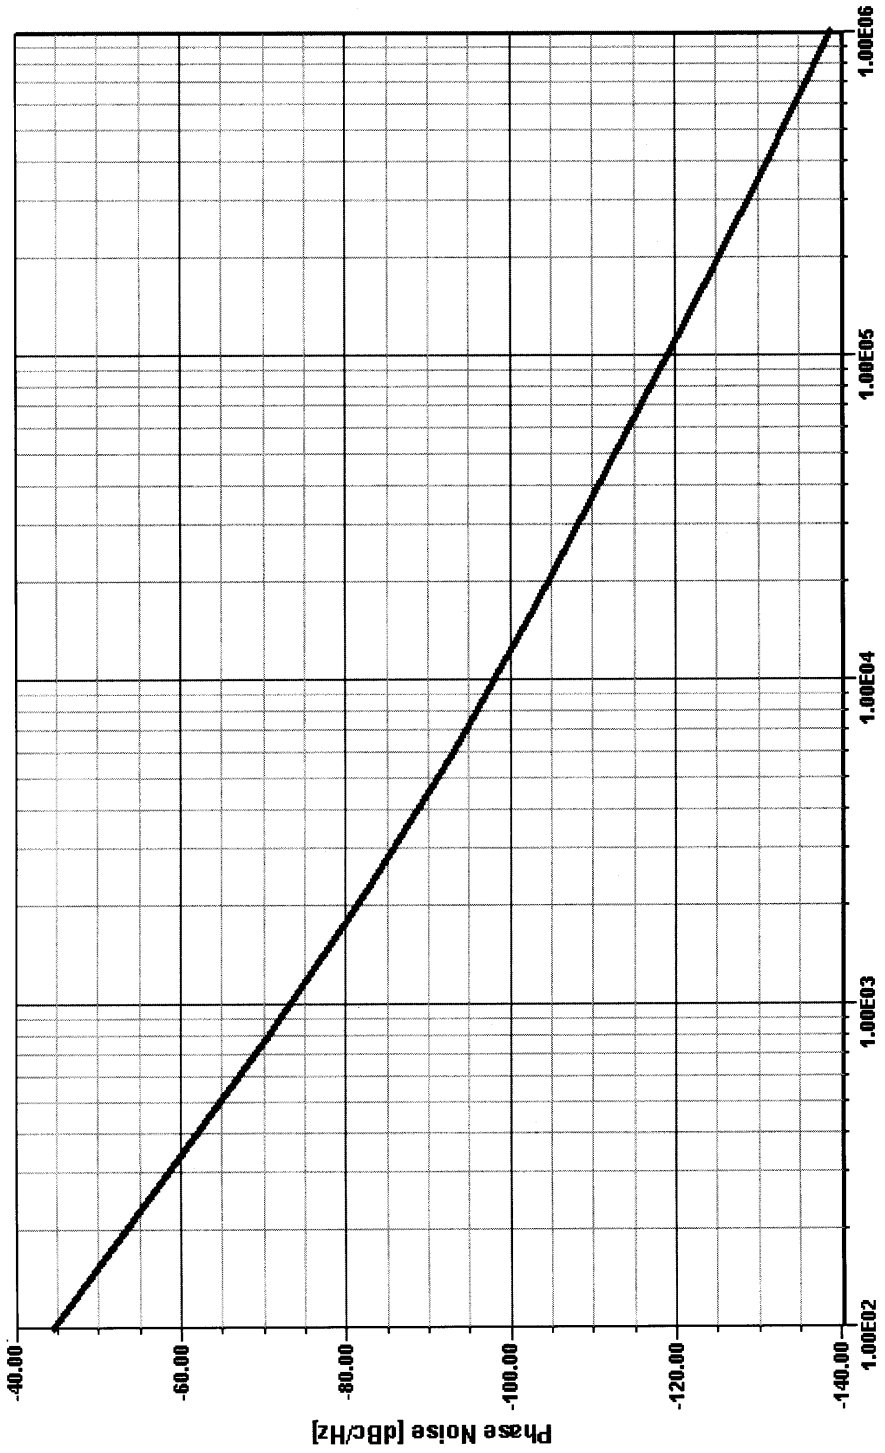

Figure 5-106 Phase noise of the two-differential-amplifier oscillator circuit.

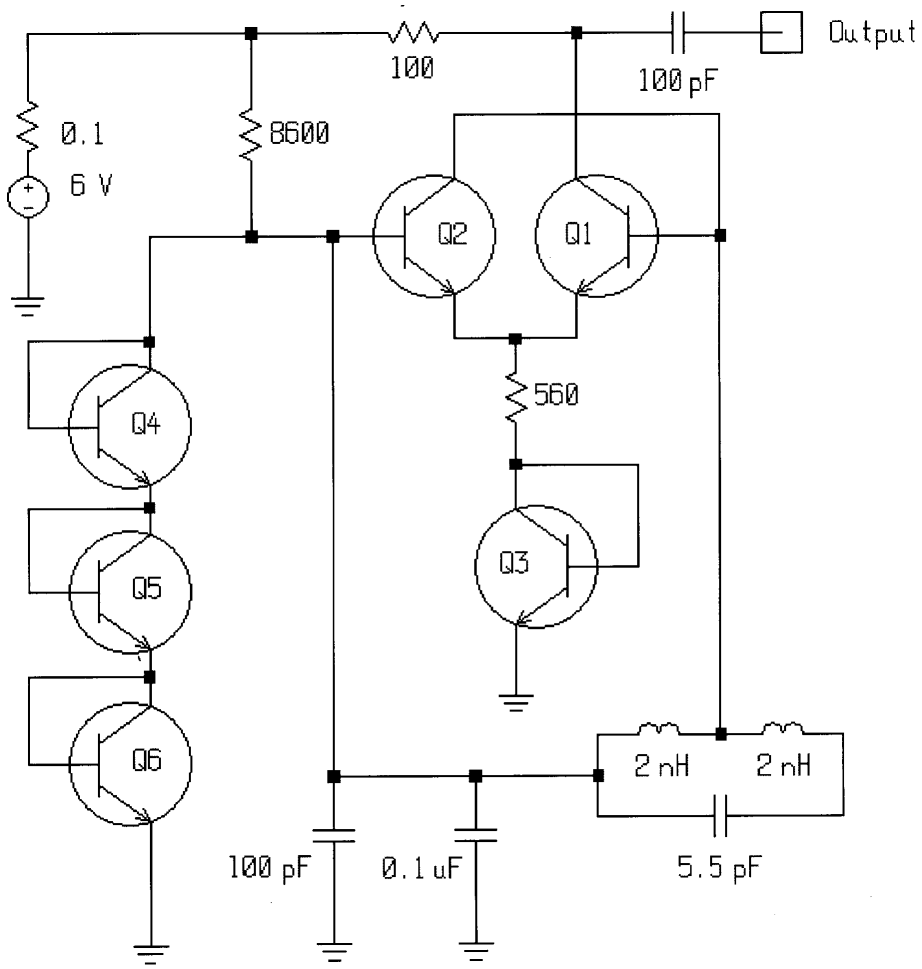

Figure 5-107 This validation circuit models the oscillator topology at the core of Motorola's MC12148 ECL oscillator IC.

inductor is approximately 167,000 mm^2, which is ~14% of a typical IC. For GaAs substrate, the resulting Q would be about 5; for silicon, as we already saw, 20 is already a very high value.

The customer can use PCB traces for the required inductance instead of external surface-mount inductors (cost: $0.03 each, most expensive passive component!). It must be pointed out that even for a nonintegrated approach, the higher VCO gain is noisier by definition. This was explained in Section 5-6-2. These problems are not unique to silicon; they apply to GaAs also. Figure 5-110 shows the size relationship of on-chip capacitors and inductors compared to the actual transistor; therefore, on-chip inductors should really be avoided for reasons of space and Q. Just imagine how the picture would change if the 1.1-nH inductor had to be 11 nH instead! It would dominate the IC area, and therefore the IC cost as well.

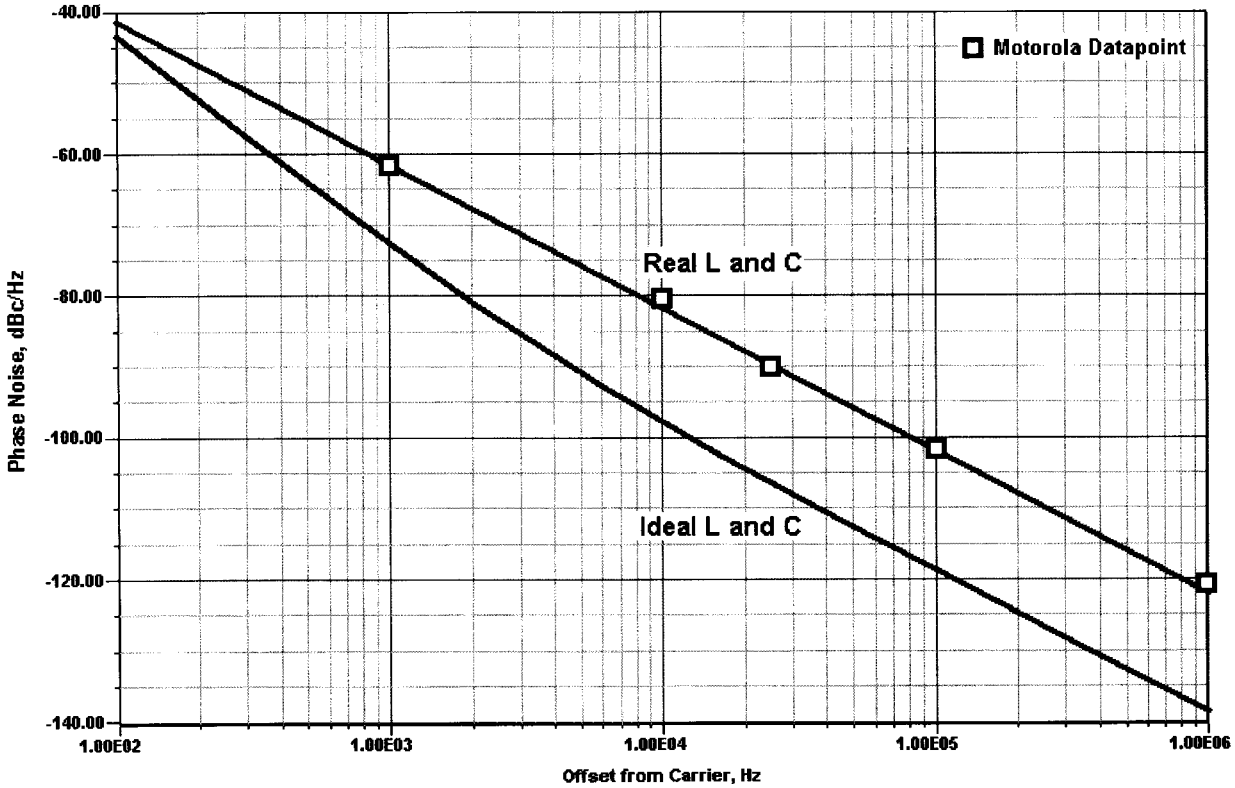

Figure 5-108 Comparison of measured versus simulated phase noise of the MC12148 differential oscillator. The simulation (1.016 GHz) predicts a phase noise of –89.54 dBc/Hz at an offset of 10 kHz (Real L and C curve), which agrees well with Motorola's specification of –89.54 dBc/Hz (typical at 930 MHz) at this offset. The Ideal L and C curve plots the simulation's phase-noise performance with ideal reactances, as opposed to the Real L and C curve, which graphs the results with realistic Q values specified for its reactive components ($Q = 250$ for its C values and $Q = 65$ for its L, all at 1 GHz).

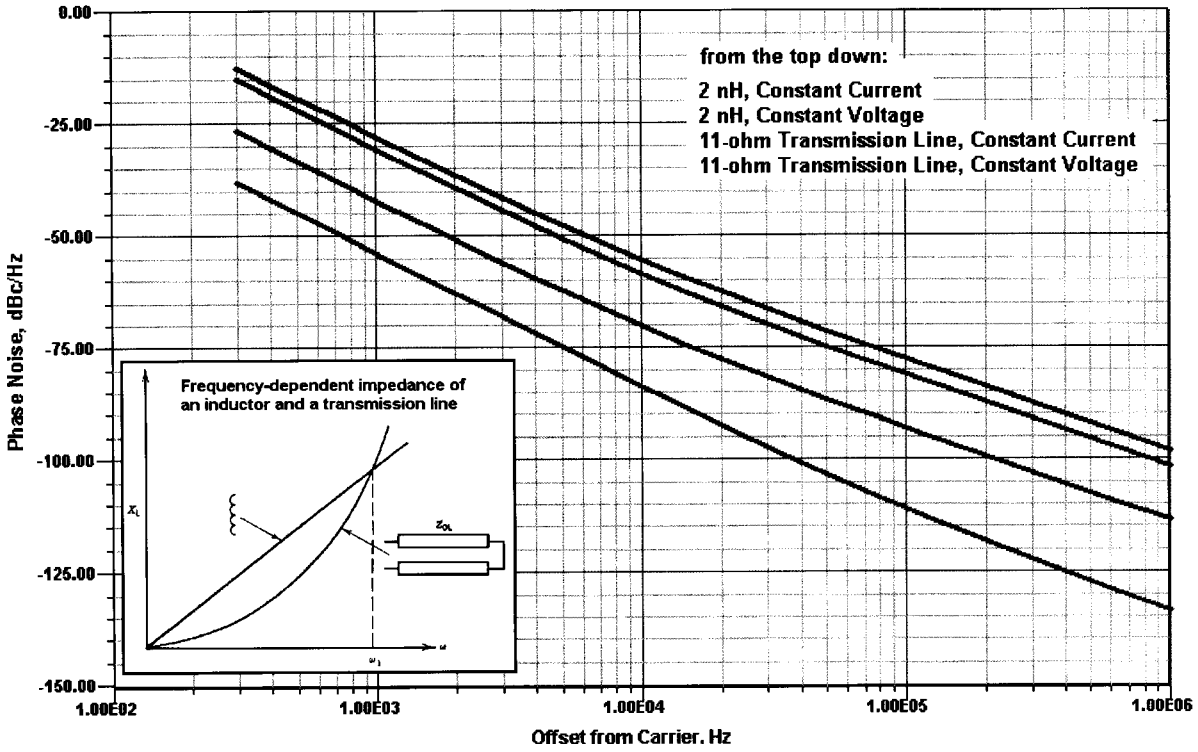

Figure 5-109 Phase-noise performance of a 2.3-GHz BJT oscillator with a resonator consisting of an inductor (2 nH) and a 1/4 λ transmission line (11 Ω, approximating the behavior of a dielectric resonator) with bias from a constant-current source and a low-impedance, resistive constant-voltage source.

5-8 DESIGN OF RF OSCILLATORS USING CAD

5-8-1 Harmonic-Balance Simulation

HB analysis performs steady-state analysis of periodically excited circuits. The circuit to be analyzed is split into linear and nonlinear subcircuits. The linear subcircuit is calculated in the frequency domain. Features of this aspect of the HB process include:

- Use of distributed models in the spectral domain
- Matrix formulation that can enable reduction of internal nodes
- Major speed advantage
- Straightforward intermodulation and mixer analysis

The nonlinear subcircuit is calculated in the time domain. Features of this aspect of the HB process include:

- Nonlinear models derived directly from device physics
- Intuitive, easy, and logical circuit representation

Figure 5-111 diagrams this approach for a MESFET amplifier. Figure 5-112 charts a general-purpose nonlinear design algorithm that includes optimization. Modern analysis tools that must provide accurate phase-noise calculation should be based on the principle of harmonic balance. Figure 5-113 shows a BJT microwave oscillator entered into the schematic-capture module of a commercially available HB simulator (Ansoft Serenade 8.0); Figure 5-114 shows this oscillator's simulated phase noise. By the way, HB analysis can also handle mixers.

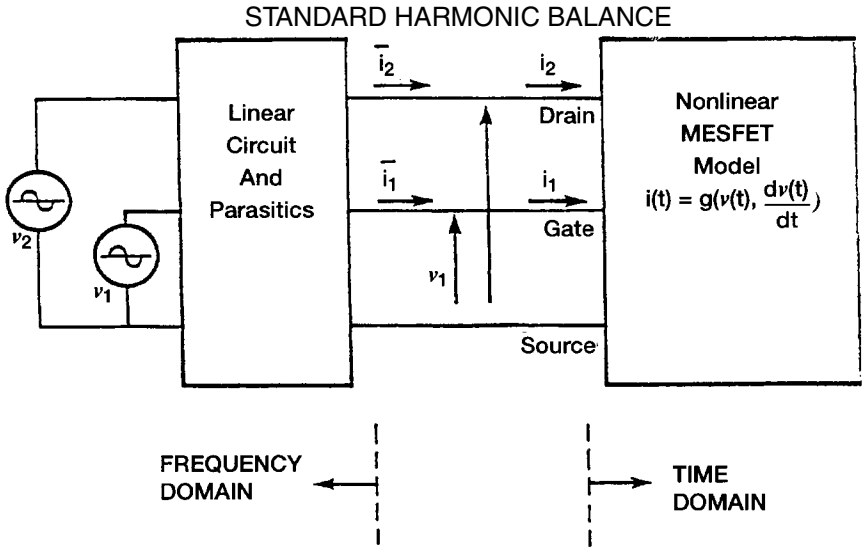

Figure 5-111 MESFET circuit partitioned into linear and nonlinear subcircuits for harmonic-balance analysis. Applied gate and drain voltages, and relevant terminal voltages and currents, are indicated.

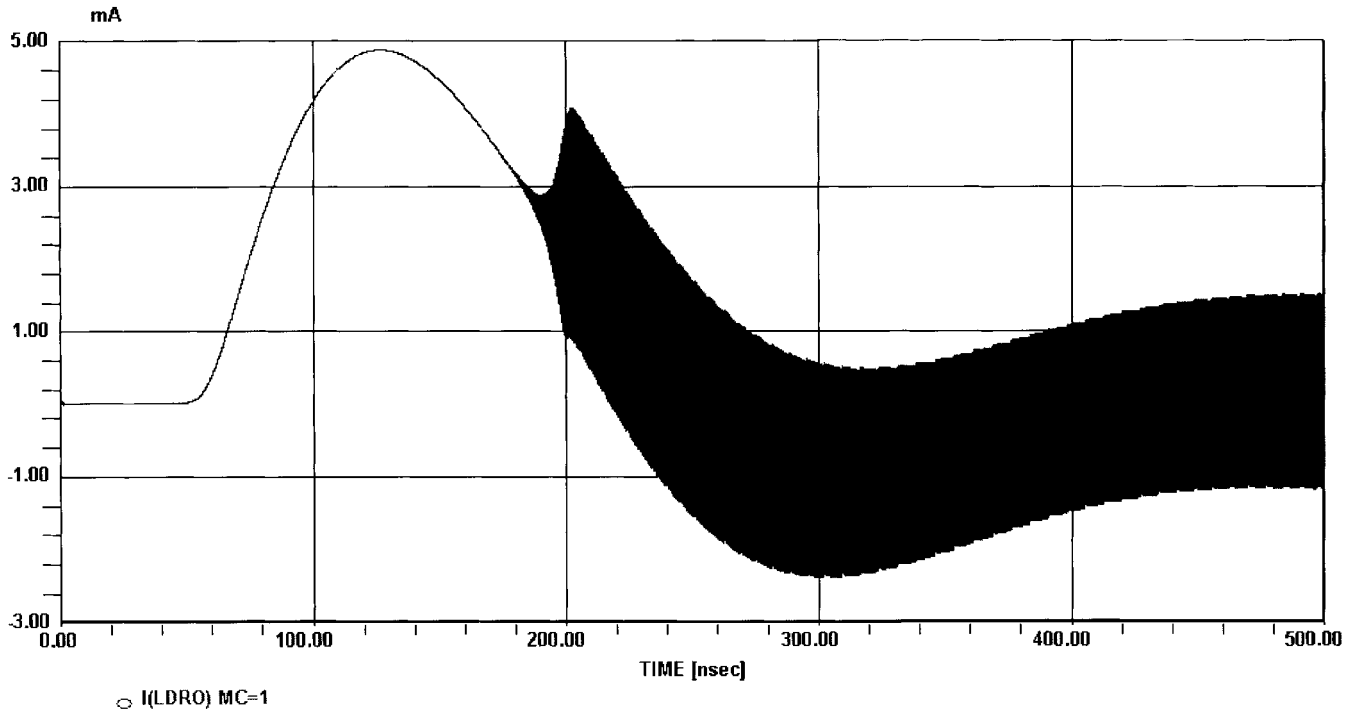

Figure 5-117 Current through the BJT DRO's equivalent resonator inductance from startup to amplitude stabilization.

5-8-2 Time-Domain Simulation

SPICE, a general-purpose simulation program capable of nonlinear dc, linear ac, and nonlinear transient analysis, is probably the most common of the time-domain methods used for nonlinear circuit analysis. Its ability to represent arbitrary time-domain waveforms and model time delays, level shifts, and the sinking and sourcing characteristics of such circuits have made it the simulator of choice for digital designers concerned with analog issues. SPICE's application in RF, microwave, and wireless circuit design is limited by its difficulties with simulating multitone excitations, and coupling and transmission-line effects—including losses, parasitics, and dispersion for distributed elements—and its inefficiency in simulating steady-state conditions.

One area in which SPICE's transient analysis capabilities can be particularly useful to RF and wireless designers is the simulation of oscillator startup. To illustrate this, we present a 3.8-GHz dielectric resonator oscillator modeled with Ansoft Corporation's Super-Spice simulator. Figure 5-115 shows how the oscillator's S_{11} response, positive throughout the simulation's frequency span of 3–5 GHz, peaks at 3.77 GHz. Figure 5-116 shows the oscillator's output voltage as the circuit starts oscillating and amplitude-stabilizes; Figure 5-117 shows the current through the equivalent inductance of the circuit's dielectric resonator across the same time span.

5-9 PHASE-NOISE IMPROVEMENTS OF INTEGRATED RF AND MILLIMETER-WAVE OSCILLATORS *

5-9-1 Introduction

The generation of microwave and millimeter-wave frequencies can be done by lower-frequency VCOs multiplied up in frequency, such as that provided by comb generators; by using hybrid GaAsFET-based oscillators with external resonators; or—for the best phase noise obtainable—YIG oscillators whose physical size and cost do not always provide a practical solution. A significant improvement in oscillator noise performance can be obtained with a novel feedback circuit that uses internally generated noise and cancels the close-in noise in a bandwidth of up to 1 MHz. This results in a phase noise improvement of more than 15 dB at microwave frequencies for the same topology, and the feedback system can be made part of the biasing circuit. This feedback circuit can be used over a wide frequency range and works well at VHF/UHF frequencies and in the millimeter-wave area.

5-9-2 Review of Noise Analysis

Section 5-6 of this chapter covered noise in oscillators in detail, so we will merely review oscillator noise issues here. The first linear model for a basic oscillator, without considering semiconductor noise, was developed by Leeson in 1966 [9] and has been quoted in numerous applications.

The phase noise of a VCO is completely determined by

*This section is based on a paper given at the Fifth International Workshop on Integrated Nonlinear Microwave and Millimeterwave Circuits, sponsored by IEEE at Gerhard-Mercator University, Duisburg, Germany, October 1–2, 1998.

$$£(f_m) = 10 \log\left\{\left[1 + \frac{f_0^2}{(2f_m Q_{\text{load}})^2}\right]\left(1 + \frac{f_c}{f_m}\right)\frac{FkT}{2P_{s,\text{av}}} + \frac{2kTRK_0^2}{f_m^2}\right\} \tag{5-135}$$

where $£(f_m)$ = ratio of sideband power in a 1-Hz bandwidth at f_m to total power in dB
f_m = frequency offset
f_0 = center frequency
f_c = flicker frequency
Q_{load} = loaded Q of the tuned circuit
F = noise factor
$kT = 4.1 \times 10^{-21}$ at 300 K (room temperature)
$P_{s,\text{av}}$ = average power at oscillator output
R = equivalent noise resistance of tuning diode (typically 200 Ω to 10 kΩ)
K_0 = oscillator voltage gain

When adding an isolating amplifier the noise of an *LC* oscillator is determined by

$$S_\phi(f_m) = [a_R F_0^4 + a_E(F_0/2Q_L)^2]/f_m^3$$
$$+ [(2GFkT/P_0)(F_0/2Q_L)^2]/f_m^2$$
$$+ 2a_R Q_L F_0^3/f_m^2$$
$$+ a_E/f_m + 2GFkT/P_0$$

where G = compressed power gain of the loop amplifier
F = noise factor of the loop amplifier
k = Boltzmann's constant
T = temperature in kelvins
P_0 = carrier power level (in watts) at the output of the loop amplifier
F_0 = carrier frequency in hertz
f_m = carrier offset frequency in hertz
$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop
a_R, a_E = flicker noise constants for the resonator and loop amplifier, respectively

In 1978, Dieter Scherer from Hewlett-Packard added the $(1 + f_c/f_m)$ term, which addresses the 1/*f* noise or flicker corner frequency [25]. The 1/*f* frequency phenomenon is based on the surface effects inside the semiconductor and varies from 50 Hz for silicon FETs, to 5 kHz and more for silicon microwave bipolar transistors, to 1 MHz and higher for GaAsFETs. As a rule of thumb, one can state that the higher the frequency of operation, the higher the f_T for the active device, the higher the flicker corner frequency will be. Figure 5-118 shows the spectral distribution as a function of offset frequency. This linearization was first discovered by individuals from NIST, formerly the National Bureau of Standards, in Boulder, Colorado. The left corner is dominated by the flicker corner frequency and the oscillator itself shows at the output a combination of modulation and conversion

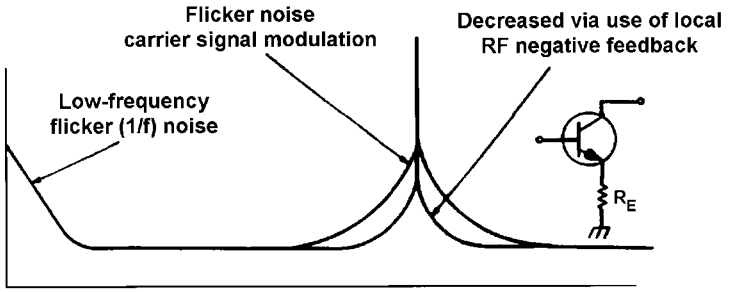

Figure 5-118 Reduction of transistor flicker-of-phase noise via use of local negative feedback (emitter resistance), showing, for a BJT, the flicker noise or corner frequency, as well as the phase noise that results from the flicker noise. The negative feedback from the unbypassed emitter resistor reduces the flicker noise by up to 40 dB [26, 27].

noise. In addition to the $1/f$ noise, the real-life oscillator exhibits a wideband noise, which is due to nonlinearities—specifically, the AM-to-PM conversion resulting from nonlinear capacitance and transconductance of the transistor. This complete linear "noise equation" was first published by Rohde et al. [2]. Therefore, the noise model for the transistor had to be enhanced by describing this mechanism. Essentially, it is equal to a tuning diode coupled to the resonator, which is modulated by thermal noise, and therefore results in a higher phase-noise contribution than the oscillator itself. This noise equation also has Q playing a major role. The phase noise, therefore, ignoring other frequencies, is proportional to $1/Q^2$. In monolithic circuits, the loss of transmission lines, which determines the Q, is related to the substrate material. One has little choice of material, particularly in microwave and millimeter-wave oscillators. Printed resonators sadly provide low Q at these frequencies. A similar problem related to the material is the choices of tuning diodes. In many, if not all, cases, one uses a GaAsFET with the gate connected to the drain or to the source as a tuning diode, and the resulting Q is also disappointing.

The example in Figure 5-118 takes advantage of a microwave bipolar transistor and also is applicable for heterojunction bipolar transistors (HBTs). The transconductance of the bipolar transistor, which is approximately 39 mA/V, increases to values up to 20 times larger than exhibited by GaAsFETs. This method of using negative feedback reduces the gain of the GaAsFET too much and is, therefore, not applicable.

5-9-3 Workarounds

When looking at the modes of operation of test sets for phase-noise measurement, the one method that requires only one signal generator is most desirable. Based on the frequency discriminator method, it uses a cable of appropriate length that acts as a delay line. The oscillator under test drives a double-balanced mixer [one port directly (LO port)] and drives the RF port "delayed" via the delay line cable, and the mixer is therefore driven by the same frequency with a different phase. This setup has been used for phase-noise measurements very successfully. One can easily connect a low-noise FFT-based audio spectrum analyzer to the mixer output and measure the signal-to-noise ratio as a function of offset. With modern FFT analyzers available up to 10 MHz and higher, a fast and reliable measurement can be done. The length of the cable determines the frequency range over which an accurate

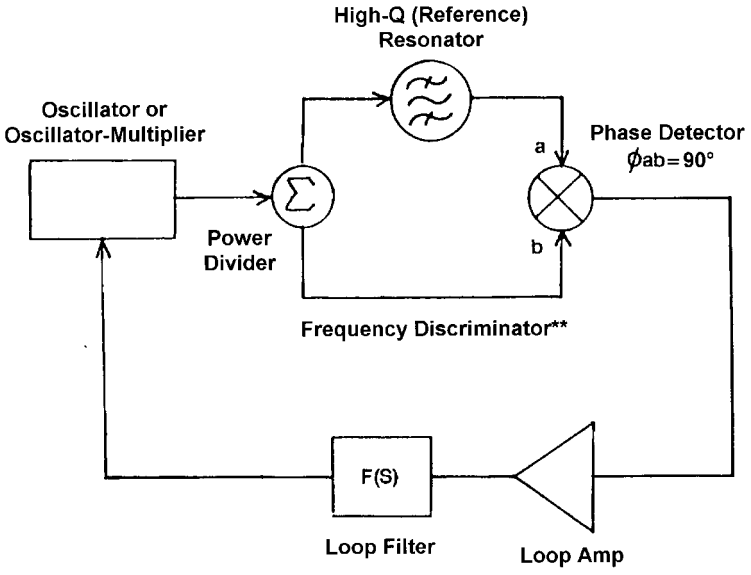
measurement is possible. This phase-noise information (dc and ac voltage) at the output can be used to modulate the VCO and improve the phase noise in the frequency range over which this method is applicable. Fluke and other companies have built signal generators based on this principle to improve the phase noise. The drawback of this method is that the delay line acts like a band-limiting filter, and, therefore, one cannot compensate over a large range of frequencies. The delay line in question, responsible for the phase shift, can also be substituted by a high-Q resonator. By closing the loop, one can "clean up" the phase noise of the device under test (DUT). The difficulty with this is that it requires an external high-Q resonator. One might as well use the same resonator for the oscillator. Therefore, this method is not suitable for MMICs. See Figure 5-119 for more details.

As far as the actual measurement is concerned, one has to observe certain limitations of the test setup as explained in Figure 5-120. When using the delay line instead of a high-Q resonator (low loss is assumed for coaxial cable), one needs to determine the physical length of the cable. The physical length of the cable determines the delay and, therefore, the discriminator noise floor as a function of the offset frequency. Typically, 8 feet of RG-8/U cable results in a delay of 12 ns. As can be seen from Figure 5-121, it is advisable to have several lengths of cable depending on the range of frequency for which one wants to do the measurements under different lengths of cable [28].

Since we are primarily concerned about the flicker noise, here is another, similar, approach to "cleaning up" the flicker noise, as shown in Figure 5-122. The bandwidth over which this technique works depends on the bandwidth of the phase detector system, which can be made fairly wide. A derivative of this will provide a useful solution.

5-9-4 Reduction of Flicker Noise

From inspecting a device datasheet, one is always pleasantly surprised about very low spot noise figures, while the 1/f corner frequency is rarely specified at all. The mechanism that



**Resonator may be operated in reflection mode as well as transmission mode.

Figure 5-119 AFC stabilization of an external oscillator.

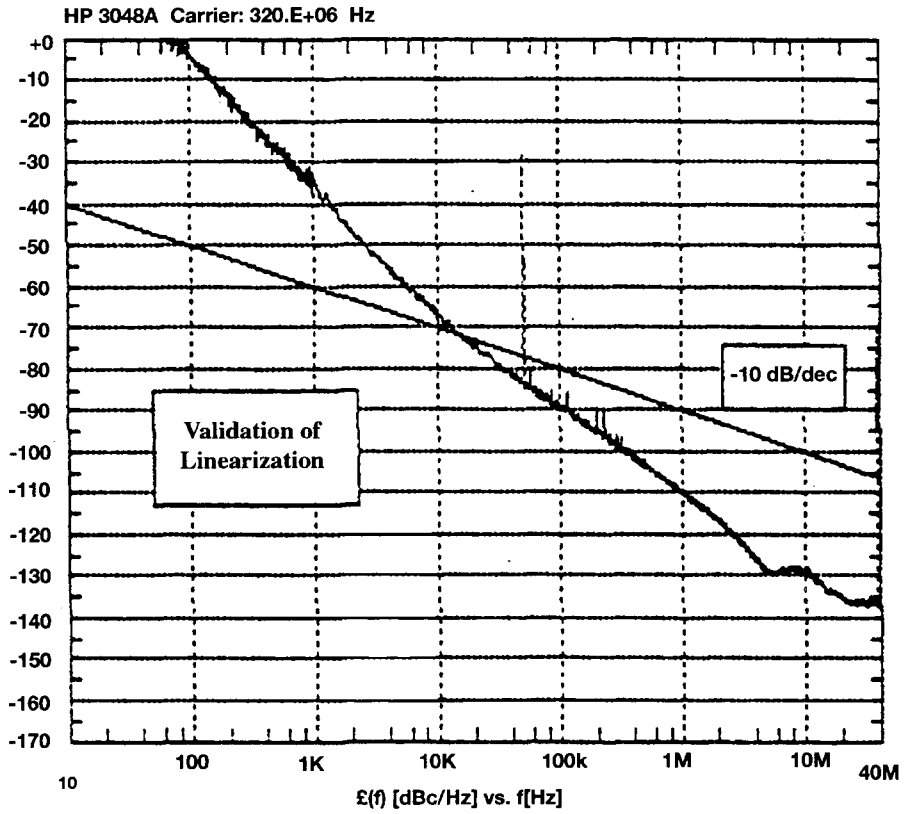


Figure 5-120 Display of a typical phase-noise measurement using the delay line principle. This method is only applicable where $x = \sin(x)$. The measurements above the solid line violate this relationship and therefore are not valid.

transforms the noise, which is generated by the $1/f$ contribution into what we referred to as modulation noise, is the AM-to-PM conversion. If one could "linearize" the transistor, the flicker noise effect would drastically be reduced.

