To Professor Vittorio Rizzoli

who has been instrumental in the development of the powerful harmonic-balance analysis tool, specifically Microwave Harmonica, which is part of Ansoft's Serenade Design Environment. Most of the success enjoyed by Compact Software, now part of Ansoft, continues to be based on his far-reaching contributions.

CONTENTS

Foreword xiii

Preface xv

1 Introduction to Wireless Circuit Design 1

1-1 Overview / 1
1-2 System Functions / 3
1-3 The Radio Channel and Modulation Requirements / 5
1-3-1 Introduction / 5
1-3-2 Channel Impulse Response / 7
1-3-3 Doppler Effect / 13
1-3-4 Transfer Function / 14
1-3-5 Time Response of Channel Impulse Response and Transfer Function / 14
1-3-6 Lessons Learned / 17
1-3-7 Wireless Signal Example: The TDMA System in GSM / 18
1-4 About Bits, Symbols, and Waveforms / 29
1-4-1 Introduction / 29
1-4-2 Some Fundamentals of Digital Modulation Techniques / 38
1-5 Analysis of Wireless Systems / 47
1-5-1 Analog and Digital Receiver Designs / 47
1-5-2 Transmitters / 58
1-6 Building Blocks / 81
1-7 System Specifications and Their Relationship to Circuit Design / 83
1-7-1 System Noise and Noise Floor / 83
1-7-2 System Amplitude and Phase Behavior / 88
1-8 Testing / 114
1-8-1 Introduction / 114
1-8-2 Transmission and Reception Quality / 114
1-8-3 Base-Station Simulation / 118
1-8-4 GSM / 118

1-8-5 DECT / 118
1-9 Converting C/N or SNR to E_b/N_0 / 120

2 Models for Active Devices 123

2-1 Diodes / 124
2-1-1 Large-Signal Diode Model / 124
2-1-2 Mixer and Detector Diodes / 128
2-1-3 PIN Diodes / 135
2-1-4 Tuning Diodes / 153
2-2 Bipolar Transistors / 198
2-2-1 Transistor Structure Types / 198
2-2-2 Large-Signal Behavior of Bipolar Transistors / 199
2-2-3 Large-Signal Transistors in the Forward-Active Region / 209
2-2-4 Effects of Collector Voltage on Large-Signal Characteristics in the Forward-Active Region / 225
2-2-5 Saturation and Inverse Active Regions / 227
2-2-6 Small-Signal Models of Bipolar Transistors / 232
2-3 Field-Effect Transistors / 237
2-3-1 Large-Signal Behavior of JFETs / 246
2-3-2 Small-Signal Behavior of JFETs / 249
2-3-3 Large-Signal Behavior of MOSFETs / 254
2-3-4 Small-Signal Model of the MOS Transistor in Saturation / 262
2-3-5 Short-Channel Effects in FETs / 266
2-3-6 Small-Signal Models of MOSFETs / 271
2-3-7 GaAs MESFETs / 301
2-3-8 Small-Signal GaAs MESFET Model / 310
2-4 Parameter Extraction of Active Devices / 322
2-4-1 Introduction / 322
2-4-2 Typical SPICE Parameters / 322
2-4-3 Noise Modeling / 323
2-4-4 Scalable Device Models / 333
2-4-5 Conclusions / 348
2-4-6 Device Libraries / 359
2-4-7 A Novel Approach for Simulation at Low Voltage and Near Pinchoff Voltage / 359
2-4-8 Example: Improving the BFR193W Model / 370

3 Amplifier Design with BJTs and FETs 375

3-1 Properties of Amplifiers / 375
3-1-1 Introduction / 375
3-1-2 Gain / 380
3-1-3 Noise Figure (NF) / 385
3-1-4 Linearity / 415
3-1-5 AGC / 431
3-1-6 Bias and Power Voltage and Current (Power Consumption) / 436

3-2 Amplifier Gain, Stability, and Matching / 441
3-2-1 Scattering Parameter Relationships / 442
3-2-2 Low-Noise Amplifiers / 448
3-2-3 High-Gain Amplifiers / 466
3-2-4 Low-Voltage Open-Collector Design / 477
3-3 Single-Stage FeedBack Amplifiers / 490
3-3-1 Lossless or Noiseless Feedback / 495
3-3-2 Broadband Matching / 496
3-4 Two-Stage Amplifiers / 497
3-5 Amplifiers with Three or More Stages / 507
3-5-1 Stability of Multistage Amplifiers / 512
3-6 A Novel Approach to Voltage-Controlled Tuned Filters Including CAD Validation / 513
3-6-1 Diode Performance / 513
3-6-2 A VHF Example / 516
3-6-3 An HF/VHF Voltage-Controlled Filter / 518
3-6-4 Improving the VHF Filter / 521
3-6-5 Conclusion / 521
3-7 Differential Amplifiers / 522
3-8 Frequency Doublers / 526
3-9 Multistage Amplifiers with Automatic Gain Control (AGC) / 532
3-10 Biasing / 534
3-10-1 RF Biasing / 543
3-10-2 dc Biasing / 543
3-10-3 dc Biasing of IC-Type Amplifiers / 547
3-11 Push–Pull/Parallel Amplifiers / 547
3-12 Power Amplifiers / 550
3-12-1 Example 1: 7-W Class C BJT Amplifier for 1.6 GHz / 550
3-12-2 Impedance Matching Networks Applied to RF Power Transistors / 565
3-12-3 Example 2: Low-Noise Amplifier Using Distributed Elements / 585
3-12-4 Example 3: 1-W Amplifier Using the CLY15 / 589
3-12-5 Example 4: 90-W Push–Pull BJT Amplifier at 430 MHz / 598
3-12-6 Quasiparallel Transistors for Improved Linearity / 600
3-12-7 Distribution Amplifiers / 602
3-12-8 Stability Analysis of a Power Amplifier / 602
3-13 Power Amplifier Datasheets and Manufacturer-Recommended Applications / 611

4 Mixer Design 636

4-1 Introduction / 636
4-2 Properties of Mixers / 639
4-2-1 Conversion Gain/Loss / 639
4-2-2 Noise Figure / 641
4-2-3 Linearity / 645
4-2-4 LO Drive Level / 647

4-2-5 Interport Isolation / 647
4-2-6 Port VSWR / 647
4-2-7 dc Offset / 647
4-2-8 dc Polarity / 649
4-2-9 Power Consumption / 649
4-3 Diode Mixers / 649
4-3-1 Single-Diode Mixer / 650
4-3-2 Single-Balanced Mixer / 652
4-3-3 Diode-Ring Mixer / 659
4-4 Transistor Mixers / 678
4-4-1 BJT Gilbert Cell / 679
4-4-2 BJT Gilbert Cell with Feedback / 682
4-4-3 FET Mixers / 684
4-4-4 MOSFET Gilbert Cell / 693
4-4-5 GaAsFET Single-Gate Switch / 694

5 RF/Wireless Oscillators 716

5-1 Introduction to Frequency Control / 716
5-2 Background / 716
5-3 Oscillator Design / 719
5-3-1 Basics of Oscillators / 719
5-4 Oscillator Circuits / 735
5-4-1 Hartley / 735
5-4-2 Colpitts / 735
5-4-3 Clapp–Gouriet / 736
5-5 Design of RF Oscillators / 736
5-5-1 General Thoughts on Transistor Oscillators / 736
5-5-2 Two-Port Microwave/RF Oscillator Design / 741
5-5-3 Ceramic-Resonator Oscillators / 745
5-5-4 Using a Microstrip Inductor as the Oscillator Resonator / 748
5-5-5 Hartley Microstrip Resonator Oscillator / 756
5-5-6 Crystal Oscillators / 756
5-5-7 Voltage-Controlled Oscillators / 758
5-5-8 Diode-Tuned Resonant Circuits / 765
5-5-9 Practical Circuits / 771
5-6 Noise in Oscillators / 778
5-6-1 Linear Approach to the Calculation of Oscillator Phase Noise / 778
5-6-2 AM-to-PM Conversion / 788
5-6-3 Nonlinear Approach to the Calculation of Oscillator Phase Noise / 798
5-7 Oscillators in Practice / 813
5-7-1 Oscillator Specifications / 813
5-7-2 More Practical Circuits / 814
5-8 Design of RF Oscillators Using CAD / 825
5-8-1 Harmonic-Balance Simulation / 825
5-8-2 Time-Domain Simulation / 831

5-9 Phase-Noise Improvements of Integrated RF and Millimeter-Wave Oscillators / 831
5-9-1 Introduction / 831
5-9-2 Review of Noise Analysis / 831
5-9-3 Workarounds / 833
5-9-4 Reduction of Flicker Noise / 834
5-9-5 Applications to Integrated Oscillators / 835
5-9-6 Summary / 842

6 Wireless Synthesizers 848

6-1 Introduction / 848
6-2 Phase-Locked Loops / 848
6-2-1 PLL Basics / 848
6-2-2 Phase/Frequency Comparators / 851
6-2-3 Filters for Phase Detectors Providing Voltage Output / 863
6-2-4 Charge-Pump-Based Phase-Locked Loops / 867
6-2-5 How to Do a Practical PLL Design Using CAD / 876
6-3 Fractional-*N*-Division PLL Synthesis / 880
6-3-1 The Fractional-*N* Principle / 880
6-3-2 Spur-Suppression Techniques / 882
6-4 Direct Digital Synthesis / 889

APPENDIXES

A HBT High-Frequency Modeling and Integrated Parameter Extraction 900

A-1 Introduction / 900
A-2 High-Frequency HBT Modeling / 901
A-2-1 dc and Small-Signal Model / 902
A-2-2 Linearized T Model / 904
A-2-3 Linearized Hybrid-π Model / 906
A-3 Integrated Parameter Extraction / 907
A-3-1 Formulation of Integrated Parameter Extraction / 908
A-3-2 Model Optimization / 908
A-4 Noise Model Validation / 909
A-5 Parameter Extraction of an HBT Model / 913
A-6 Conclusions / 921

B Nonlinear Microwave Circuit Design Using Multiharmonic Load-Pull Simulation Technique 923

B-1 Introduction / 923
B-2 Multiharmonic Load-Pull Simulation Using Harmonic Balance / 924
B-2-1 Formulation of Multiharmonic Load-Pull Simulation / 924
B-2-2 Systematic Design Procedure / 925

B-3 Application of Multiharmonic Load-Pull Simulation / 927
B-3-1 Narrowband Power Amplifier Design / 927
B-3-2 Frequency Doubler Design / 933
B-4 Conclusions / 937
B-5 Note on the Practicality of Load-Pull-Based Design / 937

INDEX **939**

FOREWORD

One of the wonderful things about living in these times is the chance to witness, and occasionally be part of, major technological trends with often profound impacts on society and people's lives. At the risk of stating the obvious, one of the greatest technological trends has been the growth of wireless personal communication—the development and success of a variety of cellular and personal communication system technologies, such as GSM, CDMA, and Wireless Data and Messaging, and the spreading of the systems enabled by these technologies worldwide. The impact on people's lives has been significant, not only in their ability to stay in touch with their business associates and with their families, but often in the ability to save lives and prevent crime. On some occasions, people who have never before used a plain old telephone have made their first long distance communication using the most advanced satellite or digital cellular technology. This growth of wireless communication has encompassed new frequencies, driven efforts to standardize communication protocols and frequencies to enable people to communicate better as part of a global network, and has encompassed new wireless applications. The wireless web is with us, and advances in wireless global positioning technology are likely to provide more examples of lifesaving experiences due to the ability to send help precisely and rapidly to where help is urgently needed.

RF and microwave circuit design has been the key enabler for this growth and success in wireless communication. To a very large extent, the ability to mass produce high quality, dependable wireless products has been achieved through the advances of some incredible RF design engineers, sometimes working alone, oftentimes working and sharing ideas as part of a virtual community of RF engineers. During these past few years, these advances have generated a gradual demystification of RF and microwave circuitry, moving RF techniques ever so reluctantly from "black art" to science. Dr. Ulrich Rohde has long impressed many of us as one of the principal leaders in these advances.

In this book, *RF/Microwave Circuit Design for Wireless Applications*, Dr. Rohde helps clarify RF theory and its reduction to practical applications in developing RF circuits. The book provides insights into the semiconductor technologies, and how appropriate technology decisions can be made. Then, the book discusses—first in overview, then in detail—each of the RF circuit blocks involved in wireless applications: the amplifiers, mixers, oscillators, and frequency synthesizers that work together to amplify and extract the signal from an often hostile environment of noise and reflected signals. Dr. Rohde's unique expertise in VCO and PLL design is particularly valuable in these unusually difficult designs.

It is a personal pleasure to write this foreword—Dr. Rohde has provided guest lectures to engineers at Motorola, and provided suggestions on paths to take and paths to avoid to several design engineers. The value his insights have provided are impossible to measure, but are so substantial that we owe him a "thanks" that can never be expressed strongly enough. I believe that his impact on the larger RF community is even more substantial. This book helps share his expertise in a widely available form.

ERIC MAASS
Director of Operations, Wireless Transceiver Products
Motorola, SPS

PREFACE

When I started two years ago to write a book on wireless technology—specifically, circuit design—I had hoped that the explosion of the technology had stabilized. To my surprise, however, the technology is far from settled, and I found myself in a constant chase to catch up with the latest developments. Such a chase requires a fast engine like the Concorde.

In the case of this somewhat older technology, its speed still has not been surpassed by any other commercial approach. This tells us there is a lot of design technology that needs to be understood or modified to handle today's needs. Because of the very demanding calculation effort required in circuit design, this book makes heavy use of the most modern CAD tools. Hewlett-Packard was kind enough to provide us with a copy of their Advanced Design System (ADS), which also comes with matching synthesis and a wideband CDMA library. Unfortunately, some of the mechanics of getting us started on the software collided with the already delayed publication schedule of this book, and we were only in a position to reference their advanced capability and not really demonstrate it. The use of this software,

including the one from Eagleware, which was also provided to us, needed to be deferred to the next edition of this book. To give a consistent presentation, we decided to stay with the Ansoft tools. One of the most time-consuming efforts was the actual modeling job, since we wanted to make sure all circuits would work properly. There are too many publications showing incomplete or nonworking designs.

On the positive side, trade journals give valuable insight into state-of-the-art designs, and it is recommended that all engineers subscribe to them. Some of the major publications include:

Applied Microwave & Wireless
Electronic Design
Electronic Engineering Europe
Microwave Journal
Microwaves & RF
Microwave Product Digest (MPD)
RF Design
Wireless Systems Design

There are also several conferences that have excellent proceedings, which can be obtained either in book form or on CD:

GaAs IC Symposium (annual; sponsored by IEEE-EDS, IEEE-MTT)
IEEE International Solid-State Circuits Conference (annual)
IEEE MTT-S International Microwave Symposium (annual)

There may be other useful conferences along these lines that are announced in the trade journals mentioned above. There are also workshops associated with conferences, such as the recent "Designing RF Receivers for Wireless Systems," associated with the IEEE MTT-S.

Other useful tools include courses, such as *Introduction to RF/MW Design*, a four-day short course offered by Besser Associates.

Wireless design can be split into a digital part, which has to do with the various modulation and demodulation capabilities (advantages and disadvantages), and an analog part, the description of which comprises most of this book.

The analog part is complicated by the fact that we have three competing technologies. Given the fact that cost, space, and power consumption are issues for handheld and battery-operated applications, CMOS has been a strong contender in the area of cordless telephones because of its relaxed signal-to-noise-ratio specifications compared with cellular telephones. CMOS is much noisier than bipolar and GaAs technologies. One of the problems then is the input/output stage at UHF/SHF frequencies. Here we find a fierce battle between silicon-germanium (SiGe) transistors and GaAs technology. Most prescalers are bipolar, and most power amplifiers are based on GaAs FETs or LDMOS transistors for base stations. The most competitive technologies are the SiGe transistors and, of course, GaAs, the latter being the most expensive of the three mentioned. In the silicon-germanium area, IBM and Maxim seem to be the leaders, with many others trying to catch up.

Another important issue is differentiation between handheld or battery-operated applications and base stations. Most designers, who are tasked to look into battery-operated devices, ultimately resort to using available integrated circuits, which seem to change every six to nine months, with new offerings. Given the multiple choices, we have not yet seen a

systematic approach to selecting the proper IC families and their members. We have therefore decided to give some guidelines for the designer applications of ICs, focusing mainly on high-performance applications. In the case of high-performance applications, low power consumption is not that big an issue; dynamic range in its various forms tends to be more important. Most of these circuits are designed in discrete portions or use discrete parts. Anyone who has a reasonable antenna and has a line of sight to New York City, with the antenna connected to a spectrum analyzer, will immediately understand this. Between telephones, both cordless and cellular, high-powered pagers, and other services, the spectrum analyzer will be overwhelmed by these signals. IC applications for handsets and other applications already value their parts as "good." Their third-order intercept points are better than −10 dBm, while the real professional having to design a fixed station is looking for at least +10 dBm, if not more. This applies not only to amplifiers but also to mixer and oscillator performance. We therefore decided to give examples of this dynamic range. The brief surveys of current ICs included in Chapter 1 were assembled for the purpose of showing typical specifications and practical needs. It is useful that large companies make both cellular telephones and integrated circuits or their discrete implementation for base stations. We strongly believe that the circuits selected by us will be useful for all applications.

Chapter 1 is an introduction to digital modulation, which forms the foundation of wireless radiocommunication and its performance evaluation. We decided to leave the discussion of actual implementation to more qualified individuals. Since the standards for these modulations are still in a state of flux, we felt it would not be possible to attack all angles. Chapter 1 contains some very nice material from various sources including tutorial material from my German company, Rohde & Schwarz in Munich—specifically, from the digital modulation portion of their 1998 *Introductory Training for Sales Engineers* CD. *Note*: On a few rare occasions, we have used either a picture or an equation more than once so the reader need not refer to a previous chapter for full understanding of a discussion.

Chapter 2 is a comprehensive introduction to the various semiconductor technologies to enable the designer to make an educated decision. Relevant material such as PIN diodes have also been covered. In many applications, the transistors are being used close to their electrical limits, such as a combination of low voltage and low current. The f_T dependence, noise figure, and large-signal performance have to be evaluated. Another important application for diodes is their use as switches, as well as variable capacitances frequently referred to as tuning diodes. In order for the reader to better understand the meaning of the various semiconductor parameters, we have included a variety of datasheets and some small applications showing which technology is best for a particular application. In linear applications, noise figure is extremely important; in nonlinear applications, the distortion products need to be known. Therefore, this chapter includes not only the linear performance of semiconductors, but also their nonlinear behavior, including even some details on parameter extraction. Given the number of choices the designer has today and the frequent lack of complete data from manufacturers, these are important issues.

Chapter 3, the longest chapter, has the most detailed analysis and guidelines for discrete and integrated amplifiers, providing deep insight into semiconductor performance and circuitry necessary to get the best results from the devices. We deal with the properties of the amplifiers, gain stability, and matching, and we evaluate one-, two-, and three-stage amplifiers with internal dc coupling and feedback, as are frequently found in integrated circuits. In doing so, we also provide examples of ICs currently on the market, knowing that every six months more sophisticated devices will appear. Another important topic in this chapter is the choice of bias point and matching for digital signal handling, and we provide

insight into such complex issues as the adjacent channel power ratio, which is related to a form of distortion caused by the amplifier in its particular operating mode. To connect these amplifiers, impedance matching is a big issue, and we evaluate some couplers and broadband matching circuits useful at these high frequencies, as well as providing a tracking filter as preselector, using tuning diodes. Discussion of differential amplifiers, frequency doublers, AGC, biasing and push-pull/parallel amplifiers comes next, followed by an in-depth section on power amplifiers, including several practical examples and an investigation of amplifier stability analysis. A selection of power-amplifier datasheets and manufacturer-recommended applications rounds out this chapter.

Chapter 4 is a detailed analysis of the available mixer circuits that are applicable to the wireless frequency range. The design and the necessary mathematics to calculate the difference between insertion loss and noise figure are both presented. The reader is given insight into the differences between passive and active mixers, additive and multiplicative mixers, and other useful hints. We have also added some very clever circuits from companies such as Motorola and Siemens, as they are available as ICs.

Chapter 5, on oscillators, is a logical next step, as many amplifiers turn out to oscillate. After a brief introduction explaining why voltage-controlled oscillators (VCOs) are needed, we cover the necessary conditions for oscillation and its resulting phase noise for various configurations, including microwave oscillators and the very important ceramic-resonator-based oscillator. This chapter walks the reader through the various noise-contributing factors and the performance differences between discrete and integrated oscillators and their performance. Here too, a large number of novel circuits are covered.

Chapter 6 deals with the frequency synthesizer, which depends heavily on the oscillators shown in Chapter 5 and different system configurations to obtain the best performance. All components of a synthesizer, such as loop filters and phase/frequency discriminators, are evaluated along with their actual performance. Included are further applications for commercial synthesizer chips. Of course, the principles of the direct digital frequency synthesizer, as well as the fractional-*N*-division synthesizer, are covered. The fractional-*N*-division synthesizer is probably one of the most exciting implementations of synthesizers, and we have added patent information for those interested in coming up with their own designs.

The book then ends with two appendixes. Appendix A is an exciting approach to high-frequency modeling and integrated parameter extraction for HBTs. An enhanced noise model has been developed that gives significant improvement in the accuracy of determining the performance of these devices.

Appendix B is another CAD-based application for determining circuit performance—specifically, how to implement load-pulling simulation.

Appendix C is an electronic reproduction of a manual for a GSM handset application board that can be downloaded via web browser or ftp program from Wiley's public ftp area at ftp://ftp.wiley.com/public/sci-tech-med/microwave. It is probably the most exciting portion for the reader who would like to know how everything is put together for a mobile wireless application. Again, since every few months more clever ICs are available, some of the power consumption parameters and applications may vary relative to the system discussed, but all new designs will certainly be based on its general principles.

We would like to thank the many engineers from Ansoft, Alpha Industries, Motorola, National Semiconductor, Philips, Rohde & Schwarz, and Siemens Semiconductor (now Infineon Technologies) for supplying current information and giving permission to reproduce some excellent material.

In the area of permissions, National Semiconductor has specifically asked us to include the following passage, which applies to all their permissions:

LIFE SUPPORT POLICY

NATIONAL'S PRODUCTS ARE NOT AUTHORIZED FOR USE AS CRITICAL COMPONENTS IN LIFE SUPPORT DEVICES OR SYSTEMS WITHOUT THE EXPRESS WRITTEN APPROVAL OF THE PRESIDENT OF NATIONAL SEMICONDUCTOR CORPORATION.

As used herein:

1. Life support devices or systems are devices or systems which (a) are intended for surgical implant into the body or (b) support or sustain life and whose failure to perform, when properly used in accordance with instructions for use provided in the labeling, can be reasonably expected to result in a significant injury to the user.
2. A critical component is any component of a life support device or system whose failure to perform can be reasonably expected to cause the failure of the life support device or system, or to affect its safety or effectiveness.

I am also grateful to John Wiley & Sons, specifically George Telecki, for tolerating the several slips in schedule, which were the result of the complexity of this effort.

INTRODUCTION TO WIRELESS CIRCUIT DESIGN

1-1 OVERVIEW

Wireless circuits are not that different from commonly known two-way radio, television, and broadcast arrangements. Some of them require high linearity in modulation (TV picture); some work via relay stations (two-way radio). The real differences lie in the fact that the cell sizes are much smaller, and that in most cases we attempt multiple channel use (reuse) using time-division multiplex, spread spectrum, or some other efficient means of reducing the bandwidth required for communication. One can argue that the wireless circuits include simple devices, such as garage-door openers and wireless keys for automobiles (we have seen many cases where strong interfering signals prevented the car owners from reclaiming their cars until the interfering signal disappeared). Another longtime favorite is cordless telephones: initially, 50-MHz models with essentially no privacy protection; later, more sophisticated models that operate at 900 MHz; and now, dual-band designs that use 900 MHz and 2.4 GHz.

The largest wireless growth area is probably the cellular telephones. The two major applications are the handsets, commonly referred to as cell phones or occasionally as "handies," and the base stations. The base stations have many more problems with large-signal-handling linearity at high power, although handset users may run into similar problems. An example of this is the waiting area of an airport, where many travelers are trying to conduct last-minute business: In one instance, we concluded that about 30% of all the people present were on the air! It would have been fun to evaluate this receiver-hostile environment with a spectrum analyzer.

From such use comes anxiety factors, the lesser of which is "When will my battery die?"—a spare battery tends to help—and the greater of which the ongoing question, "Will this cell-phone transmitter harm my body?" [22]. A brief comment for the self-proclaimed experts in this area: A 50–100-kW TV transmitter, specifically its video or picture portion, connected to a high-gain antenna, emits levels of energy in line-of-sight paths that by far exceed the pulsed energy from a cell phone. Specifically, the duration of energy is signifi-

cantly smaller, and the absolute energy is more than a thousandfold higher, than the radio frequency (RF) supposedly harming us from the cellular phone. Handheld two-way radios have been used for the last 30 years or so by police and other security interests, operating in the frequency range from 50 to 900 MHz with antennas close to the users' heads, and there are no known cases of cancer or any other illnesses caused by these handheld radios. Recent studies in England, debatably or not, showed that the reaction-time level of people using cell phones actually *increased*—but then there are always the skeptics and politically motivated who ignore the facts, try to influence the media, and have their 15 minutes of fame (as Andy Warhol used to say).

As to the "harmful" radiation, Figure 1-1 shows the simulated radiation of a Motorola flip phone. While there are no absolute values attached to the pattern colors, it is interesting to see that the antenna extension inside the plastic casing also radiates, but most of the energy definitely is emitted by the top of the antenna. It seems to be a good idea to hold the telephone in such a way that the antenna points away from the head, "just in case." The user will find a "warm" sensation that will have more to do with the efficiency of the RF power amplifier heating up the case than the effect of radiation.

With this introduction in place, we will first take a look at a typical ultra-high-frequency/super-high-frequency (UHF/SHF) transceiver and explain the path from the microphone to the antenna and back. After this, we will inspect the radio channel and its effect on various methods of digital modulation. Analysis of wireless receivers and transmitters will be next, followed by a look at available building blocks and how they affect the overall system. To validate proper system operation, a fairly large number of measurements and tests must be performed, and conveying their purpose and importance will necessitate the definition of a number of system characteristics and concepts, such as dynamic range. Finally, after this is done, we will look at the issue of wireless system testing. Again, we intend to

Figure 1-1 Simulated antenna radiation of a Motorola flip phone.

give guidance applicable to battery-operated, handheld operation as well as high-powered base stations.

1-2 SYSTEM FUNCTIONS

A cellular telephone is a hybrid between a double-sideband and frequency-modulated [FM; or phase-modulated (PM)] transceiver. The actual transmission is not continuous but is pulsed, and because of the pulse spectrum there is a signal bandwidth concern due to keying transients, not unlike intermodulation products of a single-sideband (SSB) transceiver cluttering up adjacent channels. The cellular telephone is also a linear transceiver in the sense that its signal-handling circuitry must be sufficiently amplitude- and phase-linear to preserve the modulation characteristics of the AM/PM hybrid emissions it transmits and receives. Containing such an emission's spectral regrowth, which affects operation on adjacent channels, is not unlike the linearity requirements we encounter in SSB transceivers—requirements so stringent that amplifiers must be run nearly in Class A to meet them. The time-division multiple access (TDMA) operating mode, which allows many stations to use the same frequency through the use of short, precisely timed transmissions, requires a system that transmits with a small duty cycle, putting much less thermal stress on a power amplifier than continuous operation. Power management, including a sleep mode, is another important issue in handset design.

Figure 1-2 shows the block diagram of a handheld transceiver. This is applicable for cellular telephones and other systems that allow full duplex. For those not too familiar with transceivers, here is a "walk" through the block diagram. The RF signal intercepted by the antenna is fed through a duplex filter into a front end consisting of a preamplifier, an additional filter, and a mixer. The duplexer is optimized more for separating transmit and receive frequencies than extreme selectivity, but because of the typical low field strengths of incoming signals, it provides enough selectivity to guard the receiver path against overload and intermodulation products. The preamplifier is either a single transistor or a cascode arrangement with a filter following it. These high-band filters, mostly supplied by Murata, are typically surface acoustic wave (SAW) filters with very small dimensions. We would already like to point out in this part of the block diagram that these filters typically have high-impedance inputs and outputs (somewhere between 200 Ω and 1 kΩ), therefore eliminating the nice test-setup possibilities typically provided in a 50-Ω system. Generally, integrated circuit (IC)-type mixers also operate at high impedances, which makes matching easier. The filter following the mixer is responsible for reducing the image, and then we go to the intermediate frequency (IF) and demodulation. The particular chip or chips mentioned here, supplied by Philips, are set out for a double-conversion receiver, and the demodulation is accomplished with a quadrature detector for FM analog modulation. The rest of the circuitry on the horizontal path does digital signal processing (DSP) and overall control functions. The four blocks at the far right refer to the central processor, which handles such things as display, power management, and information storage (such as frequently used telephone numbers). A nice overview about DSP in "readable" form is given by Kostic [1].

The transmit portion consists of an independent synthesizer that is modulated. There are dual synthesizer chips available to accommodate this. Both receive and transmit frequencies are controlled by a miniature temperature-compensated crystal oscillator (TCXO). One of its outputs is also used as the system master clock for all the digital activities. The output of the voltage-controlled oscillator (VCO) is then amplified and fed to the antenna through the

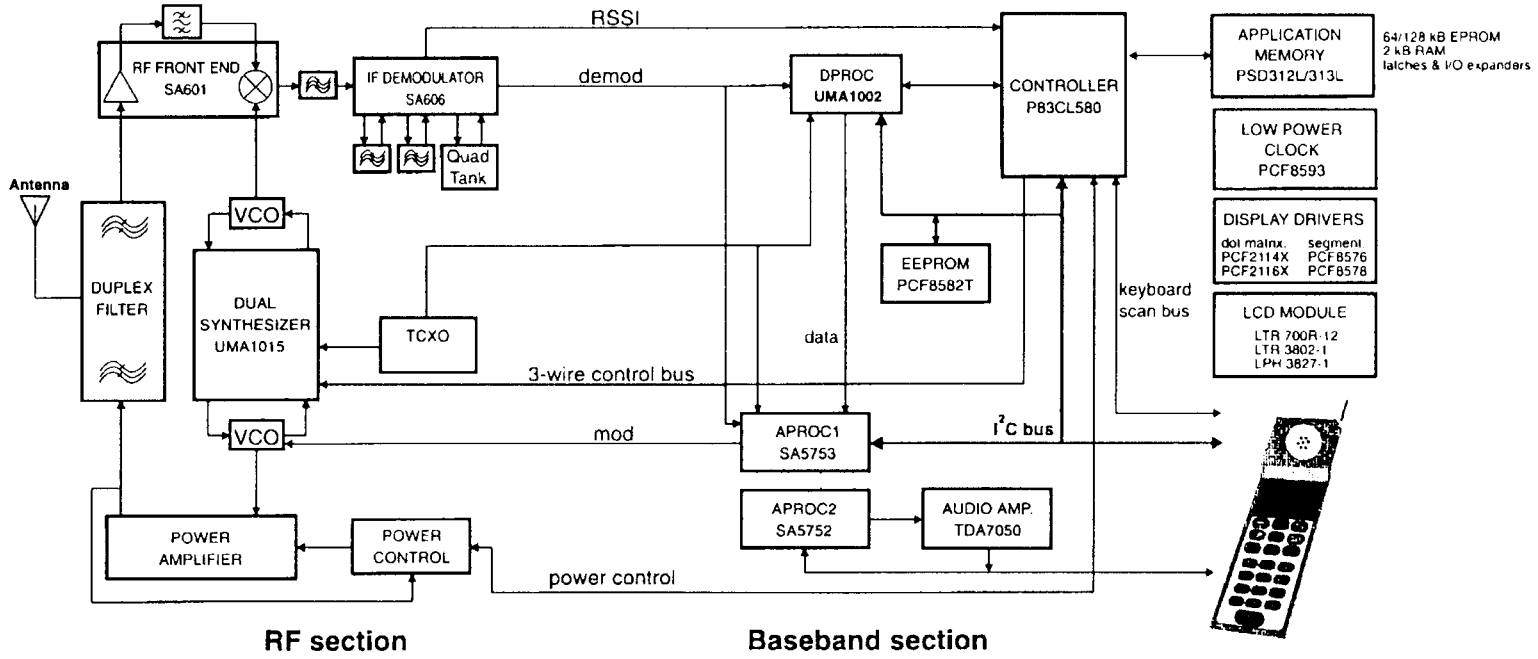

Figure 1-2 Block diagram of a handheld cellular telephone transceiver.

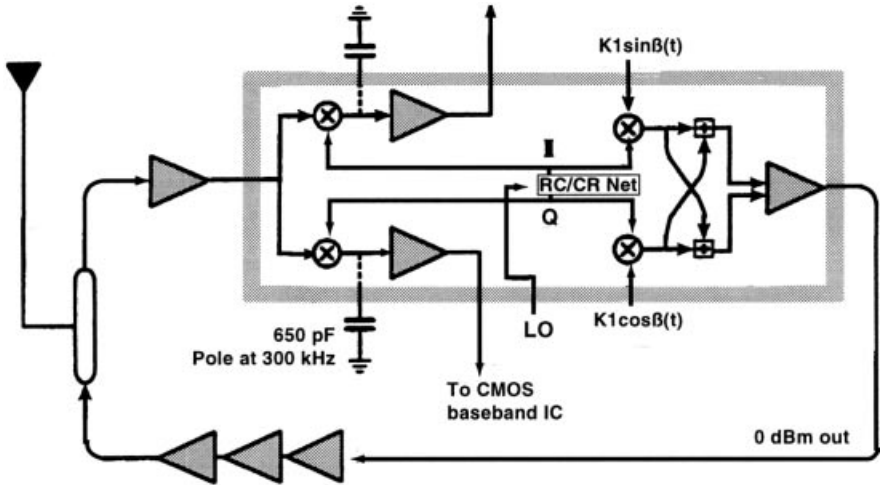

Figure 1-3 Single-chip direct-conversion transceiver by Alcatel. Channel selection is accomplished at baseband by low-pass switched-capacitor filters in a companion mixed-signal complementary metal-oxide semiconductor (CMOS) IC. A trimmed resistance-capacitance/capacitance-resistance (RC/CR) network generates the necessary quadrature signals for the chip's mixers.

same duplex filter as the receive portion. There are also schemes available for advanced modulation methods, specifically, code- , frequency-, and time-division multiple access (CDMA, FDMA, and TDMA, respectively). In these cases, the transmitter is not active all the time, and the duplexer can be replaced with a diode switch using a quarter-wavelength transmission line together with a PIN diode for the required switching.

Many modern devices use "zero IF" or direct conversion, which simplifies the IF or modulation portion of the unit significantly. Figure 1-3 shows an Alcatel single-chip direct-conversion transceiver. The signal is fed to an image-reject mixer with the local oscillator (LO) in quadrature, and the selectivity is obtained by manipulating the "audio bandwidth." Today we have a large number of implementations using different schemes that are beyond the scope of this book; therefore, we have decided to limit ourselves to a basic introduction because most of the relevant demodulation and coding are done in DSP, for which we will give appropriate references. A nice overview of different architectures is found in Razavi [2].

1-3 THE RADIO CHANNEL AND MODULATION REQUIREMENTS

1-3-1 Introduction

The transmission of information from a fixed station to a mobile is considerably influenced by the characteristics of the radio channel. The RF signal not only arrives at the receiving antenna on the direct path but is normally reflected by natural and artificial obstacles in its way. Consequently the signal arrives at the receiver several times in the form of echoes, which are superimposed on the direct signal (Figure 1-4). This superposition may be an advantage as the energy received in this case is greater than in single-path reception. This feature is made use of in the digital audio broadcasting (DAB) single-frequency network. However,

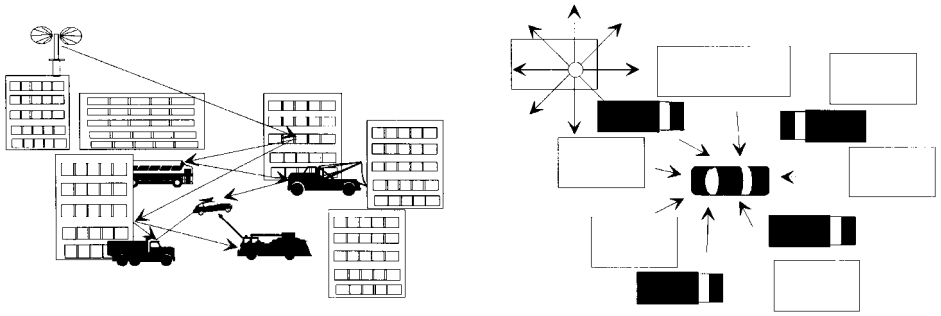

Figure 1-4 Mobile receiver affected by fading.

this characteristic may be a disadvantage when the different waves cancel each other under unfavorable phase conditions. In conventional car radio reception this effect is known as fading. It is particularly annoying when the vehicle stops in an area where the field strength is reduced because of fading (e.g., at traffic lights). Additional difficulties arise when digital signals are transmitted. If strong echo signals (compared to the directly received signal) arrive at the receiver with a delay on the order of a symbol period or more, time-adjacent symbols interfere with each other. In addition, the receive frequency may be falsified at high vehicle speeds because of the Doppler effect so that the receiver may have problems in estimating the instantaneous phase in the case of angle-modulated carriers. Both effects lead to a high symbol error rate even if the field strength is sufficiently high. Radio broadcasting systems using conventional frequency modulation are hardly affected by these interfering effects. If an analog system is replaced by a digital one that is expected to offer advantages over the previous system, it has to be ensured that these advantages—for example, better audiofrequency signal/noise (AF S/N) and the possibility of supplementary services for the subscriber—are not at the expense of reception in hilly terrain or at high vehicle speeds because of extreme fading.

For this reason a modulation method combined with suitable error protection has to be found for mobile reception in a typical radio channel, which is immune to fading, echo, and Doppler effects.

With a view to this, more detailed information on the radio channel is required. The channel can be described by means of a model. In the worst case, which may be the case for reception in built-up areas, it can be assumed that the mobile receives the signal on several indirect paths but not on a direct one. The signals are reflected, for example, by large buildings; the resulting signal delays are relatively long. In the vicinity of the receiver these paths are split up into a great number of subpaths; the delays of these signals are relatively short. These signals may again be reflected by buildings but also by other vehicles or natural obstacles like trees. Assuming the subpaths are statistically independent of each other, the superimposed signals at the antenna input cause considerable time- and position-dependent field-strength variations with an amplitude obeying the Rayleigh distribution (Figures 1-5 and 1-6).

If a direct path is received in addition, the distribution changes to the Rice distribution, and finally, when the direct path becomes dominant, the distribution follows the Gaussian distribution with the field strength of the direct path being used as the center value.

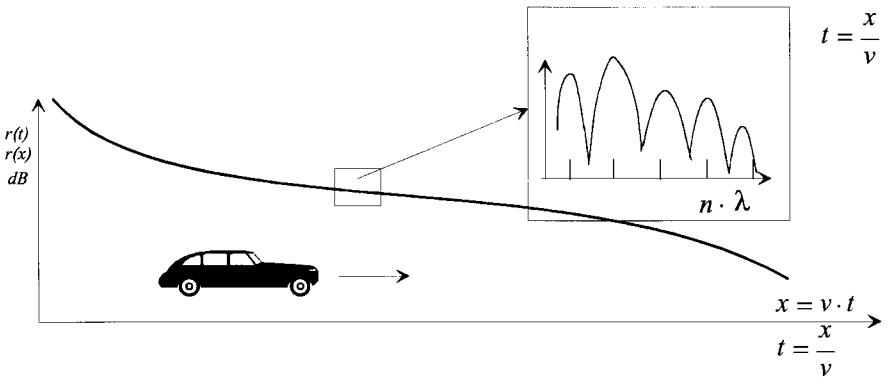

Figure 1-5 Receive signal as a function of time or position.

In a Rayleigh channel the bit error rate (BER) increases dramatically compared to the BER in an additive white Gaussian noise (AWGN) channel (Figure 1-7).

1-3-2 Channel Impulse Response

This scenario can be demonstrated by means of the channel impulse response. Let's assume that a very short pulse of extremely high amplitude [in the ideal case, a Dirac pulse $\delta(t)$] is sent by the transmitting antenna at a time $t_0 = 0$. This pulse arrives at the receiving antenna direct and in the form of reflections with different delays τ_i and different amplitudes because of path losses. The impulse response of the radio channel is the sum of all received pulses (Figure 1-8). Since the mobile receiver and also some of the reflecting objects are moving, the channel impulse response is a function of time and of delays τ_i; that is, it corresponds to

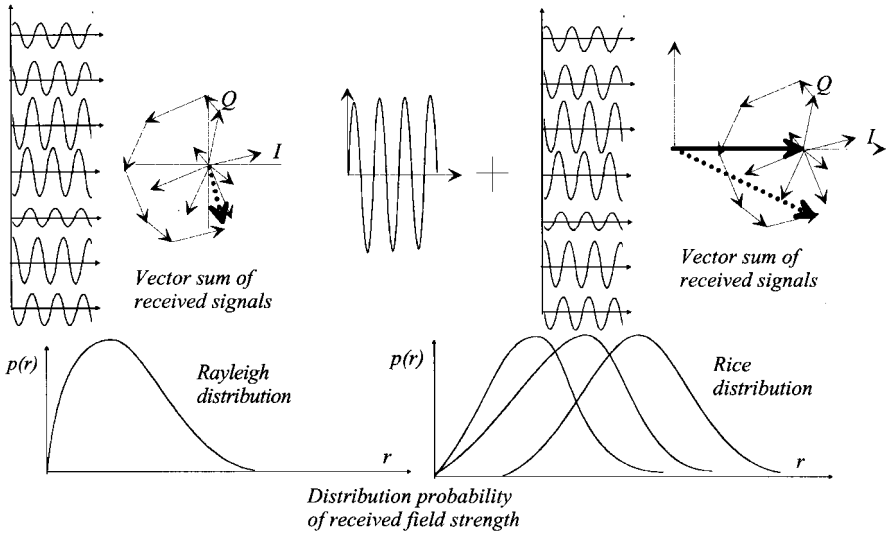

Figure 1-6 Rayleigh and Rice distributions.

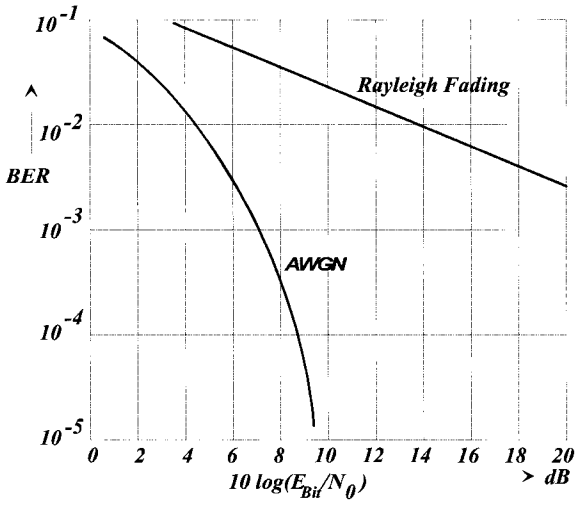

Figure 1-7 BER in a Rayleigh channel.

$$h(t,\tau) = \sum_{N} a_i \delta(t - \tau_i) \tag{1-1}$$

This shows that delta functions sent at different times t cause different reactions in the radio channel.

In many experimental investigations different landscape models with typical echo profiles were created. The most important are:

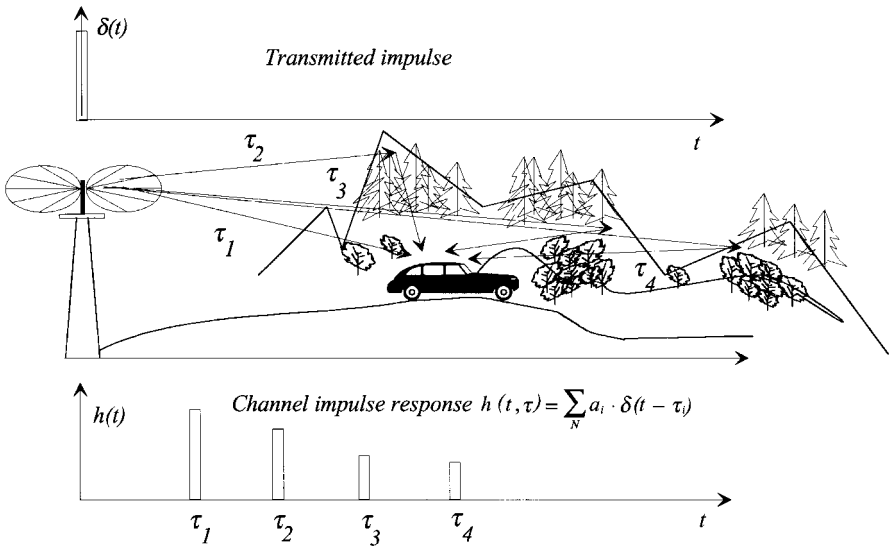

Figure 1-8 Channel impulse response.

- Rural area (RA)
- Typical urban area (TU)
- Bad urban area (BA)
- Hilly terrain (HT)

The channel impulse response informs on how the received power is distributed to the individual echoes. A parameter, the "delay spread," can be calculated from the channel impulse response, permitting an approximate description of typical landscape models (Figure 1-9).

The delay spread also roughly informs on the modulation parameters, carrier frequency, symbol period, and duration of guard interval, which have to be selected in relation to each other. If the receiver is located in an area with a high delay spread (e.g., in hilly terrain), echoes of the symbols sent at different times are superimposed when broadband modulation methods with a short symbol period are used. In the case of DAB, this problem is aggravated by the use of single-frequency networks. An adjacent transmitter emitting the same information on the same frequency has the effect of an artificial echo (Figure 1-10).

A constructive superposition of echoes is only possible if the symbol period is much greater than the delay spread. The following holds:

$$T_s > 10T_d \tag{1-2}$$

This has the consequence that relatively narrowband modulation methods have to be used. If this is not possible, channel equalizing is required.

For channel equalizing, a continuous estimation of the radio channel is necessary. The estimation is performed with the aid of a periodic transmission of data known to the receiver. In networks according to the Groupe Speciale Mobile (GSM) standards a midamble consisting of 26 bits—the training sequence—is transmitted with every burst. The training

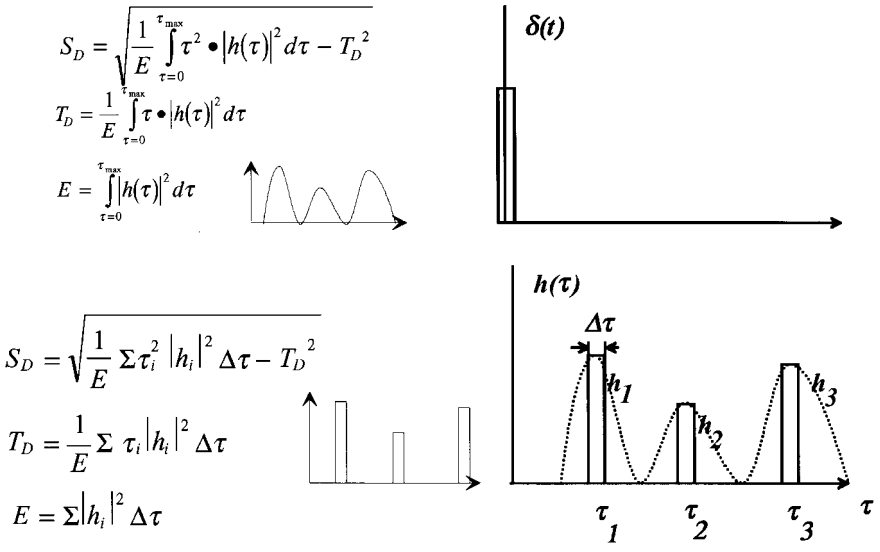

Figure 1-9 Calculation of delay spread.

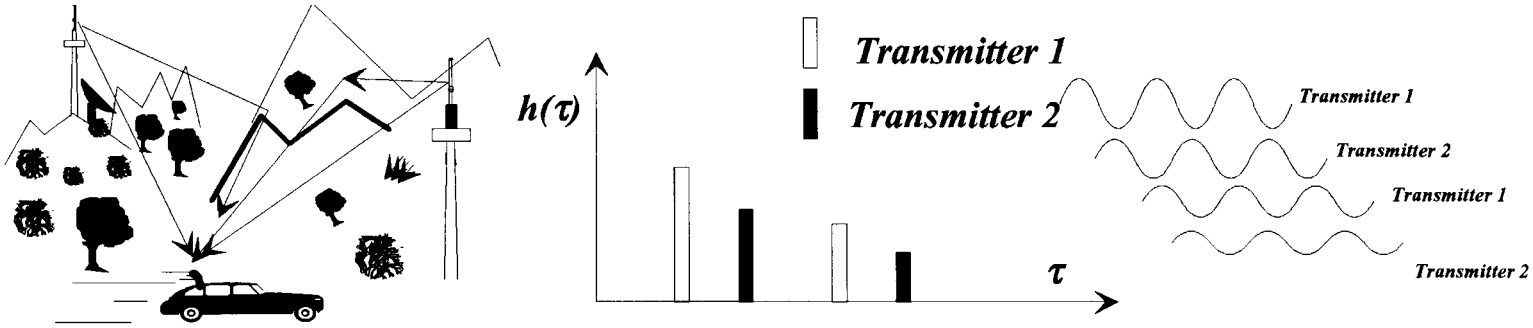

Figure 1-10 Artificial and natural echoes in the single-frequency network.

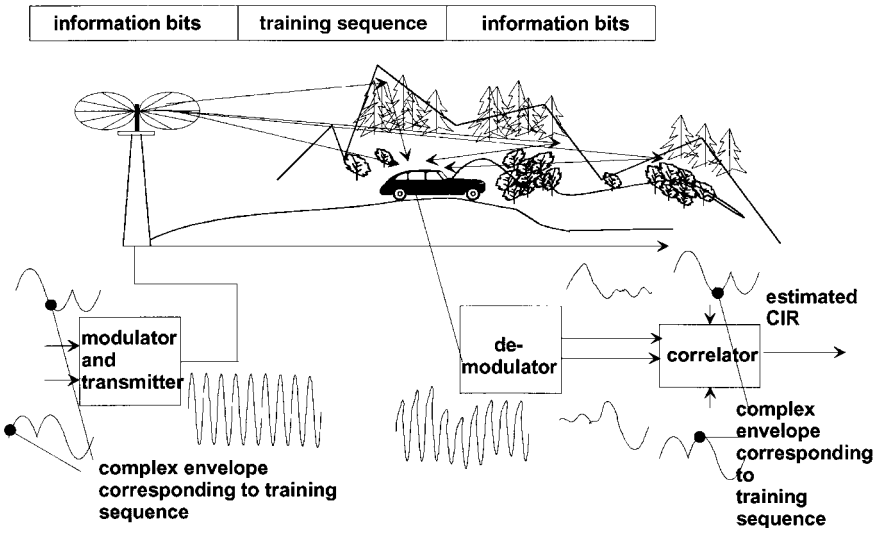

Figure 1-11 Channel estimation.

sequence corresponds to a characteristic pattern of I/Q signals that is kept in a memory in the receiver. The baseband signals of every received training sequence are correlated with the stored ones. From this correlation the channel can be estimated, and the properties of the estimated channel will then be fed to the equalizer (Figure 1-11).

The equalizer uses the Viterbi algorithm (maximum sequence likelihood estimation) for the estimation of the phases, which most likely have been sent at the sampling times. From these phases the information bits are calculated (Figure 1-12). A well-designed equalizer then will superimpose the energies of the single echoes constructively, so that the result in an area where the echoes are not too much delayed—delay times up to 16 μs have to be tolerated by a receiver—is better than in an area with no significant echoes (Figure 1-13).

Remaining bit errors are eliminated using another Viterbi decoder at the transmitter for the convolutionally encoded data sequences.

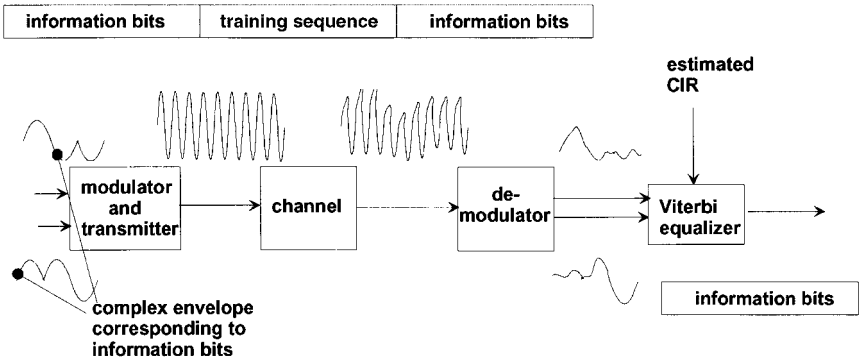

Figure 1-12 Channel equalization.

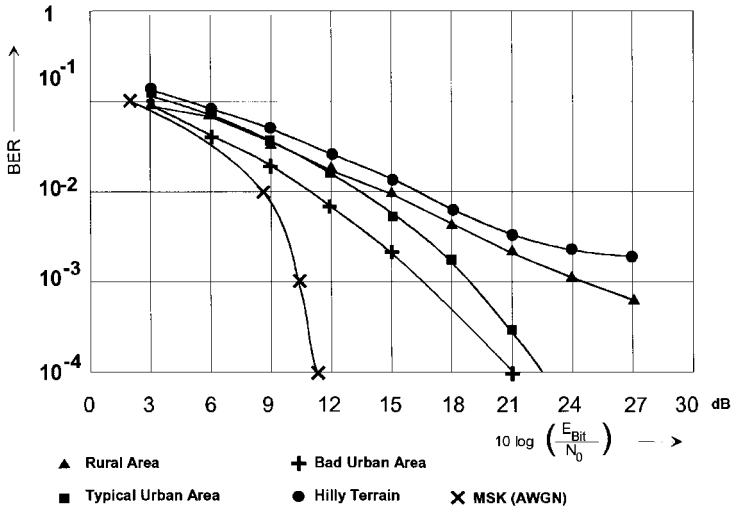

Figure 1-13 BERs after the channel equalizer in different areas.

The ability of a mobile receiver to work in a hostile environment, such as the radio channel with echoes, must be proved. The test is performed with the aid of a fading simulator. The fading simulator simulates different scenarios with different delay times and different Doppler profiles. A signal generator generates undistorted I/Q modulated RF signals, which are downconverted into the baseband. Here the I/Q signals are digitized and split into different channels, where they are delayed and attenuated, and where Doppler effects are superimposed. After combination of these distorted signals at the output of the baseband section of the simulator these signals modulate the RF carrier, which is the test signal for the receiver under test (Figure 1-14).

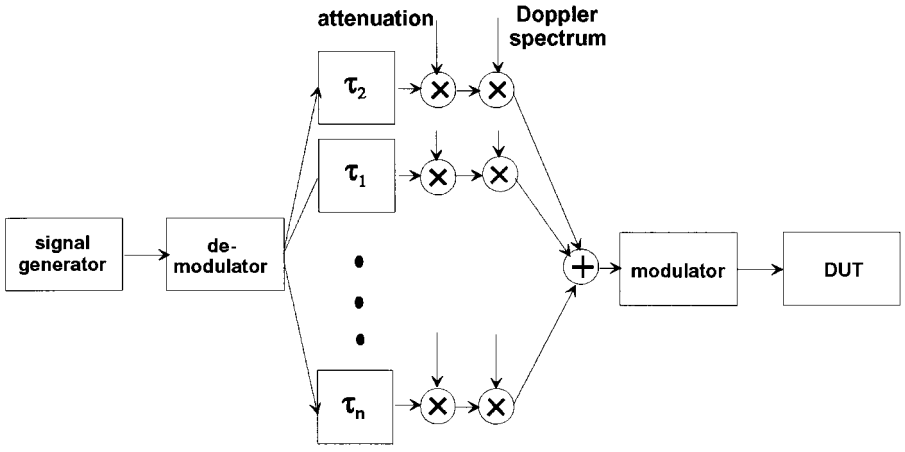

Figure 1-14 Fading simulator.

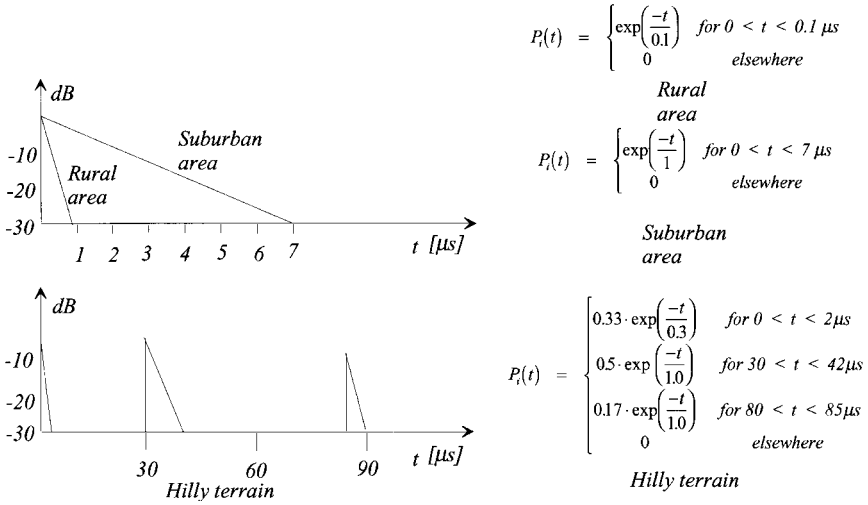

Figure 1-15 Typical landscape profiles.

To make the tests comparable, the Groupe Speciale Mobile (GSM) recommends typical profiles, for example,

- Rural area (RAx)
- Typical urban (TUx)
- Hilly terrain (HTx)

where number and strengths of the echoes and the Doppler spectra are prescribed (Figure 1-15).

1-3-3 Doppler Effect

Since the mobile receiver and some of the reflecting objects are in motion, the receive frequency is shifted because of the Doppler effect. In the case of single-path reception, this shift is calculated as follows:

$$f_d = \frac{v}{c} f_c \cos \alpha \tag{1-3}$$

where v = speed of vehicle
c = speed of light
f = carrier frequency
α = angle between v and the line connecting transmitter and receiver

In the case of multipath reception the signals on the individual paths arrive at the receiving antenna with different Doppler shifts because of the different angles α_i, and the receive spectrum is spread. Assuming an equal distribution of the angles of incidence, the power density spectrum can be calculated as follows:

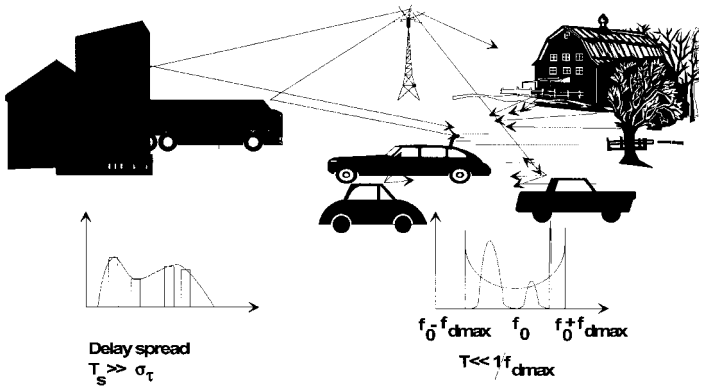

Figure 1-16 Doppler spread.

$$P(f) = \frac{1}{\pi} \frac{1}{\sqrt{f_d^2 - f^2}} \quad \text{for } |f| < |f_d| \tag{1-4}$$

where f_d = maximum Doppler frequency

Of course, other Doppler spectra are possible in addition to the pure Doppler shift described above: for example, spectra with a Gaussian distribution using one or several maxima. A Doppler spread can be calculated from the Doppler spectrum analogously to the delay spread (Figure 1-16).

1-3-4 Transfer Function

The fast Fourier transform (FFT) value of the channel impulse response is the transfer function $H(f, t)$ of the radio channel, which is also time dependent. The transfer function describes the attenuation of frequencies in the transmission channel. When examining the frequency dependence it will be evident that the influence of the transmission channel on two sine-wave signals of different frequencies becomes greater with increasing frequency difference. This behavior can adequately be described by the coherence bandwidth, which is approximately equal to the reciprocal delay spread; that is,

$$(\Delta f)_c = \frac{1}{T_d} \tag{1-5}$$

If the coherence bandwidth is sufficiently wide and, consequently, the associated delay spread is small, the channel is not frequency selective. This means that all frequencies are subject to the same fading. If the coherence bandwidth is narrow and the associated delay spread wide, even very close adjacent frequencies are attenuated differently by the channel. The effect on a broadband-modulated carrier with respect to the coherence bandwidth is obvious. The sidebands important for the transmitted information are attenuated to a different degree. The result is a considerable distortion of the receive signal combined with a high bit error rate even if the received field strength is high. This characteristic of the radio channel again speaks for the use of narrowband modulation methods (Figure 1-17).

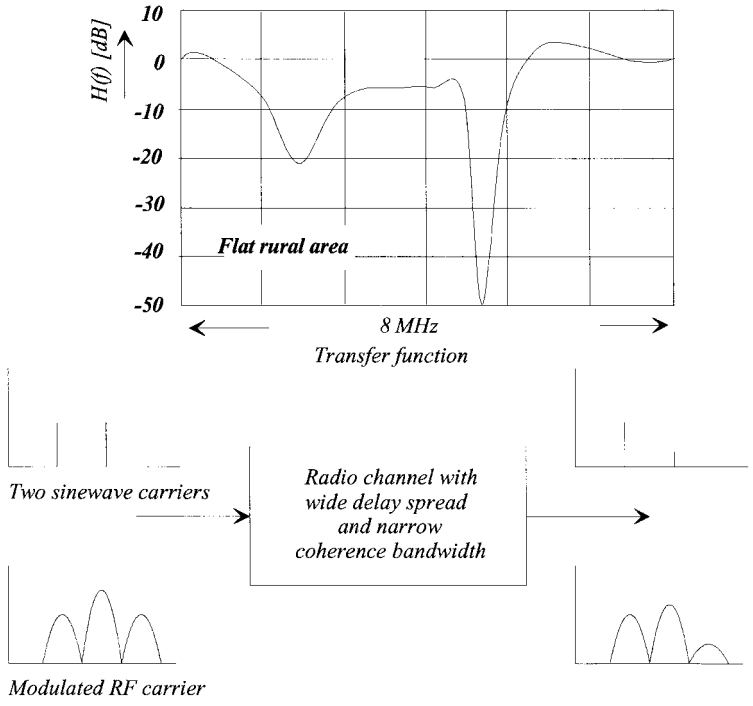

Figure 1-17 Effect of transfer function on modulated RF signals.

1-3-5 Time Response of Channel Impulse Response and Transfer Function

The time response of the radio channel can be derived from the Doppler spread. It is assumed that the channel rapidly varies at high vehicle speeds. The time variation of the radio channel can be described by a figure, the coherence time, which is analogous to the coherence bandwidth. This calculated value is the reciprocal bandwidth of the Doppler spectrum. A wide Doppler spectrum therefore indicates that the channel impulse response and the transfer function vary rapidly with time (Figure 1-18). If the Doppler spread is reduced to a single

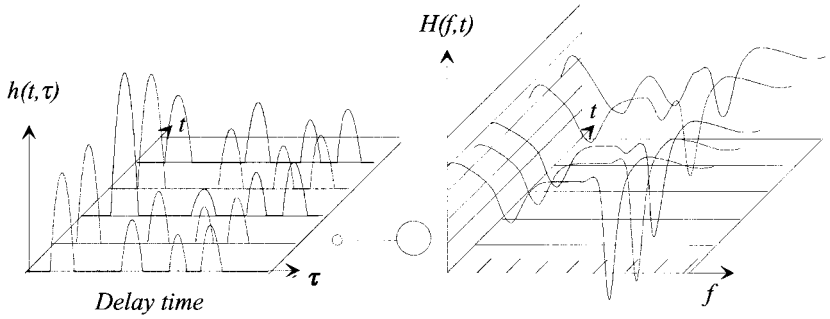

Figure 1-18 Channel impulse response and transfer function as a function of time.

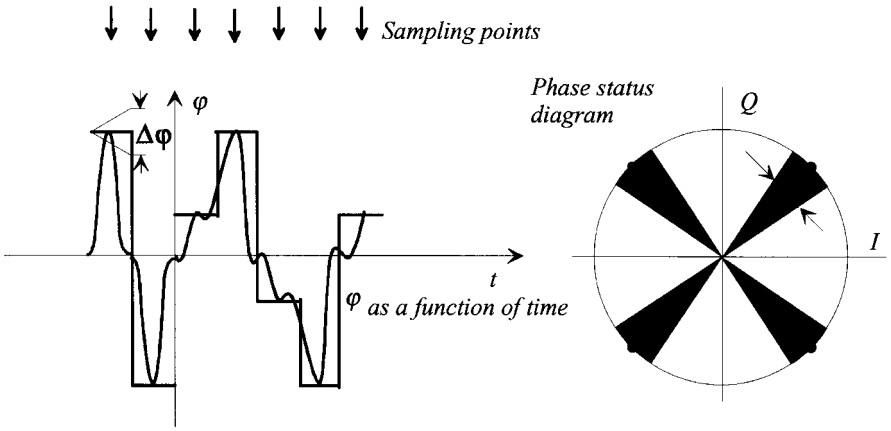

Figure 1-19 Phase uncertainty caused by Doppler effect.

line, the channel is time invariant. In other words, if the vehicle has stopped or moves at a constant speed in a terrain without reflecting objects, the channel impulse response and the transfer function measured at different times are the same.

The effect on information transmission will be illustrated in an example. In the case of *M*-ary phase shift keying (MPSK) modulation using hard keying, the transmitter holds the carrier phase for a certain period of time; that is, for the symbol period *T*. In the case of soft keying with low-pass-filtered baseband signals for limiting the modulated RF carrier, the nominal phase is reached at a specific time, the sampling time. In both cases the phase error $\varphi_f = f_d T_S$ is superimposed onto the nominal phase angle, which yields a phase uncertainty of $\Delta\varphi = 2\varphi_f$ at the receiver. The longer the symbol period the greater the angle deviation (Figure 1-19). Considering this characteristic of the transmission channel, a short symbol period of $T_S << (\Delta t)_c$ should be used. However, this requires broadband modulation methods.

Figure 1-20 shows the field strength or power arriving at the mobile receiver if the vehicle moves in a Rayleigh distribution channel. Since the phase depends on the vehicle position,

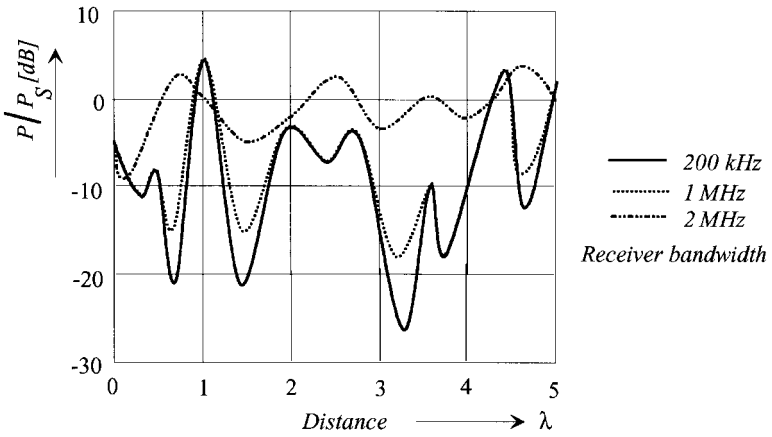

Figure 1-20 Effect of bandwidth on fading.

the receiver moves through positions of considerably differing field strength at different times (time dependence of radio channel). In the case of frequency-selective channels this applies to one frequency only; that is, to a receiver using a narrowband IF filter for narrowband emissions. As Figure 1-20 shows, this effect can be reduced by increasing the bandwidth of the emitted signal and consequently the receiver bandwidth.

1-3-6 Lessons Learned

The strongly frequency-selective channel causing inadmissible distortion of the broadband-modulated carrier and channel impulse responses like those expected in a hilly terrain speak in favor of narrowband modulation methods with long symbol periods. In hilly terrain extensively delayed echoes cause intersymbol interference when broadband modulation with short symbol periods is used. On the other hand, narrowband modulation has the disadvantage that the signals arrive at the receiver considerably attenuated and reception may be interrupted for an indefinite period of time. The burst errors occurring in digital information transmission cannot be corrected even with the most elaborate error protection methods.

These transmission interruptions can be avoided by using broadband modulation methods, but these are sensitive to strongly frequency-selective channels. Since broadband modulation is obtained through the use of short symbol periods, broadband modulation is unsuitable when greatly delayed echoes are expected.

It remains to be defined when a signal is considered a narrowband and when a broadband signal. This question shall be answered with the aid of an example. Apart from extremely narrowband analog modulation methods—as are used for sound broadcasting in the long-wave, mediumwave, and shortwave bands—FM sound broadcasting transmissions in the VHF bands are narrowband. In the case of digital modulation this means that transmissions with a rate of 400 kbps modulated onto a carrier with a bandwidth efficiency of 1.5 (bps)Hz over a bandwidth of approximately 300 kHz can be regarded as narrowband transmissions according to the definition above. Consequently, a DAB signal with this gross bit rate would be a narrowband signal and suitable for transmission on the radio channel with restrictions only. Based on the experience with conventional FM broadcasting systems in large cities and hilly terrain, this was obvious from the very beginning.

Consequently, it is necessary to find ways for spreading the band artificially without reducing the bandwidth efficiency. This means that a large band must be available for the transmission of several programs, the full bandwidth being used by all the programs without mutual interference.

Several approaches can be adopted to tackle the problem (Figure 1-21). One way would be a continuous change of the transmit and receive frequency according to a defined pattern (frequency hopping). This method is used in mobile radio, for instance, but only marginal investigations have been made in this respect for DAB.

Another possibility is to multiply the symbols of the individual programs with digital signals (pseudo-noise function) using a much higher bit rate so that a higher symbol rate is obtained. In this case the different programs are assigned different functions, which must be orthogonal to each other (code-division multiple access, CDMA). The “chopped” bit streams of the individual programs are modulated onto carriers of identical frequency and the modulated carriers are added. A correlation receiver knowing the pseudo-noise function divides the incoming CDMA signal into the individual programs. The disadvantage is obvious. Symbol periods are very short and elaborate means will be required for compensating the intersymbol interference.

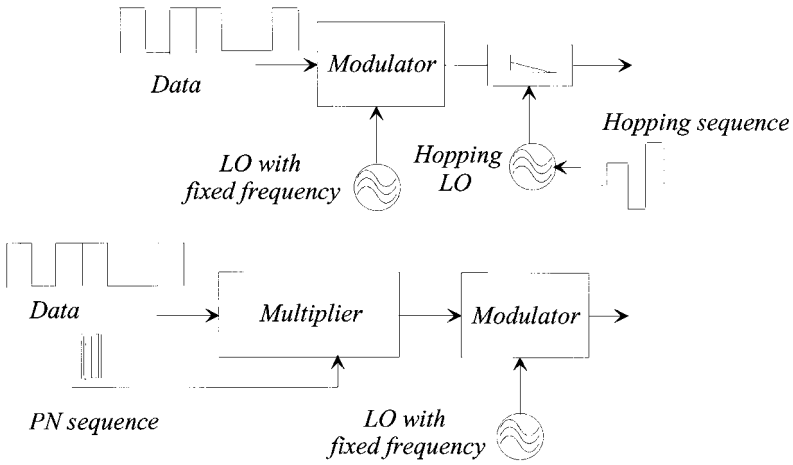

Figure 1-21 Band spreading by frequency hopping and CDMA.

A different approach has been chosen for DAB, which does not involve continuous and elaborate channel measurements, so that it would be possible to use favorably priced receivers as are demanded in the field of consumer electronics. The method used for DAB is a multicarrier method, where the information to be transmitted is spread onto many carriers using time and frequency interleaving. The terms time and frequency interleaving will be explained in the course of this discussion. The result is a broadband transmission method with long symbol periods. However, certain limitations caused by the Doppler effect will have to be accepted particularly at high carrier frequencies.

1-3-7 Wireless Signal Example: The TDMA System in GSM

Frequency-Division Multiple Access (FDMA). In analog radio systems the trend has always been toward a more efficient utilization of the available frequency spectrum by reducing the channel spacing. The number of radio channels obtained at a channel spacing of 12.5 kHz is of course twice that obtained at 25 kHz. However, any improvement brings about its disadvantage: the narrower the channel spacing, the higher the required frequency accuracy and the lower the possible maximum deviation of the frequency modulation. The latter leads to a poorer transmission quality due to the lower S/N ratio. Furthermore, the gaps between the channels, which must be a number of kilohertz wide for safety reasons, also reduce the available system bandwidth (see Figures 1-22 and 1-23).

The use of an available system spectrum divided into individual frequency channels enables the user to simultaneously access a multitude of different frequencies. This multiple access is called *frequency-division multiple access* (FDMA). Consequently, all radio systems with a spectrum divided into channels are FDMA systems. At present, the technically useful limit is reached with a channel spacing of 10–12.5 kHz.

Advantages of FDMA

- Simultaneous access to a given bandwidth by many subscribers
- Increase in the number of channels through reduction of channel spacing

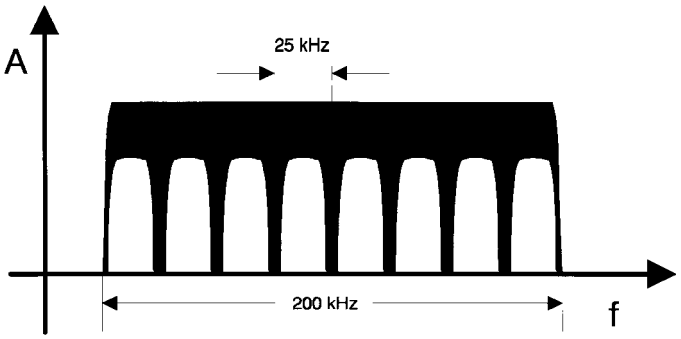

Figure 1-22 Channel spacing in broadband/narrowband systems.

Disadvantages of FDMA

- Higher frequency accuracy required
- Transmission quality decreasing with reduction of channel bandwidth
- Better rejection filters required
- One transmitter/receiver required per channel

Time-Division Multiple Access (TDMA). With TDMA systems, the available bandwidth is divided into considerably fewer, and therefore wider, channels than in FDMA systems. Each of these channels is available to several subscribers quasi-simultaneously. (See Figure 1-24.) However, a given subscriber can use the whole channel for a very short period (timeslot) only; for the rest of the time, no access is available. This serial access of several users is repeated within a fixed time frame.

Advantages of TDMA

- Simultaneous use of a specific bandwidth by a great number of subscribers
- Depending on the number of available timeslots, several subscribers can be served by one transmitter/receiver

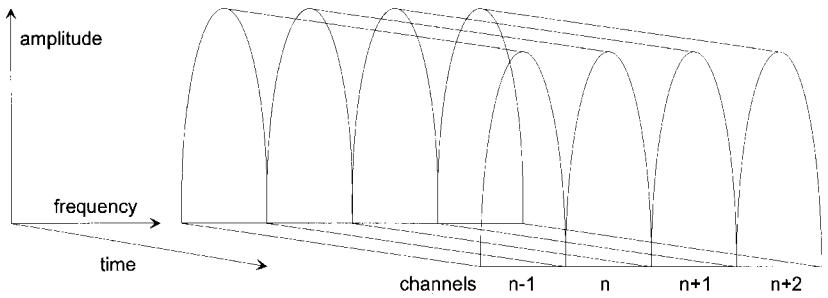

Figure 1-23 Frequency-division multiple access (FDMA).

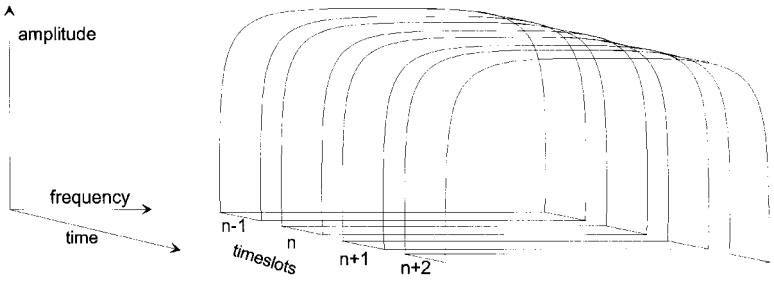

Figure 1-24 Time-division multiple access (TDMA).

- Transmitter and receiver are not permanently switched on (saves battery power)
- The RF section may carry out other tasks in the intervals between transmission and reception
- Reduced susceptibility to frequency-selective fading in the case of larger channel bandwidths

Disadvantages of TDMA

- Accurate time synchronization of subscribers required
- Higher processor capacity required
- Broadband modulators required

Code-Division Multiple Access (CDMA). The increasing use of low-priced and powerful signal processors allows a less common technique of multiple access to be employed in mass communication systems. In the case of *code-division multiple access* (CDMA), the whole system bandwidth is available to all subscribers at any time; that is, all send and receive simultaneously, with each using a specific code (Figure 1-25).

Logic "1" represents a certain bit sequence; logic "0" is the inversion of this sequence. The different signals are distinguished in the receiver by means of a cross-correlation of the received signal, which comprises a great number of codes, with the bit sequence expected so that the desired transmission signal can be detected.

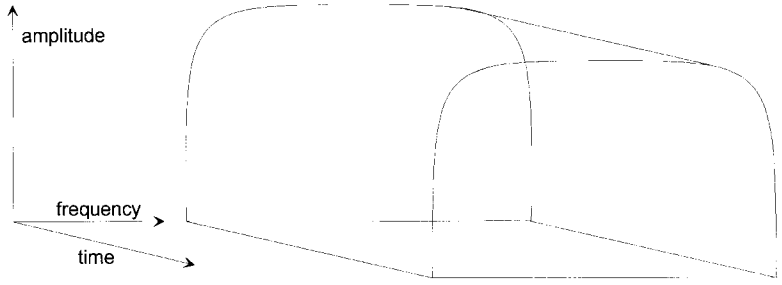

Figure 1-25 Code-division multiple access (CDMA).

Advantages of CDMA

- Simultaneous use of a specific channel or subband by many subscribers
- Several signals can be received simultaneously by one receiver
- Reduced susceptibility to frequency-selective fading in the case of large channel bandwidths
- More subscribers can be served
- Reduced costs for radio network planning

Disadvantages of CDMA

- Accurate time synchronization of subscribers required
- Fast transmitter power control over a wide dynamic range
- No experience with use in mass communication

TDMA in GSM

RF Data. In spite of the competition with other mobile radio systems, a common frequency band could be defined for GSM worldwide. All operators who signed the GSM memorandum of understanding committed themselves to install their GSM systems within the standardized frequency range. The competition for frequencies mainly affects countries using NMT900, the frequency range of which corresponds to the GSM P band. TACS also partly overlaps the GSM P band; the G1 band is completely within the TACS range. Cordless telephones operating in accordance with the CT1 standard also use the upper end of the GSM P band. CT1+ telephones, which had been assigned a frequency range below the P band years ago to protect them against GSM, have now been ousted by the G1 band. See Table 1-1.

Table 1-1 RF data for GSM900 and GSM1800

Variable	GSM900		GSM1800
Frequency range	P band	G1 band	
Uplink (MHz)			
(MS transmitting)	890–915	880–890	1710–1785
Downlink (MHz)			
(BTS transmitting)	935–960	925–935	1805–1880
Duplex spacing (MHz)	45	45	95
Spectrum (MHz)	2×25	2×10	2×75
Frequency channels	124	49	374
Channel numbers (ARFCN)	1–124	975–1023	512–885
Channel spacing	200 kHz		
Modulation	GMSK with BxT = 0.3		
Data transmission rate	270.833 kbps		
Bit duration	3.69 µs		

Since each frequency channel is divided into eight timeslots, transmitter and receiver operate in an intermittent mode, with the receive and transmit time in the upper and lower channels shifted by three timeslots (Figure 1-26). Although this alternative sending and receiving scheme operates in half-duplex rather than full-duplex operation, the received signal sounds continuous to the user.

TDMA Structure

FRAME AND MULTIFRAME. All GSM radio channels are organized in frames of approximately 4.62-ms duration. The frames are continuously repeated. Each frame is divided into 8 timeslots of approximately 577 μs each. A timeslot contains an information packet, the burst. The 26-type multiframes are used on all timeslots containing a traffic channel (voice and/or data); the 51-type multiframes on all timeslots are reserved for control channels. See Figure 1-27.

The TDMA structure uses other frame types above the multiframe level, as shown in Table 1-2.

TDMA TIMERS. The frame number within the hyperframe is counted continually so that counting of the TDMA clock restarts after approximately 3.5 hours. The frame number therefore represents a time unit in the GSM system. Similar to time counting, where the seconds are combined into minutes, hours, and days, GSM does not count the absolute frame numbers but uses timers instead. These timers are structured as shown in Table 1-3.

The absolute frame number is obtained by a multiplication of the three timers. However, on certain occasions a short version of the timers is used.

Burst Structures. Information between base station and mobile is sent in the timeslots. In each slot a certain amount of information—that is, a burst—can be transmitted. Normally the timeslot is occupied by the normal burst (Figure 1-28), which is used for signaling as well as for voice and data transmission.

Each part of the burst serves a specific purpose as described below.

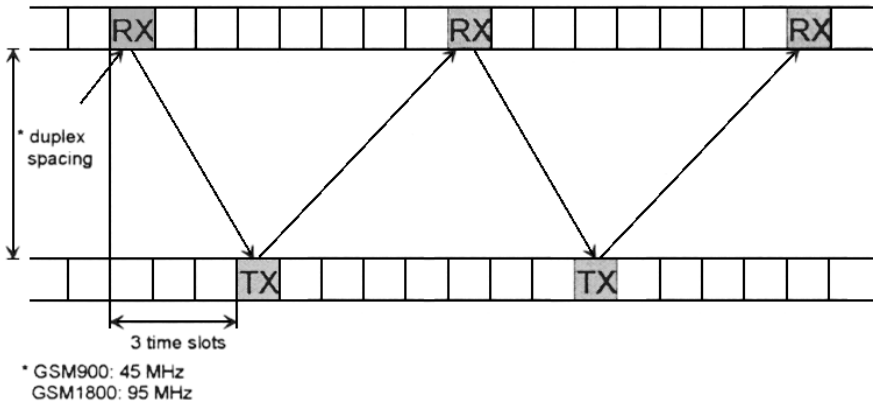

Figure 1-26 Duplex spacing of transmission and reception.

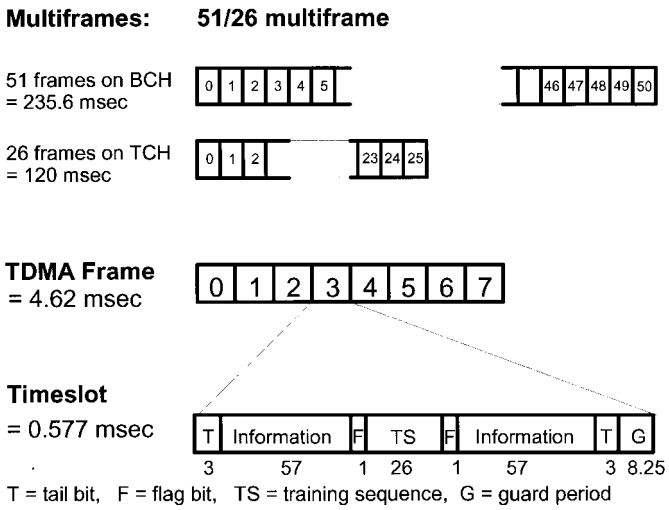

Figure 1-27 Timeslot, frame, and multiframe.

Information Bits. The normal burst is able to transmit 2×57 information bits. Since this information can be replaced every 4.62 ms during an ongoing call, the average theoretical transmission rate is

$$114 \text{ bits} \div 4.62 \text{ ms} \approx 24.7 \text{ kbps} \tag{1-6}$$

At the same time, this rate also represents the maximum transmission rate that can be obtained in the GSM system using one timeslot per transmission per time frame. Consequently, the transmission rate could be increased only if more than one timeslot is used for the transmission.

The bit rate is much lower in the control channels; that is, the above transmission rate is only attained by the mobile station if a traffic channel has been set up. In this case, the base station and the mobile station use a signaling channel, which also uses up capacity, in addition to the voice or data channel. Table 1-4 shows the assignment of the theoretically available capacity with a traffic channel setup.

Table 1-2 Superframes and hyperframes

Superframe	= 51 × 26 frames
	= 1326 frames
	= 6.12 s
Hyperframe	= 2048 frames
	= 2.715.648 frames
	= 3 h, 29 min, 3.5 s

T2:	= FN mod 26	Range:	0–25
T3:	= FN mod 51	Range:	0–50
FN (Frame Number)		Range:	0 2715647
FN_{max}	$= 51 \times 26 \times 2048 - 1$		

Training Sequence. In the middle of the normal burst, a 26-bit training sequence, the bit sequence of which is known to the receiver, is sent. The *training-sequence code* (TSC) can be one of eight different sequences. These sequences are stored in all receivers, and at the beginning of a transmission, the base transceiver station (BTS) decides on the TSC to be used. The training sequence serves two main purposes: bit synchronization and estimation of channel impulse response.

BIT SYNCHRONIZATION. Data transmitted via the air interface are in the asynchronous mode; that is, the receiver has to regenerate the bit clock from the data stream. To enable synchronization in the receiver, the transmitter adds synchronization bits to the information stream. Therefore, in normal data transmission, data telegrams start with a "...10101010..." sequence so that the receiver can regenerate the bit clock. A predefined bit word informs the receiver when the actual information (block synchronization) starts. A receiver synchronized in this way is able to decode the data stream online. The training sequence of the burst has to assume both synchronization tasks. Since it is in the middle of the burst, direct decoding is not possible.

Each burst must first be stored in the receiver and then decoded by postprocessing. The reason for using this method is the second task of the training sequence. Synchronization itself is carried out by means of cross-correlation; that is, the expected training sequence is compared (correlated) to the center of the received burst and to the beginning and end of the training sequence so that the bit clock is also known. A burst containing other than the expected training sequence cannot be synchronized and decoded.

COMPENSATION OF MULTIPATH RECEPTION. The signal from the transmitter (in Figure 1-29, BTS → MS; the same applies also in the opposite direction) arrives at the receiver not only along the direct path but also via various other paths as a result of reflection and diffraction caused by obstacles in the signal path.

Propagation conditions on these additional paths differ from those on the direct path. For instance, we can expect signals traveling via additional paths to exhibit:

- Longer travel times because of increased path length

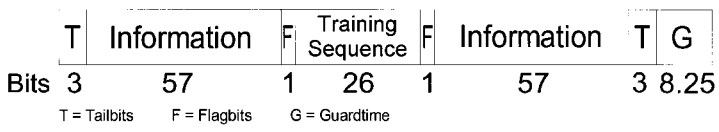

Figure 1-28 Normal burst.

Table 1-4 Transmission bit rates

	Information	Error Protection	Total
Traffic channel			22.8 kbps
Voice (full rate)	13.0 kbps	9.8 kbps	
Data	2.4 kbps	20.4 kbps	
	4.8 kbps	18.0 kbps	
	9.6 kbps	13.2 kbps	
Control channels			0.95 kbps
Idle frame			0.95 kbps
Total			**24.7 kbps**

- Various strengths
- Different Doppler shifts

Because of the different travel times, the signals arrive with a different phase at the receiving antenna. Depending on this phase, components may be canceled—that is, they may totally disappear—or added so that a high-quality signal is received for only a short period of time. RF level variations are statistically distributed; level shifts due to fading may be as great as 40 dB.

In addition to RF level fading, another annoying effect is encountered that, uncompensated, would make correct signal decoding rather difficult. Because of the additional distance the signal travels via the indirect path, the signal arriving at the receiving antenna exhibits time delay of its modulation in addition to variable phase shifts. The total of all channel responses to a single transmitted pulse is called *channel impulse response* (CIR, Figure 1-30). If the indirect path is only 1 kilometer longer, the GSM echo bit reaches the receiver later than the directly received bit and thus interferes with the next bit received. This *intersymbol interference* (ISI) may occur over several bits in succession. With delays of up to 15 µs,

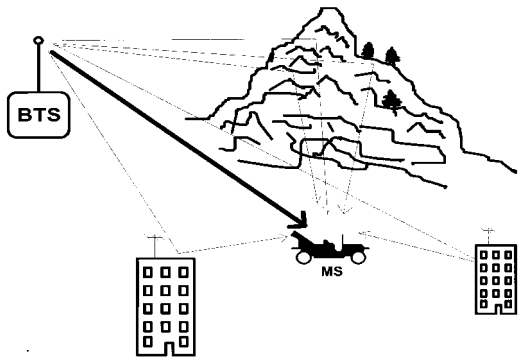

Figure 1-29 Multipath reception due to reflection and diffraction. The *base transceiver station* (BTS) is transmitting to the *mobile station* (MS).

differentiating the desired-signal components from echoes becomes more and more difficult. This problem can also be solved with the aid of the training sequence. The echoes on the delayed paths also contain the training sequence. The correlation used for detecting the original training sequence may also be used for detecting the training-sequence echoes as well as their delay and loss. With the aid of this information, the received signal can be corrected by a channel equalizer.

Guard Period. Transmission in each timeslot is terminated with a guard period (Figure 1-31) of 8.25 bit periods (≈ 30 μs). During this time the level of the burst must be reduced from nominal to a minimum value (by up to 70 dB) and the burst is modulated with so-called dummy bits (logic 1); that is, no information is transmitted. The user of the next timeslot should start sending during this guard period so that his burst has reached nominal power when the actual transmission in the timeslot starts. This means that the switching time that cannot be used for transmitting information is used twice.

Delay Correction. The integrity of a timeslot depends on whether the subscribers send only during the period assigned to them and otherwise keep quiet. This is only possible when all subscribers are accurately synchronized. For practical reasons, the clock signal is generated by the BTS and the mobile stations synchronize to it. Conflicts with adjacent timeslots may occur in the uplink where several subscribers have to share the same channel. Although several subscribers are addressed in the downlink, signals can only be transmitted by the BTS.

We will now examine the effect of a distance of 10 km between an MS and a BTS (Figure 1-32). Synchronization of the MS is as follows:

Delay over 10 km = 33.3 μs (distance ÷ velocity of light).
The sync signals from the BTS require this time for transmission.
→ MS is synchronized by 33.3 μs too late.

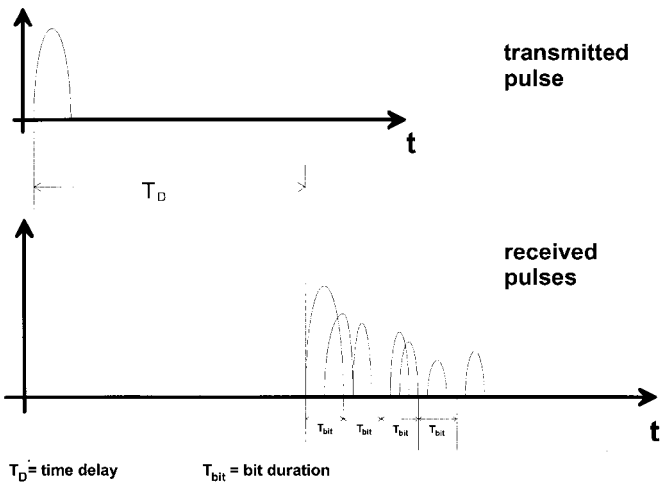

Figure 1-30 Channel impulse response.

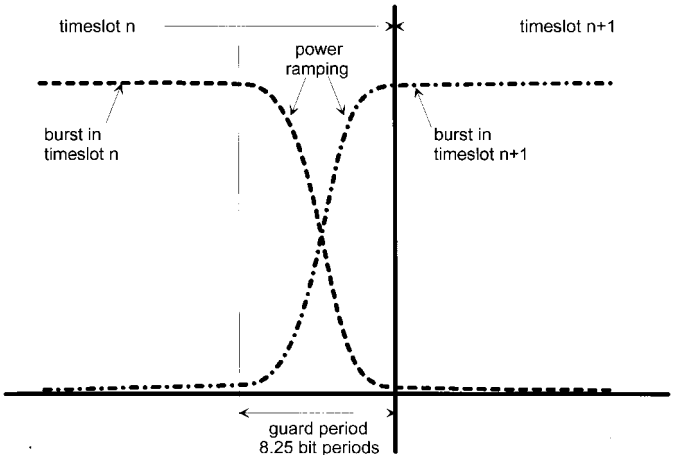

Figure 1-31 Guard period at the end of each timeslot.

MS sends a burst at the correct time from its point of view.
→ The burst is sent 33.3 µs too late.
Signal delay over a distance of 10 km → the burst requires another 33.3 µs. From the point of view of the BTS, the burst arrives with a delay of twice the delay time. Transmission cannot be made in the assigned timeslot and interferes with the next one.

The guard period at the end of each burst is only approximately 30 µs long and fully used in the example above. The greater the distance between the MS and BTS, the greater the effect of the signal delay. The only way to solve this problem is to make the MS send the burst at an earlier time. To do so, the distance between the MS and BTS must be known. The BTS determines the distance by means of a delay measurement and informs the MS of the actual delay. As a result, the MS corrects its transmission time so that the signals again arrive time-synchronized with the other mobiles at the BTS antenna.

In GSM, this procedure is called *timing advance* (TA) and is carried out continuously for all active mobile stations. Every 480 ms, a new TA value is sent to all active mobiles. A few limiting values of the GSM system can be deduced from the TA:

1. The TA is transmitted as a 6-bit word. Numerals from 0 to 63 can be represented with 6 bits. For instance, a TA of 10 means that for an MS from which bursts arrive with

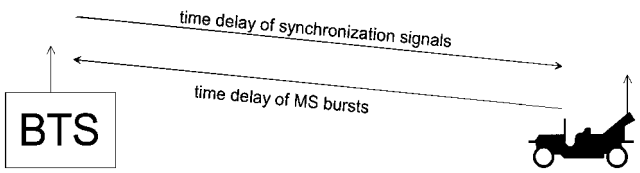

Figure 1-32 Signal delay and its effect.

a delay of 10 bit periods, transmission must be advanced by this amount. Since the TA is transmitted as an absolute value, a maximum delay of 232.5 μs (63 × 3.69 μs) can be signaled and corrected. This maximum double delay corresponds to a distance of approximately 34.9 km.

2. With the aid of the TA, the distance between the MS and the BTS can be determined. Since the smallest delay increment is a bit period, the resolution for a distance of one half of the delay corresponds to one bit period and therefore to approximately 550 m.

This synchronization scheme cannot solve an inherent problem: The delay of *the very first burst* sent by an MS cannot be corrected because, with contact between the MS and BTS yet to be established, the MS has not yet received an appropriate TA value from the BTS. Yet, if the mobile sends a normally timed burst, it may spill over into the next timeslot and interfere with transmission from another MS. To avoid causing interference in such cases, the mobile uses a special burst at the beginning of a transmission or when no valid TA has been received. Called the *access burst*, it is considerably shorter than a normal burst. The next section describes the access burst and other additional burst types in greater detail.

Burst Types. In addition to the normal burst described before, other bursts, including the access burst, are available for special purposes (Figure 1-33).

FREQUENCY CORRECTION BURST. The 142 "fixed bits" of the *frequency correction burst* (FCB) are all set to logic 0. With Gaussian minimum shift keying (GMSK), the type of modulation used in GSM, a stationary carrier frequency deviation, in this case approximately 67.7 kHz, is generated with this burst. The FCB is sent by the BTS only and used by the mobile for synchronization to the carrier frequency and for compensating a possible Doppler shift. It is sent by the BTS every 10 frames (approximately every 46 ms), but only in the timeslot 0 and only on a single (the C0) carrier.

SYNCHRONIZATION BURST. One frame after the frequency correction burst, but also in timeslot 0, the synchronization burst (SB) is transmitted. This burst is sent only by the BTS, and only on the C0 carrier. A particular difference between it and the normal burst is its considerably longer training sequence. Like the 26-bit training sequence of a normal burst, the SB's training sequence is also used for bit synchronization. Due to the great length of the sequence, synchronization can be more exact.

The twice 39 encrypted bits comprise timers T1, T2, and T3 in a coded form, and also the *base-station identification code* (BSIC). When this "GSM time" is received, the MS is synchronized to the BTS.

DUMMY BURST. A BTS must send continuously—that is, in all timeslots—on its C0 carrier because this carrier is used by the MS to find the nearest BTS and for evaluating reception quality. If no normal burst is available for transmission in a timeslot, the BTS sends dummy bursts instead, as the carrier cannot be transmitted without a modulation signal. Only the BTS sends dummy bursts, and only on the C0 carrier.

ACCESS BURST. As already pointed out, the access burst is sent when the MS first calls the BTS as a means of minimizing interference to other mobile transmitters (MTs) while initiating a delay measurement and the determination of the TA. In most cases, the access

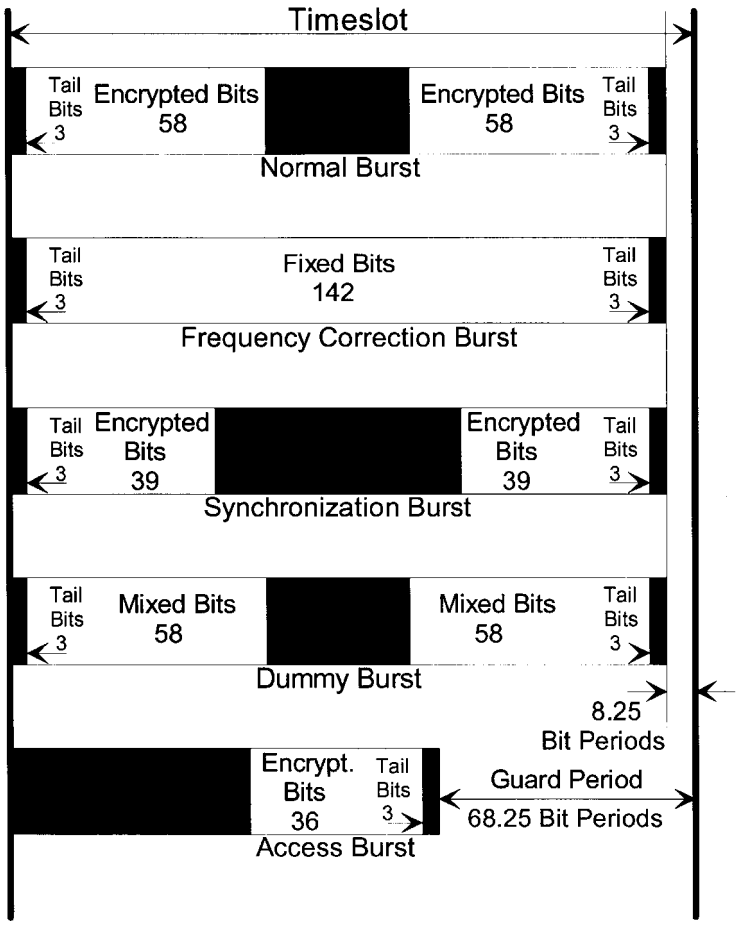

Figure 1-33 Burst types.

burst is also sent on the C0 carrier in the uplink direction, but in the case of a handover it may be transmitted on any carrier.

1-4 ABOUT BITS, SYMBOLS, AND WAVEFORMS

1-4-1 Introduction

Digital modulation of an RF carrier is the allocation of physically existing RF waveforms to the single elements of an alphabet of logical symbols where the number of allowed waveforms is equal to the number of logical elements of the alphabet (Figure 1-34). The most common alphabet is the binary one with the two logical symbols "0" and "1," but we will also deal with quaternary, octernary, and hexadecimal alphabets or more generally with *M*-ary alphabets comprising many more elements when discussing the signal generation with

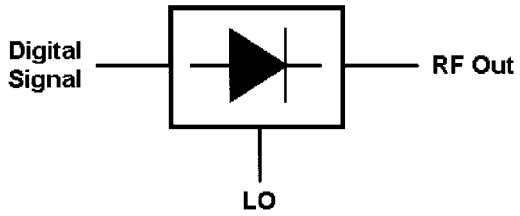

Figure 1-34 At base, digital modulation involves frequency shifting a baseband digital signal to RF. In practice, the process is more complicated than this because of bandwidth constraints on the resulting RF signal.

signal generators and dedicated software packages. The waveforms representing these symbols differ from each other by their parameter's amplitude $a(t)$, their frequency $f(t)$, and their phase $\varphi(t)$.

A modulator therefore is nothing more than a device by which this allocation is performed (Figure 1-35). From a coder it receives the logical symbols and emits at its output the corresponding waveforms $s_i(t)$. The waveform generation may be done by using a set of distinct generators (e.g., two oscillators to generate two signals with different frequencies in the case of binary frequency shift keying), by classical amplitude or frequency modulators, or by more sophisticated equipment such as I/Q modulators for M-ary modulations.

On their way across the RF channel from the transmitter to the receiver, these waveforms are distorted by noise and other disturbing properties of the RF channel.

The task of the receiver is to interpret the received waveforms $r_i(t)$ and to reallocate the proper logical symbols to them. For this purpose it is not necessary to reconstruct the original waveforms from the distorted ones (Figure 1-36). The important thing is to find out which

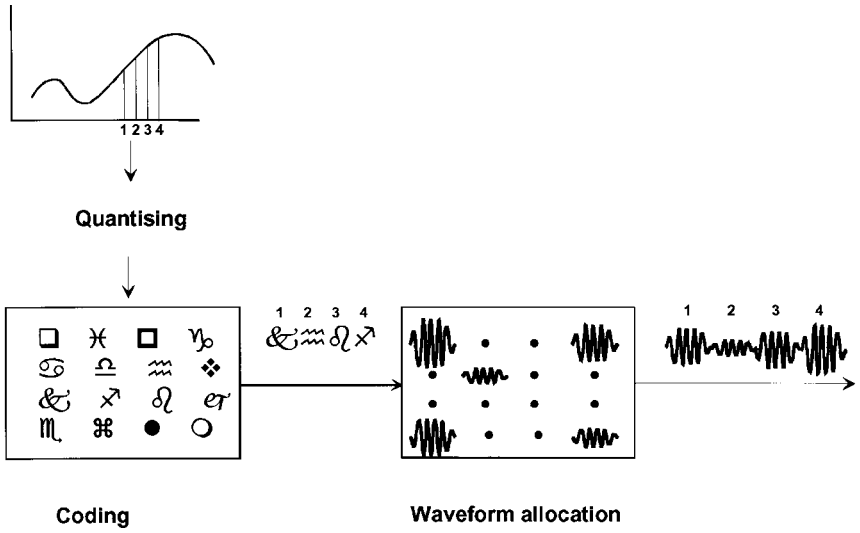

Figure 1-35 Digital modulator.

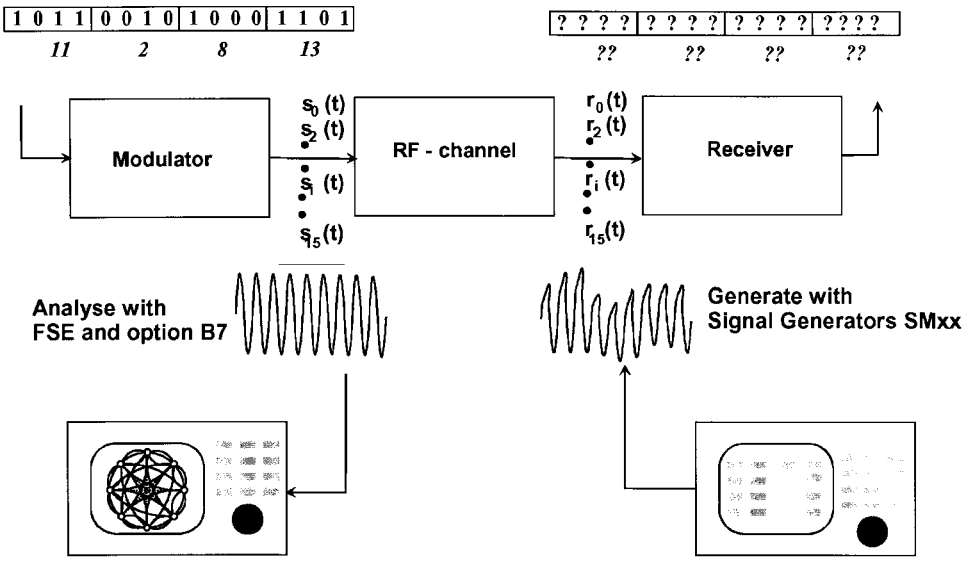

Figure 1-36 The information channel.

symbol has most probably been sent when a certain signal $r_i(t)$ has been received, a process that is known as maximum likelihood estimation.

For meaningful receiver tests, therefore, waveforms have to be generated that mimic real, distorted signals to prove the ability of a receiver to tolerate waveform distortions to a certain extent.

Representation of a Modulated RF Carrier. The waveform of a modulated RF carrier can be expressed as

$$s(t) = a(t)\cos[2\pi f_c(t)t + \varphi(t)] \tag{1-7}$$

and is defined by its amplitude $a(t)$, its carrier frequency $f_c(t)$, and its phase $\varphi(t)$. All three parameters are time variant and may be altered to generate different waveforms to represent logical symbols. If the occupied bandwidth of this modulated carrier is narrow compared to the carrier frequency f_c, we call this signal the *RF-bandpass signal* (Figure 1-37).

As any frequency variation causes a phase variation and vice versa a phase variation always causes a frequency variation, we can replace any frequency modulation by a corresponding phase modulation. Therefore we simplify the above equation to

$$s(t) = a(t)\cos[2\pi f_c t + \varphi(t)] \tag{1-8}$$

that is, we consider the carrier frequency as a constant and concentrate all frequency and phase variations into the parameter $\varphi(t)$.

For our purposes, a more suitable representation is

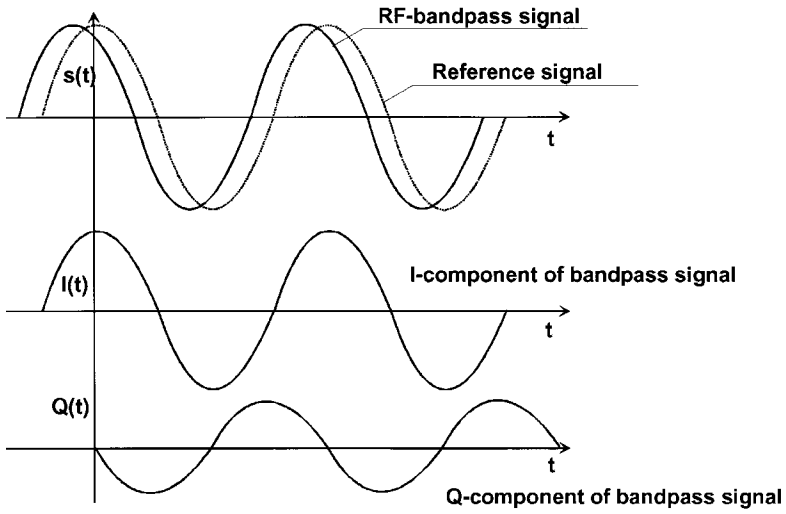

Figure 1-37 The bandpass signal and the I/Q representation of a carrier.

$$a(t)\cos[2\pi f_c t + \varphi(t)] = \cos[\varphi(t)]a(t)\cos(2\pi f_c t)$$

$$-\sin[\varphi(t)]a(t)\sin(2\pi f_c t) \tag{1-9}$$

which we call the *I/Q* representation of the RF signal. I/Q means that we have an I (in-phase) signal, namely, $\cos[\varphi(t)]a(t)\cos(2\pi f_c t)$, and a Q (quadrature) signal, namely, $-\sin[\varphi(t)]a(t)\sin(2\pi f_c t)$. These equations help us a lot in understanding an I/Q modulator. Because of the phase difference of 90° between the two carrier components, these are said to be *orthogonal* to each other.

All the information about the (modulated) carrier with the carrier frequency f_c is contained in the terms

$$c_I(t) = a(t)\cos[\varphi(t)] \tag{1-10}$$

$$c_Q(t) = a(t)\sin[\varphi(t)] \tag{1-11}$$

and, lazy as we are, we therefore disregard the terms $\cos(2\pi f_c t)$ and $-\sin(2\pi f_c t)$ from further consideration and denote the above signals $c_I(t)$ and $c_Q(t)$ as the components of the *complex baseband waveform* or *baseband signal*.

This leads us immediately to the *vector representation* of the signal, where we consider the two components $c_I(t)$ and $c_Q(t)$ of the complex baseband signal as the time-variant components of a time-variant vector with the vector length $a(t)$ and the angle to the I-axis $\varphi(t)$.We also get

$$a(t) = \sqrt{c_I^2(t) + c_Q^2(t)} \tag{1-12}$$

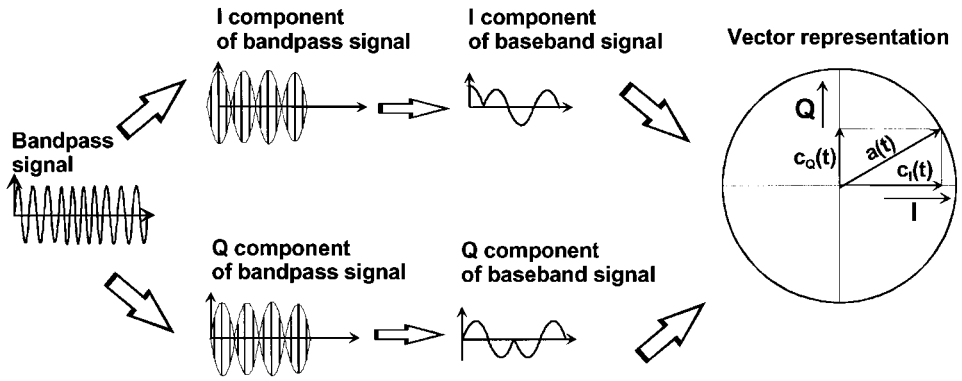

Figure 1-38 Different forms of signal representation.

$$\varphi(t) = \arctan\left(\frac{c_Q}{c_I}\right) \tag{1-13}$$

The vector can be depicted in the I/Q area (Figure 1-38).

Generation of the Modulated Carrier. Once we have realized that the modulated carrier can be represented as the sum of its I and Q components, which are the product of the two baseband components with two orthogonal RF carriers of the same frequency, it is easy to understand the hardware of the modulator (Figure 1-39). An unmodulated RF carrier is split up into two equal oscillations $\cos(2\pi ft)$, one of the two is then shifted by 0.5π and therefore is described by $-\sin(2\pi ft)$. The component $\cos(2\pi ft)$ is multiplied with the I component of the baseband signal $c_I(t)$; the other one, $-\sin(2\pi ft)$, is multiplied with the Q component $c_Q(t)$ of the baseband signal. Each multiplication may be performed using a double-balanced mixer. Afterward the two RF components are added in a simple power combiner. As it is difficult to shift the carrier by 90° over a broad frequency range, the modulated carrier is generated at an intermediate frequency and then upconverted to the wanted output frequency in a second mixer stage.

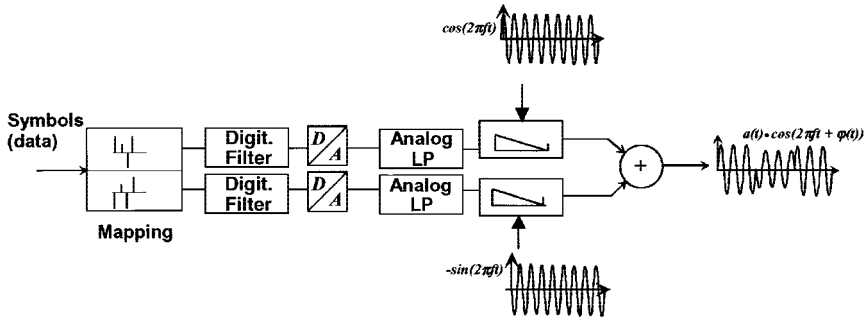

Figure 1-39 Principle of a digital I/Q modulator.

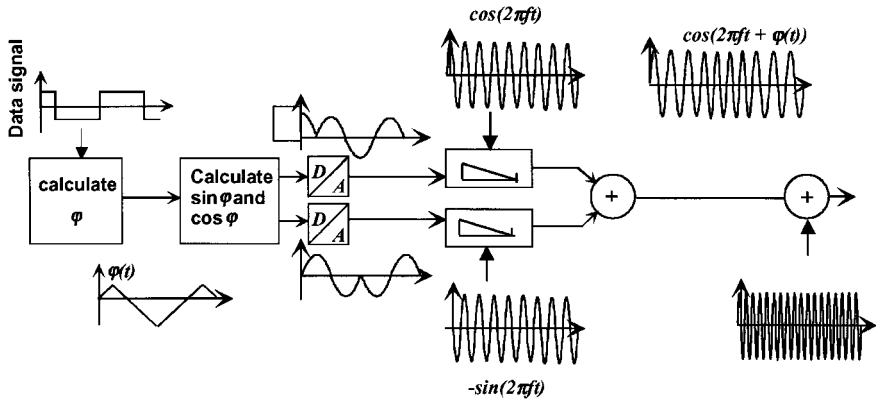

Figure 1-40 I/Q modulation (MSK and GMSK).

The baseband signals are generated by mapping every digital symbol onto a pair of digital pulses, which are fed to digital baseband filters. The output signal of these filters is D/A converted and smoothed by analog low-pass filters.

Figure 1-40 shows another example where, for a given modulation (MSK or GMSK), the instantaneous phase and then the corresponding cosinusoid and sinusoid, which modulate the two carrier components, are calculated from the data signal.

Digital designs of the modulator also exist, in which the IF-carrier generation, the time-variant phase shift, the multiplication with the baseband signals, and the sum of the components are calculated in a digital signal processor, the output of which is D/A converted and upconverted to the output frequency in the classical way. A further possibility is the generation of the modulated carrier with direct digital synthesis (DDS), as used in the Rohde & Schwarz SME signal generator.

Mapping the Data onto the Baseband Waveforms. The next question is: "How do we generate the baseband waveforms $c_I(t)$ and $c_Q(t)$?" There is no general answer to this question, as the generation of the baseband waveforms depends on the type of modulation. The following short descriptions will suffice for the moment.

Linear Modulations (All Kinds of Amplitude and Phase Shift Keying, and *M*-ary QAM)

- For binary amplitude and phase shift keying (ASK and BPSK), the data signal itself represented as a unipolar (ASK) or bipolar (BPSK) nonreturn-to-zero (NRZ) signal is the baseband waveform $c_I(t)$; the component $c_Q(t)$ does not exist.
- For *M*-ary phase shift keying and *M*-ary quadrature amplitude modulation, *N* bits are combined to form new symbols that are elements of an alphabet with $M = 2N$ elements. In the simplest case, every symbol is allocated an I and a Q amplitude during the symbol duration, which is *N* times the bit duration. The modulating signals $c_I(t)$ and $c_Q(t)$ are then staircase functions, and the modulated carrier has a time-varying envelope with the instantaneous amplitude $a(t)$ (Figure 1-41). Because the steps of the envelope cause unwanted side lobes of the RF spectrum, the baseband signals are filtered to smooth the shape of the RF envelope and reduce the occupied bandwidth of the modulated RF signal.

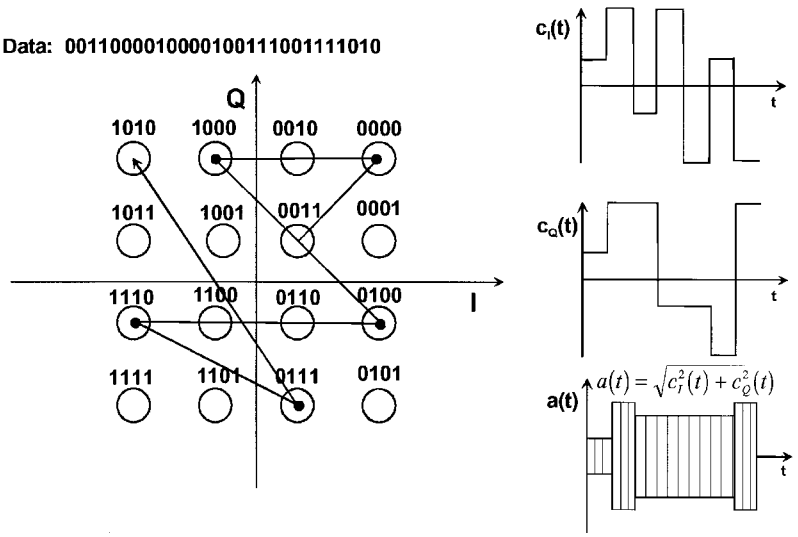

Figure 1-41 Constellation diagram, and baseband and RF signals of 16-QAM.

Nonlinear Modulations (Frequency Shift Keying, Minimum Shift Keying, and Gaussian Minimum Shift Keying)

- Despite the fact that *M*-ary frequency shift keying (FSK) could be performed using an I/Q modulator, for this type of modulation much simpler equipment such as a voltage-controlled oscillator is used as a frequency modulator. Figure 1-42 shows an example of quaternary frequency shift keying (4FSK), which also is known as 4 pulse-amplitude modulation/frequency modulation (4PAM/FM). This term indicates that every two bits are combined to a dibit that is mapped onto a baseband pulse with an amplitude taking on one of four possible levels. The pulse then is shaped by a baseband filter before being fed to the frequency modulator.
- If more precise modulations are required (e.g., MSK and GMSK, which also turn out to be frequency modulations), first the instantaneous phase of the modulated RF carrier is calculated from the data. The corresponding sine and cosine values that form the modulating baseband signals $c_I(t)$ and $c_Q(t)$ are determined from a lookup table. This operation is the reason for the fact that frequency modulation is called a nonlinear modulation.

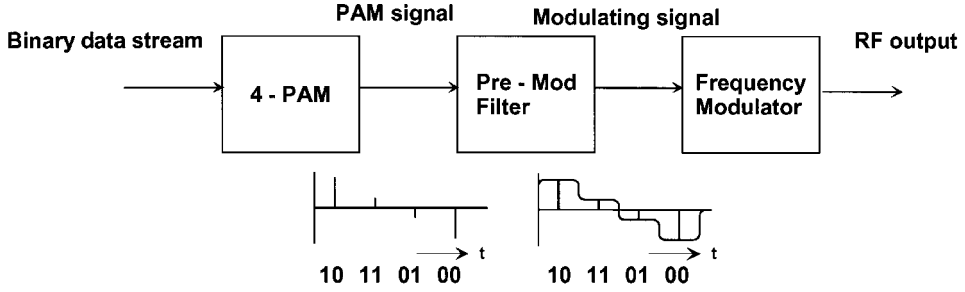

Figure 1-42 4PAM/FM.

The Spectrum of a Digitally Modulated Carrier. It is the task of any transmission process to occupy as little bandwidth as possible. The absolute lower limit in the baseband is half the symbol rate of the baseband signal, where for M-ary modulation the symbol rate r_{Symbol} is equal to the bit rate divided by $ld\,(M)$. This lower limit is only theoretical as ideal rectangular filters, which cannot be realized, were necessary. Therefore, in practice, a minimum baseband bandwidth of about $0.75r_{\text{Symbol}}$ has to be taken into account.

With linear modulation, the occupied bandwidth in the RF range is twice the occupied baseband bandwidth. This follows from the lag theorem, according to which the double-sided spectrum of a time function is shifted from $f = 0$ to the frequency $f = f_c$ when the time function is multiplied with $\cos(2\pi f_c t)$ (Figure 1-43).

Expressing this with formulas, we find

$$c(t) \quad \circ\!\!-\!\!\bullet \quad C(f) \tag{1-14}$$

$$e^{j2\pi f_0 t}c(t) \quad \circ\!\!-\!\!\bullet \quad C(f - f_0) \tag{1-15}$$

Therefore, if the baseband spectrum is limited by a low-pass filter, the RF spectrum is limited as if it were filtered by an RF bandpass filter with twice the bandwidth of the baseband filter.

Demodulation of Digitally Modulated Carriers. The demodulation process is an estimation process. The receiver compares the received waveform with all the possible waveforms and decides which symbol has been received. The waveform allocated is the one that is most similar to the received signal. This process is also called *maximum likelihood estimation*.

Figure 1-44 shows a possible demodulator. The received signals are cross-correlated with the stored ones in M correlators. High output from a given correlator indicates a match between its stored symbol and a symbol in the incoming signal.

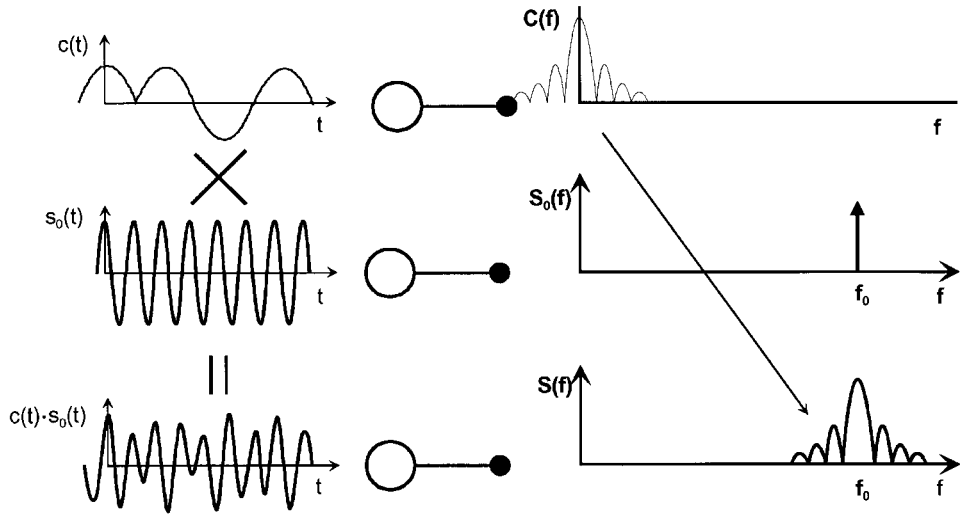

Figure 1-43 Occupied bandwidth in the baseband and the RF range.

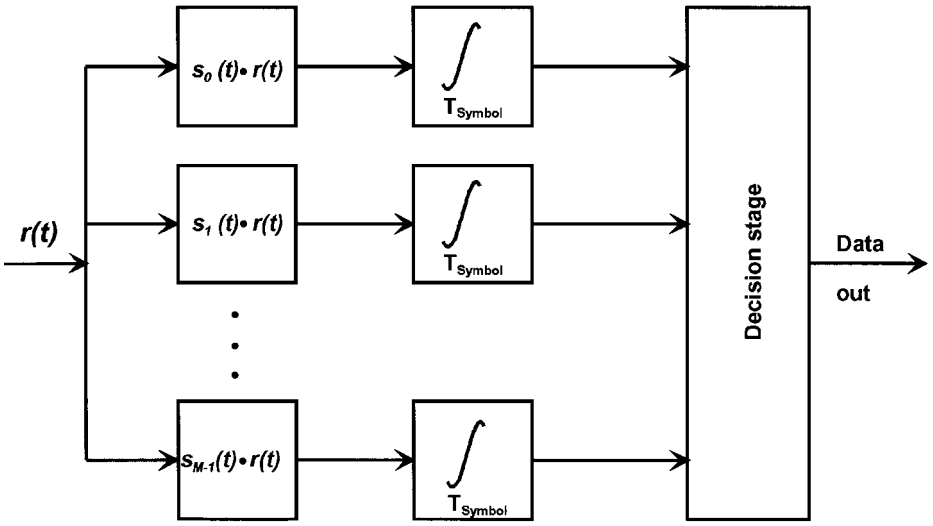

Figure 1-44 Correlation receiver.

As can easily be seen, such a receiver is quite complex. Therefore, other principles of receivers have been studied. The most often used receiver is based on an I/Q demodulator, the principle of which is shown in Figure 1-45.

The received signal is split into two equal components. One component is multiplied with the reconstructed carrier signal, the other with its orthogonal counterpart; that is, the $\pi/2$-shifted reconstructed carrier. After low-pass filtering, this multiplication delivers the I and the Q components of the baseband signal, which is more or less distorted by interference, multipath, and noise in the radio channel. These demodulated baseband signals then can be A/D converted and treated using simple or sophisticated algorithms to decide which symbols were originally sent. This type of demodulation requires an exact reconstruction of the unmodulated carrier, with respect not only to frequency but also to phase, and is called *coherent demodulation*. While the frequency recovery is in principle quite simple, the

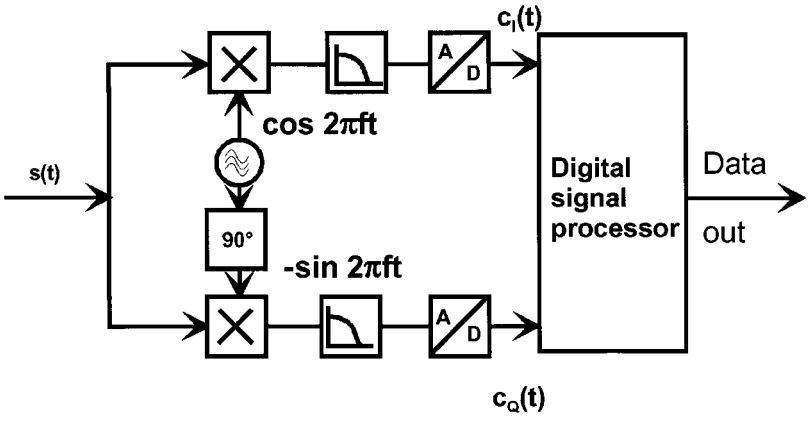

Figure 1-45 Coherent demodulation.

acquisition and tracking of the signal phase require complex signal processing of the baseband signal.

Coherent demodulation and its accompanying costly signal acquisition and tracking are necessary for all types of phase and quadrature amplitude modulation in which any part of the transmitted information is coded in the absolute phase of the carrier. It only can be avoided when the information is coded in the phase difference of two sequential waveforms. Such modulation schemes are called *differential phase modulation*. Examples of such modulation include differential binary phase shift keying (DBPSK) and differential quadriphase shift keying (DQPSK) and their derivatives.

The following list shows common digital modulation types and the telecommunication systems that use them:

BPSK—Satellite radio links, GPS, Inmarsat
QPSK—Satellite radio links, GPS, IS-95
OQPSK—IS-95 (reverse link)
π/4-QPSK—NADC, PHS, PDC. TETRA
GMSK—GSM, DCS 1800
GFSK (Gaussian FSK)—DECT
COFDM (coded orthogonal frequency-division multiplexing)—DAB, DVB

1-4-2 Some Fundamentals of Digital Modulation Techniques

The first waveforms that were used for "digital modulation" were amplitude shift keying (ASK), similar to on/off-keyed Morse code, and phase shift keying (similar to FM). Figure 1-46 shows the resulting waveforms in the time domain. It is also useful to look at them in the phase domain—the in-phase (I) and quadrature (Q) planes. From Figure 1-47 we see that ASK has only two states: no signal and signal at I (in-phase), while phase shift keying can have two states: +I and –I. In the frequency domain, ASK and BPSK have the output spectra

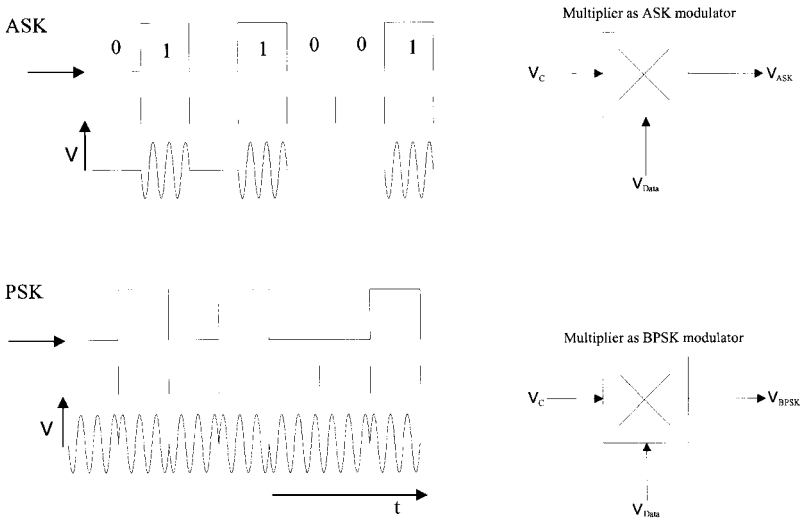

Figure 1-46 Amplitude shift keying (ASK) and phase shift keying (PSK) in the time domain.

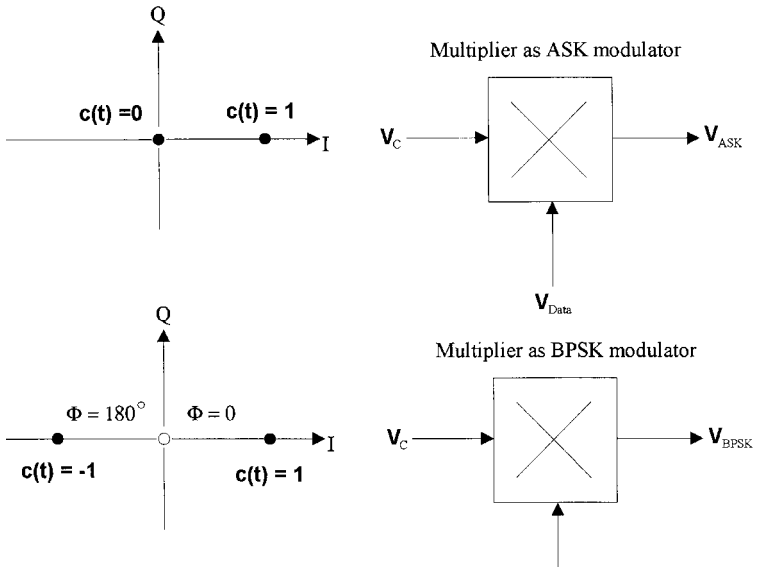

Figure 1-47 ASK and PSK in the I/Q plane.

shown in Figure 1-48. These output spectra, with their (sin *X*)/*X* appearance, depend on the rise and decay times and duty cycle of the modulating signal.

BPSK sends one data bit per signal state. Another way to put this is that each of BPSK's two signal states is a *symbol* that stands for just one bit—0 or 1. Transmitting more than one bit per symbol would allow us to improve our data throughput per unit of time, and this is

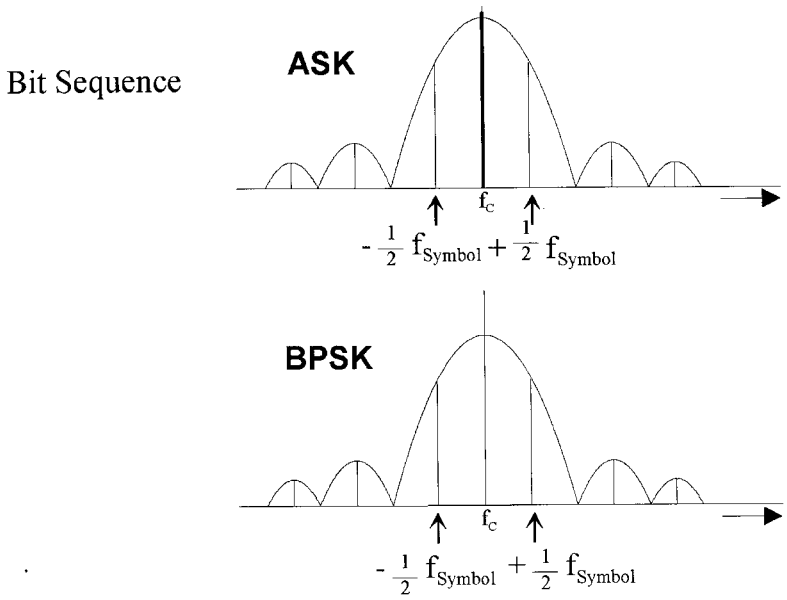

Figure 1-48 ASK and BPSK in the frequency domain.

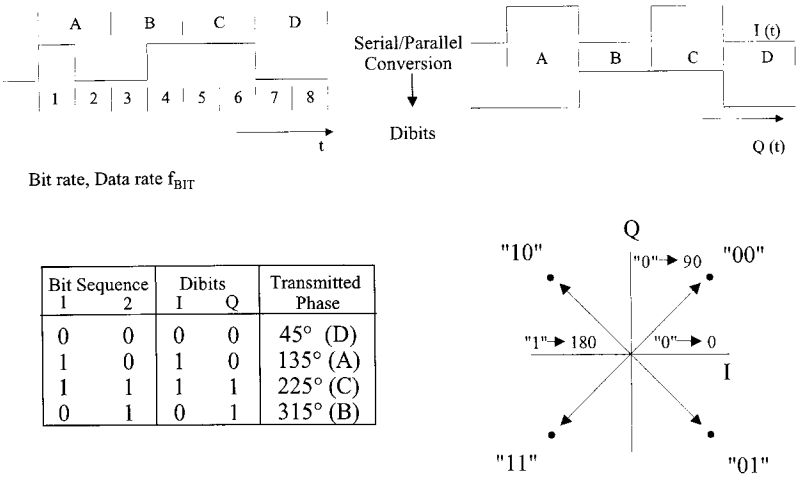

Bit Sequence 1	2	Dibits I	Q	Transmitted Phase
0	0	0	0	45° (D)
1	0	1	0	135° (A)
1	1	1	1	225° (C)
0	1	0	1	315° (B)

Figure 1-49 Quadrature PSK (QPSK) modulator (I/Q modulator).

exactly what's done in quadrature PSK (QPSK), which uses *four* possible signal states as symbols for 2-bit sequences called *dibits* (Figure 1-49). Figure 1-50 shows a QPSK modulator and the QPSK constellation diagram; Figure 1-51 shows the result of QPSK in the time and frequency domains; Figure 1-52 shows a spectrogram of an actual QPSK emission.

Moving from ASK to BPSK or QPSK results in increased resistance to noise. Figure 1-53 illustrates this by graphing bit error rate versus signal-to-noise ratio (here expressed as 10 log (E_{bit}/N_0), where E_{bit} is energy per bit and N_0 is the noise [23]). Figure 1-54 compares the maximum interference voltages for BPSK and QPSK.

Figure 1-55 shows bandwidth requirements and constellation diagrams for BPSK and QPSK. Unfiltered BPSK and QPSK are purely angle-modulated emissions; for each, all symbols are transmitted at the same amplitude. As we'll see, however, bandwidth-limiting a BPSK or QPSK signal to minimize adjacent-channel interference results in envelope variations that must be preserved through careful circuit design if bit errors are to be minimized.

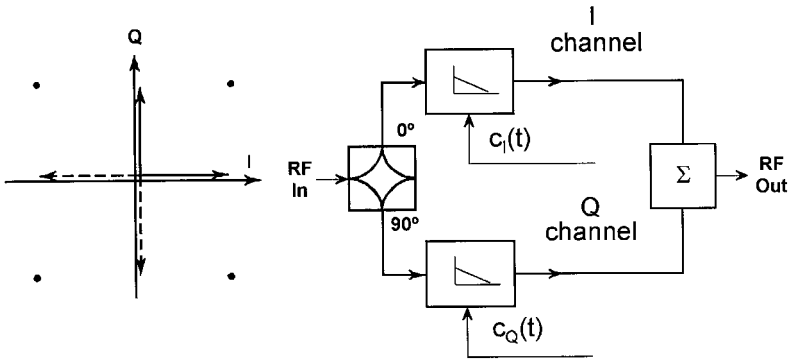

Figure 1-50 QPSK constellation diagram (*left*) and modulator (*right*).

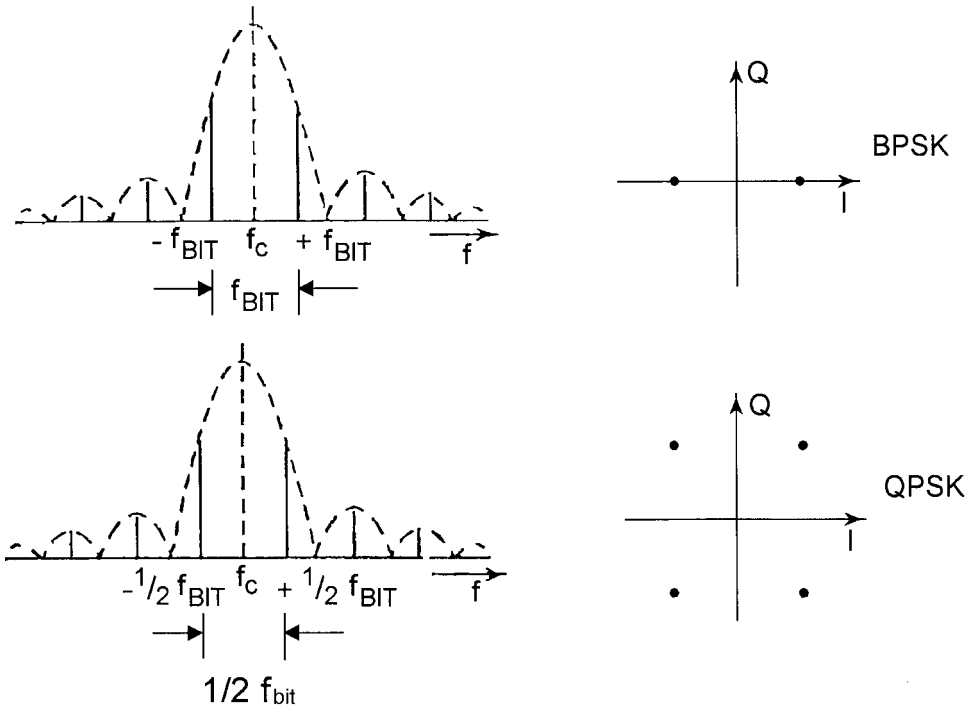

Figure 1-55 Bandwidth requirements (*left*) and constellation diagrams (*right*) for BPSK and QPSK. For each emission, all symbols are transmitted at the same amplitude, as is indicated by their equidistance from the constellation origin.

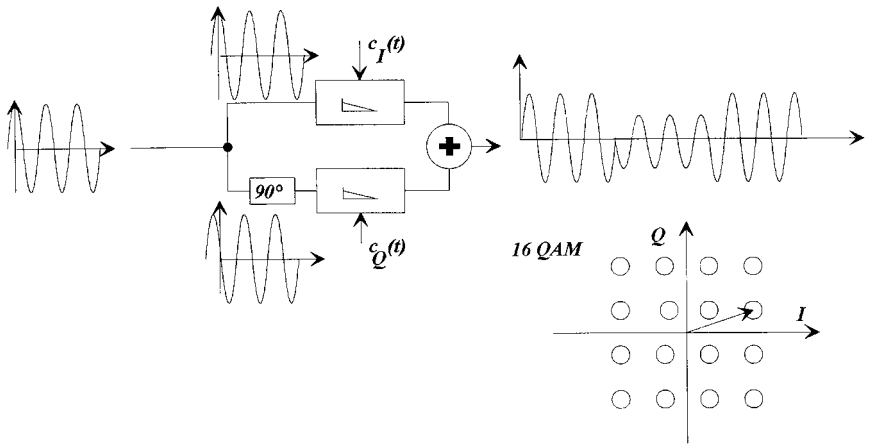

Figure 1-56 Quadrature amplitude modulation (QAM), with constellation diagram for 16-state QAM (16-QAM). Because transitions between QAM symbols involve shifts in phase *and amplitude*; even unfiltered QAM is a combination of amplitude and angle modulation.

Further increases in bit rate per symbol are possible with phase-modulation schemes that divide the 360° of each carrier cycle into increasingly smaller segments. Transmitting 3 bits per symbol, with each symbol spaced from its neighbors by 45°, gives 8-PSK; transmitting four bits per symbol, with each symbol spaced from its neighbors by 22.5°, results in 16-PSK. Increasing the data rate by increasing the number of bits per symbol doesn't give us something for nothing, however: The smaller the phase difference between adjacent symbols, the greater the likelihood that phase shifts resulting from phase noise, multipath reception, and other sources of phase perturbation will cause demodulation errors.

Modulation schemes that differentiate their data symbols through a combination of phase *and amplitude* shifts are susceptible to disturbances in amplitude in addition to phase. Figure 1-56 shows the modulator and constellation diagram for 16-state quadrature amplitude

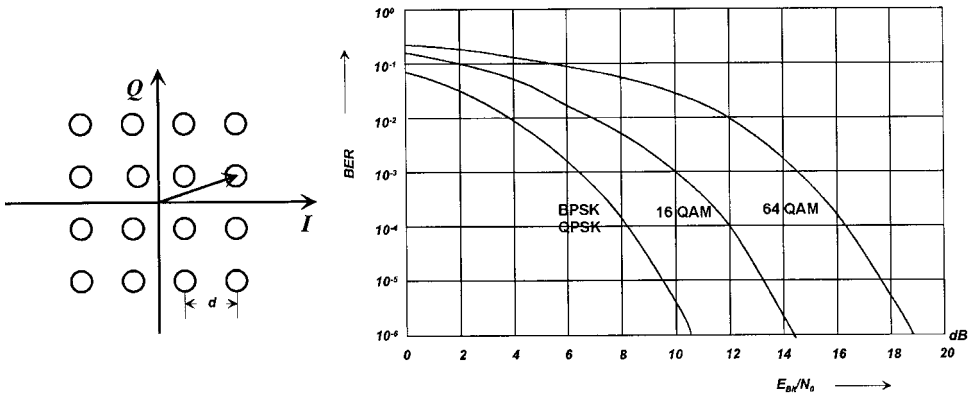

Figure 1-57 Bit error rate versus E_{bit}/N_0 for BPSK/QPSK, 16-QAM, and 64-QAM, showing the significantly greater SNR necessary for a given BER as the number of signal states is increased. In 64-QAM, each symbol represents 6 bits.

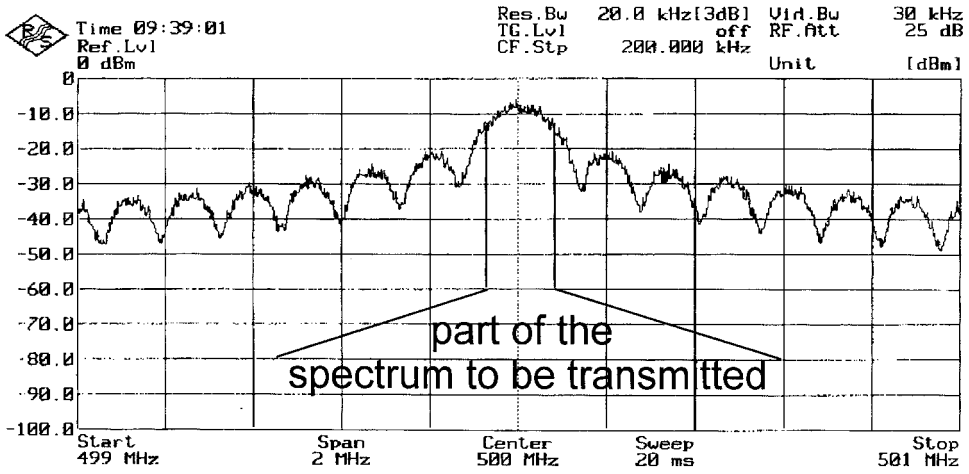

Figure 1-58 QPSK spectrum resulting from pseudorandom binary sequence (PRBS) data. Most of an angle-modulated emission's infinite sidebands are unnecessary for communication and can be removed by filtering—at the cost of introducing amplitude variations that must be sufficiently preserved to keep the bit error rate low.

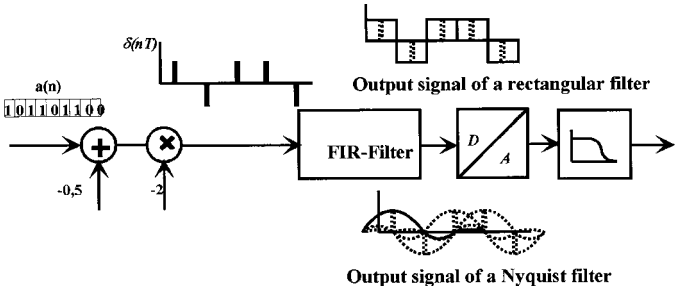

Figure 1-59 Baseband filtering. Figure 1-60 shows the result for QPSK.

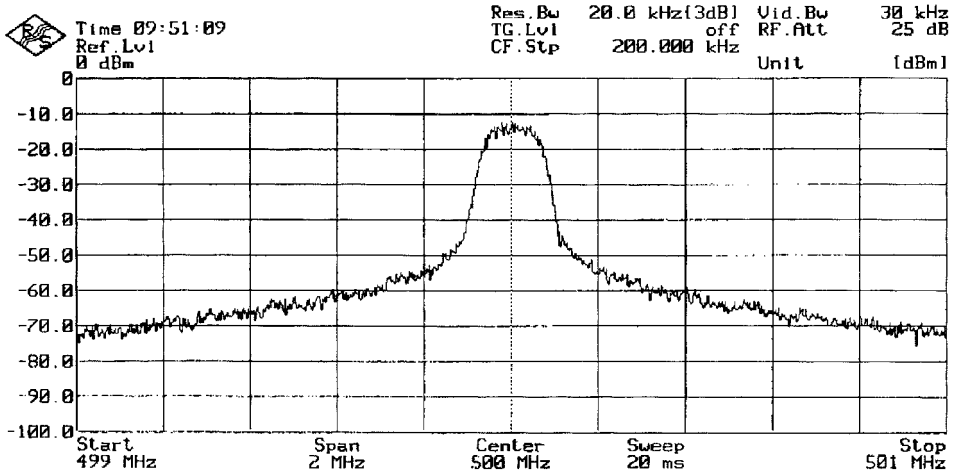

Figure 1-60 Spectrum of a band-limited QPSK signal.

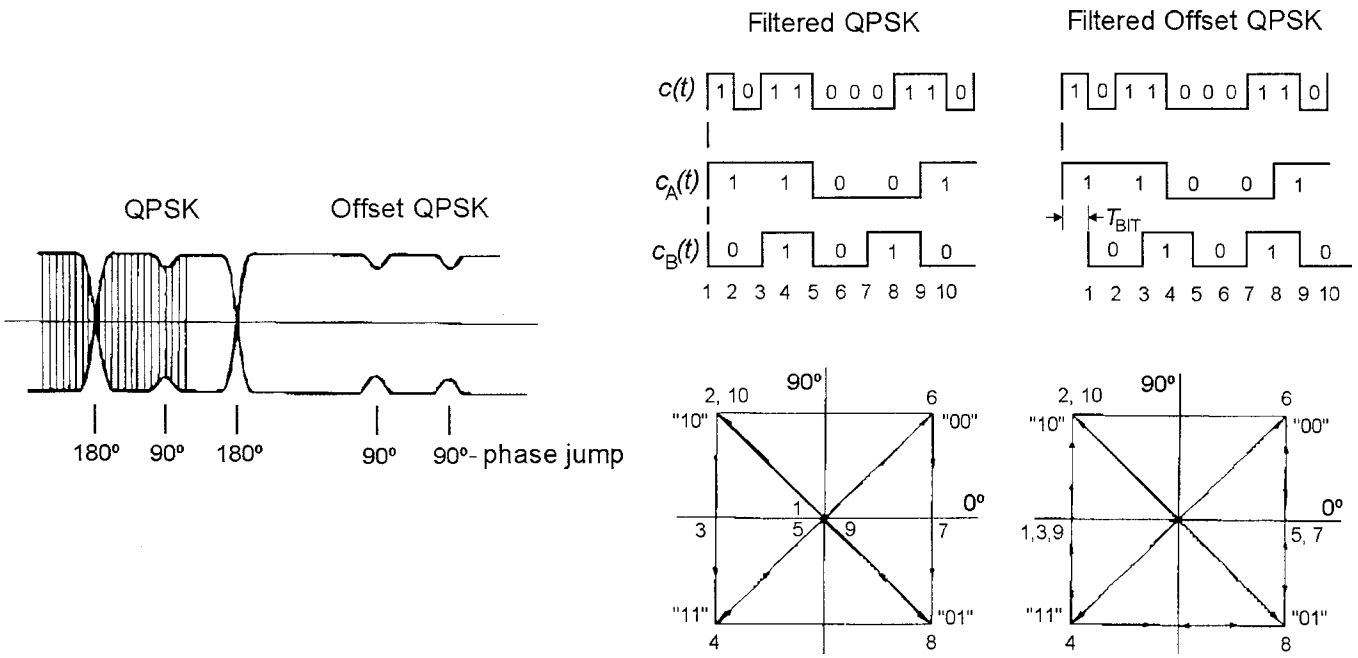

Figure 1-61 Offset QPSK (OQPSK) exhibits reduced envelope variations compared to standard QPSK by time-offsetting the I and Q channels.

modulation (16-QAM), in which each symbol represents 4 bits. Figure 1-57 shows bit error rate versus SNR for BPSK/QPSK, and 16- and 64-QAM. QAM systems can support very high bit rates—*if* sufficient SNR can be maintained and disturbances in signal amplitude and phase can be kept under control [3].

The infinite number of sidebands produced by angle modulation must be reduced by filtering to minimize the spectrum occupied by an emission to just that necessary for communication (Figure 1-58). Considerations of filter realizability and transmitter frequency agility dictate that this filtering must be done at baseband (Figure 1-59). The filter characteristics are optimized in accordance with the modulation scheme used (Figure 1-60). The filtering is done in using DSP, minimizing component count and resulting in characteristics that are essentially temperature independent and identical from unit to unit.

Fundamental angle-modulation theory tells us that the envelope of an angle-modulated signal does not vary in amplitude. Such an emission could be amplified in highly nonlinear stages without distortion. But because angle-modulated signals must be band-limited for practical use, and because band-limiting an angle-modulated signal strips away sideband energy that would contribute to its envelope constancy, the emissions used in modern wireless systems, even those that do not involve intentional amplitude modulation, vary in amplitude with modulation. How much a wireless emission's amplitude varies depends on the degree of filtering and the particular modulation scheme used. Various schemes, many of which rely on particular synergies of coding, modulation, and filtering, have been devised for minimizing amplitude variation in digitally modulated signals. Figure 1-61 shows one [offset QPSK (OQPSK)]; Figure 1-62 compares the spectra of three [QPSK, minimum shift keying (MSK), and Gaussian MSK (GMSK)]. Detailed discussion of such techniques is more concerned with coding, logic circuitry, and software than with radio hardware and is therefore beyond the scope of this book. What is important to the circuit designer is that stages handling the emission(s) on which a system depends must be sufficiently amplitude-linear to maintain the modulation integrity of the signal and, in the case of transmitters, to keep adjacent-channel interference and other spurious emissions within acceptable levels.

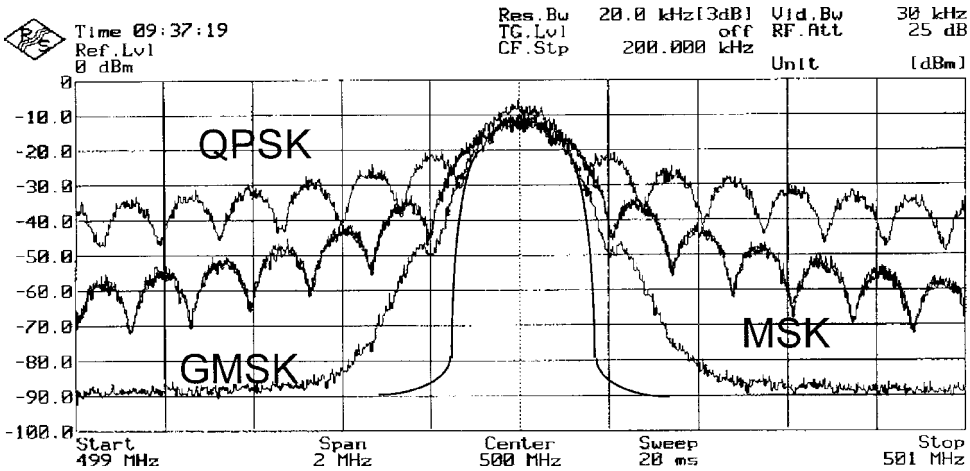

Figure 1-62 Comparison of QPSK, MSK, and GMSK.

1-5 ANALYSIS OF WIRELESS SYSTEMS

1-5-1 Analog and Digital Receiver Designs

For the purpose of showing the capability of modern computer-aided design (CAD), we now show first an analog receiver and following this an analog/digital receiver with its functionality and performance.

Receiver Design Examples

Analog Receiver Design. A transmitter modulates information signals onto an RF carrier for the purpose of efficient transmission over a noise-filled radio channel. The RF receiver's job is to demodulate that information signal while maintaining a sufficient signal-to-noise ratio (SNR). This must be done for widely varying input RF power level and with the presence of noise and interferers.

Modern communication standards place requirements on key system specifications, such as RF sensitivity and spurious response rejection. These system specifications must then be separated into individual circuit specifications via an accurate overall system model. CAD can play a major role in modeling systems and in determining the individual component requirements. A 2.4-GHz dual-down conversion system (see Figure 1-63) will be used as an example. The first IF is 200 MHz and the second IF is 45 MHz.

As a signal propagates from the transmitter to the receiver it is subject to path loss and multipath, resulting in extremely low signal levels at the receive antenna. RF sensitivity is a measure of how well a receiver can respond to these weak signals. It is specified differently for analog and digital receivers. For analog receivers there are several sensitivity measures, including minimum discernible signal (MDS), signal-to-noise plus and distortion ratio (SINAD), and noise figure. For digital receivers the typical sensitivity measure is maximum bit error rate (BER) at a given RF level. Typically, a required SINAD at the baseband demodulator output is specified over a given RF input power range. For example, audio measurements may require 12-dB SINAD at the audio output over RF input powers ranging from −110 to −35 dBm. This can then be translated to a minimum carrier-to-noise (C/N) ratio at the demodulator input to achieve a 12-dB SINAD at the demodulator output (see Figure 1-64).

Determining receiver sensitivity requires accurate determination of each component's noise contribution. Modern CAD software, such as Symphony by Ansoft, can model noise from each stage in the system including oscillator phase noise. The C/N ratio can then be plotted as a function of input power (see Figure 1-65).

This plot enables straightforward determination of the minimum input power level to achieve a certain C/N ratio. Once the sensitivity has been specified the necessary gain, or

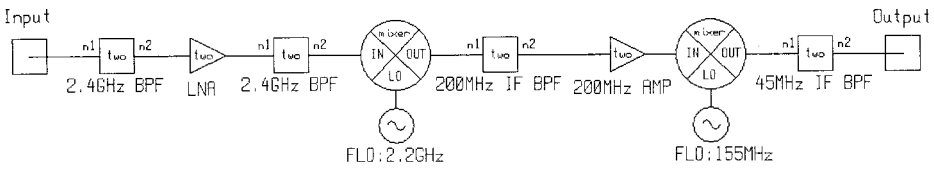

Figure 1-63 Dual-downconversion receiver schematic.

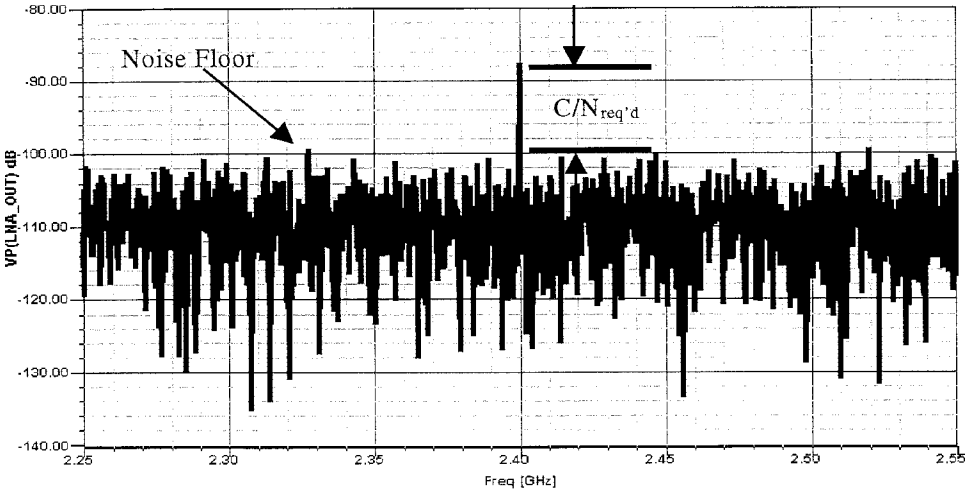

Figure 1-64 Receiver sensitivity measure showing required C/N.

loss, of each component can be determined. A budget calculation (see Table 1-5) can be used to examine the effects of each component on a particular system response.

Another key system parameter is receiver spurious response. The receiver's mixers typically cause the spurious responses. The RF and LO harmonics mix and create spurious responses at the desired IF frequency. These spurious responses can be characterized [4] by the equation

$$\pm mf_{\mathrm{RF}} \pm nf_{\mathrm{LO}} = \pm f_{\mathrm{IF}} \tag{1-16}$$

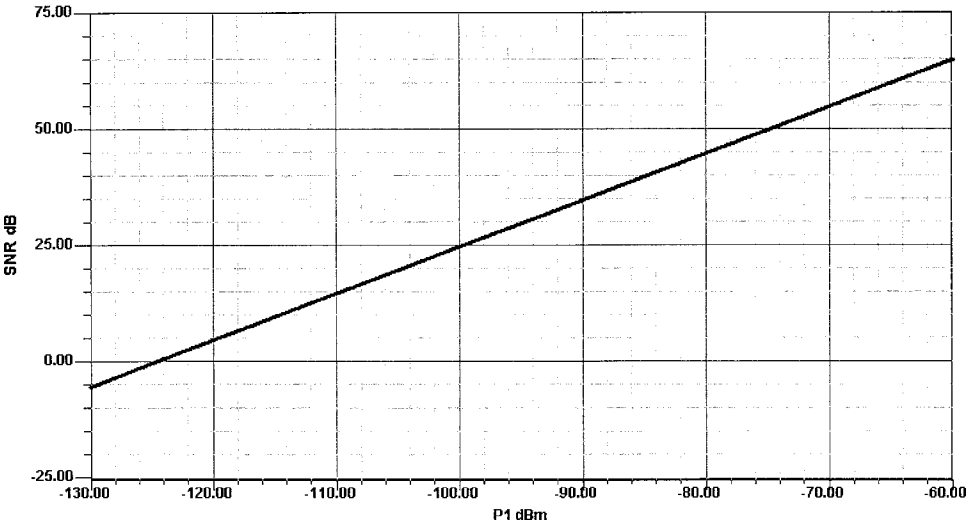

Figure 1-65 C/N ratio versus input RF power level.

Table 1-5 Budget calculation for the ΔS_{21} across each system component accounting for impedance mismatches

200 MHz AMP	22.21
MIXER_2	–8.43
45 MHz IF BPF	–0.42

Some spurious responses, or spurs, can be especially problematic because they may be too close to the intended IF to filter, thus masking the actual information-bearing signal. These spurious responses and their prediction can be especially troublesome if the receiver is operated near saturation. The analysis can then be refined by including a spur table that predicts the spur level relative to the IF signal. The spur's power at the output of a mixer is calculated using the spur table provided for this mixer. Once generated, each spur is carried through the remainder of the system with all mismatches accounted for. The output power level of each spur is shown in Table 1-6. Another useful output is the RF and LO indices, which indicate the origin of each spur.

In addition to sensitivity and spurious response calculations, an analog system can be analyzed in a CAD tool such as Symphony for gain, output power, noise figure, third-order intercept point, intermodulation distortion (IMD; due to multiple carriers), system budget, and dynamic range.

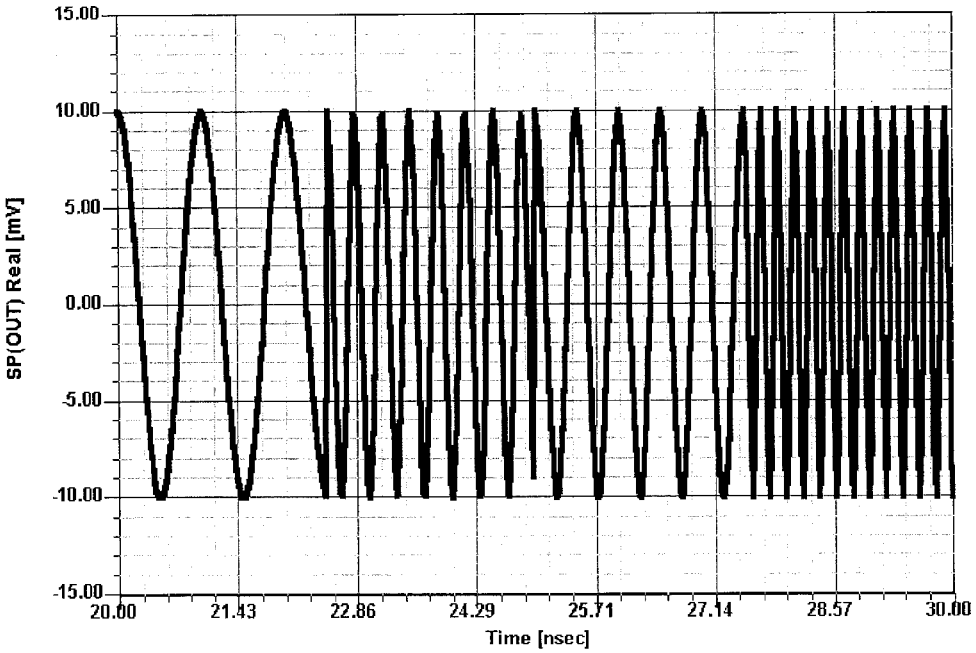

Figure 1-66 4FSK signal generated in Symphony.

Mixed-Mode MFSK Communication System. Next, a mixed-mode (digital and RF) communication system will be described and simulated. In this example digital symbols will be used to modulate an 8-GHz carrier. The system uses *M*-ary frequency shift keying (MFSK) bandpass modulation with a data rate of 40 Mbps. Convolutional coding is employed as a means of forward error correction. The system includes digital signal processing sections as well as RF sections and channel modeling. Several critical system parameters will be examined, including BER. FSK modulation can be described [5] by the equation

$$s_i(t) = \sqrt{\frac{2E}{T}} \cos(\omega_i t + \phi) \tag{1-17}$$

where $i = 1, \ldots, M$. So the frequency term will have M discrete values with almost instantaneous jumps between each frequency value (see Figure 1-66). These rapid jumps between frequencies in an FSK system lead to increased spectral content.

Figure 1-67 shows a block diagram of the complete system. The system can be split into several major functional subsystems—the baseband modulator, the RF transmitter section, channel model, RF receiver, clock recovery circuitry, and baseband demodulator. Looking specifically at the baseband modulator circuitry (Figure 1-68), a pseudorandom bit source is used and the bit rate is set to 40 MHz.

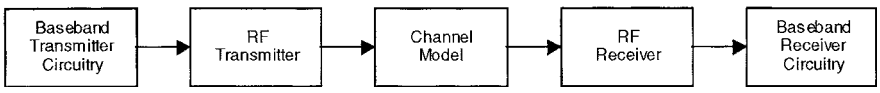

Figure 1-67 Mixed RF/DSP MFSK communication system simulated in Symphony.

A convolutional encoder then produces two coded bits per data bit and increases the bit rate to 80 MHz. The purpose of the convolutional encoder is to add redundancy to improve the received BER. A binary-to-*M*-ary encoder then assigns one symbol to every 2 bits, creating the four levels for the 4FSK, effectively halving the bit rate down to 40 MHz again. The signal is then scaled and upsampled. To decrease the bandwidth, a root-raised cosine filter is used to shape the pulses. The filtered signal then serves as the input to the frequency modulator. The RF section (see Figure 1-69) includes the transmitter that modulates the baseband signal onto an 8-GHz carrier.

That signal is amplified and then filtered to remove any harmonics. The signal is then passed through an additive white Gaussian noise model. The received signal is filtered, amplified, and downconverted twice to baseband. After carrier demodulation the signal is then sent through the clock recovery circuitry. Clock recovery is employed to ensure that sampling of the received signal is executed at the correct instances. This recovered timing information is then used as a clock signal for sample and hold circuitry. Clock recovery in this system was achieved using a phase-locked loop (PLL) configuration. The schematic for the clock recovery circuit is shown in Figure 1-70.

At the heart of the clock recovery circuit is the phase comparator element and the frequency modulator. The inputs to the phase comparator consist of a sample of the received data signal and the output of the feedback path that contains the frequency modulator. The frequency modulator reacts to phase differences in its own carrier and the received data signal. The output of the frequency modulator is fed back into the phase comparator, whose output is dependent on the phase differential at its inputs. The phase of the frequency modulator continually reacts to the output of the phase comparator and eventually lock is achieved. Once the timing of the received signal is locked onto, the clock that feeds the sample and hold will be properly aligned and correct signal sampling will be assured.

Figure 1-71 shows the received signal (filtered and unfiltered) as well as the recovered clock and the final data. Equalizer circuitry is then used to compensate for channel effects, which degrade the transmitted signal. The equalizer acts to undo or adapt the receiver to the effects of the channel. The equalizer employed in this MFSK system is the recursive least squares equalizer. The equalizer consists of a filter of *N* taps that undergoes an optimization in order to compensate for the channel effects. The equalizer depends on a known training sequence in order to adapt itself to the channel. The equalizer model updates the filter coefficients based on the input signal and the error signal (i.e., the difference between the output of the equalizer and the actual desired output). The update (optimization) is based on the recursive least squares algorithm. Several equalizers are available in Symphony, including complex least mean square equalizer, complex recursive least squares equalizer, least mean square equalizer, recursive least squares equalizer, and the Viterbi equalizer. After equalization, the BER of the system is analyzed versus SNR (see Figure 1-72).

PLL CAD SIMULATION. The Symphony system simulator also allows us to evaluate the performance of phase-locked loops. Figure 1-73 shows the block diagram of a PLL in which the VCO is synchronized against a reference. For the purpose of demonstrating the capability, we have selected a 1:1 loop with a crossover point of about 100 kHz, meaning that the loop gain is 1 at this frequency.

Figure 1-74 shows the system's simulated open- and closed-loop phase-noise performance. At the crossover point, the loop is running out of gain. The reason why the closed-loop noise increases above 2 kHz has to do with the noise contribution of various components of the loop system. The highest improvement occurs at 100 Hz, and as the loop gain decreases,

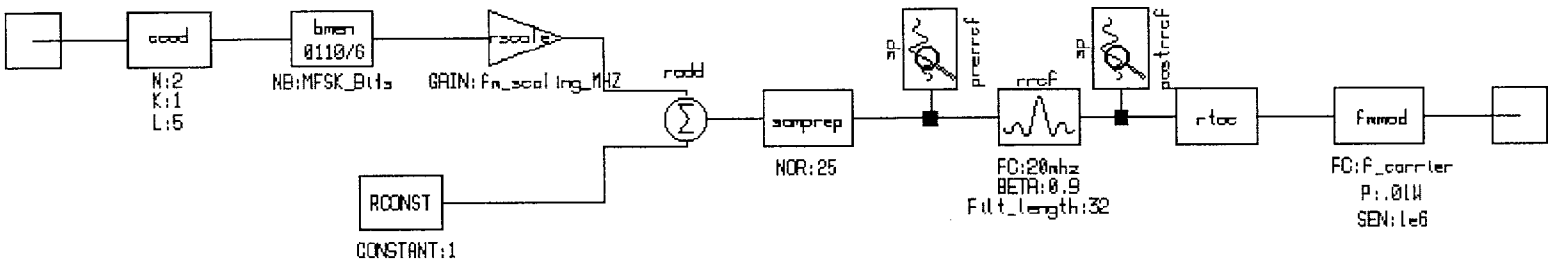

Figure 1-68 MFSK baseband circuitry including frequency modulator.

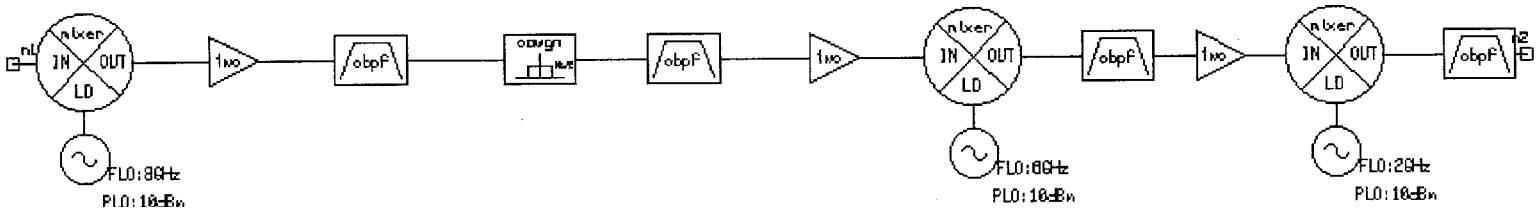

Figure 1-69 RF section including Gaussian noise channel model.

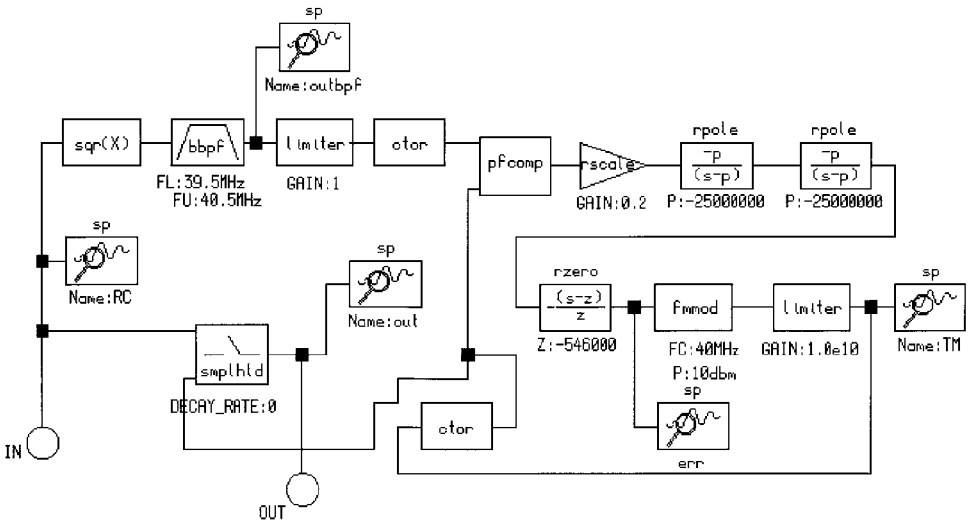

Figure 1-70 Clock recovery circuitry.

the improvement vanishes. Therefore it is desirable to make the loop bandwidth as wide as possible, as this also improves the loop's switching speed. On the other hand, as the phase noise of the free-running oscillator crosses over the phase noise of the reference noise, divider noise, and other noise contributors, one can make the noise actually worse than that of the free-running state. In a single-loop system, a compromise must be made between phase noise, switching speed, and bandwidth. A first-order approximation for switching speed is $2/f_L$, where f_L is the loop bandwidth. Assuming a loop bandwidth of 100 kHz, the switching speed

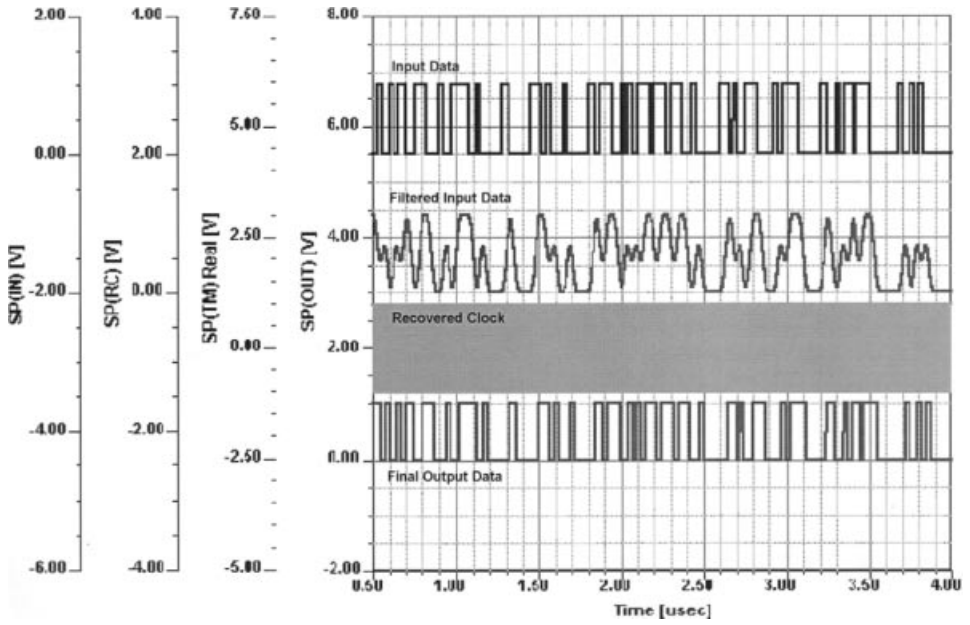

Figure 1-71 Input data, filtered input data, recovered clock, and final output data for the MFSK communication system.

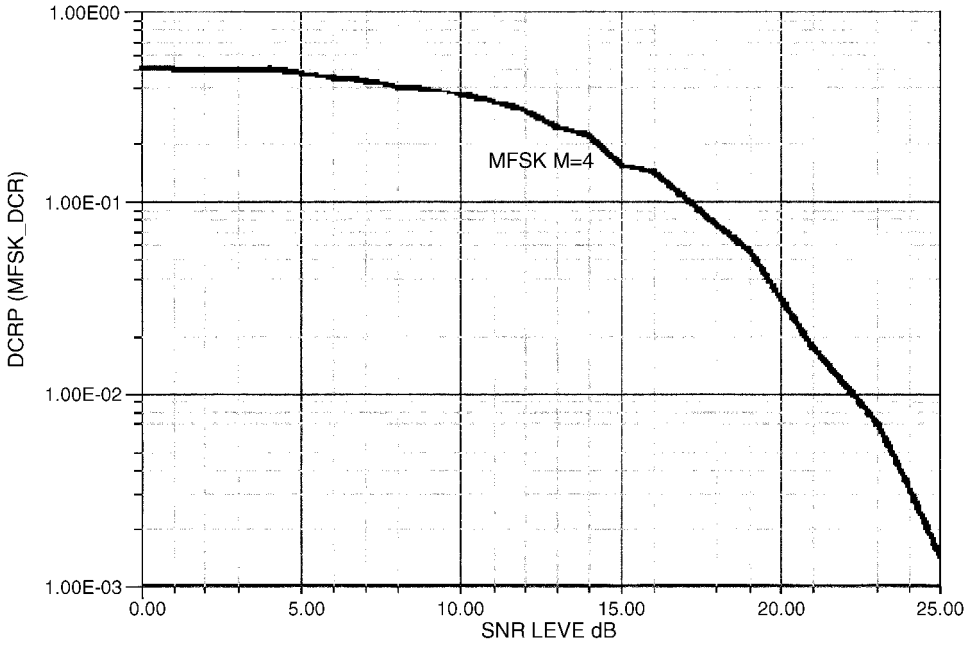

Figure 1-72 BER versus SNR for the MFSK system.

will be 20 μs. Looking at Figure 1-74, we can clearly see the trend from 200 Hz to 100 kHz. Because of the resolution of the sampling time (computation time), the open-loop phase noise below 150 Hz is too low and could be corrected by a straight-line extrapolation from 500 Hz toward 100 Hz. We have left the drawing uncorrected to show the effect of not-quite-adequate resolution.

Since we have already referenced analog and digital waveforms, we need to mention that the current system in place worldwide is referenced as the second-generation (2G) system.

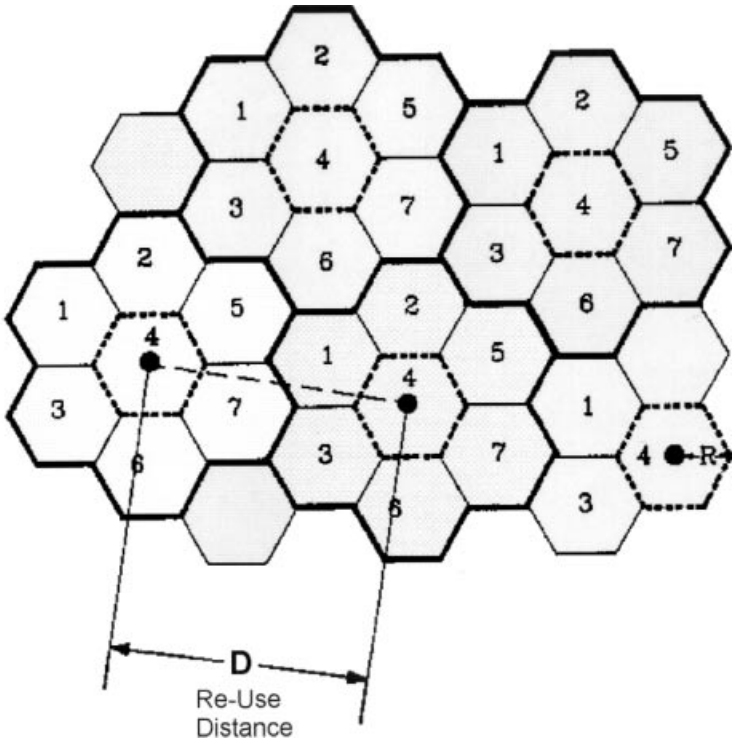

Figure 1-76 Cellular structure. $W = N \times B_C$, where W is the full bandwidth and B_C is the bandwidth per cell. The number of channels/cell = B_C/B_U, where B_U is bandwidth per user (FDMA) or N users (TDMA). $D = R\sqrt{3N}$.

The all-digital, adaptive-bandwidth third-generation (3G) system is being discussed in Europe, Japan, and the United States [6]. This is not without headaches. The Groupe Speciale Mobile (GSM) system in Europe still has potential to grow and is not under any urgent pressure to be upgraded. The opposite is true in Japan, because Japan is running out of capacity and needs to go to wideband CDMA. The important perceived advantage of this is that the number of simultaneous users can be extremely high: there is much less interference because of orthogonal modulation types with extremely low correlation and adaptive bandwidth. The actual definitions are still in flux, with the discussions dominated by the United States. This domination stems from the National Security Agency being determined to be able to eavesdrop on conversations that are none of their business (drug smuggling is always used as an excuse) but invites invasion of monitoring without proper court authorization. This is a very hot issue. The other similar problem has to do with patents. This type of technology is somewhat dominated by Qualcomm, a U.S. company, which likes to send a bill for patent infringement to everybody, possibly even to users. A similar speculation took place with the introduction of digital audio tapes and their duplication and is occurring nowadays with CDs carrying either music recordings or movies. This issue is driven by money and not by technology.

That said, Table 1-7 shows cellular and cordless standards, everything referring to 2G. Figure 1-75 shows the multiplexing schemes used. Table 1-8 shows the parameters of cellular and cordless systems. Figure 1-76 shows the cellular structure.

1-5-2 Transmitters

Since it is possible to generate any type of modulation using DSP, including those described in this chapter, a DSP-based transmitter can also be built. A good example of this is the Philips SA900, which is truly universal.

Introduction to the SA900.* The SA900 (Figure 1-77) is a truly universal in-phase and quadrature (I/Q) radio transmitter that can perform many types of analog and digital modulation including AM, FM, SSB, QAM, BPSK, QPSK, and FSK. It is a highly integrated system that saves space and cost for the manufacturers producing cellular and wireless products. The device allows baseband signals to directly modulate the I/Q carriers, which are generated by an internal phase shift network, in the 1-GHz range, and to maintain good linearity required for a linear modulation scheme (e.g., $\pi/4$-DQPSK). It contains an on-chip frequency divider, phase detector, and VCO, which can be built into a phase-locked loop (PLL) frequency synthesizer to create a transmit offset frequency. Its unique internal design allows frequency conversion without having an external image rejection filter for eliminating the sum term after mixing. The SA900 meets the specifications required by the IS-54, the industry standard for North America Digital Cellular (NADC) system. Here we review the basic concept of I/Q modulation and discuss the key points when designing the SA900 for an RF transmitter.

I/Q Modulation. Any bandpass RF signals can be represented in polar form by

$$s(t) = A(t)\cos[\omega_c t + \phi(t)] \tag{1-18}$$

where $A(t)$ is the signal envelope and $\phi(t)$ is the phase. By using the trigonometric identities, we can represent Eq. (1-18) in rectangular form by

$$s(t) = \mathrm{I}(t)\cos(\omega_c t) - \mathrm{Q}(t)\sin(\omega_c t) \tag{1-19}$$

where $\mathrm{I}(t) = A(t)\cos[\phi(t)]$
$\mathrm{Q}(t) = A(t)\sin[\phi(t)]$

Since the baseband signals $\mathrm{I}(t)$ and $\mathrm{Q}(t)$ modulate two exactly 90° out-of-phase carriers $\cos(\omega_c t)$ and $-\sin(\omega_c t)$, respectively, we call the system implementing Eq. (1-19) an in-phase and quadrature (I/Q) modulator. Figure 1-78 shows the mathematics and hardware implementation of an I/Q modulator.

The local oscillator, usually a VCO within a PLL, generates the carrier and is split into two equal signals. One goes directly into a double-balanced mixer to form the I-channel and the other one goes into the other mixer via a 90° phase shifter (realized by passive elements) to provide the Q-channel. The baseband signals $\mathrm{I}(t)$ and $\mathrm{Q}(t)$, either analog or digital in nature, modulate the carrier to produce the I and Q components, which are finally combined to form the desired RF transmitting signal. Since any RF signal can be represented in the I/Q form, any modulation scheme can be implemented by an I/Q modulator.

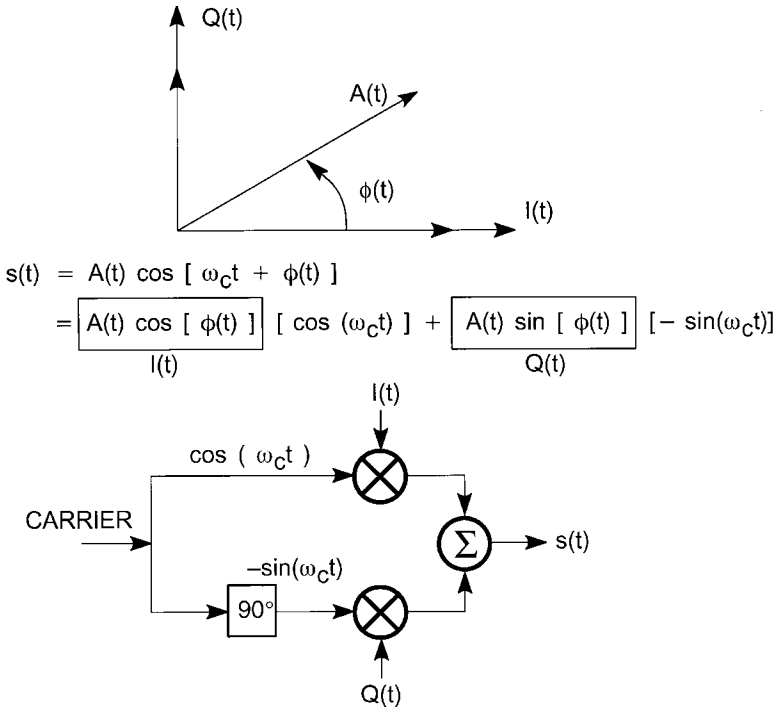

Figure 1-78 Mathematical representation and hardware implementation of I/Q modulator.

Linear Digital Modulation. Linear digital modulation techniques depend on varying the phase and/or magnitude of an analog carrier according to digital information: ones and zeros. This digital information can be the output of an analog-to-digital converter (e.g., voice codec), or it can be digital data in some standard formats (e.g., ASCII). The most popular digital signaling format is nonreturn-to-zero (NRZ), where 1's and 0's are converted into signals with amplitudes of 1 and –1, respectively, in a symbol duration. Since an NRZ signal has infinite bandwidth, transmit filters have to be used to limit the spectral spreading. To ensure each NRZ symbol does not smear into its neighbors due to low-pass filtering and channel distortion, causing intersymbol interference (ISI), the frequency response of the low-pass filter has to satisfy Nyquist criteria. One example of this type of filter is the linear phase square-root-raised cosine filter. Together with the same type of filter for receive low-pass filtering, the signal is guaranteed ISI-free in a Gaussian environment. One straightforward technique of transmitting such a band-limited signals through communication channels would be to apply it directly to the mixer of the I channel to generate an RF signal. This is known as binary phase shift keying (BPSK), where the phase of the carrier is shifted 180(to transmit a data change from 0 to 1 or 1 to 0.

Quadrature or quaternary phase shift keying (QPSK) is a much more common type of modulation scheme used in mobile and satellite communications. It has four possible states (90° apart) and each of them represents 2 bits of data. Figure 1-79 shows the baseband generator for QPSK (without the differential phase encoder). NRZ data bits go through the serial-to-parallel converter (see Figure 1-80) and are mapped in accordance to some rules to generate I and Q values. The generic rule states that the values of I and Q components are 1 and 1 for the data bits "11" (45°) and –1 and –1 for the data bits "00" (–135°). These discrete signals have to be band-limited by Nyquist low-pass filters to be ISI-free.

A more sophisticated way of mapping results in π/4-DQPSK (D for differential encoding), which is chosen for North America Digital Cellular (IS-54), Personal Digital Cellular (PDC) in Japan, and Personal Handy Phone System (PHS) in Japan. In this scheme, consecutive pairs of bits are encoded into one of the four possible phases: π/4 for "11," 3π/4 for "01," –3π/4 for "00," and –π/4 for "10." However, unlike the previous case that "11" is always π/4 and "00" is always –3π/4, the encoded phases are the degrees that the carrier has to shift at each sampling instances. Thus the information is contained in the phase difference (differential) instead of absolute phase for π/4-DQPSK.

A better way to tell the difference between QPSK and π/4-DQPSK is by looking at the signal constellation diagram, shown in Figure 1-81, which displays the possible values of I and Q vectors and changes of state. A constellation diagram is also known as a phase diagram because it shows the phase of the carrier at the sampling point. Note that the phases of QPSK are assigned for every 2 bits of data; therefore it can transmit twice as much information as BPSK in a given bandwidth; that is, it is more bandwidth-efficient. The 8-PSK is another type of modulation used for high-efficiency requirements. It maps 3 bits into eight phases, 45° apart, in the constellation. More spectrally efficient modulation can be created by

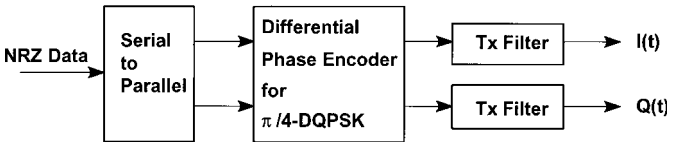

Figure 1-79 QPSK and π/4-DQPSK baseband generator.

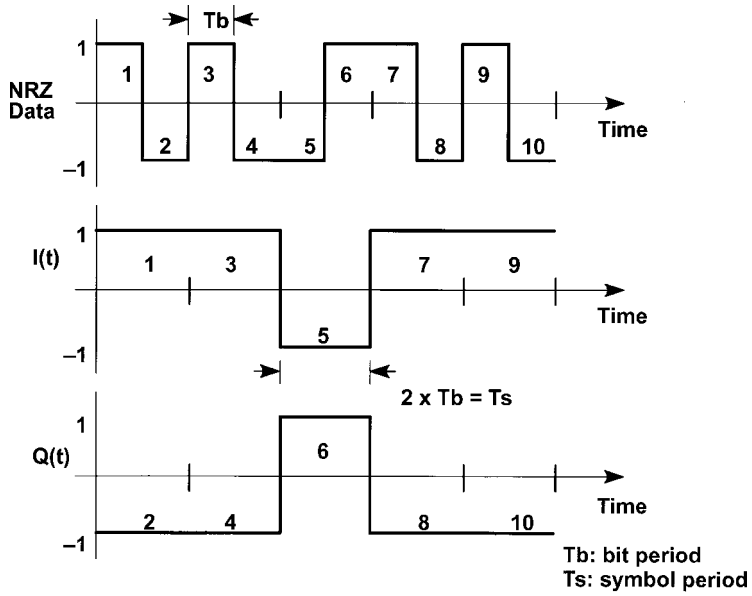

Figure 1-80 Serial-to-parallel conversion.

mapping more bits into one phase at each sampling point. However, as we add states to the signal constellation, the signal susceptibility to noise increases because the difference between states decreases. Then, a higher carrier-to-noise (C/N) ratio is required to maintain the same bit error rate.

One common misconception is that since π/4-DQPSK has eight states, it is just another type of 8-PSK. Note, however, that at every sampling instant, the carrier of π/4-DQPSK is allowed to switch to only one of the four possible states (see Figure 1-81). So we still have two data bits that get encoded into four phases. Thus π/4-DQPSK has the same spectral efficiency as QPSK for the same carrier power. The reason for using this modulation scheme is twofold. First, the envelope fluctuation, which causes spectral spreading due to nonlinearity of transmitter and amplifier, is reduced because the maximum phase shift is 135° instead

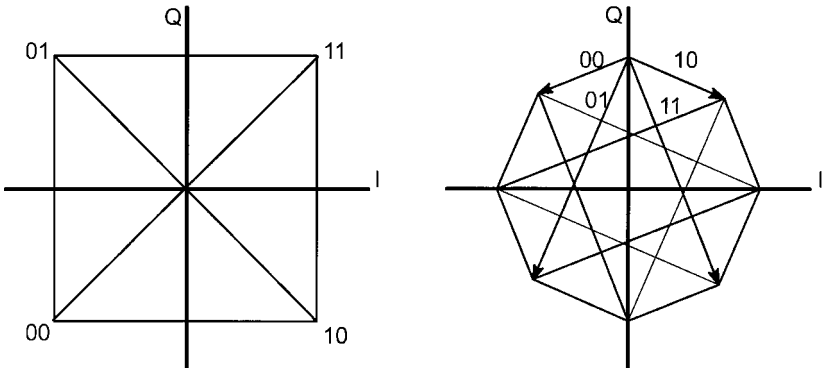

Figure 1-81 Signal constellation of QPSK and π/4-DQPSK.

of 180°. Second, the signal can be demodulated noncoherently, which simplifies the receiver circuitry by eliminating the need for carrier recovery.

Digital and Analog FM. Another family of digital modulation is categorized by frequency change of the carrier instead of phase and/or amplitude change. One member of this family is frequency shift keying (FSK), where the carrier switches between two frequencies. FSK is also known as digital FM because it can be generated by feeding the NRZ data stream into an analog VCO. FSK appears as a unit circle in the signal constellation because the RF signal envelope is constant and the phase is continuous. Baseband filtering is usually applied for FSK to limit the RF bandwidth of the signal so that more channels can fit into a given frequency band.

One common modulation of this type is known as Gaussian minimum shift keying (GMSK), which is used for GSM and some other wireless applications. GMSK can be generated by following its definition: band-limit the NRZ data stream by a Gaussian low-pass filter, then modulate a VCO with modulation index (2 × frequency deviation/bit rate) set to 0.5. In other words, the single-sided frequency deviation is one-fourth of the bit rate ($\Delta f = R/4$).

Another way of generating GMSK is by I/Q modulator. Referring back to Eq. (1-19), any RF signal can be split into I and Q components. Unlike the QPSK mentioned before, baseband I(t) and Q(t) are not discrete points for FM signals; rather, they are continuous functions of time. The way to produce FM is shown in Figure 1-82. We first store all the possible values of $\cos[\phi(t)]$ and $\sin[\phi(t)]$ in a ROM lookup table, which will be addressed by the incoming data to generate the I and Q samples. The output data from the ROM is then applied to D/A converters, after low-pass filtering for signal smoothing, to produce the analog baseband I and Q signals. This method guarantees the modulation index to be exactly 0.5, which is required for coherent detection of GMSK (e.g., the GSM system). The same I/Q principle can also be applied to generating analog FM signals.

Single-Sideband AM (SSB AM). AM signals can be divided into three types: the conventional AM, double sideband suppressed carrier AM (DSBSC AM), and SSBSC AM. The first type is not attractive because for 100% modulation, two-thirds of the transmit signal power appears in the carrier, which itself conveys none of the information added by modulation. By using a balanced mixer (e.g., a Gilbert cell), one can generate DSBSC AM, where the carrier is totally suppressed and only the upper and lower sidebands are present. However, this is still not the best because the information is transmitted twice, once in each sideband. To further increase the efficiency of transmission, only one sideband is needed to deliver the information. The SSBSC AM can be generated by an I/Q modulator with the baseband information feeding the modulator (by quadrature), as shown in Figure 1-83. This modulation technique can greatly reduce the bandwidth of the signal and allows more signals to be transmitted in a given frequency band. This topic is discussed in detail in [7].

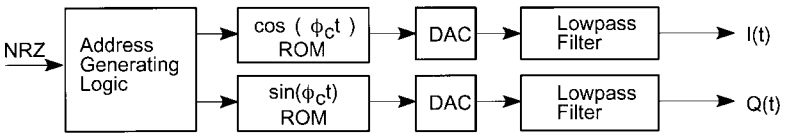

Figure 1-82 Digital FM (e.g., GMSK) baseband I/Q generator.

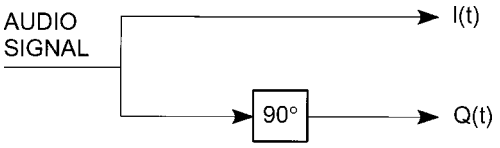

Figure 1-83 Baseband processing for SSBSC AM.

System Architecture. There are usually two schemes, the dual conversion and direct conversion, used for implementing transmit modulators. Dual conversion is simpler to implement by modulating an oscillator at lower frequency and then upconverting to the carrier frequency. This scheme, however, is more expensive due to the need for additional filtering and more printed circuit (PC) board space. By using only one mixer, direct conversion requires fewer components but is harder to implement.

The problems that direct conversion suffers are carrier leakage and modulated signal coupling. Poor RF isolation of the surface mount packages will allow the carrier to be present at the transmitter output, thus making it difficult to have –40 dBc carrier suppression. In addition, modulated RF signal would couple back to the oscillator (usually a VCO in a PLL synthesizer loop) and cause modulation distortion.

Based on the concept of dual conversion, the SA900 uses an image-reject mixer to eliminate the need for IF filtering and allow monolithic integration. The transmit carrier (LO) is downconverted by the frequency synthesized by the on-chip VCO, which operates from 90 to 140 MHz. This LO is then modulated by the baseband I/Q signals to obtain a complex modulation scheme. The image (sum term) after mixing and LO are sufficiently suppressed by the image-reject mixer. Any residual amounts can be further suppressed by an external duplex filter.

Figures 1-84 and 1-85, respectively, show how the SA900 can be used in frequency-division duplex (FDD) and time-division duplex (TDD) transceivers. Note that the LO for both systems is running at a frequency that is higher than the transmit frequency, thus minimizing carrier leakage. In the FDD system only one external VCO is required for generating both transmit and receive LO signals when using the SA900.

Figure 1-86 shows the IS-54 front-end chipset that consists of the SA601, SA7025, SA900, and SA637. This receiver architecture (SA637) supports a digital magnitude/phase baseband

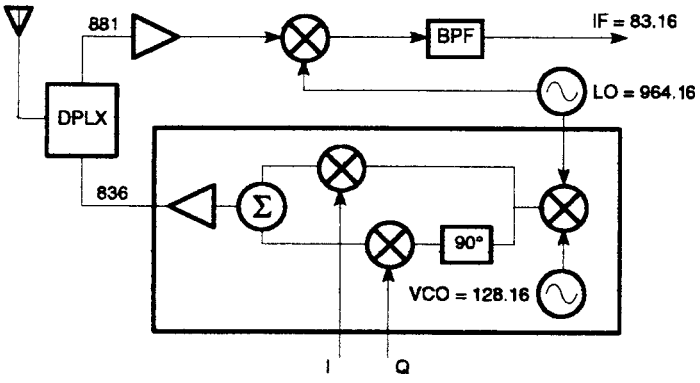

Figure 1-84 FDD system using SA900.

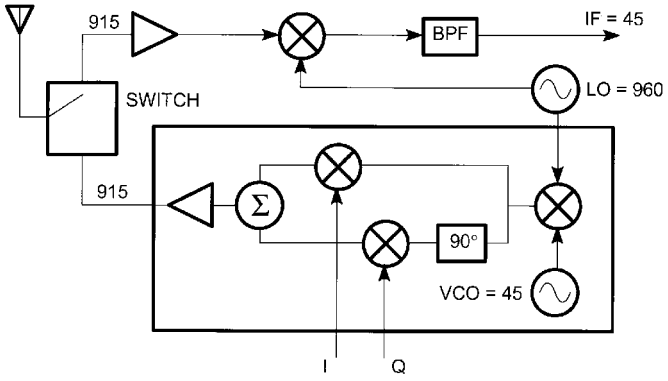

Figure 1-85 TDD system using SA900.

demodulator. An alternate configuration will be using the SA606 FM/IF receiver in conjunction with an external I/Q demodulator IC. Table 1-9 shows the possible configurations for the IS-54 handsets using the SA900 as transmitters.

Designing with the SA900

Baseband I/Q Inputs. The baseband modulation inputs are designed to be driven differentially for the SA900 to operate at its best. The I and Q inputs should have a dc offset of $V_{CC}/2$, which is externally provided by common DSP chips. If all four inputs are biased from the same source, the device can tolerate ±0.5-V dc error; however, inaccuracy of dc bias between I1/I2 or Q1/Q2 causes reduced suppression of the carrier. Thus, it is important to have a well-regulated dc supply for I and Q signal biasing. The bandwidth of the inputs is much higher than the specified 2 MHz. Approximately 2 dB of power loss will be experienced if the I and Q inputs are 50 MHz.

The SA900 generates a minimum of 0 dBm of power to a 50-Ω load when the amplitude of the I and Q signals are 400 mV P-P. The output power will decrease by 6 dB for every 50% decrease in I/Q amplitude. Single-ended I and Q sources can be used but are not recommended due to the degradation in carrier suppression (more than 10 dB compared to differential). In addition, the entire noise performance of the device will suffer. $V_{CC}/2$ should be applied to I2 and Q2 pins if the part is driven single-endedly.

Transmit Local Oscillator. The transmit local oscillator path consists of a TXLO input buffer, LO output buffer, VCO, image-reject mixer, and phase shift network. Together with a few external components, this section provides the I and Q carriers for modulation.

The TXLO inputs and LO outputs are designed to be used in an external PLL that synthesizes different frequencies for channel selection. The RF signal being generated is fed into TXLO inputs and then comes out of LO outputs to complete the system synthesizer loop. The TXLO inputs are differential in nature and have a voltage standing wave ratio (VSWR) of 2:1 with input impedance of 50 Ω. Single-ended sources can be used by ac grounding the TXLO_2 input, as done on the demo board. This signal should also be ac coupled into the TXLO_1 input. The frequency range for these inputs is from 900 to 1040 MHz while the input power should be between −10 and −13 dBm. The output level will be changed significantly if the input level is below −25 dBm.

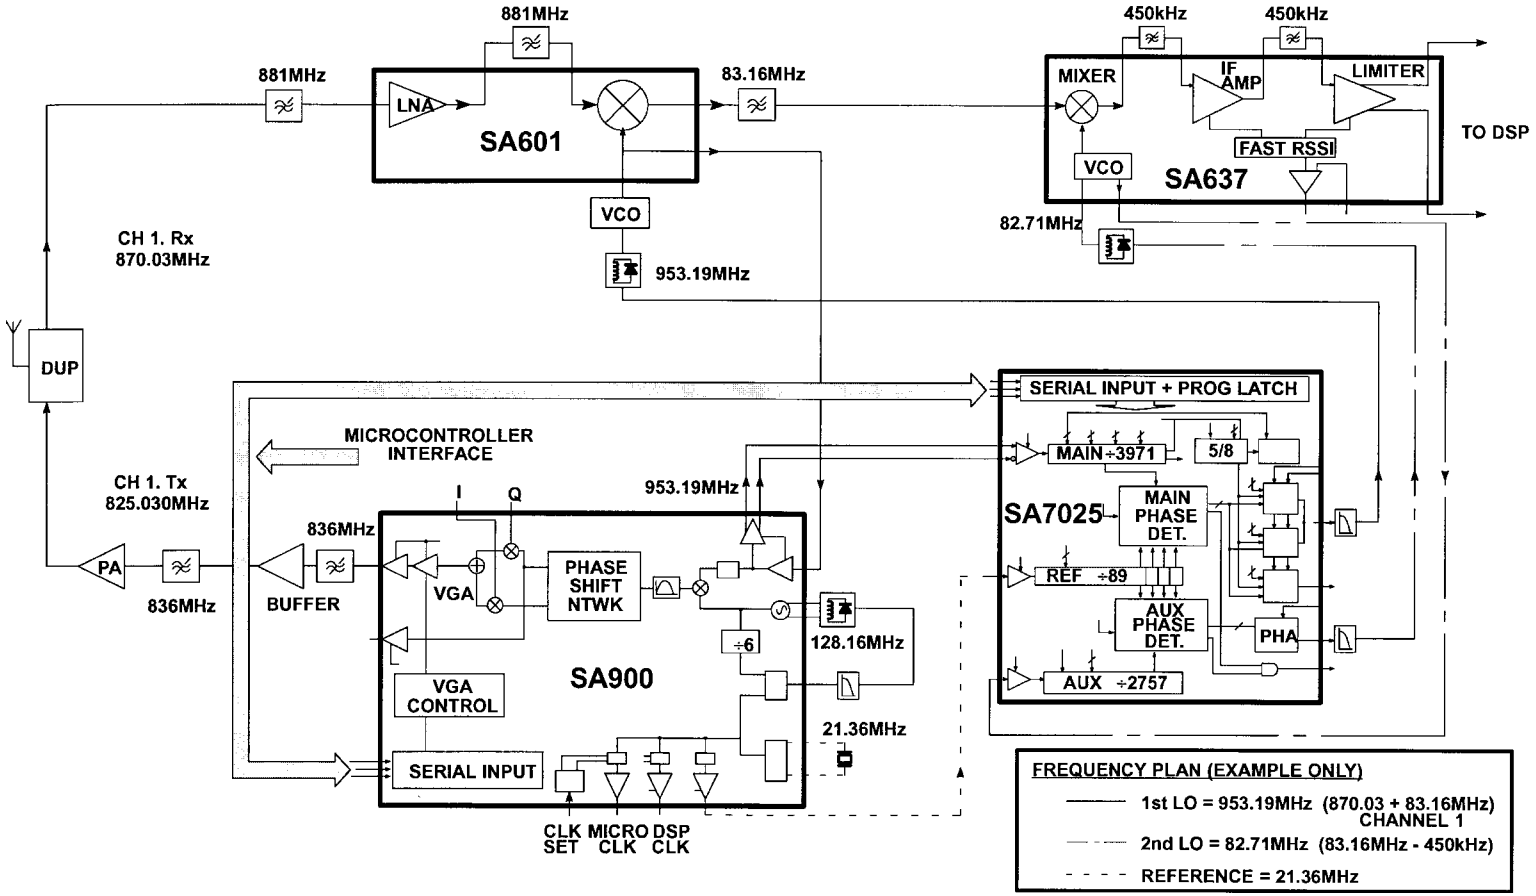

Figure 1-86 IS-54 front-end chipset from Philips.

Table 1-9 Possible configurations for IS-54 handsets

Rx First IF	On-Chip VCO Frequency	On-Chip ÷ *N* Value	Crystal Frequency
83.16 MHz	128.16 MHz	6	21.36 MHz
71.64 MHz	116.64 MHz	6	19.44 MHz
45 MHz	90 MHz	6	15 MHz
84.6 MHz	129.6 MHz	9	14.4 MHz

The output power of the LO buffered signal changes by about 2 dB when the SA900 is in a different mode of operation. Typical values are –13.5 dBm and –15.5 dBm for DUAL mode and STANDBY mode, respectively.

The 90° phase shift network, realized by resistor–capacitor (RC) networks, is capable of operating over a wide frequency range. Even though their frequency characteristics are optimized for cellular band, the part can also be used in other applications in a different band. In such cases, designers have to test the part experimentally to find out the performance, such as sideband suppression, carrier suppression, and image rejection.

Crystal Oscillator. The crystal oscillator (XTAL_1 and XTAL_2 pins) is used to provide a reference frequency between 10 and 45 MHz for the phase detector and the three on-chip clocks. It can be configured as a crystal oscillator using an external crystal and capacitors, or it can be driven by an external source. In the latter case, pin XTAL_2 can be left floating. Information regarding crystal oscillator design can be found in [8].

VCO. The VCO, together with the phase detector, the divider, and an external low-pass filter, can form a PLL for the transmit offset frequency. The image-reject mixer downconverts the TXLO signal to the RF carrier by the amount of VCO frequency. Thus the TXLO frequency should be the desired channel frequency plus the IF offset generated by the VCO. Note that the part will not function if the VCO section is not used.

The VCO is designed for generating IF frequency between 90 and 140 MHz. Together with an external varactor diode and resonator, it can be configured as an oscillator as shown in Figure 1-87.

The resonant frequency of such a circuit is

$$f_{\text{VCO}} = \frac{1}{2\pi\sqrt{LC_T}} \tag{1-20}$$

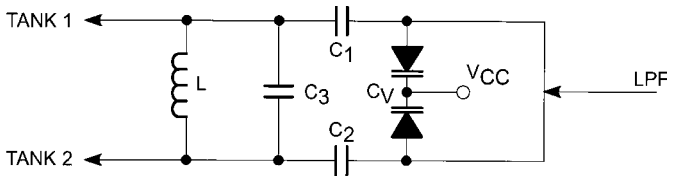

Figure 1-87 VCO tank circuit.

where $C_T = (C_1 \parallel C_2 \parallel C_V) + C_3$. C_V is a varactor diode, which changes capacitance as the voltage across it varies.

Calculation

$$C_1 = C_2 = 33 \text{ pF}$$

$$C_3 = 5.6 \text{ pF}$$

$$C_V = 33.5 \text{ pF @ } 2.5 \text{ V}$$

$$L = 100 \text{ nH}$$

$$C_T = 5.6 + (1/33 + 1/33 + 1/33.5)^{-1} = 16.7 \text{ pF}$$

$$f_{\text{VCO}} = \frac{1}{2\pi(100\text{E} - 9 \times 16.7\text{E} - 12)^{0.5}} = 123\text{MHz}$$

On the demo board, a 1:1 ratio RF transformer is also included to allow single-ended external source driving differential inputs when the VCO is not used.

When designing the VCO, careful printed circuit board (PCB) layout has to be made. Traces have to be short to avoid the parasitic capacitance and inductance that may cause unwanted oscillation. Referring to Eq. (1-20), there are a large number of combinations of L and C_T values that will give the same resonant frequency. If undesired spurs are found in the design due to PCB layout, experimenting with a different set of LC values may sometimes solve the problem.

Output Impedance Matching. The equivalent output impedance at the DUALTX pin is approximately equal to 600 Ω in parallel with 2 pF at 830 MHz. It has to be matched properly to generate maximum power into a 50-Ω load (e.g., a SAW filter). Figure 1-88 shows the recommended matching network. The shunt inductor (L_1) is used to provide maximum swing at the output (short at dc) and also provide reactance to make the real impedance 50 Ω looking

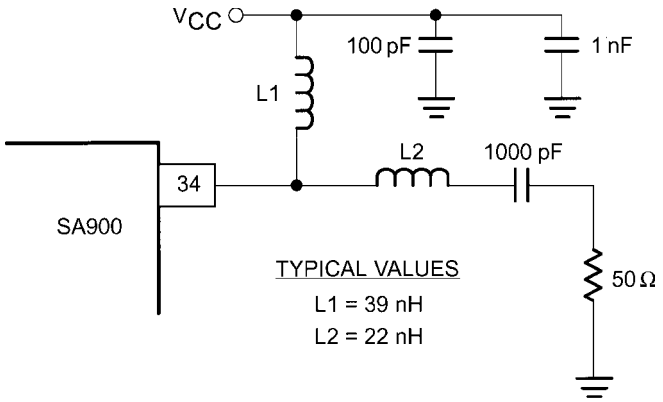

Figure 1-88 DUALTX output matching network.

into the matching network. The remaining negative reactance is canceled by the series inductor (L_2). The values used on the demo board can be used as a reference but may not be suitable if a different layout is implemented. The two shunt capacitors are included to bypass the high-frequency RF signal, avoiding direct coupling into V_{CC}. The series ac coupling capacitor is used to maintain the proper bias for the output stage. Their values are big enough to be left out in the impedance matching calculation.

Using a network analyzer to measure the SA900's output *S* characteristic is necessary for obtaining optimum matching, which generates maximum output power. Figure 1-89 shows how to match the output impedance to a 50-Ω load at 915 MHz. First, calibrate the network analyzer to the DUALTX SMA connector on the demo board. Then, short the point where the series inductor is located and use the DELAY feature of the network analyzer to move the point of reference in the Smith Chart to the leftmost point. Now the network analyzer is calibrated to the beginning of the matching network, not just the SMA connector. The frequency response (Figure 1-89a) shows that the "dip" is around 830 MHz, the frequency where the board was originally matched. The Smith Chart shows that it requires less inductance to bring the marker to the center of the chart (50 Ω). By using a 15-nH series inductor, the "dip" was moved closer to 915 MHz (–15 dB) and a better match is achieved (Figure 1-89b).

On-Chip Clocks. The crystal oscillator is buffered to provide three external clock signals: CLK1, CLK2, and MCLK. Table 1-10 shows the divide ratio and the controlling mechanism. CLK1 is usually used for the system synthesizer (e.g., SA7025) reference. Since MCLK is active all the time, it is ideal for providing the master clock for the microcontroller. When the device is in STANDBY mode, CLK1 and MCLK provide the clock signals necessary for receiving RF signals. CLK2 can also be used as a clock for the digital signal processing (DSP) chip.

Modes of Operation. The SA900 is intended for either AMPS mode (analog cellular) or DUAL mode (digital cellular, IS-54) operation. When the device is running in AMPS mode, the I/Q modulator, variable gain amplifier (VGA), and phase shifter are disabled. The fixed-gain amplifier is powered up during AMPS mode operation. However, since the divide ratio is too low (6, 7, or 8), the comparison frequency of the on-board PLL is too high, making it very difficult for the loop bandwidth to be less than 300 Hz for analog frequency modulation. The device includes two power-saving modes of operation that disable partial circuitry to reduce the power consumption of the overall chip. The SLEEP mode disables all the circuitry except the master clock (MCLK pin) of the SA900. The STANDBY mode shuts down everything except the TXLO buffer, MCLK, and CLK1, which allows the system synthesizer (e.g., SA7025) to continue running. These two power-saving modes are common to both AMPS and DUAL mode operation. The SA900 draws 60 mA in the DUAL mode, reduced to 3 mA and 8 mA, respectively, in the SLEEP and STANDBY modes.

The TXEN pin is for hardware powering down the modulator and synthesizer. The falling edge of the signal disables the modulator and synthesizer while the rising edge enables the modulator. To power down the synthesizer using software, send a data word with the SE bit set to "0" ("1" for enable). The synthesizer will be disabled right after the strobe signal is transmitted. Either SE or TXEN going low will turn off the synthesizer. This operation is common to both the AMPS and DUAL modes.

Performance of the SA900

Performance Criteria. Since the I/Q modulator is a universal transmitter, measuring only the frequency stability and modulation index of a generated FM signal would not be useful for other modulation schemes. Measurement parameters should be general enough so that they can represent the performance of modulators when applying different types of modulation and allow fair comparisons among different I/Q modulators. Based on this idea, two measurement techniques—in-phase modulation and quadrature modulation—are used for evaluating I/Q modulators.

The in-phase modulation relies on injecting two equal frequencies and phase signals at f_{mod} into the I and Q inputs. The result of this modulation is two sidebands appearing at f_{mod} offset from the carrier, with the carrier totally suppressed. This is also known as double-sideband (DSB) conversion. The quadrature modulation requires two equal frequencies (but 90° out-of-phase signals) being injected into the I and Q inputs. The result is a single-sideband suppressed carrier (SSBSC) signal with either the upper or lower sideband at f_{mod} carrier offset being suppressed. This is also known as single-sideband (SSB) upconversion. Figure 1-90 summarizes these two tests.

In a practical system, imperfection of an I/Q modulator is directly related to these two measurements. Sideband and carrier suppression from the quadrature modulation test will show the amount of gain imbalance, phase imbalance, and dc offset. On the other hand, intermodulation product suppression from the in-phase modulation test will show the linearity of an I/Q modulator. When making measurements, it is important to have well-balanced I and Q baseband modulating signals for measurement since the signal imperfection will translate into degraded sideband and carrier suppression.

Performance Graphs. In making those measurements for the demo board, the following parameters were used:

In-Phase Modulation

PIN 43 I1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 0°
PIN 42 I2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 180°
PIN 41 Q1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 0°
PIN 40 Q2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 180°

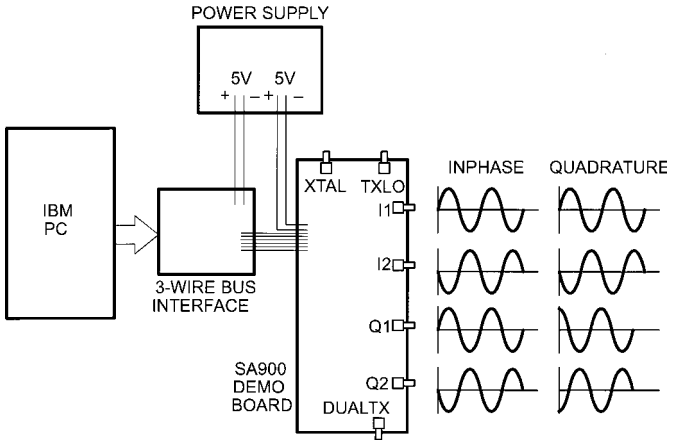

Figure 1-90 In-phase and quadrature modulation test.

Quadrature Modulation

PIN 43 I1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 0°
PIN 42 I2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 180°
PIN 41 Q1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 90°
PIN 40 Q2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 270°

Figure 1-91 illustrates what the typical output spectra would be if in-phase and quadrature modulation were applied to an I/Q modulator. Quadrature modulation will produce lower sideband (LSB) or upper sideband (USB) signal, depending on the phase angle between the I and Q signals. The SA900 was designed to have USB suppressed when the I signal leads the Q signal. The undesired signals are carrier breakthrough and the harmonic products of the baseband modulating signals sitting at $f_c \pm nf_{\text{mod}}$, where n is an integer ≥ 2.

Referring to Figure 1-91a, the output power is 1.3 dBm (cable loss = 0.7 dB) for the LSB while better than 38 dBc of carrier, sideband, and harmonics suppression is measured. The USB suppression of better than 26 dBc implies the residual AM of the transmit signal is better than 5%, a requirement of the IS-54 specification.

The in-phase modulation test will generate both LSB and USB. Beside these two tones, the carrier breakthrough and the harmonics, intermodulation (IM) products will all appear at the output. The odd IM products are dominant, and they satisfy the following rules: Let $f_1 = f_c - f_{\text{mod}}$, and $f_2 = f_c + f_{\text{mod}}$.

$$\text{Third-order IM:} \quad 2f_1 - f_2 = f_c - 3f_{\text{mod}}, \quad 2f_2 - f_1 = f_c + 3f_{\text{mod}}$$

$$\text{Fifth-order IM:} \quad 3f_1 - 2f_2 = f_c - 5f_{\text{mod}}, \quad 3f_2 - 2f_1 = f_c + 5f_{\text{mod}}$$

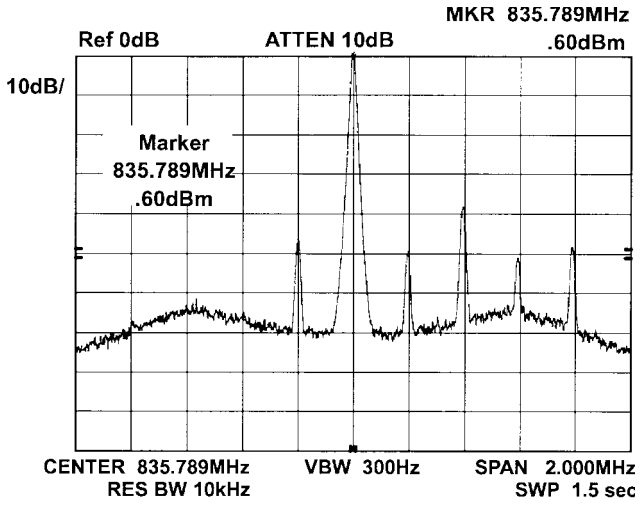
$$\text{Seventh order IM:} \quad 4f_1 - 3f_2 = f_c - 7f_{\text{mod}}, \quad 4f_2 - 3f_1 = f_c + 7f_{\text{mod}}$$

Referring to Figure 1-91b, the LSB and USB are –1.6 dBm (cable loss = 0.7 dB), which is 3 dB less than the measured power for the quadrature modulation test. The IM3 is better than –35 dBc. IM products of much higher orders are totally suppressed.

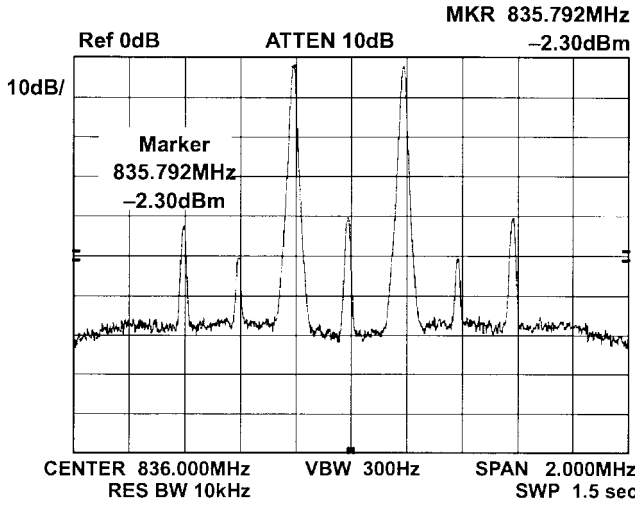
Amplitude and Phase Imbalance. Both amplitude and phase imbalance (error) of an I/Q modulator can be calculated directly from the SSB performance plots. Assuming that phase error equals ϕ radians and amplitude error equals K. The sideband suppression, X, in dBc can be expressed as (see the section entitled "I/Q Modulator Equations" for the derivation):

$$\text{SSB suppression,} \quad X(\text{dBc}) = 10 \log\left(\frac{K^2 + 2 \times K \times \cos(\phi) + 1}{K^2 - 2 \times K \times \cos(\phi) + 1}\right) \tag{1-21}$$

Collecting the like terms and expressing ϕ in terms of K and X, we find



a. Quadrature Test (SSB Up-conversion)



b. In-phase Test (DSB Up-conversion)

Figure 1-91 Typical SA900 output spectra.

$$\phi = \cos^{-1}\left(\frac{10^{X/10} \times K^2 + 10^{X/10} - 1 - K^2}{2 \times K + 2 \times K \times 10^{X/10}}\right) \tag{1-22}$$

For a given X, there will be a set of ϕ and K that satisfies Eq. (1-22). We can represent this relationship graphically, as shown in Figure 1-92. The contours show the phase and amplitude errors for SSB suppression, X, from 44 to 26 dBc. When X equals 40 dBc, phase error is less than 1.2° with an amplitude error of 0 dB. By the same token, the amplitude error is less than 0.2 dB with a 0° phase error.

Spectral Mask. To fully characterize the performance of an I/Q modulator, measurements of the power spectral density of various digital modulation schemes have to be made. Figures 1-93a and 1-93b show the measured spectral masks of IS-54 and PDC standards, which designate π/4-DQPSK as the modulation format.

GMSK is a digital modulation scheme widely used for wireless and mobile communications. Figure 1-93c shows the spectral mask of the modulation format required by GSM, the digital cellular standard in Europe. At carrier offsets of 200 and 300 kHz, the power of the signal is suppressed by 46 and 58 dB, respectively, which is well within the GSM specification.

Power ON Time. The power ON time for the SA900 is mainly determined by the loop bandwidth of the on-board PLL frequency synthesizer. It can be measured by using the HP 53310A modulation domain analyzer set to the EXTERNAL TRIGGERED mode. The STROBE signal from a three-wire bus is used to trigger the equipment. Figure 1-94 shows that the part can be powered up and locked in about 62 μs.

ISM Band Application. In the United States the industrial, scientific, and medical (ISM) band from 902 to 928 MHz is attractive because users are allowed, without having a license, to use transmit powers up to 1 watt in frequency hopping or direct sequence CDMA operation. The wide bandwidth nature of the SA900 fits well into this application. Figure 1-95 shows the output spectra of the SA900, illustrating how well the image-reject mixer works. A common IF (45 MHz) was chosen to be the offset frequency, and then injected externally into the VCO pins. The closest images (± 45 MHz), are down more than 36 dBc.

I/Q Modulator Equations. Assume an imperfect I/Q modulator with gain error K and phase error ϕ, modulated by quadrature I/Q signals (SSB upconversion) ω_m. Then the signal, $s(t)$, at the output of the I/Q modulator becomes

$$s(t) = K\cos(\omega_c t + \phi)\cos(\omega_m t) - \sin(\omega_c t)\cos(\omega_m t + 90°) \tag{1-23}$$

Using trigonometric identity and letting $\omega_c - \omega_m = A$ and $\omega_c + \omega_m = B$, we obtain

$$s(t) = \frac{K}{2}\cos(At + \phi) + \frac{K}{2}\cos(Bt + \phi) + \frac{1}{2}\cos(At) - \frac{1}{2}\cos(Bt) \tag{1-24}$$

Assume the information is in the LSB—that is, A—and the spur is the USB—that is, B. We have

$$\text{Signal} = \frac{K}{2}\cos A \cos\phi + \frac{1}{2}\cos A - \frac{K}{2}\sin A \sin\phi \tag{1-25}$$

$$\text{Noise} = \frac{K}{2}\cos B \cos\phi + \frac{1}{2}\cos B - \frac{K}{2}\sin B \sin\phi \tag{1-26}$$

To find the power, we have to evaluate the envelope (amplitude) of these two signals. Recall that for any given bandpass signal in rectangular form, that is, bandpass signal = $X \cos \omega_t - Y \sin \omega_t$, the envelope is

$$\text{Envelope} = (X^2 + Y^2)^{0.5}$$

Therefore, from Eqs. (1-25) and (1-26)

$$\text{Signal} = \left[\left(\frac{K}{2}\cos\phi + \frac{1}{2}\right)^2 + \left(\frac{K}{2}\sin\phi\right)^2\right]^{0.5} \tag{1-27}$$

$$\text{Noise} = \left[\left(\frac{K}{2}\cos\phi - \frac{1}{2}\right)^2 + \left(\frac{K}{2}\sin\phi\right)^2\right]^{0.5} \tag{1-28}$$

Finally, the S/N ratio can be found by taking 10 log the ratio of Eqs. (1-27) and (1-28):

$$S/N = 10\log\left(\frac{K^2 + 2K\cos\phi + 1}{K^2 - 2K\cos\phi + 1}\right) \tag{1-29}$$

1-6 BUILDING BLOCKS

Our earlier block diagram already referred to a variety of integrated circuits that can be used to build a wireless system—in particular, a portable telephone. If we open any of the earlier-mentioned magazines and go through its advertising section, we will find many suppliers of subsystems/components that fit this requirement.

They can be split into various technologies. The following list is a product overview of next-generation advances in wireless technology taken from an ad of Stanford Microdevices, one of the very aggressive component/subsystem companies:

- New SX amplifiers featuring 2.4-GHz MMICs
- GaAs heterojunction bipolar transistor (HBT) discrete transistors (100 mW to 10 W)
- InP/GaAs (indium phosphate/gallium arsenide) high-linearity gain blocks
- Millimeter-wave product line featuring ICs for LMDS
- Silicon–germanium product line (gain blocks and low-noise amplifiers)
- SXQ power modules for cellular and PCS applications
- Power modules featuring 4–25-W power amplifiers for land mobile amplifiers
- Thirty- to 120-W silicon LDMOS power transistors for PCS, CDMA, and W-CDMA
- SAW filters featuring integrated transceiver modules
- Electro-optic and data communications products

More information about Stanford products is available at **http://www.stanfordmicro.com/**. Another interesting company along these lines is Maxim Integrated Products

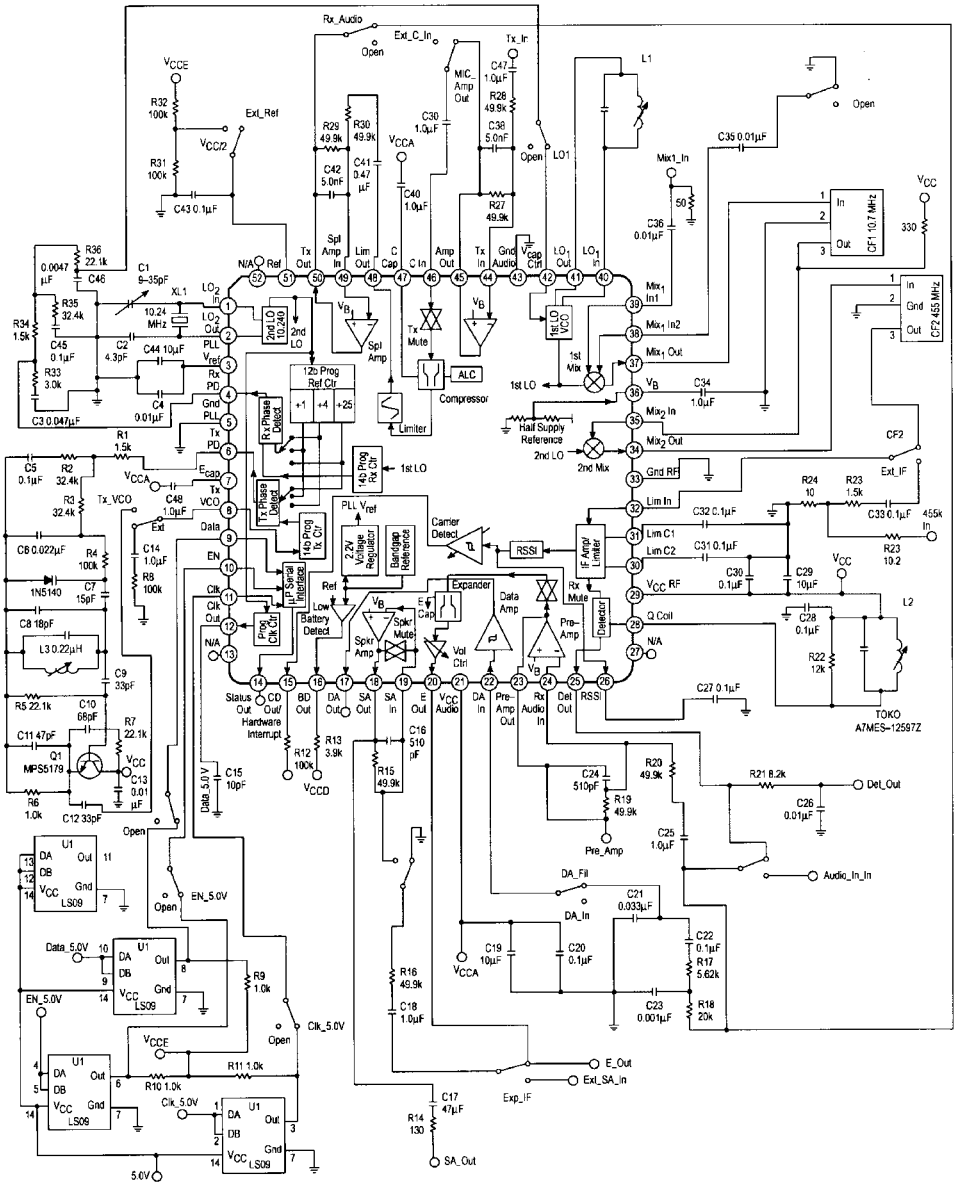

Figure 1-96 MC13109FB universal cordless telephone subsystem IC.

(**http://www.maxim-ic-com/**). They distribute an Analog Design Solutions brochure describing, among other things, the industry's first SiGe RFICs for improved radio front-end performance (1999). On the base-station side, companies such as Hewlett-Packard and Synergy Microwave produce high-performance components/modules as they are needed in the more hostile environment of base-station operation. The offerings in the field are changing very rapidly, and the best way to deal with this is to obtain subscriptions to the magazines mentioned earlier or contact manufacturers directly. Among those not mentioned are Alpha, Ericsson, Siemens (now Infineon Technologies), Motorola, and NEC.

In the beginning of this chapter we looked at block diagrams; here we focus on building blocks. Most manufacturers will try to move to the highest possible integration while avoiding external components. Figure 1-96, a test circuit for Motorola's MC13109FB cordless telephone subsystem IC, shows the level of complexity needed to test such an IC with all its functionality.

Another key issue at those frequencies is to really know a component's frequency dependencies. Figure 1-97 shows a good example. Typical components are capacitors and inductors as reactive elements, and resistors as passive elements. Depending on the type of integration, one may also have to look into the noise performance of integrated resistors. Examination of this issue is best achieved through discussions with the foundries. Along these lines, the dielectric material on which these surface-mounted components are mounted plays a big role and must be addressed individually.

Besser Associates of Los Altos, California, among other firms, offers a very nice one-day short course titled "Wireless Circuit Components: Measurements, Models and Data Extraction."

Table 1-11 presents a sampling of RFICs for wireless applications. These types of ICs, which were taken from Motorola, are made in similar form by many companies. The selection guide is useful in starting off with a design that is less integrated, therefore allowing the designer to have access to portions of the circuit that later "disappear" inside the IC.

[a]Dual PLL.

1-7 SYSTEM SPECIFICATIONS AND THEIR RELATIONSHIP TO CIRCUIT DESIGN

Wireless communication involves a large range of signal powers—from levels on the order of 10^{-18} watt (at the receiver input) to 10^{2} watts (at a base-station transmitter output). A receiver must be able to demodulate signals that have been attenuated billions of times through propagation; a transmitter must be able to produce a properly modulated signal at a frequency suitable for propagation, at a level high enough to overcome worst-case propagation losses and provide a useful signal at the receiver. Gain is therefore an essential attribute of wireless systems. Because no single active device can provide all the gain required for transmission or reception, we must distribute the gain among multiple stages, designing each for optimum performance across the power span it bridges.

Two inescapable realities impose limits on the gain and absolute power output we may achieve with a given circuit: All real electrical and electronic networks generate noise to some degree, and all real electrical and electronic networks distort the signals applied to them to some degree. A signal weaker than a circuit's inherent noise cannot be amplified by that circuit because it remains indistinguishable from the noise. A signal that exceeds the power-handling capability of the circuit to which it is applied may be degraded, even rendered useless, by the resulting distortion. The following sections examine issues particular to system noise and linearity performance.

1-7-1 System Noise and Noise Floor

Assuming that a system's gain is sufficient, the weakest signal that may be processed satisfactorily, a figure of merit referred to as *noise floor* or (in receivers) *minimum detectable signal* (*MDS*), is limited by thermal noise, assumed to be equal to the noise power available from a resistor at 290 K (about 17 °C or 62 °F), an arbitrary reference value near standard room temperature. The noise power is equal to

$$P_n = kTB \tag{1-30}$$

where P_n is the noise power, k is Boltzmann's constant (1.38×10^{-23} watts per kelvin), T is the temperature in kelvins, and B is the bandwidth (in hertz) in which the noise appears. For $T = 290$ K, P_n is therefore 4.00×10^{-18} watts, or –174 dBm in a 1-Hz bandwidth. Increasing B to a value suitable for digital communications, such as 160 kHz for a GSM system, admits more noise to the network, raising the minimum noise power against which an incoming signal must compete to –122 dBm.

If the noise figure and bandwidth are known, the noise floor can be calculated using the equation

$$\text{Noise floor} = -174 \text{ dBm} + NF + 10 \log B \tag{1-31}$$

The trouble with this equation is that the "integrated" bandwidth depends so much on the selectivity shape factor, which is not always known. Figure 1-98 shows the translation of the bandwidth of a single tuned circuit with its Gaussian shape into its rectangular equivalent. The transformation is done by sizing the rectangle such that A′ = A and B′ = B; when this is true, the area of the rectangle equals the area under the curve.

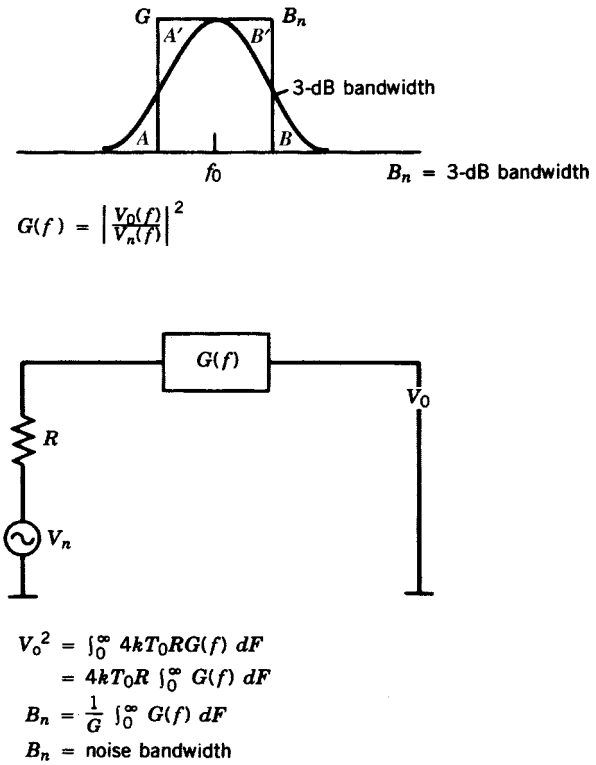

Figure 1-98 Graphical and mathematical explanation of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

Signal-to-Noise Ratio (S/N, SNR) and Sensitivity. Successful radiocommunication depends on the achievement of a specified minimum ratio of signal power to noise power, expressed in decibels, at the output of the receiver. The input voltage, expressed in absolute units or decibels relative to a microvolt (dBμV), necessary to achieve a particular signal-to-noise ratio in a particular bandwidth may be specified as a figure of merit called *sensitivity*. Because techniques used to measure S/N actually measure the ratio of signal-*plus-noise* to noise, specifications may refer to (or imply) S+N/N or (S+N)/N rather than S/N. The difference between (S+N)/N and S/N becomes negligible at high ratios of signal to noise; even at an SNR of 10 dB—a common value—the difference is only 0.46 dB [9].

Most receivers are designed to operate optimally when connected to an antenna system of a specified impedance (commonly 50 Ω), but relatively few receivers exhibit this design load impedance at their input terminals; that is, they are not designed for a conjugate input match. It is therefore customary to specify sensitivity in terms of "open circuit" voltage—the signal voltage that, with the receiver's antenna input terminated in its design antenna impedance, results in the desired ratio of signal to noise. If, as is commonly the case, the input voltage for a given SNR is determined using instrumentation calibrated in terms of *closed*-circuit voltage—that is, in terms of voltage across a load resistance equal to the instrument's source resistance—the voltage indicated will be one-half the open-circuit value for the SNR specified [10]. By convention, the open-circuit measurement condition is indicated by a sensitivity specification in volts of electromotive force (EMF). Specifying sensitivity in

terms of available signal power (usually decibels relative to 1 mW, or dBm) eliminates this open/closed-circuit confusion.

SINAD Ratio. Extending the measurement of signal-plus-noise to noise to include distortion results in a figure of merit called *SINAD* (signal-plus-noise-and-distortion), commonly applied to FM receivers:

$$SINAD = 10 \log_{10}\left(\frac{S+N+D}{N+D}\right) \tag{1-32}$$

where *SINAD* is in decibels, S is signal power, N is noise power, and D is distortion power. At a SINAD ratio of 12 dB—a common specification—the noise-and-distortion power is 25% that of the desired signal. As is true of (S+N)/N, SINAD closely approximates S/N at high ratios of signal to noise.

Bit Error Rate and Noise. For digital systems, signal-to-noise ratio and bit error rate are related. As introduced earlier, depending on the waveform, coding, and filtering, different BERs are related to particular SNRs (Figure 1-99). The SNR also depends on the interference from the synthesizer, as will be seen in the section on adjacent-channel power ratio (ACPR). Since a digital transmitter is always involved, in the on-the-air testing the laboratory measurement of SINAD cannot quite be correlated. At the IF level, we find the handover point between the transceiver's analog front end and its digital portion, and a standard noise-figure test setup, such as the one by Hewlett-Packard, is still a valuable instrument for evaluating noise figure and signal-to-noise ratio.

Here is an example for a digital measurement: Assume that we use a test generator like the SMIQ to evaluate a front end having an 8.8-dB noise figure. A 384-kbps π/4-DQPSK digital modulation signal (–5 dBm) is applied to the transceiver front end. Testing at 2.47 GHz, we find that the error vector magnitude (EVM; defined later in this section) is about 3.89% in transmit and about 1.37% in receive. To determine the receive sensitivity of the RF front end, the signal from the digitally modulated generator (at –95 dBm) is applied to the

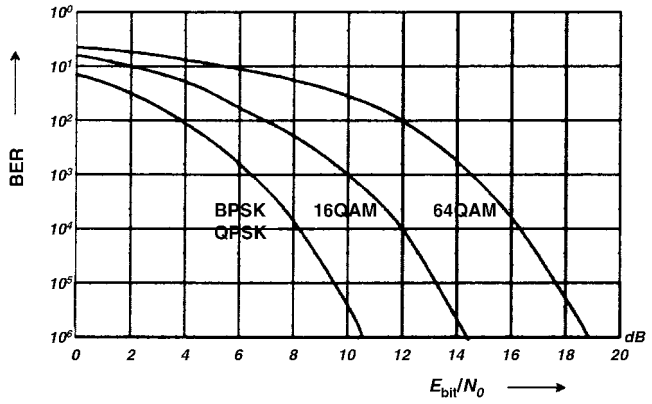

Figure 1-99 Bit error rate versus E_{bit}/N_0 for BPSK/QPSK, 16-QAM, and 64-QAM, showing the significantly greater SNR necessary for a given BER as the number of signal states is increased.

RF front end in receive mode. The measured EVM at 2.47 GHz is now 20%. By using the equation

$$S/N = -20 \log (EVM) \tag{1-33}$$

we see that the ratio that corresponds to an EVM of 20% is 14 dB, since

$$S/N = \frac{(E_S R_{S)}}{N_0 B} \tag{1-34}$$

where E_S is the energy of a symbol, R_S is the symbol rate, N_0 is the noise power density, and B is the bandwidth. Assuming a π/4-DQPSK signal and ratio of 14 dB, it can be determined that

$$E_S/N_0 = (S/N)\ (B/R_S) = 17 \text{ dB} \tag{1-35}$$

Assuming that the BER is 1E – 5, the required E_S/N_0 is 10 dB. Hence, from the definition of the sensitivity,

$$\begin{aligned} \text{Sensitivity} &= -144 + NF + R_S + E_S/N_0 \\ &= -144 + 8.8 + 10 \log(384/2) + 10 \\ &= -102 \text{ dBm} \end{aligned} \tag{1-36}$$

The value –144 is derived from kT_0 by taking the bandwidth into consideration.

The result obtained in Eq. (1-36) is consistent with the obtained E_S/N_0 of 17 dB from the measurement at –95 dBm input power [since –102 + (17 – 10) = –95]. Hence, it was determined that the receive sensitivity of the RF front end is approximately –102 dBm. We can then determine the dynamic range (DR) from

$$DR = \text{P}_{-1\text{dB}} - \text{Sensitivity} = -21 - 102 = 81 \text{ dB} \tag{1-37}$$

Noise Factor and Noise Figure. The noise floor predicted by Eq. (1-30) cannot be achieved and maintained in any real network or system of networks because all real networks generate noise. Determining how closely the SNR achieved at a given input level approaches the SNR achievable at that input level in a noiseless network is therefore of high interest to the circuit and system designer. The degree to which a network's noise contribution degrades the noise floor predicted by Eq. (1-30) is evaluated by its *noise factor* (*F*), which is expressed as the ratio

$$F = \frac{N_{\text{in}} + N_{\text{added}}}{N_{\text{in}}} \tag{1-38}$$

where F is the noise factor, N_{in} is the noise power available from the source, and N_{added} is the noise power added by the network, with both powers determined in the same bandwidth. Expressing this ratio in decibels ($10 \log_{10} F$) returns the *noise figure* (*NF*), a bandwidth-

independent figure of merit of great value in evaluating the noise performance of networks and communication systems. We can also express NF as the ratio of the network's input SNR to its output SNR:

$$NF = 10 \log_{10} \left[\frac{(S_{in}/N_{in})}{(S_{out}/N_{out})} \right] \tag{1-39}$$

where NF is the noise figure in decibels, S is signal power, and N is noise power, with the input and output values of these quantities signified by the subscripts and all powers determined in the same bandwidth. The noise figure of an ideal noiseless network is 0 dB; for all real, noisy networks, NF is positive. The NF of a lossy passive device is equal to its insertion loss.

Noise figure can also be defined for antennas and antenna systems:

$$NF_{ant} = 10 \log_{10} \frac{N_t + N_{ant}}{N_t} \tag{1-40}$$

where NF_{ant} is the antenna system noise figure in decibels, N_t is the antenna system's thermal noise power, as defined in Eq. (1-30), and N_{ant} is the total noise power picked up by the antenna system. From the lower end of the radio spectrum, and decreasingly up to approximately 400 MHz, noise intercepted by an antenna system from atmospheric, human-generated, and galactic sources will dominate NF_{ant} (Figure 1-100), and N_t can be considered as equivalent to the noise power of a resistor at 290 K. Atmospheric noise subsides above 40 MHz; from this region to perhaps 700 MHz, N_t is still largely negligible, with noise from human-generated and/or sky sources largely determining an antenna's noise figure. At these frequencies, an antenna's directivity and orientation relative to noise sources play a critical role in determining its noise figure; a strongly directive antenna located in a city suburb, for instance, exhibits a significantly higher noise figure when pointed toward the city center than

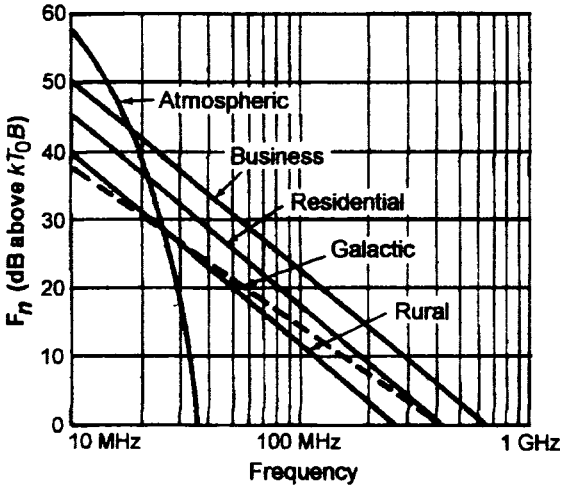

Figure 1-100 The higher the frequency, the more quiet the RF environment becomes, although the noise profile of specific sources may contradict this general rule.

it exhibits when pointed toward a more sparsely populated area. At frequencies above about 700 MHz, the RF environment is generally quieter, allowing receiver NF, not antenna NF, to more routinely limit a wireless receiver's sensitivity. At these frequencies, the concept of *noise temperature* is commonly used to evaluate the quietness of a receiver, its antenna system and its RF environment. Noise temperature is particularly useful in designing systems for space communication an antenna for which may be cooled, through radiation of a portion its own noise into the RF-cold sky, to a noise temperature an order of magnitude below 290 K.

Noise Figure of Cascaded Networks. The noise figure of two networks in cascade may be determined from

$$NF_{\text{total}} = 10 \log_{10}\left(F_1 + \frac{F_2 - 1}{G_1}\right) \tag{1-41}$$

where NF is the noise figure in dB, F_1 is the noise factor of the first network, F_2 is the noise factor of the second network, and G_1 is the gain (as a numerical ratio, *not* in dB) [11]. The noise figure of a system with more than two stages can be evaluated through repeated iterations of Eq. (1-41). Note that Eq. (1-41) assumes two conditions: (1) that F_1 and F_2 are determined in the same bandwidth, and (2) that the networks' input and output terminations are resistive—a condition that is commonly *not* true of RF amplifiers optimized for lowest noise. Equation (1-41) can be expanded to account for bandwidth, but accounting for complex terminations requires the use of *noise correlation matrix* techniques as described by Rohde et al. [9].

1-7-2 System Amplitude and Phase Behavior

If we could build electronic systems that were absolutely amplitude- and phase-linear, radiocommunication system design would be greatly simplified. An amplifier designed for a power gain of 10 dB, for example, would merely increase the power of all signals at its input by a factor of 10, regardless of their frequencies, while perfectly maintaining their relative phases. But all real electrical and electronic networks, even those designed (or supposed) to be amplitude- and phase-linear, exhibit amplitude and phase nonlinearity to some degree, just as they all generate noise to some degree.

The effects of amplitude nonlinearity, generically referred to as *nonlinear distortion*, include the generation, through *harmonic distortion* and/or *intermodulation distortion* (IMD), of output signals at frequencies not present at a system's input. Nonlinear distortion also results in *gain compression*—changes in system gain with changes in input-signal level. By convention, when workers in electronics refer to or consider a network's "linearity," they usually mean its *amplitude* linearity; likewise, by "distortion" they usually mean *nonlinear* distortion.

The effects of phase or frequency nonlinearity are generically referred to as *linear distortion* because they occur independently of signal amplitude and polarity. We often intentionally apply linear distortion through *filtering*, which modifies the amplitude relationships among existing spectral components of a signal without creating any new frequencies. Another linear-distortion effect, *phase* or *delay distortion*, results in the delay of signals of differing frequencies by differing amounts of time. In a system where signal phase conveys

information, as is true of most wireless links, phase distortion can seriously degrade communication.

The fact that all real networks are amplitude- and angle-nonlinear to some degree means that all real networks modify the amplitude and angle characteristics of the signals they handle. What is perhaps less obvious is that subjecting a signal to amplitude and angle nonlinearities causes "crosstalk" between its amplitude and angle characteristics. For example, through a nonlinear distortion effect called AM-to-PM conversion, changes in a signal's amplitude result in changes in its phase. Filtering an angle-modulated signal produces the reverse effect: Deprived by the filter's selectivity of spectral components necessary to maintain its envelope constancy, the signal emerges from the filter as a combination of angle and amplitude modulation.

Spectral Considerations of Analog and Digitally Modulated Signals. Many wireless modulation schemes exist and even more are proposed; all use angle (usually phase) modulation or a combination of phase and amplitude modulation using an emission format engineered to achieve multiple goals of information throughput, robustness, spectral and hardware efficiency, and reproducibility. Digital modulation is standard in mainstream wireless applications because it allows increased channel capacity, and immunity to noise and distortion, compared to analog systems. At the circuit-design level, the particulars of whether, or to what degree, a modulation scheme is AM, PM, analog, or digital matters less than the actual angle and amplitude characteristics of the signal(s) involved, and the tolerances within which these characteristics can be expected and allowed to vary.

A system's amplitude linearity is of major concern because of its relation to energy efficiency, receiver dynamic range, and transmitter spectral purity. Energy efficiency, important because many wireless applications use battery power, generally decreases inversely with amplitude linearity. Yet, sufficient amplitude linearity must be guaranteed in the front-end circuitry of wireless receivers subjected to multiple strong signals, and in all wireless receiver and transmitter stages handling variable-envelope signals.

Some digital modulation schemes, designed to be distortion-tolerant, produce constant-envelope signals; Gaussian minimum shift keying (GMSK) and Feher's quadrature phase shift keying (FQPSK) are examples of these. Such signals can be processed in highly nonlinear circuitry—for example, an RF power amplifier operated in saturation to maximize efficiency—without degrading their spectral composition. Other digital modulation schemes result in the emission—ideally—of a single PM sideband, with the carrier and all other sideband components suppressed. Such a signal exhibits, of necessity, phase and amplitude variations; the IS-54 cellular standard's $\pi/4$ differential quadrature phase shift keying ($\pi/4$-DQPSK) scheme, which results in envelope fluctuations of 3–6 dB, exemplifies this [12]. Intermodulation distortion among such a signal's spectral components can generate products that fall outside the bandwidth painstakingly controlled in the modulation process. This *spectral regrowth* must be minimized to prevent adjacent-channel interference (Figure 1-101).

For a better understanding, Figure 1-102 shows the various channels and the energy levels associated with them.

Amplitude Linearity Issues and Figures of Merit. A network's amplitude nonlinearity can be characterized by the expansion

$$y = k_1 f(x) + k_2[f(x)]^2 + k_3[f(x)]^3 + \text{higher-order terms} \tag{1-42}$$

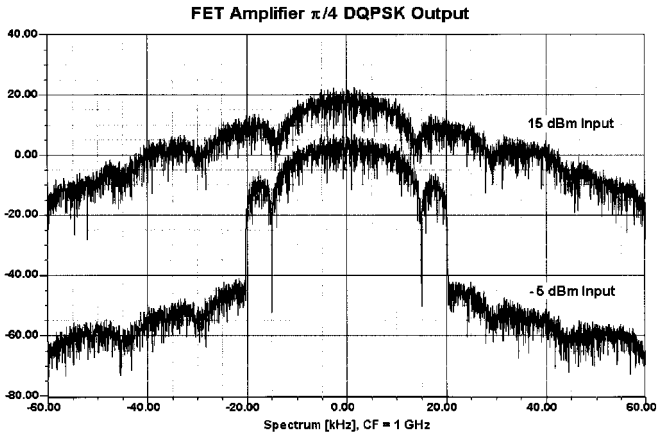

Figure 1-101 *Spectral regrowth* results when a variable-envelope emission, π/4-DQPSK in this case, is subjected to significant nonlinear distortion. This graph shows the simulated performance of a MESFET power amplifier operating at 1 GHz; the amplifier is 6 dB into compression when driven at 15 dBm.

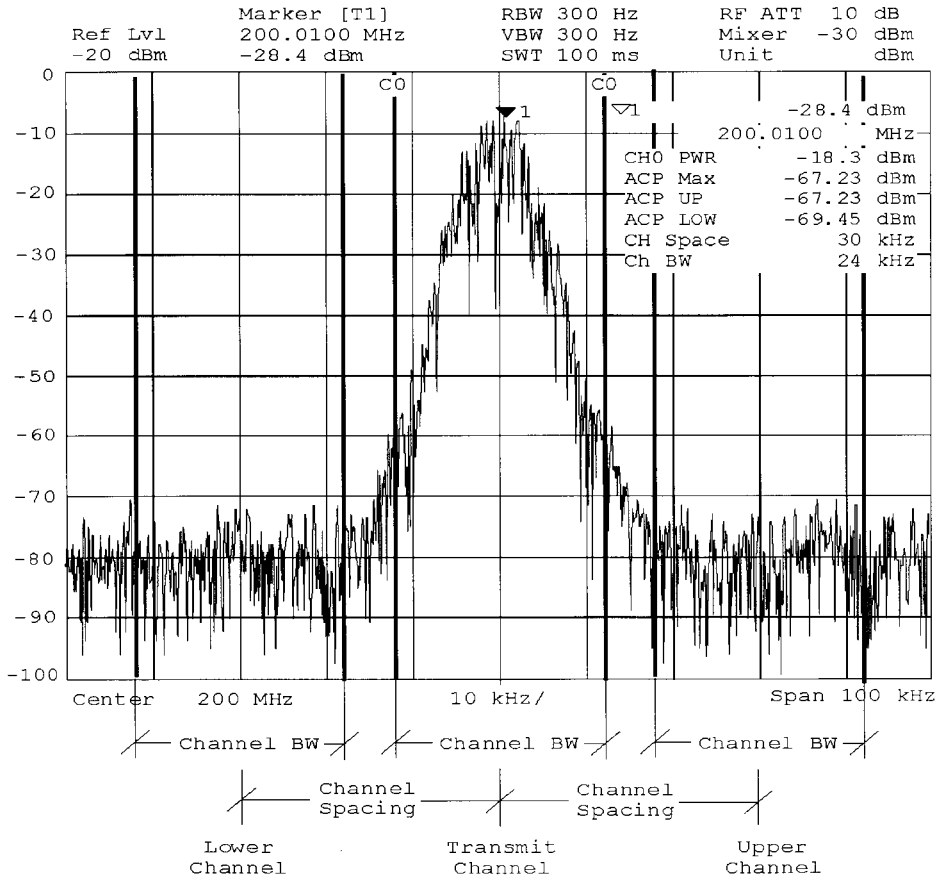

Figure 1-102 NADC signal and parameters, including channel spacing and channel bandwidth.

where y represents the output, the coefficients k_n represent complex quantities whose values can be determined by an analysis of the output waveforms, and $f(x)$ represents the input. Even though all practical networks exhibit amplitude nonlinearity, we can (and often do) refer to many networks as "linear." We say this of networks that are *sufficiently amplitude-linear for our purposes*—for example, weakly nonlinear networks in which small-signal operation is assumed even though the signal levels involved are sufficient to cause slight distortion. For many practical purposes, the first three terms of Eq. (1-42) adequately describe such a network's nonlinearity:

$$y = k_1 f(x) + k_2[f(x)]^2 + k_3[f(x)]^3 \tag{1-43}$$

In adopting this simplification, we assume also that the nonlinearity is frequency independent—that is, the network has sufficient bandwidth to allow all of the products predicted by Eq. (1-43) to appear at its output terminals unperturbed [13].

When multiple signals are present in a network, even weak nonlinearity can result in profound consequences. To illustrate this, we'll let $f(x)$ consist of two sinusoidal signals:

$$f(x) = A_1 \cos\omega_1 t + A_2 \cos\omega_2 t \tag{1-44}$$

We'll assume that ω_1 and ω_2 are close enough so that the coefficients k_i can be considered equal for both signals. We'll also assume for simplicity that all of the k_i are real. If Eq. (1-43) describes the network's response to an input $f(x)$, the response will be

$$\begin{aligned} y &= k_1(A_1 \cos\omega_1 t + A_2 \cos\omega_2 t) + k_2(A_1 \cos\omega_1 t + A_2 \cos\omega_2 t)^2 + k_3(A_1 \cos\omega_1 t + A_2 \cos\omega_2 t)^3 \\ &= k_1(A_2 \cos\omega_1 t + A_2 \cos\omega_2 t) \\ &\quad + k_2\left[A_1^2 \frac{1+\cos 2\omega_1 t}{2} + A_2^2 \frac{1+\cos 2\omega_2 t}{2} + A_1 A_2 \frac{\cos(\omega_1+\omega_2)t + \cos(\omega_1-\omega_2)t}{2}\right] \\ &\quad + k_3 \left\{ \begin{array}{l} \left[\left[A_1^3\left(\dfrac{\cos\omega_1 t}{2} + \dfrac{\cos\omega_2 t}{4} + \dfrac{\cos 3\omega_1 t}{4}\right) + A_2^3\left(\dfrac{3\cos\omega_2 t}{4} + \dfrac{\cos 3\omega_2 t}{4}\right)\right]\right] \\ + A_1^2 A_2[\tfrac{3}{2}\cos\omega_2 t + \tfrac{3}{4}\cos(2\omega_1 - \omega_2)t + \tfrac{3}{4}\cos(2\omega_1 - \omega_2)t] \\ + A_2^2 A_1[\tfrac{3}{2}\cos\omega_1 t + \tfrac{3}{4}\cos(2\omega_2 + \omega_1)t + \tfrac{3}{4}\cos(2\omega_2 - \omega_1)t] \end{array} \right\} \end{aligned} \tag{1-45}$$

The k_1 term of Eq. (1-45) represents the results of amplitude-linear behavior. No new frequency components have appeared; the two sine waves have merely been "rescaled" by k_1.

The second- and third-order terms of Eq. (1-45) represent the effects of harmonic distortion and intermodulation distortion. Second-order effects include second-harmonic distortion (the production of new signals at $2\omega_1$ and $2\omega_2$) and IMD (the production of new signals at $\omega_1 + \omega_2$ and $\omega_1 - \omega_2$). Third-order effects include gain compression, third-harmonic distortion (the production of new signals at $3\omega_1$ and $3\omega_2$), and IMD (the production of new signals at $2\omega_1 \pm \omega_2$ and $2\omega_2 \pm \omega_1$).

Gain Compression. Gain compression occurs when a network cannot increase its output amplitude in linear proportion to an amplitude increase at its input; gain *saturation* occurs when a network's output amplitude stops increasing (in practice, it may actually decrease) with increases in input amplitude. We can deduce from Eq. (1-45) that the amplitude of the $\cos\omega_1 t$ signal has become

$$A_1' = k_1 A_1 + k_3\left(\tfrac{3}{4}A_1^3 + \frac{3}{2}A_1 A_2^2\right) \tag{1-46}$$

Because k_3 will normally be negative, a large signal $A_2 \cos\omega_2 t$ can effectively mask a smaller signal $A_1 \cos\omega_1 t$ by reducing the network's gain. This third-order effect, known as *blocking* or *desensitization* when it occurs in a receiver, is a special case of gain compression. The presence of additional signals results in a greater reduction in gain; the gain reduction for each signal is a function of the relative levels of all signals present. A receiver's blocking behavior may be characterized in terms of the level of off-channel signal necessary to reduce the strength of an in-passband signal by a specified value, typically 1 dB; alternatively, the decibel ratio of the off-channel signal's power to the receiver's noise-floor power may be cited as *blocking dynamic range*. Desensitization may also be characterized in terms of the off-channel signal power necessary to degrade a system's SNR by a specified value.

Multiple signals need not be present for gain compression to occur. If only one signal is present, the ratio of gain with distortion to the network's idealized (linear) gain is

$$A_1' = \frac{k_1 + k_3\left(\tfrac{3}{4}A_1^2\right)}{k_1} \tag{1-47}$$

This is referred to as the *single-tone gain-compression factor*. Figure 1-103 shows how the k_3 term causes a network's gain to deviate from the ideal. The point at which a network's power gain is down 1 dB from the ideal for a single signal is a figure of merit known as the *1-dB compression point* (P_{-1dB}). Many networks (including many receiving and low-level transmitting circuits, such as low-noise amplifiers, mixers, and IF amplifiers) are usually operated under small-signal conditions—at levels sufficiently below P_{-1dB} to maintain high linearity. As we'll see, however, some networks (including power amplifiers for wireless systems) may be operated under large-signal conditions—near or in compression—to achieve optimum efficiency at some specified level of linearity. Figure 1-104 shows what happens when a digital emission that uses amplitude to convey information is subjected to amplitude compression.

Intermodulation. The new signals produced through intermodulation distortion (IMD) can profoundly affect the performance even of systems operated far below gain compression (Figure 1-105). IMD products of significant power can appear at frequencies remote from, in, and/or near the system passband, resulting in demodulation errors (in reception) and interference to other communications (in transmission). Where an IMD product appears relative to the passband depends on the passband width and center frequency, the frequencies of the signals present at the system input, and the order of the nonlinearity involved. These factors also determine the strength of an IMD product relative to the desired signal.

Second-order IMD (IM_2) results, for an input consisting of two signals ω_1 and ω_2, in the production of new signals at $\omega_1 + \omega_2$ and $\omega_1 - \omega_2$; third-order IMD (IM_3) results, for an input

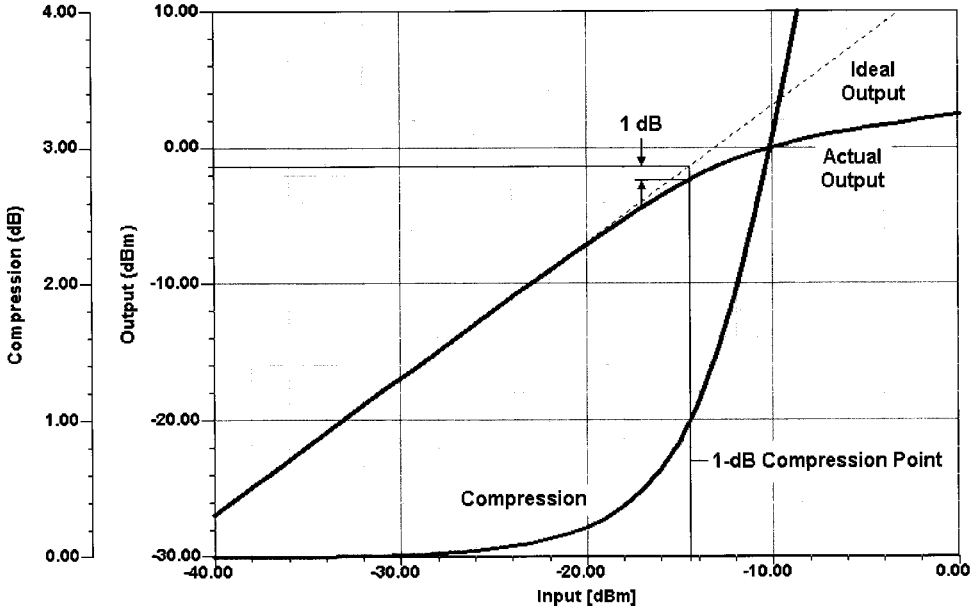

Figure 1-103 The power level at which a network's power output is down 1 dB relative to that of its ideally linear equivalent is a figure of merit known as the *1-dB compression point* (P_{-1dB}). The 1-dB compression point can be expressed relative to input power ($P_{-1dB,in}$) or output power ($P_{-1dB,out}$). For the amplifier simulated here, $P_{-1dB,in} \approx -14.5$ dBm and $P_{-1dB,out} \approx -1.3$ dBm.

consisting of two signals ω_1 and ω_2, in the production of new signals at $2\omega_1 \pm \omega_2$ and $2\omega_2 \pm \omega_1$.

Under small-signal conditions—that is, at levels well below compression—the power of an IM_2 product varies by 2 dB, and the power of an IM_3 product varies by 3 dB, per decibel change in input power level. This allows us to derive a network figure of merit, the *intermodulation intercept point* (*IP*), for a given IM order by extrapolating a network's linear and IM responses to their point of intersection (Figure 1-106)—the point at which their powers would be equal if compression did not occur. The intercept point for a given IM order

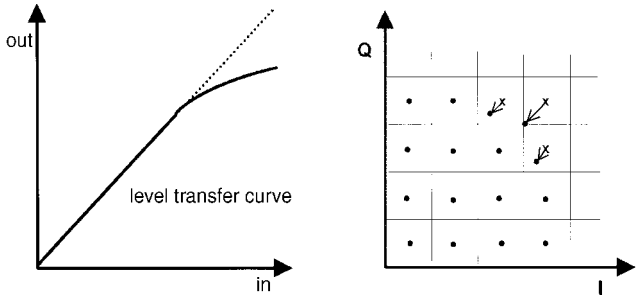

Figure 1-104 Influence of differential amplitude error (compression) on a QAM constellation.

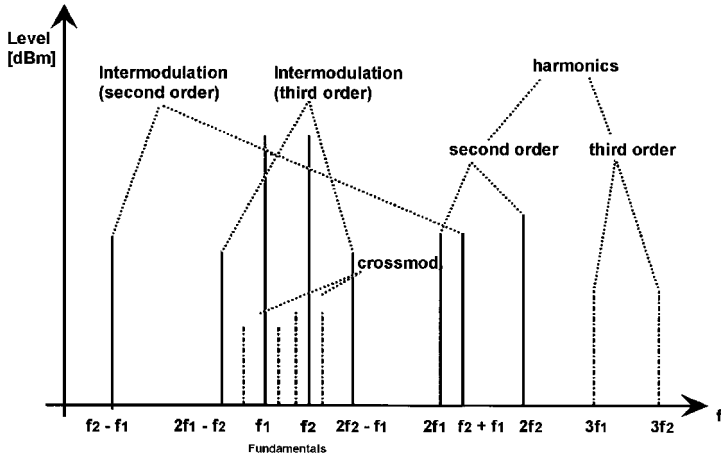

Figure 1-105 Relationships between fundamental and spurious signals, including harmonics and products of intermodulation.

n can be expressed, and should always be characterized, relative to input power ($IP_{n,\text{in}}$) or output power ($IP_{n,\text{out}}$); the IP_{in} and IP_{out} values differ by the network's linear gain. For equal-level test tones, $IP_{n,\text{in}}$ can be determined by

$$IP_{n,\text{in}} = \frac{nP_A - P_{\text{IM}_n}}{n-1} \tag{1-48}$$

where n is the order, P_A is the input power (of one tone), P_{IM_n} is the power of the IM product, and IP is the intercept point. The intercept point for cascaded networks can be determined from

$$IP_{2,\text{in}} = \frac{1}{\left(\frac{1}{\sqrt{IP1}} + \frac{G}{\sqrt{IP2}}\right)^2} \tag{1-49}$$

for IP_2 and from

$$IP_{3,\text{in}} = \frac{1}{\frac{1}{IP1} + \frac{G}{IP2}} \tag{1-50}$$

for IP_3. In both equations, $IP1$ is the input intercept of Stage 1 in watts, $IP2$ is the input intercept of Stage 2 in watts, and G is the gain of Stage 1 (as a numerical ratio, *not* in decibels). Both equations assume the worst-case condition, in which the distortion products of both stages add in-phase.

The ratio of the signal power to the IM-product power, the *distortion ratio*, can be expressed as

$$R_{dn} = (n-1)\left[IP_{n,\text{in}} - P_{\text{in}}\right] \tag{1-51}$$

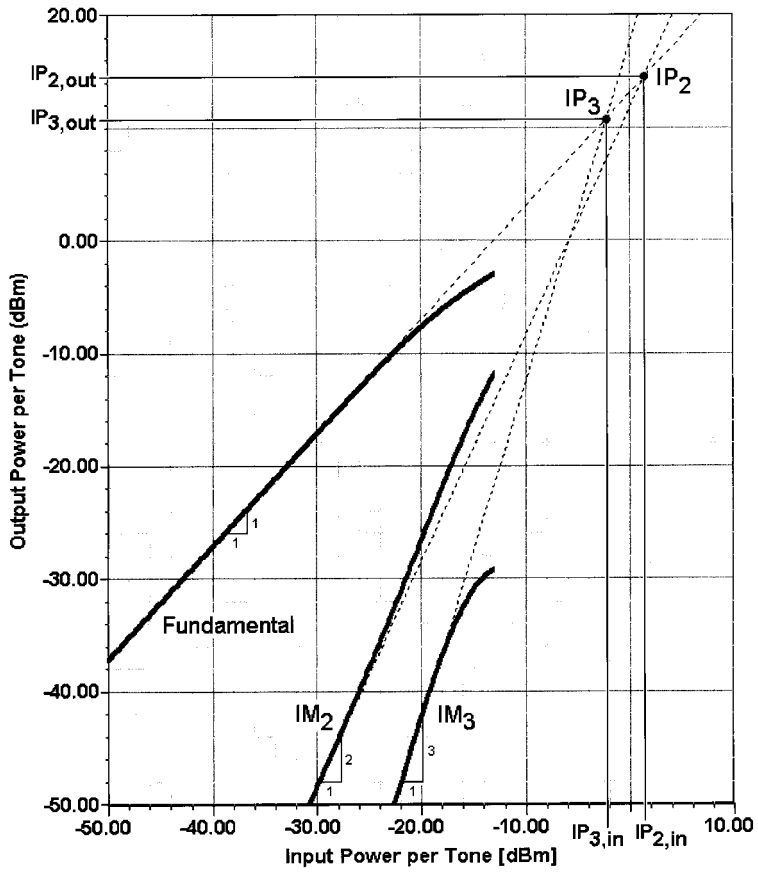

Figure 1-106 The level at which the power of one of a network's IM products equals that of the network's linear output is a figure of merit known as the *intermodulation intercept point* (*IP*). The intercept point for a given IM order *n* can be expressed, and should always be characterized, relative to input power ($IP_{n,in}$) or output power ($IP_{n,out}$); the IP_{in} and IP_{out} values differ by the network's linear gain. For the amplifier simulated here, $IP_{2,in} \approx 1.5$ dBm, $IP_{2,out} \approx 14.5$ dBm, $IP_{3,in} \approx -2.3$ dBm, and $IP_{3,out} \approx 10.7$ dBm. Each curve depicts the power in one tone of the response evaluated.

where n is the order, R_{dn} is the distortion ratio, $IP_{n,in}$ is the input intercept point, and P_{in} is the input power of one tone.

Discussions of IMD have traditionally downplayed the importance of IM_2 because the incidental distributed filtering contributed by the tuned circuitry once common in radiocommunication systems was usually enough to render out-of-passband IM_2 products caused by in-passband signals, and in-passband IM_2 products caused by out-of-passband signals, vanishingly weak compared to fundamental and IM_3 signals. In broadband systems that operate at bandwidths of an octave or more, however, in-passband signals may produce significantly strong in-passband IM_2 and second-harmonic products. In such applications, balanced circuit structures (such as push–pull amplifiers and balanced mixers) can be used to minimize IM_2 and other even-order nonlinear products.

As with IM_2, which IM_3 products are important depends on the spacing of the signals involved and the relative width of the system passband. If ω_1 and ω_2 are of approximately

the same frequency, the additive products $2\omega_1 + \omega_2$ and $2\omega_2 + \omega_1$ will be outside the passband of a narrowband system. The subtractive products $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$, however, will likely appear near or within the system passband. The IM_3 performance of any network subjected to multiple signals is therefore of critical importance, and an array of IM_3-related, sometimes application-specific, figures of merit has evolved as a result.

Dynamic Range. As we have seen, thermal noise sets the lower limit of the power span over which a network can operate. Distortion—that is, degradation by distortion of the signal's ability to convey information—sets the upper limit of a network's power span. Because the power level at which distortion becomes intolerable varies with signal type and application, a generic definition has evolved: The upper limit of a network's power span is the level at which the power of one IM product of a specified order is equal in power to the network's noise floor. The ratio of the noise-floor power to the upper-limit signal power is referred to as the network's *dynamic range* (*DR*), often more carefully characterized as *two-tone IMD dynamic range*, which, when evaluated with equal-power test tones, is a figure of merit commonly used to characterize receivers. When $IP_{n,\text{in}}$ and MDS are known, IMD DR can be determined from

$$DR_n = \frac{(n-1)[IP_{n,\text{in}} - MDS]}{n} \tag{1-52}$$

where *DR* is the dynamic range in decibels, *n* is the order, IP_{in} is the input intercept power in dBm, and *MDS* is the minimum detectable signal power in dBm.

Dynamic Measure: A New Receiver Figure of Merit. Taken by themselves, the IP_n and DR figures of merit can be misleading in the sense that broadband, resistive attenuation directly improves them by the amount of attenuation added while directly degrading NF by the same amount. The NF and MDS figures of merit can mislead us because they convey no sense of suitability to task. This can be significant when we interconnect networks and systems of differing noise floors and IMD dynamic ranges—as we do, for example, when connecting a receiver to an antenna. As a means of better evaluating a receiver's front-end performance, the authors propose a new figure of merit, *dynamic measure*, defined as

$$DM = [(IP_{3,\text{in}} + \text{Att}) - (NF_r + \text{Att} + NF_{ant})]\frac{NF_r}{NF_r + \text{Att}} \tag{1-53}$$

where *DM* is the dynamic measure, a dimensionless number; $IP_{3,\text{in}}$ is the receiver's third-order input intercept in dBμV (instead of dBm) without any added attenuation; NF_r is the receiver noise figure in dB without any added attenuation; NF_{ant} is the antenna-system noise figure in dB as determined by Eq. (1-40); and Att is the decibel value of any added attenuation, which is sometimes used to shift the upper and lower limits of a system's dynamic range to higher absolute signal levels, increasing $IP_{3,\text{in}}$ at the expense of making the system more "deaf." Our dynamic measure figure of merit takes this trade-off into account to allow more straightforward comparisons of systems that have the same dynamic range but different sensitivities. Setting NF_{ant} equal to zero allows evaluation of receiver performance under laboratory conditions; setting NF_{ant} equal to the measured or expected NF of the antenna system to which the receiver will be connected allows evaluation of receiver performance in a system sense. Rather than express IP_3 in dBm, we are going to

express it in dBμV. This is necessary because for negative values of the difference between IP_3 and the added noise figure, the multiplier term will make the result larger when its numerical value is less than 1.

The usefulness of the dynamic measure figure of merit is evident when we consider several examples.

Example 1. Here we evaluate a receiver that exhibits the characteristics $IP_{3,\text{in}} = 16$ dBm(123 dBμV), $NF_r = 8$ dB, and $NF_{\text{ant}} = 10$ dB. We calculate its laboratory DM by setting NF_{ant} equal to 0:

$$DM = [123 - (8 + 0)]\frac{8}{8 + 0} = [115]1 = 115 \tag{1-54}$$

Setting NF_{ant} equal to 10 returns the receiver's system DM:

$$DM = [123 - (8 + 10)]\frac{8}{8 + 0} = [115]1 = 105 \tag{1-55}$$

Example 2. This setup consists of the Example 1 receiver with a 10-dB pad switched in, resulting in the characteristics $IP_{3,\text{in}} = 26$ dBm(133 dBμV), $NF_r = 18$ dB, and $NF_{\text{ant}} = 10$ dB. Setting NF_{ant} equal to 0, we calculate its laboratory DM as

$$DM = [133 - (8 + 10 + 0)]\frac{8}{8 + 10} = [115]0.4444 = 51.1 \tag{1-56}$$

A comparison with Eq. (1-54) shows that, although inserting the 10-dB pad has shifted $IP_{3,\text{in}}$ from 16 dBm (123 dBμV) to 26 dBm (133 dBμV), it has also increased the resulting NF from 8 to 18 dB, reducing the DM from 115 to 51.1. Inserting the pad also degrades the receiver's system DM compared to Example 1, as we see by setting NF_{ant} equal to 10:

$$DM = [133 - (8 + 10 + 10)]\frac{8}{8 + 10} = [105]0.4444 = 46.7 \tag{1-57}$$

Example 3. On the other hand, had we inserted 2 dB of attenuation rather than 10 dB [$IP_{3,\text{in}} = 18$ dBm (125 dBμV), $NF_r = 10$ dB, and $NF_{\text{ant}} = 10$ dB], the laboratory DM would have been

$$DM = [125 - (8 + 2 + 0)]\frac{8}{8 + 2} = [115]0.8 = 92 \tag{1-58}$$

and the system DM would have been

$$DM = [125 - (8 + 2 + 10)]\frac{8}{8 + 2} = [105]0.8 = 84 \tag{1-59}$$

Table 1-12 shows these and several additional examples for comparison.

The interested reader will notice the following: The receiver in Example 1 (base NF 8 dB) was unnecessarily sensitive compared to the antenna NF of 10 dB, so adding a 2-dB pad increased the intercept point by 2 dB and matched the antenna noise floor. Yet, the equation rightfully indicates a loss of dynamic measure. The relationship between NF_{ant} and NF_r is not taken

Table 1-12 Eight dynamic measure cases compared

Example	System	Base $IP_{3,in}$ (dBm)	Base $IP_{3,in}$ (dBμV)	Attenuation (dB)	Resulting $IP_{3,in}$ (dBm)	Resulting $IP_{3,in}$ (dBμV)	Base NF_r (dB)	Resulting NF_r (dB)	NF_{ant} (dB)	DM_{lab}	DM_{system}
1	HF receiver	16.0	123.0	0.0	16.0	123.0	8.0	8.0	10.0	115.0	105.0
2	HF receiver with 10-dB pad	16.0	123.0	10.0	26.0	133.0	8.0	18.0	10.0	51.1	46.7
3	HF receiver with 2-dB pad	16.0	123.0	2.0	18.0	125.0	8.0	10.0	10.0	92.0	84.0

into consideration. Also, we have decided to leave it to the reader to develop a formula that deals with the addition of a preamplifier rather than an attenuator. This will complicate the formula because the preamplifier's gain and noise figure are not necessarily related.