Figure 5-123 shows two variations on an approach that is consistent with the previous method. In Figure 5-123a, the noise across the 56-Ω emitter resistor of oscillator transistor Q1 is sampled, amplified and inverted in Q2, and used to modulate Q1's base voltage. A low-frequency, general-purpose *npn* transistor (BC848C) is used at Q2. A high-frequency, higher-power transistor (BFR93A) is used at Q1; an HBT could also be used. Figure 5-123b shows the same approach using a variation of the *pnp* active biasing circuit shown in Figure 3-192. Figure 5-124 shows the phase-noise performance for the circuit of Figure 5-123a.

5-9-5 Applications to Integrated Oscillators

Figure 5-125 shows a silicon-based BiCMOS technology wireless oscillator. The three big inductors can be seen easily. This design by Motorola is a good candidate for using this innovative technology. Applying this feedback technology, we measure the phase noise shown in Figure 5-126.

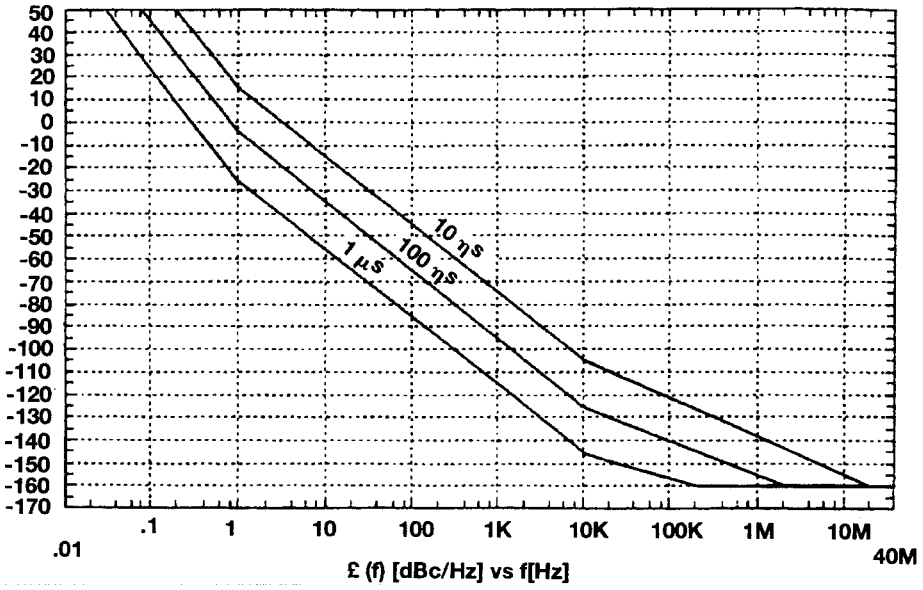

Figure 5-121 Dynamic range as a function of cable delay. A delay of 1 μs is ideal for microwave frequencies.

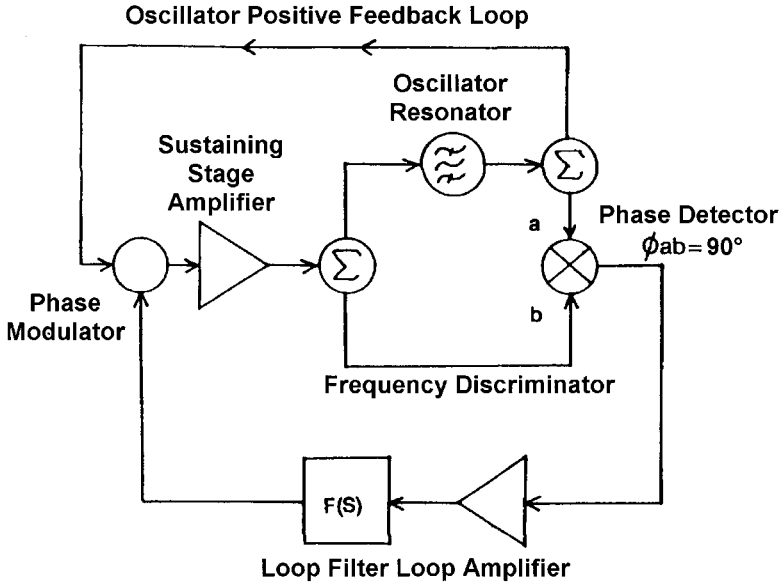

Figure 5-122 Noise reduction in an oscillator whose signal flicker-of-frequency noise is primarily due to sustaining stage flicker-of-phase noise. A phase perturbation in the sustaining stage produces a frequency change in the oscillator, which produces a change in the signal phase shift through the resonator detected as the phase detector. The resonator may be operated simultaneously in transmission line and reflection modes in the oscillator in the oscillator and discriminator portions of the circuit, respectively.

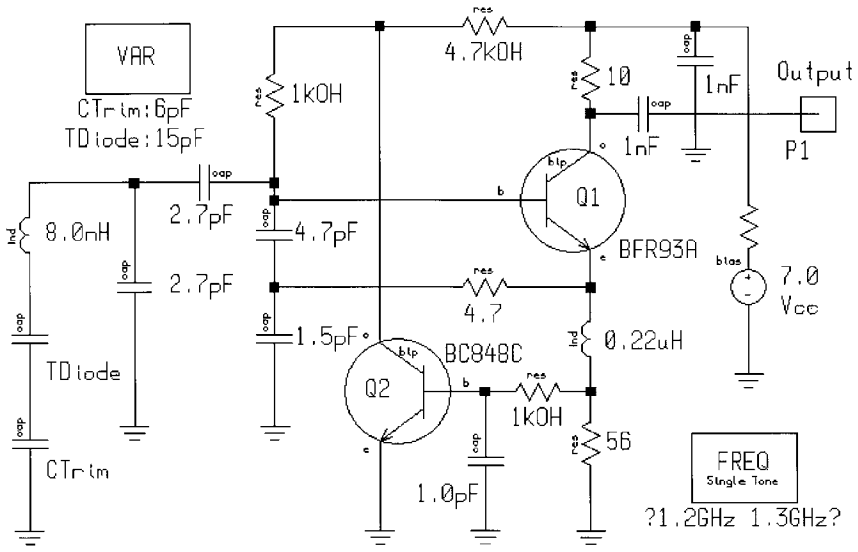
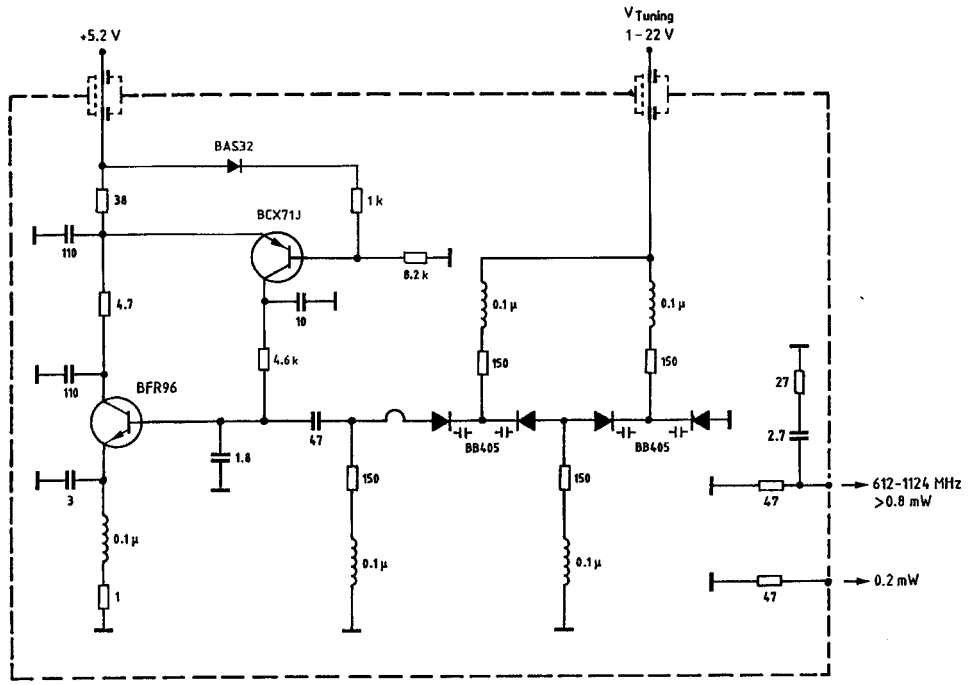


(a)



(b)

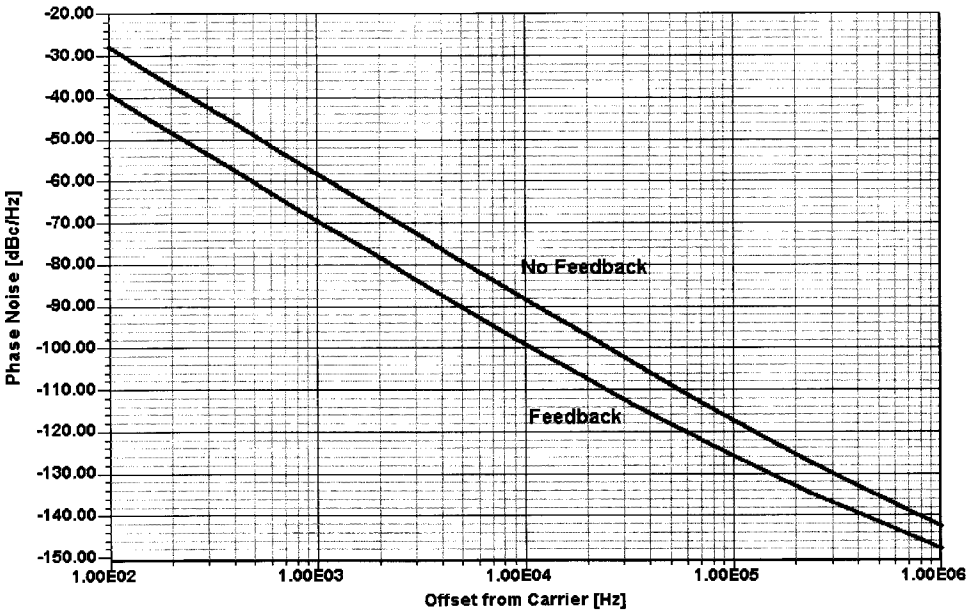

Figure 5-124 Phase noise of the oscillator in Figure 5-123a with and without noise feedback.

Moving up into the millimeter-wave area, one of the target oscillators is the Ka-band MMIC voltage-controlled oscillator designed for Ka-band smart munitions applications (Figure 5-127). This voltage-controlled oscillator MMIC employs 0.25-μm gate length, double-heterojunction, pseudomorphic, high-electron-mobility transistor (PHEMT) technology. This is a custom chip developed by Martin Marietta under the U.S. Government MMIC program. Ansoft Serenade tools were used in this design.

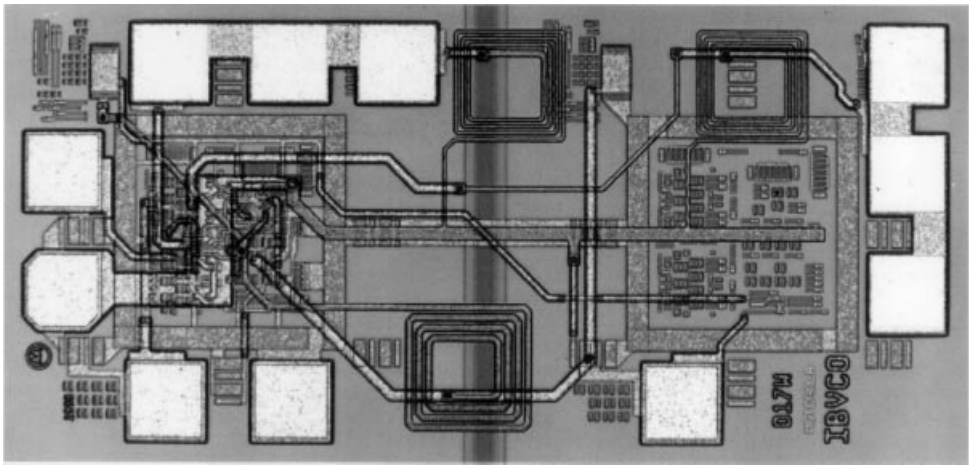

Figure 5-125 Layout of the Motorola 800-MHz monolithic differential oscillator IC in Si technology.

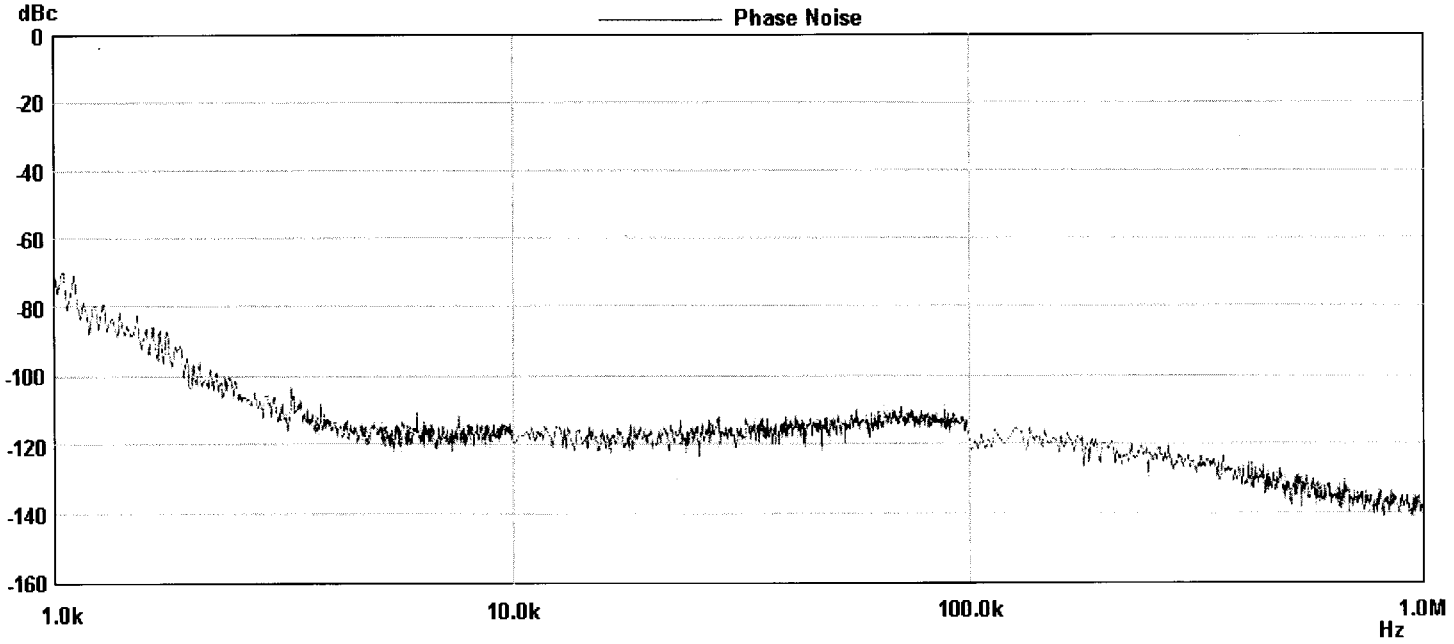

Figure 5-126 Phase noise of the oscillator of Figure 5-125. The noise floor is limited by the on-board isolation amplifier.

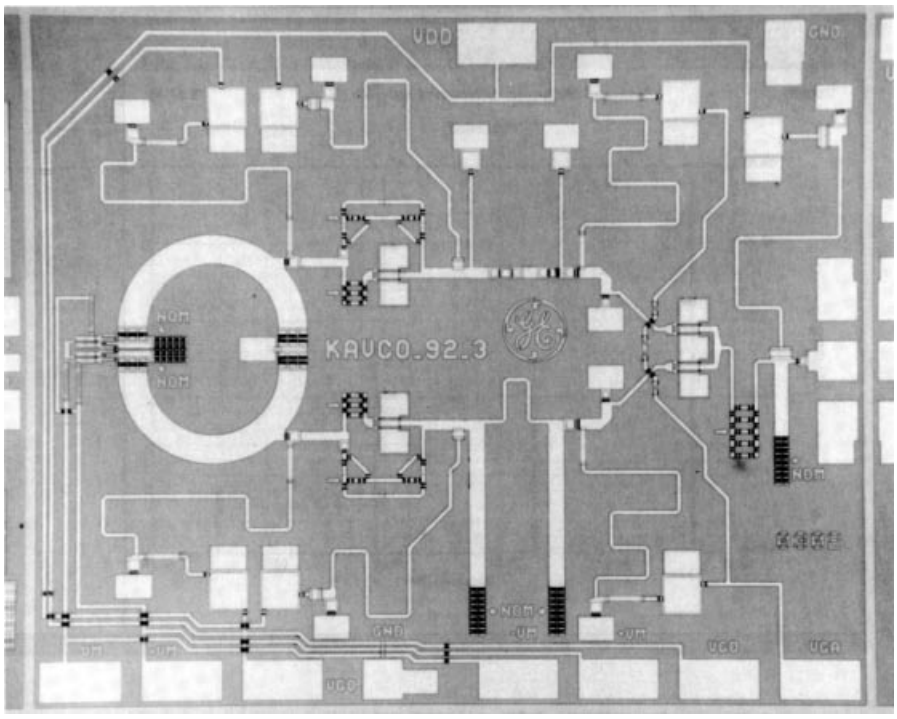

Figure 5-127 Layout of the Ka-band voltage-controlled oscillator.

Features

- Fundamental-mode, differential-ring VCO
- Electronically tunable
- Output power greater than 16 dBm
- Power-added efficiency (PAE) of 13%
- Compact size for easy integration with power amplifier
- 0.25-μm pseudomorphic HEMTs

Specifications

- Frequency range: Ka band
- Output power: 16 dBm minimum

When applying the same technology as shown in the previous bipolar example, the phase noise can be reduced significantly. Since field-effect transistors require a negative gate voltage, it is possible to sample the noise in the drain current using a resistor, amplify the noise with an appropriate loop amplifier, and modulate the gate voltage within a 1-MHz bandwidth.

A spectrum analyzer measurement of this oscillator type, as shown in Figure 5-128, indicates a phase noise of −78.6 dBc/Hz at an offset frequency of 100 kHz at a center frequency of 38 GHz, while the closed-loop phase noise of Figure 5-129 using the compen-

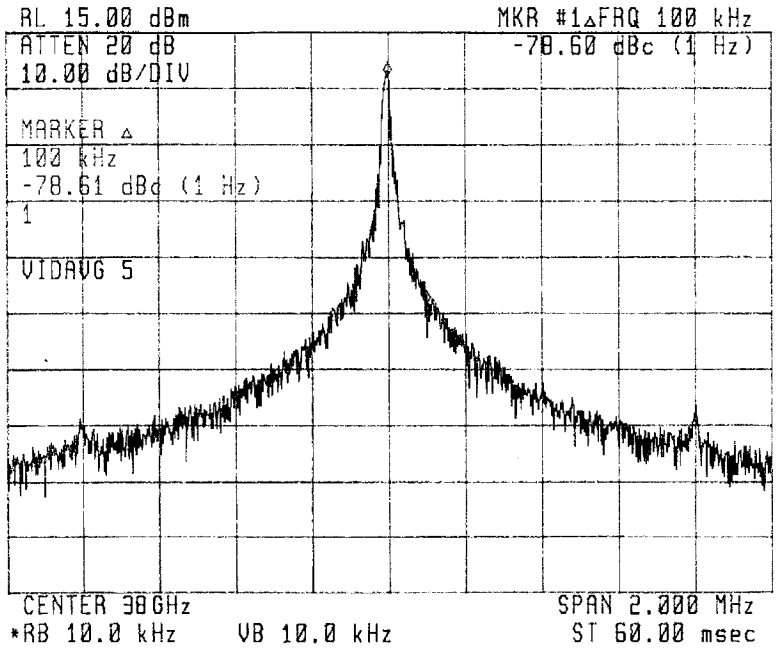

Figure 5-128 Spectrogram of the 38-GHz free-running push–pull VCO shown in Figure 5-127.

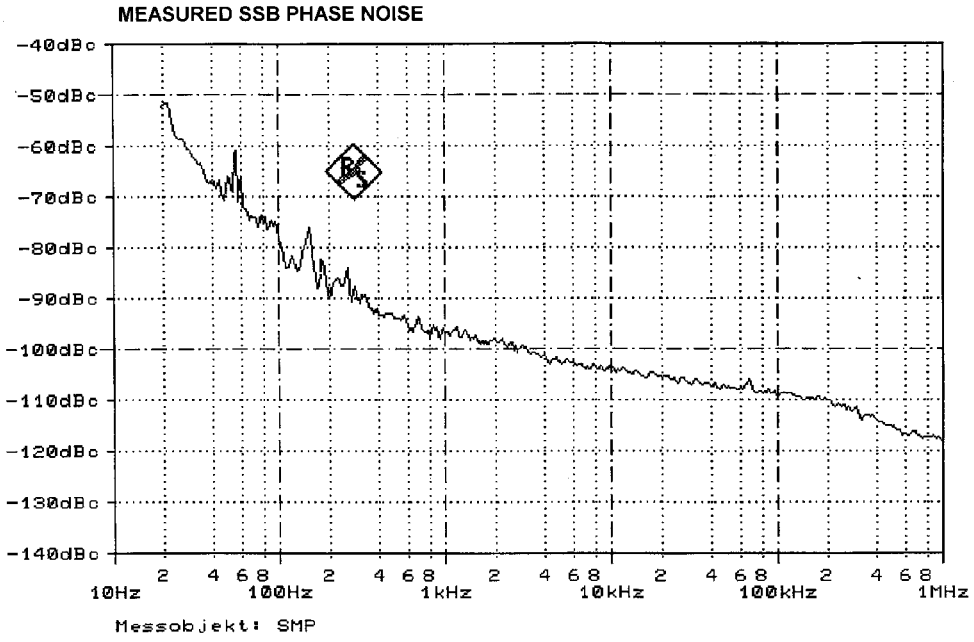

Figure 5-129 Phase-noise performance of a 38-GHz oscillator with phase-noise “clean-up” system.

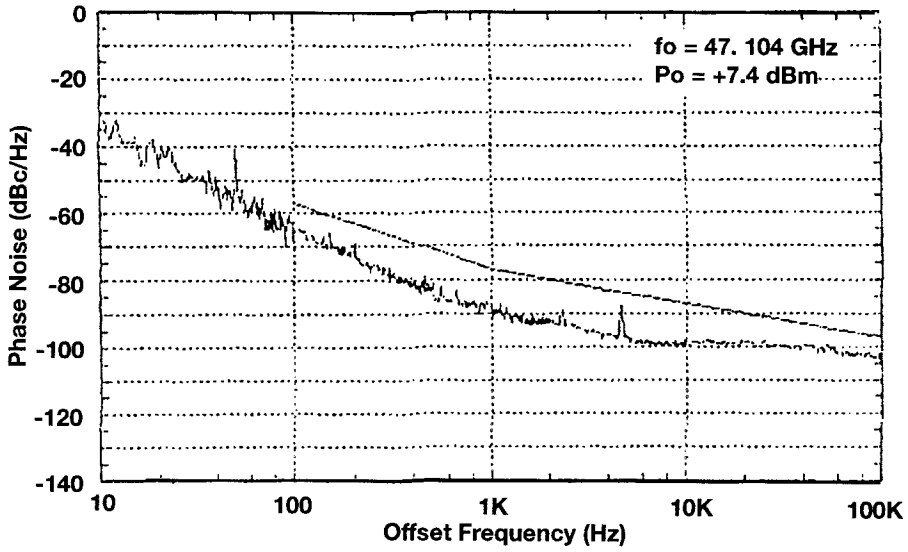

Figure 5-130 A 47-GHz loop-stabilized VCO with phase-noise performance similar to that of Figure 5-129.

sation scheme indicates a phase noise of about −108 dBc/Hz at 100 kHz. This is consistent with reported results from other researchers who have used complicated phase-locked loops to achieve similar performance as seen in Figure 5-130.

5-9-6 Summary

A novel method of improving the phase noise of oscillators has been demonstrated. This approach works well for low-frequency oscillators such as 1000 MHz up to the millimeter-wave range. It only requires an additional wideband dc biasing circuit, which applies noise feedback. The correctness of the theory has been demonstrated by appropriate validation.

WIRELESS SYNTHESIZERS

6-1 INTRODUCTION

Increasing integration has drastically narrowed the range of component choices open to wireless synthesizer designers. The design of a high-performance synthesizer is largely reduced to selecting the most advanced synthesizer integrated circuit (IC) and, if the synthesizer uses a phase-locked loop (PLL), designing or obtaining the best voltage-controlled oscillator (VCO). This chapter covers synthesizer theory, evaluation, and design, including PLL and direct digital synthesis (DDS) techniques. Going into all the details of frequency synthesizers would be beyond the scope of this book. For depth and background on this subject, we recommend the book by Rohde [1].

6-2 PHASE-LOCKED LOOPS

6-2-1 PLL Basics

Figure 6-1 shows a complete PLL synthesizer block diagram indicating the areas over which the designer actually has control. Once the VCO signal has been translated from analog to quasidigital (square-wave) form in circuitry similar to a line receiver, the synthesizer IC takes over. The VCO receives an analog control signal that results from the integration of digital pulses from a phase/frequency discriminator. Modern phase/frequency discriminators, which are part of the PLL IC, use edge-triggered loop locks and generate correcting pulses of either positive or negative sign. The output portion of such a phase detector is frequently referred to as a *charge pump* because the resulting dc control voltage, which ultimately determines the oscillator frequency, is processed by a loop filter containing at least one large capacitor that is charged or discharged as necessary to maintain the control-voltage level necessary for loop lock.

Figure 6-2 shows the block diagram of a single-loop synthesizer. Unless special techniques are used, such as the *fractional-N-division* principle, the step size or channel frequency spacing is equal to the reference frequency. When describing frequency synthesizers mathe-

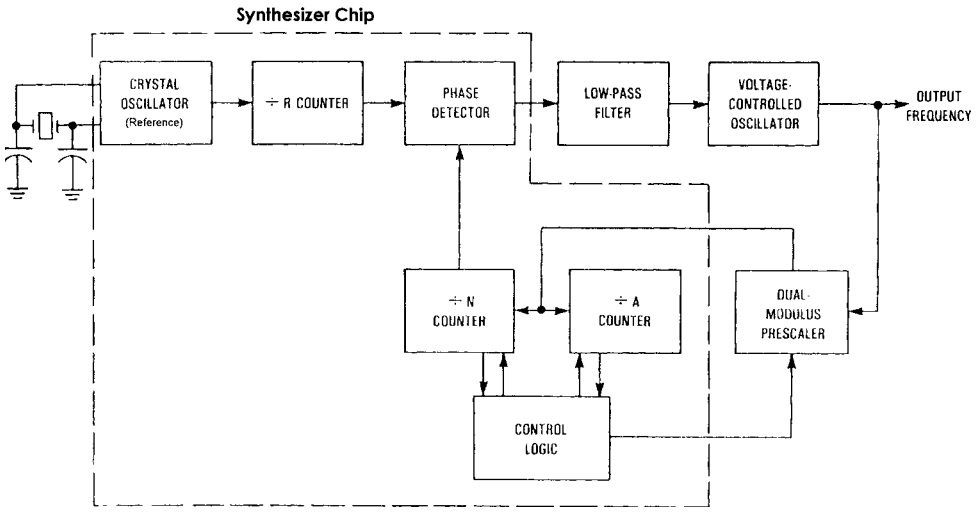

Figure 6-1 Block diagram of an integrated frequency synthesizer. In this case, the designer has control over the VCO and the loop filter; the reference oscillator is part of the chip. In most cases (up to 2.5 GHz), the dual-modulus prescaler is also inside the chip.

matically, we usually use a linearized model. Because most effects occurring in the phase detector are highly nonlinear, only the so-called piecewise-linear treatment allows adequate approximation.

We assume that the VCO shown in Figure 6-2 is tunable over the frequency range from 410 to 510 MHz. Its output is divided to the reference frequency in a programmable divider (i.e., divide by N) whose output is fed to one of the input of the phase/frequency detector and compared with the reference frequency supplied to the other input. The loop filter at the output of the phase detector suppresses reference-frequency components while also serving as an integrator. The dc control voltage at the output of the loop filter tunes the VCO until the divided frequency and phase equal those of the reference. In this simple example with the divider set to 45,000 and the reference set to 1 kHz, the VCO is controlled to a frequency of 450 MHz. A fixed division of the frequency standard output produces the reference frequency of the appropriate step size. Frequency standards are typically operated at 1, 5, or 10 MHz to take advantage of high crystal stability. A 5-MHz frequency standard would be

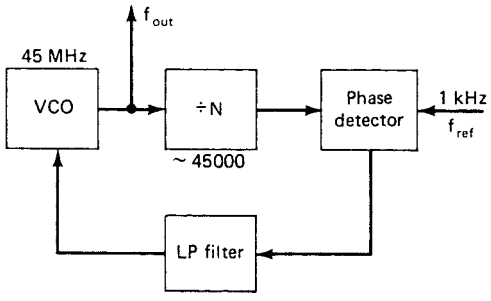

Figure 6-2 Block diagram of a single-loop synthesizer.

divided by 500 in the example. The operating range of the PLL is determined by the maximum operating frequency of the programmable divider, by its division-range ratio, and by the tuning range of the VCO.

The PLL is nonlinear because the phase detector is nonlinear. However, it can be accurately approximated by a linear model when the loop is in lock. The response, when the loop is closed, may be expressed as

$$\frac{\theta_c(s)}{\theta_r(s)} \equiv B(s) = \frac{\text{Forward gain}}{1 + \text{Open-loop gain}}$$

$$= \frac{G(s)}{1 + G(s)/N} \tag{6-1}$$

where $G(s) = G_1(s)G_2(s)F(s)/s$, and θ_c and θ_r are the phases of the controlled oscillator and the reference, respectively.

When the loop is locked, it is assumed that the phase-detector output voltage is proportional to the difference in phase between its inputs; that is,

$$V_\theta = K_\theta(\theta_r - \theta_i) \tag{6-2}$$

where V_θ is the output voltage of the phase detector, and θ_r and θ_i are the phases of the reference signal and the divided VCO signal, respectively. K_θ is the phase-detector gain factor and has the dimensions of volts per radian. It is also assumed that the VCO can be modeled as a linear device whose output frequency differs from its free-running frequency by an increment of frequency

$$2\pi\delta f = K_0 V_c \tag{6-3}$$

where V_c is the voltage of the output of the low-pass filter, and K_0 is the VCO gain factor with the dimensions of radians per second per volt. Because frequency is the time derivative of phase, the VCO operation can be described as

$$2\pi\delta f \equiv \frac{d\theta_c}{dt} = K_0 V_c \tag{6-4}$$

With these assumptions, the PLL may be represented by the linear model shown in Figure 6-3.

The linear transfer function relating $\theta_c(s)$ and $\theta_r(s)$ is

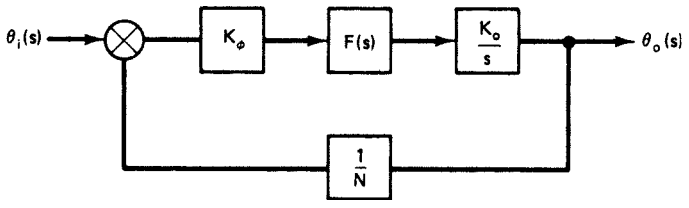

Figure 6-3 Block diagram of a linearized model of a PLL.

$$B(s) = \frac{\theta_c(s)}{\theta_r(s)} = \frac{K_\theta K_0 F(s)/s}{1 + K_\theta K_0 F(s)/Ns} \tag{6-5}$$

The forward gain is

$$G(s) = \frac{K_\theta K_0 F(s)}{s} \tag{6-6}$$

and the open-loop gain is

$$G(s)H(s) = \frac{K_\theta K_0 F(s)}{Ns} \tag{6-7}$$

which leads to the transfer formula of Eq. (6-1).

There are various choices of filter response $F(s)$. Because the VCO by itself is an integrator, we can use a simple *RC* filter following the phase detector. This arrangement is called a *Type 1* filter. Because the components used, together with feedthrough capacitors and other stray effects, can cause excess phase shift, it is necessary to ensure that stability criteria are satisfied. If the gain of a passive loop is too small to provide adequate drift stability of the output phase, especially if a high division ratio is used, the best solution to this problem is the use of an amplifier as an integrator. In most frequency synthesizers, the active-filter-integrator approach is preferred to the passive one. Some frequency synthesizer chips have a single-ended output. In such cases, the use of an additional integrator requires some precautions.

6-2-2 Phase/Frequency Comparators

The phase/frequency comparator can be divided into two types:

1. Phase detectors.
2. Phase-frequency comparators.

This means that the phase comparator has limited means to compare two signals and only accepts phase, not frequency, information. In this case, particular measures have to be taken to pull the VCO into the locking range. The phase comparators require special locking help. Here we are analyzing only the performance.

Diode Rings. The diode ring is normally driven with two signals with sinusoidal waveform and also is some sort of mixer. Here it will suffice to derive the gain characteristic K_θ of the device. If the input signal is $\theta_i = A_i \sin \omega_o t$, and the reference signal is $\theta_r = A_r \sin(\omega_o t + \phi)$, where ϕ is the phase difference between the two signals, the output signal θ_e is

$$\theta_e = \theta_i \theta_r = \frac{A_i A_r}{2} K \cos \phi - \frac{A_i A_r}{2} K \cos(2\omega_o t + \phi) \tag{6-8}$$

where K is the mixer gain. One of the primary functions of the low-pass filter is to eliminate the second-harmonic term before it reaches the VCO. The second harmonic will be assumed to be filtered out and only the first term will be considered, so

$$\theta_e = \frac{A_t A_r}{2} K \cos \phi \tag{6-9}$$

When the error signal is zero, $\phi = \pi/2$. Thus, the error signal is proportional to phase differences from 90°. For small changes in phase $\Delta\phi$,

$$\theta_e \cong \frac{\pi}{2} + \Delta\phi = \frac{A_t A_r}{2} K \left[\cos\left(\frac{\pi}{2} + \Delta\phi \right) \right]$$

$$= \frac{A_t A_r}{2} K \sin \Delta\phi \tag{6-10}$$

For a small phase perturbation $\Delta\phi$,

$$\theta_e \cong \frac{A_t A_r K}{2} \Delta\phi \tag{6-11}$$

The phase-detector output was assumed to be

$$\theta_e = K(\theta_i - \theta_o) \tag{6-12}$$

and the phase detector scale factor K_θ is given by

$$K_\theta = \frac{A_t A_r K}{2} \tag{6-13}$$

The phase-detector scale factor K_θ depends on the input signal amplitudes; the device can be considered linear only for constant-amplitude input signals and for small deviations in phase. For larger deviations in phase,

$$\theta_e = K_\theta \sin \Delta\phi \tag{6-14}$$

which describes a nonlinear relation between θ_e and ϕ.