Triple-Beat Distortion and Cross-Modulation. P_{-1dB} is a single-tone figure of merit; blocking, intercept point, and dynamic range evaluate two-tone behavior. For networks that must handle AM and composite (AM and angle modulation) signals very linearly, such as television transmitters and cable TV distribution systems, a three-tone figure of merit called *triple-beat distortion* has gained acceptance. Signals at ω_1 and ω_2 (closely spaced) and ω_3 (positioned far away from ω_1 and ω_2) are applied to the network under test, at levels, frequencies, and spacings that vary with the application. One triple-beat distortion figure of merit is the ratio, expressed in decibels, of the IM product at $\omega_3 + (\omega_2 - \omega_1)$ to one of the network's linear outputs at a specified output level. Alternatively, the triple-beat figure of merit may express the network output level at which a specified triple-beat ratio occurs.

Triple-beat distortion is the mechanism underlying cross-modulation, a form of intermodulation in which one or more AM signals present in a network amplitude-modulate all

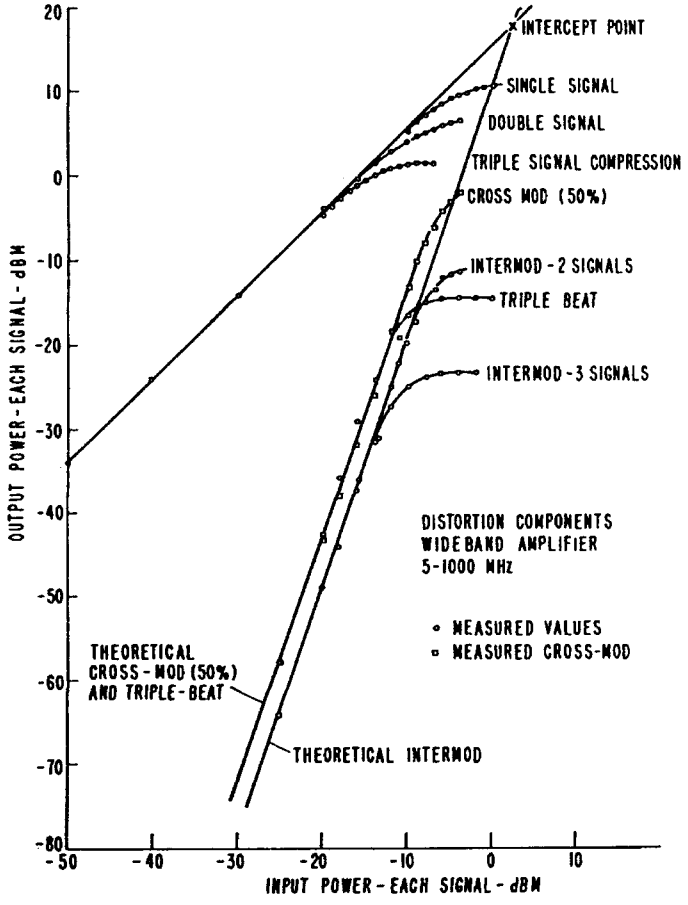

Figure 1-107 Measured distortion components in a wideband (5–1000 MHz) amplifier. Figure 1-108 shows a magnified view of the gain-compression region [15].

signals present in the network [14]. Angle-modulation-based wireless systems are largely immune to such effects.

Figures 1-107 and 1-108 graph the results of gain compression, two-tone intermodulation, cross-modulation, and triple-beat testing on a wideband (5–1000 MHz) amplifier.

Noise Power Ratio. Triple-beat testing is one way of improving on two-tone testing as a means of evaluating a network's intermodulation behavior in the presence of multiple signals. Another figure of merit, *noise power ratio* (*NPR*), uses thermal noise as a test signal. The test measures the introduction, by IM, of noise into a quiet slot created by the insertion of a bandstop filter, equal in stopband width to the width of the measurement channel, between the noise generator and the network under test (Figure 1-109).

Large-Signal Effects. Except for P_{-1dB}, the figures of merit discussed so far evaluate amplitude nonlinearity under small-signal conditions. At input powers that drive a network into gain compression and saturation, IM products of odd orders higher than 3 become significant, and curves, dips, and nulls appear in their characteristics (Figure 1-110). Phase shifts related to nonlinear (primarily voltage-dependent) capacitances in solid-state devices are one cause of these effects. Under such conditions, a network may exhibit hysteresis, with its behavior at any given instant depending not only on the voltage or current applied to it but also on its recent history [16].

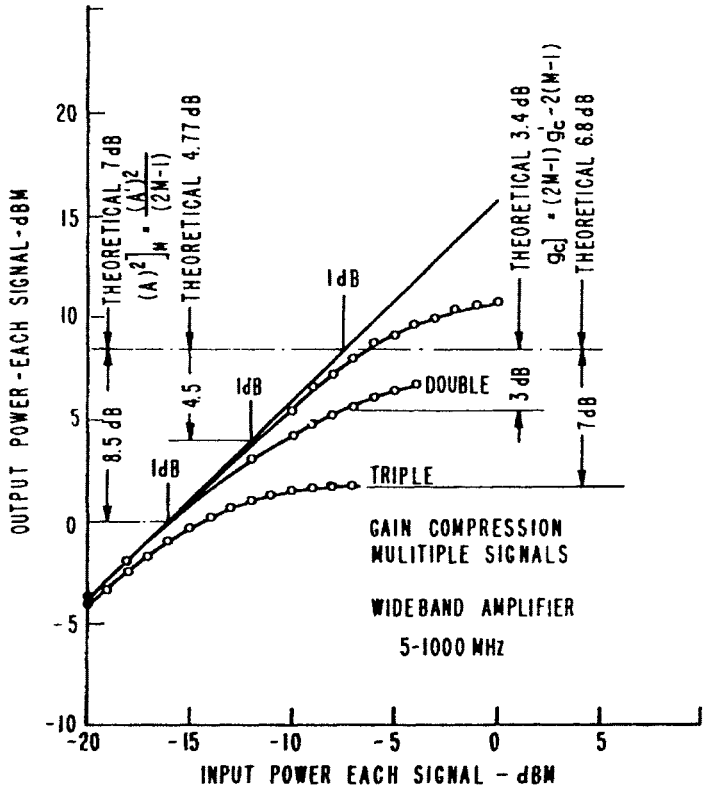

Figure 1-108 Measured multiple-signal gain compression of the 5- to 1000-MHz amplifier [15].

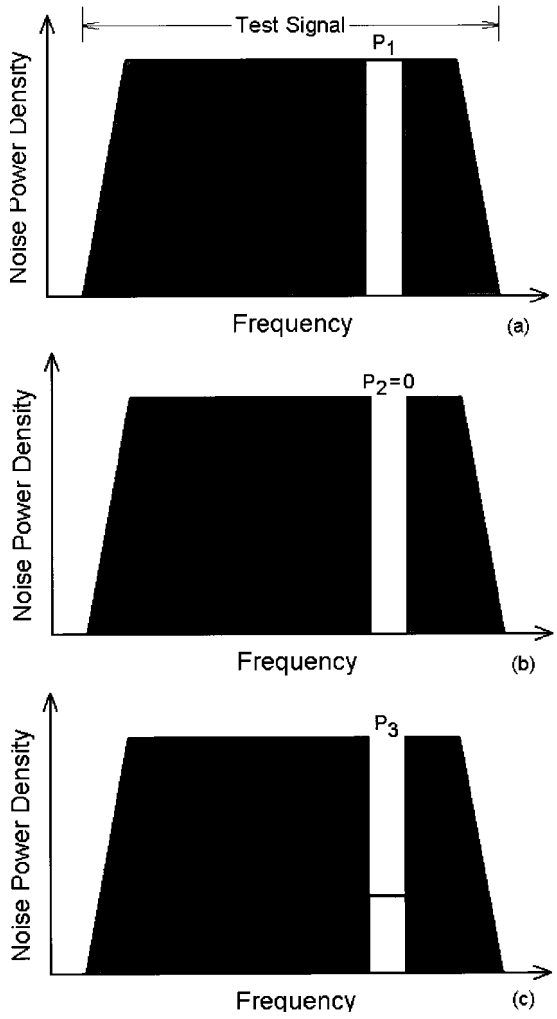

Figure 1-109 Determining a network's *noise power ratio* (*NPR*) involves the application of a test signal consisting of thermal noise [15]. (a) The reference measurement-channel noise power, P_1, is then measured. (b) Next, a bandstop filter is placed between the noise generator and network under test to keep the test signal out of the measurement channel. Assuming sufficient filter attenuation, if the network were absolutely noiseless and linear, the ideal noise power in the measurement channel, P_2, would then be zero. (c) In practice, the network's own thermal noise and intermodulation between noise components outside the measurement channel result in an actual measurement-channel noise power (P_3) greater than zero. The noise power ratio equals P_1/P_3.

AM-to-PM Conversion. The nonlinear distortion effects we've discussed so far can be termed *AM-to-AM distortion*—distortion that, to a degree that depends on the amplitude of the signal(s) applied to the network, results in changes in the network's gain and/or production of signals at new frequencies. AM-to-PM distortion can also occur. As a network nears saturation, part of its driving signal goes into shifting the bias point(s) of its active device(s), changing their drive-dependent reactances and shifting the phase of the output signal relative to its value at input levels below compression (Figures 1-111 and 1-112). This

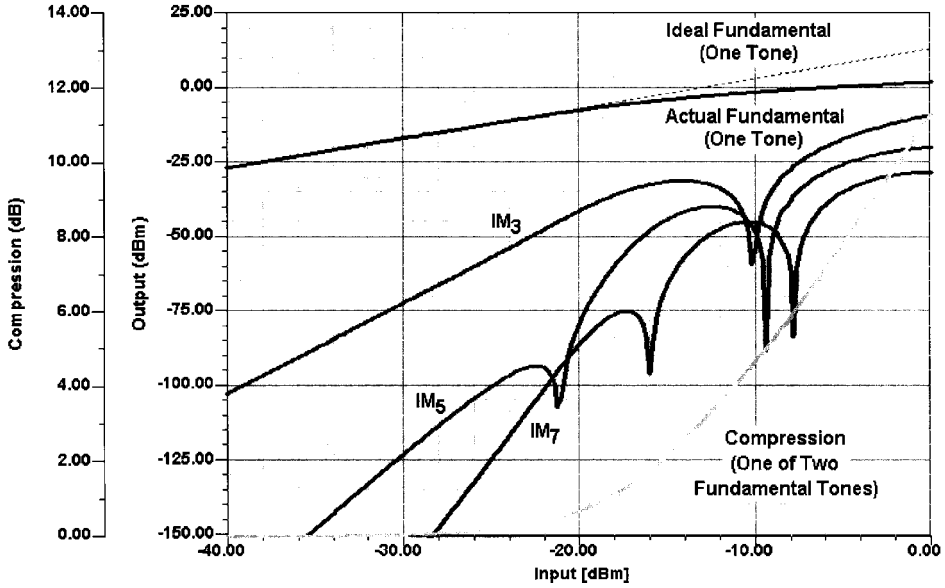

Figure 1-110 As a network is driven into compression, IM products at odd orders higher than 3 become significant, and phase shifts in power-dependent device capacitances cause curves and dips in the IM characteristics. The onset of these departures from IM-response linearity occurs at generally lower input power levels for higher IM orders; their severity, and their position on the IM curves, differs among the various products of a given order and varies with network topology and tone spacing. Figures of merit based on straight-line IM responses fail to usefully predict nonlinear network behavior under these conditions. This graph shows the simulated performance of a single-BJT broadband amplifier driven by two equal-amplitude tones at 10 and 11 MHz.

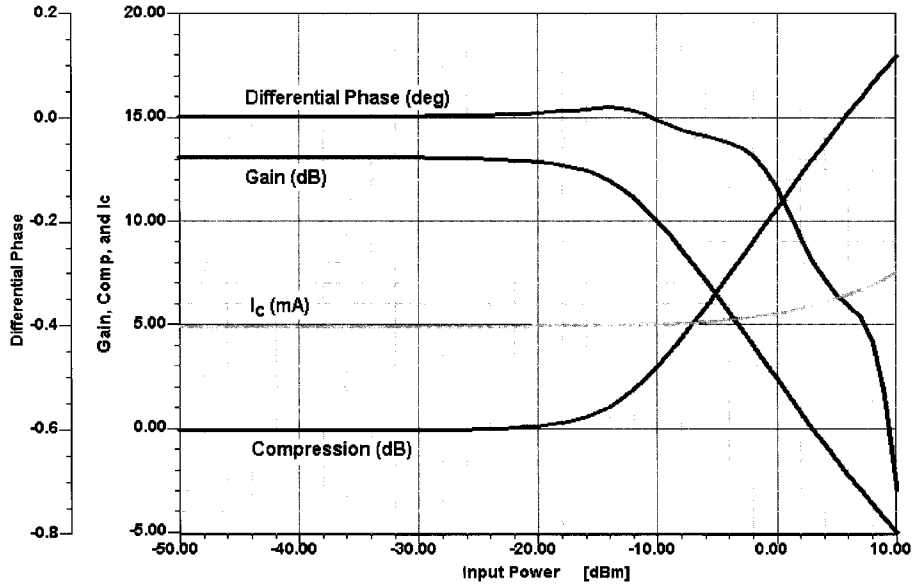

Figure 1-111 Driving a network into compression and saturation shifts the bias point(s) of its active device(s), changing their drive-dependent reactances and shifting the phase of the output signal relative to its value at input levels below compression. This graph shows the simulated performance of a single-BJT broadband amplifier driven by a single tone at 10 MHz.

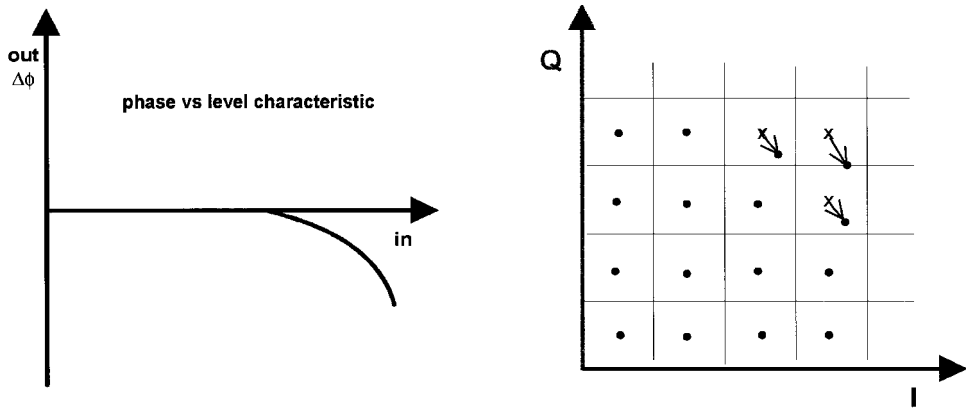

Figure 1-112 Influence of differential phase error (AM-to-PM conversion) on a QAM constellation.

effect, *AM-to-PM conversion*, can cause incidental phase modulation that degrades the performance of digital communication systems.

Spectral Regrowth and Adjacent-Channel Power Ratio. Spectral regrowth occurs largely as a result of third-, fifth-, and seventh-order IMD in power amplifiers operated near or in compression—at power levels where hysteretic IM effects result in poor agreement between measured behavior and predictions based on small-signal IM figures of merit [17]. We therefore evaluate the impact of spectral regrowth more directly, using a figure of merit called *adjacent-channel power ratio* (ACPR). ACPR measurement techniques that incorporate memory can be used to increase ACPR predictions for networks that exhibit saturation hysteresis [18]. Figure 1-113 shows the critical relationship between compression, power-added efficiency, and ACPR in a MESFET power amplifier.

Phase Response Issues and Figures of Merit. We have already seen how large-signal nonlinear distortion can result in amplitude-dependent phase shifts through AM-to-PM conversion. Because phase linearity is critical at *all* signal levels in PM systems, especially those using digital modulation, we must also consider linear distortion in evaluating networks used in wireless systems.

Differential Group Delay. Every frequency-selective network subjects signals passing through it to some degree of time delay. Ideally, this delay, also known as *group* or *envelope delay*, does not vary with frequency; that is, the network's phase shift versus frequency response is monotonic and linear. In practice, a network's time delay varies across its passband, transition bands, and stopbands, exhibiting curvature, ripple, and transition-band peaks (Figure 1-114). The network's *differential* group delay—its group-delay spread—is therefore of considerable importance. This is especially so in digitally modulated systems, where the resulting phase distortion can cause errors in modulation and demodulation.

Effects of Phase Noise. As Chapter 5 will discuss in detail, the phase of an oscillator's output signal is subject to random phase variations (Figures 1-115 and 1-116). Called *phase noise*, this effect is often quantified as the decibel ratio of the phase-noise power in a single

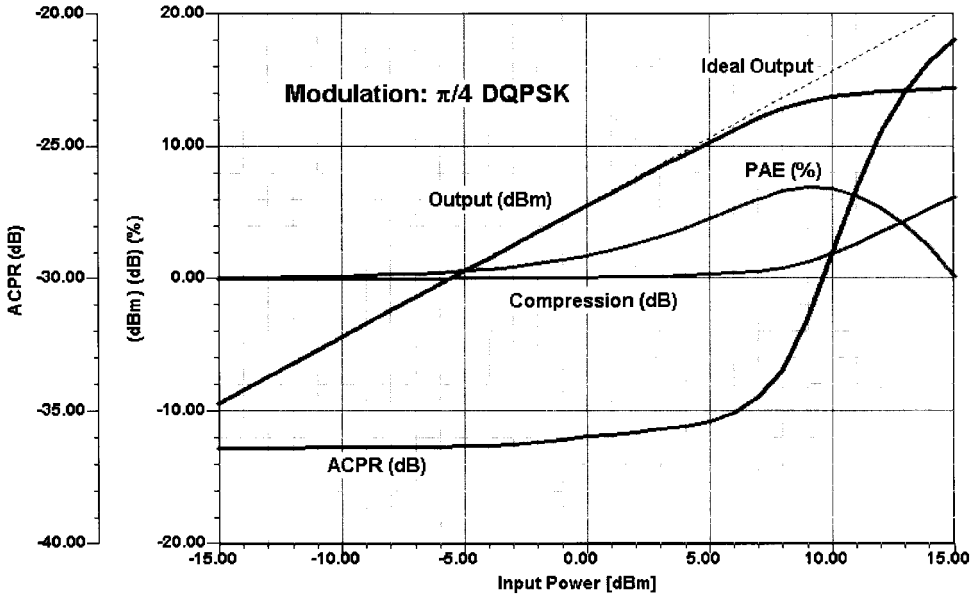

Figure 1-113 Keeping adjacent-channel interference under control can involve a critical trade-off between a wireless transmitter's power-added efficiency (PAE) and ACPR, as shown in this graph of the simulated behavior of the 1-GHz MESFET power amplifier introduced into Figure 1-101. As the amplifier is driven into compression, a peak occurs in the PAE response—in this case, at P_{-1dB}—and the ACPR rises sharply.

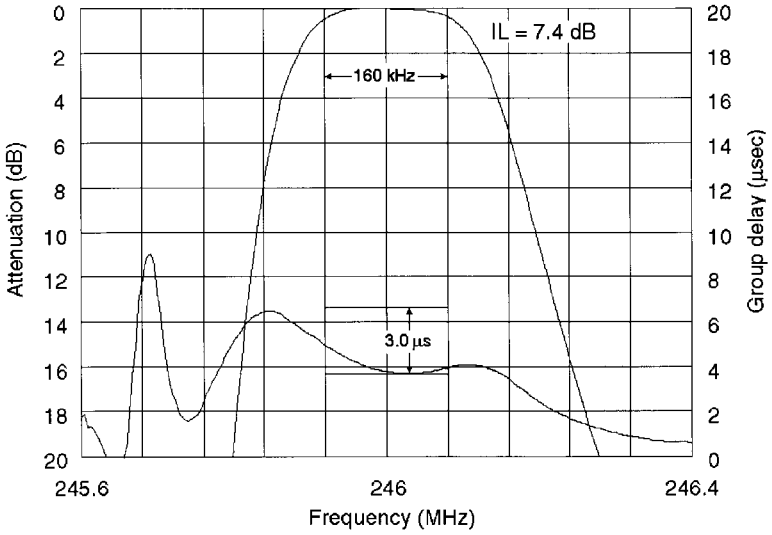

Figure 1-114 Close-in amplitude and group-delay responses for a 246-MHz SAW filter designed for GSM applications [19]. This filter is well within its 3.0-μs differential group-delay specification across its passband (160 kHz at –3 dB); the peaks just outside the passband limits are characteristic of a network's transition-band phase response.

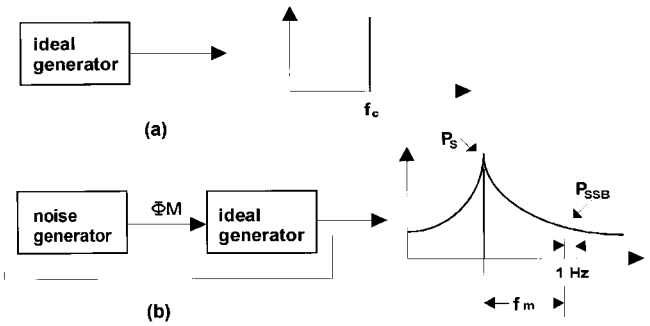

Figure 1-115 SSB phase noise. (a) An ideal signal generator would produce an absolutely pure carrier. (b) A real signal generator acts like an ideal generator driven by a noise generator, producing a noise-modulated carrier.

(the upper or lower) phase-noise sideband, in a 1-Hz bandwidth centered at a specified frequency offset from the oscillator carrier, to the carrier power (Figure 1-117); alternatively, it may be specified in degrees rms. A microwave voltage-controlled oscillator, for instance, might exhibit an SSB phase noise of –95 dBc/Hz at 10 kHz. Oscillator phase noise may manifest itself, through a mechanism known as *reciprocal mixing*, as the emission of unacceptably strong noise outside a transmitter's occupied bandwidth or as an increase in receiver noise floor. Phase noise may also directly introduce phase errors that result in modulation and demodulation errors.

Because the oscillators used for frequency translation in wireless systems are usually embedded in phase-locked loops, their phase-noise characteristics differ from those of "bare" oscillators as shown in Figures 1-118 and 1-119. Figures 1-120 and 1-121 show the measured phase noise of the Rohde & Schwarz SMY and SMIQ signal generators. The SMY is a low-cost signal source, while the SMIQ is a very high performance signal generator capable of being programmed for all digital modulations; therefore, their PLL systems exhibit different phase-noise versus frequency responses as the measured results show.

Reciprocal Mixing. In reciprocal mixing, incoming signals mix with LO sideband energy to produce IF output (Figure 1-122). Because one of the two signals is usually noise, the resulting IF output is usually noise. (Reciprocal mixing effects are not limited to noise;

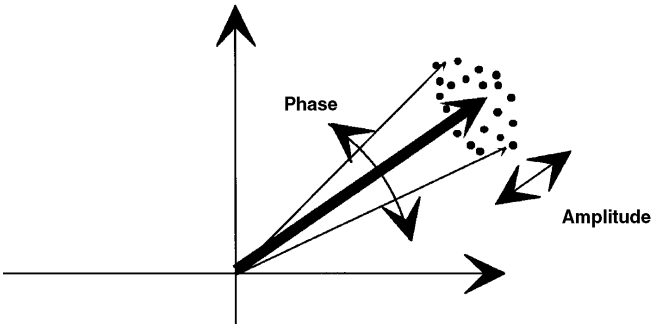

Figure 1-116 Oscillator noise can be split into amplitude and phase components.

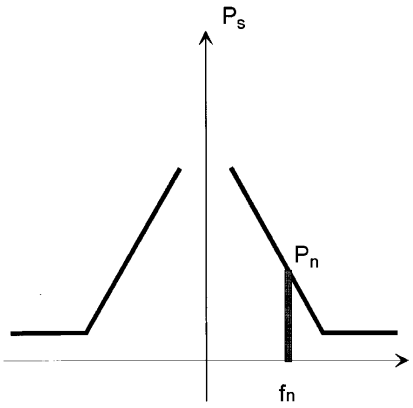


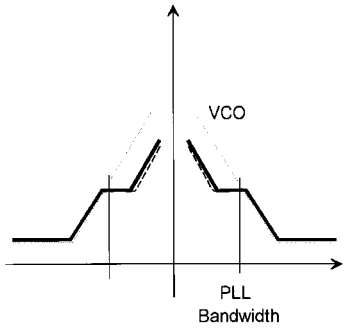
$$L(f) = 10 * \log \frac{P_n}{P_s}$$

P_n = Sideband noise in 1-Hz bandwidth at offset frequency f_n

P_S = Total signal power

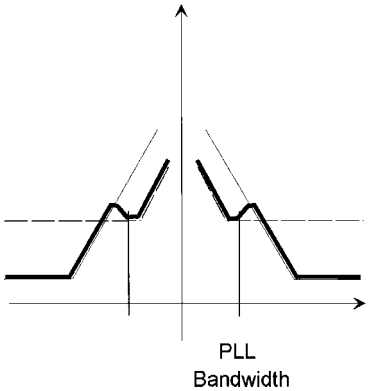
Single-sideband phase noise is expressed in dBc measured in a bandwidth of 1 Hz [dBc(Hz)] at offset frequency f_n.

Figure 1-117 Phase noise calculation.



Phase Noise is controlled by reference phase noise within PLL bandwidth and follows VCO noise outside PLL bandwidth

Figure 1-118 Phase noise of an oscillator controlled by a phase-locked loop.



Improper designed PLL bandwidth

Phase noise increases outside of PLL bandwidth

Figure 1-119 Effect of improper loop-filter design.

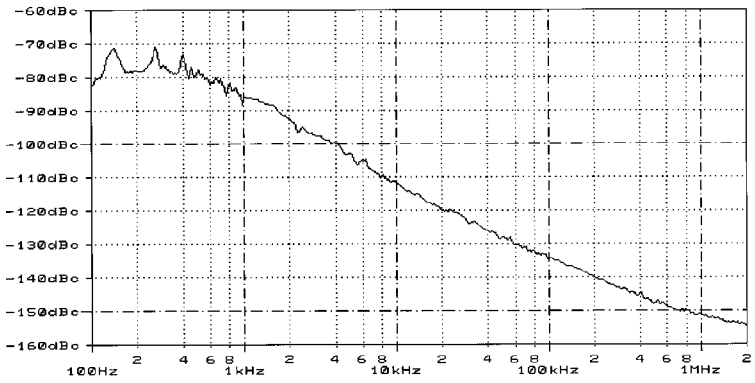


Figure 1-120 Measured phase noise of the Rohde & Schwarz SMY signal generator at 1 GHz. This signal generator has no provision for digital modulation and therefore shows the best possible phase noise in its class.

discrete-frequency oscillator sideband components, such as those resulting from crosstalk to or reference energy on a VCO's control line, or the discrete-frequency spurious signals endemic to direct digital synthesis, can also mix incoming signals to IF.) In practice, the resulting noise-floor increase can compromise the receiver's ability to detect weak signals and achieve a high IMD dynamic range; on the test bench, noise from reciprocal mixing may invalidate desensitization, cross-modulation, and IM testing by obscuring the weak signals that must be measured in making these tests.

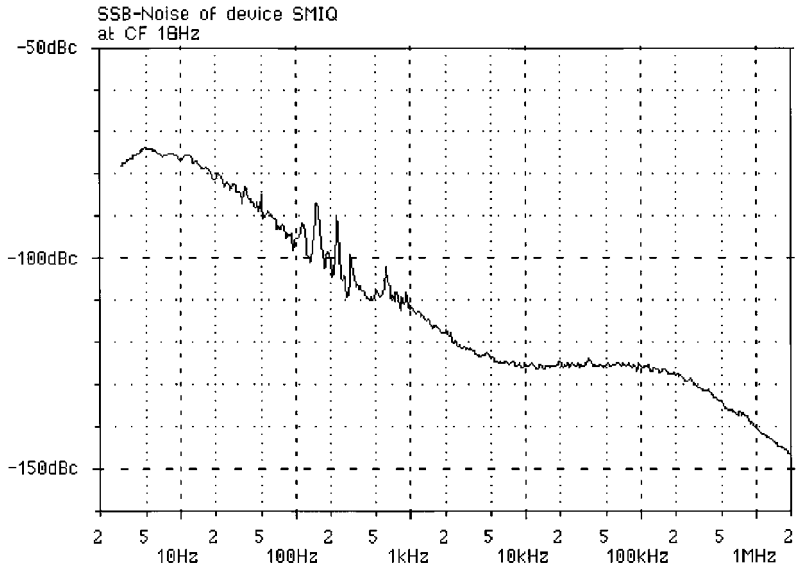

Figure 1-121 Measured phase noise of the Rohde & Schwarz SMIQ signal generator at 1 GHz. This signal generator is optimized for all digital modulation capabilities and can be configured via appropriate programming. Above 10 kHz, the influence of the wideband loop becomes noticeable; above 200 kHz, the resonator *Q* takes over.

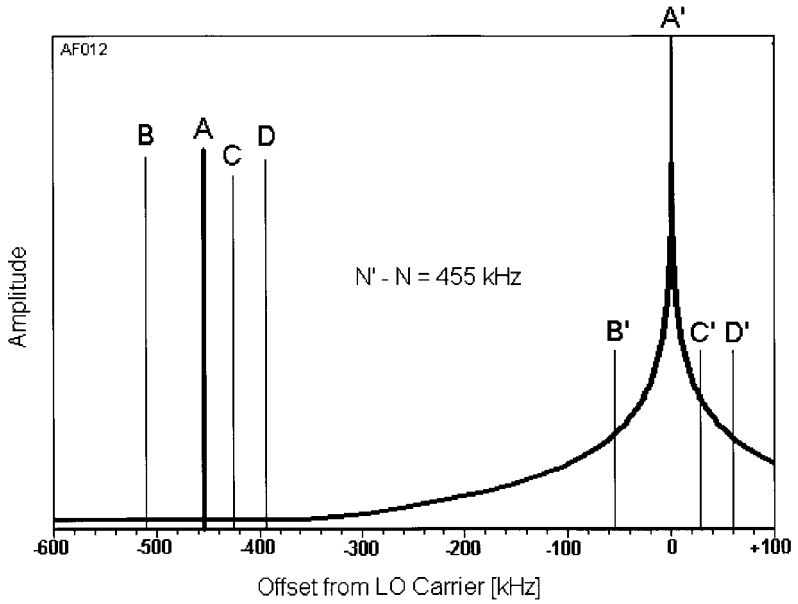

Figure 1-122 Reciprocal mixing occurs when incoming signals mix energy from an oscillator's sidebands to the IF. In this example, the oscillator is tuned so that its carrier, at A′, heterodynes the desired signal, A, to the 455 kHz as intended; at the same time, the undesired signals B, C, and D mix the oscillator noise sideband energy at B′, C′, and D′, respectively, to the IF. Depending on the levels of the interfering signals and the noise sideband energy, the result may be a significant rise in the receiver noise floor.

Figure 1-123 shows a typical arrangement of a dual-conversion receiver with local oscillators. The signal coming from the antenna is filtered by an arrangement of tuned circuits referred to as providing *input selectivity*. For a minimum attenuation in the passband, an operating bandwidth of

$$B = \frac{f}{\sqrt{2}Q_L}$$

is needed. This approximate formula is valid for the insertion loss of about 1 dB due to loaded Q.

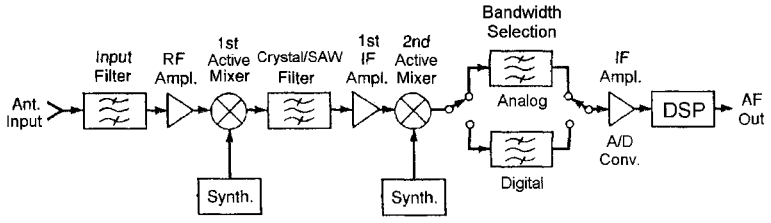

Figure 1-123 Block diagram of an analog/digital receiver showing the signal path from antenna to audio output. No AGC or other auxiliary circuits are shown. This receiver principle can be used for all types of modulation, since the demodulation is done in the DSP block.

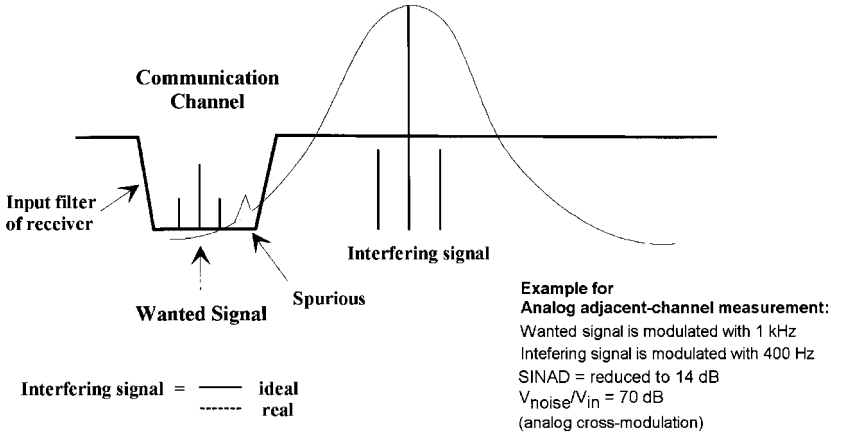

Figure 1-124 Principle of selectivity measurement for analog receivers.

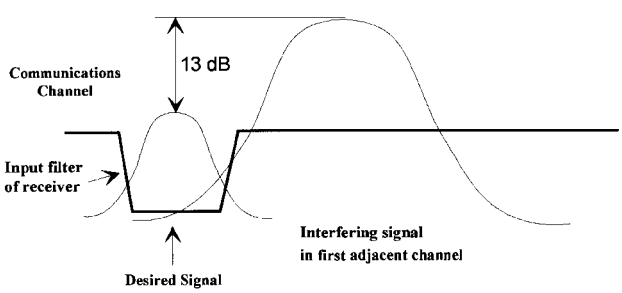
The filter in the first IF is typically either a SAW filter (in the frequency range from 500 MHz to 1 GHz) or a crystal filter (45–120 MHz). Typical insertion loss is 6 dB. Since these resonators have significantly higher Q than LC circuits, the bandwidth for the first IF will vary from ±5 to ±500 kHz. It is now obvious that the first RF filter does not protect the first IF because of its wider bandwidth. For typical communication receivers, IF bandwidths from 150 Hz to 1 MHz are found; for digital modulation, the bandwidth varies roughly from 30 kHz to 1 MHz. Therefore, the IF filter in the second IF has to accommodate these bandwidths; otherwise, the second mixer easily gets into trouble from overloading. This also means that both synthesizer paths must be of low-noise and low-spurious design. The second IF of this arrangement (Figure 1-123) can be either analog or digital, or even zero-IF. In practical terms, there are good reasons for using IFs like 50/3 kHz, as in hi-fi audio equipment such as the Walkman, with DSP processing at this frequency (50/3 kHz) using the low-cost modules found in mass-market consumer products.

Figures 1-124 and 1-125 show the principle of selectivity measurement for both analog and digital signals. The main difference is that the occupied bandwidth for the digital system can be significantly wider, and yet both signals can be interfered with by either a noise synthesizer/first LO or a synthesizer that has unwanted spurious frequencies. Such a spurious signal is shown in Figure 1-124. In the case of Figure 1-124, the analog adjacent-channel



Example of ACP suppression:

	Requirement	Good Generator
NADC		
30kHz from carrier	<-26 dBc	-51 dBc
60kHz "	<-45 dBc	-70 dBc
90kHz "	<-49 dBc	-75 dBc
PDC		
50kHz from carrier	<-45 dBc	-65 dBc
100kHz "	<-60 dBc	-76 dBc

Figure 1-125 Principle of selectivity measurement for digital receivers.

measurement has some of the characteristics of cross-modulation and intermodulation, while in the digital system the problem with the adjacent-channel power suppression is more obvious. Rarely has the concept of adjacent-channel power (ACP) been used with analog systems. Also, to meet the standards, signal generators have to be used that are better, with some headroom, than the required dynamic measurement. We have therefore included in Figure 1-125 the achievable performance for a practical signal generator—in this case, the Rohde & Schwarz SMHU58.

Because reciprocal mixing produces the effect of noise leakage around IF filtering, it plays a role in determining a receiver's dynamic selectivity (Figure 1-126). There is little value in using IF filtering that exhibits more stopband rejection than a value 3–10 dB greater than that which results in an acceptable reciprocal mixing level.

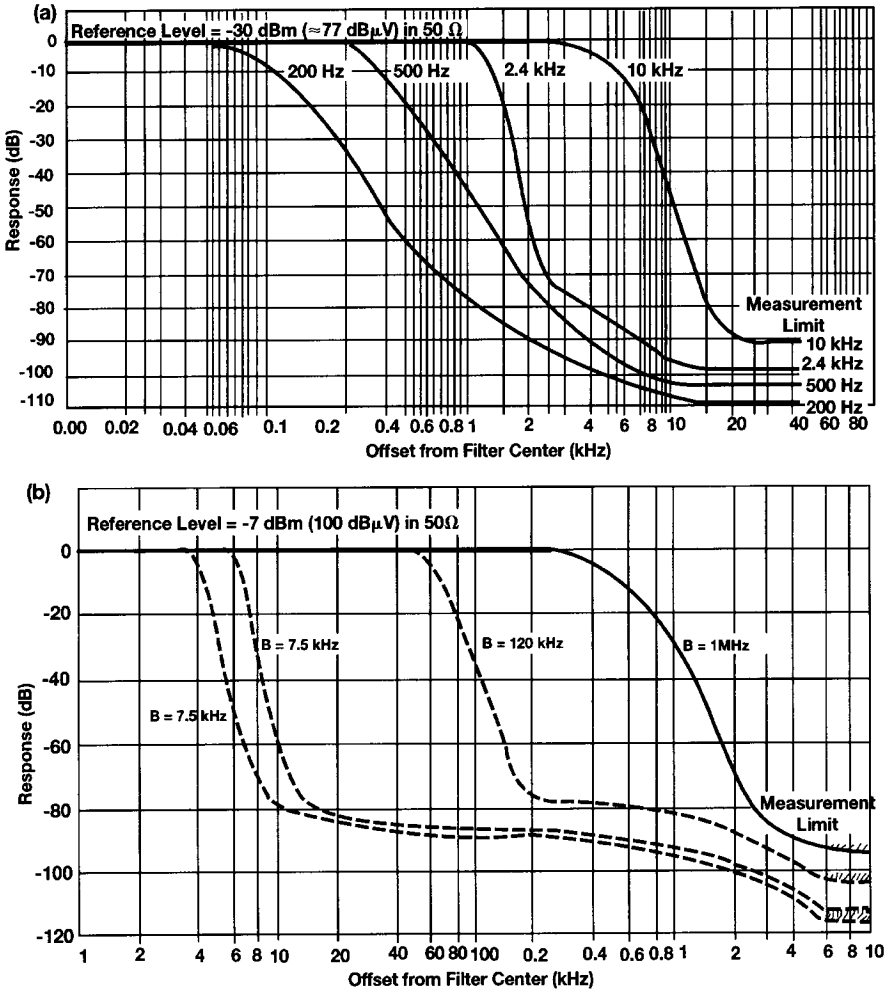


Figure 1-126 Dynamic selectivity versus IF bandwidth for (a) the Rohde & Schwarz ESH2 test receiver (9 kHz to 30 MHz) and (b) the Rohde & Schwarz ESV test receiver (10 MHz to 1 GHz). Reciprocal mixing widens the ESH2's 2.4-kHz response below –70 dB (–100 dBm) at (a) and the ESV's 7.5-, 12-, and 120-kHz responses below approximately –80 dB (–87 dBm) at (b).

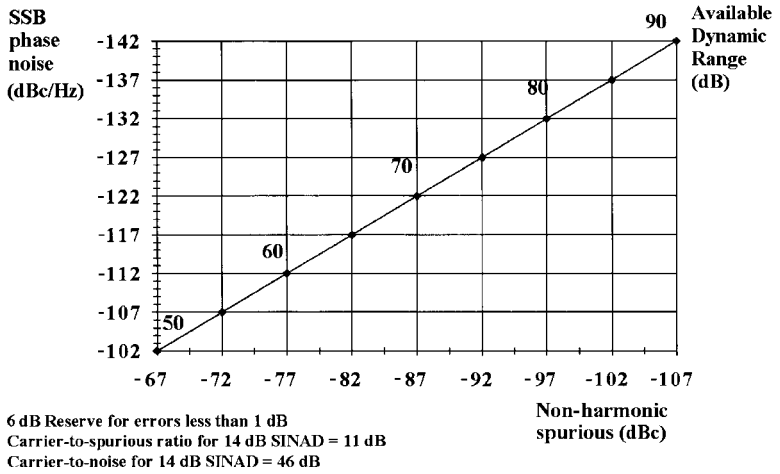

Figure 1-127 This graph shows the available dynamic range, which is determined either by the masking of the unwanted signal by phase noise or by discrete spurious signals. As far as the culprit synthesizer is concerned, it can be either the local oscillator or the effect of a strong adjacent-channel signal that takes over the function of the local oscillator.

Although additional RF selectivity can reduce the number of signals that contribute to the noise, improving the LO's spectral purity is the only effective way to reduce reciprocal mixing noise from *all* signals present at a mixer's RF port.

Factoring in the effect of discrete spurious signals with that of oscillator phase noise can give us the useful dynamic range of which an instrument or receiver is capable (Figure 1-127).

In evaluating the performance of digital wireless systems, we are interested in determining a receiver's resistance to adjacent-channel signals.

Phase Errors. In PM systems, especially those employing digital modulation, oscillator phase noise contributes directly to modulation and demodulation errors by introducing random phase variations that cannot be corrected by phase-locking techniques (Figure 1-128). The greater the number of phase states a modulation scheme entails, the greater its sensitivity to phase noise.

When an output signal is produced by mixing two signals, the resulting phase noise depends on whether the input signals are *correlated*—all referred to the same system clock—or uncorrelated, as shown in Figure 1-129.

Error Vector Magnitude. Several earlier figures (1-104, 1-112, and 1-128) have shown how particular sources of amplitude and/or phase error can shift the values of a digital emission's data states toward decision boundaries, resulting in increased BER due to intersymbol interference. Figures 1-130, 1-131, and 1-132 show three additional sources of such errors.

A figure of merit known as *error vector magnitude* (*EVM*) has been developed as a sensitive indicator of the presence and severity of such errors. An emission's error vector magnitude is the magnitude of the phasor difference as a function of time between an ideal reference signal and the measured transmitted signal after its timing, amplitude, frequency, phase, and dc offset have been modified by circuitry and/or propagation. Figure 1-133 illustrates the EVM concept.

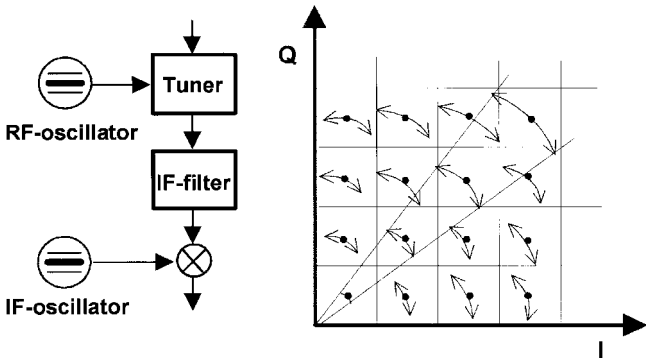

Figure 1-128 Phase noise is critical to digitally modulated communication systems because of the modulation errors it can introduce. Intersymbol interference (ISI), accompanied by a rise in BER, results when state values become so badly error-blurred that they fall into the regions of adjacent states. This drawing depicts only the results of phase errors introduced by phase noise; in actual systems, thermal noise, AM-to-PM conversion, differential group delay, propagation, and other factors may also contribute to the spreading of state amplitude and phase values.

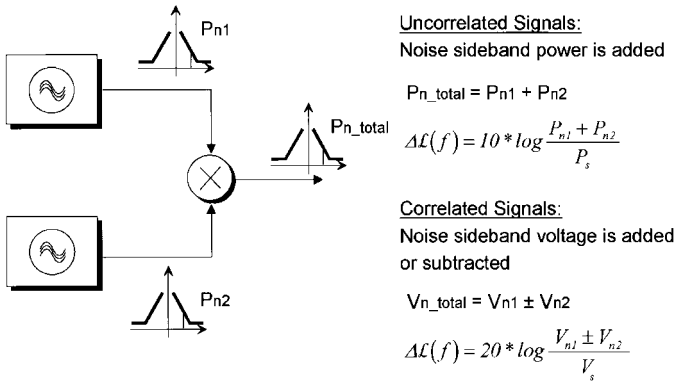

Figure 1-129 The noise sideband power of a signal that results from mixing two signals depends on whether the signals are correlated—referenced to the same system clock—or uncorrelated.

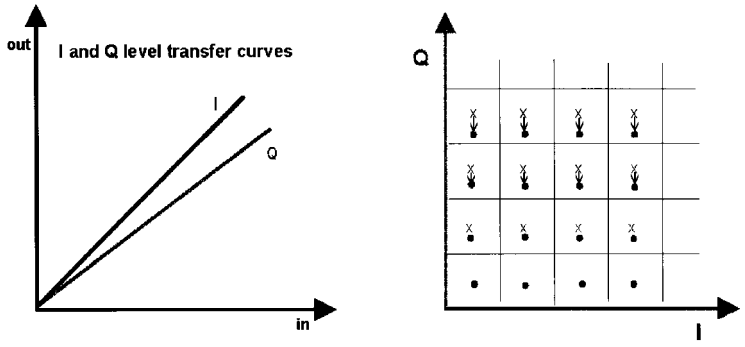

Figure 1-130 Effect of gain imbalance between I and Q channels on a data signal's phase constellation.

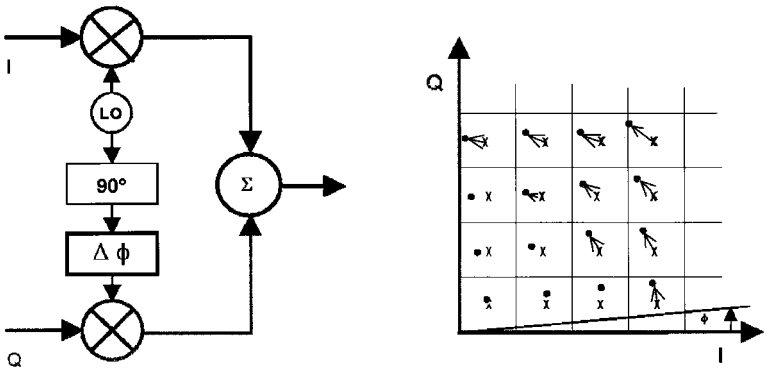

Figure 1-131 Effect of quadrature offset on a data signal's phase constellation.

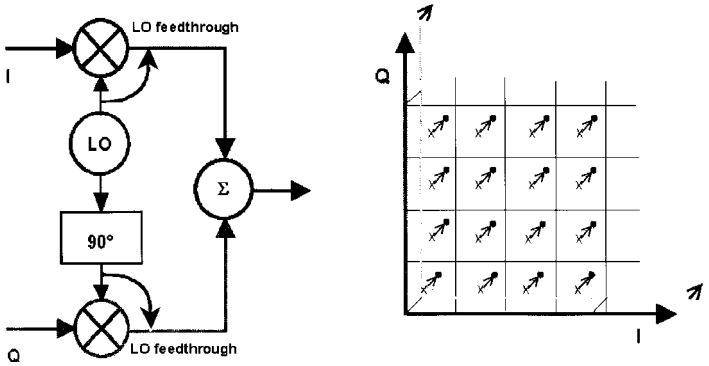

Figure 1-132 Effect of LO-feedthrough-based IQ offset on a data signal's phase constellation.

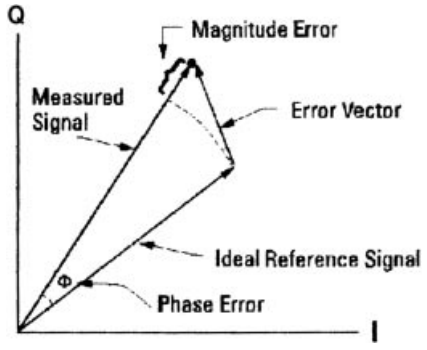

Figure 1-133 Representing errors in a digitally modulated signal's in-phase (I) and quadrature (Q) values relative to the ideal as a single error vector allows us to derive the resulting *error vector magnitude* (*EVM*), a sensitive indicator of transmission quality [20].

1-8 TESTING

1-8-1 Introduction

Testing of digital circuits deviates from the typical analog measurements, and yet the analog measurements are still necessary and related. As an example, the second-generation (2G) cellular telephone standards really have addressed only the transfer of voice and are just beginning to look into the transfer of data. Some services allow limited "e-mails," which are really messages that appear on the handset LCD after a delay. The future 3G standards with adaptive bandwidth will address high-speed data and video.

Since the major use of 2G phones is voice, information such as signal-to-noise ratio as a function of many things is important. In particular, because of the Doppler effect and the use of digital rather than analog signals, where the phase information is significant, the designer ends up using coding schemes for error correction—specifically, forward error correction (FEC). The signal-to-noise ratio as we know it from analog circuits now determines the bit error rate (BER), and its tolerable values depend on the type of modulation used. Because of correlation, it is possible to "rescue" a voice with a bit error rate of 1E – 4, but for higher data rates with little, if any, correlation, we are looking for BERs down to 1E – 9. The actual bit error rate depends on the type of filtering, coding, modulation, and demodulation. In several earlier figures (1-53 and 1-57) we related BER to signal-to-noise ratio; this is a key issue in receiver design.

Another problem in receivers that has to do with the transmitter of a second station is adjacent-channel power ratio (ACPR). Given the fact that a transmitter handling digital modulation delivers its power in pulses, its transmission may affect adjacent channels by producing transient spurious signals similar to what we call *splatter* in analog SSB systems. This is a function of the linearity of the transmitter system all the way out to the antenna and forces most designers to resort to less-efficient Class A operation. As possible alternatives, some researchers are looking into Class D and E modulation, more about which is found in the power amplifier section of Chapter 3.

It is actually not uncommon to do many linear measurements, and then by using correlation equations translate these measured results into their digital equivalents. Therefore, the robustness of the signal as a function of antenna signal at the receiver site, constant or known phase relationships, and high adjacent power ratios will provide good transfer characteristics.

1-8-2 Transmission and Reception Quality

The acoustic transmission and reproduction quality of a mobile phone is the most important characteristic in everyday use. Accurate and reproducible measurements of a cellular phone's frequency response cannot be achieved with static sinewave tones (SINAD measurements) because of coder and decoder algorithms. In this case, test signals simulating the characteristic of the human voice—that is, tones that are harmonic multiples of the fundamental—are required. A so-called vocoder is used to produce the lowest possible data rate. Instead of the actual voice, only the filter and fundamental parameters required for signal reconstruction are transmitted. Particularly in the medium and higher audiofrequency ranges, the static sinusoidal tones become a more or less stochastic output signal. For example, if a tone of approximately 2.5 kHz is applied to the telephone at a constant sound pressure, the amplitude of the signal obtained at the vocoder output varies by approximately 20 dB. In type-approval

tests, where highly accurate measurements are required, the coder and decoder are excluded from the measurement.

Whether the results obtained for the fundamental frequency are favorable depends on how far the values coincide with the clock of the coding algorithm. Through a skillful choice of fundamental frequencies, test signals with overlapping spectral distribution can be generated, giving a sufficient number of test points in subsequent measurements at different fundamental frequencies so that a practically continuous frequency response curve is obtained. Evaluation can be done by means of FFT analysis with a special window function and selection of result bins. The results are sorted and smoothed by the software and display in the form of a frequency response curve. Depending on the measurement, a program calculates the sending or receiving loudness rating in line with CCITT P.79 and shows the result.

Acoustic measurements relevant to GSM 11.10 include:

- Sending frequency response
- Sending loudness rating
- Receiving frequency response
- Receiving loudness rating
- Sidetone masking rating
- Listener sidetone rating
- Echo loss
- Stability margin
- Distortion sending
- Distortion receiving
- Idle channel noise receiving
- Idle channel noise sending

There are two categories of testing. One is a full-compliance test for all channels and all combinations of capabilities; the other is a production tester with evaluation of the typical characteristic data. Both Hewlett-Packard and Rohde & Schwarz are the leading companies in this area, and as the technology develops further, different equipment will be made available. Figure 1-134 shows a Rohde & Schwarz radiocommunication tester capable of evaluating cellular systems. Table 1-13 shows the typical specifications required to make the appropriate cellular telephone measurements.

The test setup must be capable of measuring key IS-95 parameters, using the following:

- Frame errors
- Waveform quality
- Error vector magnitude
- Phase error
- Magnitude error
- Carrier feedthrough
- Frequency accuracy
- Power measurements
- Base-station signaling for mobile testing

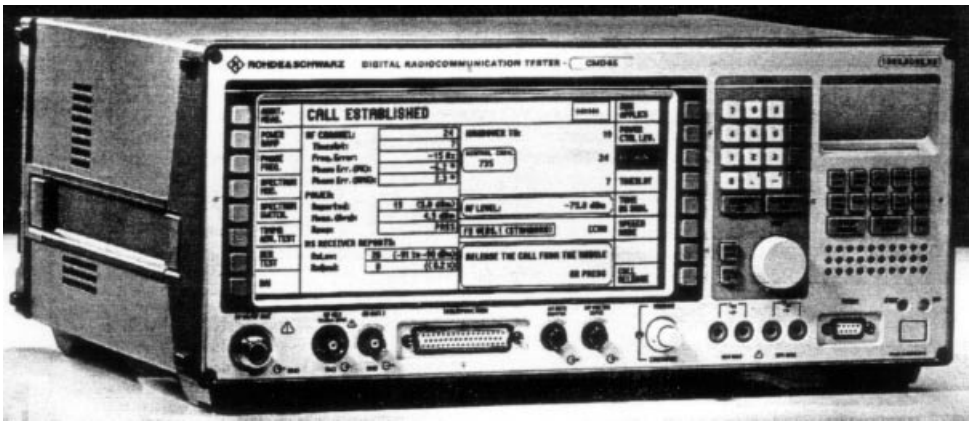

Figure 1-134 The Rohde & Schwarz CMD 65 digital radiocommunication tester can be used to measure all the relevant specifications of cellular telephones.

Table 1-13 Digital radiocommunication tester model CMD 80

SIGNAL GENERATOR	
Frequency	
Range	869–894 MHz
Resolution	1 Hz
Error	Same as timebase
Output level	
RF IN/OUT	–20 to –124 dBm
RF OUT2	0 to –105 dBm
Resolution	0.1 dB
Error (RF IN/OUT)	≤1.5 dB
Modulation	
Carrier suppression	–30 dBc
ANALYZER	
Frequency	
Range	824–849 MHz
Resolution	1 Hz
Error	Same as timebase
Power measurement	
Reference level range	
RF IN/OUT (full scale)	+41 to –28 dBm
RF IN2 (full scale)	0 to –69 dBm
Measurement error, absolute	±1.5 dB
Measurement error, relative	≤0.4 dB (ref. level to –40 dB)
Dynamic range	50 dB below reference level

Table 1-13 (Continued)

Modulation analyzer	
ρ error (25 ± 10) °C	0.003 (for ρ = 0.9–1)
Frequency measurement range	± 3 kHz
Frequency measurement error	Reference ±30 Hz
Timing measurement error	±60 ns
TIMEBASE	
Standard timebase	
Nominal frequency	10 MHz
Frequency drift in temperature range 0–35 °C	$\leq 1.5 \times 10^{-6}$
Frequency aging	$\leq 0.5 \times 10^{-6}$/yr (at 35 °C)
OCXO reference oscillator	
Nominal frequency	10 MHz
Frequency drift in temperature range 0–45 °C	$\leq 1 \times 10^{-7}$
Frequency aging	$\leq 2 \times 10^{-7}$/yr $\leq 0.5 \times 10^{-9}$/day after 30 days of operation
Warm-up time (at 25 °C)	approx. 5 min
Reference frequency inputs/outputs	
Synchronization input (frequency selectable)	100 kHz to 40 MHz, step 10 kHz
Impedance	approx. 100 Ω
Level	0 dBm to TTL
Synchronization output	
Frequency	10 MHz or frequency at synchronization input
Level	TTL, R_{out} = 50 Ω
AWGN generator	
Equivalent noise bandwidth	1.8 MHz typ.
Gain adjustment range	–20 to +6 dB of forward channel power
dc Voltage measurements	
Range	0 to ±30 V
Resolution	10 mV
Error	2% + resolution
dc Current measurements	
Mode	averaging, +peak, –peak
Range	0 to ±10 A
Common mode rejection	±30 V
Shunt resistance	50 mΩ
Resolution for averaging	1mA/10 mA
Resolution for peak	10 mA
Residual indication	<10 mA
Error	<2% + resolution + residual indication

1-8-3 Base-Station Simulation

Simulating a CDMA (IS-95) base station involves:

- Synchronization of mobile
- Registration of mobile
- Incoming/outgoing call origination
- Handoff

During the call, the tester must verify the handset's RF performance and check the correct operation of the basic signaling features. The best testers do not rely on any special test modes in the mobile station, performing their measurements under conditions almost identical to those in a real network. A voice loop-back allows quick verification of the performance of a mobile as it is perceived by the user.

1-8-4 GSM

Measurement, test, and adjustment capabilities for GSM should include:

- Synchronization of mobile phone with base station (which is simulated by CTS)
- Location update
- Call setup (incoming/outgoing)
- Call release (incoming/outgoing)
- Control and measurement of transmitter power
- Handover (channel change)
- Sensitivity, including bit error rate (BER) and raw bit error rate (RBER); limit sensitivity via search routine; RxLev and RxQual
- Phase and frequency error
- Power ramp versus time
- Timing error
- AFC (automatic frequency correction) and RSSI (radio signal strength indication)
- I/Q modulator adjustment
- Echo test (voice test, includes also testing of loudspeaker and microphone)
- Functional test of mobile's keypad through display of dialed number
- Display of IMSI (international mobile subscriber identity), IMEI (international mobile equipment identity), power class, and revision level
- Short message service (SMS)

1-8-5 DECT

Measurement, test, and adjustment capabilities for DECT should include:

- Synchronization of DUT with the CTS
- Call setup
- Call release
- Echo test

Often BER diagrams do not have C/N as abscissa (FIG) but E_b/N_0, which is the energy per information bit E_b referred to the normalized noise power N_0 [1]. C/N describes the ratios in the transmission channel, SNR the signals after the √cos receive filter. The following applies:

$$C/N = SNR + k_{roll\ off}\ [dB]$$

In converting the two quantities, some factors have to be taken into account as shown by equations 1 and 2 on the right.

To determine C/N [dB] or E_b/N_0 [dB], the logarithmic ratios have to be corrected using the following factors:

- Factor for Reed-Solomon FEC*

$$k_{FEC} = 10 \times \lg \frac{188}{204}$$

$$k_{FEC} = -0.3547\ [dB]$$

- Factors for QPSK/QAM modulation

$$k_{QPSK/QAM} = 10 \times \lg(m)$$

Modulation	m	$k_{QPSK/QAM}$ [dB]
QPSK	2	3.0103
16QAM	4	6.0206
64QAM	6	7.7815
256QAM	8	9.0309

- Factor for coding rate (P = 1 for QAM)*

$$k_P = 10 \times \lg(P)$$

Modulation	P	k_P [dB]
QPSK	1/2	–3.0103
	2/3	–1.7609
	3/4	–1.2494
	5/6	–0.7918
	7/8	–0.5799
QAM	1	0

- Factor for √cos roll-off filtering in demodulator/receiver

$$k_{roll\ off} = 10 \times \lg\left(1 - \frac{\alpha}{4}\right)$$

Modulation	α	$k_{roll\ off}$ [dB]
DVB-C	0.15	–0.1660
DVB-S	0.35	–0.3977

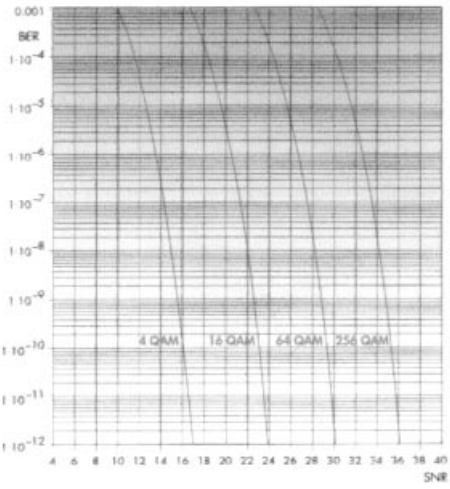
* To be taken into account if E_b only refers to the information bits; not to be taken into account if E_b refers to all bits transmitted (information plus error control bits)

$$C/N = E_b/N_0 + 10 \times \lg\frac{188}{204} + 10 \times \lg(m) + 10 \times \lg(P) - 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

Equation 1

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m) - 10 \times \lg(P) + 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

Equation 2



BER referred to SNR for 4, 16, 64 and 256QAM

The types of correction factor required depend on whether measurement is made

- in the transmission channel,
- before or after Viterbi correction,
- with QAM or QPSK modulation.

Examples of conversion equations –

For **in-channel** measurements with QAM transmission, the following applies:

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m)\ [dB]$$

The factors for √cos roll-off filtering and puncturing rate are not needed.

For measurements in the **QAM demodulator**, √cos roll-off filtering filtering has to be taken into account.

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m) + 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

For measurements in the **satellite demodulator** with QPSK, the equation for determining the BER as a function of E_b/N_0 after Viterbi FEC is as follows:

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m) - 10 \times \lg(P) + 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

In the latter case all correction factors are included.

INTRODUCTION TO WIRELESS CIRCUIT DESIGN

1-1 OVERVIEW

Wireless circuits are not that different from commonly known two-way radio, television, and broadcast arrangements. Some of them require high linearity in modulation (TV picture); some work via relay stations (two-way radio). The real differences lie in the fact that the cell sizes are much smaller, and that in most cases we attempt multiple channel use (reuse) using time-division multiplex, spread spectrum, or some other efficient means of reducing the bandwidth required for communication. One can argue that the wireless circuits include simple devices, such as garage-door openers and wireless keys for automobiles (we have seen many cases where strong interfering signals prevented the car owners from reclaiming their cars until the interfering signal disappeared). Another longtime favorite is cordless telephones: initially, 50-MHz models with essentially no privacy protection; later, more sophisticated models that operate at 900 MHz; and now, dual-band designs that use 900 MHz and 2.4 GHz.

The largest wireless growth area is probably the cellular telephones. The two major applications are the handsets, commonly referred to as cell phones or occasionally as "handies," and the base stations. The base stations have many more problems with large-signal-handling linearity at high power, although handset users may run into similar problems. An example of this is the waiting area of an airport, where many travelers are trying to conduct last-minute business: In one instance, we concluded that about 30% of all the people present were on the air! It would have been fun to evaluate this receiver-hostile environment with a spectrum analyzer.

From such use comes anxiety factors, the lesser of which is "When will my battery die?"—a spare battery tends to help—and the greater of which the ongoing question, "Will this cell-phone transmitter harm my body?" [22]. A brief comment for the self-proclaimed experts in this area: A 50–100-kW TV transmitter, specifically its video or picture portion, connected to a high-gain antenna, emits levels of energy in line-of-sight paths that by far exceed the pulsed energy from a cell phone. Specifically, the duration of energy is signifi-

cantly smaller, and the absolute energy is more than a thousandfold higher, than the radio frequency (RF) supposedly harming us from the cellular phone. Handheld two-way radios have been used for the last 30 years or so by police and other security interests, operating in the frequency range from 50 to 900 MHz with antennas close to the users' heads, and there are no known cases of cancer or any other illnesses caused by these handheld radios. Recent studies in England, debatably or not, showed that the reaction-time level of people using cell phones actually *increased*—but then there are always the skeptics and politically motivated who ignore the facts, try to influence the media, and have their 15 minutes of fame (as Andy Warhol used to say).

As to the "harmful" radiation, Figure 1-1 shows the simulated radiation of a Motorola flip phone. While there are no absolute values attached to the pattern colors, it is interesting to see that the antenna extension inside the plastic casing also radiates, but most of the energy definitely is emitted by the top of the antenna. It seems to be a good idea to hold the telephone in such a way that the antenna points away from the head, "just in case." The user will find a "warm" sensation that will have more to do with the efficiency of the RF power amplifier heating up the case than the effect of radiation.

With this introduction in place, we will first take a look at a typical ultra-high-frequency/super-high-frequency (UHF/SHF) transceiver and explain the path from the microphone to the antenna and back. After this, we will inspect the radio channel and its effect on various methods of digital modulation. Analysis of wireless receivers and transmitters will be next, followed by a look at available building blocks and how they affect the overall system. To validate proper system operation, a fairly large number of measurements and tests must be performed, and conveying their purpose and importance will necessitate the definition of a number of system characteristics and concepts, such as dynamic range. Finally, after this is done, we will look at the issue of wireless system testing. Again, we intend to

Figure 1-1 Simulated antenna radiation of a Motorola flip phone.

give guidance applicable to battery-operated, handheld operation as well as high-powered base stations.

1-2 SYSTEM FUNCTIONS

A cellular telephone is a hybrid between a double-sideband and frequency-modulated [FM; or phase-modulated (PM)] transceiver. The actual transmission is not continuous but is pulsed, and because of the pulse spectrum there is a signal bandwidth concern due to keying transients, not unlike intermodulation products of a single-sideband (SSB) transceiver cluttering up adjacent channels. The cellular telephone is also a linear transceiver in the sense that its signal-handling circuitry must be sufficiently amplitude- and phase-linear to preserve the modulation characteristics of the AM/PM hybrid emissions it transmits and receives. Containing such an emission's spectral regrowth, which affects operation on adjacent channels, is not unlike the linearity requirements we encounter in SSB transceivers—requirements so stringent that amplifiers must be run nearly in Class A to meet them. The time-division multiple access (TDMA) operating mode, which allows many stations to use the same frequency through the use of short, precisely timed transmissions, requires a system that transmits with a small duty cycle, putting much less thermal stress on a power amplifier than continuous operation. Power management, including a sleep mode, is another important issue in handset design.

Figure 1-2 shows the block diagram of a handheld transceiver. This is applicable for cellular telephones and other systems that allow full duplex. For those not too familiar with transceivers, here is a "walk" through the block diagram. The RF signal intercepted by the antenna is fed through a duplex filter into a front end consisting of a preamplifier, an additional filter, and a mixer. The duplexer is optimized more for separating transmit and receive frequencies than extreme selectivity, but because of the typical low field strengths of incoming signals, it provides enough selectivity to guard the receiver path against overload and intermodulation products. The preamplifier is either a single transistor or a cascode arrangement with a filter following it. These high-band filters, mostly supplied by Murata, are typically surface acoustic wave (SAW) filters with very small dimensions. We would already like to point out in this part of the block diagram that these filters typically have high-impedance inputs and outputs (somewhere between 200 Ω and 1 kΩ), therefore eliminating the nice test-setup possibilities typically provided in a 50-Ω system. Generally, integrated circuit (IC)-type mixers also operate at high impedances, which makes matching easier. The filter following the mixer is responsible for reducing the image, and then we go to the intermediate frequency (IF) and demodulation. The particular chip or chips mentioned here, supplied by Philips, are set out for a double-conversion receiver, and the demodulation is accomplished with a quadrature detector for FM analog modulation. The rest of the circuitry on the horizontal path does digital signal processing (DSP) and overall control functions. The four blocks at the far right refer to the central processor, which handles such things as display, power management, and information storage (such as frequently used telephone numbers). A nice overview about DSP in "readable" form is given by Kostic [1].

The transmit portion consists of an independent synthesizer that is modulated. There are dual synthesizer chips available to accommodate this. Both receive and transmit frequencies are controlled by a miniature temperature-compensated crystal oscillator (TCXO). One of its outputs is also used as the system master clock for all the digital activities. The output of the voltage-controlled oscillator (VCO) is then amplified and fed to the antenna through the

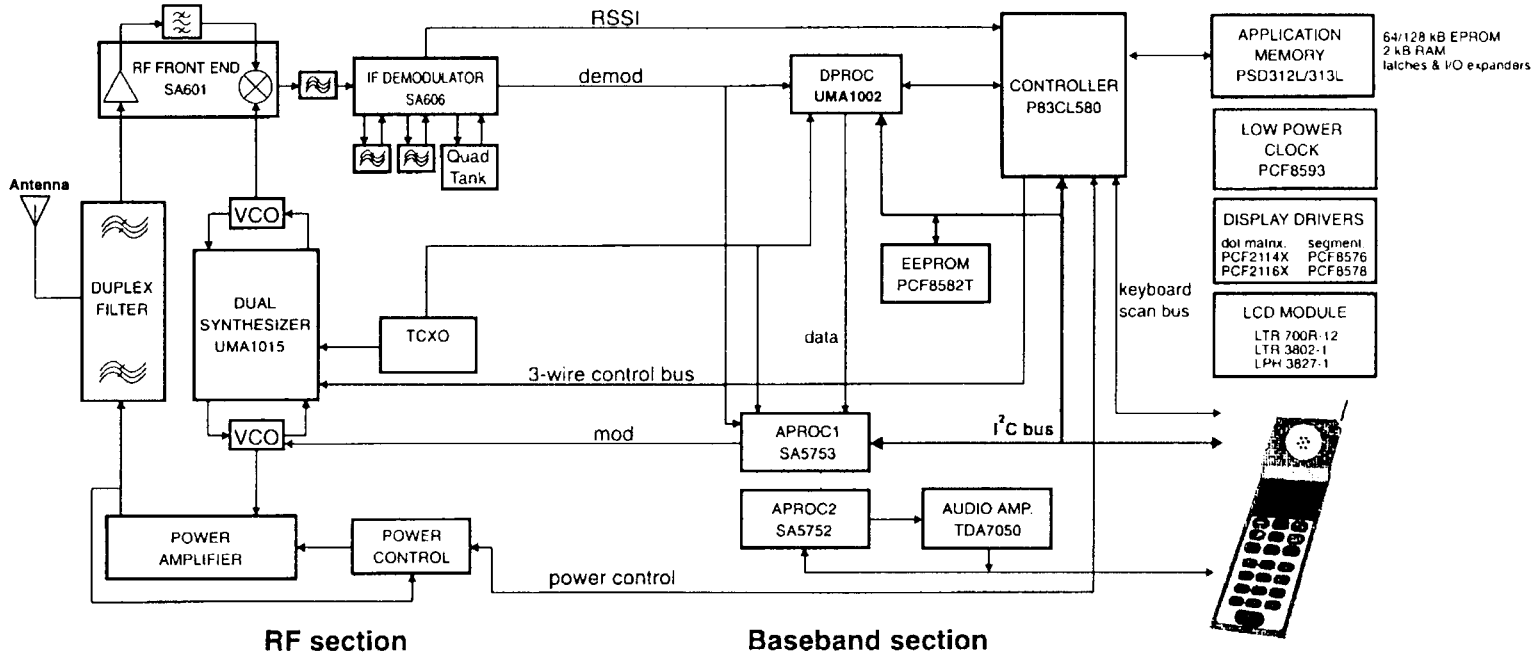

Figure 1-2 Block diagram of a handheld cellular telephone transceiver.

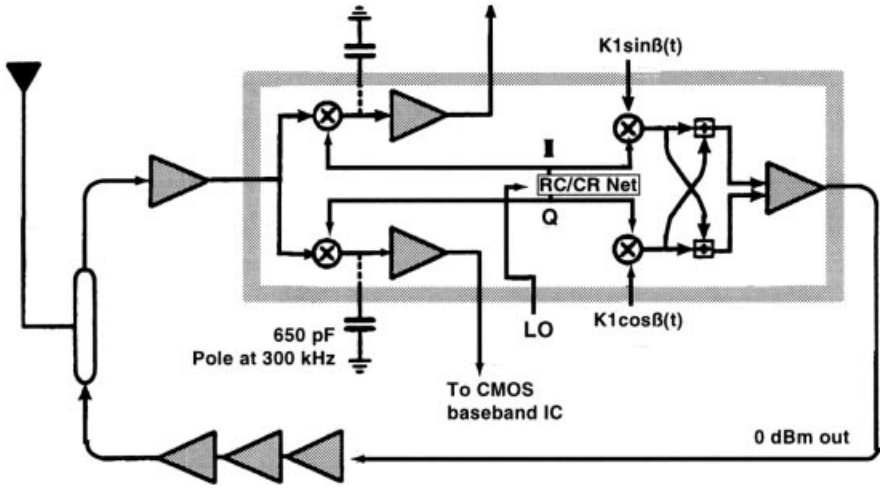

Figure 1-3 Single-chip direct-conversion transceiver by Alcatel. Channel selection is accomplished at baseband by low-pass switched-capacitor filters in a companion mixed-signal complementary metal-oxide semiconductor (CMOS) IC. A trimmed resistance-capacitance/capacitance-resistance (RC/CR) network generates the necessary quadrature signals for the chip's mixers.

same duplex filter as the receive portion. There are also schemes available for advanced modulation methods, specifically, code- , frequency-, and time-division multiple access (CDMA, FDMA, and TDMA, respectively). In these cases, the transmitter is not active all the time, and the duplexer can be replaced with a diode switch using a quarter-wavelength transmission line together with a PIN diode for the required switching.

Many modern devices use "zero IF" or direct conversion, which simplifies the IF or modulation portion of the unit significantly. Figure 1-3 shows an Alcatel single-chip direct-conversion transceiver. The signal is fed to an image-reject mixer with the local oscillator (LO) in quadrature, and the selectivity is obtained by manipulating the "audio bandwidth." Today we have a large number of implementations using different schemes that are beyond the scope of this book; therefore, we have decided to limit ourselves to a basic introduction because most of the relevant demodulation and coding are done in DSP, for which we will give appropriate references. A nice overview of different architectures is found in Razavi [2].

1-3 THE RADIO CHANNEL AND MODULATION REQUIREMENTS

1-3-1 Introduction

The transmission of information from a fixed station to a mobile is considerably influenced by the characteristics of the radio channel. The RF signal not only arrives at the receiving antenna on the direct path but is normally reflected by natural and artificial obstacles in its way. Consequently the signal arrives at the receiver several times in the form of echoes, which are superimposed on the direct signal (Figure 1-4). This superposition may be an advantage as the energy received in this case is greater than in single-path reception. This feature is made use of in the digital audio broadcasting (DAB) single-frequency network. However,

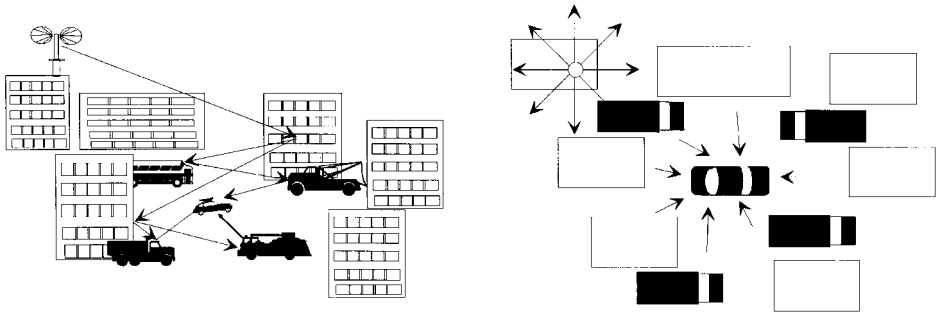

Figure 1-4 Mobile receiver affected by fading.

this characteristic may be a disadvantage when the different waves cancel each other under unfavorable phase conditions. In conventional car radio reception this effect is known as fading. It is particularly annoying when the vehicle stops in an area where the field strength is reduced because of fading (e.g., at traffic lights). Additional difficulties arise when digital signals are transmitted. If strong echo signals (compared to the directly received signal) arrive at the receiver with a delay on the order of a symbol period or more, time-adjacent symbols interfere with each other. In addition, the receive frequency may be falsified at high vehicle speeds because of the Doppler effect so that the receiver may have problems in estimating the instantaneous phase in the case of angle-modulated carriers. Both effects lead to a high symbol error rate even if the field strength is sufficiently high. Radio broadcasting systems using conventional frequency modulation are hardly affected by these interfering effects. If an analog system is replaced by a digital one that is expected to offer advantages over the previous system, it has to be ensured that these advantages—for example, better audiofrequency signal/noise (AF S/N) and the possibility of supplementary services for the subscriber—are not at the expense of reception in hilly terrain or at high vehicle speeds because of extreme fading.

For this reason a modulation method combined with suitable error protection has to be found for mobile reception in a typical radio channel, which is immune to fading, echo, and Doppler effects.

With a view to this, more detailed information on the radio channel is required. The channel can be described by means of a model. In the worst case, which may be the case for reception in built-up areas, it can be assumed that the mobile receives the signal on several indirect paths but not on a direct one. The signals are reflected, for example, by large buildings; the resulting signal delays are relatively long. In the vicinity of the receiver these paths are split up into a great number of subpaths; the delays of these signals are relatively short. These signals may again be reflected by buildings but also by other vehicles or natural obstacles like trees. Assuming the subpaths are statistically independent of each other, the superimposed signals at the antenna input cause considerable time- and position-dependent field-strength variations with an amplitude obeying the Rayleigh distribution (Figures 1-5 and 1-6).

If a direct path is received in addition, the distribution changes to the Rice distribution, and finally, when the direct path becomes dominant, the distribution follows the Gaussian distribution with the field strength of the direct path being used as the center value.

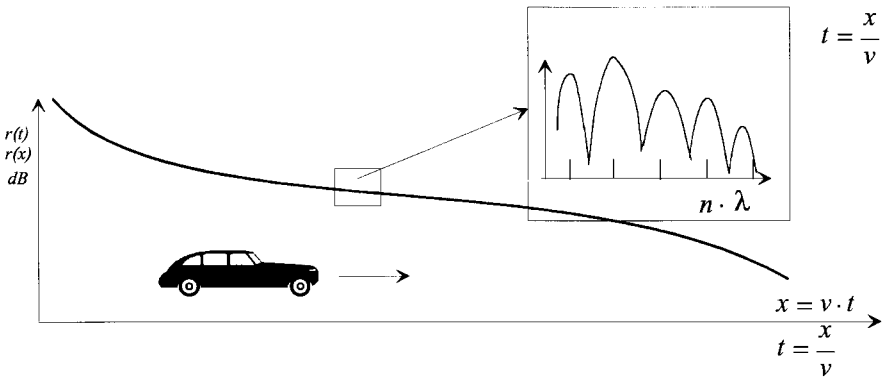

Figure 1-5 Receive signal as a function of time or position.

In a Rayleigh channel the bit error rate (BER) increases dramatically compared to the BER in an additive white Gaussian noise (AWGN) channel (Figure 1-7).

1-3-2 Channel Impulse Response

This scenario can be demonstrated by means of the channel impulse response. Let's assume that a very short pulse of extremely high amplitude [in the ideal case, a Dirac pulse $\delta(t)$] is sent by the transmitting antenna at a time $t_0 = 0$. This pulse arrives at the receiving antenna direct and in the form of reflections with different delays τ_i and different amplitudes because of path losses. The impulse response of the radio channel is the sum of all received pulses (Figure 1-8). Since the mobile receiver and also some of the reflecting objects are moving, the channel impulse response is a function of time and of delays τ_i; that is, it corresponds to

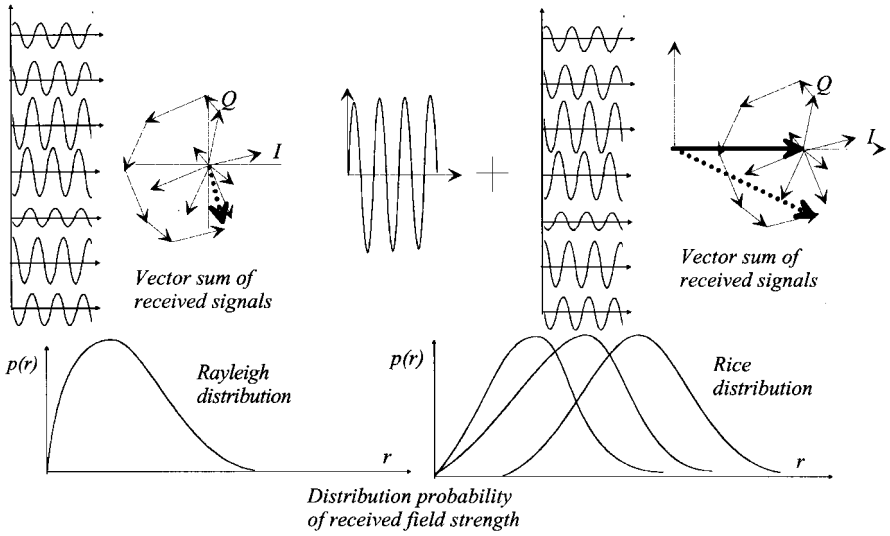

Figure 1-6 Rayleigh and Rice distributions.

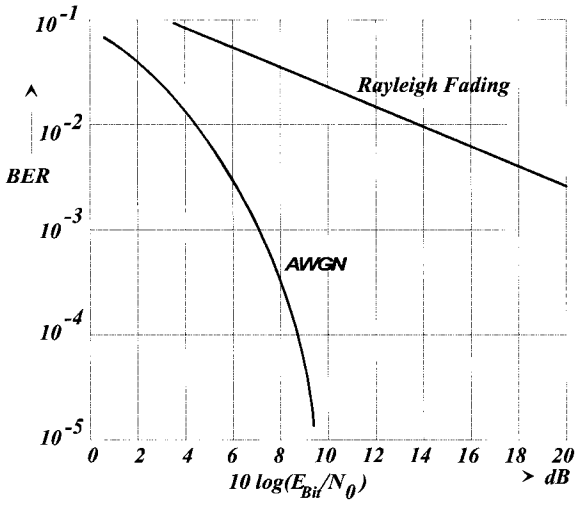

Figure 1-7 BER in a Rayleigh channel.

$$h(t,\tau) = \sum_{N} a_i \delta(t - \tau_i) \tag{1-1}$$

This shows that delta functions sent at different times t cause different reactions in the radio channel.

In many experimental investigations different landscape models with typical echo profiles were created. The most important are:

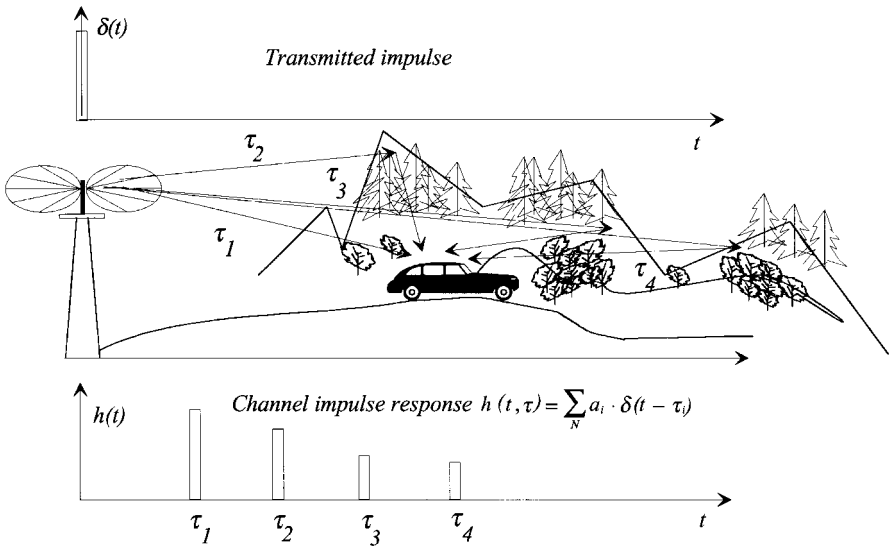

Figure 1-8 Channel impulse response.

- Rural area (RA)
- Typical urban area (TU)
- Bad urban area (BA)
- Hilly terrain (HT)

The channel impulse response informs on how the received power is distributed to the individual echoes. A parameter, the "delay spread," can be calculated from the channel impulse response, permitting an approximate description of typical landscape models (Figure 1-9).

The delay spread also roughly informs on the modulation parameters, carrier frequency, symbol period, and duration of guard interval, which have to be selected in relation to each other. If the receiver is located in an area with a high delay spread (e.g., in hilly terrain), echoes of the symbols sent at different times are superimposed when broadband modulation methods with a short symbol period are used. In the case of DAB, this problem is aggravated by the use of single-frequency networks. An adjacent transmitter emitting the same information on the same frequency has the effect of an artificial echo (Figure 1-10).

A constructive superposition of echoes is only possible if the symbol period is much greater than the delay spread. The following holds:

$$T_s > 10T_d \tag{1-2}$$

This has the consequence that relatively narrowband modulation methods have to be used. If this is not possible, channel equalizing is required.

For channel equalizing, a continuous estimation of the radio channel is necessary. The estimation is performed with the aid of a periodic transmission of data known to the receiver. In networks according to the Groupe Speciale Mobile (GSM) standards a midamble consisting of 26 bits—the training sequence—is transmitted with every burst. The training

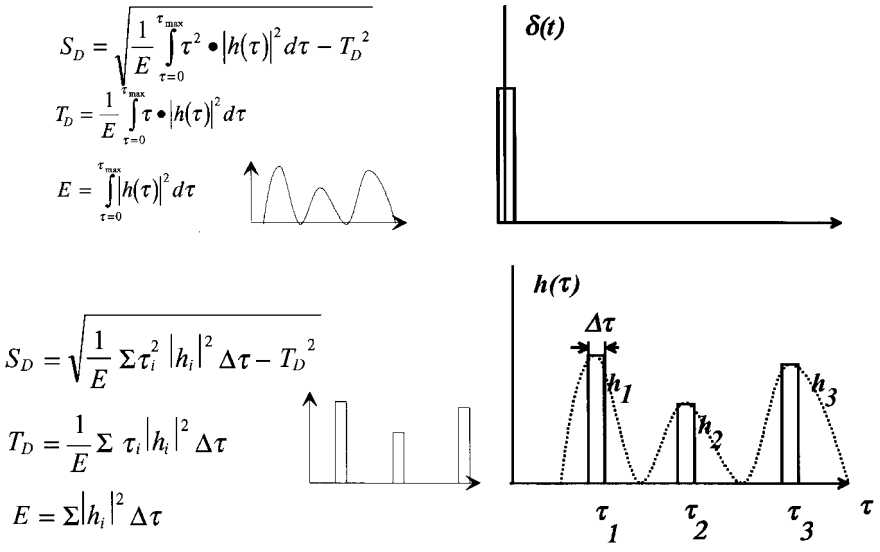

Figure 1-9 Calculation of delay spread.

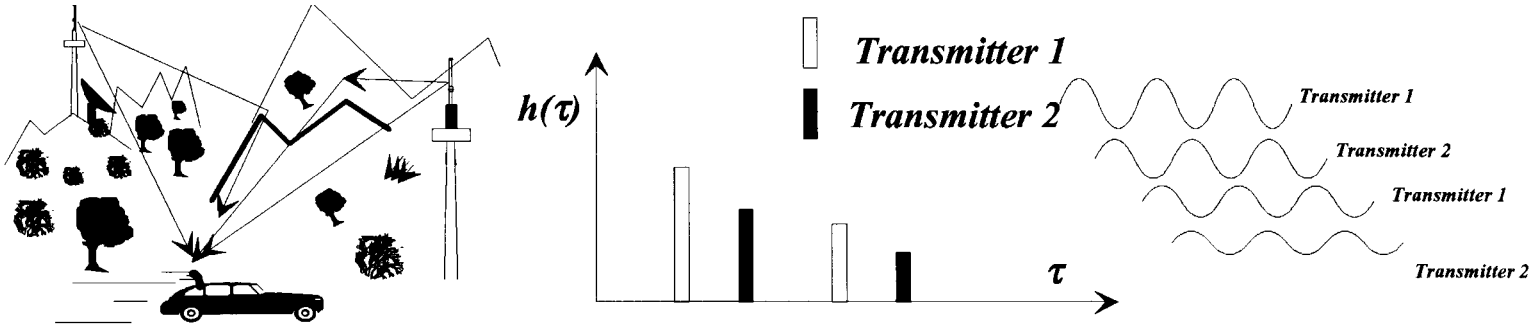

Figure 1-10 Artificial and natural echoes in the single-frequency network.

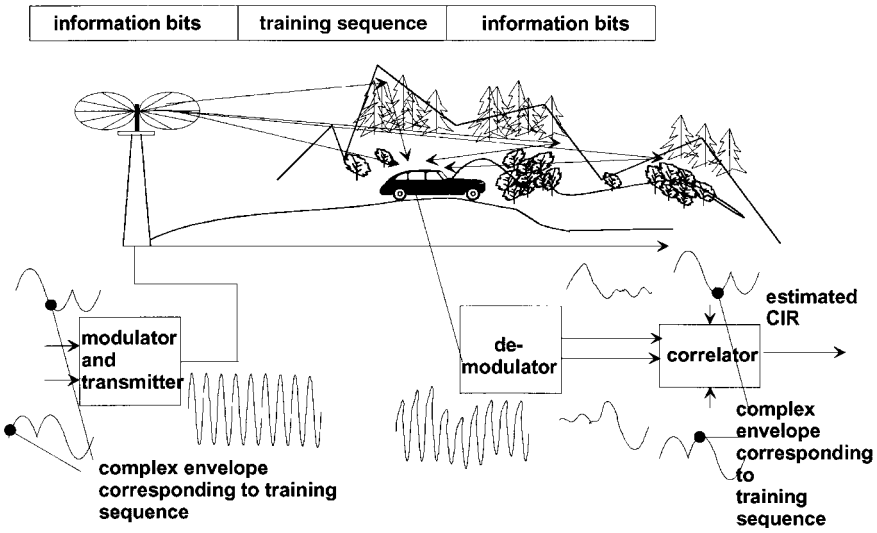

Figure 1-11 Channel estimation.

sequence corresponds to a characteristic pattern of I/Q signals that is kept in a memory in the receiver. The baseband signals of every received training sequence are correlated with the stored ones. From this correlation the channel can be estimated, and the properties of the estimated channel will then be fed to the equalizer (Figure 1-11).

The equalizer uses the Viterbi algorithm (maximum sequence likelihood estimation) for the estimation of the phases, which most likely have been sent at the sampling times. From these phases the information bits are calculated (Figure 1-12). A well-designed equalizer then will superimpose the energies of the single echoes constructively, so that the result in an area where the echoes are not too much delayed—delay times up to 16 μs have to be tolerated by a receiver—is better than in an area with no significant echoes (Figure 1-13).

Remaining bit errors are eliminated using another Viterbi decoder at the transmitter for the convolutionally encoded data sequences.

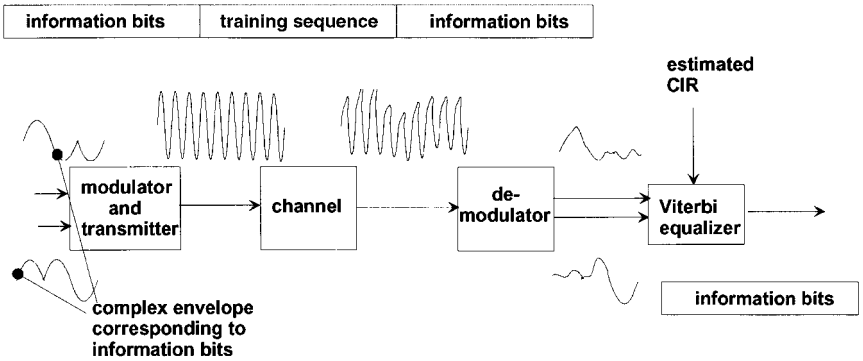

Figure 1-12 Channel equalization.

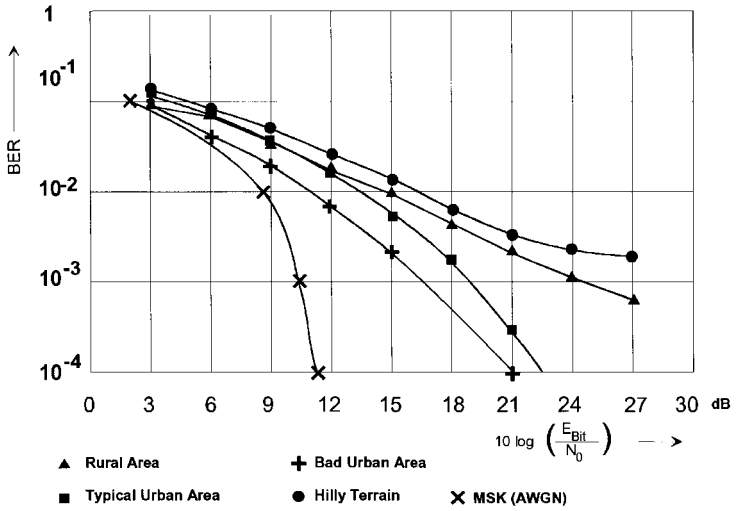

Figure 1-13 BERs after the channel equalizer in different areas.

The ability of a mobile receiver to work in a hostile environment, such as the radio channel with echoes, must be proved. The test is performed with the aid of a fading simulator. The fading simulator simulates different scenarios with different delay times and different Doppler profiles. A signal generator generates undistorted I/Q modulated RF signals, which are downconverted into the baseband. Here the I/Q signals are digitized and split into different channels, where they are delayed and attenuated, and where Doppler effects are superimposed. After combination of these distorted signals at the output of the baseband section of the simulator these signals modulate the RF carrier, which is the test signal for the receiver under test (Figure 1-14).

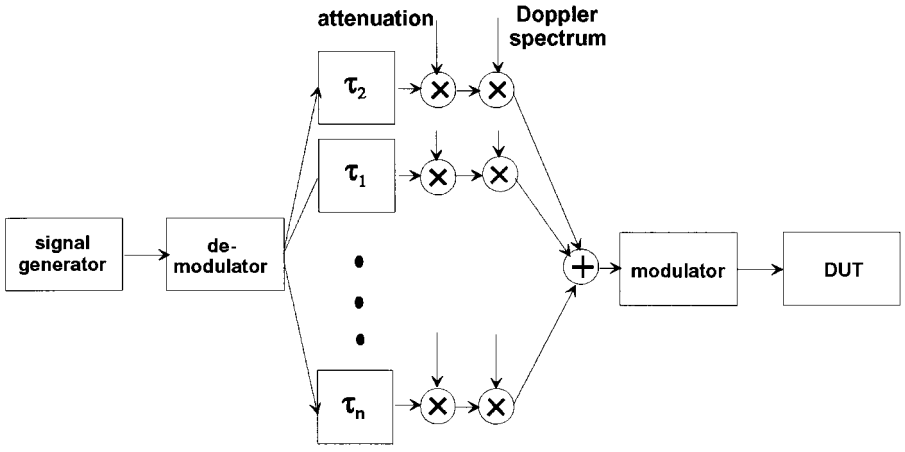

Figure 1-14 Fading simulator.

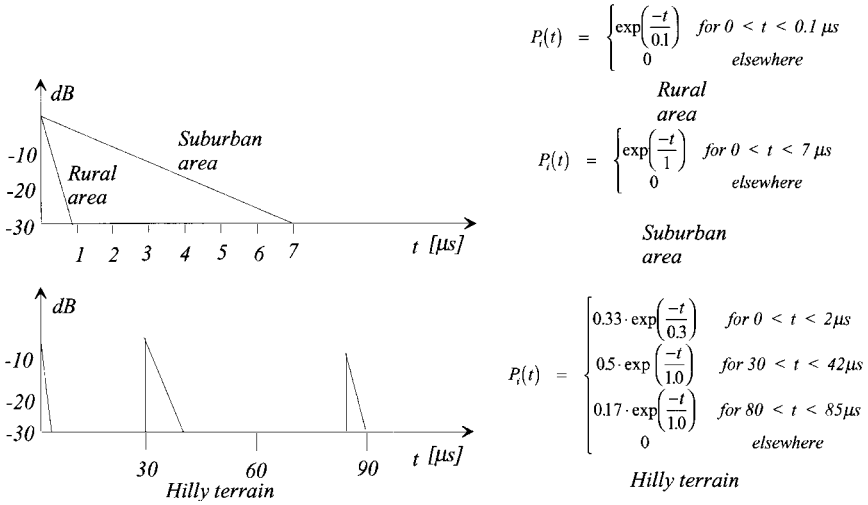

Figure 1-15 Typical landscape profiles.

To make the tests comparable, the Groupe Speciale Mobile (GSM) recommends typical profiles, for example,

- Rural area (RAx)
- Typical urban (TUx)
- Hilly terrain (HTx)

where number and strengths of the echoes and the Doppler spectra are prescribed (Figure 1-15).

1-3-3 Doppler Effect

Since the mobile receiver and some of the reflecting objects are in motion, the receive frequency is shifted because of the Doppler effect. In the case of single-path reception, this shift is calculated as follows:

$$f_d = \frac{v}{c} f_c \cos \alpha \tag{1-3}$$

where v = speed of vehicle
c = speed of light
f = carrier frequency
α = angle between v and the line connecting transmitter and receiver

In the case of multipath reception the signals on the individual paths arrive at the receiving antenna with different Doppler shifts because of the different angles α_i, and the receive spectrum is spread. Assuming an equal distribution of the angles of incidence, the power density spectrum can be calculated as follows:

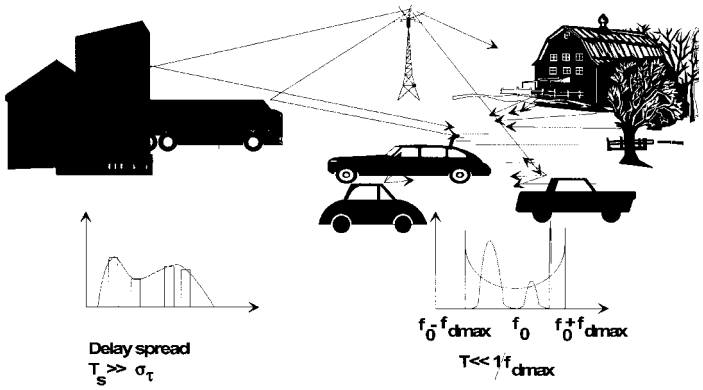

Figure 1-16 Doppler spread.

$$P(f) = \frac{1}{\pi} \frac{1}{\sqrt{f_d^2 - f^2}} \quad \text{for } |f| < |f_d| \tag{1-4}$$

where f_d = maximum Doppler frequency

Of course, other Doppler spectra are possible in addition to the pure Doppler shift described above: for example, spectra with a Gaussian distribution using one or several maxima. A Doppler spread can be calculated from the Doppler spectrum analogously to the delay spread (Figure 1-16).

1-3-4 Transfer Function

The fast Fourier transform (FFT) value of the channel impulse response is the transfer function $H(f, t)$ of the radio channel, which is also time dependent. The transfer function describes the attenuation of frequencies in the transmission channel. When examining the frequency dependence it will be evident that the influence of the transmission channel on two sine-wave signals of different frequencies becomes greater with increasing frequency difference. This behavior can adequately be described by the coherence bandwidth, which is approximately equal to the reciprocal delay spread; that is,

$$(\Delta f)_c = \frac{1}{T_d} \tag{1-5}$$

If the coherence bandwidth is sufficiently wide and, consequently, the associated delay spread is small, the channel is not frequency selective. This means that all frequencies are subject to the same fading. If the coherence bandwidth is narrow and the associated delay spread wide, even very close adjacent frequencies are attenuated differently by the channel. The effect on a broadband-modulated carrier with respect to the coherence bandwidth is obvious. The sidebands important for the transmitted information are attenuated to a different degree. The result is a considerable distortion of the receive signal combined with a high bit error rate even if the received field strength is high. This characteristic of the radio channel again speaks for the use of narrowband modulation methods (Figure 1-17).

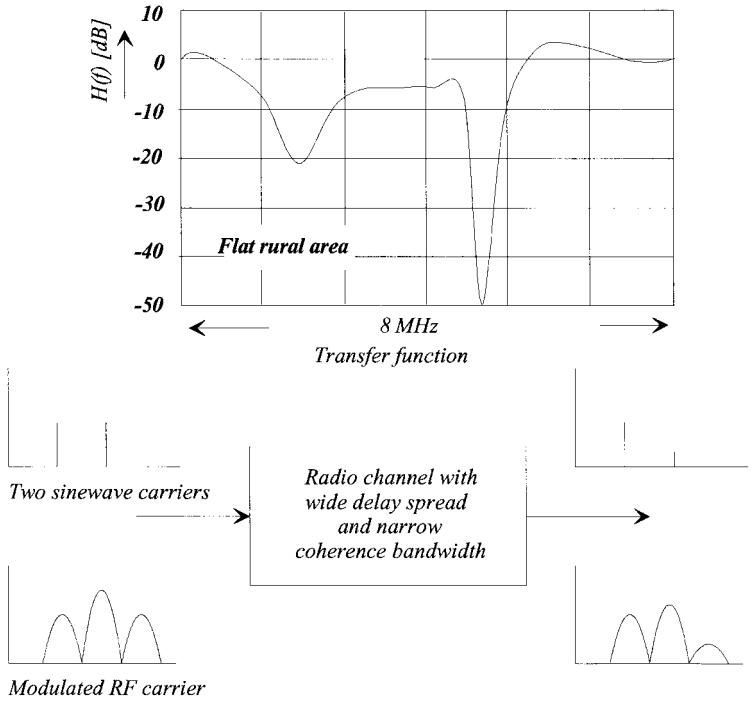

Figure 1-17 Effect of transfer function on modulated RF signals.

1-3-5 Time Response of Channel Impulse Response and Transfer Function

The time response of the radio channel can be derived from the Doppler spread. It is assumed that the channel rapidly varies at high vehicle speeds. The time variation of the radio channel can be described by a figure, the coherence time, which is analogous to the coherence bandwidth. This calculated value is the reciprocal bandwidth of the Doppler spectrum. A wide Doppler spectrum therefore indicates that the channel impulse response and the transfer function vary rapidly with time (Figure 1-18). If the Doppler spread is reduced to a single

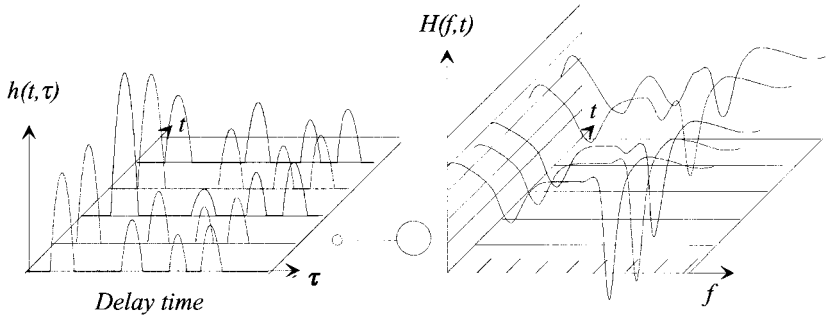

Figure 1-18 Channel impulse response and transfer function as a function of time.

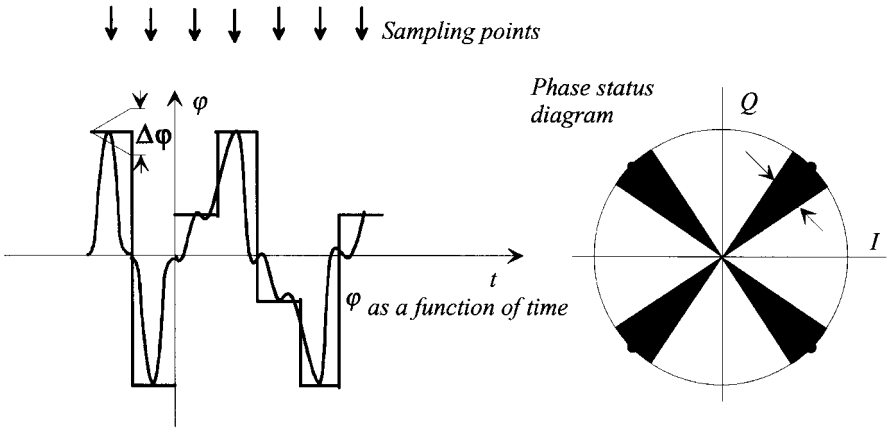

Figure 1-19 Phase uncertainty caused by Doppler effect.

line, the channel is time invariant. In other words, if the vehicle has stopped or moves at a constant speed in a terrain without reflecting objects, the channel impulse response and the transfer function measured at different times are the same.

The effect on information transmission will be illustrated in an example. In the case of *M*-ary phase shift keying (MPSK) modulation using hard keying, the transmitter holds the carrier phase for a certain period of time; that is, for the symbol period *T*. In the case of soft keying with low-pass-filtered baseband signals for limiting the modulated RF carrier, the nominal phase is reached at a specific time, the sampling time. In both cases the phase error $\varphi_f = f_d T_S$ is superimposed onto the nominal phase angle, which yields a phase uncertainty of $\Delta\varphi = 2\varphi_f$ at the receiver. The longer the symbol period the greater the angle deviation (Figure 1-19). Considering this characteristic of the transmission channel, a short symbol period of $T_S << (\Delta t)_c$ should be used. However, this requires broadband modulation methods.

Figure 1-20 shows the field strength or power arriving at the mobile receiver if the vehicle moves in a Rayleigh distribution channel. Since the phase depends on the vehicle position,

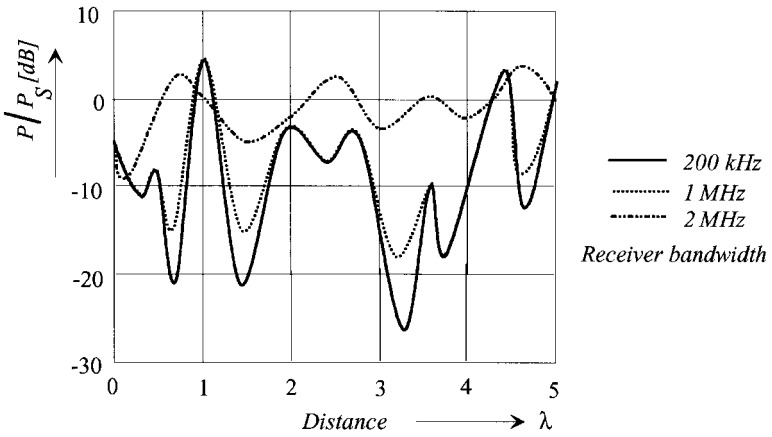

Figure 1-20 Effect of bandwidth on fading.

the receiver moves through positions of considerably differing field strength at different times (time dependence of radio channel). In the case of frequency-selective channels this applies to one frequency only; that is, to a receiver using a narrowband IF filter for narrowband emissions. As Figure 1-20 shows, this effect can be reduced by increasing the bandwidth of the emitted signal and consequently the receiver bandwidth.

1-3-6 Lessons Learned

The strongly frequency-selective channel causing inadmissible distortion of the broadband-modulated carrier and channel impulse responses like those expected in a hilly terrain speak in favor of narrowband modulation methods with long symbol periods. In hilly terrain extensively delayed echoes cause intersymbol interference when broadband modulation with short symbol periods is used. On the other hand, narrowband modulation has the disadvantage that the signals arrive at the receiver considerably attenuated and reception may be interrupted for an indefinite period of time. The burst errors occurring in digital information transmission cannot be corrected even with the most elaborate error protection methods.

These transmission interruptions can be avoided by using broadband modulation methods, but these are sensitive to strongly frequency-selective channels. Since broadband modulation is obtained through the use of short symbol periods, broadband modulation is unsuitable when greatly delayed echoes are expected.

It remains to be defined when a signal is considered a narrowband and when a broadband signal. This question shall be answered with the aid of an example. Apart from extremely narrowband analog modulation methods—as are used for sound broadcasting in the long-wave, mediumwave, and shortwave bands—FM sound broadcasting transmissions in the VHF bands are narrowband. In the case of digital modulation this means that transmissions with a rate of 400 kbps modulated onto a carrier with a bandwidth efficiency of 1.5 (bps)Hz over a bandwidth of approximately 300 kHz can be regarded as narrowband transmissions according to the definition above. Consequently, a DAB signal with this gross bit rate would be a narrowband signal and suitable for transmission on the radio channel with restrictions only. Based on the experience with conventional FM broadcasting systems in large cities and hilly terrain, this was obvious from the very beginning.

Consequently, it is necessary to find ways for spreading the band artificially without reducing the bandwidth efficiency. This means that a large band must be available for the transmission of several programs, the full bandwidth being used by all the programs without mutual interference.

Several approaches can be adopted to tackle the problem (Figure 1-21). One way would be a continuous change of the transmit and receive frequency according to a defined pattern (frequency hopping). This method is used in mobile radio, for instance, but only marginal investigations have been made in this respect for DAB.

Another possibility is to multiply the symbols of the individual programs with digital signals (pseudo-noise function) using a much higher bit rate so that a higher symbol rate is obtained. In this case the different programs are assigned different functions, which must be orthogonal to each other (code-division multiple access, CDMA). The “chopped” bit streams of the individual programs are modulated onto carriers of identical frequency and the modulated carriers are added. A correlation receiver knowing the pseudo-noise function divides the incoming CDMA signal into the individual programs. The disadvantage is obvious. Symbol periods are very short and elaborate means will be required for compensating the intersymbol interference.

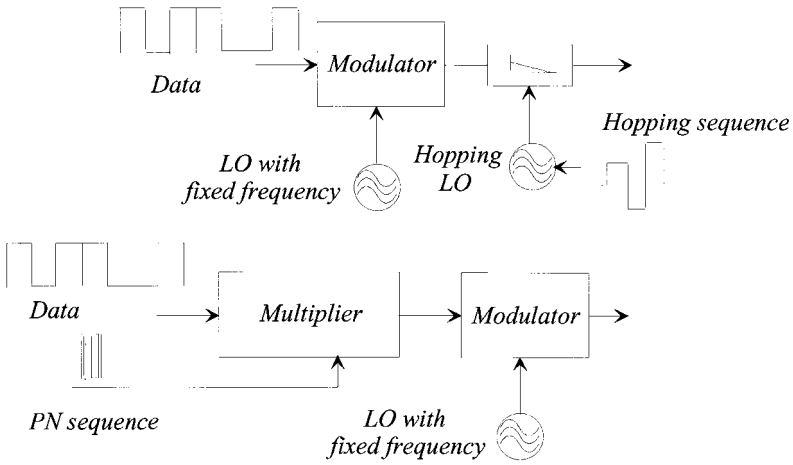

Figure 1-21 Band spreading by frequency hopping and CDMA.

A different approach has been chosen for DAB, which does not involve continuous and elaborate channel measurements, so that it would be possible to use favorably priced receivers as are demanded in the field of consumer electronics. The method used for DAB is a multicarrier method, where the information to be transmitted is spread onto many carriers using time and frequency interleaving. The terms time and frequency interleaving will be explained in the course of this discussion. The result is a broadband transmission method with long symbol periods. However, certain limitations caused by the Doppler effect will have to be accepted particularly at high carrier frequencies.

1-3-7 Wireless Signal Example: The TDMA System in GSM

Frequency-Division Multiple Access (FDMA). In analog radio systems the trend has always been toward a more efficient utilization of the available frequency spectrum by reducing the channel spacing. The number of radio channels obtained at a channel spacing of 12.5 kHz is of course twice that obtained at 25 kHz. However, any improvement brings about its disadvantage: the narrower the channel spacing, the higher the required frequency accuracy and the lower the possible maximum deviation of the frequency modulation. The latter leads to a poorer transmission quality due to the lower S/N ratio. Furthermore, the gaps between the channels, which must be a number of kilohertz wide for safety reasons, also reduce the available system bandwidth (see Figures 1-22 and 1-23).

The use of an available system spectrum divided into individual frequency channels enables the user to simultaneously access a multitude of different frequencies. This multiple access is called *frequency-division multiple access* (FDMA). Consequently, all radio systems with a spectrum divided into channels are FDMA systems. At present, the technically useful limit is reached with a channel spacing of 10–12.5 kHz.

Advantages of FDMA

- Simultaneous access to a given bandwidth by many subscribers
- Increase in the number of channels through reduction of channel spacing

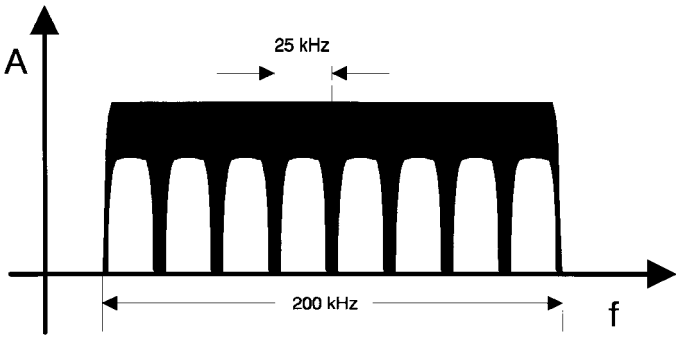

Figure 1-22 Channel spacing in broadband/narrowband systems.

Disadvantages of FDMA

- Higher frequency accuracy required
- Transmission quality decreasing with reduction of channel bandwidth
- Better rejection filters required
- One transmitter/receiver required per channel

Time-Division Multiple Access (TDMA). With TDMA systems, the available bandwidth is divided into considerably fewer, and therefore wider, channels than in FDMA systems. Each of these channels is available to several subscribers quasi-simultaneously. (See Figure 1-24.) However, a given subscriber can use the whole channel for a very short period (timeslot) only; for the rest of the time, no access is available. This serial access of several users is repeated within a fixed time frame.

Advantages of TDMA

- Simultaneous use of a specific bandwidth by a great number of subscribers
- Depending on the number of available timeslots, several subscribers can be served by one transmitter/receiver

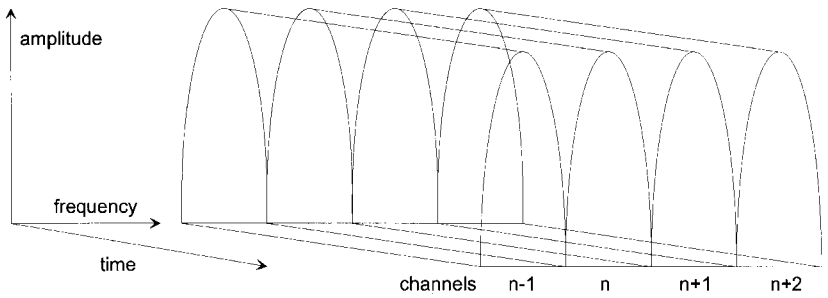

Figure 1-23 Frequency-division multiple access (FDMA).

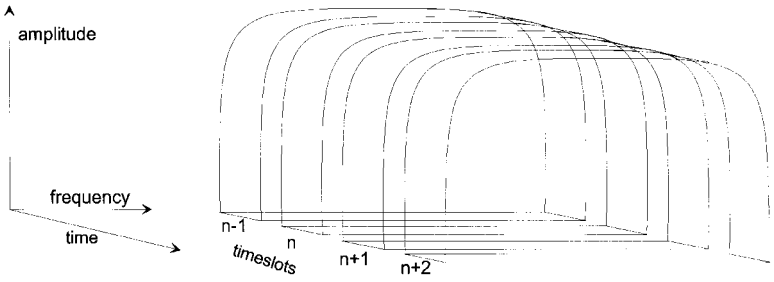

Figure 1-24 Time-division multiple access (TDMA).

- Transmitter and receiver are not permanently switched on (saves battery power)
- The RF section may carry out other tasks in the intervals between transmission and reception
- Reduced susceptibility to frequency-selective fading in the case of larger channel bandwidths

Disadvantages of TDMA

- Accurate time synchronization of subscribers required
- Higher processor capacity required
- Broadband modulators required

Code-Division Multiple Access (CDMA). The increasing use of low-priced and powerful signal processors allows a less common technique of multiple access to be employed in mass communication systems. In the case of *code-division multiple access* (CDMA), the whole system bandwidth is available to all subscribers at any time; that is, all send and receive simultaneously, with each using a specific code (Figure 1-25).

Logic "1" represents a certain bit sequence; logic "0" is the inversion of this sequence. The different signals are distinguished in the receiver by means of a cross-correlation of the received signal, which comprises a great number of codes, with the bit sequence expected so that the desired transmission signal can be detected.

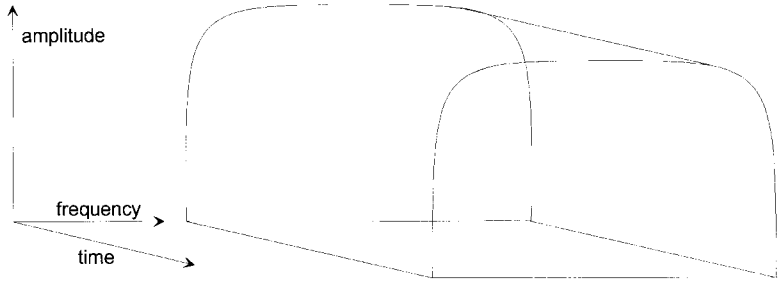

Figure 1-25 Code-division multiple access (CDMA).

Advantages of CDMA

- Simultaneous use of a specific channel or subband by many subscribers
- Several signals can be received simultaneously by one receiver
- Reduced susceptibility to frequency-selective fading in the case of large channel bandwidths
- More subscribers can be served
- Reduced costs for radio network planning

Disadvantages of CDMA

- Accurate time synchronization of subscribers required
- Fast transmitter power control over a wide dynamic range
- No experience with use in mass communication

TDMA in GSM

RF Data. In spite of the competition with other mobile radio systems, a common frequency band could be defined for GSM worldwide. All operators who signed the GSM memorandum of understanding committed themselves to install their GSM systems within the standardized frequency range. The competition for frequencies mainly affects countries using NMT900, the frequency range of which corresponds to the GSM P band. TACS also partly overlaps the GSM P band; the G1 band is completely within the TACS range. Cordless telephones operating in accordance with the CT1 standard also use the upper end of the GSM P band. CT1+ telephones, which had been assigned a frequency range below the P band years ago to protect them against GSM, have now been ousted by the G1 band. See Table 1-1.

Table 1-1 RF data for GSM900 and GSM1800

Variable	GSM900		GSM1800
Frequency range	P band	G1 band	
Uplink (MHz)			
(MS transmitting)	890–915	880–890	1710–1785
Downlink (MHz)			
(BTS transmitting)	935–960	925–935	1805–1880
Duplex spacing (MHz)	45	45	95
Spectrum (MHz)	2×25	2×10	2×75
Frequency channels	124	49	374
Channel numbers (ARFCN)	1–124	975–1023	512–885
Channel spacing	200 kHz		
Modulation	GMSK with BxT = 0.3		
Data transmission rate	270.833 kbps		
Bit duration	3.69 µs		

Since each frequency channel is divided into eight timeslots, transmitter and receiver operate in an intermittent mode, with the receive and transmit time in the upper and lower channels shifted by three timeslots (Figure 1-26). Although this alternative sending and receiving scheme operates in half-duplex rather than full-duplex operation, the received signal sounds continuous to the user.

TDMA Structure

FRAME AND MULTIFRAME. All GSM radio channels are organized in frames of approximately 4.62-ms duration. The frames are continuously repeated. Each frame is divided into 8 timeslots of approximately 577 μs each. A timeslot contains an information packet, the burst. The 26-type multiframes are used on all timeslots containing a traffic channel (voice and/or data); the 51-type multiframes on all timeslots are reserved for control channels. See Figure 1-27.

The TDMA structure uses other frame types above the multiframe level, as shown in Table 1-2.

TDMA TIMERS. The frame number within the hyperframe is counted continually so that counting of the TDMA clock restarts after approximately 3.5 hours. The frame number therefore represents a time unit in the GSM system. Similar to time counting, where the seconds are combined into minutes, hours, and days, GSM does not count the absolute frame numbers but uses timers instead. These timers are structured as shown in Table 1-3.

The absolute frame number is obtained by a multiplication of the three timers. However, on certain occasions a short version of the timers is used.

Burst Structures. Information between base station and mobile is sent in the timeslots. In each slot a certain amount of information—that is, a burst—can be transmitted. Normally the timeslot is occupied by the normal burst (Figure 1-28), which is used for signaling as well as for voice and data transmission.

Each part of the burst serves a specific purpose as described below.

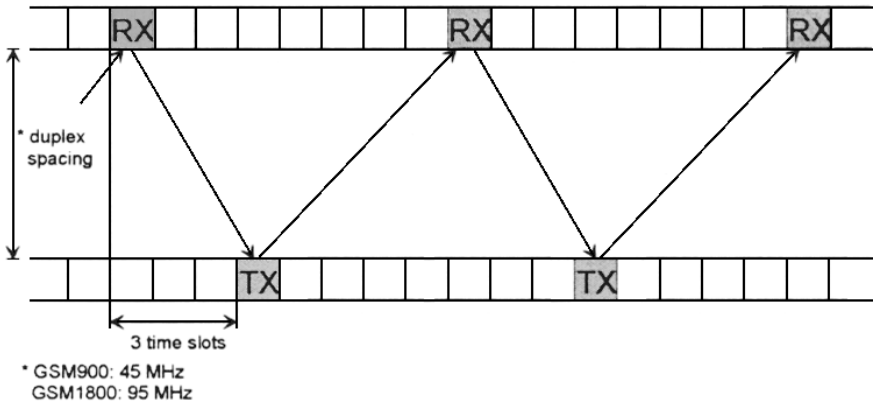

Figure 1-26 Duplex spacing of transmission and reception.

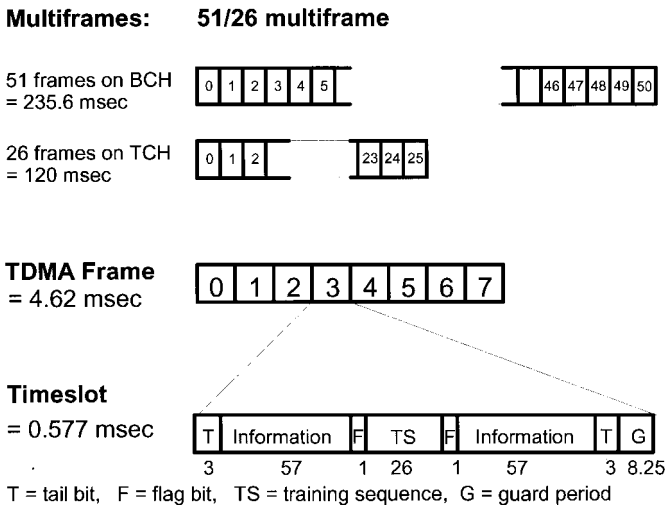

Figure 1-27 Timeslot, frame, and multiframe.

Information Bits. The normal burst is able to transmit 2×57 information bits. Since this information can be replaced every 4.62 ms during an ongoing call, the average theoretical transmission rate is

$$114 \text{ bits} \div 4.62 \text{ ms} \approx 24.7 \text{ kbps} \tag{1-6}$$

At the same time, this rate also represents the maximum transmission rate that can be obtained in the GSM system using one timeslot per transmission per time frame. Consequently, the transmission rate could be increased only if more than one timeslot is used for the transmission.

The bit rate is much lower in the control channels; that is, the above transmission rate is only attained by the mobile station if a traffic channel has been set up. In this case, the base station and the mobile station use a signaling channel, which also uses up capacity, in addition to the voice or data channel. Table 1-4 shows the assignment of the theoretically available capacity with a traffic channel setup.

Table 1-2 Superframes and hyperframes

Superframe	= 51 × 26 frames

T3:	= FN mod 51	Range:	0–50
FN (Frame Number)		Range:	0 2715647
FN_{max}	$= 51 \times 26 \times 2048 - 1$		

Training Sequence. In the middle of the normal burst, a 26-bit training sequence, the bit sequence of which is known to the receiver, is sent. The *training-sequence code* (TSC) can be one of eight different sequences. These sequences are stored in all receivers, and at the beginning of a transmission, the base transceiver station (BTS) decides on the TSC to be used. The training sequence serves two main purposes: bit synchronization and estimation of channel impulse response.

BIT SYNCHRONIZATION. Data transmitted via the air interface are in the asynchronous mode; that is, the receiver has to regenerate the bit clock from the data stream. To enable synchronization in the receiver, the transmitter adds synchronization bits to the information stream. Therefore, in normal data transmission, data telegrams start with a "...10101010..." sequence so that the receiver can regenerate the bit clock. A predefined bit word informs the receiver when the actual information (block synchronization) starts. A receiver synchronized in this way is able to decode the data stream online. The training sequence of the burst has to assume both synchronization tasks. Since it is in the middle of the burst, direct decoding is not possible.

Each burst must first be stored in the receiver and then decoded by postprocessing. The reason for using this method is the second task of the training sequence. Synchronization itself is carried out by means of cross-correlation; that is, the expected training sequence is compared (correlated) to the center of the received burst and to the beginning and end of the training sequence so that the bit clock is also known. A burst containing other than the expected training sequence cannot be synchronized and decoded.

COMPENSATION OF MULTIPATH RECEPTION. The signal from the transmitter (in Figure 1-29, BTS → MS; the same applies also in the opposite direction) arrives at the receiver not only along the direct path but also via various other paths as a result of reflection and diffraction caused by obstacles in the signal path.

Propagation conditions on these additional paths differ from those on the direct path. For instance, we can expect signals traveling via additional paths to exhibit:

- Longer travel times because of increased path length

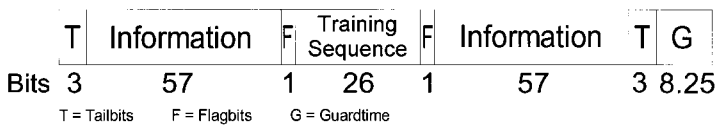

Figure 1-28 Normal burst.

Table 1-4 Transmission bit rates

	Information	Error Protection	Total
Traffic channel			22.8 kbps
Voice (full rate)	13.0 kbps	9.8 kbps	
Data	2.4 kbps	20.4 kbps	
	4.8 kbps	18.0 kbps	
	9.6 kbps	13.2 kbps	
Control channels			0.95 kbps
Idle frame			0.95 kbps
Total			**24.7 kbps**

- Various strengths
- Different Doppler shifts

Because of the different travel times, the signals arrive with a different phase at the receiving antenna. Depending on this phase, components may be canceled—that is, they may totally disappear—or added so that a high-quality signal is received for only a short period of time. RF level variations are statistically distributed; level shifts due to fading may be as great as 40 dB.

In addition to RF level fading, another annoying effect is encountered that, uncompensated, would make correct signal decoding rather difficult. Because of the additional distance the signal travels via the indirect path, the signal arriving at the receiving antenna exhibits time delay of its modulation in addition to variable phase shifts. The total of all channel responses to a single transmitted pulse is called *channel impulse response* (CIR, Figure 1-30). If the indirect path is only 1 kilometer longer, the GSM echo bit reaches the receiver later than the directly received bit and thus interferes with the next bit received. This *intersymbol interference* (ISI) may occur over several bits in succession. With delays of up to 15 µs,

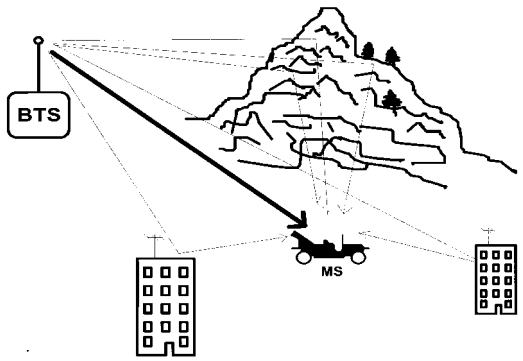

Figure 1-29 Multipath reception due to reflection and diffraction. The *base transceiver station* (BTS) is transmitting to the *mobile station* (MS).

differentiating the desired-signal components from echoes becomes more and more difficult. This problem can also be solved with the aid of the training sequence. The echoes on the delayed paths also contain the training sequence. The correlation used for detecting the original training sequence may also be used for detecting the training-sequence echoes as well as their delay and loss. With the aid of this information, the received signal can be corrected by a channel equalizer.

Guard Period. Transmission in each timeslot is terminated with a guard period (Figure 1-31) of 8.25 bit periods (≈ 30 μs). During this time the level of the burst must be reduced from nominal to a minimum value (by up to 70 dB) and the burst is modulated with so-called dummy bits (logic 1); that is, no information is transmitted. The user of the next timeslot should start sending during this guard period so that his burst has reached nominal power when the actual transmission in the timeslot starts. This means that the switching time that cannot be used for transmitting information is used twice.

Delay Correction. The integrity of a timeslot depends on whether the subscribers send only during the period assigned to them and otherwise keep quiet. This is only possible when all subscribers are accurately synchronized. For practical reasons, the clock signal is generated by the BTS and the mobile stations synchronize to it. Conflicts with adjacent timeslots may occur in the uplink where several subscribers have to share the same channel. Although several subscribers are addressed in the downlink, signals can only be transmitted by the BTS.

We will now examine the effect of a distance of 10 km between an MS and a BTS (Figure 1-32). Synchronization of the MS is as follows:

Delay over 10 km = 33.3 μs (distance ÷ velocity of light).
The sync signals from the BTS require this time for transmission.
→ MS is synchronized by 33.3 μs too late.

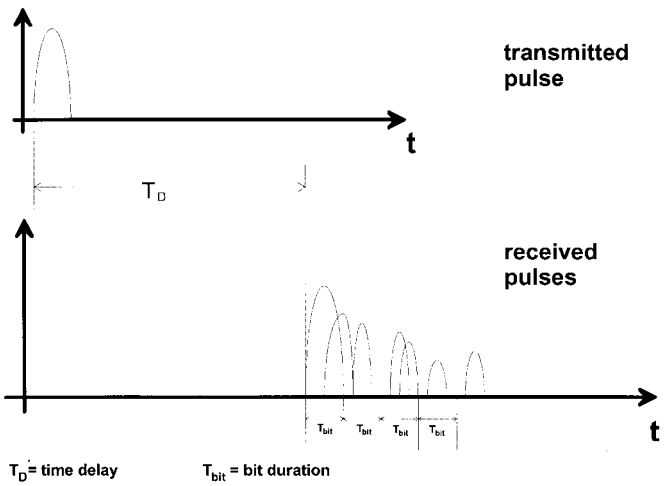

Figure 1-30 Channel impulse response.

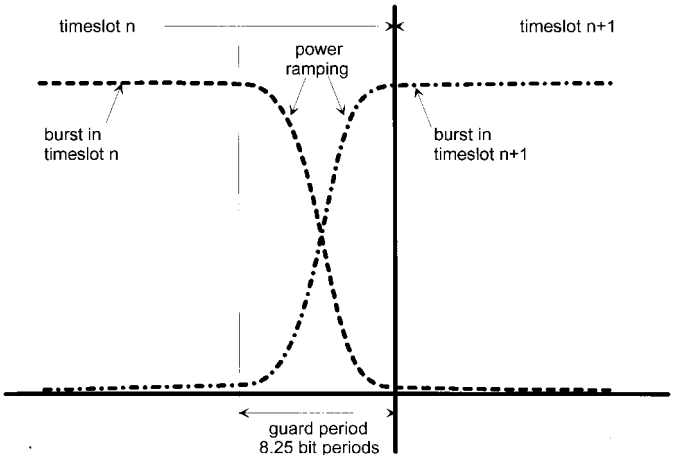

Figure 1-31 Guard period at the end of each timeslot.

MS sends a burst at the correct time from its point of view.
→ The burst is sent 33.3 µs too late.
Signal delay over a distance of 10 km → the burst requires another 33.3 µs. From the point of view of the BTS, the burst arrives with a delay of twice the delay time. Transmission cannot be made in the assigned timeslot and interferes with the next one.

The guard period at the end of each burst is only approximately 30 µs long and fully used in the example above. The greater the distance between the MS and BTS, the greater the effect of the signal delay. The only way to solve this problem is to make the MS send the burst at an earlier time. To do so, the distance between the MS and BTS must be known. The BTS determines the distance by means of a delay measurement and informs the MS of the actual delay. As a result, the MS corrects its transmission time so that the signals again arrive time-synchronized with the other mobiles at the BTS antenna.

In GSM, this procedure is called *timing advance* (TA) and is carried out continuously for all active mobile stations. Every 480 ms, a new TA value is sent to all active mobiles. A few limiting values of the GSM system can be deduced from the TA:

1. The TA is transmitted as a 6-bit word. Numerals from 0 to 63 can be represented with 6 bits. For instance, a TA of 10 means that for an MS from which bursts arrive with

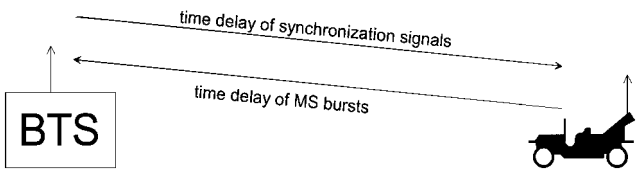

Figure 1-32 Signal delay and its effect.

a delay of 10 bit periods, transmission must be advanced by this amount. Since the TA is transmitted as an absolute value, a maximum delay of 232.5 μs (63 × 3.69 μs) can be signaled and corrected. This maximum double delay corresponds to a distance of approximately 34.9 km.

2. With the aid of the TA, the distance between the MS and the BTS can be determined. Since the smallest delay increment is a bit period, the resolution for a distance of one half of the delay corresponds to one bit period and therefore to approximately 550 m.

This synchronization scheme cannot solve an inherent problem: The delay of *the very first burst* sent by an MS cannot be corrected because, with contact between the MS and BTS yet to be established, the MS has not yet received an appropriate TA value from the BTS. Yet, if the mobile sends a normally timed burst, it may spill over into the next timeslot and interfere with transmission from another MS. To avoid causing interference in such cases, the mobile uses a special burst at the beginning of a transmission or when no valid TA has been received. Called the *access burst*, it is considerably shorter than a normal burst. The next section describes the access burst and other additional burst types in greater detail.

Burst Types. In addition to the normal burst described before, other bursts, including the access burst, are available for special purposes (Figure 1-33).

FREQUENCY CORRECTION BURST. The 142 "fixed bits" of the *frequency correction burst* (FCB) are all set to logic 0. With Gaussian minimum shift keying (GMSK), the type of modulation used in GSM, a stationary carrier frequency deviation, in this case approximately 67.7 kHz, is generated with this burst. The FCB is sent by the BTS only and used by the mobile for synchronization to the carrier frequency and for compensating a possible Doppler shift. It is sent by the BTS every 10 frames (approximately every 46 ms), but only in the timeslot 0 and only on a single (the C0) carrier.

SYNCHRONIZATION BURST. One frame after the frequency correction burst, but also in timeslot 0, the synchronization burst (SB) is transmitted. This burst is sent only by the BTS, and only on the C0 carrier. A particular difference between it and the normal burst is its considerably longer training sequence. Like the 26-bit training sequence of a normal burst, the SB's training sequence is also used for bit synchronization. Due to the great length of the sequence, synchronization can be more exact.

The twice 39 encrypted bits comprise timers T1, T2, and T3 in a coded form, and also the *base-station identification code* (BSIC). When this "GSM time" is received, the MS is synchronized to the BTS.

DUMMY BURST. A BTS must send continuously—that is, in all timeslots—on its C0 carrier because this carrier is used by the MS to find the nearest BTS and for evaluating reception quality. If no normal burst is available for transmission in a timeslot, the BTS sends dummy bursts instead, as the carrier cannot be transmitted without a modulation signal. Only the BTS sends dummy bursts, and only on the C0 carrier.

ACCESS BURST. As already pointed out, the access burst is sent when the MS first calls the BTS as a means of minimizing interference to other mobile transmitters (MTs) while initiating a delay measurement and the determination of the TA. In most cases, the access

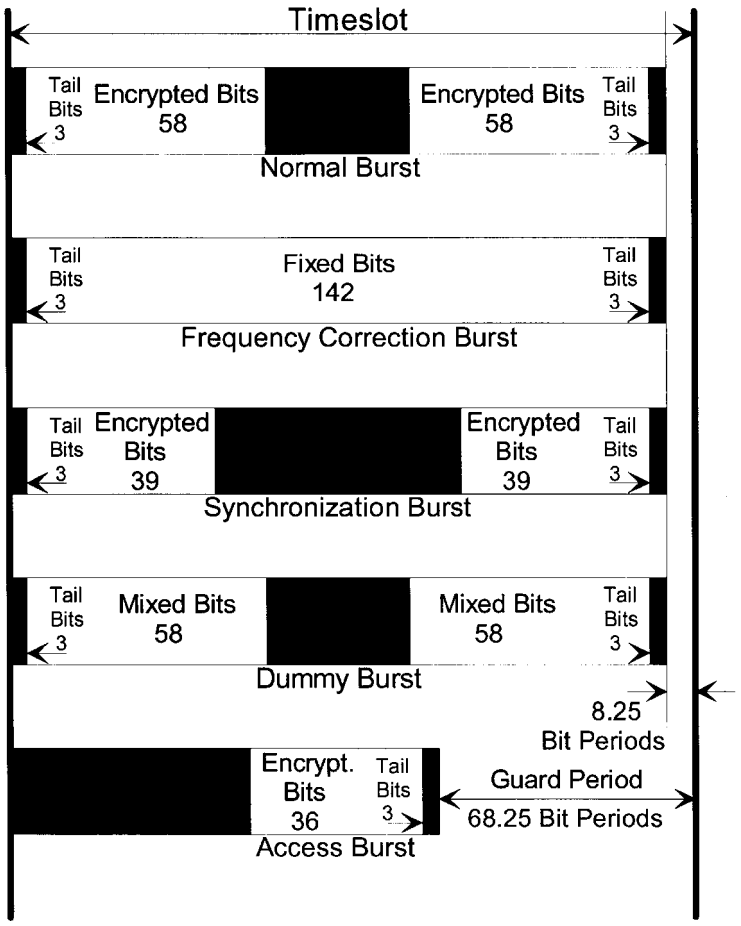

Figure 1-33 Burst types.

burst is also sent on the C0 carrier in the uplink direction, but in the case of a handover it may be transmitted on any carrier.

1-4 ABOUT BITS, SYMBOLS, AND WAVEFORMS

1-4-1 Introduction

Digital modulation of an RF carrier is the allocation of physically existing RF waveforms to the single elements of an alphabet of logical symbols where the number of allowed waveforms is equal to the number of logical elements of the alphabet (Figure 1-34). The most common alphabet is the binary one with the two logical symbols "0" and "1," but we will also deal with quaternary, octernary, and hexadecimal alphabets or more generally with *M*-ary alphabets comprising many more elements when discussing the signal generation with

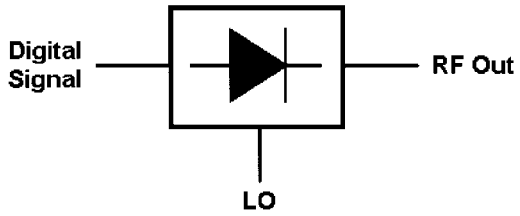

Figure 1-34 At base, digital modulation involves frequency shifting a baseband digital signal to RF. In practice, the process is more complicated than this because of bandwidth constraints on the resulting RF signal.

signal generators and dedicated software packages. The waveforms representing these symbols differ from each other by their parameter's amplitude $a(t)$, their frequency $f(t)$, and their phase $\varphi(t)$.

A modulator therefore is nothing more than a device by which this allocation is performed (Figure 1-35). From a coder it receives the logical symbols and emits at its output the corresponding waveforms $s_i(t)$. The waveform generation may be done by using a set of distinct generators (e.g., two oscillators to generate two signals with different frequencies in the case of binary frequency shift keying), by classical amplitude or frequency modulators, or by more sophisticated equipment such as I/Q modulators for M-ary modulations.

On their way across the RF channel from the transmitter to the receiver, these waveforms are distorted by noise and other disturbing properties of the RF channel.

The task of the receiver is to interpret the received waveforms $r_i(t)$ and to reallocate the proper logical symbols to them. For this purpose it is not necessary to reconstruct the original waveforms from the distorted ones (Figure 1-36). The important thing is to find out which

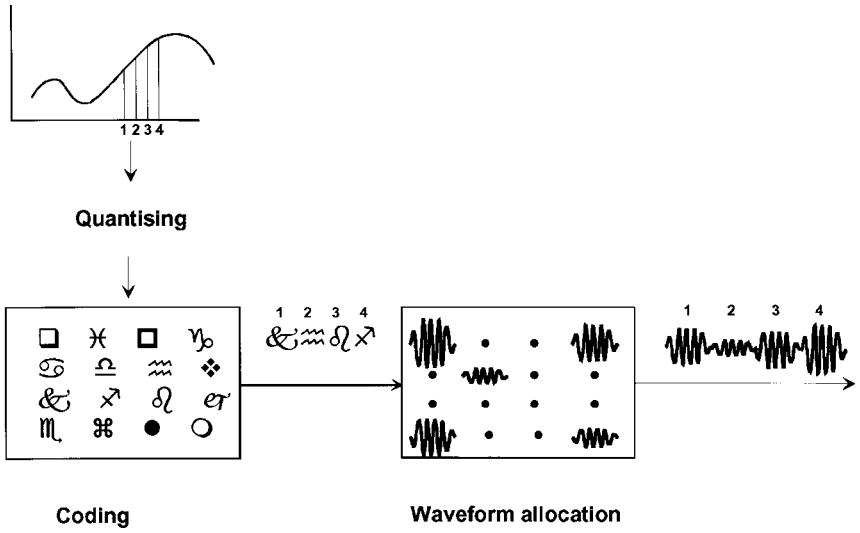

Figure 1-35 Digital modulator.

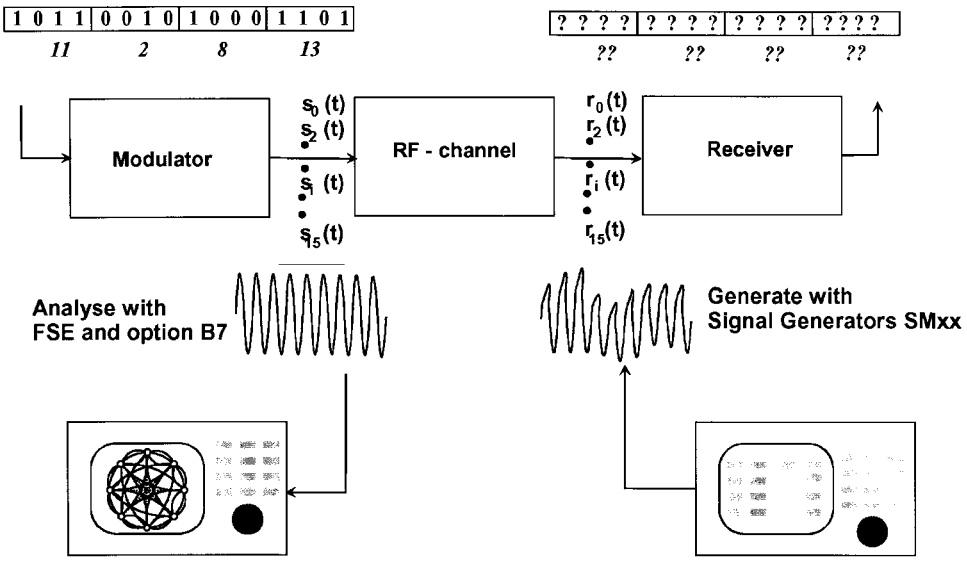

Figure 1-36 The information channel.

symbol has most probably been sent when a certain signal $r_i(t)$ has been received, a process that is known as maximum likelihood estimation.

For meaningful receiver tests, therefore, waveforms have to be generated that mimic real, distorted signals to prove the ability of a receiver to tolerate waveform distortions to a certain extent.

Representation of a Modulated RF Carrier. The waveform of a modulated RF carrier can be expressed as

$$s(t) = a(t)\cos[2\pi f_c(t)t + \varphi(t)] \tag{1-7}$$

and is defined by its amplitude $a(t)$, its carrier frequency $f_c(t)$, and its phase $\varphi(t)$. All three parameters are time variant and may be altered to generate different waveforms to represent logical symbols. If the occupied bandwidth of this modulated carrier is narrow compared to the carrier frequency f_c, we call this signal the *RF-bandpass signal* (Figure 1-37).

As any frequency variation causes a phase variation and vice versa a phase variation always causes a frequency variation, we can replace any frequency modulation by a corresponding phase modulation. Therefore we simplify the above equation to

$$s(t) = a(t)\cos[2\pi f_c t + \varphi(t)] \tag{1-8}$$

that is, we consider the carrier frequency as a constant and concentrate all frequency and phase variations into the parameter $\varphi(t)$.

For our purposes, a more suitable representation is

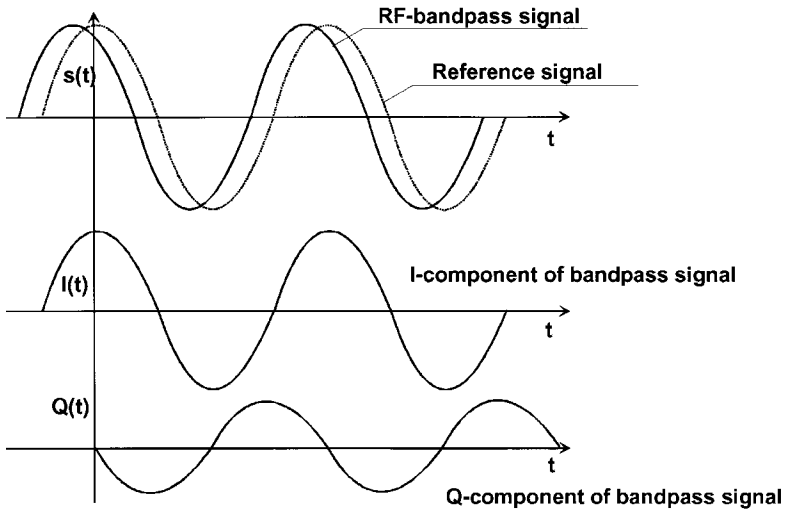

Figure 1-37 The bandpass signal and the I/Q representation of a carrier.

$$a(t)\cos[2\pi f_c t + \varphi(t)] = \cos[\varphi(t)]a(t)\cos(2\pi f_c t)$$

$$-\sin[\varphi(t)]a(t)\sin(2\pi f_c t) \tag{1-9}$$

which we call the *I/Q* representation of the RF signal. I/Q means that we have an I (in-phase) signal, namely, $\cos[\varphi(t)]a(t)\cos(2\pi f_c t)$, and a Q (quadrature) signal, namely, $-\sin[\varphi(t)]a(t)\sin(2\pi f_c t)$. These equations help us a lot in understanding an I/Q modulator. Because of the phase difference of 90° between the two carrier components, these are said to be *orthogonal* to each other.

All the information about the (modulated) carrier with the carrier frequency f_c is contained in the terms

$$c_I(t) = a(t)\cos[\varphi(t)] \tag{1-10}$$

$$c_Q(t) = a(t)\sin[\varphi(t)] \tag{1-11}$$

and, lazy as we are, we therefore disregard the terms $\cos(2\pi f_c t)$ and $-\sin(2\pi f_c t)$ from further consideration and denote the above signals $c_I(t)$ and $c_Q(t)$ as the components of the *complex baseband waveform* or *baseband signal*.

This leads us immediately to the *vector representation* of the signal, where we consider the two components $c_I(t)$ and $c_Q(t)$ of the complex baseband signal as the time-variant components of a time-variant vector with the vector length $a(t)$ and the angle to the I-axis $\varphi(t)$.We also get

$$a(t) = \sqrt{c_I^2(t) + c_Q^2(t)} \tag{1-12}$$

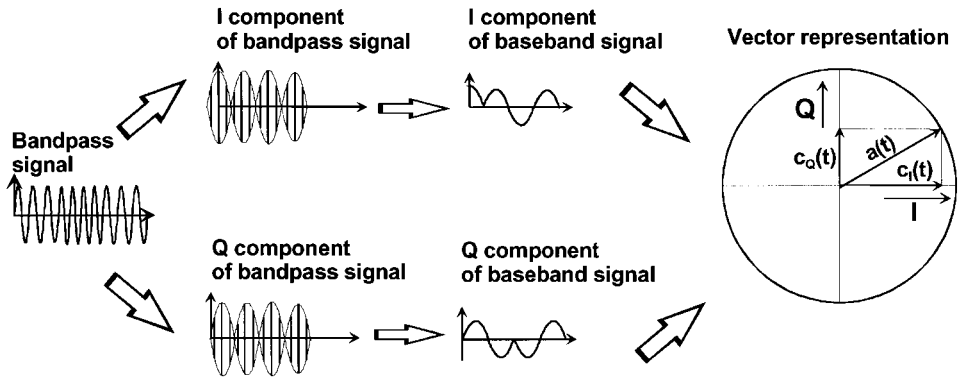

Figure 1-38 Different forms of signal representation.

$$\varphi(t) = \arctan\left(\frac{c_Q}{c_I}\right) \tag{1-13}$$

The vector can be depicted in the I/Q area (Figure 1-38).

Generation of the Modulated Carrier. Once we have realized that the modulated carrier can be represented as the sum of its I and Q components, which are the product of the two baseband components with two orthogonal RF carriers of the same frequency, it is easy to understand the hardware of the modulator (Figure 1-39). An unmodulated RF carrier is split up into two equal oscillations $\cos(2\pi ft)$, one of the two is then shifted by 0.5π and therefore is described by $-\sin(2\pi ft)$. The component $\cos(2\pi ft)$ is multiplied with the I component of the baseband signal $c_I(t)$; the other one, $-\sin(2\pi ft)$, is multiplied with the Q component $c_Q(t)$ of the baseband signal. Each multiplication may be performed using a double-balanced mixer. Afterward the two RF components are added in a simple power combiner. As it is difficult to shift the carrier by 90° over a broad frequency range, the modulated carrier is generated at an intermediate frequency and then upconverted to the wanted output frequency in a second mixer stage.

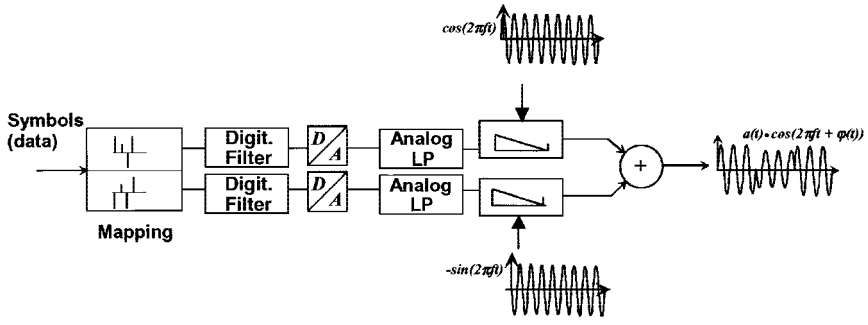

Figure 1-39 Principle of a digital I/Q modulator.

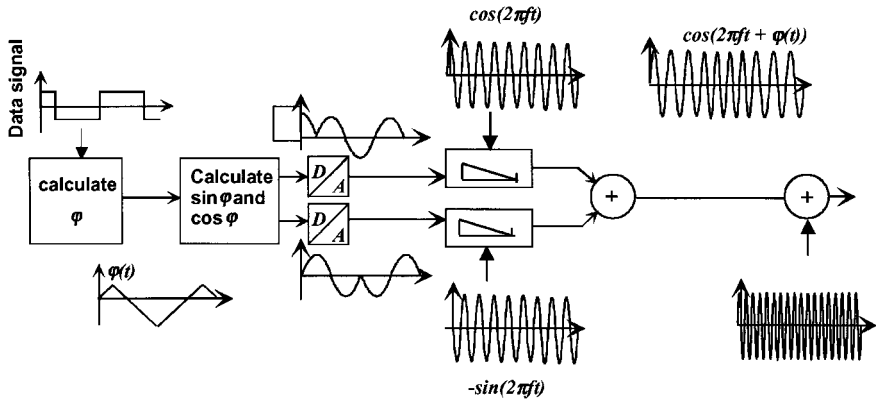

Figure 1-40 I/Q modulation (MSK and GMSK).

The baseband signals are generated by mapping every digital symbol onto a pair of digital pulses, which are fed to digital baseband filters. The output signal of these filters is D/A converted and smoothed by analog low-pass filters.

Figure 1-40 shows another example where, for a given modulation (MSK or GMSK), the instantaneous phase and then the corresponding cosinusoid and sinusoid, which modulate the two carrier components, are calculated from the data signal.

Digital designs of the modulator also exist, in which the IF-carrier generation, the time-variant phase shift, the multiplication with the baseband signals, and the sum of the components are calculated in a digital signal processor, the output of which is D/A converted and upconverted to the output frequency in the classical way. A further possibility is the generation of the modulated carrier with direct digital synthesis (DDS), as used in the Rohde & Schwarz SME signal generator.

Mapping the Data onto the Baseband Waveforms. The next question is: "How do we generate the baseband waveforms $c_I(t)$ and $c_Q(t)$?" There is no general answer to this question, as the generation of the baseband waveforms depends on the type of modulation. The following short descriptions will suffice for the moment.

Linear Modulations (All Kinds of Amplitude and Phase Shift Keying, and *M*-ary QAM)

- For binary amplitude and phase shift keying (ASK and BPSK), the data signal itself represented as a unipolar (ASK) or bipolar (BPSK) nonreturn-to-zero (NRZ) signal is the baseband waveform $c_I(t)$; the component $c_Q(t)$ does not exist.
- For *M*-ary phase shift keying and *M*-ary quadrature amplitude modulation, *N* bits are combined to form new symbols that are elements of an alphabet with $M = 2N$ elements. In the simplest case, every symbol is allocated an I and a Q amplitude during the symbol duration, which is *N* times the bit duration. The modulating signals $c_I(t)$ and $c_Q(t)$ are then staircase functions, and the modulated carrier has a time-varying envelope with the instantaneous amplitude $a(t)$ (Figure 1-41). Because the steps of the envelope cause unwanted side lobes of the RF spectrum, the baseband signals are filtered to smooth the shape of the RF envelope and reduce the occupied bandwidth of the modulated RF signal.

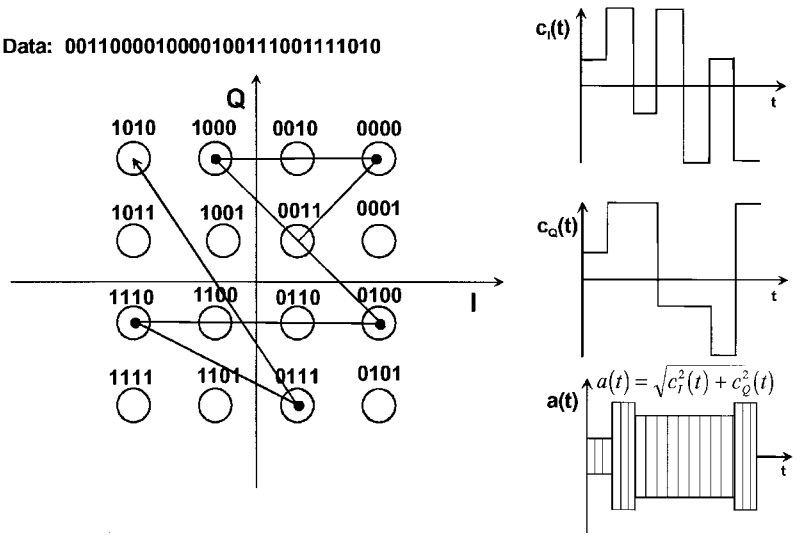

Figure 1-41 Constellation diagram, and baseband and RF signals of 16-QAM.

Nonlinear Modulations (Frequency Shift Keying, Minimum Shift Keying, and Gaussian Minimum Shift Keying)

- Despite the fact that *M*-ary frequency shift keying (FSK) could be performed using an I/Q modulator, for this type of modulation much simpler equipment such as a voltage-controlled oscillator is used as a frequency modulator. Figure 1-42 shows an example of quaternary frequency shift keying (4FSK), which also is known as 4 pulse-amplitude modulation/frequency modulation (4PAM/FM). This term indicates that every two bits are combined to a dibit that is mapped onto a baseband pulse with an amplitude taking on one of four possible levels. The pulse then is shaped by a baseband filter before being fed to the frequency modulator.
- If more precise modulations are required (e.g., MSK and GMSK, which also turn out to be frequency modulations), first the instantaneous phase of the modulated RF carrier is calculated from the data. The corresponding sine and cosine values that form the modulating baseband signals $c_I(t)$ and $c_Q(t)$ are determined from a lookup table. This operation is the reason for the fact that frequency modulation is called a nonlinear modulation.

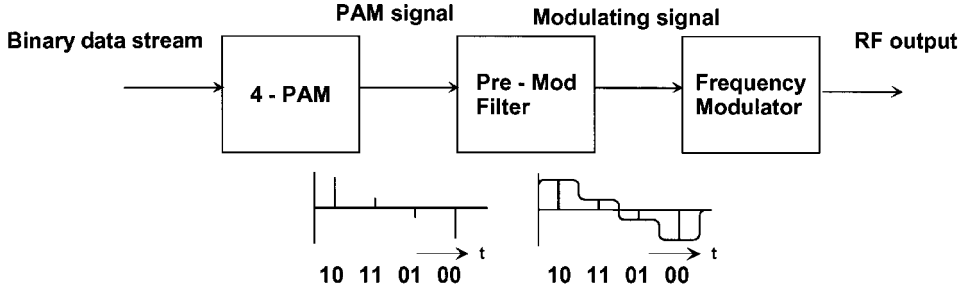

Figure 1-42 4PAM/FM.

The Spectrum of a Digitally Modulated Carrier. It is the task of any transmission process to occupy as little bandwidth as possible. The absolute lower limit in the baseband is half the symbol rate of the baseband signal, where for M-ary modulation the symbol rate r_{Symbol} is equal to the bit rate divided by $ld\,(M)$. This lower limit is only theoretical as ideal rectangular filters, which cannot be realized, were necessary. Therefore, in practice, a minimum baseband bandwidth of about $0.75r_{\text{Symbol}}$ has to be taken into account.

With linear modulation, the occupied bandwidth in the RF range is twice the occupied baseband bandwidth. This follows from the lag theorem, according to which the double-sided spectrum of a time function is shifted from $f = 0$ to the frequency $f = f_c$ when the time function is multiplied with $\cos(2\pi f_c t)$ (Figure 1-43).

Expressing this with formulas, we find

$$c(t) \quad \circ\!\!-\!\!\bullet \quad C(f) \tag{1-14}$$

$$e^{j2\pi f_0 t}c(t) \quad \circ\!\!-\!\!\bullet \quad C(f - f_0) \tag{1-15}$$

Therefore, if the baseband spectrum is limited by a low-pass filter, the RF spectrum is limited as if it were filtered by an RF bandpass filter with twice the bandwidth of the baseband filter.

Demodulation of Digitally Modulated Carriers. The demodulation process is an estimation process. The receiver compares the received waveform with all the possible waveforms and decides which symbol has been received. The waveform allocated is the one that is most similar to the received signal. This process is also called *maximum likelihood estimation*.

Figure 1-44 shows a possible demodulator. The received signals are cross-correlated with the stored ones in M correlators. High output from a given correlator indicates a match between its stored symbol and a symbol in the incoming signal.

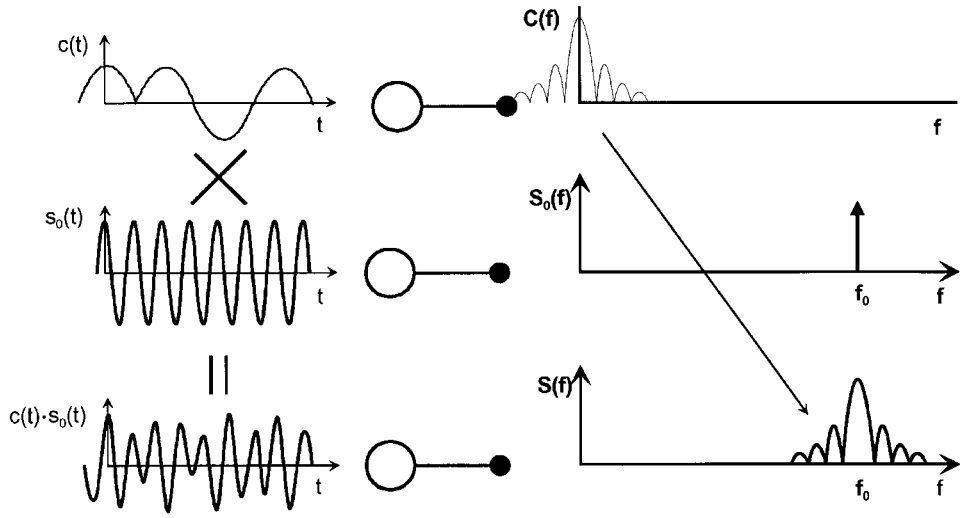

Figure 1-43 Occupied bandwidth in the baseband and the RF range.

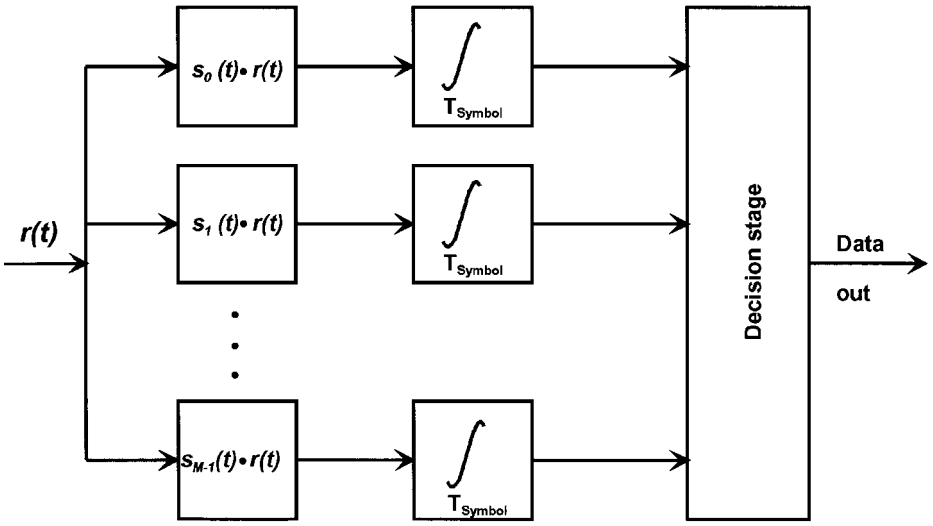

Figure 1-44 Correlation receiver.

As can easily be seen, such a receiver is quite complex. Therefore, other principles of receivers have been studied. The most often used receiver is based on an I/Q demodulator, the principle of which is shown in Figure 1-45.

The received signal is split into two equal components. One component is multiplied with the reconstructed carrier signal, the other with its orthogonal counterpart; that is, the $\pi/2$-shifted reconstructed carrier. After low-pass filtering, this multiplication delivers the I and the Q components of the baseband signal, which is more or less distorted by interference, multipath, and noise in the radio channel. These demodulated baseband signals then can be A/D converted and treated using simple or sophisticated algorithms to decide which symbols were originally sent. This type of demodulation requires an exact reconstruction of the unmodulated carrier, with respect not only to frequency but also to phase, and is called *coherent demodulation*. While the frequency recovery is in principle quite simple, the

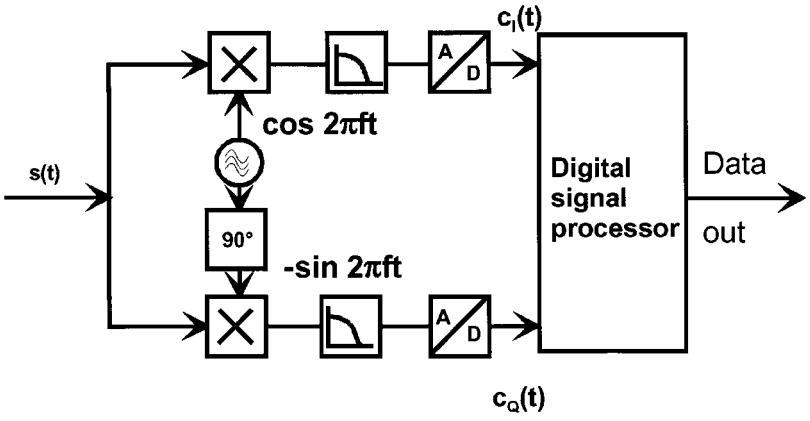

Figure 1-45 Coherent demodulation.

acquisition and tracking of the signal phase require complex signal processing of the baseband signal.

Coherent demodulation and its accompanying costly signal acquisition and tracking are necessary for all types of phase and quadrature amplitude modulation in which any part of the transmitted information is coded in the absolute phase of the carrier. It only can be avoided when the information is coded in the phase difference of two sequential waveforms. Such modulation schemes are called *differential phase modulation*. Examples of such modulation include differential binary phase shift keying (DBPSK) and differential quadriphase shift keying (DQPSK) and their derivatives.

The following list shows common digital modulation types and the telecommunication systems that use them:

BPSK—Satellite radio links, GPS, Inmarsat
QPSK—Satellite radio links, GPS, IS-95
OQPSK—IS-95 (reverse link)
π/4-QPSK—NADC, PHS, PDC. TETRA
GMSK—GSM, DCS 1800
GFSK (Gaussian FSK)—DECT
COFDM (coded orthogonal frequency-division multiplexing)—DAB, DVB

1-4-2 Some Fundamentals of Digital Modulation Techniques

The first waveforms that were used for "digital modulation" were amplitude shift keying (ASK), similar to on/off-keyed Morse code, and phase shift keying (similar to FM). Figure 1-46 shows the resulting waveforms in the time domain. It is also useful to look at them in the phase domain—the in-phase (I) and quadrature (Q) planes. From Figure 1-47 we see that ASK has only two states: no signal and signal at I (in-phase), while phase shift keying can have two states: +I and –I. In the frequency domain, ASK and BPSK have the output spectra

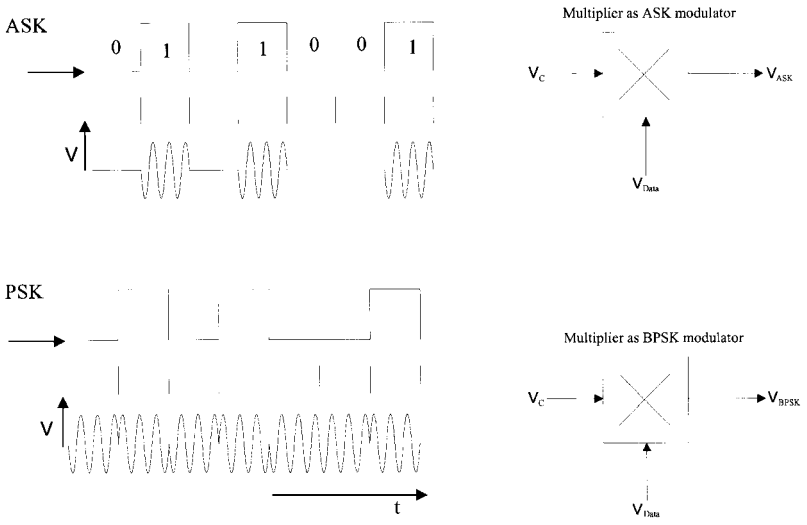

Figure 1-46 Amplitude shift keying (ASK) and phase shift keying (PSK) in the time domain.

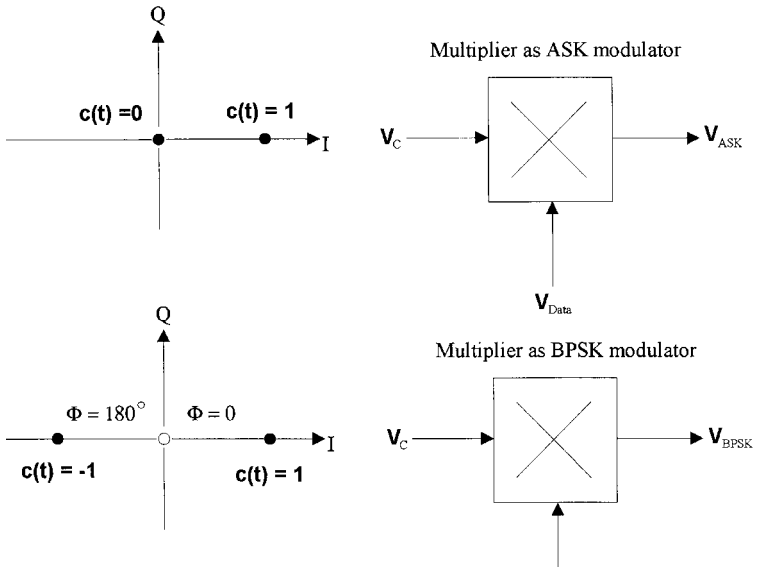

Figure 1-47 ASK and PSK in the I/Q plane.

shown in Figure 1-48. These output spectra, with their (sin *X*)/*X* appearance, depend on the rise and decay times and duty cycle of the modulating signal.

BPSK sends one data bit per signal state. Another way to put this is that each of BPSK's two signal states is a *symbol* that stands for just one bit—0 or 1. Transmitting more than one bit per symbol would allow us to improve our data throughput per unit of time, and this is

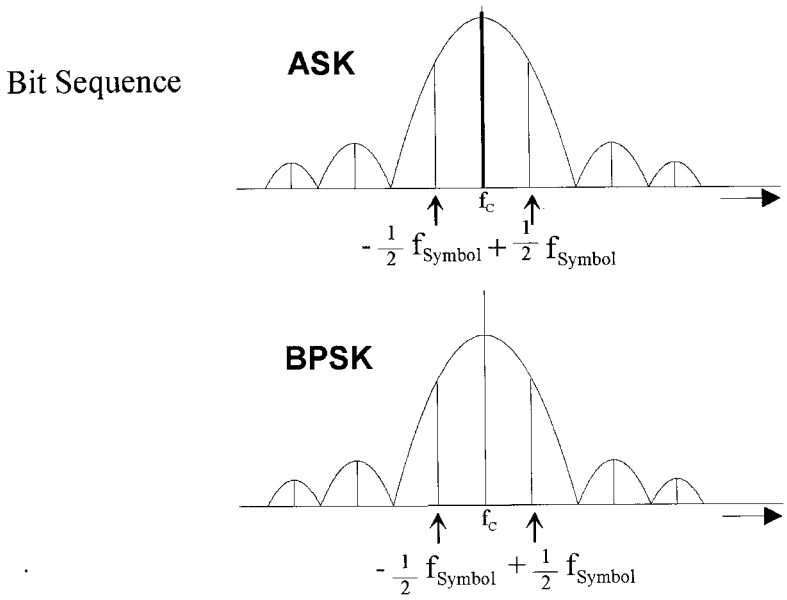

Figure 1-48 ASK and BPSK in the frequency domain.

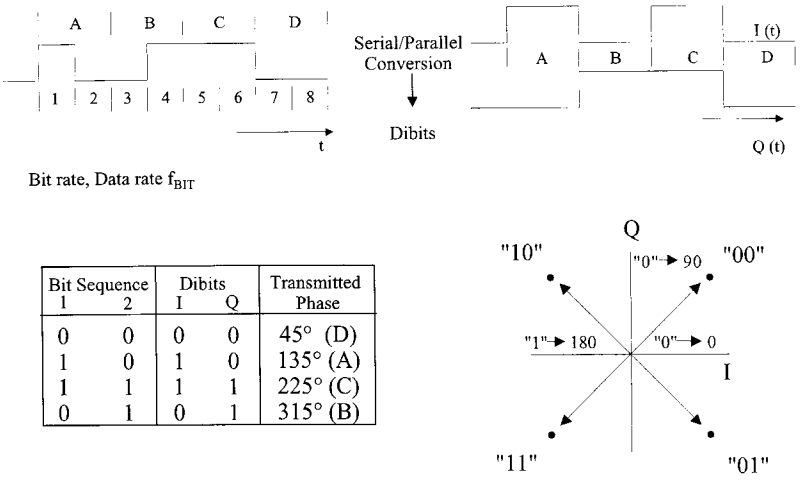

Bit Sequence 1	2	Dibits I	Q	Transmitted Phase
0	0	0	0	45° (D)
1	0	1	0	135° (A)
1	1	1	1	225° (C)
0	1	0	1	315° (B)

Figure 1-49 Quadrature PSK (QPSK) modulator (I/Q modulator).

exactly what's done in quadrature PSK (QPSK), which uses *four* possible signal states as symbols for 2-bit sequences called *dibits* (Figure 1-49). Figure 1-50 shows a QPSK modulator and the QPSK constellation diagram; Figure 1-51 shows the result of QPSK in the time and frequency domains; Figure 1-52 shows a spectrogram of an actual QPSK emission.

Moving from ASK to BPSK or QPSK results in increased resistance to noise. Figure 1-53 illustrates this by graphing bit error rate versus signal-to-noise ratio (here expressed as 10 log (E_{bit}/N_0), where E_{bit} is energy per bit and N_0 is the noise [23]). Figure 1-54 compares the maximum interference voltages for BPSK and QPSK.

Figure 1-55 shows bandwidth requirements and constellation diagrams for BPSK and QPSK. Unfiltered BPSK and QPSK are purely angle-modulated emissions; for each, all symbols are transmitted at the same amplitude. As we'll see, however, bandwidth-limiting a BPSK or QPSK signal to minimize adjacent-channel interference results in envelope variations that must be preserved through careful circuit design if bit errors are to be minimized.

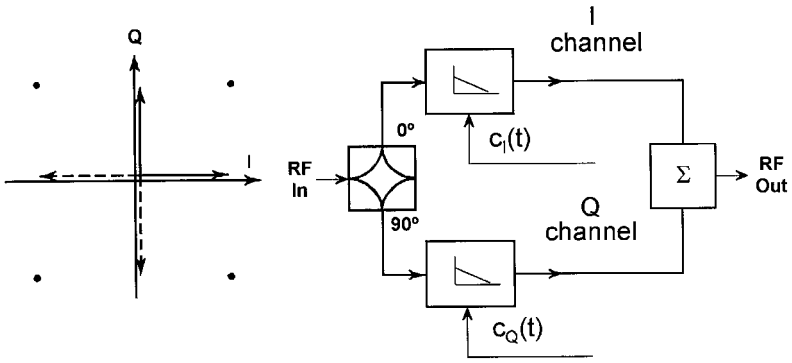

Figure 1-50 QPSK constellation diagram (*left*) and modulator (*right*).

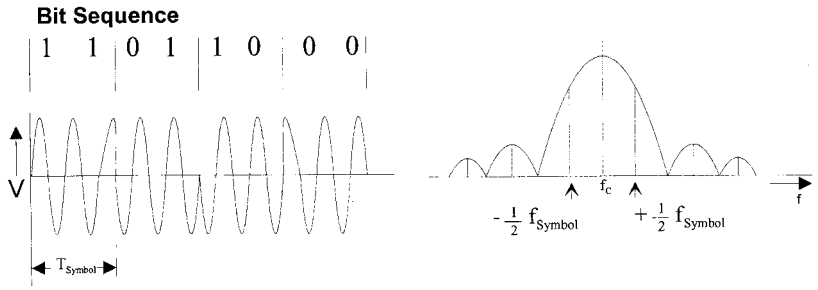

Figure 1-51 Result of QPSK modulation in the time and frequency domains.

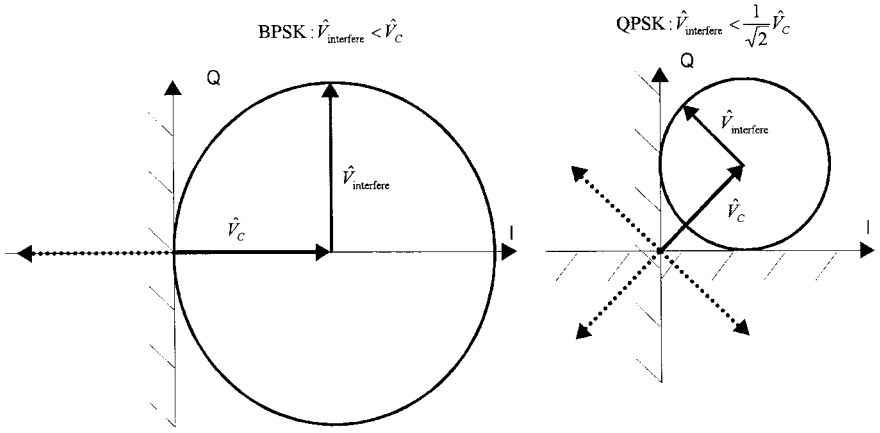

Figure 1-54 Maximum interference voltages for BPSK and QPSK, where $\hat{V}_C$ is the carrier voltage of the desired signal and $\hat{V}_{interfere}$ is the carrier voltage of the interfering signal.

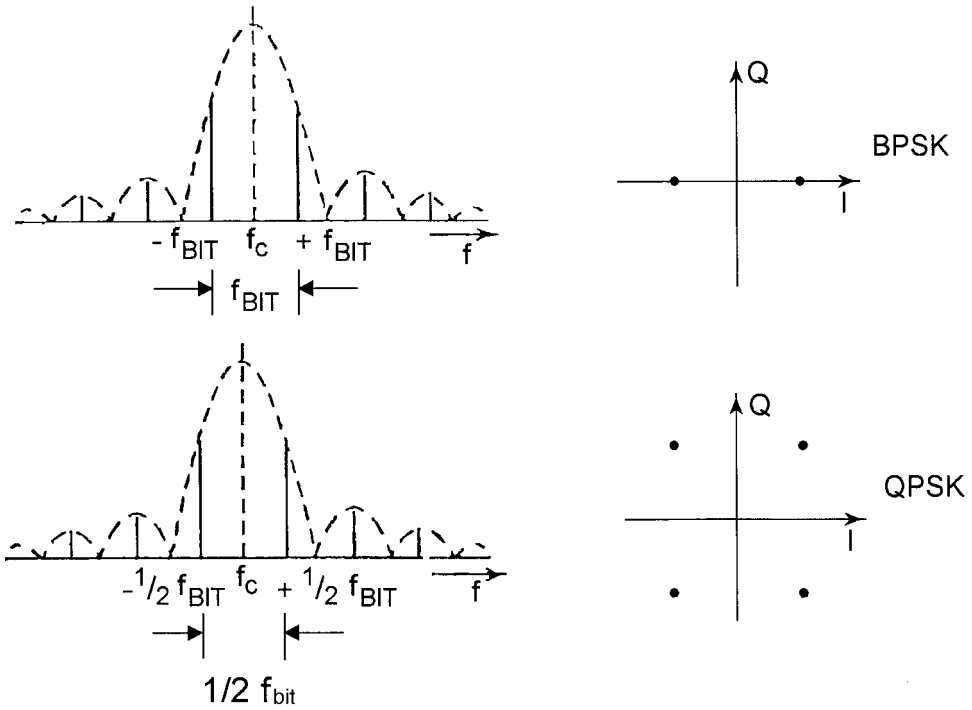

Figure 1-55 Bandwidth requirements (*left*) and constellation diagrams (*right*) for BPSK and QPSK. For each emission, all symbols are transmitted at the same amplitude, as is indicated by their equidistance from the constellation origin.

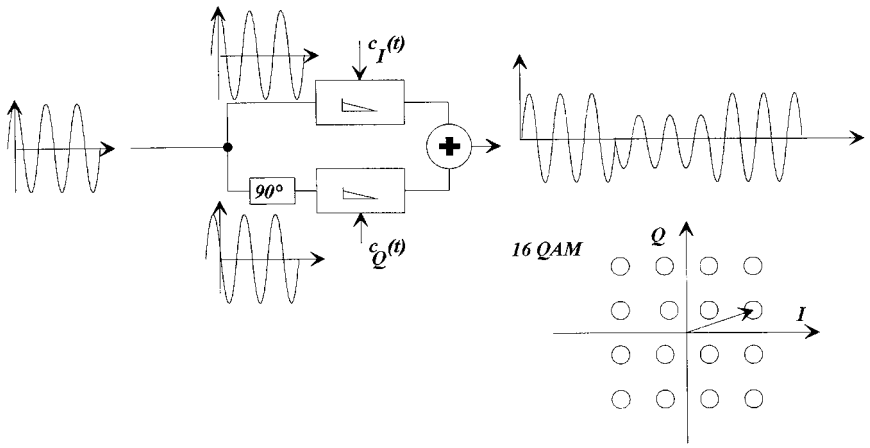

Figure 1-56 Quadrature amplitude modulation (QAM), with constellation diagram for 16-state QAM (16-QAM). Because transitions between QAM symbols involve shifts in phase *and amplitude*; even unfiltered QAM is a combination of amplitude and angle modulation.

Further increases in bit rate per symbol are possible with phase-modulation schemes that divide the 360° of each carrier cycle into increasingly smaller segments. Transmitting 3 bits per symbol, with each symbol spaced from its neighbors by 45°, gives 8-PSK; transmitting four bits per symbol, with each symbol spaced from its neighbors by 22.5°, results in 16-PSK. Increasing the data rate by increasing the number of bits per symbol doesn't give us something for nothing, however: The smaller the phase difference between adjacent symbols, the greater the likelihood that phase shifts resulting from phase noise, multipath reception, and other sources of phase perturbation will cause demodulation errors.

Modulation schemes that differentiate their data symbols through a combination of phase *and amplitude* shifts are susceptible to disturbances in amplitude in addition to phase. Figure 1-56 shows the modulator and constellation diagram for 16-state quadrature amplitude

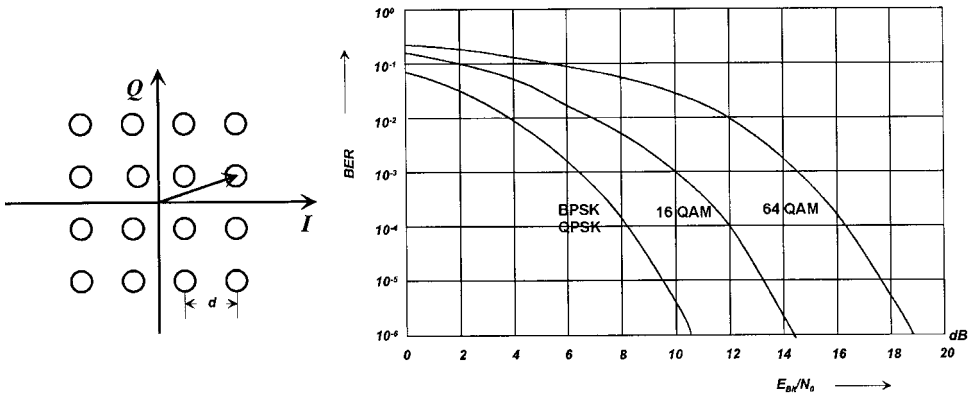

Figure 1-57 Bit error rate versus E_{bit}/N_0 for BPSK/QPSK, 16-QAM, and 64-QAM, showing the significantly greater SNR necessary for a given BER as the number of signal states is increased. In 64-QAM, each symbol represents 6 bits.

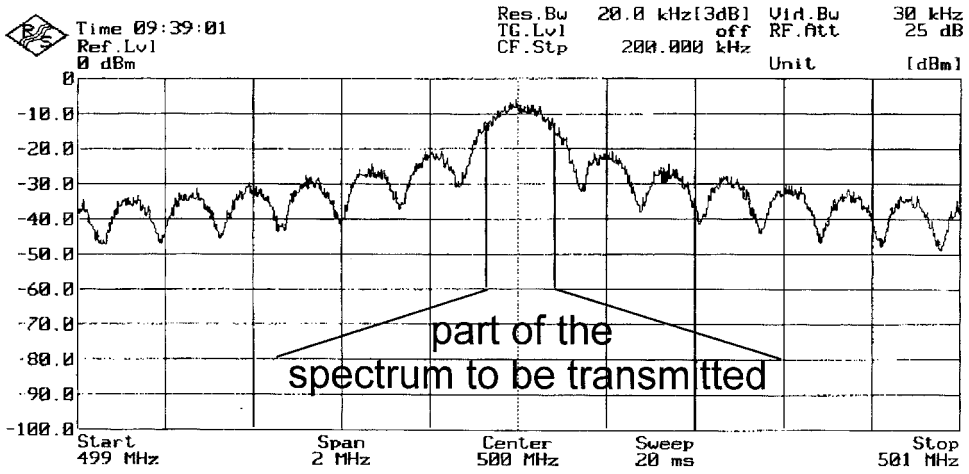

Figure 1-58 QPSK spectrum resulting from pseudorandom binary sequence (PRBS) data. Most of an angle-modulated emission's infinite sidebands are unnecessary for communication and can be removed by filtering—at the cost of introducing amplitude variations that must be sufficiently preserved to keep the bit error rate low.

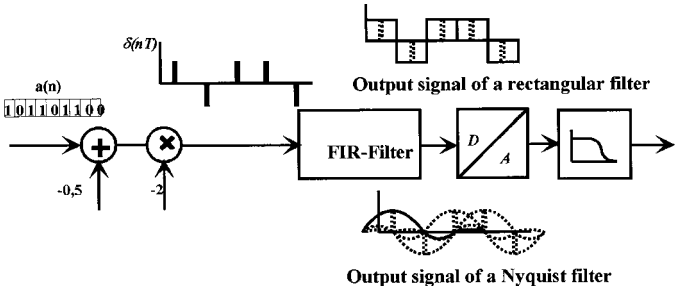

Figure 1-59 Baseband filtering. Figure 1-60 shows the result for QPSK.

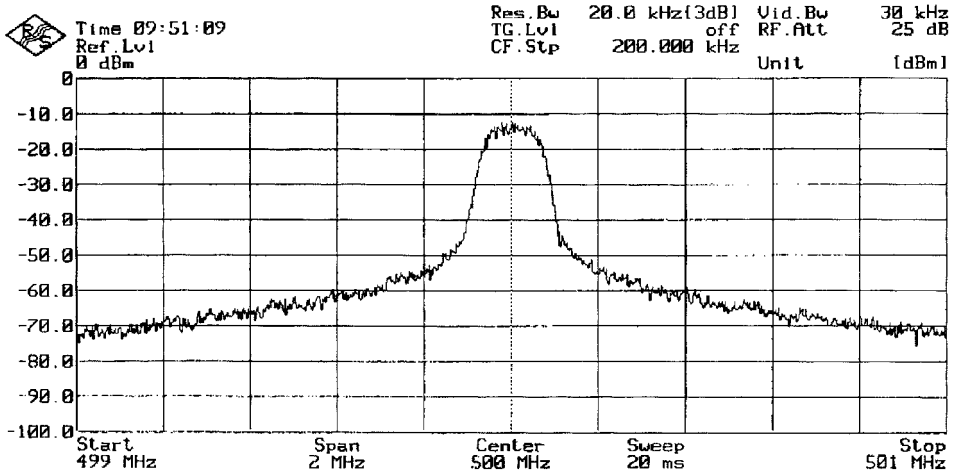

Figure 1-60 Spectrum of a band-limited QPSK signal.

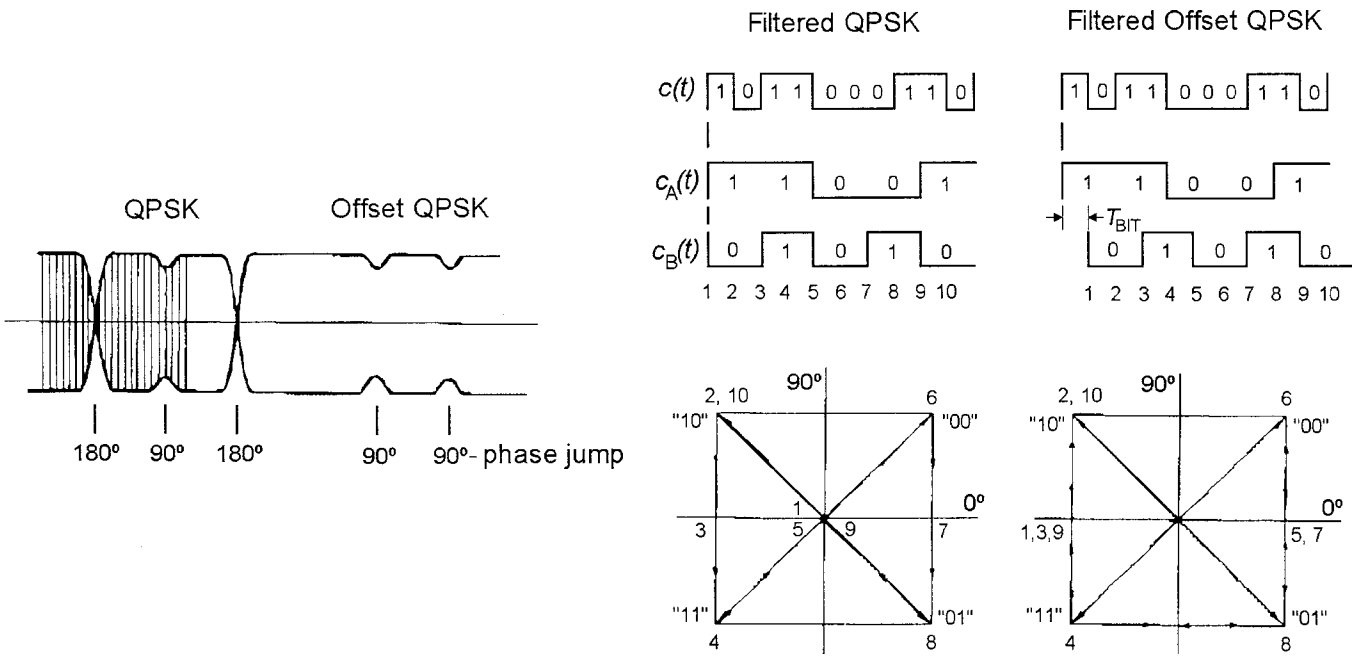

Figure 1-61 Offset QPSK (OQPSK) exhibits reduced envelope variations compared to standard QPSK by time-offsetting the I and Q channels.

modulation (16-QAM), in which each symbol represents 4 bits. Figure 1-57 shows bit error rate versus SNR for BPSK/QPSK, and 16- and 64-QAM. QAM systems can support very high bit rates—*if* sufficient SNR can be maintained and disturbances in signal amplitude and phase can be kept under control [3].

The infinite number of sidebands produced by angle modulation must be reduced by filtering to minimize the spectrum occupied by an emission to just that necessary for communication (Figure 1-58). Considerations of filter realizability and transmitter frequency agility dictate that this filtering must be done at baseband (Figure 1-59). The filter characteristics are optimized in accordance with the modulation scheme used (Figure 1-60). The filtering is done in using DSP, minimizing component count and resulting in characteristics that are essentially temperature independent and identical from unit to unit.

Fundamental angle-modulation theory tells us that the envelope of an angle-modulated signal does not vary in amplitude. Such an emission could be amplified in highly nonlinear stages without distortion. But because angle-modulated signals must be band-limited for practical use, and because band-limiting an angle-modulated signal strips away sideband energy that would contribute to its envelope constancy, the emissions used in modern wireless systems, even those that do not involve intentional amplitude modulation, vary in amplitude with modulation. How much a wireless emission's amplitude varies depends on the degree of filtering and the particular modulation scheme used. Various schemes, many of which rely on particular synergies of coding, modulation, and filtering, have been devised for minimizing amplitude variation in digitally modulated signals. Figure 1-61 shows one [offset QPSK (OQPSK)]; Figure 1-62 compares the spectra of three [QPSK, minimum shift keying (MSK), and Gaussian MSK (GMSK)]. Detailed discussion of such techniques is more concerned with coding, logic circuitry, and software than with radio hardware and is therefore beyond the scope of this book. What is important to the circuit designer is that stages handling the emission(s) on which a system depends must be sufficiently amplitude-linear to maintain the modulation integrity of the signal and, in the case of transmitters, to keep adjacent-channel interference and other spurious emissions within acceptable levels.

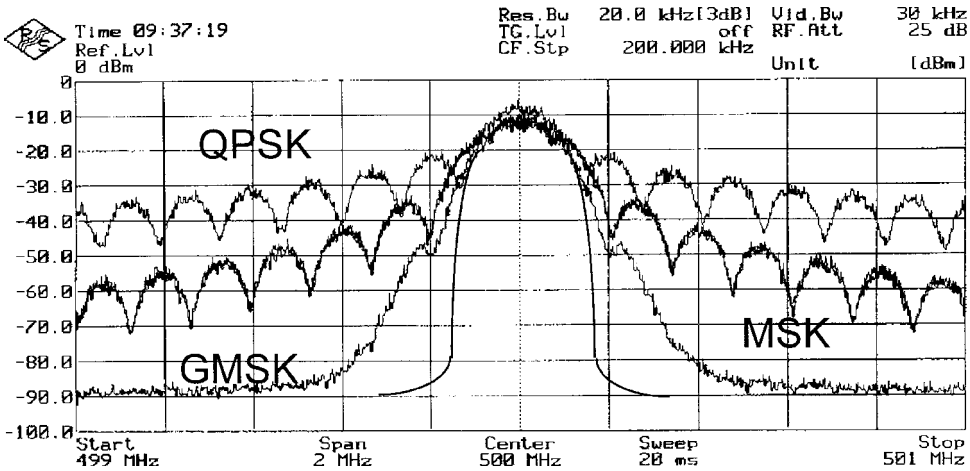

Figure 1-62 Comparison of QPSK, MSK, and GMSK.

1-5 ANALYSIS OF WIRELESS SYSTEMS

1-5-1 Analog and Digital Receiver Designs

For the purpose of showing the capability of modern computer-aided design (CAD), we now show first an analog receiver and following this an analog/digital receiver with its functionality and performance.

Receiver Design Examples

Analog Receiver Design. A transmitter modulates information signals onto an RF carrier for the purpose of efficient transmission over a noise-filled radio channel. The RF receiver's job is to demodulate that information signal while maintaining a sufficient signal-to-noise ratio (SNR). This must be done for widely varying input RF power level and with the presence of noise and interferers.

Modern communication standards place requirements on key system specifications, such as RF sensitivity and spurious response rejection. These system specifications must then be separated into individual circuit specifications via an accurate overall system model. CAD can play a major role in modeling systems and in determining the individual component requirements. A 2.4-GHz dual-down conversion system (see Figure 1-63) will be used as an example. The first IF is 200 MHz and the second IF is 45 MHz.

As a signal propagates from the transmitter to the receiver it is subject to path loss and multipath, resulting in extremely low signal levels at the receive antenna. RF sensitivity is a measure of how well a receiver can respond to these weak signals. It is specified differently for analog and digital receivers. For analog receivers there are several sensitivity measures, including minimum discernible signal (MDS), signal-to-noise plus and distortion ratio (SINAD), and noise figure. For digital receivers the typical sensitivity measure is maximum bit error rate (BER) at a given RF level. Typically, a required SINAD at the baseband demodulator output is specified over a given RF input power range. For example, audio measurements may require 12-dB SINAD at the audio output over RF input powers ranging from −110 to −35 dBm. This can then be translated to a minimum carrier-to-noise (C/N) ratio at the demodulator input to achieve a 12-dB SINAD at the demodulator output (see Figure 1-64).

Determining receiver sensitivity requires accurate determination of each component's noise contribution. Modern CAD software, such as Symphony by Ansoft, can model noise from each stage in the system including oscillator phase noise. The C/N ratio can then be plotted as a function of input power (see Figure 1-65).

This plot enables straightforward determination of the minimum input power level to achieve a certain C/N ratio. Once the sensitivity has been specified the necessary gain, or

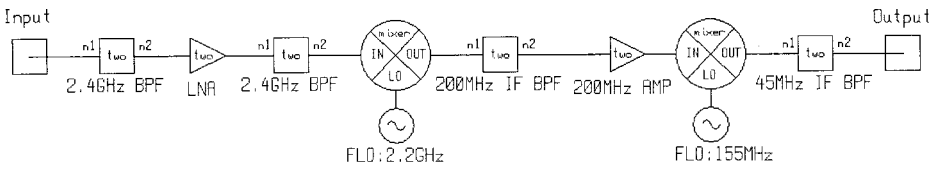

Figure 1-63 Dual-downconversion receiver schematic.

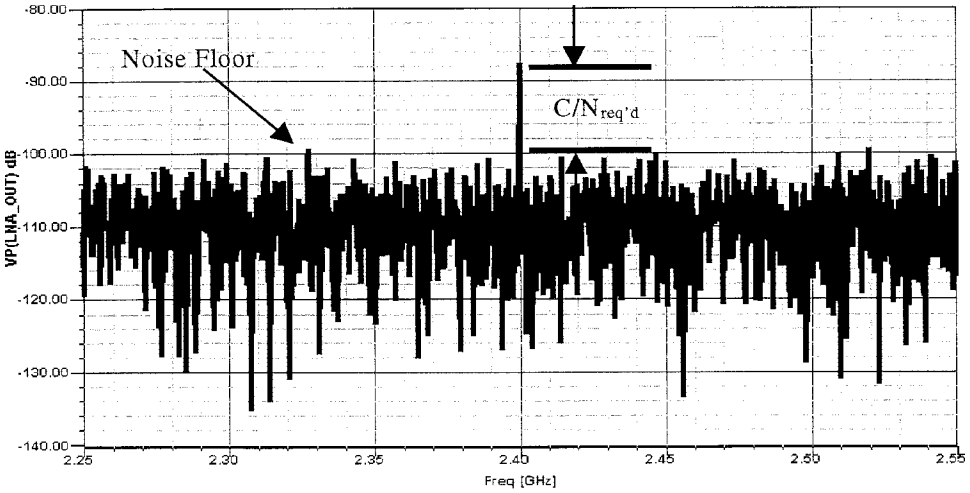

Figure 1-64 Receiver sensitivity measure showing required C/N.

loss, of each component can be determined. A budget calculation (see Table 1-5) can be used to examine the effects of each component on a particular system response.

Another key system parameter is receiver spurious response. The receiver's mixers typically cause the spurious responses. The RF and LO harmonics mix and create spurious responses at the desired IF frequency. These spurious responses can be characterized [4] by the equation

$$\pm mf_{\mathrm{RF}} \pm nf_{\mathrm{LO}} = \pm f_{\mathrm{IF}} \tag{1-16}$$

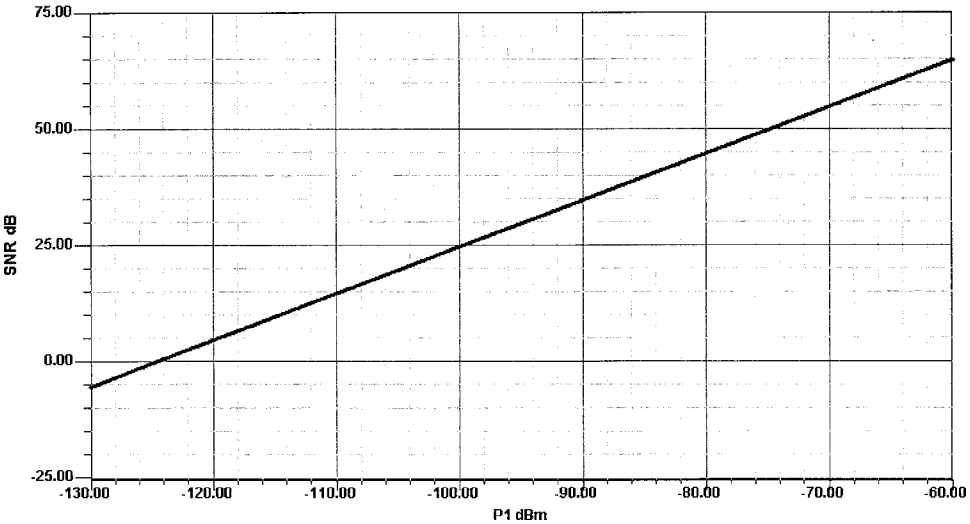

Figure 1-65 C/N ratio versus input RF power level.

Table 1-5 Budget calculation for the ΔS_{21} across each system component accounting for impedance mismatches

Names	ΔS_{21} (dB)

200 MHz IF BPF	–3.85
200 MHz AMP	22.21
MIXER_2	–8.43
45 MHz IF BPF	–0.42

Some spurious responses, or spurs, can be especially problematic because they may be too close to the intended IF to filter, thus masking the actual information-bearing signal. These spurious responses and their prediction can be especially troublesome if the receiver is operated near saturation. The analysis can then be refined by including a spur table that predicts the spur level relative to the IF signal. The spur's power at the output of a mixer is calculated using the spur table provided for this mixer. Once generated, each spur is carried through the remainder of the system with all mismatches accounted for. The output power level of each spur is shown in Table 1-6. Another useful output is the RF and LO indices, which indicate the origin of each spur.

In addition to sensitivity and spurious response calculations, an analog system can be analyzed in a CAD tool such as Symphony for gain, output power, noise figure, third-order intercept point, intermodulation distortion (IMD; due to multiple carriers), system budget, and dynamic range.

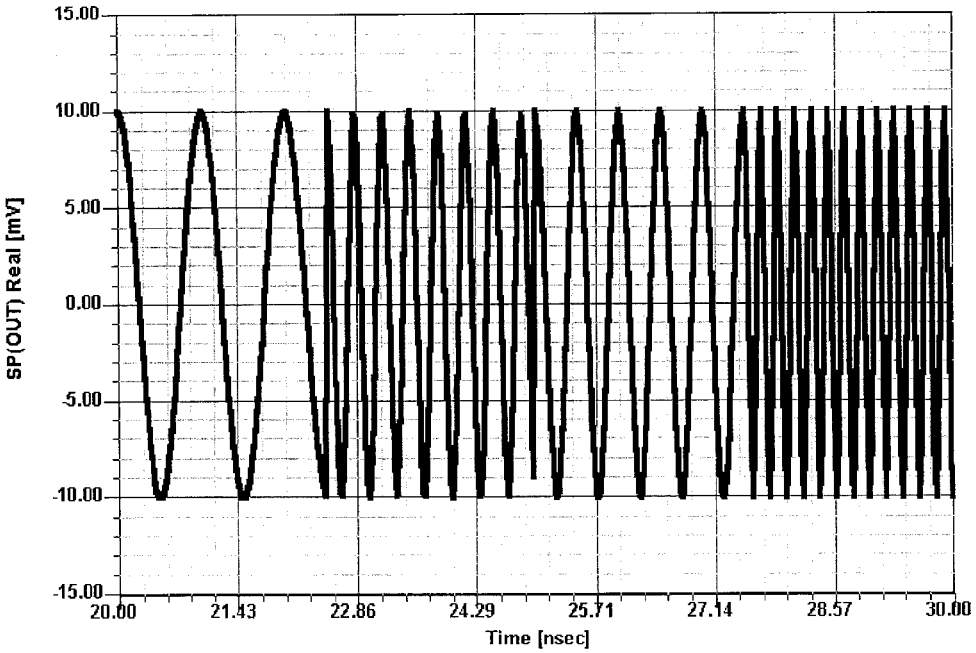

Figure 1-66 4FSK signal generated in Symphony.

Mixed-Mode MFSK Communication System. Next, a mixed-mode (digital and RF) communication system will be described and simulated. In this example digital symbols will be used to modulate an 8-GHz carrier. The system uses *M*-ary frequency shift keying (MFSK) bandpass modulation with a data rate of 40 Mbps. Convolutional coding is employed as a means of forward error correction. The system includes digital signal processing sections as well as RF sections and channel modeling. Several critical system parameters will be examined, including BER. FSK modulation can be described [5] by the equation

$$s_i(t) = \sqrt{\frac{2E}{T}} \cos(\omega_i t + \phi) \tag{1-17}$$

where $i = 1, \ldots, M$. So the frequency term will have M discrete values with almost instantaneous jumps between each frequency value (see Figure 1-66). These rapid jumps between frequencies in an FSK system lead to increased spectral content.

Figure 1-67 shows a block diagram of the complete system. The system can be split into several major functional subsystems—the baseband modulator, the RF transmitter section, channel model, RF receiver, clock recovery circuitry, and baseband demodulator. Looking specifically at the baseband modulator circuitry (Figure 1-68), a pseudorandom bit source is used and the bit rate is set to 40 MHz.

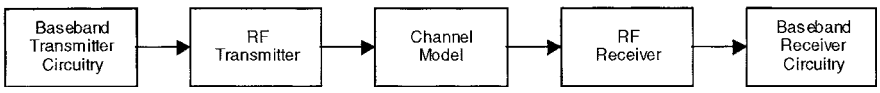

Figure 1-67 Mixed RF/DSP MFSK communication system simulated in Symphony.

A convolutional encoder then produces two coded bits per data bit and increases the bit rate to 80 MHz. The purpose of the convolutional encoder is to add redundancy to improve the received BER. A binary-to-*M*-ary encoder then assigns one symbol to every 2 bits, creating the four levels for the 4FSK, effectively halving the bit rate down to 40 MHz again. The signal is then scaled and upsampled. To decrease the bandwidth, a root-raised cosine filter is used to shape the pulses. The filtered signal then serves as the input to the frequency modulator. The RF section (see Figure 1-69) includes the transmitter that modulates the baseband signal onto an 8-GHz carrier.

That signal is amplified and then filtered to remove any harmonics. The signal is then passed through an additive white Gaussian noise model. The received signal is filtered, amplified, and downconverted twice to baseband. After carrier demodulation the signal is then sent through the clock recovery circuitry. Clock recovery is employed to ensure that sampling of the received signal is executed at the correct instances. This recovered timing information is then used as a clock signal for sample and hold circuitry. Clock recovery in this system was achieved using a phase-locked loop (PLL) configuration. The schematic for the clock recovery circuit is shown in Figure 1-70.

At the heart of the clock recovery circuit is the phase comparator element and the frequency modulator. The inputs to the phase comparator consist of a sample of the received data signal and the output of the feedback path that contains the frequency modulator. The frequency modulator reacts to phase differences in its own carrier and the received data signal. The output of the frequency modulator is fed back into the phase comparator, whose output is dependent on the phase differential at its inputs. The phase of the frequency modulator continually reacts to the output of the phase comparator and eventually lock is achieved. Once the timing of the received signal is locked onto, the clock that feeds the sample and hold will be properly aligned and correct signal sampling will be assured.

Figure 1-71 shows the received signal (filtered and unfiltered) as well as the recovered clock and the final data. Equalizer circuitry is then used to compensate for channel effects, which degrade the transmitted signal. The equalizer acts to undo or adapt the receiver to the effects of the channel. The equalizer employed in this MFSK system is the recursive least squares equalizer. The equalizer consists of a filter of *N* taps that undergoes an optimization in order to compensate for the channel effects. The equalizer depends on a known training sequence in order to adapt itself to the channel. The equalizer model updates the filter coefficients based on the input signal and the error signal (i.e., the difference between the output of the equalizer and the actual desired output). The update (optimization) is based on the recursive least squares algorithm. Several equalizers are available in Symphony, including complex least mean square equalizer, complex recursive least squares equalizer, least mean square equalizer, recursive least squares equalizer, and the Viterbi equalizer. After equalization, the BER of the system is analyzed versus SNR (see Figure 1-72).

PLL CAD SIMULATION. The Symphony system simulator also allows us to evaluate the performance of phase-locked loops. Figure 1-73 shows the block diagram of a PLL in which the VCO is synchronized against a reference. For the purpose of demonstrating the capability, we have selected a 1:1 loop with a crossover point of about 100 kHz, meaning that the loop gain is 1 at this frequency.

Figure 1-74 shows the system's simulated open- and closed-loop phase-noise performance. At the crossover point, the loop is running out of gain. The reason why the closed-loop noise increases above 2 kHz has to do with the noise contribution of various components of the loop system. The highest improvement occurs at 100 Hz, and as the loop gain decreases,

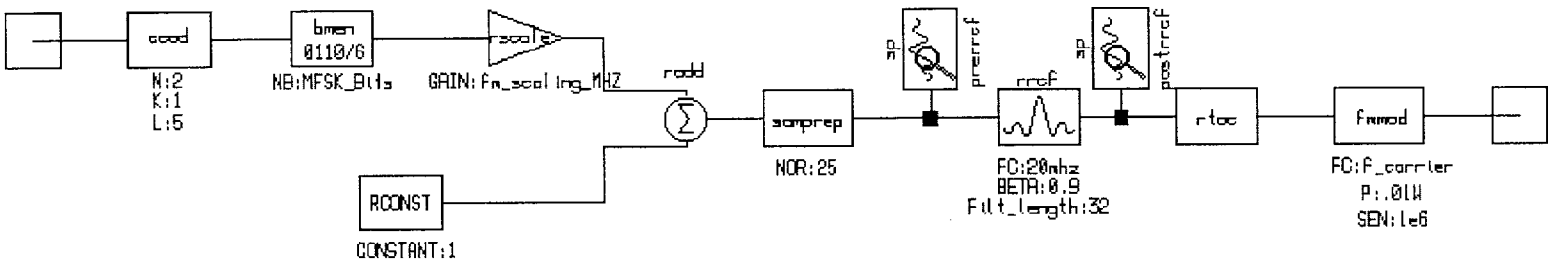

Figure 1-68 MFSK baseband circuitry including frequency modulator.

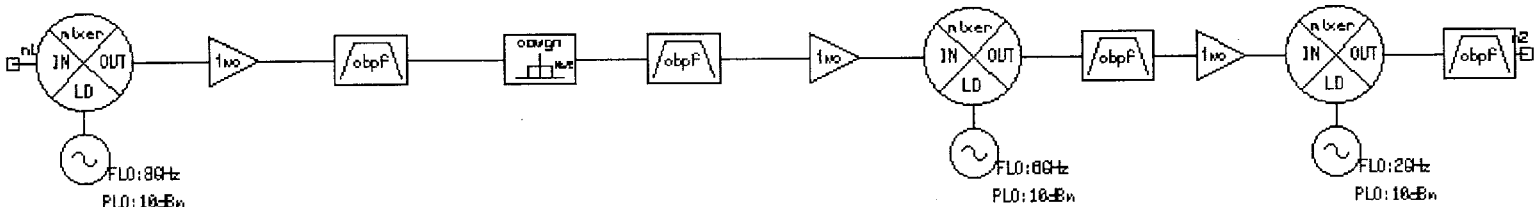

Figure 1-69 RF section including Gaussian noise channel model.

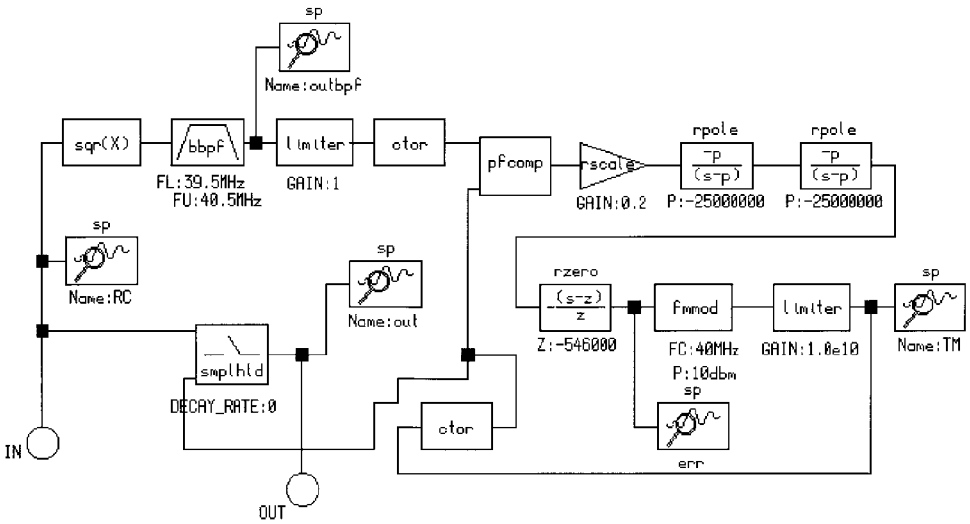

Figure 1-70 Clock recovery circuitry.

the improvement vanishes. Therefore it is desirable to make the loop bandwidth as wide as possible, as this also improves the loop's switching speed. On the other hand, as the phase noise of the free-running oscillator crosses over the phase noise of the reference noise, divider noise, and other noise contributors, one can make the noise actually worse than that of the free-running state. In a single-loop system, a compromise must be made between phase noise, switching speed, and bandwidth. A first-order approximation for switching speed is $2/f_L$, where f_L is the loop bandwidth. Assuming a loop bandwidth of 100 kHz, the switching speed

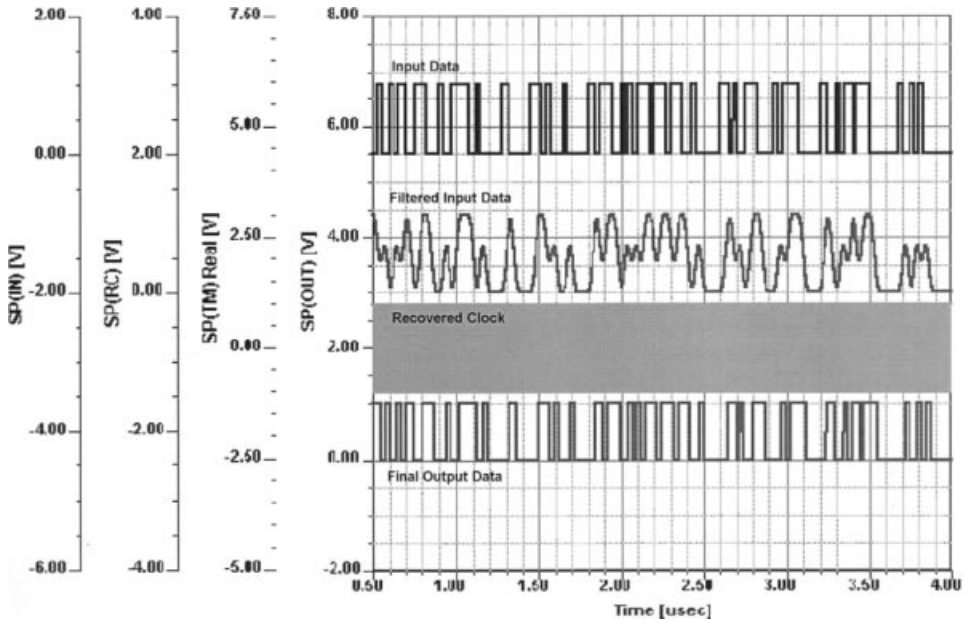

Figure 1-71 Input data, filtered input data, recovered clock, and final output data for the MFSK communication system.

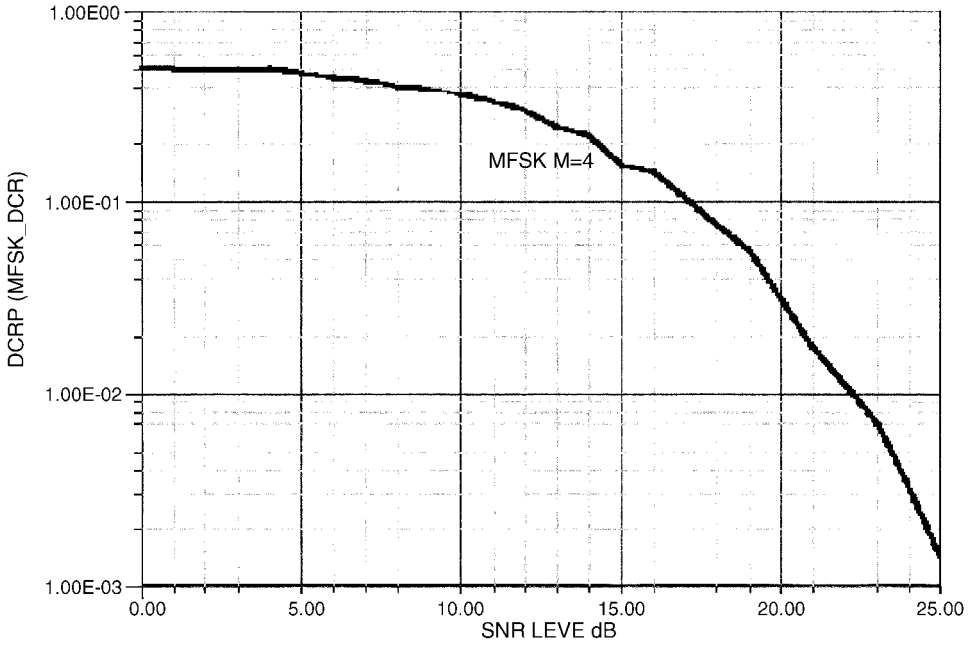

Figure 1-72 BER versus SNR for the MFSK system.

will be 20 μs. Looking at Figure 1-74, we can clearly see the trend from 200 Hz to 100 kHz. Because of the resolution of the sampling time (computation time), the open-loop phase noise below 150 Hz is too low and could be corrected by a straight-line extrapolation from 500 Hz toward 100 Hz. We have left the drawing uncorrected to show the effect of not-quite-adequate resolution.

Since we have already referenced analog and digital waveforms, we need to mention that the current system in place worldwide is referenced as the second-generation (2G) system.

The all-digital, adaptive-bandwidth third-generation (3G) system is being discussed in Europe, Japan, and the United States [6]. This is not without headaches. The Groupe Speciale Mobile (GSM) system in Europe still has potential to grow and is not under any urgent pressure to be upgraded. The opposite is true in Japan, because Japan is running out of capacity and needs to go to wideband CDMA. The important perceived advantage of this is that the number of simultaneous users can be extremely high: there is much less interference because of orthogonal modulation types with extremely low correlation and adaptive bandwidth. The actual definitions are still in flux, with the discussions dominated by the United States. This domination stems from the National Security Agency being determined to be able to eavesdrop on conversations that are none of their business (drug smuggling is always used as an excuse) but invites invasion of monitoring without proper court authorization. This is a very hot issue. The other similar problem has to do with patents. This type of technology is somewhat dominated by Qualcomm, a U.S. company, which likes to send a bill for patent infringement to everybody, possibly even to users. A similar speculation took place with the introduction of digital audio tapes and their duplication and is occurring nowadays with CDs carrying either music recordings or movies. This issue is driven by money and not by technology.

That said, Table 1-7 shows cellular and cordless standards, everything referring to 2G. Figure 1-75 shows the multiplexing schemes used. Table 1-8 shows the parameters of cellular and cordless systems. Figure 1-76 shows the cellular structure.

1-5-2 Transmitters

Since it is possible to generate any type of modulation using DSP, including those described in this chapter, a DSP-based transmitter can also be built. A good example of this is the Philips SA900, which is truly universal.

Introduction to the SA900.* The SA900 (Figure 1-77) is a truly universal in-phase and quadrature (I/Q) radio transmitter that can perform many types of analog and digital modulation including AM, FM, SSB, QAM, BPSK, QPSK, and FSK. It is a highly integrated system that saves space and cost for the manufacturers producing cellular and wireless products. The device allows baseband signals to directly modulate the I/Q carriers, which are generated by an internal phase shift network, in the 1-GHz range, and to maintain good linearity required for a linear modulation scheme (e.g., $\pi/4$-DQPSK). It contains an on-chip frequency divider, phase detector, and VCO, which can be built into a phase-locked loop (PLL) frequency synthesizer to create a transmit offset frequency. Its unique internal design allows frequency conversion without having an external image rejection filter for eliminating the sum term after mixing. The SA900 meets the specifications required by the IS-54, the industry standard for North America Digital Cellular (NADC) system. Here we review the basic concept of I/Q modulation and discuss the key points when designing the SA900 for an RF transmitter.

I/Q Modulation. Any bandpass RF signals can be represented in polar form by

$$s(t) = A(t)\cos[\omega_c t + \phi(t)] \tag{1-18}$$

where $A(t)$ is the signal envelope and $\phi(t)$ is the phase. By using the trigonometric identities, we can represent Eq. (1-18) in rectangular form by

$$s(t) = \mathrm{I}(t)\cos(\omega_c t) - \mathrm{Q}(t)\sin(\omega_c t) \tag{1-19}$$

where $\mathrm{I}(t) = A(t)\cos[\phi(t)]$
$\mathrm{Q}(t) = A(t)\sin[\phi(t)]$

Since the baseband signals $\mathrm{I}(t)$ and $\mathrm{Q}(t)$ modulate two exactly 90° out-of-phase carriers $\cos(\omega_c t)$ and $-\sin(\omega_c t)$, respectively, we call the system implementing Eq. (1-19) an in-phase and quadrature (I/Q) modulator. Figure 1-78 shows the mathematics and hardware implementation of an I/Q modulator.

The local oscillator, usually a VCO within a PLL, generates the carrier and is split into two equal signals. One goes directly into a double-balanced mixer to form the I-channel and the other one goes into the other mixer via a 90° phase shifter (realized by passive elements) to provide the Q-channel. The baseband signals $\mathrm{I}(t)$ and $\mathrm{Q}(t)$, either analog or digital in nature, modulate the carrier to produce the I and Q components, which are finally combined to form the desired RF transmitting signal. Since any RF signal can be represented in the I/Q form, any modulation scheme can be implemented by an I/Q modulator.

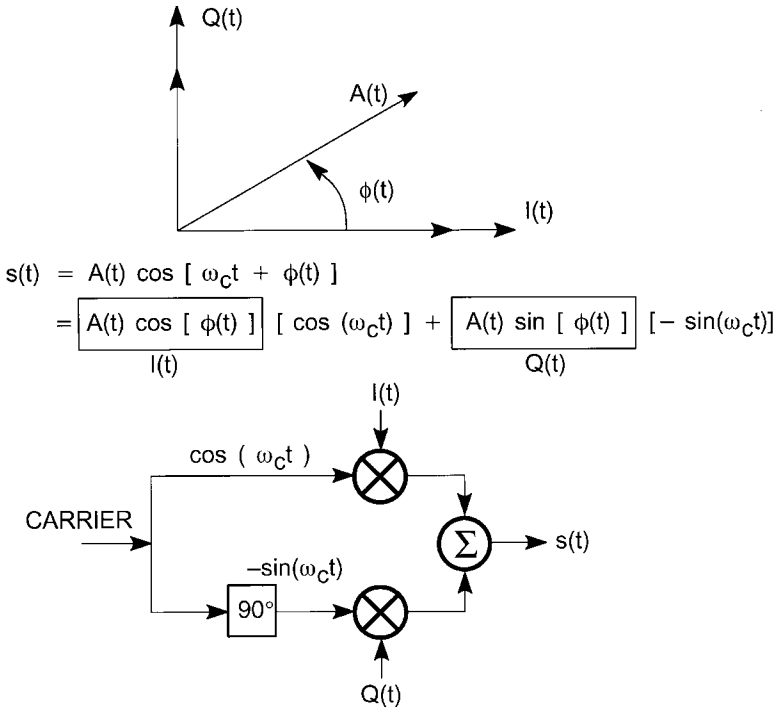

Figure 1-78 Mathematical representation and hardware implementation of I/Q modulator.

Linear Digital Modulation. Linear digital modulation techniques depend on varying the phase and/or magnitude of an analog carrier according to digital information: ones and zeros. This digital information can be the output of an analog-to-digital converter (e.g., voice codec), or it can be digital data in some standard formats (e.g., ASCII). The most popular digital signaling format is nonreturn-to-zero (NRZ), where 1's and 0's are converted into signals with amplitudes of 1 and –1, respectively, in a symbol duration. Since an NRZ signal has infinite bandwidth, transmit filters have to be used to limit the spectral spreading. To ensure each NRZ symbol does not smear into its neighbors due to low-pass filtering and channel distortion, causing intersymbol interference (ISI), the frequency response of the low-pass filter has to satisfy Nyquist criteria. One example of this type of filter is the linear phase square-root-raised cosine filter. Together with the same type of filter for receive low-pass filtering, the signal is guaranteed ISI-free in a Gaussian environment. One straightforward technique of transmitting such a band-limited signals through communication channels would be to apply it directly to the mixer of the I channel to generate an RF signal. This is known as binary phase shift keying (BPSK), where the phase of the carrier is shifted 180(to transmit a data change from 0 to 1 or 1 to 0.

Quadrature or quaternary phase shift keying (QPSK) is a much more common type of modulation scheme used in mobile and satellite communications. It has four possible states (90° apart) and each of them represents 2 bits of data. Figure 1-79 shows the baseband generator for QPSK (without the differential phase encoder). NRZ data bits go through the serial-to-parallel converter (see Figure 1-80) and are mapped in accordance to some rules to generate I and Q values. The generic rule states that the values of I and Q components are 1 and 1 for the data bits "11" (45°) and –1 and –1 for the data bits "00" (–135°). These discrete signals have to be band-limited by Nyquist low-pass filters to be ISI-free.

A more sophisticated way of mapping results in π/4-DQPSK (D for differential encoding), which is chosen for North America Digital Cellular (IS-54), Personal Digital Cellular (PDC) in Japan, and Personal Handy Phone System (PHS) in Japan. In this scheme, consecutive pairs of bits are encoded into one of the four possible phases: π/4 for "11," 3π/4 for "01," –3π/4 for "00," and –π/4 for "10." However, unlike the previous case that "11" is always π/4 and "00" is always –3π/4, the encoded phases are the degrees that the carrier has to shift at each sampling instances. Thus the information is contained in the phase difference (differential) instead of absolute phase for π/4-DQPSK.

A better way to tell the difference between QPSK and π/4-DQPSK is by looking at the signal constellation diagram, shown in Figure 1-81, which displays the possible values of I and Q vectors and changes of state. A constellation diagram is also known as a phase diagram because it shows the phase of the carrier at the sampling point. Note that the phases of QPSK are assigned for every 2 bits of data; therefore it can transmit twice as much information as BPSK in a given bandwidth; that is, it is more bandwidth-efficient. The 8-PSK is another type of modulation used for high-efficiency requirements. It maps 3 bits into eight phases, 45° apart, in the constellation. More spectrally efficient modulation can be created by

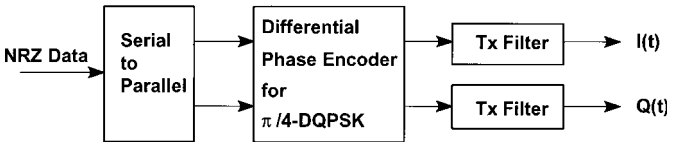

Figure 1-79 QPSK and π/4-DQPSK baseband generator.

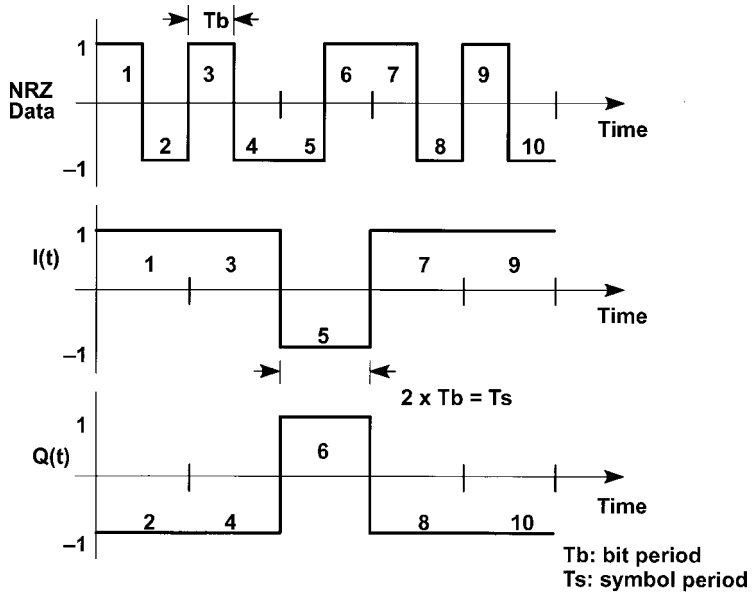

Figure 1-80 Serial-to-parallel conversion.

mapping more bits into one phase at each sampling point. However, as we add states to the signal constellation, the signal susceptibility to noise increases because the difference between states decreases. Then, a higher carrier-to-noise (C/N) ratio is required to maintain the same bit error rate.

One common misconception is that since π/4-DQPSK has eight states, it is just another type of 8-PSK. Note, however, that at every sampling instant, the carrier of π/4-DQPSK is allowed to switch to only one of the four possible states (see Figure 1-81). So we still have two data bits that get encoded into four phases. Thus π/4-DQPSK has the same spectral efficiency as QPSK for the same carrier power. The reason for using this modulation scheme is twofold. First, the envelope fluctuation, which causes spectral spreading due to nonlinearity of transmitter and amplifier, is reduced because the maximum phase shift is 135° instead

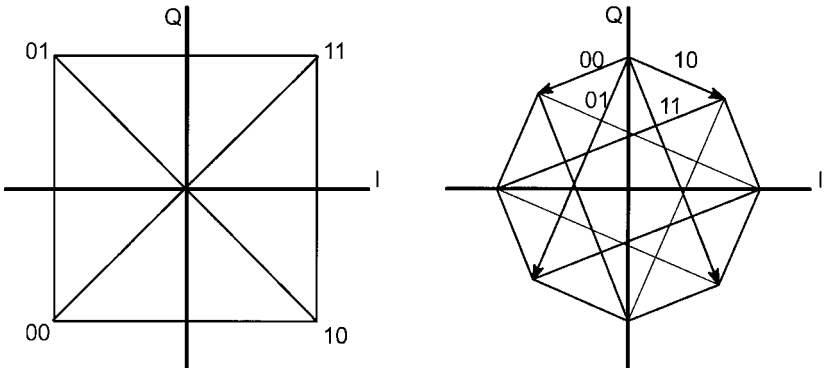

Figure 1-81 Signal constellation of QPSK and π/4-DQPSK.

of 180°. Second, the signal can be demodulated noncoherently, which simplifies the receiver circuitry by eliminating the need for carrier recovery.

Digital and Analog FM. Another family of digital modulation is categorized by frequency change of the carrier instead of phase and/or amplitude change. One member of this family is frequency shift keying (FSK), where the carrier switches between two frequencies. FSK is also known as digital FM because it can be generated by feeding the NRZ data stream into an analog VCO. FSK appears as a unit circle in the signal constellation because the RF signal envelope is constant and the phase is continuous. Baseband filtering is usually applied for FSK to limit the RF bandwidth of the signal so that more channels can fit into a given frequency band.

One common modulation of this type is known as Gaussian minimum shift keying (GMSK), which is used for GSM and some other wireless applications. GMSK can be generated by following its definition: band-limit the NRZ data stream by a Gaussian low-pass filter, then modulate a VCO with modulation index (2 × frequency deviation/bit rate) set to 0.5. In other words, the single-sided frequency deviation is one-fourth of the bit rate ($\Delta f = R/4$).

Another way of generating GMSK is by I/Q modulator. Referring back to Eq. (1-19), any RF signal can be split into I and Q components. Unlike the QPSK mentioned before, baseband I(t) and Q(t) are not discrete points for FM signals; rather, they are continuous functions of time. The way to produce FM is shown in Figure 1-82. We first store all the possible values of $\cos[\phi(t)]$ and $\sin[\phi(t)]$ in a ROM lookup table, which will be addressed by the incoming data to generate the I and Q samples. The output data from the ROM is then applied to D/A converters, after low-pass filtering for signal smoothing, to produce the analog baseband I and Q signals. This method guarantees the modulation index to be exactly 0.5, which is required for coherent detection of GMSK (e.g., the GSM system). The same I/Q principle can also be applied to generating analog FM signals.

Single-Sideband AM (SSB AM). AM signals can be divided into three types: the conventional AM, double sideband suppressed carrier AM (DSBSC AM), and SSBSC AM. The first type is not attractive because for 100% modulation, two-thirds of the transmit signal power appears in the carrier, which itself conveys none of the information added by modulation. By using a balanced mixer (e.g., a Gilbert cell), one can generate DSBSC AM, where the carrier is totally suppressed and only the upper and lower sidebands are present. However, this is still not the best because the information is transmitted twice, once in each sideband. To further increase the efficiency of transmission, only one sideband is needed to deliver the information. The SSBSC AM can be generated by an I/Q modulator with the baseband information feeding the modulator (by quadrature), as shown in Figure 1-83. This modulation technique can greatly reduce the bandwidth of the signal and allows more signals to be transmitted in a given frequency band. This topic is discussed in detail in [7].

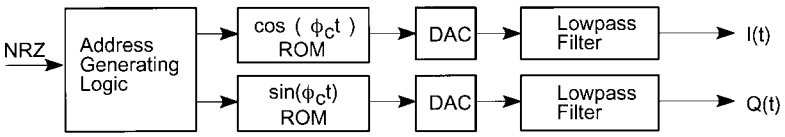

Figure 1-82 Digital FM (e.g., GMSK) baseband I/Q generator.

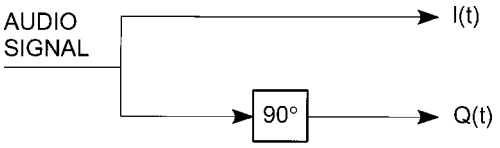

Figure 1-83 Baseband processing for SSBSC AM.

System Architecture. There are usually two schemes, the dual conversion and direct conversion, used for implementing transmit modulators. Dual conversion is simpler to implement by modulating an oscillator at lower frequency and then upconverting to the carrier frequency. This scheme, however, is more expensive due to the need for additional filtering and more printed circuit (PC) board space. By using only one mixer, direct conversion requires fewer components but is harder to implement.

The problems that direct conversion suffers are carrier leakage and modulated signal coupling. Poor RF isolation of the surface mount packages will allow the carrier to be present at the transmitter output, thus making it difficult to have –40 dBc carrier suppression. In addition, modulated RF signal would couple back to the oscillator (usually a VCO in a PLL synthesizer loop) and cause modulation distortion.

Based on the concept of dual conversion, the SA900 uses an image-reject mixer to eliminate the need for IF filtering and allow monolithic integration. The transmit carrier (LO) is downconverted by the frequency synthesized by the on-chip VCO, which operates from 90 to 140 MHz. This LO is then modulated by the baseband I/Q signals to obtain a complex modulation scheme. The image (sum term) after mixing and LO are sufficiently suppressed by the image-reject mixer. Any residual amounts can be further suppressed by an external duplex filter.

Figures 1-84 and 1-85, respectively, show how the SA900 can be used in frequency-division duplex (FDD) and time-division duplex (TDD) transceivers. Note that the LO for both systems is running at a frequency that is higher than the transmit frequency, thus minimizing carrier leakage. In the FDD system only one external VCO is required for generating both transmit and receive LO signals when using the SA900.

Figure 1-86 shows the IS-54 front-end chipset that consists of the SA601, SA7025, SA900, and SA637. This receiver architecture (SA637) supports a digital magnitude/phase baseband

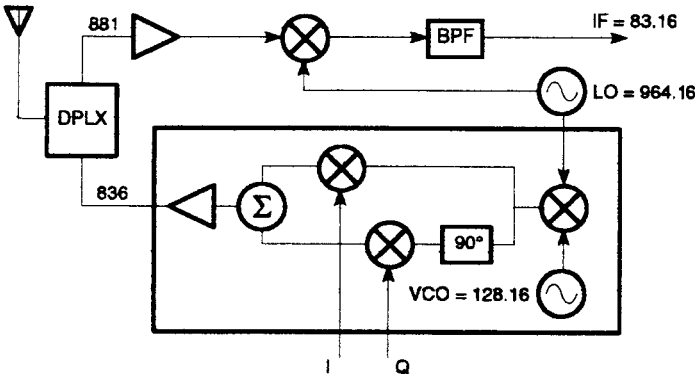

Figure 1-84 FDD system using SA900.

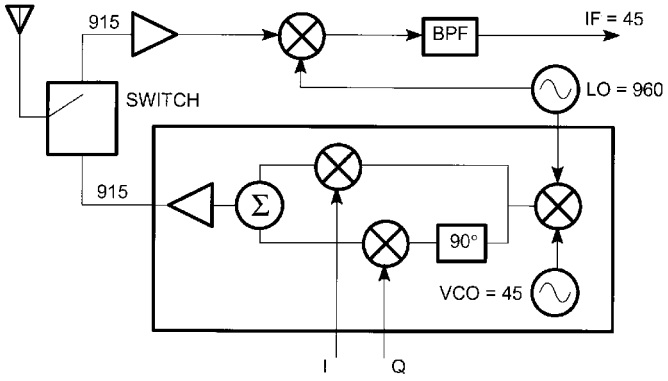

Figure 1-85 TDD system using SA900.

demodulator. An alternate configuration will be using the SA606 FM/IF receiver in conjunction with an external I/Q demodulator IC. Table 1-9 shows the possible configurations for the IS-54 handsets using the SA900 as transmitters.

Designing with the SA900

Baseband I/Q Inputs. The baseband modulation inputs are designed to be driven differentially for the SA900 to operate at its best. The I and Q inputs should have a dc offset of $V_{CC}/2$, which is externally provided by common DSP chips. If all four inputs are biased from the same source, the device can tolerate ±0.5-V dc error; however, inaccuracy of dc bias between I1/I2 or Q1/Q2 causes reduced suppression of the carrier. Thus, it is important to have a well-regulated dc supply for I and Q signal biasing. The bandwidth of the inputs is much higher than the specified 2 MHz. Approximately 2 dB of power loss will be experienced if the I and Q inputs are 50 MHz.

The SA900 generates a minimum of 0 dBm of power to a 50-Ω load when the amplitude of the I and Q signals are 400 mV P-P. The output power will decrease by 6 dB for every 50% decrease in I/Q amplitude. Single-ended I and Q sources can be used but are not recommended due to the degradation in carrier suppression (more than 10 dB compared to differential). In addition, the entire noise performance of the device will suffer. $V_{CC}/2$ should be applied to I2 and Q2 pins if the part is driven single-endedly.

Transmit Local Oscillator. The transmit local oscillator path consists of a TXLO input buffer, LO output buffer, VCO, image-reject mixer, and phase shift network. Together with a few external components, this section provides the I and Q carriers for modulation.

The TXLO inputs and LO outputs are designed to be used in an external PLL that synthesizes different frequencies for channel selection. The RF signal being generated is fed into TXLO inputs and then comes out of LO outputs to complete the system synthesizer loop. The TXLO inputs are differential in nature and have a voltage standing wave ratio (VSWR) of 2:1 with input impedance of 50 Ω. Single-ended sources can be used by ac grounding the TXLO_2 input, as done on the demo board. This signal should also be ac coupled into the TXLO_1 input. The frequency range for these inputs is from 900 to 1040 MHz while the input power should be between −10 and −13 dBm. The output level will be changed significantly if the input level is below −25 dBm.

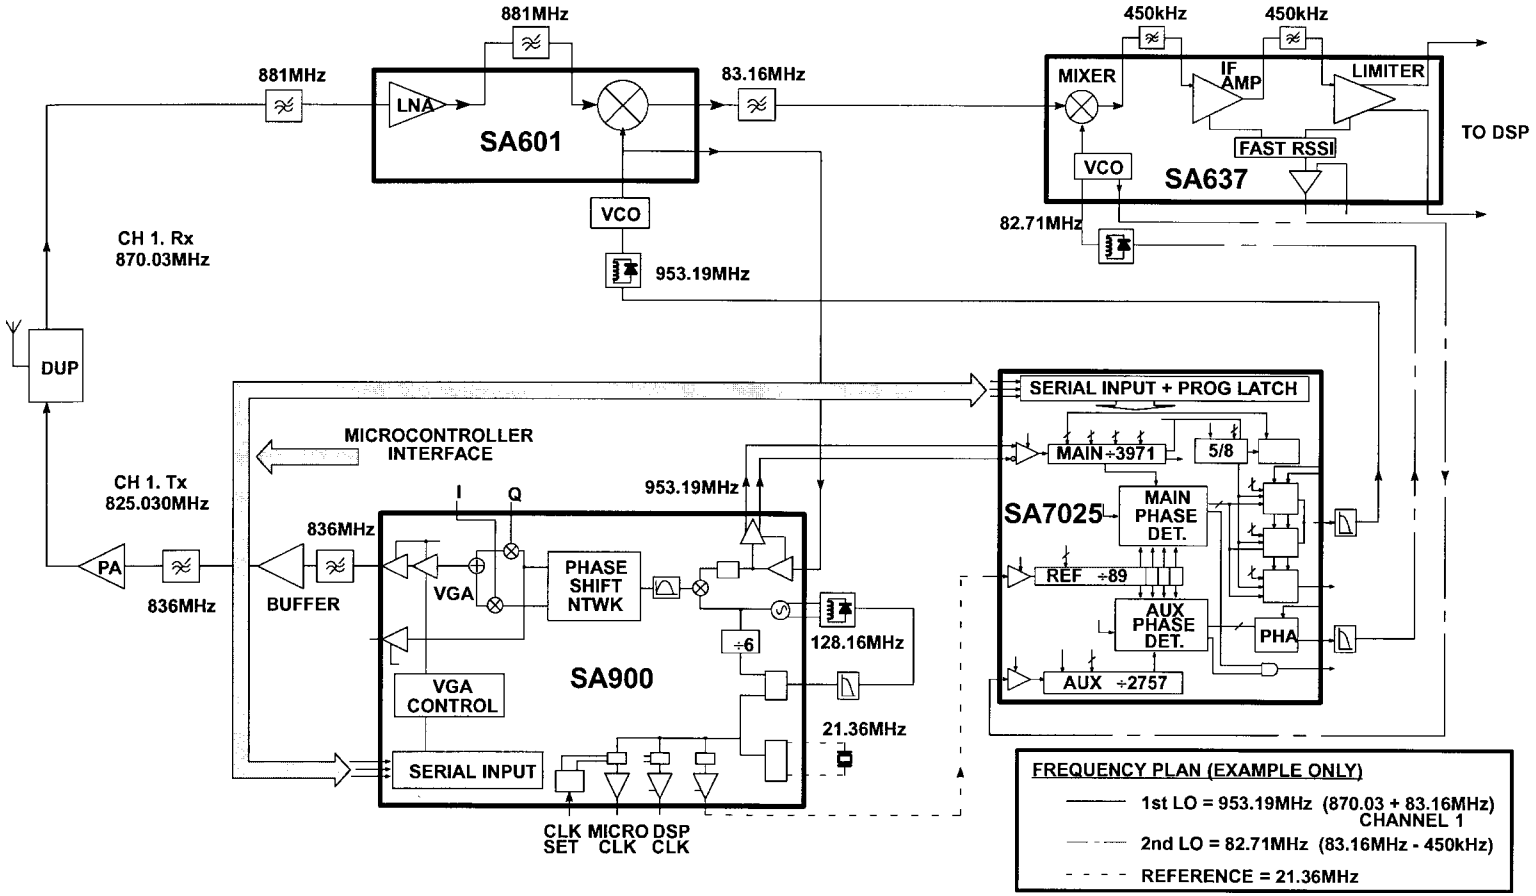

Figure 1-86 IS-54 front-end chipset from Philips.

Table 1-9 Possible configurations for IS-54 handsets

Rx First IF	On-Chip VCO Frequency	On-Chip ÷ *N* Value	Crystal Frequency
83.16 MHz	128.16 MHz	6	21.36 MHz
71.64 MHz	116.64 MHz	6	19.44 MHz
45 MHz	90 MHz	6	15 MHz
84.6 MHz	129.6 MHz	9	14.4 MHz

The output power of the LO buffered signal changes by about 2 dB when the SA900 is in a different mode of operation. Typical values are –13.5 dBm and –15.5 dBm for DUAL mode and STANDBY mode, respectively.

The 90° phase shift network, realized by resistor–capacitor (RC) networks, is capable of operating over a wide frequency range. Even though their frequency characteristics are optimized for cellular band, the part can also be used in other applications in a different band. In such cases, designers have to test the part experimentally to find out the performance, such as sideband suppression, carrier suppression, and image rejection.

Crystal Oscillator. The crystal oscillator (XTAL_1 and XTAL_2 pins) is used to provide a reference frequency between 10 and 45 MHz for the phase detector and the three on-chip clocks. It can be configured as a crystal oscillator using an external crystal and capacitors, or it can be driven by an external source. In the latter case, pin XTAL_2 can be left floating. Information regarding crystal oscillator design can be found in [8].

VCO. The VCO, together with the phase detector, the divider, and an external low-pass filter, can form a PLL for the transmit offset frequency. The image-reject mixer downconverts the TXLO signal to the RF carrier by the amount of VCO frequency. Thus the TXLO frequency should be the desired channel frequency plus the IF offset generated by the VCO. Note that the part will not function if the VCO section is not used.

The VCO is designed for generating IF frequency between 90 and 140 MHz. Together with an external varactor diode and resonator, it can be configured as an oscillator as shown in Figure 1-87.

The resonant frequency of such a circuit is

$$f_{\text{VCO}} = \frac{1}{2\pi\sqrt{LC_T}} \tag{1-20}$$

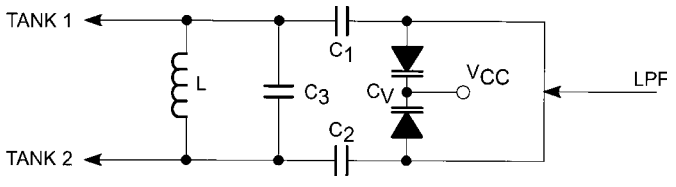

Figure 1-87 VCO tank circuit.

where $C_T = (C_1 \parallel C_2 \parallel C_V) + C_3$. C_V is a varactor diode, which changes capacitance as the voltage across it varies.

Calculation

$$C_1 = C_2 = 33 \text{ pF}$$

$$C_3 = 5.6 \text{ pF}$$

$$C_V = 33.5 \text{ pF @ } 2.5 \text{ V}$$

$$L = 100 \text{ nH}$$

$$C_T = 5.6 + (1/33 + 1/33 + 1/33.5)^{-1} = 16.7 \text{ pF}$$

$$f_{\text{VCO}} = \frac{1}{2\pi(100\text{E} - 9 \times 16.7\text{E} - 12)^{0.5}} = 123\text{MHz}$$

On the demo board, a 1:1 ratio RF transformer is also included to allow single-ended external source driving differential inputs when the VCO is not used.

When designing the VCO, careful printed circuit board (PCB) layout has to be made. Traces have to be short to avoid the parasitic capacitance and inductance that may cause unwanted oscillation. Referring to Eq. (1-20), there are a large number of combinations of L and C_T values that will give the same resonant frequency. If undesired spurs are found in the design due to PCB layout, experimenting with a different set of LC values may sometimes solve the problem.

Output Impedance Matching. The equivalent output impedance at the DUALTX pin is approximately equal to 600 Ω in parallel with 2 pF at 830 MHz. It has to be matched properly to generate maximum power into a 50-Ω load (e.g., a SAW filter). Figure 1-88 shows the recommended matching network. The shunt inductor (L_1) is used to provide maximum swing at the output (short at dc) and also provide reactance to make the real impedance 50 Ω looking

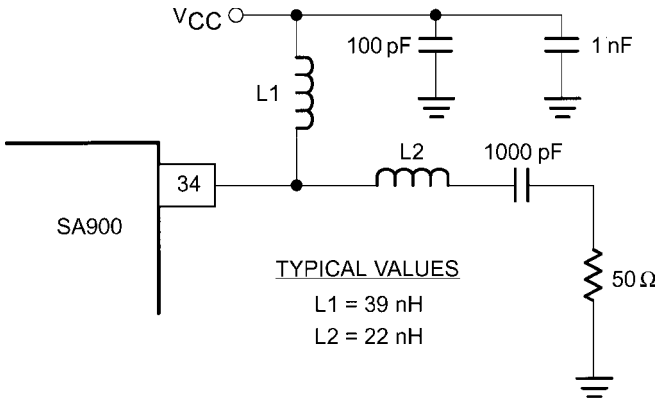

Figure 1-88 DUALTX output matching network.

into the matching network. The remaining negative reactance is canceled by the series inductor (L_2). The values used on the demo board can be used as a reference but may not be suitable if a different layout is implemented. The two shunt capacitors are included to bypass the high-frequency RF signal, avoiding direct coupling into V_{CC}. The series ac coupling capacitor is used to maintain the proper bias for the output stage. Their values are big enough to be left out in the impedance matching calculation.

Using a network analyzer to measure the SA900's output *S* characteristic is necessary for obtaining optimum matching, which generates maximum output power. Figure 1-89 shows how to match the output impedance to a 50-Ω load at 915 MHz. First, calibrate the network analyzer to the DUALTX SMA connector on the demo board. Then, short the point where the series inductor is located and use the DELAY feature of the network analyzer to move the point of reference in the Smith Chart to the leftmost point. Now the network analyzer is calibrated to the beginning of the matching network, not just the SMA connector. The frequency response (Figure 1-89a) shows that the "dip" is around 830 MHz, the frequency where the board was originally matched. The Smith Chart shows that it requires less inductance to bring the marker to the center of the chart (50 Ω). By using a 15-nH series inductor, the "dip" was moved closer to 915 MHz (–15 dB) and a better match is achieved (Figure 1-89b).

On-Chip Clocks. The crystal oscillator is buffered to provide three external clock signals: CLK1, CLK2, and MCLK. Table 1-10 shows the divide ratio and the controlling mechanism. CLK1 is usually used for the system synthesizer (e.g., SA7025) reference. Since MCLK is active all the time, it is ideal for providing the master clock for the microcontroller. When the device is in STANDBY mode, CLK1 and MCLK provide the clock signals necessary for receiving RF signals. CLK2 can also be used as a clock for the digital signal processing (DSP) chip.

Modes of Operation. The SA900 is intended for either AMPS mode (analog cellular) or DUAL mode (digital cellular, IS-54) operation. When the device is running in AMPS mode, the I/Q modulator, variable gain amplifier (VGA), and phase shifter are disabled. The fixed-gain amplifier is powered up during AMPS mode operation. However, since the divide ratio is too low (6, 7, or 8), the comparison frequency of the on-board PLL is too high, making it very difficult for the loop bandwidth to be less than 300 Hz for analog frequency modulation. The device includes two power-saving modes of operation that disable partial circuitry to reduce the power consumption of the overall chip. The SLEEP mode disables all the circuitry except the master clock (MCLK pin) of the SA900. The STANDBY mode shuts down everything except the TXLO buffer, MCLK, and CLK1, which allows the system synthesizer (e.g., SA7025) to continue running. These two power-saving modes are common to both AMPS and DUAL mode operation. The SA900 draws 60 mA in the DUAL mode, reduced to 3 mA and 8 mA, respectively, in the SLEEP and STANDBY modes.

The TXEN pin is for hardware powering down the modulator and synthesizer. The falling edge of the signal disables the modulator and synthesizer while the rising edge enables the modulator. To power down the synthesizer using software, send a data word with the SE bit set to "0" ("1" for enable). The synthesizer will be disabled right after the strobe signal is transmitted. Either SE or TXEN going low will turn off the synthesizer. This operation is common to both the AMPS and DUAL modes.

Performance of the SA900

Performance Criteria. Since the I/Q modulator is a universal transmitter, measuring only the frequency stability and modulation index of a generated FM signal would not be useful for other modulation schemes. Measurement parameters should be general enough so that they can represent the performance of modulators when applying different types of modulation and allow fair comparisons among different I/Q modulators. Based on this idea, two measurement techniques—in-phase modulation and quadrature modulation—are used for evaluating I/Q modulators.

The in-phase modulation relies on injecting two equal frequencies and phase signals at f_{mod} into the I and Q inputs. The result of this modulation is two sidebands appearing at f_{mod} offset from the carrier, with the carrier totally suppressed. This is also known as double-sideband (DSB) conversion. The quadrature modulation requires two equal frequencies (but 90° out-of-phase signals) being injected into the I and Q inputs. The result is a single-sideband suppressed carrier (SSBSC) signal with either the upper or lower sideband at f_{mod} carrier offset being suppressed. This is also known as single-sideband (SSB) upconversion. Figure 1-90 summarizes these two tests.

In a practical system, imperfection of an I/Q modulator is directly related to these two measurements. Sideband and carrier suppression from the quadrature modulation test will show the amount of gain imbalance, phase imbalance, and dc offset. On the other hand, intermodulation product suppression from the in-phase modulation test will show the linearity of an I/Q modulator. When making measurements, it is important to have well-balanced I and Q baseband modulating signals for measurement since the signal imperfection will translate into degraded sideband and carrier suppression.

Performance Graphs. In making those measurements for the demo board, the following parameters were used:

In-Phase Modulation

PIN 43 I1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 0°
PIN 42 I2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 180°
PIN 41 Q1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 0°
PIN 40 Q2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 180°

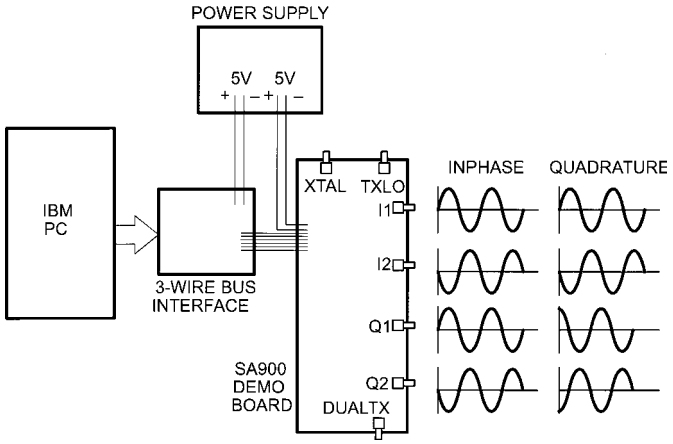

Figure 1-90 In-phase and quadrature modulation test.

Quadrature Modulation

PIN 43 I1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 0°
PIN 42 I2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 180°
PIN 41 Q1 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 90°
PIN 40 Q2 = 400 mV P-P, dc = $V_{CC}/2$ at 200 kHz, Phase = 270°

Figure 1-91 illustrates what the typical output spectra would be if in-phase and quadrature modulation were applied to an I/Q modulator. Quadrature modulation will produce lower sideband (LSB) or upper sideband (USB) signal, depending on the phase angle between the I and Q signals. The SA900 was designed to have USB suppressed when the I signal leads the Q signal. The undesired signals are carrier breakthrough and the harmonic products of the baseband modulating signals sitting at $f_c \pm nf_{\text{mod}}$, where n is an integer ≥ 2.

Referring to Figure 1-91a, the output power is 1.3 dBm (cable loss = 0.7 dB) for the LSB while better than 38 dBc of carrier, sideband, and harmonics suppression is measured. The USB suppression of better than 26 dBc implies the residual AM of the transmit signal is better than 5%, a requirement of the IS-54 specification.

The in-phase modulation test will generate both LSB and USB. Beside these two tones, the carrier breakthrough and the harmonics, intermodulation (IM) products will all appear at the output. The odd IM products are dominant, and they satisfy the following rules: Let $f_1 = f_c - f_{\text{mod}}$, and $f_2 = f_c + f_{\text{mod}}$.

$$\text{Third-order IM:} \quad 2f_1 - f_2 = f_c - 3f_{\text{mod}}, \quad 2f_2 - f_1 = f_c + 3f_{\text{mod}}$$

$$\text{Fifth-order IM:} \quad 3f_1 - 2f_2 = f_c - 5f_{\text{mod}}, \quad 3f_2 - 2f_1 = f_c + 5f_{\text{mod}}$$

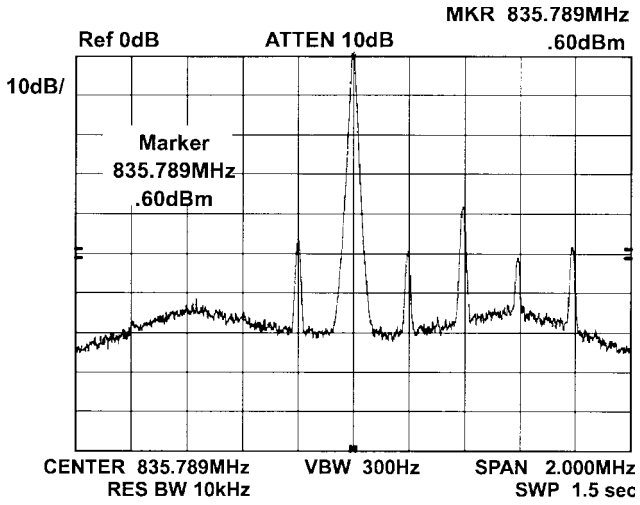
$$\text{Seventh order IM:} \quad 4f_1 - 3f_2 = f_c - 7f_{\text{mod}}, \quad 4f_2 - 3f_1 = f_c + 7f_{\text{mod}}$$

Referring to Figure 1-91b, the LSB and USB are –1.6 dBm (cable loss = 0.7 dB), which is 3 dB less than the measured power for the quadrature modulation test. The IM3 is better than –35 dBc. IM products of much higher orders are totally suppressed.

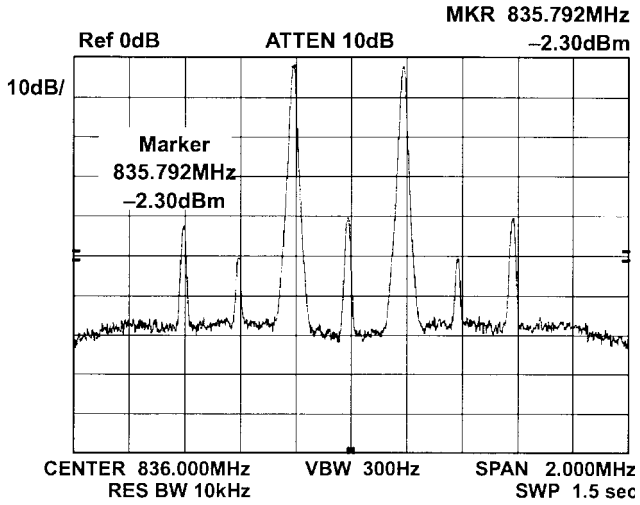
Amplitude and Phase Imbalance. Both amplitude and phase imbalance (error) of an I/Q modulator can be calculated directly from the SSB performance plots. Assuming that phase error equals ϕ radians and amplitude error equals K. The sideband suppression, X, in dBc can be expressed as (see the section entitled "I/Q Modulator Equations" for the derivation):

$$\text{SSB suppression,} \quad X(\text{dBc}) = 10 \log\left(\frac{K^2 + 2 \times K \times \cos(\phi) + 1}{K^2 - 2 \times K \times \cos(\phi) + 1}\right) \tag{1-21}$$

Collecting the like terms and expressing ϕ in terms of K and X, we find



a. Quadrature Test (SSB Up-conversion)



b. In-phase Test (DSB Up-conversion)

Figure 1-91 Typical SA900 output spectra.

$$\phi = \cos^{-1}\left(\frac{10^{X/10} \times K^2 + 10^{X/10} - 1 - K^2}{2 \times K + 2 \times K \times 10^{X/10}}\right) \tag{1-22}$$

For a given X, there will be a set of ϕ and K that satisfies Eq. (1-22). We can represent this relationship graphically, as shown in Figure 1-92. The contours show the phase and amplitude errors for SSB suppression, X, from 44 to 26 dBc. When X equals 40 dBc, phase error is less than 1.2° with an amplitude error of 0 dB. By the same token, the amplitude error is less than 0.2 dB with a 0° phase error.

Spectral Mask. To fully characterize the performance of an I/Q modulator, measurements of the power spectral density of various digital modulation schemes have to be made. Figures 1-93a and 1-93b show the measured spectral masks of IS-54 and PDC standards, which designate π/4-DQPSK as the modulation format.

GMSK is a digital modulation scheme widely used for wireless and mobile communications. Figure 1-93c shows the spectral mask of the modulation format required by GSM, the digital cellular standard in Europe. At carrier offsets of 200 and 300 kHz, the power of the signal is suppressed by 46 and 58 dB, respectively, which is well within the GSM specification.

Power ON Time. The power ON time for the SA900 is mainly determined by the loop bandwidth of the on-board PLL frequency synthesizer. It can be measured by using the HP 53310A modulation domain analyzer set to the EXTERNAL TRIGGERED mode. The STROBE signal from a three-wire bus is used to trigger the equipment. Figure 1-94 shows that the part can be powered up and locked in about 62 μs.

ISM Band Application. In the United States the industrial, scientific, and medical (ISM) band from 902 to 928 MHz is attractive because users are allowed, without having a license, to use transmit powers up to 1 watt in frequency hopping or direct sequence CDMA operation. The wide bandwidth nature of the SA900 fits well into this application. Figure 1-95 shows the output spectra of the SA900, illustrating how well the image-reject mixer works. A common IF (45 MHz) was chosen to be the offset frequency, and then injected externally into the VCO pins. The closest images (± 45 MHz), are down more than 36 dBc.

I/Q Modulator Equations. Assume an imperfect I/Q modulator with gain error K and phase error ϕ, modulated by quadrature I/Q signals (SSB upconversion) ω_m. Then the signal, $s(t)$, at the output of the I/Q modulator becomes

$$s(t) = K\cos(\omega_c t + \phi)\cos(\omega_m t) - \sin(\omega_c t)\cos(\omega_m t + 90°) \tag{1-23}$$

Using trigonometric identity and letting $\omega_c - \omega_m = A$ and $\omega_c + \omega_m = B$, we obtain

$$s(t) = \frac{K}{2}\cos(At + \phi) + \frac{K}{2}\cos(Bt + \phi) + \frac{1}{2}\cos(At) - \frac{1}{2}\cos(Bt) \tag{1-24}$$

Assume the information is in the LSB—that is, A—and the spur is the USB—that is, B. We have

$$\text{Signal} = \frac{K}{2}\cos A \cos\phi + \frac{1}{2}\cos A - \frac{K}{2}\sin A \sin\phi \tag{1-25}$$

$$\text{Noise} = \frac{K}{2}\cos B \cos\phi + \frac{1}{2}\cos B - \frac{K}{2}\sin B \sin\phi \tag{1-26}$$

To find the power, we have to evaluate the envelope (amplitude) of these two signals. Recall that for any given bandpass signal in rectangular form, that is, bandpass signal = $X \cos \omega_t - Y \sin \omega_t$, the envelope is

$$\text{Envelope} = (X^2 + Y^2)^{0.5}$$

Therefore, from Eqs. (1-25) and (1-26)

$$\text{Signal} = \left[\left(\frac{K}{2}\cos\phi + \frac{1}{2}\right)^2 + \left(\frac{K}{2}\sin\phi\right)^2\right]^{0.5} \tag{1-27}$$

$$\text{Noise} = \left[\left(\frac{K}{2}\cos\phi - \frac{1}{2}\right)^2 + \left(\frac{K}{2}\sin\phi\right)^2\right]^{0.5} \tag{1-28}$$

Finally, the S/N ratio can be found by taking 10 log the ratio of Eqs. (1-27) and (1-28):

$$S/N = 10\log\left(\frac{K^2 + 2K\cos\phi + 1}{K^2 - 2K\cos\phi + 1}\right) \tag{1-29}$$

1-6 BUILDING BLOCKS

Our earlier block diagram already referred to a variety of integrated circuits that can be used to build a wireless system—in particular, a portable telephone. If we open any of the earlier-mentioned magazines and go through its advertising section, we will find many suppliers of subsystems/components that fit this requirement.

They can be split into various technologies. The following list is a product overview of next-generation advances in wireless technology taken from an ad of Stanford Microdevices, one of the very aggressive component/subsystem companies:

- New SX amplifiers featuring 2.4-GHz MMICs
- GaAs heterojunction bipolar transistor (HBT) discrete transistors (100 mW to 10 W)
- InP/GaAs (indium phosphate/gallium arsenide) high-linearity gain blocks
- Millimeter-wave product line featuring ICs for LMDS
- Silicon–germanium product line (gain blocks and low-noise amplifiers)
- SXQ power modules for cellular and PCS applications
- Power modules featuring 4–25-W power amplifiers for land mobile amplifiers
- Thirty- to 120-W silicon LDMOS power transistors for PCS, CDMA, and W-CDMA
- SAW filters featuring integrated transceiver modules
- Electro-optic and data communications products

More information about Stanford products is available at **http://www.stanfordmicro.com/**. Another interesting company along these lines is Maxim Integrated Products

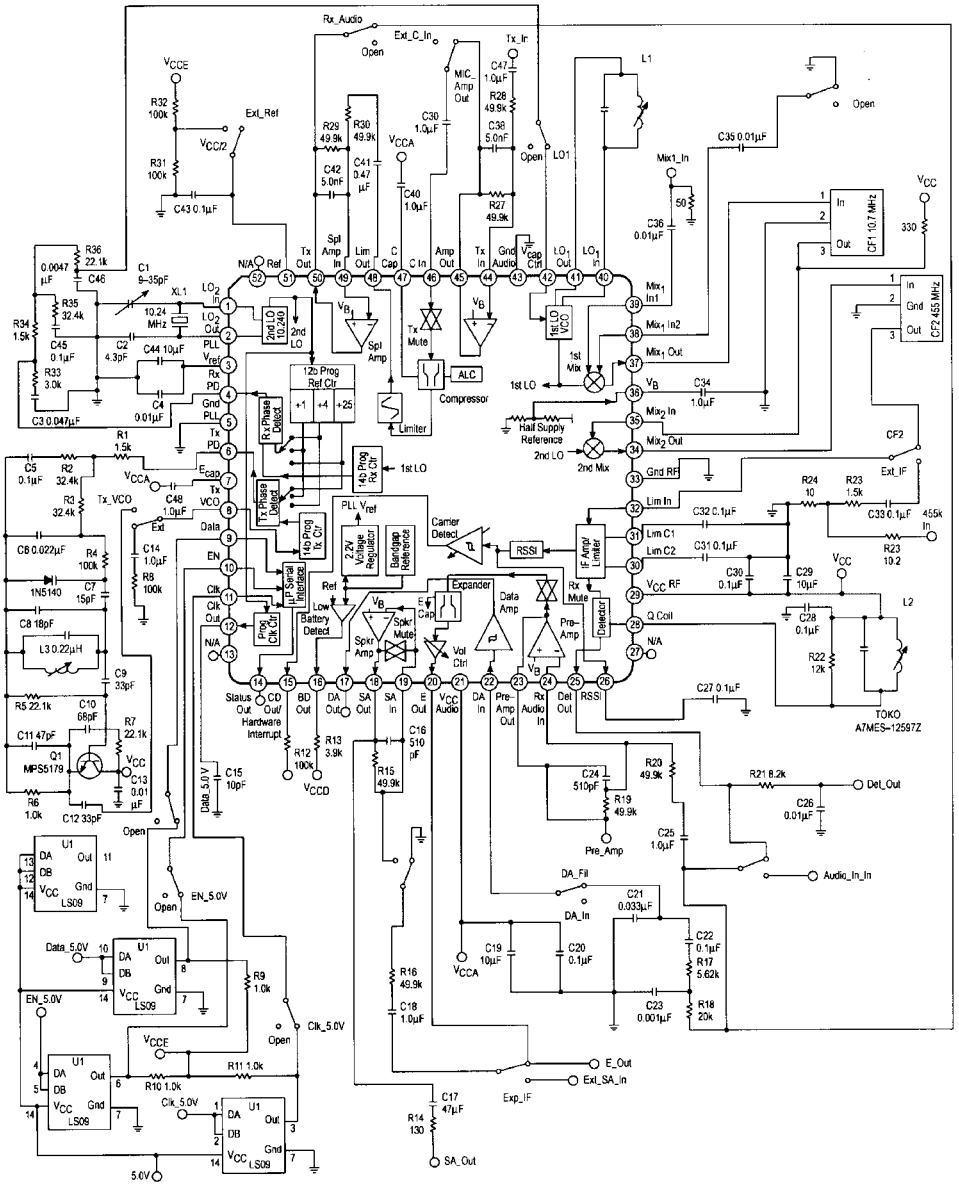

Figure 1-96 MC13109FB universal cordless telephone subsystem IC.

(**http://www.maxim-ic-com/**). They distribute an Analog Design Solutions brochure describing, among other things, the industry's first SiGe RFICs for improved radio front-end performance (1999). On the base-station side, companies such as Hewlett-Packard and Synergy Microwave produce high-performance components/modules as they are needed in the more hostile environment of base-station operation. The offerings in the field are changing very rapidly, and the best way to deal with this is to obtain subscriptions to the magazines mentioned earlier or contact manufacturers directly. Among those not mentioned are Alpha, Ericsson, Siemens (now Infineon Technologies), Motorola, and NEC.

In the beginning of this chapter we looked at block diagrams; here we focus on building blocks. Most manufacturers will try to move to the highest possible integration while avoiding external components. Figure 1-96, a test circuit for Motorola's MC13109FB cordless telephone subsystem IC, shows the level of complexity needed to test such an IC with all its functionality.

Another key issue at those frequencies is to really know a component's frequency dependencies. Figure 1-97 shows a good example. Typical components are capacitors and inductors as reactive elements, and resistors as passive elements. Depending on the type of integration, one may also have to look into the noise performance of integrated resistors. Examination of this issue is best achieved through discussions with the foundries. Along these lines, the dielectric material on which these surface-mounted components are mounted plays a big role and must be addressed individually.

Besser Associates of Los Altos, California, among other firms, offers a very nice one-day short course titled "Wireless Circuit Components: Measurements, Models and Data Extraction."

Table 1-11 presents a sampling of RFICs for wireless applications. These types of ICs, which were taken from Motorola, are made in similar form by many companies. The selection guide is useful in starting off with a design that is less integrated, therefore allowing the designer to have access to portions of the circuit that later "disappear" inside the IC.

1-7 SYSTEM SPECIFICATIONS AND THEIR RELATIONSHIP TO CIRCUIT DESIGN

Wireless communication involves a large range of signal powers—from levels on the order of 10^{-18} watt (at the receiver input) to 10^{2} watts (at a base-station transmitter output). A receiver must be able to demodulate signals that have been attenuated billions of times through propagation; a transmitter must be able to produce a properly modulated signal at a frequency suitable for propagation, at a level high enough to overcome worst-case propagation losses and provide a useful signal at the receiver. Gain is therefore an essential attribute of wireless systems. Because no single active device can provide all the gain required for transmission or reception, we must distribute the gain among multiple stages, designing each for optimum performance across the power span it bridges.

Two inescapable realities impose limits on the gain and absolute power output we may achieve with a given circuit: All real electrical and electronic networks generate noise to some degree, and all real electrical and electronic networks distort the signals applied to them to some degree. A signal weaker than a circuit's inherent noise cannot be amplified by that circuit because it remains indistinguishable from the noise. A signal that exceeds the power-handling capability of the circuit to which it is applied may be degraded, even rendered useless, by the resulting distortion. The following sections examine issues particular to system noise and linearity performance.

1-7-1 System Noise and Noise Floor

Assuming that a system's gain is sufficient, the weakest signal that may be processed satisfactorily, a figure of merit referred to as *noise floor* or (in receivers) *minimum detectable signal* (*MDS*), is limited by thermal noise, assumed to be equal to the noise power available from a resistor at 290 K (about 17 °C or 62 °F), an arbitrary reference value near standard room temperature. The noise power is equal to

$$P_n = kTB \tag{1-30}$$

where P_n is the noise power, k is Boltzmann's constant (1.38×10^{-23} watts per kelvin), T is the temperature in kelvins, and B is the bandwidth (in hertz) in which the noise appears. For $T = 290$ K, P_n is therefore 4.00×10^{-18} watts, or –174 dBm in a 1-Hz bandwidth. Increasing B to a value suitable for digital communications, such as 160 kHz for a GSM system, admits more noise to the network, raising the minimum noise power against which an incoming signal must compete to –122 dBm.

If the noise figure and bandwidth are known, the noise floor can be calculated using the equation

$$\text{Noise floor} = -174 \text{ dBm} + NF + 10 \log B \tag{1-31}$$

The trouble with this equation is that the "integrated" bandwidth depends so much on the selectivity shape factor, which is not always known. Figure 1-98 shows the translation of the bandwidth of a single tuned circuit with its Gaussian shape into its rectangular equivalent. The transformation is done by sizing the rectangle such that A′ = A and B′ = B; when this is true, the area of the rectangle equals the area under the curve.

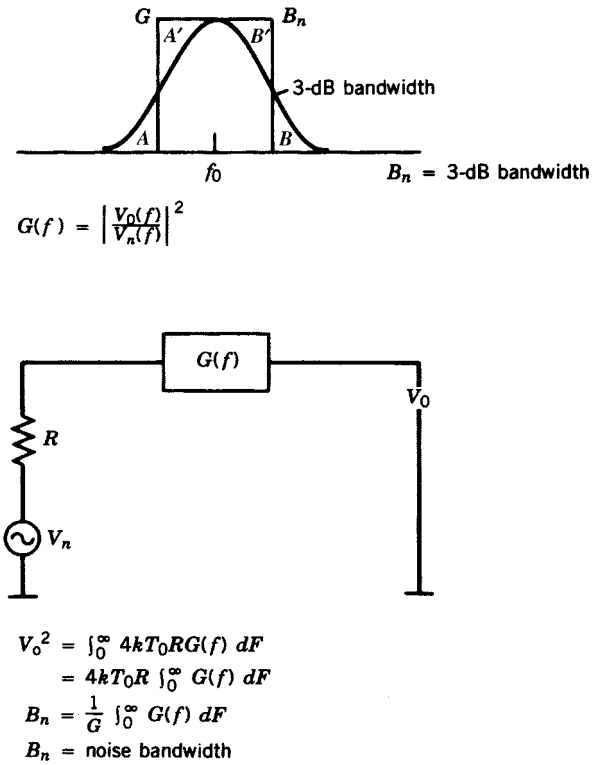

Figure 1-98 Graphical and mathematical explanation of the noise bandwidth from a comparison of the Gaussian-shaped bandwidth to the rectangular filter response.

Signal-to-Noise Ratio (S/N, SNR) and Sensitivity. Successful radiocommunication depends on the achievement of a specified minimum ratio of signal power to noise power, expressed in decibels, at the output of the receiver. The input voltage, expressed in absolute units or decibels relative to a microvolt (dBμV), necessary to achieve a particular signal-to-noise ratio in a particular bandwidth may be specified as a figure of merit called *sensitivity*. Because techniques used to measure S/N actually measure the ratio of signal-*plus-noise* to noise, specifications may refer to (or imply) S+N/N or (S+N)/N rather than S/N. The difference between (S+N)/N and S/N becomes negligible at high ratios of signal to noise; even at an SNR of 10 dB—a common value—the difference is only 0.46 dB [9].

Most receivers are designed to operate optimally when connected to an antenna system of a specified impedance (commonly 50 Ω), but relatively few receivers exhibit this design load impedance at their input terminals; that is, they are not designed for a conjugate input match. It is therefore customary to specify sensitivity in terms of "open circuit" voltage—the signal voltage that, with the receiver's antenna input terminated in its design antenna impedance, results in the desired ratio of signal to noise. If, as is commonly the case, the input voltage for a given SNR is determined using instrumentation calibrated in terms of *closed*-circuit voltage—that is, in terms of voltage across a load resistance equal to the instrument's source resistance—the voltage indicated will be one-half the open-circuit value for the SNR specified [10]. By convention, the open-circuit measurement condition is indicated by a sensitivity specification in volts of electromotive force (EMF). Specifying sensitivity in

terms of available signal power (usually decibels relative to 1 mW, or dBm) eliminates this open/closed-circuit confusion.

SINAD Ratio. Extending the measurement of signal-plus-noise to noise to include distortion results in a figure of merit called *SINAD* (signal-plus-noise-and-distortion), commonly applied to FM receivers:

$$SINAD = 10 \log_{10}\left(\frac{S+N+D}{N+D}\right) \tag{1-32}$$

where *SINAD* is in decibels, S is signal power, N is noise power, and D is distortion power. At a SINAD ratio of 12 dB—a common specification—the noise-and-distortion power is 25% that of the desired signal. As is true of (S+N)/N, SINAD closely approximates S/N at high ratios of signal to noise.