In frequency synthesizers, the reference is typically generated from a reference oscillator and is lower than the VCO frequency, which is divided by a programmable divider. Both signals, therefore, are square waves rather than sine waves, and theoretically, a diode ring can be driven by those two signals.

A drawback to the diode-ring phase detector is that its output voltage is very small—several hundred millivolts at most. A postdetector dc amplifier, which will unavoidably introduce noise, is therefore required.

Edge-Triggered JK Master–Slave Flip-Flops. The fundamental idea of the sequential phase comparator we will be dealing with is that there are two outputs available, one to charge and one to discharge a capacitor. Output 1 then is high if the Signal 1 frequency is

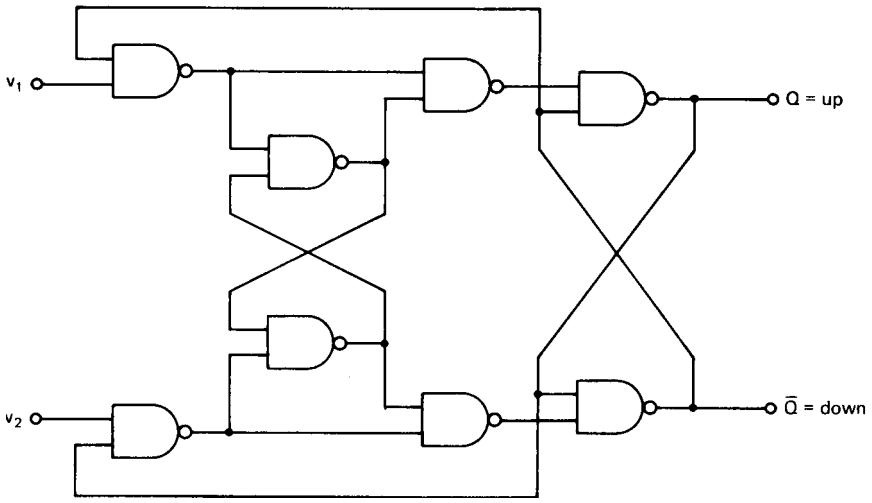

Figure 6-4 Edge-triggered JK master–slave flip-flop.

greater than the Signal 2 frequency; or if the two frequencies are equal, if Signal 1 leads Signal 2 in phase.

Output 2 is high if the frequency of Signal 2 is greater than that of Signal 1, or if the signal frequencies are the same and Signal 2 leads Signal 1 in phase.

Figure 6-4 shows the minimum configuration to build such a phase comparator. It can be operated from -2π to $+2\pi$, and an active amplifier is recommended as a charge pump. The Q output of the JK master–slave flip-flop is set to one by the negative edge of Signal 1, while the negative edge of Signal 2 resets it to zero. Therefore, the output $\overline{Q}$ is the complement of Q. The output voltage $\overline{V}$ is defined as the weighted duty cycle of Q and $\overline{Q}$ This means that a positive contribution is made when $Q = 1$ and a negative contribution (discharge) is made when $Q = 0$. The averaging and filtering of the unwanted ac component is done by a subsequent integrator. The integrator then is called a *charge pump*, as the loop capacitor is being charged and discharged depending on whether Q is high or low.

If the system using the JK flip-flop is not in lock, and there is a large difference between frequencies f_1 and f_2 at the output, the output will not be zero, but instead will be positive or negative relative to one-half the supply voltage. This is an advantage and indicates that this system is frequency sensitive. We therefore call it a *phase/frequency comparator* because it is capable of detecting both phase and frequency offsets. In its locking and pull-in performance, it is similar to an exclusive-OR gate.

For better understanding, let us look at a few cases where the system is in lock. It should be noted that whereas the exclusive-OR gate is sensitive to the duty cycle of the input signals, the JK flip-flop responds only to the edges, and therefore the phase/frequency comparator can be used for asymmetrical waveforms. Let us assume first that the input Signals 1 and 2 have the same frequency. Figure 6-5 shows what happens if the phase error is about 0, π, and 2π. In those cases, the duty cycle at the output is about 0%, 50%, or 100%, respectively. The narrow output pulses may cause spikes on the power-supply line and lines in the vicinity, and precautions must be taken to filter them.

The output voltage $\overline{V}$ is the average of the signal Q and is a linear function of the phase error.

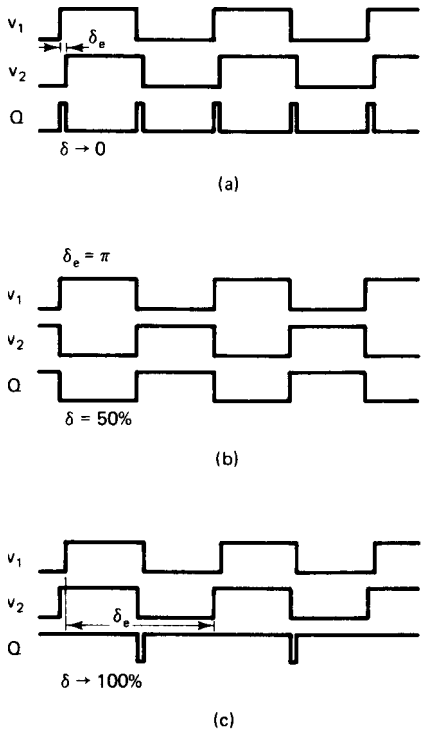

Figure 6-5 Performance of the JK phase/frequency comparator for different input signals.

Now let us take a look at several cases where the system is not in lock. Figure 6-6 shows the case where f_1 is substantially higher than f_2. As a result, the output duty cycle is close to 100% and the VCO frequency is being pulled up to higher frequencies. If the frequency at Input 2 is much higher than that at Input 1, the opposite is true. This proves that the device is sensitive to frequency changes.

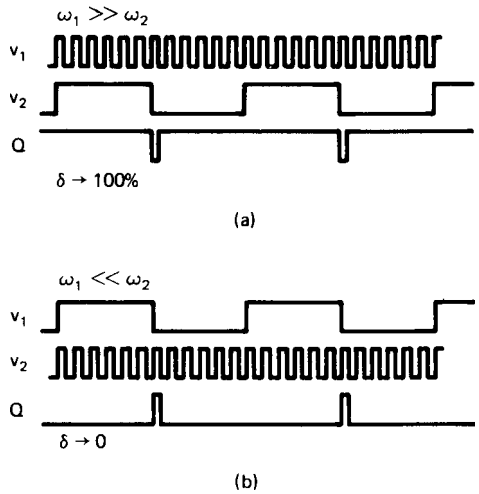

Figure 6-6 Phase-detector output for two input frequencies that are substantially different.

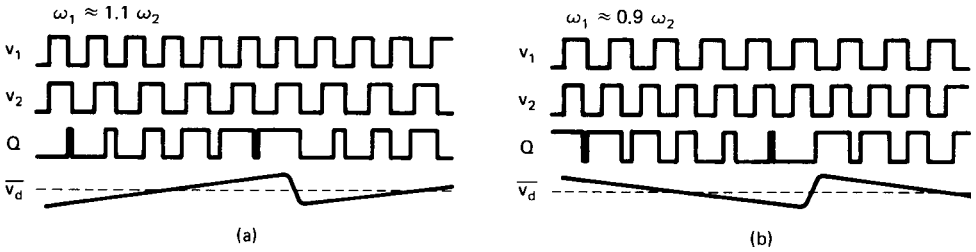

Figure 6-7 Performance of the phase detector for small frequency differences.

In cases where both frequencies are about the same, as shown in Figure 6-7, the crossover area is not clearly defined. The first picture shows the case where f_2 is 10% higher than f_1 and the duty cycle is changing periodically between 0% and 100%. Therefore, the ac voltages look like a sawtooth, with a rate equal to the difference of both frequencies. The same holds true if the two inputs are reversed. In the case where both frequencies are identical, the JK flip-flop behaves the same as an exclusive-OR gate. From this discussion, it can be concluded that, while this phase/frequency comparator was included to explain how it works, it is not a very desirable device for practical purposes because of the uncertainty of its behavior close to lock.

Digital Tristate Comparators. The digital tristate phase/frequency comparator is probably the most universally used and most important next to the sample/hold comparator. Although the diode-ring and exclusive-OR gate phase detectors have some applications, the tristate phase/frequency comparator can be used widely. Even in cases where a sample/hold comparator theoretically could be used, it may be inferior as far as reference attenuation or noise is concerned, but it is generally well-behaved. Unfortunately, the tristate system is very complex and shows a number of unusual phenomena. Such a digital tristate comparator is shown in Figure 6-8 using two D flip-flops and a NAND gate. The Q_2 output signal is filtered with the low-pass filter. The operation of this logic circuit is readily analyzed using the state-transition diagram, as shown in Figure 6-9. The D flip-flop outputs go high on the leading edge of their respective clock inputs and remain high until they are reset. The reset

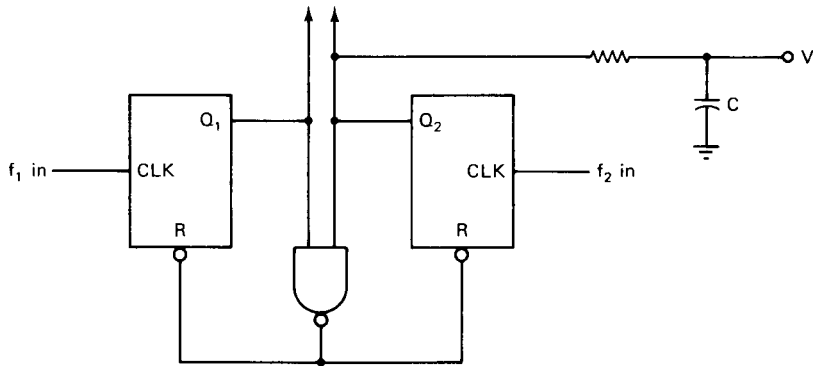

Figure 6-8 Phase detector with two D flip-flops and a NAND gate. In this book, this type of phase detector will be called a tristate comparator.

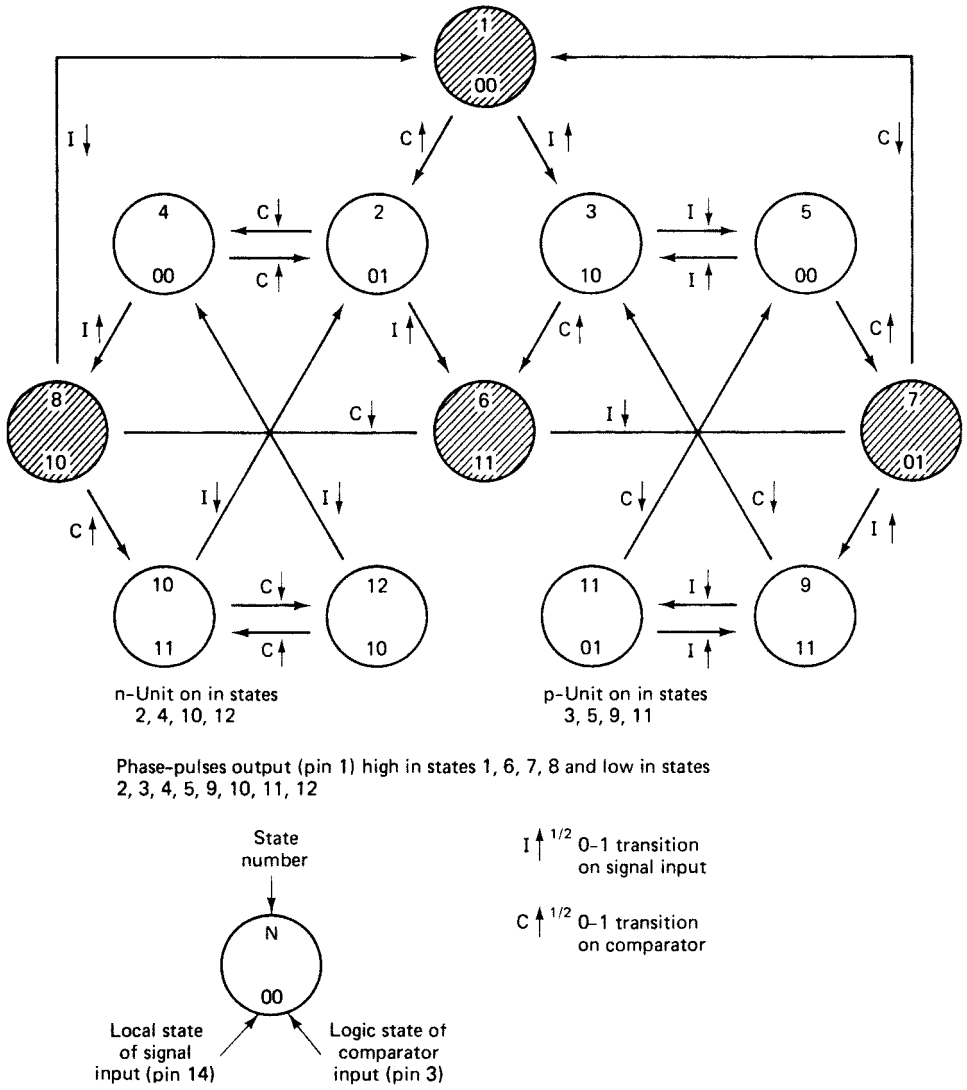

Figure 6-9 Logic diagram of the tristate detector.

signal occurs when both inputs are high. When both signals are in phase and of the same frequency, both outputs will remain low, and no signal will be applied to the operational amplifier. When the two frequencies are the same, the dc output voltage transfer characteristic will be as shown in Figure 6-10. If the two signal frequencies are not the same, the output voltage will depend on both the relative frequency difference and the phase difference. The timing diagram of Figure 6-11 illustrates the case in which $f_2 = 3f_1$. In part (a) of the figure, the leading edge of f_1 occurs just after that of f_2, so that Q_2 is high 50% of the time, and the average value of the PD output is 50%. In Figure 6-11b, the leading edge of f_1 occurs just before that of f_2, so Q_2 is high almost all the time and the average output voltage is approximately V.

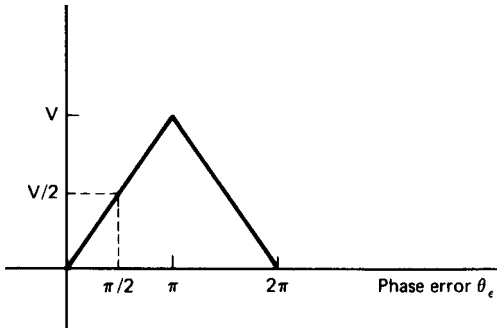

Figure 6-10 Transfer characteristic of the tristate phase/frequency comparator.

The output voltage averaged over all of the phase differences is then 67% for $f_2 = 3f_1$. In general, it can be said that the average output (averaged over all the phase differences) is given by

$$V_{\text{ave}} = 1 - \frac{f_1}{f_2} V \tag{6-15}$$

provided that f_2 is greater than f_1. This expression is plotted in Figure 6-12 together with the cases in which f_1 is greater than f_2.

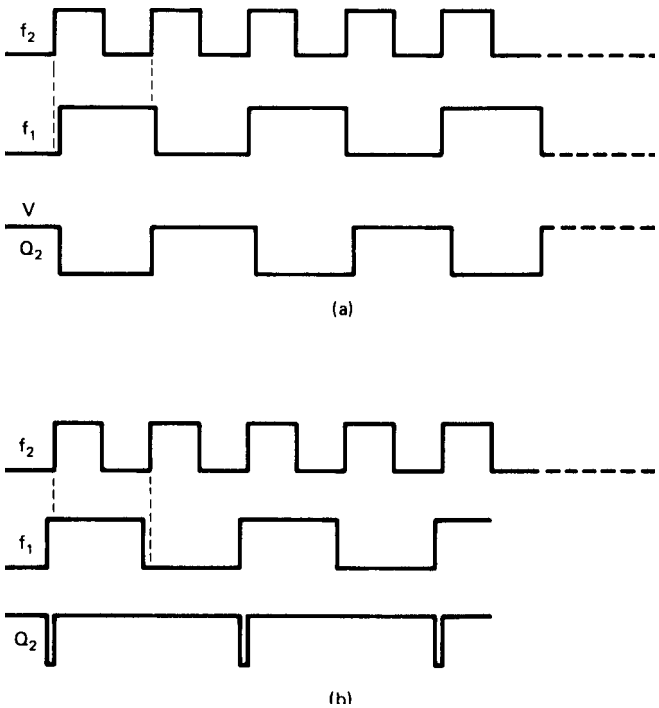

Figure 6-11 Output waveform of the tristate frequency comparator for different input frequencies.

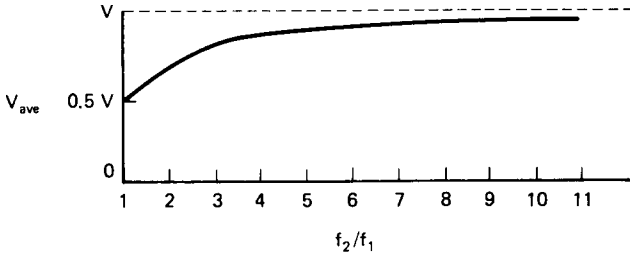

Figure 6-12 Average output voltage as a function of frequency ratio.

The digital network used in this realization is only one of a large number of logic circuits that could be used. Many IC manufacturers now produce a *quad-D* circuit that functions much like the dual-D flip-flop; the main difference is that when the frequency of one signal is more than twice that of the other signal, the corresponding output will be high all of the time. Therefore, a larger voltage is applied to the VCO and the loop response is faster. An example of the quad-D circuit is shown in Figure 6-13.

The most popular digital tristate phase/frequency comparator on the market is the one used in the CD4046 PLL IC, shown in Figure 6-14. It contains an additional phase comparator, an exclusive-OR gate that can be used as a lock indicator. In addition, two FETs are used to sum the two outputs. A slightly faster version in TTL technique is the Motorola MC4044. The fastest version in ECL is the MC12040, also made by Motorola, shown in Figure 6-15. Sometimes it is convenient to build the phase/frequency comparator in discrete technique to add additional features. Figure 6-16 shows an example.

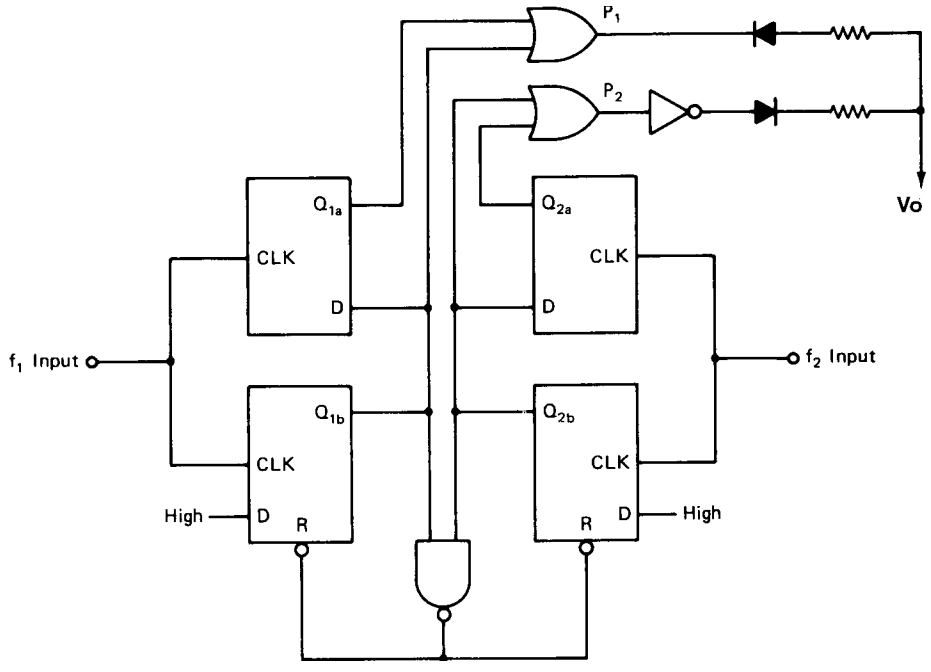

Figure 6-13 Example of a quad-D circuit.

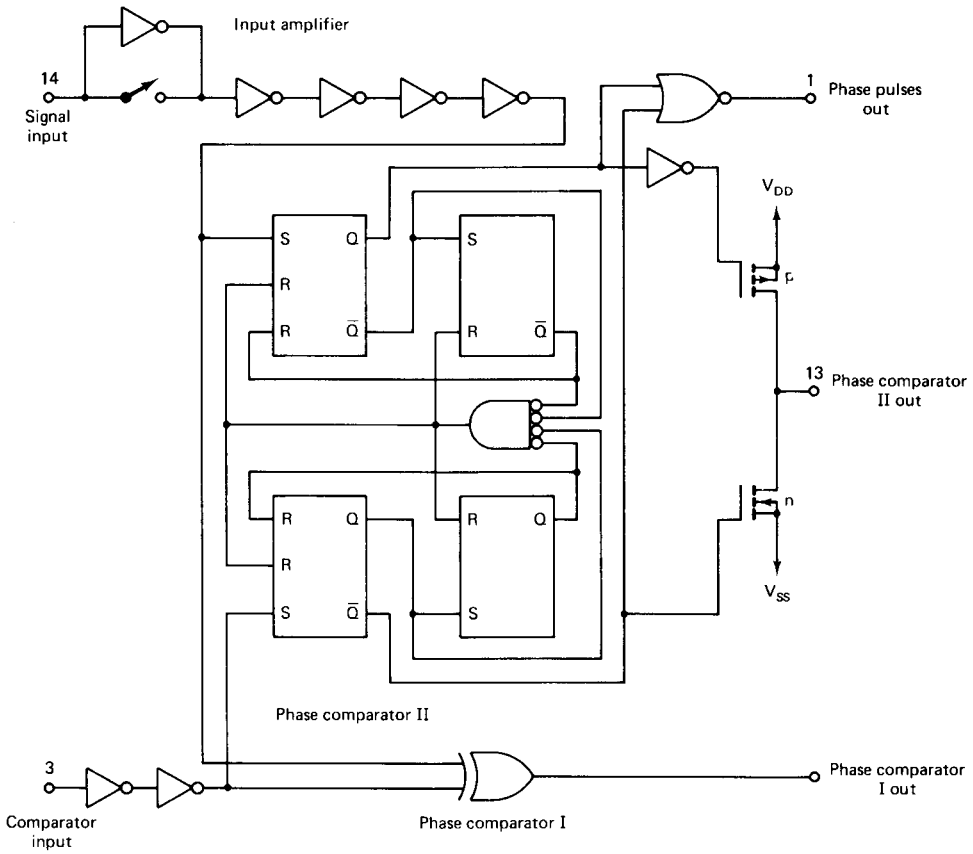

Figure 6-14 Block diagram of CD4046 phase/frequency comparator. (Courtesy of Motorola Semiconductor Products, Inc.)

This particular tristate phase/frequency comparator has a peculiarity that was first mentioned by Egan and Clark [2]. When actually building a phase-locked loop with this phase/frequency comparator, or that of the CD4046 type, by going through the normal mathematical design routine, it becomes apparent that the expected performance and the actual results differ as follows:

1. The reference suppression will be better than expected.
2. The phase error or tracking will be worse than expected.
3. The phase margin will differ and the system may not lock despite the fact that the calculation is correct.

The reason for all this is due to two effects:

1. The flip-flops are not absolutely alike, and as a result of this, the output in the crossover region is not zero.
2. If there is no or very little correction voltage required, the gain of the phase detector will drop substantially.

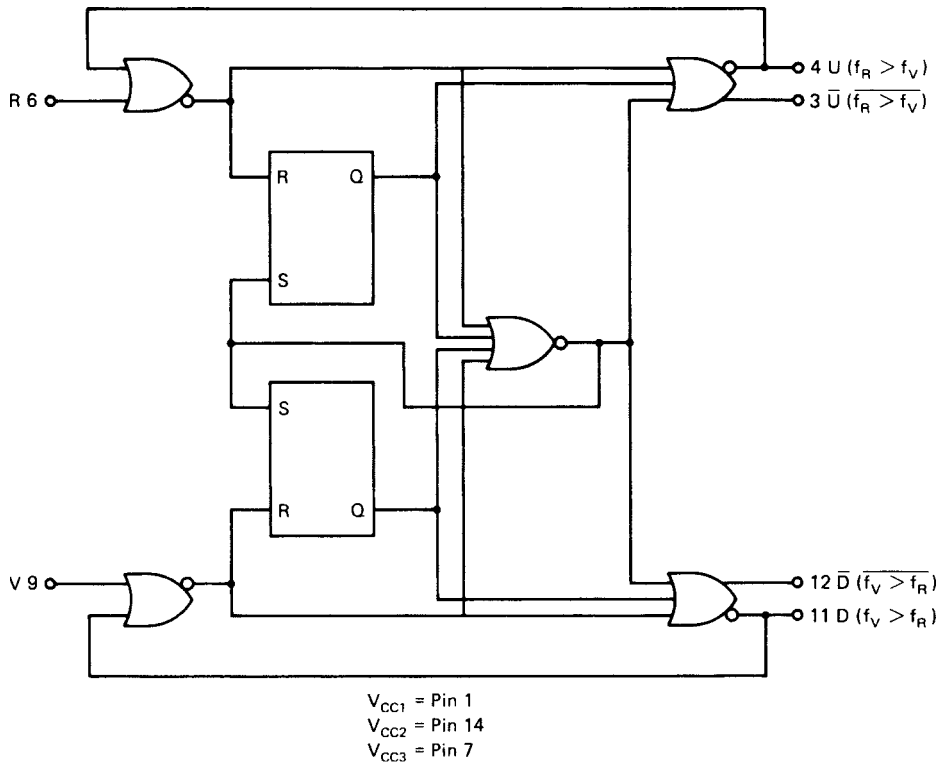

Figure 6-15 Block diagram of Motorola MC12040 phase/frequency comparator. (Courtesy of Motorola Semiconductor Products, Inc.)

Let us assume the ideal situation where the output of the phase/frequency comparator feeding the charge pump does not have to correct any error, the system is drift free, and there are no leakage currents. The holding capacitor of the charge pump would maintain constant voltage and, as there is no drift, no correction voltage would be necessary.

The flip-flops, however, introduce a certain amount of jitter, and a certain amount of jitter is also introduced by the frequency dividers, both the reference divider and the programmable divider. This jitter results in an uncertainty regarding the zero crossings, and extremely narrow pulses will appear at the output of the summation amplifier used in the CD4046.

Under the ideal assumption that there are no corrections required and those pulses would not exist, the reference suppression would be infinite, as there is no output. Therefore, the reference suppression—disregarding the effect of the loop filter—depends only on how well this condition is met.

The change of gain seems somewhat surprising, but as we think of it, if there is no correction and no update, there is also no gain. It is impossible to meet this condition, which is fortunate, but with regard to the temperature stability and aging characteristics of some devices, predicting actual performance may be difficult.

There are several remedies to this problem. A simple version is to introduce a controlled amount of leakage. While the electrolytic capacitor required in the charge pump will have some leakage, it is better to set a leakage current that is independent of temperature and

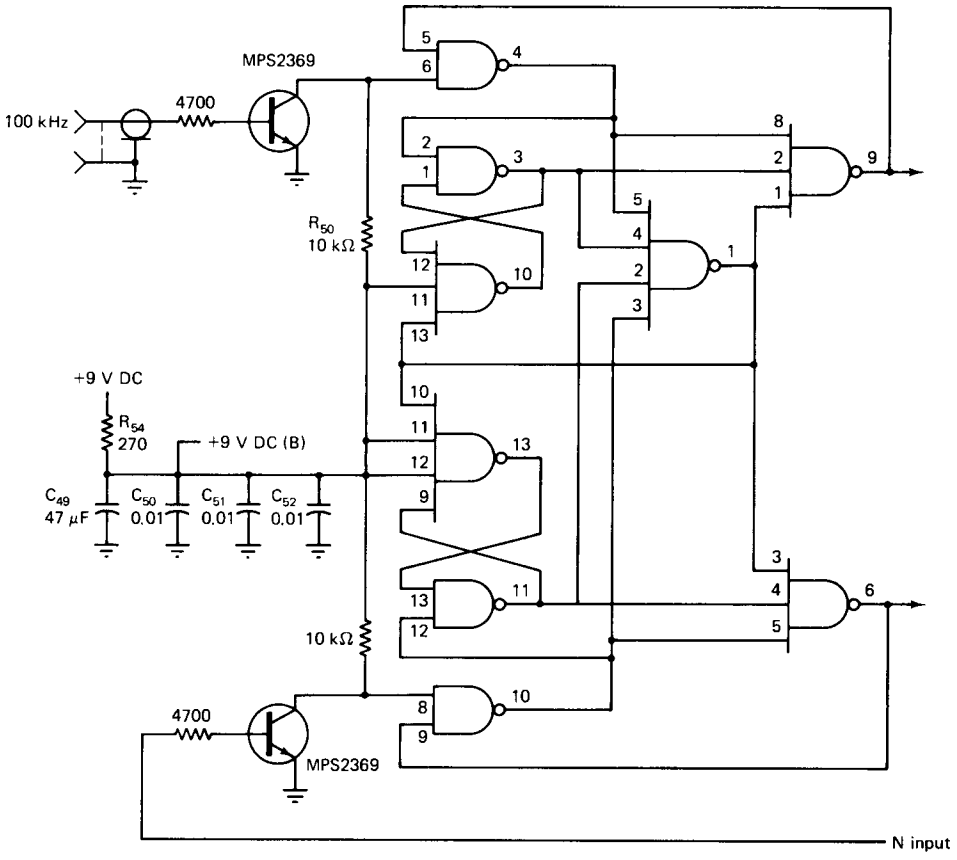

Figure 6-16 Possible version of tristate phase/frequency comparator.

aging. This can be accomplished by putting a 1-MΩ resistor from the output of the CD4046 to ground. The phase/frequency comparator then has to deliver an output current, and this output current is determined by a resistor that can be independent of temperature and other effects. As a result of this, the duty cycle of the output pulses of the phase/frequency comparator will change and the pulses will become wider. The wider the pulse, the more energy it contains; therefore, the wider the pulse, the more the reference suppression degrades.

It is theoretically possible to connect one side of the 1-MΩ resistor, instead of to ground, to the wiper of a potentiometer, and set the voltage in such a manner that this offset is compensated; but again, since the phase will shift theoretically, one must adjust the potentiometer according to the actual phase error. This is not a very convenient arrangement.

A somewhat better method was proposed by Fairchild several years ago, and the hardware was possibly realized in newer ICs. It was proposed to insert a gate in one of the output arms of the phase/frequency comparator before the signal is fed to the summation amplifier and a periodic current disturbance introduced. This disturbance has the same rate as the reference frequency and is of extremely short duration, such that the output contains only fairly high harmonics of the reference, which is easily filtered as it contains very little energy. This periodic disturbance upsets the output of the phase/frequency comparator and has an effect

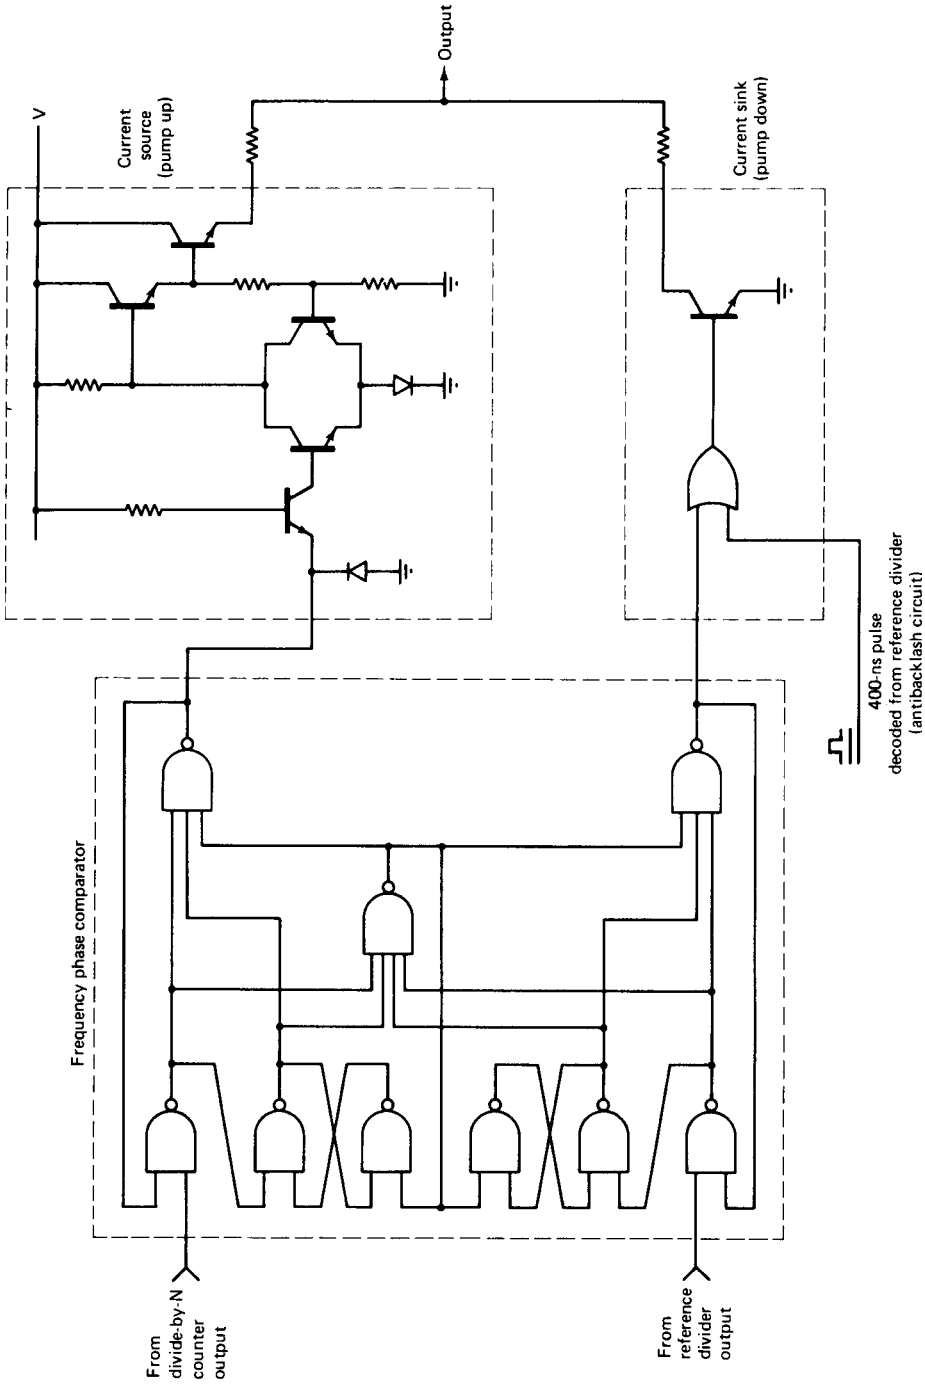

Figure 6-17 Tristate detector with antibacklash circuit included.