Bit Error Rate and Noise. For digital systems, signal-to-noise ratio and bit error rate are related. As introduced earlier, depending on the waveform, coding, and filtering, different BERs are related to particular SNRs (Figure 1-99). The SNR also depends on the interference from the synthesizer, as will be seen in the section on adjacent-channel power ratio (ACPR). Since a digital transmitter is always involved, in the on-the-air testing the laboratory measurement of SINAD cannot quite be correlated. At the IF level, we find the handover point between the transceiver's analog front end and its digital portion, and a standard noise-figure test setup, such as the one by Hewlett-Packard, is still a valuable instrument for evaluating noise figure and signal-to-noise ratio.

Here is an example for a digital measurement: Assume that we use a test generator like the SMIQ to evaluate a front end having an 8.8-dB noise figure. A 384-kbps π/4-DQPSK digital modulation signal (–5 dBm) is applied to the transceiver front end. Testing at 2.47 GHz, we find that the error vector magnitude (EVM; defined later in this section) is about 3.89% in transmit and about 1.37% in receive. To determine the receive sensitivity of the RF front end, the signal from the digitally modulated generator (at –95 dBm) is applied to the

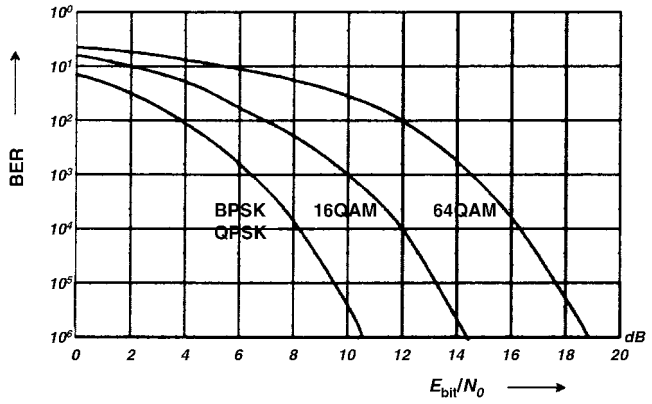

Figure 1-99 Bit error rate versus E_{bit}/N_0 for BPSK/QPSK, 16-QAM, and 64-QAM, showing the significantly greater SNR necessary for a given BER as the number of signal states is increased.

RF front end in receive mode. The measured EVM at 2.47 GHz is now 20%. By using the equation

$$S/N = -20 \log (EVM) \tag{1-33}$$

we see that the ratio that corresponds to an EVM of 20% is 14 dB, since

$$S/N = \frac{(E_S R_{S)}}{N_0 B} \tag{1-34}$$

where E_S is the energy of a symbol, R_S is the symbol rate, N_0 is the noise power density, and B is the bandwidth. Assuming a π/4-DQPSK signal and ratio of 14 dB, it can be determined that

$$E_S/N_0 = (S/N)\ (B/R_S) = 17 \text{ dB} \tag{1-35}$$

Assuming that the BER is 1E – 5, the required E_S/N_0 is 10 dB. Hence, from the definition of the sensitivity,

$$\begin{aligned} \text{Sensitivity} &= -144 + NF + R_S + E_S/N_0 \\ &= -144 + 8.8 + 10 \log(384/2) + 10 \\ &= -102 \text{ dBm} \end{aligned} \tag{1-36}$$

The value –144 is derived from kT_0 by taking the bandwidth into consideration.

The result obtained in Eq. (1-36) is consistent with the obtained E_S/N_0 of 17 dB from the measurement at –95 dBm input power [since –102 + (17 – 10) = –95]. Hence, it was determined that the receive sensitivity of the RF front end is approximately –102 dBm. We can then determine the dynamic range (DR) from

$$DR = \text{P}_{-1\text{dB}} - \text{Sensitivity} = -21 - 102 = 81 \text{ dB} \tag{1-37}$$

Noise Factor and Noise Figure. The noise floor predicted by Eq. (1-30) cannot be achieved and maintained in any real network or system of networks because all real networks generate noise. Determining how closely the SNR achieved at a given input level approaches the SNR achievable at that input level in a noiseless network is therefore of high interest to the circuit and system designer. The degree to which a network's noise contribution degrades the noise floor predicted by Eq. (1-30) is evaluated by its *noise factor* (*F*), which is expressed as the ratio

$$F = \frac{N_{\text{in}} + N_{\text{added}}}{N_{\text{in}}} \tag{1-38}$$

where F is the noise factor, N_{in} is the noise power available from the source, and N_{added} is the noise power added by the network, with both powers determined in the same bandwidth. Expressing this ratio in decibels ($10 \log_{10} F$) returns the *noise figure* (*NF*), a bandwidth-

independent figure of merit of great value in evaluating the noise performance of networks and communication systems. We can also express NF as the ratio of the network's input SNR to its output SNR:

$$NF = 10 \log_{10} \left[\frac{(S_{in}/N_{in})}{(S_{out}/N_{out})} \right] \tag{1-39}$$

where NF is the noise figure in decibels, S is signal power, and N is noise power, with the input and output values of these quantities signified by the subscripts and all powers determined in the same bandwidth. The noise figure of an ideal noiseless network is 0 dB; for all real, noisy networks, NF is positive. The NF of a lossy passive device is equal to its insertion loss.

Noise figure can also be defined for antennas and antenna systems:

$$NF_{ant} = 10 \log_{10} \frac{N_t + N_{ant}}{N_t} \tag{1-40}$$

where NF_{ant} is the antenna system noise figure in decibels, N_t is the antenna system's thermal noise power, as defined in Eq. (1-30), and N_{ant} is the total noise power picked up by the antenna system. From the lower end of the radio spectrum, and decreasingly up to approximately 400 MHz, noise intercepted by an antenna system from atmospheric, human-generated, and galactic sources will dominate NF_{ant} (Figure 1-100), and N_t can be considered as equivalent to the noise power of a resistor at 290 K. Atmospheric noise subsides above 40 MHz; from this region to perhaps 700 MHz, N_t is still largely negligible, with noise from human-generated and/or sky sources largely determining an antenna's noise figure. At these frequencies, an antenna's directivity and orientation relative to noise sources play a critical role in determining its noise figure; a strongly directive antenna located in a city suburb, for instance, exhibits a significantly higher noise figure when pointed toward the city center than

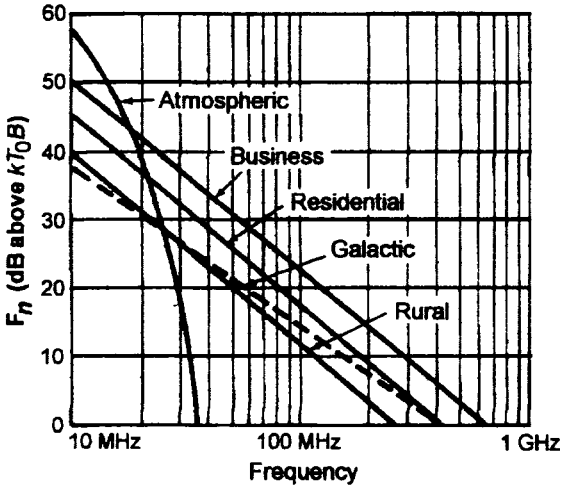

Figure 1-100 The higher the frequency, the more quiet the RF environment becomes, although the noise profile of specific sources may contradict this general rule.

it exhibits when pointed toward a more sparsely populated area. At frequencies above about 700 MHz, the RF environment is generally quieter, allowing receiver NF, not antenna NF, to more routinely limit a wireless receiver's sensitivity. At these frequencies, the concept of *noise temperature* is commonly used to evaluate the quietness of a receiver, its antenna system and its RF environment. Noise temperature is particularly useful in designing systems for space communication an antenna for which may be cooled, through radiation of a portion its own noise into the RF-cold sky, to a noise temperature an order of magnitude below 290 K.

Noise Figure of Cascaded Networks. The noise figure of two networks in cascade may be determined from

$$NF_{\text{total}} = 10 \log_{10}\left(F_1 + \frac{F_2 - 1}{G_1}\right) \tag{1-41}$$

where NF is the noise figure in dB, F_1 is the noise factor of the first network, F_2 is the noise factor of the second network, and G_1 is the gain (as a numerical ratio, *not* in dB) [11]. The noise figure of a system with more than two stages can be evaluated through repeated iterations of Eq. (1-41). Note that Eq. (1-41) assumes two conditions: (1) that F_1 and F_2 are determined in the same bandwidth, and (2) that the networks' input and output terminations are resistive—a condition that is commonly *not* true of RF amplifiers optimized for lowest noise. Equation (1-41) can be expanded to account for bandwidth, but accounting for complex terminations requires the use of *noise correlation matrix* techniques as described by Rohde et al. [9].

1-7-2 System Amplitude and Phase Behavior

If we could build electronic systems that were absolutely amplitude- and phase-linear, radiocommunication system design would be greatly simplified. An amplifier designed for a power gain of 10 dB, for example, would merely increase the power of all signals at its input by a factor of 10, regardless of their frequencies, while perfectly maintaining their relative phases. But all real electrical and electronic networks, even those designed (or supposed) to be amplitude- and phase-linear, exhibit amplitude and phase nonlinearity to some degree, just as they all generate noise to some degree.

The effects of amplitude nonlinearity, generically referred to as *nonlinear distortion*, include the generation, through *harmonic distortion* and/or *intermodulation distortion* (IMD), of output signals at frequencies not present at a system's input. Nonlinear distortion also results in *gain compression*—changes in system gain with changes in input-signal level. By convention, when workers in electronics refer to or consider a network's "linearity," they usually mean its *amplitude* linearity; likewise, by "distortion" they usually mean *nonlinear* distortion.

The effects of phase or frequency nonlinearity are generically referred to as *linear distortion* because they occur independently of signal amplitude and polarity. We often intentionally apply linear distortion through *filtering*, which modifies the amplitude relationships among existing spectral components of a signal without creating any new frequencies. Another linear-distortion effect, *phase* or *delay distortion*, results in the delay of signals of differing frequencies by differing amounts of time. In a system where signal phase conveys

information, as is true of most wireless links, phase distortion can seriously degrade communication.

The fact that all real networks are amplitude- and angle-nonlinear to some degree means that all real networks modify the amplitude and angle characteristics of the signals they handle. What is perhaps less obvious is that subjecting a signal to amplitude and angle nonlinearities causes "crosstalk" between its amplitude and angle characteristics. For example, through a nonlinear distortion effect called AM-to-PM conversion, changes in a signal's amplitude result in changes in its phase. Filtering an angle-modulated signal produces the reverse effect: Deprived by the filter's selectivity of spectral components necessary to maintain its envelope constancy, the signal emerges from the filter as a combination of angle and amplitude modulation.

Spectral Considerations of Analog and Digitally Modulated Signals. Many wireless modulation schemes exist and even more are proposed; all use angle (usually phase) modulation or a combination of phase and amplitude modulation using an emission format engineered to achieve multiple goals of information throughput, robustness, spectral and hardware efficiency, and reproducibility. Digital modulation is standard in mainstream wireless applications because it allows increased channel capacity, and immunity to noise and distortion, compared to analog systems. At the circuit-design level, the particulars of whether, or to what degree, a modulation scheme is AM, PM, analog, or digital matters less than the actual angle and amplitude characteristics of the signal(s) involved, and the tolerances within which these characteristics can be expected and allowed to vary.

A system's amplitude linearity is of major concern because of its relation to energy efficiency, receiver dynamic range, and transmitter spectral purity. Energy efficiency, important because many wireless applications use battery power, generally decreases inversely with amplitude linearity. Yet, sufficient amplitude linearity must be guaranteed in the front-end circuitry of wireless receivers subjected to multiple strong signals, and in all wireless receiver and transmitter stages handling variable-envelope signals.

Some digital modulation schemes, designed to be distortion-tolerant, produce constant-envelope signals; Gaussian minimum shift keying (GMSK) and Feher's quadrature phase shift keying (FQPSK) are examples of these. Such signals can be processed in highly nonlinear circuitry—for example, an RF power amplifier operated in saturation to maximize efficiency—without degrading their spectral composition. Other digital modulation schemes result in the emission—ideally—of a single PM sideband, with the carrier and all other sideband components suppressed. Such a signal exhibits, of necessity, phase and amplitude variations; the IS-54 cellular standard's $\pi/4$ differential quadrature phase shift keying ($\pi/4$-DQPSK) scheme, which results in envelope fluctuations of 3–6 dB, exemplifies this [12]. Intermodulation distortion among such a signal's spectral components can generate products that fall outside the bandwidth painstakingly controlled in the modulation process. This *spectral regrowth* must be minimized to prevent adjacent-channel interference (Figure 1-101).

For a better understanding, Figure 1-102 shows the various channels and the energy levels associated with them.

Amplitude Linearity Issues and Figures of Merit. A network's amplitude nonlinearity can be characterized by the expansion

$$y = k_1 f(x) + k_2[f(x)]^2 + k_3[f(x)]^3 + \text{higher-order terms} \tag{1-42}$$

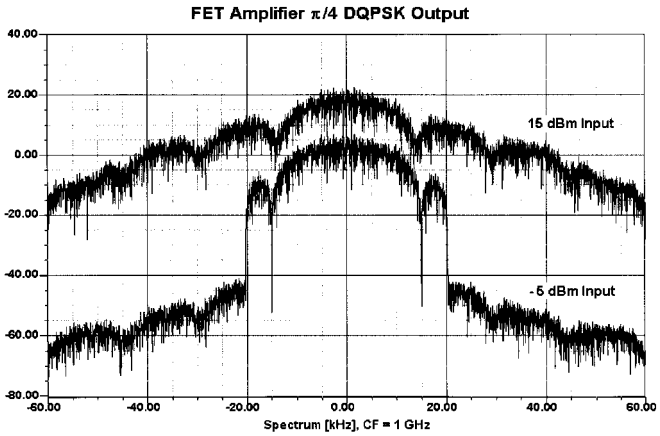

Figure 1-101 *Spectral regrowth* results when a variable-envelope emission, π/4-DQPSK in this case, is subjected to significant nonlinear distortion. This graph shows the simulated performance of a MESFET power amplifier operating at 1 GHz; the amplifier is 6 dB into compression when driven at 15 dBm.

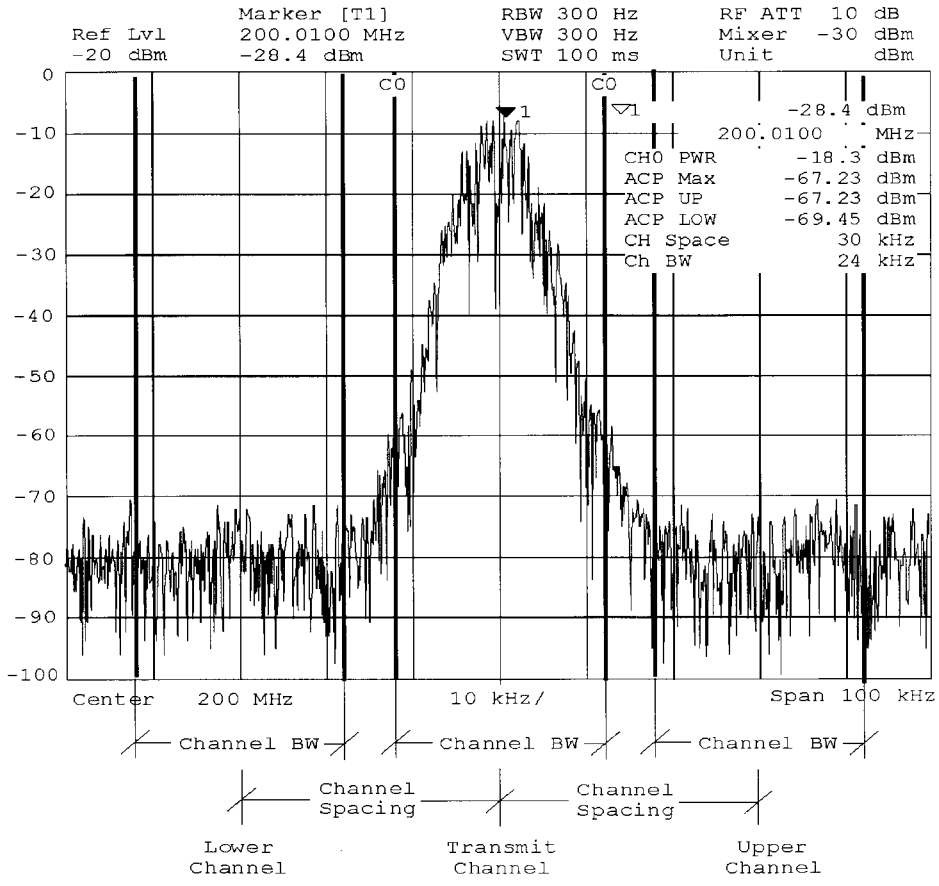

Figure 1-102 NADC signal and parameters, including channel spacing and channel bandwidth.

where y represents the output, the coefficients k_n represent complex quantities whose values can be determined by an analysis of the output waveforms, and $f(x)$ represents the input. Even though all practical networks exhibit amplitude nonlinearity, we can (and often do) refer to many networks as "linear." We say this of networks that are *sufficiently amplitude-linear for our purposes*—for example, weakly nonlinear networks in which small-signal operation is assumed even though the signal levels involved are sufficient to cause slight distortion. For many practical purposes, the first three terms of Eq. (1-42) adequately describe such a network's nonlinearity:

$$y = k_1 f(x) + k_2[f(x)]^2 + k_3[f(x)]^3 \tag{1-43}$$

In adopting this simplification, we assume also that the nonlinearity is frequency independent—that is, the network has sufficient bandwidth to allow all of the products predicted by Eq. (1-43) to appear at its output terminals unperturbed [13].

When multiple signals are present in a network, even weak nonlinearity can result in profound consequences. To illustrate this, we'll let $f(x)$ consist of two sinusoidal signals:

$$f(x) = A_1 \cos\omega_1 t + A_2 \cos\omega_2 t \tag{1-44}$$

We'll assume that ω_1 and ω_2 are close enough so that the coefficients k_i can be considered equal for both signals. We'll also assume for simplicity that all of the k_i are real. If Eq. (1-43) describes the network's response to an input $f(x)$, the response will be

$$\begin{aligned} y &= k_1(A_1 \cos\omega_1 t + A_2 \cos\omega_2 t) + k_2(A_1 \cos\omega_1 t + A_2 \cos\omega_2 t)^2 + k_3(A_1 \cos\omega_1 t + A_2 \cos\omega_2 t)^3 \\ &= k_1(A_2 \cos\omega_1 t + A_2 \cos\omega_2 t) \\ &\quad + k_2\left[A_1^2 \frac{1+\cos 2\omega_1 t}{2} + A_2^2 \frac{1+\cos 2\omega_2 t}{2} + A_1 A_2 \frac{\cos(\omega_1+\omega_2)t + \cos(\omega_1-\omega_2)t}{2}\right] \\ &\quad + k_3 \left\{ \begin{array}{l} \left[\left[A_1^3\left(\dfrac{\cos\omega_1 t}{2} + \dfrac{\cos\omega_2 t}{4} + \dfrac{\cos 3\omega_1 t}{4}\right) + A_2^3\left(\dfrac{3\cos\omega_2 t}{4} + \dfrac{\cos 3\omega_2 t}{4}\right)\right]\right] \\ + A_1^2 A_2[\tfrac{3}{2}\cos\omega_2 t + \tfrac{3}{4}\cos(2\omega_1 - \omega_2)t + \tfrac{3}{4}\cos(2\omega_1 - \omega_2)t] \\ + A_2^2 A_1[\tfrac{3}{2}\cos\omega_1 t + \tfrac{3}{4}\cos(2\omega_2 + \omega_1)t + \tfrac{3}{4}\cos(2\omega_2 - \omega_1)t] \end{array} \right\} \end{aligned} \tag{1-45}$$

The k_1 term of Eq. (1-45) represents the results of amplitude-linear behavior. No new frequency components have appeared; the two sine waves have merely been "rescaled" by k_1.

The second- and third-order terms of Eq. (1-45) represent the effects of harmonic distortion and intermodulation distortion. Second-order effects include second-harmonic distortion (the production of new signals at $2\omega_1$ and $2\omega_2$) and IMD (the production of new signals at $\omega_1 + \omega_2$ and $\omega_1 - \omega_2$). Third-order effects include gain compression, third-harmonic distortion (the production of new signals at $3\omega_1$ and $3\omega_2$), and IMD (the production of new signals at $2\omega_1 \pm \omega_2$ and $2\omega_2 \pm \omega_1$).

Gain Compression. Gain compression occurs when a network cannot increase its output amplitude in linear proportion to an amplitude increase at its input; gain *saturation* occurs when a network's output amplitude stops increasing (in practice, it may actually decrease) with increases in input amplitude. We can deduce from Eq. (1-45) that the amplitude of the $\cos\omega_1 t$ signal has become

$$A_1' = k_1 A_1 + k_3\left(\tfrac{3}{4}A_1^3 + \frac{3}{2}A_1 A_2^2\right) \tag{1-46}$$

Because k_3 will normally be negative, a large signal $A_2 \cos\omega_2 t$ can effectively mask a smaller signal $A_1 \cos\omega_1 t$ by reducing the network's gain. This third-order effect, known as *blocking* or *desensitization* when it occurs in a receiver, is a special case of gain compression. The presence of additional signals results in a greater reduction in gain; the gain reduction for each signal is a function of the relative levels of all signals present. A receiver's blocking behavior may be characterized in terms of the level of off-channel signal necessary to reduce the strength of an in-passband signal by a specified value, typically 1 dB; alternatively, the decibel ratio of the off-channel signal's power to the receiver's noise-floor power may be cited as *blocking dynamic range*. Desensitization may also be characterized in terms of the off-channel signal power necessary to degrade a system's SNR by a specified value.

Multiple signals need not be present for gain compression to occur. If only one signal is present, the ratio of gain with distortion to the network's idealized (linear) gain is

$$A_1' = \frac{k_1 + k_3\left(\tfrac{3}{4}A_1^2\right)}{k_1} \tag{1-47}$$

This is referred to as the *single-tone gain-compression factor*. Figure 1-103 shows how the k_3 term causes a network's gain to deviate from the ideal. The point at which a network's power gain is down 1 dB from the ideal for a single signal is a figure of merit known as the *1-dB compression point* (P_{-1dB}). Many networks (including many receiving and low-level transmitting circuits, such as low-noise amplifiers, mixers, and IF amplifiers) are usually operated under small-signal conditions—at levels sufficiently below P_{-1dB} to maintain high linearity. As we'll see, however, some networks (including power amplifiers for wireless systems) may be operated under large-signal conditions—near or in compression—to achieve optimum efficiency at some specified level of linearity. Figure 1-104 shows what happens when a digital emission that uses amplitude to convey information is subjected to amplitude compression.

Intermodulation. The new signals produced through intermodulation distortion (IMD) can profoundly affect the performance even of systems operated far below gain compression (Figure 1-105). IMD products of significant power can appear at frequencies remote from, in, and/or near the system passband, resulting in demodulation errors (in reception) and interference to other communications (in transmission). Where an IMD product appears relative to the passband depends on the passband width and center frequency, the frequencies of the signals present at the system input, and the order of the nonlinearity involved. These factors also determine the strength of an IMD product relative to the desired signal.

Second-order IMD (IM_2) results, for an input consisting of two signals ω_1 and ω_2, in the production of new signals at $\omega_1 + \omega_2$ and $\omega_1 - \omega_2$; third-order IMD (IM_3) results, for an input

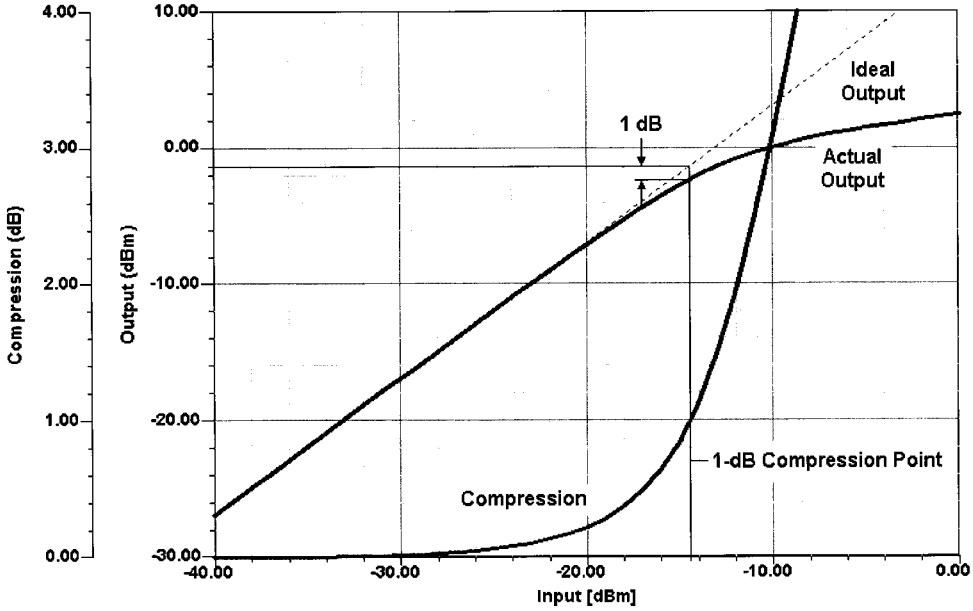

Figure 1-103 The power level at which a network's power output is down 1 dB relative to that of its ideally linear equivalent is a figure of merit known as the *1-dB compression point* (P_{-1dB}). The 1-dB compression point can be expressed relative to input power ($P_{-1dB,in}$) or output power ($P_{-1dB,out}$). For the amplifier simulated here, $P_{-1dB,in} \approx -14.5$ dBm and $P_{-1dB,out} \approx -1.3$ dBm.

consisting of two signals ω_1 and ω_2, in the production of new signals at $2\omega_1 \pm \omega_2$ and $2\omega_2 \pm \omega_1$.

Under small-signal conditions—that is, at levels well below compression—the power of an IM_2 product varies by 2 dB, and the power of an IM_3 product varies by 3 dB, per decibel change in input power level. This allows us to derive a network figure of merit, the *intermodulation intercept point* (*IP*), for a given IM order by extrapolating a network's linear and IM responses to their point of intersection (Figure 1-106)—the point at which their powers would be equal if compression did not occur. The intercept point for a given IM order

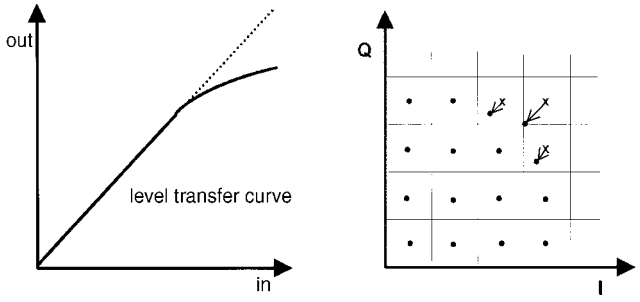

Figure 1-104 Influence of differential amplitude error (compression) on a QAM constellation.

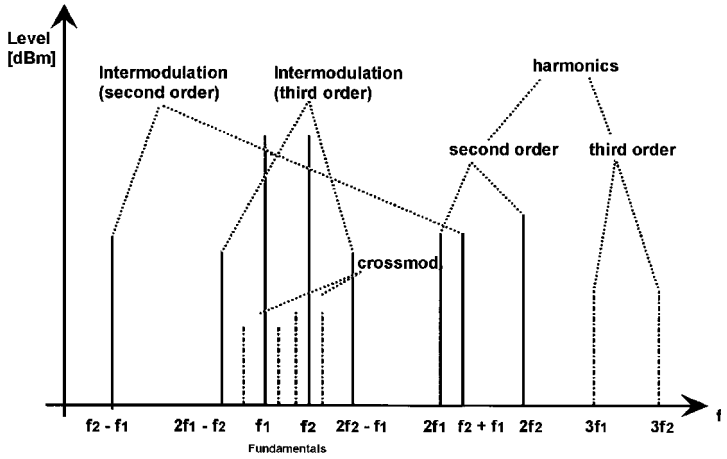

Figure 1-105 Relationships between fundamental and spurious signals, including harmonics and products of intermodulation.

n can be expressed, and should always be characterized, relative to input power ($IP_{n,\text{in}}$) or output power ($IP_{n,\text{out}}$); the IP_{in} and IP_{out} values differ by the network's linear gain. For equal-level test tones, $IP_{n,\text{in}}$ can be determined by

$$IP_{n,\text{in}} = \frac{nP_A - P_{\text{IM}_n}}{n-1} \tag{1-48}$$

where n is the order, P_A is the input power (of one tone), P_{IM_n} is the power of the IM product, and IP is the intercept point. The intercept point for cascaded networks can be determined from

$$IP_{2,\text{in}} = \frac{1}{\left(\frac{1}{\sqrt{IP1}} + \frac{G}{\sqrt{IP2}}\right)^2} \tag{1-49}$$

for IP_2 and from

$$IP_{3,\text{in}} = \frac{1}{\frac{1}{IP1} + \frac{G}{IP2}} \tag{1-50}$$

for IP_3. In both equations, $IP1$ is the input intercept of Stage 1 in watts, $IP2$ is the input intercept of Stage 2 in watts, and G is the gain of Stage 1 (as a numerical ratio, *not* in decibels). Both equations assume the worst-case condition, in which the distortion products of both stages add in-phase.

The ratio of the signal power to the IM-product power, the *distortion ratio*, can be expressed as

$$R_{dn} = (n-1)\left[IP_{n,\text{in}} - P_{\text{in}}\right] \tag{1-51}$$

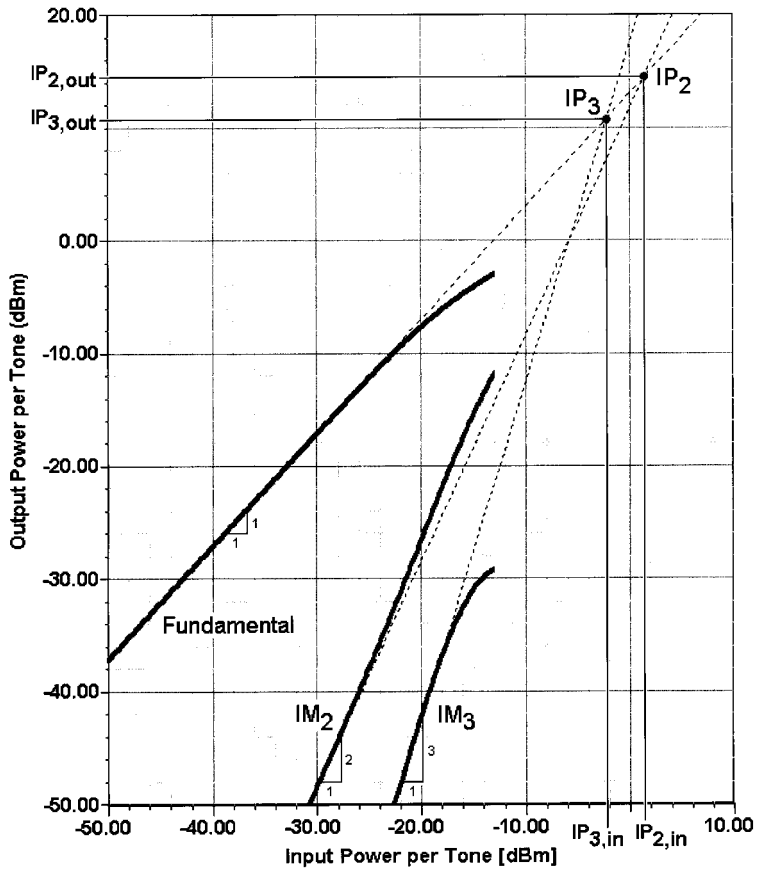

Figure 1-106 The level at which the power of one of a network's IM products equals that of the network's linear output is a figure of merit known as the *intermodulation intercept point* (*IP*). The intercept point for a given IM order *n* can be expressed, and should always be characterized, relative to input power ($IP_{n,in}$) or output power ($IP_{n,out}$); the IP_{in} and IP_{out} values differ by the network's linear gain. For the amplifier simulated here, $IP_{2,in} \approx 1.5$ dBm, $IP_{2,out} \approx 14.5$ dBm, $IP_{3,in} \approx -2.3$ dBm, and $IP_{3,out} \approx 10.7$ dBm. Each curve depicts the power in one tone of the response evaluated.

where n is the order, R_{dn} is the distortion ratio, $IP_{n,in}$ is the input intercept point, and P_{in} is the input power of one tone.

Discussions of IMD have traditionally downplayed the importance of IM_2 because the incidental distributed filtering contributed by the tuned circuitry once common in radiocommunication systems was usually enough to render out-of-passband IM_2 products caused by in-passband signals, and in-passband IM_2 products caused by out-of-passband signals, vanishingly weak compared to fundamental and IM_3 signals. In broadband systems that operate at bandwidths of an octave or more, however, in-passband signals may produce significantly strong in-passband IM_2 and second-harmonic products. In such applications, balanced circuit structures (such as push–pull amplifiers and balanced mixers) can be used to minimize IM_2 and other even-order nonlinear products.

As with IM_2, which IM_3 products are important depends on the spacing of the signals involved and the relative width of the system passband. If ω_1 and ω_2 are of approximately

the same frequency, the additive products $2\omega_1 + \omega_2$ and $2\omega_2 + \omega_1$ will be outside the passband of a narrowband system. The subtractive products $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$, however, will likely appear near or within the system passband. The IM_3 performance of any network subjected to multiple signals is therefore of critical importance, and an array of IM_3-related, sometimes application-specific, figures of merit has evolved as a result.

Dynamic Range. As we have seen, thermal noise sets the lower limit of the power span over which a network can operate. Distortion—that is, degradation by distortion of the signal's ability to convey information—sets the upper limit of a network's power span. Because the power level at which distortion becomes intolerable varies with signal type and application, a generic definition has evolved: The upper limit of a network's power span is the level at which the power of one IM product of a specified order is equal in power to the network's noise floor. The ratio of the noise-floor power to the upper-limit signal power is referred to as the network's *dynamic range* (*DR*), often more carefully characterized as *two-tone IMD dynamic range*, which, when evaluated with equal-power test tones, is a figure of merit commonly used to characterize receivers. When $IP_{n,\text{in}}$ and MDS are known, IMD DR can be determined from

$$DR_n = \frac{(n-1)[IP_{n,\text{in}} - MDS]}{n} \tag{1-52}$$

where *DR* is the dynamic range in decibels, *n* is the order, IP_{in} is the input intercept power in dBm, and *MDS* is the minimum detectable signal power in dBm.

Dynamic Measure: A New Receiver Figure of Merit. Taken by themselves, the IP_n and DR figures of merit can be misleading in the sense that broadband, resistive attenuation directly improves them by the amount of attenuation added while directly degrading NF by the same amount. The NF and MDS figures of merit can mislead us because they convey no sense of suitability to task. This can be significant when we interconnect networks and systems of differing noise floors and IMD dynamic ranges—as we do, for example, when connecting a receiver to an antenna. As a means of better evaluating a receiver's front-end performance, the authors propose a new figure of merit, *dynamic measure*, defined as

$$DM = [(IP_{3,\text{in}} + \text{Att}) - (NF_r + \text{Att} + NF_{ant})]\frac{NF_r}{NF_r + \text{Att}} \tag{1-53}$$

where *DM* is the dynamic measure, a dimensionless number; $IP_{3,\text{in}}$ is the receiver's third-order input intercept in dBμV (instead of dBm) without any added attenuation; NF_r is the receiver noise figure in dB without any added attenuation; NF_{ant} is the antenna-system noise figure in dB as determined by Eq. (1-40); and Att is the decibel value of any added attenuation, which is sometimes used to shift the upper and lower limits of a system's dynamic range to higher absolute signal levels, increasing $IP_{3,\text{in}}$ at the expense of making the system more "deaf." Our dynamic measure figure of merit takes this trade-off into account to allow more straightforward comparisons of systems that have the same dynamic range but different sensitivities. Setting NF_{ant} equal to zero allows evaluation of receiver performance under laboratory conditions; setting NF_{ant} equal to the measured or expected NF of the antenna system to which the receiver will be connected allows evaluation of receiver performance in a system sense. Rather than express IP_3 in dBm, we are going to

express it in dBμV. This is necessary because for negative values of the difference between IP_3 and the added noise figure, the multiplier term will make the result larger when its numerical value is less than 1.

The usefulness of the dynamic measure figure of merit is evident when we consider several examples.

Example 1. Here we evaluate a receiver that exhibits the characteristics $IP_{3,\text{in}} = 16$ dBm(123 dBμV), $NF_r = 8$ dB, and $NF_{\text{ant}} = 10$ dB. We calculate its laboratory DM by setting NF_{ant} equal to 0:

$$DM = [123 - (8 + 0)]\frac{8}{8 + 0} = [115]1 = 115 \tag{1-54}$$

Setting NF_{ant} equal to 10 returns the receiver's system DM:

$$DM = [123 - (8 + 10)]\frac{8}{8 + 0} = [115]1 = 105 \tag{1-55}$$

Example 2. This setup consists of the Example 1 receiver with a 10-dB pad switched in, resulting in the characteristics $IP_{3,\text{in}} = 26$ dBm(133 dBμV), $NF_r = 18$ dB, and $NF_{\text{ant}} = 10$ dB. Setting NF_{ant} equal to 0, we calculate its laboratory DM as

$$DM = [133 - (8 + 10 + 0)]\frac{8}{8 + 10} = [115]0.4444 = 51.1 \tag{1-56}$$

A comparison with Eq. (1-54) shows that, although inserting the 10-dB pad has shifted $IP_{3,\text{in}}$ from 16 dBm (123 dBμV) to 26 dBm (133 dBμV), it has also increased the resulting NF from 8 to 18 dB, reducing the DM from 115 to 51.1. Inserting the pad also degrades the receiver's system DM compared to Example 1, as we see by setting NF_{ant} equal to 10:

$$DM = [133 - (8 + 10 + 10)]\frac{8}{8 + 10} = [105]0.4444 = 46.7 \tag{1-57}$$

Example 3. On the other hand, had we inserted 2 dB of attenuation rather than 10 dB [$IP_{3,\text{in}} = 18$ dBm (125 dBμV), $NF_r = 10$ dB, and $NF_{\text{ant}} = 10$ dB], the laboratory DM would have been

$$DM = [125 - (8 + 2 + 0)]\frac{8}{8 + 2} = [115]0.8 = 92 \tag{1-58}$$

and the system DM would have been

$$DM = [125 - (8 + 2 + 10)]\frac{8}{8 + 2} = [105]0.8 = 84 \tag{1-59}$$

Table 1-12 shows these and several additional examples for comparison.

The interested reader will notice the following: The receiver in Example 1 (base NF 8 dB) was unnecessarily sensitive compared to the antenna NF of 10 dB, so adding a 2-dB pad increased the intercept point by 2 dB and matched the antenna noise floor. Yet, the equation rightfully indicates a loss of dynamic measure. The relationship between NF_{ant} and NF_r is not taken

Table 1-12 Eight dynamic measure cases compared

Example	System	Base $IP_{3,in}$ (dBm)	Base $IP_{3,in}$ (dBμV)	Attenuation (dB)	Resulting $IP_{3,in}$ (dBm)	Resulting $IP_{3,in}$ (dBμV)	Base NF_r (dB)	Resulting NF_r (dB)	NF_{ant} (dB)	DM_{lab}	DM_{system}
1	HF receiver	16.0	123.0	0.0	16.0	123.0	8.0	8.0	10.0	115.0	105.0

into consideration. Also, we have decided to leave it to the reader to develop a formula that deals with the addition of a preamplifier rather than an attenuator. This will complicate the formula because the preamplifier's gain and noise figure are not necessarily related.

Triple-Beat Distortion and Cross-Modulation. P_{-1dB} is a single-tone figure of merit; blocking, intercept point, and dynamic range evaluate two-tone behavior. For networks that must handle AM and composite (AM and angle modulation) signals very linearly, such as television transmitters and cable TV distribution systems, a three-tone figure of merit called *triple-beat distortion* has gained acceptance. Signals at ω_1 and ω_2 (closely spaced) and ω_3 (positioned far away from ω_1 and ω_2) are applied to the network under test, at levels, frequencies, and spacings that vary with the application. One triple-beat distortion figure of merit is the ratio, expressed in decibels, of the IM product at $\omega_3 + (\omega_2 - \omega_1)$ to one of the network's linear outputs at a specified output level. Alternatively, the triple-beat figure of merit may express the network output level at which a specified triple-beat ratio occurs.

Triple-beat distortion is the mechanism underlying cross-modulation, a form of intermodulation in which one or more AM signals present in a network amplitude-modulate all

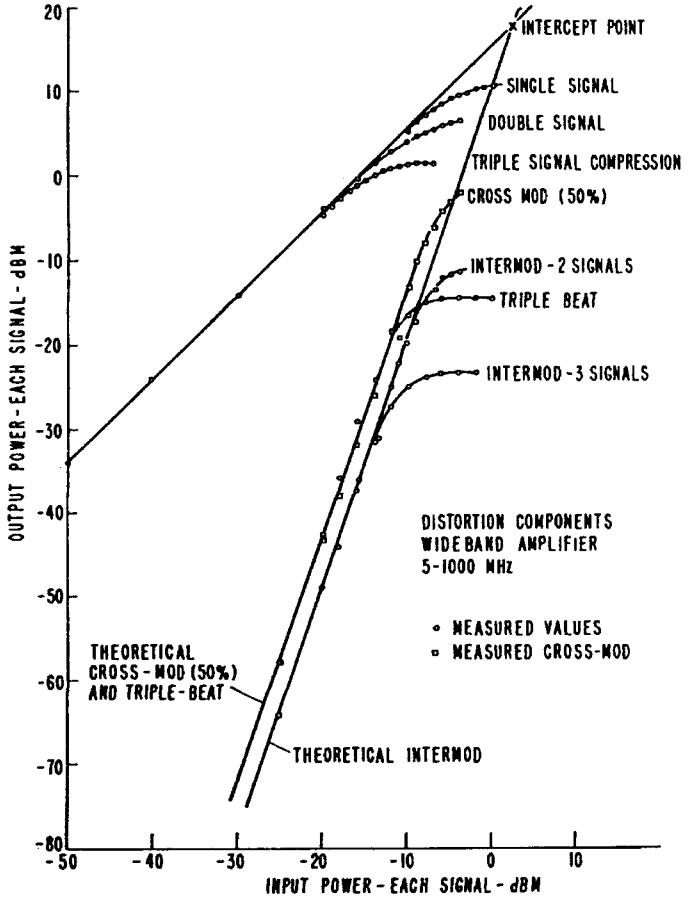

Figure 1-107 Measured distortion components in a wideband (5–1000 MHz) amplifier. Figure 1-108 shows a magnified view of the gain-compression region [15].

signals present in the network [14]. Angle-modulation-based wireless systems are largely immune to such effects.

Figures 1-107 and 1-108 graph the results of gain compression, two-tone intermodulation, cross-modulation, and triple-beat testing on a wideband (5–1000 MHz) amplifier.

Noise Power Ratio. Triple-beat testing is one way of improving on two-tone testing as a means of evaluating a network's intermodulation behavior in the presence of multiple signals. Another figure of merit, *noise power ratio* (*NPR*), uses thermal noise as a test signal. The test measures the introduction, by IM, of noise into a quiet slot created by the insertion of a bandstop filter, equal in stopband width to the width of the measurement channel, between the noise generator and the network under test (Figure 1-109).

Large-Signal Effects. Except for P_{-1dB}, the figures of merit discussed so far evaluate amplitude nonlinearity under small-signal conditions. At input powers that drive a network into gain compression and saturation, IM products of odd orders higher than 3 become significant, and curves, dips, and nulls appear in their characteristics (Figure 1-110). Phase shifts related to nonlinear (primarily voltage-dependent) capacitances in solid-state devices are one cause of these effects. Under such conditions, a network may exhibit hysteresis, with its behavior at any given instant depending not only on the voltage or current applied to it but also on its recent history [16].

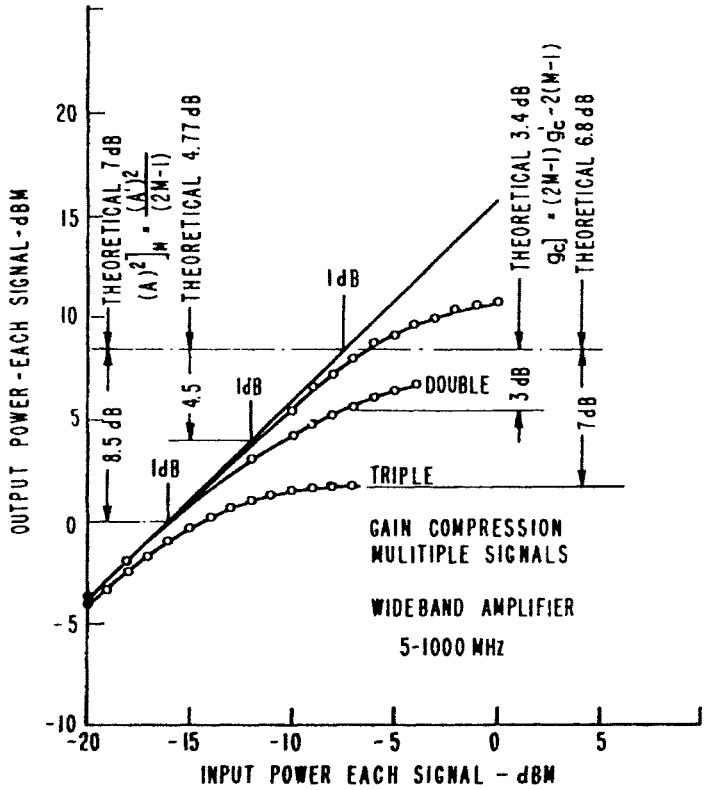

Figure 1-108 Measured multiple-signal gain compression of the 5- to 1000-MHz amplifier [15].

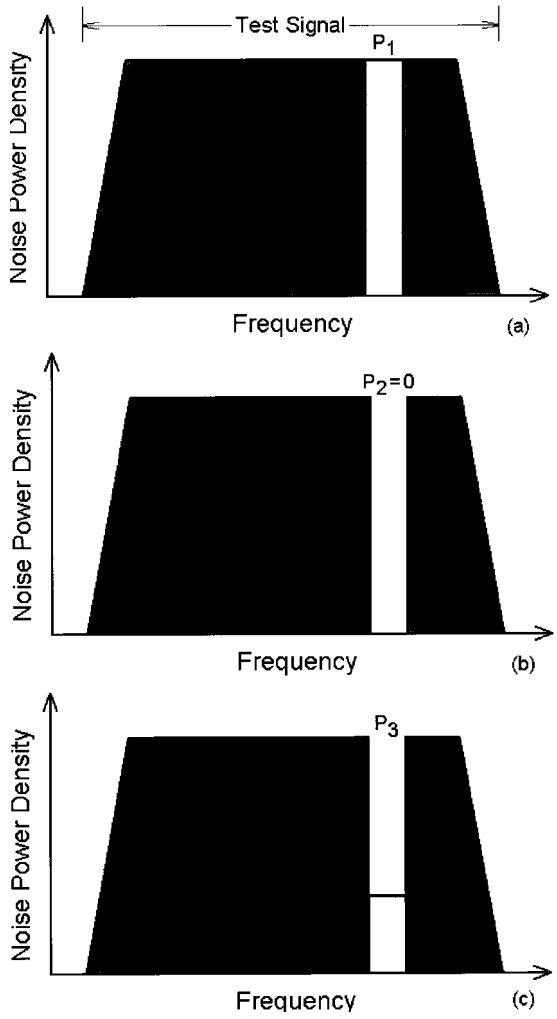

Figure 1-109 Determining a network's *noise power ratio* (*NPR*) involves the application of a test signal consisting of thermal noise [15]. (a) The reference measurement-channel noise power, P_1, is then measured. (b) Next, a bandstop filter is placed between the noise generator and network under test to keep the test signal out of the measurement channel. Assuming sufficient filter attenuation, if the network were absolutely noiseless and linear, the ideal noise power in the measurement channel, P_2, would then be zero. (c) In practice, the network's own thermal noise and intermodulation between noise components outside the measurement channel result in an actual measurement-channel noise power (P_3) greater than zero. The noise power ratio equals P_1/P_3.

AM-to-PM Conversion. The nonlinear distortion effects we've discussed so far can be termed *AM-to-AM distortion*—distortion that, to a degree that depends on the amplitude of the signal(s) applied to the network, results in changes in the network's gain and/or production of signals at new frequencies. AM-to-PM distortion can also occur. As a network nears saturation, part of its driving signal goes into shifting the bias point(s) of its active device(s), changing their drive-dependent reactances and shifting the phase of the output signal relative to its value at input levels below compression (Figures 1-111 and 1-112). This

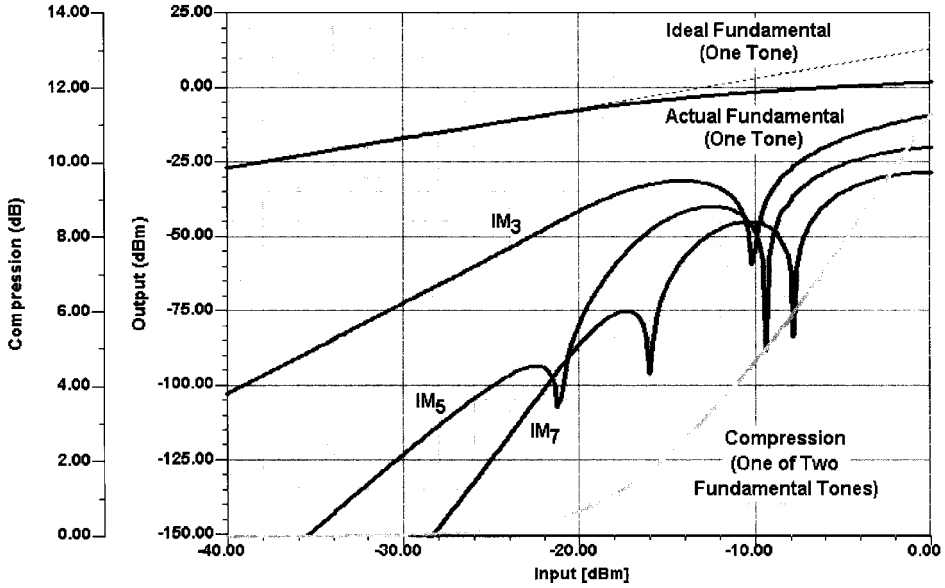

Figure 1-110 As a network is driven into compression, IM products at odd orders higher than 3 become significant, and phase shifts in power-dependent device capacitances cause curves and dips in the IM characteristics. The onset of these departures from IM-response linearity occurs at generally lower input power levels for higher IM orders; their severity, and their position on the IM curves, differs among the various products of a given order and varies with network topology and tone spacing. Figures of merit based on straight-line IM responses fail to usefully predict nonlinear network behavior under these conditions. This graph shows the simulated performance of a single-BJT broadband amplifier driven by two equal-amplitude tones at 10 and 11 MHz.

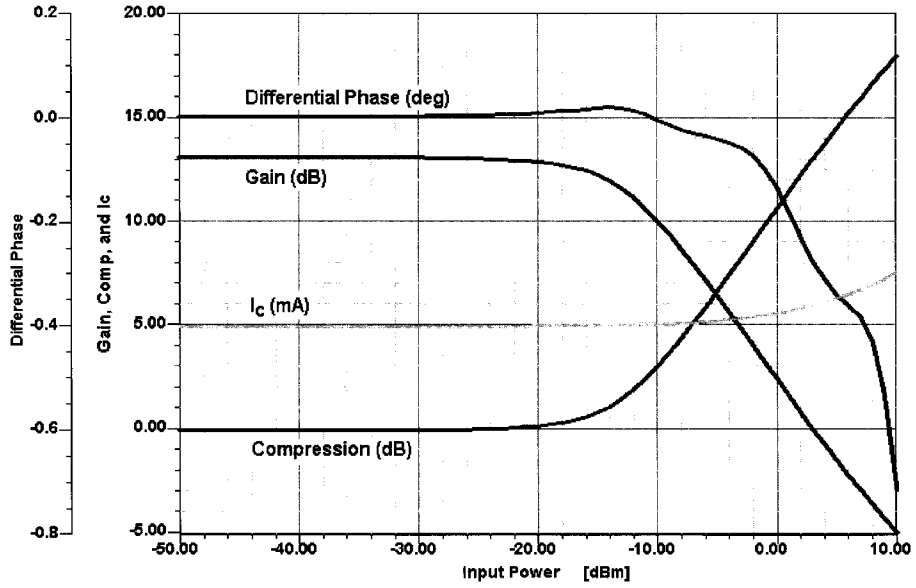

Figure 1-111 Driving a network into compression and saturation shifts the bias point(s) of its active device(s), changing their drive-dependent reactances and shifting the phase of the output signal relative to its value at input levels below compression. This graph shows the simulated performance of a single-BJT broadband amplifier driven by a single tone at 10 MHz.

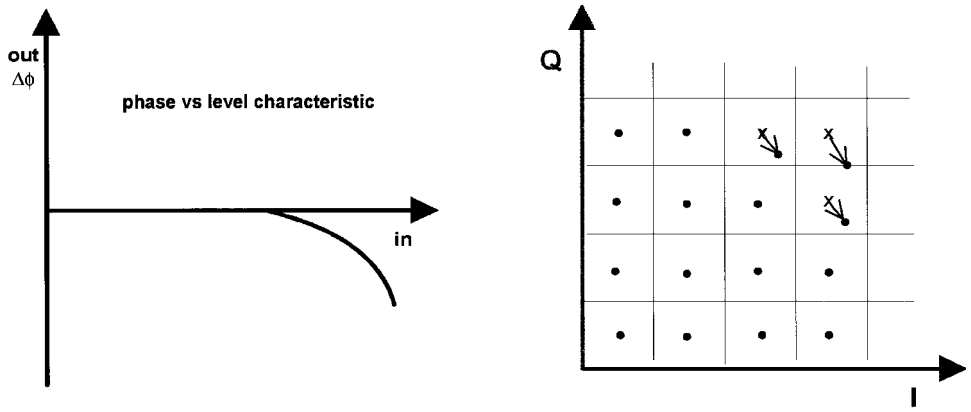

Figure 1-112 Influence of differential phase error (AM-to-PM conversion) on a QAM constellation.

effect, *AM-to-PM conversion*, can cause incidental phase modulation that degrades the performance of digital communication systems.

Spectral Regrowth and Adjacent-Channel Power Ratio. Spectral regrowth occurs largely as a result of third-, fifth-, and seventh-order IMD in power amplifiers operated near or in compression—at power levels where hysteretic IM effects result in poor agreement between measured behavior and predictions based on small-signal IM figures of merit [17]. We therefore evaluate the impact of spectral regrowth more directly, using a figure of merit called *adjacent-channel power ratio* (ACPR). ACPR measurement techniques that incorporate memory can be used to increase ACPR predictions for networks that exhibit saturation hysteresis [18]. Figure 1-113 shows the critical relationship between compression, power-added efficiency, and ACPR in a MESFET power amplifier.

Phase Response Issues and Figures of Merit. We have already seen how large-signal nonlinear distortion can result in amplitude-dependent phase shifts through AM-to-PM conversion. Because phase linearity is critical at *all* signal levels in PM systems, especially those using digital modulation, we must also consider linear distortion in evaluating networks used in wireless systems.

Differential Group Delay. Every frequency-selective network subjects signals passing through it to some degree of time delay. Ideally, this delay, also known as *group* or *envelope delay*, does not vary with frequency; that is, the network's phase shift versus frequency response is monotonic and linear. In practice, a network's time delay varies across its passband, transition bands, and stopbands, exhibiting curvature, ripple, and transition-band peaks (Figure 1-114). The network's *differential* group delay—its group-delay spread—is therefore of considerable importance. This is especially so in digitally modulated systems, where the resulting phase distortion can cause errors in modulation and demodulation.

Effects of Phase Noise. As Chapter 5 will discuss in detail, the phase of an oscillator's output signal is subject to random phase variations (Figures 1-115 and 1-116). Called *phase noise*, this effect is often quantified as the decibel ratio of the phase-noise power in a single

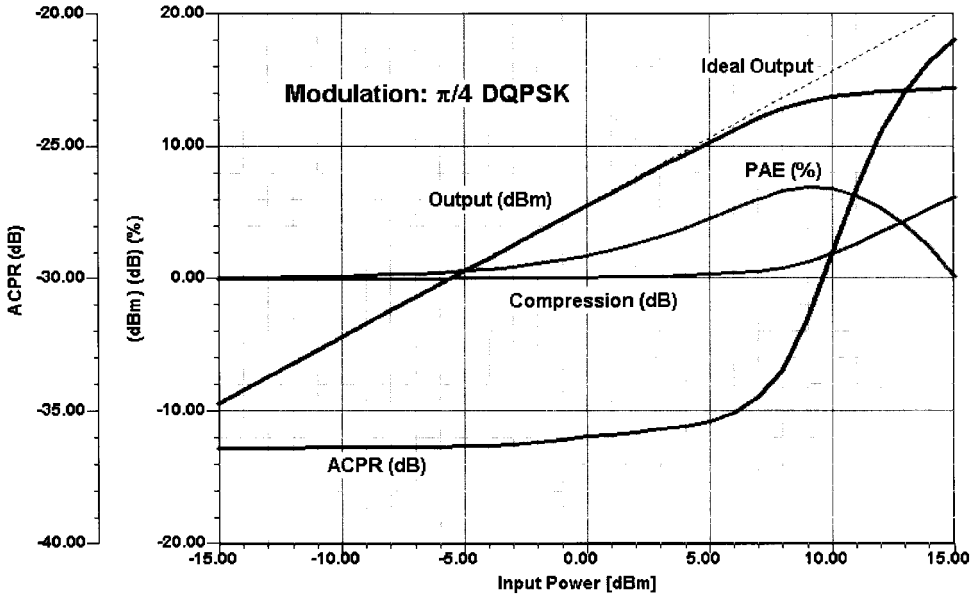

Figure 1-113 Keeping adjacent-channel interference under control can involve a critical trade-off between a wireless transmitter's power-added efficiency (PAE) and ACPR, as shown in this graph of the simulated behavior of the 1-GHz MESFET power amplifier introduced into Figure 1-101. As the amplifier is driven into compression, a peak occurs in the PAE response—in this case, at P_{-1dB}—and the ACPR rises sharply.

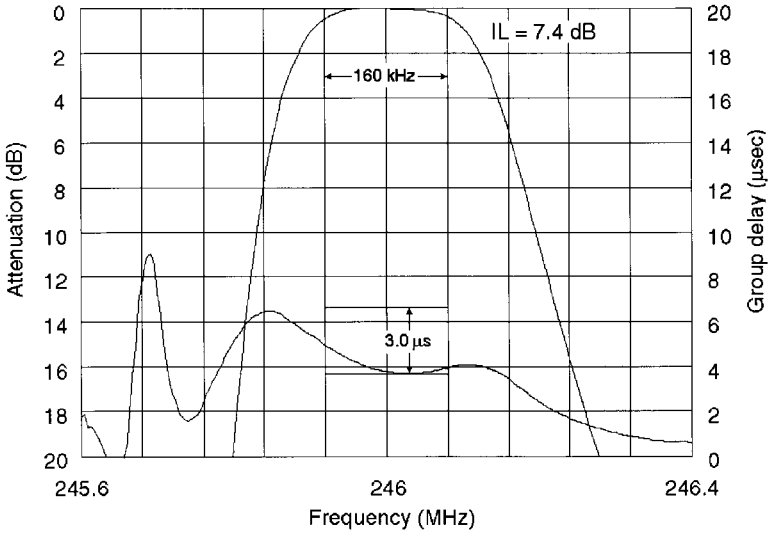

Figure 1-114 Close-in amplitude and group-delay responses for a 246-MHz SAW filter designed for GSM applications [19]. This filter is well within its 3.0-μs differential group-delay specification across its passband (160 kHz at –3 dB); the peaks just outside the passband limits are characteristic of a network's transition-band phase response.

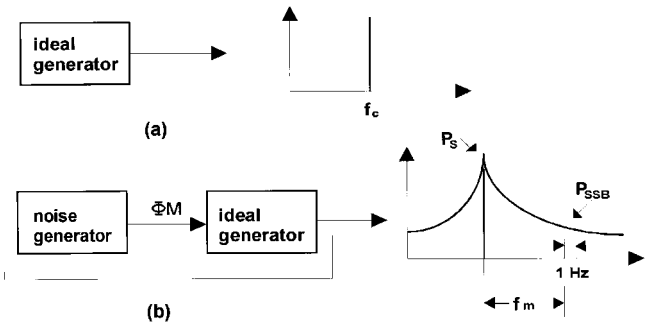

Figure 1-115 SSB phase noise. (a) An ideal signal generator would produce an absolutely pure carrier. (b) A real signal generator acts like an ideal generator driven by a noise generator, producing a noise-modulated carrier.

(the upper or lower) phase-noise sideband, in a 1-Hz bandwidth centered at a specified frequency offset from the oscillator carrier, to the carrier power (Figure 1-117); alternatively, it may be specified in degrees rms. A microwave voltage-controlled oscillator, for instance, might exhibit an SSB phase noise of –95 dBc/Hz at 10 kHz. Oscillator phase noise may manifest itself, through a mechanism known as *reciprocal mixing*, as the emission of unacceptably strong noise outside a transmitter's occupied bandwidth or as an increase in receiver noise floor. Phase noise may also directly introduce phase errors that result in modulation and demodulation errors.

Because the oscillators used for frequency translation in wireless systems are usually embedded in phase-locked loops, their phase-noise characteristics differ from those of "bare" oscillators as shown in Figures 1-118 and 1-119. Figures 1-120 and 1-121 show the measured phase noise of the Rohde & Schwarz SMY and SMIQ signal generators. The SMY is a low-cost signal source, while the SMIQ is a very high performance signal generator capable of being programmed for all digital modulations; therefore, their PLL systems exhibit different phase-noise versus frequency responses as the measured results show.

Reciprocal Mixing. In reciprocal mixing, incoming signals mix with LO sideband energy to produce IF output (Figure 1-122). Because one of the two signals is usually noise, the resulting IF output is usually noise. (Reciprocal mixing effects are not limited to noise;

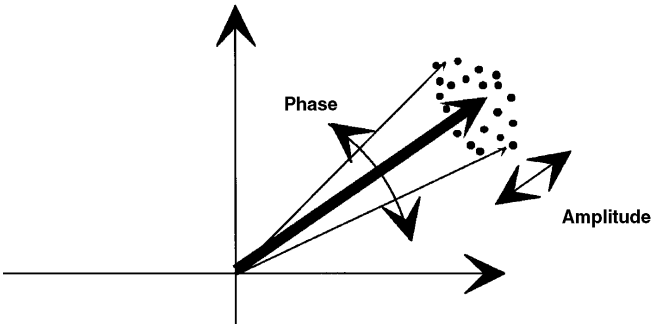

Figure 1-116 Oscillator noise can be split into amplitude and phase components.

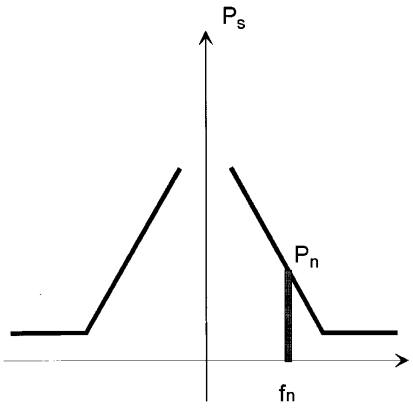


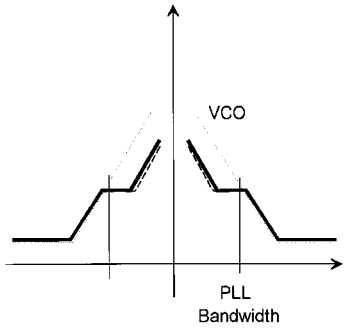
$$L(f) = 10 * \log \frac{P_n}{P_s}$$

P_n = Sideband noise in 1-Hz bandwidth at offset frequency f_n

P_S = Total signal power

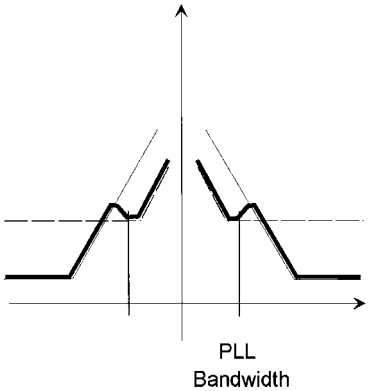
Single-sideband phase noise is expressed in dBc measured in a bandwidth of 1 Hz [dBc(Hz)] at offset frequency f_n.

Figure 1-117 Phase noise calculation.



Phase Noise is controlled by reference phase noise within PLL bandwidth and follows VCO noise outside PLL bandwidth

Figure 1-118 Phase noise of an oscillator controlled by a phase-locked loop.



Improper designed PLL bandwidth

Phase noise increases outside of PLL bandwidth

Figure 1-119 Effect of improper loop-filter design.

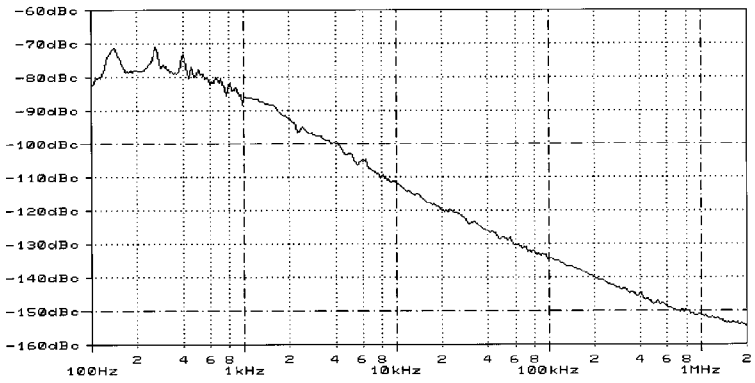


Figure 1-120 Measured phase noise of the Rohde & Schwarz SMY signal generator at 1 GHz. This signal generator has no provision for digital modulation and therefore shows the best possible phase noise in its class.

discrete-frequency oscillator sideband components, such as those resulting from crosstalk to or reference energy on a VCO's control line, or the discrete-frequency spurious signals endemic to direct digital synthesis, can also mix incoming signals to IF.) In practice, the resulting noise-floor increase can compromise the receiver's ability to detect weak signals and achieve a high IMD dynamic range; on the test bench, noise from reciprocal mixing may invalidate desensitization, cross-modulation, and IM testing by obscuring the weak signals that must be measured in making these tests.

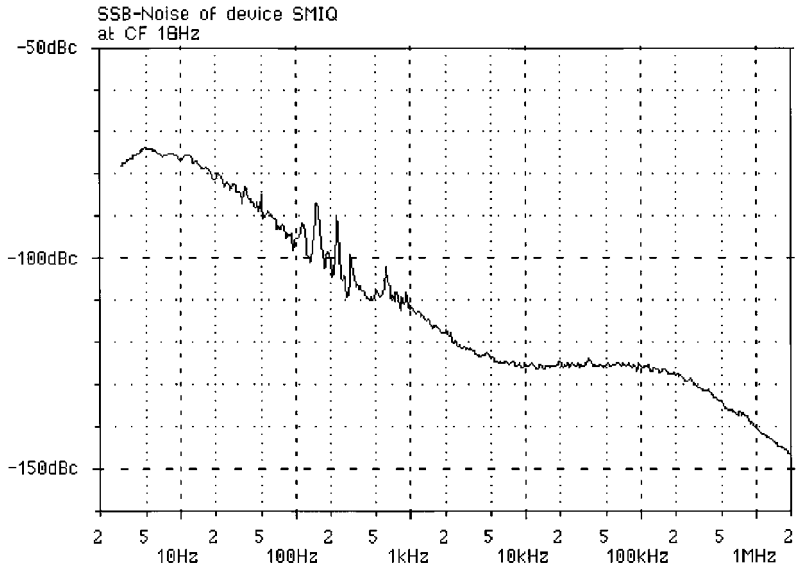

Figure 1-121 Measured phase noise of the Rohde & Schwarz SMIQ signal generator at 1 GHz. This signal generator is optimized for all digital modulation capabilities and can be configured via appropriate programming. Above 10 kHz, the influence of the wideband loop becomes noticeable; above 200 kHz, the resonator *Q* takes over.

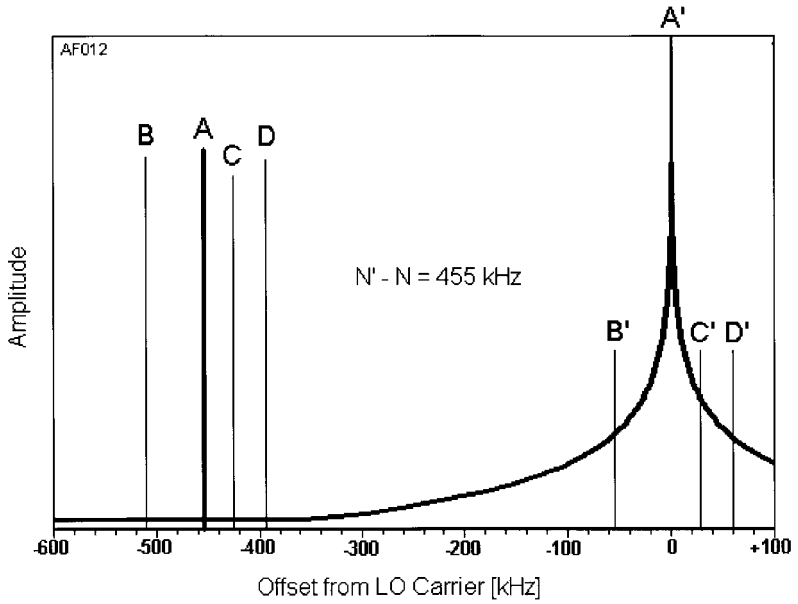

Figure 1-122 Reciprocal mixing occurs when incoming signals mix energy from an oscillator's sidebands to the IF. In this example, the oscillator is tuned so that its carrier, at A′, heterodynes the desired signal, A, to the 455 kHz as intended; at the same time, the undesired signals B, C, and D mix the oscillator noise sideband energy at B′, C′, and D′, respectively, to the IF. Depending on the levels of the interfering signals and the noise sideband energy, the result may be a significant rise in the receiver noise floor.

Figure 1-123 shows a typical arrangement of a dual-conversion receiver with local oscillators. The signal coming from the antenna is filtered by an arrangement of tuned circuits referred to as providing *input selectivity*. For a minimum attenuation in the passband, an operating bandwidth of

$$B = \frac{f}{\sqrt{2}Q_L}$$

is needed. This approximate formula is valid for the insertion loss of about 1 dB due to loaded Q.

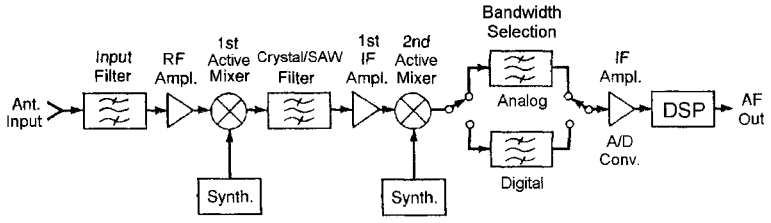

Figure 1-123 Block diagram of an analog/digital receiver showing the signal path from antenna to audio output. No AGC or other auxiliary circuits are shown. This receiver principle can be used for all types of modulation, since the demodulation is done in the DSP block.

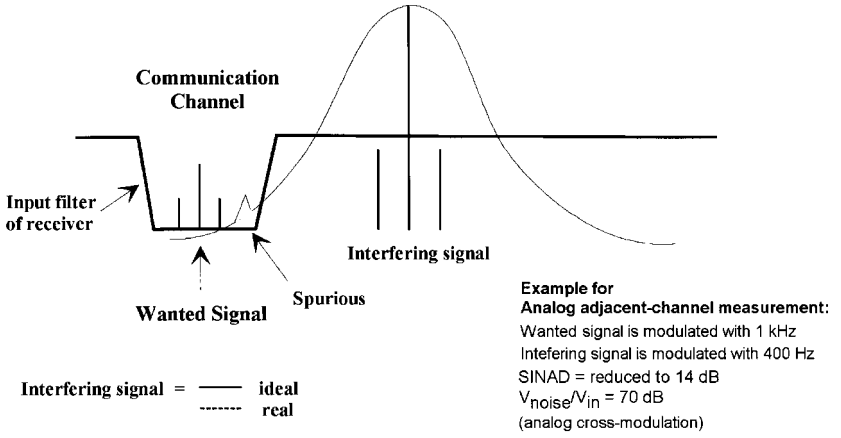

Figure 1-124 Principle of selectivity measurement for analog receivers.

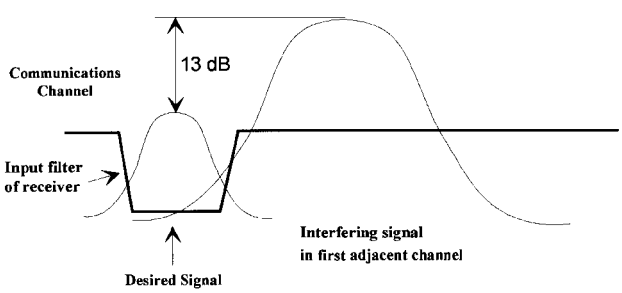
The filter in the first IF is typically either a SAW filter (in the frequency range from 500 MHz to 1 GHz) or a crystal filter (45–120 MHz). Typical insertion loss is 6 dB. Since these resonators have significantly higher Q than LC circuits, the bandwidth for the first IF will vary from ±5 to ±500 kHz. It is now obvious that the first RF filter does not protect the first IF because of its wider bandwidth. For typical communication receivers, IF bandwidths from 150 Hz to 1 MHz are found; for digital modulation, the bandwidth varies roughly from 30 kHz to 1 MHz. Therefore, the IF filter in the second IF has to accommodate these bandwidths; otherwise, the second mixer easily gets into trouble from overloading. This also means that both synthesizer paths must be of low-noise and low-spurious design. The second IF of this arrangement (Figure 1-123) can be either analog or digital, or even zero-IF. In practical terms, there are good reasons for using IFs like 50/3 kHz, as in hi-fi audio equipment such as the Walkman, with DSP processing at this frequency (50/3 kHz) using the low-cost modules found in mass-market consumer products.

Figures 1-124 and 1-125 show the principle of selectivity measurement for both analog and digital signals. The main difference is that the occupied bandwidth for the digital system can be significantly wider, and yet both signals can be interfered with by either a noise synthesizer/first LO or a synthesizer that has unwanted spurious frequencies. Such a spurious signal is shown in Figure 1-124. In the case of Figure 1-124, the analog adjacent-channel



Example of ACP suppression:

	Requirement	Good Generator
NADC		
30kHz from carrier	<-26 dBc	-51 dBc
60kHz "	<-45 dBc	-70 dBc
90kHz "	<-49 dBc	-75 dBc
PDC		
50kHz from carrier	<-45 dBc	-65 dBc
100kHz "	<-60 dBc	-76 dBc

Figure 1-125 Principle of selectivity measurement for digital receivers.

measurement has some of the characteristics of cross-modulation and intermodulation, while in the digital system the problem with the adjacent-channel power suppression is more obvious. Rarely has the concept of adjacent-channel power (ACP) been used with analog systems. Also, to meet the standards, signal generators have to be used that are better, with some headroom, than the required dynamic measurement. We have therefore included in Figure 1-125 the achievable performance for a practical signal generator—in this case, the Rohde & Schwarz SMHU58.

Because reciprocal mixing produces the effect of noise leakage around IF filtering, it plays a role in determining a receiver's dynamic selectivity (Figure 1-126). There is little value in using IF filtering that exhibits more stopband rejection than a value 3–10 dB greater than that which results in an acceptable reciprocal mixing level.

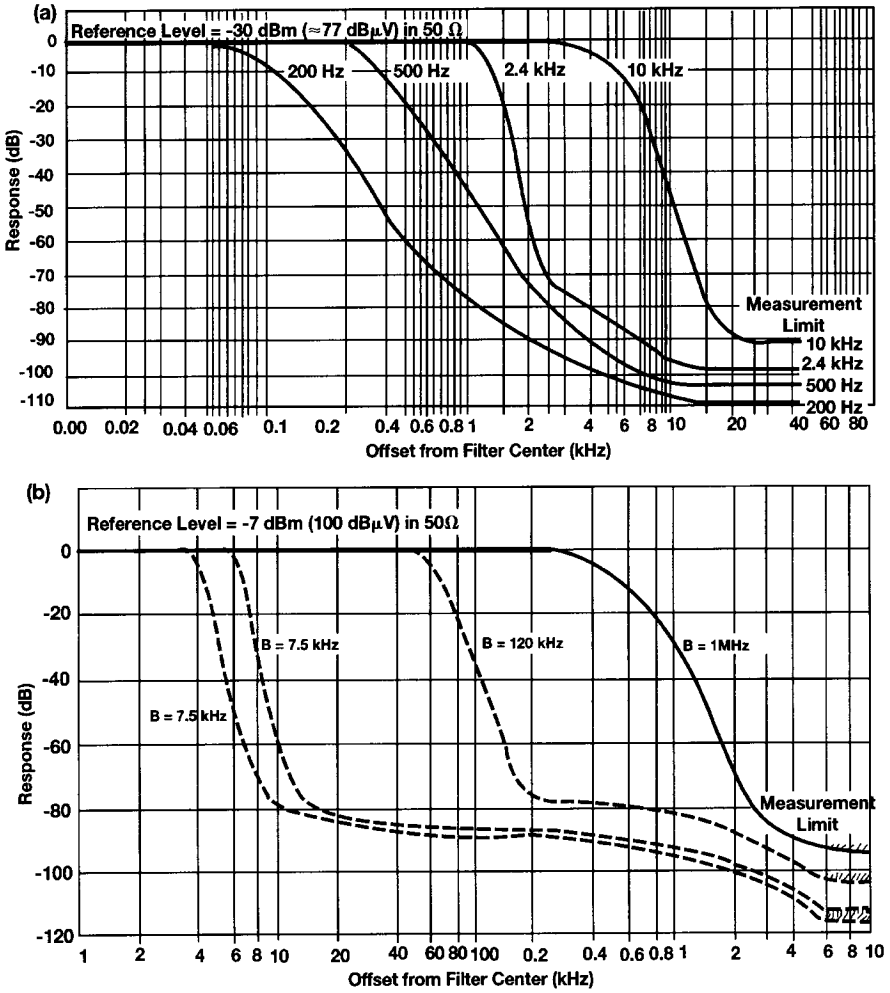


Figure 1-126 Dynamic selectivity versus IF bandwidth for (a) the Rohde & Schwarz ESH2 test receiver (9 kHz to 30 MHz) and (b) the Rohde & Schwarz ESV test receiver (10 MHz to 1 GHz). Reciprocal mixing widens the ESH2's 2.4-kHz response below –70 dB (–100 dBm) at (a) and the ESV's 7.5-, 12-, and 120-kHz responses below approximately –80 dB (–87 dBm) at (b).

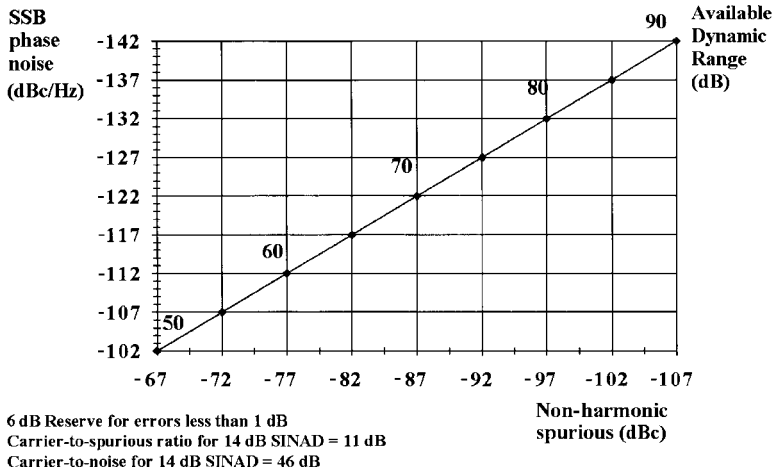

Figure 1-127 This graph shows the available dynamic range, which is determined either by the masking of the unwanted signal by phase noise or by discrete spurious signals. As far as the culprit synthesizer is concerned, it can be either the local oscillator or the effect of a strong adjacent-channel signal that takes over the function of the local oscillator.

Although additional RF selectivity can reduce the number of signals that contribute to the noise, improving the LO's spectral purity is the only effective way to reduce reciprocal mixing noise from *all* signals present at a mixer's RF port.

Factoring in the effect of discrete spurious signals with that of oscillator phase noise can give us the useful dynamic range of which an instrument or receiver is capable (Figure 1-127).

In evaluating the performance of digital wireless systems, we are interested in determining a receiver's resistance to adjacent-channel signals.

Phase Errors. In PM systems, especially those employing digital modulation, oscillator phase noise contributes directly to modulation and demodulation errors by introducing random phase variations that cannot be corrected by phase-locking techniques (Figure 1-128). The greater the number of phase states a modulation scheme entails, the greater its sensitivity to phase noise.

When an output signal is produced by mixing two signals, the resulting phase noise depends on whether the input signals are *correlated*—all referred to the same system clock—or uncorrelated, as shown in Figure 1-129.

Error Vector Magnitude. Several earlier figures (1-104, 1-112, and 1-128) have shown how particular sources of amplitude and/or phase error can shift the values of a digital emission's data states toward decision boundaries, resulting in increased BER due to intersymbol interference. Figures 1-130, 1-131, and 1-132 show three additional sources of such errors.

A figure of merit known as *error vector magnitude* (*EVM*) has been developed as a sensitive indicator of the presence and severity of such errors. An emission's error vector magnitude is the magnitude of the phasor difference as a function of time between an ideal reference signal and the measured transmitted signal after its timing, amplitude, frequency, phase, and dc offset have been modified by circuitry and/or propagation. Figure 1-133 illustrates the EVM concept.

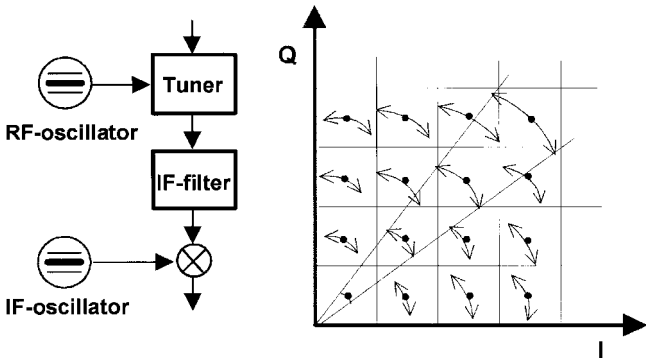

Figure 1-128 Phase noise is critical to digitally modulated communication systems because of the modulation errors it can introduce. Intersymbol interference (ISI), accompanied by a rise in BER, results when state values become so badly error-blurred that they fall into the regions of adjacent states. This drawing depicts only the results of phase errors introduced by phase noise; in actual systems, thermal noise, AM-to-PM conversion, differential group delay, propagation, and other factors may also contribute to the spreading of state amplitude and phase values.

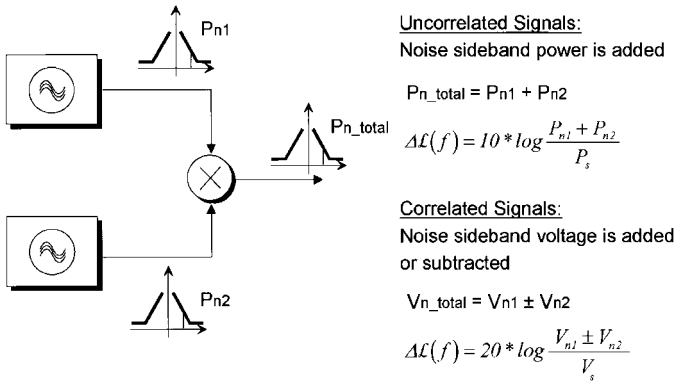

Figure 1-129 The noise sideband power of a signal that results from mixing two signals depends on whether the signals are correlated—referenced to the same system clock—or uncorrelated.

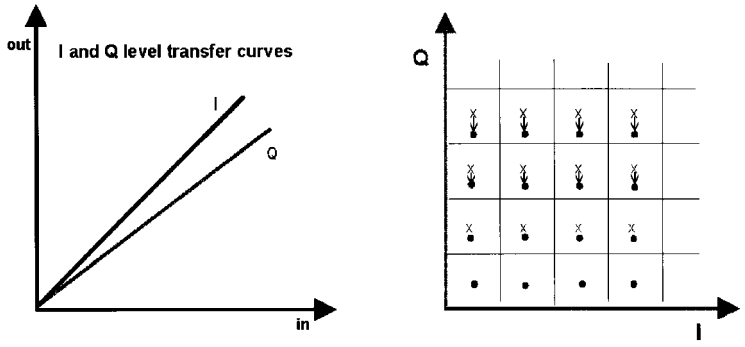

Figure 1-130 Effect of gain imbalance between I and Q channels on a data signal's phase constellation.

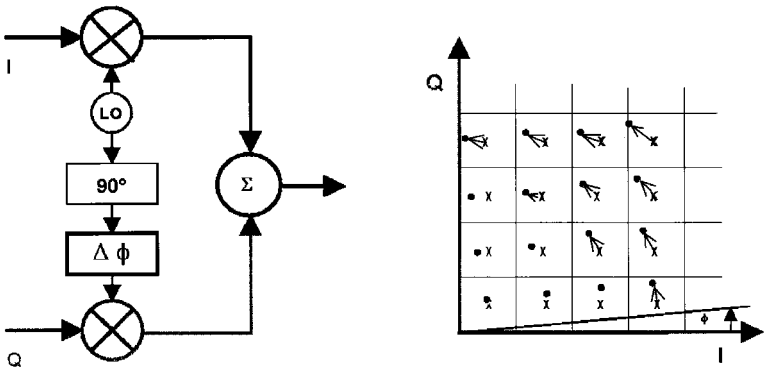

Figure 1-131 Effect of quadrature offset on a data signal's phase constellation.

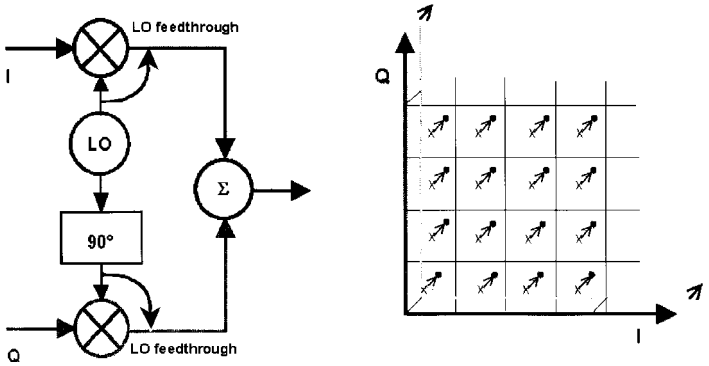

Figure 1-132 Effect of LO-feedthrough-based IQ offset on a data signal's phase constellation.

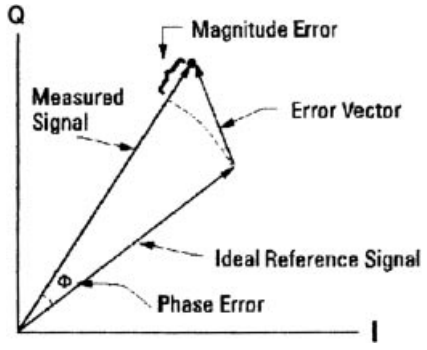

Figure 1-133 Representing errors in a digitally modulated signal's in-phase (I) and quadrature (Q) values relative to the ideal as a single error vector allows us to derive the resulting *error vector magnitude* (*EVM*), a sensitive indicator of transmission quality [20].

1-8 TESTING

1-8-1 Introduction

Testing of digital circuits deviates from the typical analog measurements, and yet the analog measurements are still necessary and related. As an example, the second-generation (2G) cellular telephone standards really have addressed only the transfer of voice and are just beginning to look into the transfer of data. Some services allow limited "e-mails," which are really messages that appear on the handset LCD after a delay. The future 3G standards with adaptive bandwidth will address high-speed data and video.

Since the major use of 2G phones is voice, information such as signal-to-noise ratio as a function of many things is important. In particular, because of the Doppler effect and the use of digital rather than analog signals, where the phase information is significant, the designer ends up using coding schemes for error correction—specifically, forward error correction (FEC). The signal-to-noise ratio as we know it from analog circuits now determines the bit error rate (BER), and its tolerable values depend on the type of modulation used. Because of correlation, it is possible to "rescue" a voice with a bit error rate of 1E – 4, but for higher data rates with little, if any, correlation, we are looking for BERs down to 1E – 9. The actual bit error rate depends on the type of filtering, coding, modulation, and demodulation. In several earlier figures (1-53 and 1-57) we related BER to signal-to-noise ratio; this is a key issue in receiver design.

Another problem in receivers that has to do with the transmitter of a second station is adjacent-channel power ratio (ACPR). Given the fact that a transmitter handling digital modulation delivers its power in pulses, its transmission may affect adjacent channels by producing transient spurious signals similar to what we call *splatter* in analog SSB systems. This is a function of the linearity of the transmitter system all the way out to the antenna and forces most designers to resort to less-efficient Class A operation. As possible alternatives, some researchers are looking into Class D and E modulation, more about which is found in the power amplifier section of Chapter 3.

It is actually not uncommon to do many linear measurements, and then by using correlation equations translate these measured results into their digital equivalents. Therefore, the robustness of the signal as a function of antenna signal at the receiver site, constant or known phase relationships, and high adjacent power ratios will provide good transfer characteristics.

1-8-2 Transmission and Reception Quality

The acoustic transmission and reproduction quality of a mobile phone is the most important characteristic in everyday use. Accurate and reproducible measurements of a cellular phone's frequency response cannot be achieved with static sinewave tones (SINAD measurements) because of coder and decoder algorithms. In this case, test signals simulating the characteristic of the human voice—that is, tones that are harmonic multiples of the fundamental—are required. A so-called vocoder is used to produce the lowest possible data rate. Instead of the actual voice, only the filter and fundamental parameters required for signal reconstruction are transmitted. Particularly in the medium and higher audiofrequency ranges, the static sinusoidal tones become a more or less stochastic output signal. For example, if a tone of approximately 2.5 kHz is applied to the telephone at a constant sound pressure, the amplitude of the signal obtained at the vocoder output varies by approximately 20 dB. In type-approval

tests, where highly accurate measurements are required, the coder and decoder are excluded from the measurement.

Whether the results obtained for the fundamental frequency are favorable depends on how far the values coincide with the clock of the coding algorithm. Through a skillful choice of fundamental frequencies, test signals with overlapping spectral distribution can be generated, giving a sufficient number of test points in subsequent measurements at different fundamental frequencies so that a practically continuous frequency response curve is obtained. Evaluation can be done by means of FFT analysis with a special window function and selection of result bins. The results are sorted and smoothed by the software and display in the form of a frequency response curve. Depending on the measurement, a program calculates the sending or receiving loudness rating in line with CCITT P.79 and shows the result.

Acoustic measurements relevant to GSM 11.10 include:

- Sending frequency response
- Sending loudness rating
- Receiving frequency response
- Receiving loudness rating
- Sidetone masking rating
- Listener sidetone rating
- Echo loss
- Stability margin
- Distortion sending
- Distortion receiving
- Idle channel noise receiving
- Idle channel noise sending

There are two categories of testing. One is a full-compliance test for all channels and all combinations of capabilities; the other is a production tester with evaluation of the typical characteristic data. Both Hewlett-Packard and Rohde & Schwarz are the leading companies in this area, and as the technology develops further, different equipment will be made available. Figure 1-134 shows a Rohde & Schwarz radiocommunication tester capable of evaluating cellular systems. Table 1-13 shows the typical specifications required to make the appropriate cellular telephone measurements.

The test setup must be capable of measuring key IS-95 parameters, using the following:

- Frame errors
- Waveform quality
- Error vector magnitude
- Phase error
- Magnitude error
- Carrier feedthrough
- Frequency accuracy
- Power measurements
- Base-station signaling for mobile testing

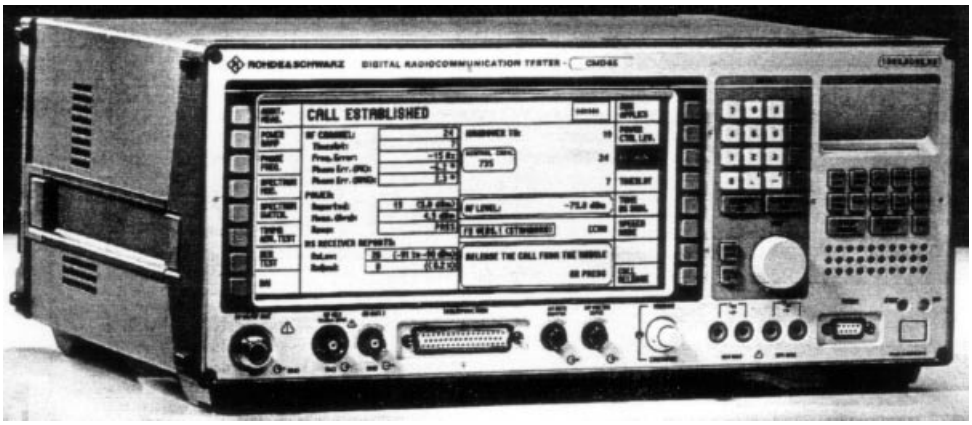

Figure 1-134 The Rohde & Schwarz CMD 65 digital radiocommunication tester can be used to measure all the relevant specifications of cellular telephones.

Table 1-13 Digital radiocommunication tester model CMD 80

SIGNAL GENERATOR	
Frequency	
Range	869–894 MHz
Resolution	1 Hz
Error	Same as timebase
Output level	
RF IN/OUT	–20 to –124 dBm
RF OUT2	0 to –105 dBm
Resolution	0.1 dB
Error (RF IN/OUT)	≤1.5 dB
Modulation	
Carrier suppression	–30 dBc
ANALYZER	
Frequency	
Range	824–849 MHz
Resolution	1 Hz
Error	Same as timebase
Power measurement	
Reference level range	
RF IN/OUT (full scale)	+41 to –28 dBm
RF IN2 (full scale)	0 to –69 dBm
Measurement error, absolute	±1.5 dB
Measurement error, relative	≤0.4 dB (ref. level to –40 dB)
Dynamic range	50 dB below reference level

Table 1-13 (Continued)

Modulation analyzer	
ρ error (25 ± 10) °C	0.003 (for ρ = 0.9–1)
Frequency measurement range	± 3 kHz
Frequency measurement error	Reference ±30 Hz
Timing measurement error	±60 ns
TIMEBASE	
Standard timebase	
Nominal frequency	10 MHz
Frequency drift in temperature range 0–35 °C	$\leq 1.5 \times 10^{-6}$
Frequency aging	$\leq 0.5 \times 10^{-6}$/yr (at 35 °C)
OCXO reference oscillator	
Nominal frequency	10 MHz
Frequency drift in temperature range 0–45 °C	$\leq 1 \times 10^{-7}$
Frequency aging	$\leq 2 \times 10^{-7}$/yr $\leq 0.5 \times 10^{-9}$/day after 30 days of operation
Warm-up time (at 25 °C)	approx. 5 min
Reference frequency inputs/outputs	
Synchronization input (frequency selectable)	100 kHz to 40 MHz, step 10 kHz
Impedance	approx. 100 Ω
Level	0 dBm to TTL
Synchronization output	
Frequency	10 MHz or frequency at synchronization input
Level	TTL, R_{out} = 50 Ω
AWGN generator	
Equivalent noise bandwidth	1.8 MHz typ.
Gain adjustment range	–20 to +6 dB of forward channel power
dc Voltage measurements	
Range	0 to ±30 V
Resolution	10 mV
Error	2% + resolution
dc Current measurements	
Mode	averaging, +peak, –peak
Range	0 to ±10 A
Common mode rejection	±30 V
Shunt resistance	50 mΩ
Resolution for averaging	1mA/10 mA
Resolution for peak	10 mA
Residual indication	<10 mA
Error	<2% + resolution + residual indication

1-8-3 Base-Station Simulation

Simulating a CDMA (IS-95) base station involves:

- Synchronization of mobile
- Registration of mobile
- Incoming/outgoing call origination
- Handoff

During the call, the tester must verify the handset's RF performance and check the correct operation of the basic signaling features. The best testers do not rely on any special test modes in the mobile station, performing their measurements under conditions almost identical to those in a real network. A voice loop-back allows quick verification of the performance of a mobile as it is perceived by the user.

1-8-4 GSM

Measurement, test, and adjustment capabilities for GSM should include:

- Synchronization of mobile phone with base station (which is simulated by CTS)
- Location update
- Call setup (incoming/outgoing)
- Call release (incoming/outgoing)
- Control and measurement of transmitter power
- Handover (channel change)
- Sensitivity, including bit error rate (BER) and raw bit error rate (RBER); limit sensitivity via search routine; RxLev and RxQual
- Phase and frequency error
- Power ramp versus time
- Timing error
- AFC (automatic frequency correction) and RSSI (radio signal strength indication)
- I/Q modulator adjustment
- Echo test (voice test, includes also testing of loudspeaker and microphone)
- Functional test of mobile's keypad through display of dialed number
- Display of IMSI (international mobile subscriber identity), IMEI (international mobile equipment identity), power class, and revision level
- Short message service (SMS)

1-8-5 DECT

Measurement, test, and adjustment capabilities for DECT should include:

- Synchronization of DUT with the CTS
- Call setup
- Call release
- Echo test

Often BER diagrams do not have C/N as abscissa (FIG) but E_b/N_0, which is the energy per information bit E_b referred to the normalized noise power N_0 [1]. C/N describes the ratios in the transmission channel, SNR the signals after the √cos receive filter. The following applies:

$$C/N = SNR + k_{roll\ off}\ [dB]$$

In converting the two quantities, some factors have to be taken into account as shown by equations 1 and 2 on the right.

To determine C/N [dB] or E_b/N_0 [dB], the logarithmic ratios have to be corrected using the following factors:

- Factor for Reed-Solomon FEC*

$$k_{FEC} = 10 \times \lg \frac{188}{204}$$

$$k_{FEC} = -0.3547\ [dB]$$

- Factors for QPSK/QAM modulation

$$k_{QPSK/QAM} = 10 \times \lg(m)$$

Modulation	m	$k_{QPSK/QAM}$ [dB]
QPSK	2	3.0103
16QAM	4	6.0206
64QAM	6	7.7815
256QAM	8	9.0309

- Factor for coding rate (P = 1 for QAM)*

$$k_P = 10 \times \lg(P)$$

Modulation	P	k_P [dB]
QPSK	1/2	–3.0103
	2/3	–1.7609
	3/4	–1.2494
	5/6	–0.7918
	7/8	–0.5799
QAM	1	0

- Factor for √cos roll-off filtering in demodulator/receiver

$$k_{roll\ off} = 10 \times \lg\left(1 - \frac{\alpha}{4}\right)$$

Modulation	α	$k_{roll\ off}$ [dB]
DVB-C	0.15	–0.1660
DVB-S	0.35	–0.3977

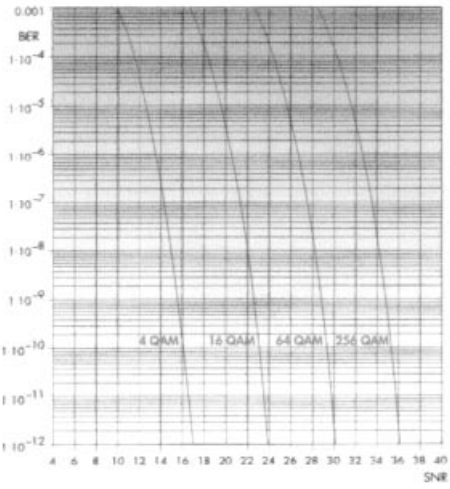
* To be taken into account if E_b only refers to the information bits; not to be taken into account if E_b refers to all bits transmitted (information plus error control bits)

$$C/N = E_b/N_0 + 10 \times \lg\frac{188}{204} + 10 \times \lg(m) + 10 \times \lg(P) - 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

Equation 1

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m) - 10 \times \lg(P) + 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

Equation 2



BER referred to SNR for 4, 16, 64 and 256QAM

The types of correction factor required depend on whether measurement is made

- in the transmission channel,
- before or after Viterbi correction,
- with QAM or QPSK modulation.

Examples of conversion equations –

For **in-channel** measurements with QAM transmission, the following applies:

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m)\ [dB]$$

The factors for √cos roll-off filtering and puncturing rate are not needed.

For measurements in the **QAM demodulator**, √cos roll-off filtering filtering has to be taken into account.

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m) + 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

For measurements in the **satellite demodulator** with QPSK, the equation for determining the BER as a function of E_b/N_0 after Viterbi FEC is as follows:

$$E_b/N_0 = C/N - 10 \times \lg\frac{188}{204} - 10 \times \lg(m) - 10 \times \lg(P) + 10 \times \lg\left(1 - \frac{\alpha}{4}\right)\ [dB]$$

In the latter case all correction factors are included.

MODELS FOR ACTIVE DEVICES

Because we are dealing with amplifiers, both small-signal and power, oscillators, and active mixers, active devices will play a major role in circuit design. At our frequency range of interest (about 1000 MHz and above), distributed elements predominate, and even in device modeling we must consider some distributed effects such as packaging.

As we dive into providing functional explanations of the active devices used in practical circuits, there is some temptation not to provide enough information on semiconductor behavior. Because manufacturers of microwave products will use the services of a foundry or specify semiconductors from their suppliers, we will cover the device operation in depth. That said, for the beginner looking into designing circuits from high frequencies to low microwave frequencies, we will provide examples of a variety of devices unique to this frequency range. Some treatment of device physics will therefore be useful in providing a basic understanding of the nonlinear behavior of active devices and modeling in preparing for practical circuits using a computer-aided-design (CAD) tool. For CAD applications, we assume the user will have access to nonlinear CAD software, such as a high-performance SPICE program or a harmonic-balance program, such as Ansoft Serenade 8.0 or its derivatives. It is interesting that most semiconductor houses today still only offer very limited nonlinear data sets, while in the linear area a large body of useful data is made available, mostly on CDs. What CAD does for us—and this applies to SPICE and harmonic-balance programs alike—is predict the dc bias point of a device in the context of its surrounding circuitry. Configuring the simulation to drive the device into large-signal operation provides us with insight into the various forms of distortion and compression.

In evaluating active devices for RF circuit design, we have a few different technologies to consider. First, we will examine the semiconductor junction diode—a basic *pn* junction—and venture from there to the bipolar transistor. An investigation of metal-oxide semiconductor (MOS) devices, another important set of semiconductors for medium frequencies, will follow. We will also examine the gallium arsenide metal-gate Schottky field-effect transistor (GaAs MESFET) and members of its family. Since critical large-signal parameters for some devices may not be available from their manufacturers, we will examine

parameter-extraction techniques and problems. For various device types, we will provide insight into the noise properties of the device.

2-1 DIODES*

The diode model contains a nonlinear current source that follows the Shockley equation:

$$\text{Current} = \text{IS}\left(e^{V_j/\text{N}V_t} - 1\right) \tag{2-1}$$

where V_j = voltage across the junction
V_t = thermal voltage (= kT/q)

These values, with the model parameters IS and N, are used to model the current–voltage effects of the semiconductor junction. This does not include the nonideal operation of real diodes. For example, at low currents (less than 1 nA), other semiconductor processes that increase the flow of currents become noticeable.

By setting IS to different values, we can obtain the characteristics of other devices, such as a Schottky barrier diode, or a silicon diffused-junction diode. High-current effects are modeled, grossly, by including a series resistance that is intended to combine the effects of bulk resistance (the material on each side of the junction) and high-level injection. At high currents, the observed diode current stops following the Shockley form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/\text{N}V_t} \tag{2-2}$$

and approaches a modified form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/2\text{N}V_t} \tag{2-3}$$

2-1-1 Large-Signal Diode Model

Three diode models are used in the industry:

- Microwave diode model
- PIN diode model
- Enhanced SPICE diode model

Figure 2-1 shows the large-signal microwave diode model. Its keywords appear in Table 2-1. This model can also be used to simulate varactor diodes.

Table 2-2 lists SPICE parameters for a selection of Schottky mixer diodes by Alpha.

In most cases, the diode capacitance is modeled by a voltage-dependent capacitor, which is connected in parallel with the nonlinear current generator described previously, to represent the charge-storage effects of the junction. There are two components to this charge

- The reverse-voltage capacitive effect of the depletion region
- The forward-voltage charge represented by mobile carriers in the diode junction

*Portions of this chapter's diode coverage are based on material in Alpha Industries Semiconductor Application Reports 80800, 80200, and 80500. Used with permission.

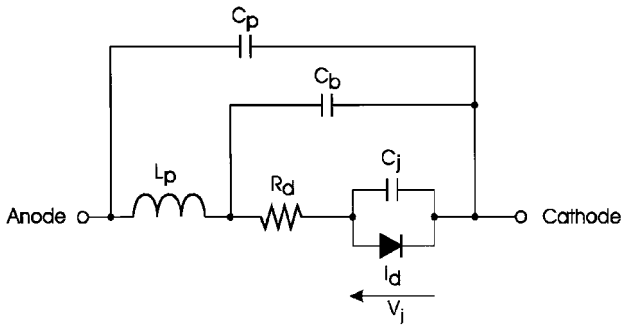

Figure 2-1 The large-signal microwave diode model. This model is temperature dependent.

Reverse-voltage capacitance follows the simple approximation that the depletion region (the area of the junction that is depleted of carriers) serves as the gap between the "plates" of a capacitor. This region varies in thickness, and therefore the capacitance varies with applied voltage. For a step (abrupt) junction, or linearly graded junction, the capacitance approximation is

Table 2-1 Large-signal microwave diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
JS	Saturation current	ampere	0
ALFA	Slope factor of conduction current	/volt	38.696
JB	Breakdown saturation current	ampere	10 mA
VB	Breakdown voltage	volt	$-\infty$
E	Power-law parameter of breakdown current	—	10.0
CT0	Zero-bias depletion capacitance	farad	0
FI	Built-in barrier potential	volt	0.8
GAMA	Capacitance power-law parameter	0.5	
GC1	Varactor capacitance polynomial coefficient 1	/volt	0.0
GC2	Varactor capacitance polynomial coefficient 2	/volt^2	0.0
GC3	Varactor capacitance polynomial coefficient 3	/volt^3	0.0
CD0	Zero-bias diffusion capacitance (*pn* diodes)	farad	0
AFAC	Slope factor of diffusion capacitance	/volt	38.696
R0	Bias-dependent part of series resistance in forward-bias condition	ohm	0
T	Intrinsic time constant of depletion layer for abrupt-junction diodes	second	0
KF	Flicker noise coefficient	—	0.0
AF	Flicker noise exponent	—	1.0
FCP	Flicker noise frequency shape factor	—	1.0
AREA	Area multiplier	—	1.0
	Extrinsic Model		
CP	Package parasitic capacitance	farad	0.0
CB	Beam-lead parasitic capacitance	farad	0.0
LP	Package parasitic inductance	henry	0.0

$$\text{Capacitance} = \frac{C_{J0}}{\left(1 - V_j/\phi\right)^M} \tag{2-4}$$

where C_{J0} is the zero-bias value, ϕ (phi) is the junction barrier potential, and M is the grading coefficient that varies ($\frac{1}{2}$ is used for step junctions and $\frac{1}{3}$ is used for linearly graded junctions, and most junctions are somewhere in between).

There is often confusion about the barrier potential, which appears in the capacitance equation. From capacitance measurements, ϕ (model parameter VJ, and not to be confused with V_j in the equations) takes on a value of nearly 0.7 volt for regular (silicon) junction diodes and a range of 0.58–0.85 volt for various Schottky barrier diodes. This value is sometimes confused with the forward-current voltage drop of the diode or the energy gap of the material; it is *neither* of these.

Varying M generates a variety of reverse-bias capacitance characteristics. Inspection of the capacitance formula reveals that it predicts infinite capacitance for a forward bias, which is not the case for a real junction. Several depletion-capacitance formulas have been proposed that more correctly fit observed operation; however, SPICE uses a simple approach: For forward biases beyond some fraction (set by the parameter FC) of the value for ϕ, the capacitance is calculated as the linear extrapolation of the capacitance at the departure. This provides a continuous numerical result and does not affect circuit operation significantly because, for forward bias, the device capacitance is normally dominated by diffusion capacitance.

The diffusion charge (and therefore the capacitance) varies with forward current and is simply modeled as a transit time (model parameter TT) for the carriers to cross the diffusion region of the junction. The total charge is

$$\text{Diffusion charge} = \text{Device current} \times \text{Transit time} \tag{2-5}$$

and capacitance is the derivative, with respect to bias, of this:

$$\text{Diffusion capacitance} = \text{TT}\,\frac{\text{IS}}{\text{N}V_t}\,e^{V_j/\text{N}V_t} \tag{2-6}$$

Diffusion charge manifests itself as the *storage time* of a switching diode, which is the time required to discharge the diffusion charge in the junction, which must happen before the junction can be reverse-biased (switched off). Storage time is normally specified as the time to discharge the junction so that it is supporting only a fraction (typically 10%) of the initial reverse current. First, a forward current is supplied to the device to charge the junction. Then, as quickly as possible, a reverse current is supplied to the device. Internally, the junction is still forward-biased to a voltage nearly the same as before the switch in current; the junction is still conducting at the forward-current rate. This internal current adds to the external current as the total current discharging the junction. As the junction voltage decreases, the internal current falls off exponentially (according to the Shockley equation). This system is a relatively simple differential equation that can be solved to an explicit equation for the TT parameter (assuming complete discharge) as follows:

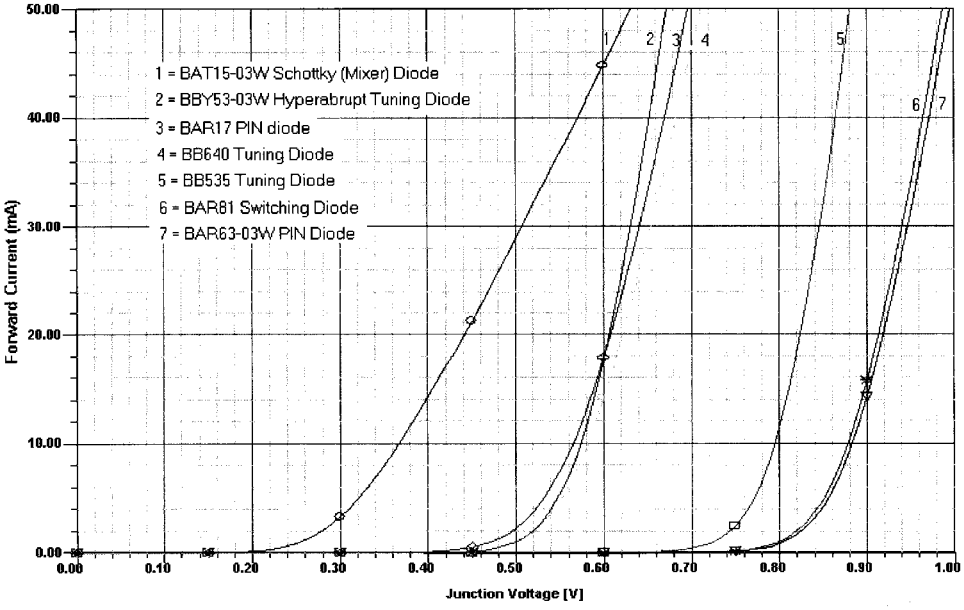

Figure 2-2 The dc *I–V* curves for seven diodes, showing the various barrier voltages that result from different doping profiles.

$$\text{Transit time} = \frac{\text{Storage time}}{\ln\left(\dfrac{I_F - I_R}{-I_R}\right)} \tag{2-7}$$

The diffusion charge dominates the reverse recovery characteristic of the diode. During the last part of the recovery, as the junction becomes reverse-biased, the depletion capacitance dominates. This causes the small tail at the end of the discharge cycle. Total capacitance is taken to be the sum of these capacitances: the depletion approximation dominates for reverse bias as the device current is small, and the diffusion proximity dominates for forward bias as the device current is large.

A special case for diode application is the switching diode, and its description and application will be part of a later chapter. Figure 2-2 shows the dc *I–V* curves, which indicate the different voltage potentials that are a result of the different doping profiles.

2-1-2 Mixer and Detector Diodes

Electrical Characteristics and Physics of Schottky Barriers. Schottky barrier diodes differ from junction diodes in that current flow involves only one type of carrier instead of both types. That is, in *n*-type Schottky barrier diodes the forward current consists of holes flowing from the *n*-type material into the metal.

Diode action results from a contact potential set up between the metal and the semiconductor, similar to the voltage between the two metals in a thermocouple. When metal is brought into contact with an *n*-type semiconductor (during fabrication of the chip), electronics diffuse out of the semiconductor into the metal, leaving a region under the contact that

has no free electrons ("depletion layer"). This region contains donor atoms that are positively charged (because each lost its excess electron), and this charge makes the semiconductor positive with respect to the metal. Diffusion continues until the semiconductor is so positive with respect to the metal that no more electrons can go into the metal. The internal voltage difference between the metal and the semiconductor is called the contact potential and is usually in the range of 0.3–0.8 volt for typical Schottky diodes. A cross section is shown in Figure 2-3.

When a positive voltage is applied to the metal, the internal voltage is reduced, and electrons can flow into the metal. The process is similar to thermionic emission of electrons from the hot cathode of a vacuum tube, except that the electrons are "escaping" into a metal instead of into a vacuum. Unlike the vacuum tube case, room temperature is "hot" enough for this to happen if enough voltage is applied. However, only those electronics whose thermal energy happens to be many times the average can escape, and these "hot electrons" account for all the forward current from the semiconductor into the metal.

One important thing to note is that there is no flow of minority carriers from the metal into the semiconductor and thus no neutral plasma of holes and electrons is formed. Therefore, if the forward voltage is removed, current stops "instantly," and reverse voltage can be established in a few picoseconds. There is no delay effect to charge storage as in junction diodes. This accounts for the exclusive use of barrier diodes in microwave mixers, where the diode must switch conductance states at microwave oscillator rates.

The current–voltage relationship for a barrier diode is described by the Richardson equation (which also applies to thermionic emission from a cathode). The derivation is given in many textbooks (e.g., Sze).

$$I = AA_{\mathrm{RC}}T^2 \exp\left(-\frac{q\phi_B}{kT}\right)\left[\exp\left(\frac{qV_J}{kT}\right) - M\right] \tag{2-8}$$

where A = area (cm^2)

A_{RC} = modified Richardson constant ($\mathrm{A}/K^2 \cdot \mathrm{cm}^2$)

k = Boltzmann's constant

T = absolute temperature (K)

ϕ_{B} = barrier height in volts

V_J = external voltage across the depletion layer (positive for external voltage) = $V - IR_S$

R_S = series resistance

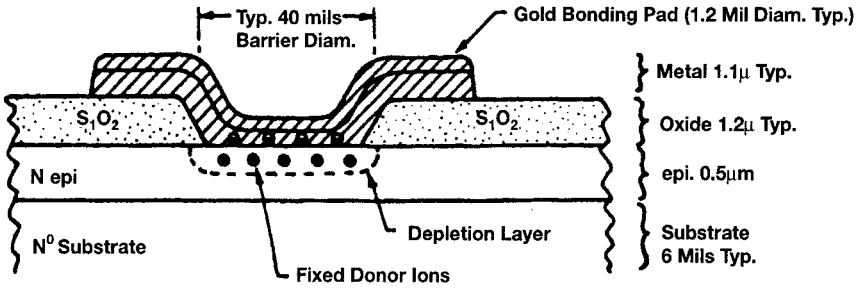

Figure 2-3 Schottky diode chip cross section.

M = avalanche multiplication factor
I = diode current in amperes (positive forward current)

The barrier height, ϕ_B, is typically a few tenths of a volt higher than the contact potential, ϕ_C (about 0.15 V higher than ϕ_C for silicon). This equation agrees well with experimental data for diodes without surface leakage, but it is difficult to use because A_{RC}, ϕ_B, and M are all dependent on applied voltage.

The major cause for variation in ϕ_B with voltage is the "image effect," in which the barrier height is lowered as the electric field near the metal is increased, especially at the edges. A better equation for circuit designers to use is one in which all parameters are independent of voltage and current. The simplest one that agrees reasonably well with Richardson's equation is

$$I = I_S\left[\exp\left(\frac{V_J}{0.028}\right) - 1 + \frac{K}{\left(1 - V_B/V\right)}\right] \tag{2-9}$$

where I_S = saturation current (a temperature-dependent quantity)
0.028 = nkT/q at room temperature (n = 1.08)
n = forward slope factor (derived from the variation of ϕ_B with forward voltage)
K = reverse slope factor (expressing the variation of ϕ_B with reverse voltage)
V_B = breakdown voltage (the voltage at which M = 1)

As before, V and I are considered positive for forward bias and negative for reverse bias.

Typical ranges for these parameters for microwave Schottky and point-contact mixer diodes are:

I_S = 10^{-12} to 10^{-5} A
n = 1.04–1.10
R_S = 2–20 Ω
K = 8–100
V_B = 2–20 V

The quantities I_S and 0.028 are strongly temperature dependent, while both R_S and V_B increase with temperature to a slight degree. R_S increases with current at high current levels (due to carrier velocity saturation) but is essentially independent of current at 10 mA and below for mixer diodes. Thus, for normal mixer and detector operation, R_S can be considered constant.

Agreement between Eqs. (2-8) and (2-9) is not perfect but Eq. (2-9) is much easier to use and is preferred by most circuit designers. A comparison of the two equations near zero bias gives the following relationship between zero-bias barrier height, ϕ_0, and saturation current:

$$I_S = AA_{RC}T^2\exp - \frac{q\phi_0}{kT}$$

$$\cong \left(\frac{10^7 A}{\text{cm}^2}\right)A\exp\left(-\frac{\phi_0}{0.026}\right) \quad \text{(for } n \text{ silicon at room temperature)} \tag{2-10}$$

Small-Signal Parameters. By combining Eqs. (2-9) and (2-10), the values of the parameters in Eq. (2-9) can be derived from a few simple measurements. Many specific equations can be derived, but the following are commonly used for production measurements:

$$R_S = \frac{V_{F10} - V_{F1} - 0.065}{0.009} \quad (\text{for } n = 1.08) \tag{2-11}$$

$$\phi_0 = \frac{V_{F1} - 0.001R_S + 0.28 + 0.12\log_{10} D}{1.08} \tag{2-12}$$

$$n = \frac{V_{F1} - V_{F0.1} - 0.0009R_S}{0.060} \tag{2-13}$$

$$K = \left(\frac{I_{R1}}{I_S} - 1\right)V_B \tag{2-14}$$

$$I_S = \exp\left(-\frac{V_{F1}}{0.028} + \frac{R_S}{28}\right) \quad (\text{in mA}) \tag{2-15}$$

where $V_{F0.1}$, V_{F1}, and V_{F10} are the forward voltages at 0.1, 1, and 10 mA, respectively, and I_{R1} is the reverse current at 1 volt. (The derivation of these equations requires that I_S be small compared to 0.1 mA.) The quantity D is the diameter of the metal–silicon contact in mils.

Measuring V_{F1} at 1 mA and 10 mA instead of some other current levels leads to the best accuracy for typical mixer diodes.

The total dynamic resistance for a forward-biased diode is given by

$$R_T = \frac{dV}{dI} = R_S + \frac{nkT}{q(I + I_S)} = R_S + R_B \tag{2-16}$$

and

$$R_B = \frac{28}{I + I_S} \quad \text{at room temperature (with } I \text{ and } I_S \text{ in mA, } n = 1.08) \tag{2-17}$$

This equation is also good at zero bias (unless K is very large or there is significant surface leakage). That is,

$$R_0 = R_S + \frac{28}{I_S} \tag{2-18}$$

For reverse voltages of a few volts, the dynamic resistance is dominated by the K term:

$$R_R = \text{Reverse resistance} = \frac{dV}{dI} \cong \frac{V_B}{KI_S} \tag{2-19}$$

For typical values of I_S, R_0 is larger than 5000 Ω and R_R is larger than 100 kΩ. For some zero-bias Schottky applications, it is desirable for R_0 to be made smaller than this.

The factors that determine R_S are (1) the thickness of the epitaxial layer, (2) the epitaxial layer doping level (N_D), (3) the barrier diameter, (4) the substrate resistivity ("spreading resistance"), (5) the contact resistances of the metals used for the barrier and the substrate contact, and (6) the resistance associated with the bonding wire or whisker. The barrier height is about 0.15 volt higher than the contact potential between the barrier metal and the semiconductor and is influenced by the method used to apply the metal, conditions at the edge of the junction, and the doping level. Saturation current depends on barrier height, junction area, and temperature; and the slope factors, n and K, depend on doping level, punchthrough voltage, and edge conditions.

Junction Capacitance. The capacitance of a Schottky barrier chip results mainly from two sources: the depletion layer under the metal–semiconductor contact and the capacitance of the oxide layer under the bonding pad (the so-called overlay capacitance). The bonding pad is required because the typical Schottky barrier diameter is so small that it is impractical to bond directly to the metal on the junction. If the semiconductor epitaxial layer is uniformly doped, the capacitance–voltage characteristic is similar to that of a textbook "abrupt-junction" diode.

$$C_J = \frac{\varepsilon_S \varepsilon_0 A'}{X_D} + C_0 \tag{2-20}$$

$$X_D = \sqrt{\frac{2\varepsilon_S \varepsilon_0 (\phi_C - V)}{qN}} \tag{2-21}$$

where ϕ = contact potential
C_0 = overlay (bonding pad) capacitance
ε_S = dielectric constant of the semiconductor ($\cong$ 12 for Si or GaAs)
N = doping level for the epitaxial layer
A' = effective contact area, including fringing corrections

In practical terms, the capacitance can be related to the 0-V barrier capacitance defined by

$$C_{B0} = \frac{\varepsilon_S \varepsilon_0 A'}{X_{D0}} \tag{2-22}$$

where

$$X_{D0} = \sqrt{\left(\frac{1.3 \times 10^{15}}{N_D}\right)\phi_C} \quad \text{(in } \mu\text{m)} \tag{2-23}$$

The resulting C–V relationship can be written

$$C_J = \frac{C_{B0}}{\sqrt{1 - V/\phi_C}} + C_0 \tag{2-24}$$

The contact potential, ϕ_C, is related to the barrier height as follows:

$$\phi_C = \phi_B - 0.026\left[1 + L_n\left(\frac{N_C}{N}\right)\right] \tag{2-25}$$

The theoretical meaning of these terms can be clarified by looking at Figure 2-4.

Parameter Trade-Offs

Barrier Height. The barrier height of a Schottky diode is important because it directly determines the forward voltage. In order to get a good noise figure, the LO drive voltage, V_L, must be large compared to V_T, which is essentially V_{F1}. Normally, it is best to have a low

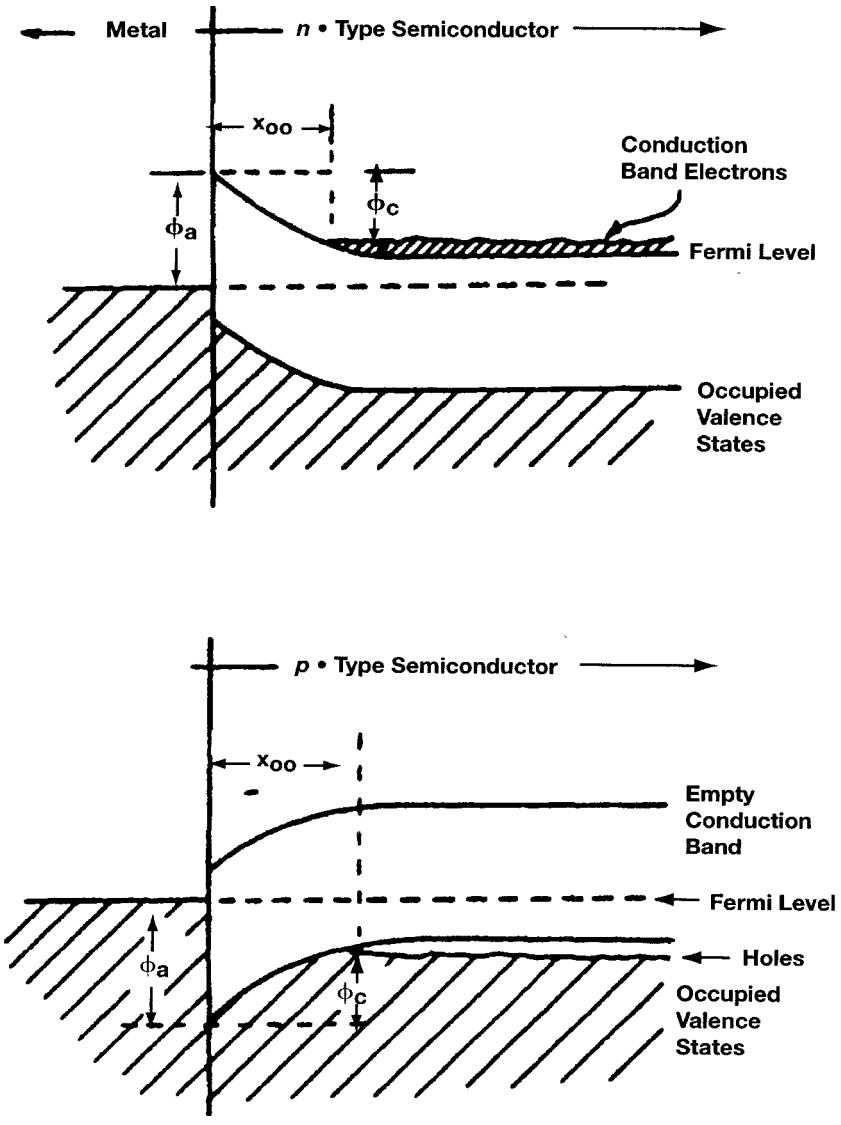

Figure 2-4 Schottky diode band diagrams.

Table 2-3 LO power and V_{F1} for various applications

Type	Typical V_{F1}	LO Power	Application
"Zero bias"	0.10–0.25	< 0.1 mW	Mainly for detectors
Low barrier	0.25–0.35	0.2–2 mW	Low-drive mixers
Medium barrier	0.35–0.50	0.5–10 mW	General purpose
High barrier	0.50–0.80	> 10 mW	High dynamic range

forward voltage (low V_{F1}), or low drive) diode, to reduce the amount of LO power needed. However, if high dynamic range is important, high LO power is needed, and the diode can have a higher V_F and should also have a high V_B (see Table 2-3).

Noise Figure Versus LO Power. At low LO drive levels, the noise figure is poor because of poor conversion loss, due to a too-low conduction angle. At very high LO drive levels, the noise figure again increases due to diode heating, excess noise, and reverse conduction.

If a high LO drive level is needed, for example, to get higher dynamic range, a high V_B (> 5 V) should be specified. However, Nature requires that you pay for this with higher R_S (lower f_C), so the noise figure will be degraded compared to what could be obtained with diodes designed for lower LO drive. Forward voltage and breakdown are basically independent parameters, but high breakdown is not needed or desirable unless high LO power is used.

Such a high-breakdown diode will have low reverse current (which is important only if the diode has to run hot).

Silicon Versus GaAs. Typical silicon Schottky diodes have cutoff frequencies in the 800–200-GHz range, which is good enough through the Ku band.

At the Ku band and above, or for image-enhanced mixers, higher f_C may be needed, which calls for the use of GaAs diodes. These have lower R_S due to higher mobility, which translates to cutoff frequencies in the 400–1000-GHz range.

However, if your IF is low, be careful; GaAs diodes have high 1/*f* noise. They also have high V_{F1}, so more LO power is required.

C_J Versus Frequency. There is quite a lot of latitude in choosing C_J. However, in general, the capacitive reactance should be a little lower than the transformed line impedance (Z_0). If Z_0 is not known, a good way to start is to use $X_C = 100\ \Omega$. Experience has shown that most practical mixers use an X_C near this value (a little higher in waveguide, and lower in 50-Ω systems). This translates to the following rule of thumb for choosing the junction capacitance of a diode for operation at frequency *f* (in GHz):

$$C_{J0} \approx \frac{100}{\omega}$$

$$\approx \frac{1.6}{f} \quad \text{(in pF)} \tag{2-26}$$

In order to evaluate possible tolerances, we show the range of forward current as a function of diode voltage (Figure 2-5), the junction capacitance as a function of the bias voltage

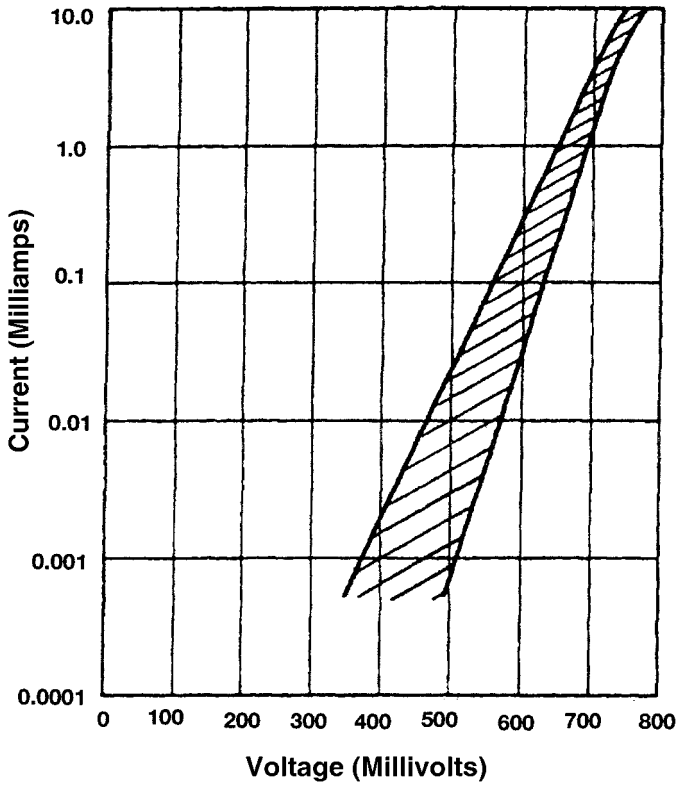

Figure 2-5 Forward dc characteristic curve range—current versus voltage.

(Figure 2-6), and finally some important RF parameters, such as noise figure and IF impedance, as a function of the local-oscillator drive (Figure 2-7).

Mixer Diodes. As an example of some of the parameters for mixer diodes, Table 2-4 gives data on some of the X-band mixer diodes. NF is measured at 9.375 GHz.

Linear Diode Model. Figure 2-8 shows the linear diode model. Its keywords appear in Table 2-5.

The circuit simulators, such as those supplied by Ansoft and Hewlett-Packard, provide a model library that has SPICE-type parameters for diodes (regular diodes, varactor diodes, and PIN diodes) as well as bipolar transistors and FETs, which will be discussed later.

2-1-3 PIN Diodes

Introduction. The PIN diode, in comparison with other microwave semiconductor devices, is fairly easy to understand. This makes possible the reduction of its complex behavior to relatively simple terms.

We do not attempt to describe the many possible microwave circuits in which PIN diodes are used. Rather, we attempt to explain the behavior of the diode in all aspects, giving the facts and some of the theory behind the facts. We offer the circuit designer the opportunity

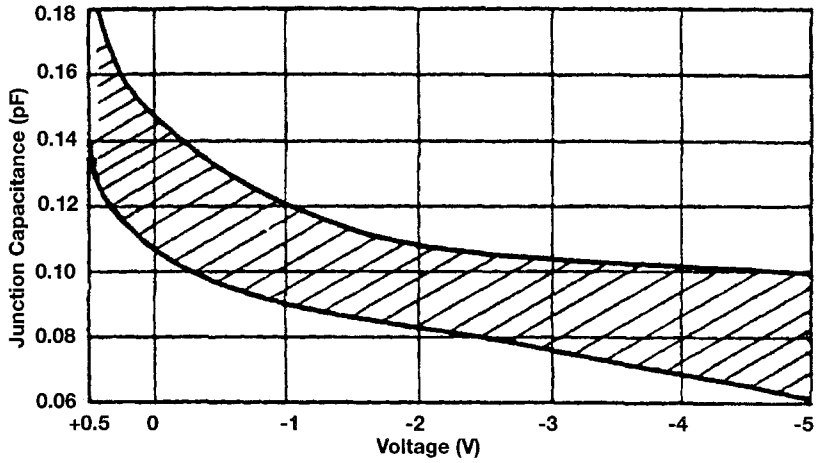

Figure 2-6 Junction capacitance range versus voltage.

to understand the PIN, so that he/she can understand its behavior in circuits. We assume the reader knows the circuit equations; to that knowledge we hope to add diode equations.

Most of the material presented consists of generalized data and explanations of the behavior of PIN diodes; we conclude with a brief description of circuit performance, test methods, and some hints on proper PIN specification writing.

The user can then evaluate the trade-offs involved in diode design and performance and be able to select the most nearly optimum diode from the wide range of diodes offered.

Large-Signal PIN Diode Model. Figure 2-9 shows the large-signal model for a PIN diode. Table 2-6 lists its keywords.

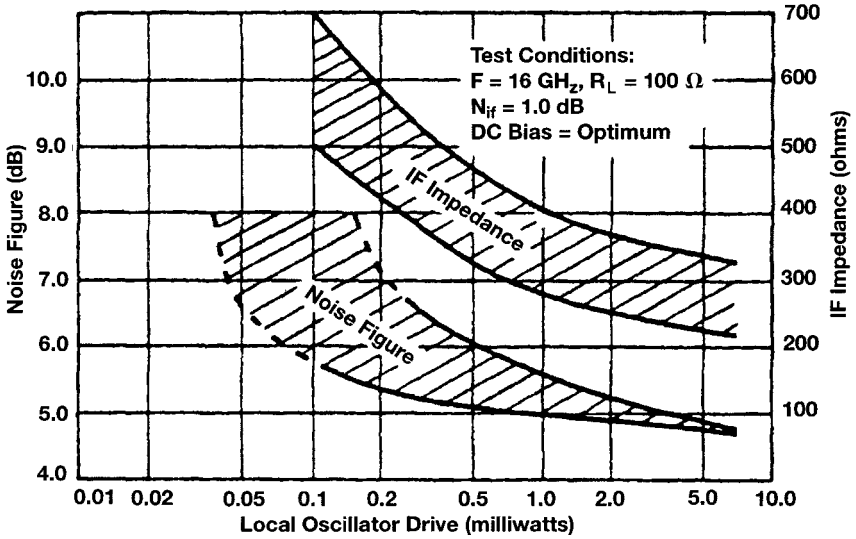

Figure 2-7 RF parameters versus local-oscillator drive level.

Table 2-4 X-band mixer diode data

Material	Barrier	Typical V_F (@1 mA)	Typical F_{C0} (GHz)	Typical R_S (Ω)	Typical C_{J0} (pF)	Maximum NF (dB)
n GaAs	High	0.70	1000	—	0.15	5.0[a]
n GaAs (BL)	High	0.70	500	—	0.15	6.0[a]
n GaAs (chip)	High	0.70	1000	—	0.15	5.3[a]

[a]Specified for N_F = 1.0 dB.

Basic Theory: Variable Resistance. Intrinsic or "pure" silicon, as it can be grown in a laboratory, is an almost lossless dielectric. Some of is physical properties include:

Dielectric constant (relative)	12
Dielectric strength	400 V/mil (approximate)
Specific density	2.3
Specific heat	0.72 J/g · °C
Thermal conductivity	1.5 W/cm · °C
Resistivity	300,000 Ω/cm

Since a PIN diode is valuable essentially because it is a variable resistor, let us concentrate initially on the resistivity. Consider a volume comparable to a typical PIN diode chip, say, 20 mils in diameter and 2 mils thick. This chip has a dc resistance of about 0.75 MΩ. High

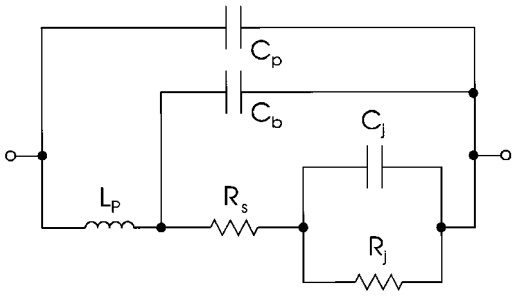

Figure 2-8 The linear diode model. This model is temperature dependent.

Table 2-5 Linear diode model keywords

Keyword	Description	Unit	Default
LP	Package inductance	henry	0.0
CB	Beam-lead capacitance	farad	0.0

RJ	Junction resistance	ohm	
CJ	Junction capacitance	farad	

resistivity in any material indicates that most of the likely carriers of electric charge, electrons and holes, are tightly held in the crystal lattice and cannot "conduct."

In real life there are impurities, typically boron, that cannot be segregated out of the crystal. Such impurities contribute carriers, holes or electrons, that are not very tightly bound to the lattice and therefore lower the resistivity of the silicon.

Through various techniques we can adjust the level of impurities, called *dopants*, to produce resistivities ranging from 10 kΩ/cm (for good PIN diodes) to 0.001 Ω/cm (for substrates).

If the impurity adds "electrons" to the crystal, it is called a *donor*; if it adds holes it is called an *acceptor*. Boron adds holes, hence it is an acceptor, and the silicon plus boron combination is called *p*-type, or *positive*, because it has an excess of positive carriers. Phosphorus, on the other hand, is a *donor*, adding electrons, and the corresponding mix is *n*-type, or *negative*.

Notes on the PIN Diode Model

1. The PIN diode model is used to model a bias-dependent RF resistance for use in PIN diode circuits such as attenuators and switches. The resistance varies from RMAX to RS using the R function above. A typical R versus *I* characteristic is shown in Figure 2-10 with parameters IS = 5.96 nA, RS = 2.016, RMAX = 6500, K1 = 0.1272, K2 = 1.0, N = 2.077.
2. The transit-time parameter, TT, can also be used to approximately model a switching PIN diode's reverse-recovery time—a value often provided by diode manufacturers.
3. Diode breakdown can be modeled by specifying IBV and BV parameters.

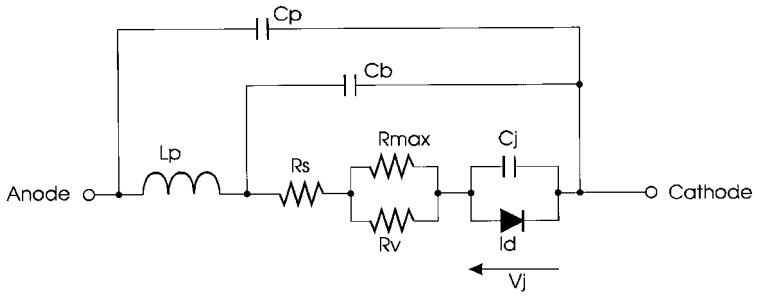

Figure 2-9 The large-signal PIN diode model. This model is temperature dependent.

Table 2-6 PIN diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
IS	Saturation current	ampere	1.0E–14
N	Emission coefficient		1.0
IBV	Magnitude of current at the reverse breakdown voltage	ampere	1.0E–10
BV	Magnitude of the reverse breakdown voltage	volt	∞
FC	Coefficient for forward-bias depletion capacitance		0.5

4. The reverse-bias capacitance characteristics can be more accurately modeled than the common expression derived from *pn* junction theory. The capacitance grading coefficient exponent can be expressed as a polynomial function of voltage by specifying values for GC1, GC2, and GC3.
5. The PIN diode model was derived from J. Walston, "SPICE Circuit Yields Recipe for PIN Diode," *Microwaves & RF*, November 1992.
6. Following Simon M. Sze, *Physics of Semiconductor Devices* (New York: John Wiley, 1982), the variable resistance may be modeled by setting

$$\text{K1} = \frac{3}{8} V_T \frac{W^2}{D_a \tau_a} \qquad \text{K2} = 1.0$$

where W is the width of the intrinsic region, D_a is the ambipolar diffusion coefficient, τ_a is the ambipolar lifetime, and V_T is the thermal voltage.

There are many concepts important to the physicist, but not to the diode user, that elaborate on the impact of impurities on the behavior of silicon. These can be studied in Watson [1]. The more carriers added, the lower the resistivity.

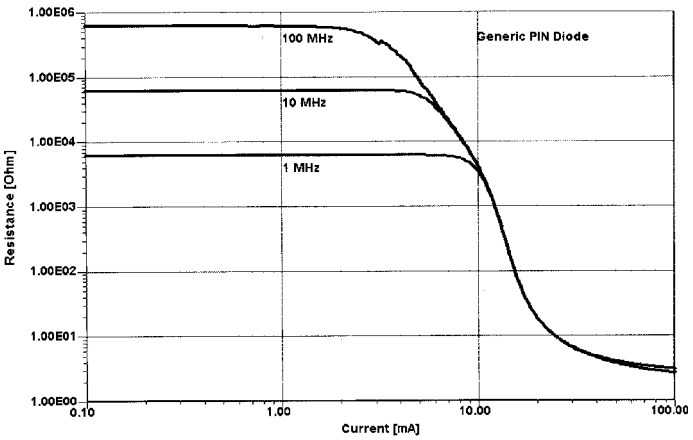

Figure 2-10 Simulated PIN diode resistance as a function of dc at 1, 10, and 100 MHz.

If one wished to vary the resistance of a given diode, in principle he/she could bring it into a semiconductor laboratory, add or subtract carriers as desired, and perhaps even make the process reversible. However, this is a slow, expensive, and impractical way to make a variable resistor; one would be better advised to take a wrench and a soldering iron and replace a component.

The PIN diode derives its value from the fact that the free-charge-carrier concentration in silicon, and hence its resistance, can be varied electronically by means of current from a simple bias supply. This can be done rapidly (in nanoseconds in some cases), reversibly, repeatably, and accurately. The thing that makes this possible is called a *junction*, the interface between the relatively pure silicon in the middle of the PIN diode (the I stands for *intrinsic*) and the heavily doped layers on either end, p^+ and n^+. The p^+ region is rich in holes; the n^+ region is rich in electrons. Both of these regions have low resistance. The I region is the variable resistive element in the diode (see Figure 2-11). In the absence of any external bias, internal effects within the crystal keep the charges fixed; the resistance of the I region is high.

When the p^+ region (anode) is biased positively with respect to the n^+ region (cathode), the interface potential "barrier" is overcome, and direct current flows in the form of holes

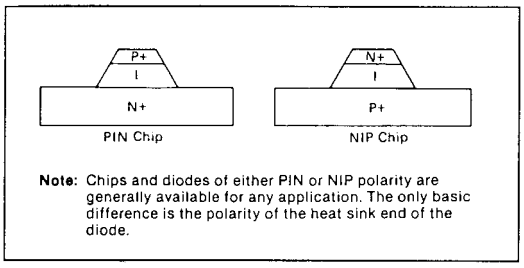

Figure 2-11 General outline of PIN diode construction.

streaming from p^+ toward n^+, with electrons moving in the opposite direction; we say that free carriers have been injected into the I region. The resistance of the I region becomes low.

The number of free carriers within the I region determines the resistivity of the region and thus the resistance of the diode.

Consider "one hole" and "one electron" drifting in opposite directions in the I region under the impetus of the applied field. Under certain conditions, imperfections in the silicon may cause these carriers to recombine. They are no longer available to constitute current or to lower the resistivity of the I region.

It can be shown that the amount of "recombination" between holes and electrons that continuously takes place in a semiconductor is governed by a property of the lattice called *lifetime*. In fact, lifetime is defined as the reciprocal of recombination rate.

Thus, $Q_S = Q_0 \exp(-t/T_L)$, where Q_S is the total amount of free charge "stored" in the I region, and T_L is the lifetime, or the mean time between recombination events. In the steady-state condition, the bias supply must deliver current to maintain a constant Q_S. The required current is

$$I_{\text{dc}} = \frac{Q_S d}{dt} = \frac{-Q_S}{T_L} \tag{2-27}$$

or $Q_S = I_{\text{dc}} T_L$, dropping the minus sign.

Ignoring some details that are not crucial to this section, we can now calculate the resistance of a given diode, of area A and thickness W. (W stands for *base width*, the width or thickness of the intrinsic layer.) The p^+ and n^+ regions have essentially zero resistance, as they are very heavily doped.

The resistivity of a given material is inversely proportional to the number of free carriers, N, and the mobility (not quite the same as velocity) of the carriers. Thus,

$$\rho = \frac{1}{q(\mu_n N + \mu_p P)} \tag{2-28}$$

where μ_n and μ_p are mobilities of electrons and holes, and N and P are numbers of electrons and holes. Simplifying, we find

$$\rho = \frac{C}{Q_S d} \tag{2-29}$$

where C is a collection of constants, and $Q_S d$ is the stored charge density (numbers per unit volume). For our piece of silicon, volume is WA, and

$$Q_S d = \frac{Q_S}{WA} \tag{2-30}$$

The resistivity is

$$\rho = \frac{CWA}{Q_S} \tag{2-31}$$

and the resistance is

$$R_S = \rho \frac{W}{A} = \frac{CW^2}{I_{\text{dc}} T_L} \tag{2-32}$$

This is a fundamental equation in PIN diode theory and design.

Rigorous analysis shows that

$$R = \frac{2kT/q}{I_f} \sinh\left(\frac{W}{2\sqrt{DT_L}} \tan^{-1}\left[\sinh\frac{W}{2\sqrt{DT_L}}\right]\right) \tag{2-33}$$

where k = Boltzmann's constant
T = temperature (in kelvins)
D = diffusion coefficient = $\mu kt/q$

For most PIN diodes, W/DT_L is less than unity, and the equation simplifies to the simple equation above.

Typical data on R_S as a function of bias current are shown in Figure 2-12. Many design choices are available, as the data indicate. Many combinations of W and T_L have been developed to satisfy the full range of applications.

Breakdown Voltage, Capacitance, Q Factor. The previous section on R_S explained how a PIN can become a low resistance, or a "short." This paragraph will describe the other state: a high impedance, or an "open." Clearly, the better PIN diode is the one that has the better on/off ratio at the frequency and power level of interest.

If we return to the undoped or intrinsic I region, we note that it is an almost lossless dielectric. As such, it has a dielectric strength of about 400 V/mil, and all PIN diodes have

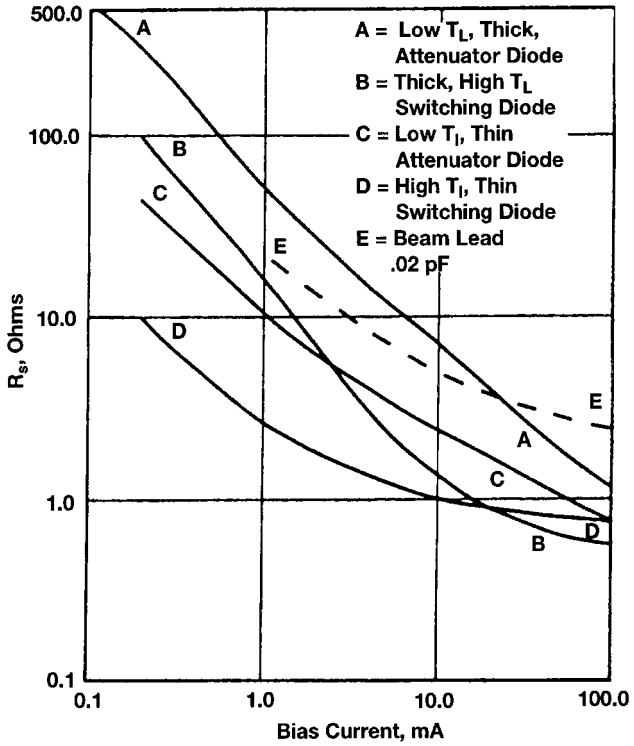

Figure 2-12 Typical series resistance as a function of bias (1 GHz).

a parameter called V_b, breakdown voltage, which is a direct measure of the width of the I region. Voltage in excess of this parameter results in a rapid increase in current flow (called avalanche current); see Figure 2-13. When the negative bias voltage is below the bulk breakdown of the I region, a few nanoamperes will be drawn. As V_b is approached, the leakage current increases often gradually, as is exaggerated in the curve. This current is primarily caused by less-than-perfect diode fabrication, although there is some contribution from temperature. Typically, the leakage current occurs at the periphery of the I region. For this reason, various *passivation* materials (silicon dioxide, silicon nitride, hard glass) are grown or deposited to protect and stabilize this surface and minimize leakage. These techniques have been well advanced over the years, and PIN diode reliability has improved as a result.

Most diodes are specified in terms of minimum V_b for a nominal leakage, usually 10 μA.

It will be noted later that RF voltage swings in excess of the rated V_b are permitted, for the mechanisms causing leakage current do not always respond at radiofrequencies. However, bulk breakdown is effectively instantaneous, and that voltage should never be exceeded.

The next characteristic of our "open" circuit is the capacitance. In simplest form, the capacitance of a PIN diode is determined by the area and width of the I region and the dielectric constant of silicon; however, we have discussed the fact that intrinsic material does contain some carriers and therefore has some conductivity. An *E* field could not exist unless all these carriers were swept out, or depleted.

Application of a reverse bias accomplishes this. At zero bias, the excess carriers on either side of the junction are separated, held apart, by "built-in" fields. This is the contact potential (about 0.5 V for silicon). If there are only a few excess carriers in the I region, this "potential" can separate the charges more easily. The junction "widens" in the sense that, starting at the p^+ and I interface, there is a region of no free carriers called the *depletion zone*. Beyond this depletion zone, the I region still contains the free charges with which it started. With the application of reverse bias, the depletion zone widens.

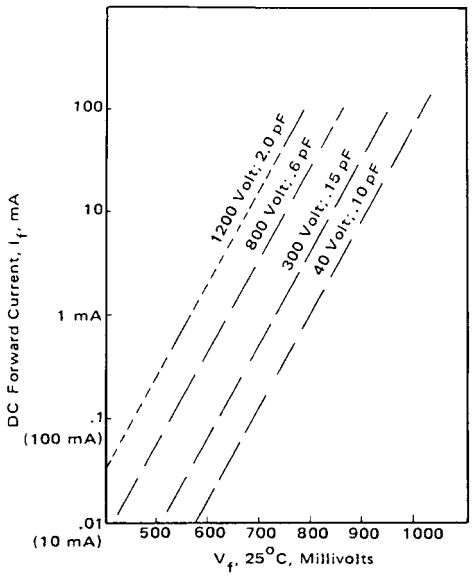

Figure 2-13 Current versus voltage for various PIN diodes.

Eventually, at a bias equal to a so-called *punchthrough* voltage (V_{PT}), the depletion zone fills the entire I region. At this voltage, the 1-MHz capacitance bottoms out and the diode Q reaches its maximum. Figure 2-14 illustrates the equivalent circuit of the I region before punchthrough.

Some very interesting facts can be derived from this model. Consider the undepleted region; this is a lossy dielectric consisting of a volume (area A, length ℓ) of silicon of permittivity 12 and resistivity ε. The capacitance is

$$12\frac{\varepsilon_0 A}{\ell} \tag{2-34}$$

and the admittance is

$$2\pi\frac{12\varepsilon_0 A}{\ell} \tag{2-35}$$

The resistance is $\varepsilon\ell/A$ and the conductance is $A/\varepsilon\ell$.

At very low frequencies, the undepleted zone looks like a pure resistor. At very high frequencies it looks like a lossy capacitor. The "crossover" frequency depends on the resistivity of the I-region material. For ε of 160 Ω/cm, the frequency is 1 GHz. Higher resistivity is generally used for PINs—say, 1000 Ω/cm, and the crossover frequency is 160 MHz.

Diode manufacturers measure junction capacitance at 1 MHz; clearly, what is measured is the depletion-zone capacitance.

If the I region thickness is W and the depletion is X_d, the undepleted region is $(W - X_d)$.

The capacitance of the depleted zone is, proportionally,

$$\frac{1}{X_d} \tag{2-36}$$

and of the undepleted zone,

$$\frac{1}{W - X_d} \tag{2-37}$$

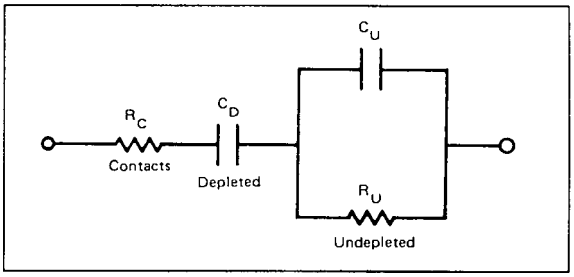

Figure 2-14 Equivalent circuit of I region before punchthrough.

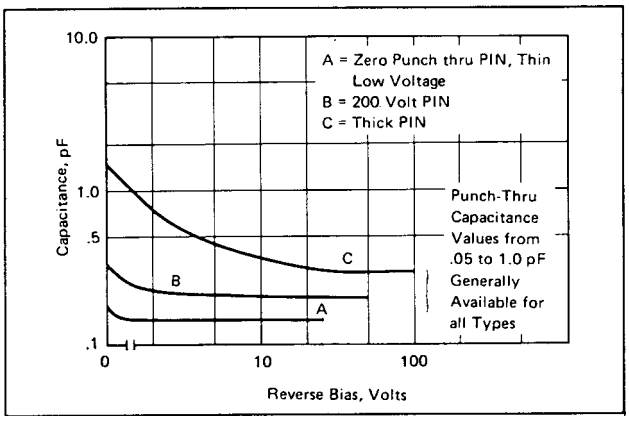

Figure 2-15 Typical 1-MHz capacitance.

The 1-MHz capacitance as a function of reverse bias is seen in Figure 2-15. The 1-MHz capacitance decreases with bias until punchthrough, where $X_d = W$. However, at microwave frequencies well above the crossover, the junction looks like two capacitors in series:

$$C_T = \frac{C_d C_u}{C_d + C_u} \propto \frac{1}{W} \tag{2-38}$$

That is, the microwave capacitance tends to be constant, independent of X_d and bias voltage.

However, since the undepleted zone is lossy, an increase in bias up to the punchthrough voltage reduces the loss.

At any given frequency, the equivalent network can now be drawn as Figure 2-16. R_v is now the equivalent series resistance of the undepleted region. Typical R_v data are shown in Figure 2-17. An alternate equivalent network is shown in Figure 2-18, and typical R shunt data are shown in Figure 2-19.

A good way to understand the effects of series resistance is to observe the insertion loss of a PIN chip shunt mounted in a 50-Ω line, as shown in Figure 2-20. An accepted way to include reverse loss in the figure of merit of a PIN diode is to write

$$Q = \frac{1}{2\pi + \sqrt{R_s R_v C}} \tag{2-39}$$

where R_s and R_v are measured under the expected forward- and reverse-bias conditions at the frequency of interest.

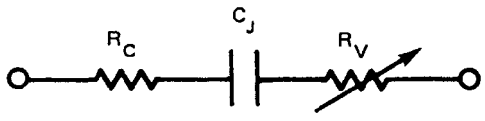

Figure 2-16 Simplified equivalent series circuit.

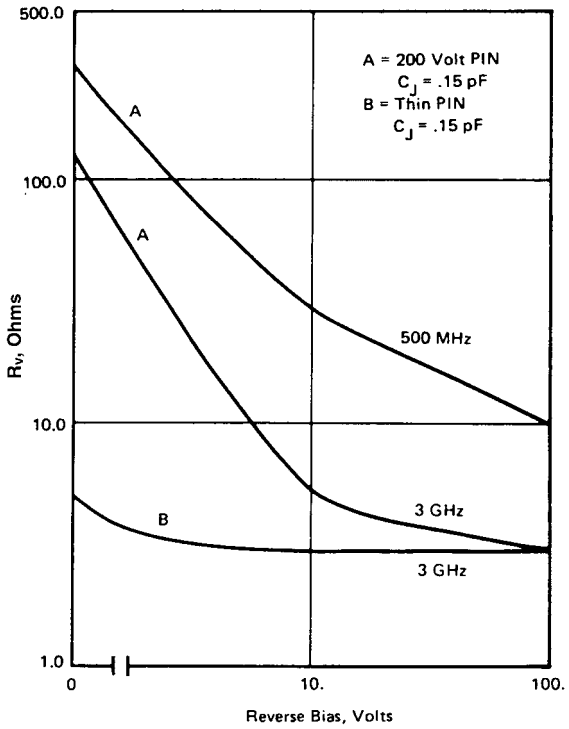

Figure 2-17 Reverse series resistance R_V.

The punchthrough voltage is a function of the resistivity and thickness of the I region. It is advisable to measure loss as a function of bias voltage and RF voltage to determine if the correct diode has been selected for your application. (*Note*: At frequencies below crossover, and diodes with thin I regions, the effective junction capacitance can increase substantially at low forward bias, on the order of 1–200 μA.)

Incidentally, if you are working with PIN or NIP chips that do not have an opaque covering, note that PIN diodes are photosensitive. Incident light causes photogeneration of carriers in the I region, increasing the chip's insertion loss.

PIN Diode Applications. If the intrinsic zone is thick (10–100 μm), we then have a high-reverse-voltage rectifier with a low forward-voltage drop at high current or, in other

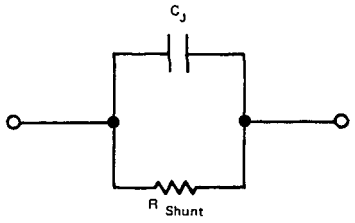

Figure 2-18 Simplified equivalent circuit, shunt.

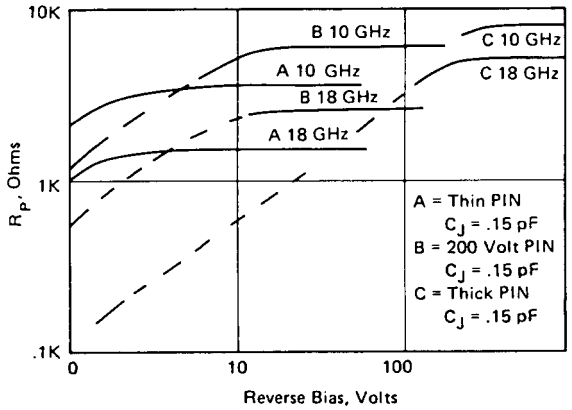

Figure 2-19 Reverse shunt resistance, R_p.

words, a highly efficient rectifier. The low forward voltage results from the fact that the conductivity of the I zone can be modulated by large amounts of charge carriers injected from the *p* and the *n* zones.

Another application of PIN diodes is the high-frequency (HF) field. Here, the fact is exploited that, due to the long carrier lifetime at frequencies beyond approximately 10 MHz, a rectifying effect will no longer occur and the PIN diode rather behaves like a real resistance, the magnitude of which depends on the forward direct current passed by the device and

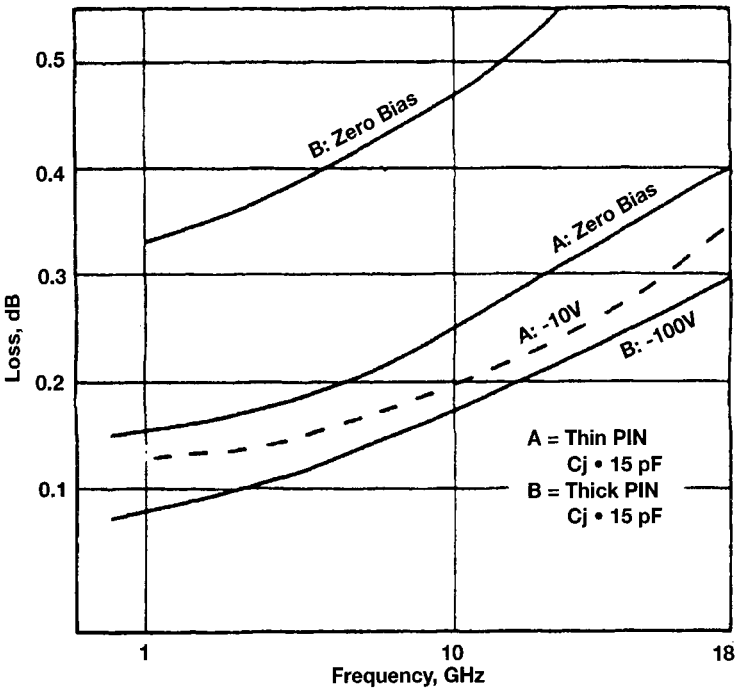

Figure 2-20 Insertion loss versus frequency.

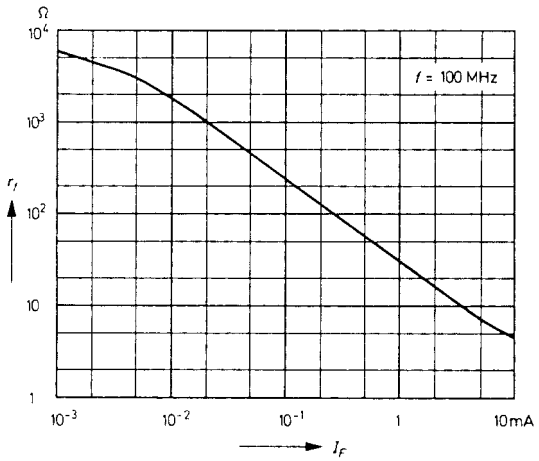

Figure 2-21 Forward resistance versus forward current.

produces an equal effect on both half waves of the HF signal. In view of this behavior, the PIN diode can be used as a switch or a variable resistor for HF signals. Thus it becomes possible, for example, to subject an HF signal to amplitude modulation by means of an AF-controlled PIN diode.

An important application of PIN diodes that has found favor in recent times is for dc-operated attenuators in TV tuners and antenna distribution amplifiers. Figure 2-21 shows the real HF forward resistance r_f as a function of the forward current I_f, measured at 100 MHz. Figures 2-22 and 2-23 show second-order IMD and cross-modulation for PIN diodes.

Applying the PIN in Amplitude Control of High-Frequency Signals. In conventional transistorized TV tuners, automatic gain control (AGC) is usually achieved by varying the emitter current of the input transistor. This method exploits the fact that the input transistor exhibits maximum gain at a certain level of emitter current and that this gain decreases when the emitter current is either increased or decreased relative to this point. Since modulation capacity and cross-modulation resistance grow with the emitter current, "upward" gain control has lately become the preferred solution, and according to it, gain reduction is achieved by an increase of the input transistor's emitter current. An input stage based on this design, therefore, is least resistant to cross-modulation when receiving a signal from a weak transmitter because it is operating at or below the point at which AGC action begins. This effect is particularly disadvantageous when the signal of a weak transmitter is to be received in the presence of a strong local transmitter. The unsatisfactory cross-modulation properties of such an input stage manifest themselves more and more frequently in the form of image perturbations as the TV reception band is crowded by an increasing number of transmitters. Another disadvantage is the variation in the transistor parameters that results from the control action. The variations affect antenna matching at the input and the response of the RF filter at the output.

To obviate these problems, methods being adopted today provide for the input stage to be equipped with cross-modulation-resistant transistors with fixed bias, gain control being provided by a variable attenuator preceding the transistor(s). The input-filter termination

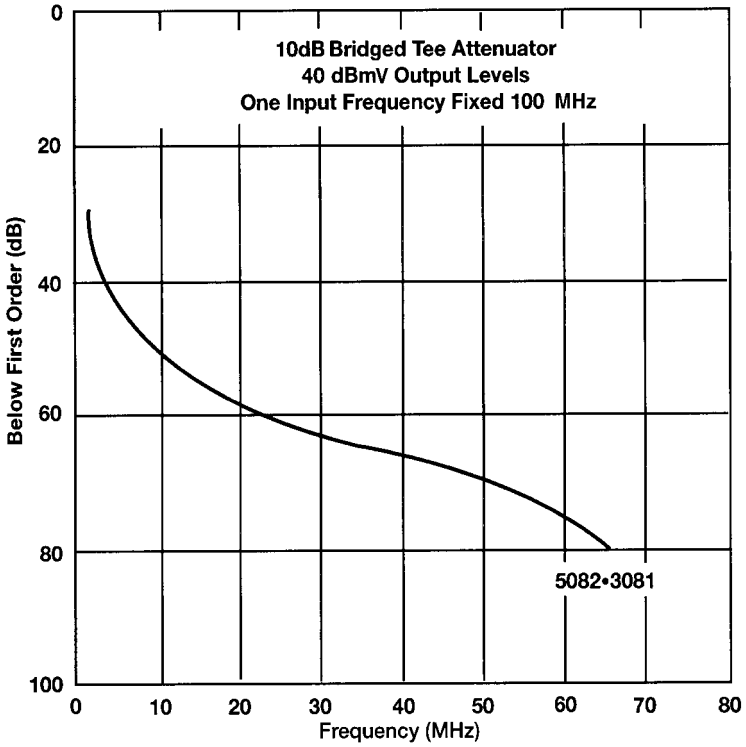

Figure 2-22 Second-order IMD in a PIN diode. Equation (1-48) can be used to determine the diode's IP_2 from the absolute values of its fundamental and IM_2 outputs.

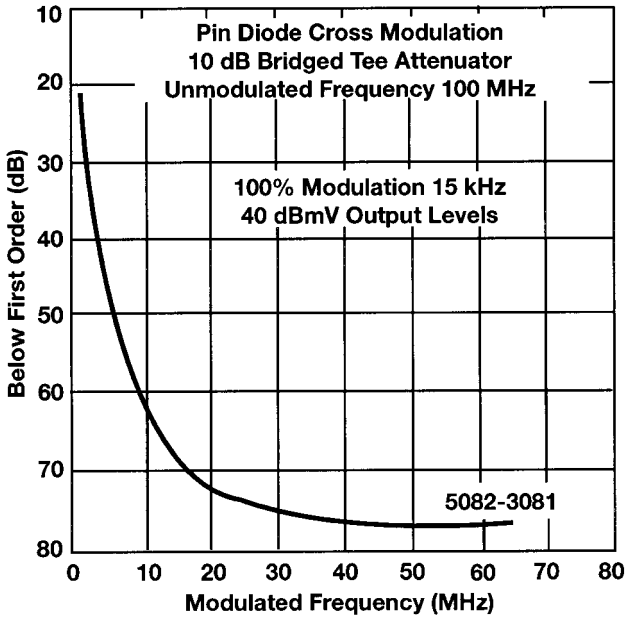

Figure 2-23 Cross-modulation in a PIN diode. Equation (2-61) relates cross-modulation level to IMD.

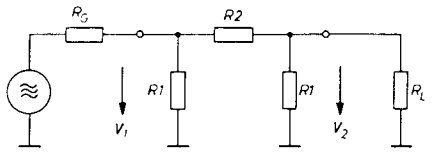

Figure 2-24 Basic circuit of a π-mode filter attenuator.

provided by this attenuator must be independent of the degree of attenuation to preserve the filter's response characteristics.

The first two requirements are met by the properties of the PIN diode and the latter requirement can be met by designing a PIN diode control in the form of a π network, a schematic of which is shown in Figure 2-24. The attenuation of a matched π network is expressed by the following equations:

$$\frac{a}{\text{dB}} = 20 \log \frac{Z + R_2}{R_2 - Z} \tag{2-40}$$

$$\frac{a}{\text{dB}} = 20 \log \left(\frac{R_1}{Z} + \sqrt{\frac{R_1^2}{Z^2} + 1} \right) \tag{2-41}$$

Figure 2-25 plots the relationship between the resistance levels of R_1 and R_2 and the input and output voltages of the π network. Figure 2-26 shows the circuit diagram of an implementation of the π network composed of PIN diodes. The resistance characteristic required according to Figure 2-25 is achieved approximately by varying the control current I_{co}.

If the control current I_{co} in Figure 2-26 equals zero, then—due to the fact that $R_1 = R_2$ and $R_3 = R_4$—the auxiliary voltage V_h causes forward currents of equal magnitude to flow through diodes D_1 and D_3. The voltage drops across R_1 and R_2 are of equal magnitude, so that no current passes through diode D_2. Therefore, the latter presents a high resistance, whereas D_1 and D_3 present a low resistance. Under these conditions, the network produces maximum attenuation. A control current I_{co} reduces the forward currents through D_1 and D_3 and allows a forward current to be passed by diode D_2. When it has attained its maximum value, diodes

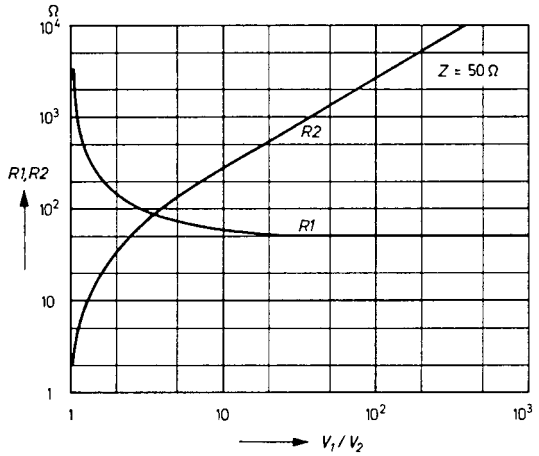

Figure 2-25 Values of R_1 and R_2 in Figure 2-24 versus relation of input and output voltage.

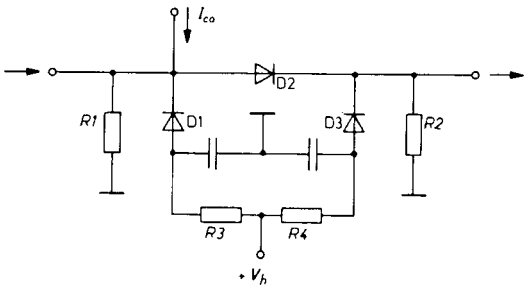

Figure 2-26 PIN diode π-mode attenuator.

D_1 and D_3 are blocked—that is, they are high-ohmic—and D_2 is low-ohmic. Under these conditions, the network produces its minimum attenuation.

If the maximum attenuation of the π network is to be increased, it is possible to make the two shunt diodes D_1 and D_3 more low-ohmic than the impedance Z, although this would reduce the reflection coefficient of attenuation. For example, if a reflection coefficient of about 7 dB is accepted over the entire control range, then a maximum attenuation of 25–30 dB could be achieved in the VHF range. The series inductances of the transverse diodes and the shunt capacitance of the series diode are responsible for this relatively unsatisfactory value. Improved attenuation is brought about with the integrated π network described in the next section.

Example: A PIN Diode π Network for TV Tuners. The since-discontinued TDA1053 is an example of an integrated PIN π network attenuator intended for TV-tuner use. It comprises three silicon planar PIN diodes connected to form a π network (Figure 2-27) and serves for the electronic amplitude control of the input signals of TV tuners and antenna distribution amplifiers in the 40–1000-MHz range. Its input and output impedances remain constant over the entire control range. This can also be achieved with discrete diodes.

The TDA1053 was normally supplied with vertical leads. The characteristics stated below apply to devices of this configuration.

MAXIMUM RATINGS OF INDIVIDUAL DIODES

Reverse voltage	V_R	30	V
Forward current at $T_{amb} = 25$ °C	I_F	50	mA
Junction temperature	T_j	125	°C
Storage temperature range	T_s	−55 to +125	°C

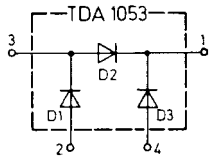

Figure 2-27 Internal circuitry of the TDA1053.

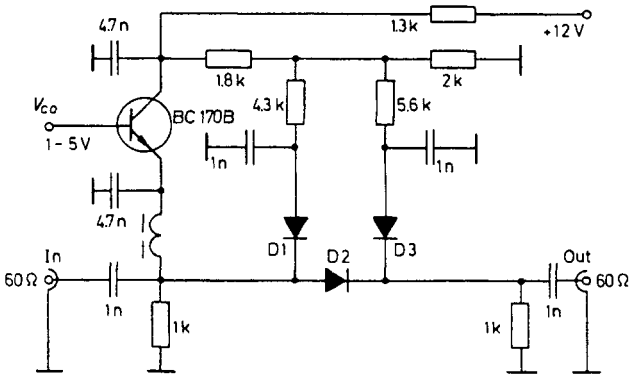

Figure 2-28 Test and application circuit.

MAXIMUM RATINGS OF THE π NETWORK

Ambient operating temperature range when operating according to Figure 2-28	T_{amb}	100	°C

CHARACTERISTICS OF INDIVIDUAL DIODES AT T_{amb} = 25 °C

Forward voltage at I_F = 50 mA	V_F	< 1.2	V
Forward current at V_R = 15 V	I_R	< 500	nA
Differential forward resistance:			
At I_F = 10 mA, f = 100 MHz	r_f	5	Ω
At I_F = 10 µA, f = 100 MHz	r_f	1.4	kΩ

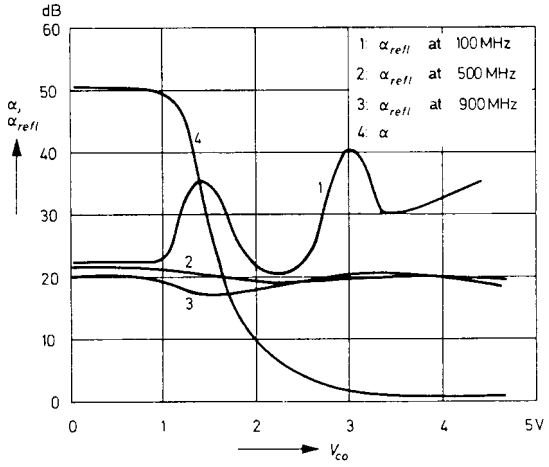

Figure 2-29 Attenuation and reflection attenuation versus control voltage.

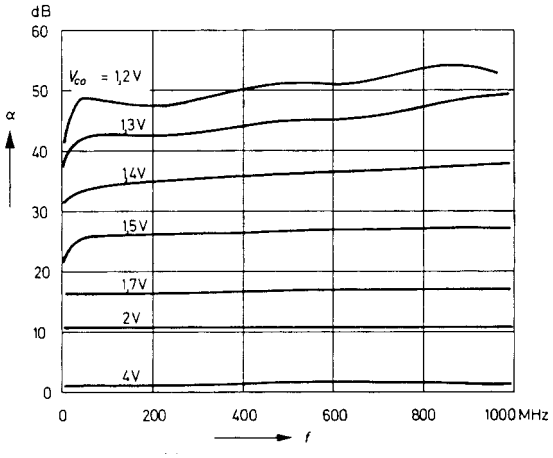

Figure 2-30 Attenuation versus frequency.

CHARACTERISTICS IN THE TEST CIRCUIT (FIGURE 2-28) AT T_{amb} = 25 °C

Voltage for 1% cross-modulation	V_{cr}	1	V
Attenuation in the 40–1000-MHz range:			
At V_{co} = 1.5 V (1–2 V)	a_{max}	45 (> 36)	dB
At V_{co} = 5 V (4–5 V)	a_{min}	1.5 (< 2)	dB
Reflection coefficient in the 40–1000-MHz range over the entire control range, depending on circuit design	a_{refl}	20 (> 16)	dB

These data reveal that the compact design of the three PIN diodes in a common 50B4 plastic package guarantees favorable values for minimum and maximum attenuation, as well as reflection attenuation. The test and application circuit shown in Figure 2-28 also comprises the transistor control-signal amplifier. The typical characteristic of the attenuation and the reflection attenuation for this circuit are shown in Figure 2-29, as a function of the control voltage V_{co}. Figure 2-30 shows the attenuation at different control voltages, as a function of frequency.

2-1-4 Tuning Diodes

Introduction. In recent years, continuous development of tuning diodes—also known as *varactors* or *varicaps*—together with increased commercial and military use has led to substantial improvement in Q, reproducibility, and reliability. Concurrently, new techniques for producing and controlling a hyperabrupt dopant profile in the semiconductor permit the capacitance–voltage law to be much faster than the classical square root or cube root behavior.

Current tuning diode materials include silicon and gallium arsenide; silicon is favored for low cost and lower Q applications from HF through microwave frequencies. Hyperabrupt varactors, also of silicon, are finding many applications in commercial television tuners, where their high tuning ratios, linear tuning, and low cost are needed. New developments include low-capacitance hyperabrupts for microwave and wireless applications.

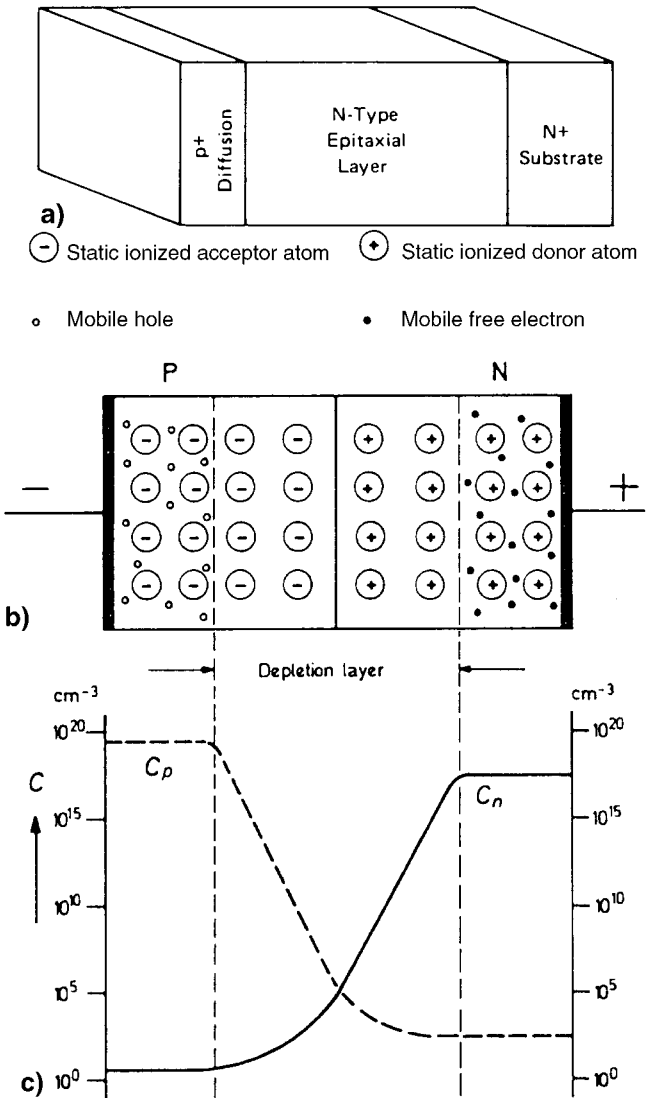

Figure 2-31 (a) Basic PIN structure; (b) cross section of a reverse-biased *pn* junction; and (c) density distribution of free charge carriers.

Gallium arsenide is used with high operating frequency and dictates the highest Q possible, as in parametric amplifiers and millimeter multipliers.

This section will acquaint the reader with tuning diodes: how they work, and what they can or cannot be expected to do in an electronic circuit. The basic properties of a tuning diode will be described in terms of the parameters that manufacturers use in characterizing them. The following topics will also be addressed:

- Capacitance ratio with respect to voltage and voltage breakdown
- Q as a function of design and operating conditions

- Stability—leakage current, temperature coefficient, and post-tuning drift
- Distortion products
- Packaging parasitics
- Applications—suggestions on how to specify a varactor

Tuning Diode Physics

Introduction. All junction diodes are made up of the same physical parts: a *pn* junction, a carefully controlled epitaxial layer, and a very-low-resistance substrate. These parts are shown in Figure 2-31.

No matter what type of junction device we are discussing—a tuning diode, a step-recovery diode, or a PIN diode—these parts are all present; the main difference between these devices is the resistivity and thickness of the epitaxial layer. Tuning diodes and multiplier diodes need epitaxial layers where both the resistivity and thickness are carefully controlled.

Abrupt Junction. An abrupt-junction diode is one in which the p^+ diffused region of the diode is much more highly doped than the epitaxial layer. Also, the high doping drops to the doping level of the epitaxial layer in a distance that is short compared to the epitaxial layer thickness, and the doping level of the epitaxial layer is constant over its thickness. This is shown in Figure 2-32, with the corresponding C–V curve shown in Figure 2-33. When these requirements are satisfied, the diode capacity, diode area, epitaxial layer doping level, and diode voltage are related by

$$\frac{C(V)}{A} = K\left(\frac{N}{V+\varphi}\right)^n \tag{2-42}$$

where $C(V)$ = capacitance of the diode at voltage V
A = area of the diode
N = doping level of the epitaxial layer

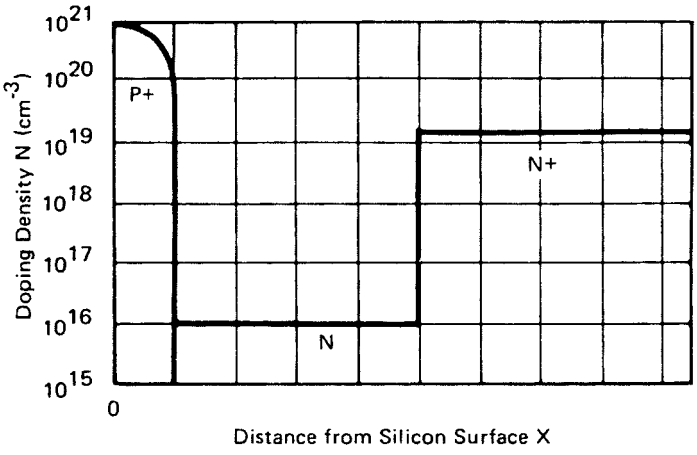

Figure 2-32 *N–X* abrupt junction.

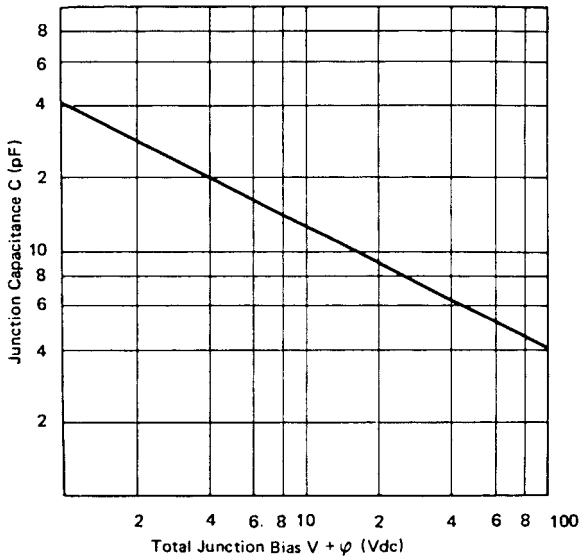

Figure 2-33 Capacitance versus total junction bias for abrupt-junction diode.

V = voltage applied to the diode
φ = built-in potential of the diode (0.6–0.8 V)
n = slope of diode C–V curve; $n \approx 0.5$ for an abrupt-junction diode
K = constant

As a consequence of the physical properties of a *pn* junction, a depletion layer is formed between the *p* and *n* regions whose width depends on the voltage applied to the diode. The capacitance of the diode is inversely proportional to the width of the depletion layer; that is, $C \sim 1/\ell_0$. In addition, the series resistance of the diode is proportional to the width of the undepleted epitaxial layer. Thus, as diode reverse bias is increased, the depletion layer increases, causing a decrease in capacitance and a decrease in series resistance. As the diode reverse bias is increased further, a point is reached where the electric field caused by the reverse bias reaches a critical level, and current through the diode increases rapidly; this is

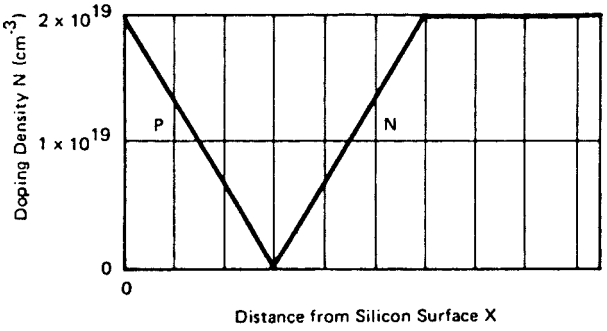

Figure 2-34 *N–X* linearly graded junction.

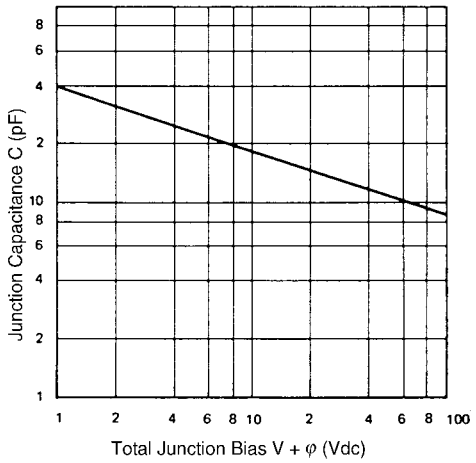

Figure 2-35 Capacitance versus total junction bias for linearly graded junction.

breakdown voltage of the diode. If, at the breakdown voltage, the epitaxial layer is not completely depleted, the diode will have excessive series resistance. Conversely, if the epitaxial layer is depleted before the breakdown voltage is reached, no further capacitance decrease occurs after the total depletion, and a condition called *punchthrough* occurs.

While, in the ideal case, voltage breakdown will occur just as the epitaxial layer is totally depleted, this seldom occurs in practice, and we generally have a condition of either punchthrough or excess series resistance.

Linearly Graded Junction. If, instead of the junction profile shown in Figure 2-32, we have a p^+ region and an n region whose doping levels increase linearly with distance from the pn junction as shown in Figure 2-34, with its corresponding C–V curve in Figure 2-35, then we have what is called a linearly graded junction diode. This diode follows Eq. (2-42) with the exception that the exponent n is equal to $\frac{1}{3}$. This means that, for a given voltage change, the linearly graded junction will have a smaller capacitance change than an abrupt-junction diode. Since, in most cases, the designer is looking for the maximum

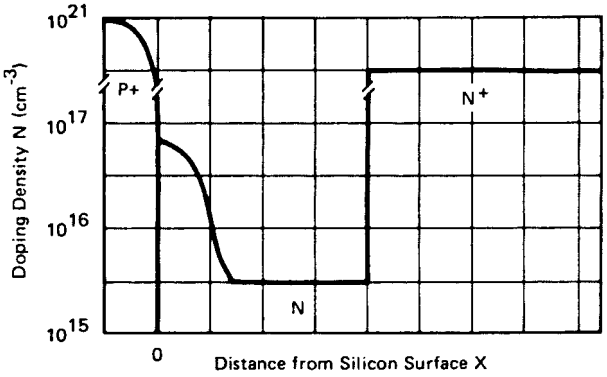

Figure 2-36 *N–X* hyperabrupt-junction diode.

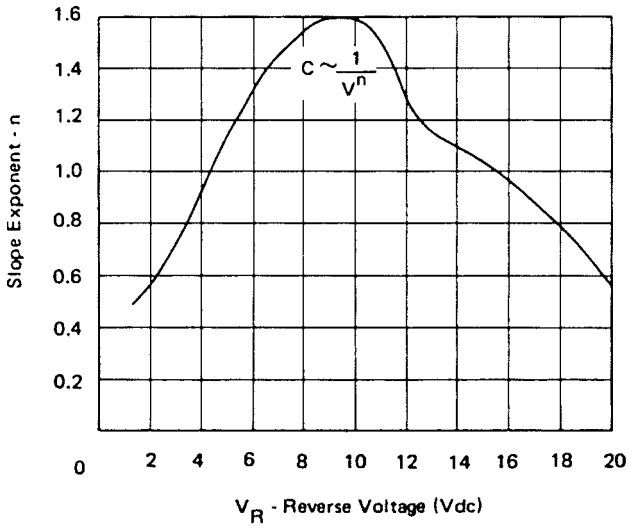

Figure 2-37 Typical *n* versus reverse voltage characteristic for hyperabrupt-junction diode.

capacitance change obtainable, the linearly graded junction is not used as a tuning diode. This structure found its greatest use several years ago as a "cube law" multiplier, but even this use has decreased as new structures have been developed.

Hyperabrupt Junction. The hyperabrupt-junction diode provides a greater capacitance change than the abrupt-junction diode for a given voltage change, as well as a linear frequency versus voltage characteristic over a limited voltage range. The structure of the hyperabrupt-junction diode is shown in Figure 2-36 and can be seen to be an abrupt-junction diode with an additional, increased doping level at the *pn* junction. This diode also follows Eq. (2-42) with the exception that n is not a function of voltage and is generally in the range of 0.5–2. A typical curve of n versus voltage is shown in Figure 2-37.

The C–V curve in a hyperabrupt-junction diode is shown in Figure 2-38 and is seen to start at a high value of capacitance per unit area at low bias (high epitaxial doping) and change to a lower value of capacitance per unit area (low epitaxial doping) at high bias. The details of the curve depend on details of the shape of the more highly doped region near the *pn* junction.

Unfortunately, with a hyperabrupt-junction diode, you must settle for a lower Q than an abrupt-junction diode with the same breakdown voltage and same capacitance at 4 V.

It should be noted that any diode that has an n value that exceeds 0.5 at any bias voltage is, by definition, a hyperabrupt-junction diode. Thus, the hyperabrupt-junction diode family can have an infinite number of different C–V curves. Since the abrupt-junction diode has a well-defined C–V curve, the capacitance value at one voltage is sufficient to define the C–V capacitance at any other voltage. This is not the case for the hyperabrupt-junction diode. In order to adequately define the C–V characteristics of a hyperabrupt-junction diode, two and sometimes three points on the curve must be specified.

Silicon Versus Gallium Arsenide. Everything mentioned so far applies to both silicon and gallium arsenide (GaAs) diodes. The main difference between silicon and GaAs from a

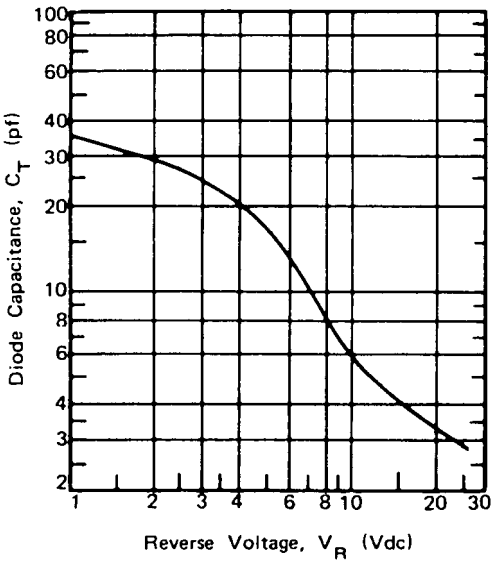

Figure 2-38 Capacitance versus junction bias for hyperabrupt-junction diode.

user's point of view is that higher Q can be obtained from GaAs devices. This is due to the lower resistivity of GaAs from a given doping level N. The resistivity of the epitaxial layer, or substrate, of a diode is given by

$$\rho = \frac{1}{Ne\mu} \tag{2-43}$$

where ρ = the resistivity
N = the doping level of the layer
e = the charge on an electron
μ = is the mobility of the charge carriers in the layer

Gallium arsenide has a mobility about four times that of silicon and, thus, a lower resistivity and higher Q for a given doping level N. Since diode capacitance is proportional to $\sqrt{N}$, independent of resistivity, a silicon diode and a GaAs diode of equal area and doping will have a capacitance difference proportional to the square root of the dielectric constant ratio. This gives the GaAs diode a 5% higher capacitance and is thus of little practical significance. The penalty paid for using GaAs is an unpassivated diode and a more expensive diode due to higher material and processing costs. If the higher Q of the GaAs device is not really needed, a substantial price saving will be obtained by using a silicon device.

Planar Versus Mesa Construction. The two basic construction techniques used to manufacture tuning diodes are planar and mesa; cross sections for both of these devices are shown in Figure 2-39. The planar process, which is the backbone of the integrated circuit industry, lends itself to large-volume production techniques and is the one used for the 1N series of tuning diodes. Mesa processing, on the other hand, requires more

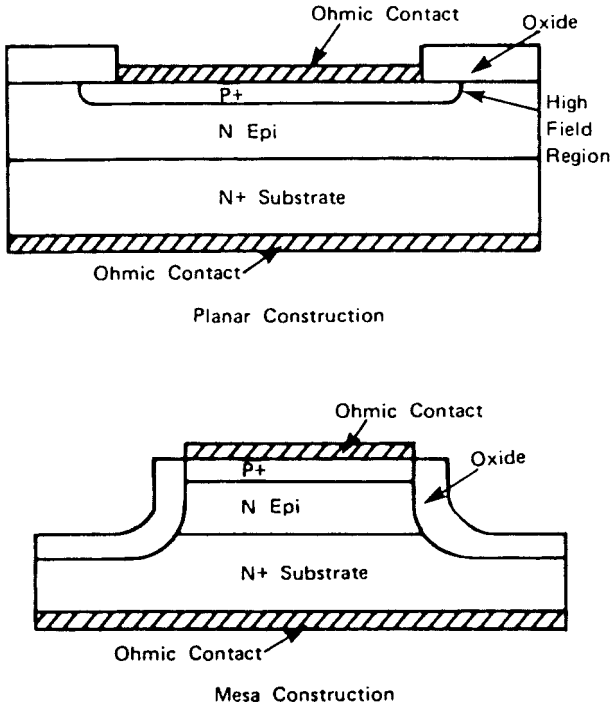

Figure 2-39 Cross sections of planar and mesa devices.

processing steps and is generally done on a wafer-by-wafer basis. This results in a more costly process and thus a more expensive diode. All microwave tuning diodes are of mesa design because of greatly higher Q. Due to the relatively small radius of curvature at the junction edge of a planar diode, the electric field in this area is greater than the electric field in the center (flat) portions of the junction. As a result, the breakdown voltage of the diode is determined by both the epitaxial resistivity and the radius of curvature of the junction edge. Thus, for a given breakdown voltage, a planar diode must use higher resistivity epitaxial material than a mesa diode, which has a completely flat junction. The end result is that the planar diode has a greater series resistance than a mesa diode for the same capacitance and breakdown voltage, and thus lower Q.

Capacitance

Capacitance Ratio. From the user's point of view, the capacitance ratio is simply the capacitance change available in the circuit. Thus, a user tuning from, say, –4 to –45 volts defines capacitance ratio as

$$R = \frac{C_T(-4)}{C_T(-45)} \tag{2-44}$$

where C_T includes C_J plus C_P plus C_F. The manufacturer, however, defines C_T as $C_J + C_P$.

To explore the significance of this difference, let's take two examples, one with a large C_J and another with a small C_J, in chip, package, and "typical" fringe situations. Both are 45-V tuning varactors.

Device	C_{J0}	C_{J45}	Ratio
A	0.6 pF	0.1 pF	6.0
B	15.0 pF	2.5 pF	6.0

Put both devices in a standard 023 package with C_P (strap and ceramic) of 0.18 pF:

Device	C_{T0}	C_{T45}	Ratio
C	0.78 pF	0.28 pF	2.75
D	15.18 pF	2.68 pF	5.67

Notice the drop in capacitance ratio, especially for the low-C_J diode. If we now add a typical 0.04 pF for external fringe capacitance, we get the following results:

Device	C_{T0}	C_{T45}	Ratio
C	0.82 pF	0.32 pF	2.56
D	15.22 pF	2.72 pF	5.6

The reduction in capacitance ratio, and thus circuit tuning capability, by the fringing fields is quite obvious and amounts to 7% in this example.

Because of the often stringent specifications on tuning ratio, it is mandatory that the manufacturer and customer clearly agree on the exact design of the holder used to measure the varactor in question.

Having described how to measure capacitance, it is relatively easy to describe the results. The section on diode physics described the various types of "laws," or C–V curves, and we will not repeat them here. Nonetheless, several important points must be covered.

The first is "available capacitance swing." The laws indicate a steadily decreasing capacitance with voltage, which indicates that the epitaxial region is widening and the electric field is increasing. (For an abrupt junction, since $C \propto 1/\sqrt{V}$, the depletion zone with W is increasing as $\sqrt{V}$, and the electric field V/W increases as $\sqrt{V}$.)

Two things can happen:

1. The junction width widens so that the entire intrinsic region is depleted. The capacitance bottoms out, resulting in voltage punchthrough.
2. The electric field exceeds the dielectric strength of silicon (or GaAs), and "solid-state discharge" or "avalanche" current is drawn.

The diode impedance drops, the varactor no longer "varacts," and circuit operation ceases. Moreover, if more than a few milliamperes of current is drawn, localized overheating may destroy the diode, resulting in breakdown voltage. All varactors are characterized for breakdown voltage—for example, 45 V minimum.

The theoretical tuning varactor is designed so that the punchthrough occurs at a voltage equal to the voltage breakdown of the diode. Logically, this means that in order to obtain

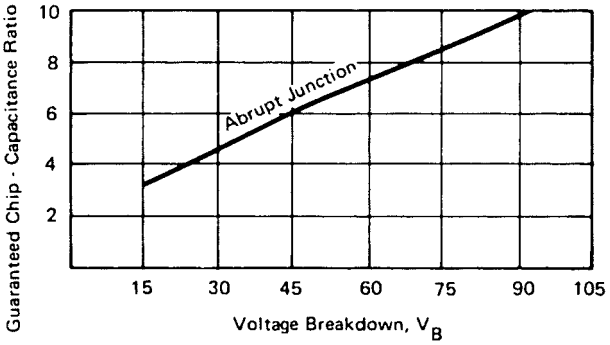

Figure 2-40 Capacitance ratio versus breakdown voltage.

greater tuning ratios, it is necessary to be able to increase the depletion-layer width without reaching punchthrough or breakdown. You must have a thicker epitaxial region to make this possible.

Figure 2-40 shows catalog ratio values, from zero bias to breakdown, as a function of breakdown voltage necessary. In the next section, on Q, we will discuss other elements in your choice of V_B.

To complete this section, we should mention that semiconductor processing control has been refined so well that capacitance tracking to within ±1% over the full range from zero to breakdown is now readily obtainable in production quantities.

Temperature Coefficient of Capacitance (T_{CC}). Unfortunately, since most datasheets give the value of T_{CC} at 4 V, it is sometimes assumed that this value applies at all bias voltages. This is not the case. Consider Eq. (2-45), a rewritten form of Eq. (2-42):

$$C(V) = \frac{C(O)}{(V + \varphi)^n} \tag{2-45}$$

Taking the derivative of this with respect to temperature T we have

$$\frac{dC(V)}{dT} = \frac{+nC(O)}{(v + \varphi)(v + \phi)^n} \frac{d\varphi}{dT} \tag{2-45a}$$

or, after substituting Eq. (2-45):

$$T_{CC} = \frac{1}{C(V)} \frac{dC(V)}{dT} = \frac{-n}{(V + \varphi)} \frac{d\varphi}{dT} \tag{2-46}$$

As a first approximation, we can say that $d\varphi/dT = -2.3$ mV/°C over the temperature range of interest.

From Eq. (2-46) we can draw the following conclusions:

1. The temperature coefficient is inversely proportional to the applied voltage.
2. The temperature coefficient is directly proportional to the diode slope, n.

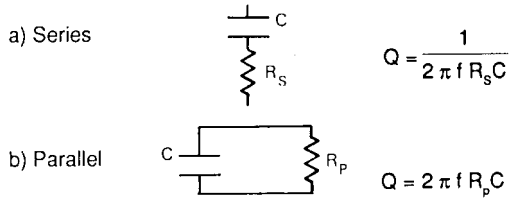
For an abrupt-junction diode that has a constant value of n (0.5), the temperature coefficient has a smooth curve in the form $K/(v + \varphi)$. However, in the case of hyperabrupt-junction diodes, n is a function of voltage, and the shape of the T_{CC} curve depends on the details of the $n(V)$ curve. A typical T_{CC} curve for an abrupt-junction diode is shown in Figure 2-41 and for an Alpha DKV6520 series hyperabrupt-junction diode in Figure 2-42. The inflection in the hyperabrupt T_{CC} is due to the fact that in this voltage range $n(V)$ is increasing faster than $1/V$, giving an increase in T_{CC}. It should also be noted, however, that over the range of the T_{CC} minimum the temperature coefficient is relatively constant, and operation in this area may be advantageous in some applications where a restricted tuning range can be used.

Q Factor or Diode Loss

Definitions. The classical definition of the Q of any device or circuit is

$$Q = \frac{2\pi \times \text{Energy stored}}{\text{Energy dissipated per cycle}} \tag{2-47}$$

For a capacitor, two formulations are possible:



Clearly, the two definitions must be equal at any frequency, which establishes

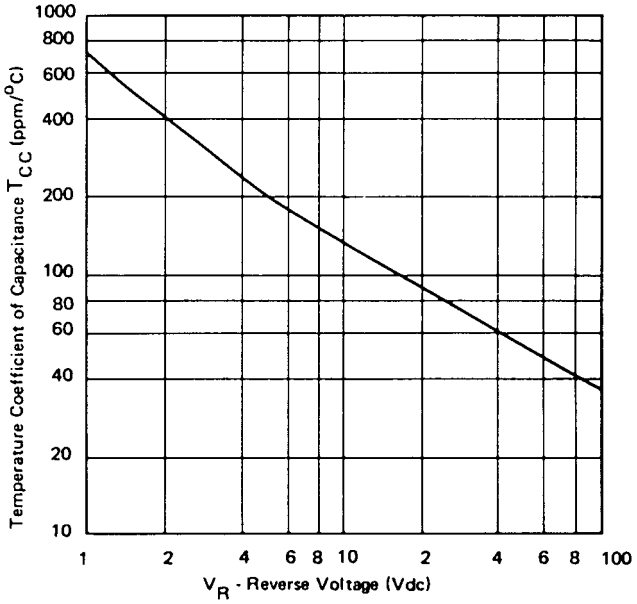


Figure 2-41 Temperature coefficient of capacitance versus tuning voltage for an abrupt-junction diode.

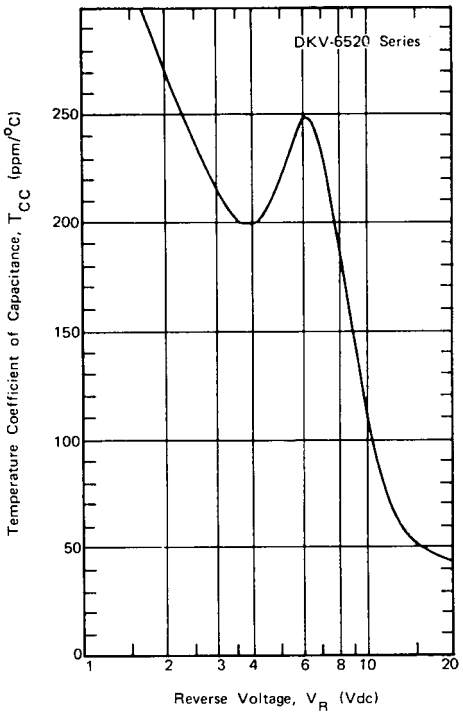

Figure 2-42 Temperature coefficient of capacitance versus tuning voltage ($T_A = 25$ °C) hyperabrupt-junction diode.

$$R_P = \frac{1}{(2\pi f)^2 C^2 R_S} \tag{2-48}$$

In the case of a high-Q tuning diode, the proper physical model is the series configuration, because the depleted region is almost perfectly pure capacitance, and the undepleted region, due to its relatively low resistivity, is almost a pure resistor in series with the capacitance. Furthermore, the contact resistances are also clearly in series. Q, then, for a tuning diode, is given by

$$Q_{(-v)} = \frac{1}{2\pi f_o R_{(-v)} C_{(-v)}} \tag{2-49}$$

where f_o is the operating frequency, $C_{(-v)}$ is the junction capacitance, and $R_{(-v)} = R(\text{epi}) + R_{C'}$, the sum of the resistance of the undepleted epitaxial layer and the fixed contact resistance.

Cutoff frequency, f_c, is defined as that frequency at which Q equals unity. Thus,

$$f_{c_{(-v)}} = \frac{1}{2\pi R_{(-v)} C_{(-v)}} \tag{2-50}$$

Historically, the tuning diode business has specified Q at 50 MHz, despite the fact that Q values of microwave diodes are so high that it is almost impossible to measure them at 50

Table 2-7 Parameters for 0.6-pF diode

Breakdown Voltage V_B	Resistivity ($\Omega \cdot$ cm)	Junction Diameter (mills)	Epitaxial Region (μm)	Depleted Epitaxial $V = -4$ V (μm)	Undepleted Epitaxial $V = -4$ V (μm)	R Undepleted (Ω)	R_{sp} (Ω)	Q_4
30	0.31	2.4	1.37	0.54	0.83	0.81	0.18	5200
45	0.52	2.8	2.25	0.73	1.52	1.86	0.15	2600
60	0.74	3.2	3.20	0.90	2.30	3.24	0.13	1500
90	1.25	3.7	5.27	1.21	4.06	7.17	0.10	700

MHz. Instead, as discussed below, Q is measured at microwave frequencies (e.g., 1–3 GHz) and related to 50 MHz by the relationship

$$Q_{(f1)} = Q_{(f2)} \frac{f_2}{f_1} \tag{2-51}$$

which derives quickly from the assumption that f_c is independent of the measuring frequency.

Since both junction capacitance and epitaxial layer resistance are functions of the applied bias, it is not possible to calculate Q as a function of bias from a measurement of capacitance alone. Catalog specifications typically show Q at –4 V, together with the capacitance at two or more voltages.

Relative to $Q_{(-4)}$, Q increases faster than the reduction in capacitance for bias greater than 4 V and, conversely, decreases faster for bias less than 4 V.

In the following section, we will discuss the diode design parameters that determine Q. Following this, we will describe some elementary Q measurement techniques.

Causes. In the discussion of device physics, the resistivity of the epitaxial region was discussed, together with its impact on punchthrough and breakdown. For example, Table 2-7 supplies typical resistivity and relative parameters of 0.6 pF ($C_{J(4)}$) diodes of different breakdowns. If we remember that if at any bias lower than breakdown the epitaxial region is not completely depleted, it follows that the undepleted portion presents a resistance in series with the pure capacitance of the depleted zone. The magnitude of this "undepleted" resistance is also shown in the table.

The entry R_{sp} ($R_{spreading}$) is the series resistance between the epitaxial region and the low-resistivity substrate. The calculations are for idealized cylindrical epitaxial regions of uniform resistivity, low-resistivity contact on the anode (top), and low-resistivity substrate on the cathode. This resistance is constant, independent of bias; also shown are epitaxial thickness region and width of the depletion zone at –4 V bias.

Note the substantial reduction in Q for high-voltage diodes caused by the increased epitaxial layer resistance; this is true for any value of capacitance or any type of junction. For greater voltage breakdown, the epitaxial region thickness must be increased, which requires an increase in epitaxial layer resistivity; the higher the resistivity of the undepleted zone, multiplied by the fact that it is much wider for high-voltage diodes, means the resistance increases substantially.

Consequently, a rule of thumb emerges: For maximum Q, never choose a tuning diode with a voltage breakdown in excess of what is needed for the necessary tuning range. If the

Table 2-8 ***Q*** **versus bias for 0.6-pF diode**

Breakdown Voltage V_B	C_{J0}	$Q(0)$	$C_J(-4)$	$Q(-4)$	$C_J(-10)$	Q (−10)	$C_J(-30)$	$Q(-30)$	$C_J(-45)$	$Q(-45)$	$C_J(-60)$	$Q(-60)$	$C_J(-90)$	Q(−90)

Table 2-9 Capacitance ratios (C_{J0}/C_JV_B)

Breakdown Voltage V_B	Optimum Ratio	Minimum Guaranteed Ratio	$Q_{(-4)}$ Typical
30	6.2	4.5	3000
45	7.5	6.0	2500
60	8.4	7.5	1400
90	10.2	8.7	650

required tuning range is an octave, requiring a 4:1 ratio, the selection of a 30-V diode will result in diode losses half those of a 60-V diode.

Table 2-8 lists capacitance and Q for each of these chips as a function of bias. Please remember that Q is calculated at 50 MHz.

Table 2-9 rewrites the data of Table 2-8 to show available capacitance ratios between zero bias and breakdown. The first column is the theoretical optimum, as tabulated. The second column is the typical catalog specification. The reduction in tuning ratio below theoretical optima is caused by nonideal junction fabrication. The junctions are never perfectly abrupt.

Although the tables and numbers given refer to abrupt-junction silicon devices, the principle applies without exception to all types of tuning diodes. For comparison, Table 2-10 lists available ratios and Q values for a number of different varactors. The high Q values for GaAs and the low values for hyperabrupts are apparent.

One last point: The Q values and series resistance refer to chips only. The effects of package parasitics will be discussed later, but it is important to consider circuit contact losses here. For low-capacitance diodes—for example, $C_{J4} = 0.6$ pF—the epitaxial region contributes a high value of resistance and dominates Q except at punchthrough. Diode contact losses are less significant.

Post-Tuning Drift. Post-tuning drift (PTD) is the change in oscillator frequency with time after the tuning voltage has stabilized. The minimization of PTD has assumed greater importance with the design of more sophisticated electronic countermeasure systems, where rapid, accurate frequency changes are required.

Table 2-10 Comparative Tuning Diodes

Type	C_{J0}	Breakdown Voltage V_B	$Q_{(-4)}$[a]	Ratio C_{J0}/C_JV_B[a]
Silicon abrupt	1.0	30	5,000	4.5
Silicon abrupt	2.5	30	4,600	4.5
Silicon abrupt	5.0	30	3,800	4.5
Gallium arsenide abrupt	1.0	25	10,000	3.6
Gallium arsenide abrupt	0.5	10	17,000	2.5
Silicon hyperabrupt	50.0	22	300	17.0
Silicon hyperabrupt	2.5	22	500	14

[a] Minimum guaranteed.

Post-tuning drift can be characterized as short-term and long-term. Short-term PTD occurs in the time range of tens of nanoseconds to a few seconds, while long-term PTD occurs in the time range of seconds to minutes, hours, or days.

Short-term PTD is mainly dependent on the thermal properties of the diode and is improved by high Q (low power loss) and flip chip construction. Long-term PTD depends on oxide stability and freedom of mobile charge in the oxide. It should be noted that actual oscillation frequency change may occur even with a perfect tuning diode because of variation with frequency in the power dissipated by the diode, changes in the diode heat-sink temperature, and frequency changes due to other circuit elements. Less than 0.01% short- and long-term PTD can be obtained.

Distortion Products. Inasmuch as nonlinear components generate harmonics and other distortion products, an understanding of this mechanism is of prime interest to the circuit designer. In some instances, the distortion products are the desired end result of the circuit design, as in frequency multipliers, where harmonics of the input signal frequency are the required output signal. For other applications, such as tuning-diode-tuned linear circuits, distortion products are extremely undesirable, and in some instances the end product specification may set a maximum limit on the distortion products allowed.

Cross-Modulation. Cross-modulation is the transfer of the modulation on one signal to another signal and is caused by third-order and higher odd-order nonlinearities in the behavior of the device. Rewriting Eq. (2-42) we have

$$C(V) = \frac{C_0}{(1 + V/\varphi)^n} \tag{2-52}$$

where C_0 = capacitance
V = applied voltage = $V_0 + v$
V_0 = dc applied voltage
v = ac applied voltage

Then, for a desired signal of

$$S_1 = v_1 \sin \omega_1 t \tag{2-53}$$

and a second, amplitude-modulated signal of

$$S_2 = v_2(1 + m \cos \omega_m t)\sin \omega_2 t \tag{2-54}$$

it can be shown that the cross-modulation, γ, defined by

$$\text{Output signal} \sim v_1 \sin \omega_1 t + \gamma \sin (\omega_1 \pm \omega_m)t \tag{2-55}$$

is found to be

$$\gamma = \frac{n(n+1)mv_2^2}{4(V_0+\varphi)^2} \tag{2-56}$$

From this equation it can be seen that cross-modulation is:

- Proportional to the square of the interfering signal
- Directly proportional to the interfering signal's modulation index, m
- Independent of the strength of the desired signal
- Independent of the frequencies of the desired and interfering signals (assuming that the nonlinearity to which both signals are subjected is sufficiently frequency-indiscriminate so this is the case)
- Present for all values of n; that is, no value of n gives zero cross-modulation

Solving Eq. (2-56) for the signal level v_2 required to produce cross-modulation of value γ, we have

$$v_2 = \frac{2(V_0+\phi)\gamma}{n(n+1)^m} \tag{2-57}$$

The interfering signal levels required to produce 1% cross-modulation from a 30%-modulated interfering signal applied to an abrupt-junction diode and a hyperabrupt-junction diode are shown in Figure 2-43.

From this figure, it can be seen that the hyperabrupt-junction diode is more susceptible to cross-modulation than the abrupt-junction diode in the region of maximum slope of the

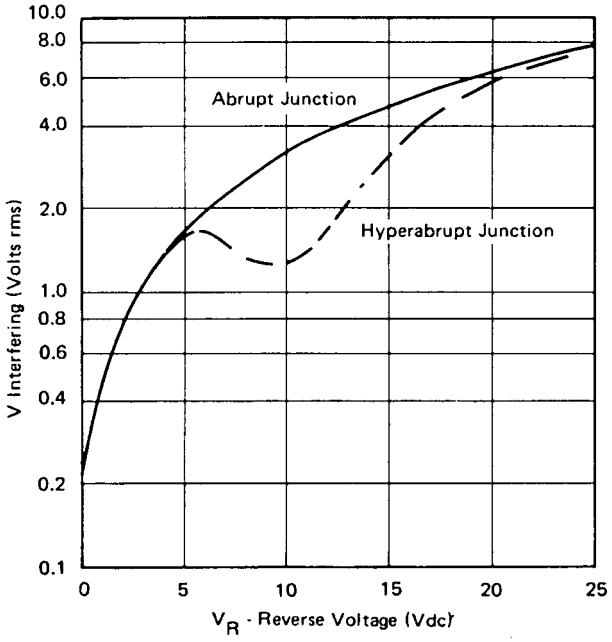

Figure 2-43 Interfering signal (30% amplitude modulated) level versus bias for 1% cross-modulation for abrupt-junction and hyperabrupt-junction diodes.

hyperabrupt-junction diode. For many applications, however, distortion products will be generated by other devices, such as transistors, at signal levels considerably below those given in Figure 2-43.

Intermodulation. Intermodulation is the production of undesired frequencies in the form

$$\sin(2\omega_1 t - \omega_2 t) \quad \text{and} \quad \sin(\omega_1 t - 2\omega_2 t) \tag{2-58}$$

from an input signal in the form of

$$v(\cos \omega_1 t + \cos \omega_2 t) \tag{2-59}$$

From an analysis similar to that done for cross-modulation, it can be shown that

$$\text{Intermodulation} = \frac{n(n+1)v^2}{8(V_0 + \varphi)^2} \tag{2-60}$$

or

$$\text{Cross-modulation} = (2m) \times \text{Intermodulation} \tag{2-61}$$

Harmonic Distortion. Harmonic distortion products are integral multiples of the signal frequencies and decrease in amplitude as the harmonic number decreases. Due to passband considerations and amplitude decrease with harmonic number, the second harmonic is the one of prime concern. Again, it can be shown that the second harmonic, v_2, of a signal of amplitude v_1 is

$$v_2 = \frac{n}{3(V_0 + \phi)} v_1^2 \tag{2-62}$$

Figure 2-44 shows the signal level required to produce 10% second-harmonic distortion in an abrupt-junction and a hyperabrupt-junction diode. Again, as in the case of cross-modulation, the hyperabrupt-junction diode is slightly worse than the abrupt-junction diode in the region of maximum slope of the hyperabrupt-junction diode.

Reduction of Distortion Products. In some cases, the signal levels applied to the diode generate distortion products larger than desirable for the circuit application. In this case, significant reduction in the distortion products can be achieved by using two diodes in a back-to-back configuration, as shown in Figure 2-45. Analysis shows that the fundamental signal components through the diodes are in phase and add, while some distortion products are out of phase and cancel, thus improving distortion performance.

Since the gradient of the electrical field produced in the depletion layer by a reverse bias applied to the device is proportional to the space charge density, the following equations can be written for the junction width W as a function of the reverse bias V_R:

For an Abrupt *pn* Junction (Alloyed Diodes)

$$W = {}_2\sqrt{2\frac{\varepsilon_r \varepsilon_0}{q}\left(\frac{1}{C_p} + \frac{1}{C_n}\right)(V_R + V_D)} \tag{2-63}$$

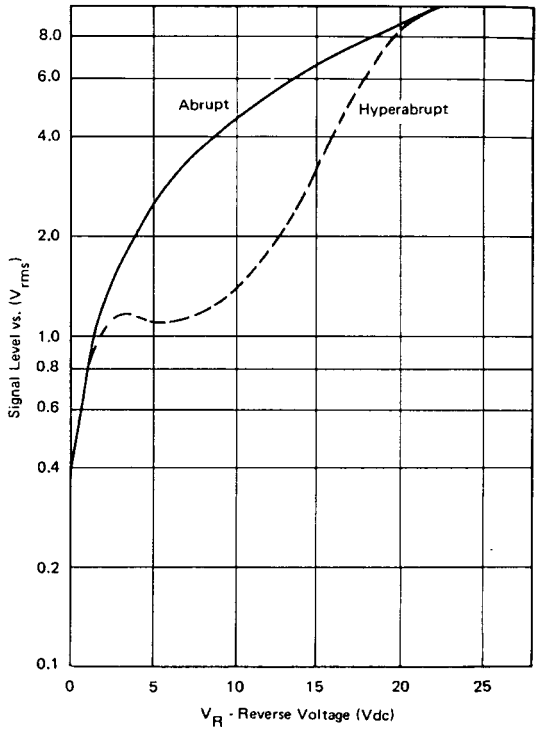

Figure 2-44 Signal level versus reverse voltage for 10% harmonic distortion.

For Linear *pn* Junctions (Single-Diffused Diodes, such as BA110–BA112)

$$W = \sqrt[3]{12\frac{\varepsilon_r \varepsilon_0}{aq}(V_R + V_D)} \tag{2-64}$$

where a is the impurity gradient within the depletion layer, ε_0 is the absolute dielectric constant ($8.85 \times 10^{-14}\ A_s/V_{cm}$, and $\varepsilon_r \approx 12$, the relative dielectric constant of silicon.

The junction capacitance, which is inversely proportional to the junction width, therefore varies in alloyed diodes with the square root, and in single-diffused diodes with the cube root of the externally applied reverse bias, and can be calculated from the general equation

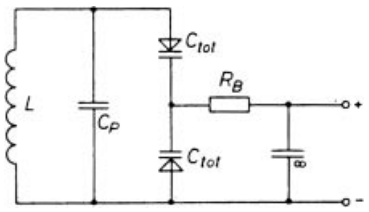

Figure 2-45 Back-to-back diodes. C_P is a fixed parallel capacitance, R_B is a bias decoupling resistor, and the capacitor marked ∞ is a low-impedance bypass.

$$C = \frac{\varepsilon_r \varepsilon_0 S}{W} \tag{2-65}$$

where S is the surface area of the *pn* junction. By way of approximation, we can also use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{2-66}$$

where all constants and all parameters determined by the manufacturing process are contained in K. The exponent n is a measure of the slope of the capacitance/voltage characteristics and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction. Figure 2-46 shows the capacitance/voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation has been indicated which, although purely formal, describes the practical characteristics better than Eq. (2-66):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{2-67}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is a voltage. The exponent m is much less dependent on voltage than the exponent n in Eq. (2-66).

Equations (2-63) through (2-67) express the pure junction capacitance of the capacitance diode, but to this must still be added a constant capacitance, determined by structure parameters, in order to obtain the diode capacitance C_{tot}, which interests the user. With high inverse voltages—that is, low junction capacitance—a difference will therefore arise between the theoretical capacitance/voltage characteristic according to Eq. (2-66) and the practical characteristic, as shown in Figure 2-47.

The operating range of a capacitance diode or its useful capacitance ratio

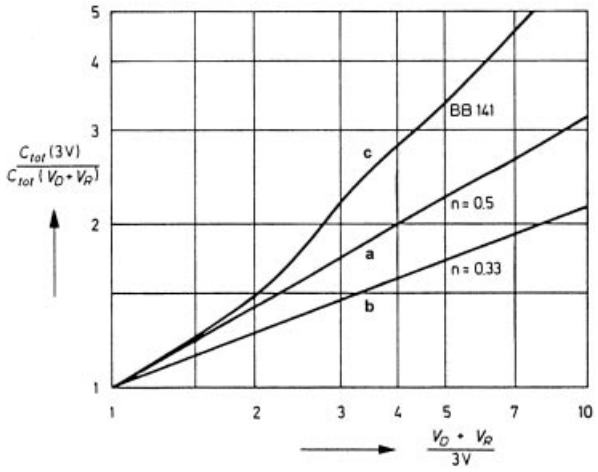

Figure 2-46 Capacitance/voltage characteristic for (a) an alloyed capacitance diode, n = 0.5; (b) a diffused capacitance diode, n = 0.33; and (c) a wide-range tuner diode (BB141).

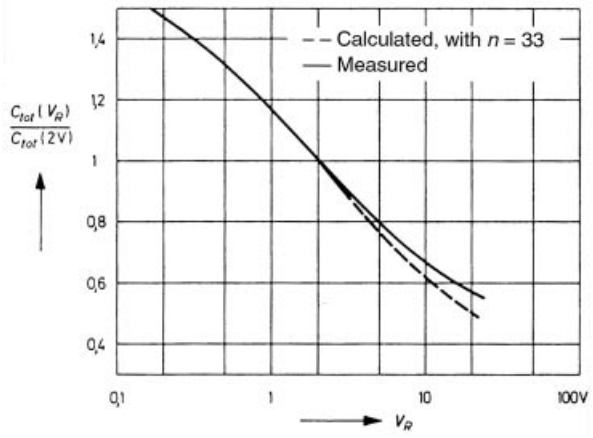

Figure 2-47 Capacitance/voltage characteristic of the BA110 diode.

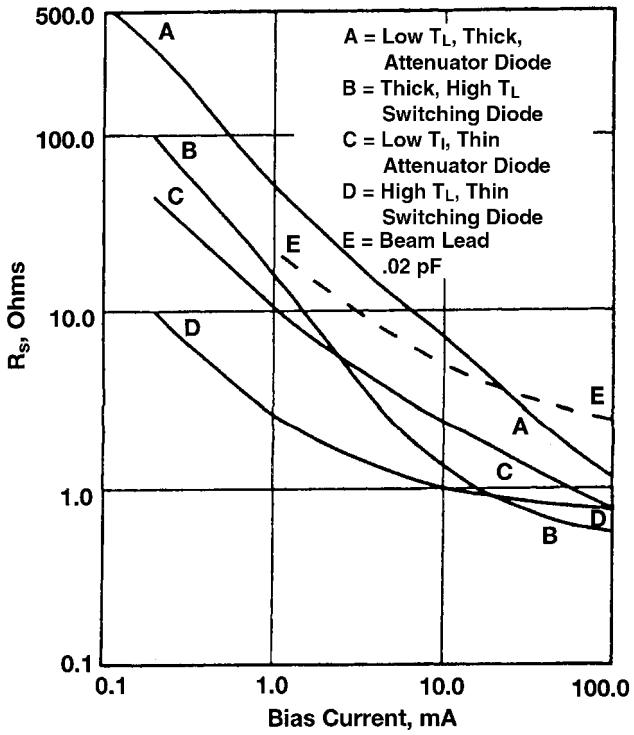

Figure 2-48 Basic current/voltage and capacitance/voltage characteristics.

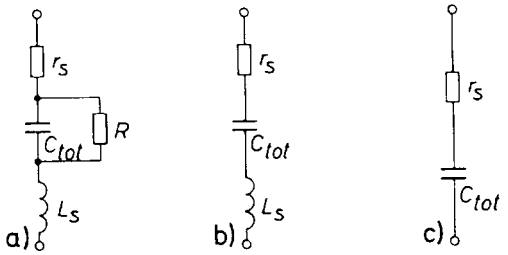

Figure 2-49 Equivalent circuits for capacitance diodes: (a) complete circuit, (b) simplified circuit, and (c) further simplification for low frequencies.

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R\min})}{C_{\text{tot}}(V_{R\max})} \tag{2-68}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage either into the forward mode or the breakdown mode. Otherwise, rectification, which would shift the diode's bias and considerably affect its figure of merit, would take place. Figure 2-48 plots the capacitance/voltage characteristics of a capacitance diode to clarify the relationship. The useful operating range lies between the voltages

$$V_{\min} > \hat{V} - V_F \quad \text{and} \quad V_{\max} < V_{(\text{BR})R} - \hat{V} \tag{2-69}$$

As has already been indicated, the exponent n for large-capacitance-ratio or tuning diodes used today for TV tuners is not constant but voltage-dependent and subject to manufacturing tolerances. This means that the capacitance/voltage characteristic of these diodes is likewise subject to manufacturing tolerances. Since, in a TV tuner, it is necessary for two or three circuits to be tuned uniformly, tuner diodes must be selected empirically for identical characteristics and supplied in equipment lots.

Electrical Properties of Tuning Diodes. In this section, the electrical properties of capacitance diodes are described, with reference to data published on the tuner diodes BB141 and BB142.

Equivalent Circuit. Since a capacitance diode is not an ideal capacitor, it is useful to introduce an equivalent circuit that can serve as a basis for discussing the diode's electrical properties. Figure 2-49 shows various types of equivalent circuits.

The complete equivalent circuit (Figure 2-49a), which conforms closely to physical conditions, comprises, in addition to the diode capacitance C_{tot}, the series resistance r_S and the series inductance L_S, and also the reverse resistance $R = dV_R/dI_R$. At higher frequencies, this resistance can usually be disregarded, so that the equivalent circuit is simplified in terms of Figure 2-49b—the configuration usually employed. In many cases, the series inductance can also be disregarded, in which case we obtain Figure 2-49c.

Capacitance. Figure 2-50 shows the capacitance/voltage characteristic borrowed from the datasheets of diodes BB141 and BB142. As this characteristic, like most characteristics published in datasheets, represents merely a typical curve, it would not convey sufficient

information for the user to dimension a tuner. Therefore, the datasheets contain additional data on capacitance and useful capacitance ratio:

Capacitance		BB141A (pF)	BB141B (pF)	BB142 (pF)
At $V_R = 1$ V	C_{tot}	16	19	17
At $V_R = 3$ V	C_{tot}	11	13	12
At $V_R = 25$ V	C_{tot}	2–2.35	2.25–2.65	2–3

$$\text{Useful capacitance ratio} = \frac{C_{tot}(3\text{ V})}{C_{tot}(25\text{ V})} = 4 \text{ to } 6$$

On the basis of the spread of the diode capacitance C_{tot} guaranteed for $V_R = 25$ V, it is possible to calculate the tuner with the aid of the spread guaranteed for the capacitance ratio.

Three further capacitance graphs are shown in Figures 2-51 through 2-53. Figure 2-51 shows a (typical) curve representing the normalized slope as a function of the reverse voltage, Figure 2-52 the normalized capacitance as a function of the junction temperature, and Figure 2-53 the temperature coefficient of the capacitance as a function of the reverse voltage.

The variation of diode capacitance with ambient temperature, as shown in Figures 2-52 and 2-53, is really only a function of the temperature dependence of the diffusion voltage [see Eq. (2-66)]. The diffusion voltage drops with rising temperatures by about 2 mV/°C , which means that the diode capacitance rises with temperature. The influence of the diffusion voltage, and thus the temperature coefficient of the capacitance, decreases as the reverse voltage rises. It is therefore advisable to run a capacitance diode with as high a reverse voltage as the required capacitance ratio permits. Compensation for the dependence of capacitance on temperature will be discussed later.

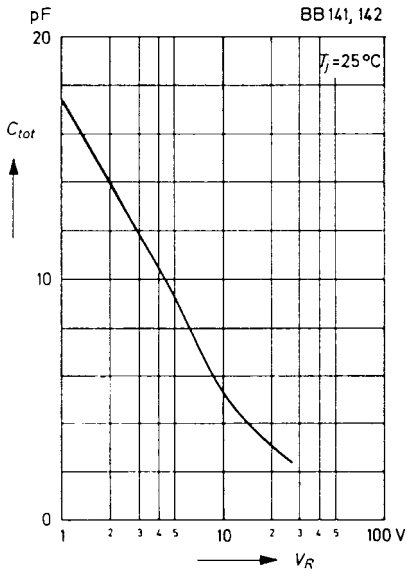

Figure 2-50 Capacitance/voltage characteristic of diodes BB141 and BB142.

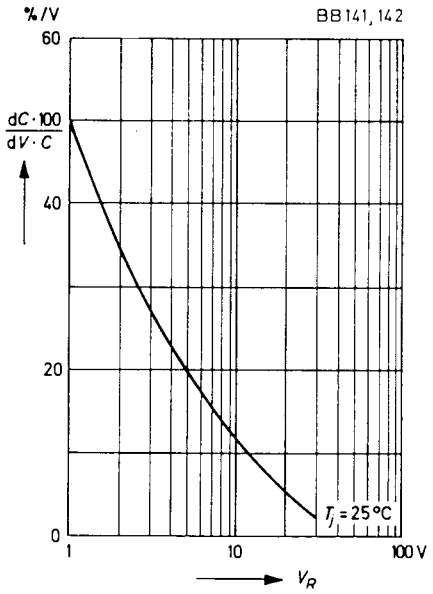

Figure 2-51 Slope (normalized) as a function of the reverse voltage.

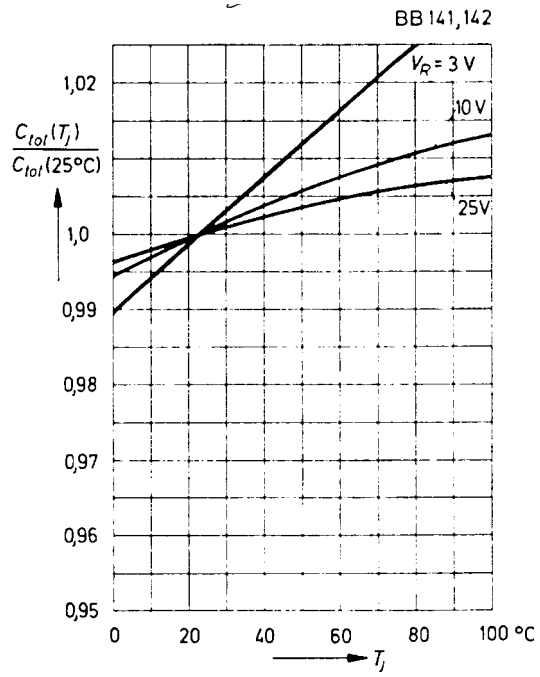

Figure 2-52 Capacitance (normalized) as a function of the junction temperature.

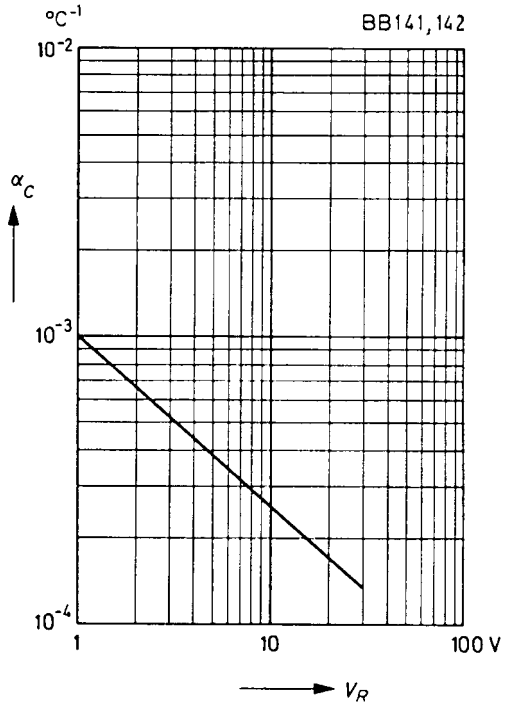

Figure 2-53 Temperature coefficient of capacitance as a function of the reverse voltage.

Series Resistance, Figure of Merit (Q). Since capacitance diodes are intended for employment in resonant circuits, indications are required as to the circuit attenuation that they produce. Usually, the series resistance or the figure of merit that can be calculated therefrom is indicated. With reference to the equivalent circuit shown in Figure 2-49a, the figure of merit (or Q factor) is calculated:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S + 1/\omega C_{\text{tot}} R} \tag{2-70}$$

Figure 2-54 shows the theoretical (normalized) Q as a function of frequency. With the frequency range of 10–1000 MHz, which is essential for tuner diodes, the parallel resistance R caused by the reverse current (see Figure 2-49b) can be disregarded, and Eq. (2-70) can be simplified to read as follows:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S} \tag{2-71}$$

In Figure 2-55, Q is plotted as a function of frequency for the tuner diodes BB141 and BB142. The datasheet indicates, in addition to this curve, the value of the series resistance at $f = 470$ MHz and $C_{\text{tot}} = 9$ pF:

	BB141A, BB141B	BB142
Series resistance (r_S)	0.6 (< 0.8)	0.9 (< 1.2)

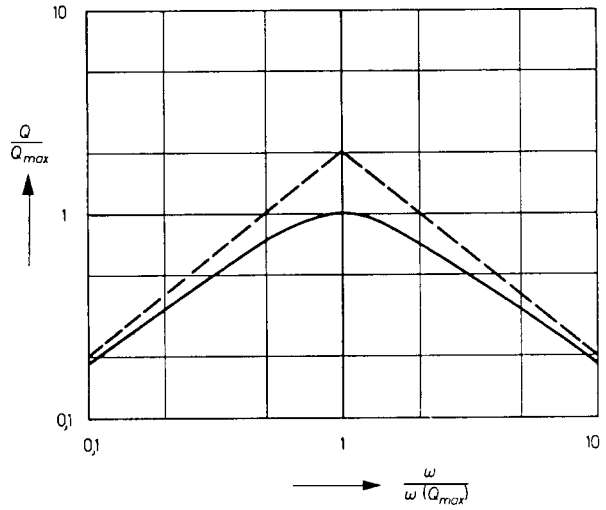

Figure 2-54 *Q* (normalized) as a function of frequency.

Since the diode capacitance and the series resistance decrease as the reverse voltage rises, Q is likewise dependent on the reverse voltage. It is smallest at a low reverse voltage, that is, at a low frequency. The series and parallel capacitances inevitable in a diode-tuned resonant circuit influence the effective Q of the tuning capacitance, as will be described later.

Series Inductance, Series Resonant Frequency, Cutoff Frequency for Q = 1. These three parameters define the behavior of the diode at high frequencies when the influence of

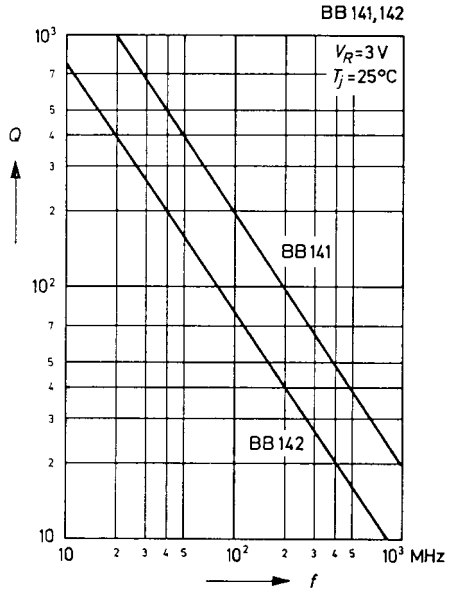

Figure 2-55 *Q* as a function of frequency.

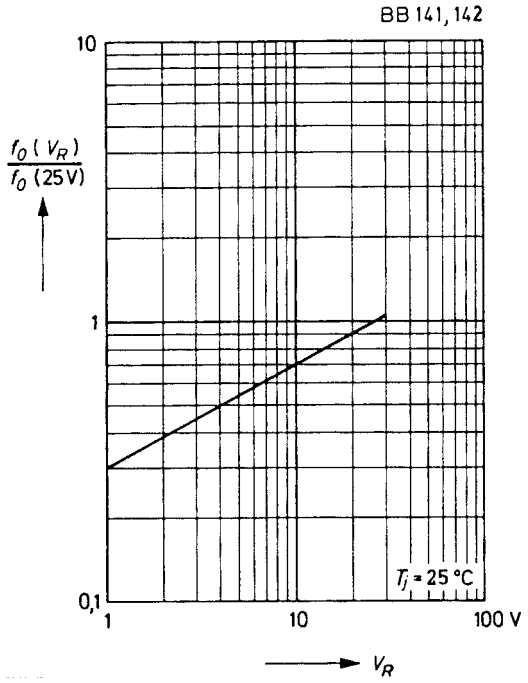

Figure 2-56 Series-resonant frequency (normalized) as a function of the reverse voltage.

the series inductance can no longer be neglected. The parameter on which the calculation is based is the series inductance L_S, which is determined by the connection leads. As indicated in Figure 2-49a, it is in series with the capacitance and, given a suitable frequency, forms a series-resonant circuit therewith. In that case

$$\omega L_S = \frac{1}{\omega C_{\text{tot}}} \tag{2-72}$$

and the series-resonant frequency is

$$f_0 = \frac{1}{2\pi\sqrt{C_{\text{tot}} L_S}} \tag{2-73}$$

Above this frequency, the impedance of the diode is inductive, but it depends on the reverse voltage. Figure 2-56 shows how the (normalized) series-resonant frequency depends on the reverse voltage for the tuner diodes BB141 and BB142.

The cutoff frequency for $Q = 1$ is defined as the frequency at which Q assumes the value of unity. In a rough calculation, the reactive impedance of the diode capacitance can be neglected and the frequency f_{Q1} obtained for the condition in which the inductive reactance equals the series resistance:

$$\omega L_S = r_S \tag{2-74}$$

$$f_{Q1} = \frac{r_S}{2\pi L_S} \tag{2-75}$$

For the tuner diodes BB141 and BB142, Figure 2-57 shows how the (normalized) cutoff frequency depends on the reverse voltage. The datasheets contain the following numerical information:

		BB141	BB142	
Series inductance measured 1.5 mm from the case	L_S	2.5	2.5	nH
Series-resonant frequency at $V_R = 25$ V	f_0	2	1.8	GHz
Cutoff frequency for $Q = 1$ at $V_R = 3$ V	f_{Q1}	24	16	GHz

Depending on the intended application, either the series-resonant frequency or the cutoff frequency for $Q = 1$ determines the maximum useful frequency range.

Leakage Current, Breakdown Voltage. These two parameters mark the dc performance of the diode when a reverse bias is applied to it. In the databook for the tuner diodes BB141 and BB142, the breakdown voltage is quoted as follows:

$$\text{Reverse breakdown voltage at } I_R = 100\ \mu\text{A}: \quad V_{(BR)R} > 30\ \text{V}$$

This means that the maximum reverse voltage that may be applied to the diode as a tuning voltage is 30 V.

The leakage current for the above-mentioned tuner diodes is guaranteed as follows:

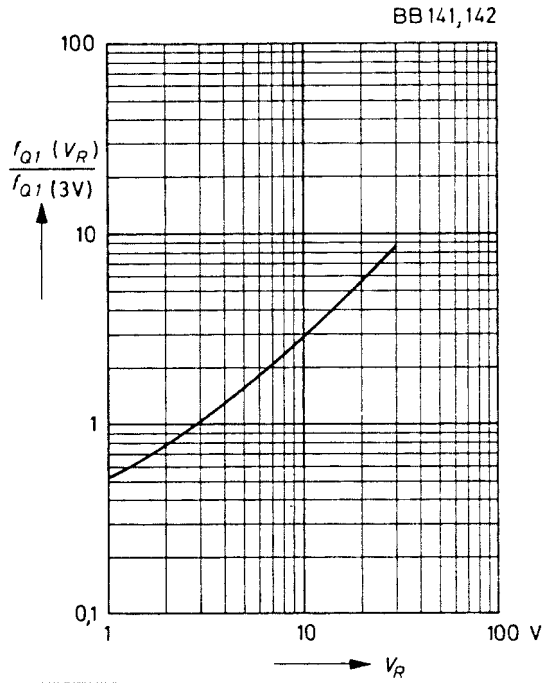

Figure 2-57 Cutoff frequency for $Q = 1$ (normalized) as a function of the reverse voltage.

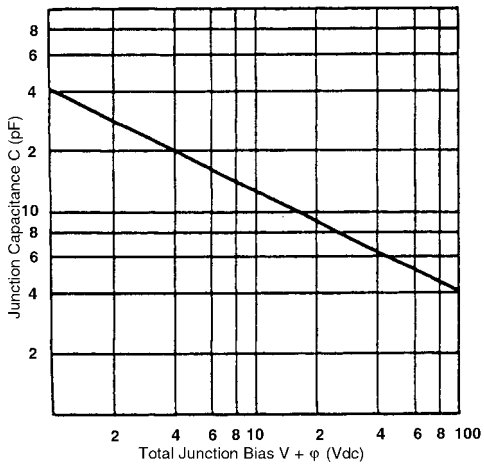

Figure 2-58 Leakage current as a function of reverse voltage.

$$\text{Leakage current at } V_R = 28 \text{ V:} \quad I_R < 50 \text{ nA}$$

Moreover, Figure 2-58 shows a graph that illustrates the leakage current as a function of the reverse voltage. Since this current is temperature dependent (as with every silicon diode)—it doubles with each temperature rise of about 10 °C—care should be taken when dimensioning the tuner circuit that the leakage current does not cause inadmissible voltage variations at increased ambient temperatures.

Matching of Tuner Diodes, Uniform Parameters. As has already been mentioned, the capacitance versus voltage characteristics of modern tuner diodes are subject to a certain scatter, so that it becomes necessary to test these diodes to obtain equipment lots empirically.

Diode-Tuned Resonant Circuits

Tuner Diode in the Parallel-Resonant Circuit. Figures 2-59, 2-60, and 2-61 illustrate three basic circuits for the tuning of parallel-resonant circuits by means of capacitance diodes.

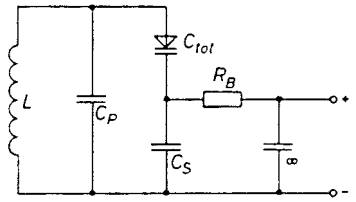

Figure 2-59 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the series capacitor.

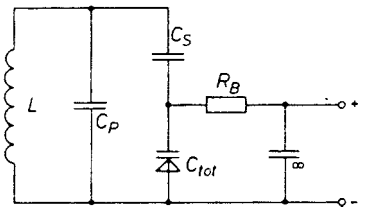

Figure 2-60 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the diode.

In the circuit diagram of Figure 2-59, the tuning voltage is applied to the tuner diode via the input coil and the bias resistor R_B. Series-connected to the tuner diode is the series capacitor C_S, which completes the circuit for ac but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling capacitor preceding the bias resistor is large enough for its value to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_C. We have the equation

$$R_C = R_B\left(1 + \frac{C_S}{C_{\text{tot}}}\right)^2 \tag{2-76}$$

If in this equation the diode capacitance is substituted by the resonant circuit frequency ω, we obtain

$$R_C = R_B\left(\frac{\omega^2 LC_S}{1 - \omega^2 LC_P}\right)^2 \tag{2-77}$$

The resistive loss R_C caused by the bias resistor R_B is seen to be highly frequency dependent, and this may result in the bandwidth of the tuned circuit being independent of frequency if the capacitance of the series capacitor C_S is not chosen sufficiently high.

Figure 2-60 shows that the tuning voltage can also be applied directly and in parallel to the tuner diode. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_C = R_B\left(\frac{1 + C_{\text{tot}}}{C_S}\right)^2 \tag{2-78}$$

and

$$R_C = R_B\left(\frac{\omega^2 LC_S}{\omega^2 L(C_S + C_P) - 1}\right)^2 \tag{2-79}$$

The influence of the bias resistor R_B in this case is larger than in the circuit of Figure 2-60, provided that

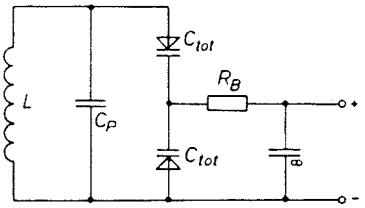

Figure 2-61 Parallel-resonant circuit with two tuner diodes.

$$C_S^2 > C_S(C_{\text{tot}} + C_P) + C_{\text{tot}}C_P \tag{2-80}$$

This is usually the case because the largest possible capacitance will be preferred for the series capacitor C_S, and the smallest for the shunt capacitance C_P. The circuit of Figure 2-59 is therefore normally preferred to that of Figure 2-60. An exception would be the case in which the resonant circuit is meant to be additionally damped by means of the bias resistor at higher frequencies.

In the circuit of Figure 2-61, the resonant circuit is tuned by two tuner diodes that are connected in parallel via the coil for tuning purpose, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation (see section entitled "Modifying the Diode Capacitance by the Applied ac Voltage") takes effect in opposite directions in these diodes and therefore cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuner diodes, is transformed into the circuit at a constant ratio throughout the whole tuning range. Given two identical, loss-free tuner diodes, we obtain the expression

$$R_C = 4R_B \tag{2-81}$$

Capacitances Connected in Parallel or Series with the Tuner Diode. Figures 2-59 and 2-60 show that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuner diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. As far as possible, the value of the series capacitor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases, as, for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency, this is not possible and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{\text{tot}} \frac{1}{1 + C_{\text{tot}}/C_S} \tag{2-82}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuner diode, increases to

$$Q^* = Q\left(1 + \frac{C_{\text{tot}}}{C_S}\right) \tag{2-83}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{\max}}{C^*_{\min}} = \frac{C_{\max}}{C_{\min}} \frac{1 + C_{\min}/C_S}{1 + C_{\max}/C_S} \tag{2-84}$$

where $C_{\max}$ and $C_{\min}$ are the maximum and minimum capacitances of the tuner diode.

On the other hand, the advantage is gained that, due to capacitive potential division, the amplitude of the alternating voltage applied to the tuning diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{\text{tot}}/C} \tag{2-85}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance $C_{\max}$ of the tuner diode and a higher useful capacitance ratio. The influence exerted by the series capacitor, then, can actually be kept lower than Eq. (2-83) would suggest.

The parallel capacitance C_P that appears in Figures 2-59 to 2-61 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}} \left(1 + \frac{C_P}{C_{\text{tot}}} \right) \tag{2-86}$$

The Q of the effective tuning capacitance, as derived from the Q of the tuner diode, is

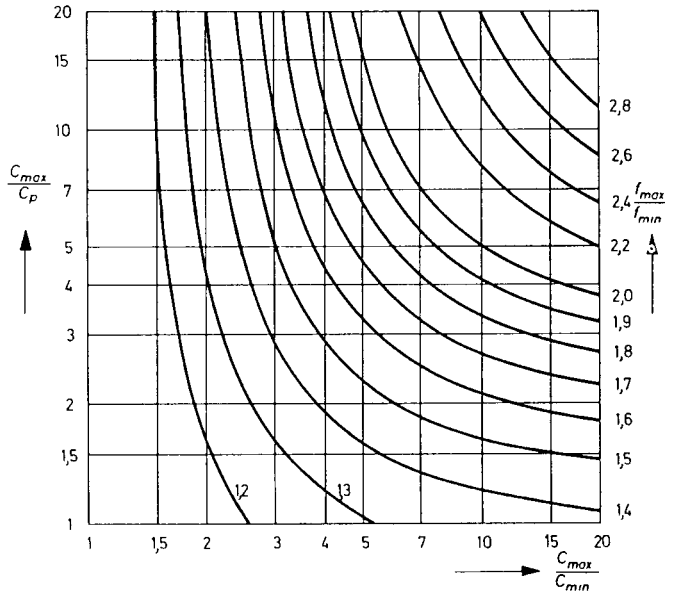

Figure 2-62 Diagram for determining the capacitance ratio and minimum capacitance.

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{2-87}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance ratio is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}} \frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{max}}} \tag{2-88}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the circuit-design stage.

TUNING RANGE. The frequency range over which a parallel-resonant circuit according to Figure 2-59 can be tuned by means of the tuner diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit.

The ratio can be found from

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{1 + \frac{\dfrac{C_{\text{max}}}{C_P\,(1 + C_{\text{max}}/C_S)}}{1 + \dfrac{C_{\text{max}}}{C_P\,(C_{\text{max}}/C_{\text{min}} + C_{\text{max}}/C_S)}}} \tag{2-89}$$

In many cases, the series capacitor can be chosen large enough for its effect to be negligible. In that case, Eq. (2-89) is simplified as follows:

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{\frac{1 + C_{\text{max}}/C_P}{1 + C_{\text{min}}/C_P}} \tag{2-89a}$$

From this equation, the diagram shown in Figure 2-62 is computed. With the aid of this diagram, the tuner diode parameters required for tuning a resonant circuit over a stipulated frequency range—that is, the maximum capacitance and the capacitance ratio—can be determined.

Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced according to Eq. (2-84).

TRACKING. Some applications require the maintenance of a fixed frequency relationship between two or more tuned circuits as their tuning is simultaneously adjusted. Referred to as *tracking*, this technique requires narrow tolerances of capacitance versus tuning voltage. Minimizing tracking error requires special care if the tracking circuits must cover the same frequency span beginning at different start and end frequencies, as is necessary when simultaneously tuning oscillator and mixer/RF circuitry in a superheterodyne receiver. Then, tracking error must be minimized by means of series and shunt capacitances in accordance with methods known from variable capacitors. The frequency deviations that must be anticipated are summarized in the equation

$$\frac{df}{f} = -\frac{1}{2}\frac{dC_0}{C_0} - \frac{1}{2}\frac{d(L-L_0)}{L} - \frac{1}{2}\frac{dL_0}{L_0} + \frac{n}{2}\frac{dV_R}{V_R + V_D} \tag{2-90}$$

The spread of parameters dC_0/C_0 and dL_0/L_0 can only be compensated by varying the circuit inductances $d(L–L_0)/L$ or by varying the bias $dV_R/(V_R + V_D)$.

Modulating the Diode Capacitance by the Applied ac Voltage. In normal operation, the sum of the tuning voltage and the alternating signal voltage of the resonant circuits is applied to the tuner diode. The bias, and thus the capacitance, of the tuner diode therefore varies at the rhythm of the alternating voltage. Due the nonlinear character of the capacitance versus voltage curve, voltage distortions and capacitance shifts are inevitable, and these must be kept within adequate limits. This is done by maintaining the ac applied to the diode(s) at sufficiently low ac amplitude and by choosing an adequate minimum value for the tuning voltage. In the resonant circuit, a tuner diode is modulated predominantly by a current free from harmonics, according to the equation

$$i = \hat{i}\cos \omega t \tag{2-91}$$

The alternating voltage across the diode is

$$v = (V_R + V_D)\left[\left(1 + \frac{\hat{i}(1-n)}{\omega C_{\text{tot}} V_R}\sin \omega t\right)^{1/(1-n)} - 1\right] \tag{2-92}$$

An evaluation of this equation shows that especially the first harmonic makes its appearance. The capacitance shift caused by the alternating voltage superimposed on the tuning voltage is shown in Figure 2-63. However, the voltage distortion, and thus the capacitance shift, can be largely avoided if two tuner diodes are used, as in Figure 2-61.

COMPENSATING TEMPERATURE DEPENDENCE. As has already been mentioned, variations are caused in the capacitance of the diode mainly by the dependence of the diffusion voltage on

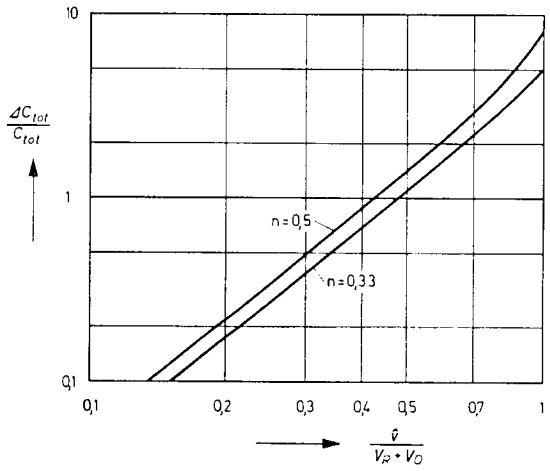

Figure 2-63 Capacitance increase as a function of the ac voltage drop across the tuner diode.

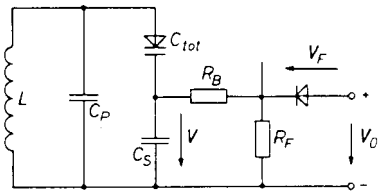

Figure 2-64 Temperature-compensation circuit with diode.

temperature. In a diode-tuned resonant circuit, the temperature coefficient of the resonant frequency, therefore, depends on the tuning voltage and thus on the resonant frequency. It is therefore impossible to compensate the temperature dependence of the resonant frequency by means of temperature-dependent capacitors—the method usually adopted for mechanically tuned circuits.

To achieve satisfactory compensation, the tuning voltage should be increased by an amount equal to that by which the diffusion voltage of the diode is reduced with rising temperature; that is, by approximately 2 mV/°C. This can be done easily by connecting a forward-biased silicon diode in series with the source of the tuning voltage, as shown in Figure 2-64. Since the forward voltage of the diode varies by –2 mV/°C with ambient temperature, the voltage

$$V = V_0 + V_D - V_F$$

which determines the bias of the tuner diode, and therefore also the diode capacitance, is almost temperature independent. In practice, it is advisable to feed this diode with additional current via the resistor R_F to keep its differential forward resistance sufficiently low and thus to prevent capacitive noise voltages from leaking into the tuning circuit.

To prevent the load placed by the resistor R_F on the source of the tuning voltage from fluctuating in a manner depending on the tuning voltage, a circuit such as shown in Figure 2-65 may be used in which the emitter diode of the transistor effects the compensation, and the only load placed on the source of the tuning voltage is the base current of this transistor.

Dynamic Stability. The resonant frequency of a diode-tuned RF circuit follows the equation

$$f = f_0 \sqrt{\left(\frac{V_R + V_D}{V_{R0} + V_D}\right)^n} \tag{2-93}$$

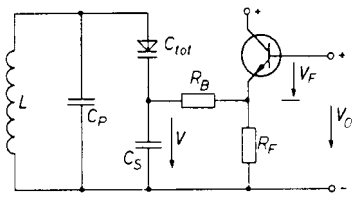

Figure 2-65 Temperature-compensation circuit with transistor.

The frequency f_0 is set with the aid of the circuit inductance when the tuning voltage equals V_{R0}. Since the signal amplitude in the circuit depends on the field strength of the received transmitter and since the resonant frequency of the circuit depends on the amplitude, undesirable feedback between the tuning voltage and the received alternating voltage may occur at the tuner diode. A disturbance that has a similar effect is the microphonic effect, which can sometimes be observed with mechanically variable capacitors. In an investigation of the feedback in diode-tuned resonant circuits, the following assumptions were made:

- The impedance of the antenna (or of the signal generator) is negligible.
- The full alternating voltage is applied to the diode (whereas, in practice, the series capacitor brings about a potential division).
- The capacitance versus voltage characteristic is an exponential function.
- The Q of this circuit is independent of the amplitude of the alternating voltage.

As a result of a high alternating voltage at the resonant circuit, three undesirable effects—harmonic generation, frequency shift, and cross-modulation—are encountered.

HARMONIC GENERATION. The nonlinearity of the capacitance versus voltage characteristic produces harmonics. However, the selectivity of the receiver reduces the effects of these harmonics to noise level.

FREQUENCY SHIFT. When a sinusoidal voltage v is applied to the tuner diode of the RF circuit, the variation of the diode capacitance does not follow the sine law, but the equation

$$\frac{C_\omega}{C} = \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{-n} \tag{2-94}$$

This results in a change of the resonant frequency of the circuit. The inductive slope of the resonant curve steepens and may even turn back. This could lead to bistable behavior of the resonant circuit. The change of frequency takes place as if the tuning voltage, and thus the resonant frequency, has decreased. The order of magnitude of this change of resonant frequency was determined with the aid of a computer from Fourier analysis of

$$\frac{\Delta f}{f} = 1 + \frac{1}{2\pi} \int_0^{2\pi} \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{n/2} d(\omega t) \tag{2-95}$$

Figure 2-66 shows the admissible alternating voltage at the diode, computed for a 2% frequency shift, as a function of the tuning voltage. The measured values differ by not more than 10% from the computed values. Since the Q of the circuits is about 50 for the VHF as well as the UHF range, a 2% frequency shift is permissible.

CROSS-MODULATION. Cross-modulation is a disturbance caused by nonlinearities of the characteristics of the components concerned. The modulation of an undesired amplitude-modulated signal is here transferred to the carrier of the amplitude-modulated intelligence signal. Cross-modulation is virtually independent of the amplitude of the intelligence signal.

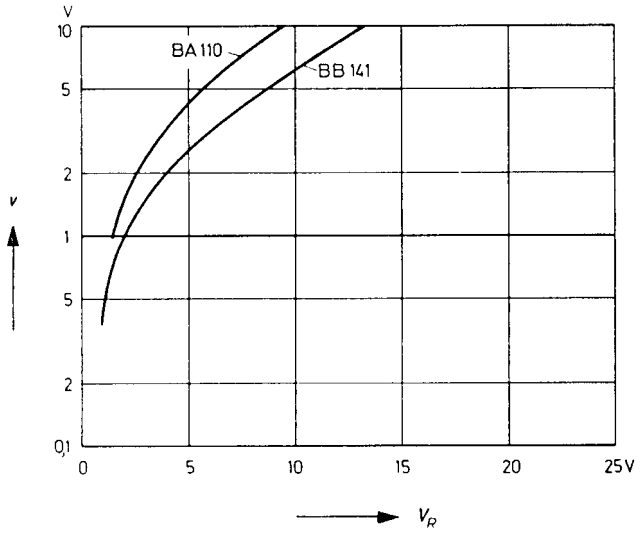

Figure 2-66 Admissible alternating voltage for a 2% frequency shift as a function of tuning voltage.

The cross-modulation factor for tuner diodes is

$$k = \frac{v^2}{(V_R + V_D)^2} m_v \frac{n(n+1)}{2} \tag{2-96}$$

Resolving this equation in terms of v, we obtain

$$v = \frac{V_R + V_D}{n} \sqrt{\frac{2kn}{m_v (n+1)}} \tag{2-97}$$

The usual definition of the cross-modulation percentage for measurement purposes is as follows: A 100% modulated noise signal ($m_v = 1$) of amplitude v is received simultaneously with the intelligence signal in the diode-tuned RF circuit. If a 1% modulation of the signal carrier by the noise signal takes place, this amounts to a cross-modulation factor $k = 0.01$. We thus obtain for tuner diodes

$$V = 0.14 \frac{V_R + V_D}{n} \sqrt{\frac{n}{n+1}} \tag{2-98}$$

Figure 2-67 gives the graphs for this equation. In practical operation, FM and VHF/UHF tuners equipped with the tuner diodes BB121 or BB141 exhibit merely the cross-modulation caused by the BJTs or FETs employed. For bipolar transistors, $v \approx 15$–100 mV; for FETs, 100–300 mV.

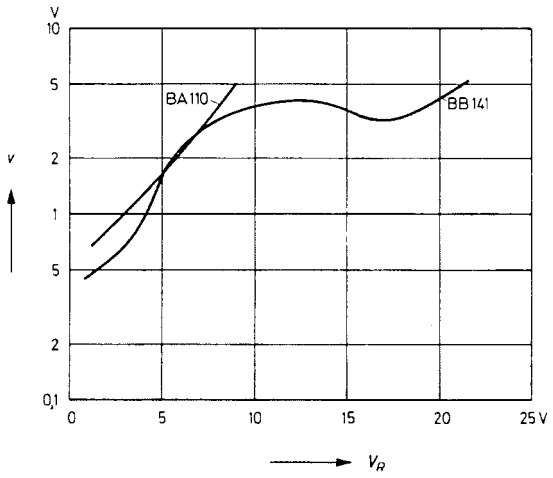

Figure 2-67 Graphical representation of Eq. (2-98).

Static Stability. To ensure trouble-free operation, the static parameters of the tuner diodes, especially the leakage current, must be taken into account. When differentiating the expression for the tuning voltage

$$V_R = V_B - I_R R_B \tag{2-99}$$

we obtain for a known leakage current I_R the tuning voltage variation

$$dV_R = dV_B - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} + dV_B \right) \tag{2-100}$$

This leads to a change in the resonant frequency

$$\frac{df}{f} = \frac{n}{2(V_R + V_D)} \left[dV_D - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} \right) + dV_B \right] \tag{2-101}$$

The resonant frequency is more stable the smaller the exponent n and the higher the tuning voltage V_R. The influence of the temperature dependence of the diffusion voltage V_D and its compensation have already been discussed. If the series bias resistance R_B is not too high, the effect of its variation ($dR_B/R_{B)}$ and the effect of the temperature dependence of the leakage current—doubling for every 10 °C temperature rise—may be neglected.

Generating the Tuning Voltage. The supply voltage V_B in Eq. (2-101) exerts an influence in many respects. The temperature coefficient of the voltage source—usually, for economic reasons, only a Zener diode is provided for stabilization—affects conditions not only with ambient temperature variations, but also when the Zener diode heats up after the set is switched on, or when its operating current varies. Because external temperature compensation of the operating voltage of the Zener diode cannot cover all detrimental effects and, moreover, increases the series bias resistance R_B, as well as any variations the latter may

undergo, the use of a temperature-compensated Zener diode, such as the 1N4065A (nominal Zener voltage, 33 V; temperature coefficient, 0.002 °C/W), is recommended.

Diode Switches. The diode switches described here differ somewhat from the switching diodes used in computer and pulse technology. Whereas in the case of switching diodes the signal itself triggers the switching operation—current does or does not pass through the switching diode depending on the signal level—diode switches allow an alternating current to be switched on or off by means of a direct voltage or a direct current. Figure 2-68 shows an example of the use of diode switches.

Diode Switch Technology. Special manufacturing techniques are needed to attain the low junction capacitance, low differential forward resistance r_F, and the low-inductance structure required for the special applications envisaged. Two conflicting requirements have to be met: On the one hand, a high-resistivity basic material should be used and the diode area should be kept as small as possible to minimize the junction capacitance for a given reverse voltage; on the other hand, the bulk resistance should be kept low. The size of the junction area, therefore, can represent only a compromise between these two requirements. To obtain a low bulk resistance R_B despite the use of high-resistivity silicon around the junction, the diodes are manufactured by the epitaxial process, characterized by a thin high-resistivity layer on a low-resistivity substrate. If the forward current I_F is sufficiently high, then the specific resistance of the epitaxial layer does not affect the bulk resistance, because under these conditions the resistivity of this layer is considerably reduced by being flooded with carriers.

The junction impedance Z_j is somewhat more critical (Figure 2-69). It is composed of the junction capacitance C_S, which does not depend on current, the current-dependent diffusion capacitance

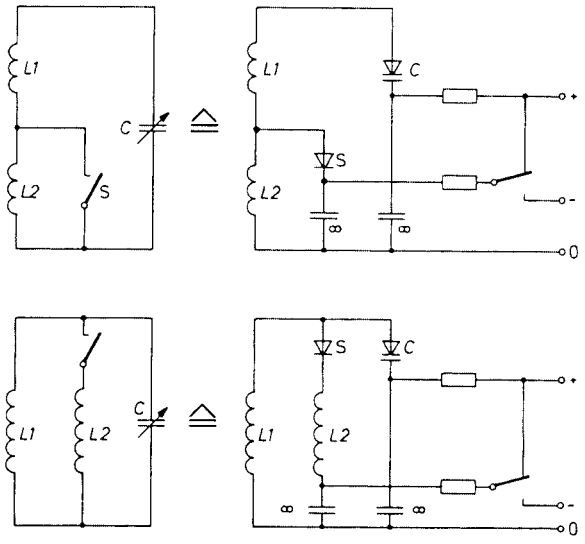

Figure 2-68 Comparison of mechanically and electronically tuned and switched resonant circuits.

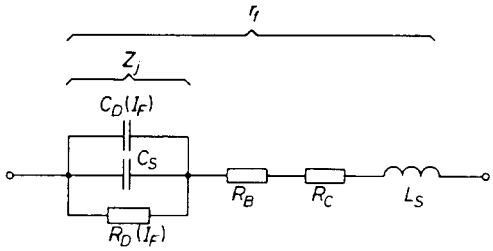

Figure 2-69 Equivalent circuit of diode switches in the frequency range from 1 MHz to 1 GHz.

$$C_D = \frac{\mathfrak{t}_p I_F}{V_T} \tag{2-102}$$

and the diffusion resistance

$$R_D = \frac{V_T}{I_F} \tag{2-103}$$

where $\mathfrak{t}_p$ is the lifetime of the minority charge carriers and

$$V_T = \frac{kT}{q} = 26 \text{ mV} \tag{2-104}$$

is the voltage equivalent of thermal energy. The resistive component of the impedance Z_j is calculated as follows:

$$\text{Re}(Z_j) = \frac{R_D}{1 + \omega^2 R_D^2 (C_S + C_D)^2} \tag{2-105}$$

As can be seen from the following approximations, this resistance becomes rather dependent on current at higher frequencies:

$$\text{For } I_F \to 0 \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega^2 C_S^2 V_T} \tag{2-106}$$

$$\text{For } I_F \to \infty \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega t_p I_F} \tag{2-107}$$

In Figure 2-70 the differential forward resistance is plotted as a function of the forward current. The only parameter by which the differential forward resistance can be reduced for a given current and a given frequency according to Eq. (2-107) is the carrier lifetime. Steps will have to be taken, therefore, to make the carrier lifetime as long as possible.

Because diode switches are designed for applications up to the gigahertz range, a geometry resulting in a low inherent capacitance and inductance had to be used. Furthermore, the device had to be assembled in such a way that virtually no additional contact resistance R_C was introduced. For this reason, a double-plug construction (hard-glass pressure contacts)

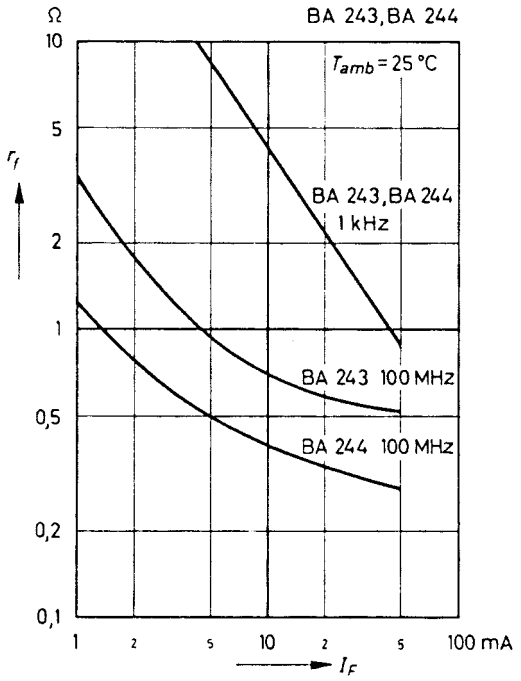

Figure 2-70 Differential forward resistance as a function of forward current.

was chosen to avoid the S- or U-bends customary with other encapsulations. The system is pressure-clamped between two stud-shaped enlargements of the connecting leads, the necessary high pressure being produced as the glass shrinks during cooling. This construction results in an encapsulation of short length (only 4 mm) and low series inductance, the advantages of which can be fully exploited because soldered connections to the leads can be made directly at the glass body.

Diode Switch Data. The silicon planar diode switches BA243 and BA244 are designed for electronic band selection in tuners in the frequency range from 10 to 1000 MHz. The differential forward resistance remains constant and is very low over a wide frequency and current range. The diode capacitance is likewise small and independent of voltage through a wide range. The devices are characterized by low-inductance geometry. The BA243 is intended for the VHF range, and the BA244 for the UHF range. See Table 2-11.

Resonant Circuits Incorporating Diode Switches. Figure 2-71 illustrates the function of the diode switch with reference to a parallel-resonant circuit whose resonant frequency can be switched by short-circuiting part of the circuit inductance. Such a switching procedure may be necessary for a VHF tuner, for example, to switch from band I to band III, because the frequencies of these bands are too far apart.

Capacitor C_K represents the capacitance of the resonant circuit. The symbol ∞ at capacitor C is meant to indicate that the value of this capacitor should be chosen to be much higher than the circuit capacitance. C completes the ac circuit when the inductor L_2 is shorted and

Table 2-11 BA243/244 specifications

Maximum Ratings			
Reverse voltage	V_R	20	V
Forward current at $T_A = 25$ °C	I_F	100	mA
Junction temperature	T_j	150	°C
Storage temperature range	T_s	–55 to +150	°C
Characteristics at $T_A = 25$ °C			
Forward voltage at $I_F = 100$ mA	V_F	<1	V
Leakage current at $V_R = 15$ V	I_R	< 100	nA
Dynamic forward resistance at $f = 50$–1000 MHz, $I_F = 10$ mA			
BA243	r_F	0.7 (< 1)	Ω
BA244	r_F	0.4 (< 0.5)	Ω
Relative variation of dynamic forward resistance with the variation of forward current in the range of $I_F + 2$–40 mA	$\frac{\Delta r_F 100}{r_F \Delta I_F}$	5	%/mA
Capacitance at $V_R = 15$ V, $f = 1$ MHz	C_{tot}	1.3 (< 2)	pF
Relative variation of capacitance with the variation of reverse voltage in the range of $V_R = 7$–20 V, $f = 100$ MHz	$\frac{\Delta C_{tot} 100}{C_{tot} \Delta V_R}$	1	%/V
Series inductance across case	L_S	2.5	nH

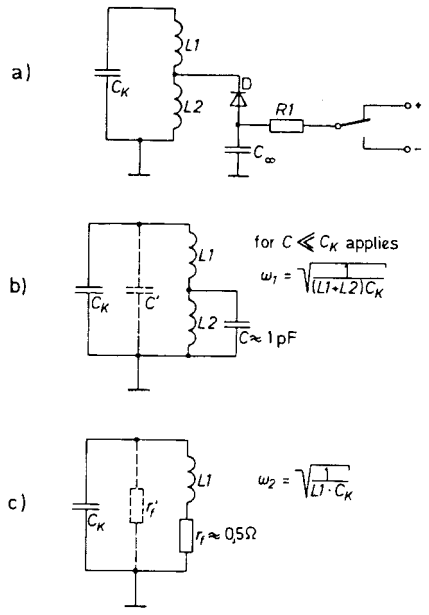

Figure 2-71 (a) Diode switch as bandswitch, shorting a partial inductance; (b) equivalent circuit with blocked diode switch; (c) equivalent circuit with conducting diode switch.

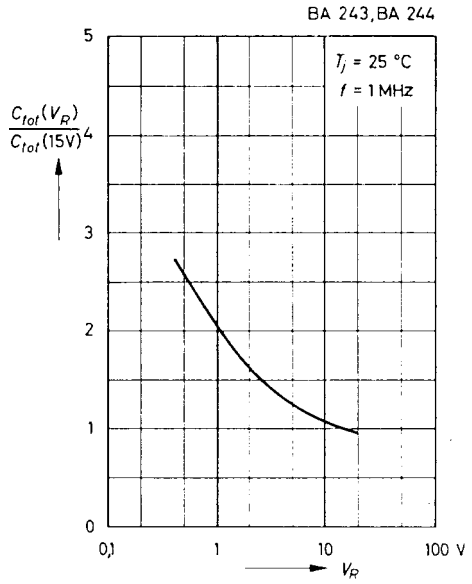

Figure 2-72 Capacitance as a function of the reverse voltage.

enables the switching or reverse voltage to be applied at a point of virtually zero RF potential. The resistor R_1 limits the diode current in the forward direction.

At a reverse voltage of $V_R = 15$ V, for example, the diode switch represents a 1-pF capacitor, as shown in Figure 2-71b. This represents parasitic capacitance C' in the circuit, which reduces the effective capacitance variation of the resonant circuit in the case of capacitive tuning. The capacitance C' is small enough to be negligible in most cases relative to the wiring and winding capacitances. Figure 2-72 shows the relative capacitance of the blocked-diode switches, as a function of the reverse voltage.

At a forward current of, for example, 10 mA, the diode has a differential resistance of approximately 0.5 Ω (see Figure 2-70). The effect of this resistance r_F on the resonant circuit is illustrated in Figure 2-71c. Conversion of a series loss resistance r_F into a parallel loss resistance r'_F is based on the following considerations: The equivalent parallel resistance r'_F affects the tuned circuit in the same way as the series resistance r_F; that is, the Q of the circuit should be the same in both cases. If one assumes that $\omega L >> r_F$, the equivalent of parallel resistance can be expressed as follows:

$$Q = \frac{\omega L_1}{r_F} = \frac{r'_F}{\omega L_1} \tag{2-108}$$

$$r'_f = \frac{(\omega L_1)^2}{r_F} \tag{2-109}$$

An evaluation of this equation shows that a differential resistance $r_F \approx 0.5$ Ω can be tolerated in most applications as regards amplification and selectivity.

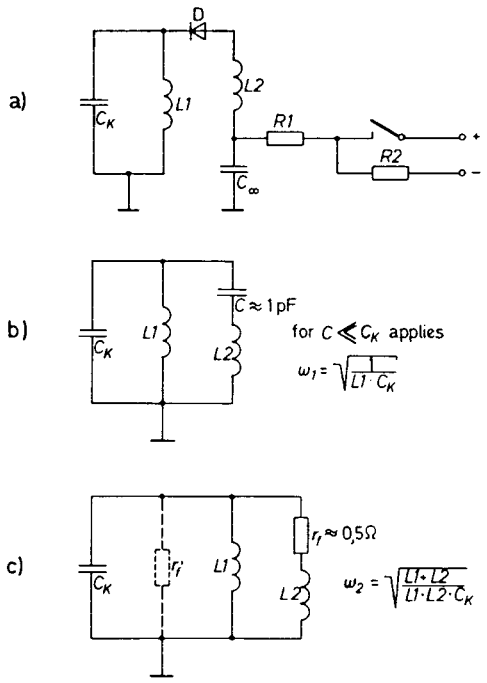

Figure 2-73 (a) Diode switch as a bandswitch, with an inductance in parallel; (b) equivalent circuit with blocked-diode switch; (c) equivalent circuit with conducting diode switch.

Instead of altering the resonant frequency of a tuned circuit by short-circuiting part of its inductance, the same result can be obtained by connecting a second inductance in parallel. The use of the diode switch for this purpose is illustrated in Figure 2-73. This differs from the one shown in Figure 2-71 in that the circuit inductance consists of either L_1 or of L_1 and L_2 in parallel. By applying a permanent negative bias to the diode via a high-value resistor R_2, it is possible to dispense with the use of one switch contact. Figure 2-73b shows the equivalent circuit for the diode under reverse-bias conditions (corresponding to a low resonant frequency), and Figure 2-73c shows the equivalent circuit under forward-bias conditions (corresponding to a higher resonant frequency).

In radio and television receivers, it usually is possible to derive the necessary reverse bias for the diode by rectification of the local oscillator signal, since the power required for blocking the diodes is extremely small. Note that under reverse-bias conditions the inductance L_2 and the capacitance C form a series-tuned acceptor circuit. However, this capacitance being extremely small, any undesirable effects due to its presence can normally be avoided. The same diode switching arrangements described for single-tuned circuits can also be employed in multisection bandpass and broadband filters.

In the following paragraph, a practical example for the use of diode switches will be given, and it will be seen that it is possible, in principle, to replace all of the mechanical RF switch contacts normally employed in receivers by diode switches. In cases where application of the diode dc potentials to a "cold" point in the circuit is not feasible, it may be necessary to apply them via *LC* or *RC* isolating networks.

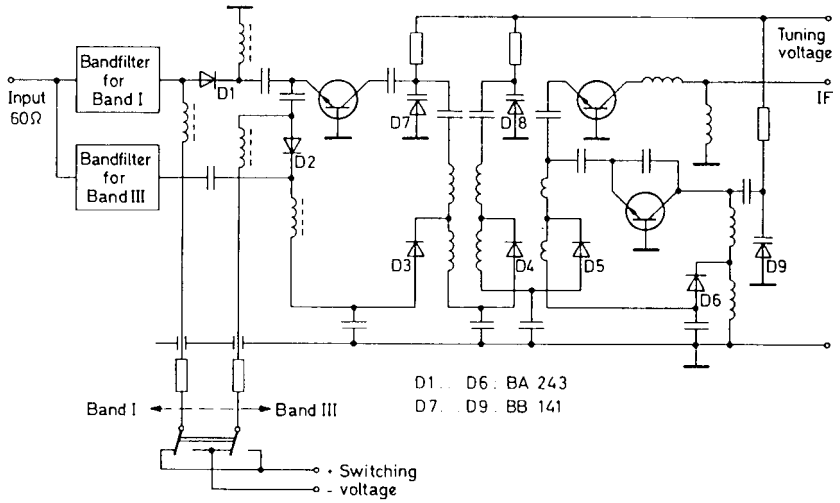

Figure 2-74 Schematic of a VHF television tuner with electronic band selection.

Use of the Diode Switch in a Television Receiver. Figure 2-74 shows the schematic of an electronically tuned and switched band I (48–62 MHz)/band III (175–224 MHz) TV tuner that requires switching of the input filter, bandpass filter, and oscillator circuit. These switching functions are performed by BA243 diode switches. As is customary in most European countries, in this example a broadband input filter between the antenna and the first RF transistor is used rather than a selective front-end circuit. In view of the need to correct noise and power matching over a relatively large frequency range, a switchable filter is employed in most tuners, switching being effected in this case by means of diodes D_1 and D_2.

Diodes D_3–D_6 are used for band-filter switching, for switching the coupling to the mixer transistor, and for switching the oscillator frequency. To minimize the bias-current requirements (each diode requires a bias current of approximately 10 mA), all diodes that are to be activated at the same time are connected in series. This arrangement requires only a few additional RF chokes, which are easily provided because of the high frequencies involved. The direct current required for the diode switches could be obtained by simple rectification, for example, from the heater circuit of the television receiver CRT, and the diode reverse bias could be obtained by rectification of the local oscillator signal, in which case the minute additional power requirement would have to be allowed for in the oscillator design.

A technically sophisticated design for a television tuner takes the form of a combined VHF/UHF unit incorporating electronically switched circuits in which several elements would be common. Such an all-band tuner can be assembled from only three transistors and a combined VHF/UHF band filter in $\lambda/2$ or $\lambda/4$ technology for UHF reception. The VHF circuits are short-circuited when the UHF position is selected.

Multistandard TV receivers require a large number of switch contacts in the tuner, the IF amplifier, the video amplifier, and the time base. The use of diode switches is particularly advantageous in this situation because it renders the physical layout of the equipment virtually independent of the location of the controls and obviates the need for long RF cable runs, which may be prone to interference.

2-2 BIPOLAR TRANSISTORS

2-2-1 Transistor Structure Types

All current RF silicon transistors are of the bipolar *npn* planar epitaxial type. Briefly, the significance of each of these terms is as follows.

Bipolar. In its broadest sense, it is the basic structure shown schematically in Figure 2-75, that is, the familiar three-semiconductor-region structure. *Bipolar* specifically means that the charge carriers of both negative (electron) and positive (hole) polarities are involved in the transistor action. In way of contrast, unipolar types include the junction-gate and insulated-gate field-effect transistors, which are basically one- or two-semiconductor-region structures in which carriers of a single polarity dominate.

npn. This abbreviation is for *negative–positive–negative* and identifies the regions of the structure as to polarity of the dominant or majority carrier in each region. The other polarity type is *pnp*. (See Figure 2-75.)

Silicon. Silicon (Si) is one of two elements from the fourth column of the periodic table that are in widespread use for transistor fabrication [the other is germanium (Ge)]. Other materials used include the compound gallium arsenide (GaAs). Although silicon is in predominant use because it results in the most favorable compromise among high-frequency, high-temperature, high-reliability, and ease-of-use attributes of the usable semiconductor material, silicon–germanium (SiGe) technology is increasingly important because it affords high-frequency performance unachievable with silicon alone.

Planar. The term planar denotes that both emitter–base and base–collector junctions of the transistor intersect the device surface in a common plane (hence, a better term might be *coplanar*). However, the real significance of the so-called planar structure is that the technique of diffusing dopants through an oxide mask, used in fabricating such a structure, results in junctions being formed beneath a protective oxide layer. These protected junctions are less prone to the surface problems sometimes associated with other types of structures, such as the mesa.

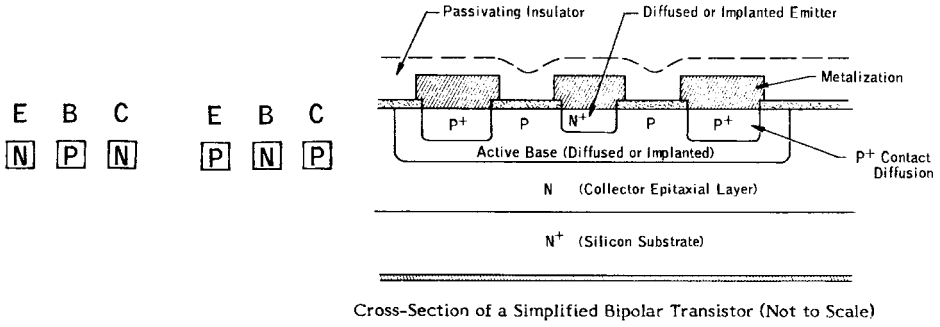

Figure 2-75 Transistor structure schematic.

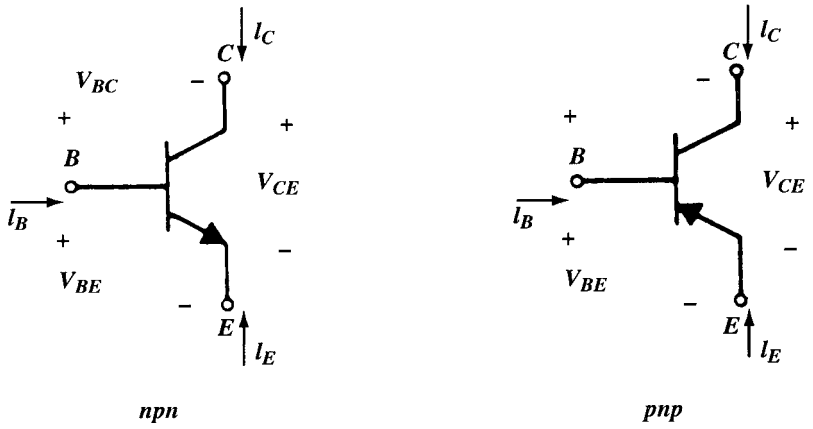

Figure 2-76 Bipolar transistor sign convention.

Epitaxial. This term, as it is commonly used, is actually a shortening of the term *epitaxial-collector*. That is, the collector region of the transistor is formed by the epitaxial technique, rather than by diffusion, which is commonly used to form the base and emitter regions. The epitaxial layer is formed by condensing a single-crystal film of semiconductor material on a wafer or substrate that is usually of the same material. Thus, an epitaxial (collector) transistor is one in which the collector region is formed on a low-resistivity substrate. Subsequently, the base and emitter regions are diffused into the "epi" layer. The epitaxial technique lends itself to precise tailoring of collector-region thickness and resistivity with consequent improved device performance and uniformity.

2-2-2 Large-Signal Behavior of Bipolar Transistors*

In this section, the large-signal or dc behavior of bipolar transistors is considered. Large-signal models are developed for the calculation of total currents and voltages in transistor circuits, and such effects as breakdown-voltage limitations, which are usually not included in models, are also considered. Second-order effects, such as current-gain variation with collector current and Early voltage, can be important in many circuits and are treated in detail.

The sign conventions used for bipolar transistor currents and voltages are shown in Figure 2-76. All bias currents for both *npn* and *pnp* transistors are assumed positive going into the device.

Electrical and Performance Characteristics and Specifications. Electrical characteristics may be described as uniquely defined, measurable electrical transistor properties that are not a function of the measuring circuit or apparatus (except insofar as standard terminations and measurement accuracy are concerned). Performance or operating characteristics are also electrical properties but they are, in general, not unique because their values depend on the measuring circuit (in particular, source and load impedance, which may be arbitrary). As might be expected, the terms are often used somewhat loosely (and sometimes

* Portions of this section, Sections 2-2-3 through 2-2-5, and Sections 2-3-3 through 2-3-6 are based on Paul R. Gray and Robert G. Meyer, *Analysis and Design of Analog Integrated Circuits*, 3rd ed., ©1993 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

interchangeably), especially in cases where only subtle differences are involved. The terms are generally used on transistor datasheets to segregate (for emphasis) under performance or operating characteristics those properties most directly applicable to the primary intended application.

Performance (Operating) Characteristics. Of the numerous performance characteristics that can be specified for high-frequency transistors, perhaps the most fundamental and pertinent characteristics are:

- Power gain and noise figure, for small-signal applications
- Power gain, power output, and efficiency, for large-signal applications

All of these characteristics are, of course, functions of frequency, bias temperature, and so on, and to completely characterize a transistor over its full frequency, bias, and temperature ranges would be prohibitively costly. Consequently, characterization data are given only for restricted ranges of these variables. These data should portray sufficiently the capabilities of a particular device for its intended applications. In the case of maximum ratings, some applications may require additional characterization by the user or through applications assistance from the manufacturer.

POWER GAIN

G_{max}. Of the various definitions for the measurement of power flow in an active two-port device, such as a transistor, two are unique enough to allow specification without recourse to specifying the complete measuring circuit in detail. One of these definitions is termed *maximum available gain* (G_{max}) and is the power gain obtained when the input and output ports are simultaneously conjugately matched to source and load impedances, respectively. Implicit in this definition is the assumption that the two-port is unconditionally stable; that is, that no combination of input/output tuning can result in increasing gain to the point of oscillation.

$|S_{21}|^2$. The other unique power gain is the gain realized when the transistor is inserted between a source and load with identical impedances (in practice, usually $50 + j0\ \Omega$). This particular insertion of transducer gain happens to coincide with the usual definition of the two-port forward scattering parameter, S_{21}. More precisely, it is equal to the magnitude squared of this parameter and is therefore often identified by the symbol $|S_{21}|^2$. For wideband applications, $|S_{21}|^2$ is important because wideband terminations "not too different from 50 Ω" are more easily realized than are wideband transforming networks that provide the matching required for G_{max}.

NOISE FIGURE. A common measure of the noise generated by an active two-port device—noise that sets a lower limit on amplifier sensitivity—is noise factor (F). This is defined as

$$F = \frac{\text{Input signal-to-noise ratio}}{\text{Output signal-to-noise ratio}} \tag{2-110}$$

or more generally as

$$F = \frac{\text{Total output noise power}}{\text{Output power due to source resistance}} \tag{2-111}$$

At high frequencies, spot noise factor or noise factor for a small fractional bandwidth (say, 1%) is used and is usually expressed as *noise figure* (*NF*), in decibels:

$$NF = 10 \log F \tag{2-112}$$

As already discussed, noise figure is a function of source impedance (as well as functions of frequency, bias, etc.) and hence, there is an infinity of noise figures associated with a given device corresponding to the infinity of possible impedances that may be presented to the device input. The only unique one, in the sense that it does not involve arbitrary source impedances, is $NF_{\min}$, the minimum noise figure obtained (at a given bias and frequency) when the input is tuned to optimize this parameter. This is the noise figure value commonly given on datasheets.

In practical amplifiers that involve more than one stage, *overall noise factor* (F_O) is given by

$$F_O = F_1 + \frac{F_2 - 1}{G_1} + \cdots + \frac{F_n - 1}{G_{(n-1)}} \tag{2-113}$$

where n = number of stages
G_n = gain of the nth stage
F_n = noise factor of the nth stage

This expression emphasizes the important fact that for low-noise amplifiers, the first stage must be designed for the lowest noise figure and highest gain possible. [Note that the noise contribution of the second stage is divided (reduced) by the gain of the first stage.] Since the optimum source impedance and bias currents for optimum gain and noise figure do not often coincide, very careful circuit design is required to minimize overall noise figure. For more accuracy, we recommend the noise correlation approach.

POWER OUTPUT. This characteristic is important for both amplifier and oscillator transistors. In both cases, it is extremely circuit sensitive. For amplifiers, maximum useful output is often limited to that power output level at which gain has compressed 1 dB, an indicator of the upper limit of the device's linearity range. For oscillators, it is merely a quantitative measure of RF power for given dc input power.

EFFICIENCY. In the most general sense, this characteristic expresses as a percentage the ratio of RF power output to the total circuit input power, both dc and RF. That expression is efficiency, η, defined as

$$\eta = \frac{P_O}{P_i + P_{\text{dc}}} \times 100 \tag{2-114}$$

where P_O = RF output power
P_i = RF input power
P_{dc} = total dc power input

Since for oscillator transistors there is no RF power input, and for amplifier transistors the maximum input RF power is calculable from the power gain and power output specifications,

the inclusion of P_i in efficiency is redundant. Moreover, since the major portion of the dc power is dissipated by the transistor collector, a more restricted definition of efficiency is pertinent. This parameter, termed *collector efficiency* (η_C), is given by

$$\eta_C = \frac{P_O}{P_{CC}} \times 100 \tag{2-115}$$

where $P_{CC} = V_{CC} \times I_{CC}$
V_{CC} = collector supply voltage
I_{CC} = collector supply current

Electrical Characteristics. Electrical characteristics may be conveniently classified into two main types, dc and ac.

dc CHARACTERISTICS. The importance of dc characteristics of high-frequency transistors lies primarily in biasing and reliability considerations. However, certain dc characteristics are also directly related to high-frequency performance. For example, high-frequency noise figure is affected by dc current gain. The dc characteristics discussed here are those usually found on high-frequency transistor datasheets.

$V_{(BR)CBO}$, I_{CBO}. These two parameters serve to characterize the reverse-biased collector–base *pn* junction and are defined as follows (with the aid of Figure 2-77a). The collector–base breakdown voltage, $V_{(BR)CBO}$, identifies the voltage at which collector current tends to increase without limit, usually due to the high electric field developed across the junction. This voltage sets a limit on the maximum transistor operating voltage and, as mentioned before under maximum ratings, usually is the basis for the collector–base maximum voltage rating. $V_{(BR)CBO}$ should be specified at a value of $I_C = I_{C1}$ in the figure, which is within the avalanche (or high slope) region of the device's reverse characteristic. Typical values of I_{C1} are in the 1–10-μA region for high-frequency transistors.

To further define the quality of the reverse *I–V* characteristic, a specification is usually placed on the collector cutoff current, I_{CBO}, which is measured at some value of collector–base voltage less than $V_{(BR)CBO}$. For a good-quality silicon junction ("sharp" instead of soft; see Figure 2-77a), I_{CBO} is in the nanoampere range.

$V_{(BR)EBO}$, I_{EBO}. These two parameters characterize the reverse-biased emitter–base *pn* junction in an analogous manner to the collector–base junction parameters $V_{(BR)CBO}$ and I_{CBO}, given above, and are shown in Figure 2-77b. No further discussion of these parameters will be given here.

$V_{(BR)CEO}$, I_{CEO}. The collector–emitter breakdown voltage and cutoff current are somewhat more complex in nature than the collector–base and emitter–base parameters. In the latter two, only a single *pn* diode is involved. In the collector–emitter case, two diodes are involved. Moreover, each is influenced by the other through transistor action, since the reverse current of the collector–base diode flows through the emitter–base junction as forward current. Thus, the collector–base reverse current is amplified by the dc current gain of the transistor, resulting in:

- I_{CEO} being greater than I_{CBO} (for a given voltage)
- Typically, the familiar negative-resistance region in the *I–V* characteristic as shown in Figure 2-77c.

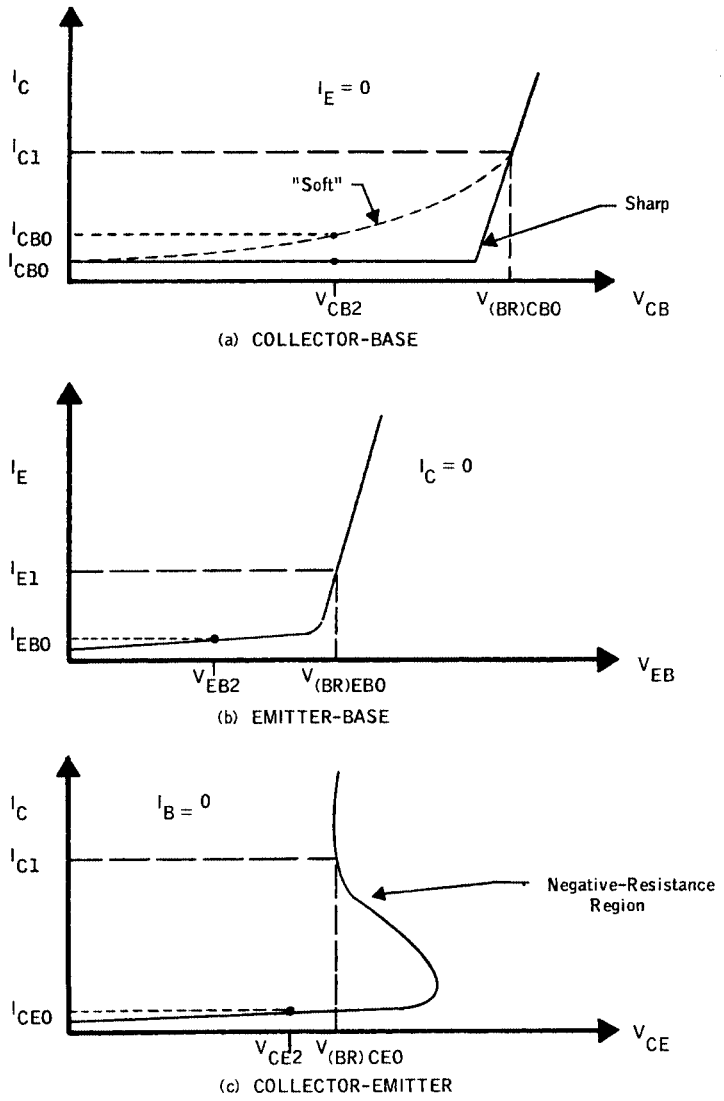

Figure 2-77 Transistor reverse *I–V* characteristics.

Consequently, $V_{(BR)CEO}$ is typically specified at collector currents one to three orders of magnitude higher than in the case of $V_{(BR)CBO}$ and $V_{(BR)EBO}$ to establish the minimum value of this characteristic.

h_{fe}. This parameter is simply the dc common-emitter current gain; that is, the ratio of collector current to base current at some specified collector voltage and current.

ac CHARACTERISTICS. Of the numerous ac characteristics defined for transistors, only relatively few are commonly used in characterizing high-frequency transistors. Some of the more pertinent parameters are briefly covered here.

S Parameters. By far the most useful and conveniently measured set of two-port parameters for transistor high-frequency (roughly 100 MHz and above) characterization is

the *S*-parameter or scattering-matrix set. These parameters completely and uniquely define the small-signal gain and input/output immittance properties of any linear "black box." (By definition, a transistor or any active device is linear under small-signal conditions.) However, these parameters reveal nothing (except possibly indirectly and approximately) about large-signal or noise behavior. Simply interpreted (more general definitions and other interpretations abound in the technical literature), the *S* parameters are merely insertion gains, forward and reverse, and reflection coefficients, input and output, with driven and nondriven ports both terminated in equal impedances, usually $50 + j0\ \Omega$. Such an interpretation tends to make *S* parameters very attractive, once some familiarity is gained, at high (especially microwave) frequencies, since the power flow or gain and reflection-coefficient concepts are more intuitively meaningful than voltage and current conceptual schemes. It should also be mentioned that *S*-parameters can be converted through straightforward matrix transformations to other two-port parameter sets, such as *h*-, *y*-, and *z*-parameters.

Proceeding with more specific definitions, the *S*-parameters are defined analytically by

$$b_1 = S_{11}a_1 + S_{12}a_2 \tag{2-116}$$

$$b_2 = S_{21}a_1 + S_{22}a_2 \tag{2-117}$$

or, in matrix form,

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} \tag{2-118}$$

where, referring to Figure 2-78

a_1 = (incoming power at Port 1)$^{1/2}$
b_1 = (outgoing power at Port 1)$^{1/2}$
a_2 = (incoming power at Port 2)$^{1/2}$
b_2 = (outgoing power at Port 2)$^{1/2}$
E_1, E_2 = electrical stimuli at Port 1, Port 2

From the figure and defining linear equations, for $E_2 = 0$, then $a_2 = 0$, and (skipping through numerous rigorous steps)

$$S_{11} = \frac{b_1}{a_1}$$

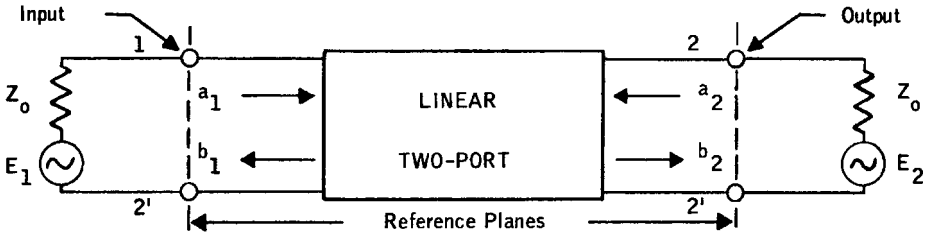

Figure 2-78 Two-port *S*-parameter definition.

$$= \left(\frac{\text{Outgoing input power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \frac{\text{Reflected voltage}}{\text{Incident voltage}}$$

$$= \text{Input reflection coefficient} \tag{2-119}$$

$$S_{21} = \frac{b_2}{a_1}$$

$$= \left(\frac{\text{Outgoing output power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \left(\frac{\text{Output power}}{\text{Available input power}}\right)^{1/2}$$

$$= (\text{Forward transducer gain})^{1/2} \tag{2-120}$$

or, more precisely in the case of S_{21}:

$$\text{Forward transducer gain} = G_{\text{TF}} = |S_{21}|^2 \tag{2-121}$$

$$Z_i = Z_o \tag{2-122}$$

Similarly, at Port 2 for $E_1 = 0$, then $a_1 = 0$, and

$$S_{22} = \frac{b_2}{a_2} = \text{Output reflection coefficient} \tag{2-123}$$

$$S_{12} = \frac{b_1}{a_2} = (\text{Reverse transducer gain})^{1/2} \tag{2-124}$$

$$G_{\text{TR}} = |S_{12}|^2 \tag{2-125}$$

Since many measurement systems display *S*-parameter magnitudes in decibels, the following relationships are particularly useful:

$$|S_{11}|_{\text{dB}} = 10\log|S_{11}|^2$$

$$= 20\log|S_{11}| \tag{2-126}$$

$$|S_{22}|_{\text{dB}} = 20\log|S_{22}| \tag{2-127}$$

$$|S_{21}|_{\text{dB}} = 10\log|S_{21}|^2$$

$$= 20 \log|S_{21}|$$

$$= 10 \log|G_{TF}| = |G_{TF}|_{dB} \tag{2-128}$$

$$|S_{12}|_{dB} = 10 \log|S_{12}|^2$$

$$= 20 \log|S_{12}|$$

$$= 10 \log|G_{TR}| = |G_{TR}|_{dB} \tag{2-129}$$

Figure 2-79 shows an example of the use of *S* parameters in transistor stage design.

Transition Frequency. One of the better known, but perhaps least understood, figures of merit for high-frequency transistors is the so-called transition frequency, f_T. Part of the misunderstanding that appears to exist is due to the use of the misleading (but common, for

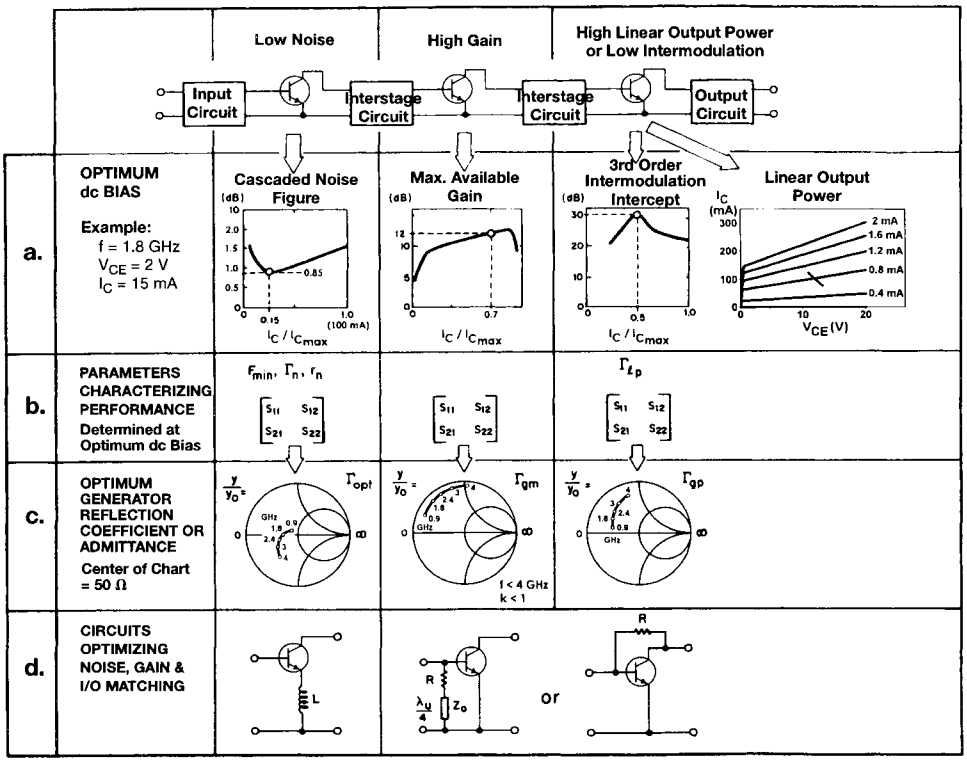

Figure 2-79 Key parameters in applying a BJT in low-noise front-end, high-gain, and linear-power stages. (a) The BJT characteristics that lead to optimum dc bias for a low-noise front end; (b) parameters characterizing device performance; (c) Γ_{opt} for the first stage, and S_{11} and S_{22} for the output stage as simulated by CAD software. The example is based on the Siemens BJTs BFP420 (low-noise stage), BFP450 (high-gain stage), and BFG235 (output stage). Circuits to optimize stage noise, gain, and I/O matching are shown in (d). (Presentation based on Figure 14 in Charles A. Liechti, "Microwave Field-Effect Transistors—1976," *IEEE Trans. Microwave Theory Tech.,* vol. MTT-24, pp. 279–300, June 1976.)

historical reasons) term *short-circuit gain–bandwidth product* for this parameter. By definition, f_T is that characteristic frequency described by the equation

$$f_T = h_{fe} \times f_{\text{meas}} \tag{2-130}$$

where h_{fe} is the magnitude of the small-signal common-emitter short-circuit current gain, and f_{meas} is the frequency of measurement, chosen such that

$$2 \le h_{fe} \le \frac{h_{fe0}}{2} \tag{2-131}$$

where h_{fe0} is the low-frequency value of h_{fe}.

To varying degrees of approximation, depending on the transistor type, f_T is the frequency at which h_{fe} approximates unity. It is not, in general, the frequency at which h_{fe} is precisely equal to unity. To clarify these points further, consider the plot of h_{fe} against frequency sketched in Figure 2-80.

At low frequencies, $f << f_B$, h_{fe} is constant and equal to h_{fe0}.

At f_B, h_{fe} has decreased to 0.707 h_{fe0}; that is, f_B is the 3-dB cutoff frequency for common-emitter short-circuit current gain, h_{fe}.

For frequencies such that

$$2f_B < f < f_T \tag{2-132}$$

h_{fe} varies inversely proportional to frequency. That is, the f_T defining relationship holds:

$$h_{fe} \times f_{\text{meas}} = \text{constant} = f_T \tag{2-133}$$

At frequencies approaching f_T, other parameters, especially package parasitics, can cause $|h_{fe}|$ to depart significantly from this $1/f$ variation. Therefore, the frequency, f_1, at which $|h_{fe}|$ actually equals unity can be somewhat different from f_T.

Applying these frequency-gain characteristics to the common-emitter wideband, low-pass amplifiers gives rise to the terminology of f_T being a "gain–bandwidth product." However,

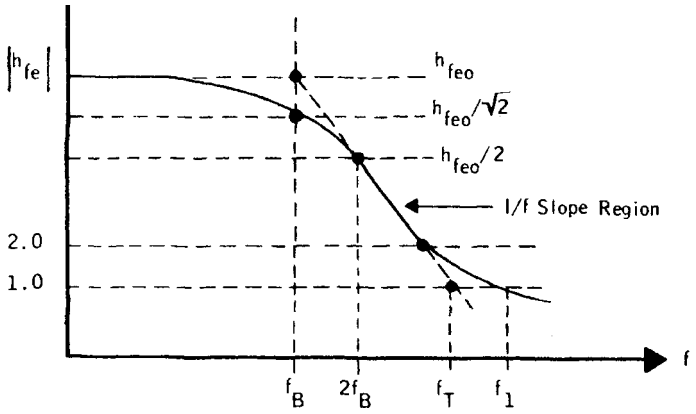

Figure 2-80 $|h_{fe}|$ frequency characteristics.

this is an optimistic approximation at best, since the product of low-frequency circuit gain and the 3-dB cutoff frequency is reduced from f_T by an amount that depends on circuit impedances.

The real significance of f_T lies in the fact that it is a measure of certain internal transistor parameters that do, in fact, affect high-frequency performance: for example, gain (though not in the convenient quantitative manner implied by the term "gain–bandwidth product"). In particular, good high-frequency noise performance requires that f_T be high. Thus, f_T is included on transistor datasheets primarily as a figure of merit, not as a parameter to be used directly in design.

Collector–Base Time Constant, $r_b'C_c$. This is an internal device parameter that relates only indirectly to high-frequency performance. It is primarily a measure of internal feedback within the transistor. It also relates to transistor high-frequency impedance. As the name says (in symbols), it is a measure of transistor base resistance and collector capacitance in combination; however, except for certain low-frequency transistors, it cannot be considered the simple two-element lumped *RC* time constant implied by the terminology. (In high-frequency transistors, base resistance and collector impedance must be considered to be distributed when considered in detail). As a figure of merit, it is included on transistor datasheets to indicate how well base resistance and collector impedance have been minimized. It also allows the estimation of certain gain properties of the transistor (see the $f_{\max}$ parameter, which we'll describe shortly).

Collector–Base Capacitance, C_{cb}. This parameter is simply the total collector–base *pn* junction capacitance measured at a low frequency (typically, 1 MHz), where it can be considered a single lumped element. For high-frequency transistors it is, of course, desirable that C_{cb} be small from bandwidth and stability considerations as well as from gain considerations alone.

Maximum Frequency of Oscillation, $f_{\max}$. This is another figure-of-merit parameter, as opposed to measurable parameters directly usable in the application of transistors. Its importance stems from the following approximate relationships (which will not be derived here):

$$f_{\max} \approx \left(\frac{f_T}{8\pi r_b' C_C} \right)^{1/2} \tag{2-134}$$

$$G_{\max} \approx \left(\frac{f_{\max}}{f_{\text{oper}}} \right)^2 \tag{2-135}$$

These expressions illustrate in a quantitative way the importance and the interrelationship between high f_T and low $r_b'C_C$ insofar as high-frequency gain is concerned. However, since they are approximations and since their derivation involves several assumptions that are not always valid, they must be interpreted with caution. For example, the expression for $G_{\max}$ is obviously not applicable at low frequencies, since as $f \to 0$, $G_{\max} \to \infty$, according to this expression. As a rule of thumb, the $G_{\max}$ expression is a reasonable approximation for frequencies such that

$$5 > \frac{f_{\max}}{f_{\text{oper}}} > 1 \tag{2-136}$$

For accurate analysis of transistor gain and stability, a complete set of two-port parameters must be employed in exact expressions, such as those from which the approximations shown above were derived.

Datasheet Transistor Specifications. The following is a reprint of a Siemens microwave transistor datasheet. This 25-GHz f_T transistor will soon be replaced by a 40-GHz family, based on a silicon–germanium design. Key parameters describing the transistor are:

- The dc parameters, such as maximum current and voltage and dissipation
- Noise figure as a function of generator impedance, bias point, and frequency
- Frequency-dependent behavior, typically expressed in *S* parameters, and also as a function of bias point and frequency
- Large-signal performance to be calculated based on a nonlinear model, such as the Gummel–Poon

The transistor description typically gives details about packaging, as the Gummel–Poon model is intrinsic (without parasitics). Not only does the package determine the parasitics, it also affects the device's ability to transfer heat to its heat sink. The following figures, reproduced with permission from the datasheet for the BFP420 transistor by Siemens (now Infineon Technologies), are a typical representation of the dc-I_C curves, *S* parameters, and noise parameters of a normal, packaged microwave transistor. Besides its dc parameters and capacitance, there are other critical parameters. A BJT's noise figure is a strong function of its dc current gain, and one can determine a 3-dB cutoff frequency referred to as f_T, which shows the gain roll-off as a function of collector current and frequency. Another important measure or figure of merit is $f_{\max}$, the maximum frequency of oscillation:

$$f_{\max} = \sqrt{\frac{|Y_{21}|}{16\pi R_{bb} C_{be} C_{bc}}} \tag{2-137}$$

Figure 2-81 shows a photograph of the die for the BFP420.

Since the intercept point is an important figure of merit, Figure 2-82 shows intercept point as a function of bias point for the BFR93AW BJT. We wish more manufacturers would supply this information.

2-2-3 Large-Signal Transistors in the Forward-Active Region

We saw in the diode case that its description is physics-based and it is, therefore, logical to apply the same modeling for the transistors. The first complete modeling for transistors was described in the Gummel–Poon model, but many engineers use the somewhat more simpler Ebers–Moll model. By combining two diodes, the parasitic elements, and the base separating resistor, we can show the "intrinsic" nonlinear model for the bipolar transistor.

Many equations that have been published contain some approximations, but for exact nonlinear analysis, we have to resort to the somewhat more complex or complete equations as shown in Appendix A for the bipolar model.

Recently, some other models have been proposed by researchers, such as the MEXTRAM models (Philips), but the trouble with these models is that while they may give quite good results for RF applications, it is virtually impossible to obtain parameters for them. So far the only industry-standard model is the Gummel–Poon, and to the authors' knowledge there

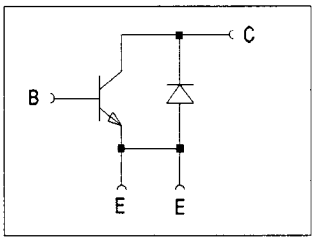
Institut für Mobil- und Satellitenfunktechnik (IMST)
© 1996 SIEMENS AG

For non-linear simulation:

- Use transistor chip parameters in Berkeley SPICE 2G.6 syntax for all simulators.
- If you need simulation of the reverse characteristics, add the diode with the C'-E'-diode data between collector and emitter.
- Simulation of the package is not necessary for frequencies < 100 MHz.
  For higher frequencies add the wiring of the package equivalent circuit around the non-linear transistor and diode model.

Note:

- This transistor is constructed in a common emitter configuration. This feature causes an additional, reverse biased diode between emitter and collector, which does not effect normal operation.



Transistor Schematic Diagram

The common emitter configuration shows the following advantages:

- Higher gain because of lower emitter inductance.
- Power is dissipated via the grounded emitter leads, because the chip is mounted on the copper emitter leadframe.

Please note, that the broadest lead is the emitter lead.

- The AC-Characteristics are verified by random sampling.

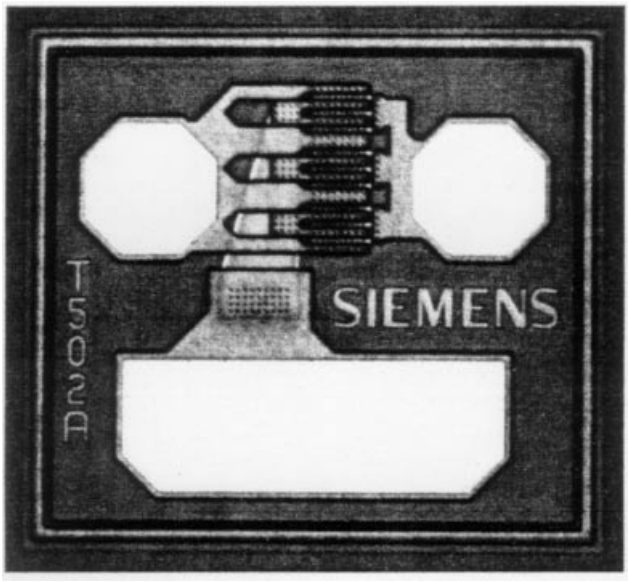


Figure 2-81 Photograph of the BFP420 die (310 × 290 μm). The bonding pad for the base is at the upper right; for the collector at the upper left. The large, lower pad connects to the emitter.

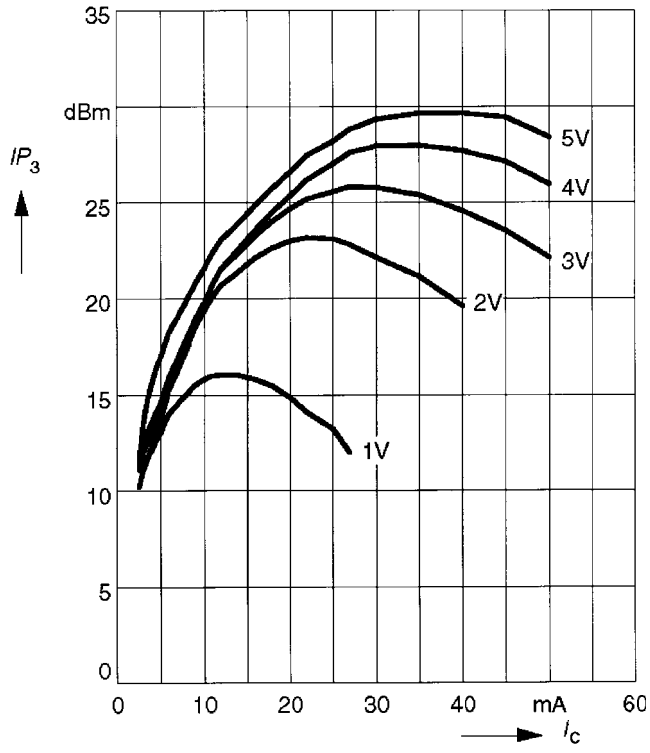

Figure 2-82 $IP_{3,out}$ versus I_C at five values of V_{CE} for the BRF93AW BJT.

are no accepted or affordable parameter extractor programs available, not even to consider the cost of hardware for such extractions. Hewlett-Packard recently published a system with a hardware cost in the vicinity of $1 million.

A typical *npn* planar bipolar transistor structure is shown in Figure 2-83a, where collector, base, and emitter are labeled *C*, *B*, and *E*, respectively. The impurity doping density in the base and the emitter of such a transistor is not constant but varies with distance from the top surface. However, many of the characteristics of such a device can be predicted by analyzing

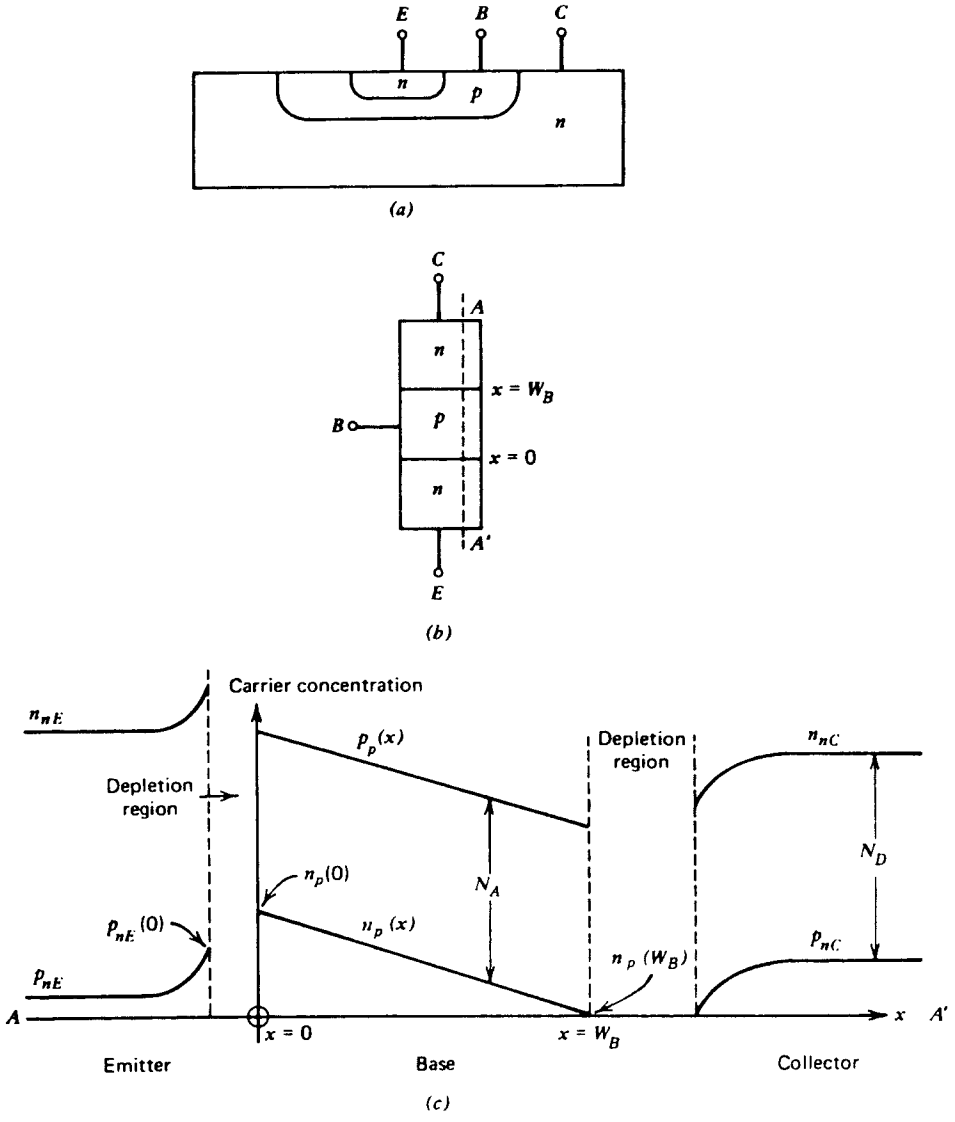

Figure 2-83 (a) Cross section of a typical *npn* planar bipolar transistor structure; (b) idealized transistor structure; (*c*) carrier concentrations along the cross section *AA*′ of the transistor in (b). Uniform doping densities are assumed. (Not to scale)

the idealized transistor structure shown in Figure 2-83b. In this structure, the base and emitter doping densities are assumed constant, and this is sometimes called a "uniform-base" transistor. Where possible in the following analyses, the equations for the uniform-base analysis are expressed in a form that applies also to nonuniform-base transistors.

A cross section AA' is taken through the device of Figure 2-83b and carrier concentrations along this section are plotted in Figure 2-83c. Hole concentrations are denoted by p and electron concentrations by n with subscripts p or n representing p-type or n-type regions. The n-type emitter and collector regions are distinguished by subscripts E and C, respectively. The carrier concentrations shown in Figure 2-83c apply to a device in the *forward-active region*. That is, the base–emitter junction is forward-biased and the base–collector junction is reverse-biased. The minority-carrier concentrations in the base at the edges of the depletion regions can be calculated from a Boltzmann approximation to the Fermi–Dirac distribution function to give [2]

$$n_p(0) = n_{po} \exp \frac{V_{BE}}{V_T} \tag{2-138}$$

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \simeq 0 \tag{2-139}$$

where W_B is the width of the base from the base–emitter junction depletion layer edge of the base–collector depletion layer edge and n_{po} is the equilibrium concentration of electrons in the base. Note that V_{BC} is negative for an *npn* transistor in the forward-active region and thus $n_p(W_B)$ is very small. Low-level injection conditions are assumed in the derivation of Eqs. (2-138) and (2-139). This means that the minority-carrier concentrations are always assumed much smaller than the majority-carrier concentrations.

If *recombination* of holes and electrons in the base is small, it can be shown that the minority-carrier concentration $n_p(x)$ in the base varies *linearly* with distance [3]. Thus, a straight line can be drawn joining the concentrations at $x = 0$ and $x = W_B$ in Figure 2-83c.

For charge neutrality in the base, it is necessary that

$$N_A + n_p(x) = p_p(x) \tag{2-140}$$

and thus

$$p_p(x) - n_p(x) = N_A \tag{2-141}$$

where $p_p(x)$ is the hole concentration in the base and N_A is the base doping density that is assumed constant. Equation (2-141) indicates that the hole and electron concentrations are separated by a constant amount and thus $p_p(x)$ also varies linearly with distance.

Collector current is produced by minority-carrier electrons in the base diffusing in the direction of the concentration gradient and being swept across the collector–base depletion region by the field existing there. The diffusion current density due to electrons in the base is

$$J_n = qD_n \frac{dn_p(x)}{dx} \tag{2-142}$$

where D_n is the diffusion constant for electrons. From Figure 2-83c,

$$J_n = -qD_n \frac{n_p(0)}{W_B} \tag{2-143}$$

If I_C is the collector current and is taken as positive flowing *into* the collector, it follows from Eq. (2-143) that

$$I_C = qA D_n \frac{n_p(0)}{W_B} \tag{2-144}$$

where A is the cross-sectional area of the emitter. Substitution of Eq. (2-138) into Eq. (2-144) gives

$$I_C = \frac{qAD_n n_{po}}{W_B} \exp \frac{V_{BE}}{V_T} \tag{2-145}$$

$$= I_S \exp \frac{V_{BE}}{V_T} \tag{2-146}$$

where

$$I_S = \frac{qA D_n n_{po}}{W_B} \tag{2-147}$$

and I_S is a constant used to describe the transfer characteristic of the transistor in the forward-active region. Equation (2-147) can be expressed in terms of the base doping density by noting that [4]

$$n_{po} = \frac{n_i^2}{N_A} \tag{2-148}$$

and substitution of Eq. (2-148) in Eq. (2-147) gives

$$I_S = \frac{qAD_n n_i^2}{W_B N_A} = \frac{qA\overline{D}_n n_i^2}{Q_B} \tag{2-149}$$

where $Q_B = W_B N_A$ is the number of doping atoms in the base per unit area of the emitter and n_i is the intrinsic carrier concentration in silicon. In this form Eq. (2-149) applies to both uniform- and nonuniform-base transistors and D_n has been replaced by $\overline{D}_n$, which is an average effective value of the electron diffusion constant in the base. This is necessary for nonuniform-base devices because the diffusion constant is a function of impurity concentration. Typical values of I_S as given by Eq. (2-149) are 10^{-14} to 10^{-16} A.

Equation (2-146) gives the collector current as a function of base–emitter voltage. The base current I_B is also an important parameter and, at moderate current levels, consists of two major components. One of these (I_{B1}) represents recombination of holes and electrons in the base and is proportional to the minority-carrier charge Q_e in the base. From Figure 2-83c, the minority-carrier charge in the base is

$$Q_e = \frac{1}{2} n_p(0) W_B q A \tag{2-150}$$

and we have

$$I_{B1} = \frac{Q_e}{\tau_b} = \frac{1}{2} \frac{n_p(0) W_B q A}{\tau_b} \tag{2-151}$$

where τ_b is the minority-carrier lifetime in the base. I_{B1} represents a flow of majority holes from the base lead into the base region. Substitution of Eq. (2-138) into Eq. (2-151) gives

$$I_{B1} = \frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} \exp \frac{V_{BE}}{V_T} \tag{2-152}$$

The second major component of base current (usually the dominant one in the integrated-circuit *npn* devices) is due to injection of holes from the base into the emitter. This current component depends on the gradient of minority-carrier holes into the emitter and is [5]

$$I_{B2} = \frac{q A D_p}{L_p} p_{nE}(0) \tag{2-153}$$

where D_p is the diffusion constant for holes and L_p is the diffusion length (assumed small) for holes in the emitter. $p_{nE}(0)$ is the concentration of holes in the emitter at the edge of the depletion region and is

$$P_{nE}(0) = p_{nEo} \exp \frac{V_{BE}}{V_T} \tag{2-154}$$

If N_D is the donor atom concentration in the emitter (assumed constant) then

$$p_{nEo} \simeq \frac{n_i^2}{N_D} \tag{2-155}$$

The emitter is deliberately doped much more heavily than the base, making N_D large and p_{nEo} small, so that the base-current component, I_{B2}, is minimized.

Substitution of Eqs. (2-154) and (2-155) into Eq. (2-153) gives

$$I_{B2} = \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \exp \frac{V_{BE}}{V_T} \tag{2-156}$$

The total base current, I_B, is the sum of I_{B1} and I_{B2}:

$$I_B = I_{B1} + I_{B2} = \left(\frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} + \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \right) \exp \frac{V_{BE}}{V_T} \tag{2-157}$$

Although this equation was derived assuming uniform base and emitter doping, it gives the correct functional dependence of I_B on device parameters for practical double-diffused

nonuniform-base devices. Second-order components of I_B, which are important at low current levels, are considered later.

Since I_C in Eq. (2-146) and I_B into Eq. (2-147) are both proportional to $\exp(V_{BE}/V_T)$ in this analysis, the base current can be expressed in terms of collector current as

$$I_B = \frac{I_C}{\beta_F} \tag{2-158}$$

where β_F is the forward current gain. An expression for β_F can be calculated by substituting Eqs. (2-145) and (2-157) into Eq. (2-158) to give

$$\beta_F = \frac{qAD_n n_{po}/W_B}{\frac{1}{2}\frac{n_{po}W_B qA}{\tau_b} + \frac{qAD_p n_i^2}{L_p N_D}} = \frac{1}{\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-159}$$

where Eq. (2-148) has been substituted for n_{po}. Equation (2-159) shows that β_F is maximized by minimizing the base width W_B and maximizing the ratio of emitter to base doping densities N_D/N_A. Typical values of β_F for *npn* transistors in integrated circuits are 50–500, whereas lateral *pnp* transistors have values of 10–100. Finally, the emitter current is

$$I_E = -(I_C + I_B) = -\left(I_C + \frac{I_C}{\beta_F}\right) = -\frac{I_C}{\alpha_F} \tag{2-160}$$

where

$$\alpha_F = \frac{\beta_F}{1+\beta_F} \tag{2-161}$$

The value of α_F can be expressed in terms of device parameters by substituting Eq. (2-159) into Eq. (2-161) to obtain

$$\alpha_F = \frac{1}{1+\frac{1}{\beta_F}} = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \simeq \alpha_T \gamma \tag{2-162}$$

where

$$\alpha_T = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n}} \tag{2-163}$$

$$\gamma = \frac{1}{1+\frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-164}$$

The validity of Eq. (2-162) depends on $W_B^2/2\tau_b D_n << 1$ and $(D_p/D_n)(W_B/L_p)(N_A/N_D) << 1$, and this is always true if β_F is large [see Eq. (2-159)]. The term γ in Eq. (2-162) is

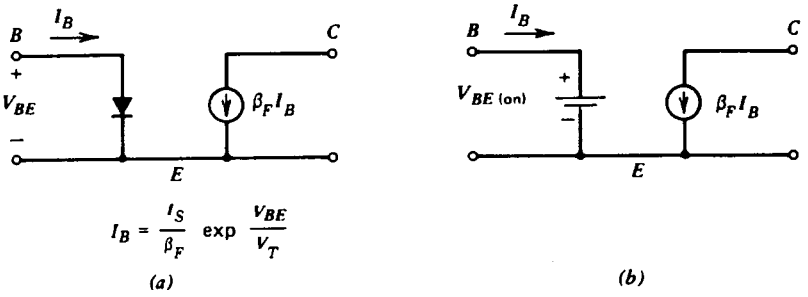

Figure 2-84 Large-signal models of *npn* transistors for use in bias calculations. (a) Circuit incorporating an input diode. (b) Simplified circuit with an input voltage source.

called the *emitter injection efficiency* and is equal to the ratio of the electron current (*npn* transistor) injected into the base from the emitter to the total hole and electron current crossing the base–emitter junction. Ideally $\gamma \to 1$, and this is achieved by making N_D/N_A large and W_B small. In that case very little reverse injection occurs from base to emitter.

The term α_T in Eq. (2-162) is called the *base transport factor* and represents the fraction of carriers injected into the base (from the emitter) that reach the collector. Ideally $\alpha_T \to 1$, and this is achieved by making W_B small. It is evident from the above development that fabrication changes that cause α_T and γ to approach unity also maximize the value of β_F of the transistor.

The results derived above allow formulation of a large-signal model of the transistor suitable for bias-circuit calculations with devices in the forward-active region. One such circuit is shown in Figure 2-84 and consists of a base–emitter diode to model Eq. (2-157) and a controlled collector-current generator to model Eq. (2-158). Note that the collector voltage ideally has no influence on the collector current and the collector node acts as a high-impedance current source. A simpler version of this equivalent circuit, which is often useful, is shown in Figure 2-84b, where the input diode has been replaced by a battery with a value $V_{BE(\text{on})}$, which is usually 0.6–0.7 V. This represents the fact that in the forward-active region the base–emitter voltage varies very little because of the steep slope of the exponential characteristic. In some circuits the temperature coefficient of $V_{BE(\text{on})}$ is important and a typical value for this is –2 mV/°C. The equivalent circuits of Figure 2-84 apply for *npn* transistors. For *pnp* devices the corresponding equivalent circuits are shown in Figure 2-85.

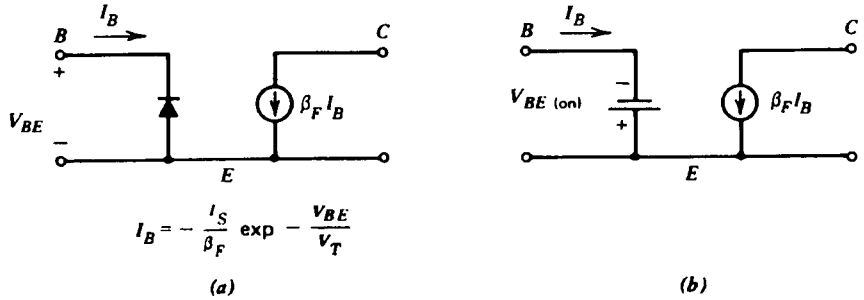

Figure 2-85 Large-signal models of *pnp* transistors corresponding to the circuits of Figure 2-84.

2-2-4 Effects of Collector Voltage on Large-Signal Characteristics in the Forward-Active Region

In the analysis of the previous section, the collector–base junction was assumed reverse-biased and ideally had no effect on the collector currents. This is a useful approximation for first-order calculations, but it is not strictly true in practice. There are occasions where the influence of collector voltage on collector current is important, and this will now be investigated.

The collector voltage has a dramatic effect on the collector current in two regions of device operation. These are the saturation (V_{CE} approaches zero) and breakdown (V_{CE} very large) regions that will be considered later. For values of collector–emitter voltage V_{CE} between these extremes, the collector current increases slowly as V_{CE} increases. The reason for this can be seen from Figure 2-86, which is a sketch of the minority-carrier concentration in the base of the transistor. Consider the effect of changes in V_{CE} on the carrier concentration for constant V_{BE}. Since V_{BE} is constant, the change in V_{CB} equals the change in V_{CE}, and this causes an increase in the collector–base depletion-layer width as shown. The change in the base width of the transistor, ΔW_B, equals the change in depletion-layer width and causes an increase ΔI_C in the collector current.

From Eqs. (2-146) and (2-149) we have

$$I_C = \frac{qA\bar{D}_n n_i^2}{Q_B} \exp \frac{V_{BE}}{V_T} \tag{2-165}$$

Differentiation of Eq. (2-165) yields

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{qA\bar{D}_n n_i^2}{Q_B^2} \left(\exp \frac{V_{BE}}{V_T} \right) \frac{dQ_B}{dV_{CE}} \tag{2-166}$$

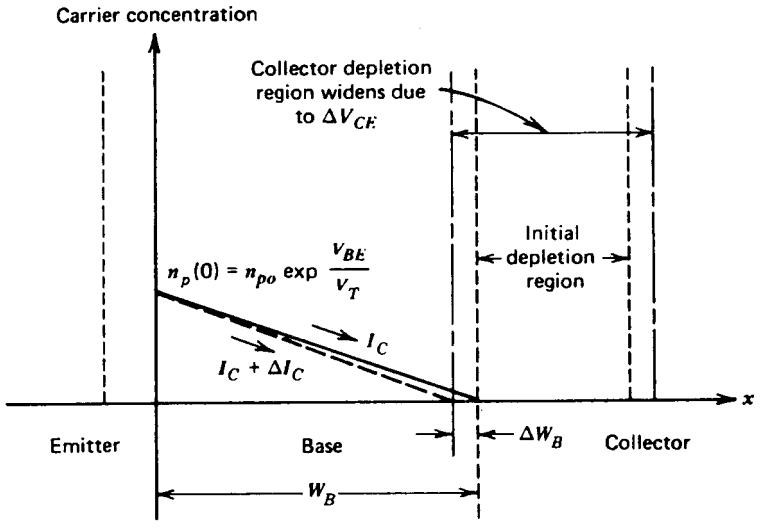

Figure 2-86 Effect of increases in V_{CE} on the collector depletion region and base width of a bipolar transistor.

and substitution of Eq. (2-165) in Eq. (2-166) gives

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{Q_B}\frac{dQ_B}{dV_{CE}} \tag{2-167}$$

For a uniform-base transistor $Q_B = W_B N_A$ and Eq. (2-167) becomes

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{W_B}\frac{dW_B}{dV_{CE}} \tag{2-168}$$

Note that since the base width *decreases* as V_{CE} increases, dW_B/dV_{CE} in Eq. (2-168) is negative and thus $\partial I_C/\partial V_{CE}$ is positive. dW_B/dV_{CE} is a function of the bias value of V_{CE}, but the variation is typically small for a reverse-biased junction and dW_B/dV_{CE} is often assumed constant. The resulting predictions agree adequately with experimental results.

Equation (2-168) shows that $\partial I_C/\partial V_{CE}$ is proportional to the collector-bias current and inversely proportional to the transistor base width. Thus narrow-base transistors show a greater dependence of I_C on V_{CE} in the forward-active region. The dependence of $\partial I_C/\partial V_{CE}$ on I_C results in typical transistor output characteristics as shown in Figure 2-87. In accordance with the assumptions made in the foregoing analysis, these characteristics are shown for constant values of V_{BE}. However, in most integrated-circuit transistors the base current is dependent only on V_{BE} and not on V_{CE}, and thus constant-base-current characteristics can often be used in the following calculation. The reason for this is that the base current is usually dominated by the I_{B2} component of Eq. (2-156), which has no dependence on V_{CE}. Extrapolation of the characteristics of Figure 2-87 back to the V_{CE} axis gives an intercept V_A called the Early voltage, where

$$V_A = \frac{I_C}{\dfrac{\partial I_C}{\partial V_{CE}}} \tag{2-169}$$

Substitution of Eq. (2-168) in Eq. (2-169) gives

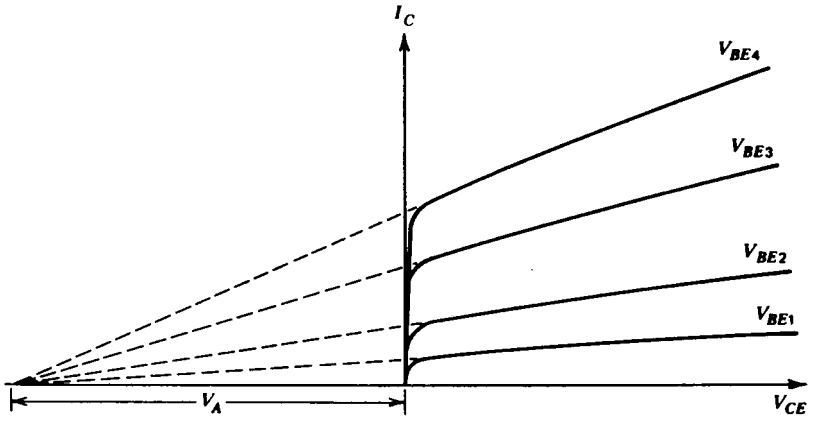

Figure 2-87 Bipolar transistor output characteristics showing the Early voltage, V_A.

$$V_A = -W_B \frac{dV_{CE}}{dW_B} \tag{2-170}$$

which is a constant, independent of I_C. Thus all the characteristics extrapolate to the same point on the V_{CE} axis. The variation of I_C with V_{CE} is called the Early effect and V_A is a common model parameter for circuit-analysis computer programs. Typical values of V_A for integrated-circuit transistors are 15–100 V. The inclusion of Early effect in dc bias calculations is usually limited to computer analysis because of the complexity introduced into the calculation. However, the influence of the Early effect is often dominant in small-signal calculations for high-gain circuits and this point will be considered later.

Finally, the influence of the Early effect on the transistor large-signal characteristics in the forward-active region can be represented approximately by modifying Eq. (2-146) to

$$I_C = I_S \left(1 + \frac{V_{BE}}{V_A}\right) \exp \frac{V_{BE}}{V_T} \tag{2-171}$$

This is a common means of representing the device output characteristics for computer simulation.

2-2-5 Saturation and Inverse Active Regions

Saturation is a region of device operation that is usually avoided in analog circuits because the transistor gain is very low in this region. Saturation is much more commonly encountered in digital circuits, where it provides a well-specified output voltage that represents a logic state. In saturation, both emitter–base and collector–base junctions are forward biased. Consequently, the collector–emitter voltage V_{CE} is quite small and usually in the range 0.05–0.3 V. The carrier concentrations in a saturated *npn* transistor with uniform base doping are shown in Figure 2-88. The minority-carrier concentration in the base of the edge of the depletion region is again given by Eq. (2-139) as

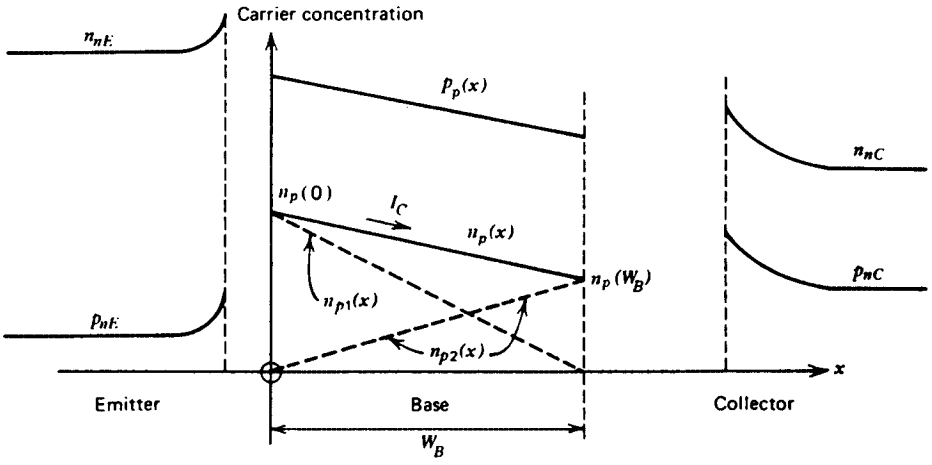

Figure 2-88 Carrier concentrations in a saturated *npn* transistor. (Not to scale)

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \tag{2-172}$$

but since V_{BC} is now positive, the value of $n_p(W_B)$ is no longer negligible. Consequently, changes in V_{CE} with V_{BE} held constant (which cause equal changes in V_{BC}) directly affect $n_p(W_B)$. Since the collector current is proportional to the slope of the minority-carrier concentration in the base [see Eq. (2-142)], it is also proportional to $[n_p(0) - (n_p(W_B)]$ from Figure 2-88. Thus, changes in $n_p(W_B)$ directly affect the collector current, and the collector node of the transistor appears to have a *low impedance*. As V_{CE} is decreased in saturation with V_{BE} held constant, V_{BC} increases as does $n_p(W_B)$ from Eq. (2-172). Thus, from Figure 2-88 the collector current decreases because the slope of the carrier concentration decreases. This gives rise to the saturation region of the $I_C - V_{CE}$ characteristic shown in Figure 2-89. The slope of the $I_C - V_{CE}$ characteristic in this region is largely determined by the resistance in series with the collector lead due to the finite resistivity of the *n*-type collector material. A useful model for the transistor in this region is shown in Figure 2-90

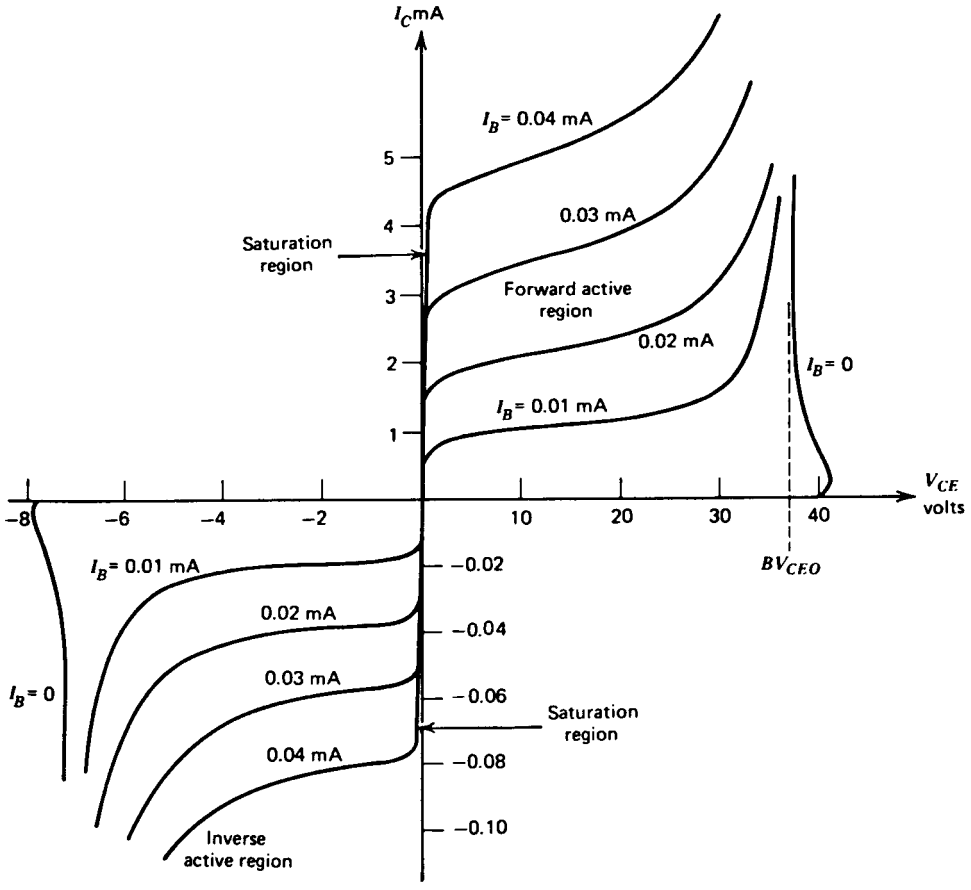

Figure 2-89 Typical $I_C - V_{CE}$ characteristics for an *npn* bipolar transistor. Note the different scales for positive and negative currents and voltages.

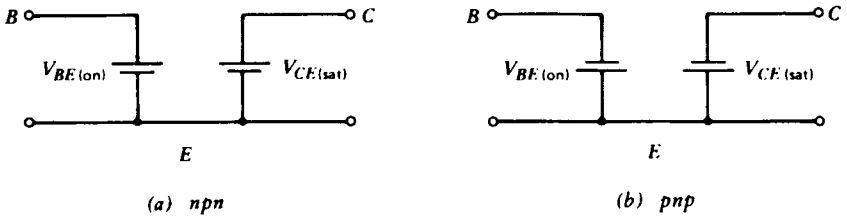

Figure 2-90 Large-signal models for bipolar transistors in the saturation region.

and consists of a fixed voltage source to represent $V_{BE(on)}$, and a fixed voltage source to represent the collector–emitter voltage $V_{CE(sat)}$. A more accurate but more complex model includes a resistor in series with the collector. This resistor can have a value ranging from 20 to 500 Ω, depending on the device structure.

An additional aspect of transistor behavior in the saturation region is apparent from Figure 2-88. For a given collector current, there is now a much larger amount of stored charge in the base than there is in the forward-active region. Thus the base-current contribution represented by Eq. (2-152) will be larger in saturation. In addition, since the collector–base junction is now forward biased, there is a new base-current component due to injection of carriers from the base to the collector. These two effects result in a base current I_B in saturation, which is larger than in the forward-active region for a given collector current I_C. Ratio I_C/I_B in saturation is often referred to as the *forced* β and is always less than β_F. As the forced β is made lower with respect to β_F, the device is said to be more *heavily saturated*.

The minority-carrier concentration in saturation, shown in Figure 2-88, is a straight line joining the two end points, assuming that recombination is small. This can be represented by a linear superposition of the two dotted distributions as shown. The justification for this is that the terminal currents depend *linearly* on the concentrations $n_p(0)$ and $n_p(W_B)$. This picture of device-carrier concentrations can be used to derive some general equations describing transistor behavior. Each of the distributions in Figure 2-88 is considered separately and the two contributions are combined. The *emitter* current that would result from $n_{p1}(x)$ above is given by the classical diode equation

$$I_{EF} = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) \tag{2-173}$$

where I_{ES} is a constant that is often referred to as the "saturation current" of the junction (no connection with the transistor saturation described above). Equation (2-173) predicts that the junction current is given by $I_{EF} \simeq I_{ES}$ with a reverse-bias voltage applied. However, in practice Eq. (2-173) is applicable only in the forward-bias region, since second-order effects dominate under reverse-bias conditions and typically result in a junction current several orders of magnitude larger than I_{ES}. The junction current that flows under reverse-bias conditions is often called the "leakage current" of the junction.

Returning to Figure 2-88, we can describe the *collector* current resulting from $n_{p2}(x)$ alone as

$$I_{CR} = -I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-174}$$

where I_{CS} is a constant. The total collector current I_C is given by I_{CR} plus the fraction of I_{EF} that reaches the collector (allowing for recombination and reverse emitter injection). Thus,

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-175}$$

where α_F has been defined previously by Eq. (2-162). Similarly, the total emitter current is composed of I_{EF} plus the fraction of I_{CR} that reaches the emitter with the transistor acting in an inverted mode. Thus,

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + \alpha_R I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-176}$$

where α_R is the ratio of emitter to collector current with the transistor operating *inverted* (i.e., with the collector–base junction forward biased and emitting carriers into the base and the emitter–base junction reverse biased and collecting carriers). Typical values of α_R are 0.5–0.8. An inverse current gain β_R is also defined,

$$\beta_R = \frac{\alpha_R}{1 - \alpha_R} \tag{2-177}$$

and has typical values 1–5. This is the current gain of the transistor when operated inverted and is much lower than β_F because the device geometry and doping densities are designed to maximize β_F. The inverse-active region of device operation occurs for V_{CE} negative in an *npn* transistor and is shown in Figure 2-89. In order to display these characteristics adequately in the same figure as the forward-active region, the negative voltage and current scales have been expanded. The inverse-active mode of operation is rarely encountered in analog circuits.

Equations (2-175) and (2-176) describe *npn* transistor operation in the saturation region when V_{BE} and V_{BC} are both positive, and also in the forward-active and inverse-active regions. These equations are from the *Ebers–Moll* equations. In the forward-active region, they degenerate into a form similar to that of Eqs. (2-146), (2-158), and (2-160) derived earlier. This can be shown by putting V_{BE} positive and V_{BC} negative in Eqs. (2-175) and (2-176) to obtain

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_{CS} \tag{2-178}$$

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \alpha_R I_{CS} \tag{2-179}$$

Equation (2-178) is similar in form to Eq. (2-146) except that leakage currents that were previously neglected have now been included. This minor difference is significant only at high temperatures or very low operating currents. Comparison of Eq. (2-178) with Eq. (2-146) allows us to identify $I_S = \alpha_F I_{ES}$ and it can be shown [6] in general that

$$\alpha_F I_{ES} = \alpha_R I_{CS} = I_S \tag{2-180}$$

where this expression represents a reciprocity condition. Using Eq. (2-180) in Eqs. (2-175) and (2-176) allows the Ebers–Moll equations to be expressed in the general form

$$I_C = I_S\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \frac{I_S}{\alpha_R}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-181}$$

$$I_E = -\frac{I_S}{\alpha_F}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_S\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-182}$$

This form is often used for computer representation of transistor large-signal behavior.

The effect of leakage currents mentioned above can be further illustrated as follows. In the forward-active region, we have, from Eq. (2-179),

$$I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) = -I_E - \alpha_R I_{CS} \tag{2-183}$$

Substitution of Eq. (2-183) in Eq. (2-178) gives

$$I_C = -\alpha_F I_E + I_{CO} \tag{2-184}$$

where

$$I_{CO} = I_{CS}(1 - \alpha_R\alpha_F) \tag{2-185}$$

and I_{CO} is the collector–base leakage current with the emitter open. Although I_{CO} is given theoretically by Eq. (2-185), in practice, surface leakage effects dominate when the collector–base junction is reverse biased and I_{CO} is typically several orders of magnitude larger than the value given by Eq. (2-185). However, Eq. (2-184) is still valid if the appropriate measured value for I_{CO} is used. Typical values of I_{CO} are 10^{-10} to 10^{-12} A at 25 °C, and the magnitude doubles about every 8 °C. As a consequence, these leakage terms can become very significant at high temperatures. For example, consider the base current I_B. This is

$$I_B = -(I_C + I_E) \tag{2-186}$$

If I_E is calculated from Eq. (2-184) and substituted in Eq. (2-186), the result is

$$I_B = \frac{1 - \alpha_F}{\alpha_F} I_C - \frac{I_{CO}}{\alpha_F} \tag{2-187}$$

But from Eq. (2-161)

$$\beta_f = \frac{\alpha_F}{1 - \alpha_F} \tag{2-188}$$

and use of Eq. (2-188) in Eq. (2-187) gives

$$I_B = \frac{I_C}{\beta_F} - \frac{I_{CO}}{\alpha_F} \tag{2-189}$$

Since the two terms in Eq. (2-189) have opposite signs, the effect of I_{CO} is to *decrease* the magnitude of the external base current at a given value of collector current.

2-2-6 Small-Signal Models of Bipolar Transistors

Figure 2-91 shows the small-signal equivalent BJT model. It consists of an intrinsic model and a package model. Table 2-12 lists its keywords.

In order to better understand the difference between the various technologies, we show Table 2-13, which allows the reader to compare their performances.

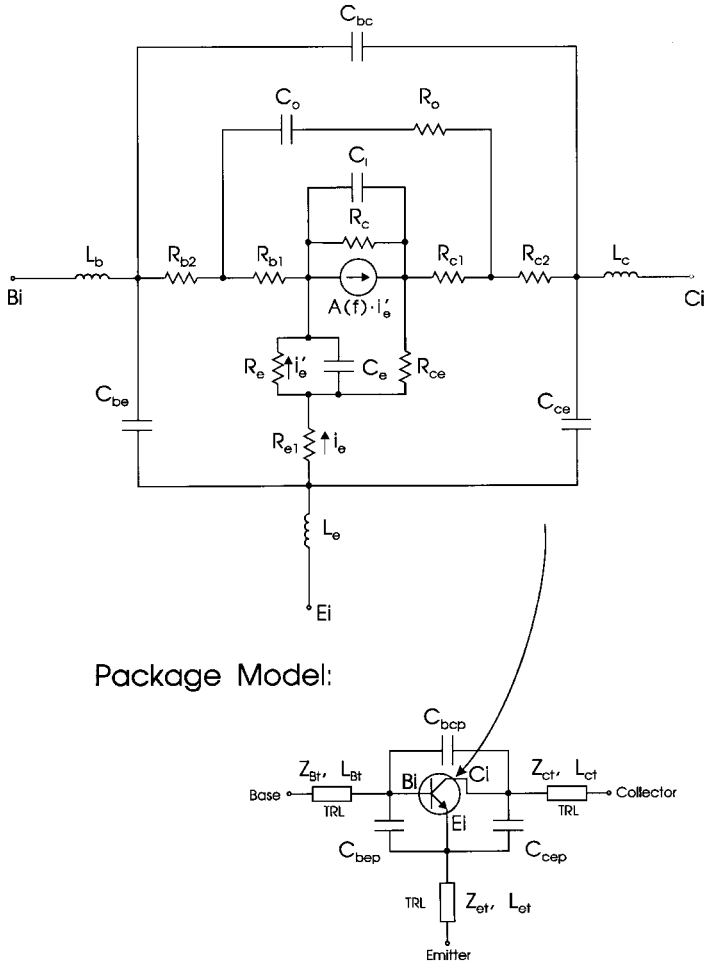

Figure 2-91 Linear BJT model.

Table 2-12 Small-signal equivalent BJT model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
A	Ratio of I_C to I_E at dc		0.0

LCT	Collector transmission line length at $\varepsilon_r = 1$	meter	0.0
LET	Emitter transmission line length at $\varepsilon_r = 1$	meter	0.0

Notes:

1. $A \equiv \alpha = I_c/I_e$; β = dc current gain = $\alpha(1 - \alpha)$.
2. The bipolar current gain in this model is described by

$$\mathrm{A} = \mathrm{A}(0) = \frac{e^{-j\omega\mathrm{T}}}{1 + j\,(f/F)}$$

where $\omega = 2\,\pi f$ and f is frequency.

3. The current source is controlled by the current through R_e. The current generator has a cutoff frequency with respect to the total emitter current, I_E:

$$\mathrm{F} = g_m/2\pi C_e$$

where $g_m = 1/R_e$. This frequency becomes infinite for the default value for C_e (0.0). The parammeter F specifies the frequency roll-off for the current generator with respect to the current through R_e. Effectively, this frequency parameter may be used to model additional delays in the device.

[a] 1.0 µm Design Rule; NF = 3.25 dB, G_A = 12 dB at I_C = 2 mA, freq. = 2 GHz for $16 \times 1 \times 2 \ \mu m^2$; Resistors: 150 Ω/sq. (mono), 300 Ω/sq. (mono), 500 Ω/sq. (poly); Layers of metal, Schottky diodes, linear capacitor (silicided n^+ poly/n^+Si); Gate length = 0.68 µm (*n*-ch)/0.8 µm (*p*-ch), Gate Oxide = 12.5 nm (3 V)/15 nm (5 V), V_{th} = 0.65 V (*n*-ch)/–0.9 V (*p*-ch), Gm (µS/µm) = 204 (*n*-ch)/65 (*p*-ch).

[b] 0.6 µm Design Rule; Gold metallization, ILD: polyimide; Inductors: $Q > 10$ for $L \leq 10$ nH; Capacitors: $Q > 25$ for $C \leq 20$ pF; Schottky diodes (f_c = 100 GHz), Zener diodes, MIS capacitor, thin film resistors, and LPNP, 10 mask process.

[c] Analog devices using this process.

[d] LPNP F_t = 80 MHz; three-layer metallization; Schottky diodes (R_sC_j ~ 4 ps); Implanted resistors: 200 Ω/sq.; Poly resistors: 400/2000 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[e] LPNP F_t = 85 MHz; two-layer metallization; Schottky diodes (R_sC_j ~ 0.8 ps); Implanted resistors: 170/600/1200 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[f] L_n = 0.8 µm, T_{ox} = 18 nm, V_{th} = 0.76 V (nmos), V_{th} = –0.78 V (pmos), 2poly-MIM capacitor: 2.7 fF/µm^2, Schottkys, inductors.

[g] Not known if this process is in production.

[h] 0.8 µm Design Rules; 2.5 fF/µm^2 MIS capacitor; 600 MHz PJFET; 12L; F_t = 4 GHz VPNP; poly resistors 80/400/2000 Ω/sq.

[i] Targeted for 900-MHz GSM radio front-end blocks, a CT2 cordless single-chip radio, and DECT (digital enhanced cordless telephones).

[j] Targeted for multimode 900-MHz GSM, 1.8-GHz PCN and 1.9-GHz PCS based systems. Company is also evaluating integrating SiGe in HSB3.

2-3 FIELD-EFFECT TRANSISTORS

Both diodes and *pnp/npn* transistors work on the injection principle, which means the base–emitter junction generates either free electrons or other carriers, which are being "collected" by the collector connection and the base connection controls it. While this is a fairly complex process, its physics is well understood, and its latest spin-offs, heterojunction BJTs and silicon–germanium transistors, seem to offer a bright future.

In opposition to this, the field-effect transistor (FET) controls the electronic conduction in a solid by an electric field, and this concept actually predates the invention of the bipolar transistor. J. E. Lilienfeld filed for a patent on such a device in 1925 (U.S. Patent No. 1,745,175), and W. Shockley presented a comprehensive theory of the FET in 1952. It took until 1960 before the first commercially available FETs came on the market.

Several types of semiconductor materials have been used for making FETs: silicon, germanium, gallium arsenide, and others have been used. By far the most widely used is silicon, followed now by gallium arsenide.

The FET is a class of electronic semiconductor device in which the conduction of a "channel" between source (*S*) and drain (*D*) terminals is controlled by an electric field impressed on the channel via a gate (*G*) terminal. The conduction channel may utilize *n*-type carriers (electrons) or *p*-type carriers (holes). The electric field that controls the channel conduction may be introduced via a *pn* junction [for a "junction" FET (JFET)], a metal plate separated from the semiconductor channel by an oxide dielectric [for a metal-oxide semiconductor (MOS) FET], or a combination of the two methods. The polarity of the controlling electrical field is a function of the type of carriers in the channel. A FET "family tree" is shown in Figure 2-92.

For today's microwave and RF integrated circuits, the JFET with its high-frequency problems (low cutoff frequency) and large variation in parameters, such as transconductance and pinchoff voltage, has fallen out of favor and is mainly used in discrete circuits such as two-way radios or other RF applications that tolerate these wide variations and temperature dependence. The most-used FET types are MOS for small-signal applications, LDMOS (lateral diffused MOS) for power applications, and GaAs MESFET for lower-power applications (low-voltage applications) as well as high-power applications (recent advertisements by NEC have shown output power up to 100 W). Additional information on the FET family is shown in Figure 2-93.

All members of the FET family are high-impedance-input devices. Figure 2-94 shows the key operating parameters for MOSFETs and MESFETs in low-noise stages, high-gain stages, and linearized power stages. The linearization also improves the matching. This figure is similar to its counterpart in Section 2-2-2.

The following several pages present a typical example of a datasheet* for a JFET (U310) and the chip (NZA) on which it is based, followed by an example of a device with a much higher dynamic range (the CP640 family). The CP640 family and devices similar to them are being replaced by low-power LDMOS, which are not yet well-documented. At least one company, InterFET, is devoted entirely to producing discrete JFETs and JFET-related hybrid and small-scale-integration IC products.

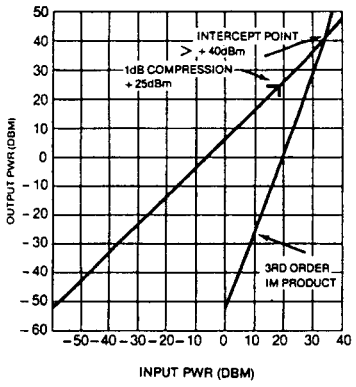
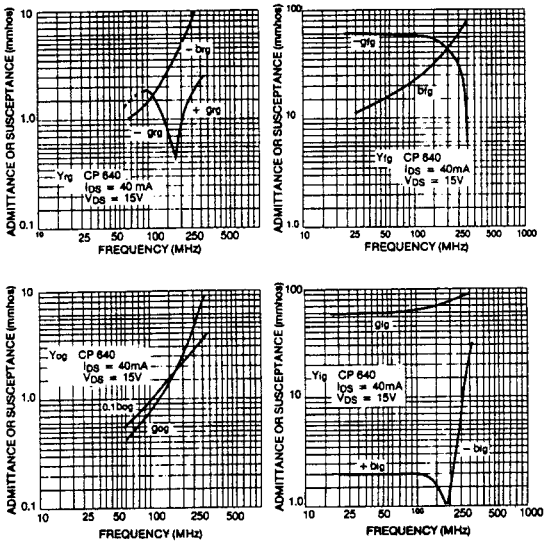
TYPICAL INTERCEPT AND COMPRESSION POINT





2-3-1 Large-Signal Behavior of JFETs

A section view of a junction field-effect transistor (JFET) is shown in Figure 2-95. This structure contains, between the source and the drain contacts, an *n*-type "channel" embedded in a *p*-type silicon substrate. If it is assumed that the *pn* junction forms a barrier to current flow, then it can be seen that channel conduction is a function of the channel width, length, and thickness and of the density and mobility of the carriers. In this structure, current can flow equally well in either direction through the channel; that is, the drain can be positive or negative with respect to the source.

Since we have found that the SPICE models for JFETs are really incomplete and give poor answers, we will only briefly touch here on the JFET's performance. The modified Materka model, one of the best GaAsFET models, turns out to be best suited for JFETs because both transistors act similarly in the dc area. Both have a gate-to-source diode that becomes conductive above 0.7 V at the input and they are also quite similar in other respects. Their equivalent circuits are also quite similar, as parameter extractions for both approaches have shown.

In general, in a three-terminal device, the drain current I_D is a function of two variables: V_{DS} and V_{GS}. This function is best represented by families of characteristic curves, as shown in Figure 2-96. These curves are for the "common source" configuration, with the drain as the output and the gate as the input. They reveal that for this device, if V_{DS} is greater than about 2 V (but less than the drain breakdown), I_D is primarily determined by the gate voltage V_{GS}. Under these conditions it is valid for small signals to characterize the FET by a single transfer characteristic curve, commonly called the "forward transconductance curve," such as the upper curve shown in Figure 2-96b. Some of the relationships between the forward transfer curve and the output characteristic curves of Figure 2-96a will be examined. The value of V_{GS} that reduces I_D to approximately zero is the gate–source cutoff voltage, $V_{GS(\text{off})}$. With reference to the output curve, Figure 2-96a, note that the drain current at $V_{GS} = 0$ tends to become saturated at a drain voltage approximately equal in magnitude to $-V_{GS(\text{off})}$. This drain voltage is often referred to as the pinchoff voltage V_P; however, in this section pinchoff voltage is used interchangeably with gate–source cutoff voltage. V_P will have the same meaning as $V_{GS(\text{off})}$. The symbol I_{DSS} is commonly used to indicate the value of saturated drain current at $V_{GS} = 0$.

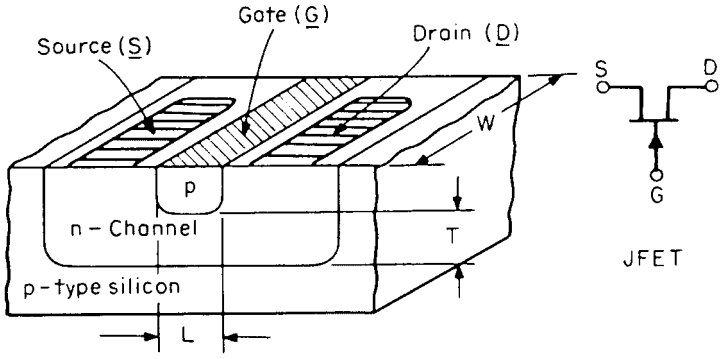


Figure 2-95 Junction field-effect transistor [9].

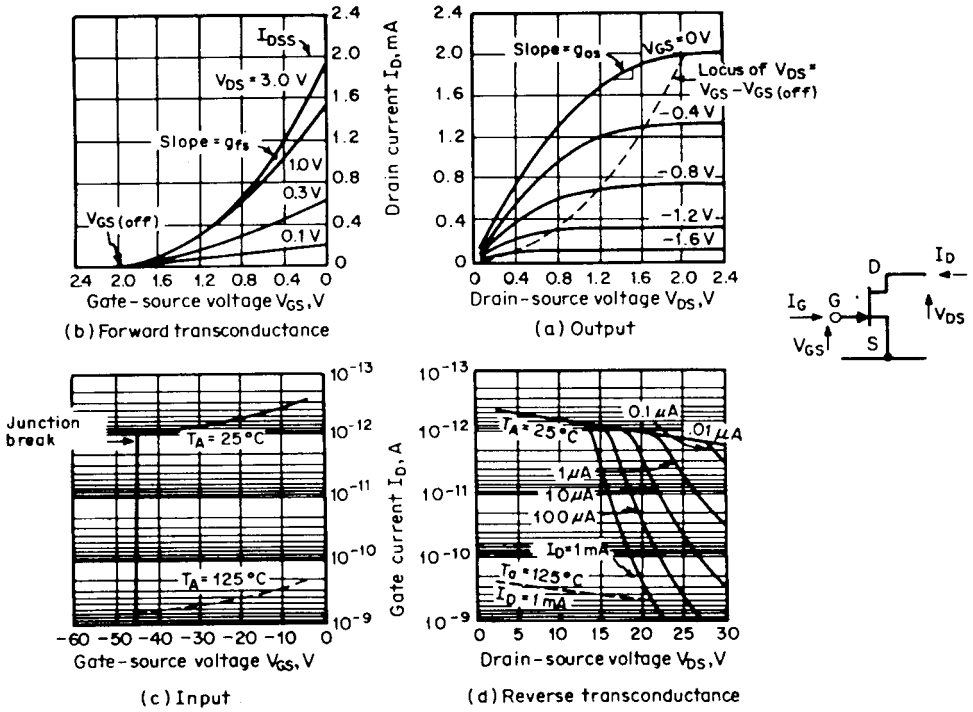

Figure 2-96 Static characteristics of an *n*-channel JFET.

The forward transconductance characteristic of Figure 2-96b can be approximated by a power law relation expressed as

$$I_D = I_{DSS}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^n \tag{2-190}$$

if $V_{DS} \geq -V_{GS(\text{off})}$. By differentiation the small-signal transconductance g_{fs} is given by

$$g_{fs} = \frac{dI_D}{dV_{GS}} = -n\frac{I_{DSS}}{V_{GS(\text{off})}}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^{n-1} \tag{2-191}$$

Some texts indicate a value of $\frac{3}{2}$ for n; however, experimental measurements on a number of n-channel JFET geometries indicate that the exponent n is close to 2, which is the value derived in an approximate treatment by R. D. Middlebrook [10].

A useful relationship between g_{fso}, I_{DSS}, and $V_{GS(\text{off})}$ is derived from the ratio of Eqs. (2-190) and (2-191):

$$\frac{g_{gs}}{I_D} = n(V_{GS} - V_{GS(\text{off})})^{-1} \tag{2-192}$$

At $V_{GS} = 0$, $I_D = I_{DSS}$ and $g_{fs} = g_{fso}$. Using 2 as the value of the constant n leads to

$$g_{fso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-193}$$

For n-channel FETs I_{DSS} is positive and $V_{GS(\text{off})}$ is negative; for p-channel FETs I_{DSS} is negative and $V_{GS(\text{off})}$ is positive; thus g_{fs} is a positive quantity for both p- and n-channel FETs.

Equation (2-190) indicates that for $V_{GS} = V_{GS(\text{off})}$, $I_D = 0$. In a real device this does not happen. Starting from zero, as the gate voltage is made more negative, the drain current decreases until it reaches a very low value equal to the drain-leakage current. At this value, the source current will consist of source–gate leakage. Any further increase in the magnitude of the negative gate voltage will result in an increase in I_D leakage. For the small-signal device illustrated, this minimum I_D is on the order of 2×10^{-13} A.

For some types of applications of the FET, it is helpful to understand the characteristics at very low values of V_{DS}, such as those shown in Figure 2-97. A "very low value" is one that is small compared to the magnitude of $V_{GS} - V_{GS(\text{off})}$. In this region, V_{DS} is small enough to have little effect on channel thickness, so that the I_D/V_{DS} slope is nearly linear. Since the slope is a function of V_{GS}, the FET can be utilized as a voltage-controlled resistor. The conductance slope ($\Delta I_D/V_{DS}$) at $V_{DS} = 0$ is approximately a linear function of $V_{GS} - V_{GS(\text{off})}$.

If g_{ds} at $V_{GS} = 0$ is given the term g_{dso}, then

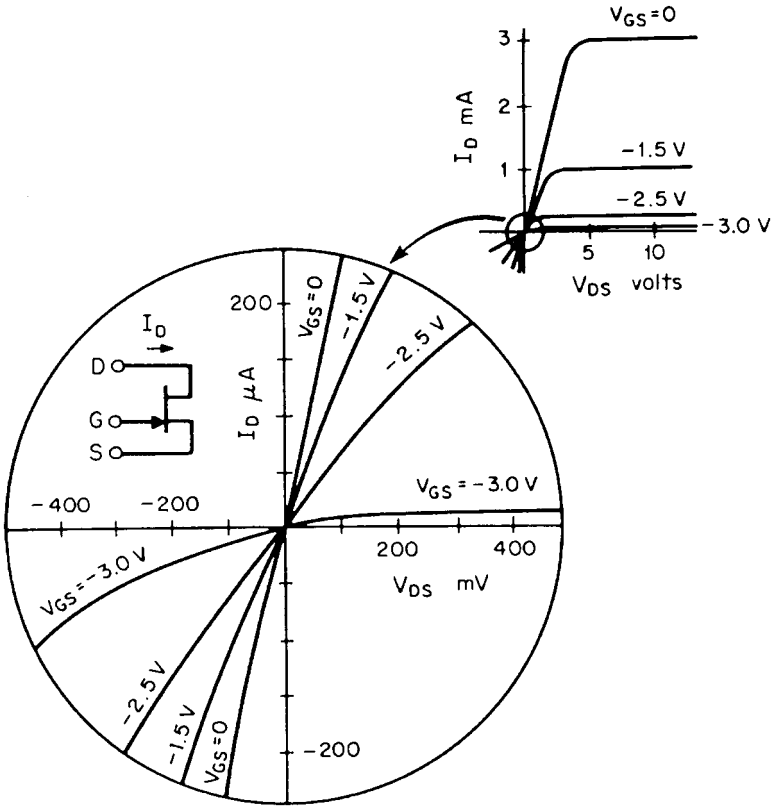

Figure 2-97 Enlargement of n-channel output characteristic around $V_{DS} = 0$.

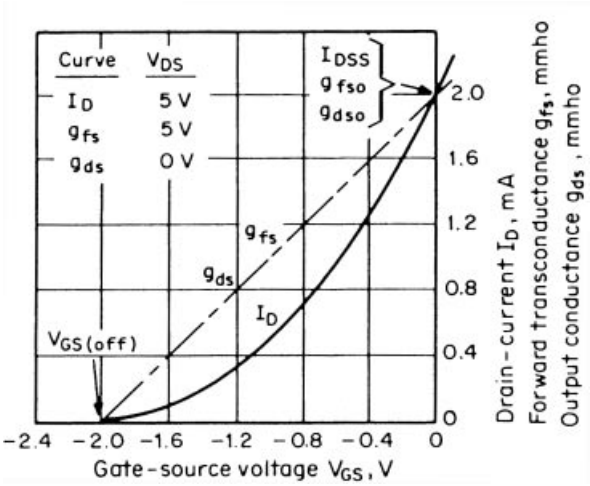

Figure 2-98 JFET I_D, g_{fs}, and g_{ds}.

$$g_{ds} = g_{dso}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right) \tag{2-194}$$

with $V_{DS} = 0$. A plot of this characteristic is shown in Figure 2-98, along with g_{fs} and I_D characteristics.

The relationship between g_{dso}, $V_{GS(\text{off})}$, and I_{DSS} is given by the equation

$$g_{dso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-195}$$

where I_{DSS} and $V_{GS(\text{off})}$ are as indicated in Figure 2-96. It is important to note that Eqs. (2-194) and (2-195) and the g_{ds} curve of Figure 2-98 are valid only for the case where V_{DS} is very small compared to V_P. Drain–source conductance at higher values of V_{DS} will be discussed later. FETs designed to be used as voltage-controlled resistors typically have a high $V_{GS(\text{off})}$ because the $V_{DS}/(V_{GS} - V_{GS(\text{off})})$ ratio should be low to keep distortion low. The actual large-signal JFET model as used in most simulators is shown in Figure 2-99, including a list of its intrinsic keywords (Table 2-14). Again, we had very little luck using this model as published by several SPICE CAD software manufacturers as offered. While we cannot judge on the quality of the parameters that came with the software, it was not possible to closely match even optimized sets of parameters to this large-signal model and obtain acceptable results. However, since the modified Materka model worked very well for this, we recommend that this popular JFET model not be used at frequencies above 10 MHz.

2-3-2 Small-Signal Behavior of JFETs

Figure 2-100 shows the small-signal equivalent transistor model we would recommend. It consists of an empirical FET model and a package model. Table 2-15 lists its keywords. Its advantage is that its built-in noise model is very accurate, even for JFETs and metal semiconductor FETs.

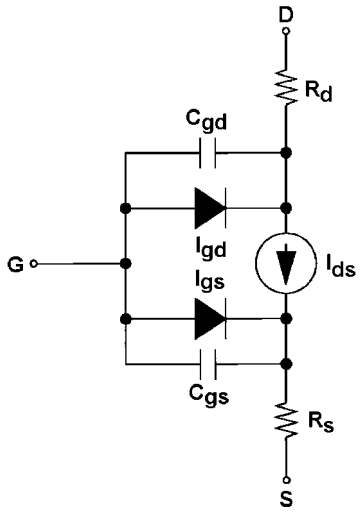

Figure 2-99 The nonlinear JFET model. Table 2-14 lists its intrinsic and extrinsic parameters. In our opinion, this model is limited to frequencies below 10 MHz; above this frequency, the modified Materka model should replace it.

Table 2-14 Large-signal JFET model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
NJF/PJF	Channel-type selection (NJF = *n*-channel, PJF = *p*-channel)		NJF
VT0	Threshold voltage	volt	–2.0
BETA	Transconductance coefficient	ampere/volt^2	1.0E–4
LAMB	Channel-length modulation	/volt	0.0
IS	Gate-junction saturation current	ampere	1.0E–14
PB	Gate-junction potential	volt	1.0
FC	Forward-bias depletion capacitance coefficient		0.5
CGS	Zero-bias gate–source junction capacitance	farad	0.0
CGD	Zero-bias gate–drain junction capacitance	farad	0.0
T	Channel transit-time delay	second	0.0
KF	Flicker noise coefficient		0.0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
SN	Switch to turn device shot noise on (1) or off (0)		1
AREA	Area multiplier		1.0
NOIS	Reference label to a set of noise data		
NAME	Required user-specified name up to 8 characters		
	Extrinsic Model		
RD	Drain ohmic resistance	ohm	0.0
RS	Source ohmic resistance	ohm	0.0

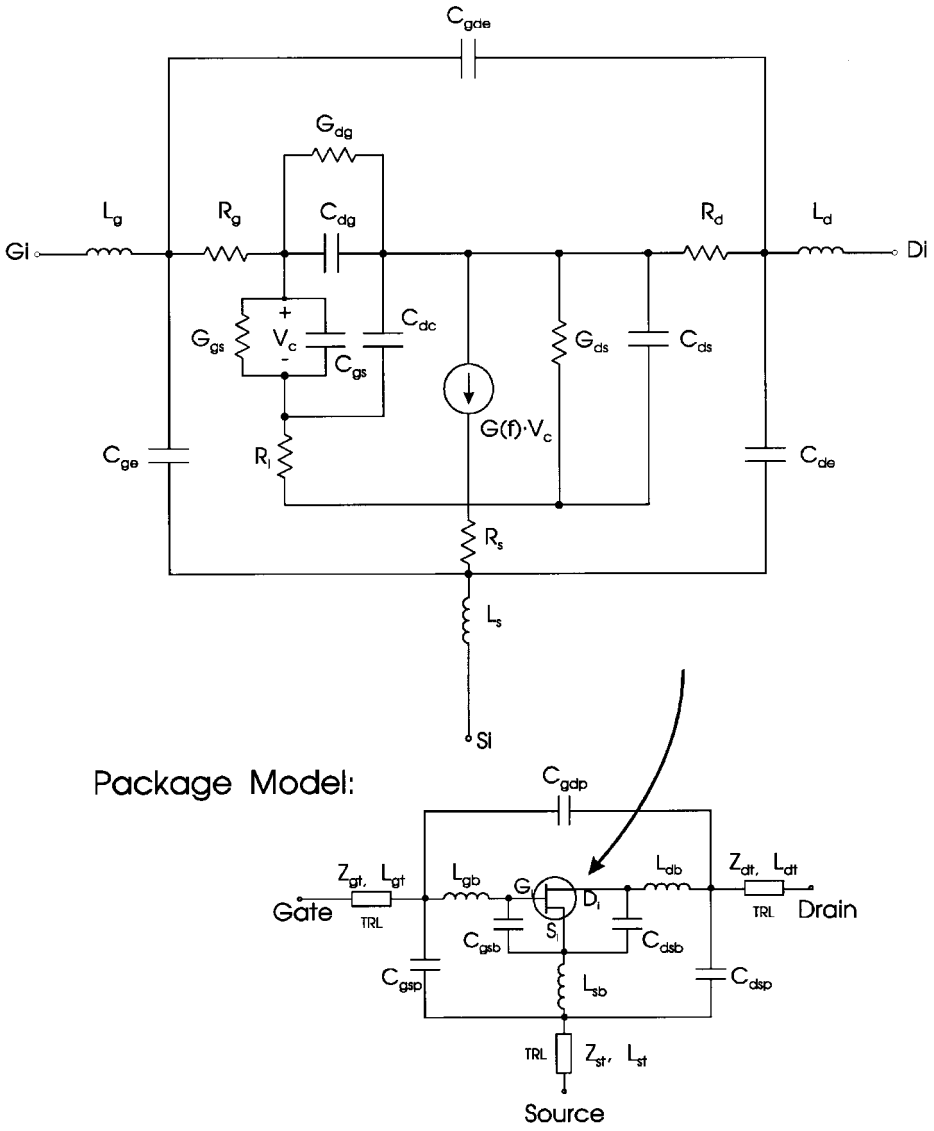

Figure 2-100 Linear FET model.

Electrical noise generated within a JFET is usually represented by equivalent noise sources, $\overline{e}_n$ and $\overline{i}_n$. Both noise voltage $\overline{e}_n$ and noise current $\overline{i}_n$ are frequency dependent and have the characteristics shown in Figure 2-101.

An equivalent noise circuit is shown in Figure 2-102. Above the frequency f_1, $\overline{e}_n$ is approximately given by

$$\overline{e}_n \cong \left(4KTB\,\frac{0.67}{g_{fs}}\right)^{1/2} \tag{2-196}$$

label	User-defined term that refers to temperature coefficient		

[a]The transconductance of this model may be approximately described by $g_m = G\,\frac{e^{-j\omega T}}{1 + j(f/F)}$ where $\omega = 2\pi f$ and f is frequency.
[b]The flicker noise frequency dependence is given by $1/(f/F_c)^{\mathrm{FCP}}$.

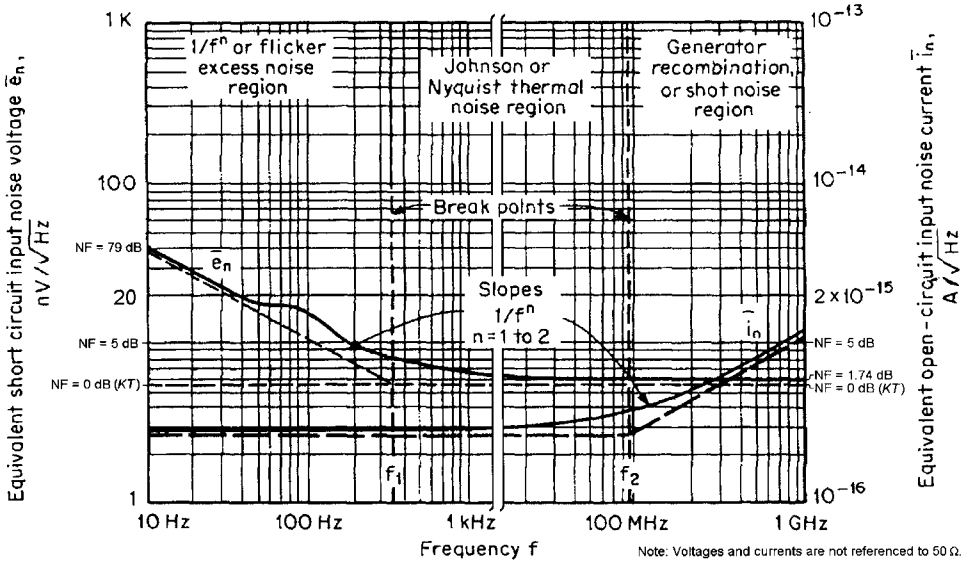

Figure 2-101 JFET noise characteristics.

where $K = 1.374 \times 10^{-23}$ J/K

T = absolute temperature in kelvins (273 K = 0 °C)

B = frequency range in hertz

g_{fs} = transconductance of FET

With the input short-circuited, the noise voltage across the load R_L resulting from the FET is

$$\text{Output noise voltage} = \bar{e}_n A_V \tag{2-197}$$

Below the frequency f_1, $\bar{e}_n$ increases proportional to $1/f^n$ and is expressed as

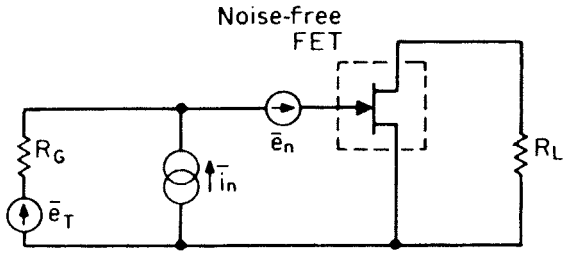

Figure 2-102 Equivalent noise circuit of the FET.

$$\bar{e}_n = \left[4KTB \left(\frac{0.67}{g_{fs}} \right) \left(1 + \frac{f_1}{f^n} \right)^{1/2} \right] \tag{2-198}$$

The low-frequency corner frequency f_1 for JFETs is typically in the 100-Hz to 1-kHz range, and the exponent n is usually between 1 and 2. As indicated by the equations, $\bar{e}_n$ is inversely proportional to the square root of g_{fs}.

The equivalent input noise current $\bar{i}_n$ is caused by the current in the gate-to-channel junction. Its approximate value below f_2 is

$$\bar{i}_n = (2qI_G B)^{1/2} \tag{2-199}$$

where $q = 1.602 \times 10^{-19}$
B = frequency range in hertz
I_G = dc gate current

This expression is fairly accurate when I_G is the result of the active device conductance. Typically, $\bar{i}_n$ will be lower than the calculated value because part of I_G is due to conductance across the device package.

At higher frequencies (above f_2),

$$\bar{i}_n = \left(\frac{4KTB}{R_P} \right)^{1/2} \tag{2-200}$$

where R_P is the real part of gate input impedance. R_P, in terms of Y_{11}, can range from several tens of megohms (at audiofrequencies) to 1 kΩ or less (at VHF/UHF frequencies). The high-frequency corner f_2 is typically in the range of 5–50 kHz and more than 100 MHz for high-frequency devices.

Another form of noise is known as "popcorn" or burst noise, the causes of which have not been completely identified. It shows up as a random short-duration step-function change in drain current, equivalent to an input gate–source voltage change of a few tenths of a microvolt. It is not unlike big bubbles on the surface of boiling water.

As far as the noise is concerned, we can also state that the Materka built-in proprietary noise model is significantly more accurate than the one mentioned above [11–14]. This model is implemented, with minimal documentation of its inner workings because of its proprietary nature, in the linear portion of the circuit simulator in Ansoft's Serenade Design Environment. In many cases, the manufacturer supplies only limited data, so it is most convenient that after SPICE-type parameter extraction is done by using the Scout program, one even gets good noise prediction for JFETs using the modified Materka model.

2-3-3 Large-Signal Behavior of MOSFETs

Metal-oxide-semiconductor field-effect transistors (MOSFETs) are important components in contemporary analog integrated circuits. Whereas initial applications were centered on all-MOS processes, combined bipolar and MOS processes give the designer the best of both worlds. A major advantage of MOS processes for realizing analog functions is that complex, dense digital functions can be realized on the same chip.

Transfer Characteristics of MOS Devices. A cross section of a typical enhancement-mode *n*-channel MOS transistor (NMOS) is shown in Figure 2-103a. Heavily doped *n*-type source and drain regions are fabricated in a *p*-type substrate (often called the body). A thick layer of silicon dioxide is grown over the substrate material and a conductive gate material (metal or polycrystalline silicon) covers this oxide between source and drain. The operation of the device is very similar to that of a JFET in that the gate–source voltage is used to modify the conductance of the region under the gate. This allows the gate voltage to control the current flowing between source and drain, giving gain in analog circuits and switching characteristics in digital circuits.

The enhancement-mode NMOS device of Figure 2-103a shows significant conduction between source and drain only when an *n*-type channel exists under the gate, and this is the origin of the "*n*-channel" designation. The term "enhancement mode" refers to the fact that no conduction occurs for $V_{GS} = 0$, and thus the channel must be "enhanced" to cause conduction. MOS devices can be made equally well by using an *n*-type substrate with a *p*-type conducting channel. Such devices are called enhancement-mode *p*-channel MOS transistors (PMOS). In technologies employing one or the other of these device types, the circuit symbol of Figure 2-103b is commonly used for either one. In complementary MOS technology (CMOS) both device types are present and the circuit symbols of Figure 2-103c will be used to distinguish them. In PMOS and NMOS technologies, the substrate is common to all devices, invariably connected to a dc power supply voltage, and usually not shown on the circuit diagram. In CMOS technology, however, devices of one type or another are fabricated in individual, separate isolation regions, which may or may not be connected to a power supply voltage. If these isolation regions *are* connected to the appropriate power supply, the symbols of Figure 2-103c will be used and the substrate connection will not be shown. If the individual isolation regions are connected elsewhere, however, the devices will be represented by the symbols of Figure 2-103d, where the substrate is labeled *B*. Finally, in NMOS technology an additional device type called a "depletion-mode" device is usually available. This is a conducting channel implanted between the source and drain so that conduction occurs for $V_{GS} = 0$. This device has characteristics that are almost identical to that of a JFET and will be represented by the symbol of Figure 2-103e.

The derivation of the transfer characteristics of the enhancement-mode NMOS device of Figure 2-103a begins by noting that with $V_{GS} = 0$, the source and drain regions are separated by back-to-back *pn* junctions. These junctions are formed between the *n*-type source and drain regions and the *p*-type substrate, resulting in an extremely high resistance (about 10^{12} Ω) between drain and source when the device is off.

Now consider substrate, source, and drain grounded and a positive voltage V_{GS} applied to the gate as shown in Figure 2-104. The gate and substrate then form the plates of a capacitor with the SiO_2 as a dielectric. Positive charge accumulates on the gate and the negative charge in the substrate. Initially, the negative charge in the *p*-type substrate is manifested by creation of a *depletion region* and resulting exclusion of holes under the gate. This is shown in Figure 2-104. The depletion-layer width *X* under the oxide is

$$X = \left(\frac{2\varepsilon\phi}{qN_A} \right)^{1/2} \tag{2-201}$$

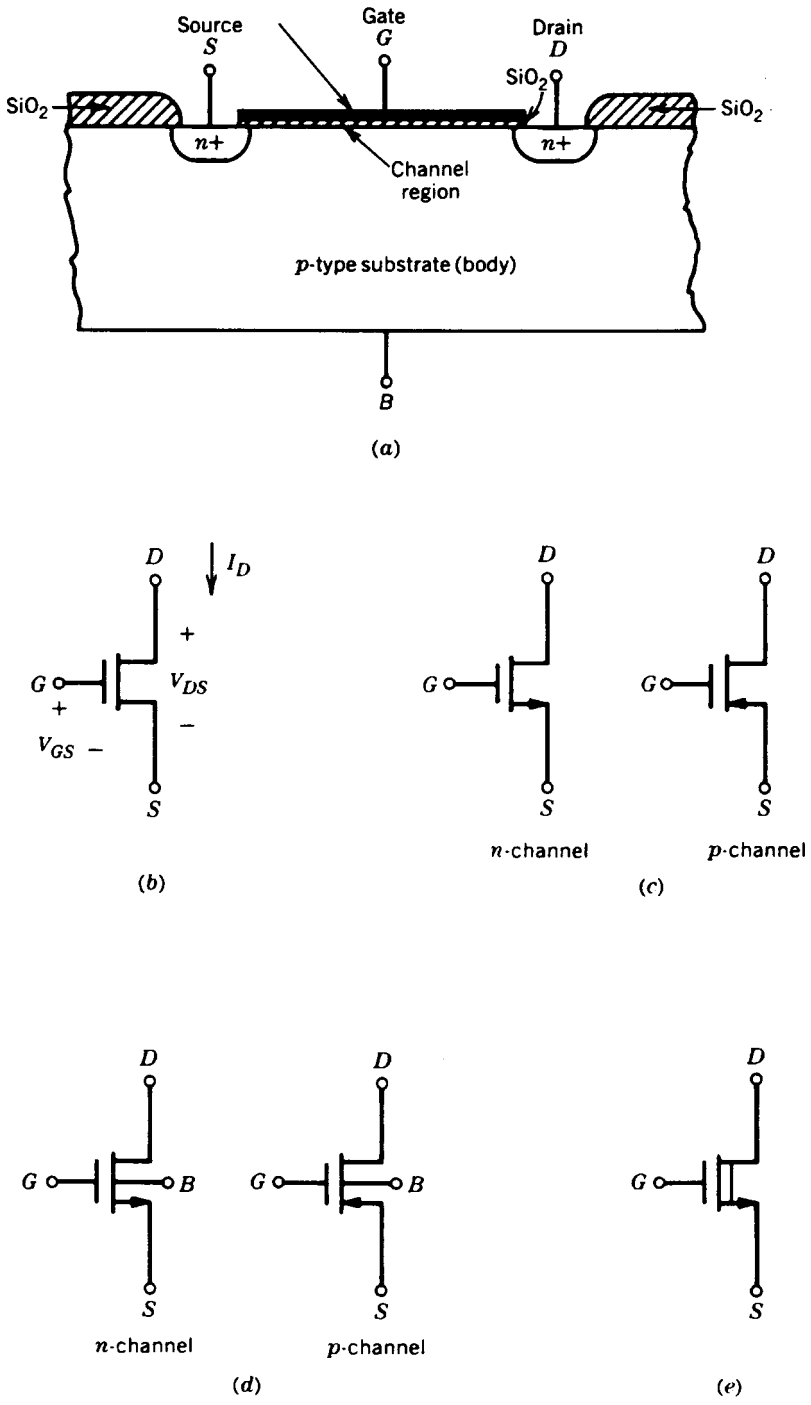

Figure 2-103 (a) Typical enhancement-mode NMOS structure. (b) Enhancement-mode NMOS or PMOS circuit symbol when one device type only is present. (c) NMOS and PMOS symbols used in CMOS circuits. (d) NMOS and PMOS symbols used when the substrate connection is nonstandard. (e) Depletion MOS device symbol.

where ϕ is the potential in the depletion layer at the oxide–silicon interface, N_A atoms/cm^3 is the doping density (assumed constant) of the p-type substrate, and ε is the permittivity of the silicon. The charge per unit area in this depletion region is

$$Q = qN_A X = \sqrt{2qN_A \varepsilon \phi} \tag{2-202}$$

When the potential in the silicon reaches a critical value equal to twice the Fermi level, $\phi_f \simeq 0.3$ V, a phenomenon known as "inversion" occurs [15]. Further increases in gate voltage produce no further changes in the depletion-layer width but instead a thin layer of electronics is induced in the depletion layer directly under the oxide. This produces a continuous n-type region with the source and drain regions and is the conducting channel between source and drain. This channel can then be modulated by increases or decreases in the gate voltage. In the presence of an inversion layer, and with no substrate bias, the depletion region contains a fixed charge

$$Q_{b0} = \sqrt{2qN_A \varepsilon 2\phi_f} \tag{2-203}$$

If a substrate bias voltage V_{SB} (source positive for n-channel devices) is applied between source and substrate, the potential required to produce inversion becomes $(2\phi_f + V_{SB})$ and the charge stored in the depletion region in general is

$$Q_b = \sqrt{2qN_A \varepsilon (2\phi_f + V_{SB})} \tag{2-204}$$

The gate voltage V_{GS}, required to produce an inversion layer, is called the threshold voltage V_t and can now be calculated. This voltage consists of several components. First, a voltage $[2\phi_f + (Q_b/C_{ox})]$ is required to sustain the depletion-layer charge Q_b, where C_{ox} is the gate oxide capacitance per unit area. Second, a work-function difference ϕ_{ms} exists between the

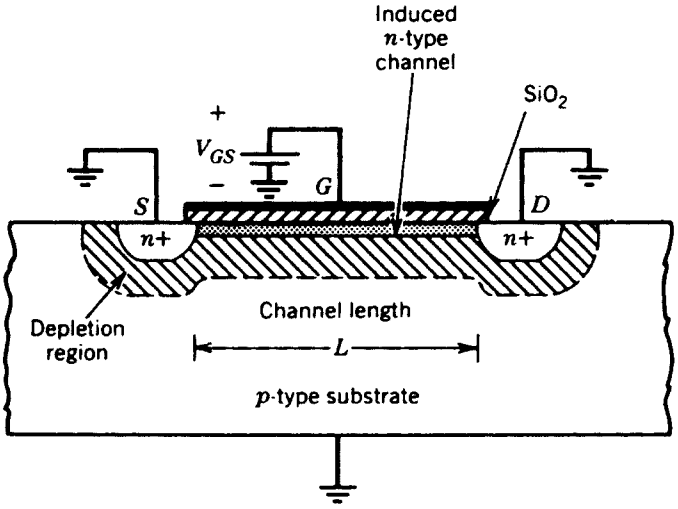

Figure 2-104 Idealized NMOS device cross section with positive V_{GS} applied, showing depletion regions and the induced channel.

gate metal and the silicon. Third, there is always charge density Q_{ss} (positive) in the oxide at the silicon interface. This is caused by crystal discontinuities at the Si–SiO_2 interface and must be compensated by a gate voltage contribution of $-Q_{ss}/C_{ox}$. Thus we have a threshold voltage

$$V_t = \phi_{ms} + 2\phi_f + \frac{Q_b}{C_{ox}} - \frac{Q_{ss}}{C_{ox}}$$

$$= \phi_{ms} + 2\phi_f + \frac{Q_{b0}}{C_{ox}} - \frac{Q_{ss}}{C_{ox}} + \frac{Q_b - Q_{b0}}{C_{ox}} \tag{2-205}$$

$$= V_{t0} + \gamma\left(\sqrt{2\phi_f + V_{SB}} - \sqrt{2\phi_f}\right) \tag{2-206}$$

where Eqs. (2-203) and (2-204) have been used and V_{t0} is the threshold voltage with $V_{SB} = 0$. The parameter γ is defined as

$$\gamma = \frac{1}{C_{ox}}\sqrt{2q\varepsilon N_A} \tag{2-207}$$

and

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{2-208}$$

where ε_{ox} and t_{ox} are the permittivity and thickness of the oxide, respectively. A typical value of γ is 0.5 $V^{1/2}$ and $C_{ox} = 3.5 \times 10^{-4}$ pF/μ^2 for $t_{ox} = 0.1$ μm.

In practice, the value of V_{t0} is usually adjusted in processing by implanting additional impurities into the channel region. Extra *p*-type impurities are implanted in the channel to make $V_{t0} \simeq 0.5$–1.5 V for *n*-channel enhancement devices. By implanting *n*-type impurities in the channel region, a conducting channel can be formed, even for $V_{GS} = 0$. This MOS transistor is called a depletion device, with typical values of V_{t0} in the range –1 to –4 V. If Q_i is the charge density per unit area due to the implant, then the threshold voltage given by Eq. (2-205) is shifted by approximately Q_i/C_{ox}.

The preceding equations can now be used to calculate the large-signal characteristics of an NMOS transistor. For purposes of analysis the source is assumed grounded and bias voltages V_{GS}, V_{DS}, and V_{SB} are applied as shown in Figure 2-105. If V_{GS} is greater than V_t, a conducting channel exists and V_{DS} causes a larger reverse bias from drain to substrate than exists from source to substrate, and thus a wider depletion region exists at the drain. However, for simplicity, we assume that the voltage drop along the channel itself is small so that the depletion layer is constant along the channel.

At a distance *y* along the channel the voltage with respect to the source is $V(y)$ and the gate-to-channel voltage at that point is $V_{GS} - V(y)$. We assume this voltage exceeds the threshold voltage V_t, and thus the induced electron charge per unit area in the channel is

$$Q_I(y) = C_{ox}[V_{GS} - V(y) - V_t] \tag{2-209}$$

The resistance *dR* of a length *dy* of the channel is

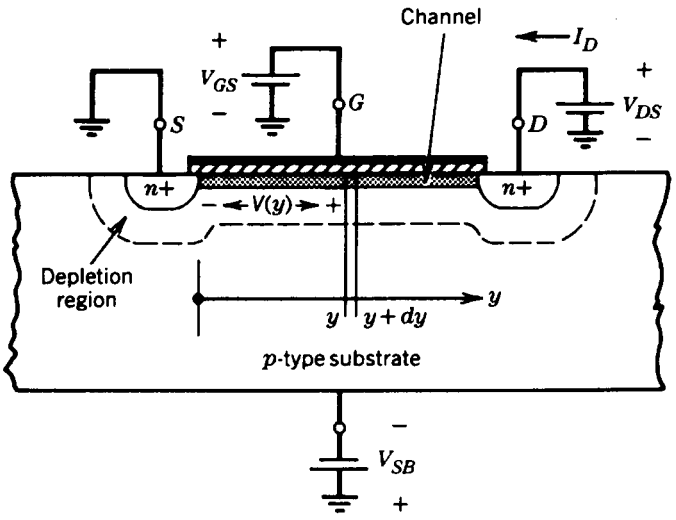

Figure 2-105 NMOS device with bias voltages applied.

$$dR = \frac{dy}{W\mu_n Q_I(y)} \tag{2-210}$$

where W is the width of the device, perpendicular to the plane of Figure 2-105, and μ_n is the average electron mobility of the channel.

The voltage drop dV along the length of the channel dy is

$$dV = I_D\, dR = \frac{I_D}{W\mu_n Q_I(y)}\, dy \tag{2-211}$$

If L is the total channel length, then substitution of Eq. (2-209) into Eq. (2-211) and integration gives

$$\int_0^L I_D\, dy = \int_0^{V_{DS}} W\mu_n C_{\text{ox}}(V_{GS} - V - V_t)\, dV \tag{2-212}$$

This results in

$$I_D = \frac{k'}{2}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-213}$$

where

$$k' = \mu_n C_{\text{ox}} = \frac{\mu_n \varepsilon_{\text{ox}}}{t_{\text{ox}}} \tag{2-214}$$

Equation (2-213) is important and describes the I–V characteristics of an MOS transistor, assuming a continuous induced channel. A typical value of k' for $t_{\text{ox}} = 0.1$ μm is about 20 μA/V^2 for an n-channel device.

As the value of V_{DS} is increased, the induced conducting channel narrows at the drain end and Eq. (2-209) indicates that Q_I at the drain end approaches zero as V_{DS} approaches $(V_{GS} - V_t)$. This results in the same pinchoff phenomenon as occurs in a JFET, and further increases in V_{DS} produce little change in I_D. Equation (2-213) is thus no longer valid if V_{DS} is greater than $(V_{GS} - V_t)$. The value of I_D in this region is obtained by substituting $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-213), giving

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 \tag{2-215}$$

for an MOS transistor in the pinchoff region. As in the case of a JFET, the drain current in the pinchoff region varies slightly as the drain voltage is varied. This is due to the presence of a depletion region between the physical pinchoff point in the channel at the drain end and the drain region itself. If this depletion-layer width is X_d, then the *effective* channel length is given by

$$L_{\text{eff}} = L - X_d \tag{2-216}$$

If L_{eff} is used in place of L in Eq. (2-215), we obtain a more accurate formula for the pinchoff region:

$$I_D = \frac{k'}{2}\frac{W}{L_{\text{eff}}}(V_{GS} - V_t)^2 \tag{2-217}$$

The fact that X_d (and thus L_{eff}) is a function of the drain–source voltage results in a variation of I_D and V_{DS} in the pinchoff region. Using Eqs. (2-216) and (2-217), we obtain

$$\frac{\partial I_D}{\partial V_{DS}} = -\frac{k'}{2}\frac{W}{L_{\text{eff}}^2}(V_{GS} - V_t)^2\frac{dL_{\text{eff}}}{dV_{DS}} \tag{2-218}$$

and thus

$$\frac{\partial I_D}{\partial V_{DS}} = \frac{I_D}{L_{\text{eff}}}\frac{dX_d}{dV_{DS}} \tag{2-219}$$

This equation is analogous to Eq. (2-168) for bipolar transistors. Following a similar procedure, a voltage analogous to the Early voltage can be defined as

$$V_A = \frac{I_D}{\partial I_D/\partial V_{DS}} \tag{2-220}$$

and thus

$$V_A = L_{\text{eff}}\left(\frac{dX_d}{dV_{DS}}\right)^{-1} \tag{2-221}$$

For MOS transistors, the most widely used parameter for the characterization of output resistance is

$$\lambda = \frac{1}{V_A} \tag{2-222}$$

As in the bipolar case, the large-signal properties of the transistor can be approximated by assuming that λ and V_A are constants, independent of bias conditions. Thus we can formulate a better approximation to the I–V characteristics as

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 (1 + \lambda V_{DS}) \tag{2-223}$$

In practical MOS transistors variation of X_d with voltage is complicated by the fact that the field distribution in the drain depletion region is not one dimensional. A vertical component in the field distribution is introduced by the potential difference between the gate and channel and the gate and drain. As a result, the calculation of λ from the device structure is quite different [16], and it is usually necessary to develop effective values of λ from experimental data. The parameter λ is a linear function of effective channel length and is an increasing function of the doping level in the channel. Typical values of λ are in the range 0.05–0.005 V^{-1}. Note that, in the case of a JFET, the pinchoff region for MOS devices is often called the *saturation* region.

A plot of I_D versus V_{DS} for an NMOS transistor is shown in Figure 2-106. Below pinchoff, the device behaves as a nonlinear voltage-controlled resistor, which is often called the *ohmic* or *triode* region. Above pinchoff, the device approximates a voltage-controlled current source. Note that for depletion MOS devices, V_t is negative and I_D is finite, even for $V_{GS} = 0$. For PMOS devices, all polarities of voltage and current are reversed.

The results as previously derived can be used to form a large-signal model of an MOS transistor. The model topology in the pinchoff region is the same as that for the JFET, but using Eq. (2-215) for the controlled-current generator.

MOS Device Voltage Limitations. The voltage limitations of MOS transistors depend on the gate length L. For small values of L (less than about 10 μm), the drain-depletion region

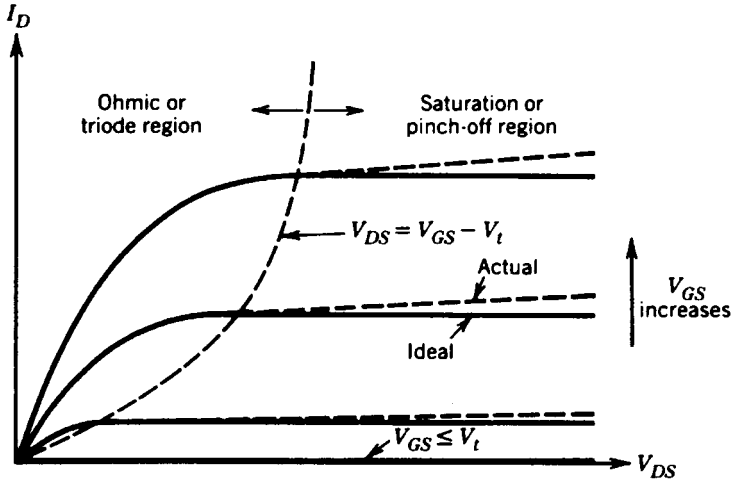

Figure 2-106 NMOS device characteristics.

exerts an appreciable influence on the channel. This causes I_D to rise with increasing V_{DS} in a similar fashion to the bipolar transistor curves of Figure 2-89.

For long channel lengths, the drain-depletion region has little effect on the channel and the I_D-versus-V_{DS} curves follow closely the ideal curves of Figure 2-106. Eventually the drain–substrate *pn*-junction breakdown voltage is exceeded and a sharp breakdown characteristic is obtained, which is similar to the JFET characteristic.

In addition to V_{DS} limitations, MOS devices must also be protected against excessive gate voltages. Typical gate oxides break down with about 25–50 V applied from gate to channel, and this process is destructive to the transistor.

2-3-4 Small-Signal Model of the MOS Transistor in Saturation

The preceding large-signal equations can now be used to derive the small-signal model of the MOS transistor in the saturation or pinchoff region. The important equations are (2-220) and (2-206). Note from Eq. (2-206) that the source–substrate voltage V_{BS} affects V_t, and thus I_D. This is due to the influence of the substrate acting as a second gate and is called *body effect*. As a consequence, I_D is a function of both V_{GS} and V_{BS}, and we require *two* transconductance generators in the small-signal model as shown in Figure 2-107. Variations in the voltage v_{bs} from source to body cause current $g_{mb}v_{bs}$ to flow from drain to source. Note that the body (or substrate) of an NMOS integrated circuit is usually connected to the most negative supply voltage and is thus an ac ground. However, the source connection can have a significant ac voltage impressed on it. Parasitic resistances due to the channel contact regions should be included in series with the source and drain of the model but are usually neglected in hand calculations. These resistances have an inverse dependence on channel width W and have typical values of 50–100 Ω for devices with W of about 1 μm.

The parameters of Figure 2-107 can be determined from Eq. (2-223) by differentiating.

$$g_m = \frac{\partial I_D}{\partial V_{GS}} = k' \frac{W}{L} (V_{GS} - V_t)(1 + \lambda V_{DS}) \tag{2-224}$$

If $\lambda V_{DS} << 1$, this is often approximated as

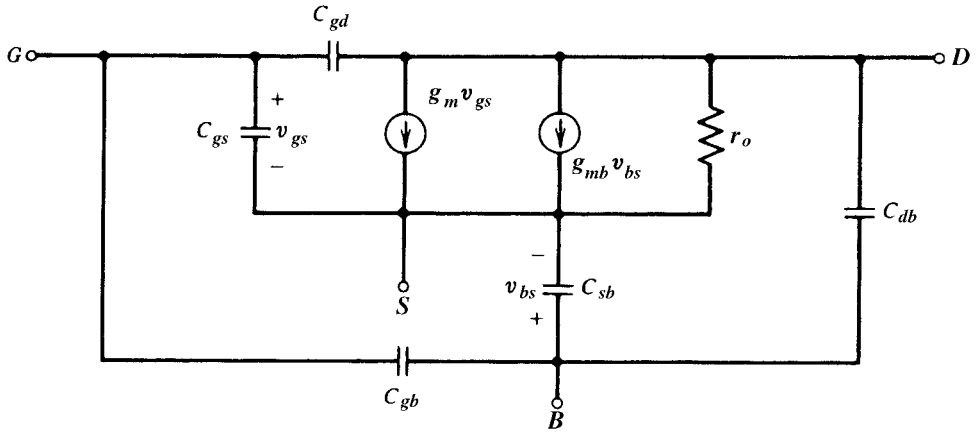

Figure 2-107 Small-signal MOS transistor equivalent circuit.

$$g_m = k' \frac{W}{L} (V_{GS} - V_t) = \sqrt{2k' \frac{W}{L} I_D} \tag{2-225}$$

Like the JFET and unlike the bipolar transistor, the transconductance of the MOSFET depends on both bias current and the *W*/*L* ratio (also on the oxide thickness via *k*′). Similarly,

$$g_{mb} = \frac{\partial I_D}{\partial V_{BS}} = -k' \frac{W}{L} (V_{GS} - V_t) (1 + \lambda V_{DS}) \frac{\partial V_t}{\partial V_{BS}} \tag{2-226}$$

From Eq. (2-206)

$$\frac{\partial V_t}{\partial V_{BS}} = -\frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = -\chi \tag{2-227}$$

where this equation defines a factor χ. This parameter is equal to the rate of change of threshold voltage with body bias voltage. One obtains

$$\chi = \frac{C_{js}}{C_{\text{ox}}} \tag{2-228}$$

where C_{js} is the capacitance per unit area of the depletion region under the channel, assuming a one-sided step junction with a built-in potential $\psi_0 = 2\phi_f$.

Substitution of Eq. (2-227) into Eq. (2-226) gives

$$g_{mb} = \frac{\gamma k' (W/L) (V_{GS} - V_t) (1 + \lambda V_{DS})}{2\sqrt{2\phi_f + V_{SB}}} \tag{2-229}$$

Again, if $\lambda V_{DS} << 1$, we have

$$g_{mb} = \frac{\gamma \sqrt{k' (W/L) I_D}}{\sqrt{2(2\phi_f + V_{SB})}} \tag{2-230}$$

An important quantity is the ratio g_{mb}/g_m, and from Eqs. (2-224) and (2-229) we find

$$\frac{g_{mb}}{g_m} = \frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = \chi \tag{2-231}$$

The factor χ is typically in the range 0.1–0.3.

Finally, the small-signal output resistance can be obtained directly from Eq. (2-218):

$$r_o = \left(\frac{\partial I_D}{\partial V_{DS}} \right)^{-1} = \frac{L_{\text{eff}}}{I_D} \left(\frac{dX_d}{dV_{DS}} \right)^{-1} \tag{2-232}$$

and using Eqs. (2-221) and (2-222), we find

$$r_o = \frac{1}{\lambda I_D} = \frac{V_A}{I_D} \tag{2-233}$$

Small-signal model capacitances are also shown in Figure 2-107. Of these, only the gate–source capacitance C_{gs} is intrinsic to the device operation in the saturation region. Capacitances C_{sb} and C_{db} are parasitic depletion-region capacitances between the substrate and the source and drain regions, respectively. These can be expressed as follows:

$$C_{sb} = \frac{C_{sb0}}{(1 + V_{SB}/\psi_0)^{1/2}} \tag{2-234}$$

$$C_{db} = \frac{C_{db0}}{(1 + V_{DB}/\psi_0)^{1/2}} \tag{2-235}$$

These capacitances are proportional to the gate and source region areas (including sidewalls), and C_{sb} also includes depletion-region capacitance from the induced channel in the body.

Capacitance C_{gb} between gate and substrate models parasitic oxide capacitance between the gate contact material and the substrate outside the active-device area. This is a constant capacitance and models coupling between polysilicon and metal interconnects and the underlying substrate. In fact, parasitic capacitance of this type underlies all polysilicon and metal traces on the chip and should be taken into account when simulating and calculating high-frequency circuit and device performance. Typical values depend on oxide thicknesses and range from about 0.04 to 0.15 fF per square micron of interconnect, with fringing effects becoming important for narrow lines (several microns or less in width).

Capacitances C_{gs} and C_{gd} exist from gate to source and drain, respectively. If C_{ox} is the oxide capacitance per unit area from gate to channel then the total capacitance under the gate is $C_{\text{ox}}WL$. This capacitance is intrinsic to the device operation and models the gate control of the channel conductance. In the ohmic region of device operation, this capacitance is split equally between source and drain so that $C_{gs} = C_{gd} = 1/2C_{\text{ox}}WL$. However, in the saturation region, the channel is very narrow at the drain end and the drain voltage exerts little influence on either the channel or the gate charge. As a consequence, the intrinsic portion of C_{gd} is essentially zero in the saturation region and C_{gd} then consists of a constant parasitic oxide-capacitance contribution due to gate overlap of the drain region. This is on the order of 1–10 fF for small devices.

In order to calculate the corresponding value of C_{gs} in the saturation region, we must calculate the total charge Q_T stored in the channel. This can be obtained by integrating Eq. (2-209) to obtain

$$Q_T = WC_{\text{ox}} \int_0^L [V_{GS} - V(y) - V_t]dy \tag{2-236}$$

Substituting for dy/dV from Eq. (2-211) into Eq. (2-236), we find

$$Q_T = \frac{W^2 C_{\text{ox}}^2 \mu_n}{I_D} \int_0^{V_{GS}-V_t} (V_{GS} - V - V_t)^2 dV \tag{2-237}$$

where the limit $y = L$ corresponds to $V = (V_{GS} - V_t)$ in saturation. Solution of Eq. (2-237) and use of Eqs. (2-214) and (2-215) gives

$$Q_T = \frac{2}{3} WLC_{\text{ox}}(V_{GS} - V_t) \tag{2-238}$$

and thus

$$C_{gs} = \frac{\partial Q_T}{\partial V_{GS}} = \frac{2}{3} WLC_{\text{ox}} \tag{2-239}$$

In addition, there is a contribution to C_{gs} from the constant parasitic oxide capacitance due to gate overlap of the source region.

The f_T of the MOSFET is given by

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs} + C_{gd} + C_{gb}} \tag{2-240}$$

The dependence of MOSFET f_T on device and process parameters can be seen by assuming that the intrinsic device capacitance G_{gs} dominates. Thus from Eq. (2-240) we have

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs}} \tag{2-241}$$

Substituting in Eq. (2-241) for g_m from Eq. (2-225) and C_{gs} from Eq. (2-239) we find for a MOSFET

$$f_T = 1.5 \frac{\mu_n}{2\pi L^2} (V_{GS} - V_t) \tag{2-242}$$

It is interesting to compare this with the intrinsic f_T of a bipolar transistor when parasitic depletion-layer capacitance is neglected. From

$$f_T = \frac{1}{2\pi\tau_F} \tag{2-243}$$

and substituting for τ_f and using the Einstein relationship $D_n/\mu_n = kT/q = V_T$, we find for a bipolar transistor

$$f_T = 2 \frac{\mu_n}{2\pi W_B^2} V_T \tag{2-244}$$

The similarity in form between Eqs. (2-242) and (2-244) is striking. In both cases the intrinsic device f_T increases as the inverse square of the critical device dimension across which carriers are in transit. The voltage V_t = 26 mV is fixed for a bipolar transistor, but MOSFET f_T can be increased by operating at high values of $(V_{GS} - V_t)$. Note that the base width W_B in a bipolar transistor is a vertical dimension determined by diffusions or implants and can typically be made much smaller than the channel length L of a MOSFET, which depends on surface geometry and photolithographic processes. Thus bipolar transistors generally have higher f_T than MOSFETs made with comparable processing. Finally, Eq. (2-242) was derived assuming that the MOSFET square law is valid. However, as discussed in Section 2-3-5, submicron MOSFETs depart significantly from square-law characteristics, and we find that for such devices f_T increases as L^{-1} rather than L^{-2}.

2-3-5 Short-Channel Effects in FETs

The evolution of integrated-circuit processing techniques has led to continuing reductions in both the horizontal and vertical dimensions of the active devices (the minimum allowed dimension of passive devices has also increased). This trend is driven primarily by economics in that more devices and circuits can be processed at one time on a given wafer. A second benefit has been that the frequency capability of the active devices continues to increase, as intrinsic f_T values increase with smaller dimensions while parasitic capacitances decrease.

Vertical dimensions such as the base width of a bipolar transistor in production processes may now be on the order of 0.05 μm or less, whereas horizontal dimensions such as bipolar emitter width or FET gate length may be significantly less than 1 μm. Even at these very small dimensions, the large-signal and small-signal models of bipolar transistors given in previous sections remain valid. However, significant short-channel effects become important in FETs of all types at channel lengths on the order of 1 μm or less and require modifications to the FET models given previously. The primary effect is to modify the classical FET square-law transfer characteristic in the saturation region to make the device more closely approach an ideal linear transfer function. Note, however, that even in processes with submicron capability, many of the FETs in a given analog circuit may be deliberately chosen to be larger than the minimum size and may be well approximated by the square-law model.

The most important short-channel effect in FETs is due to velocity saturation of carriers in the channel [17]. At low electric field values, the linear relation between carrier velocity and field implied by Eqs. (2-210) and (2-211) is valid. At high fields, however, the carrier velocities approach the thermal velocities and subsequently the carrier velocities increase more slowly with increasing field. This is illustrated in Figure 2-108, which shows typical measured electron drift velocity v_d versus tangential electric field strength magnitude $\mathscr{E}$ in an NMOS surface channel. Note that at low field values the velocity is proportional to the field, while at high fields the velocity approaches a constant value called the scattering-limited velocity v_{scl}. A first-order analytical approximation to this curve is

$$v_d = \frac{\mu_n \mathscr{E}}{1 + \mathscr{E}/\mathscr{E}_c} \tag{2-245}$$

where $\mathscr{E} \simeq 1.5 \times 10^6$ V/m and $\mu_n \simeq 0.07$ m^2/V · s is the low-field mobility. Equation (2-245) is also plotted in Figure 2-108. From Eq. (2-245), as $\mathscr{E} \to \infty$ we have $v_{\text{scl}} = \mu_n \mathscr{E}_c$. At the critical field value $\mathscr{E}_c$, the carrier velocity is a factor of 2 less than the low-field formula would predict. In a device with a channel length $L = 1$ μm, we need a voltage drop of only 1.5 V along the channel to have an average field equal to $\mathscr{E}_c$, and this condition is readily achieved in small MOSFETs. Similar results are found for PMOS devices.

As an example of the effects of velocity saturation on FET characteristics, we consider the example of the MOSFET. In the analysis of "Transfer Characteristics of MOS Devices" in Section 2-3-3, we now use the more general expression

$$I_D = WQ_I(y)v_d(y) \tag{2-246}$$

Substituting Eq. (2-245) into Eq. (2-246) and using

$$\mathscr{E} = \frac{dV}{dy} \tag{2-247}$$

for the magnitude of the field, we find that

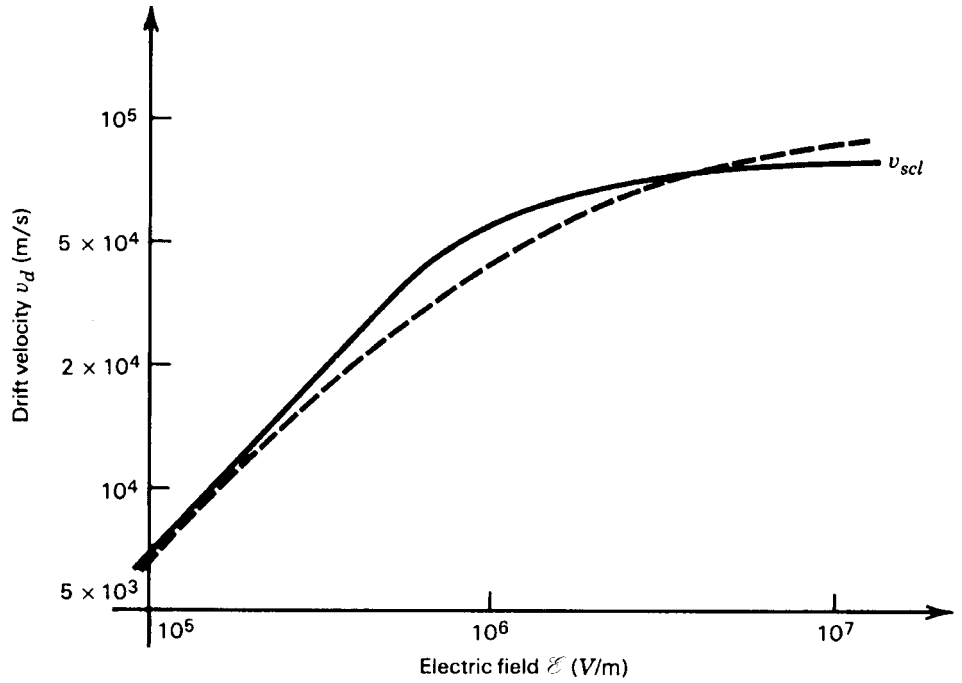

Figure 2-108 Typical measured electron drift velocity v_d versus tangent electric field $\mathscr{E}$ in an MOS surface channel (solid line). Also shown (dotted line) is the analytical approximation of Eq. (2.245) with $\mathscr{E}_c = 1.5 \times 10^6$ V/m and $\mu_n = 0.07$ m^2/V · s.

$$I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right) = WQ_I(y)\mu_n\frac{dV}{dy} \tag{2-248}$$

Note that as $\mathscr{E}_c \to \infty$ and velocity saturation becomes negligible, Eq. (2-248) approaches the original equation (2-211).

Integrating Eq. (2-248) along the channel we obtain

$$\int_0^L I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right)dy = \int_0^{V_{DS}} WQ_I(y)\mu_n dV \tag{2-249}$$

and thus

$$I_D = \frac{\mu_n C_{ox}}{2\left(1 + \dfrac{1}{\mathscr{E}_c}\dfrac{V_{DS}}{L}\right)}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-250}$$

The quantity V_{DS}/L in Eq. (2-250) can be interpreted as the average field in the channel. If this is comparable to $\mathscr{E}_c$, the drain current for a given V_{DS} is less than the simple expression (2-213) would predict.

Equation (2-250) is valid in the triode region. The MOSFET transfer function in saturation can be obtained by using $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-250) to obtain

$$I_D = \frac{k'}{2[1 + \theta(V_{GS} - V_t)]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-251}$$

where $\theta = 1/L\mathscr{E}_c$ and has the dimension volts^{-1}. For $L = 1$ μm, a typical value is $\theta \approx 0.7\ \text{V}^{-1}$. Note that in the presence of velocity saturation effects, the device enters the saturation region for $V_{DS} < (V_{GS} - V_t)$. However, Eq. (2-251) still gives a good estimate of the saturation current.

Thus far, we have only considered the effects of the tangential field due to the V_{DS} along the channel when examining velocity saturation effects. However, there exists a normal field originating from the gate voltage that also inhibits channel carrier mobility. Since the normal field depends on the value of V_{GS}, we find that an empirical modification to θ in Eq. (2-251) can adequately model this effect. In practice, θ is determined by a best fit to measured device characteristics.

Returning to Eq. (2-251) we note that for very short channel lengths, θ becomes large and Eq. (2-251) reduces to

$$I_D \propto (V_{GS} - V_t) \tag{2-252}$$

Thus, the FET characteristics tend toward a *linear* transfer function as the channel length becomes very small (less than 1 μm).

Equation (2-251) has a simple circuit representation. Consider the circuit of Figure 2-109, where an ideal square-law MOSFET has a resistance R_{SX} in series with the source of the FET. Assume

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V'_{GS} - V_t)^2 \tag{2-253}$$

Now

$$V_{GS} = V'_{GS} + I_D R_{SX} \tag{2-254}$$

and substituting Eq. (2-254) into Eq. (2-253) we find that

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V_{GS} - I_D R_{SX} - V_t)^2 \tag{2-255}$$

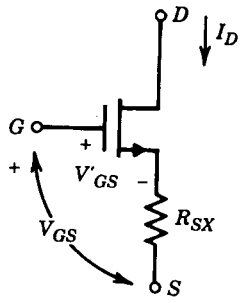

Figure 2-109 Model of velocity saturation of a MOSFET by addition of a series source resistance to an ideal square-law device.

Rearranging Eq. (2-255) we find

$$I_D = \frac{\mu C_{\text{ox}}}{2\left[1 + \mu C_{\text{ox}} \frac{W}{L} R_{SX}(V_{GS} - V_t)\right]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-256}$$

This has exactly the same form as Eq. (2-251) if we identify

$$\theta = \mu C_{\text{ox}} \frac{W}{L} R_{SX} \tag{2-257}$$

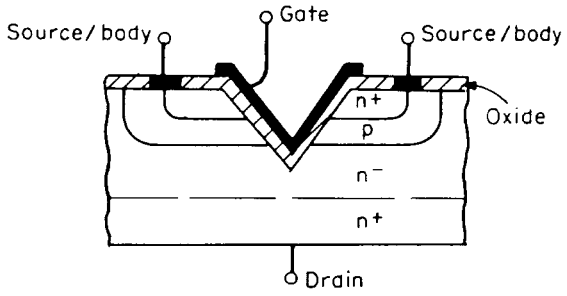
Substituting $\theta = 1/L\mathscr{E}_c$ into Eq. (2-257) we have

$$R_{SX} = \frac{1}{\mathscr{E}_c} \frac{1}{\mu C_{\text{ox}}} \frac{1}{W} \tag{2-258}$$

Thus, the influence of velocity saturation on the large-signal characteristics of a FET can be modeled to first order by a resistor R_{SX} in series with the source of an ideal square-law device. Note that R_{SX} varies inversely with W, as does the intrinsic physical series resistance due to source and drain contact regions. Typically, R_{SX} is larger than the physical series resistance. For $W = 2\ \mu\text{m}$, $\mu C_{\text{ox}} = 40\ \mu\text{A}/V^2$, and $\mathscr{E}_c = 1.5 \times 10^6$ V/m, we find $R_{SX} = 8\ \text{k}\Omega$.

The foregoing analysis has developed a modified large-signal mode for the MOSFET including velocity saturation effects. Small-signal MOSFET modeling for small devices can still be done using the equivalent circuit of Figure 2-107 if the values of g_m and g_{mb} are modified to account for the effects of velocity saturation using Eq. (2-251).

Figure 2-110 shows a cross section of VMOS (vertical MOS) and DMOS (double-diffused MOS) transistors. There is also a TMOS device—a Motorola variant of VMOS—and the



(a) VMOS (vertical channel MOS)

Figure 2-110 Cross section of (a) VMOS and (b) DMOS FETs.

now very popular LDMOS (lateral diffused MOS) power transistor (Figures 2-111 and 2-112). LDMOS FETs operate from a single supply (approximately 8 V and up) and are available for output powers surpassing 100 W at 2 GHz. The feedback capacitance is much lower than VMOS, TMOS, and earlier models, significantly improving circuit stability.

Following is a listing of Motorola high-power LDMOS transistors capable of operation up to 2 GHz:

2-3-6 Small-Signal Models of MOSFETs

Subthreshold Conduction in MOSFETs. The MOSFET analysis of Section 2-3-3 focused on the normal region of operation where this is a well-defined conducting channel under the gate. Changes in the gate voltage are assumed to cause changes in the channel charge only, and not in the depletion region below. However, for gate voltages less than the extrapolated threshold voltage V_t, the applied gate potential affects both the depletion-region charge and the channel charge, which is then very small but not zero. The device can thus conduct finite (but small) current for $V_{GS} < V_t$, so that Eq. (2-215) is not valid in this region. The electrons in the n^+ source region of an NMOS transistor can overcome the potential barrier to the p-type substrate and enter the channel region. This process is very similar to the turn-on of a bipolar transistor, and in fact the MOSFET characteristics in this subthreshold region (also called weak inversion) are very similar to those of a bipolar transistor. Analysis [19] shows that in the subthreshold region of the MOSFET characteristics can be defined by the equation

$$I_D = k_x \frac{W}{L} e^{V_{GS}/nV_T}(1 - e^{-V_{DS}/V_T}) \tag{2-259}$$

where k_x depends on process parameters and $n \simeq 1.5$. The value of n is not equal to unity in this case (as it is for the bipolar transistor) because the applied voltage V_{GS} appears partially at the silicon surface and partially across the depletion layer.

To illustrate this effect, we show measured NMOS characteristics plotted on three different scales in Figure 2-113. In Figure 2-113a we show the transfer characteristic in the forward-active region plotted on linear scales. For this device W = 20 μm and L = 20 μm and short-channel effects are negligible. The same data are plotted in Figure 2-113b as $\sqrt{I_D}$ versus V_{GS}. The resulting straight line shows that the device characteristic is close to an ideal square law. Plots like this are commonly used to obtain V_t by extrapolation (0.7 V in this case) and also k' from the slope of the curve (54 μA/V^2 in this case). Note that near the threshold voltage, the curve deviates from the straight line representing the square law. This is the subthreshold region. The data are plotted a third time in Figure 2-113c on log–linear scales. The straight line obtained for $V_{GS} < V_t$ fits Eq. (2-259) with n = 1.5. At currents below 10^{-12} A, the effect of leakage currents becomes evident.

The major application of subthreshold operation is in very low power applications at relatively low signal frequencies. The limitation to low signal frequencies occurs because the MOSFET f_T becomes very small. Since the device capacitances at very low bias currents

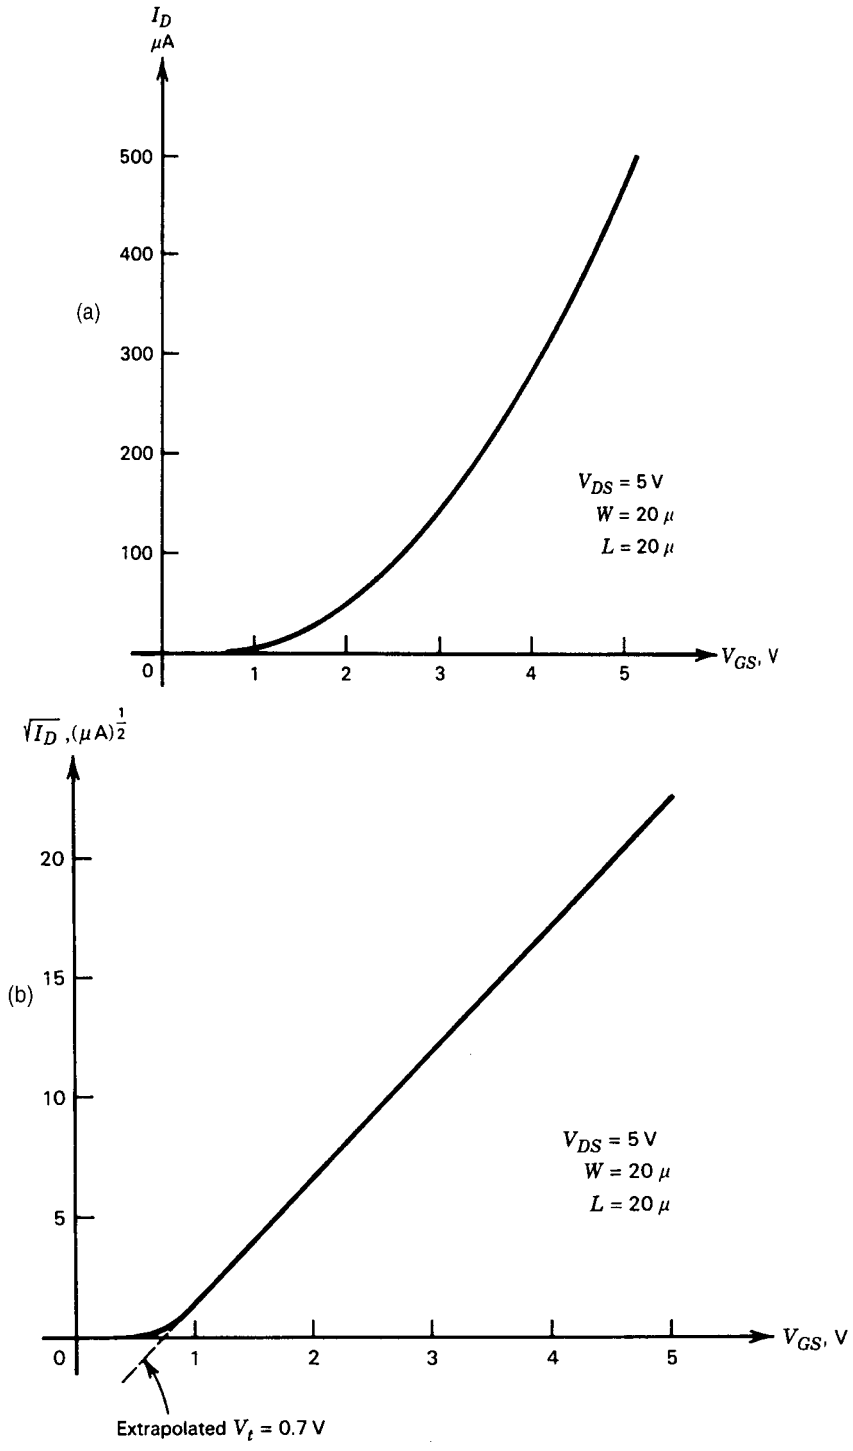

Figure 2-113 (a) Measured NMOS transfer characteristic in the forward-active region. (b) Data from part (a) plotted as $\sqrt{I_D}$ versus V_{GS} showing the square-law characteristic. (c) Data from part (a) plotted on log–linear scales showing the exponential characteristic of the subthreshold region.

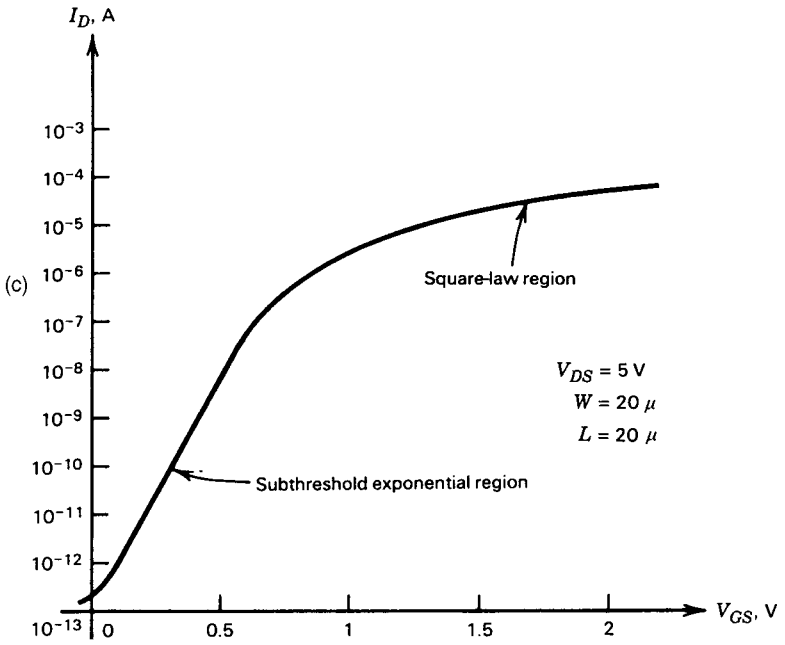

Figure 2-113. (*Continued*)

are essentially fixed, and the small-signal g_m calculated from Eq. (2-259) becomes proportional to I_D, we see that the value of f_T becomes very small at very low values of I_D.

Substrate Flow in MOSFETs. As the reverse-bias voltages on the device are increased, carriers traversing the depletion regions gain sufficient energy to create new hole–electron pairs in lattice collisions by a process known as *impact ionization.* Eventually, at high enough bias voltages, the process results in large avalanche currents. For collector–base bias voltages well below the breakdown value, a small enhanced current flow may occur across the collector–base junction due to this process with little apparent effect on the device characteristics.

Impact ionization also occurs in MOSFETs but has a significantly different effect on the device characteristics. This is because the channel electrons (for the case of NMOS) create hole–electron pairs in lattice collisions in the drain depletion region, and some of the resulting holes then flow to the substrate, creating a substrate current. (The electrons created

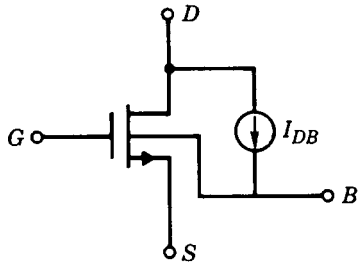

Figure 2-114 Representation of impact ionization in a MOSFET by a drain–substrate current generator.

in the process flow out the drain terminal.) The carriers created by impact ionization are thus not confined within the device as they are in a bipolar transistor. The effect of this phenomenon can be modeled by inclusion of a controlled current generator I_{DB} from drain to substrate, as shown in Figure 2-114 for an NMOS device. The magnitude of this substrate current depends on the voltage across the drain depletion region (which determines the energy of the ionizing channel electrons), and also on the drain current (which is the rate at which channel electrons enter the depletion region). It has been found empirically [20] that the current I_{DB} can be expressed as

$$I_{DB} = K_1(V_{DS} - V_{DS,\text{sat}})I_D e^{-[K_2/(V_{DS}-V_{DS,\text{sat}})]} \tag{2-260}$$

where K_1 and K_2 are process-dependent parameters and $V_{DS,\text{sat}}$ is the value of V_{DS} where the drain characteristics enter the saturation region. Typical values for NMOS devices are $K_1 = 5\ \text{V}^{-1}$ and $K_2 = 30$ V. The effect is generally much less significant in PMOS devices because the holes carrying the charge in the channel are much less efficient in creating hole–electron pairs than are energetic electrons.

The major impact of this phenomenon on circuit performance is that a parasitic resistance from drain to substrate now exists. Since the substrate of an NMOS device in a *p*-substrate process is an ac ground (the common substrate terminal must always be connected to the most negative supply voltage in the circuit), the parasitic resistance shunts the drain to ground and can be a limiting factor in many circuit designs. Differentiating Eq. (2-260) we find for the drain–substrate small-signal conductance

$$g_{db} = \frac{\partial I_{DB}}{\partial V_D}$$

$$= K_2 \frac{I_{DB}}{(V_{DS} - V_{DS,\text{sat}})^2} \tag{2-261}$$

where the gate and source are assumed held at fixed potentials.

In IC applications for RF/UHF circuits, many not-yet-solved problems remain:

1. The flicker corner frequency for MOS devices is somewhere between 100 kHz and 1 MHz.
2. Because of backplane problems in ICs, such as the substrate capacitance, also relative to the source, the performance of an IC-MOS/CMOS is not as good as expected if these effects are not considered.
3. Discrete devices, such as *n*-channel MOS devices, which are also available as dual-gate MOSFETs, can work well up to 1200 MHz. Such performance is not yet shown in silicon-based RFICs.
4. For RF power devices, such as LDMOS and others mentioned, promising results are only shown for discrete devices. There are no equivalent ICs on the market yet.

It will be interesting to see how this technology will work itself upward in frequency. Its main advantage is the BiCMOS process, which allows the mixing of analog and digital circuits nicely. Heterojunction transistors, such as SiGe, are inherently much more linear

and, for the same performance, require less current than MOS technology. On the other hand, we have not seen large-scale production SiGe-based ICs.

In the following five pages, we reproduce the datasheet for the Siemens (now Infineon Technologies) BF999 single-gate MOSFET.* Above 500 MHz, a dual-gate (also referred to as tetrode) MOSFET, such as the BF998, is preferred over a single-gate device. The main reasons for this are:

1. Internally, it is equivalent to two single-gate devices connected in a cascade arrangement, with the output device operating in the grounded-gate configuration, which entirely avoids the Miller effect and therefore remains stable at higher frequencies, operating up to 1.2 GHz.
2. The second gate can be used for AGC. As the Gate 2 voltage changes, the gain varies heavily.
3. By applying a local oscillator signal to Gate 2, this configuration can be used as a mixer.

The major drawbacks of these devices are their wide tolerances and temperature sensitivity. They follow to some degree the CMOS design but seem to have better performance.

The BF995, also called a tetrode, is in reality a dual-gate MOSFET specified to only 300 MHz; however, we are reproducing its datasheet* because the one more applicable for wireless circuits, the BF1005, does not have such a complete set of data.

To demonstrate the capabilities of low-voltage LDMOS transistors, we show the MRF5003 datasheet.† This device is intended for low-voltage applications down to 7.5 V. To the best of our knowledge, this is the lowest-voltage LDMOS transistor on the market. Other members of this family, which produce 5 W (MRF5005) and 15 W (MRF5015), begin to require higher supply voltages. Just to make sure it is not forgotten, the advantage of LDMOS is, besides lower-voltage operation, much-reduced feedback capacitance. LDMOS devices are now available that operate above 1 GHz and produce 60 W. There is now some competition with the recently introduced NEC GaAsFET, which goes up to 100 W in a similar frequency range.

MRF5003

3.0 W, 7.5 V, 512 MHz
N–CHANNEL
BROADBAND
RF POWER FET

The MRF5003 is designed for broadband commercial and industrial applications at frequencies to 520 MHz. The high gain and broadband performance of this device makes it ideal for large–signal, common source amplifier applications in 7.5 Volt and 12.5 Volt mobile, portable, and base station FM equipment.

- Guaranteed Performance at 512 MHz, 7.5 Volts
  Output Power = 3.0 Watts
  Power Gain = 9.5 dB
  Efficiency = 45%
- Characterized with Series Equivalent Large–Signal Impedance Parameters
- S–Parameter Characterization at High Bias Levels
- Excellent Thermal Stability
- All Gold Metal for Ultra Reliability
- Capable of Handling 20:1 VSWR, @ 15.5 Vdc, 512 MHz, 2.0 dB Overdrive
- Suitable for 12.5 Volt Applications
- True Surface Mount Package
- Available in Tape and Reel by Adding R1 Suffix to Part Number.
  R1 Suffix = 500 Units per 16 mm, 7 inch Reel.
- Circuit board photomaster available upon request by contacting
  RF Tactical Marketing in Phoenix, AZ.

DESIGN CONSIDERATIONS

The MRF5003 is a common–source, RF power, N–Channel enhancement mode, Metal–Oxide Semiconductor Field–Effect Transistor (MOSFET). Motorola RF MOSFETs feature a vertical structure with a planar design. Motorola Application Note AN211A, "FETs in Theory and Practice", is suggested reading for those not familiar with the construction and characteristics of FETs.

This surface mount packaged device was designed primarily for VHF and UHF power amplifier applications. Manufacturability is improved by utilizing the tape and reel capability for fully automated pick and placement of parts.

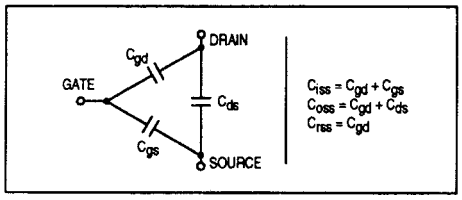
The major advantages of RF power MOSFETs include high gain, simple bias systems, relative immunity from thermal runaway, and the ability to withstand severely mismatched loads without suffering damage.

MOSFET CAPACITANCES

The physical structure of a MOSFET results in capacitors between all three terminals. The metal oxide gate structure determines the capacitors from gate–to–drain (C_{gd}), and gate–to–source (C_{gs}). The PN junction formed during fabrication of the RF MOSFET results in a junction capacitance from drain–to–source (C_{ds}). These capacitances are characterized as input (C_{iss}), output (C_{oss}) and reverse transfer (C_{rss}) capacitances on data sheets. The relationships between the inter–terminal capacitances and those given on data sheets are shown below. The C_{iss} can be specified in two ways:

1. Drain shorted to source and positive voltage at the gate.
2. Positive voltage of the drain in respect to source and zero volts at the gate.

In the latter case, the numbers are lower. However, neither method represents the actual operating conditions in RF applications.



DRAIN CHARACTERISTICS

One critical figure of merit for a FET is its static resistance in the full–on condition. This on–resistance, $R_{DS(on)}$, occurs in the linear region of the output characteristic and is specified at a specific gate–source voltage and drain current. The drain–source voltage under these conditions is termed $V_{DS(on)}$. For MOSFETs, $V_{DS(on)}$ has a positive temperature coefficient at high temperatures because it contributes to the power dissipation within the device.

GATE CHARACTERISTICS

The gate of the RF MOSFET is a polysilicon material, and is electrically isolated from the source by a layer of oxide. The input resistance is very high — on the order of $10^9\ \Omega$ — resulting in a leakage current of a few nanoamperes.

Gate control is achieved by applying a positive voltage to the gate greater than the gate–to–source threshold voltage, $V_{GS(th)}$.

Gate Voltage Rating — Never exceed the gate voltage rating. Exceeding the rated V_{GS} can result in permanent damage to the oxide layer in the gate region.

Gate Termination — The gates of these devices are essentially capacitors. Circuits that leave the gate open–circuited or floating should be avoided. These conditions can result in turn–on of the devices due to voltage build–up on the input capacitor due to leakage currents or pickup.

Gate Protection — These devices do not have an internal monolithic zener diode from gate–to–source. If gate protection is required, an external zener diode is recommended with appropriate RF decoupling.

Using a resistor to keep the gate–to–source impedance low also helps dampen transients and serves another important function. Voltage transients on the drain can be coupled to the gate through the parasitic gate–drain capacitance. If the gate–to–source impedance and the rate of voltage change on the drain are both high, then the signal coupled to the gate may be large enough to exceed the gate–threshold voltage and turn the device on.

DC BIAS

Since the MRF5003 is an enhancement mode FET, drain current flows only when the gate is at a higher potential than the source. See Figure 8 for a typical plot of drain current versus gate voltage. RF power FETs operate optimally with a quiescent drain current (I_{DQ}), whose value is application dependent. The MRF5003 was characterized at I_{DQ} = 50 mA, which is the suggested value of bias current for typical applications. For special applications such as linear amplification, I_{DQ} may have to be selected to optimize the critical parameters.

The gate is a dc open circuit and draws no current. Therefore, the gate bias circuit may generally be just a simple resistive divider network. Some special applications may require a more elaborate bias system.

GAIN CONTROL

Power output of the MRF5003 may be controlled from its rated value down to zero (negative gain) with a low power dc control signal, thus facilitating applications such as manual gain control, ALC/AGC and modulation systems. Figure 16 is an example of output power variation with gate–source bias voltage. This characteristic is very dependent on frequency and load line.

MOUNTING

The specified maximum thermal resistance of 14°C/W assumes a majority of the 0.100″ x 0.200″ source contact on the back side of the package is in good contact with an appropriate heat sink. In the test fixture shown in Figure 1, the device is clamped directly to a copper pedestal. In the demonstration amplifier, the device was mounted on top of the G10 circuit board and heat removal was accomplished through several solder filled plated through holes. As with all RF power devices, the goal of the thermal design should be to minimize the temperature at the back side of the package.

AMPLIFIER DESIGN

Impedance matching networks similar to those used with bipolar transistors are suitable for the MRF5003. For examples see Motorola Application Note AN721, "Impedance Matching Networks Applied to RF Power Transistors." Both small–signal S–parameters and large–signal impedances are provided. While the S–parameters will not produce an exact design solution for high power operation, they do yield a good first approximation. This is an additional advantage of RF power MOSFETs.

Since RF power MOSFETs are triode devices, they are not unilateral. This coupled with the very high gain of the MRF5003 yield a device capable of self oscillation. Stability may be achieved by techniques such as drain loading, input shunt resistive loading, or output to input feedback. Different stabilizing techniques were applied to the test fixture and demonstration amplifiers. The RF test fixture implements a parallel resistor and capacitor in series with the gate while the demonstration amplifier utilizes a 43 Ω shunt resistor from gate to ground. Both circuits have a load line selected for a higher efficiency, lower gain, and more stable operating region.

Two port stability analysis with the MRF5003 S–parameters provides a useful tool for selection of loading or feedback circuitry to assure stable operation. See Motorola Application Note AN215A, "RF Small–Signal Design Using Two–Port Parameters," for a discussion of two port network theory and stability.

2-3-7 GaAs MESFETs

Introduction. More than twenty years ago, for RF applications, the JFET was the dominant FET. As mentioned earlier, its major disadvantage is the fact that the f_T cutoff frequency, defined as

$$f_T = g_m / 2\pi C_{GS} \tag{2-262}$$

limits the operating range of this semiconductor device to 1 GHz at most. Also, the JFET's temperature sensitivity and loose tolerances in transconductance and other RF-related values made it difficult to use. Finally, no RFICs made use of this technology. While at the moment silicon-based MOS technology probably is the most cost-effective and is produced in the largest quantities, it does not rival the metal-semiconductor FET designed on GaAs technology. Figure 2-115 shows the structure of the silicon MOSFET, silicon JFET, and the GaAs MESFET.

Large-Signal Behavior of GaAs MESFETs. The mathematics for the large-signal behavior of the GaAsFET is basically quite similar to that for the JFET; however, the computations for JFET channel current, diode currents, and capacitance are much simpler than for the GaAsFET. Temperature effects are embedded in all the equations for all the transistors mentioned so far. In our opinion, the modified Materka model used by Ansoft and a large number of users is the most complete one; however, the following models are supported by most CAD tools:

- Chalmers (Angelov)
- Curtice–Ettenberg cubic
- Curtice quadratic
- IAF (Berroth)
- ITT PFET and TFET
- Modified Materka–Kacprzak
- Physics-based MESFET
- Raytheon (Statz)
- TriQuint (TOM-1, TOM-2, and TOM-3)
- With some restrictions, metal-insulator-semiconductor FETs (MISFETs), modulation-doped FETs (MODFETs), and high-electron-mobility transistors (HEMTs)

The main advantages of GaAsFET technology derive from the fact that it uses a metal-semiconductor junction with a barrier voltage of 0.8 V, its input capacitance is typically less than 0.2 pF, and the reverse feedback capacitance is less than 0.02 pF, or roughly 10% of the input capacitance. As a result of this, $f_{\max}$ is approximately five times higher than f_T. Table 2-16 shows a comparison of silicon BJT and GaAsFET technologies. While $f_{\max}$ for the bipolar transistor is

$$f_{\max} \simeq \sqrt{\frac{f_t}{8\pi r'_{bb} C_C}} \tag{2-263}$$

the $f_{\max}$ determination for the GaAsFET is given by

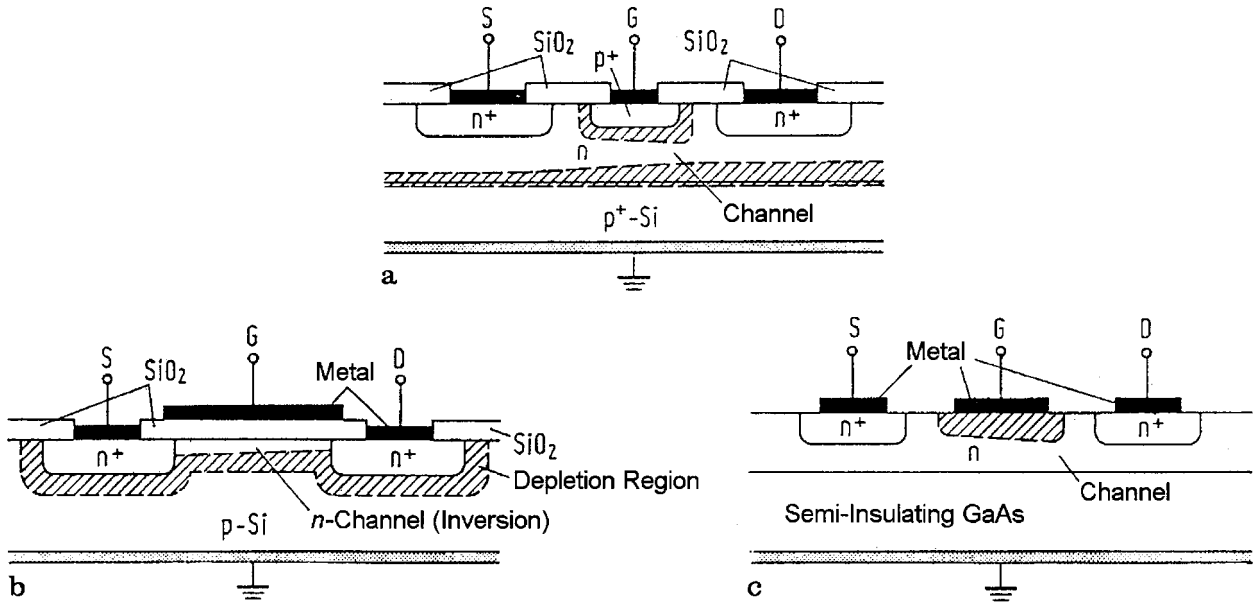

Figure 2-115 This picture is provided to differentiate between the structure of the three technologies. (a) The JFET and (b) the MOSFET are based on silicon; (c) the GaAsFET is based on semi-insulating GaAs. While the MOS transistor has silicon dioxide (SiO_2) as gate insulation, both the JFET and GaAs MESFET have a diode from gate to source, with a barrier voltage of 0.65 V for silicon and 0.8 V for GaAs.

Table 2-16 Comparison of Si BJT, SiGe HBT, and GaAsFET technologies

	Si Bipolar	SiGe HBT	GaAs FET
f_T	25 GHz	100 GHz	22 GHz
$f_{\max}$	40 GHz	200 GHz	110 GHz
Features	Low cost, low 1/*f* noise (5 kHz)	Low 1/*f* noise, very low distortion, high cost, IC only	Highest flexibility, lowest NF_0, well established

$$f_{\max} = \frac{f_T}{2}\sqrt{\frac{R_0}{R_i + R_s + R_g}} \tag{2-264}$$

As a sample calculation,

$$f_{\max}\ \frac{21.9\text{ GHz}}{2}\sqrt{\frac{450}{1 + 1.5 + 2}} = 110\text{ GHz} \tag{2-265}$$

The three major drawbacks of the GaAsFET are:

1. Much higher flicker corner frequency (somewhere between 10 and 100 MHz), probably due to a lack of surface passivation.
2. Much higher output conductance. This tends to load down any circuit connected to the drain. On the other hand, since the transconductance is quite high for even low currents, these devices have very high gains at low frequencies, which can make them quite unstable. In the saturated mode it is not uncommon to find a drain–source resistance of 100–500 Ω, while BJTs and JFETs offer values of several kilohms and higher.
3. Because of the very high flicker corner frequency (from 10 to 100 MHz), MESFETs are really not useful for low-noise mixers and oscillators, and unless there are no devices available in the frequency range above 30 GHz, they should be avoided for these applications.

As to the MESFET's construction and dc properties, Figure 2-116 shows a MESFET's cross section and dc *I*–*V* characteristics.

It was outlined in the beginning that while the GaAsFET is a close relative to the JFET and MOSFET, its actual behavior was found to be described best by a set of analytic equations. The first such model was the one by Curtice in the form of quadratic and cubic models, but it does not have enough derivatives to give enough insight into subtle things such as third- and higher-order intermodulation distortion and accurate harmonic generation. Other researchers have addressed various areas, but we still find that the Materka model has the best approximation, especially using the two-transistor approach outlined later [20, 21]. The large-signal topology for all FETs consists of an intrinsic model with some extrinsic parameters, further complicated by the package, as shown by Figures 2-117 and 2-118. Table 2-17 lists their keywords. The actual intrinsic model and its parameter definition depend on the particular model and since designs using GaAsFET will always be done using CAD tools, we will not go into any details of the equations but will list them. They are not dissimilar from the JFET and MOSFET equations.

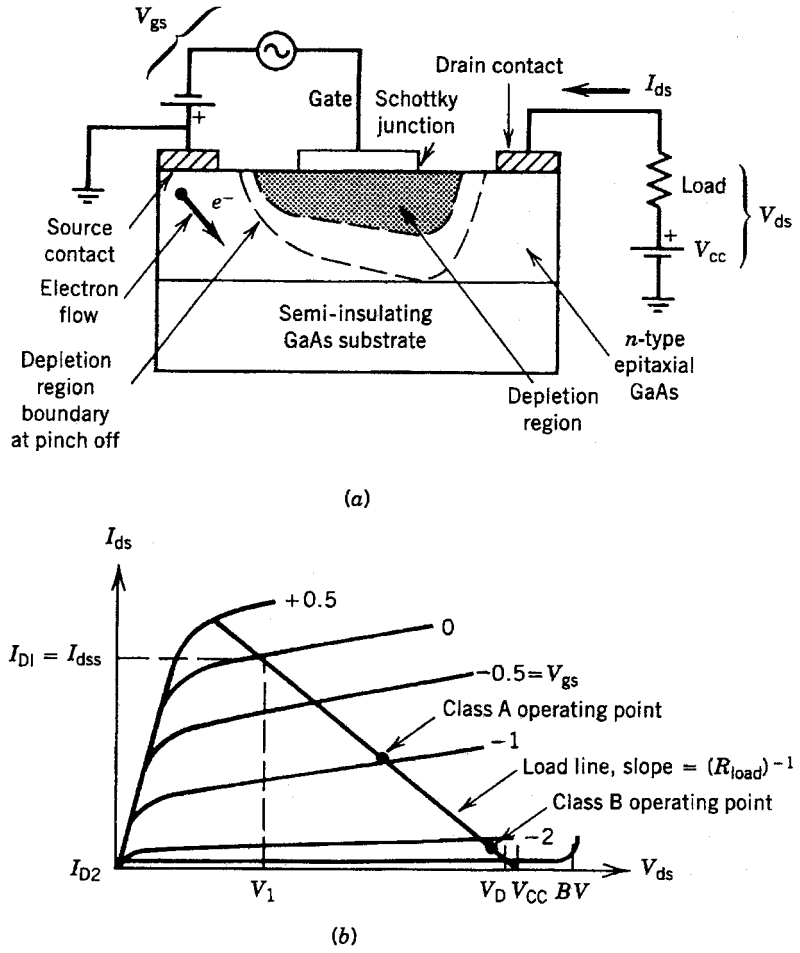

Figure 2-116 (a) Cross section and bias circuit and (b) dc *I–V* curve, including ac load line, for a MESFET.

The Modified Materka-Kacprzak Model Figure 2-119 shows the intrinsic model of the Materka FET. Table 2-18 lists its keywords.

Large-Signal Equations

Device Equations

V_{gsi} = Intrinsic gate–source voltage
V_{dsi} = Intrinsic drain–source voltage
V_1 = Voltage across C_{GS} and R_i
V_{gdi} = Intrinsic gate–drain voltage
$V_T = kT_J/q$ (thermal voltage)
k = Boltzmann's constant
q = Electron charge
T_J = Analysis temperature (kelvins)

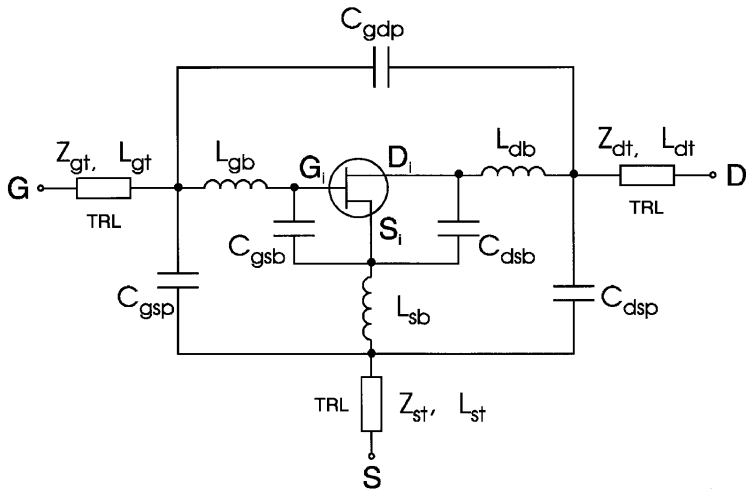

Figure 2-117 MESFET extrinsic model.

Channel Current

$$I_{ds} = \mathrm{IDSS}\left(1 + \mathrm{SS}\,\frac{V_{dsi}}{\mathrm{IDSS}}\right)\left(1 - \frac{V_{gsi}(t-T)}{\mathrm{VP0} + \mathrm{GAMA}V_{dsi}}\right)^{(\mathrm{E}+\mathrm{KE}V_{gsi}(t-T))}$$

$$\times \tanh\left(\frac{\mathrm{SL}V_{dsi}}{\mathrm{IDSS}(1 - \mathrm{KG}V_{gsi}(t-T))}\right)$$

Diode

$$I_{gd} = I_{gdc} - \begin{cases} \mathrm{IB0}\,\exp[-\mathrm{AFAB}(V_{gdi} + \mathrm{VBC})] \\ \dfrac{\mathrm{GMAX}}{4}\,\{\tanh[\mathrm{K1D}(V_{gsi} - \mathrm{K2D})] - 1\}\,[V_{gdi} + \mathrm{VBC} - \sqrt{(V_{gdi} + \mathrm{VBC})^2 + \mathrm{K3D}}] \end{cases}$$

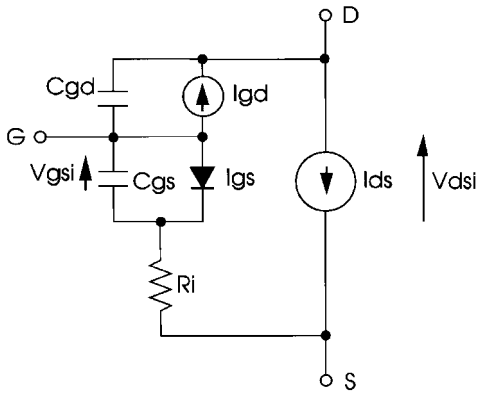

Figure 2-119 Intrinsic model of the modified Materka–Kacprzak MESFET.

where

$$I_{gdc} = \text{IG0}[\exp(\text{AFAB}V_{gdi}) - 1]$$

Channel Resistance

$$R_i = \begin{cases} \text{R10}(1 - \text{KR}V_{gsi}), & \text{KR}V_{gsi} < 1.0 \\ 0, & \text{KR}V_{gsi} \geq 1.0 \end{cases}$$

Capacitance Model

$$C_{gs} = \text{CGS0}\frac{F1F2}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F3$$

$$C_{gd} = \text{CGS0}\frac{F1F3}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F2$$

where

$$F1 = \frac{1}{2}\left(1 + \frac{V_{\text{eff}} - V_T}{\sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}}\right)$$

$$F2 = \frac{1}{2}\left(1 + \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

Table 2-18 Materka–Kacprzak MESFET model keywords

Keyword	Description	Unit	Default
	Area, Noise, and Name		
AREA	Area multiplier		1.0
KFN	Flicker noise coefficient (Materka model only)[a]		0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
	Channel Current Model		
IDSS	Drain saturation current for $V_{GS} = 0$	ampere	0.1
VP0	Pinchoff voltage for $V_{DS} = 0$	volt	–2.0
GAMA	Voltage slope parameter of pinchoff voltage	/volt	0.0
E	Constant part of power-law parameter		2.0
KE	Dependence of power law on V_{GS}	/volt	0.0
SL	Slope of the $V_{GS} = 0$ drain characteristic in the linear region	ampere/volt	0.15
KG	Drain dependence on V_{GS} in the linear region	/volt	0.0
SS	Slope of the drain characteristic in the saturated region	ampere/volt	0.0
T	Channel transit-time delay	second	0.0
IG0	Diode saturation current	ampere	0
AFAG	Slope factor of forward diode current	/volt	38.696
IB0	Breakdown saturation current	ampere	0
AFAB	Slope factor of breakdown current	/volt	0
VBC	Breakdown voltage	volt	∞
GMAX	Breakdown conductance	ampere/volt	0
K1D	Fitting parameter	/volt	0
K2D	Fitting parameter	volt	0
K3D	Fitting parameter	$volt^2$	0
R10	Intrinsic channel resistance for $V_{GS} = 0$	ohm	0.0
KR	Slope factor of intrinsic channel resistance	/volt	0.0
	Materka Capacitance Model		
C10	Gate–source Schottky barrier capacitance for $V_{GS} = 0$	farad	0.0
K1	Slope parameter of gate–source capacitance	/volt	1.25
MGS	Gate–source grading coefficient		0.5
C1S	Constant parasitic component of gate–source capacitance	farad	0.0
CF0	Gate–drain feedback capacitance for $V_{GD} = 0$	farad	0.0
KF	Slope parameter of gate–drain feedback capacitance	/volt	1.25
MGD	Gate–drain grading coefficient		0.5
FCC	Forward-bias depletion capacitance coefficient		0.8

[a]The flicker noise parameter of the Materka model is KFN so as not to conflict with the KF parameter in the capacitance model.

$$F3 = \frac{1}{2}\left(1 - \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

$$V_{\text{new}} = \begin{cases} A1, & A1 < \text{VMAX} \\ \text{VMAX}, & A1 \geq \text{VMAX} \end{cases}$$

$$A1 = \frac{1}{2}\left(V_{\text{eff}} + V_T + \sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}\right)$$

$$V_{\text{eff}} = \frac{1}{2}\left(V_{gsi} + V_{gdi} + \sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}\right)$$

$$V_T = \text{VP0} + \text{GAMA}\, V_{dsi}$$

$$\delta = 0.2$$

Some of the modifications to the Materka model have been done by Ansoft under various Department of Defense contracts, and by Raytheon and Texas Instruments under similar contracts, with Ansoft being a subcontractor.

The most relevant equation is really the channel current. Its derivatives are largely responsible for the accuracy of the intermodulation distortion, power-added efficiency, and, of course, its dc *I–V* curves.

Enhancement/Depletion FETs To make the designer's life more difficult, it turns out that there are two types of GaAsFETs:

1. *Depletion FETs (DFETs).* Most similar to the JFET; here V_G must be negative to control the device. They are the most commonly produced and are the FET type most referred to in this book.

On one hand:

- They require a negative gate voltage with respect to the source.
- Self-bias allows operation from a single supply voltage.

On the other hand:

- For low-voltage operation, a negative voltage generator may be required.
- Supply voltage must be doubled to accommodate full-swing operation.

2. *Enhancement FETs (EFETs).* Most similar to the MOSFET; here V_G must be positive to bring life to the device. Practically speaking, EFETs are used mostly in integrated circuits; they're typically not available in discrete, packaged form.

On one hand:

- They need only positive supply for biasing.
- They provide higher g_m/mA (for same device width)—5.1 mS versus 3.9 mS at 8 mA.

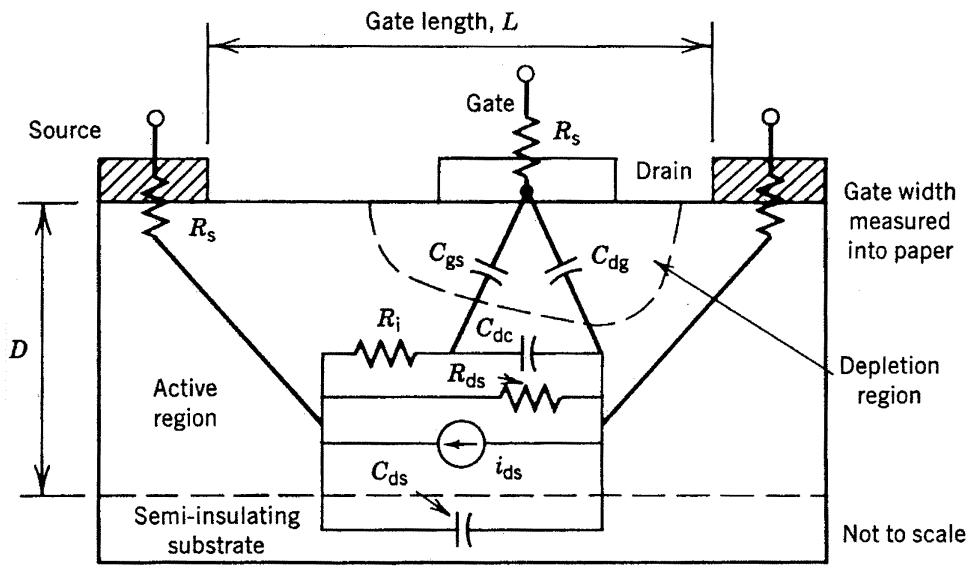

Figure 2-120 Location of lumped-element components for a MESFET.

- They are good for low-power LNAs, giving slightly better NF that DFETs, an NF of 1 dB at 1 GHz, and $I_{dd} < 10$ mA.

On the other hand:

- They have a very limited gate bias range (V_{GS} between 0.15 and 0.7 V).
- The gate conduction degrades NF and input impedance.
- The gate capacitance is higher than that of DFETs.
- The linearity is not as good as that of DFETs.

With today's technologies, all GaAs devices are *n*-channel; we have not seen any *p*-channels yet. More information about biasing will be given in the next chapter.

Figure 2-120 is a lumped-element, two-part equivalent circuit of a MESFET showing the location of lumped-element components.

2-3-8 Small-Signal GaAs MESFET Model

Figure 2-121 shows the applicable linear equivalent circuit for a MESFET and Table 2-19 lists its keywords. As with the MOS transistors, there is a gallium-arsenide dual-gate MOSFET available that is used mostly in special circuits, such as preamplifiers and mixers, whose IF has to be significantly higher than the flicker corner frequency, for example, higher than 200 MHz.

The following two datasheets* show typical GaAsFETs, both low-noise and medium-power. Such devices are, of course, available from a large variety of manufacturers—to name at least two, Siemens and the Nippon Electric Company, which is represented in the United States by California Eastern Laboratories.

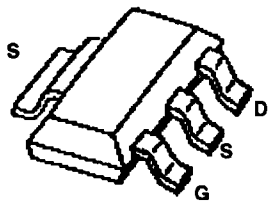
SIEMENS GaAs FET **CLY 15**

Datasheet

* Power amplifier for mobile phones
* For frequencies from 400 MHz to 2.5 GHz
* Operating voltage range: 2.7 to 6 V
* P_{out} at V_D=3V, f=1.8 GHz typ. 31.5 dBm
* Efficiency better 50%



ESD: Electrostatic discharge sensitive device, observe handling precautions!

2-4 PARAMETER EXTRACTION OF ACTIVE DEVICES

2-4-1 Introduction

We have already seen that all linear models that are used on the market are really derived from large-signal models, and it is our point that the quality of the model depends mostly on the quality of the parameters used to describe the model.

As far as modeling is concerned there are two options. The first option is a physics-based model, which can be applied to items such as diodes and bipolar transistors, including its most advanced versions, such as HBTs, SiGe versions, and other future derivatives. The bipolar transistor is essentially a combination of two diodes whereby the base–emitter junction generates the electrons or holes (depending on how the reader is accustomed to viewing the process) and then transfers those to the collector. The emitter, as its name states, emits the charged particles and the collector collects them, minus some current losses, which are expressed in the current gain of the device. A current gain (β) of 100 means that the collector receives 1% less than the emitter emits.

The second modeling option involves the construction of an analytical mathematic equivalent for the device modeled. Earlier in this chapter, we went through a detailed physics-based derivation about the inner workings of these devices, explaining how, for a given dc bias point, one can simplify them to a small-signal equivalent circuit. This is possible since we assume that the RF current and voltages are less than 1% of the dc equivalent currents and voltages. Reducing a device's complex nonlinear equivalent circuit to a quasistatic linear equivalent circuit allows its manufacturer to generate and publish sets of *S* parameters for it. These parameters are bias, voltage, and temperature dependent. At higher frequencies, parasitics play an enormous role in determining a device's RF performance.

A device operating at signal levels that are more than 1% of its dc equivalent currents and voltages must be evaluated in terms of large-signal performance. Most of the large-signal-equivalent circuits for nonbipolar devices, such as FETs (MOS, silicon JFETs, and members of the GaAsFET family), are analytic approximations that essentially bear no physical insight into the inner workings of the transistors. This fact is particularly painful because to look at high-order intermodulation distortion, one needs to have third and fourth derivatives of mathematically continuous equations. The SPICE approach cannot easily be translated into modern harmonic-balance simulators because such cop-outs as IF THEN ELSE statements in programming provide everything else but a continuous model. In the case of our own work, we used complicated curve-fitting equations to obtain analytic equations and their derivatives to accurately provide a large-signal model that is valid over a wide range of dc and RF.

2-4-2 Typical SPICE Parameters

Since we are about to evaluate bipolar microwave transistors, junction FETs, MOSFETs (model level 3), and GaAsFETs, Tables 2-20, 2-21, 2-22, and 2-23 list typical parameters for the devices we have used. These parameters can be obtained by the Scout program with the appropriate measurements. The BSIM model for MOSFETs, applicable for submicron technology transistors, requires an enormous level of parameter extraction and has not fully been validated for the LDMOS-type transistors currently favored for RF and microwave applications.

Table 2-20 BFR193W BJT

IS = 2.738E – 16	BF = 125	NF = 0.95341

TF = 1.8828E – 11	XTF = 0.69477	VTF = 0.8
ITF = 0.00096893	PTF = 0	CJC = 9.3503E – 13
VJC = 1.1828	MJC = 0.30002	XCJC = 0.053563
TR = 1.0037E – 09	VJS = 0.75	MJS = 0
XTB = 0	EG = 1.11	XTI = 3
FCC = 0.72063	LB = 0.57E – 9	LC = 0.00E – 9
LE = 0.43E – 9	CBCP = 0.101E – 12	CCEP = 0.175E – 12
CBEP = 0.061E – 12	VCMX = 10 V	

The meaning and significance of the various parameters is best explored in a book on SPICE or semiconductor physics [22–24].

2-4-3 Noise Modeling

Diode Noise Model. The noise model for the diodes (Figure 2-122 and Table 2-24) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

The noise generators in the diode noise model are the series parasitic resistance, R_S, and the intrinsic junction. Figure 2-122 illustrates the intrinsic junction noise generator. Let Δf be the bandwidth (usually normalized to 1 Hz). The intrinsic noise generator has a mean-square value of

$$\langle i_{Dn}^2 \rangle = 2qI_D\,\Delta f + \mathrm{KF}\,\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\,\Delta f \tag{2-266}$$

Notes on the Diode Noise Model:

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.

[a]The currently implemented model for the junction FET is too primitive for serious RF applications. We have therefore taken the approach (liberty) of using the Materka parameter extraction approach for silicon junction FETs. This has resulted in unparalleled high-quality parameters; in particular, the knee voltage behavior has significantly improved, as well as the overall frequency response.

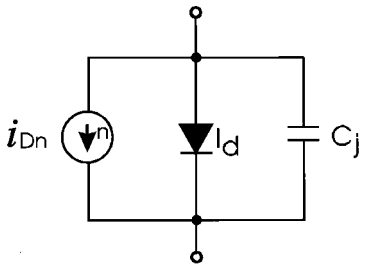

Figure 2-122 Equivalent noise circuit for a diode chip.

Table 2.24 Diode noise model keywords

Keyword	Description	Unit	Default
ID	Required bias current for the data point	Ampere	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner fequency	hertz	

2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.
3. The corner frequency noise model uses the system noise floor to internally compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the diode parameters and *kT*.
4. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

BJT Noise Model. The noise model for the Gummel–Poon BJT model consists of two contributions: shot noise and flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications) (see Table 2-25).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Bias-Independent Flicker Noise Coefficient*. This option involves the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying The Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with the bias point).

Notes on the BJT Noise Model:

Table 2.25 BJT noise model keywords

Keyword	Description	Unit	Default
IB	Required base bias current for the data point	ampere	
VCE	Required collector–emitter voltage for the data point	volt	
VBS	Base–substrate voltage required for LPNP type when four nodes are used	volt	
VCS	Collector–substrate voltage required for NPN or PNP type when four nodes are used	volt	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as bipolar noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model of course considers the actual operating temperature, which must be supplied to the model.

Figure 2-123 shows the BJT noise model. Let Δf be the bandwidth (usually normalized to a 1-Hz bandwidth). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{bn}^2 \rangle = 2qI_B \,\Delta f + \text{KF}\,\frac{I_B^{\text{AF}}}{f^{\text{FCP}}}\,\Delta f \tag{2-267}$$

$$\langle i_{cn}^2 \rangle = 2qI_C \Delta f \tag{2-268}$$

$$\langle i_{R_{bb}}^2 \rangle = \frac{4kT}{R_{bb}}\,\Delta f \tag{2-269}$$

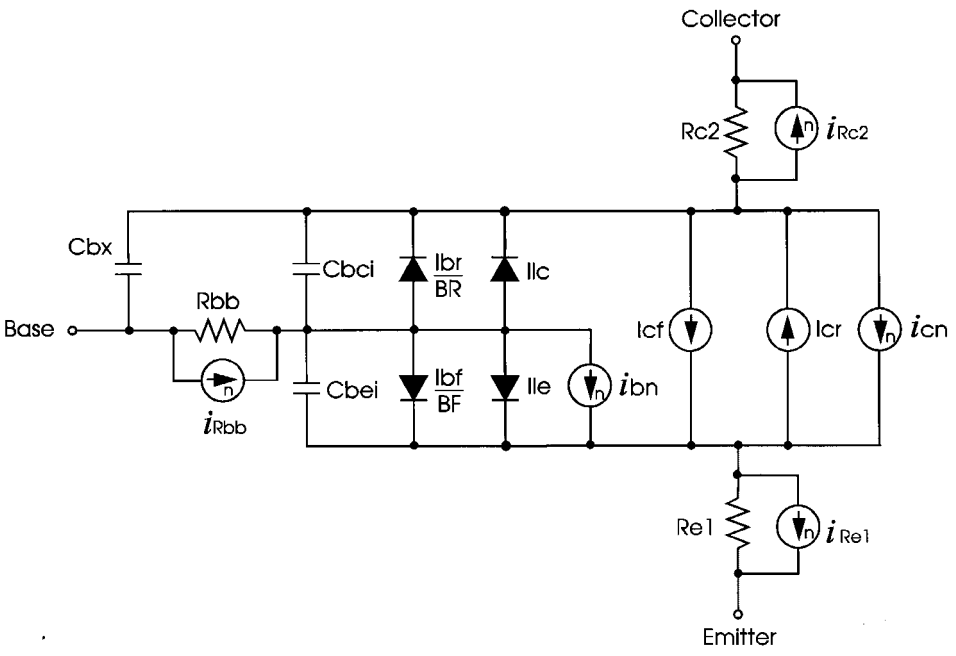

Figure 2-123 BJT noise model (not showing extrinsic parasitics). Current sources with *n* are noise sources.

$$\langle i_{R_{e1}}^2 \rangle = \frac{4kT}{R_{e1}} \Delta f \tag{2-270}$$

$$\langle i_{R_{c2}}^2 \rangle = \frac{4kT}{R_{c2}} \Delta f \tag{2-271}$$

$$I_B = \frac{I_{bf}}{BF} + I_{le} \tag{2-272}$$

$$I_C = I_{cf} - I_{cr} \tag{2-273}$$

JFET and MESFET Noise Models. The noise model for the FETs consists of two contributions: the shot noise and the flicker noise. There are two options to specify noise in the FET model:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (Table 2-26) to determine the flicker noise (this option is usually sufficient for most applications). The shot noise will be automatically computed using the SPICE equation.
2. Using bias-dependent flicker noise coefficients through a reference in the DATA block (specifying KF and AF at multiple bias points) and specifying the four noise parameters [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at multiple bias points.

Option 1: *Specifying the Enhanced SPICE Noise Model.* Option 1 is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model. The drain noise model has the form

$$\langle |I_{dn}|^2 \rangle = 4K_B T \frac{2g_m}{3} \Delta f + \text{KF} \frac{|I_D|^{\text{AF}}}{f^{\text{FCP}}} \Delta f \tag{2-274}$$

Table 2.26 FET noise model keywords

Keyword	Description	Unit	Default
FN	Noise data measurement frequency	hertz	1.0 GHz
VGS	Required gate–source voltage for the data point	volt	
VDS	Required drain–source voltage for the data point	volt	
FMIN	Required minimum noise figure in dB at FN		
MGO	Required magnitude of optimum noise reflection coefficient at FN		
PGO	Required phase of optimum noise reflection coefficient at FN		
RN	Required normalized noise resistance at FN		
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

where the shot noise is derived from g_m and the flicker noise is proportional to KF and the drain channel current, I_D, and inversely proportional to frequency. The AF and FCP parameters tailor the flicker noise dependence on bias and frequency, respectively.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows the specification of the complex bias-dependent nature of the shot noise and flicker noise. At high frequencies, the equivalent noise sources are correlated (the SPICE noise model does not account for this correlation). The complete evaluation of the shot noise sources can be determined from the four noise parameters. Since these are functions of bias, they can be specified over the (V_{GS}, V_{DS}) bias plane.

Additionally, a bias-dependent flicker noise coefficient (i.e., KF and AF vary with current) can be specified.

The MESFET noise model uses the four measured noise data [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at one frequency and multiple arbitrary bias points. The program uses these data and the FET model parameters to de-embed the noise data to an intrinsic noise model. The intrinsic model is accurate at all frequencies and, therefore, can predict the noise performance at all frequencies given data at just one frequency point. Built-in bias-dependent characteristics are used if multi-bias noise data are not provided.

Notes on the FET Noise Model

1. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
2. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Noise in a MESFET is produced by sources intrinsic to the device. The same approach, but with different flicker corner frequencies, is highly applicable to JFETs and MOSFETs. For more detail as to simulation, see the Element library book for the active-device portion of Ansoft's Serenade Design Environment product. The equivalent noisy circuit of an intrinsic FET is represented in Figure 2-124.

The intrinsic FET is internally represented as a noiseless nonlinear two-port with one equivalent noise current connected across the gate–source terminal, and one across the drain–source terminal. The correlations of the gate and drain noise current sources are

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \frac{\omega^2 C_{gs}^2}{g_m} R \tag{2-275}$$

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \, g_m P \tag{2-276}$$

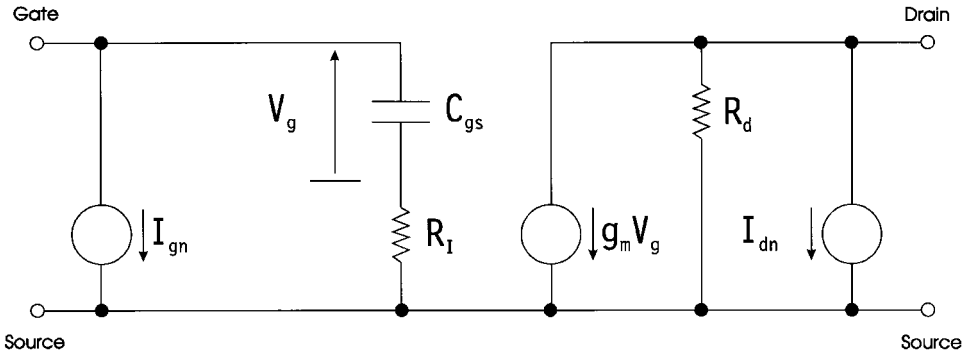

Figure 2-124 Equivalent noise circuit of an intrinsic FET device.

$$\langle I_{gn} I_{dn}^{*} \rangle = 4K_B T\, \Delta f\, j\omega C_{gs} \sqrt{PR}\, C \tag{2-277}$$

The correlation matrix of the noise current sources is

$$C_{dc}(\omega) = \frac{2}{\pi} K_B T\, d\omega \begin{bmatrix} \dfrac{\omega^2 C_{gs}^2}{g_m} R & -j\omega C_{gs}\sqrt{PR}\, C \\ j\omega C_{gs}\sqrt{PR}\, C & g_m P \end{bmatrix} \tag{2-278}$$

The gate and drain noise parameters R and P and the correlation coefficient C are related to the physical noise sources acting in the channel and are functions of the device structure and bias noise parameters. By defining measured noise parameters, $F_{\min}$, R_n, and Γ_{opt}, and using a noise de-embedding procedure, the parameters R, P, and C and the intrinsic noise correlation matrix of a FET device as functions of device bias are determined by the program.

In addition to the noise sources shown above, the flicker (1/f) noise can also be modeled by means of a noise current source connected in parallel with the intrinsic drain port. The flicker noise component in a narrow band, Δf, is expressed in the form

$$\langle |I_f|^2 \rangle = \mathrm{Q}\, \Delta f \frac{|I_D|^{\mathrm{AF}}}{f^{\mathrm{FCP}}} \tag{2-279}$$

where I_D is the instantaneous value of the channel current, and Q, AF, and FCP are empirical parameters. In most practical cases, AF and FCP are directly obtained from measurements (typically, AF = 2 and FCP = 1), while Q is not. In Ansoft's Serenade Design Environment, Q is either provided directly using KF or is computed by providing the flicker corner frequency (FC). FC is the frequency at which the flicker noise equals the shot/diffusion noise. The corner frequency is defined by the equation

$$\mathrm{Q} \frac{|I_D|^{\mathrm{AF}}}{f_{\mathrm{C}}^{\mathrm{FCP}}} = g_m P \tag{2-280}$$

Given the corner frequency FC and the measurement bias point V_{gs} and V_{ds}, the program automatically computes I_D, g_m, and P, and finally Q.

More information on FET noise modeling can be found in the literature [25–31].

MOSFET Noise Model. The MOSFET noise model (Figure 2-125 and Table 2-27) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. It can be turned off by specifying SN = 0. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).

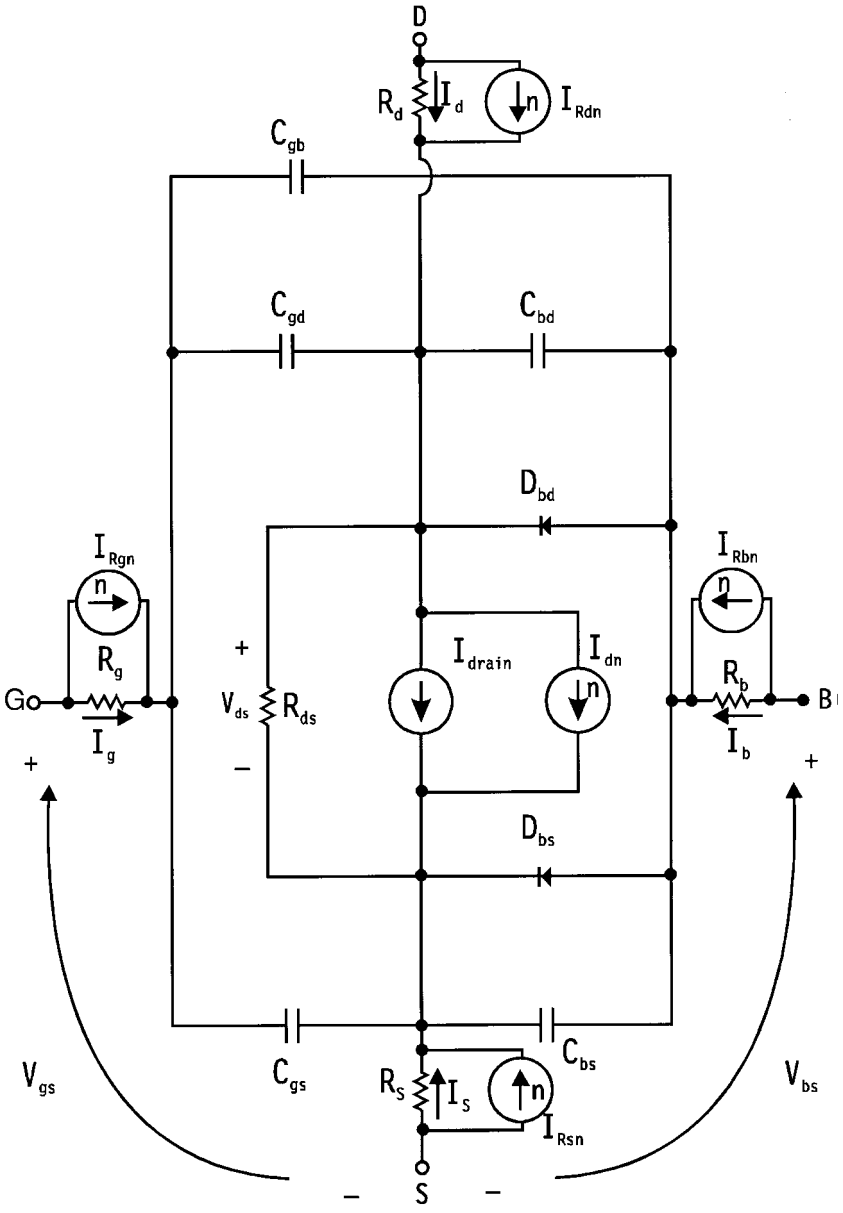

Figure 2-125 Equivalent noise circuit of an intrinsic MOSFET device.

Table 2.27 MOSFET noise model keywords

Keyword	Description	Unit	Default
VGS	Required gate–source bias for the data point	volt	
VDS	Required drain–source for the data point	volt	
VBS	Required drain–bulk for the data point	volt	
KF	Flicker noise coefficient		1.0E–13
AFT	Bias exponent of the flicker noise model		2.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

2. Using bias-dependent flicker noise coefficients through a reference (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Enhanced SPICE Noise Model.* This option is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model (the flicker noise is considered bias dependent).

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with drain current). The MOSFET noise model data are given and referenced by a model parameter.

Notes on the MOSFET Noise Model

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as MOSFET noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Let Δf be the bandwidth (normalized to 1 Hz). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{dn}^2 \rangle = \frac{8kTg_m}{3}\Delta f + \mathrm{KF}\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\Delta f$$

$$\langle i_{Rgn}^2 \rangle = 4\frac{kT}{R_g}\Delta f$$

$$\langle i_{Rdn}^2 \rangle = 4\frac{kT}{R_d}\Delta f$$

$$\langle i_{Rsn}^2 \rangle = 4\frac{kT}{R_s}\Delta f$$

$$\langle i_{Rbn}^2 \rangle = 4\frac{kT}{R_b}\Delta f$$

We include this MOSFET noise model (used for quite awhile) for completeness. At the moment, we do not know which MOSFET noise model the industry will settle on in the future.

Modern CAD tools, such as Ansoft's Serenade product, use these models to generate quite accurate noise data based on a good linear equivalent model. Internally Serenade uses the noise-correlation-matrix method (first introduced by Russer). The same noise-correlation techniques apply to BJTs, all FETs except MOS, and HBTs (such as SiGe devices).

2-4-4 Scalable Device Models

Since diodes and transistors are scalable, here are guidelines for how to scale them:

Microwave Diode

$$I_D = Area \times I_D$$
$$C_j = Area \times C_j$$
$$R_D = R_D/\text{Area}$$

PIN Diode

$$I_D = \text{Area} \times I_D$$
$$C_j = \text{Area} \times C_j$$
$$R_S = R_S/\text{Area}$$
$$R_{\max} = R_{\max}/\text{Area}$$

Bipolar

$$I_{bf} = \text{Area} \times I_{bf} \qquad I_{br} = \text{Area} \times I_{br}$$
$$I_{le} = \text{Area} \times I_{le} \qquad I_{lc} = \text{Area} \times I_{lc}$$
$$I_{cf} = \text{Area} \times I_{cf} \qquad I_{cr} = \text{Area} \times I_{cr}$$
$$C_{bc} = \text{Area} \times C_{bc} \qquad C_{be} = \text{Area} \times C_{be}$$
$$C_{bx} = \text{Area} \times C_{bx} \qquad R_{bb} = R_{bb}/\text{Area}$$
$$\text{RB2} = \text{RB2/Area} \qquad \text{RC2} = \text{RC2/Area}$$
$$\text{RE1} = \text{RE1/Area} \qquad I_{jss} = I_{jss} \times \text{Area}$$
$$C_{jss} = C_{jss} \times \text{Area}$$

Materka FET

$$\begin{aligned}
\text{IGSS} &= \text{IGSS} \times \text{Area} \\
\text{CGS0} &= \text{CGS0} \times \text{Area} \\
\text{CGS1} &= \text{CGS1} \times \text{Area} \\
\text{CDVC} &= \text{CDVC} \times \text{Area} \\
\text{CDVS} &= \text{CDVS} \times \text{Area} \\
R_G &= R_G \times \text{Area}/(\text{Number of fingers} \times 2) \\
R_D &= R_D/\text{Area} \\
R_S &= R_S/\text{Area}
\end{aligned}$$

Generating a Databank for Parameter Extraction. Given the fact that one can measure with an automated system (Rohde & Schwarz, Hewlett-Packard) the bias-dependent *S* parameters of any active device, bipolar and FET, and furthermore, that Hewlett-Packard makes a computer-controllable dc *I–V* curve tracer, we can generate a huge databank that allows us to have corresponding values for both RF and dc operating points. To validate this, one needs to run a large-signal simulator, such as Ansoft's Serenade Design Environment, or its equivalent from other manufacturers, enter the large-signal parameters, and generate a set of *S*-parameters that correspond to the dc values for which we have measurements. The agreement between measured and predicted points for both RF and dc values is a good measure to evaluate the accuracy of the parameter extraction and the simulator's performance. We cannot stress often enough, however, the fact that while most simulator models are quite good, the weakest point of the link is the parameter extraction program.

Currently, the best parameter extraction for bipolar transistors and FETs, excluding the BSIM model, is implemented in the Scout program by Ansoft, based on modified techniques found in the literature. These techniques are based on the fact that present-day nonlinear modeling of microwave devices, especially FETs, is not exactly adequate to describe all effects found within these devices. In the case of FETs, the most troublesome parameter is R_{DS}, which is really more bias dependent than practically all existing models take into consideration. Techniques used in published extraction methods extract nonlinear models independently for each section of a device model, and then assume that the proper response will be generated when all parts are put together. For instance, many extraction techniques independently fit the *I–V* data of the section describing the *I–V* curves and then fit the *C–V* data to the equivalent small-signal models. This results in an approximation to the bias-dependent response of the complete model.

In the technique used in the Scout program, model parameters are extracted simultaneously so the effects between model sections are accounted for and the device is treated as a whole. The most critical area happens to be in the linear region, typically around the pinchoff area, and for very small supply voltages. The Scout techniques use measured data taken at a wide variety of bias ranges and frequencies to define the model response. The possible solution region for the complete model becomes well identified and uniqueness of solution is vastly improved. The Scout program is interactive in nature and displays simultaneously measured versus predicted data. This allows for fine-tuning of the parameters.

Over the years, the industry has adapted a large number of models. Those supported by the Scout parameter extraction program include:

- *npn* Gummel–Poon BJT
- *pnp* Gummel–Poon BJT

- *npn* heterojunction BJT
- *pnp* heterojunction BJT
- General-purpose *n*-channel JFET
- General-purpose *p*-channel JFET
- Chalmers (Angelov) MESFET/HEMT
- Curtice–Ettenberg cubic MESFET/HEMT
- Curtice quadratic MESFET/HEMT
- IAF (Berroth) MESFET/HEMT
- Modified Materka–Kacprzak MESFET/HEMT
- Raytheon (Statz) MESFET/HEMT
- TriQuint (TOM-1 and TOM-2) MESFET/HEMT
- Ansoft physics-based MESFET

The Ansoft physics-based MESFET model is unique and politically sensitive because its users are essentially required to enter all device fabrication parameters to get the appropriate answer, and most, if not all, companies will stay away from handing out such company proprietary recipes. The validation of this model was done using manufacturing data for transistors that were developed under government contract and therefore accessible for the team members. Compact Software/Ansoft over the last ten years has been involved in a large number of government-funded research and development programs, and practically all modern modeling implementations and their validation were done in conjunction with the largest semiconductor manufacturers.

As far as further validation is concerned, besides our looking at the matching of dc *I–V* curves and *S* parameters, important parameters such as 1-dB compression point, power-added efficiency, and harmonic content are important criteria to evaluate the quality of such an undertaking. As far as hardware is concerned, one needs to have a network analyzer, such as the HP8510 or its equivalent. Its selection is determined by the highest cutoff frequency where measurements are necessary. A dc feed capability, up to several amperes, through the measuring ports, and appropriate power supplies are essential, as is a dc *I–V* curve tracer (HP4145). The built-in various optimizers of the program establish the best possible match between the selected parameters and the measured results.

The area of proper modeling has always been fascinating because the active-device model can make or break first-pass success. Figure 2-126 shows the doubler gain comparison of a model supplied by NEC (the device manufacturer, parameter extraction done with Scout, and parameter extraction supplied from the *Microwave Engineering Europe* (*MEE*) magazine in its CAD review of May 1994). It is somewhat unclear where the *MEE* model came from. The actual task given by *MEE* was to simulate a frequency doubler against measured data. This type of simulation required two areas of high precision, one being the model and the other being the electromagnetic modeling of the discontinuities of the circuit—in this case, a stub element. The circuit itself was very simple. The manufacturer-supplied data gave the poorest results (we believe the parameter extraction came from a third party not quite up to speed in this area). The results that came from the Scout parameter extraction and the third one that *MEE* supplied were fairly close, yet the Scout solution, including the electromagnetic simulation part, gave the best answer. More simulators have since appeared on the market, and it would be interesting to revisit this topic. Figure 2-127 shows a physical layout of the doubler circuit.

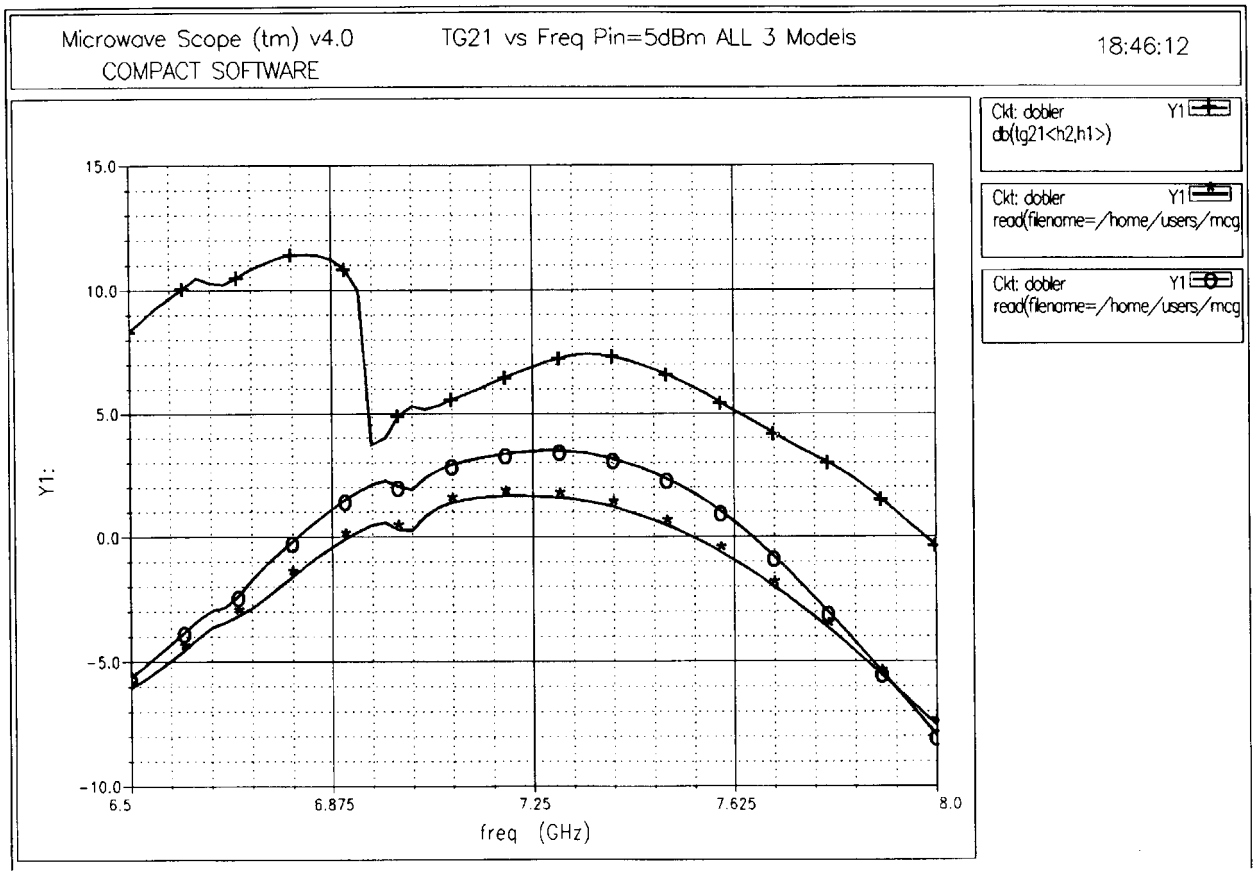

Figure 2-126 Gain comparison of a MESFET doubler based on the three device models used: NEC (+), Ansoft (O), and *Microwave Engineering Europe* (*).

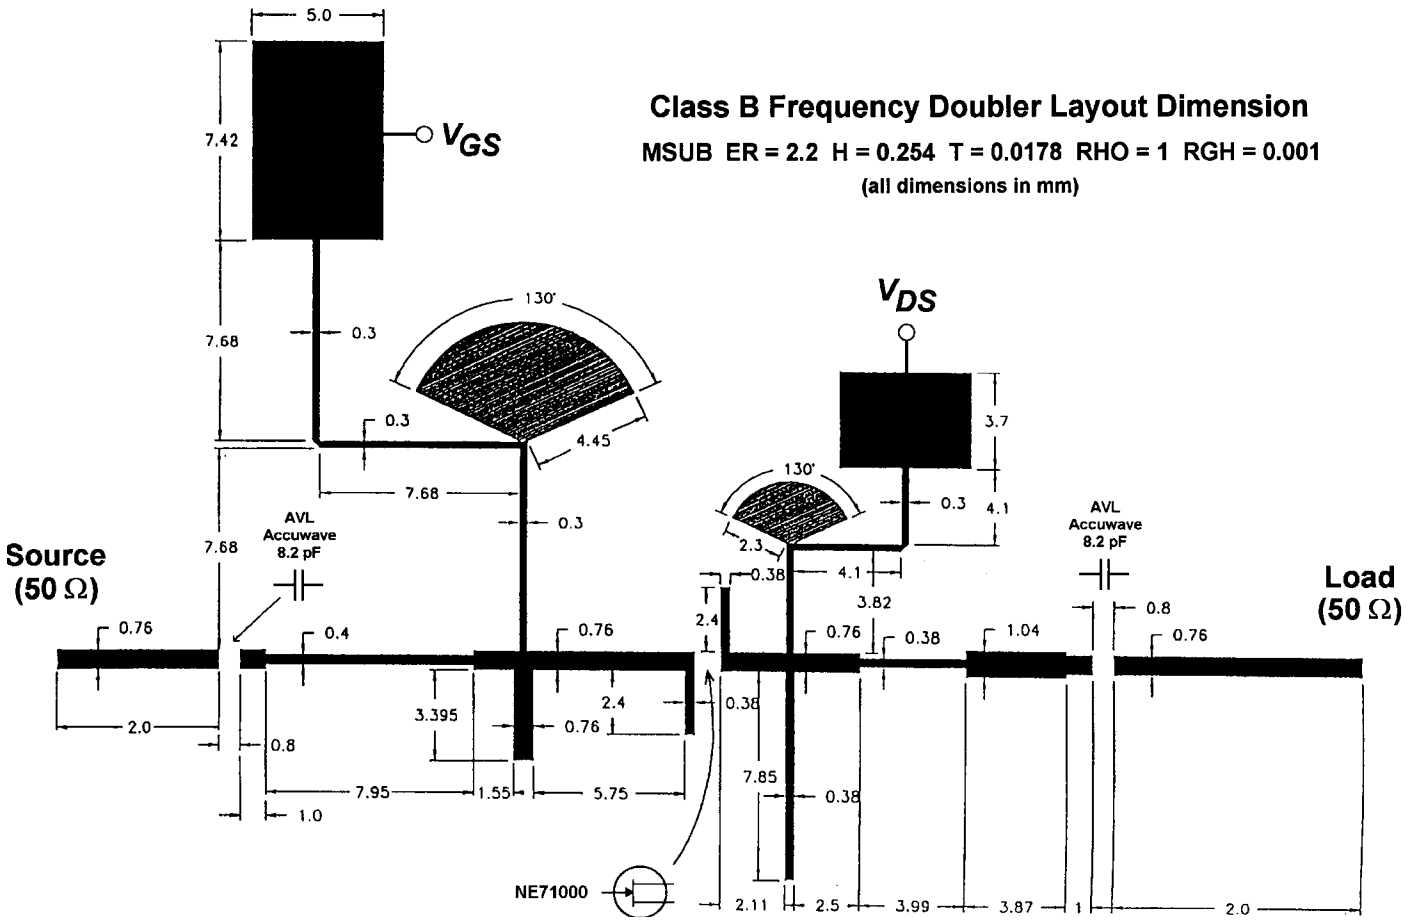

Figure 2-127 Layout of the MESFET doubler.

Test Setup. The measuring equipment required for the actual extraction includes:

- Semiconductor parameter analyzer (HP4145)
- Vector network analyzer (ZVR, HP8510, W360)
- Bias supplies and meters
- Power RF source, power meters, spectrum analyzer, and so on

The required software tools include:

- GPIB controller: Compact NETCOM (network analyzer control program)
- Parameter extraction performed by Scout
- Small-signal and harmonic-balance validation: Serenade nonlinear analysis (Microwave Harmonica) or its equivalent

After we have assembled all these tools, the device extraction process can begin. It will follow the flow as shown in Figure 2-128. Depending on the numbers for the dc/ac measurement, this process can take up to two hours. The Scout program, with its built-in optimizer, can take another two hours. It is therefore reasonable to assume a thorough parameter extraction of a device will take about one day.

Parameter Extraction. As we have outlined, the parameter extraction program Scout, which is optimized for high-frequency and millimeter-wave application, is a Windows-based parameter extraction and optimization program. It requires a network-communication program to acquire dc and *S* parameter measurement data. It supports interactive device fitting and optimization and supports the various models listed earlier. For ease of use, it has an attractive graphical user interface with multiple windows, as can be seen from Figure 2-129. Hewlett-Packard offers more general RF parameter extraction programs, but we did not have access to those. We also expect that some other companies will develop similar tools. An interesting program named HarPE, developed by Professor John Bandler in Canada, may have been withdrawn from the market after his company merger with HP. The program was acclaimed to provide quite good results using measured harmonics. One of the unfortunate deficiencies of most BJT parameter extraction programs known to us is the fact that (as one

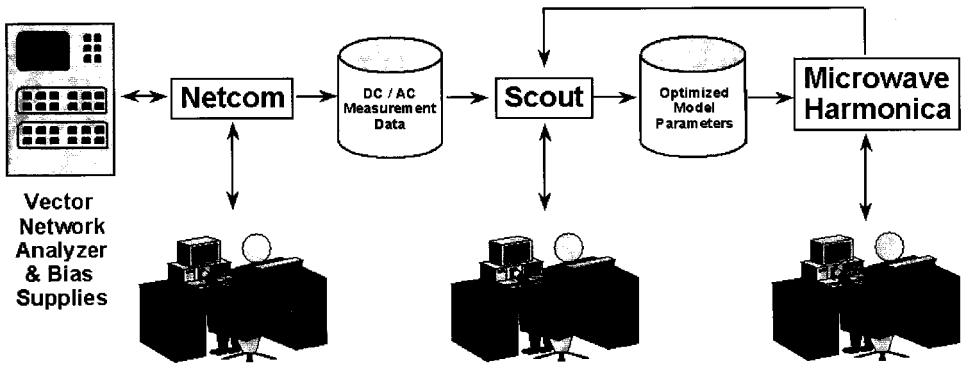

Figure 2-128 Flowchart of the parameter extraction process.

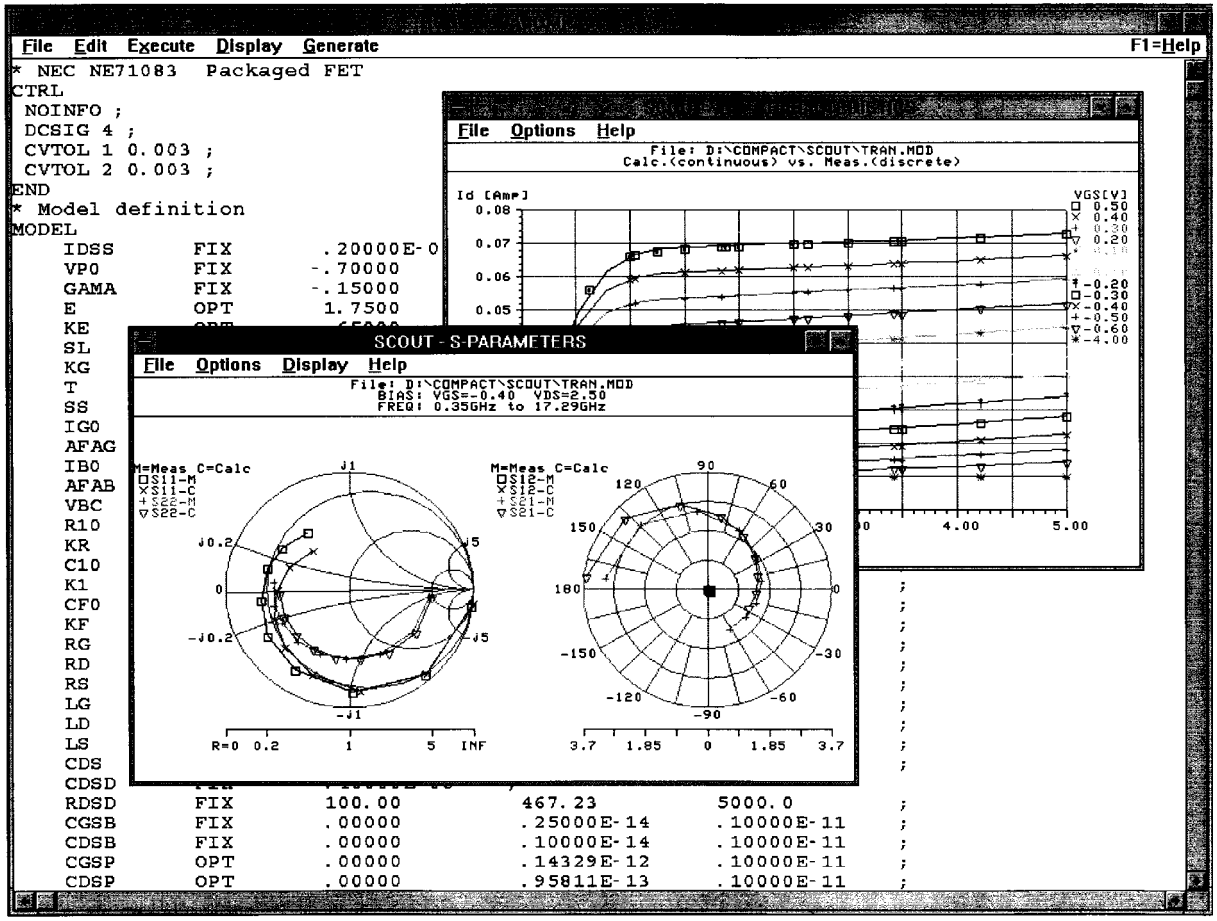

Figure 2-129 The Scout user interface.

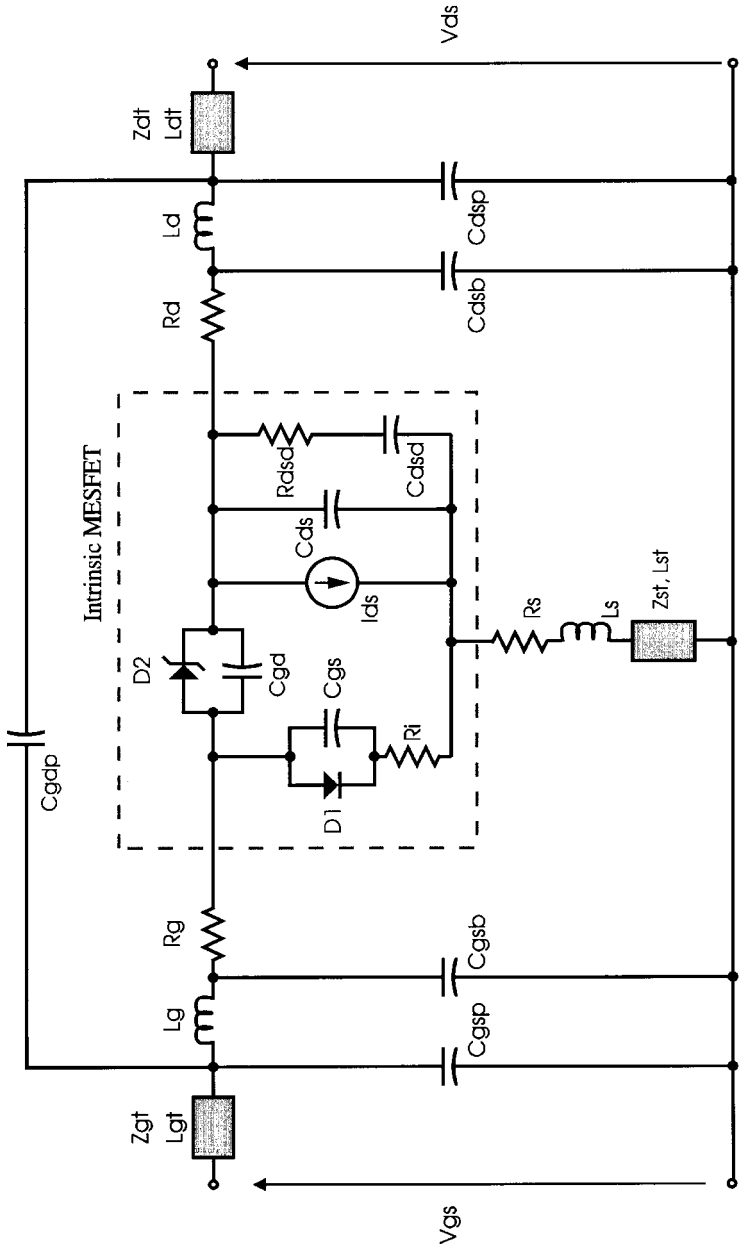

Figure 2-130 Intrinsic model and complete chip/package model.

example) the sensitivity to determine the actual base-spreading resistor for bipolar transistors is poor. The only useful workaround is considering the noise figure of the device, given the fact that the midrange noise factor of any bipolar transistor can be calculated from

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-281)

By solving the equation for R'_{bb}, since we know that R_g, the generator impedance, is 50 Ω, and the emitter diffusion resistance (26 mV/I_C) can be determined from the bias point, we can already eliminate the need to extract R'_{bb} from the HP test equipment. By using HP's program, errors of a factor up to 10 are not uncommon because of the low sensitivity for this parameter. Another headache in the case of the BJT is the determination of the excess phase (PTF) and forward and reverse transit time (TF and TR, respectively). The lack of quality modeling can best be found by examining the measured versus predicted values of S_{22}. Again, practically all the parameter extraction programs we have seen so far suffer from this deficiency.

MESFETs. In the case of a member of the MESFET family, a model as shown in Figure 2-130 is used. It consists of an intrinsic model and a complete chip/package parasitic model. In the case of the MESFET, to obtain first-class results, the following measurements are necessary:

- Dc *I*–*V* measurements
- Dc diode measurements
- Cold-FET and forward-biased-gate *S* parameters
- *S*-parameter measurements over bias
- Harmonic power measurements
- *Z*-Parameter Equations for Figure 2-131

In order to simplify the modeling, it is useful to do cold-FET [Figure 2-131 and Eqs. (2-282), (2-283), and (2-284)] and pinched-FET [Figure 2-132 and Eqs. (2-285), (2-286), and (2-287)] measurements to derive some of the intrinsic or extrinsic values.

$$Z_{11} = R_s + R_g + R_{gs} + \alpha_g R_{ch} + j\omega(L_g + L_s) \tag{2-282}$$

$$Z_{12} = Z_{21} = R_s + \alpha R_{ch} + j\omega L_s \tag{2-283}$$

$$Z_{22} = R_s + R_d + 2\alpha R_{ch} + j\omega(L_s + L_d) \tag{2-284}$$

Capacitance Equations for Figure 2-132

$$C_b = -\frac{\text{Im}(Y_{12})}{\omega} \tag{2-285}$$

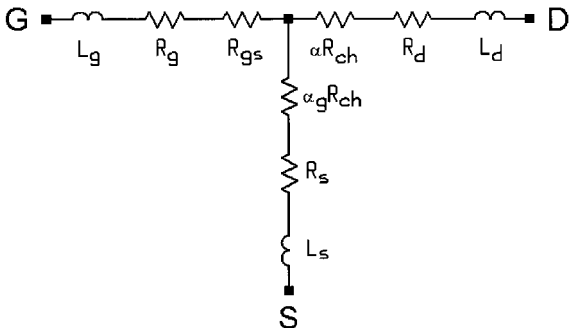

Figure 2-131 Forward-biased gate FET model for cold-FET (V_{DS} = 0, V_{GS} 0) measurements. This approach allows direct extraction of parasitic resistances and inductances.

$$C_{pg} = \frac{\mathrm{Im}(Y_{11})}{\omega} - 2C_b \tag{2-286}$$

$$C_{pd} + C_{ds} = \frac{\mathrm{Im}(Y_{22})}{\omega} - C_b \tag{2-287}$$

For the highest accuracy, the following extraction strategies are recommended:

- Pre-extraction using basic dc and *S* parameters—for example, C_{GS} from S_{11}
- Six extraction steps to determine parameters:
  Basic dc model
  Advanced dc model
  Basic ac model
  Advanced ac model
  Package determination
  Diode characterization
- Large-signal validation
  Power compression and bias shift
  Harmonic power comparison
  Intermodulation characterization

As an example, we are going to use the popular and well-characterized NE71000, which is not a particularly modern device, but has been used for various research projects. Figure

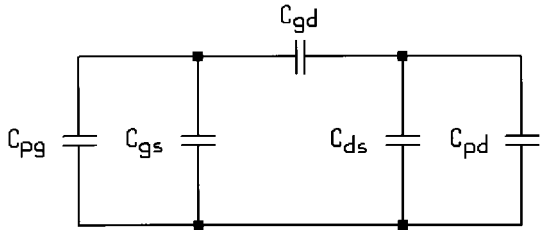

Figure 2-132 Pinched-FET (V_{DS} = 0, V_{GS} *VP*) model. This approach allows direct extraction of parasitic gate and drain capacitances.

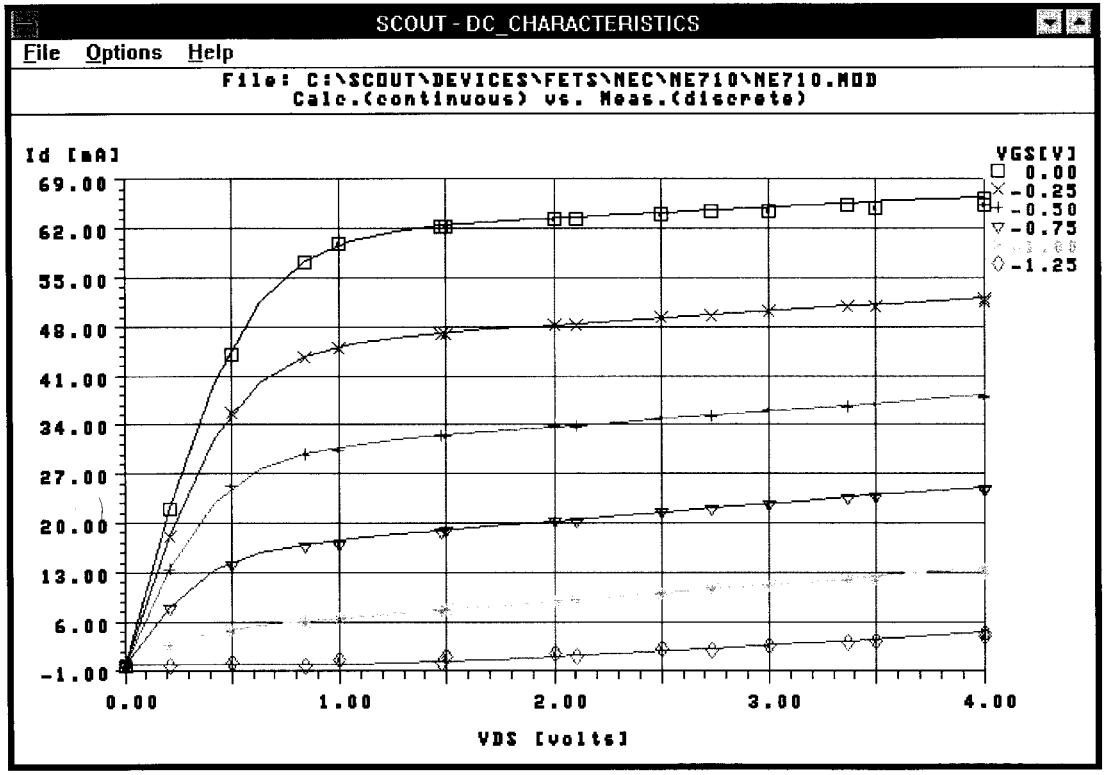

Figure 2-133 Measured NE71000 dc *I–V* curves versus those simulated using the Ansoft Materka model.

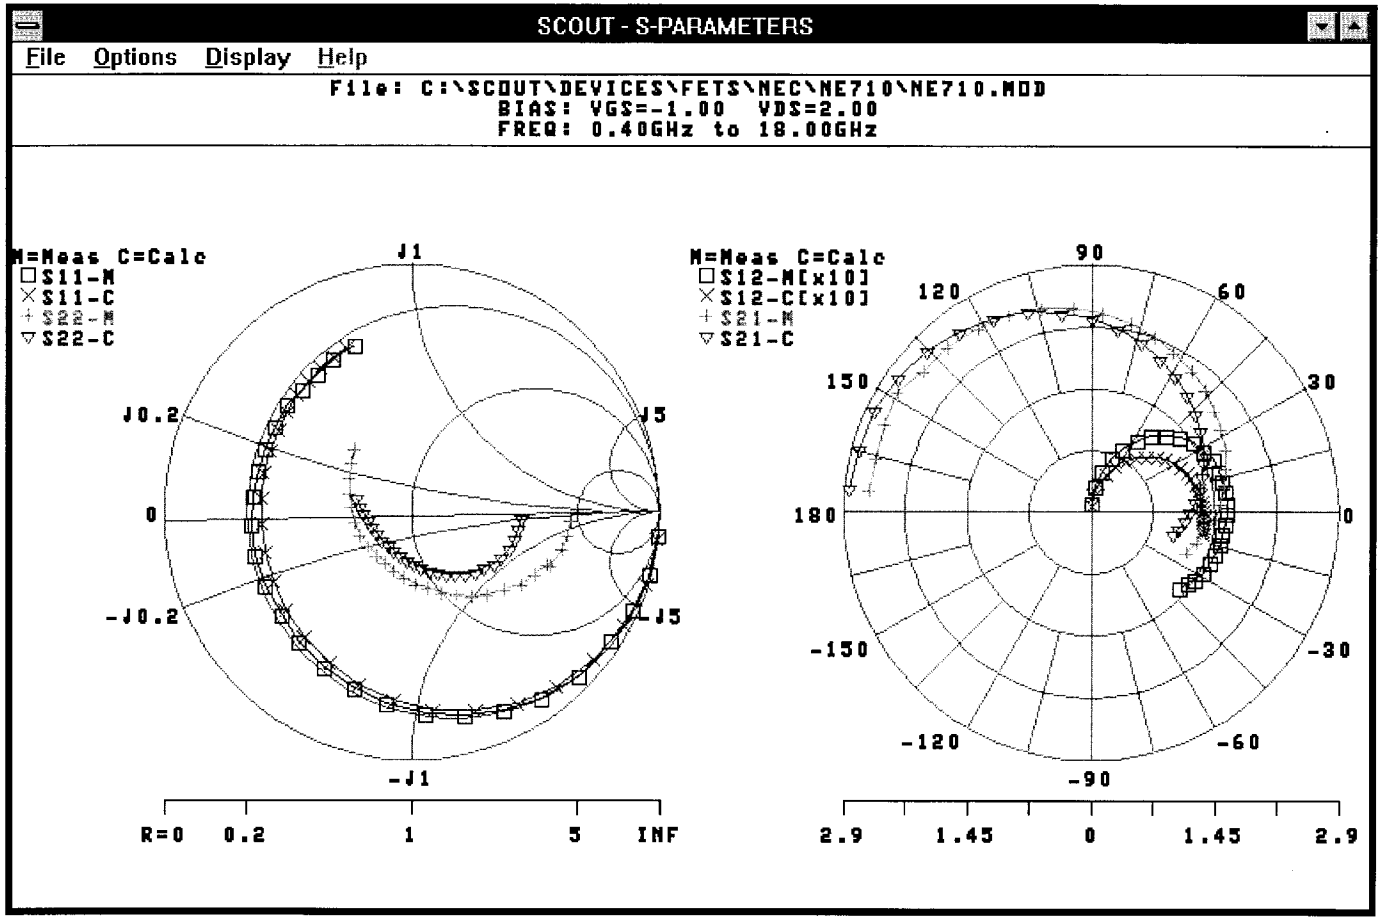

Figure 2-134 Measured versus calculated NE71000 *S* parameters for $V_{GS} = -1.00$ and $V_{DS} = 2.00$.

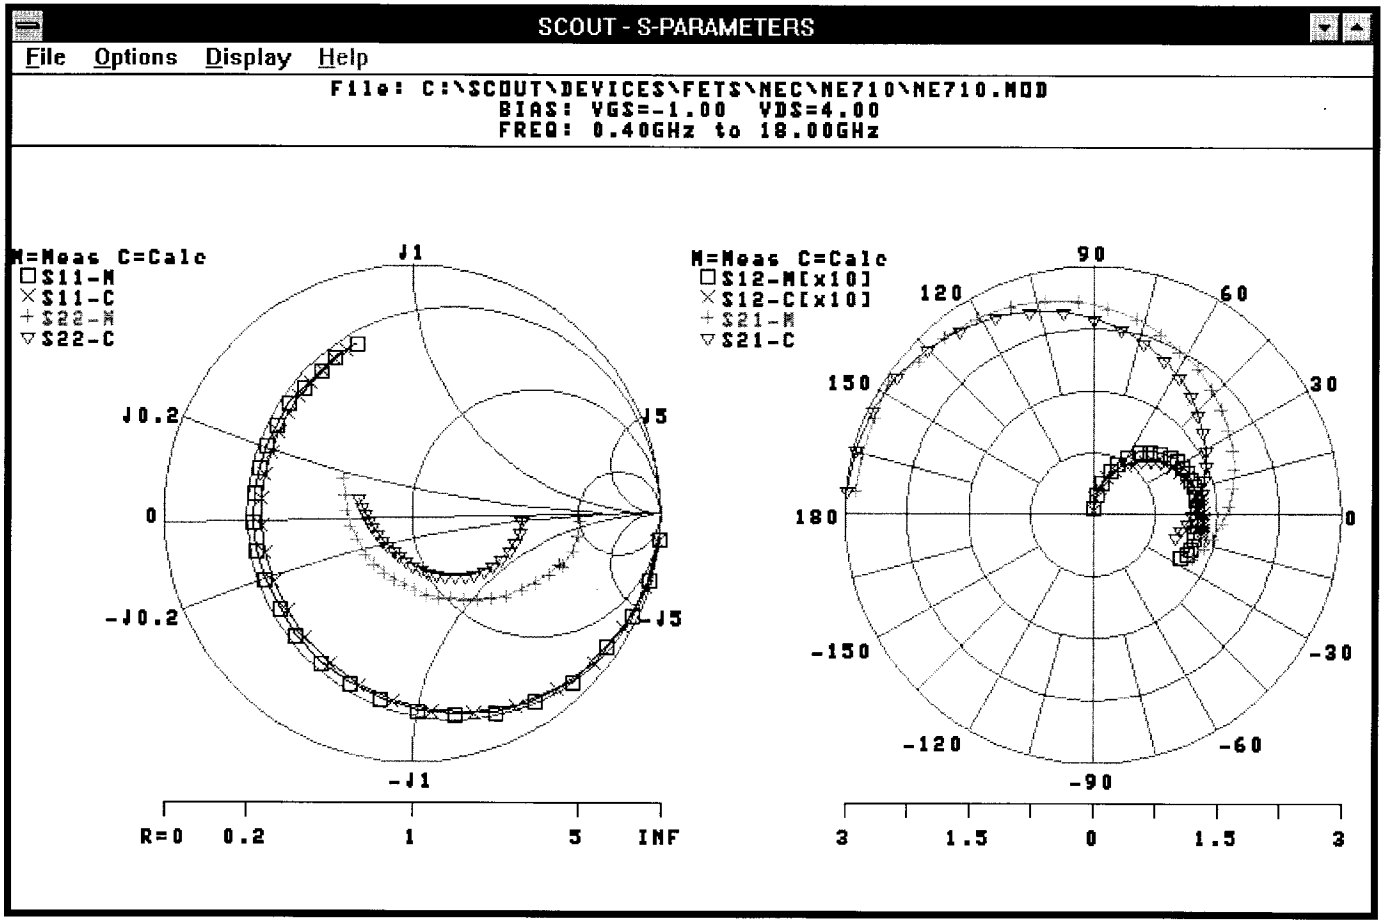

Figure 2-135 Measured versus calculated NE71000 *S* parameters for V_{GS} = –1.00 and V_{DS} = 4.00.

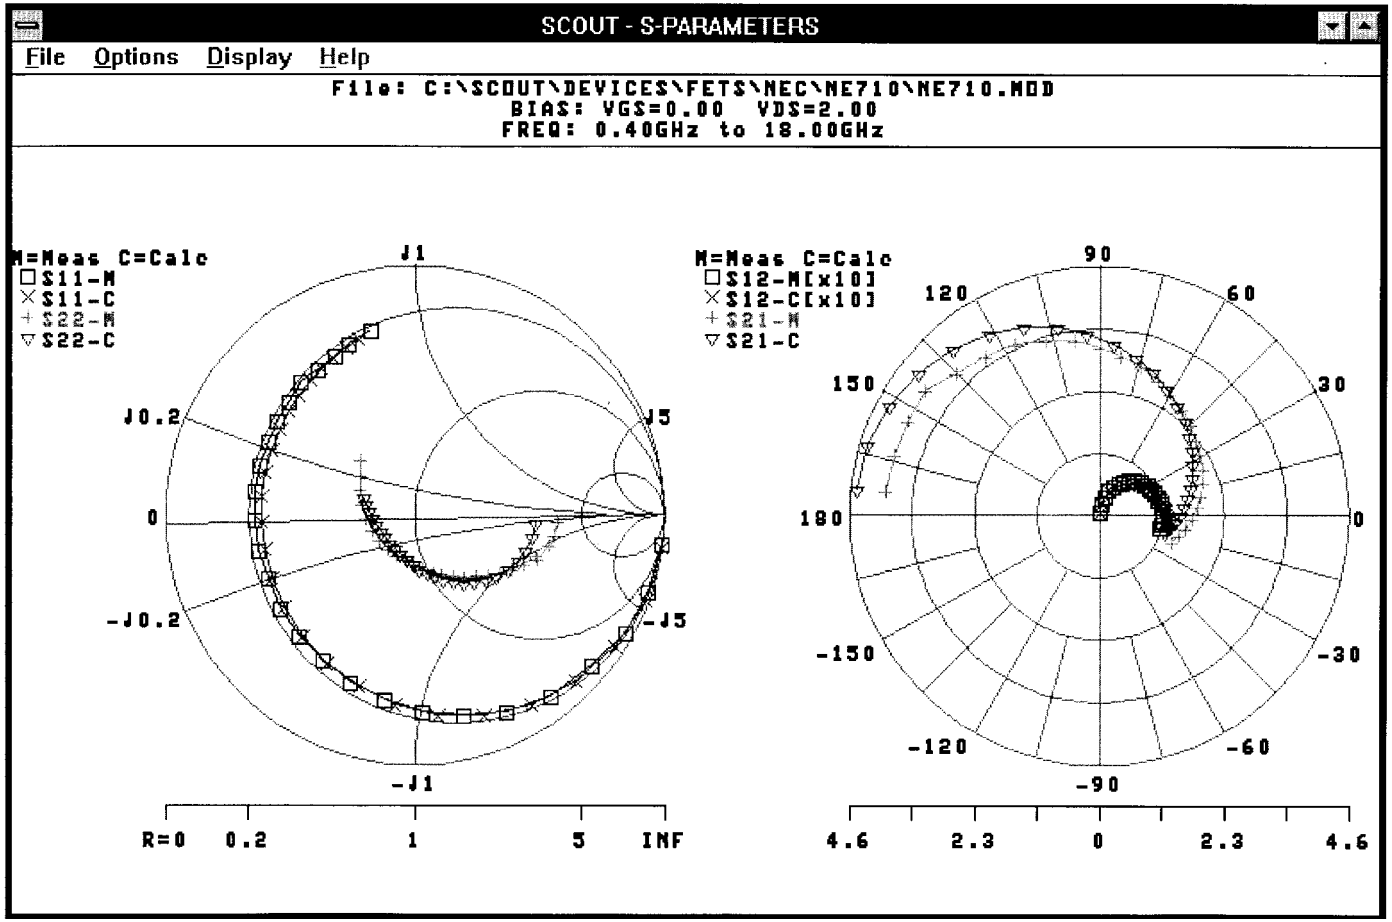

Figure 2-136 Measured versus calculated NE71000 *S* parameters for V_{GS} = 0.00 and V_{DS} = 2.00.

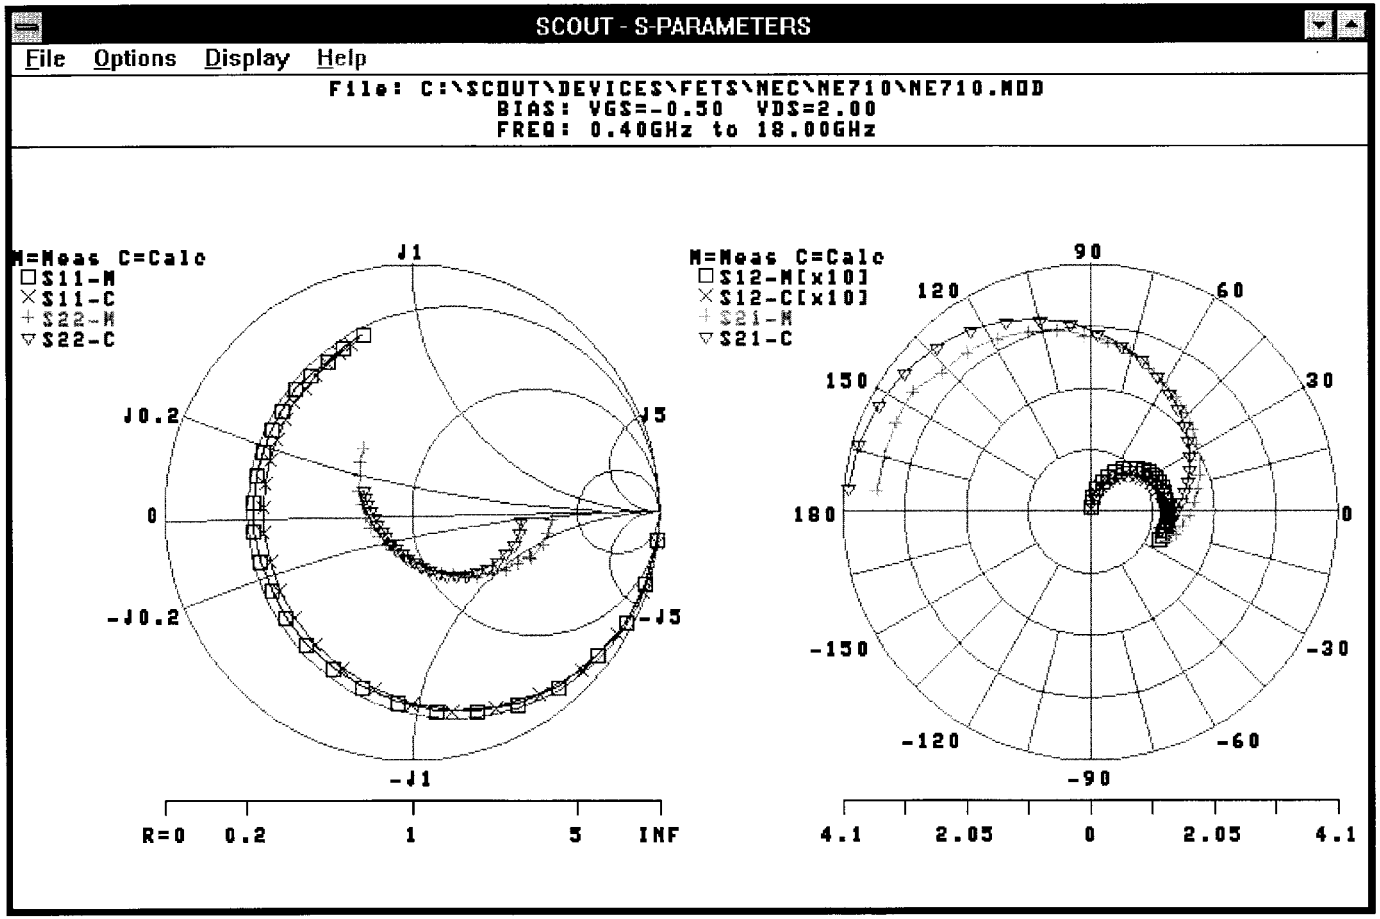

Figure 2-137 Measured versus calculated NE71000 *S* parameters for V_{GS} = –0.50 and V_{DS} = 2.00.

2-133 shows measured versus simulated dc I–V curves for the NE71000. The agreement between measured and predicted dc I–V curves is quite good. In a similar fashion, we obtain the S-parameter fits over bias. They are shown in Figures 2-134 through 2-137.

As mentioned above, 1-dB compression, power saturation, and drain current are functions of the drive. This particular model point is not particularly impressive. We believe this has to do with the original Materka model.

Having brought up the subject of models, Figure 2-138 compares measured data with that obtained with the Angelov, cubic, quadratic, TriQuint, Raytheon, and Materka models. The figure shows that there is no perfect model yet. To put this in perspective, in Figure 2-139 we show the dc I–V error bars for these six models. This graph shows that the least errors for the dc measurement versus modeling are obtained with the Curtice cubic model, followed by the modified Materka model (implemented in Serenade) and TriQuint models. The difference in S parameter matching for RF application is significantly more relevant for the designer.

Things become much more interesting if we compare the S-parameter errors between the Materka shown in Figure 2-140, the Curtice cubic model (Figure 2-141), and the TOM model (Figure 2-142). Improved modeling regarding the R_{DS} is being developed, and we will discuss this at the end of this chapter.

Since the trend is to go to low-voltage power RF operation, several issues must be battled:

- Models are most inaccurate at low V_{DS} and near pinchoff.
- Modeling of low-voltage operation is adversely impacted.
- Thermal effects must be considered, but older models do not account for this.

A Case Study. As a case study, we will consider the Oki KGF1608 power MESFET (0.5 μm × 28 mm). Figures 2-143 and 2-144 show the dc I–V curves and S parameters, respectively. The resolution of the S parameters, based on the scale used, is not particularly impressive.

Figure 2-145 shows the dc I–V curves, with load line, for the KGF1608; the self-heating effect of the transistor can be seen in the droop of the top two curves. Figures 2-146 and 2-147 show drain current and output power versus drive, respectively. The test conditions for these three figures were f = 850 MHz, V_{DS} = 3.4 V, and V_{DS} = 2.025 V.

2-4-5 Conclusions

From all plots of dc and ac error contours, dc I–V curves, and dc error bar charts we can draw the following conclusions.

Dc errors

- *In the Saturation Region*. All the models considered work very well, with a relative error of less than 15%. This means that all models are suitable for typical applications where the device operates in the saturation region.
- *In the Linear Region.* Though the errors in the saturation region are similar for different models, the errors in the linear region are quite different. The Materka, Curtice cubic, and TriQuint models behave better than other models in the linear region. The relative errors of these three models are less than 10%, while other models have more than 60% relative errors at some points.

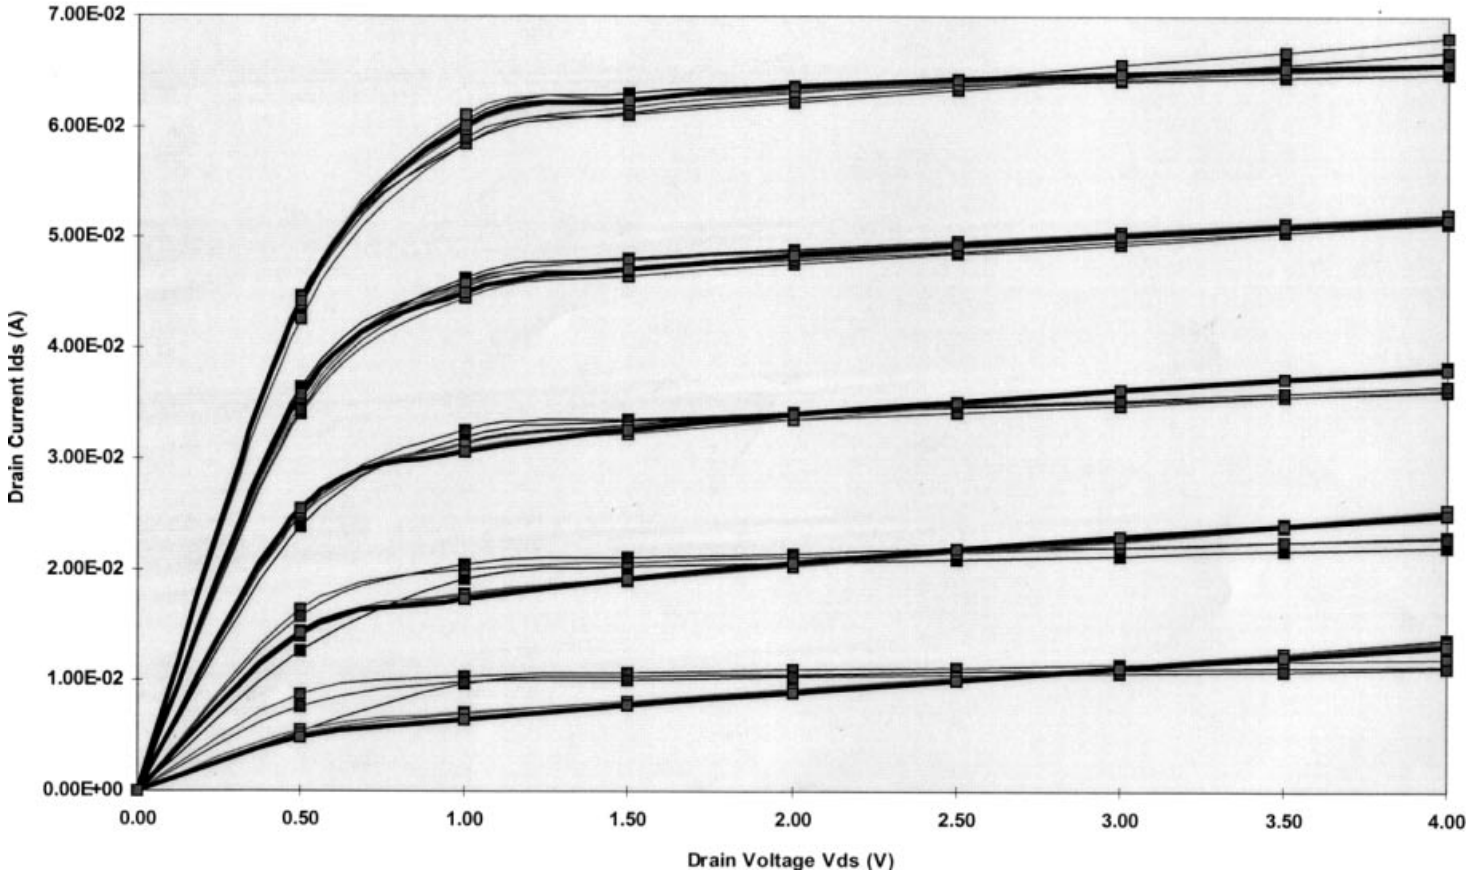

Figure 2-138 Comparison of dc models: Chalmers (Angelov), Curtice cubic, Curtice quadratic, Materka, Raytheon, and TOM (TriQuint).

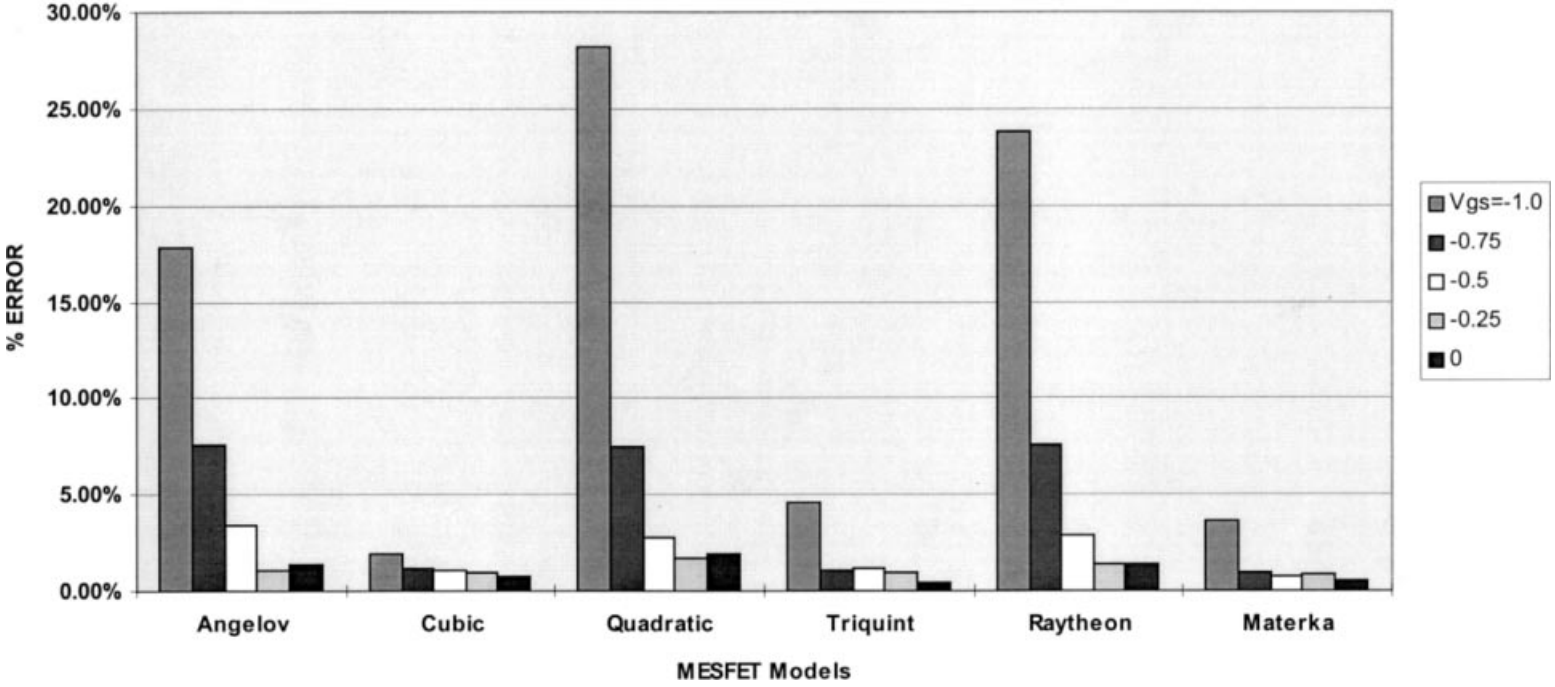

Figure 2-139 Dc *I–V* error bars: Chalmers (Angelov), Curtice cubic, Curtice quadratic, Materka, Raytheon, and TOM.

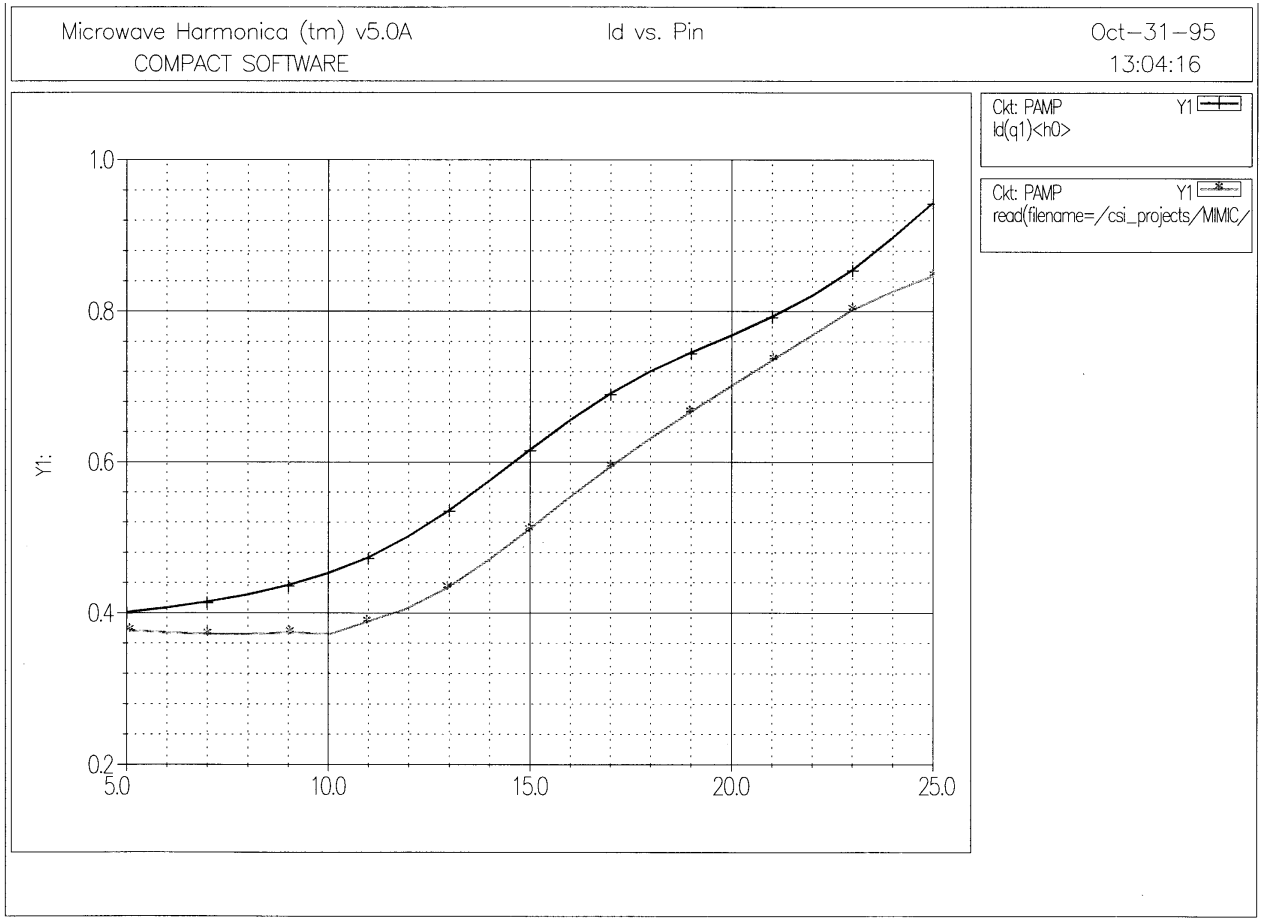

Figure 2-146 Measured versus calculated drain current for the KGF1608 MESFET.