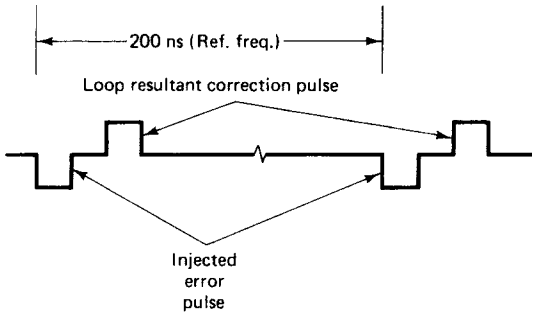

Figure 6-18 Output of phase/frequency detector with antibacklash circuit.

similar to that of a leakage resistor. The advantage of this method, however, is that this is done at a fairly high frequency and does not introduce low-frequency noise, which the 1-MΩ resistor does.

Figure 6-17 shows the circuit that accomplishes this, and Figure 6-18 shows the effect on the output pulses. The charge pump output exhibits a short negative-going pulse followed immediately by a short positive-going pulse. This can also be called an *antibacklash* feature, and it prevents operating in the dead zone. (This zone is not really a dead zone because of leakage currents in the tuning diode.) The duration and proximity of these pulses are such that they cause no net change in the charge of the integrator. Figure 6-19 shows the response of a phase/frequency detector near loop lock, including the dead zone; this may not be true for ECL.

6-2-3 Filters for Phase Detectors Providing Voltage Output

Figure 6-20 shows the passive *RC* filter for the second-order loop typically used in PLL synthesizers. The transfer characteristic of the filter is

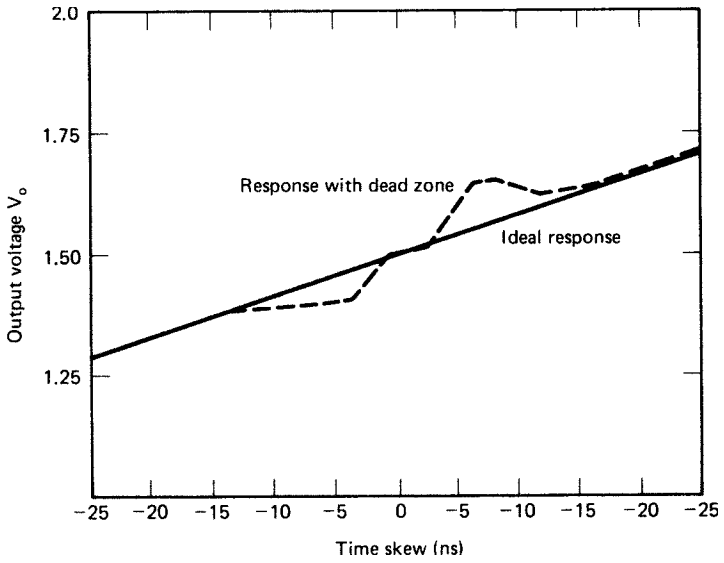

Figure 6-19 Response of phase/frequency detector near loop lock, resulting in a dead zone.

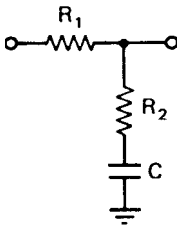

Figure 6-20 Schematic diagram of a typical passive *RC* filter.

$$\frac{V_0(s)}{V_I(s)} = \frac{1 + s\tau_2}{1 + s(\tau_1 + \tau_2)} \tag{6-16}$$

where $\tau_1 = R_1C$ and $\tau_2 = R_2C$.

Figure 6-21 shows the schematic for the active filter for the second-order loop. Its transfer characteristic is

$$\frac{V_0(s)}{V_I(s)} = \frac{1 + s\tau_2}{s\tau_1} \tag{6-17}$$

where $\tau_1 = R_1C$ and $\tau_2 = R_2C$.

If only one active integrator is used, we have a *Type 1* PLL. If two integrators are used, as in building an active filter, we have a *Type 2 second-order* loop. Here, *second-order* refers to the denominator polynomial of the transfer function. If we insert a simple low-pass filter such as the one shown in Figure 6-20, but with $R_2 = 0$, we obtain

$$F(s) = \frac{1}{1 + s\tau} \tag{6-18}$$

If we let $K = K_0K_\theta/N$, the transfer function $B(s)$ becomes

$$B(s) = \frac{N}{s^2/\omega_n^2 + 2\zeta s/\omega_n + 1} \tag{6-19}$$

where $\omega_n = \sqrt{K/\tau}$ and $2\zeta = \omega_n/K = \sqrt{1/K\tau}$. Here, ζ is the damping factor of the loop and ω_n is the natural frequency.

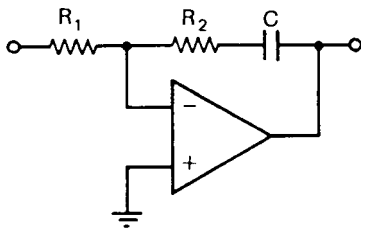

Figure 6-21 Schematic diagram of an active filter for a second-order loop.

The frequency response of the second-order transfer function is determined by ζ. For $\zeta = 0.707$, the transfer function becomes the second-order maximally flat, or Butterworth, response. For values of $\zeta < 0.707$, the gain exhibits peaking in the frequency domain. The maximum value of the frequency response can be found by setting the derivative of its maximum to zero. The frequency at which the maximum occurs is

$$\omega_p = \omega_n \sqrt{1 - 2\zeta^2} \tag{6-20}$$

The 3-dB bandwidth B is found to be

$$B = f_n[1 - 2\zeta^2 + (2 - 4\zeta^2 + 4\zeta^4)^{1/2}]^{1/2} \tag{6-21}$$

where $f_n = \omega_n/2\pi$.

The time required for the output to rise from 10% to 90% of its final value is the rise time t_r. It is approximately related to the system bandwidth by the relation

$$t_r = \frac{2.2}{B} \tag{6-22}$$

The *RC* time constant of this simple filter determines both the natural loop frequency and the damping factor ζ. To improve the performance of the filter, we need more flexibility. When the series resistor R_2 is not zero, we obtain the original *RC* filter of Figure 6-20. The transfer function of this filter is

$$B(s) = \frac{N[s\omega_n(2\zeta - \omega_n/K) + \omega_n^2]}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{6-23}$$

where $\omega_n = \sqrt{K/\tau}$ and $2\zeta = (1 + K\tau_2)/\sqrt{K\tau}$ and τ is written for $\tau_1 + \tau_2$.

The determination of the 3-dB bandwidth for this general Type 1 second-order loop is somewhat more complex than the earlier computation, but after calculation, we obtain

$$B = f_n[a + (a^2 + 1)^{1/2}]^{1/2} \tag{6-24}$$

where we have written

$$a = 2\zeta^2 + 1 - \frac{\omega_n(4\zeta - \omega_n/K)}{K} \tag{6-25}$$

The noise bandwidth of the Type 1 second-order loop is

$$B_n = \pi f_n \left(\zeta + \frac{1}{4\zeta}\right) \tag{6-26}$$

In the case of the active filter, where we have two integrators, the closed-loop transfer function of the Type 2 second-order PLL with a perfect integrator is

$$B(s) = \frac{N(2\zeta\omega_n s + \omega_n^2)}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{6-27}$$

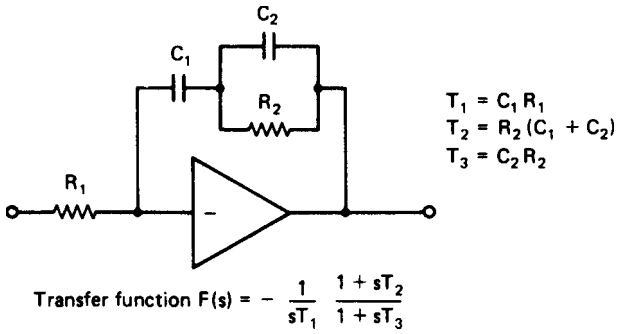

Figure 6-22 Schematic diagram of an active filter for a third-order loop.

where $\omega_n = (KR_2/\tau_2 R_1)^{1/2}$, $2\zeta = (K\tau_2 R_2/R_1)^{1/2}$, and $K = K_\theta K_0/N$, as usual. The 3-dB bandwidth of the Type 2 second-order filter is

$$B = f_n \left\{ 2\zeta^2 + 1 + \left[(2\zeta^2 + 1)^2 + 1 \right]^{1/2} \right\}^{1/2} \tag{6-28}$$

and the noise bandwidth is

$$B_n = \frac{(KR_2/R_1) + (1/\tau_2)}{4} \tag{6-29}$$

The Type 2 third-order loop is defined by the active integrator, as shown in Figure 6-22. The additional capacitor across the second resistor increases suppression of the reference frequency. The advantage of the higher-order loop is that, for the same loop bandwidth, it offers more reference-frequency suppression than the second-order loop. Conversely, for the same suppression it offers a faster lock-in time. More details are given in Rohde [1].

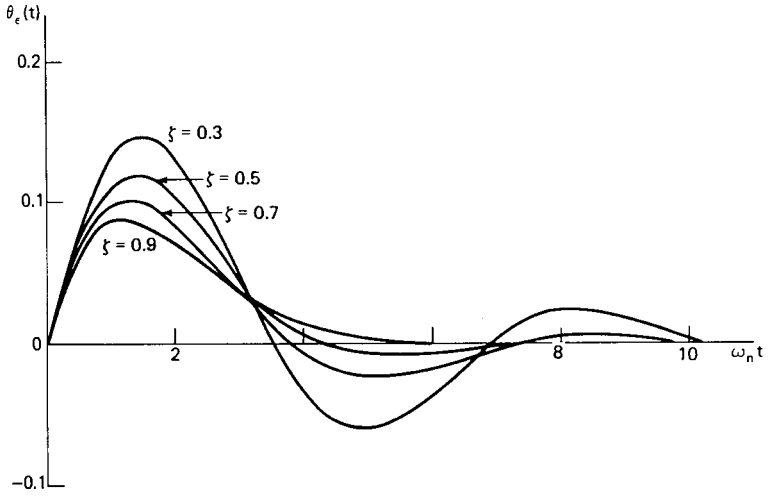

Figure 6-23 The error response of a Type 1 second-order PLL to unit-step change in frequency for various damping ratios ζ with K constant. The steady-state error $2\zeta/\omega = 1/K$.

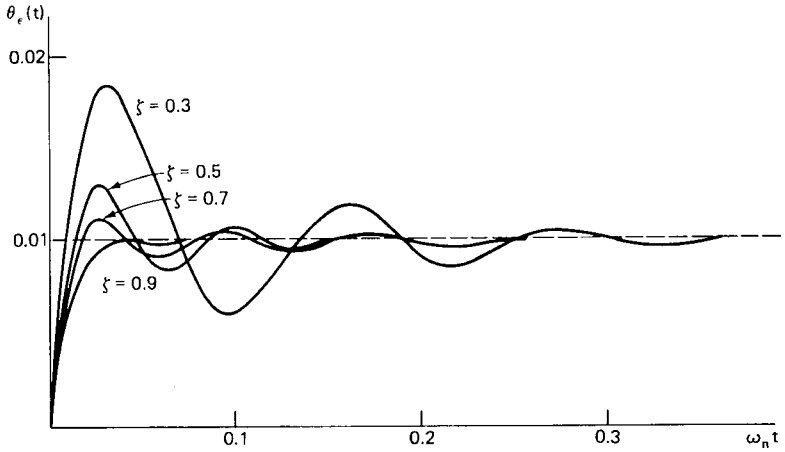

Figure 6-24 The error response of a Type 2 second-order PLL to unit-step change in frequency for various damping ratios ζ with ω_n constant. The steady-state error is zero.

Transient Response. The Laplace transform can be used to calculate the response of the PLL to a change in frequency. Figure 6-23 shows the normalized output response of the Type 1 second-order loop, and Figure 6-24 shows the normalized output response of the Type 2 second-order loop. We determine from both functions that a damping ratio of 0.707 will produce a peak overshoot of less than 10% for the Type 1 second-order loop and of less than 20% for the Type 2 second-order loop when $\omega_n t \geq 4.5$. The settling time is therefore determined to be $t_s = 4.5/\omega_n$. For more details on the actual design of synthesizer loops, the reader should refer to Rohde [1].

The Philips UMA1018M is an example of the synthesizer implementations now available in IC form. Designed for use in portable radiotelephones, the UMA1018M contains two frequency synthesizers. One, intended for first-LO use, can operate at input frequencies from 50 to 1.25 GHz; the second, intended for use as the second or "IF" LO in a double-conversion system, can operate at input frequencies from 20 to 300 MHz. Both loops use the same reference signal (3–40 MHz), which must be supplied by an external crystal oscillator. Figure 6-25 shows the UMA1018M's block diagram; Figure 6-26 shows the block diagram of a sample UMA1018M application; and Figure 6-27 shows a UMA1018M application schematic. Finally, Figures 6-28 and 6-29 show a UMA1018M-based system's close-in phase noise and reference suppression, respectively.

6-2-4 Charge-Pump-Based Phase-Locked Loops*

The basic drawback of the conventional phase/frequency detector, expressed in V/rad, is its dead-zone phenomenon. The loop gain is really determined by the linearity of the phase detector. Its can drop to zero when no correction is needed. One way around this had been to provide an external resistance, connected between the phase-detector output and common, that draws current but reduces the reference suppression. A more modern way to overcome

*Portions of this section are based on information contained in the National Semiconductor datasheet "LMX1501A/LMX1511 PLLatinum™ 1.1 GHz Frequency Synthesizer for RF Personal Communications," November 1995. Used with permission.

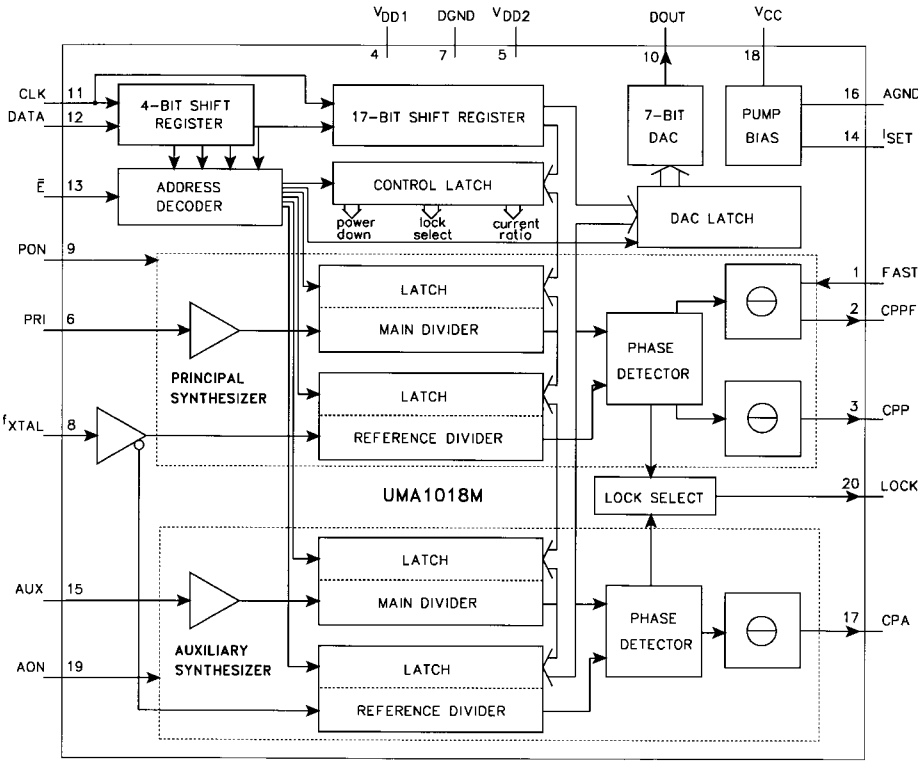

Figure 6-25 Block diagram of the Philips UMA1018M dual-synthesizer chip.

this problem is to resort to a charge pump. Figure 6-30 uses a CMOS-based charge pump, with the resistor R_L limiting the available current.

If more control over the actual current is needed, here is a recommendation by National Semiconductor that improves the flexibility.

External Charge Pump. Figure 6-31 shows one possible architecture for an external charge-pump current source. The signals ϕ_p and ϕ_r in the diagram correspond to the phase-detector outputs of the National LMX1501/1511 frequency synthesizers. These logic signals are converted into current pulses, using the circuitry shown in Figure 6-31, to enable either charging or discharging of the loop filter components to control the PLL's output frequency.

Referring to Figure 6-31, the design goal is to generate a 5-mA current that is relatively constant to within 5 V of the power-supply rail. To accomplish this, it is important to establish as large a voltage drop across R_5 and R_8 as possible without saturating Q_2 and Q_4. Approximately 300 mV provides a good compromise, allowing the current source reference generated to be relatively repeatable in the absence of good Q_1–Q_2, Q_3–Q_4 matching (matched transistor pairs are recommended.) The ϕ_p and ϕ_r outputs are rated for a maximum load current of 1 mA, while 5-mA current sources are desired. The voltages developed across R_4 and R_9 will consequently be approximately 258 mV, or 42 mV < R_8–R_5, due to the current density differences [0.026 × ln(5 mA/1 mA)] through the Q_1–Q_2, Q_3–Q_4 pairs.

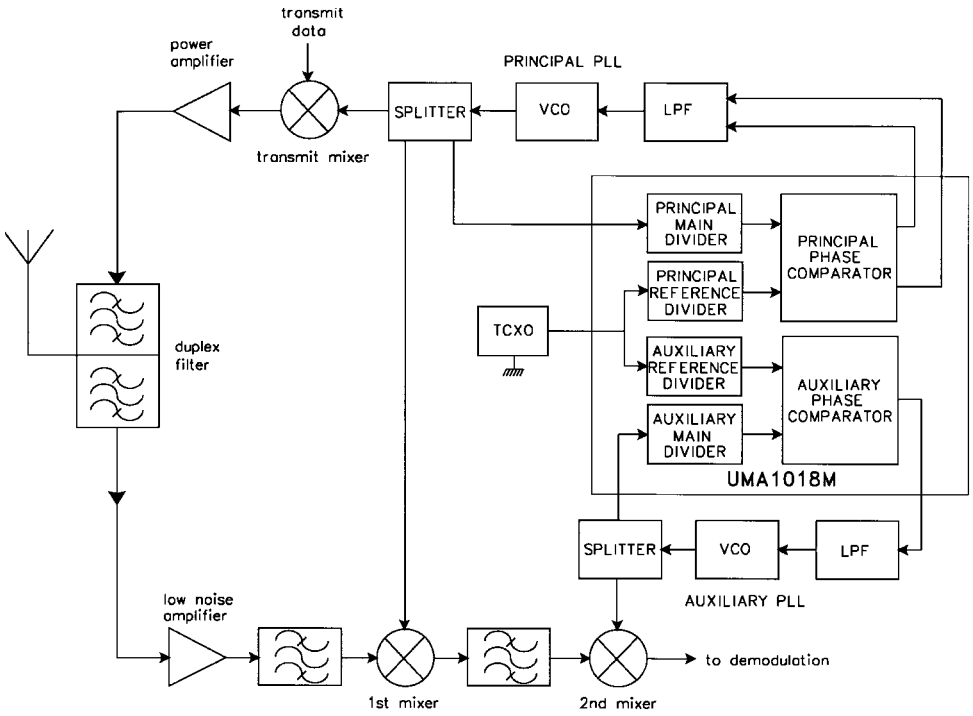

Figure 6-26 Block diagram of a typical UMA1018M application.

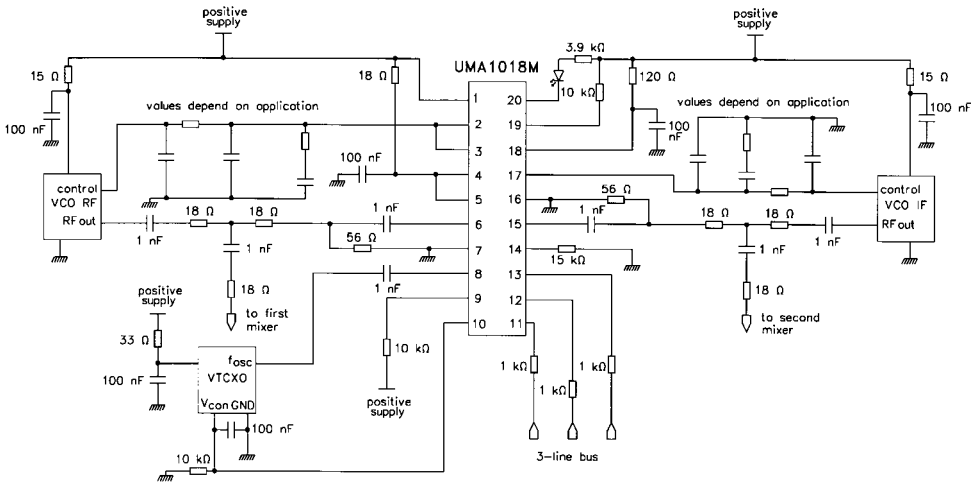

Figure 6-27 Schematic of a typical UMA1018M application.

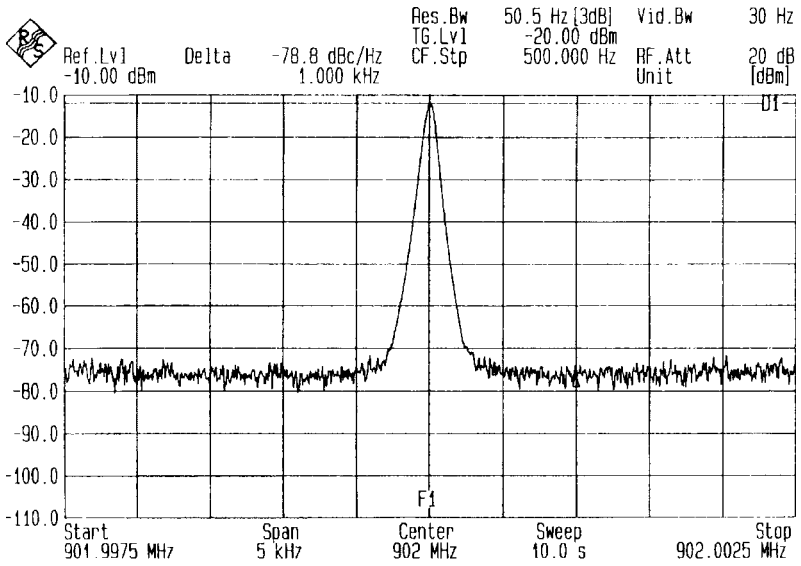

Figure 6-28 Close-in noise of a UMA1018M-based system (principal synthesizer).

To calculate the value of R_7, it is necessary to first estimate the forward base-to-emitter voltage drop (V_{fn}, V_{fp}) of the transistors used, the V_{OL} drop of ϕ_p, and the V_{OH} drop of ϕ_r under 1-mA loads (ϕ_p's $V_{OL} < 0.1$V and ϕ_r's $V_{OH} < 0.1$V).

Knowing these parameters along with the desired current allows us to design a simple external charge pump. Separating the pump-up and pump-down circuits facilitates the nodal analysis and gives the following equations:

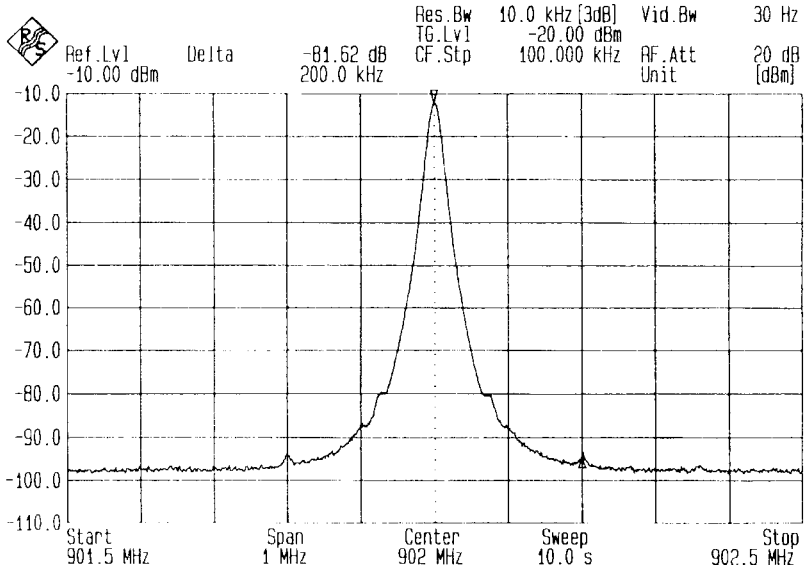

Figure 6-29 Wideband output spectrum of a UMA1018M-based system (principal synthesizer) showing reference-frequency breakthrough.

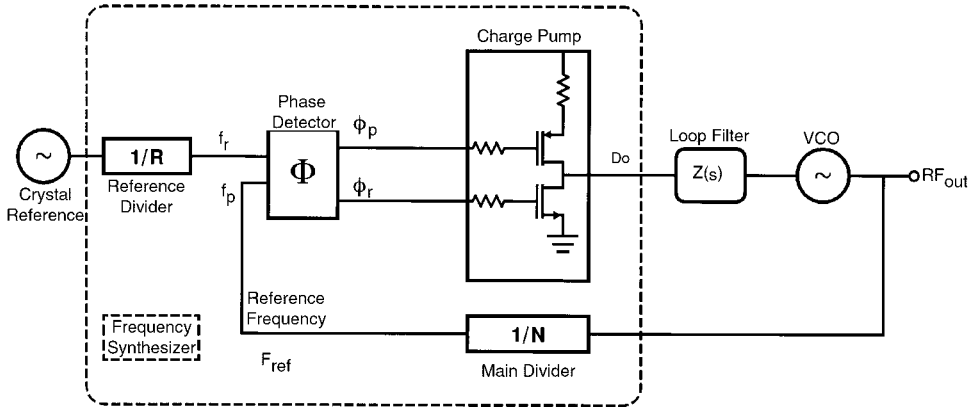

Figure 6-30 A basic charge-pump PLL.

$$R_4 = \frac{V_{R5} - V_T \times \ln(i_{\text{source}}/i_{p\,\max})}{i_{\text{source}}} \tag{6-30}$$

$$R_9 = \frac{V_{R8} - V_T \times \ln(i_{\text{sink}}/i_{n\,\max})}{i_{\text{sink}}} \tag{6-31}$$

$$R_5 = \frac{V_{R5} \times (\beta_p + 1)}{i_{p\,\max} \times (\beta_p + 1) - i_{\text{source}}} \tag{6-32}$$

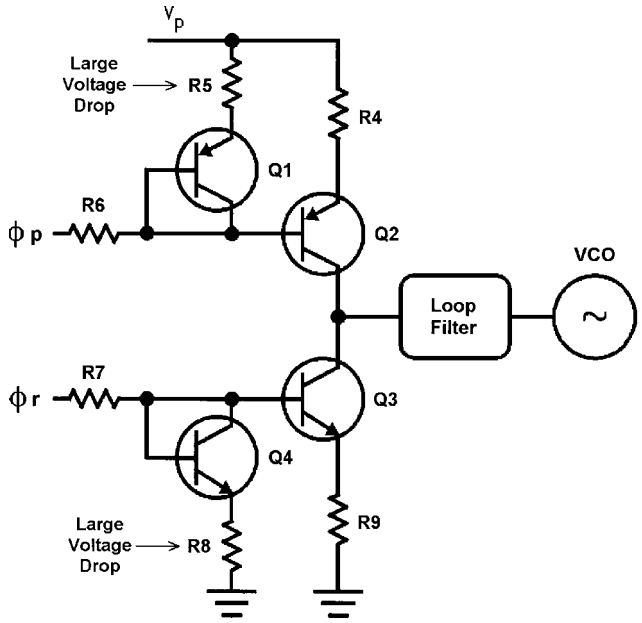

Figure 6-31 External charge-pump current source.

$$R_8 = \frac{V_{R8} \times (\beta_n + 1)}{i_{r\,\max} \times (\beta_n + 1) - i_{\text{source}}} \tag{6-33}$$

$$R_6 = \frac{(V_p - V_{VOL\phi_p}) - (V_{R5} + V_{fp})}{i_{p\,\max}} \tag{6-34}$$

$$R_7 = \frac{(V_p - V_{VOH\phi_r}) - (V_{R8} + V_{fn})}{i_{\max}} \tag{6-35}$$

Example

Typical Device Parameters: $\beta_n = 100$, $\beta_p = 50$.
Typical System Parameters: $V_p = 5.0$ V; $V_{cntl} = 0.5$ V – 4.5 V; $V_{\phi p} = 0.0$ V; $V_{\phi r} = 5.0$ V.
Design Parameters: $I_{\text{sink}} = I_{\text{source}} = 5.0$ mA; $V_{fn} = V_{fp} = 0.8$ V; $I_{r\,\max} = I_{p\,\max} = 1$mA; $V_{R8} = V_{R5} = 0.3$ V; $V_{OL\phi_p} = V_{OH\phi_r} = 100$mV.

Therefore, select

$$R_4 = R_9 = \frac{0.3\text{ V} - 0.026 \times \ln(5.0\text{ mA} \div 1.0\text{ mA})}{5\text{ mA}} = 51.6\ \Omega \tag{6-36}$$

$$R_5 = \frac{0.3\text{ V} \times (50 + 1)}{1.0\text{ mA} \times (50 + 1) - 5.0\text{ mA}} = 332\ \Omega \tag{6-37}$$

$$R_8 = \frac{0.3\text{ V} \times (100 - 1)}{1.0\text{ mA} \times (100 + 1) - 5.0\text{ mA}} = 315.6\ \Omega \tag{6-38}$$

$$R_6 = R_7 = \frac{(5\text{ V} - 0.1\text{ V}) - (0.3\text{ V} + 0.8\text{ V})}{1.0\text{ mA}} = 3.8\ \text{k}\Omega \tag{6-39}$$

Design Example: A Passive PLL Filter. Figure 6-32 shows the loop filter topology we will use for this example. The advantage of a passive filter as opposed to an active filter is that the filter itself introduces no noise, while the active filter using an op-amp can frequently cause more harm than good because of its noise contribution.

The time constants that determine the pole and zero frequencies of the filter shown in Figure 6-32 are

$$\tau_1 = R_2 \frac{C_1 C_2}{C_1 + C_2} \tag{6-40}$$

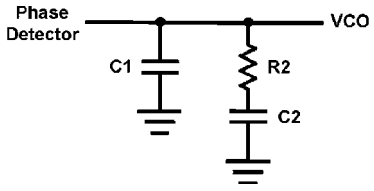

Figure 6-32 Schematic of the second-order loop filter.

and

$$\tau_2 = R_2 C_2 \tag{6-41}$$

The required values for τ_1 and τ_2 depend on the values we specify for the loop bandwidth, ω_p (equal to the frequency at which the loop's gain falls to 0 dB, or unity), and phase margin, ϕ_p, which is defined as the difference between 180° and the loop's phase shift at ω_p. For the best loop performance, we require a phase margin of 45°. The loop bandwidth must carefully be chosen with regard to lock time, phase noise, stability, and the reference-energy suppression. In this example, we will design our loop based on 10% of the reference frequency (f_{ref}, 200 kHz), so $\omega_p = 2\pi \times 20$ kHz, or 125.6 kHz. The required values for τ_1 and τ_2 can be determined from

$$\tau_1 = \frac{\sec \phi_p - \tan \phi_p}{\omega_p} \tag{6-42}$$

and

$$\tau_2 = \frac{1}{\omega_p^2 \tau_1} \tag{6-43}$$

From the time constants τ_1 and τ_2 and the loop bandwidth ω_p, we obtain the values for C_1, C_2, and R_2 as follows:

$$C_1 = \frac{\tau_1}{\tau_2} \frac{K_\phi K_{\text{VCO}}}{\omega_p^2 \tau_1} \sqrt{\frac{1 + (\omega_p \tau_2)^2}{1 + (\omega_p \tau_1)^2}} \tag{6-44}$$

$$C_2 = C_1 \left(\frac{\tau_2}{\tau_1} - 1 \right) \tag{6-45}$$

$$R_2 = \frac{\tau_2}{C_2} \tag{6-46}$$

where K_{VCO} = VCO tuning voltage constant (frequency versus voltage ratio) in MHz/V

K_ϕ = phase-detector/charge-pump gain constant (its ratio of current output to input phase differential) in mA

N = main divider ratio

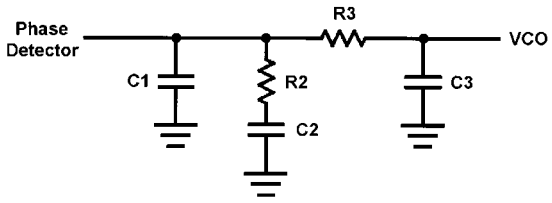

Figure 6-33 Third-order loop filter for greater reference-energy suppression.

If additional suppression of the loop's reference frequency is needed, a low-pass filter section can be added, resulting in the third-order loop filter shown in Figure 6-33.

The additional reference-frequency attenuation provided by R_3C_3 can be found from

$$\text{Atten} = 20 \log[(2\pi f_{\text{ref}} R_3 C_3)^2 + 1] \tag{6-47}$$

The low-pass section contributes an additional pole, which must be low enough to provide significant additional reference attenuation and high enough ($\geq 5\ \omega_p$) not to compromise the loop's stability. The time constant τ_3 of the added low-pass section can be found from

$$\tau_3 = R_3 C_3 \tag{6-48}$$

We can find τ_3 for a given value of additional attenuation from

$$\tau_3 = \frac{\sqrt{10^{(\text{Atten}/20)} - 1}}{2\pi f_{\text{ref}}} \tag{6-49}$$

To compensate for the added low-pass section, we recalculate the filter component values using the new loop bandwidth, ω_c, which can be found from

$$\omega_c = \frac{(\tan \phi)(\tau_1 + \tau_3)}{(\tau_1 + \tau_3)^2 + \tau_1 \tau_3} \left(\sqrt{1 + \frac{(\tau_1 + \tau_3)^2 + \tau_1 \tau_3}{[(\tan \phi)(\tau_1 + \tau_3)]^2}} - 1 \right) \tag{6-50}$$

We then reduce the phase-margin degradation caused by R_3C_3 by increasing C_1 and C_2 while slightly decreasing R_2. Calculating new values for C_1, C_2, and R_2 requires that we first determine the value for τ_2 as modified by R_3C_3:

$$\tau_2' = \frac{1}{\omega_c^2(\tau_1 + \tau_3)} \tag{6-51}$$

We can calculate C_1 as

$$C_1 = \frac{\tau_1}{\tau_2'} \frac{K_\phi K_{\text{VCO}}}{\omega_c^2 N} \left(\frac{1 + \omega_c^2 \tau_2'^2}{(1 + \omega_c^2 \tau_1^2)(1 + \omega_c^2 \tau_3^2)} \right)^{1/2} \tag{6-52}$$

As with the original second-order filter, C_2 and R_2 are calculated by means of Eqs. (6-45) and (6-46), respectively.