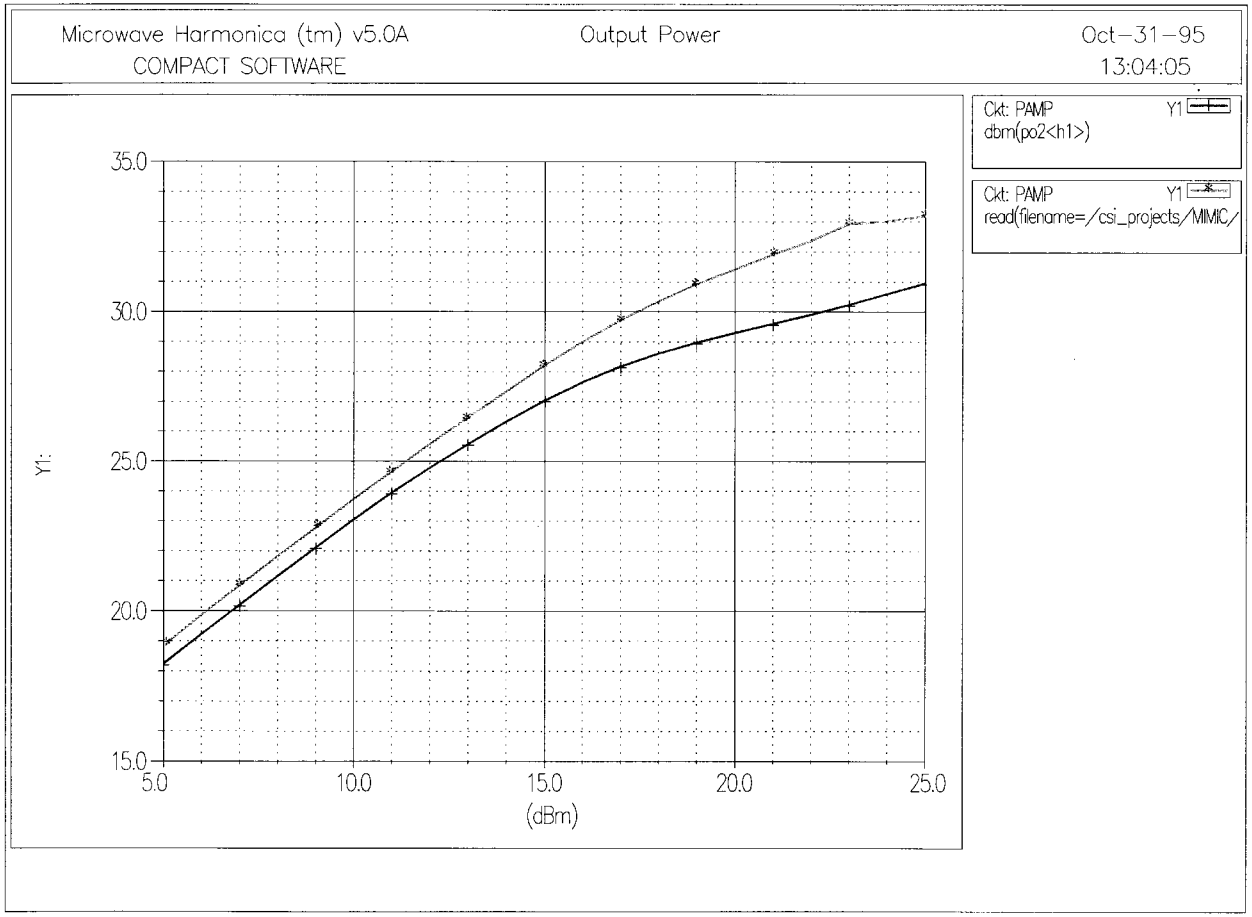

Figure 2-147 Measured versus calculated output power for the KGF1608 MESFET.

ac Errors. From the ac error contour plots we can see that the Chalmers (Angelov) model emerges as the most accurate for ac small-signal operation. The comparison also shows that all models considered are good for ac operations biased in the saturation region with a typical relative error of less than 15%. However, the ac relative errors are much higher in the linear region, particularly for the Curtice quadratic model, which exhibits more than 80% error at some points.

Notes. The above conclusions are based on the matching between the simulated responses of different models and the measured data from a typical NE71000 device; the models may behave differently for a different device. It is not possible to draw any broad-based conclusions as to what model is the best. In order to select the most suitable model for your application, you must consider all the factors, such as bias range, frequency range, and small-signal or large-signal operation, according to your experiences in device modeling.

2-4-6 Device Libraries

All these measurements lead to a nonlinear device library. Figures 2-148 and 2-149 shows a typical datasheet for a device in the library with measured and modeled data. The previous high-power example does not always lead to acceptable results as the models are far from being fully developed. We also show the simulation results using the physics-based model for FETs.

Physics-Based MESFET Modeling. We mentioned a physics-based model earlier. Figure 2-150 shows the measured versus predicted dc *I–V*, I/O power, and *S* parameters for an Alpha Industries MBE MESFET developed under a government contract. The simulation does not handle the trapped energy, which explains the negative slope on the third trace of the output dc *I–V* curve.

The process for bipolar transistors is quite similar and less tricky than the ones just described. Good examples can be found in the user manual for Compact Scout.

2-4-7 A Novel Approach for Simulation at Low Voltage and Near Pinchoff Voltage

As mentioned earlier, the most critical zone is the area of operating the FET both close to the pinchoff voltage and at low operating voltages. A crucial reason for the inadequate results is the modeling of the drain–source resistance as a function of bias point. This is particularly important in calculating the power-added efficiency. When doing your modeling, there is always a temptation to look at both high currents and operating voltages. Figure 2-151 shows a reasonable agreement between measured and predicted dc *I–V* performance. However, the very moment the transistor is modeled close to the linear region (Figure 2-152), things change drastically and the results from 0 to 6 mA have little resemblance to those from 0 to 50 mA. The modified Materka model (Figures 2-153 and 2-154) gives a significantly better match than the Angelov model.

In order to overcome the modeling inaccuracy for the FETs, Thomas Meier of Siemens AG in Munich has come up with the concept of combining two transistors in parallel, whereby the second one is not really connected for dc (Figure 2-155). Figure 2-156 compares measured and simulated R_{DS} using this new approach.

NE67300

Manufacturer : **NEC**
Model Keyword : **NE - 67300**
Device Type : **Mesfet**
Model Type : **Materka**
Package Type : **Chip**

Electrical Characteristics:
Idss : 40mA
Vp : 1.1V
Gain : 8.5dB @ 18GHz
P1db : N/A
Fmin : N/A

Model Data Range:
Vgs : -1.2V to 0.0V
Vds : 0.0V to 4.0V
Freq: 0.4GHz to 18GHz

Verification :
Type : Power sweep, 50Ω
Vgs : -0.6V Vds : 3.0V Ids : 30mA Freq: 6.0GHz

Comments : The S-parameters that appear in the figure were measured and simulated with wire bonds present. The length of each wire bond is approximately 30 mils. To obtain the S-parameters for the manufacture's data sheets, the wire bond inductances would be removed from the equivalent circuit.

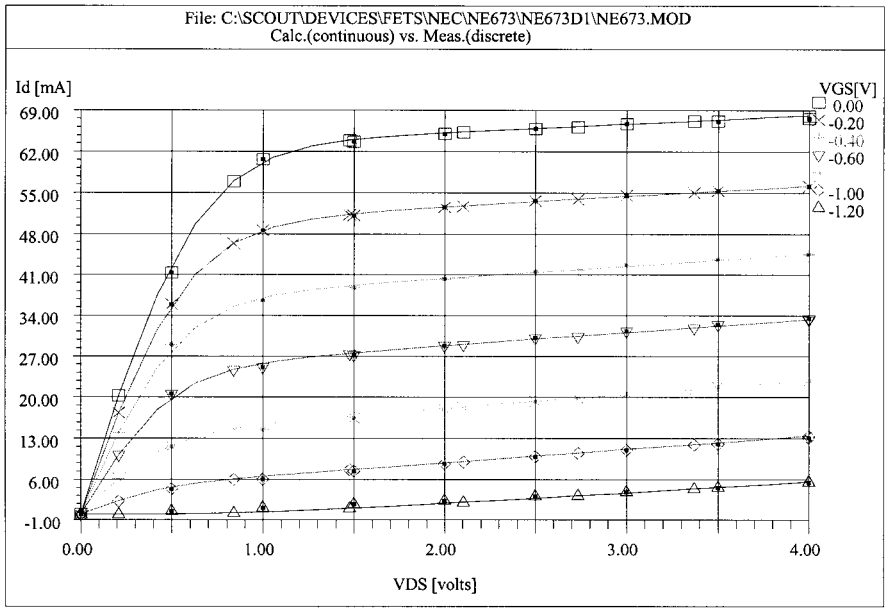

Figure 2-148 Page 1 of a nonlinear device library datasheet for the NE67300.

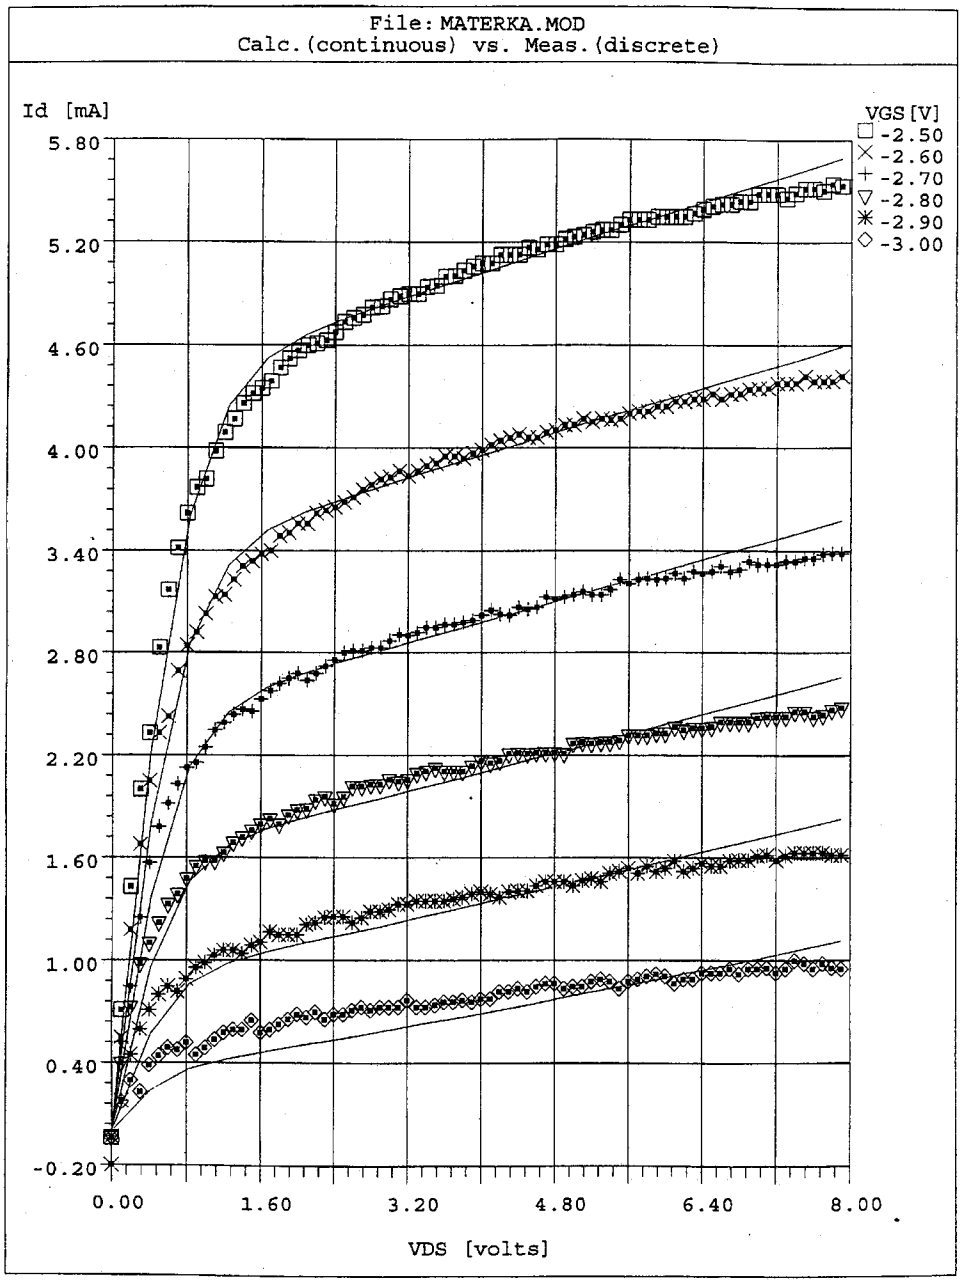

Figure 2-154 Low-I_D dc I–V curves for the modified Materka FET model.

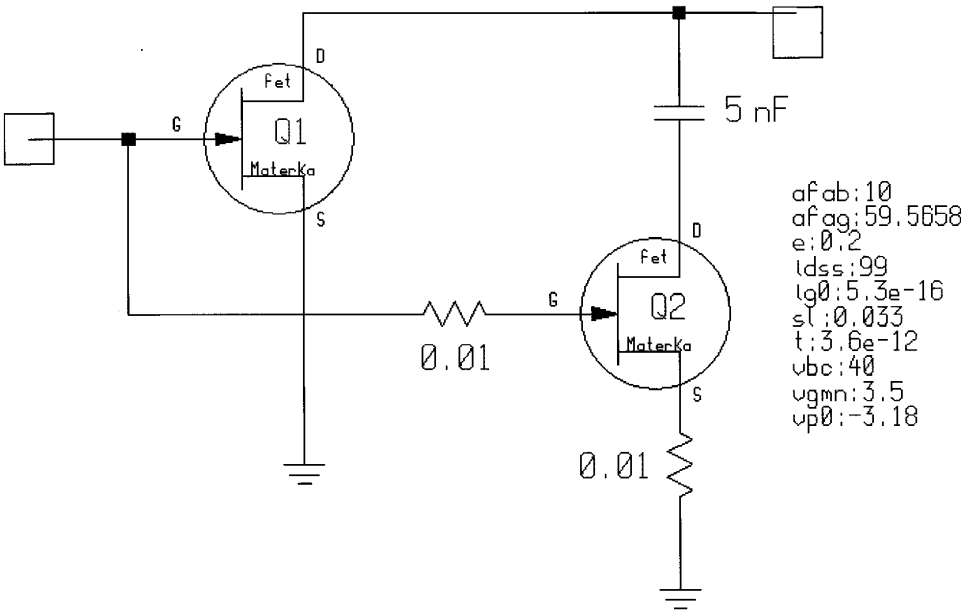

Figure 2-155 By putting two transistors in parallel, with the second one having no dc connection at the drain, one can simulate a dynamic R_{DS} quite well. Regardless of parameter values used for Q1, the parameters listed are necessary to get an accurate R_{DS} result.

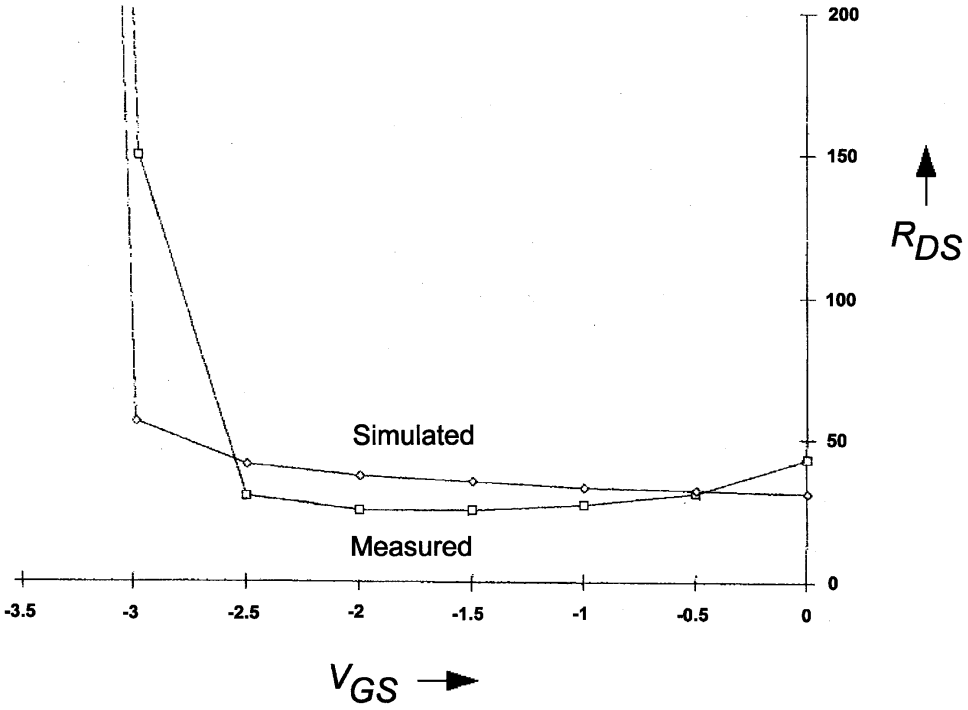

Figure 2-156 Measured versus simulated R_{DS} for the paralleled MESFET approach.

One might ask the question: "Why not fix the existing models?" It turns out that in order to get the best possible convergence and speed, one has to use analytic derivatives for voltage and current; at least the first and second derivatives, if not the third, are required. The programming of such a model becomes so difficult, however, and the calculation of its derivative is so highly likely to have subtle errors, that it turns out that the parallel configuration shown in Figure 2-155 is the best possible compromise for fast computation and accurate results.

A similar approach for bipolar transistors has been discussed by Philips with their MEXTRAM model. However, we have not seen any parameter extraction for this model and also we have not seen any industry acceptance for it. While, in principle, it will cover all derivatives of all members of the BJT family, its topology consists out of three discrete transistors connected and we doubt very much that a reliable parameter extraction program/mathematically continuous model for nonlinear simulation is supplied by the university that developed this jointly with Philips. At the time of writing this book, Philips has not yet provided us with the code for both, and until this happens, we are not in a position to qualify this any further.

2-4-8 Example: Improving the BFR193W Model

We have already mentioned the difficulty encountering the proper base-spreading resistor values and others by using standard parameter extraction programs. Table 2-28 is a copy from the Siemens semiconductor book showing Gummel–Poon Berkeley SPICE syntax parameters for the BFR193W BJT.

The first thing that will happen is that the observant reader will notice that the minimum possible base-spreading resistor, RBM (valid at large current densities), is larger than the actual base-spreading resistor, RB, "claimed to be measured" at 1 Ω (see Table 2-28).

Another headache is caused by the measured noise performance of the same device at an operating point of 10 mA. Using the above-mentioned simplified equation

Table 2.28. BFR193W transistor chip data: SPICE parameters (Gummel–Poon model, Berkeley–SPICE 2G.6 syntax)

All parameters are ready to use, no scaling is necessary. Extracted on behalf of SIEMENS Small Signal Semiconductors by Institut für Mobil-und Satellitenfunktechnik (IMST).

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-288)

we obtain the following results:

1. Inserting 1 Ω (value for RB provided by IMST) and R_B = 15 Ω (measured by the authors), here are the interesting results:

$$F = 1 + \frac{1}{50} + \frac{2.6}{100} = 1.046 \tag{2-289}$$

as noise factor or, as noise figure, F (dB) = 0.2 dB (IMST).

2. Or using the measured 15 Ω, one obtains

$$f = 1 + \frac{15}{50} + \frac{2.6}{100} = 1.326 \tag{2-290}$$

as noise factor or, as noise figure, F (dB) = 1.22.

The Siemens datasheet claims a noise figure of 1.3 dB, and therefore the measured versus calculated data differ by 0.08 dB. Since our noise figure was calculated well below f_T, which is seen from the fact that there are no frequency-dependent terms in the noise figure calculation, it is not unusual that the 900-MHz noise figure is 1.3 dB or slightly higher. This simple example shows how easy it is to provide measurement data that are inconsistent with the laws of physics. It is therefore highly recommended to add the noise figure as an additional parameter in the parameter extraction to reduce the number of variables—specifically, those for which the standard extraction has little sensitivity.

The collector–emitter junction capacitance is another important parameter that frequently gets measured incorrectly. The way around this is to remember the definition

$$f_{\max} = \sqrt{\frac{f_T}{8\pi R'_{bb} C_c}} \tag{2-291}$$

f_T can be measured from the 3-dB point of the emitter current gain (β) and R'_{bb} was just computed above, so the equation can be solved for C_c, as there is a relationship between measured $g_{\max}$ and $f_{\max}$. There are several correlations between the parameters of the equivalent circuit as published in different places, and therefore one can restrict the degree of freedom within the optimization process and obtain much better results. This approach is applicable to all types of transistors, bipolar and FET, and can be used to improve the accuracy of parameters that not only affect a transistor's RF performance but also its noise performance.

MODELS FOR ACTIVE DEVICES

Because we are dealing with amplifiers, both small-signal and power, oscillators, and active mixers, active devices will play a major role in circuit design. At our frequency range of interest (about 1000 MHz and above), distributed elements predominate, and even in device modeling we must consider some distributed effects such as packaging.

As we dive into providing functional explanations of the active devices used in practical circuits, there is some temptation not to provide enough information on semiconductor behavior. Because manufacturers of microwave products will use the services of a foundry or specify semiconductors from their suppliers, we will cover the device operation in depth. That said, for the beginner looking into designing circuits from high frequencies to low microwave frequencies, we will provide examples of a variety of devices unique to this frequency range. Some treatment of device physics will therefore be useful in providing a basic understanding of the nonlinear behavior of active devices and modeling in preparing for practical circuits using a computer-aided-design (CAD) tool. For CAD applications, we assume the user will have access to nonlinear CAD software, such as a high-performance SPICE program or a harmonic-balance program, such as Ansoft Serenade 8.0 or its derivatives. It is interesting that most semiconductor houses today still only offer very limited nonlinear data sets, while in the linear area a large body of useful data is made available, mostly on CDs. What CAD does for us—and this applies to SPICE and harmonic-balance programs alike—is predict the dc bias point of a device in the context of its surrounding circuitry. Configuring the simulation to drive the device into large-signal operation provides us with insight into the various forms of distortion and compression.

In evaluating active devices for RF circuit design, we have a few different technologies to consider. First, we will examine the semiconductor junction diode—a basic *pn* junction—and venture from there to the bipolar transistor. An investigation of metal-oxide semiconductor (MOS) devices, another important set of semiconductors for medium frequencies, will follow. We will also examine the gallium arsenide metal-gate Schottky field-effect transistor (GaAs MESFET) and members of its family. Since critical large-signal parameters for some devices may not be available from their manufacturers, we will examine

parameter-extraction techniques and problems. For various device types, we will provide insight into the noise properties of the device.

2-1 DIODES*

The diode model contains a nonlinear current source that follows the Shockley equation:

$$\text{Current} = \text{IS}\left(e^{V_j/\text{N}V_t} - 1\right) \tag{2-1}$$

where V_j = voltage across the junction
V_t = thermal voltage (= kT/q)

These values, with the model parameters IS and N, are used to model the current–voltage effects of the semiconductor junction. This does not include the nonideal operation of real diodes. For example, at low currents (less than 1 nA), other semiconductor processes that increase the flow of currents become noticeable.

By setting IS to different values, we can obtain the characteristics of other devices, such as a Schottky barrier diode, or a silicon diffused-junction diode. High-current effects are modeled, grossly, by including a series resistance that is intended to combine the effects of bulk resistance (the material on each side of the junction) and high-level injection. At high currents, the observed diode current stops following the Shockley form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/\text{N}V_t} \tag{2-2}$$

and approaches a modified form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/2\text{N}V_t} \tag{2-3}$$

2-1-1 Large-Signal Diode Model

Three diode models are used in the industry:

- Microwave diode model
- PIN diode model
- Enhanced SPICE diode model

Figure 2-1 shows the large-signal microwave diode model. Its keywords appear in Table 2-1. This model can also be used to simulate varactor diodes.

Table 2-2 lists SPICE parameters for a selection of Schottky mixer diodes by Alpha.

In most cases, the diode capacitance is modeled by a voltage-dependent capacitor, which is connected in parallel with the nonlinear current generator described previously, to represent the charge-storage effects of the junction. There are two components to this charge

- The reverse-voltage capacitive effect of the depletion region
- The forward-voltage charge represented by mobile carriers in the diode junction

*Portions of this chapter's diode coverage are based on material in Alpha Industries Semiconductor Application Reports 80800, 80200, and 80500. Used with permission.

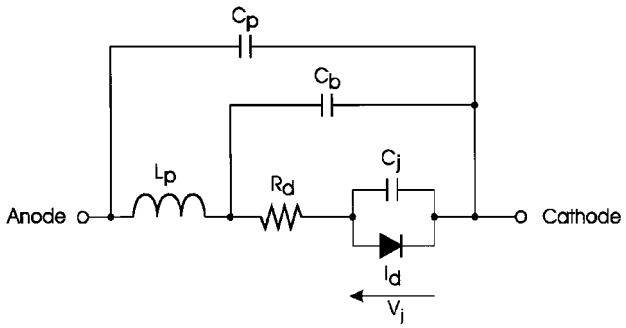

Figure 2-1 The large-signal microwave diode model. This model is temperature dependent.

Reverse-voltage capacitance follows the simple approximation that the depletion region (the area of the junction that is depleted of carriers) serves as the gap between the "plates" of a capacitor. This region varies in thickness, and therefore the capacitance varies with applied voltage. For a step (abrupt) junction, or linearly graded junction, the capacitance approximation is

Table 2-1 Large-signal microwave diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
JS	Saturation current	ampere	0

$$\text{Capacitance} = \frac{C_{J0}}{\left(1 - V_j/\phi\right)^M} \tag{2-4}$$

where C_{J0} is the zero-bias value, ϕ (phi) is the junction barrier potential, and M is the grading coefficient that varies ($\frac{1}{2}$ is used for step junctions and $\frac{1}{3}$ is used for linearly graded junctions, and most junctions are somewhere in between).

There is often confusion about the barrier potential, which appears in the capacitance equation. From capacitance measurements, ϕ (model parameter VJ, and not to be confused with V_j in the equations) takes on a value of nearly 0.7 volt for regular (silicon) junction diodes and a range of 0.58–0.85 volt for various Schottky barrier diodes. This value is sometimes confused with the forward-current voltage drop of the diode or the energy gap of the material; it is *neither* of these.

Varying M generates a variety of reverse-bias capacitance characteristics. Inspection of the capacitance formula reveals that it predicts infinite capacitance for a forward bias, which is not the case for a real junction. Several depletion-capacitance formulas have been proposed that more correctly fit observed operation; however, SPICE uses a simple approach: For forward biases beyond some fraction (set by the parameter FC) of the value for ϕ, the capacitance is calculated as the linear extrapolation of the capacitance at the departure. This provides a continuous numerical result and does not affect circuit operation significantly because, for forward bias, the device capacitance is normally dominated by diffusion capacitance.

The diffusion charge (and therefore the capacitance) varies with forward current and is simply modeled as a transit time (model parameter TT) for the carriers to cross the diffusion region of the junction. The total charge is

$$\text{Diffusion charge} = \text{Device current} \times \text{Transit time} \tag{2-5}$$

and capacitance is the derivative, with respect to bias, of this:

$$\text{Diffusion capacitance} = \text{TT}\,\frac{\text{IS}}{\text{N}V_t}\,e^{V_j/\text{N}V_t} \tag{2-6}$$

Diffusion charge manifests itself as the *storage time* of a switching diode, which is the time required to discharge the diffusion charge in the junction, which must happen before the junction can be reverse-biased (switched off). Storage time is normally specified as the time to discharge the junction so that it is supporting only a fraction (typically 10%) of the initial reverse current. First, a forward current is supplied to the device to charge the junction. Then, as quickly as possible, a reverse current is supplied to the device. Internally, the junction is still forward-biased to a voltage nearly the same as before the switch in current; the junction is still conducting at the forward-current rate. This internal current adds to the external current as the total current discharging the junction. As the junction voltage decreases, the internal current falls off exponentially (according to the Shockley equation). This system is a relatively simple differential equation that can be solved to an explicit equation for the TT parameter (assuming complete discharge) as follows:

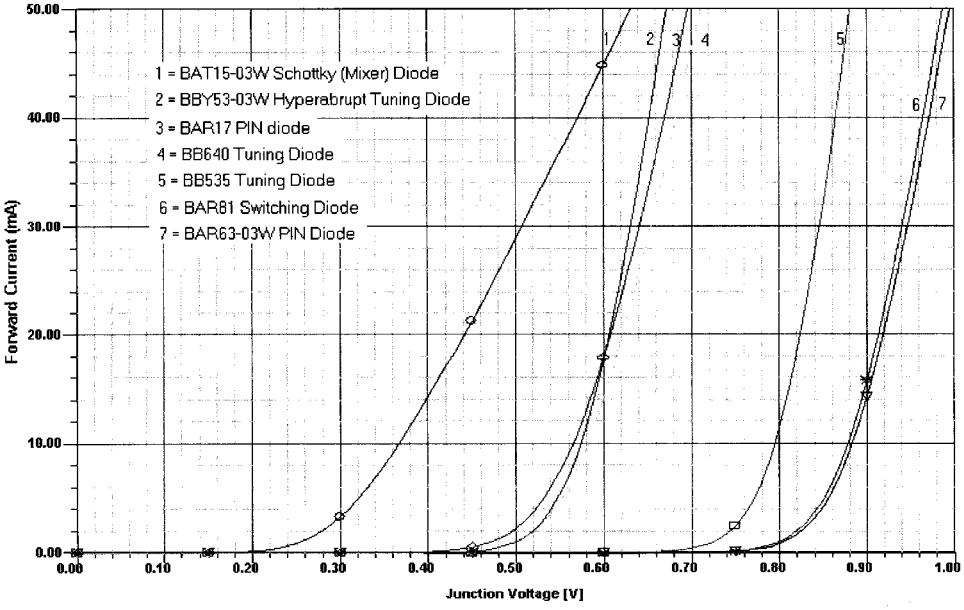

Figure 2-2 The dc *I–V* curves for seven diodes, showing the various barrier voltages that result from different doping profiles.

$$\text{Transit time} = \frac{\text{Storage time}}{\ln\left(\dfrac{I_F - I_R}{-I_R}\right)} \tag{2-7}$$

The diffusion charge dominates the reverse recovery characteristic of the diode. During the last part of the recovery, as the junction becomes reverse-biased, the depletion capacitance dominates. This causes the small tail at the end of the discharge cycle. Total capacitance is taken to be the sum of these capacitances: the depletion approximation dominates for reverse bias as the device current is small, and the diffusion proximity dominates for forward bias as the device current is large.

A special case for diode application is the switching diode, and its description and application will be part of a later chapter. Figure 2-2 shows the dc *I–V* curves, which indicate the different voltage potentials that are a result of the different doping profiles.

2-1-2 Mixer and Detector Diodes

Electrical Characteristics and Physics of Schottky Barriers. Schottky barrier diodes differ from junction diodes in that current flow involves only one type of carrier instead of both types. That is, in *n*-type Schottky barrier diodes the forward current consists of holes flowing from the *n*-type material into the metal.

Diode action results from a contact potential set up between the metal and the semiconductor, similar to the voltage between the two metals in a thermocouple. When metal is brought into contact with an *n*-type semiconductor (during fabrication of the chip), electronics diffuse out of the semiconductor into the metal, leaving a region under the contact that

has no free electrons ("depletion layer"). This region contains donor atoms that are positively charged (because each lost its excess electron), and this charge makes the semiconductor positive with respect to the metal. Diffusion continues until the semiconductor is so positive with respect to the metal that no more electrons can go into the metal. The internal voltage difference between the metal and the semiconductor is called the contact potential and is usually in the range of 0.3–0.8 volt for typical Schottky diodes. A cross section is shown in Figure 2-3.

When a positive voltage is applied to the metal, the internal voltage is reduced, and electrons can flow into the metal. The process is similar to thermionic emission of electrons from the hot cathode of a vacuum tube, except that the electrons are "escaping" into a metal instead of into a vacuum. Unlike the vacuum tube case, room temperature is "hot" enough for this to happen if enough voltage is applied. However, only those electronics whose thermal energy happens to be many times the average can escape, and these "hot electrons" account for all the forward current from the semiconductor into the metal.

One important thing to note is that there is no flow of minority carriers from the metal into the semiconductor and thus no neutral plasma of holes and electrons is formed. Therefore, if the forward voltage is removed, current stops "instantly," and reverse voltage can be established in a few picoseconds. There is no delay effect to charge storage as in junction diodes. This accounts for the exclusive use of barrier diodes in microwave mixers, where the diode must switch conductance states at microwave oscillator rates.

The current–voltage relationship for a barrier diode is described by the Richardson equation (which also applies to thermionic emission from a cathode). The derivation is given in many textbooks (e.g., Sze).

$$I = AA_{\mathrm{RC}}T^2 \exp\left(-\frac{q\phi_B}{kT}\right)\left[\exp\left(\frac{qV_J}{kT}\right) - M\right] \tag{2-8}$$

where A = area (cm^2)

A_{RC} = modified Richardson constant ($\mathrm{A}/K^2 \cdot \mathrm{cm}^2$)

k = Boltzmann's constant

T = absolute temperature (K)

ϕ_{B} = barrier height in volts

V_J = external voltage across the depletion layer (positive for external voltage) = $V - IR_S$

R_S = series resistance

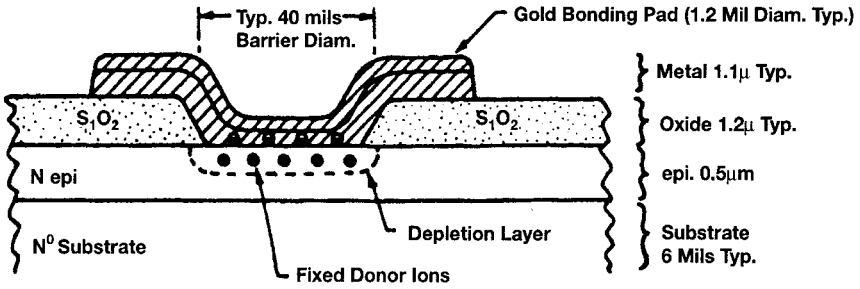

Figure 2-3 Schottky diode chip cross section.

M = avalanche multiplication factor
I = diode current in amperes (positive forward current)

The barrier height, ϕ_B, is typically a few tenths of a volt higher than the contact potential, ϕ_C (about 0.15 V higher than ϕ_C for silicon). This equation agrees well with experimental data for diodes without surface leakage, but it is difficult to use because A_{RC}, ϕ_B, and M are all dependent on applied voltage.

The major cause for variation in ϕ_B with voltage is the "image effect," in which the barrier height is lowered as the electric field near the metal is increased, especially at the edges. A better equation for circuit designers to use is one in which all parameters are independent of voltage and current. The simplest one that agrees reasonably well with Richardson's equation is

$$I = I_S\left[\exp\left(\frac{V_J}{0.028}\right) - 1 + \frac{K}{\left(1 - V_B/V\right)}\right] \tag{2-9}$$

where I_S = saturation current (a temperature-dependent quantity)
0.028 = nkT/q at room temperature (n = 1.08)
n = forward slope factor (derived from the variation of ϕ_B with forward voltage)
K = reverse slope factor (expressing the variation of ϕ_B with reverse voltage)
V_B = breakdown voltage (the voltage at which M = 1)

As before, V and I are considered positive for forward bias and negative for reverse bias.

Typical ranges for these parameters for microwave Schottky and point-contact mixer diodes are:

I_S = 10^{-12} to 10^{-5} A
n = 1.04–1.10
R_S = 2–20 Ω
K = 8–100
V_B = 2–20 V

The quantities I_S and 0.028 are strongly temperature dependent, while both R_S and V_B increase with temperature to a slight degree. R_S increases with current at high current levels (due to carrier velocity saturation) but is essentially independent of current at 10 mA and below for mixer diodes. Thus, for normal mixer and detector operation, R_S can be considered constant.

Agreement between Eqs. (2-8) and (2-9) is not perfect but Eq. (2-9) is much easier to use and is preferred by most circuit designers. A comparison of the two equations near zero bias gives the following relationship between zero-bias barrier height, ϕ_0, and saturation current:

$$I_S = AA_{RC}T^2\exp - \frac{q\phi_0}{kT}$$

$$\cong \left(\frac{10^7 A}{\text{cm}^2}\right)A\exp\left(-\frac{\phi_0}{0.026}\right) \quad \text{(for } n \text{ silicon at room temperature)} \tag{2-10}$$

Small-Signal Parameters. By combining Eqs. (2-9) and (2-10), the values of the parameters in Eq. (2-9) can be derived from a few simple measurements. Many specific equations can be derived, but the following are commonly used for production measurements:

$$R_S = \frac{V_{F10} - V_{F1} - 0.065}{0.009} \quad (\text{for } n = 1.08) \tag{2-11}$$

$$\phi_0 = \frac{V_{F1} - 0.001R_S + 0.28 + 0.12\log_{10} D}{1.08} \tag{2-12}$$

$$n = \frac{V_{F1} - V_{F0.1} - 0.0009R_S}{0.060} \tag{2-13}$$

$$K = \left(\frac{I_{R1}}{I_S} - 1\right)V_B \tag{2-14}$$

$$I_S = \exp\left(-\frac{V_{F1}}{0.028} + \frac{R_S}{28}\right) \quad (\text{in mA}) \tag{2-15}$$

where $V_{F0.1}$, V_{F1}, and V_{F10} are the forward voltages at 0.1, 1, and 10 mA, respectively, and I_{R1} is the reverse current at 1 volt. (The derivation of these equations requires that I_S be small compared to 0.1 mA.) The quantity D is the diameter of the metal–silicon contact in mils.

Measuring V_{F1} at 1 mA and 10 mA instead of some other current levels leads to the best accuracy for typical mixer diodes.

The total dynamic resistance for a forward-biased diode is given by

$$R_T = \frac{dV}{dI} = R_S + \frac{nkT}{q(I + I_S)} = R_S + R_B \tag{2-16}$$

and

$$R_B = \frac{28}{I + I_S} \quad \text{at room temperature (with } I \text{ and } I_S \text{ in mA, } n = 1.08) \tag{2-17}$$

This equation is also good at zero bias (unless K is very large or there is significant surface leakage). That is,

$$R_0 = R_S + \frac{28}{I_S} \tag{2-18}$$

For reverse voltages of a few volts, the dynamic resistance is dominated by the K term:

$$R_R = \text{Reverse resistance} = \frac{dV}{dI} \cong \frac{V_B}{KI_S} \tag{2-19}$$

For typical values of I_S, R_0 is larger than 5000 Ω and R_R is larger than 100 kΩ. For some zero-bias Schottky applications, it is desirable for R_0 to be made smaller than this.

The factors that determine R_S are (1) the thickness of the epitaxial layer, (2) the epitaxial layer doping level (N_D), (3) the barrier diameter, (4) the substrate resistivity ("spreading resistance"), (5) the contact resistances of the metals used for the barrier and the substrate contact, and (6) the resistance associated with the bonding wire or whisker. The barrier height is about 0.15 volt higher than the contact potential between the barrier metal and the semiconductor and is influenced by the method used to apply the metal, conditions at the edge of the junction, and the doping level. Saturation current depends on barrier height, junction area, and temperature; and the slope factors, n and K, depend on doping level, punchthrough voltage, and edge conditions.

Junction Capacitance. The capacitance of a Schottky barrier chip results mainly from two sources: the depletion layer under the metal–semiconductor contact and the capacitance of the oxide layer under the bonding pad (the so-called overlay capacitance). The bonding pad is required because the typical Schottky barrier diameter is so small that it is impractical to bond directly to the metal on the junction. If the semiconductor epitaxial layer is uniformly doped, the capacitance–voltage characteristic is similar to that of a textbook "abrupt-junction" diode.

$$C_J = \frac{\varepsilon_S \varepsilon_0 A'}{X_D} + C_0 \tag{2-20}$$

$$X_D = \sqrt{\frac{2\varepsilon_S \varepsilon_0 (\phi_C - V)}{qN}} \tag{2-21}$$

where ϕ = contact potential
C_0 = overlay (bonding pad) capacitance
ε_S = dielectric constant of the semiconductor ($\cong$ 12 for Si or GaAs)
N = doping level for the epitaxial layer
A' = effective contact area, including fringing corrections

In practical terms, the capacitance can be related to the 0-V barrier capacitance defined by

$$C_{B0} = \frac{\varepsilon_S \varepsilon_0 A'}{X_{D0}} \tag{2-22}$$

where

$$X_{D0} = \sqrt{\left(\frac{1.3 \times 10^{15}}{N_D}\right)\phi_C} \quad \text{(in } \mu\text{m)} \tag{2-23}$$

The resulting C–V relationship can be written

$$C_J = \frac{C_{B0}}{\sqrt{1 - V/\phi_C}} + C_0 \tag{2-24}$$

The contact potential, ϕ_C, is related to the barrier height as follows:

$$\phi_C = \phi_B - 0.026\left[1 + L_n\left(\frac{N_C}{N}\right)\right] \tag{2-25}$$

The theoretical meaning of these terms can be clarified by looking at Figure 2-4.

Parameter Trade-Offs

Barrier Height. The barrier height of a Schottky diode is important because it directly determines the forward voltage. In order to get a good noise figure, the LO drive voltage, V_L, must be large compared to V_T, which is essentially V_{F1}. Normally, it is best to have a low

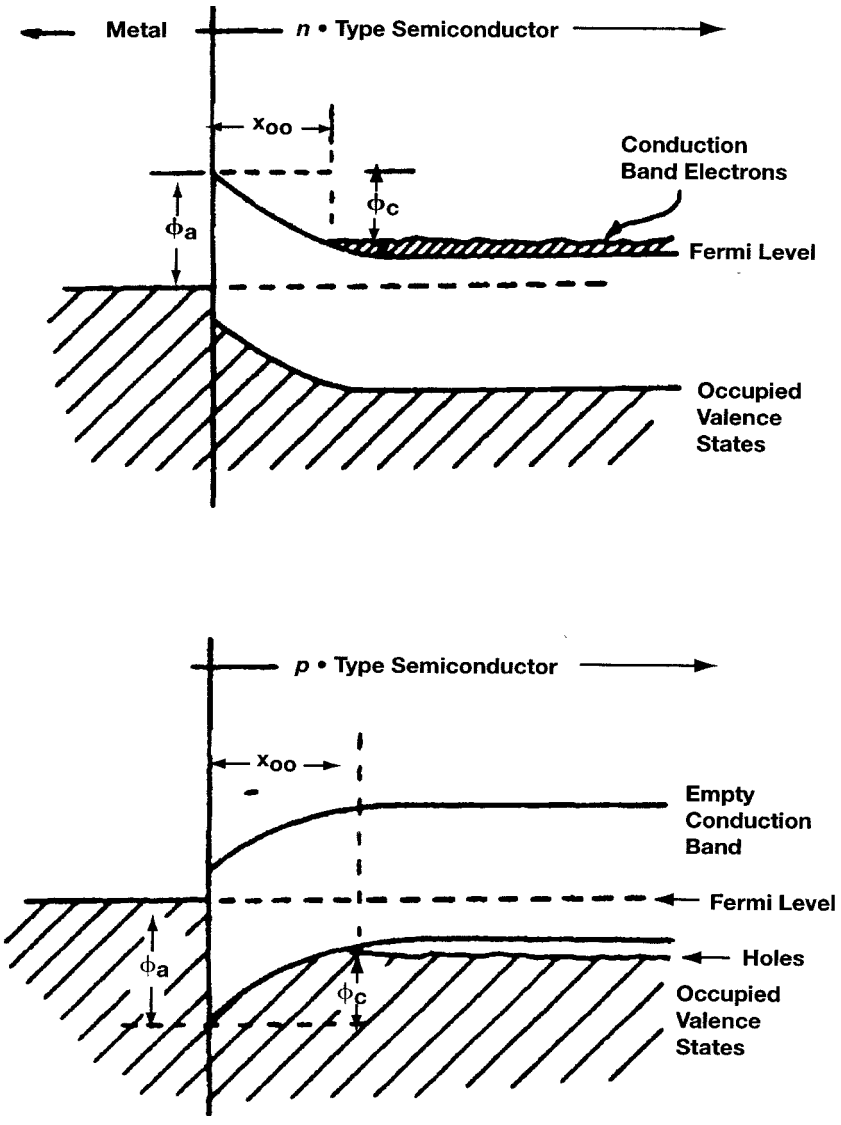

Figure 2-4 Schottky diode band diagrams.

Table 2-3 LO power and V_{F1} for various applications

Type	Typical V_{F1}	LO Power	Application
"Zero bias"	0.10–0.25	< 0.1 mW	Mainly for detectors
Low barrier	0.25–0.35	0.2–2 mW	Low-drive mixers
Medium barrier	0.35–0.50	0.5–10 mW	General purpose
High barrier	0.50–0.80	> 10 mW	High dynamic range

forward voltage (low V_{F1}), or low drive) diode, to reduce the amount of LO power needed. However, if high dynamic range is important, high LO power is needed, and the diode can have a higher V_F and should also have a high V_B (see Table 2-3).

Noise Figure Versus LO Power. At low LO drive levels, the noise figure is poor because of poor conversion loss, due to a too-low conduction angle. At very high LO drive levels, the noise figure again increases due to diode heating, excess noise, and reverse conduction.

If a high LO drive level is needed, for example, to get higher dynamic range, a high V_B (> 5 V) should be specified. However, Nature requires that you pay for this with higher R_S (lower f_C), so the noise figure will be degraded compared to what could be obtained with diodes designed for lower LO drive. Forward voltage and breakdown are basically independent parameters, but high breakdown is not needed or desirable unless high LO power is used.

Such a high-breakdown diode will have low reverse current (which is important only if the diode has to run hot).

Silicon Versus GaAs. Typical silicon Schottky diodes have cutoff frequencies in the 800–200-GHz range, which is good enough through the Ku band.

At the Ku band and above, or for image-enhanced mixers, higher f_C may be needed, which calls for the use of GaAs diodes. These have lower R_S due to higher mobility, which translates to cutoff frequencies in the 400–1000-GHz range.

However, if your IF is low, be careful; GaAs diodes have high 1/*f* noise. They also have high V_{F1}, so more LO power is required.

C_J Versus Frequency. There is quite a lot of latitude in choosing C_J. However, in general, the capacitive reactance should be a little lower than the transformed line impedance (Z_0). If Z_0 is not known, a good way to start is to use $X_C = 100\ \Omega$. Experience has shown that most practical mixers use an X_C near this value (a little higher in waveguide, and lower in 50-Ω systems). This translates to the following rule of thumb for choosing the junction capacitance of a diode for operation at frequency *f* (in GHz):

$$C_{J0} \approx \frac{100}{\omega}$$

$$\approx \frac{1.6}{f} \quad \text{(in pF)} \tag{2-26}$$

In order to evaluate possible tolerances, we show the range of forward current as a function of diode voltage (Figure 2-5), the junction capacitance as a function of the bias voltage

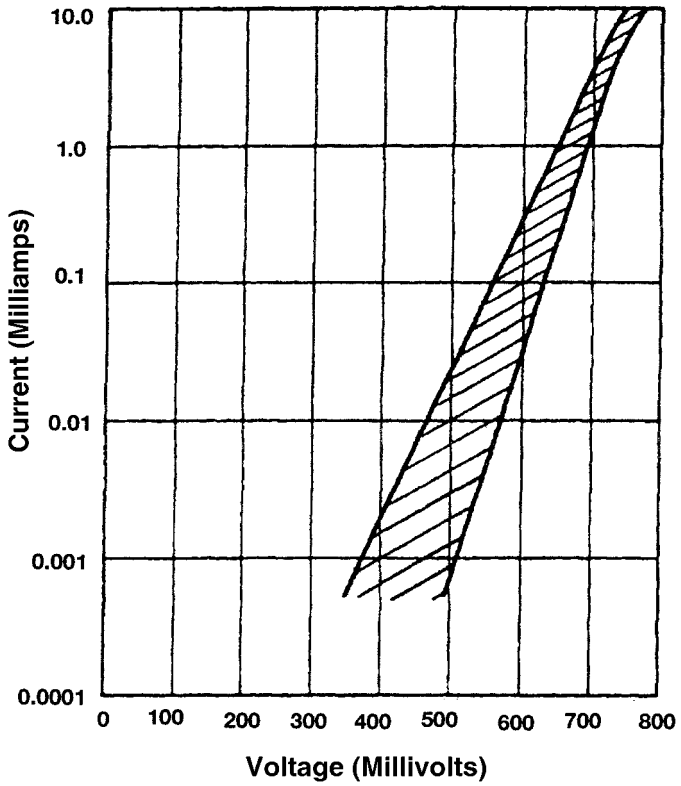

Figure 2-5 Forward dc characteristic curve range—current versus voltage.

(Figure 2-6), and finally some important RF parameters, such as noise figure and IF impedance, as a function of the local-oscillator drive (Figure 2-7).

Mixer Diodes. As an example of some of the parameters for mixer diodes, Table 2-4 gives data on some of the X-band mixer diodes. NF is measured at 9.375 GHz.

Linear Diode Model. Figure 2-8 shows the linear diode model. Its keywords appear in Table 2-5.

The circuit simulators, such as those supplied by Ansoft and Hewlett-Packard, provide a model library that has SPICE-type parameters for diodes (regular diodes, varactor diodes, and PIN diodes) as well as bipolar transistors and FETs, which will be discussed later.

2-1-3 PIN Diodes

Introduction. The PIN diode, in comparison with other microwave semiconductor devices, is fairly easy to understand. This makes possible the reduction of its complex behavior to relatively simple terms.

We do not attempt to describe the many possible microwave circuits in which PIN diodes are used. Rather, we attempt to explain the behavior of the diode in all aspects, giving the facts and some of the theory behind the facts. We offer the circuit designer the opportunity

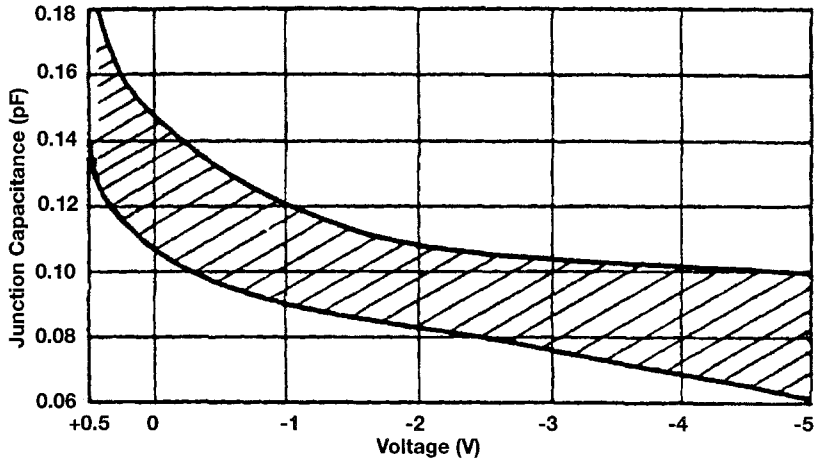

Figure 2-6 Junction capacitance range versus voltage.

to understand the PIN, so that he/she can understand its behavior in circuits. We assume the reader knows the circuit equations; to that knowledge we hope to add diode equations.

Most of the material presented consists of generalized data and explanations of the behavior of PIN diodes; we conclude with a brief description of circuit performance, test methods, and some hints on proper PIN specification writing.

The user can then evaluate the trade-offs involved in diode design and performance and be able to select the most nearly optimum diode from the wide range of diodes offered.

Large-Signal PIN Diode Model. Figure 2-9 shows the large-signal model for a PIN diode. Table 2-6 lists its keywords.

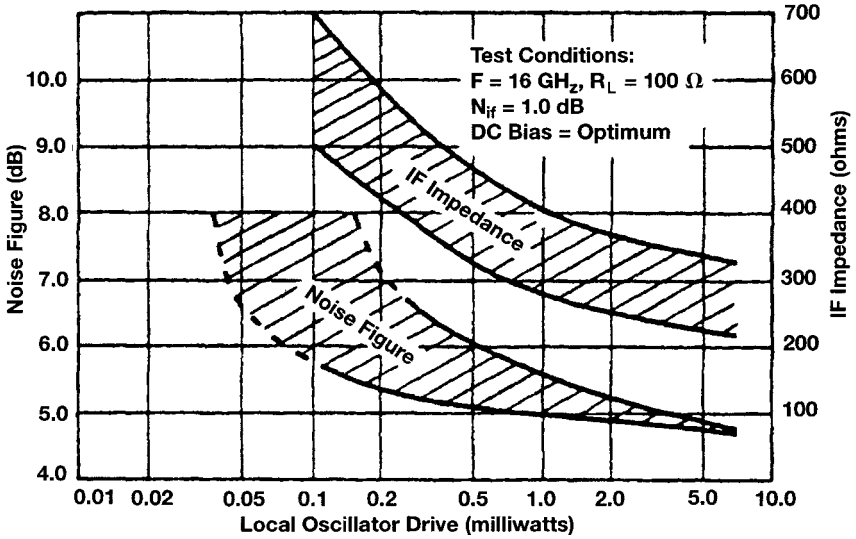

Figure 2-7 RF parameters versus local-oscillator drive level.

Table 2-4 X-band mixer diode data

Material	Barrier	Typical V_F (@1 mA)	Typical F_{C0} (GHz)	Typical R_S (Ω)	Typical C_{J0} (pF)	Maximum NF (dB)
n GaAs	High	0.70	1000	—	0.15	5.0[a]
n GaAs (BL)	High	0.70	500	—	0.15	6.0[a]
n GaAs (chip)	High	0.70	1000	—	0.15	5.3[a]
n Silicon (BL)	Low	0.28	150	6	0.20	6.5
n Silicon (quad)	Low	0.28	150	6	0.20	6.5
p Silicon (BL)	Low	0.28	150	12	0.20	6.5
n Silicon (BL)	High	0.60	100	8	0.20	6.5
n Silicon (quad)	High	0.60	100	8	0.20	6.5
n Silicon	Low	0.28	200	6	0.15	5.5
p Silicon	Low	0.28	200	18	0.14	6.0
p Silicon	Medium	0.40	150	150	0.12	6.5

p Silicon	Low	0.28	150	12	0.18	6.5

[a]Specified for N_F = 1.0 dB.

Basic Theory: Variable Resistance. Intrinsic or "pure" silicon, as it can be grown in a laboratory, is an almost lossless dielectric. Some of is physical properties include:

Dielectric constant (relative)	12
Dielectric strength	400 V/mil (approximate)
Specific density	2.3
Specific heat	0.72 J/g · °C
Thermal conductivity	1.5 W/cm · °C
Resistivity	300,000 Ω/cm

Since a PIN diode is valuable essentially because it is a variable resistor, let us concentrate initially on the resistivity. Consider a volume comparable to a typical PIN diode chip, say, 20 mils in diameter and 2 mils thick. This chip has a dc resistance of about 0.75 MΩ. High

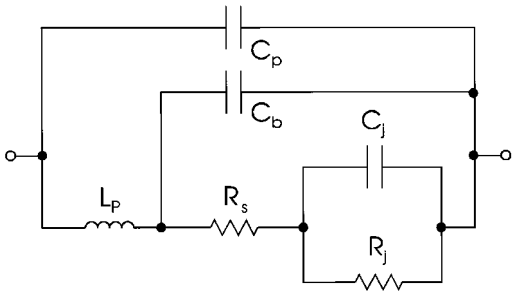

Figure 2-8 The linear diode model. This model is temperature dependent.

Table 2-5 Linear diode model keywords

Keyword	Description	Unit	Default
LP	Package inductance	henry	0.0

resistivity in any material indicates that most of the likely carriers of electric charge, electrons and holes, are tightly held in the crystal lattice and cannot "conduct."

In real life there are impurities, typically boron, that cannot be segregated out of the crystal. Such impurities contribute carriers, holes or electrons, that are not very tightly bound to the lattice and therefore lower the resistivity of the silicon.

Through various techniques we can adjust the level of impurities, called *dopants*, to produce resistivities ranging from 10 kΩ/cm (for good PIN diodes) to 0.001 Ω/cm (for substrates).

If the impurity adds "electrons" to the crystal, it is called a *donor*; if it adds holes it is called an *acceptor*. Boron adds holes, hence it is an acceptor, and the silicon plus boron combination is called *p*-type, or *positive*, because it has an excess of positive carriers. Phosphorus, on the other hand, is a *donor*, adding electrons, and the corresponding mix is *n*-type, or *negative*.

Notes on the PIN Diode Model

1. The PIN diode model is used to model a bias-dependent RF resistance for use in PIN diode circuits such as attenuators and switches. The resistance varies from RMAX to RS using the R function above. A typical R versus *I* characteristic is shown in Figure 2-10 with parameters IS = 5.96 nA, RS = 2.016, RMAX = 6500, K1 = 0.1272, K2 = 1.0, N = 2.077.
2. The transit-time parameter, TT, can also be used to approximately model a switching PIN diode's reverse-recovery time—a value often provided by diode manufacturers.
3. Diode breakdown can be modeled by specifying IBV and BV parameters.

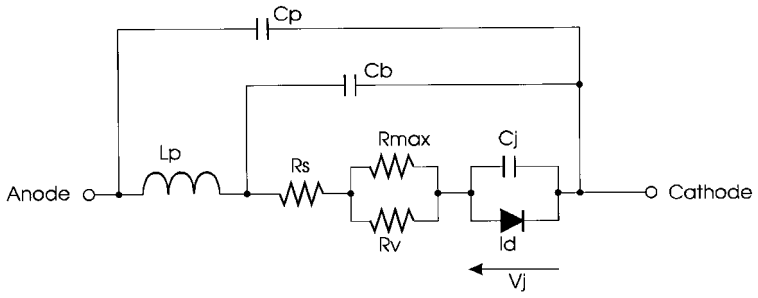

Figure 2-9 The large-signal PIN diode model. This model is temperature dependent.

Table 2-6 PIN diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
IS	Saturation current	ampere	1.0E–14
N	Emission coefficient		1.0
IBV	Magnitude of current at the reverse breakdown voltage	ampere	1.0E–10
BV	Magnitude of the reverse breakdown voltage	volt	∞
FC	Coefficient for forward-bias depletion capacitance		0.5
CJ0	Zero-bias *pn* junction capacitance	farad	0.0
VJ	Built-in junction potential	volt	1.0
M	*pn* Junction grading coefficient		0.5
GC1	Varactor capacitance polynomial coefficient 1	/volt	0.0
GC2	Varactor capacitance polynomial coefficient 2	/volt^2	0.0
GC3	Varactor capacitance polynomial coefficient 3	/volt^3	0.0
TT	Transit time	second	0.0
K1	Variable resistance coefficient	volt	0.0
K2	Variable resistance current exponent		1.0
RMAX	Maximum resistance of PIN intrinsic region	ohm	0.0
KF	Flicker noise coefficient		0.0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
AREA	Area multiplier		1.0
	Extrinsic Model		
RS	Series resistance (minimum resistance of PIN diode)	ohm	0.0
CP	Package parasitic capacitance	farad	0.0
CB	Beam-lead parasitic capacitance	farad	0.0
LP	Package parasitic inductance	henry	0.0

4. The reverse-bias capacitance characteristics can be more accurately modeled than the common expression derived from *pn* junction theory. The capacitance grading coefficient exponent can be expressed as a polynomial function of voltage by specifying values for GC1, GC2, and GC3.
5. The PIN diode model was derived from J. Walston, "SPICE Circuit Yields Recipe for PIN Diode," *Microwaves & RF*, November 1992.
6. Following Simon M. Sze, *Physics of Semiconductor Devices* (New York: John Wiley, 1982), the variable resistance may be modeled by setting

$$\text{K1} = \frac{3}{8} V_T \frac{W^2}{D_a \tau_a} \qquad \text{K2} = 1.0$$

where W is the width of the intrinsic region, D_a is the ambipolar diffusion coefficient, τ_a is the ambipolar lifetime, and V_T is the thermal voltage.

There are many concepts important to the physicist, but not to the diode user, that elaborate on the impact of impurities on the behavior of silicon. These can be studied in Watson [1]. The more carriers added, the lower the resistivity.

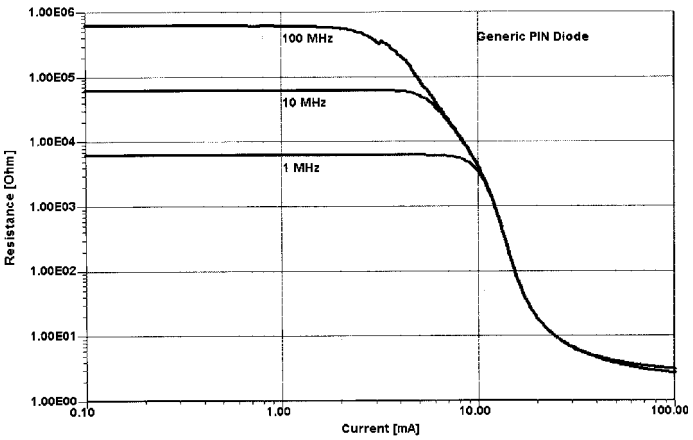

Figure 2-10 Simulated PIN diode resistance as a function of dc at 1, 10, and 100 MHz.

If one wished to vary the resistance of a given diode, in principle he/she could bring it into a semiconductor laboratory, add or subtract carriers as desired, and perhaps even make the process reversible. However, this is a slow, expensive, and impractical way to make a variable resistor; one would be better advised to take a wrench and a soldering iron and replace a component.

The PIN diode derives its value from the fact that the free-charge-carrier concentration in silicon, and hence its resistance, can be varied electronically by means of current from a simple bias supply. This can be done rapidly (in nanoseconds in some cases), reversibly, repeatably, and accurately. The thing that makes this possible is called a *junction*, the interface between the relatively pure silicon in the middle of the PIN diode (the I stands for *intrinsic*) and the heavily doped layers on either end, p^+ and n^+. The p^+ region is rich in holes; the n^+ region is rich in electrons. Both of these regions have low resistance. The I region is the variable resistive element in the diode (see Figure 2-11). In the absence of any external bias, internal effects within the crystal keep the charges fixed; the resistance of the I region is high.

When the p^+ region (anode) is biased positively with respect to the n^+ region (cathode), the interface potential "barrier" is overcome, and direct current flows in the form of holes

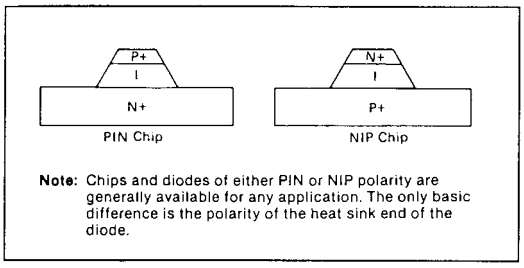

Figure 2-11 General outline of PIN diode construction.

streaming from p^+ toward n^+, with electrons moving in the opposite direction; we say that free carriers have been injected into the I region. The resistance of the I region becomes low.

The number of free carriers within the I region determines the resistivity of the region and thus the resistance of the diode.

Consider "one hole" and "one electron" drifting in opposite directions in the I region under the impetus of the applied field. Under certain conditions, imperfections in the silicon may cause these carriers to recombine. They are no longer available to constitute current or to lower the resistivity of the I region.

It can be shown that the amount of "recombination" between holes and electrons that continuously takes place in a semiconductor is governed by a property of the lattice called *lifetime*. In fact, lifetime is defined as the reciprocal of recombination rate.

Thus, $Q_S = Q_0 \exp(-t/T_L)$, where Q_S is the total amount of free charge "stored" in the I region, and T_L is the lifetime, or the mean time between recombination events. In the steady-state condition, the bias supply must deliver current to maintain a constant Q_S. The required current is

$$I_{\text{dc}} = \frac{Q_S d}{dt} = \frac{-Q_S}{T_L} \tag{2-27}$$

or $Q_S = I_{\text{dc}} T_L$, dropping the minus sign.

Ignoring some details that are not crucial to this section, we can now calculate the resistance of a given diode, of area A and thickness W. (W stands for *base width*, the width or thickness of the intrinsic layer.) The p^+ and n^+ regions have essentially zero resistance, as they are very heavily doped.

The resistivity of a given material is inversely proportional to the number of free carriers, N, and the mobility (not quite the same as velocity) of the carriers. Thus,

$$\rho = \frac{1}{q(\mu_n N + \mu_p P)} \tag{2-28}$$

where μ_n and μ_p are mobilities of electrons and holes, and N and P are numbers of electrons and holes. Simplifying, we find

$$\rho = \frac{C}{Q_S d} \tag{2-29}$$

where C is a collection of constants, and $Q_S d$ is the stored charge density (numbers per unit volume). For our piece of silicon, volume is WA, and

$$Q_S d = \frac{Q_S}{WA} \tag{2-30}$$

The resistivity is

$$\rho = \frac{CWA}{Q_S} \tag{2-31}$$

and the resistance is

$$R_S = \rho \frac{W}{A} = \frac{CW^2}{I_{\text{dc}} T_L} \tag{2-32}$$

This is a fundamental equation in PIN diode theory and design.

Rigorous analysis shows that

$$R = \frac{2kT/q}{I_f} \sinh\left(\frac{W}{2\sqrt{DT_L}} \tan^{-1}\left[\sinh\frac{W}{2\sqrt{DT_L}}\right]\right) \tag{2-33}$$

where k = Boltzmann's constant
T = temperature (in kelvins)
D = diffusion coefficient = $\mu kt/q$

For most PIN diodes, W/DT_L is less than unity, and the equation simplifies to the simple equation above.

Typical data on R_S as a function of bias current are shown in Figure 2-12. Many design choices are available, as the data indicate. Many combinations of W and T_L have been developed to satisfy the full range of applications.

Breakdown Voltage, Capacitance, Q Factor. The previous section on R_S explained how a PIN can become a low resistance, or a "short." This paragraph will describe the other state: a high impedance, or an "open." Clearly, the better PIN diode is the one that has the better on/off ratio at the frequency and power level of interest.

If we return to the undoped or intrinsic I region, we note that it is an almost lossless dielectric. As such, it has a dielectric strength of about 400 V/mil, and all PIN diodes have

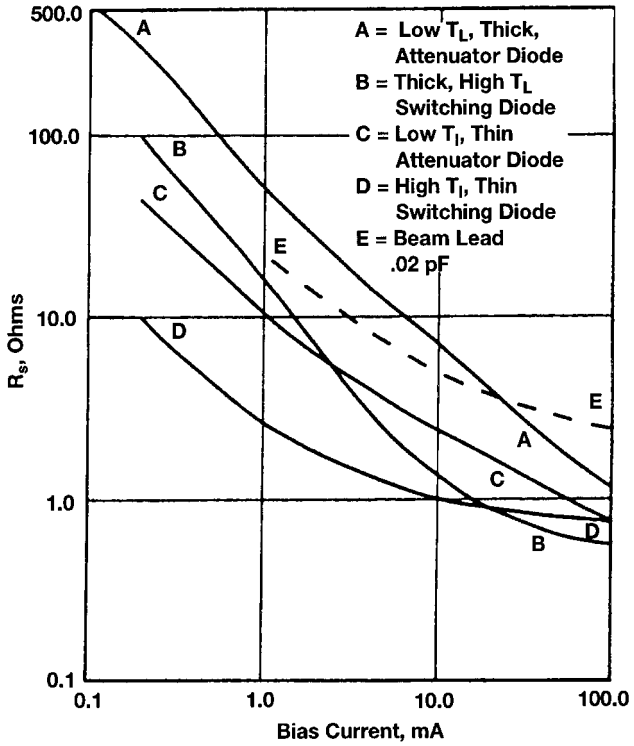

Figure 2-12 Typical series resistance as a function of bias (1 GHz).

a parameter called V_b, breakdown voltage, which is a direct measure of the width of the I region. Voltage in excess of this parameter results in a rapid increase in current flow (called avalanche current); see Figure 2-13. When the negative bias voltage is below the bulk breakdown of the I region, a few nanoamperes will be drawn. As V_b is approached, the leakage current increases often gradually, as is exaggerated in the curve. This current is primarily caused by less-than-perfect diode fabrication, although there is some contribution from temperature. Typically, the leakage current occurs at the periphery of the I region. For this reason, various *passivation* materials (silicon dioxide, silicon nitride, hard glass) are grown or deposited to protect and stabilize this surface and minimize leakage. These techniques have been well advanced over the years, and PIN diode reliability has improved as a result.

Most diodes are specified in terms of minimum V_b for a nominal leakage, usually 10 μA.

It will be noted later that RF voltage swings in excess of the rated V_b are permitted, for the mechanisms causing leakage current do not always respond at radiofrequencies. However, bulk breakdown is effectively instantaneous, and that voltage should never be exceeded.

The next characteristic of our "open" circuit is the capacitance. In simplest form, the capacitance of a PIN diode is determined by the area and width of the I region and the dielectric constant of silicon; however, we have discussed the fact that intrinsic material does contain some carriers and therefore has some conductivity. An *E* field could not exist unless all these carriers were swept out, or depleted.

Application of a reverse bias accomplishes this. At zero bias, the excess carriers on either side of the junction are separated, held apart, by "built-in" fields. This is the contact potential (about 0.5 V for silicon). If there are only a few excess carriers in the I region, this "potential" can separate the charges more easily. The junction "widens" in the sense that, starting at the p^+ and I interface, there is a region of no free carriers called the *depletion zone*. Beyond this depletion zone, the I region still contains the free charges with which it started. With the application of reverse bias, the depletion zone widens.

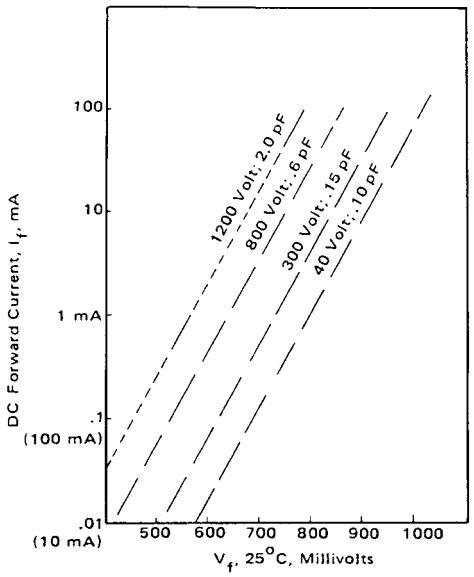

Figure 2-13 Current versus voltage for various PIN diodes.

Eventually, at a bias equal to a so-called *punchthrough* voltage (V_{PT}), the depletion zone fills the entire I region. At this voltage, the 1-MHz capacitance bottoms out and the diode Q reaches its maximum. Figure 2-14 illustrates the equivalent circuit of the I region before punchthrough.

Some very interesting facts can be derived from this model. Consider the undepleted region; this is a lossy dielectric consisting of a volume (area A, length ℓ) of silicon of permittivity 12 and resistivity ε. The capacitance is

$$12\frac{\varepsilon_0 A}{\ell} \tag{2-34}$$

and the admittance is

$$2\pi\frac{12\varepsilon_0 A}{\ell} \tag{2-35}$$

The resistance is $\varepsilon\ell/A$ and the conductance is $A/\varepsilon\ell$.

At very low frequencies, the undepleted zone looks like a pure resistor. At very high frequencies it looks like a lossy capacitor. The "crossover" frequency depends on the resistivity of the I-region material. For ε of 160 Ω/cm, the frequency is 1 GHz. Higher resistivity is generally used for PINs—say, 1000 Ω/cm, and the crossover frequency is 160 MHz.

Diode manufacturers measure junction capacitance at 1 MHz; clearly, what is measured is the depletion-zone capacitance.

If the I region thickness is W and the depletion is X_d, the undepleted region is $(W - X_d)$.

The capacitance of the depleted zone is, proportionally,

$$\frac{1}{X_d} \tag{2-36}$$

and of the undepleted zone,

$$\frac{1}{W - X_d} \tag{2-37}$$

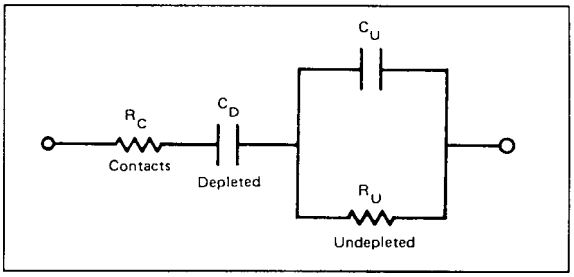

Figure 2-14 Equivalent circuit of I region before punchthrough.

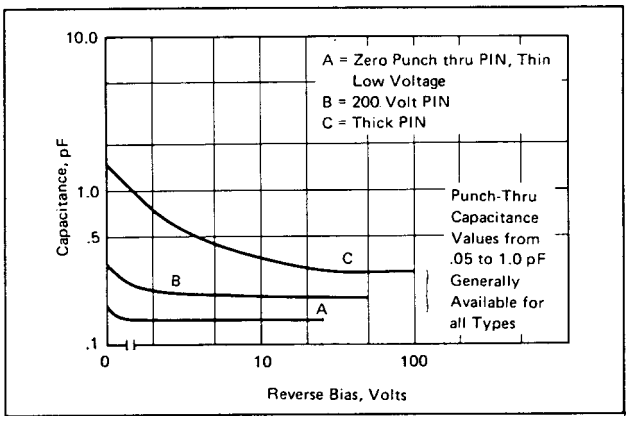

Figure 2-15 Typical 1-MHz capacitance.

The 1-MHz capacitance as a function of reverse bias is seen in Figure 2-15. The 1-MHz capacitance decreases with bias until punchthrough, where $X_d = W$. However, at microwave frequencies well above the crossover, the junction looks like two capacitors in series:

$$C_T = \frac{C_d C_u}{C_d + C_u} \propto \frac{1}{W} \tag{2-38}$$

That is, the microwave capacitance tends to be constant, independent of X_d and bias voltage.

However, since the undepleted zone is lossy, an increase in bias up to the punchthrough voltage reduces the loss.

At any given frequency, the equivalent network can now be drawn as Figure 2-16. R_v is now the equivalent series resistance of the undepleted region. Typical R_v data are shown in Figure 2-17. An alternate equivalent network is shown in Figure 2-18, and typical R shunt data are shown in Figure 2-19.

A good way to understand the effects of series resistance is to observe the insertion loss of a PIN chip shunt mounted in a 50-Ω line, as shown in Figure 2-20. An accepted way to include reverse loss in the figure of merit of a PIN diode is to write

$$Q = \frac{1}{2\pi + \sqrt{R_s R_v C}} \tag{2-39}$$

where R_s and R_v are measured under the expected forward- and reverse-bias conditions at the frequency of interest.

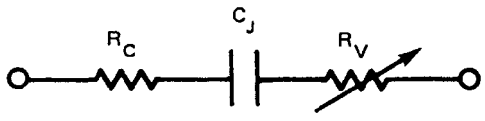

Figure 2-16 Simplified equivalent series circuit.

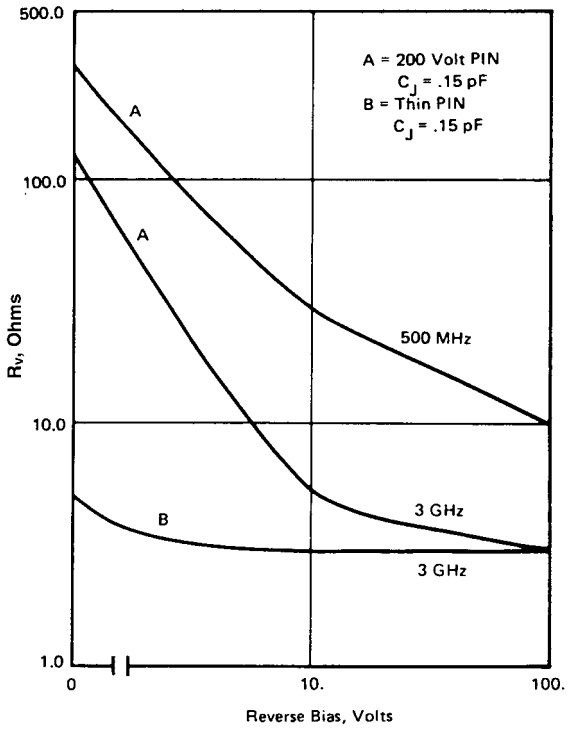

Figure 2-17 Reverse series resistance R_V.

The punchthrough voltage is a function of the resistivity and thickness of the I region. It is advisable to measure loss as a function of bias voltage and RF voltage to determine if the correct diode has been selected for your application. (*Note*: At frequencies below crossover, and diodes with thin I regions, the effective junction capacitance can increase substantially at low forward bias, on the order of 1–200 μA.)

Incidentally, if you are working with PIN or NIP chips that do not have an opaque covering, note that PIN diodes are photosensitive. Incident light causes photogeneration of carriers in the I region, increasing the chip's insertion loss.

PIN Diode Applications. If the intrinsic zone is thick (10–100 μm), we then have a high-reverse-voltage rectifier with a low forward-voltage drop at high current or, in other

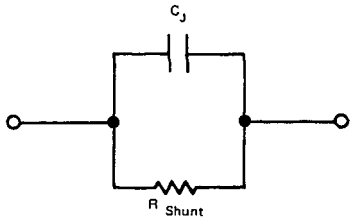

Figure 2-18 Simplified equivalent circuit, shunt.

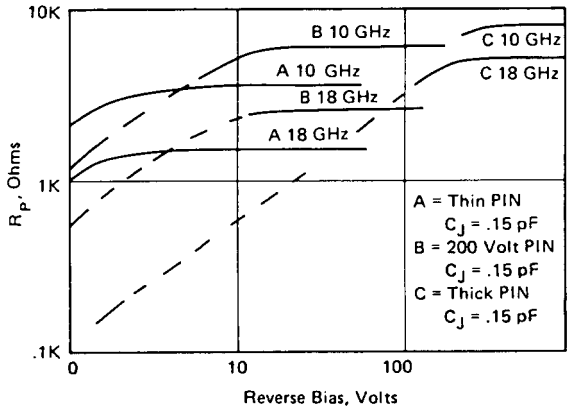

Figure 2-19 Reverse shunt resistance, R_p.

words, a highly efficient rectifier. The low forward voltage results from the fact that the conductivity of the I zone can be modulated by large amounts of charge carriers injected from the *p* and the *n* zones.

Another application of PIN diodes is the high-frequency (HF) field. Here, the fact is exploited that, due to the long carrier lifetime at frequencies beyond approximately 10 MHz, a rectifying effect will no longer occur and the PIN diode rather behaves like a real resistance, the magnitude of which depends on the forward direct current passed by the device and

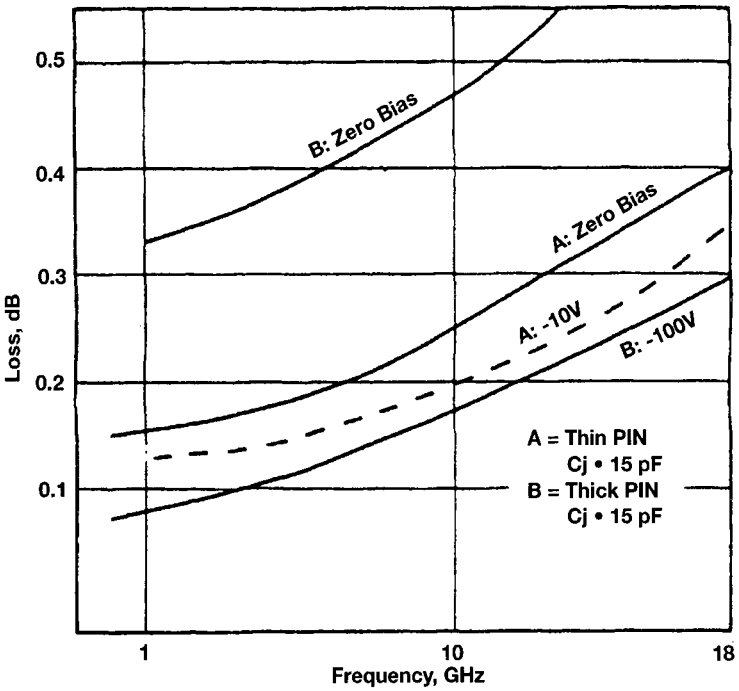

Figure 2-20 Insertion loss versus frequency.

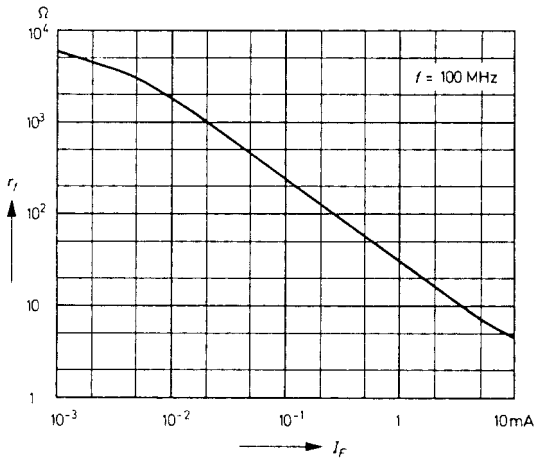

Figure 2-21 Forward resistance versus forward current.

produces an equal effect on both half waves of the HF signal. In view of this behavior, the PIN diode can be used as a switch or a variable resistor for HF signals. Thus it becomes possible, for example, to subject an HF signal to amplitude modulation by means of an AF-controlled PIN diode.

An important application of PIN diodes that has found favor in recent times is for dc-operated attenuators in TV tuners and antenna distribution amplifiers. Figure 2-21 shows the real HF forward resistance r_f as a function of the forward current I_f, measured at 100 MHz. Figures 2-22 and 2-23 show second-order IMD and cross-modulation for PIN diodes.

Applying the PIN in Amplitude Control of High-Frequency Signals. In conventional transistorized TV tuners, automatic gain control (AGC) is usually achieved by varying the emitter current of the input transistor. This method exploits the fact that the input transistor exhibits maximum gain at a certain level of emitter current and that this gain decreases when the emitter current is either increased or decreased relative to this point. Since modulation capacity and cross-modulation resistance grow with the emitter current, "upward" gain control has lately become the preferred solution, and according to it, gain reduction is achieved by an increase of the input transistor's emitter current. An input stage based on this design, therefore, is least resistant to cross-modulation when receiving a signal from a weak transmitter because it is operating at or below the point at which AGC action begins. This effect is particularly disadvantageous when the signal of a weak transmitter is to be received in the presence of a strong local transmitter. The unsatisfactory cross-modulation properties of such an input stage manifest themselves more and more frequently in the form of image perturbations as the TV reception band is crowded by an increasing number of transmitters. Another disadvantage is the variation in the transistor parameters that results from the control action. The variations affect antenna matching at the input and the response of the RF filter at the output.

To obviate these problems, methods being adopted today provide for the input stage to be equipped with cross-modulation-resistant transistors with fixed bias, gain control being provided by a variable attenuator preceding the transistor(s). The input-filter termination

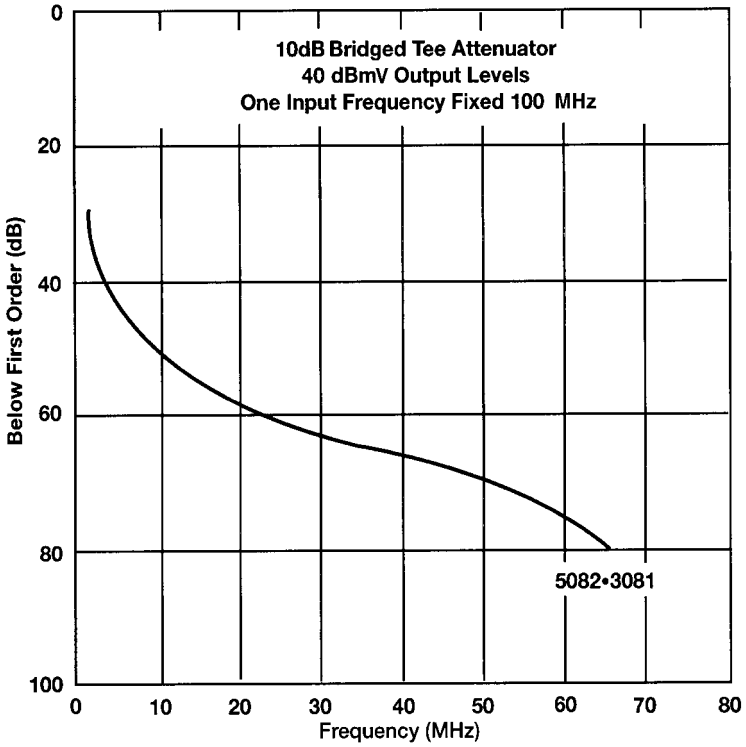

Figure 2-22 Second-order IMD in a PIN diode. Equation (1-48) can be used to determine the diode's IP_2 from the absolute values of its fundamental and IM_2 outputs.

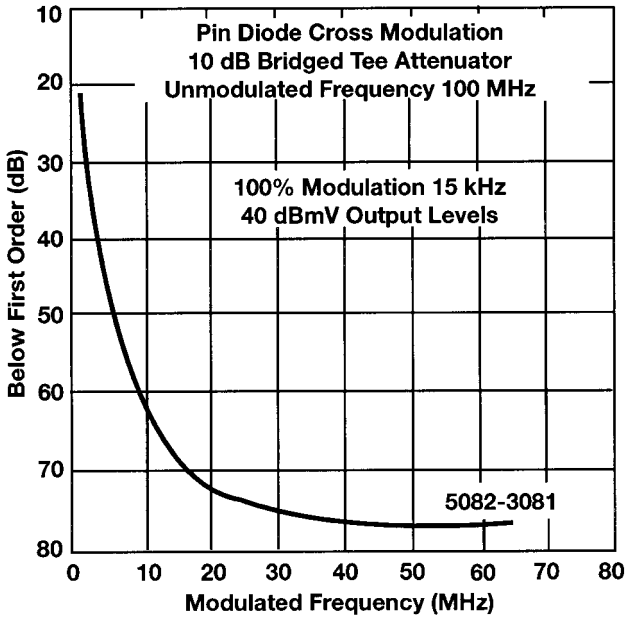

Figure 2-23 Cross-modulation in a PIN diode. Equation (2-61) relates cross-modulation level to IMD.

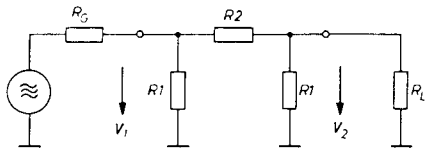

Figure 2-24 Basic circuit of a π-mode filter attenuator.

provided by this attenuator must be independent of the degree of attenuation to preserve the filter's response characteristics.

The first two requirements are met by the properties of the PIN diode and the latter requirement can be met by designing a PIN diode control in the form of a π network, a schematic of which is shown in Figure 2-24. The attenuation of a matched π network is expressed by the following equations:

$$\frac{a}{\text{dB}} = 20 \log \frac{Z + R_2}{R_2 - Z} \tag{2-40}$$

$$\frac{a}{\text{dB}} = 20 \log \left(\frac{R_1}{Z} + \sqrt{\frac{R_1^2}{Z^2} + 1} \right) \tag{2-41}$$

Figure 2-25 plots the relationship between the resistance levels of R_1 and R_2 and the input and output voltages of the π network. Figure 2-26 shows the circuit diagram of an implementation of the π network composed of PIN diodes. The resistance characteristic required according to Figure 2-25 is achieved approximately by varying the control current I_{co}.

If the control current I_{co} in Figure 2-26 equals zero, then—due to the fact that $R_1 = R_2$ and $R_3 = R_4$—the auxiliary voltage V_h causes forward currents of equal magnitude to flow through diodes D_1 and D_3. The voltage drops across R_1 and R_2 are of equal magnitude, so that no current passes through diode D_2. Therefore, the latter presents a high resistance, whereas D_1 and D_3 present a low resistance. Under these conditions, the network produces maximum attenuation. A control current I_{co} reduces the forward currents through D_1 and D_3 and allows a forward current to be passed by diode D_2. When it has attained its maximum value, diodes

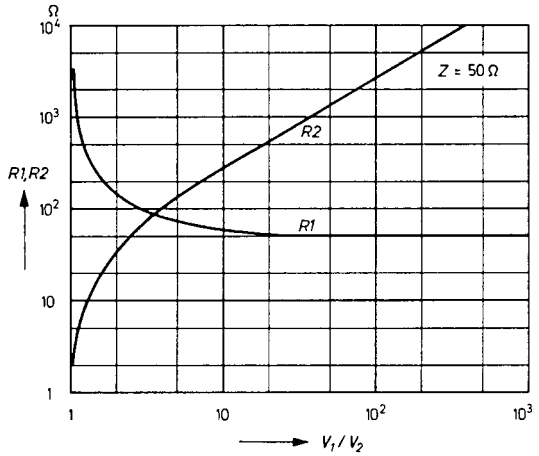

Figure 2-25 Values of R_1 and R_2 in Figure 2-24 versus relation of input and output voltage.

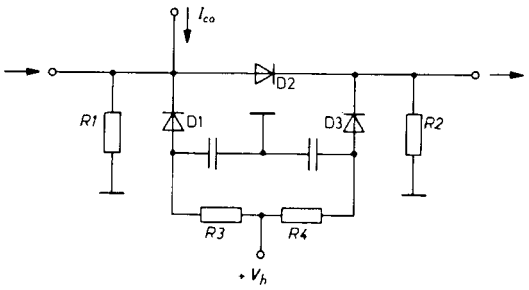

Figure 2-26 PIN diode π-mode attenuator.

D_1 and D_3 are blocked—that is, they are high-ohmic—and D_2 is low-ohmic. Under these conditions, the network produces its minimum attenuation.

If the maximum attenuation of the π network is to be increased, it is possible to make the two shunt diodes D_1 and D_3 more low-ohmic than the impedance Z, although this would reduce the reflection coefficient of attenuation. For example, if a reflection coefficient of about 7 dB is accepted over the entire control range, then a maximum attenuation of 25–30 dB could be achieved in the VHF range. The series inductances of the transverse diodes and the shunt capacitance of the series diode are responsible for this relatively unsatisfactory value. Improved attenuation is brought about with the integrated π network described in the next section.

Example: A PIN Diode π Network for TV Tuners. The since-discontinued TDA1053 is an example of an integrated PIN π network attenuator intended for TV-tuner use. It comprises three silicon planar PIN diodes connected to form a π network (Figure 2-27) and serves for the electronic amplitude control of the input signals of TV tuners and antenna distribution amplifiers in the 40–1000-MHz range. Its input and output impedances remain constant over the entire control range. This can also be achieved with discrete diodes.

The TDA1053 was normally supplied with vertical leads. The characteristics stated below apply to devices of this configuration.

MAXIMUM RATINGS OF INDIVIDUAL DIODES

Reverse voltage	V_R	30	V
Forward current at $T_{amb} = 25$ °C	I_F	50	mA
Junction temperature	T_j	125	°C
Storage temperature range	T_s	−55 to +125	°C

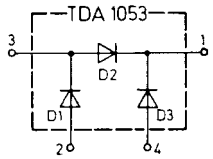

Figure 2-27 Internal circuitry of the TDA1053.

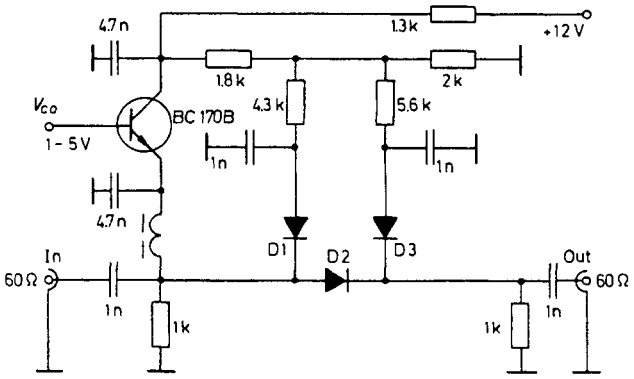

Figure 2-28 Test and application circuit.

MAXIMUM RATINGS OF THE π NETWORK

Ambient operating temperature range when operating according to Figure 2-28	T_{amb}	100	°C

CHARACTERISTICS OF INDIVIDUAL DIODES AT T_{amb} = 25 °C

Forward voltage at I_F = 50 mA	V_F	< 1.2	V
Forward current at V_R = 15 V	I_R	< 500	nA
Differential forward resistance:			
At I_F = 10 mA, f = 100 MHz	r_f	5	Ω
At I_F = 10 µA, f = 100 MHz	r_f	1.4	kΩ

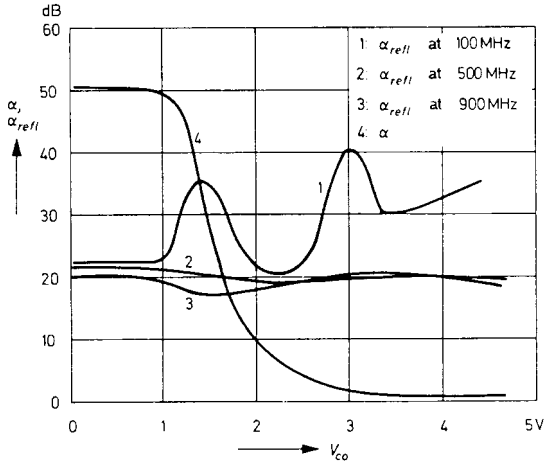

Figure 2-29 Attenuation and reflection attenuation versus control voltage.

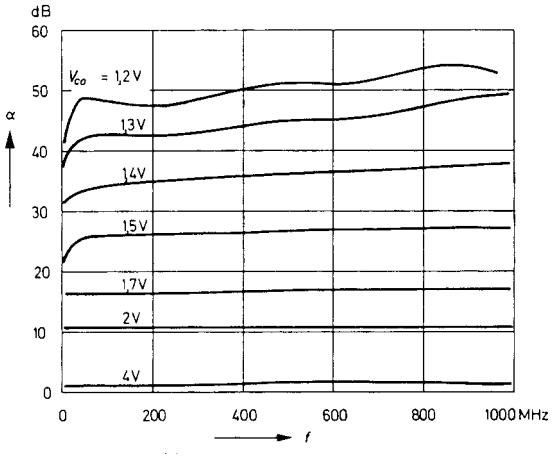

Figure 2-30 Attenuation versus frequency.

CHARACTERISTICS IN THE TEST CIRCUIT (FIGURE 2-28) AT T_{amb} = 25 °C

Voltage for 1% cross-modulation	V_{cr}	1	V
Attenuation in the 40–1000-MHz range:			
At V_{co} = 1.5 V (1–2 V)	a_{max}	45 (> 36)	dB
At V_{co} = 5 V (4–5 V)	a_{min}	1.5 (< 2)	dB
Reflection coefficient in the 40–1000-MHz range over the entire control range, depending on circuit design	a_{refl}	20 (> 16)	dB

These data reveal that the compact design of the three PIN diodes in a common 50B4 plastic package guarantees favorable values for minimum and maximum attenuation, as well as reflection attenuation. The test and application circuit shown in Figure 2-28 also comprises the transistor control-signal amplifier. The typical characteristic of the attenuation and the reflection attenuation for this circuit are shown in Figure 2-29, as a function of the control voltage V_{co}. Figure 2-30 shows the attenuation at different control voltages, as a function of frequency.

2-1-4 Tuning Diodes

Introduction. In recent years, continuous development of tuning diodes—also known as *varactors* or *varicaps*—together with increased commercial and military use has led to substantial improvement in Q, reproducibility, and reliability. Concurrently, new techniques for producing and controlling a hyperabrupt dopant profile in the semiconductor permit the capacitance–voltage law to be much faster than the classical square root or cube root behavior.

Current tuning diode materials include silicon and gallium arsenide; silicon is favored for low cost and lower Q applications from HF through microwave frequencies. Hyperabrupt varactors, also of silicon, are finding many applications in commercial television tuners, where their high tuning ratios, linear tuning, and low cost are needed. New developments include low-capacitance hyperabrupts for microwave and wireless applications.

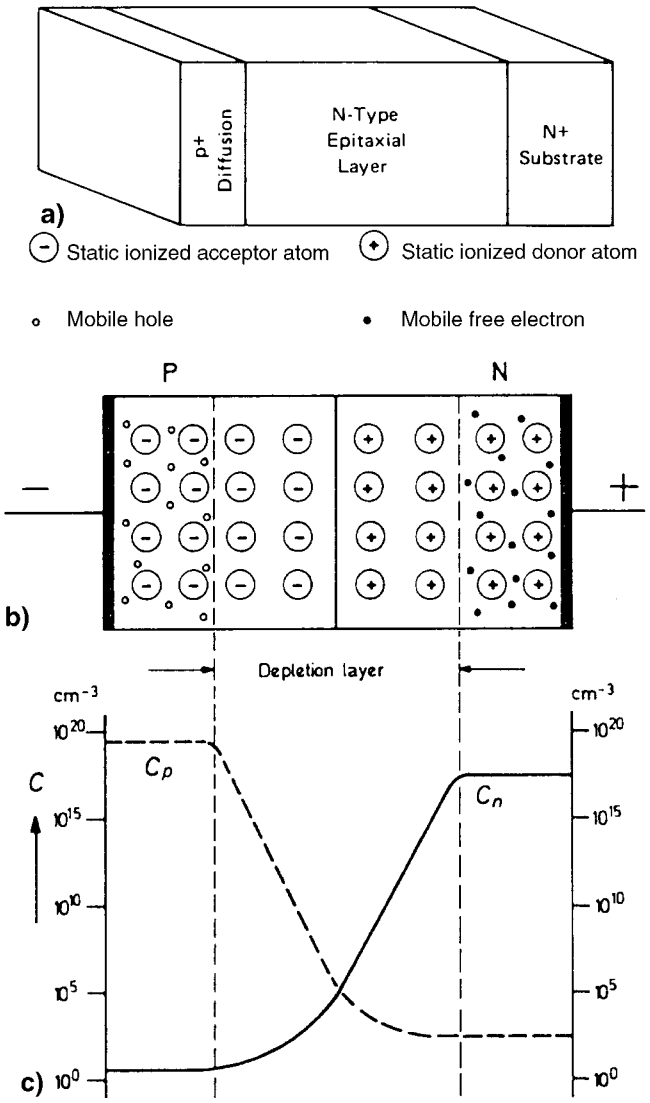

Figure 2-31 (a) Basic PIN structure; (b) cross section of a reverse-biased *pn* junction; and (c) density distribution of free charge carriers.

Gallium arsenide is used with high operating frequency and dictates the highest Q possible, as in parametric amplifiers and millimeter multipliers.

This section will acquaint the reader with tuning diodes: how they work, and what they can or cannot be expected to do in an electronic circuit. The basic properties of a tuning diode will be described in terms of the parameters that manufacturers use in characterizing them. The following topics will also be addressed:

- Capacitance ratio with respect to voltage and voltage breakdown
- Q as a function of design and operating conditions

- Stability—leakage current, temperature coefficient, and post-tuning drift
- Distortion products
- Packaging parasitics
- Applications—suggestions on how to specify a varactor

Tuning Diode Physics

Introduction. All junction diodes are made up of the same physical parts: a *pn* junction, a carefully controlled epitaxial layer, and a very-low-resistance substrate. These parts are shown in Figure 2-31.

No matter what type of junction device we are discussing—a tuning diode, a step-recovery diode, or a PIN diode—these parts are all present; the main difference between these devices is the resistivity and thickness of the epitaxial layer. Tuning diodes and multiplier diodes need epitaxial layers where both the resistivity and thickness are carefully controlled.

Abrupt Junction. An abrupt-junction diode is one in which the p^+ diffused region of the diode is much more highly doped than the epitaxial layer. Also, the high doping drops to the doping level of the epitaxial layer in a distance that is short compared to the epitaxial layer thickness, and the doping level of the epitaxial layer is constant over its thickness. This is shown in Figure 2-32, with the corresponding C–V curve shown in Figure 2-33. When these requirements are satisfied, the diode capacity, diode area, epitaxial layer doping level, and diode voltage are related by

$$\frac{C(V)}{A} = K\left(\frac{N}{V+\varphi}\right)^n \tag{2-42}$$

where $C(V)$ = capacitance of the diode at voltage V
A = area of the diode
N = doping level of the epitaxial layer

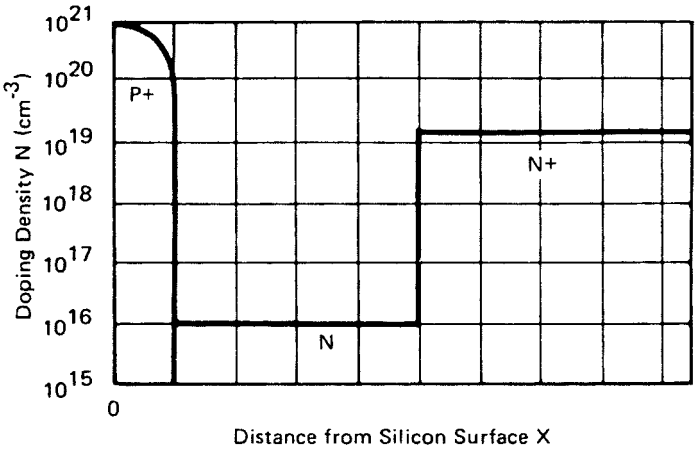

Figure 2-32 *N–X* abrupt junction.

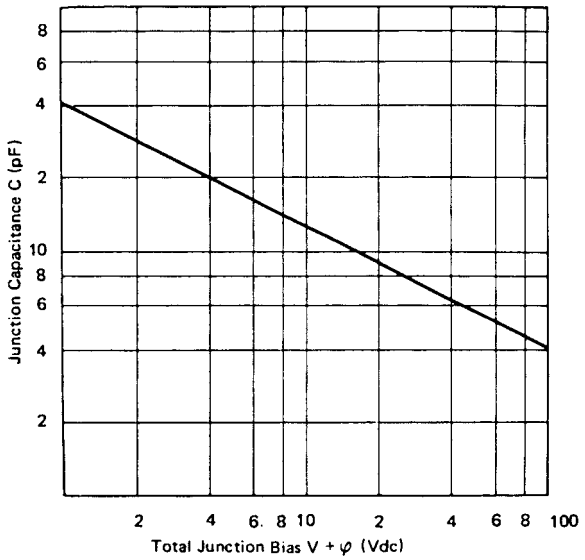

Figure 2-33 Capacitance versus total junction bias for abrupt-junction diode.

V = voltage applied to the diode
φ = built-in potential of the diode (0.6–0.8 V)
n = slope of diode C–V curve; $n \approx 0.5$ for an abrupt-junction diode
K = constant

As a consequence of the physical properties of a *pn* junction, a depletion layer is formed between the *p* and *n* regions whose width depends on the voltage applied to the diode. The capacitance of the diode is inversely proportional to the width of the depletion layer; that is, $C \sim 1/\ell_0$. In addition, the series resistance of the diode is proportional to the width of the undepleted epitaxial layer. Thus, as diode reverse bias is increased, the depletion layer increases, causing a decrease in capacitance and a decrease in series resistance. As the diode reverse bias is increased further, a point is reached where the electric field caused by the reverse bias reaches a critical level, and current through the diode increases rapidly; this is

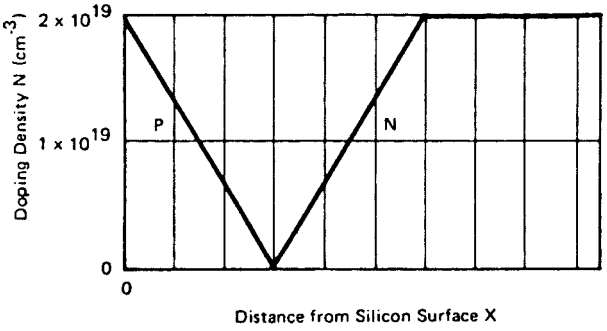

Figure 2-34 *N–X* linearly graded junction.

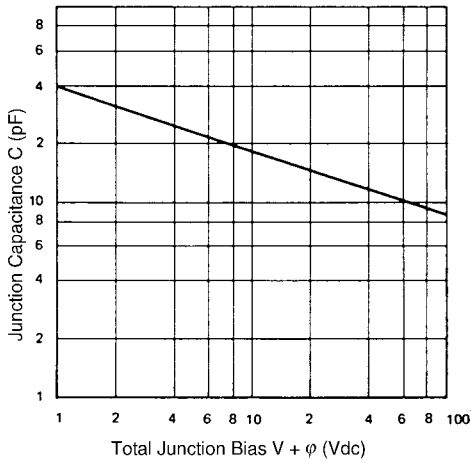

Figure 2-35 Capacitance versus total junction bias for linearly graded junction.

breakdown voltage of the diode. If, at the breakdown voltage, the epitaxial layer is not completely depleted, the diode will have excessive series resistance. Conversely, if the epitaxial layer is depleted before the breakdown voltage is reached, no further capacitance decrease occurs after the total depletion, and a condition called *punchthrough* occurs.

While, in the ideal case, voltage breakdown will occur just as the epitaxial layer is totally depleted, this seldom occurs in practice, and we generally have a condition of either punchthrough or excess series resistance.

Linearly Graded Junction. If, instead of the junction profile shown in Figure 2-32, we have a p^+ region and an n region whose doping levels increase linearly with distance from the pn junction as shown in Figure 2-34, with its corresponding C–V curve in Figure 2-35, then we have what is called a linearly graded junction diode. This diode follows Eq. (2-42) with the exception that the exponent n is equal to $\frac{1}{3}$. This means that, for a given voltage change, the linearly graded junction will have a smaller capacitance change than an abrupt-junction diode. Since, in most cases, the designer is looking for the maximum

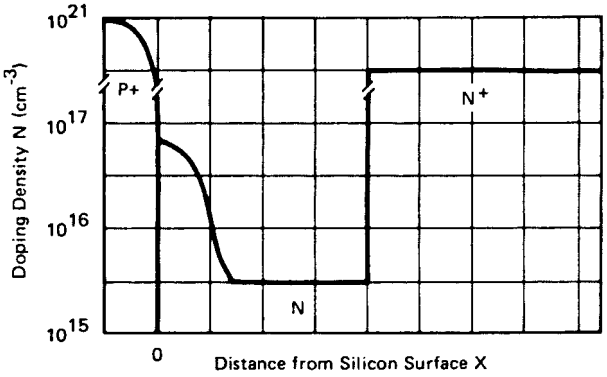

Figure 2-36 *N–X* hyperabrupt-junction diode.

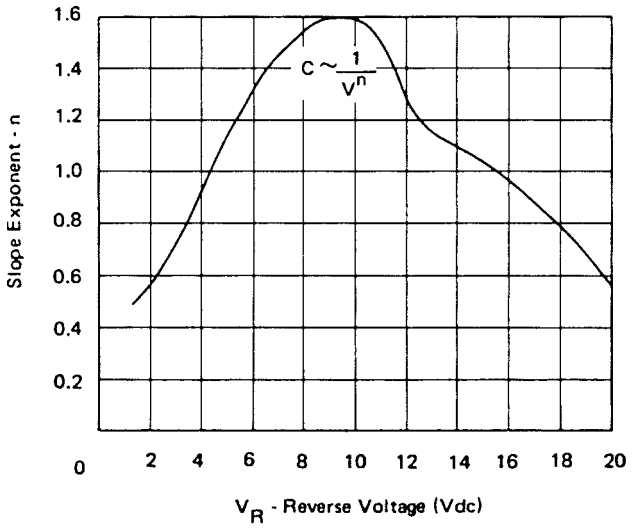

Figure 2-37 Typical *n* versus reverse voltage characteristic for hyperabrupt-junction diode.

capacitance change obtainable, the linearly graded junction is not used as a tuning diode. This structure found its greatest use several years ago as a "cube law" multiplier, but even this use has decreased as new structures have been developed.

Hyperabrupt Junction. The hyperabrupt-junction diode provides a greater capacitance change than the abrupt-junction diode for a given voltage change, as well as a linear frequency versus voltage characteristic over a limited voltage range. The structure of the hyperabrupt-junction diode is shown in Figure 2-36 and can be seen to be an abrupt-junction diode with an additional, increased doping level at the *pn* junction. This diode also follows Eq. (2-42) with the exception that n is not a function of voltage and is generally in the range of 0.5–2. A typical curve of n versus voltage is shown in Figure 2-37.

The C–V curve in a hyperabrupt-junction diode is shown in Figure 2-38 and is seen to start at a high value of capacitance per unit area at low bias (high epitaxial doping) and change to a lower value of capacitance per unit area (low epitaxial doping) at high bias. The details of the curve depend on details of the shape of the more highly doped region near the *pn* junction.

Unfortunately, with a hyperabrupt-junction diode, you must settle for a lower Q than an abrupt-junction diode with the same breakdown voltage and same capacitance at 4 V.

It should be noted that any diode that has an n value that exceeds 0.5 at any bias voltage is, by definition, a hyperabrupt-junction diode. Thus, the hyperabrupt-junction diode family can have an infinite number of different C–V curves. Since the abrupt-junction diode has a well-defined C–V curve, the capacitance value at one voltage is sufficient to define the C–V capacitance at any other voltage. This is not the case for the hyperabrupt-junction diode. In order to adequately define the C–V characteristics of a hyperabrupt-junction diode, two and sometimes three points on the curve must be specified.

Silicon Versus Gallium Arsenide. Everything mentioned so far applies to both silicon and gallium arsenide (GaAs) diodes. The main difference between silicon and GaAs from a

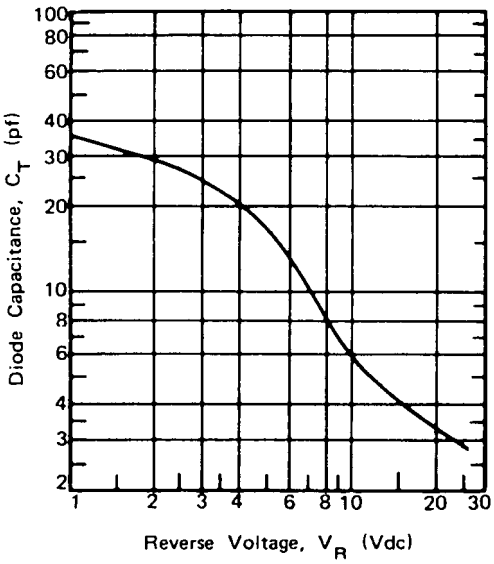

Figure 2-38 Capacitance versus junction bias for hyperabrupt-junction diode.

user's point of view is that higher Q can be obtained from GaAs devices. This is due to the lower resistivity of GaAs from a given doping level N. The resistivity of the epitaxial layer, or substrate, of a diode is given by

$$\rho = \frac{1}{Ne\mu} \tag{2-43}$$

where ρ = the resistivity
N = the doping level of the layer
e = the charge on an electron
μ = is the mobility of the charge carriers in the layer

Gallium arsenide has a mobility about four times that of silicon and, thus, a lower resistivity and higher Q for a given doping level N. Since diode capacitance is proportional to $\sqrt{N}$, independent of resistivity, a silicon diode and a GaAs diode of equal area and doping will have a capacitance difference proportional to the square root of the dielectric constant ratio. This gives the GaAs diode a 5% higher capacitance and is thus of little practical significance. The penalty paid for using GaAs is an unpassivated diode and a more expensive diode due to higher material and processing costs. If the higher Q of the GaAs device is not really needed, a substantial price saving will be obtained by using a silicon device.

Planar Versus Mesa Construction. The two basic construction techniques used to manufacture tuning diodes are planar and mesa; cross sections for both of these devices are shown in Figure 2-39. The planar process, which is the backbone of the integrated circuit industry, lends itself to large-volume production techniques and is the one used for the 1N series of tuning diodes. Mesa processing, on the other hand, requires more

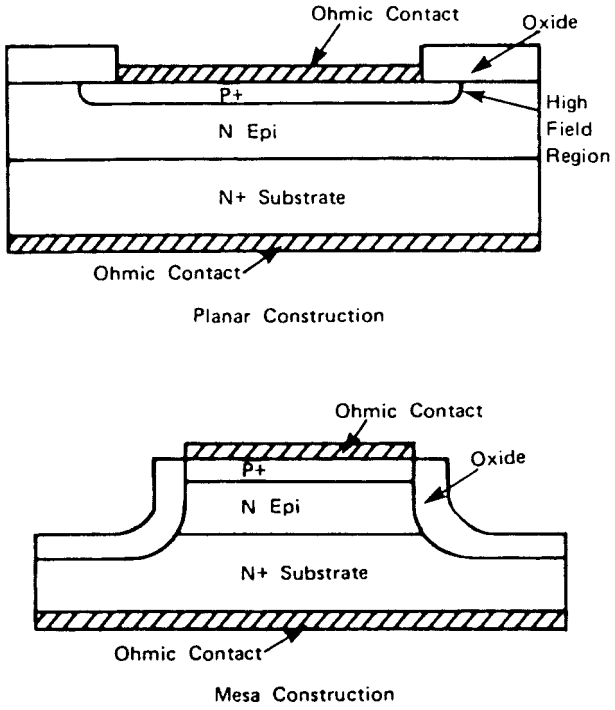

Figure 2-39 Cross sections of planar and mesa devices.

processing steps and is generally done on a wafer-by-wafer basis. This results in a more costly process and thus a more expensive diode. All microwave tuning diodes are of mesa design because of greatly higher Q. Due to the relatively small radius of curvature at the junction edge of a planar diode, the electric field in this area is greater than the electric field in the center (flat) portions of the junction. As a result, the breakdown voltage of the diode is determined by both the epitaxial resistivity and the radius of curvature of the junction edge. Thus, for a given breakdown voltage, a planar diode must use higher resistivity epitaxial material than a mesa diode, which has a completely flat junction. The end result is that the planar diode has a greater series resistance than a mesa diode for the same capacitance and breakdown voltage, and thus lower Q.

Capacitance

Capacitance Ratio. From the user's point of view, the capacitance ratio is simply the capacitance change available in the circuit. Thus, a user tuning from, say, –4 to –45 volts defines capacitance ratio as

$$R = \frac{C_T(-4)}{C_T(-45)} \tag{2-44}$$

where C_T includes C_J plus C_P plus C_F. The manufacturer, however, defines C_T as $C_J + C_P$.

To explore the significance of this difference, let's take two examples, one with a large C_J and another with a small C_J, in chip, package, and "typical" fringe situations. Both are 45-V tuning varactors.

Device	C_{J0}	C_{J45}	Ratio
A	0.6 pF	0.1 pF	6.0
B	15.0 pF	2.5 pF	6.0

Put both devices in a standard 023 package with C_P (strap and ceramic) of 0.18 pF:

Device	C_{T0}	C_{T45}	Ratio
C	0.78 pF	0.28 pF	2.75
D	15.18 pF	2.68 pF	5.67

Notice the drop in capacitance ratio, especially for the low-C_J diode. If we now add a typical 0.04 pF for external fringe capacitance, we get the following results:

Device	C_{T0}	C_{T45}	Ratio
C	0.82 pF	0.32 pF	2.56
D	15.22 pF	2.72 pF	5.6

The reduction in capacitance ratio, and thus circuit tuning capability, by the fringing fields is quite obvious and amounts to 7% in this example.

Because of the often stringent specifications on tuning ratio, it is mandatory that the manufacturer and customer clearly agree on the exact design of the holder used to measure the varactor in question.

Having described how to measure capacitance, it is relatively easy to describe the results. The section on diode physics described the various types of "laws," or C–V curves, and we will not repeat them here. Nonetheless, several important points must be covered.

The first is "available capacitance swing." The laws indicate a steadily decreasing capacitance with voltage, which indicates that the epitaxial region is widening and the electric field is increasing. (For an abrupt junction, since $C \propto 1/\sqrt{V}$, the depletion zone with W is increasing as $\sqrt{V}$, and the electric field V/W increases as $\sqrt{V}$.)

Two things can happen:

1. The junction width widens so that the entire intrinsic region is depleted. The capacitance bottoms out, resulting in voltage punchthrough.
2. The electric field exceeds the dielectric strength of silicon (or GaAs), and "solid-state discharge" or "avalanche" current is drawn.

The diode impedance drops, the varactor no longer "varacts," and circuit operation ceases. Moreover, if more than a few milliamperes of current is drawn, localized overheating may destroy the diode, resulting in breakdown voltage. All varactors are characterized for breakdown voltage—for example, 45 V minimum.

The theoretical tuning varactor is designed so that the punchthrough occurs at a voltage equal to the voltage breakdown of the diode. Logically, this means that in order to obtain

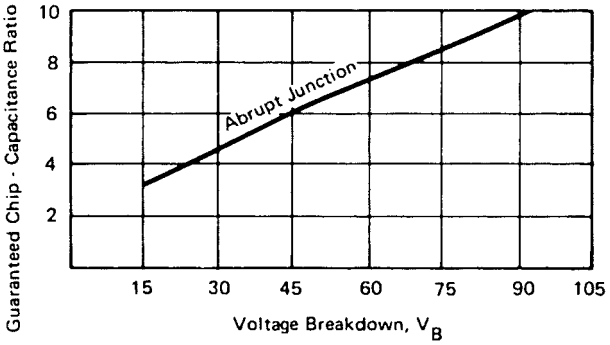

Figure 2-40 Capacitance ratio versus breakdown voltage.

greater tuning ratios, it is necessary to be able to increase the depletion-layer width without reaching punchthrough or breakdown. You must have a thicker epitaxial region to make this possible.

Figure 2-40 shows catalog ratio values, from zero bias to breakdown, as a function of breakdown voltage necessary. In the next section, on Q, we will discuss other elements in your choice of V_B.

To complete this section, we should mention that semiconductor processing control has been refined so well that capacitance tracking to within ±1% over the full range from zero to breakdown is now readily obtainable in production quantities.

Temperature Coefficient of Capacitance (T_{CC}). Unfortunately, since most datasheets give the value of T_{CC} at 4 V, it is sometimes assumed that this value applies at all bias voltages. This is not the case. Consider Eq. (2-45), a rewritten form of Eq. (2-42):

$$C(V) = \frac{C(O)}{(V + \varphi)^n} \tag{2-45}$$

Taking the derivative of this with respect to temperature T we have

$$\frac{dC(V)}{dT} = \frac{+nC(O)}{(v + \varphi)(v + \phi)^n} \frac{d\varphi}{dT} \tag{2-45a}$$

or, after substituting Eq. (2-45):

$$T_{CC} = \frac{1}{C(V)} \frac{dC(V)}{dT} = \frac{-n}{(V + \varphi)} \frac{d\varphi}{dT} \tag{2-46}$$

As a first approximation, we can say that $d\varphi/dT = -2.3$ mV/°C over the temperature range of interest.

From Eq. (2-46) we can draw the following conclusions:

1. The temperature coefficient is inversely proportional to the applied voltage.
2. The temperature coefficient is directly proportional to the diode slope, n.

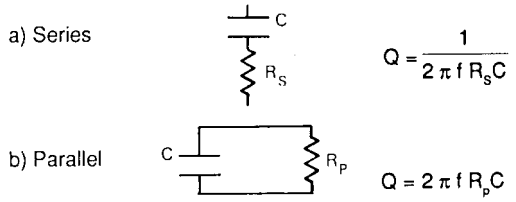
For an abrupt-junction diode that has a constant value of n (0.5), the temperature coefficient has a smooth curve in the form $K/(v + \varphi)$. However, in the case of hyperabrupt-junction diodes, n is a function of voltage, and the shape of the T_{CC} curve depends on the details of the $n(V)$ curve. A typical T_{CC} curve for an abrupt-junction diode is shown in Figure 2-41 and for an Alpha DKV6520 series hyperabrupt-junction diode in Figure 2-42. The inflection in the hyperabrupt T_{CC} is due to the fact that in this voltage range $n(V)$ is increasing faster than $1/V$, giving an increase in T_{CC}. It should also be noted, however, that over the range of the T_{CC} minimum the temperature coefficient is relatively constant, and operation in this area may be advantageous in some applications where a restricted tuning range can be used.

Q Factor or Diode Loss

Definitions. The classical definition of the Q of any device or circuit is

$$Q = \frac{2\pi \times \text{Energy stored}}{\text{Energy dissipated per cycle}} \tag{2-47}$$

For a capacitor, two formulations are possible:



Clearly, the two definitions must be equal at any frequency, which establishes

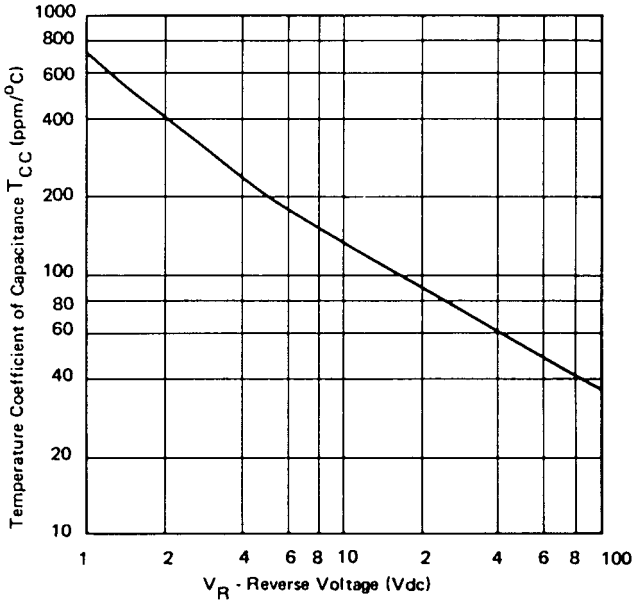


Figure 2-41 Temperature coefficient of capacitance versus tuning voltage for an abrupt-junction diode.

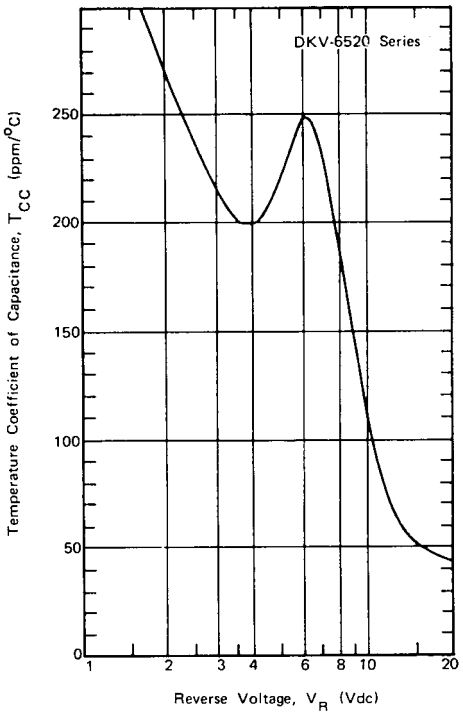

Figure 2-42 Temperature coefficient of capacitance versus tuning voltage ($T_A = 25$ °C) hyperabrupt-junction diode.

$$R_P = \frac{1}{(2\pi f)^2 C^2 R_S} \tag{2-48}$$

In the case of a high-Q tuning diode, the proper physical model is the series configuration, because the depleted region is almost perfectly pure capacitance, and the undepleted region, due to its relatively low resistivity, is almost a pure resistor in series with the capacitance. Furthermore, the contact resistances are also clearly in series. Q, then, for a tuning diode, is given by

$$Q_{(-v)} = \frac{1}{2\pi f_o R_{(-v)} C_{(-v)}} \tag{2-49}$$

where f_o is the operating frequency, $C_{(-v)}$ is the junction capacitance, and $R_{(-v)} = R(\text{epi}) + R_{C'}$, the sum of the resistance of the undepleted epitaxial layer and the fixed contact resistance.

Cutoff frequency, f_c, is defined as that frequency at which Q equals unity. Thus,

$$f_{c_{(-v)}} = \frac{1}{2\pi R_{(-v)} C_{(-v)}} \tag{2-50}$$

Historically, the tuning diode business has specified Q at 50 MHz, despite the fact that Q values of microwave diodes are so high that it is almost impossible to measure them at 50

Table 2-7 Parameters for 0.6-pF diode

Breakdown Voltage V_B	Resistivity ($\Omega \cdot$ cm)	Junction Diameter (mills)	Epitaxial Region (μm)	Depleted Epitaxial $V = -4$ V (μm)	Undepleted Epitaxial $V = -4$ V (μm)	R Undepleted (Ω)	R_{sp} (Ω)	Q_4
30	0.31	2.4	1.37	0.54	0.83	0.81	0.18	5200
45	0.52	2.8	2.25	0.73	1.52	1.86	0.15	2600
60	0.74	3.2	3.20	0.90	2.30	3.24	0.13	1500
90	1.25	3.7	5.27	1.21	4.06	7.17	0.10	700

MHz. Instead, as discussed below, Q is measured at microwave frequencies (e.g., 1–3 GHz) and related to 50 MHz by the relationship

$$Q_{(f1)} = Q_{(f2)} \frac{f_2}{f_1} \tag{2-51}$$

which derives quickly from the assumption that f_c is independent of the measuring frequency.

Since both junction capacitance and epitaxial layer resistance are functions of the applied bias, it is not possible to calculate Q as a function of bias from a measurement of capacitance alone. Catalog specifications typically show Q at –4 V, together with the capacitance at two or more voltages.

Relative to $Q_{(-4)}$, Q increases faster than the reduction in capacitance for bias greater than 4 V and, conversely, decreases faster for bias less than 4 V.

In the following section, we will discuss the diode design parameters that determine Q. Following this, we will describe some elementary Q measurement techniques.

Causes. In the discussion of device physics, the resistivity of the epitaxial region was discussed, together with its impact on punchthrough and breakdown. For example, Table 2-7 supplies typical resistivity and relative parameters of 0.6 pF ($C_{J(4)}$) diodes of different breakdowns. If we remember that if at any bias lower than breakdown the epitaxial region is not completely depleted, it follows that the undepleted portion presents a resistance in series with the pure capacitance of the depleted zone. The magnitude of this "undepleted" resistance is also shown in the table.

The entry R_{sp} ($R_{spreading}$) is the series resistance between the epitaxial region and the low-resistivity substrate. The calculations are for idealized cylindrical epitaxial regions of uniform resistivity, low-resistivity contact on the anode (top), and low-resistivity substrate on the cathode. This resistance is constant, independent of bias; also shown are epitaxial thickness region and width of the depletion zone at –4 V bias.

Note the substantial reduction in Q for high-voltage diodes caused by the increased epitaxial layer resistance; this is true for any value of capacitance or any type of junction. For greater voltage breakdown, the epitaxial region thickness must be increased, which requires an increase in epitaxial layer resistivity; the higher the resistivity of the undepleted zone, multiplied by the fact that it is much wider for high-voltage diodes, means the resistance increases substantially.

Consequently, a rule of thumb emerges: For maximum Q, never choose a tuning diode with a voltage breakdown in excess of what is needed for the necessary tuning range. If the

Table 2-8 ***Q*** **versus bias for 0.6-pF diode**

Breakdown Voltage V_B	C_{J0}	$Q(0)$	$C_J(-4)$	$Q(-4)$	$C_J(-10)$	Q (−10)	$C_J(-30)$	$Q(-30)$	$C_J(-45)$	$Q(-45)$	$C_J(-60)$	$Q(-60)$	$C_J(-90)$	Q(−90)

45	7.5	6.0	2500
60	8.4	7.5	1400
90	10.2	8.7	650

required tuning range is an octave, requiring a 4:1 ratio, the selection of a 30-V diode will result in diode losses half those of a 60-V diode.

Table 2-8 lists capacitance and Q for each of these chips as a function of bias. Please remember that Q is calculated at 50 MHz.

Table 2-9 rewrites the data of Table 2-8 to show available capacitance ratios between zero bias and breakdown. The first column is the theoretical optimum, as tabulated. The second column is the typical catalog specification. The reduction in tuning ratio below theoretical optima is caused by nonideal junction fabrication. The junctions are never perfectly abrupt.

Although the tables and numbers given refer to abrupt-junction silicon devices, the principle applies without exception to all types of tuning diodes. For comparison, Table 2-10 lists available ratios and Q values for a number of different varactors. The high Q values for GaAs and the low values for hyperabrupts are apparent.

One last point: The Q values and series resistance refer to chips only. The effects of package parasitics will be discussed later, but it is important to consider circuit contact losses here. For low-capacitance diodes—for example, $C_{J4} = 0.6$ pF—the epitaxial region contributes a high value of resistance and dominates Q except at punchthrough. Diode contact losses are less significant.

Post-Tuning Drift. Post-tuning drift (PTD) is the change in oscillator frequency with time after the tuning voltage has stabilized. The minimization of PTD has assumed greater importance with the design of more sophisticated electronic countermeasure systems, where rapid, accurate frequency changes are required.

Table 2-10 Comparative Tuning Diodes

Type	C_{J0}	Breakdown Voltage V_B	$Q_{(-4)}$[a]	Ratio C_{J0}/C_JV_B[a]
Silicon abrupt	1.0	30	5,000	4.5
Silicon abrupt	2.5	30	4,600	4.5
Silicon abrupt	5.0	30	3,800	4.5
Gallium arsenide abrupt	1.0	25	10,000	3.6
Gallium arsenide abrupt	0.5	10	17,000	2.5
Silicon hyperabrupt	50.0	22	300	17.0
Silicon hyperabrupt	2.5	22	500	14

[a] Minimum guaranteed.

Post-tuning drift can be characterized as short-term and long-term. Short-term PTD occurs in the time range of tens of nanoseconds to a few seconds, while long-term PTD occurs in the time range of seconds to minutes, hours, or days.

Short-term PTD is mainly dependent on the thermal properties of the diode and is improved by high Q (low power loss) and flip chip construction. Long-term PTD depends on oxide stability and freedom of mobile charge in the oxide. It should be noted that actual oscillation frequency change may occur even with a perfect tuning diode because of variation with frequency in the power dissipated by the diode, changes in the diode heat-sink temperature, and frequency changes due to other circuit elements. Less than 0.01% short- and long-term PTD can be obtained.

Distortion Products. Inasmuch as nonlinear components generate harmonics and other distortion products, an understanding of this mechanism is of prime interest to the circuit designer. In some instances, the distortion products are the desired end result of the circuit design, as in frequency multipliers, where harmonics of the input signal frequency are the required output signal. For other applications, such as tuning-diode-tuned linear circuits, distortion products are extremely undesirable, and in some instances the end product specification may set a maximum limit on the distortion products allowed.

Cross-Modulation. Cross-modulation is the transfer of the modulation on one signal to another signal and is caused by third-order and higher odd-order nonlinearities in the behavior of the device. Rewriting Eq. (2-42) we have

$$C(V) = \frac{C_0}{(1 + V/\varphi)^n} \tag{2-52}$$

where C_0 = capacitance
V = applied voltage = $V_0 + v$
V_0 = dc applied voltage
v = ac applied voltage

Then, for a desired signal of

$$S_1 = v_1 \sin \omega_1 t \tag{2-53}$$

and a second, amplitude-modulated signal of

$$S_2 = v_2(1 + m \cos \omega_m t)\sin \omega_2 t \tag{2-54}$$

it can be shown that the cross-modulation, γ, defined by

$$\text{Output signal} \sim v_1 \sin \omega_1 t + \gamma \sin (\omega_1 \pm \omega_m)t \tag{2-55}$$

is found to be

$$\gamma = \frac{n(n+1)mv_2^2}{4(V_0+\varphi)^2} \tag{2-56}$$

From this equation it can be seen that cross-modulation is:

- Proportional to the square of the interfering signal
- Directly proportional to the interfering signal's modulation index, m
- Independent of the strength of the desired signal
- Independent of the frequencies of the desired and interfering signals (assuming that the nonlinearity to which both signals are subjected is sufficiently frequency-indiscriminate so this is the case)
- Present for all values of n; that is, no value of n gives zero cross-modulation

Solving Eq. (2-56) for the signal level v_2 required to produce cross-modulation of value γ, we have

$$v_2 = \frac{2(V_0+\phi)\gamma}{n(n+1)^m} \tag{2-57}$$

The interfering signal levels required to produce 1% cross-modulation from a 30%-modulated interfering signal applied to an abrupt-junction diode and a hyperabrupt-junction diode are shown in Figure 2-43.

From this figure, it can be seen that the hyperabrupt-junction diode is more susceptible to cross-modulation than the abrupt-junction diode in the region of maximum slope of the

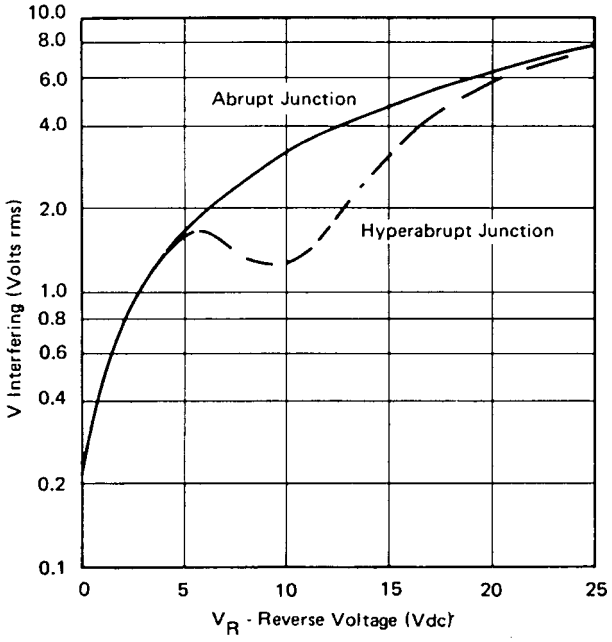

Figure 2-43 Interfering signal (30% amplitude modulated) level versus bias for 1% cross-modulation for abrupt-junction and hyperabrupt-junction diodes.

hyperabrupt-junction diode. For many applications, however, distortion products will be generated by other devices, such as transistors, at signal levels considerably below those given in Figure 2-43.

Intermodulation. Intermodulation is the production of undesired frequencies in the form

$$\sin(2\omega_1 t - \omega_2 t) \quad \text{and} \quad \sin(\omega_1 t - 2\omega_2 t) \tag{2-58}$$

from an input signal in the form of

$$v(\cos \omega_1 t + \cos \omega_2 t) \tag{2-59}$$

From an analysis similar to that done for cross-modulation, it can be shown that

$$\text{Intermodulation} = \frac{n(n+1)v^2}{8(V_0 + \varphi)^2} \tag{2-60}$$

or

$$\text{Cross-modulation} = (2m) \times \text{Intermodulation} \tag{2-61}$$

Harmonic Distortion. Harmonic distortion products are integral multiples of the signal frequencies and decrease in amplitude as the harmonic number decreases. Due to passband considerations and amplitude decrease with harmonic number, the second harmonic is the one of prime concern. Again, it can be shown that the second harmonic, v_2, of a signal of amplitude v_1 is

$$v_2 = \frac{n}{3(V_0 + \phi)} v_1^2 \tag{2-62}$$

Figure 2-44 shows the signal level required to produce 10% second-harmonic distortion in an abrupt-junction and a hyperabrupt-junction diode. Again, as in the case of cross-modulation, the hyperabrupt-junction diode is slightly worse than the abrupt-junction diode in the region of maximum slope of the hyperabrupt-junction diode.

Reduction of Distortion Products. In some cases, the signal levels applied to the diode generate distortion products larger than desirable for the circuit application. In this case, significant reduction in the distortion products can be achieved by using two diodes in a back-to-back configuration, as shown in Figure 2-45. Analysis shows that the fundamental signal components through the diodes are in phase and add, while some distortion products are out of phase and cancel, thus improving distortion performance.

Since the gradient of the electrical field produced in the depletion layer by a reverse bias applied to the device is proportional to the space charge density, the following equations can be written for the junction width W as a function of the reverse bias V_R:

For an Abrupt *pn* Junction (Alloyed Diodes)

$$W = {}_2\sqrt{2\frac{\varepsilon_r \varepsilon_0}{q}\left(\frac{1}{C_p} + \frac{1}{C_n}\right)(V_R + V_D)} \tag{2-63}$$

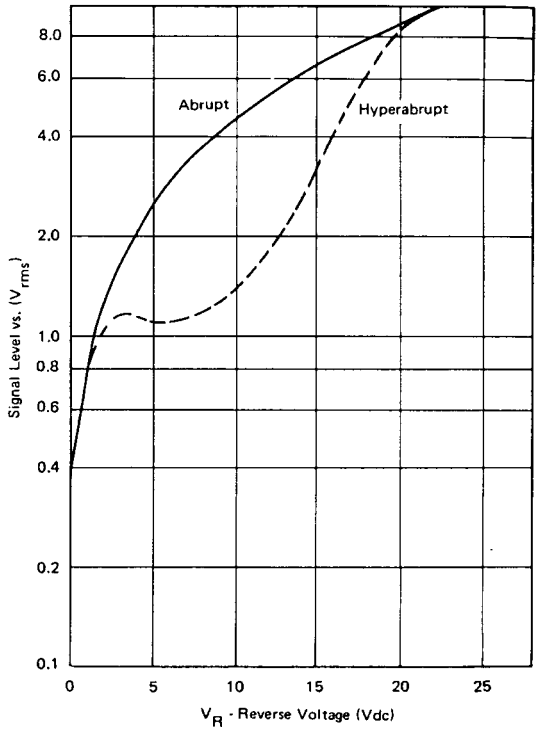

Figure 2-44 Signal level versus reverse voltage for 10% harmonic distortion.

For Linear *pn* Junctions (Single-Diffused Diodes, such as BA110–BA112)

$$W = \sqrt[3]{12\frac{\varepsilon_r \varepsilon_0}{aq}(V_R + V_D)} \tag{2-64}$$

where a is the impurity gradient within the depletion layer, ε_0 is the absolute dielectric constant ($8.85 \times 10^{-14}\ A_s/V_{cm}$, and $\varepsilon_r \approx 12$, the relative dielectric constant of silicon.

The junction capacitance, which is inversely proportional to the junction width, therefore varies in alloyed diodes with the square root, and in single-diffused diodes with the cube root of the externally applied reverse bias, and can be calculated from the general equation

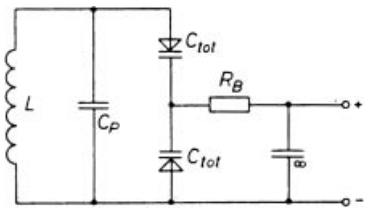

Figure 2-45 Back-to-back diodes. C_P is a fixed parallel capacitance, R_B is a bias decoupling resistor, and the capacitor marked ∞ is a low-impedance bypass.

$$C = \frac{\varepsilon_r \varepsilon_0 S}{W} \tag{2-65}$$

where S is the surface area of the *pn* junction. By way of approximation, we can also use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{2-66}$$

where all constants and all parameters determined by the manufacturing process are contained in K. The exponent n is a measure of the slope of the capacitance/voltage characteristics and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction. Figure 2-46 shows the capacitance/voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation has been indicated which, although purely formal, describes the practical characteristics better than Eq. (2-66):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{2-67}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is a voltage. The exponent m is much less dependent on voltage than the exponent n in Eq. (2-66).

Equations (2-63) through (2-67) express the pure junction capacitance of the capacitance diode, but to this must still be added a constant capacitance, determined by structure parameters, in order to obtain the diode capacitance C_{tot}, which interests the user. With high inverse voltages—that is, low junction capacitance—a difference will therefore arise between the theoretical capacitance/voltage characteristic according to Eq. (2-66) and the practical characteristic, as shown in Figure 2-47.

The operating range of a capacitance diode or its useful capacitance ratio

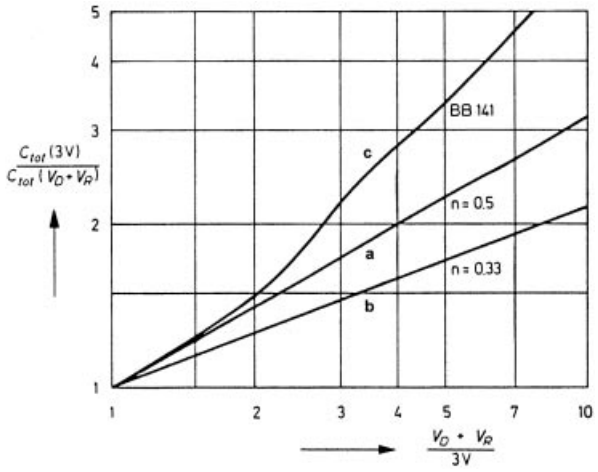

Figure 2-46 Capacitance/voltage characteristic for (a) an alloyed capacitance diode, n = 0.5; (b) a diffused capacitance diode, n = 0.33; and (c) a wide-range tuner diode (BB141).

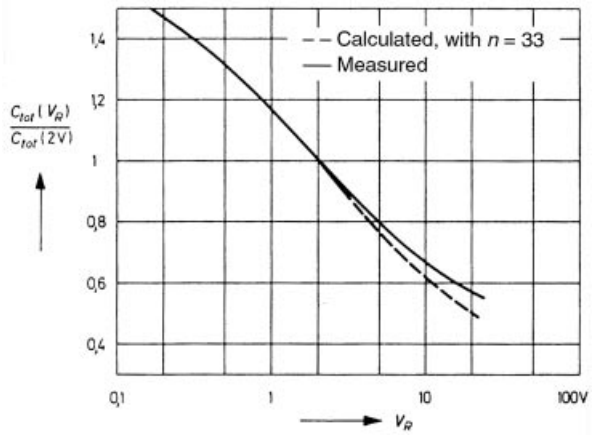

Figure 2-47 Capacitance/voltage characteristic of the BA110 diode.

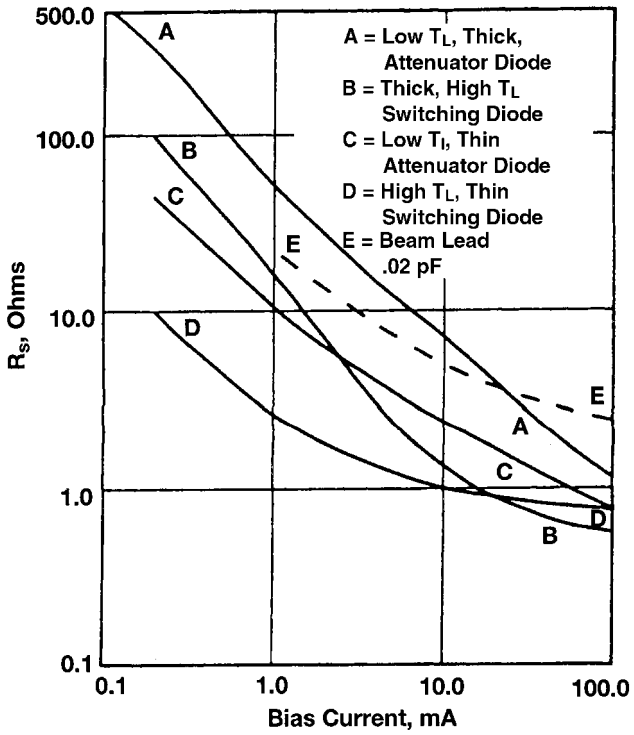

Figure 2-48 Basic current/voltage and capacitance/voltage characteristics.

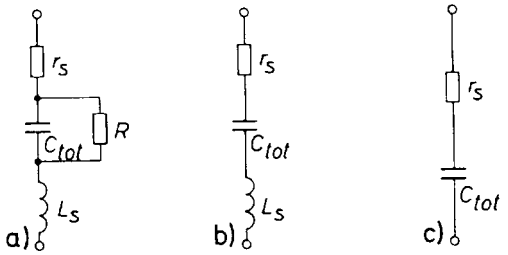

Figure 2-49 Equivalent circuits for capacitance diodes: (a) complete circuit, (b) simplified circuit, and (c) further simplification for low frequencies.

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R\min})}{C_{\text{tot}}(V_{R\max})} \tag{2-68}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage either into the forward mode or the breakdown mode. Otherwise, rectification, which would shift the diode's bias and considerably affect its figure of merit, would take place. Figure 2-48 plots the capacitance/voltage characteristics of a capacitance diode to clarify the relationship. The useful operating range lies between the voltages

$$V_{\min} > \hat{V} - V_F \quad \text{and} \quad V_{\max} < V_{(\text{BR})R} - \hat{V} \tag{2-69}$$

As has already been indicated, the exponent n for large-capacitance-ratio or tuning diodes used today for TV tuners is not constant but voltage-dependent and subject to manufacturing tolerances. This means that the capacitance/voltage characteristic of these diodes is likewise subject to manufacturing tolerances. Since, in a TV tuner, it is necessary for two or three circuits to be tuned uniformly, tuner diodes must be selected empirically for identical characteristics and supplied in equipment lots.

Electrical Properties of Tuning Diodes. In this section, the electrical properties of capacitance diodes are described, with reference to data published on the tuner diodes BB141 and BB142.

Equivalent Circuit. Since a capacitance diode is not an ideal capacitor, it is useful to introduce an equivalent circuit that can serve as a basis for discussing the diode's electrical properties. Figure 2-49 shows various types of equivalent circuits.

The complete equivalent circuit (Figure 2-49a), which conforms closely to physical conditions, comprises, in addition to the diode capacitance C_{tot}, the series resistance r_S and the series inductance L_S, and also the reverse resistance $R = dV_R/dI_R$. At higher frequencies, this resistance can usually be disregarded, so that the equivalent circuit is simplified in terms of Figure 2-49b—the configuration usually employed. In many cases, the series inductance can also be disregarded, in which case we obtain Figure 2-49c.

Capacitance. Figure 2-50 shows the capacitance/voltage characteristic borrowed from the datasheets of diodes BB141 and BB142. As this characteristic, like most characteristics published in datasheets, represents merely a typical curve, it would not convey sufficient

information for the user to dimension a tuner. Therefore, the datasheets contain additional data on capacitance and useful capacitance ratio:

Capacitance		BB141A (pF)	BB141B (pF)	BB142 (pF)
At $V_R = 1$ V	C_{tot}	16	19	17
At $V_R = 3$ V	C_{tot}	11	13	12
At $V_R = 25$ V	C_{tot}	2–2.35	2.25–2.65	2–3

$$\text{Useful capacitance ratio} = \frac{C_{tot}(3\text{ V})}{C_{tot}(25\text{ V})} = 4 \text{ to } 6$$

On the basis of the spread of the diode capacitance C_{tot} guaranteed for $V_R = 25$ V, it is possible to calculate the tuner with the aid of the spread guaranteed for the capacitance ratio.

Three further capacitance graphs are shown in Figures 2-51 through 2-53. Figure 2-51 shows a (typical) curve representing the normalized slope as a function of the reverse voltage, Figure 2-52 the normalized capacitance as a function of the junction temperature, and Figure 2-53 the temperature coefficient of the capacitance as a function of the reverse voltage.

The variation of diode capacitance with ambient temperature, as shown in Figures 2-52 and 2-53, is really only a function of the temperature dependence of the diffusion voltage [see Eq. (2-66)]. The diffusion voltage drops with rising temperatures by about 2 mV/°C , which means that the diode capacitance rises with temperature. The influence of the diffusion voltage, and thus the temperature coefficient of the capacitance, decreases as the reverse voltage rises. It is therefore advisable to run a capacitance diode with as high a reverse voltage as the required capacitance ratio permits. Compensation for the dependence of capacitance on temperature will be discussed later.

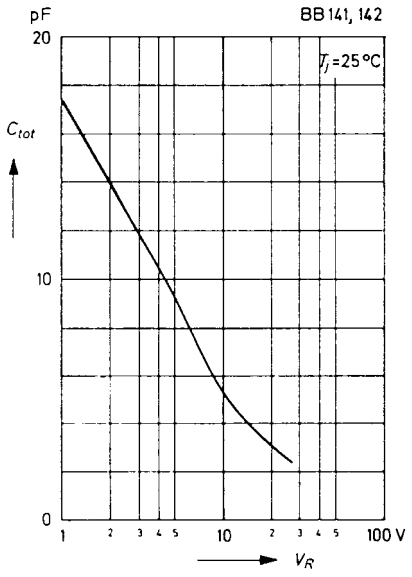

Figure 2-50 Capacitance/voltage characteristic of diodes BB141 and BB142.

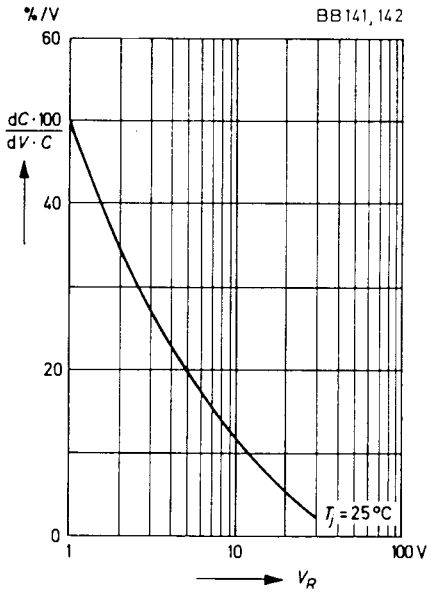

Figure 2-51 Slope (normalized) as a function of the reverse voltage.

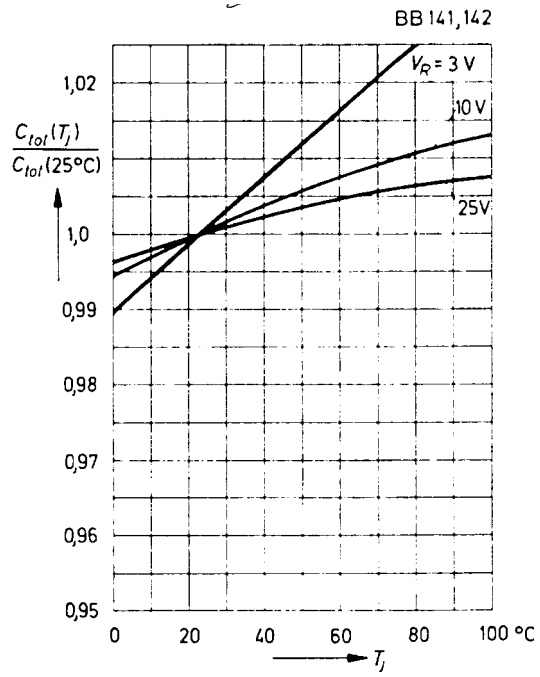

Figure 2-52 Capacitance (normalized) as a function of the junction temperature.

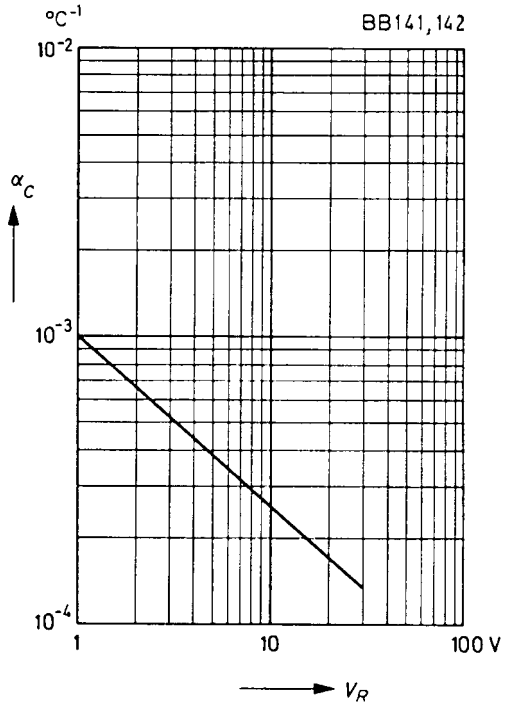

Figure 2-53 Temperature coefficient of capacitance as a function of the reverse voltage.

Series Resistance, Figure of Merit (Q). Since capacitance diodes are intended for employment in resonant circuits, indications are required as to the circuit attenuation that they produce. Usually, the series resistance or the figure of merit that can be calculated therefrom is indicated. With reference to the equivalent circuit shown in Figure 2-49a, the figure of merit (or Q factor) is calculated:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S + 1/\omega C_{\text{tot}} R} \tag{2-70}$$

Figure 2-54 shows the theoretical (normalized) Q as a function of frequency. With the frequency range of 10–1000 MHz, which is essential for tuner diodes, the parallel resistance R caused by the reverse current (see Figure 2-49b) can be disregarded, and Eq. (2-70) can be simplified to read as follows:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S} \tag{2-71}$$

In Figure 2-55, Q is plotted as a function of frequency for the tuner diodes BB141 and BB142. The datasheet indicates, in addition to this curve, the value of the series resistance at $f = 470$ MHz and $C_{\text{tot}} = 9$ pF:

	BB141A, BB141B	BB142
Series resistance (r_S)	0.6 (< 0.8)	0.9 (< 1.2)

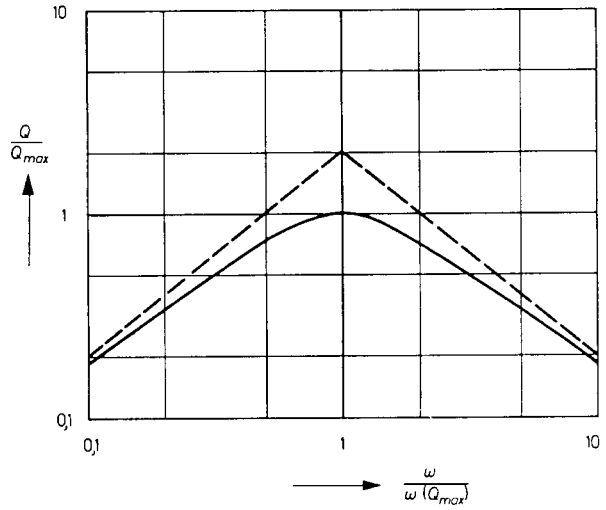

Figure 2-54 *Q* (normalized) as a function of frequency.

Since the diode capacitance and the series resistance decrease as the reverse voltage rises, Q is likewise dependent on the reverse voltage. It is smallest at a low reverse voltage, that is, at a low frequency. The series and parallel capacitances inevitable in a diode-tuned resonant circuit influence the effective Q of the tuning capacitance, as will be described later.

Series Inductance, Series Resonant Frequency, Cutoff Frequency for Q = 1. These three parameters define the behavior of the diode at high frequencies when the influence of

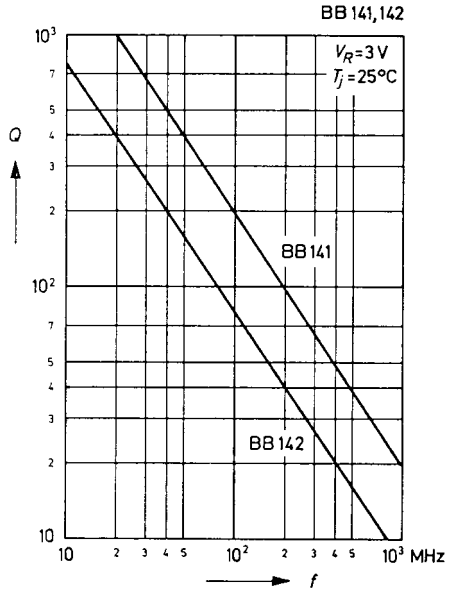

Figure 2-55 *Q* as a function of frequency.

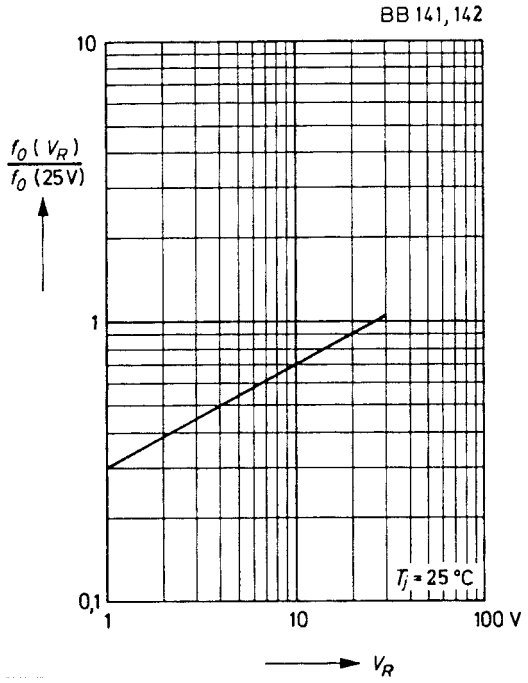

Figure 2-56 Series-resonant frequency (normalized) as a function of the reverse voltage.

the series inductance can no longer be neglected. The parameter on which the calculation is based is the series inductance L_S, which is determined by the connection leads. As indicated in Figure 2-49a, it is in series with the capacitance and, given a suitable frequency, forms a series-resonant circuit therewith. In that case

$$\omega L_S = \frac{1}{\omega C_{\text{tot}}} \tag{2-72}$$

and the series-resonant frequency is

$$f_0 = \frac{1}{2\pi\sqrt{C_{\text{tot}} L_S}} \tag{2-73}$$

Above this frequency, the impedance of the diode is inductive, but it depends on the reverse voltage. Figure 2-56 shows how the (normalized) series-resonant frequency depends on the reverse voltage for the tuner diodes BB141 and BB142.

The cutoff frequency for $Q = 1$ is defined as the frequency at which Q assumes the value of unity. In a rough calculation, the reactive impedance of the diode capacitance can be neglected and the frequency f_{Q1} obtained for the condition in which the inductive reactance equals the series resistance:

$$\omega L_S = r_S \tag{2-74}$$

$$f_{Q1} = \frac{r_S}{2\pi L_S} \tag{2-75}$$

For the tuner diodes BB141 and BB142, Figure 2-57 shows how the (normalized) cutoff frequency depends on the reverse voltage. The datasheets contain the following numerical information:

		BB141	BB142	
Series inductance measured 1.5 mm from the case	L_S	2.5	2.5	nH
Series-resonant frequency at $V_R = 25$ V	f_0	2	1.8	GHz
Cutoff frequency for $Q = 1$ at $V_R = 3$ V	f_{Q1}	24	16	GHz

Depending on the intended application, either the series-resonant frequency or the cutoff frequency for $Q = 1$ determines the maximum useful frequency range.

Leakage Current, Breakdown Voltage. These two parameters mark the dc performance of the diode when a reverse bias is applied to it. In the databook for the tuner diodes BB141 and BB142, the breakdown voltage is quoted as follows:

$$\text{Reverse breakdown voltage at } I_R = 100\ \mu\text{A}: \quad V_{(BR)R} > 30\ \text{V}$$

This means that the maximum reverse voltage that may be applied to the diode as a tuning voltage is 30 V.

The leakage current for the above-mentioned tuner diodes is guaranteed as follows:

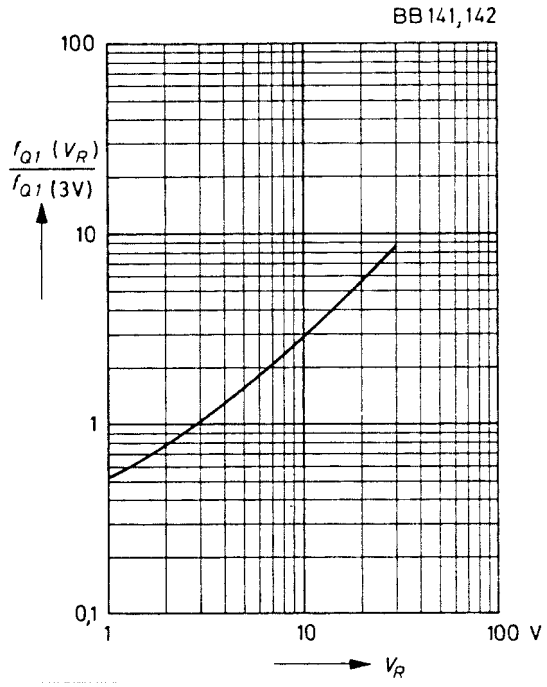

Figure 2-57 Cutoff frequency for $Q = 1$ (normalized) as a function of the reverse voltage.

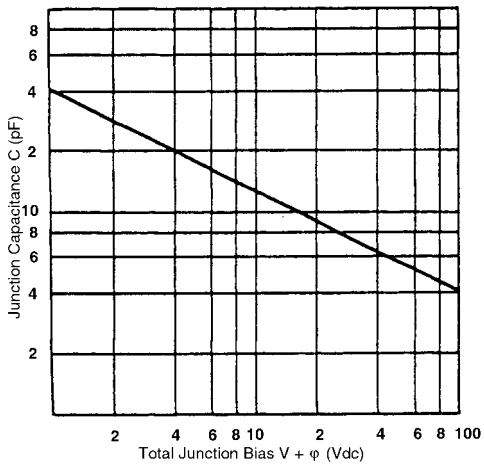

Figure 2-58 Leakage current as a function of reverse voltage.

$$\text{Leakage current at } V_R = 28 \text{ V:} \quad I_R < 50 \text{ nA}$$

Moreover, Figure 2-58 shows a graph that illustrates the leakage current as a function of the reverse voltage. Since this current is temperature dependent (as with every silicon diode)—it doubles with each temperature rise of about 10 °C—care should be taken when dimensioning the tuner circuit that the leakage current does not cause inadmissible voltage variations at increased ambient temperatures.

Matching of Tuner Diodes, Uniform Parameters. As has already been mentioned, the capacitance versus voltage characteristics of modern tuner diodes are subject to a certain scatter, so that it becomes necessary to test these diodes to obtain equipment lots empirically.

Diode-Tuned Resonant Circuits

Tuner Diode in the Parallel-Resonant Circuit. Figures 2-59, 2-60, and 2-61 illustrate three basic circuits for the tuning of parallel-resonant circuits by means of capacitance diodes.

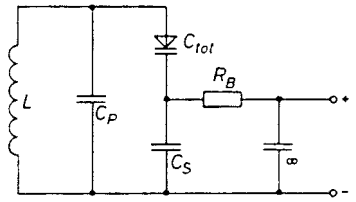

Figure 2-59 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the series capacitor.

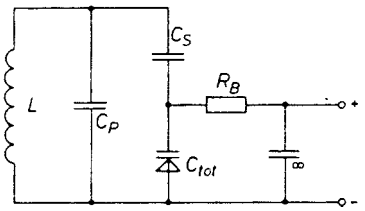

Figure 2-60 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the diode.

In the circuit diagram of Figure 2-59, the tuning voltage is applied to the tuner diode via the input coil and the bias resistor R_B. Series-connected to the tuner diode is the series capacitor C_S, which completes the circuit for ac but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling capacitor preceding the bias resistor is large enough for its value to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_C. We have the equation

$$R_C = R_B\left(1 + \frac{C_S}{C_{\text{tot}}}\right)^2 \tag{2-76}$$

If in this equation the diode capacitance is substituted by the resonant circuit frequency ω, we obtain

$$R_C = R_B\left(\frac{\omega^2 LC_S}{1 - \omega^2 LC_P}\right)^2 \tag{2-77}$$

The resistive loss R_C caused by the bias resistor R_B is seen to be highly frequency dependent, and this may result in the bandwidth of the tuned circuit being independent of frequency if the capacitance of the series capacitor C_S is not chosen sufficiently high.

Figure 2-60 shows that the tuning voltage can also be applied directly and in parallel to the tuner diode. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_C = R_B\left(\frac{1 + C_{\text{tot}}}{C_S}\right)^2 \tag{2-78}$$

and

$$R_C = R_B\left(\frac{\omega^2 LC_S}{\omega^2 L(C_S + C_P) - 1}\right)^2 \tag{2-79}$$

The influence of the bias resistor R_B in this case is larger than in the circuit of Figure 2-60, provided that

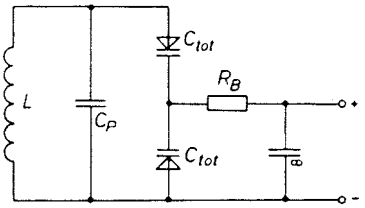

Figure 2-61 Parallel-resonant circuit with two tuner diodes.

$$C_S^2 > C_S(C_{\text{tot}} + C_P) + C_{\text{tot}}C_P \tag{2-80}$$

This is usually the case because the largest possible capacitance will be preferred for the series capacitor C_S, and the smallest for the shunt capacitance C_P. The circuit of Figure 2-59 is therefore normally preferred to that of Figure 2-60. An exception would be the case in which the resonant circuit is meant to be additionally damped by means of the bias resistor at higher frequencies.

In the circuit of Figure 2-61, the resonant circuit is tuned by two tuner diodes that are connected in parallel via the coil for tuning purpose, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation (see section entitled "Modifying the Diode Capacitance by the Applied ac Voltage") takes effect in opposite directions in these diodes and therefore cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuner diodes, is transformed into the circuit at a constant ratio throughout the whole tuning range. Given two identical, loss-free tuner diodes, we obtain the expression

$$R_C = 4R_B \tag{2-81}$$

Capacitances Connected in Parallel or Series with the Tuner Diode. Figures 2-59 and 2-60 show that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuner diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. As far as possible, the value of the series capacitor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases, as, for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency, this is not possible and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{\text{tot}} \frac{1}{1 + C_{\text{tot}}/C_S} \tag{2-82}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuner diode, increases to

$$Q^* = Q\left(1 + \frac{C_{\text{tot}}}{C_S}\right) \tag{2-83}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{\max}}{C^*_{\min}} = \frac{C_{\max}}{C_{\min}} \frac{1 + C_{\min}/C_S}{1 + C_{\max}/C_S} \tag{2-84}$$

where $C_{\max}$ and $C_{\min}$ are the maximum and minimum capacitances of the tuner diode.

On the other hand, the advantage is gained that, due to capacitive potential division, the amplitude of the alternating voltage applied to the tuning diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{\text{tot}}/C} \tag{2-85}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance $C_{\max}$ of the tuner diode and a higher useful capacitance ratio. The influence exerted by the series capacitor, then, can actually be kept lower than Eq. (2-83) would suggest.

The parallel capacitance C_P that appears in Figures 2-59 to 2-61 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}} \left(1 + \frac{C_P}{C_{\text{tot}}} \right) \tag{2-86}$$

The Q of the effective tuning capacitance, as derived from the Q of the tuner diode, is

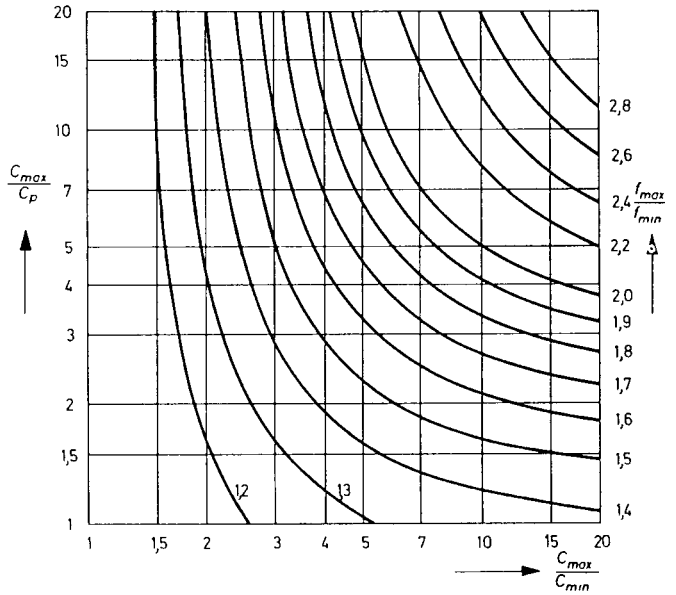

Figure 2-62 Diagram for determining the capacitance ratio and minimum capacitance.

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{2-87}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance ratio is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}} \frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{max}}} \tag{2-88}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the circuit-design stage.

TUNING RANGE. The frequency range over which a parallel-resonant circuit according to Figure 2-59 can be tuned by means of the tuner diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit.

The ratio can be found from

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{1 + \frac{\dfrac{C_{\text{max}}}{C_P\,(1 + C_{\text{max}}/C_S)}}{1 + \dfrac{C_{\text{max}}}{C_P\,(C_{\text{max}}/C_{\text{min}} + C_{\text{max}}/C_S)}}} \tag{2-89}$$

In many cases, the series capacitor can be chosen large enough for its effect to be negligible. In that case, Eq. (2-89) is simplified as follows:

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{\frac{1 + C_{\text{max}}/C_P}{1 + C_{\text{min}}/C_P}} \tag{2-89a}$$

From this equation, the diagram shown in Figure 2-62 is computed. With the aid of this diagram, the tuner diode parameters required for tuning a resonant circuit over a stipulated frequency range—that is, the maximum capacitance and the capacitance ratio—can be determined.

Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced according to Eq. (2-84).

TRACKING. Some applications require the maintenance of a fixed frequency relationship between two or more tuned circuits as their tuning is simultaneously adjusted. Referred to as *tracking*, this technique requires narrow tolerances of capacitance versus tuning voltage. Minimizing tracking error requires special care if the tracking circuits must cover the same frequency span beginning at different start and end frequencies, as is necessary when simultaneously tuning oscillator and mixer/RF circuitry in a superheterodyne receiver. Then, tracking error must be minimized by means of series and shunt capacitances in accordance with methods known from variable capacitors. The frequency deviations that must be anticipated are summarized in the equation

$$\frac{df}{f} = -\frac{1}{2}\frac{dC_0}{C_0} - \frac{1}{2}\frac{d(L-L_0)}{L} - \frac{1}{2}\frac{dL_0}{L_0} + \frac{n}{2}\frac{dV_R}{V_R + V_D} \tag{2-90}$$

The spread of parameters dC_0/C_0 and dL_0/L_0 can only be compensated by varying the circuit inductances $d(L–L_0)/L$ or by varying the bias $dV_R/(V_R + V_D)$.

Modulating the Diode Capacitance by the Applied ac Voltage. In normal operation, the sum of the tuning voltage and the alternating signal voltage of the resonant circuits is applied to the tuner diode. The bias, and thus the capacitance, of the tuner diode therefore varies at the rhythm of the alternating voltage. Due the nonlinear character of the capacitance versus voltage curve, voltage distortions and capacitance shifts are inevitable, and these must be kept within adequate limits. This is done by maintaining the ac applied to the diode(s) at sufficiently low ac amplitude and by choosing an adequate minimum value for the tuning voltage. In the resonant circuit, a tuner diode is modulated predominantly by a current free from harmonics, according to the equation

$$i = \hat{i}\cos \omega t \tag{2-91}$$

The alternating voltage across the diode is

$$v = (V_R + V_D)\left[\left(1 + \frac{\hat{i}(1-n)}{\omega C_{\text{tot}} V_R}\sin \omega t\right)^{1/(1-n)} - 1\right] \tag{2-92}$$

An evaluation of this equation shows that especially the first harmonic makes its appearance. The capacitance shift caused by the alternating voltage superimposed on the tuning voltage is shown in Figure 2-63. However, the voltage distortion, and thus the capacitance shift, can be largely avoided if two tuner diodes are used, as in Figure 2-61.

COMPENSATING TEMPERATURE DEPENDENCE. As has already been mentioned, variations are caused in the capacitance of the diode mainly by the dependence of the diffusion voltage on

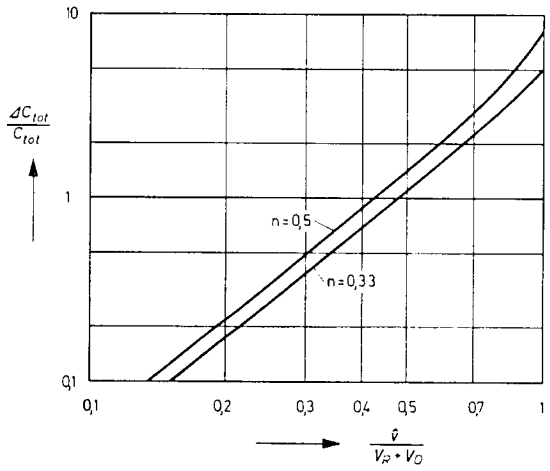

Figure 2-63 Capacitance increase as a function of the ac voltage drop across the tuner diode.

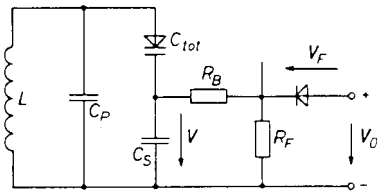

Figure 2-64 Temperature-compensation circuit with diode.

temperature. In a diode-tuned resonant circuit, the temperature coefficient of the resonant frequency, therefore, depends on the tuning voltage and thus on the resonant frequency. It is therefore impossible to compensate the temperature dependence of the resonant frequency by means of temperature-dependent capacitors—the method usually adopted for mechanically tuned circuits.

To achieve satisfactory compensation, the tuning voltage should be increased by an amount equal to that by which the diffusion voltage of the diode is reduced with rising temperature; that is, by approximately 2 mV/°C. This can be done easily by connecting a forward-biased silicon diode in series with the source of the tuning voltage, as shown in Figure 2-64. Since the forward voltage of the diode varies by –2 mV/°C with ambient temperature, the voltage

$$V = V_0 + V_D - V_F$$

which determines the bias of the tuner diode, and therefore also the diode capacitance, is almost temperature independent. In practice, it is advisable to feed this diode with additional current via the resistor R_F to keep its differential forward resistance sufficiently low and thus to prevent capacitive noise voltages from leaking into the tuning circuit.

To prevent the load placed by the resistor R_F on the source of the tuning voltage from fluctuating in a manner depending on the tuning voltage, a circuit such as shown in Figure 2-65 may be used in which the emitter diode of the transistor effects the compensation, and the only load placed on the source of the tuning voltage is the base current of this transistor.

Dynamic Stability. The resonant frequency of a diode-tuned RF circuit follows the equation

$$f = f_0 \sqrt{\left(\frac{V_R + V_D}{V_{R0} + V_D}\right)^n} \tag{2-93}$$

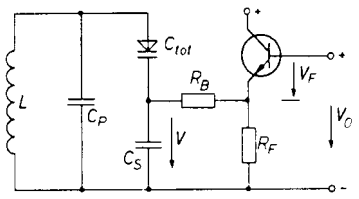

Figure 2-65 Temperature-compensation circuit with transistor.

The frequency f_0 is set with the aid of the circuit inductance when the tuning voltage equals V_{R0}. Since the signal amplitude in the circuit depends on the field strength of the received transmitter and since the resonant frequency of the circuit depends on the amplitude, undesirable feedback between the tuning voltage and the received alternating voltage may occur at the tuner diode. A disturbance that has a similar effect is the microphonic effect, which can sometimes be observed with mechanically variable capacitors. In an investigation of the feedback in diode-tuned resonant circuits, the following assumptions were made:

- The impedance of the antenna (or of the signal generator) is negligible.
- The full alternating voltage is applied to the diode (whereas, in practice, the series capacitor brings about a potential division).
- The capacitance versus voltage characteristic is an exponential function.
- The Q of this circuit is independent of the amplitude of the alternating voltage.

As a result of a high alternating voltage at the resonant circuit, three undesirable effects—harmonic generation, frequency shift, and cross-modulation—are encountered.

HARMONIC GENERATION. The nonlinearity of the capacitance versus voltage characteristic produces harmonics. However, the selectivity of the receiver reduces the effects of these harmonics to noise level.

FREQUENCY SHIFT. When a sinusoidal voltage v is applied to the tuner diode of the RF circuit, the variation of the diode capacitance does not follow the sine law, but the equation

$$\frac{C_\omega}{C} = \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{-n} \tag{2-94}$$

This results in a change of the resonant frequency of the circuit. The inductive slope of the resonant curve steepens and may even turn back. This could lead to bistable behavior of the resonant circuit. The change of frequency takes place as if the tuning voltage, and thus the resonant frequency, has decreased. The order of magnitude of this change of resonant frequency was determined with the aid of a computer from Fourier analysis of

$$\frac{\Delta f}{f} = 1 + \frac{1}{2\pi} \int_0^{2\pi} \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{n/2} d(\omega t) \tag{2-95}$$

Figure 2-66 shows the admissible alternating voltage at the diode, computed for a 2% frequency shift, as a function of the tuning voltage. The measured values differ by not more than 10% from the computed values. Since the Q of the circuits is about 50 for the VHF as well as the UHF range, a 2% frequency shift is permissible.

CROSS-MODULATION. Cross-modulation is a disturbance caused by nonlinearities of the characteristics of the components concerned. The modulation of an undesired amplitude-modulated signal is here transferred to the carrier of the amplitude-modulated intelligence signal. Cross-modulation is virtually independent of the amplitude of the intelligence signal.

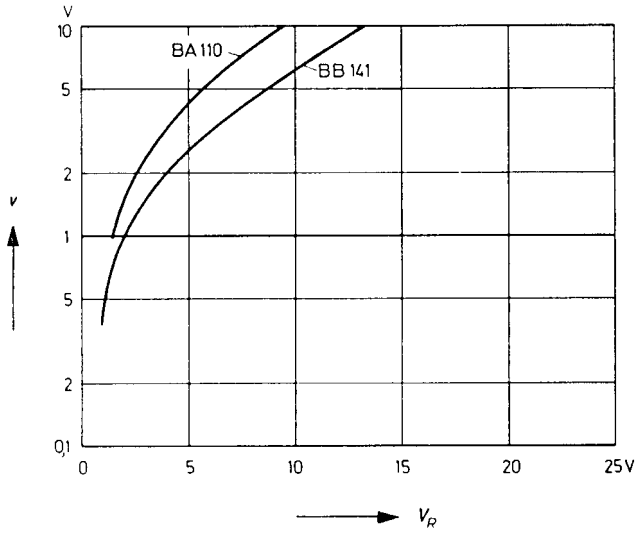

Figure 2-66 Admissible alternating voltage for a 2% frequency shift as a function of tuning voltage.

The cross-modulation factor for tuner diodes is

$$k = \frac{v^2}{(V_R + V_D)^2} m_v \frac{n(n+1)}{2} \tag{2-96}$$

Resolving this equation in terms of v, we obtain

$$v = \frac{V_R + V_D}{n} \sqrt{\frac{2kn}{m_v (n+1)}} \tag{2-97}$$

The usual definition of the cross-modulation percentage for measurement purposes is as follows: A 100% modulated noise signal ($m_v = 1$) of amplitude v is received simultaneously with the intelligence signal in the diode-tuned RF circuit. If a 1% modulation of the signal carrier by the noise signal takes place, this amounts to a cross-modulation factor $k = 0.01$. We thus obtain for tuner diodes

$$V = 0.14 \frac{V_R + V_D}{n} \sqrt{\frac{n}{n+1}} \tag{2-98}$$

Figure 2-67 gives the graphs for this equation. In practical operation, FM and VHF/UHF tuners equipped with the tuner diodes BB121 or BB141 exhibit merely the cross-modulation caused by the BJTs or FETs employed. For bipolar transistors, $v \approx 15$–100 mV; for FETs, 100–300 mV.

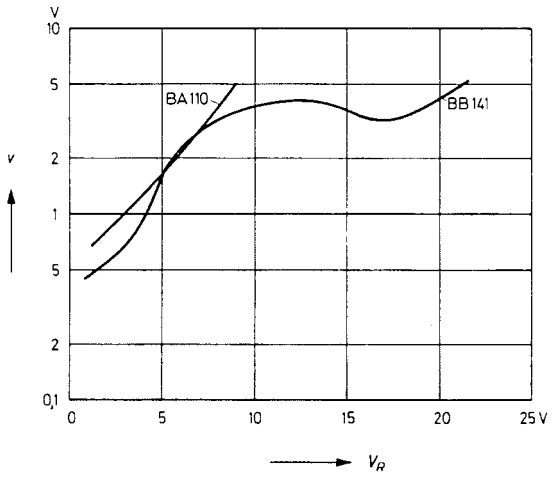

Figure 2-67 Graphical representation of Eq. (2-98).

Static Stability. To ensure trouble-free operation, the static parameters of the tuner diodes, especially the leakage current, must be taken into account. When differentiating the expression for the tuning voltage

$$V_R = V_B - I_R R_B \tag{2-99}$$

we obtain for a known leakage current I_R the tuning voltage variation

$$dV_R = dV_B - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} + dV_B \right) \tag{2-100}$$

This leads to a change in the resonant frequency

$$\frac{df}{f} = \frac{n}{2(V_R + V_D)} \left[dV_D - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} \right) + dV_B \right] \tag{2-101}$$

The resonant frequency is more stable the smaller the exponent n and the higher the tuning voltage V_R. The influence of the temperature dependence of the diffusion voltage V_D and its compensation have already been discussed. If the series bias resistance R_B is not too high, the effect of its variation ($dR_B/R_{B)}$ and the effect of the temperature dependence of the leakage current—doubling for every 10 °C temperature rise—may be neglected.

Generating the Tuning Voltage. The supply voltage V_B in Eq. (2-101) exerts an influence in many respects. The temperature coefficient of the voltage source—usually, for economic reasons, only a Zener diode is provided for stabilization—affects conditions not only with ambient temperature variations, but also when the Zener diode heats up after the set is switched on, or when its operating current varies. Because external temperature compensation of the operating voltage of the Zener diode cannot cover all detrimental effects and, moreover, increases the series bias resistance R_B, as well as any variations the latter may

undergo, the use of a temperature-compensated Zener diode, such as the 1N4065A (nominal Zener voltage, 33 V; temperature coefficient, 0.002 °C/W), is recommended.

Diode Switches. The diode switches described here differ somewhat from the switching diodes used in computer and pulse technology. Whereas in the case of switching diodes the signal itself triggers the switching operation—current does or does not pass through the switching diode depending on the signal level—diode switches allow an alternating current to be switched on or off by means of a direct voltage or a direct current. Figure 2-68 shows an example of the use of diode switches.

Diode Switch Technology. Special manufacturing techniques are needed to attain the low junction capacitance, low differential forward resistance r_F, and the low-inductance structure required for the special applications envisaged. Two conflicting requirements have to be met: On the one hand, a high-resistivity basic material should be used and the diode area should be kept as small as possible to minimize the junction capacitance for a given reverse voltage; on the other hand, the bulk resistance should be kept low. The size of the junction area, therefore, can represent only a compromise between these two requirements. To obtain a low bulk resistance R_B despite the use of high-resistivity silicon around the junction, the diodes are manufactured by the epitaxial process, characterized by a thin high-resistivity layer on a low-resistivity substrate. If the forward current I_F is sufficiently high, then the specific resistance of the epitaxial layer does not affect the bulk resistance, because under these conditions the resistivity of this layer is considerably reduced by being flooded with carriers.

The junction impedance Z_j is somewhat more critical (Figure 2-69). It is composed of the junction capacitance C_S, which does not depend on current, the current-dependent diffusion capacitance

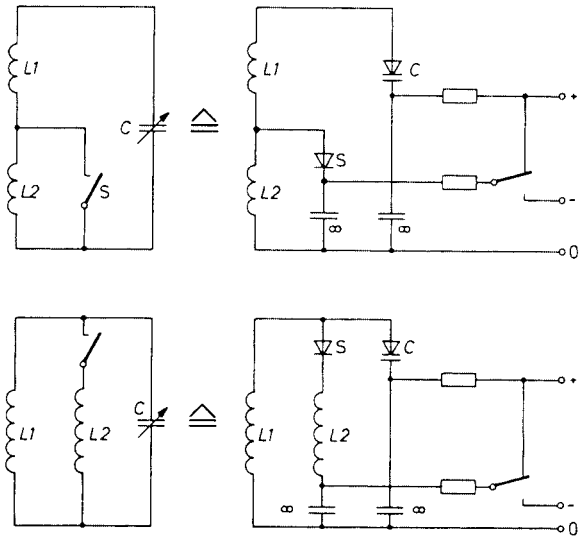

Figure 2-68 Comparison of mechanically and electronically tuned and switched resonant circuits.

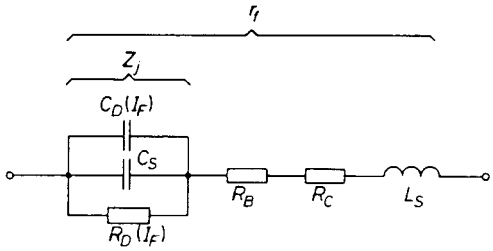

Figure 2-69 Equivalent circuit of diode switches in the frequency range from 1 MHz to 1 GHz.

$$C_D = \frac{\mathfrak{t}_p I_F}{V_T} \tag{2-102}$$

and the diffusion resistance

$$R_D = \frac{V_T}{I_F} \tag{2-103}$$

where $\mathfrak{t}_p$ is the lifetime of the minority charge carriers and

$$V_T = \frac{kT}{q} = 26 \text{ mV} \tag{2-104}$$

is the voltage equivalent of thermal energy. The resistive component of the impedance Z_j is calculated as follows:

$$\text{Re}(Z_j) = \frac{R_D}{1 + \omega^2 R_D^2 (C_S + C_D)^2} \tag{2-105}$$

As can be seen from the following approximations, this resistance becomes rather dependent on current at higher frequencies:

$$\text{For } I_F \to 0 \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega^2 C_S^2 V_T} \tag{2-106}$$

$$\text{For } I_F \to \infty \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega t_p I_F} \tag{2-107}$$

In Figure 2-70 the differential forward resistance is plotted as a function of the forward current. The only parameter by which the differential forward resistance can be reduced for a given current and a given frequency according to Eq. (2-107) is the carrier lifetime. Steps will have to be taken, therefore, to make the carrier lifetime as long as possible.

Because diode switches are designed for applications up to the gigahertz range, a geometry resulting in a low inherent capacitance and inductance had to be used. Furthermore, the device had to be assembled in such a way that virtually no additional contact resistance R_C was introduced. For this reason, a double-plug construction (hard-glass pressure contacts)

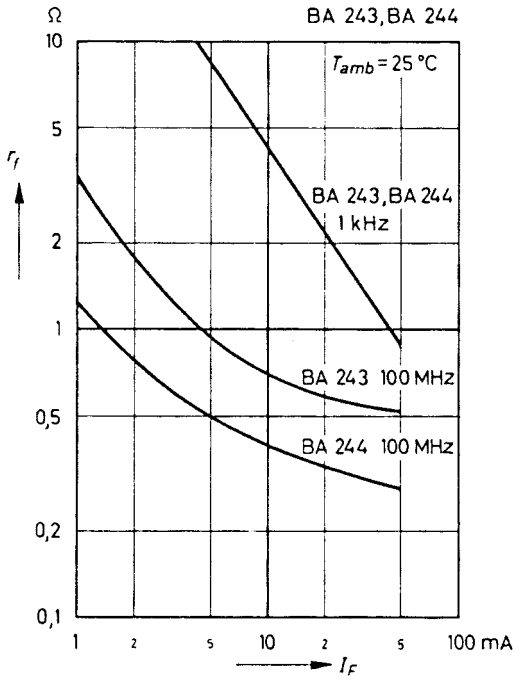

Figure 2-70 Differential forward resistance as a function of forward current.

was chosen to avoid the S- or U-bends customary with other encapsulations. The system is pressure-clamped between two stud-shaped enlargements of the connecting leads, the necessary high pressure being produced as the glass shrinks during cooling. This construction results in an encapsulation of short length (only 4 mm) and low series inductance, the advantages of which can be fully exploited because soldered connections to the leads can be made directly at the glass body.

Diode Switch Data. The silicon planar diode switches BA243 and BA244 are designed for electronic band selection in tuners in the frequency range from 10 to 1000 MHz. The differential forward resistance remains constant and is very low over a wide frequency and current range. The diode capacitance is likewise small and independent of voltage through a wide range. The devices are characterized by low-inductance geometry. The BA243 is intended for the VHF range, and the BA244 for the UHF range. See Table 2-11.

Resonant Circuits Incorporating Diode Switches. Figure 2-71 illustrates the function of the diode switch with reference to a parallel-resonant circuit whose resonant frequency can be switched by short-circuiting part of the circuit inductance. Such a switching procedure may be necessary for a VHF tuner, for example, to switch from band I to band III, because the frequencies of these bands are too far apart.

Capacitor C_K represents the capacitance of the resonant circuit. The symbol ∞ at capacitor C is meant to indicate that the value of this capacitor should be chosen to be much higher than the circuit capacitance. C completes the ac circuit when the inductor L_2 is shorted and

Table 2-11 BA243/244 specifications

Maximum Ratings			
Reverse voltage	V_R	20	V
Forward current at $T_A = 25$ °C	I_F	100	mA
Junction temperature	T_j	150	°C
Storage temperature range	T_s	–55 to +150	°C
Characteristics at $T_A = 25$ °C			
Forward voltage at $I_F = 100$ mA	V_F	<1	V
Leakage current at $V_R = 15$ V	I_R	< 100	nA
Dynamic forward resistance at $f = 50$–1000 MHz, $I_F = 10$ mA			
BA243	r_F	0.7 (< 1)	Ω
BA244	r_F	0.4 (< 0.5)	Ω
Relative variation of dynamic forward resistance with the variation of forward current in the range of $I_F + 2$–40 mA	$\frac{\Delta r_F 100}{r_F \Delta I_F}$	5	%/mA
Capacitance at $V_R = 15$ V, $f = 1$ MHz	C_{tot}	1.3 (< 2)	pF
Relative variation of capacitance with the variation of reverse voltage in the range of $V_R = 7$–20 V, $f = 100$ MHz	$\frac{\Delta C_{tot} 100}{C_{tot} \Delta V_R}$	1	%/V
Series inductance across case	L_S	2.5	nH

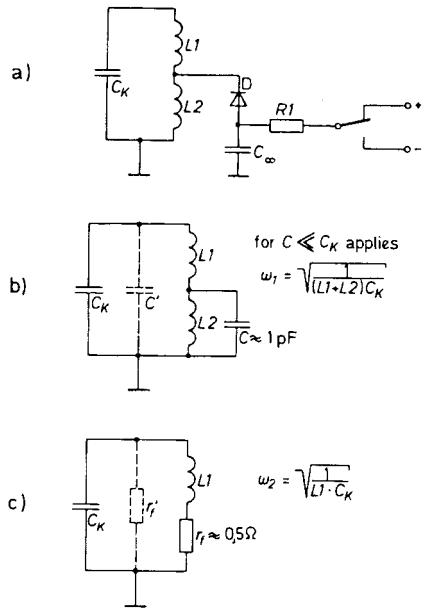

Figure 2-71 (a) Diode switch as bandswitch, shorting a partial inductance; (b) equivalent circuit with blocked diode switch; (c) equivalent circuit with conducting diode switch.

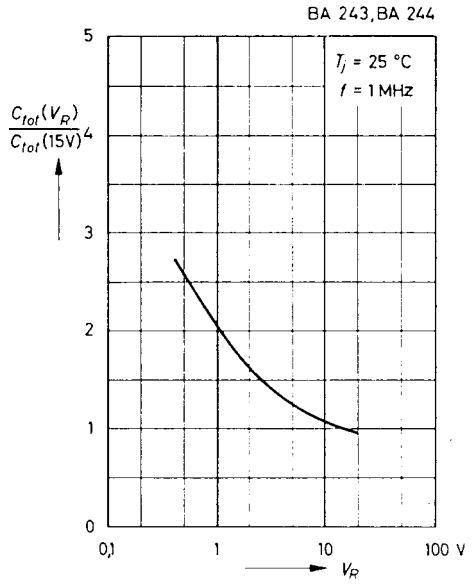

Figure 2-72 Capacitance as a function of the reverse voltage.

enables the switching or reverse voltage to be applied at a point of virtually zero RF potential. The resistor R_1 limits the diode current in the forward direction.

At a reverse voltage of $V_R = 15$ V, for example, the diode switch represents a 1-pF capacitor, as shown in Figure 2-71b. This represents parasitic capacitance C' in the circuit, which reduces the effective capacitance variation of the resonant circuit in the case of capacitive tuning. The capacitance C' is small enough to be negligible in most cases relative to the wiring and winding capacitances. Figure 2-72 shows the relative capacitance of the blocked-diode switches, as a function of the reverse voltage.

At a forward current of, for example, 10 mA, the diode has a differential resistance of approximately 0.5 Ω (see Figure 2-70). The effect of this resistance r_F on the resonant circuit is illustrated in Figure 2-71c. Conversion of a series loss resistance r_F into a parallel loss resistance r'_F is based on the following considerations: The equivalent parallel resistance r'_F affects the tuned circuit in the same way as the series resistance r_F; that is, the Q of the circuit should be the same in both cases. If one assumes that $\omega L >> r_F$, the equivalent of parallel resistance can be expressed as follows:

$$Q = \frac{\omega L_1}{r_F} = \frac{r'_F}{\omega L_1} \tag{2-108}$$

$$r'_f = \frac{(\omega L_1)^2}{r_F} \tag{2-109}$$

An evaluation of this equation shows that a differential resistance $r_F \approx 0.5$ Ω can be tolerated in most applications as regards amplification and selectivity.

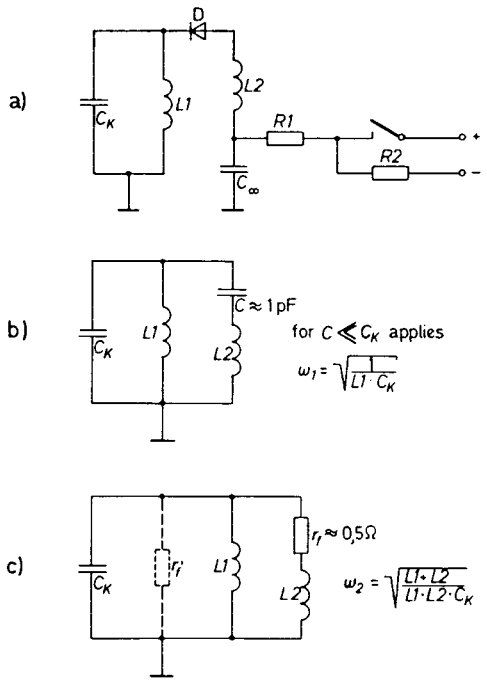

Figure 2-73 (a) Diode switch as a bandswitch, with an inductance in parallel; (b) equivalent circuit with blocked-diode switch; (c) equivalent circuit with conducting diode switch.

Instead of altering the resonant frequency of a tuned circuit by short-circuiting part of its inductance, the same result can be obtained by connecting a second inductance in parallel. The use of the diode switch for this purpose is illustrated in Figure 2-73. This differs from the one shown in Figure 2-71 in that the circuit inductance consists of either L_1 or of L_1 and L_2 in parallel. By applying a permanent negative bias to the diode via a high-value resistor R_2, it is possible to dispense with the use of one switch contact. Figure 2-73b shows the equivalent circuit for the diode under reverse-bias conditions (corresponding to a low resonant frequency), and Figure 2-73c shows the equivalent circuit under forward-bias conditions (corresponding to a higher resonant frequency).

In radio and television receivers, it usually is possible to derive the necessary reverse bias for the diode by rectification of the local oscillator signal, since the power required for blocking the diodes is extremely small. Note that under reverse-bias conditions the inductance L_2 and the capacitance C form a series-tuned acceptor circuit. However, this capacitance being extremely small, any undesirable effects due to its presence can normally be avoided. The same diode switching arrangements described for single-tuned circuits can also be employed in multisection bandpass and broadband filters.

In the following paragraph, a practical example for the use of diode switches will be given, and it will be seen that it is possible, in principle, to replace all of the mechanical RF switch contacts normally employed in receivers by diode switches. In cases where application of the diode dc potentials to a "cold" point in the circuit is not feasible, it may be necessary to apply them via *LC* or *RC* isolating networks.

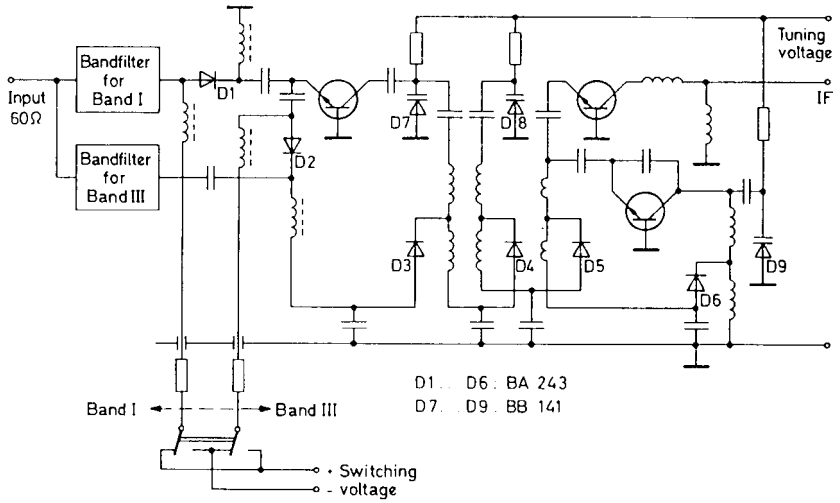

Figure 2-74 Schematic of a VHF television tuner with electronic band selection.

Use of the Diode Switch in a Television Receiver. Figure 2-74 shows the schematic of an electronically tuned and switched band I (48–62 MHz)/band III (175–224 MHz) TV tuner that requires switching of the input filter, bandpass filter, and oscillator circuit. These switching functions are performed by BA243 diode switches. As is customary in most European countries, in this example a broadband input filter between the antenna and the first RF transistor is used rather than a selective front-end circuit. In view of the need to correct noise and power matching over a relatively large frequency range, a switchable filter is employed in most tuners, switching being effected in this case by means of diodes D_1 and D_2.

Diodes D_3–D_6 are used for band-filter switching, for switching the coupling to the mixer transistor, and for switching the oscillator frequency. To minimize the bias-current requirements (each diode requires a bias current of approximately 10 mA), all diodes that are to be activated at the same time are connected in series. This arrangement requires only a few additional RF chokes, which are easily provided because of the high frequencies involved. The direct current required for the diode switches could be obtained by simple rectification, for example, from the heater circuit of the television receiver CRT, and the diode reverse bias could be obtained by rectification of the local oscillator signal, in which case the minute additional power requirement would have to be allowed for in the oscillator design.

A technically sophisticated design for a television tuner takes the form of a combined VHF/UHF unit incorporating electronically switched circuits in which several elements would be common. Such an all-band tuner can be assembled from only three transistors and a combined VHF/UHF band filter in $\lambda/2$ or $\lambda/4$ technology for UHF reception. The VHF circuits are short-circuited when the UHF position is selected.

Multistandard TV receivers require a large number of switch contacts in the tuner, the IF amplifier, the video amplifier, and the time base. The use of diode switches is particularly advantageous in this situation because it renders the physical layout of the equipment virtually independent of the location of the controls and obviates the need for long RF cable runs, which may be prone to interference.

2-2 BIPOLAR TRANSISTORS

2-2-1 Transistor Structure Types

All current RF silicon transistors are of the bipolar *npn* planar epitaxial type. Briefly, the significance of each of these terms is as follows.

Bipolar. In its broadest sense, it is the basic structure shown schematically in Figure 2-75, that is, the familiar three-semiconductor-region structure. *Bipolar* specifically means that the charge carriers of both negative (electron) and positive (hole) polarities are involved in the transistor action. In way of contrast, unipolar types include the junction-gate and insulated-gate field-effect transistors, which are basically one- or two-semiconductor-region structures in which carriers of a single polarity dominate.

npn. This abbreviation is for *negative–positive–negative* and identifies the regions of the structure as to polarity of the dominant or majority carrier in each region. The other polarity type is *pnp*. (See Figure 2-75.)

Silicon. Silicon (Si) is one of two elements from the fourth column of the periodic table that are in widespread use for transistor fabrication [the other is germanium (Ge)]. Other materials used include the compound gallium arsenide (GaAs). Although silicon is in predominant use because it results in the most favorable compromise among high-frequency, high-temperature, high-reliability, and ease-of-use attributes of the usable semiconductor material, silicon–germanium (SiGe) technology is increasingly important because it affords high-frequency performance unachievable with silicon alone.

Planar. The term planar denotes that both emitter–base and base–collector junctions of the transistor intersect the device surface in a common plane (hence, a better term might be *coplanar*). However, the real significance of the so-called planar structure is that the technique of diffusing dopants through an oxide mask, used in fabricating such a structure, results in junctions being formed beneath a protective oxide layer. These protected junctions are less prone to the surface problems sometimes associated with other types of structures, such as the mesa.

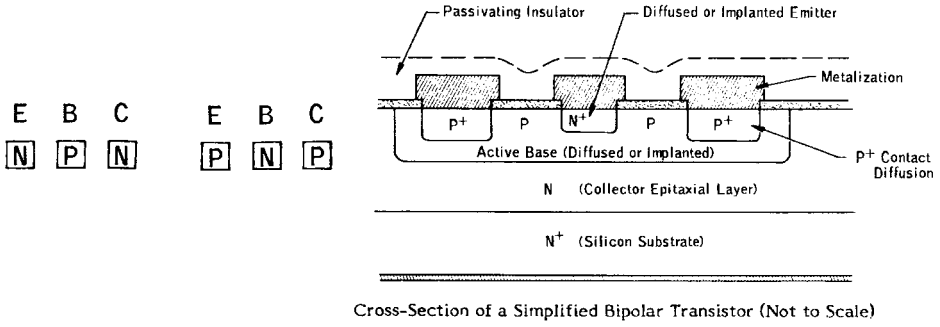

Figure 2-75 Transistor structure schematic.

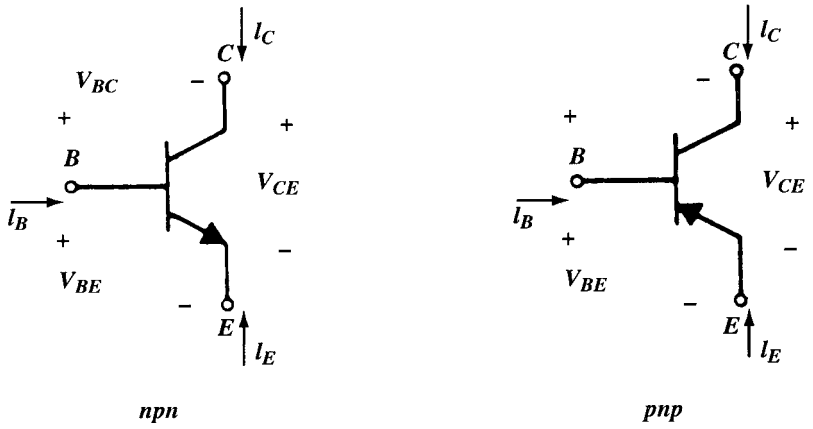

Figure 2-76 Bipolar transistor sign convention.

Epitaxial. This term, as it is commonly used, is actually a shortening of the term *epitaxial-collector*. That is, the collector region of the transistor is formed by the epitaxial technique, rather than by diffusion, which is commonly used to form the base and emitter regions. The epitaxial layer is formed by condensing a single-crystal film of semiconductor material on a wafer or substrate that is usually of the same material. Thus, an epitaxial (collector) transistor is one in which the collector region is formed on a low-resistivity substrate. Subsequently, the base and emitter regions are diffused into the "epi" layer. The epitaxial technique lends itself to precise tailoring of collector-region thickness and resistivity with consequent improved device performance and uniformity.

2-2-2 Large-Signal Behavior of Bipolar Transistors*

In this section, the large-signal or dc behavior of bipolar transistors is considered. Large-signal models are developed for the calculation of total currents and voltages in transistor circuits, and such effects as breakdown-voltage limitations, which are usually not included in models, are also considered. Second-order effects, such as current-gain variation with collector current and Early voltage, can be important in many circuits and are treated in detail.

The sign conventions used for bipolar transistor currents and voltages are shown in Figure 2-76. All bias currents for both *npn* and *pnp* transistors are assumed positive going into the device.

Electrical and Performance Characteristics and Specifications. Electrical characteristics may be described as uniquely defined, measurable electrical transistor properties that are not a function of the measuring circuit or apparatus (except insofar as standard terminations and measurement accuracy are concerned). Performance or operating characteristics are also electrical properties but they are, in general, not unique because their values depend on the measuring circuit (in particular, source and load impedance, which may be arbitrary). As might be expected, the terms are often used somewhat loosely (and sometimes

* Portions of this section, Sections 2-2-3 through 2-2-5, and Sections 2-3-3 through 2-3-6 are based on Paul R. Gray and Robert G. Meyer, *Analysis and Design of Analog Integrated Circuits*, 3rd ed., ©1993 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

interchangeably), especially in cases where only subtle differences are involved. The terms are generally used on transistor datasheets to segregate (for emphasis) under performance or operating characteristics those properties most directly applicable to the primary intended application.

Performance (Operating) Characteristics. Of the numerous performance characteristics that can be specified for high-frequency transistors, perhaps the most fundamental and pertinent characteristics are:

- Power gain and noise figure, for small-signal applications
- Power gain, power output, and efficiency, for large-signal applications

All of these characteristics are, of course, functions of frequency, bias temperature, and so on, and to completely characterize a transistor over its full frequency, bias, and temperature ranges would be prohibitively costly. Consequently, characterization data are given only for restricted ranges of these variables. These data should portray sufficiently the capabilities of a particular device for its intended applications. In the case of maximum ratings, some applications may require additional characterization by the user or through applications assistance from the manufacturer.

POWER GAIN

G_{max}. Of the various definitions for the measurement of power flow in an active two-port device, such as a transistor, two are unique enough to allow specification without recourse to specifying the complete measuring circuit in detail. One of these definitions is termed *maximum available gain* (G_{max}) and is the power gain obtained when the input and output ports are simultaneously conjugately matched to source and load impedances, respectively. Implicit in this definition is the assumption that the two-port is unconditionally stable; that is, that no combination of input/output tuning can result in increasing gain to the point of oscillation.

$|S_{21}|^2$. The other unique power gain is the gain realized when the transistor is inserted between a source and load with identical impedances (in practice, usually $50 + j0\ \Omega$). This particular insertion of transducer gain happens to coincide with the usual definition of the two-port forward scattering parameter, S_{21}. More precisely, it is equal to the magnitude squared of this parameter and is therefore often identified by the symbol $|S_{21}|^2$. For wideband applications, $|S_{21}|^2$ is important because wideband terminations "not too different from 50 Ω" are more easily realized than are wideband transforming networks that provide the matching required for G_{max}.

NOISE FIGURE. A common measure of the noise generated by an active two-port device—noise that sets a lower limit on amplifier sensitivity—is noise factor (F). This is defined as

$$F = \frac{\text{Input signal-to-noise ratio}}{\text{Output signal-to-noise ratio}} \tag{2-110}$$

or more generally as

$$F = \frac{\text{Total output noise power}}{\text{Output power due to source resistance}} \tag{2-111}$$

At high frequencies, spot noise factor or noise factor for a small fractional bandwidth (say, 1%) is used and is usually expressed as *noise figure* (*NF*), in decibels:

$$NF = 10 \log F \tag{2-112}$$

As already discussed, noise figure is a function of source impedance (as well as functions of frequency, bias, etc.) and hence, there is an infinity of noise figures associated with a given device corresponding to the infinity of possible impedances that may be presented to the device input. The only unique one, in the sense that it does not involve arbitrary source impedances, is $NF_{\min}$, the minimum noise figure obtained (at a given bias and frequency) when the input is tuned to optimize this parameter. This is the noise figure value commonly given on datasheets.

In practical amplifiers that involve more than one stage, *overall noise factor* (F_O) is given by

$$F_O = F_1 + \frac{F_2 - 1}{G_1} + \cdots + \frac{F_n - 1}{G_{(n-1)}} \tag{2-113}$$

where n = number of stages
G_n = gain of the nth stage
F_n = noise factor of the nth stage

This expression emphasizes the important fact that for low-noise amplifiers, the first stage must be designed for the lowest noise figure and highest gain possible. [Note that the noise contribution of the second stage is divided (reduced) by the gain of the first stage.] Since the optimum source impedance and bias currents for optimum gain and noise figure do not often coincide, very careful circuit design is required to minimize overall noise figure. For more accuracy, we recommend the noise correlation approach.

POWER OUTPUT. This characteristic is important for both amplifier and oscillator transistors. In both cases, it is extremely circuit sensitive. For amplifiers, maximum useful output is often limited to that power output level at which gain has compressed 1 dB, an indicator of the upper limit of the device's linearity range. For oscillators, it is merely a quantitative measure of RF power for given dc input power.

EFFICIENCY. In the most general sense, this characteristic expresses as a percentage the ratio of RF power output to the total circuit input power, both dc and RF. That expression is efficiency, η, defined as

$$\eta = \frac{P_O}{P_i + P_{\text{dc}}} \times 100 \tag{2-114}$$

where P_O = RF output power
P_i = RF input power
P_{dc} = total dc power input

Since for oscillator transistors there is no RF power input, and for amplifier transistors the maximum input RF power is calculable from the power gain and power output specifications,

the inclusion of P_i in efficiency is redundant. Moreover, since the major portion of the dc power is dissipated by the transistor collector, a more restricted definition of efficiency is pertinent. This parameter, termed *collector efficiency* (η_C), is given by

$$\eta_C = \frac{P_O}{P_{CC}} \times 100 \tag{2-115}$$

where $P_{CC} = V_{CC} \times I_{CC}$
V_{CC} = collector supply voltage
I_{CC} = collector supply current

Electrical Characteristics. Electrical characteristics may be conveniently classified into two main types, dc and ac.

dc CHARACTERISTICS. The importance of dc characteristics of high-frequency transistors lies primarily in biasing and reliability considerations. However, certain dc characteristics are also directly related to high-frequency performance. For example, high-frequency noise figure is affected by dc current gain. The dc characteristics discussed here are those usually found on high-frequency transistor datasheets.

$V_{(BR)CBO}$, I_{CBO}. These two parameters serve to characterize the reverse-biased collector–base *pn* junction and are defined as follows (with the aid of Figure 2-77a). The collector–base breakdown voltage, $V_{(BR)CBO}$, identifies the voltage at which collector current tends to increase without limit, usually due to the high electric field developed across the junction. This voltage sets a limit on the maximum transistor operating voltage and, as mentioned before under maximum ratings, usually is the basis for the collector–base maximum voltage rating. $V_{(BR)CBO}$ should be specified at a value of $I_C = I_{C1}$ in the figure, which is within the avalanche (or high slope) region of the device's reverse characteristic. Typical values of I_{C1} are in the 1–10-μA region for high-frequency transistors.

To further define the quality of the reverse *I–V* characteristic, a specification is usually placed on the collector cutoff current, I_{CBO}, which is measured at some value of collector–base voltage less than $V_{(BR)CBO}$. For a good-quality silicon junction ("sharp" instead of soft; see Figure 2-77a), I_{CBO} is in the nanoampere range.

$V_{(BR)EBO}$, I_{EBO}. These two parameters characterize the reverse-biased emitter–base *pn* junction in an analogous manner to the collector–base junction parameters $V_{(BR)CBO}$ and I_{CBO}, given above, and are shown in Figure 2-77b. No further discussion of these parameters will be given here.

$V_{(BR)CEO}$, I_{CEO}. The collector–emitter breakdown voltage and cutoff current are somewhat more complex in nature than the collector–base and emitter–base parameters. In the latter two, only a single *pn* diode is involved. In the collector–emitter case, two diodes are involved. Moreover, each is influenced by the other through transistor action, since the reverse current of the collector–base diode flows through the emitter–base junction as forward current. Thus, the collector–base reverse current is amplified by the dc current gain of the transistor, resulting in:

- I_{CEO} being greater than I_{CBO} (for a given voltage)
- Typically, the familiar negative-resistance region in the *I–V* characteristic as shown in Figure 2-77c.

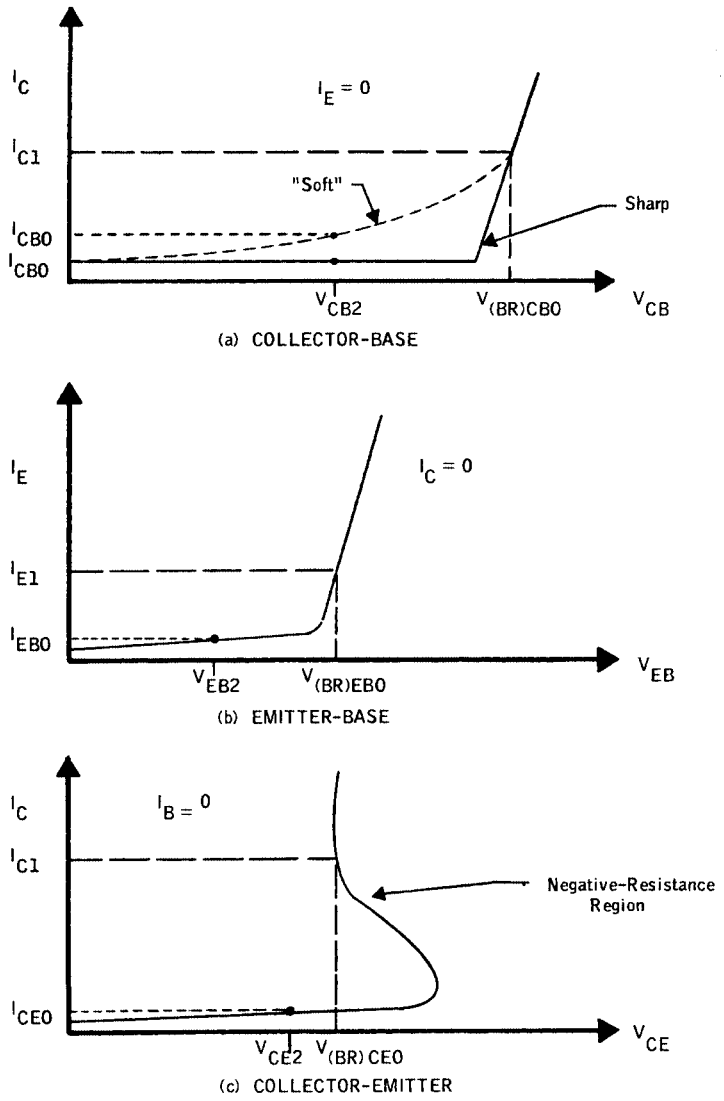

Figure 2-77 Transistor reverse *I–V* characteristics.

Consequently, $V_{(BR)CEO}$ is typically specified at collector currents one to three orders of magnitude higher than in the case of $V_{(BR)CBO}$ and $V_{(BR)EBO}$ to establish the minimum value of this characteristic.

h_{fe}. This parameter is simply the dc common-emitter current gain; that is, the ratio of collector current to base current at some specified collector voltage and current.

ac CHARACTERISTICS. Of the numerous ac characteristics defined for transistors, only relatively few are commonly used in characterizing high-frequency transistors. Some of the more pertinent parameters are briefly covered here.

S Parameters. By far the most useful and conveniently measured set of two-port parameters for transistor high-frequency (roughly 100 MHz and above) characterization is

the *S*-parameter or scattering-matrix set. These parameters completely and uniquely define the small-signal gain and input/output immittance properties of any linear "black box." (By definition, a transistor or any active device is linear under small-signal conditions.) However, these parameters reveal nothing (except possibly indirectly and approximately) about large-signal or noise behavior. Simply interpreted (more general definitions and other interpretations abound in the technical literature), the *S* parameters are merely insertion gains, forward and reverse, and reflection coefficients, input and output, with driven and nondriven ports both terminated in equal impedances, usually $50 + j0\ \Omega$. Such an interpretation tends to make *S* parameters very attractive, once some familiarity is gained, at high (especially microwave) frequencies, since the power flow or gain and reflection-coefficient concepts are more intuitively meaningful than voltage and current conceptual schemes. It should also be mentioned that *S*-parameters can be converted through straightforward matrix transformations to other two-port parameter sets, such as *h*-, *y*-, and *z*-parameters.

Proceeding with more specific definitions, the *S*-parameters are defined analytically by

$$b_1 = S_{11}a_1 + S_{12}a_2 \tag{2-116}$$

$$b_2 = S_{21}a_1 + S_{22}a_2 \tag{2-117}$$

or, in matrix form,

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} \tag{2-118}$$

where, referring to Figure 2-78

a_1 = (incoming power at Port 1)$^{1/2}$
b_1 = (outgoing power at Port 1)$^{1/2}$
a_2 = (incoming power at Port 2)$^{1/2}$
b_2 = (outgoing power at Port 2)$^{1/2}$
E_1, E_2 = electrical stimuli at Port 1, Port 2

From the figure and defining linear equations, for $E_2 = 0$, then $a_2 = 0$, and (skipping through numerous rigorous steps)

$$S_{11} = \frac{b_1}{a_1}$$

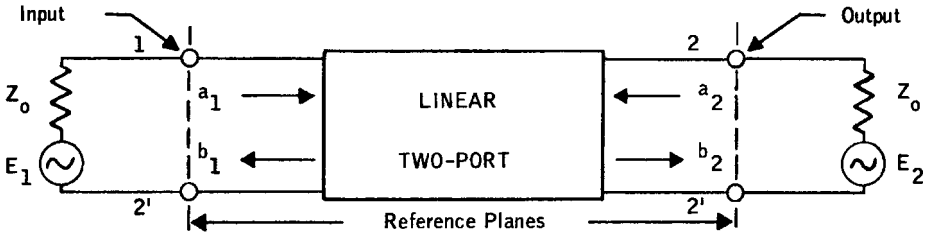

Figure 2-78 Two-port *S*-parameter definition.

$$= \left(\frac{\text{Outgoing input power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \frac{\text{Reflected voltage}}{\text{Incident voltage}}$$

$$= \text{Input reflection coefficient} \tag{2-119}$$

$$S_{21} = \frac{b_2}{a_1}$$

$$= \left(\frac{\text{Outgoing output power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \left(\frac{\text{Output power}}{\text{Available input power}}\right)^{1/2}$$

$$= (\text{Forward transducer gain})^{1/2} \tag{2-120}$$

or, more precisely in the case of S_{21}:

$$\text{Forward transducer gain} = G_{\text{TF}} = |S_{21}|^2 \tag{2-121}$$

$$Z_i = Z_o \tag{2-122}$$

Similarly, at Port 2 for $E_1 = 0$, then $a_1 = 0$, and

$$S_{22} = \frac{b_2}{a_2} = \text{Output reflection coefficient} \tag{2-123}$$

$$S_{12} = \frac{b_1}{a_2} = (\text{Reverse transducer gain})^{1/2} \tag{2-124}$$

$$G_{\text{TR}} = |S_{12}|^2 \tag{2-125}$$

Since many measurement systems display *S*-parameter magnitudes in decibels, the following relationships are particularly useful:

$$|S_{11}|_{\text{dB}} = 10\log|S_{11}|^2$$

$$= 20\log|S_{11}| \tag{2-126}$$

$$|S_{22}|_{\text{dB}} = 20\log|S_{22}| \tag{2-127}$$

$$|S_{21}|_{\text{dB}} = 10\log|S_{21}|^2$$

$$= 20 \log|S_{21}|$$

$$= 10 \log|G_{TF}| = |G_{TF}|_{dB} \tag{2-128}$$

$$|S_{12}|_{dB} = 10 \log|S_{12}|^2$$

$$= 20 \log|S_{12}|$$

$$= 10 \log|G_{TR}| = |G_{TR}|_{dB} \tag{2-129}$$

Figure 2-79 shows an example of the use of *S* parameters in transistor stage design.

Transition Frequency. One of the better known, but perhaps least understood, figures of merit for high-frequency transistors is the so-called transition frequency, f_T. Part of the misunderstanding that appears to exist is due to the use of the misleading (but common, for

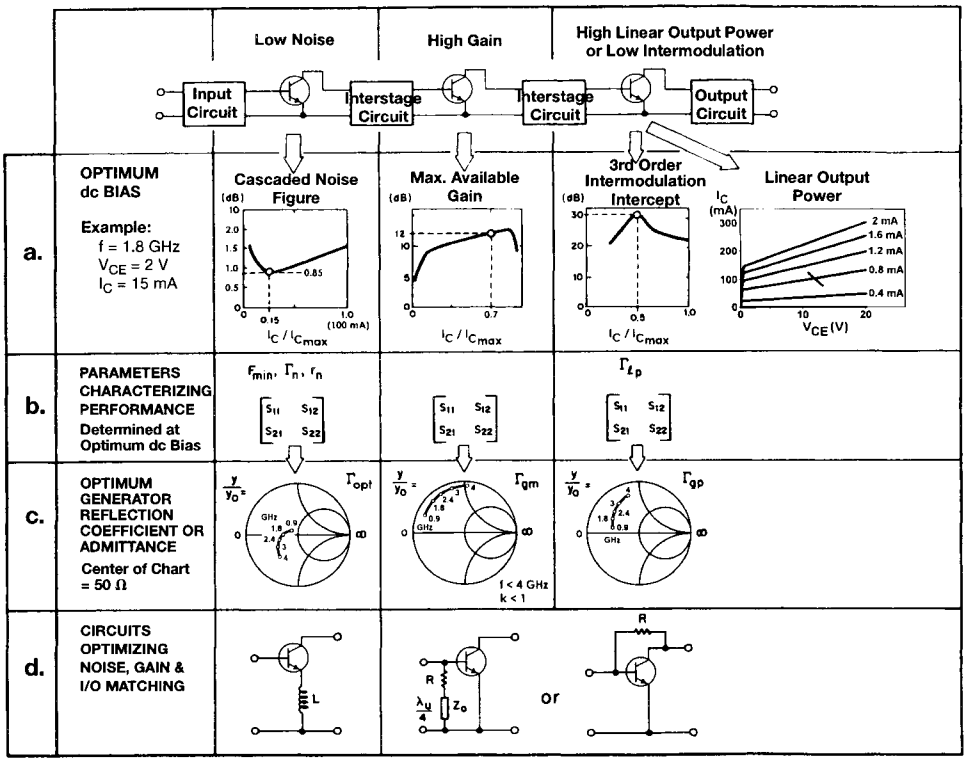

Figure 2-79 Key parameters in applying a BJT in low-noise front-end, high-gain, and linear-power stages. (a) The BJT characteristics that lead to optimum dc bias for a low-noise front end; (b) parameters characterizing device performance; (c) Γ_{opt} for the first stage, and S_{11} and S_{22} for the output stage as simulated by CAD software. The example is based on the Siemens BJTs BFP420 (low-noise stage), BFP450 (high-gain stage), and BFG235 (output stage). Circuits to optimize stage noise, gain, and I/O matching are shown in (d). (Presentation based on Figure 14 in Charles A. Liechti, "Microwave Field-Effect Transistors—1976," *IEEE Trans. Microwave Theory Tech.,* vol. MTT-24, pp. 279–300, June 1976.)

historical reasons) term *short-circuit gain–bandwidth product* for this parameter. By definition, f_T is that characteristic frequency described by the equation

$$f_T = h_{fe} \times f_{\text{meas}} \tag{2-130}$$

where h_{fe} is the magnitude of the small-signal common-emitter short-circuit current gain, and f_{meas} is the frequency of measurement, chosen such that

$$2 \le h_{fe} \le \frac{h_{fe0}}{2} \tag{2-131}$$

where h_{fe0} is the low-frequency value of h_{fe}.

To varying degrees of approximation, depending on the transistor type, f_T is the frequency at which h_{fe} approximates unity. It is not, in general, the frequency at which h_{fe} is precisely equal to unity. To clarify these points further, consider the plot of h_{fe} against frequency sketched in Figure 2-80.

At low frequencies, $f << f_B$, h_{fe} is constant and equal to h_{fe0}.

At f_B, h_{fe} has decreased to 0.707 h_{fe0}; that is, f_B is the 3-dB cutoff frequency for common-emitter short-circuit current gain, h_{fe}.

For frequencies such that

$$2f_B < f < f_T \tag{2-132}$$

h_{fe} varies inversely proportional to frequency. That is, the f_T defining relationship holds:

$$h_{fe} \times f_{\text{meas}} = \text{constant} = f_T \tag{2-133}$$

At frequencies approaching f_T, other parameters, especially package parasitics, can cause $|h_{fe}|$ to depart significantly from this $1/f$ variation. Therefore, the frequency, f_1, at which $|h_{fe}|$ actually equals unity can be somewhat different from f_T.

Applying these frequency-gain characteristics to the common-emitter wideband, low-pass amplifiers gives rise to the terminology of f_T being a "gain–bandwidth product." However,

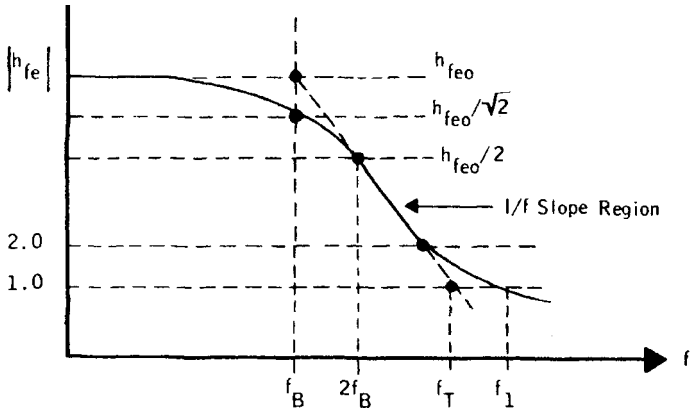

Figure 2-80 $|h_{fe}|$ frequency characteristics.

this is an optimistic approximation at best, since the product of low-frequency circuit gain and the 3-dB cutoff frequency is reduced from f_T by an amount that depends on circuit impedances.

The real significance of f_T lies in the fact that it is a measure of certain internal transistor parameters that do, in fact, affect high-frequency performance: for example, gain (though not in the convenient quantitative manner implied by the term "gain–bandwidth product"). In particular, good high-frequency noise performance requires that f_T be high. Thus, f_T is included on transistor datasheets primarily as a figure of merit, not as a parameter to be used directly in design.

Collector–Base Time Constant, $r_b'C_c$. This is an internal device parameter that relates only indirectly to high-frequency performance. It is primarily a measure of internal feedback within the transistor. It also relates to transistor high-frequency impedance. As the name says (in symbols), it is a measure of transistor base resistance and collector capacitance in combination; however, except for certain low-frequency transistors, it cannot be considered the simple two-element lumped *RC* time constant implied by the terminology. (In high-frequency transistors, base resistance and collector impedance must be considered to be distributed when considered in detail). As a figure of merit, it is included on transistor datasheets to indicate how well base resistance and collector impedance have been minimized. It also allows the estimation of certain gain properties of the transistor (see the $f_{\max}$ parameter, which we'll describe shortly).

Collector–Base Capacitance, C_{cb}. This parameter is simply the total collector–base *pn* junction capacitance measured at a low frequency (typically, 1 MHz), where it can be considered a single lumped element. For high-frequency transistors it is, of course, desirable that C_{cb} be small from bandwidth and stability considerations as well as from gain considerations alone.

Maximum Frequency of Oscillation, $f_{\max}$. This is another figure-of-merit parameter, as opposed to measurable parameters directly usable in the application of transistors. Its importance stems from the following approximate relationships (which will not be derived here):

$$f_{\max} \approx \left(\frac{f_T}{8\pi r_b' C_C} \right)^{1/2} \tag{2-134}$$

$$G_{\max} \approx \left(\frac{f_{\max}}{f_{\text{oper}}} \right)^2 \tag{2-135}$$

These expressions illustrate in a quantitative way the importance and the interrelationship between high f_T and low $r_b'C_C$ insofar as high-frequency gain is concerned. However, since they are approximations and since their derivation involves several assumptions that are not always valid, they must be interpreted with caution. For example, the expression for $G_{\max}$ is obviously not applicable at low frequencies, since as $f \to 0$, $G_{\max} \to \infty$, according to this expression. As a rule of thumb, the $G_{\max}$ expression is a reasonable approximation for frequencies such that

$$5 > \frac{f_{\max}}{f_{\text{oper}}} > 1 \tag{2-136}$$

For accurate analysis of transistor gain and stability, a complete set of two-port parameters must be employed in exact expressions, such as those from which the approximations shown above were derived.

Datasheet Transistor Specifications. The following is a reprint of a Siemens microwave transistor datasheet. This 25-GHz f_T transistor will soon be replaced by a 40-GHz family, based on a silicon–germanium design. Key parameters describing the transistor are:

- The dc parameters, such as maximum current and voltage and dissipation
- Noise figure as a function of generator impedance, bias point, and frequency
- Frequency-dependent behavior, typically expressed in *S* parameters, and also as a function of bias point and frequency
- Large-signal performance to be calculated based on a nonlinear model, such as the Gummel–Poon

The transistor description typically gives details about packaging, as the Gummel–Poon model is intrinsic (without parasitics). Not only does the package determine the parasitics, it also affects the device's ability to transfer heat to its heat sink. The following figures, reproduced with permission from the datasheet for the BFP420 transistor by Siemens (now Infineon Technologies), are a typical representation of the dc-I_C curves, *S* parameters, and noise parameters of a normal, packaged microwave transistor. Besides its dc parameters and capacitance, there are other critical parameters. A BJT's noise figure is a strong function of its dc current gain, and one can determine a 3-dB cutoff frequency referred to as f_T, which shows the gain roll-off as a function of collector current and frequency. Another important measure or figure of merit is $f_{\max}$, the maximum frequency of oscillation:

$$f_{\max} = \sqrt{\frac{|Y_{21}|}{16\pi R_{bb} C_{be} C_{bc}}} \tag{2-137}$$

Figure 2-81 shows a photograph of the die for the BFP420.

Since the intercept point is an important figure of merit, Figure 2-82 shows intercept point as a function of bias point for the BFR93AW BJT. We wish more manufacturers would supply this information.

2-2-3 Large-Signal Transistors in the Forward-Active Region

We saw in the diode case that its description is physics-based and it is, therefore, logical to apply the same modeling for the transistors. The first complete modeling for transistors was described in the Gummel–Poon model, but many engineers use the somewhat more simpler Ebers–Moll model. By combining two diodes, the parasitic elements, and the base separating resistor, we can show the "intrinsic" nonlinear model for the bipolar transistor.

Many equations that have been published contain some approximations, but for exact nonlinear analysis, we have to resort to the somewhat more complex or complete equations as shown in Appendix A for the bipolar model.

Recently, some other models have been proposed by researchers, such as the MEXTRAM models (Philips), but the trouble with these models is that while they may give quite good results for RF applications, it is virtually impossible to obtain parameters for them. So far the only industry-standard model is the Gummel–Poon, and to the authors' knowledge there

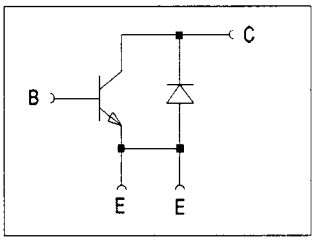
For non-linear simulation:

- Use transistor chip parameters in Berkeley SPICE 2G.6 syntax for all simulators.
- If you need simulation of the reverse characteristics, add the diode with the C'-E'-diode data between collector and emitter.
- Simulation of the package is not necessary for frequencies < 100 MHz.
  For higher frequencies add the wiring of the package equivalent circuit around the non-linear transistor and diode model.

Note:

- This transistor is constructed in a common emitter configuration. This feature causes an additional, reverse biased diode between emitter and collector, which does not effect normal operation.



Transistor Schematic Diagram

The common emitter configuration shows the following advantages:

- Higher gain because of lower emitter inductance.
- Power is dissipated via the grounded emitter leads, because the chip is mounted on the copper emitter leadframe.

Please note, that the broadest lead is the emitter lead.

- The AC-Characteristics are verified by random sampling.

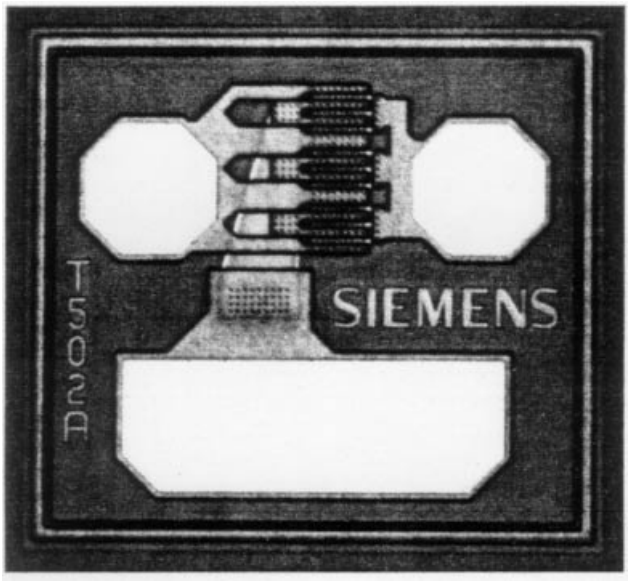


Figure 2-81 Photograph of the BFP420 die (310 × 290 μm). The bonding pad for the base is at the upper right; for the collector at the upper left. The large, lower pad connects to the emitter.

are no accepted or affordable parameter extractor programs available, not even to consider the cost of hardware for such extractions. Hewlett-Packard recently published a system with a hardware cost in the vicinity of $1 million.

A typical *npn* planar bipolar transistor structure is shown in Figure 2-83a, where collector, base, and emitter are labeled *C*, *B*, and *E*, respectively. The impurity doping density in the base and the emitter of such a transistor is not constant but varies with distance from the top surface. However, many of the characteristics of such a device can be predicted by analyzing

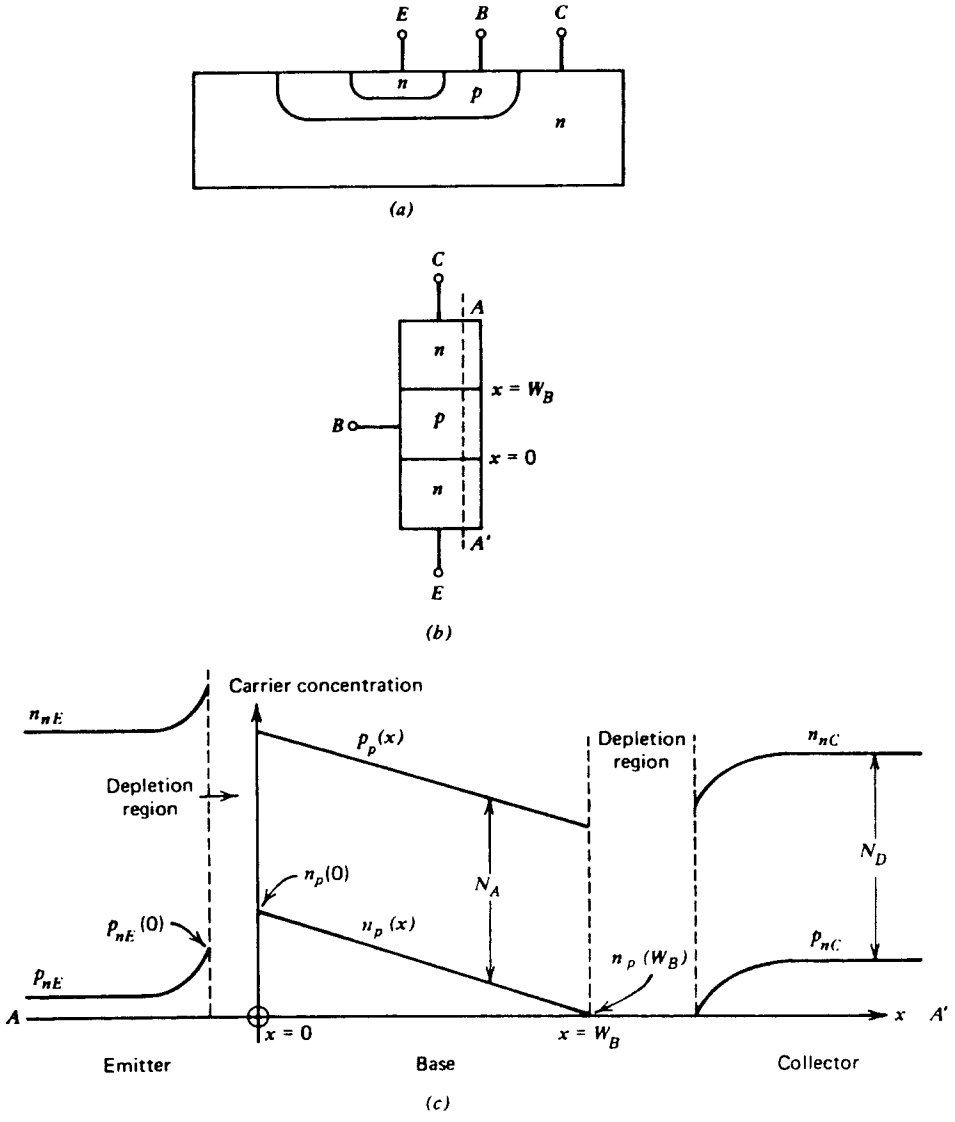

Figure 2-83 (a) Cross section of a typical *npn* planar bipolar transistor structure; (b) idealized transistor structure; (*c*) carrier concentrations along the cross section *AA*′ of the transistor in (b). Uniform doping densities are assumed. (Not to scale)

the idealized transistor structure shown in Figure 2-83b. In this structure, the base and emitter doping densities are assumed constant, and this is sometimes called a "uniform-base" transistor. Where possible in the following analyses, the equations for the uniform-base analysis are expressed in a form that applies also to nonuniform-base transistors.

A cross section AA' is taken through the device of Figure 2-83b and carrier concentrations along this section are plotted in Figure 2-83c. Hole concentrations are denoted by p and electron concentrations by n with subscripts p or n representing p-type or n-type regions. The n-type emitter and collector regions are distinguished by subscripts E and C, respectively. The carrier concentrations shown in Figure 2-83c apply to a device in the *forward-active region*. That is, the base–emitter junction is forward-biased and the base–collector junction is reverse-biased. The minority-carrier concentrations in the base at the edges of the depletion regions can be calculated from a Boltzmann approximation to the Fermi–Dirac distribution function to give [2]

$$n_p(0) = n_{po} \exp \frac{V_{BE}}{V_T} \tag{2-138}$$

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \simeq 0 \tag{2-139}$$

where W_B is the width of the base from the base–emitter junction depletion layer edge of the base–collector depletion layer edge and n_{po} is the equilibrium concentration of electrons in the base. Note that V_{BC} is negative for an *npn* transistor in the forward-active region and thus $n_p(W_B)$ is very small. Low-level injection conditions are assumed in the derivation of Eqs. (2-138) and (2-139). This means that the minority-carrier concentrations are always assumed much smaller than the majority-carrier concentrations.

If *recombination* of holes and electrons in the base is small, it can be shown that the minority-carrier concentration $n_p(x)$ in the base varies *linearly* with distance [3]. Thus, a straight line can be drawn joining the concentrations at $x = 0$ and $x = W_B$ in Figure 2-83c.

For charge neutrality in the base, it is necessary that

$$N_A + n_p(x) = p_p(x) \tag{2-140}$$

and thus

$$p_p(x) - n_p(x) = N_A \tag{2-141}$$

where $p_p(x)$ is the hole concentration in the base and N_A is the base doping density that is assumed constant. Equation (2-141) indicates that the hole and electron concentrations are separated by a constant amount and thus $p_p(x)$ also varies linearly with distance.

Collector current is produced by minority-carrier electrons in the base diffusing in the direction of the concentration gradient and being swept across the collector–base depletion region by the field existing there. The diffusion current density due to electrons in the base is

$$J_n = qD_n \frac{dn_p(x)}{dx} \tag{2-142}$$

where D_n is the diffusion constant for electrons. From Figure 2-83c,

$$J_n = -qD_n \frac{n_p(0)}{W_B} \tag{2-143}$$

If I_C is the collector current and is taken as positive flowing *into* the collector, it follows from Eq. (2-143) that

$$I_C = qA D_n \frac{n_p(0)}{W_B} \tag{2-144}$$

where A is the cross-sectional area of the emitter. Substitution of Eq. (2-138) into Eq. (2-144) gives

$$I_C = \frac{qAD_n n_{po}}{W_B} \exp \frac{V_{BE}}{V_T} \tag{2-145}$$

$$= I_S \exp \frac{V_{BE}}{V_T} \tag{2-146}$$

where

$$I_S = \frac{qA D_n n_{po}}{W_B} \tag{2-147}$$

and I_S is a constant used to describe the transfer characteristic of the transistor in the forward-active region. Equation (2-147) can be expressed in terms of the base doping density by noting that [4]

$$n_{po} = \frac{n_i^2}{N_A} \tag{2-148}$$

and substitution of Eq. (2-148) in Eq. (2-147) gives

$$I_S = \frac{qAD_n n_i^2}{W_B N_A} = \frac{qA\overline{D}_n n_i^2}{Q_B} \tag{2-149}$$

where $Q_B = W_B N_A$ is the number of doping atoms in the base per unit area of the emitter and n_i is the intrinsic carrier concentration in silicon. In this form Eq. (2-149) applies to both uniform- and nonuniform-base transistors and D_n has been replaced by $\overline{D}_n$, which is an average effective value of the electron diffusion constant in the base. This is necessary for nonuniform-base devices because the diffusion constant is a function of impurity concentration. Typical values of I_S as given by Eq. (2-149) are 10^{-14} to 10^{-16} A.

Equation (2-146) gives the collector current as a function of base–emitter voltage. The base current I_B is also an important parameter and, at moderate current levels, consists of two major components. One of these (I_{B1}) represents recombination of holes and electrons in the base and is proportional to the minority-carrier charge Q_e in the base. From Figure 2-83c, the minority-carrier charge in the base is

$$Q_e = \frac{1}{2} n_p(0) W_B q A \tag{2-150}$$

and we have

$$I_{B1} = \frac{Q_e}{\tau_b} = \frac{1}{2} \frac{n_p(0) W_B q A}{\tau_b} \tag{2-151}$$

where τ_b is the minority-carrier lifetime in the base. I_{B1} represents a flow of majority holes from the base lead into the base region. Substitution of Eq. (2-138) into Eq. (2-151) gives

$$I_{B1} = \frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} \exp \frac{V_{BE}}{V_T} \tag{2-152}$$

The second major component of base current (usually the dominant one in the integrated-circuit *npn* devices) is due to injection of holes from the base into the emitter. This current component depends on the gradient of minority-carrier holes into the emitter and is [5]

$$I_{B2} = \frac{q A D_p}{L_p} p_{nE}(0) \tag{2-153}$$

where D_p is the diffusion constant for holes and L_p is the diffusion length (assumed small) for holes in the emitter. $p_{nE}(0)$ is the concentration of holes in the emitter at the edge of the depletion region and is

$$P_{nE}(0) = p_{nEo} \exp \frac{V_{BE}}{V_T} \tag{2-154}$$

If N_D is the donor atom concentration in the emitter (assumed constant) then

$$p_{nEo} \simeq \frac{n_i^2}{N_D} \tag{2-155}$$

The emitter is deliberately doped much more heavily than the base, making N_D large and p_{nEo} small, so that the base-current component, I_{B2}, is minimized.

Substitution of Eqs. (2-154) and (2-155) into Eq. (2-153) gives

$$I_{B2} = \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \exp \frac{V_{BE}}{V_T} \tag{2-156}$$

The total base current, I_B, is the sum of I_{B1} and I_{B2}:

$$I_B = I_{B1} + I_{B2} = \left(\frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} + \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \right) \exp \frac{V_{BE}}{V_T} \tag{2-157}$$

Although this equation was derived assuming uniform base and emitter doping, it gives the correct functional dependence of I_B on device parameters for practical double-diffused

nonuniform-base devices. Second-order components of I_B, which are important at low current levels, are considered later.

Since I_C in Eq. (2-146) and I_B into Eq. (2-147) are both proportional to $\exp(V_{BE}/V_T)$ in this analysis, the base current can be expressed in terms of collector current as

$$I_B = \frac{I_C}{\beta_F} \tag{2-158}$$

where β_F is the forward current gain. An expression for β_F can be calculated by substituting Eqs. (2-145) and (2-157) into Eq. (2-158) to give

$$\beta_F = \frac{qAD_n n_{po}/W_B}{\frac{1}{2}\frac{n_{po}W_B qA}{\tau_b} + \frac{qAD_p n_i^2}{L_p N_D}} = \frac{1}{\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-159}$$

where Eq. (2-148) has been substituted for n_{po}. Equation (2-159) shows that β_F is maximized by minimizing the base width W_B and maximizing the ratio of emitter to base doping densities N_D/N_A. Typical values of β_F for *npn* transistors in integrated circuits are 50–500, whereas lateral *pnp* transistors have values of 10–100. Finally, the emitter current is

$$I_E = -(I_C + I_B) = -\left(I_C + \frac{I_C}{\beta_F}\right) = -\frac{I_C}{\alpha_F} \tag{2-160}$$

where

$$\alpha_F = \frac{\beta_F}{1+\beta_F} \tag{2-161}$$

The value of α_F can be expressed in terms of device parameters by substituting Eq. (2-159) into Eq. (2-161) to obtain

$$\alpha_F = \frac{1}{1+\frac{1}{\beta_F}} = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \simeq \alpha_T \gamma \tag{2-162}$$

where

$$\alpha_T = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n}} \tag{2-163}$$

$$\gamma = \frac{1}{1+\frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-164}$$

The validity of Eq. (2-162) depends on $W_B^2/2\tau_b D_n << 1$ and $(D_p/D_n)(W_B/L_p)(N_A/N_D) << 1$, and this is always true if β_F is large [see Eq. (2-159)]. The term γ in Eq. (2-162) is

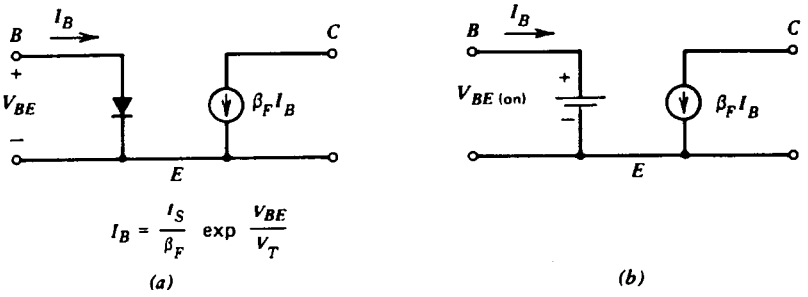

Figure 2-84 Large-signal models of *npn* transistors for use in bias calculations. (a) Circuit incorporating an input diode. (b) Simplified circuit with an input voltage source.

called the *emitter injection efficiency* and is equal to the ratio of the electron current (*npn* transistor) injected into the base from the emitter to the total hole and electron current crossing the base–emitter junction. Ideally $\gamma \to 1$, and this is achieved by making N_D/N_A large and W_B small. In that case very little reverse injection occurs from base to emitter.

The term α_T in Eq. (2-162) is called the *base transport factor* and represents the fraction of carriers injected into the base (from the emitter) that reach the collector. Ideally $\alpha_T \to 1$, and this is achieved by making W_B small. It is evident from the above development that fabrication changes that cause α_T and γ to approach unity also maximize the value of β_F of the transistor.

The results derived above allow formulation of a large-signal model of the transistor suitable for bias-circuit calculations with devices in the forward-active region. One such circuit is shown in Figure 2-84 and consists of a base–emitter diode to model Eq. (2-157) and a controlled collector-current generator to model Eq. (2-158). Note that the collector voltage ideally has no influence on the collector current and the collector node acts as a high-impedance current source. A simpler version of this equivalent circuit, which is often useful, is shown in Figure 2-84b, where the input diode has been replaced by a battery with a value $V_{BE(\text{on})}$, which is usually 0.6–0.7 V. This represents the fact that in the forward-active region the base–emitter voltage varies very little because of the steep slope of the exponential characteristic. In some circuits the temperature coefficient of $V_{BE(\text{on})}$ is important and a typical value for this is –2 mV/°C. The equivalent circuits of Figure 2-84 apply for *npn* transistors. For *pnp* devices the corresponding equivalent circuits are shown in Figure 2-85.

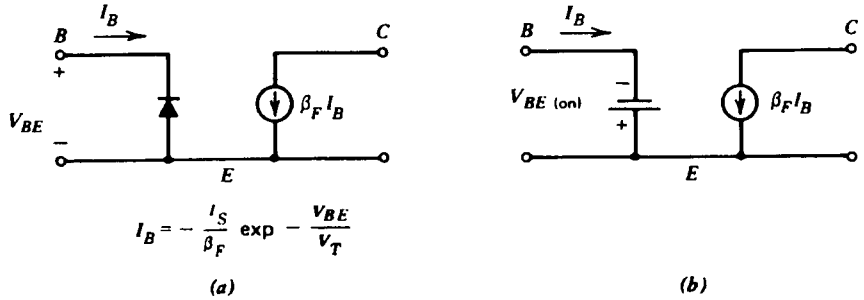

Figure 2-85 Large-signal models of *pnp* transistors corresponding to the circuits of Figure 2-84.

2-2-4 Effects of Collector Voltage on Large-Signal Characteristics in the Forward-Active Region

In the analysis of the previous section, the collector–base junction was assumed reverse-biased and ideally had no effect on the collector currents. This is a useful approximation for first-order calculations, but it is not strictly true in practice. There are occasions where the influence of collector voltage on collector current is important, and this will now be investigated.

The collector voltage has a dramatic effect on the collector current in two regions of device operation. These are the saturation (V_{CE} approaches zero) and breakdown (V_{CE} very large) regions that will be considered later. For values of collector–emitter voltage V_{CE} between these extremes, the collector current increases slowly as V_{CE} increases. The reason for this can be seen from Figure 2-86, which is a sketch of the minority-carrier concentration in the base of the transistor. Consider the effect of changes in V_{CE} on the carrier concentration for constant V_{BE}. Since V_{BE} is constant, the change in V_{CB} equals the change in V_{CE}, and this causes an increase in the collector–base depletion-layer width as shown. The change in the base width of the transistor, ΔW_B, equals the change in depletion-layer width and causes an increase ΔI_C in the collector current.

From Eqs. (2-146) and (2-149) we have

$$I_C = \frac{qA\bar{D}_n n_i^2}{Q_B} \exp \frac{V_{BE}}{V_T} \tag{2-165}$$

Differentiation of Eq. (2-165) yields

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{qA\bar{D}_n n_i^2}{Q_B^2} \left(\exp \frac{V_{BE}}{V_T} \right) \frac{dQ_B}{dV_{CE}} \tag{2-166}$$

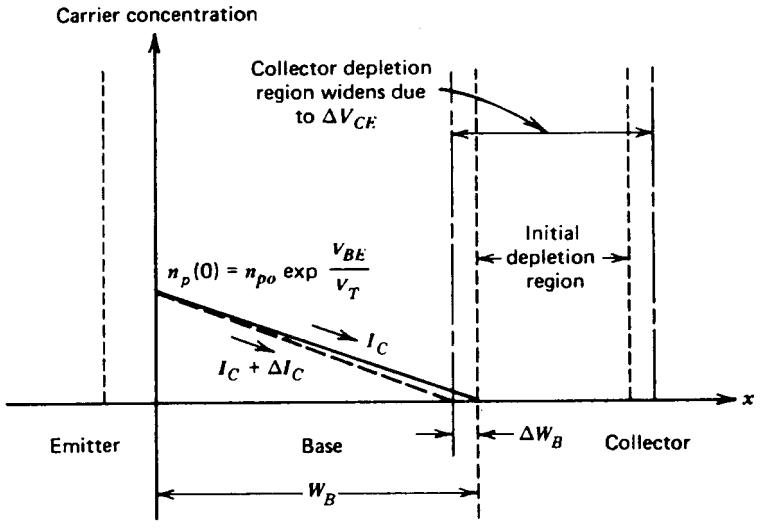

Figure 2-86 Effect of increases in V_{CE} on the collector depletion region and base width of a bipolar transistor.

and substitution of Eq. (2-165) in Eq. (2-166) gives

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{Q_B}\frac{dQ_B}{dV_{CE}} \tag{2-167}$$

For a uniform-base transistor $Q_B = W_B N_A$ and Eq. (2-167) becomes

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{W_B}\frac{dW_B}{dV_{CE}} \tag{2-168}$$

Note that since the base width *decreases* as V_{CE} increases, dW_B/dV_{CE} in Eq. (2-168) is negative and thus $\partial I_C/\partial V_{CE}$ is positive. dW_B/dV_{CE} is a function of the bias value of V_{CE}, but the variation is typically small for a reverse-biased junction and dW_B/dV_{CE} is often assumed constant. The resulting predictions agree adequately with experimental results.

Equation (2-168) shows that $\partial I_C/\partial V_{CE}$ is proportional to the collector-bias current and inversely proportional to the transistor base width. Thus narrow-base transistors show a greater dependence of I_C on V_{CE} in the forward-active region. The dependence of $\partial I_C/\partial V_{CE}$ on I_C results in typical transistor output characteristics as shown in Figure 2-87. In accordance with the assumptions made in the foregoing analysis, these characteristics are shown for constant values of V_{BE}. However, in most integrated-circuit transistors the base current is dependent only on V_{BE} and not on V_{CE}, and thus constant-base-current characteristics can often be used in the following calculation. The reason for this is that the base current is usually dominated by the I_{B2} component of Eq. (2-156), which has no dependence on V_{CE}. Extrapolation of the characteristics of Figure 2-87 back to the V_{CE} axis gives an intercept V_A called the Early voltage, where

$$V_A = \frac{I_C}{\dfrac{\partial I_C}{\partial V_{CE}}} \tag{2-169}$$

Substitution of Eq. (2-168) in Eq. (2-169) gives

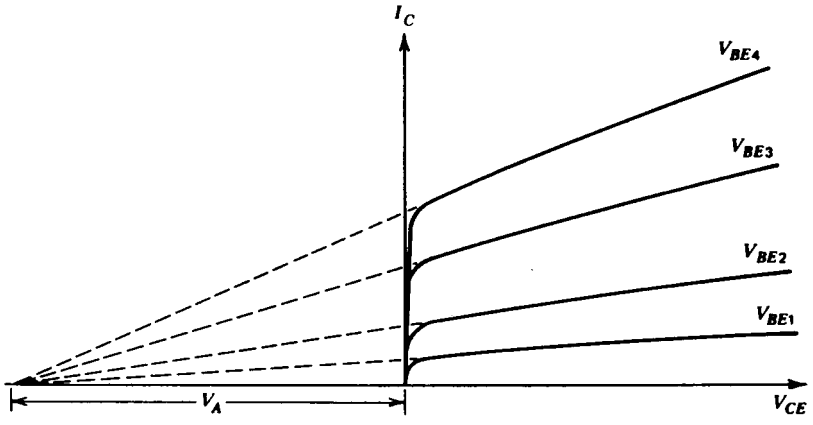

Figure 2-87 Bipolar transistor output characteristics showing the Early voltage, V_A.

$$V_A = -W_B \frac{dV_{CE}}{dW_B} \tag{2-170}$$

which is a constant, independent of I_C. Thus all the characteristics extrapolate to the same point on the V_{CE} axis. The variation of I_C with V_{CE} is called the Early effect and V_A is a common model parameter for circuit-analysis computer programs. Typical values of V_A for integrated-circuit transistors are 15–100 V. The inclusion of Early effect in dc bias calculations is usually limited to computer analysis because of the complexity introduced into the calculation. However, the influence of the Early effect is often dominant in small-signal calculations for high-gain circuits and this point will be considered later.

Finally, the influence of the Early effect on the transistor large-signal characteristics in the forward-active region can be represented approximately by modifying Eq. (2-146) to

$$I_C = I_S \left(1 + \frac{V_{BE}}{V_A}\right) \exp \frac{V_{BE}}{V_T} \tag{2-171}$$

This is a common means of representing the device output characteristics for computer simulation.

2-2-5 Saturation and Inverse Active Regions

Saturation is a region of device operation that is usually avoided in analog circuits because the transistor gain is very low in this region. Saturation is much more commonly encountered in digital circuits, where it provides a well-specified output voltage that represents a logic state. In saturation, both emitter–base and collector–base junctions are forward biased. Consequently, the collector–emitter voltage V_{CE} is quite small and usually in the range 0.05–0.3 V. The carrier concentrations in a saturated *npn* transistor with uniform base doping are shown in Figure 2-88. The minority-carrier concentration in the base of the edge of the depletion region is again given by Eq. (2-139) as

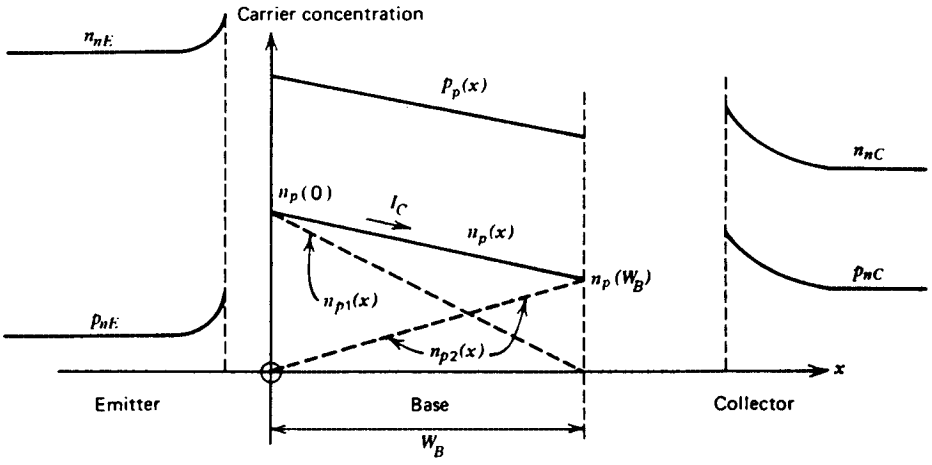

Figure 2-88 Carrier concentrations in a saturated *npn* transistor. (Not to scale)

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \tag{2-172}$$

but since V_{BC} is now positive, the value of $n_p(W_B)$ is no longer negligible. Consequently, changes in V_{CE} with V_{BE} held constant (which cause equal changes in V_{BC}) directly affect $n_p(W_B)$. Since the collector current is proportional to the slope of the minority-carrier concentration in the base [see Eq. (2-142)], it is also proportional to $[n_p(0) - (n_p(W_B)]$ from Figure 2-88. Thus, changes in $n_p(W_B)$ directly affect the collector current, and the collector node of the transistor appears to have a *low impedance*. As V_{CE} is decreased in saturation with V_{BE} held constant, V_{BC} increases as does $n_p(W_B)$ from Eq. (2-172). Thus, from Figure 2-88 the collector current decreases because the slope of the carrier concentration decreases. This gives rise to the saturation region of the $I_C - V_{CE}$ characteristic shown in Figure 2-89. The slope of the $I_C - V_{CE}$ characteristic in this region is largely determined by the resistance in series with the collector lead due to the finite resistivity of the *n*-type collector material. A useful model for the transistor in this region is shown in Figure 2-90

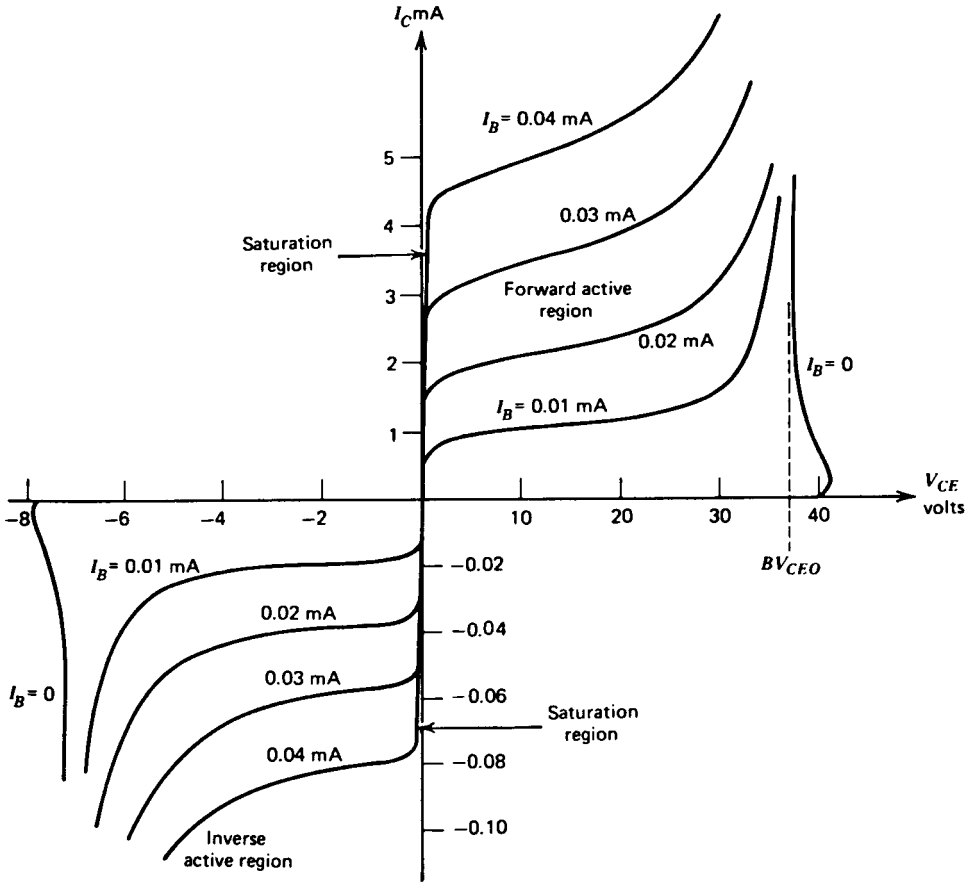

Figure 2-89 Typical $I_C - V_{CE}$ characteristics for an *npn* bipolar transistor. Note the different scales for positive and negative currents and voltages.

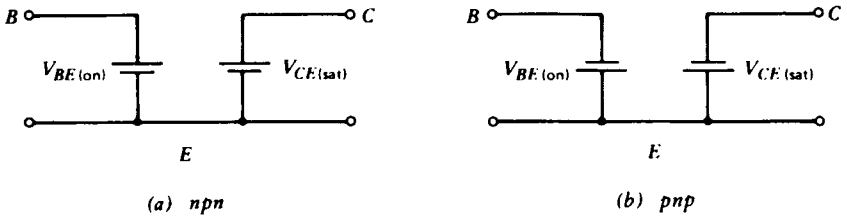

Figure 2-90 Large-signal models for bipolar transistors in the saturation region.

and consists of a fixed voltage source to represent $V_{BE(on)}$, and a fixed voltage source to represent the collector–emitter voltage $V_{CE(sat)}$. A more accurate but more complex model includes a resistor in series with the collector. This resistor can have a value ranging from 20 to 500 Ω, depending on the device structure.

An additional aspect of transistor behavior in the saturation region is apparent from Figure 2-88. For a given collector current, there is now a much larger amount of stored charge in the base than there is in the forward-active region. Thus the base-current contribution represented by Eq. (2-152) will be larger in saturation. In addition, since the collector–base junction is now forward biased, there is a new base-current component due to injection of carriers from the base to the collector. These two effects result in a base current I_B in saturation, which is larger than in the forward-active region for a given collector current I_C. Ratio I_C/I_B in saturation is often referred to as the *forced* β and is always less than β_F. As the forced β is made lower with respect to β_F, the device is said to be more *heavily saturated*.

The minority-carrier concentration in saturation, shown in Figure 2-88, is a straight line joining the two end points, assuming that recombination is small. This can be represented by a linear superposition of the two dotted distributions as shown. The justification for this is that the terminal currents depend *linearly* on the concentrations $n_p(0)$ and $n_p(W_B)$. This picture of device-carrier concentrations can be used to derive some general equations describing transistor behavior. Each of the distributions in Figure 2-88 is considered separately and the two contributions are combined. The *emitter* current that would result from $n_{p1}(x)$ above is given by the classical diode equation

$$I_{EF} = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) \tag{2-173}$$

where I_{ES} is a constant that is often referred to as the "saturation current" of the junction (no connection with the transistor saturation described above). Equation (2-173) predicts that the junction current is given by $I_{EF} \simeq I_{ES}$ with a reverse-bias voltage applied. However, in practice Eq. (2-173) is applicable only in the forward-bias region, since second-order effects dominate under reverse-bias conditions and typically result in a junction current several orders of magnitude larger than I_{ES}. The junction current that flows under reverse-bias conditions is often called the "leakage current" of the junction.

Returning to Figure 2-88, we can describe the *collector* current resulting from $n_{p2}(x)$ alone as

$$I_{CR} = -I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-174}$$

where I_{CS} is a constant. The total collector current I_C is given by I_{CR} plus the fraction of I_{EF} that reaches the collector (allowing for recombination and reverse emitter injection). Thus,

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-175}$$

where α_F has been defined previously by Eq. (2-162). Similarly, the total emitter current is composed of I_{EF} plus the fraction of I_{CR} that reaches the emitter with the transistor acting in an inverted mode. Thus,

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + \alpha_R I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-176}$$

where α_R is the ratio of emitter to collector current with the transistor operating *inverted* (i.e., with the collector–base junction forward biased and emitting carriers into the base and the emitter–base junction reverse biased and collecting carriers). Typical values of α_R are 0.5–0.8. An inverse current gain β_R is also defined,

$$\beta_R = \frac{\alpha_R}{1 - \alpha_R} \tag{2-177}$$

and has typical values 1–5. This is the current gain of the transistor when operated inverted and is much lower than β_F because the device geometry and doping densities are designed to maximize β_F. The inverse-active region of device operation occurs for V_{CE} negative in an *npn* transistor and is shown in Figure 2-89. In order to display these characteristics adequately in the same figure as the forward-active region, the negative voltage and current scales have been expanded. The inverse-active mode of operation is rarely encountered in analog circuits.

Equations (2-175) and (2-176) describe *npn* transistor operation in the saturation region when V_{BE} and V_{BC} are both positive, and also in the forward-active and inverse-active regions. These equations are from the *Ebers–Moll* equations. In the forward-active region, they degenerate into a form similar to that of Eqs. (2-146), (2-158), and (2-160) derived earlier. This can be shown by putting V_{BE} positive and V_{BC} negative in Eqs. (2-175) and (2-176) to obtain

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_{CS} \tag{2-178}$$

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \alpha_R I_{CS} \tag{2-179}$$

Equation (2-178) is similar in form to Eq. (2-146) except that leakage currents that were previously neglected have now been included. This minor difference is significant only at high temperatures or very low operating currents. Comparison of Eq. (2-178) with Eq. (2-146) allows us to identify $I_S = \alpha_F I_{ES}$ and it can be shown [6] in general that

$$\alpha_F I_{ES} = \alpha_R I_{CS} = I_S \tag{2-180}$$

where this expression represents a reciprocity condition. Using Eq. (2-180) in Eqs. (2-175) and (2-176) allows the Ebers–Moll equations to be expressed in the general form

$$I_C = I_S\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \frac{I_S}{\alpha_R}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-181}$$

$$I_E = -\frac{I_S}{\alpha_F}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_S\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-182}$$

This form is often used for computer representation of transistor large-signal behavior.

The effect of leakage currents mentioned above can be further illustrated as follows. In the forward-active region, we have, from Eq. (2-179),

$$I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) = -I_E - \alpha_R I_{CS} \tag{2-183}$$

Substitution of Eq. (2-183) in Eq. (2-178) gives

$$I_C = -\alpha_F I_E + I_{CO} \tag{2-184}$$

where

$$I_{CO} = I_{CS}(1 - \alpha_R\alpha_F) \tag{2-185}$$

and I_{CO} is the collector–base leakage current with the emitter open. Although I_{CO} is given theoretically by Eq. (2-185), in practice, surface leakage effects dominate when the collector–base junction is reverse biased and I_{CO} is typically several orders of magnitude larger than the value given by Eq. (2-185). However, Eq. (2-184) is still valid if the appropriate measured value for I_{CO} is used. Typical values of I_{CO} are 10^{-10} to 10^{-12} A at 25 °C, and the magnitude doubles about every 8 °C. As a consequence, these leakage terms can become very significant at high temperatures. For example, consider the base current I_B. This is

$$I_B = -(I_C + I_E) \tag{2-186}$$

If I_E is calculated from Eq. (2-184) and substituted in Eq. (2-186), the result is

$$I_B = \frac{1 - \alpha_F}{\alpha_F} I_C - \frac{I_{CO}}{\alpha_F} \tag{2-187}$$

But from Eq. (2-161)

$$\beta_f = \frac{\alpha_F}{1 - \alpha_F} \tag{2-188}$$

and use of Eq. (2-188) in Eq. (2-187) gives

$$I_B = \frac{I_C}{\beta_F} - \frac{I_{CO}}{\alpha_F} \tag{2-189}$$

Since the two terms in Eq. (2-189) have opposite signs, the effect of I_{CO} is to *decrease* the magnitude of the external base current at a given value of collector current.

2-2-6 Small-Signal Models of Bipolar Transistors

Figure 2-91 shows the small-signal equivalent BJT model. It consists of an intrinsic model and a package model. Table 2-12 lists its keywords.

In order to better understand the difference between the various technologies, we show Table 2-13, which allows the reader to compare their performances.

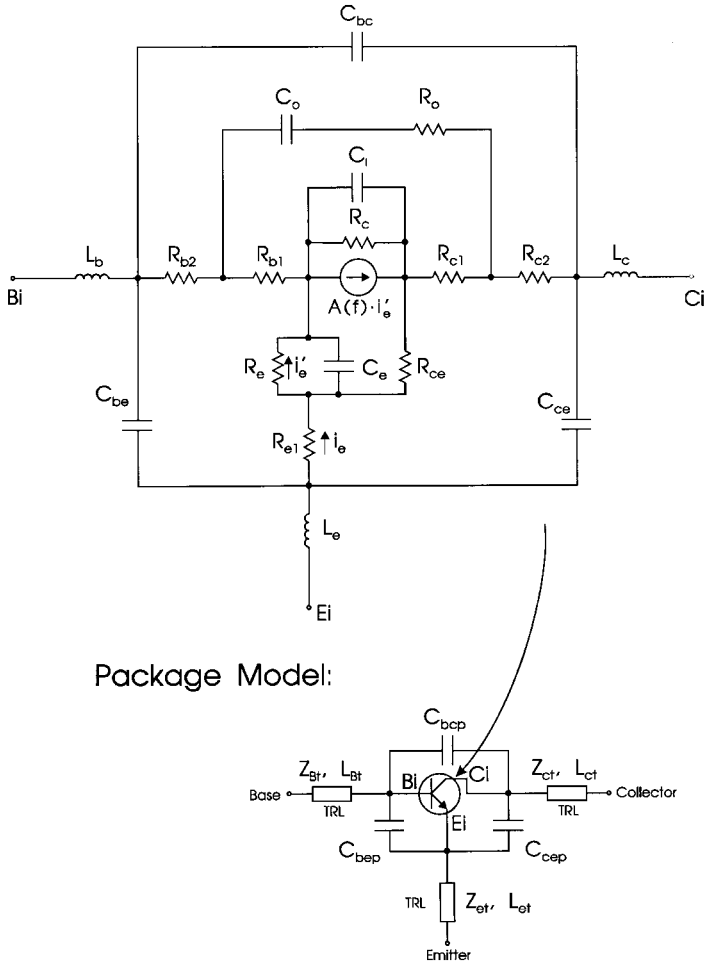

Figure 2-91 Linear BJT model.

Table 2-12 Small-signal equivalent BJT model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
A	Ratio of I_C to I_E at dc		0.0
RE	Emitter resistance	ohm	0.0
F	Current generator roll-off frequency	hertz	∞
T	Time delay	second	0.0
CE	Emitter capacitance	farad	0.0
CI	Collector capacitance	farad	0.0
RCE	Collector–emitter resistance	ohm	∞
RC	Collector resistance	ohm	∞
RO	Extrinsic base–collector resistance	ohm	0.0
CO	Extrinsic base–collector capacitance	farad	0.0
RB1	Intrinsic base resistance (R_{bb})	ohm	0.0
RC1	Parasitic collector resistance	ohm	0.0
RE1	Parasitic emitter resistance	ohm	0.0
RB2	Parasitic base resistance	ohm	0.0
RC2	Parasitic collector resistance	ohm	0.0
CBE	Base-to-emitter package capacitance	farad	0.0
CBC	Base-to-collector package capacitance	farad	0.0
CCE	Collector-to-emitter package capacitance	farad	0.0
LB	Base-lead inductance	henry	0.0
LC	Collector-lead inductance	henry	0.0
LE	Emitter-lead inductance	henry	0.0
TJ	Chip temperature	Kelvin	298
NFAC	Noise factor proportional to drive		1.0
FC	Flicker noise (1/*f* noise) corner frequency	hertz	50
	Package Model		
CBCP	Base-to-collector package capacitance	farad	0.0
CBEP	Base-to-emitter package capacitance	farad	0.0
CCEP	Collector-to-emitter package capacitance	farad	0.0
ZBT	Base transmission line impedance	ohm	50
ZCT	Collector transmission line impedance	ohm	50
ZET	Emitter transmission line impedance	ohm	50
LBT	Base transmission line length at $\varepsilon_r = 1$	meter	0.0
LCT	Collector transmission line length at $\varepsilon_r = 1$	meter	0.0
LET	Emitter transmission line length at $\varepsilon_r = 1$	meter	0.0

Notes:

1. $A \equiv \alpha = I_c/I_e$; β = dc current gain = $\alpha(1 - \alpha)$.
2. The bipolar current gain in this model is described by

$$\mathrm{A} = \mathrm{A}(0) = \frac{e^{-j\omega\mathrm{T}}}{1 + j\,(f/F)}$$

where $\omega = 2\,\pi f$ and f is frequency.

3. The current source is controlled by the current through R_e. The current generator has a cutoff frequency with respect to the total emitter current, I_E:

$$\mathrm{F} = g_m/2\pi C_e$$

where $g_m = 1/R_e$. This frequency becomes infinite for the default value for C_e (0.0). The parammeter F specifies the frequency roll-off for the current generator with respect to the current through R_e. Effectively, this frequency parameter may be used to model additional delays in the device.

[a] 1.0 µm Design Rule; NF = 3.25 dB, G_A = 12 dB at I_C = 2 mA, freq. = 2 GHz for $16 \times 1 \times 2 \ \mu m^2$; Resistors: 150 Ω/sq. (mono), 300 Ω/sq. (mono), 500 Ω/sq. (poly); Layers of metal, Schottky diodes, linear capacitor (silicided n^+ poly/n^+Si); Gate length = 0.68 µm (*n*-ch)/0.8 µm (*p*-ch), Gate Oxide = 12.5 nm (3 V)/15 nm (5 V), V_{th} = 0.65 V (*n*-ch)/–0.9 V (*p*-ch), Gm (µS/µm) = 204 (*n*-ch)/65 (*p*-ch).

[b] 0.6 µm Design Rule; Gold metallization, ILD: polyimide; Inductors: $Q > 10$ for $L \leq 10$ nH; Capacitors: $Q > 25$ for $C \leq 20$ pF; Schottky diodes (f_c = 100 GHz), Zener diodes, MIS capacitor, thin film resistors, and LPNP, 10 mask process.

[c] Analog devices using this process.

[d] LPNP F_t = 80 MHz; three-layer metallization; Schottky diodes (R_sC_j ~ 4 ps); Implanted resistors: 200 Ω/sq.; Poly resistors: 400/2000 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[e] LPNP F_t = 85 MHz; two-layer metallization; Schottky diodes (R_sC_j ~ 0.8 ps); Implanted resistors: 170/600/1200 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[f] L_n = 0.8 µm, T_{ox} = 18 nm, V_{th} = 0.76 V (nmos), V_{th} = –0.78 V (pmos), 2poly-MIM capacitor: 2.7 fF/µm^2, Schottkys, inductors.

[g] Not known if this process is in production.

[h] 0.8 µm Design Rules; 2.5 fF/µm^2 MIS capacitor; 600 MHz PJFET; 12L; F_t = 4 GHz VPNP; poly resistors 80/400/2000 Ω/sq.

[i] Targeted for 900-MHz GSM radio front-end blocks, a CT2 cordless single-chip radio, and DECT (digital enhanced cordless telephones).

[j] Targeted for multimode 900-MHz GSM, 1.8-GHz PCN and 1.9-GHz PCS based systems. Company is also evaluating integrating SiGe in HSB3.

2-3 FIELD-EFFECT TRANSISTORS

Both diodes and *pnp/npn* transistors work on the injection principle, which means the base–emitter junction generates either free electrons or other carriers, which are being "collected" by the collector connection and the base connection controls it. While this is a fairly complex process, its physics is well understood, and its latest spin-offs, heterojunction BJTs and silicon–germanium transistors, seem to offer a bright future.

In opposition to this, the field-effect transistor (FET) controls the electronic conduction in a solid by an electric field, and this concept actually predates the invention of the bipolar transistor. J. E. Lilienfeld filed for a patent on such a device in 1925 (U.S. Patent No. 1,745,175), and W. Shockley presented a comprehensive theory of the FET in 1952. It took until 1960 before the first commercially available FETs came on the market.

Several types of semiconductor materials have been used for making FETs: silicon, germanium, gallium arsenide, and others have been used. By far the most widely used is silicon, followed now by gallium arsenide.

The FET is a class of electronic semiconductor device in which the conduction of a "channel" between source (*S*) and drain (*D*) terminals is controlled by an electric field impressed on the channel via a gate (*G*) terminal. The conduction channel may utilize *n*-type carriers (electrons) or *p*-type carriers (holes). The electric field that controls the channel conduction may be introduced via a *pn* junction [for a "junction" FET (JFET)], a metal plate separated from the semiconductor channel by an oxide dielectric [for a metal-oxide semiconductor (MOS) FET], or a combination of the two methods. The polarity of the controlling electrical field is a function of the type of carriers in the channel. A FET "family tree" is shown in Figure 2-92.

For today's microwave and RF integrated circuits, the JFET with its high-frequency problems (low cutoff frequency) and large variation in parameters, such as transconductance and pinchoff voltage, has fallen out of favor and is mainly used in discrete circuits such as two-way radios or other RF applications that tolerate these wide variations and temperature dependence. The most-used FET types are MOS for small-signal applications, LDMOS (lateral diffused MOS) for power applications, and GaAs MESFET for lower-power applications (low-voltage applications) as well as high-power applications (recent advertisements by NEC have shown output power up to 100 W). Additional information on the FET family is shown in Figure 2-93.

All members of the FET family are high-impedance-input devices. Figure 2-94 shows the key operating parameters for MOSFETs and MESFETs in low-noise stages, high-gain stages, and linearized power stages. The linearization also improves the matching. This figure is similar to its counterpart in Section 2-2-2.

The following several pages present a typical example of a datasheet* for a JFET (U310) and the chip (NZA) on which it is based, followed by an example of a device with a much higher dynamic range (the CP640 family). The CP640 family and devices similar to them are being replaced by low-power LDMOS, which are not yet well-documented. At least one company, InterFET, is devoted entirely to producing discrete JFETs and JFET-related hybrid and small-scale-integration IC products.

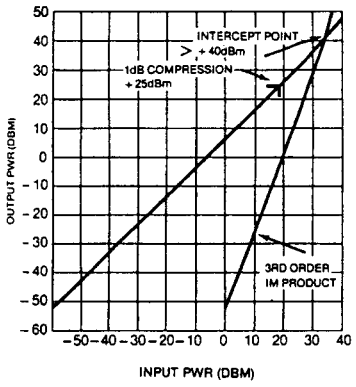
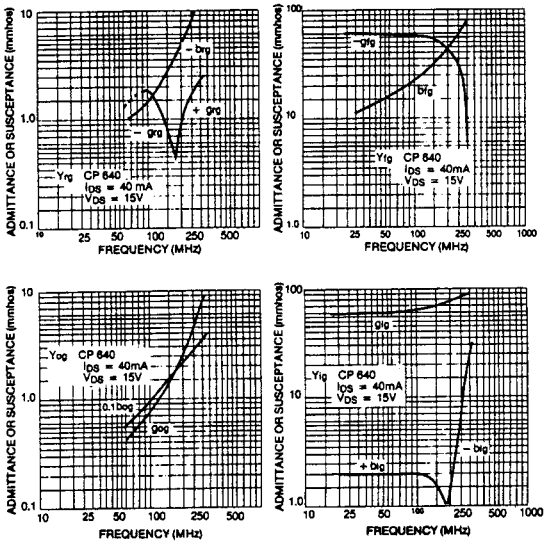
TYPICAL INTERCEPT AND COMPRESSION POINT





2-3-1 Large-Signal Behavior of JFETs

A section view of a junction field-effect transistor (JFET) is shown in Figure 2-95. This structure contains, between the source and the drain contacts, an *n*-type "channel" embedded in a *p*-type silicon substrate. If it is assumed that the *pn* junction forms a barrier to current flow, then it can be seen that channel conduction is a function of the channel width, length, and thickness and of the density and mobility of the carriers. In this structure, current can flow equally well in either direction through the channel; that is, the drain can be positive or negative with respect to the source.

Since we have found that the SPICE models for JFETs are really incomplete and give poor answers, we will only briefly touch here on the JFET's performance. The modified Materka model, one of the best GaAsFET models, turns out to be best suited for JFETs because both transistors act similarly in the dc area. Both have a gate-to-source diode that becomes conductive above 0.7 V at the input and they are also quite similar in other respects. Their equivalent circuits are also quite similar, as parameter extractions for both approaches have shown.

In general, in a three-terminal device, the drain current I_D is a function of two variables: V_{DS} and V_{GS}. This function is best represented by families of characteristic curves, as shown in Figure 2-96. These curves are for the "common source" configuration, with the drain as the output and the gate as the input. They reveal that for this device, if V_{DS} is greater than about 2 V (but less than the drain breakdown), I_D is primarily determined by the gate voltage V_{GS}. Under these conditions it is valid for small signals to characterize the FET by a single transfer characteristic curve, commonly called the "forward transconductance curve," such as the upper curve shown in Figure 2-96b. Some of the relationships between the forward transfer curve and the output characteristic curves of Figure 2-96a will be examined. The value of V_{GS} that reduces I_D to approximately zero is the gate–source cutoff voltage, $V_{GS(\text{off})}$. With reference to the output curve, Figure 2-96a, note that the drain current at $V_{GS} = 0$ tends to become saturated at a drain voltage approximately equal in magnitude to $-V_{GS(\text{off})}$. This drain voltage is often referred to as the pinchoff voltage V_P; however, in this section pinchoff voltage is used interchangeably with gate–source cutoff voltage. V_P will have the same meaning as $V_{GS(\text{off})}$. The symbol I_{DSS} is commonly used to indicate the value of saturated drain current at $V_{GS} = 0$.

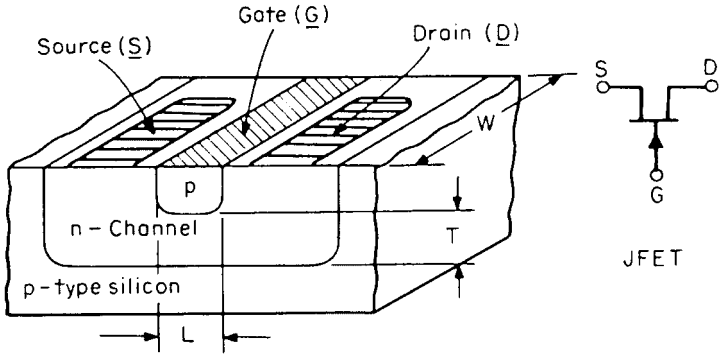


Figure 2-95 Junction field-effect transistor [9].

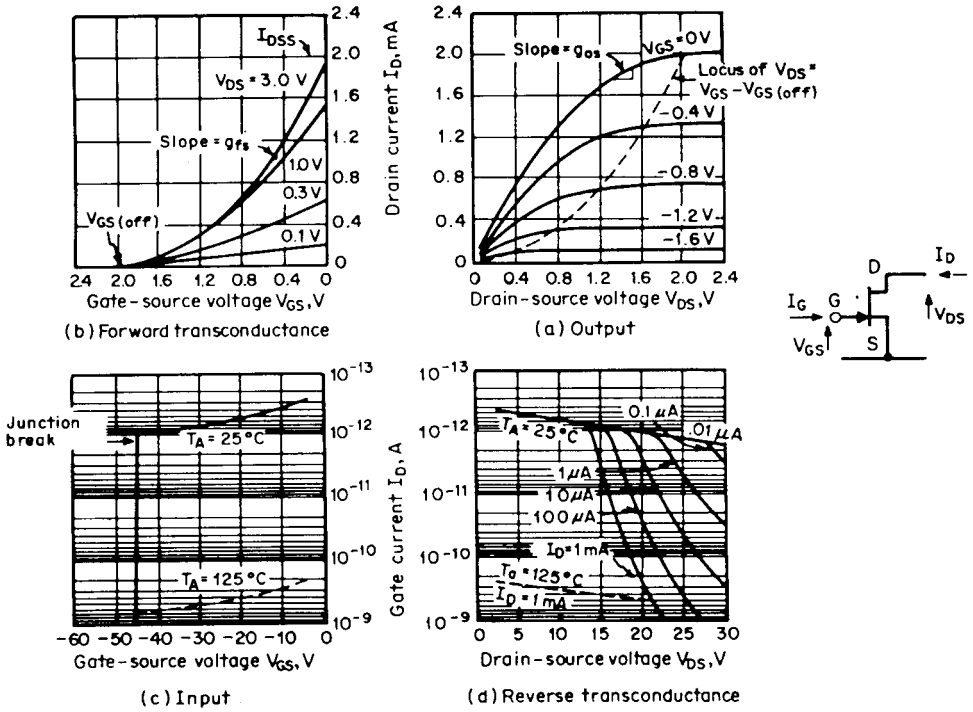

Figure 2-96 Static characteristics of an *n*-channel JFET.

The forward transconductance characteristic of Figure 2-96b can be approximated by a power law relation expressed as

$$I_D = I_{DSS}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^n \tag{2-190}$$

if $V_{DS} \geq -V_{GS(\text{off})}$. By differentiation the small-signal transconductance g_{fs} is given by

$$g_{fs} = \frac{dI_D}{dV_{GS}} = -n\frac{I_{DSS}}{V_{GS(\text{off})}}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^{n-1} \tag{2-191}$$

Some texts indicate a value of $\frac{3}{2}$ for n; however, experimental measurements on a number of n-channel JFET geometries indicate that the exponent n is close to 2, which is the value derived in an approximate treatment by R. D. Middlebrook [10].

A useful relationship between g_{fso}, I_{DSS}, and $V_{GS(\text{off})}$ is derived from the ratio of Eqs. (2-190) and (2-191):

$$\frac{g_{gs}}{I_D} = n(V_{GS} - V_{GS(\text{off})})^{-1} \tag{2-192}$$

At $V_{GS} = 0$, $I_D = I_{DSS}$ and $g_{fs} = g_{fso}$. Using 2 as the value of the constant n leads to

$$g_{fso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-193}$$

For n-channel FETs I_{DSS} is positive and $V_{GS(\text{off})}$ is negative; for p-channel FETs I_{DSS} is negative and $V_{GS(\text{off})}$ is positive; thus g_{fs} is a positive quantity for both p- and n-channel FETs.

Equation (2-190) indicates that for $V_{GS} = V_{GS(\text{off})}$, $I_D = 0$. In a real device this does not happen. Starting from zero, as the gate voltage is made more negative, the drain current decreases until it reaches a very low value equal to the drain-leakage current. At this value, the source current will consist of source–gate leakage. Any further increase in the magnitude of the negative gate voltage will result in an increase in I_D leakage. For the small-signal device illustrated, this minimum I_D is on the order of 2×10^{-13} A.

For some types of applications of the FET, it is helpful to understand the characteristics at very low values of V_{DS}, such as those shown in Figure 2-97. A "very low value" is one that is small compared to the magnitude of $V_{GS} - V_{GS(\text{off})}$. In this region, V_{DS} is small enough to have little effect on channel thickness, so that the I_D/V_{DS} slope is nearly linear. Since the slope is a function of V_{GS}, the FET can be utilized as a voltage-controlled resistor. The conductance slope ($\Delta I_D/V_{DS}$) at $V_{DS} = 0$ is approximately a linear function of $V_{GS} - V_{GS(\text{off})}$.

If g_{ds} at $V_{GS} = 0$ is given the term g_{dso}, then

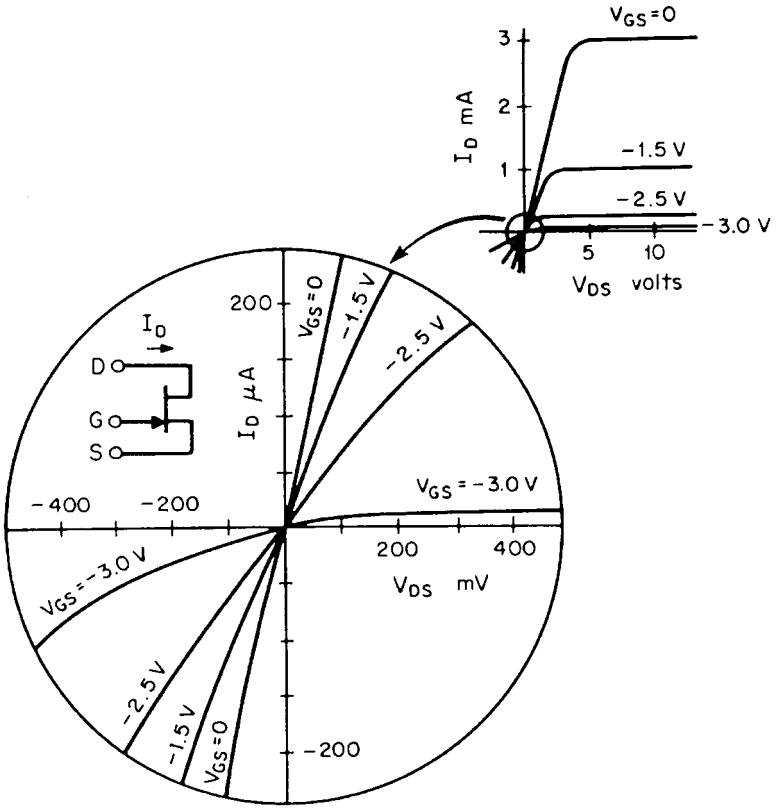

Figure 2-97 Enlargement of n-channel output characteristic around $V_{DS} = 0$.

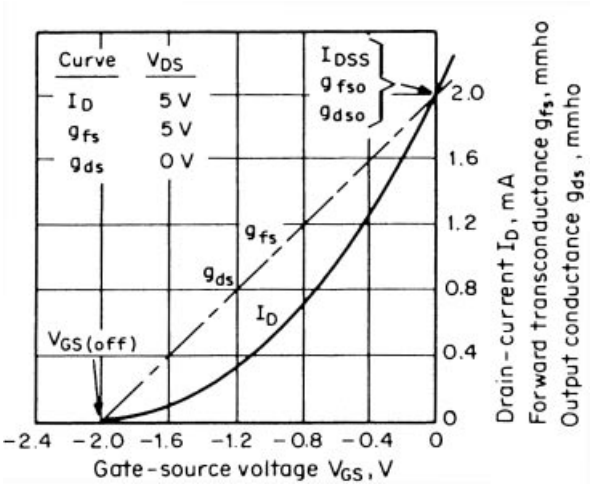

Figure 2-98 JFET I_D, g_{fs}, and g_{ds}.

$$g_{ds} = g_{dso}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right) \tag{2-194}$$

with $V_{DS} = 0$. A plot of this characteristic is shown in Figure 2-98, along with g_{fs} and I_D characteristics.

The relationship between g_{dso}, $V_{GS(\text{off})}$, and I_{DSS} is given by the equation

$$g_{dso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-195}$$

where I_{DSS} and $V_{GS(\text{off})}$ are as indicated in Figure 2-96. It is important to note that Eqs. (2-194) and (2-195) and the g_{ds} curve of Figure 2-98 are valid only for the case where V_{DS} is very small compared to V_P. Drain–source conductance at higher values of V_{DS} will be discussed later. FETs designed to be used as voltage-controlled resistors typically have a high $V_{GS(\text{off})}$ because the $V_{DS}/(V_{GS} - V_{GS(\text{off})})$ ratio should be low to keep distortion low. The actual large-signal JFET model as used in most simulators is shown in Figure 2-99, including a list of its intrinsic keywords (Table 2-14). Again, we had very little luck using this model as published by several SPICE CAD software manufacturers as offered. While we cannot judge on the quality of the parameters that came with the software, it was not possible to closely match even optimized sets of parameters to this large-signal model and obtain acceptable results. However, since the modified Materka model worked very well for this, we recommend that this popular JFET model not be used at frequencies above 10 MHz.

2-3-2 Small-Signal Behavior of JFETs

Figure 2-100 shows the small-signal equivalent transistor model we would recommend. It consists of an empirical FET model and a package model. Table 2-15 lists its keywords. Its advantage is that its built-in noise model is very accurate, even for JFETs and metal semiconductor FETs.

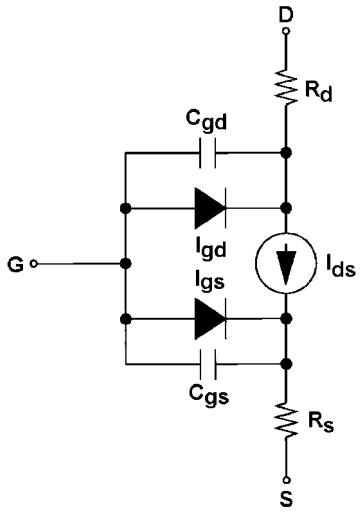

Figure 2-99 The nonlinear JFET model. Table 2-14 lists its intrinsic and extrinsic parameters. In our opinion, this model is limited to frequencies below 10 MHz; above this frequency, the modified Materka model should replace it.

Table 2-14 Large-signal JFET model keywords

Keyword	Description	Unit	Default

[a]The transconductance of this model may be approximately described by $g_m = G\,\frac{e^{-j\omega T}}{1 + j(f/F)}$ where $\omega = 2\pi f$ and f is frequency.
[b]The flicker noise frequency dependence is given by $1/(f/F_c)^{\mathrm{FCP}}$.

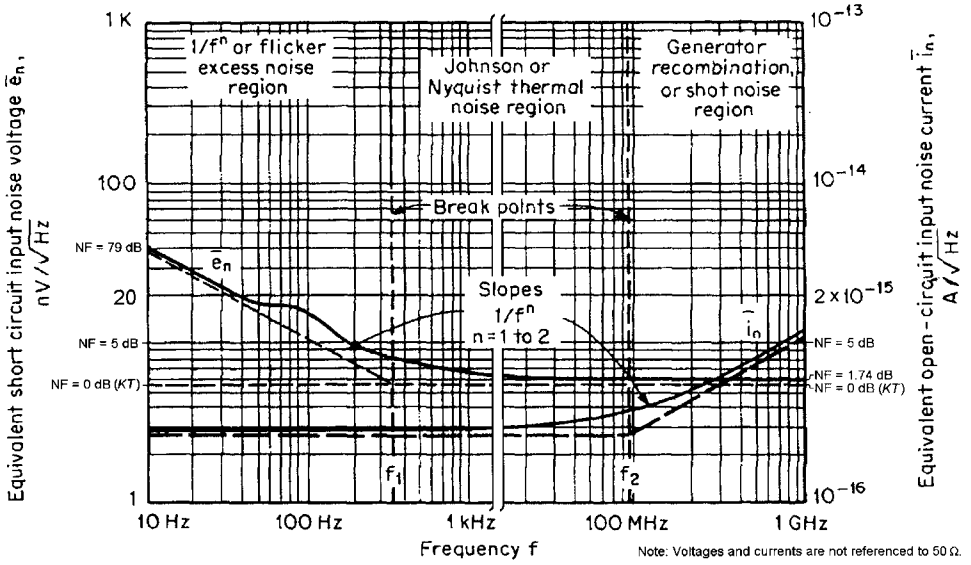

Figure 2-101 JFET noise characteristics.

where $K = 1.374 \times 10^{-23}$ J/K

T = absolute temperature in kelvins (273 K = 0 °C)

B = frequency range in hertz

g_{fs} = transconductance of FET

With the input short-circuited, the noise voltage across the load R_L resulting from the FET is

$$\text{Output noise voltage} = \bar{e}_n A_V \tag{2-197}$$

Below the frequency f_1, $\bar{e}_n$ increases proportional to $1/f^n$ and is expressed as

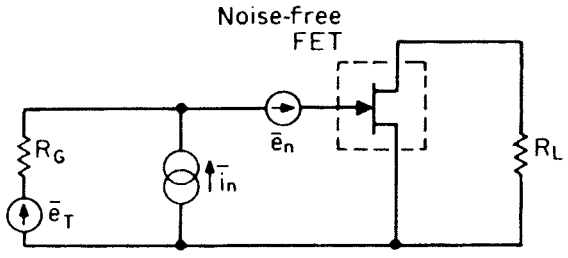

Figure 2-102 Equivalent noise circuit of the FET.

$$\bar{e}_n = \left[4KTB \left(\frac{0.67}{g_{fs}} \right) \left(1 + \frac{f_1}{f^n} \right)^{1/2} \right] \tag{2-198}$$

The low-frequency corner frequency f_1 for JFETs is typically in the 100-Hz to 1-kHz range, and the exponent n is usually between 1 and 2. As indicated by the equations, $\bar{e}_n$ is inversely proportional to the square root of g_{fs}.

The equivalent input noise current $\bar{i}_n$ is caused by the current in the gate-to-channel junction. Its approximate value below f_2 is

$$\bar{i}_n = (2qI_G B)^{1/2} \tag{2-199}$$

where $q = 1.602 \times 10^{-19}$
B = frequency range in hertz
I_G = dc gate current

This expression is fairly accurate when I_G is the result of the active device conductance. Typically, $\bar{i}_n$ will be lower than the calculated value because part of I_G is due to conductance across the device package.

At higher frequencies (above f_2),

$$\bar{i}_n = \left(\frac{4KTB}{R_P} \right)^{1/2} \tag{2-200}$$

where R_P is the real part of gate input impedance. R_P, in terms of Y_{11}, can range from several tens of megohms (at audiofrequencies) to 1 kΩ or less (at VHF/UHF frequencies). The high-frequency corner f_2 is typically in the range of 5–50 kHz and more than 100 MHz for high-frequency devices.

Another form of noise is known as "popcorn" or burst noise, the causes of which have not been completely identified. It shows up as a random short-duration step-function change in drain current, equivalent to an input gate–source voltage change of a few tenths of a microvolt. It is not unlike big bubbles on the surface of boiling water.

As far as the noise is concerned, we can also state that the Materka built-in proprietary noise model is significantly more accurate than the one mentioned above [11–14]. This model is implemented, with minimal documentation of its inner workings because of its proprietary nature, in the linear portion of the circuit simulator in Ansoft's Serenade Design Environment. In many cases, the manufacturer supplies only limited data, so it is most convenient that after SPICE-type parameter extraction is done by using the Scout program, one even gets good noise prediction for JFETs using the modified Materka model.

2-3-3 Large-Signal Behavior of MOSFETs

Metal-oxide-semiconductor field-effect transistors (MOSFETs) are important components in contemporary analog integrated circuits. Whereas initial applications were centered on all-MOS processes, combined bipolar and MOS processes give the designer the best of both worlds. A major advantage of MOS processes for realizing analog functions is that complex, dense digital functions can be realized on the same chip.

Transfer Characteristics of MOS Devices. A cross section of a typical enhancement-mode *n*-channel MOS transistor (NMOS) is shown in Figure 2-103a. Heavily doped *n*-type source and drain regions are fabricated in a *p*-type substrate (often called the body). A thick layer of silicon dioxide is grown over the substrate material and a conductive gate material (metal or polycrystalline silicon) covers this oxide between source and drain. The operation of the device is very similar to that of a JFET in that the gate–source voltage is used to modify the conductance of the region under the gate. This allows the gate voltage to control the current flowing between source and drain, giving gain in analog circuits and switching characteristics in digital circuits.

The enhancement-mode NMOS device of Figure 2-103a shows significant conduction between source and drain only when an *n*-type channel exists under the gate, and this is the origin of the "*n*-channel" designation. The term "enhancement mode" refers to the fact that no conduction occurs for $V_{GS} = 0$, and thus the channel must be "enhanced" to cause conduction. MOS devices can be made equally well by using an *n*-type substrate with a *p*-type conducting channel. Such devices are called enhancement-mode *p*-channel MOS transistors (PMOS). In technologies employing one or the other of these device types, the circuit symbol of Figure 2-103b is commonly used for either one. In complementary MOS technology (CMOS) both device types are present and the circuit symbols of Figure 2-103c will be used to distinguish them. In PMOS and NMOS technologies, the substrate is common to all devices, invariably connected to a dc power supply voltage, and usually not shown on the circuit diagram. In CMOS technology, however, devices of one type or another are fabricated in individual, separate isolation regions, which may or may not be connected to a power supply voltage. If these isolation regions *are* connected to the appropriate power supply, the symbols of Figure 2-103c will be used and the substrate connection will not be shown. If the individual isolation regions are connected elsewhere, however, the devices will be represented by the symbols of Figure 2-103d, where the substrate is labeled *B*. Finally, in NMOS technology an additional device type called a "depletion-mode" device is usually available. This is a conducting channel implanted between the source and drain so that conduction occurs for $V_{GS} = 0$. This device has characteristics that are almost identical to that of a JFET and will be represented by the symbol of Figure 2-103e.

The derivation of the transfer characteristics of the enhancement-mode NMOS device of Figure 2-103a begins by noting that with $V_{GS} = 0$, the source and drain regions are separated by back-to-back *pn* junctions. These junctions are formed between the *n*-type source and drain regions and the *p*-type substrate, resulting in an extremely high resistance (about 10^{12} Ω) between drain and source when the device is off.

Now consider substrate, source, and drain grounded and a positive voltage V_{GS} applied to the gate as shown in Figure 2-104. The gate and substrate then form the plates of a capacitor with the SiO_2 as a dielectric. Positive charge accumulates on the gate and the negative charge in the substrate. Initially, the negative charge in the *p*-type substrate is manifested by creation of a *depletion region* and resulting exclusion of holes under the gate. This is shown in Figure 2-104. The depletion-layer width *X* under the oxide is

$$X = \left(\frac{2\varepsilon\phi}{qN_A} \right)^{1/2} \tag{2-201}$$

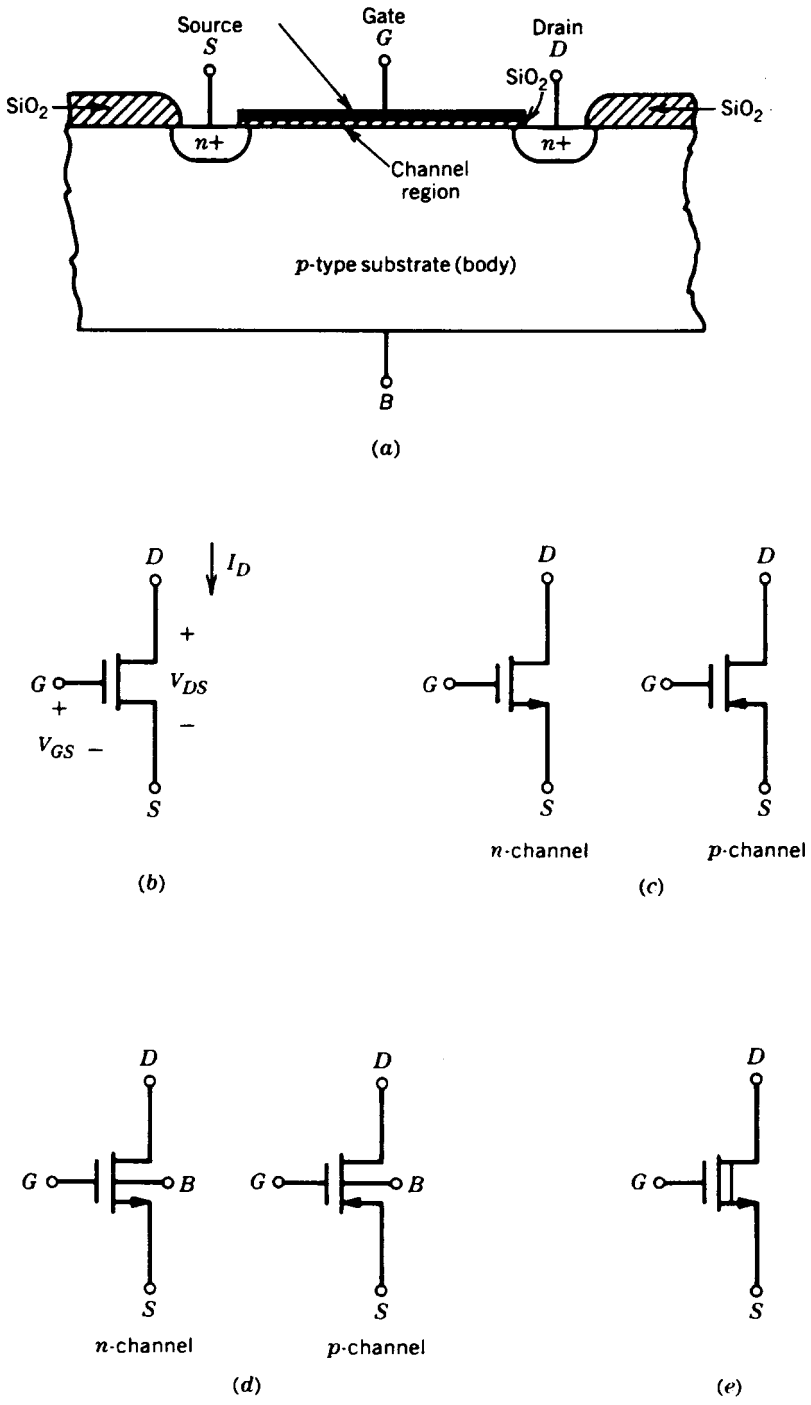

Figure 2-103 (a) Typical enhancement-mode NMOS structure. (b) Enhancement-mode NMOS or PMOS circuit symbol when one device type only is present. (c) NMOS and PMOS symbols used in CMOS circuits. (d) NMOS and PMOS symbols used when the substrate connection is nonstandard. (e) Depletion MOS device symbol.

where ϕ is the potential in the depletion layer at the oxide–silicon interface, N_A atoms/cm^3 is the doping density (assumed constant) of the p-type substrate, and ε is the permittivity of the silicon. The charge per unit area in this depletion region is

$$Q = qN_A X = \sqrt{2qN_A \varepsilon \phi} \tag{2-202}$$

When the potential in the silicon reaches a critical value equal to twice the Fermi level, $\phi_f \simeq 0.3$ V, a phenomenon known as "inversion" occurs [15]. Further increases in gate voltage produce no further changes in the depletion-layer width but instead a thin layer of electronics is induced in the depletion layer directly under the oxide. This produces a continuous n-type region with the source and drain regions and is the conducting channel between source and drain. This channel can then be modulated by increases or decreases in the gate voltage. In the presence of an inversion layer, and with no substrate bias, the depletion region contains a fixed charge

$$Q_{b0} = \sqrt{2qN_A \varepsilon 2\phi_f} \tag{2-203}$$

If a substrate bias voltage V_{SB} (source positive for n-channel devices) is applied between source and substrate, the potential required to produce inversion becomes $(2\phi_f + V_{SB})$ and the charge stored in the depletion region in general is

$$Q_b = \sqrt{2qN_A \varepsilon (2\phi_f + V_{SB})} \tag{2-204}$$

The gate voltage V_{GS}, required to produce an inversion layer, is called the threshold voltage V_t and can now be calculated. This voltage consists of several components. First, a voltage $[2\phi_f + (Q_b/C_{ox})]$ is required to sustain the depletion-layer charge Q_b, where C_{ox} is the gate oxide capacitance per unit area. Second, a work-function difference ϕ_{ms} exists between the

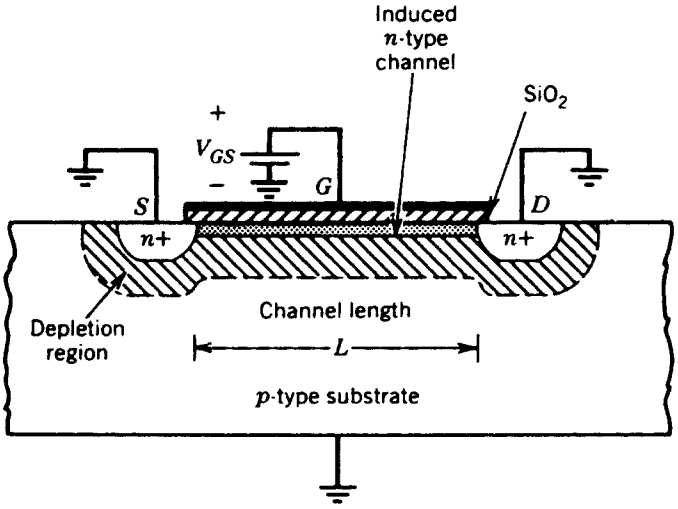

Figure 2-104 Idealized NMOS device cross section with positive V_{GS} applied, showing depletion regions and the induced channel.

gate metal and the silicon. Third, there is always charge density Q_{ss} (positive) in the oxide at the silicon interface. This is caused by crystal discontinuities at the Si–SiO_2 interface and must be compensated by a gate voltage contribution of $-Q_{ss}/C_{ox}$. Thus we have a threshold voltage

$$V_t = \phi_{ms} + 2\phi_f + \frac{Q_b}{C_{ox}} - \frac{Q_{ss}}{C_{ox}}$$

$$= \phi_{ms} + 2\phi_f + \frac{Q_{b0}}{C_{ox}} - \frac{Q_{ss}}{C_{ox}} + \frac{Q_b - Q_{b0}}{C_{ox}} \tag{2-205}$$

$$= V_{t0} + \gamma\left(\sqrt{2\phi_f + V_{SB}} - \sqrt{2\phi_f}\right) \tag{2-206}$$

where Eqs. (2-203) and (2-204) have been used and V_{t0} is the threshold voltage with $V_{SB} = 0$. The parameter γ is defined as

$$\gamma = \frac{1}{C_{ox}}\sqrt{2q\varepsilon N_A} \tag{2-207}$$

and

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{2-208}$$

where ε_{ox} and t_{ox} are the permittivity and thickness of the oxide, respectively. A typical value of γ is 0.5 $V^{1/2}$ and $C_{ox} = 3.5 \times 10^{-4}$ pF/μ^2 for $t_{ox} = 0.1$ μm.

In practice, the value of V_{t0} is usually adjusted in processing by implanting additional impurities into the channel region. Extra *p*-type impurities are implanted in the channel to make $V_{t0} \simeq 0.5$–1.5 V for *n*-channel enhancement devices. By implanting *n*-type impurities in the channel region, a conducting channel can be formed, even for $V_{GS} = 0$. This MOS transistor is called a depletion device, with typical values of V_{t0} in the range –1 to –4 V. If Q_i is the charge density per unit area due to the implant, then the threshold voltage given by Eq. (2-205) is shifted by approximately Q_i/C_{ox}.

The preceding equations can now be used to calculate the large-signal characteristics of an NMOS transistor. For purposes of analysis the source is assumed grounded and bias voltages V_{GS}, V_{DS}, and V_{SB} are applied as shown in Figure 2-105. If V_{GS} is greater than V_t, a conducting channel exists and V_{DS} causes a larger reverse bias from drain to substrate than exists from source to substrate, and thus a wider depletion region exists at the drain. However, for simplicity, we assume that the voltage drop along the channel itself is small so that the depletion layer is constant along the channel.

At a distance *y* along the channel the voltage with respect to the source is $V(y)$ and the gate-to-channel voltage at that point is $V_{GS} - V(y)$. We assume this voltage exceeds the threshold voltage V_t, and thus the induced electron charge per unit area in the channel is

$$Q_I(y) = C_{ox}[V_{GS} - V(y) - V_t] \tag{2-209}$$

The resistance *dR* of a length *dy* of the channel is

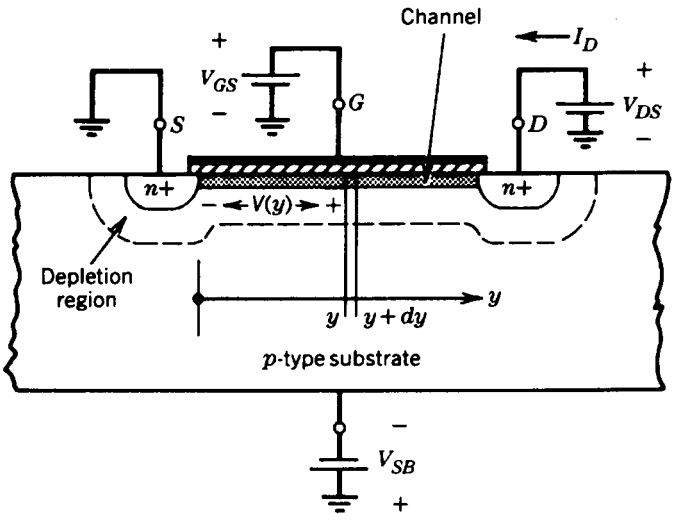

Figure 2-105 NMOS device with bias voltages applied.

$$dR = \frac{dy}{W\mu_n Q_I(y)} \tag{2-210}$$

where W is the width of the device, perpendicular to the plane of Figure 2-105, and μ_n is the average electron mobility of the channel.

The voltage drop dV along the length of the channel dy is

$$dV = I_D\, dR = \frac{I_D}{W\mu_n Q_I(y)}\, dy \tag{2-211}$$

If L is the total channel length, then substitution of Eq. (2-209) into Eq. (2-211) and integration gives

$$\int_0^L I_D\, dy = \int_0^{V_{DS}} W\mu_n C_{\text{ox}}(V_{GS} - V - V_t)\, dV \tag{2-212}$$

This results in

$$I_D = \frac{k'}{2}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-213}$$

where

$$k' = \mu_n C_{\text{ox}} = \frac{\mu_n \varepsilon_{\text{ox}}}{t_{\text{ox}}} \tag{2-214}$$

Equation (2-213) is important and describes the I–V characteristics of an MOS transistor, assuming a continuous induced channel. A typical value of k' for $t_{\text{ox}} = 0.1$ μm is about 20 μA/V^2 for an n-channel device.

As the value of V_{DS} is increased, the induced conducting channel narrows at the drain end and Eq. (2-209) indicates that Q_I at the drain end approaches zero as V_{DS} approaches $(V_{GS} - V_t)$. This results in the same pinchoff phenomenon as occurs in a JFET, and further increases in V_{DS} produce little change in I_D. Equation (2-213) is thus no longer valid if V_{DS} is greater than $(V_{GS} - V_t)$. The value of I_D in this region is obtained by substituting $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-213), giving

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 \tag{2-215}$$

for an MOS transistor in the pinchoff region. As in the case of a JFET, the drain current in the pinchoff region varies slightly as the drain voltage is varied. This is due to the presence of a depletion region between the physical pinchoff point in the channel at the drain end and the drain region itself. If this depletion-layer width is X_d, then the *effective* channel length is given by

$$L_{\text{eff}} = L - X_d \tag{2-216}$$

If L_{eff} is used in place of L in Eq. (2-215), we obtain a more accurate formula for the pinchoff region:

$$I_D = \frac{k'}{2}\frac{W}{L_{\text{eff}}}(V_{GS} - V_t)^2 \tag{2-217}$$

The fact that X_d (and thus L_{eff}) is a function of the drain–source voltage results in a variation of I_D and V_{DS} in the pinchoff region. Using Eqs. (2-216) and (2-217), we obtain

$$\frac{\partial I_D}{\partial V_{DS}} = -\frac{k'}{2}\frac{W}{L_{\text{eff}}^2}(V_{GS} - V_t)^2\frac{dL_{\text{eff}}}{dV_{DS}} \tag{2-218}$$

and thus

$$\frac{\partial I_D}{\partial V_{DS}} = \frac{I_D}{L_{\text{eff}}}\frac{dX_d}{dV_{DS}} \tag{2-219}$$

This equation is analogous to Eq. (2-168) for bipolar transistors. Following a similar procedure, a voltage analogous to the Early voltage can be defined as

$$V_A = \frac{I_D}{\partial I_D/\partial V_{DS}} \tag{2-220}$$

and thus

$$V_A = L_{\text{eff}}\left(\frac{dX_d}{dV_{DS}}\right)^{-1} \tag{2-221}$$

For MOS transistors, the most widely used parameter for the characterization of output resistance is

$$\lambda = \frac{1}{V_A} \tag{2-222}$$

As in the bipolar case, the large-signal properties of the transistor can be approximated by assuming that λ and V_A are constants, independent of bias conditions. Thus we can formulate a better approximation to the I–V characteristics as

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 (1 + \lambda V_{DS}) \tag{2-223}$$

In practical MOS transistors variation of X_d with voltage is complicated by the fact that the field distribution in the drain depletion region is not one dimensional. A vertical component in the field distribution is introduced by the potential difference between the gate and channel and the gate and drain. As a result, the calculation of λ from the device structure is quite different [16], and it is usually necessary to develop effective values of λ from experimental data. The parameter λ is a linear function of effective channel length and is an increasing function of the doping level in the channel. Typical values of λ are in the range 0.05–0.005 V^{-1}. Note that, in the case of a JFET, the pinchoff region for MOS devices is often called the *saturation* region.

A plot of I_D versus V_{DS} for an NMOS transistor is shown in Figure 2-106. Below pinchoff, the device behaves as a nonlinear voltage-controlled resistor, which is often called the *ohmic* or *triode* region. Above pinchoff, the device approximates a voltage-controlled current source. Note that for depletion MOS devices, V_t is negative and I_D is finite, even for $V_{GS} = 0$. For PMOS devices, all polarities of voltage and current are reversed.

The results as previously derived can be used to form a large-signal model of an MOS transistor. The model topology in the pinchoff region is the same as that for the JFET, but using Eq. (2-215) for the controlled-current generator.

MOS Device Voltage Limitations. The voltage limitations of MOS transistors depend on the gate length L. For small values of L (less than about 10 μm), the drain-depletion region

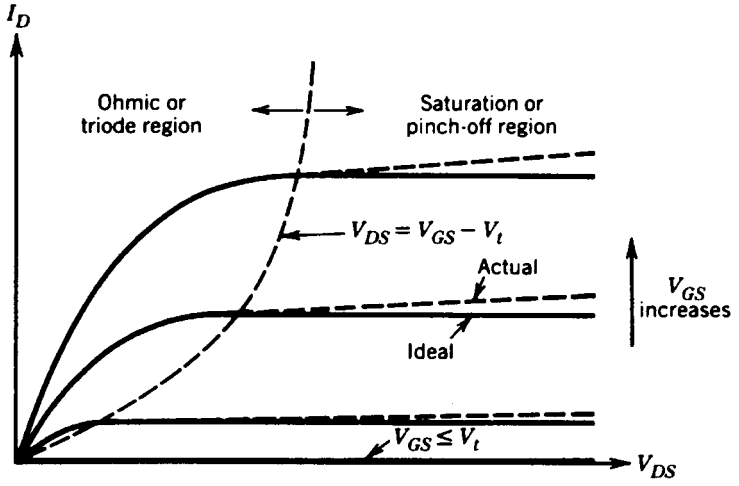

Figure 2-106 NMOS device characteristics.

exerts an appreciable influence on the channel. This causes I_D to rise with increasing V_{DS} in a similar fashion to the bipolar transistor curves of Figure 2-89.

For long channel lengths, the drain-depletion region has little effect on the channel and the I_D-versus-V_{DS} curves follow closely the ideal curves of Figure 2-106. Eventually the drain–substrate *pn*-junction breakdown voltage is exceeded and a sharp breakdown characteristic is obtained, which is similar to the JFET characteristic.

In addition to V_{DS} limitations, MOS devices must also be protected against excessive gate voltages. Typical gate oxides break down with about 25–50 V applied from gate to channel, and this process is destructive to the transistor.

2-3-4 Small-Signal Model of the MOS Transistor in Saturation

The preceding large-signal equations can now be used to derive the small-signal model of the MOS transistor in the saturation or pinchoff region. The important equations are (2-220) and (2-206). Note from Eq. (2-206) that the source–substrate voltage V_{BS} affects V_t, and thus I_D. This is due to the influence of the substrate acting as a second gate and is called *body effect*. As a consequence, I_D is a function of both V_{GS} and V_{BS}, and we require *two* transconductance generators in the small-signal model as shown in Figure 2-107. Variations in the voltage v_{bs} from source to body cause current $g_{mb}v_{bs}$ to flow from drain to source. Note that the body (or substrate) of an NMOS integrated circuit is usually connected to the most negative supply voltage and is thus an ac ground. However, the source connection can have a significant ac voltage impressed on it. Parasitic resistances due to the channel contact regions should be included in series with the source and drain of the model but are usually neglected in hand calculations. These resistances have an inverse dependence on channel width W and have typical values of 50–100 Ω for devices with W of about 1 μm.

The parameters of Figure 2-107 can be determined from Eq. (2-223) by differentiating.

$$g_m = \frac{\partial I_D}{\partial V_{GS}} = k' \frac{W}{L} (V_{GS} - V_t)(1 + \lambda V_{DS}) \tag{2-224}$$

If $\lambda V_{DS} << 1$, this is often approximated as

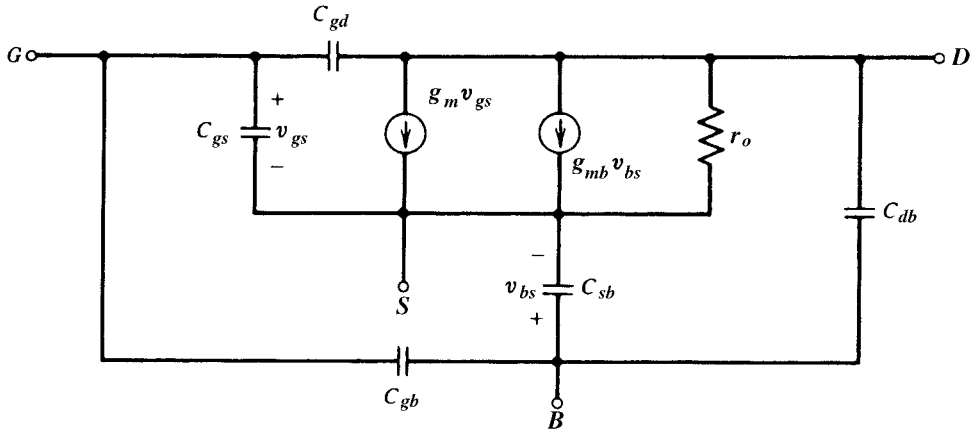

Figure 2-107 Small-signal MOS transistor equivalent circuit.

$$g_m = k' \frac{W}{L} (V_{GS} - V_t) = \sqrt{2k' \frac{W}{L} I_D} \tag{2-225}$$

Like the JFET and unlike the bipolar transistor, the transconductance of the MOSFET depends on both bias current and the *W*/*L* ratio (also on the oxide thickness via *k*′). Similarly,

$$g_{mb} = \frac{\partial I_D}{\partial V_{BS}} = -k' \frac{W}{L} (V_{GS} - V_t) (1 + \lambda V_{DS}) \frac{\partial V_t}{\partial V_{BS}} \tag{2-226}$$

From Eq. (2-206)

$$\frac{\partial V_t}{\partial V_{BS}} = -\frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = -\chi \tag{2-227}$$

where this equation defines a factor χ. This parameter is equal to the rate of change of threshold voltage with body bias voltage. One obtains

$$\chi = \frac{C_{js}}{C_{\text{ox}}} \tag{2-228}$$

where C_{js} is the capacitance per unit area of the depletion region under the channel, assuming a one-sided step junction with a built-in potential $\psi_0 = 2\phi_f$.

Substitution of Eq. (2-227) into Eq. (2-226) gives

$$g_{mb} = \frac{\gamma k' (W/L) (V_{GS} - V_t) (1 + \lambda V_{DS})}{2\sqrt{2\phi_f + V_{SB}}} \tag{2-229}$$

Again, if $\lambda V_{DS} << 1$, we have

$$g_{mb} = \frac{\gamma \sqrt{k' (W/L) I_D}}{\sqrt{2(2\phi_f + V_{SB})}} \tag{2-230}$$

An important quantity is the ratio g_{mb}/g_m, and from Eqs. (2-224) and (2-229) we find

$$\frac{g_{mb}}{g_m} = \frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = \chi \tag{2-231}$$

The factor χ is typically in the range 0.1–0.3.

Finally, the small-signal output resistance can be obtained directly from Eq. (2-218):

$$r_o = \left(\frac{\partial I_D}{\partial V_{DS}} \right)^{-1} = \frac{L_{\text{eff}}}{I_D} \left(\frac{dX_d}{dV_{DS}} \right)^{-1} \tag{2-232}$$

and using Eqs. (2-221) and (2-222), we find

$$r_o = \frac{1}{\lambda I_D} = \frac{V_A}{I_D} \tag{2-233}$$

Small-signal model capacitances are also shown in Figure 2-107. Of these, only the gate–source capacitance C_{gs} is intrinsic to the device operation in the saturation region. Capacitances C_{sb} and C_{db} are parasitic depletion-region capacitances between the substrate and the source and drain regions, respectively. These can be expressed as follows:

$$C_{sb} = \frac{C_{sb0}}{(1 + V_{SB}/\psi_0)^{1/2}} \tag{2-234}$$

$$C_{db} = \frac{C_{db0}}{(1 + V_{DB}/\psi_0)^{1/2}} \tag{2-235}$$

These capacitances are proportional to the gate and source region areas (including sidewalls), and C_{sb} also includes depletion-region capacitance from the induced channel in the body.

Capacitance C_{gb} between gate and substrate models parasitic oxide capacitance between the gate contact material and the substrate outside the active-device area. This is a constant capacitance and models coupling between polysilicon and metal interconnects and the underlying substrate. In fact, parasitic capacitance of this type underlies all polysilicon and metal traces on the chip and should be taken into account when simulating and calculating high-frequency circuit and device performance. Typical values depend on oxide thicknesses and range from about 0.04 to 0.15 fF per square micron of interconnect, with fringing effects becoming important for narrow lines (several microns or less in width).

Capacitances C_{gs} and C_{gd} exist from gate to source and drain, respectively. If C_{ox} is the oxide capacitance per unit area from gate to channel then the total capacitance under the gate is $C_{\text{ox}}WL$. This capacitance is intrinsic to the device operation and models the gate control of the channel conductance. In the ohmic region of device operation, this capacitance is split equally between source and drain so that $C_{gs} = C_{gd} = 1/2C_{\text{ox}}WL$. However, in the saturation region, the channel is very narrow at the drain end and the drain voltage exerts little influence on either the channel or the gate charge. As a consequence, the intrinsic portion of C_{gd} is essentially zero in the saturation region and C_{gd} then consists of a constant parasitic oxide-capacitance contribution due to gate overlap of the drain region. This is on the order of 1–10 fF for small devices.

In order to calculate the corresponding value of C_{gs} in the saturation region, we must calculate the total charge Q_T stored in the channel. This can be obtained by integrating Eq. (2-209) to obtain

$$Q_T = WC_{\text{ox}} \int_0^L [V_{GS} - V(y) - V_t]dy \tag{2-236}$$

Substituting for dy/dV from Eq. (2-211) into Eq. (2-236), we find

$$Q_T = \frac{W^2 C_{\text{ox}}^2 \mu_n}{I_D} \int_0^{V_{GS}-V_t} (V_{GS} - V - V_t)^2 dV \tag{2-237}$$

where the limit $y = L$ corresponds to $V = (V_{GS} - V_t)$ in saturation. Solution of Eq. (2-237) and use of Eqs. (2-214) and (2-215) gives

$$Q_T = \frac{2}{3} WLC_{\text{ox}}(V_{GS} - V_t) \tag{2-238}$$

and thus

$$C_{gs} = \frac{\partial Q_T}{\partial V_{GS}} = \frac{2}{3} WLC_{\text{ox}} \tag{2-239}$$

In addition, there is a contribution to C_{gs} from the constant parasitic oxide capacitance due to gate overlap of the source region.

The f_T of the MOSFET is given by

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs} + C_{gd} + C_{gb}} \tag{2-240}$$

The dependence of MOSFET f_T on device and process parameters can be seen by assuming that the intrinsic device capacitance G_{gs} dominates. Thus from Eq. (2-240) we have

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs}} \tag{2-241}$$

Substituting in Eq. (2-241) for g_m from Eq. (2-225) and C_{gs} from Eq. (2-239) we find for a MOSFET

$$f_T = 1.5 \frac{\mu_n}{2\pi L^2} (V_{GS} - V_t) \tag{2-242}$$

It is interesting to compare this with the intrinsic f_T of a bipolar transistor when parasitic depletion-layer capacitance is neglected. From

$$f_T = \frac{1}{2\pi\tau_F} \tag{2-243}$$

and substituting for τ_f and using the Einstein relationship $D_n/\mu_n = kT/q = V_T$, we find for a bipolar transistor

$$f_T = 2 \frac{\mu_n}{2\pi W_B^2} V_T \tag{2-244}$$

The similarity in form between Eqs. (2-242) and (2-244) is striking. In both cases the intrinsic device f_T increases as the inverse square of the critical device dimension across which carriers are in transit. The voltage V_t = 26 mV is fixed for a bipolar transistor, but MOSFET f_T can be increased by operating at high values of $(V_{GS} - V_t)$. Note that the base width W_B in a bipolar transistor is a vertical dimension determined by diffusions or implants and can typically be made much smaller than the channel length L of a MOSFET, which depends on surface geometry and photolithographic processes. Thus bipolar transistors generally have higher f_T than MOSFETs made with comparable processing. Finally, Eq. (2-242) was derived assuming that the MOSFET square law is valid. However, as discussed in Section 2-3-5, submicron MOSFETs depart significantly from square-law characteristics, and we find that for such devices f_T increases as L^{-1} rather than L^{-2}.

2-3-5 Short-Channel Effects in FETs

The evolution of integrated-circuit processing techniques has led to continuing reductions in both the horizontal and vertical dimensions of the active devices (the minimum allowed dimension of passive devices has also increased). This trend is driven primarily by economics in that more devices and circuits can be processed at one time on a given wafer. A second benefit has been that the frequency capability of the active devices continues to increase, as intrinsic f_T values increase with smaller dimensions while parasitic capacitances decrease.

Vertical dimensions such as the base width of a bipolar transistor in production processes may now be on the order of 0.05 μm or less, whereas horizontal dimensions such as bipolar emitter width or FET gate length may be significantly less than 1 μm. Even at these very small dimensions, the large-signal and small-signal models of bipolar transistors given in previous sections remain valid. However, significant short-channel effects become important in FETs of all types at channel lengths on the order of 1 μm or less and require modifications to the FET models given previously. The primary effect is to modify the classical FET square-law transfer characteristic in the saturation region to make the device more closely approach an ideal linear transfer function. Note, however, that even in processes with submicron capability, many of the FETs in a given analog circuit may be deliberately chosen to be larger than the minimum size and may be well approximated by the square-law model.

The most important short-channel effect in FETs is due to velocity saturation of carriers in the channel [17]. At low electric field values, the linear relation between carrier velocity and field implied by Eqs. (2-210) and (2-211) is valid. At high fields, however, the carrier velocities approach the thermal velocities and subsequently the carrier velocities increase more slowly with increasing field. This is illustrated in Figure 2-108, which shows typical measured electron drift velocity v_d versus tangential electric field strength magnitude $\mathscr{E}$ in an NMOS surface channel. Note that at low field values the velocity is proportional to the field, while at high fields the velocity approaches a constant value called the scattering-limited velocity v_{scl}. A first-order analytical approximation to this curve is

$$v_d = \frac{\mu_n \mathscr{E}}{1 + \mathscr{E}/\mathscr{E}_c} \tag{2-245}$$

where $\mathscr{E} \simeq 1.5 \times 10^6$ V/m and $\mu_n \simeq 0.07$ m^2/V · s is the low-field mobility. Equation (2-245) is also plotted in Figure 2-108. From Eq. (2-245), as $\mathscr{E} \to \infty$ we have $v_{\text{scl}} = \mu_n \mathscr{E}_c$. At the critical field value $\mathscr{E}_c$, the carrier velocity is a factor of 2 less than the low-field formula would predict. In a device with a channel length $L = 1$ μm, we need a voltage drop of only 1.5 V along the channel to have an average field equal to $\mathscr{E}_c$, and this condition is readily achieved in small MOSFETs. Similar results are found for PMOS devices.

As an example of the effects of velocity saturation on FET characteristics, we consider the example of the MOSFET. In the analysis of "Transfer Characteristics of MOS Devices" in Section 2-3-3, we now use the more general expression

$$I_D = WQ_I(y)v_d(y) \tag{2-246}$$

Substituting Eq. (2-245) into Eq. (2-246) and using

$$\mathscr{E} = \frac{dV}{dy} \tag{2-247}$$

for the magnitude of the field, we find that

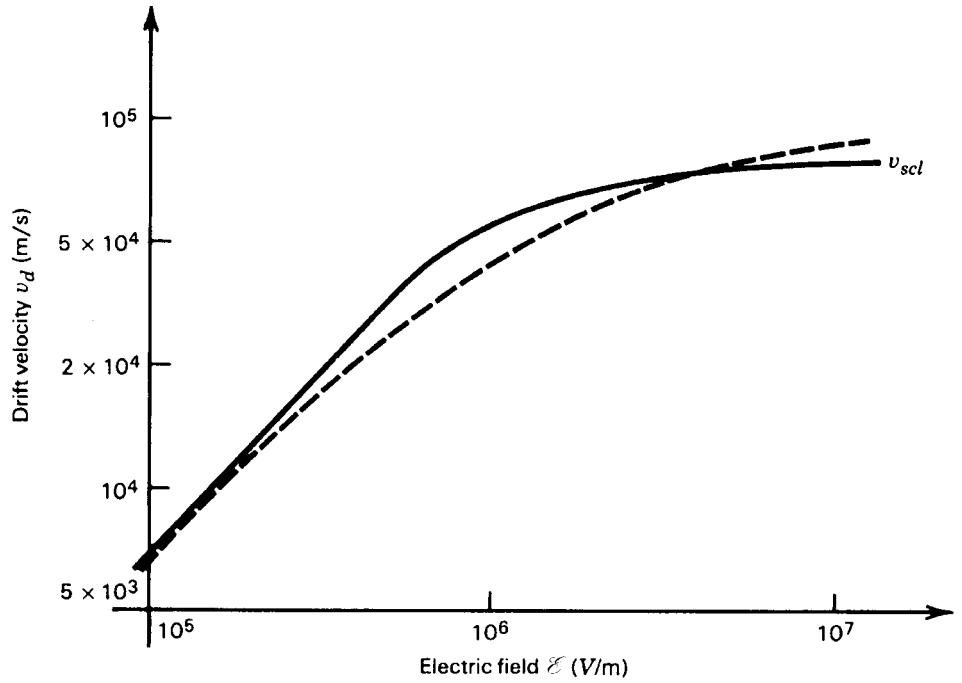

Figure 2-108 Typical measured electron drift velocity v_d versus tangent electric field $\mathscr{E}$ in an MOS surface channel (solid line). Also shown (dotted line) is the analytical approximation of Eq. (2.245) with $\mathscr{E}_c = 1.5 \times 10^6$ V/m and $\mu_n = 0.07$ m^2/V · s.

$$I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right) = WQ_I(y)\mu_n\frac{dV}{dy} \tag{2-248}$$

Note that as $\mathscr{E}_c \to \infty$ and velocity saturation becomes negligible, Eq. (2-248) approaches the original equation (2-211).

Integrating Eq. (2-248) along the channel we obtain

$$\int_0^L I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right)dy = \int_0^{V_{DS}} WQ_I(y)\mu_n dV \tag{2-249}$$

and thus

$$I_D = \frac{\mu_n C_{ox}}{2\left(1 + \dfrac{1}{\mathscr{E}_c}\dfrac{V_{DS}}{L}\right)}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-250}$$

The quantity V_{DS}/L in Eq. (2-250) can be interpreted as the average field in the channel. If this is comparable to $\mathscr{E}_c$, the drain current for a given V_{DS} is less than the simple expression (2-213) would predict.

Equation (2-250) is valid in the triode region. The MOSFET transfer function in saturation can be obtained by using $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-250) to obtain

$$I_D = \frac{k'}{2[1 + \theta(V_{GS} - V_t)]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-251}$$

where $\theta = 1/L\mathscr{E}_c$ and has the dimension volts^{-1}. For $L = 1$ μm, a typical value is $\theta \approx 0.7\ \text{V}^{-1}$. Note that in the presence of velocity saturation effects, the device enters the saturation region for $V_{DS} < (V_{GS} - V_t)$. However, Eq. (2-251) still gives a good estimate of the saturation current.

Thus far, we have only considered the effects of the tangential field due to the V_{DS} along the channel when examining velocity saturation effects. However, there exists a normal field originating from the gate voltage that also inhibits channel carrier mobility. Since the normal field depends on the value of V_{GS}, we find that an empirical modification to θ in Eq. (2-251) can adequately model this effect. In practice, θ is determined by a best fit to measured device characteristics.

Returning to Eq. (2-251) we note that for very short channel lengths, θ becomes large and Eq. (2-251) reduces to

$$I_D \propto (V_{GS} - V_t) \tag{2-252}$$

Thus, the FET characteristics tend toward a *linear* transfer function as the channel length becomes very small (less than 1 μm).

Equation (2-251) has a simple circuit representation. Consider the circuit of Figure 2-109, where an ideal square-law MOSFET has a resistance R_{SX} in series with the source of the FET. Assume

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V'_{GS} - V_t)^2 \tag{2-253}$$

Now

$$V_{GS} = V'_{GS} + I_D R_{SX} \tag{2-254}$$

and substituting Eq. (2-254) into Eq. (2-253) we find that

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V_{GS} - I_D R_{SX} - V_t)^2 \tag{2-255}$$

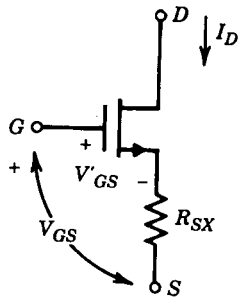

Figure 2-109 Model of velocity saturation of a MOSFET by addition of a series source resistance to an ideal square-law device.

Rearranging Eq. (2-255) we find

$$I_D = \frac{\mu C_{\text{ox}}}{2\left[1 + \mu C_{\text{ox}} \frac{W}{L} R_{SX}(V_{GS} - V_t)\right]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-256}$$

This has exactly the same form as Eq. (2-251) if we identify

$$\theta = \mu C_{\text{ox}} \frac{W}{L} R_{SX} \tag{2-257}$$

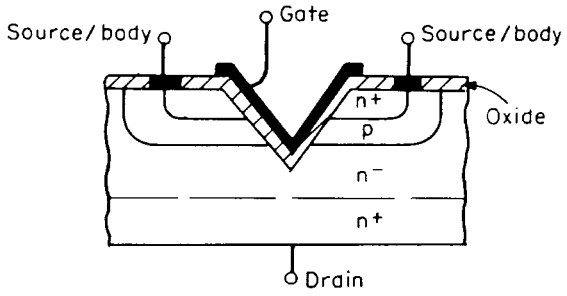
Substituting $\theta = 1/L\mathscr{E}_c$ into Eq. (2-257) we have

$$R_{SX} = \frac{1}{\mathscr{E}_c} \frac{1}{\mu C_{\text{ox}}} \frac{1}{W} \tag{2-258}$$

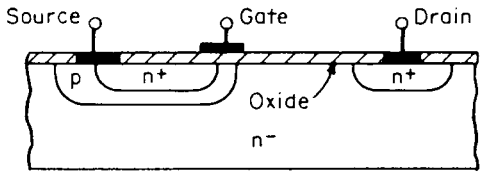
Thus, the influence of velocity saturation on the large-signal characteristics of a FET can be modeled to first order by a resistor R_{SX} in series with the source of an ideal square-law device. Note that R_{SX} varies inversely with W, as does the intrinsic physical series resistance due to source and drain contact regions. Typically, R_{SX} is larger than the physical series resistance. For $W = 2\ \mu\text{m}$, $\mu C_{\text{ox}} = 40\ \mu\text{A}/V^2$, and $\mathscr{E}_c = 1.5 \times 10^6$ V/m, we find $R_{SX} = 8\ \text{k}\Omega$.

The foregoing analysis has developed a modified large-signal mode for the MOSFET including velocity saturation effects. Small-signal MOSFET modeling for small devices can still be done using the equivalent circuit of Figure 2-107 if the values of g_m and g_{mb} are modified to account for the effects of velocity saturation using Eq. (2-251).

Figure 2-110 shows a cross section of VMOS (vertical MOS) and DMOS (double-diffused MOS) transistors. There is also a TMOS device—a Motorola variant of VMOS—and the



(a) VMOS (vertical channel MOS)



(b) DMOS (double-diffused MOS)

Figure 2-110 Cross section of (a) VMOS and (b) DMOS FETs.

now very popular LDMOS (lateral diffused MOS) power transistor (Figures 2-111 and 2-112). LDMOS FETs operate from a single supply (approximately 8 V and up) and are available for output powers surpassing 100 W at 2 GHz. The feedback capacitance is much lower than VMOS, TMOS, and earlier models, significantly improving circuit stability.

Following is a listing of Motorola high-power LDMOS transistors capable of operation up to 2 GHz:

2-3-6 Small-Signal Models of MOSFETs

Subthreshold Conduction in MOSFETs. The MOSFET analysis of Section 2-3-3 focused on the normal region of operation where this is a well-defined conducting channel under the gate. Changes in the gate voltage are assumed to cause changes in the channel charge only, and not in the depletion region below. However, for gate voltages less than the extrapolated threshold voltage V_t, the applied gate potential affects both the depletion-region charge and the channel charge, which is then very small but not zero. The device can thus conduct finite (but small) current for $V_{GS} < V_t$, so that Eq. (2-215) is not valid in this region. The electrons in the n^+ source region of an NMOS transistor can overcome the potential barrier to the p-type substrate and enter the channel region. This process is very similar to the turn-on of a bipolar transistor, and in fact the MOSFET characteristics in this subthreshold region (also called weak inversion) are very similar to those of a bipolar transistor. Analysis [19] shows that in the subthreshold region of the MOSFET characteristics can be defined by the equation

$$I_D = k_x \frac{W}{L} e^{V_{GS}/nV_T}(1 - e^{-V_{DS}/V_T}) \tag{2-259}$$

where k_x depends on process parameters and $n \simeq 1.5$. The value of n is not equal to unity in this case (as it is for the bipolar transistor) because the applied voltage V_{GS} appears partially at the silicon surface and partially across the depletion layer.

To illustrate this effect, we show measured NMOS characteristics plotted on three different scales in Figure 2-113. In Figure 2-113a we show the transfer characteristic in the forward-active region plotted on linear scales. For this device W = 20 μm and L = 20 μm and short-channel effects are negligible. The same data are plotted in Figure 2-113b as $\sqrt{I_D}$ versus V_{GS}. The resulting straight line shows that the device characteristic is close to an ideal square law. Plots like this are commonly used to obtain V_t by extrapolation (0.7 V in this case) and also k' from the slope of the curve (54 μA/V^2 in this case). Note that near the threshold voltage, the curve deviates from the straight line representing the square law. This is the subthreshold region. The data are plotted a third time in Figure 2-113c on log–linear scales. The straight line obtained for $V_{GS} < V_t$ fits Eq. (2-259) with n = 1.5. At currents below 10^{-12} A, the effect of leakage currents becomes evident.

The major application of subthreshold operation is in very low power applications at relatively low signal frequencies. The limitation to low signal frequencies occurs because the MOSFET f_T becomes very small. Since the device capacitances at very low bias currents

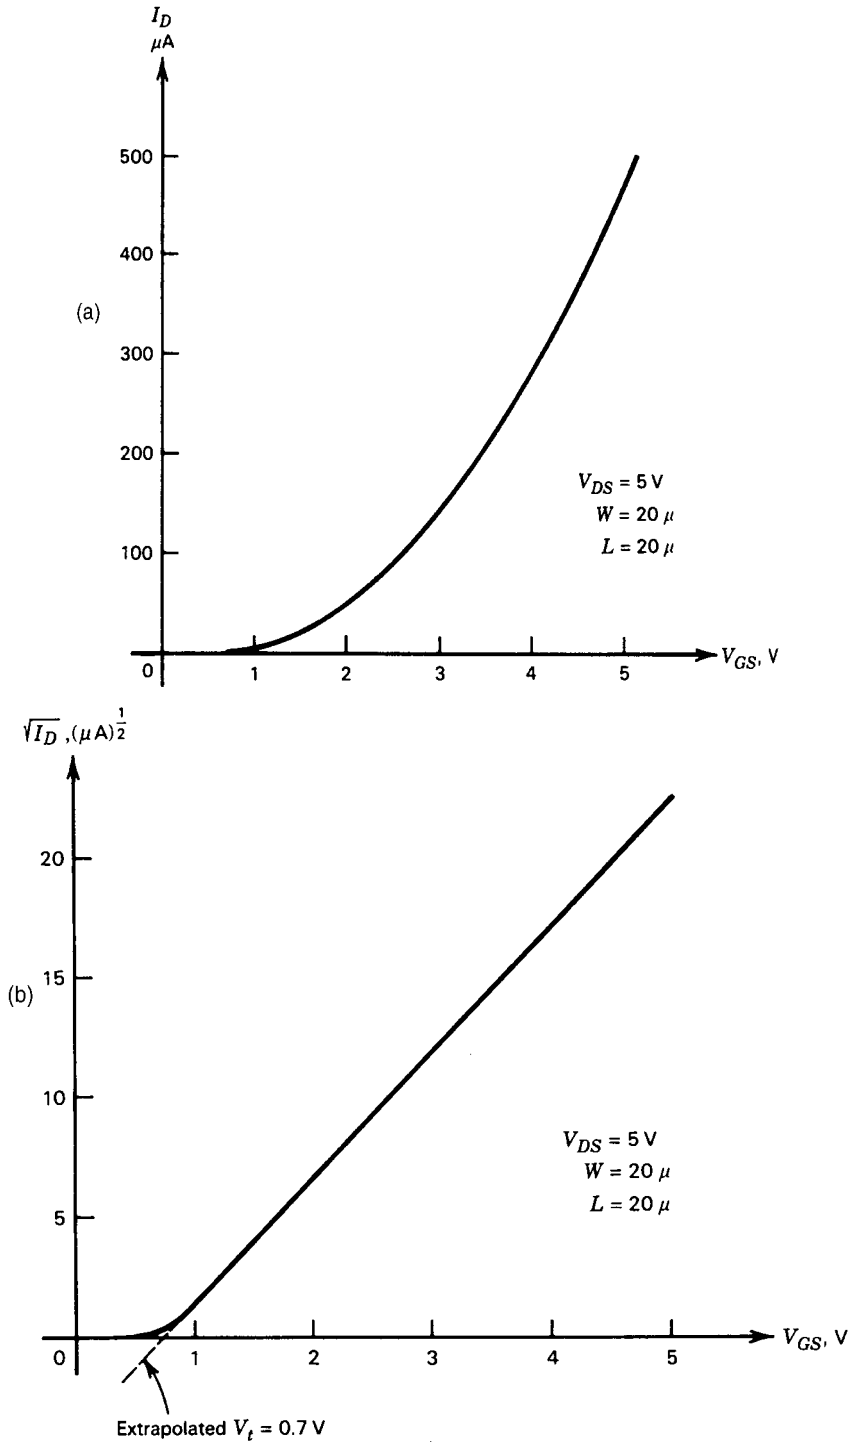

Figure 2-113 (a) Measured NMOS transfer characteristic in the forward-active region. (b) Data from part (a) plotted as $\sqrt{I_D}$ versus V_{GS} showing the square-law characteristic. Figure 2-113. (*Continued*)

are essentially fixed, and the small-signal g_m calculated from Eq. (2-259) becomes proportional to I_D, we see that the value of f_T becomes very small at very low values of I_D.

Substrate Flow in MOSFETs. As the reverse-bias voltages on the device are increased, carriers traversing the depletion regions gain sufficient energy to create new hole–electron pairs in lattice collisions by a process known as *impact ionization.* Eventually, at high enough bias voltages, the process results in large avalanche currents. For collector–base bias voltages well below the breakdown value, a small enhanced current flow may occur across the collector–base junction due to this process with little apparent effect on the device characteristics.

Impact ionization also occurs in MOSFETs but has a significantly different effect on the device characteristics. This is because the channel electrons (for the case of NMOS) create hole–electron pairs in lattice collisions in the drain depletion region, and some of the resulting holes then flow to the substrate, creating a substrate current. (The electrons created

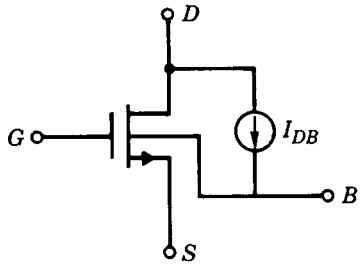

Figure 2-114 Representation of impact ionization in a MOSFET by a drain–substrate current generator.

in the process flow out the drain terminal.) The carriers created by impact ionization are thus not confined within the device as they are in a bipolar transistor. The effect of this phenomenon can be modeled by inclusion of a controlled current generator I_{DB} from drain to substrate, as shown in Figure 2-114 for an NMOS device. The magnitude of this substrate current depends on the voltage across the drain depletion region (which determines the energy of the ionizing channel electrons), and also on the drain current (which is the rate at which channel electrons enter the depletion region). It has been found empirically [20] that the current I_{DB} can be expressed as

$$I_{DB} = K_1(V_{DS} - V_{DS,\text{sat}})I_D e^{-[K_2/(V_{DS}-V_{DS,\text{sat}})]} \tag{2-260}$$

where K_1 and K_2 are process-dependent parameters and $V_{DS,\text{sat}}$ is the value of V_{DS} where the drain characteristics enter the saturation region. Typical values for NMOS devices are $K_1 = 5\ \text{V}^{-1}$ and $K_2 = 30$ V. The effect is generally much less significant in PMOS devices because the holes carrying the charge in the channel are much less efficient in creating hole–electron pairs than are energetic electrons.

The major impact of this phenomenon on circuit performance is that a parasitic resistance from drain to substrate now exists. Since the substrate of an NMOS device in a *p*-substrate process is an ac ground (the common substrate terminal must always be connected to the most negative supply voltage in the circuit), the parasitic resistance shunts the drain to ground and can be a limiting factor in many circuit designs. Differentiating Eq. (2-260) we find for the drain–substrate small-signal conductance

$$g_{db} = \frac{\partial I_{DB}}{\partial V_D}$$

$$= K_2 \frac{I_{DB}}{(V_{DS} - V_{DS,\text{sat}})^2} \tag{2-261}$$

where the gate and source are assumed held at fixed potentials.

In IC applications for RF/UHF circuits, many not-yet-solved problems remain:

1. The flicker corner frequency for MOS devices is somewhere between 100 kHz and 1 MHz.
2. Because of backplane problems in ICs, such as the substrate capacitance, also relative to the source, the performance of an IC-MOS/CMOS is not as good as expected if these effects are not considered.
3. Discrete devices, such as *n*-channel MOS devices, which are also available as dual-gate MOSFETs, can work well up to 1200 MHz. Such performance is not yet shown in silicon-based RFICs.
4. For RF power devices, such as LDMOS and others mentioned, promising results are only shown for discrete devices. There are no equivalent ICs on the market yet.

It will be interesting to see how this technology will work itself upward in frequency. Its main advantage is the BiCMOS process, which allows the mixing of analog and digital circuits nicely. Heterojunction transistors, such as SiGe, are inherently much more linear

and, for the same performance, require less current than MOS technology. On the other hand, we have not seen large-scale production SiGe-based ICs.

In the following five pages, we reproduce the datasheet for the Siemens (now Infineon Technologies) BF999 single-gate MOSFET.* Above 500 MHz, a dual-gate (also referred to as tetrode) MOSFET, such as the BF998, is preferred over a single-gate device. The main reasons for this are:

1. Internally, it is equivalent to two single-gate devices connected in a cascade arrangement, with the output device operating in the grounded-gate configuration, which entirely avoids the Miller effect and therefore remains stable at higher frequencies, operating up to 1.2 GHz.
2. The second gate can be used for AGC. As the Gate 2 voltage changes, the gain varies heavily.
3. By applying a local oscillator signal to Gate 2, this configuration can be used as a mixer.

The major drawbacks of these devices are their wide tolerances and temperature sensitivity. They follow to some degree the CMOS design but seem to have better performance.

The BF995, also called a tetrode, is in reality a dual-gate MOSFET specified to only 300 MHz; however, we are reproducing its datasheet* because the one more applicable for wireless circuits, the BF1005, does not have such a complete set of data.

To demonstrate the capabilities of low-voltage LDMOS transistors, we show the MRF5003 datasheet.† This device is intended for low-voltage applications down to 7.5 V. To the best of our knowledge, this is the lowest-voltage LDMOS transistor on the market. Other members of this family, which produce 5 W (MRF5005) and 15 W (MRF5015), begin to require higher supply voltages. Just to make sure it is not forgotten, the advantage of LDMOS is, besides lower-voltage operation, much-reduced feedback capacitance. LDMOS devices are now available that operate above 1 GHz and produce 60 W. There is now some competition with the recently introduced NEC GaAsFET, which goes up to 100 W in a similar frequency range.

3.0 W, 7.5 V, 512 MHz
N–CHANNEL
BROADBAND
RF POWER FET

The MRF5003 is designed for broadband commercial and industrial applications at frequencies to 520 MHz. The high gain and broadband performance of this device makes it ideal for large–signal, common source amplifier applications in 7.5 Volt and 12.5 Volt mobile, portable, and base station FM equipment.

- Guaranteed Performance at 512 MHz, 7.5 Volts
  Output Power = 3.0 Watts
  Power Gain = 9.5 dB
  Efficiency = 45%
- Characterized with Series Equivalent Large–Signal Impedance Parameters
- S–Parameter Characterization at High Bias Levels
- Excellent Thermal Stability
- All Gold Metal for Ultra Reliability
- Capable of Handling 20:1 VSWR, @ 15.5 Vdc, 512 MHz, 2.0 dB Overdrive
- Suitable for 12.5 Volt Applications
- True Surface Mount Package
- Available in Tape and Reel by Adding R1 Suffix to Part Number.
  R1 Suffix = 500 Units per 16 mm, 7 inch Reel.
- Circuit board photomaster available upon request by contacting
  RF Tactical Marketing in Phoenix, AZ.

DESIGN CONSIDERATIONS

The MRF5003 is a common–source, RF power, N–Channel enhancement mode, Metal–Oxide Semiconductor Field–Effect Transistor (MOSFET). Motorola RF MOSFETs feature a vertical structure with a planar design. Motorola Application Note AN211A, "FETs in Theory and Practice", is suggested reading for those not familiar with the construction and characteristics of FETs.

This surface mount packaged device was designed primarily for VHF and UHF power amplifier applications. Manufacturability is improved by utilizing the tape and reel capability for fully automated pick and placement of parts.

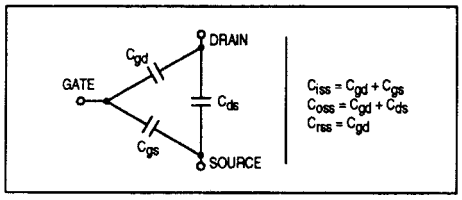
The major advantages of RF power MOSFETs include high gain, simple bias systems, relative immunity from thermal runaway, and the ability to withstand severely mismatched loads without suffering damage.

MOSFET CAPACITANCES

The physical structure of a MOSFET results in capacitors between all three terminals. The metal oxide gate structure determines the capacitors from gate–to–drain (C_{gd}), and gate–to–source (C_{gs}). The PN junction formed during fabrication of the RF MOSFET results in a junction capacitance from drain–to–source (C_{ds}). These capacitances are characterized as input (C_{iss}), output (C_{oss}) and reverse transfer (C_{rss}) capacitances on data sheets. The relationships between the inter–terminal capacitances and those given on data sheets are shown below. The C_{iss} can be specified in two ways:

1. Drain shorted to source and positive voltage at the gate.
2. Positive voltage of the drain in respect to source and zero volts at the gate.

In the latter case, the numbers are lower. However, neither method represents the actual operating conditions in RF applications.



DRAIN CHARACTERISTICS

One critical figure of merit for a FET is its static resistance in the full–on condition. This on–resistance, $R_{DS(on)}$, occurs in the linear region of the output characteristic and is specified at a specific gate–source voltage and drain current. The drain–source voltage under these conditions is termed $V_{DS(on)}$. For MOSFETs, $V_{DS(on)}$ has a positive temperature coefficient at high temperatures because it contributes to the power dissipation within the device.

GATE CHARACTERISTICS

The gate of the RF MOSFET is a polysilicon material, and is electrically isolated from the source by a layer of oxide. The input resistance is very high — on the order of $10^9\ \Omega$ — resulting in a leakage current of a few nanoamperes.

Gate control is achieved by applying a positive voltage to the gate greater than the gate–to–source threshold voltage, $V_{GS(th)}$.

Gate Voltage Rating — Never exceed the gate voltage rating. Exceeding the rated V_{GS} can result in permanent damage to the oxide layer in the gate region.

Gate Termination — The gates of these devices are essentially capacitors. Circuits that leave the gate open–circuited or floating should be avoided. These conditions can result in turn–on of the devices due to voltage build–up on the input capacitor due to leakage currents or pickup.

Gate Protection — These devices do not have an internal monolithic zener diode from gate–to–source. If gate protection is required, an external zener diode is recommended with appropriate RF decoupling.

Using a resistor to keep the gate–to–source impedance low also helps dampen transients and serves another important function. Voltage transients on the drain can be coupled to the gate through the parasitic gate–drain capacitance. If the gate–to–source impedance and the rate of voltage change on the drain are both high, then the signal coupled to the gate may be large enough to exceed the gate–threshold voltage and turn the device on.

DC BIAS

Since the MRF5003 is an enhancement mode FET, drain current flows only when the gate is at a higher potential than the source. See Figure 8 for a typical plot of drain current versus gate voltage. RF power FETs operate optimally with a quiescent drain current (I_{DQ}), whose value is application dependent. The MRF5003 was characterized at I_{DQ} = 50 mA, which is the suggested value of bias current for typical applications. For special applications such as linear amplification, I_{DQ} may have to be selected to optimize the critical parameters.

The gate is a dc open circuit and draws no current. Therefore, the gate bias circuit may generally be just a simple resistive divider network. Some special applications may require a more elaborate bias system.

GAIN CONTROL

Power output of the MRF5003 may be controlled from its rated value down to zero (negative gain) with a low power dc control signal, thus facilitating applications such as manual gain control, ALC/AGC and modulation systems. Figure 16 is an example of output power variation with gate–source bias voltage. This characteristic is very dependent on frequency and load line.

MOUNTING

The specified maximum thermal resistance of 14°C/W assumes a majority of the 0.100″ x 0.200″ source contact on the back side of the package is in good contact with an appropriate heat sink. In the test fixture shown in Figure 1, the device is clamped directly to a copper pedestal. In the demonstration amplifier, the device was mounted on top of the G10 circuit board and heat removal was accomplished through several solder filled plated through holes. As with all RF power devices, the goal of the thermal design should be to minimize the temperature at the back side of the package.

AMPLIFIER DESIGN

Impedance matching networks similar to those used with bipolar transistors are suitable for the MRF5003. For examples see Motorola Application Note AN721, "Impedance Matching Networks Applied to RF Power Transistors." Both small–signal S–parameters and large–signal impedances are provided. While the S–parameters will not produce an exact design solution for high power operation, they do yield a good first approximation. This is an additional advantage of RF power MOSFETs.

Since RF power MOSFETs are triode devices, they are not unilateral. This coupled with the very high gain of the MRF5003 yield a device capable of self oscillation. Stability may be achieved by techniques such as drain loading, input shunt resistive loading, or output to input feedback. Different stabilizing techniques were applied to the test fixture and demonstration amplifiers. The RF test fixture implements a parallel resistor and capacitor in series with the gate while the demonstration amplifier utilizes a 43 Ω shunt resistor from gate to ground. Both circuits have a load line selected for a higher efficiency, lower gain, and more stable operating region.

Two port stability analysis with the MRF5003 S–parameters provides a useful tool for selection of loading or feedback circuitry to assure stable operation. See Motorola Application Note AN215A, "RF Small–Signal Design Using Two–Port Parameters," for a discussion of two port network theory and stability.

2-3-7 GaAs MESFETs

Introduction. More than twenty years ago, for RF applications, the JFET was the dominant FET. As mentioned earlier, its major disadvantage is the fact that the f_T cutoff frequency, defined as

$$f_T = g_m / 2\pi C_{GS} \tag{2-262}$$

limits the operating range of this semiconductor device to 1 GHz at most. Also, the JFET's temperature sensitivity and loose tolerances in transconductance and other RF-related values made it difficult to use. Finally, no RFICs made use of this technology. While at the moment silicon-based MOS technology probably is the most cost-effective and is produced in the largest quantities, it does not rival the metal-semiconductor FET designed on GaAs technology. Figure 2-115 shows the structure of the silicon MOSFET, silicon JFET, and the GaAs MESFET.

Large-Signal Behavior of GaAs MESFETs. The mathematics for the large-signal behavior of the GaAsFET is basically quite similar to that for the JFET; however, the computations for JFET channel current, diode currents, and capacitance are much simpler than for the GaAsFET. Temperature effects are embedded in all the equations for all the transistors mentioned so far. In our opinion, the modified Materka model used by Ansoft and a large number of users is the most complete one; however, the following models are supported by most CAD tools:

- Chalmers (Angelov)
- Curtice–Ettenberg cubic
- Curtice quadratic
- IAF (Berroth)
- ITT PFET and TFET
- Modified Materka–Kacprzak
- Physics-based MESFET
- Raytheon (Statz)
- TriQuint (TOM-1, TOM-2, and TOM-3)
- With some restrictions, metal-insulator-semiconductor FETs (MISFETs), modulation-doped FETs (MODFETs), and high-electron-mobility transistors (HEMTs)

The main advantages of GaAsFET technology derive from the fact that it uses a metal-semiconductor junction with a barrier voltage of 0.8 V, its input capacitance is typically less than 0.2 pF, and the reverse feedback capacitance is less than 0.02 pF, or roughly 10% of the input capacitance. As a result of this, $f_{\max}$ is approximately five times higher than f_T. Table 2-16 shows a comparison of silicon BJT and GaAsFET technologies. While $f_{\max}$ for the bipolar transistor is

$$f_{\max} \simeq \sqrt{\frac{f_t}{8\pi r'_{bb} C_C}} \tag{2-263}$$

the $f_{\max}$ determination for the GaAsFET is given by

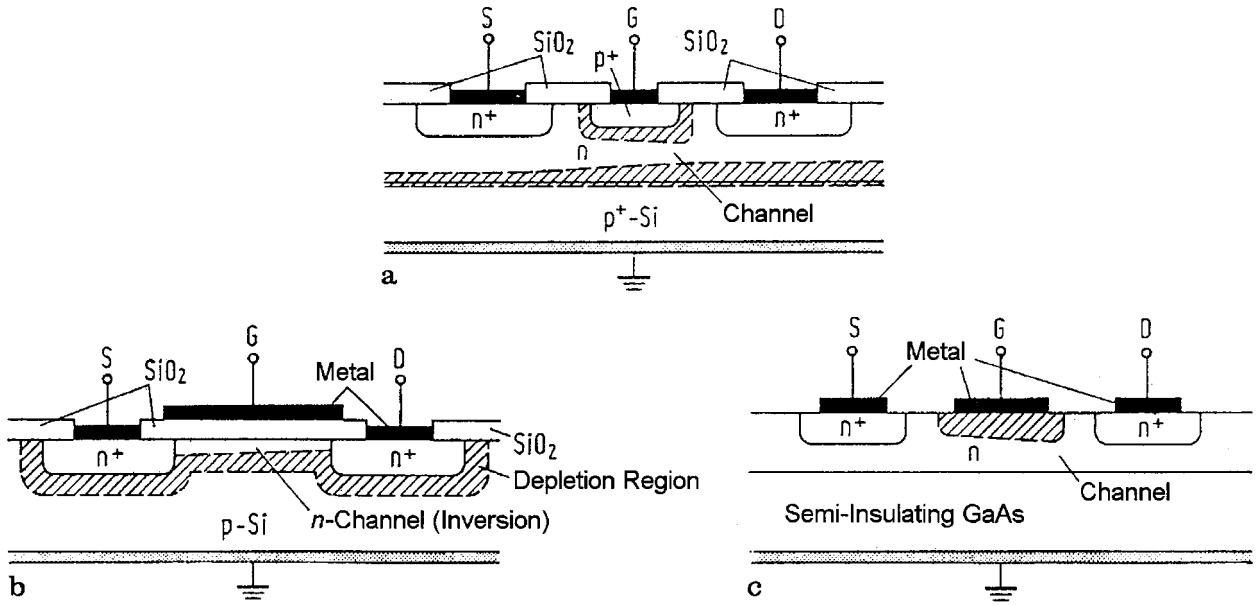

Figure 2-115 This picture is provided to differentiate between the structure of the three technologies. (a) The JFET and (b) the MOSFET are based on silicon; (c) the GaAsFET is based on semi-insulating GaAs. While the MOS transistor has silicon dioxide (SiO_2) as gate insulation, both the JFET and GaAs MESFET have a diode from gate to source, with a barrier voltage of 0.65 V for silicon and 0.8 V for GaAs.

Table 2-16 Comparison of Si BJT, SiGe HBT, and GaAsFET technologies

	Si Bipolar	SiGe HBT	GaAs FET
f_T	25 GHz	100 GHz	22 GHz
$f_{\max}$	40 GHz	200 GHz	110 GHz
Features	Low cost, low 1/*f* noise (5 kHz)	Low 1/*f* noise, very low distortion, high cost, IC only	Highest flexibility, lowest NF_0, well established

$$f_{\max} = \frac{f_T}{2}\sqrt{\frac{R_0}{R_i + R_s + R_g}} \tag{2-264}$$

As a sample calculation,

$$f_{\max}\ \frac{21.9\text{ GHz}}{2}\sqrt{\frac{450}{1 + 1.5 + 2}} = 110\text{ GHz} \tag{2-265}$$

The three major drawbacks of the GaAsFET are:

1. Much higher flicker corner frequency (somewhere between 10 and 100 MHz), probably due to a lack of surface passivation.
2. Much higher output conductance. This tends to load down any circuit connected to the drain. On the other hand, since the transconductance is quite high for even low currents, these devices have very high gains at low frequencies, which can make them quite unstable. In the saturated mode it is not uncommon to find a drain–source resistance of 100–500 Ω, while BJTs and JFETs offer values of several kilohms and higher.
3. Because of the very high flicker corner frequency (from 10 to 100 MHz), MESFETs are really not useful for low-noise mixers and oscillators, and unless there are no devices available in the frequency range above 30 GHz, they should be avoided for these applications.

As to the MESFET's construction and dc properties, Figure 2-116 shows a MESFET's cross section and dc *I*–*V* characteristics.

It was outlined in the beginning that while the GaAsFET is a close relative to the JFET and MOSFET, its actual behavior was found to be described best by a set of analytic equations. The first such model was the one by Curtice in the form of quadratic and cubic models, but it does not have enough derivatives to give enough insight into subtle things such as third- and higher-order intermodulation distortion and accurate harmonic generation. Other researchers have addressed various areas, but we still find that the Materka model has the best approximation, especially using the two-transistor approach outlined later [20, 21]. The large-signal topology for all FETs consists of an intrinsic model with some extrinsic parameters, further complicated by the package, as shown by Figures 2-117 and 2-118. Table 2-17 lists their keywords. The actual intrinsic model and its parameter definition depend on the particular model and since designs using GaAsFET will always be done using CAD tools, we will not go into any details of the equations but will list them. They are not dissimilar from the JFET and MOSFET equations.

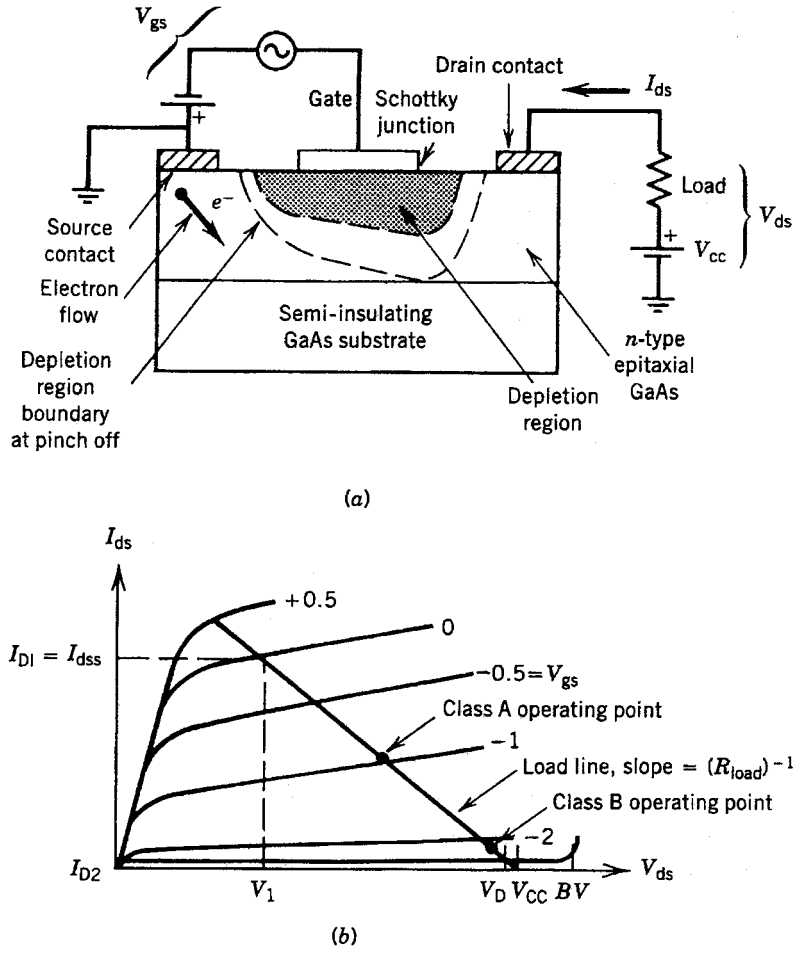

Figure 2-116 (a) Cross section and bias circuit and (b) dc *I–V* curve, including ac load line, for a MESFET.

The Modified Materka-Kacprzak Model Figure 2-119 shows the intrinsic model of the Materka FET. Table 2-18 lists its keywords.

Large-Signal Equations

Device Equations

V_{gsi} = Intrinsic gate–source voltage
V_{dsi} = Intrinsic drain–source voltage
V_1 = Voltage across C_{GS} and R_i
V_{gdi} = Intrinsic gate–drain voltage
$V_T = kT_J/q$ (thermal voltage)
k = Boltzmann's constant
q = Electron charge
T_J = Analysis temperature (kelvins)

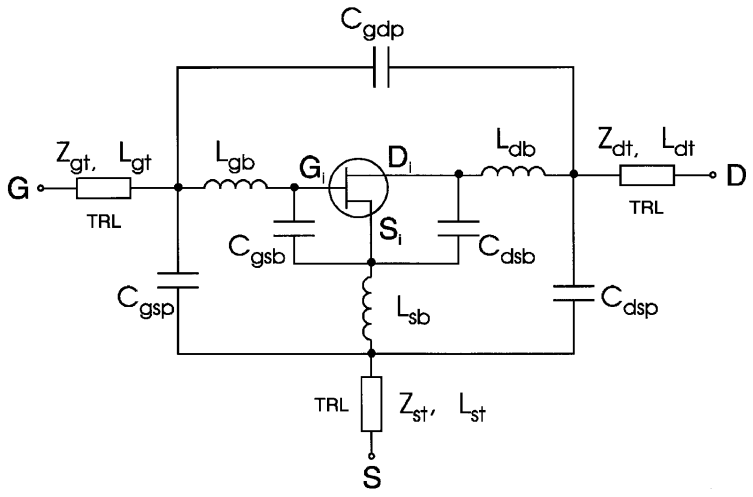

Figure 2-117 MESFET extrinsic model.

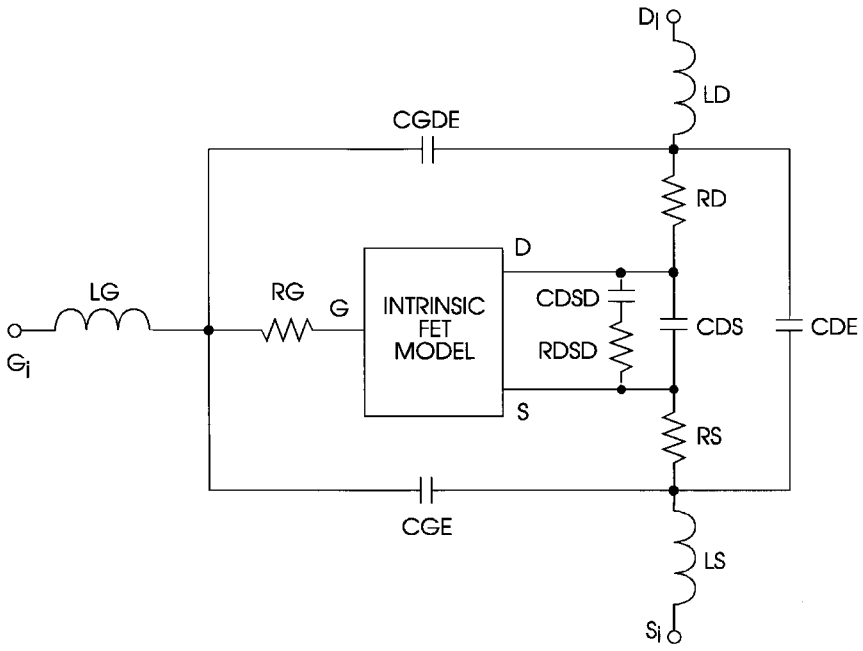

Figure 2-118 MESFET package model.

Table 2-17 Large-signal MESFET model keywords

Keyword	Description	Unit	Default
	Extrinsic Parameters		
RG	Gate bulk and ohmic resistance	ohm	0.0
RD	Drain bulk and ohmic resistance	ohm	0.0
RS	Source bulk and ohmic resistance	ohm	0.0
LG	Gate-lead inductance (metallization)	henry	0.0
LD	Drain-lead inductance (metallization)	henry	0.0
LS	Source-lead inductance (via)	henry	0.0
CDS	Drain–source capacitance	farad	0.0
CDSD	Low-frequency trapping capacitor	farad	0.0
RDSD	Channel trapping resistance	ohm	∞
CGE	Gate–source electrode capacitance	farad	0.0
CDE	Drain–source electrode capacitance	farad	0.0
CGDE	Gate–drain electrode capacitance	farad	0.0
LGB	Gate wirebond inductance	henry	0.0
LDB	Drain wirebond inductance	henry	0.0
LSB	Source wirebond inductance	henry	0.0
CGSB	Gate bondpad to source capacitance	farad	0.0
CDSB	Drain bondpad to source capacitance	farad	0.0
CGSP	Gate-to-source package capacitance	farad	0.0
CDSP	Drain-to-source package capacitance	farad	0.0
CGDP	Gate-to-drain package capacitance	farad	0.0
ZGT	Gate transmission line impedance	ohm	50
ZDT	Drain transmission line impedance	ohm	50
ZST	Source transmission line impedance	ohm	50
LGT	Gate transmission line length for $\varepsilon_r = 1$	meter	0.0
LDT	Drain transmission line length for $\varepsilon_r = 1$	meter	0.0
LST	Source transmission line length for $\varepsilon_r = 1$	meter	0.0

Channel Current

$$I_{ds} = \mathrm{IDSS}\left(1 + \mathrm{SS}\,\frac{V_{dsi}}{\mathrm{IDSS}}\right)\left(1 - \frac{V_{gsi}(t-T)}{\mathrm{VP0} + \mathrm{GAMA}V_{dsi}}\right)^{(\mathrm{E}+\mathrm{KE}V_{gsi}(t-T))}$$

$$\times \tanh\left(\frac{\mathrm{SL}V_{dsi}}{\mathrm{IDSS}(1 - \mathrm{KG}V_{gsi}(t-T))}\right)$$

Diode

$$I_{gd} = I_{gdc} - \begin{cases} \mathrm{IB0}\,\exp[-\mathrm{AFAB}(V_{gdi} + \mathrm{VBC})] \\ \dfrac{\mathrm{GMAX}}{4}\,\{\tanh[\mathrm{K1D}(V_{gsi} - \mathrm{K2D})] - 1\}\,[V_{gdi} + \mathrm{VBC} - \sqrt{(V_{gdi} + \mathrm{VBC})^2 + \mathrm{K3D}}] \end{cases}$$

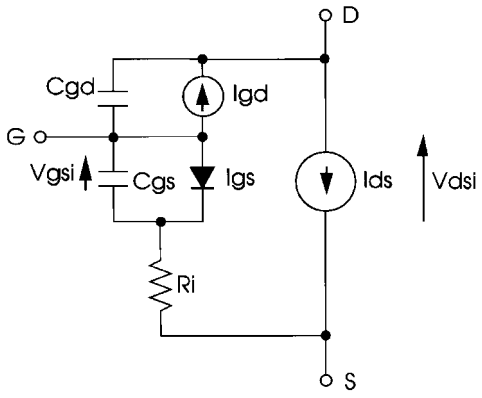

Figure 2-119 Intrinsic model of the modified Materka–Kacprzak MESFET.

where

$$I_{gdc} = \text{IG0}[\exp(\text{AFAB}V_{gdi}) - 1]$$

Channel Resistance

$$R_i = \begin{cases} \text{R10}(1 - \text{KR}V_{gsi}), & \text{KR}V_{gsi} < 1.0 \\ 0, & \text{KR}V_{gsi} \geq 1.0 \end{cases}$$

Capacitance Model

$$C_{gs} = \text{CGS0}\frac{F1F2}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F3$$

$$C_{gd} = \text{CGS0}\frac{F1F3}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F2$$

where

$$F1 = \frac{1}{2}\left(1 + \frac{V_{\text{eff}} - V_T}{\sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}}\right)$$

$$F2 = \frac{1}{2}\left(1 + \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

Table 2-18 Materka–Kacprzak MESFET model keywords

Keyword	Description	Unit	Default
	Area, Noise, and Name		
AREA	Area multiplier		1.0
KFN	Flicker noise coefficient (Materka model only)[a]		0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
	Channel Current Model		
IDSS	Drain saturation current for $V_{GS} = 0$	ampere	0.1
VP0	Pinchoff voltage for $V_{DS} = 0$	volt	–2.0
GAMA	Voltage slope parameter of pinchoff voltage	/volt	0.0
E	Constant part of power-law parameter		2.0
KE	Dependence of power law on V_{GS}	/volt	0.0
SL	Slope of the $V_{GS} = 0$ drain characteristic in the linear region	ampere/volt	0.15
KG	Drain dependence on V_{GS} in the linear region	/volt	0.0
SS	Slope of the drain characteristic in the saturated region	ampere/volt	0.0
T	Channel transit-time delay	second	0.0
IG0	Diode saturation current	ampere	0
AFAG	Slope factor of forward diode current	/volt	38.696
IB0	Breakdown saturation current	ampere	0
AFAB	Slope factor of breakdown current	/volt	0
VBC	Breakdown voltage	volt	∞
GMAX	Breakdown conductance	ampere/volt	0
K1D	Fitting parameter	/volt	0
K2D	Fitting parameter	volt	0
K3D	Fitting parameter	$volt^2$	0
R10	Intrinsic channel resistance for $V_{GS} = 0$	ohm	0.0
KR	Slope factor of intrinsic channel resistance	/volt	0.0
	Materka Capacitance Model		
C10	Gate–source Schottky barrier capacitance for $V_{GS} = 0$	farad	0.0
K1	Slope parameter of gate–source capacitance	/volt	1.25
MGS	Gate–source grading coefficient		0.5
C1S	Constant parasitic component of gate–source capacitance	farad	0.0
CF0	Gate–drain feedback capacitance for $V_{GD} = 0$	farad	0.0
KF	Slope parameter of gate–drain feedback capacitance	/volt	1.25
MGD	Gate–drain grading coefficient		0.5
FCC	Forward-bias depletion capacitance coefficient		0.8

[a]The flicker noise parameter of the Materka model is KFN so as not to conflict with the KF parameter in the capacitance model.

$$F3 = \frac{1}{2}\left(1 - \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

$$V_{\text{new}} = \begin{cases} A1, & A1 < \text{VMAX} \\ \text{VMAX}, & A1 \geq \text{VMAX} \end{cases}$$

$$A1 = \frac{1}{2}\left(V_{\text{eff}} + V_T + \sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}\right)$$

$$V_{\text{eff}} = \frac{1}{2}\left(V_{gsi} + V_{gdi} + \sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}\right)$$

$$V_T = \text{VP0} + \text{GAMA}\, V_{dsi}$$

$$\delta = 0.2$$

Some of the modifications to the Materka model have been done by Ansoft under various Department of Defense contracts, and by Raytheon and Texas Instruments under similar contracts, with Ansoft being a subcontractor.

The most relevant equation is really the channel current. Its derivatives are largely responsible for the accuracy of the intermodulation distortion, power-added efficiency, and, of course, its dc *I–V* curves.

Enhancement/Depletion FETs To make the designer's life more difficult, it turns out that there are two types of GaAsFETs:

1. *Depletion FETs (DFETs).* Most similar to the JFET; here V_G must be negative to control the device. They are the most commonly produced and are the FET type most referred to in this book.

On one hand:

- They require a negative gate voltage with respect to the source.
- Self-bias allows operation from a single supply voltage.

On the other hand:

- For low-voltage operation, a negative voltage generator may be required.
- Supply voltage must be doubled to accommodate full-swing operation.

2. *Enhancement FETs (EFETs).* Most similar to the MOSFET; here V_G must be positive to bring life to the device. Practically speaking, EFETs are used mostly in integrated circuits; they're typically not available in discrete, packaged form.

On one hand:

- They need only positive supply for biasing.
- They provide higher g_m/mA (for same device width)—5.1 mS versus 3.9 mS at 8 mA.

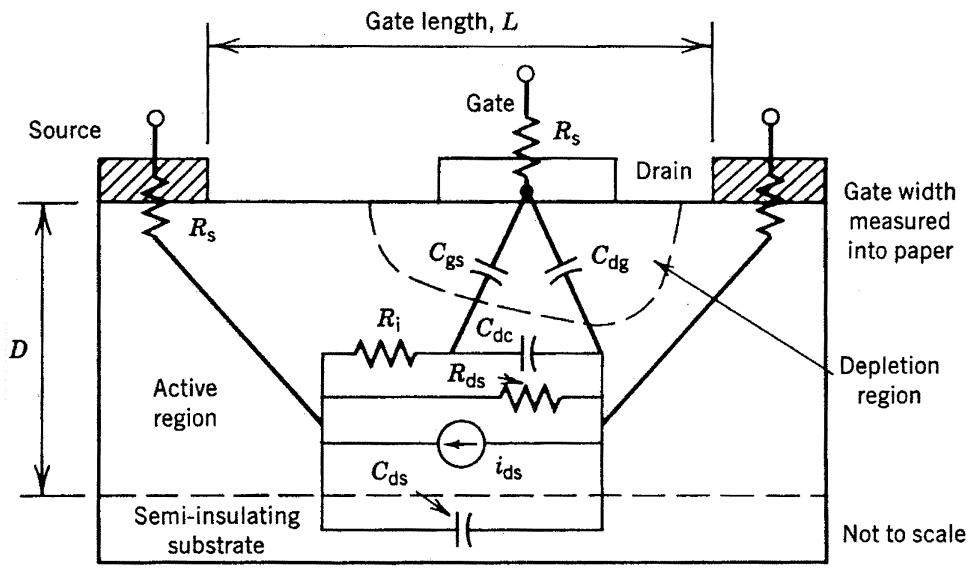

Figure 2-120 Location of lumped-element components for a MESFET.

- They are good for low-power LNAs, giving slightly better NF that DFETs, an NF of 1 dB at 1 GHz, and $I_{dd} < 10$ mA.

On the other hand:

- They have a very limited gate bias range (V_{GS} between 0.15 and 0.7 V).
- The gate conduction degrades NF and input impedance.
- The gate capacitance is higher than that of DFETs.
- The linearity is not as good as that of DFETs.

With today's technologies, all GaAs devices are *n*-channel; we have not seen any *p*-channels yet. More information about biasing will be given in the next chapter.

Figure 2-120 is a lumped-element, two-part equivalent circuit of a MESFET showing the location of lumped-element components.

2-3-8 Small-Signal GaAs MESFET Model

Figure 2-121 shows the applicable linear equivalent circuit for a MESFET and Table 2-19 lists its keywords. As with the MOS transistors, there is a gallium-arsenide dual-gate MOSFET available that is used mostly in special circuits, such as preamplifiers and mixers, whose IF has to be significantly higher than the flicker corner frequency, for example, higher than 200 MHz.

The following two datasheets* show typical GaAsFETs, both low-noise and medium-power. Such devices are, of course, available from a large variety of manufacturers—to name at least two, Siemens and the Nippon Electric Company, which is represented in the United States by California Eastern Laboratories.

2-4 PARAMETER EXTRACTION OF ACTIVE DEVICES

2-4-1 Introduction

We have already seen that all linear models that are used on the market are really derived from large-signal models, and it is our point that the quality of the model depends mostly on the quality of the parameters used to describe the model.

As far as modeling is concerned there are two options. The first option is a physics-based model, which can be applied to items such as diodes and bipolar transistors, including its most advanced versions, such as HBTs, SiGe versions, and other future derivatives. The bipolar transistor is essentially a combination of two diodes whereby the base–emitter junction generates the electrons or holes (depending on how the reader is accustomed to viewing the process) and then transfers those to the collector. The emitter, as its name states, emits the charged particles and the collector collects them, minus some current losses, which are expressed in the current gain of the device. A current gain (β) of 100 means that the collector receives 1% less than the emitter emits.

The second modeling option involves the construction of an analytical mathematic equivalent for the device modeled. Earlier in this chapter, we went through a detailed physics-based derivation about the inner workings of these devices, explaining how, for a given dc bias point, one can simplify them to a small-signal equivalent circuit. This is possible since we assume that the RF current and voltages are less than 1% of the dc equivalent currents and voltages. Reducing a device's complex nonlinear equivalent circuit to a quasistatic linear equivalent circuit allows its manufacturer to generate and publish sets of *S* parameters for it. These parameters are bias, voltage, and temperature dependent. At higher frequencies, parasitics play an enormous role in determining a device's RF performance.

A device operating at signal levels that are more than 1% of its dc equivalent currents and voltages must be evaluated in terms of large-signal performance. Most of the large-signal-equivalent circuits for nonbipolar devices, such as FETs (MOS, silicon JFETs, and members of the GaAsFET family), are analytic approximations that essentially bear no physical insight into the inner workings of the transistors. This fact is particularly painful because to look at high-order intermodulation distortion, one needs to have third and fourth derivatives of mathematically continuous equations. The SPICE approach cannot easily be translated into modern harmonic-balance simulators because such cop-outs as IF THEN ELSE statements in programming provide everything else but a continuous model. In the case of our own work, we used complicated curve-fitting equations to obtain analytic equations and their derivatives to accurately provide a large-signal model that is valid over a wide range of dc and RF.

2-4-2 Typical SPICE Parameters

Since we are about to evaluate bipolar microwave transistors, junction FETs, MOSFETs (model level 3), and GaAsFETs, Tables 2-20, 2-21, 2-22, and 2-23 list typical parameters for the devices we have used. These parameters can be obtained by the Scout program with the appropriate measurements. The BSIM model for MOSFETs, applicable for submicron technology transistors, requires an enormous level of parameter extraction and has not fully been validated for the LDMOS-type transistors currently favored for RF and microwave applications.

ITF = 0.00096893	PTF = 0	CJC = 9.3503E – 13
VJC = 1.1828	MJC = 0.30002	XCJC = 0.053563
TR = 1.0037E – 09	VJS = 0.75	MJS = 0
XTB = 0	EG = 1.11	XTI = 3
FCC = 0.72063	LB = 0.57E – 9	LC = 0.00E – 9
LE = 0.43E – 9	CBCP = 0.101E – 12	CCEP = 0.175E – 12
CBEP = 0.061E – 12	VCMX = 10 V	

The meaning and significance of the various parameters is best explored in a book on SPICE or semiconductor physics [22–24].

2-4-3 Noise Modeling

Diode Noise Model. The noise model for the diodes (Figure 2-122 and Table 2-24) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

The noise generators in the diode noise model are the series parasitic resistance, R_S, and the intrinsic junction. Figure 2-122 illustrates the intrinsic junction noise generator. Let Δf be the bandwidth (usually normalized to 1 Hz). The intrinsic noise generator has a mean-square value of

$$\langle i_{Dn}^2 \rangle = 2qI_D\,\Delta f + \mathrm{KF}\,\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\,\Delta f \tag{2-266}$$

Notes on the Diode Noise Model:

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.

[a]The currently implemented model for the junction FET is too primitive for serious RF applications. We have therefore taken the approach (liberty) of using the Materka parameter extraction approach for silicon junction FETs. This has resulted in unparalleled high-quality parameters; in particular, the knee voltage behavior has significantly improved, as well as the overall frequency response.

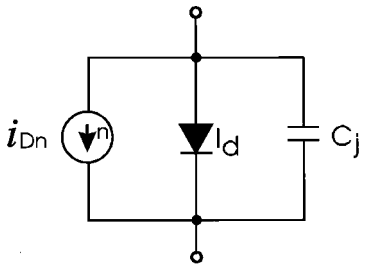

Figure 2-122 Equivalent noise circuit for a diode chip.

Table 2.24 Diode noise model keywords

Keyword	Description	Unit	Default
ID	Required bias current for the data point	Ampere	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner fequency	hertz	

2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.
3. The corner frequency noise model uses the system noise floor to internally compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the diode parameters and *kT*.
4. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

BJT Noise Model. The noise model for the Gummel–Poon BJT model consists of two contributions: shot noise and flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications) (see Table 2-25).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Bias-Independent Flicker Noise Coefficient*. This option involves the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying The Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with the bias point).

Notes on the BJT Noise Model:

Table 2.25 BJT noise model keywords

Keyword	Description	Unit	Default
IB	Required base bias current for the data point	ampere	
VCE	Required collector–emitter voltage for the data point	volt	
VBS	Base–substrate voltage required for LPNP type when four nodes are used	volt	
VCS	Collector–substrate voltage required for NPN or PNP type when four nodes are used	volt	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as bipolar noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model of course considers the actual operating temperature, which must be supplied to the model.

Figure 2-123 shows the BJT noise model. Let Δf be the bandwidth (usually normalized to a 1-Hz bandwidth). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{bn}^2 \rangle = 2qI_B \,\Delta f + \text{KF}\,\frac{I_B^{\text{AF}}}{f^{\text{FCP}}}\,\Delta f \tag{2-267}$$

$$\langle i_{cn}^2 \rangle = 2qI_C \Delta f \tag{2-268}$$

$$\langle i_{R_{bb}}^2 \rangle = \frac{4kT}{R_{bb}}\,\Delta f \tag{2-269}$$

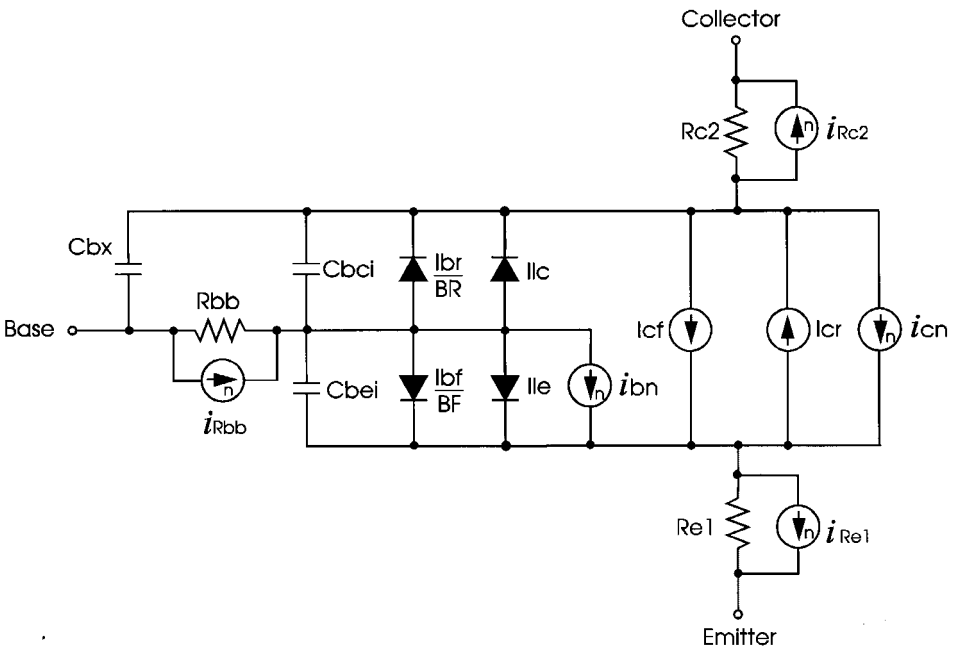

Figure 2-123 BJT noise model (not showing extrinsic parasitics). Current sources with *n* are noise sources.

$$\langle i_{R_{e1}}^2 \rangle = \frac{4kT}{R_{e1}} \Delta f \tag{2-270}$$

$$\langle i_{R_{c2}}^2 \rangle = \frac{4kT}{R_{c2}} \Delta f \tag{2-271}$$

$$I_B = \frac{I_{bf}}{BF} + I_{le} \tag{2-272}$$

$$I_C = I_{cf} - I_{cr} \tag{2-273}$$

JFET and MESFET Noise Models. The noise model for the FETs consists of two contributions: the shot noise and the flicker noise. There are two options to specify noise in the FET model:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (Table 2-26) to determine the flicker noise (this option is usually sufficient for most applications). The shot noise will be automatically computed using the SPICE equation.
2. Using bias-dependent flicker noise coefficients through a reference in the DATA block (specifying KF and AF at multiple bias points) and specifying the four noise parameters [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at multiple bias points.

Option 1: *Specifying the Enhanced SPICE Noise Model.* Option 1 is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model. The drain noise model has the form

$$\langle |I_{dn}|^2 \rangle = 4K_B T \frac{2g_m}{3} \Delta f + \text{KF} \frac{|I_D|^{\text{AF}}}{f^{\text{FCP}}} \Delta f \tag{2-274}$$

Table 2.26 FET noise model keywords

Keyword	Description	Unit	Default
FN	Noise data measurement frequency	hertz	1.0 GHz
VGS	Required gate–source voltage for the data point	volt	
VDS	Required drain–source voltage for the data point	volt	
FMIN	Required minimum noise figure in dB at FN		
MGO	Required magnitude of optimum noise reflection coefficient at FN		
PGO	Required phase of optimum noise reflection coefficient at FN		
RN	Required normalized noise resistance at FN		
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

where the shot noise is derived from g_m and the flicker noise is proportional to KF and the drain channel current, I_D, and inversely proportional to frequency. The AF and FCP parameters tailor the flicker noise dependence on bias and frequency, respectively.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows the specification of the complex bias-dependent nature of the shot noise and flicker noise. At high frequencies, the equivalent noise sources are correlated (the SPICE noise model does not account for this correlation). The complete evaluation of the shot noise sources can be determined from the four noise parameters. Since these are functions of bias, they can be specified over the (V_{GS}, V_{DS}) bias plane.

Additionally, a bias-dependent flicker noise coefficient (i.e., KF and AF vary with current) can be specified.

The MESFET noise model uses the four measured noise data [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at one frequency and multiple arbitrary bias points. The program uses these data and the FET model parameters to de-embed the noise data to an intrinsic noise model. The intrinsic model is accurate at all frequencies and, therefore, can predict the noise performance at all frequencies given data at just one frequency point. Built-in bias-dependent characteristics are used if multi-bias noise data are not provided.

Notes on the FET Noise Model

1. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
2. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Noise in a MESFET is produced by sources intrinsic to the device. The same approach, but with different flicker corner frequencies, is highly applicable to JFETs and MOSFETs. For more detail as to simulation, see the Element library book for the active-device portion of Ansoft's Serenade Design Environment product. The equivalent noisy circuit of an intrinsic FET is represented in Figure 2-124.

The intrinsic FET is internally represented as a noiseless nonlinear two-port with one equivalent noise current connected across the gate–source terminal, and one across the drain–source terminal. The correlations of the gate and drain noise current sources are

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \frac{\omega^2 C_{gs}^2}{g_m} R \tag{2-275}$$

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \, g_m P \tag{2-276}$$

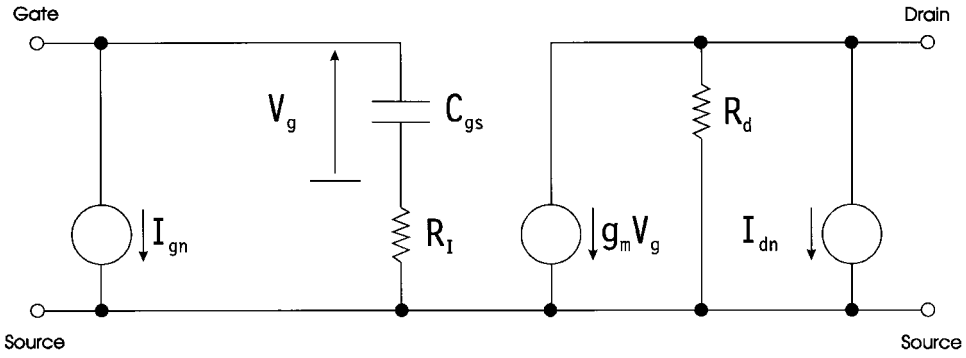

Figure 2-124 Equivalent noise circuit of an intrinsic FET device.

$$\langle I_{gn} I_{dn}^{*} \rangle = 4K_B T\, \Delta f\, j\omega C_{gs} \sqrt{PR}\, C \tag{2-277}$$

The correlation matrix of the noise current sources is

$$C_{dc}(\omega) = \frac{2}{\pi} K_B T\, d\omega \begin{bmatrix} \dfrac{\omega^2 C_{gs}^2}{g_m} R & -j\omega C_{gs}\sqrt{PR}\, C \\ j\omega C_{gs}\sqrt{PR}\, C & g_m P \end{bmatrix} \tag{2-278}$$

The gate and drain noise parameters R and P and the correlation coefficient C are related to the physical noise sources acting in the channel and are functions of the device structure and bias noise parameters. By defining measured noise parameters, $F_{\min}$, R_n, and Γ_{opt}, and using a noise de-embedding procedure, the parameters R, P, and C and the intrinsic noise correlation matrix of a FET device as functions of device bias are determined by the program.

In addition to the noise sources shown above, the flicker (1/f) noise can also be modeled by means of a noise current source connected in parallel with the intrinsic drain port. The flicker noise component in a narrow band, Δf, is expressed in the form

$$\langle |I_f|^2 \rangle = \mathrm{Q}\, \Delta f \frac{|I_D|^{\mathrm{AF}}}{f^{\mathrm{FCP}}} \tag{2-279}$$

where I_D is the instantaneous value of the channel current, and Q, AF, and FCP are empirical parameters. In most practical cases, AF and FCP are directly obtained from measurements (typically, AF = 2 and FCP = 1), while Q is not. In Ansoft's Serenade Design Environment, Q is either provided directly using KF or is computed by providing the flicker corner frequency (FC). FC is the frequency at which the flicker noise equals the shot/diffusion noise. The corner frequency is defined by the equation

$$\mathrm{Q} \frac{|I_D|^{\mathrm{AF}}}{f_{\mathrm{C}}^{\mathrm{FCP}}} = g_m P \tag{2-280}$$

Given the corner frequency FC and the measurement bias point V_{gs} and V_{ds}, the program automatically computes I_D, g_m, and P, and finally Q.

More information on FET noise modeling can be found in the literature [25–31].

MOSFET Noise Model. The MOSFET noise model (Figure 2-125 and Table 2-27) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. It can be turned off by specifying SN = 0. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).

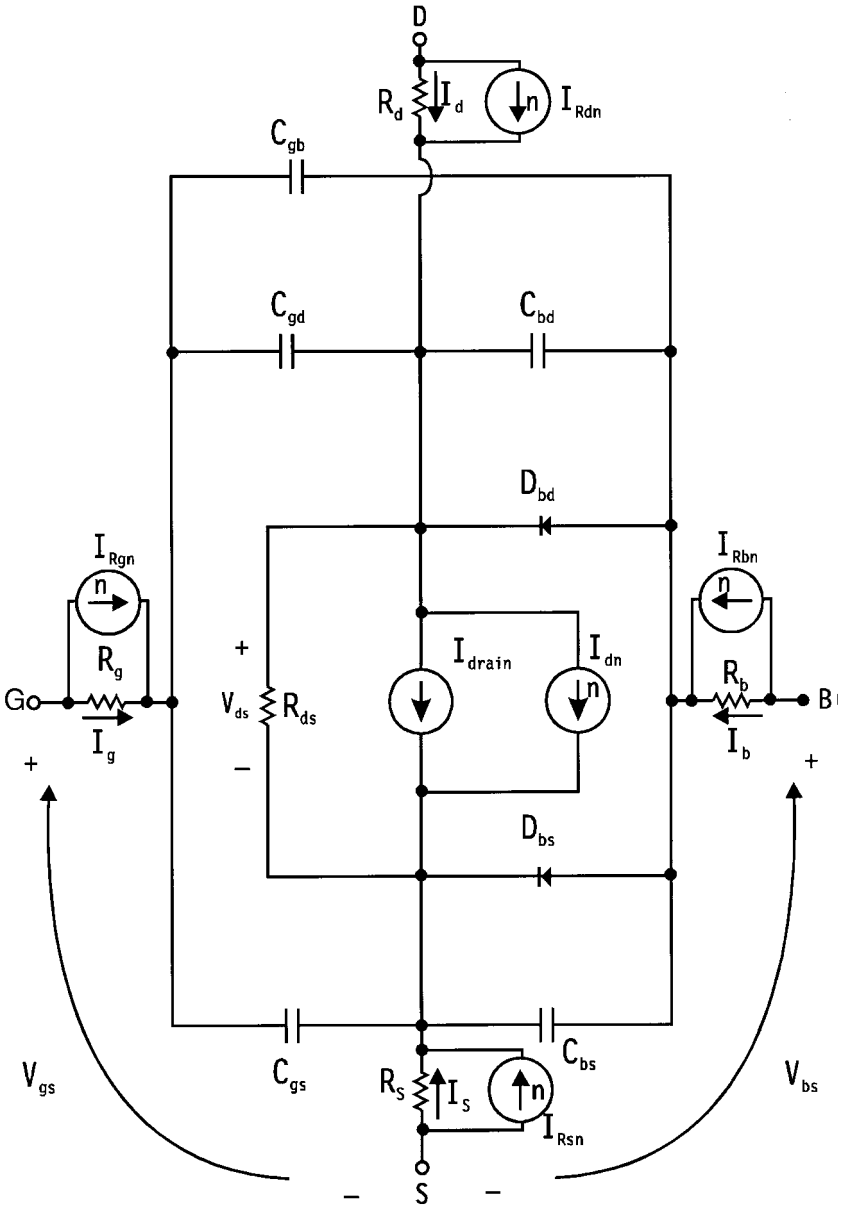

Figure 2-125 Equivalent noise circuit of an intrinsic MOSFET device.

Table 2.27 MOSFET noise model keywords

Keyword	Description	Unit	Default
VGS	Required gate–source bias for the data point	volt	
VDS	Required drain–source for the data point	volt	
VBS	Required drain–bulk for the data point	volt	
KF	Flicker noise coefficient		1.0E–13
AFT	Bias exponent of the flicker noise model		2.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

2. Using bias-dependent flicker noise coefficients through a reference (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Enhanced SPICE Noise Model.* This option is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model (the flicker noise is considered bias dependent).

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with drain current). The MOSFET noise model data are given and referenced by a model parameter.

Notes on the MOSFET Noise Model

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as MOSFET noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Let Δf be the bandwidth (normalized to 1 Hz). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{dn}^2 \rangle = \frac{8kTg_m}{3}\Delta f + \mathrm{KF}\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\Delta f$$

$$\langle i_{Rgn}^2 \rangle = 4\frac{kT}{R_g}\Delta f$$

$$\langle i_{Rdn}^2 \rangle = 4\frac{kT}{R_d}\Delta f$$

$$\langle i_{Rsn}^2 \rangle = 4\frac{kT}{R_s}\Delta f$$

$$\langle i_{Rbn}^2 \rangle = 4\frac{kT}{R_b}\Delta f$$

We include this MOSFET noise model (used for quite awhile) for completeness. At the moment, we do not know which MOSFET noise model the industry will settle on in the future.

Modern CAD tools, such as Ansoft's Serenade product, use these models to generate quite accurate noise data based on a good linear equivalent model. Internally Serenade uses the noise-correlation-matrix method (first introduced by Russer). The same noise-correlation techniques apply to BJTs, all FETs except MOS, and HBTs (such as SiGe devices).

2-4-4 Scalable Device Models

Since diodes and transistors are scalable, here are guidelines for how to scale them:

Microwave Diode

$$I_D = Area \times I_D$$
$$C_j = Area \times C_j$$
$$R_D = R_D/\text{Area}$$

PIN Diode

$$I_D = \text{Area} \times I_D$$
$$C_j = \text{Area} \times C_j$$
$$R_S = R_S/\text{Area}$$
$$R_{\max} = R_{\max}/\text{Area}$$

Bipolar

$$I_{bf} = \text{Area} \times I_{bf} \qquad I_{br} = \text{Area} \times I_{br}$$
$$I_{le} = \text{Area} \times I_{le} \qquad I_{lc} = \text{Area} \times I_{lc}$$
$$I_{cf} = \text{Area} \times I_{cf} \qquad I_{cr} = \text{Area} \times I_{cr}$$
$$C_{bc} = \text{Area} \times C_{bc} \qquad C_{be} = \text{Area} \times C_{be}$$
$$C_{bx} = \text{Area} \times C_{bx} \qquad R_{bb} = R_{bb}/\text{Area}$$
$$\text{RB2} = \text{RB2/Area} \qquad \text{RC2} = \text{RC2/Area}$$
$$\text{RE1} = \text{RE1/Area} \qquad I_{jss} = I_{jss} \times \text{Area}$$
$$C_{jss} = C_{jss} \times \text{Area}$$

Materka FET

$$\begin{aligned}
\text{IGSS} &= \text{IGSS} \times \text{Area} \\
\text{CGS0} &= \text{CGS0} \times \text{Area} \\
\text{CGS1} &= \text{CGS1} \times \text{Area} \\
\text{CDVC} &= \text{CDVC} \times \text{Area} \\
\text{CDVS} &= \text{CDVS} \times \text{Area} \\
R_G &= R_G \times \text{Area}/(\text{Number of fingers} \times 2) \\
R_D &= R_D/\text{Area} \\
R_S &= R_S/\text{Area}
\end{aligned}$$

Generating a Databank for Parameter Extraction. Given the fact that one can measure with an automated system (Rohde & Schwarz, Hewlett-Packard) the bias-dependent *S* parameters of any active device, bipolar and FET, and furthermore, that Hewlett-Packard makes a computer-controllable dc *I–V* curve tracer, we can generate a huge databank that allows us to have corresponding values for both RF and dc operating points. To validate this, one needs to run a large-signal simulator, such as Ansoft's Serenade Design Environment, or its equivalent from other manufacturers, enter the large-signal parameters, and generate a set of *S*-parameters that correspond to the dc values for which we have measurements. The agreement between measured and predicted points for both RF and dc values is a good measure to evaluate the accuracy of the parameter extraction and the simulator's performance. We cannot stress often enough, however, the fact that while most simulator models are quite good, the weakest point of the link is the parameter extraction program.

Currently, the best parameter extraction for bipolar transistors and FETs, excluding the BSIM model, is implemented in the Scout program by Ansoft, based on modified techniques found in the literature. These techniques are based on the fact that present-day nonlinear modeling of microwave devices, especially FETs, is not exactly adequate to describe all effects found within these devices. In the case of FETs, the most troublesome parameter is R_{DS}, which is really more bias dependent than practically all existing models take into consideration. Techniques used in published extraction methods extract nonlinear models independently for each section of a device model, and then assume that the proper response will be generated when all parts are put together. For instance, many extraction techniques independently fit the *I–V* data of the section describing the *I–V* curves and then fit the *C–V* data to the equivalent small-signal models. This results in an approximation to the bias-dependent response of the complete model.

In the technique used in the Scout program, model parameters are extracted simultaneously so the effects between model sections are accounted for and the device is treated as a whole. The most critical area happens to be in the linear region, typically around the pinchoff area, and for very small supply voltages. The Scout techniques use measured data taken at a wide variety of bias ranges and frequencies to define the model response. The possible solution region for the complete model becomes well identified and uniqueness of solution is vastly improved. The Scout program is interactive in nature and displays simultaneously measured versus predicted data. This allows for fine-tuning of the parameters.

Over the years, the industry has adapted a large number of models. Those supported by the Scout parameter extraction program include:

- *npn* Gummel–Poon BJT
- *pnp* Gummel–Poon BJT

- *npn* heterojunction BJT
- *pnp* heterojunction BJT
- General-purpose *n*-channel JFET
- General-purpose *p*-channel JFET
- Chalmers (Angelov) MESFET/HEMT
- Curtice–Ettenberg cubic MESFET/HEMT
- Curtice quadratic MESFET/HEMT
- IAF (Berroth) MESFET/HEMT
- Modified Materka–Kacprzak MESFET/HEMT
- Raytheon (Statz) MESFET/HEMT
- TriQuint (TOM-1 and TOM-2) MESFET/HEMT
- Ansoft physics-based MESFET

The Ansoft physics-based MESFET model is unique and politically sensitive because its users are essentially required to enter all device fabrication parameters to get the appropriate answer, and most, if not all, companies will stay away from handing out such company proprietary recipes. The validation of this model was done using manufacturing data for transistors that were developed under government contract and therefore accessible for the team members. Compact Software/Ansoft over the last ten years has been involved in a large number of government-funded research and development programs, and practically all modern modeling implementations and their validation were done in conjunction with the largest semiconductor manufacturers.

As far as further validation is concerned, besides our looking at the matching of dc *I–V* curves and *S* parameters, important parameters such as 1-dB compression point, power-added efficiency, and harmonic content are important criteria to evaluate the quality of such an undertaking. As far as hardware is concerned, one needs to have a network analyzer, such as the HP8510 or its equivalent. Its selection is determined by the highest cutoff frequency where measurements are necessary. A dc feed capability, up to several amperes, through the measuring ports, and appropriate power supplies are essential, as is a dc *I–V* curve tracer (HP4145). The built-in various optimizers of the program establish the best possible match between the selected parameters and the measured results.

The area of proper modeling has always been fascinating because the active-device model can make or break first-pass success. Figure 2-126 shows the doubler gain comparison of a model supplied by NEC (the device manufacturer, parameter extraction done with Scout, and parameter extraction supplied from the *Microwave Engineering Europe* (*MEE*) magazine in its CAD review of May 1994). It is somewhat unclear where the *MEE* model came from. The actual task given by *MEE* was to simulate a frequency doubler against measured data. This type of simulation required two areas of high precision, one being the model and the other being the electromagnetic modeling of the discontinuities of the circuit—in this case, a stub element. The circuit itself was very simple. The manufacturer-supplied data gave the poorest results (we believe the parameter extraction came from a third party not quite up to speed in this area). The results that came from the Scout parameter extraction and the third one that *MEE* supplied were fairly close, yet the Scout solution, including the electromagnetic simulation part, gave the best answer. More simulators have since appeared on the market, and it would be interesting to revisit this topic. Figure 2-127 shows a physical layout of the doubler circuit.

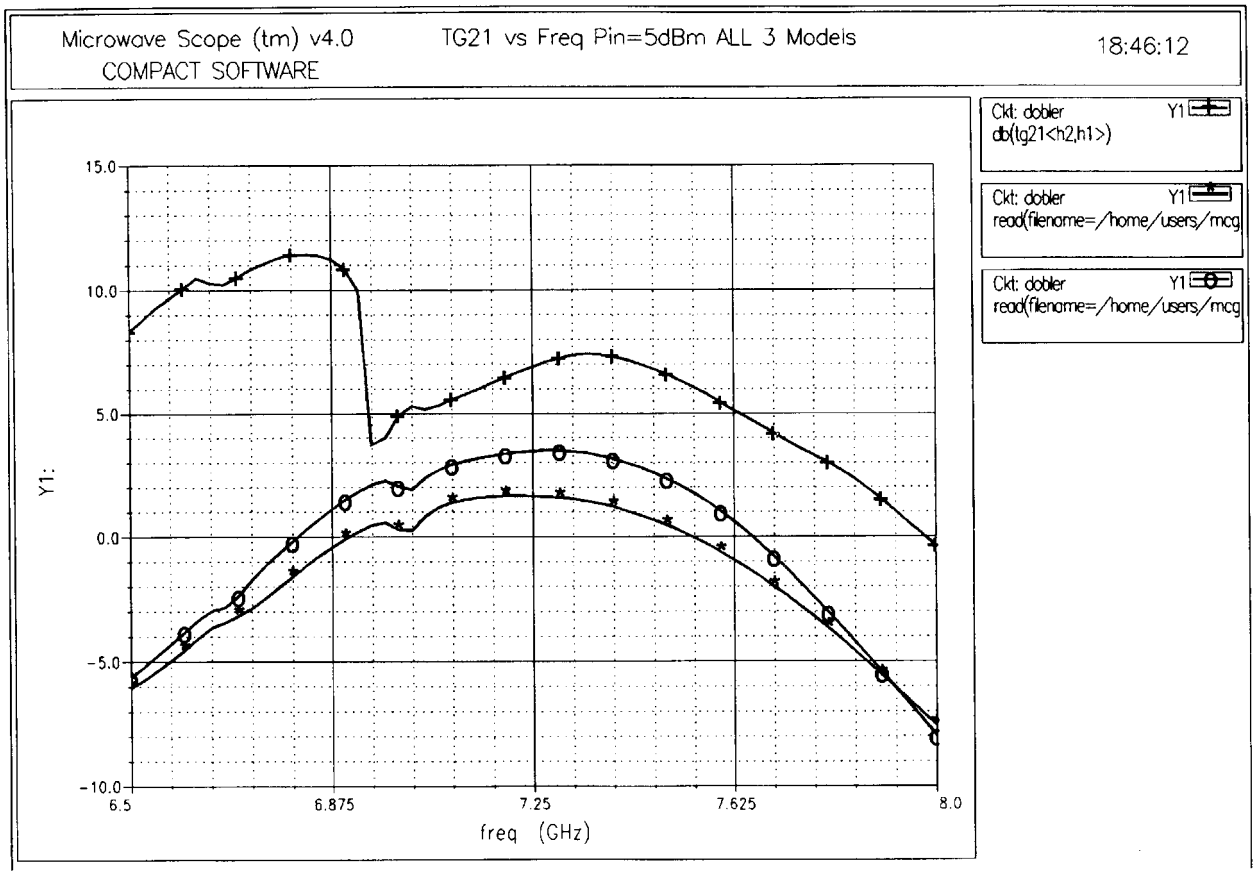

Figure 2-126 Gain comparison of a MESFET doubler based on the three device models used: NEC (+), Ansoft (O), and *Microwave Engineering Europe* (*).

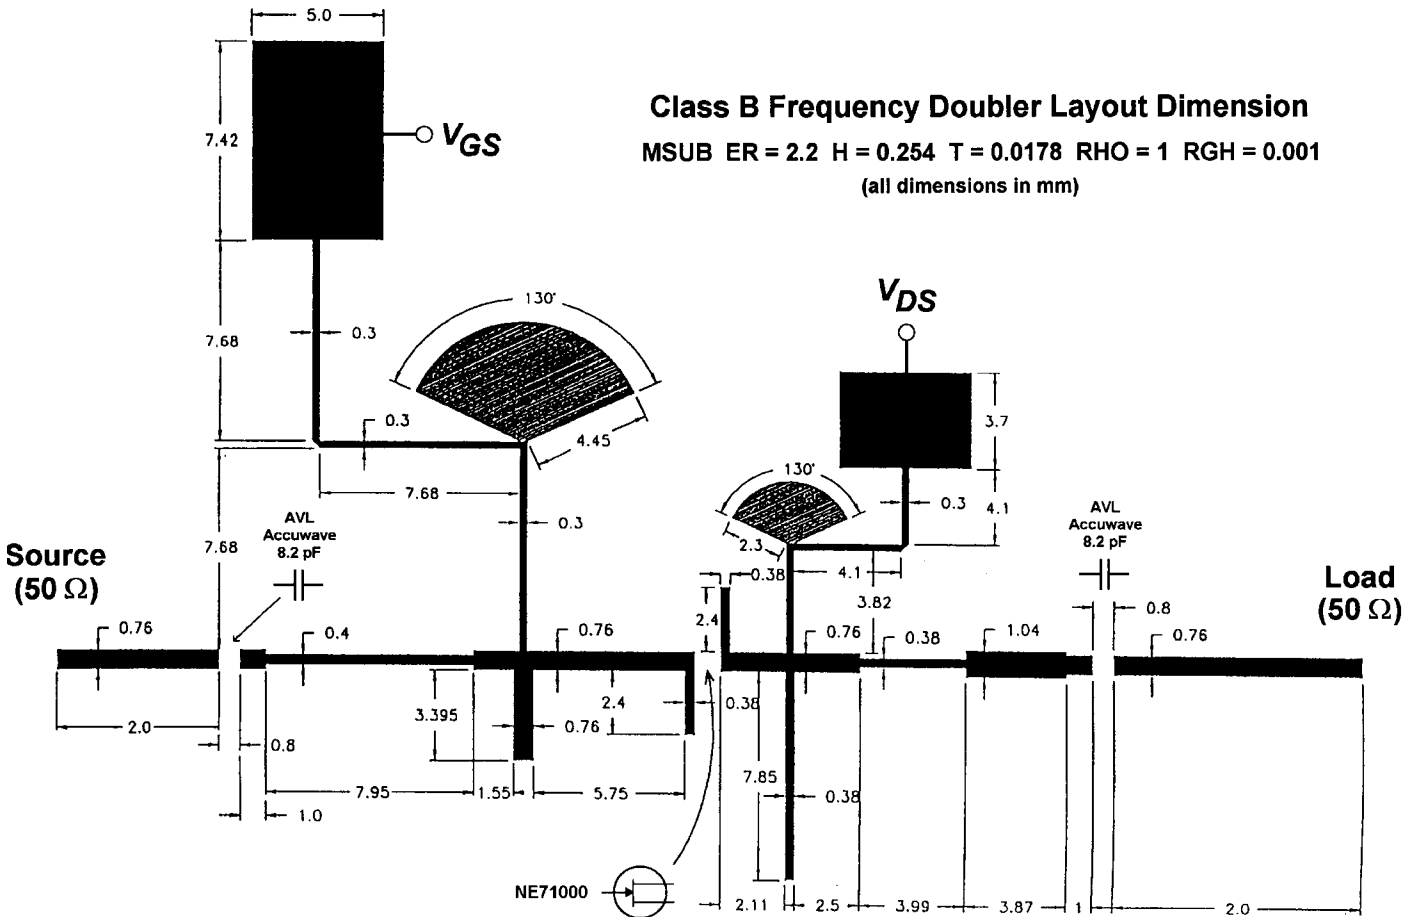

Figure 2-127 Layout of the MESFET doubler.

Test Setup. The measuring equipment required for the actual extraction includes:

- Semiconductor parameter analyzer (HP4145)
- Vector network analyzer (ZVR, HP8510, W360)
- Bias supplies and meters
- Power RF source, power meters, spectrum analyzer, and so on

The required software tools include:

- GPIB controller: Compact NETCOM (network analyzer control program)
- Parameter extraction performed by Scout
- Small-signal and harmonic-balance validation: Serenade nonlinear analysis (Microwave Harmonica) or its equivalent

After we have assembled all these tools, the device extraction process can begin. It will follow the flow as shown in Figure 2-128. Depending on the numbers for the dc/ac measurement, this process can take up to two hours. The Scout program, with its built-in optimizer, can take another two hours. It is therefore reasonable to assume a thorough parameter extraction of a device will take about one day.

Parameter Extraction. As we have outlined, the parameter extraction program Scout, which is optimized for high-frequency and millimeter-wave application, is a Windows-based parameter extraction and optimization program. It requires a network-communication program to acquire dc and *S* parameter measurement data. It supports interactive device fitting and optimization and supports the various models listed earlier. For ease of use, it has an attractive graphical user interface with multiple windows, as can be seen from Figure 2-129. Hewlett-Packard offers more general RF parameter extraction programs, but we did not have access to those. We also expect that some other companies will develop similar tools. An interesting program named HarPE, developed by Professor John Bandler in Canada, may have been withdrawn from the market after his company merger with HP. The program was acclaimed to provide quite good results using measured harmonics. One of the unfortunate deficiencies of most BJT parameter extraction programs known to us is the fact that (as one

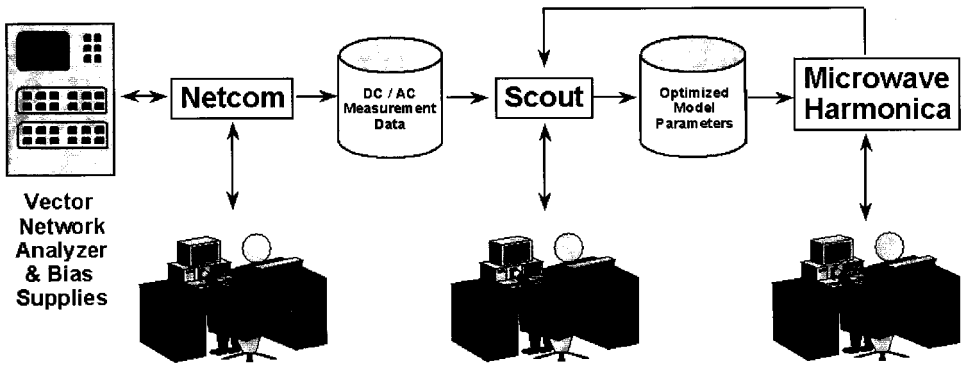

Figure 2-128 Flowchart of the parameter extraction process.

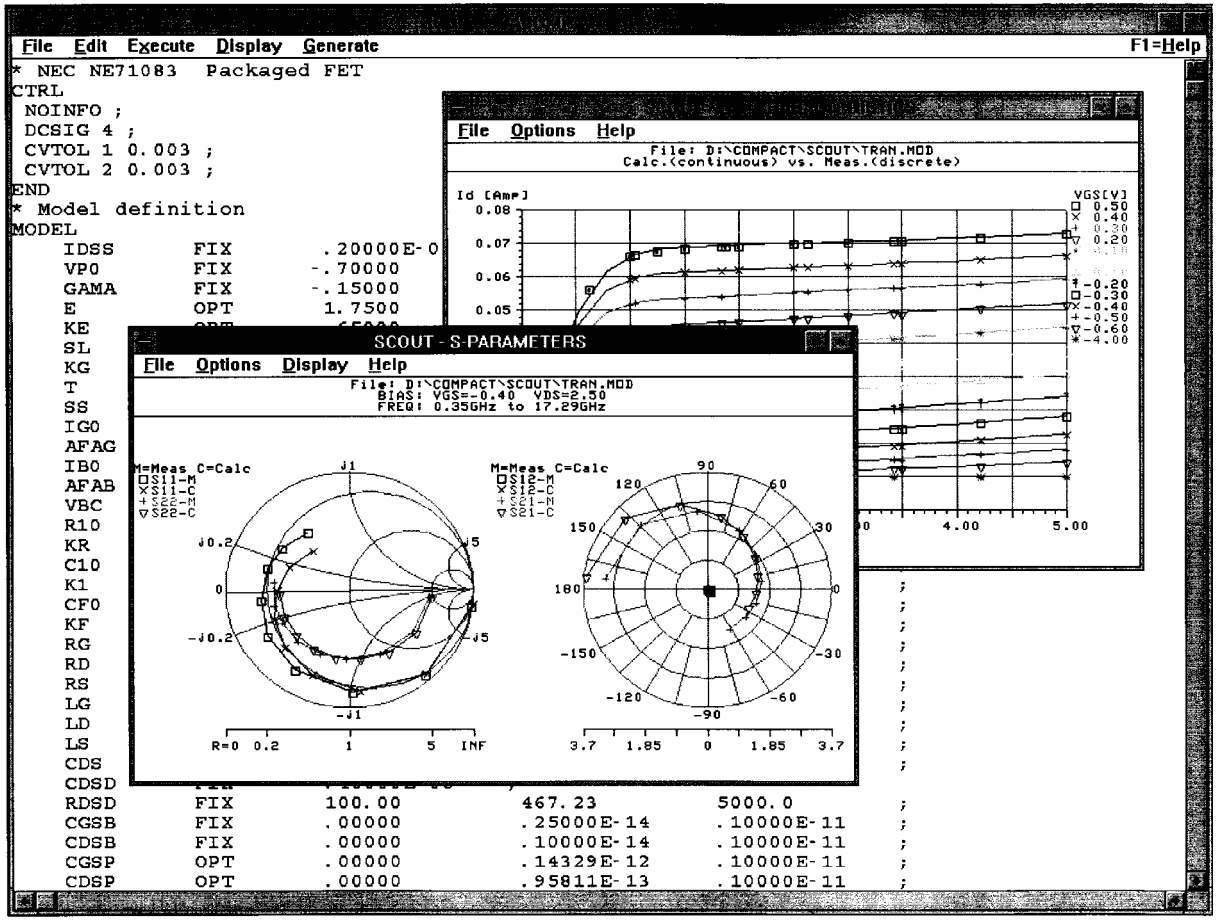

Figure 2-129 The Scout user interface.

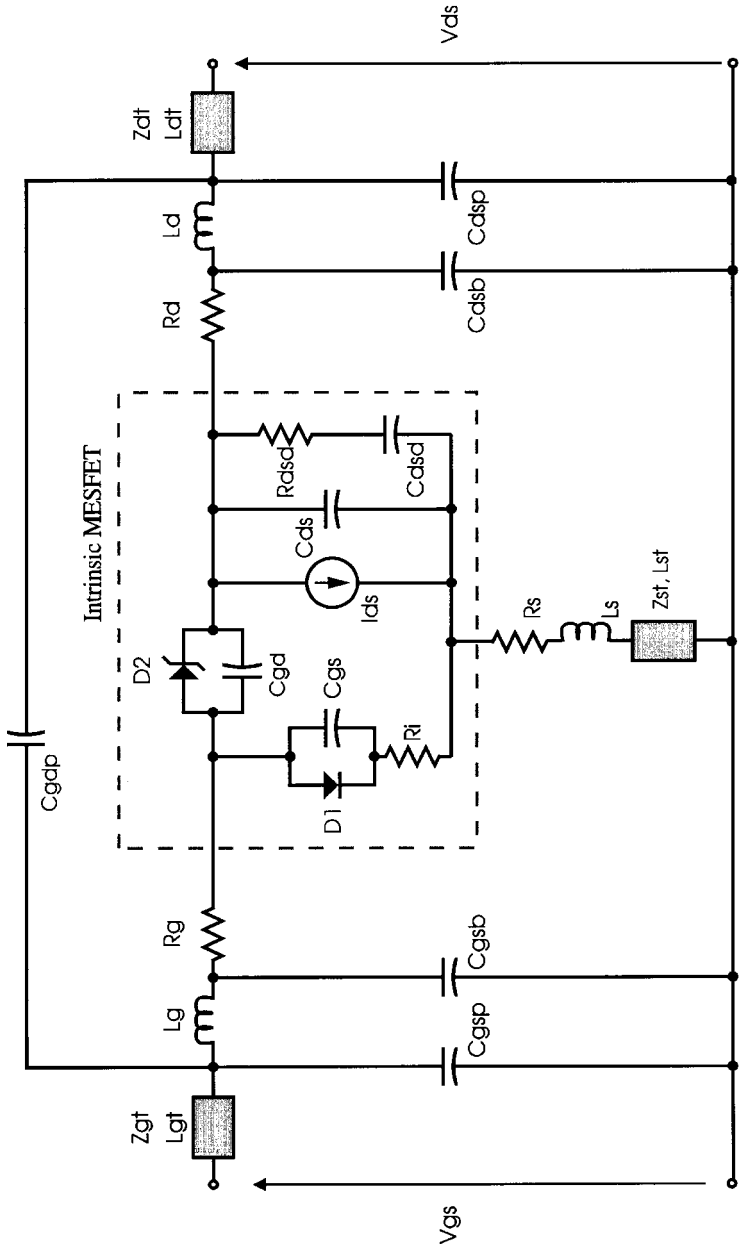

Figure 2-130 Intrinsic model and complete chip/package model.

example) the sensitivity to determine the actual base-spreading resistor for bipolar transistors is poor. The only useful workaround is considering the noise figure of the device, given the fact that the midrange noise factor of any bipolar transistor can be calculated from

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-281)

By solving the equation for R'_{bb}, since we know that R_g, the generator impedance, is 50 Ω, and the emitter diffusion resistance (26 mV/I_C) can be determined from the bias point, we can already eliminate the need to extract R'_{bb} from the HP test equipment. By using HP's program, errors of a factor up to 10 are not uncommon because of the low sensitivity for this parameter. Another headache in the case of the BJT is the determination of the excess phase (PTF) and forward and reverse transit time (TF and TR, respectively). The lack of quality modeling can best be found by examining the measured versus predicted values of S_{22}. Again, practically all the parameter extraction programs we have seen so far suffer from this deficiency.

MESFETs. In the case of a member of the MESFET family, a model as shown in Figure 2-130 is used. It consists of an intrinsic model and a complete chip/package parasitic model. In the case of the MESFET, to obtain first-class results, the following measurements are necessary:

- Dc *I*–*V* measurements
- Dc diode measurements
- Cold-FET and forward-biased-gate *S* parameters
- *S*-parameter measurements over bias
- Harmonic power measurements
- *Z*-Parameter Equations for Figure 2-131

In order to simplify the modeling, it is useful to do cold-FET [Figure 2-131 and Eqs. (2-282), (2-283), and (2-284)] and pinched-FET [Figure 2-132 and Eqs. (2-285), (2-286), and (2-287)] measurements to derive some of the intrinsic or extrinsic values.

$$Z_{11} = R_s + R_g + R_{gs} + \alpha_g R_{ch} + j\omega(L_g + L_s) \tag{2-282}$$

$$Z_{12} = Z_{21} = R_s + \alpha R_{ch} + j\omega L_s \tag{2-283}$$

$$Z_{22} = R_s + R_d + 2\alpha R_{ch} + j\omega(L_s + L_d) \tag{2-284}$$

Capacitance Equations for Figure 2-132

$$C_b = -\frac{\text{Im}(Y_{12})}{\omega} \tag{2-285}$$

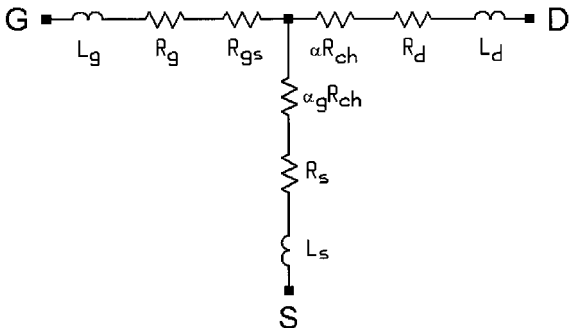

Figure 2-131 Forward-biased gate FET model for cold-FET (V_{DS} = 0, V_{GS} 0) measurements. This approach allows direct extraction of parasitic resistances and inductances.

$$C_{pg} = \frac{\mathrm{Im}(Y_{11})}{\omega} - 2C_b \tag{2-286}$$

$$C_{pd} + C_{ds} = \frac{\mathrm{Im}(Y_{22})}{\omega} - C_b \tag{2-287}$$

For the highest accuracy, the following extraction strategies are recommended:

- Pre-extraction using basic dc and *S* parameters—for example, C_{GS} from S_{11}
- Six extraction steps to determine parameters:
  Basic dc model
  Advanced dc model
  Basic ac model
  Advanced ac model
  Package determination
  Diode characterization
- Large-signal validation
  Power compression and bias shift
  Harmonic power comparison
  Intermodulation characterization

As an example, we are going to use the popular and well-characterized NE71000, which is not a particularly modern device, but has been used for various research projects. Figure

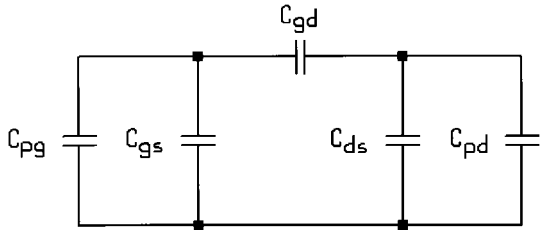

Figure 2-132 Pinched-FET (V_{DS} = 0, V_{GS} *VP*) model. This approach allows direct extraction of parasitic gate and drain capacitances.

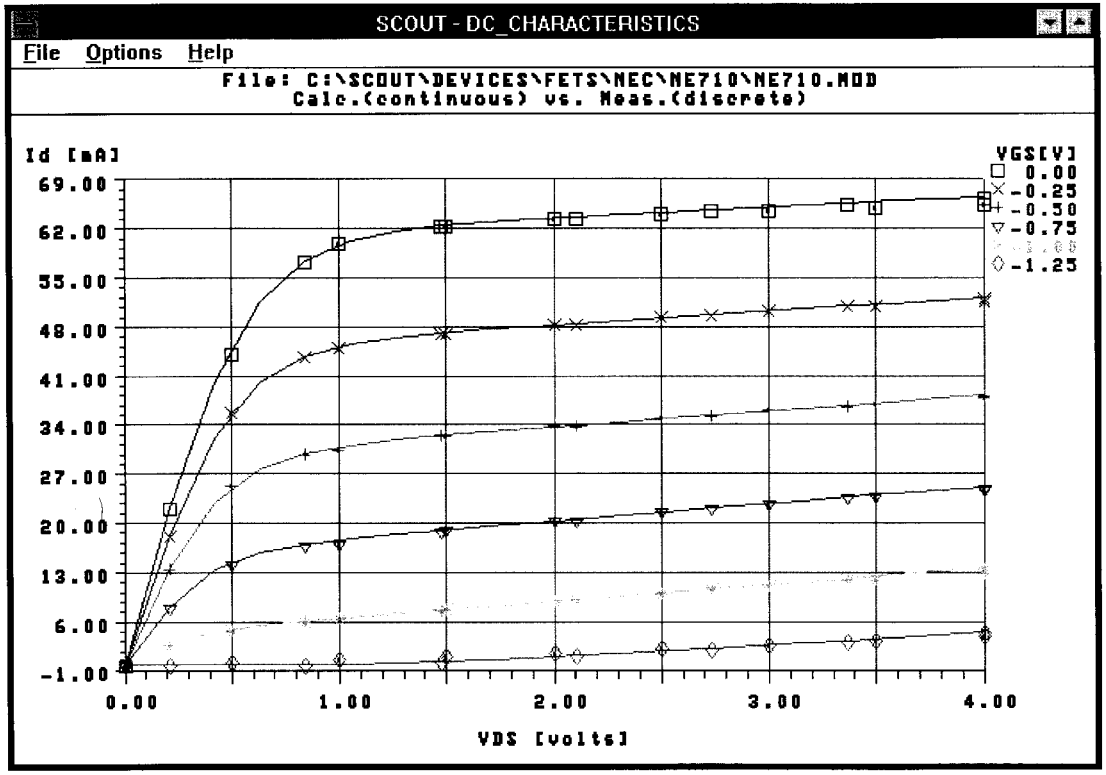

Figure 2-133 Measured NE71000 dc *I–V* curves versus those simulated using the Ansoft Materka model.

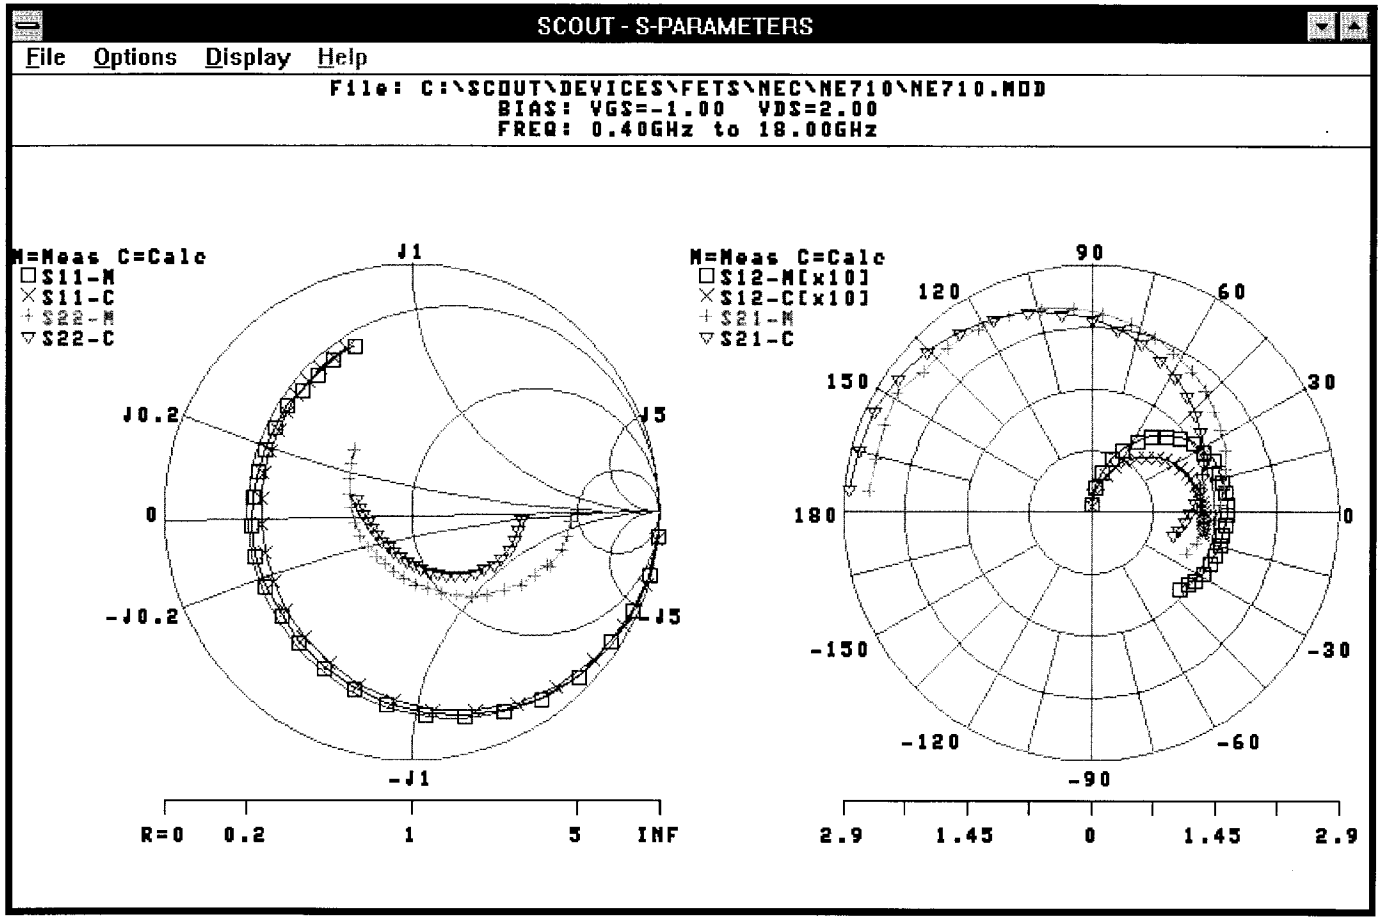

Figure 2-134 Measured versus calculated NE71000 *S* parameters for $V_{GS} = -1.00$ and $V_{DS} = 2.00$.

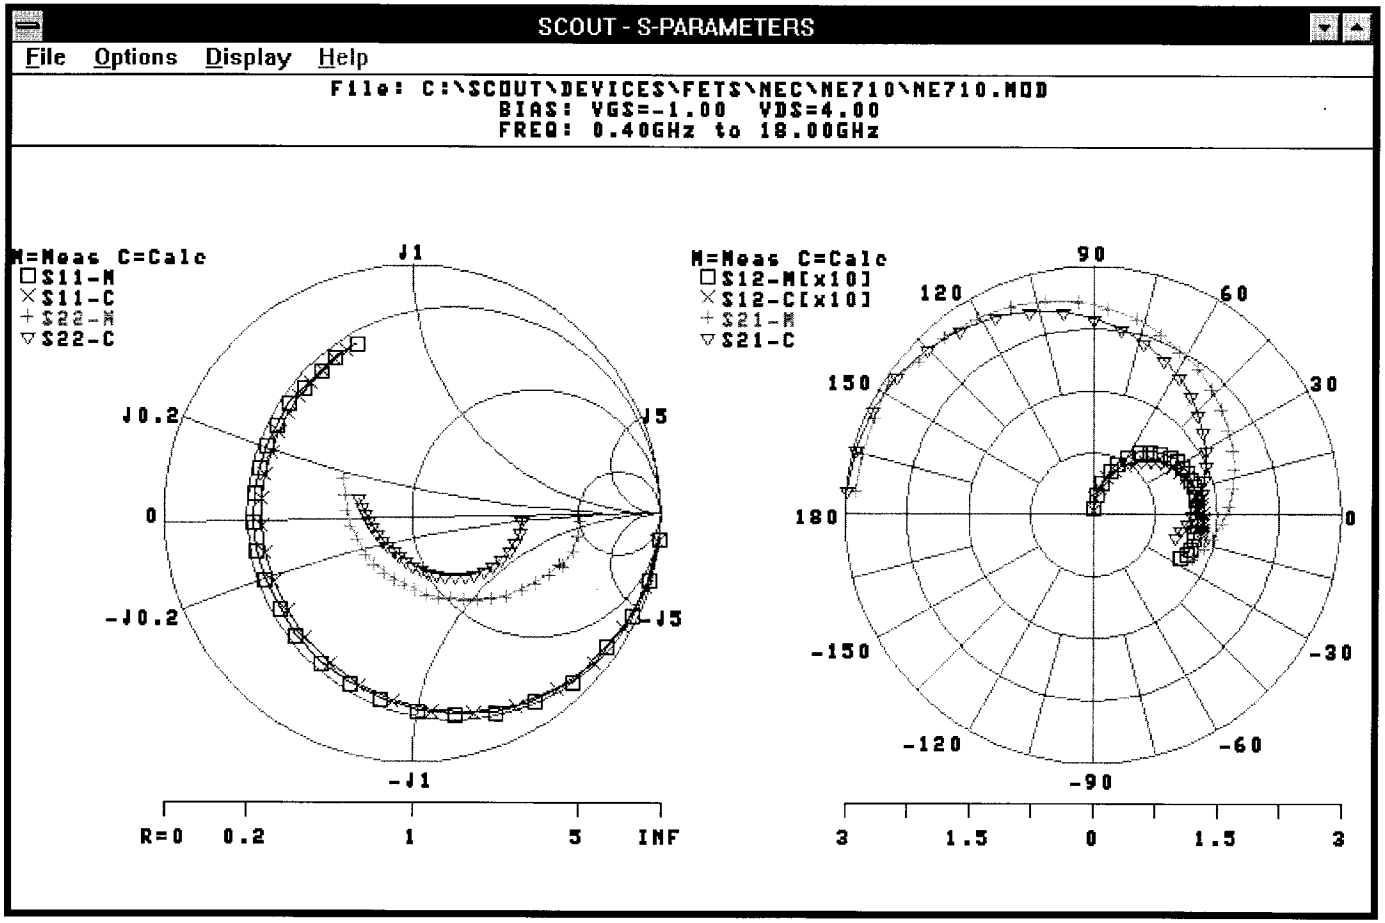

Figure 2-135 Measured versus calculated NE71000 *S* parameters for V_{GS} = –1.00 and V_{DS} = 4.00.

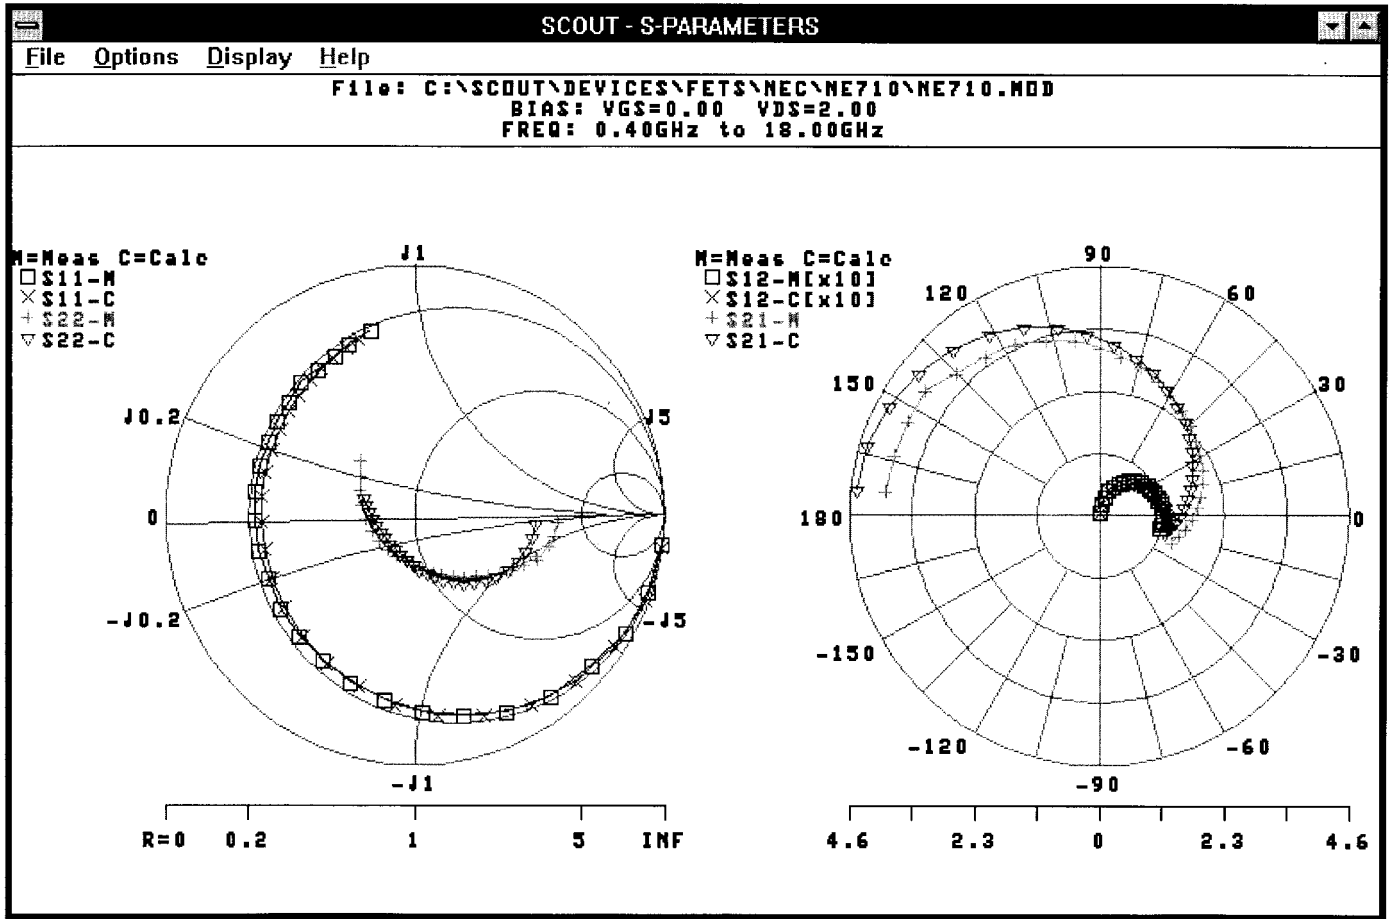

Figure 2-136 Measured versus calculated NE71000 *S* parameters for V_{GS} = 0.00 and V_{DS} = 2.00.

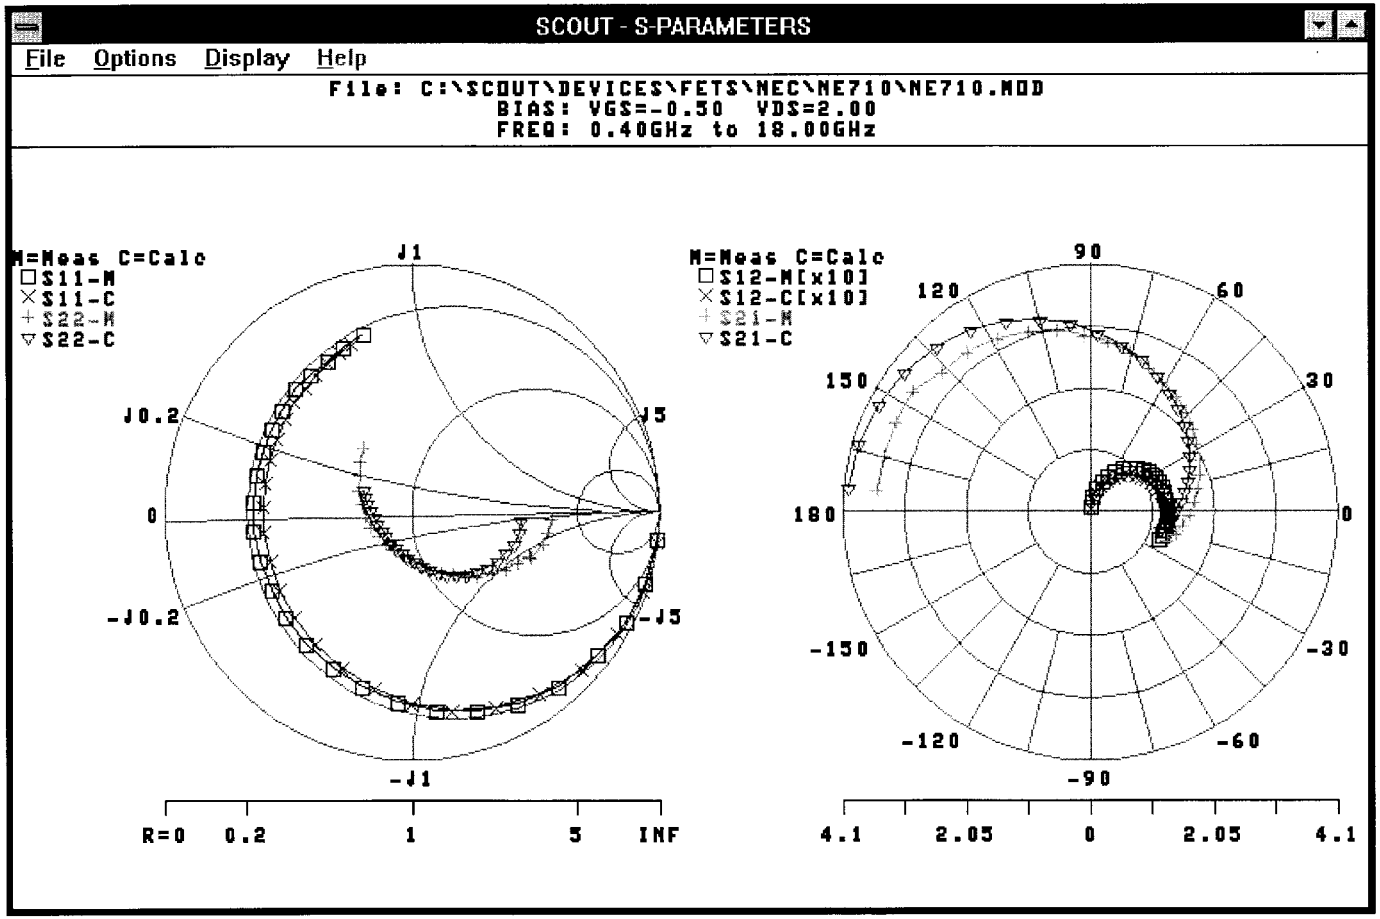

Figure 2-137 Measured versus calculated NE71000 *S* parameters for V_{GS} = –0.50 and V_{DS} = 2.00.

2-133 shows measured versus simulated dc I–V curves for the NE71000. The agreement between measured and predicted dc I–V curves is quite good. In a similar fashion, we obtain the S-parameter fits over bias. They are shown in Figures 2-134 through 2-137.

As mentioned above, 1-dB compression, power saturation, and drain current are functions of the drive. This particular model point is not particularly impressive. We believe this has to do with the original Materka model.

Having brought up the subject of models, Figure 2-138 compares measured data with that obtained with the Angelov, cubic, quadratic, TriQuint, Raytheon, and Materka models. The figure shows that there is no perfect model yet. To put this in perspective, in Figure 2-139 we show the dc I–V error bars for these six models. This graph shows that the least errors for the dc measurement versus modeling are obtained with the Curtice cubic model, followed by the modified Materka model (implemented in Serenade) and TriQuint models. The difference in S parameter matching for RF application is significantly more relevant for the designer.

Things become much more interesting if we compare the S-parameter errors between the Materka shown in Figure 2-140, the Curtice cubic model (Figure 2-141), and the TOM model (Figure 2-142). Improved modeling regarding the R_{DS} is being developed, and we will discuss this at the end of this chapter.

Since the trend is to go to low-voltage power RF operation, several issues must be battled:

- Models are most inaccurate at low V_{DS} and near pinchoff.
- Modeling of low-voltage operation is adversely impacted.
- Thermal effects must be considered, but older models do not account for this.

A Case Study. As a case study, we will consider the Oki KGF1608 power MESFET (0.5 μm × 28 mm). Figures 2-143 and 2-144 show the dc I–V curves and S parameters, respectively. The resolution of the S parameters, based on the scale used, is not particularly impressive.

Figure 2-145 shows the dc I–V curves, with load line, for the KGF1608; the self-heating effect of the transistor can be seen in the droop of the top two curves. Figures 2-146 and 2-147 show drain current and output power versus drive, respectively. The test conditions for these three figures were f = 850 MHz, V_{DS} = 3.4 V, and V_{DS} = 2.025 V.

2-4-5 Conclusions

From all plots of dc and ac error contours, dc I–V curves, and dc error bar charts we can draw the following conclusions.

Dc errors

- *In the Saturation Region*. All the models considered work very well, with a relative error of less than 15%. This means that all models are suitable for typical applications where the device operates in the saturation region.
- *In the Linear Region.* Though the errors in the saturation region are similar for different models, the errors in the linear region are quite different. The Materka, Curtice cubic, and TriQuint models behave better than other models in the linear region. The relative errors of these three models are less than 10%, while other models have more than 60% relative errors at some points.

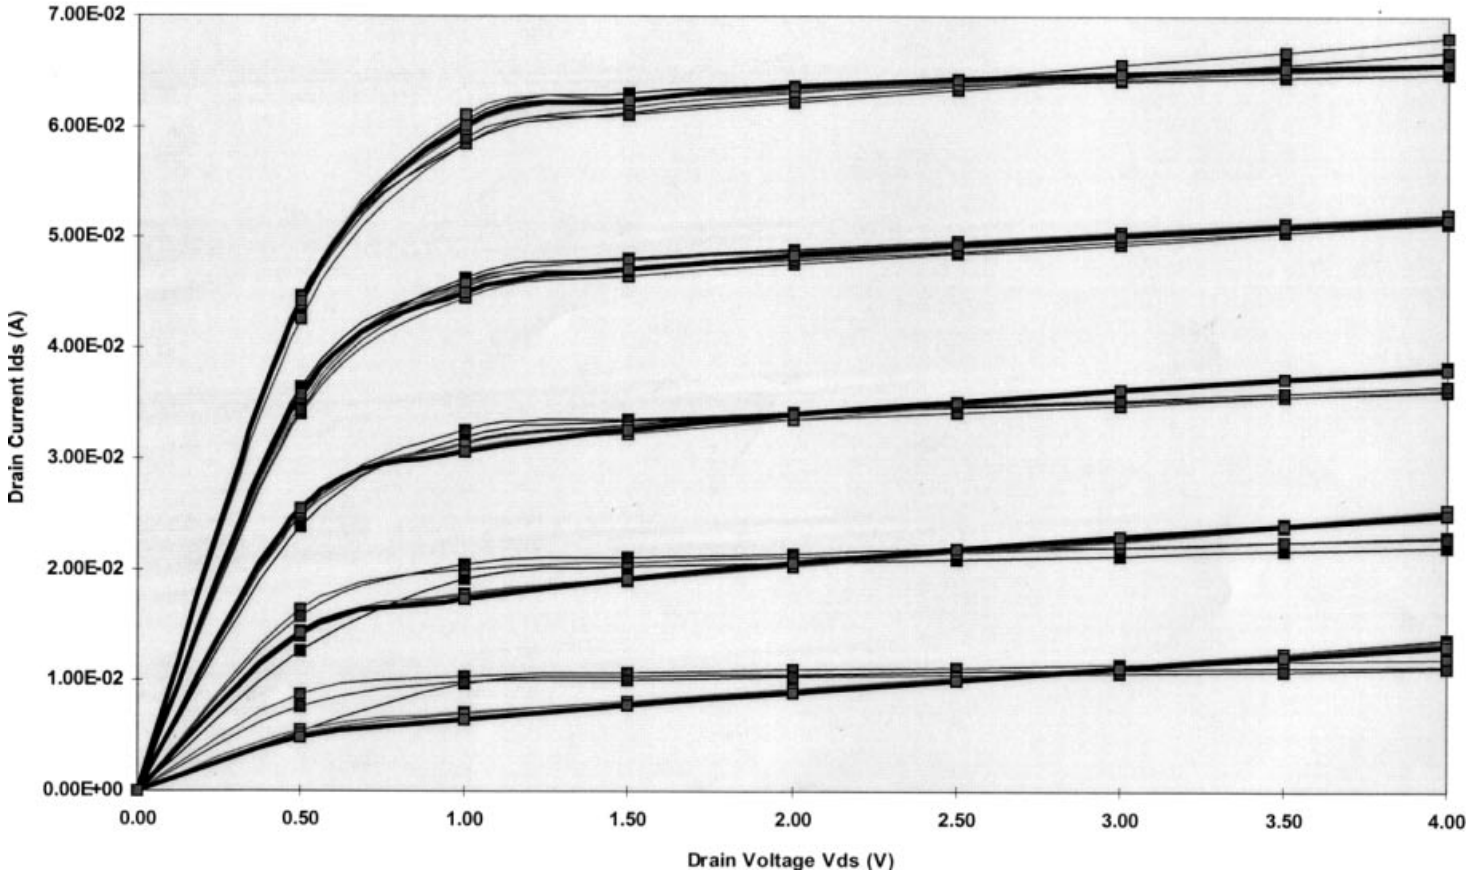

Figure 2-138 Comparison of dc models: Chalmers (Angelov), Curtice cubic, Curtice quadratic, Materka, Raytheon, and TOM (TriQuint).

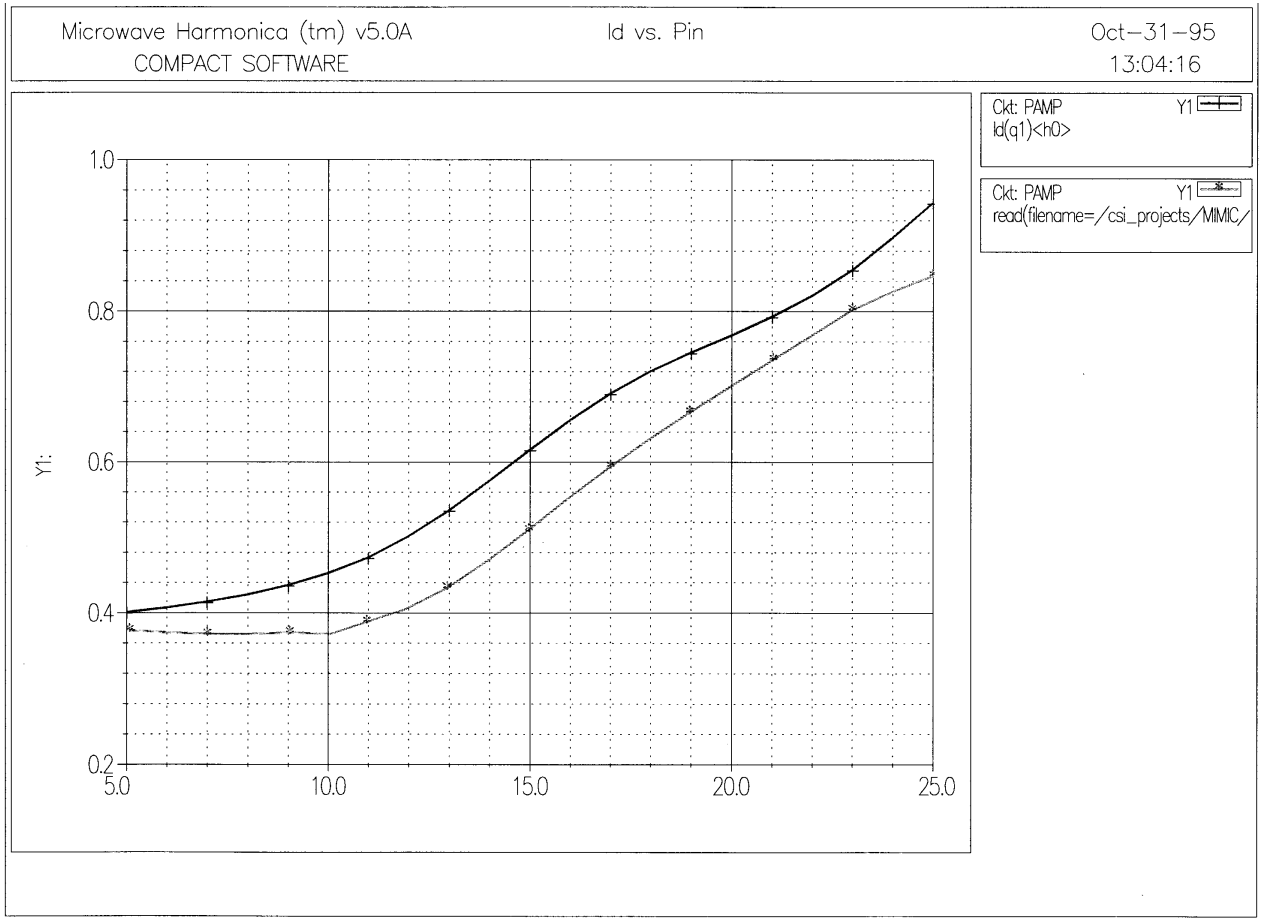

Figure 2-146 Measured versus calculated drain current for the KGF1608 MESFET.

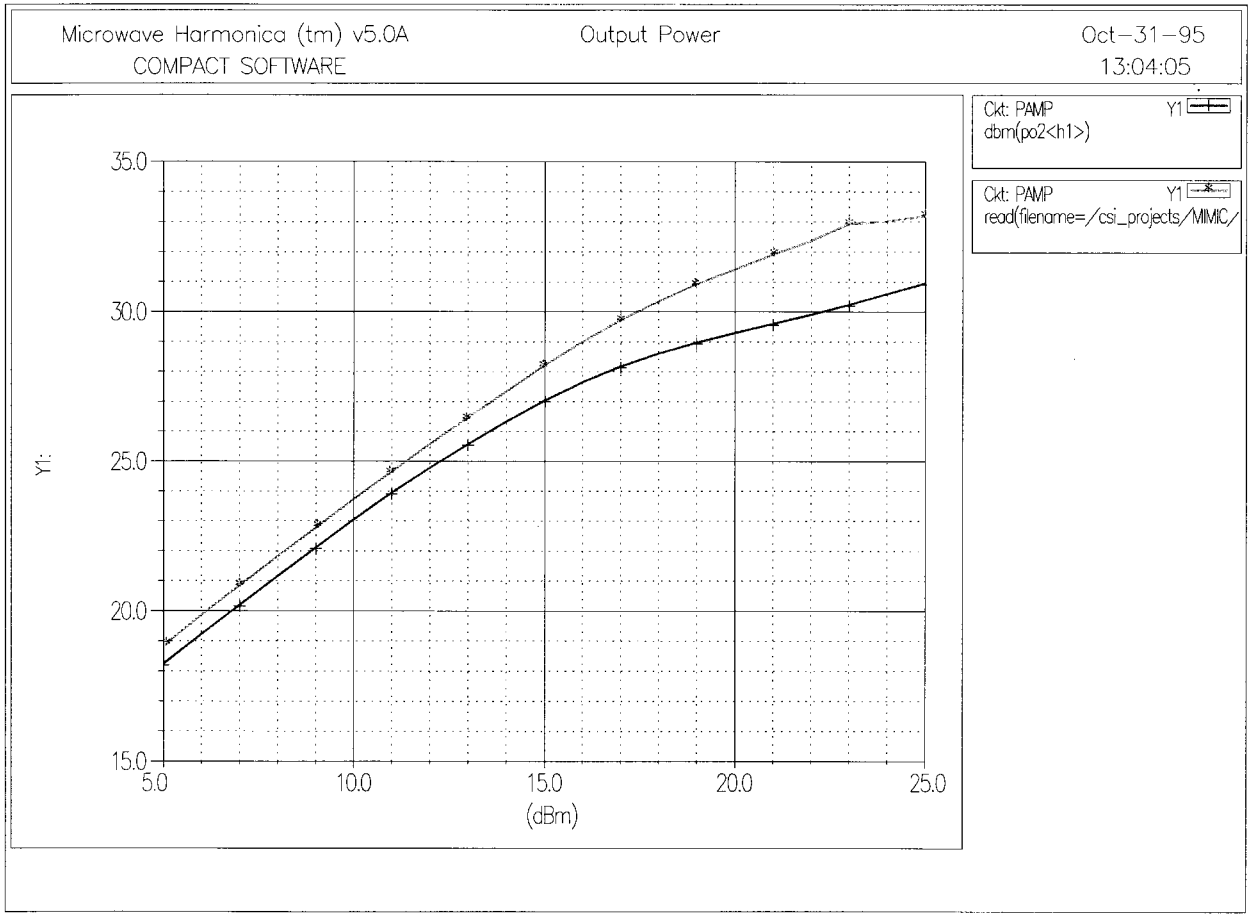

Figure 2-147 Measured versus calculated output power for the KGF1608 MESFET.

ac Errors. From the ac error contour plots we can see that the Chalmers (Angelov) model emerges as the most accurate for ac small-signal operation. The comparison also shows that all models considered are good for ac operations biased in the saturation region with a typical relative error of less than 15%. However, the ac relative errors are much higher in the linear region, particularly for the Curtice quadratic model, which exhibits more than 80% error at some points.

Notes. The above conclusions are based on the matching between the simulated responses of different models and the measured data from a typical NE71000 device; the models may behave differently for a different device. It is not possible to draw any broad-based conclusions as to what model is the best. In order to select the most suitable model for your application, you must consider all the factors, such as bias range, frequency range, and small-signal or large-signal operation, according to your experiences in device modeling.

2-4-6 Device Libraries

All these measurements lead to a nonlinear device library. Figures 2-148 and 2-149 shows a typical datasheet for a device in the library with measured and modeled data. The previous high-power example does not always lead to acceptable results as the models are far from being fully developed. We also show the simulation results using the physics-based model for FETs.

Physics-Based MESFET Modeling. We mentioned a physics-based model earlier. Figure 2-150 shows the measured versus predicted dc *I–V*, I/O power, and *S* parameters for an Alpha Industries MBE MESFET developed under a government contract. The simulation does not handle the trapped energy, which explains the negative slope on the third trace of the output dc *I–V* curve.

The process for bipolar transistors is quite similar and less tricky than the ones just described. Good examples can be found in the user manual for Compact Scout.

2-4-7 A Novel Approach for Simulation at Low Voltage and Near Pinchoff Voltage

As mentioned earlier, the most critical zone is the area of operating the FET both close to the pinchoff voltage and at low operating voltages. A crucial reason for the inadequate results is the modeling of the drain–source resistance as a function of bias point. This is particularly important in calculating the power-added efficiency. When doing your modeling, there is always a temptation to look at both high currents and operating voltages. Figure 2-151 shows a reasonable agreement between measured and predicted dc *I–V* performance. However, the very moment the transistor is modeled close to the linear region (Figure 2-152), things change drastically and the results from 0 to 6 mA have little resemblance to those from 0 to 50 mA. The modified Materka model (Figures 2-153 and 2-154) gives a significantly better match than the Angelov model.

In order to overcome the modeling inaccuracy for the FETs, Thomas Meier of Siemens AG in Munich has come up with the concept of combining two transistors in parallel, whereby the second one is not really connected for dc (Figure 2-155). Figure 2-156 compares measured and simulated R_{DS} using this new approach.

NE67300

Manufacturer : **NEC**
Model Keyword : **NE - 67300**
Device Type : **Mesfet**
Model Type : **Materka**
Package Type : **Chip**

Electrical Characteristics:
Idss : 40mA
Vp : 1.1V
Gain : 8.5dB @ 18GHz
P1db : N/A
Fmin : N/A

Model Data Range:
Vgs : -1.2V to 0.0V
Vds : 0.0V to 4.0V
Freq: 0.4GHz to 18GHz

Verification :
Type : Power sweep, 50Ω
Vgs : -0.6V Vds : 3.0V Ids : 30mA Freq: 6.0GHz

Comments : The S-parameters that appear in the figure were measured and simulated with wire bonds present. The length of each wire bond is approximately 30 mils. To obtain the S-parameters for the manufacture's data sheets, the wire bond inductances would be removed from the equivalent circuit.

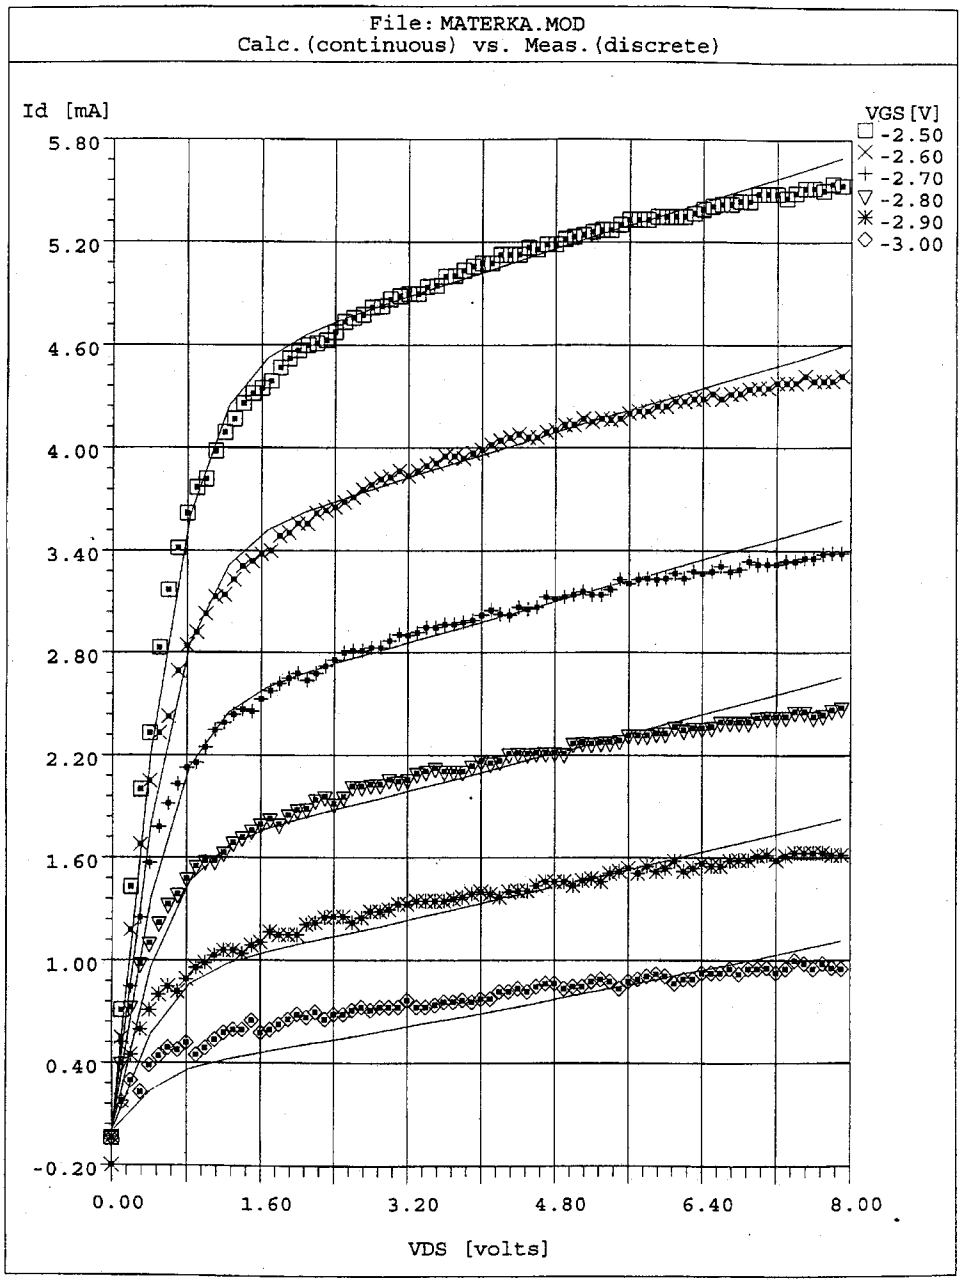

Figure 2-154 Low-I_D dc I–V curves for the modified Materka FET model.

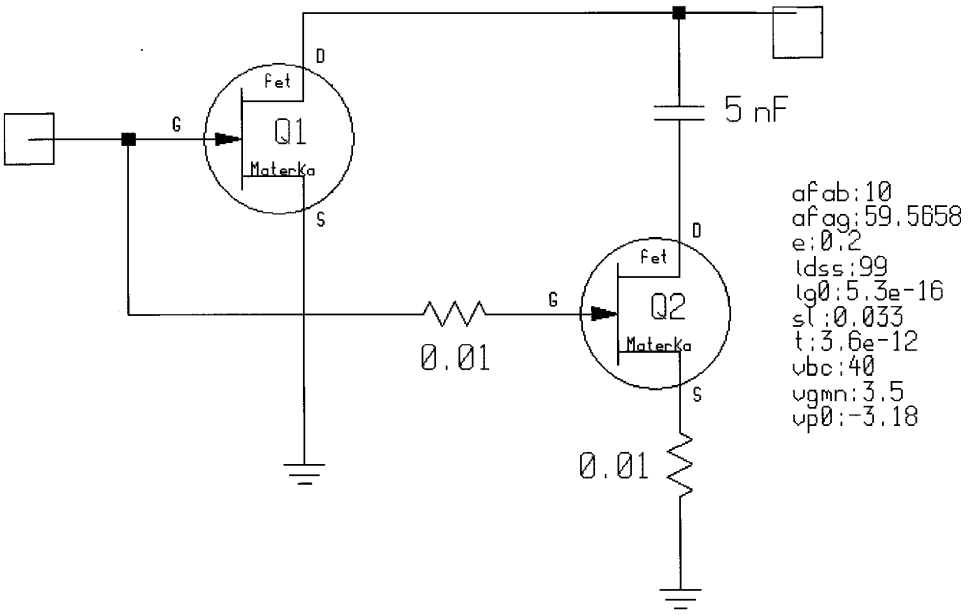

Figure 2-155 By putting two transistors in parallel, with the second one having no dc connection at the drain, one can simulate a dynamic R_{DS} quite well. Regardless of parameter values used for Q1, the parameters listed are necessary to get an accurate R_{DS} result.

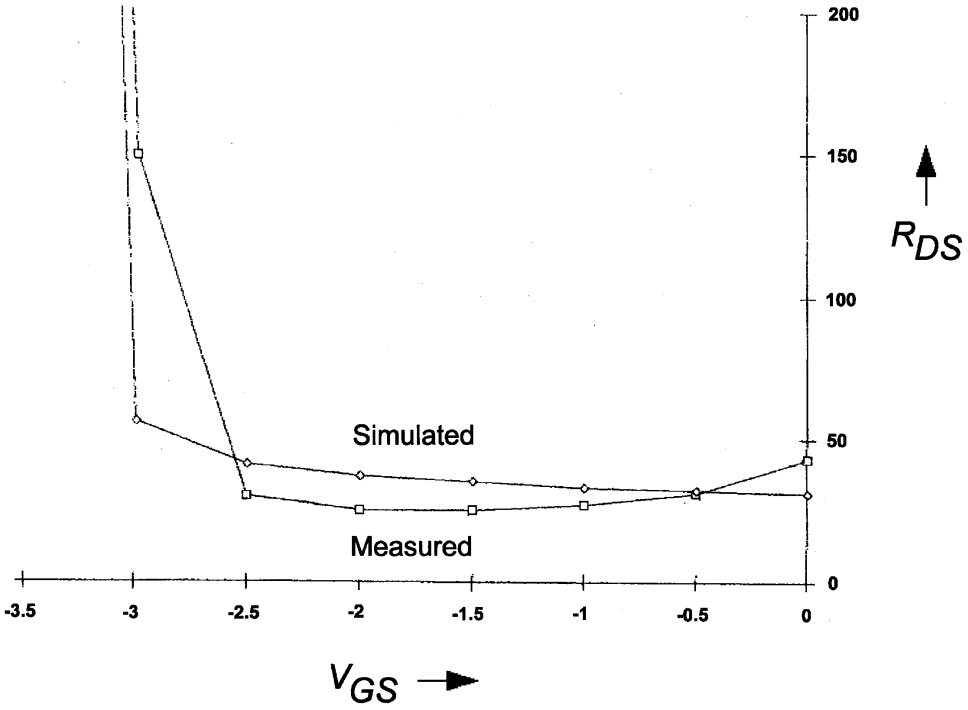

Figure 2-156 Measured versus simulated R_{DS} for the paralleled MESFET approach.

One might ask the question: "Why not fix the existing models?" It turns out that in order to get the best possible convergence and speed, one has to use analytic derivatives for voltage and current; at least the first and second derivatives, if not the third, are required. The programming of such a model becomes so difficult, however, and the calculation of its derivative is so highly likely to have subtle errors, that it turns out that the parallel configuration shown in Figure 2-155 is the best possible compromise for fast computation and accurate results.

A similar approach for bipolar transistors has been discussed by Philips with their MEXTRAM model. However, we have not seen any parameter extraction for this model and also we have not seen any industry acceptance for it. While, in principle, it will cover all derivatives of all members of the BJT family, its topology consists out of three discrete transistors connected and we doubt very much that a reliable parameter extraction program/mathematically continuous model for nonlinear simulation is supplied by the university that developed this jointly with Philips. At the time of writing this book, Philips has not yet provided us with the code for both, and until this happens, we are not in a position to qualify this any further.

2-4-8 Example: Improving the BFR193W Model

We have already mentioned the difficulty encountering the proper base-spreading resistor values and others by using standard parameter extraction programs. Table 2-28 is a copy from the Siemens semiconductor book showing Gummel–Poon Berkeley SPICE syntax parameters for the BFR193W BJT.

The first thing that will happen is that the observant reader will notice that the minimum possible base-spreading resistor, RBM (valid at large current densities), is larger than the actual base-spreading resistor, RB, "claimed to be measured" at 1 Ω (see Table 2-28).

Another headache is caused by the measured noise performance of the same device at an operating point of 10 mA. Using the above-mentioned simplified equation

Table 2.28. BFR193W transistor chip data: SPICE parameters (Gummel–Poon model, Berkeley–SPICE 2G.6 syntax)

All parameters are ready to use, no scaling is necessary. Extracted on behalf of SIEMENS Small Signal Semiconductors by Institut für Mobil-und Satellitenfunktechnik (IMST).

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-288)

we obtain the following results:

1. Inserting 1 Ω (value for RB provided by IMST) and R_B = 15 Ω (measured by the authors), here are the interesting results:

$$F = 1 + \frac{1}{50} + \frac{2.6}{100} = 1.046 \tag{2-289}$$

as noise factor or, as noise figure, F (dB) = 0.2 dB (IMST).

2. Or using the measured 15 Ω, one obtains

$$f = 1 + \frac{15}{50} + \frac{2.6}{100} = 1.326 \tag{2-290}$$

as noise factor or, as noise figure, F (dB) = 1.22.

The Siemens datasheet claims a noise figure of 1.3 dB, and therefore the measured versus calculated data differ by 0.08 dB. Since our noise figure was calculated well below f_T, which is seen from the fact that there are no frequency-dependent terms in the noise figure calculation, it is not unusual that the 900-MHz noise figure is 1.3 dB or slightly higher. This simple example shows how easy it is to provide measurement data that are inconsistent with the laws of physics. It is therefore highly recommended to add the noise figure as an additional parameter in the parameter extraction to reduce the number of variables—specifically, those for which the standard extraction has little sensitivity.

The collector–emitter junction capacitance is another important parameter that frequently gets measured incorrectly. The way around this is to remember the definition

$$f_{\max} = \sqrt{\frac{f_T}{8\pi R'_{bb} C_c}} \tag{2-291}$$

f_T can be measured from the 3-dB point of the emitter current gain (β) and R'_{bb} was just computed above, so the equation can be solved for C_c, as there is a relationship between measured $g_{\max}$ and $f_{\max}$. There are several correlations between the parameters of the equivalent circuit as published in different places, and therefore one can restrict the degree of freedom within the optimization process and obtain much better results. This approach is applicable to all types of transistors, bipolar and FET, and can be used to improve the accuracy of parameters that not only affect a transistor's RF performance but also its noise performance.

MODELS FOR ACTIVE DEVICES

Because we are dealing with amplifiers, both small-signal and power, oscillators, and active mixers, active devices will play a major role in circuit design. At our frequency range of interest (about 1000 MHz and above), distributed elements predominate, and even in device modeling we must consider some distributed effects such as packaging.

As we dive into providing functional explanations of the active devices used in practical circuits, there is some temptation not to provide enough information on semiconductor behavior. Because manufacturers of microwave products will use the services of a foundry or specify semiconductors from their suppliers, we will cover the device operation in depth. That said, for the beginner looking into designing circuits from high frequencies to low microwave frequencies, we will provide examples of a variety of devices unique to this frequency range. Some treatment of device physics will therefore be useful in providing a basic understanding of the nonlinear behavior of active devices and modeling in preparing for practical circuits using a computer-aided-design (CAD) tool. For CAD applications, we assume the user will have access to nonlinear CAD software, such as a high-performance SPICE program or a harmonic-balance program, such as Ansoft Serenade 8.0 or its derivatives. It is interesting that most semiconductor houses today still only offer very limited nonlinear data sets, while in the linear area a large body of useful data is made available, mostly on CDs. What CAD does for us—and this applies to SPICE and harmonic-balance programs alike—is predict the dc bias point of a device in the context of its surrounding circuitry. Configuring the simulation to drive the device into large-signal operation provides us with insight into the various forms of distortion and compression.

In evaluating active devices for RF circuit design, we have a few different technologies to consider. First, we will examine the semiconductor junction diode—a basic *pn* junction—and venture from there to the bipolar transistor. An investigation of metal-oxide semiconductor (MOS) devices, another important set of semiconductors for medium frequencies, will follow. We will also examine the gallium arsenide metal-gate Schottky field-effect transistor (GaAs MESFET) and members of its family. Since critical large-signal parameters for some devices may not be available from their manufacturers, we will examine

parameter-extraction techniques and problems. For various device types, we will provide insight into the noise properties of the device.

2-1 DIODES*

The diode model contains a nonlinear current source that follows the Shockley equation:

$$\text{Current} = \text{IS}\left(e^{V_j/\text{N}V_t} - 1\right) \tag{2-1}$$

where V_j = voltage across the junction
V_t = thermal voltage (= kT/q)

These values, with the model parameters IS and N, are used to model the current–voltage effects of the semiconductor junction. This does not include the nonideal operation of real diodes. For example, at low currents (less than 1 nA), other semiconductor processes that increase the flow of currents become noticeable.

By setting IS to different values, we can obtain the characteristics of other devices, such as a Schottky barrier diode, or a silicon diffused-junction diode. High-current effects are modeled, grossly, by including a series resistance that is intended to combine the effects of bulk resistance (the material on each side of the junction) and high-level injection. At high currents, the observed diode current stops following the Shockley form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/\text{N}V_t} \tag{2-2}$$

and approaches a modified form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/2\text{N}V_t} \tag{2-3}$$

2-1-1 Large-Signal Diode Model

Three diode models are used in the industry:

- Microwave diode model
- PIN diode model
- Enhanced SPICE diode model

Figure 2-1 shows the large-signal microwave diode model. Its keywords appear in Table 2-1. This model can also be used to simulate varactor diodes.

Table 2-2 lists SPICE parameters for a selection of Schottky mixer diodes by Alpha.

In most cases, the diode capacitance is modeled by a voltage-dependent capacitor, which is connected in parallel with the nonlinear current generator described previously, to represent the charge-storage effects of the junction. There are two components to this charge

- The reverse-voltage capacitive effect of the depletion region
- The forward-voltage charge represented by mobile carriers in the diode junction

*Portions of this chapter's diode coverage are based on material in Alpha Industries Semiconductor Application Reports 80800, 80200, and 80500. Used with permission.

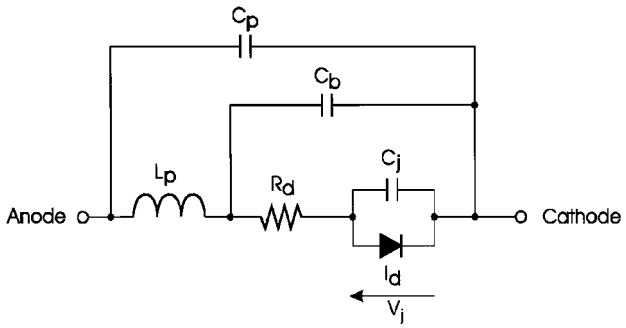

Figure 2-1 The large-signal microwave diode model. This model is temperature dependent.

Reverse-voltage capacitance follows the simple approximation that the depletion region (the area of the junction that is depleted of carriers) serves as the gap between the "plates" of a capacitor. This region varies in thickness, and therefore the capacitance varies with applied voltage. For a step (abrupt) junction, or linearly graded junction, the capacitance approximation is

Table 2-1 Large-signal microwave diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
JS	Saturation current	ampere	0
ALFA	Slope factor of conduction current	/volt	38.696

$$\text{Capacitance} = \frac{C_{J0}}{\left(1 - V_j/\phi\right)^M} \tag{2-4}$$

where C_{J0} is the zero-bias value, ϕ (phi) is the junction barrier potential, and M is the grading coefficient that varies ($\frac{1}{2}$ is used for step junctions and $\frac{1}{3}$ is used for linearly graded junctions, and most junctions are somewhere in between).

There is often confusion about the barrier potential, which appears in the capacitance equation. From capacitance measurements, ϕ (model parameter VJ, and not to be confused with V_j in the equations) takes on a value of nearly 0.7 volt for regular (silicon) junction diodes and a range of 0.58–0.85 volt for various Schottky barrier diodes. This value is sometimes confused with the forward-current voltage drop of the diode or the energy gap of the material; it is *neither* of these.

Varying M generates a variety of reverse-bias capacitance characteristics. Inspection of the capacitance formula reveals that it predicts infinite capacitance for a forward bias, which is not the case for a real junction. Several depletion-capacitance formulas have been proposed that more correctly fit observed operation; however, SPICE uses a simple approach: For forward biases beyond some fraction (set by the parameter FC) of the value for ϕ, the capacitance is calculated as the linear extrapolation of the capacitance at the departure. This provides a continuous numerical result and does not affect circuit operation significantly because, for forward bias, the device capacitance is normally dominated by diffusion capacitance.

The diffusion charge (and therefore the capacitance) varies with forward current and is simply modeled as a transit time (model parameter TT) for the carriers to cross the diffusion region of the junction. The total charge is

$$\text{Diffusion charge} = \text{Device current} \times \text{Transit time} \tag{2-5}$$

and capacitance is the derivative, with respect to bias, of this:

$$\text{Diffusion capacitance} = \text{TT}\,\frac{\text{IS}}{\text{N}V_t}\,e^{V_j/\text{N}V_t} \tag{2-6}$$

Diffusion charge manifests itself as the *storage time* of a switching diode, which is the time required to discharge the diffusion charge in the junction, which must happen before the junction can be reverse-biased (switched off). Storage time is normally specified as the time to discharge the junction so that it is supporting only a fraction (typically 10%) of the initial reverse current. First, a forward current is supplied to the device to charge the junction. Then, as quickly as possible, a reverse current is supplied to the device. Internally, the junction is still forward-biased to a voltage nearly the same as before the switch in current; the junction is still conducting at the forward-current rate. This internal current adds to the external current as the total current discharging the junction. As the junction voltage decreases, the internal current falls off exponentially (according to the Shockley equation). This system is a relatively simple differential equation that can be solved to an explicit equation for the TT parameter (assuming complete discharge) as follows:

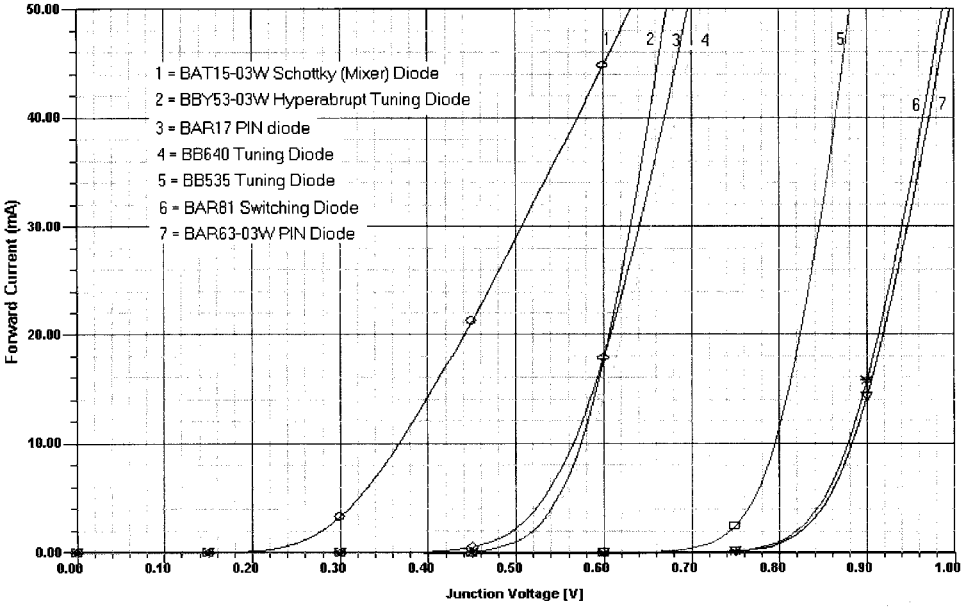

Figure 2-2 The dc *I–V* curves for seven diodes, showing the various barrier voltages that result from different doping profiles.

$$\text{Transit time} = \frac{\text{Storage time}}{\ln\left(\dfrac{I_F - I_R}{-I_R}\right)} \tag{2-7}$$

The diffusion charge dominates the reverse recovery characteristic of the diode. During the last part of the recovery, as the junction becomes reverse-biased, the depletion capacitance dominates. This causes the small tail at the end of the discharge cycle. Total capacitance is taken to be the sum of these capacitances: the depletion approximation dominates for reverse bias as the device current is small, and the diffusion proximity dominates for forward bias as the device current is large.

A special case for diode application is the switching diode, and its description and application will be part of a later chapter. Figure 2-2 shows the dc *I–V* curves, which indicate the different voltage potentials that are a result of the different doping profiles.

2-1-2 Mixer and Detector Diodes

Electrical Characteristics and Physics of Schottky Barriers. Schottky barrier diodes differ from junction diodes in that current flow involves only one type of carrier instead of both types. That is, in *n*-type Schottky barrier diodes the forward current consists of holes flowing from the *n*-type material into the metal.

Diode action results from a contact potential set up between the metal and the semiconductor, similar to the voltage between the two metals in a thermocouple. When metal is brought into contact with an *n*-type semiconductor (during fabrication of the chip), electronics diffuse out of the semiconductor into the metal, leaving a region under the contact that

has no free electrons ("depletion layer"). This region contains donor atoms that are positively charged (because each lost its excess electron), and this charge makes the semiconductor positive with respect to the metal. Diffusion continues until the semiconductor is so positive with respect to the metal that no more electrons can go into the metal. The internal voltage difference between the metal and the semiconductor is called the contact potential and is usually in the range of 0.3–0.8 volt for typical Schottky diodes. A cross section is shown in Figure 2-3.

When a positive voltage is applied to the metal, the internal voltage is reduced, and electrons can flow into the metal. The process is similar to thermionic emission of electrons from the hot cathode of a vacuum tube, except that the electrons are "escaping" into a metal instead of into a vacuum. Unlike the vacuum tube case, room temperature is "hot" enough for this to happen if enough voltage is applied. However, only those electronics whose thermal energy happens to be many times the average can escape, and these "hot electrons" account for all the forward current from the semiconductor into the metal.

One important thing to note is that there is no flow of minority carriers from the metal into the semiconductor and thus no neutral plasma of holes and electrons is formed. Therefore, if the forward voltage is removed, current stops "instantly," and reverse voltage can be established in a few picoseconds. There is no delay effect to charge storage as in junction diodes. This accounts for the exclusive use of barrier diodes in microwave mixers, where the diode must switch conductance states at microwave oscillator rates.

The current–voltage relationship for a barrier diode is described by the Richardson equation (which also applies to thermionic emission from a cathode). The derivation is given in many textbooks (e.g., Sze).

$$I = AA_{\mathrm{RC}}T^2 \exp\left(-\frac{q\phi_B}{kT}\right)\left[\exp\left(\frac{qV_J}{kT}\right) - M\right] \tag{2-8}$$

where A = area (cm^2)

A_{RC} = modified Richardson constant ($\mathrm{A}/K^2 \cdot \mathrm{cm}^2$)

k = Boltzmann's constant

T = absolute temperature (K)

ϕ_{B} = barrier height in volts

V_J = external voltage across the depletion layer (positive for external voltage) = $V - IR_S$

R_S = series resistance

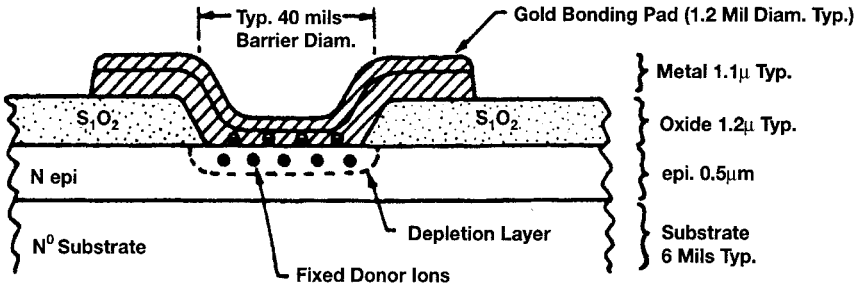

Figure 2-3 Schottky diode chip cross section.

M = avalanche multiplication factor
I = diode current in amperes (positive forward current)

The barrier height, ϕ_B, is typically a few tenths of a volt higher than the contact potential, ϕ_C (about 0.15 V higher than ϕ_C for silicon). This equation agrees well with experimental data for diodes without surface leakage, but it is difficult to use because A_{RC}, ϕ_B, and M are all dependent on applied voltage.

The major cause for variation in ϕ_B with voltage is the "image effect," in which the barrier height is lowered as the electric field near the metal is increased, especially at the edges. A better equation for circuit designers to use is one in which all parameters are independent of voltage and current. The simplest one that agrees reasonably well with Richardson's equation is

$$I = I_S\left[\exp\left(\frac{V_J}{0.028}\right) - 1 + \frac{K}{\left(1 - V_B/V\right)}\right] \tag{2-9}$$

where I_S = saturation current (a temperature-dependent quantity)
0.028 = nkT/q at room temperature (n = 1.08)
n = forward slope factor (derived from the variation of ϕ_B with forward voltage)
K = reverse slope factor (expressing the variation of ϕ_B with reverse voltage)
V_B = breakdown voltage (the voltage at which M = 1)

As before, V and I are considered positive for forward bias and negative for reverse bias.

Typical ranges for these parameters for microwave Schottky and point-contact mixer diodes are:

I_S = 10^{-12} to 10^{-5} A
n = 1.04–1.10
R_S = 2–20 Ω
K = 8–100
V_B = 2–20 V

The quantities I_S and 0.028 are strongly temperature dependent, while both R_S and V_B increase with temperature to a slight degree. R_S increases with current at high current levels (due to carrier velocity saturation) but is essentially independent of current at 10 mA and below for mixer diodes. Thus, for normal mixer and detector operation, R_S can be considered constant.

Agreement between Eqs. (2-8) and (2-9) is not perfect but Eq. (2-9) is much easier to use and is preferred by most circuit designers. A comparison of the two equations near zero bias gives the following relationship between zero-bias barrier height, ϕ_0, and saturation current:

$$I_S = AA_{RC}T^2\exp - \frac{q\phi_0}{kT}$$

$$\cong \left(\frac{10^7 A}{\text{cm}^2}\right)A\exp\left(-\frac{\phi_0}{0.026}\right) \quad \text{(for } n \text{ silicon at room temperature)} \tag{2-10}$$

Small-Signal Parameters. By combining Eqs. (2-9) and (2-10), the values of the parameters in Eq. (2-9) can be derived from a few simple measurements. Many specific equations can be derived, but the following are commonly used for production measurements:

$$R_S = \frac{V_{F10} - V_{F1} - 0.065}{0.009} \quad (\text{for } n = 1.08) \tag{2-11}$$

$$\phi_0 = \frac{V_{F1} - 0.001R_S + 0.28 + 0.12\log_{10} D}{1.08} \tag{2-12}$$

$$n = \frac{V_{F1} - V_{F0.1} - 0.0009R_S}{0.060} \tag{2-13}$$

$$K = \left(\frac{I_{R1}}{I_S} - 1\right)V_B \tag{2-14}$$

$$I_S = \exp\left(-\frac{V_{F1}}{0.028} + \frac{R_S}{28}\right) \quad (\text{in mA}) \tag{2-15}$$

where $V_{F0.1}$, V_{F1}, and V_{F10} are the forward voltages at 0.1, 1, and 10 mA, respectively, and I_{R1} is the reverse current at 1 volt. (The derivation of these equations requires that I_S be small compared to 0.1 mA.) The quantity D is the diameter of the metal–silicon contact in mils.

Measuring V_{F1} at 1 mA and 10 mA instead of some other current levels leads to the best accuracy for typical mixer diodes.

The total dynamic resistance for a forward-biased diode is given by

$$R_T = \frac{dV}{dI} = R_S + \frac{nkT}{q(I + I_S)} = R_S + R_B \tag{2-16}$$

and

$$R_B = \frac{28}{I + I_S} \quad \text{at room temperature (with } I \text{ and } I_S \text{ in mA, } n = 1.08) \tag{2-17}$$

This equation is also good at zero bias (unless K is very large or there is significant surface leakage). That is,

$$R_0 = R_S + \frac{28}{I_S} \tag{2-18}$$

For reverse voltages of a few volts, the dynamic resistance is dominated by the K term:

$$R_R = \text{Reverse resistance} = \frac{dV}{dI} \cong \frac{V_B}{KI_S} \tag{2-19}$$

For typical values of I_S, R_0 is larger than 5000 Ω and R_R is larger than 100 kΩ. For some zero-bias Schottky applications, it is desirable for R_0 to be made smaller than this.

The factors that determine R_S are (1) the thickness of the epitaxial layer, (2) the epitaxial layer doping level (N_D), (3) the barrier diameter, (4) the substrate resistivity ("spreading resistance"), (5) the contact resistances of the metals used for the barrier and the substrate contact, and (6) the resistance associated with the bonding wire or whisker. The barrier height is about 0.15 volt higher than the contact potential between the barrier metal and the semiconductor and is influenced by the method used to apply the metal, conditions at the edge of the junction, and the doping level. Saturation current depends on barrier height, junction area, and temperature; and the slope factors, n and K, depend on doping level, punchthrough voltage, and edge conditions.

Junction Capacitance. The capacitance of a Schottky barrier chip results mainly from two sources: the depletion layer under the metal–semiconductor contact and the capacitance of the oxide layer under the bonding pad (the so-called overlay capacitance). The bonding pad is required because the typical Schottky barrier diameter is so small that it is impractical to bond directly to the metal on the junction. If the semiconductor epitaxial layer is uniformly doped, the capacitance–voltage characteristic is similar to that of a textbook "abrupt-junction" diode.

$$C_J = \frac{\varepsilon_S \varepsilon_0 A'}{X_D} + C_0 \tag{2-20}$$

$$X_D = \sqrt{\frac{2\varepsilon_S \varepsilon_0 (\phi_C - V)}{qN}} \tag{2-21}$$

where ϕ = contact potential
C_0 = overlay (bonding pad) capacitance
ε_S = dielectric constant of the semiconductor ($\cong$ 12 for Si or GaAs)
N = doping level for the epitaxial layer
A' = effective contact area, including fringing corrections

In practical terms, the capacitance can be related to the 0-V barrier capacitance defined by

$$C_{B0} = \frac{\varepsilon_S \varepsilon_0 A'}{X_{D0}} \tag{2-22}$$

where

$$X_{D0} = \sqrt{\left(\frac{1.3 \times 10^{15}}{N_D}\right)\phi_C} \quad \text{(in } \mu\text{m)} \tag{2-23}$$

The resulting C–V relationship can be written

$$C_J = \frac{C_{B0}}{\sqrt{1 - V/\phi_C}} + C_0 \tag{2-24}$$

The contact potential, ϕ_C, is related to the barrier height as follows:

$$\phi_C = \phi_B - 0.026\left[1 + L_n\left(\frac{N_C}{N}\right)\right] \tag{2-25}$$

The theoretical meaning of these terms can be clarified by looking at Figure 2-4.

Parameter Trade-Offs

Barrier Height. The barrier height of a Schottky diode is important because it directly determines the forward voltage. In order to get a good noise figure, the LO drive voltage, V_L, must be large compared to V_T, which is essentially V_{F1}. Normally, it is best to have a low

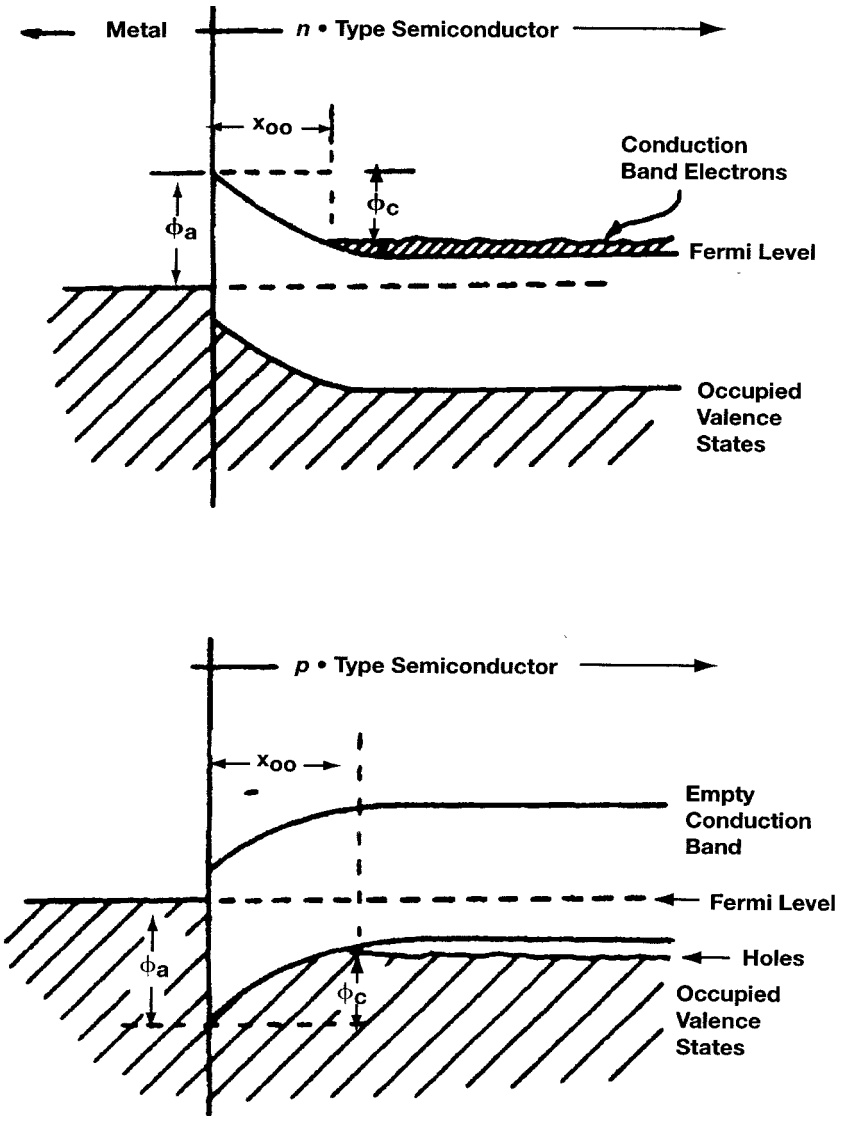

Figure 2-4 Schottky diode band diagrams.

Table 2-3 LO power and V_{F1} for various applications

Type	Typical V_{F1}	LO Power	Application
"Zero bias"	0.10–0.25	< 0.1 mW	Mainly for detectors
Low barrier	0.25–0.35	0.2–2 mW	Low-drive mixers
Medium barrier	0.35–0.50	0.5–10 mW	General purpose
High barrier	0.50–0.80	> 10 mW	High dynamic range

forward voltage (low V_{F1}), or low drive) diode, to reduce the amount of LO power needed. However, if high dynamic range is important, high LO power is needed, and the diode can have a higher V_F and should also have a high V_B (see Table 2-3).

Noise Figure Versus LO Power. At low LO drive levels, the noise figure is poor because of poor conversion loss, due to a too-low conduction angle. At very high LO drive levels, the noise figure again increases due to diode heating, excess noise, and reverse conduction.

If a high LO drive level is needed, for example, to get higher dynamic range, a high V_B (> 5 V) should be specified. However, Nature requires that you pay for this with higher R_S (lower f_C), so the noise figure will be degraded compared to what could be obtained with diodes designed for lower LO drive. Forward voltage and breakdown are basically independent parameters, but high breakdown is not needed or desirable unless high LO power is used.

Such a high-breakdown diode will have low reverse current (which is important only if the diode has to run hot).

Silicon Versus GaAs. Typical silicon Schottky diodes have cutoff frequencies in the 800–200-GHz range, which is good enough through the Ku band.

At the Ku band and above, or for image-enhanced mixers, higher f_C may be needed, which calls for the use of GaAs diodes. These have lower R_S due to higher mobility, which translates to cutoff frequencies in the 400–1000-GHz range.

However, if your IF is low, be careful; GaAs diodes have high 1/*f* noise. They also have high V_{F1}, so more LO power is required.

C_J Versus Frequency. There is quite a lot of latitude in choosing C_J. However, in general, the capacitive reactance should be a little lower than the transformed line impedance (Z_0). If Z_0 is not known, a good way to start is to use $X_C = 100\ \Omega$. Experience has shown that most practical mixers use an X_C near this value (a little higher in waveguide, and lower in 50-Ω systems). This translates to the following rule of thumb for choosing the junction capacitance of a diode for operation at frequency *f* (in GHz):

$$C_{J0} \approx \frac{100}{\omega}$$

$$\approx \frac{1.6}{f} \quad \text{(in pF)} \tag{2-26}$$

In order to evaluate possible tolerances, we show the range of forward current as a function of diode voltage (Figure 2-5), the junction capacitance as a function of the bias voltage

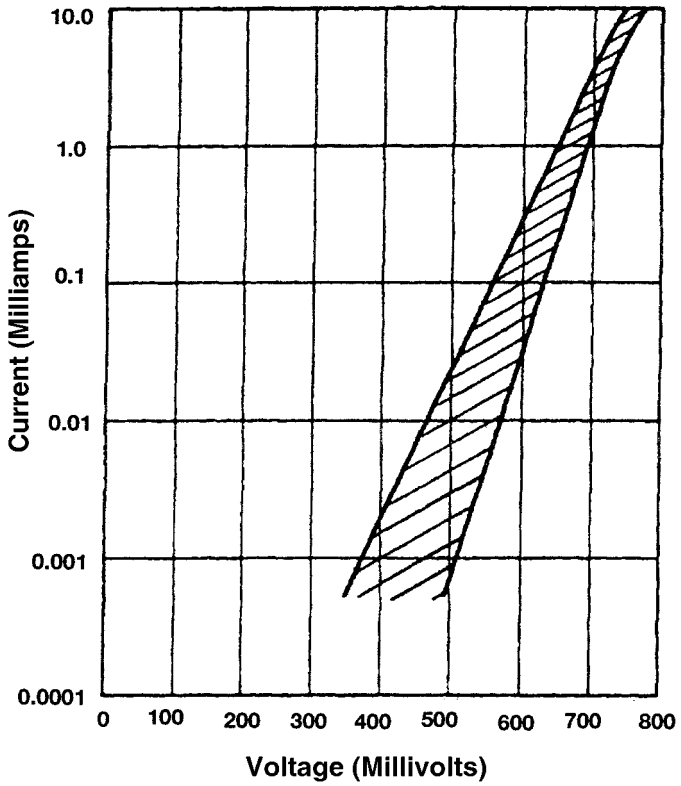

Figure 2-5 Forward dc characteristic curve range—current versus voltage.

(Figure 2-6), and finally some important RF parameters, such as noise figure and IF impedance, as a function of the local-oscillator drive (Figure 2-7).

Mixer Diodes. As an example of some of the parameters for mixer diodes, Table 2-4 gives data on some of the X-band mixer diodes. NF is measured at 9.375 GHz.

Linear Diode Model. Figure 2-8 shows the linear diode model. Its keywords appear in Table 2-5.

The circuit simulators, such as those supplied by Ansoft and Hewlett-Packard, provide a model library that has SPICE-type parameters for diodes (regular diodes, varactor diodes, and PIN diodes) as well as bipolar transistors and FETs, which will be discussed later.

2-1-3 PIN Diodes

Introduction. The PIN diode, in comparison with other microwave semiconductor devices, is fairly easy to understand. This makes possible the reduction of its complex behavior to relatively simple terms.

We do not attempt to describe the many possible microwave circuits in which PIN diodes are used. Rather, we attempt to explain the behavior of the diode in all aspects, giving the facts and some of the theory behind the facts. We offer the circuit designer the opportunity

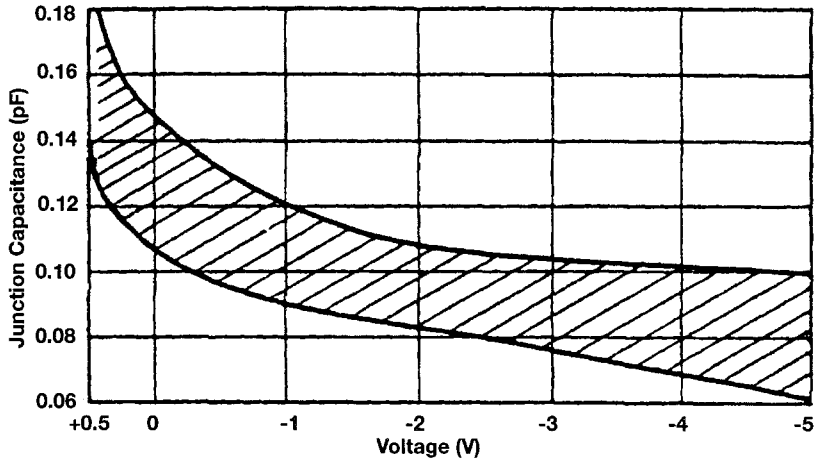

Figure 2-6 Junction capacitance range versus voltage.

to understand the PIN, so that he/she can understand its behavior in circuits. We assume the reader knows the circuit equations; to that knowledge we hope to add diode equations.

Most of the material presented consists of generalized data and explanations of the behavior of PIN diodes; we conclude with a brief description of circuit performance, test methods, and some hints on proper PIN specification writing.

The user can then evaluate the trade-offs involved in diode design and performance and be able to select the most nearly optimum diode from the wide range of diodes offered.

Large-Signal PIN Diode Model. Figure 2-9 shows the large-signal model for a PIN diode. Table 2-6 lists its keywords.

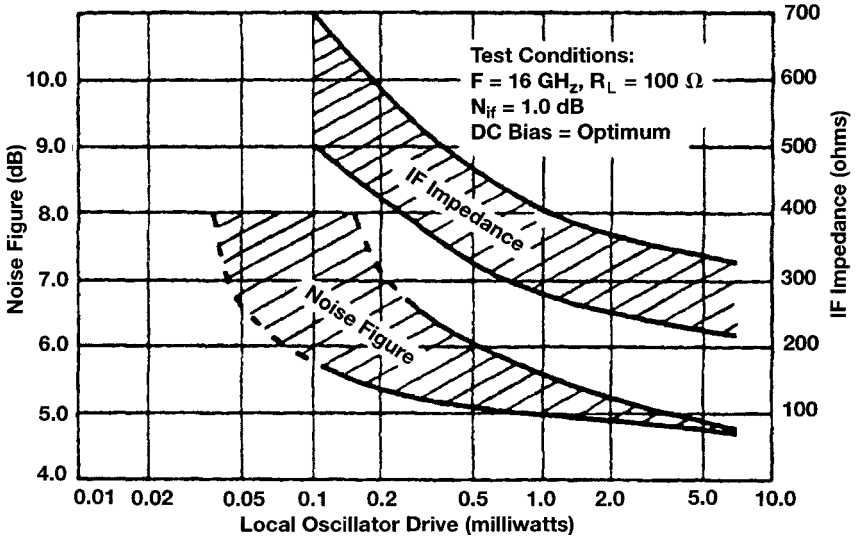

Figure 2-7 RF parameters versus local-oscillator drive level.

Table 2-4 X-band mixer diode data

Material	Barrier	Typical V_F (@1 mA)	Typical F_{C0} (GHz)	Typical R_S (Ω)	Typical C_{J0} (pF)	Maximum NF (dB)
n GaAs	High	0.70	1000	—	0.15	5.0[a]
n GaAs (BL)	High	0.70	500	—	0.15	6.0[a]
n GaAs (chip)	High	0.70	1000	—	0.15	5.3[a]
n Silicon (BL)	Low	0.28	150	6	0.20	6.5
n Silicon (quad)	Low	0.28	150	6	0.20	6.5

[a]Specified for N_F = 1.0 dB.

Basic Theory: Variable Resistance. Intrinsic or "pure" silicon, as it can be grown in a laboratory, is an almost lossless dielectric. Some of is physical properties include:

Dielectric constant (relative)	12
Dielectric strength	400 V/mil (approximate)
Specific density	2.3
Specific heat	0.72 J/g · °C
Thermal conductivity	1.5 W/cm · °C
Resistivity	300,000 Ω/cm

Since a PIN diode is valuable essentially because it is a variable resistor, let us concentrate initially on the resistivity. Consider a volume comparable to a typical PIN diode chip, say, 20 mils in diameter and 2 mils thick. This chip has a dc resistance of about 0.75 MΩ. High

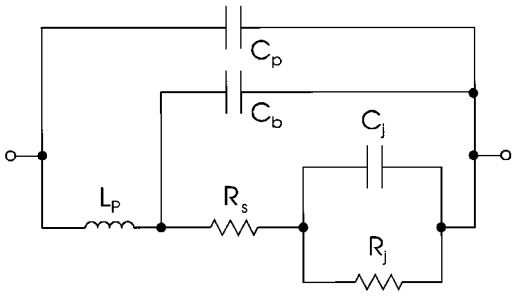

Figure 2-8 The linear diode model. This model is temperature dependent.

Table 2-5 Linear diode model keywords

Keyword	Description	Unit	Default
LP	Package inductance	henry	0.0
CB	Beam-lead capacitance	farad	0.0
CP	Package capacitance	farad	0.0
RS	Contact resistance	ohm	0.0
RJ	Junction resistance	ohm	
CJ	Junction capacitance	farad	

resistivity in any material indicates that most of the likely carriers of electric charge, electrons and holes, are tightly held in the crystal lattice and cannot "conduct."

In real life there are impurities, typically boron, that cannot be segregated out of the crystal. Such impurities contribute carriers, holes or electrons, that are not very tightly bound to the lattice and therefore lower the resistivity of the silicon.

Through various techniques we can adjust the level of impurities, called *dopants*, to produce resistivities ranging from 10 kΩ/cm (for good PIN diodes) to 0.001 Ω/cm (for substrates).

If the impurity adds "electrons" to the crystal, it is called a *donor*; if it adds holes it is called an *acceptor*. Boron adds holes, hence it is an acceptor, and the silicon plus boron combination is called *p*-type, or *positive*, because it has an excess of positive carriers. Phosphorus, on the other hand, is a *donor*, adding electrons, and the corresponding mix is *n*-type, or *negative*.

Notes on the PIN Diode Model

1. The PIN diode model is used to model a bias-dependent RF resistance for use in PIN diode circuits such as attenuators and switches. The resistance varies from RMAX to RS using the R function above. A typical R versus *I* characteristic is shown in Figure 2-10 with parameters IS = 5.96 nA, RS = 2.016, RMAX = 6500, K1 = 0.1272, K2 = 1.0, N = 2.077.
2. The transit-time parameter, TT, can also be used to approximately model a switching PIN diode's reverse-recovery time—a value often provided by diode manufacturers.
3. Diode breakdown can be modeled by specifying IBV and BV parameters.

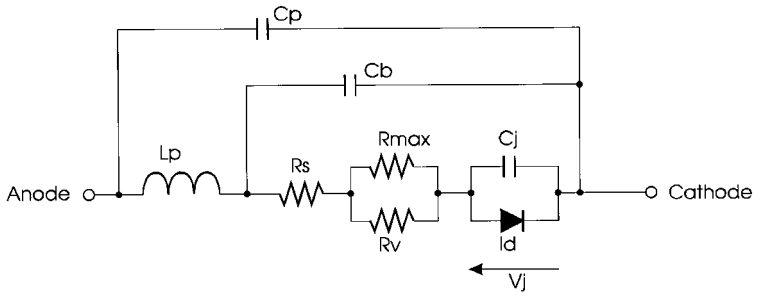

Figure 2-9 The large-signal PIN diode model. This model is temperature dependent.

Table 2-6 PIN diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
IS	Saturation current	ampere	1.0E–14
N	Emission coefficient		1.0
IBV	Magnitude of current at the reverse breakdown voltage	ampere	1.0E–10
BV	Magnitude of the reverse breakdown voltage	volt	∞
FC	Coefficient for forward-bias depletion capacitance		0.5
CJ0	Zero-bias *pn* junction capacitance	farad	0.0
VJ	Built-in junction potential	volt	1.0
M	*pn* Junction grading coefficient		0.5
GC1	Varactor capacitance polynomial coefficient 1	/volt	0.0
GC2	Varactor capacitance polynomial coefficient 2	/volt^2	0.0
GC3	Varactor capacitance polynomial coefficient 3	/volt^3	0.0
TT	Transit time	second	0.0
K1	Variable resistance coefficient	volt	0.0
K2	Variable resistance current exponent		1.0
RMAX	Maximum resistance of PIN intrinsic region	ohm	0.0
KF	Flicker noise coefficient		0.0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
AREA	Area multiplier		1.0
	Extrinsic Model		
RS	Series resistance (minimum resistance of PIN diode)	ohm	0.0
CP	Package parasitic capacitance	farad	0.0
CB	Beam-lead parasitic capacitance	farad	0.0
LP	Package parasitic inductance	henry	0.0

4. The reverse-bias capacitance characteristics can be more accurately modeled than the common expression derived from *pn* junction theory. The capacitance grading coefficient exponent can be expressed as a polynomial function of voltage by specifying values for GC1, GC2, and GC3.
5. The PIN diode model was derived from J. Walston, "SPICE Circuit Yields Recipe for PIN Diode," *Microwaves & RF*, November 1992.
6. Following Simon M. Sze, *Physics of Semiconductor Devices* (New York: John Wiley, 1982), the variable resistance may be modeled by setting

$$\text{K1} = \frac{3}{8} V_T \frac{W^2}{D_a \tau_a} \qquad \text{K2} = 1.0$$

where W is the width of the intrinsic region, D_a is the ambipolar diffusion coefficient, τ_a is the ambipolar lifetime, and V_T is the thermal voltage.

There are many concepts important to the physicist, but not to the diode user, that elaborate on the impact of impurities on the behavior of silicon. These can be studied in Watson [1]. The more carriers added, the lower the resistivity.

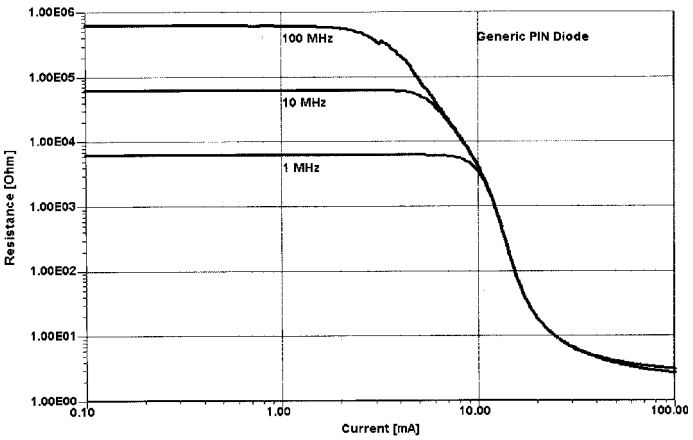

Figure 2-10 Simulated PIN diode resistance as a function of dc at 1, 10, and 100 MHz.

If one wished to vary the resistance of a given diode, in principle he/she could bring it into a semiconductor laboratory, add or subtract carriers as desired, and perhaps even make the process reversible. However, this is a slow, expensive, and impractical way to make a variable resistor; one would be better advised to take a wrench and a soldering iron and replace a component.

The PIN diode derives its value from the fact that the free-charge-carrier concentration in silicon, and hence its resistance, can be varied electronically by means of current from a simple bias supply. This can be done rapidly (in nanoseconds in some cases), reversibly, repeatably, and accurately. The thing that makes this possible is called a *junction*, the interface between the relatively pure silicon in the middle of the PIN diode (the I stands for *intrinsic*) and the heavily doped layers on either end, p^+ and n^+. The p^+ region is rich in holes; the n^+ region is rich in electrons. Both of these regions have low resistance. The I region is the variable resistive element in the diode (see Figure 2-11). In the absence of any external bias, internal effects within the crystal keep the charges fixed; the resistance of the I region is high.

When the p^+ region (anode) is biased positively with respect to the n^+ region (cathode), the interface potential "barrier" is overcome, and direct current flows in the form of holes

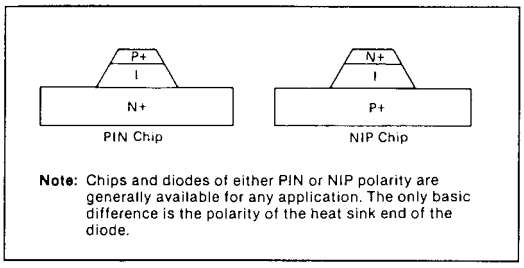

Figure 2-11 General outline of PIN diode construction.

streaming from p^+ toward n^+, with electrons moving in the opposite direction; we say that free carriers have been injected into the I region. The resistance of the I region becomes low.

The number of free carriers within the I region determines the resistivity of the region and thus the resistance of the diode.

Consider "one hole" and "one electron" drifting in opposite directions in the I region under the impetus of the applied field. Under certain conditions, imperfections in the silicon may cause these carriers to recombine. They are no longer available to constitute current or to lower the resistivity of the I region.

It can be shown that the amount of "recombination" between holes and electrons that continuously takes place in a semiconductor is governed by a property of the lattice called *lifetime*. In fact, lifetime is defined as the reciprocal of recombination rate.

Thus, $Q_S = Q_0 \exp(-t/T_L)$, where Q_S is the total amount of free charge "stored" in the I region, and T_L is the lifetime, or the mean time between recombination events. In the steady-state condition, the bias supply must deliver current to maintain a constant Q_S. The required current is

$$I_{\text{dc}} = \frac{Q_S d}{dt} = \frac{-Q_S}{T_L} \tag{2-27}$$

or $Q_S = I_{\text{dc}} T_L$, dropping the minus sign.

Ignoring some details that are not crucial to this section, we can now calculate the resistance of a given diode, of area A and thickness W. (W stands for *base width*, the width or thickness of the intrinsic layer.) The p^+ and n^+ regions have essentially zero resistance, as they are very heavily doped.

The resistivity of a given material is inversely proportional to the number of free carriers, N, and the mobility (not quite the same as velocity) of the carriers. Thus,

$$\rho = \frac{1}{q(\mu_n N + \mu_p P)} \tag{2-28}$$

where μ_n and μ_p are mobilities of electrons and holes, and N and P are numbers of electrons and holes. Simplifying, we find

$$\rho = \frac{C}{Q_S d} \tag{2-29}$$

where C is a collection of constants, and $Q_S d$ is the stored charge density (numbers per unit volume). For our piece of silicon, volume is WA, and

$$Q_S d = \frac{Q_S}{WA} \tag{2-30}$$

The resistivity is

$$\rho = \frac{CWA}{Q_S} \tag{2-31}$$

and the resistance is

$$R_S = \rho \frac{W}{A} = \frac{CW^2}{I_{\text{dc}} T_L} \tag{2-32}$$

This is a fundamental equation in PIN diode theory and design.

Rigorous analysis shows that

$$R = \frac{2kT/q}{I_f} \sinh\left(\frac{W}{2\sqrt{DT_L}} \tan^{-1}\left[\sinh\frac{W}{2\sqrt{DT_L}}\right]\right) \tag{2-33}$$

where k = Boltzmann's constant
T = temperature (in kelvins)
D = diffusion coefficient = $\mu kt/q$

For most PIN diodes, W/DT_L is less than unity, and the equation simplifies to the simple equation above.

Typical data on R_S as a function of bias current are shown in Figure 2-12. Many design choices are available, as the data indicate. Many combinations of W and T_L have been developed to satisfy the full range of applications.

Breakdown Voltage, Capacitance, Q Factor. The previous section on R_S explained how a PIN can become a low resistance, or a "short." This paragraph will describe the other state: a high impedance, or an "open." Clearly, the better PIN diode is the one that has the better on/off ratio at the frequency and power level of interest.

If we return to the undoped or intrinsic I region, we note that it is an almost lossless dielectric. As such, it has a dielectric strength of about 400 V/mil, and all PIN diodes have

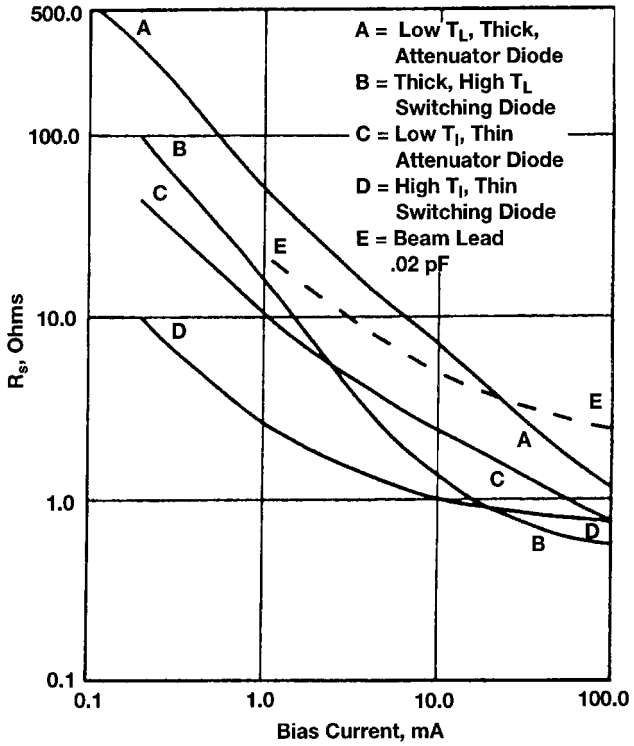

Figure 2-12 Typical series resistance as a function of bias (1 GHz).

a parameter called V_b, breakdown voltage, which is a direct measure of the width of the I region. Voltage in excess of this parameter results in a rapid increase in current flow (called avalanche current); see Figure 2-13. When the negative bias voltage is below the bulk breakdown of the I region, a few nanoamperes will be drawn. As V_b is approached, the leakage current increases often gradually, as is exaggerated in the curve. This current is primarily caused by less-than-perfect diode fabrication, although there is some contribution from temperature. Typically, the leakage current occurs at the periphery of the I region. For this reason, various *passivation* materials (silicon dioxide, silicon nitride, hard glass) are grown or deposited to protect and stabilize this surface and minimize leakage. These techniques have been well advanced over the years, and PIN diode reliability has improved as a result.

Most diodes are specified in terms of minimum V_b for a nominal leakage, usually 10 μA.

It will be noted later that RF voltage swings in excess of the rated V_b are permitted, for the mechanisms causing leakage current do not always respond at radiofrequencies. However, bulk breakdown is effectively instantaneous, and that voltage should never be exceeded.

The next characteristic of our "open" circuit is the capacitance. In simplest form, the capacitance of a PIN diode is determined by the area and width of the I region and the dielectric constant of silicon; however, we have discussed the fact that intrinsic material does contain some carriers and therefore has some conductivity. An *E* field could not exist unless all these carriers were swept out, or depleted.

Application of a reverse bias accomplishes this. At zero bias, the excess carriers on either side of the junction are separated, held apart, by "built-in" fields. This is the contact potential (about 0.5 V for silicon). If there are only a few excess carriers in the I region, this "potential" can separate the charges more easily. The junction "widens" in the sense that, starting at the p^+ and I interface, there is a region of no free carriers called the *depletion zone*. Beyond this depletion zone, the I region still contains the free charges with which it started. With the application of reverse bias, the depletion zone widens.

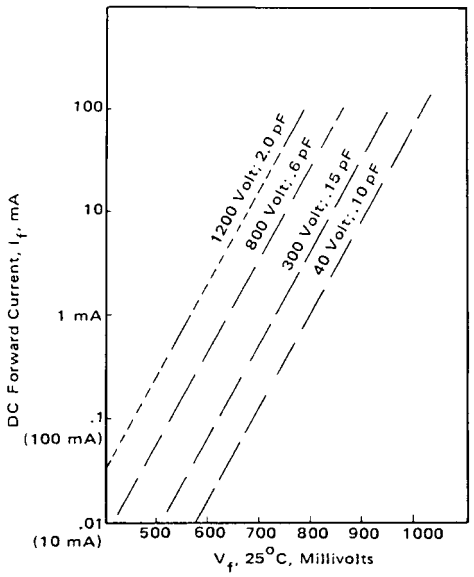

Figure 2-13 Current versus voltage for various PIN diodes.

Eventually, at a bias equal to a so-called *punchthrough* voltage (V_{PT}), the depletion zone fills the entire I region. At this voltage, the 1-MHz capacitance bottoms out and the diode Q reaches its maximum. Figure 2-14 illustrates the equivalent circuit of the I region before punchthrough.

Some very interesting facts can be derived from this model. Consider the undepleted region; this is a lossy dielectric consisting of a volume (area A, length ℓ) of silicon of permittivity 12 and resistivity ε. The capacitance is

$$12\frac{\varepsilon_0 A}{\ell} \tag{2-34}$$

and the admittance is

$$2\pi\frac{12\varepsilon_0 A}{\ell} \tag{2-35}$$

The resistance is $\varepsilon\ell/A$ and the conductance is $A/\varepsilon\ell$.

At very low frequencies, the undepleted zone looks like a pure resistor. At very high frequencies it looks like a lossy capacitor. The "crossover" frequency depends on the resistivity of the I-region material. For ε of 160 Ω/cm, the frequency is 1 GHz. Higher resistivity is generally used for PINs—say, 1000 Ω/cm, and the crossover frequency is 160 MHz.

Diode manufacturers measure junction capacitance at 1 MHz; clearly, what is measured is the depletion-zone capacitance.

If the I region thickness is W and the depletion is X_d, the undepleted region is $(W - X_d)$.

The capacitance of the depleted zone is, proportionally,

$$\frac{1}{X_d} \tag{2-36}$$

and of the undepleted zone,

$$\frac{1}{W - X_d} \tag{2-37}$$

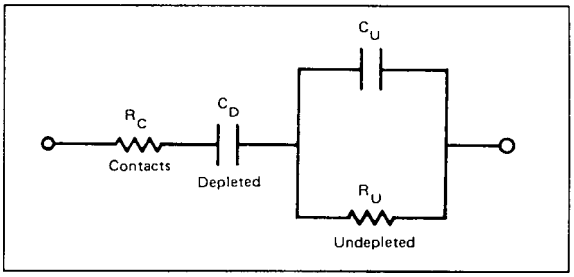

Figure 2-14 Equivalent circuit of I region before punchthrough.

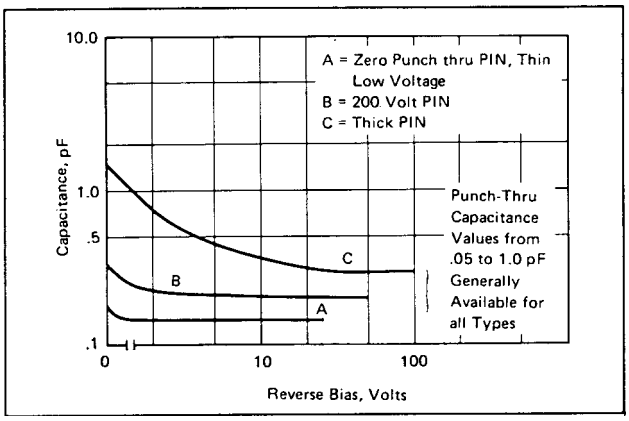

Figure 2-15 Typical 1-MHz capacitance.

The 1-MHz capacitance as a function of reverse bias is seen in Figure 2-15. The 1-MHz capacitance decreases with bias until punchthrough, where $X_d = W$. However, at microwave frequencies well above the crossover, the junction looks like two capacitors in series:

$$C_T = \frac{C_d C_u}{C_d + C_u} \propto \frac{1}{W} \tag{2-38}$$

That is, the microwave capacitance tends to be constant, independent of X_d and bias voltage.

However, since the undepleted zone is lossy, an increase in bias up to the punchthrough voltage reduces the loss.

At any given frequency, the equivalent network can now be drawn as Figure 2-16. R_v is now the equivalent series resistance of the undepleted region. Typical R_v data are shown in Figure 2-17. An alternate equivalent network is shown in Figure 2-18, and typical R shunt data are shown in Figure 2-19.

A good way to understand the effects of series resistance is to observe the insertion loss of a PIN chip shunt mounted in a 50-Ω line, as shown in Figure 2-20. An accepted way to include reverse loss in the figure of merit of a PIN diode is to write

$$Q = \frac{1}{2\pi + \sqrt{R_s R_v C}} \tag{2-39}$$

where R_s and R_v are measured under the expected forward- and reverse-bias conditions at the frequency of interest.

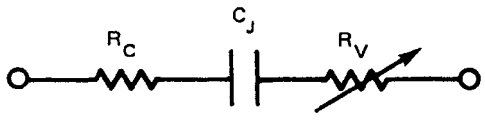

Figure 2-16 Simplified equivalent series circuit.

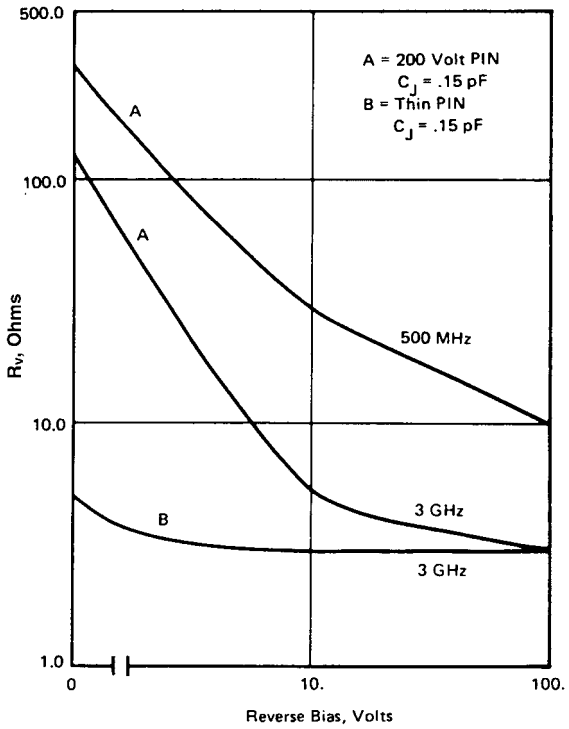

Figure 2-17 Reverse series resistance R_V.

The punchthrough voltage is a function of the resistivity and thickness of the I region. It is advisable to measure loss as a function of bias voltage and RF voltage to determine if the correct diode has been selected for your application. (*Note*: At frequencies below crossover, and diodes with thin I regions, the effective junction capacitance can increase substantially at low forward bias, on the order of 1–200 μA.)

Incidentally, if you are working with PIN or NIP chips that do not have an opaque covering, note that PIN diodes are photosensitive. Incident light causes photogeneration of carriers in the I region, increasing the chip's insertion loss.

PIN Diode Applications. If the intrinsic zone is thick (10–100 μm), we then have a high-reverse-voltage rectifier with a low forward-voltage drop at high current or, in other

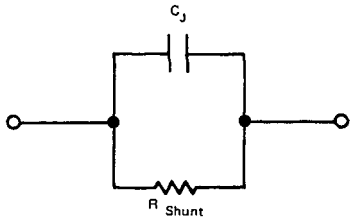

Figure 2-18 Simplified equivalent circuit, shunt.

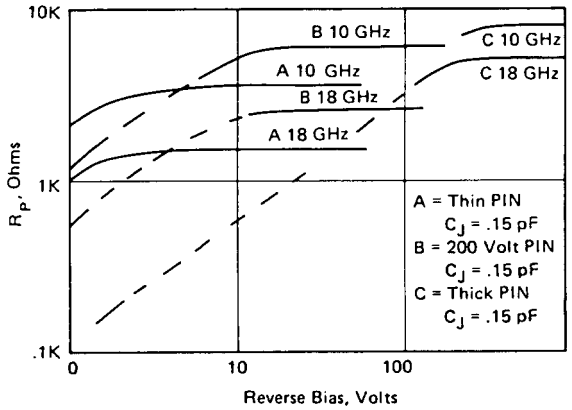

Figure 2-19 Reverse shunt resistance, R_p.

words, a highly efficient rectifier. The low forward voltage results from the fact that the conductivity of the I zone can be modulated by large amounts of charge carriers injected from the *p* and the *n* zones.

Another application of PIN diodes is the high-frequency (HF) field. Here, the fact is exploited that, due to the long carrier lifetime at frequencies beyond approximately 10 MHz, a rectifying effect will no longer occur and the PIN diode rather behaves like a real resistance, the magnitude of which depends on the forward direct current passed by the device and

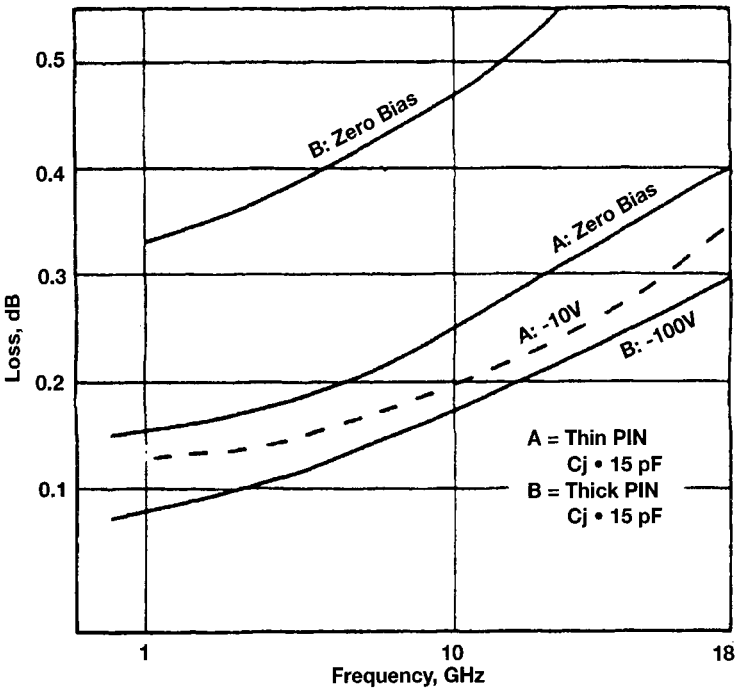

Figure 2-20 Insertion loss versus frequency.

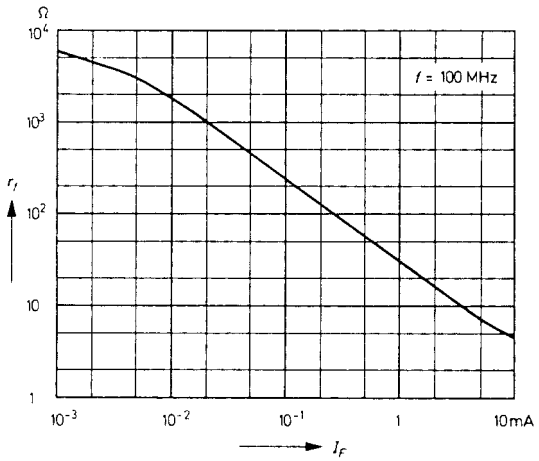

Figure 2-21 Forward resistance versus forward current.

produces an equal effect on both half waves of the HF signal. In view of this behavior, the PIN diode can be used as a switch or a variable resistor for HF signals. Thus it becomes possible, for example, to subject an HF signal to amplitude modulation by means of an AF-controlled PIN diode.

An important application of PIN diodes that has found favor in recent times is for dc-operated attenuators in TV tuners and antenna distribution amplifiers. Figure 2-21 shows the real HF forward resistance r_f as a function of the forward current I_f, measured at 100 MHz. Figures 2-22 and 2-23 show second-order IMD and cross-modulation for PIN diodes.

Applying the PIN in Amplitude Control of High-Frequency Signals. In conventional transistorized TV tuners, automatic gain control (AGC) is usually achieved by varying the emitter current of the input transistor. This method exploits the fact that the input transistor exhibits maximum gain at a certain level of emitter current and that this gain decreases when the emitter current is either increased or decreased relative to this point. Since modulation capacity and cross-modulation resistance grow with the emitter current, "upward" gain control has lately become the preferred solution, and according to it, gain reduction is achieved by an increase of the input transistor's emitter current. An input stage based on this design, therefore, is least resistant to cross-modulation when receiving a signal from a weak transmitter because it is operating at or below the point at which AGC action begins. This effect is particularly disadvantageous when the signal of a weak transmitter is to be received in the presence of a strong local transmitter. The unsatisfactory cross-modulation properties of such an input stage manifest themselves more and more frequently in the form of image perturbations as the TV reception band is crowded by an increasing number of transmitters. Another disadvantage is the variation in the transistor parameters that results from the control action. The variations affect antenna matching at the input and the response of the RF filter at the output.

To obviate these problems, methods being adopted today provide for the input stage to be equipped with cross-modulation-resistant transistors with fixed bias, gain control being provided by a variable attenuator preceding the transistor(s). The input-filter termination

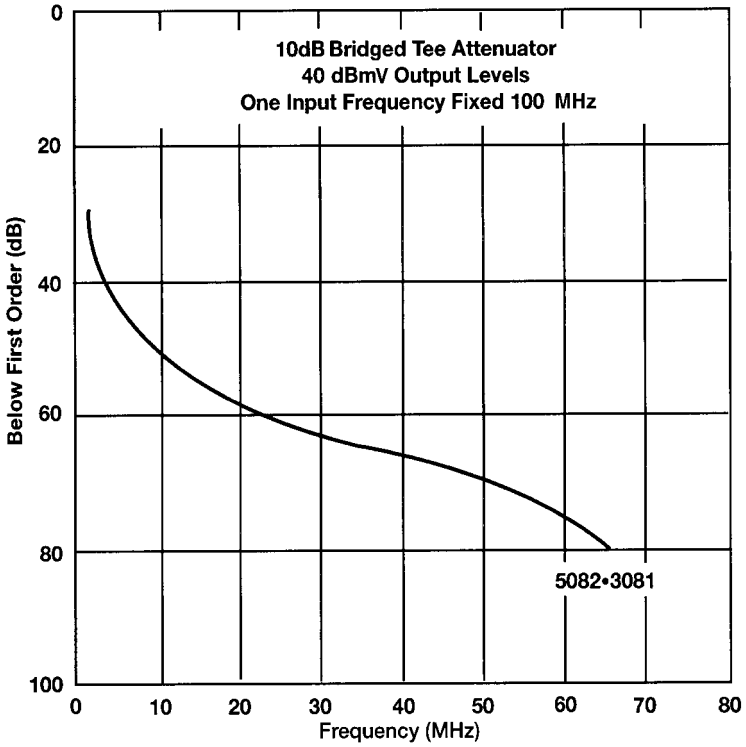

Figure 2-22 Second-order IMD in a PIN diode. Equation (1-48) can be used to determine the diode's IP_2 from the absolute values of its fundamental and IM_2 outputs.

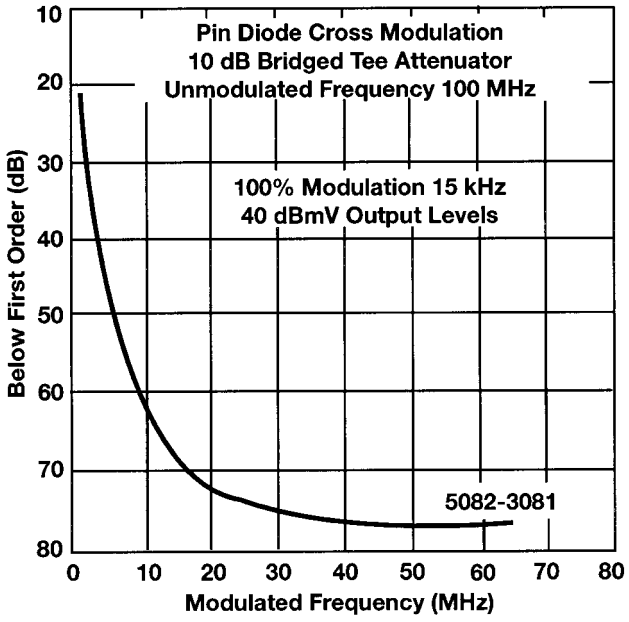

Figure 2-23 Cross-modulation in a PIN diode. Equation (2-61) relates cross-modulation level to IMD.

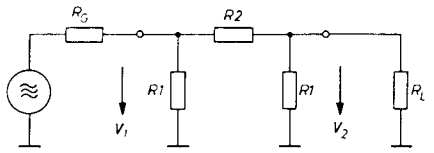

Figure 2-24 Basic circuit of a π-mode filter attenuator.

provided by this attenuator must be independent of the degree of attenuation to preserve the filter's response characteristics.

The first two requirements are met by the properties of the PIN diode and the latter requirement can be met by designing a PIN diode control in the form of a π network, a schematic of which is shown in Figure 2-24. The attenuation of a matched π network is expressed by the following equations:

$$\frac{a}{\text{dB}} = 20 \log \frac{Z + R_2}{R_2 - Z} \tag{2-40}$$

$$\frac{a}{\text{dB}} = 20 \log \left(\frac{R_1}{Z} + \sqrt{\frac{R_1^2}{Z^2} + 1} \right) \tag{2-41}$$

Figure 2-25 plots the relationship between the resistance levels of R_1 and R_2 and the input and output voltages of the π network. Figure 2-26 shows the circuit diagram of an implementation of the π network composed of PIN diodes. The resistance characteristic required according to Figure 2-25 is achieved approximately by varying the control current I_{co}.

If the control current I_{co} in Figure 2-26 equals zero, then—due to the fact that $R_1 = R_2$ and $R_3 = R_4$—the auxiliary voltage V_h causes forward currents of equal magnitude to flow through diodes D_1 and D_3. The voltage drops across R_1 and R_2 are of equal magnitude, so that no current passes through diode D_2. Therefore, the latter presents a high resistance, whereas D_1 and D_3 present a low resistance. Under these conditions, the network produces maximum attenuation. A control current I_{co} reduces the forward currents through D_1 and D_3 and allows a forward current to be passed by diode D_2. When it has attained its maximum value, diodes

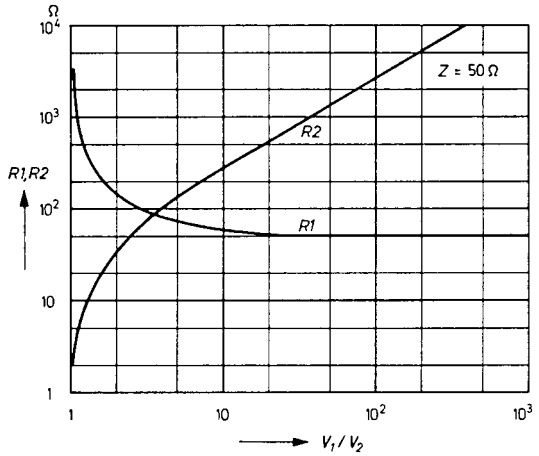

Figure 2-25 Values of R_1 and R_2 in Figure 2-24 versus relation of input and output voltage.

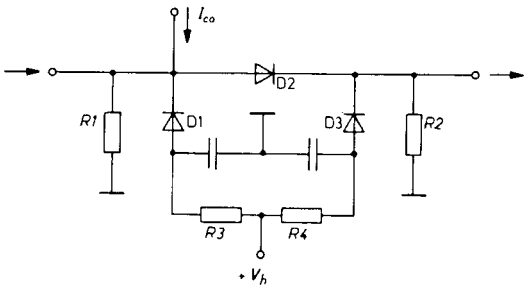

Figure 2-26 PIN diode π-mode attenuator.

D_1 and D_3 are blocked—that is, they are high-ohmic—and D_2 is low-ohmic. Under these conditions, the network produces its minimum attenuation.

If the maximum attenuation of the π network is to be increased, it is possible to make the two shunt diodes D_1 and D_3 more low-ohmic than the impedance Z, although this would reduce the reflection coefficient of attenuation. For example, if a reflection coefficient of about 7 dB is accepted over the entire control range, then a maximum attenuation of 25–30 dB could be achieved in the VHF range. The series inductances of the transverse diodes and the shunt capacitance of the series diode are responsible for this relatively unsatisfactory value. Improved attenuation is brought about with the integrated π network described in the next section.

Example: A PIN Diode π Network for TV Tuners. The since-discontinued TDA1053 is an example of an integrated PIN π network attenuator intended for TV-tuner use. It comprises three silicon planar PIN diodes connected to form a π network (Figure 2-27) and serves for the electronic amplitude control of the input signals of TV tuners and antenna distribution amplifiers in the 40–1000-MHz range. Its input and output impedances remain constant over the entire control range. This can also be achieved with discrete diodes.

The TDA1053 was normally supplied with vertical leads. The characteristics stated below apply to devices of this configuration.

MAXIMUM RATINGS OF INDIVIDUAL DIODES

Reverse voltage	V_R	30	V
Forward current at $T_{amb} = 25$ °C	I_F	50	mA
Junction temperature	T_j	125	°C
Storage temperature range	T_s	−55 to +125	°C

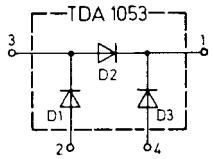

Figure 2-27 Internal circuitry of the TDA1053.

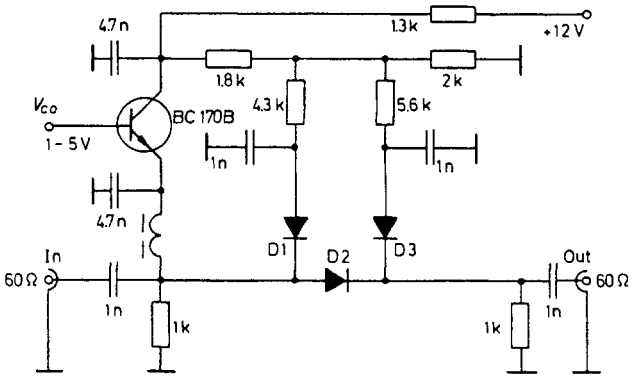

Figure 2-28 Test and application circuit.