The values of R_3 and C_3 are somewhat arbitrary. The following rules of thumb apply: The value of C_3 should be less than that of C_1 and C_2, and preferably $\leq C_1/10$ to keep τ_3 from interacting with τ_1 and τ_2. Also, R_3 should be $\geq 2R_2$. Any capacitance already present on the VCO tuning line, including the input capacitance of the tuning diode(s), must be allowed for in selecting the value actually used for C_3 in the constructed loop filter.

The conversion from the voltage gain of a VCO to the charge current as needed here can be obtained from the formula [3]

$$K_\phi = \frac{I_{\text{charge}}}{2\pi f_R C_R} \tag{6-53}$$

which can be solved for the charge current, I_{charge}, as

$$I_{\text{charge}} = K_\phi 2\pi f_R C_R \tag{6-54}$$

where K_ϕ is the phase-detector/charge-pump gain factor in V/rad, f_R is the reference frequency, and C_R is the memory ("ramp") capacitance, typically 0.1 μF. The loop filters of Figures 6-32 and 6-33 include C_R as C_1.

Example. Design a third-order loop filter for a 900-MHz synthesizer with a 200-kHz reference based on the following parameters:

$K_{\text{VCO}} = 20$ MHz/V
$K_\phi = 5$ mA
$N = 4500$
$\omega_p = 2\pi \times 20$ kHz = 1.256E5
$\phi_p = 45°$
Atten = 20 dB

$$\tau_1 = \frac{\sec \phi_p - \tan \phi_p}{\omega_p} = 3.29\text{E}{-6} \tag{6-55}$$

$$\tau_3 = \frac{\sqrt{10^{(20/20)}} - 1}{(2\pi \times 200\text{E}3)^2} = 2.387\text{E}{-6} \tag{6-56}$$

$$\omega_c = \frac{3.29\text{E}{-6} + 2.387\text{E}{-6}}{[(3.29\text{E}{-6} + 2.387\text{E}{-6})^2 + 3.29\text{E}{-6} \times 2.387\text{E}{-6})]} \times \left(1 + \sqrt{\frac{3.29\text{E}{-6} + 2.387\text{E}{-6})^2 + 3.29\text{E}{-6} \times 2.387\text{E}{-6}}{[(3.29\text{E}{-6} + 2.387\text{E}{-6})]^2}}\right) - 1 \tag{6-57}$$

$$= 7.045\text{E}4 \tag{6-58}$$

$$\tau_2 = \frac{1}{(7.045\text{E}4)^2 \times (3.29\text{E}{-6} + 2.387\text{E}{-6})} = 3.549\text{E}{-5}$$

$$C_1 = \left(\frac{3.29\text{E}{-6}\ (5.0\text{E}{-3}) \times 20\text{E}6}{3.549\text{E}{-5}\ (7.045\text{E}4)^2 \times 4500}\right) \times \left(\frac{1 + (7.0454\text{E}4)^2 \times (3.549\text{E}{-5})^2}{[1 + (7.045\text{E}4)^2 \times (3.29\text{E}{-6})^2][1 + (7.045\text{E}4)^2 \times (2.39\text{E}{-6})^2]}\right)^{1/2} \tag{6.59}$$

$$= 1.085 \text{ nF}$$

$$C_2 = 1.085 \text{ nF} \times \left(\frac{3.55\text{E}{-5}}{3.29\text{E}{-6}} - 1 \right) = 10.6 \text{ nF} \tag{6-60}$$

$$R_2 = \frac{3.55\text{E}{-5}}{10.6\text{E}{-9}} = 3.35 \text{ k}\Omega \tag{6-61}$$

If we choose $R_3 = 22$ kΩ, then

$$C_3 = \frac{2.34\text{E}{-6}}{22\text{E}3} = 106 \text{ pF} \tag{6-62}$$

Selecting the nearest standard value for each component gives $C_1 = 1000$ pF, $R_2 = 3.3$ kΩ, $C_2 = 10$ nF, $R_3 = 22$ kΩ, and $C_3 = 100$ pF.

6-2-5 How to Do a Practical PLL Design Using CAD

1. Have a modern CAD tool give you a synthesized oscillator, such as a quarter-wave microstrip oscillator (Figure 6-34). Here we have used Compact Software's PLL Design Kit. (There are other similar programs on the market.) The loop synthesis program will ask you to specify the oscillator transistor's dc current and so on, and it will calculate the circuit's output power.

2. Ask your design tool for the oscillator's open- and closed-loop phase noise as a function of other noise sources (Figure 6-35). The program must consider the tuning diode as a major noise contributor. Here the loop bandwidth has been made too wide and makes the actual

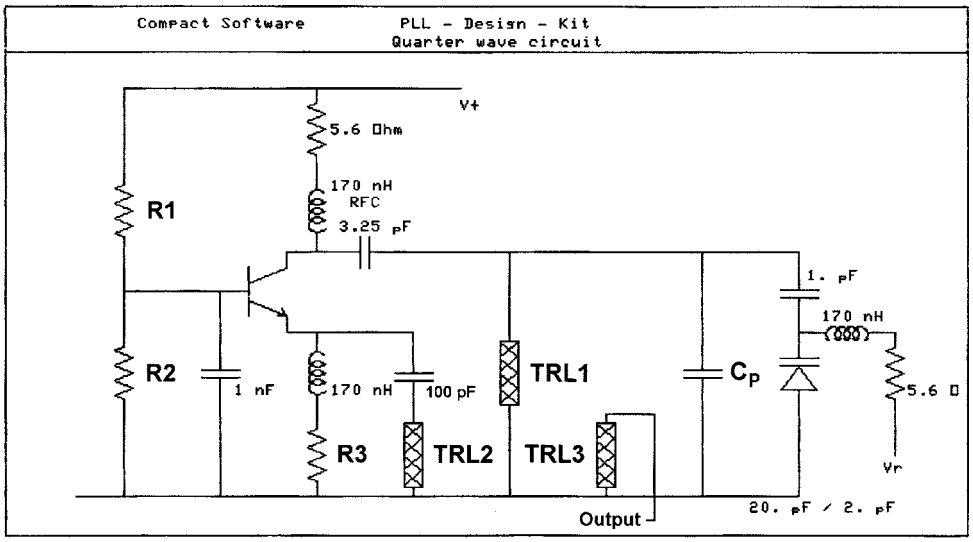

Figure 6-34 To design a PLL, begin with a suitable CAD-generated oscillator. This 900-MHz circuit is similar to that of the ceramic-resonator oscillator shown in Figure 5-33. TRL_1, TRL_2, and TRL_3 are coupled transmission lines; the resonator, TRL_1, is slightly less than λ/4 at the operating frequency. TRL_2 provides feedback, and TRL_3 provides output coupling. R_1, R_2, and R_3 must be specified; C_P must be determined according to the desired tuned range.

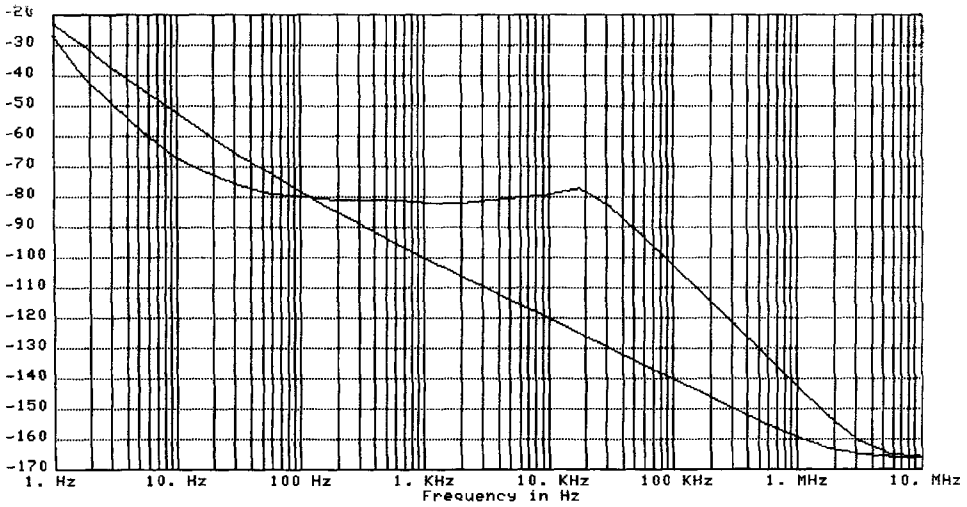

Figure 6-35 Predicted open- and closed-loop phase noise for the oscillator shown in Figure 6-34. The portion of the closed-loop curve up to 20 kHz represents the phase noise of the loop's crystal reference oscillator multiplied up. The VCO operates at 900 MHz; the reference frequency is 200 kHz. For references of 2 and 20 MHz, the phase noise would drop by 20 and 40 dB, respectively. See Table 6-1 and Figure 6-36.

phase noise worse. This plot is valid only if the dividers are the only noise contributors. The phase/frequency detector also adds noise following the equation

$$\mathcal{L} = \mathcal{L}_0 + 10 \log(F_r)$$

where $\mathcal{L}_0$ is a constant that is equivalent to the phase/frequency-detector noise with F_r = 1 Hz. $\mathcal{L}$ as a function of F_r is given below for standard PLL chips:

Table 6-1 Phase noise v. reference frequency derived from a high-performance 50-MHz crystal oscillator and multiplied to 880 MHz

Offset from Carrier	Phase Noise of 50-MHz Standard Oscillator (dBc/Hz)	Phase Noise in dBc/Hz After Dividing the Standard Down to: and Multiplying the Result to 880 MHz:		
		25 kHz	1.25 MHz	50 MHz
10 Hz	–80	–55	–55	–55
100 Hz	–110	–69	–85	–85
1 kHz	–140	–69	–103	–115
10 kHz	–160	–69	–103	–135
100 kHz	–160	–69	–103	–135
1 MHz	–160	–69	–103	–135

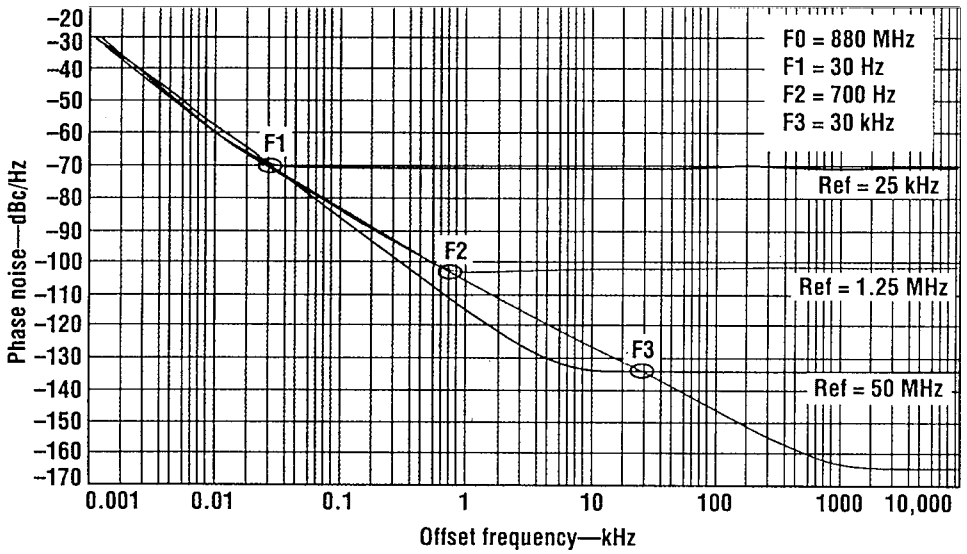

Figure 6-36 Result of dividing a 50-MHz standard oscillator down to different reference frequencies and then multiplying these frequencies to 880 MHz. The continuing line below breakpoint F3 shows the performance of the free-running 50-MHz oscillator.

$\mathcal{L}$ (dBc/Hz)	F_r (Hz)
−168 to −170	10k
−164 to −168	30k
−155 to −160	200k
−150 to −155	1M
−145	10M

3. Ask your synthesis program to design a loop filter for best performance, meaning a phase margin of 45° (Figure 6-37). Here we have arbitrarily included an additional low-pass filter with a cutoff frequency of 30 kHz to illustrate its effect on the loop performance.

4. Generate a Bode plot for the loop design and check the loop's phase margin at f_0, the frequency at which the loop gain is 0 dB. In this example, the plot (Figure 6-38) shows that because of the 30-kHz low-pass filter, we achieve only about 12° phase margin instead of the desired 45°. We can also see that the slope of the gain response through f_0 is not maintained at 6 dB/octave (20 dB/decade) over a sufficiently wide gain span. Maintaining the 6-dB/octave slope for loop-gain values of +10 to −10 dB is essential.

We can determine from Figure 6-38 that the loop gain is (60 dB at 200 kHz, the loop's reference frequency (f_{ref}). Adding this to the phase-detector's reference suppression (at least 40 dB) would appear to net us an overall reference suppression of 100 dB, but in any real implementation, crosstalk on the PLL PC board would reduce this value to between 80 and 90 dB.

5. As a result of the insufficient phase margin, the loop rings (Figure 6-39), locking in 322 μs instead of a possible 80 μs—a lock time four times as long as intended. Achievement of a phase margin of 45°, sometimes characterized merely as a rule of thumb, minimizes

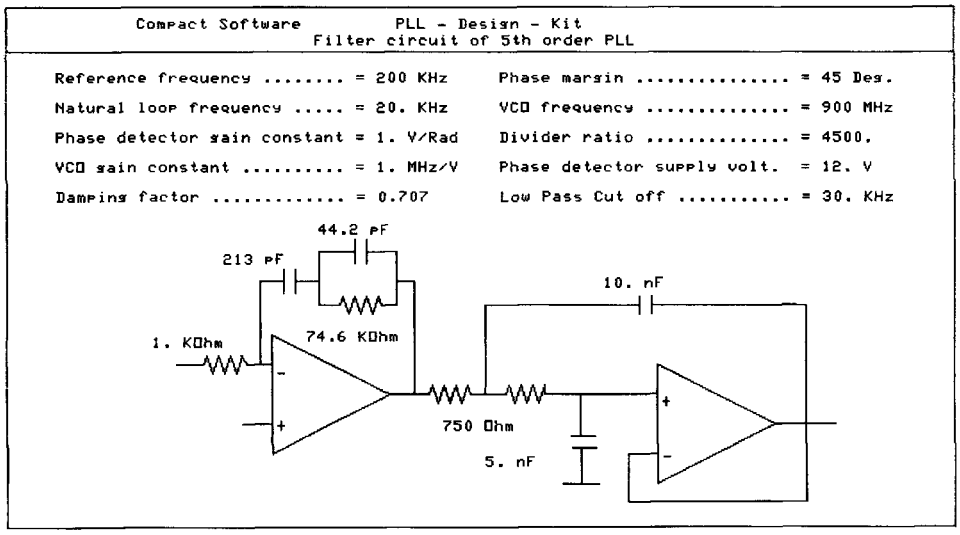

Figure 6-37 CAD-generated loop filter design based on a reference frequency of 200 kHz, a loop bandwidth of 20 kHz, and the optimum phase margin of 45°. We have arbitrarily included a 30-kHz low-pass filter to illustrate its effects on loop performance.

locking time and overshoot. Values less than 45° result in excessive overshoot and ringing, as shown here, and values greater than 45° result in an overdamped loop that crawls into lock.

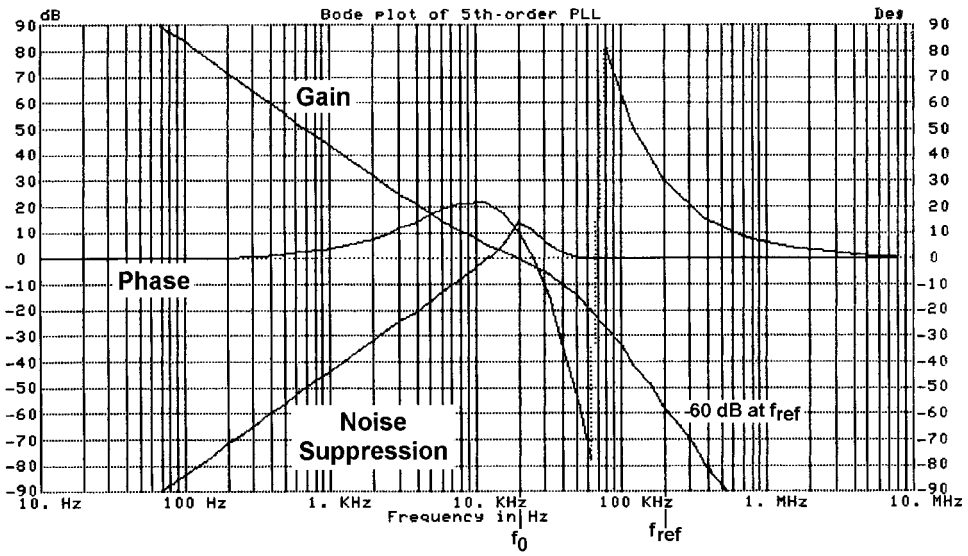

Figure 6-38 Bode plot for the PLL. The 30-kHz low-pass filter disallows a phase margin of 45° at f_0; instead, the margin is only about 20°.

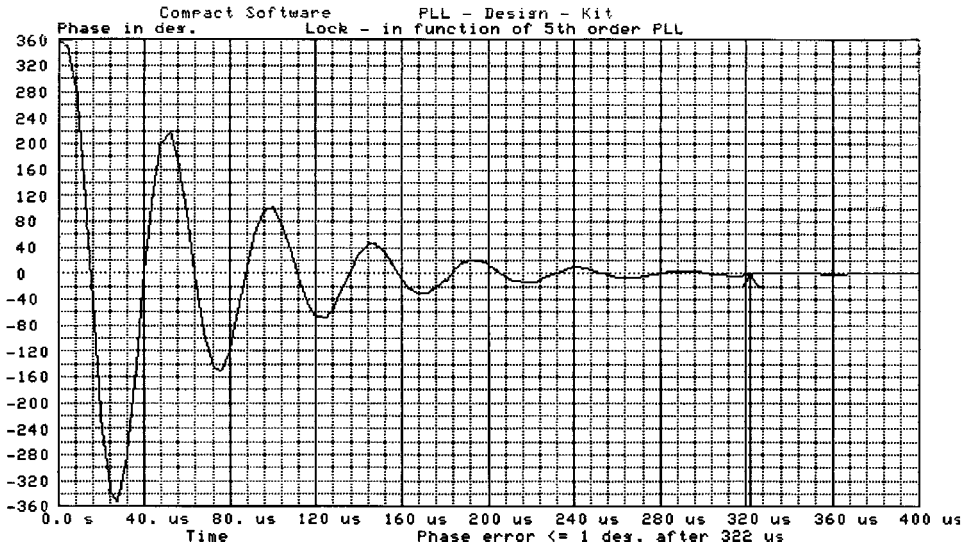

Figure 6-39 Lock-in response of the PLL. As a result of the insufficient phase margin, the loop is underdamped and takes 322 μs to achieve lock.

6-3 FRACTIONAL-*N*-DIVISION PLL SYNTHESIS

6-3-1 The Fractional-*N* Principle

The principle of the fractional-*N* PLL synthesizer has been around for awhile. In the past, implementation of this has been done in an analog system. It would be ideal to be able to build a single-loop synthesizer with a 1.25- or 50-MHz reference and yet obtain the desired step-size resolution, such as 25 kHz. This would lead to the much smaller division ratio and much better phase-noise performance.

An alternative would be for N to take on fractional values. The output frequency could then be changed in fractional increments of the reference frequency. Although a digital divider cannot provide a fractional division ratio, ways can be found to accomplish the same task effectively.

The most frequently used method is to divide the output frequency by $N + 1$ every M cycles and to divide by N the rest of the time. The effective division ratio is then $N + 1/M$, and the average output frequency is given by

$$f_o = \left(N + \frac{1}{M}\right) f_r \tag{6-63}$$

This expression shows that f_o can be varied in fractional increments of the reference frequency by varying M. The technique is equivalent to constructing a fractional divider, but the fractional part of the division is actually implemented using a phase accumulator. The phase accumulator approach is illustrated by the following example. This method can be expanded to frequencies much higher than 6 GHz using the appropriate synchronous dividers.

Example. Consider the problem of generating 899.8 MHz using a fractional-*N* loop with a 50-MHz reference frequency,

$$899.8 \text{ MHz} = 50 \text{ MHz}\left(N + \frac{K}{F}\right)$$

The integral part of the division *N* has to be set to 17 and the fractional part *K*/*F* needs to be 996/1000 (the fractional part *K*/*F* is not a integer); the VCO output has to be divided by 996 every 1000 cycles. This can easily be implemented by adding the number 0.996 to the contents of an accumulator every cycle. Every time the accumulator overflows, the divider divides by 18 rather than by 17. Only the fractional value of the addition is retained in the phase accumulator. If we move to the lower band or try to generate 850.2 MHz, *N* remains 17 and *K*/*F* becomes 4/1000. This method of using fractional division was first introduced by using analog implementation and noise cancellation, but today it is implemented totally as a digital approach. The necessary resolution is obtained from the dual-modulus prescaling, which allows for a well-established method of achieving a high-performance frequency synthesizer operating at UHF and higher frequencies. Dual-modulus prescaling avoids the loss of resolution in a system compared to a simple prescaler; it allows a VCO step equal to the value of the reference frequency to be obtained. This method needs an additional counter and the dual-modulus prescaler then divides one or two values depending on the state of its control. The only drawback of prescalers is the minimum division ratio of the prescaler for approximately N^2. The dual-modulus divider is the key to implementing the fractional-*N* synthesizer principle. Although the fractional-*N* technique appears to have a good potential of solving the resolution limitation, it also has its own complications. Typically, an overflow from the phase accumulator, which is the adder with the output feedback to the input after being latched, is used to change the instantaneous division ratio. Each overflow produces a jitter at the output frequency, caused by the fractional division, and is limited to the fractional portion of the desired division ratio.

In our case, we had chosen a step size of 200 kHz, and yet the discrete sidebands vary from 200 kHz for *K*/*F* = 4/1000 to 49.8 MHz for *K*/*F* = 996/1000. It will become the task of the loop filter to remove those discrete spurious frequencies. While in the past the removal of the discrete spurs has been accomplished by using analog techniques, various digital methods are now available. The microprocessor has to solve the following equation:

$$N^* = \left(N + \frac{K}{F}\right) = [N(F - K) + (N + 1)K] \tag{6-64}$$

Example. For F_o = 850.2 MHz, we obtain

$$N^* = \frac{850.2 \text{ MHz}}{50 \text{ } MHz} = 17.004$$

Following the formula above,

$$N^* = \left(N + \frac{K}{F}\right) = \frac{[17(1000 - 4) + (17 + 1) \times 4]}{1000}$$

$$= \frac{16932 + 72}{1000} = 17.004$$

$$F_o = 50 \text{ MHz} \times \frac{(16932 + 72)}{1000}$$

$$= 846.6 \text{ MHz} + 3.6 \text{ MHz}$$

$$= 850.2 \text{ MHz}$$

By increasing the number of accumulators, frequency resolution much below 1-Hz step size is possible with the same switching speed.

There is an interesting, generic problem associated with *all* fractional-*N* synthesizers. Assume for a moment that we use our 50-MHz reference and generate a 550-MHz output frequency. This means our division factor is 11. Aside from reference-frequency sidebands (±50 MHz) and harmonics, there will be no unwanted spurious frequencies. Of course, the reference sidebands will be suppressed by the loop filter by more than 90 dB. For reasons of phase noise and switching speed, a loop bandwidth of 100 kHz has been considered. Now, taking advantage of the fractional-*N* principle, say we want to operate at an offset of 30 kHz (550.03 MHz). With this new output frequency, the inherent spurious-signal reduction mechanism in the fractional-*N* chip limits the reduction to about 55 dB. Part of the reason why the spurious-signal suppression is less in this case is that the phase/frequency detector acts as a mixer, collecting both the 50-MHz reference (and its harmonics) and 550.03 MHz. Mixing the 11th reference harmonic (550 MHz) and the output frequency (550.03 MHz) results in output at 30 kHz; since the loop bandwidth is 100 kHz, it adds nothing to the suppression of this signal. To solve this, we could consider narrowing the loop bandwidth to 10% of the offset. A 30-kHz offset would equate to a loop bandwidth of 3 kHz, at which the loop speed might still be acceptable, but for a 1-kHz offset, the necessary loop bandwidth of 100 Hz would make the loop too slow. A better way is to use a different reference frequency—one that would place the resulting spurious product considerably outside the 100-kHz loop filter window. If, for instance, we used a 49-MHz reference, multiplication by 11 would result in 539 MHz. Mixing this with 550.03 MHz would result in spurious signals at ±11.03 MHz, a frequency so far outside the loop bandwidth that it would essentially disappear. Starting with a VHF, low-phase-noise crystal oscillator, such as 130 MHz, one can implement an intelligent reference-frequency selection to avoid these discrete spurious signals. An additional method of reducing the spurious contents is maintaining a division ratio greater than 12 in all cases. Actual tests have shown that these reference-based spurious frequencies can be repeatably suppressed by 80–90 dB.

6-3-2 Spur-Suppression Techniques

While several methods have been proposed in the literature [4–9], the method of reducing the noise by using a sigma-delta modulator has shown the most promise. The concept is to get rid of the low-frequency phase error by rapidly switching the division ratio to eliminate the gradual phase error at the discriminatory input. By changing the division ratio rapidly between different values, the phase errors occur in both polarities, positive as well as negative, and at an accelerated rate that explains the phenomenon of high-frequency noise push-up. This noise, which is converted to a voltage by the phase/frequency discriminator and loop filter, is filtered out by the low-pass filter. The main problem associated with this noise shaping technique is that the noise power rises rapidly with frequency. Figure 6-40 shows noise contributions with such a sigma-delta modulator in place.

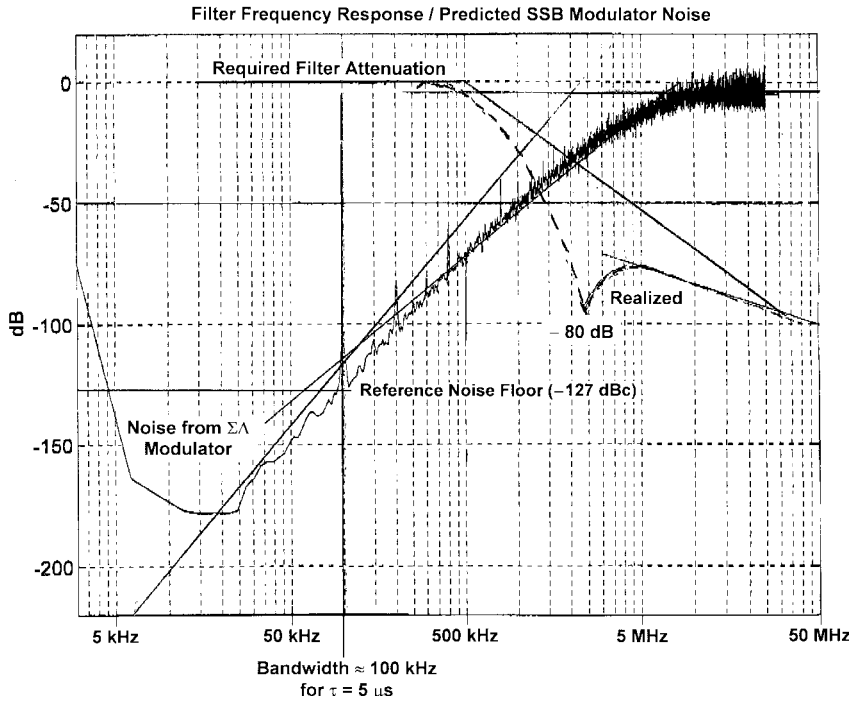

Figure 6-40 The filter frequency response/phase-noise analysis graph shows the required attenuation for the reference frequency of 50 MHz and the noise generated by the sigma-delta converter (three steps) as a function of the offset frequency. It becomes apparent that the sigma-delta converter noise dominates above 80 kHz unless attenuated.

On the other hand, we can now, for the first time, build a single-loop synthesizer with switching times as fast as 6 μs and very little phase-noise deterioration inside the loop bandwidth, as seen in Figure 6-40. Since this system maintains the good phase noise of the ceramic-resonator-based oscillator, the resulting performance is significantly better than the phase noise expected from high-end signal generators. However, this method does not allow us to increase the loop bandwidth beyond the 100-kHz limit, where the noise contribution of the sigma-delta modulator takes over.

Table 6-2 shows some of the modern spur-suppression methods. These three-stage sigma-delta methods with larger accumulators have the most potential [4–9].

Table 6-2 Modern spur-suppression methods

Technique	Feature	Problem
DAC phase estimation	Cancel spur by DAC	Analog mismatch
Pulse generation	Insert pulses	Interpolation jitter
Phase interpolation	Inherent fractional divider	Interpolation jitter
Random jittering	Randomize divider	Frequency jitter
Sigma-delta modulation	Modulate division ratio	Quantization noise

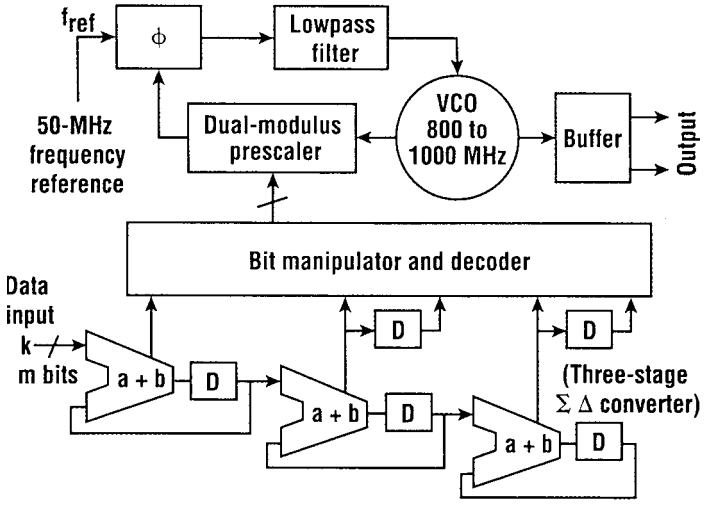

Figure 6-41 Block diagram of the fractional-*N* synthesizer built using a custom IC capable of operation at reference frequencies up to 150 MHz. The frequency is extensible up to 3 GHz using binary (÷2, ÷4, ÷8, etc.) and fixed-division counters.

The power spectral response of the phase noise for the three-stage sigma-delta modulator is calculated from

$$L(f) = \frac{(2\pi)^2}{12 f_{\text{ref}}} [2\sin(\pi f / f_{\text{ref}})]^{2(n-1)} \text{ rad}^2/\text{Hz} \tag{6-65}$$

where n is the number of the stage of the cascaded sigma-delta modulator [10]. Equation (6-65) shows that the phase noise resulting from the fractional controller is attenuated to negligible levels close to the center frequency, and further from the center frequency, the phase noise is increased rapidly and must be filtered out prior to the tuning input of the VCO to prevent unacceptable degradation of spectral purity. A loop filter must be used to filter the noise in the PLL loop. Figure 6-40 shows the plot of the phase noise versus the offset frequency from the center frequency. A fractional-*N* synthesizer with a three-stage sigma-delta modulator as shown in Figure 6-41 has been built. The synthesizer consists of a phase/frequency detector, an active low-pass filter (LPF), a voltage-controlled oscillator (VCO), a dual-modulus prescaler, a three-stage sigma-delta modulator, and a buffer. Figure 6-42 shows the inner workings of the chip in greater detail.

After designing, building, and predicting the phase-noise performance of this synthesizer, it becomes clear that measuring the phase noise of such a system becomes tricky. Standard measurement techniques that use a reference synthesizer would not provide enough resolution because there are no synthesized signal generators on the market good enough to measure such low values of phase noise. Therefore, we had to build a comb generator that would take the output of the oscillator and multiply this up 10–20 times.