MAXIMUM RATINGS OF THE π NETWORK

Ambient operating temperature range when operating according to Figure 2-28	T_{amb}	100	°C

CHARACTERISTICS OF INDIVIDUAL DIODES AT T_{amb} = 25 °C

Forward voltage at I_F = 50 mA	V_F	< 1.2	V
Forward current at V_R = 15 V	I_R	< 500	nA
Differential forward resistance:			
At I_F = 10 mA, f = 100 MHz	r_f	5	Ω
At I_F = 10 µA, f = 100 MHz	r_f	1.4	kΩ

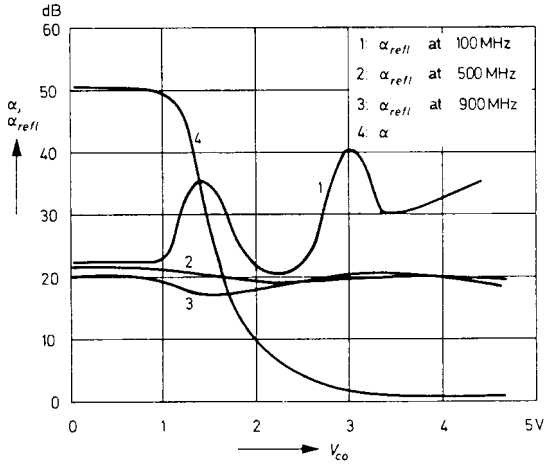

Figure 2-29 Attenuation and reflection attenuation versus control voltage.

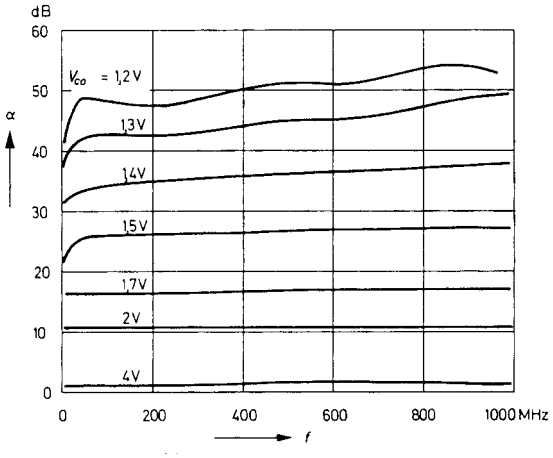

Figure 2-30 Attenuation versus frequency.

CHARACTERISTICS IN THE TEST CIRCUIT (FIGURE 2-28) AT T_{amb} = 25 °C

Voltage for 1% cross-modulation	V_{cr}	1	V
Attenuation in the 40–1000-MHz range:			
At V_{co} = 1.5 V (1–2 V)	a_{max}	45 (> 36)	dB
At V_{co} = 5 V (4–5 V)	a_{min}	1.5 (< 2)	dB
Reflection coefficient in the 40–1000-MHz range over the entire control range, depending on circuit design	a_{refl}	20 (> 16)	dB

These data reveal that the compact design of the three PIN diodes in a common 50B4 plastic package guarantees favorable values for minimum and maximum attenuation, as well as reflection attenuation. The test and application circuit shown in Figure 2-28 also comprises the transistor control-signal amplifier. The typical characteristic of the attenuation and the reflection attenuation for this circuit are shown in Figure 2-29, as a function of the control voltage V_{co}. Figure 2-30 shows the attenuation at different control voltages, as a function of frequency.

2-1-4 Tuning Diodes

Introduction. In recent years, continuous development of tuning diodes—also known as *varactors* or *varicaps*—together with increased commercial and military use has led to substantial improvement in Q, reproducibility, and reliability. Concurrently, new techniques for producing and controlling a hyperabrupt dopant profile in the semiconductor permit the capacitance–voltage law to be much faster than the classical square root or cube root behavior.

Current tuning diode materials include silicon and gallium arsenide; silicon is favored for low cost and lower Q applications from HF through microwave frequencies. Hyperabrupt varactors, also of silicon, are finding many applications in commercial television tuners, where their high tuning ratios, linear tuning, and low cost are needed. New developments include low-capacitance hyperabrupts for microwave and wireless applications.

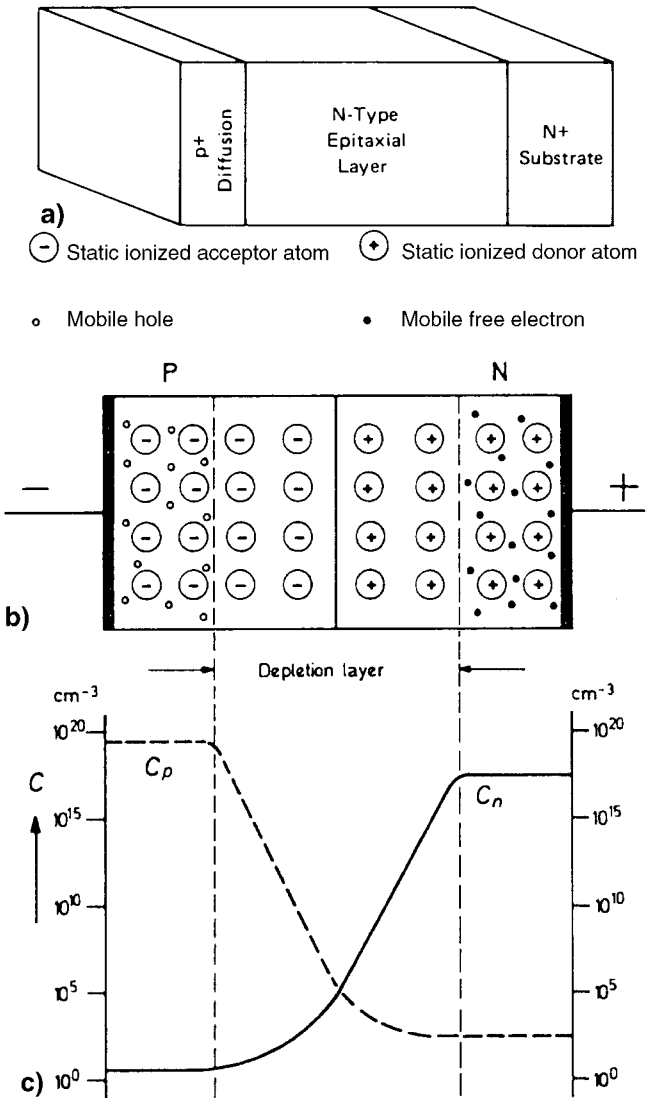

Figure 2-31 (a) Basic PIN structure; (b) cross section of a reverse-biased *pn* junction; and (c) density distribution of free charge carriers.

Gallium arsenide is used with high operating frequency and dictates the highest Q possible, as in parametric amplifiers and millimeter multipliers.

This section will acquaint the reader with tuning diodes: how they work, and what they can or cannot be expected to do in an electronic circuit. The basic properties of a tuning diode will be described in terms of the parameters that manufacturers use in characterizing them. The following topics will also be addressed:

- Capacitance ratio with respect to voltage and voltage breakdown
- Q as a function of design and operating conditions

- Stability—leakage current, temperature coefficient, and post-tuning drift
- Distortion products
- Packaging parasitics
- Applications—suggestions on how to specify a varactor

Tuning Diode Physics

Introduction. All junction diodes are made up of the same physical parts: a *pn* junction, a carefully controlled epitaxial layer, and a very-low-resistance substrate. These parts are shown in Figure 2-31.

No matter what type of junction device we are discussing—a tuning diode, a step-recovery diode, or a PIN diode—these parts are all present; the main difference between these devices is the resistivity and thickness of the epitaxial layer. Tuning diodes and multiplier diodes need epitaxial layers where both the resistivity and thickness are carefully controlled.

Abrupt Junction. An abrupt-junction diode is one in which the p^+ diffused region of the diode is much more highly doped than the epitaxial layer. Also, the high doping drops to the doping level of the epitaxial layer in a distance that is short compared to the epitaxial layer thickness, and the doping level of the epitaxial layer is constant over its thickness. This is shown in Figure 2-32, with the corresponding C–V curve shown in Figure 2-33. When these requirements are satisfied, the diode capacity, diode area, epitaxial layer doping level, and diode voltage are related by

$$\frac{C(V)}{A} = K\left(\frac{N}{V+\varphi}\right)^n \tag{2-42}$$

where $C(V)$ = capacitance of the diode at voltage V
A = area of the diode
N = doping level of the epitaxial layer

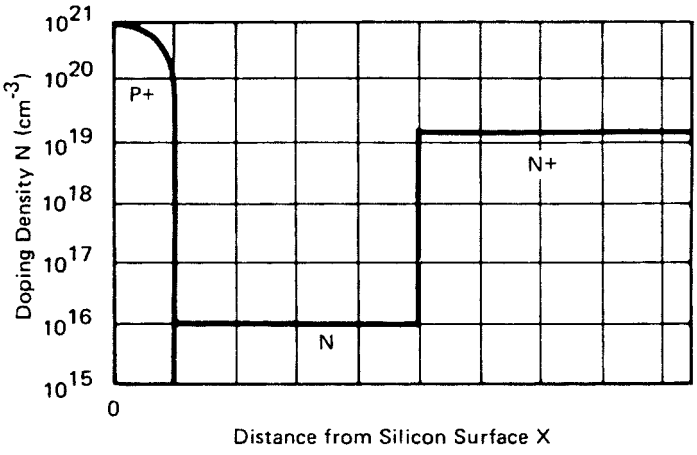

Figure 2-32 *N–X* abrupt junction.

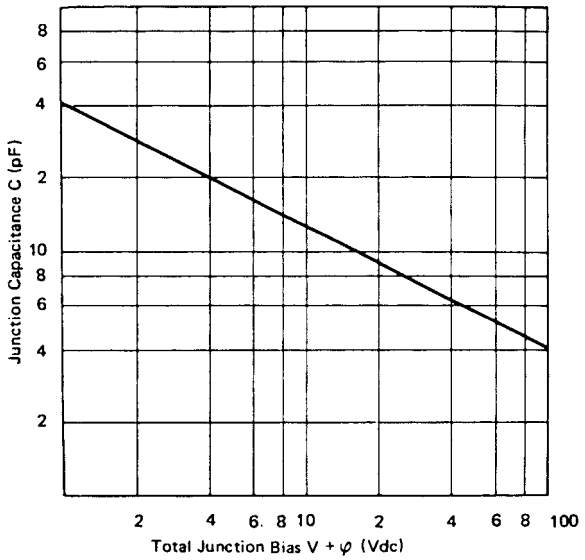

Figure 2-33 Capacitance versus total junction bias for abrupt-junction diode.

V = voltage applied to the diode
φ = built-in potential of the diode (0.6–0.8 V)
n = slope of diode C–V curve; $n \approx 0.5$ for an abrupt-junction diode
K = constant

As a consequence of the physical properties of a *pn* junction, a depletion layer is formed between the *p* and *n* regions whose width depends on the voltage applied to the diode. The capacitance of the diode is inversely proportional to the width of the depletion layer; that is, $C \sim 1/\ell_0$. In addition, the series resistance of the diode is proportional to the width of the undepleted epitaxial layer. Thus, as diode reverse bias is increased, the depletion layer increases, causing a decrease in capacitance and a decrease in series resistance. As the diode reverse bias is increased further, a point is reached where the electric field caused by the reverse bias reaches a critical level, and current through the diode increases rapidly; this is

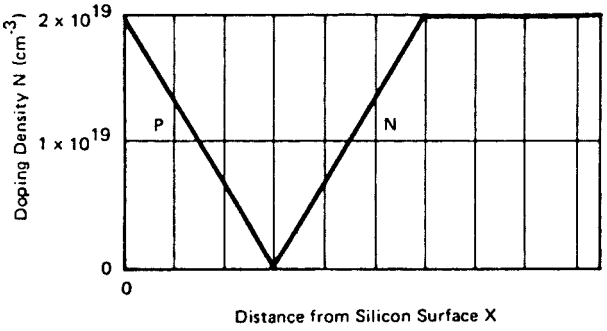

Figure 2-34 *N–X* linearly graded junction.

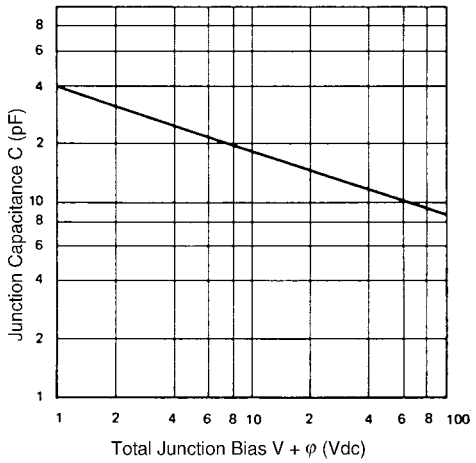

Figure 2-35 Capacitance versus total junction bias for linearly graded junction.

breakdown voltage of the diode. If, at the breakdown voltage, the epitaxial layer is not completely depleted, the diode will have excessive series resistance. Conversely, if the epitaxial layer is depleted before the breakdown voltage is reached, no further capacitance decrease occurs after the total depletion, and a condition called *punchthrough* occurs.

While, in the ideal case, voltage breakdown will occur just as the epitaxial layer is totally depleted, this seldom occurs in practice, and we generally have a condition of either punchthrough or excess series resistance.

Linearly Graded Junction. If, instead of the junction profile shown in Figure 2-32, we have a p^+ region and an n region whose doping levels increase linearly with distance from the pn junction as shown in Figure 2-34, with its corresponding C–V curve in Figure 2-35, then we have what is called a linearly graded junction diode. This diode follows Eq. (2-42) with the exception that the exponent n is equal to $\frac{1}{3}$. This means that, for a given voltage change, the linearly graded junction will have a smaller capacitance change than an abrupt-junction diode. Since, in most cases, the designer is looking for the maximum

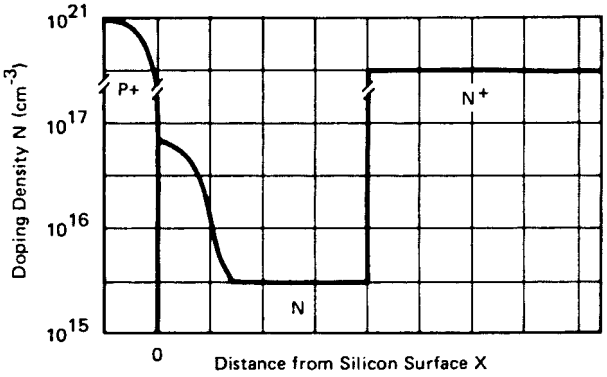

Figure 2-36 *N–X* hyperabrupt-junction diode.

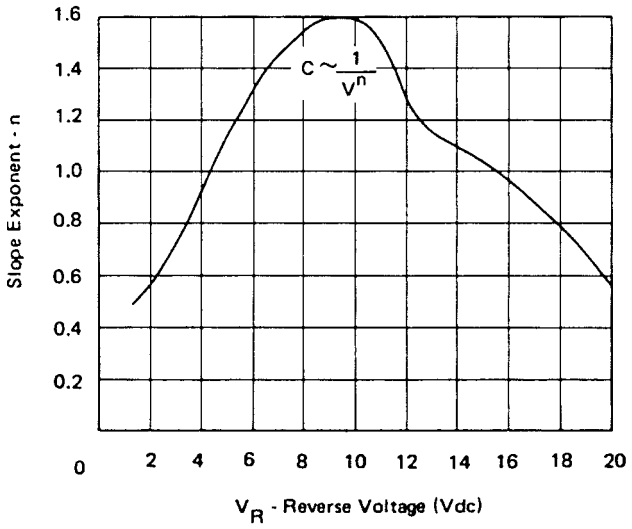

Figure 2-37 Typical *n* versus reverse voltage characteristic for hyperabrupt-junction diode.

capacitance change obtainable, the linearly graded junction is not used as a tuning diode. This structure found its greatest use several years ago as a "cube law" multiplier, but even this use has decreased as new structures have been developed.

Hyperabrupt Junction. The hyperabrupt-junction diode provides a greater capacitance change than the abrupt-junction diode for a given voltage change, as well as a linear frequency versus voltage characteristic over a limited voltage range. The structure of the hyperabrupt-junction diode is shown in Figure 2-36 and can be seen to be an abrupt-junction diode with an additional, increased doping level at the *pn* junction. This diode also follows Eq. (2-42) with the exception that n is not a function of voltage and is generally in the range of 0.5–2. A typical curve of n versus voltage is shown in Figure 2-37.

The C–V curve in a hyperabrupt-junction diode is shown in Figure 2-38 and is seen to start at a high value of capacitance per unit area at low bias (high epitaxial doping) and change to a lower value of capacitance per unit area (low epitaxial doping) at high bias. The details of the curve depend on details of the shape of the more highly doped region near the *pn* junction.

Unfortunately, with a hyperabrupt-junction diode, you must settle for a lower Q than an abrupt-junction diode with the same breakdown voltage and same capacitance at 4 V.

It should be noted that any diode that has an n value that exceeds 0.5 at any bias voltage is, by definition, a hyperabrupt-junction diode. Thus, the hyperabrupt-junction diode family can have an infinite number of different C–V curves. Since the abrupt-junction diode has a well-defined C–V curve, the capacitance value at one voltage is sufficient to define the C–V capacitance at any other voltage. This is not the case for the hyperabrupt-junction diode. In order to adequately define the C–V characteristics of a hyperabrupt-junction diode, two and sometimes three points on the curve must be specified.

Silicon Versus Gallium Arsenide. Everything mentioned so far applies to both silicon and gallium arsenide (GaAs) diodes. The main difference between silicon and GaAs from a

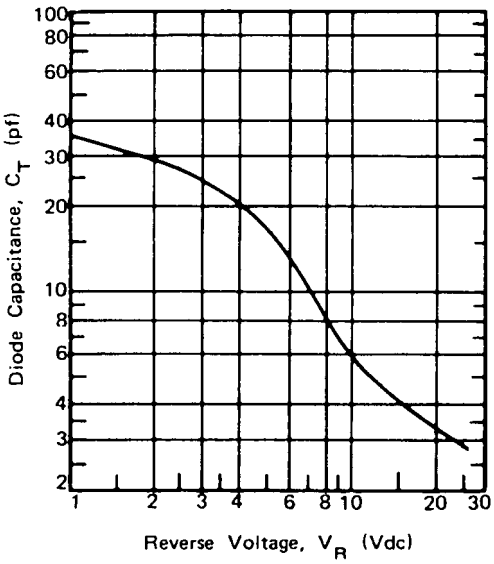

Figure 2-38 Capacitance versus junction bias for hyperabrupt-junction diode.

user's point of view is that higher Q can be obtained from GaAs devices. This is due to the lower resistivity of GaAs from a given doping level N. The resistivity of the epitaxial layer, or substrate, of a diode is given by

$$\rho = \frac{1}{Ne\mu} \tag{2-43}$$

where ρ = the resistivity
N = the doping level of the layer
e = the charge on an electron
μ = is the mobility of the charge carriers in the layer

Gallium arsenide has a mobility about four times that of silicon and, thus, a lower resistivity and higher Q for a given doping level N. Since diode capacitance is proportional to $\sqrt{N}$, independent of resistivity, a silicon diode and a GaAs diode of equal area and doping will have a capacitance difference proportional to the square root of the dielectric constant ratio. This gives the GaAs diode a 5% higher capacitance and is thus of little practical significance. The penalty paid for using GaAs is an unpassivated diode and a more expensive diode due to higher material and processing costs. If the higher Q of the GaAs device is not really needed, a substantial price saving will be obtained by using a silicon device.

Planar Versus Mesa Construction. The two basic construction techniques used to manufacture tuning diodes are planar and mesa; cross sections for both of these devices are shown in Figure 2-39. The planar process, which is the backbone of the integrated circuit industry, lends itself to large-volume production techniques and is the one used for the 1N series of tuning diodes. Mesa processing, on the other hand, requires more

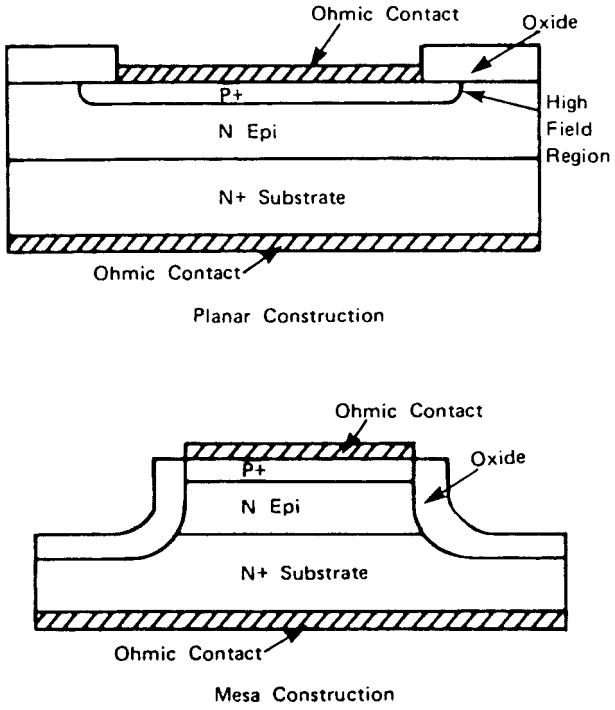

Figure 2-39 Cross sections of planar and mesa devices.

processing steps and is generally done on a wafer-by-wafer basis. This results in a more costly process and thus a more expensive diode. All microwave tuning diodes are of mesa design because of greatly higher Q. Due to the relatively small radius of curvature at the junction edge of a planar diode, the electric field in this area is greater than the electric field in the center (flat) portions of the junction. As a result, the breakdown voltage of the diode is determined by both the epitaxial resistivity and the radius of curvature of the junction edge. Thus, for a given breakdown voltage, a planar diode must use higher resistivity epitaxial material than a mesa diode, which has a completely flat junction. The end result is that the planar diode has a greater series resistance than a mesa diode for the same capacitance and breakdown voltage, and thus lower Q.

Capacitance

Capacitance Ratio. From the user's point of view, the capacitance ratio is simply the capacitance change available in the circuit. Thus, a user tuning from, say, –4 to –45 volts defines capacitance ratio as

$$R = \frac{C_T(-4)}{C_T(-45)} \tag{2-44}$$

where C_T includes C_J plus C_P plus C_F. The manufacturer, however, defines C_T as $C_J + C_P$.

To explore the significance of this difference, let's take two examples, one with a large C_J and another with a small C_J, in chip, package, and "typical" fringe situations. Both are 45-V tuning varactors.

Device	C_{J0}	C_{J45}	Ratio
A	0.6 pF	0.1 pF	6.0
B	15.0 pF	2.5 pF	6.0

Put both devices in a standard 023 package with C_P (strap and ceramic) of 0.18 pF:

Device	C_{T0}	C_{T45}	Ratio
C	0.78 pF	0.28 pF	2.75
D	15.18 pF	2.68 pF	5.67

Notice the drop in capacitance ratio, especially for the low-C_J diode. If we now add a typical 0.04 pF for external fringe capacitance, we get the following results:

Device	C_{T0}	C_{T45}	Ratio
C	0.82 pF	0.32 pF	2.56
D	15.22 pF	2.72 pF	5.6

The reduction in capacitance ratio, and thus circuit tuning capability, by the fringing fields is quite obvious and amounts to 7% in this example.

Because of the often stringent specifications on tuning ratio, it is mandatory that the manufacturer and customer clearly agree on the exact design of the holder used to measure the varactor in question.

Having described how to measure capacitance, it is relatively easy to describe the results. The section on diode physics described the various types of "laws," or C–V curves, and we will not repeat them here. Nonetheless, several important points must be covered.

The first is "available capacitance swing." The laws indicate a steadily decreasing capacitance with voltage, which indicates that the epitaxial region is widening and the electric field is increasing. (For an abrupt junction, since $C \propto 1/\sqrt{V}$, the depletion zone with W is increasing as $\sqrt{V}$, and the electric field V/W increases as $\sqrt{V}$.)

Two things can happen:

1. The junction width widens so that the entire intrinsic region is depleted. The capacitance bottoms out, resulting in voltage punchthrough.
2. The electric field exceeds the dielectric strength of silicon (or GaAs), and "solid-state discharge" or "avalanche" current is drawn.

The diode impedance drops, the varactor no longer "varacts," and circuit operation ceases. Moreover, if more than a few milliamperes of current is drawn, localized overheating may destroy the diode, resulting in breakdown voltage. All varactors are characterized for breakdown voltage—for example, 45 V minimum.

The theoretical tuning varactor is designed so that the punchthrough occurs at a voltage equal to the voltage breakdown of the diode. Logically, this means that in order to obtain

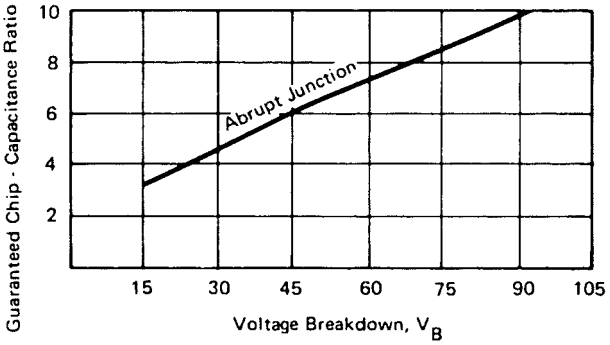

Figure 2-40 Capacitance ratio versus breakdown voltage.

greater tuning ratios, it is necessary to be able to increase the depletion-layer width without reaching punchthrough or breakdown. You must have a thicker epitaxial region to make this possible.

Figure 2-40 shows catalog ratio values, from zero bias to breakdown, as a function of breakdown voltage necessary. In the next section, on Q, we will discuss other elements in your choice of V_B.

To complete this section, we should mention that semiconductor processing control has been refined so well that capacitance tracking to within ±1% over the full range from zero to breakdown is now readily obtainable in production quantities.

Temperature Coefficient of Capacitance (T_{CC}). Unfortunately, since most datasheets give the value of T_{CC} at 4 V, it is sometimes assumed that this value applies at all bias voltages. This is not the case. Consider Eq. (2-45), a rewritten form of Eq. (2-42):

$$C(V) = \frac{C(O)}{(V + \varphi)^n} \tag{2-45}$$

Taking the derivative of this with respect to temperature T we have

$$\frac{dC(V)}{dT} = \frac{+nC(O)}{(v + \varphi)(v + \phi)^n} \frac{d\varphi}{dT} \tag{2-45a}$$

or, after substituting Eq. (2-45):

$$T_{CC} = \frac{1}{C(V)} \frac{dC(V)}{dT} = \frac{-n}{(V + \varphi)} \frac{d\varphi}{dT} \tag{2-46}$$

As a first approximation, we can say that $d\varphi/dT = -2.3$ mV/°C over the temperature range of interest.

From Eq. (2-46) we can draw the following conclusions:

1. The temperature coefficient is inversely proportional to the applied voltage.
2. The temperature coefficient is directly proportional to the diode slope, n.

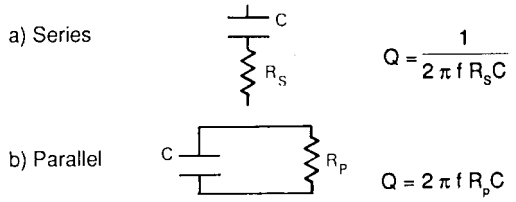
For an abrupt-junction diode that has a constant value of n (0.5), the temperature coefficient has a smooth curve in the form $K/(v + \varphi)$. However, in the case of hyperabrupt-junction diodes, n is a function of voltage, and the shape of the T_{CC} curve depends on the details of the $n(V)$ curve. A typical T_{CC} curve for an abrupt-junction diode is shown in Figure 2-41 and for an Alpha DKV6520 series hyperabrupt-junction diode in Figure 2-42. The inflection in the hyperabrupt T_{CC} is due to the fact that in this voltage range $n(V)$ is increasing faster than $1/V$, giving an increase in T_{CC}. It should also be noted, however, that over the range of the T_{CC} minimum the temperature coefficient is relatively constant, and operation in this area may be advantageous in some applications where a restricted tuning range can be used.

Q Factor or Diode Loss

Definitions. The classical definition of the Q of any device or circuit is

$$Q = \frac{2\pi \times \text{Energy stored}}{\text{Energy dissipated per cycle}} \tag{2-47}$$

For a capacitor, two formulations are possible:



Clearly, the two definitions must be equal at any frequency, which establishes

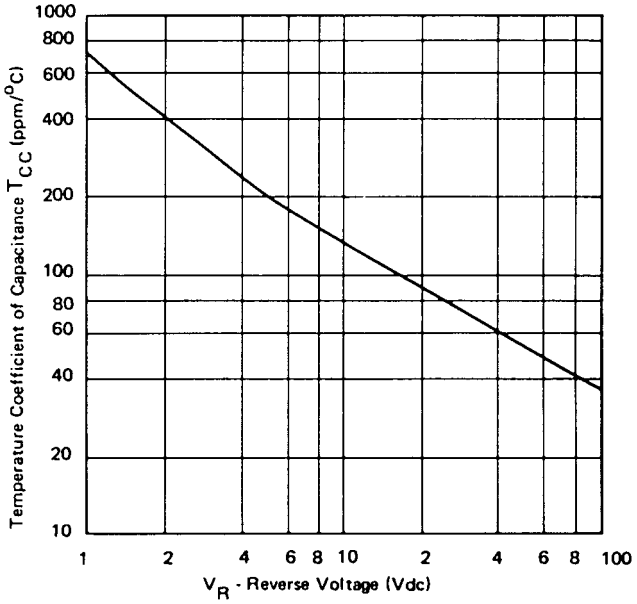


Figure 2-41 Temperature coefficient of capacitance versus tuning voltage for an abrupt-junction diode.

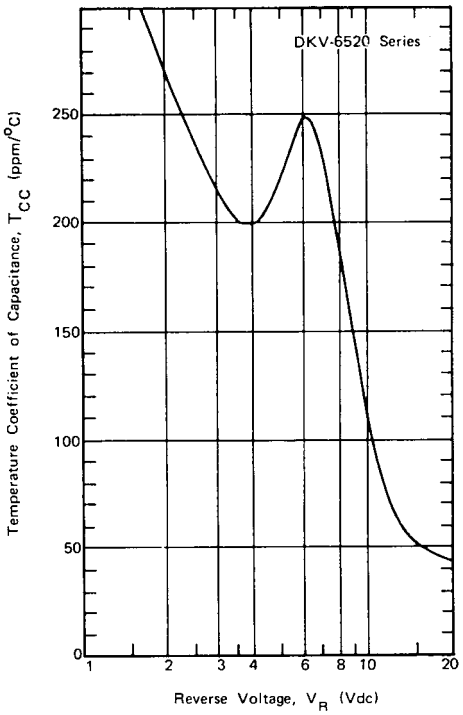

Figure 2-42 Temperature coefficient of capacitance versus tuning voltage ($T_A = 25$ °C) hyperabrupt-junction diode.

$$R_P = \frac{1}{(2\pi f)^2 C^2 R_S} \tag{2-48}$$

In the case of a high-Q tuning diode, the proper physical model is the series configuration, because the depleted region is almost perfectly pure capacitance, and the undepleted region, due to its relatively low resistivity, is almost a pure resistor in series with the capacitance. Furthermore, the contact resistances are also clearly in series. Q, then, for a tuning diode, is given by

$$Q_{(-v)} = \frac{1}{2\pi f_o R_{(-v)} C_{(-v)}} \tag{2-49}$$

where f_o is the operating frequency, $C_{(-v)}$ is the junction capacitance, and $R_{(-v)} = R(\text{epi}) + R_{C'}$, the sum of the resistance of the undepleted epitaxial layer and the fixed contact resistance.

Cutoff frequency, f_c, is defined as that frequency at which Q equals unity. Thus,

$$f_{c_{(-v)}} = \frac{1}{2\pi R_{(-v)} C_{(-v)}} \tag{2-50}$$

Historically, the tuning diode business has specified Q at 50 MHz, despite the fact that Q values of microwave diodes are so high that it is almost impossible to measure them at 50

Table 2-7 Parameters for 0.6-pF diode

Breakdown Voltage V_B	Resistivity ($\Omega \cdot$ cm)	Junction Diameter (mills)	Epitaxial Region (μm)	Depleted Epitaxial $V = -4$ V (μm)	Undepleted Epitaxial $V = -4$ V (μm)	R Undepleted (Ω)	R_{sp} (Ω)	Q_4
30	0.31	2.4	1.37	0.54	0.83	0.81	0.18	5200
45	0.52	2.8	2.25	0.73	1.52	1.86	0.15	2600
60	0.74	3.2	3.20	0.90	2.30	3.24	0.13	1500
90	1.25	3.7	5.27	1.21	4.06	7.17	0.10	700

MHz. Instead, as discussed below, Q is measured at microwave frequencies (e.g., 1–3 GHz) and related to 50 MHz by the relationship

$$Q_{(f1)} = Q_{(f2)} \frac{f_2}{f_1} \tag{2-51}$$

which derives quickly from the assumption that f_c is independent of the measuring frequency.

Since both junction capacitance and epitaxial layer resistance are functions of the applied bias, it is not possible to calculate Q as a function of bias from a measurement of capacitance alone. Catalog specifications typically show Q at –4 V, together with the capacitance at two or more voltages.

Relative to $Q_{(-4)}$, Q increases faster than the reduction in capacitance for bias greater than 4 V and, conversely, decreases faster for bias less than 4 V.

In the following section, we will discuss the diode design parameters that determine Q. Following this, we will describe some elementary Q measurement techniques.

Causes. In the discussion of device physics, the resistivity of the epitaxial region was discussed, together with its impact on punchthrough and breakdown. For example, Table 2-7 supplies typical resistivity and relative parameters of 0.6 pF ($C_{J(4)}$) diodes of different breakdowns. If we remember that if at any bias lower than breakdown the epitaxial region is not completely depleted, it follows that the undepleted portion presents a resistance in series with the pure capacitance of the depleted zone. The magnitude of this "undepleted" resistance is also shown in the table.

The entry R_{sp} ($R_{spreading}$) is the series resistance between the epitaxial region and the low-resistivity substrate. The calculations are for idealized cylindrical epitaxial regions of uniform resistivity, low-resistivity contact on the anode (top), and low-resistivity substrate on the cathode. This resistance is constant, independent of bias; also shown are epitaxial thickness region and width of the depletion zone at –4 V bias.

Note the substantial reduction in Q for high-voltage diodes caused by the increased epitaxial layer resistance; this is true for any value of capacitance or any type of junction. For greater voltage breakdown, the epitaxial region thickness must be increased, which requires an increase in epitaxial layer resistivity; the higher the resistivity of the undepleted zone, multiplied by the fact that it is much wider for high-voltage diodes, means the resistance increases substantially.

Consequently, a rule of thumb emerges: For maximum Q, never choose a tuning diode with a voltage breakdown in excess of what is needed for the necessary tuning range. If the

Table 2-8 ***Q*** **versus bias for 0.6-pF diode**

Table 2-9 Capacitance ratios (C_{J0}/C_JV_B)

Breakdown Voltage V_B	Optimum Ratio	Minimum Guaranteed Ratio	$Q_{(-4)}$ Typical
30	6.2	4.5	3000
45	7.5	6.0	2500
60	8.4	7.5	1400
90	10.2	8.7	650

required tuning range is an octave, requiring a 4:1 ratio, the selection of a 30-V diode will result in diode losses half those of a 60-V diode.

Table 2-8 lists capacitance and Q for each of these chips as a function of bias. Please remember that Q is calculated at 50 MHz.

Table 2-9 rewrites the data of Table 2-8 to show available capacitance ratios between zero bias and breakdown. The first column is the theoretical optimum, as tabulated. The second column is the typical catalog specification. The reduction in tuning ratio below theoretical optima is caused by nonideal junction fabrication. The junctions are never perfectly abrupt.

Although the tables and numbers given refer to abrupt-junction silicon devices, the principle applies without exception to all types of tuning diodes. For comparison, Table 2-10 lists available ratios and Q values for a number of different varactors. The high Q values for GaAs and the low values for hyperabrupts are apparent.

One last point: The Q values and series resistance refer to chips only. The effects of package parasitics will be discussed later, but it is important to consider circuit contact losses here. For low-capacitance diodes—for example, $C_{J4} = 0.6$ pF—the epitaxial region contributes a high value of resistance and dominates Q except at punchthrough. Diode contact losses are less significant.

Post-Tuning Drift. Post-tuning drift (PTD) is the change in oscillator frequency with time after the tuning voltage has stabilized. The minimization of PTD has assumed greater importance with the design of more sophisticated electronic countermeasure systems, where rapid, accurate frequency changes are required.

Table 2-10 Comparative Tuning Diodes

Type	C_{J0}	Breakdown Voltage V_B	$Q_{(-4)}$[a]	Ratio C_{J0}/C_JV_B[a]
Silicon abrupt	1.0	30	5,000	4.5
Silicon abrupt	2.5	30	4,600	4.5
Silicon abrupt	5.0	30	3,800	4.5
Gallium arsenide abrupt	1.0	25	10,000	3.6
Gallium arsenide abrupt	0.5	10	17,000	2.5
Silicon hyperabrupt	50.0	22	300	17.0
Silicon hyperabrupt	2.5	22	500	14

[a] Minimum guaranteed.

Post-tuning drift can be characterized as short-term and long-term. Short-term PTD occurs in the time range of tens of nanoseconds to a few seconds, while long-term PTD occurs in the time range of seconds to minutes, hours, or days.

Short-term PTD is mainly dependent on the thermal properties of the diode and is improved by high Q (low power loss) and flip chip construction. Long-term PTD depends on oxide stability and freedom of mobile charge in the oxide. It should be noted that actual oscillation frequency change may occur even with a perfect tuning diode because of variation with frequency in the power dissipated by the diode, changes in the diode heat-sink temperature, and frequency changes due to other circuit elements. Less than 0.01% short- and long-term PTD can be obtained.

Distortion Products. Inasmuch as nonlinear components generate harmonics and other distortion products, an understanding of this mechanism is of prime interest to the circuit designer. In some instances, the distortion products are the desired end result of the circuit design, as in frequency multipliers, where harmonics of the input signal frequency are the required output signal. For other applications, such as tuning-diode-tuned linear circuits, distortion products are extremely undesirable, and in some instances the end product specification may set a maximum limit on the distortion products allowed.

Cross-Modulation. Cross-modulation is the transfer of the modulation on one signal to another signal and is caused by third-order and higher odd-order nonlinearities in the behavior of the device. Rewriting Eq. (2-42) we have

$$C(V) = \frac{C_0}{(1 + V/\varphi)^n} \tag{2-52}$$

where C_0 = capacitance
V = applied voltage = $V_0 + v$
V_0 = dc applied voltage
v = ac applied voltage

Then, for a desired signal of

$$S_1 = v_1 \sin \omega_1 t \tag{2-53}$$

and a second, amplitude-modulated signal of

$$S_2 = v_2(1 + m \cos \omega_m t)\sin \omega_2 t \tag{2-54}$$

it can be shown that the cross-modulation, γ, defined by

$$\text{Output signal} \sim v_1 \sin \omega_1 t + \gamma \sin (\omega_1 \pm \omega_m)t \tag{2-55}$$

is found to be

$$\gamma = \frac{n(n+1)mv_2^2}{4(V_0+\varphi)^2} \tag{2-56}$$

From this equation it can be seen that cross-modulation is:

- Proportional to the square of the interfering signal
- Directly proportional to the interfering signal's modulation index, m
- Independent of the strength of the desired signal
- Independent of the frequencies of the desired and interfering signals (assuming that the nonlinearity to which both signals are subjected is sufficiently frequency-indiscriminate so this is the case)
- Present for all values of n; that is, no value of n gives zero cross-modulation

Solving Eq. (2-56) for the signal level v_2 required to produce cross-modulation of value γ, we have

$$v_2 = \frac{2(V_0+\phi)\gamma}{n(n+1)^m} \tag{2-57}$$

The interfering signal levels required to produce 1% cross-modulation from a 30%-modulated interfering signal applied to an abrupt-junction diode and a hyperabrupt-junction diode are shown in Figure 2-43.

From this figure, it can be seen that the hyperabrupt-junction diode is more susceptible to cross-modulation than the abrupt-junction diode in the region of maximum slope of the

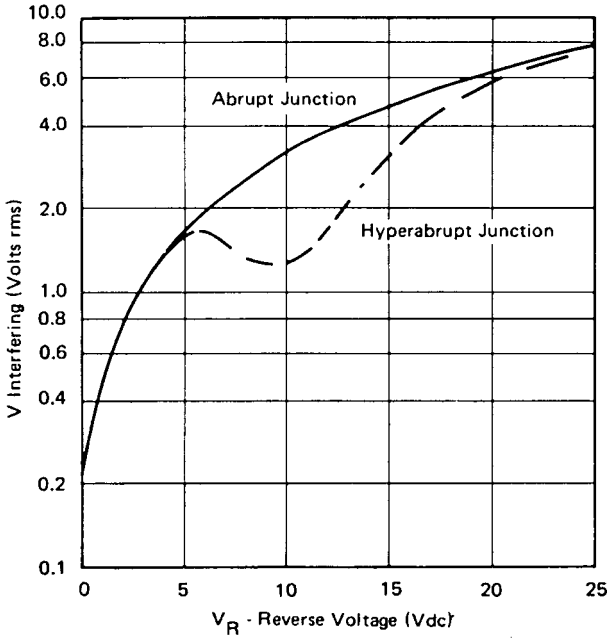

Figure 2-43 Interfering signal (30% amplitude modulated) level versus bias for 1% cross-modulation for abrupt-junction and hyperabrupt-junction diodes.

hyperabrupt-junction diode. For many applications, however, distortion products will be generated by other devices, such as transistors, at signal levels considerably below those given in Figure 2-43.

Intermodulation. Intermodulation is the production of undesired frequencies in the form

$$\sin(2\omega_1 t - \omega_2 t) \quad \text{and} \quad \sin(\omega_1 t - 2\omega_2 t) \tag{2-58}$$

from an input signal in the form of

$$v(\cos \omega_1 t + \cos \omega_2 t) \tag{2-59}$$

From an analysis similar to that done for cross-modulation, it can be shown that

$$\text{Intermodulation} = \frac{n(n+1)v^2}{8(V_0 + \varphi)^2} \tag{2-60}$$

or

$$\text{Cross-modulation} = (2m) \times \text{Intermodulation} \tag{2-61}$$

Harmonic Distortion. Harmonic distortion products are integral multiples of the signal frequencies and decrease in amplitude as the harmonic number decreases. Due to passband considerations and amplitude decrease with harmonic number, the second harmonic is the one of prime concern. Again, it can be shown that the second harmonic, v_2, of a signal of amplitude v_1 is

$$v_2 = \frac{n}{3(V_0 + \phi)} v_1^2 \tag{2-62}$$

Figure 2-44 shows the signal level required to produce 10% second-harmonic distortion in an abrupt-junction and a hyperabrupt-junction diode. Again, as in the case of cross-modulation, the hyperabrupt-junction diode is slightly worse than the abrupt-junction diode in the region of maximum slope of the hyperabrupt-junction diode.

Reduction of Distortion Products. In some cases, the signal levels applied to the diode generate distortion products larger than desirable for the circuit application. In this case, significant reduction in the distortion products can be achieved by using two diodes in a back-to-back configuration, as shown in Figure 2-45. Analysis shows that the fundamental signal components through the diodes are in phase and add, while some distortion products are out of phase and cancel, thus improving distortion performance.

Since the gradient of the electrical field produced in the depletion layer by a reverse bias applied to the device is proportional to the space charge density, the following equations can be written for the junction width W as a function of the reverse bias V_R:

For an Abrupt *pn* Junction (Alloyed Diodes)

$$W = {}_2\sqrt{2\frac{\varepsilon_r \varepsilon_0}{q}\left(\frac{1}{C_p} + \frac{1}{C_n}\right)(V_R + V_D)} \tag{2-63}$$

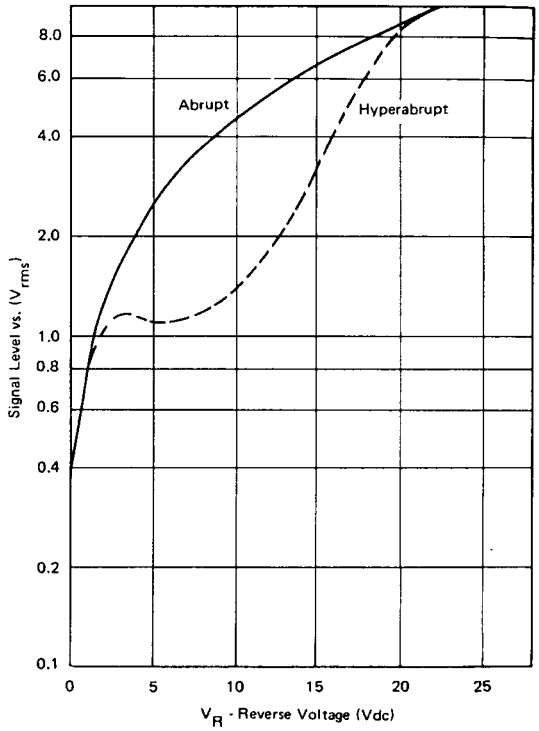

Figure 2-44 Signal level versus reverse voltage for 10% harmonic distortion.

For Linear *pn* Junctions (Single-Diffused Diodes, such as BA110–BA112)

$$W = \sqrt[3]{12\frac{\varepsilon_r \varepsilon_0}{aq}(V_R + V_D)} \tag{2-64}$$

where a is the impurity gradient within the depletion layer, ε_0 is the absolute dielectric constant ($8.85 \times 10^{-14}\ A_s/V_{cm}$, and $\varepsilon_r \approx 12$, the relative dielectric constant of silicon.

The junction capacitance, which is inversely proportional to the junction width, therefore varies in alloyed diodes with the square root, and in single-diffused diodes with the cube root of the externally applied reverse bias, and can be calculated from the general equation

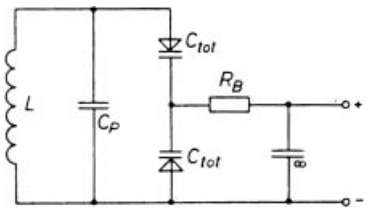

Figure 2-45 Back-to-back diodes. C_P is a fixed parallel capacitance, R_B is a bias decoupling resistor, and the capacitor marked ∞ is a low-impedance bypass.

$$C = \frac{\varepsilon_r \varepsilon_0 S}{W} \tag{2-65}$$

where S is the surface area of the *pn* junction. By way of approximation, we can also use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{2-66}$$

where all constants and all parameters determined by the manufacturing process are contained in K. The exponent n is a measure of the slope of the capacitance/voltage characteristics and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction. Figure 2-46 shows the capacitance/voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation has been indicated which, although purely formal, describes the practical characteristics better than Eq. (2-66):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{2-67}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is a voltage. The exponent m is much less dependent on voltage than the exponent n in Eq. (2-66).

Equations (2-63) through (2-67) express the pure junction capacitance of the capacitance diode, but to this must still be added a constant capacitance, determined by structure parameters, in order to obtain the diode capacitance C_{tot}, which interests the user. With high inverse voltages—that is, low junction capacitance—a difference will therefore arise between the theoretical capacitance/voltage characteristic according to Eq. (2-66) and the practical characteristic, as shown in Figure 2-47.

The operating range of a capacitance diode or its useful capacitance ratio

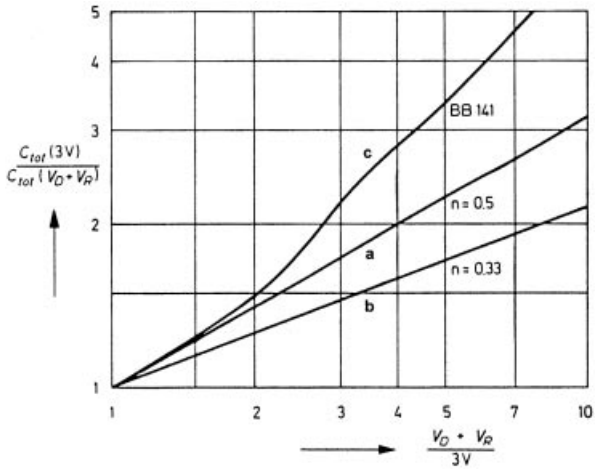

Figure 2-46 Capacitance/voltage characteristic for (a) an alloyed capacitance diode, n = 0.5; (b) a diffused capacitance diode, n = 0.33; and (c) a wide-range tuner diode (BB141).

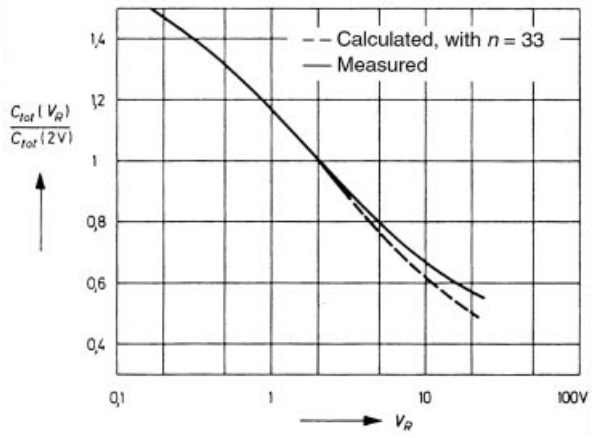

Figure 2-47 Capacitance/voltage characteristic of the BA110 diode.

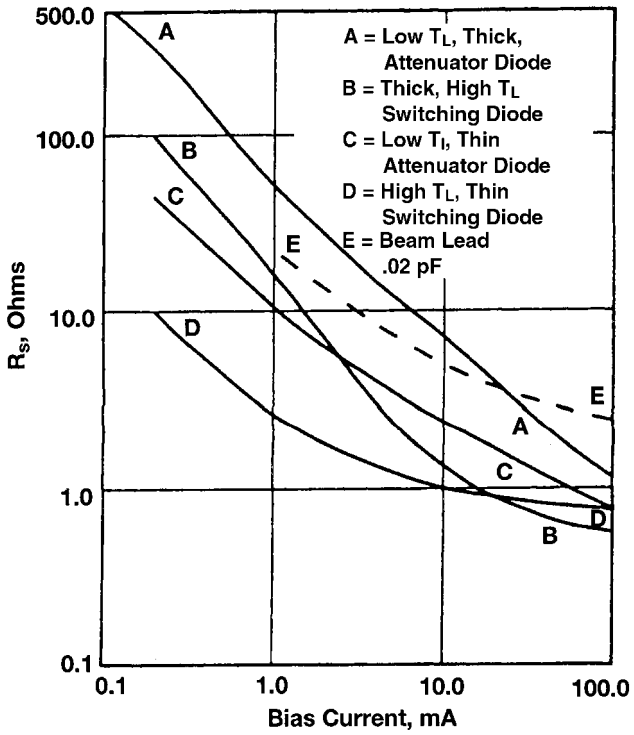

Figure 2-48 Basic current/voltage and capacitance/voltage characteristics.

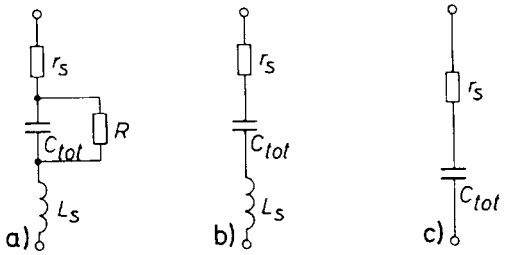

Figure 2-49 Equivalent circuits for capacitance diodes: (a) complete circuit, (b) simplified circuit, and (c) further simplification for low frequencies.

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R\min})}{C_{\text{tot}}(V_{R\max})} \tag{2-68}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage either into the forward mode or the breakdown mode. Otherwise, rectification, which would shift the diode's bias and considerably affect its figure of merit, would take place. Figure 2-48 plots the capacitance/voltage characteristics of a capacitance diode to clarify the relationship. The useful operating range lies between the voltages

$$V_{\min} > \hat{V} - V_F \quad \text{and} \quad V_{\max} < V_{(\text{BR})R} - \hat{V} \tag{2-69}$$

As has already been indicated, the exponent n for large-capacitance-ratio or tuning diodes used today for TV tuners is not constant but voltage-dependent and subject to manufacturing tolerances. This means that the capacitance/voltage characteristic of these diodes is likewise subject to manufacturing tolerances. Since, in a TV tuner, it is necessary for two or three circuits to be tuned uniformly, tuner diodes must be selected empirically for identical characteristics and supplied in equipment lots.

Electrical Properties of Tuning Diodes. In this section, the electrical properties of capacitance diodes are described, with reference to data published on the tuner diodes BB141 and BB142.

Equivalent Circuit. Since a capacitance diode is not an ideal capacitor, it is useful to introduce an equivalent circuit that can serve as a basis for discussing the diode's electrical properties. Figure 2-49 shows various types of equivalent circuits.

The complete equivalent circuit (Figure 2-49a), which conforms closely to physical conditions, comprises, in addition to the diode capacitance C_{tot}, the series resistance r_S and the series inductance L_S, and also the reverse resistance $R = dV_R/dI_R$. At higher frequencies, this resistance can usually be disregarded, so that the equivalent circuit is simplified in terms of Figure 2-49b—the configuration usually employed. In many cases, the series inductance can also be disregarded, in which case we obtain Figure 2-49c.

Capacitance. Figure 2-50 shows the capacitance/voltage characteristic borrowed from the datasheets of diodes BB141 and BB142. As this characteristic, like most characteristics published in datasheets, represents merely a typical curve, it would not convey sufficient

information for the user to dimension a tuner. Therefore, the datasheets contain additional data on capacitance and useful capacitance ratio:

Capacitance		BB141A (pF)	BB141B (pF)	BB142 (pF)
At $V_R = 1$ V	C_{tot}	16	19	17
At $V_R = 3$ V	C_{tot}	11	13	12
At $V_R = 25$ V	C_{tot}	2–2.35	2.25–2.65	2–3

$$\text{Useful capacitance ratio} = \frac{C_{tot}(3\text{ V})}{C_{tot}(25\text{ V})} = 4 \text{ to } 6$$

On the basis of the spread of the diode capacitance C_{tot} guaranteed for $V_R = 25$ V, it is possible to calculate the tuner with the aid of the spread guaranteed for the capacitance ratio.

Three further capacitance graphs are shown in Figures 2-51 through 2-53. Figure 2-51 shows a (typical) curve representing the normalized slope as a function of the reverse voltage, Figure 2-52 the normalized capacitance as a function of the junction temperature, and Figure 2-53 the temperature coefficient of the capacitance as a function of the reverse voltage.

The variation of diode capacitance with ambient temperature, as shown in Figures 2-52 and 2-53, is really only a function of the temperature dependence of the diffusion voltage [see Eq. (2-66)]. The diffusion voltage drops with rising temperatures by about 2 mV/°C , which means that the diode capacitance rises with temperature. The influence of the diffusion voltage, and thus the temperature coefficient of the capacitance, decreases as the reverse voltage rises. It is therefore advisable to run a capacitance diode with as high a reverse voltage as the required capacitance ratio permits. Compensation for the dependence of capacitance on temperature will be discussed later.

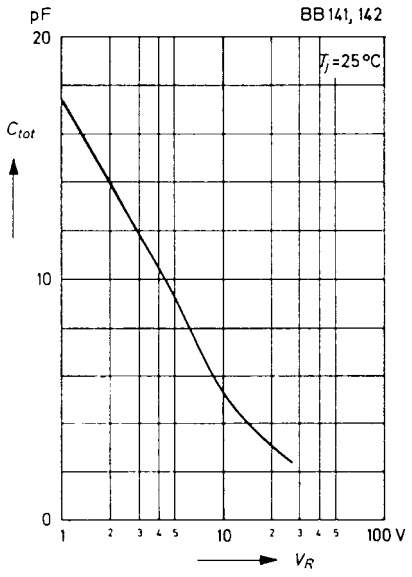

Figure 2-50 Capacitance/voltage characteristic of diodes BB141 and BB142.

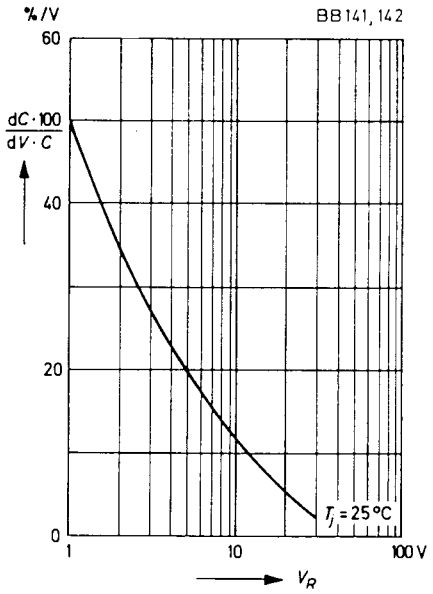

Figure 2-51 Slope (normalized) as a function of the reverse voltage.

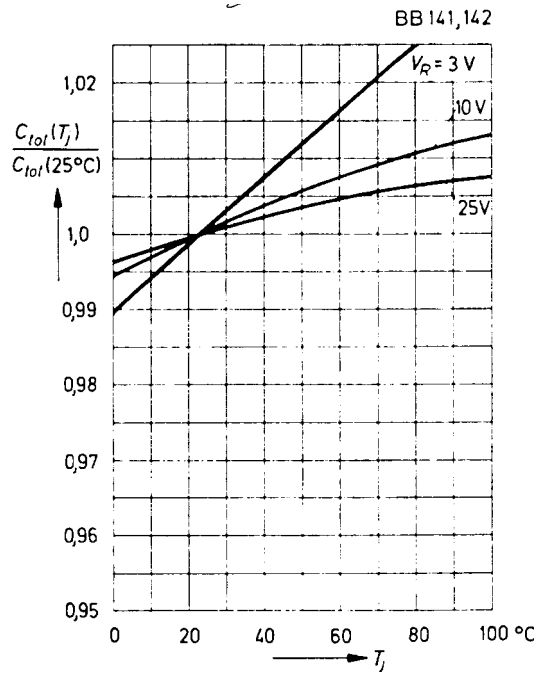

Figure 2-52 Capacitance (normalized) as a function of the junction temperature.

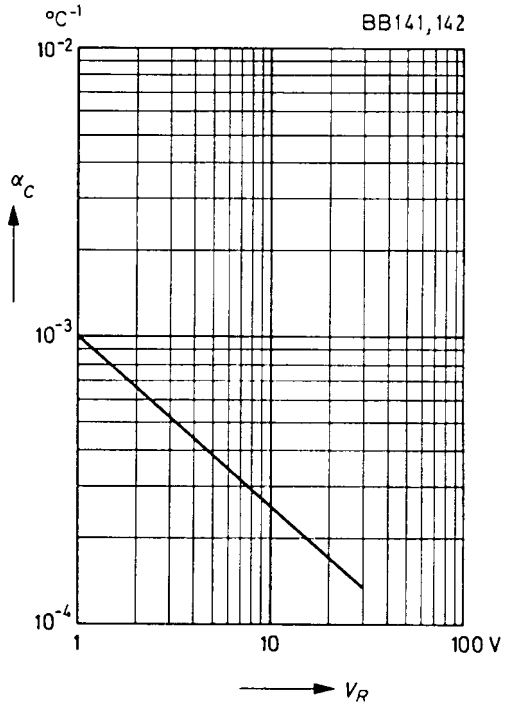

Figure 2-53 Temperature coefficient of capacitance as a function of the reverse voltage.

Series Resistance, Figure of Merit (Q). Since capacitance diodes are intended for employment in resonant circuits, indications are required as to the circuit attenuation that they produce. Usually, the series resistance or the figure of merit that can be calculated therefrom is indicated. With reference to the equivalent circuit shown in Figure 2-49a, the figure of merit (or Q factor) is calculated:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S + 1/\omega C_{\text{tot}} R} \tag{2-70}$$

Figure 2-54 shows the theoretical (normalized) Q as a function of frequency. With the frequency range of 10–1000 MHz, which is essential for tuner diodes, the parallel resistance R caused by the reverse current (see Figure 2-49b) can be disregarded, and Eq. (2-70) can be simplified to read as follows:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S} \tag{2-71}$$

In Figure 2-55, Q is plotted as a function of frequency for the tuner diodes BB141 and BB142. The datasheet indicates, in addition to this curve, the value of the series resistance at $f = 470$ MHz and $C_{\text{tot}} = 9$ pF:

	BB141A, BB141B	BB142
Series resistance (r_S)	0.6 (< 0.8)	0.9 (< 1.2)

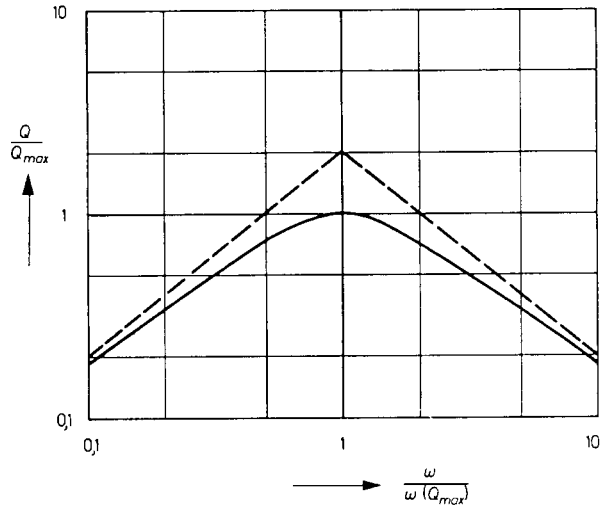

Figure 2-54 *Q* (normalized) as a function of frequency.

Since the diode capacitance and the series resistance decrease as the reverse voltage rises, Q is likewise dependent on the reverse voltage. It is smallest at a low reverse voltage, that is, at a low frequency. The series and parallel capacitances inevitable in a diode-tuned resonant circuit influence the effective Q of the tuning capacitance, as will be described later.

Series Inductance, Series Resonant Frequency, Cutoff Frequency for Q = 1. These three parameters define the behavior of the diode at high frequencies when the influence of

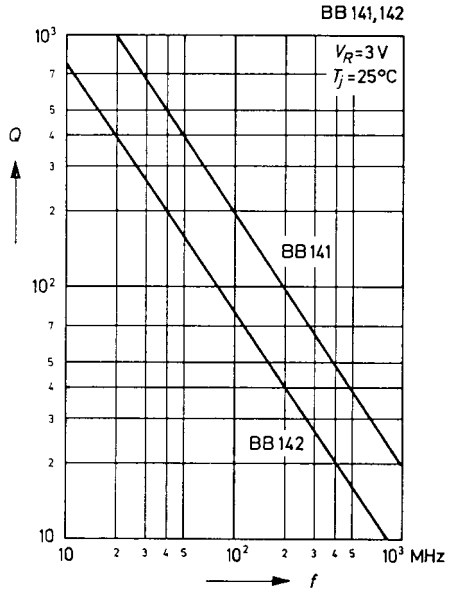

Figure 2-55 *Q* as a function of frequency.

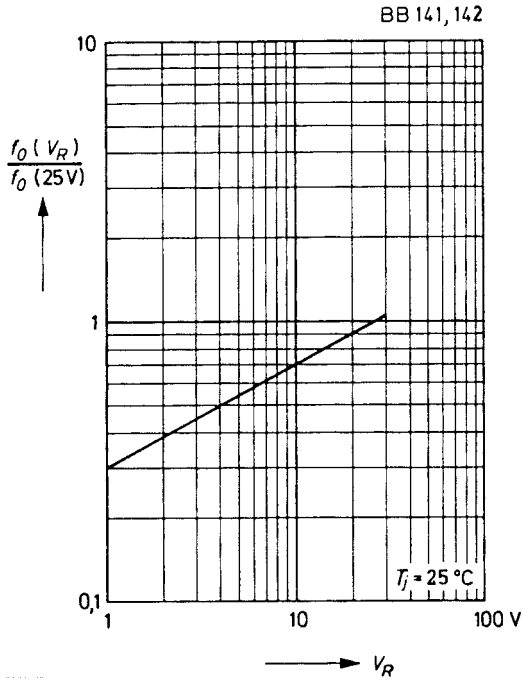

Figure 2-56 Series-resonant frequency (normalized) as a function of the reverse voltage.

the series inductance can no longer be neglected. The parameter on which the calculation is based is the series inductance L_S, which is determined by the connection leads. As indicated in Figure 2-49a, it is in series with the capacitance and, given a suitable frequency, forms a series-resonant circuit therewith. In that case

$$\omega L_S = \frac{1}{\omega C_{\text{tot}}} \tag{2-72}$$

and the series-resonant frequency is

$$f_0 = \frac{1}{2\pi\sqrt{C_{\text{tot}} L_S}} \tag{2-73}$$

Above this frequency, the impedance of the diode is inductive, but it depends on the reverse voltage. Figure 2-56 shows how the (normalized) series-resonant frequency depends on the reverse voltage for the tuner diodes BB141 and BB142.

The cutoff frequency for $Q = 1$ is defined as the frequency at which Q assumes the value of unity. In a rough calculation, the reactive impedance of the diode capacitance can be neglected and the frequency f_{Q1} obtained for the condition in which the inductive reactance equals the series resistance:

$$\omega L_S = r_S \tag{2-74}$$

$$f_{Q1} = \frac{r_S}{2\pi L_S} \tag{2-75}$$

For the tuner diodes BB141 and BB142, Figure 2-57 shows how the (normalized) cutoff frequency depends on the reverse voltage. The datasheets contain the following numerical information:

		BB141	BB142	
Series inductance measured 1.5 mm from the case	L_S	2.5	2.5	nH
Series-resonant frequency at $V_R = 25$ V	f_0	2	1.8	GHz
Cutoff frequency for $Q = 1$ at $V_R = 3$ V	f_{Q1}	24	16	GHz

Depending on the intended application, either the series-resonant frequency or the cutoff frequency for $Q = 1$ determines the maximum useful frequency range.

Leakage Current, Breakdown Voltage. These two parameters mark the dc performance of the diode when a reverse bias is applied to it. In the databook for the tuner diodes BB141 and BB142, the breakdown voltage is quoted as follows:

$$\text{Reverse breakdown voltage at } I_R = 100\ \mu\text{A}: \quad V_{(BR)R} > 30\ \text{V}$$

This means that the maximum reverse voltage that may be applied to the diode as a tuning voltage is 30 V.

The leakage current for the above-mentioned tuner diodes is guaranteed as follows:

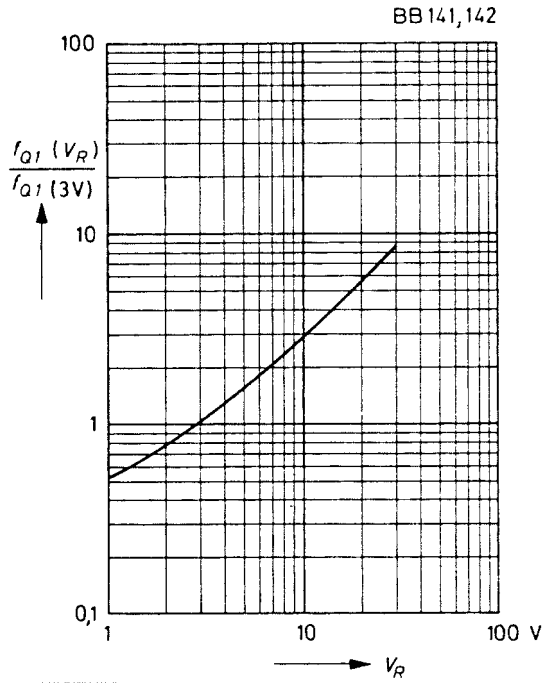

Figure 2-57 Cutoff frequency for $Q = 1$ (normalized) as a function of the reverse voltage.

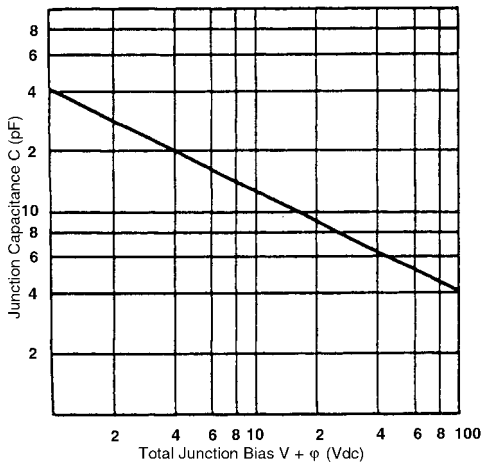

Figure 2-58 Leakage current as a function of reverse voltage.

$$\text{Leakage current at } V_R = 28 \text{ V:} \quad I_R < 50 \text{ nA}$$

Moreover, Figure 2-58 shows a graph that illustrates the leakage current as a function of the reverse voltage. Since this current is temperature dependent (as with every silicon diode)—it doubles with each temperature rise of about 10 °C—care should be taken when dimensioning the tuner circuit that the leakage current does not cause inadmissible voltage variations at increased ambient temperatures.

Matching of Tuner Diodes, Uniform Parameters. As has already been mentioned, the capacitance versus voltage characteristics of modern tuner diodes are subject to a certain scatter, so that it becomes necessary to test these diodes to obtain equipment lots empirically.

Diode-Tuned Resonant Circuits

Tuner Diode in the Parallel-Resonant Circuit. Figures 2-59, 2-60, and 2-61 illustrate three basic circuits for the tuning of parallel-resonant circuits by means of capacitance diodes.

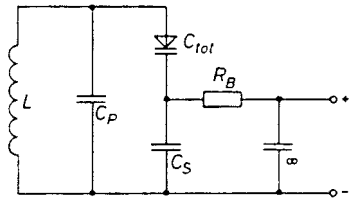

Figure 2-59 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the series capacitor.

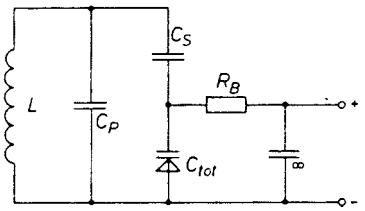

Figure 2-60 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the diode.

In the circuit diagram of Figure 2-59, the tuning voltage is applied to the tuner diode via the input coil and the bias resistor R_B. Series-connected to the tuner diode is the series capacitor C_S, which completes the circuit for ac but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling capacitor preceding the bias resistor is large enough for its value to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_C. We have the equation

$$R_C = R_B\left(1 + \frac{C_S}{C_{\text{tot}}}\right)^2 \tag{2-76}$$

If in this equation the diode capacitance is substituted by the resonant circuit frequency ω, we obtain

$$R_C = R_B\left(\frac{\omega^2 LC_S}{1 - \omega^2 LC_P}\right)^2 \tag{2-77}$$

The resistive loss R_C caused by the bias resistor R_B is seen to be highly frequency dependent, and this may result in the bandwidth of the tuned circuit being independent of frequency if the capacitance of the series capacitor C_S is not chosen sufficiently high.

Figure 2-60 shows that the tuning voltage can also be applied directly and in parallel to the tuner diode. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_C = R_B\left(\frac{1 + C_{\text{tot}}}{C_S}\right)^2 \tag{2-78}$$

and

$$R_C = R_B\left(\frac{\omega^2 LC_S}{\omega^2 L(C_S + C_P) - 1}\right)^2 \tag{2-79}$$

The influence of the bias resistor R_B in this case is larger than in the circuit of Figure 2-60, provided that

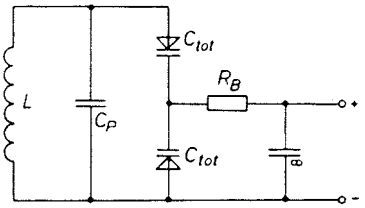

Figure 2-61 Parallel-resonant circuit with two tuner diodes.

$$C_S^2 > C_S(C_{\text{tot}} + C_P) + C_{\text{tot}}C_P \tag{2-80}$$

This is usually the case because the largest possible capacitance will be preferred for the series capacitor C_S, and the smallest for the shunt capacitance C_P. The circuit of Figure 2-59 is therefore normally preferred to that of Figure 2-60. An exception would be the case in which the resonant circuit is meant to be additionally damped by means of the bias resistor at higher frequencies.

In the circuit of Figure 2-61, the resonant circuit is tuned by two tuner diodes that are connected in parallel via the coil for tuning purpose, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation (see section entitled "Modifying the Diode Capacitance by the Applied ac Voltage") takes effect in opposite directions in these diodes and therefore cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuner diodes, is transformed into the circuit at a constant ratio throughout the whole tuning range. Given two identical, loss-free tuner diodes, we obtain the expression

$$R_C = 4R_B \tag{2-81}$$

Capacitances Connected in Parallel or Series with the Tuner Diode. Figures 2-59 and 2-60 show that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuner diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. As far as possible, the value of the series capacitor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases, as, for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency, this is not possible and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{\text{tot}} \frac{1}{1 + C_{\text{tot}}/C_S} \tag{2-82}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuner diode, increases to

$$Q^* = Q\left(1 + \frac{C_{\text{tot}}}{C_S}\right) \tag{2-83}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{\max}}{C^*_{\min}} = \frac{C_{\max}}{C_{\min}} \frac{1 + C_{\min}/C_S}{1 + C_{\max}/C_S} \tag{2-84}$$

where $C_{\max}$ and $C_{\min}$ are the maximum and minimum capacitances of the tuner diode.

On the other hand, the advantage is gained that, due to capacitive potential division, the amplitude of the alternating voltage applied to the tuning diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{\text{tot}}/C} \tag{2-85}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance $C_{\max}$ of the tuner diode and a higher useful capacitance ratio. The influence exerted by the series capacitor, then, can actually be kept lower than Eq. (2-83) would suggest.

The parallel capacitance C_P that appears in Figures 2-59 to 2-61 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}} \left(1 + \frac{C_P}{C_{\text{tot}}} \right) \tag{2-86}$$

The Q of the effective tuning capacitance, as derived from the Q of the tuner diode, is

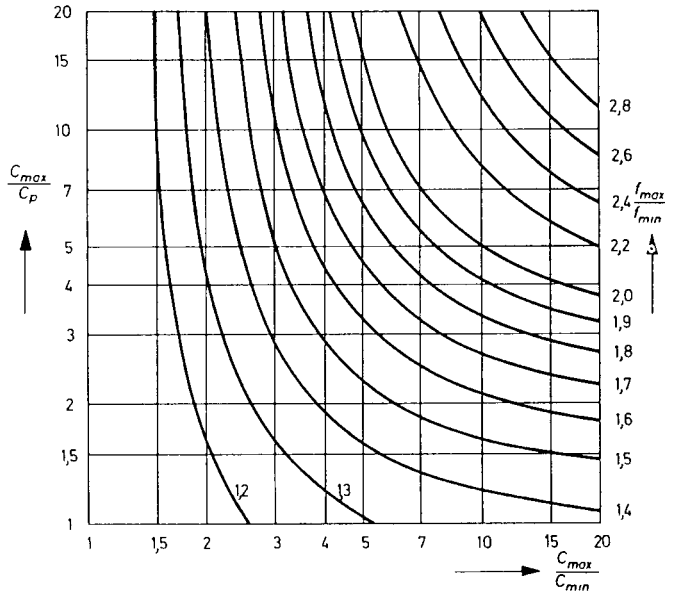

Figure 2-62 Diagram for determining the capacitance ratio and minimum capacitance.

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{2-87}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance ratio is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}} \frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{max}}} \tag{2-88}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the circuit-design stage.

TUNING RANGE. The frequency range over which a parallel-resonant circuit according to Figure 2-59 can be tuned by means of the tuner diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit.

The ratio can be found from

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{1 + \frac{\dfrac{C_{\text{max}}}{C_P\,(1 + C_{\text{max}}/C_S)}}{1 + \dfrac{C_{\text{max}}}{C_P\,(C_{\text{max}}/C_{\text{min}} + C_{\text{max}}/C_S)}}} \tag{2-89}$$

In many cases, the series capacitor can be chosen large enough for its effect to be negligible. In that case, Eq. (2-89) is simplified as follows:

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{\frac{1 + C_{\text{max}}/C_P}{1 + C_{\text{min}}/C_P}} \tag{2-89a}$$

From this equation, the diagram shown in Figure 2-62 is computed. With the aid of this diagram, the tuner diode parameters required for tuning a resonant circuit over a stipulated frequency range—that is, the maximum capacitance and the capacitance ratio—can be determined.

Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced according to Eq. (2-84).

TRACKING. Some applications require the maintenance of a fixed frequency relationship between two or more tuned circuits as their tuning is simultaneously adjusted. Referred to as *tracking*, this technique requires narrow tolerances of capacitance versus tuning voltage. Minimizing tracking error requires special care if the tracking circuits must cover the same frequency span beginning at different start and end frequencies, as is necessary when simultaneously tuning oscillator and mixer/RF circuitry in a superheterodyne receiver. Then, tracking error must be minimized by means of series and shunt capacitances in accordance with methods known from variable capacitors. The frequency deviations that must be anticipated are summarized in the equation

$$\frac{df}{f} = -\frac{1}{2}\frac{dC_0}{C_0} - \frac{1}{2}\frac{d(L-L_0)}{L} - \frac{1}{2}\frac{dL_0}{L_0} + \frac{n}{2}\frac{dV_R}{V_R + V_D} \tag{2-90}$$

The spread of parameters dC_0/C_0 and dL_0/L_0 can only be compensated by varying the circuit inductances $d(L–L_0)/L$ or by varying the bias $dV_R/(V_R + V_D)$.

Modulating the Diode Capacitance by the Applied ac Voltage. In normal operation, the sum of the tuning voltage and the alternating signal voltage of the resonant circuits is applied to the tuner diode. The bias, and thus the capacitance, of the tuner diode therefore varies at the rhythm of the alternating voltage. Due the nonlinear character of the capacitance versus voltage curve, voltage distortions and capacitance shifts are inevitable, and these must be kept within adequate limits. This is done by maintaining the ac applied to the diode(s) at sufficiently low ac amplitude and by choosing an adequate minimum value for the tuning voltage. In the resonant circuit, a tuner diode is modulated predominantly by a current free from harmonics, according to the equation

$$i = \hat{i}\cos \omega t \tag{2-91}$$

The alternating voltage across the diode is

$$v = (V_R + V_D)\left[\left(1 + \frac{\hat{i}(1-n)}{\omega C_{\text{tot}} V_R}\sin \omega t\right)^{1/(1-n)} - 1\right] \tag{2-92}$$

An evaluation of this equation shows that especially the first harmonic makes its appearance. The capacitance shift caused by the alternating voltage superimposed on the tuning voltage is shown in Figure 2-63. However, the voltage distortion, and thus the capacitance shift, can be largely avoided if two tuner diodes are used, as in Figure 2-61.

COMPENSATING TEMPERATURE DEPENDENCE. As has already been mentioned, variations are caused in the capacitance of the diode mainly by the dependence of the diffusion voltage on

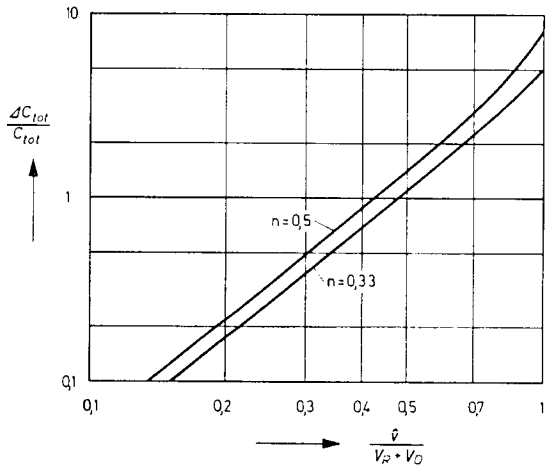

Figure 2-63 Capacitance increase as a function of the ac voltage drop across the tuner diode.

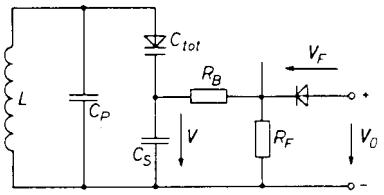

Figure 2-64 Temperature-compensation circuit with diode.

temperature. In a diode-tuned resonant circuit, the temperature coefficient of the resonant frequency, therefore, depends on the tuning voltage and thus on the resonant frequency. It is therefore impossible to compensate the temperature dependence of the resonant frequency by means of temperature-dependent capacitors—the method usually adopted for mechanically tuned circuits.

To achieve satisfactory compensation, the tuning voltage should be increased by an amount equal to that by which the diffusion voltage of the diode is reduced with rising temperature; that is, by approximately 2 mV/°C. This can be done easily by connecting a forward-biased silicon diode in series with the source of the tuning voltage, as shown in Figure 2-64. Since the forward voltage of the diode varies by –2 mV/°C with ambient temperature, the voltage

$$V = V_0 + V_D - V_F$$

which determines the bias of the tuner diode, and therefore also the diode capacitance, is almost temperature independent. In practice, it is advisable to feed this diode with additional current via the resistor R_F to keep its differential forward resistance sufficiently low and thus to prevent capacitive noise voltages from leaking into the tuning circuit.

To prevent the load placed by the resistor R_F on the source of the tuning voltage from fluctuating in a manner depending on the tuning voltage, a circuit such as shown in Figure 2-65 may be used in which the emitter diode of the transistor effects the compensation, and the only load placed on the source of the tuning voltage is the base current of this transistor.

Dynamic Stability. The resonant frequency of a diode-tuned RF circuit follows the equation

$$f = f_0 \sqrt{\left(\frac{V_R + V_D}{V_{R0} + V_D}\right)^n} \tag{2-93}$$

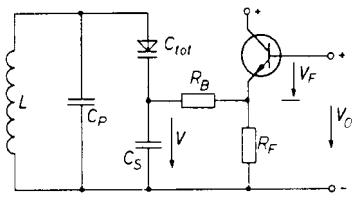

Figure 2-65 Temperature-compensation circuit with transistor.

The frequency f_0 is set with the aid of the circuit inductance when the tuning voltage equals V_{R0}. Since the signal amplitude in the circuit depends on the field strength of the received transmitter and since the resonant frequency of the circuit depends on the amplitude, undesirable feedback between the tuning voltage and the received alternating voltage may occur at the tuner diode. A disturbance that has a similar effect is the microphonic effect, which can sometimes be observed with mechanically variable capacitors. In an investigation of the feedback in diode-tuned resonant circuits, the following assumptions were made:

- The impedance of the antenna (or of the signal generator) is negligible.
- The full alternating voltage is applied to the diode (whereas, in practice, the series capacitor brings about a potential division).
- The capacitance versus voltage characteristic is an exponential function.
- The Q of this circuit is independent of the amplitude of the alternating voltage.

As a result of a high alternating voltage at the resonant circuit, three undesirable effects—harmonic generation, frequency shift, and cross-modulation—are encountered.

HARMONIC GENERATION. The nonlinearity of the capacitance versus voltage characteristic produces harmonics. However, the selectivity of the receiver reduces the effects of these harmonics to noise level.

FREQUENCY SHIFT. When a sinusoidal voltage v is applied to the tuner diode of the RF circuit, the variation of the diode capacitance does not follow the sine law, but the equation

$$\frac{C_\omega}{C} = \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{-n} \tag{2-94}$$

This results in a change of the resonant frequency of the circuit. The inductive slope of the resonant curve steepens and may even turn back. This could lead to bistable behavior of the resonant circuit. The change of frequency takes place as if the tuning voltage, and thus the resonant frequency, has decreased. The order of magnitude of this change of resonant frequency was determined with the aid of a computer from Fourier analysis of

$$\frac{\Delta f}{f} = 1 + \frac{1}{2\pi} \int_0^{2\pi} \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{n/2} d(\omega t) \tag{2-95}$$

Figure 2-66 shows the admissible alternating voltage at the diode, computed for a 2% frequency shift, as a function of the tuning voltage. The measured values differ by not more than 10% from the computed values. Since the Q of the circuits is about 50 for the VHF as well as the UHF range, a 2% frequency shift is permissible.

CROSS-MODULATION. Cross-modulation is a disturbance caused by nonlinearities of the characteristics of the components concerned. The modulation of an undesired amplitude-modulated signal is here transferred to the carrier of the amplitude-modulated intelligence signal. Cross-modulation is virtually independent of the amplitude of the intelligence signal.

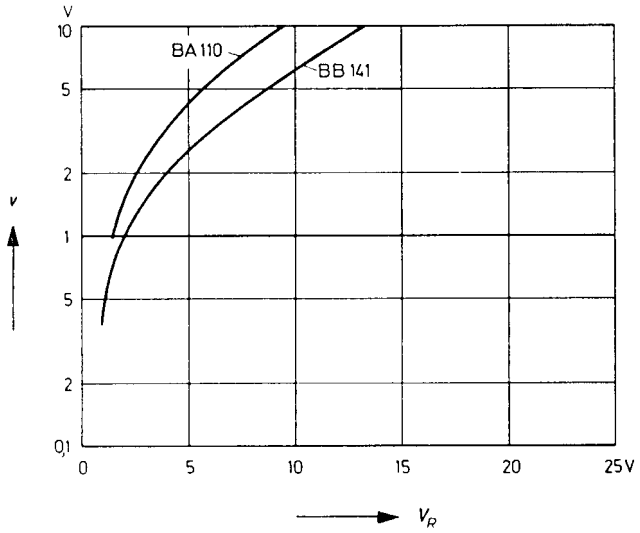

Figure 2-66 Admissible alternating voltage for a 2% frequency shift as a function of tuning voltage.

The cross-modulation factor for tuner diodes is

$$k = \frac{v^2}{(V_R + V_D)^2} m_v \frac{n(n+1)}{2} \tag{2-96}$$

Resolving this equation in terms of v, we obtain

$$v = \frac{V_R + V_D}{n} \sqrt{\frac{2kn}{m_v (n+1)}} \tag{2-97}$$

The usual definition of the cross-modulation percentage for measurement purposes is as follows: A 100% modulated noise signal ($m_v = 1$) of amplitude v is received simultaneously with the intelligence signal in the diode-tuned RF circuit. If a 1% modulation of the signal carrier by the noise signal takes place, this amounts to a cross-modulation factor $k = 0.01$. We thus obtain for tuner diodes

$$V = 0.14 \frac{V_R + V_D}{n} \sqrt{\frac{n}{n+1}} \tag{2-98}$$

Figure 2-67 gives the graphs for this equation. In practical operation, FM and VHF/UHF tuners equipped with the tuner diodes BB121 or BB141 exhibit merely the cross-modulation caused by the BJTs or FETs employed. For bipolar transistors, $v \approx 15$–100 mV; for FETs, 100–300 mV.

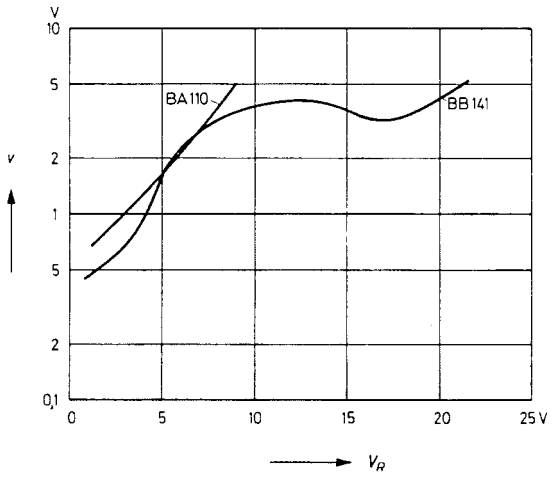

Figure 2-67 Graphical representation of Eq. (2-98).

Static Stability. To ensure trouble-free operation, the static parameters of the tuner diodes, especially the leakage current, must be taken into account. When differentiating the expression for the tuning voltage

$$V_R = V_B - I_R R_B \tag{2-99}$$

we obtain for a known leakage current I_R the tuning voltage variation

$$dV_R = dV_B - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} + dV_B \right) \tag{2-100}$$

This leads to a change in the resonant frequency

$$\frac{df}{f} = \frac{n}{2(V_R + V_D)} \left[dV_D - R_B I_R \left(\frac{dR_B}{R_B} + \frac{dI_R}{I_R} \right) + dV_B \right] \tag{2-101}$$

The resonant frequency is more stable the smaller the exponent n and the higher the tuning voltage V_R. The influence of the temperature dependence of the diffusion voltage V_D and its compensation have already been discussed. If the series bias resistance R_B is not too high, the effect of its variation ($dR_B/R_{B)}$ and the effect of the temperature dependence of the leakage current—doubling for every 10 °C temperature rise—may be neglected.

Generating the Tuning Voltage. The supply voltage V_B in Eq. (2-101) exerts an influence in many respects. The temperature coefficient of the voltage source—usually, for economic reasons, only a Zener diode is provided for stabilization—affects conditions not only with ambient temperature variations, but also when the Zener diode heats up after the set is switched on, or when its operating current varies. Because external temperature compensation of the operating voltage of the Zener diode cannot cover all detrimental effects and, moreover, increases the series bias resistance R_B, as well as any variations the latter may

undergo, the use of a temperature-compensated Zener diode, such as the 1N4065A (nominal Zener voltage, 33 V; temperature coefficient, 0.002 °C/W), is recommended.

Diode Switches. The diode switches described here differ somewhat from the switching diodes used in computer and pulse technology. Whereas in the case of switching diodes the signal itself triggers the switching operation—current does or does not pass through the switching diode depending on the signal level—diode switches allow an alternating current to be switched on or off by means of a direct voltage or a direct current. Figure 2-68 shows an example of the use of diode switches.

Diode Switch Technology. Special manufacturing techniques are needed to attain the low junction capacitance, low differential forward resistance r_F, and the low-inductance structure required for the special applications envisaged. Two conflicting requirements have to be met: On the one hand, a high-resistivity basic material should be used and the diode area should be kept as small as possible to minimize the junction capacitance for a given reverse voltage; on the other hand, the bulk resistance should be kept low. The size of the junction area, therefore, can represent only a compromise between these two requirements. To obtain a low bulk resistance R_B despite the use of high-resistivity silicon around the junction, the diodes are manufactured by the epitaxial process, characterized by a thin high-resistivity layer on a low-resistivity substrate. If the forward current I_F is sufficiently high, then the specific resistance of the epitaxial layer does not affect the bulk resistance, because under these conditions the resistivity of this layer is considerably reduced by being flooded with carriers.

The junction impedance Z_j is somewhat more critical (Figure 2-69). It is composed of the junction capacitance C_S, which does not depend on current, the current-dependent diffusion capacitance

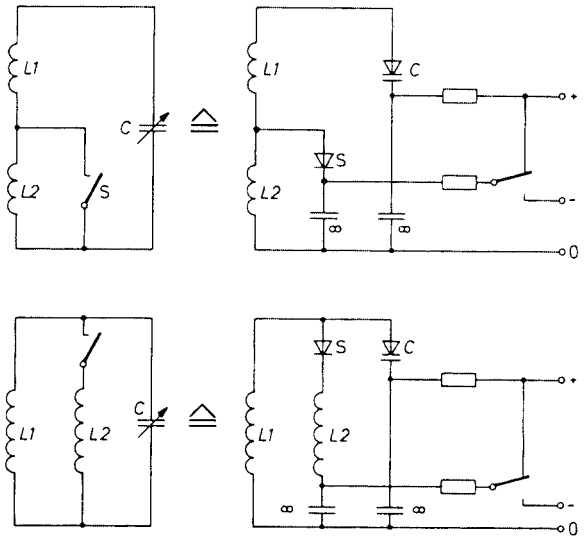

Figure 2-68 Comparison of mechanically and electronically tuned and switched resonant circuits.

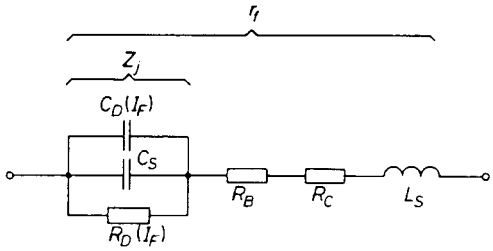

Figure 2-69 Equivalent circuit of diode switches in the frequency range from 1 MHz to 1 GHz.

$$C_D = \frac{\mathfrak{t}_p I_F}{V_T} \tag{2-102}$$

and the diffusion resistance

$$R_D = \frac{V_T}{I_F} \tag{2-103}$$

where $\mathfrak{t}_p$ is the lifetime of the minority charge carriers and

$$V_T = \frac{kT}{q} = 26 \text{ mV} \tag{2-104}$$

is the voltage equivalent of thermal energy. The resistive component of the impedance Z_j is calculated as follows:

$$\text{Re}(Z_j) = \frac{R_D}{1 + \omega^2 R_D^2 (C_S + C_D)^2} \tag{2-105}$$

As can be seen from the following approximations, this resistance becomes rather dependent on current at higher frequencies:

$$\text{For } I_F \to 0 \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega^2 C_S^2 V_T} \tag{2-106}$$

$$\text{For } I_F \to \infty \quad \text{Re}(Z_j) \approx \frac{I_F}{\omega t_p I_F} \tag{2-107}$$

In Figure 2-70 the differential forward resistance is plotted as a function of the forward current. The only parameter by which the differential forward resistance can be reduced for a given current and a given frequency according to Eq. (2-107) is the carrier lifetime. Steps will have to be taken, therefore, to make the carrier lifetime as long as possible.

Because diode switches are designed for applications up to the gigahertz range, a geometry resulting in a low inherent capacitance and inductance had to be used. Furthermore, the device had to be assembled in such a way that virtually no additional contact resistance R_C was introduced. For this reason, a double-plug construction (hard-glass pressure contacts)

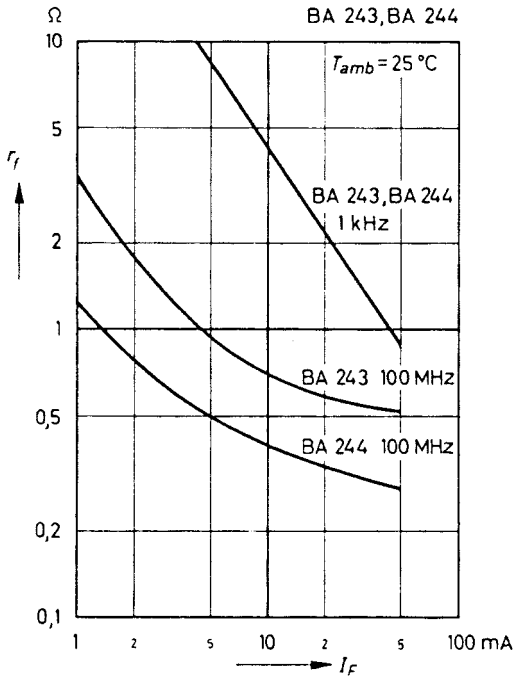

Figure 2-70 Differential forward resistance as a function of forward current.

was chosen to avoid the S- or U-bends customary with other encapsulations. The system is pressure-clamped between two stud-shaped enlargements of the connecting leads, the necessary high pressure being produced as the glass shrinks during cooling. This construction results in an encapsulation of short length (only 4 mm) and low series inductance, the advantages of which can be fully exploited because soldered connections to the leads can be made directly at the glass body.

Diode Switch Data. The silicon planar diode switches BA243 and BA244 are designed for electronic band selection in tuners in the frequency range from 10 to 1000 MHz. The differential forward resistance remains constant and is very low over a wide frequency and current range. The diode capacitance is likewise small and independent of voltage through a wide range. The devices are characterized by low-inductance geometry. The BA243 is intended for the VHF range, and the BA244 for the UHF range. See Table 2-11.

Resonant Circuits Incorporating Diode Switches. Figure 2-71 illustrates the function of the diode switch with reference to a parallel-resonant circuit whose resonant frequency can be switched by short-circuiting part of the circuit inductance. Such a switching procedure may be necessary for a VHF tuner, for example, to switch from band I to band III, because the frequencies of these bands are too far apart.

Capacitor C_K represents the capacitance of the resonant circuit. The symbol ∞ at capacitor C is meant to indicate that the value of this capacitor should be chosen to be much higher than the circuit capacitance. C completes the ac circuit when the inductor L_2 is shorted and

Table 2-11 BA243/244 specifications

Maximum Ratings			
Reverse voltage	V_R	20	V
Forward current at $T_A = 25$ °C	I_F	100	mA
Junction temperature	T_j	150	°C
Storage temperature range	T_s	–55 to +150	°C
Characteristics at $T_A = 25$ °C			
Forward voltage at $I_F = 100$ mA	V_F	<1	V
Leakage current at $V_R = 15$ V	I_R	< 100	nA
Dynamic forward resistance at $f = 50$–1000 MHz, $I_F = 10$ mA			
BA243	r_F	0.7 (< 1)	Ω
BA244	r_F	0.4 (< 0.5)	Ω
Relative variation of dynamic forward resistance with the variation of forward current in the range of $I_F + 2$–40 mA	$\frac{\Delta r_F 100}{r_F \Delta I_F}$	5	%/mA
Capacitance at $V_R = 15$ V, $f = 1$ MHz	C_{tot}	1.3 (< 2)	pF
Relative variation of capacitance with the variation of reverse voltage in the range of $V_R = 7$–20 V, $f = 100$ MHz	$\frac{\Delta C_{tot} 100}{C_{tot} \Delta V_R}$	1	%/V
Series inductance across case	L_S	2.5	nH

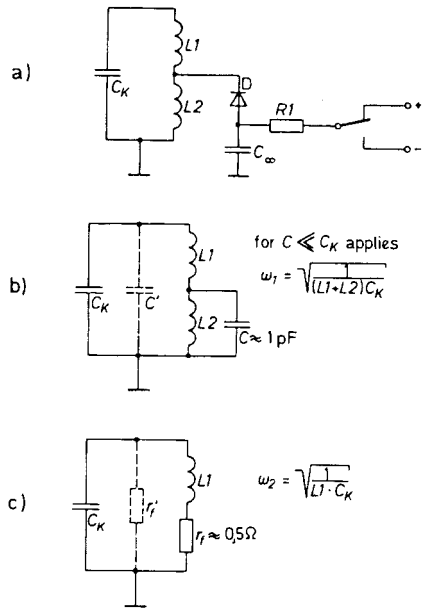

Figure 2-71 (a) Diode switch as bandswitch, shorting a partial inductance; (b) equivalent circuit with blocked diode switch; (c) equivalent circuit with conducting diode switch.

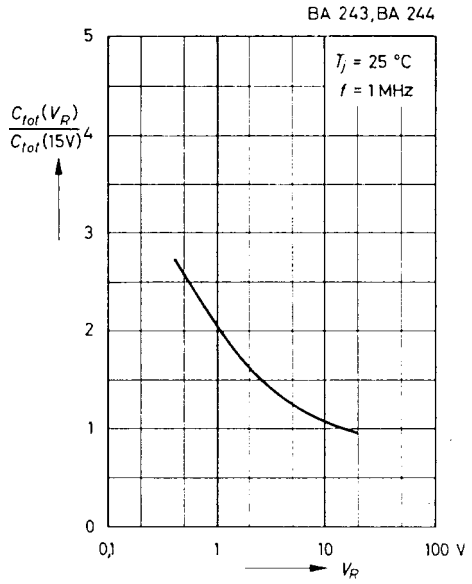

Figure 2-72 Capacitance as a function of the reverse voltage.

enables the switching or reverse voltage to be applied at a point of virtually zero RF potential. The resistor R_1 limits the diode current in the forward direction.

At a reverse voltage of $V_R = 15$ V, for example, the diode switch represents a 1-pF capacitor, as shown in Figure 2-71b. This represents parasitic capacitance C' in the circuit, which reduces the effective capacitance variation of the resonant circuit in the case of capacitive tuning. The capacitance C' is small enough to be negligible in most cases relative to the wiring and winding capacitances. Figure 2-72 shows the relative capacitance of the blocked-diode switches, as a function of the reverse voltage.

At a forward current of, for example, 10 mA, the diode has a differential resistance of approximately 0.5 Ω (see Figure 2-70). The effect of this resistance r_F on the resonant circuit is illustrated in Figure 2-71c. Conversion of a series loss resistance r_F into a parallel loss resistance r'_F is based on the following considerations: The equivalent parallel resistance r'_F affects the tuned circuit in the same way as the series resistance r_F; that is, the Q of the circuit should be the same in both cases. If one assumes that $\omega L >> r_F$, the equivalent of parallel resistance can be expressed as follows:

$$Q = \frac{\omega L_1}{r_F} = \frac{r'_F}{\omega L_1} \tag{2-108}$$

$$r'_f = \frac{(\omega L_1)^2}{r_F} \tag{2-109}$$

An evaluation of this equation shows that a differential resistance $r_F \approx 0.5$ Ω can be tolerated in most applications as regards amplification and selectivity.

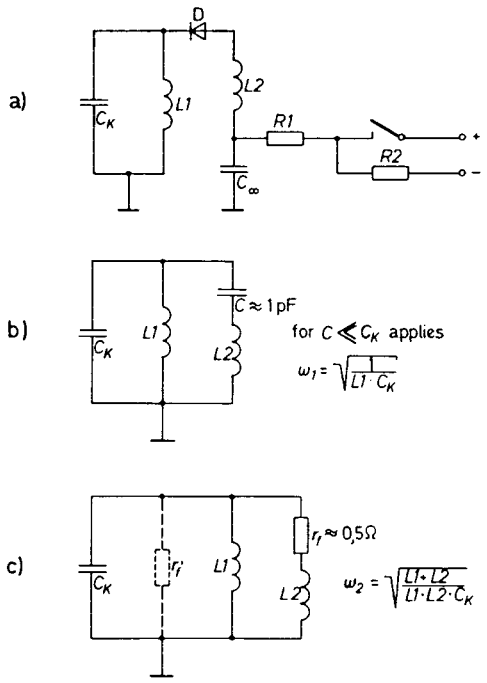

Figure 2-73 (a) Diode switch as a bandswitch, with an inductance in parallel; (b) equivalent circuit with blocked-diode switch; (c) equivalent circuit with conducting diode switch.

Instead of altering the resonant frequency of a tuned circuit by short-circuiting part of its inductance, the same result can be obtained by connecting a second inductance in parallel. The use of the diode switch for this purpose is illustrated in Figure 2-73. This differs from the one shown in Figure 2-71 in that the circuit inductance consists of either L_1 or of L_1 and L_2 in parallel. By applying a permanent negative bias to the diode via a high-value resistor R_2, it is possible to dispense with the use of one switch contact. Figure 2-73b shows the equivalent circuit for the diode under reverse-bias conditions (corresponding to a low resonant frequency), and Figure 2-73c shows the equivalent circuit under forward-bias conditions (corresponding to a higher resonant frequency).

In radio and television receivers, it usually is possible to derive the necessary reverse bias for the diode by rectification of the local oscillator signal, since the power required for blocking the diodes is extremely small. Note that under reverse-bias conditions the inductance L_2 and the capacitance C form a series-tuned acceptor circuit. However, this capacitance being extremely small, any undesirable effects due to its presence can normally be avoided. The same diode switching arrangements described for single-tuned circuits can also be employed in multisection bandpass and broadband filters.

In the following paragraph, a practical example for the use of diode switches will be given, and it will be seen that it is possible, in principle, to replace all of the mechanical RF switch contacts normally employed in receivers by diode switches. In cases where application of the diode dc potentials to a "cold" point in the circuit is not feasible, it may be necessary to apply them via *LC* or *RC* isolating networks.

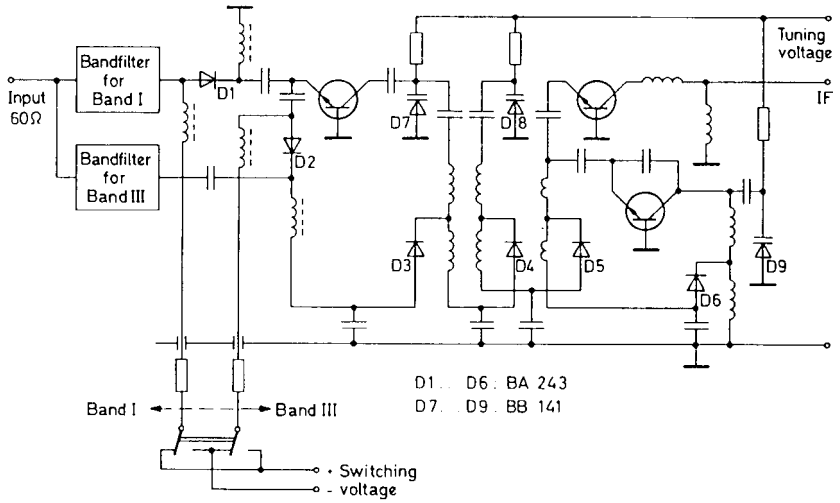

Figure 2-74 Schematic of a VHF television tuner with electronic band selection.

Use of the Diode Switch in a Television Receiver. Figure 2-74 shows the schematic of an electronically tuned and switched band I (48–62 MHz)/band III (175–224 MHz) TV tuner that requires switching of the input filter, bandpass filter, and oscillator circuit. These switching functions are performed by BA243 diode switches. As is customary in most European countries, in this example a broadband input filter between the antenna and the first RF transistor is used rather than a selective front-end circuit. In view of the need to correct noise and power matching over a relatively large frequency range, a switchable filter is employed in most tuners, switching being effected in this case by means of diodes D_1 and D_2.

Diodes D_3–D_6 are used for band-filter switching, for switching the coupling to the mixer transistor, and for switching the oscillator frequency. To minimize the bias-current requirements (each diode requires a bias current of approximately 10 mA), all diodes that are to be activated at the same time are connected in series. This arrangement requires only a few additional RF chokes, which are easily provided because of the high frequencies involved. The direct current required for the diode switches could be obtained by simple rectification, for example, from the heater circuit of the television receiver CRT, and the diode reverse bias could be obtained by rectification of the local oscillator signal, in which case the minute additional power requirement would have to be allowed for in the oscillator design.

A technically sophisticated design for a television tuner takes the form of a combined VHF/UHF unit incorporating electronically switched circuits in which several elements would be common. Such an all-band tuner can be assembled from only three transistors and a combined VHF/UHF band filter in $\lambda/2$ or $\lambda/4$ technology for UHF reception. The VHF circuits are short-circuited when the UHF position is selected.

Multistandard TV receivers require a large number of switch contacts in the tuner, the IF amplifier, the video amplifier, and the time base. The use of diode switches is particularly advantageous in this situation because it renders the physical layout of the equipment virtually independent of the location of the controls and obviates the need for long RF cable runs, which may be prone to interference.

2-2 BIPOLAR TRANSISTORS

2-2-1 Transistor Structure Types

All current RF silicon transistors are of the bipolar *npn* planar epitaxial type. Briefly, the significance of each of these terms is as follows.

Bipolar. In its broadest sense, it is the basic structure shown schematically in Figure 2-75, that is, the familiar three-semiconductor-region structure. *Bipolar* specifically means that the charge carriers of both negative (electron) and positive (hole) polarities are involved in the transistor action. In way of contrast, unipolar types include the junction-gate and insulated-gate field-effect transistors, which are basically one- or two-semiconductor-region structures in which carriers of a single polarity dominate.

npn. This abbreviation is for *negative–positive–negative* and identifies the regions of the structure as to polarity of the dominant or majority carrier in each region. The other polarity type is *pnp*. (See Figure 2-75.)

Silicon. Silicon (Si) is one of two elements from the fourth column of the periodic table that are in widespread use for transistor fabrication [the other is germanium (Ge)]. Other materials used include the compound gallium arsenide (GaAs). Although silicon is in predominant use because it results in the most favorable compromise among high-frequency, high-temperature, high-reliability, and ease-of-use attributes of the usable semiconductor material, silicon–germanium (SiGe) technology is increasingly important because it affords high-frequency performance unachievable with silicon alone.

Planar. The term planar denotes that both emitter–base and base–collector junctions of the transistor intersect the device surface in a common plane (hence, a better term might be *coplanar*). However, the real significance of the so-called planar structure is that the technique of diffusing dopants through an oxide mask, used in fabricating such a structure, results in junctions being formed beneath a protective oxide layer. These protected junctions are less prone to the surface problems sometimes associated with other types of structures, such as the mesa.

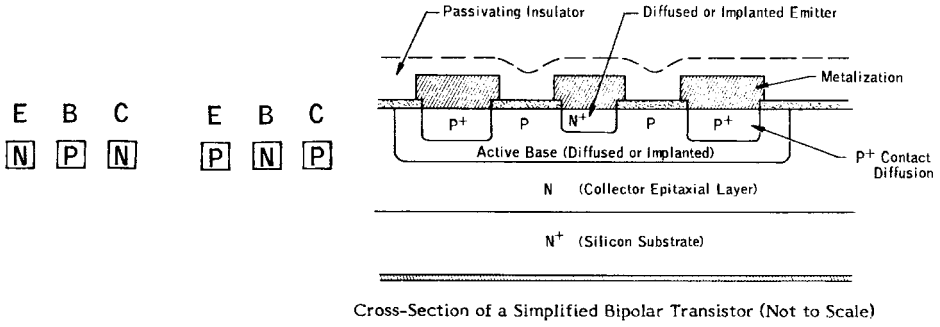

Figure 2-75 Transistor structure schematic.

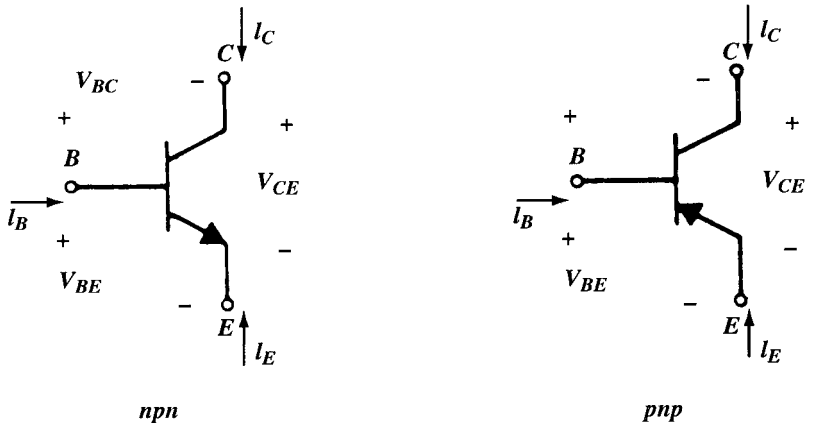

Figure 2-76 Bipolar transistor sign convention.

Epitaxial. This term, as it is commonly used, is actually a shortening of the term *epitaxial-collector*. That is, the collector region of the transistor is formed by the epitaxial technique, rather than by diffusion, which is commonly used to form the base and emitter regions. The epitaxial layer is formed by condensing a single-crystal film of semiconductor material on a wafer or substrate that is usually of the same material. Thus, an epitaxial (collector) transistor is one in which the collector region is formed on a low-resistivity substrate. Subsequently, the base and emitter regions are diffused into the "epi" layer. The epitaxial technique lends itself to precise tailoring of collector-region thickness and resistivity with consequent improved device performance and uniformity.

2-2-2 Large-Signal Behavior of Bipolar Transistors*

In this section, the large-signal or dc behavior of bipolar transistors is considered. Large-signal models are developed for the calculation of total currents and voltages in transistor circuits, and such effects as breakdown-voltage limitations, which are usually not included in models, are also considered. Second-order effects, such as current-gain variation with collector current and Early voltage, can be important in many circuits and are treated in detail.

The sign conventions used for bipolar transistor currents and voltages are shown in Figure 2-76. All bias currents for both *npn* and *pnp* transistors are assumed positive going into the device.

Electrical and Performance Characteristics and Specifications. Electrical characteristics may be described as uniquely defined, measurable electrical transistor properties that are not a function of the measuring circuit or apparatus (except insofar as standard terminations and measurement accuracy are concerned). Performance or operating characteristics are also electrical properties but they are, in general, not unique because their values depend on the measuring circuit (in particular, source and load impedance, which may be arbitrary). As might be expected, the terms are often used somewhat loosely (and sometimes

* Portions of this section, Sections 2-2-3 through 2-2-5, and Sections 2-3-3 through 2-3-6 are based on Paul R. Gray and Robert G. Meyer, *Analysis and Design of Analog Integrated Circuits*, 3rd ed., ©1993 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

interchangeably), especially in cases where only subtle differences are involved. The terms are generally used on transistor datasheets to segregate (for emphasis) under performance or operating characteristics those properties most directly applicable to the primary intended application.

Performance (Operating) Characteristics. Of the numerous performance characteristics that can be specified for high-frequency transistors, perhaps the most fundamental and pertinent characteristics are:

- Power gain and noise figure, for small-signal applications
- Power gain, power output, and efficiency, for large-signal applications

All of these characteristics are, of course, functions of frequency, bias temperature, and so on, and to completely characterize a transistor over its full frequency, bias, and temperature ranges would be prohibitively costly. Consequently, characterization data are given only for restricted ranges of these variables. These data should portray sufficiently the capabilities of a particular device for its intended applications. In the case of maximum ratings, some applications may require additional characterization by the user or through applications assistance from the manufacturer.

POWER GAIN

G_{max}. Of the various definitions for the measurement of power flow in an active two-port device, such as a transistor, two are unique enough to allow specification without recourse to specifying the complete measuring circuit in detail. One of these definitions is termed *maximum available gain* (G_{max}) and is the power gain obtained when the input and output ports are simultaneously conjugately matched to source and load impedances, respectively. Implicit in this definition is the assumption that the two-port is unconditionally stable; that is, that no combination of input/output tuning can result in increasing gain to the point of oscillation.

$|S_{21}|^2$. The other unique power gain is the gain realized when the transistor is inserted between a source and load with identical impedances (in practice, usually $50 + j0\ \Omega$). This particular insertion of transducer gain happens to coincide with the usual definition of the two-port forward scattering parameter, S_{21}. More precisely, it is equal to the magnitude squared of this parameter and is therefore often identified by the symbol $|S_{21}|^2$. For wideband applications, $|S_{21}|^2$ is important because wideband terminations "not too different from 50 Ω" are more easily realized than are wideband transforming networks that provide the matching required for G_{max}.

NOISE FIGURE. A common measure of the noise generated by an active two-port device—noise that sets a lower limit on amplifier sensitivity—is noise factor (F). This is defined as

$$F = \frac{\text{Input signal-to-noise ratio}}{\text{Output signal-to-noise ratio}} \tag{2-110}$$

or more generally as

$$F = \frac{\text{Total output noise power}}{\text{Output power due to source resistance}} \tag{2-111}$$

At high frequencies, spot noise factor or noise factor for a small fractional bandwidth (say, 1%) is used and is usually expressed as *noise figure* (*NF*), in decibels:

$$NF = 10 \log F \tag{2-112}$$

As already discussed, noise figure is a function of source impedance (as well as functions of frequency, bias, etc.) and hence, there is an infinity of noise figures associated with a given device corresponding to the infinity of possible impedances that may be presented to the device input. The only unique one, in the sense that it does not involve arbitrary source impedances, is $NF_{\min}$, the minimum noise figure obtained (at a given bias and frequency) when the input is tuned to optimize this parameter. This is the noise figure value commonly given on datasheets.

In practical amplifiers that involve more than one stage, *overall noise factor* (F_O) is given by

$$F_O = F_1 + \frac{F_2 - 1}{G_1} + \cdots + \frac{F_n - 1}{G_{(n-1)}} \tag{2-113}$$

where n = number of stages
G_n = gain of the nth stage
F_n = noise factor of the nth stage

This expression emphasizes the important fact that for low-noise amplifiers, the first stage must be designed for the lowest noise figure and highest gain possible. [Note that the noise contribution of the second stage is divided (reduced) by the gain of the first stage.] Since the optimum source impedance and bias currents for optimum gain and noise figure do not often coincide, very careful circuit design is required to minimize overall noise figure. For more accuracy, we recommend the noise correlation approach.

POWER OUTPUT. This characteristic is important for both amplifier and oscillator transistors. In both cases, it is extremely circuit sensitive. For amplifiers, maximum useful output is often limited to that power output level at which gain has compressed 1 dB, an indicator of the upper limit of the device's linearity range. For oscillators, it is merely a quantitative measure of RF power for given dc input power.

EFFICIENCY. In the most general sense, this characteristic expresses as a percentage the ratio of RF power output to the total circuit input power, both dc and RF. That expression is efficiency, η, defined as

$$\eta = \frac{P_O}{P_i + P_{\text{dc}}} \times 100 \tag{2-114}$$

where P_O = RF output power
P_i = RF input power
P_{dc} = total dc power input

Since for oscillator transistors there is no RF power input, and for amplifier transistors the maximum input RF power is calculable from the power gain and power output specifications,

the inclusion of P_i in efficiency is redundant. Moreover, since the major portion of the dc power is dissipated by the transistor collector, a more restricted definition of efficiency is pertinent. This parameter, termed *collector efficiency* (η_C), is given by

$$\eta_C = \frac{P_O}{P_{CC}} \times 100 \tag{2-115}$$

where $P_{CC} = V_{CC} \times I_{CC}$
V_{CC} = collector supply voltage
I_{CC} = collector supply current

Electrical Characteristics. Electrical characteristics may be conveniently classified into two main types, dc and ac.

dc CHARACTERISTICS. The importance of dc characteristics of high-frequency transistors lies primarily in biasing and reliability considerations. However, certain dc characteristics are also directly related to high-frequency performance. For example, high-frequency noise figure is affected by dc current gain. The dc characteristics discussed here are those usually found on high-frequency transistor datasheets.

$V_{(BR)CBO}$, I_{CBO}. These two parameters serve to characterize the reverse-biased collector–base *pn* junction and are defined as follows (with the aid of Figure 2-77a). The collector–base breakdown voltage, $V_{(BR)CBO}$, identifies the voltage at which collector current tends to increase without limit, usually due to the high electric field developed across the junction. This voltage sets a limit on the maximum transistor operating voltage and, as mentioned before under maximum ratings, usually is the basis for the collector–base maximum voltage rating. $V_{(BR)CBO}$ should be specified at a value of $I_C = I_{C1}$ in the figure, which is within the avalanche (or high slope) region of the device's reverse characteristic. Typical values of I_{C1} are in the 1–10-μA region for high-frequency transistors.

To further define the quality of the reverse *I–V* characteristic, a specification is usually placed on the collector cutoff current, I_{CBO}, which is measured at some value of collector–base voltage less than $V_{(BR)CBO}$. For a good-quality silicon junction ("sharp" instead of soft; see Figure 2-77a), I_{CBO} is in the nanoampere range.

$V_{(BR)EBO}$, I_{EBO}. These two parameters characterize the reverse-biased emitter–base *pn* junction in an analogous manner to the collector–base junction parameters $V_{(BR)CBO}$ and I_{CBO}, given above, and are shown in Figure 2-77b. No further discussion of these parameters will be given here.

$V_{(BR)CEO}$, I_{CEO}. The collector–emitter breakdown voltage and cutoff current are somewhat more complex in nature than the collector–base and emitter–base parameters. In the latter two, only a single *pn* diode is involved. In the collector–emitter case, two diodes are involved. Moreover, each is influenced by the other through transistor action, since the reverse current of the collector–base diode flows through the emitter–base junction as forward current. Thus, the collector–base reverse current is amplified by the dc current gain of the transistor, resulting in:

- I_{CEO} being greater than I_{CBO} (for a given voltage)
- Typically, the familiar negative-resistance region in the *I–V* characteristic as shown in Figure 2-77c.

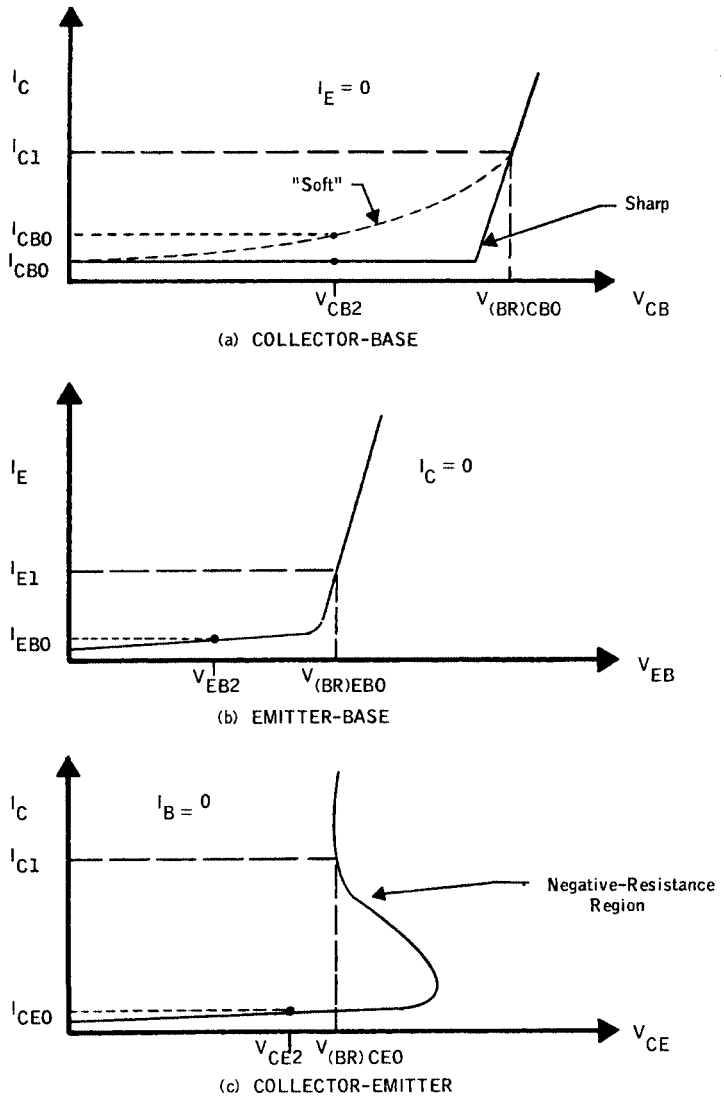

Figure 2-77 Transistor reverse *I–V* characteristics.

Consequently, $V_{(BR)CEO}$ is typically specified at collector currents one to three orders of magnitude higher than in the case of $V_{(BR)CBO}$ and $V_{(BR)EBO}$ to establish the minimum value of this characteristic.

h_{fe}. This parameter is simply the dc common-emitter current gain; that is, the ratio of collector current to base current at some specified collector voltage and current.

ac CHARACTERISTICS. Of the numerous ac characteristics defined for transistors, only relatively few are commonly used in characterizing high-frequency transistors. Some of the more pertinent parameters are briefly covered here.

S Parameters. By far the most useful and conveniently measured set of two-port parameters for transistor high-frequency (roughly 100 MHz and above) characterization is

the *S*-parameter or scattering-matrix set. These parameters completely and uniquely define the small-signal gain and input/output immittance properties of any linear "black box." (By definition, a transistor or any active device is linear under small-signal conditions.) However, these parameters reveal nothing (except possibly indirectly and approximately) about large-signal or noise behavior. Simply interpreted (more general definitions and other interpretations abound in the technical literature), the *S* parameters are merely insertion gains, forward and reverse, and reflection coefficients, input and output, with driven and nondriven ports both terminated in equal impedances, usually $50 + j0\ \Omega$. Such an interpretation tends to make *S* parameters very attractive, once some familiarity is gained, at high (especially microwave) frequencies, since the power flow or gain and reflection-coefficient concepts are more intuitively meaningful than voltage and current conceptual schemes. It should also be mentioned that *S*-parameters can be converted through straightforward matrix transformations to other two-port parameter sets, such as *h*-, *y*-, and *z*-parameters.

Proceeding with more specific definitions, the *S*-parameters are defined analytically by

$$b_1 = S_{11}a_1 + S_{12}a_2 \tag{2-116}$$

$$b_2 = S_{21}a_1 + S_{22}a_2 \tag{2-117}$$

or, in matrix form,

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} \tag{2-118}$$

where, referring to Figure 2-78

a_1 = (incoming power at Port 1)$^{1/2}$
b_1 = (outgoing power at Port 1)$^{1/2}$
a_2 = (incoming power at Port 2)$^{1/2}$
b_2 = (outgoing power at Port 2)$^{1/2}$
E_1, E_2 = electrical stimuli at Port 1, Port 2

From the figure and defining linear equations, for $E_2 = 0$, then $a_2 = 0$, and (skipping through numerous rigorous steps)

$$S_{11} = \frac{b_1}{a_1}$$

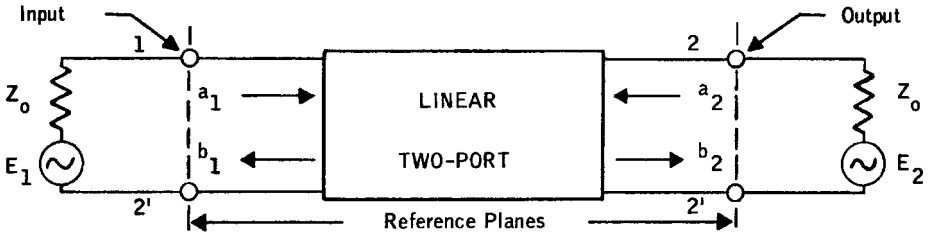

Figure 2-78 Two-port *S*-parameter definition.

$$= \left(\frac{\text{Outgoing input power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \frac{\text{Reflected voltage}}{\text{Incident voltage}}$$

$$= \text{Input reflection coefficient} \tag{2-119}$$

$$S_{21} = \frac{b_2}{a_1}$$

$$= \left(\frac{\text{Outgoing output power}}{\text{incoming input power}}\right)^{1/2}$$

$$= \left(\frac{\text{Output power}}{\text{Available input power}}\right)^{1/2}$$

$$= (\text{Forward transducer gain})^{1/2} \tag{2-120}$$

or, more precisely in the case of S_{21}:

$$\text{Forward transducer gain} = G_{\text{TF}} = |S_{21}|^2 \tag{2-121}$$

$$Z_i = Z_o \tag{2-122}$$

Similarly, at Port 2 for $E_1 = 0$, then $a_1 = 0$, and

$$S_{22} = \frac{b_2}{a_2} = \text{Output reflection coefficient} \tag{2-123}$$

$$S_{12} = \frac{b_1}{a_2} = (\text{Reverse transducer gain})^{1/2} \tag{2-124}$$

$$G_{\text{TR}} = |S_{12}|^2 \tag{2-125}$$

Since many measurement systems display *S*-parameter magnitudes in decibels, the following relationships are particularly useful:

$$|S_{11}|_{\text{dB}} = 10\log|S_{11}|^2$$

$$= 20\log|S_{11}| \tag{2-126}$$

$$|S_{22}|_{\text{dB}} = 20\log|S_{22}| \tag{2-127}$$

$$|S_{21}|_{\text{dB}} = 10\log|S_{21}|^2$$

$$= 20 \log|S_{21}|$$

$$= 10 \log|G_{TF}| = |G_{TF}|_{dB} \tag{2-128}$$

$$|S_{12}|_{dB} = 10 \log|S_{12}|^2$$

$$= 20 \log|S_{12}|$$

$$= 10 \log|G_{TR}| = |G_{TR}|_{dB} \tag{2-129}$$

Figure 2-79 shows an example of the use of *S* parameters in transistor stage design.

Transition Frequency. One of the better known, but perhaps least understood, figures of merit for high-frequency transistors is the so-called transition frequency, f_T. Part of the misunderstanding that appears to exist is due to the use of the misleading (but common, for

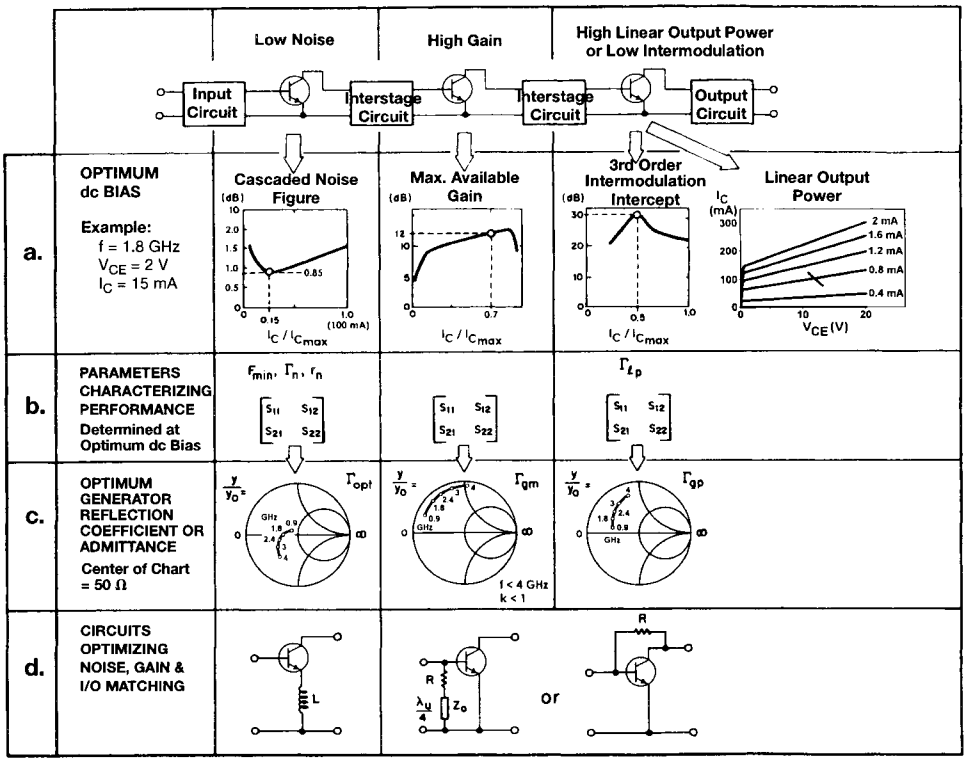

Figure 2-79 Key parameters in applying a BJT in low-noise front-end, high-gain, and linear-power stages. (a) The BJT characteristics that lead to optimum dc bias for a low-noise front end; (b) parameters characterizing device performance; (c) Γ_{opt} for the first stage, and S_{11} and S_{22} for the output stage as simulated by CAD software. The example is based on the Siemens BJTs BFP420 (low-noise stage), BFP450 (high-gain stage), and BFG235 (output stage). Circuits to optimize stage noise, gain, and I/O matching are shown in (d). (Presentation based on Figure 14 in Charles A. Liechti, "Microwave Field-Effect Transistors—1976," *IEEE Trans. Microwave Theory Tech.,* vol. MTT-24, pp. 279–300, June 1976.)

historical reasons) term *short-circuit gain–bandwidth product* for this parameter. By definition, f_T is that characteristic frequency described by the equation

$$f_T = h_{fe} \times f_{\text{meas}} \tag{2-130}$$

where h_{fe} is the magnitude of the small-signal common-emitter short-circuit current gain, and f_{meas} is the frequency of measurement, chosen such that

$$2 \le h_{fe} \le \frac{h_{fe0}}{2} \tag{2-131}$$

where h_{fe0} is the low-frequency value of h_{fe}.

To varying degrees of approximation, depending on the transistor type, f_T is the frequency at which h_{fe} approximates unity. It is not, in general, the frequency at which h_{fe} is precisely equal to unity. To clarify these points further, consider the plot of h_{fe} against frequency sketched in Figure 2-80.

At low frequencies, $f << f_B$, h_{fe} is constant and equal to h_{fe0}.

At f_B, h_{fe} has decreased to 0.707 h_{fe0}; that is, f_B is the 3-dB cutoff frequency for common-emitter short-circuit current gain, h_{fe}.

For frequencies such that

$$2f_B < f < f_T \tag{2-132}$$

h_{fe} varies inversely proportional to frequency. That is, the f_T defining relationship holds:

$$h_{fe} \times f_{\text{meas}} = \text{constant} = f_T \tag{2-133}$$

At frequencies approaching f_T, other parameters, especially package parasitics, can cause $|h_{fe}|$ to depart significantly from this $1/f$ variation. Therefore, the frequency, f_1, at which $|h_{fe}|$ actually equals unity can be somewhat different from f_T.

Applying these frequency-gain characteristics to the common-emitter wideband, low-pass amplifiers gives rise to the terminology of f_T being a "gain–bandwidth product." However,

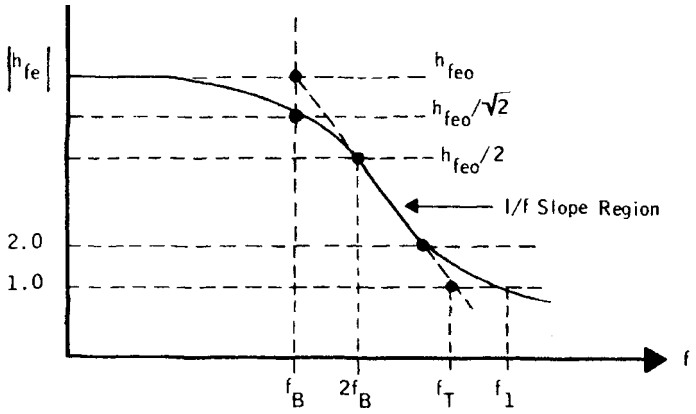

Figure 2-80 $|h_{fe}|$ frequency characteristics.

this is an optimistic approximation at best, since the product of low-frequency circuit gain and the 3-dB cutoff frequency is reduced from f_T by an amount that depends on circuit impedances.

The real significance of f_T lies in the fact that it is a measure of certain internal transistor parameters that do, in fact, affect high-frequency performance: for example, gain (though not in the convenient quantitative manner implied by the term "gain–bandwidth product"). In particular, good high-frequency noise performance requires that f_T be high. Thus, f_T is included on transistor datasheets primarily as a figure of merit, not as a parameter to be used directly in design.

Collector–Base Time Constant, $r_b'C_c$. This is an internal device parameter that relates only indirectly to high-frequency performance. It is primarily a measure of internal feedback within the transistor. It also relates to transistor high-frequency impedance. As the name says (in symbols), it is a measure of transistor base resistance and collector capacitance in combination; however, except for certain low-frequency transistors, it cannot be considered the simple two-element lumped *RC* time constant implied by the terminology. (In high-frequency transistors, base resistance and collector impedance must be considered to be distributed when considered in detail). As a figure of merit, it is included on transistor datasheets to indicate how well base resistance and collector impedance have been minimized. It also allows the estimation of certain gain properties of the transistor (see the $f_{\max}$ parameter, which we'll describe shortly).

Collector–Base Capacitance, C_{cb}. This parameter is simply the total collector–base *pn* junction capacitance measured at a low frequency (typically, 1 MHz), where it can be considered a single lumped element. For high-frequency transistors it is, of course, desirable that C_{cb} be small from bandwidth and stability considerations as well as from gain considerations alone.

Maximum Frequency of Oscillation, $f_{\max}$. This is another figure-of-merit parameter, as opposed to measurable parameters directly usable in the application of transistors. Its importance stems from the following approximate relationships (which will not be derived here):

$$f_{\max} \approx \left(\frac{f_T}{8\pi r_b' C_C} \right)^{1/2} \tag{2-134}$$

$$G_{\max} \approx \left(\frac{f_{\max}}{f_{\text{oper}}} \right)^2 \tag{2-135}$$

These expressions illustrate in a quantitative way the importance and the interrelationship between high f_T and low $r_b'C_C$ insofar as high-frequency gain is concerned. However, since they are approximations and since their derivation involves several assumptions that are not always valid, they must be interpreted with caution. For example, the expression for $G_{\max}$ is obviously not applicable at low frequencies, since as $f \to 0$, $G_{\max} \to \infty$, according to this expression. As a rule of thumb, the $G_{\max}$ expression is a reasonable approximation for frequencies such that

$$5 > \frac{f_{\max}}{f_{\text{oper}}} > 1 \tag{2-136}$$

For accurate analysis of transistor gain and stability, a complete set of two-port parameters must be employed in exact expressions, such as those from which the approximations shown above were derived.

Datasheet Transistor Specifications. The following is a reprint of a Siemens microwave transistor datasheet. This 25-GHz f_T transistor will soon be replaced by a 40-GHz family, based on a silicon–germanium design. Key parameters describing the transistor are:

- The dc parameters, such as maximum current and voltage and dissipation
- Noise figure as a function of generator impedance, bias point, and frequency
- Frequency-dependent behavior, typically expressed in *S* parameters, and also as a function of bias point and frequency
- Large-signal performance to be calculated based on a nonlinear model, such as the Gummel–Poon

The transistor description typically gives details about packaging, as the Gummel–Poon model is intrinsic (without parasitics). Not only does the package determine the parasitics, it also affects the device's ability to transfer heat to its heat sink. The following figures, reproduced with permission from the datasheet for the BFP420 transistor by Siemens (now Infineon Technologies), are a typical representation of the dc-I_C curves, *S* parameters, and noise parameters of a normal, packaged microwave transistor. Besides its dc parameters and capacitance, there are other critical parameters. A BJT's noise figure is a strong function of its dc current gain, and one can determine a 3-dB cutoff frequency referred to as f_T, which shows the gain roll-off as a function of collector current and frequency. Another important measure or figure of merit is $f_{\max}$, the maximum frequency of oscillation:

$$f_{\max} = \sqrt{\frac{|Y_{21}|}{16\pi R_{bb} C_{be} C_{bc}}} \tag{2-137}$$

Figure 2-81 shows a photograph of the die for the BFP420.

Since the intercept point is an important figure of merit, Figure 2-82 shows intercept point as a function of bias point for the BFR93AW BJT. We wish more manufacturers would supply this information.

2-2-3 Large-Signal Transistors in the Forward-Active Region

We saw in the diode case that its description is physics-based and it is, therefore, logical to apply the same modeling for the transistors. The first complete modeling for transistors was described in the Gummel–Poon model, but many engineers use the somewhat more simpler Ebers–Moll model. By combining two diodes, the parasitic elements, and the base separating resistor, we can show the "intrinsic" nonlinear model for the bipolar transistor.

Many equations that have been published contain some approximations, but for exact nonlinear analysis, we have to resort to the somewhat more complex or complete equations as shown in Appendix A for the bipolar model.

Recently, some other models have been proposed by researchers, such as the MEXTRAM models (Philips), but the trouble with these models is that while they may give quite good results for RF applications, it is virtually impossible to obtain parameters for them. So far the only industry-standard model is the Gummel–Poon, and to the authors' knowledge there

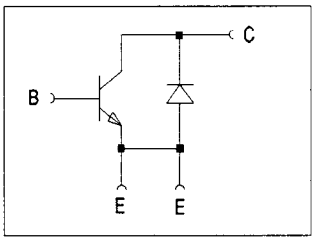
For non-linear simulation:

- Use transistor chip parameters in Berkeley SPICE 2G.6 syntax for all simulators.
- If you need simulation of the reverse characteristics, add the diode with the C'-E'-diode data between collector and emitter.
- Simulation of the package is not necessary for frequencies < 100 MHz.
  For higher frequencies add the wiring of the package equivalent circuit around the non-linear transistor and diode model.

Note:

- This transistor is constructed in a common emitter configuration. This feature causes an additional, reverse biased diode between emitter and collector, which does not effect normal operation.



Transistor Schematic Diagram

The common emitter configuration shows the following advantages:

- Higher gain because of lower emitter inductance.
- Power is dissipated via the grounded emitter leads, because the chip is mounted on the copper emitter leadframe.

Please note, that the broadest lead is the emitter lead.

- The AC-Characteristics are verified by random sampling.

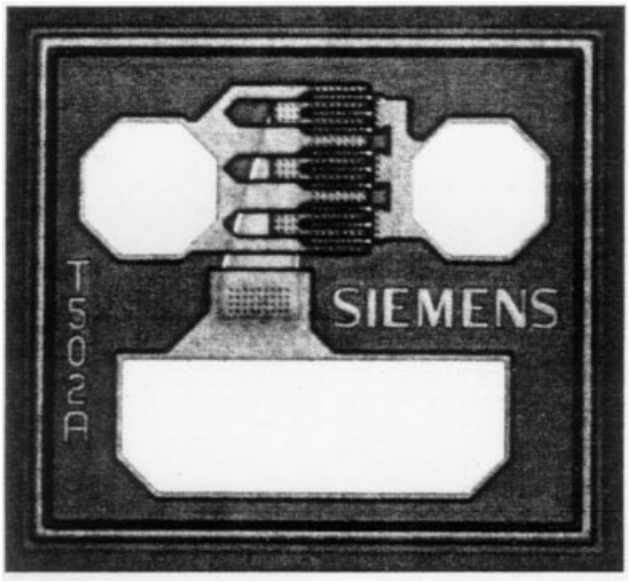


Figure 2-81 Photograph of the BFP420 die (310 × 290 μm). The bonding pad for the base is at the upper right; for the collector at the upper left. The large, lower pad connects to the emitter.

are no accepted or affordable parameter extractor programs available, not even to consider the cost of hardware for such extractions. Hewlett-Packard recently published a system with a hardware cost in the vicinity of $1 million.

A typical *npn* planar bipolar transistor structure is shown in Figure 2-83a, where collector, base, and emitter are labeled *C*, *B*, and *E*, respectively. The impurity doping density in the base and the emitter of such a transistor is not constant but varies with distance from the top surface. However, many of the characteristics of such a device can be predicted by analyzing

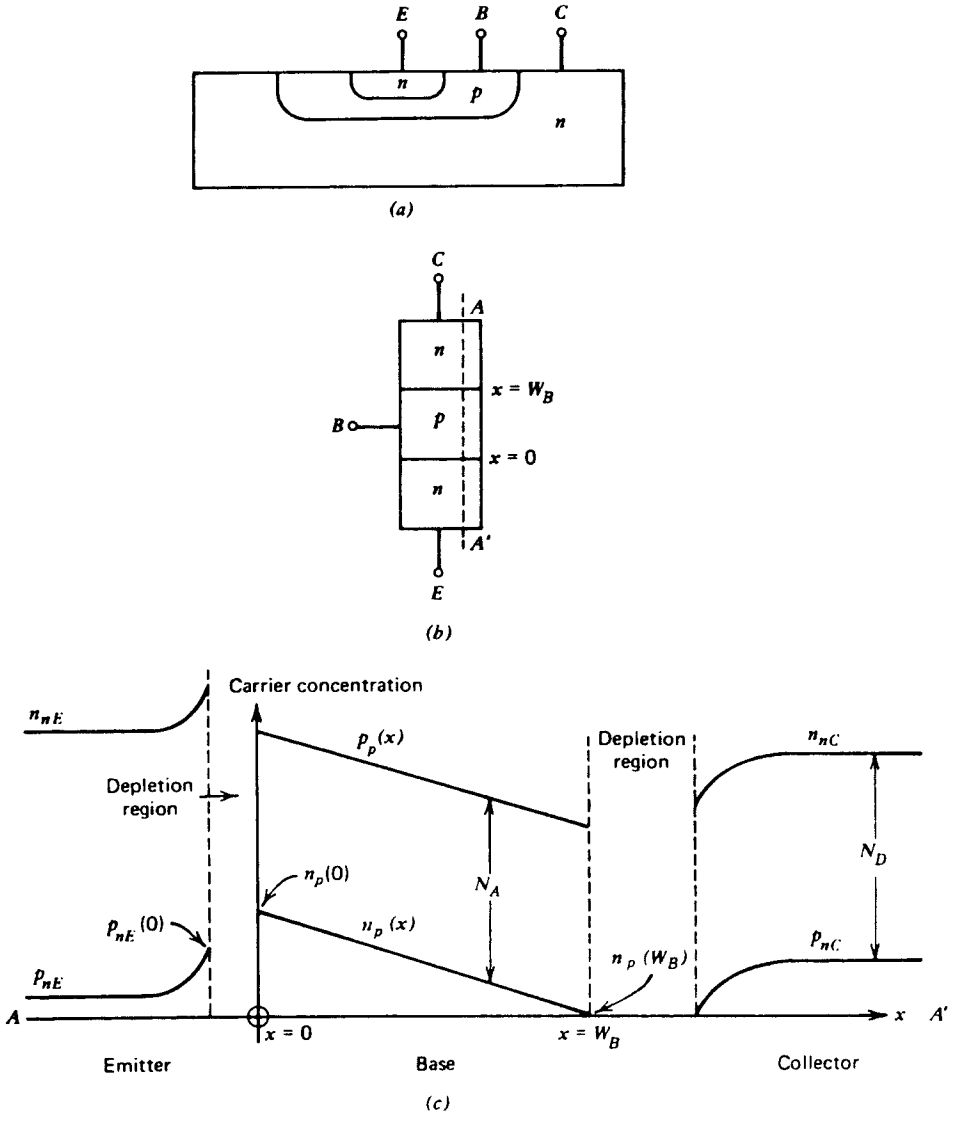

Figure 2-83 (a) Cross section of a typical *npn* planar bipolar transistor structure; (b) idealized transistor structure; (*c*) carrier concentrations along the cross section *AA*′ of the transistor in (b). Uniform doping densities are assumed. (Not to scale)

the idealized transistor structure shown in Figure 2-83b. In this structure, the base and emitter doping densities are assumed constant, and this is sometimes called a "uniform-base" transistor. Where possible in the following analyses, the equations for the uniform-base analysis are expressed in a form that applies also to nonuniform-base transistors.

A cross section AA' is taken through the device of Figure 2-83b and carrier concentrations along this section are plotted in Figure 2-83c. Hole concentrations are denoted by p and electron concentrations by n with subscripts p or n representing p-type or n-type regions. The n-type emitter and collector regions are distinguished by subscripts E and C, respectively. The carrier concentrations shown in Figure 2-83c apply to a device in the *forward-active region*. That is, the base–emitter junction is forward-biased and the base–collector junction is reverse-biased. The minority-carrier concentrations in the base at the edges of the depletion regions can be calculated from a Boltzmann approximation to the Fermi–Dirac distribution function to give [2]

$$n_p(0) = n_{po} \exp \frac{V_{BE}}{V_T} \tag{2-138}$$

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \simeq 0 \tag{2-139}$$

where W_B is the width of the base from the base–emitter junction depletion layer edge of the base–collector depletion layer edge and n_{po} is the equilibrium concentration of electrons in the base. Note that V_{BC} is negative for an *npn* transistor in the forward-active region and thus $n_p(W_B)$ is very small. Low-level injection conditions are assumed in the derivation of Eqs. (2-138) and (2-139). This means that the minority-carrier concentrations are always assumed much smaller than the majority-carrier concentrations.

If *recombination* of holes and electrons in the base is small, it can be shown that the minority-carrier concentration $n_p(x)$ in the base varies *linearly* with distance [3]. Thus, a straight line can be drawn joining the concentrations at $x = 0$ and $x = W_B$ in Figure 2-83c.

For charge neutrality in the base, it is necessary that

$$N_A + n_p(x) = p_p(x) \tag{2-140}$$

and thus

$$p_p(x) - n_p(x) = N_A \tag{2-141}$$

where $p_p(x)$ is the hole concentration in the base and N_A is the base doping density that is assumed constant. Equation (2-141) indicates that the hole and electron concentrations are separated by a constant amount and thus $p_p(x)$ also varies linearly with distance.

Collector current is produced by minority-carrier electrons in the base diffusing in the direction of the concentration gradient and being swept across the collector–base depletion region by the field existing there. The diffusion current density due to electrons in the base is

$$J_n = qD_n \frac{dn_p(x)}{dx} \tag{2-142}$$

where D_n is the diffusion constant for electrons. From Figure 2-83c,

$$J_n = -qD_n \frac{n_p(0)}{W_B} \tag{2-143}$$

If I_C is the collector current and is taken as positive flowing *into* the collector, it follows from Eq. (2-143) that

$$I_C = qA D_n \frac{n_p(0)}{W_B} \tag{2-144}$$

where A is the cross-sectional area of the emitter. Substitution of Eq. (2-138) into Eq. (2-144) gives

$$I_C = \frac{qAD_n n_{po}}{W_B} \exp \frac{V_{BE}}{V_T} \tag{2-145}$$

$$= I_S \exp \frac{V_{BE}}{V_T} \tag{2-146}$$

where

$$I_S = \frac{qA D_n n_{po}}{W_B} \tag{2-147}$$

and I_S is a constant used to describe the transfer characteristic of the transistor in the forward-active region. Equation (2-147) can be expressed in terms of the base doping density by noting that [4]

$$n_{po} = \frac{n_i^2}{N_A} \tag{2-148}$$

and substitution of Eq. (2-148) in Eq. (2-147) gives

$$I_S = \frac{qAD_n n_i^2}{W_B N_A} = \frac{qA\overline{D}_n n_i^2}{Q_B} \tag{2-149}$$

where $Q_B = W_B N_A$ is the number of doping atoms in the base per unit area of the emitter and n_i is the intrinsic carrier concentration in silicon. In this form Eq. (2-149) applies to both uniform- and nonuniform-base transistors and D_n has been replaced by $\overline{D}_n$, which is an average effective value of the electron diffusion constant in the base. This is necessary for nonuniform-base devices because the diffusion constant is a function of impurity concentration. Typical values of I_S as given by Eq. (2-149) are 10^{-14} to 10^{-16} A.

Equation (2-146) gives the collector current as a function of base–emitter voltage. The base current I_B is also an important parameter and, at moderate current levels, consists of two major components. One of these (I_{B1}) represents recombination of holes and electrons in the base and is proportional to the minority-carrier charge Q_e in the base. From Figure 2-83c, the minority-carrier charge in the base is

$$Q_e = \frac{1}{2} n_p(0) W_B q A \tag{2-150}$$

and we have

$$I_{B1} = \frac{Q_e}{\tau_b} = \frac{1}{2} \frac{n_p(0) W_B q A}{\tau_b} \tag{2-151}$$

where τ_b is the minority-carrier lifetime in the base. I_{B1} represents a flow of majority holes from the base lead into the base region. Substitution of Eq. (2-138) into Eq. (2-151) gives

$$I_{B1} = \frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} \exp \frac{V_{BE}}{V_T} \tag{2-152}$$

The second major component of base current (usually the dominant one in the integrated-circuit *npn* devices) is due to injection of holes from the base into the emitter. This current component depends on the gradient of minority-carrier holes into the emitter and is [5]

$$I_{B2} = \frac{q A D_p}{L_p} p_{nE}(0) \tag{2-153}$$

where D_p is the diffusion constant for holes and L_p is the diffusion length (assumed small) for holes in the emitter. $p_{nE}(0)$ is the concentration of holes in the emitter at the edge of the depletion region and is

$$P_{nE}(0) = p_{nEo} \exp \frac{V_{BE}}{V_T} \tag{2-154}$$

If N_D is the donor atom concentration in the emitter (assumed constant) then

$$p_{nEo} \simeq \frac{n_i^2}{N_D} \tag{2-155}$$

The emitter is deliberately doped much more heavily than the base, making N_D large and p_{nEo} small, so that the base-current component, I_{B2}, is minimized.

Substitution of Eqs. (2-154) and (2-155) into Eq. (2-153) gives

$$I_{B2} = \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \exp \frac{V_{BE}}{V_T} \tag{2-156}$$

The total base current, I_B, is the sum of I_{B1} and I_{B2}:

$$I_B = I_{B1} + I_{B2} = \left(\frac{1}{2} \frac{n_{po} W_B q A}{\tau_b} + \frac{q A D_p}{L_p} \frac{n_i^2}{N_D} \right) \exp \frac{V_{BE}}{V_T} \tag{2-157}$$

Although this equation was derived assuming uniform base and emitter doping, it gives the correct functional dependence of I_B on device parameters for practical double-diffused

nonuniform-base devices. Second-order components of I_B, which are important at low current levels, are considered later.

Since I_C in Eq. (2-146) and I_B into Eq. (2-147) are both proportional to $\exp(V_{BE}/V_T)$ in this analysis, the base current can be expressed in terms of collector current as

$$I_B = \frac{I_C}{\beta_F} \tag{2-158}$$

where β_F is the forward current gain. An expression for β_F can be calculated by substituting Eqs. (2-145) and (2-157) into Eq. (2-158) to give

$$\beta_F = \frac{qAD_n n_{po}/W_B}{\frac{1}{2}\frac{n_{po}W_B qA}{\tau_b} + \frac{qAD_p n_i^2}{L_p N_D}} = \frac{1}{\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-159}$$

where Eq. (2-148) has been substituted for n_{po}. Equation (2-159) shows that β_F is maximized by minimizing the base width W_B and maximizing the ratio of emitter to base doping densities N_D/N_A. Typical values of β_F for *npn* transistors in integrated circuits are 50–500, whereas lateral *pnp* transistors have values of 10–100. Finally, the emitter current is

$$I_E = -(I_C + I_B) = -\left(I_C + \frac{I_C}{\beta_F}\right) = -\frac{I_C}{\alpha_F} \tag{2-160}$$

where

$$\alpha_F = \frac{\beta_F}{1+\beta_F} \tag{2-161}$$

The value of α_F can be expressed in terms of device parameters by substituting Eq. (2-159) into Eq. (2-161) to obtain

$$\alpha_F = \frac{1}{1+\frac{1}{\beta_F}} = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n} + \frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \simeq \alpha_T \gamma \tag{2-162}$$

where

$$\alpha_T = \frac{1}{1+\frac{W_B^2}{2\tau_b D_n}} \tag{2-163}$$

$$\gamma = \frac{1}{1+\frac{D_p}{D_n}\frac{W_B}{L_p}\frac{N_A}{N_D}} \tag{2-164}$$

The validity of Eq. (2-162) depends on $W_B^2/2\tau_b D_n << 1$ and $(D_p/D_n)(W_B/L_p)(N_A/N_D) << 1$, and this is always true if β_F is large [see Eq. (2-159)]. The term γ in Eq. (2-162) is

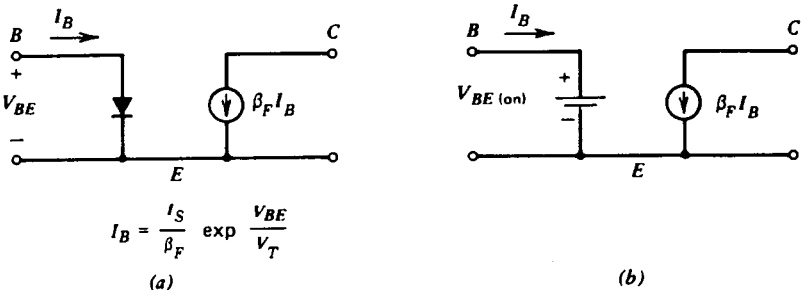

Figure 2-84 Large-signal models of *npn* transistors for use in bias calculations. (a) Circuit incorporating an input diode. (b) Simplified circuit with an input voltage source.

called the *emitter injection efficiency* and is equal to the ratio of the electron current (*npn* transistor) injected into the base from the emitter to the total hole and electron current crossing the base–emitter junction. Ideally $\gamma \to 1$, and this is achieved by making N_D/N_A large and W_B small. In that case very little reverse injection occurs from base to emitter.

The term α_T in Eq. (2-162) is called the *base transport factor* and represents the fraction of carriers injected into the base (from the emitter) that reach the collector. Ideally $\alpha_T \to 1$, and this is achieved by making W_B small. It is evident from the above development that fabrication changes that cause α_T and γ to approach unity also maximize the value of β_F of the transistor.

The results derived above allow formulation of a large-signal model of the transistor suitable for bias-circuit calculations with devices in the forward-active region. One such circuit is shown in Figure 2-84 and consists of a base–emitter diode to model Eq. (2-157) and a controlled collector-current generator to model Eq. (2-158). Note that the collector voltage ideally has no influence on the collector current and the collector node acts as a high-impedance current source. A simpler version of this equivalent circuit, which is often useful, is shown in Figure 2-84b, where the input diode has been replaced by a battery with a value $V_{BE(\text{on})}$, which is usually 0.6–0.7 V. This represents the fact that in the forward-active region the base–emitter voltage varies very little because of the steep slope of the exponential characteristic. In some circuits the temperature coefficient of $V_{BE(\text{on})}$ is important and a typical value for this is –2 mV/°C. The equivalent circuits of Figure 2-84 apply for *npn* transistors. For *pnp* devices the corresponding equivalent circuits are shown in Figure 2-85.

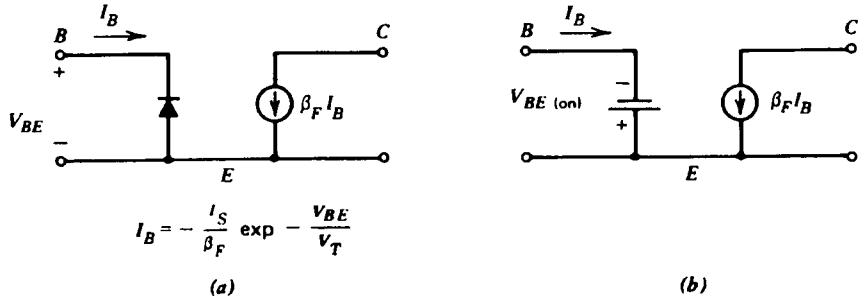

Figure 2-85 Large-signal models of *pnp* transistors corresponding to the circuits of Figure 2-84.

2-2-4 Effects of Collector Voltage on Large-Signal Characteristics in the Forward-Active Region

In the analysis of the previous section, the collector–base junction was assumed reverse-biased and ideally had no effect on the collector currents. This is a useful approximation for first-order calculations, but it is not strictly true in practice. There are occasions where the influence of collector voltage on collector current is important, and this will now be investigated.

The collector voltage has a dramatic effect on the collector current in two regions of device operation. These are the saturation (V_{CE} approaches zero) and breakdown (V_{CE} very large) regions that will be considered later. For values of collector–emitter voltage V_{CE} between these extremes, the collector current increases slowly as V_{CE} increases. The reason for this can be seen from Figure 2-86, which is a sketch of the minority-carrier concentration in the base of the transistor. Consider the effect of changes in V_{CE} on the carrier concentration for constant V_{BE}. Since V_{BE} is constant, the change in V_{CB} equals the change in V_{CE}, and this causes an increase in the collector–base depletion-layer width as shown. The change in the base width of the transistor, ΔW_B, equals the change in depletion-layer width and causes an increase ΔI_C in the collector current.

From Eqs. (2-146) and (2-149) we have

$$I_C = \frac{qA\bar{D}_n n_i^2}{Q_B} \exp \frac{V_{BE}}{V_T} \tag{2-165}$$

Differentiation of Eq. (2-165) yields

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{qA\bar{D}_n n_i^2}{Q_B^2} \left(\exp \frac{V_{BE}}{V_T} \right) \frac{dQ_B}{dV_{CE}} \tag{2-166}$$

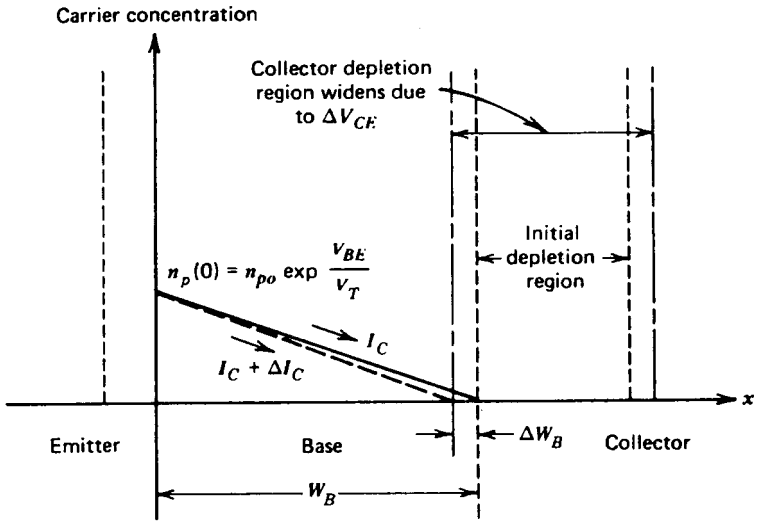

Figure 2-86 Effect of increases in V_{CE} on the collector depletion region and base width of a bipolar transistor.

and substitution of Eq. (2-165) in Eq. (2-166) gives

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{Q_B}\frac{dQ_B}{dV_{CE}} \tag{2-167}$$

For a uniform-base transistor $Q_B = W_B N_A$ and Eq. (2-167) becomes

$$\frac{\partial I_C}{\partial V_{CE}} = -\frac{I_C}{W_B}\frac{dW_B}{dV_{CE}} \tag{2-168}$$

Note that since the base width *decreases* as V_{CE} increases, dW_B/dV_{CE} in Eq. (2-168) is negative and thus $\partial I_C/\partial V_{CE}$ is positive. dW_B/dV_{CE} is a function of the bias value of V_{CE}, but the variation is typically small for a reverse-biased junction and dW_B/dV_{CE} is often assumed constant. The resulting predictions agree adequately with experimental results.

Equation (2-168) shows that $\partial I_C/\partial V_{CE}$ is proportional to the collector-bias current and inversely proportional to the transistor base width. Thus narrow-base transistors show a greater dependence of I_C on V_{CE} in the forward-active region. The dependence of $\partial I_C/\partial V_{CE}$ on I_C results in typical transistor output characteristics as shown in Figure 2-87. In accordance with the assumptions made in the foregoing analysis, these characteristics are shown for constant values of V_{BE}. However, in most integrated-circuit transistors the base current is dependent only on V_{BE} and not on V_{CE}, and thus constant-base-current characteristics can often be used in the following calculation. The reason for this is that the base current is usually dominated by the I_{B2} component of Eq. (2-156), which has no dependence on V_{CE}. Extrapolation of the characteristics of Figure 2-87 back to the V_{CE} axis gives an intercept V_A called the Early voltage, where

$$V_A = \frac{I_C}{\dfrac{\partial I_C}{\partial V_{CE}}} \tag{2-169}$$

Substitution of Eq. (2-168) in Eq. (2-169) gives

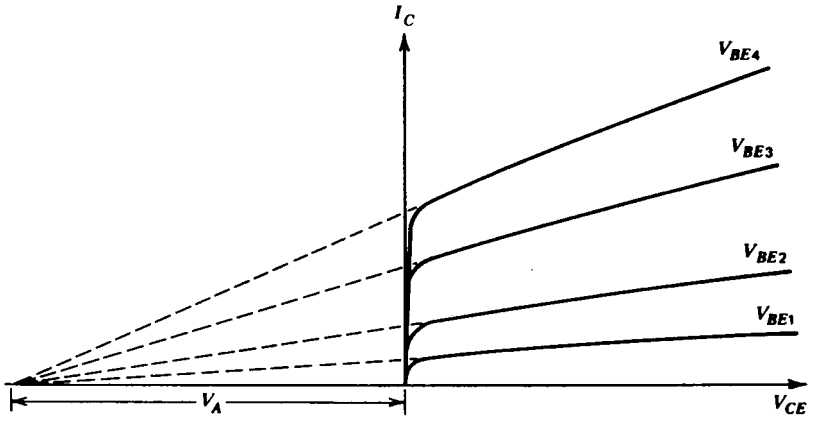

Figure 2-87 Bipolar transistor output characteristics showing the Early voltage, V_A.

$$V_A = -W_B \frac{dV_{CE}}{dW_B} \tag{2-170}$$

which is a constant, independent of I_C. Thus all the characteristics extrapolate to the same point on the V_{CE} axis. The variation of I_C with V_{CE} is called the Early effect and V_A is a common model parameter for circuit-analysis computer programs. Typical values of V_A for integrated-circuit transistors are 15–100 V. The inclusion of Early effect in dc bias calculations is usually limited to computer analysis because of the complexity introduced into the calculation. However, the influence of the Early effect is often dominant in small-signal calculations for high-gain circuits and this point will be considered later.

Finally, the influence of the Early effect on the transistor large-signal characteristics in the forward-active region can be represented approximately by modifying Eq. (2-146) to

$$I_C = I_S \left(1 + \frac{V_{BE}}{V_A}\right) \exp \frac{V_{BE}}{V_T} \tag{2-171}$$

This is a common means of representing the device output characteristics for computer simulation.

2-2-5 Saturation and Inverse Active Regions

Saturation is a region of device operation that is usually avoided in analog circuits because the transistor gain is very low in this region. Saturation is much more commonly encountered in digital circuits, where it provides a well-specified output voltage that represents a logic state. In saturation, both emitter–base and collector–base junctions are forward biased. Consequently, the collector–emitter voltage V_{CE} is quite small and usually in the range 0.05–0.3 V. The carrier concentrations in a saturated *npn* transistor with uniform base doping are shown in Figure 2-88. The minority-carrier concentration in the base of the edge of the depletion region is again given by Eq. (2-139) as

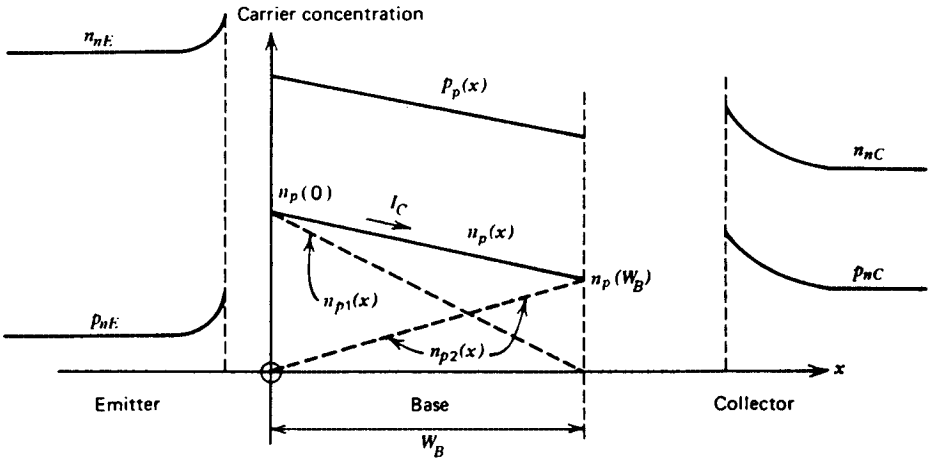

Figure 2-88 Carrier concentrations in a saturated *npn* transistor. (Not to scale)

$$n_p(W_B) = n_{po} \exp \frac{V_{BC}}{V_T} \tag{2-172}$$

but since V_{BC} is now positive, the value of $n_p(W_B)$ is no longer negligible. Consequently, changes in V_{CE} with V_{BE} held constant (which cause equal changes in V_{BC}) directly affect $n_p(W_B)$. Since the collector current is proportional to the slope of the minority-carrier concentration in the base [see Eq. (2-142)], it is also proportional to $[n_p(0) - (n_p(W_B)]$ from Figure 2-88. Thus, changes in $n_p(W_B)$ directly affect the collector current, and the collector node of the transistor appears to have a *low impedance*. As V_{CE} is decreased in saturation with V_{BE} held constant, V_{BC} increases as does $n_p(W_B)$ from Eq. (2-172). Thus, from Figure 2-88 the collector current decreases because the slope of the carrier concentration decreases. This gives rise to the saturation region of the $I_C - V_{CE}$ characteristic shown in Figure 2-89. The slope of the $I_C - V_{CE}$ characteristic in this region is largely determined by the resistance in series with the collector lead due to the finite resistivity of the *n*-type collector material. A useful model for the transistor in this region is shown in Figure 2-90

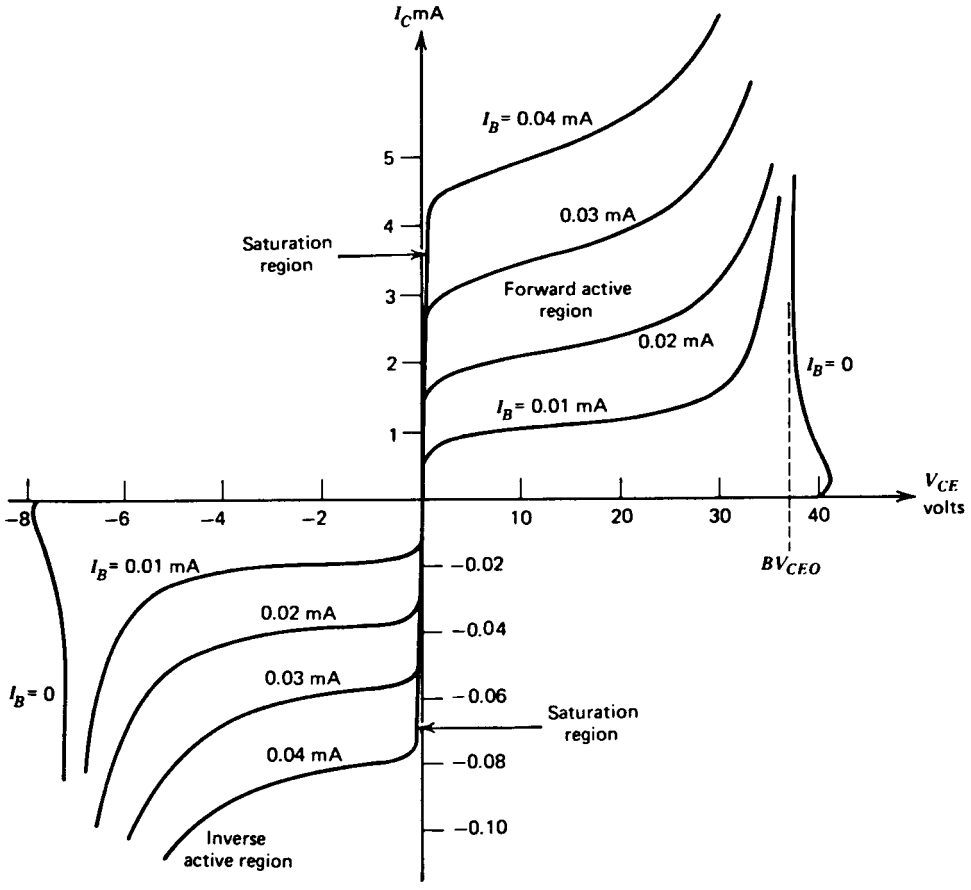

Figure 2-89 Typical $I_C - V_{CE}$ characteristics for an *npn* bipolar transistor. Note the different scales for positive and negative currents and voltages.

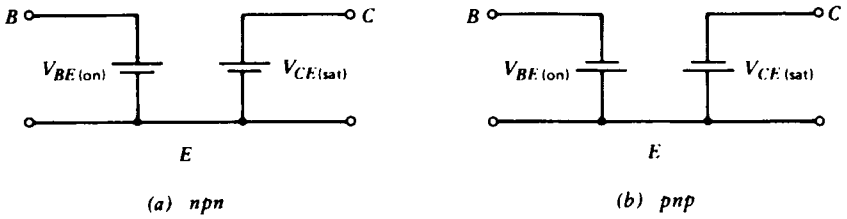

Figure 2-90 Large-signal models for bipolar transistors in the saturation region.

and consists of a fixed voltage source to represent $V_{BE(on)}$, and a fixed voltage source to represent the collector–emitter voltage $V_{CE(sat)}$. A more accurate but more complex model includes a resistor in series with the collector. This resistor can have a value ranging from 20 to 500 Ω, depending on the device structure.

An additional aspect of transistor behavior in the saturation region is apparent from Figure 2-88. For a given collector current, there is now a much larger amount of stored charge in the base than there is in the forward-active region. Thus the base-current contribution represented by Eq. (2-152) will be larger in saturation. In addition, since the collector–base junction is now forward biased, there is a new base-current component due to injection of carriers from the base to the collector. These two effects result in a base current I_B in saturation, which is larger than in the forward-active region for a given collector current I_C. Ratio I_C/I_B in saturation is often referred to as the *forced* β and is always less than β_F. As the forced β is made lower with respect to β_F, the device is said to be more *heavily saturated*.

The minority-carrier concentration in saturation, shown in Figure 2-88, is a straight line joining the two end points, assuming that recombination is small. This can be represented by a linear superposition of the two dotted distributions as shown. The justification for this is that the terminal currents depend *linearly* on the concentrations $n_p(0)$ and $n_p(W_B)$. This picture of device-carrier concentrations can be used to derive some general equations describing transistor behavior. Each of the distributions in Figure 2-88 is considered separately and the two contributions are combined. The *emitter* current that would result from $n_{p1}(x)$ above is given by the classical diode equation

$$I_{EF} = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) \tag{2-173}$$

where I_{ES} is a constant that is often referred to as the "saturation current" of the junction (no connection with the transistor saturation described above). Equation (2-173) predicts that the junction current is given by $I_{EF} \simeq I_{ES}$ with a reverse-bias voltage applied. However, in practice Eq. (2-173) is applicable only in the forward-bias region, since second-order effects dominate under reverse-bias conditions and typically result in a junction current several orders of magnitude larger than I_{ES}. The junction current that flows under reverse-bias conditions is often called the "leakage current" of the junction.

Returning to Figure 2-88, we can describe the *collector* current resulting from $n_{p2}(x)$ alone as

$$I_{CR} = -I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-174}$$

where I_{CS} is a constant. The total collector current I_C is given by I_{CR} plus the fraction of I_{EF} that reaches the collector (allowing for recombination and reverse emitter injection). Thus,

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-175}$$

where α_F has been defined previously by Eq. (2-162). Similarly, the total emitter current is composed of I_{EF} plus the fraction of I_{CR} that reaches the emitter with the transistor acting in an inverted mode. Thus,

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + \alpha_R I_{CS}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-176}$$

where α_R is the ratio of emitter to collector current with the transistor operating *inverted* (i.e., with the collector–base junction forward biased and emitting carriers into the base and the emitter–base junction reverse biased and collecting carriers). Typical values of α_R are 0.5–0.8. An inverse current gain β_R is also defined,

$$\beta_R = \frac{\alpha_R}{1 - \alpha_R} \tag{2-177}$$

and has typical values 1–5. This is the current gain of the transistor when operated inverted and is much lower than β_F because the device geometry and doping densities are designed to maximize β_F. The inverse-active region of device operation occurs for V_{CE} negative in an *npn* transistor and is shown in Figure 2-89. In order to display these characteristics adequately in the same figure as the forward-active region, the negative voltage and current scales have been expanded. The inverse-active mode of operation is rarely encountered in analog circuits.

Equations (2-175) and (2-176) describe *npn* transistor operation in the saturation region when V_{BE} and V_{BC} are both positive, and also in the forward-active and inverse-active regions. These equations are from the *Ebers–Moll* equations. In the forward-active region, they degenerate into a form similar to that of Eqs. (2-146), (2-158), and (2-160) derived earlier. This can be shown by putting V_{BE} positive and V_{BC} negative in Eqs. (2-175) and (2-176) to obtain

$$I_C = \alpha_F I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_{CS} \tag{2-178}$$

$$I_E = -I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \alpha_R I_{CS} \tag{2-179}$$

Equation (2-178) is similar in form to Eq. (2-146) except that leakage currents that were previously neglected have now been included. This minor difference is significant only at high temperatures or very low operating currents. Comparison of Eq. (2-178) with Eq. (2-146) allows us to identify $I_S = \alpha_F I_{ES}$ and it can be shown [6] in general that

$$\alpha_F I_{ES} = \alpha_R I_{CS} = I_S \tag{2-180}$$

where this expression represents a reciprocity condition. Using Eq. (2-180) in Eqs. (2-175) and (2-176) allows the Ebers–Moll equations to be expressed in the general form

$$I_C = I_S\left(\exp\frac{V_{BE}}{V_T} - 1\right) - \frac{I_S}{\alpha_R}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-181}$$

$$I_E = -\frac{I_S}{\alpha_F}\left(\exp\frac{V_{BE}}{V_T} - 1\right) + I_S\left(\exp\frac{V_{BC}}{V_T} - 1\right) \tag{2-182}$$

This form is often used for computer representation of transistor large-signal behavior.

The effect of leakage currents mentioned above can be further illustrated as follows. In the forward-active region, we have, from Eq. (2-179),

$$I_{ES}\left(\exp\frac{V_{BE}}{V_T} - 1\right) = -I_E - \alpha_R I_{CS} \tag{2-183}$$

Substitution of Eq. (2-183) in Eq. (2-178) gives

$$I_C = -\alpha_F I_E + I_{CO} \tag{2-184}$$

where

$$I_{CO} = I_{CS}(1 - \alpha_R\alpha_F) \tag{2-185}$$

and I_{CO} is the collector–base leakage current with the emitter open. Although I_{CO} is given theoretically by Eq. (2-185), in practice, surface leakage effects dominate when the collector–base junction is reverse biased and I_{CO} is typically several orders of magnitude larger than the value given by Eq. (2-185). However, Eq. (2-184) is still valid if the appropriate measured value for I_{CO} is used. Typical values of I_{CO} are 10^{-10} to 10^{-12} A at 25 °C, and the magnitude doubles about every 8 °C. As a consequence, these leakage terms can become very significant at high temperatures. For example, consider the base current I_B. This is

$$I_B = -(I_C + I_E) \tag{2-186}$$

If I_E is calculated from Eq. (2-184) and substituted in Eq. (2-186), the result is

$$I_B = \frac{1 - \alpha_F}{\alpha_F} I_C - \frac{I_{CO}}{\alpha_F} \tag{2-187}$$

But from Eq. (2-161)

$$\beta_f = \frac{\alpha_F}{1 - \alpha_F} \tag{2-188}$$

and use of Eq. (2-188) in Eq. (2-187) gives

$$I_B = \frac{I_C}{\beta_F} - \frac{I_{CO}}{\alpha_F} \tag{2-189}$$

Since the two terms in Eq. (2-189) have opposite signs, the effect of I_{CO} is to *decrease* the magnitude of the external base current at a given value of collector current.

2-2-6 Small-Signal Models of Bipolar Transistors

Figure 2-91 shows the small-signal equivalent BJT model. It consists of an intrinsic model and a package model. Table 2-12 lists its keywords.

In order to better understand the difference between the various technologies, we show Table 2-13, which allows the reader to compare their performances.

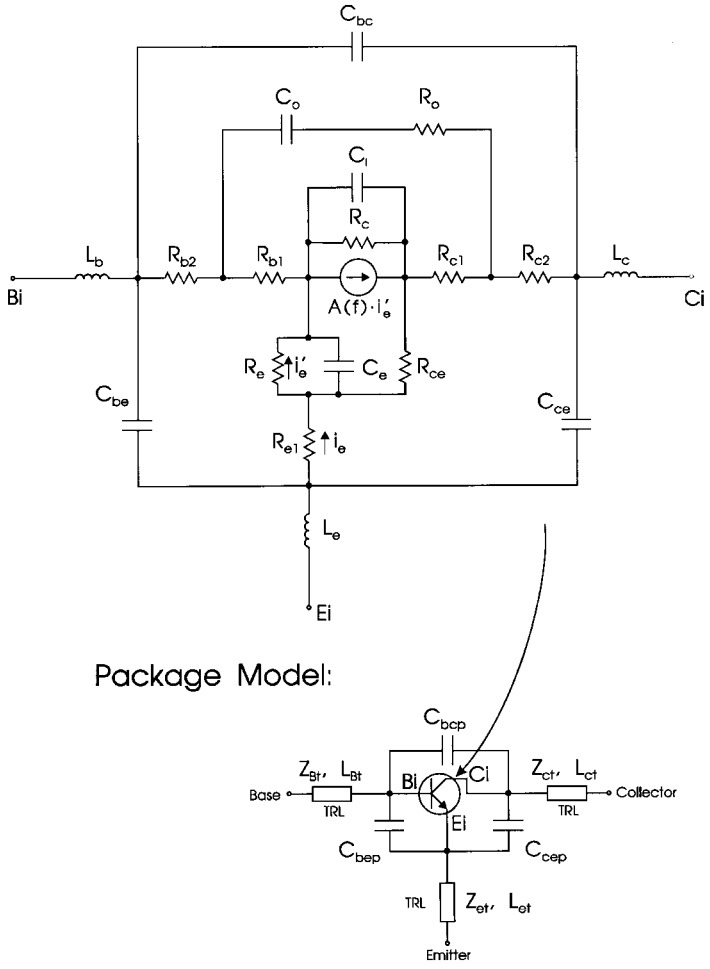

Figure 2-91 Linear BJT model.

Table 2-12 Small-signal equivalent BJT model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
A	Ratio of I_C to I_E at dc		0.0
RE	Emitter resistance	ohm	0.0
F	Current generator roll-off frequency	hertz	∞
T	Time delay	second	0.0
CE	Emitter capacitance	farad	0.0
CI	Collector capacitance	farad	0.0
RCE	Collector–emitter resistance	ohm	∞
RC	Collector resistance	ohm	∞
RO	Extrinsic base–collector resistance	ohm	0.0
CO	Extrinsic base–collector capacitance	farad	0.0
RB1	Intrinsic base resistance (R_{bb})	ohm	0.0
RC1	Parasitic collector resistance	ohm	0.0
RE1	Parasitic emitter resistance	ohm	0.0
RB2	Parasitic base resistance	ohm	0.0
RC2	Parasitic collector resistance	ohm	0.0
CBE	Base-to-emitter package capacitance	farad	0.0
CBC	Base-to-collector package capacitance	farad	0.0
CCE	Collector-to-emitter package capacitance	farad	0.0
LB	Base-lead inductance	henry	0.0
LC	Collector-lead inductance	henry	0.0
LE	Emitter-lead inductance	henry	0.0
TJ	Chip temperature	Kelvin	298
NFAC	Noise factor proportional to drive		1.0
FC	Flicker noise (1/*f* noise) corner frequency	hertz	50
	Package Model		
CBCP	Base-to-collector package capacitance	farad	0.0
CBEP	Base-to-emitter package capacitance	farad	0.0
CCEP	Collector-to-emitter package capacitance	farad	0.0
ZBT	Base transmission line impedance	ohm	50
ZCT	Collector transmission line impedance	ohm	50
ZET	Emitter transmission line impedance	ohm	50
LBT	Base transmission line length at $\varepsilon_r = 1$	meter	0.0
LCT	Collector transmission line length at $\varepsilon_r = 1$	meter	0.0
LET	Emitter transmission line length at $\varepsilon_r = 1$	meter	0.0

Notes:

1. $A \equiv \alpha = I_c/I_e$; β = dc current gain = $\alpha(1 - \alpha)$.
2. The bipolar current gain in this model is described by

$$\mathrm{A} = \mathrm{A}(0) = \frac{e^{-j\omega\mathrm{T}}}{1 + j\,(f/F)}$$

where $\omega = 2\,\pi f$ and f is frequency.

3. The current source is controlled by the current through R_e. The current generator has a cutoff frequency with respect to the total emitter current, I_E:

$$\mathrm{F} = g_m/2\pi C_e$$

where $g_m = 1/R_e$. This frequency becomes infinite for the default value for C_e (0.0). The parammeter F specifies the frequency roll-off for the current generator with respect to the current through R_e. Effectively, this frequency parameter may be used to model additional delays in the device.

[a] 1.0 µm Design Rule; NF = 3.25 dB, G_A = 12 dB at I_C = 2 mA, freq. = 2 GHz for $16 \times 1 \times 2 \ \mu m^2$; Resistors: 150 Ω/sq. (mono), 300 Ω/sq. (mono), 500 Ω/sq. (poly); Layers of metal, Schottky diodes, linear capacitor (silicided n^+ poly/n^+Si); Gate length = 0.68 µm (*n*-ch)/0.8 µm (*p*-ch), Gate Oxide = 12.5 nm (3 V)/15 nm (5 V), V_{th} = 0.65 V (*n*-ch)/–0.9 V (*p*-ch), Gm (µS/µm) = 204 (*n*-ch)/65 (*p*-ch).

[b] 0.6 µm Design Rule; Gold metallization, ILD: polyimide; Inductors: $Q > 10$ for $L \leq 10$ nH; Capacitors: $Q > 25$ for $C \leq 20$ pF; Schottky diodes (f_c = 100 GHz), Zener diodes, MIS capacitor, thin film resistors, and LPNP, 10 mask process.

[c] Analog devices using this process.

[d] LPNP F_t = 80 MHz; three-layer metallization; Schottky diodes (R_sC_j ~ 4 ps); Implanted resistors: 200 Ω/sq.; Poly resistors: 400/2000 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[e] LPNP F_t = 85 MHz; two-layer metallization; Schottky diodes (R_sC_j ~ 0.8 ps); Implanted resistors: 170/600/1200 Ω/sq.; NiCr thin film resistors (50 Ω/sq.) with laser trim option; MOS capacitor.

[f] L_n = 0.8 µm, T_{ox} = 18 nm, V_{th} = 0.76 V (nmos), V_{th} = –0.78 V (pmos), 2poly-MIM capacitor: 2.7 fF/µm^2, Schottkys, inductors.

[g] Not known if this process is in production.

[h] 0.8 µm Design Rules; 2.5 fF/µm^2 MIS capacitor; 600 MHz PJFET; 12L; F_t = 4 GHz VPNP; poly resistors 80/400/2000 Ω/sq.

[i] Targeted for 900-MHz GSM radio front-end blocks, a CT2 cordless single-chip radio, and DECT (digital enhanced cordless telephones).

[j] Targeted for multimode 900-MHz GSM, 1.8-GHz PCN and 1.9-GHz PCS based systems. Company is also evaluating integrating SiGe in HSB3.

2-3 FIELD-EFFECT TRANSISTORS

Both diodes and *pnp/npn* transistors work on the injection principle, which means the base–emitter junction generates either free electrons or other carriers, which are being "collected" by the collector connection and the base connection controls it. While this is a fairly complex process, its physics is well understood, and its latest spin-offs, heterojunction BJTs and silicon–germanium transistors, seem to offer a bright future.

In opposition to this, the field-effect transistor (FET) controls the electronic conduction in a solid by an electric field, and this concept actually predates the invention of the bipolar transistor. J. E. Lilienfeld filed for a patent on such a device in 1925 (U.S. Patent No. 1,745,175), and W. Shockley presented a comprehensive theory of the FET in 1952. It took until 1960 before the first commercially available FETs came on the market.

Several types of semiconductor materials have been used for making FETs: silicon, germanium, gallium arsenide, and others have been used. By far the most widely used is silicon, followed now by gallium arsenide.

The FET is a class of electronic semiconductor device in which the conduction of a "channel" between source (*S*) and drain (*D*) terminals is controlled by an electric field impressed on the channel via a gate (*G*) terminal. The conduction channel may utilize *n*-type carriers (electrons) or *p*-type carriers (holes). The electric field that controls the channel conduction may be introduced via a *pn* junction [for a "junction" FET (JFET)], a metal plate separated from the semiconductor channel by an oxide dielectric [for a metal-oxide semiconductor (MOS) FET], or a combination of the two methods. The polarity of the controlling electrical field is a function of the type of carriers in the channel. A FET "family tree" is shown in Figure 2-92.

For today's microwave and RF integrated circuits, the JFET with its high-frequency problems (low cutoff frequency) and large variation in parameters, such as transconductance and pinchoff voltage, has fallen out of favor and is mainly used in discrete circuits such as two-way radios or other RF applications that tolerate these wide variations and temperature dependence. The most-used FET types are MOS for small-signal applications, LDMOS (lateral diffused MOS) for power applications, and GaAs MESFET for lower-power applications (low-voltage applications) as well as high-power applications (recent advertisements by NEC have shown output power up to 100 W). Additional information on the FET family is shown in Figure 2-93.

All members of the FET family are high-impedance-input devices. Figure 2-94 shows the key operating parameters for MOSFETs and MESFETs in low-noise stages, high-gain stages, and linearized power stages. The linearization also improves the matching. This figure is similar to its counterpart in Section 2-2-2.

The following several pages present a typical example of a datasheet* for a JFET (U310) and the chip (NZA) on which it is based, followed by an example of a device with a much higher dynamic range (the CP640 family). The CP640 family and devices similar to them are being replaced by low-power LDMOS, which are not yet well-documented. At least one company, InterFET, is devoted entirely to producing discrete JFETs and JFET-related hybrid and small-scale-integration IC products.

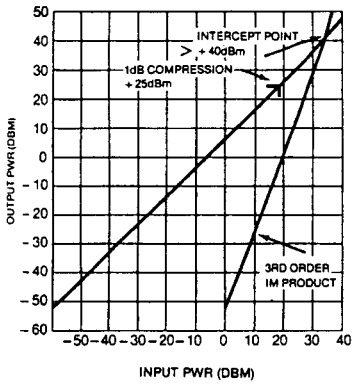
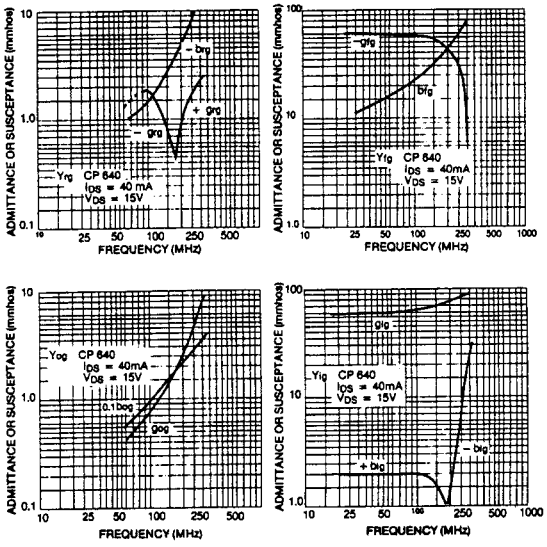
TYPICAL INTERCEPT AND COMPRESSION POINT





2-3-1 Large-Signal Behavior of JFETs

A section view of a junction field-effect transistor (JFET) is shown in Figure 2-95. This structure contains, between the source and the drain contacts, an *n*-type "channel" embedded in a *p*-type silicon substrate. If it is assumed that the *pn* junction forms a barrier to current flow, then it can be seen that channel conduction is a function of the channel width, length, and thickness and of the density and mobility of the carriers. In this structure, current can flow equally well in either direction through the channel; that is, the drain can be positive or negative with respect to the source.

Since we have found that the SPICE models for JFETs are really incomplete and give poor answers, we will only briefly touch here on the JFET's performance. The modified Materka model, one of the best GaAsFET models, turns out to be best suited for JFETs because both transistors act similarly in the dc area. Both have a gate-to-source diode that becomes conductive above 0.7 V at the input and they are also quite similar in other respects. Their equivalent circuits are also quite similar, as parameter extractions for both approaches have shown.

In general, in a three-terminal device, the drain current I_D is a function of two variables: V_{DS} and V_{GS}. This function is best represented by families of characteristic curves, as shown in Figure 2-96. These curves are for the "common source" configuration, with the drain as the output and the gate as the input. They reveal that for this device, if V_{DS} is greater than about 2 V (but less than the drain breakdown), I_D is primarily determined by the gate voltage V_{GS}. Under these conditions it is valid for small signals to characterize the FET by a single transfer characteristic curve, commonly called the "forward transconductance curve," such as the upper curve shown in Figure 2-96b. Some of the relationships between the forward transfer curve and the output characteristic curves of Figure 2-96a will be examined. The value of V_{GS} that reduces I_D to approximately zero is the gate–source cutoff voltage, $V_{GS(\text{off})}$. With reference to the output curve, Figure 2-96a, note that the drain current at $V_{GS} = 0$ tends to become saturated at a drain voltage approximately equal in magnitude to $-V_{GS(\text{off})}$. This drain voltage is often referred to as the pinchoff voltage V_P; however, in this section pinchoff voltage is used interchangeably with gate–source cutoff voltage. V_P will have the same meaning as $V_{GS(\text{off})}$. The symbol I_{DSS} is commonly used to indicate the value of saturated drain current at $V_{GS} = 0$.

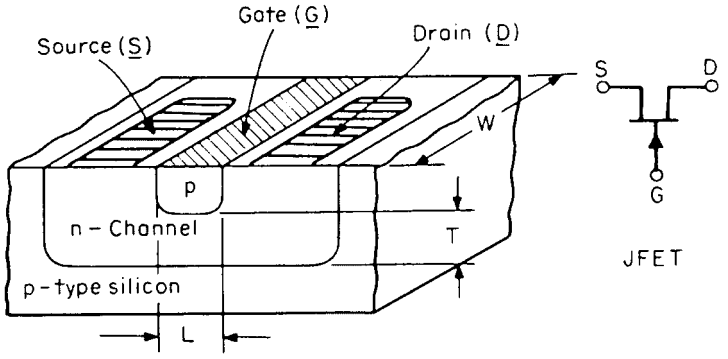


Figure 2-95 Junction field-effect transistor [9].

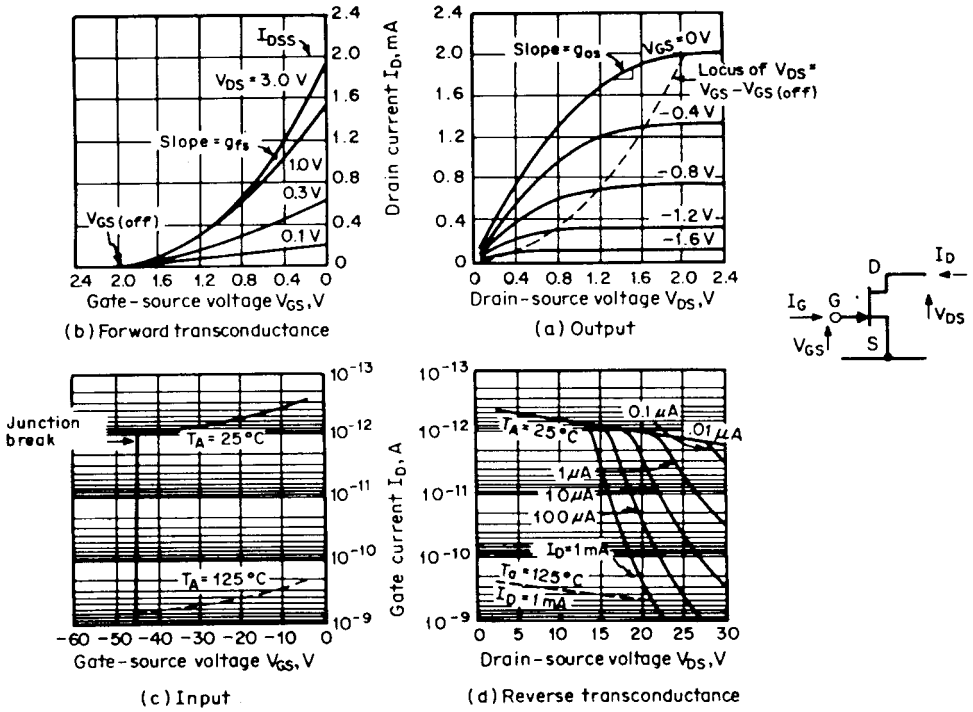

Figure 2-96 Static characteristics of an *n*-channel JFET.

The forward transconductance characteristic of Figure 2-96b can be approximated by a power law relation expressed as

$$I_D = I_{DSS}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^n \tag{2-190}$$

if $V_{DS} \geq -V_{GS(\text{off})}$. By differentiation the small-signal transconductance g_{fs} is given by

$$g_{fs} = \frac{dI_D}{dV_{GS}} = -n\frac{I_{DSS}}{V_{GS(\text{off})}}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right)^{n-1} \tag{2-191}$$

Some texts indicate a value of $\frac{3}{2}$ for n; however, experimental measurements on a number of n-channel JFET geometries indicate that the exponent n is close to 2, which is the value derived in an approximate treatment by R. D. Middlebrook [10].

A useful relationship between g_{fso}, I_{DSS}, and $V_{GS(\text{off})}$ is derived from the ratio of Eqs. (2-190) and (2-191):

$$\frac{g_{gs}}{I_D} = n(V_{GS} - V_{GS(\text{off})})^{-1} \tag{2-192}$$

At $V_{GS} = 0$, $I_D = I_{DSS}$ and $g_{fs} = g_{fso}$. Using 2 as the value of the constant n leads to

$$g_{fso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-193}$$

For n-channel FETs I_{DSS} is positive and $V_{GS(\text{off})}$ is negative; for p-channel FETs I_{DSS} is negative and $V_{GS(\text{off})}$ is positive; thus g_{fs} is a positive quantity for both p- and n-channel FETs.

Equation (2-190) indicates that for $V_{GS} = V_{GS(\text{off})}$, $I_D = 0$. In a real device this does not happen. Starting from zero, as the gate voltage is made more negative, the drain current decreases until it reaches a very low value equal to the drain-leakage current. At this value, the source current will consist of source–gate leakage. Any further increase in the magnitude of the negative gate voltage will result in an increase in I_D leakage. For the small-signal device illustrated, this minimum I_D is on the order of 2×10^{-13} A.

For some types of applications of the FET, it is helpful to understand the characteristics at very low values of V_{DS}, such as those shown in Figure 2-97. A "very low value" is one that is small compared to the magnitude of $V_{GS} - V_{GS(\text{off})}$. In this region, V_{DS} is small enough to have little effect on channel thickness, so that the I_D/V_{DS} slope is nearly linear. Since the slope is a function of V_{GS}, the FET can be utilized as a voltage-controlled resistor. The conductance slope ($\Delta I_D/V_{DS}$) at $V_{DS} = 0$ is approximately a linear function of $V_{GS} - V_{GS(\text{off})}$.

If g_{ds} at $V_{GS} = 0$ is given the term g_{dso}, then

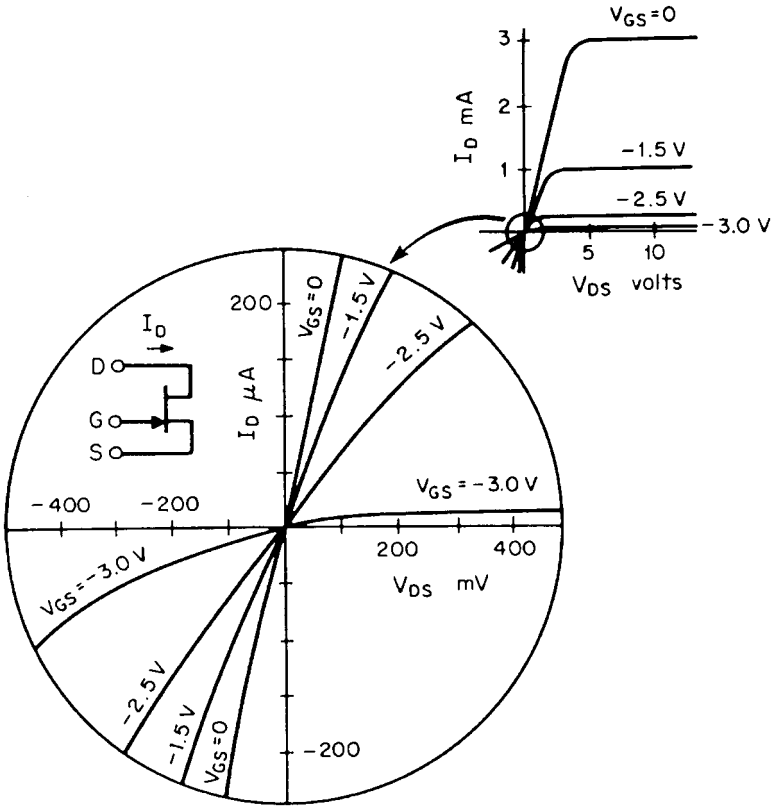

Figure 2-97 Enlargement of n-channel output characteristic around $V_{DS} = 0$.

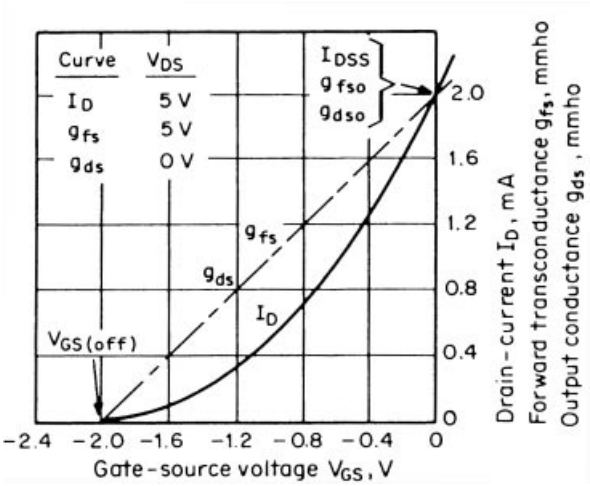

Figure 2-98 JFET I_D, g_{fs}, and g_{ds}.

$$g_{ds} = g_{dso}\left(1 - \frac{V_{GS}}{V_{GS(\text{off})}}\right) \tag{2-194}$$

with $V_{DS} = 0$. A plot of this characteristic is shown in Figure 2-98, along with g_{fs} and I_D characteristics.

The relationship between g_{dso}, $V_{GS(\text{off})}$, and I_{DSS} is given by the equation

$$g_{dso} = -2\frac{I_{DSS}}{V_{GS(\text{off})}} \tag{2-195}$$

where I_{DSS} and $V_{GS(\text{off})}$ are as indicated in Figure 2-96. It is important to note that Eqs. (2-194) and (2-195) and the g_{ds} curve of Figure 2-98 are valid only for the case where V_{DS} is very small compared to V_P. Drain–source conductance at higher values of V_{DS} will be discussed later. FETs designed to be used as voltage-controlled resistors typically have a high $V_{GS(\text{off})}$ because the $V_{DS}/(V_{GS} - V_{GS(\text{off})})$ ratio should be low to keep distortion low. The actual large-signal JFET model as used in most simulators is shown in Figure 2-99, including a list of its intrinsic keywords (Table 2-14). Again, we had very little luck using this model as published by several SPICE CAD software manufacturers as offered. While we cannot judge on the quality of the parameters that came with the software, it was not possible to closely match even optimized sets of parameters to this large-signal model and obtain acceptable results. However, since the modified Materka model worked very well for this, we recommend that this popular JFET model not be used at frequencies above 10 MHz.

2-3-2 Small-Signal Behavior of JFETs

Figure 2-100 shows the small-signal equivalent transistor model we would recommend. It consists of an empirical FET model and a package model. Table 2-15 lists its keywords. Its advantage is that its built-in noise model is very accurate, even for JFETs and metal semiconductor FETs.

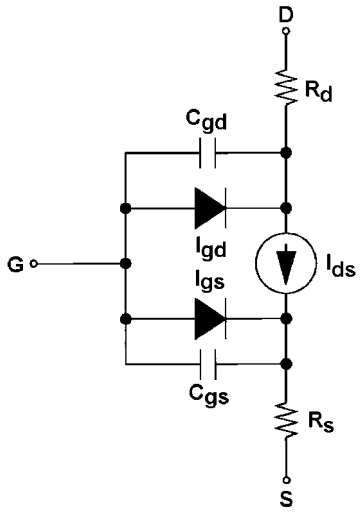

Figure 2-99 The nonlinear JFET model. Table 2-14 lists its intrinsic and extrinsic parameters. In our opinion, this model is limited to frequencies below 10 MHz; above this frequency, the modified Materka model should replace it.

Table 2-14 Large-signal JFET model keywords

Keyword	Description	Unit	Default

FCP	Shape factor of the 1/*f* noise response		1.0
label	User-defined term that refers to temperature coefficient		

[a]The transconductance of this model may be approximately described by $g_m = G\,\frac{e^{-j\omega T}}{1 + j(f/F)}$ where $\omega = 2\pi f$ and f is frequency.
[b]The flicker noise frequency dependence is given by $1/(f/F_c)^{\mathrm{FCP}}$.

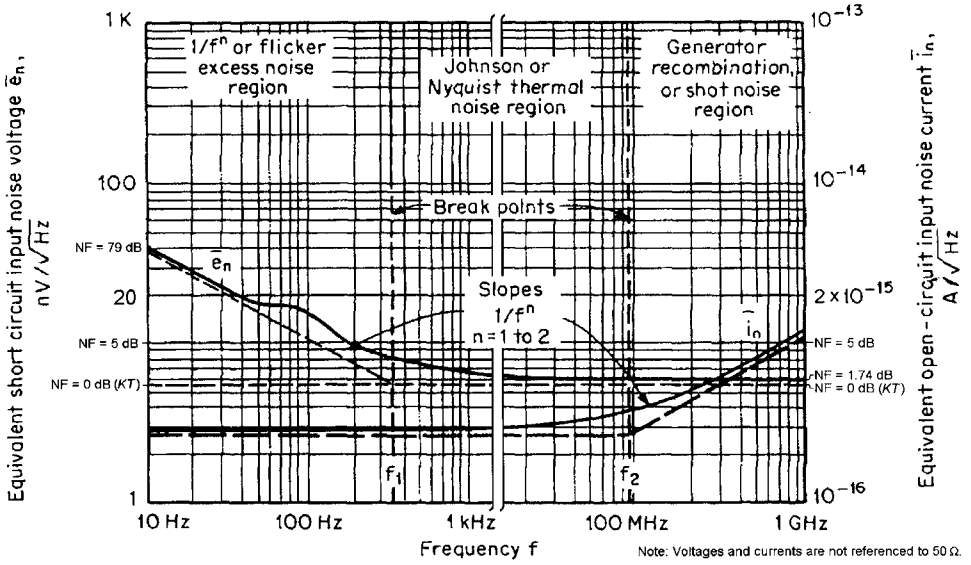

Figure 2-101 JFET noise characteristics.

where $K = 1.374 \times 10^{-23}$ J/K

T = absolute temperature in kelvins (273 K = 0 °C)

B = frequency range in hertz

g_{fs} = transconductance of FET

With the input short-circuited, the noise voltage across the load R_L resulting from the FET is

$$\text{Output noise voltage} = \bar{e}_n A_V \tag{2-197}$$

Below the frequency f_1, $\bar{e}_n$ increases proportional to $1/f^n$ and is expressed as

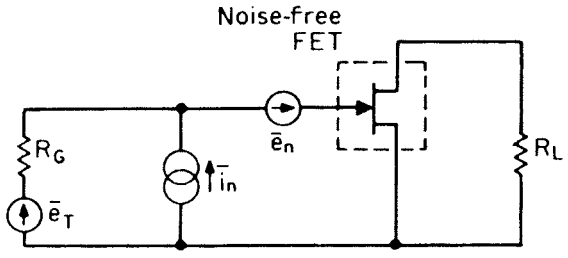

Figure 2-102 Equivalent noise circuit of the FET.

$$\bar{e}_n = \left[4KTB \left(\frac{0.67}{g_{fs}} \right) \left(1 + \frac{f_1}{f^n} \right)^{1/2} \right] \tag{2-198}$$

The low-frequency corner frequency f_1 for JFETs is typically in the 100-Hz to 1-kHz range, and the exponent n is usually between 1 and 2. As indicated by the equations, $\bar{e}_n$ is inversely proportional to the square root of g_{fs}.

The equivalent input noise current $\bar{i}_n$ is caused by the current in the gate-to-channel junction. Its approximate value below f_2 is

$$\bar{i}_n = (2qI_G B)^{1/2} \tag{2-199}$$

where $q = 1.602 \times 10^{-19}$
B = frequency range in hertz
I_G = dc gate current

This expression is fairly accurate when I_G is the result of the active device conductance. Typically, $\bar{i}_n$ will be lower than the calculated value because part of I_G is due to conductance across the device package.

At higher frequencies (above f_2),

$$\bar{i}_n = \left(\frac{4KTB}{R_P} \right)^{1/2} \tag{2-200}$$

where R_P is the real part of gate input impedance. R_P, in terms of Y_{11}, can range from several tens of megohms (at audiofrequencies) to 1 kΩ or less (at VHF/UHF frequencies). The high-frequency corner f_2 is typically in the range of 5–50 kHz and more than 100 MHz for high-frequency devices.

Another form of noise is known as "popcorn" or burst noise, the causes of which have not been completely identified. It shows up as a random short-duration step-function change in drain current, equivalent to an input gate–source voltage change of a few tenths of a microvolt. It is not unlike big bubbles on the surface of boiling water.

As far as the noise is concerned, we can also state that the Materka built-in proprietary noise model is significantly more accurate than the one mentioned above [11–14]. This model is implemented, with minimal documentation of its inner workings because of its proprietary nature, in the linear portion of the circuit simulator in Ansoft's Serenade Design Environment. In many cases, the manufacturer supplies only limited data, so it is most convenient that after SPICE-type parameter extraction is done by using the Scout program, one even gets good noise prediction for JFETs using the modified Materka model.

2-3-3 Large-Signal Behavior of MOSFETs

Metal-oxide-semiconductor field-effect transistors (MOSFETs) are important components in contemporary analog integrated circuits. Whereas initial applications were centered on all-MOS processes, combined bipolar and MOS processes give the designer the best of both worlds. A major advantage of MOS processes for realizing analog functions is that complex, dense digital functions can be realized on the same chip.

Transfer Characteristics of MOS Devices. A cross section of a typical enhancement-mode *n*-channel MOS transistor (NMOS) is shown in Figure 2-103a. Heavily doped *n*-type source and drain regions are fabricated in a *p*-type substrate (often called the body). A thick layer of silicon dioxide is grown over the substrate material and a conductive gate material (metal or polycrystalline silicon) covers this oxide between source and drain. The operation of the device is very similar to that of a JFET in that the gate–source voltage is used to modify the conductance of the region under the gate. This allows the gate voltage to control the current flowing between source and drain, giving gain in analog circuits and switching characteristics in digital circuits.

The enhancement-mode NMOS device of Figure 2-103a shows significant conduction between source and drain only when an *n*-type channel exists under the gate, and this is the origin of the "*n*-channel" designation. The term "enhancement mode" refers to the fact that no conduction occurs for $V_{GS} = 0$, and thus the channel must be "enhanced" to cause conduction. MOS devices can be made equally well by using an *n*-type substrate with a *p*-type conducting channel. Such devices are called enhancement-mode *p*-channel MOS transistors (PMOS). In technologies employing one or the other of these device types, the circuit symbol of Figure 2-103b is commonly used for either one. In complementary MOS technology (CMOS) both device types are present and the circuit symbols of Figure 2-103c will be used to distinguish them. In PMOS and NMOS technologies, the substrate is common to all devices, invariably connected to a dc power supply voltage, and usually not shown on the circuit diagram. In CMOS technology, however, devices of one type or another are fabricated in individual, separate isolation regions, which may or may not be connected to a power supply voltage. If these isolation regions *are* connected to the appropriate power supply, the symbols of Figure 2-103c will be used and the substrate connection will not be shown. If the individual isolation regions are connected elsewhere, however, the devices will be represented by the symbols of Figure 2-103d, where the substrate is labeled *B*. Finally, in NMOS technology an additional device type called a "depletion-mode" device is usually available. This is a conducting channel implanted between the source and drain so that conduction occurs for $V_{GS} = 0$. This device has characteristics that are almost identical to that of a JFET and will be represented by the symbol of Figure 2-103e.

The derivation of the transfer characteristics of the enhancement-mode NMOS device of Figure 2-103a begins by noting that with $V_{GS} = 0$, the source and drain regions are separated by back-to-back *pn* junctions. These junctions are formed between the *n*-type source and drain regions and the *p*-type substrate, resulting in an extremely high resistance (about 10^{12} Ω) between drain and source when the device is off.

Now consider substrate, source, and drain grounded and a positive voltage V_{GS} applied to the gate as shown in Figure 2-104. The gate and substrate then form the plates of a capacitor with the SiO_2 as a dielectric. Positive charge accumulates on the gate and the negative charge in the substrate. Initially, the negative charge in the *p*-type substrate is manifested by creation of a *depletion region* and resulting exclusion of holes under the gate. This is shown in Figure 2-104. The depletion-layer width *X* under the oxide is

$$X = \left(\frac{2\varepsilon\phi}{qN_A} \right)^{1/2} \tag{2-201}$$

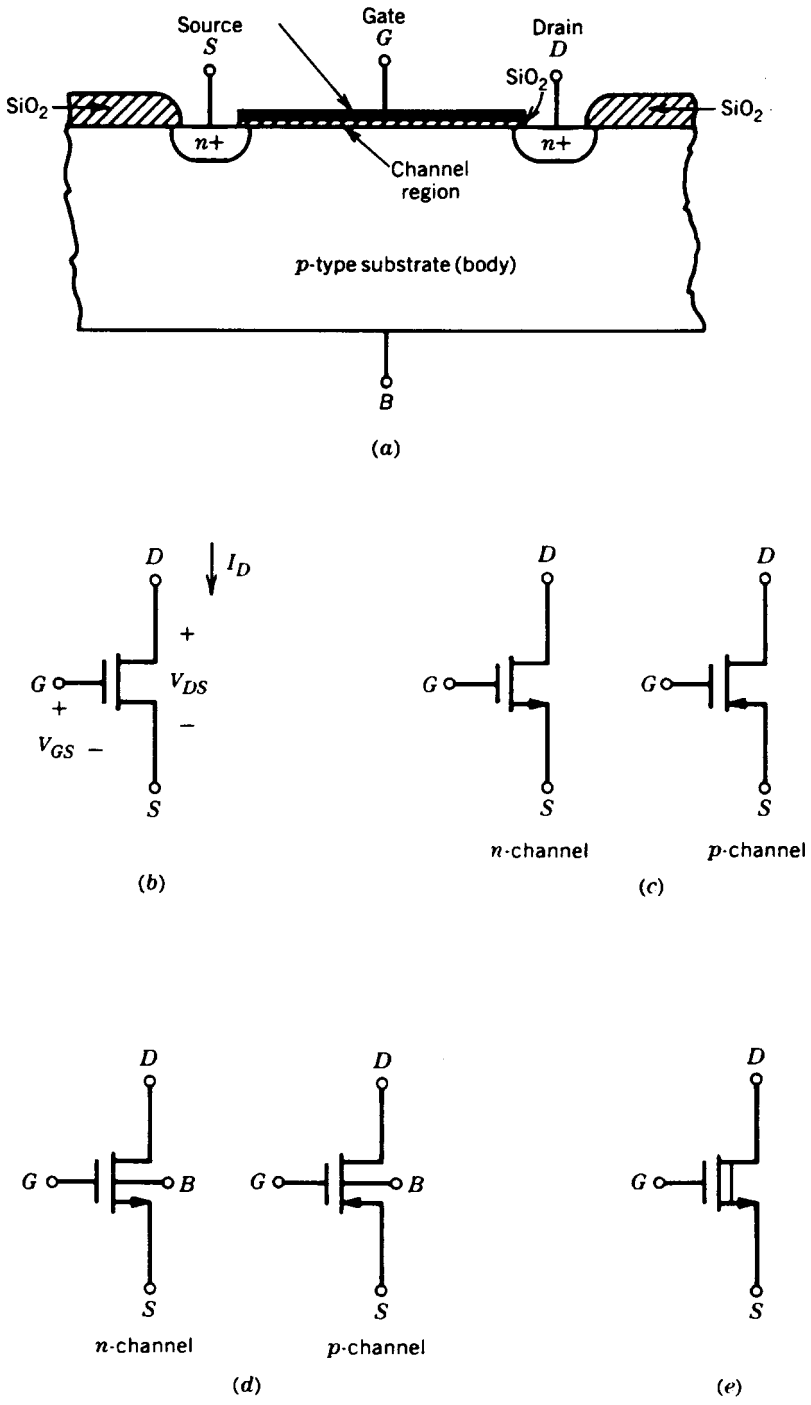

Figure 2-103 (a) Typical enhancement-mode NMOS structure. (b) Enhancement-mode NMOS or PMOS circuit symbol when one device type only is present. (c) NMOS and PMOS symbols used in CMOS circuits. (d) NMOS and PMOS symbols used when the substrate connection is nonstandard. (e) Depletion MOS device symbol.

where ϕ is the potential in the depletion layer at the oxide–silicon interface, N_A atoms/cm^3 is the doping density (assumed constant) of the p-type substrate, and ε is the permittivity of the silicon. The charge per unit area in this depletion region is

$$Q = qN_A X = \sqrt{2qN_A \varepsilon \phi} \tag{2-202}$$

When the potential in the silicon reaches a critical value equal to twice the Fermi level, $\phi_f \simeq 0.3$ V, a phenomenon known as "inversion" occurs [15]. Further increases in gate voltage produce no further changes in the depletion-layer width but instead a thin layer of electronics is induced in the depletion layer directly under the oxide. This produces a continuous n-type region with the source and drain regions and is the conducting channel between source and drain. This channel can then be modulated by increases or decreases in the gate voltage. In the presence of an inversion layer, and with no substrate bias, the depletion region contains a fixed charge

$$Q_{b0} = \sqrt{2qN_A \varepsilon 2\phi_f} \tag{2-203}$$

If a substrate bias voltage V_{SB} (source positive for n-channel devices) is applied between source and substrate, the potential required to produce inversion becomes $(2\phi_f + V_{SB})$ and the charge stored in the depletion region in general is

$$Q_b = \sqrt{2qN_A \varepsilon (2\phi_f + V_{SB})} \tag{2-204}$$

The gate voltage V_{GS}, required to produce an inversion layer, is called the threshold voltage V_t and can now be calculated. This voltage consists of several components. First, a voltage $[2\phi_f + (Q_b/C_{ox})]$ is required to sustain the depletion-layer charge Q_b, where C_{ox} is the gate oxide capacitance per unit area. Second, a work-function difference ϕ_{ms} exists between the

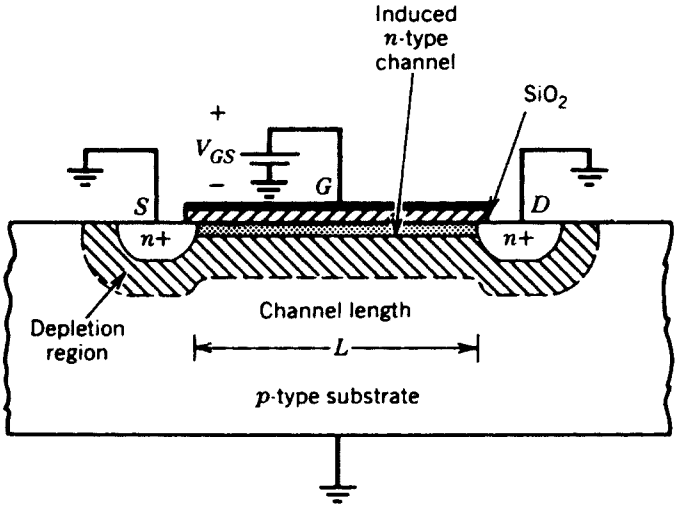

Figure 2-104 Idealized NMOS device cross section with positive V_{GS} applied, showing depletion regions and the induced channel.

gate metal and the silicon. Third, there is always charge density Q_{ss} (positive) in the oxide at the silicon interface. This is caused by crystal discontinuities at the Si–SiO_2 interface and must be compensated by a gate voltage contribution of $-Q_{ss}/C_{ox}$. Thus we have a threshold voltage

$$V_t = \phi_{ms} + 2\phi_f + \frac{Q_b}{C_{ox}} - \frac{Q_{ss}}{C_{ox}}$$

$$= \phi_{ms} + 2\phi_f + \frac{Q_{b0}}{C_{ox}} - \frac{Q_{ss}}{C_{ox}} + \frac{Q_b - Q_{b0}}{C_{ox}} \tag{2-205}$$

$$= V_{t0} + \gamma\left(\sqrt{2\phi_f + V_{SB}} - \sqrt{2\phi_f}\right) \tag{2-206}$$

where Eqs. (2-203) and (2-204) have been used and V_{t0} is the threshold voltage with $V_{SB} = 0$. The parameter γ is defined as

$$\gamma = \frac{1}{C_{ox}}\sqrt{2q\varepsilon N_A} \tag{2-207}$$

and

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{2-208}$$

where ε_{ox} and t_{ox} are the permittivity and thickness of the oxide, respectively. A typical value of γ is 0.5 $V^{1/2}$ and $C_{ox} = 3.5 \times 10^{-4}$ pF/μ^2 for $t_{ox} = 0.1$ μm.

In practice, the value of V_{t0} is usually adjusted in processing by implanting additional impurities into the channel region. Extra *p*-type impurities are implanted in the channel to make $V_{t0} \simeq 0.5$–1.5 V for *n*-channel enhancement devices. By implanting *n*-type impurities in the channel region, a conducting channel can be formed, even for $V_{GS} = 0$. This MOS transistor is called a depletion device, with typical values of V_{t0} in the range –1 to –4 V. If Q_i is the charge density per unit area due to the implant, then the threshold voltage given by Eq. (2-205) is shifted by approximately Q_i/C_{ox}.

The preceding equations can now be used to calculate the large-signal characteristics of an NMOS transistor. For purposes of analysis the source is assumed grounded and bias voltages V_{GS}, V_{DS}, and V_{SB} are applied as shown in Figure 2-105. If V_{GS} is greater than V_t, a conducting channel exists and V_{DS} causes a larger reverse bias from drain to substrate than exists from source to substrate, and thus a wider depletion region exists at the drain. However, for simplicity, we assume that the voltage drop along the channel itself is small so that the depletion layer is constant along the channel.

At a distance *y* along the channel the voltage with respect to the source is $V(y)$ and the gate-to-channel voltage at that point is $V_{GS} - V(y)$. We assume this voltage exceeds the threshold voltage V_t, and thus the induced electron charge per unit area in the channel is

$$Q_I(y) = C_{ox}[V_{GS} - V(y) - V_t] \tag{2-209}$$

The resistance *dR* of a length *dy* of the channel is

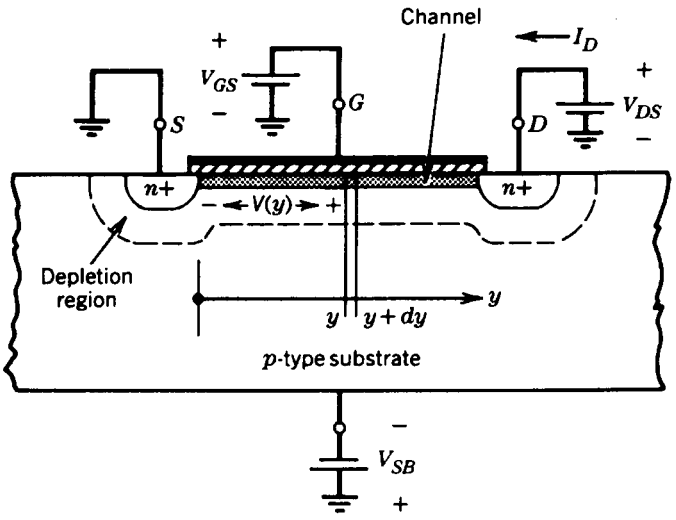

Figure 2-105 NMOS device with bias voltages applied.

$$dR = \frac{dy}{W\mu_n Q_I(y)} \tag{2-210}$$

where W is the width of the device, perpendicular to the plane of Figure 2-105, and μ_n is the average electron mobility of the channel.

The voltage drop dV along the length of the channel dy is

$$dV = I_D\, dR = \frac{I_D}{W\mu_n Q_I(y)}\, dy \tag{2-211}$$

If L is the total channel length, then substitution of Eq. (2-209) into Eq. (2-211) and integration gives

$$\int_0^L I_D\, dy = \int_0^{V_{DS}} W\mu_n C_{\text{ox}}(V_{GS} - V - V_t)\, dV \tag{2-212}$$

This results in

$$I_D = \frac{k'}{2}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-213}$$

where

$$k' = \mu_n C_{\text{ox}} = \frac{\mu_n \varepsilon_{\text{ox}}}{t_{\text{ox}}} \tag{2-214}$$

Equation (2-213) is important and describes the I–V characteristics of an MOS transistor, assuming a continuous induced channel. A typical value of k' for $t_{\text{ox}} = 0.1$ μm is about 20 μA/V^2 for an n-channel device.

As the value of V_{DS} is increased, the induced conducting channel narrows at the drain end and Eq. (2-209) indicates that Q_I at the drain end approaches zero as V_{DS} approaches $(V_{GS} - V_t)$. This results in the same pinchoff phenomenon as occurs in a JFET, and further increases in V_{DS} produce little change in I_D. Equation (2-213) is thus no longer valid if V_{DS} is greater than $(V_{GS} - V_t)$. The value of I_D in this region is obtained by substituting $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-213), giving

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 \tag{2-215}$$

for an MOS transistor in the pinchoff region. As in the case of a JFET, the drain current in the pinchoff region varies slightly as the drain voltage is varied. This is due to the presence of a depletion region between the physical pinchoff point in the channel at the drain end and the drain region itself. If this depletion-layer width is X_d, then the *effective* channel length is given by

$$L_{\text{eff}} = L - X_d \tag{2-216}$$

If L_{eff} is used in place of L in Eq. (2-215), we obtain a more accurate formula for the pinchoff region:

$$I_D = \frac{k'}{2}\frac{W}{L_{\text{eff}}}(V_{GS} - V_t)^2 \tag{2-217}$$

The fact that X_d (and thus L_{eff}) is a function of the drain–source voltage results in a variation of I_D and V_{DS} in the pinchoff region. Using Eqs. (2-216) and (2-217), we obtain

$$\frac{\partial I_D}{\partial V_{DS}} = -\frac{k'}{2}\frac{W}{L_{\text{eff}}^2}(V_{GS} - V_t)^2\frac{dL_{\text{eff}}}{dV_{DS}} \tag{2-218}$$

and thus

$$\frac{\partial I_D}{\partial V_{DS}} = \frac{I_D}{L_{\text{eff}}}\frac{dX_d}{dV_{DS}} \tag{2-219}$$

This equation is analogous to Eq. (2-168) for bipolar transistors. Following a similar procedure, a voltage analogous to the Early voltage can be defined as

$$V_A = \frac{I_D}{\partial I_D/\partial V_{DS}} \tag{2-220}$$

and thus

$$V_A = L_{\text{eff}}\left(\frac{dX_d}{dV_{DS}}\right)^{-1} \tag{2-221}$$

For MOS transistors, the most widely used parameter for the characterization of output resistance is

$$\lambda = \frac{1}{V_A} \tag{2-222}$$

As in the bipolar case, the large-signal properties of the transistor can be approximated by assuming that λ and V_A are constants, independent of bias conditions. Thus we can formulate a better approximation to the I–V characteristics as

$$I_D = \frac{k'}{2}\frac{W}{L}(V_{GS} - V_t)^2 (1 + \lambda V_{DS}) \tag{2-223}$$

In practical MOS transistors variation of X_d with voltage is complicated by the fact that the field distribution in the drain depletion region is not one dimensional. A vertical component in the field distribution is introduced by the potential difference between the gate and channel and the gate and drain. As a result, the calculation of λ from the device structure is quite different [16], and it is usually necessary to develop effective values of λ from experimental data. The parameter λ is a linear function of effective channel length and is an increasing function of the doping level in the channel. Typical values of λ are in the range 0.05–0.005 V^{-1}. Note that, in the case of a JFET, the pinchoff region for MOS devices is often called the *saturation* region.

A plot of I_D versus V_{DS} for an NMOS transistor is shown in Figure 2-106. Below pinchoff, the device behaves as a nonlinear voltage-controlled resistor, which is often called the *ohmic* or *triode* region. Above pinchoff, the device approximates a voltage-controlled current source. Note that for depletion MOS devices, V_t is negative and I_D is finite, even for $V_{GS} = 0$. For PMOS devices, all polarities of voltage and current are reversed.

The results as previously derived can be used to form a large-signal model of an MOS transistor. The model topology in the pinchoff region is the same as that for the JFET, but using Eq. (2-215) for the controlled-current generator.

MOS Device Voltage Limitations. The voltage limitations of MOS transistors depend on the gate length L. For small values of L (less than about 10 μm), the drain-depletion region

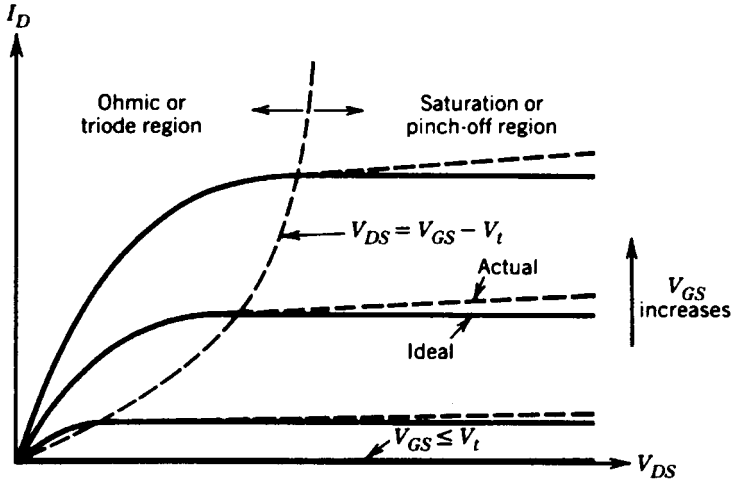

Figure 2-106 NMOS device characteristics.

exerts an appreciable influence on the channel. This causes I_D to rise with increasing V_{DS} in a similar fashion to the bipolar transistor curves of Figure 2-89.

For long channel lengths, the drain-depletion region has little effect on the channel and the I_D-versus-V_{DS} curves follow closely the ideal curves of Figure 2-106. Eventually the drain–substrate *pn*-junction breakdown voltage is exceeded and a sharp breakdown characteristic is obtained, which is similar to the JFET characteristic.

In addition to V_{DS} limitations, MOS devices must also be protected against excessive gate voltages. Typical gate oxides break down with about 25–50 V applied from gate to channel, and this process is destructive to the transistor.

2-3-4 Small-Signal Model of the MOS Transistor in Saturation

The preceding large-signal equations can now be used to derive the small-signal model of the MOS transistor in the saturation or pinchoff region. The important equations are (2-220) and (2-206). Note from Eq. (2-206) that the source–substrate voltage V_{BS} affects V_t, and thus I_D. This is due to the influence of the substrate acting as a second gate and is called *body effect*. As a consequence, I_D is a function of both V_{GS} and V_{BS}, and we require *two* transconductance generators in the small-signal model as shown in Figure 2-107. Variations in the voltage v_{bs} from source to body cause current $g_{mb}v_{bs}$ to flow from drain to source. Note that the body (or substrate) of an NMOS integrated circuit is usually connected to the most negative supply voltage and is thus an ac ground. However, the source connection can have a significant ac voltage impressed on it. Parasitic resistances due to the channel contact regions should be included in series with the source and drain of the model but are usually neglected in hand calculations. These resistances have an inverse dependence on channel width W and have typical values of 50–100 Ω for devices with W of about 1 μm.

The parameters of Figure 2-107 can be determined from Eq. (2-223) by differentiating.

$$g_m = \frac{\partial I_D}{\partial V_{GS}} = k' \frac{W}{L} (V_{GS} - V_t)(1 + \lambda V_{DS}) \tag{2-224}$$

If $\lambda V_{DS} << 1$, this is often approximated as

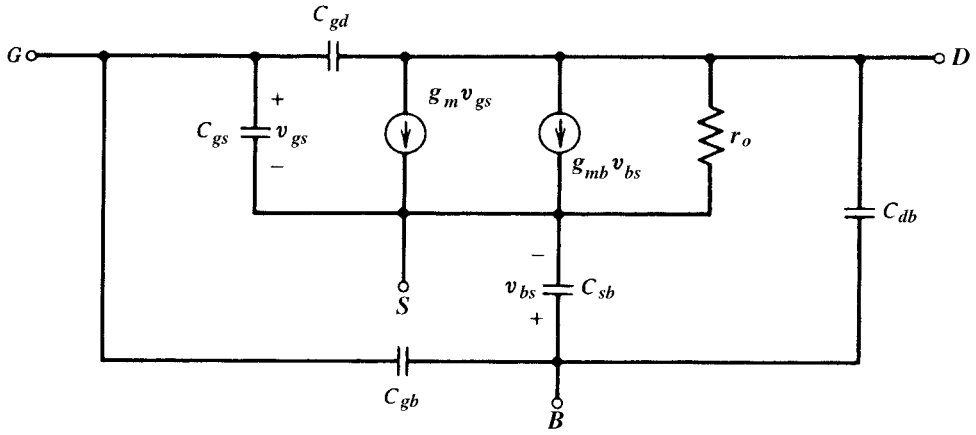

Figure 2-107 Small-signal MOS transistor equivalent circuit.

$$g_m = k' \frac{W}{L} (V_{GS} - V_t) = \sqrt{2k' \frac{W}{L} I_D} \tag{2-225}$$

Like the JFET and unlike the bipolar transistor, the transconductance of the MOSFET depends on both bias current and the *W*/*L* ratio (also on the oxide thickness via *k*′). Similarly,

$$g_{mb} = \frac{\partial I_D}{\partial V_{BS}} = -k' \frac{W}{L} (V_{GS} - V_t) (1 + \lambda V_{DS}) \frac{\partial V_t}{\partial V_{BS}} \tag{2-226}$$

From Eq. (2-206)

$$\frac{\partial V_t}{\partial V_{BS}} = -\frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = -\chi \tag{2-227}$$

where this equation defines a factor χ. This parameter is equal to the rate of change of threshold voltage with body bias voltage. One obtains

$$\chi = \frac{C_{js}}{C_{\text{ox}}} \tag{2-228}$$

where C_{js} is the capacitance per unit area of the depletion region under the channel, assuming a one-sided step junction with a built-in potential $\psi_0 = 2\phi_f$.

Substitution of Eq. (2-227) into Eq. (2-226) gives

$$g_{mb} = \frac{\gamma k' (W/L) (V_{GS} - V_t) (1 + \lambda V_{DS})}{2\sqrt{2\phi_f + V_{SB}}} \tag{2-229}$$

Again, if $\lambda V_{DS} << 1$, we have

$$g_{mb} = \frac{\gamma \sqrt{k' (W/L) I_D}}{\sqrt{2(2\phi_f + V_{SB})}} \tag{2-230}$$

An important quantity is the ratio g_{mb}/g_m, and from Eqs. (2-224) and (2-229) we find

$$\frac{g_{mb}}{g_m} = \frac{\gamma}{2\sqrt{2\phi_f + V_{SB}}} = \chi \tag{2-231}$$

The factor χ is typically in the range 0.1–0.3.

Finally, the small-signal output resistance can be obtained directly from Eq. (2-218):

$$r_o = \left(\frac{\partial I_D}{\partial V_{DS}} \right)^{-1} = \frac{L_{\text{eff}}}{I_D} \left(\frac{dX_d}{dV_{DS}} \right)^{-1} \tag{2-232}$$

and using Eqs. (2-221) and (2-222), we find

$$r_o = \frac{1}{\lambda I_D} = \frac{V_A}{I_D} \tag{2-233}$$

Small-signal model capacitances are also shown in Figure 2-107. Of these, only the gate–source capacitance C_{gs} is intrinsic to the device operation in the saturation region. Capacitances C_{sb} and C_{db} are parasitic depletion-region capacitances between the substrate and the source and drain regions, respectively. These can be expressed as follows:

$$C_{sb} = \frac{C_{sb0}}{(1 + V_{SB}/\psi_0)^{1/2}} \tag{2-234}$$

$$C_{db} = \frac{C_{db0}}{(1 + V_{DB}/\psi_0)^{1/2}} \tag{2-235}$$

These capacitances are proportional to the gate and source region areas (including sidewalls), and C_{sb} also includes depletion-region capacitance from the induced channel in the body.

Capacitance C_{gb} between gate and substrate models parasitic oxide capacitance between the gate contact material and the substrate outside the active-device area. This is a constant capacitance and models coupling between polysilicon and metal interconnects and the underlying substrate. In fact, parasitic capacitance of this type underlies all polysilicon and metal traces on the chip and should be taken into account when simulating and calculating high-frequency circuit and device performance. Typical values depend on oxide thicknesses and range from about 0.04 to 0.15 fF per square micron of interconnect, with fringing effects becoming important for narrow lines (several microns or less in width).

Capacitances C_{gs} and C_{gd} exist from gate to source and drain, respectively. If C_{ox} is the oxide capacitance per unit area from gate to channel then the total capacitance under the gate is $C_{\text{ox}}WL$. This capacitance is intrinsic to the device operation and models the gate control of the channel conductance. In the ohmic region of device operation, this capacitance is split equally between source and drain so that $C_{gs} = C_{gd} = 1/2C_{\text{ox}}WL$. However, in the saturation region, the channel is very narrow at the drain end and the drain voltage exerts little influence on either the channel or the gate charge. As a consequence, the intrinsic portion of C_{gd} is essentially zero in the saturation region and C_{gd} then consists of a constant parasitic oxide-capacitance contribution due to gate overlap of the drain region. This is on the order of 1–10 fF for small devices.

In order to calculate the corresponding value of C_{gs} in the saturation region, we must calculate the total charge Q_T stored in the channel. This can be obtained by integrating Eq. (2-209) to obtain

$$Q_T = WC_{\text{ox}} \int_0^L [V_{GS} - V(y) - V_t]dy \tag{2-236}$$

Substituting for dy/dV from Eq. (2-211) into Eq. (2-236), we find

$$Q_T = \frac{W^2 C_{\text{ox}}^2 \mu_n}{I_D} \int_0^{V_{GS}-V_t} (V_{GS} - V - V_t)^2 dV \tag{2-237}$$

where the limit $y = L$ corresponds to $V = (V_{GS} - V_t)$ in saturation. Solution of Eq. (2-237) and use of Eqs. (2-214) and (2-215) gives

$$Q_T = \frac{2}{3} WLC_{\text{ox}}(V_{GS} - V_t) \tag{2-238}$$

and thus

$$C_{gs} = \frac{\partial Q_T}{\partial V_{GS}} = \frac{2}{3} WLC_{\text{ox}} \tag{2-239}$$

In addition, there is a contribution to C_{gs} from the constant parasitic oxide capacitance due to gate overlap of the source region.

The f_T of the MOSFET is given by

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs} + C_{gd} + C_{gb}} \tag{2-240}$$

The dependence of MOSFET f_T on device and process parameters can be seen by assuming that the intrinsic device capacitance G_{gs} dominates. Thus from Eq. (2-240) we have

$$f_T = \frac{1}{2\pi} \frac{g_m}{C_{gs}} \tag{2-241}$$

Substituting in Eq. (2-241) for g_m from Eq. (2-225) and C_{gs} from Eq. (2-239) we find for a MOSFET

$$f_T = 1.5 \frac{\mu_n}{2\pi L^2} (V_{GS} - V_t) \tag{2-242}$$

It is interesting to compare this with the intrinsic f_T of a bipolar transistor when parasitic depletion-layer capacitance is neglected. From

$$f_T = \frac{1}{2\pi\tau_F} \tag{2-243}$$

and substituting for τ_f and using the Einstein relationship $D_n/\mu_n = kT/q = V_T$, we find for a bipolar transistor

$$f_T = 2 \frac{\mu_n}{2\pi W_B^2} V_T \tag{2-244}$$

The similarity in form between Eqs. (2-242) and (2-244) is striking. In both cases the intrinsic device f_T increases as the inverse square of the critical device dimension across which carriers are in transit. The voltage V_t = 26 mV is fixed for a bipolar transistor, but MOSFET f_T can be increased by operating at high values of $(V_{GS} - V_t)$. Note that the base width W_B in a bipolar transistor is a vertical dimension determined by diffusions or implants and can typically be made much smaller than the channel length L of a MOSFET, which depends on surface geometry and photolithographic processes. Thus bipolar transistors generally have higher f_T than MOSFETs made with comparable processing. Finally, Eq. (2-242) was derived assuming that the MOSFET square law is valid. However, as discussed in Section 2-3-5, submicron MOSFETs depart significantly from square-law characteristics, and we find that for such devices f_T increases as L^{-1} rather than L^{-2}.

2-3-5 Short-Channel Effects in FETs

The evolution of integrated-circuit processing techniques has led to continuing reductions in both the horizontal and vertical dimensions of the active devices (the minimum allowed dimension of passive devices has also increased). This trend is driven primarily by economics in that more devices and circuits can be processed at one time on a given wafer. A second benefit has been that the frequency capability of the active devices continues to increase, as intrinsic f_T values increase with smaller dimensions while parasitic capacitances decrease.

Vertical dimensions such as the base width of a bipolar transistor in production processes may now be on the order of 0.05 μm or less, whereas horizontal dimensions such as bipolar emitter width or FET gate length may be significantly less than 1 μm. Even at these very small dimensions, the large-signal and small-signal models of bipolar transistors given in previous sections remain valid. However, significant short-channel effects become important in FETs of all types at channel lengths on the order of 1 μm or less and require modifications to the FET models given previously. The primary effect is to modify the classical FET square-law transfer characteristic in the saturation region to make the device more closely approach an ideal linear transfer function. Note, however, that even in processes with submicron capability, many of the FETs in a given analog circuit may be deliberately chosen to be larger than the minimum size and may be well approximated by the square-law model.

The most important short-channel effect in FETs is due to velocity saturation of carriers in the channel [17]. At low electric field values, the linear relation between carrier velocity and field implied by Eqs. (2-210) and (2-211) is valid. At high fields, however, the carrier velocities approach the thermal velocities and subsequently the carrier velocities increase more slowly with increasing field. This is illustrated in Figure 2-108, which shows typical measured electron drift velocity v_d versus tangential electric field strength magnitude $\mathscr{E}$ in an NMOS surface channel. Note that at low field values the velocity is proportional to the field, while at high fields the velocity approaches a constant value called the scattering-limited velocity v_{scl}. A first-order analytical approximation to this curve is

$$v_d = \frac{\mu_n \mathscr{E}}{1 + \mathscr{E}/\mathscr{E}_c} \tag{2-245}$$

where $\mathscr{E} \simeq 1.5 \times 10^6$ V/m and $\mu_n \simeq 0.07$ m^2/V · s is the low-field mobility. Equation (2-245) is also plotted in Figure 2-108. From Eq. (2-245), as $\mathscr{E} \to \infty$ we have $v_{\text{scl}} = \mu_n \mathscr{E}_c$. At the critical field value $\mathscr{E}_c$, the carrier velocity is a factor of 2 less than the low-field formula would predict. In a device with a channel length $L = 1$ μm, we need a voltage drop of only 1.5 V along the channel to have an average field equal to $\mathscr{E}_c$, and this condition is readily achieved in small MOSFETs. Similar results are found for PMOS devices.

As an example of the effects of velocity saturation on FET characteristics, we consider the example of the MOSFET. In the analysis of "Transfer Characteristics of MOS Devices" in Section 2-3-3, we now use the more general expression

$$I_D = WQ_I(y)v_d(y) \tag{2-246}$$

Substituting Eq. (2-245) into Eq. (2-246) and using

$$\mathscr{E} = \frac{dV}{dy} \tag{2-247}$$

for the magnitude of the field, we find that

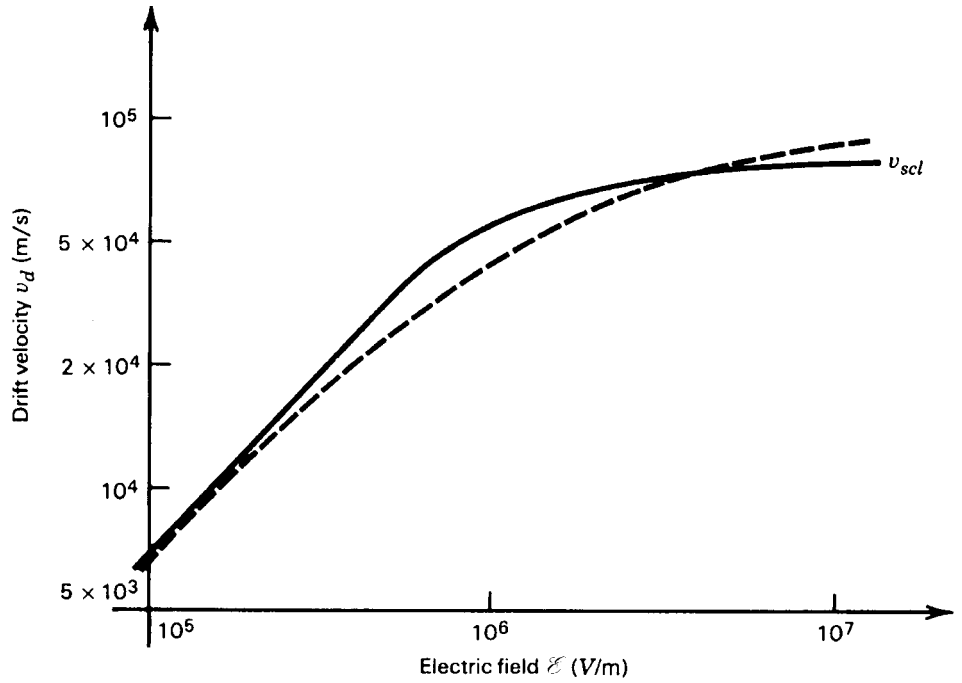

Figure 2-108 Typical measured electron drift velocity v_d versus tangent electric field $\mathscr{E}$ in an MOS surface channel (solid line). Also shown (dotted line) is the analytical approximation of Eq. (2.245) with $\mathscr{E}_c = 1.5 \times 10^6$ V/m and $\mu_n = 0.07$ m^2/V · s.

$$I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right) = WQ_I(y)\mu_n\frac{dV}{dy} \tag{2-248}$$

Note that as $\mathscr{E}_c \to \infty$ and velocity saturation becomes negligible, Eq. (2-248) approaches the original equation (2-211).

Integrating Eq. (2-248) along the channel we obtain

$$\int_0^L I_D\left(1 + \frac{1}{\mathscr{E}_c}\frac{dV}{dy}\right)dy = \int_0^{V_{DS}} WQ_I(y)\mu_n dV \tag{2-249}$$

and thus

$$I_D = \frac{\mu_n C_{ox}}{2\left(1 + \dfrac{1}{\mathscr{E}_c}\dfrac{V_{DS}}{L}\right)}\frac{W}{L}[2(V_{GS} - V_t)V_{DS} - V_{DS}^2] \tag{2-250}$$

The quantity V_{DS}/L in Eq. (2-250) can be interpreted as the average field in the channel. If this is comparable to $\mathscr{E}_c$, the drain current for a given V_{DS} is less than the simple expression (2-213) would predict.

Equation (2-250) is valid in the triode region. The MOSFET transfer function in saturation can be obtained by using $V_{DS} = (V_{GS} - V_t)$ in Eq. (2-250) to obtain

$$I_D = \frac{k'}{2[1 + \theta(V_{GS} - V_t)]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-251}$$

where $\theta = 1/L\mathscr{E}_c$ and has the dimension volts^{-1}. For $L = 1$ μm, a typical value is $\theta \approx 0.7\ \text{V}^{-1}$. Note that in the presence of velocity saturation effects, the device enters the saturation region for $V_{DS} < (V_{GS} - V_t)$. However, Eq. (2-251) still gives a good estimate of the saturation current.

Thus far, we have only considered the effects of the tangential field due to the V_{DS} along the channel when examining velocity saturation effects. However, there exists a normal field originating from the gate voltage that also inhibits channel carrier mobility. Since the normal field depends on the value of V_{GS}, we find that an empirical modification to θ in Eq. (2-251) can adequately model this effect. In practice, θ is determined by a best fit to measured device characteristics.

Returning to Eq. (2-251) we note that for very short channel lengths, θ becomes large and Eq. (2-251) reduces to

$$I_D \propto (V_{GS} - V_t) \tag{2-252}$$

Thus, the FET characteristics tend toward a *linear* transfer function as the channel length becomes very small (less than 1 μm).

Equation (2-251) has a simple circuit representation. Consider the circuit of Figure 2-109, where an ideal square-law MOSFET has a resistance R_{SX} in series with the source of the FET. Assume

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V'_{GS} - V_t)^2 \tag{2-253}$$

Now

$$V_{GS} = V'_{GS} + I_D R_{SX} \tag{2-254}$$

and substituting Eq. (2-254) into Eq. (2-253) we find that

$$I_D = \frac{\mu C_{\text{ox}}}{2} \frac{W}{L} (V_{GS} - I_D R_{SX} - V_t)^2 \tag{2-255}$$

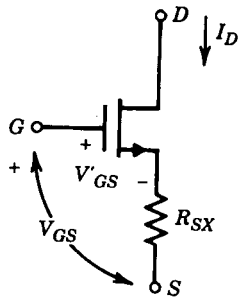

Figure 2-109 Model of velocity saturation of a MOSFET by addition of a series source resistance to an ideal square-law device.

Rearranging Eq. (2-255) we find

$$I_D = \frac{\mu C_{\text{ox}}}{2\left[1 + \mu C_{\text{ox}} \frac{W}{L} R_{SX}(V_{GS} - V_t)\right]} \frac{W}{L} (V_{GS} - V_t)^2 \tag{2-256}$$

This has exactly the same form as Eq. (2-251) if we identify

$$\theta = \mu C_{\text{ox}} \frac{W}{L} R_{SX} \tag{2-257}$$

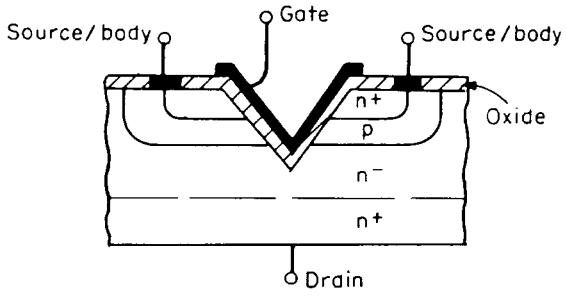
Substituting $\theta = 1/L\mathscr{E}_c$ into Eq. (2-257) we have

$$R_{SX} = \frac{1}{\mathscr{E}_c} \frac{1}{\mu C_{\text{ox}}} \frac{1}{W} \tag{2-258}$$

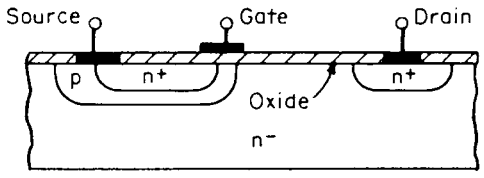
Thus, the influence of velocity saturation on the large-signal characteristics of a FET can be modeled to first order by a resistor R_{SX} in series with the source of an ideal square-law device. Note that R_{SX} varies inversely with W, as does the intrinsic physical series resistance due to source and drain contact regions. Typically, R_{SX} is larger than the physical series resistance. For $W = 2\ \mu\text{m}$, $\mu C_{\text{ox}} = 40\ \mu\text{A}/V^2$, and $\mathscr{E}_c = 1.5 \times 10^6$ V/m, we find $R_{SX} = 8\ \text{k}\Omega$.

The foregoing analysis has developed a modified large-signal mode for the MOSFET including velocity saturation effects. Small-signal MOSFET modeling for small devices can still be done using the equivalent circuit of Figure 2-107 if the values of g_m and g_{mb} are modified to account for the effects of velocity saturation using Eq. (2-251).

Figure 2-110 shows a cross section of VMOS (vertical MOS) and DMOS (double-diffused MOS) transistors. There is also a TMOS device—a Motorola variant of VMOS—and the



(a) VMOS (vertical channel MOS)



(b) DMOS (double-diffused MOS)

Figure 2-110 Cross section of (a) VMOS and (b) DMOS FETs.

now very popular LDMOS (lateral diffused MOS) power transistor (Figures 2-111 and 2-112). LDMOS FETs operate from a single supply (approximately 8 V and up) and are available for output powers surpassing 100 W at 2 GHz. The feedback capacitance is much lower than VMOS, TMOS, and earlier models, significantly improving circuit stability.

Following is a listing of Motorola high-power LDMOS transistors capable of operation up to 2 GHz:

2-3-6 Small-Signal Models of MOSFETs

Subthreshold Conduction in MOSFETs. The MOSFET analysis of Section 2-3-3 focused on the normal region of operation where this is a well-defined conducting channel under the gate. Changes in the gate voltage are assumed to cause changes in the channel charge only, and not in the depletion region below. However, for gate voltages less than the extrapolated threshold voltage V_t, the applied gate potential affects both the depletion-region charge and the channel charge, which is then very small but not zero. The device can thus conduct finite (but small) current for $V_{GS} < V_t$, so that Eq. (2-215) is not valid in this region. The electrons in the n^+ source region of an NMOS transistor can overcome the potential barrier to the p-type substrate and enter the channel region. This process is very similar to the turn-on of a bipolar transistor, and in fact the MOSFET characteristics in this subthreshold region (also called weak inversion) are very similar to those of a bipolar transistor. Analysis [19] shows that in the subthreshold region of the MOSFET characteristics can be defined by the equation

$$I_D = k_x \frac{W}{L} e^{V_{GS}/nV_T}(1 - e^{-V_{DS}/V_T}) \tag{2-259}$$

where k_x depends on process parameters and $n \simeq 1.5$. The value of n is not equal to unity in this case (as it is for the bipolar transistor) because the applied voltage V_{GS} appears partially at the silicon surface and partially across the depletion layer.

To illustrate this effect, we show measured NMOS characteristics plotted on three different scales in Figure 2-113. In Figure 2-113a we show the transfer characteristic in the forward-active region plotted on linear scales. For this device W = 20 μm and L = 20 μm and short-channel effects are negligible. The same data are plotted in Figure 2-113b as $\sqrt{I_D}$ versus V_{GS}. The resulting straight line shows that the device characteristic is close to an ideal square law. Plots like this are commonly used to obtain V_t by extrapolation (0.7 V in this case) and also k' from the slope of the curve (54 μA/V^2 in this case). Note that near the threshold voltage, the curve deviates from the straight line representing the square law. This is the subthreshold region. The data are plotted a third time in Figure 2-113c on log–linear scales. The straight line obtained for $V_{GS} < V_t$ fits Eq. (2-259) with n = 1.5. At currents below 10^{-12} A, the effect of leakage currents becomes evident.

The major application of subthreshold operation is in very low power applications at relatively low signal frequencies. The limitation to low signal frequencies occurs because the MOSFET f_T becomes very small. Since the device capacitances at very low bias currents

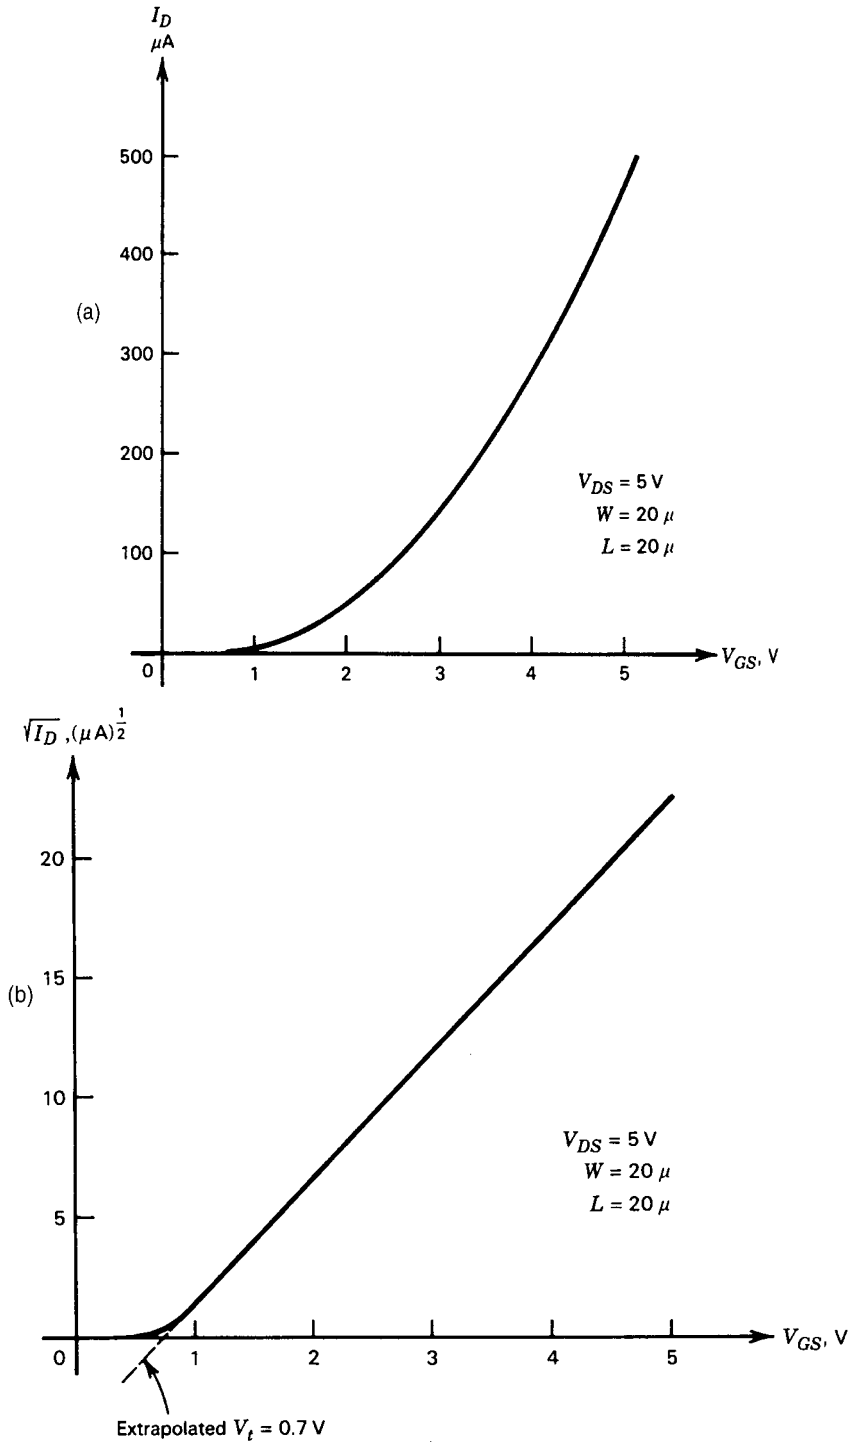

Figure 2-113 (a) Measured NMOS transfer characteristic in the forward-active region. (b) Data from part (a) plotted as $\sqrt{I_D}$ versus V_{GS} showing the square-law characteristic. (c) Data from part (a) plotted on log–linear scales showing the exponential characteristic of the subthreshold region.

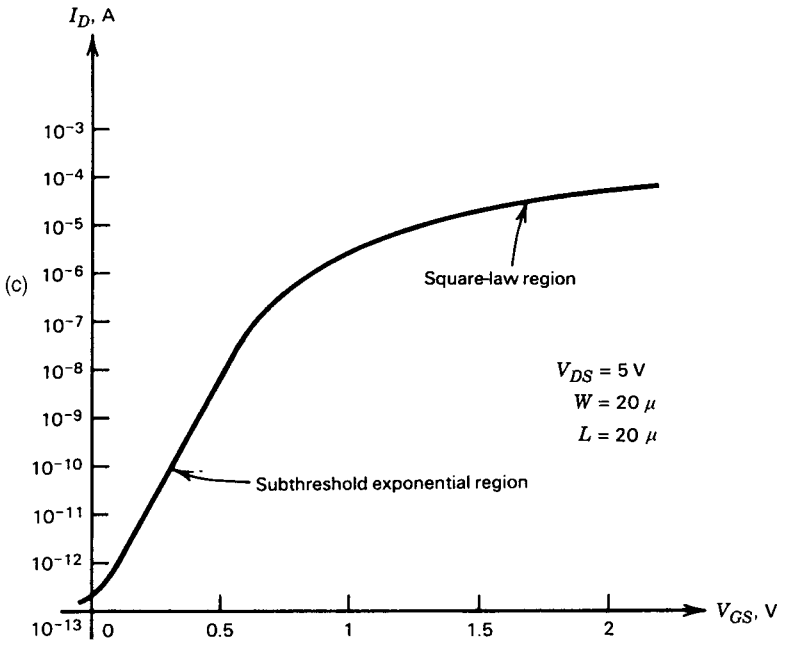

Figure 2-113. (*Continued*)

are essentially fixed, and the small-signal g_m calculated from Eq. (2-259) becomes proportional to I_D, we see that the value of f_T becomes very small at very low values of I_D.

Substrate Flow in MOSFETs. As the reverse-bias voltages on the device are increased, carriers traversing the depletion regions gain sufficient energy to create new hole–electron pairs in lattice collisions by a process known as *impact ionization.* Eventually, at high enough bias voltages, the process results in large avalanche currents. For collector–base bias voltages well below the breakdown value, a small enhanced current flow may occur across the collector–base junction due to this process with little apparent effect on the device characteristics.

Impact ionization also occurs in MOSFETs but has a significantly different effect on the device characteristics. This is because the channel electrons (for the case of NMOS) create hole–electron pairs in lattice collisions in the drain depletion region, and some of the resulting holes then flow to the substrate, creating a substrate current. (The electrons created

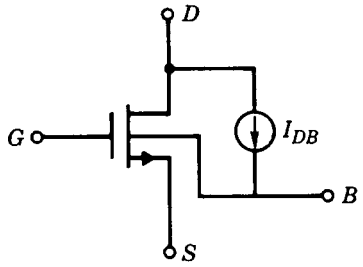

Figure 2-114 Representation of impact ionization in a MOSFET by a drain–substrate current generator.

in the process flow out the drain terminal.) The carriers created by impact ionization are thus not confined within the device as they are in a bipolar transistor. The effect of this phenomenon can be modeled by inclusion of a controlled current generator I_{DB} from drain to substrate, as shown in Figure 2-114 for an NMOS device. The magnitude of this substrate current depends on the voltage across the drain depletion region (which determines the energy of the ionizing channel electrons), and also on the drain current (which is the rate at which channel electrons enter the depletion region). It has been found empirically [20] that the current I_{DB} can be expressed as

$$I_{DB} = K_1(V_{DS} - V_{DS,\text{sat}})I_D e^{-[K_2/(V_{DS}-V_{DS,\text{sat}})]} \tag{2-260}$$

where K_1 and K_2 are process-dependent parameters and $V_{DS,\text{sat}}$ is the value of V_{DS} where the drain characteristics enter the saturation region. Typical values for NMOS devices are $K_1 = 5\ \text{V}^{-1}$ and $K_2 = 30$ V. The effect is generally much less significant in PMOS devices because the holes carrying the charge in the channel are much less efficient in creating hole–electron pairs than are energetic electrons.

The major impact of this phenomenon on circuit performance is that a parasitic resistance from drain to substrate now exists. Since the substrate of an NMOS device in a *p*-substrate process is an ac ground (the common substrate terminal must always be connected to the most negative supply voltage in the circuit), the parasitic resistance shunts the drain to ground and can be a limiting factor in many circuit designs. Differentiating Eq. (2-260) we find for the drain–substrate small-signal conductance

$$g_{db} = \frac{\partial I_{DB}}{\partial V_D}$$

$$= K_2 \frac{I_{DB}}{(V_{DS} - V_{DS,\text{sat}})^2} \tag{2-261}$$

where the gate and source are assumed held at fixed potentials.

In IC applications for RF/UHF circuits, many not-yet-solved problems remain:

1. The flicker corner frequency for MOS devices is somewhere between 100 kHz and 1 MHz.
2. Because of backplane problems in ICs, such as the substrate capacitance, also relative to the source, the performance of an IC-MOS/CMOS is not as good as expected if these effects are not considered.
3. Discrete devices, such as *n*-channel MOS devices, which are also available as dual-gate MOSFETs, can work well up to 1200 MHz. Such performance is not yet shown in silicon-based RFICs.
4. For RF power devices, such as LDMOS and others mentioned, promising results are only shown for discrete devices. There are no equivalent ICs on the market yet.

It will be interesting to see how this technology will work itself upward in frequency. Its main advantage is the BiCMOS process, which allows the mixing of analog and digital circuits nicely. Heterojunction transistors, such as SiGe, are inherently much more linear

and, for the same performance, require less current than MOS technology. On the other hand, we have not seen large-scale production SiGe-based ICs.

In the following five pages, we reproduce the datasheet for the Siemens (now Infineon Technologies) BF999 single-gate MOSFET.* Above 500 MHz, a dual-gate (also referred to as tetrode) MOSFET, such as the BF998, is preferred over a single-gate device. The main reasons for this are:

1. Internally, it is equivalent to two single-gate devices connected in a cascade arrangement, with the output device operating in the grounded-gate configuration, which entirely avoids the Miller effect and therefore remains stable at higher frequencies, operating up to 1.2 GHz.
2. The second gate can be used for AGC. As the Gate 2 voltage changes, the gain varies heavily.
3. By applying a local oscillator signal to Gate 2, this configuration can be used as a mixer.

The major drawbacks of these devices are their wide tolerances and temperature sensitivity. They follow to some degree the CMOS design but seem to have better performance.

The BF995, also called a tetrode, is in reality a dual-gate MOSFET specified to only 300 MHz; however, we are reproducing its datasheet* because the one more applicable for wireless circuits, the BF1005, does not have such a complete set of data.

To demonstrate the capabilities of low-voltage LDMOS transistors, we show the MRF5003 datasheet.† This device is intended for low-voltage applications down to 7.5 V. To the best of our knowledge, this is the lowest-voltage LDMOS transistor on the market. Other members of this family, which produce 5 W (MRF5005) and 15 W (MRF5015), begin to require higher supply voltages. Just to make sure it is not forgotten, the advantage of LDMOS is, besides lower-voltage operation, much-reduced feedback capacitance. LDMOS devices are now available that operate above 1 GHz and produce 60 W. There is now some competition with the recently introduced NEC GaAsFET, which goes up to 100 W in a similar frequency range.

RF POWER FET

The MRF5003 is designed for broadband commercial and industrial applications at frequencies to 520 MHz. The high gain and broadband performance of this device makes it ideal for large–signal, common source amplifier applications in 7.5 Volt and 12.5 Volt mobile, portable, and base station FM equipment.

- Guaranteed Performance at 512 MHz, 7.5 Volts
  Output Power = 3.0 Watts
  Power Gain = 9.5 dB
  Efficiency = 45%
- Characterized with Series Equivalent Large–Signal Impedance Parameters
- S–Parameter Characterization at High Bias Levels
- Excellent Thermal Stability
- All Gold Metal for Ultra Reliability
- Capable of Handling 20:1 VSWR, @ 15.5 Vdc, 512 MHz, 2.0 dB Overdrive
- Suitable for 12.5 Volt Applications
- True Surface Mount Package
- Available in Tape and Reel by Adding R1 Suffix to Part Number.
  R1 Suffix = 500 Units per 16 mm, 7 inch Reel.
- Circuit board photomaster available upon request by contacting
  RF Tactical Marketing in Phoenix, AZ.

DESIGN CONSIDERATIONS

The MRF5003 is a common–source, RF power, N–Channel enhancement mode, Metal–Oxide Semiconductor Field–Effect Transistor (MOSFET). Motorola RF MOSFETs feature a vertical structure with a planar design. Motorola Application Note AN211A, "FETs in Theory and Practice", is suggested reading for those not familiar with the construction and characteristics of FETs.

This surface mount packaged device was designed primarily for VHF and UHF power amplifier applications. Manufacturability is improved by utilizing the tape and reel capability for fully automated pick and placement of parts.

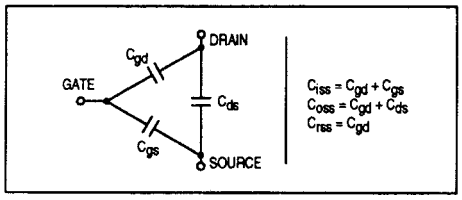
The major advantages of RF power MOSFETs include high gain, simple bias systems, relative immunity from thermal runaway, and the ability to withstand severely mismatched loads without suffering damage.

MOSFET CAPACITANCES

The physical structure of a MOSFET results in capacitors between all three terminals. The metal oxide gate structure determines the capacitors from gate–to–drain (C_{gd}), and gate–to–source (C_{gs}). The PN junction formed during fabrication of the RF MOSFET results in a junction capacitance from drain–to–source (C_{ds}). These capacitances are characterized as input (C_{iss}), output (C_{oss}) and reverse transfer (C_{rss}) capacitances on data sheets. The relationships between the inter–terminal capacitances and those given on data sheets are shown below. The C_{iss} can be specified in two ways:

1. Drain shorted to source and positive voltage at the gate.
2. Positive voltage of the drain in respect to source and zero volts at the gate.

In the latter case, the numbers are lower. However, neither method represents the actual operating conditions in RF applications.



DRAIN CHARACTERISTICS

One critical figure of merit for a FET is its static resistance in the full–on condition. This on–resistance, $R_{DS(on)}$, occurs in the linear region of the output characteristic and is specified at a specific gate–source voltage and drain current. The drain–source voltage under these conditions is termed $V_{DS(on)}$. For MOSFETs, $V_{DS(on)}$ has a positive temperature coefficient at high temperatures because it contributes to the power dissipation within the device.

GATE CHARACTERISTICS

The gate of the RF MOSFET is a polysilicon material, and is electrically isolated from the source by a layer of oxide. The input resistance is very high — on the order of $10^9\ \Omega$ — resulting in a leakage current of a few nanoamperes.

Gate control is achieved by applying a positive voltage to the gate greater than the gate–to–source threshold voltage, $V_{GS(th)}$.

Gate Voltage Rating — Never exceed the gate voltage rating. Exceeding the rated V_{GS} can result in permanent damage to the oxide layer in the gate region.

Gate Termination — The gates of these devices are essentially capacitors. Circuits that leave the gate open–circuited or floating should be avoided. These conditions can result in turn–on of the devices due to voltage build–up on the input capacitor due to leakage currents or pickup.

Gate Protection — These devices do not have an internal monolithic zener diode from gate–to–source. If gate protection is required, an external zener diode is recommended with appropriate RF decoupling.

Using a resistor to keep the gate–to–source impedance low also helps dampen transients and serves another important function. Voltage transients on the drain can be coupled to the gate through the parasitic gate–drain capacitance. If the gate–to–source impedance and the rate of voltage change on the drain are both high, then the signal coupled to the gate may be large enough to exceed the gate–threshold voltage and turn the device on.

DC BIAS

Since the MRF5003 is an enhancement mode FET, drain current flows only when the gate is at a higher potential than the source. See Figure 8 for a typical plot of drain current versus gate voltage. RF power FETs operate optimally with a quiescent drain current (I_{DQ}), whose value is application dependent. The MRF5003 was characterized at I_{DQ} = 50 mA, which is the suggested value of bias current for typical applications. For special applications such as linear amplification, I_{DQ} may have to be selected to optimize the critical parameters.

The gate is a dc open circuit and draws no current. Therefore, the gate bias circuit may generally be just a simple resistive divider network. Some special applications may require a more elaborate bias system.

GAIN CONTROL

Power output of the MRF5003 may be controlled from its rated value down to zero (negative gain) with a low power dc control signal, thus facilitating applications such as manual gain control, ALC/AGC and modulation systems. Figure 16 is an example of output power variation with gate–source bias voltage. This characteristic is very dependent on frequency and load line.

MOUNTING

The specified maximum thermal resistance of 14°C/W assumes a majority of the 0.100″ x 0.200″ source contact on the back side of the package is in good contact with an appropriate heat sink. In the test fixture shown in Figure 1, the device is clamped directly to a copper pedestal. In the demonstration amplifier, the device was mounted on top of the G10 circuit board and heat removal was accomplished through several solder filled plated through holes. As with all RF power devices, the goal of the thermal design should be to minimize the temperature at the back side of the package.

AMPLIFIER DESIGN

Impedance matching networks similar to those used with bipolar transistors are suitable for the MRF5003. For examples see Motorola Application Note AN721, "Impedance Matching Networks Applied to RF Power Transistors." Both small–signal S–parameters and large–signal impedances are provided. While the S–parameters will not produce an exact design solution for high power operation, they do yield a good first approximation. This is an additional advantage of RF power MOSFETs.

Since RF power MOSFETs are triode devices, they are not unilateral. This coupled with the very high gain of the MRF5003 yield a device capable of self oscillation. Stability may be achieved by techniques such as drain loading, input shunt resistive loading, or output to input feedback. Different stabilizing techniques were applied to the test fixture and demonstration amplifiers. The RF test fixture implements a parallel resistor and capacitor in series with the gate while the demonstration amplifier utilizes a 43 Ω shunt resistor from gate to ground. Both circuits have a load line selected for a higher efficiency, lower gain, and more stable operating region.

Two port stability analysis with the MRF5003 S–parameters provides a useful tool for selection of loading or feedback circuitry to assure stable operation. See Motorola Application Note AN215A, "RF Small–Signal Design Using Two–Port Parameters," for a discussion of two port network theory and stability.

2-3-7 GaAs MESFETs

Introduction. More than twenty years ago, for RF applications, the JFET was the dominant FET. As mentioned earlier, its major disadvantage is the fact that the f_T cutoff frequency, defined as

$$f_T = g_m / 2\pi C_{GS} \tag{2-262}$$

limits the operating range of this semiconductor device to 1 GHz at most. Also, the JFET's temperature sensitivity and loose tolerances in transconductance and other RF-related values made it difficult to use. Finally, no RFICs made use of this technology. While at the moment silicon-based MOS technology probably is the most cost-effective and is produced in the largest quantities, it does not rival the metal-semiconductor FET designed on GaAs technology. Figure 2-115 shows the structure of the silicon MOSFET, silicon JFET, and the GaAs MESFET.

Large-Signal Behavior of GaAs MESFETs. The mathematics for the large-signal behavior of the GaAsFET is basically quite similar to that for the JFET; however, the computations for JFET channel current, diode currents, and capacitance are much simpler than for the GaAsFET. Temperature effects are embedded in all the equations for all the transistors mentioned so far. In our opinion, the modified Materka model used by Ansoft and a large number of users is the most complete one; however, the following models are supported by most CAD tools:

- Chalmers (Angelov)
- Curtice–Ettenberg cubic
- Curtice quadratic
- IAF (Berroth)
- ITT PFET and TFET
- Modified Materka–Kacprzak
- Physics-based MESFET
- Raytheon (Statz)
- TriQuint (TOM-1, TOM-2, and TOM-3)
- With some restrictions, metal-insulator-semiconductor FETs (MISFETs), modulation-doped FETs (MODFETs), and high-electron-mobility transistors (HEMTs)

The main advantages of GaAsFET technology derive from the fact that it uses a metal-semiconductor junction with a barrier voltage of 0.8 V, its input capacitance is typically less than 0.2 pF, and the reverse feedback capacitance is less than 0.02 pF, or roughly 10% of the input capacitance. As a result of this, $f_{\max}$ is approximately five times higher than f_T. Table 2-16 shows a comparison of silicon BJT and GaAsFET technologies. While $f_{\max}$ for the bipolar transistor is

$$f_{\max} \simeq \sqrt{\frac{f_t}{8\pi r'_{bb} C_C}} \tag{2-263}$$

the $f_{\max}$ determination for the GaAsFET is given by

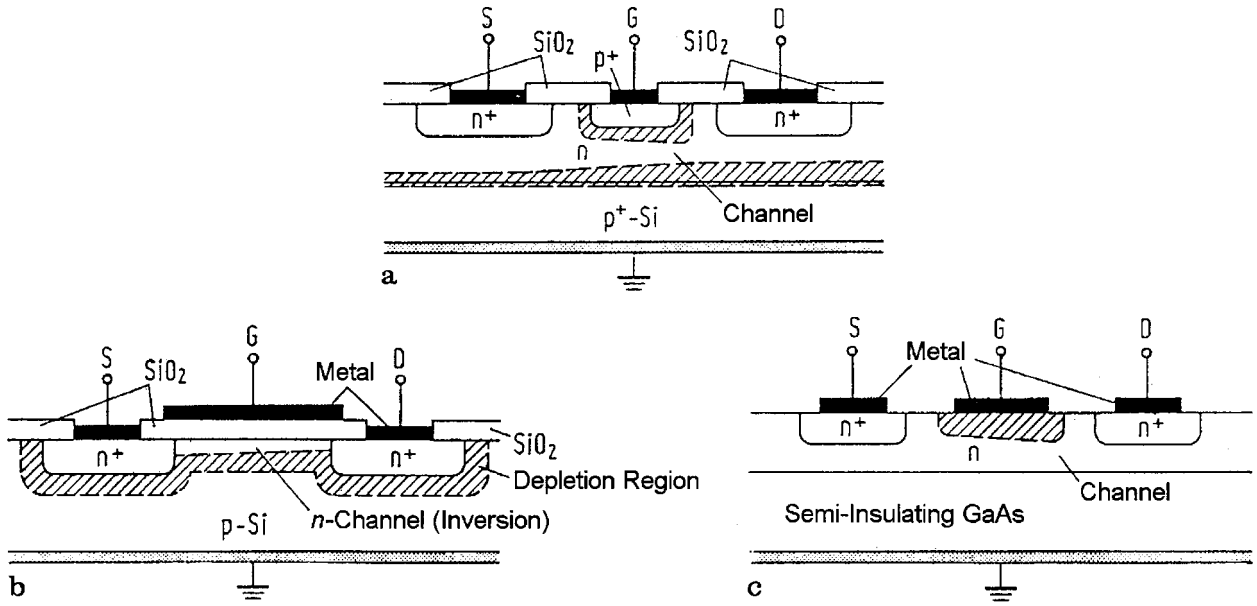

Figure 2-115 This picture is provided to differentiate between the structure of the three technologies. (a) The JFET and (b) the MOSFET are based on silicon; (c) the GaAsFET is based on semi-insulating GaAs. While the MOS transistor has silicon dioxide (SiO_2) as gate insulation, both the JFET and GaAs MESFET have a diode from gate to source, with a barrier voltage of 0.65 V for silicon and 0.8 V for GaAs.