Passive phase-noise measurement systems, based on delay lines, are not selective, and the comb generator confuses them. However, the Rohde & Schwarz FSEM spectrum analyzer with the K-4 option has sufficient resolution to be used for phase-noise measurements. All of the Rohde & Schwarz FSE-series spectrum analyzers use a somewhat more discrete

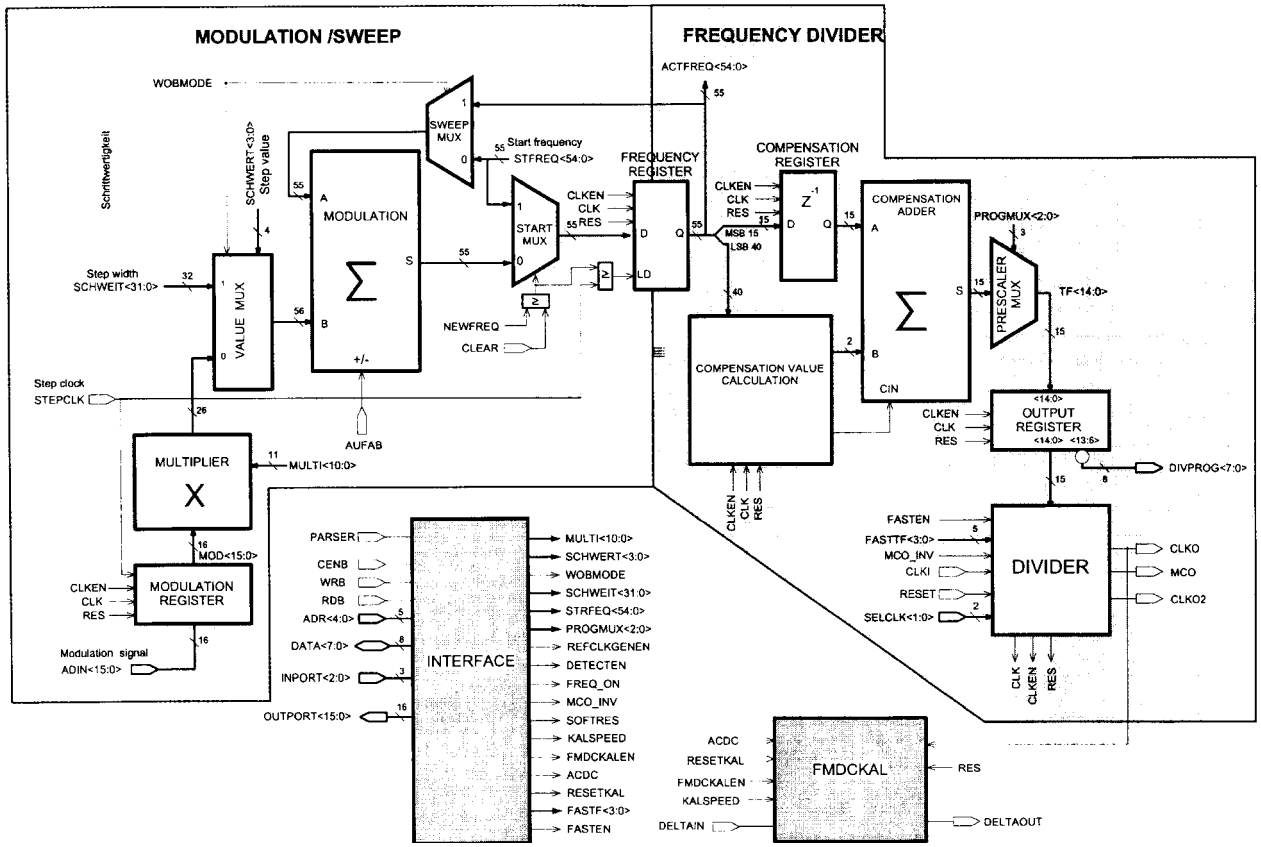

Figure 6-42 Detailed block diagram of the inner workings of the fractional-*N*-division synthesizer chip.

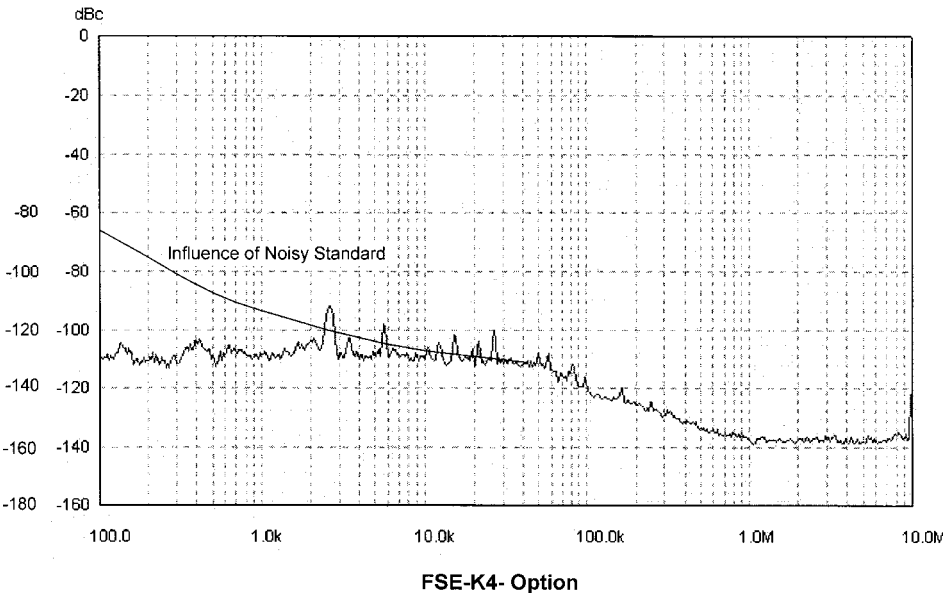

Figure 6-43 Measured phase noise of the fractional-*N*-division synthesizer using a custom-built, high-performance 50-MHz crystal oscillator as reference, with the calculated degradation due to a noisy reference plotted for comparison. Both synthesizer and spectrum analyzer use the same reference.

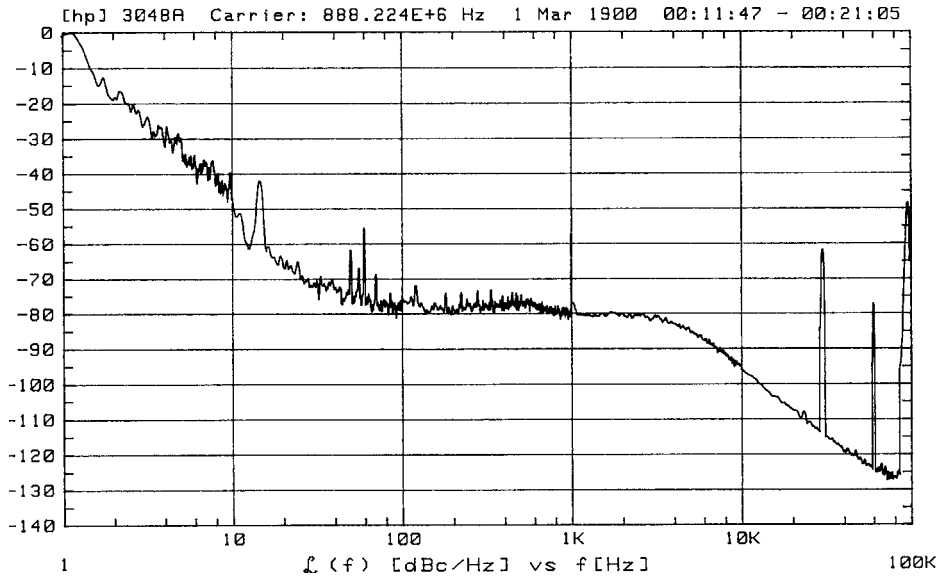

Figure 6-44 Measured phase noise of an 880-MHz synthesizer using a conventional synthesizer chip. Comparing this to Figure 6-43, we see that a large improvement is possible using fractional-*N*-division synthesizers, as shown in this product description.

fractional-division synthesizer with a 100-MHz reference. Based on the multiplication factor of 10, it turns out that there is enough dynamic range in the FSEM analyzer with the K-4 option to be used for phase-noise measurement. The useful frequency range off the carrier for the system is 100 Hz to 10 MHz—perfect for this measurement.

Figure 6-43 shows the measured phase noise of the final frequency synthesizer.

During the measurements, we determined that we needed a 50-MHz crystal oscillator with better phase noise. Upon examination of the measured phase noise shown in Figure 6-43, it can be seen that the oscillator used as the reference was significantly better. Otherwise, this phase noise would not have been possible. Also, the loop filter cutoff frequency of about 100 kHz can be recognized by the roll-off in Figure 6-43. This fractional-*N*-division synthesizer with a high-performance VCO has a significantly better phase noise than other example systems in this frequency range. To demonstrate this improvement, phase-noise measurements were made on standard systems, using typical synthesizer chips. Although the phase

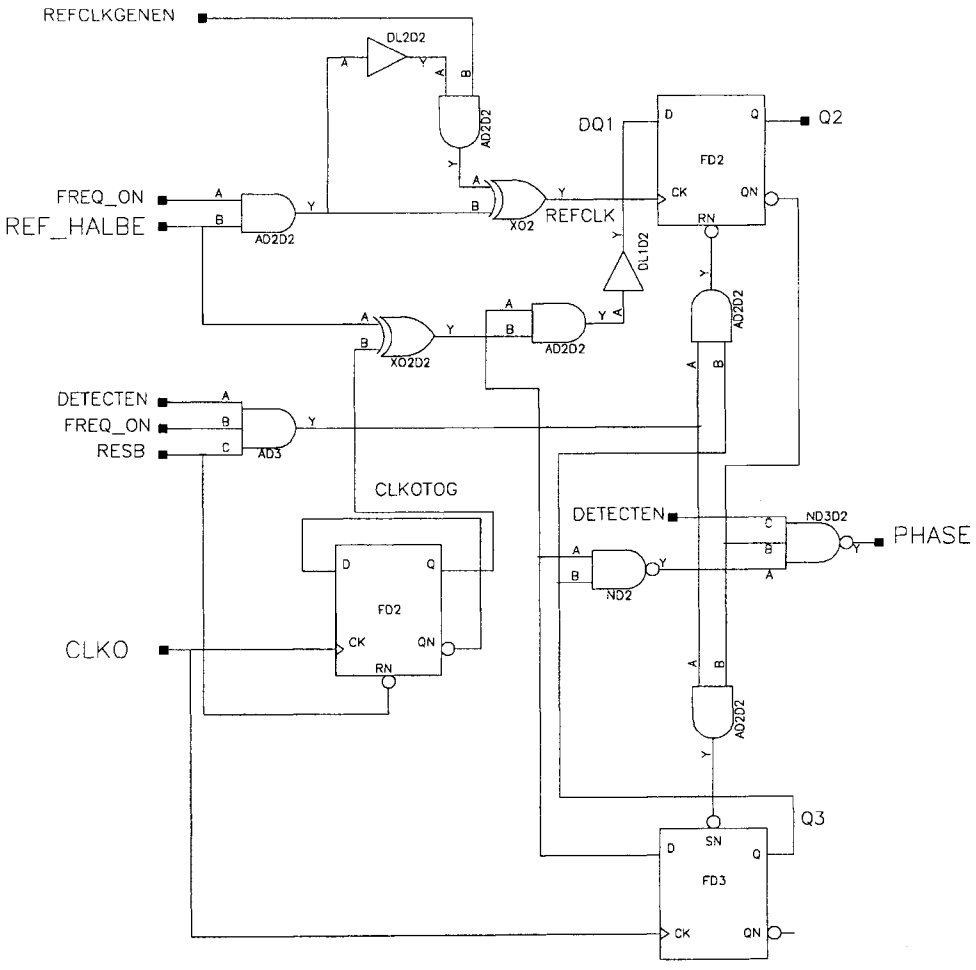

Figure 6-45 Custom-built phase detector with a noise floor of better than –168 dB. This phase detector shows extremely low phase jitter.

noise by itself and the synthesizer design are quite good, they are no match for this new approach, as can be seen in Figure 6-44 [11].

By combining the very best available technologies, such as using high-end VCOs with ceramic-resonator-based tuned circuits or high-*Q LC* arrangements including microstrips on Teflon material and modern fractional-*N*-division synthesizer blocks that can operate with a 50-MHz reference, it is possible to build an extremely high-quality system.

We have also learned that the limits of this technology are determined by the reference crystal oscillator and possibly the phase detector used; these must be specially designed to match the synthesizer's performance. (Figure 6-45 shows a block diagram of the phase detector.) Due to the very large bandwidth, switching speeds at 6 μs were made possible. The resolution of the synthesizer itself depends on the accumulator size. Step sizes of 25 kHz up to several megahertz were successfully tested. For wideband applications, some of the critical points are at 10 kHz where –120 dBc/Hz is desired, at 800 kHz, better than –153 dBc/Hz, and at 3 MHz, better than –155 dBc/Hz.

As validation, three types of synthesizers have been built: one covering 75–105 MHz, with 1-Hz resolution, for an HF transceiver; another covering 700–2000 MHz; and a third covering 2700–3500 MHz, also with better than 1-Hz resolution.

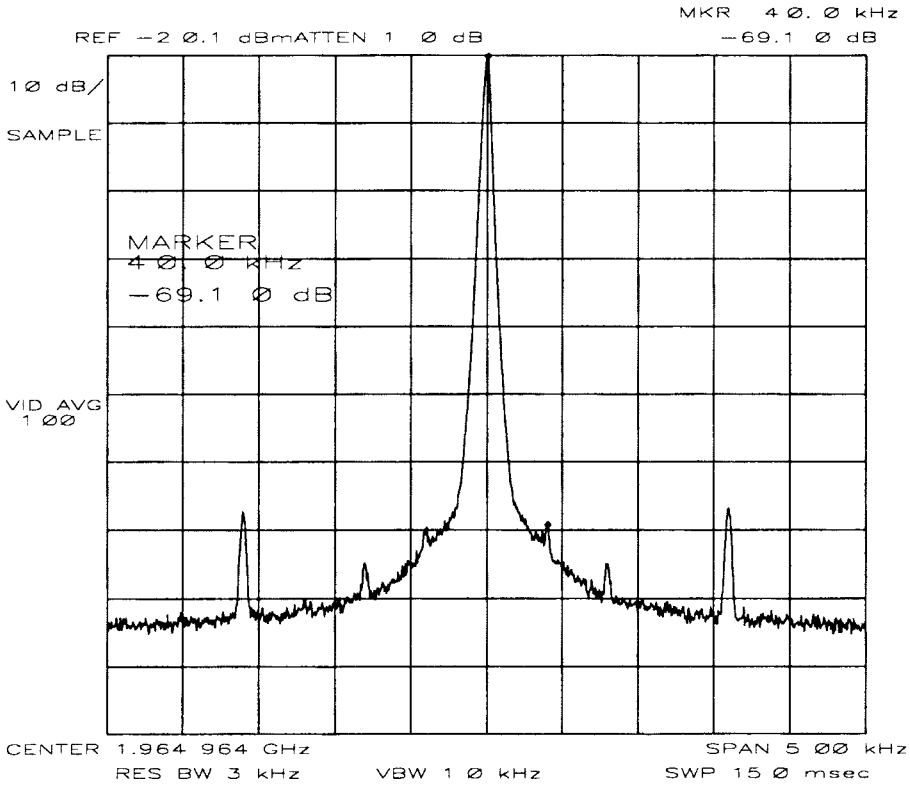

Figure 6-46 Result of fractional spur measurement for an LMX2350-based synthesizer. The spurs at ±40 kHz are –69.1 dBc (fractional compensation = 4/16); the center frequency is 1.964964 GHz. (Reprinted with permission of National Semiconductor Corporation.)

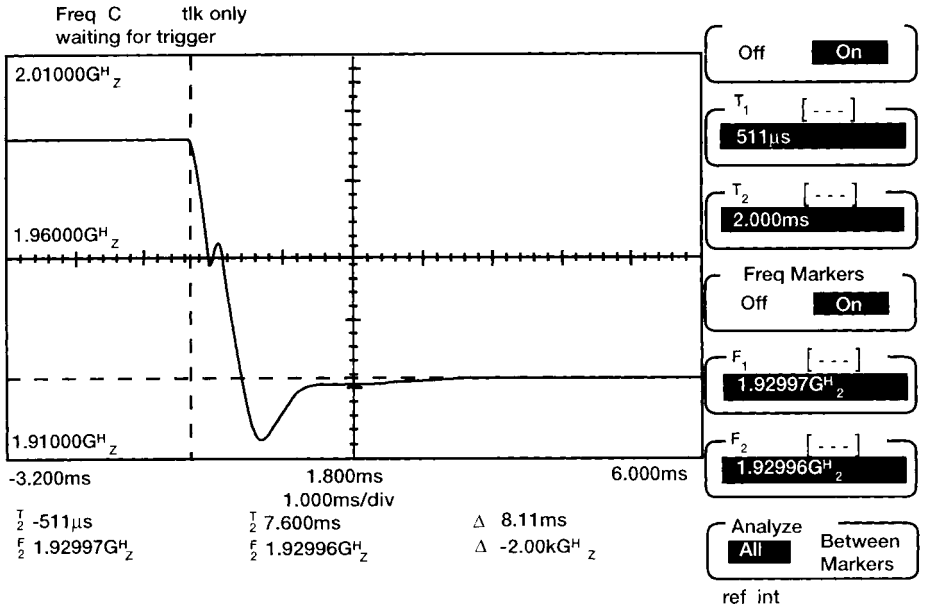

Figure 6-47 Result of lock time measurement for an LMX2350 based synthesizers (Reprinted with permission of National Semiconductor Corporation.)

The fractional-*N* PLL implementations described so far are intended mainly for high-performance, base-station applications. Simplified, highly integrated versions are available for mass-market wireless applications. One solution, National Semiconductor's LMX235*x* family, implements a fractional-*N* RF synthesizer and an integer-*N* IF synthesizer in one IC. The LMX2350's RF synthesizer can operate at input frequency up to 2.5 GHz; the LMX2352's, up to 1.2 GHz. The IF synthesizer in both parts can operate from 10 to 550 MHz. Figure 6-46 shows the close-in output spectrum of an LMX2350-based synthesizer at 1.965 GHz, and Figure 6-47 shows its lock time. A sample LMX2350 application is shown in Figure 6-48.

Fractional-*N* synthesizer chips are also available from Philips. Examples of Philips fractional-*N* parts include the SA7016DH (1.3 GHz), SA7025DK (main synthesizer, 1.0 GHz; auxiliary synthesizer, 150 MHz), SA7026DK (1.3 GHz/550 MHz), SA8016DH (2.5 GHz), SA8025ADK (1.8 GHz/150 MHz), and SA8026DK (2.5 GHz/550 MHz).

6-4 DIRECT DIGITAL SYNTHESIS

Direct digital frequency synthesis (DDFS), also referred to as *direct digital synthesis* (DDS), consists of generating a digital representation of the desired signal and then using a D/A converter to convert the digital representation to an analog waveform. Recent advances in high-speed microelectronics, particularly the microprocessor, make DDS practical at frequencies in and below the high-frequency band (as of this writing). Systems can be compact, use low power, and provide very fine frequency resolution with virtually instantaneous frequency changes. DDS is finding increasing application, particularly in conjunction with PLL synthesizers.

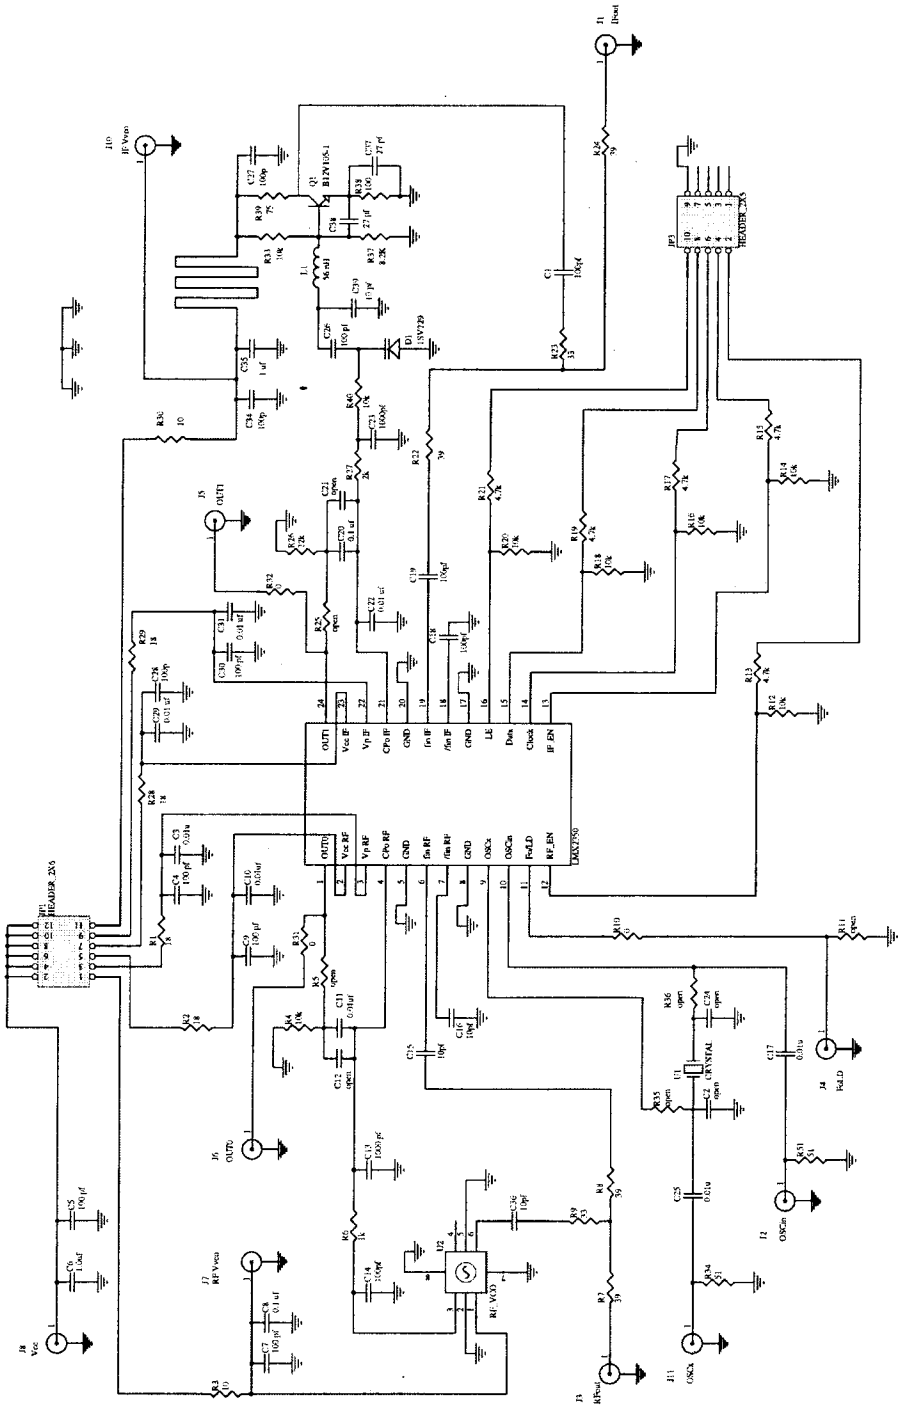

Figure 6-48 LMX2350 sample application schematic. (Reprinted with permission of National Semiconductor Corporation.)

DDS uses a single-frequency source (clock) as a time reference. One method of digitally generating the values of a sine wave is to solve the digital recursion relation as follows:

$$Y_n = [2\cos(2\pi ft)]Y_{n-1} - Y_{n-2} \tag{6-66}$$

This is solved by $Y_n = \cos(2\pi fnt)$. There are at least two problems with this method, however. The noise can increase until a limit cycle (nonlinear oscillation) occurs. Also, the finite word length used to represent $\cos(2\pi ft)$ places a limitation on the frequency resolution. Another method of DDS, direct table lookup, consists of storing the sinusoidal amplitude coefficients for successive phase increments in memory. Advances in miniaturization and the lowering cost of ROM make this the most frequently used technique.

One method of direct table lookup outputs the same N points for each cycle of the sine wave and changes the output frequency by adjusting the rate at which the points are computed. It is relatively difficult to obtain fine frequency resolution with this approach, so a modified table-lookup method is generally used. It is this method that we describe here. The function $\cos(2\pi ft)$ is approximated by outputting the function $\cos(2\pi fnT)$ for $n = 1, 2, 3, \ldots$, where T is the interval between conversions of digital words in the D/A converter and n represents the successive sample numbers. The sampling frequency, or rate, of the system is $1/T$. The lowest output frequency waveform contains N distinct points in its waveform, as illustrated in Figure 6-49. A waveform of twice the frequency can be generated, using the same sampling rate, but outputting every other data point. A waveform k times as fast is obtained by outputting every kth point at the same rate $1/T$. The frequency resolution, then, is the same as the lowest frequency, f_L.

The maximum output frequency is selected so that it is an integral multiple of f_L; that is, $f_U = kf_L$. If P points are used in the waveform of the highest frequency, N ($=kP$) points are used in the lowest frequency waveform. The number N is limited by the available memory size. The minimum value that P can assume is usually taken to be four. With this small value of P, the output contains many harmonics of the desired frequency. These can be removed by the use of low-pass filtering in the D/A output. For $P = 4$, the period of the highest frequency is $4T$, resulting in $f_U = 4f_L$. Thus, the highest attainable frequency is determined by the fastest sampling rate possible.

In the design of this type of DDS, the following guidelines apply:

- The desired frequency resolution determines the lowest output frequency f_L.
- The number of D/A conversions used to generate f_L is $N = 4k = 4f_U/f_L$ provided that four conversions are used to generate f_U ($P = 4$).
- The maximum output frequency f_U is limited by the maximum sampling rate of the DDS, $f_U \leq 1/4T$. Conversely, $T \leq 1/4f_U$.

The architecture of the complete DDS is shown in Figure 6-50. To generate nf_L, the integer n addresses the register, and each clock cycle kn is added to the content of the accumulator so that the content of the memory address register is increased by kn. Each knth point of the memory is addressed, and the content of this memory location is transferred to the D/A converter to produce the output sampled waveform.

To complete the DDS, the memory size and length (number of bits) of the memory word must be determined. The word length is determined by system noise requirements. The amplitude of the D/A output is that of an exact sinusoid corrupted with the deterministic noise due to truncation caused by the finite length of the digital words (quantization noise).

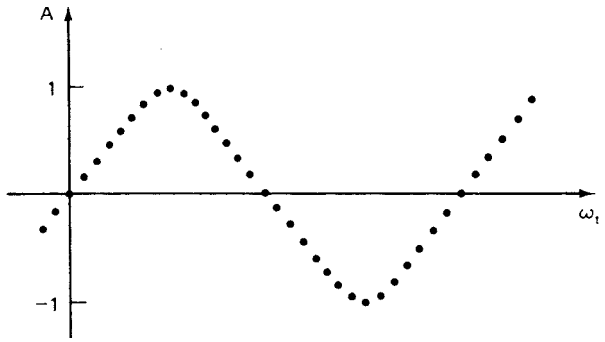

Figure 6-49 Synthesized waveform generated by direct digital synthesis.

If an $(n + 1)$-bit word length (including one sign bit) is used and the output of the A/D converter varies between ±1, the mean noise from the quantization will be

$$\rho^2 = \frac{1}{12}\left(\frac{1}{2}\right)^{2n} = \frac{1}{3}\left(\frac{1}{2}\right)^{2(n+1)} \tag{6-67}$$

The mean noise is averaged over all possible waveforms. For a worst-case waveform, the noise is a square wave with amplitude and $\frac{1}{2}(\frac{1}{2})^n$ and$\rho^2 = \frac{1}{4}(\frac{1}{2})^{2n}$. For each bit added to the word length, the spectral purity improves by 6 dB.

The main drawback of the low-power DDS is that it is limited to relatively low frequencies. The upper frequency is directly related to the maximum usable clock frequency; today, the limit is about 1 GHz. DDS tends to be noisier than other methods, but adequate spectral purity can be obtained if sufficient low-pass filtering is used at the output. DDS systems are easily constructed using readily available microprocessors. The combination of DDS for fine frequency resolution plus other synthesis techniques to

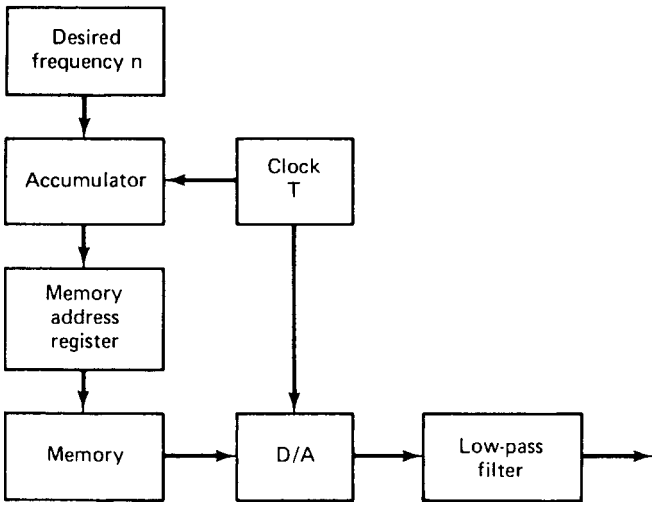

Figure 6-50 Block diagram of a direct digital frequency synthesizer.

obtain higher-frequency output can provide high resolution with very rapid setting time after a frequency change. This is especially valuable for frequency-hopping spread-spectrum systems.

Figure 6-51 shows the functional block diagram of a DDS system. In analyzing both the resolution and signal-to-noise ratio (or rather signal-to-spurious performance) of the DDS, one has to know the resolution and input frequencies. As an example, if the input frequency is approximately 35 MHz and the implementation is for a 32-bit device, the frequency resolution compared to the input frequency is 35E6 ÷ 2^{32} = 35E6 ÷ 4.294967296E9 or 0.00815 Hz ≈ 0.01 Hz. Given the fact that modern shortwave radios with a first IF of about 75 MHz will have an oscillator between 75 and 105 MHz, the resolution at the output range is more than adequate. In practice, one would use the microprocessor to round it to the next increment of 1 Hz relative to the output frequency.

As to the spurious response, the worst-case spurious response is approximately 20 log 2^R, where R is the resolution of the digital/analog converter. For an 8-bit A/D converter, this would mean approximately 48 dB down (worst case), as the output loop would have an analog filter to suppress close-in spurious noise. In our application, we will use an 8-bit external D/A converter. However, devices such as the Analog Devices AD7008 DDS modulator have a 10-bit resolution, as shown in Figure 6-52. Ten bits of resolution can translate into 20 log 2^{10}, or 60 dB of suppression. The actual spurious response would be much better. The current production designs for communication applications, such as shortwave transceivers, despite the fact that they are resorting to a combination of PLLs and DDSs, still end up somewhat complicated. By using 10 MHz from the DDS and using a single-loop PLL system, one can easily extend the operation to above 1 GHz but with higher complexity and power consumption.

Figure 6-53 shows the necessary components of a single-PLL system. Some communication equipment uses this approach.

Figure 6-54 shows the combination of a standard PLL and DDS, as implemented in the ICOM IC-736 HF/6-meter transceiver. This approach uses DDS in a frequency range between 500 kHz and 1 MHz. This frequency is upconverted either to 60 MHz for the shortwave band or 90 MHz for the 6-meter ham band. The resulting frequency is used as an auxiliary LO to convert the frequency of the first LO (69.0415 to 102.0115 MHz) down to the synthesizer IF between 8.5 and 41.5 MHz. There is an additional divide-by-2 stage in the loop, which therefore requires a reference frequency of 250 kHz instead of 500 kHz. This is done to extend the operating range of the synthesizer chip, including its prescaler's capability of operating at much higher frequencies, although it does not have such a hybrid DDS approach incorporated (Figure 6-55).

While this approach obtains a fairly small division ratio, it is still a four-loop synthesizer. One loop is the DDS itself. The second is the translator loop that mixes the DDS up to 60 MHz. The third is the main loop responsible for the desired output frequency. The fourth loop, so to speak, is the generation of the auxiliary LO frequencies at 60 and 90 MHz, which are derived from the 30-MHz frequency standard. For reasons of good phase noise, it employs a total of five VCOs. Because this loop's division ratio varies between 80 and 17, its gain is subject to considerable variation.

The 10.7-MHz signal from the crystal filter goes to a single-chip PLL (U5, a Motorola MC145170), which contains all the necessary dividers and the phase/frequency discriminator. The operational amplifier (U6, an OPA27) is driven from a 28-V source, and the negative supply of the OPA27 is connected as a voltage doubler, which receives its ac voltage from the synthesizer IC. This trick allows extension of the VCO control voltage. The output from

APPENDIX A

HBT HIGH-FREQUENCY MODELING AND INTEGRATED PARAMETER EXTRACTION*

This appendix presents, for the first time, a novel nonlinear model for accurate dc, small-signal, and noise characterization of AlGaAs/GaAs heterojunction bipolar transistors (HBTs). A new set of equations are introduced to take into account the bias, temperature, and frequency dependencies in noise calculations. This model provides significant improvement in predicting small-signal noise for HBT-based circuits. We also present an integrated method for accurate HBT model parameter extraction by fitting the dc, multibias *S*-parameter, and noise measurements simultaneously. The extracted model provides accurate small-signal, dc, and noise characteristics. This technique is general and can be used for parameter extraction of other microwave devices such as MESFETs and HEMTs. Our new HBT model is validated using devices from different foundries. An integrated parameter extraction technique is demonstrated for a foundry HBT, and excellent results are obtained.

A-1 INTRODUCTION

With the increasing demand of high-speed and high signal-to-noise ratio (SNR) in analog and digital communication, high-frequency and low-noise circuits and systems are becoming more important. This leads to immense interest in the application of heterojunction bipolar transistors (HBTs) for high-speed digital and microwave circuits. HBTs, combining high transconductance, output resistance, and power density with high breakdown voltage [1], are rapidly becoming viable candidates for low-noise amplifier (LNA) applications across the entire microwave frequency spectrum and well into the millimeter bands. A particularly important application is in monolithic microwave integrated circuits (MMICs), where highly

*©1997 IEEE. Reprinted, with permission, from *IEEE Trans. Microwave Theory Tech.*, Vol. 45, No. 12, December 1997, pp. 2493–2502.

accurate bias- and temperature-dependent noise models are critical for first-pass design success.

Accurate device models are critical to the success of the design of nonlinear microwave circuits such as amplifiers, oscillators, mixers, receivers, and synthesizers [2–5], particularly in MMIC design [6]. Many HBT models have been developed during the last two decades using Monte Carlo methods [7, 8] and models based on the Gummel–Poon (GP) bipolar junction transistor (BJT) model [9, 10]. However, these models suffer from either computationally intensive or inadequate device performance prediction, especially in noise characterization.

Low-noise microwave circuit design engineers are often frustrated that the noise responses of the fabricated circuits are quite different from the results obtained using CAD programs. Several design passes may be necessary to meet specifications. Even in mixer designs, the noise of the fabricated circuits may be significantly higher than that predicted by the CAD tool. The discrepancy arises primarily from the poor estimation of the device noise figure.

Parameter extraction by fitting the model responses to measurements is the primary method of obtaining the model parameter values of equivalent circuit models. Conventionally, parameter extraction is based on dc, *S*-parameter, and large-signal measurements (e.g., [11–13]). The models extracted are suitable for dc, small-signal, and large-signal analysis. However, noise analysis with these models often contains substantial errors.

In this appendix, a novel HBT model for high-frequency and low-noise applications is presented. This model is based on a new formulation that takes into account the bias, temperature, and frequency dependencies of the device noise characteristics to provide accurate performance prediction. Two types of noise equivalent circuits, a linearized T model and a hybrid-π model, are derived from the modified GP model described in the literature [14–17]. Self-heating effects are also taken into consideration using the thermal equivalent circuits.

We also present an integrated parameter extraction approach by fitting the model responses to the dc, multibias *S*-parameter, and multibias noise measurements simultaneously. The models extracted not only provide precise characterization of device small-signal and dc responses but also give accurate prediction of device noise performance. The models can be used in a variety of applications for small-signal and large-signal analysis as well as noise analysis. The advantages of our approach become more significant in the design of low-noise microwave circuits.

Our new HBT model is presented in Section A-2. The integrated parameter extraction technique is addressed in Section A-3. HBT model validation using devices from various foundries is given in Section A-4. Section A-5 demonstrates the HBT model parameter extraction for a foundry device. Two models are extracted: *Model 1* is based on dc and *S*-parameter measurements, while *Model 2* is based on dc, *S*-parameter, and noise measurements. Model 1 shows large errors in noise performance even though the dc and *S*-parameter fits are good. Model 2 provides accurate prediction in dc, *S*-parameter, and noise responses.

A-2 HIGH-FREQUENCY HBT MODELING

The equivalent circuit of our HBT model consists of three parts: intrinsic circuit, device parasitics, and package parasitics as shown in Figure A-1. The device and package parasitics play a very important role in high-frequency modeling. Without considering these parasitics, the model would not be able to predict the ac performance accurately. A typical equivalent

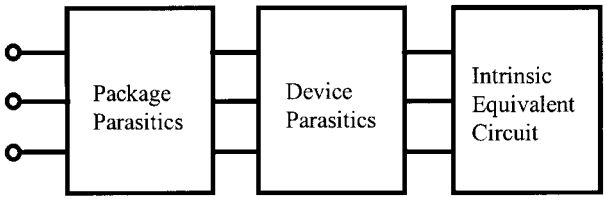

Figure A-1 The three parts of the equivalent circuit for the HBT model.

circuit representing package parasitics is shown in Figure A-2. The schematic of the intrinsic, extrinsic, and thermal circuits for our HBT model is depicted in Figure A-3. This circuit is a modified GP model implemented in SPICE [18]. The base resistor R_{bb} in the original GP model is split into R_{b1} and R_{b2}, and a base capacitor C_{bx} is added between these two resistors. This modification is necessary for accurate HBT characterization at high frequencies. Additional base resistors and capacitors have been added to the model in [19] for the SPICE equivalent circuits. However, these components are external to the device and noise correlation is not able to be taken into account in SPICE simulators. In our work, R_{b1}, R_{b2}, and C_{bx} are inside the device model incorporated into the harmonic-balance simulator [20], which takes into account the noise correlation and provides a much more accurate noise prediction. The detailed dc, capacitance, and transient-time equations of the model are available in [20], which is derived from [10,15].

A-2-1 dc and Small-Signal Model

Using the intrinsic base–emitter voltage V_{be} and collector–emitter voltage V_{ce} shown in Figure A-3 as state variables, we can write the HBT model equations as

$$I_B = I_B(\phi, V_{be}, V_{ce}, T_j(\phi, V_{be}, V_{ce})) \tag{A-1a}$$

$$I_C = I_C(\phi, V_{be}, V_{ce}, T_j(\phi, V_{be}, V_{ce})) \tag{A-1b}$$

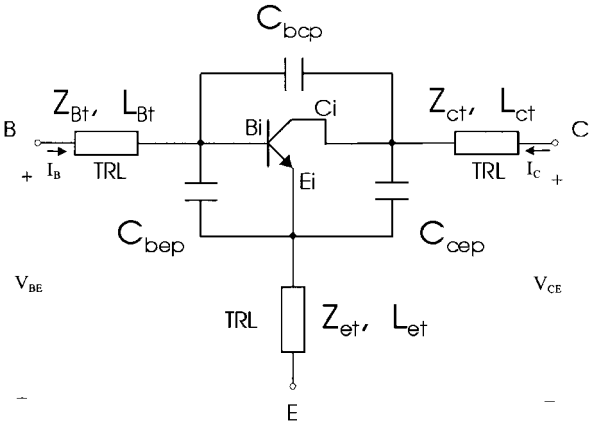

Figure A-2 A typical equivalent circuit representing package parasitics of HBTs.

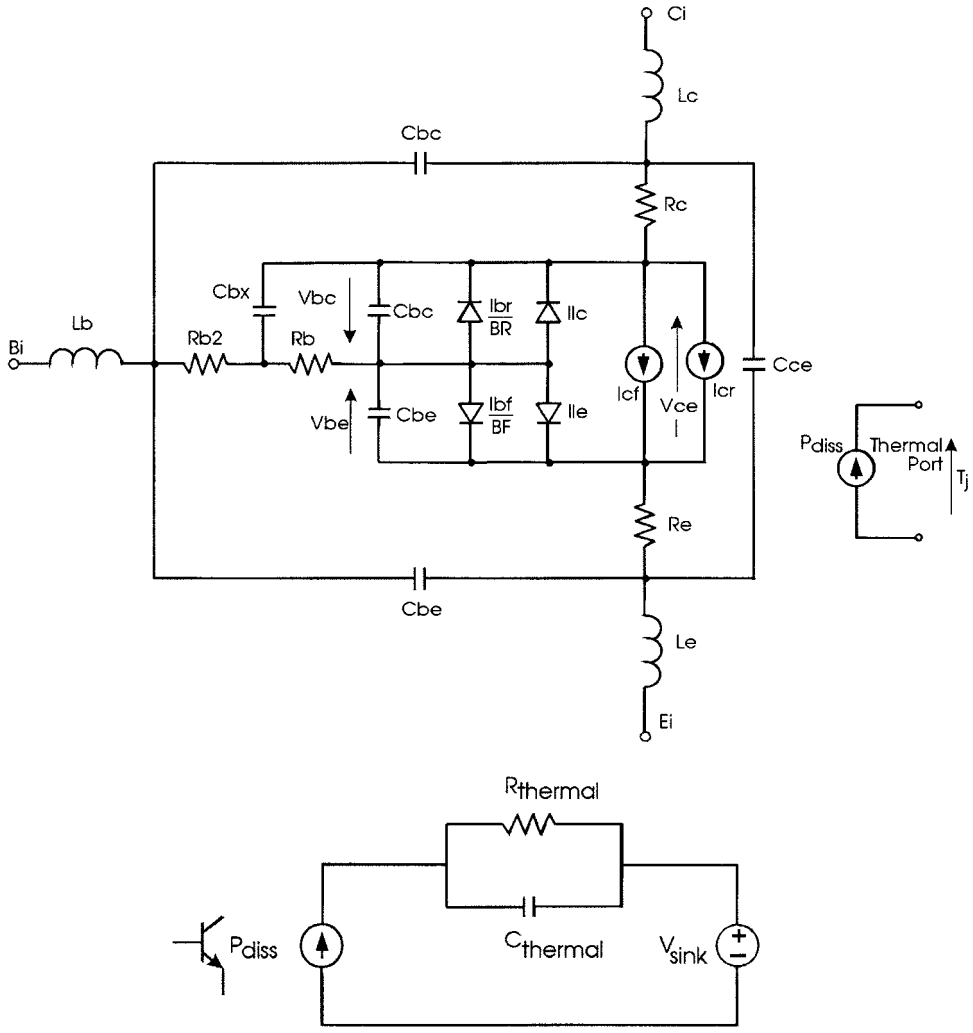

Figure A-3 Schematic of the intrinsic, extrinsic, and thermal circuits for the HBT model.

$$V_{BE} = V_{BE}(\phi, V_{be}, V_{ce}, T_j(\phi, V_{be}, V_{ce})) \tag{A-1c}$$

$$V_{CE} = V_{CE}(\phi, V_{be}, V_{ce}, T_j(\phi, V_{be}, V_{ce})) \tag{A-1d}$$

which indicate that the extrinsic base current I_B, collector current I_C, base–emitter voltage V_{BE}, and the collector–emitter voltage V_{CE}, as shown in Figure A-2, are functions of model parameters ϕ, state variables V_{be} and V_{ce}, and temperature T_j. The device temperature T_j is also dependent on the model parameters and state variables. Any two equations in Eqs. (A1a)–(A1d) can be used to solve for the state variables. We use Eqs. (A-1a) and (A-1d) with a Newton method in our dc simulation to obtain the dc operating points and produce constant-I_B versus V_{CE} curves. For a fixed set of parameters ϕ, the Newton iteration is written as

$$\begin{bmatrix} V_{be} \\ V_{ce} \end{bmatrix}^{k+1} = \begin{bmatrix} V_{be} \\ V_{ce} \end{bmatrix}^{k} - \left(\begin{bmatrix} \dfrac{\partial I_B}{\partial V_{be}} & \dfrac{\partial V_{CE}}{\partial V_{be}} \\ \dfrac{\partial I_B}{\partial V_{ce}} & \dfrac{\partial V_{CE}}{\partial V_{ce}} \end{bmatrix}^{k} \right)^{-1} \begin{bmatrix} I_B - I_B^M \\ V_{CE} - V_{CE}^M \end{bmatrix}^{k} \tag{A-2}$$

where I_B^M and V_{CE}^M are the measured or applied base bias current and collector–emitter voltage. The entries to the Jacobian matrix can be obtained by deriving Eqs. (A1a) and (A1d) with respect to the corresponding state variable; for instance,

$$\frac{\partial I_B}{\partial V_{be}} = \frac{\partial I_B}{\partial V_{be}} + \frac{\partial I_B}{\partial T_j}\frac{\partial T_j}{\partial V_{be}} \tag{A-3}$$

In our implementation, these entries are calculated analytically, which significantly reduces the computational time compared to the perturbation method used in other implementations (e.g., [10, 15]).

After the dc bias point is obtained, a small-signal equivalent circuit is then established by linearizing the model at the bias point, and this is used for *S*-parameter and noise calculations. Two types of small-signal models are discussed in the following sections. As we will see, the bias, temperature, and frequency dependencies are taken into account in model evaluations for small-signal and noise simulation.

A-2-2 Linearized T Model

The equivalent circuit for the linearized T model is sketched in Figure A-4. We add a collector–emitter resistor R_{ce} into the conventional T model [18] to provide more accurate device performance prediction. R_{ce} is also critical in parameter extraction for a good match between modeled and measured responses. The intrinsic linearized parameters A_0, C_i, R_c, R_e, C_e, and R_{ce} are functions of ϕ, V_{be}, V_{ce}, and T_j obtained in the dc simulation. For example,

$$A_0 = A_0(\phi, V_{be}, V_{ce}, T_j(\phi, V_{be}, V_{ce})) = \left. \frac{\dfrac{\partial I_c'}{\partial V_{be}}}{\dfrac{\partial I_b'}{\partial V_{be}} + \dfrac{\partial I_c'}{\partial V_{be}}} \right|_{\phi, V_{be}, V_{ce}, T_j = \text{constant}} \tag{A-4}$$

where

$$I_c' = I_{cf} - I_{cr}$$

$$I_b' = \frac{I_{bf}}{BF} + I_{le}$$

I_{cf}, I_{cr}, I_{bf}, and I_{le} are illustrated in Figure A-3, and BF is the ideal forward current gain.

For the noise responses, the minimum noise figure $F_{\min}$, the optimal noise reflection coefficient Γ_{opt} and the equivalent normalized noise resistance R_N are calculated using the following equations [16, 17]:

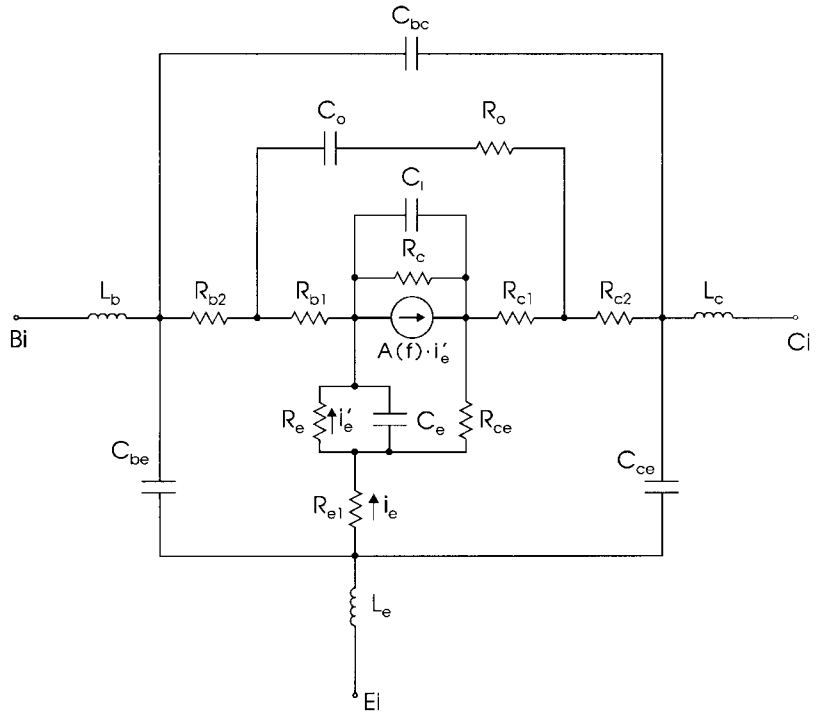

Figure A-4 The linearized T model for small-signal and noise calculations.

$$F_{\min} = a\,\frac{R_{b1} + R_{\text{opt}}}{R_e} + \left(1 + \frac{f^2}{f_b^2}\right)\frac{1}{A_0} + \frac{F_C}{1+f} \tag{A-5}$$

The optimum source resistance is calculated by

$$R_{\text{opt}} = \left[R_{b1}^2 - X_{\text{opt}}^2 + \left(1 + \frac{f^2}{f_b^2}\right)\frac{R_e(2R_{b1} + R_e)}{A_0 a}\right]^{1/2} \tag{A-6}$$

the optimum source reactance is

$$X_{\text{opt}} = \left(1 + \frac{f^2}{f_b^2}\right)\frac{2\pi f C_e R_e^2}{A_0 a} \tag{A-7}$$

and the normalized noise resistance is

$$R_N = R_{b1}\left(\alpha + 1 - \frac{1}{A_0}\right) + \frac{R_e}{2}\left\{\alpha + \frac{R_{b1}^2}{R_e^2}\left[1 - A_0 + \frac{f^2}{f_b^2} + \frac{f^2}{f_e^2} + \left(\frac{1}{A_0} - 1 - \frac{f^2}{f_b f_e}\right)^2\right]\right\} \tag{A-8}$$

where f is the operating frequency, f_b is the cutoff frequency of the ac common-base current gain $A(f)$, A_0 is the dc current gain, and F_C is the flicker noise corner frequency. The flicker

noise used for small-signal noise calculation is different from the one used for large-signal noise evaluation [20]. The coefficients α, a, and f_e are calculated as follows:

$$\alpha = \frac{1 + (f/f_b)^2}{A_0^2} \tag{A-9}$$

$$a = \left[\left(1 + \frac{f^2}{f_b^2}\right)\left(1 + \frac{f^2}{f_b^2}\right) - A_0\right]\frac{1}{A_0} \tag{A-10}$$

$$f_e = \frac{1}{2\pi N_{\text{fac}} C_e R_e^2} \tag{A-11}$$

where N_{fac} is a noise factor.

In addition to the above calculation, the effect of the device and package parasitic circuits is added to obtain the overall noise response using a common two-port noise evaluation method.

A-2-3 Linearized Hybrid-π Model

The equivalent circuit for the linearized hybrid-π model is shown in Figure A-5. The intrinsic linearized parameters Y_{be}, Y_{bc}, G_{m0}, and G_0 are functions of model parameters ϕ, V_{be}, V_{ce}, and T_j obtained in the dc simulation. For example,

$$G_{m0} = G_{m0}\left(\phi, V_{be}, V_{ce}, T_j(\phi, V_{be}, V_{ce})\right) = \left.\frac{\partial I_c'}{\partial V_{be}}\right|_{\phi, V_{be}, V_{ce}, T_j = \text{constant}} \tag{A-12}$$

The intrinsic noise model of this hybrid-π circuit is developed by incorporating the correlation of the noise sources and the frequency dependency of the noise sources. The normalized noise correlation matrix can be written

$$C = \frac{1}{4KT_jB}\begin{bmatrix} \overline{i_b i_b^*} & \overline{i_b i_c^*} \\ \overline{i_c i_b^*} & \overline{i_c i_c^*} \end{bmatrix} \tag{A-13}$$

where

$$\overline{i_b i_b^*} = 4KT_j\text{Re}[Y_{11}]B - 2qI_bB \tag{A-14a}$$

$$\overline{i_c i_b^*} = 2KT_j(G_m - 2\text{Re}[Y_{12}])B - 2qI_cB \tag{A-14b}$$

$$\overline{i_c i_c^*} = 4KT_j\text{Re}[Y_{22}]B + 2qI_cB \tag{A-14c}$$

where K is the Boltzmann constant, B is the bandwidth, q is the electron charge, and I_b and I_c are the intrinsic base and collector currents, respectively. Y_{11}, Y_{12}, and Y_{22} correspond to the intrinsic Y-matrix of the intrinsic model, as shown in Figure A-5 (region within the heavy box), and $\text{Re}[Y_{ij}]$ represents the real part of Y_{ij}.

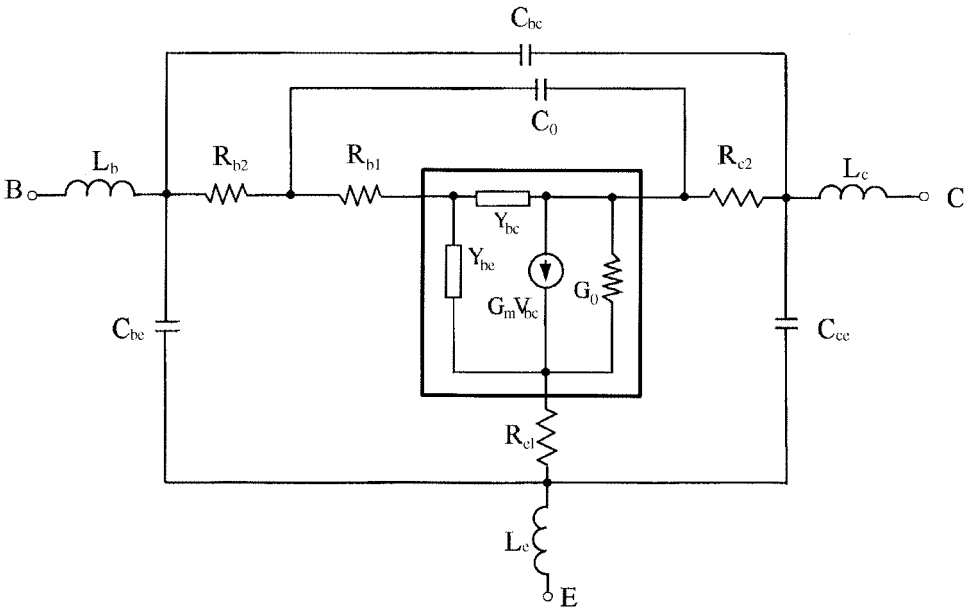

Figure A-5 The linearized hybrid-π model for small-signal and noise calculations.

At zero frequency (dc), the noise power terms $\overline{i_b i_b^*}$ and $\overline{i_c i_c^*}$ of the intrinsic device reduce to the SPICE shot noise model. Also, the cross-correlation terms reduce to zero, indicating that there is no noise component common to both the collector and base currents.

The intrinsic noise parameters (R_N, $F_{\min}$, Γ_{opt}) are derived from the correlation matrix C of Eq. (A-13) as

$$R_N = C_{11} \tag{A-15}$$

$$G_{\text{opt}} = \sqrt{\frac{C_{22}}{C_{11}} - \left(\frac{\text{Im}(C_{12})}{C_{11}}\right)^2} \tag{A-16}$$

$$B_{\text{opt}} = \frac{\text{Im}(C_{12})}{C_{11}} \tag{A-17}$$

$$F_{\min} = 1 + 2\sqrt{C_{11}C_{22} - \text{Im}(C_{12})^2 + \text{Re}(C_{12})} \tag{A-18}$$

where $\text{Re}(C_{12})$ and $\text{Im}(C_{12})$ are the real part and imaginary part of C_{12}, respectively.

A-3 INTEGRATED PARAMETER EXTRACTION

In this section we present integrated parameter extraction by fitting the dc, multibias *S*-parameter, and noise measurements simultaneously.

A-3-1 Formulation of Integrated Parameter Extraction

The objective function for optimization in our integrated parameter extraction includes dc, *S*-parameter, and noise measurements. It is formulated as

$$E_{\text{total}}(\phi) = E_{\text{dc}}(\phi) + E_S(\phi) + E_N(\phi) \tag{A-19}$$

where ϕ are the model parameters to be extracted, E_{total} is the total error, and

$$E_{\text{dc}}(\phi) = \sum_{i=1}^{N_{\text{dc}}} \sum_{k,l}^{N_P} \| W_{\text{dc}_{ikl}} [R_{\text{dc}_{ikl}}(\phi) - M_{\text{dc}_{ikl}}] \| \tag{A-20a}$$

$$E_S(\phi) = \sum_{i=1}^{N_{S\text{dc}}} \sum_{j=1}^{N_{SF}} \sum_{k,l}^{N_P} \| W_{S_{ijkl}} [R_{S_{ijkl}}(\phi) - M_{S_{ijkl}}] \| \tag{A-20b}$$

$$E_N(\phi) = \sum_{i=1}^{N_{N\text{dc}}} \sum_{j=1}^{N_{NF}} \sum_{k}^{N_{NP}} \| W_{N_{ijk}} [R_{N_{ijk}}(\phi) - M_{N_{ijk}}] \| \tag{A-20c}$$

are the dc error, *S*-parameter error, and noise error, respectively. N_P is the number of ports of the device. N_{dc} is the number of dc measurement points. $N_{S\text{dc}}$ and N_{SF} are, respectively, the number of bias points and frequencies at which the *S*-parameter measurements are taken. N_{NP} is the number of noise parameters and $N_{N\text{dc}}$ and N_{NF} are, respectively, the number of bias points and frequencies at which the noise measurements are taken. The *R*'s and *M*'s are the model responses and the corresponding measurements. The *W*'s are the weighting factors applied to the corresponding errors. The $\|\bullet\|$ denotes the least-squares norm. A Levenberg–Marquardt optimization process was applied to

$$\underset{\phi}{\text{minimize}} \quad E_{\text{total}}(\phi) \tag{A-21}$$

The dc, multibias *S*-parameter, and multibias noise measurements are simultaneously matched to the model responses during optimization. A direct parameter extraction and systematic optimization strategy [21] can be used for efficient model extraction.

A-3-2 Model Optimization

The optimization scheme consists of two iteration loops. The first iteration loop is for dc simulation to obtain the dc operation point as described in Section A-2. The second loop is used for adjusting the model parameters ϕ to match the model responses to the measurements. This procedure can be described by the following algorithm.

Step 1: Initialize the model parameter ϕ.
Step 2: Initialize the state variables V_{be} and V_{ce}.
Step 3: Perform dc simulation at each bias point to obtain the solution for state variables using the Newton iteration of Eq. (A-2).
Step 4: Obtain the linearized small-signal circuit and calculate the model responses including the *S*-parameters and noise parameters at each bias point and frequency.

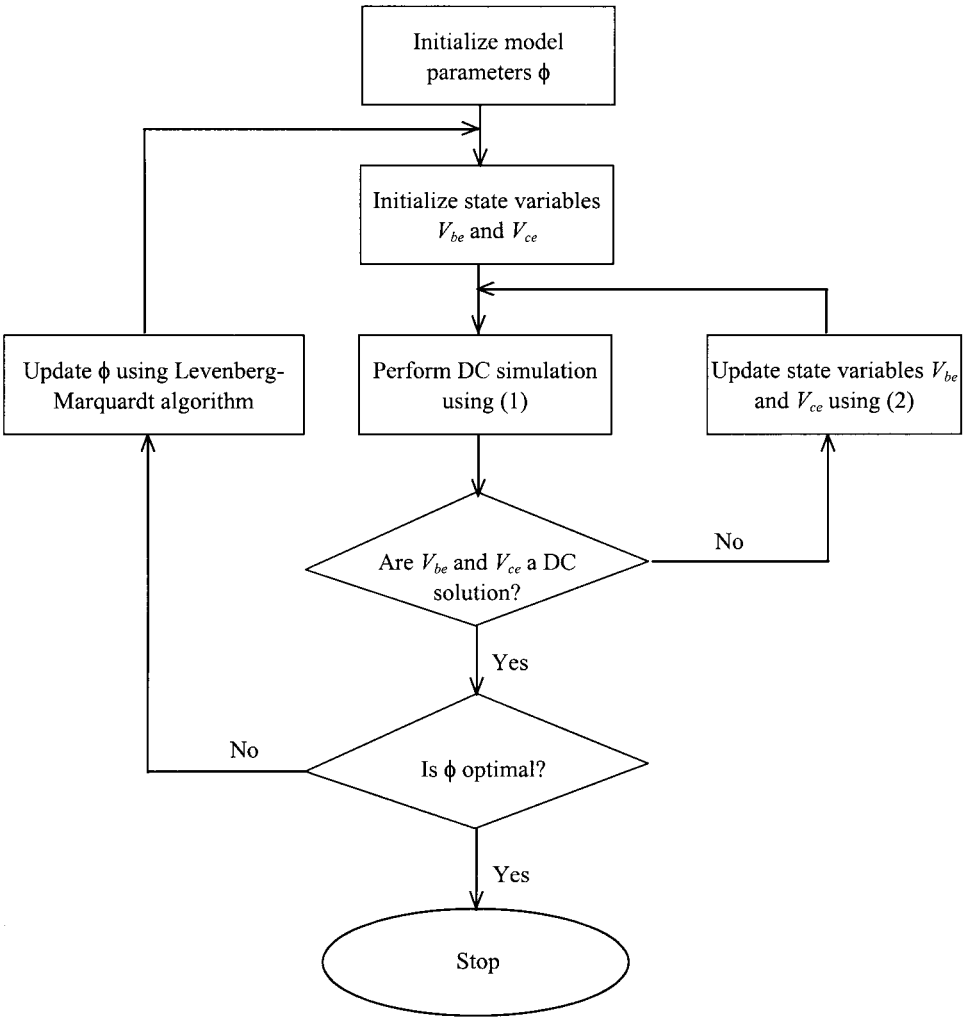

Figure A-6 Flowchart for model optimization.

Step 5: Calculate the objective function for optimization using Eqs. (A-19) and (A-20).
Step 6: If ϕ is optimal, stop. Otherwise, update ϕ according to the Levenberg–Marquardt optimization algorithm and go to *Step 2*.

This algorithm is illustrated by the flowchart in Figure A-6.

A-4 NOISE MODEL VALIDATION

We use the linearized hybrid-π model for noise model validation in this section and leave the linearized T model for the integrated parameter extraction example, which will be discussed in Section A-5.

To validate the model, on-wafer bias- and temperature-dependent noise parameter measurements are performed using the ATN-NP5 system for various foundries. Parameter extraction is performed using the procedure and model described above.

Figure A-7 compares the measured and modeled noise parameters for a foundry HBT biased at V_{CE} = 2 V and I_B = 428 μA. Two models are compared with the measured result: our model (referred to as Mod-PI) and the SPICE shot noise model (referred as MOD-SPICE), which is used in SPICE and harmonic-balance simulators. From the results it is evident that at lower frequencies both models show the same predictions; however, for the reasons explained earlier, at higher frequencies the SPICE noise model deviates rapidly from the measurements, while our model is very consistent with the measurements.

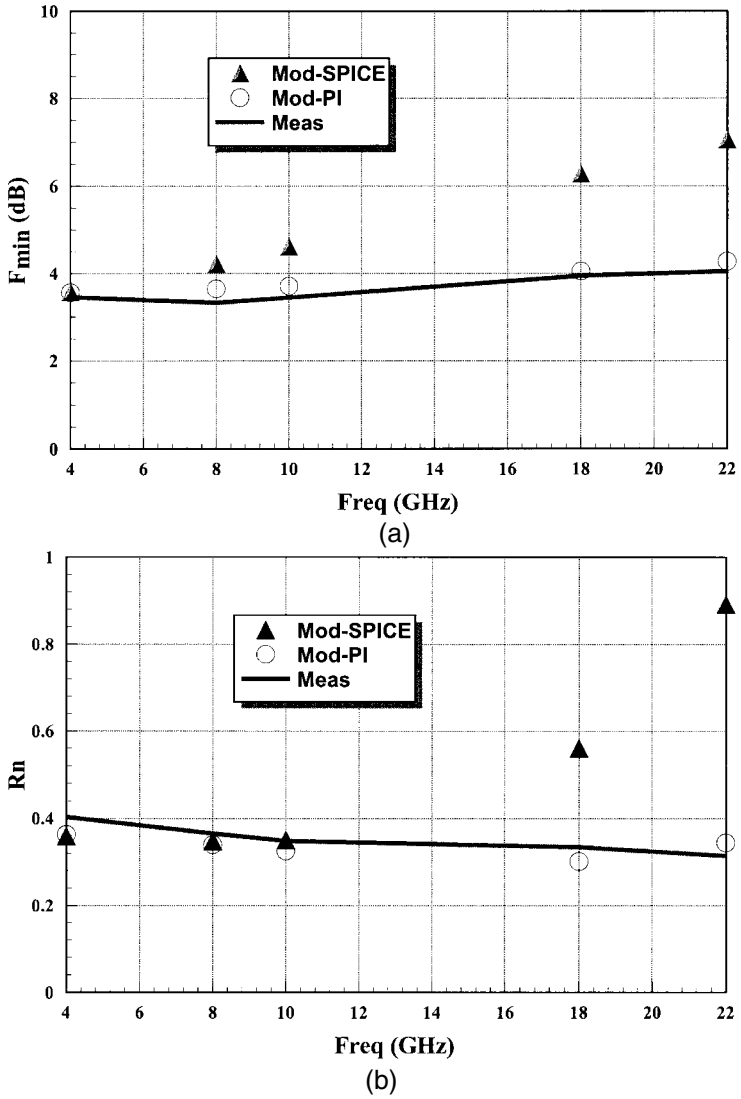

Figure A-7 Comparison of measured and modeled (Ansoft model and SPICE) noise parameters: (a) $F_{\min}$ and (b) R_n as a function of frequency for V_{CE} = 2.0 V and I_B = 428 μA.

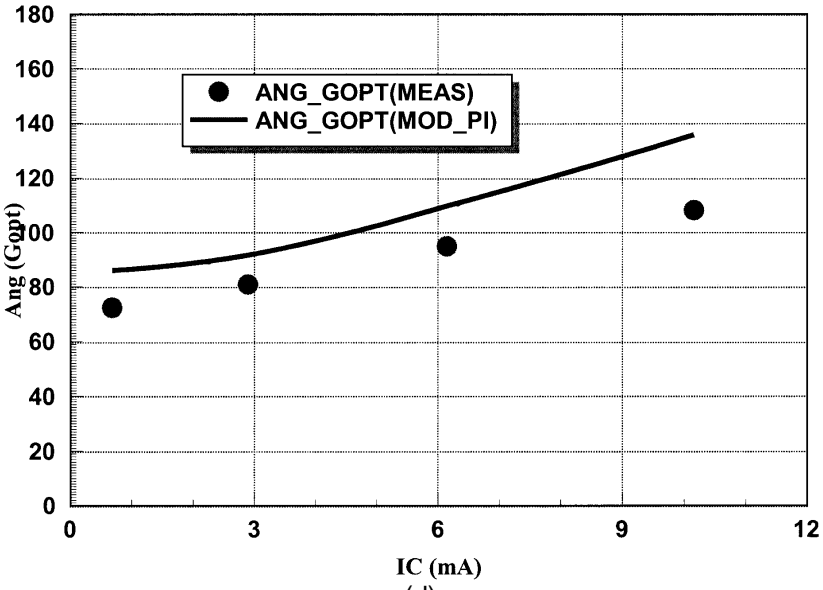
(c)



(d)

Figure A-8 (*Continued*)

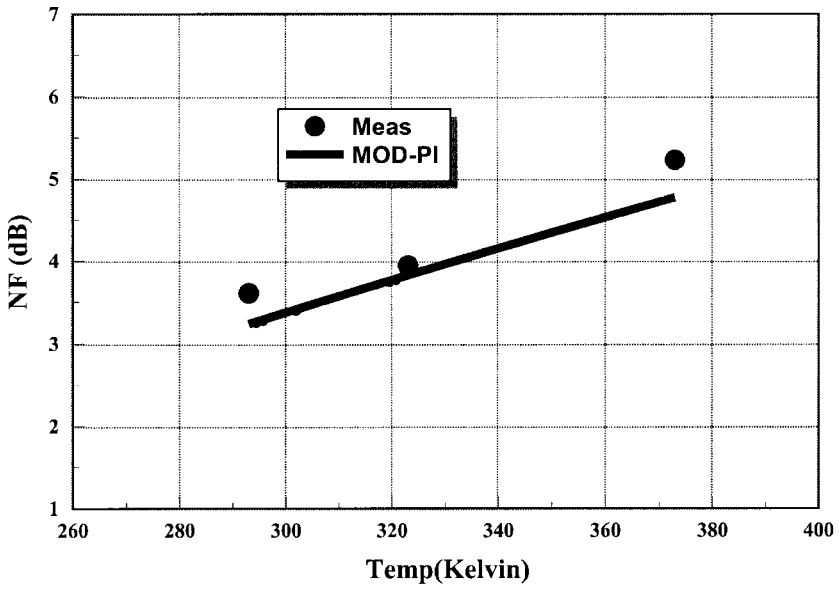


Figure A-9 Temperature dependency of the noise figure at 10 GHz, with the device biased at V_{CE} = 1 V and I_B = 100 μA. Temperature was varied from 20 to 100 °C.

The next validation process is the model's accuracy with bias. For this case, the base current is varied from 50 to 200 μA, and V_{CE} is set to 2 V. The frequency is 10 GHz. Figure A-8 illustrates the bias-dependent noise characteristics for a foundry HBT. Very good correlation is obtained between the measured and modeled noise parameters.

Finally, the temperature-dependent model is validated as shown in Figure A-9. The noise figure of the HBT is plotted versus temperature in kelvins. In this case, the device is biased at V_{CE} =1 V and I_B = 100 μA and the temperature varied from 293 to 373 K (20 to 100 °C). We can see a very good match between the measured and modeled results.

A-5 PARAMETER EXTRACTION OF AN HBT MODEL

Parameter extraction of an HBT model is carried out using the linearized T model illustrated in Section A-2.

The data used for parameter extraction include dc measurements at 60 points, and *S*-parameter measurements and noise measurements at 9 bias points and 17 frequencies. Two models are extracted: Model 1 using dc and *S*-parameter measurements and Model 2 using dc, *S*-parameter, and noise measurements. The modeled and measured dc responses are plotted in Figure A-10. The modeled and measured *S* parameters at three bias points are shown in Figures A-11 through A-13. The modeled and measured minimum noise figures at three bias points are shown in Figures A-14 through A-16. From Figures A-11 through A-13 we can see that the dc responses and *S* parameters of both models match the measurements very well. However, the noise responses of Model 2 are much closer to the measurements than those of Model 1, which are illustrated in Figures A-14 through A-16. If both models are used for noise analysis in circuit design, Model 2 will provide much more accurate results than Model 1.