Table 2-16 Comparison of Si BJT, SiGe HBT, and GaAsFET technologies

	Si Bipolar	SiGe HBT	GaAs FET
f_T	25 GHz	100 GHz	22 GHz
$f_{\max}$	40 GHz	200 GHz	110 GHz
Features	Low cost, low 1/*f* noise (5 kHz)	Low 1/*f* noise, very low distortion, high cost, IC only	Highest flexibility, lowest NF_0, well established

$$f_{\max} = \frac{f_T}{2}\sqrt{\frac{R_0}{R_i + R_s + R_g}} \tag{2-264}$$

As a sample calculation,

$$f_{\max}\ \frac{21.9\text{ GHz}}{2}\sqrt{\frac{450}{1 + 1.5 + 2}} = 110\text{ GHz} \tag{2-265}$$

The three major drawbacks of the GaAsFET are:

1. Much higher flicker corner frequency (somewhere between 10 and 100 MHz), probably due to a lack of surface passivation.
2. Much higher output conductance. This tends to load down any circuit connected to the drain. On the other hand, since the transconductance is quite high for even low currents, these devices have very high gains at low frequencies, which can make them quite unstable. In the saturated mode it is not uncommon to find a drain–source resistance of 100–500 Ω, while BJTs and JFETs offer values of several kilohms and higher.
3. Because of the very high flicker corner frequency (from 10 to 100 MHz), MESFETs are really not useful for low-noise mixers and oscillators, and unless there are no devices available in the frequency range above 30 GHz, they should be avoided for these applications.

As to the MESFET's construction and dc properties, Figure 2-116 shows a MESFET's cross section and dc *I*–*V* characteristics.

It was outlined in the beginning that while the GaAsFET is a close relative to the JFET and MOSFET, its actual behavior was found to be described best by a set of analytic equations. The first such model was the one by Curtice in the form of quadratic and cubic models, but it does not have enough derivatives to give enough insight into subtle things such as third- and higher-order intermodulation distortion and accurate harmonic generation. Other researchers have addressed various areas, but we still find that the Materka model has the best approximation, especially using the two-transistor approach outlined later [20, 21]. The large-signal topology for all FETs consists of an intrinsic model with some extrinsic parameters, further complicated by the package, as shown by Figures 2-117 and 2-118. Table 2-17 lists their keywords. The actual intrinsic model and its parameter definition depend on the particular model and since designs using GaAsFET will always be done using CAD tools, we will not go into any details of the equations but will list them. They are not dissimilar from the JFET and MOSFET equations.

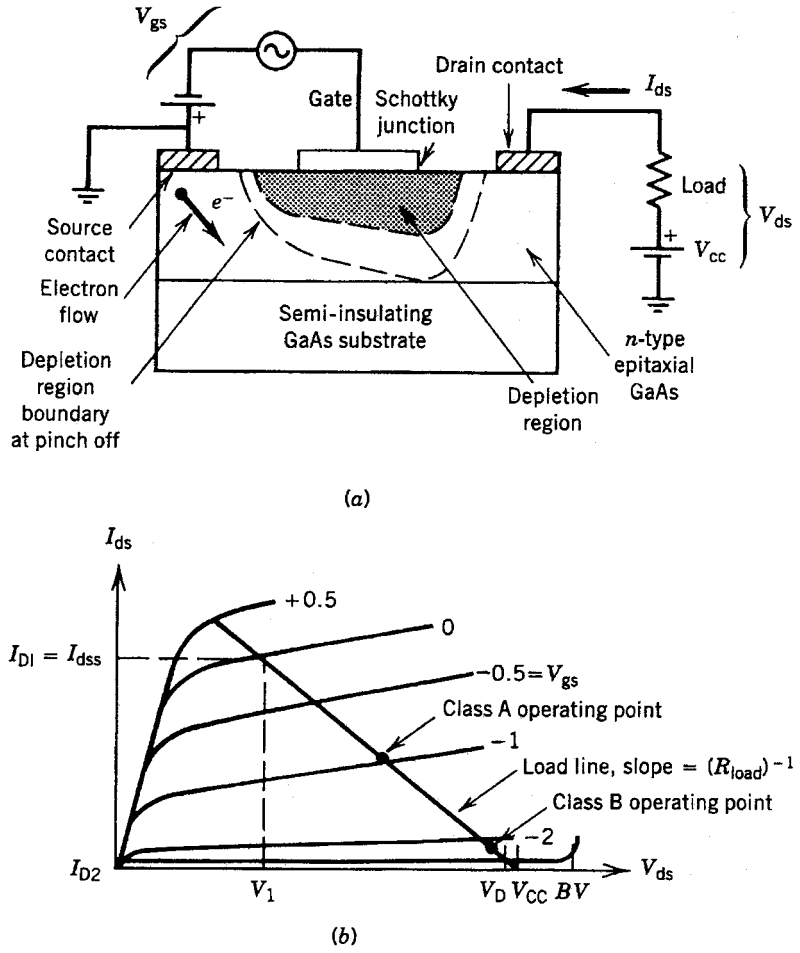

Figure 2-116 (a) Cross section and bias circuit and (b) dc *I–V* curve, including ac load line, for a MESFET.

The Modified Materka-Kacprzak Model Figure 2-119 shows the intrinsic model of the Materka FET. Table 2-18 lists its keywords.

Large-Signal Equations

Device Equations

V_{gsi} = Intrinsic gate–source voltage
V_{dsi} = Intrinsic drain–source voltage
V_1 = Voltage across C_{GS} and R_i
V_{gdi} = Intrinsic gate–drain voltage
$V_T = kT_J/q$ (thermal voltage)
k = Boltzmann's constant
q = Electron charge
T_J = Analysis temperature (kelvins)

Channel Current

$$I_{ds} = \mathrm{IDSS}\left(1 + \mathrm{SS}\,\frac{V_{dsi}}{\mathrm{IDSS}}\right)\left(1 - \frac{V_{gsi}(t-T)}{\mathrm{VP0} + \mathrm{GAMA}V_{dsi}}\right)^{(\mathrm{E}+\mathrm{KE}V_{gsi}(t-T))}$$

$$\times \tanh\left(\frac{\mathrm{SL}V_{dsi}}{\mathrm{IDSS}(1 - \mathrm{KG}V_{gsi}(t-T))}\right)$$

Diode

$$I_{gd} = I_{gdc} - \begin{cases} \mathrm{IB0}\,\exp[-\mathrm{AFAB}(V_{gdi} + \mathrm{VBC})] \\ \dfrac{\mathrm{GMAX}}{4}\,\{\tanh[\mathrm{K1D}(V_{gsi} - \mathrm{K2D})] - 1\}\,[V_{gdi} + \mathrm{VBC} - \sqrt{(V_{gdi} + \mathrm{VBC})^2 + \mathrm{K3D}}] \end{cases}$$

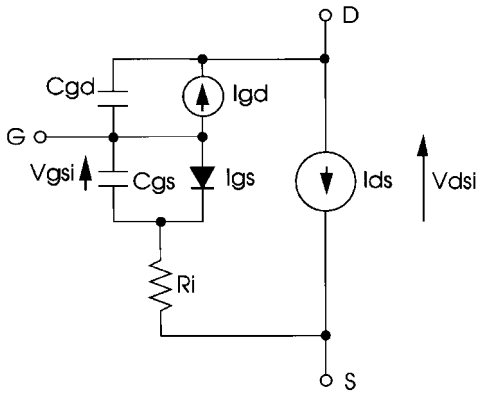

Figure 2-119 Intrinsic model of the modified Materka–Kacprzak MESFET.

where

$$I_{gdc} = \text{IG0}[\exp(\text{AFAB}V_{gdi}) - 1]$$

Channel Resistance

$$R_i = \begin{cases} \text{R10}(1 - \text{KR}V_{gsi}), & \text{KR}V_{gsi} < 1.0 \\ 0, & \text{KR}V_{gsi} \geq 1.0 \end{cases}$$

Capacitance Model

$$C_{gs} = \text{CGS0}\frac{F1F2}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F3$$

$$C_{gd} = \text{CGS0}\frac{F1F3}{\sqrt{1 - \dfrac{V_{\text{new}}}{\text{VBI}}}} + \text{CGD0}\ F2$$

where

$$F1 = \frac{1}{2}\left(1 + \frac{V_{\text{eff}} - V_T}{\sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}}\right)$$

$$F2 = \frac{1}{2}\left(1 + \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

Table 2-18 Materka–Kacprzak MESFET model keywords

Keyword	Description	Unit	Default
	Area, Noise, and Name		
AREA	Area multiplier		1.0
KFN	Flicker noise coefficient (Materka model only)[a]		0
AF	Flicker noise exponent		1.0
FCP	Flicker noise frequency shape factor		1.0
	Channel Current Model		
IDSS	Drain saturation current for $V_{GS} = 0$	ampere	0.1
VP0	Pinchoff voltage for $V_{DS} = 0$	volt	–2.0
GAMA	Voltage slope parameter of pinchoff voltage	/volt	0.0
E	Constant part of power-law parameter		2.0
KE	Dependence of power law on V_{GS}	/volt	0.0
SL	Slope of the $V_{GS} = 0$ drain characteristic in the linear region	ampere/volt	0.15
KG	Drain dependence on V_{GS} in the linear region	/volt	0.0
SS	Slope of the drain characteristic in the saturated region	ampere/volt	0.0
T	Channel transit-time delay	second	0.0
IG0	Diode saturation current	ampere	0
AFAG	Slope factor of forward diode current	/volt	38.696
IB0	Breakdown saturation current	ampere	0
AFAB	Slope factor of breakdown current	/volt	0
VBC	Breakdown voltage	volt	∞
GMAX	Breakdown conductance	ampere/volt	0
K1D	Fitting parameter	/volt	0
K2D	Fitting parameter	volt	0
K3D	Fitting parameter	$volt^2$	0
R10	Intrinsic channel resistance for $V_{GS} = 0$	ohm	0.0
KR	Slope factor of intrinsic channel resistance	/volt	0.0
	Materka Capacitance Model		
C10	Gate–source Schottky barrier capacitance for $V_{GS} = 0$	farad	0.0
K1	Slope parameter of gate–source capacitance	/volt	1.25
MGS	Gate–source grading coefficient		0.5
C1S	Constant parasitic component of gate–source capacitance	farad	0.0
CF0	Gate–drain feedback capacitance for $V_{GD} = 0$	farad	0.0
KF	Slope parameter of gate–drain feedback capacitance	/volt	1.25
MGD	Gate–drain grading coefficient		0.5
FCC	Forward-bias depletion capacitance coefficient		0.8

[a]The flicker noise parameter of the Materka model is KFN so as not to conflict with the KF parameter in the capacitance model.

$$F3 = \frac{1}{2}\left(1 - \frac{V_{gsi} - V_{gdi}}{\sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}}\right)$$

$$V_{\text{new}} = \begin{cases} A1, & A1 < \text{VMAX} \\ \text{VMAX}, & A1 \geq \text{VMAX} \end{cases}$$

$$A1 = \frac{1}{2}\left(V_{\text{eff}} + V_T + \sqrt{(V_{\text{eff}} - V_T)^2 + \delta^2}\right)$$

$$V_{\text{eff}} = \frac{1}{2}\left(V_{gsi} + V_{gdi} + \sqrt{(V_{gsi} - V_{gdi})^2 + (1/\text{ALFA})^2}\right)$$

$$V_T = \text{VP0} + \text{GAMA}\, V_{dsi}$$

$$\delta = 0.2$$

Some of the modifications to the Materka model have been done by Ansoft under various Department of Defense contracts, and by Raytheon and Texas Instruments under similar contracts, with Ansoft being a subcontractor.

The most relevant equation is really the channel current. Its derivatives are largely responsible for the accuracy of the intermodulation distortion, power-added efficiency, and, of course, its dc *I–V* curves.

Enhancement/Depletion FETs To make the designer's life more difficult, it turns out that there are two types of GaAsFETs:

1. *Depletion FETs (DFETs).* Most similar to the JFET; here V_G must be negative to control the device. They are the most commonly produced and are the FET type most referred to in this book.

On one hand:

- They require a negative gate voltage with respect to the source.
- Self-bias allows operation from a single supply voltage.

On the other hand:

- For low-voltage operation, a negative voltage generator may be required.
- Supply voltage must be doubled to accommodate full-swing operation.

2. *Enhancement FETs (EFETs).* Most similar to the MOSFET; here V_G must be positive to bring life to the device. Practically speaking, EFETs are used mostly in integrated circuits; they're typically not available in discrete, packaged form.

On one hand:

- They need only positive supply for biasing.
- They provide higher g_m/mA (for same device width)—5.1 mS versus 3.9 mS at 8 mA.

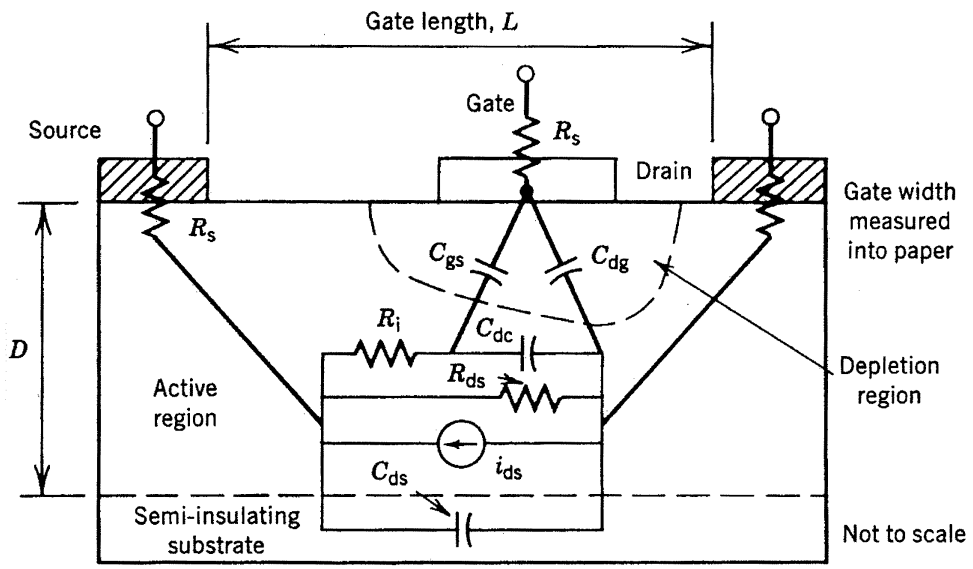

Figure 2-120 Location of lumped-element components for a MESFET.

- They are good for low-power LNAs, giving slightly better NF that DFETs, an NF of 1 dB at 1 GHz, and $I_{dd} < 10$ mA.

On the other hand:

- They have a very limited gate bias range (V_{GS} between 0.15 and 0.7 V).
- The gate conduction degrades NF and input impedance.
- The gate capacitance is higher than that of DFETs.
- The linearity is not as good as that of DFETs.

With today's technologies, all GaAs devices are *n*-channel; we have not seen any *p*-channels yet. More information about biasing will be given in the next chapter.

Figure 2-120 is a lumped-element, two-part equivalent circuit of a MESFET showing the location of lumped-element components.

2-3-8 Small-Signal GaAs MESFET Model

Figure 2-121 shows the applicable linear equivalent circuit for a MESFET and Table 2-19 lists its keywords. As with the MOS transistors, there is a gallium-arsenide dual-gate MOSFET available that is used mostly in special circuits, such as preamplifiers and mixers, whose IF has to be significantly higher than the flicker corner frequency, for example, higher than 200 MHz.

The following two datasheets* show typical GaAsFETs, both low-noise and medium-power. Such devices are, of course, available from a large variety of manufacturers—to name at least two, Siemens and the Nippon Electric Company, which is represented in the United States by California Eastern Laboratories.

CGSP	Gate-to-source package capacitance	farad	0.0
CDSP	Drain-to-source package capacitance	farad	0.0
CGDP	Gate-to-drain package capacitance	farad	0.0
ZGT	Gate transmission line impedance	ohm	50
ZDT	Drain transmission line impedance	ohm	50
ZST	Source transmission line impedance	ohm	50
LGT	Gate transmission line length for at $\varepsilon_r = 1$	meter	0.0
LDT	Drain transmission line length for at $\varepsilon_r = 1$	meter	0.0
LST	Source transmission line length for at $\varepsilon_r = 1$	meter	0.0
FC	Corner frequency of flicker (1/*f*) noise[b]	hertz	10 MHz
FCP	Shape factor of the 1/*f* noise response	1.0	
label	User-defined term that refers to temperature coefficient		

[a]The transconductance of this model may approximately be described by $g_m = G\dfrac{e^{-j\omega T}}{1 = j(f/F)}$ where $\omega = 2\pi f$ and f is frequency.

[b]The flicker noise frequency dependence is given by $1/(f/F_c)^{\mathrm{FCP}}$

SIEMENS AlGaAs / InGaAs HEMT CFY 77

Datasheet

Features

* Very low noise
* Very high gain
* For low noise front end amplifiers up to 20 GHz
* For DBS down converters

2-4 PARAMETER EXTRACTION OF ACTIVE DEVICES

2-4-1 Introduction

We have already seen that all linear models that are used on the market are really derived from large-signal models, and it is our point that the quality of the model depends mostly on the quality of the parameters used to describe the model.

As far as modeling is concerned there are two options. The first option is a physics-based model, which can be applied to items such as diodes and bipolar transistors, including its most advanced versions, such as HBTs, SiGe versions, and other future derivatives. The bipolar transistor is essentially a combination of two diodes whereby the base–emitter junction generates the electrons or holes (depending on how the reader is accustomed to viewing the process) and then transfers those to the collector. The emitter, as its name states, emits the charged particles and the collector collects them, minus some current losses, which are expressed in the current gain of the device. A current gain (β) of 100 means that the collector receives 1% less than the emitter emits.

The second modeling option involves the construction of an analytical mathematic equivalent for the device modeled. Earlier in this chapter, we went through a detailed physics-based derivation about the inner workings of these devices, explaining how, for a given dc bias point, one can simplify them to a small-signal equivalent circuit. This is possible since we assume that the RF current and voltages are less than 1% of the dc equivalent currents and voltages. Reducing a device's complex nonlinear equivalent circuit to a quasistatic linear equivalent circuit allows its manufacturer to generate and publish sets of *S* parameters for it. These parameters are bias, voltage, and temperature dependent. At higher frequencies, parasitics play an enormous role in determining a device's RF performance.

A device operating at signal levels that are more than 1% of its dc equivalent currents and voltages must be evaluated in terms of large-signal performance. Most of the large-signal-equivalent circuits for nonbipolar devices, such as FETs (MOS, silicon JFETs, and members of the GaAsFET family), are analytic approximations that essentially bear no physical insight into the inner workings of the transistors. This fact is particularly painful because to look at high-order intermodulation distortion, one needs to have third and fourth derivatives of mathematically continuous equations. The SPICE approach cannot easily be translated into modern harmonic-balance simulators because such cop-outs as IF THEN ELSE statements in programming provide everything else but a continuous model. In the case of our own work, we used complicated curve-fitting equations to obtain analytic equations and their derivatives to accurately provide a large-signal model that is valid over a wide range of dc and RF.

2-4-2 Typical SPICE Parameters

Since we are about to evaluate bipolar microwave transistors, junction FETs, MOSFETs (model level 3), and GaAsFETs, Tables 2-20, 2-21, 2-22, and 2-23 list typical parameters for the devices we have used. These parameters can be obtained by the Scout program with the appropriate measurements. The BSIM model for MOSFETs, applicable for submicron technology transistors, requires an enormous level of parameter extraction and has not fully been validated for the LDMOS-type transistors currently favored for RF and microwave applications.

Table 2-20 BFR193W BJT

IS = 2.738E – 16	BF = 125	NF = 0.95341

VAR = 3.8742	IKR = 0.037925	ISC = 3.7409E – 17
NC = 0.94371	RB = 15	IRB = 0.00091763
RBM = 1.8368	RE1 = 0.76534	RC2 = 0.11938
CJE = 1.1824E – 15	VJE = 0.70276	MJE = 0.48654
TF = 1.8828E – 11	XTF = 0.69477	VTF = 0.8
ITF = 0.00096893	PTF = 0	CJC = 9.3503E – 13
VJC = 1.1828	MJC = 0.30002	XCJC = 0.053563
TR = 1.0037E – 09	VJS = 0.75	MJS = 0
XTB = 0	EG = 1.11	XTI = 3
FCC = 0.72063	LB = 0.57E – 9	LC = 0.00E – 9
LE = 0.43E – 9	CBCP = 0.101E – 12	CCEP = 0.175E – 12
CBEP = 0.061E – 12	VCMX = 10 V	

The meaning and significance of the various parameters is best explored in a book on SPICE or semiconductor physics [22–24].

2-4-3 Noise Modeling

Diode Noise Model. The noise model for the diodes (Figure 2-122 and Table 2-24) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

The noise generators in the diode noise model are the series parasitic resistance, R_S, and the intrinsic junction. Figure 2-122 illustrates the intrinsic junction noise generator. Let Δf be the bandwidth (usually normalized to 1 Hz). The intrinsic noise generator has a mean-square value of

$$\langle i_{Dn}^2 \rangle = 2qI_D\,\Delta f + \mathrm{KF}\,\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\,\Delta f \tag{2-266}$$

Notes on the Diode Noise Model:

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.

[a]The currently implemented model for the junction FET is too primitive for serious RF applications. We have therefore taken the approach (liberty) of using the Materka parameter extraction approach for silicon junction FETs. This has resulted in unparalleled high-quality parameters; in particular, the knee voltage behavior has significantly improved, as well as the overall frequency response.

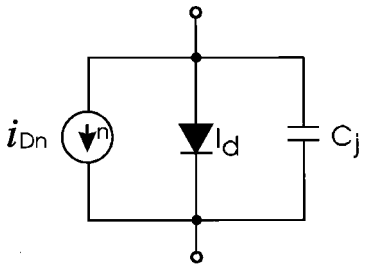

Figure 2-122 Equivalent noise circuit for a diode chip.

Table 2.24 Diode noise model keywords

Keyword	Description	Unit	Default
ID	Required bias current for the data point	Ampere	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner fequency	hertz	

2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.
3. The corner frequency noise model uses the system noise floor to internally compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the diode parameters and *kT*.
4. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

BJT Noise Model. The noise model for the Gummel–Poon BJT model consists of two contributions: shot noise and flicker noise. The shot noise is computed automatically and does not require any parameters. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications) (see Table 2-25).
2. Using bias-dependent flicker noise coefficients (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Bias-Independent Flicker Noise Coefficient*. This option involves the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying The Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with the bias point).

Notes on the BJT Noise Model:

Table 2.25 BJT noise model keywords

Keyword	Description	Unit	Default
IB	Required base bias current for the data point	ampere	
VCE	Required collector–emitter voltage for the data point	volt	
VBS	Base–substrate voltage required for LPNP type when four nodes are used	volt	
VCS	Collector–substrate voltage required for NPN or PNP type when four nodes are used	volt	
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as bipolar noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model of course considers the actual operating temperature, which must be supplied to the model.

Figure 2-123 shows the BJT noise model. Let Δf be the bandwidth (usually normalized to a 1-Hz bandwidth). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{bn}^2 \rangle = 2qI_B \,\Delta f + \text{KF}\,\frac{I_B^{\text{AF}}}{f^{\text{FCP}}}\,\Delta f \tag{2-267}$$

$$\langle i_{cn}^2 \rangle = 2qI_C \Delta f \tag{2-268}$$

$$\langle i_{R_{bb}}^2 \rangle = \frac{4kT}{R_{bb}}\,\Delta f \tag{2-269}$$

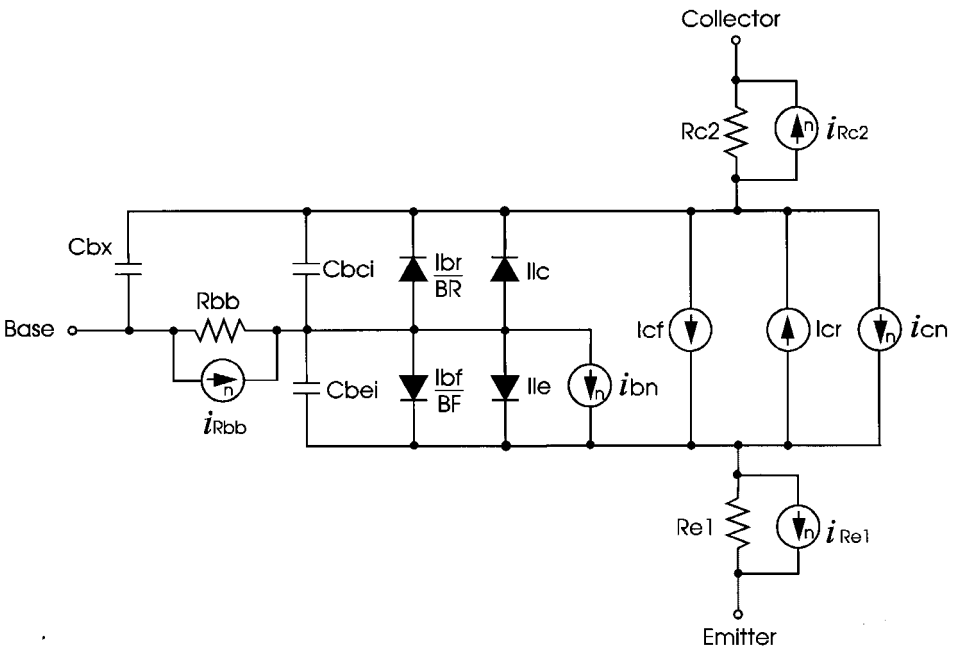

Figure 2-123 BJT noise model (not showing extrinsic parasitics). Current sources with *n* are noise sources.

$$\langle i_{R_{e1}}^2 \rangle = \frac{4kT}{R_{e1}} \Delta f \tag{2-270}$$

$$\langle i_{R_{c2}}^2 \rangle = \frac{4kT}{R_{c2}} \Delta f \tag{2-271}$$

$$I_B = \frac{I_{bf}}{BF} + I_{le} \tag{2-272}$$

$$I_C = I_{cf} - I_{cr} \tag{2-273}$$

JFET and MESFET Noise Models. The noise model for the FETs consists of two contributions: the shot noise and the flicker noise. There are two options to specify noise in the FET model:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (Table 2-26) to determine the flicker noise (this option is usually sufficient for most applications). The shot noise will be automatically computed using the SPICE equation.
2. Using bias-dependent flicker noise coefficients through a reference in the DATA block (specifying KF and AF at multiple bias points) and specifying the four noise parameters [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at multiple bias points.

Option 1: *Specifying the Enhanced SPICE Noise Model.* Option 1 is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model. The drain noise model has the form

$$\langle |I_{dn}|^2 \rangle = 4K_B T \frac{2g_m}{3} \Delta f + \text{KF} \frac{|I_D|^{\text{AF}}}{f^{\text{FCP}}} \Delta f \tag{2-274}$$

Table 2.26 FET noise model keywords

Keyword	Description	Unit	Default
FN	Noise data measurement frequency	hertz	1.0 GHz
VGS	Required gate–source voltage for the data point	volt	
VDS	Required drain–source voltage for the data point	volt	
FMIN	Required minimum noise figure in dB at FN		
MGO	Required magnitude of optimum noise reflection coefficient at FN		
PGO	Required phase of optimum noise reflection coefficient at FN		
RN	Required normalized noise resistance at FN		
KF	Flicker noise coefficient		0.0
AF	Bias exponent of the flicker noise model		1.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

where the shot noise is derived from g_m and the flicker noise is proportional to KF and the drain channel current, I_D, and inversely proportional to frequency. The AF and FCP parameters tailor the flicker noise dependence on bias and frequency, respectively.

1. Shot noise is always present unless it is turned off. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows the specification of the complex bias-dependent nature of the shot noise and flicker noise. At high frequencies, the equivalent noise sources are correlated (the SPICE noise model does not account for this correlation). The complete evaluation of the shot noise sources can be determined from the four noise parameters. Since these are functions of bias, they can be specified over the (V_{GS}, V_{DS}) bias plane.

Additionally, a bias-dependent flicker noise coefficient (i.e., KF and AF vary with current) can be specified.

The MESFET noise model uses the four measured noise data [$F_{\min}$, Γ_{opt} (magnitude and phase), and R_n] at one frequency and multiple arbitrary bias points. The program uses these data and the FET model parameters to de-embed the noise data to an intrinsic noise model. The intrinsic model is accurate at all frequencies and, therefore, can predict the noise performance at all frequencies given data at just one frequency point. Built-in bias-dependent characteristics are used if multi-bias noise data are not provided.

Notes on the FET Noise Model

1. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
2. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Noise in a MESFET is produced by sources intrinsic to the device. The same approach, but with different flicker corner frequencies, is highly applicable to JFETs and MOSFETs. For more detail as to simulation, see the Element library book for the active-device portion of Ansoft's Serenade Design Environment product. The equivalent noisy circuit of an intrinsic FET is represented in Figure 2-124.

The intrinsic FET is internally represented as a noiseless nonlinear two-port with one equivalent noise current connected across the gate–source terminal, and one across the drain–source terminal. The correlations of the gate and drain noise current sources are

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \frac{\omega^2 C_{gs}^2}{g_m} R \tag{2-275}$$

$$\langle |I_{gn}|^2 \rangle = 4K_B T \, \Delta f \, g_m P \tag{2-276}$$

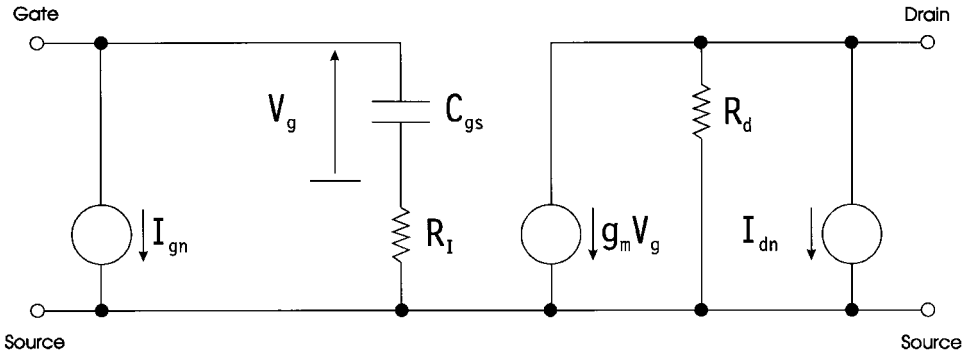

Figure 2-124 Equivalent noise circuit of an intrinsic FET device.

$$\langle I_{gn} I_{dn}^{*} \rangle = 4K_B T\, \Delta f\, j\omega C_{gs} \sqrt{PR}\, C \tag{2-277}$$

The correlation matrix of the noise current sources is

$$C_{dc}(\omega) = \frac{2}{\pi} K_B T\, d\omega \begin{bmatrix} \dfrac{\omega^2 C_{gs}^2}{g_m} R & -j\omega C_{gs}\sqrt{PR}\, C \\ j\omega C_{gs}\sqrt{PR}\, C & g_m P \end{bmatrix} \tag{2-278}$$

The gate and drain noise parameters R and P and the correlation coefficient C are related to the physical noise sources acting in the channel and are functions of the device structure and bias noise parameters. By defining measured noise parameters, $F_{\min}$, R_n, and Γ_{opt}, and using a noise de-embedding procedure, the parameters R, P, and C and the intrinsic noise correlation matrix of a FET device as functions of device bias are determined by the program.

In addition to the noise sources shown above, the flicker (1/f) noise can also be modeled by means of a noise current source connected in parallel with the intrinsic drain port. The flicker noise component in a narrow band, Δf, is expressed in the form

$$\langle |I_f|^2 \rangle = \mathrm{Q}\, \Delta f \frac{|I_D|^{\mathrm{AF}}}{f^{\mathrm{FCP}}} \tag{2-279}$$

where I_D is the instantaneous value of the channel current, and Q, AF, and FCP are empirical parameters. In most practical cases, AF and FCP are directly obtained from measurements (typically, AF = 2 and FCP = 1), while Q is not. In Ansoft's Serenade Design Environment, Q is either provided directly using KF or is computed by providing the flicker corner frequency (FC). FC is the frequency at which the flicker noise equals the shot/diffusion noise. The corner frequency is defined by the equation

$$\mathrm{Q} \frac{|I_D|^{\mathrm{AF}}}{f_{\mathrm{C}}^{\mathrm{FCP}}} = g_m P \tag{2-280}$$

Given the corner frequency FC and the measurement bias point V_{gs} and V_{ds}, the program automatically computes I_D, g_m, and P, and finally Q.

More information on FET noise modeling can be found in the literature [25–31].

MOSFET Noise Model. The MOSFET noise model (Figure 2-125 and Table 2-27) consists of two contributions: the shot noise and the flicker noise. The shot noise is computed automatically and does not require any parameters. It can be turned off by specifying SN = 0. The flicker noise can be specified in two ways:

1. Using the enhanced SPICE noise model by specifying KF, AF, and FCP in the model parameter list (this option is usually sufficient for most applications).

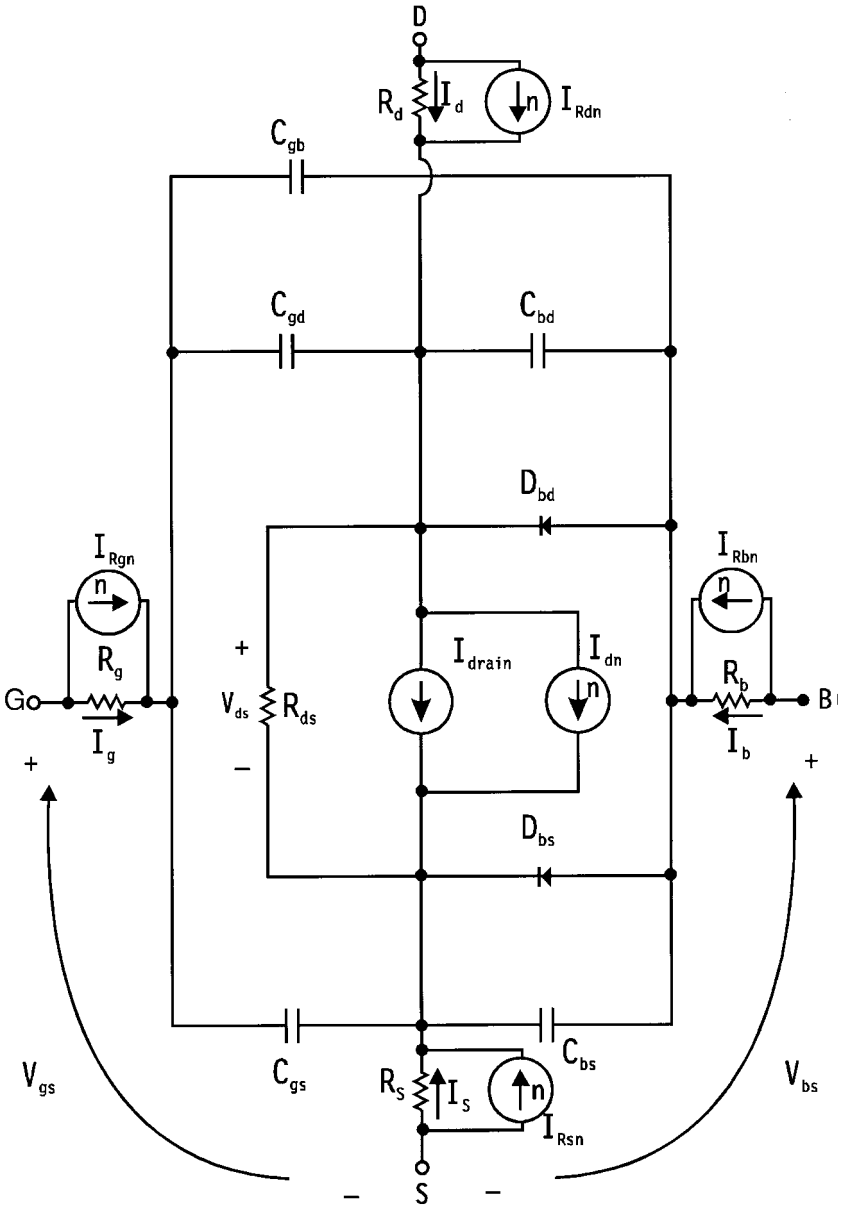

Figure 2-125 Equivalent noise circuit of an intrinsic MOSFET device.

Table 2.27 MOSFET noise model keywords

Keyword	Description	Unit	Default
VGS	Required gate–source bias for the data point	volt	
VDS	Required drain–source for the data point	volt	
VBS	Required drain–bulk for the data point	volt	
KF	Flicker noise coefficient		1.0E–13
AFT	Bias exponent of the flicker noise model		2.0
FCP	Frequency exponent of the flicker noise model		1.0
FC	Flicker noise corner frequency	hertz	

2. Using bias-dependent flicker noise coefficients through a reference (specifying KF and AF at multiple bias points).

Option 1: *Specifying the Enhanced SPICE Noise Model.* This option is the straightforward specification of KF, AF, and FCP that are constant with bias, as in the SPICE noise model (the flicker noise is considered bias dependent).

1. Shot noise is always present unless the SN parameter is set to zero. Turning noise off is useful for comparing the total circuit noise that is generated by the nonlinear devices and that generated by the linear circuit components.
2. If the value of KF is specified as zero, then the flicker noise will not be contributed by the device and only shot noise is considered in the intrinsic model.

Option 2: *Specifying the Bias-Dependent Flicker Noise Coefficient or Flicker Corner Frequency.* This option allows a bias-dependent flicker noise coefficient (i.e., KF and AF vary with drain current). The MOSFET noise model data are given and referenced by a model parameter.

Notes on the MOSFET Noise Model

1. KF, AF, and FC can be specified as bias dependent. If only one set of noise data is specified, the corresponding bias point is not meaningful because all parameters are considered constant over all bias values. However, the bias point is needed for the program to identify the data as MOSFET noise data.
2. The corner frequency noise model option uses the system noise floor to compute the flicker noise coefficient, KF. The system noise floor is computed by the program using the transistor parameters and kT.
3. This noise model, of course, considers the actual operating temperature, which must be supplied to the model.

Let Δf be the bandwidth (normalized to 1 Hz). The noise generators introduced in the intrinsic device are shown below and have mean-square values of

$$\langle i_{dn}^2 \rangle = \frac{8kTg_m}{3}\Delta f + \mathrm{KF}\frac{I_D^{\mathrm{AF}}}{f^{\mathrm{FCP}}}\Delta f$$

$$\langle i_{Rgn}^2 \rangle = 4\frac{kT}{R_g}\Delta f$$

$$\langle i_{Rdn}^2 \rangle = 4\frac{kT}{R_d}\Delta f$$

$$\langle i_{Rsn}^2 \rangle = 4\frac{kT}{R_s}\Delta f$$

$$\langle i_{Rbn}^2 \rangle = 4\frac{kT}{R_b}\Delta f$$

We include this MOSFET noise model (used for quite awhile) for completeness. At the moment, we do not know which MOSFET noise model the industry will settle on in the future.

Modern CAD tools, such as Ansoft's Serenade product, use these models to generate quite accurate noise data based on a good linear equivalent model. Internally Serenade uses the noise-correlation-matrix method (first introduced by Russer). The same noise-correlation techniques apply to BJTs, all FETs except MOS, and HBTs (such as SiGe devices).

2-4-4 Scalable Device Models

Since diodes and transistors are scalable, here are guidelines for how to scale them:

Microwave Diode

$$I_D = Area \times I_D$$
$$C_j = Area \times C_j$$
$$R_D = R_D/\text{Area}$$

PIN Diode

$$I_D = \text{Area} \times I_D$$
$$C_j = \text{Area} \times C_j$$
$$R_S = R_S/\text{Area}$$
$$R_{\max} = R_{\max}/\text{Area}$$

Bipolar

$$I_{bf} = \text{Area} \times I_{bf} \qquad I_{br} = \text{Area} \times I_{br}$$
$$I_{le} = \text{Area} \times I_{le} \qquad I_{lc} = \text{Area} \times I_{lc}$$
$$I_{cf} = \text{Area} \times I_{cf} \qquad I_{cr} = \text{Area} \times I_{cr}$$
$$C_{bc} = \text{Area} \times C_{bc} \qquad C_{be} = \text{Area} \times C_{be}$$
$$C_{bx} = \text{Area} \times C_{bx} \qquad R_{bb} = R_{bb}/\text{Area}$$
$$\text{RB2} = \text{RB2/Area} \qquad \text{RC2} = \text{RC2/Area}$$
$$\text{RE1} = \text{RE1/Area} \qquad I_{jss} = I_{jss} \times \text{Area}$$
$$C_{jss} = C_{jss} \times \text{Area}$$

Materka FET

$$\begin{aligned}
\text{IGSS} &= \text{IGSS} \times \text{Area} \\
\text{CGS0} &= \text{CGS0} \times \text{Area} \\
\text{CGS1} &= \text{CGS1} \times \text{Area} \\
\text{CDVC} &= \text{CDVC} \times \text{Area} \\
\text{CDVS} &= \text{CDVS} \times \text{Area} \\
R_G &= R_G \times \text{Area}/(\text{Number of fingers} \times 2) \\
R_D &= R_D/\text{Area} \\
R_S &= R_S/\text{Area}
\end{aligned}$$

Generating a Databank for Parameter Extraction. Given the fact that one can measure with an automated system (Rohde & Schwarz, Hewlett-Packard) the bias-dependent *S* parameters of any active device, bipolar and FET, and furthermore, that Hewlett-Packard makes a computer-controllable dc *I–V* curve tracer, we can generate a huge databank that allows us to have corresponding values for both RF and dc operating points. To validate this, one needs to run a large-signal simulator, such as Ansoft's Serenade Design Environment, or its equivalent from other manufacturers, enter the large-signal parameters, and generate a set of *S*-parameters that correspond to the dc values for which we have measurements. The agreement between measured and predicted points for both RF and dc values is a good measure to evaluate the accuracy of the parameter extraction and the simulator's performance. We cannot stress often enough, however, the fact that while most simulator models are quite good, the weakest point of the link is the parameter extraction program.

Currently, the best parameter extraction for bipolar transistors and FETs, excluding the BSIM model, is implemented in the Scout program by Ansoft, based on modified techniques found in the literature. These techniques are based on the fact that present-day nonlinear modeling of microwave devices, especially FETs, is not exactly adequate to describe all effects found within these devices. In the case of FETs, the most troublesome parameter is R_{DS}, which is really more bias dependent than practically all existing models take into consideration. Techniques used in published extraction methods extract nonlinear models independently for each section of a device model, and then assume that the proper response will be generated when all parts are put together. For instance, many extraction techniques independently fit the *I–V* data of the section describing the *I–V* curves and then fit the *C–V* data to the equivalent small-signal models. This results in an approximation to the bias-dependent response of the complete model.

In the technique used in the Scout program, model parameters are extracted simultaneously so the effects between model sections are accounted for and the device is treated as a whole. The most critical area happens to be in the linear region, typically around the pinchoff area, and for very small supply voltages. The Scout techniques use measured data taken at a wide variety of bias ranges and frequencies to define the model response. The possible solution region for the complete model becomes well identified and uniqueness of solution is vastly improved. The Scout program is interactive in nature and displays simultaneously measured versus predicted data. This allows for fine-tuning of the parameters.

Over the years, the industry has adapted a large number of models. Those supported by the Scout parameter extraction program include:

- *npn* Gummel–Poon BJT
- *pnp* Gummel–Poon BJT

- *npn* heterojunction BJT
- *pnp* heterojunction BJT
- General-purpose *n*-channel JFET
- General-purpose *p*-channel JFET
- Chalmers (Angelov) MESFET/HEMT
- Curtice–Ettenberg cubic MESFET/HEMT
- Curtice quadratic MESFET/HEMT
- IAF (Berroth) MESFET/HEMT
- Modified Materka–Kacprzak MESFET/HEMT
- Raytheon (Statz) MESFET/HEMT
- TriQuint (TOM-1 and TOM-2) MESFET/HEMT
- Ansoft physics-based MESFET

The Ansoft physics-based MESFET model is unique and politically sensitive because its users are essentially required to enter all device fabrication parameters to get the appropriate answer, and most, if not all, companies will stay away from handing out such company proprietary recipes. The validation of this model was done using manufacturing data for transistors that were developed under government contract and therefore accessible for the team members. Compact Software/Ansoft over the last ten years has been involved in a large number of government-funded research and development programs, and practically all modern modeling implementations and their validation were done in conjunction with the largest semiconductor manufacturers.

As far as further validation is concerned, besides our looking at the matching of dc *I–V* curves and *S* parameters, important parameters such as 1-dB compression point, power-added efficiency, and harmonic content are important criteria to evaluate the quality of such an undertaking. As far as hardware is concerned, one needs to have a network analyzer, such as the HP8510 or its equivalent. Its selection is determined by the highest cutoff frequency where measurements are necessary. A dc feed capability, up to several amperes, through the measuring ports, and appropriate power supplies are essential, as is a dc *I–V* curve tracer (HP4145). The built-in various optimizers of the program establish the best possible match between the selected parameters and the measured results.

The area of proper modeling has always been fascinating because the active-device model can make or break first-pass success. Figure 2-126 shows the doubler gain comparison of a model supplied by NEC (the device manufacturer, parameter extraction done with Scout, and parameter extraction supplied from the *Microwave Engineering Europe* (*MEE*) magazine in its CAD review of May 1994). It is somewhat unclear where the *MEE* model came from. The actual task given by *MEE* was to simulate a frequency doubler against measured data. This type of simulation required two areas of high precision, one being the model and the other being the electromagnetic modeling of the discontinuities of the circuit—in this case, a stub element. The circuit itself was very simple. The manufacturer-supplied data gave the poorest results (we believe the parameter extraction came from a third party not quite up to speed in this area). The results that came from the Scout parameter extraction and the third one that *MEE* supplied were fairly close, yet the Scout solution, including the electromagnetic simulation part, gave the best answer. More simulators have since appeared on the market, and it would be interesting to revisit this topic. Figure 2-127 shows a physical layout of the doubler circuit.

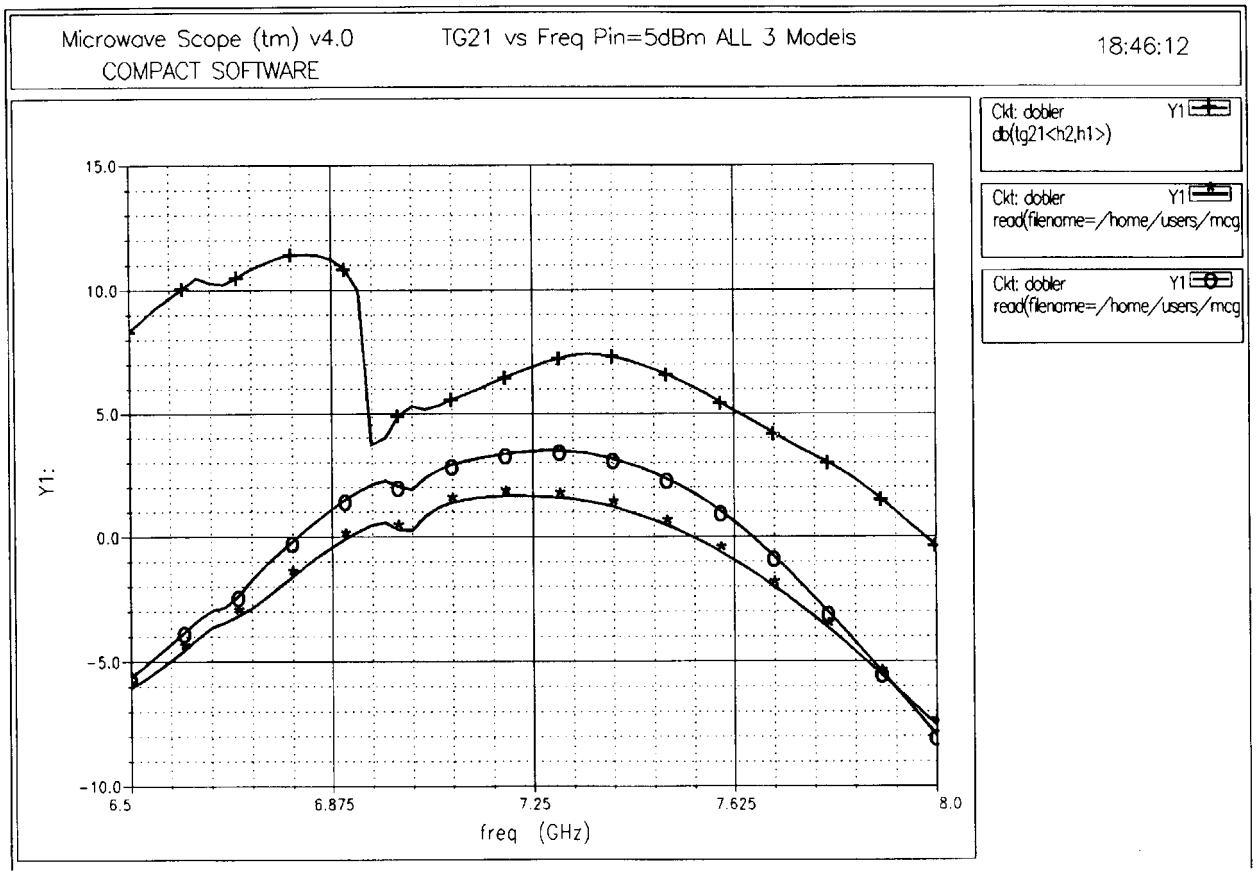

Figure 2-126 Gain comparison of a MESFET doubler based on the three device models used: NEC (+), Ansoft (O), and *Microwave Engineering Europe* (*).

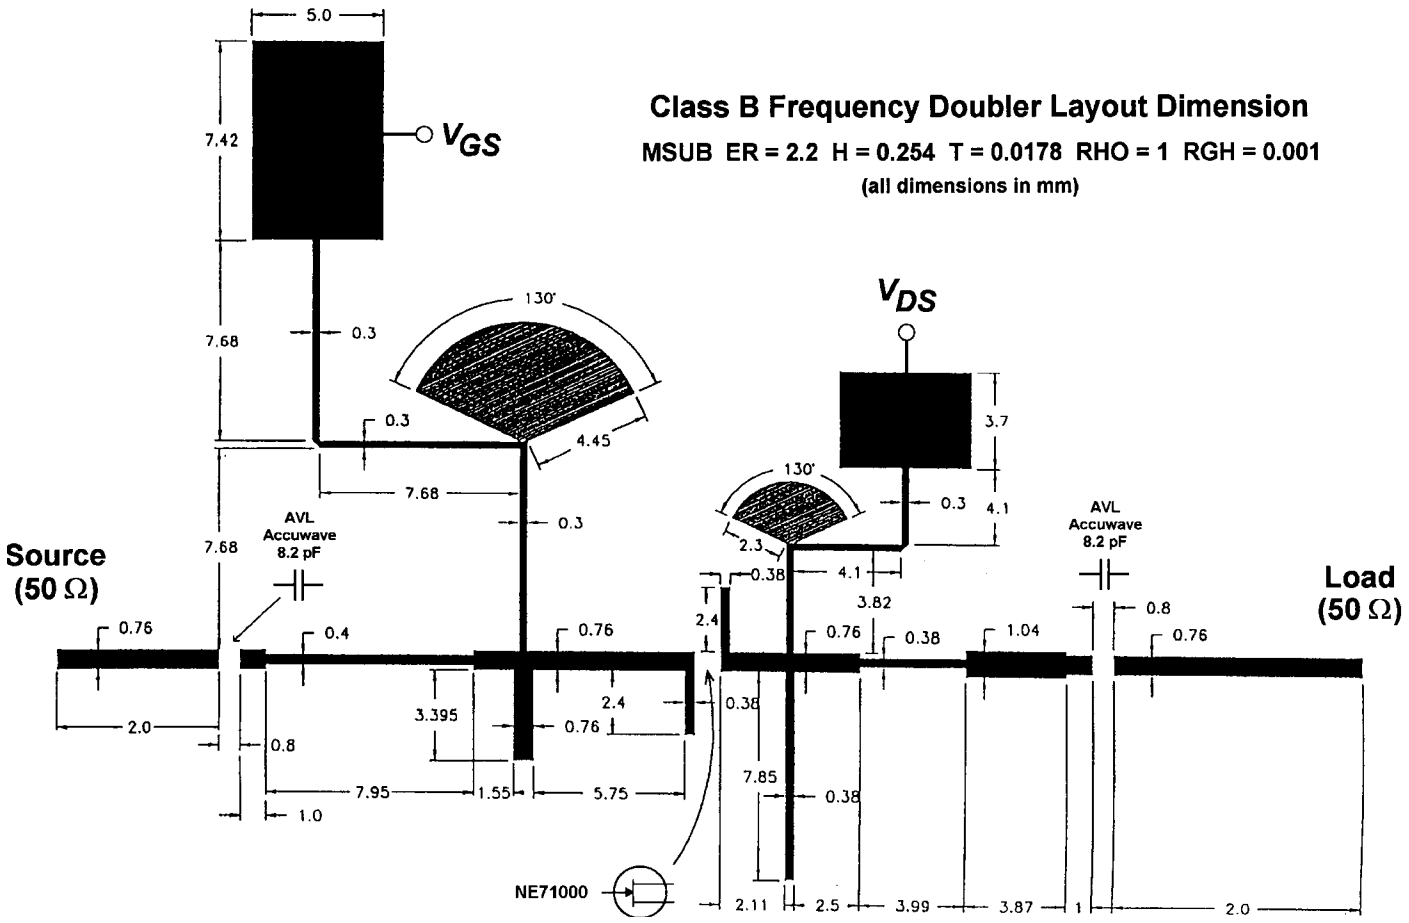

Figure 2-127 Layout of the MESFET doubler.

Test Setup. The measuring equipment required for the actual extraction includes:

- Semiconductor parameter analyzer (HP4145)
- Vector network analyzer (ZVR, HP8510, W360)
- Bias supplies and meters
- Power RF source, power meters, spectrum analyzer, and so on

The required software tools include:

- GPIB controller: Compact NETCOM (network analyzer control program)
- Parameter extraction performed by Scout
- Small-signal and harmonic-balance validation: Serenade nonlinear analysis (Microwave Harmonica) or its equivalent

After we have assembled all these tools, the device extraction process can begin. It will follow the flow as shown in Figure 2-128. Depending on the numbers for the dc/ac measurement, this process can take up to two hours. The Scout program, with its built-in optimizer, can take another two hours. It is therefore reasonable to assume a thorough parameter extraction of a device will take about one day.

Parameter Extraction. As we have outlined, the parameter extraction program Scout, which is optimized for high-frequency and millimeter-wave application, is a Windows-based parameter extraction and optimization program. It requires a network-communication program to acquire dc and *S* parameter measurement data. It supports interactive device fitting and optimization and supports the various models listed earlier. For ease of use, it has an attractive graphical user interface with multiple windows, as can be seen from Figure 2-129. Hewlett-Packard offers more general RF parameter extraction programs, but we did not have access to those. We also expect that some other companies will develop similar tools. An interesting program named HarPE, developed by Professor John Bandler in Canada, may have been withdrawn from the market after his company merger with HP. The program was acclaimed to provide quite good results using measured harmonics. One of the unfortunate deficiencies of most BJT parameter extraction programs known to us is the fact that (as one

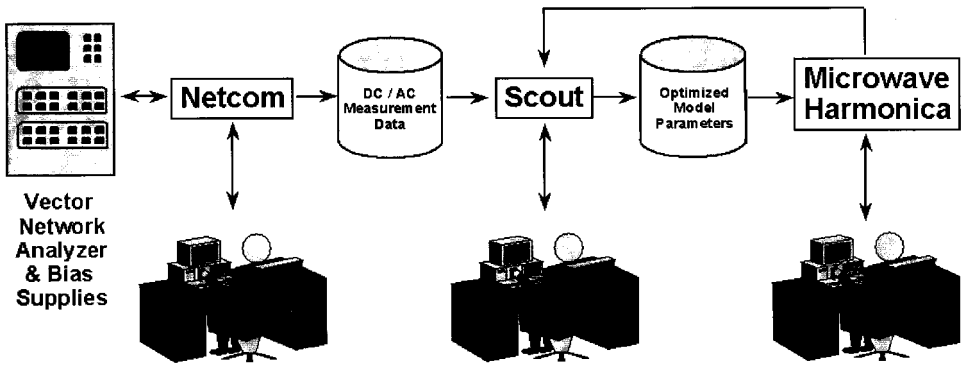

Figure 2-128 Flowchart of the parameter extraction process.

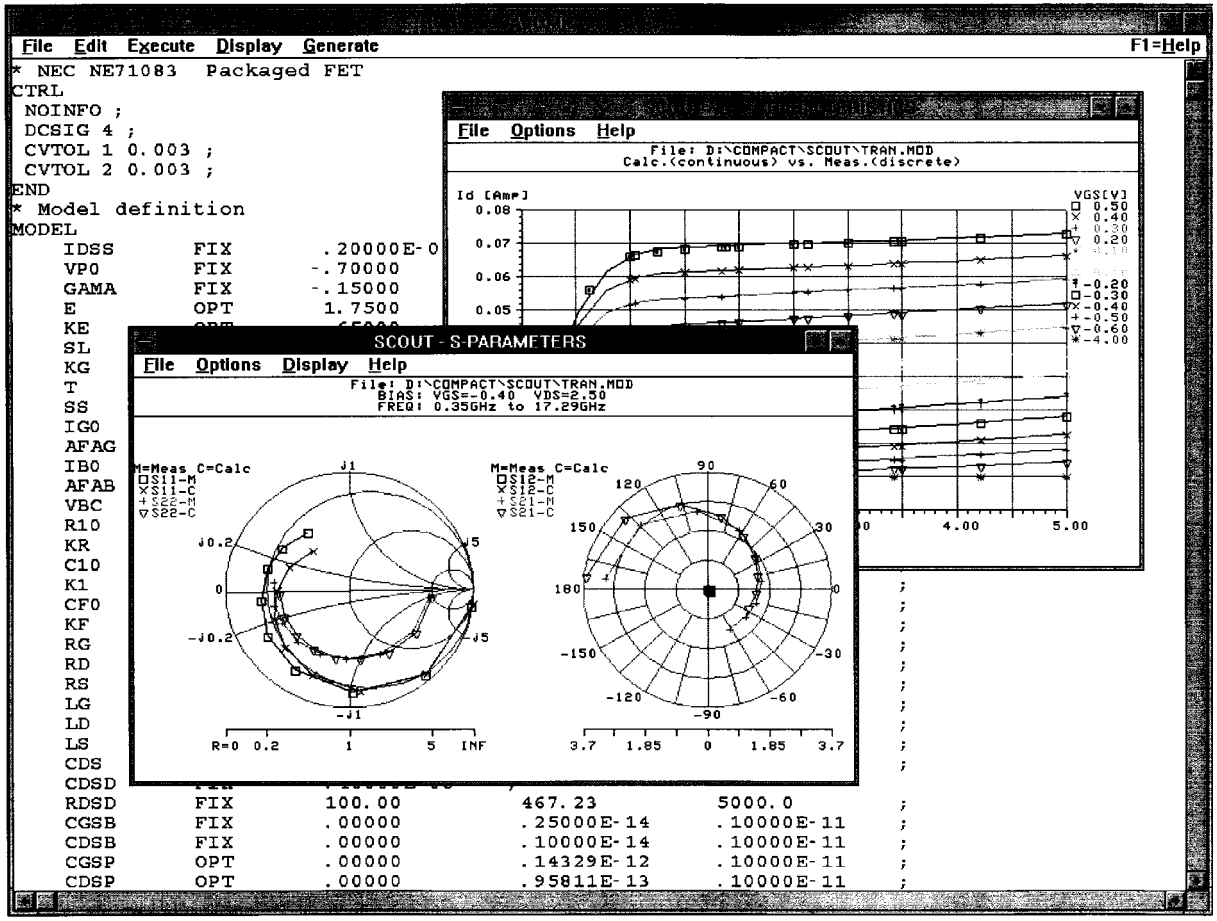

Figure 2-129 The Scout user interface.

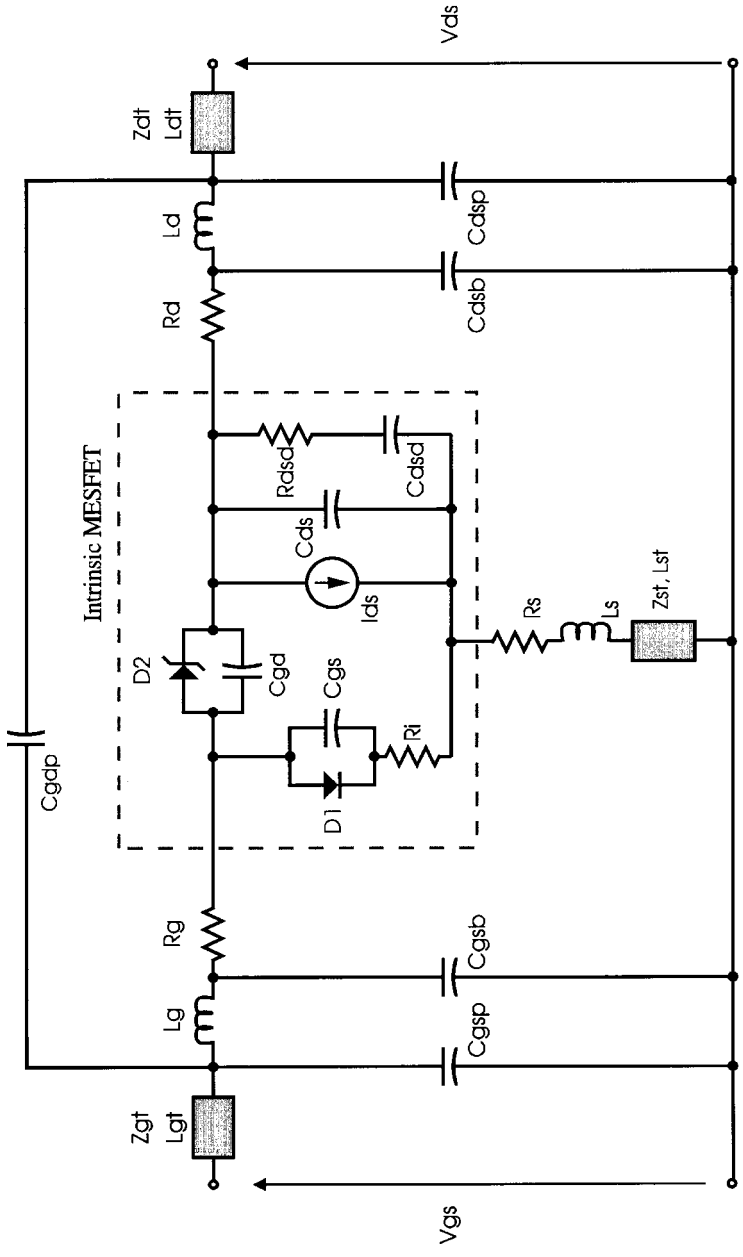

Figure 2-130 Intrinsic model and complete chip/package model.

example) the sensitivity to determine the actual base-spreading resistor for bipolar transistors is poor. The only useful workaround is considering the noise figure of the device, given the fact that the midrange noise factor of any bipolar transistor can be calculated from

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-281)

By solving the equation for R'_{bb}, since we know that R_g, the generator impedance, is 50 Ω, and the emitter diffusion resistance (26 mV/I_C) can be determined from the bias point, we can already eliminate the need to extract R'_{bb} from the HP test equipment. By using HP's program, errors of a factor up to 10 are not uncommon because of the low sensitivity for this parameter. Another headache in the case of the BJT is the determination of the excess phase (PTF) and forward and reverse transit time (TF and TR, respectively). The lack of quality modeling can best be found by examining the measured versus predicted values of S_{22}. Again, practically all the parameter extraction programs we have seen so far suffer from this deficiency.

MESFETs. In the case of a member of the MESFET family, a model as shown in Figure 2-130 is used. It consists of an intrinsic model and a complete chip/package parasitic model. In the case of the MESFET, to obtain first-class results, the following measurements are necessary:

- Dc *I*–*V* measurements
- Dc diode measurements
- Cold-FET and forward-biased-gate *S* parameters
- *S*-parameter measurements over bias
- Harmonic power measurements
- *Z*-Parameter Equations for Figure 2-131

In order to simplify the modeling, it is useful to do cold-FET [Figure 2-131 and Eqs. (2-282), (2-283), and (2-284)] and pinched-FET [Figure 2-132 and Eqs. (2-285), (2-286), and (2-287)] measurements to derive some of the intrinsic or extrinsic values.

$$Z_{11} = R_s + R_g + R_{gs} + \alpha_g R_{ch} + j\omega(L_g + L_s) \tag{2-282}$$

$$Z_{12} = Z_{21} = R_s + \alpha R_{ch} + j\omega L_s \tag{2-283}$$

$$Z_{22} = R_s + R_d + 2\alpha R_{ch} + j\omega(L_s + L_d) \tag{2-284}$$

Capacitance Equations for Figure 2-132

$$C_b = -\frac{\text{Im}(Y_{12})}{\omega} \tag{2-285}$$

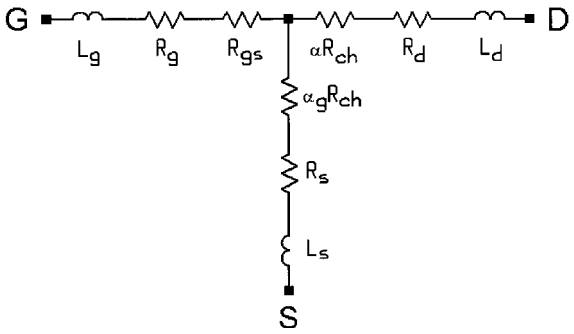

Figure 2-131 Forward-biased gate FET model for cold-FET (V_{DS} = 0, V_{GS} 0) measurements. This approach allows direct extraction of parasitic resistances and inductances.

$$C_{pg} = \frac{\mathrm{Im}(Y_{11})}{\omega} - 2C_b \tag{2-286}$$

$$C_{pd} + C_{ds} = \frac{\mathrm{Im}(Y_{22})}{\omega} - C_b \tag{2-287}$$

For the highest accuracy, the following extraction strategies are recommended:

- Pre-extraction using basic dc and *S* parameters—for example, C_{GS} from S_{11}
- Six extraction steps to determine parameters:
  Basic dc model
  Advanced dc model
  Basic ac model
  Advanced ac model
  Package determination
  Diode characterization
- Large-signal validation
  Power compression and bias shift
  Harmonic power comparison
  Intermodulation characterization

As an example, we are going to use the popular and well-characterized NE71000, which is not a particularly modern device, but has been used for various research projects. Figure

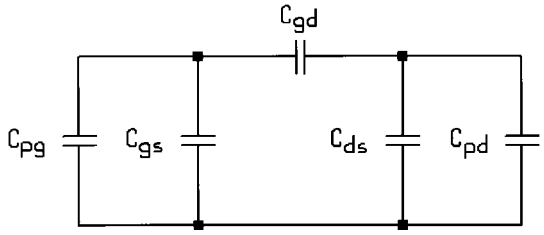

Figure 2-132 Pinched-FET (V_{DS} = 0, V_{GS} *VP*) model. This approach allows direct extraction of parasitic gate and drain capacitances.

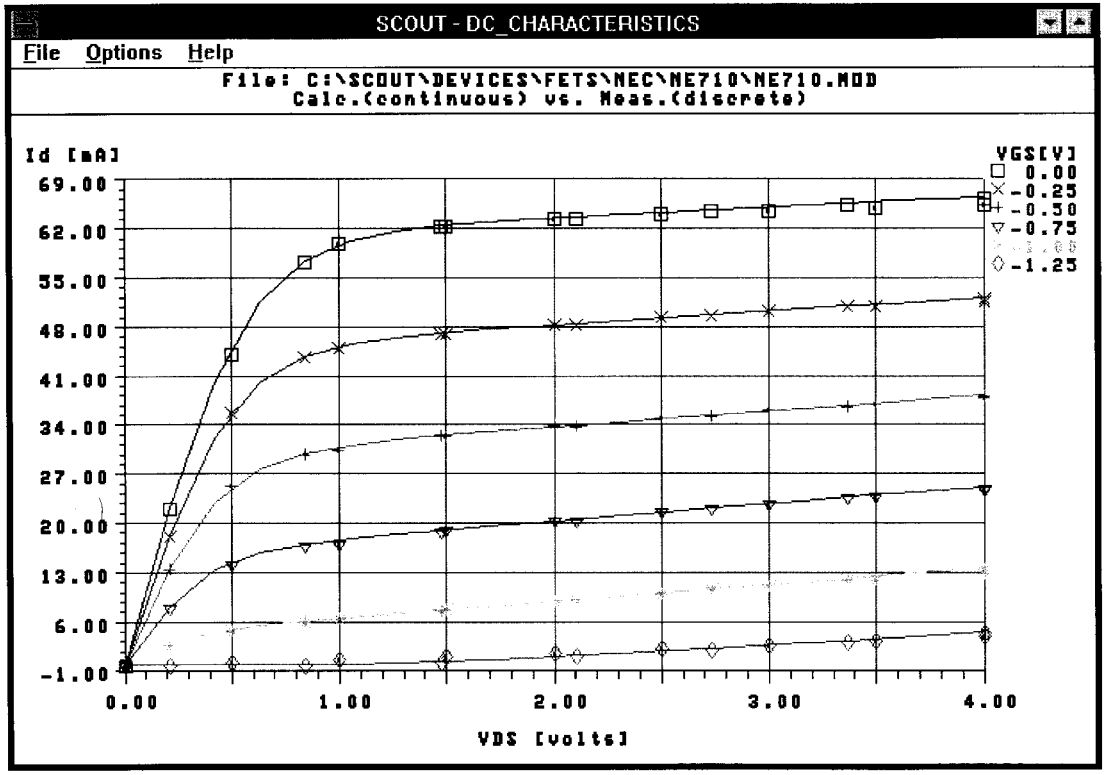

Figure 2-133 Measured NE71000 dc *I–V* curves versus those simulated using the Ansoft Materka model.

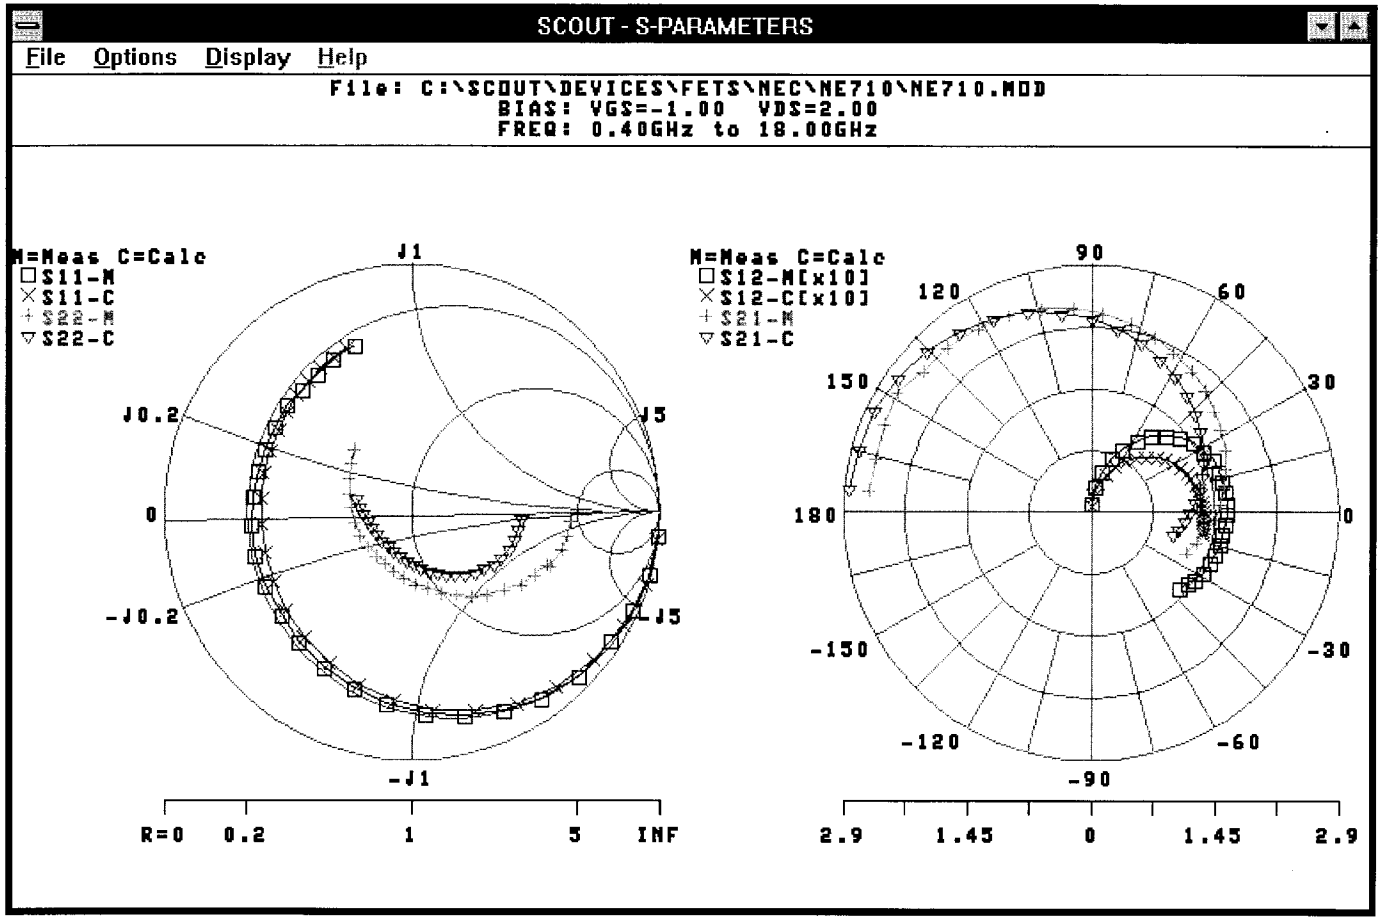

Figure 2-134 Measured versus calculated NE71000 *S* parameters for $V_{GS} = -1.00$ and $V_{DS} = 2.00$.

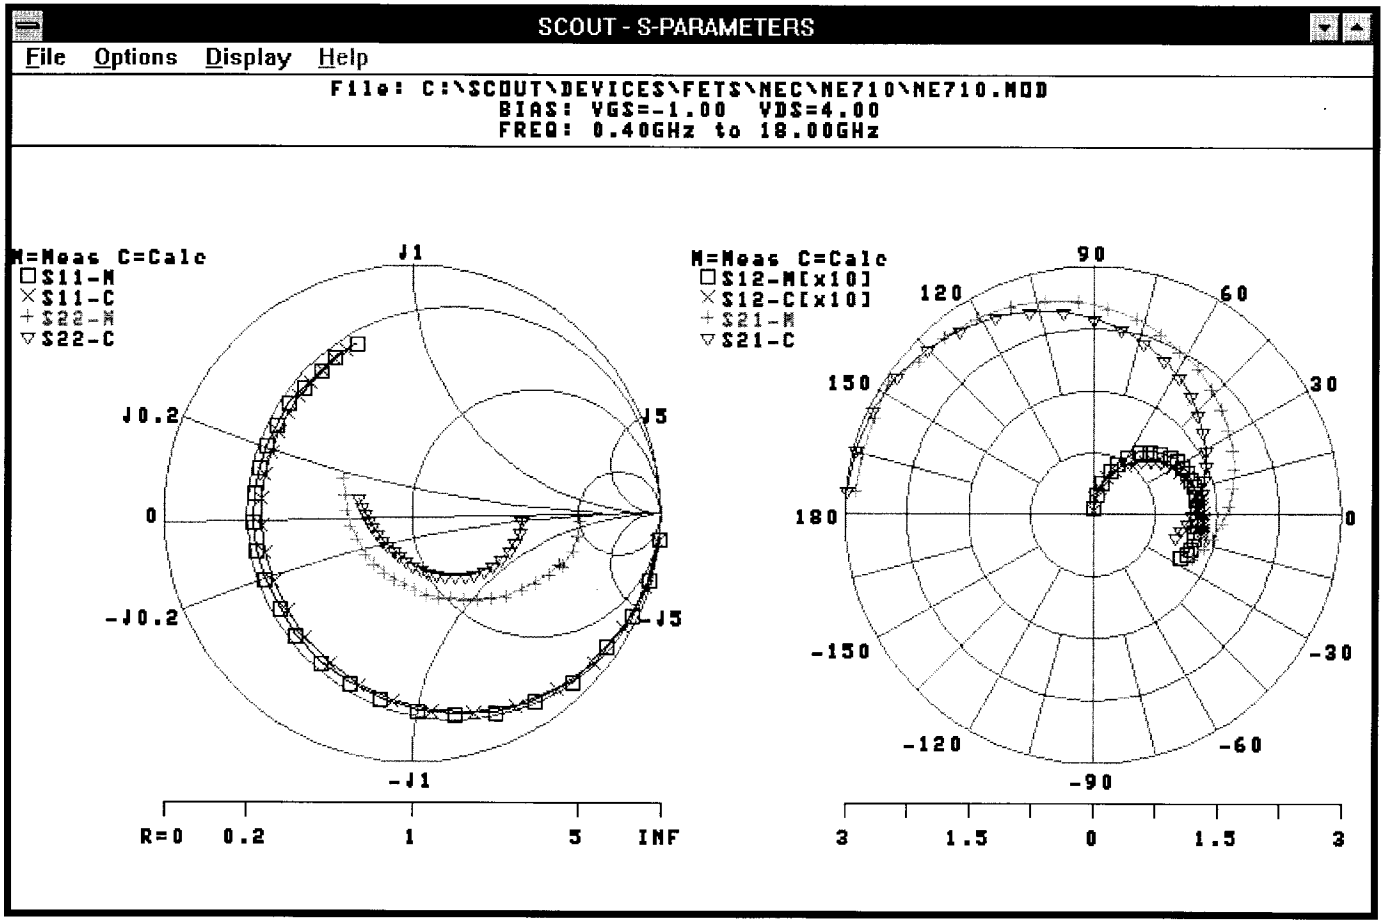

Figure 2-135 Measured versus calculated NE71000 *S* parameters for V_{GS} = –1.00 and V_{DS} = 4.00.

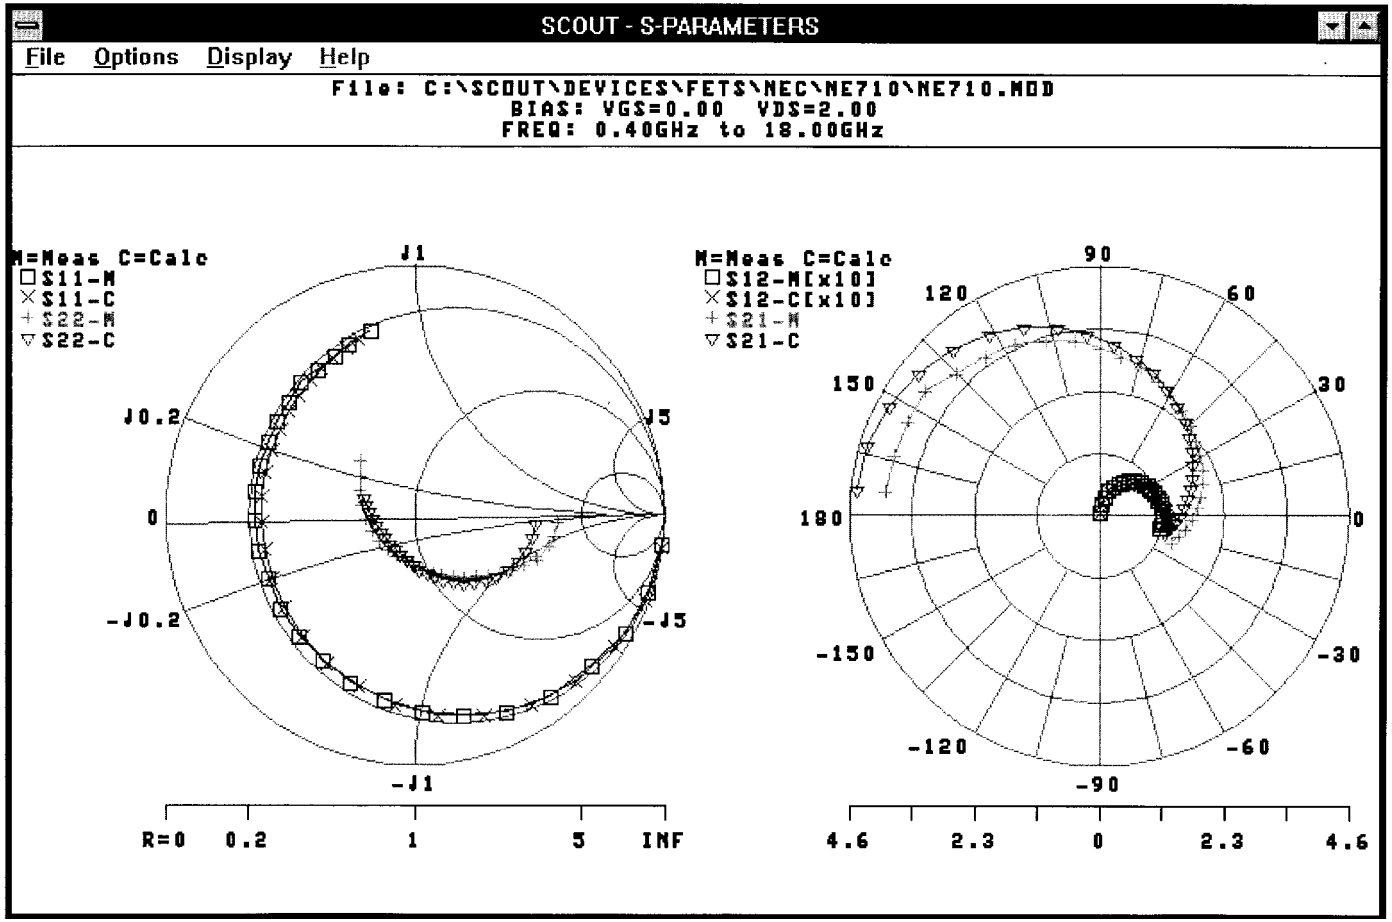

Figure 2-136 Measured versus calculated NE71000 *S* parameters for V_{GS} = 0.00 and V_{DS} = 2.00.

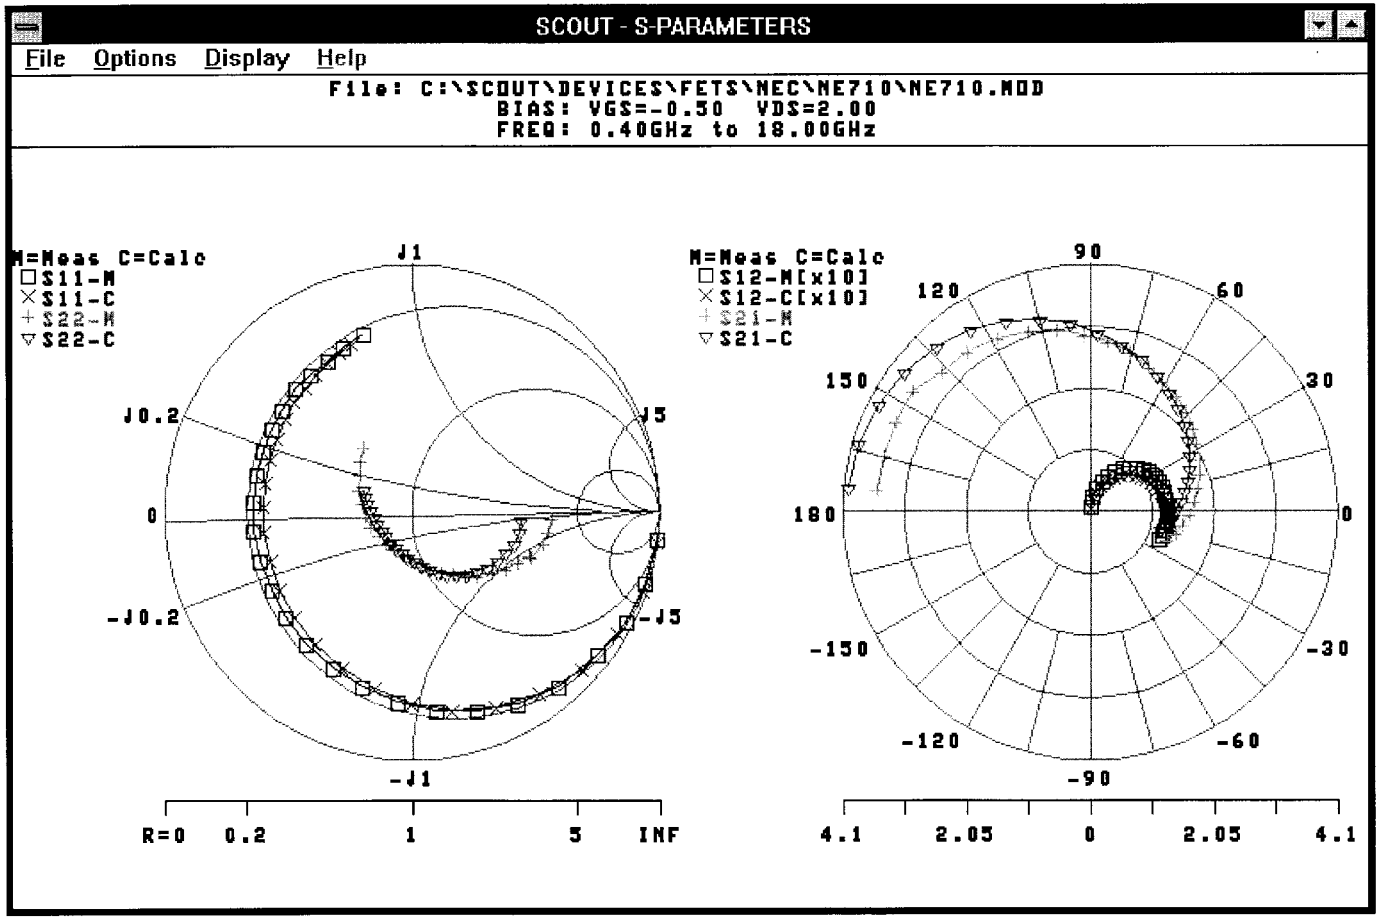

Figure 2-137 Measured versus calculated NE71000 *S* parameters for V_{GS} = –0.50 and V_{DS} = 2.00.

2-133 shows measured versus simulated dc I–V curves for the NE71000. The agreement between measured and predicted dc I–V curves is quite good. In a similar fashion, we obtain the S-parameter fits over bias. They are shown in Figures 2-134 through 2-137.

As mentioned above, 1-dB compression, power saturation, and drain current are functions of the drive. This particular model point is not particularly impressive. We believe this has to do with the original Materka model.

Having brought up the subject of models, Figure 2-138 compares measured data with that obtained with the Angelov, cubic, quadratic, TriQuint, Raytheon, and Materka models. The figure shows that there is no perfect model yet. To put this in perspective, in Figure 2-139 we show the dc I–V error bars for these six models. This graph shows that the least errors for the dc measurement versus modeling are obtained with the Curtice cubic model, followed by the modified Materka model (implemented in Serenade) and TriQuint models. The difference in S parameter matching for RF application is significantly more relevant for the designer.

Things become much more interesting if we compare the S-parameter errors between the Materka shown in Figure 2-140, the Curtice cubic model (Figure 2-141), and the TOM model (Figure 2-142). Improved modeling regarding the R_{DS} is being developed, and we will discuss this at the end of this chapter.

Since the trend is to go to low-voltage power RF operation, several issues must be battled:

- Models are most inaccurate at low V_{DS} and near pinchoff.
- Modeling of low-voltage operation is adversely impacted.
- Thermal effects must be considered, but older models do not account for this.

A Case Study. As a case study, we will consider the Oki KGF1608 power MESFET (0.5 μm × 28 mm). Figures 2-143 and 2-144 show the dc I–V curves and S parameters, respectively. The resolution of the S parameters, based on the scale used, is not particularly impressive.

Figure 2-145 shows the dc I–V curves, with load line, for the KGF1608; the self-heating effect of the transistor can be seen in the droop of the top two curves. Figures 2-146 and 2-147 show drain current and output power versus drive, respectively. The test conditions for these three figures were f = 850 MHz, V_{DS} = 3.4 V, and V_{DS} = 2.025 V.

2-4-5 Conclusions

From all plots of dc and ac error contours, dc I–V curves, and dc error bar charts we can draw the following conclusions.

Dc errors

- *In the Saturation Region*. All the models considered work very well, with a relative error of less than 15%. This means that all models are suitable for typical applications where the device operates in the saturation region.
- *In the Linear Region.* Though the errors in the saturation region are similar for different models, the errors in the linear region are quite different. The Materka, Curtice cubic, and TriQuint models behave better than other models in the linear region. The relative errors of these three models are less than 10%, while other models have more than 60% relative errors at some points.

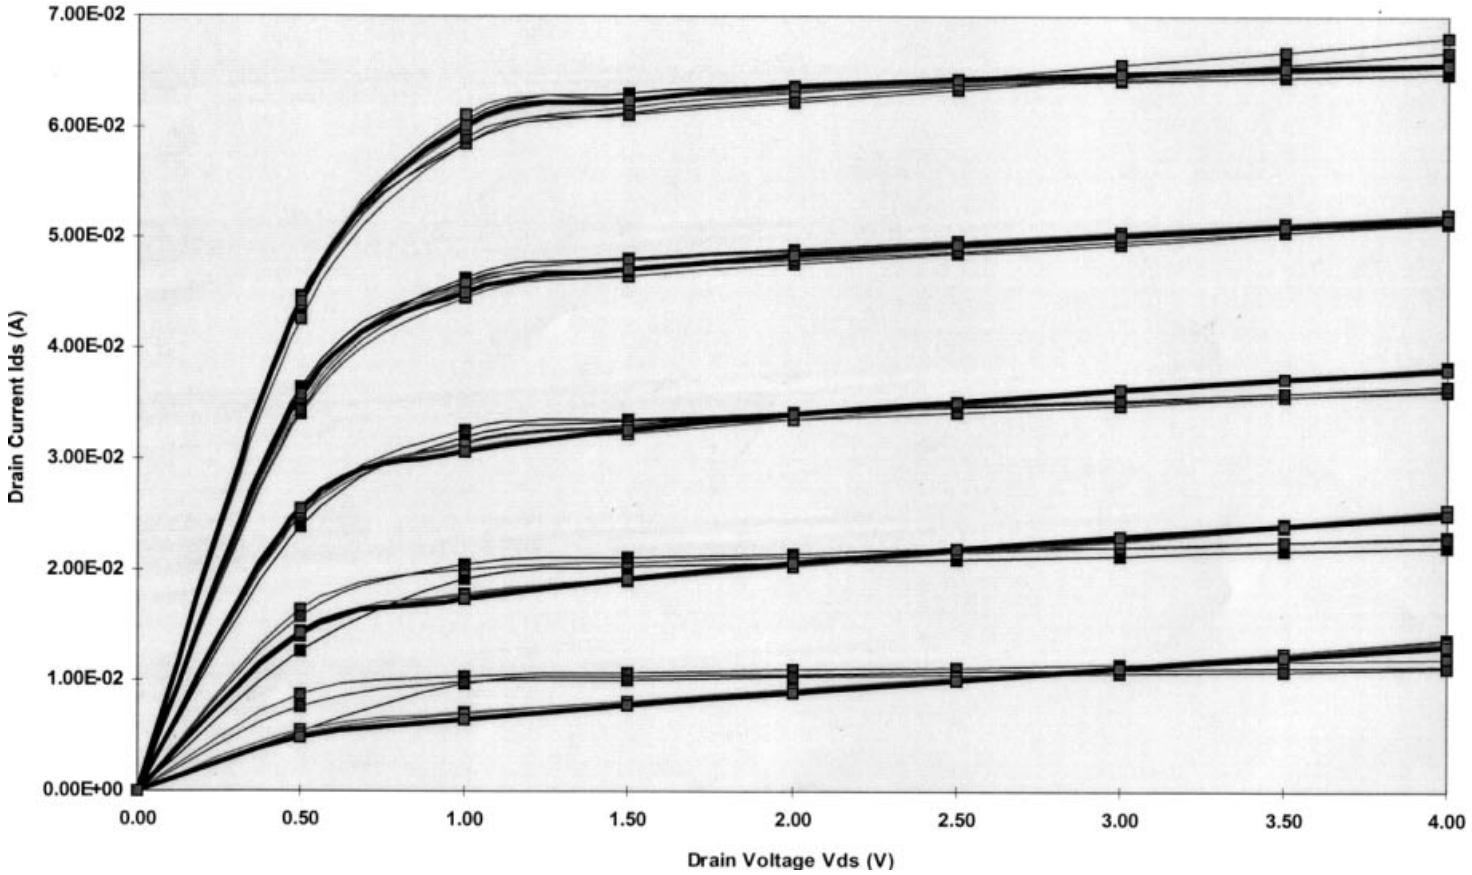

Figure 2-138 Comparison of dc models: Chalmers (Angelov), Curtice cubic, Curtice quadratic, Materka, Raytheon, and TOM (TriQuint).

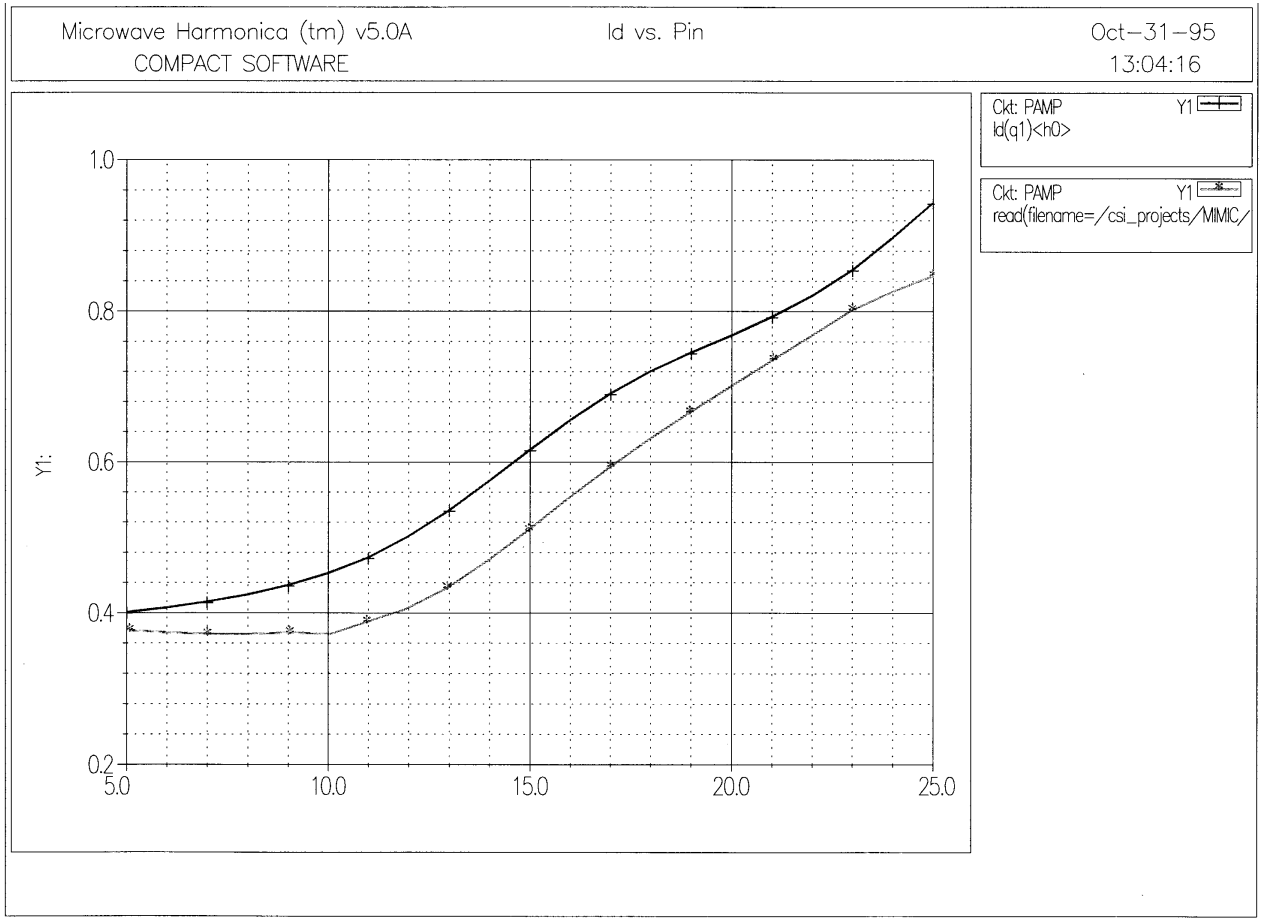

Figure 2-146 Measured versus calculated drain current for the KGF1608 MESFET.

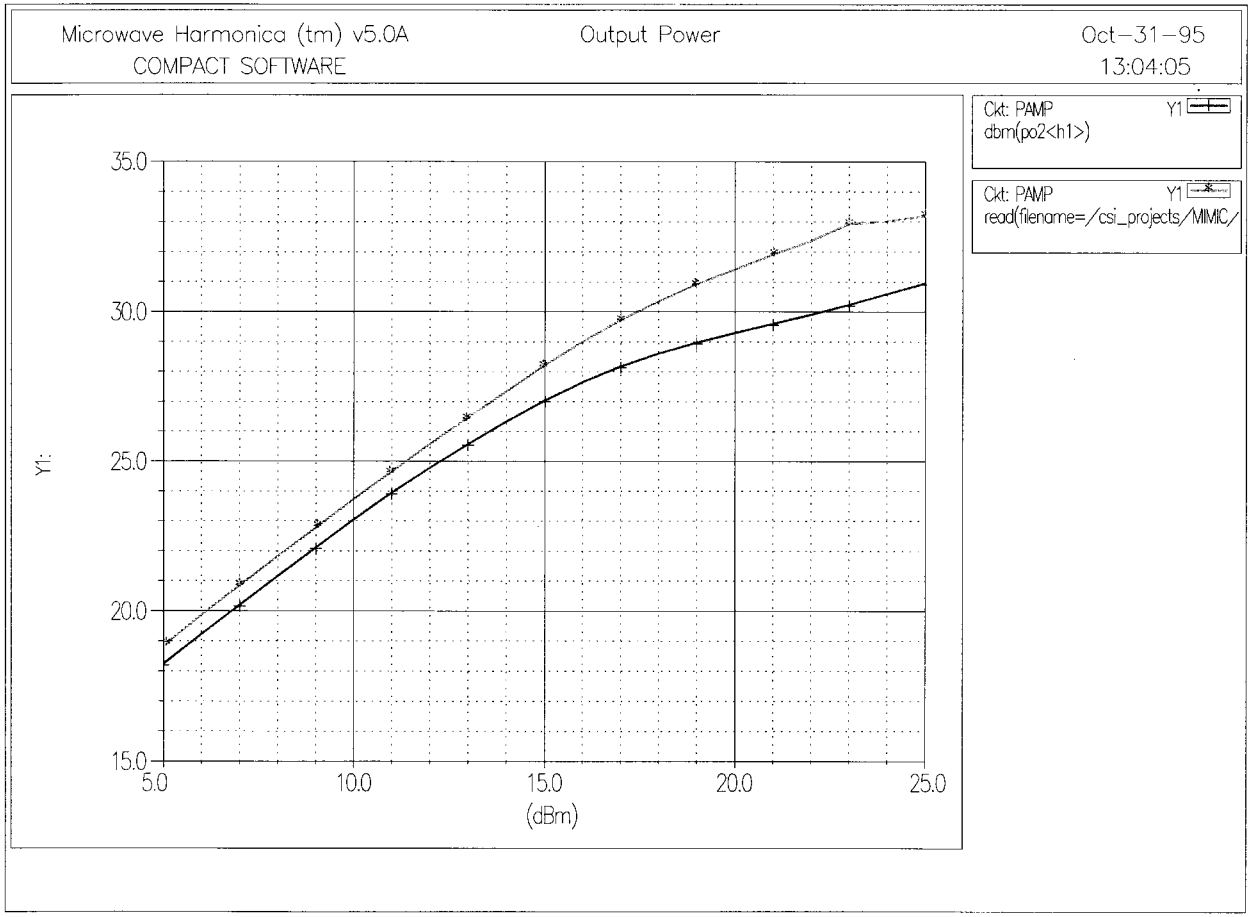

Figure 2-147 Measured versus calculated output power for the KGF1608 MESFET.

ac Errors. From the ac error contour plots we can see that the Chalmers (Angelov) model emerges as the most accurate for ac small-signal operation. The comparison also shows that all models considered are good for ac operations biased in the saturation region with a typical relative error of less than 15%. However, the ac relative errors are much higher in the linear region, particularly for the Curtice quadratic model, which exhibits more than 80% error at some points.

Notes. The above conclusions are based on the matching between the simulated responses of different models and the measured data from a typical NE71000 device; the models may behave differently for a different device. It is not possible to draw any broad-based conclusions as to what model is the best. In order to select the most suitable model for your application, you must consider all the factors, such as bias range, frequency range, and small-signal or large-signal operation, according to your experiences in device modeling.

2-4-6 Device Libraries

All these measurements lead to a nonlinear device library. Figures 2-148 and 2-149 shows a typical datasheet for a device in the library with measured and modeled data. The previous high-power example does not always lead to acceptable results as the models are far from being fully developed. We also show the simulation results using the physics-based model for FETs.

Physics-Based MESFET Modeling. We mentioned a physics-based model earlier. Figure 2-150 shows the measured versus predicted dc *I–V*, I/O power, and *S* parameters for an Alpha Industries MBE MESFET developed under a government contract. The simulation does not handle the trapped energy, which explains the negative slope on the third trace of the output dc *I–V* curve.

The process for bipolar transistors is quite similar and less tricky than the ones just described. Good examples can be found in the user manual for Compact Scout.

2-4-7 A Novel Approach for Simulation at Low Voltage and Near Pinchoff Voltage

As mentioned earlier, the most critical zone is the area of operating the FET both close to the pinchoff voltage and at low operating voltages. A crucial reason for the inadequate results is the modeling of the drain–source resistance as a function of bias point. This is particularly important in calculating the power-added efficiency. When doing your modeling, there is always a temptation to look at both high currents and operating voltages. Figure 2-151 shows a reasonable agreement between measured and predicted dc *I–V* performance. However, the very moment the transistor is modeled close to the linear region (Figure 2-152), things change drastically and the results from 0 to 6 mA have little resemblance to those from 0 to 50 mA. The modified Materka model (Figures 2-153 and 2-154) gives a significantly better match than the Angelov model.

In order to overcome the modeling inaccuracy for the FETs, Thomas Meier of Siemens AG in Munich has come up with the concept of combining two transistors in parallel, whereby the second one is not really connected for dc (Figure 2-155). Figure 2-156 compares measured and simulated R_{DS} using this new approach.

NE67300

Manufacturer : **NEC**
Model Keyword : **NE - 67300**
Device Type : **Mesfet**
Model Type : **Materka**
Package Type : **Chip**

Electrical Characteristics:
Idss : 40mA
Vp : 1.1V
Gain : 8.5dB @ 18GHz
P1db : N/A
Fmin : N/A

Model Data Range:
Vgs : -1.2V to 0.0V
Vds : 0.0V to 4.0V
Freq: 0.4GHz to 18GHz

Verification :
Type : Power sweep, 50Ω
Vgs : -0.6V Vds : 3.0V Ids : 30mA Freq: 6.0GHz

Comments : The S-parameters that appear in the figure were measured and simulated with wire bonds present. The length of each wire bond is approximately 30 mils. To obtain the S-parameters for the manufacture's data sheets, the wire bond inductances would be removed from the equivalent circuit.

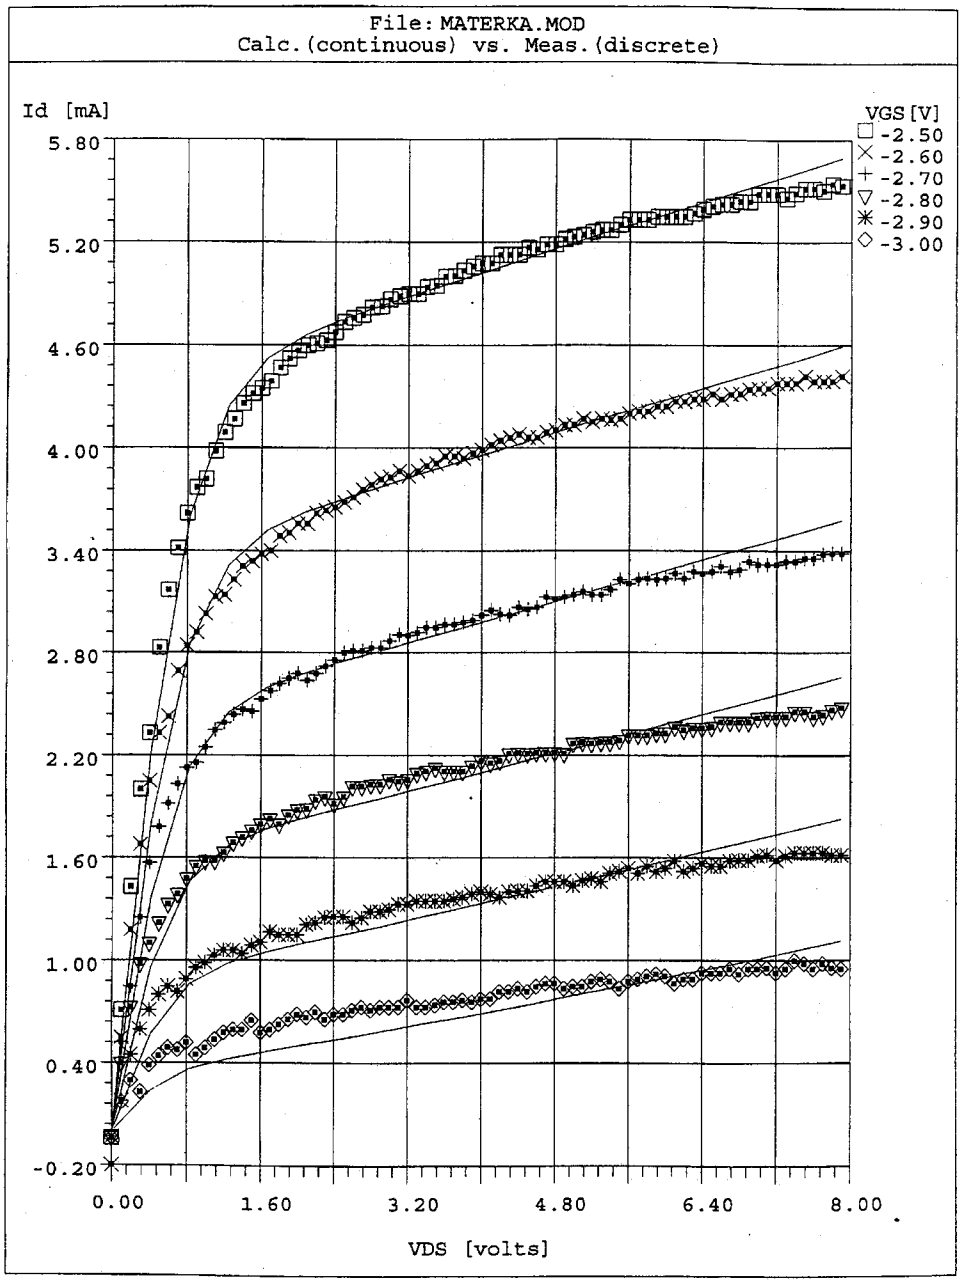

Figure 2-154 Low-I_D dc I–V curves for the modified Materka FET model.

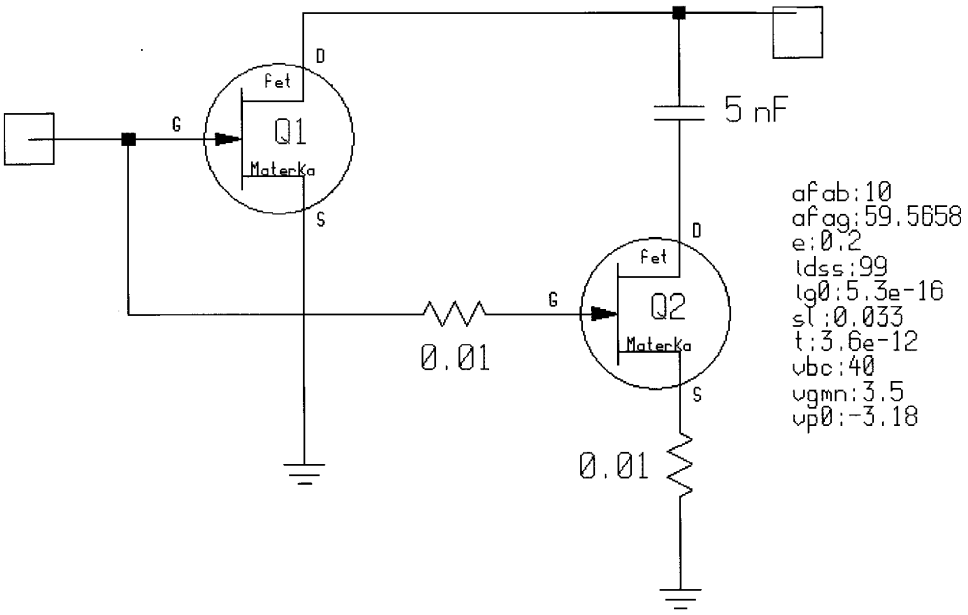

Figure 2-155 By putting two transistors in parallel, with the second one having no dc connection at the drain, one can simulate a dynamic R_{DS} quite well. Regardless of parameter values used for Q1, the parameters listed are necessary to get an accurate R_{DS} result.

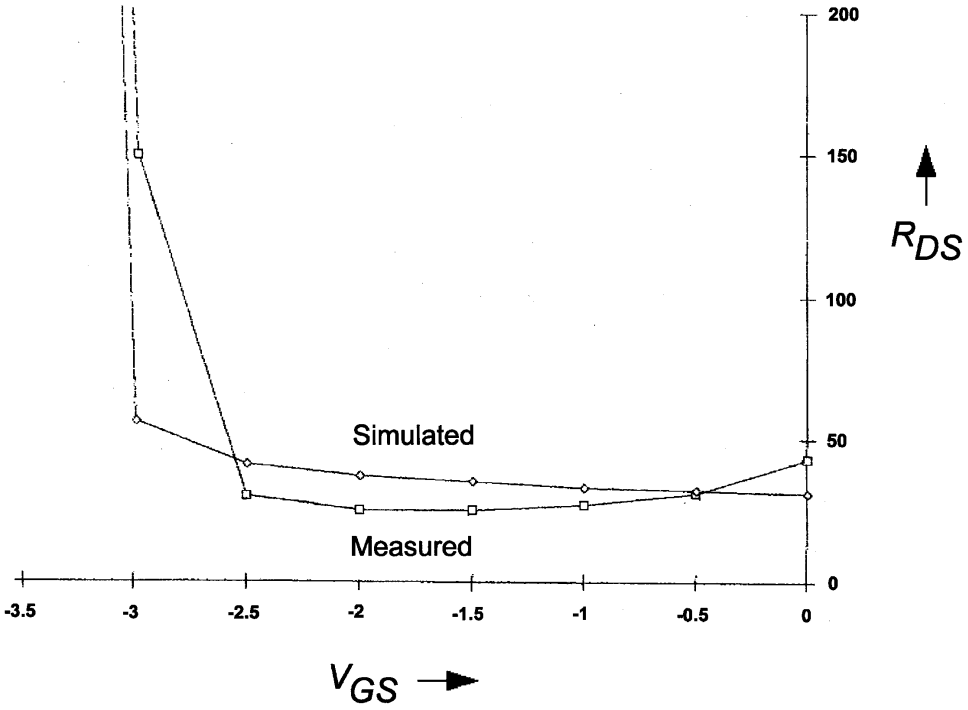

Figure 2-156 Measured versus simulated R_{DS} for the paralleled MESFET approach.

One might ask the question: "Why not fix the existing models?" It turns out that in order to get the best possible convergence and speed, one has to use analytic derivatives for voltage and current; at least the first and second derivatives, if not the third, are required. The programming of such a model becomes so difficult, however, and the calculation of its derivative is so highly likely to have subtle errors, that it turns out that the parallel configuration shown in Figure 2-155 is the best possible compromise for fast computation and accurate results.

A similar approach for bipolar transistors has been discussed by Philips with their MEXTRAM model. However, we have not seen any parameter extraction for this model and also we have not seen any industry acceptance for it. While, in principle, it will cover all derivatives of all members of the BJT family, its topology consists out of three discrete transistors connected and we doubt very much that a reliable parameter extraction program/mathematically continuous model for nonlinear simulation is supplied by the university that developed this jointly with Philips. At the time of writing this book, Philips has not yet provided us with the code for both, and until this happens, we are not in a position to qualify this any further.

2-4-8 Example: Improving the BFR193W Model

We have already mentioned the difficulty encountering the proper base-spreading resistor values and others by using standard parameter extraction programs. Table 2-28 is a copy from the Siemens semiconductor book showing Gummel–Poon Berkeley SPICE syntax parameters for the BFR193W BJT.

The first thing that will happen is that the observant reader will notice that the minimum possible base-spreading resistor, RBM (valid at large current densities), is larger than the actual base-spreading resistor, RB, "claimed to be measured" at 1 Ω (see Table 2-28).

Another headache is caused by the measured noise performance of the same device at an operating point of 10 mA. Using the above-mentioned simplified equation

Table 2.28. BFR193W transistor chip data: SPICE parameters (Gummel–Poon model, Berkeley–SPICE 2G.6 syntax)

IS	=	0.2738	fA	BF	=	125	—	NF	=	0.95341	—

All parameters are ready to use, no scaling is necessary. Extracted on behalf of SIEMENS Small Signal Semiconductors by Institut für Mobil-und Satellitenfunktechnik (IMST).

$$F = 1 + \frac{R'_{bb}}{R_g} + \frac{0.5(26\ \text{mV}/I_C)}{R_g}$$

(approximate equation at medium frequencies) (2-288)

we obtain the following results:

1. Inserting 1 Ω (value for RB provided by IMST) and R_B = 15 Ω (measured by the authors), here are the interesting results:

$$F = 1 + \frac{1}{50} + \frac{2.6}{100} = 1.046 \tag{2-289}$$

as noise factor or, as noise figure, F (dB) = 0.2 dB (IMST).

2. Or using the measured 15 Ω, one obtains

$$f = 1 + \frac{15}{50} + \frac{2.6}{100} = 1.326 \tag{2-290}$$

as noise factor or, as noise figure, F (dB) = 1.22.

The Siemens datasheet claims a noise figure of 1.3 dB, and therefore the measured versus calculated data differ by 0.08 dB. Since our noise figure was calculated well below f_T, which is seen from the fact that there are no frequency-dependent terms in the noise figure calculation, it is not unusual that the 900-MHz noise figure is 1.3 dB or slightly higher. This simple example shows how easy it is to provide measurement data that are inconsistent with the laws of physics. It is therefore highly recommended to add the noise figure as an additional parameter in the parameter extraction to reduce the number of variables—specifically, those for which the standard extraction has little sensitivity.

The collector–emitter junction capacitance is another important parameter that frequently gets measured incorrectly. The way around this is to remember the definition

$$f_{\max} = \sqrt{\frac{f_T}{8\pi R'_{bb} C_c}} \tag{2-291}$$

f_T can be measured from the 3-dB point of the emitter current gain (β) and R'_{bb} was just computed above, so the equation can be solved for C_c, as there is a relationship between measured $g_{\max}$ and $f_{\max}$. There are several correlations between the parameters of the equivalent circuit as published in different places, and therefore one can restrict the degree of freedom within the optimization process and obtain much better results. This approach is applicable to all types of transistors, bipolar and FET, and can be used to improve the accuracy of parameters that not only affect a transistor's RF performance but also its noise performance.

MODELS FOR ACTIVE DEVICES

Because we are dealing with amplifiers, both small-signal and power, oscillators, and active mixers, active devices will play a major role in circuit design. At our frequency range of interest (about 1000 MHz and above), distributed elements predominate, and even in device modeling we must consider some distributed effects such as packaging.

As we dive into providing functional explanations of the active devices used in practical circuits, there is some temptation not to provide enough information on semiconductor behavior. Because manufacturers of microwave products will use the services of a foundry or specify semiconductors from their suppliers, we will cover the device operation in depth. That said, for the beginner looking into designing circuits from high frequencies to low microwave frequencies, we will provide examples of a variety of devices unique to this frequency range. Some treatment of device physics will therefore be useful in providing a basic understanding of the nonlinear behavior of active devices and modeling in preparing for practical circuits using a computer-aided-design (CAD) tool. For CAD applications, we assume the user will have access to nonlinear CAD software, such as a high-performance SPICE program or a harmonic-balance program, such as Ansoft Serenade 8.0 or its derivatives. It is interesting that most semiconductor houses today still only offer very limited nonlinear data sets, while in the linear area a large body of useful data is made available, mostly on CDs. What CAD does for us—and this applies to SPICE and harmonic-balance programs alike—is predict the dc bias point of a device in the context of its surrounding circuitry. Configuring the simulation to drive the device into large-signal operation provides us with insight into the various forms of distortion and compression.

In evaluating active devices for RF circuit design, we have a few different technologies to consider. First, we will examine the semiconductor junction diode—a basic *pn* junction—and venture from there to the bipolar transistor. An investigation of metal-oxide semiconductor (MOS) devices, another important set of semiconductors for medium frequencies, will follow. We will also examine the gallium arsenide metal-gate Schottky field-effect transistor (GaAs MESFET) and members of its family. Since critical large-signal parameters for some devices may not be available from their manufacturers, we will examine

parameter-extraction techniques and problems. For various device types, we will provide insight into the noise properties of the device.

2-1 DIODES*

The diode model contains a nonlinear current source that follows the Shockley equation:

$$\text{Current} = \text{IS}\left(e^{V_j/\text{N}V_t} - 1\right) \tag{2-1}$$

where V_j = voltage across the junction
V_t = thermal voltage (= kT/q)

These values, with the model parameters IS and N, are used to model the current–voltage effects of the semiconductor junction. This does not include the nonideal operation of real diodes. For example, at low currents (less than 1 nA), other semiconductor processes that increase the flow of currents become noticeable.

By setting IS to different values, we can obtain the characteristics of other devices, such as a Schottky barrier diode, or a silicon diffused-junction diode. High-current effects are modeled, grossly, by including a series resistance that is intended to combine the effects of bulk resistance (the material on each side of the junction) and high-level injection. At high currents, the observed diode current stops following the Shockley form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/\text{N}V_t} \tag{2-2}$$

and approaches a modified form

$$I_{\text{forward}} = \text{IS} \times e^{V_j/2\text{N}V_t} \tag{2-3}$$

2-1-1 Large-Signal Diode Model

Three diode models are used in the industry:

- Microwave diode model
- PIN diode model
- Enhanced SPICE diode model

Figure 2-1 shows the large-signal microwave diode model. Its keywords appear in Table 2-1. This model can also be used to simulate varactor diodes.

Table 2-2 lists SPICE parameters for a selection of Schottky mixer diodes by Alpha.

In most cases, the diode capacitance is modeled by a voltage-dependent capacitor, which is connected in parallel with the nonlinear current generator described previously, to represent the charge-storage effects of the junction. There are two components to this charge

- The reverse-voltage capacitive effect of the depletion region
- The forward-voltage charge represented by mobile carriers in the diode junction

*Portions of this chapter's diode coverage are based on material in Alpha Industries Semiconductor Application Reports 80800, 80200, and 80500. Used with permission.

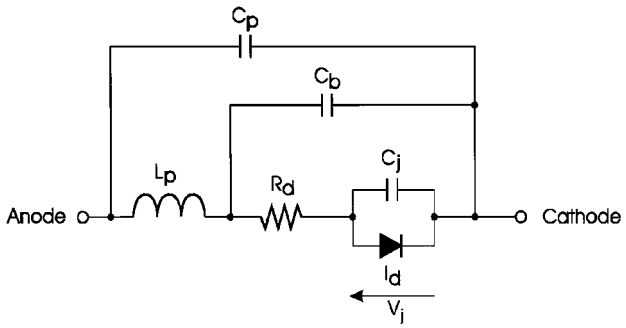

Figure 2-1 The large-signal microwave diode model. This model is temperature dependent.

Reverse-voltage capacitance follows the simple approximation that the depletion region (the area of the junction that is depleted of carriers) serves as the gap between the "plates" of a capacitor. This region varies in thickness, and therefore the capacitance varies with applied voltage. For a step (abrupt) junction, or linearly graded junction, the capacitance approximation is

Table 2-1 Large-signal microwave diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
JS	Saturation current	ampere	0
ALFA	Slope factor of conduction current	/volt	38.696
JB	Breakdown saturation current	ampere	10 mA
VB	Breakdown voltage	volt	$-\infty$

$$\text{Capacitance} = \frac{C_{J0}}{\left(1 - V_j/\phi\right)^M} \tag{2-4}$$

where C_{J0} is the zero-bias value, ϕ (phi) is the junction barrier potential, and M is the grading coefficient that varies ($\frac{1}{2}$ is used for step junctions and $\frac{1}{3}$ is used for linearly graded junctions, and most junctions are somewhere in between).

There is often confusion about the barrier potential, which appears in the capacitance equation. From capacitance measurements, ϕ (model parameter VJ, and not to be confused with V_j in the equations) takes on a value of nearly 0.7 volt for regular (silicon) junction diodes and a range of 0.58–0.85 volt for various Schottky barrier diodes. This value is sometimes confused with the forward-current voltage drop of the diode or the energy gap of the material; it is *neither* of these.

Varying M generates a variety of reverse-bias capacitance characteristics. Inspection of the capacitance formula reveals that it predicts infinite capacitance for a forward bias, which is not the case for a real junction. Several depletion-capacitance formulas have been proposed that more correctly fit observed operation; however, SPICE uses a simple approach: For forward biases beyond some fraction (set by the parameter FC) of the value for ϕ, the capacitance is calculated as the linear extrapolation of the capacitance at the departure. This provides a continuous numerical result and does not affect circuit operation significantly because, for forward bias, the device capacitance is normally dominated by diffusion capacitance.

The diffusion charge (and therefore the capacitance) varies with forward current and is simply modeled as a transit time (model parameter TT) for the carriers to cross the diffusion region of the junction. The total charge is

$$\text{Diffusion charge} = \text{Device current} \times \text{Transit time} \tag{2-5}$$

and capacitance is the derivative, with respect to bias, of this:

$$\text{Diffusion capacitance} = \text{TT}\,\frac{\text{IS}}{\text{N}V_t}\,e^{V_j/\text{N}V_t} \tag{2-6}$$

Diffusion charge manifests itself as the *storage time* of a switching diode, which is the time required to discharge the diffusion charge in the junction, which must happen before the junction can be reverse-biased (switched off). Storage time is normally specified as the time to discharge the junction so that it is supporting only a fraction (typically 10%) of the initial reverse current. First, a forward current is supplied to the device to charge the junction. Then, as quickly as possible, a reverse current is supplied to the device. Internally, the junction is still forward-biased to a voltage nearly the same as before the switch in current; the junction is still conducting at the forward-current rate. This internal current adds to the external current as the total current discharging the junction. As the junction voltage decreases, the internal current falls off exponentially (according to the Shockley equation). This system is a relatively simple differential equation that can be solved to an explicit equation for the TT parameter (assuming complete discharge) as follows:

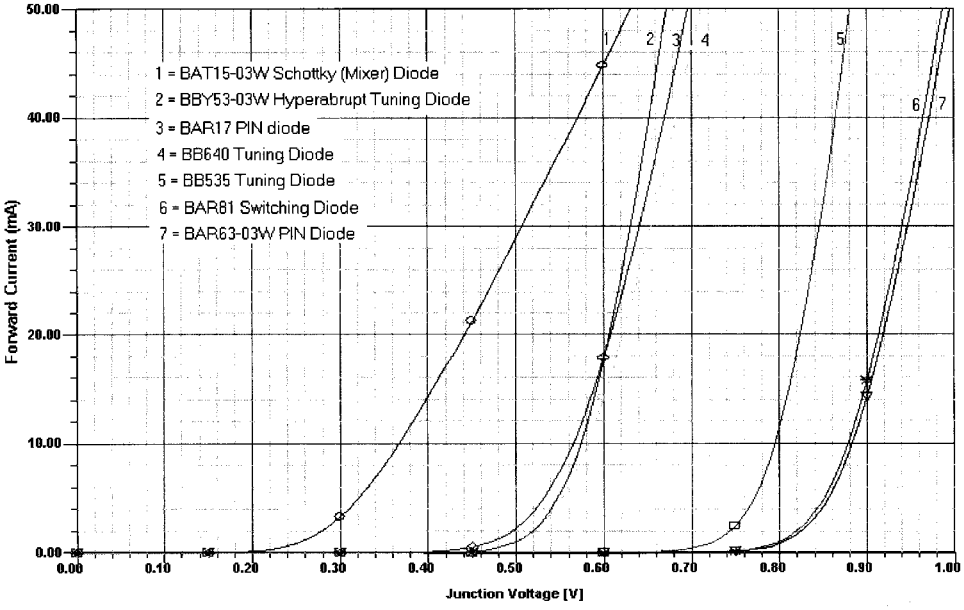

Figure 2-2 The dc *I–V* curves for seven diodes, showing the various barrier voltages that result from different doping profiles.

$$\text{Transit time} = \frac{\text{Storage time}}{\ln\left(\dfrac{I_F - I_R}{-I_R}\right)} \tag{2-7}$$

The diffusion charge dominates the reverse recovery characteristic of the diode. During the last part of the recovery, as the junction becomes reverse-biased, the depletion capacitance dominates. This causes the small tail at the end of the discharge cycle. Total capacitance is taken to be the sum of these capacitances: the depletion approximation dominates for reverse bias as the device current is small, and the diffusion proximity dominates for forward bias as the device current is large.

A special case for diode application is the switching diode, and its description and application will be part of a later chapter. Figure 2-2 shows the dc *I–V* curves, which indicate the different voltage potentials that are a result of the different doping profiles.

2-1-2 Mixer and Detector Diodes

Electrical Characteristics and Physics of Schottky Barriers. Schottky barrier diodes differ from junction diodes in that current flow involves only one type of carrier instead of both types. That is, in *n*-type Schottky barrier diodes the forward current consists of holes flowing from the *n*-type material into the metal.

Diode action results from a contact potential set up between the metal and the semiconductor, similar to the voltage between the two metals in a thermocouple. When metal is brought into contact with an *n*-type semiconductor (during fabrication of the chip), electronics diffuse out of the semiconductor into the metal, leaving a region under the contact that

has no free electrons ("depletion layer"). This region contains donor atoms that are positively charged (because each lost its excess electron), and this charge makes the semiconductor positive with respect to the metal. Diffusion continues until the semiconductor is so positive with respect to the metal that no more electrons can go into the metal. The internal voltage difference between the metal and the semiconductor is called the contact potential and is usually in the range of 0.3–0.8 volt for typical Schottky diodes. A cross section is shown in Figure 2-3.

When a positive voltage is applied to the metal, the internal voltage is reduced, and electrons can flow into the metal. The process is similar to thermionic emission of electrons from the hot cathode of a vacuum tube, except that the electrons are "escaping" into a metal instead of into a vacuum. Unlike the vacuum tube case, room temperature is "hot" enough for this to happen if enough voltage is applied. However, only those electronics whose thermal energy happens to be many times the average can escape, and these "hot electrons" account for all the forward current from the semiconductor into the metal.

One important thing to note is that there is no flow of minority carriers from the metal into the semiconductor and thus no neutral plasma of holes and electrons is formed. Therefore, if the forward voltage is removed, current stops "instantly," and reverse voltage can be established in a few picoseconds. There is no delay effect to charge storage as in junction diodes. This accounts for the exclusive use of barrier diodes in microwave mixers, where the diode must switch conductance states at microwave oscillator rates.

The current–voltage relationship for a barrier diode is described by the Richardson equation (which also applies to thermionic emission from a cathode). The derivation is given in many textbooks (e.g., Sze).

$$I = AA_{\mathrm{RC}}T^2 \exp\left(-\frac{q\phi_B}{kT}\right)\left[\exp\left(\frac{qV_J}{kT}\right) - M\right] \tag{2-8}$$

where A = area (cm^2)

A_{RC} = modified Richardson constant ($\mathrm{A}/K^2 \cdot \mathrm{cm}^2$)

k = Boltzmann's constant

T = absolute temperature (K)

ϕ_{B} = barrier height in volts

V_J = external voltage across the depletion layer (positive for external voltage) = $V - IR_S$

R_S = series resistance

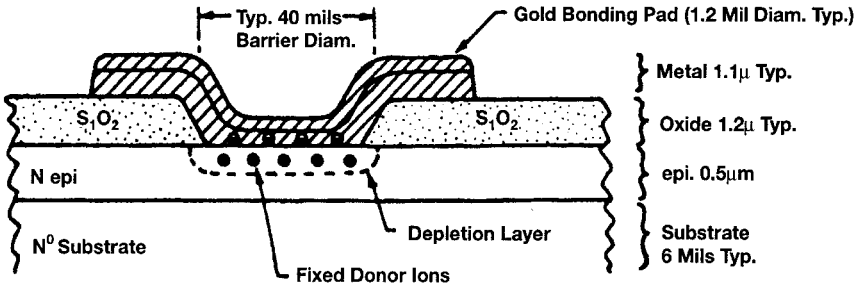

Figure 2-3 Schottky diode chip cross section.

M = avalanche multiplication factor
I = diode current in amperes (positive forward current)

The barrier height, ϕ_B, is typically a few tenths of a volt higher than the contact potential, ϕ_C (about 0.15 V higher than ϕ_C for silicon). This equation agrees well with experimental data for diodes without surface leakage, but it is difficult to use because A_{RC}, ϕ_B, and M are all dependent on applied voltage.

The major cause for variation in ϕ_B with voltage is the "image effect," in which the barrier height is lowered as the electric field near the metal is increased, especially at the edges. A better equation for circuit designers to use is one in which all parameters are independent of voltage and current. The simplest one that agrees reasonably well with Richardson's equation is

$$I = I_S\left[\exp\left(\frac{V_J}{0.028}\right) - 1 + \frac{K}{\left(1 - V_B/V\right)}\right] \tag{2-9}$$

where I_S = saturation current (a temperature-dependent quantity)
0.028 = nkT/q at room temperature (n = 1.08)
n = forward slope factor (derived from the variation of ϕ_B with forward voltage)
K = reverse slope factor (expressing the variation of ϕ_B with reverse voltage)
V_B = breakdown voltage (the voltage at which M = 1)

As before, V and I are considered positive for forward bias and negative for reverse bias.

Typical ranges for these parameters for microwave Schottky and point-contact mixer diodes are:

I_S = 10^{-12} to 10^{-5} A
n = 1.04–1.10
R_S = 2–20 Ω
K = 8–100
V_B = 2–20 V

The quantities I_S and 0.028 are strongly temperature dependent, while both R_S and V_B increase with temperature to a slight degree. R_S increases with current at high current levels (due to carrier velocity saturation) but is essentially independent of current at 10 mA and below for mixer diodes. Thus, for normal mixer and detector operation, R_S can be considered constant.

Agreement between Eqs. (2-8) and (2-9) is not perfect but Eq. (2-9) is much easier to use and is preferred by most circuit designers. A comparison of the two equations near zero bias gives the following relationship between zero-bias barrier height, ϕ_0, and saturation current:

$$I_S = AA_{RC}T^2\exp - \frac{q\phi_0}{kT}$$

$$\cong \left(\frac{10^7 A}{\text{cm}^2}\right)A\exp\left(-\frac{\phi_0}{0.026}\right) \quad \text{(for } n \text{ silicon at room temperature)} \tag{2-10}$$

Small-Signal Parameters. By combining Eqs. (2-9) and (2-10), the values of the parameters in Eq. (2-9) can be derived from a few simple measurements. Many specific equations can be derived, but the following are commonly used for production measurements:

$$R_S = \frac{V_{F10} - V_{F1} - 0.065}{0.009} \quad (\text{for } n = 1.08) \tag{2-11}$$

$$\phi_0 = \frac{V_{F1} - 0.001R_S + 0.28 + 0.12\log_{10} D}{1.08} \tag{2-12}$$

$$n = \frac{V_{F1} - V_{F0.1} - 0.0009R_S}{0.060} \tag{2-13}$$

$$K = \left(\frac{I_{R1}}{I_S} - 1\right)V_B \tag{2-14}$$

$$I_S = \exp\left(-\frac{V_{F1}}{0.028} + \frac{R_S}{28}\right) \quad (\text{in mA}) \tag{2-15}$$

where $V_{F0.1}$, V_{F1}, and V_{F10} are the forward voltages at 0.1, 1, and 10 mA, respectively, and I_{R1} is the reverse current at 1 volt. (The derivation of these equations requires that I_S be small compared to 0.1 mA.) The quantity D is the diameter of the metal–silicon contact in mils.

Measuring V_{F1} at 1 mA and 10 mA instead of some other current levels leads to the best accuracy for typical mixer diodes.

The total dynamic resistance for a forward-biased diode is given by

$$R_T = \frac{dV}{dI} = R_S + \frac{nkT}{q(I + I_S)} = R_S + R_B \tag{2-16}$$

and

$$R_B = \frac{28}{I + I_S} \quad \text{at room temperature (with } I \text{ and } I_S \text{ in mA, } n = 1.08) \tag{2-17}$$

This equation is also good at zero bias (unless K is very large or there is significant surface leakage). That is,

$$R_0 = R_S + \frac{28}{I_S} \tag{2-18}$$

For reverse voltages of a few volts, the dynamic resistance is dominated by the K term:

$$R_R = \text{Reverse resistance} = \frac{dV}{dI} \cong \frac{V_B}{KI_S} \tag{2-19}$$

For typical values of I_S, R_0 is larger than 5000 Ω and R_R is larger than 100 kΩ. For some zero-bias Schottky applications, it is desirable for R_0 to be made smaller than this.

The factors that determine R_S are (1) the thickness of the epitaxial layer, (2) the epitaxial layer doping level (N_D), (3) the barrier diameter, (4) the substrate resistivity ("spreading resistance"), (5) the contact resistances of the metals used for the barrier and the substrate contact, and (6) the resistance associated with the bonding wire or whisker. The barrier height is about 0.15 volt higher than the contact potential between the barrier metal and the semiconductor and is influenced by the method used to apply the metal, conditions at the edge of the junction, and the doping level. Saturation current depends on barrier height, junction area, and temperature; and the slope factors, n and K, depend on doping level, punchthrough voltage, and edge conditions.

Junction Capacitance. The capacitance of a Schottky barrier chip results mainly from two sources: the depletion layer under the metal–semiconductor contact and the capacitance of the oxide layer under the bonding pad (the so-called overlay capacitance). The bonding pad is required because the typical Schottky barrier diameter is so small that it is impractical to bond directly to the metal on the junction. If the semiconductor epitaxial layer is uniformly doped, the capacitance–voltage characteristic is similar to that of a textbook "abrupt-junction" diode.

$$C_J = \frac{\varepsilon_S \varepsilon_0 A'}{X_D} + C_0 \tag{2-20}$$

$$X_D = \sqrt{\frac{2\varepsilon_S \varepsilon_0 (\phi_C - V)}{qN}} \tag{2-21}$$

where ϕ = contact potential
C_0 = overlay (bonding pad) capacitance
ε_S = dielectric constant of the semiconductor ($\cong$ 12 for Si or GaAs)
N = doping level for the epitaxial layer
A' = effective contact area, including fringing corrections

In practical terms, the capacitance can be related to the 0-V barrier capacitance defined by

$$C_{B0} = \frac{\varepsilon_S \varepsilon_0 A'}{X_{D0}} \tag{2-22}$$

where

$$X_{D0} = \sqrt{\left(\frac{1.3 \times 10^{15}}{N_D}\right)\phi_C} \quad \text{(in } \mu\text{m)} \tag{2-23}$$

The resulting C–V relationship can be written

$$C_J = \frac{C_{B0}}{\sqrt{1 - V/\phi_C}} + C_0 \tag{2-24}$$

The contact potential, ϕ_C, is related to the barrier height as follows:

$$\phi_C = \phi_B - 0.026\left[1 + L_n\left(\frac{N_C}{N}\right)\right] \tag{2-25}$$

The theoretical meaning of these terms can be clarified by looking at Figure 2-4.

Parameter Trade-Offs

Barrier Height. The barrier height of a Schottky diode is important because it directly determines the forward voltage. In order to get a good noise figure, the LO drive voltage, V_L, must be large compared to V_T, which is essentially V_{F1}. Normally, it is best to have a low

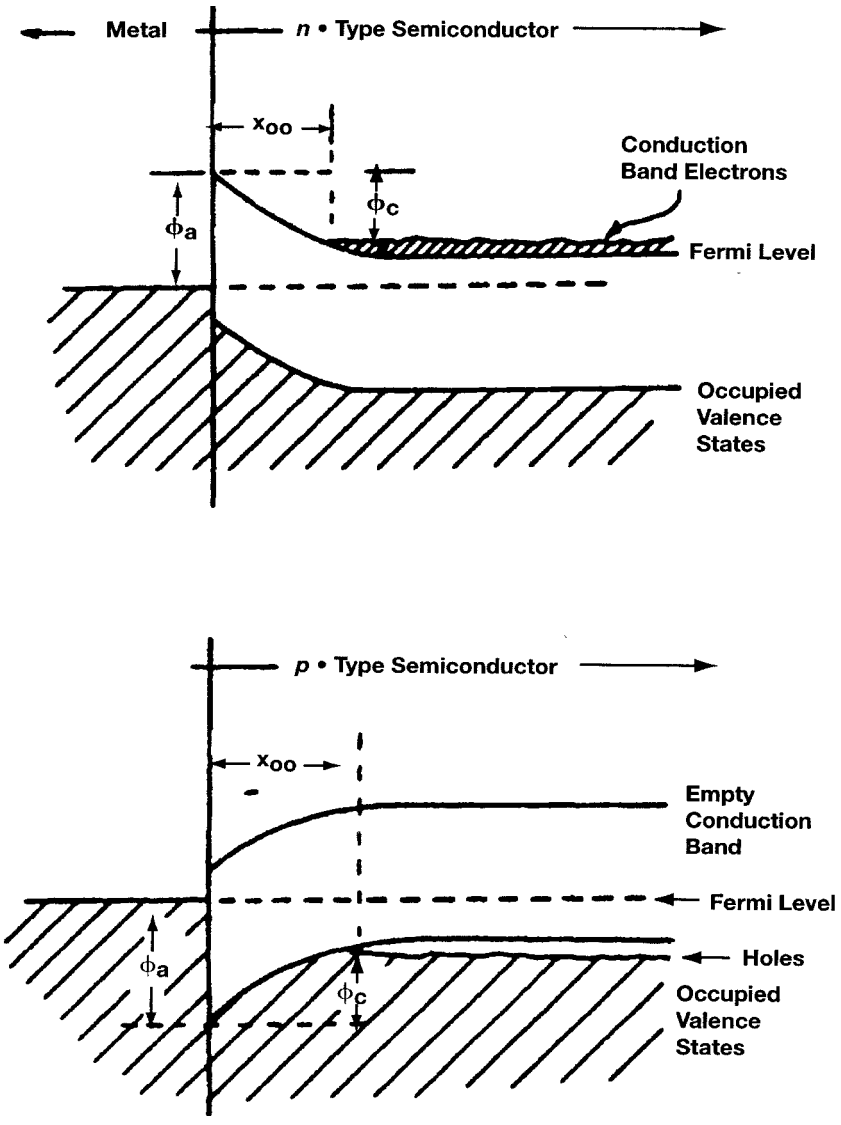

Figure 2-4 Schottky diode band diagrams.

Table 2-3 LO power and V_{F1} for various applications

Type	Typical V_{F1}	LO Power	Application
"Zero bias"	0.10–0.25	< 0.1 mW	Mainly for detectors
Low barrier	0.25–0.35	0.2–2 mW	Low-drive mixers
Medium barrier	0.35–0.50	0.5–10 mW	General purpose
High barrier	0.50–0.80	> 10 mW	High dynamic range

forward voltage (low V_{F1}), or low drive) diode, to reduce the amount of LO power needed. However, if high dynamic range is important, high LO power is needed, and the diode can have a higher V_F and should also have a high V_B (see Table 2-3).

Noise Figure Versus LO Power. At low LO drive levels, the noise figure is poor because of poor conversion loss, due to a too-low conduction angle. At very high LO drive levels, the noise figure again increases due to diode heating, excess noise, and reverse conduction.

If a high LO drive level is needed, for example, to get higher dynamic range, a high V_B (> 5 V) should be specified. However, Nature requires that you pay for this with higher R_S (lower f_C), so the noise figure will be degraded compared to what could be obtained with diodes designed for lower LO drive. Forward voltage and breakdown are basically independent parameters, but high breakdown is not needed or desirable unless high LO power is used.

Such a high-breakdown diode will have low reverse current (which is important only if the diode has to run hot).

Silicon Versus GaAs. Typical silicon Schottky diodes have cutoff frequencies in the 800–200-GHz range, which is good enough through the Ku band.

At the Ku band and above, or for image-enhanced mixers, higher f_C may be needed, which calls for the use of GaAs diodes. These have lower R_S due to higher mobility, which translates to cutoff frequencies in the 400–1000-GHz range.

However, if your IF is low, be careful; GaAs diodes have high 1/*f* noise. They also have high V_{F1}, so more LO power is required.

C_J Versus Frequency. There is quite a lot of latitude in choosing C_J. However, in general, the capacitive reactance should be a little lower than the transformed line impedance (Z_0). If Z_0 is not known, a good way to start is to use $X_C = 100\ \Omega$. Experience has shown that most practical mixers use an X_C near this value (a little higher in waveguide, and lower in 50-Ω systems). This translates to the following rule of thumb for choosing the junction capacitance of a diode for operation at frequency *f* (in GHz):

$$C_{J0} \approx \frac{100}{\omega}$$

$$\approx \frac{1.6}{f} \quad \text{(in pF)} \tag{2-26}$$

In order to evaluate possible tolerances, we show the range of forward current as a function of diode voltage (Figure 2-5), the junction capacitance as a function of the bias voltage

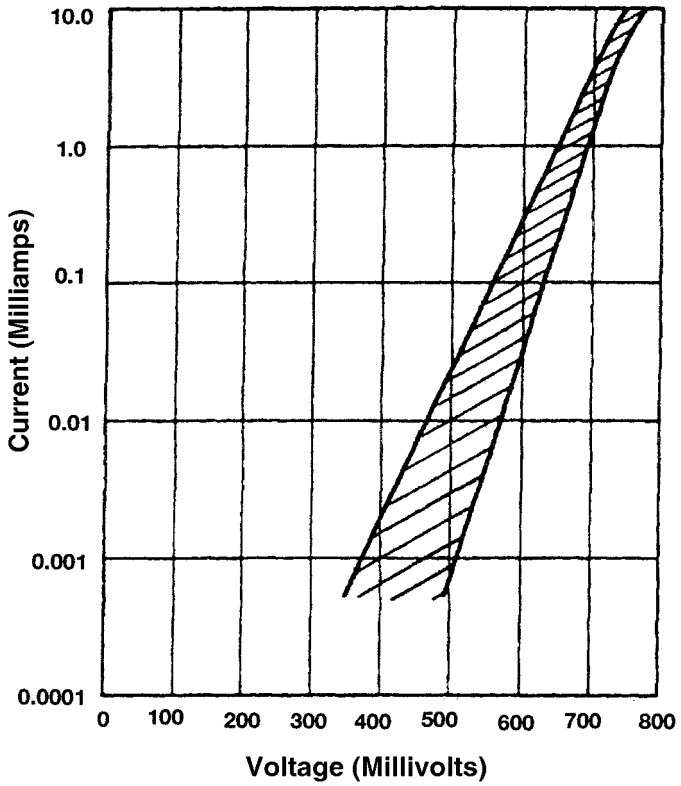

Figure 2-5 Forward dc characteristic curve range—current versus voltage.

(Figure 2-6), and finally some important RF parameters, such as noise figure and IF impedance, as a function of the local-oscillator drive (Figure 2-7).

Mixer Diodes. As an example of some of the parameters for mixer diodes, Table 2-4 gives data on some of the X-band mixer diodes. NF is measured at 9.375 GHz.

Linear Diode Model. Figure 2-8 shows the linear diode model. Its keywords appear in Table 2-5.

The circuit simulators, such as those supplied by Ansoft and Hewlett-Packard, provide a model library that has SPICE-type parameters for diodes (regular diodes, varactor diodes, and PIN diodes) as well as bipolar transistors and FETs, which will be discussed later.

2-1-3 PIN Diodes

Introduction. The PIN diode, in comparison with other microwave semiconductor devices, is fairly easy to understand. This makes possible the reduction of its complex behavior to relatively simple terms.

We do not attempt to describe the many possible microwave circuits in which PIN diodes are used. Rather, we attempt to explain the behavior of the diode in all aspects, giving the facts and some of the theory behind the facts. We offer the circuit designer the opportunity

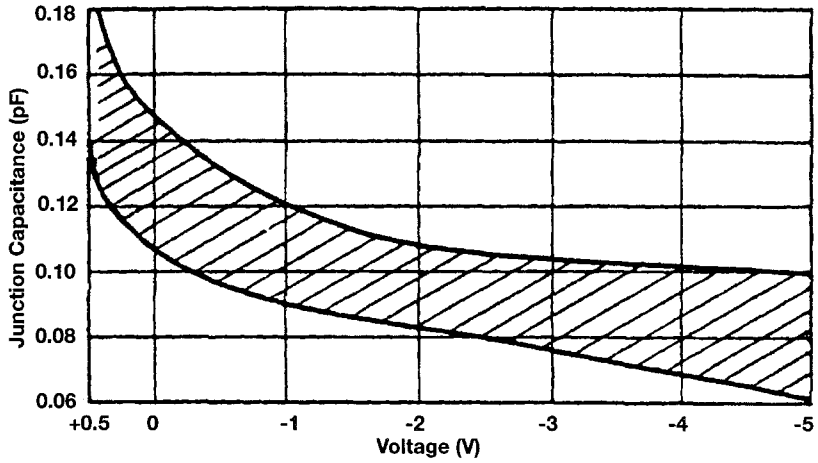

Figure 2-6 Junction capacitance range versus voltage.

to understand the PIN, so that he/she can understand its behavior in circuits. We assume the reader knows the circuit equations; to that knowledge we hope to add diode equations.

Most of the material presented consists of generalized data and explanations of the behavior of PIN diodes; we conclude with a brief description of circuit performance, test methods, and some hints on proper PIN specification writing.

The user can then evaluate the trade-offs involved in diode design and performance and be able to select the most nearly optimum diode from the wide range of diodes offered.

Large-Signal PIN Diode Model. Figure 2-9 shows the large-signal model for a PIN diode. Table 2-6 lists its keywords.

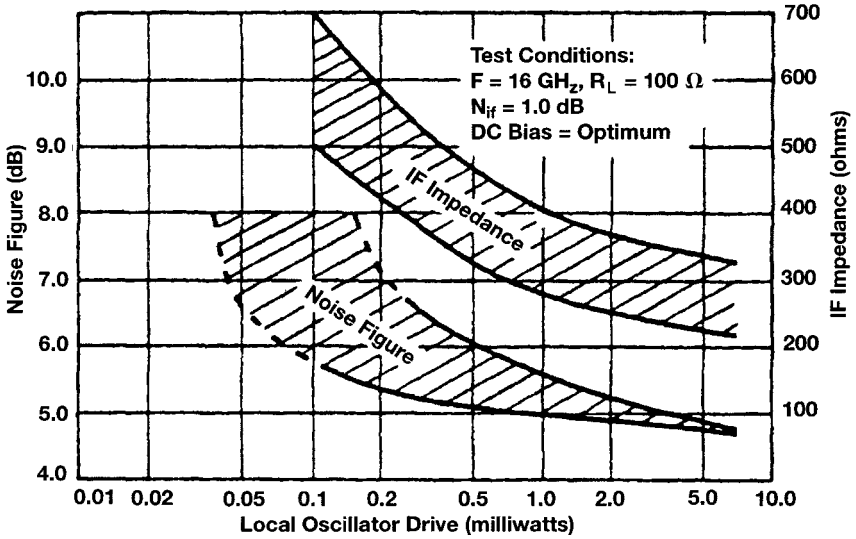

Figure 2-7 RF parameters versus local-oscillator drive level.

Table 2-4 X-band mixer diode data

Material	Barrier	Typical V_F (@1 mA)	Typical F_{C0} (GHz)	Typical R_S (Ω)	Typical C_{J0} (pF)	Maximum NF (dB)
n GaAs	High	0.70	1000	—	0.15	5.0[a]
n GaAs (BL)	High	0.70	500	—	0.15	6.0[a]

[a]Specified for N_F = 1.0 dB.

Basic Theory: Variable Resistance. Intrinsic or "pure" silicon, as it can be grown in a laboratory, is an almost lossless dielectric. Some of is physical properties include:

Dielectric constant (relative)	12
Dielectric strength	400 V/mil (approximate)
Specific density	2.3
Specific heat	0.72 J/g · °C
Thermal conductivity	1.5 W/cm · °C
Resistivity	300,000 Ω/cm

Since a PIN diode is valuable essentially because it is a variable resistor, let us concentrate initially on the resistivity. Consider a volume comparable to a typical PIN diode chip, say, 20 mils in diameter and 2 mils thick. This chip has a dc resistance of about 0.75 MΩ. High

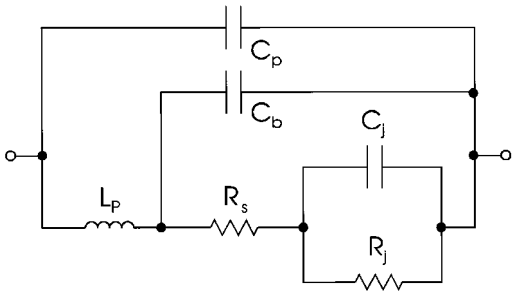

Figure 2-8 The linear diode model. This model is temperature dependent.

Table 2-5 Linear diode model keywords

Keyword	Description	Unit	Default
LP	Package inductance	henry	0.0
CB	Beam-lead capacitance	farad	0.0

RJ	Junction resistance	ohm	
CJ	Junction capacitance	farad	

resistivity in any material indicates that most of the likely carriers of electric charge, electrons and holes, are tightly held in the crystal lattice and cannot "conduct."

In real life there are impurities, typically boron, that cannot be segregated out of the crystal. Such impurities contribute carriers, holes or electrons, that are not very tightly bound to the lattice and therefore lower the resistivity of the silicon.

Through various techniques we can adjust the level of impurities, called *dopants*, to produce resistivities ranging from 10 kΩ/cm (for good PIN diodes) to 0.001 Ω/cm (for substrates).

If the impurity adds "electrons" to the crystal, it is called a *donor*; if it adds holes it is called an *acceptor*. Boron adds holes, hence it is an acceptor, and the silicon plus boron combination is called *p*-type, or *positive*, because it has an excess of positive carriers. Phosphorus, on the other hand, is a *donor*, adding electrons, and the corresponding mix is *n*-type, or *negative*.

Notes on the PIN Diode Model

1. The PIN diode model is used to model a bias-dependent RF resistance for use in PIN diode circuits such as attenuators and switches. The resistance varies from RMAX to RS using the R function above. A typical R versus *I* characteristic is shown in Figure 2-10 with parameters IS = 5.96 nA, RS = 2.016, RMAX = 6500, K1 = 0.1272, K2 = 1.0, N = 2.077.
2. The transit-time parameter, TT, can also be used to approximately model a switching PIN diode's reverse-recovery time—a value often provided by diode manufacturers.
3. Diode breakdown can be modeled by specifying IBV and BV parameters.

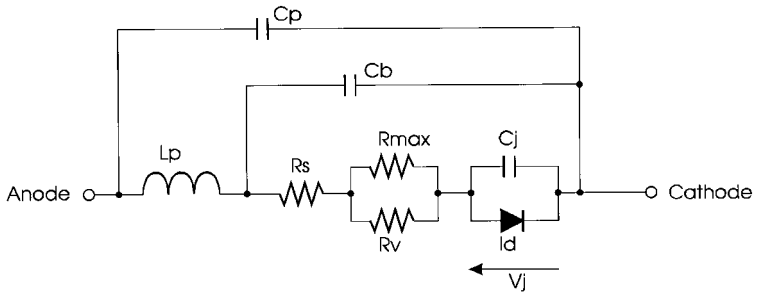

Figure 2-9 The large-signal PIN diode model. This model is temperature dependent.

Table 2-6 PIN diode model keywords

Keyword	Description	Unit	Default
	Intrinsic Model		
IS	Saturation current	ampere	1.0E–14
N	Emission coefficient		1.0
IBV	Magnitude of current at the reverse breakdown voltage	ampere	1.0E–10
BV	Magnitude of the reverse breakdown voltage	volt	∞
FC	Coefficient for forward-bias depletion capacitance		0.5
CJ0	Zero-bias *pn* junction capacitance	farad	0.0
VJ	Built-in junction potential	volt	1.0
M	*pn* Junction grading coefficient		0.5
GC1	Varactor capacitance polynomial coefficient 1	/volt	0.0

LP	Package parasitic inductance	henry	0.0

4. The reverse-bias capacitance characteristics can be more accurately modeled than the common expression derived from *pn* junction theory. The capacitance grading coefficient exponent can be expressed as a polynomial function of voltage by specifying values for GC1, GC2, and GC3.
5. The PIN diode model was derived from J. Walston, "SPICE Circuit Yields Recipe for PIN Diode," *Microwaves & RF*, November 1992.
6. Following Simon M. Sze, *Physics of Semiconductor Devices* (New York: John Wiley, 1982), the variable resistance may be modeled by setting

$$\text{K1} = \frac{3}{8} V_T \frac{W^2}{D_a \tau_a} \qquad \text{K2} = 1.0$$

where W is the width of the intrinsic region, D_a is the ambipolar diffusion coefficient, τ_a is the ambipolar lifetime, and V_T is the thermal voltage.

There are many concepts important to the physicist, but not to the diode user, that elaborate on the impact of impurities on the behavior of silicon. These can be studied in Watson [1]. The more carriers added, the lower the resistivity.

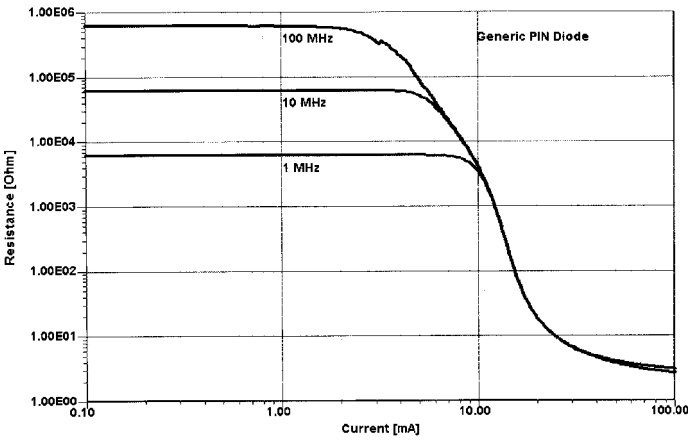

Figure 2-10 Simulated PIN diode resistance as a function of dc at 1, 10, and 100 MHz.

If one wished to vary the resistance of a given diode, in principle he/she could bring it into a semiconductor laboratory, add or subtract carriers as desired, and perhaps even make the process reversible. However, this is a slow, expensive, and impractical way to make a variable resistor; one would be better advised to take a wrench and a soldering iron and replace a component.

The PIN diode derives its value from the fact that the free-charge-carrier concentration in silicon, and hence its resistance, can be varied electronically by means of current from a simple bias supply. This can be done rapidly (in nanoseconds in some cases), reversibly, repeatably, and accurately. The thing that makes this possible is called a *junction*, the interface between the relatively pure silicon in the middle of the PIN diode (the I stands for *intrinsic*) and the heavily doped layers on either end, p^+ and n^+. The p^+ region is rich in holes; the n^+ region is rich in electrons. Both of these regions have low resistance. The I region is the variable resistive element in the diode (see Figure 2-11). In the absence of any external bias, internal effects within the crystal keep the charges fixed; the resistance of the I region is high.

When the p^+ region (anode) is biased positively with respect to the n^+ region (cathode), the interface potential "barrier" is overcome, and direct current flows in the form of holes

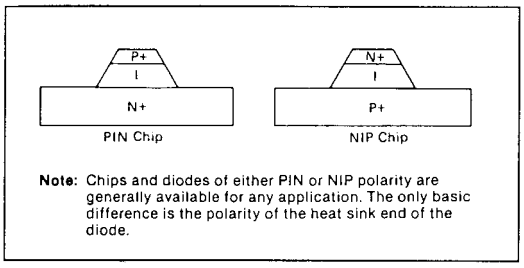

Figure 2-11 General outline of PIN diode construction.

streaming from p^+ toward n^+, with electrons moving in the opposite direction; we say that free carriers have been injected into the I region. The resistance of the I region becomes low.

The number of free carriers within the I region determines the resistivity of the region and thus the resistance of the diode.

Consider "one hole" and "one electron" drifting in opposite directions in the I region under the impetus of the applied field. Under certain conditions, imperfections in the silicon may cause these carriers to recombine. They are no longer available to constitute current or to lower the resistivity of the I region.

It can be shown that the amount of "recombination" between holes and electrons that continuously takes place in a semiconductor is governed by a property of the lattice called *lifetime*. In fact, lifetime is defined as the reciprocal of recombination rate.

Thus, $Q_S = Q_0 \exp(-t/T_L)$, where Q_S is the total amount of free charge "stored" in the I region, and T_L is the lifetime, or the mean time between recombination events. In the steady-state condition, the bias supply must deliver current to maintain a constant Q_S. The required current is

$$I_{\text{dc}} = \frac{Q_S d}{dt} = \frac{-Q_S}{T_L} \tag{2-27}$$

or $Q_S = I_{\text{dc}} T_L$, dropping the minus sign.

Ignoring some details that are not crucial to this section, we can now calculate the resistance of a given diode, of area A and thickness W. (W stands for *base width*, the width or thickness of the intrinsic layer.) The p^+ and n^+ regions have essentially zero resistance, as they are very heavily doped.

The resistivity of a given material is inversely proportional to the number of free carriers, N, and the mobility (not quite the same as velocity) of the carriers. Thus,

$$\rho = \frac{1}{q(\mu_n N + \mu_p P)} \tag{2-28}$$

where μ_n and μ_p are mobilities of electrons and holes, and N and P are numbers of electrons and holes. Simplifying, we find

$$\rho = \frac{C}{Q_S d} \tag{2-29}$$

where C is a collection of constants, and $Q_S d$ is the stored charge density (numbers per unit volume). For our piece of silicon, volume is WA, and

$$Q_S d = \frac{Q_S}{WA} \tag{2-30}$$

The resistivity is

$$\rho = \frac{CWA}{Q_S} \tag{2-31}$$

and the resistance is

$$R_S = \rho \frac{W}{A} = \frac{CW^2}{I_{\text{dc}} T_L} \tag{2-32}$$

This is a fundamental equation in PIN diode theory and design.

Rigorous analysis shows that

$$R = \frac{2kT/q}{I_f} \sinh\left(\frac{W}{2\sqrt{DT_L}} \tan^{-1}\left[\sinh\frac{W}{2\sqrt{DT_L}}\right]\right) \tag{2-33}$$

where k = Boltzmann's constant
T = temperature (in kelvins)
D = diffusion coefficient = $\mu kt/q$

For most PIN diodes, W/DT_L is less than unity, and the equation simplifies to the simple equation above.

Typical data on R_S as a function of bias current are shown in Figure 2-12. Many design choices are available, as the data indicate. Many combinations of W and T_L have been developed to satisfy the full range of applications.

Breakdown Voltage, Capacitance, Q Factor. The previous section on R_S explained how a PIN can become a low resistance, or a "short." This paragraph will describe the other state: a high impedance, or an "open." Clearly, the better PIN diode is the one that has the better on/off ratio at the frequency and power level of interest.

If we return to the undoped or intrinsic I region, we note that it is an almost lossless dielectric. As such, it has a dielectric strength of about 400 V/mil, and all PIN diodes have

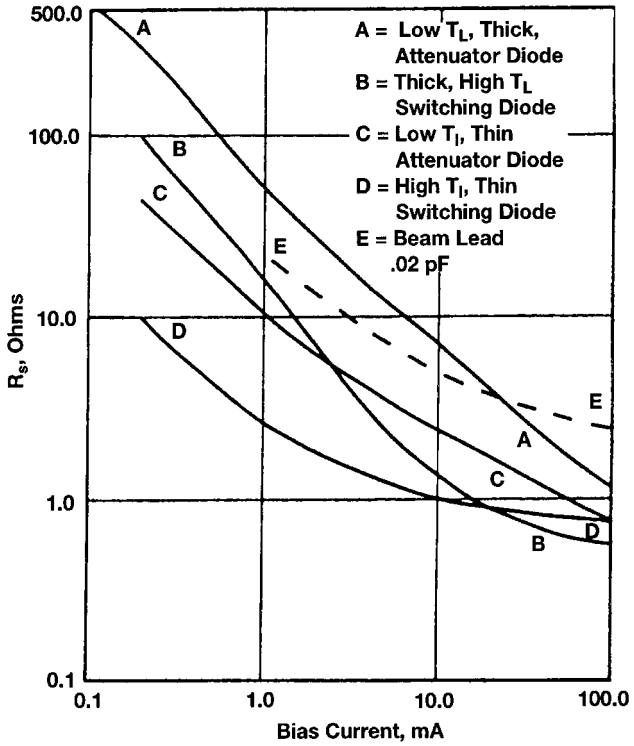

Figure 2-12 Typical series resistance as a function of bias (1 GHz).

a parameter called V_b, breakdown voltage, which is a direct measure of the width of the I region. Voltage in excess of this parameter results in a rapid increase in current flow (called avalanche current); see Figure 2-13. When the negative bias voltage is below the bulk breakdown of the I region, a few nanoamperes will be drawn. As V_b is approached, the leakage current increases often gradually, as is exaggerated in the curve. This current is primarily caused by less-than-perfect diode fabrication, although there is some contribution from temperature. Typically, the leakage current occurs at the periphery of the I region. For this reason, various *passivation* materials (silicon dioxide, silicon nitride, hard glass) are grown or deposited to protect and stabilize this surface and minimize leakage. These techniques have been well advanced over the years, and PIN diode reliability has improved as a result.

Most diodes are specified in terms of minimum V_b for a nominal leakage, usually 10 μA.

It will be noted later that RF voltage swings in excess of the rated V_b are permitted, for the mechanisms causing leakage current do not always respond at radiofrequencies. However, bulk breakdown is effectively instantaneous, and that voltage should never be exceeded.

The next characteristic of our "open" circuit is the capacitance. In simplest form, the capacitance of a PIN diode is determined by the area and width of the I region and the dielectric constant of silicon; however, we have discussed the fact that intrinsic material does contain some carriers and therefore has some conductivity. An *E* field could not exist unless all these carriers were swept out, or depleted.

Application of a reverse bias accomplishes this. At zero bias, the excess carriers on either side of the junction are separated, held apart, by "built-in" fields. This is the contact potential (about 0.5 V for silicon). If there are only a few excess carriers in the I region, this "potential" can separate the charges more easily. The junction "widens" in the sense that, starting at the p^+ and I interface, there is a region of no free carriers called the *depletion zone*. Beyond this depletion zone, the I region still contains the free charges with which it started. With the application of reverse bias, the depletion zone widens.

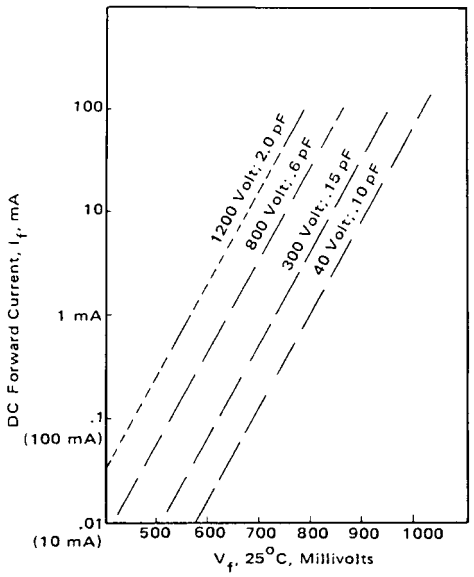

Figure 2-13 Current versus voltage for various PIN diodes.

Eventually, at a bias equal to a so-called *punchthrough* voltage (V_{PT}), the depletion zone fills the entire I region. At this voltage, the 1-MHz capacitance bottoms out and the diode Q reaches its maximum. Figure 2-14 illustrates the equivalent circuit of the I region before punchthrough.

Some very interesting facts can be derived from this model. Consider the undepleted region; this is a lossy dielectric consisting of a volume (area A, length ℓ) of silicon of permittivity 12 and resistivity ε. The capacitance is

$$12\frac{\varepsilon_0 A}{\ell} \tag{2-34}$$

and the admittance is

$$2\pi\frac{12\varepsilon_0 A}{\ell} \tag{2-35}$$

The resistance is $\varepsilon\ell/A$ and the conductance is $A/\varepsilon\ell$.

At very low frequencies, the undepleted zone looks like a pure resistor. At very high frequencies it looks like a lossy capacitor. The "crossover" frequency depends on the resistivity of the I-region material. For ε of 160 Ω/cm, the frequency is 1 GHz. Higher resistivity is generally used for PINs—say, 1000 Ω/cm, and the crossover frequency is 160 MHz.

Diode manufacturers measure junction capacitance at 1 MHz; clearly, what is measured is the depletion-zone capacitance.

If the I region thickness is W and the depletion is X_d, the undepleted region is $(W - X_d)$.

The capacitance of the depleted zone is, proportionally,

$$\frac{1}{X_d} \tag{2-36}$$

and of the undepleted zone,

$$\frac{1}{W - X_d} \tag{2-37}$$

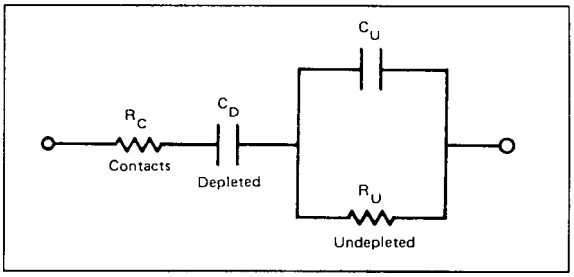

Figure 2-14 Equivalent circuit of I region before punchthrough.

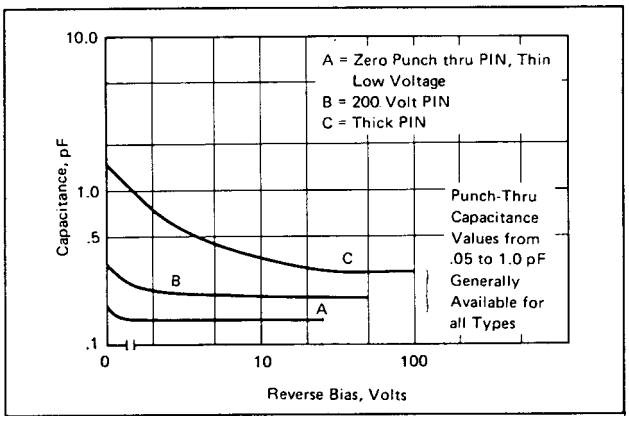

Figure 2-15 Typical 1-MHz capacitance.

The 1-MHz capacitance as a function of reverse bias is seen in Figure 2-15. The 1-MHz capacitance decreases with bias until punchthrough, where $X_d = W$. However, at microwave frequencies well above the crossover, the junction looks like two capacitors in series:

$$C_T = \frac{C_d C_u}{C_d + C_u} \propto \frac{1}{W} \tag{2-38}$$

That is, the microwave capacitance tends to be constant, independent of X_d and bias voltage.

However, since the undepleted zone is lossy, an increase in bias up to the punchthrough voltage reduces the loss.

At any given frequency, the equivalent network can now be drawn as Figure 2-16. R_v is now the equivalent series resistance of the undepleted region. Typical R_v data are shown in Figure 2-17. An alternate equivalent network is shown in Figure 2-18, and typical R shunt data are shown in Figure 2-19.

A good way to understand the effects of series resistance is to observe the insertion loss of a PIN chip shunt mounted in a 50-Ω line, as shown in Figure 2-20. An accepted way to include reverse loss in the figure of merit of a PIN diode is to write

$$Q = \frac{1}{2\pi + \sqrt{R_s R_v C}} \tag{2-39}$$

where R_s and R_v are measured under the expected forward- and reverse-bias conditions at the frequency of interest.

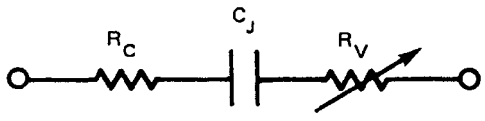

Figure 2-16 Simplified equivalent series circuit.

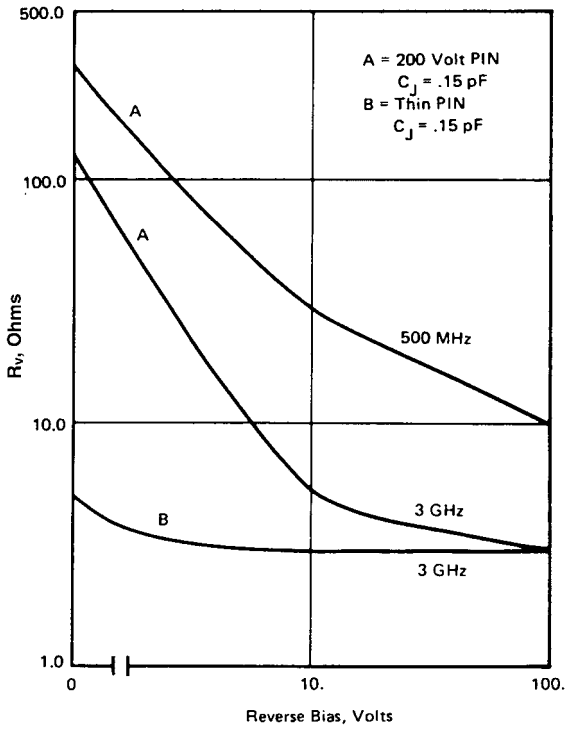

Figure 2-17 Reverse series resistance R_V.

The punchthrough voltage is a function of the resistivity and thickness of the I region. It is advisable to measure loss as a function of bias voltage and RF voltage to determine if the correct diode has been selected for your application. (*Note*: At frequencies below crossover, and diodes with thin I regions, the effective junction capacitance can increase substantially at low forward bias, on the order of 1–200 μA.)

Incidentally, if you are working with PIN or NIP chips that do not have an opaque covering, note that PIN diodes are photosensitive. Incident light causes photogeneration of carriers in the I region, increasing the chip's insertion loss.

PIN Diode Applications. If the intrinsic zone is thick (10–100 μm), we then have a high-reverse-voltage rectifier with a low forward-voltage drop at high current or, in other

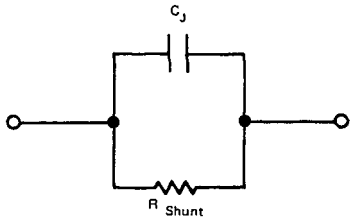

Figure 2-18 Simplified equivalent circuit, shunt.

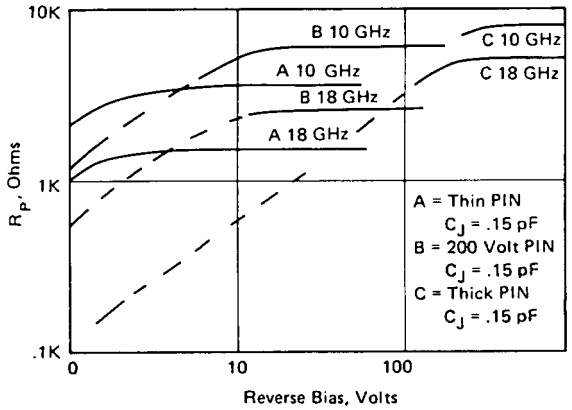

Figure 2-19 Reverse shunt resistance, R_p.

words, a highly efficient rectifier. The low forward voltage results from the fact that the conductivity of the I zone can be modulated by large amounts of charge carriers injected from the *p* and the *n* zones.

Another application of PIN diodes is the high-frequency (HF) field. Here, the fact is exploited that, due to the long carrier lifetime at frequencies beyond approximately 10 MHz, a rectifying effect will no longer occur and the PIN diode rather behaves like a real resistance, the magnitude of which depends on the forward direct current passed by the device and

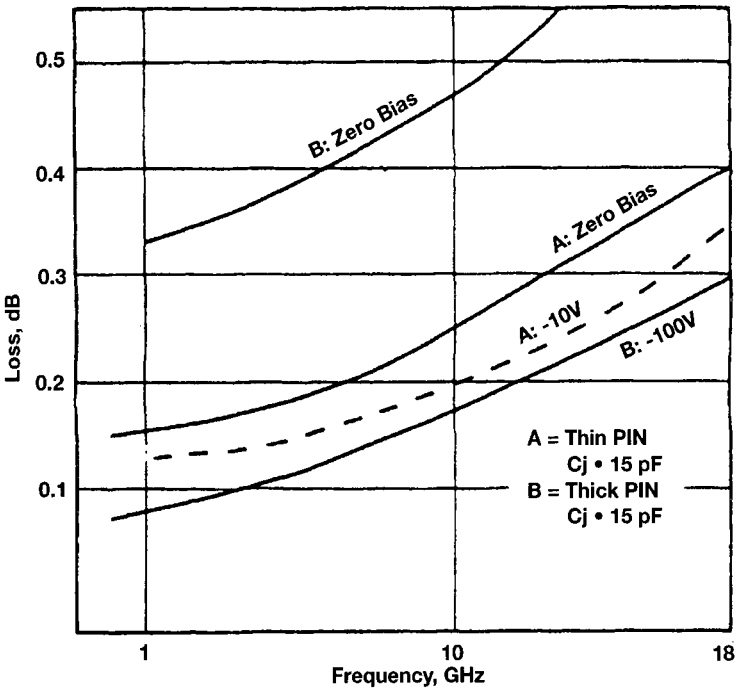

Figure 2-20 Insertion loss versus frequency.

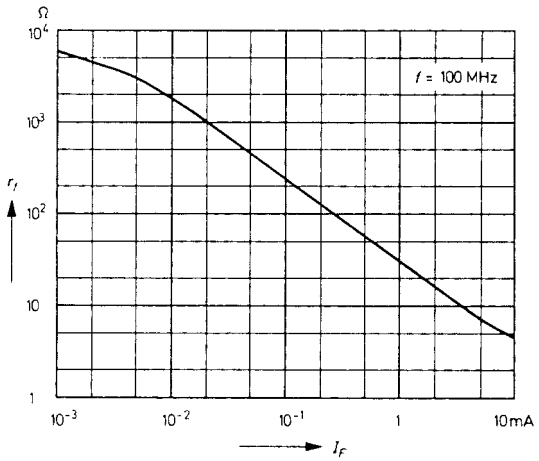

Figure 2-21 Forward resistance versus forward current.

produces an equal effect on both half waves of the HF signal. In view of this behavior, the PIN diode can be used as a switch or a variable resistor for HF signals. Thus it becomes possible, for example, to subject an HF signal to amplitude modulation by means of an AF-controlled PIN diode.

An important application of PIN diodes that has found favor in recent times is for dc-operated attenuators in TV tuners and antenna distribution amplifiers. Figure 2-21 shows the real HF forward resistance r_f as a function of the forward current I_f, measured at 100 MHz. Figures 2-22 and 2-23 show second-order IMD and cross-modulation for PIN diodes.

Applying the PIN in Amplitude Control of High-Frequency Signals. In conventional transistorized TV tuners, automatic gain control (AGC) is usually achieved by varying the emitter current of the input transistor. This method exploits the fact that the input transistor exhibits maximum gain at a certain level of emitter current and that this gain decreases when the emitter current is either increased or decreased relative to this point. Since modulation capacity and cross-modulation resistance grow with the emitter current, "upward" gain control has lately become the preferred solution, and according to it, gain reduction is achieved by an increase of the input transistor's emitter current. An input stage based on this design, therefore, is least resistant to cross-modulation when receiving a signal from a weak transmitter because it is operating at or below the point at which AGC action begins. This effect is particularly disadvantageous when the signal of a weak transmitter is to be received in the presence of a strong local transmitter. The unsatisfactory cross-modulation properties of such an input stage manifest themselves more and more frequently in the form of image perturbations as the TV reception band is crowded by an increasing number of transmitters. Another disadvantage is the variation in the transistor parameters that results from the control action. The variations affect antenna matching at the input and the response of the RF filter at the output.

To obviate these problems, methods being adopted today provide for the input stage to be equipped with cross-modulation-resistant transistors with fixed bias, gain control being provided by a variable attenuator preceding the transistor(s). The input-filter termination

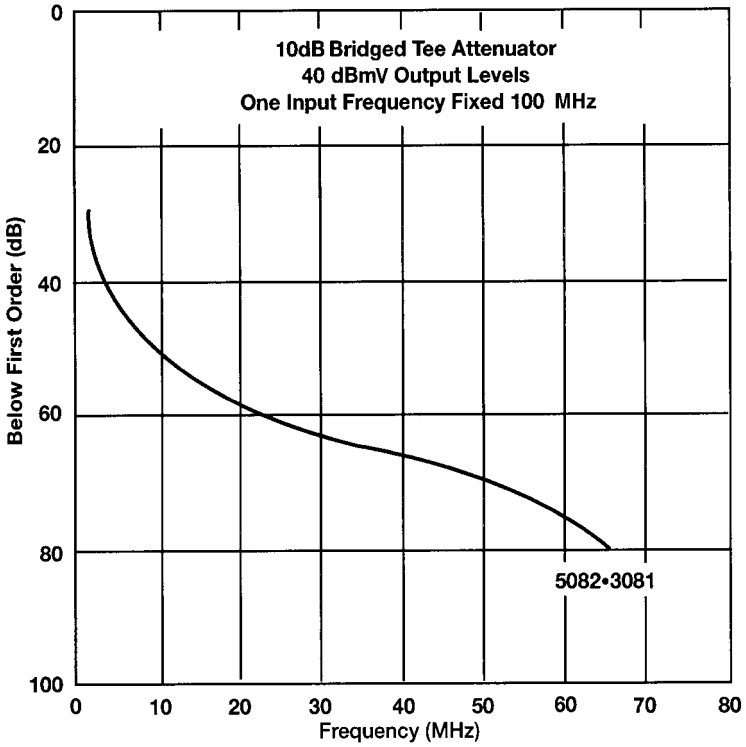

Figure 2-22 Second-order IMD in a PIN diode. Equation (1-48) can be used to determine the diode's IP_2 from the absolute values of its fundamental and IM_2 outputs.

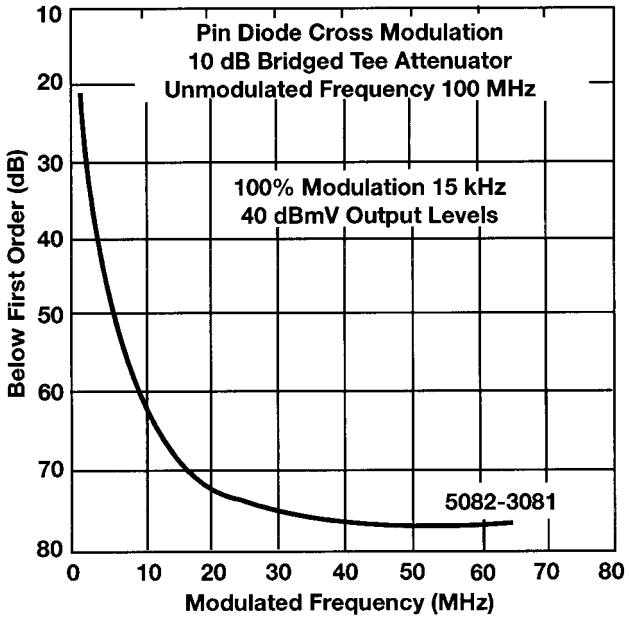

Figure 2-23 Cross-modulation in a PIN diode. Equation (2-61) relates cross-modulation level to IMD.

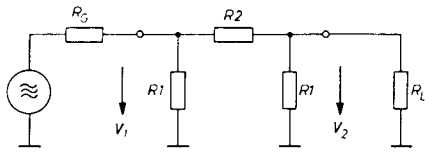

Figure 2-24 Basic circuit of a π-mode filter attenuator.

provided by this attenuator must be independent of the degree of attenuation to preserve the filter's response characteristics.

The first two requirements are met by the properties of the PIN diode and the latter requirement can be met by designing a PIN diode control in the form of a π network, a schematic of which is shown in Figure 2-24. The attenuation of a matched π network is expressed by the following equations:

$$\frac{a}{\text{dB}} = 20 \log \frac{Z + R_2}{R_2 - Z} \tag{2-40}$$

$$\frac{a}{\text{dB}} = 20 \log \left(\frac{R_1}{Z} + \sqrt{\frac{R_1^2}{Z^2} + 1} \right) \tag{2-41}$$

Figure 2-25 plots the relationship between the resistance levels of R_1 and R_2 and the input and output voltages of the π network. Figure 2-26 shows the circuit diagram of an implementation of the π network composed of PIN diodes. The resistance characteristic required according to Figure 2-25 is achieved approximately by varying the control current I_{co}.

If the control current I_{co} in Figure 2-26 equals zero, then—due to the fact that $R_1 = R_2$ and $R_3 = R_4$—the auxiliary voltage V_h causes forward currents of equal magnitude to flow through diodes D_1 and D_3. The voltage drops across R_1 and R_2 are of equal magnitude, so that no current passes through diode D_2. Therefore, the latter presents a high resistance, whereas D_1 and D_3 present a low resistance. Under these conditions, the network produces maximum attenuation. A control current I_{co} reduces the forward currents through D_1 and D_3 and allows a forward current to be passed by diode D_2. When it has attained its maximum value, diodes

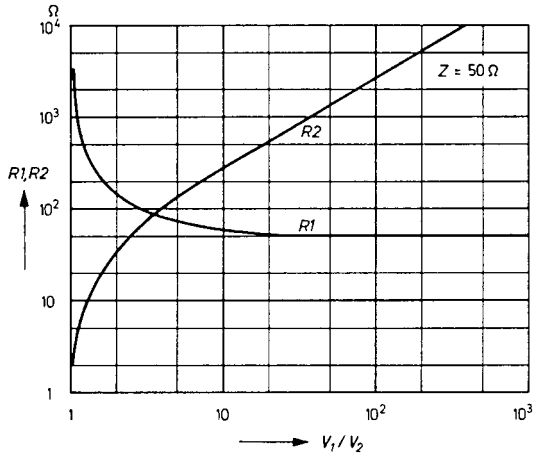

Figure 2-25 Values of R_1 and R_2 in Figure 2-24 versus relation of input and output voltage.

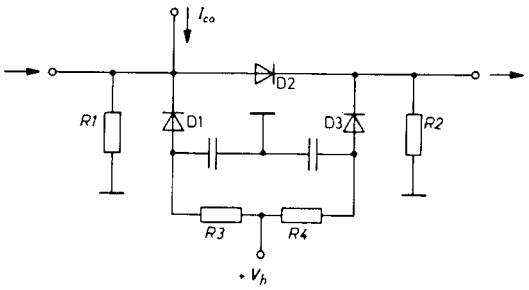

Figure 2-26 PIN diode π-mode attenuator.

D_1 and D_3 are blocked—that is, they are high-ohmic—and D_2 is low-ohmic. Under these conditions, the network produces its minimum attenuation.

If the maximum attenuation of the π network is to be increased, it is possible to make the two shunt diodes D_1 and D_3 more low-ohmic than the impedance Z, although this would reduce the reflection coefficient of attenuation. For example, if a reflection coefficient of about 7 dB is accepted over the entire control range, then a maximum attenuation of 25–30 dB could be achieved in the VHF range. The series inductances of the transverse diodes and the shunt capacitance of the series diode are responsible for this relatively unsatisfactory value. Improved attenuation is brought about with the integrated π network described in the next section.

Example: A PIN Diode π Network for TV Tuners. The since-discontinued TDA1053 is an example of an integrated PIN π network attenuator intended for TV-tuner use. It comprises three silicon planar PIN diodes connected to form a π network (Figure 2-27) and serves for the electronic amplitude control of the input signals of TV tuners and antenna distribution amplifiers in the 40–1000-MHz range. Its input and output impedances remain constant over the entire control range. This can also be achieved with discrete diodes.

The TDA1053 was normally supplied with vertical leads. The characteristics stated below apply to devices of this configuration.

MAXIMUM RATINGS OF INDIVIDUAL DIODES

Reverse voltage	V_R	30	V
Forward current at $T_{amb} = 25$ °C	I_F	50	mA
Junction temperature	T_j	125	°C
Storage temperature range	T_s	−55 to +125	°C

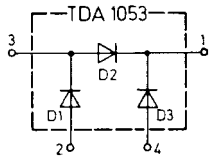

Figure 2-27 Internal circuitry of the TDA1053.

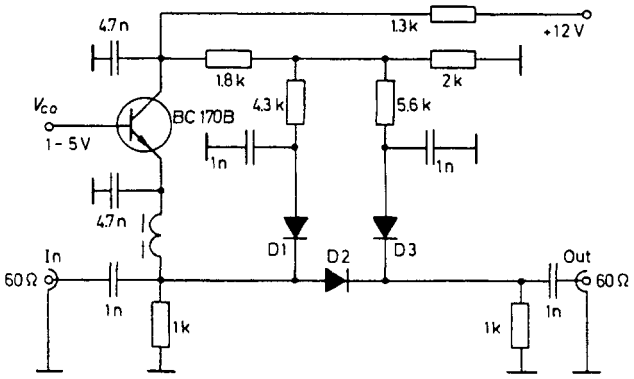

Figure 2-28 Test and application circuit.

MAXIMUM RATINGS OF THE π NETWORK

Ambient operating temperature range when operating according to Figure 2-28	T_{amb}	100	°C

CHARACTERISTICS OF INDIVIDUAL DIODES AT T_{amb} = 25 °C

Forward voltage at I_F = 50 mA	V_F	< 1.2	V
Forward current at V_R = 15 V	I_R	< 500	nA
Differential forward resistance:			
At I_F = 10 mA, f = 100 MHz	r_f	5	Ω
At I_F = 10 µA, f = 100 MHz	r_f	1.4	kΩ

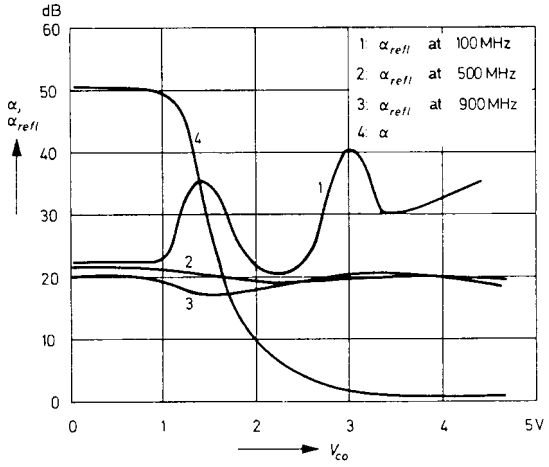

Figure 2-29 Attenuation and reflection attenuation versus control voltage.

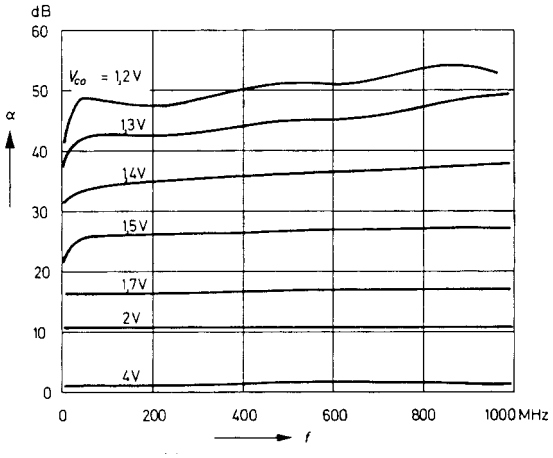

Figure 2-30 Attenuation versus frequency.

CHARACTERISTICS IN THE TEST CIRCUIT (FIGURE 2-28) AT T_{amb} = 25 °C

Voltage for 1% cross-modulation	V_{cr}	1	V
Attenuation in the 40–1000-MHz range:			
At V_{co} = 1.5 V (1–2 V)	a_{max}	45 (> 36)	dB
At V_{co} = 5 V (4–5 V)	a_{min}	1.5 (< 2)	dB
Reflection coefficient in the 40–1000-MHz range over the entire control range, depending on circuit design	a_{refl}	20 (> 16)	dB

These data reveal that the compact design of the three PIN diodes in a common 50B4 plastic package guarantees favorable values for minimum and maximum attenuation, as well as reflection attenuation. The test and application circuit shown in Figure 2-28 also comprises the transistor control-signal amplifier. The typical characteristic of the attenuation and the reflection attenuation for this circuit are shown in Figure 2-29, as a function of the control voltage V_{co}. Figure 2-30 shows the attenuation at different control voltages, as a function of frequency.

2-1-4 Tuning Diodes

Introduction. In recent years, continuous development of tuning diodes—also known as *varactors* or *varicaps*—together with increased commercial and military use has led to substantial improvement in Q, reproducibility, and reliability. Concurrently, new techniques for producing and controlling a hyperabrupt dopant profile in the semiconductor permit the capacitance–voltage law to be much faster than the classical square root or cube root behavior.

Current tuning diode materials include silicon and gallium arsenide; silicon is favored for low cost and lower Q applications from HF through microwave frequencies. Hyperabrupt varactors, also of silicon, are finding many applications in commercial television tuners, where their high tuning ratios, linear tuning, and low cost are needed. New developments include low-capacitance hyperabrupts for microwave and wireless applications.

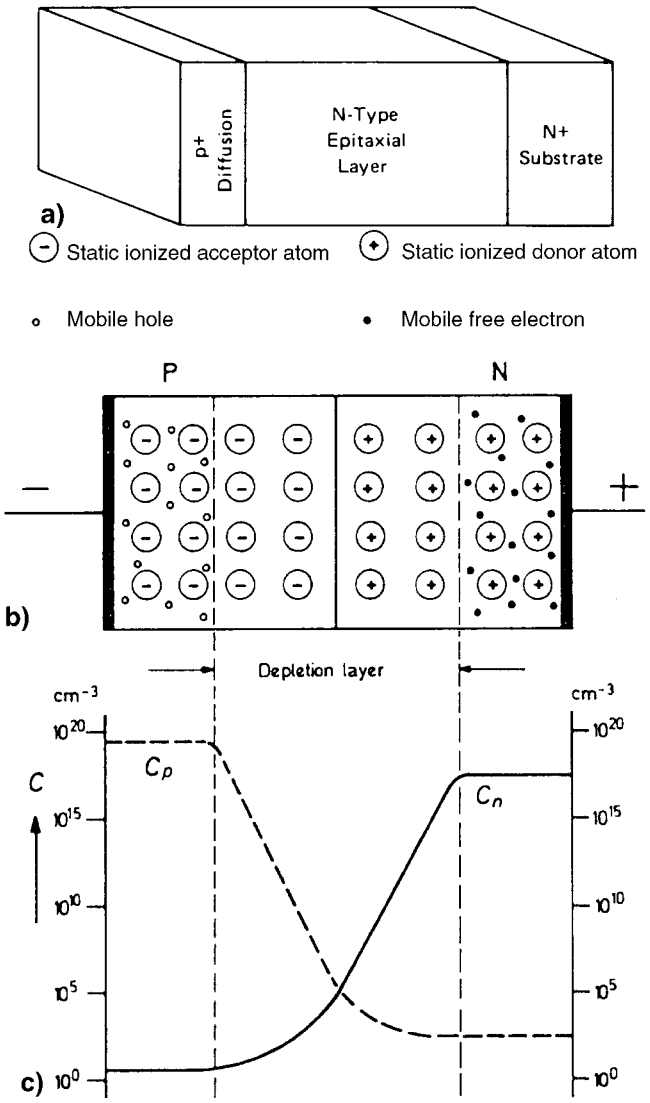

Figure 2-31 (a) Basic PIN structure; (b) cross section of a reverse-biased *pn* junction; and (c) density distribution of free charge carriers.

Gallium arsenide is used with high operating frequency and dictates the highest Q possible, as in parametric amplifiers and millimeter multipliers.

This section will acquaint the reader with tuning diodes: how they work, and what they can or cannot be expected to do in an electronic circuit. The basic properties of a tuning diode will be described in terms of the parameters that manufacturers use in characterizing them. The following topics will also be addressed:

- Capacitance ratio with respect to voltage and voltage breakdown
- Q as a function of design and operating conditions

- Stability—leakage current, temperature coefficient, and post-tuning drift
- Distortion products
- Packaging parasitics
- Applications—suggestions on how to specify a varactor

Tuning Diode Physics

Introduction. All junction diodes are made up of the same physical parts: a *pn* junction, a carefully controlled epitaxial layer, and a very-low-resistance substrate. These parts are shown in Figure 2-31.

No matter what type of junction device we are discussing—a tuning diode, a step-recovery diode, or a PIN diode—these parts are all present; the main difference between these devices is the resistivity and thickness of the epitaxial layer. Tuning diodes and multiplier diodes need epitaxial layers where both the resistivity and thickness are carefully controlled.

Abrupt Junction. An abrupt-junction diode is one in which the p^+ diffused region of the diode is much more highly doped than the epitaxial layer. Also, the high doping drops to the doping level of the epitaxial layer in a distance that is short compared to the epitaxial layer thickness, and the doping level of the epitaxial layer is constant over its thickness. This is shown in Figure 2-32, with the corresponding C–V curve shown in Figure 2-33. When these requirements are satisfied, the diode capacity, diode area, epitaxial layer doping level, and diode voltage are related by

$$\frac{C(V)}{A} = K\left(\frac{N}{V+\varphi}\right)^n \tag{2-42}$$

where $C(V)$ = capacitance of the diode at voltage V
A = area of the diode
N = doping level of the epitaxial layer

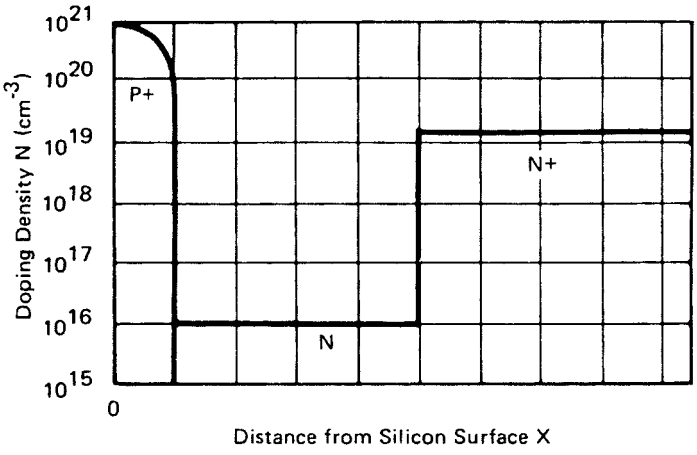

Figure 2-32 *N–X* abrupt junction.

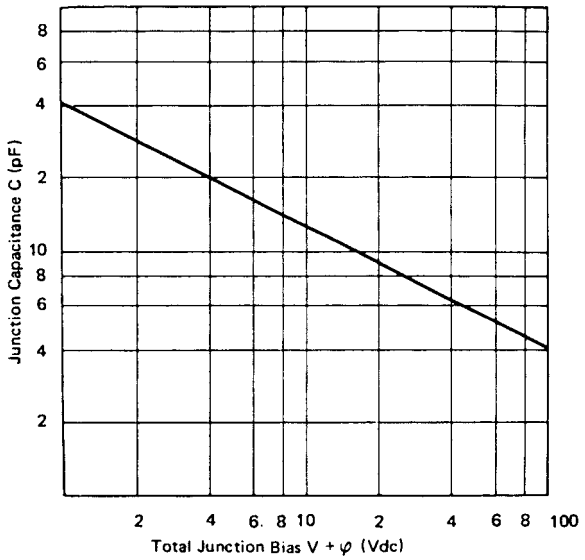

Figure 2-33 Capacitance versus total junction bias for abrupt-junction diode.

V = voltage applied to the diode
φ = built-in potential of the diode (0.6–0.8 V)
n = slope of diode C–V curve; $n \approx 0.5$ for an abrupt-junction diode
K = constant

As a consequence of the physical properties of a *pn* junction, a depletion layer is formed between the *p* and *n* regions whose width depends on the voltage applied to the diode. The capacitance of the diode is inversely proportional to the width of the depletion layer; that is, $C \sim 1/\ell_0$. In addition, the series resistance of the diode is proportional to the width of the undepleted epitaxial layer. Thus, as diode reverse bias is increased, the depletion layer increases, causing a decrease in capacitance and a decrease in series resistance. As the diode reverse bias is increased further, a point is reached where the electric field caused by the reverse bias reaches a critical level, and current through the diode increases rapidly; this is

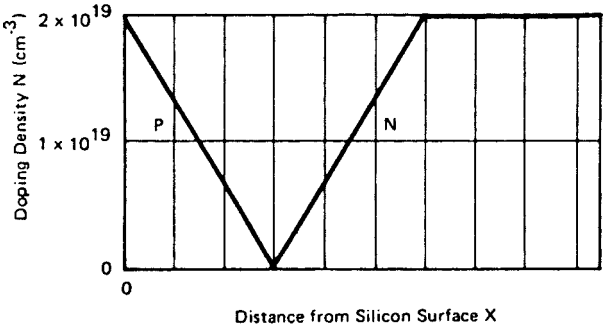

Figure 2-34 *N–X* linearly graded junction.

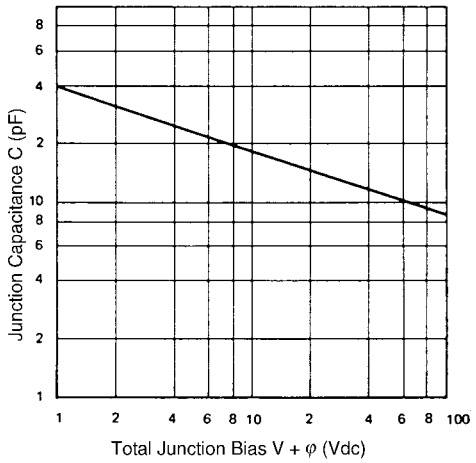

Figure 2-35 Capacitance versus total junction bias for linearly graded junction.

breakdown voltage of the diode. If, at the breakdown voltage, the epitaxial layer is not completely depleted, the diode will have excessive series resistance. Conversely, if the epitaxial layer is depleted before the breakdown voltage is reached, no further capacitance decrease occurs after the total depletion, and a condition called *punchthrough* occurs.

While, in the ideal case, voltage breakdown will occur just as the epitaxial layer is totally depleted, this seldom occurs in practice, and we generally have a condition of either punchthrough or excess series resistance.

Linearly Graded Junction. If, instead of the junction profile shown in Figure 2-32, we have a p^+ region and an n region whose doping levels increase linearly with distance from the pn junction as shown in Figure 2-34, with its corresponding C–V curve in Figure 2-35, then we have what is called a linearly graded junction diode. This diode follows Eq. (2-42) with the exception that the exponent n is equal to $\frac{1}{3}$. This means that, for a given voltage change, the linearly graded junction will have a smaller capacitance change than an abrupt-junction diode. Since, in most cases, the designer is looking for the maximum

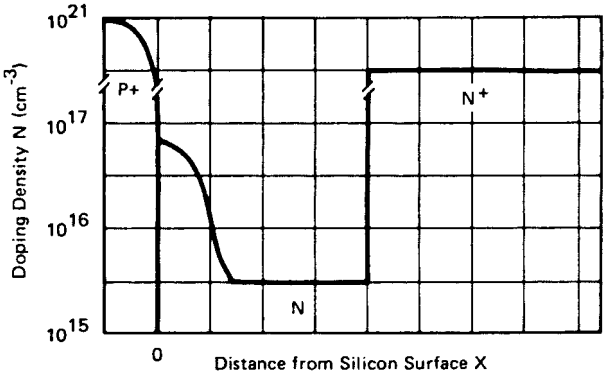

Figure 2-36 *N–X* hyperabrupt-junction diode.

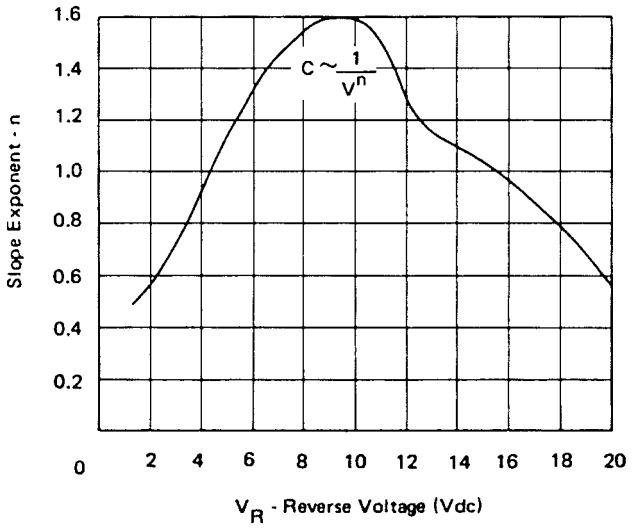

Figure 2-37 Typical *n* versus reverse voltage characteristic for hyperabrupt-junction diode.

capacitance change obtainable, the linearly graded junction is not used as a tuning diode. This structure found its greatest use several years ago as a "cube law" multiplier, but even this use has decreased as new structures have been developed.

Hyperabrupt Junction. The hyperabrupt-junction diode provides a greater capacitance change than the abrupt-junction diode for a given voltage change, as well as a linear frequency versus voltage characteristic over a limited voltage range. The structure of the hyperabrupt-junction diode is shown in Figure 2-36 and can be seen to be an abrupt-junction diode with an additional, increased doping level at the *pn* junction. This diode also follows Eq. (2-42) with the exception that n is not a function of voltage and is generally in the range of 0.5–2. A typical curve of n versus voltage is shown in Figure 2-37.

The C–V curve in a hyperabrupt-junction diode is shown in Figure 2-38 and is seen to start at a high value of capacitance per unit area at low bias (high epitaxial doping) and change to a lower value of capacitance per unit area (low epitaxial doping) at high bias. The details of the curve depend on details of the shape of the more highly doped region near the *pn* junction.

Unfortunately, with a hyperabrupt-junction diode, you must settle for a lower Q than an abrupt-junction diode with the same breakdown voltage and same capacitance at 4 V.

It should be noted that any diode that has an n value that exceeds 0.5 at any bias voltage is, by definition, a hyperabrupt-junction diode. Thus, the hyperabrupt-junction diode family can have an infinite number of different C–V curves. Since the abrupt-junction diode has a well-defined C–V curve, the capacitance value at one voltage is sufficient to define the C–V capacitance at any other voltage. This is not the case for the hyperabrupt-junction diode. In order to adequately define the C–V characteristics of a hyperabrupt-junction diode, two and sometimes three points on the curve must be specified.

Silicon Versus Gallium Arsenide. Everything mentioned so far applies to both silicon and gallium arsenide (GaAs) diodes. The main difference between silicon and GaAs from a

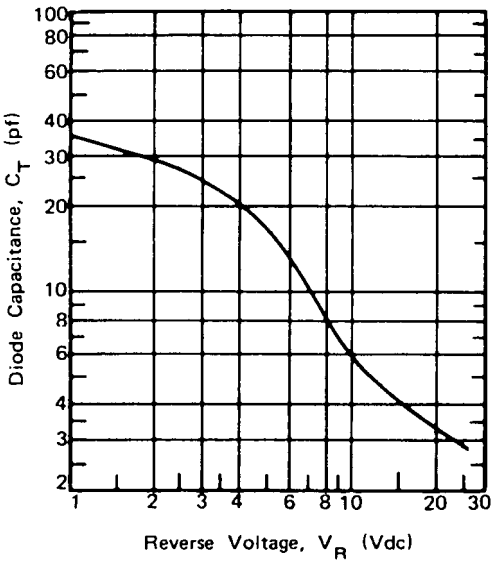

Figure 2-38 Capacitance versus junction bias for hyperabrupt-junction diode.

user's point of view is that higher Q can be obtained from GaAs devices. This is due to the lower resistivity of GaAs from a given doping level N. The resistivity of the epitaxial layer, or substrate, of a diode is given by

$$\rho = \frac{1}{Ne\mu} \tag{2-43}$$

where ρ = the resistivity
N = the doping level of the layer
e = the charge on an electron
μ = is the mobility of the charge carriers in the layer

Gallium arsenide has a mobility about four times that of silicon and, thus, a lower resistivity and higher Q for a given doping level N. Since diode capacitance is proportional to $\sqrt{N}$, independent of resistivity, a silicon diode and a GaAs diode of equal area and doping will have a capacitance difference proportional to the square root of the dielectric constant ratio. This gives the GaAs diode a 5% higher capacitance and is thus of little practical significance. The penalty paid for using GaAs is an unpassivated diode and a more expensive diode due to higher material and processing costs. If the higher Q of the GaAs device is not really needed, a substantial price saving will be obtained by using a silicon device.

Planar Versus Mesa Construction. The two basic construction techniques used to manufacture tuning diodes are planar and mesa; cross sections for both of these devices are shown in Figure 2-39. The planar process, which is the backbone of the integrated circuit industry, lends itself to large-volume production techniques and is the one used for the 1N series of tuning diodes. Mesa processing, on the other hand, requires more

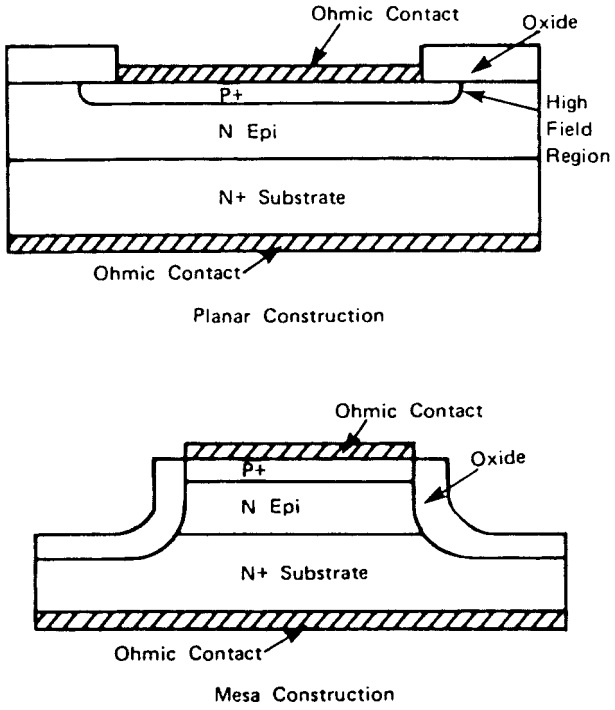

Figure 2-39 Cross sections of planar and mesa devices.

processing steps and is generally done on a wafer-by-wafer basis. This results in a more costly process and thus a more expensive diode. All microwave tuning diodes are of mesa design because of greatly higher Q. Due to the relatively small radius of curvature at the junction edge of a planar diode, the electric field in this area is greater than the electric field in the center (flat) portions of the junction. As a result, the breakdown voltage of the diode is determined by both the epitaxial resistivity and the radius of curvature of the junction edge. Thus, for a given breakdown voltage, a planar diode must use higher resistivity epitaxial material than a mesa diode, which has a completely flat junction. The end result is that the planar diode has a greater series resistance than a mesa diode for the same capacitance and breakdown voltage, and thus lower Q.

Capacitance

Capacitance Ratio. From the user's point of view, the capacitance ratio is simply the capacitance change available in the circuit. Thus, a user tuning from, say, –4 to –45 volts defines capacitance ratio as

$$R = \frac{C_T(-4)}{C_T(-45)} \tag{2-44}$$

where C_T includes C_J plus C_P plus C_F. The manufacturer, however, defines C_T as $C_J + C_P$.

To explore the significance of this difference, let's take two examples, one with a large C_J and another with a small C_J, in chip, package, and "typical" fringe situations. Both are 45-V tuning varactors.

Device	C_{J0}	C_{J45}	Ratio
A	0.6 pF	0.1 pF	6.0
B	15.0 pF	2.5 pF	6.0

Put both devices in a standard 023 package with C_P (strap and ceramic) of 0.18 pF:

Device	C_{T0}	C_{T45}	Ratio
C	0.78 pF	0.28 pF	2.75
D	15.18 pF	2.68 pF	5.67

Notice the drop in capacitance ratio, especially for the low-C_J diode. If we now add a typical 0.04 pF for external fringe capacitance, we get the following results:

Device	C_{T0}	C_{T45}	Ratio
C	0.82 pF	0.32 pF	2.56
D	15.22 pF	2.72 pF	5.6

The reduction in capacitance ratio, and thus circuit tuning capability, by the fringing fields is quite obvious and amounts to 7% in this example.

Because of the often stringent specifications on tuning ratio, it is mandatory that the manufacturer and customer clearly agree on the exact design of the holder used to measure the varactor in question.

Having described how to measure capacitance, it is relatively easy to describe the results. The section on diode physics described the various types of "laws," or C–V curves, and we will not repeat them here. Nonetheless, several important points must be covered.

The first is "available capacitance swing." The laws indicate a steadily decreasing capacitance with voltage, which indicates that the epitaxial region is widening and the electric field is increasing. (For an abrupt junction, since $C \propto 1/\sqrt{V}$, the depletion zone with W is increasing as $\sqrt{V}$, and the electric field V/W increases as $\sqrt{V}$.)

Two things can happen:

1. The junction width widens so that the entire intrinsic region is depleted. The capacitance bottoms out, resulting in voltage punchthrough.
2. The electric field exceeds the dielectric strength of silicon (or GaAs), and "solid-state discharge" or "avalanche" current is drawn.

The diode impedance drops, the varactor no longer "varacts," and circuit operation ceases. Moreover, if more than a few milliamperes of current is drawn, localized overheating may destroy the diode, resulting in breakdown voltage. All varactors are characterized for breakdown voltage—for example, 45 V minimum.

The theoretical tuning varactor is designed so that the punchthrough occurs at a voltage equal to the voltage breakdown of the diode. Logically, this means that in order to obtain

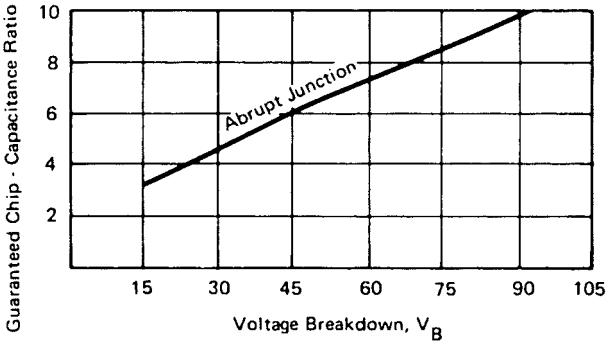

Figure 2-40 Capacitance ratio versus breakdown voltage.

greater tuning ratios, it is necessary to be able to increase the depletion-layer width without reaching punchthrough or breakdown. You must have a thicker epitaxial region to make this possible.

Figure 2-40 shows catalog ratio values, from zero bias to breakdown, as a function of breakdown voltage necessary. In the next section, on Q, we will discuss other elements in your choice of V_B.

To complete this section, we should mention that semiconductor processing control has been refined so well that capacitance tracking to within ±1% over the full range from zero to breakdown is now readily obtainable in production quantities.

Temperature Coefficient of Capacitance (T_{CC}). Unfortunately, since most datasheets give the value of T_{CC} at 4 V, it is sometimes assumed that this value applies at all bias voltages. This is not the case. Consider Eq. (2-45), a rewritten form of Eq. (2-42):

$$C(V) = \frac{C(O)}{(V + \varphi)^n} \tag{2-45}$$

Taking the derivative of this with respect to temperature T we have

$$\frac{dC(V)}{dT} = \frac{+nC(O)}{(v + \varphi)(v + \phi)^n} \frac{d\varphi}{dT} \tag{2-45a}$$

or, after substituting Eq. (2-45):

$$T_{CC} = \frac{1}{C(V)} \frac{dC(V)}{dT} = \frac{-n}{(V + \varphi)} \frac{d\varphi}{dT} \tag{2-46}$$

As a first approximation, we can say that $d\varphi/dT = -2.3$ mV/°C over the temperature range of interest.

From Eq. (2-46) we can draw the following conclusions:

1. The temperature coefficient is inversely proportional to the applied voltage.
2. The temperature coefficient is directly proportional to the diode slope, n.

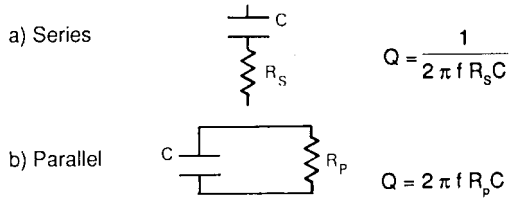
For an abrupt-junction diode that has a constant value of n (0.5), the temperature coefficient has a smooth curve in the form $K/(v + \varphi)$. However, in the case of hyperabrupt-junction diodes, n is a function of voltage, and the shape of the T_{CC} curve depends on the details of the $n(V)$ curve. A typical T_{CC} curve for an abrupt-junction diode is shown in Figure 2-41 and for an Alpha DKV6520 series hyperabrupt-junction diode in Figure 2-42. The inflection in the hyperabrupt T_{CC} is due to the fact that in this voltage range $n(V)$ is increasing faster than $1/V$, giving an increase in T_{CC}. It should also be noted, however, that over the range of the T_{CC} minimum the temperature coefficient is relatively constant, and operation in this area may be advantageous in some applications where a restricted tuning range can be used.

Q Factor or Diode Loss

Definitions. The classical definition of the Q of any device or circuit is

$$Q = \frac{2\pi \times \text{Energy stored}}{\text{Energy dissipated per cycle}} \tag{2-47}$$

For a capacitor, two formulations are possible:



Clearly, the two definitions must be equal at any frequency, which establishes

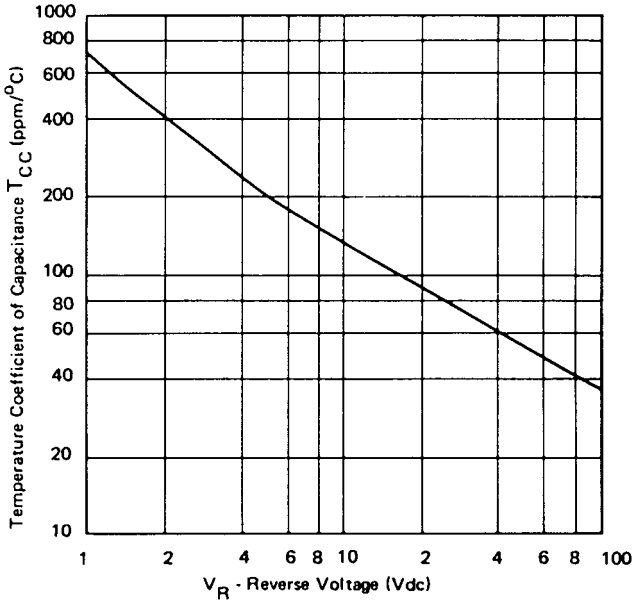


Figure 2-41 Temperature coefficient of capacitance versus tuning voltage for an abrupt-junction diode.

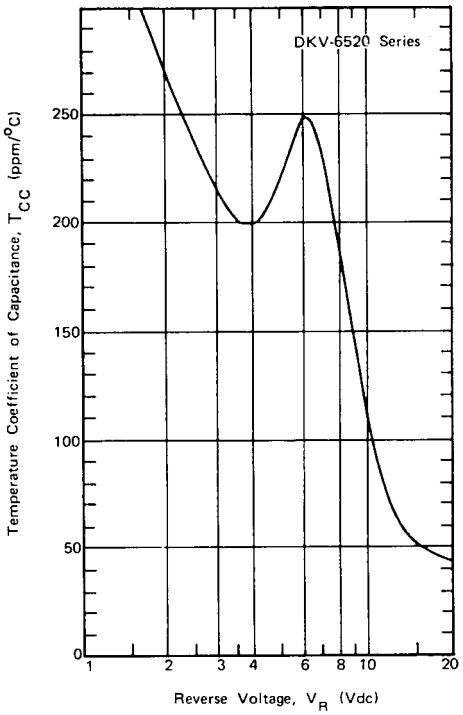

Figure 2-42 Temperature coefficient of capacitance versus tuning voltage ($T_A = 25$ °C) hyperabrupt-junction diode.

$$R_P = \frac{1}{(2\pi f)^2 C^2 R_S} \tag{2-48}$$

In the case of a high-Q tuning diode, the proper physical model is the series configuration, because the depleted region is almost perfectly pure capacitance, and the undepleted region, due to its relatively low resistivity, is almost a pure resistor in series with the capacitance. Furthermore, the contact resistances are also clearly in series. Q, then, for a tuning diode, is given by

$$Q_{(-v)} = \frac{1}{2\pi f_o R_{(-v)} C_{(-v)}} \tag{2-49}$$

where f_o is the operating frequency, $C_{(-v)}$ is the junction capacitance, and $R_{(-v)} = R(\text{epi}) + R_{C'}$, the sum of the resistance of the undepleted epitaxial layer and the fixed contact resistance.

Cutoff frequency, f_c, is defined as that frequency at which Q equals unity. Thus,

$$f_{c_{(-v)}} = \frac{1}{2\pi R_{(-v)} C_{(-v)}} \tag{2-50}$$

Historically, the tuning diode business has specified Q at 50 MHz, despite the fact that Q values of microwave diodes are so high that it is almost impossible to measure them at 50

Table 2-7 Parameters for 0.6-pF diode

Breakdown Voltage V_B	Resistivity ($\Omega \cdot$ cm)	Junction Diameter (mills)	Epitaxial Region (μm)	Depleted Epitaxial $V = -4$ V (μm)	Undepleted Epitaxial $V = -4$ V (μm)	R Undepleted (Ω)	R_{sp} (Ω)	Q_4
30	0.31	2.4	1.37	0.54	0.83	0.81	0.18	5200
45	0.52	2.8	2.25	0.73	1.52	1.86	0.15	2600
60	0.74	3.2	3.20	0.90	2.30	3.24	0.13	1500
90	1.25	3.7	5.27	1.21	4.06	7.17	0.10	700

MHz. Instead, as discussed below, Q is measured at microwave frequencies (e.g., 1–3 GHz) and related to 50 MHz by the relationship

$$Q_{(f1)} = Q_{(f2)} \frac{f_2}{f_1} \tag{2-51}$$

which derives quickly from the assumption that f_c is independent of the measuring frequency.

Since both junction capacitance and epitaxial layer resistance are functions of the applied bias, it is not possible to calculate Q as a function of bias from a measurement of capacitance alone. Catalog specifications typically show Q at –4 V, together with the capacitance at two or more voltages.

Relative to $Q_{(-4)}$, Q increases faster than the reduction in capacitance for bias greater than 4 V and, conversely, decreases faster for bias less than 4 V.

In the following section, we will discuss the diode design parameters that determine Q. Following this, we will describe some elementary Q measurement techniques.

Causes. In the discussion of device physics, the resistivity of the epitaxial region was discussed, together with its impact on punchthrough and breakdown. For example, Table 2-7 supplies typical resistivity and relative parameters of 0.6 pF ($C_{J(4)}$) diodes of different breakdowns. If we remember that if at any bias lower than breakdown the epitaxial region is not completely depleted, it follows that the undepleted portion presents a resistance in series with the pure capacitance of the depleted zone. The magnitude of this "undepleted" resistance is also shown in the table.

The entry R_{sp} ($R_{spreading}$) is the series resistance between the epitaxial region and the low-resistivity substrate. The calculations are for idealized cylindrical epitaxial regions of uniform resistivity, low-resistivity contact on the anode (top), and low-resistivity substrate on the cathode. This resistance is constant, independent of bias; also shown are epitaxial thickness region and width of the depletion zone at –4 V bias.

Note the substantial reduction in Q for high-voltage diodes caused by the increased epitaxial layer resistance; this is true for any value of capacitance or any type of junction. For greater voltage breakdown, the epitaxial region thickness must be increased, which requires an increase in epitaxial layer resistivity; the higher the resistivity of the undepleted zone, multiplied by the fact that it is much wider for high-voltage diodes, means the resistance increases substantially.

Consequently, a rule of thumb emerges: For maximum Q, never choose a tuning diode with a voltage breakdown in excess of what is needed for the necessary tuning range. If the

Table 2-8 ***Q*** **versus bias for 0.6-pF diode**

Breakdown Voltage V_B	C_{J0}	$Q(0)$	$C_J(-4)$	$Q(-4)$	$C_J(-10)$	Q (−10)	$C_J(-30)$	$Q(-30)$	$C_J(-45)$	$Q(-45)$	$C_J(-60)$	$Q(-60)$	$C_J(-90)$	Q(−90)

60	8.4	7.5	1400
90	10.2	8.7	650

required tuning range is an octave, requiring a 4:1 ratio, the selection of a 30-V diode will result in diode losses half those of a 60-V diode.

Table 2-8 lists capacitance and Q for each of these chips as a function of bias. Please remember that Q is calculated at 50 MHz.

Table 2-9 rewrites the data of Table 2-8 to show available capacitance ratios between zero bias and breakdown. The first column is the theoretical optimum, as tabulated. The second column is the typical catalog specification. The reduction in tuning ratio below theoretical optima is caused by nonideal junction fabrication. The junctions are never perfectly abrupt.

Although the tables and numbers given refer to abrupt-junction silicon devices, the principle applies without exception to all types of tuning diodes. For comparison, Table 2-10 lists available ratios and Q values for a number of different varactors. The high Q values for GaAs and the low values for hyperabrupts are apparent.

One last point: The Q values and series resistance refer to chips only. The effects of package parasitics will be discussed later, but it is important to consider circuit contact losses here. For low-capacitance diodes—for example, $C_{J4} = 0.6$ pF—the epitaxial region contributes a high value of resistance and dominates Q except at punchthrough. Diode contact losses are less significant.

Post-Tuning Drift. Post-tuning drift (PTD) is the change in oscillator frequency with time after the tuning voltage has stabilized. The minimization of PTD has assumed greater importance with the design of more sophisticated electronic countermeasure systems, where rapid, accurate frequency changes are required.

Table 2-10 Comparative Tuning Diodes

Type	C_{J0}	Breakdown Voltage V_B	$Q_{(-4)}$[a]	Ratio C_{J0}/C_JV_B[a]
Silicon abrupt	1.0	30	5,000	4.5
Silicon abrupt	2.5	30	4,600	4.5
Silicon abrupt	5.0	30	3,800	4.5
Gallium arsenide abrupt	1.0	25	10,000	3.6
Gallium arsenide abrupt	0.5	10	17,000	2.5
Silicon hyperabrupt	50.0	22	300	17.0
Silicon hyperabrupt	2.5	22	500	14

[a] Minimum guaranteed.

Post-tuning drift can be characterized as short-term and long-term. Short-term PTD occurs in the time range of tens of nanoseconds to a few seconds, while long-term PTD occurs in the time range of seconds to minutes, hours, or days.

Short-term PTD is mainly dependent on the thermal properties of the diode and is improved by high Q (low power loss) and flip chip construction. Long-term PTD depends on oxide stability and freedom of mobile charge in the oxide. It should be noted that actual oscillation frequency change may occur even with a perfect tuning diode because of variation with frequency in the power dissipated by the diode, changes in the diode heat-sink temperature, and frequency changes due to other circuit elements. Less than 0.01% short- and long-term PTD can be obtained.

Distortion Products. Inasmuch as nonlinear components generate harmonics and other distortion products, an understanding of this mechanism is of prime interest to the circuit designer. In some instances, the distortion products are the desired end result of the circuit design, as in frequency multipliers, where harmonics of the input signal frequency are the required output signal. For other applications, such as tuning-diode-tuned linear circuits, distortion products are extremely undesirable, and in some instances the end product specification may set a maximum limit on the distortion products allowed.

Cross-Modulation. Cross-modulation is the transfer of the modulation on one signal to another signal and is caused by third-order and higher odd-order nonlinearities in the behavior of the device. Rewriting Eq. (2-42) we have

$$C(V) = \frac{C_0}{(1 + V/\varphi)^n} \tag{2-52}$$

where C_0 = capacitance
V = applied voltage = $V_0 + v$
V_0 = dc applied voltage
v = ac applied voltage

Then, for a desired signal of

$$S_1 = v_1 \sin \omega_1 t \tag{2-53}$$

and a second, amplitude-modulated signal of

$$S_2 = v_2(1 + m \cos \omega_m t)\sin \omega_2 t \tag{2-54}$$

it can be shown that the cross-modulation, γ, defined by

$$\text{Output signal} \sim v_1 \sin \omega_1 t + \gamma \sin (\omega_1 \pm \omega_m)t \tag{2-55}$$

is found to be

$$\gamma = \frac{n(n+1)mv_2^2}{4(V_0+\varphi)^2} \tag{2-56}$$

From this equation it can be seen that cross-modulation is:

- Proportional to the square of the interfering signal
- Directly proportional to the interfering signal's modulation index, m
- Independent of the strength of the desired signal
- Independent of the frequencies of the desired and interfering signals (assuming that the nonlinearity to which both signals are subjected is sufficiently frequency-indiscriminate so this is the case)
- Present for all values of n; that is, no value of n gives zero cross-modulation

Solving Eq. (2-56) for the signal level v_2 required to produce cross-modulation of value γ, we have

$$v_2 = \frac{2(V_0+\phi)\gamma}{n(n+1)^m} \tag{2-57}$$

The interfering signal levels required to produce 1% cross-modulation from a 30%-modulated interfering signal applied to an abrupt-junction diode and a hyperabrupt-junction diode are shown in Figure 2-43.

From this figure, it can be seen that the hyperabrupt-junction diode is more susceptible to cross-modulation than the abrupt-junction diode in the region of maximum slope of the

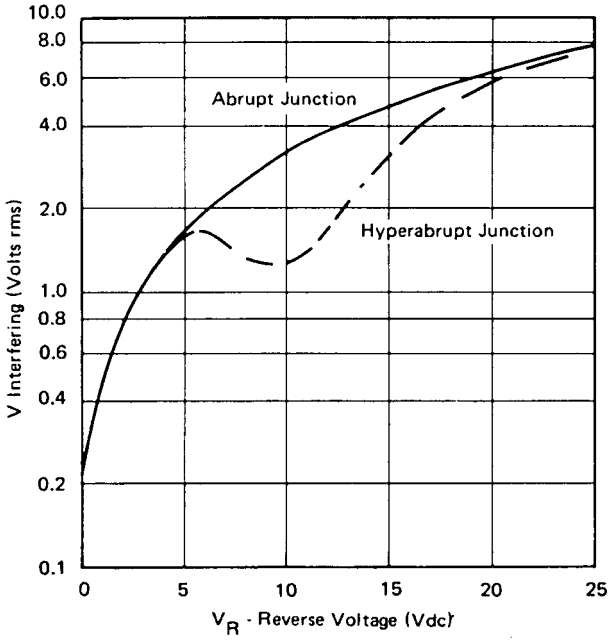

Figure 2-43 Interfering signal (30% amplitude modulated) level versus bias for 1% cross-modulation for abrupt-junction and hyperabrupt-junction diodes.

hyperabrupt-junction diode. For many applications, however, distortion products will be generated by other devices, such as transistors, at signal levels considerably below those given in Figure 2-43.

Intermodulation. Intermodulation is the production of undesired frequencies in the form

$$\sin(2\omega_1 t - \omega_2 t) \quad \text{and} \quad \sin(\omega_1 t - 2\omega_2 t) \tag{2-58}$$

from an input signal in the form of

$$v(\cos \omega_1 t + \cos \omega_2 t) \tag{2-59}$$

From an analysis similar to that done for cross-modulation, it can be shown that

$$\text{Intermodulation} = \frac{n(n+1)v^2}{8(V_0 + \varphi)^2} \tag{2-60}$$

or

$$\text{Cross-modulation} = (2m) \times \text{Intermodulation} \tag{2-61}$$

Harmonic Distortion. Harmonic distortion products are integral multiples of the signal frequencies and decrease in amplitude as the harmonic number decreases. Due to passband considerations and amplitude decrease with harmonic number, the second harmonic is the one of prime concern. Again, it can be shown that the second harmonic, v_2, of a signal of amplitude v_1 is

$$v_2 = \frac{n}{3(V_0 + \phi)} v_1^2 \tag{2-62}$$

Figure 2-44 shows the signal level required to produce 10% second-harmonic distortion in an abrupt-junction and a hyperabrupt-junction diode. Again, as in the case of cross-modulation, the hyperabrupt-junction diode is slightly worse than the abrupt-junction diode in the region of maximum slope of the hyperabrupt-junction diode.

Reduction of Distortion Products. In some cases, the signal levels applied to the diode generate distortion products larger than desirable for the circuit application. In this case, significant reduction in the distortion products can be achieved by using two diodes in a back-to-back configuration, as shown in Figure 2-45. Analysis shows that the fundamental signal components through the diodes are in phase and add, while some distortion products are out of phase and cancel, thus improving distortion performance.

Since the gradient of the electrical field produced in the depletion layer by a reverse bias applied to the device is proportional to the space charge density, the following equations can be written for the junction width W as a function of the reverse bias V_R:

For an Abrupt *pn* Junction (Alloyed Diodes)

$$W = {}_2\sqrt{2\frac{\varepsilon_r \varepsilon_0}{q}\left(\frac{1}{C_p} + \frac{1}{C_n}\right)(V_R + V_D)} \tag{2-63}$$

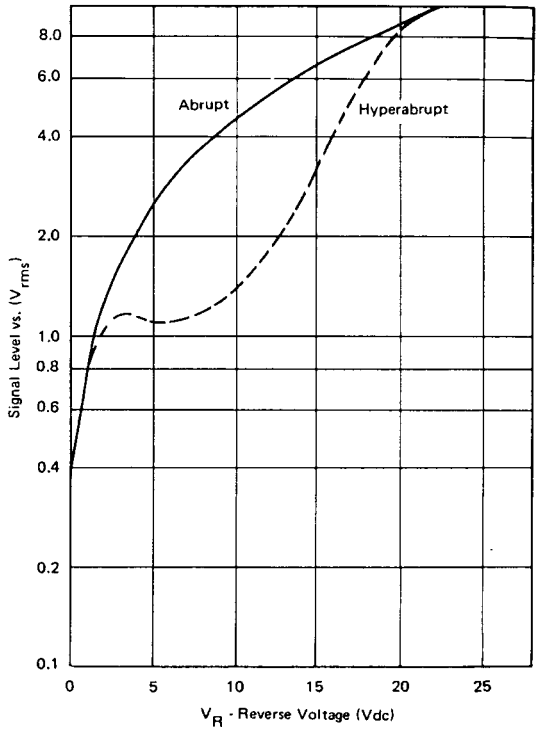

Figure 2-44 Signal level versus reverse voltage for 10% harmonic distortion.

For Linear *pn* Junctions (Single-Diffused Diodes, such as BA110–BA112)

$$W = \sqrt[3]{12\frac{\varepsilon_r \varepsilon_0}{aq}(V_R + V_D)} \tag{2-64}$$

where a is the impurity gradient within the depletion layer, ε_0 is the absolute dielectric constant ($8.85 \times 10^{-14}\ A_s/V_{cm}$, and $\varepsilon_r \approx 12$, the relative dielectric constant of silicon.

The junction capacitance, which is inversely proportional to the junction width, therefore varies in alloyed diodes with the square root, and in single-diffused diodes with the cube root of the externally applied reverse bias, and can be calculated from the general equation

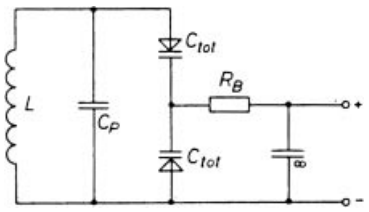

Figure 2-45 Back-to-back diodes. C_P is a fixed parallel capacitance, R_B is a bias decoupling resistor, and the capacitor marked ∞ is a low-impedance bypass.

$$C = \frac{\varepsilon_r \varepsilon_0 S}{W} \tag{2-65}$$

where S is the surface area of the *pn* junction. By way of approximation, we can also use the equation

$$C = \frac{K}{(V_R + V_D)^n} \tag{2-66}$$

where all constants and all parameters determined by the manufacturing process are contained in K. The exponent n is a measure of the slope of the capacitance/voltage characteristics and is 0.5 for alloyed diodes, 0.33 for single-diffused diodes, and (on average) 0.75 for tuner diodes with a hyperabrupt *pn* junction. Figure 2-46 shows the capacitance/voltage characteristics of an alloyed, a diffused, and a tuner diode.

Recently, an equation has been indicated which, although purely formal, describes the practical characteristics better than Eq. (2-66):

$$C = C_0 \left(\frac{A}{A + V_R} \right)^m \tag{2-67}$$

where C_0 is the capacitance at $V_R = 0$, and A is a constant whose dimension is a voltage. The exponent m is much less dependent on voltage than the exponent n in Eq. (2-66).

Equations (2-63) through (2-67) express the pure junction capacitance of the capacitance diode, but to this must still be added a constant capacitance, determined by structure parameters, in order to obtain the diode capacitance C_{tot}, which interests the user. With high inverse voltages—that is, low junction capacitance—a difference will therefore arise between the theoretical capacitance/voltage characteristic according to Eq. (2-66) and the practical characteristic, as shown in Figure 2-47.

The operating range of a capacitance diode or its useful capacitance ratio

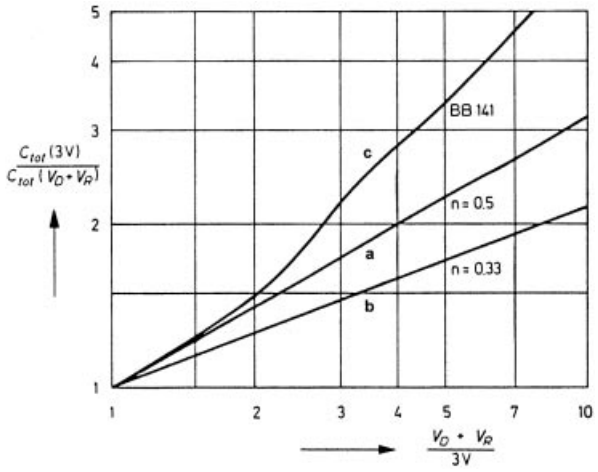

Figure 2-46 Capacitance/voltage characteristic for (a) an alloyed capacitance diode, n = 0.5; (b) a diffused capacitance diode, n = 0.33; and (c) a wide-range tuner diode (BB141).

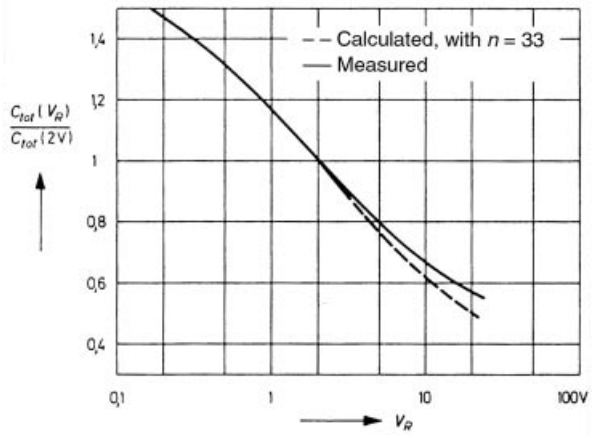

Figure 2-47 Capacitance/voltage characteristic of the BA110 diode.

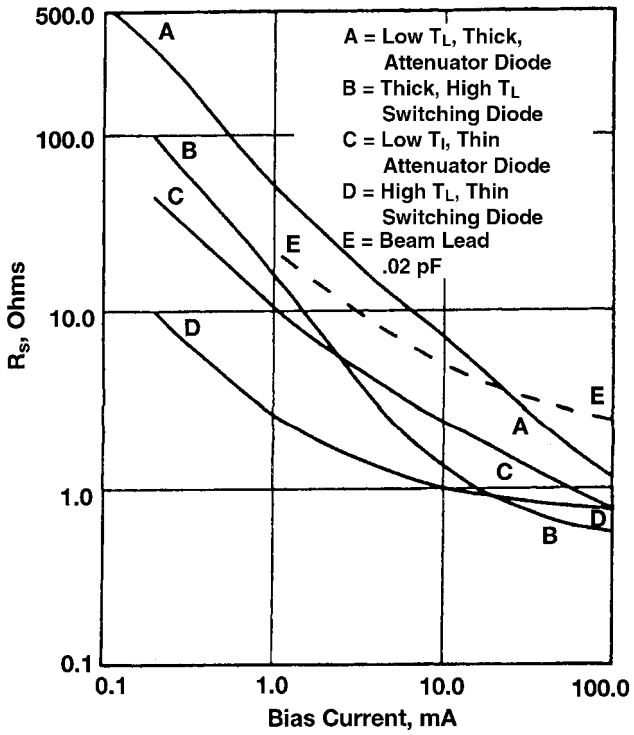

Figure 2-48 Basic current/voltage and capacitance/voltage characteristics.

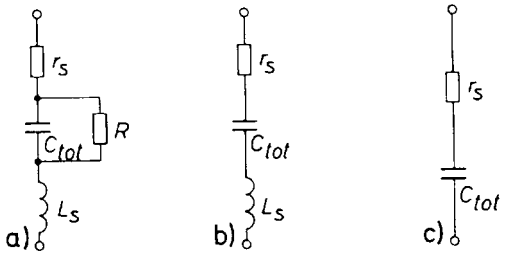

Figure 2-49 Equivalent circuits for capacitance diodes: (a) complete circuit, (b) simplified circuit, and (c) further simplification for low frequencies.

$$\frac{C_{\max}}{C_{\min}} = \frac{C_{\text{tot}}(V_{R\min})}{C_{\text{tot}}(V_{R\max})} \tag{2-68}$$

is limited by the fact that the diode must not be driven by the alternating voltage superimposed on the tuning voltage either into the forward mode or the breakdown mode. Otherwise, rectification, which would shift the diode's bias and considerably affect its figure of merit, would take place. Figure 2-48 plots the capacitance/voltage characteristics of a capacitance diode to clarify the relationship. The useful operating range lies between the voltages

$$V_{\min} > \hat{V} - V_F \quad \text{and} \quad V_{\max} < V_{(\text{BR})R} - \hat{V} \tag{2-69}$$

As has already been indicated, the exponent n for large-capacitance-ratio or tuning diodes used today for TV tuners is not constant but voltage-dependent and subject to manufacturing tolerances. This means that the capacitance/voltage characteristic of these diodes is likewise subject to manufacturing tolerances. Since, in a TV tuner, it is necessary for two or three circuits to be tuned uniformly, tuner diodes must be selected empirically for identical characteristics and supplied in equipment lots.

Electrical Properties of Tuning Diodes. In this section, the electrical properties of capacitance diodes are described, with reference to data published on the tuner diodes BB141 and BB142.

Equivalent Circuit. Since a capacitance diode is not an ideal capacitor, it is useful to introduce an equivalent circuit that can serve as a basis for discussing the diode's electrical properties. Figure 2-49 shows various types of equivalent circuits.

The complete equivalent circuit (Figure 2-49a), which conforms closely to physical conditions, comprises, in addition to the diode capacitance C_{tot}, the series resistance r_S and the series inductance L_S, and also the reverse resistance $R = dV_R/dI_R$. At higher frequencies, this resistance can usually be disregarded, so that the equivalent circuit is simplified in terms of Figure 2-49b—the configuration usually employed. In many cases, the series inductance can also be disregarded, in which case we obtain Figure 2-49c.

Capacitance. Figure 2-50 shows the capacitance/voltage characteristic borrowed from the datasheets of diodes BB141 and BB142. As this characteristic, like most characteristics published in datasheets, represents merely a typical curve, it would not convey sufficient

information for the user to dimension a tuner. Therefore, the datasheets contain additional data on capacitance and useful capacitance ratio:

Capacitance		BB141A (pF)	BB141B (pF)	BB142 (pF)
At $V_R = 1$ V	C_{tot}	16	19	17
At $V_R = 3$ V	C_{tot}	11	13	12
At $V_R = 25$ V	C_{tot}	2–2.35	2.25–2.65	2–3

$$\text{Useful capacitance ratio} = \frac{C_{tot}(3\text{ V})}{C_{tot}(25\text{ V})} = 4 \text{ to } 6$$

On the basis of the spread of the diode capacitance C_{tot} guaranteed for $V_R = 25$ V, it is possible to calculate the tuner with the aid of the spread guaranteed for the capacitance ratio.

Three further capacitance graphs are shown in Figures 2-51 through 2-53. Figure 2-51 shows a (typical) curve representing the normalized slope as a function of the reverse voltage, Figure 2-52 the normalized capacitance as a function of the junction temperature, and Figure 2-53 the temperature coefficient of the capacitance as a function of the reverse voltage.

The variation of diode capacitance with ambient temperature, as shown in Figures 2-52 and 2-53, is really only a function of the temperature dependence of the diffusion voltage [see Eq. (2-66)]. The diffusion voltage drops with rising temperatures by about 2 mV/°C , which means that the diode capacitance rises with temperature. The influence of the diffusion voltage, and thus the temperature coefficient of the capacitance, decreases as the reverse voltage rises. It is therefore advisable to run a capacitance diode with as high a reverse voltage as the required capacitance ratio permits. Compensation for the dependence of capacitance on temperature will be discussed later.

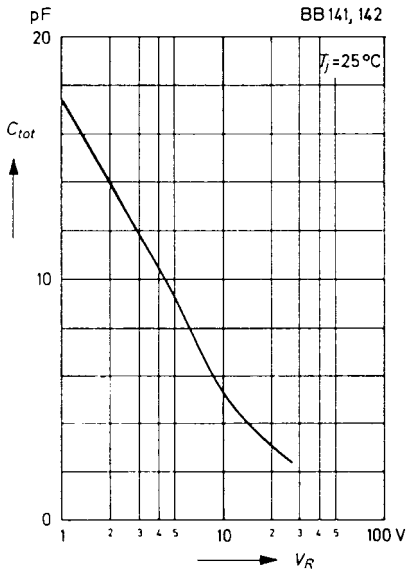

Figure 2-50 Capacitance/voltage characteristic of diodes BB141 and BB142.

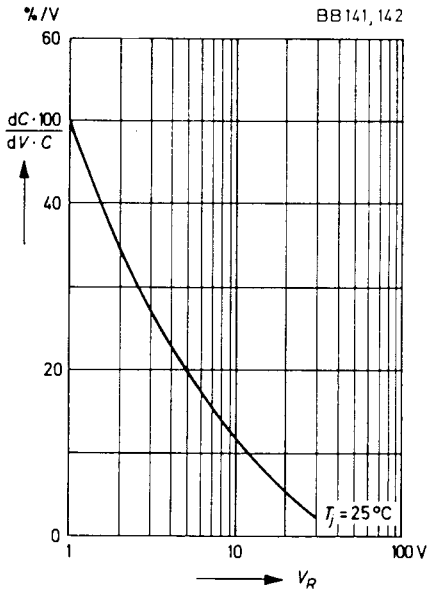

Figure 2-51 Slope (normalized) as a function of the reverse voltage.

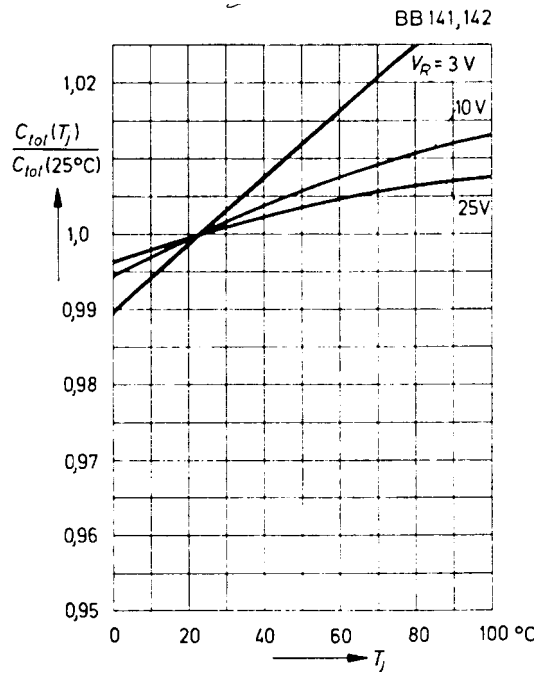

Figure 2-52 Capacitance (normalized) as a function of the junction temperature.

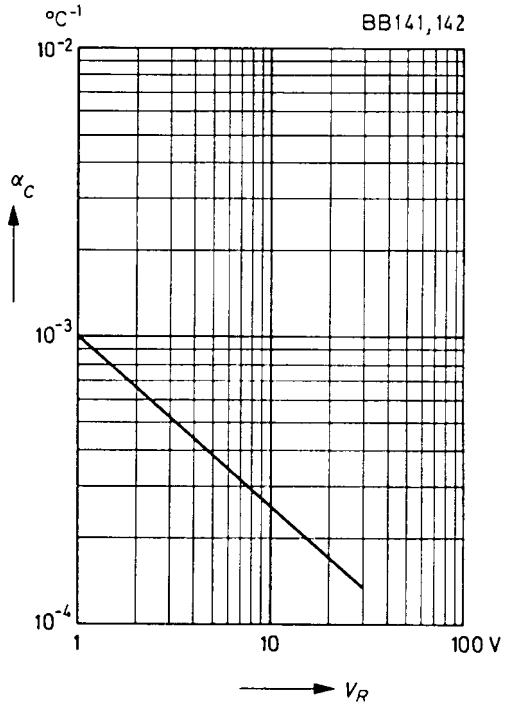

Figure 2-53 Temperature coefficient of capacitance as a function of the reverse voltage.

Series Resistance, Figure of Merit (Q). Since capacitance diodes are intended for employment in resonant circuits, indications are required as to the circuit attenuation that they produce. Usually, the series resistance or the figure of merit that can be calculated therefrom is indicated. With reference to the equivalent circuit shown in Figure 2-49a, the figure of merit (or Q factor) is calculated:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S + 1/\omega C_{\text{tot}} R} \tag{2-70}$$

Figure 2-54 shows the theoretical (normalized) Q as a function of frequency. With the frequency range of 10–1000 MHz, which is essential for tuner diodes, the parallel resistance R caused by the reverse current (see Figure 2-49b) can be disregarded, and Eq. (2-70) can be simplified to read as follows:

$$Q = \frac{1}{\omega C_{\text{tot}} r_S} \tag{2-71}$$

In Figure 2-55, Q is plotted as a function of frequency for the tuner diodes BB141 and BB142. The datasheet indicates, in addition to this curve, the value of the series resistance at $f = 470$ MHz and $C_{\text{tot}} = 9$ pF:

	BB141A, BB141B	BB142
Series resistance (r_S)	0.6 (< 0.8)	0.9 (< 1.2)

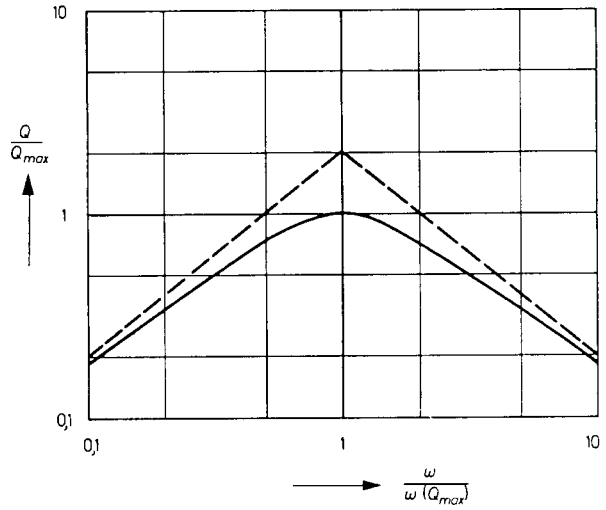

Figure 2-54 *Q* (normalized) as a function of frequency.

Since the diode capacitance and the series resistance decrease as the reverse voltage rises, Q is likewise dependent on the reverse voltage. It is smallest at a low reverse voltage, that is, at a low frequency. The series and parallel capacitances inevitable in a diode-tuned resonant circuit influence the effective Q of the tuning capacitance, as will be described later.

Series Inductance, Series Resonant Frequency, Cutoff Frequency for Q = 1. These three parameters define the behavior of the diode at high frequencies when the influence of

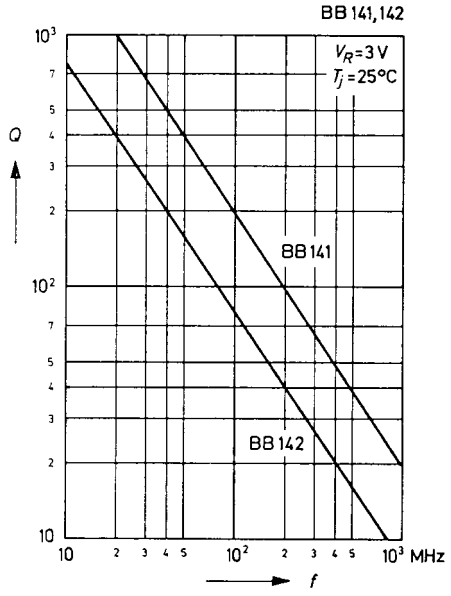

Figure 2-55 *Q* as a function of frequency.

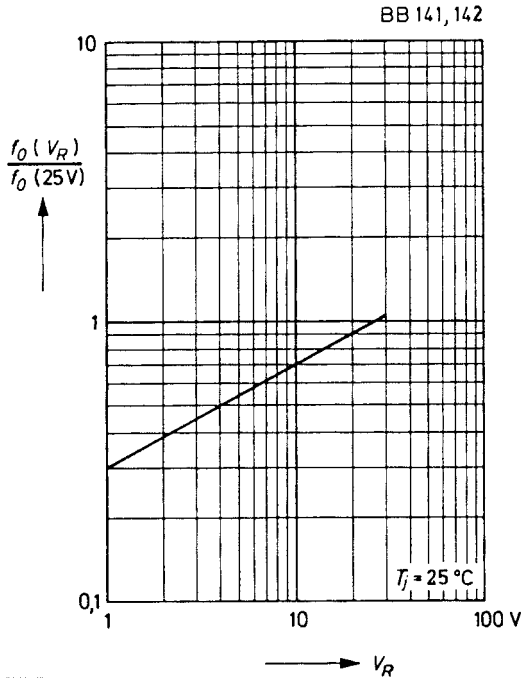

Figure 2-56 Series-resonant frequency (normalized) as a function of the reverse voltage.

the series inductance can no longer be neglected. The parameter on which the calculation is based is the series inductance L_S, which is determined by the connection leads. As indicated in Figure 2-49a, it is in series with the capacitance and, given a suitable frequency, forms a series-resonant circuit therewith. In that case

$$\omega L_S = \frac{1}{\omega C_{\text{tot}}} \tag{2-72}$$

and the series-resonant frequency is

$$f_0 = \frac{1}{2\pi\sqrt{C_{\text{tot}} L_S}} \tag{2-73}$$

Above this frequency, the impedance of the diode is inductive, but it depends on the reverse voltage. Figure 2-56 shows how the (normalized) series-resonant frequency depends on the reverse voltage for the tuner diodes BB141 and BB142.

The cutoff frequency for $Q = 1$ is defined as the frequency at which Q assumes the value of unity. In a rough calculation, the reactive impedance of the diode capacitance can be neglected and the frequency f_{Q1} obtained for the condition in which the inductive reactance equals the series resistance:

$$\omega L_S = r_S \tag{2-74}$$

$$f_{Q1} = \frac{r_S}{2\pi L_S} \tag{2-75}$$

For the tuner diodes BB141 and BB142, Figure 2-57 shows how the (normalized) cutoff frequency depends on the reverse voltage. The datasheets contain the following numerical information:

		BB141	BB142	
Series inductance measured 1.5 mm from the case	L_S	2.5	2.5	nH
Series-resonant frequency at $V_R = 25$ V	f_0	2	1.8	GHz
Cutoff frequency for $Q = 1$ at $V_R = 3$ V	f_{Q1}	24	16	GHz

Depending on the intended application, either the series-resonant frequency or the cutoff frequency for $Q = 1$ determines the maximum useful frequency range.

Leakage Current, Breakdown Voltage. These two parameters mark the dc performance of the diode when a reverse bias is applied to it. In the databook for the tuner diodes BB141 and BB142, the breakdown voltage is quoted as follows:

$$\text{Reverse breakdown voltage at } I_R = 100\ \mu\text{A}: \quad V_{(BR)R} > 30\ \text{V}$$

This means that the maximum reverse voltage that may be applied to the diode as a tuning voltage is 30 V.

The leakage current for the above-mentioned tuner diodes is guaranteed as follows:

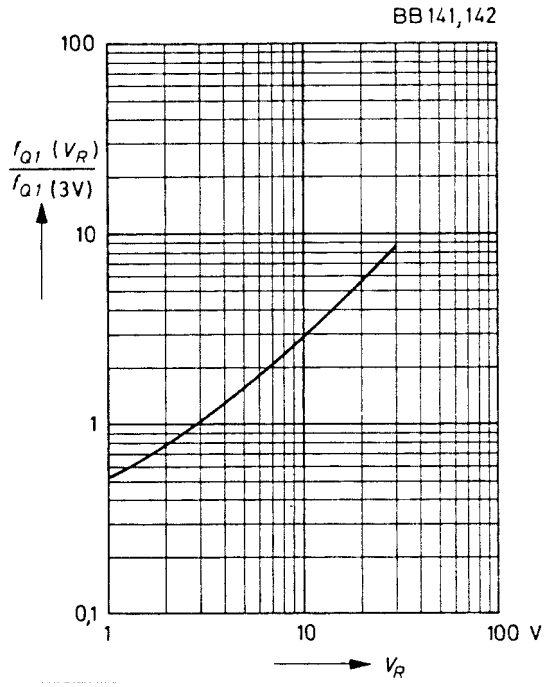

Figure 2-57 Cutoff frequency for $Q = 1$ (normalized) as a function of the reverse voltage.

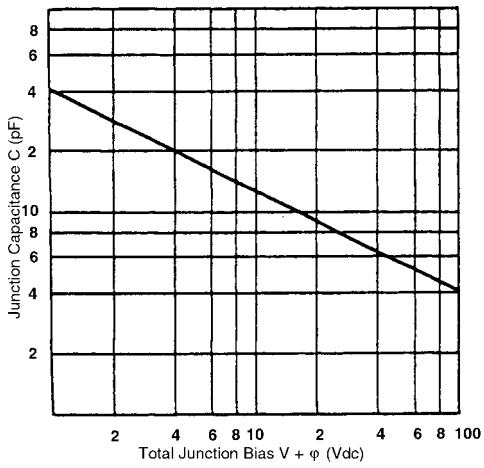

Figure 2-58 Leakage current as a function of reverse voltage.

$$\text{Leakage current at } V_R = 28 \text{ V:} \quad I_R < 50 \text{ nA}$$

Moreover, Figure 2-58 shows a graph that illustrates the leakage current as a function of the reverse voltage. Since this current is temperature dependent (as with every silicon diode)—it doubles with each temperature rise of about 10 °C—care should be taken when dimensioning the tuner circuit that the leakage current does not cause inadmissible voltage variations at increased ambient temperatures.

Matching of Tuner Diodes, Uniform Parameters. As has already been mentioned, the capacitance versus voltage characteristics of modern tuner diodes are subject to a certain scatter, so that it becomes necessary to test these diodes to obtain equipment lots empirically.

Diode-Tuned Resonant Circuits

Tuner Diode in the Parallel-Resonant Circuit. Figures 2-59, 2-60, and 2-61 illustrate three basic circuits for the tuning of parallel-resonant circuits by means of capacitance diodes.

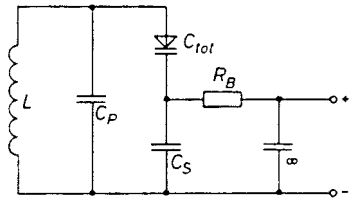

Figure 2-59 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the series capacitor.

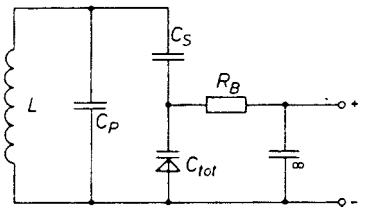

Figure 2-60 Parallel-resonant circuit with tuner diode, and bias resistor parallel to the diode.

In the circuit diagram of Figure 2-59, the tuning voltage is applied to the tuner diode via the input coil and the bias resistor R_B. Series-connected to the tuner diode is the series capacitor C_S, which completes the circuit for ac but isolates the cathode of the tuner diode from the coil and thus from the negative terminal of the tuning voltage. Moreover, a fixed parallel capacitance C_P is provided. The decoupling capacitor preceding the bias resistor is large enough for its value to be disregarded in the following discussion. Since for high-frequency purposes the biasing resistor is connected in parallel with the series capacitor, it is transformed into the circuit as an additional equivalent shunt resistance R_C. We have the equation

$$R_C = R_B\left(1 + \frac{C_S}{C_{\text{tot}}}\right)^2 \tag{2-76}$$

If in this equation the diode capacitance is substituted by the resonant circuit frequency ω, we obtain

$$R_C = R_B\left(\frac{\omega^2 LC_S}{1 - \omega^2 LC_P}\right)^2 \tag{2-77}$$

The resistive loss R_C caused by the bias resistor R_B is seen to be highly frequency dependent, and this may result in the bandwidth of the tuned circuit being independent of frequency if the capacitance of the series capacitor C_S is not chosen sufficiently high.

Figure 2-60 shows that the tuning voltage can also be applied directly and in parallel to the tuner diode. For the parallel loss resistance transformed into the circuit, we have the expression

$$R_C = R_B\left(\frac{1 + C_{\text{tot}}}{C_S}\right)^2 \tag{2-78}$$

and

$$R_C = R_B\left(\frac{\omega^2 LC_S}{\omega^2 L(C_S + C_P) - 1}\right)^2 \tag{2-79}$$

The influence of the bias resistor R_B in this case is larger than in the circuit of Figure 2-60, provided that

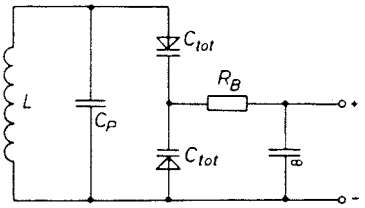

Figure 2-61 Parallel-resonant circuit with two tuner diodes.

$$C_S^2 > C_S(C_{\text{tot}} + C_P) + C_{\text{tot}}C_P \tag{2-80}$$

This is usually the case because the largest possible capacitance will be preferred for the series capacitor C_S, and the smallest for the shunt capacitance C_P. The circuit of Figure 2-59 is therefore normally preferred to that of Figure 2-60. An exception would be the case in which the resonant circuit is meant to be additionally damped by means of the bias resistor at higher frequencies.

In the circuit of Figure 2-61, the resonant circuit is tuned by two tuner diodes that are connected in parallel via the coil for tuning purpose, but series-connected in opposition for high-frequency signals. This arrangement has the advantage that the capacitance shift caused by the ac modulation (see section entitled "Modifying the Diode Capacitance by the Applied ac Voltage") takes effect in opposite directions in these diodes and therefore cancels itself. The bias resistor R_B, which applies the tuning voltage to the tuner diodes, is transformed into the circuit at a constant ratio throughout the whole tuning range. Given two identical, loss-free tuner diodes, we obtain the expression

$$R_C = 4R_B \tag{2-81}$$

Capacitances Connected in Parallel or Series with the Tuner Diode. Figures 2-59 and 2-60 show that a capacitor is usually in series with the tuner diode, in order to close the circuit for alternating current and, at the same time, to isolate one terminal of the tuner diode from the rest of the circuit with respect to direct current, so as to enable the tuning voltage to be applied to the diode. As far as possible, the value of the series capacitor C_S will be chosen such that the effective capacitance variation is not restricted. However, in some cases, as, for example, in the oscillator circuit of receivers whose intermediate frequency is of the order of magnitude of the reception frequency, this is not possible and the influence of the series capacitance will then have to be taken into account. By connecting the capacitor C_S, assumed to be lossless, in series with the diode capacitance C_{tot}, the tuning capacitance is reduced to the value

$$C^* = C_{\text{tot}} \frac{1}{1 + C_{\text{tot}}/C_S} \tag{2-82}$$

The Q of the effective tuning capacitance, taking into account the Q of the tuner diode, increases to

$$Q^* = Q\left(1 + \frac{C_{\text{tot}}}{C_S}\right) \tag{2-83}$$

The useful capacitance ratio is reduced to the value

$$\frac{C^*_{\max}}{C^*_{\min}} = \frac{C_{\max}}{C_{\min}} \frac{1 + C_{\min}/C_S}{1 + C_{\max}/C_S} \tag{2-84}$$

where $C_{\max}$ and $C_{\min}$ are the maximum and minimum capacitances of the tuner diode.

On the other hand, the advantage is gained that, due to capacitive potential division, the amplitude of the alternating voltage applied to the tuning diode is reduced to

$$\hat{v}^* = \hat{v} \frac{1}{1 + C_{\text{tot}}/C} \tag{2-85}$$

so that the lower value of the tuning voltage can be smaller, and this results in a higher maximum capacitance $C_{\max}$ of the tuner diode and a higher useful capacitance ratio. The influence exerted by the series capacitor, then, can actually be kept lower than Eq. (2-83) would suggest.

The parallel capacitance C_P that appears in Figures 2-59 to 2-61 is always present, since wiring capacitances are inevitable and every coil has its self-capacitance. By treating the capacitance C_P, assumed to be lossless, as a shunt capacitance, the total tuning capacitance rises value and, if C_S is assumed to be large enough to be disregarded, we obtain

$$C^* = C_{\text{tot}} \left(1 + \frac{C_P}{C_{\text{tot}}} \right) \tag{2-86}$$

The Q of the effective tuning capacitance, as derived from the Q of the tuner diode, is

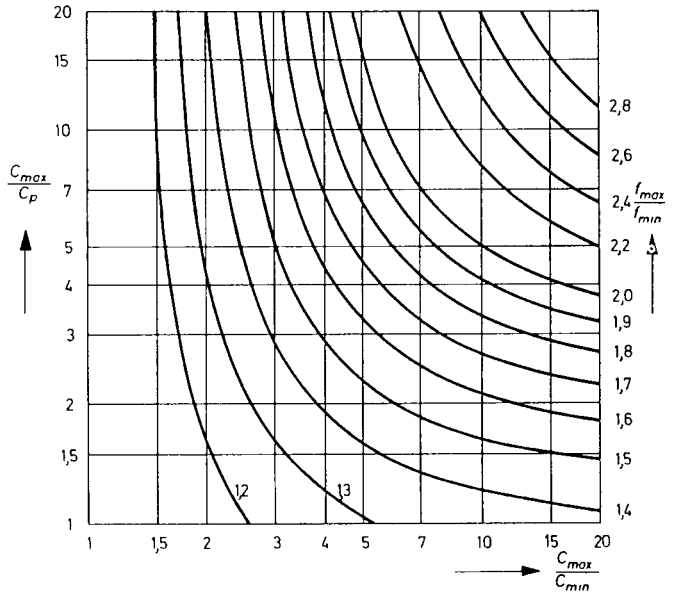

Figure 2-62 Diagram for determining the capacitance ratio and minimum capacitance.

$$Q^* = Q\left(1 + \frac{C_P}{C_{\text{tot}}}\right) \tag{2-87}$$

or, in other words, it rises with the magnitude of the parallel capacitance. The useful capacitance ratio is reduced:

$$\frac{C^*_{\text{max}}}{C^*_{\text{min}}} = \frac{C_{\text{max}}}{C_{\text{min}}} \frac{1 + C_P/C_{\text{max}}}{1 + C_P/C_{\text{max}}} \tag{2-88}$$

In view of the fact that even a comparatively small shunt capacitance reduces the capacitance ratio considerably, it is necessary to ensure low wiring and coil capacitances in the circuit-design stage.

TUNING RANGE. The frequency range over which a parallel-resonant circuit according to Figure 2-59 can be tuned by means of the tuner diode depends on the useful capacitance ratio of the diode and on the parallel and series capacitances present in the circuit.

The ratio can be found from

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{1 + \frac{\dfrac{C_{\text{max}}}{C_P\,(1 + C_{\text{max}}/C_S)}}{1 + \dfrac{C_{\text{max}}}{C_P\,(C_{\text{max}}/C_{\text{min}} + C_{\text{max}}/C_S)}}} \tag{2-89}$$

In many cases, the series capacitor can be chosen large enough for its effect to be negligible. In that case, Eq. (2-89) is simplified as follows:

$$\frac{f_{\text{max}}}{f_{\text{min}}} = \sqrt{\frac{1 + C_{\text{max}}/C_P}{1 + C_{\text{min}}/C_P}} \tag{2-89a}$$

From this equation, the diagram shown in Figure 2-62 is computed. With the aid of this diagram, the tuner diode parameters required for tuning a resonant circuit over a stipulated frequency range—that is, the maximum capacitance and the capacitance ratio—can be determined.

Whenever the series capacitance C_S cannot be disregarded, the effective capacitance ratio is reduced according to Eq. (2-84).

TRACKING. Some applications require the maintenance of a fixed frequency relationship between two or more tuned circuits as their tuning is simultaneously adjusted. Referred to as *tracking*, this technique requires narrow tolerances of capacitance versus tuning voltage. Minimizing tracking error requires special care if the tracking circuits must cover the same frequency span beginning at different start and end frequencies, as is necessary when simultaneously tuning oscillator and mixer/RF circuitry in a superheterodyne receiver. Then, tracking error must be minimized by means of series and shunt capacitances in accordance with methods known from variable capacitors. The frequency deviations that must be anticipated are summarized in the equation

$$\frac{df}{f} = -\frac{1}{2}\frac{dC_0}{C_0} - \frac{1}{2}\frac{d(L-L_0)}{L} - \frac{1}{2}\frac{dL_0}{L_0} + \frac{n}{2}\frac{dV_R}{V_R + V_D} \tag{2-90}$$

The spread of parameters dC_0/C_0 and dL_0/L_0 can only be compensated by varying the circuit inductances $d(L–L_0)/L$ or by varying the bias $dV_R/(V_R + V_D)$.

Modulating the Diode Capacitance by the Applied ac Voltage. In normal operation, the sum of the tuning voltage and the alternating signal voltage of the resonant circuits is applied to the tuner diode. The bias, and thus the capacitance, of the tuner diode therefore varies at the rhythm of the alternating voltage. Due the nonlinear character of the capacitance versus voltage curve, voltage distortions and capacitance shifts are inevitable, and these must be kept within adequate limits. This is done by maintaining the ac applied to the diode(s) at sufficiently low ac amplitude and by choosing an adequate minimum value for the tuning voltage. In the resonant circuit, a tuner diode is modulated predominantly by a current free from harmonics, according to the equation

$$i = \hat{i}\cos \omega t \tag{2-91}$$

The alternating voltage across the diode is

$$v = (V_R + V_D)\left[\left(1 + \frac{\hat{i}(1-n)}{\omega C_{\text{tot}} V_R}\sin \omega t\right)^{1/(1-n)} - 1\right] \tag{2-92}$$

An evaluation of this equation shows that especially the first harmonic makes its appearance. The capacitance shift caused by the alternating voltage superimposed on the tuning voltage is shown in Figure 2-63. However, the voltage distortion, and thus the capacitance shift, can be largely avoided if two tuner diodes are used, as in Figure 2-61.

COMPENSATING TEMPERATURE DEPENDENCE. As has already been mentioned, variations are caused in the capacitance of the diode mainly by the dependence of the diffusion voltage on

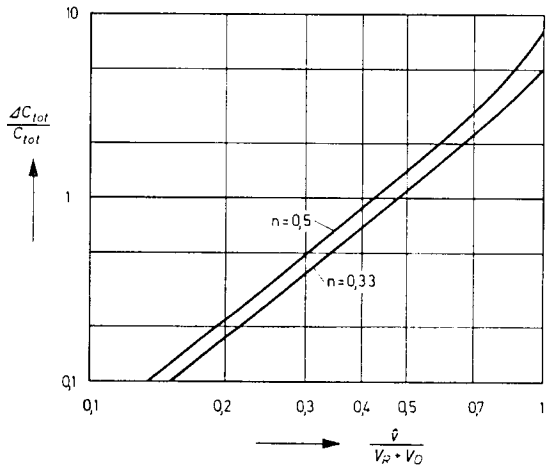

Figure 2-63 Capacitance increase as a function of the ac voltage drop across the tuner diode.

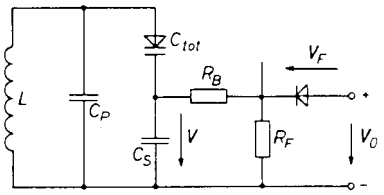

Figure 2-64 Temperature-compensation circuit with diode.

temperature. In a diode-tuned resonant circuit, the temperature coefficient of the resonant frequency, therefore, depends on the tuning voltage and thus on the resonant frequency. It is therefore impossible to compensate the temperature dependence of the resonant frequency by means of temperature-dependent capacitors—the method usually adopted for mechanically tuned circuits.

To achieve satisfactory compensation, the tuning voltage should be increased by an amount equal to that by which the diffusion voltage of the diode is reduced with rising temperature; that is, by approximately 2 mV/°C. This can be done easily by connecting a forward-biased silicon diode in series with the source of the tuning voltage, as shown in Figure 2-64. Since the forward voltage of the diode varies by –2 mV/°C with ambient temperature, the voltage

$$V = V_0 + V_D - V_F$$

which determines the bias of the tuner diode, and therefore also the diode capacitance, is almost temperature independent. In practice, it is advisable to feed this diode with additional current via the resistor R_F to keep its differential forward resistance sufficiently low and thus to prevent capacitive noise voltages from leaking into the tuning circuit.

To prevent the load placed by the resistor R_F on the source of the tuning voltage from fluctuating in a manner depending on the tuning voltage, a circuit such as shown in Figure 2-65 may be used in which the emitter diode of the transistor effects the compensation, and the only load placed on the source of the tuning voltage is the base current of this transistor.

Dynamic Stability. The resonant frequency of a diode-tuned RF circuit follows the equation

$$f = f_0 \sqrt{\left(\frac{V_R + V_D}{V_{R0} + V_D}\right)^n} \tag{2-93}$$

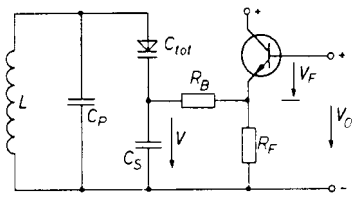

Figure 2-65 Temperature-compensation circuit with transistor.

The frequency f_0 is set with the aid of the circuit inductance when the tuning voltage equals V_{R0}. Since the signal amplitude in the circuit depends on the field strength of the received transmitter and since the resonant frequency of the circuit depends on the amplitude, undesirable feedback between the tuning voltage and the received alternating voltage may occur at the tuner diode. A disturbance that has a similar effect is the microphonic effect, which can sometimes be observed with mechanically variable capacitors. In an investigation of the feedback in diode-tuned resonant circuits, the following assumptions were made:

- The impedance of the antenna (or of the signal generator) is negligible.
- The full alternating voltage is applied to the diode (whereas, in practice, the series capacitor brings about a potential division).
- The capacitance versus voltage characteristic is an exponential function.
- The Q of this circuit is independent of the amplitude of the alternating voltage.

As a result of a high alternating voltage at the resonant circuit, three undesirable effects—harmonic generation, frequency shift, and cross-modulation—are encountered.

HARMONIC GENERATION. The nonlinearity of the capacitance versus voltage characteristic produces harmonics. However, the selectivity of the receiver reduces the effects of these harmonics to noise level.

FREQUENCY SHIFT. When a sinusoidal voltage v is applied to the tuner diode of the RF circuit, the variation of the diode capacitance does not follow the sine law, but the equation

$$\frac{C_\omega}{C} = \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{-n} \tag{2-94}$$

This results in a change of the resonant frequency of the circuit. The inductive slope of the resonant curve steepens and may even turn back. This could lead to bistable behavior of the resonant circuit. The change of frequency takes place as if the tuning voltage, and thus the resonant frequency, has decreased. The order of magnitude of this change of resonant frequency was determined with the aid of a computer from Fourier analysis of

$$\frac{\Delta f}{f} = 1 + \frac{1}{2\pi} \int_0^{2\pi} \left(1 + \frac{v}{V_R + V_D} \sin \omega t\right)^{n/2} d(\omega t) \tag{2-95}$$

Figure 2-66 shows the admissible alternating voltage at the diode, computed for a 2% frequency shift, as a function of the tuning voltage. The measured values differ by not more than 10% from the computed values. Since the Q of the circuits is about 50 for the VHF as well as the UHF range, a 2% frequency shift is permissible.

CROSS-MODULATION. Cross-modulation is a disturbance caused by nonlinearities of the characteristics of the components concerned. The modulation of an undesired amplitude-modulated signal is here transferred to the carrier of the amplitude-modulated intelligence signal. Cross-modulation is virtually independent of the amplitude of the intelligence signal.

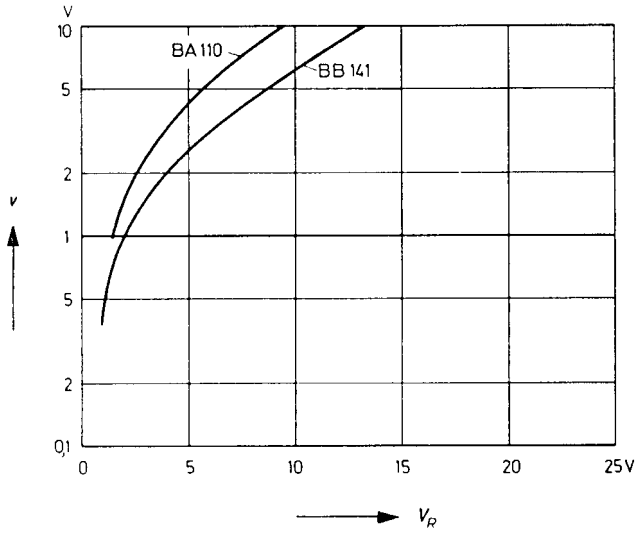

Figure 2-66 Admissible alternating voltage for a 2% frequency shift as a function of tuning voltage.

The cross-modulation factor for tuner diodes is

$$k = \frac{v^2}{(V_R + V_D)^2} m_v \frac{n(n+1)}{2} \tag{2-96}$$

Resolving this equation in terms of v, we obtain

$$v = \frac{V_R + V_D}{n} \sqrt{\frac{2kn}{m_v (n+1)}} \tag{2-97}$$