A-6 CONCLUSIONS

We have presented a novel nonlinear model for accurate dc, small-signal, and noise characterization of AlGaAs/GaAs HBTs. Two linearized model topologies have been described. Our model takes into account the bias, temperature, and frequency dependencies for small-signal and noise calculations and provides accurate device performance prediction. The model has been validated using devices from different foundries. This model can be implemented into SPICE or harmonic-balance simulators, thereby facilitating the design of microwave integrated circuits that incorporate HBTs. Our innovative noise calculation method can similarly be applied to the noise calculations of the FET device family.

We have exploited an integrated parameter extraction method fitting dc, multibias *S*-parameter, and multibias noise measurements simultaneously. The models extracted using this approach are capable of predicting the device small-signal responses and dc characteristics as well as noise performances accurately and can be used in a wide range of applications. Microwave circuit design engineers will benefit from such models, which allow the attainment of first-pass circuit design and thus reduce development cost. This creative technique is general and can be used for parameter extraction of other devices.

ACKNOWLEDGMENT

The work on which this appendix is based was sponsored, in part, by the Air Force Phase II SBIR Program Contract Number F33615-95-C-1707 on bias-dependent noise modeling of HBTs. The authors gratefully acknowledge discussions with Dr. Bob Pucel and thank Bob Neidhard of WL/ELM, Wright Patterson Air Force Base, for providing measurements. Participation of the two foundries toward model validation is greatly appreciated.

APPENDIX B

NONLINEAR MICROWAVE CIRCUIT DESIGN USING MULTIHARMONIC LOAD-PULL SIMULATION TECHNIQUE*

This appendix presents practical applications of the multiharmonic load-pull simulation technique to the design of nonlinear microwave circuits. A systematic scheme using multiharmonic load-pull simulation explores the effects of each harmonic termination on the circuit performance and finds the optimal load at each harmonic. The circuit performance can significantly be improved following this systematic design procedure. This approach provides an efficient means of nonlinear microwave circuit design. Its advantages are illustrated for the design of two power amplifiers and a frequency doubler.

B-1 INTRODUCTION

With the rapid development of wireless communication in recent years, the quality of the nonlinear circuits, such as power amplifiers, oscillators, and frequency doublers, is becoming an increasingly critical component of the entire communication system. A good design of such nonlinear circuits can significantly improve the performance of the system and reduce its cost.

The harmonic-balance (HB) technique has widely been used for nonlinear microwave circuit design since its implementation in commercial CAD software. Many new applications have been developed for the HB method such as stability analysis [1, 2] and load-pull simulation [3]. Load-pull techniques and harmonic load tuning have been used successfully for large-signal device characterization and nonlinear circuit design (e.g., [4–7]). However,

*This appendix is based on Qian Cai, Jason Gerber, Chao-Ren Chang, and Ulrich L. Rohde, "Nonlinear Microwave Circuit Design Using Multi-harmonic Load-Pull Simulation Technique," *Int. J. Microwave Millimeter-Wave Computer-Aided Eng.*, 1999.

the design procedure has never been described systematically. This prevents or restricts the practical usage of the load-pull techniques.

Here we present a systematic scheme to use the load-pull technique efficiently in nonlinear microwave circuit design. Multiharmonic load-pull simulation using the HB method is used as a vehicle for our presentation. Response contours are simulated by sampling the corresponding harmonic impedance of the selected tuner connected to the input or output port. Optimal harmonic impedances are located from the response contours. A step by step design procedure is described.

Our process can be classified into two major steps: finding the optimal loading at each harmonic and checking the power levels of higher harmonics. By checking the power levels of higher harmonics, we can readily see the effects of higher harmonic loading on the circuit performance. Further steps are carried out based on the investigation of the higher harmonic loading effects. It is a very effective way for microwave engineers to achieve good, if not the best, results in nonlinear circuit design.

The multiharmonic load-pull simulation is presented in Section B-2. Applications of multiharmonic load-pull simulation to nonlinear circuit design are addressed in Section B-3. The circuit designs of two power amplifiers and a frequency doubler are demonstrated.

B-2 MULTIHARMONIC LOAD-PULL SIMULATION USING HARMONIC BALANCE

B-2-1 Formulation of Multiharmonic Load-Pull Simulation

The multiharmonic load-pull simulation is implemented within the nonlinear simulator, Microwave Harmonica [8], which uses an efficient HB technique [9]. The circuit topology for the multiharmonic load-pull simulation can be sketched generally as Figure B-1, where M tuners are placed at the M external ports considered. The formulation can generally be expressed as

$$E(X, Z) = 0 \tag{B-1}$$

where E is the vector of HB errors, X is the set of all harmonic state variables, and Z is the set of harmonic loads on all external ports. The kth subvector of E can be written

$$E_k(X, Z) = A(k\omega_0, Z)\Phi(X, Z) + B(k\omega_0, Z)\Psi(X, Z) + D(k\omega_0, Z) \tag{B-2}$$

where $0 \le k \le N_H$ (N_H is the number of harmonics used in the simulation), A and B are circuit matrices, D is a set of driving functions, and Φ and Ψ are, respectively, the harmonic vectors of instantaneous voltages v and currents i at the nonlinear subnetwork ports.

The harmonic loads Z can be written in the following matrix form:

$$Z = \begin{bmatrix} Z_1(0\omega_0) & Z_1(1\omega_0) & \cdots & Z_1(N_H\omega_0) \\ Z_2(0\omega_0) & Z_2(1\omega_0) & \cdots & Z_2(N_H\omega_0) \\ \vdots & \vdots & \vdots & \vdots \\ Z_M(0\omega_0) & Z_M(1\omega_0) & \cdots & Z_M(N_H\omega_0) \end{bmatrix} \tag{B-3}$$

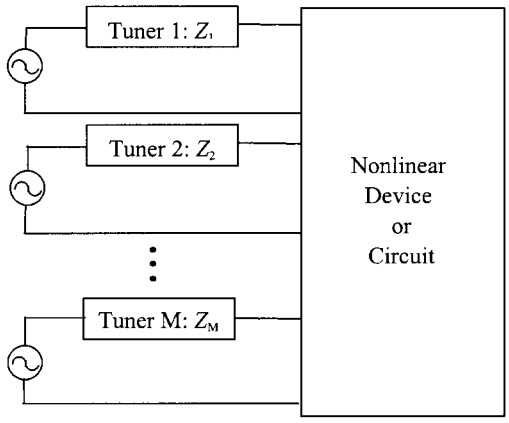

Figure B-1 Circuit topology for multiharmonic load-pull simulation.

where M is the number of external ports considered and $Z_i(k\omega_0)$ is the load at the kth harmonic and the ith port with $(0\omega_0)$ representing the dc component. The purpose of multiharmonic load-pull simulation is to find the optimal harmonic loading with respect to the design specifications. An impedance sampling method is used in our implementation of multiharmonic load-pull simulation. Only one component of Z is sampled at the defined impedance plane while the others are kept constant at each step. The HB simulation is performed at each sampling point to solve for the circuit responses specified. After the simulations are finished at all sampling points, load-pull contours are plotted on the Smith Chart and then the optimal point is located.

B-2-2 Systematic Design Procedure

Without losing generality, and for easy illustration, we consider the two-port circuit shown in Figure B-2, where tuners are placed at the source and load ports. The impedance sampling is achieved by adjusting the tuner parameters, which can be described as follows.

$R_i(k\omega_0)$—The resistance at the ith tuner and the kth harmonic, $i = 1, 2$, and $k = 1, 2, \ldots, N_H$.
$X_i(k\omega_0)$—The reactance at the ith tuner and the kth harmonic, $i = 1, 2$, and $k = 1, 2, \ldots, N_H$.

In order to obtain a uniform sampling of points, the tuner impedance is mapped to a reflection coefficient using a reference impedance Z_r and the mapping equation

$$\Gamma_i(k\omega_0) = \frac{Z_i(k\omega_0) - Z_r}{Z_i(k\omega_0) + Z_r} \tag{B-4}$$

The impedance sampling is transferred to two sweeps: the magnitude of $\Gamma_i(k\omega_0)$ $[|\Gamma_i(k\omega_0)|]$ from 0 to 1 and the angle of $\Gamma_i(k\omega_0)$ $[\angle\Gamma_i(k\omega_0)]$ from 0° to 360°. Only the impedance at one selected tuner i and one harmonic k, that is, $\Gamma_i(k\omega_0)$, is allowed to be tuned at a time and the other harmonic impedances are fixed at any meaningful values. In the following presentation we select $Z_r = 50\ \Omega$.

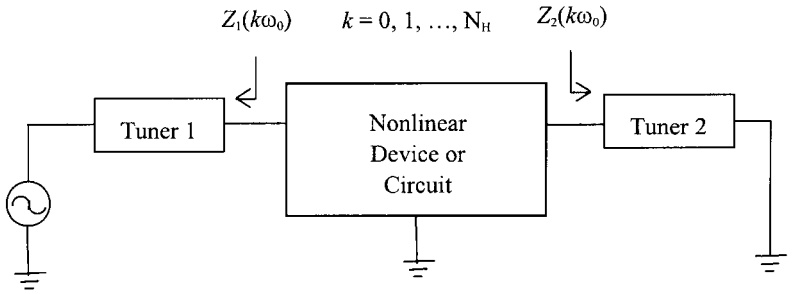

Figure B-2 Circuit schematic of a typical two-port nonlinear circuit.

The systematic design procedure can be described as follows:

Step 1: Start load-pull simulation by sampling the impedance at the fundamental frequency $Z_i(\omega_0)$ and find the optimal load $Z_{io}(\omega_0)$.

Step 2: Fix $Z_i(\omega_0)$ at $Z_{io}(\omega_0)$ and check the output spectrum to see the effects of higher harmonic loads on the circuit responses. If the effects of higher harmonic loads are significant, let $k = 2$, and go on to *Step 3*. Otherwise stop.

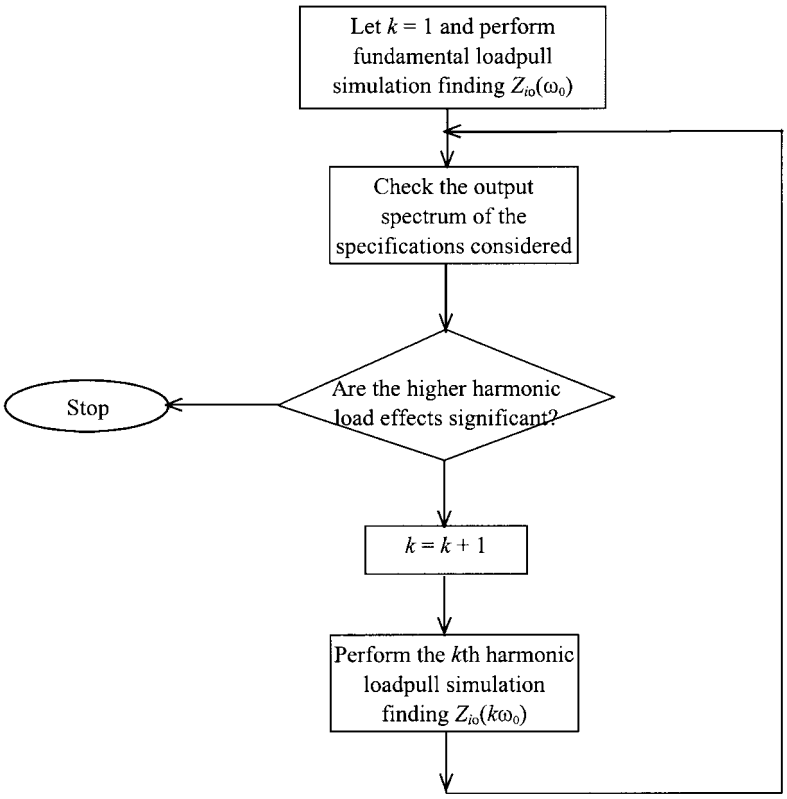

Figure B-3 Flowchart of design procedure using multiharmonic load-pull simulation.

Step 3: Perform load-pull simulation by sampling the kth harmonic impedance $Z_i(k\omega_0)$ and find the optimal load $Z_{io}(k\omega_0)$.

Step 4: Fix $Z_i(k\omega_0)$ at $Z_{io}(k\omega_0)$ and check the output spectrum to see the effects of higher harmonic loads on the circuit responses. If the effects of higher harmonic loads are significant, let $k = k + 1$, and go to *Step 3*. Otherwise stop.

This procedure can be repeated for all the tuners to achieve the optimal solution. It can be summed up as a load-pull simulation and spectrum-checking process. The flowchart in Figure B-3 illustrates this procedure.

B-3 APPLICATION OF MULTIHARMONIC LOAD-PULL SIMULATION

B-3-1 Narrowband Power Amplifier Design

Two power amplifiers, Amplifier 1 and Amplifier 2, are considered. The amplifiers are designed to operate at 0.5 GHz. The circuit schematic used for amplifier design is shown in Figure B-4. A Siemens power MESFET CLY10 [10] is used in our design. The MESFET is modeled by the modified Materka model [11] implemented in Microwave Harmonica [8]. Without losing generality, and for easy illustration, we fix all harmonic impedances of Tuner 1 (at the source port) at 50 Ω and tune Tuner 2 (at the load port) for both examples. Six harmonics are used in the HB simulation.

In Amplifier 1, the MESFET is biased at $V_{gs} = -1.3$ V and $V_{ds} = 5$ V, and the amplifier is designed as a normal Class A type with an input power of 10 dBm. Following the procedure described above, we perform load-pull simulation by sampling $Z_2(\omega_0)$ of Tuner 2 while other harmonic impedances of Tuner 2 are fixed at 50 Ω. The load-pull contours of power gain and power-added efficiency (PAE) are plotted in Figure B-5. The optimal load $Z_{2o}(\omega_0)$ is found to be $9.07 + j12.99$, at which the power gain is 18.54 dB and PAE is about 20%. The output power spectrum at this point is plotted in Figure B-6. By checking the output power spectrum of Figure B-6, we can see that the power levels at all higher harmonics are very small. Therefore, the higher harmonic loads will not have significant effects on the amplifier performance. To verify this conclusion, we perform load-pull simulation by sampling $Z_2(2\omega_0)$ of Tuner 2 while $Z_2(\omega_0)$ is fixed at $Z_{2o}(\omega_0)$. It is found that the best performance with respect to power gain and PAE is obtained for purely reactive second-harmonic loads, which is consistent with the results obtained by Berini et al. [5]. The output power versus the phase of $\Gamma_2(2\omega_0)$ is shown in Figure B-7, from which we can see that the influence of $Z_2(2\omega_0)$ is very small and our conclusion is justified.

Figure B-6 Output power spectrum of Amplifier 1 when $Z_2(\omega_0) = Z_{2o}(\omega_0)$.

In order to illustrate the effects of higher harmonic loading on the amplifier performance, the MESFET is biased at $V_{gs} = -2.0$ V and $V_{ds} = 5$ V, and the input power is increased to 20 dBm in Amplifier 2. Figure B-8 shows the contours of power gain and PAE at the fundamental load-pull simulation. The optimal load $Z_{2o}(\omega_0)$ is $4.31 + j13.30$ for power gain (12.66 dB)

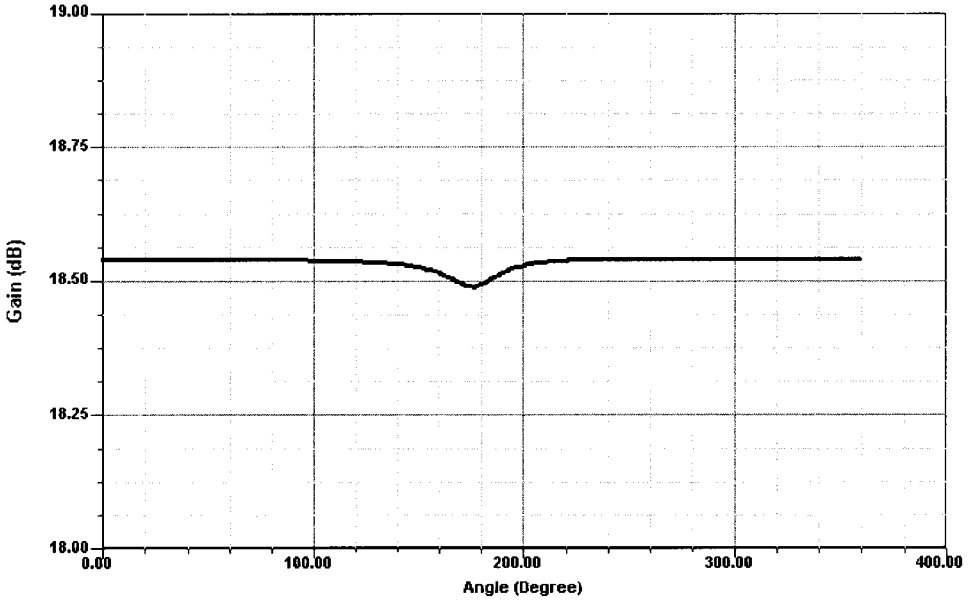

Figure B-7 Power gain versus the phase of $\Gamma_2(2\omega_0)$ for Amplifier 1.

and 7.61 + j13.11 for PAE (44.28%). Though a compromise between the power gain and PAE can be obtained, we select 7.61 + j13.11 as our $Z_{2o}(\omega_0)$ and consider the PAE as the primary specification throughout the following process. The output spectrum at this point is shown in Figure B-9, which indicates that the output power levels at higher harmonics are significant, and thus the higher harmonic loads are critical to the amplifier performance.

By fixing $Z_2(\omega_0)$ at 7.61 + j13.11 and sampling $Z_2(2\omega_0)$, we perform the second-harmonic load-pull simulation. The contours of PAE are shown in Figure B-10, which also indicates that the best point for the second-harmonic load will be pure reactance near the short-circuit point. The effect of the phase of $\Gamma_2(2\omega_0)$ on PAE is shown in Figure B-11. The optimal value of $Z_{2o}(2\omega_0)$ is –j6.58, where the phase of $\Gamma_2(2\omega_0)$ is 195°. The PAE is improved from 44.28% to 47.18%. The output power spectrum at $Z_2(\omega_0)$ = 7.61 + j13.11 and at $Z_2(2\omega_0)$ = –j6.58 is shown in Figure B-12. From Figure B-12, we can see that the amplifier performance can be further improved by a proper third-harmonic load. The third-harmonic load-pull simulation is carried out by sampling $Z_2(3\omega_0)$ while $Z_2(\omega_0)$ and $Z_2(2\omega_0)$ are maintained at their optimal values. $Z_{2o}(3\omega_0)$ is found to be –j65.16 at which the value of PAE is 47.66%. Following the same procedure, we perform load-pull simulations up to the sixth harmonic. The results are as follows:

Harmonic Load	Optimal Value
$Z_2(\omega_0)$	7.61 + j13.11
$Z_2(2\omega_0)$	–j6.58
$Z_2(3\omega_0)$	–j65.16
$Z_2(4\omega_0)$	–j2.18
$Z_2(5\omega_0)$	–j28.81
$Z_2(6\omega_0)$	–j23.32

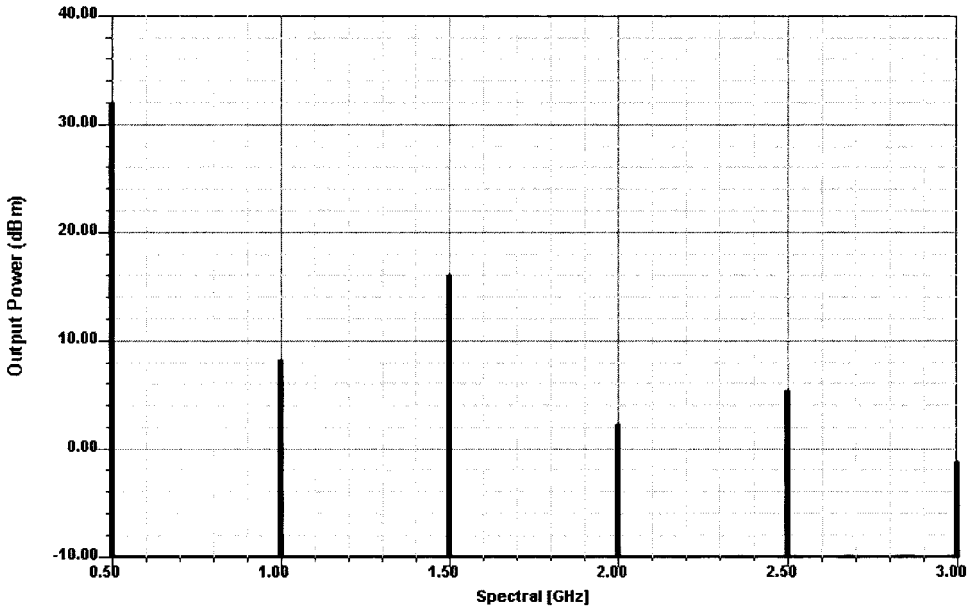

Figure B-9 Output power spectrum of Amplifier 2 when $Z_2(\omega_0) = Z_{2o}(\omega_0)$.

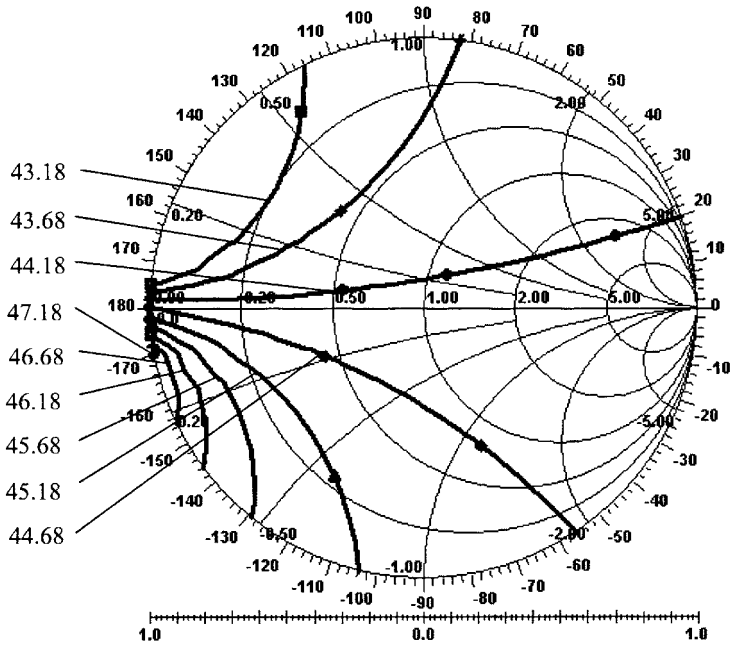

Figure B-10 Load-pull contours of PAE (%) of Amplifier 2 obtained from the second-harmonic load-pull simulation.

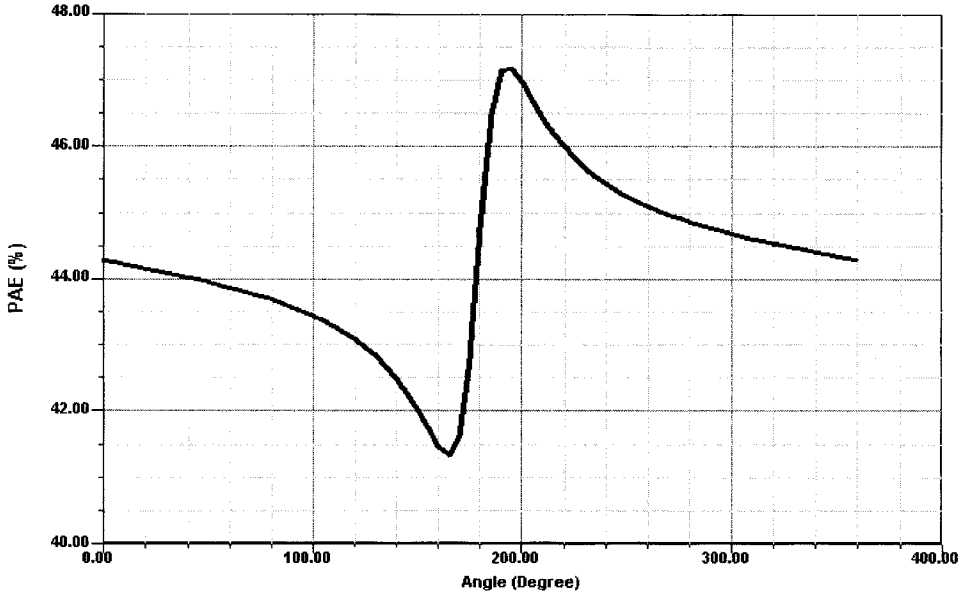

Figure B-11 PAE versus the phase of $\Gamma_2(2\omega_0)$ for Amplifier 2.

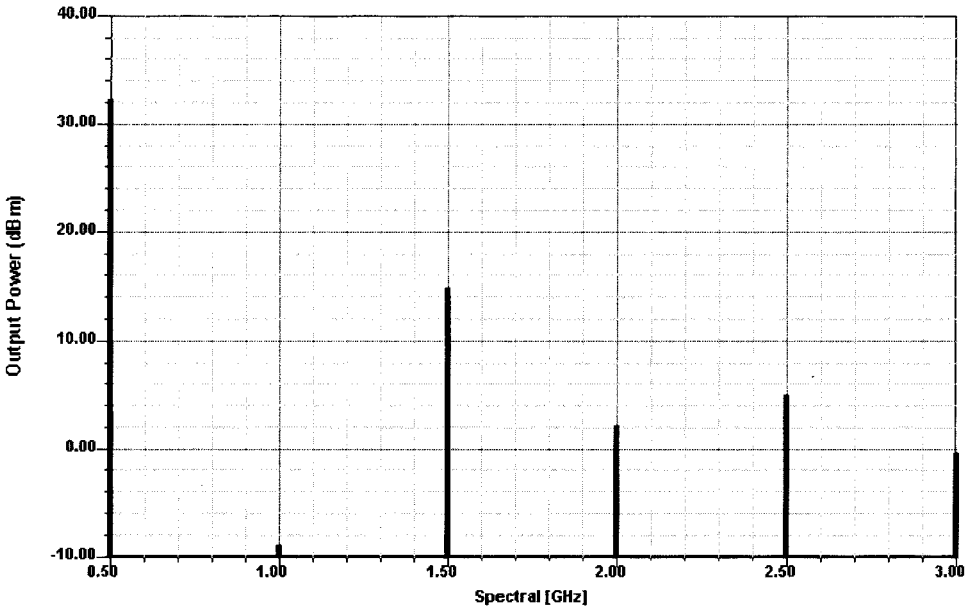

Figure B-12 Output power spectrum of Amplifier 2 when $Z_2(\omega_0) = Z_{2o}(\omega_0)$ and $Z_2(2\omega_0) = Z_{2o}(2\omega_0)$.

The PAE is 48.13% and power gain is 12.38 dB at the final design. The output power spectrum of the final design is shown in Figure B-13, which indicates that the output power levels at the second and higher harmonics have been suppressed significantly compared to the ones shown in Figure B-9.

B-3-2 Frequency Doubler Design

The circuit schematic shown in Figure B-14 is used for the frequency doubler design. The MESFET is biased at pinchoff, with $V_{gs} = -1.9$ V and $V_{ds} = 5$ V. The frequency of the input waveform is 5 GHz and the input power is 3 dBm. Six harmonics are considered in the HB simulation. Both Z_S and Z_L are 50 Ω. The conversion gain (CG) and the spectral purity (SP), are considered as the design specifications, calculated, respectively, by

$$CG = \frac{P_L(2\omega_0)}{P_{avs}(\omega_0)} \tag{B-5}$$

and

$$SP = \frac{P_L(2\omega_0)}{\sum_{k=1,\, k\neq 2}^{N_H} P_L(k\omega_0)} \tag{B-6}$$

where P_L is the power delivered to the load Z_L and P_{avs} is the available source power. In addition to the load-pull simulation, we also perform source-pull simulation in the design.

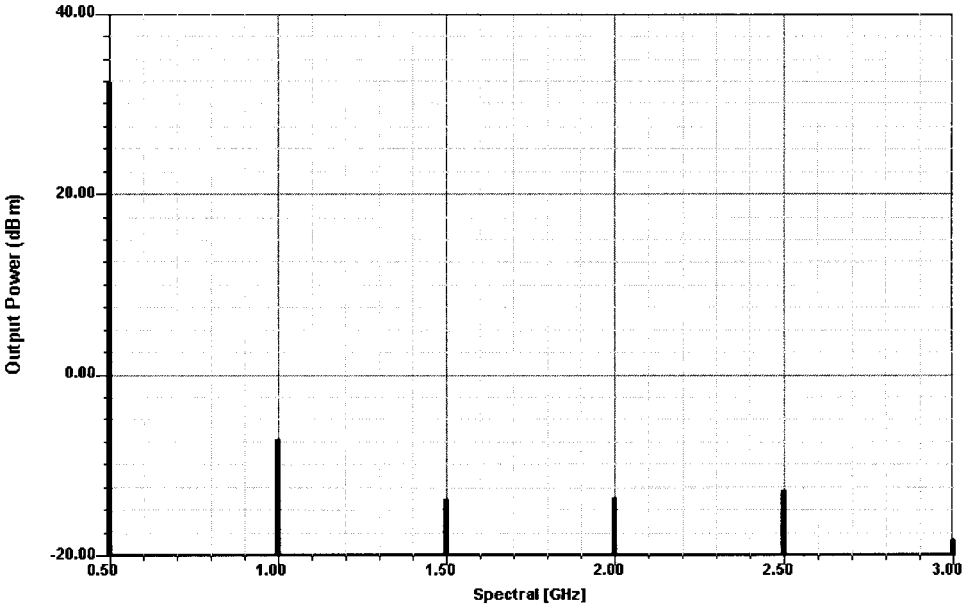

Figure B-13 Output power spectrum of Amplifier 2 at the final design.

Note that the harmonic impedance $Z_i(k\omega_0)$ is the tuner impedance without the load Z_L or the source impedance Z_S, and $\Gamma_i(k\omega_0)$ is the reflection coefficient of the tuner only in this design example.

First, the fundamental load-pull simulation is performed by sampling $\Gamma_2(\omega_0)$ at Tuner 2 while the impedances of all harmonics at Tuner 1 and other harmonic impedances of Tuner 2 are fixed at 0 Ω. The contours of SP with respect to $\Gamma_2(\omega_0)$ are plotted in Figure B-15, from which we can see that the optimal tuner impedance is infinity, which means that the fundamental harmonic component of the output waveform should be completely reflected by an open circuit. We select $1 \angle 0$ as the optimal point $[\Gamma_{2o}(\omega_0)]$, at which the SP is 13.21 dB and the CG is –9.75 dB. The second-harmonic load-pull simulation is performed by

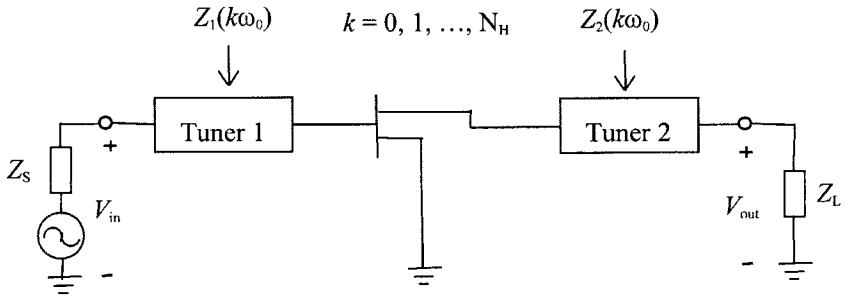

Figure B-14 Circuit topology for frequency doubler design using multiharmonic load-pull simulation.

sampling $\Gamma_2(2\omega_0)$ with $\Gamma_2(\omega_0)$ being fixed at $\Gamma_{2o}(\omega_0)$. The contours of SP with respect to $\Gamma_2(2\omega_0)$ are plotted in Figure B-16. The $\Gamma_{2o}(2\omega_0)$ is found to be $1 \angle 50$, at which the SP is improved from 13.21 to 18.14 dB and the CG from –9.75 to –5.89 dB. Following the same procedure, the load-pull simulation is performed up to the sixth harmonic. It is found that all the optimal harmonic impedances of Tuner 2 are infinity, except for the second harmonic, at which the optimal impedance is found to be $j127.23$. At the end of the load-pull simulation, the SP is 25.28 dB and the CG is –5.87 dB. The CG cannot be improved very much by tuning the harmonic impedances of Tuner 2.

The source-pull simulation is carried out by sampling the harmonic impedances of Tuner 1 using the same procedure as load-pull simulation with all the harmonic impedances of Tuner 2 being fixed at their optimal values. It is found that the most dominant harmonic impedance of Tuner 1 is the fundamental harmonic impedance. The optimal impedances at other harmonics of Tuner 1 turn out to be 0. The contours of CG with respect to $\Gamma_1(\omega_0)$ obtained by fundamental source-pull simulation with other harmonic impedances of Tuner 1 set to 0 Ω are plotted in Figure B-17. The $\Gamma_{1o}(\omega_0)$ is found to be $1 \angle 40$. The CG is significantly improved from –5.87 to 2.07 dB with a minor 0.5-dB degradation of spectral purity. The input and output voltage waveforms under the optimal termination conditions are shown in Figure B-18, from which we can see that the frequency of the output voltage is doubled to 10 GHz with a reasonable gain. The distortion of the input voltage waveform is due to the reflection of the higher-order harmonic voltages.

B-4 CONCLUSIONS

We have presented practical applications of multiharmonic load-pull simulation to the design of nonlinear microwave circuits. A systematic procedure has been addressed for effective circuit design. It has been demonstrated that the circuit performance can be improved significantly by a proper design of harmonic loads. This method can be applied to the design of nonlinear microwave circuits such as the power amplifier and frequency doubler to achieve the optimal solution and to utilize the maximum potential of the devices employed in the circuits.

B-5 NOTE ON THE PRACTICALITY OF LOAD-PULL-BASED DESIGN

From the standpoint that the wireless designer cannot have access to too many design aids, load-pull-based design techniques can serve as a valuable addition to the wireless designer's toolbox. We caution, however, that the current surge of interest in load-pull design techniques may owe as much to fashion and wishful thinking as it does to the practical achievability of the improved hardware performance that load-pull analysis may predict. Realizing the gain, PAE, and spectral-purity predictions of analyses like those presented here depends on the realization of optimum, controllable terminations at the signal fundamental *and its significant harmonics*—a nontrivial design challenge to say the least.

ACKNOWLEDGMENT

The work on which this appendix is based was sponsored under the DARPA MAFET Thrust 1 program, Agreement No. MDA972-96-3-0001. Partial contributions of Dr. Solti Peng of TI, Dallas, Texas, to some of the materials presented here are gratefully acknowledged.
